Fig. 2. Arrhenius plot of the rate constants of the ion-pairs of polystyrylsodium in different solvents [68c] (measurements in excess NaBPh$_4$). HMPA = hexamethylphosphoric triamide, DME = dimethoxyethane, THF = tetrahydrofuran, 3-Me-THF = 3-methyltetrahydrofuran, THP = tetrahydropyran.

Non-polar solvents, such as benzene, cyclohexane or monomeric styrene, are no longer capable of solvating the contact ion pair *(13)*. The growing chains form associates, and the polymerization accordingly takes place more slowly. Alkyllithium compounds, which are the preferred initiators because of their solubility, also form such associates; this additionally retards the polymerization[71-73].

In the absence of impurities, the anionic polymerization of styrene in polar and non-polar media takes place without chain termination and without chain transfer[67,68]. Hence, in contrast to the case of free radical polymerization, the molecular weight distribution of the product is very narrow and, in the extreme case, corresponds to a Poisson distribution[74].

If, after consumption of the monomeric styrene, the chain end is not deactivated by addition of a protonic substance, the chain continues to be active, giving so-called "living polymers". The polymer anion can continue to add further monomer, including other monomer types. This fact is used industrially for the synthesis of block copolymers of a defined structure[37]. Either polymerization is continued at the living chain end by addition of other monomers, resulting in linear block copolymers; or separately produced living polymers are coupled by means of bifunctional or multifunctional reagents, to give linear or radially branched block copolymers (Scheme 3). Both methods are employed industrially in the manufacture of thermoplastic styrene-butadiene copolymers having properties ranging from those of rubber through thermoplastic elastomers to impact-resistant thermoplastics[75,76]. Intensive work is being carried out in this sector. Certain combinations of properties can be obtained deliberately by means of novel coupling agents[77,78] and comonomers[79,80]. One example is the improvement in flow by increased branching or stellar arrangement of the molecule chains[81-83].

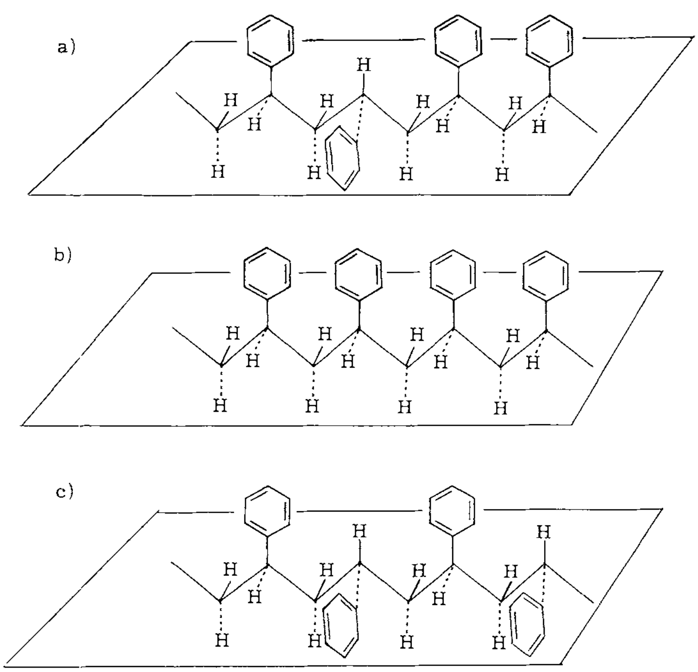
### 2.1.3. Coordinative Polymerization

The coordinative polymerization of styrene over complex Ziegler catalysts produces, alongside stereochemically irregular, atactic polystyrene, in particular isotactic polystyrene in which neighboring phenyl nuclei have sterically similar configuration (Scheme 4)[84-86]. Syndiotactic polystyrene, in which the phenyl nuclei are arranged in alternately opposite configurations, has hitherto not been discovered[87]. The catalysts used have a strong influence on the steric structure of the polymer[86]. The mechanism of coordinative polymerization of styrene is known only in outline; however, information[88] gathered from the analogous reaction of ethylene and propylene is largely applicable.

Coordinative polymerization of styrene has hitherto not achieved any practical importance, though isotactic polystyrene, because it has a substantially higher heat distortion temperature than atactic polystyrene[86], would appear to be of interest as a component of mixtures[89-91]. Development products[92] marketed towards the end of the 1960's were



Scheme 4. a) Atactic, b) isotactic, c) syndiotactic polystyrene.

however withdrawn, largely because of the low degree of crystallinity, the low rate of crystallization, processing difficulties, and the unsatisfactory mechanical properties of the isotactic polystyrene[86,93,94].

### 2.2. Copolymerization

Copolymerization of styrene is extremely important industrially, since it allows the pattern of properties of thermoplastic styrene polymers to be varied within wide limits[31]. In addition to random copolymerization (for reviews see [31,95-99]), it is above all graft copolymerization and anionic block copolymerization (see Section 2.1.2), which have acquired practical importance.

The random copolymerization of styrene can be initiated by free radicals or ionically. Differences from styrene homopolymerization are a result of the comonomers having different polarity and different reactivity from styrene. These factors especially affect chain propagation, since one of the monomers is preferred for addition to a particular chain end and for solvation of the growing chain[100-102]. However, the desired copolymer compositions can be achieved by making use of the copolymerization parameters derived from kinetic and quantum-chemical considerations. This approach is utilized industrially[31] in the manufacture of SAN, styrene/methyl methacrylate and styrene/maleic anhydride copolymers having various compositions.

The graft copolymerization of styrene with butadiene- or other rubbers is of vital importance in the manufacture of high-impact styrene polymers[103]. Such products consist of a polystyrene matrix with embedded rubber particles. In most cases, these particles are not compact but contain occluded matrix material ("cell particles", Fig. 3[104]). The heterogeneous rubber particles form a separate phase; they are also referred to as the soft component, in contrast to the hard component or matrix. The grafted rubber acts as an emulsifier in the polystyrene-rubber two-phase system and is responsible for the anchoring of the rubber in the polystyrene matrix[104-106,136]. Industrially, the graft copolymerization is carried out exclusively by free radical methods[107,108].

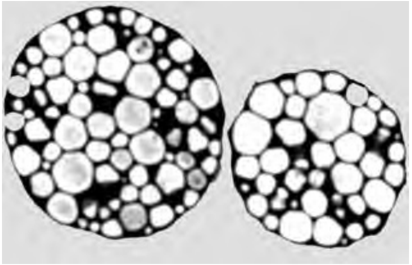


Fig. 3. Cell particles. Light phase: polystyrene, dark phase: polybutadiene.

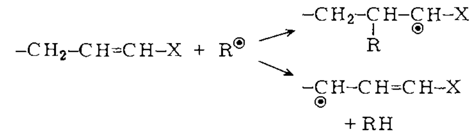
The mechanism of the free radical grafting of styrene onto rubber has not been completely elucidated. The following initiation reactions have been discussed[109-113] (Scheme 5): An initiator radical or polymer radical $R^{\odot}$ can add onto the double bonds in the rubber or can, through chain transfer, abstract an activated hydrogen atom, in general from an allyl structure. In addition, homopolymer is also formed. All three reactions take place in parallel, and depending on the nature of the radical initiator and of any solvent used, as well as on the chosen temperature, addition or H abstraction dominates. For example, in polybutadiene rubbers addition increases with increasing 1,2-vinyl content[111,114], whilst in polyisoprene and EPDM rubbers[*] hydrogen abstraction predominates[115,116]. Polypropylene, polyethylene and polybutyl acrylate undergo grafting exclusively by H abstraction[117,118]. *tert*-Butoxy radicals released from initiators favor hydrogen abstraction, whilst alkyl radicals preferably undergo addition to double bonds[119]. In graft copolymerization using an added initiator, grafting occurs preferentially *via* the primary radicals, whilst thermal graft copolymerization is initiated by polymer radicals[111,120].



$$-CH_2-CH{=}CH-X + R^{\odot} \rightarrow \begin{cases} -CH_2-\underset{R}{CH}-\overset{\odot}{C}H-X \\ -\underset{\odot}{C}H-CH{=}CH-X + RH \end{cases}$$

Scheme 5. X = H, alkyl or polymer; $R^{\odot}$ = initiator or polymer radical.

The kinetics of graft copolymerization substantially correspond to those of styrene homopolymerization. Differences occur at low rubber concentrations and at high conversions, due to cross-linking reactions[108,121]. The molecular weight and polydispersity of the grafted polystyrene chains correspond, as a first approximation, to those of the matrix polystyrene[122]. At high conversions, the preferential solvation of the rubber, and the gel effect[**], cause an increase in the mo-

[**] Gel effect: In highly viscous reaction solution the diffusion of the polymer molecules and hence also the chain termination are hindered. The diffusion of the monomer to the reaction site and thus the growth step of the chain reaction remain unaffected. This increases reaction rate and molecular weight equally (see also [38]).

lecular weight of the grafted polystyrene[123]. The proportion of grafted polystyrene depends on a large number of parameters; important amongst these are the polymerization process, the catalyst system, the chain transfer agent and the nature and amount of the rubber[111,124-126].

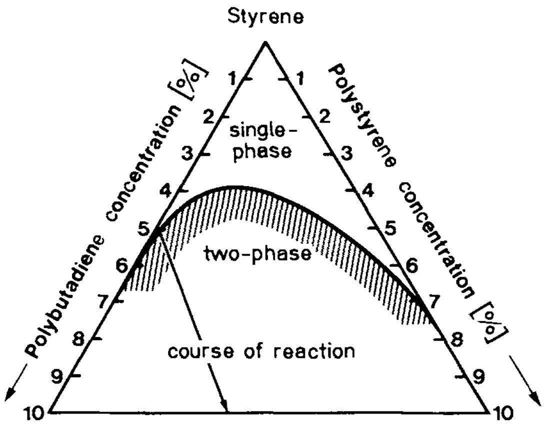

Fig. 4. Phase diagram of the styrene/polystyrene/polybutadiene system [132].

Most kinetic calculations do not allow for the fact that the styrene/polystyrene/rubber system is a two-phase system. The rate of polymerization is assumed to be the same in both phases[111]. *Rosen*[127] has, making allowance for the phase separation which starts even at very low conversions (Fig. 4), derived an equation for the maximum degree of grafting $f$.

$$f = \frac{\nu_R}{\nu_S}\ln\left(1+\frac{\nu_S}{\nu_R}\chi\right)$$

$\nu_R$, $\nu_S$ = phase volume of rubber and of polystyrene in styrene, respectively, $\chi$ = conversion

Experiments have confirmed the basic predictions of this equation.

### 2.3. Properties of the Polymer Solutions

The viscosity of polystyrene solutions increases sharply with molecular weight and concentration. Increases of more than 6 orders of magnitude during polymerization are not rare (Fig. 5)[128-130] and cause problems in mixing in the reactor, in heat removal, and in the gel effect[28,107]. The viscoelastic properties of the polystyrene solutions add to the difficulty of overcoming these problems[131]. Nevertheless, the styrene polymerization process is now well understood.

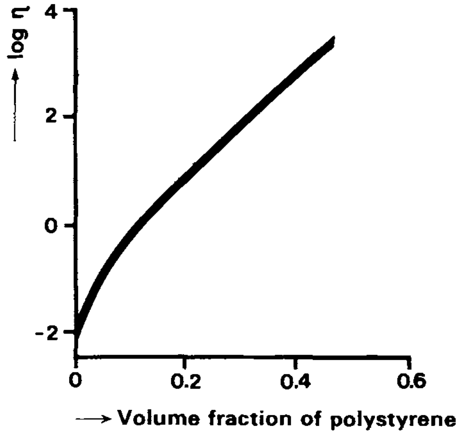

Fig. 5. Viscosity of polystyrene-styrene solutions as a function of the volume fraction of polystyrene [130].

The course of the two-phase grafting reaction can advantageously be represented in a phase diagram for ternary systems (see Fig. 4)[132-135]. If styrene is polymerized in the presence of dissolved rubber, the originally homogeneous solution undergoes phase separation even at very low conversion. The solution of polystyrene in monomer, and the solution of rubber in monomer, are incompatible and form an oil-in-oil emulsion[136]. When the volume of the polystyrene solution reaches, and exceeds, the volume of the rubber solution, phase inversion occurs. The cohesion barriers attributable to

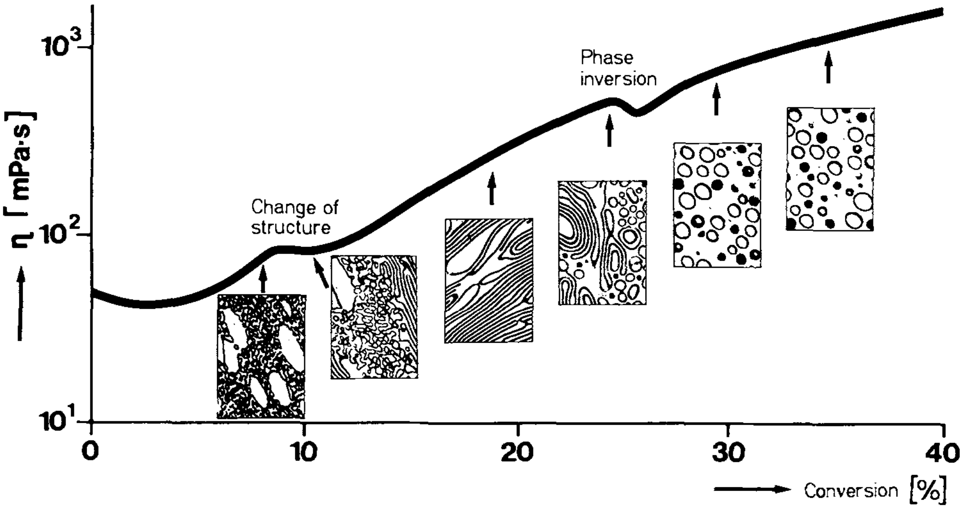

Fig. 6. Viscosity-conversion curve and structural change phenomena in the manufacture of high-impact polystyrene with capsule particle morphology.

the viscosity of the solution are overcome by the shearing action of the stirrer[137]. It is in this stage of the reaction that the particle size spectrum of the rubber phase (which is now the dispersed phase) is adjusted as required[104, 138-141]. The phase inversion can be detected from the fall and rise in the viscosity/conversion curve (Fig. 6)[142, 143].

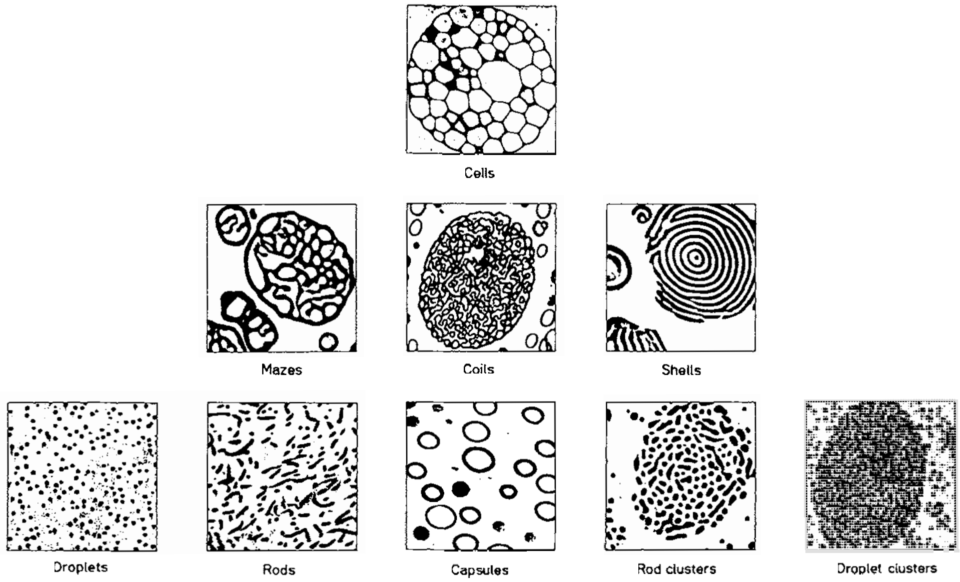

Fig. 7. Particle structures encountered in high-impact polystyrene

Styrene-butadiene block- and graft-copolymers form domain structures in styrene solution with various arrangements depending on their chemical structure[104, 109, 136, 144-149]. The ratio of polystyrene component to rubber component, which is a deciding factor in the particular structure, varies during polymerization, as a result of grafting and of embedding of low molecular weight polystyrene components[150]. When the limit of stability of the particular structural type is exceeded, complicated structural change processes start. Figure 6 shows a sequence of such structural changes during the polymerization of a styrene-butadiene block copolymer (impact resistant polystyrene), as well as the corresponding viscosity/conversion curve. The fall in the curve before phase inversion indicates the change in the domain structure of the rubber solution. The particle-formation process comes to an end even at relatively low conversions. The resulting morphology undergoes no further change up to high conversions, and is ultimately fixed by the cross-linking of the rubber phase[114, 142, 151]. The type of particle in the rubber-modified polystyrene accordingly depends on the domain structure of the rubber solution and on the grafting. If these parameters are varied, high-impact polystyrenes having very different particle structures are obtained (Fig. 7)[104, 149, 152-154].

### 2.4. Industrial Processes

For crystal polystyrene and high-impact polystyrene, and for styrene copolymers, continuous mass polymerization and solution polymerization processes have found acceptance. Expandable polystyrene is preferably produced by the suspension process, and high-impact styrene copolymers, such as ABS and ASA polymers[155], are preferably produced in emulsion. Gas phase polymerization is not used[156, 157]. Figures 8a and 8b illustrate the development of the industrially most important processes of manufacture, from the first process to be used industrially, namely the polystyrene III process of BASF[28], to today's mass polymerization process for the manufacture of modified and unmodified styrene homopolymers and copolymers[28] (for a detailed description of all the processes see [28, 31, 103, 107, 108, 156, 158-161]).

## 3. Structure and Properties

In this article, the "structure" of a styrene polymer means its molecular and morphological structure, whilst its "properties" are the processing properties and utility properties, in the broadest sense. The latter-mentioned properties determine the possible uses of the polymer as a material of construction; and it is these possibilities which provide the stimuli for development and improvement.

Amongst the large number of processing properties and utility properties, we have selected the following as being the most important:

- stiffness
- toughness
- heat distortion resistance
- flowability
- surface gloss and transparency

The structure the the styrene polymers is determined by the molecular parameters of molecular weight, molecular weight distribution, and content of low molecular weight materials, and, in the case of rubber-modified products, additionally by the following morphological parameters: rubber content, phase volume ratio, particle size and particle size distribution, degree of grafting and degree of cross-linking of the rubber. In order to relate structure to properties, parameters must be defined which enable quantitative comparisons to be made (for test methods see [103,162]).

### 3.1. Stiffness

The stiffness is the resistance of a body to elastic deformation by external forces. Polystyrene is a visco-elastic material. Its behavior under external load and at low deformations can be expressed in terms of the modulus of elasticity (or Young's modulus) $E$ or the shear modulus $G$. These moduli are time-dependent; under constant deformation, the stress relaxes, whilst under constant stress the material creeps. In order to be able to separate the viscous and elastic components, the moduli are generally measured by dynamic methods[162]. In the definition of the shear modulus $G^*$

$$G^* = G' + \mathrm{i}\,G''$$

$G'$ is the storage modulus and $G''$ is the loss modulus on shearing. $G'$ is the actual measure of stiffness at room temperature; it is one or two orders of magnitude greater than $G''$. Hence, the complex moduli can themselves be employed as a measure of the stiffness and, for example, Young's modulus $E$ easily derivable from tensile experiments can be employed. This, however, is only true at temperatures which are sufficiently below the glass transition temperature ($T_g$) that the temperature-dependence of $G'$ or $E'$ is small. At the glass transition temperature $T_g$, $G'$ and $E'$ decrease by several orders of magnitude (Fig. 9).

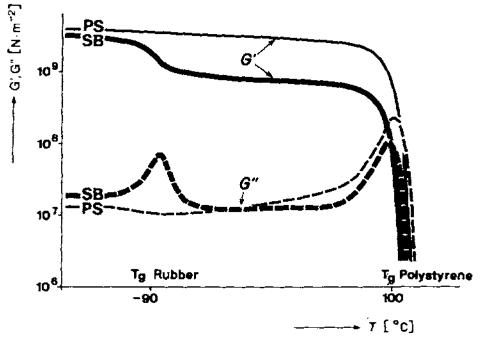

Fig. 9. Storage modulus $G'$ and loss modulus $G''$ of polystyrene (PS) and high-impact polystyrene (SB) as a function of temperature.

In isotropic test specimens of polystyrene, the moduli are independent of the direction of the external stress. In articles for practical use, this precondition in general does not apply, because the flow which occurs during the manufacturing process impresses preferred directions. Young's modulus is greatly increased in such directions and decreases in directions at right angles thereto. In polystyrene, use is made of this property, for example in biaxially oriented films.

Above a critical limit ($2\,M_c = 70000$), the moduli of polystyrene are independent of the molecular weight. This has been confirmed by *Fellers* and *Chapman*[163] in both tensile and compression experiments. $M_c$ is related to the critical entanglement length; this is the lowest molecular weight that allows the polystyrene chains to intertwine (cf. also [164]). According to *Fox* and *Loshak*[165] the exponent in the viscosity/molecular weight function $\eta \sim M^\alpha$ changes from $\alpha = 1$ to $\alpha = 3.4$ at molecular weight $M_c = 35000$. This molecular weight is equated with the critical entanglement length of the polystyrene molecule. *Fellers* and *Kee*[166] observed that the curves of the breaking stress and of the crazing stress (cf. Section 3.2 for crazes) plotted against molecular weight intersect at $2M_c = 70000$. *Wellinghoff* and *Baer*[167] found that crazing only becomes detectable by electron microscopy at molecular weights of about 30000; at lower molecular weights, the crazes show no fibrillation. This suggests that *Fox*'s interpretation is correct, though a more recent view holds that the exponent changes progressively from 1 to 3.4[168].

The addition of a few per cent of a low molecular weight lubricant also produces no change in the stiffness of polystyrene. On the other hand, the addition of compatible polymers alters the moduli which can be calculated by an almost linear function from the ratio in the mixture. This can be demonstrated, for example, for the case of mixtures of high-impact polystyrene and poly-2,6-dimethylphenylene oxide (PPO)[169,170].

The situation is different in the case of rubber-modified polystyrene. It is true that in this material the stiffness is substantially determined by the properties of the matrix, but the presence of the rubber particles causes a considerable decrease in the storage modulus $G'$ at temperatures above the glass transition temperature of the rubber (Fig. 9). $G'$ decreases noticeably at the glass transition temperature of the rubber, whilst $G''$ passes through a maximum at this point. It was in this way that *Buchdahl* and *Nielsen*[171] for the first time, in 1950, proved the two-phase nature of rubber-modified polystyrenes. Subsequently, *Cigna*[172] showed that the decrease in $G'$ was not dependent on the rubber content, but on the proportion by volume of the soft component phase; accordingly, the rubber particle acts as a unit. This has subsequently been repeatedly confirmed[139,173] (Fig. 10).

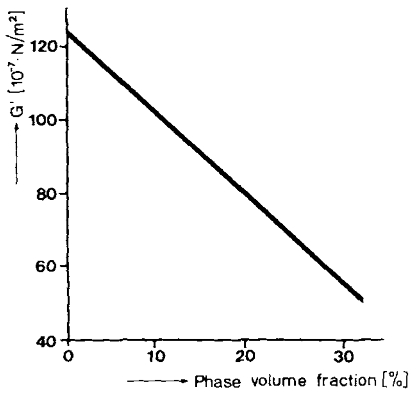

Fig. 10. Dependence of the storage modulus $G'$ of high-impact polystyrene on the proportion by volume of the soft component phase (after [172]).

In addition, the moduli depend, albeit to a lesser degree, on the size and degree of cross-linking of the particles. *M. Baer*[139] has described the decrease in modulus of elasticity with particle size (Fig. 11). We have found that the modulus of elasticity decreases with increasing swelling index[*] of the soft component. Since the degree of swelling is an indirect measure of the cross-linking of the rubber component, increasing cross-linking is associated with an increasing modulus of elasticity (Fig. 12).

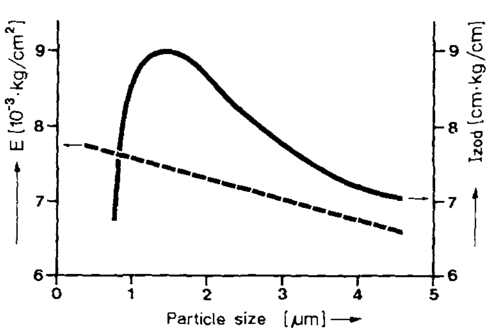

Fig. 11. Modulus of elasticity $E$ as a function of particle size (after [139]) and impact strength (Izod) of impact resistant polystyrene as a function of particle size (after [219]).

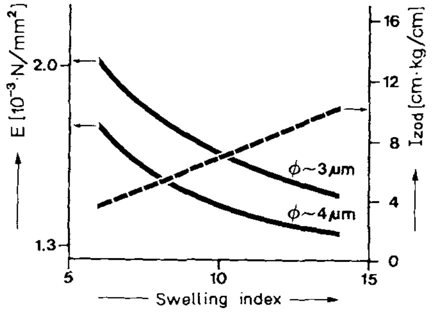

Fig. 12. Modulus of elasticity $E$ and impact strength (Izod) as a function of the swelling index (after [219]).

Many attempts have been made to calculate the modulus of a two-phase material from the moduli of the components, as a function of the phase ratio[174-176]. *Cigna* and *Bohn*[172,177] have compared the various approximations; none of the models proved capable of describing the experimental data quantitatively. They are, however, very good approximations. The reason for the deviations from the models may be that no account has been taken of the dependence of the moduli on the particle size and state of cross-linking.

### 3.2. Toughness

A material is described as tough if, under load, it undergoes not only elastic but also plastic deformation. Polystyrene becomes tough when modified with rubber. Such materials has been manufactured industrially since the end of the 1940's.

It was appreciated at a very early stage that mixtures of styrene and rubber have a two-phase structure[171]. These mixtures exhibit stress whitening when stretched to the yield point. Originally, this phenomenon was interpreted as being the formation of a large number of micro-cracks in the polystyrene matrix, bridged by the rubber particles[178]. However, this concept had to be abandoned because the rubber—according to this model—can at most absorb 10% of the fracture energy actually needed[179].

On the other hand, *Sauer et al.*[180,181] found, as early as 1949, that a sample of polystyrene was able to absorb considerable tensile stresses even though the sample was entirely pervaded by micro-cracks. On the basis of X-ray analyses, these authors postulated that the cracks had to be bridged by highly stretched matrix material. They called these cracks "craze cracks", which later come to be known just as "crazes" (Fig. 13). It took 13 years until this was confirmed

---

[*] The swelling index is defined as the ratio of the wet to dry weight of the gel centrifuged from toluene solution.

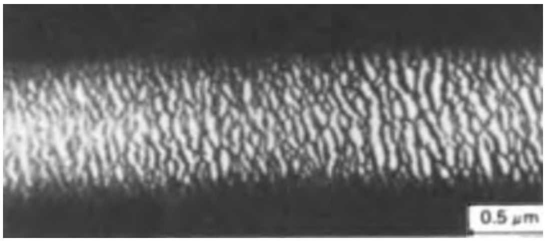

Fig. 13. Crazing in polystyrene.

by *Spurr* and *Niegisch*[182]. Subsequently, *Kambour* confirmed the structure of the crazes, determined the proportion of voids, and showed that crazes were also the preliminary stages of fracture[183]. *Bucknall* and *Smith*[184] then related crazing to stress whitening and to impact strength. Today, a craze is understood as a flat void which is spanned by fibrils of oriented polymer material (Fig. 13).

The mechanism which initiates the phenomenon of crazing is still under dispute, but it appears that the conception proposed by *Argon*[185,186] is gaining acceptance over the stress criterion of *Sternstein et al.*[187]. *Argon* interprets the formation of crazes as being due to a three-stage process: 1. Formation of stable micropores under stress; 2. formation of a craze nucleus by plastic extension of the pores; 3. expansion of the nucleus into a planar yield zone. Micropores generate predominately in zones of high stress, *i. e.* in the neighborhood of flaws or in the equatorial region of a rubber particle. The fact that crazes are formed at flaws has recently been shown once again[188]. The volume and number of micropores, on elongation of high-impact polystyrene, could be determined by means of small-angle X-ray scattering measurements.

In addition to crazing, there is a second deformation mechanism, namely shear flow. In polystyrene, it mostly manifests itself only in compression experiments[190], and in tensile experiments it is only observed with highly oriented samples[191]. During shear flow, there is no formation of voids in the material, as happens with crazing, and instead narrow plane zones inclined at roughly 45° to the stress direction are formed. The deformation of numerous thermoplastics takes place by this mechanism. There are also transitional cases between crazing and shear flow[170].

Crazes form at the interface between particles and matrix[192-195] or at the internal interfaces of the particles[196]. The particles themselves are stress concentrators; in their equatorial plane relative to the stress direction, a stress peak results[193], which initiates the craze. This effect is intensified by the overlap of the stress fields of adjacent particles[197-199]. Thermal stresses between the matrix and the particles also contribute to craze initiation[200-202].

After initiation, the crazes grow as a flat disk perpendicular to the stress direction. The spread of crazes can be hindered by the rubber particles and the crazes may stop, or branch, at such particles[203]. The agreement between theory and practice argues in favor of this mechanism: The impact strength, plotted as a function of the particle size, passes through a maximum[204,205] (Fig. 11).

The resistance of crazes to further deformation is also a factor in the impact strength. During such further deformation, the fibrillar crazed material is stretched further, becomes more highly oriented and consequently becomes strengthened (a phenomenon referred to as "strain hardening")[206]. The fibrils have an initial thickness of 250—500 Å, but a final thickness of only 100 Å[207].

"Toughness" is an all-embracing term. The resistance to failure at high deformation is important in selecting a material for a particular application, but cannot be expressed in terms of a single measured property. The toughness depends not only on the temperature but also on the rate of application of the stress, the dimensions and the internal state of the specimen (extent and direction of any orientation), and the type of stress.

In fracture mechanics, an attempt is made to express toughness in terms of a single constant for the material. According to *Griffith*[208] and *Irwin et al.*[209] a crack begins to extend if, in a material having a Young's modulus $E$ and a Poisson's ratio $\nu$, a critical stress $\sigma_c$ is reached at a sharp notch of length $a$. In that case, the following equation applies:

$$G_{IC} = \frac{\pi a(1-\nu^2)}{E}\sigma_c^2$$

$G_{IC}$ is the critical fracture energy. This equation applies to brittle fracture. Tough materials are more accurately described by a model proposed by *Dugdale*[210], in terms of the yield stress $\sigma_y$ and the corresponding critical strain $\delta_c$.

$$J_{IC} = \sigma_y\,\delta_c$$

*Plati* and *Williams*[211] have shown that the result of impact strength measurements can be described in terms of $G_{IC}$ or $J_{IC}$ independently of the geometry of the specimen. Nevertheless, these parameters have hitherto not found any acceptance in industrial practice. Instead, industry prefers to quote the results of standard tests. In the main, these are:

1. Impact test and notched impact test (Charpy test, Fig. 14a)[*].
2. Impact test or notched impact test (Izod test, Fig. 14b)[**].
3. Falling weight tests on round discs[***].

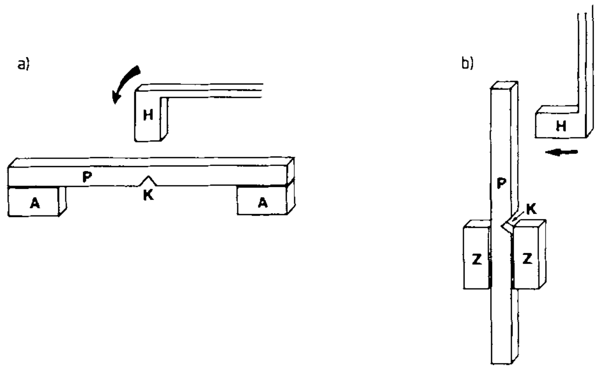

Fig. 14. Outline of the principles of two methods for measuring impact strength: a) Charpy test, b) Izod test. A = support, P = specimen, H = hammer, K = notch, Z = clamp.

The tests are mostly carried out on injection-molded test specimens. The ground state of the isotropic material and a certain amount of orientation are measured; this leads to

---

[*] DIN 53453, ISO 179 or ASTM-D 256, B [212].

[**] ASTM-D 256, A (cf. Fig. 11 and 12).

[***] DIN 53443 or ASTM-D 1709.

higher values in cases 1 and 2, and to lower values in case 3, than are obtained with isotropic material.

Form-annealed or compression-molded test specimens are isotropic[213,214]; they should be used for comparisons of materials. On the other hand, if a test simulating practical conditions and relating to a particular end use is intended, then the falling weight test (case 3) is more appropriate than cases 1 and 2[215].

Given a test method, the toughness can be related to the structure of the polymers.

The molecular weight is a significant factor only in the lower range. Low molecular weight polystyrene is extremely brittle. Using a special technique, ***Robertson***[216] succeeded in measuring $G_{IC}$ in crystal polystyrene down to a molecular weight of 3000. The measurements showed a jump of 2 orders of magnitude between $\bar{M}_n = 50000$ and $\bar{M}_n = 100000$. Similarly, ***Hauss***[217] found an abrupt increase in impact strength between $\bar{M}_w = 80000$ and $\bar{M}_w = 160000$, but no dependence on molecular weight above this value (Fig. 15). In the high-impact polystyrene, ***Wagner*** and ***Robeson***[151] showed that the addition of 5% of low molecular weight polystyrene dramatically reduces the impact strength, whilst the addition of an equal amount of high molecular weight polystyrene has virtually no effect.

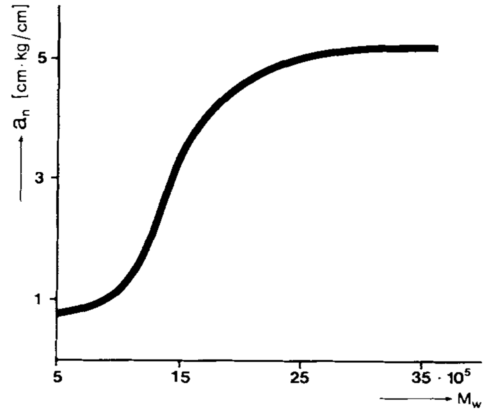

Fig. 15. Impact strength $a_n$ of crystalline polystyrene as a function of the molecular weight $M_w$ [217].

The molecular weight distribution has only little influence on the toughness of polystyrene[218], as long as the parts with $M_n < 10000$ remain negligible.

Low molecular weight lubricants such as paraffin oil or phthalic acid esters have hardly any effect on the toughness of crystal polystyrene. In high-impact polystyrene they slightly improve the toughness (Fig. 16).

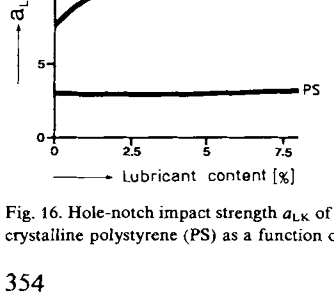

Fig. 16. Hole-notch impact strength $a_{LK}$ of impact resistant polystyrene (SB) and crystalline polystyrene (PS) as a function of the content of mineral oil.

The rubber content of high-impact polystyrenes has only an indirect effect on the toughness, the critical factor is the phase volume fraction of the soft component phase. Occluded matrix material must be regarded as part of this volume[139,172,219]. According to *Cigna et al.*[219] the impact strength increases linearly with gel content and with swelling index (Fig. 12, 17). Examined as a function of the rubber particle size, the impact strength goes through a maximum at particle sizes of from 1 to 2 μm (Fig. 11).

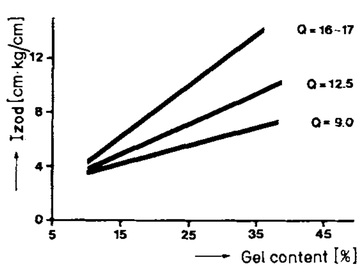

Fig. 17. Impact strength (Izod) of impact resistant polystyrene as a function of gel content (according to [219]). $Q$ = swelling index.

Finally, the anchoring of the particles in the matrix is also very important. The anchoring occurs *via* the grafted shell which forms during and after phase inversion. In thermal polymerization, anchoring can only be influenced by the temperatures used during the reaction. The use of grafting initiators increases grafting and also has an effect on the particle size[104].

### 3.3. Heat Distortion Temperature

The heat distortion temperature is the upper limit at which the material is serviceable. It is closely related to the glass transition temperature of the matrix polymer, the latter being the temperature at which rearrangements of sizable chain segments, with 50 or more chain units, become possible.

Within the range which is of practical interest, the molecular weight and molecular weight distribution have no effect on the glass transition temperature of crystal polystyrene. At low degrees of polymerization, the glass transition temperature decreases greatly; thermodynamic considerations lead to an entropy relationship between the glass transition temperature and the number-average degree of polymerization. *Überreiter* und *Kanig*[220,221] interpret the dependence in terms of the effect of the proportion of chain ends on the free volume (for a recent theoretical treatment see [222]).

However, it is only in homogeneous polymers that the glass transition temperature is a direct indication of the heat distortion temperature; in multi-phase systems, *i.e.* partially crystalline polymers or rubber modified polymers, a method which is a direct measure of stability of shape is required. The measurement of the Vicat softening temperature has found general acceptance for this purpose[*].

Low molecular weight additives have a great influence on the heat distortion temperature, the more so the greater their compatibility with the matrix. In practice, fatty acid esters, phthalic acid esters and, in the main, mineral oils are used as

---

[*] VST/B/50 according to DIN 53460 (ISO 306). The Vicat temperature is the temperature at which a needle, having a standard tip of 1 mm² area, penetrates, under a load of 50 N/mm², to a depth of 1 mm into the small test sheet of polymer, which is heated in a liquid bath at 50 °C/h [212].

auxiliaries to improve the flow of the polymers without adverse effect on the mechanical properties. The main disadvantage of such additives is that they reduce the heat distortion temperature. The degree of such influence, as a function of the concentration of the auxiliary, differs according to the auxiliary employed and is, *inter alia,* dependent on its solubility parameters (see also [223]).

Modification with rubber also influences the heat distortion temperature of the material; however, the glass transition temperatures of the components remain unaffected. The heat distortion temperature is largely determined by the glass transition temperature of the matrix. Accordingly, the Vicat softening temperature of high-impact polystyrenes is only a few degrees lower than that of unmodified polystyrene.

If a lubricant is incorporated into high-impact polystyrene, it distributes itself between the hard and the soft phase; accordingly, the distribution coefficient is a further parameter in the resulting heat distortion point. However, such factors are negligible in practice, since the changes in concentration are small.

### 3.4. Flowability

Polystyrene is processed virtually exclusively as a melt. Accordingly, the flow of the melt or, more precisely, its rheological character is the most important processing characteristic. If a polymer melt is exposed to shearing stress $\tau$, it undergoes elastic and plastic deformation simultaneously. To some extent, the melt can recover from impressed deformations $\gamma$, especially at temperatures only slightly above the glass transition temperature. The elastic component of the deformation $\gamma_r$ is described by the shear compliance

$$J_e^0 = \gamma_r/\tau$$

and the viscous component by the viscosity

$$\eta = \tau/\dot{\gamma}$$

The viscosity depends on the rate of deformation $\dot{\gamma}$; however, at low shearing rates many polymer melts exhibit Newtonian behavior. The viscosity tends to a constant value ("zero viscosity"), which is usually employed as a measure of the viscous behavior of a melt. $J_e^0$ and $\eta_0$ describe the behavior of a visco-elastic melt with time; if the shear stress is removed, the deformation recovers by the amount of the elastic deformation component (Fig. 18). Because they can be simply converted into shear, creep measurements are most suitable for determining $J_e^0$. The reversible shear deformation $\gamma_r$ has only to be replaced by the reversible elongation $\varepsilon_r$. The two parameters $J_e^0$ and $\eta_0$ together can be used to estimate the relaxation time $\bar{t}_r$, from the equation

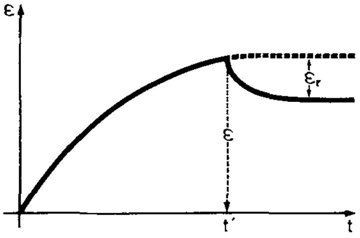

Fig. 18. Determination of the reversible elongation $\varepsilon_r$ of a polymer melt in a creep test (schematic). The sample is subjected to a constant stress $\sigma$ at constant temperature, and the stress is released at time $t'$.

$$\bar{t}_r = \eta_0 J_e^0$$

To obtain a rough estimate of the flow in general, and to compare products with one another, a single-point measurement is frequently employed, namely the apparent viscosity measured in a capillary viscometer under standard conditions[*]. However, it is well known that this measurement can, in practice, lead to considerable errors in forecasting properties. Hence, for a more precise assessment, the flow curve is employed. In this curve, the shear stress is plotted on a double logarithmic scale against the shear rate. Many polymer melts obey an exponential law:

$$\tau = C\dot{\gamma}^n$$

If they do, the flow curve in a double logarithmic scale gives the exponent $n$ as the slope of a straight line; given the value of $n$, the viscosity can be compared with that of a standard state, $\eta_s$, by eliminating the constant $C$:

$$\frac{\eta_1}{\eta_s} = \left(\frac{\dot{\gamma}_1}{\dot{\gamma}_s}\right)^{n-1}$$

*Han*[225] has found $n$ to be 0.29 for high-impact polystyrene.

The most important factor affecting the flow of polystyrene is the molecular weight. *Casale, Porter,* and *Johnson*[226] have derived the equation

$$\log \eta_0 = 3.38 \log \bar{M}_w - 13.08$$

from data in the literature, coupled with their own measurements. On the other hand, the zero viscosity does not depend on the molecular weight distribution. Only at relatively high shearing rates is a drop in viscosity observed (Fig. 19)[227].

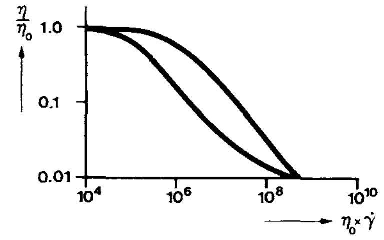

Fig. 19. Dependence of flow of polystyrene on molecular weight distribution (represented in the form of a master curve [227]).

In contrast to the zero viscosity, $J_e^0$ is independent of the molecular weight, but depends greatly on the molecular weight distribution. Polymers with a broad molecular weight distribution have a substantially higher $J_e^0$ than those with a narrow distribution. For this purpose the molecular weight distribution cannot, as is usually the case, be represented by the polymolecularity index $\bar{M}_w/\bar{M}_n$ or a higher moment of this type, since it is virtually exclusively the high molecular weight polystyrene component which affects the result (Fig-

---

[*] "Melt index" according to DIN 53735, ISO 1133 [224].

ure 20)[228]. In practice, this has the effect that the finished article from polystyrene with broader MWD contains more frozen-in elastic stresses; the article is more highly oriented and, when heated to above the glass transition temperature, shrinks more than an article made from polymer with a narrow distribution.

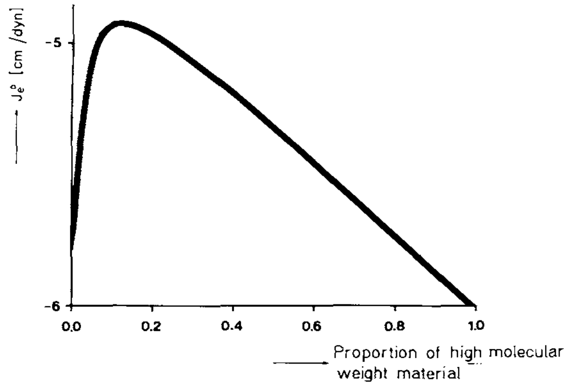

Fig. 20. Equilibrium yield $J_e^0$ as a function of the proportion of high molecular weight component in a mixture of two polystyrene samples of narrow molecular weight distribution (according to [228]).

An addition of rubber greatly increases the viscosity[225]. In the case of ABS[155], it is also dependent on the rubber particle size; small particles lead to higher viscosity. The thickness of the grafted shell also plays a part; plotted as a function of this thickness, the viscosity passes through a minimum[229]. The applicability of these results to high-impact polystyrene is subject to certain limitations, since in such a polystyrene grafting also affects the interior of the particles.

The addition of low molecular weight lubricants greatly reduces the viscosity of the polymers and is therefore a method generally employed to improve the flow. The effect is similar for crystal polystyrene and high-impact polystyrene and amounts to a shift of the viscosity/shear stress curve toward lower viscosity values. The amount of the shift is proportional to the concentration of lubricant; the effect is less pronounced at high shear rates than at lower rates.

For a given shear stress, the elastic deformation of the melt is less for high-impact polystyrene than for crystal polystyrene. Accordingly, melt fracture occurs in high-impact polystyrene at substantially higher shear rates than in crystal polystyrene[230]. "Die swell"[231] is also a measure of the elastic properties of a melt. As a strand of melt leaves a die, the imposed elastic stresses relax. The result is an increase in cross-section. Die swell decreases with increasing grafted rubber content[232].

### 3.5. Surface Structure and Transparency

The surface structure of injection-molded or thermoformed articles is critical for many applications. In some cases high gloss may be demanded, whilst in others matt surfaces may be preferred. On the other hand, transparency is a basic characteristic of unmodified polystyrene.

It is only in high-impact polystyrenes that gloss and transparency present a problem. The rubber particles remove the transparency and change the gloss for the worse. If the particles are made smaller, the gloss is improved but other properties may be adversely affected. In injection molding, it is possible to choose the process conditions (injection speed, mold temperature and follow-up pressure) so as to ensure that the gloss is preserved. In extrusion, the surface of high-impact polystyrene can be laminated with crystal polystyrene, but this has adverse effects on the mechanical strength[233]. A further alternative is a high rate of extrusion, since this tends to cause the rubber particles to migrate into the interior of the extruded sheet[234]. In recent times, attempts have been made to tackle the problem of gloss, both in injection molding and in extrusion, by changing the size and morphological structure of the particles. High-impact polystyrenes with capsule particles of ≈0.5 μm diameter (Fig. 7) give very glossy articles[104].

Approaching the problem through the morphology of the particles also gives improved transparency. Capsule-particle polystyrenes are translucent and can be used for clear-on-contact packaging. Full transparency is achievable by either matching the refractive index of the matrix and the disperse phase, for example by co-polymerization with methyl methacrylate, or by making the scattering centers small compared to the wavelength of the light and at the same time ensuring a uniform arrangement of these centers[109]. This may be achieved, for example, by anionic polymerization of styrene and butadiene to give block copolymers in which the styrene component predominates. Such polymers exhibit microscopic phase separation (Fig. 21). This provides a basis for synthesizing glass-clear transparent high-impact polystyrenes.

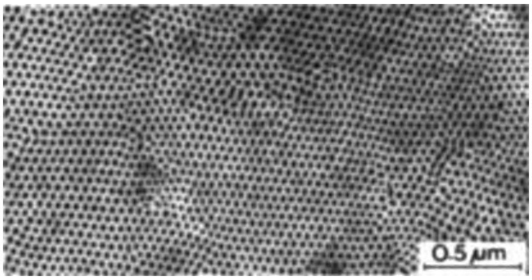

Fig. 21. Morphology of a styrene-butadiene-styrene ternary block copolymer (S/B/S proportions [%] = 37.5/25/37.5).

### 3.6. Property Combinations

We have shown that certain properties of polystyrene depend on the structure of the polymer. Figure 22 gives a diagrammatic survey of the various relationships. However, what matters in practical use of the material is a combination of properties, which must be appropriate to the particular application. A packaging material demands different combinations of properties than a material used for an electrical instrument housing, and a refrigerator door liner demands different properties from those of a yoghurt beaker. The appropriate combination of properties is, in most cases, a compromise. For example, the same step, say adding more of the soft component, has opposing effects on the toughness and on the stiffness; a gain in toughness is accompanied by a loss in stiffness. If flow is improved with lubricants, it adversely affects the heat distortion resistance, whilst if it is improved by lowering the molecular weight, it adversely affects the toughness. Smaller particles favor gloss in high-impact polystyrene, but improve toughness only down to an optimum value of the particle size. The know-how of the manufacturer amounts to his ability to offer the largest possible number of property combinations of maximum usefulness.

## 4. Processing and Use

### 4.1. Processing

Fabricators buy polystyrene in granular form. The material can be obtained without colorant (crystal, natural) or colored (opaque or transparent). The material is likely to be stored before processing and when it is used, care must be taken to remove moisture picked up from the atmosphere. In some factories, the material is separately pre-dried, whilst others use vented processing machines.

Polystyrene, as a construction material, is mainly injection-molded and extruded. Injection molding was used as long ago as 1930. The first machines were plunger injection-molding machines; today, exclusively screw injection-molding machines are used. Nowadays, there are large machines with clamping forces up to 25 MN, capable of producing moldings weighing up to 30 kg; there are also high-speed machines with multiple cavity molds, capable, for example, of producing 46 yoghurt beakers per minute[235].

Extrusion of polystyrene also dates back to the 1930's. One of the first cases of polystyrene extrusion was the production of biaxially oriented "Styroflex" polystyrene film, which from 1938 was employed for marine cable insulation. Nowadays, about 30% of the polystyrene is extruded to produce films or sheets; single-screw extruders with screw diameters of up to 200 mm and a driving power of 500 KW can process up to 2 tonnes of polystyrene per hour.

To produce shaped articles, the film or sheet is thermoformed. For this purpose, it is reheated to the thermoelastic state and is drawn into a mold by suction (see *e.g.* [161,236]; special versions see [237-240]; detailed description of the whole range of processing methods see [236,241,242]).

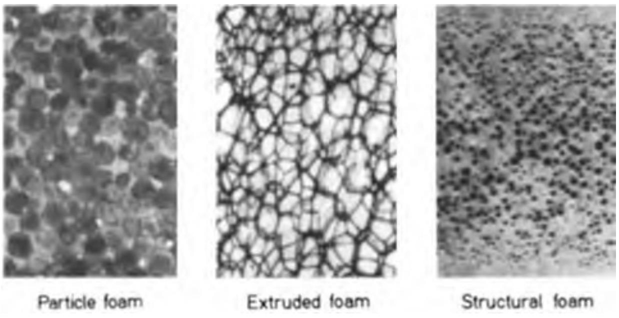

Fig. 23. Various structures of foamed polystyrene.

A detailed discussion of the processing of polystyrene to foamed articles is beyond the scope of this article (see [243]). The products are classifiable as particle foam, extruded foam, and structural foam (Fig. 23). The particle foam products are produced from expandable polystyrene beads or granules (EPS); the products may be either moldings or foam blocks which are subsequently split into boards. Extruded foam is obtained by extruding EPS or by direct gassing of polystyrene in an extruder; this results in foam boards and sheets. Structural foam has a higher density than the preceding products and is generally produced by injection molding of polystyrene containing chemical blowing agents. It is particularly employed for furniture components.

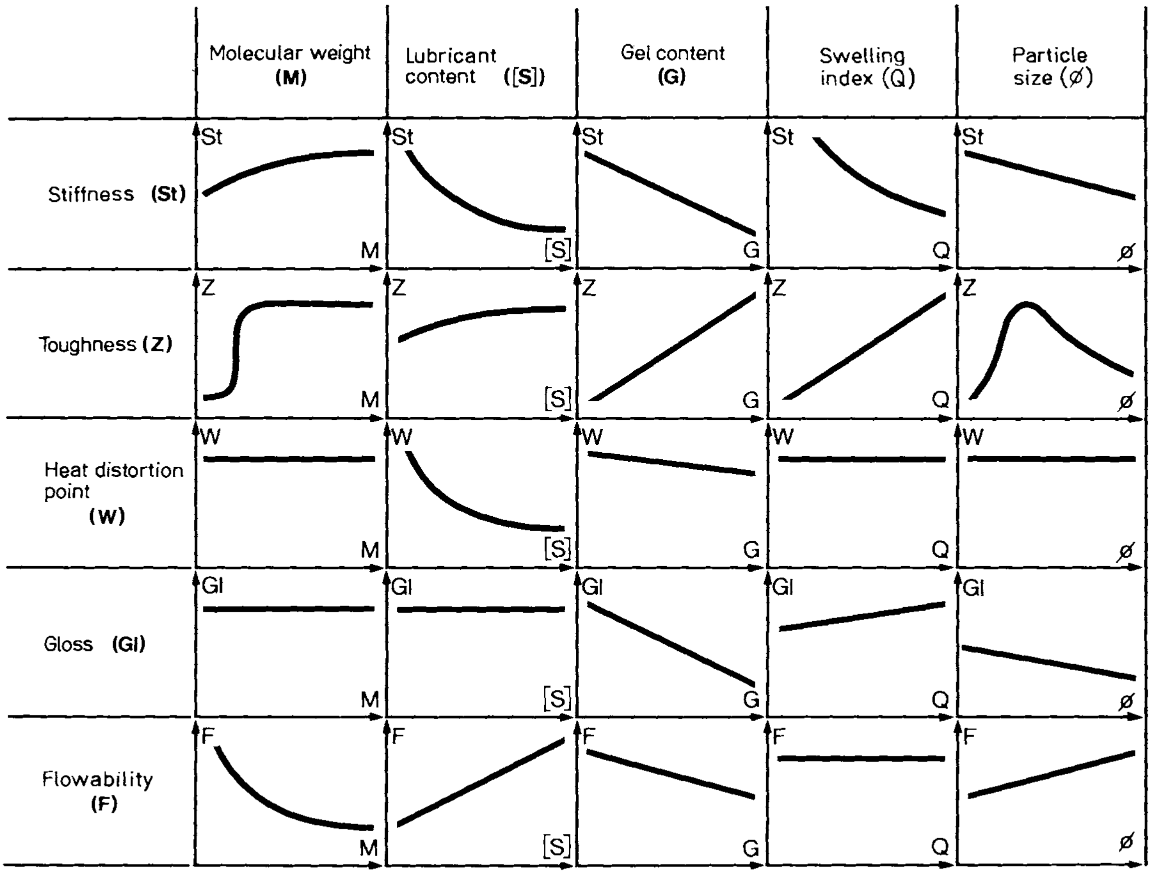

Fig. 22. Schematic representation of the interrelationships between structure and properties of polystyrenes.

Polystyrene articles can be processed further, and aftertreated, in a variety of ways, which include welding, glueing, surface-coating, printing, electroplating *etc.*

### 4.2. Uses

Because they have a good balance of properties, are easy and cheap to process, and have a low price per unit volume, thermoplastic styrene polymers have a wide range of uses, extending from high quality technical applications, for example as a material of construction in the electrical, automotive and office machine industries, to mass-production applications, for example for packaging and promotional articles, for domestic and camping items, for toys, for refrigerator and furniture components, for water pipes and for heat insulation[237,239,244-246]. The range of uses is constantly growing. Thermoplastic styrene polymers are replacing traditional materials, opening up new fields of application and finding entirely novel uses. Some recent examples are the new stress-crack-resistant polystyrenes in refrigerator construction, translucent high-impact polystyrenes in packaging, transparent super-high-impact styrene copolymers in the medical sector and flame-retardent polystyrene foams in the building trade[239,244,245].

## 5. Prospects

Since *Hermann Staudinger*'s basic work and the first industrial production of polystyrene in 1930, there has been a fundamental change in the situation. Macromolecular chemistry has become a discipline of its own, and the manufacture and processing of thermoplastics have developed into a widely diversified field with ramifications in chemical technology, mechanical engineering and process engineering.

There have also been changes in the tasks for the future and in development trends. Changes in the economic situation, particularly the fact that crude oil, as a raw material and source of energy, is becoming scarcer and more expensive, present other but not less fascinating challenges than in the pioneering period.

The theory of styrene polymerization has still not been fully elucidated. Not only the kinetics at high conversions, including the gel effect[50,61,62,247], but also the initiation of thermal polymerization are still a matter of dispute. Styrene polymerization has also become a model reaction for the behavior of commercial-scale reactors[157,248-250]. Copolymerization, too, offers numerous possibilities of modifying the properties of polymers. One example is the manufacture of purely organic ionomeric polystyrenes by incorporating cationic and anionic comonomers[251]. Ionomers open up new combinations of flow and mechanical properties. Considerable interest is also being shown in chemical modification of the polymers. Sulfonation, on the one hand, and chloromethylation, on the other, have long been used for the manufacture of ion exchangers from cross-linked polystyrene[258]; work is now proceeding more in the direction of polymer catalysts. Examples are the replacement of polystyrene by $-P(C_6H_5)_2$ as polymeric reagent for Wittig reactions[253] or the bonding of copper to aminated polystyrene as catalyst in the oxidative coupling of 2,6-dimethylphenol to give PPO[254]. Work is also being carried out on the bonding of biologically active enzymes to polymeric carriers[255-257]. In organic chemistry there are many applications for polymeric reagents (see [258-260]).

Increasing interest attaches to the graft reaction of styrene to synthetic or natural fibers, sheeting, boards and finished articles for improving the surface properties[261,262]. Attempts to polymerize natural materials such as wood flour and starch into polystyrene[263] are to be seen in the light of the increasing scarcity of raw materials.

Intensive efforts are being made in the field of polymer blends. The compatibility of polystyrene with PPO and the partial compatibility of ABS[155] with PVC, PMMA and polycarbonate have long been known[264]. More recently, still further polymer blends of industrial interest have been discovered, *e.g.* polystyrene with tetramethylbisphenol-A-polycarbonate[265] and ABS with polysulfones made compatible with polar pendant groups[266]. The object of this work is to unite the properties of the components to give a new combination. Particular attention is being paid to improving the heat distortion temperature of the blends; other main objectives are greater weathering resistance and better flame retardency.

Attempts are also currently being made to modify the property profile of impact-resistant polystyrene by morphological variation. Toughness, stiffness, flow and transparency can thus be varied within wide limits. The varied structures of rubber particles have been the subject of very recent, intensive investigation; their development offers very promising prospects[149,153].

Anionic polymerization may acquire greater interest as a process of manufacture. Block copolymers of very diverse structures (binary, ternary and multiblock products, radial block copolymers, comb structures and ABC-multicomponent systems) have already opened up a wide field of investigation and promise to yield further valuable results, since unusual combinations of properties, such as great toughness coupled with complete transparency, or great toughness coupled with good flow, can be achieved. Partially hydrogenated derivatives are also gaining in interest, not only as viscosity index improvers in mineral oils, but also as materials of construction.

In development work, priority is being given to measures which help to save energy. The manufacture of traditional materials requires more energy than does the manufacture of plastics[267,268]. In the USA, in 1977 alone, the use of plastics in building, packaging and household appliances saved 38 million barrels of crude oil[268].

All the stages of the polystyrene manufacturing process, from benzene and ethylene *via* ethylbenzene and styrene to polystyrene, up to its processing, must be scrutinized for further possible ways of saving energy. Thus, it has been proposed to utilize—by means of heat pumps—the heat of polymerization from the manufacture of polystyrene in order to degas the polymer melts, or to integrate the production of semi-finished and finished articles with the polymerization plant, since the latter in any case produces polymer melt[269]. Saving energy is also an important aspect in the development of equipment for injection molding[270], extrusion[271] and no-waste thermoforming[272].

These remarks will suffice to show that the development of polystyrene has not reached the end of the road. A number of scientific and technical innovations can still be expected for polystyrene, and its economic development can be viewed with optimism. The path which *Hermann Staudinger* trod in his pioneering work leads on.

*We thank our colleagues Drs. J. Stabenow, G. Wassmuth, and H. Breuer for their kind support of this work.*

# Polymers with Metal-Like Conductivity—A Review of their Synthesis, Structure and Properties

## By Gerhard Wegner[*]

**Polymers such as polyacetylene, which have an extended π-electron system in their backbone, or like poly(*p*-phenylene) consist of a sequence of aromatic rings are excellent insulators in their native state and can be transformed by oxidation or reduction in the solid state into conductive CT-complexes which exhibit metal-like conduction characteristics. The chemical and physical processes involved and the reasons for the observed quasimetallic conductivity are not yet fully understood. The real structure of these materials in chemical and physical terms, *i. e.* their complicated morphology and texture, as well as the results available on the structure-property relationships of the "organic metals" must be considered when discussing their properties. In other words, a discussion of conductive polymers should be based on what is known of the highly conducting CT-complexes of low-molecular weight compounds. The discovery of the highly conducting polymer complexes has opened up a new interdisciplinary field of research which borders on polymer science, solid-state and semiconductor physics and on organic solid-state chemistry. It is hoped that this area will lead to numerous novel materials and technical applications.**

## 1. Introduction

### 1.1. Polymers as Materials

Strength, elasticity, plasticity, toughness and frictional resistance are properties which are described as typical of metals, but today are also characteristic of many polymers. Metals have therefore been replaced by plastics in many areas of application. This, however, is not the case with one of the most salient properties of metals—their electrical conductivity. Although the manufacture of electrical units would have been impossible without the development of polymers for insulation, the question of producing macromolecular materials which exhibit a conductivity similar to that of metals has long been posed. The importance of this question lies in the significance of being able to process such materials in the forms of films, foils or fibers according to the standard procedures of the plastics' industry so that they can act as a substitute for metals.

Despite numerous and concerted attempts, especially by preparative chemists, it was not until very recently that the

Stefan-Meier-Strasse 31, D-7800 Freiburg (Germany)

production of macromolecular materials whose conductivity and conductivity characteristics were the same or closely similar to those of metals was possible. From monographs[1-4] and review articles[5-7] it can be gleaned that ideas concerning the relationships between the molecular structure, and the structure and electrical properties of macromolecular solids have neither been fully developed, nor have insights available from other fields been given sufficient consideration.

It comes as no surprise then, that the stimulus for the present research in this area of conducting polymers comes not from preparative organic or macromolecular chemistry, but rather from solid-state and semiconductor physics. Preparative chemists have long attempted to synthesize macromolecules with an extended $\pi$-electron system as a constituent part of the main chain. It was hoped that the delocalization of the electrons, assumed to take place in such systems, would necessarily lead to a high concentration of charge carriers in the transport of current. Within the framework of these model considerations, the low conductivity of polymer $\pi$-bonded systems observed experimentally was claimed to be due to impurities in the polymer, breaks in the $\pi$-bonding system by chain ends, and conformational and similar defects. It is known today, however, that polymers with polyconjugated structures in the main chain are insulators in the ground state; even irradiation by light only produces a limited number of charge carriers since the dominant absorption in the visible region of the spectrum of such polymers is due to the formation of an exciton and not to the transition of an electron from the valence into the conduction band.

New insights were introduced by *Heeger* and *MacDiarmid et al.* in 1977. In their work, they demonstrated for the first time that polyacetylene (PA), which is a semiconductor with a relatively large band gap, exhibits a dramatic increase in specific conductivity if it is treated with strong oxidizing or reducing agents[8-10]. When a thin film of *cis*-polyacetylene, obtained by polymerization of acetylene on the surface of a solution of suitable catalysts in an inert solvent, was treated with iodine, bromine, $AsF_5$ or sodium naphthalide, its conductivity increased from an initial value of approximately $10^{-9}\ \Omega^{-1}\ cm^{-1}$ to approximately $5\cdot10^{2}\ \Omega^{-1}\ cm^{-1}$. Data concerning the electrical and optical properties of the conductive polymer, *e.g.* the small dependence of the conductivity on the temperature and the dramatic increase in the absorption in the infrared with increasing degree of conversion, was interpreted within the framework of theories of phase transitions from semiconductors to metals. The behavior of the polymer was comparable to that of classical semiconductors[11], *e.g.* silicon, which upon doping with donors or acceptors, can be transformed into a conducting state. The reactions of the polymer with, for example, halides, pseudohalides, alkali metals or alkali metal derivatives was, therefore, using the language of semiconductor physics, termed "doping".

### 1.2. A Survey of Organic Metals and Polymeric Conductors

As shown in Figure 1, *Heeger* and *MacDiarmid et al.* observed an increase in the conductivity of PA when doped with typical dopants. Figure 2 presents a broad summary of the temperature dependence of the electrical conductivity of several materials compared to that of doped PA.

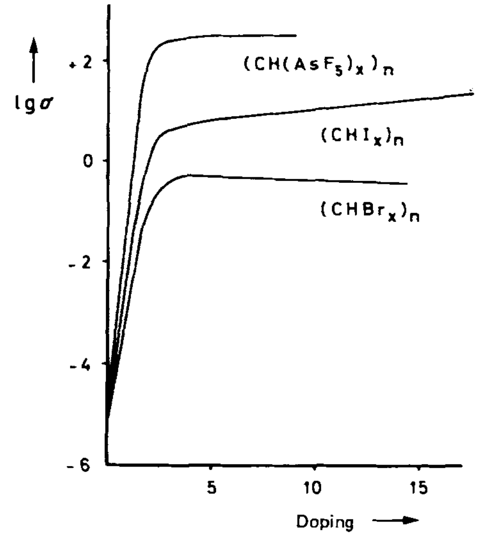

Fig. 1. Specific conductivity $\sigma[\Omega^{-1}\ cm^{-1}]$ of polyacetylene (PA) *versus* the concentration [mol% relative to —CH—] of the dopants $AsF_5$, $I_2$, $Br_2$ (after *Heeger et al.* [11]).

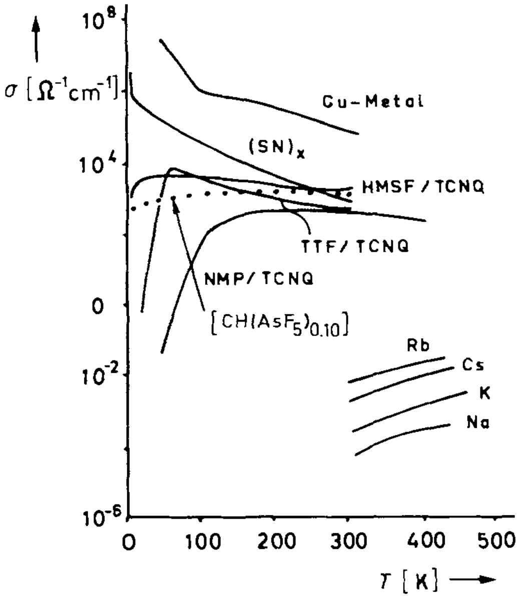

Fig. 2. Temperature dependence of the specific conductivity $\sigma$ of some organic CT-complexes and conductive polymers; all data from [13]. See text for abbreviations; the curves denoting Rb, Cs, K, Na refer to the alkali metal salts of TCNQ.

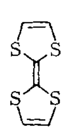
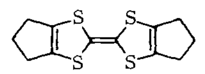
The discovery of conductive PA led to considerable research activity on "organic metals". This term indicates that materials, produced by methods of organic chemistry, can exhibit electrical properties which resemble those of metals[12-14].

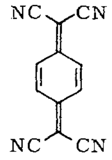
The most prominant example of such an organic metal is the charge-transfer-complex produced from tetrathiofulvalene (TTF) and tetracyanoquinodimethane (TCNQ). The electrical behavior of this material is also shown in Figure 2. In addition, two other salts of TCNQ with the *N*-methyl phenazinium cation (NMP) and hexamethylenetetraselenofulvalene (HMSF) are also mentioned.



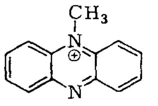
TTF



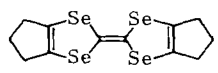
HMTTF



TCNQ



NMP



HMSF

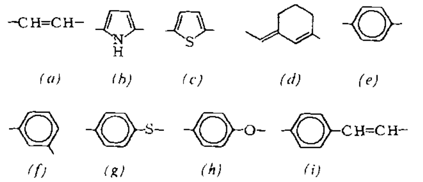
These CT-salts exhibit, just as doped PA, either a temperature independent or even increasing conductivity with decreasing temperatures. The latter is the behavior typical of metals such as copper.

In semiconductors, σ increases with temperature. The alkalimetal salts of TCNQ serve as an example of this phenomenon and are shown in Figure 2.

Polymeric sulfur nitride, $(SN)_x$, also possesses characteristic metallic properties and, in addition, at a temperature of *ca.* 0.5 K becomes superconducting. The chemical and physical properties of this interesting and unusual material have been discussed in detail in a recent review[15]. Since it seems to be a material with little or no analogies to other polymers or low molecular weight model compounds, it will not be discussed further.

Following the fundamental observations of *Heeger* and *MacDiarmid et al.*, further polymers which became conducting upon doping were quickly found (Table 1).

Table 1. Direct current conductivity of some doped polymers with the fundamental units *(a)*–*(i)* [a].



| Fundamental Unit | Doping material/ counterion | c [b] | σ [$\Omega^{-1}$ $cm^{-1}$] | Ref. |
|---|---|---|---|---|
| *(a)* [c] | $I_2$ | 0.25 | 360 | [10, 13] |
| | $Br_2$ [g] | 0.10 | 0.5 | [10, 11] |
| | $AsF_5$ | 0.28 | 560 | [10, 11] |
| | $AgClO_4$ | 0.036 [d] | 3.0 | [16] |
| | Sodium naphthalide | 0.28 [e] | 80 | [10, 11] |
| | $(n\text{-}C_4H_9)_4NClO_4$ [f] | 0.06 [d] | 970 | [17] |
| *(b)* | $BF_4^{\ominus}$ | 0.25 | 100 | [18] |
| *(c)* | $I_2$ | 0.10 | $3.4 \cdot 10^{-4}$ | [19] |
| *(d)* | $I_2$ | ca. 0.1 | ca. 0.1 | [20] |
| *(e)* | $AsF_5$ | 0.42 | 145 | [21, 22] |
| | Potassium naphthalide | 0.57 | 7 | [21, 22] |
| *(f)* | $AsF_5$ | 1.0 | $10^{-3}$ | [23, 24] |
| *(g)* | $AsF_5$ | ca. 1.0 | 1 | [24, 25] |
| *(h)* | $AsF_5$ | 0.4 | $10^{-3}$ | [26] |
| *(i)* [h] | $AsF_5$ | 0.75 | 3 | [27] |

[a] All values are valid at room temperature. [b] In mol/mol of the fundamental unit. [c] *cis*-Structure. [d] Concentration of $ClO_4^{\ominus}$. [e] Concentration of $Na^{\oplus}$. [f] Carrier electrolyte for anodic oxidation. [g] Starting from *trans*-PA. [h] Oligomers with $\bar{P}_n \sim 3$–5.

The significance of these polymeric conductors can be readily gathered from Table 2. If one considers the conductivity per unit weight, then conductive polymers are not far removed from the better conducting metals. This has, naturally, led to speculation concerning the possible technical applications for these polymers.

Table 2. Density ρ, conductivity σ, and σ/ρ of various materials.

| Material [a] | ρ [g $cm^{-3}$] | σ [$\Omega^{-1}$ $cm^{-1}$] | σ/ρ [$cm^2$ $g^{-1}$ $\Omega^{-1}$] |
|---|---|---|---|
| Cu | 8.92 | $6.5 \cdot 10^5$ | $7.6 \cdot 10^4$ |
| Au | 19.3 | $4.1 \cdot 10^5$ | $2.1 \cdot 10^4$ |
| Fe | 7.86 | $1.0 \cdot 10^5$ | $1.3 \cdot 10^4$ |
| $(SN)_n$ | 2.3 | $3.7 \cdot 10^3$ [b] | $1.6 \cdot 10^3$ |
| Hg | 13.6 | $1.0 \cdot 10^4$ | $7.4 \cdot 10^2$ |
| *cis* $[CH(AsF_5)_{0.14}]_n$ [c] | 0.8 | $5.6 \cdot 10^2$ | $7.0 \cdot 10^2$ |
| TTF·TCNQ | ≈1.0 | $7 \cdot 10^2$ [d] | $7 \cdot 10^2$ |
| TTF·TCNQ | ≈1.0 | 10 [e] | 10 |

[a] All values were determined at 300 K. [b] Measured in the chain direction [15]. [c] Polyacetylene, doped with $AsF_5$ (cf. Table 1). [d] Measured on a single crystal in the direction of greatest conductivity. [e] Measured on a polycrystalline sample.

The conductivity data presented in Table 1 has, however, by no means been optimized. Rather, it is merely the initial results of investigations in this field.

In this article the chemical and physical structure of the most important polymers, which become conductive through doping as well as the structure of these conductive polymer complexes will be discussed. Special emphasis will be placed on the chemistry of doping. Moreover, structural and functional features common to organic metals and conductive polymers will be indicated and discussed within the framework of present knowledge of the nature of charge carriers and transport processes in organic metals.

## 2. Polyacetylene PA

### 2.1. Synthesis

The method of preparation of PA described by *Shirakawa* and *Ikeda*[28,29] serves as the starting point for the majority of investigations into the structure, conductivity, optical and magnetic properties of pure and doped PA. Termed the "Shirakawa technique", this procedure involves blowing acetylene onto the quiescent surface of a concentrated solution of a Ziegler catalyst in an inert solvent: the most suitable Ziegler catalyst for this procedure consists of titanium tetrabutoxide and triethylaluminum. A thin layer of PA is immediately formed and floats on the surface. This black shiny film has a thickness of between 1 μm and several mm, depending upon the quantity of acetylene used, and can be removed intact from the reaction medium and, after purification and drying procedures made conductive through suitable doping. A widely employed variant of this technique involves wetting the interior of a glass vessel or the surface of a glass plate with a capillary film of the catalyst solution. Acetylene is then blown onto these surfaces to the desired amount, producing a thin layer of the polymer on an inert carrier[29]. The complex super-molecular structure of the films produced have the structural features of a hard foam and will be discussed in the following section. The layers of PA, which are erroneously called films in the literature[10,11], are inhomogeneous networks of low density. In short, the network itself is built up from clusters of morphological units consisting of individual compact particles of polyacetylene. The nature of these layers is shown in Figure 3. Macroscopically, however, these layers give the impression of a compact film with a silverish, almost metallic luster.

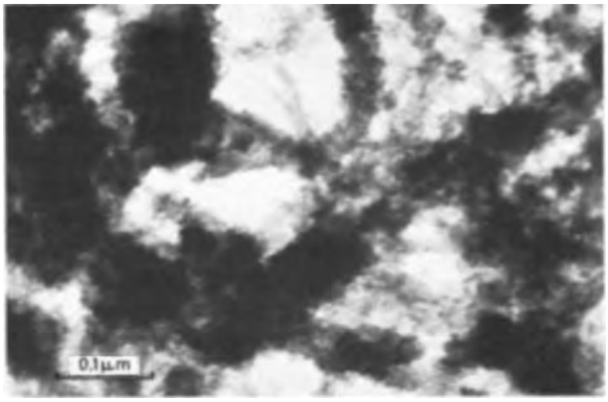


Fig. 3. Electron micrograph (TEM) of a layer of polyacetylene prepared by the Shirakawa-technique [29].

The catalysts used for the polymerization of acetylene in the Shirakawa technique were first described by *Natta et al.* in 1958[30]. Although *Natta* and co-workers conducted extensive investigations into the polymerization of acetylene using Ziegler catalysts, very little of this work was published[31]. They were able, however, to demonstrate that PA is formed as an insoluble, semicrystalline red powder if the monomer is bubbled into a solution of the catalyst system in a hydrocarbon solvent. X-ray diffraction studies led them to the correct conclusion that they had obtained *trans*-polyacetylene[30].

Due to the insolubility and oxidative instability of PA, they did not succeed in obtaining the polymer in the form required for measurements of its solid-state properties, or applicative purposes. Bearing these difficulties in mind, it is clear that the technique developed by *Shirakawa et al.*[28,29], involving the *in situ* production of free standing films of almost arbitrary dimension, was a noteable step forward. From these thin films, *Shirakawa* and *Ikeda* were able to obtain excellently resolved IR[28] and Raman spectra[32]. These allowed a comparison to be made between the experimentally obtained band positions and those calculated by normal coordinate analysis of the polymer vibrations. It was also shown that *cis*-PA *(1a)* was essentially formed at polymerization temperatures below 255 K and that *trans*-PA *(1b)* was produced exclusively at temperatures above 373 K.

At intermediate temperatures, polymers having, in part, the *trans*-structure are produced; the increase being proportional to the polymerization temperature. The spectroscopic data indicate, however, that block copolymers are formed between *cis*- and *trans*-PA with a temperature dependent block-length distribution[28] and not a random copolymer between individual units of either *cis*- or *trans*-configuration.

It seems probable that the triple bond of the monomer is always opened *via* a *cis*-insertion mechanism and that the *trans*-structure *(1a)* is only obtained through thermal isomerization of the initially formed polymer *(1b)*. This follows from the observation that *cis*-PA is thermally unstable and isomerizes slowly at 0 °C; at temperatures above 100 °C, however, the isomerization is rapid and irreversible and leads to the thermodynamically stable *trans*-isomer[32-35]. Although the *trans*-cisoid structure *(1c)* has not yet been experimentally detected, it has been discussed as an intermediate in the thermal *cis*-*trans*-isomerization[36].

*(1a)*

*(1b)*

*(1c)*

Polymerization of acetylene with Ziegler catalysts, as described by *Natta et al.*, has prompted numerous other investigations. These have resulted in the discovery of additional catalytically active systems, which however, are not true Ziegler catalysts.

Table 3. Some catalytically active systems for the polymerization of acetylene.

| Catalyst system | | | Ref. |
|---|---|---|---|
| $Ti(OR)_4$ | + $AlR_3$ | | [28, 30, 40, 41] |
| $Co(NO_3)_2$ | + $NaBH_4$ | (EtOH) | [37] |
| $NiX_2$ [a] | + $PPh_3$ | (pressure) | [42] |
| $NiX_2$ | + $PPh_3$ | + $NaBH_4$ | [43] |
| $CoX_2$ | + $PPh_3$ | + $NaBH_4$ | [44] |
| $Fe(dmg)_x 2py$ | + $AlEt_3$ | | [45] |
| Fe(acac) | + $AlR_3$ | | [46] |
| $FeCl_3$ | + PhMgBr | | [47] |
| $Ni(CO)_2$ | + $PPh_3$ | | [48] |

[a] X = Halogen.

The most important of these systems are shown in Table 3. *Luttinger*'s[37] account of a catalytically very active system, resulting from the reaction of cobalt and nickel salts with $NaBH_4$, deserves special mention. With this catalyst, acetylene can be polymerized at normal pressure in numerous solvents including water: polymerization is thus possible without the exclusion of moisture. The polymerization proceeds at temperatures between −80 and 20 °C in ethanol[38,39]: *cis*-PA is formed as a voluminous mass of very fine crystalline particles, when acetylene is passed into a cooled, stirred solution of the catalyst at −30 °C. Thin layers are obtained if the polymerization is carried out on the surface of capillary films of the catalyst solution on inert carriers. After appropriate purification and drying procedures, these do not differ from

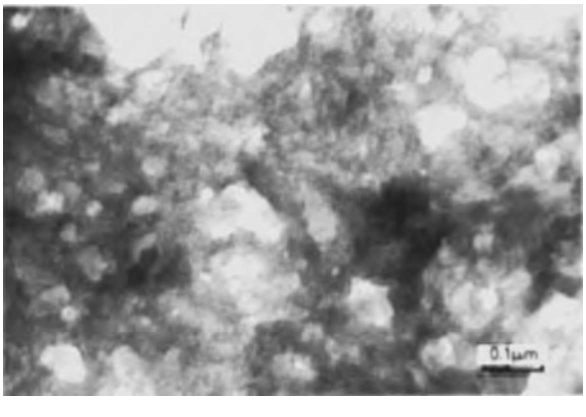

Fig. 4. Electron micrograph (TEM) of a thin layer of PA prepared with the aid of a Luttinger catalyst [37] in a procedure described in [39].

the "films" obtained through the Shirawaka technique, *i.e.*, they possess the same morphological structure, and within the framework of the reproducibility of the conductivity experiments, identical electrical properties to that of the Shirakawa material. Figure 4 shows an electron micrograph obtained from this type of thin layer.

*cis*-PA obtained by *Luttinger's* method may be thermally isomerized to *trans*-PA. Isomerization at room temperature clearly proceeds more slowly than with material produced by the *Shirakawa* method. It occurs, however, within minutes at temperatures of approximately 130 °C. In the following section, additional important distinctions between these two materials will be further discussed.

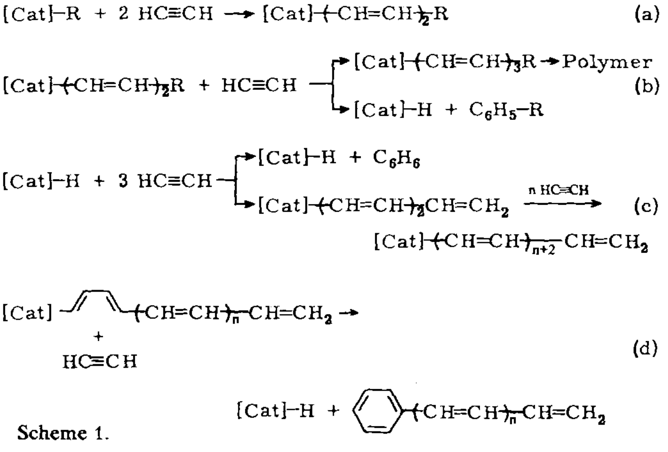
## 2.2. Polymerization Mechanism and Molecular Weight

Little is known concerning the mechanism of polymerization of acetylene. The majority of Ziegler catalysts cyclomerize acetylene to benzene, cyclooctatetraene, styrene and similar products[40,41,49-51]: PA is only produced as a by-product in small yields. Similar results are also found with other catalyst systems, specifically those based on nickel as the heavy metal component[50]. The catalyst discovered by *Natta*, which is used in the Shirakawa technique, as well as that found by *Luttinger*, have proven optimal for the maximum yield of PA. Nevertheless, cyclomerization also proceeds in these systems as a side reaction.

Consequently, a reaction mechanism should be able to explain the simultaneous formation of cyclic oligomers and linear polymers.

*Ikeda* and *Tamaki*[51] have demonstrated that ethylbenzene is produced in small quantities when the typical Ziegler catalyst TiCl$_4$/AlEt$_3$ is used and that the ethyl group originates from the catalyst.

Without speculating about the stereochemistry of the catalytically active complexes, the following simplified scheme shown in Scheme 1 is proposed:



Scheme 1.

In this scheme, the formation of benzene, styrene, cyclooctatetraene, *etc.* result from transfer reactions with the monomer at the degree of polymerization 3 and 4. In addition, the chain length of the polymer is limited by transfer reactions with the monomer, *e.g.* after eq. (d). This leads to formation of, vinyl and phenyl end groups, among others.

The insolubility of the polymer has until now prevented a direct determination of the end groups and the molecular weights. Recently, however, soluble derivatives of polyacetylene have been obtained by polymer analogous reactions, and this has enabled the molecular weights and their distribution to be determined for the first time. The information obtained from these investigations is of considerable significance to the discussion of the mechanisms of conductivity in the doped polymer.

Soluble derivatives of polyacetylenes can be prepared by chlorination or hydrogenation, provided that certain conditions are met. As was previously demonstrated by *Natta et al.*[30], PA takes up the calculated amount of chlorine quickly and almost quantitatively if it is reacted at 0—5 °C. However, a colorless and insoluble product is obtained, the properties of which somewhat resemble those of chlorinated polyvinyl chloride.

If, however, PA prepared following the method of *Luttinger*[37] at $T \leq 243$ K, is chlorinated *immediately* after the polymerization has been stopped, a completely soluble chlorinated PA is obtained[52,53]. When the polymer is stored for some time at −30 °C, however, an insoluble portion remains after chlorination, the amount of which increases with increasing storage time (Fig. 5). This increase in insoluble fraction can be considered as a crude measure of the spontaneous cross-linking which proceeds even at such low temperatures.

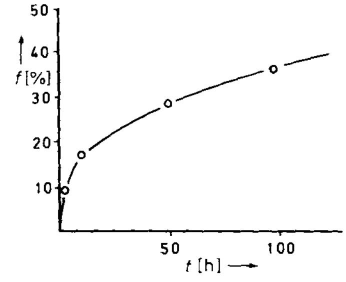


Fig. 5. Fraction *f* of PA which became insoluble by spontaneous cross-linking and could not be converted to a soluble, chlorinated product, as a function of the storage time *t* at −30 °C.

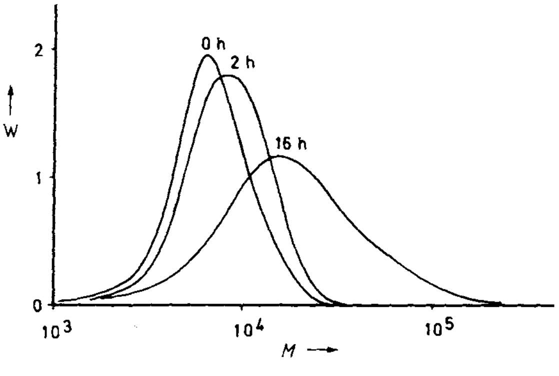

Fig. 6. Molecular weight distribution of the soluble chlorinated PA; chlorination immediately following the synthesis; 2 h and 16 h storage time at 0 °C, w is the logarithmic probability.

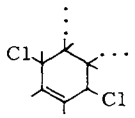
The presence and the formation of cross-links can be demonstrated more quantitatively by gel permeation chromatographic (GPC) analysis of the soluble portion isolated in each experiment. Figure 6 shows the molecular weight distributions determined by GPC for PA prepared over a Luttinger catalyst, worked-up at 0 °C, chlorinated immediately, and stored for periods of two and sixteen hours respectively prior to the chlorination. The chlorination was carried out at

0 °C. The average molecular weight, $\bar{M}_n$, increases from 5900 (corresponding to a degree of polymerization $\bar{P}_n \hat{=} 100$) for the native PA, to 9100 after 2 h and 12800 after 16 h. Simultaneously, the distribution broadens, as expected for cross-linking and the yield of the soluble product decreases.

Only approximately 75% of the chlorine calculated if all double bonds had reacted is taken up. IR- and NMR-spectra indicate that structures of the type *(2)* may be responsible for

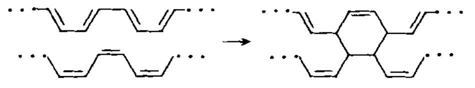


*(2)*

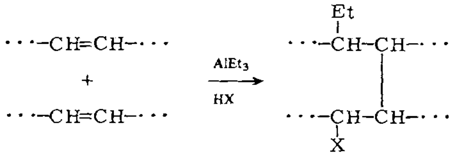
the deficit in chlorine up-take. Such structures can be formed by intramolecular cyclization during the course of the chlorination. PA prepared by the Shirakawa technique can never be entirely solubilized by chlorination; only when the polymerization was carried out in aliphatic hydrocarbons at $T \leq 243$ K, could a soluble fraction be extracted from the chlorinated product. The GPC elution curve of this fraction corresponded to a highly aged, *i.e.* strongly cross-linked, Luttinger-polymer.

It must be concluded from these results, that PA tends to undergo spontaneous cross-linking reactions and, moreover, that cross-linking even occurs during the polymerization if the Shirakawa technique is used. The cross-links may possibly be formed with assistance of components of the catalyst system.

Possible reactions leading to cross-links are cycloadditions of the Diels-Alder reaction type [eq. (e)], and additions assisted by fragments of the Ziegler catalyst [eq. (f)].



(e)



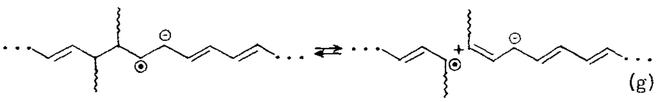
$$\begin{array}{c}\cdots\!-\!CH\!=\!CH\!-\!\cdots\\ +\\ \cdots\!-\!CH\!=\!CH\!-\!\cdots\end{array} \xrightarrow[HX]{AlEt_3} \begin{array}{c}Et\\ |\\ \cdots\!-\!CH\!-\!CH\!-\!\cdots\\ |\\ \cdots\!-\!CH\!-\!CH\!-\!\cdots\\ |\\ X\end{array} \quad (f)$$

X = OH, Cl etc.

Regarding the morphological structure of PA, it must be concluded that these cross-linking and branching reactions originate predominantly in the irregular boundary layers of the single polymer particles, and that they will be favored by the formation of packing and conformation defects during the *cis-trans*-isomerization[52]. For mechanistic considerations and certain material properties it is interesting to note that the degree of polymerization of the nascent polymers, as far as the Luttinger catalysts are concerned, is independent of the type and concentration of the metal salt. Moreover, it is also independent of the conversion and is little influenced by temperature[53].

Similar results are also noted in materials produced with Ziegler catalysts. *Shirakawa et al.*[54,55] have demonstrated that PA, which is initially reacted ("doped") with either sodium or potassium naphthalide, will be hydrogenated if kept for *ca.* 20 h under hydrogen pressure at temperatures ranging from 175 to 260 °C. Soluble polyethylene of average molecular weight $5700 < \bar{M}_n < 7900$ is obtained showing a heterogeneity $\overline{DP}_w/\overline{DP}_n = 2.4$. This corresponds to a $\overline{DP}_n \hat{=} 200$—300.

The reaction of PA with, for example potassium naphthalide, gives rise to polymeric structures with radical anion character. Their existence has been proven by further reaction with methanol by which partial hydrogenation is effected[56]. Hydrogenolysis of the branch-points, must be considered [eq. (g)], if branched or cross-linked polymers are hydrogenated under the aforementioned conditions[57].



(g)

The results of the hydrogenation, therefore, at best allow conclusions to be drawn concerning the average length of the branches and consequently, the original chain length *prior* to cross-linking. The nature of the partially branched and cross-linked system can, however, only be investigated using the method of chlorination, since rupture of the chain is not to be expected with this method.

The considerable mechanical strength observed[52] in PA layers ("films") can, therefore, only be explained through the additional cross-linking of the single morphological subunits over reactions between the individual surfaces and particle boundaries. It cannot be explained by invoking high molecular weight of the nascent polymers.

## 2.3. Morphology and Crystal Structure

The polymerization of acetylene proceeds with simultaneous crystallization of the polymer. In this manner, the same morphological structures are consistently produced, largely uninfluenced by the catalyst type and concentration ratio[38,39]. As Figures 3 and 4 demonstrate, the polymer reaction product consists of an aggregation of very small particles which assemble into network-like structures. Lamellae of irregularly shaped and ill-defined boundaries are identified as the smallest morphological units. These exhibit a thickness of 50—100 Å and an average diameter of up to 2000 Å. These units, aggregated to form a loose network, superficially give the impression of an irregular network of fibers. It is not difficult to arrive at this impression, given the poorly resolved SEM micrographs of the thin layers produced using the Shirakawa-technique[11,29,58]. Moreover, since very high catalyst concentrations are necessarily used in the Shirakawa-technique, gels of metal hydroxides are formed under the conditions used in the work-up of the nascent layers. These give rise to a number of artifacts in the course of the preparation of the micrographs which have been misinterpreted as structural features of PA[59].

Such textures are only defined as fibers or fibrils when the polymer chains within the crystallites are preferentially oriented parallel to a unique morphological direction. This direction is called the fiber-axis. These textures give rise to fiber diagrams on X-ray or electron diffraction. These, loosely speaking, contain a similar amount of information as the rotation photograph of a single crystal mounted along one of its main axes. Preparations with fiber-like textures, which are consequently oriented with regard to the chain direction, are usually obtained if partially crystalline films are stretched or if the solution or the melt of crystallizable polymers is spun. The latter can be considered as crystallization occurring in a shear gradient.

In the case of PA, which crystallizes *in statu nascendi,* it has not been possible thus far to obtain layers or films exhibiting a fiber texture, even if the layers initially obtained are subsequently stretched. Layers prepared by the Shirakawa-technique stretched threefold, immediately after synthesis, exhibit optical and electrical anisotropy[52]. These layers, however, are almost isotropic with respect to X-ray diffraction. The ratio of conductivity parallel and normal to the stretch direction ($\sigma_{\|}/\sigma_{\perp} \geq 10$; $\sigma_{\|} \geq 3000\ \Omega^{-1}\ \text{cm}^{-1}$), observed for PA doped with $AsF_5$[11], may also be explained as arising from an alteration in the percolation behavior (cf. Section 3.3). It is not necessary to assume a large scale orientation of the individual chains in order to account for these conductivity effects. Information concerning the crystal structure and chain direction and their relations to the sample morphology is best obtained by electron diffraction. The most important results from such investigations are as follows[39, 57].

The diffraction patterns from preparations of *cis*-PA, such as those shown in Figures 3 and 4, consist of Debye rings, even when the smallest diffraction aperture was selected and correspond to an area in the sample of approximately 1000 Å diameter. The majority of the sites in such a preparation produce Debye patterns in which all of the rings may be indexed as hk0 reflections. In only a few cases, patterns with 00k reflections are obtained. It must, therefore, be concluded that the morphological units are preferably unaxially oriented with respect to the geometry of the diffraction experiment such that the electron beam enters the morphological units parallel to the chain directions. Only rarely, when the electron beam meets an aggregation of lamellae such that it enters normal to their front end surfaces, may the 001 reflection appear.

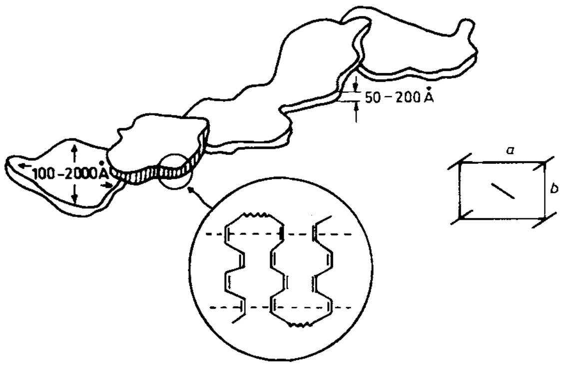


Fig. 7. Morphological units in pristine *cis*-PA and their aggregation to clusters [39]. The chain direction is normal to the surfaces of the lamellae. Chain folding is probable. The chain packing in the *a,b*-plane is indicated, the setting angle is, however, arbitarily chosen.

The model of the morphological structure and chain order in *cis*-PA thus obtained is sketched in Figure 7. Considering the results of the molecular weight determination it must be accepted (Section 2.2) that the chains present in a single lamella are folded several times, since the observed chain length far surpasses the thickness of the lamellae. It is probable that different lamellae are connected to each other *via* tie-molecules. However, at present, no definite assertion can be made regarding this point.

The unit cell parameters of *cis*-PA, based on sixteen observed reflections, have been derived and are compiled in Table 4. They agree well with the values estimated from X-ray data by *Baughman et al.*[60, 61], and uncertainty only exists over the space group. If the space group Pmna proposed by *Baughman* was correct, the 001 reflection observed by *Lieser et al.*[39] should not be observed. In addition, the setting angle (*i. e.* the angle between the plane of the chain and the *a*-axis) cannot yet be specified experimentally. *Bauthman et al.*[60, 61] have approached this problem using packing calculations: the results, however, depend strongly on the input data. Theoretical considerations regarding the interchain interaction require information about the setting angle. The experimental determination of this value is therefore an important goal.

Table 4. Data on the unit cells of *cis*- und *trans*-PA [63] at 120 K and. 300 K respectively.

| | *a* [Å] | *b* [Å] | *c* [Å] [a] | $\gamma$ | *Z* | $\rho$ [g cm$^{-3}$] |
|---|---|---|---|---|---|---|
| *cis*-PA<br>orthorhombic | 7.74 | 4.32 | 4.47 | 90 | 2 | 1.16 |
| *trans*-PA | | | | | | |
| Modification I<br>orthorhombic | 5.62 | 4.92 | 2.592 | 90 | 2 | 1.2 |
| Modification II<br>monoclinic | 3.73 | 3.63 | 2.44 | 98 | 1 | 1.27 |

[a] Chain-direction.

The quality of the available scattering data is not yet sufficient to allow a reasonable structural analysis from which bond lengths and angles can be derived. The numerous quantum chemical calculations so far published concerning the electronic structure and the nature of bonding in PA rely, consequently, on somewhat dubious assumptions on the distances between atoms and the bond angles.

*trans*-PA is produced by annealing *cis*-PA between 100—150 °C. The reaction proceeds as a phase transition without recognizable alteration of the morphology. In contrast to the situation prior to the phase transition, a Debye ring arising from a relatively strong 002 reflection is observed in the electron diffraction pattern. This indicates that the chains have tilted within the lamellae during the progress of the phase transition and that they now lie preferentially inclined to the lamellae surfaces.

A further modification of *trans*-PA was obtained by *W. H. Meyer* using polymerization under extreme shear conditions[62, 63]. *Meyer* has shown that fibrous PA is formed when acetylene is polymerized inside the gap of a Couette arrangement using the conventional Ziegler catalyst, *i. e.,* polymerization occurs inside a gap of approximately 1—2 mm in width between a cylinder rotating at 1000 r.p.m. and the wall of a cylindrical reaction vessel. *trans*-PA precipitates on the wall of the cylinder in the form of a thin, highly oriented layer. An electron micrograph of this layer is shown in Figure 8.

The electron diffraction pattern indicates a well-oriented aggregation of fibrous crystals of polymer. The unit cell data recorded in Table 4 under Modification I are evaluated from an analysis of this fiber diagram. The unit cell differs from that of *trans*-PA, obtained under normal conditions (Modification II) in that it exhibits higher symmetry but lower density. This is due to the surprisingly large value of the fiber peri-

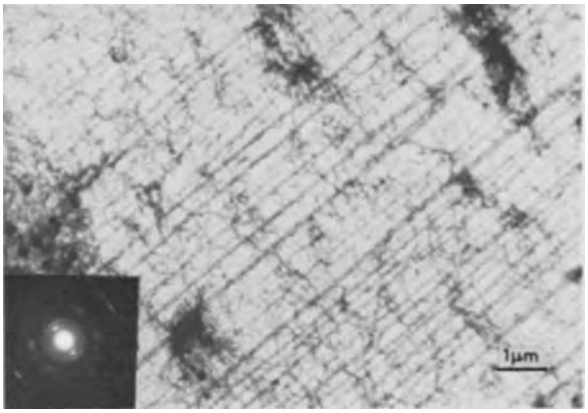

Fig. 8. Morphology of PA synthesized under application of a shear gradient.

od. The fiber period specifies the translational period in the chain direction. Assuming values of 1.35 Å and 1.46 Å for the lengths of the double and single bond, respectively, a bond angle of approximately 135° is calculated for *trans*-PA in Modification I; on the other hand, the expected value of 120° is derived from the data in Modification II.

Unambiguous crystallographic relationships exist between the unit cells of *cis*- and *trans*-PA. These enable the characterization of the phase transformation as a shear deformation and the prediction of twinned structures[63]. The twinning gives rise to phase boundaries or domain walls with components oblique to the chain direction, even in the well-oriented and fibrous preparations of *trans*-PA produced according to the method of *W. H. Meyer.* Modification II may be interpreted in terms of a strongly disturbed lattice of Modification I, insofar as the packing of the chains is concerned[63].

Due to the inconclusiveness of the existing data, assertions concerning bond angles and lengths can only be set forth with a large degree of uncertainty. X-ray crystallographic results clearly prove, however, that different bond lengths, *i. e.*, double and single bonds are present in the polymer. This is in agreement with spectroscopic data, especially with the resonance enhanced Raman spectra[32].

In the resonance Raman spectra of *trans*-PA, two strong bands at 1474 $cm^{-1}$ and 1080 $cm^{-1}$, as well as a weaker band at 1016 $cm^{-1}$ appear. In accordance with interpretations of the spectra of oligoenes, carotinoids and similar unsaturated compounds, the band at 1474 $cm^{-1}$ is ascribed to the double bond; the band at 1080 $cm^{-1}$ to the vibration of the single bond. The corresponding spectra of the pure *cis*-PA can not be obtained for practical reasons because *cis-trans*-isomerization readily occurs in the laser beam. If Raman spectra of *cis*-PA are recorded at $-78\,°C$, however, a strong band from the double bond vibration at 1552 $cm^{-1}$ and two bands from the single bonds at 1262 $cm^{-1}$ and 920 $cm^{-1}$ are observed. It can be concluded from this, in agreement with the IR data, that PA is present in the *cis*-transoid form *(1b)*[32].

A normal coordinate analysis of *cis*- and *trans*-PA has been presented, which enables identification of the IR active bands[28]. The IR spectrum of *trans*-PA only shows bands at 3013 $cm^{-1}$ (C—H valence vibration), 1292 $cm^{-1}$ (C—H in-plane deformation) and 1015 $cm^{-1}$ (C—H out-of-plane deformation). The 1015 $cm^{-1}$ band is reasonably strong and can be utilized as a diagnostic indicator. *cis*-PA shows, among others, strong bands at 1329 $cm^{-1}$ (C—H in-plane deformation), 740 $cm^{-1}$ (C—H out-of-plane deformation) and 446 $cm^{-1}$ (C—C—C deformational vibration). *Shirakawa* and *Ikeda*[28] have also investigated the spectra of fully and partially deuterated PA.

High resolution $^{13}C$-NMR spectra of solid *cis*- and *trans*-PA have been obtained using proton enhancement methods with magic angle sample rotation[64]. The chemical shift of the *trans*-C atoms is +139 ppm (relative to TMS), comparable to that of the central C atoms of butadiene (+137.2 ppm) and *trans*-hexatriene (+137.4 ppm). The chemical shift of the *cis*-polymer (+129 ppm) is close to that observed for the carbon atoms of benzene (+128 ppm). Besides these signals another small peak at higher field has been observed, which was attributed to $sp^3$-hybridized C-atoms. This may originate from the cross-linking reactions which proceed spontaneously.

The UV/VIS spectrum of *cis*-PA contains a very broad band with a peak at 594 nm and a shoulder at 560 nm; a continuous unstructured absorption of decreasing intensity extends into the UV range. A thin translucent layer of *cis*-PA appears wine-red on inspection. An exact value of the extinction coefficient cannot yet be determined due to the complex morphology of the samples. The value, however, should be of the order of $10^5$ to $10^6$ $cm^{-1}$ at the peak maximum[11]. In thin layer, *trans*-PA appears dark blue. The broad peak, with unstructured absorption lies at 700 nm.

So far, it has generally been assumed that these spectra arise from infinitely extended chains of *cis*- and *trans*-PA. Whether this view can still be held, in the light of recent information on the real structure of the samples, requires to be studied. In any case, it must be borne in mind that a single chain cannot be extended rectilinearly within the morphological units of the present samples over more than an average of 20 to 40 double bonds. The sequence of conjugated bonds then comes to an end, either by cross-linking or by extension of the chain into the disordered lamellar surface *via* conformational defects.

Moreover, investigations concerning what extent the width of the absorption peaks relate to the distribution of the lengths of effectively conjugated sequences and crystal size effects, respectively, should be undertaken. This follows from what is known about the structurally related poly(diacetylenes), which can be obtained in the form of perfect crystals without defects and which exhibit a much lower peak half-width[15].

### 2.4. Copolymers

Acetylene can be copolymerized with 1-alkynes using the technique described by *Shirakawa.* Possible comonomers are, for example, 1-propyne, 1-hexyne, phenylacetylene or propargyl alcohol[50]. Given the conditions of acetylene polymerization, these monomers by themselves only give rise to cyclic oligomers or linear polymers of limited degree of polymerization[40,48]. Mixtures of copolymers are formed, if acetylene is copolymerized with 1-hexyne[38] or 1-propyne[66]. With increasing feed of 1-hexyne, the fraction of a polymer or rather, oligomer, rich in comonomer and soluble in toluene increases. The soluble copolymers exhibit molecular weights of 500—1500. They tend to autoxidize rapidly.

The morphology of the acetylene/1-propyne copolymers is quite different from that of the pure polyacetylene produced by the Shirakawa technique and consists of thin layers of an accumulation of irregular clumps at higher comonomer content which amalgamate into smooth films. Nevertheless, as with pure PA, a similar increase in conductivity is observed upon treatment with gaseous $\mathrm{AsF_5}$. The final values which can be reached, decrease drastically with increasing comonomer content. *Chien et al.*[66] have explained this phenomenon as being due to an increasing disturbance of the planarity of the conjugated main chain.

## 2.5. Chemical Reactions Leading to Improvement in Conductivity

Despite numerous difficulties, which have so far prevented an exact characterization of PA, it is generally accepted that the rise in conductivity exhibited in Figure 1 originates from a chemical reaction between the polymer and the dopant[16,57,67,68]. This reaction is characterized by charge transfer from the dopant to the polymer. An ionic state of the polymer, delocalized along the backbone is formed, along with a counterion which is derived from the dopant. All reactions causing a marked increase in conductivity can be classified as redox reactions. The reactions of polymer chains with silver perchlorate[16].

$$(\mathrm{CH{=}CH})_n + \mathrm{AgClO_4} \longrightarrow (\mathrm{CH{=}CH})_n^{\oplus\odot} + \mathrm{ClO_4^{\ominus}} + \mathrm{Ag} \qquad \text{(h)}$$

or with iodine[10,60,61,68]

$$2\,(\mathrm{CH{=}CH})_n + 3\,\mathrm{I_2} \longrightarrow 2\,(\mathrm{CH{=}CH})_n^{\oplus\odot} + 2\,\mathrm{I_3^{\ominus}} \qquad \text{(i)}$$

serve as examples. In these reactions, segments of the polymer chain of length n are oxidized and structures are formed having the character of a delocalized radical cation. The length n can be identified, for example, with the length of the PA chain between the two surfaces of the fundamental morphological units. The idea that pure CT-complexes are formed between the chain and, for example, iodine, which was originally proposed by *Shirakawa et al.*[8], is no longer tenable. Raman spectroscopic studies indicate[16,69,70] that after having reacted, iodine is present as $\mathrm{I_3^{\ominus}}$ and probably as $\mathrm{I_5^{\ominus}}$ as well, bromine as $\mathrm{Br_3^{\ominus}}$. Microcrystalline, pure silver is one of the products of the reaction with $\mathrm{AgClO_4}$.

PA is usually doped by exposing the pristine layers of the polymer to the dopant, which may be either gaseous or dissolved in an inert solvent. Toluene, for example, is used as the solvent in the case of $\mathrm{AgClO_4}$; iodine as a dopant is usually applied from the gas phase at a predefined partial pressure.

Arsenic pentafluoride, which is a gas at room temperature, is often used as a dopant. It reacts with the polymer according to

$$2\,(\mathrm{CH{=}CH}) + 3\,\mathrm{AsF_5} \longrightarrow 2\,(\mathrm{CH{=}CH})^{\oplus\odot} + 2\,\mathrm{AsF_6^{\ominus}} + \mathrm{AsF_3} \qquad \text{(j)}$$

as was convincingly demonstrated by *Clarke et al.*[71,72] on the basis of IR-, Raman- and EXAFS-data. $\mathrm{AsF_3}$ can be sublimed *in vacuo* from the polymeric product. PA therefore reacts analogously to graphite, whose electrical conductivity increases markedly on reaction with $\mathrm{AsF_5}$[73]. $\mathrm{AsF_5}$ oxidizes the carbon layers of graphite[73–75] and the reaction products, $\mathrm{AsF_6^-}$ and $\mathrm{AsF_3}$ are thereby intercalated jointly with excess $\mathrm{AsF_5}$ between the carbon layers.

Side reactions, which lead to fluorination of the polymer, apparently occur in the course of doping. This is in part due to the fact that $\mathrm{AsF_5}$ hydrolyzes readily and an admixture of hydrogen fluoride can only be separated with difficulty.

The elemental analysis of PA doped with $\mathrm{AsF_5}$ can, therefore, not be brought easily into agreement with equation (j). This has prompted *MacDiarmid*[68] to propose other reactions as well, and to discuss other species, such as $\mathrm{As_2F_{10}^{2\ominus}}$. In the light of the results concerning the doping of graphite, poly(*p*-phenylene) and other polymers, and the electrochemical reaction behavior discussed below, it must be assumed that eq. (j) describes the principal reaction occurring which is of prime importance for the phenomenon of conductivity.

Numerous oxidizing agents have so far proven to be suitable dopants for PA. Among others, the salts[76] $\mathrm{NO_2^{\oplus}X^{\ominus}}$ and $\mathrm{NO^{\oplus}X^{\ominus}}$ with $\mathrm{X = SbF_6, SbCl_6, BF_4}$ have been used. However, the vapor of 98 percent $\mathrm{H_2SO_4}$ or 71 percent $\mathrm{HClO_4}$[76], as well as inorganic peroxides such as $\mathrm{FSO_2{-}O{-}O{-}SO_2F}$, have also been shown to work: The latter is applied as a solution in $\mathrm{SO_2F_2}$[77].

Undoubtably, the most elegant method of doping is accomplished by electrochemical oxidation of PA in the presence of a suitable supporting electrolyte. An electrolysis cell is set up for this purpose in which a thin layer of PA serves as the anode and a tetraalkylammonium salt of a not too nucleophilic anion, dissolved in an inert solvent, acts as the supporting electrolyte. Examples of suitable solvents are $\mathrm{CH_2Cl_2}$ or propylene carbonate. The polymer is oxidized at a working voltage of approximately 9 V at a current of 1—43 mA giving rise to a conductive structure. The anode reaction may be formulated:

$$(\mathrm{CH{=}CH})_n + \mathrm{R_4N^{\oplus}X^{\ominus}} \longrightarrow [(\mathrm{CH{=}CH})_n^{\odot\oplus}\mathrm{X^-}] + \mathrm{R_4N^{\oplus}} + e \qquad \text{(k)}$$

If a layer of PA is used as the cathode as well, cathodic reduction of the polymer takes place[68,79] as follows

$$(\mathrm{CH{=}CH})_n + \mathrm{R_4N^{\oplus}X^{\ominus}} + e \longrightarrow [(\mathrm{CH{=}CH})_n^{\odot\oplus}\mathrm{R_4N^{\oplus}}] + \mathrm{X^{\ominus}}$$

and the reduced polymer becomes conducting[89]. The negative charges on the polymer are compensated by tetraalkylammonium ions. Such an electrolysis cell functions after charging of the PA electrodes as a voltaic element in the reverse way. The entire reaction can then be described as an electrochemical equilibrium:

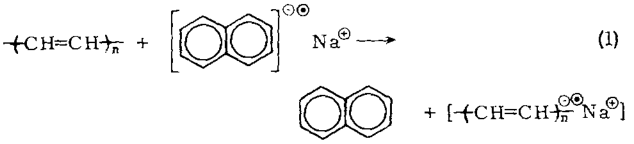
$$2\,(\mathrm{CH{=}CH})_n + \mathrm{R_4N^{\oplus}X^{\ominus}} \rightleftarrows [(\mathrm{CH{=}CH})_n^{\oplus\odot}\mathrm{X^{\ominus}}] + [(\mathrm{CH{=}CH})_n^{\ominus\odot}\mathrm{R_4N^{\oplus}}]$$

According to *MacDiarmid*[79], such a voltaic cell constructed from approximately 0.1 mm thick layers of PA exhibits a voltage of 2.5 V after charging (if no current is drawn) and delivers a current of up to 22 mA in a circuit of minimal resistance at an apparent electrode surface of only 1 cm$^2$.

All species, which are not so nucleophilic that they would react irreversibly with the radical cation sites formed upon oxidation on the polymer chain, may serve as anions $\mathrm{X^{\ominus}}$. So far, the species $\mathrm{BF_4^{\ominus}}$, $\mathrm{SbF_6^{\ominus}}$, $\mathrm{SbCl_6^{\ominus}}$, $\mathrm{AsF_6^{\ominus}}$, $\mathrm{PF_6^{\ominus}}$, $\mathrm{I_3^{\ominus}}$, $\mathrm{ClO_4^{\ominus}}$, $\mathrm{CF_3SO_3^{\ominus}}$ and similar anions, have proven to be suitable[76]. Similar considerations are appropriate for the cations which serve to compensate the anion radical sites delocalized on the polymer chain. So far, only tetraalkylammonium ions $R_4N^{\oplus}$ have been used. The substituents R (*e.g.* $CH_3$-, *n*-$C_4H_9$-, *etc.*) were selected according to the solubility characteristics of the salt used as the supporting electrolyte in the reaction medium.

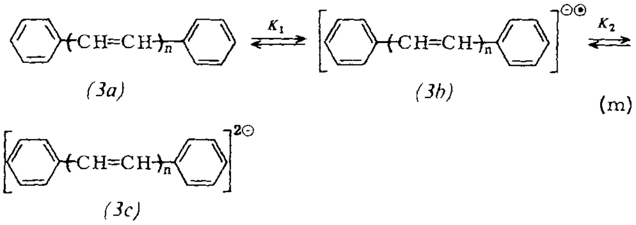
In this connection it is worth mentioning that the method of electrochemical oxidation or reduction is excellently suited for the production of radical ion salts of arenes[81-83] and heterocycles[84,85]. In part, this has already been known for some time. Under appropriate conditions of electrolysis, crystals of these salts precipitate and grow on the electrodes. These crystals, in general, exhibit high conductivity and can be classified as organic metals[83,85].

The reduction of PA to a conductive derivative can also be accomplished by treating the polymer with alkali metals or, even better, with sodium or potassium naphthalide in THF. This transformation is described in eq. (l) as a redox reaction, which is analogous to the well-characterized reactivity of the corresponding α,ω-diphenyloligoenes *(3)*[86].



(l)

*Hoijtink et al.*[86,87] have not only determined the optical and ESR spectra of the radical anions of the compounds *(3b)* $1<n<6$ but also the electrochemical redox potentials and values for the equilibrium constants $K_1$ and $K_2$ of the reactions described by eq. (m).



*(3a)* *(3b)* *(3c)*

(m)

It follows, that the reduction of the oligoene *(3a)* always leads to a mixture of the radical anion *(3b)* and the dianion *(3c)*, the partners of a dis- and syn-proportionation equilibrium, respectively.

$$2\,(3b) \overset{K}{\rightleftharpoons} (3a) + (3c) \qquad \text{(n)}$$

This fact, which can be formulated in an analogous manner for the radical cations produced according to eq. (h)—(k), must be taken into account when discussing, in detail, all reactions which play a role in the doping of PA.

In contrast to the reactions described by eq. (m) and (n), which take place under homogeneous conditions, the doping of PA in the solid state occurs at the surface of particles of complex morphology. Consequently, no exact assertion on the position of the equilibria may be formulated, by analogy to eq. (m) and (n), at present.

Finally, it should be mentioned that oxygen may act as a dopant if it acts upon pristine PA in small quantities[33,88,89]. At higher concentration, larger exposure times, and especially at higher temperatures, irreversible oxidation takes place and cuprene is formed[50] (cuprene, a material similar to cork, is formed by polymerization of acetylene at higher temperatures).

## 3. Electrical Conductivity and Mechanisms of Charge Transport

### 3.1. Definitions and Concepts

Investigation of the conductivity of organic metals requires a basic understanding of the electrical behavior of the solid state. Some of the most important definitions and relationships are summarized in the following short section, without claim to their completeness, in order to facilitate a discussion concerning the mechanisms of charge transport. For additional information, the reader is referred to the literature[1,13,14,90].

3.1.1. Electrical Conductivity of Metals

The electric behavior of metals is described by Ohm's Law, which states that at constant temperatures a current density, $j$, will adjust itself proportional to an external electrical field, $E$. The tensor $(\sigma)$ describing the electrical conductivity is independent of time and electrical field strength.

$$j = (\sigma) E$$

$j$ is maintained by a flux of charge carriers in the field direction. Assuming a conduction by $n$ electrons of charge $e$ per unit volume, $j$ corresponds to an average drift velocity, $\bar{v}_{\mathrm{dr}}$

$$\bar{v}_{\mathrm{dr}} = -j/en$$

For the case of direct current, $j$ and $\bar{v}_{\mathrm{dr}}$ are constant with time, and therefore

$$j = -e \cdot n \cdot \bar{v}_{\mathrm{dr}} = (\sigma) \cdot E.$$

The conductivity may hence be expressed as

$$\sigma = n \cdot e \cdot \mu \quad [\Omega^{-1}\,\mathrm{cm}^{-1}]$$

The constant $\mu$, termed mobility, is equivalent to $\sigma$ and is defined as

$$\mu = |\bar{v}_{\mathrm{dr}}|/|E| \quad [\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}]$$

$\mu$ can be experimentally determined by measuring $\sigma$, if $n$ is known. The electrons do not move freely in the field, rather they are scattered by phonons; that is, by the thermal density fluctuations of the lattice and by lattice defects. The phonon density increases with increasing temperature. Lattice defects may normally be considered as static and temperature independent scattering centers. Therefore, the temperature dependence of the resistivity $\rho = \sigma^{-1}$ follows Matthiesen's rule

$$\rho(T) = \rho_{\mathrm{R}} + \rho_{\mathrm{P}}(T)$$

where $\rho_{\mathrm{R}}$ is the portion of the total resistivity of an isotropic metal due to the scattering by defects and $\rho_{\mathrm{P}}$ is that portion caused by the phonons.

As a consequence $\rho$ increases with temperature for metals. $\rho_{\mathrm{P}}(T)$ increases proportionally to $T^5$ at $T \ll \theta$ and proportionally to $T$ at $T \gg \theta$ ($\theta$ is the Debye temperature). The residual resistivity $\rho_R$ is controlled by additives (creation of lattice defects).

If the dimensions of a metal sample decrease in comparison to the mean free path of the charge carriers between two scattering events, (*e.g.* in thin evaporation layers or fine threads) the resistivity may increase due to additional scattering events at the surfaces. Consequently, the resistivity calculated from the sample dimension is no longer a material constant in small samples.

This may be of importance when the conductivity data of doped PA are evaluated, since the charge transport takes place in this material inside very small particles, the dimensions of which are of the same order of magnitude as the expected value of the mean free path. Experimental data may serve to illustrate the above equations.

Using copper as an example, it is found that $\sigma(300\,\mathrm{K}) = 0.65 \times 10^6$ ($\Omega^{-1}$ cm$^{-1}$) with $n = 0.85 \times 10^{23}$ (conduction electrons cm$^{-3}$), the mobility $\mu(300\,\mathrm{K}) = 46$ (cm$^2$ V s$^{-1}$), and the mean free path $\bar{l}$ between two scattering events by phonons is $\bar{l}(300\,\mathrm{K}) = 420$ Å. These values increase by a factor of $10^3$ to $10^5$ at 4 K, the exact value depending on the purity of the sample.

### 3.1.2. Semiconductors

In semiconductors all valence electrons are situated in bound states at $T = 0$ (*i.e.* the valence band is filled and the conduction band is empty). The band gap may be interpreted to be the bonding energy of the valence electrons.

At finite temperatures, some of the atoms or molecules are thermally ionized, with the number of electrons in the conduction band being equal to the number of holes ("defect electrons") in the valence band. The electrons in the conduction band serve to maintain a current in an external electrical field, as described for metals. In addition, these holes move in the opposite direction.

This motion of electrons (holes) ceases when they recombine with the holes (electrons) and return to a bound state. In thermal equilibrium, these recombination events, along with the thermal excitation events, are in equilibrium. The equilibrium concentration of both the holes and the conduction electrons is equal and dependent of temperature. If the concentration of the conduction electrons is $n$ and that of the holes in the valence band $p$, then the expression for the electrical conductivity is (isotropic solid):

$$\sigma = e(n\,\mu_e + p\,\mu_p)$$

with $\mu_e$ and $\mu_p$ being the mobility of the electrons and holes, respectively. In other words, according to their mobility, the electrons and the holes contribute independently to the total conductivity. The magnitude of the conductivity depends on the number and the efficiency of the scattering processes occurring *via* phonons and defect sites, in the same way as has been previously discussed for metals.

In contrast to the behavior of metals, $n$ and $p$ are characteristically temperature dependent for individual semiconductors. In the simplest case, where the current is maintained by electron and hole pairs and all charge carriers have the same isotropic mobility, the concentration of the charge carriers at temperature $T$ is given by

$$n = p = (n_0 \cdot p_0)^{1/2} \cdot \exp(-E_A/(2kT))$$

and the temperature dependence of $\sigma$ by

$$\sigma(T) = e(\mu_e(T) + \mu_p(T))\, n_0 \cdot p_0^{1/2} \exp(-E_A/(2kT)) \tag{o}$$

$E_A$ represents the activation energy for the formation of the charge carriers (*i.e.* the electron-hole-pairs) and may be identified as the magnitude of the band gap; $k$ is the Boltzmann constant.

When $E_A \gg kT$, the behavior of a semiconductor is determined essentially by the exponential term of eq. (o); thus, $\sigma$ increases exponentially with temperature. If it is the case, however, that $E_A \leq 2kT$ or that the charge carriers are formed athermally, as for example by photoexcitation, the temperature dependence of the conductivity is determined by the pre-exponential factor of eq. (o).

By analogy to eq. (o), an equation has been formulated by *Epstein* and *Conwell*[91]

$$\sigma(T)/\sigma(T_R) = A\,T^{-\alpha} \exp(-E_A/(kT))$$

which describes the temperature dependence of the conductivity, normalized with regard to a reference temperature $T_R$. Experimentally[83,91,92], it has been found that $0.5 \leq \alpha \leq 2.5$ in organic metals.

The anisotropic mobility of the charge carriers in organic materials has seldom been experimentally determined. *Karl*[93] has impressively demonstrated, using anthracene, that the magnitude and temperature coefficient of the mobility does not only significantly depend on the purity of the molecular crystal, but also that both are extremely anisotropic. For the temperature interval 100 K $< T <$ 300 K, almost isotropic mobility of the holes $\mu_p \approx T^{-1.5}$ is found: the mobility of the electrons is, however, strongly anisotropic $\mu_{ea} \approx T^{-1.57}$, $\mu_{eb} \approx T^{-0.84}$ and $\mu_{ec} \approx T^{+0.16}$. The indices *a, b, c* refer to the axes of the anthracene unit cell.

For organic metals, (*e.g.* TFF-TCNQ) *Weger*[94] has developed a comprehensive, if not undisputed[95], theory by means of which the proportionality $\sigma \sim T^{-2}$ frequently found in this class of materials, can be interpreted by invoking special scattering processes. *Weger* correctly points out that one should differentiate between conductivity at constant pressure and constant volume. Because of the usually strong anisotropic temperature and pressure dependence of the lattice constants in organic materials, the conductivity should only be considered normalized for constant lattice dimensions.

## 3.2. Charge Transport and Structure

The electrical conductivity of doped PA and similar polymers must be discussed on the basis of available information pertaining to the charge transport and structure of organic metals. While it is not necessary to refer to the comprehensive theoretical background developed for organic metals, it must be noted that the high conductivity observed always accompanies certain packing modes of the molecules in the conductive crystals. All organic metals consist of molecular crystals of charge-transfer complexes. Almost all complexes of donors and acceptors crystallize in the form of mixed stacks, as indicated in Figure 9a; crystals which exhibit this type of packing are insulating. Only those crystals, in

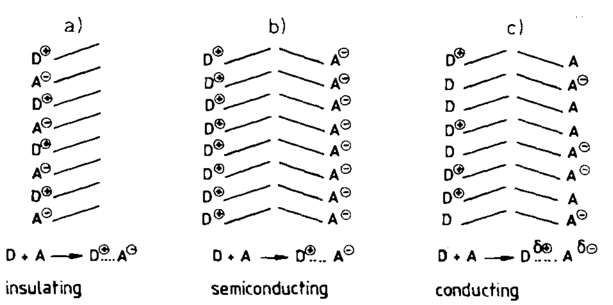


Fig. 9. Schematic view of the packing in organic CT-crystals. a) Insulating, b) semiconducting, and c) conducting CT-complex.

which the donating and accepting molecules after charge-transfer are found in segregated stacks, are conducting.

If, however, a full charge is transferred, as shown schematically in Figure 9b, a semiconductor results. An organic metal is only formed if there is a partial transfer of charge and, therefore, the stack of the acceptor molecules consists of a mixture of neutral and negatively charged units while the donor stack consists of a mixture of neutral and positive units (Fig. 9c). This is the pattern found in the conductive crystals of TTF-TCNQ. Such a crystal may also be described as an organic salt, consisting of two independent but interpenetrating lattices of stacks of TTF-cations and TCNQ-anions. It has, in fact, been demonstrated[13,14] that the charge transport proceeds independently in the two stacks; the TCNQ-stack supporting a current of electrons, the TTF-stack a current of holes.

The charge transport may be described, in a quasi-chemical formulation, as an exchange process. This is sketched in Figure 10b, which depicts the situation inside the TCNQ-stack. A partial charge transfer from the donor to the acceptor stack is understood as resulting in a random placement of neutral and negatively charged (radical anion) TCNQ molecules along a single stack. Electron transport is now described as a diffusive exchange of charge between free and occupied positions along a chain of such molecules.

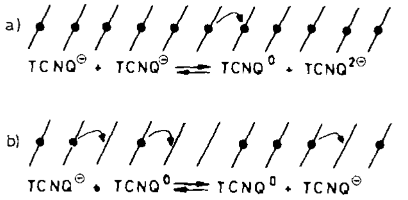

Fig. 10. Model of charge transport within a CT-complex using TCNQ as an example: a) at complete charge transfer from the donor to the acceptor (TCNQ); b) at only partial reduction of the acceptor.

If, however, complete charge transfer has taken place as depicted in Figures 9b and 10a (*i. e.* if each TCNQ-molecule carries a negative charge), the transport of charge must be described, in the present context, as a disproportionation. This requires considerable energy, since an electron has to travel to a lattice site already occupied by a negative charge; thus a large Coulomb potential has to be overcome, and hence, a semiconductor results (cf. in this context, the behavior of the alkali-salts of TCNQ exhibited in Fig. 2).

The bonding relationship within the stacks of an organic metal can be characterized from Figure 10b as a CT-interaction between neutral molecules and the radical ions formed from them. The numerous successful syntheses of salts exhibiting metallic conductivity[13,14,84,85] prove this description to be correct. Among others, mention must be made of the salts derived from TTF and its derivatives with simple anions X$^{\ominus}$ of low nucleophilicity exhibiting the general formula (TTF)$_y^{\oplus}$X$^{\ominus}$, as well as compounds of TCNQ with cations K$^{\oplus}$ of low electrophilicity of composition (TCNQ)$_y^{\ominus}$K$^{\oplus}$, with $1 < y < 3$.

According to this concept, the conductivity relates essentially to the structure of the lattice and to the packing of the molecules and not so much to structural pecularities of the individual molecules, as was previously often assumed[96]. In particular, the question of under what conditions the desired structure of stacks may be formed is principally a problem of the kinetics of crystallization and not a question of the electronic structure of the individual molecules[97].

The radical cation salts of simple aryls may serve as suitable examples to demonstrate some of these ideas. These materials exhibit conductivities of the order $1 < \sigma(300\,K) < 1000$ $\Omega^{-1}$ cm$^{-1}$. In addition, they may be considered as excellent models for doped PA and other conductive polymers. They are obtained by electrochemical oxidation (using a suitable supporting electrolyte, such as $n$Bu$_4$N$^{\oplus}$X$^{\ominus}$ with X = ClO$_4$, PF$_6$, ASF$_6$, SbCl$_6$, *etc.*) of, *e. g.*, naphthalene[81,82], fluoroanthene, perylene, pyrene[83,132], as single crystals having metallic luster, and exhibit the general formula (Aryl)$_2^{\cdot\oplus}$X$^{\ominus}$.

The desired packing shown in Figure 9c is realized in these crystals; the aryls are stacked with a distance of 3.2 Å between the planes of the rings. The projection of the crystal structure of [fluoroanthene]$_2^{\cdot\oplus}$PF$_6^{\ominus}$ onto and along the stacking axis is exhibited in Figure 11[83].

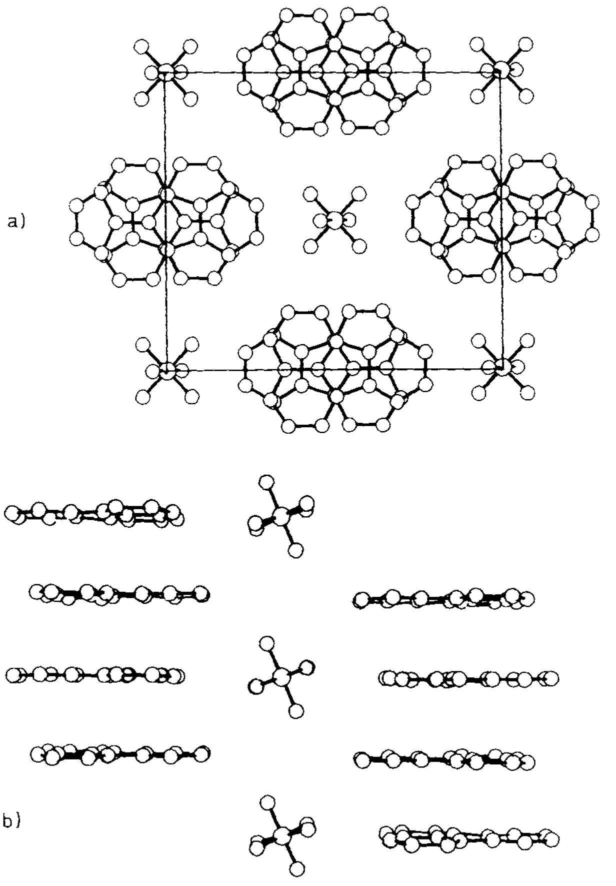

Fig. 11. Crystal structure [131] of the organic metal [Fluoroanthene]$_2^{\cdot\oplus}$PF$_6^{\ominus}$, projection a) on the stack-axis, and b) along the stack-axes.

With this background and considering the nature of the chemical reactions which proceed in the doping of PA (which have been previously discussed in Section 2.5), it is concluded that the conductivity in doped PA relies on the same type of interactions as are sketched in Figures 9c and 10b for the radical ion salts of simple aryls (cf. Fig. 1). Within the framework of these ideas, radical ions of individual polymer sequences consisting of n double bonds are formed when the doping agent reacts at, and with the surface of the morphological units of PA. These sequences extend between the surfaces of the lamellar structures and stabilize themselves by forming CT-complexes with adjacent and still neutral sequences. The doping proceeds to the extent at which, on the average, each conjugated chain sequence between conformative defects or cross-links has been transformed into the complex structure. The charge of the radical ions, which is situated on the sequences delocalized along the chains, is compensated by counter-ions. These are either intercalated in layers between the chains or deposited on the surfaces of the morphological units.

The original lattice breaks down in the course of doping PA. This is shown experimentally by the disappearance of the Bragg reflections. The latter remain, however, for some period of time during the doping, albeit with decreasing intensity. This is due to the fact that the doping proceeds inhomogeneously and individual morphological units become doped at different rates. Samples which have reached maximum conductivity are, however, amorphous as revealed by X-ray investigation. Hence, exact data on the packing of the chains and the counter-ions are not available at present and analogies have to be relied upon.

Presumably, charge transport takes place within a morphological unit normal to the chain direction as indicated by the exchange process sketched in Figure 10b. In other words, it is expected that a high mobility of the charge carriers exists normal to the chain direction, even in the absence of perfect crystalline order. It is another problem as to how the electric contact is made where the surfaces of the individual morphological units touch each other and where contact resistances are build up which have not thus far been characterized.

These ideas are contradictory to those proposed by, among others, *Heeger et al.*[11,80], *Chien et al.*[98], and *Rice et al.*[99,100]. These authors claim that the conductivity mainly arises from the transport of charge along individual chains. Apart from the fact that they incorrectly assumed that PA, as obtained by the Shirakawa procedure, consists of a network of extended fibers and fibrils of infinitely long extended chains, they did not take into account the expected interactions between neighboring chains. Rather, these authors believe that the charge carriers migrate along a single chain in a manner similar to delocalization of charge along an extended $\pi$-bonded system and that the constraints of strictly one-dimensional diffusion apply. Such a state of a charged $\pi$-bonded chain may be described mathematically as a soliton[99,100][*]. The chemical structure *(4)* envisaged in this context is the radical cation previously discussed in eq. (h)—(k). Any interactions with adjacent chains are, however, not allowed. The radical site in *(4)* is termed a "neutral" soliton and the site of the positive charge a "charged" soliton. It is only the latter which is able to transport a charge if an external electrical field is applied.

*(4)*

Unfortunately, until now, no successful measurements on samples in which the orientation of the chains with regard to the direction of the field was known have been reported (see Section 3.1). Hence, the question whether the charge transport occurs in a direction across the chains or along the individual chains, which is basic to the understanding of the electrical phenomena in doped polymers, cannot yet be answered experimentally.

### 3.3. Electrical Conductivity as a Percolation Problem

So far, the exponential increase in conductivity with increasing degree of conversion observed in the course of doping of PA has not been dealt with (see Fig. 1). Similar behavior is also found in other polymers. This is shown in Figure 12. It may therefore be asked whether the observed behavior may not be explained by a universal law.

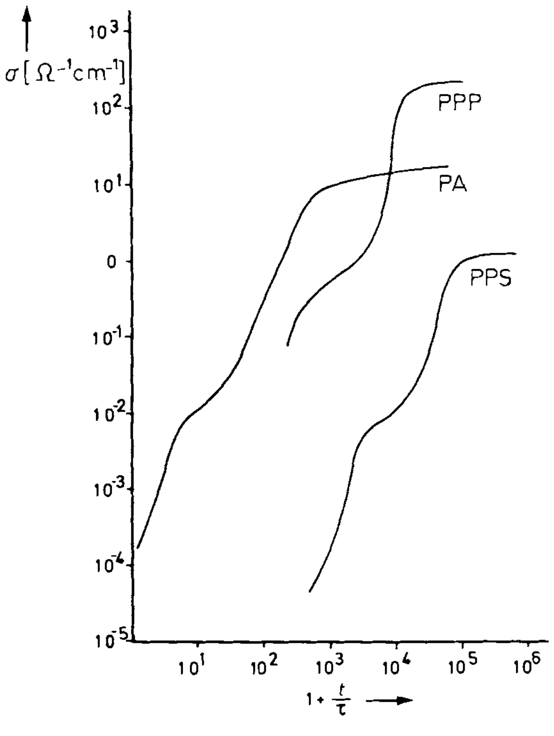

Fig. 12. Increase of the specific conductivity $\sigma$ with reaction time $t$ ($\tau = 1$ s) during doping of poly(*p*-phenylene) (PPP) [21, 22] [$\sigma_{max} = 145\ \Omega^{-1}\ cm^{-1}$, $AsF_5$, 455 torr] and poly(*p*-phenylene sulfide) (PPS) [$\sigma_{max} = 1\ \Omega^{-1}\ cm^{-1}$, $AsF_5$] [23, 24] as well as of polyacetylene (PA) [$\sigma_{max} = 15\ \Omega^{-1}\ cm^{-1}$, $I_2$, $2\cdot 10^{-2}$ torr] [89].

PA is semicrystalline, as are other polymers which may be made conductive by oxidation or reduction. The doping is inhomogeneous and occurs within and at the surfaces of the morphological subunits. It has been shown that polyacetylene is built-up from lamellar subunits of limited thickness with a lateral extension of approximately 1000 Å. Charge transport is only possible across the boundary of the particles at points of contact.

---

[*] In this context, the term soliton refers to the non-linear excited state of the chain; this operates in such a way that the $\pi$-electron wave function undergoes a 180° phase change at the site of the excited state. The excited state has free rotation along the chain. An analogues phenomenon is the well-known mobile replacement in single crystals.

The doping proceeds inhomogeneously, and in addition at low conversions, individual single particles are the first to react and become conductive[101]. Charge transport cannot yet take place since these particles remain isolated by the surrounding particles, which are still in their pristine insulating state. A macroscopic current may only begin to flow if sufficient particles have become conductive so that a path between the electrodes is formed. At this point, then, a jump in the conductivity and conductivity behavior must be experimentally observed if a critical concentration of the doping reagent has been applied. With increasing conversion, further paths and bridges will be formed until all of the morphological units have assumed the same conductive state. When this is the case, the saturation value of the conductivity will be reached. This process is illustrated in a two-dimensional model in Figures 13a—c.

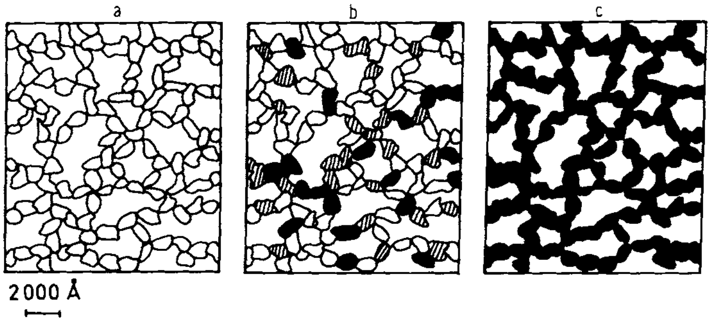

Fig. 13. Percolation model to explain the increase in conductivity during the doping of PA. a) All morphological structures are in their pristine, insulating state. b) State of the system at $\varphi_L < \varphi_L^c$; the black particles have already reached their maximum conductivity; the gray particles have not yet reached their final conductivity. c) State of the system whem maximum conductivity has been reached.

The electrical behavior of mixtures of two phases, each having a very different conductivity, has been investigated theoretically[102] as well as experimentally[103-105]. In the framework of percolation theory, the average conductivity $\sigma$ of a system undergoes a transition, termed "percolation", if the conductive phase attains a critical volume fraction $\varphi_L^c$.

The macroscopic properties of the system may be described, in a manner similar to thermal phase transitions, by universal "scaling laws". These are independent of the physical and chemical details of the system and depend only on their topology.

Above and in the vicinity of the critical volume fraction $\varphi_L^c$ at which percolation commences, the theory predicts that the conductivity should follow a simple exponential law

$$\sigma = \sigma_0(\varphi_L - \varphi_L^c)^t \qquad \varphi_L > \varphi_L^c$$

Below $\varphi_L^c$, it is predicted that

$$\sigma = \sigma_0'(\varphi_L^c - \varphi_L)^{-s}$$

The exponents t and s are constants, as are the pre-exponentials $\sigma_0$ and $\sigma_0'$. While the exponents are universal constants, the values of which have been predicted to be $|t| = 1.6$ and $|s| = 0.7$ for three-dimensional randomly placed particles, this is not true for the pre-exponential factors and $\varphi_L^c$ at which percolation occurs. The critical volume fraction $\varphi_L^c$ is dependent upon the dimensionality of the system, the arrangement of the particles, their degree of dispersion, and other morphological details of the system. Values of the pre-exponential factors $\sigma_0$ and $\sigma_0'$ may be calculated only when the conduction mechanism is known and specific models are assumed.

It is of considerable relevance when applying percolation theory, that all information concerning the dimensionality and topology of the system is contained in the terms $(\varphi_L - \varphi_L^c)^t$ and $(\varphi_L^c - \varphi_L)^{-s}$, respectively, while details of the mechanism of charge transport are contained in the pre-exponential factors. These can be determined experimentally.

In order to apply the theory to the doping of PA it is assumed that the individual particles are arranged in the form of a three-dimensional network, similar to that depicted in Fig. 13. It is further assumed that a single particle which has begun to react with the dopant, reacts to the saturation value much faster, due to kinetic or thermodynamic reasons, than an adjacent particle which is still in its pristine non-conductive state.

Since a partially converted particle may become conductive if the mechanism of conductivity—as discussed in Section 3.2—is dependent on charge transfer between adjacent chains, *via* a redox process, it would be expected that some conductivity would arise prior to the percolation between completely doped particles by percolation through partially reacted morphological units.

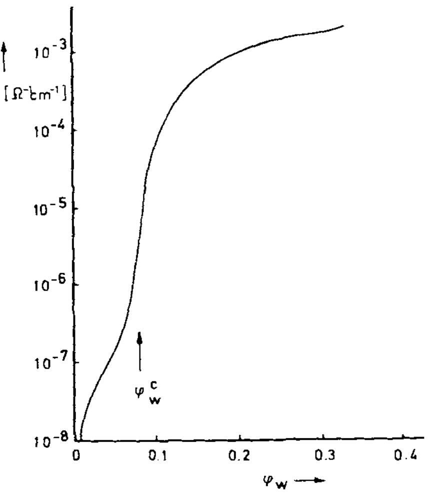

Fig. 14. Conductivity of a water-in-oil emulsion as a function of the volume fraction of the water droplets. This is a model case for percolation [105].

*Lagues* and *Sauteray*[105] have investigated a system, which serves as a model for the present discussion. For a water-in-oil emulsion of very fine droplets, having a diameter of approximately 100 Å, the conductivity increases in proportion to the volume fraction of the water phase $\varphi_W$, as shown in Figure 14. At $\varphi_W^c = 0.078$, percolation is observed. The conductivity above this value is proportional to $(\varphi_W - 0.078)^{1.55}$ and hence the theoretically expected behavior is observed. Below the critical concentration, the conductivity arises *via* Brownian motion of the electrically charged water droplets and is consequently proportional to the diffusion coefficient of the charge carriers. The authors mentioned above define this behavior as "stirred percolation", in contrast to the model, discussed initially, which is described as a "frozen" system.

The increase in conductivity as a function of the critical volume fraction of the aqueous phase, shown in Figure 14, exhibits a surprising similarity to the behavior of PA and other doped polymers as a function of time. In this comparison, it is assumed that the conversion of the sample is approximately proportional to the contact time with the dopant.

In fact, an evaluation of what is presently considered to be the best values for the dependence of the conductivity of PA from the concentration of iodine[89] results in the curve shown in Figure 15. In order to utilize the available published data in percolation theory, it is assumed that each morphological subunit accepts only a maximum number of iodine atoms and that the dimensions of these morphological subunits fluctuate very little around an average value, *i.e.*, it is assumed that they may be represented by an average particle volume. The unknown volume fraction $\varphi_L$, may then be replaced by the concentration of iodine $c$ consumed by the sample. Figure 15 shows the curve is that of $c > c^c$ calculated from

$$\sigma = 5(c-500)^{1.6}$$

and is in excellent agreement with the assumption of three-dimensional percolation. For $c < c^c$ it was found that $\sigma = 2.4 \cdot c^{1.0}$, *i.e.*, the conductivity is determined by the diffusion of the existing charge carriers between the still poorly conducting particles.

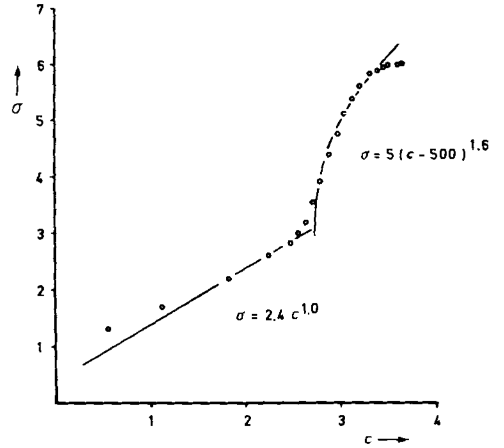

Fig. 15. Conductivity of PA as a function of the iodine concentration (arbitary units); o: data from [89]; solid curve calculated according to the equation in text.

The available data are not yet sufficiently extensive and precise to either sufficiently substantiate the behavior upon doping within the framework of percolation theory, or to attempt an evaluation and discussion of the magnitude of $c^c$ and $\sigma_0$. Nevertheless, it is certain that a more comprehensive alternative has been proposed, in which conductivity data is based on a physical model. This alternative accounts better than other theories for the real physical structure of the samples.

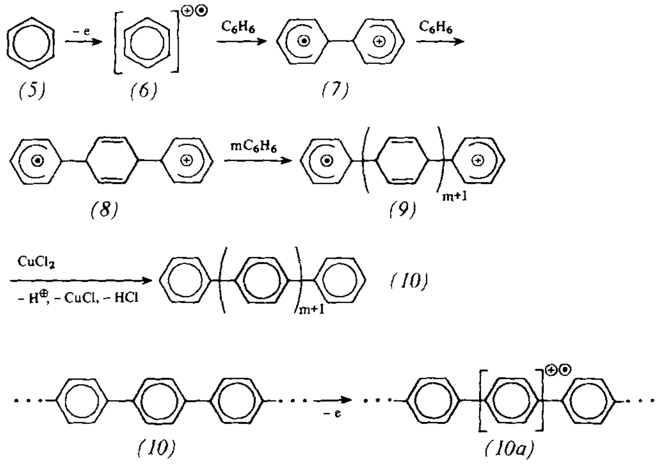
The explanations for the exponential increase of conductivity with increasing content of doping published in the literature, principally stem from the physics of semiconductors. In addition, they all rely on the assumption that PA is similar to semiconductors built up from rather large crystals and that the dopant enters lattice sites such as defects or is intercalated at interstitial sites[67,68,80].

As previously demonstrated, these assumptions are inappropriate. Further analysis of the conduction behavior and theoretical considerations can only be successful therefore, if the topological effects (which are described by percolation theory) are separated from other effects (which take place on the surface and within the single morphological subunits of the polymer).

## 4. Additional Polymers Exhibiting Conductivity

### 4.1. Poly-(*p*-phenylene) (PPP)

Poly-(*p*-phenylene) (PPP) *(10)* is obtained in quantitative yield as an insoluble and infusible powder when benzene is polymerized over $AlCl_3/CuCl_2$ (molar ratio 2:1) as a catalyst and reaction component[106]. Similarly, other reagents which act as both oxidants and Friedel-Crafts catalysts may be used for the polymerization, *e.g.*, $FeCl_3$, $MoCl_5$, *etc.* After *Kovacic*[106,107], the polymerization proceeds *via* radical cations such as *(6)*—*(9)* as the active intermediates according to a mechanism which explains the formation of branches and cross-links as well as by-products during the work-up procedures.

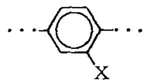


Benzene is initially oxidized to the cation radical *(6)* which dimerizes to the species *(7)* and rapidly adds further monomer *via* the cationically active chain end to form *(8)*. The oligomer or polymer with the quinoid structure *(9)* is subsequently oxidized by the oxidant present in the reaction medium to the polymer *(10)*.

Since the redox potential of the oligophenylenes decreases with increasing chain length, the polymer *(10)* itself is further oxidized to *(10a)*. Units of *(10a)* exhibiting the structure and reactivity of radical cations are thereby formed. These are the sites for branching, and in turn give rise to side reactions during the work-up. The ability of the radical cations derived from benzene or oligophenylenes to undergo electrophilic additions to aryls is well documented by cyclic voltammetry and the electrochemically induced oligomerization of arenes[108].

The structure *(10a)* explains why PPP is black immediately after its synthesis and prior to purification: purification is generally achieved by extracting the polymer with boiling hydrochloric acid. The spin density is reported to be $10^{21}$ spins·g$^{-1}$, *i.e.*, approximately one unpaired electron for every eight phenylene units.

After work-up, the brownish-red colored polymer still possesses a spin density[1,7,109] of *ca.* $10^{18}$ spins g$^{-1}$. Elemental analysis indicates that chlorine (1—4%), oxygen (<5%), copper (0.1—0.2%) and aluminum (0.3—0.6%) are present even in well purified PPP[106,107,110]. This indicates the presence of structures of type *(11)* in the polymer[107].



*(11)*, X = OH, Cl

The UV/VIS-spectrum of the purified polymer exhibits a broad absorption band with maximum at $\lambda = 385$—$395$ mm. The data may be interpreted by assuming that the constitutive units are essentially all linked to each other in *para*-positions. The presence of branching, however, is also highly probable[106]. The degree of polymerization of the polymers produced following *Kovacic*'s method are clearly smaller than was originally assumed[106]. More recent investigations by *Kovacic et al.*[111] seem to indicate that the polymer is, in part, cross-linked. Perhydrogenated oligomers of degree of polymerization 7.5 can be extracted from the polymer after hydrogenation, in a yield of approximately 5%. It seems reasonable to assume that the cross-linking occurs essentially *via* radical combination of the adjacent chains of structures such as *(10a)*.

Little is known about the morphological structure of the polymer[110,111], which consists of lamellar to grainy structures: it has a specific surface of approximately 50 m$^2$ g$^{-1}$. This value varies considerably, however, depending on the polymerization conditions. The discussion of the crystal structure and the chain packing is, therefore, limited to an analysis of the powder diagrams[111] and to comparisons with the known crystal structures of some oligophenylenes[21,22]. The orthorhombic unit cell most likely has the dimensions $a = 7.81$, $b = 5.53$, $c = 4.20$ Å (chain direction): it contains two chains. The density of the crystalline phase is reported to be $\rho_c = 1.39$ g cm$^{-3}$. Since the density of amorphous PPP is unknown, the crystallinity of the polymer samples cannot be evaluated.

PPP has a specific conductivity of $\sigma < 10^{-11}$ $\Omega^{-1}$ cm$^{-1}$ in purified from. *Baughman et al.*[21,22,112] have demonstrated that $\sigma$ increases exponentially if the polymer is treated with oxidants such as, $AsF_5$, $SbF_5$, $SbCl_5$ or reductants such as sodium, potassium, lithium or sodium naphthalide or similar reagents.

The increase in conductivity of PPP as a function of the contact time, *i.e.* with conversion on doping with $AsF_5$, is shown in Figure 12 as an example. A limiting value of the conductivity is reached at $\sigma = 145$ $\Omega^{-1}$ cm$^{-1}$ at a conversion of approximately 0.3 mol $AsF_5$ per mol of the constitutive units.

It is unclear how $AsF_5$ reacts. Elemental analysis produces a ratio As:F = 1:4 for the doped polymer[112]; in addition, HF seems to be split off in the course of the doping. The reaction behavior of oligomer model compounds as, for example terphenyl, suggests that fluorination may proceed as a side reaction. By taking into account what is known about the reaction behavior of PA, it is reasonable to assume that the radical cations of the structure *(10a)* formed by oxidation are compensated by $AsF_6^{\ominus}$ counterions. The As:F ratio found is then explained by assuming that part of the $AsF_3$ formed by disproportionation of $AsF_5$ fluorinates the polymer and gives rise to volatile by-products.

In contrast to PA, PPP cannot be made conductive by exposure to iodine or bromine. If PPP is reduced by, for example, potassium naphthalide dissolved in tetrahydrofuran, a conductivity of only $\sigma \leq 10$ $\Omega^{-1}$ cm$^{-1}$ is found despite the higher conversion (*ca.* 0.6 mol potassium per mol constitutive unit)[21,22].

Similar to PA, the activation energy of the conductivity decreases from 0.7 eV for the pure polymer to very small values for the doped material. If PPP is doped with $AsF_5$, the conductivity measured at 10 K is only smaller than that found at room temperature by a factor of 0.45[27].

The conductivity is electronic in nature. *Shaklette et al.*[112] report a charge carrier density of $2.2 \cdot 10^{27}$ m$^{-3}$ and a mobility of the charge carriers (holes) of 10 cm$^2$ V$^{-1}$ s$^{-1}$ for the polymer doped with $AsF_5$. The same authors found an electron mobility of $10^{-2}$ cm$^2$ V$^{-1}$ s$^{-1}$, when the polymer is doped with potassium naphthalide.

Considering the complex structure and morphology of the polymer, these data should not be used to come to premature conclusions on the relation between chemical and physical structure and conductivity behavior. An unexpectedly low value of the Pauli paramagnetism is, for example, obtained from the temperature dependence of the static susceptibility of PPP doped with $SbF_5$. The Pauli paramagnetism, $\chi_{Pauli}$, is defined as the susceptibility which arises from the spin of the charge-carriers. The value of $\chi_{Pauli} \leq 10^{-7}$ emu cm$^3$ mol$^{-1}$ $\pi$-bonded C-atoms determined for PPP·$SbF_5$ should be compared with that of a typical metal, for example, sodium ($\chi_{Pauli} = 2 \cdot 10^{-5}$ emu cm$^3$ mol$^{-1}$) and for HMTTF-TCNQ, a typical organic metal ($\chi_{Pauli} = 1.2 \cdot 10^{-5}$ emu cm$^3$ per mol of $\pi$-bonded C-atoms).

It is difficult to reconcile this result with the assumption that the conductivity arises according to a band model. Rather, it seems to suggest a "hopping process" and may be related to the previous discussion assuming that the equilibrium discussed by eq (n) is shifted to the side of disproportionation products in the solid doped polymers; hence the spin density, as determined experimentally for the samples made conductive by $SbF_5$, is smaller by a factor of at least $10^{-4}$ than the spin density calculated from the elemental analysis (content of antimony).

*Peo et al.*[109] propose, therefore, that the charge transport takes place by compensation of spins, since a high conductivity with metal-like temperature dependence is found and because in the case of PPP a charge transport *via* charged but spinless solitons cannot be reasonably assumed for structural grounds PPP[21,22].

Moreover, it is interesting to note that oligophenylenes such as terphenyl, quarterphenyl and sexiphenyl can be doped with $AsF_5$. Highly conducting complexes having a greenish-golden luster are formed by this reaction[112]. As may be expected from the work of *Kovacic*[106,111], combination of the initially formed radical cations gives rise to higher oligomers and polymers in the course of the doping of these compounds, in the form either of single crystals or polycrystalline powders[112]. The oligomers, as well as PPP, become X-ray-amorphous upon doping. It is therefore unreasonable to discuss possible intermolecular interactions or intercalation structures of the doped polymer on the basis of known packing of the polymer or of the oligomers, because the doping proceeds with destruction and/or reorganization of the packing.

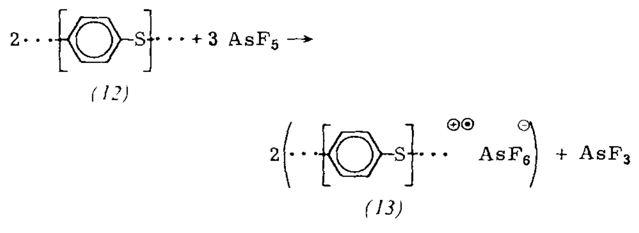
### 4.2. Poly(thio-1,4-phenylene) (PPS)

Poly(thio-1,4-phenylene) (poly-(phenylene sulfide), PPS) *(12)* becomes conductive when treated with AsF$_5$[24,25,113], although the maximum values of conductivity reached so far are only of the order of 1 $\Omega^{-1}$ cm$^{-1}$. This result is of great interest, however, since PPS is the first example of a polymer which can be doped, but which is moldable and soluble. It may, therefore, independent of the conditions of the synthesis, be produced in specifically selected forms such as fibers, films or threads.

PPS is obtained industrially by reaction of dichlorobenzene with sodium sulfide in *N*-methylpyrrolidone[114,115]. It precipitates as a white powder and is soluble in high boiling solvents. Presumably, the degree of polymerization is not very large; a determination of the number of end groups resulted in values of $40 < \bar{P}_n < 130$, for material prepared using pyridine as solvent[116].

The melting point of the commercially produced polymer of density $\rho = 1.35$ g cm$^{-3}$ is reported to be 288 °C; a brownish discoloration and cross-linking is observed if the polymer is melted in air. The glass temperature is reported to be 85 °C[114].

The lattice of PPS[117] is completely destroyed by reaction with AsF$_5$. The amorphous adduct of AsF$_5$ and the constitutive units of the polymer reaches the maximum conductivity[24,113] at a molar ratio of AsF$_5$ to the polymeric building units of 1:1. *Rabolt et al.*[25] assume that a reaction of *(12)* with AsF$_5$ occurs with formation of radical cations *(13)* as follows.

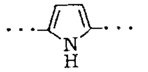


The presence of AsF$_6^{\ominus}$ ions is revealed by their characteristic IR absorption at 705 cm$^{-1}$[113].

Pure PPS is an excellent insulator ($\sigma \leq 10^{-16}$ $\Omega^{-1}$ cm$^{-1}$). Its conductivity rises exponentially in contact with AsF$_5$, as shown in Figure 12. The conductivity characteristics change in the course of the doping from that of a semiconductor to that of a semimetal. The activation energy of the conductivity is *ca.* 0.5 eV for the pure polymer and *ca.* 0.06 eV for the polymer doped to the maximum level. The colorless PPS assumes a dark blue to blue-black color in the course of reaction with AsF$_5$; a continuous absorption in the IR region, however, only develops at very large conversion. Such a continuous absorption would be expected for materials containing free and mobile charge carriers. The conductivity caused by reaction with AsF$_5$ can be destroyed by treating the doped polymers with ammonia or amines, whereby, however, the polymer seems to cross-link. The thermoelectric power (+40 μV K$^{-1}$) and the behavior in semiconductor contacts having a Schottky carrier configuration indicates that the current is maintained by positive charge carriers. There are literature reports that the structurally related polymers poly(thio-1,3-phenylene) and poly(1,4-phenylene oxide) can be reacted with AsF$_5$ and give conductive adducts as well (cf. Table 1).

### 4.3. Polypyrrole

*Kanazawa* and *Diaz et al.*[18,118,119] have described the electrochemical polymerization of pyrrole, which proceeds with simultaneous doping. When a solution of pyrrole (0.06 M) in 99% aqueous acetonitrile is electrolyzed in the presence of Et$_4$N$^{\oplus}$BF$_4^{\ominus}$ (0.1 M) as the supporting electrolyte, a blue-black film of an insoluble polymer precipitates on the anode. Its IR spectrum exhibits bands, which are characteristic of the pyrrole ring. The films contain BF$_4^{\ominus}$ ions in a molar ratio *ca.* 1:4 with respect to the pyrrole rings. The authors assume, following earlier literature data[120], that the constitutive units of the polymer are linked to each other *via* the α-C-atoms of the pyrrole rings. Consequently, the idealized structure *(14)* is proposed



*(14)*

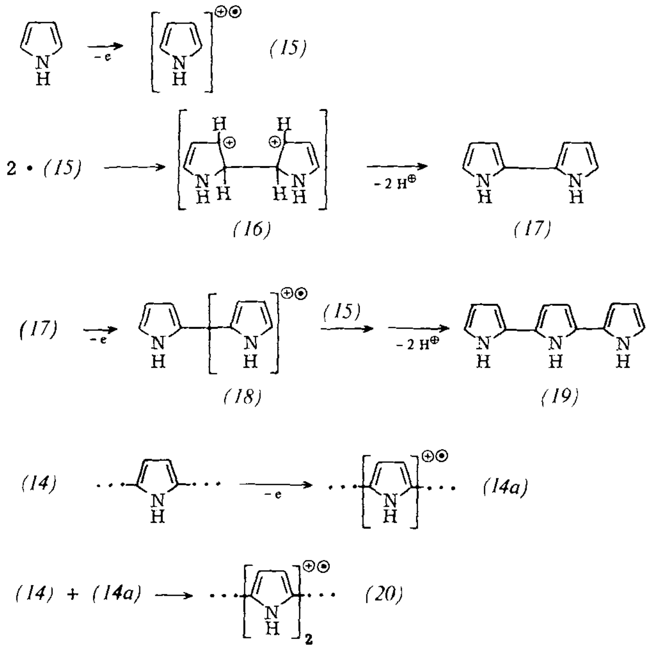
The films exhibit a conductivity of $\sigma = 100$ $\Omega^{-1}$ cm$^{-1}$, which is readily reproducible. $\sigma$ is weakly dependent on temperature and decreases from 100 $\Omega^{-1}$ cm$^{-1}$ at 300 K to 30 $\Omega^{-1}$ cm$^{-1}$ at 80 K; it is assumed that defect electrons (holes) act as the charge carriers. The conductive films of density 1.48 g cm$^{-3}$ are stable in air for long periods of time and, moreover, can be heated to temperatures approaching 100 °C without any essential alteration of their electrical properties. They are X-ray-amorphous. A diffuse halo, which is obtained by electron diffraction, corresponding to a *d*-value of 3.4 Å, is presumed to be caused by the characteristic distance between the ring planes of pyrrole rings in adjacent chains[18,118].

*N*-Methylpyrrole can be polymerized in a similar fashion, but results only in conductivities of the order of $\sigma \leq 10^{-3}$ $\Omega^{-1}$ cm$^{-1}$.

When pyrrole and *N*-methylpyrrole are copolymerized, films precipitate on the electrode whose conductivity is proportional to the composition of the copolymer between the limiting values of the two homopolymers.

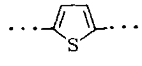
Unfortunately, little is known about the exact chemical structure of these interesting polymers or on the mechanism of their formation. One interesting observation concerns the polymerization mechanism. A polymer is not formed when Et$_4$N$^{\oplus}$Br$^{\ominus}$ is used as the supporting electrolyte. Considering the experimental results obtained in the electrocrystallization of the radical salts of simple arenes, TTF, TCNQ and similar compounds, the following reaction sequence is proposed to explain the formation of a conductive polymer film on the electrode:

Initially, the radical cation *(15)* is formed by a redox reaction; it dimerizes to the adduct *(16)* having the structure of a dication, which stabilizes itself by deprotonation to give the stable dimer of pyrrole *(17)*. This reaction may proceed with the help of excess monomer acting as a base. By subsequent oxidation of the dimer to *(18)*, combination with the radical ion of the monomer and deprotonation *(19)* is formed, and in this way the oligomer grows. Since the solubility of the oligomers decreases with increasing degree of polymerization, they finally precipitate on the electrode. There, further oxidation of the constitutive units of the polymer *(14)* to the radical cations *(14a)* takes place. These, in turn, may react with the constitutive units of an adjacent chain to form a conductive charge-transfer complex *(20)* of a similar nature to that previously discussed.



The inhibiting effect of $Et_4N^{\oplus}Br^{\ominus}$ is now explained by the trapping of the unstable dication *(16)* from which the dibromide is obtained. In contrast, $BF_4^{\ominus}$ is not sufficiently nucleophilic and, therefore, the intermediate stabilizes itself by rearomatization to *(17)*.

It would be unreasonable to assume that the dimerization of the radical cations occurs exclusively at the α-C-atom of the pyrrole ring. Consequently, isomeric structures, branching and cross-linking must be expected that would help to explain the insolubility and the lack of crystallinity.

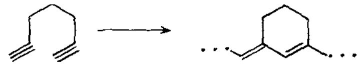


*(21)*

The conductivity of poly(2,5-thienylene) *(21)*, which is structurally related to *(14)*, increases if treated with iodine[19]; the values so far measured, however, are only comparable to very poor semiconductors (cf. Table 1).

### 4.4. Additional Polyacetylenes

1,6-Heptadiyne *(22)* can be polymerized by Ziegler-catalysts[20,121]. A black film with silvery luster is obtained which, contrary to PA, does not consist of a network of individual morphological units but, rather, is presumed to be completely amorphous and homogeneous[20]. The chemical structure of the insoluble polymer is formulated in *(23)* on the basis of spectroscopic evidence. It is implicitly assumed that the monomer *(22)* reacts *via* a cyclopolymerization mechanism.



*(22)* *(23)*

The polymer *(23)* becomes conductive when doped with the reagents previously described for PA[20]; the conductivity is clearly below the values which may be reached in the case of PA (cf. Table 1) but the polymer should exhibit good thermal and oxidative stability.

Poly(phenylacetylene) (PPP) is a well known and relatively thoroughly investigated material. It is soluble, relatively stable and can be prepared as the mostly *cis*-, as well as, mostly *trans*-isomer.

The orange-red *cis*-isomer is obtained almost exclusively as an amorphous powder using $MoCl_5$ as the catalyst at reaction temperatures below 40 °C[122,123]. A polymer of mostly *trans*-structure and reddish-brown color is obtained when $WCl_6$ is used as the catalyst. Crystalline *cis*-PPA precipitates in the form of an insoluble orange-red powder in the course of polymerization with $Fe(acac)/Al(Bu)_3$ as catalyst and isomerizes at 120—130 °C to the soluble *trans*-isomer[124,125]. While a large number of other catalytically active systems have been reported[124,126,127], the mechanism of polymerization is still rather unclear. The polymers normally exhibit molecular weights of $\overline{M}_n \leq 10^4$.

Both amorphous and crystalline PPA rapidly take up halogens *e.g.* up to 50 mol% when exposed to gaseous iodine or bromine at room temperature. The conductivity rises, thereby, by 7 orders of magnitude from *ca.* $10^{-12}\ \Omega^{-1}\ cm^{-1}$ to *ca.* $10^{-5}\ \Omega^{-1}\ cm^{-1}$. The activation energy of the conductivity decreases steadily from approximately 0.8 eV to 0.2 eV with increasing iodine content[128]. The electrical behavior and the kinetics of the halogen uptake do not depend on the molecular weight.

Contrary to the behavior of PA and other conductive polymers, iodine and iodine-containing compounds separate at the anode when the d.c. conductivity is measured. All the results are in accord with the assumption that the conductivity arises *via* predominantly ionic mechanisms. It is believed that a charge-transfer complex is formed between the halogen and those segments of the polymer[129] in which mobile $I_3^{\ominus}$- or $I_5^{\ominus}$-ions provide the charge transport. The concentration dependence of σ is explained by a concentration dependent equilibrium in which the ionic charge carriers are formed[129].

It appears that the steric hindrance caused by the phenyl residues prevents the formation of stable CT-complexes between adjacent chains, in the case of PPA. Since a distance of 3.2 Å between the planes of the rings or double bonds of adjacent chains is a necessary requirement for complex formation (cf. Section 3.2 and Fig. 11), there is little hope in finding conductive complexes of unsaturated polymers with non-planar or freely rotating side groups. This may also be the reason why the production of conductive complexes by doping polydiacetylenes[130] has only recently been successful.

## 5. Future Developments

Research activities of the last three years, which have formed the main topic of the present discussion, have unambiguously demonstrated that polymers with metal-like conductivity can be realized. It is not necessary to prepare such polymers by lengthy synthesis or complicated procedures. Rather, they are obtained by extremely simple polymerizations, starting from easily prepared monomers which, in most cases, are already available on the industrial scale. Examples of such monomers are acetylene, benzene and pyrrole, among others. This fact is obviously of great importance for the further scientific and industrial development of the area.

The greatest obstacle still existing is to stabilize the level of conductivity of the doped polymers for periods of more than 24 hours. Most of the applications which might result from doped polymers require, however, the conductivity data to be constant and should approximately meet the durability of the usual plastic materials.

It should be remembered in this context, however, that many years of research and development were necessary to provide the plastics and synthetic fibers of current industrial importance with sufficient stability against autoxidation, hydrolysis and photochemical degradation. Further research in the area of conductive polymers will, therefore, primarily concentrate on how the radical ions, which have been found to be the chemical basis of the conductivity, can be stabilized. This problem cannot be solved without investigating the redox chemistry of polyunsaturated and polyaromatic compounds in much more detail; it is of major interest, as well, to investigate the influence of the counterions ("dopants") on the chemical reactivity of the conductive polymers. In this context, the relation between morphology, conductivity and chemical reactivity is of prime importance, because the doping, as well as the subsequent reactions leading to the decline of the conductivity, start as surface reactions. The future will, therefore, see many more attempts to prepare different polymer morphologies and textures which may be eventually doped and become conductive. A further interesting problem viewed from the chemical engineering point of view, is how the polymerization can proceed simultaneously with doping, by analogy with the electrochemical syntheses of polypyrrole.

Possible applications of the conductive polymers will result firstly from their rather low specific weight and secondly, from certain advantages they may have in production—provided that long term stability can be reached—compared to the current metallurgical methods. A prognosis as to what extent polymers may eventually replace metals seems unsubstantiated in the light of the presently available data. Nevertheless, one can imagine that doped polymers may soon find a limited application in certain areas of the aerospace and electronics industries.

A quite different area of application could develop from their possible usage as electrodes or components of batteries. This aspect has already been mentioned in Section 2.5. It is predominantly their low weight with high capacity and the unlimited specification with regard to possible designs which may lead to speculations or possible applications in the automobile industry.

Finally, mention should be made of the photophysics of the doped and partially doped polymers. Since the absorption bands of the conductive polymers cover a large portion of the visible spectrum, sunlight may be converted into electrical energy by photovoltaic cells composed of suitable combinations of p- and n-doped polymers. The feasibility of these ideas has been demonstrated, although the efficiency is as yet very low. As long as the problem of the long term stability of the polymers is not solved, too great an optimism is unwarranted at present. On the other hand, it should always be remembered when a prognosis is made, that very few people had the imagination and the courage to predict the current developments of, for example, semiconductor technology when the results of the first investigations into the behavior of silicon and germanium became known. In any case, further research on the electric and electronic properties of polymers with metal-like conductivity is a major and quite remarkable scientific challenge.

*For numerous discussions, suggestions and the permission to mention yet unpublished data and results, the following persons are greatly acknowledged: Dr. V. Enkelmann, Dr. C. H. Kröhnke, Dr. G. Lieser, Dr. B. Morra, Dr. W. Meyer (Zürich) and W. Müller. The Bundesministerium für Forschung und Technologie, the Stiftung Volkswagenwerk and the Fonds der Chemischen Industrie are also greatly acknowledged, for financial support of the work of the Freiburg Institute in the area of conductive polymers and organic metals.*

## Photochemical Hydroformylation[**]

By *Manfred J. Mirbach, Nicholaos Topalsavoglu, Tuyet Nhu Phu, Marlis F. Mirbach* and *Alfons Saus*[*]

Hydroformylation of olefins with molecular hydrogen and carbon monoxide to aldehydes is a reaction of industrial importance. We report here for the first time on the influence of light on high pressure hydroformylations catalyzed by cobalt and rhodium compounds[1]. We have found that UV irradiation leads, on the one hand, to reduction of metallic salts to catalytically active carbonyl metal compounds [eq. (a)], and, on the other, even to acceleration of the hydroformylation by increased formation of carbonyl(hydrido)metal derivatives when using carbonylmetal compounds [eq. (b)].

$$\mathrm{Co^{II}_{solv}} \xrightarrow[\mathrm{CO/H_2 + L}]{h\nu} \mathrm{HCo(CO)_3L} \qquad \text{(a)}$$

$$\mathrm{Co_2(CO)_8} + \mathrm{P}(n\mathrm{Bu})_3 \xrightarrow[\mathrm{CO/H_2}]{h\nu} \mathrm{HCo(CO)_3P}(n\mathrm{Bu})_3 \qquad \text{(b)}$$

$\mathrm{L} = \mathrm{CO}, \mathrm{P}(n\mathrm{Bu})_3$; 85 °C/80 bar; in MeOH

Infrared spectroscopy reveals that a carbonyl(hydrido)cobalt complex is formed photochemically in the presence of tri-*n*-butylphosphane and cobalt acetate, in methanol. This complex initiates the well-known catalytic cycle[2]. However, the hydrido complex, which is the active catalyst, is *not* formed in hydrocarbons (*e.g.* methylcyclohexane) where, consequently, no product is obtained[3].

Photochemically initiated hydroformylation of straight-chain 1-alkenes to the corresponding aldehydes (or acetals) features mild reaction conditions and high selectivity (Table 1). Propene, *e.g.*, can be hydroformylated to *n*-butyraldehyde with a selectivity ≥99%.

Table 1. Photochemical hydroformylation of olefins and dienes with $CO/H_2$ (1:1) at 80 bar [a].

366 nm is 0.03 at 75 °C/80 bar $CO/H_2$. It rises with increasing synthesis gas pressure.

When using cobalt catalysts modified with phosphane the corresponding alkanes will also be obtained as by-products from 1-octene, propene and cyclohexene (10 to 15%); in the case of styrene, even hydrogenation to ethylbenzene becomes the main reaction.

It is of preparative interest that photochemical hydroformylation does not lead to formation of a deposit on the lamp shaft, which prevents practical application of many other photochemical reactions.

If $Co/PR_3$ complexes are used, the hydroformylation of 1-octene and propene is entirely photocatalytic, *i. e.* hydroformylated products are only obtained on irradiation; the reaction stops in the dark (see Fig. 1). A different behavior is observed in the absence of phosphane. Using cobalt acetate, the hydroformylation of 1-alkenes is photoinitiated, *i. e.* irradiation is required for the first two hours only, the reaction will then continue thermally. On using $Co_2(CO)_8$ as catalyst, the reaction procedes almost identically with or without irradiation.

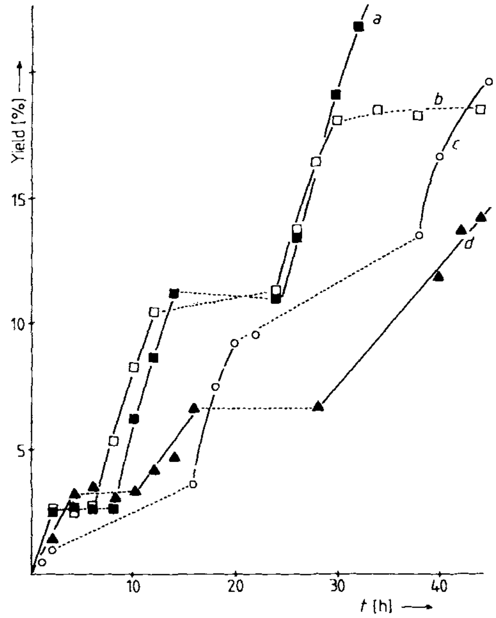

Fig. 1. Hydroformylation product yields over reaction time; (—) with UV irradiation, (···) without UV irradiation. *a:* 1-Octene/$Co_2(CO)_8/(nPBu)_3$; *b:* 1-Octene/$Co(OAc)_2/(nPBu)_3$; *c:* Cyclohexene/$Co(OAc)_2$; *d:* Propene/$Co(OAc)_2/P(nBu)_3$. Reaction conditions: 85 °C/80 bar $CO/H_2=(1:1)$, 0.017 mol/dm³ Co, 0.17 mol/dm³ $P(nBu)_3$ in methanol (500 cm³); lamp: TQ 718 (Hanau), Pyrex filter.

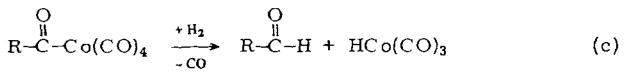
The different behavior depending on the kind of catalyst is explained in terms of the rate-determining step of the hydroformylation of reactive olefins with the relatively reactive catalyst $Co_2(CO)_8$ being at the end of the catalytic cycle: it is the reaction of the acyltetracarbonylcobalt complex to give aldehyde and $HCo(CO)_3$ [eq. (c)][5].



$$R-\overset{\displaystyle O}{\overset{\|}{C}}-Co(CO)_4 \xrightarrow[-CO]{+H_2} R-\overset{\displaystyle O}{\overset{\|}{C}}-H + HCo(CO)_3 \qquad (c)$$

If, on the other hand, less reactive olefins (*e.g.* cyclohexene) or less active phosphane-modified cobalt catalysts are used, the rate-determining step is at the beginning of the catalytic cycle [eq. (d)]. Apparently this step is thermally impossible under the mild conditions used.

$$Co_2(CO)_6L_2 \xrightarrow{+H_2} HCo(CO)_3L \qquad (d)$$

$$L = CO,\ P(nBu)_3$$

Without influencing the catalytic cycle itself, irradiation in the presence of CO and $H_2$ causes the reduction of cobalt acetate, which by itself is catalytically inactive, to $HCo(CO)_4$ or $HCo(CO)_3P(nBu)_3$, the real active species. The reaction continues only when sufficient hydrido complex has been formed.

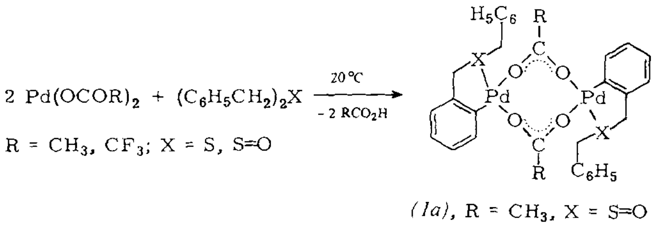
## *ortho*-Palladated Dibenzyl Sulfides and Sulfoxides from Palladium Carboxylates[**]

By *Reinhold Rüger, Walter Rittner* (deceased),
*Peter G. Jones, Wilhelm Isenberg*, and
*George M. Sheldrick*[*]

Organopalladium compounds, which are used in preparative chemistry and as catalysts, can often be prepared by using palladium(II) as an electrophilic reagent[1]. *ortho*-Metalation reactions can provide useful information as to the ligand dependence of the chemical reactivity of palladium(II) complexes[2].

*ortho*-Palladation reactions of amines, phosphanes and arsanes are well-known, whereas amongst sulfur compounds, they had only proved successful with arylthioketones[3,4].



*(1a)*, $R = CH_3$, $X = S{=}O$
*(1b)*, $R = CF_3$, $X = S{=}O$
*(1c)*, $R = CH_3$, $X = S$

[**] This work was supported by the Fonds der Chemischen Industrie.

We have now achieved *ortho*-palladation of dibenzyl sulfoxide and dibenzyl sulfide by their reactions with palladium carboxylates.

These reactions demonstrate the advantage of palladium carboxylate complexes as metalation reagents[5]; the dimeric complexes *(1a)* and *(1b)* are obtained in good yield from dibenzyl sulfoxide and palladium(II) acetate or trifluoroacetate at room temperature. *(1c)* is obtained in an analogous manner from palladium(II) acetate and dibenzyl sulfide. The structures of *(1a)*—*(1c)* were deduced from elemental analysis, IR- and $^{1}$H-NMR-spectroscopy and confirmed by an X-ray structure determination of *(1b)* (Fig. 1).

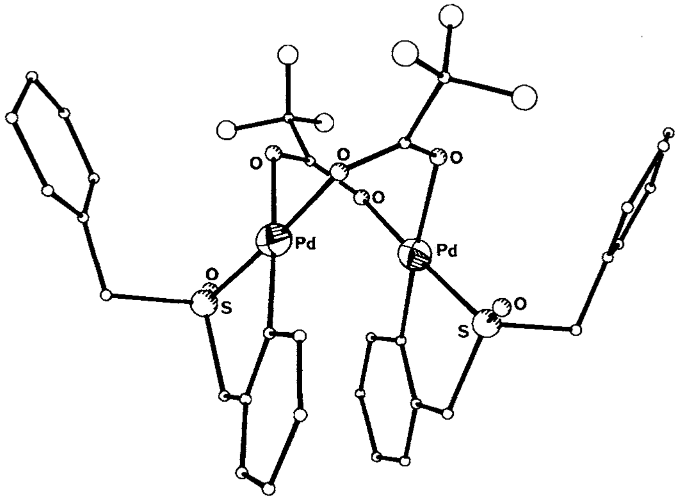

Fig. 1. Molecular structure of *(1b)* in the crystal. Monoclinic, C2/c, $a=2105(2)$, $b=1414(1)$, $c=1683(2)$ pm, $\beta=112.7(1)°$, $V=4.622$ μm$^3$, $Z=4$, $\mu=0.9$ mm$^{-1}$ (MoKα). Structure determined by heavy atom methods from 2087 diffractometer data with $F>4\sigma(F)$. Refinement (Pd, C, F, S and O anisotropic, fixed C—H bond lengths) to $R=0.14$. The high $R$ value is a result of disordered solvent and of the high thermal motion of $CF_3$ and phenyl groups.

*(1b)* crystallizes from dimethoxyethane as yellow prisms. The molecule possesses crystallographic twofold symmetry and contains two square-planar coordinated palladium atoms (Pd...Pd 289.8(3) pm). The dibenzyl sulfoxide is coordinated to the metal through the sulfur and *ortho*-carbon atom; the Pd—C bond length (194.5(2.2) pm) agrees with the sum of the covalent radii[1a]. The chelate ring angle at the metal atom is typical for this moiety (81.9(8)°)[6]. The *trans*-effect of the σ-bonded carbon is stronger than that of sulfur as is reflected in the Pd—O bond lengths. Both sulfur atoms are asymmetric centers; the structure contains the *R,R* and *S,S* forms, in which the benzyl groups are furthest apart.

The $^{1}$H-NMR spectrum of *(1a)* shows that a pair of diastereoisomers is present in solution; in the case of *(1c)* the inversion of configuration at sulfur is too fast[7] to allow this conclusion.

## A 2,3,9,10-Tetraaza-1,6,8,12-tetrasila-dispiro[4.1.4.1]dodeca-3,10-diene *via* Dimerization of a Heterocycle with Exocyclic Si=C Double-Bond[**]

By *William Clegg, Uwe Klingebiel, Sabine Pohlmann, George M. Sheldrick,* and *Peter Werner*[*]

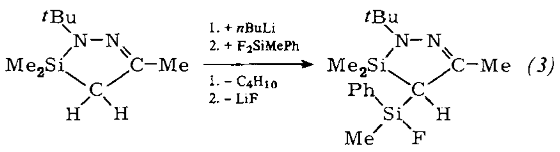
Silaethenes may be prepared in solution by elimination reactions of the type *(1a)*→*(1b)*, and identified as [2+2]-cycloadducts[1].

(1a)  (1b)

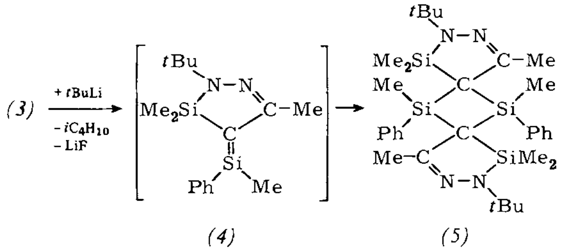
$$\underset{X}{\overset{\diagdown}{\underset{\diagup}{}}}\!\text{Si}-\underset{M}{\text{C}}\!\diagdown \xrightarrow[-MX]{} \left[\diagdown\text{Si}=\text{C}\diagdown\right]$$

X = electronegative substituent, M = alkali metal

We have obtained a novel type of compound involving the structural unit *(1b)*, by means of lithiation of the acidic methylene group of 1,2-diaza-3-sila-5-cyclopentene *(2)*[2] with *n*-butyllithium, followed by reaction with difluoro(methyl)phenylsilane to give *(3)*, and lithiation of *(3)* with subsequent elimination of LiF.



[2+2]-Cycloadducts of the intermediate 1,2-diaza-3-sila-3,5-cyclopentadienes are obtained in the reactions of fluorine-substituted 1,2-diaza-3-sila-5-cyclopentenes with organolithium reagents[3a]. However, *(3)* gives the spirocyclic product *(5)* with *tert*-butyllithium. By analogy to the formation of similar cycloadducts[3], *(5)* should be produced *via* the silanediyl-diazasilacyclopentene *(4)*.



Evidence for the existence of *(4)* comes from electron-impact (EI) and field-ionization (FI) mass spectra of *(5)*[3a]: in addition to the molecular-ion, the corresponding molecular-ion of *(4)* appeared.

Only by means of a crystal structure determination was it possible to show whether the dimer possessed the structure *(5a)* or *(5b)*, and how the substituents were arranged around the four-membered ring (Fig. 1). The two double-bonds are *trans* as in *(5a)*, but the phenyl groups on the central silicon atoms are *cis*. The middle ring is not planar (the angle between the two $Si_2C$-planes is 22.3°). In the two $SiN_2C_2$-rings the Si-atoms are displaced by 0.63 and 0.52 Å, respectively, from the plane of the other four atoms.

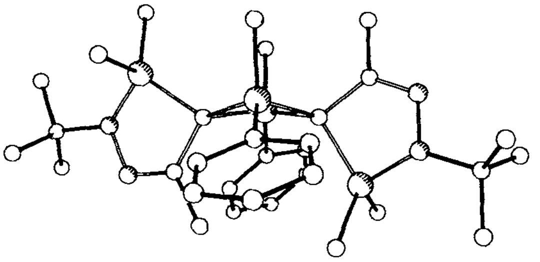

Fig. 1. Molecular structure of *(5)* in the crystal; Si- and N-atoms are shaded, H-atoms omitted. Monoclinic, $P2_1/n$, $a=11.101(2)$, $b=11.442(2)$, $c=27.806(6)$ Å, $\beta=97.56(2)°$, $Z=4$. Structure determined by direct methods from diffractometer data. Refined (Si, N, C anisotropic, H isotropic with fixed C—H bond-lengths) to $R=0.051$ for 3962 reflexions with $I>2\sigma(I)$.

*Experimental*

*(3):* A solution of 0.1 mol *(2)*[2b] in 100 $cm^3$ tetrahydrofuran is treated with 0.1 mol *n*-BuLi (15% solution in hexane) and heated for 2 h under reflux; the butane evolved is condensed in a cold trap. The resulting solution is added dropwise to 0.1 mol difluoro(methyl)phenylsilane in 100 $cm^3$ tetrahydrofuran. After evaporation of solvent, *(3)* is purified by distillation through a 30 cm Vigreux-column; yield 74%, b.p. = 112 °C/0.01 torr. A separation of the diastereoisomers (identified by NMR spectroscopy) was not successful[4].

*(5):* A solution of 0.1 mol *(3)* in 50 $cm^3$ petroleum ether is allowed to react with 0.1 mol *t*-BuLi (15% solution in pentane). After refluxing for 1 h, *(5)* is separated from solvent and LiF, and recrystallized from hexane; yield 28%, m.p. = 197 °C[5].

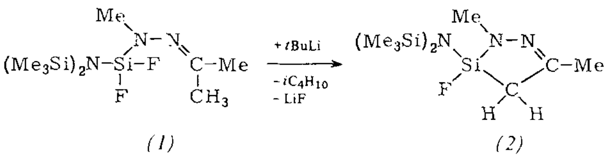
## Synthesis and Crystal Structure of a Dimeric 1,2-Diaza-3-sila-3,5-cyclopentadiene[**]

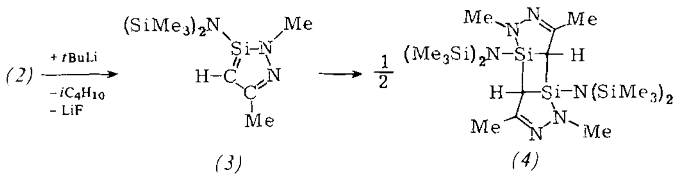
By *William Clegg, Uwe Klingebiel, George M. Sheldrick* and *Peter Werner*[*]

Substitution reactions[1] of *N*-lithiated hydrazones with fluorosilanes give products such as *(1)*. The reaction of *(1)* with organolithium derivatives leads to the substituted 1,2-diaza-3-sila-5-cyclopentene *(2)*[1]. 1,2,3-Phosphadiazoles are formed analogously from hydrazones and $PCl_3$[2]. We report here the extraction of HF from *(2)* by means of sterically hindered bases such as *tert*-butyllithium or lithium diisopropylamide (LDA).



*(1)* *(2)*

*(2)* reacts with *t*-BuLi, not with substitution of fluorine by a *tert*-butyl group, but instead with HF-elimination to give the colorless, crystalline tricyclic product *(4)*.



*(3)* *(4)*

The reaction *(2)*→*(4)* may be formulated as a dimerization of 1,2-diaza-3-sila-3,5-cyclopentadiene *(3)*, by analogy with the HCl-elimination from 1-chloro-1-sila-2,4-cyclohexadiene[3], which results in dimeric silabenzene. The electron-impact (EI) and field-ionization (FI) mass spectra of *(4)* provide evidence for the existence of *(3)*. The EI-spectrum of *(4)* shows a base-peak at $m/e=271$, corresponding to a fragment with the molecular weight of *(3)*. In the FI-spectrum of *(4)*

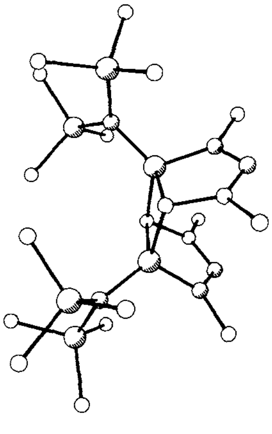


Fig. 1. Molecular structure of *(4)* in the crystal; Si- and N-atoms shaded, H-atoms omitted. Monoclinic, $P2_1/n$, $a=9.263(2)$, $b=15.960(3)$, $c=22.592(5)$ Å, $\beta=99.30(2)°$, $Z=4$. Structure determined by direct methods from diffractometer data. Refined (Si, N and C anisotropic, H isotropic, fixed C—H bond-lengths) to $R=0.051$ for 4191 reflexions with $I>2\sigma(I)$.

---

Anorganisch-Chemisches Institut der Universität
Tammannstrasse 4, D-3400 Göttingen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

both $M^{\oplus}$ and *(3)*$^{\oplus}$ are observed. Attempts to stabilize a 1,2-diaza-3-sila-3,5-cyclopentadiene by means of bulkier substituents have so far been unsuccessful.

The crystal structure determination of *(4)* (Fig. 1) shows that the three rings are almost planar (largest deviation from the calculated plane: 0.051 Å). The $SiN_2C_2$-rings are attached to the same side of the central ring, and the interplanar angles are 114.4° and 114.8°, respectively.

## *Experimental*

*(1)*: 0.1 mol acetonemethylhydrazone in 100 $cm^3$ tetrahydrofuran (THF) is lithiated with the equimolar amount of *n*-BuLi (15% solution in hexane), and the resulting solution added dropwise to 0.1 mol trifluoro[bis(trimethylsilyl)amino]silane in 100 $cm^3$ petroleum ether. After heating for 2 h under reflux the product is separated from the LiF residue and distilled through a 20 cm Vigreux-column; yield 86%, b.p. = 104 °C/13 torr[4].

*(2)*: 0.05 mol *(1)* in 50 $cm^3$ is treated with an equimolar quantity of *t*-BuLi (15% solution in *n*-pentane); the isobutane evolved is condensed in a cold trap. After refluxing for 2 h and separation from the LiF residue the sample is fractionally distilled through a 20 cm Vigreux-column. *(4)* is already present as a by-product; unreacted *(1)* may be recovered. *(1)* and *(2)* (yield 24%, b.p. = 40 °C/0.05 torr)[5] were separated by gas-chromatography (SE 30, V2A steel column, 4 m, 3/8″, 195 °C, helium).

*(4)*: 0.05 mol *(2)* in 50 $cm^3$ tetrahydrofuran is treated with an equimolar amount of *t*-BuLi (15% solution in *n*-pentane) and refluxed for 2 h. The product is recrystallized from petroleum ether; yield *ca.* 30%, m.p. = 146 °C[6].

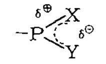
# 1,2λ$^3$,3λ$^3$-Azadiphosphiridines[**]

By *Edgar Niecke, Anke Nickloweit-Lüke,*
and *Reinhold Rüger*[*]

We recently demonstrated that phosphorus compounds of the ylidic type (*A*) and cyclic type (*B*) can be generated from isoelectronic precursors[1].

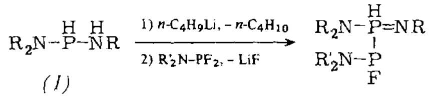
The possibility implied by this of a valence isomerization, which might occur by lowering the energy barrier of the conversion (*A*)→(*B*), stimulated investigations directed at the synthesis of the as yet unknown P—P—N system. Other than in the case of the previously described element-phosphorus-nitrogen compounds, for which the noncyclic dipolar structure (*A*), X = N—, proved to be energetically more favorable[2], a destabilization of the "homo-allyl-anion system" is to be expected for a derivative with X = N—, Y = P—.

(*A*)



(*B*)

For elimination reactions, we obtained suitable precursors by metalation of the secondary aminophosphane *(1)*[3] and subsequent reaction with aminodifluorophosphanes. This reaction leads to P—P-bonding and formation of the phosphoranes *(2a)* and *(2b)*[4].



$$R_2N{-}\overset{H}{P}{-}\overset{H}{N}R \xrightarrow[2)\ R'_2N{-}PF_2,\ -LiF]{1)\ n\text{-}C_4H_9Li,\ -n\text{-}C_4H_{10}} \begin{array}{l} R_2N{-}\overset{H}{P}{=}NR \\ \quad\ \ | \\ R'_2N{-}\underset{F}{P} \end{array}$$

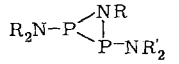
*(1)*

R = $SiMe_3$

*(2a)*, R' = $SiMe_3$
*(2b)*, R' = $CHMe_2$

Base-induced "HF"-elimination then affords *(3a)* and *(3b)* respectively, as could be demonstrated by elemental analysis and mass spectroscopy[5].

*(2a, b)* $\xrightarrow[-\,CH_4,\ -\,LiF]{CH_3Li}$



*(3a, b)*

From the NMR-data (Table 1) it is obvious that the products *(3a)* and *(3b)* are azaphosphiridines, *i. e.* compounds of type *(B)*.

Table 1. $^{31}$P-, $^1$H-, $^{13}$C-, and $^{29}$Si-NMR data of the 1,2λ$^3$,3λ$^3$-azadiphosphiridines *(3a)* and *(3b)* [a].

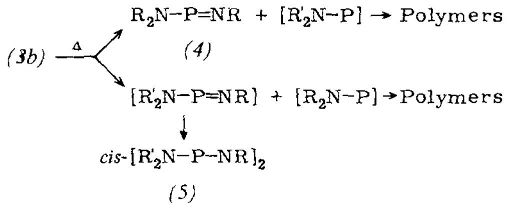
doublets, respectively. In contrast to the correspondingly *(3a)* substituted diazadiphosphetidine $[R_2N—P—NR]_2$[6] the bis(trimethylsilyl)amino groups in *(3a, b)* can rotate freely, in accord with the steric relief on going from the four- to the three-membered ring.

The configuration of *(3a, b)* cannot be deduced from NMR-data, but the *trans* arrangement of the amino groups is favored by steric arguments.

The remarkably high kinetic stability of *(3a)* may be explained by the presence of two bis(trimethylsilyl)amino groups, which are sterically and electronically stabilizing, as well as by the high symmetry of the molecule[7]. Formal substitution of a $(Me_3Si)_2N$-group by a $(Me_2CH)_2N$-group leads to a perceptible destabilization, manifesting itself in a noticeable amount of [2 + 1]-cycloreversion of *(3b)* above 50 °C, the non-polymeric reaction products of the cycloreversion being [bis(trimethylsilyl)amino](trimethylsilylimino)phosphane *(4)* as well as the dimer *(5)* of diisopropylamino(trimethylsilylimino)phosphane[8].



In the series of three-membered ring systems of type *(B)*, X = P—[9], the 1,2λ$^3$,3λ$^3$-azadiphosphiridines are the first representatives with an electronegative element in the ring (Y = N—). In comparison with the open ylide arrangement, *(A)* (X = N—, Y = P—) such a ring system could be destabilized by "push pull" substituents at the phosphorus atoms in *(3)*.

*Experimental:*

*(1)* (8.5 g, 30 mmol) is metalated with an equivalent amount of *n*-butyllithium in *n*-hexane (50 ml) at −80 °C. After addition of 30 mmol [bis(trimethylsilyl)amino]-, or (diisopropylamino)difluorophosphane, the reaction mixture is allowed to warm up to room temperature with continuous stirring. Subsequently the mixture is metalated once again at 0 °C with 30 mmol of methyllithium, (5% in diethyl ether) and stirred for another 24 h. Evaporation of the mixture furnishes a crude product (*ca.* 70% yield), which is purified by repeated distillation[10]. 5.5 g of *(3a)* (40% yield, b.p. 112–115 °C/0.5 torr) or 3.7 g of *(3b)* (35% yield, b.p. 95—100 °C/0.5 torr) is obtained.

## Photochemical Formation of and Ligand Exchange in a Cationic Dithiolatonickel Complex[**]

By *Arnd Vogler* and *Horst Kunkely*[*]

Numerous anionic and neutral transition metal complexes containing 1,2-dithiolato ligands have already been synthesized and characterized[1]. They can be reduced and oxidized reversibly. In many cases only the dithiolato ligands and not the central metal take part in the redox reactions. Electrochemical investigations have shown that cationic complexes can be obtained reversibly for a brief period of time[2]. We now report on the photochemical formation of a cationic dithiolato complex which at low temperatures is stable and at room temperature immediately undergoes a unique ligand exchange.

*cis*-1,2-Diphenylethylene-1,2-dithiolato(1,10-phenanthroline)nickel(II) *(1)*[2] is virtually insensitive to light in most solvents, whereas in chlorinated solvents it is photolyzed by light of wavelength λ < 450 nm. The quantum yield for disappearance of *(1)* is Φ = 0.003 (λ = 366 nm). All previously investigated photoreactions of metal-complexes which exclusively take place in chlorinated solvents are photooxidations[3]. We have found that *(1)* also reacts in this way:

$$\underset{(1)}{[\mathrm{Ni^{II}(phen)(S_2C_2Ph_2)}]} + \mathrm{CHCl_3} \rightarrow \underset{(1)^{\oplus}}{[\mathrm{Ni^{II}(phen)(S_2C_2Ph_2)}]^{\oplus}} + \mathrm{Cl}^{\ominus} + {}^{\odot}\mathrm{CHCl_2}$$

The complex cation *(1)*$^{\oplus}$ is stable only at low temperatures. During the photolysis of *(1)* in toluene/$CHCl_3$-glass (50:50) at 77 K it could be characterized by its ESR spectrum. Regarding electron distribution *(1)* is best described as a nickel complex containing the neutral 1,10-phenanthroline and the readily oxidizable *cis*-1,2-diphenylethylene-1,2-dithiolate dianion as ligands[2]. Consistent with this concept, the ESR signal of *(1)*$^{\oplus}$, which with $g = 2.0093$ approximates the signal of a free electron, can only be assigned to the monoanion of the dithiolato ligand.

During the photolysis of *(1)* in $CHCl_3$ at room temperature, spectral changes were observed (Fig. 1) which indicate that *(1)*$^{\oplus}$ immediately and quantitatively undergoes a novel ligand exchange with formation of the symmetric complexes

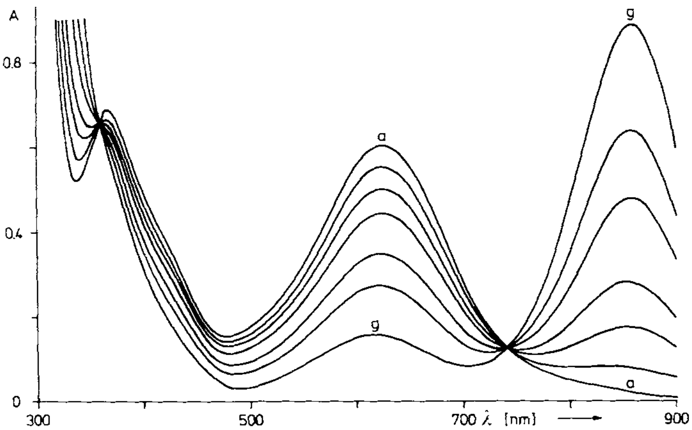

Fig. 1. Change in absorption spectrum during the photolysis of *(1)* ($1.02 \times 10^{-4}$ mol/dm$^3$) in $CHCl_3$ in a 1 cm cuvette. Excitation light: $\lambda > 350$ nm; duration of irradiation: $a = 0$, $g = 150$ min.

*(2)*[4] and *(3)*[5] in accordance with

$$\underset{(1)^{\oplus}}{2[Ni^{II}(phen)(S_2C_2Ph_2)]^{\oplus}} \rightarrow \underset{(2)}{[Ni^{II}(S_2C_2Ph_2)_2]} + \underset{(3)}{[Ni^{II}(phen)_2]^{2\oplus}}$$

Some unsymmetric, mixed dithiolato complexes have already been prepared from the symmetric complexes on reversal of this reaction[2,6]. These ligand-exchange reactions, however, proceed very slowly and require hours to days. Probably dinuclear complexes are formed as intermediates, as is often the case in solid dithiolato complexes[1].

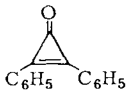
## Reaction of Dicarbonyl(cyclopentadienyl)(isobutene)iron Tetrafluoroborate with Diphenylcyclopropenone: Complexation without Ring Opening[**]

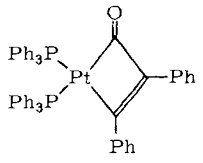
By *James B. Woell* and *Philip Boudjouk*[*]

Interest in organotransition metal complexes of cyclopropenones stems from suggestions[1] that they may be involved as intermediates in carbonylation reactions of acetylenes. Prior to this work however, isolation and characterization of such complexes have been unsuccessful[2] because the reactions of cyclopropenones with transition metal organometallic reagents typically lead to ring opening and/or the formation of complexes too unstable[2b] or too insoluble[2c] to obtain good data.

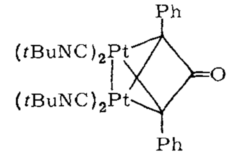
For example, tetracarbonylnickel and diphenylcyclopropenone *(1)* in benzene gave diphenylacetylene, tetracyclone and a novel π complex of tetracyclone[2a] while reactions with carbonyliron compounds produced derivatives of tetracarbonylferra-3-cyclopentene-2,5-dione in addition to tricarbonyliron complexes of diphenylacetylene and tetracyclone[2b]. Octacarbonyldicobalt and *(1)* formed an unstable salt formulated as $[(diphenylcyclopropenone)_6Co][Co(CO)_4]_2$ which generated hexacarbonyl(diphenylacetylene)dicobalt upon warming[2b]. The mode of bonding between *(1)* and cobalt was not determined.



*(1)*



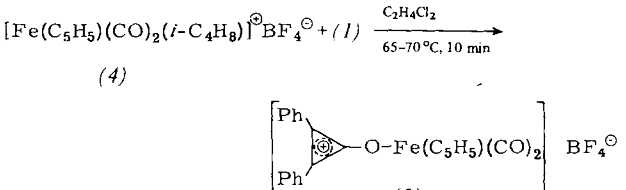
*(2)*



*(3)*

More recently, investigations of reactions of *(1)* with organoplatinum complexes have led to the synthesis of novel metallacycles; for example, *(2)* was obtained from *(1)* and $Pt(PPh_3)_4$ *via* insertion of platinum into the C—C bond of *(1)*[2d], while cleavage of the C=C linkage in *(1)*, accomplished by $Pt_3(tBuNC)_6$, gave the interesting dinuclear complex *(3)*[2e].

We have now been able to prepare dicarbonyl(cyclopentadienyl)(diphenylcyclopropenone)iron tetrafluoroborate *(5)* in 53% crude yield by treating dicarbonyl(cyclopentadienyl)(isobutene)iron tetrafluoroborate *(4)* with an excess of *(1)* in dichloroethane. Analytically pure samples of *(5)* were obtained as an air-stable red powder by recrystallization from $CH_2Cl_2$/ether.



The structural assignment is based mainly on spectroscopic data. The IR spectrum of *(5)* shows three carbonyl bands, two of which (at 2053 and 2004 cm$^{-1}$) are assigned to the carbon monoxide ligands at the iron, and one (at 1555 cm$^{-1}$) to the C=O group of the diphenylcyclopropenone. The corresponding band in free *(1)* appears at 1640 cm$^{-1}$[4]. This shift is larger than those observed for *(1)* upon its coordination to Lewis acids and hydrogen bonding solvents[2c,4b] but is similar to that in dicarbonyl(cyclopentadienyl)iron complexes of other organic carbonyl compounds[5]. The $^1$H-NMR spectrum is also consistent with structure *(5)* [($CD_3CN$, 0°): $\delta = 8.37$—8.03 (m, 4H), 8.03—7.63 (m, 6H), 5.50 (s, 5H)]. The UV-VIS spectrum [($CH_3CN$): $\lambda = 226$ ($\log\varepsilon = 4.77$), 286 (4.72), 296 (4.73), 312 cm$^{-1}$ sh] resembles that of *(1)*[6]. The diphenylcyclopropenone ligand in *(5)* is displaced by $CH_3CN$ ($t_{1/2} \approx 45$ min at 20 °C).

## A Novel Carbonyldiniobium Complex with Hydrogen Bridge[**]

By *Wolfgang A. Herrmann, Helmut Biersack, Manfred L. Ziegler*, and *Peter Wülknitz*[*]

Despite the wide variety of structural types of carbonylmetal compounds already known, only a vanishingly small number of polynuclear complexes of Group 5 elements have so far been reported[1]. The development of efficient methods for the synthesis of the half-sandwich complex *(1)*[2] has now enabled us to synthesize the first homodinuclear carbonylniobium compound having a hydrogen bridge.

Upon irradiation of *(1)* and bis($\eta^5$-cyclopentadienyl)trihydridoniobium *(2)* in tetrahydrofuran (THF) at −15 °C and subsequent column-chromatography of the crude product we obtained a crystalline, shiny-black, diamagnetic neutral complex *(3)*, which is thermally stable up to *ca.* 70 °C. This complex is air-stable in the solid state for a short period of time; in solution, however, it is extremely sensitive to oxygen.

$$\underset{(1)}{(\eta^5\text{-}C_5H_5)Nb(CO)_4} + \underset{(2)}{(\eta^5\text{-}C_5H_5)_2NbH_3} \xrightarrow[-H_2]{h\nu} \underset{(3)}{(\eta^5\text{-}C_5H_5)_3Nb_2(CO)_4H}$$

The composition of *(3)* is confirmed by elemental analysis, and by its IR and NMR spectra[7]. A conclusive elucidation of the structure, however, proved impossible from these data; therefore a single-crystal structure analysis was carried out.

Figure 1 shows that the dinuclear complex *(3)* consists of a ($\eta^5$-$C_5H_5$)Nb(CO)$_3$ fragment and a ($\eta^5$-$C_5H_5$)$_2$Nb(CO) unit, the latter formed by CO transfer, which are linked together by a bent hydrogen bond. Consistent with current opinions on metal-bridged hydrido functions the Nb—H—Nb unit might best be described, regarding the distribution of electrons, in terms of a three center bonding model[3,4]. The intermetal distance (373.8(3) pm) considerably exceeds the value to be expected on the basis of the atomic radii (294 pm[5]) and the bond lengths found in ($\eta^5$-$C_5H_5$)$_3$Nb$_3$(CO)$_7$ (304—332 pm[1b]); this is a further example of the well-documented bond lengthening effect which metal-to-metal bonds generally experience when bridged by hydrogen functionalities[4,6].

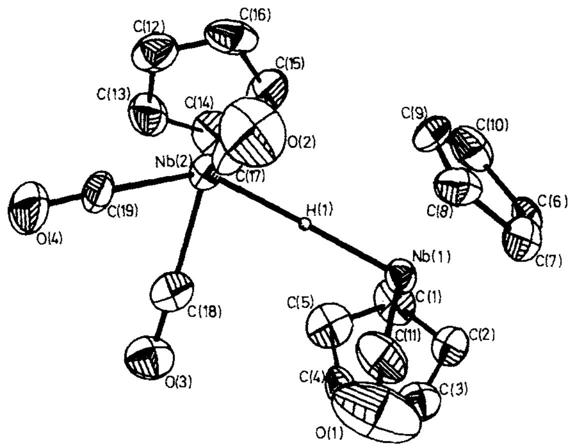

Fig. 1. ORTEP diagram of the μ-hydrido niobium complex *(3)*. The thermal vibration ellipsoids correspond to 50% probability. *(3)* crystallizes from $CH_2Cl_2$/ether in the space group $P\bar{1}(C_i^1)$ with $a = 1115.2(4)$, $b = 1341.9(6)$, $c = 1484.0(4)$ pm; $\alpha = 67.69(3)$, $\beta = 72.05(2)$, $\gamma = 69.10(3)°$; $Z = 4$ (two crystallographically independent molecules per unit cell). Triple measurement, θ-scan, P3 diffractometer program (Syntex) with absorption corrections, Mo$_{K\alpha}$ radiation, $60.0° \geq 2\theta \geq 3.0°$; 2449 independent non-zero reflections; $R_{isotropic} = 0.0828$, $R_{anisotropic} = 0.0459$. The data in Table 1 characterize one of the two crystallographically independent molecules; the bond parameters of the second molecule differ only slightly from the given data. The H-positions in *(3)* were determined from a model and the parameters were isotropically refined. The H-positions in the isomorphic compound ($\eta^5$-$C_5H_5$)(CO)$_3$V—H—Nb(CO)($\eta^5$-$C_5H_5$)$_2$[6] resulted from the difference Fourier synthesis ($R_{isotropic} = 0.067$, $R_{anisotropic} = 0.048$). *(3)* has approximate $C_s$-symmetry; the symmetry plane is defined by Nb(1) [−0.71], Nb(2) [0.01], C(19) [1.88], O(4) [−1.18], C(15) [6.34], C(11) [32.17], O(1) [53.77] (deviations from the best plane in square brackets). In the model the position of H(1) was postulated as being on this non-crystallographically determined mirror plane.

Table 1. Selected molecular parameters of *(3)*.

| Bond lengths [pm] | | Bond angles [°] | |
|---|---|---|---|
| Nb(1)—Nb(2) | 373.8(3) | Nb(1)—H(1)—Nb(2) | 167(12) |
| Nb(1)—H(1) | 186(25) | Nb(1)—C(11)—O(1) | 174.2(1.9) |
| Nb(2)—H(1) | 190(24) | Nb(2)—C(17)—O(2) | 178.4(1.6) |
| Nb(1)—C(11) | 205.1(18) | Nb(2)—C(18)—O(3) | 176.0(1.9) |
| Nb(2)—C(17) | 204.7(18) | Nb(2)—C(19)—O(4) | 177.3(1.2) |
| Nb(2)—C(18) | 205.5(14) | C(17)—Nb(2)—C(18) | 106.5(7) |
| Nb(2)—C(19) | 201.6(14) | C(18)—Nb(2)—C(19) | 69.5(6) |
| C(11)—O(1) | 116.4(24) | C(19)—Nb(2)—C(17) | 73.9(7) |
| C(17)—O(2) | 116.5(22) | | |
| C(18)—O(3) | 117.5(16) | | |
| C(19)—O(4) | 118.6(17) | | |
| Nb(1)—C(1—5) | 239.1 [a] | | |
| Nb(1)—C(6—10) | 238.9 [a] | | |
| Nb(2)—C(12—16) | 241.6 [a] | | |

[a] Mean values.

From the remarkable long-wave shift of the CO stretching frequencies of the ($\eta^5$-$C_5H_5$)Nb(CO)$_3$ fragment[7] compared to those in *(1)*[2] it appears that the coordination of the noble-gas configurated ($\eta^5$-$C_5H_5$)$_2$Nb(CO)H building block to the 16-electron species ($\eta^5$-$C_5H_5$)Nb(CO)$_3$ leads with donor sta-

[**] Metalcarbonyl Syntheses, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by Hoechst AG.—Part 6: *J. Plank, D. Riedel, W. A. Herrmann*, Angew. Chem. *92*, 961 (1980); Angew. Chem. Int. Ed. Engl. *19*, 937 (1980).

bilization to extensive charge compensations of the two components. This interpretation is consistent with the fact that the Nb—CO bond lengths in *(3)* are significantly shorter and the C—O bond lengths longer than in *(1)*[8] (Table 1). Despite the presence of the hydrogen bridge the tetragonal-pyramidal stereochemistry of the metal center Nb(2) remains largely unchanged.

### *Procedure*

All preparations must be carried out with rigorous exclusion of $O_2$ and $H_2O$.—A solution of *(1)* (1.20 g, 4.4 mmol) and *(2)*[10] (990 mg, 4.4 mmol) in THF (230 cm$^3$) is irradiated (Hg high-pressure lamp 150 watt) at $-15\,^\circ C$ in an immersion-well photoreactor[9] for *ca.* 5 h; a total of *ca.* 170 cm$^3$ of gas (CO and $H_2$) is evolved. The resulting suspension is evaporated down in a vacuum ($+20\,^\circ C$) and chromatographed on silica (Merck 7734, 0.063—0.200 mm, Act. II—III; $+15\,^\circ C$; column: $l = 80$ cm, $\varnothing = 1.4$ cm). Unreacted *(1)* is eluted as an orange-colored zone (95—120 mg; 8—10%) with *n*-pentane/benzene (5:1); with diethyl ether, the by-product $(\eta^5\text{-}C_5H_5)_2Nb(CO)H$ (red-violet zone; *ca.* 110 mg) migrates, and with diethyl ether/acetone one finally obtains the dinuclear complex *(3)* (dark-green band). Crystallization from a minimum amount of $CH_2Cl_2$/diethyl ether ($\approx 3:1$; $-20\,^\circ C$) and drying under high-vacuum affords analytically pure *(3)*; yield 380—420 mg [20—22% based on consumed *(1)*].—The isomorphic vanadium derivative $(\eta^5\text{-}C_5H_5)(CO)_3V\text{—}H\text{—}Nb(CO)(\eta^5\text{-}C_5H_5)_2$[6] is synthesized analogously and has similar physical and spectroscopic properties.

# "Spin-Stabilization" *via* Complex Formation; ESR Investigation of some Catecholamine-Semiquinones[**]

By *Hartmut B. Stegmann, H. Ulrich Bergler,*
and *Klaus Scheffler*[*]

The lifetime of 1,2-benzosemiquinone radicals is chiefly determined by two reactions. The first is the nucleophilic substitution of the radical or its oxidation product 1,2-benzoquinone at the 4- and 5-positions[1]. The second, considerably slower reaction, which can lead to modification of the primary oxidation products, is the reaction with electrophiles causing substitution at the 3- or 6-positions[2]. The attacking reagent is normally the solvent, since benzosemiquinones are, on the whole, generated in reactive solvents[3a]. In inert solvents, in which these reactions either do not occur or occur only slowly, these radial anions can be generated *via* autoxidation in the presence of organometallic cations such as triorganotin[3b] or diorganothallium[4a]. In addition, the paramagnetic state is stabilized by complex formation. This method can also be applied to sensitive hydroquinones or enediols such as ascorbic acid[4b] and hence allows intermediate paramagnetic compounds of this type to be detected and studied at low concentrations.

We therefore reacted some catecholamines with organothallium hydroxides in pyridine in the presence of atmospheric oxygen. The ESR-spectra obtained, exhibit excellent signal to noise ratios and good resolution at a linewidth of *ca.* 300 mG compared to the spectra of the radical anions generated using a flow system[5], so that signals which, in addition to the proton HFS, show a thallium splitting (cf. *e.g.* Fig. 1, large coupling) can be readily interpreted. The radical half-life is of the order of days at room temperature, and even at $+100\,^\circ C$ no irreversible change in the spectrum can be observed.

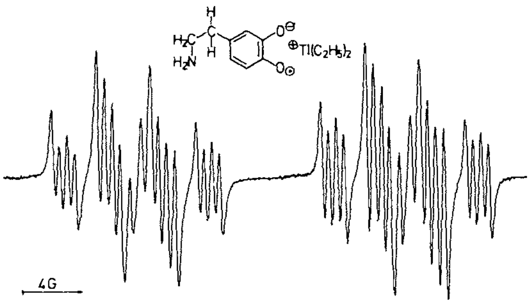

Fig. 1. ESR spectrum of the dopamine semiquinone-diethylthallium ion pair in pyridine at room temperature.

Assignment of the proton coupling constants, on the one hand, is made by comparison with variously substituted 1,2-semiquinones and, on the other, by investigation of the temperature dependence of the proton coupling constants. Values for the ESR-parameters obtained are shown in Table 1[6].

The proton coupling parameters are relatively insensitive to the variation of the organometallic cation, and similar to

previously described values (dopamine *(1)*[5], caffeic acid *(5)*[7]); the spin density and radical geometry are not influence by the heavy metal atom. Statements concerning the conformation of substituents at C-7 in solution can be made from the magnitude of the proton coupling constants and their temperature dependence[8]. In radical anions derived from dopamine *(1)*, (see Fig. 1) both protons at C-7 are equivalent at room temperature (cf. Table 1), the mean hyperconjugation angle being 60°. This implies that there is no free rotation about the C-4—C-7 bond. If both C-7-protons are assigned positions below the plane of the benzene ring, the aminomethyl group lies above this plane. The molecule is, however, not rigid, and torsional vibration about the C-4—C-7 bond occurs. In the radical anions derived from methyl-L-dopa *(2)* and L-dopamethyl ester *(3)*, the protons on C-7 are diastereotopic and the mean angle of the protons recedes 2—3° from the symmetrical position.

| | Mesityl | 21.50 | 0.30 | 3.80 | 0.85 | 3.10 | 3.10 | 0.2 | 2.00328 |
| | $C_2H_5$ | 18.10 | 0.50 | 3.70 | 1.00 | 3.00 | 3.00 | 0.3 | 2.00397 |
| Methyl-L-dopa *(2)* | $C_2H_5$ | 18.40 | 0.59 | 3.45 | 0.97 | 2.90 | 2.05 | 0.3 | 2.00388 |
| L-Dopamethyl ester *(3)* | $C_6H_5$ | 11.90 | 0.50 | 3.65 | 1.00 | 2.95 | 2.45 | 0.3 | 2.00362 |
| Apomorphine *(4)* | $C_6H_5$ | 13.55 | — | 3.65 | 1.05 | 8.60 | 1.8 | 0.5 | 2.00357 |
| | Mesityl | 24.25 | — | 3.60 | 0.98 | 8.70 | 1.8 | 0.5 | — |
| | $C_2H_5$ | 19.60 | — | 3.60 | 1.13 | 8.50 | 1.65 | 0.4 | 2.00397 |
| | *n*-$C_4H_9$ | 22.60 | — | 3.60 | 1.12 | 8.45 | 1.65 | 0.4 | 2.00384 |
| Caffeic acid *(5)* | $C_6H_5$ | 11.25 | 0.35 | 3.00 | 1.13 | 2.31 | 1.24 [c] | 0.3 | 2.00372 |
| | $CH_3$ | 20.8 | 0.43 | 2.90 | 1.21 | 2.30 | 1.21 [c] | 0.3 | — |

[a] The splittings of both $^{205}$Tl- and $^{203}$Tl-isotopes could not be separately observed; the coupling constants given are average values. [b] The given values correspond to the low-field thallium term, the lines of the high-field term are *ca.* 50 mG smaller. [c] The value given is $a_{8\text{-}H}$.

The C-7 proton coupling constants of the radical derived from apomorphine *(4)* exhibit no temperature dependence, and hence the ESR results are consistent with a relatively rigid molecule. X-ray structural investigations on apomorphine hydrochloride[9a] indicate that the asymmetrical units of the unit cell contain two molecules having different conformations. From the atom coordination values, the hyperconjugation angles[9b] of conformer A can be calculated to be 4 and 64° and those of conformer B to be 17 and 77°. However, in solutions of the apomorphine semiquinone the conformation can be determined from the proton-HFS. The corresponding hyperconjugation angles, based on the proton coupling constants, are 3.7 and 63.7°, so that the geometry of apomorphine in solution corresponds to the solid state structure A.

## σ-, π- and Mixed Electronic Structures in Radical Cations of Hydrazones[**]

By *Armin Berndt, Rudolf Bolze, Rainer Schnaut*, and *Helmut Woynar*[*]

*Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday*

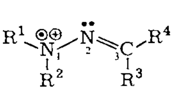
Depending on the type of substituents the radical cations *(1)* of hydrazones are present as σ-radicals in orthogonal conformation with delocalization corresponding to the resonance formulas *A*↔*B*[1], as π-radicals in planar conformation with delocalization corresponding to *C*↔*D*, or as radicals having a previously undescribed mixed σ- and π-electronic structure in twisted conformation *E* with delocalization involving participation of *F* and *G*.

---

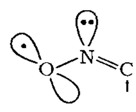
[*] Prof. Dr. A. Berndt, Dr. R. Bolze, Dipl.-Chem. R. Schnaut, Dr. H. Woynar
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

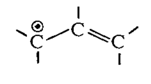
The related iminyl oxide radicals *(2)*[2] have σ-electronic structure, independent of the type of substituents, while allyl radicals *(3)* have π-electronic structure in all conformations.



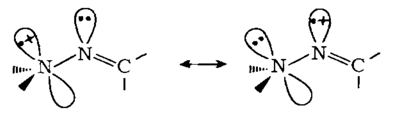
*(1)*



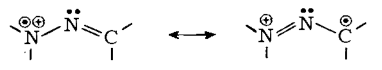
*(2)*



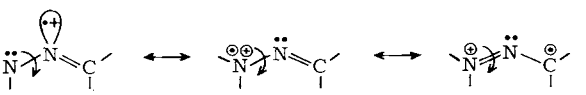
*(3)*



*A* *B*



*C* *D*



*F* *E* *G*

The radicals *(1)* can be obtained by oxidation of the corresponding hydrazones or pyrazolines in dichloromethane in a flow apparatus with tris(*p*-bromophenyl)ammoniumyl hexachloroantimonate and characterized (Table 1).

The distribution of the unpaired electron corresponding to formulas *A* and *B* is reflected in the large coupling constants of the two nitrogen atoms in *(1a)*—*(1c)*. The very small couplings of the protons of the methyl- and phenyl-substituents at $C_3$ in *(1a)* and *(1b)*, respectively, rule out participation of *D*. The large coupling of the proton bound to $C_3$ in *(1c)* is characteristic for protons in the *E*-position to the orbital of the unpaired electron in σ-radicals[3]. It must therefore have a positive sign.

Table 1. ESR coupling constants of the radical cations *(1a)*—*(1h)* [G] [a].

| *(1)* | $R^1$ | $R^2$ | $R^3$ | $R^4$ | $a_1^N$ | $a_2^N$ | $a_3^H$ | $a_N^H$ CH₃ | Electronic structure | Conformation |
|---|---|---|---|---|---|---|---|---|---|---|
| *(a)* | *t*Bu | $CH_3$ | $CH_3$ | $CH_3$ | 18.8 [b] | 15.0 [b] | 0.9 (3H) | 17.4 | σ | orthogonal |
| *(b)* | —$(CH_3)_2C(CH_2)_3C(CH_3)_2$— | | $CH_3$ | $C_6H_5$ | 19.5 [b] | 14.8 [b] | < 1 [c] | — | σ | orthogonal |
| *(c)* | —$(CH_3)_2C(CH_2)_3C(CH_3)_2$— | | H | *t*Bu | 17.4 [b] | 15.7 [b] | +12.8 (1H) | — | σ | orthogonal |
| *(d)* | $CH_3$ | —$(CH_3)_2CCH_2$— | | *t*Bu | 15.6 | <0.8 [e] | 16.2 (2H) | 20.0 | π | planar |
| *(e)* | *t*Bu | $CH_3$ | H | Aryl [d] | 11.6 | <0.4 [c] | − 6.2 (1H) [e] | 11.0 | π | planar |
| *(f)* | *t*Bu | $CH_3$ | H | *t*Bu | 16.2 | 10.2 | 2.5 (1H) | 18.2 | σ + π | twisted |
| *(g)* | $CH_3$ | $CH_3$ | $CH_3$ | $C_6H_5$ | 13.7 | 11.8 | 3.9 (3H) | 15.0 | σ + π | twisted |
| *(h)* | $CH_3$ | $CH_3$ | $C_6H_5$ | $C_6H_5$ | 13.8 | 7.5 | — [c] | 13.8 | σ + π | twisted |

[a] Gauss = $10^{-4}$ Tesla. [b] Assignment possibly reversed. [c] Not resolved. [d] Aryl = 3,5-di-*tert*-butylphenyl. [e] $a_p^H = 4.2$, $a_o^H = 2.8$.

The large coupling constants for only *one* nitrogen and for the protons of the methylene or aryl substituents on $C_3$ in *(1d)* and *(1e)* evidence the distribution of the unpaired electron corresponding to the resonance formulas *C* and *D*. The very small coupling constants of the central nitrogen atom rule out participation of the resonance structure *B*. The coupling constant of the proton on $C_3$ in *(1e)* must thus have the negative sign characteristic for π-radicals.

In *(1f)*—*(1h)* $a_2^N$ lies ***between*** the characteristic values for orthogonal σ and planar π-structures. Here the values of $a_2^N$ are considerably greater than in the case of *(1d)* and *(1e)* and show delocalization corresponding to *F*; the coupling constant of the protons of the methyl group on $C_3$ is distinctly larger in *(1g)* than in *(1a)* and *(1b)*, indicating a delocalization corresponding to *G*. For *(1f)* the coupling constant of the proton bound to $C_3$, which lies ***between*** the values typical for σ- and for π-radicals, must be composed of components of opposite sign, as would result from the presence of σ- ***and*** π-electron structure.

The unusually strong influence of substituents on the conformation, and thus on the electronic structure, of the radicals *(1)* is supposed to be due to a compensation of the loss of π-π-delocalization (maximum effect in planar conformation) by gain of π-σ-delocalization (maximum effect in orthogonal conformation) during twisting. The competition between π-π- and π-σ-delocalization markedly manifests itself in the mixed electronic structure and twisted conformation of *(1f)*, in which steric hindrance (the third conformation-determining effect with maximum repulsion in planar conformation) can play only a small role. A slight increase in steric hindrance—*(1a)* or *(1c)* compared to *(1f)*—leads to orthogonality, while increased π-π-delocalization—*(1e)* compared to *(1f)*—leads to planarity. In the corresponding substituted allyl radicals these changes effect, ***in toto***, only twists of ***ca.*** 10°[4]: The loss of π-π-delocalization in such radicals is ***not*** compensated by a gain of π-σ-delocalization.

[**] This work has been supported by the Deutsche Forschungsgemeinschaft.

been particularly successful within the field of [14]annulenes[1]. Following the preparation of the parent [14]annulene *(1)*[1a] by *Sondheimer, Vogel*[1b] and *Boekelheide*[1c] prepared the bridged derivatives *(3)* and *(4)*, respectively, which, without the steric interaction of inner hydrogens, constitute essentially flattened rigid perimeters. From the strong interdependence of the π-bonding on the mode of bridging[2] it would appear to be a useful exercise to study the result of systematically varying the molecular geometry. We describe here the synthesis and properties of *trans*-15,16-dimethyl-1,4:8,11-ethanediylidene[14]annulene (*trans*-10b,10c-dihydro-10b,10c-dimethyldicyclopenta[*ef*,*kl*]heptalene) *(5a)*, which, in a formal sense, can be derived from *(4)* simply by rotating the bridge through 90° [see formula *(2)*].

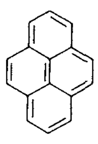
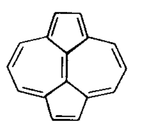
*(6)*



*(7)*



*(8)*

On the basis of spectroscopic and theoretical findings[4] the pyrene systems *(6)*—*(8)*[3] can be adequately described as vinyl-bridged [14]annulenes and, thus, as precursors of the annulenes *(3)*, *(4)*, and *(5a)*. As simple MO-models clearly demonstrate, the lowest antibonding MO of *(6)* and *(7)* constitutes a pure perimeter-orbital (with a nodal plane through the bridge) whereas that of *(8)* possesses a pronounced contribution of the ethylene π*-orbital. This is reflected in the spectroscopic properties of the dianions *(6)*$^{2-}$, *(7)*$^{2-}$ and *(8)*$^{2-}$: one finds a vanishing probability for the excess charge to reside in the bridge centers of *(6)*$^{2-}$ and *(7)*$^{2-}$ and a high π-charge density within the bridge of *(8)*$^{2-}$[3]. Accordingly, *(8)*$^{2-}$[5], but not *(6)*$^{2-}$ and *(7)*$^{2-}$[6], could be attacked at the bridge positions by electrophiles and, thus, directly transformed into a bridged perimeter-π-system.

Indeed, *(8)*, which can be prepared according to the methods of *Jutz*[7a], *Anderson*[7b], and *Hafner*[7c] can be reduced with lithium in dry, oxygen-free tetrahydrofuran (0.025 M) quantitatively to the dianion *(8)*$^{2-}$. Treating the resulting green-brown solution at −78 °C with an excess of degassed dimethyl sulfate provides, after filtration over neutral aluminum oxide and recrystallization from methanol, compound *(5a)* in 35% yield (dark red needles, m.p. 186 °C).

The molecular weight indicates the incorporation of two methyl groups; moreover, the $^1$H-NMR (δ = 8.74 (H-2), 8.77 (H-5), 8.04 (H-6), −4.53 (H-15a)) and $^{13}$C-NMR spectra (δ = 143.7 (C-1), 119.2 (135.3) (C-2), 135.3 (119.2) (C-5), 152.6 (C-6), 43.1 (C-15), 15.0 (C-15a)) leave no doubt that the addition has taken place at the bridge centers C-15 and C-16 and that the effective $D_{2h}$-symmetry of the peripheral π-system is preserved. The extreme high-field resonance of the (methyl) bridge protons and the low-field absorption of the ring protons confirm the diatropism of the 14π-perimeter.

The absorption spectrum of *(5a)* [$\lambda_{max}$ ($C_6H_{12}$) = 335 nm (ε = 136280), 346 (101900), 377 (3500), 397 (4020), 420 (5430), 440 (6200), 445 (6870), 507 (69), 550 (127), 575 (163), 603 (277)], aside from a slight hypsochromic shift, closely resembles that of *(4)*. Compounds *(4)* and *(5a)*, therefore, constitute a most appropriate subject for comparative studies on the "bridging" of annulenes which is a necessary perturbation of the ideal bonding situation of a hypothetical $D_{14h}$-perimeter.

Model considerations indicate that only the *trans*- not the *cis*-configuration of the bridge will allow for a substantial flattening of the perimeter, thus, favoring the cyclic π-conjugation[1c]. An X-ray structure analysis of *(5a)* reveals not only the *trans*-arrangement of the methyl groups but also shows that the bond lengths in the flattened π-perimeter are essentially equalized (Fig. 1)[8].

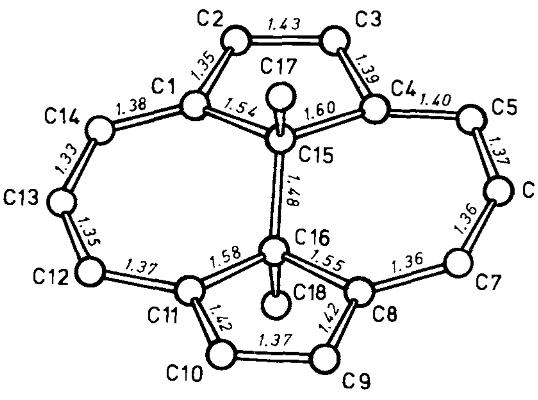


Fig. 1. Molecular structure of *(5a)*; bond lengths in Å [8].

The resulting well established description of the ground state of *(5a)* as that of a π-delocalized (aromatic) $(4n+2)\pi$-species compellingly raises the question of reactivity. Treating the annulene *(5a)* with copper nitrate in acetic anhydride affords the 6-nitro derivative *(5b)* in very good yields, thus providing a further indication of the benzene-type behavior of *(5a)*.

The protonation of *(8)*$^{2-}$ in THF does not yield the expected dihydro adduct, the 1,4:8,11-ethanediylidene[14]annulene. Methylation of *(8)*$^{2-}$ in liquid ammonia, however, does afford the parent annulene, in addition to *(5a)*, and a monomethyl adduct[9].

[5] Although the spectroscopic data predict a high $\pi$-charge density at C-15 and C-16 of *(8)*$^{2-}$ neither the spectra nor MO-calculations (HMO, PPP, CNDO) could reliably predict whether or not the charge-controlled attack of electrophilic agents would primarily occur at these positions. In the present context we don't exclude that borderline structures with covalent C-15(C-16)—Li bonds contribute to the ground state of *(8)*$^{2-}$.

[6] In agreement with these arguments we find that reaction of *(7)*$^{2-}$ with dimethyl sulfate provides the 1,6-dimethyl-1,6-dihydropyrene as well as the analogous 1,8-diadduct.

## Phenyl- and Biphenylylbicyclo[2.2.2]octane Derivatives—Two Novel Classes of Nematic Liquid Crystals[**]

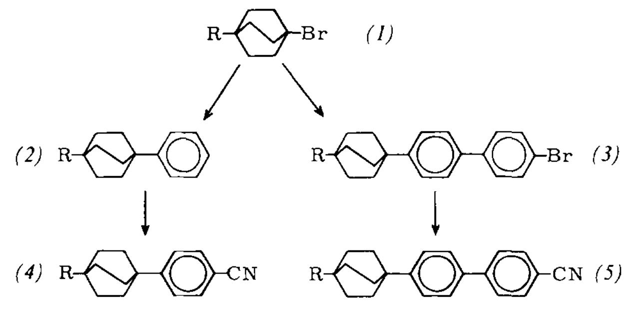
By *George W. Gray* and *Stephen M. Kelly*[*]

1-(4-cyanophenyl)bicyclo[2.2.2]octane derivatives *(4)* and 1-(4′-cyano-*p*-biphenylyl)bicyclo[2.2.2]octane derivatives *(5)* constitute two new and interesting classes of nematogens[1a]; the bicyclo[2.2.2]octane ring enhances nematic-isotropic transitions and suppresses the occurrence of smectic phases. The mesogens *(4)* and *(5)* exhibit wide-range nematic phases at significantly higher temperatures than analogous compounds containing a benzene-[1b] or cyclohexane-ring[2] in place of the bicyclo[2.2.2]octane moiety (Table 1).

Table 1. Transition temperatures [°C] of compounds *(4)* and *(5)* [a].

| | R | Crystalline→nematic or nematic→isotropic | | Nematic→isotropic | |
|---|---|---|---|---|---|
| | | *(4)* | *(5)* | *(4)* | *(5)* |
| *(a)* | $CH_3$ | 93 | 198 | (−35) [b] | (170) [b] |
| *(b)* | $C_2H_5$ | 62.5 | 188 | (−17) [b] | 221 |
| *(c)* | $n$-$C_3H_7$ | 66.5 | 180.5 | 88 | 276 |
| *(d)* | $n$-$C_4H_9$ | 75.5 | 173 | 85 | 271.5 |
| *(e)* | $n$-$C_5H_{11}$ | 62 | 159 | 100 | 269 |
| *(f)* | $n$-$C_6H_{13}$ | 72 | 133 | 86 | 259 |
| *(g)* | $n$-$C_7H_{15}$ | 61 | 141 | 95 | 250.5 |
| *(h)* | $n$-$C_8H_{17}$ | 52 | 126 [c] | 90 | 240.5 |
| *(i)* | $n$-$C_9H_{19}$ | 56 | | 90 | |

[a] The compounds gave correct elemental analyses, IR-, $^1$H-NMR- and mass spectra. The high degree of purity (≥99.9%) of *(4)* was established chromatographically. [b] Transformation into a monotropic phase. [c] Transformation of the smectic phase A into the nematic phase at 155 °C.



The mesogens *(4)* and *(5)* (Table 1) were prepared by Friedel-Crafts alkylation of either benzene or 4-bromobiphenyl with the appropriate 1-alkyl-4-bromobicyclo[2.2.2]octane derivatives *(1)* produced by the method of *Holtz* and *Stock*[3]. The nitrile group was introduced[4] in the usual way (Friedel-Crafts acetylation, haloform oxidation to yield the carboxylic acid, conversion into the amide and dehydration) into compound *(2)*, and into compound *(3)* using copper(I) cyanide[1b].

From the standpoint of their potential use in electro-optical displays, it is of interest to note here that the nematic phases *(4)* and *(5)* are similar in birefringence ($\Delta n = 0.14$) and dielectric properties ($\Delta\varepsilon = 13.3$) to the analogously substituted cyclohexane derivatives[2]. Furthermore, eutectic mixtures of the new compounds have comparably low melting points (*ca.* 0 °C), but the resulting nematic phases have much higher clearing points (90—95 °C), and this can be advantageous for certain display device requirements. In this connection, the new derivatives *(4)* and *(5)* share the excellent stability characteristics (photochemical, thermal, electrochemical) of the industrially important biphenyl and *p*-terphenyl analogues[1b], and the cyclohexane derivatives[2]. Their disadvantage lies in their relatively high viscosities (90 cP; 20 °C) compared with the analogous biphenyls (35 cP; 20 °C) and phenylcyclohexane derivatives (27 cP; 20 °C). This reflects in a low sharpness of the threshold in twisted nematic, electro-optical displays, particularly at low temperatures. However, the bicyclo[2.2.2]octane ring in *(4)* and *(5)* does give rise to much lower temperature dependencies of the splay elastic constant and the threshold voltage (0.9 and 0.22%/°C, respectively). These values are considerably lower than those for the corresponding biphenyls and cyclohexane derivatives.

Advantage has now been taken of these effects by incorporating the bicyclo[2.2.2]octane ring in various nematogenic esters. The new esters[5] show that they have considerable all-round advantages over the corresponding phenyl- or cyclohexyl-substituted esters for use in twisted nematic, electro-optical displays employing a multiplexed form of addressing.

## Separation and Determination of Sulfur Homocycles by High Pressure Liquid Chromatography—Detection of Novel Sulfur Rings[**]

By *Ralf Steudel, Hans-Joachim Mäusle, Doris Rosenbauer, Hermann Möckel,* and *Torsten Freyholdt*[*]

The known sulfur homocycles $S_n$ ($n=6$, 7, 8, 9, 10, 12, 18, 20) which have so far been prepared in pure form were identified and detected by vibrational spectroscopy in mixtures which usually are formed during preparative work-up. Attempts to separate such mixtures by thin-layer (TLC) or column chromatography (CC), led to complete decomposition (TLC), or incomplete separation with partial decomposition to $S_8$ (CC)[1]. We have now found that the homocycles $S_n$ with $n=6$—26 can be separated quantitatively without decomposition by high pressure liquid chromatography (HPLC) and thus detected and determined analytically alongside one another.

Since the thermally unstable rings $S_n$ ($n \neq 8$) rapidly decompose to $S_8$ on $SiO_2$ and $Al_2O_3$ the only potential method of separation is reversed-phase chromatography on $C_{18}$-phases (octadecylsilanes). For smaller rings ($n \leq 12$), methanol is suitable as eluting agent; for separation of the larger rings cyclohexane must be added up to 30 vol-% owing to their poorer solubility. On using a column of 25 cm length and 3.0 mm internal diameter and a flow rate of 1 $cm^3$/min, a pressure of 40—50 bar is built up[2]. Under these conditions (retention times $t_R=2$—25 min) no decomposition occurs at 26 °C, as has been established with the particularly unstable $S_7$ ($t_R \approx 3$ min) and with $S_{20}$ ($t_R \approx 13$ min) (Fig. 1a).

The retention times of the known pure rings unequivocally depend on the atomic number $n$ and so enable identification of the new compounds of the homologous series $S_n$ by inter- or extrapolation. The capacity factors $k'$ are linearly dependent on $n$ in a semilogarithmic plot, but give *two* straight lines which intercept at $n=9$ (Fig. 2). The straight lines obey the regressions $\log k' = -0.677+0.102n$ (correlation coefficient $r=0.994$) for $S_6$—$S_9$ and $\log k' = -0.319+0.064n$ ($r=0.999$) for $S_9$—$S_{20}$ (eluent: methanol/cyclohexane 80/20 vol-%).

Suitable for identification of the separated components are the seemingly intense UV absorptions of the sulfur rings at 254 nm, which enable a trace analysis [$\varepsilon_{254}(S_8)=5930$]. Using calibration solutions it could be established that the absorbance of $S_n$ ($n=7$, 8, 10, 12) in the range 0.3—1.8 mg $S_n$/100 $cm^3$ $CS_2$ is a linear function, in case of $S_6$ a non-linear function of the concentration. We ascribe the non-linearity in the case of $S_6$ to incomplete separation from the solvent $CS_2$, which can be improved by use of a $CH_3OH/H_2O$ mixture as eluent. This way a simultaneous quantitative determination of these compounds in admixture is possible. Such mixtures are formed, for example, on melting of $S_8$[3] or in the reaction of $SCl_2$ or $S_2Cl_2$ with potassium iodide[4]. From liquid sulfur which has been brought to equilibrium between 115 and 350 °C, $S_7$, $S_8$, $S_{12}$, $S_{18}$, and $S_{20}$ have been isolated after quenching, and $S_6$ has been detected spectroscopically. In addition, a species $S_x$ of high molecular weight ($\bar{x}=25$) but still soluble in $CS_2$ has been isolated as an orange-yellow resin-like mass and interpreted as a mixture of large rings. Figure 1c shows the chromatogram of $S_x$, which, as expected, contains rings with $n>18$. All other rings with $n=6$—17 have now been detected as components of liquid sulfur, some of them, howev-

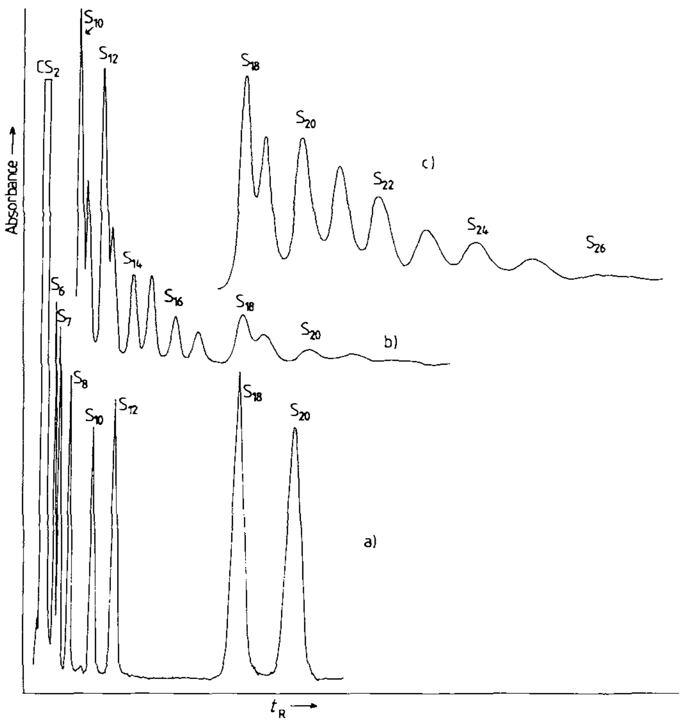

Fig. 1. a) Chromatogram of a mixture of $S_6$, $S_7$, $S_8$, $S_{10}$, $S_{12}$, $S_{18}$, and $S_{20}$ prepared from the pure components (eluent: methanol/cyclohexane 80/20 vol-%); b) chromatogram of the higher molecular weight species of sulfur formed from $SCl_2$ and KI (eluent: methanol/cyclohexane); c) chromatogram of the higher molecular weight $S_x$ from an equilibrium sulfur melt which is soluble in $CS_2$ (eluent methanol/cyclohexane 69/31 vol-%).

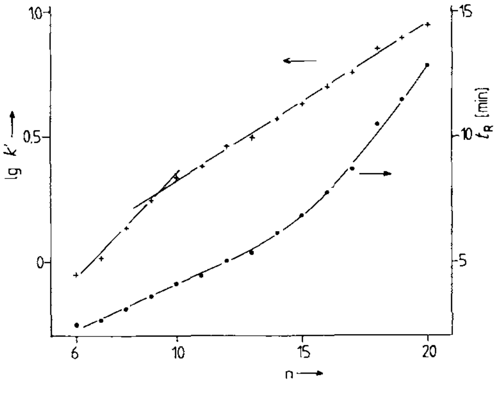

Fig. 2. Gross retention times $t_R$ and logarithm of the capacity factor $k' = (t_R - t_o)/t_o$ as a function of the atomic number $n$ of sulfur homocycles $S_n$ on elution with methanol/cyclohexane (80/20 vol-%); dead time $t_o = 1.3$ min.

[**] Sulfur Compounds, Part 74.—Part 73: *H.-J. Mäusle, R. Steudel,* Z. Anorg. Allg. Chem., in press.

*0570-0833/81/0404-0394 $ 02.50/0*

er, only in traces, especially $S_{11}$ and $S_{13}$. $S_5$ was not detectable.

In the reaction of $SCl_2$ or $S_2Cl_2$ with salt-like iodides at 25 °C, elemental sulfur is formed by decomposition of the unstable iodosulfanes according to

$$S_nCl_2 + 2\,KI \rightarrow S_nI_2 + 2\,KCl$$
$$n\,SI_2 \rightarrow S_n + n\,I_2$$
$$n\,S_2I_2 \rightarrow S_{2n} + n\,I_2$$

Chromatograms have now revealed that all rings with $n = 6$—21 are formed from $SI_2$, the relative concentrations decreasing with increasing ring size (Fig. 1b). As expected, almost only even-numbered rings are obtained from $S_2I_2$ (detected up to $n = 22$; of which the following have already been isolated previously: $S_6$, $S_{12}$, $S_{18}$, $S_{20}$ and $S_x$[4]). Hence, the existence of the homocycles $S_n$ with $n = 11$, 13—17, 19, and 21—26, for whose formation (from $S_2$) there was previously only mass spectroscopic evidence[5] has been unequivocally proven for the first time.

We have further found that the eight-membered rings $S_8$ and $Se_8$ can be quantitatively separated from each other and from heterocycles of the types $Se_nS_{8-n}$[6] and $Se_nS_{12-n}$[7]. From these results it can be expected that the composition of a large number of complex reaction mixtures of sulfur-rich compounds can be elucidated by HPLC.

## Reductive Cleavage of 3-Oxazolin-5-ones; Application to the Synthesis of β,γ-Unsaturated Ketones from Allyl *N*-Acyl-2-phenylglycinates[**]

By *Ulrich Niewöhner* and *Wolfgang Steglich*[*]

*Dedicated to Professor Appel on the occasion of his 60th birthday*

An essential step in a recently described method for the synthesis of β,γ-unsaturated ketones[1] is the cyclization of an allyl *N*-acyl-2-phenylglycinate *(1)* with $PPh_3/C_2Cl_6/NEt_3$[2] to give the 2-allyl-3-oxazolin-5-one *(2)*[3,4], which is subsequently hydrolyzed with alkali to the ketone *(3)*. Since side-reactions frequently occur during the hydrolysis we have searched for a better method for isolating the ketone.

We have found that the 3-oxazolinones *(2)* can be reductively cleaved under mild conditions by treatment with chromium(II) acetate and aqueous $H_3PO_2$ in dimethylformamide (DMF) (Method *A*)[6]. The pure β,γ-unsaturated ketones are isolated in good yields from the organic phase (Table 1), while phenylglycine remains in the aqueous solution.

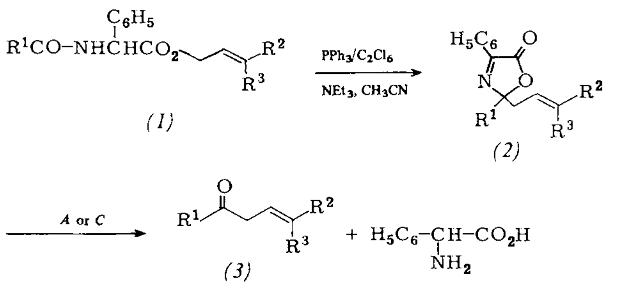

Table 1. β,γ-Unsaturated ketones *(3)* prepared from *(2)* [a].

| Compound | | Yield [%] | Method [b] | B.p. [°C/torr] [c] |
|---|---|---|---|---|
| *(3a)* |  | 94<br>85 | *A*<br>*B* | 130/0.1 [d] |
| *(3b)* |  | 97<br>47 | *A*<br>*B* | 180/0.25 |
| *(3c)* |  | 89 | *A* | |
| *(3d)* |  | 86 | *A* | 130/18 |
| *(3e)* |  | 59<br>77 | *B*<br>*C* [e] | 140/0.2 |
| *(3f)* |  | 54 | *B* | 135/14 |
| *(3g)* |  | 67 | *B* | 125/0.1 |
| *(3h)* |  | 64 | *B* | [f] |

[a] Structure and composition confirmed by NMR and IR data. [b] *A*: $Cr(OAc)_2$ reduction; *B*: $NaBH_4$ reduction and subsequent hydrolysis; *C*: $SnCl_2$ reduction. [c] Kugelrohr distillation at furnace temperature. [d] M.p. 43—45 °C (from $MeOH/H_2O$). [e] According to the ¹H-NMR spectrum contains 7% of the doubly conjugated dienone. [f] Undistilled, ¹H-NMR-pure 12-oxosqualene.

For reduction with tin(II) chloride the styrene derivative *(2e)* must be heated under reflux in citric acid, acetone, and water (method C), since the α,β-unsaturated ketone *(3e)* formed is further reduced by chromium(II) acetate to the dihydro compound[7].

A further possible method for the isolation of the ketones *(3)* is the reduction of the oxazolinones *(2)* with $NaBH_4$ in tet-

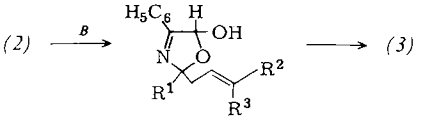
rahydrofuran (THF) and anhydrous methanol (Method B). This leads almost quantitatively to the 3-oxazolin-5-oles *(4)*[8], which are cleaved with aqueous citric acid in presence of phloroglucinol at 100 °C to give *(3)*[9].



*(4)*

*Procedure*

*(3)* (Method A): A solution of *(2)* (5 mmol) and 50% $H_3PO_2$ (5.28 cm$^3$, 50 mmol) in oxygen-free DMF (50 cm$^3$) is treated in an inert atmosphere ($N_2$) with chromium(II) acetate (4.25 g, 25 mmol). The mixture is stirred for 45 min (TLC control), filtered and the precipitate carefully washed with 3.5 N HCl and ether. After separation of the ethereal phase, the filtrate is extracted with ether and the combined ether solutions are washed free of DMF. Subsequent drying and evaporation affords the NMR-pure ketones *(3)*.

*(3)* (Method B): Anhydrous methanol (5 cm$^3$) is poured directly into an ice-cooled solution of *(2)* (5 mmol) and $NaBH_4$ (0.57 g, 15 mmol) in THF (15 cm$^3$) (evolution of $H_2$!). The reaction solution is stirred for 2—3 h at 25 °C, evaporated down *in vacuo* rendered acidic with 20% citric acid, and extracted twice with ethyl acetate. The residue *(4)*, obtained on evaporation of the combined extracts is taken up in dioxane (15 cm$^3$), treated with 5 cm$^3$ 20% citric acid and 4.05 g (25 mmol) phloroglucinol dihydrate, and the mixture heated under reflux for 1—13 h. After hydrolysis is complete (TLC monitoring), water (30 cm$^3$) is added and the mixture extracted twice with petroleum ether (40—60 °C). The combined extracts are washed successively with a saturated $NaHCO_3$ solution and water, dried, and evaporated down *in vacuo* (in the case of readily volatile ketones, Vigreux column). *(3)* is purified by Kugelrohr distillation.

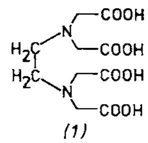
# The Stereology Concept: Novel Acidic Complexones and their Selectivity towards Cations[**]

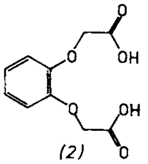
By *Reinhard Leppkes* and *Fritz Vögtle*[*]

*Dedicated to Professor Rolf Appel on the occasion of his 60th birthday*

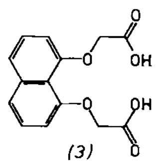
The stability constants and selectivity of ethylenediaminetetraacetic acid (ETDA) *(1)*, *O,O'*-pyrocatechol *(2)*[1] and analogous complexones in forming complexes can be varied if their donor functionalities are bonded to various anchor groups[2]. Although the anchor groups used until now have been recruited from the realms of classical chemistry with the donor functionalities separated only by a few bonds, novel possibilities exist today; for example donor centers can be attached to (proto-)[3a] phane skeletons[3b–d] at similar distances and disposition but separated by a greater number of bonds. Using these considerations as a starting point we firstly synthesized the acidic ligand systems *(4)* and *(5)*. We have characterized the ana*logy* between the *stereo*chemical disposition of the coordinating *donor* functions on going from *(3)*[4] to *(4)* and from *(1)* to *(5)* with the term *"donor-stereology"*[5].



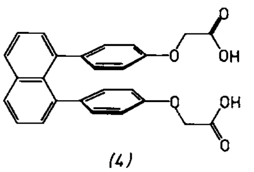
*(1)*



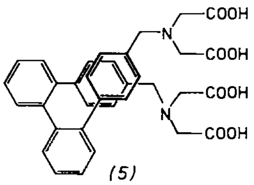
*(2)*



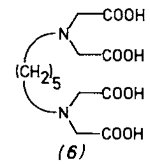
*(3)*



*(4)*



*(5)*



*(6)*

Example *(5)* illustrates that the application of this concept to the design of novel complexones meets with a high degree of success with regard to ligand efficiency.

According to *Schwarzenbach*[6a,b], EDTA forms stable monometallic complexes $[MY]^{2-}$[6c] with alkaline-earth metal ions by using both iminodiacetate groups cooperatively; the complex with hydrogen $[MHY]^-$ is only an intermediate of limited stability. In contrast, EDTA-homologues such as cadaverinetetraacetic acid *(6)* in which both donor groups are separated by a pentamethylene chain, can form complexes in which each of the iminodiacetate groups is bound to a metal ion [MY]. Among other reasons, this can be attributed to the reduction in stability caused by formation of a large chelate ring.

p$K_s$-values of the free ligand *(5)* and the stability constants of its complexes were determined by potentiometric titration[6a,b]. The stability constants of *(5)* (Table 1), which were determined in ethanol/water (1:1), are not quite as high as those of EDTA, but show structural singularities.

The stability constants found, indicate that *(5)* preferentially forms binuclear (dimetallic)[6b] complexes with the

[**] This work was supported by the Fonds der Chemischen Industrie.

smaller alkaline-earth metal ions $Mg^{2+}$ and $Ca^{2+}$; in contrast, $Sr^{2+}$ and $Ba^{2+}$ ions appear to be preferably bound as monometallic complexes (cf. $\lg K_{k_2}$ in Table 1 and Fig. 1), because one-sided complexation of a metal ion by *one* iminodiacetate—as opposed to formation of monometallic complexes by cooperative bonding of both—leads to a reduction in the magnitude of the stability of the complexes with increasing cationic radius[2]. Intramolecular cooperation of all four carboxy groups satisfactorily explains the increase in $K_{k_2}$.

Table 1. Logarithms of the stability constants [a] of *(5)* as well as (for comparison) of EDTA *(1)* and *(6)*.

| Acid | $\lg K_{k_i}$ | $Mg^{2+}$ | $Ca^{2+}$ | $Sr^{2+}$ | $Ba^{2+}$ |
|---|---|---|---|---|---|
| *(1)* | i = 1 | 2.2(8) | 3.5(1) | 2.3(0) | 2.0(7) |
| | i = 2 | 8.6(9) | 10.5(9) | 8.6(3) | 7.7(6) |
| | i = 3 | — | < 0.7 | — | — |
| *(6)* | i = 1 | 3.63 | 3.50 | 2.72 | 2.38 |
| | i = 2 | — | 4.60 | — | — |
| | i = 3 | — | 2.60 | — | — |
| *(5)* | i = 1 | 4.0 | 4.2 | 3.6 | 3.7 |
| | i = 2 | 3.6 | 4.0 | 4.3 | 4.6 |
| | i = 3 | 4.4 | 4.4 | 3.0 | 2.8 |

[a] The constants $K_{k_i}$ are defined by the following complexation equilibria:

(1) $HY^{3-} + M^{2+} \rightleftharpoons MHY^{-}$
(2) $Y^{4-} + M^{2+} \rightleftharpoons MY^{2-}$
(3) $MY^{2-} + M^{2+} \rightleftharpoons M_2Y$

They are valid at 20 °C in 0.1 N KCl [*(1)* and *(6)*] or in ethanol/water (1:1) [*(5)*] as solvent. Standard deviation ±0.1.

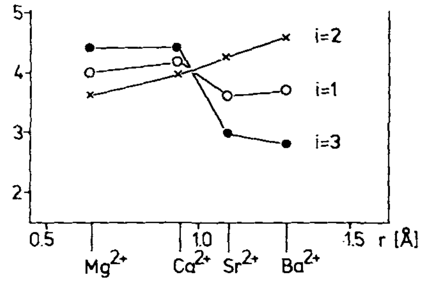

Fig. 1. Stability constants ($\lg K_{k_i}$) of *(5)* as a function of the cation radius.

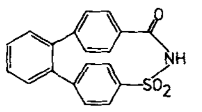
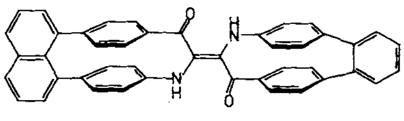
In complexation of larger cations, a phane-ring closure-like macrocyclization of the framework can apparently occur, which with *(5)* should lead to chiral (helical) structures[3b]. In this connection it would first have to be established that *cations as ring building blocks* can be incorporated ionically into large rings.

Discrimination, on the basis of ionic size, can accordingly be attributed to the spacer effect of the hydrocarbon-framework in *(5)* which is stereologous to the ethano group in EDTA, and which unlike the model compound *(1)* does not lead to the formation of complexes with small cations *via* both iminodiacetic functionalities.

Since a closely similar stereologous molecular structure does not necessarily lead to closely similar chemical behaviour, it follows that *(4)*, unlike *(2)*, does not form a crystalline potassium complex[1] under analogous conditions, but only a hemihydrate of the free carboxylic acid (elemental analysis). In consequence, the scope of application and limits of the stereology concept must be studied, especially to determine whether it is restricted to ligands ("donor-stereology") or cooperating functional groups. The examples *(7)* and *(8)* illustrate further applications.



*(7)* *"stereologous saccharin"*



*(8)* *"stereologous indigo"*

### *Procedure*

*(5)*[7]: Reaction of 4,4'''-bis(bromomethyl)-*o*-quaterphenyl[8] with dimethyl iminoacetate[9] and saponification, leads to formation of *(5)* in 72% yield; m.p. = 200—201 °C ($H_2O$) (decomp.); $^1H$-NMR ([$D_6$]DMSO, TMS int.): $\delta = 3.45$ (s, 8H, $NCH_2$), 3.75 (s, benzyl, $CH_2$).

*(4)*[7]: 1,8-diiodonaphthalene was coupled with 4-methoxyphenylmagnesium iodide to form 1,8-bis(4-methoxyphenyl)naphthalene (m.p. = 144—146 °C)[10]. Cleavage of the ether by $BBr_3$ produced 4,4'-(1,8-naphthylene)diphenol (m.p. = 253—254 °C) and reaction of this species with bromoethyl acetate in acetone followed by alkaline hydrolysis gave *(4)*$\cdot 1/2\,H_2O$, m.p. = 275—276 °C; $^1H$-NMR ([$D_6$]DMSO, TMS, int.): $\delta = 4.50$ (s, 4H, $CH_2$).

## Diastereoselective Synthesis of β-Nitro- and β-Aminoalcohols

By *Dieter Seebach, Albert K. Beck, Friedrich Lehr, Thomas Weller* and *Ernest Colvin*[*]

The nitro-aldol or Henry reaction[1] is an important process for the formation of C—C bonds. As shown in path *(a)*[1a], starting from aldehydes and nitroalkanes, β-nitroalco-

---

[*] Prof. Dr. D. Seebach, A. K. Beck, Dr. F. Lehr, Dipl.-Chem. Th. Weller, Dr. E. W. Colvin
Laboratorium für Organische Chemie
der Eidgenössischen Technischen Hochschule
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)

hols *(1)* are formed, which—with the exception of cyclization methods[2]—are obtained as mixtures of the two possible diastereomeric pairs of enantiomers (*RR/SS* and *RS/SR*). Usually, the diastereomer *A* is predominant; the ratio *A*:*B* (up to 3:1) remains unchanged if the mixture is treated with *tert*-butyl(dimethyl)silyl (TBDMS) chloride/imidazole in dimethylformamide[3] to give *(2)*.

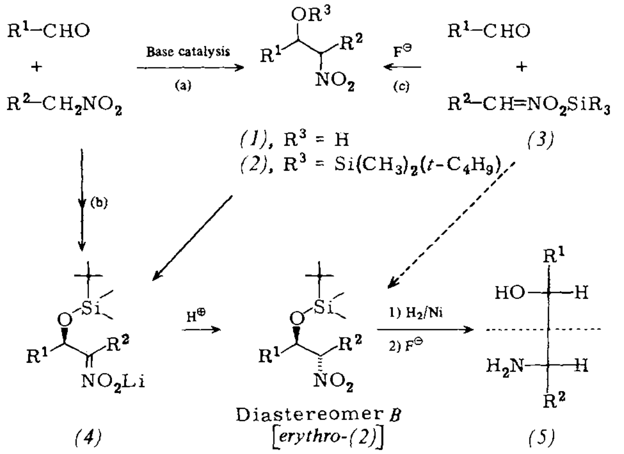

Table 1. Enrichment of the diastereomer *(B)* (probably the *erythro*-form, see text) of the classically prepared [1 a] isomeric mixtures *(2)* by deprotonation of the *O*-silyl nitroalcohols to *(4)* and low temperature protonation, and examples of the fluoride-catalyzed silylnitroaldol reaction leading to diastereomer B. The given product ratios were determined by quantitative $^{13}C$-NMR spectroscopy. The signals for the α-nitro-C-atoms are situated at $\delta = 85$—98, and those of the 2-silyloxy-C-atoms at $\delta = 70$—78; the α-nitro signals in the diastereomers *B* appear at higher field, and the α-silyloxy signals at lower field than in the corresponding diastereomers *A*. In contrast to *B*, the methyl groups of the TBDMS-function in *A* are isochronic. All compounds gave satisfactory elemental analyses. $Bu_4NF$, which had been dried over a molecular sieve, was used in path (c) [cf. *H. Gerlach, P. Kunzler*, Helv. Chim. Acta *61*, 2503 (1978)].

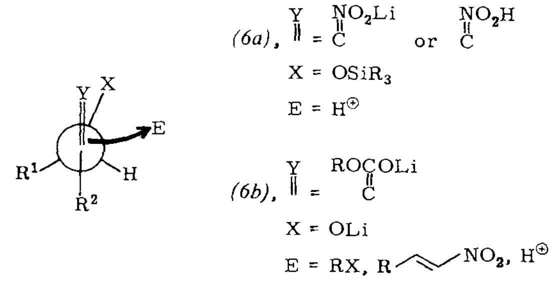
| Substituents | | Ratio of the diastereomers *B*:*A* (% B) in *(2)* | | | | | |
|---|---|---|---|---|---|---|---|
| | | before deprotonation to *(4)* | | after protonation from *(4)* | | from *(3)* path (c) | |
| *R*¹ | *R*² | | | | | | |
| $C_3H_7$ | $C_2H_5$ | 1:2.5 | (29) | 9:1 | (90) | >20:1 | (>95) |
| $CH(CH_3)_2$ | $C_2H_5$ | 1:1 | (50) | >20:1 | (>95) | | |
| $C_3H_7$ | $CH(CH_3)_2$ | 2:1 | (66) | >20:1 | (>95) | | |
| $C_5H_{11}$ | $CH_3$ | 1:1 | (50) | >20:1 | (>95) | >20:1 | (>95) |
| $C_5H_{11}$ | $C_2H_5$ | 1:2 | (34) | >20:1 | (>95) | >20:1 | (>95) |
| $C_3H_7$ | $C_7H_{15}$ | 1:2 | (34) | 4.5:1 | (82) | >20:1 | (>95) |
| $C_{10}H_{21}$ | $CH_3$ | 1:1 | (50) | >20:1 | (>95) | | |
| $C_5H_{11}$ | $C_9H_{19}$ | 1:2 | (34) | 2:1 | (66) | | |
| $C_6H_5$ | $C_2H_5$ | 1:3 | (25) | 4.5:1 | (82) | 3.5:1 | (78) |

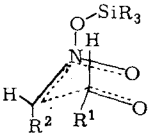
As a contribution to the diastereoselective synthesis of *open chain* compounds[4], we report a simple trick, by which *one* diastereomer-*B*- of the TBDMS-protected nitroalcohols *(2)* can be prepared, in some instances in more than 97% selectivity: Deprotonation of *(2)*, as an *A/B* mixture, (see Table 1, column 3) by lithium diisopropylamide in tetrahydrofuran at dry ice temperature afforded the enantiomeric pair *(4)*. When the resulting solution was treated with glacial acetic acid at low temperature[5] (1:1 mixture with THF, fivefold excess of acid), *(2)* was reisolated in *ca.* 80% yield. The product, in which B was previously the minor component now contained *B* as the major component [see Table 1, column 4; exceptions: $R^1 = C_3H_7$, $R^2 = CH(CH_3)_2$]. Solutions of the *aci*-nitro salts *(4)* required for diastereoselective protonation, can also be prepared by silylation of the primary adducts[6] obtained from reaction of doubly deprotonated nitroalkanes[7] and aldehydes with TBDMSCl (see path (b)).

We have now found that the direct synthesis of silyl nitroalcohols *(2)* *via* C—C bond formation, *i.e.* addition of silylated *aci*-nitro derivatives *(3)* catalyzed by fluoride ions as shown in path (c)[1c], can also be carried out diastereoselectively: The compounds *(2)* synthesized *via* this novel variation of the Henry reaction[1c] are obtained—with the exception of the benzaldehyde adduct—as practically pure diastereomers of type *B* (see Table 1, column 5), as shown by comparison of their $^1H$-NMR spectra with the spectra of compounds obtained by protonation of *(4)*.

*Preliminary* assignment of the configuration of *A* and *B* was carried out as follows: Catalytic hydrogenation of the nitro group over completely neutral, washed Raney nickel and desilylation ($Bu_4NF$/THF)[3b] gave—without loss of diastereomeric purity—the aminoalcohols *(5)*, whose *erythro*-form, according to the literature[8], should have the smaller (3—4 Hz) and whose *threo*-form the larger (*ca.* 6 Hz) vicinal [$C\underline{H}(NH_2)$—$C\underline{H}(OH)$]—coupling constant in the $^1H$-NMR spectrum.

We do not wish to speculate at present about the reasons for the diastereoselective protonation of *(4)*[9]; the result can be accounted for *via* the same model *(6)* used to describe the reactions of doubly deprotonated β-hydroxyesters[10] [cf. *(6a)* with *(6b)*].





*(7)*

The preferential formation of one diastereomer in the silyl nitro-aldol reaction [path (c)] is consistent with the mechanism suggested for the normal aldol reaction[4, 11] [see formula *(7)*].

The results described indicate firstly that nitroalcohol derivatives can be prepared diastereoselectively and also that the β-aminoalcohols *(5)*, which cannot be obtained by the opening of epoxide rings with $NH_3$ or by $HO/H_2N$-addition to alkenes (oxyamination)[12] are now accessible.

# Epimeric Equilibration and Substituent Interaction in 2-Oxetanones (β-Lactones)

By *Johann Mulzer* and *Matthias Zippel*[*]

*cis-trans*-Equilibria of *cis-trans* disubstituted four-membered rings[1] have apparently been studied to only a limited extent so far[2]. We wish to report—to our knowledge the first—successful equilibration of β-lactones (2-oxetaneones)[3] of type *(1)/(2)*.

*(1)*

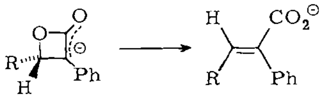
*(2)*

Table 1. Position of equilibrium and ΔG′ values for the equilibration of *(1)* to *(2)*. K = [*(1)*]/[*(2)*].

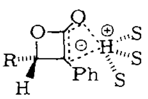
| | R | *K* [a] | Δ*G* [kcal/mol] | Δ*G* [kcal/mol] [kJ/mol] |
|---|---|---|---|---|
| *a* | $CH_3$ | 0.36 | 0.73 | 3.1 |
| *b* | $C_2H_5$ | 0.22 | 1.1 | 4.6 |
| *c* | $CH(CH_3)_2$ | 0.20 | 1.2 | 5.0 |
| *d* | $C(CH_3)_3$ | <0.02 | >2.8 | >11.7 |

[a] Determined by ¹H-NMR (precision ±2%).

The equilibration (Table 1), which is complete after 2 hours in triethylamine at 89 °C, proceeds *via* deprotonation/reprotonation at C-3; addition of $D_2O$ to the reaction mixture results in complete H/D-exchange at this center. Astonishingly, ring-opening does not occur. A free enolate ion of type *(3)* therefore cannot be an intermediate in the epimerization, since *(3)* under the reaction conditions would spontaneously isomerize to the acrylate ion *(4)*[4]. Instead, we postulate a contact ion-pair *(5)* in which the proton, enolate and solvent (S) are tightly associated.



*(3)* *(4)*

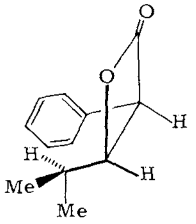


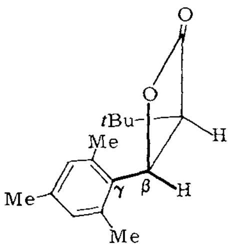
*(5)*

Although the ring substituents in *(1a—c)* are held in a rigid, almost eclipsed arrangement, the resulting van der Waals compression is insufficient for shifting the equilibrium totally to the side of *(2)*. This is only observed for *(1d)*, which possesses a bulky substituent R. In *(1a—c)*, the substituents R are always able to adopt an unhindered conformation, whereas large repulsions between the *tert*-butyl group and phenyl group cannot be avoided in *(1d)*.

The interaction of the *cis*-eclipsed substituents in β-lactones of type *(1)* manifests itself not only in the rearrangement to *(2)*, but also in the ¹H-NMR spectra. In consequence, the $CH_3$-signals in *(1c)* are clearly anisochronic ($\delta_1 = 0.47$, $\delta_2 = 1.00$ in $CCl_4$) whereas they are almost concordant in *(2c)* ($\delta_1 = 0.97$, $\delta_2 = 1.07$ in $CCl_4$). This may be due to the preferred conformation of the isopropyl group in *(1c)*; in contrast, the isopropyl group in *(2c)* enjoys almost unrestricted rotational freedom.

*(1c)*





*(1e)*

The exceedingly bulky substituents in the *cis*-lactone *(1c)* lead to a "frozen" conformation about the β—γ bond: at 37 °C the two *o*-methyl groups of the mesityl moiety have considerably different ¹H-NMR chemical shifts ($\delta_1 = 2.02$, $\delta_2 = 2.40$ in 1,2-dichlorobenzene). Coalescence of the two singlets occurs at 124 ± 1 °C, from which an energy barrier to rotation about the β,γ-bond of 23.6 kcal/mol (98.6 kJ/mol) can be estimated[5]; the value being unusually high compared to similar systems[5]. In contrast, the *o*-methyl groups of the mesityl moiety in the *trans*-isomer *(2e)* absorb isochronically at $\delta = 2.34$ (in 1,2-dichlorobenzene).

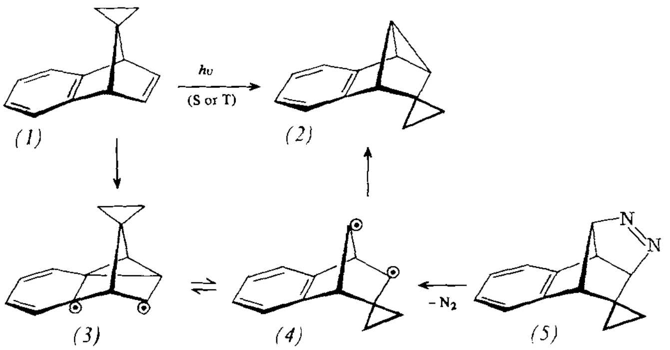
# Thermal and Photochemical Denitrogenation of a Polycyclic Azoalkane as Mechanistic Probe for the Di-π-Methane Rearrangement of 7,7-Dimethylenebenzonorbornadiene[**]

By *Waldemar Adam* and *Ottorino De Lucchi*[*]

One of the most intriguing photorearrangements to have been intensively investigated for mechanistic as well as synthetic purposes, is the ubiquitous di-π-methane rearrangement[1]. For example, 7,7-dimethylenebenzonorbornadiene *(1)* rearranges into the polycycle *(2)* on direct and sensitized photolysis[2], presumably *via* the diradicals *(3)* and *(4)*. It was recently demonstrated[3] that denitrogenation of polycyclic azoalkanes constitutes an effective route for the independent generation of such diradical intermediates and thereby substantiates experimentally the mechanism of such di-π-methane rearrangements.



*Via* the novel dipolar cycloaddition[4] of *N*-phenyl-1,2,4-triazoline-3,5-dione (PTAD) to *(1)* we prepared the polycyclic azoalkane *(5)*[5], which provides a convenient entry to the diradical manifold postulated for the di-π-methane rearrangement of *(1)*. Presently we communicate our findings on the thermal and photochemical denitrogenation of azoalkane *(5)*. Our results, *i.e.*

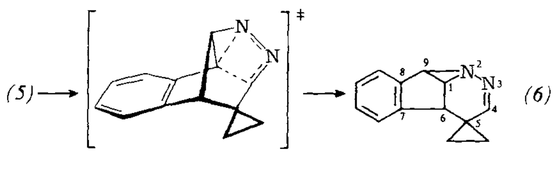
a) thermolysis of *(5)* at *ca.* 400 °C affords only *(2)*,
b) direct photolysis of *(5)* at 350 nm ($n_- \rightarrow \pi^*$ transition of the azo-chromophore) and at 254 nm ($\pi \rightarrow \pi^*$ excitation of the benzene ring) gives mainly (99.5 ± 0.3%) *(2)* and traces (*ca.* 0.5 ± 0.1%) of *(1)*,
c) benzophenone-sensitized photolysis of *(5)* at 300—330 nm results in the unusual rearrangement product *(6)*,

have important mechanistic implications on the di-π-methane rearrangement of *(1)*.

Vacuum flash pyrolysis of azoalkane *(5)* (*ca.* 400 °C/0.3 torr, substrate at 60 °C) afforded *(2)* quantitatively, which was characterized by comparison of its IR and $^1$H-NMR spectra with authentic material. By VPC analysis it was established that no *(1)* was produced in the thermal denitrogenation of *(5)*. Control experiments confirmed that the VPC detection limit was *ca.* 0.01%. Consequently, the singlet bicyclo[2.2.1]heptenediyl diradical *(4)* that is generated in the thermal denitrogenation of azoalkane *(5)* does not revert to the cyclopropanedimethyl diradical *(3)*.

Under the conditions of direct photolysis (0.01 M solution of *(5)* in pentane, Rayonet Photoreactor) the educt *(1)* was converted, as control experiments showed, into the di-π-methane product *(2)*. To suppress this menacing rearrangement, the photo-extrusion of nitrogen from *(5)* was carried out to less than 5% conversion. Product yields were established by quantitative VPC. The di-π-methane reaction *(1)*→*(2)* was negligible under these photolysis conditions. Therefore, the small amount (*ca.* 0.5%) of *(1)* formed in the photodenitrogenation of azoalkane *(5)* is an authentic primary photoproduct. We conclude again that the singlet bicyclo[2.2.1]heptenediyl diradical *(4)*, formed in the direct photolysis of azoalkane *(5)* by nitrogen loss, prefers to cyclize into *(2)*; but a small fraction rearranges *via* the diradical *(3)* into *(1)*. Clearly, the excited state energy surfaces for the di-π-methane reaction of bicycloalkadiene *(1)* and for the photodenitrogenation of azoalkane *(5)* are connected, albeit inefficiently, through the interconverting respective diradicals *(3)* and *(4)*.

Analogously to the corresponding polycycle without spirocyclopropane ring[6], the benzophenone-sensitized photolysis of azoalkane *(5)* (irradiation of a pentane solution 0.1 M in *(5)* and 1.0 M in benzophenone in a Rayonet photoreactor equipped with 300 nm lamps, using a Pyrex vessel and an aqueous $K_2Cr_2O_7$—$K_2CO_3$ filter to allow only 300—330 nm radiation to pass[3a]) gave exclusively ($^1$H-NMR) the novel rearrangement product *(6)*[7]. Unfortunately, this unexpected product *(6)* of the triplet sensitization of *(5)* did not permit us to populate the diradical manifold which connects the triplet excited state energy surfaces of the di-π-methane reaction of bicycloalkadiene *(1)* with the photodenitrogenation of azoalkane *(5)*. Consequently, no mechanistic conclusions can be drawn from our results about the behavior of the triplet diradicals *(3)* and *(4)*.



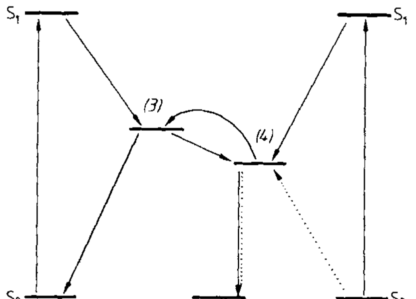


Fig. 1. Qualitative energy diagram for the pyrolytic (····) and direct photolytic (—) denitrogenation of azoalkane *(5)* and di-π-methane rearrangement of bicycloalkadiene *(1)*.

The pyrolytic and direct photolytic denitrogenations of *(5)* are mechanistically rationalized in the qualitative energy diagram shown in Figure 1. The rearrangements between the cyclopropanedimethyl diradical *(3)* and the bicyclo[2.2.1]heptenediyl diradical *(4)* interconnect the di-π-methane rearrangement of the bicycloalkadiene *(1)* and the de-

nitrogenation of azoalkane *(5)*. The energy gap between the singlet state diradicals *(3)* and *(4)* is apparently quite large so that the thermal denitrogenation of *(5)* leads exclusively to the polycycle *(2)* *via* diradical *(4)*. However, in the direct photolysis the denitrogenation of *(5)* generates a sufficiently "hot" diradical *(4)* that a small fraction suffers *retro*-di-π-methane rearrangement into bicycloalkadiene *(1)* *via* diradical *(3)*. Therefore, the diradical *(4)* constitutes an effective funnel[8] on the interconnecting singlet excited state energy surfaces for the di-π-methane rearrangement of bicycloalkadiene *(1)* and the denitrogenation of azoalkane *(5)*.

## A Novel Organometallic Cluster with $Ir_4C_2$-framework and Fluxional Hydrido Bridges

By *Jörn Müller, Helmuth Menig*, and *Joachim Pickardt*[*]

Dimeric ($\eta^4$-cyclodiene)chloroiridium complexes react with isopropylmagnesium halides in the presence of cyclodienes to form bis($\eta^4$-cyclodiene)hydridoiridium compounds[1], while in the presence of cyclotrienes, ($\eta^4$-cyclodiene)($\eta^5$-cyclodienyl)iridium complexes are produced[2]. As an example, the reaction of $[Ir(COD)Cl]_2$[3] (COD = 1,5-cyclooctadiene) with $i$-$C_3H_7MgBr$ and 1,3-cyclohexadiene proceeding *via* β-elimination of propene from the unstable (1,3-$C_6H_8$)(COD)Ir—$i$-$C_3H_7$ to ($\eta^4$-1,3-cyclohexadiene)($\eta^4$-COD)IrH which has a fluctional structure in solution, can be mentioned[1].

We have now investigated the reaction of $[Ir(COD)Cl]_2$ with $i$-$C_3H_7MgBr$ in ether in the absence of other olefinic ligands: the results indicate that the initial product, the coordinatively unsaturated (COD)Ir—$i$-$C_3H_7$ species is stabilized in an unusual way *via* formation of a polynuclear compound. An orange, diamagnetic complex *(1)*, which is air-stable in the solid state, was isolated; the empirical formula, based on the results of elemental analysis and mass spectroscopy ($M^+$ at $m/e = 1248$, based on $^{193}$Ir), corresponds to $C_{35}H_{56}Ir_4$.

The X-ray diffraction analysis[4] of *(1)* indicated an unexpected structural scheme (cf. Fig. 1). The four iridium atoms are arranged in a "butterfly-shape" and together with the acetylenic C atoms of a propyne unit form a closed six-membered cluster framework of approximate $C_s$-symmetry; compounds $Co_4(CO)_{10}(C_2Et_2)$[5], $Ru_4(CO)_{11}(C_8H_{10})$[6] and $Ir_4(CO)_5(COD)_2(C_8H_{10})$[7] have a similar $M_4C_2$ basic framework. Each Ir atom has an $\eta^4$-bonded COD ligand having the usual boat conformation. If the propyne unit is considered to be a four electron donor, the cluster still needs four electrons to complete the 60 electron configuration required by its structure and diamagnetism. These electrons are contributed by four hydrido ligands whose presence is established spectroscopically.

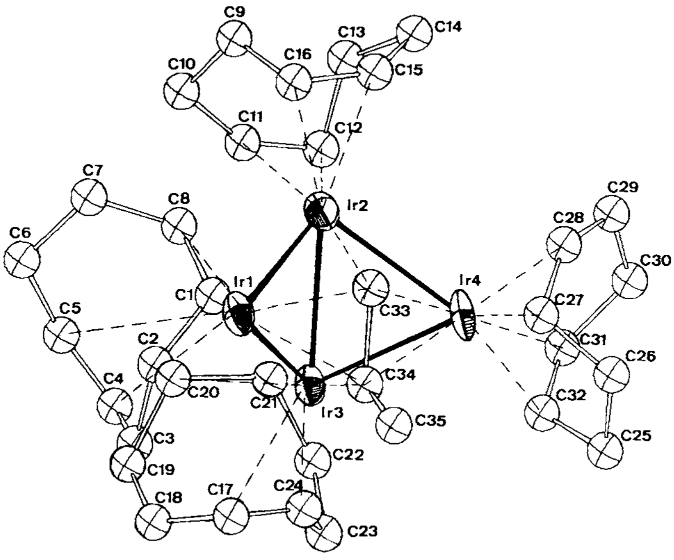

Fig. 1. ORTEP drawing of molecule *(1)*.

Institut für Anorganische und Analytische Chemie
der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

[**] π-Olefin-Iridium Complexes, Part 16. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 5: *J. Müller, W. Hähnlein, H. Menig, J. Pickardt*, J. Organomet. Chem. *197*, 95 (1980).

The IR-spectrum of *(1)* indicates that terminal hydrido hydrogen atoms are absent. In the $^1$H-NMR spectrum (80 MHz, [D$_8$]toluene) two sharp singlets, among other signals, appear at $\delta = -10.36$ and $-13.80$ (2H each), which can be assigned to two groups of $\mu_2$-hydrido bridges, which on the basis of the $C_s$-symmetry of the cluster are chemically non-equivalent. Figure 2 shows the resulting structural scheme of *(1)*. When the temperature is increased, the hydrido signals broaden, collapse together at *ca.* 45 °C and eventually form a sharp signal at $\delta = -12.07$; the other parts of the spectrum are essentially unchanged. At higher temperatures, therefore, a dynamic intramolecular exchange of hydrido hydrogen atoms, involving pairs of non-equivalent H-atoms, occurs.

The protons of the propyne unit in *(1)* can be recognized in the NMR spectrum by two sharp singlets at $\delta = 3.06$ (3H) and 5.72 (1H). These signals are absent in the spectrum of the product of the reaction of $[Ir(COD)Cl]_2$ and $i$-$C_3D_7MgBr$—evidence that the propyne unit originates from the Grignard reagent.

The complex *(1)*, $H_4(COD)_4Ir_4C_3H_4$, is one of the few organometallic clusters which does not contain CO-ligands and to our knowledge is, until now, the only closed hydridometal cluster with exclusively $\pi$-bonded olefinic ligands. In view of this, its thermal stability is surprizingly high; crystals of *(1)* do not decompose under $N_2$-atmosphere at temperatures up to 230 °C and can be vaporized into the mass spectromer at *ca.* 200 °C. It is therefore expected that further complexes of this type are synthesizable.

## *Procedure*

All operations are performed under an inert gas atmosphere. The solution of the Grignard reagent prepared from Mg (65 mg, 2.67 mmol) and $i$-$C_3H_7Br$ (0.3 cm$^3$) in 20 cm$^3$ ether, is dropped over 15 min into a suspension of $[Ir(COD)Cl]_2$ (500 mg, 0.74 mmol) in 20 cm$^3$ ether at $-50$ °C. The mixture is allowed to warm-up to room temperature and the dark brown solution irradiated for 5.5 h with UV light from an Hg high pressure lamp. (Type Q 81, supplied by Heraeus, Hanau.) The solvent is then completely removed, the residue eluted with 100 cm$^3$ hexane and filtered over 3 cm $Al_2O_3$/5% $H_2O$. The solution is concentrated and allowed to stand in the refrigerator, upon which *(1)* precipitates as a dark yellow powder; this is purified by recrystallization from hexane or a little toluene under refrigeration and produces orange red crystals. Yield 55 mg (0.044 mmol; 12%).

# Chloranil as a Catalyst for the Electrochemical Oxidation of NADH to NAD$^+$[**]

By *Horst Huck* and *Hanns-Ludwig Schmidt*[*]

An "optical test" for the specific determination of substrates by means of NAD$^+$-dependent dehydrogenases is not suitable for the analysis of turbid solutions or for continuous monitoring of concentrations; for these purposes an electrochemical process should be used. A prerequisite for the development of the corresponding "enzyme electrodes" or a preparative method for the specific electrochemical dehydrogenation of substrates is the conception of NADH-oxidizing electrodes. Such electrodes must, in particular, catalyze the dehydrogenation of NADH in an analogous way to the natural process *via* two electron steps, since one electron transitions can lead to decomposition of the coenzymes. Carbon or platinum electrodes are unsuitable because of the correspondingly high overpotentials which could lead to interference from other oxidizable materials present in the sample. A number of investigations to reduce the magnitude of this overpotential have been carried out *e.g.* by oxidative pretreatment of the carbon electrodes (resulting in reduction of the overpotential by *ca.* 200—250 mV)[1], as well as by the use of dissolved or covalently bound *o*-quinones[2]. In both cases the oxidative peak potential could be reduced from 420 to 250 mV relative to an Ag/AgCl-electrode in 0.010 M KCl (from 370 to 200 mV/SCE) in cyclic voltammetry investigations. However, the activity of the bound quinones only remained constant for a few cycles. For our purposes, we considered water-insoluble redox catalysts of sufficiently high activity, more advantageous. Tetrachloro-*p*-benzoquinone (chloranil) seemed to be particularly suitable: it has a standard redox potential of 100 mV/SCE at pH = 7, is stable and spontaneously reacts with dihydro nitrogen heterocycles *via* hydrogen abstraction[3].

Conducting electrodes of this type, consisting of pressed chloranil and graphite powder are already available[4]. However, in our investigations, we treated the basal surfaces of laterally insulated 6 mm diameter graphite electrodes with a solution of chloranil in ether and then removed the solvent by evaporation. The activity of the electrodes was investigated *via* cyclic voltammetric (Fig. 1) and potentiostatic measurements (Fig. 2) of stirred aqueous NADH solutions. The cyclic voltammograms of the NADH oxidation using an unmodified graphite electrode show peak potentials at 320 and 335 mV/SCE for the first (Fig. 1, curve $a_1$) and second (Fig. 1, curve $a_2$) sweeps respectively; the peak height remains constant after the second sweep. Voltammogram b in Figure 1 was obtained in an NADH-free solution using a graphite electrode, which had been treated with 20 µl of a 0.2 mM solution of chloranil (4 nmol): $c_1$ and $c_2$ are the curves obtained from the first and second sweeps, respectively, in the presence of NADH; here again the height of the peak maximum was constant after the second sweep. The peak maximum at 90 mV/SCE in the anodic sweep is more intense in the chloranil catalyzed anodic NADH oxidation; this can be attributed to superposition of the anodic chloranil and anodic NADH peaks. The anodic NADH peaks ob-

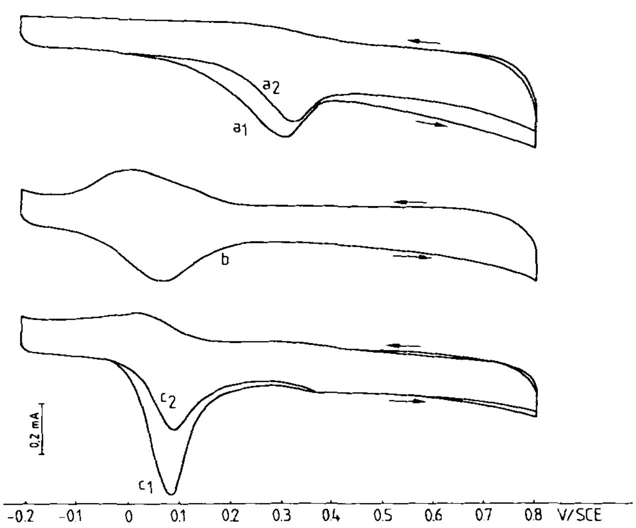

Fig. 1. Cyclic voltammograms for the investigation of the NADH oxidation in a stirred electrolyte. Starting potential −200 mV/SCE, sweep rate 100 mV/s, sensitivity 1 mA/full recorder scale. Electrolyte: 1 mM NADH, 0.1 M phosphate buffer pH 7, 1 M NaCl. $a_1$ unmodified graphite electrode (∅ 6 mm) at the first, $a_2$ at the second sweep. With 4 nmol chloranil modified graphite electrode *in absence of NADH* (b) and in presence of NADH at the first ($c_1$) and the second ($c_2$) sweep under stationary conditions.

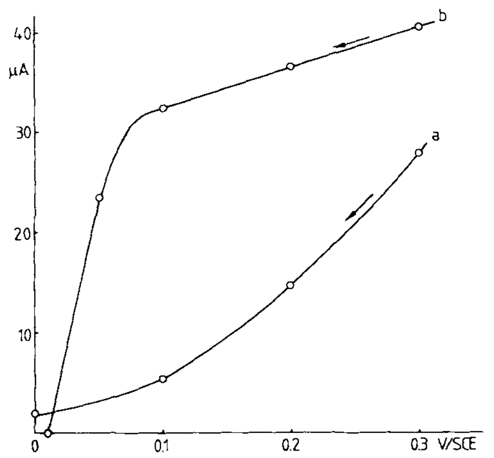

Fig. 2. Stationary current-voltage curves of stirred electrolytes (as in Fig. 1). Curve a, untreated graphite electrode, curve b graphite electrode treated with 120 nmol chloranil.

served at higher potentials are completely absent in the presence of chloranil.

The catalytic effect is particularly conspicuous in the stationary current-voltage curves obtained using controlled electrode potentials (Fig. 2). Here, the electrodes were treated with a large excess of chloranil (20 μl of a 6 mM solution, corresponding to 120 mmol). Measurements of the current were performed 2 min after each adjustment of the potential. The plot of the unmodified electrode (Fig. 2a) corresponds to the exponential course of an irreversible reaction, while that of the modified electrode (Fig. 2b) falls steeply after passing the standard redox potential of chloranil. This characteristic curve-form can be accounted for by the dependence of the potential on the surface concentration of the oxidized form of the redox catalyst, which can be reproduced using the Nernst equation. The limiting current of the plateau is caused by diffusion.

Coulometric data obtained by integrating the area under the potentiostatic current-time curves (5 $cm^3$ 1 mM NADH, 100 mV/SCE, 2 h), in conjunction with the concentration decrease of NADH determined photometrically at 340 nm, show that a two electron transfer occurs with both the modified and unmodified electrodes. No deactivation of the electrodes by fouling was observed in the treated, at 100 mV/SCE, and untreated electrodes, at 300 mV/SCE, after a 2 h investigation. However, fouling occurred with the unmodified electrode at a potential of 100 mV/SCE. Unspecific responses can be eliminated using a differential circuit of an enzyme-chloranil electrode *versus* a chloranil electrode.

The chloranil electrode can also be used with a covering dialysis membrane. However, in order to limit the decrease in sensitivity resulting, the membrane and electrolyte films must be as thin as possible.

The extraordinary activity of chloranil with respect to oxidation of NADH is probably due to formation of a charge-transfer complex. In contrast benzoquinone, whose redox potential is only 30 mV lower, is catalytically inactive. The systematic search for other catalysts for NADH-oxidation, which can be irreversibly adsorbed on carbon electrodes, has led to several heterocyclic compounds[5].

## Axially Unsymmetrical Osmium(II)-Porphyrins with Sulfur and Nitrogen Donors as Models for Cytochrome c[**]

By *Johann Walter Buchler* and *Wolfgang Kokisch*[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

Reduced cytochrome c is an electron transporting heme protein in which the $Fe^{II}$ ion is coordinated axially unsymmetrically by sulfur and nitrogen donors of the protein chain (methionine 80 and histidine 18 respectively)[1]. The central N—Fe—S unit can only be prepared from the protein-free $Fe^{II}$-porphyrin if, as in the "tail-porphyrin" of *Reed et al.*[2], at least one of the donors is covalently fixed to the periphery of the porphyrin by a side chain; otherwise only the axially symmetrical complex with two nitrogen or sulfur donors is isolated because of the kinetic lability of the heme group. In cytochrome c the N—Fe—S unit is stabilized by a double chelate effect. The inherently more stable ligand-osmium bond allowed the synthesis of the axially unsymmetrical bis-ligand-osmium(II) porphyrins *(1)* and *(2)* ("osmochromes"), which are stable without any chelate-effect.

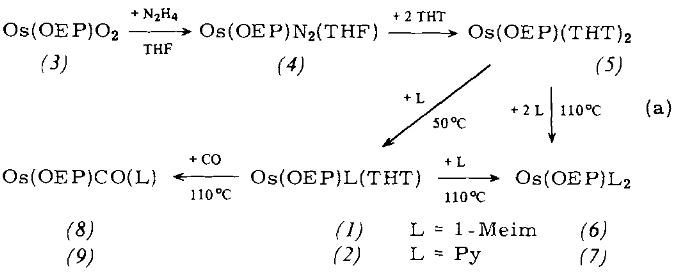
Os(OEP)LL' *(1)-(12)*

| No. | L | L' [a] | No. | L | L' [a] |
|---|---|---|---|---|---|
| *(1)* | 1-Meim | THT | *(7)* | Py | Py |
| *(2)* | Py | THT | *(8)* | 1-Meim | CO |
| *(3)* | O | O | *(9)* | Py | CO |
| *(4)* | $N_2$ | THF | *(10)* | 1-Meim | $P(OMe)_3$ |
| *(5)* | THT | THT | *(11)* | $P(OMe)_3$ | $P(OMe)_3$ |
| *(6)* | 1-Meim | 1-Meim | *(12)* | CO | THT |

[a] Abbreviations: 1-Meim = 1-methylimidazole; Py = pyridine; THF = tetrahydrofuran; THT = tetrahydrothiophene; OEP = octaethylporphyrin.

The dinitrogen complex *(4)*[3] is prepared *in situ* from the dioxoosmium(VI)-porphyrin *(3)* and converted into the bis(tetrahydrothiophene) complex *(5)*, as shown in (a). When *(5)* is warmed to 50 °C in excess 1-methylimidazole or pyridine, only the unsymmetrical osmochromes *(1)* or *(2)*[4], respectively, are formed by displacement of one of the tetrahydrothiophene ligands. In aprotic solvents *(1)* and *(2)* are stable. In methanol, oxygen induced autoxidation to osmium(III) salts ("osmichrome salts") occurs, as recently described for *(6)* and *(7)*[5a].



Above 100 °C, the aforementioned N-donors substitute the second S-donor to give the symmetrical osmochromes *(6)* or *(7)*[5], which can also be obtained directly from *(5)* at this temperature. The reverse reaction, the conversion of *(6)* into *(1)* or *(5)*, does not occur. Apparently, stability increases in the order *(5)* < *(1)* < *(6)*.

Figure 1 shows the electron excitation spectra of *(1)* and *(2)* and Figure 2 the cyclic voltammograms of the 1-methylimidazole complexes *(1)*, *(6)* and *(10)*[6a]. The half-wave potentials of the $Os^{II}/Os^{III}$ transition for systems with $L \neq L'$ lie between those of systems with $L = L'$: *(5)*, −0.26 V; *(1)*, −0.45 V; *(6)*, −0.63 V; *(2)*, −0.30 V; *(7)*, −0.37 V. The voltammograms indicate that the mixed-ligand osmochromes *(1)* and *(2)*, as well as the cytochromes and symmetrical osmochromes[5a], can be considered as reversible one electron redox systems as shown in eq. (b); thus, the osmichrome cations are inert towards substitution as well.

$$Os(OEP)LL' \rightleftarrows [Os(OEP)LL']^{\oplus} + e \qquad (b)$$

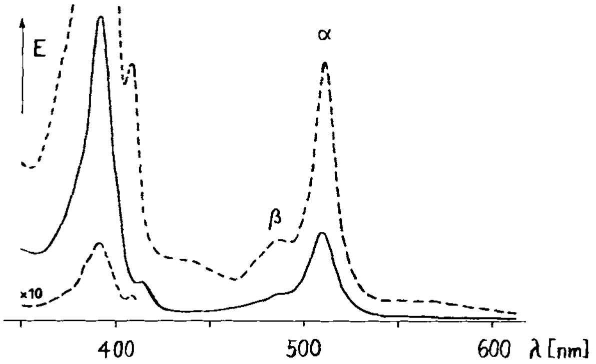


Fig. 1. Electron excitation spectra of the unsymmetrical osmochromes. *(1)* (solid line) and *(2)* (broken line). Values: $\lambda_{max}$ (lg ε): *(1)* 509 (4.37), 486 (3.83), 412 (4.01), 392 (4.90) nm; *(2)* 511 (4.58), 486 (4.08), 408 (4.57), 391 (5.06) nm. Unicam SP 1750, solvent $CH_2Cl_2$.

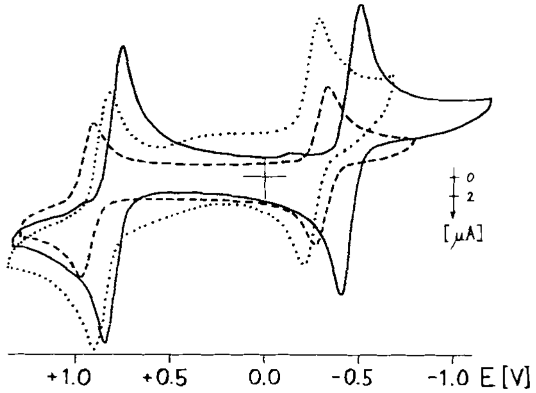

Fig. 2. Cyclic voltammograms of the unsymmetrical osmochromes *(1)* (solid line), *(2)* (broken line) and *(10)* (dotted line). Potentiostat from Princeton Applied Research, scan rate 0.1 $Vs^{-1}$, $NaCl/Hg_2Cl_2$ electrode, $CH_2Cl_2/NBu_4PF_6$. Processes at the right below 0 V are the $Os^{II}/Os^{III}$ steps, those at the left above 0.5 V the $Os^{III}/Os^{IV}$ steps.

Compounds *(1)* and *(2)*, like cytochrome c, are stable towards carbon monoxide at room temperature. As shown in (a), the sulfur donors are partially displaced in *(1)* and completely in *(2)* at 110 °C by CO to form *(8)* and *(9)* respectively[6b]. Compound *(1)* is therefore the more stable system. This is also indicated by the mass spectra. While *(1)* can be vaporized between 165° and 200 °C, without decomposition, to produce the intact molecular ion, the molecular ion from *(2)* is only observed at 170 °C; at 200 °C, apart from ions originating from decomposition of the sulfur donor, only the molecular and fragment ions of *(7)*, formed by transfer of pyrid-

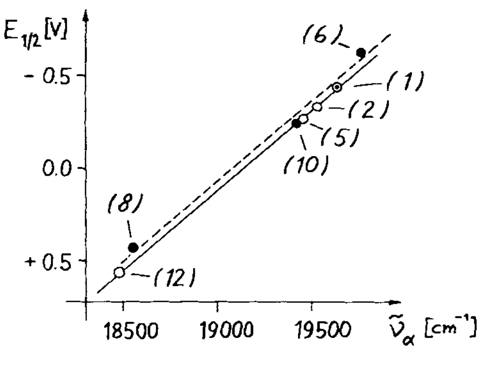

Fig. 3. Correlation between the half-wave potential of the $Os^{II}/Os^{III}$ steps ($E_{1/2}$) and the wave number of the longest wavelength absorption maxima (α-band, $\tilde{\nu}_{max}$) of the osmochromes Os(OEP) (1-Meim)L' [*(1)*, *(6)*, *(8)*, *(10)*: broken line] and Os(OEP)L(THT) [*(1)*, *(2)*, *(5)*, *(12)*; solid line].

ine, are observed. No molecular ion is formed at 180 °C by the relatively labile *(5)*.

The linear relationships between the α-band wave numbers of the absorption spectra, and the $Os^{II}/Os^{III}$-redox potentials shown in Figure 3 ("bathochromic rule"[5b, 6b, 6c]) apply not only to the tetrahydrothiophene derivatives *(1), (2), (5)* and *(12)*[6b] but also to the 1-methylimidazole derivatives *(6), (1), (10)* and *(8)*. A certain π-acceptor capacity can therefore be ascribed to the tetrahydrothiophene ligands. This result, together with the π-donor capacity of the imidazole system[5b] results in a "push-pull" stabilization of *(1)*, and also accounts for the greater chemical stability of *(1)* relative to *(2)*. In view of this inherent stability of the *trans*-arrangement of thioether and imidazole donors, cytochrome c represents a good choice by Nature.

A further detail of the cytochrome model, the difference $\Delta E = E_1 - E_2$ between the metal redox potential $E_1$ of the corresponding symmetrical bis(imidazole) and $E_2$ of the unsymmetrical thioether/imidazole systems, is reproduced by the osmochrome system. For the heme-octapeptide obtained by partial hydrolysis of cytochrome c, $\Delta E = -160$ mV[7], for the "tail-porphyrin", $\Delta E = -167$ mV[2], for the mesoheme with covalently bonded N/N- or S/N-donors, $\Delta E = -147$ mV[8a], and for the osmochromes *(6)* and *(1)*, $\Delta E = -180$ mV[8b]. By comparison of cytochromes $b_5$ and c one finds for the latter $\Delta E = -235$ mV[9]. This larger value may be attributed to a special protein-effect.

### *Procedure*

A solution of *(5)*[10] (64 mg, 7 mmol) in 11 cm³ THF/1-methylimidazole (10:1) is prepared under an argon atmosphere, warmed for 2 h at 50 °C and concentrated in a stream of argon. The residual solution is allowed to stand under argon until crystallization occurs. The black, analytically pure needles of *(1)* which precipitate (51 mg, 65%) are suction filtered, washed with methanol/water (4:1) and dried at 40 °C/$10^{-4}$ torr.

## Carbonylation of $C_5H_5Fe(CO)(CH_3)L$—a CO-Insertion and No $CH_3$-Migration[**]

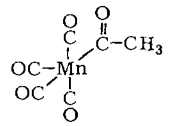
By *Henri Brunner* and *Heinz Vogt*[*]

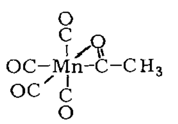
Owing to its industrial importance, CO-insertion in transition metal-alkyl bonds has been the subject of numerous investigations, particularly on the model system

$CH_3Mn(CO)_5 + CO \rightleftarrows (CH_3CO)Mn(CO)_5$[2]

It is assumed that the methyl group migrates from the Mn atom to a *cis*-oriented carbonyl group with formation of the acetyl intermediate *(1)*. The free coordination site becomes occupied by nucleophiles L = CO, PR₃ *etc.* before the square pyramid *(1)* can isomerize. This mode of reaction is supported by calculations[3] and confirmed by labeling experiments, but is not reconcilable with an $\eta^2$-acetyl intermediate *(2)*, formed by insertion of a *cis*-CO ligand in the Mn—CH₃ bond.

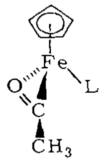
*(1)*

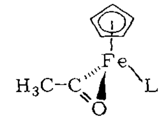




*(2)*

Ligand exchange reactions in optically active Fe-complexes and investigations on ¹³C-labeled and C₅H₅-acyl bridged Fe-complexes showed that the thermal decarbonylation of compounds of the type $C_5H_5Fe(CO)(COCH_3)L$ begins with an intramolecular substitution of the ligand L by the acetyl oxygen with stereospecific formation of the $\eta^2$-acetyl intermediate *(3)*. Ligands L′ = P(CH₃)₃, P(*n*Bu)₃ attack the intermediate *(3)* at the acetyl oxygen and open the $\eta^2$-bond of the acetyl-ligand to give the substitution products $C_5H_5Fe(CO)(COCH_3)L'$ with retention of configuration at the Fe atom. The intermediate *(3)* can rearrange to $C_5H_5Fe(CO)_2CH_3$ and be transformed into its mirror image *(3′)*; the change of configuration is slow compared to the rearrangement[5].





*(3)*, L = CO *(3′)*
*(4)*, L = $P(C_6H_5)_2NCH_3$–(*S*)–$CH(CH_3)(C_6H_5)$ *(4′)*

In the following it is shown that the carbonylation of $(-)_{436}$-*(5)*[1,6] proceeds with stereospecific insertion of the CO group present in the molecule into the Fe—CH₃ bond.

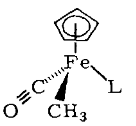
If a solution of optically pure *(5)* in benzene is allowed to stand for 5 d at room temperature under 400 bar CO, *(6)* is formed with a stereoselectivity of over 90%. Comparison of the CD spectra of *(5)* and *(6)* with those of similar complexes of known absolute configuration enables unequivocal assignement of configurations[7]. The reaction *(5)*→*(6)* is not

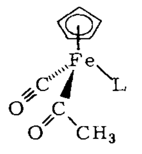
---

[*] Prof. Dr. H. Brunner, Dr. H. Vogt
Institut für Anorganische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] Optically Active Transition Metal Complexes, Part 75. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, BASF AG, and Dynamit Nobel AG.—Part 74: [1].

compatible with a migration of methyl to give an intermediate analogous to *(1)*, but only with a CO-insertion to give the $\eta^2$-acetyl intermediate *(4)*. The formation of *(4)* from *(5)* can thus be envisioned in terms of the CO ligand being inserted into the Fe—CH$_3$ bond, and the oxygen atom swinging into the position previously occupied by the carbonyl C-atom. In the presence of CO, replacement of the acetyl oxygen in the intermediate *(4)* by the newly entering CO occurs with stereospecific formation of *(6)*. The intermediate *(4)* is formed from *(5)* even at room temperature and is configurationally stable under the conditions of the carbonylation.

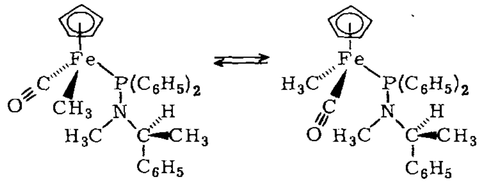




*(5)*, L = P(C$_6$H$_5$)$_2$NCH$_3$–*(S)*–CH(CH$_3$)(C$_6$H$_5$) *(6)*
*(7)*, L = P(C$_6$H$_5$)$_3$ *(8)*

This result is remarkable, because in the photochemical decarbonylation of *(8)* in tetrahydrofuran, the species *(7')* with the opposite configuration to *(7)* at the Fe-atom, is formed, consistent with the concept of a methyl migration into the position vacated by photochemical cleavage of the CO ligand[7b]. It follows, therefore, that the photochemical reaction cannot involve an $\eta^2$-acetyl intermediate, whose carbonylation according to the principle of microscopic reversibility should give the product *(7)*—and not *(7')*, as observed—in view of the stereochemistry of the reaction *(5)*→*(6)*.

*(5)* epimerizes to *(5')* at elevated temperatures. In benzene at 70 °C, approach to the diastereomeric equilibrium *(5)*⇄*(5')* (65:35) is a first order reaction (half-life 81 min) which can be followed NMR spectroscopically[1,6]. Within the limit of error an addition of the aminophosphane contained in *(5)* and *(5')* does not change the rate of the reaction. The epimerization *(5)*⇄*(5')* could be ascribed to a pseudorotation-like rearrangement of the $\eta^2$-acetyl ligand in *(4)* and *(4')*, *e.g.* by rotation about 180°.



*(5)* ⇄ *(5')*

Reaction of *(5)* with the isocyanide CNR* = (−)—CN—*(S)*—CH(CH$_3$)(C$_6$H$_5$) instead of CO in benzene requires about six hours' heating at 70 °C. The product C$_5$H$_5$Fe(COCH$_3$)(CNR*)L has an optical purity of only 50%, since the change of configuration in the intermediate *(4)*⇄*(4')* competes with the trapping reaction *(4)*+CNR*. The carbonylation of *(5)*, on the other hand, leads stereospecifically to *(6)* at room temperature, before the intermediate *(4)* can change its configuration. The variable stereoselectivities observed by *Flood*[8] in the carbonylation of *(7)* to *(8)* might be due to prior change of configuration *(7)*⇄*(7')* at the Fe-atom or, in particular in hexamethylphosphoric triamide, to S$_N$2-inversion at the Fe-atom[5].

Summarizing: Although the fragments (CO)$_3$Mn and C$_5$H$_5$Fe, and thus also the compounds (CO)$_5$MnCH$_3$ and C$_5$H$_5$Fe(CO)$_2$CH$_3$ are isoelectronic, their carbonylation proceeds *via* different routes and *via* different intermediates. This also applies in the case of the photochemical and thermal variants of the carbonylation of C$_5$H$_5$Fe(CO)(CH$_3$)L and of the decarbonylation of C$_5$H$_5$Fe(CO)(COCH$_3$)L.

## *t*Bu$_6$P$_8$ and *t*Bu$_6$As$_8$— Two New Element-Homologous Bicyclic Compounds of Different Structure[**]

By *Marianne Baudler, Jochen Hellmann, Paul Bachmann, Karl-Friedrich Tebbe, Roland Fröhlich* and *Magda Fehér*[*]

*Dedicated to Professor Rolf Appel on the occasion of his 60th birthday*

After successful identification of a large number of polycyclic phosphorus hydrides by mass spectrometric methods[1a] we attempted the synthesis of more stable derivatives[1b,c]. Analogous homonuclear skeletal structures are likely to be found in the corresponding arsanes; this could be confirmed for the pair (Me$_3$Si)$_3$P$_7$[2a] and (Me$_3$Si)$_3$As$_7$[2b]. However, examination of the bicyclic hexa-*tert*-butyloctaphosphane *(1)* and hexa-*tert*-butyloctaarsane *(2)* now gave us the first example showing that homologous phosphanes and arsanes may also display entirely different structures.

The phosphane *(1)* is obtained by cyclocondensation of diphosphorus tetraiodide with 1,2,3-tri-*tert*-butyltriphosphane[3] in the presence of a base.

$$2\ \mathrm{H}(t\mathrm{Bu})\mathrm{P{-}P}(t\mathrm{Bu})\mathrm{{-}P}(t\mathrm{Bu})\mathrm{H} + \mathrm{P_2I_4} \xrightarrow[-4\,\mathrm{Et_3N\cdot HI}]{+4\,\mathrm{Et_3N}} t\mathrm{Bu_6P_8} \qquad (1)$$

As by-products we found the monocyclic phosphanes (*t*BuP)$_3$[4a] and (*t*BuP)$_4$[4b] as well as 1,2-di-*tert*-butyl-1,2-diiododiphosphane[4c] and phosphorus iodides P$_x$I$_y$ with $x > y$. *(1)* is also obtained by dehalogenation of a 3:1 mixture of

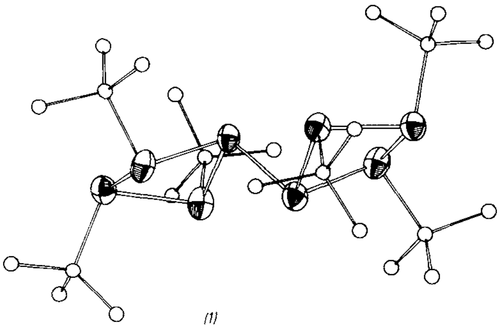
*tert*-butyl(dichloro)phosphane and phosphorus trichloride using magnesium[5].

The octaphosphane *(1)* is a colorless crystalline compound (m.p. 257 °C, dec., closed tube) which remains unaltered on exposure to air, and is only sparingly soluble in the usual solvents. The only fragment in addition to $M^{\oplus}$ ($m/e = 590$, rel. int. 100) found in the mass spectrum (field ionization, 180 °C) is $M^{\oplus}/2$ (295; 17). The $^{31}P\{^1H\}$-NMR spectrum shows two complex multiplets (3 : 1 ratio) at $\delta \approx -45$ for the *tert*-butyl substituted phosphorus nuclei and $-100$ for those bound to phosphorus only. Two singlets at $\delta = 1.27$ and 1.30 (1 : 2) due to the non-equivalent *tert*-butyl groups appear in the $^1H\{^{31}P\}$-NMR spectrum. Lines broaden continuously below $-10$ °C, but coalescence point is not passed down to $-70$ °C[6]. All spectroscopic data are only compatible with the structure of a 2,2′,3,3′,4,4′-hexa-*tert*-butyl-1,1′-bicyclotetraphosphane with the possibility of frozen rotation round the exocyclic P—P bond at low temperature. This structure is also confirmed by X-ray structure analysis (Fig. 1)[7]. All



*(1)*

Fig. 1. Crystal structure of *(1)*; parameter ranges and average values of important bond lengths [pm] and angles [°]: $221.4 \leqq d(\text{P—P}) \leqq 223.1$, $\sigma(\text{P—P}) \simeq 0.2$; $\bar{d}(\text{P—P}) = 222.1(6)$; $\bar{d}(\text{P—C}) = 188.7(4)$. $86.8 \leqq \varphi(\text{P—P—P}) \leqq 88.2$, $\sigma(\text{P—P—P}) \simeq 0.6$; $\bar{\varphi}(\text{P—P—P}) = 87.5(6)$ (endocyclic angle); $94.8 \leqq \varphi(\text{P—P—P}) \leqq 98.3$, $\sigma(\text{P—P—P}) = 0.6$; $\bar{\varphi}(\text{P—P—P}) = 96.6(17)$ (angle at the P—P bridge).

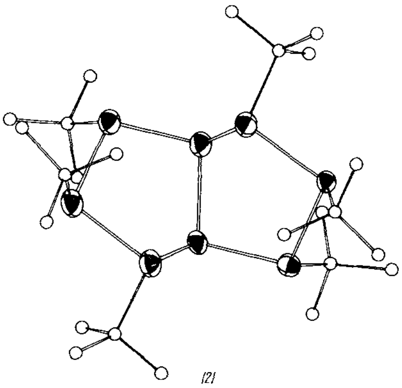
P—P distances within the non-planar tetracycles and in the bridge are almost equal. The orientation of the rings as well as the arrangement of the substituents is *all-trans*. Model studies show that strong transannular interactions between the *tert*-butyl groups prevent *(1)* having the 2,3,4,6,7,8-hexa-*tert*-butylbicyclo[3.3.0]octaphosphane structure like $Me_6P_8$, $Et_6P_8$, $iPr_6P_8$[5], and the arsenic compound *(2)*.

The arsane *(2)* was first observed as a by-product of $(t\text{BuAs})_4$, prepared from *tert*-butyl(dichloro)arsane and magnesium, a reaction where, surprisingly, partial cleavage of the As—C bonds takes place; this indicates a remarkable tendency towards the formation of *(2)*. Thus *(2)* is obtained as main product by dehalogenation of a 3 : 1 mixture of *tert*-butyl(dichloro)arsane and arsenic trichloride.

$$6\ t\text{BuAsCl}_2 + 2\ \text{AsCl}_3 + 9\ \text{Mg} \xrightarrow[-9\ \text{MgCl}_2]{} t\text{Bu}_6\text{As}_8 \quad (2)$$

The monocyclic arsanes $(t\text{BuAs})_4$ and $(t\text{BuAs})_5$ are obtained as by-products. The product ratio depends on reactant concentration and time; *(2)* can be isolated pure by means of low temperature crystallization; optimum yield was achieved under $^1H$-NMR-spectroscopic control.

Octaarsane *(2)* forms yellow platelets (m.p. 262–264 °C, closed tube), which are stable in the dark and under inert gas. The crystals are only moderately soluble in tetrahydrofuran (THF) and benzene, less soluble in *n*-pentane or *n*-hexane. Air causes rapid oxidation of *(2)*, particularly in solution. Elemental analysis (As, C, H), cryoscopic determination of the molecular weight (in benzene) and a mass spectrum (field ionization, 140 °C) confirm the composition of *(2)*; other than in *(1)*, only $M^{\oplus}$ ($m/e = 942$) appears, and no $M^{\oplus}/2$ signal. As further confirmed by $^1H$-NMR spectral data (two singlets at $\delta = 1.66$ and 1.58 in a 1 : 2 ratio), this shows that *(2)* is a 2,3,4,6,7,8-hexa-*tert*-butyl-bicyclo[3.3.0]octaarsane. The spectroscopic findings admit two configurations with the *tert*-butyl groups within each five-membered ring in *trans* position and the substituents of different five-membered rings next to the zero bridge in *cis* position. X-ray structure analysis[8] (Fig. 2) shows unambiguously the presence of the sterically preferred isomer with the *tert*-butyl groups in the 3,7 position arranged *trans* with respect to the free electron pairs of the bridgehead arsenic atoms. Both five-membered rings have twisted envelope conformations.



*(2)*

Fig. 2. Crystal structure of *(2)*; parameters, parameter ranges and average values of important bond lengths [pm] and angles [°]: $d(\text{As1—As5}) = 241.4(4)$; $\varphi(\text{As—As(1,5)—As}) = 94.8$, 94.9 (zero bridge); $243.3 \leqq d(\text{As—As}) \leqq 244.4$, $\sigma(\text{As—As}) = 0.4$; $\bar{d}(\text{As—As}) = 243.8(4)$; $\bar{d}(\text{As—C}) = 201(3)$; $97.8 \leqq \varphi(\text{As—As—As}) \leqq 107.3$, $\sigma(\text{As—As—As}) = 0.1$ (arsene pentacycles).

*Procedure*

*(1)*: A solution of 10.0 g (37.6 mmol) 1,2,3-tri-*tert*-butyltriphosphane[3] in 100 cm$^3$ *n*-pentane is vigorously stirred with 10.7 g (18.8 mmol) diphosphorus tetraiodide and 7.7 g (76.1 mmol) triethylamine for 24 h at room temperature. The mixture is then refluxed for 3 h and the solvent is removed, finally in an oil pump vacuum. The residue is dissolved in 150 cm$^3$ THF and is kept at $-78$ °C for 15 h before filtering at the same temperature. After drying, the powdery solid is extracted with 500 cm$^3$ *n*-pentane in a Soxhlet apparatus for 5 h; enriched *(1)* begins to precipitate in the extract after a while. The solution is concentrated to 100 cm$^3$, the crude product is filtered off and is recrystallized from 100 cm$^3$ boiling toluene; yield: 1.5 g (14%) colorless *(1)*.

*(2)*: A solution of 7.0 g (34.5 mmol) *tert*-butyl(dichloro)arsane and 2.1 g (11.6 mmol) arsenic trichloride in 60 cm$^3$ THF is added dropwise within 20 min into 10 cm$^3$ boiling THF containing 3.8 g magnesium. As soon as reaction commences, heating is stopped; the heat of reaction will keep the mixture boiling. While the mixture is still hot, the precipitate is removed by filtration and washed twice with 20 cm$^3$ THF. The combined filtrates are concentrated and the light yellow solid residue treated with 80 cm$^3$ hexane; remaining magnesium chloride is filtered off. The solution contains *ca.* 50 mol% of *(2)*, 30% $(t\text{BuAs})_5$, and 20% $(t\text{BuAs})_4$ (shown by $^1H$-NMR spectrum). Cooling to $-30$ °C for 5 d leads to precipitation of the yellow crude product; excess solution is si-

phoned off in the cold. Renewed dissolution in a minimum quantity of boiling *n*-hexane and crystallization at −30 °C yields 1.9 g of *(2)* with a purity of *ca.* 90% (contaminated with $(t\mathrm{BuAs})_4$); three further recrystallizations yield 1.1 g (20%) of pure *(2)*.

# —P=N— Tetramerization of a Triazaphosphole Induced by Complex Formation[**]

By *Alfred Schmidpeter, Helmut Tautz, Joachim von Seyerl* and *Gottfried Huttner*[*]

*Dedicated to Professor Rolf Appel on the occasion of his 60th birthday*

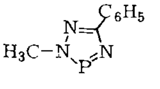
The monophospha analogues of azo compounds occur, in general, not as monomers *(1)* but as the dimers *(2)*, $n = 2$. *P*-amino derivatives with bulky substituents may be stable, at least kinetically, as monomers *(1)*[1]. With substituents having smaller spacial requirements, tri-[2a] and tetrameric[2b] *(2)*, $n = 3$, 4 are found.

*(1)*

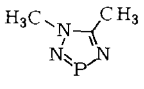
$$n\ {>}P{=}N{<} \rightleftharpoons ({>}P{-}N{<})_n$$

*(2)*

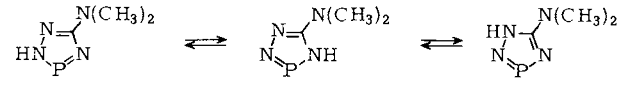
In 1,2,4,3-triazaphospholes[3] such as *(3)*—*(5)*, and other azaphospholes, the with —P=N— unit is incorporated into a 6π-system and does not usually oligomerize.



*(3)*



*(4)*



*(5a)* *(5b)* *(5c)*

In order to investigate the donor properties of the ψ-trigonal nitrogen and phosphorus atoms in these heterocycles, we prepared the $M(CO)_5$-complexes, M = Cr, Mo, W. While *(3)* and *(4)* gave P-coordinated 1:1-complexes[4], *(5)*[5] formed—despite the use of equimolar amounts of educts—complexes in which two molecules of *(5)* are bonded to an $M(CO)_5$ unit, the second apparently indirectly. The $^{31}P\{^1H\}$-NMR spectrum (Fig. 1) shows an $[AB]_2$-system which indicates a dimeric structure. $\delta^{31}P_A$ corresponds to a triply σ-bonded phosphorus and $\delta^{31}P_B$, according to the downfield

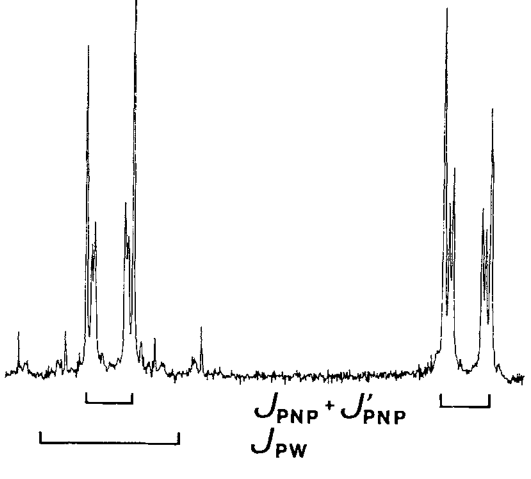


Fig. 1. $^{31}P\{^1H\}$-NMR spectrum of *(6b)* in tetrahydrofuran.

coordination shift[4] (large for M = Cr, small for M = W)[4], to a phosphorus complexed to $M(CO)_5$. The $^{183}W$-satellites of the $P_B$-signal (Fig. 1) confirm this assignment.

An X-ray structure analysis proves the products to be $[M(CO)_5]_2$ complexes *(6)* of a tetramer of *(5)*.

From the solutions of *(6)* colorless crystals of *(6)*·6THF are obtained which lose THF even at 20 °C. The crystal structure was determined on a crystal of *(6a)*·6THF fused into a capillary tube which was partly filled with the mother liquor.

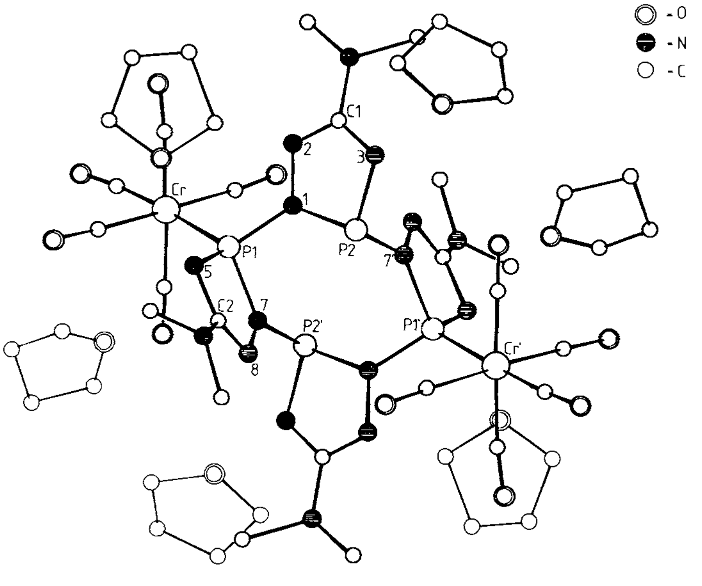

Fig. 2. Structure of the complex *(6a)*·6THF; monoclinic, space group $P2_1/c$, $a = 1987$, $b = 1151$, $c = 2193$ pm, $\beta = 138.88°$, $V = 3300$ Å$^3$, $Z = 2$, $\rho_{calc} = 1.35$ g cm$^{-3}$, $\mu = 5.2$ cm$^{-1}$. 1876 independent reflections (Syntex-P3 diffractometer, $T = -80$ °C, $2.5 \leq 2\theta \leq 40°$, $1.2 \leq \omega \leq 29.3$ s$^{-1}$, ω-scan). Structure solution system Syntex-EXTL, refined with full matrix, partially anisotropic, to $R_1 = 0.114$.

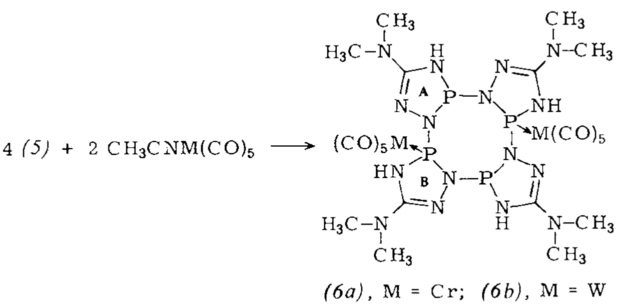
The X-ray structure analysis shows (Fig. 2) the tetramer in complex *(6)* to derive from the 4*H*-tautomer *(5b)*. This suggests that the oligomerization equilibrium *(1)*$\rightleftharpoons$*(2)* lies less to the left side with 4*H*-1,2,3,4-triazaphospholes than with the 2*H*- or 1*H*-isomers: for this reason *(3)* and *(4)*, in which these forms are fixed, behave in a different way to *(5)* when forming complexes.



*(6a)*, M = Cr; *(6b)*, M = W

The chromium complex *(6a)* possesses a crystallographic center of inversion and hence, unlike in octamethylcyclotetra(phosphazane)[2b], the eight-membered ring is not crown shaped. As a consequence of the strain in the five-membered ring, the phosphorus bond angles in the eight-membered ring are smaller (N1—P1—N7 and N1—P2—N7′ 102°) and the nitrogen bond angles larger (P1—N1—P2 126°, P1—N7—P2′ 122°) than in the said cyclotetra(phosphazane) (108 and 112°, respectively). Although two of the four phosphorus atoms are complexed and two are not the bond lengths in the eight-membered ring of *(6a)* are of note since they are almost identical (P1—N1 and P2′—N7 170 pm, P1—N7 and P2—N1 173 pm). The environment around all the nitrogen atoms is almost planar and the $PN_3$-pyramid is only slightly widened out by Cr-coordination. Intramolecular comparison indicates that formation of an $M(CO)_5^-$-complex only exerts a small structural effect on the ligands.

Both PN-bonds in the five-membered ring are lengthened considerably relative to those of a monomeric triazaphosphole[6] (to 173 pm for P1—N5, P1—N7 and P2—N1 and to 170 pm for P2—N3); the internal angles at phosphorus are contracted (to 87° for N5—P1—N7 and 86° for N1—P2—N3). The 4-position of the hydrogen bond manifests itself by the relatively long C2—N5 and C1—N3 bonds (*ca. 139* pm; in comparison C2—N8 and C1—N2 are *ca.* 127 pm). In contrast to cyclodi(phosphazane), the vicinal bonds in cyclotetra(phosphazane) only form a small dihedral angle[2b] and thereby permit the attachment of an almost planar ring (maximum deviation of the ring members from the best plane of the five-membered ring in *(6a):* 8 pm). According to this argument dimerization of an azaphosphole, on the other hand, would seem to be rather impossible.

The tetramer is only stable in the complex. Attempts to displace it using triphenylphosphane resulted in re-formation of the monomer *(5)*. The formation and dissociation of *(6)* suggest for the azaphospholes an equilibrium *(1)*$\rightleftharpoons$*(2)*, as in the analogous acyclic phosphazenes, which mostly lies far on the left-hand side: it may however be displaced to the right by a (soft) acceptor, if the latter prefers the P-atom in *(2)* to the P-atom in *(1)* as the donor[4]. In the opposite sense, with 1,3,2-benzodiazaphospholes[7], the equilibrium is shifted to the left by the *N*-coordinating (hard) acceptor $BF_3$.

## *Procedure*

*(6a, b):* Acetonitrile(pentacarbonyl)chromium or -tungsten (5 mmol) and *(5)* (10 mmol) are refluxed in 50 cm³ $CHCl_3$ for 5 h. After concentration to 10 cm³, *(6)* crystallized out; yield 75—85%.

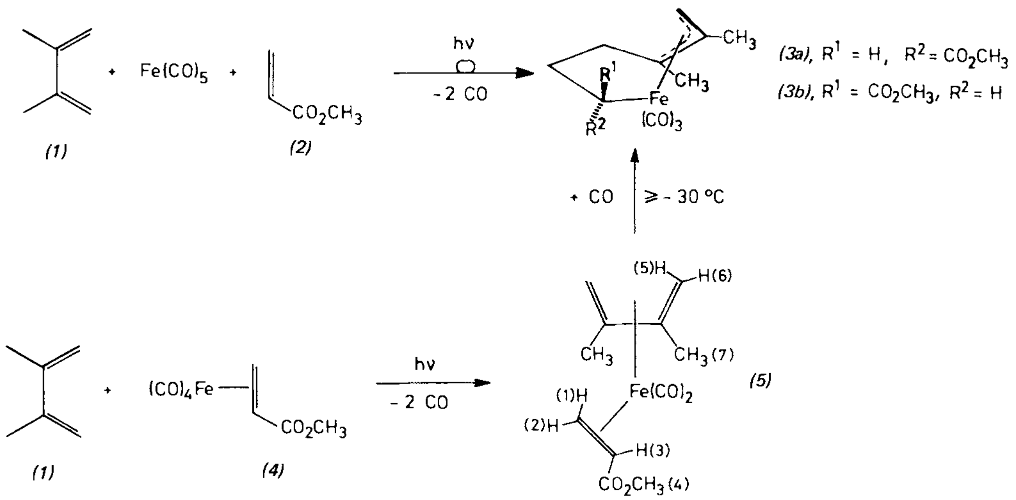
# Photochemical Synthesis of a ($\eta^4$-Diene)($\eta^2$-Olefin)Fe(CO)$_2$ Complex and Subsequent Thermal Coupling of the Ligands

By *Friedrich-Wilhelm Grevels* and *Konrad Schneider*[*]

We previously reported on the coupling of 1,3-dienes and methyl acrylates *(2)* by photochemical reaction with pentacarbonyliron, which leads, both *via* the ($\eta^4$-diene)Fe(CO)$_3$ as well as *via* the ($\eta^2$-olefin)Fe(CO)$_4$ *(4)*, to complexes of the type *(3)*[1a]. We have now succeeded in isolating an intermediate[1], the ($\eta^2$-methyl acrylate)dicarbonyl($\eta^4$-2,3-dimethylbutadiene)iron complex *(5)*.

*(5)* is obtained by irradiation—preferably at low temperature—of *(4)* and *(1)*, if the liberated CO is removed by a stream of argon. *(5)* is stable at 20 °C, but very air-sensitive in solution; in the dark it reacts with CO to give *(3)*.



Thus, it is shown that CO in Fe(CO)$_5$ is first replaced photochemically by the unsaturated ligands *(1)* and *(2)*—a process which without irradiation requires rather drastic conditions and is frequently accompanied by decomposition—and this is followed by thermal C—C coupling of the ligands with re-uptake of one CO. This reaction starts at *ca.* −30 °C and affords the isomers *(3a)* and *(3b)* in a ratio which is temperature-dependent (Fig. 1). $^{13}$C-labeled CO is distributed equally among the three CO positions of *(3a)* and *(3b)* ($^{13}$C-NMR, MS).

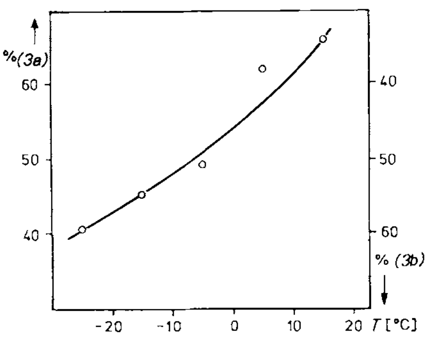


Fig. 1. Product ratio *(3a)/(3b)* in the reaction of *(5)* with CO as a function of temperature.

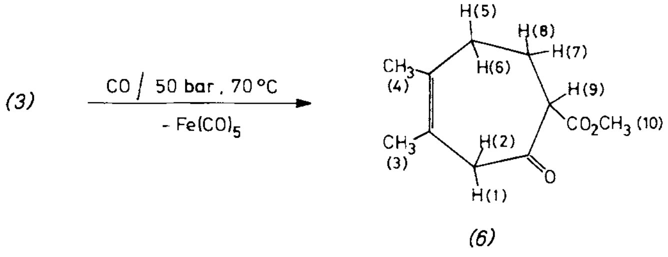
Although ($\eta^4$-diene)Fe(CO)$_3$ loses CO in good quantum yields[2], and coordinatively unsaturated $\eta^4$-(diene)Fe(CO)$_2$ has also been detected spectroscopically in low-temperature matrices[3], attempts to obtain *(5)* also from ($\eta^4$-diene)Fe(CO)$_3$ and *(2)* have so far failed.

The IR spectrum shows that *(5)* is present as a mixture, presumably of three or four species. In the metal-carbonyl region, instead of the expected two bands a total of five bands (some slightly broadened) are observed (*n*-hexane; 2023, 2018, 1981, 1977.5, 1968 cm$^{-1}$), while two bands appear in the ester-carbonyl region (1724, 1711 cm$^{-1}$). The position of the CO-stretching vibration bands—taking into account substituent-determined shifts—resembles those of known dicarbonyl($\eta^4$-cyclobutadiene)($\eta^2$-olefin)iron complexes[4a]. The $^1$H-NMR spectrum ([D$_8$]toluene) of *(5)* at 20 °C shows only one set of signals each for the olefin [$\delta = 2.20$ (1-H), 3.12 (2-H), 2.60 (3-H), 3.50 (4-H); $J_{1,2} \lesssim 3$, $J_{1,3} \approx 7$, $J_{2,3} \approx 11$ Hz] and the diene [$\delta = -0.21$, $-0.40$ (5-H, 5′-H), 1.09, 0.63 (6-H, 6′-H), 1.98, 1.83 (7-H, 7′-H)], which, however, are partly split at lower temperatures. Accordingly, the system is fluxional, with rapid exchange—presumably through rotation of the olefin[4] and of the diene[4b]—at room temperature. The changes in the spectrum on cooling are not complete until −80 °C. The relative concentrations of the precursors of *(3a)* and *(3b)*, however, do not appear to be temperature-dependent, since the intensity ratios of the carbonyliron bands in the IR spectrum of *(5)* do not change between +20 and −50 °C. It can therefore be concluded that the temperature-dependence of the product ratio *(3a)/(3b)* is kinetically determined.

As with CO, *(5)* also reacts with phosphanes, isocyanides *etc.* with coupling of the diene and the olefin to give Fe(CO)$_2$L complexes analogous to *(3)*[5].



*(6)*

Detachment of the C$_6$-chain from the metal in *(3)* is accomplished, *inter alia*, with CO. Insertion of CO takes place

with formation of the cycloheptenone derivative *(6)*[6] along with other products. The $Fe(CO)_5$ that is formed could be used again for the synthesis of *(3)*; so ultimately *(6)* is synthesized from *(1)*, *(2)*, and CO. This reaction sequence be possibly can used preparatively for the synthesis of substituted cycloheptenones[7].

*Procedure*

A solution of *(4)*[8] (2.54 g, 0.01 mol) and *(1)* (4.10 g, 0.05 mol) in diethyl ether (130 $cm^3$) is irradiated for 2.5 h at −40 °C (immersion-lamp apparatus of Solidex glass, Philips HPK 125 W Hg-lamp), with concomitant passage of Ar. The solution is evaporated down *in vacuo* and the residue chromatographed on silica gel at −40 °C. Diene-$Fe(CO)_3$ and *(4)* are eluted with pentane, and then *(5)* is eluted with pentane/diethyl ether (4+1). The oily crude product is dissolved in 5 $cm^3$ hexane; on cooling to −78 °C yellow crystals of *(5)* are formed (0.75 g, 27%), m.p. 24—25 °C.

## BOOK REVIEWS

*H. Staudinger, H. Mark* and *K. H. Meyer*—**Thesen zur Grösse und Struktur der Makromoleküle** (*H. Staudinger, H. Mark* and *K. H. Meyer*—Theses on the Size and Structure of Macromolecules). By *C. Priesner*. Verlag Chemie, Weinheim 1980. x, 389 pages, cloth, DM 98.00.

This is a "contribution to the history of macromolecular chemistry" in which the author limited himself intentionally to "a comprehensive and comparatively detailed presentation of one very important aspect", as stated in the title of the book. The main intention was to demonstrate that also during this phase of scientific evolution "the major lines of development..." emerged "from the work and ideas of many people", even though "Hermann Staudinger was one of the best known pioneers of modern high polymer chemistry".

The book is arranged in such a way that the author's presentation is supported mainly by abstracts of publications or communications. The evidence is often impressive and speaks for itself, so that only a few commentative sentences are necessary to make correlations. The first nonsystematic and systematic experiments on polymers are described in Part 1, beginning with the establishment of *Berzelius'* concept of "Polymerism" in 1833. This part ends with a detailed discussion of the work reported at the 89th Meeting of the Society of German Scientists and Physicians at Düsseldorf in 1926.

Part 2 occupies a central place and covers the subsequent period up to 1937. The feuds between *Staudinger* and *K. H. Meyer/H. Mark* as well as others, documented by substantial original material, fall into this period and are interpreted mainly as differences about priority rather than conflicts of views.

A concluding evaluation is attempted in the last part, entitled "Commentary". In all, it must be said that *Priesner* has succeeded in producing an exceptionally exciting work, even though the modern expert reader will not easily follow all reasoning, arguments, and counterarguments contained in the original texts. The many-sided views expressed with definite terminology by organic chemists, colloid chemists, physicists, and physical chemists required a veritable polymath to interpret, weigh up, and sometimes criticize, and the author rose fully to the occasion. In his rather more reserved over-all judgment of *Staudinger*, especially concerning the priority argument, the younger specialists are more likely to follow him than the older ones, or even former students of *Staudinger*.

Naturally, not everything is well done. The merits of *Pickles* are quite rightly pointed out. But *Staudinger* already mentions *Pickles* and his suggested structure of rubber in the first work "Concerning Polymerization", and not only in the fifth, which appears twice in the index (references 39 and 79). *Paul J. Flory*, who commences his well-known standard work of 1953 with an excellent historical introduction, also rightly emphasizes *Pickles'* importance, so the impression can hardly arise that his work has not been sufficiently observed (p. 22).

The "modern interpretation" on p. 120, second paragraph, is not clear. The reviewer prefers the preceding original text from *Staudinger*, which sounds remarkably up-to-date if the term "association" is replaced by "entanglement".

Did *Staudinger* win the Nobel prize in 1953 for the "viscosity formula", as claimed at the top of p. 121?

Here and there one has the impression that the author should have consulted other recognized books on polymer chemistry and polymer physics in addition to the Römpp and the Ullmann.

Full marks to Verlag Chemie for the book's layout. Pity about some printing errors.

*Heinz-Hermann Meyer* [NB 535 IE]

## Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

## Corrigendum

The following corrections should be made to the short communication entitled "Polymethinic Ring Compounds and the Polymethinic Carbonyl Group" by *Siegfried Kulpe,* Angew. Chem. Int. Ed. Engl. *20,* 271 (1981):

On p. 271, second paragraph, second line, "di- and triaminobenzoquinones" should read "di- and tetraaminobenzoquinones".

On p. 272, first paragraph, left-hand column, delete the words "tetra- and".

On p. 272, the first sentence, right-hand column, should read "The heteropolarity of this bond does *not* lead to stretching as would have to exist according to *(2b)* and *(2c)*".

# The Transition Metal-Nitrogen Multiple Bond

**By Kurt Dehnicke and Joachim Strähle**[*]

*Dedicated to Professor Josef Goubeau on the occasion of his 80th birthday*

Numerous nitrido complexes of transition metals show very short metal-nitrogen bond lengths, suggesting M≡N-triple bonds. At present, compounds of this type are being intensively investigated. In particular the molybdenum complexes are considered as model substances for the study of at least an intermediate step of $N_2$-assimilation. This article contains a review of the structure and bonding, as well as syntheses and reactions of these complexes.

## 1. Introduction

Apart from the carbyne ligand, the nitrido ligand is the strongest known π-electron donor. As a terminal ligand M≡N: its formal bond order corresponds to a triple bond. Here, the three bond lines represent one σ and two π bonds, the latter resulting from overlap of occupied π orbitals of the nitrogen with two unoccupied, symmetry allowed d-orbitals of the metal. An important reason for the high bond order is the relatively low electronegativity of the nitrogen, which qualifies it for optimal overlap in the series

$$\mathrm{M{\equiv}N{:}} \qquad \mathrm{M{=}\ddot{O}{:}} \qquad \mathrm{M{-}\ddot{F}{:}}$$

Although higher bond orders are possible in transition metal-oxygen and transition metal-fluorine bonds, the facts are on the whole expressed by the above formulation. The second condition for the occurrence of a high bond order is a sufficient supply of unoccupied d-orbitals in the transition metal, which, as a result, exists in general in a high oxidation state. Hitherto, MN multiple bonds have been found with following elements:

| | | | | | |
|---|---|---|---|---|---|
| Ti | V | Cr | Mn | Fe | |
| | Nb | Mo | (Tc) | Ru | |
| | Ta | W | Re | Os | Ir |

The most favorable conditions are provided by the elements Mo, W, Re, Ru and Os.

## 2. Bonding

### 2.1. Terminal Ligand M≡N:

The terminal nitrido ligand occurs, for example, in the tetragonal pyramidal complex anions $[MNCl_4]^-$ (M = Mo, W, Re, Ru, Os)[1-4] (see Fig. 1). The M≡N bond is ex-

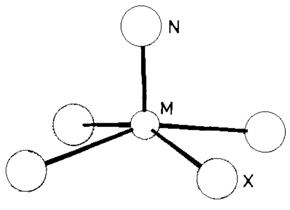

Fig. 1. Structure of anions $[MNX_4]^-$ (M = Mo, Re, Ru, Os; X = F, Cl, Br, I) with terminal nitrido ligands.

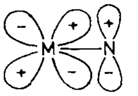
tremely short; values range between 157 pm (Ru) and 166 pm (Mo). The triple bond can be understood as a superposition of one σ bond *(1)* and two (degenerate) π bonds *(2)*.

*(1)*



*(2)*

The lone pair of electrons only bestows weak basic properties to the nitrido ligand.

## 2.2. Asymmetrical $\overset{\ominus}{M}\equiv\overset{\oplus}{N}$—M Bridges

Under certain conditions, the free electron pair at the nitrido ligand is able to form a second, significantly weaker bond to the adjacent transition metal center. The continuance of the bond axis, according to M≡N—M≡N—, leads to columnar structures, as in $ReNCl_4$[5] (Fig. 2) and $K_2ReN(CN)_4 \cdot H_2O$[6]. The ReN bond lengths differ greatly: 158 and 248 pm, 153 and 244 pm respectively. Whereas the short bond can be interpreted in the same way as the terminal one, the long bond is a σ-type, in which the occupied sp-hybrid orbital of the nitrogen overlaps with an unoccupied $d^2sp^3$-hybrid orbital of the metal, as indicated in *(3)*.

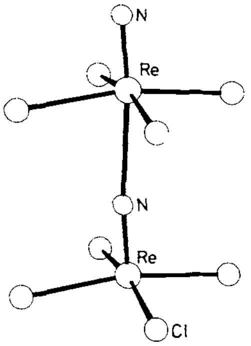


Fig. 2. Structure of $ReNCl_4$ with asymmetric nitrido bridges.

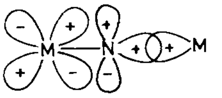
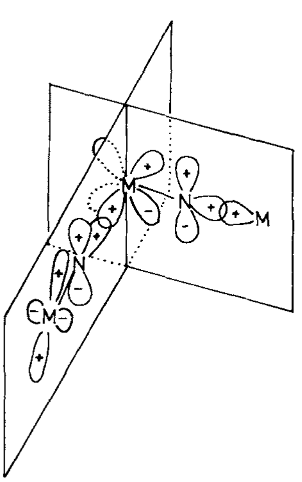


*(3)*

In this arrangement, the $d_{z^2}$- and $p_z$-orbitals involved in the hybridization of the metal are strongly and unequally involved in the σ-part of the M≡N triple bond, and hence the σ-interaction in the position *trans* to the π bond is only very weak.

A much more favorable arrangement is that shown in *(4)*, in which the second σ bond is achieved *via* an orbital perpendicular to the z-axis.

Consequently, a rectangular bonding system is formed, giving tetrameric units of type *(5)* (see Fig. 3). A zig-zag chain, which is equally possible, has not yet been observed.



*(4)*

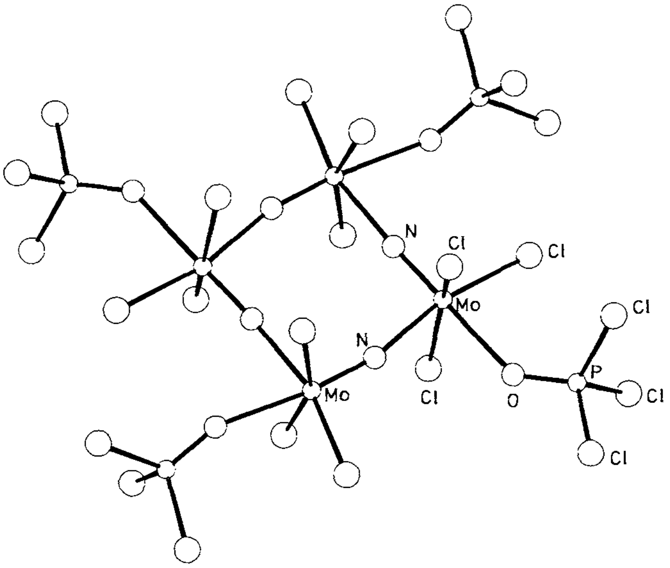


Fig. 3. Structure of the tetramer $[MoNCl_3 \cdot OPCl_3]_4$ with asymmetric nitrido bridges.

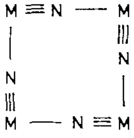
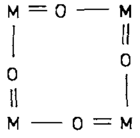
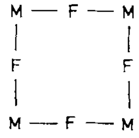


*(5)*



*(6)*



*(7)*

In fact, such tetramers occur far more frequently than polymers of the type $ReNCl_4$, as illustrated by the examples $[MoNCl_3]_4$[7] and $[MNCl_3 \cdot POCl_3]_4$ (see Fig. 3) (M = Mo, W, Re[8-10]). The long Re—N bond in the tetrameric rhenium complex is even reduced to 217 pm. It is interesting to compare these nitrido complexes with the tetrameric oxo *(6)* and fluoro complexes *(7)*, in which the differences between the alternating bond lengths decrease in the succession $[MoNCl_3 \cdot POCl_3]_4$[8], $[NbOCl_3 \cdot POCl_3]_4$[11] and $[NbF_5]_4$[12]:

| Mo≡N—Mo | Nb≡N—Nb | Nb—F—Nb | |
|---|---|---|---|
| 166 216 | 174 209 | 207 207 | [pm] |

The solvating $POCl_3$ molecules are always arranged *trans* to the π bonded ligand and are coordinated to the metal center *via* the oxygen atom (see Fig. 3). Accordingly, the bonding in the trinuclear nitridomolybdenum complex $[\{(Et_2NCS_2)_3Mo{\equiv}N\}_2Mo(S_2CNEt_2)_3]^{3+}$, which contains the Mo≡N—Mo—N≡Mo group as a structural element can be understood[13]. The structures of these types of compounds are discussed in Section 6.3.

### 2.3. Symmetrical $\overset{\frac{1}{2}\ominus}{M}=\overset{\oplus}{N}=\overset{\frac{1}{2}\ominus}{M}$ Bridges

Symmetrical nitrido bridges are observed in some binuclear complexes, *e.g.* in the recently prepared ion $[Ta_2NBr_{10}]^{3-}$[14] (see Fig. 4). The TaN bonds (185 pm) can be interpreted as double bonds. In this case, apart from two $\sigma$ bonds, the nitrido ligand forms, using the two perpendicular occupied $\pi$ orbitals, two degenerate $d\pi$-$p\pi$-$d\pi$ three centered $\pi$ molecular orbitals, each being occupied by one electron pair (see Fig. 8)[15].

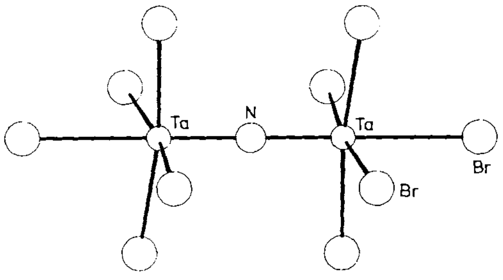


Fig. 4. Structure of the anion $[Ta_2NBr_{10}]^{3-}$ with symmetric nitrido bridges.

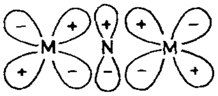

(8)

The factors responsible for the formation of symmetrical or asymmetrical bridges have not yet been completely clarified (Section 6.4). An intermediate situation is found with the nitrido bridge in the complex ion $[W_2NCl_{10}]^{2-}$[16], which contains a long (207 pm) and a short WN bond (166 pm), but where the long WN bond shows an even more distinct share of multiple bonding. This could be a consequence of one of the tungsten atoms being pentavalent and the other hexavalent, which would explain the asymmetry of the bridge. A symmetrical bridge also occurs in μ-nitrido-bis(porphyrinato)iron. To date, it is the only known nitridoiron complex[17] (see Section 6.4 for structures of these complexes).

### 2.4. N-Bridges ("Nitrido Bridges") of the Type $\overset{\ominus}{M}=\overset{\oplus}{N}=X$ (X = O, S, $PR_3$)

N-bridges of this type with X = O or S, occur in nitrosyl or thionitrosyl complexes. Nitrosyl complexes have been adequately reviewed[18] so there is no need to discuss them here further. Formally, the nitrosyl ligand is considered to be $NO^+$, which explains its extremely strong back-bonding behavior. In principle, it is suitably described by the linear arrangement M=N=O. Similar considerations seem to apply to the thionitrosyl ligand. In the complex $\pi$-$C_5H_5Cr(CO)_2NS$ it is also linear, the bond lengths CrN (169 pm) as well as NS (155 pm) suggesting $\pi$ bonding[19]. In both cases the formal oxidation number of the N atom is +3, so that these compounds are actually not real nitrido complexes.

On the other hand, this does not apply to phosphaneiminato complexes of transition metals with a linear arrangement $M=N=PPh_3$, of which three examples have already been examined by crystallographic methods[20-22]. In these complexes, real nitrido bridges are found. In the compounds $[Cl_4M=N=PPh_3]_2$ (M = Nb, Ta) (see Fig. 5) the MN- (178 pm and 180 pm respectively) and PN-bonds (164 and 159 pm respectively) can be understood as double bonds on account of their lengths; the bond angle of the bridge (171 and 177° respectively) practically corresponds to an sp-hybridization of the N atom, so that the phosphaneiminato complexes are closely related to the type discussed in Section 2.3, and should be formulated as follows:

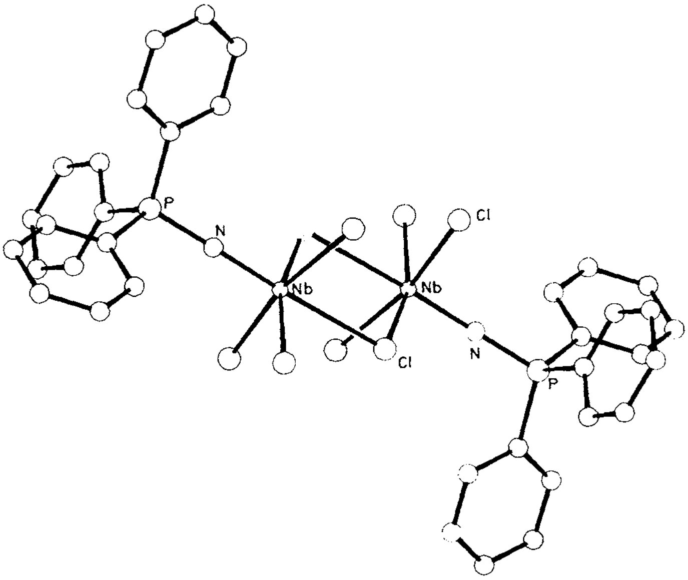

Fig. 5. Structure of the phosphaneiminato complex $[Cl_4NbNPPh_3]_2$.

$$\overset{\ominus}{M}=\overset{\oplus}{N}=PPh_3 \leftrightarrow \overset{2\ominus}{M}\equiv\overset{\oplus}{N}-\overset{\oplus}{P}Ph_3$$

### 2.5. N-Bridges ("Nitridobridges") of the Type $\overset{\ominus}{M}\equiv\overset{\oplus}{N}-X$, $M=\ddot{N}\diagdown X$ and $\overset{\ominus}{M}=\overset{\oplus}{N}R_2$

Compounds with these types of bridges have recently been reviewed[23], so they need not be discussed here in detail (for structures see Section 6.5). The ligands X, among others, are hydrogen, halogens (see Fig. 6), alkyl, aryl, silyl, $NR_2$ groups; $M\ddot{N}X$, X = $NR_2$ is a hydrazido(2−) complex.

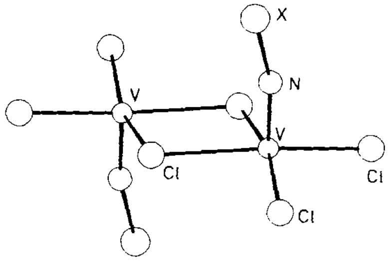

Fig. 6. Structure of the complexes $Cl_3VNX$ (X = Cl or I).

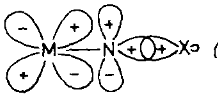
With the exception of NR and $NR_2$ respectively, all these ligands, X, in complexes of the type

$$\overset{\ominus}{M}=\overset{\oplus}{N}=\ddot{N}R \text{ or } \overset{2\ominus}{M}=\overset{\oplus}{N}=\overset{\oplus}{N}R_2$$

the ligands X show no tendency to π-bond with the central nitrogen atom, so that the N—X group has σ-character. The bonds can be interpreted in a similar way as those of M≡N—M (Section 2.2); *(9)* shows only one of the doubly degenerate π bonds of the M≡N bond.



*(9)*

The N—X σ bond thus arises *via* overlap of an sp-hybrid orbital of nitrogen with a hybrid orbital of the X-group. The bond is, contrary to the easily cleaved long bonds in the M≡N—M bridges, very stable. It should be noted that the M≡N bond of nitrene complexes (Section 6.5) should only be regarded as a triple bond when the MNX-axis is linear. This claim is supported by numerous nitrene complexes, although smaller bond angles (up to 139°) are known.

In some diazenido-complexes, which contain the $\overset{\ominus}{M}\equiv\overset{\oplus}{N}-NR_2$ group, the NN bond is shorter than a N—N single bond, so that the form $\overset{2\ominus}{M}=\overset{\oplus}{N}=\overset{\oplus}{N}R_2$ is justified.

A selection of the numerous recent examples of these types of bonds has been compiled in Table 1 (for further examples see [23]).

Table 1. Examples of structures with the characteristic groups $\overset{\ominus}{M}\equiv\overset{\oplus}{N}-X$, $\overset{\ominus}{M}=\overset{\oplus}{N}=\bar{N}R$, $\overset{\ominus}{M}\equiv\overset{\oplus}{N}-\bar{N}R_2$ and $\overset{\ominus}{M}=\overset{\oplus}{N}R_2$.

| Complex | Group | M—N [pm] | M—N—X [°] | Ref. |

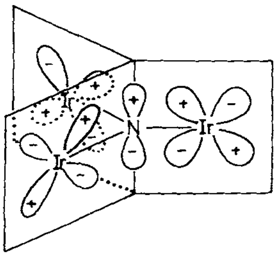
[a] diphos = ethylenebis(diphenylphosphane).

### 2.6. Nitride Bridges of the Type $M_3N$

This type of bridge has hitherto only been described in the iridium complex $(NH_4)_4[Ir_3N(SO_4)_6(H_2O)_3]$. The group $Ir_3N$ is trigonal planar; the Ir—N bond length (192 pm) indicates appreciable π bonding[38]. As shown in *(10)* the bond system can be described by three IrN σ bonds and ($p_\pi$-$d_\pi$) overlap of the occupied N($p_z$) orbital with each Ir($d_{xz}$) orbital.



*(10)*

## 3. Syntheses

The following contains a review of the most important reactions for the syntheses of nitrido compounds of transition metals. A comprehensive review, up to 1971, has been put forward by *W. P. Griffith*[39]. As far as the organoimido complexes (Section 6.5) are concerned we shall only deal with those syntheses not covered in [23].

### 3.1. Decomposition of Azides

The most effective preparative method is the reaction of azides, mostly with transition metal halides. The halogen azides, chlorine azide and because of the higher polarity of the I—N bond iodine azide, have proved to be of special utility. Thus, for example, tungsten hexachloride[40] or the pentachlorides of niobium, tantalum[41], molybdenum[40] and rhenium[42] react with chlorine azide, to form metal chloride azides:

$$WCl_6 + ClN_3 \xrightarrow[CCl_4]{} WCl_5N_3 + Cl_2 \tag{1}$$

$$MoCl_5 + ClN_3 \rightarrow MoCl_5N_3 + 1/2\,Cl_2 \tag{2}$$

The explosive metal chloride azides of molybdenum, tungsten and rhenium can be thermally decomposed in solution without any risk:

$$MCl_5N_3 \rightarrow MNCl_3 + N_2 + Cl_2 \tag{3}$$

M = Mo, W, Re

This reaction is completed within a few hours, even at room temperature[40,42]. On the other hand, the azides of niobium and tantalum are more stable and have not yet been thermally converted into nitrido complexes.

The tantalum azide $[TaCl_4N_3]_2$ has been characterized by single crystal structure analysis[41]. However, decomposition of the azides $[MN_3Cl_4]_2$ (M = Nb, Ta), occurs at room temperature upon addition of a Lewis base such as triphenylphosphane. In an analogous Staudinger reaction[43], the phosphaneiminato complexes $[Cl_4M{=}N{=}PPh_3]_2$ are obtained[21,22].

The azides $ClN_3$[44], $IN_3$[45] and $PhN_3$[46] undergo a remarkable reaction with vanadium tetrachloride; here, the NX bond of the $XN_3$ molecules is preserved and the nitrene complexes $Cl_3V{\equiv}N{-}X$ are formed (see Section 6.5). The mechanism of this reaction has not yet been clarified. In the reaction with $IN_3$, the formation of ICl and the consumption of two mol $IN_3$ per mol $VCl_4$ suggest the following reaction equation:

$$VCl_4 + 2\,IN_3 \rightarrow Cl_3V{\equiv}N{-}I + 2\,1/2\,N_2 + ICl \tag{4}$$

In the case of $ClN_3$, the intermediate azide $VCl_4N_3$ can be isolated. It presumably decomposes [eq. (6)] in a manner analogous to the Curtius reaction[47] [eq. (5)], in which an isocyanate is formed by anionotropic migration of the group R:

$$R{-}CO{-}N_3 \rightarrow R{-}N{=}C{=}O + N_2 \tag{5}$$

$$Cl_4VN_3 \rightarrow Cl_3V{\equiv}N{-}Cl + N_2 \tag{6}$$

It has been known for some time, that the reaction of organoazides with metal compounds yields nitrene complexes[23]. $MoNCl_3$ can also be prepared from $MoCl_5$ and $IN_3$; under mild conditions it is even possible to isolate an intermediate compound with an N—N bond[48]:

$$2\,MoCl_5 + 2\,IN_3 \rightarrow Cl_4Mo{=}N{-}N{=}MoCl_4 + 2\,ICl + 2\,N_2 \tag{7}$$

which can be converted into $MoNCl_3$ by thermal dissociation of $Cl_2$.

Reactions with iodine azide are transferable to metal bromides, as demonstrated by the examples for the preparation of $MoNBr_3$[49] and $WNBr_3$[72]:

$$MoBr_4 + IN_3 \xrightarrow[-IBr]{} MoBr_3N_3 \xrightarrow[-N_2]{} MoNBr_3 \tag{8}$$

$$WBr_6 + IN_3 \rightarrow WNBr_3 + IBr + Br_2 + N_2 \tag{9}$$

According to *Chatt et al.*[50], complex chloro(nitrido) compounds can be obtained by reaction of trimethylsilyl azide with molybdenum tetrachloride dissolved in acetonitrile, in the presence of complex donor molecules[50]:

$$\begin{aligned} MoCl_4(MeCN)_2 + Me_3SiN_3 + bpy \rightarrow MoNCl_3(bpy) +& \\ N_2 + 2\,MeCN + Me_3SiCl& \end{aligned} \tag{10}$$

In a similar way, the azidonitrido complexes $MoN(N_3)_3(bpy)$[51] (see Fig. 7) or $MoN(N_3)_3(py)$[52] (see Fig. 8) respectively result from the reaction of excess trimethylsilyl azide with the molybdenum(IV) complexes $MoCl_4(bpy)$ and $MoCl_4(py)_2$.

Equally, the only presently known nitrido iron complex was prepared by thermal decomposition of an azide. Azido-(α,β,γ,δ tetraphenylporphyrinato)iron(III) $(FeTPP)N_3$ reacts to form $(FeTPP)_2N$[53] with a symmetrical $Fe{=}N{=}Fe$ bridge[17]:

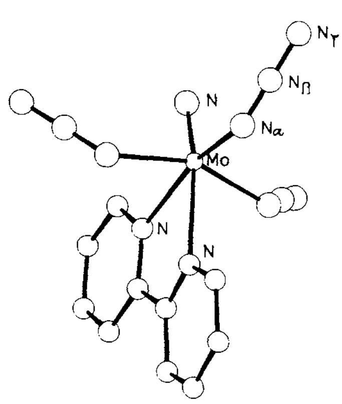


Fig. 7. Structure of the triazido(nitrido) complex $MoN(N_3)_3(bpy)$.

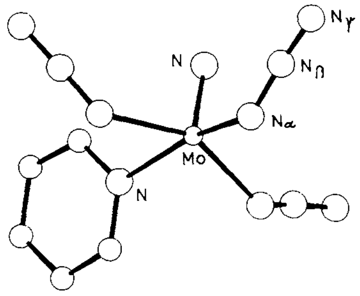

Fig. 8. Structure of the triazido(nitrido) complex $MoN(N_3)_3(py)$.

$$2\,(FeTPP)N_3 \rightarrow (FeTPP)_2N + 2\,1/2\,N_2 \tag{11}$$

Here, the nitrido ligand is able to stabilize iron in the formal oxidation state +3.5.

Even dinitrogen complexes can occasionally be converted into nitrido complexes[54]:

$$Mo(N_2)_2(diphos)_2 \xrightarrow{Me_3SiN_3} MoN(N_3)(diphos)_2 \tag{12}$$

Lastly, tetrachloronitridomolybdate is obtained from a straight-forward reaction of azide ions with molybdenum pentachloride[55]:

$$MoCl_5 + N_3^- \rightarrow [MoNCl_4]^- + N_2 + 1/2\,Cl_2 \tag{13}$$

### 3.2. Ammonolysis Reactions

The preparation of the nitridoosmate $[OsO_3N]^-$ from osmium tetraoxide and aqueous ammonia[56] has been known for some considerable time.

$$OsO_4 + NH_3 + KOH \rightarrow K[OsO_3N] + 2\,H_2O \tag{14}$$

The same holds for nitridorhenates prepared from rhenium heptaoxide[57]:

$$Re_2O_7 + 3\,KNH_2 \rightarrow K_2[ReO_3N] + K[ReO_4] + 2\,NH_3 \tag{15}$$

Recently, nitrido complexes were also prepared by thermolysis of ammonium salts[14]:

$$2\,NH_4Br + 2\,NH_4TaBr_6 \rightarrow (NH_4)_3[Ta_2NBr_{10}] + 4\,HBr \tag{16}$$

### 3.3. Reactions with Nitrogen Trichloride

Nitrogen trichloride dissolved in carbon tetrachloride reacts with $ReCl_5$ at slightly elevated temperatures[58]:

$$ReCl_5 + NCl_3 \rightarrow ReNCl_3 + 2.5\,Cl_2 \qquad (17)$$

The corresponding reaction, carried out at 0 °C, leads to the thermally sensitive nitridochloride of the heptavalent rhenium[5]:

$$ReCl_5 + NCl_3 \rightarrow ReNCl_4 + 2\,Cl_2 \qquad (18)$$

A very effective way is the synthesis of $MoNCl_3$ and $WNCl_3$ from the corresponding hexacarbonyl compounds[59]:

$$W(CO)_6 + NCl_3 \rightarrow WNCl_3 + 6\,CO \qquad (19)$$

As it is possible to obtain $NCl_3$ and $NBr_3$ from ammonium salts and halogens, the syntheses of halogeno(nitrido) complexes from ammonium halometalates and chlorine at 400—500 °C[60,61] are included in this section:

$$(NH_4)_2OsCl_6 + Cl_2 \rightarrow Os_2NCl_5 + \cdots \qquad (20)$$

Simultaneous use of ammonia and sodium hypochlorite recently led to the first nitrido[tetra(*p*-tolyl)porphyrinato]manganese(v) complex[62]:

$$Mn(TPP)OMe + NH_3 + NaOCl \rightarrow MnN(TPP) + NaCl + H_2O + MeOH \qquad (21)$$

### 3.4. Reactions with Hydrazine

Complexes of the type $ReNCl_2(PR_3)_3$ and $ReNCl_2(PR_3)_2$ can be obtained from the oxo complexes $ReOCl_3(PR_3)_2$ with hydrazine in the presence of ethanol[63–65].

### 3.5. Reaction of Vanadium Nitride with Chlorine

A method for the synthesis of halonitrene complexes, which up till now has only been verified in one case, is the reaction of vanadium nitride with gaseous chlorine; this proceeds even at 120 °C yielding $Cl_3VNCl$, as well as a small amount of $VCl_4$[66]:

$$VN + 2\,Cl_2 \rightarrow Cl_3VNCl \qquad (22)$$

Under analogous conditions, all other metal nitrides investigated yielded only pure metal halides[67].

## 4. Chemical Properties

### 4.1. Addition Reactions

Many of the reactions dealt with in this section result in formation of novel complexes with metal-nitrogen multiple bonds and are therefore useful synthetic routes to these complexes. Thus, the ternary nitridohalides $MNCl_3$ (M = Mo, W, Re, Os) and the nitridobromide $MoNBr_3$, which are associated in the crystal lattice, can be transformed into the tetrahalogeno(nitrido) complexes by treatment with the corresponding tetraphenylarsonium halides[68–71]:

$$MNCl_3 + AsPh_4Cl \xrightarrow[CH_2Cl_2]{} AsPh_4[MNCl_4] \qquad (23)$$

$$MoNBr_3 + AsPh_4Br \xrightarrow[CH_2Br_2]{} AsPh_4[MoNBr_4] \qquad (24)$$

The complex anions form tetragonal pyramids having $C_{4v}$ symmetry with the terminal nitrido ligand in an axial position.

The use of the smaller tetraethylammonium ion allowed the preparation of the six-coordinated molybdenum complex $(NEt_4)_2[MoNCl_5]$[73].

The nitrene complexes $Cl_3V{\equiv}N{-}Cl$ and $Cl_3PO(Cl_4)M{\equiv}N{-}R$ (M = Mo, W, Re; R = $CCl_3$, $C_2Cl_5$) are also capable of forming chloro complexes[33,74–76]:

$$Cl_3V{\equiv}N{-}Cl + Cl^- \rightarrow [Cl_4V{\equiv}N{-}Cl]^- \qquad (25)$$

$$Cl_3PO(Cl_4)M{\equiv}N{-}R + Cl^- \rightarrow [Cl_5M{\equiv}N{-}R]^- + POCl_3 \qquad (26)$$

In both cases, the linear group $M{\equiv}N{-}R$ is preserved. $ReNCl_4$, which is sensitive to redox reactions, is smoothly reduced to the rhenium(vi) complex by chloride or azide ions[69]:

$$ReNCl_4 + Cl^- \rightarrow [ReNCl_4]^- + 1/2\,Cl_2 \qquad (27)$$

$$ReNCl_4 + N_3^- \rightarrow [ReNCl_4]^- + 1\,1/2\,N_2 \qquad (28)$$

Phosphoryl chloride solvates the nitridohalides, forming tetrameric units having alternating long and short MN bonds. The O atom of the $POCl_3$ molecule is always arranged *trans* to the N atom at the end of the short MN bond[8–10] (see Fig. 3):

$$4\,MNCl_3 + 4\,POCl_3 \rightarrow [MNCl_3 \cdot POCl_3]_4 \qquad (29)$$

M = Mo, W, Re

In addition, the lattice of the complexes with M = W and Re contains two $POCl_3$ molecules per tetrameric unit[9,10]. With chelate ligands, such as α,α′-bipyridyl, monomeric six-coordinated complexes can be prepared[77]:

$$MoNCl_3 + bpy \rightarrow MoNCl_3(bpy) \qquad (30)$$

Relative to the strongly electrophilic character of the metal atoms, as expressed in reactions (23)—(30), the nucleophilic character of the nitrido ligand is, in general, not very distinct. Thus, neither $MoNCl_3$ nor the ion $[MoNCl_4]^-$ coordinate *via* the N atom with the strong Lewis acid $SbCl_5$. Only when the order of the MoN bond is reduced to $Mo{=}\ddot{N}$ by competitive π-interaction of fluorine ligands, is adduct formation at the nitrido ligand possible[78]:

$$[MoNF_4]^- + BF_3 \rightarrow [F_4MoN{-}BF_3]^- \qquad (31)$$

Furthermore, the oxidation state of the metal center seems to influence the donor properties of the nitrido ligand, since the rhenium(v) complexes $ReNX_2(PEt_2Ph)_3$ (X = Cl, Br) form complexes of the type $(PEt_2Ph)_3X_2Re{\equiv}N{-}BX_3$ with boron trihalides[78].

The reactions of $Cl_3V{\equiv}N{-}Cl$ with Lewis acids and Lewis bases[79] have been thoroughly investigated. Lewis bases such as phosphane or nitrogen bases always attack at the metal center. As illustrated by a crystal structure analysis of $Cl_3(bpy)VNCl$, the $V{\equiv}N{-}Cl$ group remains in linear array. $Cl_3VNCl$ does not react with Lewis acids as a base. $SbCl_5$ was used to prepare the thermally unstable trinuclear complex $Cl_3VNCl(SbCl_5)_2$, in which $Cl_3VNCl$ is linked to two molecules of $SbCl_5$ *via* Cl-bridges[79].

Sufficient nucleophilic character of the nitrido ligand is presumably a prerequisite for the formation of thionitrosyl complexes from nitrido complexes and elemental sulfur or disulfur dichloride[80]:

$$[MoN(S_2CNR_2)_3] + S \xrightarrow[CH_3CN]{} [Mo(NS)(S_2CNR_2)_3] \tag{32}$$

$R_2 = Me_2, Et_2, (CH_2)_5$

$$[ReCl_2N(PR_3)_3] + 1/2\,S_2Cl_2 \rightarrow [ReCl_2(NS)(PR_3)_3] + 1/2\,Cl_2 \tag{33}$$

$$[OsCl_3(N)L_2] + 1/2\,S_2Cl_2 \rightarrow [OsCl_3(NS)L_2] + 1/2\,Cl_2 \tag{34}$$

$L = AsPh_3, PMe_2Ph, 1/2\,bpy$

The nitrido complexes are recovered from the thionitrosyl compounds by means of tertiary phosphanes[80].

Only in the cases of ruthenium, osmium and rhenium has it been possible to obtain phosphaneiminato complexes of transition metals, containing the characteristic group $M{=}N{=}P$, using nitrido complexes and triphenylphosphane as starting materials[81,82,77]:

$$ReNCl_4 + 2\,PPh_3 \rightarrow [(Ph_3P)Cl_4Re{=}N{=}PPh_3] \tag{35}$$

More convenient for this purpose is the Staudinger reaction[21]:

$$[NbCl_4N_3]_2 + 2\,PPh_3 \rightarrow [Cl_4Nb{=}N{=}PPh_3]_2 + 2\,N_2 \tag{36}$$

The type of reaction (36) also applies to ionic azido complexes[83,84]:

$$[Cl_5MN_3]^- + PPh_3 \rightarrow [Cl_5M{=}N{=}PPh_3]^- + N_2 \tag{37}$$

$$[Br_5MN_3]^- + PPh_3 \rightarrow [Br_5M{=}N{=}PPh_3]^- + N_2 \tag{38}$$

$M = Nb, Ta$

UV-irradiation of $[Cl_5NbN_3]^-$ yielded the arsaneiminato complex $[Cl_5Nb{=}N{=}AsPh_3]^-$[84]. Several phosphaneiminato complexes of titanium and vanadium have recently been prepared by ligand exchange reactions[85]:

$$TiCl_2(S_2CNEt_2)_2 + Me_3SiNPPh_3 \rightarrow [TiCl(NPPh_3)(S_2CNEt_2)_2] + Me_3SiCl \tag{39}$$

$$VOCl_3 + 2\,Me_3SiNPPh_3 \rightarrow [VOCl(NPPh_3)_2] + 2\,Me_3SiCl \tag{40}$$

### 4.2. Substitution Reactions

Reactions of this type occur at the $M{\equiv}N$ bond as well as at the other metal-ligand bonds, resulting in the latter case, in new nitrido compounds. In general, the $M{\equiv}N$ bond is sensitive to hydrolysis, yet nitrido complexes are known which are resistant to moisture. Thus, the red $AsPh_4[MoNCl_4]$ reacts in moiste air to form the green oxo complex $AsPh_4[MoOCl_4]$[1]. The two compounds are isostructural, and the reaction could also be carried out in a single crystal. In boiling dichloromethane, the convertion of the nitrido complex into the oxo complex can even be achieved using dry oxygen[70]:

$$2[MoNCl_4]^- + O_2 \rightarrow 2[MoOCl_4]^- + N_2 \tag{41}$$

Reaction (41) is remarkable inasmuch as molybdenum(VI) is reduced to molybdenum(V) by $O_2$; however, the process cannot be reversed. The $Os{\equiv}N$ bond of the $[OsO_3N]^-$ ion is surprisingly inert towards water; the ion is transformed into the chloro(nitrido) complex by hydrochloric acid in the presence of potassium chloride[86]:

$$K[OsO_3N] + 6\,HCl + KCl \rightarrow K_2[OsNCl_5] + 3\,H_2O + Cl_2 \tag{42}$$

Recrystallization of this complex from water causes the chlorine ligand *trans* to the nitrido ligand to exchange as follows[87]:

$$K_2[OsNCl_5] + H_2O \rightarrow K[OsNCl_4(H_2O)] + KCl \tag{43}$$

Analogous reactions of the bromonitrido complexes of osmium are known[88].

Treatment of tetraphenylarsonium tetrachloro(nitrido)rhenate(VI) with thiocyanate ions in boiling methanol gives the corresponding pentakis(isothiocyanato)nitridorhenate(VI)[89]:

$$AsPh_4[ReNCl_4] + 4\,SCN^- + AsPh_4SCN \xrightarrow[CH_3OH]{} (AsPh_4)_2[ReN(NCS)_5] + 4\,Cl^- \tag{44}$$

In this complex the coordinatively unfavored position *trans* to the nitrido ligand is also occupied by an NCS group; however, the Re—N bond length is 231 pm, in contrast to a mean length of 202 pm for the four *cis*-NCS groups. The position *trans* to the nitrido ligand remains uncoordinated in exchange reactions of the $[MoNCl_4]^-$ ion[90,91]:

$$AsPh_4[MoNCl_4] + 4\,AgF \xrightarrow[CH_3CN]{} AsPh_4[MoNF_4] + 4\,AgCl \tag{45}$$

$$AsPh_4[MoNCl_4] + 4\,AgN_3 \xrightarrow[CH_2Cl_2]{} AsPh_4[MoN(N_3)_4] + 4\,AgCl \tag{46}$$

Chelate ligands such as α,α′-bipyridyl, slowly displace one chloro ligand, resulting in nitrido complexes with six-coordinated metal centers[77]:

$$[MNCl_4]^- + bpy \rightarrow [MNCl_3(bpy)] + Cl^- \tag{47}$$

$M = Mo, W, Re$

Of note is the fact that tribromonitridomolybdenum undergoes a substitution reaction with tetraphenylporphyrin[77]:

$$MoNBr_3 + H_2TPP \rightarrow [MoN(TPP)]^+Br_3^- + H_2 \tag{48}$$

The reaction of the *N*-iodine compound, $Cl_3VNI$, with bromine or chlorine produces the corresponding *N*-halogen derivatives by halogen exchange[45]:

$$Cl_3V{\equiv}N{-}I + Br_2 \rightarrow Cl_3V{\equiv}N{-}Br + IBr \tag{49}$$

$$Cl_3V{\equiv}N{-}I + Cl_2 \rightarrow Cl_3V{\equiv}N{-}Cl + ICl \tag{50}$$

Furthermore, with iodine azide, exclusively the N—I ligand reacts, to form the highly explosive *N*-azide[70]:

$$Cl_3V{\equiv}N{-}I + IN_3 \rightarrow Cl_3V{\equiv}N{-}N_3 + I_2 \qquad (51)$$

which is also obtained from the reaction of $Cl_3VNCl$ with $ClN_3$[92].

$Cl_3VNCl$ can transfer the nitrogen to 4d and 5d elements[58,70]:

$$Cl_3V{\equiv}N{-}Cl + MCl_5 \rightarrow MNCl_3 + VCl_4 + Cl_2 \qquad (52)$$
$$M = Mo,\ Re$$

The primary product is presumably $Cl_4M{-}N{\equiv}VCl_3$, in which two different metals compete for π-interaction with the nitrogen. As the d-orbitals of the 4d and 5d metals are more extensive than those of vanadium, the M≡N bond (M = Mo, Re) is favored over the VN bond, and hence the latter is cleaved.

## 5. Vibrational Spectra

In general, it is possible to determine nitrido groups or nitrene groups quickly and reliably by infrared spectroscopy, since the stretching vibrations of MN multiple bonds give rise to very strong absorptions at characteristic frequencies (for examples see Table 2). Because of the intense color of most of the substances, the vibrational data are, on the whole, confined to IR spectra; Raman spectra have only been recorded in a very few cases.

Compounds with terminal bonds of the type M≡N: normally exhibit a very intense MN stretching vibration in the region 1000—1100 cm$^{-1}$, when the metals have the oxidation number (+VI). The MN-vibration thus occurs at least 100 cm$^{-1}$ higher than the corresponding MO stretching modes, so that they can generally be easily distinguished. An exception is ν(MoN) in $[MoNF_4]^-$ at 969 cm$^{-1}$; this is, however, a result of the competitive π bonding of the fluorine ligands. When the metal is reduced to the oxidation state (+V) or (+IV), the wave number of the MN vibration is lowered to about 950 cm$^{-1}$. In structurally comparable species, depending on the position of the metal within the periodic table, the wave numbers increase from left to right along a period and generally down a group, as shown by the following examples:

$[WNCl_4]^-$ 1036 cm$^{-1}$ [68], $[ReNCl_4]^-$ 1085 cm$^{-1}$ [69],
$[OsNCl_4]^-$ 1123 cm$^{-1}$ [100],
$[RuNCl_3(AsPh_3)_2]$ 1023 cm$^{-1}$ [82], $[OsNCl_3(PEt_3)_2]$ 1070 cm$^{-1}$ [82]

The reason for this appears to be the increased ability of transition metals to effect π-overlap, which proceeds in the same direction.

Table 2. Selected frequencies of MN stretching vibrations in complexes with MN multiple bonds. 0 = P or As.

| Terminal Type M≡N: | ν(M≡N:) [cm$^{-1}$] | Ref. | Bridge Type $\overset{\ominus}{M}{\equiv}\overset{\oplus}{N}{-}M$ | ν(M≡N) [cm$^{-1}$] | Ref. |

| $[OsO_3(NR)]$ | 1184-1215 | | [86, 104] | | | | |

A similar spectroscopic situation is found in compounds with M≡N—M bridges. A strong absorption in the region of 1000—1100 cm$^{-1}$, which is occasionally split, corresponds to the stretching vibration of the short MN bond. No data is available on the vibrational frequency of the long MN bond, however this is expected to occur at very low wave numbers (<200 cm$^{-1}$). This is also the reason for the absence of significant coupling: ν(M≡N) for this type of bridge occurs in the same region as ν(M≡N) for the terminal type. The few spectra of complexes with symmetrical M=N=M bridges hitherto reliably studied, form a similar picture. Here, the two stretching vibrations should be regarded as $\nu_s$(M=N=M) and $\nu_{as}$(M=N=M); the latter appear again between 1000 and 1100 cm$^{-1}$. Since the symmetrical vibration leaves the N atom unmoved, it has a very low wave number.

An interesting aspect of the vibrational spectra of anions of the type $[X_5M{=}N{=}MX_5]^{n-}$ and of the corresponding μ-oxo complexes is a strong, sharp band which occurs at

520—540 cm$^{-1}$ in the μ-nitrido compounds and at 400—470 cm$^{-1}$ in the μ-oxo compounds, first mentioned by *Mattes et al.*[93].

Its assignment is problematic, since except for the asymmetric vibration of the bridge $\nu_{as}(M_2N)$, no absorption is expected above 500 cm$^{-1}$, this being the upper limit of the characteristic region for metal-halogen stretching vibrations. *Mattes et al.* assigned this vibration to a $\rho$(XMO) or $\rho$(XMN) mode of the species $E_u$. The IR spectrum of the anion $[Ta_2NBr_{10}]^{3-}$, apart from $\nu_{as}(Ta_2N)$ at 985 cm$^{-1}$, also shows a band of medium intensity at 735 cm$^{-1}$. This has been tentatively assigned to the bridge deformation vibration $\delta(M_2N)$[14], which due to the high mass of the $TaBr_5$ groups lies at a higher wave number than the symmetrical vibration of the bridge $\nu_s(M_2N)$.

Apparently, the situation in the anion $[W_2NCl_{10}]^{2-}$ cannot be compared herewith; this ion contains an asymmetric nitrido bridge. Here, two absorptions occur at 1015 cm$^{-1}$ and 944 cm$^{-1}$, which are assigned to WN stretching modes[16].

The vibrations of bridges of the types $M{=}N{=}X$ and $M{\equiv}N{-}X$ have to be regarded in a somewhat different way. Depending on the frequency of the NX stretching vibration, strong couplings are observed in some cases, which permit the MN stretching mode to be considered as a characteristic vibration, to a limited extent. In the phosphaneiminato complexes, significant π bonding of the $M{=}N{=}P$ type can be attributed to the PN bond on account of its short length. Here, a strong band, generally above 1100 cm$^{-1}$ is usually found (occasionally split into a doublet as a consequence of Fermi resonance), and a second band appears between 500 cm$^{-1}$ and 600 cm$^{-1}$. The former is normally described as $\nu$(PN), the latter as $\nu$(MN); more correctly these should be $\nu_{as}$(MNP) and $\nu_s$(MNP). Undoubtedly the frequencies of both vibrations are influenced by strong coupling, which accounts for the low wave number of the MN stretching vibration. Similar conditions are encountered in nitrosyl metal complexes where the MNO group is linear:

$$\overset{\ominus}{M}{=}\overset{\oplus}{N}{=}\ddot{\underset{\cdot\cdot}{O}} \quad \text{or} \quad \overset{2\ominus}{M}{-}\overset{\oplus}{N}{\equiv}\overset{\oplus}{O}{:}$$

In these cases $\nu$(NO) is assigned to frequencies between 1600 and 1700 cm$^{-1}$, and $\nu$(MN) to that at *ca.* 500 cm$^{-1}$.

On the other hand, in compounds with $M{\equiv}N{-}X$ bridges in which the ligand X does not display π bonding to the N atom, $\nu$(MN), by analogy with nitrosyl complexes, appears shifted to shorter and $\nu$(NX) to longer wave lengths as a result of vibrational coupling. The decreasing influence of coupling is especially evident in the series of compounds $Cl_3V{\equiv}N{-}X$, in which the linear arrangement of the VNX group has been confirmed by crystal structure analyses ($X = Cl$[94]; $X = I$[95]):

| | $Cl_3V{\equiv}N{-}Cl$ [44] | $Cl_3V{\equiv}N{-}Br$ [45] | $Cl_3V{\equiv}N{-}I$ [45] |
|---|---|---|---|
| $\nu$(VN) | 1107 | 1032 | 963 |
| $\nu$(NX) | 510 | 435 | 390 |

When X is an organic group, $\nu$(MN) appears at even shorter wavelengths, generally between 1200 cm$^{-1}$ and 1300 cm$^{-1}$; in this case $\nu$(NC) is shifted to longer wavelengths by more than 100 cm$^{-1}$ relative to uncoupled $\nu$(NC) stretching vibrations. Similar behavior is found in the carbyne complexes $M{\equiv}C{-}R$[96], which are related to the bridges of the type $M{\equiv}N{-}X$.

## 6. Crystal Structures

A remarkable feature of all crystal structures of nitrido and nitrene complexes (Section 6.5) is the extremely short metal-nitrogen bond length and the distinct *trans*-effect of the π bonded nitrogen ligand.

After a brief consideration of the *trans*-effect, the compounds will be discussed in detail. Characteristic data of selected compounds are compiled in Tables 3 to 7 (for the problem bond length/bond order in MoN bonds see [105]).

### 6.1. The *trans*-Effect

The *trans*-effect is the weakening of the bond to a ligand, coordinated in a position *trans* to a ligand which is particularly strongly bonded, so that substitution reactions preferentially take place at this site (see Section 4.2). Not only is the weakening evident in reactions but it is also expressed by the differences observed in the bond lengths between the central atom and *cis* or *trans*-positioned ligands: this difference can amount to 30 pm in mononuclear complexes. In the previously mentioned complex, $[ReN(NCS)_5]^{2-}$[89], the Re(NCS) bond length is 202 pm for the *cis*-ligand (relative to the nitrido nitrogen) and 231 pm for the *trans*-ligand. A similar situation is found in $[OsNCl_5]^{2-}$ (236 pm and 261 pm respectively)[106] (Fig. 9).

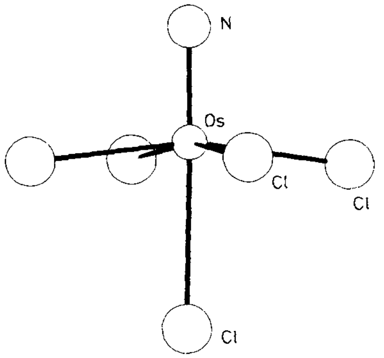

Fig. 9. Structure of the anion $[OsNCl_5]^{2-}$ with a terminal nitrido ligand.

Frequently, the *trans*-effect is so strong, that the *trans*-position is not occupied at all. As a result, in a solution of pentachloro(nitrido)molybdate in $CH_2Cl_2$, an equilibrium is observed:

$$[MoNCl_5]^{2-} \rightleftharpoons [MoNCl_4]^- + Cl^-$$

In the azido(nitrido) complex $MoN(N_3)_3(bpy)$[51] (Fig. 7) the bipyridyl ligand is bonded asymmetrically, since the nitrogen atom in the *trans*-position to the nitrido ligand can only bond very weakly to the molybdenum atom. In attempts to prepare the analogous pyridine complex, the *trans*-position remains unoccupied and the resulting compound, $MoN(N_3)_3(py)$[52] with coordination number five is formed (Fig. 8).

In general, the *trans*-effect has been attributed to electronic influences. According to *Grinberg*[107], an easily polarizable ligand causes polarization at the central atom, giving rise to an accumulation of negative charge at the *trans*-position, and, in consequence, to repulsion of the *trans*-ligand's electron sphere.

*Chatt et al.*[108] and *Orgel*[109] have interpreted the *trans*-effect as deriving from a strong $\pi$ bond. As two ligands located in *trans*-position to each other compete for the same atom orbitals, increased overlap on one side of the central atom results in a decrease of electron density and thus a weakening of the bond on the other side. This interpretation explains the distinct *trans*-effect of the nitrido ligand, which is exceedingly strongly bonded by two $\pi$ bonds in planes perpendicular to one another. It is however possible to account for the *trans*-effect with purely steric arguments. This opinion was first expressed by *Bright* and *Ibers*[106] and later by the authors[5,8]. Accordingly, the *trans*-effect is a consequence of the mutual repulsion of the ligands. The nitrido atom, which is extremely close to the central atom, displaces the *cis*-positioned ligands to the other side of the central atom. The latter atom is therefore situated above the plane of the four *cis*-positioned ligands in an octahedral coordination. Thus, the sixth coordination site can be occupied only by a weakly bonded ligand at a greater distance.

In this model it is assumed that the six ligands bonded to the same central atom already have the minimum distance to each other. If the central atom bonds especially strongly to one ligand, it is displaced from the center of the octahedron towards this ligand, thus weakening the bond to the *trans*-position.

This concept is supported by the fact that the *trans*-effect occurs particularly frequently in the sterically unfavorable square planar coordination.

Both $ReNCl_2(PPh_3)_2$[110], coordinated in the form of a tetragonal pyramid, and the octahedral $ReNCl_2(PEt_2Ph)_3$[111], have been investigated crystallographically by *Ibers et al.*, and clearly show the steric influence. In the latter six-coordinate complex the inter-ligand repulsion is so strong, that even the nitrido ligand is forced away to a bond length of 179 pm. In the five-coordinate complex only two bulky phosphane ligands are bonded to rhenium. The ReN bond length is 160 pm, which is the value expected for a triple bond. It is interesting to note, that the analogous tris(triphenylphosphane) complex $ReNCl_2(PPh_3)_3$ does not exist, presumably for similar steric reasons.

## 6.2. Structures of Mononuclear Nitrido Complexes with Square Pyramidal and Octahedral Coordination

Nitrido complexes having the stoichiometry $[MNX_4]^-$ (M = Mo, Re, Ru, Os; X = F, Cl, Br, I, $N_3$) form tetragonal pyramids with the nitrido ligand at the apex (Fig. 1). In all cases the metal atom M is situated about 55 pm above the pyramid's base. All complexes $[MNX_4]^-$, which were investigated crystallographically, have tetraphenylarsonium ions as cations since this combination was found to produce readily crystallizable products. An interesting crystallographic publication concerning AB types with $EPh_4^+$ ions (E = P, As, Sb) should be mentioned here[112]. The most important geometrical details of the complex ions are specified in Table 3, including the compounds $MoN(N_3)_3(py)$[52], $ReN(S_2CNEt_2)_2$[113] and $ReNCl_2(PPh_3)_2$, in which the coordination of the central atom is also approximately tetragonal pyramidal.

Table 3. Characteristic bond lengths and angles in selected mononuclear nitrido complexes with tetragonal pyramidal coordination.

| Compound | Bond length [pm] $M{\equiv}N$ | $M{-}X$ | Angle [°] NMX | Ref. |
|---|---|---|---|---|
| $AsPh[MoNF_4]$ | 183 | 173 | 99 | [90] |
| $AsPh_4[MoNCl_4]$ | 166 | 234.5 | 101.5 | [1] |
| $AsPh_4[MoNBr_4]$ | 163 | 248.8 | 103 | [71] |
| $AsPh_4[MoN(N_3)_4]$ | 163.0 | 206.8 | 99.5 | [91] |
| $MoN(N_3)_3(py)$ | 163.5 | 204.3 | 102.2 | [52] |
| $AsPh_4[ReNCl_4]$ | 162 | 232.2 | 103.5 | [69] |
| $ReN(S_2CNEt_2)_2$ | 165.6 | 239.1 | 107.7 | [113] |
| $ReNCl_2(PPh_3)_2$ | 160.3 | 237.7 [a] | 109.7 [a] | [110] |
| | | 244.8 [b] | 98.4 [b] | |
| $AsPh_4[RuNCl_4]$ | 157.0 | 231.0 | 104.6 | [3] |
| $AsPh_4[OsNCl_4]$ | 160 | 231.0 | 104.6 | [4] |
| $AsPh_4[OsNI_4]$ | 163 | 266.2 | 103.7 | [114] |

[a] X = Cl. [b] X = P.

It is interesting to compare the structures of $MoN(N_3)_3(py)$[52] and $[MoN(N_3)_4]^-$[91]. In the complex $MoN(N_3)_3(py)$ (Fig. 8), steric effects cause the azide groups to arrange so that the free electron pair of the $sp^2$-hybridized $N_\alpha$ atom points radially away from the nitrido ligand. The same configuration exists in three of the four azide groups of $[MoN(N_3)_4]^-$. The fourth group, which occupies the site of the pyridine ligand, is oriented in the op-

Table 4. Characteristic bond lengths and angles in selected mononuclear nitrido complexes with octahedral coordination.

| Compound | Bond length [pm] $M{\equiv}N$ | $M{-}X_{cis}$ | $M{-}X_{trans}$ | Average Angle [°] NMX | Ref. |
|---|---|---|---|---|---|
| $K_2[OsNCl_5]$ | 161 | 236.2 | 260.5 | 96.2 | [106] |
| $AsPh_4[ReN(NCS)_5]$ | 166 | 202.1 | 230.1 | 96.0 | [89] |

| | | | | 100.6 [d] | |

[a] X = Cl. [b] X = P. [c] X = bpy. [d] X = $N_3$.

posite direction, so that its free electron pair is located in the vicinity of the nitrido ligand.

Complexes with the coordination number five generally have the sterically favorable trigonal pyramidal geometry. In the nitrido complexes, however, the *trans*-effect of the nitrido ligand forces the formation of a tetragonal pyramid. In some cases the tetragonal pyramid can be replenished to form an octahedron by an additional, less tightly bonded ligand (Fig. 9). Some selected complexes of this kind are given in Table 4. Even in the octahedral complexes, the central atom is situated above the plane of the *cis*-positioned ligands. Yet the distance here (about 20 pm) is smaller than in the tetragonal pyramids.

Except for two examples, the M≡N bond lengths range from 157 to 166 pm. A comparison of the values in Tables 3 and 4 shows that oxidation state and coordination number have practically no effect on the bond lengths, which correspond to M≡N triple bonds. In $[MoNF_4]^-$[90] the $\pi$-donor ability of the fluorine ligands accounts for the very long MoN bond length which is equivalent to a low bond order, as determined from the low frequency of the MoN stretching vibration (Section 5).

Steric reasons account for the great length of the ReN bond in $ReNCl_2(PEt_2Ph)_3$[111] (Section 6.1).

### 6.3 Structures of Polynuclear Complexes with Asymmetrical Nitrido Bridges $\overset{\ominus}{M}\equiv\overset{\oplus}{N}-M$

As mentioned in Section 2.1, the free electron pair of the nitrido ligand renders it weakly basic and it can form a weak dative bond with another metal atom, resulting in a linear, highly asymmetrical nitrido bridge. This type of bridge gives rise to binuclear, trinuclear and tetranuclear complexes, as well as polymeric structures. The anion $[W_2NCl_{10}]^{2-}$[16] has hitherto been the only example of the species $[M_2YX_{10}]^{n-}$ with M = transition metal, Y = O or N and X = Cl or Br, in which an asymmetric bridge is observed. Here, it is assumed that the different oxidation states of the tungsten atoms are the decisive factor. Participation of the $d^1$ system of the tungsten(v) atom, leading to Jahn-Teller stabilization, in the $[W_2NCl_{10}]^{2-}$ ion also seems to be evident from the W...W distance (373 pm). This is significantly shorter than the W...W distance in $[WNCl_3\cdot POCl_3]_4\cdot 2\,POCl_3$ (386 pm)[9], but exactly the same as in $(HNMe_3)_2[W_4O_8Cl_4(OH_2)_4]\cdot 2\,H_2O$, which contains linear WOW bridges with alternating $W^V$ and $W^{VI}$ atoms[115].

Table 5. Characteristic bond lengths and angles in selected polynuclear complexes with asymmetric nitrido bridges $\overset{\ominus}{M}\equiv\overset{\oplus}{N}-M$.

| $\{K_2[ReN(NC)_4]\cdot H_2O\}_\infty$ | 153 | 244 | 213 [c] | — | 180 | 100 | [6] |

[a] X = Cl. [b] X = O. [c] X = N.

Further evidence should be provided by the planned structural analyses of complexes of the type $(PMe_2Ph)_3$-$Cl_2ReNMoCl_4(NCEt)$[116], which exhibit a nitrido bridge between different metal atoms.

In the trinuclear complex $[(Et_2NCS_2)_3Mo{\equiv}N]_2$-$Mo(S_2CNEt_2)_3(PF_6)_3$[13], the central Mo atom accepts the free electron pairs of two neighboring Mo≡N: groups forming a slightly bent chain Mo≡N—Mo—N≡Mo. The bond lengths in the Mo≡N—Mo bridges are, within the limits of error, the same as in $[MoNCl_3]_4$[7].

The numerous tetrameric cyclic structures are completely planar and approximately square, the edges being formed by the M≡N—M bridges (Fig. 3). The small deviation of the nitrido bridge from linearity is caused by steric effects. The van der Waals distances of neighboring N atoms within the MN eight-membered ring are comparatively short; hence, these atoms are pushed outwards slightly. Again, the strong *trans*-effect (see Section 6.1.) directs the most weakly bonded ligand to occupy a position *trans* to the nitrido ligand. In $[MoNCl_3]_4$, a Cl atom of a neighboring tetramer occupies this position and forms a very weak Cl bridge. In the $POCl_3$ adducts, $[MNCl_3\cdot OPCl_3]_4$ (Fig. 3), the *trans*-position is occupied by the oxygen atom of the Lewis base $POCl_3$. The Mo—N eight-membered ring has the same geometry in the adduct as in pure $[MoNCl_3]_4$.

$ReNCl_4$[5] and $K_2[ReN(CN)_4]\cdot H_2O$[6] form polymeric linear chains. Here, the ReN single bonds are very long (248 and 244 pm) in contrast to the other complexes with asymmetrical bridges, since they are located in *trans*-positions and are sterically influenced by the ligands in the *cis*-positions.

It is interesting to note that the MN bond length is evidently not significantly affected by the donating function of the free electron pair. The M≡N bond lengths of the tetrameric complexes in Table 5 are therefore, within the limits of error, the same as in the compounds with terminal nitrido ligands (Tables 3 and 4). Extremely short ReN bond lengths are observed in the polymers $[ReNCl_4]_\infty$[15]

and $\{K_2[ReN(CN)_4]\cdot H_2O\}_\infty$[6], however, these values have relatively high standard deviations.

## 6.4. Structures of Binuclear Complexes with Symmetrical Nitrido Bridges $\overset{\frac{1}{2}\ominus}{M}=\overset{\oplus}{N}=\overset{\frac{1}{2}\ominus}{M}$

Symmetrical nitrido bridges, $M=N=M$, are exclusively observed in binuclear complexes. When the bridges are linearly continued to form oligomeric and polymeric chains, *e.g.* in $[(Et_2NCS_2)_3Mo\equiv N]_2Mo(S_2CNEt_2)_3(PF_6)_3$[13] and in $[ReNCl_4]_\infty$[5], the *trans*-effect prevents formation of symmetrical nitrido bridges. It is however surprising, that asymmetrical bridges also occur in the tetrameric ring structures of the type $[MoNCl_3]_4$[7], since the *trans*-effect has no direct influence there. It might be possible—as in the *trans*-effect—to invoke steric effects to account for the formation of an asymmetrical bridge. The MN eight-membered ring is strained, because neighboring N atoms in the ring are situated very close to each other. Consequently, the ring is extended slightly and the nitrido bridge bonds consequently lengthened. In a symmetrical bridge this lengthening would unfavorably affect π overlap, whereas in an asymmetrical arrangement it would only influence the σ bond which is known to tolerate longer bond lengths.

In accord with this supposition, an increase in the metal-metal bond lengths of the nitrido bridges from dimeric (332—370 pm) to tetrameric (381—384 pm) and polymeric (397—406 pm) complexes is observed.

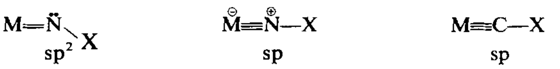
Metal-metal distances as short as 332 pm (in the iron complex $[Fe(TPP)]_2N$[17]) are possible in the symmetrical nitrido bridges of binuclear complexes, since the *cis*-positioned ligands can move away from both sides of the nitrido ligands. Thus, the metal atoms are located about 20—30 pm above the plane of the *cis*-ligands. The *trans*-position either remains unoccupied, as in the porphyrinatoiron complex, or is coordinated by a relatively weakly bonded ligand. In the ruthenium complex $[Ru_2NCl_8(H_2O)_2]^{3-}$[117] (Table 6), this ligand is a water molecule, and in $[Ta_2NBr_{10}]^{3-}$[14] a bromine atom, with a TaBr bond 23 pm longer than the bonds of the *cis*-ligands.

The metal-nitrogen bond lengths (Table 6) in the symmetrical nitrido bridges are, in view of their double bond character, longer than those in terminal nitrido ligands (Table 3). They correspond well to the values[118] expected for double bonds. In agreement with the conception of the $(d_\pi\text{-}p_\pi\text{-}d_\pi)\text{-}\pi$ overlap (Section 2.3.) in the nitrido bridge, the *cis*-ligands of the two metal atoms are arranged in eclipsed positions to each other. The complexes $[Ru_2NCl_8(H_2O)_2]^{3-}$, $[Os_2NCl_{10}]^{4-}$ and $[Ta_2NBr_{10}]^{3-}$ have $D_{4h}$ symmetry. However, it is surprising to find a staggered configuration in the iron complex $[Fe(TPP)]_2N$ with the porphyrinato ligands twisted at a torsion angle of 58°.

## 6.5. Structures of Complexes with N-Bridges ("Nitrido Bridges") $\overset{\ominus}{M}\equiv\overset{\oplus}{N}-X$ and $M=\ddot{N}\diagdown_{X}$

Complexes with the groups $M\equiv N-X$ or $M=\ddot{N}-X$ are formally derived from amines $H_2N-X$, by substitution of the two hydrogen atoms by a metal atom. In the case of transition metals in high oxidation states, the free electron pair of the nitrogen atom participates in the MN bond, resulting in a linear MNX-arrangement with a $M\equiv N$ triple bond. A bent MNX structure with an $sp^2$-hybridized nitrogen atom is only observed when the metal atom attains an inert gas configuration without the free electron pair of the nitrogen. In contrast to this, corresponding compounds of the main group elements always show a bent arrangement[79].

In order to distinguish both types, we have proposed the terms "imido" and "nitrene" complexes[79]:



$$M=\ddot{N}\diagdown_{X} \qquad \overset{\ominus}{M}\equiv\overset{\oplus}{N}-X \qquad M\equiv C-X$$

$sp^2$ | sp | sp

imido complex | nitrene complex | carbyne complex

In the electrophilic nitrene complexes a nitrene $\underset{\cdot\cdot}{\ddot{N}}-X$ is formally stabilized by bonding to the transition element. This makes them formally similar to the carbyne complexes. The nucleophilic imido complexes, on the other hand, are characterized by a free electron pair at the nitrogen atom.

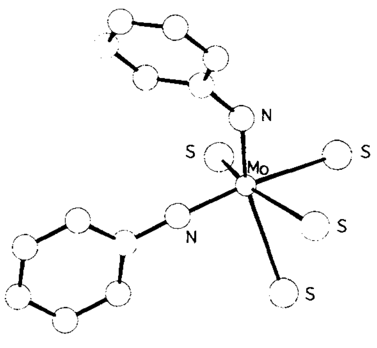


Fig. 10. Detail from the structure of the *cis*-bis(diethyldithiocarbamato)bis(phenylimido)molybdenum complex $Mo(NPh)_2(S_2CNEt_2)_2$ with bent imido and linear nitrene geometry. For the sake of clarity, only the S atoms of the diethyldithiocarbamato ligands are shown.

Table 6. Characteristic bond lengths and angles in binuclear complexes with symmetrical nitrido bridges $\overset{\frac{1}{2}\ominus}{M}=\overset{\oplus}{N}=\overset{\frac{1}{2}\ominus}{M}$.

| Compound | Bond length [pm] | | | Angle [°] | | Ref. |
|---|---|---|---|---|---|---|
| | $M=N$ | $M-X_{cis}$ | $M-X_{trans}$ | $M=N=M$ | $N=M-X_{cis}$ | |
| $K_3Ru_2NCl_8(OH_2)_2$ | 172.0 | 236 [a] | 218 [b] | 180 | 94.7 | [117] |
| $(NH_4)_3Ru_2NCl_8(OH_2)_2$ | 172.5 | 238 [a] | 220 [b] | 180 | 95 | [119] |
| $Cs_4Os_2NCl_{10}$ | 177.8 | 237.1 | 243.4 | 180 | 93.7 | [123] |
| $(NH_4)_3Ta_2NBr_{10}$ | 184.9 | 251.4 | 273.8 | 180 | 94.1 | [14] |
| $Os_2N(S_2CNMe_2)_5$ | 166.1 | 240 | 242 | 165 | 98 | [120] |
| $[(TPP)Fe]_2N$ | 176 | 199.1 [c] | — | 180 | 99.2 | [17] |

[a] X = Cl. [b] X = O. [c] X = N.

Complexes with a bent "imido" geometry have hitherto been rarely observed; in addition, the expected bond angle of 120° for $sp^2$-hybridization is significantly exceeded, whereas in compounds of main group elements, the corresponding angle is 120° or usually even smaller.

An example of an imido transition metal complex is the molybdenum compound $MoOCl_2(NH)(OPEtPh_2)_2$[28] in which the angle is 157°. The complexes *cis*-$Mo(NPh)_2(S_2CNEt_2)_2$[30] (Figure 10) and $OsO_2[NC(CH_3)_3]_2$[121] each contain a bent and a linear MNR group (see Table 7).

| $OsO_3$(N-Adamantyl) | 169.7 | 144.8 | 171.4 | [121] |
| $OsO_2[NC(CH_3)_3]_2$ | 171.0<br>171.9 | 143<br>145 | 178.9<br>155.1 | [121] |
| $RuCl_3(NPEt_2Ph)(PEt_2Ph)_2$ | 184.1 | 158.6 | 174.9 | [20] |
| $[NbCl_4(NPPh_3)]_2$ | 177.6 | 163.7 | 171.1 | [21] |
| $[TaCl_4(NPPh_3)]_2$ | 180.1 | 159.3 | 176.8 | [22] |

The metal-nitrogen distance in nitrene complexes is consistent with the value expected for a triple bond. A lengthening of the MN bond in the linear form $M{\equiv}N{-}X$ is only observed in the latter cases, in which there is a large supply of electrons and one of the two MNX groups is bent.

It is interesting to consider the NX bond lengths in the nitrene complexes more closely. On account of sp-hybridization of the nitrogen atom, the bonds are always significantly shorter than in $sp^3$-hybridization. In $Cl_3V{\equiv}N{-}Cl$[94] and $Cl_3V{\equiv}N{-}I$[95] (Fig. 6), for example, the shortest hitherto measured N—Cl and N—I bond lengths have been observed (Table 7): the values being respectively *ca.* 17 and 22 pm smaller than in halogen amines. Approximately the same difference is found in C—Cl bonds in halogen alkanes and alkynes.

Apart from halogens, organic groups and amino groups, the substituent, X, in nitrene complexes can also be an organophosphorus group. The resulting phosphaneiminato complexes also exhibit an almost linear configuration of the $M{=}N{=}PR_3$ group (see Fig. 5), in which the following mesomeric structures can be assumed on account of the observed bond lengths:

$$\overset{2\ominus}{M}{\equiv}\overset{\oplus}{N}{-}\overset{\oplus}{P}R_3 \leftrightarrow \overset{\ominus}{M}{=}\overset{\oplus}{N}{=}PR_3$$

In all cases the MNP unit is slightly bent, the bond angle being about 174°. This can be explained by $p_\pi$-$d_\pi$ overlap in the NP bond, since in the tetrahedral coordination of the phosphorus only the less favorable orbitals $d_{z^2}$ or $d_{x^2-y^2}$ can be utilized for the π bond[20].

## 7. Future Prospects

Since the fundamental investigations of *Goubeau*[124], who suggested that multiple bonds between two elements outside the first row of eight elements can occur under certain conditions, many examples have been found experimentally. Transition metals can form multiple bonds with each other, as well as with carbon, nitrogen and oxygen. The still new field of metal-nitrogen multiple bonds is rapidly expanding. Apart from the attractive structural chemistry and the remarkable bonding of these compounds, considerable stimulus has arisen from attempts to develop models of $N_2$-assimilation. Starting with the fixation of a $N_2$ molecule at a molybdenum center, the formation of the nitridomolybdenum group is an important step towards the production of ammonia in which the nitrogen is transformed into a form utilizable by plants. However, much still has to be done to clarify the complex paths of such sequences of reactions and to simulate them in the laboratory.

*We thank the Verband der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for their generous financial support of our investigations. We also wish to extend our thanks to the many co-workers who have contributed significantly to this field.*

# Photoelectron Spectra and Molecular Properties: Real-Time Gas Analysis in Flow Systems[**]

**New analytical methods (20)**

By Hans Bock and Bahman Solouki[*]

*Dedicated to Professor Heilbronner on the occasion of his 60th birthday*

For the analysis and optimization of numerous gas phase reactions in flow-systems, photoelectron spectroscopy has proven most valuable. This real-time measuring probe allows one to determine—with millimol quantities and within a few hours—the temperatures for different decomposition channels. Simultaneously, main products are characterized and, if need be, their yield can be improved. By careful performance of the experiment, short-lived and/or reactive molecules such as $P_2$, thioformaldehyde or silabenzene can be detected. PE-spectroscopic gas analysis is of particular advantage in the search for heterogeneous catalysts; they can be tested within a day using gas mixtures of varying composition over the temperature range from 300 K to 1300 K. In addition, PE-spectrometers are well-suited for on-line connection to computers; portable instruments for laboratory use are under development.

> *"Besser ist's doch wie gar nichts"*
> (Karl Valentin[1])

## 1. Introduction

The diversity and extent of instrumental analysis in the chemist's everyday routine foster scepticism towards any further method of measurement. Nonetheless, it will be attempted in this publication to present the scope of an analytical procedure for flowing gases and at the same time to focus one's attention more strongly on preparative gas phase reactions.

The topic in question is photoelectron spectroscopy, on whose "inner annular rings"—development of the method[2-5], commercial availability of high-resolution spectrometers, and the measurement of the ionization energies of thousands of molecules[2-9]—is now growing throughout the world, a more applications-related "bark". PE-spectroscopic band patterns can serve as "molecular fingerprints" for visually monitoring the course of gas phase reactions. Those of the parent molecules vanish, whereas those of the products emerge. In the following, we will report on how to "read" these band patterns[11-12], on some technical aspects of the apparatus, and on examples for gas phase reactions that can be PE-spectroscopically optimized[3,10]. This last topic ranges from temperature-dependent equilibria *via* pyrolyses, partly with detection of short-lived intermediates, to syntheses, especially with regard to heterogeneous catalysis. In the closing sections, an up-to-date summary will attempt to point out strengths and weaknesses of PE-spectroscopic gas analysis, especially in comparison to other well-established analytical methods such as gas chromatography, mass or vibrational spectroscopy.

## 2. Ionization Patterns as "Molecular Fingerprints"

Figure 1 shows a dozen PE-spectra which have been chosen as close to reality as possible in such a way that the molecules presented could occur as components of a synthesis gas mixture, an alkane bromination, or a cracking product fraction. Here, they serve as an introduction to "reading" ionization band patterns—divided according to number, shapes and regions of characteristic ionization bands. In conclusion we shall deal with how to make a qualitative estimation of expected values for ionization energies[3-7,12,13], or how to calculate them using different approximation methods and outline which criteria the ionization pattern must fulfill in order to enable a PE spectroscopic gas analysis.

### 2.1. Number of Bands

In general, PE-spectra in the range between 9 and 18 eV suffice for gas analyses (Fig. 1). The usual complete helium(I) measuring range of an instrument extends from 6 eV to 21 eV and encompasses, *e.g.*, the first ionization energy, amounting to $IE_1 = 6.01$ eV, of the phosphorus ylide

Tabatabai,* "Novel Radical Ions: Generation and Properties—An Interim Report on PES and ESR Investigations by the Frankfurt Photoelectron Group" *in J. Bargon:* Computational Methods in Chemistry, Plenum Press, New York 1980, p. 103f.—Based on lectures at the 26th IUPAC Congress in Tokyo (1977), at the ACHEMA Frankfurt (1979), at the European Conference on Molecular Spectroscopy in Frankfurt (1979), at the Mass Spectroscopy Congress in Darmstadt (1979), at the Bayer AG Leverkusen (1978), at the Dow Chemical Corporation Midland/Michigan (1980), at the Dow Corning Midland (1978), at the Fritz-Haber-Institute of the Max Planck Society Berlin (1978), at the IBM Research Center San José (1980), at the ICI Central Research Department Runcorn (1977), at the Catalysis Institute Cracow (1978), at the Max-Planck-Institute for Coal Research Mülheim (1976), at the Monsanto Central Research Department St. Louis (1977), at the Polish Academy of Sciences Warsaw (1978), at the SOHIO Research Center Cleveland (1977) as well as at numerous universities.

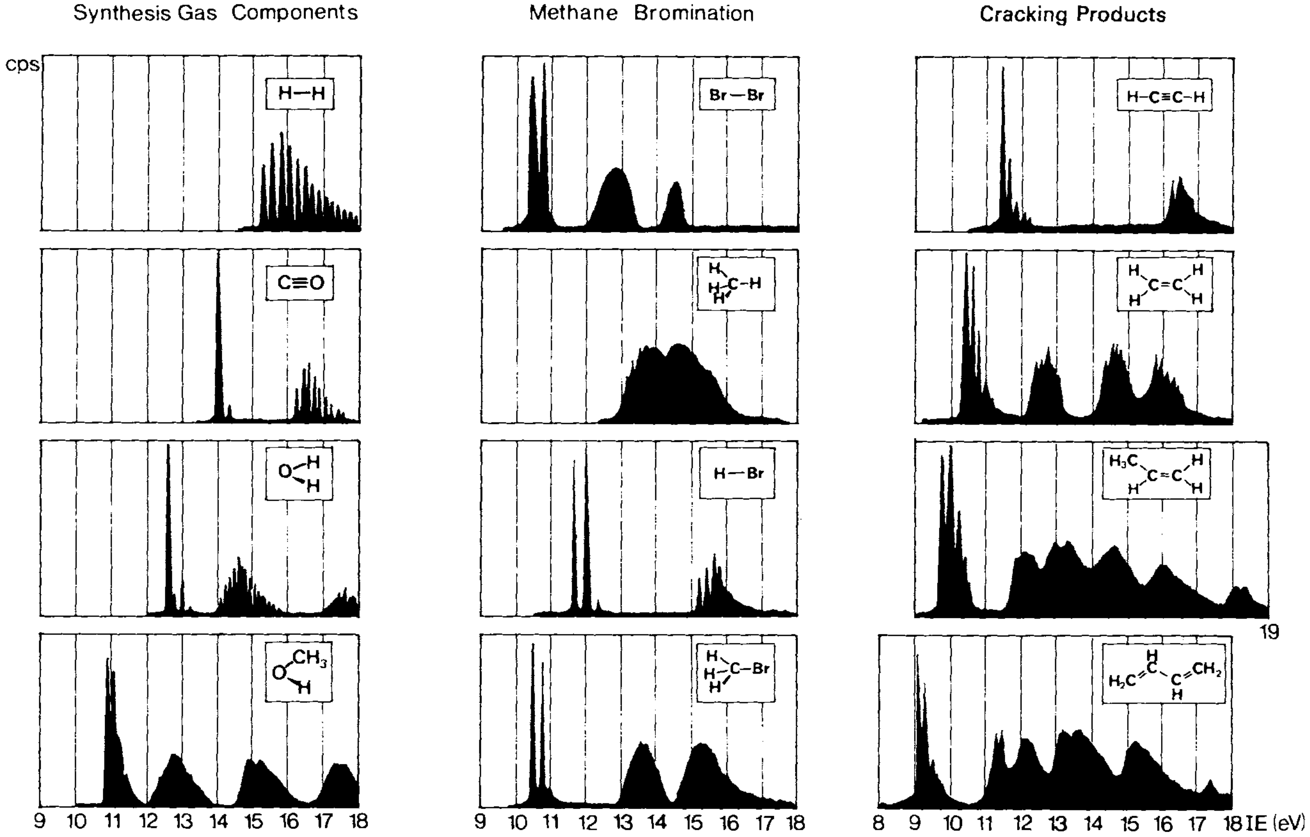

Fig. 1. Diagram containing a dozen helium(I)-photoelectron spectra of molecules as they could occur in a synthesis gas mixture, in an alkane bromination, or in a cracking products fraction. One recognizes the different band types—from sharp needles to broad hills of partially overlapping ionizations, with or without vibrational fine structure, as well as the double peaks of bromine derivatives with their distance determined by spin/orbit-coupling. The characteristic ionization patterns of the different molecules are discussed in the text arranged according to number, form, and energy range of the bands (see also Table 1).

Table 1. Additional data from the photoelectron spectra in Figure 1: number of valence electrons ($np_X + 1s_H$), from half the sum of which the number of bands in the HeI-range usually follows; recognizable radical cation vibrational fine structure $\nu_m^{\oplus}$ [cm$^{-1}$] ± 100 cm$^{-1}$ in relation to the corresponding vibrational frequency $\nu_m$ [cm$^{-1}$] of the neutral molecule; and qualitative partial assignment of the radical cation states generated by the three lowest ionizations ($IE_1$ to $IE_3$).

[a] $\pi$-double band at 16.5 eV. [b] $\sigma_{CH}$-multiple band between 14–16 eV. [c] $n_{Br}$-double band at 13 eV. [d] $\pi$-double band at 11.5 eV. [e] Only highest observed frequency given; for detailed discussion cf. [3, 4]. [f] Assignment not certain. [g] Spin/Orbit coupling $\Delta IE_{1,2} = 0.35$, 0.33 and 0.32 eV [17]. [h] Strong Jahn/Teller-distortion [3, 4]. [i] In the 3rd band $\nu_m^{\oplus} = 1290$ cm$^{-1}$ drops to nearly half that value.

$(H_5C_6)_3P{=}CH(C_6H_5)$[14] as well as the sixth of ethane, $IE_6 = 20.4$ eV[2,4,9,15]. The ionization of *a single electron at a time* occurs *via* transfer of the energy of photons generated in a helium gas discharge (see Section 3). In this way, the molecule *M* is transferred into its radical cation $M^{\ddagger}$ as well as the excited states of the latter[7]. In contrast to the electronic excitations in the visible and ultraviolet spectral regions with their selection rules, *all* single ionizations are usually allowed and therefore observable. A simplifying rule-of-thumb[6] states that in the so-called "helium(I)"-range 6 eV—21 eV *the number of observable ionizations should be equal to half the number of all element p- and hydrogen 1s-electrons formally present in the molecule*[16].

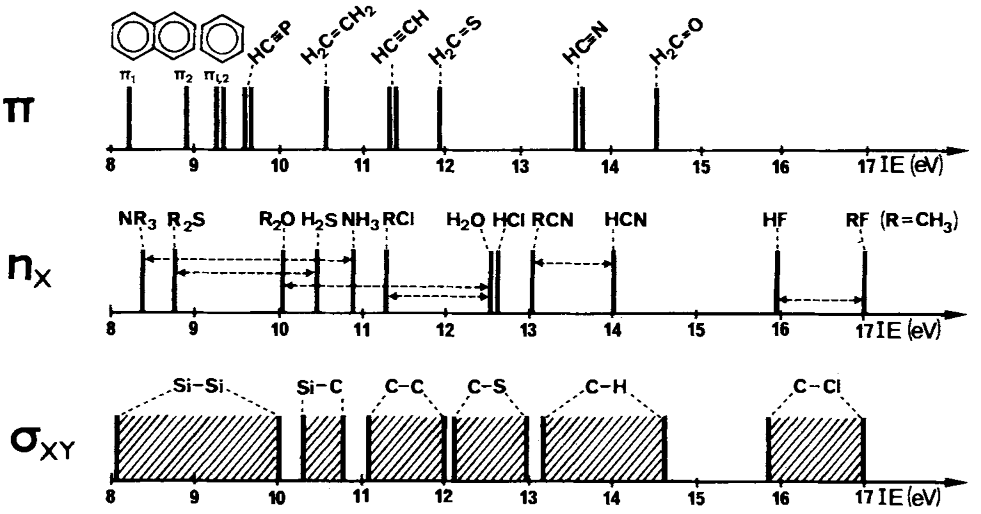
In this respect, the PE-spectra shown in Figure 1 can be viewed as follows: for the molecule H—H one expects and finds one band (with extensive vibrational fine structure); carbon monoxide formally has $2(2p_C)$- and $4(2p_O)$-valence electrons and therefore exhibits one single and one double band in the region up to 18 eV (cf. also [2-4]), water as expected shows $[2(1s_H) + 4(2p_O)] \times 1/2 = 3$ ionization bands in the He(I)-range. Methanol formally possesses $4(1s_H) + 2(2p_C) + 4(2p_O) = 10$ valence electrons and the PE spectrum up to 21 eV consequently shows five ionization bands including the double band at 15–16 eV while butadiene $C_4H_6$ shows $14/2 = 7$ He(I)-bands, two of which overlap at 13—14 eV. This counting of bands in the PE-spectra of molecules has been compiled in Table 1 together with the PE-spectroscopic information obtained from band shapes with or without vibrational fine structure, which is subsequently discussed, as well as the qualitative assignment of the radical cation states $M^{+\cdot}$ generated by the three lowest ionization energies.

## 2.2. Band Shape

The photoionization process $M + h\nu \rightarrow M^{+\cdot} + e$ occurs unimaginably fast within about $10^{-16}$ seconds. The radical cation $M^{+\cdot}$ produced by this "vertical" electron ejection therefore cannot "relax" into an equilibrium structure with a more favorable charge distribution[7], not even through molecular vibrations, which, with a period of about $10^{-14}$ seconds, take considerably more time. On the other hand, the ionizations of the neutral molecule do not only lead to electronically excited states of the radical cation $M^{+\cdot}$—as discussed previously for the example of the number of bands—but also to vibrationally excited ones[2-4]. Depending on the number of possible $M^{+\cdot}$-vibrations and the difference in their frequencies, there result in the photoelectron band patterns either needles separated from one another, or, in the case of their overlapping, broad ionization hills. Thus by inspection of the PE-spectra (Fig. 1) the following simplified band shapes can be distinguished:

- ⇒ single needles (CO, $OH_2$, $Br_2$, HBr, $H_3CBr$), which in general are assigned to the ionizations of "lone" electron pairs (Table 1). Here the constant distance of the double bands of halogen derivatives R—X (Fig. 1 and Table 1: $n_{Br}$) is due to spin/orbit-coupling which increases with ascending atomic numbers ($n_{Cl} < 0.1$, $n_{Br} \approx 0.3$, $n_I \approx 0.6$ eV[17,18]).
- ⇒ peak sequences with a width of up to about 1 eV (for example $HC{\equiv}CH$, $H_2C{=}CH_2$, $H_3C{-}CH{=}CH_2$, $H_2C{=}CH{-}HC{=}CH_2$) in most cases belong to $\pi$-ionizations, as a rule the first ionization is the most intense[3,4].
- ⇒ unstructured broad bands ($CH_4$ or derivatives $H_3C{-}X$ at $IE > 14.5$ eV) in general arise from ionizations of the $\sigma$ molecular frame, in which case numerous $M^{+\cdot}$-bands overlap.
- ⇒ peak sequences with a width of more than 1 eV ($H_2$, higher $IE_n$ of $OH_2$ or HBr): in the case of smaller molecules with only few vibrations, often at high frequencies, $\sigma$-ionizations can also exhibit vibrational fine structure.

A comparison of the vibrational frequencies before ($\nu_m$) and after ($\nu_m^{\oplus}$) ionization can be interpreted according to the size of the difference $\nu_m - \nu_m^{\oplus}$ as though "bonding" (Table 1: $H_2$ or $H_2C{=}CH_2$) or "nonbonding" (Table 1: CO, $Br_2$, HBr or $H_3CBr$) valence electrons have been ionized and therefore provides arguments for the assignment of the PE-spectra (Fig. 1 and Table 1). Own experience gathered over the years shows that gases with needle-like ionization bands can be readily analyzed PE-spectroscopically even in mixtures (cf. *e.g.* [10, 19-27]).



(1)

## 2.3. Band Ranges

From the PE-spectra (Fig. 1), chosen for their proximity to practical experience, characteristic ionization regions can be extracted according to the previously discussed partial assignment (Table 1: $IE_1$ to $IE_3$): thus $\pi_{CC}$-ionizations can be found between 9 eV—11.5 eV, the bands assigned to "lone" electron pairs $n_X$ lie for $n_O$ between 11 eV—14 eV or for $n_{Br}$ between 10.5 eV—12 eV, and $\sigma_{CH}$-ionizations in most cases occur between 13 eV—16 eV. A scale of typical $\pi_{XY}$, $n_X$ or $\sigma_{XY}$ ionization regions [see (1)], expanded for other heteroatoms, reflects the influence of the effective nuclear charge acting on the valence electrons, as already discussed for "s" and "p" electrons during the estimation of the number of PES bands[16]: fluorine derivatives are difficult and Si-compounds easy to ionize[6,7]. The upper and lower boundaries of the particular regions are also easy to comprehend and/or predict on the basis of substituent effects with which all chemists are familiar: thus methylation lowers the respective ionization energy by up to 2 eV (Fig. 1: cf. also $\Delta n_O(H{-}OH \rightarrow H_3C{-}OH)$, $\Delta n_{Br}(H{-}Br \rightarrow H_3C{-}Br)$, and, as a further example, $\Delta\pi_{CC}(H{-}HC{=}CH_2 \rightarrow H_3C{-}HC{=}CH_2$[29]). Enlarging the $\pi$ system *e.g.* by a vinyl group leads to $\pi$-splitting[5,6] (Fig. 1: ethene with $IE^{\pi} = 10.51$ eV → butadiene with $IE_1^{\pi} = 9.03$ eV and $IE_2^{\pi} = 11.46$ eV).

Beyond such considerations of plausibility, substituent effects can, in a simple way, be parametrized PE-spectroscopically and the expected values for similar compounds be estimated from them: in this way it is possible to determine, *e.g.* from the PE-spectra of the 1,1- and 1,2-dichloroethenes, the (coulomb) parameters $\alpha_\pi$ and $\alpha_{Cl}$ of the partial systems as well as the parameter $\beta_{\pi Cl}$ for the π interaction between them[30]:

$$\left.\begin{aligned}\alpha_\pi &= -10.85\ \text{eV}\\ \alpha_{Cl} &= -12.64\ \text{eV}\\ \beta_{\pi Cl} &= -\ 1.80\ \text{eV}\end{aligned}\right\}\Rightarrow\left\{\begin{array}{lll} & \text{Calc.} & \text{Obs.}\\ IE_1(H_2C{=}CH{-}Cl) & 10.09\ \text{eV} & 10.15\ \text{eV}\\ IE_2(H_2C{=}CH{-}Cl) & 13.28\ \text{eV} & 13.07\ \text{eV}\\ IE_1(Cl_2C{=}CCl_2) & 9.39\ \text{eV} & 9.35\ \text{eV}\end{array}\right. \quad (2)$$

Substituting the parameters into interaction determinants, or respectively into the equations derived from them—in the simplest case (2) into the relation

$$\begin{aligned}IE_{1,3} &= (\alpha_\pi+\alpha_{Cl})/2 \pm \sqrt{(\alpha_\pi-\alpha_{Cl})^2/4-\beta_{\pi Cl}^2}\\ &= 23.49/2\\ &\qquad \pm\sqrt{1.79^2/4-1.8^2}\\ &= 11.75 \pm 1.56\ \text{eV}\end{aligned}$$

which can be solved using any pocket calculator—in most cases yields reliable expectation values (cf. *e.g.* [4-7,28-31]). Excellent correlations between calculated and PE-spectroscopic ionization energies such as in (2) demonstrate once again the *usefulness of comparisons of equivalent states of chemically related compounds*[7], a method well suited to the chemical point of view, and which consequently makes reading PE-spectroscopic band patterns easier.

### 2.4. Calculation of Ionization Patterns

An additional advantage of PE spectroscopy consists in the possibility to calculate vertical ionization energies on different levels of approximation with the available quantum mechanical computational methods[32], *e.g.* for thioformaldehyde[13] (Fig. 2).

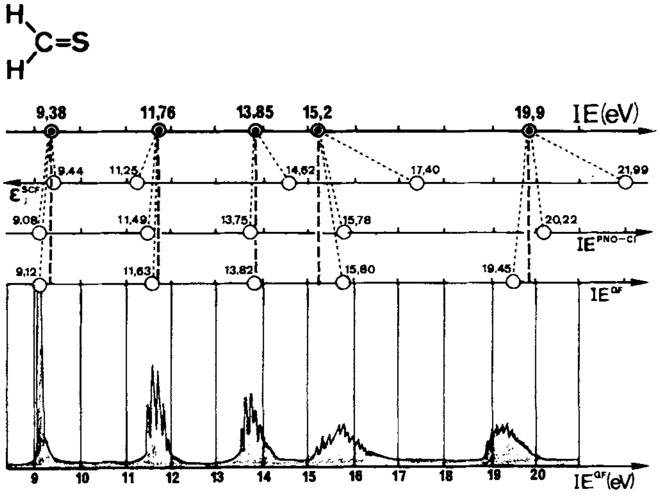


Fig. 2. Vertical PE-spectroscopic ionization energies *IE*[eV] of thioformaldehyde (⊙) and their correlation with *ab initio* SCF eigenvalues $-\varepsilon_J^{SCF}$, with energy state differences $IE^{PNO-CI}$ obtained by means of "*P*seudo *N*atural *O*rbital-*C*onfiguration *I*nteraction", and with ionization energies from *G*reen-*F*unction calculations $IE^{GF}$ (see text). The ionization pattern shown is a computer simulation based on many-body Green-function calculations [33]; it differs only slightly [7] from the authentic PE spectrum of thioformaldehyde [13].

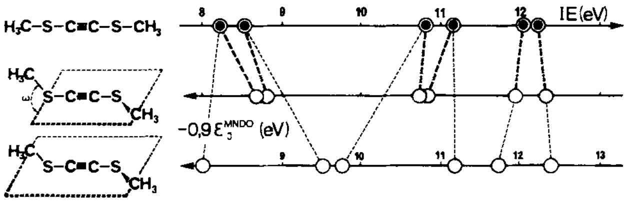
It is quite obvious that the experimental ionization energies of $H_2C{=}S$ are only unsatisfactorily approximated by *ab initio* SCF eigenvalues $-\varepsilon_J^{SCF}$[13]; Koopman's defects, that is deviations from Koopmans' theorem $IE_n^v = -\varepsilon_J^{SCF}$[3,4,16,32], of over 2 eV occur. However, calculations of molecular states which, to a large extent, include correlation effects, such as the *p*seudo *n*atural *o*rbital-*c*onfiguration *i*nteraction method, can reproduce ionization energies to within about ±0.3 eV[13]. The ionization pattern shown was calculated using many-body Green-function techniques[33] and was drawn by a mechanical plotter (!) with the additional use of some experimental results; it differs only in insignificant details[7] from the PE spectrum of thioformaldehyde.

For molecules which are either larger than, for example, benzene or have lower symmetry, exact computation takes too long. Here, the faster semi-empirical "four-letter"-methods such as the well-proven MNDO method[32] become advantageous. Although their exactness especially for radical cation state energy differences of less than 1 eV is often overestimated, they nonetheless reproduce ionization patterns in a satisfactory way, *e.g.* for bis(methylthio)acetylene[27] which can be generated by gas phase thermal decomposition of 3,4-bis(methylthio)-1,2-cyclobutenedione [see (3)].



(3)

According to electron diffraction measurements bis(methylthio)acetylene does indeed display a dihedral angle of $\omega = 86°$[34], and therefore possesses two partial π systems of the same kind, S—C═C(—S) and (S—)C═C—S[27]. As the example given here shows, the calculation of ionization patterns frequently yields further useful information beyond expectation values important for gas analysis, *e.g.* on the feasibility of oxidation to the radical cation in solution[35].

### 2.5. Ionization Patterns of Gaseous Mixtures

The PE spectra (Fig. 1) previously discussed one by one, have been placed together in the three columns "synthesis components", "methane bromination", or "cracking products". Arranging the spectra in applications-related groups was undertaken for the didactic reason of illustrating certain criteria of the PE spectroscopic analysis of gaseous mixtures:

⇒ $H_2$, CO, $H_2O$ and $H_3COH$: here the last three compounds can be recognized visually without much trouble by their separated single needles at 10.94 eV[9], 12.61 eV[2] and 14.01 eV[2] even in concentrations of only about 5 to 10%. The gaseous mixtures may additionally contain other molecules of the same composition as synthesis gas $\{n\cdot CO + m\cdot H_2\}$ with characteristic single peaks such as $H_2C{=}O$ ($IE_1 = 10.88$ eV)[9],

$HCOOCH_3$ ($IE_1 = 11.00$ eV[36]), or O=CH—HC=O ($IE_2 = 12.20$ eV[9])[36]. The only difficulties arise from the analysis of $H_2$ in mixtures of all components, since then the "observation windows" between 15—16 eV (next to CO) and 16—17 eV (next to $H_2O$ and $H_3COH$) do not lie in the same region. Our own experience[36] shows nonetheless that the distinctive vibrational fine structure (Fig. 1 and Table 1) which extends over a range of 3 eV frequently allows at least a qualitative detection.

⇒ $Br_2 + CH_4 \rightarrow HBr + H_3C—Br$: this example of a gas phase reaction shows the limits of PE-spectroscopic real time analysis, since the overlapping double bands of the educt $Br_2$ ($IE_1 = 10.53$ eV, $IE_2 = 10.85$ eV[41]), and of the product $H_3C—Br$ ($IE_1 = 10.53$ eV, $IE_2 = 10.85$ eV[17]) cannot be resolved anymore. The temperature dependence of the methane bromination, as a function of a heterogenous catalyst which is to be optimized, would have to be monitored only by means of the HBr being formed. Moreover, $CH_4$ cannot be visually detected in mixtures with $Br_2$ and $H_3C—Br$ (Fig. 1). It must, however, be pointed out that the overlap of $Br_2$ and RBr-bands, so unfortunate in this case, does not occur with other gas phase brominations[24] (cf. Fig. 10: $F_3CH + Br_2 \rightarrow F_3CBr + HBr$).

⇒ Acetylene, ethene, propene and butadiene: in each case the first bands and those assigned to π ionizations (Fig. 1 and Table 1) between 9 and 11.5 eV allow a simultaneous analysis of all components down to concentrations of about 10%. This accuracy, which is obtained by visually comparing band intensities, can be considerably increased by computerized evaluation of the spectra.

The question whether a given gas reaction in a flow system can be monitored with PE-spectroscopy, is—if the PE-spectra of all components are known—most favorably answered by means of a computer: the basis for this is the linear relationship, verified experimentally many times, between the concentrations of molecules in the gaseous mixture and their (relative) band intensities (cf. *e.g.* [37-42]). For example, mixtures with known ratios of hydrogen cyanide : cyanogen were analyzed PE-spectroscopically and the band areas planimetrically determined: this verification gave satisfactory agreement[23]. In the meantime, *e.g.* a simple program PESIMU[43] allows one to store PE spectra in 0.05 eV steps in a computer and, within minutes, to print out the expected PE spectra for gaseous mixtures composed from the constituents in any way[10,23]. This is based on the assumption of comparable photoionization cross sections, usually valid for chemically related compounds. It is on purpose that the little structured PE-spectra of the chlorosilanes $H_2SiCl_2$ and $HSiCl_3$[44], the ratio of which is important in the manufacture of pure silicon, have been chosen here as example of an application (Fig. 3).

PE-spectroscopic analysis is more complicated for $H_2SiCl_2/HSiCl_3$ mixtures than for the examples discussed up to now (Fig. 1), because the spectra are of the same type, and contain only three prominent bands: for $H_2SiCl_2$ $IE_1 = 12.53$ eV and for $HSiCl_3$ $IE_3 = 13.07$ eV and $IE_7 = 18.14$ eV[44]. It is nonetheless evident that it would be possible to carry out an optimization of reaction conditions with the aim of a maximum $H_2SiCl_2$ yield, relying on the relative intensities of the bands marked by arrows. It would of course be more favorable if the gas analysis could be performed using a small molecule such as HCl, the PE spectrum of which contains characteristic needle-like peaks (cf. Fig. 1: HBr).

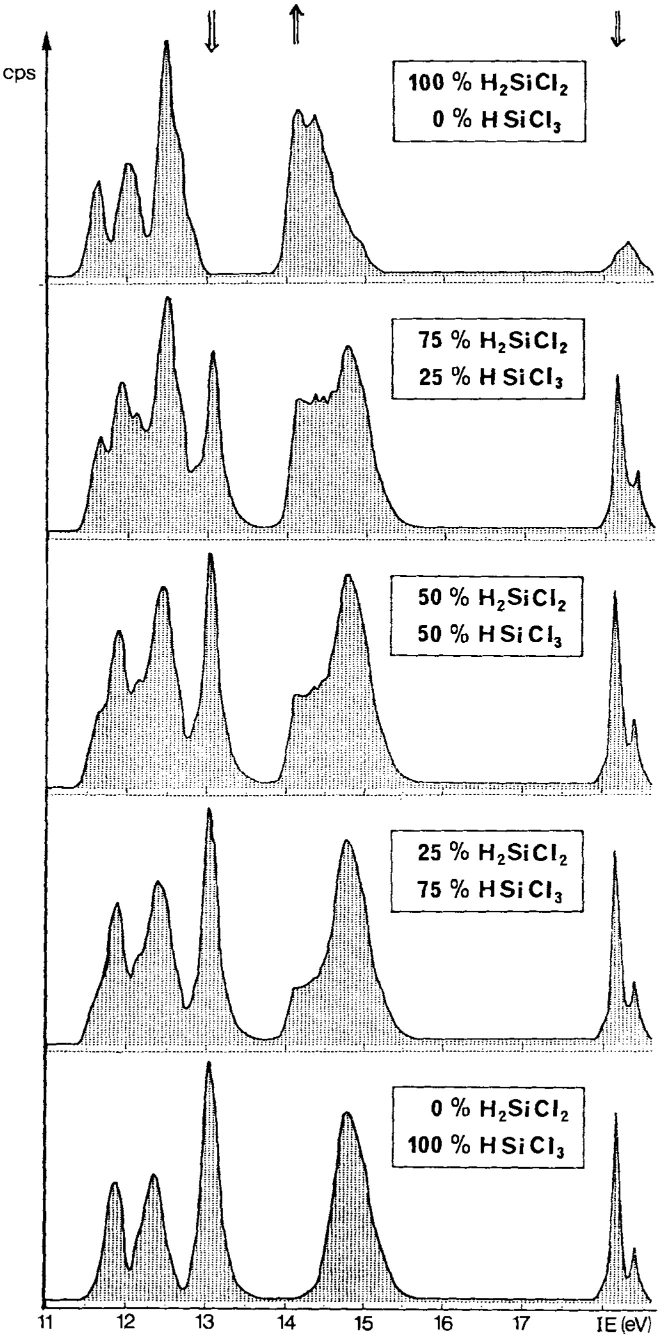


Fig. 3. Computerized PE spectra of the chlorosilanes $H_2SiCl_2$ and $HSiCl_3$ [43, 44], and computer simulation of the PE spectra of their mixtures in the ratios 75:25, 50:50, and 25:75.

### 2.6. Gas Analysis by Means of Ionization Patterns

The preceeding introduction into band number, band shape and band energy ranges of helium(I) photoelectron spectra is intended to let an observer less proficient in their interpretation recognize that their daily use does not raise any particular difficulties, just as with IR vibrational frequencies, mass spectroscopic fragments or NMR couplings. In order to identify molecules by means of their ionization patterns, it is advisable to record spectra of probable reaction products in advance. Starting from the discussed rules, a specific search among the thousands of known PE spectra is often successful, starting with looking them up in the available PE spectra collections[2-4,6,8,9], or in the original literature *via* the entries "photoelectron spectrum" in the Chemical Abstracts Chemical Compounds Register. A library of PE spectra on recall from a graphic display is currently being established at the University of Frankfurt (DEC 10 *via* PDP 11/40 terminal)[45]. For hitherto unknown PE spectra, especially for molecules produced for the first time in the gas phase, the assignment *via* a comparison of states with chemically related compounds or the quantum mechanical calculation of vertical ionization energies remain as additional possibilities, besides questioning knowledgeable colleagues. As an expansion of the above discussion, the feasibility of PE spectroscopic analyses in gaseous mixtures can be judged by comparison, projection of the spectra upon one another, or computer mixing of the PE spectra of the main components. Here needle-like PE bands as they occur on ionization of "electron pairs" or of "π systems" of smaller molecules are favorable. The scope as well as the advantages and disadvantages of PE spectroscopic gas analysis will be discussed in a final comparison (Section 5) with "competing" methods of gas analysis such as gas chromatography, mass spectroscopy or infrared spectroscopy.

## 3. Gas Analysis with Photoelectron Spectrometers

The working principle of a photoelectron spectrometer is well documented[2-6] and so lucid that it is excellently suited for the treatment of the experimental determination of ionization energies in introductory chemistry lectures[11] (cf. Fig. 4B): helium atoms are excited in a gas discharge and give off photons of energy $h\nu = 21.21$ eV. In the ionization chamber, these impact on molecules drawn into the chamber by the PE spectrometer's high vacuum system. By photoionization $h\nu + M \rightarrow M^{+\cdot} + e$, *i.e.* by supplying the respective ionization energies $IE_n$, electrons with well defined kinetic energies $E_{kin} = 21.21\ \text{eV} - IE_n$ are generated, then sorted according to energy in an electrostatic analyzer, and finally counted (cf. Fig. 1: ordinate in "counts per second", abscissa from left to right $IE_n$ and from right to left $E_{kin}$). Starting from this common working principle, useful details on the instruments and apparatus for gas analysis in flow systems have been compiled and are presented in the following sections.

### 3.1. Comments on the Instrumentation: PE Spectrometers

Of the numerous kinds of PE spectrometers two extremes will be presented here: on the one hand, a high performance instrument for research purposes (Fig. 4A), remaining at the same location in an instrument room, and to which the apparatus for the preparation of the species under investigation is connected, and, on the other, a prototype of a simple portable instrument (Fig. 4C), which is connected to a fixed apparatus for measurements.

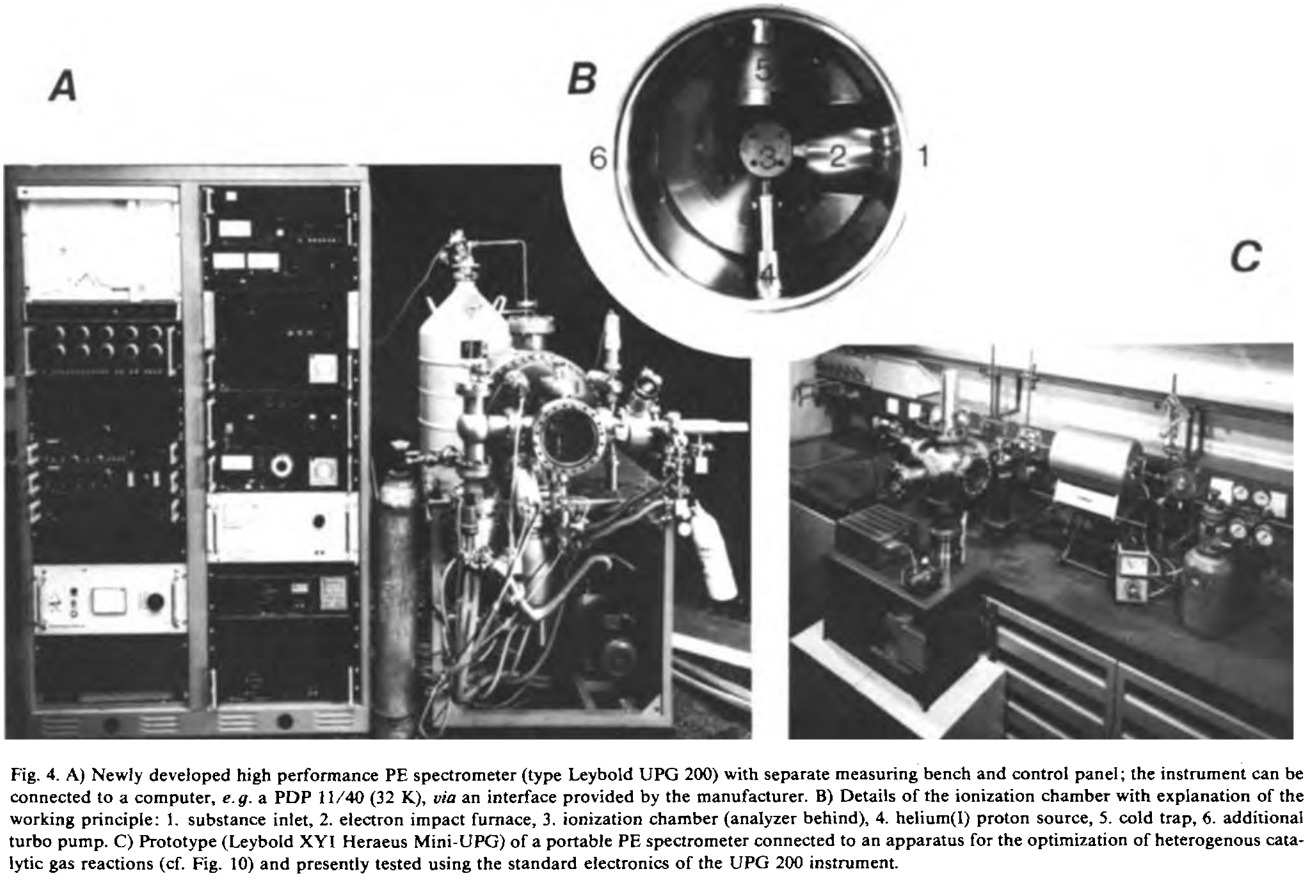

Fig. 4. A) Newly developed high performance PE spectrometer (type Leybold UPG 200) with separate measuring bench and control panel; the instrument can be connected to a computer, *e.g.* a PDP 11/40 (32 K), *via* an interface provided by the manufacturer. B) Details of the ionization chamber with explanation of the working principle: 1. substance inlet, 2. electron impact furnace, 3. ionization chamber (analyzer behind), 4. helium(I) proton source, 5. cold trap, 6. additional turbo pump. C) Prototype (Leybold XYI Heraeus Mini-UPG) of a portable PE spectrometer connected to an apparatus for the optimization of heterogenous catalytic gas reactions (cf. Fig. 10) and presently tested using the standard electronics of the UPG 200 instrument.

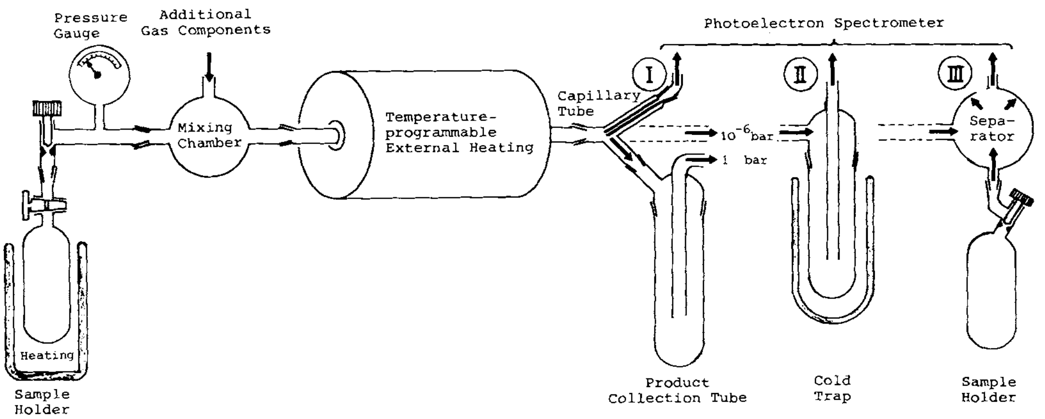

Fig. 5. Assembly kit for the apparatus needed for PE spectroscopic gas phase reactions, comprising (from left to right): substance inlet, pressure gauge for stoichiometric mixing of gases with given partial pressures, heated reaction tube (optionally empty, or filled with quartz wool or a catalyst) and some means for trapping reaction products [10]: I) For pressures of about 1 bar, reduction to the PE spectrometer's working pressure of $10^{-5}$ to $10^{-7}$ bar can be effected using a capillary tube, depending on its length and diameter. Products can be collected in a conventional way, and can be subjected to a further preparative or analytical workup, if so wished. This "capillary bleeding" is advantageous especially with hot gases [46]. II) For gas phase reactions at PES working pressures, identification of certain components in product mixtures with strongly overlapping PE-spectra is often possible by freezing out in a cold trap followed by fractional evaporation. III) Some components can be eliminated from product mixtures by an additional gas phase reaction in a separator bulb, such as *e.g.* $HCl + NH_3 \rightarrow NH_4Cl$ [13].

Both types of instruments are constructed according to the working principle described above and are comparable concerning most of the measuring conditions specified below. The following differences catch the eye: the electrostatic analyzer is built into the horizontal vacuum chamber, separate from the ionization chamber (Fig. 4A) or connected to it in the cross flange (Fig. 4C). In A, an additional turbomolecular pump makes it possible to guide the beam of molecules in a largely separate way. Resolution (A 15 meV, C < 100 meV) and maximum possible intensity (A > 100000 cps, C 30000 cps) as well as operating options and gauges for helium lamp, vacuum system or electronics are in keeping with their respective operating purposes and the very different cost of the instruments. The following comments on the instruments are subdivided according to the operating conditions, the "real time" measuring process, and the extension of the range of application:

- ⇒ operating conditions: in both types of PE spectrometers (Fig. 4A and C) the beam of molecules is pumped from a storage vessel to a cold trap in a flow system at a pressure of about $10^{-5}$ to $10^{-8}$ bar. As a rule-of-thumb, only about 1 millimol of a compound is needed for a series of measurements lasting from 6 to 10 h. Since the He(I) photons are generated in an open gas discharge, the PE spectrometer is filled with a partial pressure of helium; for calibration of the spectra one adds argon ($^2P_{3/2} = 15.76$ eV) and/or xenon ($^2P_{3/2} = 12.13$ eV)[2].
- ⇒ "real time" measurement: as already mentioned, the ionization process occurs within $10^{-16}$ s; the time needed for the measurement is, however, considerably longer: this is mainly due to the gas flow in both types of spectrometer (Fig. 4A and 4C) having to be pumped from the (usually heated) reaction zone to the ionization chamber. "Real time" measurement is therefore understood as continuous measuring without an additional delay caused by the instrument, as *e.g.* in gas chromatography. According to the rate of feed chosen, registration of a complete spectrum from 6 to 21 eV takes between 3 and 20 min with a recorder, and about $10^{-2}$ s per measured point electronically.
- ⇒ extension of the range of applications: of the innumerable possibilities, reactions at higher pressure and shorter contact time should be emphasized. The reduction of pressure between reaction tube and PE spectrometer can be effected by means of various "bleeding"-valves or, most simply—especially in the case of hot gases—by means of a reducing capillary (Fig. 5)[46]. For flow velocities which can be varied only within a limited range[3] the contact time is preferentially shortened by reducing the distance between the reaction zone and the ionization chamber—down to about 1 cm[3,47-49], depending on the type of spectrometer used (cf. Fig. 8A). The spectrometer shown (Fig. 4B: 2) is fitted with an electron impact heating system which allows one to reach temperatures of above 1500 K with a minimum distance of 2 cm between the end of the reaction zone and the ionization chamber.

Short-lived species produced thermally, by microwave discharge or by chemical reactions, and detected PE-spectroscopically (cf. *e.g.* [3,10,47]) will be reported upon in Section 4.3.

### 3.2. Comments on the Apparatus for Reactions

How to carry out gas phase reactions at various pressures and temperatures has already been discussed on a number of occasions[3,10,47,50-52]. Here a few additional useful tips concerning apparatus and reaction conditions for PE spectrometers will be given, based on experience gathered by the Frankfurt PES group[53] since 1973[10,13,21,46,49,53]. The starting point is the standard assembly (Fig. 4C or 10)[46], which can be modified in nu-

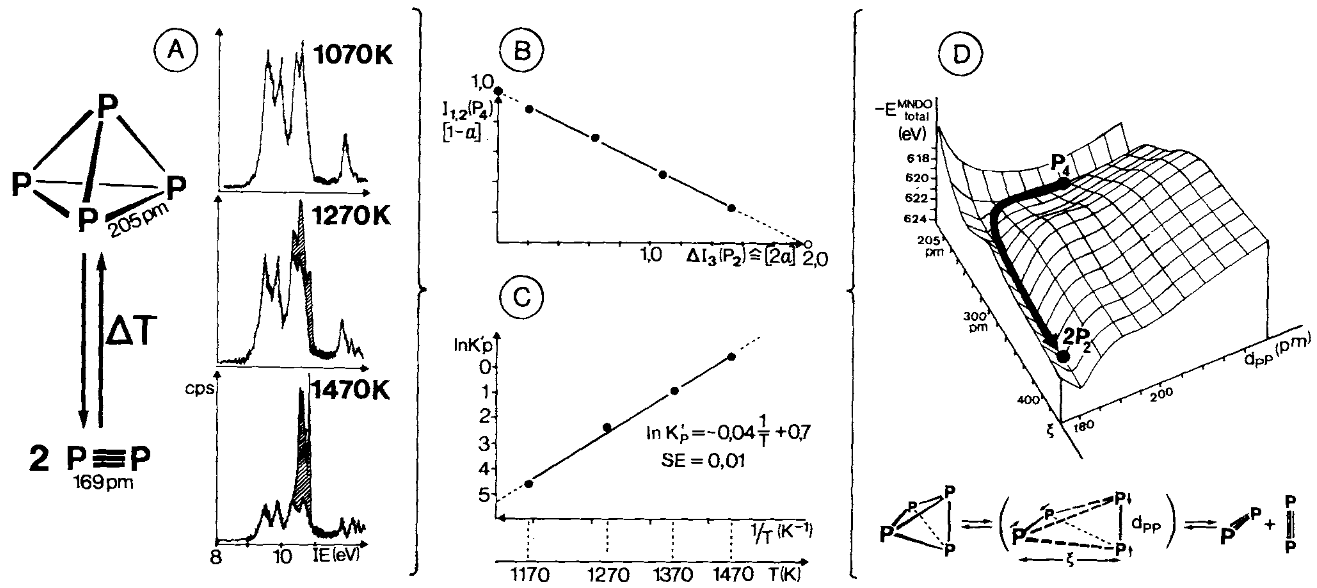

Fig. 6. The thermal equilibrium $P_4 \rightleftarrows 2P_2$. A) White phosphorus, pre-dried with acetone and distilled in a brown glass apparatus over $CaH_2$ [56], is vaporized in a PES pyrolysis assembly (Fig. 5: substance inlet without mixing bulb, oven, direct connection to the PE spectrometer). The PE spectra of the gas flow change between the temperatures of the oven given above: the intensity of the $P_4$ ionization pattern at 9—11 eV decreases, that of the $P_2$ ionization pattern at 10.5—11 eV (shaded area) increases. If the band area corresponding to the $P_4$ intensity ratio $IE_{1,2}:IE_3$ is subtracted from this band, the band intensities $IE_{1,2}(P_4) \triangleq [1-\alpha]$ and $\Delta I_3(P_2) \triangleq [2\alpha]$, proportional to the partial pressures $p$, can be plotted against one another assuming temperature independent and comparable ionization cross sections. B) The points of the resulting straight line can be converted according to $\ln K_p' = 4\alpha^2 P/(1-\alpha^2)$ and afford C) the temperature dependence of the equilibrium constant $K_p'$. The experimental values agree satisfactorily with those found in the literature (*e.g.* for 1370 *K*: at $p = 0.04$ mbar $\ln K_p' = -0.89$; literature [56], at 0.19 mbar $\ln K_p' = -0.81$) as well as with the difference in the calculated MNDO enthalpies of formation $\Delta H_{total}^{MNDO} = 180$ kJ/mol (dissociation energy [56] $E_D = 217$ kJ/mol). D) The MNDO hypersurface was calculated using the simplifying assumption that dissociation proceeded along the coordinate $\xi$ with reduction of the bond length $d_{PP}$ from 205 pm ($P_4$) to 169 pm ($P_2$), in spite of the symmetry forbidden process $T_d \rightarrow D_{2d} \rightarrow D_{\infty h}$. The PE spectroscopic measurements were carried out with 100 mg of white phosphorus during one day.

merous ways very much as with an assembly kit[10] (Fig. 5). Depending on the choice of parts for substance inlet, reaction zone and product isolation, different types of gas phase reactions, from the thermal decomposition of a compound to the heterogeneously catalyzed reaction of several components, can be analyzed PE spectroscopically and their reaction conditions optimized.

⇒ substance inlet: the vaporizing of molecules that can be brought into the gas phase without decomposition offers no difficulties, especially under vacuum conditions, and can be effected in a separate preheated oven around the extended reaction tube *e.g.* for pyrolyses of high-boiling solids. Mixing several gases is best accomplished by passing them at right angles to each other and to the reaction tube into a mixing bulb, preferentially filled with Raschig rings and heated if necessary (Fig. 5). The possibility of carrying out reactions in flow systems, *e.g.* sulfur chloride and methylamine[54] [cf. (18)] with a Daniell type burner extending into the reaction zone should also be mentioned here.

⇒ Reaction zone: generally quartz or steel tubes of 10 to 30 mm in diameter and about 400 mm long are used; lengths of the reaction zone of up to 2 m can be obtained by using spiral tubes in ovens with openings of large diameter[21]. Heterogeneous catalysts can be packed in between quartz wool wads; if necessary, the reaction tube can be positioned vertically. Ovens that can be swung open allow a faster change of tubes. The heating tube of a "flash vacuum pyrolysis" apparatus[50,51] can be installed instead of the oven and the temperature for the preparative isolation of the compound formed can be optimized. A thermocouple on the outside of the reaction vessel is sufficient for determining *relative decomposition temperatures*; in order to minimize temperature dependent equilibrium shifts after leaving the reaction zone, one has to pay attention to maintaining as short as possible a distance to the ionization chamber of the PE spectrometer. Finally, mention must be made of the protecting helium atmosphere in the PE spectrometer, which is advantageous for measurements of oxygen-sensitive compounds such as silanes $Si_nH_{2n+2}$[55], phosphorus ylides[14], or of the $P_4/P_2$ equilibrium[56] (Fig. 6).

⇒ Isolation of products: the numerous possible variations include condensation at atmospheric pressure (Fig. 5 I), freezing out with subsequent fractional evaporation of the product mixture (Fig. 5 II) or separating certain compounds as solids (Fig. 5: III). Poisonous reaction components such as cyanogen and hydrocyanic acid[46] can be rendered inoffensive by, *e.g.*, freezing them out on the surface of the cold trap of the PE spectrometer, and allowing them to thaw in a suitable decontaminating solution after removal from the spectrometer.

All in all, carrying out reactions in PE spectrometers is very versatile as far as the apparatus is concerned; the thermal energy supply in use for most preparative aims can be replaced by microwave generators or by electric discharges (Section 4.3[3,47]). When operating in a vacuum, the reaction conditions are often similar to those of the well-established "flash vacuum pyrolysis"[50,51]. Beyond this, the scope of PE spectroscopic gas analysis, discussed in the following sections with selected examples, also encompasses reactions at normal pressure, gas phase syntheses and heterogenously catalyzed reactions.

## 4. Examples of PE Spectroscopically Optimized Gas Phase Reactions

The scope and possibilities of PES gas phase analysis, both from the spectroscopic point of view and as regards the apparatus, will now be demonstrated in closer detail by means of the following selected examples:

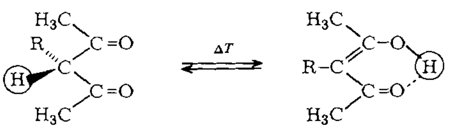
- ⇒ the measurement of the temperature dependence of equilibrium constants by means of the dissociation $P_4 \rightleftarrows 2P_2$[56],
- ⇒ the investigation of thermal reaction channels by means of the pyrolysis of vinyl azide[26,57],
- ⇒ the detection of short-lived intermediates using as example the formation of silabenzene[49,58],
- ⇒ gas phase syntheses by the reaction of thionyl chloride with ammonia to form sulfinyl imide[59],
- ⇒ the optimization of gas phase reactions with heterogeneous catalysis, using as example the bromination of trifluoromethane[24].

For each example, further literature on other reactions of that type will be cited.

### 4.1. Measurement of the Temperature Dependence of Equilibria

So far, gas phase equilibria have been investigated PE spectroscopically only in isolated instances (Table 2). Nevertheless, this type of reaction takes the lead in the examples of applications, as it can be used to demonstrate that the comparison of PE band intensities makes possible quantitative statements under certain conditions and within certain limits of error.

Already in 1974 the temperature dependence of keto/enol-tautomeric equilibria was determined from PE spectroscopic band intensities[37]; in agreement with IR or mass spectroscopic results, *e.g.*, 76% acetylacetone is found to be present in the keto form at room temperature [see eq. (4), R = H][37].



(4)

R = H, CH$_3$

The basic assumptions—*temperature independent* PE band intensities for keto- and enol-tautomers in a ratio of 1 : 1, ionization cross sections and asymmetry parameters[37]—have proven their value also in measurements on other *temperature dependent* gas phase equilibria[38–41,56,60–64] (Table 2).

The PE spectroscopic measurements of temperature dependent equilibria (Table 2) encompass reactions such as dissociations or rearrangements and phenomena of molecular dynamics such as the barriers of rotamers or vibrational excitations. Mention must be made of many other gas phase reactions (Section 4.2—4.5), for which temperature dependent yields have been optimized without, however, evaluating band intensity ratios. The survey (Table 2) shows molecular sizes between 2 atoms ($O_2$, $Cl_2$) and 16 atoms ($H_5C_6$—$SCH_3$); the range of temperatures extends from 210 K with cooling of the flow system ($N_2O_4$) to light red heat ($P_4 \rightleftarrows 2P_2$). The experimental results enable one to estimate equilibrium constants[37–39,56] or energy barriers[38,39,41,63,64] in usually satisfactory agreement with thermodynamic data from the literature, and moreover to characterize the respective partners of the equilibrium.

Table 2. Types of gas phase equilibria investigated by means of PE spectroscopy.

| Gasphase equilibrium | Ref. | *T*-range | Remarks |
|---|---|---|---|
| *Dissociation* | | | |
|  ⇄ 2 MX$_3$ | [60] | 340– 500 | 440 K: 50% MX$_3$ |
| $O_2N{-}NO_2 \rightleftarrows 2\ NO_2$ | [61] | 290– 210 | 210 K: 20% N$_2$O$_4$ |
| $P_4 \rightleftarrows 2\ P_2$ | [56] | 1000–1500 | 1270 K: 50% P$_2$ |
| *Rearrangement* | | | R$^1$ = CH$_3$, R$^2$ = H,<br>R$^3$ = CH$_3$CO, |
|  | [37] | 295– 520 | 295 K: 76% keto form |
|  | [62] | 295– 500 | 313 K: 80% oxadiazole |
| *Rotation* | | | |
|  | [63] | 300– 570 | 293 K: 76% trans |
|  | [41] | 300– 530 | 295 K: 60% trans |
|  | [38] | | |
|  | | 340– 860 | cis: 10 kJ/mol more stable |
| R = H | [64] | 300– 800 | high *T*: – H$_2$S |
| R = CH$_3$ | [39] | 295– 770 | barrier: 3 kJ/mol |
| *Vibrational excitation* | | | |
| $O_2 \rightleftarrows O_2^*$ | [40] | 295– 685 | $\nu_{OO} = 1460 \pm 260\ cm^{-1}$ |
| $Cl_2 \rightleftarrows Cl_2^*$ | [40] | – 390 | $\nu_{ClCl} = 1048 \pm 240\ cm^{-1}$ |

The equilibrium of dissociation $P_4 \rightleftarrows 2P_2$[56] has been chosen as an example that should be discussed in detail (Fig. 6) for it requires comparatively high temperatures (Table 2), illustrates the advantages of the protecting helium atmosphere in the PE spectrometer (cf. Section 3.1) and at the same time is a prerequisite for further attempts at reactions such as (5). The experimental expenditure is comparatively small (Fig. 5 and 6): 100 mg of the phosphorus vapor, which is dangerous at high temperatures, is sufficient for the one day neccessary to carry out the experiment. As can be seen from the illustration (Fig. 6A), the PES band intensities change markedly upon heating; the planimetric evaluation of the band areas yields the equilibrium constitution of P$_4$ and P$_2$ (Fig. 6B) and, after conversion, the temperature dependence of the equilibrium constant $K_p'$ (Fig. 6C). The PE spectroscopic results can be compared with thermodynamic data from the literature[56] as well as with the MNDO energy hypersurface calculated along the coordinate $\xi$ using highly simplifying assumptions (Fig. 6D). According to the latter, P$_4$ and P$_2$ lie in comparatively deep "potential energy troughs"; the difference in their MNDO total energies is very near to the considerable experimental dissociation energy of 217 kJ/mol[56]. These findings are consistent with the observed low reactivity of $P_4$ and $P_2$; thus according to further PE spectroscopic investigations[65] the equilibrium mixture does not react with cyanogen even at 1250 K:

$$\{P_4 \rightleftarrows 2\,P_2\} + NCCN \overset{\text{to 1250 K}}{\nrightarrow} P(CN)_3,\ (NC)_2PP(CN)_2\ldots \quad (5)$$

Using the assembly kit for the apparatus (Section 3.2), reactions such as (5) can also be tested PE spectroscopically on a millimole scale within one day, and—if necessary—their reaction conditions optimized.

Table 3. A selection of PE spectroscopically analyzed thermal decompositions arranged according to increasing molecular weight of the "leaving" molecule (set off in the formulas); further decomposition products are indicated by broken lines.

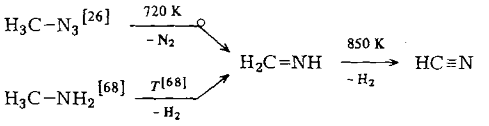
| Leaving molecule | Examples |
|---|---|
| HH |  [68], [26, 68], [70] |
| $CH_4$ |  [73] |
| HOH |  [73], [71], [72] |
| HCN |  [65], [73] |
| NN |  [74, 75], [67], [25, 62, 67, 76], [77], [78] |
| CO |  [27], [72], [72] |
| NO |  [79] |
| HSH |  [80], [19], [20, 73] |
| HCl |  [73], [21, 73], [81], [13, 81], [67], [67] |
|  |  [73], [73], [49,58] |
| OCO |  [81], [74], [83], [81] |
| OSO |  [84], [84], [84] |

### 4.2. Investigation of Thermal Reaction Channels

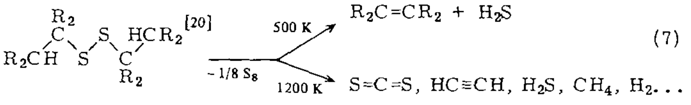
Pyrolyses in flow systems can be excellently monitored using PES gas phase analysis: the bands present vanish, new ones appear, and the temperature dependent changes allow one to optimize the conditions of decomposition, and to identify decomposition products by means of their ionization patterns. As an admittedly extreme example the pyrolysis of vinyl azide, which explodes at 70 °C[66], yielding 2*H*-azirine[66] and/or acetonitrile[57] (Fig. 7C and D) will be presented here and discussed using a section of an energy hypersurface (Fig. 7A and 7B) which has been calculated in advance.

The temperature dependent rearrangements of vinyl azide expected from the partial $C_2H_3N$-hypersurface (Fig. 7B) can be detected PE spectroscopically (Fig. 7D) if the experiments are carried out in a suitable way (Fig. 7C): the pyrolysis of vinyl azide leads, with $N_2$ elimination, mainly to 2*H*-azirine at temperatures below 650 K and to increasing amounts of acetonitrile above 650 K. Whether these two pyrolyses occur simultaneously or *via* 2*H*-azirine as an intermediate product cannot be established by the decomposition of 1,2,3-triazole, either: the $N_2$-elimination from the five-membered ring requires a higher decomposition temperature of 820 K, at which acetonitrile is observed exclusively[67].

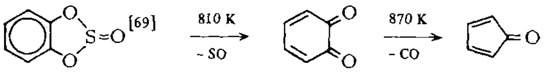
Other PE spectroscopically optimized gas phase pyrolyses (cf. Table 3) also shown several thermal decomposition channels. Examples are reactions (6)—(8).



(6)



(7)



(8)

Evidently reactions of different starting materials such as $H_3C—N_3$[26] and $H_3C—NH_2$[68] can proceed *via* the same decomposition channel (6), or one precursor such as R—SS—R[20] or $H_4C_6O_2SO$[69] can exhibit different decomposition channels as a function of temperature [(7) and (8)]. These can be independent of one another as in (7) or presumably follow each other as in (6), (8) and the reaction in Figure 7. The molecular skeleton remains unchanged at low decomposition temperatures; at higher temperatures rearrangements occur more frequently, finally leading to formation of the thermodynamically most stable products. The formation of $CS_2$ from a dialkyl disulfide, which lacks a C-atom with two CS-bonds, as observed in (7), ought to warn against hasty formulations of thermal decomposition mechanisms.

Published decomposition temperatures often differ considerably [cf. *e.g.* for (6)[26,28] or for (8)[69]], since they depend on the working pressure or on the kind of apparatus

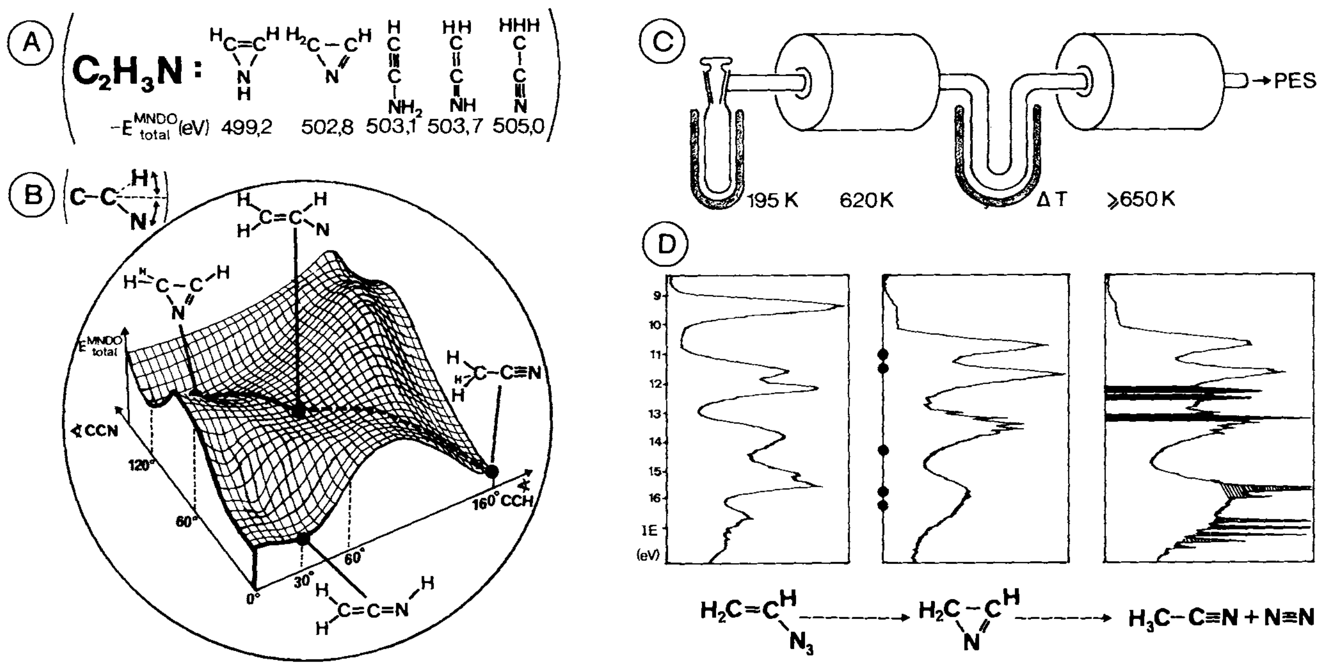


Fig. 7. A) Among its topologically possible constitutional isomers the ensemble $C_2H_3N$ comprises five molecules of "normal valence" as shown above; according to their MNDO total energies, their stability increases from 1*H*-azirine to acetonitrile. For $n=6$ atoms, a twelve-dimensional hyperspace is formed according to the $3n-6$-rule: using the angle changes Δ∢ CCN and Δ∢ CCH as coordinates, and subsequently performing a force field geometry optimization for each structure, the section B) can be calculated as an MNDO-total-energy (partial) hypersurface [57]: passing over the lowest barrier, vinyl nitrene $H_2C{=}CH\ddot{N}$, which also belongs to the $C_2H_3N$ ensemble, ought to close the ring to form 2*H*-azirine as shown in the illustration (unbroken line), and at still higher temperatures, the latter should open the ring again to form acetonitrile (broken line). In order to test this prediction, small amounts of vinyl azide (which detonates at 70 °C) were synthesized following a known procedure [66] by first reacting Cl—$H_2C$—$CH_2$—OTos with $NaN_3$ and treating the resulting Cl—$H_2C$—$CH_2$—$N_3$ with KOH. C) Vinyl azide can be vaporized without decomposition from a cooling trap at 195 K and its PE spectrum (D) can be registered [57]. By heating the quartz reaction tube filled with quartz wool to 620 K in the first oven, freezing out all condensable pyrolysis products in a U-tube cooled to 77 K and subsequent fractionated vaporization it is possible to measure the PE spectrum of 2*H*-azirine [57] (D) assigned according to $IE_n = -\varepsilon_J^{MNDO}$ (●). If the cooling bath is removed from the U-tube, and the second oven in C) is heated to temperatures above 650 K, the continuously registered PE spectra increasingly show the characteristic bands of acetonitrile (black) besides those of 2*H*-azirine (white) and $N_2$ (shaded bands) [57].

used, especially as regards diameter, length, and filling of the pyrolysis tube. In contrast to this, relative temperatures can often be given to within ±10° for comparable conditions of thermolysis using the same apparatus and internal calibration, *i.e.* reading off the temperature always at the same PES peak heights of educt and product. It is remarkable that the lowest thermal decomposition channel such as (7) at 500 °C often yields uniform products such as the alkenes. This finding is surprising in view of the usually obscure energy transmission *via* wall contacts and/or molecular collisions, and the generally unknown partition function for the vibrational and rotational degrees of freedom. The preparative possibilities to be found here are increasingly made use of, *e.g.*, in the "flash vacuum pyrolysis" technique[50-52]. A selection of the many PE spectroscopically analyzed gas phase thermolyses (Table 3) is most suitably arranged according to the smaller "leaving" molecules eliminated in each case.

The "leaving molecules" found in the Table range from molecular weight 2 (HH) to 64 (OSO); the examples chosen (cf. reviews such as [3,4,47,50,51]) together with the thermolyses (6) to (9), are only intended to illustrate the possible scope of application: Thus, cyclic sulfites, apart from $SO_2$[84] (see Table 3), can eliminate SO[69] [see (8)]. Unsaturated hydrocarbons are represented here by propene alone (Table 3), since experience has proven its value as an excellent leaving group in the gas phase generation of unstable species such as thioacrolein $H_2C{=}CH{-}HC{=}S$[73] or silabenzene $C_5SiH_6$[49,58] (Section 4.3), and since the allylic function is easily introduced into compounds, *e.g.*, *via* Grignard reactions. Special mention must be made, *e.g.*, of acetylene, which occurs as a thermodynamically favored pyrolysis product at higher temperatures[20,73]. The likewise favorable elimination of HCN has been little investigated so far; furthermore, there is a lack of PE spectroscopically determined elimination temperatures for common "leaving" molecules (Table 3) for a comparable type of reaction, such as the formation of ketene from carboxylic acid derivatives[73] [Reaction (9)].

 (9)

$$H_3C{-}C(=O)X \underset{}{\overset{T}{\rightleftarrows}} H_2C{=}C{=}O + HX \qquad (9)$$

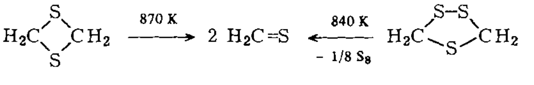
| HX | $HOCOCH_3$ | HCl | HBr | HOH | $HOC_2H_5$ | $HCH_3$ ... |
|---|---|---|---|---|---|---|
| *T* [K] | 570 | 580 | 650 | 720 | 740 | 1130 |

In this context the empirical inquiry into favorable *"thermal leaving molecules"* for specific thermolyses is of special interest. However, a numerical comparison is difficult (the heats of formation of the elements are zero by definition). As one of the "rules-of-thumb" in circulation the classification of di- and tri-atomic species *M* according to the sum of their bond dissociation energies $\sum D(XY)$ might be mentioned, which *e.g.* for HCN consists of

$HCN \rightarrow H^{\odot} + CN^{\odot} \rightarrow C + N^{\odot}\ (+H^{\odot})$[85]:

| *M* | HCN | CO | $SO_2$ | $N_2$ | $H_2O$ | $H_2S$ | HCl | HBr... | |
|---|---|---|---|---|---|---|---|---|---|
| $\sum D(XY)$ [kJ/mol] | 1270 | 1075 | 1070 | 949 | 920 | 720 | 431 | 364 | (10) |

For larger molecules, better quantitative criteria are the sums of the energies of all bonds formally involved in the decomposition, supplemented by contributions *e.g.* from reduced steric hindrance or $\pi$ systems formed[85]. The simplicity of PE spectroscopic analysis must be stressed here, which with only 1 mmol, and using an apparatus (Fig. 5) readily constructed from an assembly kit usually yields the *experimental result* in a single day!

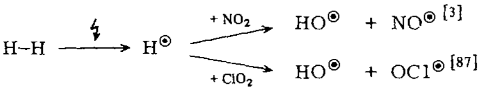


(11)

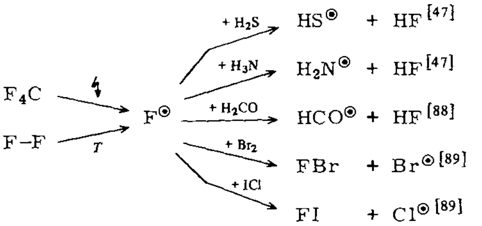
Thermal decompositions which give rise to only one volatile product, such as *e.g.* in (11)[22,71], are especially advantageous in generating short-lived molecules (Section 4.3) such as thioformaldehyde[13], first detected in interstellar space.

### 4.3. Detection of Reactive Intermediates

The detection method discussed previously—one registers changes in the PE spectroscopic band patterns (Fig. 1) of a flowing gas (Fig. 4 or 5) while varying the reaction conditions (Fig. 6 or 7) — is well suited for the detection of numerous atoms and molecules which cannot be "put into bottles" at room temperature (Table 4). Both the given conditions of the apparatus (vacuum, comparatively small amounts of the compounds, species being usually formed in their neutral ground state) and the possibility of identifying the reactive intermediates by Koopmans correlations[16] with their calculated ionization patterns $-\varepsilon_J^{SCF} = IE_n^V$ [cf. (3) or Fig. 2] are particularly advantageous.



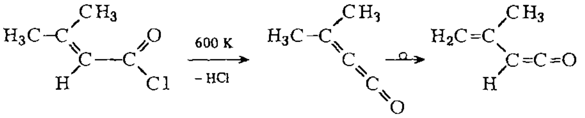
(12)



(13)

Usually the particles formed have a rather high energy, with only a few exceptions such as $O_2N{-}NO_2$[61] which is produced by cooling; they are predominantly generated using three methods: external heating of the gaseous flow, if necessary up to 2900 K[47], electrodeless microwave discharge[3,47] (Table 4: ↯), or reaction (Table 4: R) with atoms such as $H^{\odot}$[3,47,86,87] or $F^{\odot}$[3,47,88,89] formed thermally or in discharges.

A disadvantage of the microwave method is the high electron and energy density in the discharge zone, which is about 5 cm long[3,47]. Often the desired product is formed unspecifically in admixture with others, so that special methods of evaluation[3,47], such as "spectra stripping"[68], must be used in order to separate the overlapping PES bands. In comparison, reactions of atoms from microwave discharges such as $H^{\odot}$ and $F^{\odot}$ [reactions (12) and (13)] show a more homogeneous behavior[3,47]. The detection of short-lived species requires as short as possible a distance between reaction zone and ionization chamber: at a minimum distance of 1 cm particles with half-lives of about $10^{-3}$ s ought to be observable according to an estimation of the gas flow rate[26]. Thus during the thermal elimination of HCl from 3-methylcrotonic chloride the PE spectrum of the more stable tautomeric vinyl ketene is observed instead of that of the first formed isopropylidene ketene, if the distance from the pyrolysis tube to the place of measurement exceeds approximately 20 cm [reaction (14)][81].



(14)

Many transients, however, possess longer lifetimes, ranging from the order of minutes, such as HN=NH, to several hours, such as S=S=O (cf. *e.g.* the literature cited in [3]).

Since 1970, many types of "reactive intermediates" have been identified and characterized PE spectroscopically: atoms, radicals, radical anions such as $H_2C^{\cdot -}$[90], valence unsaturated molecules (Table 4), up to molecules such as $O_3$[91] or $O_2N{-}NO_2$[61], which under standard conditions quickly react to form thermodynamically more favorable products. A representative selection is presented in Table 4 (cf. [3,10,47] as well as Section 4.2).

The lifetimes of the compounds listed in Table 4 range from short-lived $^{\odot}NF_2$ or also the vibrationally excited nitrogen molecule[3,128] to those that can be isolated in pure form for short times or at low temperatures such as OOO or HCP. Many of them are not generated by thermal decomposition (Section 4.2) or in a microwave discharge [reactions (12) and (13)], but *via* the reaction of gases with solids, thus:

Table 4. "Reactive intermediates" of molecular size $M$ (x = number of atoms) which have been identified and characterized PE spectroscopically, listed according to increasing group and periodic numbers of the elements. Radicals are characterized by $M^{\odot}$, special, *i.e.* non-thermal, ways for their generation by (⊙) for (microwave) discharge and (R) for chemical reaction.

| x | *M* | Examples |
|---|---|---|
| 1 | A | H (↯) [86], N (↯) [86], O (↯) [86, 92], F [89] (↯) [3, 47, 88], Cl (↯) [3], Br (↯) [3], Ba [3, 93], Zn [3, 4, 93] |

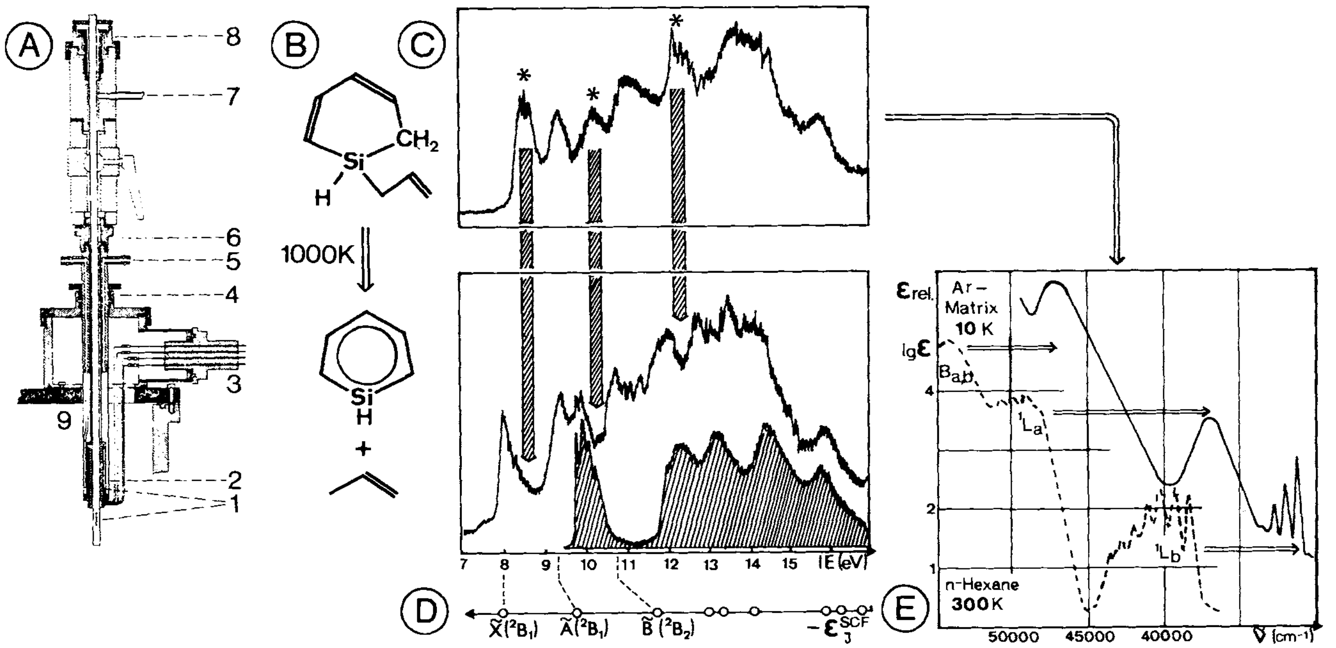

Fig. 8. PE spectroscopic detection of silabenzene [49] and its matrix isolation [131]: A) short path pyrolysis apparatus (1. Furnace over electron exit slit, 2. water cooling mantle, 3. current feed, 4. locking nut, 5. water cooling, 6. centering device, 7. backing pump connection, 8. adjusting device for internal tube, 9. PE spectrometer cavity); B), the precursor 1-allyl-1-sila-2,4-cyclohexadiene, which splits off propene quantitatively at an oven temperature of 1000 K; C) PE spectra (*: vanishing bands, shaded area: PE spectrum of propene, to be substracted); D) assignment of the three lowest radical cation states by means of an SCF calculation with a 2s(H), 7s/3p(C) and 9s/5p(Si) basis set; E) UV-spectrum of silabenzene in an Ar matrix at 10 K with band displacements of 8100, 12200 and 7000 cm⁻¹ relative to UV spectrum of benzene (broken lines).

$$\begin{array}{llll} H_2S & + (B)_\infty & \rightarrow HBS + H_2 & [108] \\ SiF_4 & + (Si)_\infty & \rightarrow SiF_2 & [104] \\ OSCl_2 & + (Ag_2S)_\infty & \rightarrow OSS + (AgCl)_\infty & [53, 106] \\ F_3CPH_2 & + (KOH)_\infty & \rightarrow FCP + (KF+H_2O)_\infty & [111] \end{array} \qquad (15)$$

In conclusion, the usefulness of PE spectroscopic investigations for the preparative isolation of a reactive intermediate will be discussed using silabenzene as an example (Table 3 and Fig. 8).

As a 6π-electron system of $C_{2v}$ symmetry, silabenzene has been the aim of numerous theoretical and experimental efforts[129]: SCF calculations have suggested its viability[49]; π ionization energies of 8.2, 9.2 and 11.5 eV were predicted from perturbation treatments[7]. However, attempts to thermolize derivatives of 1-sila-2,4-cyclohexadiene $H_7C_5SiX$ for a long time met without success because of unfavorable choice of leaving groups such as HCl [see (10)]. It was only the elimination of propene that made it possible to trap adducts[129]. The detection of silabenzene[49,58] was accomplished in the short path pyrolysis apparatus shown (Fig. 8 A). The assignment of the PE spectrum relies on an SCF calculation with a large basis set[130] (Fig. 8 C and 8 D). Using PE spectroscopically optimized conditions for the pyrolysis, the mass spektrum could be subsequently measured[130], and the preparative isolation accomplished[131]. The comparison of the UV spectrum recorded in an Ar matrix at 10 K with that of benzene (Fig. 8 E) leads us full circle: as can be calculated, the perturbations[130] show that silabenzene has a similar π electron system as benzene.

### 4.4. Testing Gas Phase Syntheses

Stoichiometric reactions of gases can often be adjusted and examinated advantageously by means of PE spectroscopy: thus one succeeds in obtaining a pure gaseous flow of the reactive intermediate sulfinylimide O=S=NH[59] (Fig. 9 and Table 4).

The gas + gas synthesis of OSNH (Fig. 9) complements the already discussed types of reactions of gases such as pyrolyses (Figs. 6—8 and Tables 2—4), discharges [Table 4 and (12), (13)] or reactions with solids [Table 4 and (15)]. Thus PE spectrometers are in general well suited for monitoring gaseous streams of pure compounds, for example to simplify the determination of structures by microwave and especially electron diffraction methods.

Gas + gas reactions can formally be subdivided into acid/base and redox reactions. Of the numerous possible applications the following should be emphasized:

⇒ detection and characterization of donor/acceptor complexes (Lewis base/Lewis acid adducts) in the gas phase, *e.g.*

$$\begin{array}{l} R_3N + Br_2 \rightarrow R_3N\cdot Br_2 \; [132] \\ R_2O + HCl \rightarrow R_2O\cdot HCl \; [133] \end{array} \qquad (16)$$

⇒ separation of gases *via* the formation of salts, *e.g.* according to

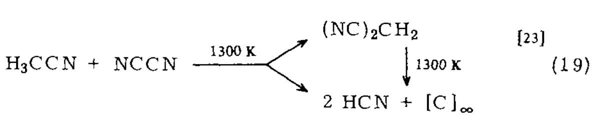
$$H{-}M{-}Cl \xrightarrow{\Delta T} \{M + HCl\} \xrightarrow{NH_3} [NH_4^{\oplus}\, Cl^{\ominus}]_\infty + M \qquad (17)$$

In this way it is possible to register the PE spectra of pure compounds such as $M = H_2C{=}S$[13], $H_2C{=}S{=}O$[73,82] or $R_2C{=}C{=}O$[73,81].

⇒ syntheses of new compounds (cf. Fig. 9), *e.g.*:

$$H_3C{-}NH_2 + SCl_2 \xrightarrow{NH_3} H_3C{-}NS + 2\,[H_3C{-}NH_3^{\oplus}\,Cl^{\ominus}]_\infty \;[54]$$
$$P_4 + 8\,NO + [C]_\infty \xrightarrow{1800\,K} 4\,PN + 2\,N_2 + 8\,CO \;[100] \qquad (18)$$

⇒ fast elucidation of gas phase reactions, *e.g.*:



$$H_3CCN + NCCN \xrightarrow{1300\,K} (NC)_2CH_2 \;[23] \xrightarrow{1300\,K} 2\,HCN + [C]_\infty \qquad (19)$$

Evidently a thermal synthesis of malononitrile from acetonitrile and cyanogen is thwarted by the fact that at the temperature necessary for the reaction the desired product already decomposes to hydrocyanic acid and graphite [cf. (10)].

The last mentioned possible application of PES analysis—elucidation of gas phase reactions including their temperature dependence within a few hours—will probably become more important with the availability of portable PE spectrometers (Fig. 4C), especially for the testing of solid state contacts for heterogeneously catalyzed gas phase reactions (Section 4.5).

### 4.5. Testing Solid State Catalysts for Gas Phase Reactions

This last section dealing with "examples of PE spectroscopically optimized gas phase reactions" should be regarded as an outlook on future developments of preparative syntheses, since according to the literature only the following three heterogenous catalyses have so far been worked out using PE spectroscopic analysis:

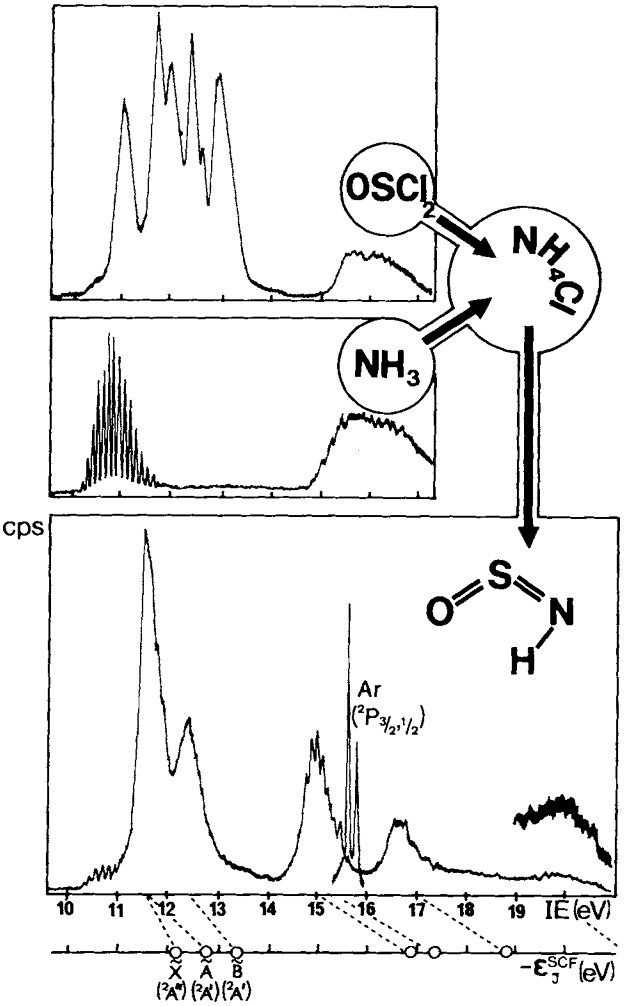


Fig. 9. The PE spectroscopically controlled gas phase synthesis of sulfinylimide: ammonolysis of sulfinyl chloride occurs both spontaneously and quantitatively upon mixing the gaseous reactants in a reaction flask. The PE spectra of the precursors and the product which do not overlap in essential regions allow one to quickly adjust the 3 : 1 stoichiometry, and to monitor it continuously. In the OSNH spectrum chosen here one recognizes a small excess of $NH_3$ by the band with its vibrational fine structure at 10.5 to 11 eV. The PE spectrum, calibrated with the Ar double peak (15.76/15.94 eV) has been assigned using an SCF calculation [59]; according to it one expects still within the He(I) range a seventh radical cation state of OSNH which can be recognized at 20.15 eV with a higher count rate.

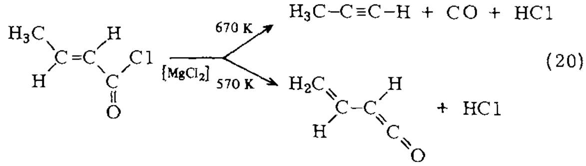
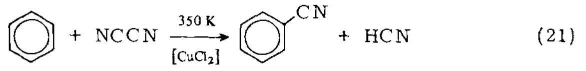
⇒ reduction of the pyrolysis temperature of crotonic acid chloride; the catalyst is $MgCl_2$ or "didymium chloride" on γ-aluminum oxide[10,73]:



⇒ cyanylation of benzene; catalyst $CuCl_2$ (partially reduced) on γ-aluminum oxide[46]:



⇒ bromination of trifluoromethane (Fig. 10); catalyst $CuF_2$ (from $CuCl_2$ by heating in an $F_3CH$ stream, 800 K, 5h) on charcoal[24]:

$$F_3CH + Br_2 \xrightarrow[\text{[CuF}_2\text{]}]{400\,K} F_3CBr + HBr \qquad (22)$$

The gas phase bromination of trifluoromethane is of technical interest, since the bromotrifluoromethane formed is used as an effective fire extinguishing agent for the protection of valuable goods. The search for suitable catalysts is worthwhile because of the corrosion problems at higher reaction temperatures. Their effectiveness is judged from the temperatures at which the PE bands of $Br_2$ and HBr are at the same height (Fig. 10). An additional advantage of PES analysis is the possibility of recognizing the initial fluorination, at high temperatures, of oxidic carriers by $F_3CH$ *via* the appearance of bands of $H_2O$, CO or $CO_2$. The exactness which can be obtained with PE spectroscopy does not exceed ±2% even in favorable cases[23] so that subsequently a refining optimization on a preparative scale had to be carried out using conventional recycling apparatus[24]. Nevertheless, there results a considerable saving of time when searching for catalysts: two tests per day and per PE spectrometer can be carried out over the temperature range of interest. Furthermore, "real time" gas analysis with a PE spectrometer set up near the catalyst zone responds without delay to the ratio of reactants, which can be adjusted smoothly at the valves.

## 5. Outlook: PE Spectroscopic Gas Analysis as a Complementary Method and as a Measuring Procedure Capable of Development

Many different methods of measurement are available for the analysis of gases in flow systems, among which gas chromatography (GC)[134,135], mass spectrometery (MS)[136-138] and vibrational spectroscopy[139-140] are well established and have been abundantly applied. With reference to PE spectroscopic gas analysis, as presented above, one must therefore inquire which advantages and disadvantages these methods possess, broadly speaking, and to what extent they complement each other.

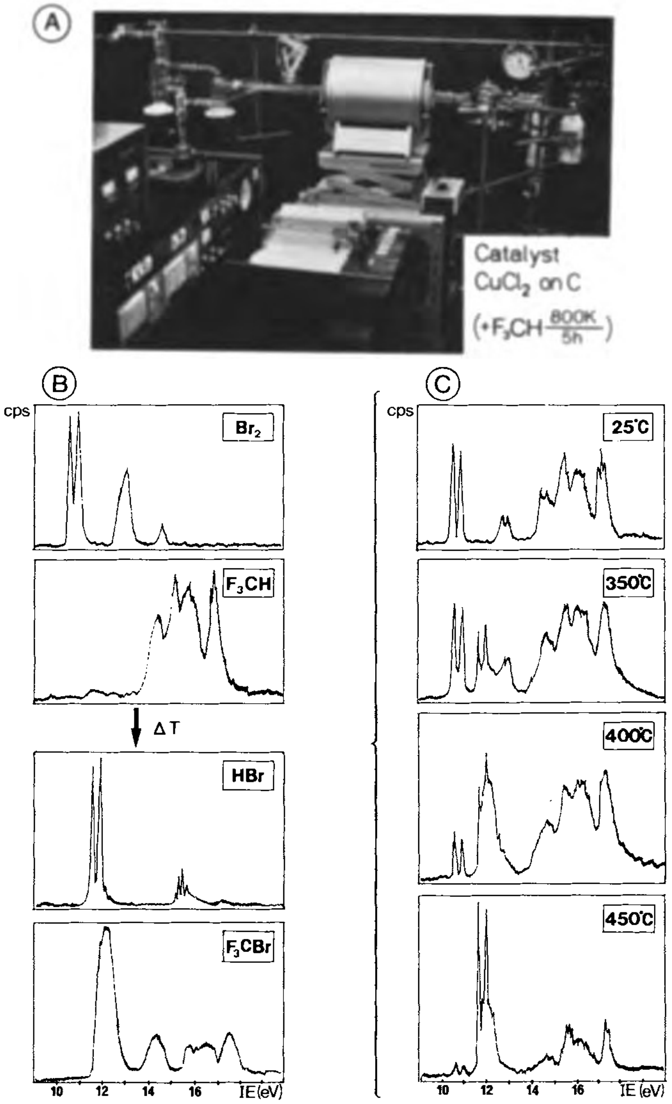


Fig. 10. The PE spectroscopic optimization of the heterogeneously catalyzed thermal bromination of trifluoromethane. A) Apparatus (from right to left): steel bottles with $F_3CH$ and $Br_2$, mixing bulb filled with Raschig rings, adjustable oven, capillary tube outlet into the PE spectrometer (cf. Fig. 5), cold traps and (not visible) oil pump. B) PE spectra of the components of the reaction, the band patterns of which obviously do not overlap completely. Particularly advantageous for gas analysis are the double peaks of HBr and $Br_2$ (cf. Fig. 1). C) Temperature dependence of the course of the Cu-catalyzed gas phase bromination: Increase and decrease of all components of the reaction can be monitored by comparison with the spectra of the pure compounds in B.

*Gas chromatography:*

advantages: well suited for mixtures and their simultaneous separation, simple as far as the instrument is concerned[134, 135]

disadvantages: no real-time measurement, unknown compounds and especially reactive intermediates can be identified only with difficulty or not at all, no information on structures or states.

*Mass spectrometry:*

advantages: even big molecules can be identified by their isotopic patterns, high sensitivity[137], elaborate measuring techniques with many extensions such as chemical ionization[138], large data bank[136].

disadvantages: fragmentation patterns of unknown products only predictable under certain conditions, digitalization[136] required for quantitative analysis, no immediate structural information, instrumentation sometimes expensive.

*Vibrational spectroscopy:*

advantages: (to be differentiated for FIR, IR and Raman, with or without Fourier transform technique) "molecular fingerprint" method with information on structure and state, sensitive, suited for kinetic investigations.

disadvantages: selection rules require many small molecules to be IR inactive, interpretation of spectra *via* normal coordinate analysis difficult, especially FIR not well suited for hot gases (emissions!), instrumental expense sometimes high.

*Photoelectron spectroscopy:*

advantages: molecular "fingerprints" with information on structure and state, favorable interpretation of spectra with MO methods, instrumentally simple, well suited for temperature dependent investigations.

disadvantages: not well suited for multicomponent mixtures and large molecules.

As can be seen from this greatly simplified comparison, none of these methods for gas analysis is perfect in every respect. In practical applications combinations such as GC/MS or PES+MS have therefore proven valuable; in many cases GC/PES would also complement each other[142].

For photoelectron spectroscopy numerous extensions of the range of applications are either now available, under development, or conceivable. Thus negative ions in the gaseous phase[3,90] or molecules adsorbed on a surface[141] can be investigated with PE spectroscopy. Portable instruments for laboratory use (Fig. 4C) and extensive computer programs[45] (multiple scan, reduction and simulation of spectra, spectral data bank for comparison) are available or presently being developed. One would also appreciate the availability of multichannel analyzers for fast registration as well as simultaneous registration of many components. As a wild speculation, one might dream of miniaturized PES probes in the flow tube and especially in the reaction zone itself.

By means of photoelectron spectroscopy, our knowledge of radical cation states has been greatly extended over the past few years, quantum mechanical calculation techniques have been tested using ionization patterns, many reactive intermediates could be characterized for the first time, and, finally, heterogeneously catalyzed gas phase reactions are being optimized. Starting from this successful balance, one may expect for the future—together with systematic investigations *e.g.* of the margins of error—a further development of photoelectron spectroscopic gas phase analysis in flow systems.

*The Frankfurt photoelectron spectroscopy group thanks Professor Edgar Heilbronner "in cumulo" for much good advice, his interest and his advancement of our research. The investigations in PE spectroscopic gas analysis were carried out together with S. Aygen, G. Bert, R. Dammel, T. Hirabayashi, S. Mohmand, H. Müller, M. Pohlenz, U. Stein, and J. Wittmann, whose impetus and dedication should be emphasized. Here as well P. Rosmus and A. Semkov have contributed to the successful outcome with their quantum mechanical calculations, H. J. Arpe (Hoechst AG) and J. Mintzer with their advice for the development of catalysts. Joint ventures were carried out together with R. Appel (Bonn), T. J. Barton (Ames, Iowa), G. Becker (Marburg), E. Block (St. Louis, Missouri), L. Horner (Mainz), G. Maier (Giessen), W. Ried (Frankfurt), H. W.Roesky (Göttingen), J. Russow (Hoechst AG), and R. Steudel (Berlin). The University of Frankfurt and the State of Hesse provided the PE spectrometers and supported the investigations; we gratefully acknowledge the additional support of the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Hoechst AG, the Max-Buchner- and Hermann-Schlosser-Foundations.*

[16] According to *Koopmans'* theorem [2-12], $IE_n = -\varepsilon_j^{SCF}$, J = n ionizations correspond to the J doubly occupid molecular orbitals. The different effective nuclear charges for p- and s-electrons enter the SCF-calculations as parameters; cf. *e.g. J. A. Pople, D. L. Beveridge:* Approximate Molecular Orbital Theory, McGraw-Hill, New York 1970, p. 71: C(2p) 10.7 eV compared to C(2s): 19.4 eV or O(2p): 15.9 eV compared to O(2s): 32.4 eV. This is why SCF molecular orbitals used for the assignment of PE-spectra possess high p-atomic orbital contributions for low ionization energies and high s-atomic orbital contributions for high ionization energies. A pefect PE-spectroscopic example for s-type ionizations are the helium(II)spectra of organic molecules studied by *E. Heilbronner* et al. [5, 15].

# Structure and Bonding in Cyclic Sulfur-Nitrogen Compounds—Molecular Orbital Considerations

**By Rolf Gleiter**[*]

*Dedicated to Professor Edgar Heilbronner on the occasion of his 60th birthday*

The molecular structures of monocyclic sulfur-nitrogen ring systems, such as $S_2N_2$, $S_3N_3^{\ominus}$, $S_4N_3^{\oplus}$ and $S_5N_5^{\oplus}$, can be considered as examples of electron rich $(4n+2)\pi$ systems. The structures of $S_4N_4$, $S_4N_4^{2\oplus}$, $P_4S_4$, $As_4S_4$ and the bicyclic structures $S_4N_5^{\ominus}$, $S_4N_5^{\oplus}$ as well as $S_5N_6$ can be rationalized on the basis of a planar tetrasulfur tetranitride with $12\pi$ electrons.

## 1. Introduction

Since the fifties, when *Becke-Goehring et al.*[1] started a revival of sulfur-nitrogen chemistry, the syntheses and structures of a large number of cyclic and bicyclic ring systems containing sulfur and nitrogen only have been reported[2]. The recent discovery of the solid state properties of $(SN)_x$ and the observation that electron rich sulfur-nitrogen compounds can serve as donors in charge-transfer complexes has spurred interest in this class of compounds. From the viewpoint of an organic chemist, accustomed to relatively straightforward synthesis, the reported procedures of preparation very often seem strange and accidental. This can be seen from Figure 1, which shows schematically the most important paths from $S_4N_4$ to various cyclic sulfur-nitrogen compounds. The structural variety is also puzzling, at least at first glance. An attempt is made in the following to rationalize the structures of most mono- and bicyclic SN compounds based on a molecular orbital (MO) model, using arguments from perturbation theory[3]. The explanations put forward rest on molecular orbital calculations using semiempirical procedures or *ab initio* methods. Both types of calculation have been proven to be reliable, at least to rationalize the gross structural features. The compounds which will be discussed in detail are shown in Figures 2 and 3, together with their most relevant structural details.

## 2. Planar Rings and the Hückel Rule

If we divide the six valence electrons of sulfur and the five valence electrons of nitrogen in a planar ring system,

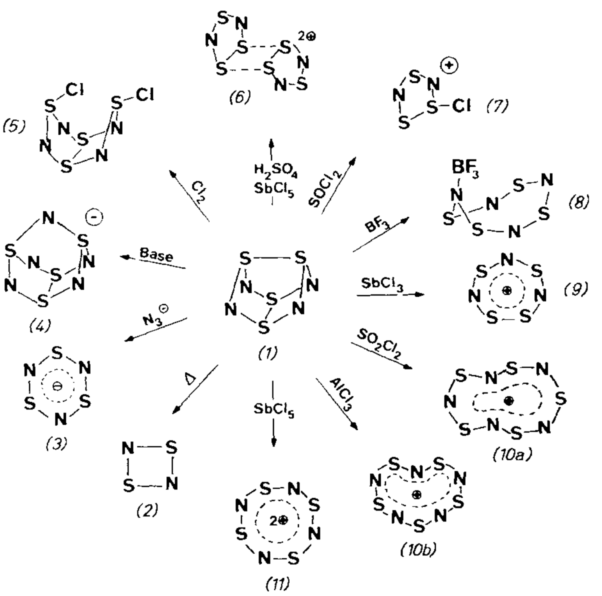

Fig. 1. Formation of various cyclic SN-compounds from $S_4N_4$.

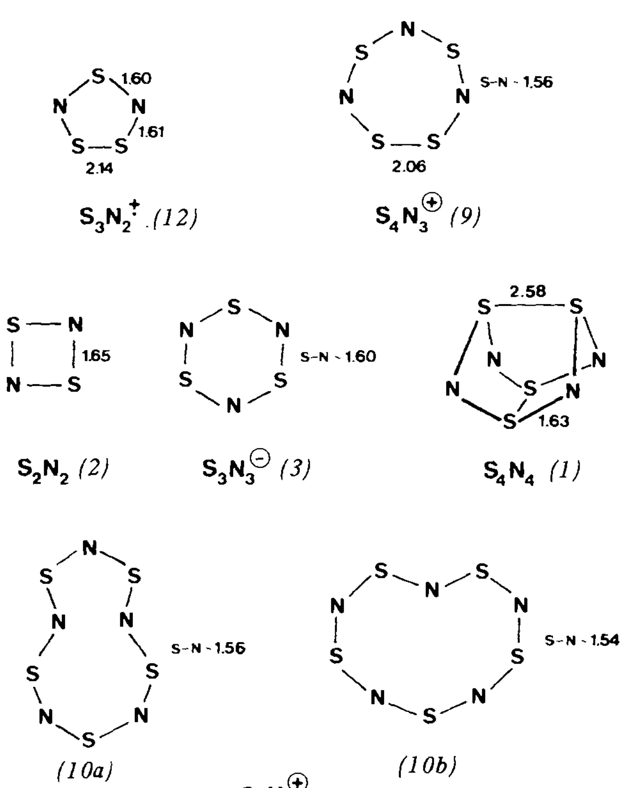

Fig. 2. Most prominent structural features of monocyclic SN-compounds of general formulae $(SN)_x$ and $S_2N(SN)_y$.

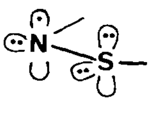
in such a way that each atom contributes one electron to a σ bond and two electrons to a lone pair, then two π-electrons are left on sulfur and one on nitrogen.



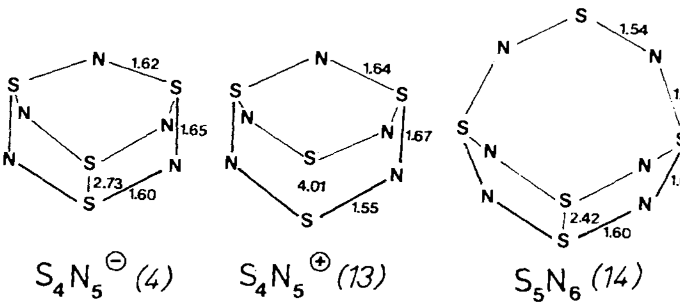


Fig. 3. Most prominent structural features of the bicyclic SN-compounds $S_4N_5^{\ominus}$, $S_4N_5^{\oplus}$ and $S_5N_6$.

Bearing this division scheme in mind, the following numbers of π-electrons for the simple monocyclic systems listed in Figure 2 can be counted:

| No. of π-electrons | Ring system | |
|---|---|---|
| 6π | $S_2N_2$ | *(2)* |
| 10π | $S_3N_3^{\ominus}$ | *(3)* |
| 10π | $S_4N_3^{\oplus}$ | *(9)* |
| 14π | $S_5N_5^{\oplus}$ | *(10)* |

In fact, planar structures have been reported[5-9] for all four systems possessing $(4n+2)\pi$-electrons[4]. This suggests that Hückel's rule[4] works well for these systems. In contrast to the case of stable organic π-systems, antibonding π* levels are also occupied in the SN rings (electron rich $(4n+2)\pi$-systems[10]). The relative stability of these systems might be due to two factors:

1) The higher electronegativity of nitrogen compared to carbon or sulfur[11], lowers the antibonding π* levels towards the bonding region.
2) The larger SN bond length in these rings reduces the mutual repulsion of any pairs of electrons relative to the corresponding hydrocarbon π-system. Thus, the total energy of the π-system is lowered[3b].

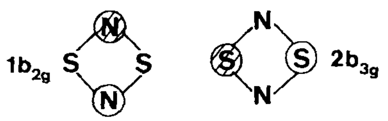
## 3. Monocyclic SN-Rings of the Type $(SN)_x$

### 3.1. Disulfur Dinitride $S_2N_2$

X-ray diffraction measurements on $S_2N_2$ *(2)* in the solid state at −130°C indicate a cyclic square planar molecule ($D_{2h}$) with a common SN bond length of 1.65 Å[5].

A detailed investigation of the electronic structure of *(2)* using *ab initio* techniques[12] and semiempirical methods[13] confirms the simple picture presented in Section 2. Using the Edmiston-Ruedenberg localization procedure[14], the set of eight canonical σ-type MO's of *(2)* can be transformed to a set of four SN σ bonds and one lone pair at each center[13a]. The remaining three occupied π-MO's from *(2)* are just the ones anticipated for a cyclobutadiene dianion. The two highest occupied MO's of *(2)* are, on theoretical grounds, predicted to be nearly degenerate and to belong to the irreducible representations $B_{3g}$ and $B_{2g}$.

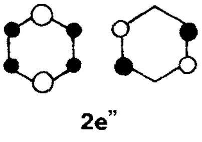
The orbital sequence predicted by several methods of calculation has been confirmed by X-ray[15] and UV-photoelectron spectroscopy[16]. It is found that inclusion of sul-



fur 3d-functions improves the numerical results, but does not change the overall picture; 3d-functions act as polarization functions. All calculations predict a surplus of negative charge at the nitrogen centers (*ca.* 0.4 e).

### 3.2. The Trisulfur Trinitride Anion $S_3N_3^\ominus$

The crystal and molecular structure of $[n\mathrm{Bu}_4\mathrm{N}^\oplus][\mathrm{S}_3\mathrm{N}_3^\ominus]$ has been determined by X-ray analysis. For the anion *(3)* a six-membered, essentially planar ring with SN bond lengths in the range 1.58 to 1.63 Å is found[6]. *Ab initio* calculations (Hartree-Fock approximation)[6] confirm the picture derived from a simple HMO treatment: the highest occupied π-MO's (2e'', see below) are π* in character and thus essentially reduce the π bond order to the contribution from the lowest lying π-orbital.



The UV spectrum (broad band at 360 nm) has been assigned to a $2a_2(\pi^*) \leftarrow 2e''(\pi^*)$ transition[6].

### 3.3. Tetrasulfur Tetranitride ($S_4N_4$)

$S_4N_4$ *(1)* is formed by reaction of $NH_3$ with sulfur chlorides having the composition, "$SCl_3$". The orange crystalline compound has been known since 1835[17]. The speculation over the structure of *(1)* has been brought to an end by an X-ray structure analysis which indicates that $S_4N_4$ has a cradle shaped structure belonging to point group $D_{2d}$[18,19]. In order to use our simple rules to deduce and understand the structure of $S_4N_4$ it has been assumed to be planar with $D_{4h}$ symmetry. The resultant π-orbital scheme is shown in Figure 4[20]. Because nitrogen has a higher electronegativity than sulfur[11] the $b_{2u}$-orbital lies below the $b_{1u}$-orbital in the MO scheme (Fig. 4).

Using Hund's rule, the twelve π electrons doubly occupy the orbitals $a_{2u}$, $e_g$, $b_{2u}$ and $b_{1u}$, while each of the components of the higher $e_g$ orbital accommodates a single electron. Thus, the $D_{4h}$ model predicts a triplet ground state and leads one to expect a Jahn-Teller effect. There are two possible ways to obtain a stable singlet ground state of $S_4N_4$: either the degeneracy of the half occupied $e_g$ level is effectively split or $e_g$ is destabilized and $a_{2u}$ stabilized. Both possibilities are shown in Figure 5.

As with other eight-membered ring systems such as cyclooctatetraene or sulfur ($S_8$), bond alternation or ring puckering might be envisaged. Examination of six possible slight deformations of $S_4N_4$ shows no or no significant splitting or switching of the orbitals and thus, no change in the multiplicity is expected[20].

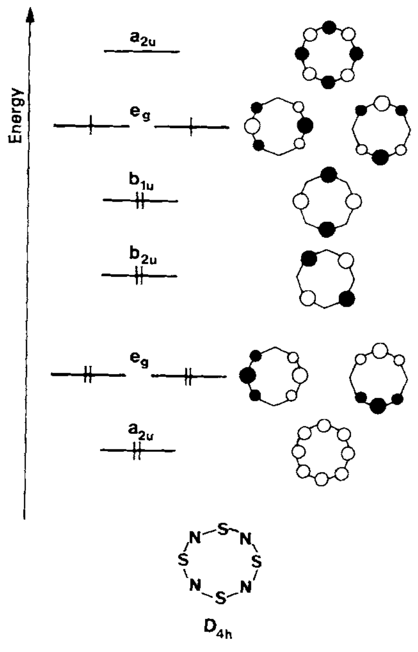


Fig. 4. π-MO scheme of the hypothetical planar $S_4N_4$.

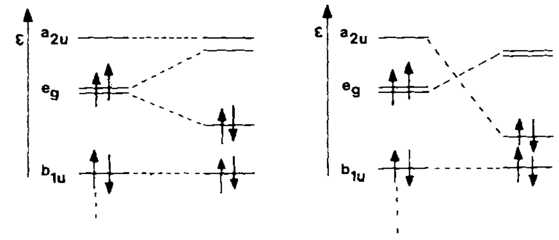

Fig. 5. Possible ways for stabilization of the singlet ground state of $S_4N_4$.

Larger effects are expected from transannular interactions: between pairs of bonds which face each other, as in the tub-form, and between opposite pairs of atoms, as in the crown or cradle conformation. The transannular interaction between opposite bonds does not lead to splitting of $e_g$ or to lowering of $a_{2u}$. The second type of transannular interaction is shown in the correlation diagram in Figure 6[20]. In the crown conformation the $a_{2u}$ level is stabilized but the $b_{1u}$ is destabilized; Formation of two transannular bonds gives a singlet ground state (Fig. 6, right)[20].

Consideration of symmetry arguments alone indicates that coupling of *two* transannular bonds leads to stabilization of the ground state. Molecular orbital calculations indicate that bond formation between the sulfur atoms in $S_4N_4$ is more efficient than between the nitrogen atoms[20,21].

A decisive factor in the stabilization of the singlet ground state is the strong interaction of the 3p orbitals of sulfur over a distance of 2.58 Å; for bond lengths between 2.8 and 2.0 Å the $3p_\sigma$-$3p_\sigma$ overlap of the two sulfur atoms is much larger than the $2p_\sigma$-$2p_\sigma$ overlap of the two nitrogen centers (Fig. 7)[20].

Using CNDO type wave functions, localized molecular orbitals for $S_4N_4$ have been derived[21a]: it is found that both the SS and the SN bonds are slightly bent single bonds with pure p-character. Electron delocalization occurs by transfer of electron density from the lone pairs on

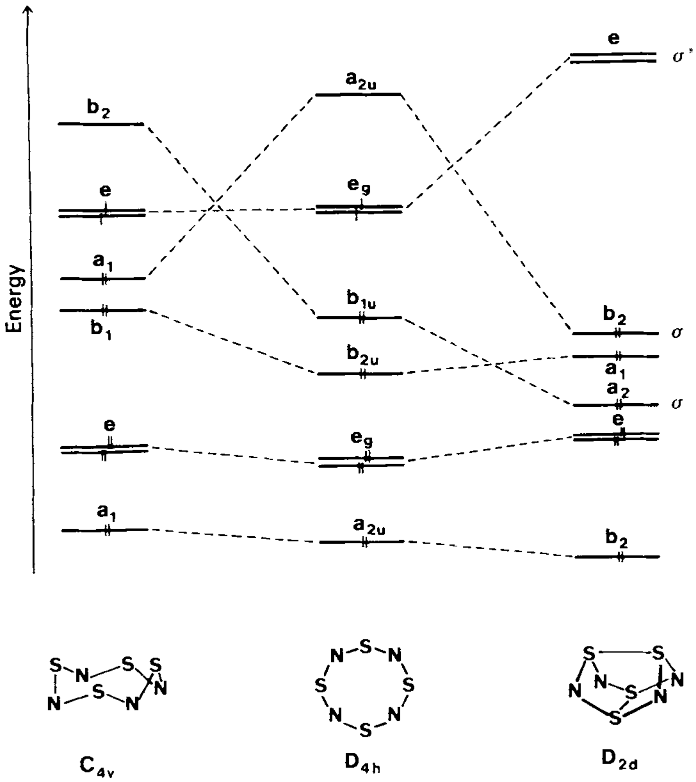

Fig. 6. Correlation between the π-MO's of a planar $S_4N_4$ with the valence MO's of $S_4N_4$ in the crown and cradle conformations.

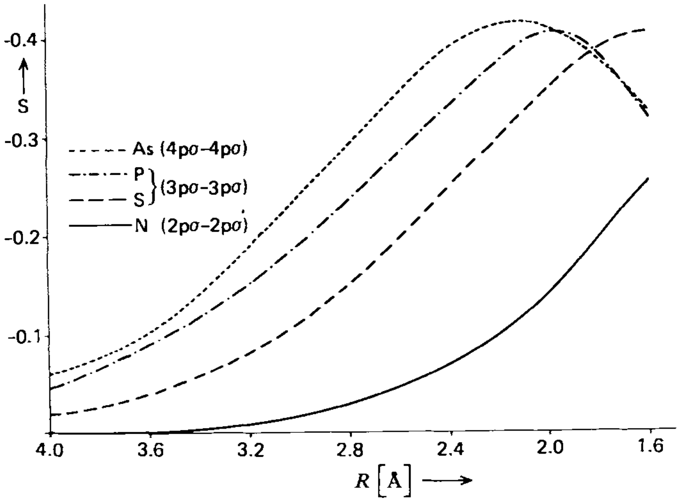

Fig. 7. $p_\sigma$-$p_\sigma$ overlap integrals S as a function of distance $R$ for N ($2p_\sigma$-$2p_\sigma$), S, P ($3p_\sigma$-$3p_\sigma$) and As ($4p_\sigma$-$4p_\sigma$).

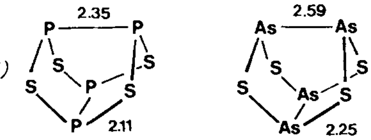
nitrogen to the neighboring sulfur atoms[13c,21]. The results obtained by semiempirical calculations have been confirmed by *ab initio* methods[16b] and X-ray and UV-photoelectron spectroscopy[16b,22] on $S_4N_4$.

### 3.4. Structures Related to $S_4N_4$

From Figure 7 it can be seen that the $p_\sigma$-$p_\sigma$ overlap integrals for P($3p_\sigma$-$3p_\sigma$) and As($4p_\sigma$-$4p_\sigma$) are larger than those for S($3p_\sigma$-$3p_\sigma$) and N($2p_\sigma$-$2p_\sigma$). From the arguments in the previous section it is understandable that in realgar, $As_4S_4$ *(16)*[23], and α-$P_4S_4$ *(15)*[24], the sulfur atoms occupy the positions "in the plane", while the transannular bonds are formed between As and P atoms respectively (Fig. 8).



*(15)* *(16)*

Fig. 8. Structures of realgar ($As_4S_4$) and α-$P_4S_4$.

$S_4N_4$ forms adducts with Lewis acids for which two types of structures result: If only one Lewis acid is bound, the $S_4N_4$ structure is changed completely and the eight-membered ring adopts a saddle-type structure (Fig. 9). Examples are the adducts with $BF_3$[25] (Fig. 9), $SbCl_5$[26], $SO_3$[27] and $FeCl_3$[28]. If $S_4N_4$ behaves as a bidentate ligand *e.g.* with CuCl, CuBr, and $CuCl_2$, the cage-like structure is retained[29]. The complexes with $BF_3$, $SbCl_5$ and $FeCl_3$ are reminiscent of the structure of $S_4N_4O_2$[30] (Fig. 9).

In the saddle-like structures, seven centers are arranged in an almost planar fashion. The resulting system is similar to a heptatrienyl fragment with ten π-electrons. In the case of adducts with Lewis acids, homoconjugation between the sulfur centers is suggested by MO calculations[31].

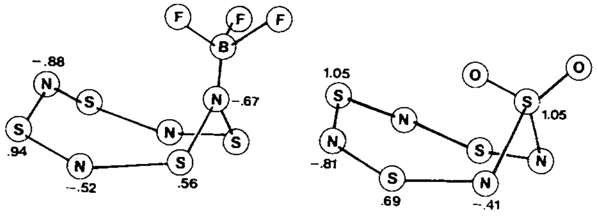


Fig. 9. Structure of $S_4N_4 \cdot BF_3$ and $S_4N_4O_2$ together with MNDO calculated net charges.

From the MO model discussed for a planar $S_4N_4$ (Section 3.3), it follows that the dianion and dication of $S_4N_4$ should have a "closed-shell" structure. Both systems, if planar, satisfy Hückel's rule[4] for aromatic 10 π- and 14 π-systems. For the dication *(11)*, three different planar structures have recently been reported[33], one with equal bond lengths and two with alternating bonds. This result can be interpreted as meaning that the energy difference between a totally delocalized species and a system with alternating bonds is small.

The structure of $S_4N_4$ can also be varied by replacement of two opposite sulfur centers by centers or fragments which provide less π-electrons, such as B—R or C—R. In the case of two boron atoms in the ring an 8 π-, and with two carbon atoms a 10 π-system, is expected. The results of preliminary calculations[31] and recent experiments[34] support this view, although things are not so simple as they appear at first sight. This is best seen from the structures which result by formally replacing two sulfur centers by an $AsR$[35,36] fragment. In the case of R = phenyl, X-ray investigations[36] clearly point out that two NSN units and two $AsC_6H_5$ units are present in the almost planar molecule, *i.e.* a delocalization of electrons by an intramolecular redox reaction has not occured.

### 3.5. The Pentasulfur Pentanitrogen Cation $S_5N_5^{\oplus}$

The results on the structure of $S_5N_5^{\oplus}$ *(10)* are puzzling. To date, two different structures are known: a heart shaped *(10b)* and an azulene-like structure *(10a)* (Fig. 2). The heart shaped structure occurs with $AlCl_4^{\ominus}$[8a] or $FeCl_4^{\ominus}$[8b], while the azulene-like structure has been found with $S_3N_3O_2^{\ominus}$ or $[SnCl_5(OPCl_3)]^{\ominus}$ as anions [9]. Both ring structures are almost planar and both have a 14π-system. Somewhat unusually, the SNS bond angles in *(10b)* are close to 180° at the N1 and N2 centers and relatively large temperature factors for N1, S2 and N2 around the tip of the heart occur (cf. Fig. 10b).

A theoretical investigation of the six possible conformers *(10a)*—*(10f)* of an $(SN)_5$ ring using the Extended Hückel (EH) method shows the problems encountered in $S_5N_5^{\oplus}$[37] are similar to those in [10]annulene[38]: the lone pairs at the sulfur and nitrogen centers restrict the number of favorable conformers to two, the heart shaped and azulene-like structures *(10b)* and *(10a)* respectively. The qualitative result of the Extended Hückel calculations can be summarized as follows: In the case of the regular 10-membered ring *(10c)* ($D_{5h}$), the angle strain reaches its maximum. In the azulene-like structure with a relatively short transannular SS separation *(10e)*, the lone pair-lone pair interaction is at a maximum. A minimum in angle strain and lone pair-lone pair interaction occurs in *(10a)*. The predicted energy difference of 2 eV between *(10a)* and *(10b)* is unusually large for two stable isomers and hence correctness of the structural data reported for *(10b)* seems doubtful. Together with the already mentioned large temperature factors for *(10b)* it seems reasonable to suggest[39] that the apparently heart shaped structure may be caused by superposition of two azulene-like structures (see Fig. 10).

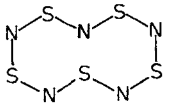
*(10e)*



*(10f)*

The explanation summarized in Fig. 10, however, is questionable if the results of recent MNDO calculations are considered[31]. The minimization of the total energy as a function of the geometrical parameters of *(10b)* and *(10a)* leads to almost identical energies with bond lengths and bond angles close to the experimental ones.

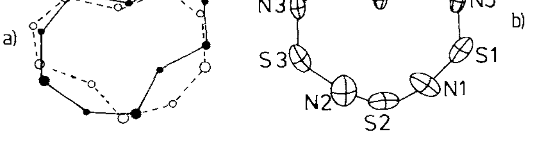


Fig. 10. a) Superposition of two azulene-like structures *(10a)* of $S_5N_5^{\oplus}$. b) Thermal ellipsoids of $S_5N_5^{\oplus}$ as reported for the heart shaped structure [8].

To clarify whether *(10b)* exists in Nature or arises from the superposition of two azulene-like structures *(10a)* (disorder or dynamic processes), a careful re-examination of the structural data is necessary. Diffraction experiments are probably the only method of reaching a decision; other methods, *e.g.* electron spectroscopy are of little help, since the electronic absorption spectra of *(10a)* and *(10b)* [40] in the visible or near UV region are predicted to be very similar, due to the similar energy of the π-levels[37].

## 4. Ring Systems of the Type $S_2N(SN)_x$

### 4.1. The Radical Cation $S_3N_2^{\oplus}$ *(12)* and its Dimer $S_6N_4^{2\oplus}$

The simplest ring system in this category is $S_3N_2$. Counting the electrons as in Section 2, leaves eight electrons for the π-system. According to the π-MO diagram (which is based on an MNDO calculation on $S_3N_2^{\oplus}$[41]) a triplet ground state seems likely, since the separation between $2a_2$ and $3b_1$ is predicted to be small (Fig. 11). One way of achieving a closed shell system is to remove or fill-in two electrons. In the case of the doubly charged cation, a stable system seems likely. For the dianion, however, two antibonding π* levels have to be occupied and thus the molecule might avoid this by fragmentation. While the dianion and dication of $S_3N_2$ are unknown, the radical cation *(12)* has been generated and investigated in solution by ESR spectroscopy and in the solid state by X-ray structure, analysis. By treating $S_4N_4$ with strong Lewis acids and sulfuric acid, $S_3N_2^{\oplus}$ *(12)* is generated[42,43], but its nature was not recognized until recently[44a]. Comparing the observed $^{33}S$ coupling constants and the results of MNDO calculations it was concluded that $S_3N_2^{\oplus}$ has a $^2A_2$ ground state[41]. Its structure in the solid state has recently been determined[45]: bond lengths and bond angles are shown in Figure 2.

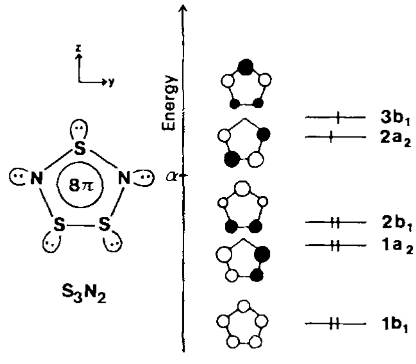

Fig. 11. Qualitative MO scheme of $S_3N_2$. For the numbering of the levels only the valence orbitals were considered.

$S_3N_2Cl^{\oplus}$ *(7)*[46] and $S_3N_2NP_3N_3F_5$ *(17)*[2] are related to $S_3N_2^{\oplus}$ *(12)* (Fig. 12). The 6π-electrons in *(7)* and *(17)* occupy the three lowest π-orbitals ($\psi_1$ to $\psi_3$) derived from a linear combination of the $p_\pi$ orbitals from the four remaining centers (Fig. 13). The resulting molecular orbitals are closely related to those of the corresponding π-system of butadiene, the main difference being that in butadiene *two,*

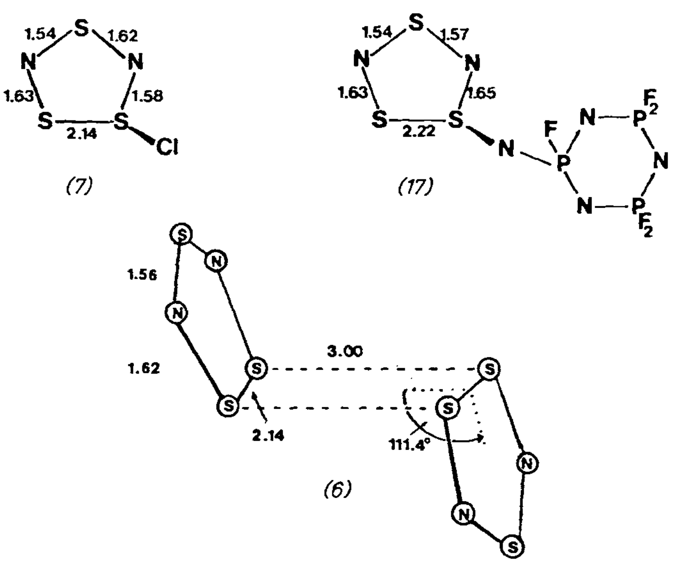

Fig. 12. Bond lengths of $S_3N_2Cl^{\oplus}$, $S_3N_2NP_3N_3F_5$ and $[S_6N_4]^{2\oplus}$.

and in $S_3N_2Cl^{\oplus}$ *three* π-levels are occupied. As a consequence of this difference, bond alternance should be less pronounced in $S_3N_2Cl^{\oplus}$. A similar conclusion is reached by considering the most likely valence structures of *(7)*[44a] and by semiempirical calculations involving all the valence electrons[44b]. These qualitative arguments agree with the experimental bond lengths (Fig. 12) found for *(7)* and *(17)* as well as for related species[2]. The MO picture of *(12)* and its congeners also allows an explanation of why other tautomers of *(7), e.g. (7a)* or *(7b)* are not found[41].

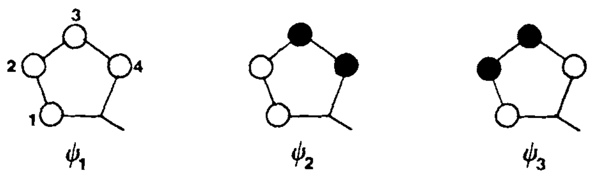

Fig. 13. Schematic representation of the occupied π-MO's of *(7)* or *(17)*.

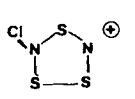
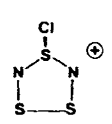
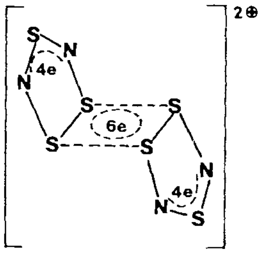
*(7a)*



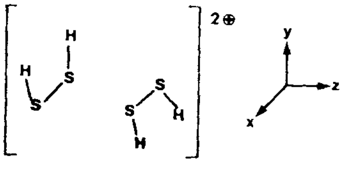


*(7b)*

If the radical cation *(12)* finds no substrate to react with, stabilization *via* dimerization is possible. The structure of the dimer $S_6N_4^{2\oplus}$ *(6)* has been determined using X-ray techniques[47]. The most interesting feature is the long SS bond (Fig. 12) between the two $S_3N_2^{\oplus}$ moieties. Considering the values of overlap integrals shown in Figure 7 and using arguments from perturbation theory, it can be shown[41] that other possible structures for a dimer are not likely. Model calculations carried out on $[H_2S_2]_2^{2\oplus}$ reveal[41] that the bonding between the two $S_3N_2^{\oplus}$ moieties can best be described as an electron-rich four-center bond. The orbital energies of the four molecular orbitals, which arise from the four $3p_z$-atomic orbitals on the sulfur centers of $[H_2S_2]_2^{2\oplus}$ *(18)*, are shown in Figure 14. The resulting linear combinations (Fig. 14) transform according to the irreducible representations $A_g$, $B_u$, $A_u$ and $B_g$ in point group $C_{2h}$. In our model dication *(18)* three MO's ($a_g$, $b_u$, $a_u$) are occupied and one MO ($b_g$) unoccupied. At large values of $R$ (>4 Å) the resulting MO's are similar to those of two isolated $H_2S_2^{\oplus}$ units. The two orbitals of π-type ($a_g$, $b_u$) and those of π*-type ($a_u$, $b_g$) are close in energy. Reduction of the distance R between the two moieties leads to stabilization of both the $a_g$ and $a_u$ levels, while the $b_u$ and $b_g$ orbitals are strongly destabilized. It is interesting to note, that



*(6)*



*(18)*

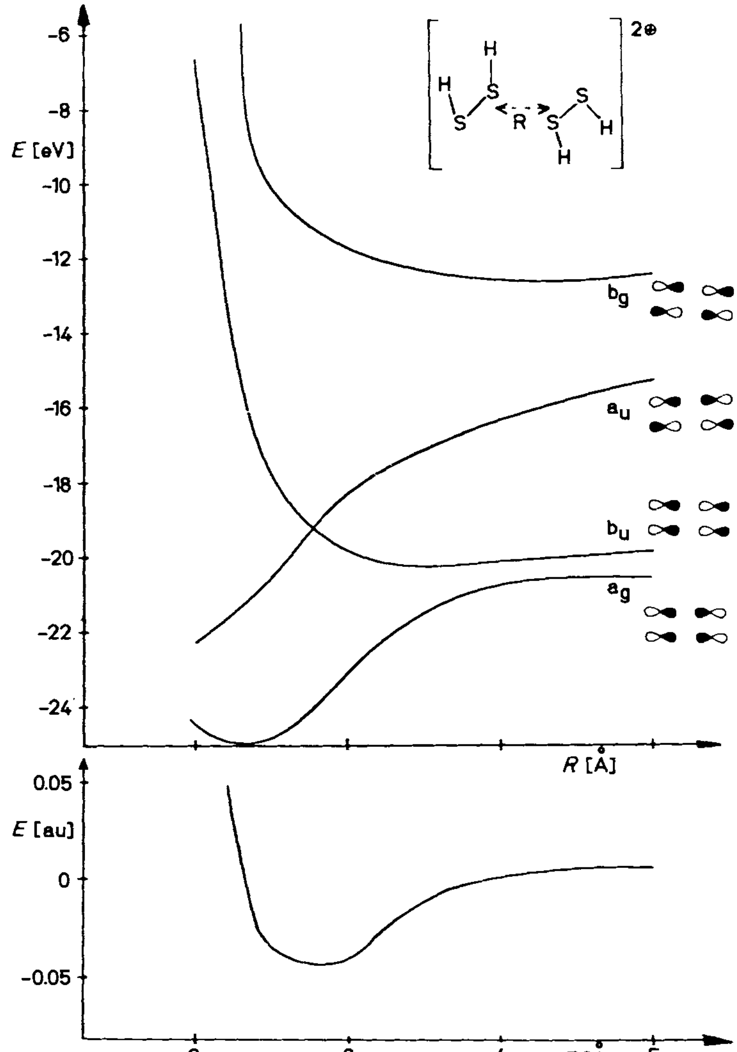


Fig. 14. Energy of the highest occupied MO's and lowest unoccupied MO's of $[H_2S_2]_2^{2\oplus}$ as a function of the distance $R$ (above), and total energy of $[H_2S_2]_2^{2\oplus}$ as a function of R (below) according to an *ab initio* calculation.

down to 3 Å the positive slope of $a_g$ and $a_u$ is larger than the negative slope of the antibonding combinations. Thus the total energy is lowered, since nuclear-nuclear repulsion is still small at these distances and reaches a minimum at around 3 Å.

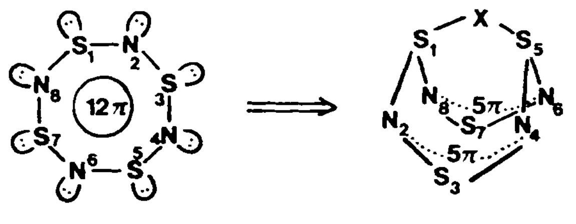
### 4.2. The Tetrasulfur Trinitrogen Cation $S_4N_3^{\oplus}$

X-ray investigations on salts containing $S_4N_3^{\oplus}$ *(9)* units[7,48] indicate planar seven-membered rings with one S—S bridge (Fig. 2). The electronic structure of *(9)* can be satisfactorily described by assuming a 10π-system. Consideration of the p-orbitals only, leads to excellent reproduction of the absorption spectrum. The first two bands in the electronic spectrum of $S_4N_3^{\oplus}$ can be assigned to $\pi^* \leftarrow \pi$ transitions[49]. The π bond-orders obtained, approximately parallel the reported bond lengths and the calculated π-electron densities are in qualitative agreement with the result of an $^{15}$N-NMR study[50].

## 5. Bicyclic Structures $S_4N_5^{\ominus}$, $S_4N_5^{\oplus}$, $S_5N_6$

Recently, bicyclic structures have also been reported in SN-chemistry: $S_4N_5^{\ominus}$ *(4)*[51], $S_4N_5^{\oplus}$ *(13)*[52] and $S_5N_6$ *(14)*[53]. Structural details are collected in Figure 3. Formally, all three can be derived from $S_4N_4$ by replacing one transannular SS bond by a nitrogen atom or an NSN-fragment. The most striking structural difference between *(4)* and *(13)* is the S3—S7 distance [cf. Fig. 3 and *(19)*], which is found to be 2.73 Å and 4.01 Å respectively. In *(14)*, as in *(4)*, a relatively short S3—S7 distance is again reported (2.92 Å)[53]. The structural differences have been rationalized using arguments from MO theory[54].

The starting point is the hypothetical planar $S_4N_4$ discussed in Section 3.3. From the twelve π-electrons in this species two π-electrons are taken from two opposite sulfur centers, *e.g.* S1 and S5, to form σ-bonds with a bridging atom X. This leaves ten π-electrons for the centers N2—S3—N4 and N6—S7—N8 in *(19)*.



*(19)*

The π MO's of these two allylic moieties are shown in Figure 15 for large (right) and small (left) S3—S7 distances, derived from an extended Hückel calculation[54]. For large distances the energy levels anticipated are those of two separate allylic π-levels, for small distances, however, considerable interaction between those MO's belonging to the irreducible representations $A_1$ and $B_2$ is predicted. The bonding combinations, with respect to a transannular interaction ($1a_1$ and $2a_1$), will be lowered in energy by reduction of the S3—S7 distance, while the antibonding combinations ($1b_2$, $2b_2$) will be raised in energy. In Figure 15 the $2p_\pi$-orbital of a bridging atom (*e.g.* N) has been added (irreducible representation $B_2$). Because of small overlap and large energy difference of the basis orbitals, their interaction with other orbitals of the same symmetry can be neglected. The corresponding energy level is indicated in Figure 15 by a broken line. Having constructed the π-MO scheme for *(19)*, it must be filled with π-electrons: in *(4)* the nitrogen bridge formally contributes two electrons, in *(13)* formally zero. Thus, in our π-molecular orbital scheme (Fig. 15), six MO's in *(4)* and five MO's in *(13)* are occupied. The occupation of six MO's results in no splitting between $2a_1$ and $2b_2$ at large S3—S7 distances. This indicates a triplet ground state and thus an unstable structure. A slight distortion towards a shorter S3—S7 distance. enlarges the HOMO-LUMO gap[55] and leads to a net stabilization. This explains the short distance in *(4)*. Occupation of five MO's (cation) leads, at short S3—S7 distances, to a small but for large S3—S7 distances to a large HOMO-LUMO gap. In addition to this electronic effect a smaller nuclear-nuclear repulsion term at large S3—S7 distances arises. Both effects shift the energy minimum for the cation to a structure with large S3—S7 distances. The π MO-schemes just discussed for *(4)* and *(13)* can be generalized: stable cage structures with short S3—S7 distances can exist if the bridge X in *(19)* provides high lying filled orbitals (*e.g.* $N^{\ominus}$, O, S, $CR_2$, $C_2H_2$, NSN, $C_3H_3^{\ominus}$...). Structures with long S3—S7 bonds are predicted if the bridging atom or group provides low lying empty orbitals (e.g. $N^{\oplus}$, $CR^{\oplus}$, BR, $C_3H_3^{\oplus}$, $NSN^{2\oplus}$...). Examples which fit into this scheme are *(14)*[53], β-$P_4S_5$ *(20a)*[56], $As_4S_5$ *(20b)*[57], $S_4N_5O^{\ominus}$ *(21)*[58], $P_4S_7$ *(22)*[59], $P_9(CH_3)_5$ *(23)*[60], as well as structures with two electron-rich substituents on S1 and S5, *e.g.* the compounds *(24)*—*(26)*[61-63]. By replacing the bridgehead sulfur atoms of *(19)* with tetravalent atoms of the fourth group, *e.g.* C or Si, the two π-fragments N2—S3—N4 and N6—S7—N8 only contain a total of eight π-electrons, since the bridgehead atoms formally contribute no π-electrons, *e.g.* in *(28)*.

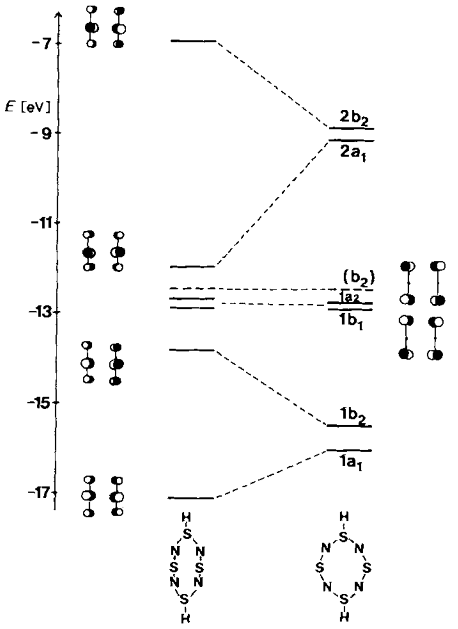


Fig. 15. Energies of the π-MO's of model compound *(19)* according to an EH-calculation of S3—S7 = 2.7 Å (left) and S3—S7 = 4.0 Å (right).

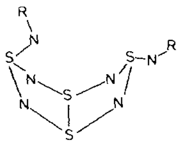
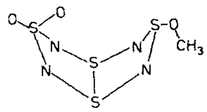
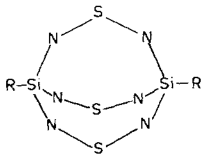
*(24)*, R = Alkyl



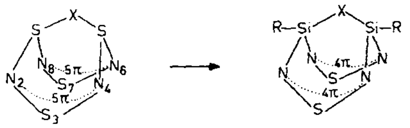
*(25)*, R = P(Ph)$_3$



*(26)*



*(27)*



*(19)* *(28)*

Accordingly, the π-system in *(27)* should contain two electrons less than that of *(14)* and a "long" S3—S7 bond relative to that of *(14)* is therefore expected for *(27)*: this is corroborated by experiment[63].

## 6. Outlook

Our knowledge of reactions of SN compounds rests mainly on isolated crystalline products which can be studied by X-ray investigation. This limitation often only allows a minor insight into what really happens during a reaction and thus, necessarily, many reactions seem very strange. So far, most of the known cyclic SN compounds have been prepared from $S_4N_4$ (Fig. 1). The products obtained under various reaction conditions indicate smaller fragment intermediates in these reactions. A promising step forward has been the isolation and characterization of a key intermediate, $S_4N^{\ominus}$ by *Chivers et al.* [64].

An alternative approach for the synthesis of novel SN-cycles by building larger systems from small fragments with proper leaving groups has been recently advocated by different groups[2a,9a,35,51,66].

The advent of $^{15}$N-NMR spectroscopy (FT-technique) has enabled reactions to be followed spectroscopically, kinetic studies to be carried out and hence the characterization of most important reaction products [67]. MO calculations of potential surfaces of cyclic and open chain SN compounds, in close connection with experimental studies, are necessary to elucidate reaction paths and the structure of key intermediates. The results show that recent MO methods are able to treat these systems properly and initial calculations of potential energy surfaces of small SN molecules[64,65] confirm this optimism.

A further problem awaiting solution is the rationalization of correlations between bond lengths and coordination number or bond lengths and bond angles, discovered recently in several laboratories[2a,39], on an MO basis. Furthermore the electron spectra of most SN compounds must be investigated in more detail: this provides an excellent test of the efficiency of theoretical models.

The role of 3d-orbitals in the bonding of the cyclic SN compounds has not been considered in this review for two reasons: 1) The qualitative explanations given for the structures are not improved by inclusion of 3d-orbitals on sulfur and 2) accurate calculations on small sulfur-nitrogen systems indicate that the 3d-orbital participation is small.

*My own work started in Basel, generously supported and stimulated by Professor E. Heilbronner. I am very grateful to R. Bartetzko who carried out most of the calculations cited. Financial assistance from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and BASF AG. is acknowledged.*

# COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

## Photochemical Synthesis of Bis($\eta^2$-methyl acrylate)tricarbonylruthenium[**]

By *Friedrich-Wilhelm Grevels, Johannes G. A. Reuvers*, and *Josef Takats*[*]

The photochemical reaction of pentacarbonyliron with suitable olefins leads, *via* ($\eta^2$-olefin)Fe(CO)$_4$, to ($\eta^2$-olefin)$_2$Fe(CO)$_3$[1a] and, finally, with linkage of the olefinic ligands, to carbonylferracyclopentane derivatives[1]. As we

[***] Permanent address: Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2 (Canada)

have already described the photochemical preparation of ($\eta^2$-olefin)Ru(CO)$_4$ complexes[2a], we report here on the conversion of these compounds into the novel ($\eta^2$-olefin)$_2$Ru(CO)$_3$ complexes.

($\eta^2$-Olefin)tetracarbonylruthenium is obtained by irradiation of dodecacarbonyltriruthenium *(2)* with visible light in the presence of excess olefin[2]. By means of an appropriate filter ($\lambda \gtrsim 370$ nm)[2a], the reaction with olefins yields ($\eta^2$-olefin)Ru(CO)$_4$ exclusively, whereas the analogous reaction with phosphorus ligands results in formation of both LRu(CO)$_4$ and L$_2$Ru(CO)$_3$ as primary products[3]. It has been postulated that the isomerization and hydrosilylation of alkenes, which is photocatalyzed by *(2)*, involves the "Ru(CO)$_3$" moiety[3a]; as yet no bis($\eta^2$-olefin) complexes containing this unit have, however, been isolated or detected.

We have now found that UV-irradiation of the colorless ($\eta^2$-olefin)Ru(CO)$_4$ complexes leads to substitution of one carbon monoxide ligand by an olefin. It is not necessary to isolate the complexes. For example, continued irradiation (through Solidex glass, $\lambda \gtrsim 280$ nm; preferably at a somewhat lower temperature) of *(2)* in the presence of excess methyl acrylate produces, *via* intermediate *(1)*, bis($\eta^2$-methyl acrylate)tricarbonylruthenium *(3)* in good yield. *(3)* can be isolated as white crystals.

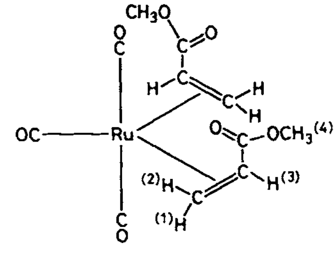
$$\underset{(2)}{\tfrac{1}{3}\,Ru_3(CO)_{12}} + CH_2{=}CH{-}CO_2CH_3 \xrightarrow{h\nu} \underset{(1)}{(CH_2{=}CH{-}CO_2CH_3)Ru(CO)_4}$$

$$\xrightarrow[+\,CH_2{=}CH{-}CO_2CH_3]{h\nu,\ -CO} \underset{(3)}{(CH_2{=}CH{-}CO_2CH_3)_2Ru(CO)_3}$$

Complex *(3)* is more stable than the analogous iron compound, which in solution loses one of the two olefinic ligands reversibly[1a]. A corresponding equilibrium involving a ($\eta^4$-methyl acrylate)Ru(CO)$_3$ species is not observed in the case of *(3)*. However, one methyl acrylate ligand can be substituted by other ligands, as described below. Pure *(3)* is stable at ambient temperature in the solid state. In solution it has limited stability, decomposition being however substantially slower than for the tetracarbonyl complex *(1)*.

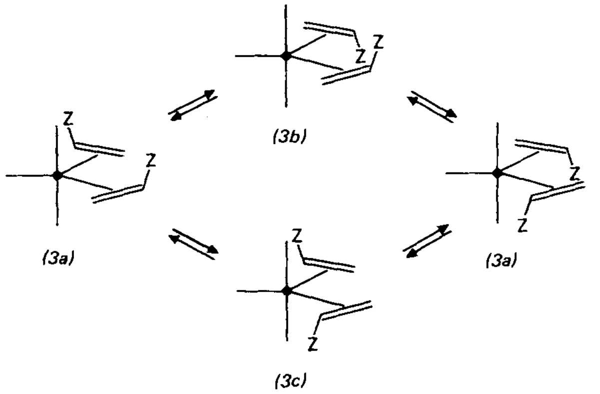
The molecular ion is not observed in the mass spectrum of *(3)*; it does, however, show the successive loss of CO ($m/e$ = 330, 302, 274; $^{102}$Ru) and/or the elimination of the olefinic ligand ($m/e$ = 272, 244, 216, 188, 186, 158, 130, and 102) as well as the formation of fragments at $m/e$ = 85, 55 (base peak), 42, 28, and 27.

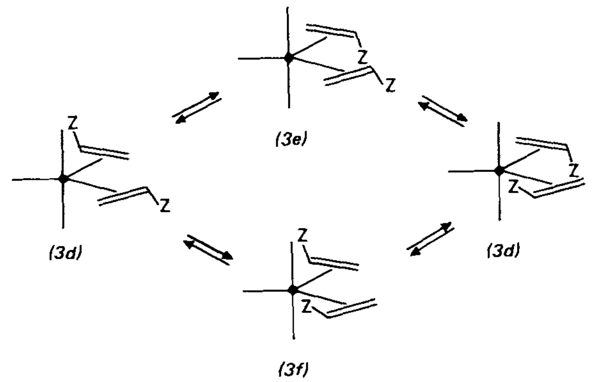
The metal carbonyl stretching bands in the infrared spectrum of *(3)* appear at 2109 (w, $A_1^{(1)}$), 2036 (st, $B_1$), and 2026/2019 (m, $A_1^{(2)}$) cm$^{-1}$. The splitting of the last band into two components, as well as the appearance of two bands at 1723/1716 cm$^{-1}$ in the ester carbonyl region, point to the presence of more than one species in solution—as will be discussed below. The intensity ratio of the metal carbonyl bands indicates local $C_{2v}$-symmetry for the M(CO)$_3$ framework, *i.e.* the two olefinic ligands should each occupy an equatorial position in the trigonal bipyramidal complex. This structural type of complex has recently been established crystallographically for tricarbonyl($\eta^4$-1,5-dimethylene-2,6-dimethylcyclooctane)iron[4a]. In the latter case, however, the coordinated double bonds are connected *via* the eight-membered ring; as such, the geometry of the complex is severely predetermined. Structure *(3a)* represents the results of the X-ray analysis[4b] of *(3)*. The complex has, as also expected for the analogous iron compound[1a,5], trigonal bipyramidal geometry, in which the olefinic ligands occupy equatorial positions with their C=C axes in the trigonal plane.



*(3a)*

The $^1$H-NMR spectrum of *(3)* (Fig. 1), recorded at 20 °C, shows two sets of signals of approximately equal intensity for the methyl acrylate ligands. The obvious suspicion that the asymmetrical structure *(3a)*, found in the solid state, is retained in solution, is, however, not correct as shown by the spectral changes occurring upon cooling. The signals broaden and, at still lower temperatures, sharpen up again to some extent. The broadening of the resonances, denoted by H(1′)—H(4′), commences prior to that of H(1″)—H(4″). The resulting relative assignments have been confirmed for the protons of both vinyl groups by double resonance experiments. Apparently, two fluxional systems are present. Of the six realistic structures that can be envisaged for *(3)* (without enantiomers) three — *(3a)*—*(3c)* and *(3d)*—*(3f)* —are interconverted by rotation around the metal-olefin bonds (Z = CO$_2$CH$_3$). Each of these processes induces (on the NMR time scale) a symmetry element ($C_2$ and $C_s$ respectively). As a result only one set of signals for each of the two systems in the fast exchange range at ambient temperature is observed. Conclusions regarding the exchange steps and the relative concentrations of the participating species cannot yet be drawn, as the spectral changes are not completed at the lowest temperatures (down to −90 °C





at 270 MHz) accessible to us. The temperature dependent changes in the $^{13}C$-NMR spectrum, which are in accord with the observations in the $^{1}H$-NMR spectrum, however, offer no additional information. An isomerization of the two systems requires the cleavage of a metal-olefin bond. Such a process should lead to coalescence of the two sets of resonances present at room temperature if it occurs sufficiently fast. This, however, is not observed up to 50 °C; above this temperature, the sample starts to decompose irreversibly. On the other hand, a slow isomerization of this type, as observed for the analogous iron compound at *ca.* 0 °C[1a], cannot be excluded.

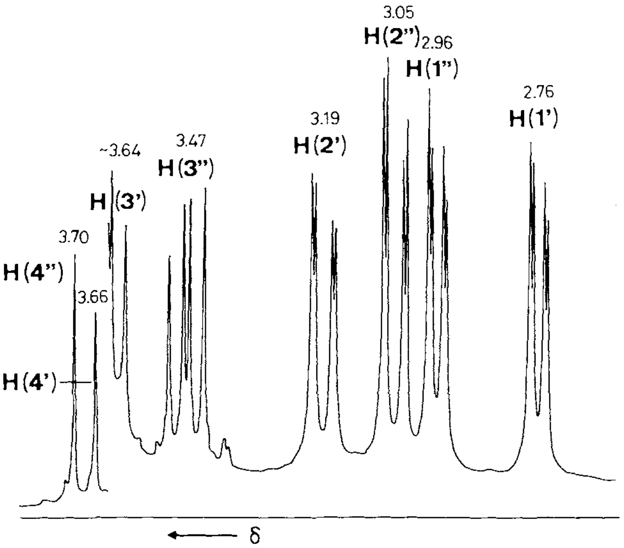


Fig. 1. 270 MHz $^{1}H$-NMR spectrum of *(3)* in $CD_2Cl_2$ at 20 °C.

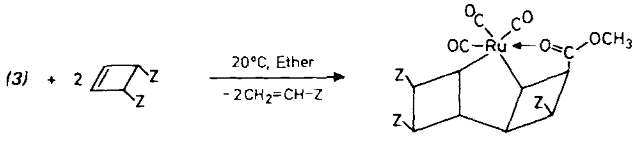
There is no indication as yet for a linkage of the methyl acrylate ligands in *(3)* to form a carbonylruthenacyclopentane derivative, which should occur at the unsubstituted β-C atoms[5]. However, if *(3)* is allowed to react with excess dimethyl 3-cyclobutene-*cis*-1,2-dicarboxylate, both methyl acrylate ligands are displaced and the tricarbonyl-6-ruthenatricyclo[5.2.0.0$^{2,5}$]nonane complex *(4)* is obtained[6], by linkage of the newly entered olefins. The structural analogy between *(4)* and the corresponding iron complex[1b] has been ascertained by X-ray structure analysis[7a]. The vibration typical of an "end-on" coordinated ester group[1b] appears at 1629 $cm^{-1}$ in the infrared spectrum[6] of *(4)*.



*(4)* ($Z = CO_2CH_3$)

$(CH_2{=}CH{-}CO_2CH_3)[(C_6H_5)_3P]Ru(CO)_3$ *(5)*

*(3)* reacts with triphenylphosphane at 0 °C to yield ($\eta^2$-methyl acrylate)tricarbonyl(triphenylphosphane)ruthenium *(5)*[6]; some tricarbonylbis(triphenylphosphane)ruthenium is also formed as a by-product, the relative amount of which increases with rising temperature. Thus, the n-donor ligand displaces methyl acrylate instead of inducing—as intended—the linkage to a ruthenacyclopentane complex. It is inferred from the IR spectrum[6] of *(5)* that several (presumably three) distinct species are present in solution. The olefin should occupy an equatorial position in the trigonal bipyramid; as found for related iron complexes, the phosphane ligand could be coordinated either axially[1a,7b,7c] or equatorially[7c]. Variable temperature $^{1}H$-NMR spectra[3b] point toward a fluxional behavior of *(5)*, effected by olefin rotation (cf. [8]) and/or axial-equatorial site exchange of the phosphane ligand (cf. [7c]). These results still, however, require completion and confirmation by the corresponding $^{13}C$- and $^{31}P$-NMR spectra.

Tricarbonylbis($\eta^2$-dimethyl fumarate)ruthenium[3b] is the second complex of this type whose structure has been determined crystallographically[9]. The structure corresponds to that of *(3)*, allowing for the presence of the two additional ester groups.

### *Procedure*

*(2)* (1.95 g, 3.05 mmol) and methyl acrylate (7.87 g, 91.5 mmol) in 250 $cm^3$ pentane, under argon, are irradiated in an immersion lamp apparatus (Solidex glass, $\lambda \gtrsim 280$ nm) at ~10 °C with a high-pressure mercury Philips HPK 125 W lamp. After *(2)* has dissolved completely and the orange color of the solution has disappeared (1–2 h), the irradiation is continued for *ca.* 6 h. If necessary, the solution is filtered and concentrated to about half the original volume. At −80 °C *(3)* precipitates as white crystals, which are separated from the mother liquor by inverse filtration and dried *in vacuo* at −30 °C. Yield 1.99 g *(3)* (61%). M.p. 36–38 °C.

## Charge Transfer Interactions between the Ligands of a Ternary ATP-$Cu^{2+}$-Phenanthroline Complex

By *William S. Sheldrick*[*]

Ternary complexes of metal ions play a significant role in biological processes, *e.g.* as enzyme-metal ion-substrate

---

[*] Priv.-Doz. Dr. W. S. Sheldrick
Gesellschaft für Biotechnologische Forschung mbH
Mascheroder Weg 1, D-3300 Braunschweig-Stöckheim (Germany)

complexes. Although the enzymatic phosphate transfer requires, in most cases, a divalent metal ion $M^{2+}$—under physiological conditions $Mg^{2+}$—and ternary enzyme-$M^{2+}$-ATP complexes are involved in this reaction, no structure of a ternary ATP complex has previously been determined. Furthermore, no X-ray structural analysis has been carried out on a binary metal ion-ATP complex. On the basis of $^1H$-NMR studies[1] on the model systems $Cu(ATP)(bpy)^{2-}$ [bpy = 2,2′-bipyridyl] and $M(ATP)(phen)^{2-}$ [$M^{2+} = Mg^{2+}$, $Zn^{2+}$; phen = 1,10-phenanthroline], which are significantly more stable than the corresponding binary complexes $M(ATP)^{2-}$, it has been suggested that these adducts may display a metal ion-bridged conformation, which allows a charge transfer interaction between the 2,2′-bipyridyl or 1,10-phenanthroline ligands and the adenine base. In this proposed structure, the metal ion coordinates both the β- and γ-phosphate oxygens of the ATP. We have now isolated the ternary complex $[Cu(ATP)(phen)]_2 \cdot 7H_2O$ *(1)* at pH = 2.8 and report here its molecular structure (Fig. 1)[2]. At this pH, N1 of the adenine is protonated[3].

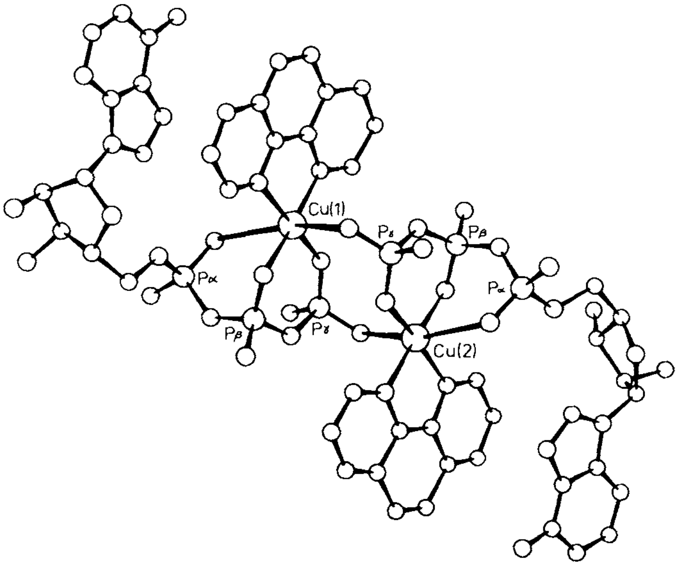

Fig. 1. Molecular structure of $[Cu(ATP)(phen)]_2$.

Both independent Cu atoms in *(1)* display a strongly distorted [4 + 2]-octahedral coordination. In each case α-, β- and γ-phosphate oxygens of an ATP are coordinated by the same $Cu^{2+}$ ion. The two phenanthroline N atoms, one ATP β- and one ATP γ-phosphate oxygen provide the equatorial ligands. The following distances were determined: Cu—$O_β$ 194.2(9) and 197.7(9); Cu—$O_γ$ 192.5(8) and 191.9(8); ($O_β$—)Cu—N 198.9(10) and 205.0(12); ($O_γ$—)Cu—N 201.3(10) and 199.3(11) pm. The coordination sphere is completed by one α-phosphate oxygen of the same ATP and one γ-phosphate oxygen of the other ATP. However, the axial Cu—$O_α$(—H) interaction is weak [Cu...$O_α$(—H) = 287.8(9) and 273.0(8) pm]. In contrast, the axial Cu—$O_γ$ distances are 228.4(8) and 227.3(9) pm respectively. As a result of the weak Cu—$O_α$(—H) interaction, the coordination of the Cu atoms is distorted somewhat in the direction of a square pyramidal geometry. Cu1 is displaced 4.4 pm from the best equatorial plane in the direction of the Cu—$O_γ$ axial bond and Cu2 by 4.3 pm. Both adenosine moieties display similar nucleotide configurations; the observed values lie in the typical regions for purine nucleotides. The conformations at the glycosidic C1′—N9 bond are *anti* ($\chi_{CN}$ = 32.3 and 5.7°), those at the C4′—C5′ bond *gauche-gauche* ($\psi_{OC}$ = 59.6 and 50.1°)[4]. The ribose moieties display the C3′-*endo*-conformation. Similar conformations are observed for both independent ATP molecules in the crystal lattice of $ATPNa_2 \cdot 3H_2O$ ($\chi_{CN}$ = 69 and 39°, $\psi_{OC}$ = 66.3 and 48.6°), whereas one ribose moiety adopts a C3′-*endo*-, the other a C2′-*endo*-conformation[5].

The crystal structure of *(1)* is stabilized by both *intra*- and intermolecular interactions between adenine and phenanthroline systems. The shortest intramolecular distances to the atoms of a phenanthroline system are observed for C8 of the first adenine [331.7 pm] and C5 of the second adenine [348.5 pm]. The base planes are not quite parallel to one another [angles = 6.7 and 5.8°]. This structure demonstrates that base stacking may be observed in ternary ATP complexes together with the involvement of all three phosphate functions in the metal coordination (the α-function albeit to a lesser extent) without the nucleotide being forced to take up an unusual conformation. In accordance with the observed structures of ternary complexes of nucleotide monophosphates[6], the adenine bases are not involved in coordination to the metal ions. It can, therefore, be assumed with some degree of certainty that metal ions preferentially coordinate the phosphate oxygens in enzyme-metal ion-ATP complexes.

1,10-Phenanthroline may be regarded as a simple model for an enzyme which binds $M(ATP)^{2-}$ more strongly than $M^{2+}$ or $ATP^{4-}$ alone, *e.g.* the system arginine kinase/$Mn(ATP)^{2-}$[7]. The present results then suggest that charge transfer interactions may play an important role in the increased stability of enzyme-$M^{2+}$-ATP complexes.

## *Experimental*

0.28 g (0.5 mmol) $ATPNa_2$ in 3 $cm^3$ $H_2O$ is added with stirring to a solution of 0.10 g (0.5 mmol) $Cu(NO_3)_2$ and 0.10 g (0.5 mmol) 1,10-phenanthroline in 6 $cm^3$ $H_2O$ at 80°C. The pH value is adjusted to 2.8 and the temperature held at 80°C for 30 min. Blue-green prismatic crystals precipitate upon slow cooling. *(1)*, which is obtained in quantitative yield, is filtered off and washed with water and methanol.

# Insertion of —CN into the Metal-Carbene Carbon Bond: A Route to Methyleneaminocarbene Complexes

By *Helmut Fischer* and *Ulrich Schubert*[*]

Owing to the polarity of the CN-bond, azomethines $R^1$—N═$CR^2R^3$ react with a wide variety of substrates[1]. Complexes formed by replacement of one of the substituents ($R^1$, $R^2$ or $R^3$) are therefore especially suited for stu-

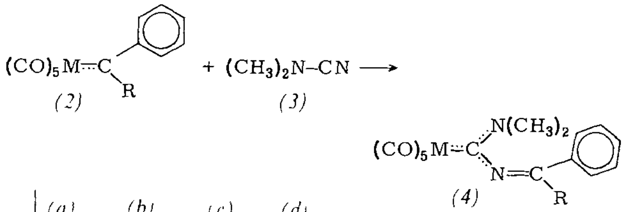
Lichtenbergstr. 4, D-8046 Garching (Germany)

dies on the influence of metal-organic fragments on the reactivity of organic functional groups. In the case of the methyleneaminocarbene complexes

$(CO)_5M{-}C(R)N{=}CR^2R^3$ *(1)*

an additional polarization and thus activation of the N=C bond could be expected, owing to the large deficiency of electrons at the carbene-carbon atom.

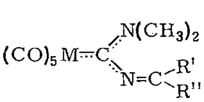
Compounds of type *(1)* are now readily accessible by reaction of arylcarbene(pentacarbonyl)chromium(0) and -tungsten(0) *(2)* with cyanamides. The complexes *(2)* react with dimethylcyanamide *(3)* almost quantitatively in polar or non-polar solvents, even at room temperature, with insertion of the CN-group into the metal-carbene carbon bond to give pentacarbonyl[dimethylamino(methyleneamino)carbene]chromium(0) and -tungsten(0) *(4)*[2].



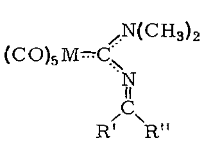
| | *(a)* | *(b)* | *(c)* | *(d)* |
|---|---|---|---|---|
| M | Cr | W | W | W |
| R | $OCH_3$ | $OCH_3$ | $C_6H_5$ | $p$-$CH_3C_6H_4$ |

The new yellow crystalline products *(4)*, which are stable under nitrogen at room temperature, are readily soluble in polar solvents, and only moderately soluble in non-polar solvents. The position of the $\nu_{CO}$ bands hardly changes on varying R, whereas the C=N stretching vibration (KBr mull) is more influenced: 1680 *(4a)*, 1677 *(4b)*, 1644 *(4c)*, and 1636 *(4d)* $cm^{-1}$; cf. 1666 $cm^{-1}$ ($H_5C_6{-}N{=}C(C_6H_5)OCH_3$) and 1611 $cm^{-1}$ ($H_5C_6{-}N{=}C(C_6H_5)_2$)[3].

The two singlets observed for the $N{-}CH_3$ protons in the $^1H$-NMR spectra indicate partial double bond character of the $C_{carb}{-}N(CH_3)$-bond. Moreover, it follows from the $^1H$-NMR spectra that only one isomer *(A, B, C, D* or *E)* is formed.



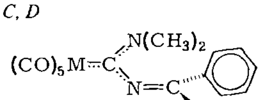
*A, B*



*C, D*

*A, C*: R' = $C_6H_5$, R'' = R

*B, D*: R' = R , R'' = $C_6H_5$



*E*

In all four isomers with parallel π-systems *(A—D)* considerable steric interactions are to be expected, either with the carbonylmetal moiety or, with the amino groups coplanar to the carbene plane in aminocarbene complexes. An X-ray structure analysis showed the presence of the isomer *E* (torsional angle N1—C1—N2—C2: 100.6°); indication of this was already provided by the yellow color of *(4)*, since in the case of *A—D* the first absorption maximum would have been expected at distinctly higher wavelengths. The equal lengths of the C1—N1 and C1—N2 bonds (see Fig. 1) prove that there is, nevertheless, π-interaction between the two nitrogen atoms and the carbene-carbon. On the basis of the observed geometry a most unusual $n_\pi$-$p_\pi$ bonding must be assumed for C1—N2. The contribution of the carbonylmetal fragment to the electronic stabilization of the carbene-carbon is small, owing to the contribution of the two organic substituents, as is evidenced by the very long Cr—C1 bond—whose unusual length is only seldom met with, even in aminocarbene complexes[5].

The $^1H$-NMR spectrum of *(4d)* (in hexachlorobutadiene) does not alter until decomposition of *(4d)* takes place, with concomitant change in color to brown. An isomerization of *E* to *A* and/or *B* or to *C* and/or *D* can therefore not be detected.

The formation of *(4)* from *(2)* and *(3)* is a second-order reaction. The rate constants *k* of a series of diphenylcarbene(pentacarbonyl)tungsten complexes, in which one of the two parahydrogen atoms is replaced by a donor group, or by an acceptor group, show a good positive correlation with the Hammett σ-constants[6]. This suggests a nucleophilic attack of the negatively polarized nitrogen of the CN group of *(3)* at the $\delta^+$-polarized carbene-carbon of *(2)* in the first reaction step. Subsequently, insertion into the $M{-}C_{carb}$ bond takes place—most likely with intermediary formation of a metallacycle. A similar mechanism was also deduced from the results of kinetic studies on the insertion of ynamines into the metal-carbene carbon bond of carbene complexes[7a], and presumed for the insertion of ethoxyacetylene in the same compounds[7b]. Complexes of type *(1)* were previously only accessible by reaction of pentacarbonyl[methoxy(methyl)carbene]chromium(0) with oximes or diphenylmethaneimine[8a] and of pentacarbonyl[methoxy(phenyl)carbene]chromium(0) with 1-aminoethanol[8b]. An investigation of the reactivity of these compounds however, was not carried out, mainly owing to the poor yields (5.7 to 21%). In addition, two complexes amino-substituted on the methylene group [$R^2 = N(C_2H_5)_2$, $R^3 = C_2H_5$] could be obtained by addition of amino(methyl)carbene- or amino(phenyl)carbene(pentacarbonyl)chromium(0) to *N,N*-diethyl-1-propynylamine[9].

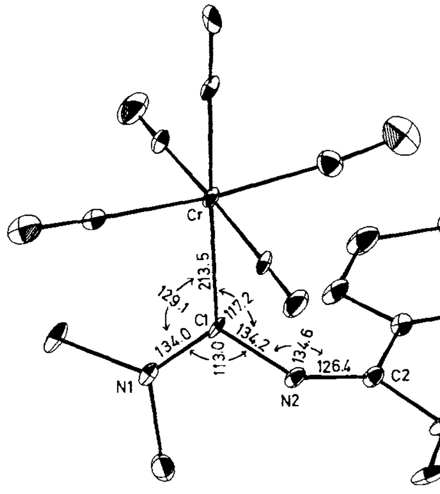


Fig. 1. Structure of complex *(4a)*. The hydrogen atoms are not shown. Standard deviations: 0.4—0.7 pm, and 0.3—0.4°.

### *Procedure*

A solution of *(2)* (1.0 mmol) and *(3)* (1.05 to 1.10 mmol) in ether (3 $cm^3$) is stirred at room temperature for one [*(2c)*] to ten hours [*(2a)*]. The initial deep-red solution turns bright yellow. After removal of solvent in a water-jet vacuum the residue is washed with $3 \times 5$ cm$^3$ of pentane; the pentane is then decanted off. After several hours' drying in a water-jet vacuum one obtains analytically pure *(4)*. *(4a)*—*(4d)*: m.p. = 69, 79, 130 (dec.), 106 °C; yields 85, 75, 80, 81%.

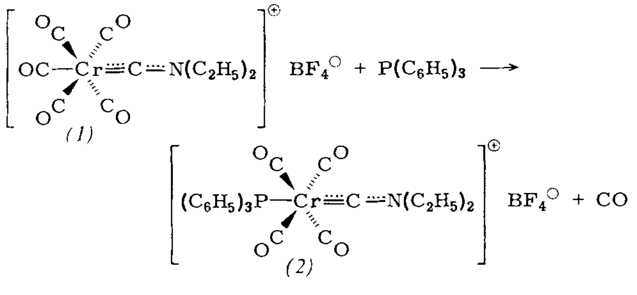
## Ligand Mobility in Carbyne Complexes[**]

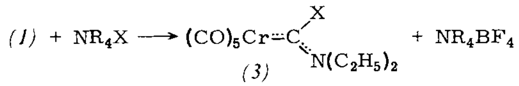
By *Helmut Fischer, Andreas Motsch, Ulrich Schubert,*
and *Dietmar Neugebauer*[*]

Pentacarbonyl(halocarbene)metal complexes are of particular interest as potential intermediates in the synthesis of halo(tetracarbonyl)carbynemetal complexes from carbene complexes and trihalides of main group III elements[1]. Thus, pentacarbonyl[diethylamino(halo)carbene]chromium(0), $(CO)_5Cr[C(X)NEt_2]$ *(3)*, X = Cl, Br, I, spontaneously rearranges in solution with loss of CO to give *trans*-$X(CO)_4CrCNEt_2$ *(5)*[2]. Replacement of the *trans*-CO group by another neutral ligand should afford valuable information on the course of this rearrangement of a carbene complex into a carbyne complex.

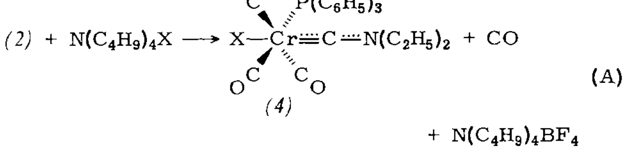
Pentacarbonyl(diethylaminocarbyne)chromium tetrafluoroborate *(1)*[3] reacts with triphenylphosphane in a first-order reaction (half-life 68 s in 1,1,2-trichloroethane at 25 °C) to give *trans*-tetracarbonyl(diethylaminocarbyne)triphenylphosphanechromium tetrafluoroborate *(2)* (red-brown crystals, decomposition above 120 °C)[4].



The *cis*-isomer of *(2)* could not be detected. In the reaction of *(2)* with $N(C_4H_9)_4X$ analogous to the preparation of *(3)* from *(1)* and tetraalkylammonium halides, however, we did not obtain *trans*-tetracarbonyl[diethylamino(halo)carbene]triphenylphosphanechromium(0), but, surprisingly, *mer*-tricarbonyl(diethylaminocarbyne)halo(triphenylphosphane)chromium *(4)*[4].

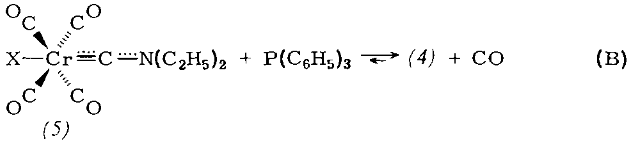


X = F, Cl, Br, I



*(a)*, X = Cl; *(b)*, X = Br; *(c)*, X = I

In *(4)* the groups originally *trans* oriented in *(2)* are in the *cis*-position, while the entering ligand ($X^-$) takes up the *trans*-position to the carbyne group. No indication could be found of the formation of *trans*-tetracarbonyl[diethylamino(halo)carbene]triphenylphosphanechromium or other isomers of *(4)*. *(4)* is also accessible from *trans*-tetracarbonyl(diethylaminocarbyne)halochromium *(5)* by CO/PPh$_3$ exchange (first-order reaction, half-life for *(5b)*→*(4b)* 129 s in 1,1,2-trichloroethane at 25 °C).



*(a)*, X = Cl; *(b)*, X = Br; *(c)*, X = I

X-ray structure analyses were carried out on *(2)* and *(4b)* (Fig. 1)[4]. Comparison with the structures of the analogous methylcarbyne complexes

[*trans*-$Me_3P(CO)_4Cr{\equiv}CMe]BCl_4$ *(6)* [5]
and *mer*-$Br(Me_3P)(CO)_3Cr{\equiv}CMe$ *(7)* [6]

showed, first of all, that the amino group could be in resonance with the metal-carbon bond[7]. As a result, the electron density at the metal in the aminocarbyne complexes is greater than in the corresponding methylcarbyne complexes. This manifests itself almost exclusively in a shortening of the metal-ligand bond length of the group *trans* to the aminocarbyne moiety (Cr—Br in *(4b)*: 257.2 pm, in *(7)*: 260.3 pm; Cr—P in *(2)*: 246.4 pm, in *(6)*: 247.4 pm; it should be remembered that metal-PMe$_3$ bond lengths are shorter than metal-PPh$_3$ bond lengths in comparable complexes).

Although the reactions *(2)*→*(4)* and *(5)*→*(4)* (at least in the case of X = Br) proceed almost equally rapidly, formation of *(4)* *via* the reaction sequence

$$(2) + X^- \rightarrow (5) + PPh_3 \rightarrow (4) + CO$$

can be ruled out, since PPh$_3$ is not exchanged in *(2)* in the presence of excess free triisopropylphosphane but CO is

replaced by this phosphane in a slow reaction with formation of $[PPh_3PiPr_3(CO)_3CrCNEt_2]BF_4$.

*(2)* reacts almost quantitatively with $Br^-$ and $I^-$ (reaction A) under pseudo-first-order conditions and with rapid removal of the extruded carbon monoxide (purging of the solution with $N_2$); on the other hand, *(4b)* and *(4c)* react further with free CO to give *(5b)* and *(5c)*, respectively, in the closed cuvette or under CO as protecting gas (back reaction of B). This back reaction can be avoided by addition of $PPh_3$ in large excess[8]. This would suggest the reaction sequence shown in Scheme 1.

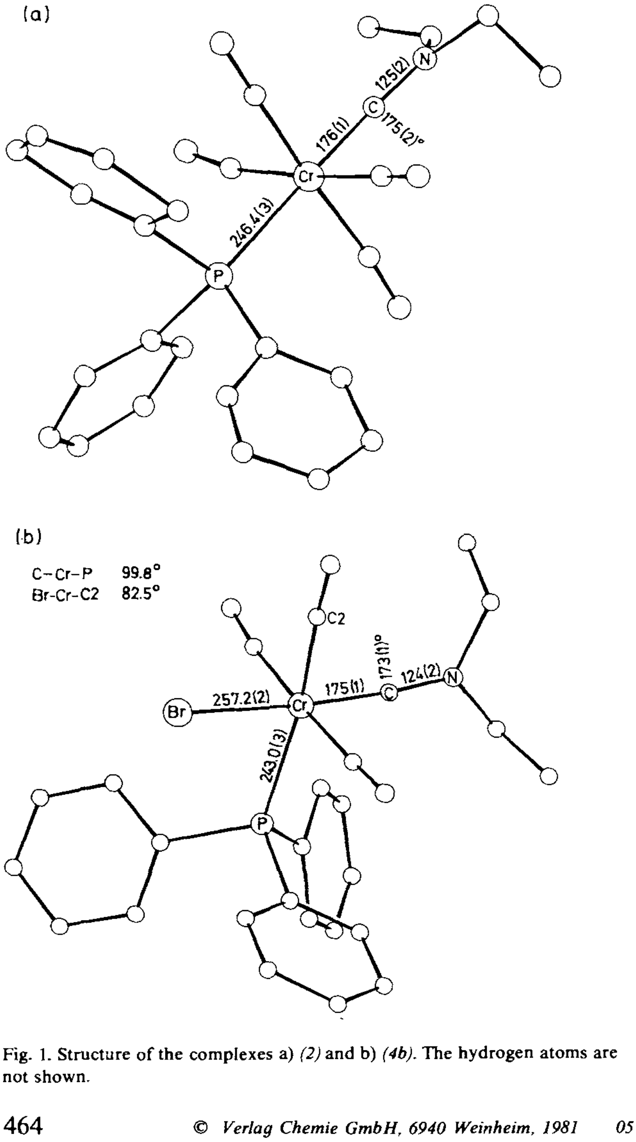

Fig. 1. Structure of the complexes a) *(2)* and b) *(4b)*. The hydrogen atoms are not shown.

Although the sequence *(2)*→*(8)*→*(11)*→*(4)* is most likely, and although neither *(9)* nor *(10)* could be hitherto detected, the sequences *(2)*→*(10)*→*(11)*→*(4)* and *(2)*→*(8)*→*(9)*→*(4)* cannot be ruled out with certainty.

The reason for the marked difference in the reaction of *(1)* and *(2)* with halides could be explained in terms of the different charge distribution in these compounds, which is also reflected in the bond lengths. The $C_{carbyne}$—N bond lengths in *(1)* (125.6(12) pm)[9] and in *(2)* (125.2(16) pm) are actually about the same size, but the Cr—$C_{carbyne}$ bond length in *(1)* (179.7(9) pm)[9] is distinctly greater than that in *(2)* (175.7(11) pm). Whereas the substantial localization of the positive charge in *(1)* at the carbyne-carbon leads very rapidly to *(3)* (with assumption of a second-order reaction $k$ can be estimated as > 1000 $dm^3\ mol^{-1}\ s^{-1}$ for X = Br in 1,1,2-trichloroethane at −30 °C), with *(2)* (here the charge is predominantly localized in the $PPh_3$—$Cr(CO)_4$ moiety) one obtains *(4)* in a substantially slower reaction primarily by a dissociative mechanism with substitution and rearrangement.

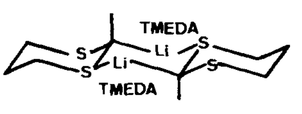
# Crystal Structure of 2-Lithio-2-phenyl-1,3-dithiane-Tetrahydrofuran-Tetramethylethylenediamine (1/1/1); Electron-Density Difference Maps for Lithio-methyl- and Lithio-phenyl-dithiane

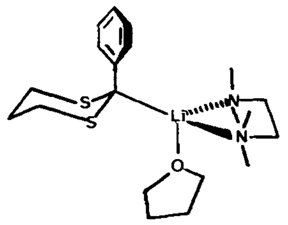
By *René Amstutz, Jack D. Dunitz,* and *Dieter Seebach*[*]

*Dedicated to Professor Edgar Heilbronner on the occasion of his 60th birthday*

The nature of the Li—C bond and of the stabilization of carbanionoid centers by adjacent third- and higher-row atoms are both still matters of debate[1]. "..., the mechanism of anion stabilization by third and higher row elements remains an unsettled and important problem. Operational criteria to distinguish charge transfer from polarization effects are difficult to devise, particularly with the limitations of working with real compounds[1c]". The main features of electron-density difference maps obtained by X-ray analysis are often identifiable, at least qualitatively, with concepts (bonding density, lone-pair electrons, π-bonds) that chemists use in discussing the electronic structure of molecules[2]. In this paper we describe evidence from such maps[2] for the existence of two different types of Li—C bond in closely related sulfur-α-substituted organolithium compounds, namely dimeric 2-lithio-2-methyl-1,3-dithianetetramethylethylenediamine (TMEDA) *(1)*[3] and the title compound *(2)*[4].

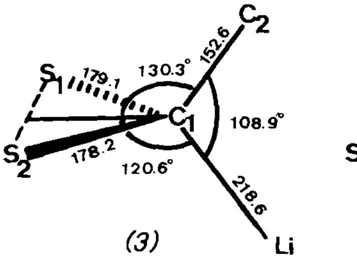


*(1)*

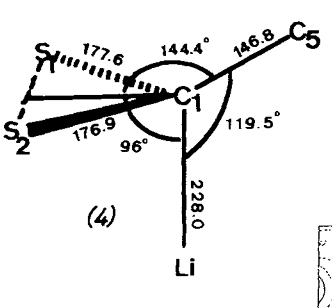


*(2)*

Crystalline *(2)* was obtained by deprotonation of phenyldithiane [0.25 M solution in hexane/tetrahydrofuran (THF) 3 : 1] with butyllithium in the presence of TMEDA (0.33 M) at −15 °C, followed by cooling to −78 °C. X-ray analysis[5] of *(2)* led to the structure depicted in Figure 1. The surroundings of the carbanionoid centers in *(1)* and *(2)* are shown in *(3)* and *(4)*, respectively.



*(3)*



*(4)*

Several features of the structure of the metalated phenyldithiane *(2)* are noteworthy. In order to achieve its usual coordination number 4, the lithium atom is bonded to the oxygen atom of a THF molecule in addition to the dithiane carbon C1 and the two nitrogen atoms of TMEDA; thus, in contrast to *(1)*, the complex *(2)* is monomeric. The phenyl group in unmetalated 2-phenyldithiane is equatorial[6] but in *(2)* is axial[7] and its plane is rotated by 90° with respect to the unmetalated compound to achieve an orientation that allows conjugative stabilization. Although the C1—C5 bond length of 147 pm indicates considerable double-bond character, the carbanionoid C1 is still far from planar (see Fig. 1). On passing from *(1)* to *(2)*, the Li—C bond length increases by 10 pm and the angle between this bond and the S1—C1—S2 bisector decreases from 121° to 96° [cf. *(3)* and *(4)*]. While these changes indicate a shift towards a π-complex type of structure in *(2)* (cf. the structure of benzyllithium-TMEDA[8]), they may appear small when considerd against the differences in reactivity between the two compounds, for example, with α,β-unsaturated carbonyl compounds[9], or against the difference of 8 units between the p$K_s$'s of the conjugate acids[1c].

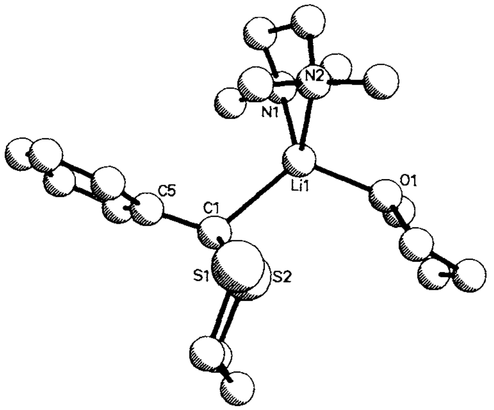


Fig. 1. Structure of complex *(2)* with H-atoms excluded (drawn by Program PLUTO, Cambridge Crystallographic Data Centre). Crystal data: Space group $P\bar{1}$; $Z=2$, $a=900.56$, $b=980.32$, $c=1295.55$ pm, $\alpha=96.28$, $\beta=97.15$, $\gamma=101.55°$, $\rho_{calc}=1.178$ g/cm³. Bond lengths [pm, $\sigma \leqslant 0.5$ pm] Li1—O1 197.0, Li1—N1 214.8, Li1—N2 211.0; angle [°, $\sigma \leqslant 0.10°$] O1—Li1—N1 105.8, O1—Li1—N2 108.8, O1—Li1—C1 117.2, C1—Li1—N1 119.8, C1—Li1—N2 114.1, N1—Li1—N2 86.9.

Electron-density difference maps ($\Delta\rho = \Delta\rho_{exp} - \Delta\rho_{calc}$) calculated for *(1)* and *(2)* show, on the whole, similar bonding density for corresponding C—C, C—N, and C—S bonds in the two structures together with lone-pair peaks in the expected directions, close to the N, O and S atoms. By far the greatest difference between the two maps occurs at the Li atoms. Figure 2 shows sections of $\Delta\rho$ for *(1)* and *(2)* in the plane of C1, Li and an N atom of TMEDA. The diffuse peaks along the bond directions may be identified as bonding or lone-pair density. At the Li atoms, $\Delta\rho$ is

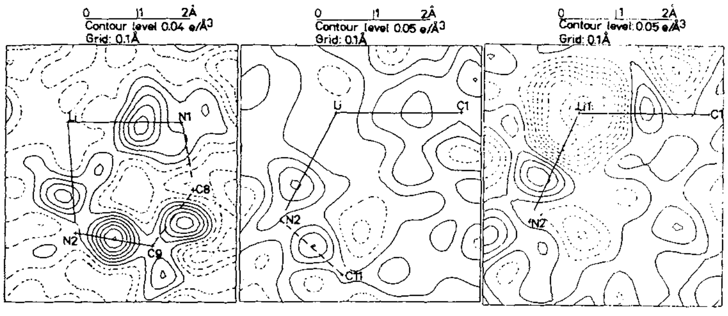

Fig. 2. Electron-density difference-maps in the planes: N1—Li—N2 and C1—Li—N2 of *(1)* and C1—Li—N2 of *(2)*. Contours at intervals of 0.05 eÅ⁻³ (negative contours dotted).

*0570-0833/81/0505-465* $ *02.50/0*

close to zero in *(1)* but strongly negative in *(2)*. By integration, the electron-density deficit on the Li atom in *(2)* is estimated to be about 0.5—0.6 electrons. Thus, from the electron-density difference maps, 2-lithio-2-methyldithiane would seem to have a covalent, at most polarized, Li—C bond, whereas 2-lithio-2-phenyldithiane can be regarded as an example of a contact ion-pair complex.

## $Ca_3AlAs_3$—An Intermetallic Analogue of the Chain Silicates[**]

By *Gerhard Cordier* and *Herbert Schäfer*[*]

*Dedicated to Professor Karl Heinrich Lieser on the occasion of his 60th birthday*

Salts with complex anions gain metallic bonding character if the nonmetallic components in their anionic moieties are replaced by semimetals—there result Zintl phases with complex anions. This transition in bond character was recently demonstrated for compounds having $Ba_4Si(Ge)As_4$ structure, in which $Si(Ge)As_4^{8-}$-tetrahedra occur, corresponding to the isosteric $Si(Ge)O_4^{4-}$ tetrahedra in the *ortho*-silicates and germanates[1]. We have now succeeded in preparing $Ca_3AlAs_3$ having $(AlAs_3)_n^{6-}$-chain anions which are isosterically and structurally completely analogous to the polysilicate(germanate) anions $(SiO_3)_n^{2-}$ and $(GeO_3)_n^{2-}$. As shown in Figure 1[2] the structure contains "*Einer-einfachketten*" (nomenclature after *Liebau*) of $AlAs_4$ tetrahedra. The Al—As atomic distances of 250.2, 250.3, 253.9 pm (2 ×) correspond to the sum of the covalent radii of these elements as quoted by *Pauling* (≙ 244 pm); they are significantly shorter than the sum of the metal (≙ 291 pm) or ionic radii (≙ 272 pm). The bond angles at the central Al atom are 102.4, 112.4 (2 ×), 108.8 (2 ×), 111.6°. These results demonstrate for the first time that chains of corner-linked tetrahedra, which are already known as basic structural units in the salts of isopolyacids of the main group elements, *e.g.* of silicon or phosphorus, can also occur in intermetallic compounds of the Zintl type.

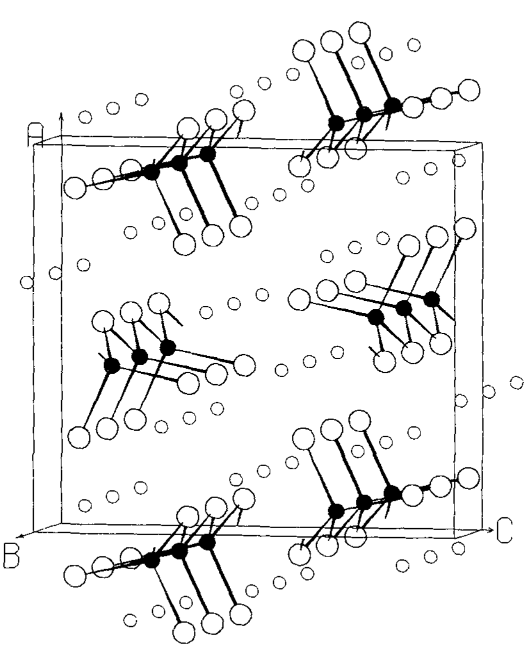

Fig. 1. Structure of $CaAlAs_3$. Small open circles ≙ Ca atoms, large open circles ≙ As atoms, small closed circles ≙ Al atoms [2].

*Experimental*

Stoichiometric amounts of the elements were heated under argon at 1200 K in corrundum crucibles contained in quartz bombs. After cooling, the reaction product was homogenized, re-heated to 1200 K, and annealed for 24 h at 900 K. The metallic-like regulus thus obtained was optically and X-ray crystallographically uniform. $Ca_3AlAs_4$ is relatively stable, but shows distinct signs of decomposition on exposure to moist atmosphere for a few days; the shiny metallic-like surfaces become dull and covered with a gray layer of unknown composition.

## Macrotricyclic Quaternary Ammonium Salts: Enzyme-Analogous Activity[**]

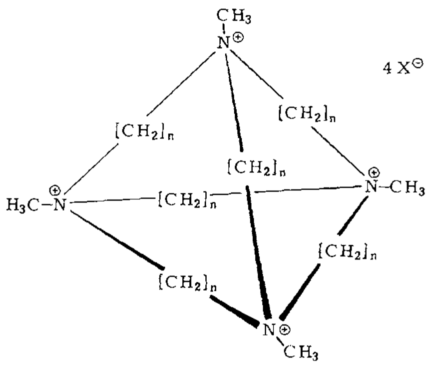
By *Franz P. Schmidtchen*[*]

Natural enzymes achieve their extraordinary specificity and catalytic activity by binding of the substrates in an en-

[*] Dr. F. P. Schmidtchen
Lehrstuhl für Organische Chemie und Biochemie
der Technischen Universität München
Lichtenbergstr. 4, D-8046 Garching (Germany)

[**] Part 3: This work was supported by the Deutsche Forschungsgemeinschaft.—Part 2: [4].

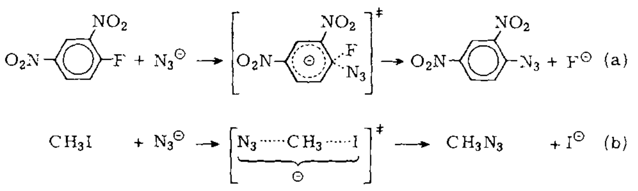
zyme pocket (active center), which is furnished with a functionality that is complementary to the rate determining transition state and therefore stabilizing. Electrostatic (salt-bridges) and hydrophobic interactions play a prominent role[1]. A great deal of attention is currently being paid to the synthesis of model enzymes—predominantly semisynthetic molecules[2] such as cyclodextrins. The fully synthetic macrotricyclic ammonium salts *(1)* and *(2)*[3] harbor a series of properties which are required of an enzyme model: they are equipped with a cavity of definite size in which a strong electropositive potential prevails, while the alkylene chains provide a hydrophobic environment. In contrast to detergents which form micelles, *(1)* and *(2)* (*e.g.* as fluorides or glucuronates) are molecular-dispersively soluble in $H_2O$ in the required concentration range (<0.1 M). The specific binding of anions[4] would lead one to expect that anionic transition states could also be bound and thus stabilized, and the accompanying reactions accelerated. We report here the influence of *(1)* and *(2)* on the reactions described in eqs. (a)—(c).



*(1)*, n = 6, $X^{\ominus} = CH_3C_6H_4SO_3^{\ominus}$
*(2)*, n = 8, $X^{\ominus} = F^{\ominus}$

While addition of *(1)* clearly inhibits the reaction of azide anions with fluoro(dinitro)benzene (FDNB) [eq. (a)], *(2)* accelerates all three reactions, in part considerably (Table 1). The catalyzed reactions (a) and (b) show saturation kinetics typical of enzymes (Fig. 1), so that a general salt effect cannot explain the observed changes in rate. The opposite influence in the reaction according to eq. (a) on addition of *(1)* or *(2)* points rather more to a specific interaction[4]. *(1)* complexes "hard" anions of suitable size about one hundred times more strongly than *(2)*. On the other hand, *(2)* is better suited for stabilizing readily polarizable anions. *(1)* and *(2)* bind azide ions in their molecular cavities ($K_D[N_3^{\ominus}\subset$ *(1)*$] = 2\times10^{-3}$ M; $K_D[N_3^{\ominus}\subset$ *(2)*$] = 1.2\times10^{-2}$ M) and thus stabilize—albeit to different extents—the educts of reaction (a). The transition state is characterized by marked electron delocalization and therefore high polarizability, so it is stabilized much better by *(2)* than by *(1)*. Also the activation entropy of the reaction (a)—owing to the larger molecular cavity and better accessibility, the activated complex in *(2)* should be easier to obtain than in *(1)*—ought to be greater in the reaction catalyzed by *(2)* than in that catalyzed by *(1)*. Indeed, the free energy of activation of the spontaneous reaction lies between that of the more rapid—addition of *(2)*—and that of the slower—addition of *(1)*.

The acceleration of enzyme-catalyzed substitutions arises in considerable part from the change in mechanism: the spontaneous reaction proceeds bimolecularly, the enzyme-catalyzed reaction monomolecularly[1]. As example in which the entropy effect does not arise, we investigated the monomolecular decomposition of *erythro*-2,3-dibromo-3-phenyl propionate (DBPP) [eq. (c)][5]. In aqueous methanol, DBPP decomposes in two ways (A and B) to the isomeric β-bromostyrenes: whereas the synchronous fragmentation gives exclusively the *Z*-isomer, monomolecular dissociation at the benzyl position affords a carbenium ion,



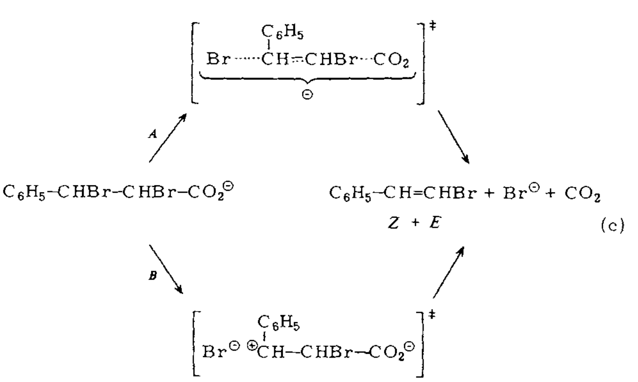


Table 1. Catalysis of the reactions (a)—(c) in 25% methanol by *(1)* and *(2)*; abbreviations, see text.

| Reaction | Concentration [M] Substrate | Catalyst | $T$ [°C] | $\frac{v_{catal.}}{v_{spont.}}$ |
|---|---|---|---|---|
| (a) | $[N_3^{\ominus}] = 10^{-2}$; $[DNFB] = 10^{-4}$ | [*(1)*] $= 10^{-2}$ | 4 | 0.5 [a] |
| (a) | $[N_3^{\ominus}] = 10^{-2}$; $[DNFB] = 10^{-4}$ | [*(2)*] $= 10^{-2}$ | 4 | 20 [a] |
| (b) | $[N_3^{\ominus}] = 6\times10^{-3}$; $[CH_3I] = 10^{-2}$ | [*(2)*] $= 10^{-2}$ | 27 | 37 [a] |
| (c) | $[DBPP] = 2\times10^{-2}$ | [*(2)*] $= 4\times10^{-2}$ | 27 | 1.8 [b]<br>$E/Z = 0.48$ |
| (c) | $[DBPP] = 2\times10^{-2}$ | — | 27 | —<br>$E/Z = 1.64$ |

[a] Initial rates. [b] Average rates after 200 min.

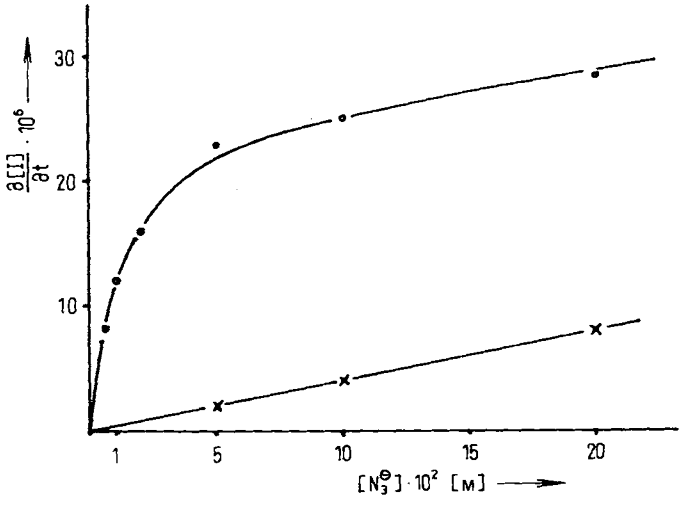

Fig. 1. Kinetics (initial rates mol/dm³·min) of the reaction (b) in 25% methanol at 27 °C without (×) and with (o) *(2)* ($10^{-2}$ M); $[CH_3I] = 10^{-2}$ M.

which is converted by cleavage of $CO_2$ into the products in a thermodynamic *E/Z* ratio ($E/Z = 9/1$).

In the spontaneous reaction ($[DBPP] = 2 \times 10^{-2}$ M; $T = 27\,°C$) we obtained 20% conversion after 200 min and an *E/Z* ratio of the bromostyrenes of 1.64. On addition of $4 \times 10^{-2}$ mol of *(2)*, the same reaction gave a 36% conversion in 200 min and an *E/Z* ratio of 0.48. This shows that *(2)* preferably—if not exclusively—catalyzes the formation of the *Z*-bromostyrene. Yet a further enzyme-analogous property of the host molecule *(2)* should be outlined here: Of the two modes of reaction of the substrate, the one which proceeds *via* the easily polarizable anionic transition state is specifically accelerated. Reaction (c) proves that the increases in rates in the catalysis by *(2)* cannot be ascribed solely to the change of molecularity of the reaction (proximity effect, reactions (a) and (b)).

The observed change in rates of the reactions (a), (b) and (c) can be qualitatively correctly predicted by means of the Hughes-Ingold rules, if *(1)* and *(2)* are regarded as dipolar aprotic "solvents". The acceleration of anionic reactions by *(2)* on going from a protic to an aprotic medium is not, however, due to destabilization of the ground state[6] but to stabilization of the transition state.

The synthetic macrotricyclic ammonium salt *(2)* takes up substrates in a molecular cavity and accelerates reactions in the inclusion complex by lowering the energy of the transition state. It has saturation kinetics and shows substrate-specificity as well as reaction-specificity, but owing to the highly symmetric molecular disposition does not show stereospecificity. On the basis of this very close analogy to the biocatalysts we propose for *(2)* the designation "artificial enzyme".

# Tetracyclo[4.1.0.0$^{2,4}$.0$^{3,5}$]heptanes from 7,8-Diazatetracyclo[4.3.0.0$^{2,4}$.0$^{3,5}$]non-7-enes[**]

By *Manfred Christl* and *Erich Brunn*[*]

*Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday*

We recently reported the first available method for the synthesis of the tetracyclo[4.1.0.0$^{2,4}$.0$^{3,5}$]heptane skeleton[1] by addition of halocarbenes to benzvalene *(1)*. The parent compound *(3a)* is formed by reduction of the 7,7-dichloro- and 7,7-dibromo-derivative. We now report on an entry to the 7-methyl- and 7-aryl-derivatives *(3b)*—*(3h)*, thus enabling this tetracyclic system to be investigated in much better detail.

The addition of diazomethane to benzvalene *(1)*[1a] affords *(2a)* in 83% yield; the reaction can also be carried out with diazoethane and 2-diazopropane (*ca.* 15 h at 20 °C in ether) as well as with phenyl- and diphenyldiazomethane and with diazofluorene (8 d at 20 °C in ether), whereupon the 1-pyrazoline derivatives *(2b)*—*(2h)*[4] (Table 1) are formed. In contrast, ethyl diazoacetate does not react with *(1)*[2].

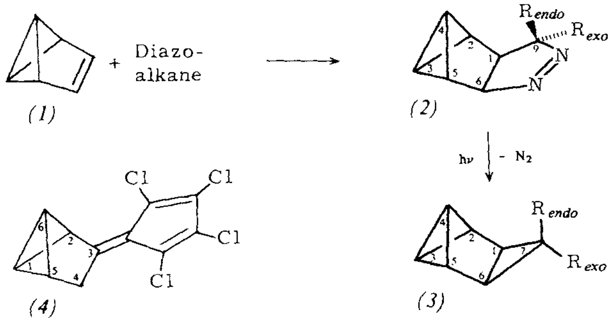

Table 1. Yields, ratios of isomers, and boiling and melting points of compounds *(2)* and *(3)*.

| $R_{exo}$ | $R_{endo}$ | Cpd. | Yield [%] | $\left(\frac{exo}{endo}\right)$ | B.p. or M.p. [°C/torr] and [°C] | Cpd. | Yield [%] | $\left(\frac{exo}{endo}\right)$ | B.p. or M.p. [°C/torr] and [°C] |
|---|---|---|---|---|---|---|---|---|---|
| H | H | *(2a)* | 83 | (—) | 55—60 (bath)/$10^{-1}$ | *(3a)* | 27 | (—) | 104/730 |
| $CH_3$ | H | *(2b)* | 58 | (1.7) | 40—50 (bath)/$10^{-3}$ | *(3b)* | 78 | (1.8) | 62—65/90—100 |
| H | $CH_3$ | *(2c)* | | | | *(3c)* | | | |
| $CH_3$ | $CH_3$ | *(2d)* | 100 | (—) | 60 (bath)/$10^{-3}$<br>35 | *(3d)* | 39 | (—) | 50-60 (bath)/15 |
| $C_6H_5$ | H | *(2e)* | 59 | (1.3) | 80—100 (bath)/$10^{-3}$ | *(3e)* | 81 | (1.5) | 40—70 (bath)/$10^{-2}$ |
| H | $C_6H_5$ | *(2f)* | | | 80—87 | *(3f)* | | | |
| $C_6H_5$ | $C_6H_5$ | *(2g)* | 72 | (—) | 152 | *(3g)* | 73 | (—) | 73—75 |
| Biphenylene | | *(2h)* | 79 | (—) | 126—128 | *(3h)* | 97 | (—) | 78—85 |

Irradiation of the 1-pyrazolines or 1-pyrazoline mixtures *(2)* in benzene solution with a high-pressure mercury lamp through Duran leads to elimination of nitrogen and formation of the tetracyclo[4.1.0.0$^{2,4}$.0$^{3,5}$]heptane derivatives *(3)*[4] (Table 1).

As molecular models clearly show, strong steric hindrance occurs between the *endo*-substituents and 4-H in the 7-*endo* substituted compounds *(3c)*, *(3d)*, *(3f)*, *(3g)* and, especially, *(3h)*, which influences the reactivity. Thus, the *endo*-isomers *(3c)* and *(3f)* of the *(3b)/(3c)*- and *(3e)/(3f)*-

mixtures rearrange into 7-methyl- and 7-phenylcycloheptatriene, respectively, even at room temperature in $CDCl_3$, probably in a process catalyzed by traces of acid, whereas the *exo*-isomers remain unchanged.

On reaction of *(1)* with tetrachlorodiazocyclopentadiene we did not observe a pyrazoline of type *(2)*. Yellow crystals with m.p. 148 °C are obtained in 11% yield, which we assign the fulvene structure *(4)*[5].

## Chemiluminescence of Tricarbonyl(chloro)(1,10-phenanthroline)rhenium(I) during the Catalytic Decomposition of Tetralinyl Hydroperoxide[**]

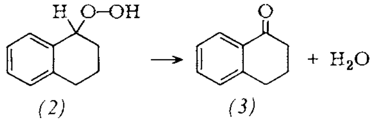
By *Arnd Vogler* and *Horst Kunkely*[*]

The thermal decomposition of organic peroxides[1a] or of hydrogen peroxide[1b] is catalyzed by transition metal complexes. This reaction is also of great importance in biological systems. In the past few years it has been shown, particularly by *Schuster et al.*, that even organic compounds are capable of catalyzing peroxide decomposition[2]. The energy liberated in this decomposition is sufficient to generate the catalyst in an electronically excited state; as a result a chemiluminescence can be observed. It is therefore necessary that the catalyst is oxidized by the peroxide in the first step. The electronic excitation takes place in the last step by reduction of the oxidized catalyst. It now seemed worthwhile checking whether this mechanism also applies to catalyses with transition metal complexes.

[Re(phen)(CO)$_3$Cl] *(1)*

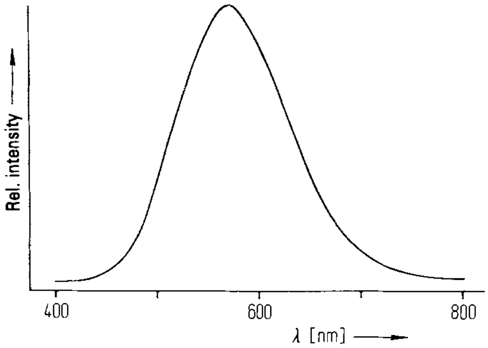
appeared to us to be a suitable candidate for such investigations, since this complex can not only be reversibly oxidized electrochemically (+1.3 V *vs.* SCE) but also undergoes an electrogenerated luminescence[3]. Moreover, it was considered essential that an attempt should be made to extend our knowledge of the chemiluminescence of transition metal complexes, about which only very little is known so far[4].

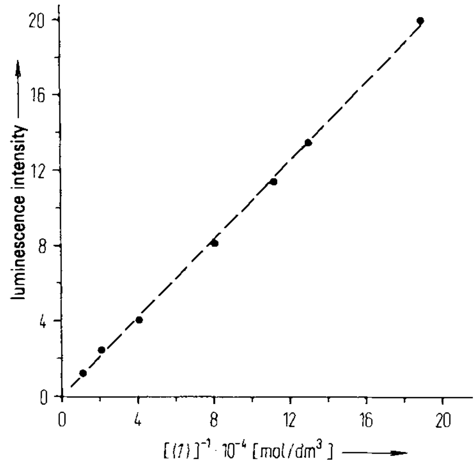
Tetralinyl hydroperoxide *(2)* decomposes only slowly in boiling tetralin, whereas on addition of the complex *(1)* an emission of bright light with concomitant rapid decomposition of *(2)* takes place producing α-tetralone *(3)* and water[5].



*(2)* *(3)*

The spectrum of this chemiluminescence (Fig. 1) is identical with that of the photoluminescence of pure *(1)*[6]. As follows from the linear dependence of the reciprocal of the intensity of chemiluminescence on the reciprocal of the concentration of the complex[7] (Fig. 2), the electronically excited rhenium complex is formed immediately as a result of a bimolecular reaction. The catalysis must therefore proceed according to the Schuster mechanism:





$$
\begin{aligned}
(1) + (2) &\rightarrow (1)^{\oplus}(2)^{\ominus}\\
(1)^{\oplus}(2)^{\ominus} &\rightarrow (1)^{\oplus}(3)^{\ominus} + H_2O\\
(1)^{\oplus}(3)^{\ominus} &\rightarrow (1)^{*} + (3)\\
(1)^{*} &\rightarrow (1) + \text{light}
\end{aligned}
$$

Institut für Anorganische Chemie der Universität
Postfach, D-8400 Regensburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Although further investigations must be carried out to confirm this mechanism[8], it should be pointed out that our observation is most likely of fundamental importance for an understanding of the catalytic decomposition of peroxides by transition metal complexes. Many complexes fulfill the prerequisite that they can be reversibly oxidized and have energetically low-lying excitation states which can take up the decomposition energy of the peroxides. The occurrence of a luminescence is not necessary. Under suitable conditions a reversal of this hydroperoxide decomposition, *i.e.* the photochemically catalyzed addition of water to a ketone, could be achieved[5b]; this would constitute a possible way of chemically storing light energy.

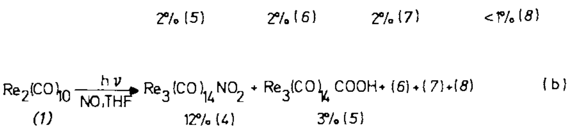
# Nitrogen Dioxide and the Isoelectronic COOH Group as 5-Electron Donors in Carbonylmetal Complexes; Preparation and Characterization of the First "Metallacarboxylic Acid"

By *Barbara K. Balbach, Frantisek Helus, Franz Oberdorfer,* and *Manfred L. Ziegler*[*]

Photolysis of $Re_2(CO)_{10}$ *(1)* in the presence of NO and cyclooctatriene (COT) leads, in accord with eq. (a), to formation of the products *(2)—(8)*, of which the hydrido-complexes *(6)—(8)* have already been described[1]. The species *(4)* and *(5)*, as well as *(6)—(8)*, are also formed on photolysis in the absence of COT [eq. (b)].



$$\underset{(1)}{Re_2(CO)_{10}} + COT \xrightarrow[NO, THF]{h\nu} \underset{5\%\ (2)}{Re_2(CO)_8C_4H_6} + \underset{2\%\ (3)}{Re_2(CO)_9C_3H_6} + \underset{10\%\ (4)}{Re_3(CO)_{14}NO_2}$$

$$+ \underset{2\%\ (5)}{Re_3(CO)_{14}COOH} + \underset{2\%\ (6)}{HRe_3(CO)_{14}} + \underset{2\%\ (7)}{H_3Re_3(CO)_{12}} + \underset{<1\%\ (8)}{H_4Re_4(CO)_{12}} \quad (a)$$

$$\underset{(1)}{Re_2(CO)_{10}} \xrightarrow[NO, THF]{h\nu} \underset{12\%\ (4)}{Re_3(CO)_{14}NO_2} + \underset{3\%\ (5)}{Re_3(CO)_{14}COOH} + (6) + (7) + (8) \quad (b)$$

We have been able to establish by an X-ray structure analysis that the two Re atoms in complex *(2)* are bridged by a butadiene ligand in *trans*-configuration. The butadiene complex *(2)* is isomorphic with the analogous manganese complex[2]; it can only be formed by a symmetric cleavage of COT. This could be of interest regarding the formation of COT from acetylene.

The new compounds *(4)* and *(5)* were characterized by elemental analyses, by their mass and IR spectra[3], and by X-ray structure analyses[4] (Fig. 1).

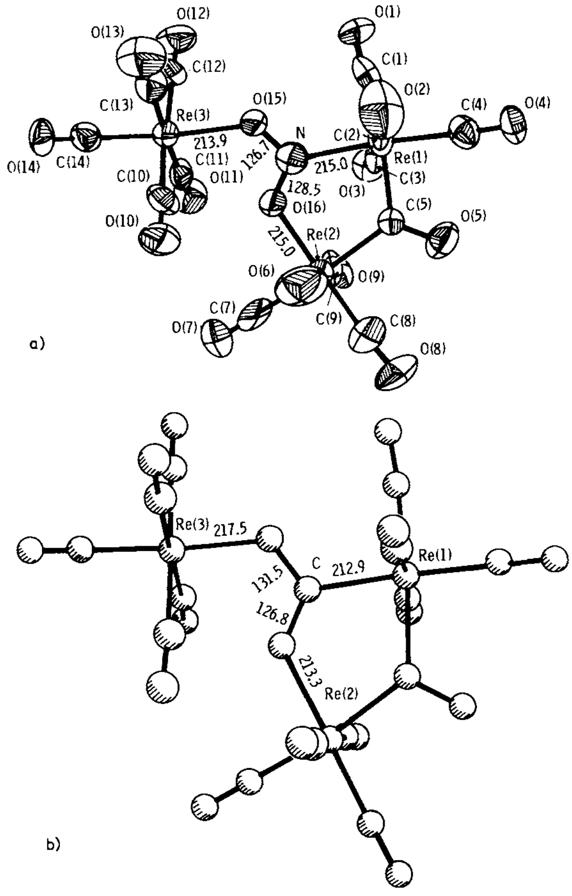


Fig. 1. a) ORTEP diagram of *(4)* projected onto the $NO_2$—Re(1) plane. b) ORTEP diagram of *(5)* projected on the COO—Re(1) plane. Bond lengths in pm.

The data obtained are consistent with a trinuclear complex without Re—Re bonding. The coherence of the species *(4)* and *(5)* is secured by a central $NO_2$ or COOH unit, both of which have 17 electrons; for the three Re atoms to uphold the 18-electron rule, these ligands must function as 5-electron donors. *(4)* and *(5)* are diamagnetic.

The IR spectrum of *(5)* contains a sharp, intense band at 3700 $cm^{-1}$, which we assign to an O—H stretching vibration; the H-atom cannot be involved in bridging. It can be replaced by deuterium by multiple dissolution of *(5)* in [D4]methanol and stirring of the solutions. As expected, the deuterated species shows a sharp band at 2700 $cm^{-1}$. Location of the H-atom in *(5)* is not possible by X-ray structure analysis. On the basis of all these experimental data, *(5)* is to be formulated as a metallacarboxylic acid in which a carbonylmetal unit corresponds to the alkyl or aryl moiety R in ROOH. Such a metallacarboxylic acid is then stable, only if both oxygen atoms of the carboxyl group are involved in coordination. The atoms of the central COO-unit and the rhenium (Re(1)) bonded to the C-atom lie,

within the limits of accuracy, in one plane; the sum of the internal angles at C and N is 360°.

*(4)* has the same molecular geometry as *(5)*, but the species are not isomorphic.

## *Procedure*

A solution of *(1)* (1.3 g, 2 mmol) in tetrahydrofuran (THF) (300 $cm^3$) is saturated with NO and cooled to $-20\,°C$. After addition of 2 $cm^3$ of freshly distilled COT the mixture is photolyzed for 3 h; the solution, which becomes deep-red on completion of reaction, warms to about 0 °C. It was evaporated down to *ca.* 50 $cm^3$, transferred onto silica gel, and dried. The dried mass was treated with *n*-hexane and the resulting suspensoid chromatographed on a column (40×2.5 cm, 0.02—0.5 silica gel, *n*-hexane). Six zones are formed: zone 1, COT + *(1)*; zone 2, *(2)*; zone 3, *(7)*; zone 4, *(6)*; zone 5, *(3)*; zone 6, *(4)*+*(5)*. Zones 4, 5, and 6 were re-chromatographed (PSC plates, Merck, silica gel F-254, 2.5 mm, benzene), affording pure *(6)*, *(3)* and *(8)*, *(3)* as a colorless solution. A further chromatographic separation had to be carried out for the separation of *(4)* and *(5)* (Nucleosil 50-10, 300×0.4 cm, *n*-hexane, 0.05 bar, 3 $cm^3$/min, 28 °C; detector 254 nm). Fractional crystallization (room temperature to $-20\,°C$, cyclohexane/ether) afforded 40 mg of *(4)* (yield 5—6%, yellow needles) and 20 mg of *(5)* (yield 2%, yellow platelets); in each case the yields are based on *(1)*.

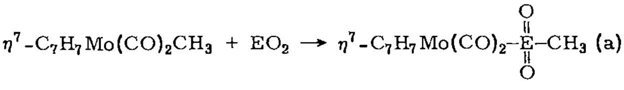
# Preparation of $\eta^7$-$C_7H_7Mo(CO)_2EO_2CH_3$ (E = S, Se, Te); the First Insertion of $TEO_2$ into a Metal-Carbon Bond

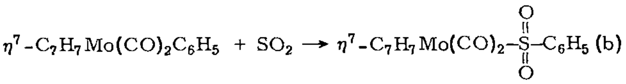
By *Winfried Dell* and *Manfred L. Ziegler*[*]

The insertion of $SO_2$ and $SeO_2$ into metal-carbon σ-bonds is already well documented[1]. The insertion of $TeO_2$ was considered as unrealizable, since the activation of a $TeO_2$ molecule appeared possible only under conditions in which the alkyl or aryl educt and/or the insertion product would no longer be stable. We have now succeeded in activating $TeO_2$ by evaporation of $TeO_2$ in a metal evaporator and condensation in an ether matrix at $-196\,°C$. The complex $\eta^7$-$C_7H_7Mo(CO)_2CH_3$ *(1)*[2], previously prepared by us, provided a species containing an extremely reactive molybdenum—methyl carbon bond suitable for an electrophilic $EO_2$ insertion (Table 1)[3]. As expected, aside from $TeO_2$, $SO_2$ and $SeO_2$ could also be inserted into the molybdenum-carbon bond [eq. (a)].



$$\eta^7\text{-}C_7H_7Mo(CO)_2CH_3 + EO_2 \longrightarrow \eta^7\text{-}C_7H_7Mo(CO)_2\text{-}\overset{O}{\underset{O}{\overset{\|}{\underset{\|}{E}}}}\text{-}CH_3 \quad (a)$$

*(1)* *(2)*, E = S; *(3)*, E = Se; *(4)*, E = Te



$$\eta^7\text{-}C_7H_7Mo(CO)_2C_6H_5 + SO_2 \longrightarrow \eta^7\text{-}C_7H_7Mo(CO)_2\text{-}\overset{O}{\underset{O}{\overset{\|}{\underset{\|}{S}}}}\text{-}C_6H_5 \quad (b)$$

*(5)* *(6)*

Analogously to the synthesis of *(1)* we were able to prepare the phenyl derivative *(5)* from $\eta^7$-$C_7H_7Mo(CO)_2Br$ and $LiC_6H_5$[2]. However, the Mo—$C_{phenyl}$ bond proved to be less reactive than the Mo—$C_{methyl}$ bond in *(1)*: with *(5)*, only the insertion of $SO_2$ could be achieved [eq. (b)].

The species *(1)*—*(6)* were characterized by elemental analysis, by their IR and $^1$H-NMR spectra and, in part, by mass spectra. The monomolecular composition of the compounds *(2)*—*(4)* followed from molecular weight determinations on *(2)* (obs. 327 (322), osmometrically, dichloroethane) and comparison of the $^1$H-NMR and IR spectra of *(2)*, *(3)*, *(4)*, and *(6)*. The phenyl derivative *(6)* had already been prepared by us by reaction of $\eta^7$-$C_7H_7Mo(CO)_2I$ with $AgSO_2C_6H_5$[4]. A characterization of the complexes *(1)*—*(6)* by X-ray structure analysis was not possible owing to their thermal instability; *(2)* can be stored for a few hours at room temperature; *(1)*, *(3)*, and *(4)* can be kept for only a few minutes.

In the $^1$H-NMR spectrum (Table 1) of *(1)*, the signal for the methyl protons appears at $\delta = -0.25$, owing to the high electron density on the methyl carbon atom; thus *(1)* is exactly predestined for such an insertion according to concepts on the mechanism of $EO_2$ insertion[3]. As expected the signals for the $CH_3$ protons in the $EO_2$-insertion products *(2)*—*(4)* appear at low field; the $\nu_{CO}$ bands of the species *(2)*—*(4)* and *(6)* are shifted to higher wave numbers compared to those of the methyl-*(1)* and of the phenyl compound *(5)*.

Table 1. Some spectroscopic data of compounds *(1)*—*(6)*.

## *Procedure*

$SeO_2$ (500 mg, 4.5 mmol) was evaporated in a metal evaporator[4] at $-196\,°C$ within 2 h (20 A, 220 V) onto an ether matrix (50 $cm^3$), heated to $-78\,°C$, and then treated with a solution of *(1)* (100 mg, 0.4 mmol) in tetrahydrofuran pre-cooled to $-78\,°C$. The reaction solution was al-

Im Neuenheimer Feld 270, D-6900 Heidelberg (Germany)

lowed to stand at this temperature for one week; the color of the solution turned from green to red. The mixture was subjected to low-temperature chromatography (−20 °C, Merck silica gel 60; 0.040—0.63 mm, $CHCl_3$/acetone 1 : 1, 30 × 2.5 cm). Two zones were eluted: the first (green) zone, was unreacted *(1)*, the second (red) zone was *(3)*; yield 44 mg, 30% based on *(1)*.

*(4)* is prepared analogously, but completion of reaction requires eight weeks (220 V, 70 A; yield 5—8%).

The red-brown crystals of *(3)* and of *(4)* are stable in an inert atmosphere for a few days or a few hours at −78 °C, respectively, at room temperature for a matter of a few minutes. *(3)* is soluble in $CH_2Cl_2$ and in polar solvents, *(4)* in ether and in polar solvents. The solutions of *(3)* and *(4)* decompose within a few minutes at room temperature.

## A Triple-Decked Sandwich Complex of Rhodium with 1,4-Diborabenzene as Bridging Ligand[**]

By *Gerhard E. Herberich, Bernd Hessner, Gottfried Huttner*, and *Laszlo Zsolnai*[*]

The known triple-decked complexes[1] have mainly 7-vertex *closo*-structures with pentagonal bipyramids as the basic framework. A five-membered ring functions as the central ligand and the apical positions are occupied by Mn, Fe, Co or Ni. The majority of these complexes contain 30 valence electrons (calculated *via* the noble gas formalism) and therefore adhere to the cluster rules[2]. Complexes having 29 and 31—34 valence electrons are known[3]. These do not correspond to another structural type but rather show a weakening of the cluster bonds[4].

The sandwich complex *(2)*[5], derived from the hypothetical 1,4-dimethyl-1,4-dibora-2,5-cyclohexadiene *(1)*, forms the novel pale yellow triple-decked sandwich cation *(3)*$^{2+}$ in $CF_3COOH$. The same cation is also obtained from *(2)* by stacking with $[(C_5Me_5)RhCl_2]_2/AlCl_3$ in $CH_2Cl_2$.

The 30 valence electron complex *(3)*$^{2+}$ is the first triple-decked complex derived from a diborabenzene derivative and simultaneously, the first with a heavy transition metal. Its hexagonal bipyramidal structure has not previously been observed in 8-vertex *closo*-polyhedra (Table 1)[6]. The bond lengths in the $C_4B_2$-ring are shorter in the sandwich complex $(C_5H_5)Co[MeB(C_2H_2)_2BMe]$[7] than in the triple-decked complex *(3)*$^{2+}$ (C—C 142 *vs.* 144 pm, B—C 151 *vs.* 154 pm).

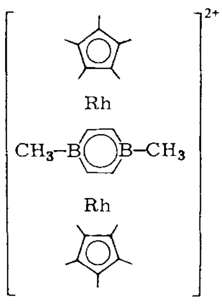
*(2)*



*(3)*$^{2+}$

Table 1. Structural data for *(3)*$^{2+}$.

| | | | |
|---|---|---|---|
| $C_4B_2Rh_2$-Polyhedra | | | |
| CC | 144 pm | RhC | 227 pm |
| CB | 154 pm | Rh—B | 233 pm |
| ∢CBC | 113° | Rh—Rh | 344,4 pm |
| $Rh(C_5Me_5)$ | | | |
| C—C | 143 pm | Rh—C | 216 pm |
| $C—C_{Me}$ | 149 pm | | |

Table 1. Structural data for *(3)*$^{2+}$.

Complex *(3)*$^{2+}$ can be electrochemically reduced in acetonitrile to the 31 electron cation *(3)*$^{+}$ (reversible one-electron transition at $E_{1/2} = -0.645$ V *vs.* SCE). Further reduction to the 32 electron neutral complex *(3)* (cathodic peak potential −1.18 V; reoxidation detectable at 2 $Vs^{-1}$ voltage scanning rate) is followed by fast degradation[8].

$$(3)^{2+} \rightleftharpoons (3)^{+} \rightleftharpoons (3) \rightarrow ?$$

### *Procedure*

a) *(2)*[7] (56 mg, 0.16 mmol) and $[(C_5Me_5)RhCl_2]_2$ (50 mg, 0.08 mmol) are treated with $AlCl_3$ (100 mg, 0.75 mmol) in 5 $cm^3$ $CH_2Cl_2$. After 15 min the color has change from dark red to yellow and the mixture is treated at 0 °C with 10 $cm^3$ $Et_2O$, followed by 10 $cm^3$ $H_2O$. Phase separation, precipitation with $NH_4PF_6$ (55 mg, 0.35 mmol) in 1 $cm^3$ $H_2O$ and recrystallization from acetone/$Et_2O$ gives 106 mg (76%) analytically pure *(3)*·$(PF_6)_2$, decomp. ⩾320 °C.

b) 1 $cm^3$ $CF_3COOH$ is added to a solution of *(2)*[7] (50 mg, 0.15 mmol) in 5 $cm^3$ $CH_2Cl_2$ at −80 °C and the mixture allowed to warm up to room temperature over 16 h. Work-up as described in a) gives 61 mg (93.5%) *(3)*·$(PF_6)_2$.

$^1$H-NMR ($CD_3NO_2$, int. TMS): $\delta = 0.91$ (s, 6H, BMe), 1.91 (s, 30H, $C_5Me_5$), 5.76 (s, 4H, $C_4B_2H_4$). $^{11}$B-NMR ($CD_3NO_2$, ext. $BF_3 \cdot Et_2O$): $\delta = 8$ (broad).

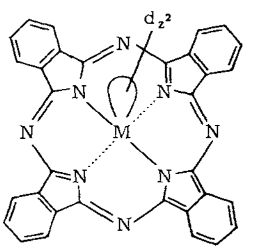
## Stable Metal-Phthalocyanines as Poison-Resistant Catalysts in Homogeneous Catalysis: Reduction of Organic Compounds with $NaBH_4$[**]

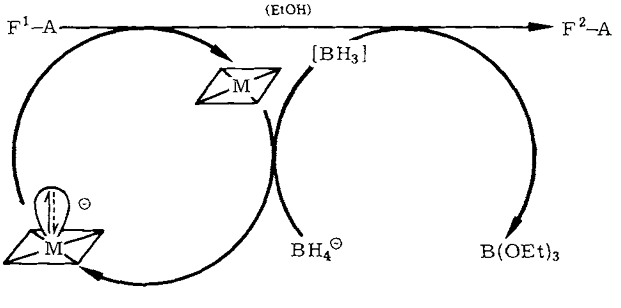
By *Heiner Eckert* and *Yvonne Kiesel*[*]

Transition metal-phthalocyanines (MPc) are extremely stable, both thermally and chemically, and hence some of them find use as fast blue dyes[1]. They can take up electrons reversibly in the $d_{z^2}$ orbital of the central atom M[2]; this predestinates them—in combination with a suitable reducing agent such as $NaBH_4$—as reduction catalysts[3].



MPc

The anions $[MPc]^{\ominus}$ of insoluble metal-phthalocyanines are soluble in polar organic solvents[2]. We recently reported on the use of the cobalt(I)-phthalocyanine anion for the selective reduction of nitro compounds[4] and for the cleavage of β-haloalkyl protecting groups[3]. $NaBH_4$ reductions[5] of nitro-[5a-c], cyano-[5a] and carbamoyl groups[5a], and of activated CC double bonds[5b,d] with addition of transition metal salts[5a,c] or catalyzed by structurally similar, but very expensive vitamin $B_{12}$[5d] or decomposable "cobaloxime"[5b,d] have also been described. Olefins and nitriles have been reduced with zinc in acidic medium in presence of vitamin $B_{12}$ as catalyst[6].



$F^1$–A and $F^2$–A see Table 1; M = VO, Mn, Fe, Co, Pd

The reduction of aliphatic and aromatic nitro- and nitroso-compounds, as well as oximes, Schiff's bases and nitriles with $NaBH_4$ under mild conditions in protic solvents (such as alcohols) at 20—25 °C to the corresponding amines can be homogeneously catalyzed with $[MPc]^{\ominus}$. CC-double bonds are hydrogenated, and halides are reduced to hydrocarbons. Arenes, aromatic halides, carboxylates and carboxamides are not attacked. The simultaneous reduction of several functional groups is also possible. The reaction rates gradually decrease along the series $C{=}C \approx Hal \approx NO_2 \approx NO > C{=}NOH \approx C{=}N{-}R > CN$; the reaction times are <30 min to 200 h. Hence, reducible groups can be successively reduced selectively under kinetic control, *e.g.* a nitronitrile to an aminonitrile or an α,β-unsaturated to a saturated nitrile (Table 1). The cata-

lysts are used in a concentration of up to 0.001 M; in the reduced soluble form $[MPc]^{\ominus}$ they change color (Table 2), thus allowing the course of the reaction to be monitored. After the reaction (in non-reducing medium), the catalyst MPc is quantitatively recovered; it can be used again for reductions without any further treatment.

Strong catalyst poisons[7] such as divalent S-compounds (β-naphthalenethiol, 1-octanethiol), or cyanide or iodide ions in tenfold excess (referred to the catalyst; equimolar referred to the educt) do not influence the rate of the reaction, or if so only slightly. This is reflected in the almost identical yields of reduction products in reactions with or without catalyst poison (Table 3). This immunity is underscored in the case of $[MPc]^{\ominus}$ catalysts with M = Fe or Co, probably owing to maximal localization of the negative charge in the "central atomic orbitals" of these $[MPc]^{\ominus}$. This finding is consistent with the results of LCAO-MO calculations on the electron-configuration of MPc[2]. The poisoning effects of the metals with d-electrons (*e.g.* $Cu^{2+}$, $Fe^{2+}$) are deactivated by their reduction to the metals under the reaction conditions. The M—C bond in alkyl-MPc complexes, which can be formed as intermediates from $[MPc]^{\ominus}$ and alkylating agents, is likewise reductively cleaved by $NaBH_4$. Thus, an organo-MPc, such as 2-hydroxyethyl-$Co^{III}$Pc, can be used with the same effect as MPc for the catalysis of reduction.

| $I^{\ominus}$ | Co | 2 | 81 | 77 |
| $Cu^{2+}$ | Co | 2 | 81 | 93 |
| HO—$CH_2$—$CH_2$—$Co^{III}$Pc | | 2 | 81 | 85 |
| $CN^{\ominus}$ | Vitamin $B_{12b}$ | 2 | 34 | 10 |

The reduction of a nitro group with $NaBH_4$ can also be catalyzed by the structurally related vitamin $B_{12}$, but the reaction is slower and susceptible to catalyst poisoning (Tables 2 and 3). Moreover, vitamin $B_{12}$ is not so favorable as the metal-phthalocyanines regarding stability, insolubility in the "non-active state", and price. The easily accessible "cobaloximes"[5b,d] (vitamin $B_{12}$ models) are readily decomposable in the reduced form and tend to undergo side reactions at the ligand[8]. While many metal-macrocycles, *e.g.* the metal-porphyrins[9], can be relatively easily demetalated, the metal in stable MPc is almost irreplaceable even under drastic conditions (e.g. 5 N HCl/reflux; 5 N NaOH/reflux; conc. $H_2SO_4$)[1a]. The sensitivity of the porphyrins to light, which leads to their photooxidation[9], is not observed in the case of the light-fast dyes MPc. Because of their stability the MPc's are guaranteed a very long life even under "hard" conditions.

The stable MPc's are thus a successful combination of soluble $[MPc]^{\ominus}$ catalysts during the reduction and insoluble MPc-procatalyst under non-reducing conditions.

## *Procedure*

MPc[1] (0.5 g, *ca.* 0.9 mmol) is added under $N_2$ to a solution of $NaBH_4$ (2.7 g, 70 mmol) in EtOH (50 $cm^3$). The deep-colored solution (or suspension) is treated with 10 mmol $F^1$—A (Table 1) and the water-cooled mixture stirred at 20—25 °C under constant pressure (Tables 1 and 2). The ice-cold mixture is then neutralized with 5 N HCl (5—10 min until completion of the initially vigorous evolution of gas; pH 6—7) and the deep-blue precipitate separated by centrifugation (5 min; 3000 rpm) and washed three times with MeOH; the catalyst MPc remains behind. For re-use the catalyst is washed three times with water and dried between 20 and 200 °C. The combined centrifugates are evaporated down and the residue partitioned between water and $CH_2Cl_2$. In the case of aliphatic amines the residue is partitioned with 1 N NaOH/ether. Volatile amines are isolated from the ether phase as $F^2$—A·HCl. Concentration and drying of the organic phase affords the products $F^2$—A. These are purified by filtration of a solution in hexane/ether in the case of neutral substances, and by filtration of their aqueous solutions in hydrochloric acid in the case of amines.

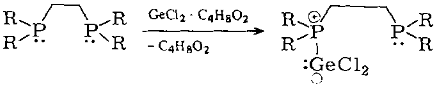
## *P,P,P′,P′*-Tetraphenylethylenediphosphane-dichlorogermanediyl: A Fluxional Phosphorus Ylide[**]

By *Wolf-Walther du Mont, Gero Rudolph,* and *Norbert Bruncks*[*]

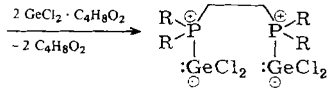
The kinetic lability of certain phosphorus ylides, phosphane chalcogenides and halogenophosphonium ions $R_3P—X$ ($X = GeCl_2$[1], $SnCl_2$[2], Te[3], $Br^+$, $I^+$[3a]) has recently been determined in the presence of non-coordinated $R_3P$. The transfer of six-electron species of heavy main group elements between phosphanes, which occurs rapidly on the $^1H$- and $^{31}P$-NMR time scales even at room temperature, can be satisfactorily described as a $P^{III}/P^{V}$ redox reaction or a "ligand exchange" process at $I^+$, $Te^0$, $Sn^{II}$ *etc.* Thus, *Scherer et al.* detected a fluxional redox system *via* transfer of tellurium in a diazadiphosphetidine derivative[3d], in which discrete $P^{III}$- and $P^{V}$-units are present in the crystal[4]. We now report the first fluxional ylide in which the "carbene analogous" dichlorogermanediyl derivative is mobile in solution at −80 °C.

*P,P,P′,P′*-tetraphenylethylenediphosphane *(1)* reacts with the $GeCl_2$-dioxane complex, depending on the stoichiometric ratio, to give the 1 : 1-complex *(2)* or the 1 : 2-complex *(3)*. Both dissolve as monomers in benzene and give $^{31}P$-$\{^1H\}$-NMR spectra consisting of *one* signal. While the $^{31}P$-singlet for *(3)* occurs at $\delta = -7$ and is consistent with a diylide structure, the considerable broadening of the $^{31}P$-NMR signal of *(2)* at $\delta = -10.2$ presents many structural possibilities. Since only one (sharp) signal appears at −80 °C in [$D_8$]toluene, apart from transfer of the ylide functionality between the phosphane groups as in *(2a)*, the chelate complex structures *(2b)* with tetragonal-pyramidal arrangement of ligands at $Ge^{II}$ or the (pseudo)-trigonal bipyramidal arrangement of ligands in *(2c)* might also be present in solution.



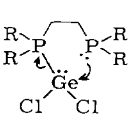
*(1)* *(2)*

*(1)*

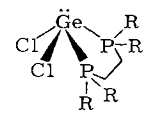


R = $C_6H_5$

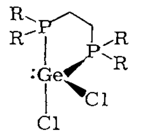
*(3)*



*(2a)*



*(2b)*



*(2c)*

In the case of *(2c)*, equilibration of the phosphane functionalities detected in the $^{31}P$-NMR spectrum implies that pseudorotation occurs at germanium. A linear Cl—Ge—Cl-arrangement is precluded on the basis of the IR-data. To clarify this problem, an X-ray structure analysis of *(2)* was therefore undertaken[5]. The data, show that the coordination sphere around the germanium in *(2c)* can be described as a distorted trigonal bipyramid, the Ge—P bond lengths are, however, very different ($Ge—P_{eq} = 251$ pm, as in $(C_6H_5)_3PGeCl_2$[6], $Ge—P_{ax} = 334$ pm, somewhat less than the van der Waals separation). Thus, the equilibration of the phosphorus atoms in solution can be satisfactorily explained by fluxion of the $\overset{\oplus}{P}—\overset{\ominus}{Ge}$-ylide *(2a)* as well as by pseudorotation of the chelate complex.

### *Procedure*

*(1)* (2.15 g, 5.4 mmol) is added to $GeCl_2$·dioxane (1.25 g, 5.4 mmol) in 30 $cm^3$ toluene. The solvent is evaporated off after 1 h, and the already pure *(2)* (2.9 g, 100%) recrystallized from toluene. Decomposition point ⩾250 °C, correct analytical data. IR (CsI/Nujol): $\nu = 270$ s, 305 vw, 335 s $cm^{-1}$ ($PGeCl_2$); $^1H$-NMR ($C_6D_6$): $\delta = 2.3$ (m); $^{31}P$-NMR ($C_6D_5CD_3$), 298 K: $\delta = -10.2$ (broad), 193 K: −10.8.

## [(−)-diop]RhCl—Catalyzed Asymmetric Addition of Bromotrichloromethane to Styrene

By *Shinji Murai, Ryoji Sugise,* and *Noboru Sonoda*[*]

Although a number of asymmetric reactions catalyzed by transition metal complexes to form C—H, C—C, C—Si, and C—O bonds with creation of chirality have been reported[1], no reactions of this type which lead to the formation of chiral carbon-halogen bonds have been reported[2] to the best of our knowledge. We describe here the first example of an asymmetric reaction, catalyzed by a chiral transition metal complex, in which the chiral center is formed as a result of carbon-bromine bond formation.

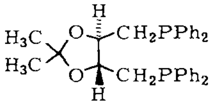
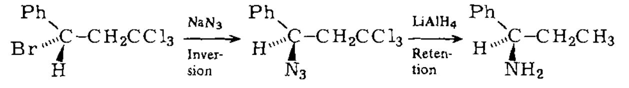
(S)-(−)-(1)



(−)-diop

The reaction of bromotrichloromethane with styrene in 2 : 1 ethanol-benzene, in the presence of an optically active phosphane-rhodium complex [(−)-diop]RhCl[3] (0.30 mmol) at 80 °C for 18 h, gave the 1 : 1-adduct *(1)* in 26% yield. The adduct *(1)* showed an optical rotation of $[\alpha]_D = -22.5$ ($c = 10.7$, $C_6H_6$) which corresponded to >32% enantiomeric excess and (*S*)-configuration.

The enantiomeric excess and the absolute configuration were determined in the following way using a sample of *(1)* with $[\alpha]_D = -11.3°$ ($c = 10.3$, $C_6H_6$) obtained in a separate run. This sample was treated with an excess of $NaN_3$ to give the azide *(2)*, which was not isolated but directly reduced with $LiAlH_4$ to (*R*)-(+)-1-phenyl-1-propylamine *(3)* which showed $[\alpha]_D = +3.43$ ($c = 8.4$, $C_6H_6$) and corresponded to an optical purity of 16%[4]. Thus, the adduct (*S*)-(−)-*(1)* with $[\alpha]_D = -22.5$ corresponds to >32% enantiomeric excess. It should be noted that the optical purity must be much higher than 32%, since $S_N2$ displacement of *(1)* with $NaN_3$ may involve partial racemization[5].



(S)-(−)-(1) (2) (R)-(+)-(3)

Since various transition metal catalysts for addition of organic halides to olefins are known[6] and a variety of chiral ligands are now available[1], the present result opens up new possibilities for asymmetric synthesis.

### *Experimental*

(*S*)-(−)-*(1)*: To a solution of styrene (9.36 g, 90 mmol) and $BrCCl_3$ (4.46 g, 22.5 mmol) in EtOH (30 $cm^3$) was added a solution of [(−)-diop]RhCl[3], prepared from $[RhCl(C_8H_{14})_2]$[7] (0.108 g, 0.30 mmol) and (−)-diop[3] (0.164 g, 0.33 mmol) in benzene (15 $cm^3$) under $N_2$. The mixture was heated under reflux for 18 h: the color of the mixture changed from green to dark brown after 30 min. Concentration and distillation gave (*S*)-(−)-*(1)* (1.78 g, 26% yield), b.p. 87–91 °C/0.6 torr[8].

Conversion *(1)*→*(3)*: A sample of *(1)* (8.51 g, 28.2 mmol) with $[\alpha]_D = -11.3$ ($c = 10.3$, $C_6H_6$), which was obtained in a separate run, was added to a solution of $NaN_3$ (4.29 g, 66 mmol) in 162 $cm^3$ of EtOH/$H_2O$ (4 : 1). The mixture was heated for 36 h at 50 °C, cooled, and treated with $H_2O$ (75 $cm^3$), $n$$Bu_2O$ (100 $cm^3$), and 40% aqueous $CaCl_2$ solution (125 $cm^3$) to separate the organic layer. The aqueous layer was extracted with $n$$Bu_2O$ (3 × 50 $cm^3$). After drying over $MgSO_4$, the combined $n$$Bu_2O$ solution containing the azide *(2)* was added dropwise to a suspension of $LiAlH_4$ (16 g, 420 mmol) in $n$$Bu_2O$ at 15 °C. The mixture was heated for 15 h at 100 °C, cooled, and made acidic with 4 N HCl. The aqueous layer was washed with $Et_2O$ (2 × 40 $cm^3$), made alkaline with conc. aqueous KOH, heated to 100 °C to dissolve the inorganic salts and after cooling extracted with $Et_2O$ (4 × 100 $cm^3$). The ethereal solution was dried over $MgSO_4$ and distilled [0.897 g, crude product (25%), b.p. ≈100° (bath temp.)/10 torr]. Redistillation afforded chemically pure (*R*)-(+)-*(3)* having $[\alpha]_D = +3.43$ ($c = 8.4$, $C_6H_6$) corresponding to 16% enantiomeric excess[4].

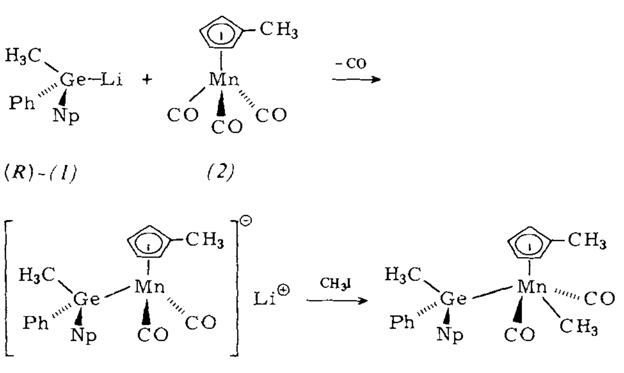
## Introduction of an Optically Active Ligand into Transition Metal Complexes with Five Independent Ligands

By *Ernesto Colomer, Robert J. P. Corriu*, and *André Vioux*[*]

Recently, we reported the introduction of an optically active triorganogermyl ligand at a transition metal site, by displacement of a CO-ligand[1]. This reaction allowed us to synthesize the optically active anion *(3)*, which was isolated as the tetraethylammonium salt *(3b)* (Table 1), from the (*R*)-enantioner of the germyllithium compound *(1)* and the tricarbonylmanganese complex *(2)*. It is assumed that the reaction proceeds with retention of configuration at germanium, since optically active germyllithium compounds are known to react with retention of configuration in substitution reactions[2]. The anion *(3)* reacts with methyl iodide affording the neutral complex *(4)*, whose crystal



(R)-(1) (2)

(S)-(3) (4)

Np = 1-Naphthyl

structure has not yet been determined. It is well known, however, that complexes with five ligands, one of which is a cyclopentadienyl moiety, have a square pyramidal geometry with the cyclopentadienyl moiety occupying the apical position[3]; from the IR spectrum, only the *diag-* (or *trans*) isomer—both CO-ligands are arranged *diagonally*[10a]—was obtained[4] (Table 1).

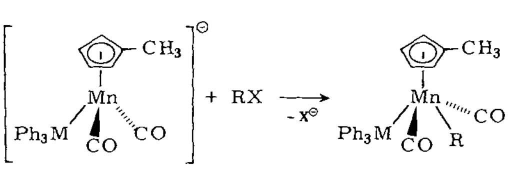
[f] (*S*)-isomer ($[\alpha]_D^{25} = +7.2$ ($C_6H_6$), +18.7 ($CH_2Cl_2$)). [g] In $C_6D_6$. [h] $C_5H_4$, two multiplets at $\delta = 3.63$ and 3.87. $C_5H_4CH_3$ and $GeCH_3$, $\delta = 1.33$. [i] $C_5H_4$, two multiplets at $\delta = 3.8$ and 4.1; $C_5H_4CH_3$, $\delta \approx 1.3$.

The triphenylgermanyl and triphenylsilyl substituted anions, *(5a)*[5] and *(5b)* respectively, were analogously alkylated with methyl iodide and benzyl bromide to the dicarbonylmanganese complexes *(6)*. The $^1$H-NMR spectrum only showed signals corresponding to the *diag*-isomer: the benzyl derivatives show a single sharp signal for the $CH_2$-group, *i.e.* the two protons—as expected for the *diag*-isomer—are magnetically equivalent (Table 1).

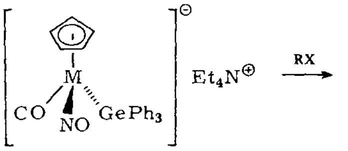


*(5a)*, M = Si
*(5b)*, M = Ge
RX = $CH_3I$, $C_6H_5CH_2Br$

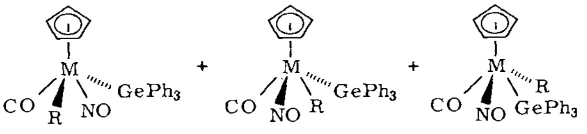
*(6a)*, M = Si, R = $CH_3$
*(6b)*, M = Si, R = $CH_2C_6H_5$
*(6c)*, M = Ge, R = $CH_3$
*(6d)*, M = Ge, R = $CH_2C_6H_5$

The alkylation of the anionic molybdenum and tungsten complexes *(7)* or *(8)*[6], respectively, can lead to the formation of three enantiomeric pairs[7]. Reaction of *(7)* with methyl iodide produced the three enantiomeric pairs *(9a)*–*(9c)* in yields of 66, 14 and 19%, respectively (determined by $^1$H-NMR spectroscopy); the pure isomer *(9a)* could be obtained in 58% yield by fractional crystallization (Table 1). Its structure was established by IR spectroscopy (Table 1). Isomers *(9b)* and *(9c)* were not isolated ($^1$H-NMR: $\delta = 4.80$ and 0.27 or 4.47 and 0.37 respectively; IR: $\nu_{CO} = 1925$ and $\nu_{NO} = 1645$ cm$^{-1}$).

In the benzyl derivative *(10a)* the $-CH_2$-protons are non-equivalent ($J = 10$ Hz) since there is a chiral center at molybdenum[8].



*(7)*, M = Mo
*(8)*, M = W
RX = $CH_3I$, $C_6H_5CH_2Br$



*(9a)* *(10a)* *(11a)*; *(9b)* *(10b)* *(11b)*; *(9c)* *(10c)* *(11c)*

*(9)*, M = Mo, R = $CH_3$; *(10)*, M = Mo, R = $C_6H_5CH_2$;
*(11)*, M = W, R = $CH_3$

These type of complexes are surprizingly—as the $^1$H-NMR spectra (in [D$_6$]dimethyl sulfoxide) show—stable up to 100 °C and no isomerization occurs (the compounds decompose first above 120 °C, but without isomerization)[9]. Complexes with five independent and different ligands are, at present, the subject of much interest[10], since they offer the possibility of synthesizing novel, stable, optically active transition metal compounds.

*Experimental*

All reactions are carried out under an $N_2$-atmosphere. In a typical experiment 326 mg (0.5 mmol) of *(7)* in 15 cm$^3$ tetrahydrofuran is treated with an excess of $CH_3I$ at room temperature. The initial brown solution becomes yellow and a precipitate of $Et_4NI$ is formed. After 15 min, the solvent is removed, the residue treated with toluene and filtered. The solution is concentrated to *ca.* 10 cm$^3$, 10 cm$^3$ hexane added and the mixture left at −20 °C. Yellow crystals of *(9a)* are obtained (157 mg, yield 58%).

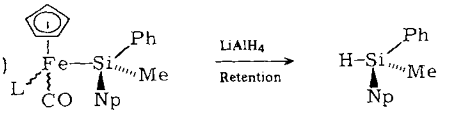
# Cleavage of Silicon- and Germanium-Cobalt Bonds: Change of Stereochemistry with Different Ligands

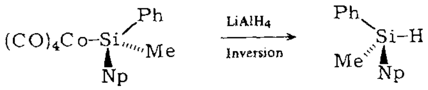
By *Geneviève Cerveau*, *Ernesto Colomer*, and *Robert J. P. Corriu*[*]

The stereochemical course of nucleophilic cleavage of Fe—Si and Co—Si bonds[1] is in good accord with the general rules for nucleophilic displacement at silicon[2]. ($\eta^5$-$C_5H_5$)(CO)LFe, a good nucleophile, is however a weakly polarizable leaving group (retention of configuration upon substitution) and $(CO)_4Co$, a poor nucleophile, a highly polarizable leaving group (inversion of configuration upon substitution)[3].



(S) (R)-(2a)

L = CO, $PPh_3$, $P(OEt)_3$; Np = 1-Naphthyl



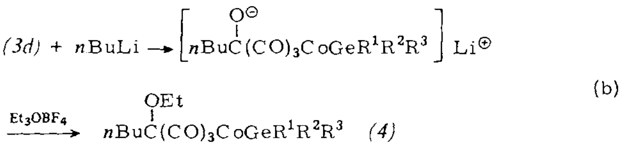
(S)-(3a) (S)-(2a)

In order to better understand the nature of Co—Si- and Co—Ge bonds, we have studied changes in the stereochemistry of the nucleophilic cleavage at silicon or germanium as a function of the electronic nature of the transition metal.

Thus, the cobalt complexes *(3a)*—*(3f)* and *(4)* (Table 1) were synthesized, under $N_2$, from the dicobalt complexes *(1)* (L = CO, $P(OPh)_3$, $PPh_3$) and the substituted silanes *(2a)* and germanes *(2b)*, respectively ($R^1$ = Me, $R^2$ = Ph, $R^3$ = 1-naphthyl [eq. (a) and (b)][4].

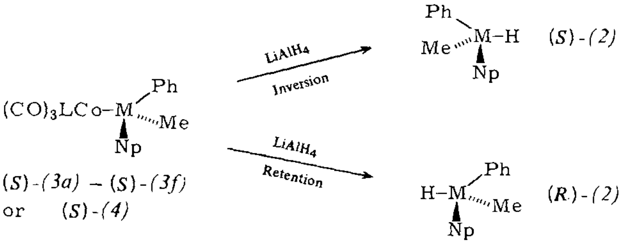
$$[(CO)_3LCo]_2 + 2R^1R^2R^3MH \longrightarrow 2\ (CO)_3LCoMR^1R^2R^3 + H_2 \quad (a)$$

*(1)* *(2a)*, M = Si *(3)*
*(2b)*, M = Ge



$$(3d) + n\text{BuLi} \longrightarrow \left[n\text{Bu}\overset{O^{\ominus}}{\overset{|}{C}}(CO)_3CoGeR^1R^2R^3\right]Li^{\oplus} \xrightarrow{Et_3OBF_4} n\text{Bu}\overset{OEt}{\overset{|}{C}}(CO)_3CoGeR^1R^2R^3 \quad (4) \qquad (b)$$

The stereochemical course of cleavage reactions with $LiAlH_4$[1b] are quite similar for silyl- and germyl-cobalt complexes and vary, depending on the ligands at cobalt, from a high degree of inversion of configuration with *(3a)* and *(3b)* or *(3d)* and *(3e)* respectively, to poor retention with *(4)* (Table 1).



(S)-(3a) – (S)-(3f) or (S)-(4) (S)-(2) (R)-(2)

The absolute configurations of the silanes[5a] and the germanes[5b], as well as that of the two tetracarbonyl complexes *(3a)* and *(3d)*[5c], were determined by X-ray structure analysis: this enabled the stereochemistry and stereoselectivity of the $LiAlH_4$-cleavage reactions to be determined unequivocally[6]. The exchange of one CO-ligand, a good π-acceptor, in the $(CO)_4Co$-residue by a good donor increases the electron density at cobalt[7] and hence reduces the nucleofugicity of the substituents. The nucleophilic cleavage of the complexes $(CO)_3LCoMR^1R^2R^3$ occurs with considerable inversion when L = CO; the degree of inversion decreases in the compounds with L = $P(OPh)_3$ and $PPh_3$. The reaction of the carbene complex *(4)*, L = C(OEt)*n*Bu, proceeds with slight retention of configuration. The σ-donor character of the ligands increases along the series (CO < $P(OPH)_3$ < $PPh_3$ < (COEt)*n*Bu). This result is in accord with the leaving group rules found in silicon chemistry[3b].

That this is only a crude analysis of the results—based on the assumption that the metal-silicon and halogen-silicon bonds are similar—is shown by the nucleophilic cleavage of $(CO)_4(NO)WGeR^1R^2R^3$[8]. In this case, a high degree of inversion of the configuration is anticipated, since the tungsten center is surrounded by five good π-acceptor ligands (NO is a better π-acceptor than CO[9]); however, a 67% retention of configuration is observed.

This inference shows that the situation is certainly more complex than can be achieved *via* a simple comparison of the properties of the Si—(or Ge)—X- and Si—(or Ge—)Co bonds. Indeed, the Ge—Co- and Ge—W-bonds are hardly comparable, since Co belongs to the first and W to the third third transition metal series.

Table 1. Some physical data and results of the stereochemical course of the reductive cleavage of complexes *(3a)*—*(3f)* and *(4)*. All novel compounds gave correct elemental analyses.

| Complex | L | M | M.p. [°C] [a] | IR $\nu_{CO}$ [cm$^{-1}$] (CHCl$_3$) [b] | $^1$H-NMR $\delta_{CH_3}$ (in $C_6D_6$/TMS) | $[\alpha]_D^{25}$ ($C_6H_6$) | Stereo-chemistry [%] [c] | $[\alpha]_D^{25}$ of $R^1R^2R^3MH$ (Pentane) [d] |
|---|---|---|---|---|---|---|---|---|

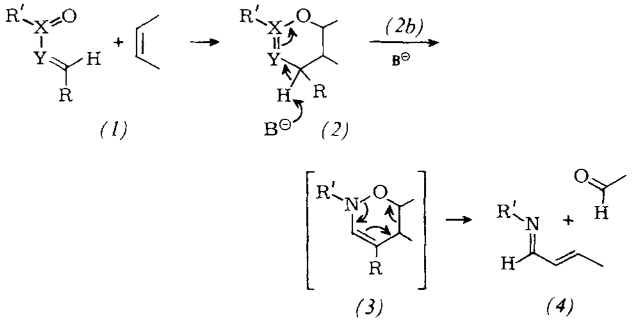
# "Isolated" Olefinic Double Bonds as 2π-Components in [8 + 2]-Cycloadditions

By *Martin Riediker* and *Walter Graf*[*]

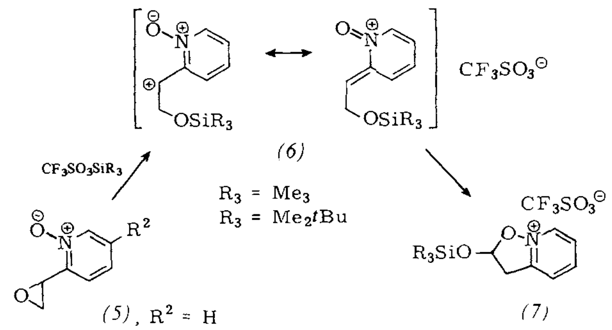
In the classical Diels-Alder reaction (D.-A. reaction with *normal* electron demand) non-activated isolated double bonds scarcely react with dienes. On the other hand, charged heterodienes such as *(1)* display excellent reactivity towards isolated olefinic double bonds even at room temperature[1-3] (D.-A. reactions with *inverse* electron demand) [cf. *(1)*→*(2)*].



*(a)*, X = C, $\overset{\oplus}{=N}$, R = H
*(b)*, $X = N^{\oplus}$, Y = CH, R = H or Alkyl
*(c)*, $X = N^{\oplus}$, Y = CH, $R = CH_2OSiR'_3$

1,2-Oxazinium salts *(2b)*[2a] enabled, *inter alia*, the cycloreversion *(3)*→*(4)*, initiated by proton abstraction *(2)*→*(3)*, to be carried out[2b].

We demonstrate here that the [8 + 2]-cycloaddition-cycloreversion sequence [cf. *(12)*→*(13)*→*(15)*] with heterocyclic *N*-oxides is a useful, and, in our opinion, potentially versatile synthetic reaction.



In the reaction of 2-oxiranylpyridine *N*-oxide *(5)* with $CF_3SO_3SiR_3$ ($R_3 = Me_3$ or $Me_2tBu$), only *(7)*, the product of a 1,2 H-shift in *(6)*, could be isolated (cf. [3]; see Table 1).

Table 1. Some physical data of the products. $^1$H-NMR in $CDCl_3$, except in the case of *(7)*, R = Me ($CD_2Cl_2$) and *(10)* ($D_2O$); δ-values, *J* in Hz; MS: *m/z*.

*(7)*, R = Me, *$^1$H-NMR: 0.18 (s, 9 H), 3.68 (d × d, J = 18, J' = 1, 1 H)*, 4.22 (d × d, *J* = 18, *J'* = 5, 1 H), 6.52 (d × d, *J* = 5, *J'* = 1, 1 H), 7.85—8.50 (m, 3 H), 8.85 (m, 1 H)

*(10)*, $^1$H-NMR: 3.08 (s, 6 H), 3.36 (s, 6 H), 6.31 (d, $J_{AB}$ = 13, 2 H), 6.66 (d, $J_{AB}$ = 13, 2 H), 8.41 (s, 4 H). On warming, a rapid change of conformation of the eight-membered ring occurs; thereby, the AB system of the methylene groups simplifies to a singlet.

*(13a)*, R = H, $^1$H-NMR: 1.00—2.50 (m, 9 H), 4.50 (d, *J* = 3, 1 H), 4.94 (m, $w_{y2}$ = 9, 1 H), 7.00—8.20 (m, 8 H), 8.73 (d × d, *J* = 6, *J'* = 1, 1 H)

*(13b)*, R = H, $^1$H-NMR: 1.43 (t, *J* = 7, 3 H), 1.25—2.50 (m, 9 H), 2.99 (d × d, $J_{AB}$ = 18, *J* = 1.6, 1 H), 3.60 (d × d, $J_{AB}$ = 18, *J* = 7, 1 H), 4.20 (q, *J* = 7, 2 H), 4.90 (m, $w_{y2}$ = 7, 1 H), 7.74 (singletoid m, 2 H), 8.90 (singletoid m, 1 H)

*(15a)*, R = H, $^1$H-NMR, *E/Z*-mixture: 1.20—1.80 (m, 4 H), 1.90—2.45 (m, 4 H), 6.75—7.80 (m, 8 H), 8.57 (m, 1 H), 9.69 (m, 1 H). Additionally for *Z*: 6.12 (t, *J* = 7, *ca.* 0.5 H), for *E*: 6.88 (t, *J* = 7, *ca.* 0.5 H); MS: 265 ($M^+$, 29%), 208 (100)

*(15a)*, R = Me, $^1$H-NMR, *E/Z*-mixture: 1.20—1.90 (m, 4 H), 2.08 (s, 3 H), 1.90—2.45 (m, 4 H), 6.95—8.00 (m, 8 H), 8.58 (m, 1 H). Additionally, for *Z*: 6.10 (t, *J* = 7, 0.6 H), for *E*: 6.84 (t, *J* = 7.5, 0.4 H); MS: 279 ($M^+$, 41%), 208 (100)

*(15b)*, R = H, $^1$H-NMR, *E/Z*-mixture (*1 : 1*): 1.20—1.80 (m, 4 H), 1.40 (t, *J* = 8, 3 H), 2.00—2.80 (m, 4 H), 4.05 (q, *J* = 8, 2 H), 7.10 (m, 2 H), 8.24 (m, 1 H), 9.72 (m, 1 H). Additionally, for *E*: 6.38 (d, *J* = 14, 1 H), 6.60 (d × t, *J* = 14, *J'* = 5, 1 H), for *Z*: 5.64 (d × t, *J* = 12, *J'* = 7, 1 H), 6.38 (d, *J* = 12, 1 H); MS: 233 ($M^+$, 28%), 176 (100)

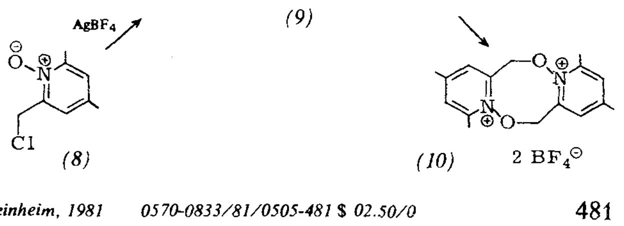
*(16a)*, R = Me, $^1$H-NMR: 1.40—2.20 (m, 8 H), superposed by 1.63 (s, 3 H), 5.98 (s, 1 H), 6.90—7.50 (m, 8 H), 8.23 (d × d, *J* = 3, *J'* = 4, 1 H); MS: 279 ($M^+$, 71%), *168 (100)*

*(17)*, $^1$H-NMR: 1.39 (t, *J* = 7, 3 H), 3.74 (s, 6 H), 3.99 (q, *J* = 7, 2 H), 4.14 (s, 2 H), 6.78 (singletoid m, 5 H), 7.99 (singletoid m, 1 H); MS: 289 ($M^+$, 24%), 272 (100)

*(18)*, $^1$H-NMR: 1.20—2.50 (m, 8 H), superposed by 1.43 (t, *J* = 7, 3 H), 4.08 (q, *J* = 7, 2 H), 4.33 (br. s, 2 H), 5.75 (br. t, *J* = 7, 1 H), 7.10 (singletoid m, 2 H), 8.20 (m, 1 H), 9.70 (m, 1 H)

The (chloromethyl)pyridine *N*-oxide derivative *(8)*, which cannot undergo such an H-shift, reacts with $AgBF_4$ to give the intermediary reactive product *(9)*, which dimerizes to *a salt of the dication (10)* (see Table 1).

The hypothetical intermediates *(6)* and *(9)* do not react with cyclohexene. However, the lifetime of the reactive in-



---

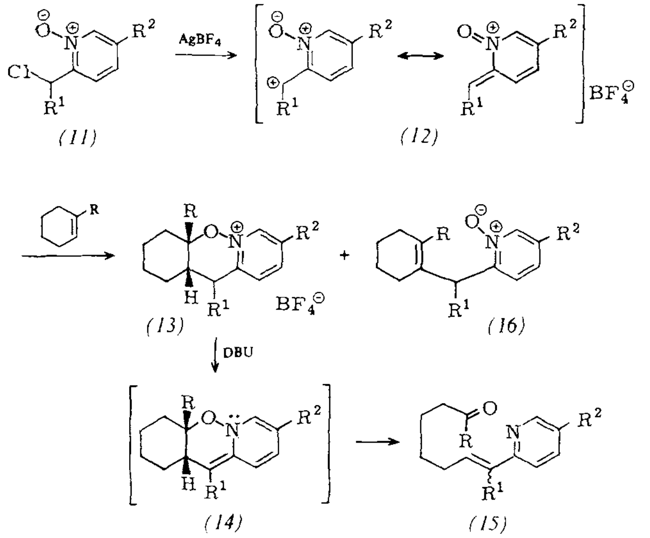
[*] Dr. W. Graf [**], Dipl.-Chem. M. Riediker
Laboratorium für Organische Chemie
der Eidgenössischen Technischen Hochschule
CH-8092 Zürich (Switzerland)

[**] Present address:
Fluka AG
CH-9470 Buchs/SG (Switzerland)

termediate can be prolonged by additional resonance stabilization of the positive charge of this tetraene so that a cycloaddition becomes possible. Thus, 2-(α-chlorobenzyl)pyridine *N*-oxide reacts in dichloromethane with $AgBF_4$ and cyclohexene in about 50% yield (Table 1 and 2), even at 0 °C, to give the cycloadduct *(13a)*, which was only observed by NMR spectroscopy.

Addition of 1.05 equiv. of diazabicyclo[5.4.0]undecene (DBU) led, after a brief red coloration (probably caused by *(14a)*, R = H) to formation of the cycloreversion product *(15a)*, R = H, as *E/Z* mixture (Table 1 and 2).

1-Methyl-1-cyclohexene reacts analogously with *(12a)*. As expected, on treatment with DBU we obtained, aside from the cycloreversion product *(15a)*, R = Me (*E/Z* mixture), principally the isomeric double-bond substitution products such as *(16a)*, R = Me.

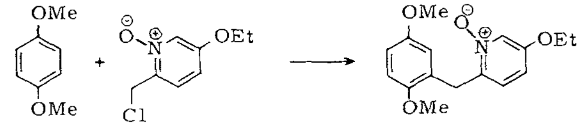


*(a)*, $R^1$ = Ph, $R^2$ = H; *(b)*, $R^1$ = H, $R^2$ = OEt

The 2-(chloromethyl)-5-ethoxypyridine *N*-oxide *(11b)* reacts with cyclohexene analogously (Table 1 and 2). A separable mixture of the substitution products *(16b)*, R = H, and the double-bond isomer with 2′-cyclohexenyl ring is obtained in *ca.* 10–20% yield.

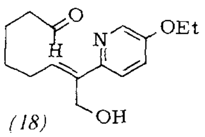
1-Methyl-1-cyclohexene, a 1,1,2-trisubstituted olefin, reacts to only a small extent with cycloaddition to give *(15b)*, R = Me; the greater part forms substitution products such as *(16b)*, R = Me, and its double-bond isomer (cf. Table 2).

In the reaction of *(11b)* with hydroquinone-dimethyl ether (1 : 1) the aromatic substitution product *(17)* is obtained in 54% yield.

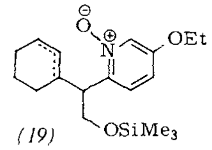


*(11b)* *(17)*

By substitution of the heteroarene ring of the reagent with a mesomeric donor, the desired cycloaddition of oxiranyl *N*-oxides such as *(5)* to isolated double bonds was also possible. Thus, *(5)*, $R^2$ = OEt, reacts with $CF_3SO_3SiMe_2tBu$ or $CF_3SO_3SiMe_3$ in $CH_2Cl_2$ in the presence of cyclohexene to give the (not isolated) cycloadduct *(13)*, R = H, $R^1 = CH_2OSiR_3$, $R^2$ = OEt, $CF_3SO_3^-$ instead of $BF_4^-$, which undergoes cycloreversion with DBU to give the compound *(18)* (Tables 1 and 2). This novel cycloaddition reaction[4] extends the palette of reactions with isolated olefinic double bonds.



*(18)*



*(19)*

### General Procedure

Cycloaddition of *(11)* to olefins: $AgBF_4$ (195 mg, 1.0 mmol) was added under Ar at room temperature to a solution of the olefin (0.5–1 mL, 5–10 mmol; distilled over Na) in dichloroethane or dichloromethane (filtered

[a] If not otherwise stated, at room temperature. [b] Total yield of the isomeric olefins. [c] Yield referred to *N*-oxide. [d] Yield referred to olefin. [e] The cycloadduct was converted *in situ*. [f] Mixture of *(16b)*, R = H, and double-bond isomer [see *(19)*]. [g] *(18)* is extremely unstable on chromatographic carrier material. [h] According to method A, cf. [3]. [i] According to method B, cf. [3]. [j] *(5)*, $R^2$ = OEt, mainly reacts with intramolecular H-shift [cf. *(7)*].

through basic Alox I). The mixture was then treated dropwise within 3 h with a solution of *(11)* (1 mmol) in 8 mL of the relevant aforementioned solvent. After filtration through celite the solution was treated with DBU (175 μL, 1.05 mmol) and then, after a further 30 min, the resulting mixture was poured into water and extracted with $CH_2Cl_2$. After separation of the aqueous phase the reaction solution was washed twice with water and once with saturated NaCl solution. The organic phase, after drying over magnesium sulfate and careful removal of solvent, gave a yellow oil, which was rapidly chromatographed on *ca.* 15 g MN-silica gel with $CH_2Cl_2/CH_3OH$ (25 : 1).

Cycloaddition of *(5)*, $R^2 = OEt$, to olefins: $CF_3SO_3SiMe_3$ (310 μL, 1.72 mmol) was added to a solution of cyclohexene (760 μL, 7.50 mmol; distilled over Na) in dichloroethane or dichloromethane. A solution of *(5)*, $R^2 = OEt$, (270 mg, 1.50 mmol) in 8 mL of one of the previously mentioned solvents was then added to the reaction mixture dropwise within 3 h. After a total of 4 h the solution was treated with DBU (260 μL, 1.75 mmol). After a further 30 min the mixture was poured into water and worked up as mentioned above. For separation, the yellow oil was rapidly chromatographed on *ca.* 40 g MN-silica gel with $CH_2/CH_3OH$, whereupon substantial amounts of *(18)* decomposed.

# $Mo^{IV}$ in Aqueous Solutions: The Trinuclear Cluster $[Mo^{IV}O_4F_9]^{5-}$, the First Species Isolated from Mineral Acid Solution[1]

By *Achim Müller, Andreas Ruck, Mechthild Dartmann,* and *Uta Reinsch-Vogell*[*]

Until 1973 it was assumed that acidic aqueous solutions containing $Mo^{IV}$ were not stable[2] ("The only well-known $Mo^{IV}$ species in aqueous solution is $[Mo(CN)_8]^{4-}$"[2a]). Following investigations carried out by *Souchay* (which had been overlooked until 1973; cf. [2b]) and by *Ardon* and *Pernick*[2b,4], it has now been clearly proven that $Mo^{IV}$ is stable in mineral acid solutions (the characteristic red color is caused by the absorption band: $\lambda$ *ca.* 505 nm; $\varepsilon/Mo \approx 60$ $dm^3\ mol^{-1}\ cm^{-1}$). From the results of numerous measurements using a variety of different methods, it was concluded that mono- or di-nuclear complexes are present[2-5]. It had, however, already been suggested in a review article[6] that some results were more indicative of trinuclear clusters.

A solution of $Mo^{IV}$ in aqueous HF was prepared by a normal cation exchange procedure[4]. Addition of excess $NH_4F$ allowed the isolation of deep red, in transmitted light red, crystalline needles of

$(NH_4)_5[Mo_3O_4F_9] \cdot NH_4F \cdot H_2O$ *(1)*

which was characterized by elemental analysis, IR- and VIS-spectra (characteristic band in the solid state reflection spectrum at $\lambda = 525$ nm) and by an X-ray crystal structure analysis[7]. In this way, the first successful isolation of a crystalline substance from a mineral acid solution of $Mo^{IV}$ without addition of a complexing agent was achieved. The structure of the anion corresponds to the $B_1$-type of trinuclear electron-poor transition metal clusters[6], in which the metal atoms (Mo—Mo = 2.505 Å) are surrounded by a distorted octahedron of oxygen and fluorine (Mo—F = 2.034 Å) and the central $\{Mo(\mu_3\text{-}O)(\mu_2\text{-}O)_3\}$-moiety $[Mo\text{-}(\mu_3\text{-}O) = 2.032,\ Mo\text{-}(\mu_2\text{-}O) = 1.920\ Å]$ can be considered as a distorted, incomplete cube (average bond lengths in brackets). *(1)* is isostructural with the corresponding W-compound, which notably was obtained from an aqueous solution of $W^V$ by addition of HF[8] (for an interpretation cf. [6]).

The electronic spectrum of the aqueous HF solution of *(1)* also shows the VIS-band observed in the solid state spectrum. The splitting of this band (doublet: A at ≈518, B at ≈535 nm), as well as the time-dependence of the relative intensities of A and B (following dissolution) and their dependence on the concentration of acid, indicates that several species of the type $[Mo_3O_4F_{9-x}(H_2O)_x]^{(5-x)-}$ *(2)* are probably present. The $F \rightarrow H_2O$ ligand exchange process cannot be identified significantly by a change of color, but only by a slight change in the electronic spectrum (increase in the intensity of A relative to B). These results, regarding the probable presence of $Mo^{IV}$ species with a central $Mo_3O_4$ cluster unit in mineral acid solutions, are clearly contrary to all previous results (Fig. 1). This also corresponds to our most recent understanding of $Mo^{IV}$, which shows a strong tendency to form trinuclear clusters (in accord with the $d^2$-configuration) in solutions containing no strong π-acceptor ligands[6]. We have assigned the observed VIS-bands A and B, following an EHMO calculation, to transitions in the $Mo_3$-cluster system (cf. also [6]).

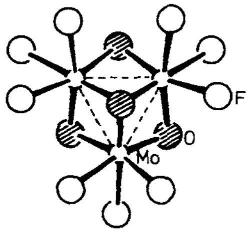

Fig. 1. Molecular structure of $[Mo_3O_4F_9]^{5-}$ in crystals of *(1)*.

## *Procedure*

A solution of $Mo^{IV}$, (from $[MoCl_6]^{3-}$ and $[MoOCl_5]^{2-}$) prepared after[4], is adsorbed on a cation exchange column (Dowex 50 WX 2) and purified with 0.5 and 1 M *p*-toluenesulfonic acid ($O_2$-free) after[4]. The exchanger is eluted with 10 $cm^3$ of a 40% aqueous solution of HF and *ca.* 20 $cm^3$ $H_2O$. $NH_4F$ (2 g) is added to the first 10 $cm^3$ of the red eluate. Dark red crystals of *(1)* precipitate (in certain cases only after slight concentration of the solution by passing nitrogen over it). Yield *ca.* 80%, relative to the Mo-content of the solution.

## BOOK REVIEWS

**Comprehensive Biochemistry.** Edited by *M. Florkin* (deceased), *A. Neuberger* and *L. L. M. van Deenen*. Vol. 19, Part B 1: Protein Metabolism. Elsevier Publishing Company, Amsterdam 1980. xx, 528 pages, 64 figs., bound, Dfl. 168.00.

This volume of "Comprehensive Biochemistry"[*] begins with a disarming declaration: "The Editors were faced with alternative possibilities: one either tried to deal with the major topic in a *comprehensive* manner, but this would have meant almost unavoidably a degree of superficiality which was unacceptable...". They therefore decided to give progress reports on somewhat randomly chosen but particularly topical areas of protein metabolism.

In their chapter, *V. M. Pain* and *M. J. Clemens* manage to summarize the present knowledge of the many components that take part in the protein synthesis machinery of the eukaryotic cell, to describe the mechanisms of their interactions, and to give the most important aspects of the regulation of translation. With the inclusion of more than 500 references up to 1979 and building-on on a corresponding chapter in Volume 24 (1977), this has obviously succeeded well. Just how long this information will remain new in the rapidly evolving field is a question that occurs time and again when using the whole work, which is evidently considered to be a long-term investment.

The sections by *P. J. Garlick* and *D. J. Millward* are devoted to the turnover of plasma proteins and enzymes in the flowing equilibrium of continuous synthesis and degradation in various tissues and in the whole organism. The first of these authors concentrated more on the regulation of the rates of these reactions *in vivo* and on the contribution this makes to the total nitrogen balance of an animal, the second on the various courses of degradation in the muscles and liver. In these painstaking and well coordinated articles, too, more than 500 publications have been worked into a clearly arranged and readable general presentation.

Protein metabolism and protein structure are closely entwined subjects. *A. J. Bailey* and *D. J. Etherington* were evidently of the opinion that our knowledge of general structural chemistry and of the metabolism of collagen and elastin has now reached such a state that it deserved a really detailed presentation, and convinced the sympathetic editors to allocate to them almost one-third of the book for a thorough review. In spite of dealing with more than 800 references, they still regard this review as not exhaustive. The main emphasis is placed on connective tissue biosynthesis during growth and on the mechanisms of degradation, thus providing more than just a basis for this research field equally important to medicine and the food industry.

*K. B. M. Reid* offers a stimulating and understandable résumé to the complement system, a proteolytic cascade system of a special kind. This complex defensive mechanism of higher organisms has many molecular special features, so that this chapter, too, will only be a snapshot from the year 1979.

With its extensive literature reviews and sensible presentation by the authors, who mostly come from the close circle of one of the editors, this topical book will undoubtedly prove a useful new publication for users in the fields of chemistry, biochemistry, pharmacology, and medicine. This major volume supplements a field always deliberately neglected in the main work, which has thus perhaps not always become "more comprehensible" but certainly "more comprehensive", in spite of the editors' reservations.

*L. Jaenicke* [NB 540 IE]

**Statistical Mechanics of the Liquid Surface.** By *C. A. Croxton*. John Wiley and Sons, Chichester 1980. xi, 345 pages, bound, £ 25.00.

Our understanding of the equilibrium properties of atomic fluids has increased so much in recent years with the help of statistical mechanics that a transition to complex systems appears to be realistic. The particular questions here are whether the principles of statistical mechanics can also be applied to the inhomogeneous region of the liquid-gas interface, and if the familiar thermodynamic concepts such as pressure, density, and chemical potential can be extended to the phase interface. Since many properties of the liquid surface are excess-quantities, which record the change in the liquid's properties on transition to the surface, and consequently require knowledge of the properties of the liquid, a statistical-mechanical description is difficult. Two quantities characterize the liquid-gaseous region: the density profile, which describes the change in density perpendicularly to the liquid surface, going from the density of the liquid to the density of its vapor, and the anisotropic pair distribution function, which gives the probability of finding a second particle at a defi-

---

[*] Cf. Angew. Chem. Int. Ed. Engl. *17*, 873 (1978).

nite distance from a selected reference particle. In contrast to the liquid—and this is decisive—this pair distribution function is still dependent on the distance of the selected particle from the liquid surface.

In the present work, the author—who has already written several books on the theory of the liquid state—gives the first résumé of the statistical-mechanical theories of the liquid surface. The relationships between the thermodynamic parameters of the liquid surface, among them surface tension, and the density profile and the anisotropic pair distribution function are shown very clearly in the first chapter. Since these functions are necessary for the determination of thermodynamic quantities, the second chapter—occupying almost one-fifth of the book—is devoted to the calculation of the density profile and the anisotropic pair distribution function for spherically-symmetric particles. On the one hand, a quasi-thermodynamic approximation is used, which means that in the transition zone between the liquid and the vapor the chemical potential and pressure must be constant to ensure thermodynamic and mechanical stability of the liquid surface. On the other hand, well-known integral equations from liquid-state theory, *e.g.* the Born-Green-Yvon equation, are used. The presentation is in places very compact and presupposes that the reader is well aquainted with the theories of the liquid state, *e.g.* with perturbation theory and the associated mathematical formalism, so that original literature may have to be consulted. However, this is facilitated by the wealth of literature citations.

The technique described in this chapter is then extended to liquid surfaces of nonspherical systems. In systems of this kind, the density profile is additionally dependent on the orientation of the molecules relative to the phase interface, and the resulting expressions are correspondingly complicated. With the aid of the perturbation theory, in which anisotropic interaction is interpreted as a perturbation of spherical interaction, relationships are derived for the surface tension, free energy, *etc.*; owing to the complexity of the expressions, the author cannot reproduce each calculation step and must refer to the original literature. The effects of dipole and quadrupole interactions on the density profile are discussed. In two-component systems the way in which the surface tension and the density profile depend on the composition of the mixture poses a new problem. In an infinitely sharp surface the component with the lower surface tension accumulates at the interface. In reality, according to theory, this anomaly is determined by the mean density of the liquid at the surface, also called surface adsorption, the density profile and the interaction between the particles. The way in which such density profiles can be calculated for linear molecules is also discussed in detail in Chapter 4.

Following the general theoretical part, the second part of the book is devoted to specific systems, and firstly to the surfaces of liquid metals which are formally two-component systems of mobile cations and conducting electrons. For the simplest model the density profiles of the cations and electrons are calculated, from these the surface tension and surface energy and their temperature variations, and thus the essential characteristics of the liquid metal surfaces. Detailed refinements of the models are then discussed. A chapter is added on the surface of quantum liquids, whose experimentally determined surface tension can be interpreted with quantized capillary waves known as "ripplones" or "surfones". A formal quantum-mechanical description shows that the surface tension is the excess quantity of an impulse current. The characteristic feature for water—Chapter 7—is the appearance of surface polarization. This polarization, as well as the surface tension, is calculated in detail. The result shows that the water molecules on the liquid surface are arranged with the protons facing outward.

The statistical-mechanical treatment of the conformational change of a polymeric on transition from bulk liquid to the surface is still far from being fully developed. The suppression of one degree of freedom at the phase interface implies a greater spread of the molecule on the surface. The effect of polymers on surface tension is shown within the framework of the Prigogine-Marechal theory, and the distribution of the polymer segments on the surface is deduced. The book then turns to liquid crystals. After a brief survey of the theory the excess quantity of free energy and the corresponding surface tension are calculated for perpendicular and parallel orientations of the molecules.

As practically no experimental work has been done on the determination of the density profile, computer simulation has a special relevance as a test for statistical-mechanical theories. Accordingly, in the penultimate chapter the techniques needed for the simulation of an inhomogeneous region are compared with those for the simulation of homogeneous liquids, and the results are discussed. The rapid development in the statistical mechanics of liquid surfaces is illustrated in the final chapter.

To summarize, the book gives a very clear presentation of the statistical-mechanical theory of the liquid surface. It contains many derivations and can therefore be used as an introduction to this field, assuming that the reader is familiar with the principles of statistical mechanics and with the theory of the liquid state. It gives an excellent review of the present state of the research and thus greatly facilitates access to the original literature. Unconditionally recommended.

*Helmut Bertagnolli* [NB 538 IE]

## Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

**Personal Computers in Chemistry.** Edited by *P. Lykos.* John Wiley & Sons, Chichester 1981. xi, 262 pp., bound, £ 14.57.—ISBN 0-471-08508-1

**Drug Design. Vol. 10. Medicinal Chemistry.** Edited by *E. J. Ariëns.* Academic Press, New York 1980. xi, 432 pp., bound, $ 49.50.—ISBN 0-12-060310-1

**Analytical Chemistry. Vol. 2. Basic Analytical Chemistry.** By *L. Pataki* and *E. Zapp.* Pergamon Press, New York 1980. xiii, 463 pp., bound, $ 55.00.—ISBN 0-08-023850-5

**Alternative Energy Sources. Part A and B.** By *J. T. Manassah.* Academic Press, New York 1981. xi, 922 pp., bound, $ 49.50 and $ 45.00.—ISBN 0-12-467101-2 and 0-12-467102-0, respectively

# The Kinetics of Intramolecular Reactions from Relaxation Time Measurements

**New analytical methods (21)**

By Joseph B. Lambert, Ronald J. Nienhuis, and Joe W. Keepers[*]

Analysis of spin-lattice relaxation ($T_1$) provides alternatives to the standard line shape procedures for the investigation of intramolecular reactions; furthermore it expands the NMR range at both the high and the low energy barrier limits. Dipole-dipole- and quadrupole-relaxation times are sensitive to very rapid processes such as methyl rotation. Analysis of relaxation in the rotating frame ($T_{1\rho}$) provides kinetics for many sorts of processes, particularly those in the dynamic range that is too rapid for line shape methods. Saturation transfer and the coalescence of relaxation times at high temperatures can be used to measure high energy barriers. The scope and limitations of these methods are described.

## 1. Introduction

The intimate association of nuclear magnetic resonance (NMR) spectroscopy with the measurement of the kinetics and energy barriers for intramolecular rate processes dates back to the early 1950's[1]. Coalescence temperature determination and complete line shape analysis methods became routine during the 1960's[2]. The problems and limitations of these methods, all of which are connected *via* the observation of the coalescence of chemical shifts or coupling constants, have been critically, examined in a recent review[3]. The range of energy barriers available to coalescence methods is approximately 4.5—27 kcal/mol. The range of amenable rate constants lies approximately between $10-10^4$ $s^{-1}$, corresponding approximately to the chemical shift range in Hz. Below this range, intramolecular processes occur too rapidly on the NMR time scale. Very low barrier processes have been studied only by alternative and usually more laborious techniques such as microwave or infrared methods. Above this range, classical methods of racemization or epimerization can be used.

One of the by-products of the revolutionary Fourier transform technique in NMR spectroscopy was the wide availability of instrumentation with which relaxation times could be measured accurately and routinely. Because relaxation times depend for the most part on molecular motion, they provide an alternative to line shape coalescence as a source of kinetic information. Depending on the mode of analysis, both the low and high ends of the NMR energy barrier range can be expanded. Applications, however, are still not numerous, so that the limits of these relaxation methods for determining energy barriers have not been fully explored.

In this review, we will examine a number of these relaxation methods. We will limit ourselves to measurements on the liquid phase. Although many interesting applications

---

to the solid state have been made, the processes and problems are somewhat different. Those relaxation methods that give quantitative kinetics will be emphasized. Relaxation times also can provide qualitative analyses of complex processes such as segmental motion and intramolecular steric effects[4], particularly in biochemical systems.

## 2. Low Energy Barriers

Line shape decoalescence has never been observed for exchanging systems with barriers below *ca.* 4.5 kcal/mol. This limit is fixed by the boiling point of the gaseous coolant used in low temperature experiments (nitrogen, b. p. = – 196 °C, but the limit in practice is *ca.* – 180 °C) and by the solubility and freezing properties of most solutions. The range is being extended by the use of increasingly higher superconducting magnetic fields. Modern methods (rotation at the magic angle = MAS = "magic angle spinning") also permit high resolution NMR-spectra of solids to be recorded and may eventually make lower temperatures and hence lower barriers available[5]. For the purposes of this section, we define low barriers as those below the present limit of classical line shape techniques. The rates are in the range $10^8$—$10^{12}$ $s^{-1}$.

### 2.1 The *Woessner* Method for Dipolar Relaxation

For a nucleus with spin 1/2, attached directly to another nucleus having the same spin, dipole-dipole relaxation [$T_1$(DD)] usually provides the dominant mechanism of spin-lattice relaxation. Smaller molecules may have spin-rotation contributions [$T_1$(SR)] and higher fields may produce chemical shift anisotropy contributions [$T_1$(CSA)]. The molecular motional processes in which we are interested, however, influence dipole-dipole relaxation, so that this contribution must be isolated from the others. The frequency of these motions is of the order of, or larger than, the resonance frequency ($\gamma B_0 \approx 10^8$ $s^{-1}$).

The overall spin-lattice relaxation time $T_1$ is given by the sum of the reciprocals of the individual terms [eq. (1)].

$$\frac{1}{T_1} = \frac{1}{T_1\,(\mathrm{DD})} + \frac{1}{T_1\,(\mathrm{other})} \tag{1}$$

in which $T_1$ (DD) is the dipole-dipole relaxation time and $T_1$ (other) represents all other contributions. The dependence of the nuclear Overhauser enhancement ($\eta$ = NOE-1) on dipole-dipole relaxation permits a direct determination of $T_1$ (DD) from the observed $T_1$ and $\eta$ [eq. (2), in which the maximal $\eta$ is 1.988 for $^{13}$C-nuclei relaxed by protons].

$$T_1\,(\mathrm{DD}) = T_1\,\frac{\eta\,(\max)}{\eta} = T_1\,\frac{1.988}{\eta} \quad (\text{for } ^{13}\text{C-H}) \tag{2}$$

Dipole-dipole relaxation results from the time-dependent reorientation of magnetic dipoles. The molecular motion that gives rise to this type of relaxation is described by an overall correlation time $\tau_c$ (the time for the molecule to rotate in solution through 1 rad). For a complex molecule, overall rotation is superimposed on internal motions within it, so that $\tau_c$ is really a composite correlation time. If the effect of a specific type of motion, such as methyl rotation, can be isolated, then it becomes possible to measure the kinetic properties of that process. In 1962, *Woessner* provided the mathematical framework for isolating methyl rotation from overall motion in certain cases[6]. It was almost a decade before the advent of Fourier transform instrumentation made possible the common application of *Woessner's* theory.

For most cases, methyl rotation has been studied by $^{13}$C-relaxation. In the extreme narrowing limit, the dipole-dipole relaxation time for a $^{13}$C nucleus is related to the effective correlation time by eq. (3):

$$1/T_1(\mathrm{DD}) = n\gamma_C^2\gamma_H^2\hbar^2 r_{CH}^{-6}\tau_c \tag{3}$$

in which $n$ is the number of protons attached to the relaxing $^{13}$C-nucleus, $\gamma_C$ and $\gamma_H$ are the $^{13}$C- and $^1$H-gyromagnetic ratios, $\hbar$ is Planck's constant divided by $2\pi$, and $r_{CH}$ is the C—H bond distance. If the molecule as a whole undergoes isotropic rotational diffusion without internal rotation, the correlation time is related to an overall diffusion coefficient $D$ by eq. (4):

$$\tau_c = 1/6\,D \tag{4}$$

In the most complex case, anisotropic motion can be described in terms of an ellipsoid tumbling about three axes at different rates ($D_1 \neq D_2 \neq D_3$). To date, all applications, however, have had to simplify the analysis by assuming that motion about two of the ellipsoidal axes occurs at the same rate ($D_1 \neq D_2 = D_3$). In this case, the dipole-dipole relaxation is given by eq. (5),

$$\frac{1}{T_1(\mathrm{DD})} = n\gamma_C^2\gamma_H^2\hbar^2 r_{CH}^{-6}\left[\frac{A}{6\,D_2} + \frac{B}{D_1 + 5\,D_2} + \frac{C}{4\,D_1 + 2\,D_2}\right] \tag{5}$$

in which $A$, $B$, and $C$ are geometric factors determined by the angle $\Delta$ between the vector connecting the dipoles (normally the C—H bond) and the internal rotation axis (C—$CH_3$), which coincides with the major axis of the molecular ellipsoid. The angles to the other ellipsoidal axes drop out when $D_2 = D_3$. The geometric constants are given by eqs. (6a)—(6c)

$$A = 1/4(3\cos^2\Delta - 1)^2 \tag{6a}$$

$$B = 3/4\sin^2 2\Delta = 3\sin^2\Delta\cos^2\Delta \tag{6b}$$

$$C = 3/4\sin^4\Delta \tag{6c}$$

We will endeavor, throughout this article, to adhere as closely as possible to the notation used by *Woessner*[6], since confusion has arisen in applications because of changes in notation. The only alterations we have made in eq. (5) from *Woessner's* eq. (45) are the use of $D$ rather than $R$ for diffusion constants (to avoid confusion with the relaxation rate $R$) and the use of two different nuclei ($^{13}$C and $^1$H). *Woessner* used a pair of identical nuclei, and hence had $\gamma^4$ and $n = 3/2$ rather than $\gamma_C^2\gamma_H^2$ and $n$ = number of attached protons. The quantity in brackets [...] in eq. (5) is the correlation time $\tau_c$ for the anisotropic motion of the molecule. When $D_1 = D_2$, the motion is isotropic, and the quantity within the brackets becomes $1/6\,D$ (since $A + B + C = 1.0$), in agreement with eq. (4).

Internal rotation of a component, *e.g.* a methyl group within a molecule, alters the effective correlation time $\tau_c$, while maintaining the internuclear (C—H) distance constant. If the internal motion is independent of the overall motion and the internal rotation occurs about the major axis of the ellipsoid, it is only necessary to add an additional diffusion term $D_i$ (*Woessner* uses $R'_1$) to the diffusion constant $D_1$ about the major axis. The exact mechanics of the addition depend on the assumed mechanism of the methyl reorientation. If the mechanism is stochastic diffusion (all rotational orientations having equal probability), then $D_1$ in eq. (5) is replaced by $(D_1 + D_i)$, in which $D_i$ is the internal methyl diffusion rate in rad/s. If the methyl group undergoes rapid jumps from one position to another, the contribution of $D_i$ to the denominator of the $C$ term is reduced by 1/4. The $D_i$ is now the jump rate in jumps/s and must be multiplied by a statistical factor $a$ ($a = 3/2$ for 120° jumps in a threefold barrier; $a = 3$ for 60° jumps in a sixfold barrier; $a = 1$ for the stochastic process). The modification of eq. (5) to include internal rotation is given in eq. (7):

$$\frac{1}{T_1^{\mathrm{CH_3}}(\mathrm{DD})} = n\hbar^2 \gamma_{\mathrm{C}}^2 \gamma_{\mathrm{H}}^2 r_{\mathrm{CH}}^{-6} \left[\frac{A}{6\,D_2} + \frac{B}{D_1 + 5\,D_2 + a\,D_i} + \frac{C}{4\,D_1 + 2\,D_2 + a\,m\,D_i}\right] \tag{7}$$

in which for the stochastic process $n = 3$ (for $CH_3$), $m = 4$, $a = 1$, and for an $r$-fold methyl jump process $n = 3$ (for $CH_3$), $m = 1$, and $a = r/2$.

The axis of internal rotation (C—$CH_3$) may not necessarily coincide with the axis of symmetry of the ellipsoid. In a later paper, *Woessner et al.*[7] introduced the appropriate allowance for any arbitrary angle $\alpha$ between these axes. A much more complex expression for $T_1$(DD) resulted as shown in eq. (8)

$$\begin{aligned}\frac{1}{T_1^{\mathrm{CH_3}}(\mathrm{DD})} = n \gamma_{\mathrm{C}}^2 \gamma_{\mathrm{H}}^2 \hbar^2 r_{\mathrm{CH}}^{-6} \Bigg[\frac{1}{2}\Bigg(&\frac{A_1}{6\,D_2} + \frac{A_2}{6\,D_2 + a\,D_i} + \frac{A_3}{6\,D_2 + a\,m\,D_i} \\ &+ \frac{B_1}{D_1 + 5\,D_2} + \frac{B2}{D_1 + 5\,D_2 + a\,D_i} + \frac{B3}{D_1 + 5\,D_2 + a\,m\,D_i} \\ &+ \frac{C1}{4\,D_1 + 2\,D_2} + \frac{C2}{4\,D_1 + 2\,D_2 + a\,D_i} + \frac{C3}{4\,D_1 + 2\,D_2 + a\,m\,D_i}\Bigg)\Bigg]\end{aligned} \tag{8}$$

in which $n = 3$ for $CH_3$ and the nine constants are given by eq. (9).

$$\begin{aligned} A1 &= 1/8(1 - 3\cos^2\alpha)^2 (3\cos^2\Delta - 1)^2 \\ A2 &= 9/16 \sin^2 2\alpha \sin^2 2\Delta \\ A3 &= 9/16 \sin^4\Delta \sin^4\alpha \\ B1 &= 3/8 \sin^2 2\alpha (3\cos^2\Delta - 1)^2 \\ B2 &= 3/4(\cos^2 2\alpha + \cos^2\alpha)\sin^2 2\Delta \\ B3 &= 3/4(\sin^2\alpha + 1/4\sin^2 2\alpha)\sin^4\Delta \\ C1 &= 3/8\sin^4\alpha(3\cos^2\Delta - 1)^2 \\ C2 &= 3/4(\sin^2\alpha + 1/4\sin^2 2\alpha)\sin^2 2\Delta \\ C3 &= 3/16[(1 + \cos^2\alpha)^2 + 4\cos^2\alpha]\sin^4\Delta \end{aligned} \tag{9}$$

When $\alpha = 0$, the coefficients $A2$, $A3$, $B1$, $B3$, $C1$, and $C2$ are zero, and the remaining three coefficients $A1$, $B2$, and $C3$, respectively, become $2A$, $2B$, and $2C$ of eq. (7). The factor of 2 difference between the two sets of coefficients in equations (7) and (8) stems from the factor 1/2 inside the square brackets in eq. (8). As in all other such expressions in this paper, the figures within the brackets represent the effective correlation time $\tau_c$. In the isotropic approximation ($D_1 = D_2$), the denominators of each fraction in the correlation time expression of eq. (8) contain $6\,D$ instead of the combination of $D_1$ and $D_2$.

To date, except in a few applications[8,9], the isotropic approximation has been utilized. Applications also normally assume that $\alpha = 0$. There has been no concensus as to whether the stochastic or the methyl jump mechanism is appropriate. Various groups have used either approach, and some groups have used both[10,11]. Because the approximations of $D_1 = D_2$ and $\alpha = 0$ are so common, it is useful to write out the specific equations that embody them. For the threefold methyl jump mechanism, $a = 3/2$ and $m = 1$, as in eq. (10a),

$$\frac{1}{T_1^{\mathrm{CH_3}}(\mathrm{DD})} = 3 \gamma_{\mathrm{C}}^2 \gamma_{\mathrm{H}}^2 \hbar^2 r_{\mathrm{CH}}^{-6} \left[\frac{A}{6\,D} + \frac{B + C}{6\,D + 3/2\,D_i}\right] \tag{10a}$$

in which $D_i$ is the methyl jump rate. For the stochastic diffusion mechanism, $a = 1$ and $m = 4$, as in eq. (10b),

$$\frac{1}{T_1^{\mathrm{CH_3}}(\mathrm{DD})} = 3 \gamma_{\mathrm{C}}^2 \gamma_{\mathrm{H}}^2 \hbar^2 r_{\mathrm{CH}}^{-6} \left[\frac{A}{6\,D} + \frac{B}{6\,D + D_i} + \frac{C}{6\,D + 4\,D_i}\right] \tag{10b}$$

in which $D_i$ is the methyl diffusion rate.

In the few cases in which the overall diffusion coefficient $D$ is known, all the quantities in eqs. (10a) and (10b) are known, except $D_i$, which can consequently be determined. Normally, $D$ is determined from eqs. (3) and (4) using $T_1$(DD) for a rigid carbon atom within the molecule, whose correlation time corresponds to the overall diffusional correlation time for the entire molecule. Consequently, the complete procedure is to measure two dipole-dipole relaxation times, one that is determined only by the overall molecular diffusion $D$ and one that is determined by the superposition of overall diffusion and internal methyl rotation $D_i$. The latter motion is extracted by the application of the *Woessner* equation, *e.g.* (10a) or (10b).

When $\alpha \neq 0$, its value must be obtained by analysis of the actual geometry of the molecule. One approach is to optimize $\alpha$ to fit the experimental relaxation times[8]. In a similar fashion, anisotropic overall motion may be taken into account[8]. In this case, there are three diffusional unknowns in eqs. (7) and (8), $D_1$, $D_2$, and $D_i$. In the *Platzer* approach, $D_2$ and the ratio $\sigma = D_1/D_2$ are optimized to fit the experimental relaxation times of rigid carbons: $D_i$ is then obtained from eq. (7). In the two existing studies of anisotropic motion, the barriers to methyl rotation are not appreciably different from those calculated according to the isotropic assumption[8,9]. Thus the isotropic analysis used by other authors seems justified.

In order to convert $D_i$ to a barrier to methyl rotation, $V_0$, the magnitude of this quantity must be measured as a function of temperature. An Arrhenius plot of the type shown in eq. (11)

$$D_i = D_{i0}\exp(-V_0/RT) \tag{11}$$

then gives $V_0$ from the slope. To date, few of the applications have measured relaxation times as a function of temperature in order to apply this equation[13]. The relaxation time and nuclear Overhauser enhancement (NOE) measurements are extremely time consuming, and at least three temperatures are necessary for a reasonable Arrhenius plot. The barrier, $V_0$, can be calculated directly by eq. (11) from $D_i$ at only one temperature if $D_{i0}$ is known[12]. This quantity is the jump rate or diffusion rate of a freely rotating methyl group ($V_0 = 0$), given by eq. (12),

$$D_{i0} = (kT/I)^{1/2} = 0.89 \times 10^{13}\ \mathrm{s}^{-1}\ (40\,^{\circ}\mathrm{C}) \tag{12}$$

in which $I$ is the moment of inertia of the methyl group.

## 2.2. Applications of the *Woessner* Method

Although *Woessner* described his theory for superimposing methyl motion on overall motion in 1962, quantitative applications did not start appearing until the early 1970's. *Grant et al.* have provided most of the foundation for these applications, in a series of papers that surveyed a large number of molecular types. In one of the earliest publications[14], they examined *o*-xylene and measured its methyl rotation barrier to be about 1.4 kcal/mol. In a more detailed comparison with literature barriers, *Grant et al.* examined relatively common materials such as acetone, dimethyl sulfoxide, methyl acetate, and *tert*-butyl chloride[14]. Finally, they investigated larger series of aromatic[12, 15] and olefinic[16] systems. The derived barriers are set out in Table 1.

Table 1. Barriers (kcal/mol) to methyl rotation by the Woessner dipolar method.

| Compound | $V_0$ [a] | $V_0$ [b] | Ref. |
|---|---|---|---|
| *Aromatic systems* | | | |
| *o*-xylene | 1.4 | | [13] |
| hemimellitene (1,2,3-trimethylbenzene) | | | [15] |
| 1,3-methyl | 1.45 | | |
| 2-methyl | free | | |

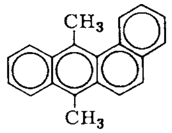
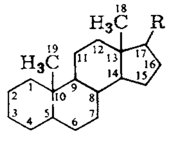
[a] Methyl jump model. [b] Stochastic diffusion model. [c] Isotropic calculation. [d] Anisotropic calculation [e] $E_a$, calculated from an Arrhenius plot. [f] Di-, tri- and tetramethylbenzofurans, see [8]. [g] The values in brackets are for the *cis*-derivatives. [h] Model not specified. [i] Calculated from the lifetimes ($\tau_i = 1/6\,D_i$) by the formulas $\tau_i^{-1} = 6\,D_{i0}e^{-V_0/RT}$, $D_{i0} = 0.89 \cdot 10^{13}\ \mathrm{s}^{-1}$. For $V_0$ values of other androstane derivatives, as well of cholesterol, *trans*-5α- and *cis*-5β-cholesterol see [17]. [j] $V_0$-values were also determined for borneol, α-pinene, isopinocampheol, isoborneol, fenchone and β-fenchol; see [13] and [20]. [k] $V_0$, calculated from eqs. (11) and (12). [l] For $V_0$-values of other methylsubstituted adamantane derivatives, see [20]. [m] For $V_0$-values of analogues methylencarbonyl and dicarbonyl compounds, see [21].

These authors found an interesting steric effect that is imposed by symmetry. In 7,12-dimethylbenzo[a]anthracene *(1)*, the higher steric congestion at the 12-position raises the barrier above the range of the *Woessner* method. The 7-methyl group has nearly identical symmetry on either side and approaches a free rotor.

(1)



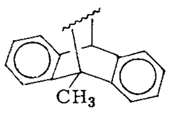


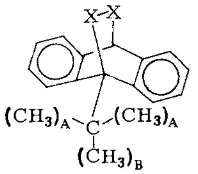
(2)

The study of saturated systems began with a comprehensive examination of steroids by *ApSimon et al.*[17]. Although they reported only lifetimes (the reciprocal of the diffusion rates multipled by six), these figures may easily be converted to barriers by application of eqs. (4), (11), and (12). Isolated values from earlier studies can be similarly treated[18]. Most of the methyl barriers in steroids *(2)* are close to 2.8 kcal/mol. The barrier is sensitive to the steric environment of the methyl group. The differences between the C-18 and C-19 barriers can be accounted for in terms of the number of *syn*-axial $CH_3$—H interactions. Replacement of a $CH_2$-group involved in a methyl *syn*-axial interaction by a CO group has a strong influence on the rotational barrier[17].

*Axelson* and *Holloway*[11] carried out a series of studies on the 9,10 adducts of 9-methyl- and 9-*tert*-butylanthracenes *(3)*, *(4)*, and *(5)*. The barrier to 9-methyl rotation was uniformly above the upper limit to the *Woessner* method in compounds of type *(3)* so that only lower limits could be set, *e.g.*, >4.5 kcal/mol. The *tert*-butyl groups in *(4)* and *(5)* contain two distinct methyl species. The unique methyl group ($CH_3$-B) gave, in each case, a barrier below the lower limit of the *Woessner* method, so that their rotation was termed free. In some cases (see Table 1), the barriers for the remaining pair of equivalent methyl groups were measured to be in the vicinity of 2.0 kcal/mol.

(3)



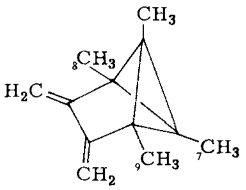


*(4)*, X = C=CH₂
*(5)*, X = C(CN)₂

In a study already alluded to, *Platzer* measured the barriers in an extensive series of methyl-substituted benzofurans[8]. The major contribution of this study, however, was the introduction of a practical method for carrying out anisotropic analyses.

We examined the rotational barriers in a large number of *p*-toluenes and *cis*- and *trans*-substituted propenes[19]. The major thrust of this work was an analysis of the factors controlling rotation of methyl groups attached to a trigonal carbon. A poor correlation of the barriers with $\sigma_R$ eliminated resonance-based phenomena such as hyperconjugation. The major controlling factor appeared to be the polar nature of the substituent, measured by $\sigma_I$. Steric effects were also present in *cis*-propene derivatives.

Two groups have reported barriers for methyl-substituted compounds related to norbornane and adamantane derivatives[13,20]. Almost all these barriers are in the range 2.2–3.1 kcal/mol (Table 1). A similar range was found for the methyl barriers in substituted tricyclo[3.1.0.0$^{2,6}$]hexanes such as *(6)*[21].



(6)

The *Woessner* method provides the most practical approach available today for the measurement of barriers in rapidly rotating methyl groups. Its upper limit is not far from the lower limit of NMR line shape coalescence methods, so the two procedures are complementary. Although lacking the accuracy of barriers determined by microwave spectroscopy, the *Woessner* barriers are easily accessible and reasonably reliable. The energy barriers in *extremely rapidly* rotating groups approaching the free rotor, still elude NMR methods based on dipolar relaxation.

To date, the only quantitative application of the *Woessner* method to rotational barriers for groups other than methyl is to the rotational barriers of the $CF_3$-group in perfluorotoluene[22]. One qualitative study of phenyl rotation in diphenyl disulfide and its Group VIb congeners has appeared[23]. The reported lifetimes can be converted to barriers of *ca.* 6.5 kcal/mol, which seemingly lie above the upper limit of the method. The authors note that internal phenyl reorientation and the overall molecular diffusion have similar lifetimes, particularly for diphenyl disulfide.

### 2.3. Notational Confusion

So far as we have been able to determine, no two papers have used the same notation for reporting the *Woessner* equation. One of the objectives of the current review is to recommend a standard notation that is as close as possible to the original introduced by *Woessner*[6].

One of the most confusing aspects of notation is the coefficient $n$ that appears in eqs. (3), (5), (7), and (8). In various places, it has appeared as 3, 3/2, or 3/4. *Woessner*'s original coefficient was 3/2[6], because his derivation was for a pair of equivalent nuclides[2]. The quantity $\gamma^4$ therefore replaced $\gamma_C^2\gamma_H^2$ in his expressions. For a single $^{13}C$ nucleus relaxed by protons, the appropriate coefficient is the number of directly attached protons that dominate the dipole-dipole relaxation, *e.g.* $n=3$ for $CH_3$. Nonetheless, we find few studies that use "3" for this coefficient along with the standard definition of the *Woessner* geometrical factors [eqs. (6) and (9)][8,9,13,17,19-22]. One set of investigators[10] modified *Woessner*'s definition of $A$, $B$, and $C$ [eq. (6)] by a factor of 4, so that, for example, $A=(3\cos^2\Delta-1)^2$. The factor of 4 was moved to the denominator of the coefficient at the front of the *Woessner* expression, so that it appears that $n=3/4$. Another set of workers made this same change in the definition of $A$, $B$, and $C$, but multiplied each of these factors by 1/4 within the expression for $\tau_c$ to compensate, so that the net result was again $n=3$[12]. Although the resulting $n$ is correct, we would still recommend retaining *Woessner*'s definition of $A$, $B$, and $C$.

For studies that include $\alpha \neq 0$, allowance has to be made for the fact that the *Woessner* $A1$ and $A$ coefficients are not comparable. As defined by *Woessner*, $A1$ becomes $2A$ when $\alpha = 0$. Some workers simply chose to redefine the $A1$ set of coefficients by a factor of 1/2 [eq. (9)], so that $n=3$[15,16]. Two groups, however, retained *Woessner*'s definitions and brought the factor of 1/2 out to the front of the expression, so that $n$ appears to be $3/2$[11,14]. This result, however, mixes geometrical factors with the proton count. In order to retain *Woessner*'s definitions and to retain the factor $n$ as the number of attached protons, we include the compensating factor of 1/2 inside the expression for $\tau_c$ within the brackets of eq. (8). Finally, one report with $\alpha \neq 0$ and $n=3/4$ is probably in error[23], since *Woessner*'s definitions are adhered to. The overall factor should be 3/2, to allow for the number of protons and the difference in definition between $A$ and $A1$. In this same report, the expression when $\alpha = 0$, uses $n=3/2$ rather than 3, so the error is consistent. It probably arose from the change in definition required when the two nuclei are different nuclides.

Because of the differences in notation for the *Woessner* geometric factors, none of the reported papers can be read casually. Detailed examination of the exact notation must be made in order to understand the meaning of $n$. We strongly recommend that $n$ be reserved for the number of attached protons, and that all other factors be relegated to the expression for $\tau_c$. Furthermore, for consistency we recommend that workers retain *Woessner*'s definitions of the geometrical factors $A$, $A1$, *etc.*

There is similar nonconformity in the notation for the methyl jump or diffusion rate. Various workers have used $D$[7,23], $R$[7,12,20], $R'$[8], $R'_1$[6], $\nu$[12], $\rho$ or $\rho_D$[15,16], $\tau_i$ (which is 1/6 of the reciprocal of the methyl diffusion rate)[17], $K$[11,21], $K'$[11], $D_i$[10,19], and $D'_i$[10,13,22]. We recommend that the usual letter for diffusion, $D$, be used, both for the overall diffusion $D$ and for the internal methyl diffusion $D_i$. The letter $\rho$ is not appropriate, because many workers use it for the ratio of the nonequivalent diffusion rates ($D_1/D_2$) in the anisotropic model (others use $\sigma$ for this ratio). We prefer to avoid $R$ (and $R_1$ in particular) because of confusion with the now standard notation for nuclear relaxation rate.

A further point of confusion is the multiplicity of representations for the differences between the methyl jump rate and the stochastic diffusion rate. Most workers have defined $D_i$ (in their notation) to be the stochastic diffusion rate or 3/2 times the jump rate. To distinguish between the two quantities, workers have used $R$ and $D$[7,13,22], $K$ and $K'$[11], or $D_i$ and $D'_i$[10], each differing by a factor of 3/2. Usage, however has not been consistent (*Woessner*'s methyl jump $D$ is *Baldo*'s stochastic $D$). In each case the preexponential $D_{i0}$ (or $K_0$, $\nu_0$, *etc.*) must also differ by a factor of 3/2 for the two mechanisms. Thus, for the stochastic diffusion model, the factor of $(kT/I)^{1/2} = 0.89 \times 10^{13}\ \mathrm{s}^{-1}$ [eq. (12)], but for the threefold methyl jump model, it is $(3/2)(kT/I)^{1/2} = 1.33 \times 10^{13}\ \mathrm{s}^{-1}$. *Ladner, Dalling,* and *Grant*[12] pointed to a resolution of this problem by taking the factor of 3/2 out of the expression for $D_i$ (they used $\nu$). To eliminate this duality of definition between the methyl jump and the stochastic diffusion models, we recommend adopting the usage of *Ladner et al.* Thus, in our eqs. (7) and (8) the symbol $D_i$ is used for the jump or diffusion rate, and the difference in definition is accounted for by the coefficient $a$ (1.0 for stochastic diffusion, $r/2$ for an $r$-fold methyl jump). This usage has the advantage of not implicitly requiring that the methyl jump mechanism always be threefold, as does the inclusion of a factor of 3/2 in the definition of the jump rate. With this notation, the preexponential $D_{i0}$ will always be $0.89 \times 10^{13}\ \mathrm{s}^{-1}$ at 40 °C, as defined in eq. (12).

After this discussion, one might naturally expect that each worker has used a different notation for the barrier to rotation. Fortunately, however, the symbol $V$ ($V_r$ or $V_0$) has wide acceptance.

### 2.4. Limitations of the *Woessner* Method

The two experimental quantities needed for derivation of a methyl rotation barrier by the *Woessner* method are the $^{13}$C-relaxation time and the nuclear Overhauser enhancement (NOE). Under optimal conditions we have found that an error, at the 90% confidence level, of 3% for the spin-lattice relaxation time and 2% for the NOE can be achieved by averaging four or five experimental runs[19]. These errors propagate through the *Woessner* calculation and result in an error at the 90% confidence level of about 10% on the final barrier, or about 0.15—0.2 kcal/mol. The percentage error is larger for barriers below 1 kcal/mol.

Several sources of systematic error have already been mentioned. The assumption of isotropic motion may not always be justified. The effect of such an assumption on the derived barrier, however, is not at all clear. The two studies that carried out both isotropic and anisotropic calculations[8,9] did not find large differences between the two approaches. The barrier from the anisotropic calculation was lower than that from the isotropic calculation in both studies (see Table 1)[8,9]. One case should be noted. Different groups measured the isotropic barrier in $C_6H_5$—$CH_3$ (0.35—0.5 kcal/mol)[19], $C_6D_5$—$CD_3$ (0.8—0.9 kcal/mol)[24], and $C_6F_5$—$CF_3$ (1.3—1.4 kcal/mol)[22], which are all well above the microwave barrier of 0.014 kcal/mol. For $C_6H_5CH_3$, however, $D_1/D_2$ [see eq. (15)] was found to be 2.2[9]. Inclusion of this factor lowered the barrier from 0.35 to 0.0 kcal/mol, in agreement with the microwave result[9].

The assumption that the methyl rotation axis coincides with the molecular symmetry axis ($\alpha = 0$) almost certainly does not hold in a number of cases. One systematic study has been carried out on the importance of this assumption[20].

The choice between the methyl jump model and the stochastic diffusion model has almost become moot. Most recently, workers have carried out calculations with both procedures[10,11,19,22], without finding systematic differences in trends within a series. The differences of about 0.2 kcal/mol are close to the experimental error. The two models respond in nearly identical fashion to substituent effects in toluenes and propenes[19]. *Blunt* and *Stothers*[10] have quoted a useful line of demarcation at 1.4 kcal/mol, with the stochastic model preferred below this figure and the methyl jump model above it. Many of the methyl rotation barriers of interest, however, fall in the 1—2 kcal/mol region and hence offer no certain choice. *Axelson* and *Holloway*[11] have reported that the methyl jump model is most accurate (±10—15%) in the region of 2—6 kcal/mol. Although the upper end of this range seems optimistic, the error these authors quote is very similar to what we described above. At the lower barrier end, as the methyl group approaches the free rotor, the dipole-dipole mechanism of relaxation becomes increasingly less important and the entire approach becomes inapplicable. An exact lower limit below which calculations are unreliable has not been reported. Most workers simply term these systems "free rotors" (Table 1). No barriers below 0.4 kcal/mol have been reported (Table 1), so that we can probably take this value as the currently accepted lower limit.

Most methyl rotation barriers are threefold, on grounds of symmetry. In toluenes, 9-methylanthracenes, and other such aromatic systems, however, the barrier may be sixfold. The parameter $a$ in eqs. (7) and (8) depends on the angle of jump ($a=r/2$ for an $r$-fold rotation). To date, calculations for $CH_3$ have assumed threefold symmetry in the methyl jump model. In the specific case of toluene, two authors have preferred the threefold model[19,24]. A sixfold barrier was used for perfluorotoluene[22]. The effect of altering the $a$ factor in eqs. (7) and (8) has not been studied.

Cross-correlation of nuclear spins has been examined very thoroughly[26]. In particular, for the protons in a methyl group this can result in nonexponential decay in the normal graphical plot for the determination of spin-lattice relaxation times[26]. The nonexponential behavior is the result of the sum of two exponentials, because the doublet and quartet methyl magnetizations can have distinct relaxation times. *Haslinger* and *Lynden-Bell*[27] have been able to determine these distinct relaxation times and to analyze them in terms of overall motion and internal methyl rotation for uroporphyrin(II) octamethyl ester. Their correlation times could be converted into barriers. These authors feel that their method may be applicable only to relatively large molecules. The use of cross-correlation effects on the $^1$H-NMR spectrum has not yet been fully exploited, and hence further advances in the determination of methyl rotation barriers in this area can be expected. The *Woessner* method uses the $^{13}$C relaxation time, and cross-correlation can also occur in the $AB_3$ system ($^{13}CH_3$)[25]. So long as the internal diffusion rate is no more than about 20 times the overall rate ($D_i/D<20$), cross correlation effects are not important[12,24]. All quantitative *Woessner* studies to date have neglected cross-correlation effects, but at very rapid relative methyl rotation rates this could lead to problems.

Because many experimentalists have not carried out relaxation time measurements as a function of temperature in these studies, another systematic error has been introduced with regard to the value of $D_{i0}$ in the Arrhenius expression in eq. (11). This error is systematically propagated in all the calculations. Although the absolute value of the barriers may be affected by the choice of value given in eq. (12), the error has no effect on the relative values within a series. Consequently, internal comparisons of barriers within a given study do not suffer from this error. Two studies[13,22] have measured $T_1$(DD) as a function of temperature, so that the Arrhenius equation could be used. The resulting values of $E_a$ showed small systematic differences from $V_0$ [eqs. (11) and (12)]. The variable temperature approach should be preferred.

All authors have used the tetrahedral value for the angle $\Delta$(H—C—C). As *Blunt* and *Stothers* have pointed out[10], this assumption can result in considerable error in the barrier. These authors found that the rotational barrier of the C-19 methyl group in cholesteryl chloride is calculated to be 0.0±2.2 kcal/mol when the tetrahedral angle is assumed, but 2.6±0.3 kcal/mol for $\Delta=113.5°$. Unfortunately, there is no reliable method of determining the value of $\Delta$. By calculation, *Blunt* and *Stothers* suggested that the ratio $T_1^{CH_3}(DD)/T_1^{CH}(DD)$ be used as a guideline. When this ratio is in the range 0.4 to 2.4, the calculated barriers are relatively independent of small changes in the magnitude of $\Delta$. In the cholesteryl chloride case, the observed ratio of 3.0 is outside this range. The ratio 3.0 has been associated with "free rotation"[18], just as 0.333 has been associated with completely hindered rotation. Non-tetrahedral values of $\Delta$, however, can bring about values of the ratio above 3.0. The vast majority of the systems recorded in Table 1 possess relaxation time ratios within the safe range. This condition must be checked for every case.

It is common practice to apply eqs. (10a) and (10b) by dividing the expression for $CH_3$ by that for a CH carbon in the rigid framework. The division eliminates the coefficients in front of the correlation time (after allowance for the different number of attached protons) and produces a simpler calculation[8,10,19]. Eq. (*13a*) gives the resulting expression for the methyl jump model, and eq. (*13b*) that for the stochastic diffusion model.

$$\frac{T_1^{CH}(DD)}{T_1^{CH_3}(DD)} = 18\left(\frac{A}{6}+\frac{B+C}{6+D_i/D}\right) \tag{13a}$$

$$\frac{T_1^{CH}(DD)}{T_1^{CH_3}(DD)} = 18\left(\frac{A}{6}+\frac{B}{6+D_i/D}+\frac{C}{6+4\,D_i/D}\right) \tag{13b}$$

Such an approach removes some systematic error in the absolute value of $r_{CH}$. Recent studies have shown that small changes in $r_{CH}$ (*e.g.* from the commonly accepted 1.09 Å to say 1.13 Å) can alter the calculation of the overall correlation time [and hence alter $D$ in eq. (4)] by up to a factor of two[28]. The division process in eqs. (*13a*) and (*13b*) removes this source of systematic error, only if $r_{CH}$ is the same for the $CH_3$ and CH carbons. In unstrained, saturated systems, this condition is probably met. For a methyl group attached to a trigonal carbon, the situation is less clear. The structure of propene determined by microwave spectroscopy is consistent with a difference of only 0.02 Å between the bond lengths for $CH_3$ (1.09 Å) and for the trigonal CH (1.07 Å). Such a difference can lead to an error in the barrier of *ca.* 15%. Such an error is comparable to the experimental error but might become more important in unusual structural situations.

From this discussion of experimental and systematic errors, it should be clear that the *Woessner* method produces, at best, semiquantitative barriers for methyl rotation. For a series of compounds, many of the systematic errors cancel or are held constant, so that comparisons within the series probably yield relatively reliable results.

## 2.5. The *Woessner* Method for Quadrupolar Relaxation

A nucleus possessing a quadrupole moment, such as $^2$H, $^{14}$N, or $^{17}$O, can relax very efficiently by interacting with the unsymmetrical electric field of the surrounding electrons[29]. Just as for dipole-dipole relaxation, the quadrupole-electric field relaxation requires tumbling of the molecule for effective coupling of the two components (relaxing nucleus and quadrupolar nucleus). If the quadrupolar nucleus is located within a portion of the molecule that is capable of internal rotation, then the total motion of the nucleus is a superposition of the internal rotation and the overall molecular motion. The geometrical analysis for anisotropic motion parallels the analysis for dipole-dipole relaxation, with changes in the coefficients that precede the expression for the correlation time. *Woessner*[7,30] has derived the appropriate relationship between $T_1$(Q) and the correlation time, which we give for both anisotropic motion [eq. (14a)] and isotropic motion [eq. (14b)].

$$\frac{1}{T_1(\mathrm{Q})} = 3/2\,\pi^2(1+1/3\,\eta^3)(e^2 q Q h^{-1})^2 \left[\frac{A}{6\,D_2} + \frac{B}{D_1+5\,D_2+a\,D_i} + \frac{C}{4\,D_1+2\,D_2+a\,m\,D_i}\right] \qquad (14a)$$

$$\frac{1}{T_1(\mathrm{Q})} = 3/2\,\pi^2(1+1/3\,\eta^3)(e^2 q Q h^{-1})^2 \left[\frac{A}{6\,D} + \frac{B}{6\,D+a\,D_i} + \frac{C}{6\,D+a\,m\,D_i}\right] \qquad (14b)$$

The asymmetry parameter $\eta$ has always been taken to be zero in this context. At least for deuterium, this ought to be a good assumption. As in the parallel expression for dipole-dipole relaxation [eqs. (7) and (10)], $a=1$ and $m=4$ for the stochastic diffusion mechanism for methyl rotation and $a=r/2$ and $m=1$ for an $r$-fold jump mechanism.

The only differences between eq. (14a) and eq. (7) are found in the constants that precede the correlation time. The factor $n$ (number of attached protons) has no relevance in a mechanism involving the relaxing nucleus and its surrounding electron cloud, and is therefore absent. The distance factor $r_{\mathrm{CH}}$ and the gyromagnetic ratios have been replaced by the quadrupole coupling constant, $(e^2 q Q h^{-1})$, in which $e$ is the charge of the electron, $eq$ the electric field gradient, and $eQ$ the nuclear quadrupole moment. Some authors replace $3/2\pi^2(e^2 q Q h^{-1})^2$ by $3/8(e^2 q Q h^{-1})^2$. The geometrical factors $A$, $B$, and $C$ have the same meaning as defined in eq. (6).

It is interesting that most reported applications of this approach have measured $T_1$(Q) as a function of temperature, so that no assumption must be made about the value of $D_{i0}$ in eq. (12). The barriers are obtained by an Arrhenius plot of the methyl jump or diffusion rate *vs.* reciprocal temperature. The experiment is somewhat easier than for the dipole-dipole method, since the NOE is not measured. It is assumed that the observed relaxation time is dominated by $T_1$(Q). Studies using this technique include examination of toluene ($^2$H relaxation)[21], dimethylformamide ($^2$H, $^{14}$N, $^{17}$O)[31], the methyl-substituted benzyl cyanides (tolylacetonitriles) ($^{14}$N)[32], and various aromatic systems ($^2$H)[33]. Related studies have provided values of $\tau_i$ by this method but did not report barriers[34-36]. The reported barriers are given in Table 2.

Table 2. Barriers (kcal/mol) to rotation from the *Woessner* quadrupolar approach.

| Compound | Bond | $V_0$ [a] | $V_0$ [b] | Ref. |
|---|---|---|---|---|
| dimethylformamide | N—$CH_3$ | | 1.4 | [31] |
| *m*-tolylacetonitrile | C—$CH_2CN$ | | 1.5 | [32] |
| *p*-tolylacetonitrile | C—$CH_2CN$ | | 1.5 | [32] |
| toluene | C—$CD_3$ | 0.93 | 0.83 | [21] |
|  | C—$CH_2D$<br>C—CHDOH<br>C—CHDOAc<br>C—CHDCl | free<br>2.7<br>2.8<br>2.9 | | [33] |
|  | C—CHDOAc | 3.3 | | [33] |
|  | O—$CH_2D$ | 1.9 | | [33] |

[a] Methyl jump model. [b] Stochastic diffusion model.

Comparison of $V_0$ for toluene measured by the $T_1$(DD) and $T_1$(Q) methods shows a difference of about 0.4 kcal/mol. These barriers are well removed from the microwave value of 0.014 kcal/mol[37]. *Woessner* and *Snowden*[21] emphasize that even a qualitative interpretation of their data demands that the methyl group in toluene is not a "free rotor", which is at variance with the microwave results. This variance may be the result of use of the isotropic approximation in the NMR measurement[9].

*Wallach*[32] studied rotation about the $CH_2CN$ group in the tolylacetonitriles. In the *o*-tolyl derivative, he found $CH_2CN$ rotation to be hindered, *i.e.*, it was above the barrier limit to the *Woessner* method. Consequently, he used this system to provide the overall diffusion rate $D$ for the determination of the internal rate $D_i$ in the *m*- and *p*-tolyl compounds. *Lehn et al.*[33] examined several C—CHDX and O—CHDX systems. By transferring the rotational rates to other molecules, they were able to report barriers for a much larger number of systems than is presented in Table 2.

Examination of the quadrupolar relaxation provides a useful alternative to the dipole-dipole procedure. The more readily obtainable data encourage the measurement of the rotational rates as a function of temperature. The study of $^2$H relaxation in $CD_3$ is probably not a viable alternative to the investigation of $^{13}$C relaxation in $^{13}CH_3$ in all cases, because of the necessity of synthesizing the deuterated derivatives. The study of $^2H$ relaxation in CHDX (X$\neq$hydrogen), however, provides an opportunity for the measurement of rotational barriers for groups that lack threefold symmetry. Applications of the quadrupolar approach for systems containing $^{14}N$, $^{17}O$, $^{11}B$, and other quadrupolar nuclei should provide continued variety in the types of systems able to be studied.

### 2.6. The *Ellis* Method for Spin-Rotation Relaxation

Quite often, the $^{13}C$ spin-lattice relaxation of a methyl group has a very large contribution from spin-rotation, $T_1$(SR), which can be evaluated from eq. (1). $T_1$(DD) is calculated from the nuclear Overhauser enhancement, and $T_1$(other) is assumed to arise entirely from spin rotation ($T_1$(SR)). *Zens* and *Ellis*[38] reasoned that the barrier to rotation of the methyl-group should be related in some way to the rotational angular momentum and hence to $T_1$(SR).

$$1/T_1(\mathrm{SR}) = 8/3\,\pi^2\hbar^{-2}\,k\,T\,C_{\parallel}^2\,I_{\parallel}[\tau_{\mathrm{SR}}] \qquad (15)$$

Eq. (15) expresses the relationship between the spin-rotation relaxation time and the temperature $T$, the Boltzmann constant $k$, the spin-rotation interaction coupling constant $C_{\parallel}$, the moment of inertia $I_{\parallel}$ about the axis of rotation, and the correlation time for angular momentum reorganization $\tau_{SR}$. It must be assumed that rotational motion about the parallel axis is much faster than motion about the perpendicular axis or of the molecule as a whole. It is unlikely that the perpendicular axis will have a significant contribution, and the overall spin-rotation can be evaluated from $T_1$(SR) for a $^{13}C$ atom not involved in the internal rotation. The dominance of internal spin-rotation has been documented for nitrite rotation in *n*-butyl nitrite (*n*-$C_4H_9$—ONO)[39].

By replacing the thermal energy term $kT$ by the expression ($kT+V_0$), *Zens* and *Ellis*[38] were able to take quenching of angular momentum by the barrier to rotation $V_0$ into account. From eleven known values of $V_0$ and measurements of $T_1$(SR), they found a semiempirical relationship [eq. (16)].

$$V_0 = (T_1(\mathrm{SR}) - 25.61)/9.783 \qquad (16)$$

This relationship, derived for 38 °C, provides a straightforward procedure for measuring barriers from spin-rotation relaxation times. These authors calculated the barriers to methyl rotation in camphor to be 3.05 kcal/mol for 8-$CH_3$, 3.26 for 9-$CH_3$, and 3.08 for 10-$CH_3$[38]. They also enumerated a number of limitations to this procedure: eq. (16) is only valid at 38 °C; it was assumed that the internal spin rotation is more dominant than the total spin-rotation, and that protons (not $^{19}F$, *etc.*) must be attached to carbon in order to calculate $T_1$(SR) by reciprocal subtraction of $T_1$(DD) (from NOE measurements!) from $T_1$ in eq. (1).

Subsequent applications of the *Zens-Ellis* equation have not been entirely successful. In particular, two studies obtained negative barriers to rotation[40,41], and a third[42] claimed that the approach is theoretically unsound. Further examination of the *Zens-Ellis* data demonstrated that the linearity of eq. (16) was false and had been caused by systematic errors in the measurement of the nuclear Overhauser effects[43]. The actual plot of $T_1$(SR) *vs.* $V_0$ has considerable curvature. *Ellis, Poole, et al.*[43] were able to fit the curve by a modification of eq. (15) that separated the correlation time into distinct overall and internal components: curves for 10° and 38 °C were presented.

The relationship between $V_0$ and $T_1$(SR) is not linear and hence barriers must be obtained from a plot. The method has not yet been thoroughly explored, so that the extent of its limitations remain unplumbed. The specification of a single temperature is a minor limitation. The range of applicable barriers has not been determined and the dominance of internal spin-rotation over overall spin-rotation has not been systematically demonstrated. One group used differences between the *Ellis* and *Woessner* barriers to determine the H—C—C angle[20]. Finally, the influence of experimental error associated with $T_1$ (observed) and NOE measurements on the accuracy of the barriers $V_0$ has not yet been examined quantitatively. Nonetheless, the method remains a useful alternative to the *Woessner* approach.

## 3. Intermediate Energy Barriers

By "intermediate barriers", we refer to those corresponding approximately to the range for line shape coalescence, *i.e. ca.* 4.5 to 27 kcal/mol. At the lower end of this range, one of the first applications of relaxation phenomenon to dynamic problems was the use of spin-echo techniques[44]. The primary aim of these experiments was to increase the dynamic range of kinetic measurements and hence to improve the accuracy of the derived barriers. The method probably does not improve significantly on lowering the barrier limit observable by NMR line shape methods. Most of these experiments preceded the Fourier transform era. Similar, if not expanded, objectives can now be attained by the $T_{1\rho}$ method, which is simpler to carry out and is available on commercial equipment. For these reasons, we will direct our attention to $T_{1\rho}$ and not attempt to further the existing review of spin-echo techniques[45].

### 3.1. Rotating Frame Relaxation ($T_{1\rho}$)

As mentioned in Section 2.1 the spin-lattice relaxation time $T_1$ is sensitive to motional processes which have rates in the vicinity of the resonance frequency, $\gamma B_0$ (*ca.* $10^8$ $s^{-1}$). Lower rates can be achieved by measuring relaxation times in the $B_1$ field, whose frequency is lower than the $B_0$ field. The measurement can be carried out by a two-pulse sequence. The magnetization is first placed in the xy plane by a 90° pulse. Then, instead of measuring the growth of magnetization in the z direction ($T_1$), the magnetization is locked in the xy plane by a continuously applied 90° phase-shifted pulse. During this pulse, the nuclear vectors rotate with the weaker $B_1$ field (precess around the rotating $B_1$ with angular frequency $\omega_1 = \gamma B_1$), rather than with the $B_0$ field (angular frequency $\omega_0 = \gamma B_0$). At the end of the lock pulse, the rate of decay of magnetization in the xy plane is measured (time constant $T_{1\rho}$). Extrapolation of the spin-locking power to zero would give $T_2$. Despite its relationship to the xy plane, the rotating frame relaxation time is called $T_{1\rho}$ (not $T_{2\rho}$) because of the similar function of the $B_0$ and $B_1$ fields for $T_1$ and $T_{1\rho}$. $T_{1\rho}$ can be defined as the time constant for decay of magnetization along the rf field $B_1$, which is rotating in the xy plane perpendicular to the direction of $B_0$. If decoupling is required, it is gated-off during the spin-locking pulse.

*Meiboom* first carried out $T_{1\rho}$ experiments[46], and *Deverell et al.*[47] demonstrated their applicability to kinetics. The latter authors pointed out that dipole-dipole, spin-rotation, *etc.*, contributions should be similar for $T_1$ and $T_{1\rho}$. Because of different frequency sensitivities, however, the two relaxation times differ in contributions from exchange processes, $T_{1\rho}$ being sensitive to slower rates. The net $T_{1\rho}$ (exchange) due to the rate process is obtained by reciprocal subtraction of $T_1$ from $T_{1\rho}$ (observed) [eq. (17)].

$$\frac{1}{T_{1\rho}(\text{exch.})} = \frac{1}{T_{1\rho}(\text{obs.})} - \frac{1}{T_1} \tag{17}$$

For exchange between two sites with equal population, the net $T_{1\rho}$(exch.) is related to the spin-locking frequency $\omega_1$, the mean lifetime $\tau = 1/k$ ($k$ is the rate constant for the exchange process), and the chemical shift difference between the exchanging sites $\Delta\nu$ (in Hz) by eq. (18).

$$\frac{1}{T_{1\rho}(\text{exch.})} = \pi^2(\Delta\nu)^2 \frac{\tau}{1+\omega_1^2\tau^2} \tag{18}$$

The desired quantity in eq. (18) is $\tau$, the reciprocal of the exchange rate, from which the barrier $\Delta G^{+}$ can be calculated. Measurement of $\tau$ as a function of temperature of course gives $\Delta H^{+}$ (or $E_a$) and $\Delta S^{+}$ (or $\log A$). If the slow exchange $\Delta\nu$ is known, then $\tau$ can be obtained directly from eq. (18). Such an experiment would be equivalent to the study of decoalescence in the slow exchange limit. Decoalescence cannot normally be studied unless that limit is achieved and $\Delta\nu$ is measured[*]. The $T_{1\rho}$ method, however, does not require achieving the slow exchange limit and measuring $\Delta\nu$. A plot of $T_{1\rho}$(exch.) as a function of $\omega_1^2$ will give $\tau$ and $\Delta\nu$ from the slope and intercept. Thus, the $T_{1\rho}$ method offers the considerable advantage of determining fast kinetics without necessarily achieving the slow exchange line shape limit. The practical kinetic range for the method is about $10^2$—$10^6$ s$^{-1}$. Thus it overlaps with, and slightly expands upon, the lower limit of line shape methods.

Although a number of applications of $T_{1\rho}$ to the solid state have been reported, applications to kinetics in solution are only just being carried out. *Stilbs* and *Moseley*[48] obtained the barrier to amide rotation in urea ($^1$H measurements, $\Delta G^{+} = 10.8$ kcal/mol) and in tetramethylurea ($^{13}$C measurements, 6.1 kcal/mol) from $T_{1\rho}$. By variation of $\omega_1$, they were able to measure $\Delta\nu$ well above the coalescence temperature. Thus for tetramethylurea, the measurements were at −115 and −120 °C, while the coalescence temperature is close to −150 °C. These authors also carried out a Monte Carlo error analysis on their data.

*Doddrell et al.* measured the rotational barrier to C—C bond rotation between the aldehyde group and the phenyl moiety from the $^{13}$C $T_{1\rho}$ in benzaldehyde ($\Delta H^{+} = 7.3$ kcal/mol) and *p*-methoxybenzaldehyde (8.7 kcal/mol)[49]. These measurements were made 100—120 °C above the known coalescence temperatures. The same group[49] has measured the ring reversal barrier in 1,1-dimethylpiperidinium iodide ($\Delta H^{+} = 10.5$ kcal/mol, $\Delta G^{+}(-3\,°\text{C}) = 10.0$ kcal/mol) from $T_{1\rho}$ of the methyl carbons. From $\Delta G^{+}$, the coalescence temperature was calculated to be about −50 °C, well below the freezing point of the aqueous solution needed to dissolve this salt. The ring reversal barrier in *cis*-decalin has also been measured from $T_{1\rho}$[50], and applications to conformational operations in polypeptides have appeared[51].

The $T_{1\rho}$ method suffers from few of the systematic errors associated with the *Woessner* method, but it cannot treat the very rapid rotational processes that the *Woessner* method can. The method is not restricted by the symmetry of the exchanging entities — as the *Woessner* method is — to CH$_3$ and CH$_2$X groups. As yet, the $T_{1\rho}$ procedure has not been extended to exchange between sites with unequal populations. The commercial availability of spectrometers that now can measure $T_{1\rho}$ certainly should encourage applications of the method. Because of its high accuracy and its applicability to fast kinetics without the necessity of obtaining the slow exchange $\Delta\nu$, rotating frame relaxation methods should achieve broad acceptance in the future.

## 4. High Energy Barriers

The methods discussed in this Section provide slower rates than those that line shape techniques could provide on the same system. The barriers are at the upper end of, or above the line shape coalescence range.

### 4.1. Saturation Transfer or the *Forsén-Hoffman* Method

Although the modification of the Bloch equations for chemical exchange processes had been achieved by *McConnell* in 1958[52], it remained for *Forsén* and *Hoffman*[53] to exploit the theory and provide an alternative line shape analysis. In a two spin system, saturation of one resonance (B) causes transfer of magnetization to another resonance (A) that is in chemical exchange with it. *Forsén* and *Hoffman* showed how the analysis of the peak perturbations at A can provide both relaxation times and the rate constants for exchange. The method may be used qualitatively to demonstrate the identity of specific spins undergoing the exchange process. Many of the qualitative applications have been discussed in a review[54].

The Bloch expression for the change in magnetization ($M_z^A$) at site A is made up of one decay term in $T_{1A}$ for normal relaxation to equilibrium ($M_0^A$) and a second decay term in $\tau_A$ (the reciprocal of the A→B rate constant) for transfer of spin from A to B *via* the exchange process [eq. (19)]. There is no term in $\tau_B$ because of the saturation condition.

$$-\frac{\mathrm{d}M_z^A(t)}{\mathrm{d}t} = \frac{(M_z^A(t) - M_z^A(0))}{T_{1A}} + \frac{M_z^A(t)}{\tau_A} \tag{19}$$

---

[*] Note: In the simplest case considered here, $\Delta\nu$ can also be obtained from the "half-width" at the coalescence point.

Equation (19) is normally rewritten in terms of a total lifetime $\tau_{1A}$ [eq. (20)]

$$\frac{1}{\tau_{1A}} = \frac{1}{\tau_A} + \frac{1}{T_{1A}} \tag{20}$$

that includes both spin-lattice relaxation and exchange [eq. (21)].

$$\frac{dM_z^A(t)}{dt} = \frac{M_z^A(0)}{T_{1A}} - \frac{M_z^A(t)}{\tau_{1A}} \tag{21}$$

The solution to this differential equation is given by eq. (22).

$$M_z^A(t) = M_z^A(0)\left[\frac{\tau_{1A}}{\tau_A}\exp^{(-t/\tau_{1A})} + \frac{\tau_{1A}}{T_{1A}}\right] \tag{22}$$

Peak heights are taken as a valid measure of $M_z(t)$. When $t$ approaches infinity, eq. (22) can be rearranged to give eq. (23).

$$\frac{M_z^A(\infty)}{M_z^A(0)} = \frac{\tau_{1A}}{T_{1A}} \tag{23}$$

Thus, measurement of $M_z(0)$ and $M_z(\infty)$ gives the ratio of $T_{1A}$ to $\tau_{1A}$. If $T_{1A}$ can be measured independently, then $\tau_{1A}$ and hence $\tau_A$ can be obtained. Alternatively, one can plot $\log[M_z^A(t) - M_z^A(\infty)]$ *vs.* $t$ [from eq. (22)] to give a straight line with slope $\tau_{1A}$, whence $T_{1A}$ and $\tau_A$. A similar set of experiments in which A is saturated and B is observed would give $T_{1B}$ and $\tau_B$.

Despite the attractiveness of this approach, very few quantitative applications appeared prior to the Fourier transform era. As *Mann*[55] pointed out, the method described by *Forsén* and *Hoffman* requires repetitive scanning through the resonance at least once a second, in order to provide an independent measure of $T_{1A}$. A few spectrometers were set up to carry out such experiments (the old Sanborn recorder was particularly good for this purpose).

*Anet* and *Bourne* examined [D$_{11}$]cyclohexane by the original *Forsén-Hoffman* method[56]. Saturation of the axial or equatorial proton in the temperature range −97 to −117 °C, when coupled with line shape analysis from the range −24 to −82 °C, provided very accurate parameters for the barrier to ring reversal ($\Delta G^{+} = 10.22$ kcal/mol, $\Delta H^{+} = 10.8$ kcal/mol, and $\Delta S^{+} = 2.8$ eu). The fact that the exchanging axial and equatorial protons are in different molecules avoids another problem. Irradiation at the resonance frequency of a nucleus can cause nuclear Overhauser polarization effects on and removal of coupling to other nuclei within the same molecule. These effects can confuse analysis of saturation transfer. In another early application, *Kabakoff* and *Namanworth*[57] obtained the activation energy to rotation around the cyclopropyl-C$^{\oplus}$ bond in the cyclopropyldimethylcarbenium ion ($E_a = 13.7$ kcal/mol, $\log A = 12.2$).

The advent of pulsed Fourier transform $^{13}$C techniques obviated most of the drawbacks to the *Forsén-Hoffman* method. Use of a dilute (natural abundance) $^{13}$C spin means that the irradiated and observed nuclei are almost certainly not in the same molecule, so that decoupling and Overhauser effects no longer confuse the analysis. Possibly more important, pulsed Fourier transform operation provides an independent measure of $T_1$, so that rapid, repetitive scanning is not necessary. Instead of saturating the B nucleus, the Fourier transform procedure normally inverts B selectively with a 180° pulse, followed by a 90° observation pulse. Because of exchange effects between $T_{1A}$ and $T_{1B}$ (Section 4.2), however, this method gives a valid $T_1$ only when $T_{1A} = T_{1B}$[55]. *Boekelheide et al.*[58] measured the barrier to ring reversal in [2.2]metaparacyclophanes from $^1$H-NMR spectra, assuming equal relaxation times, as $\Delta H^{+} = 17.0$, $\Delta S^{+} = -8.8$ eu. *Mann*[55] reported the first $^{13}$C (dilute spin) application of the *Forsén-Hoffman* method, for ring reversal in *cis*-decalin, with independent measurement of $T_1$ and the assumption that $T_1^A = T_1^B$. His *Forsén-Hoffman* studies between −70 and −45 °C were supplemented by line shape kinetics up to about +40 °C. With CD$_2$Cl$_2$ as solvent, he obtained $\Delta H^{+} = 12.35$ kcal/mol, $\Delta S^{+} = 0.15$ eu, $E_a = 12.85$ kcal/mol, $\log A = 12.85$, and $\Delta G^{+}(27\,°\mathrm{C}) = 12.30$ kcal/mol. The figures for CD$_3$C$_6$H$_5$ were $\Delta H^{+} = 12.47$ kcal/mol, $\Delta S^{+} = 0.06$ eu, $E_a = 12.97$ kcal/mol, $\log A = 12.97$, $\Delta G^{+}(27\,°\mathrm{C}) = 12.45$ kcal/mol. In a later study, *Mann*[59] presented a method applying his procedure to systems in which $T_{1A} \neq T_{1B}$. For dimethylformamide, he combined the *Forsén-Hoffman* method (40.5 to 59 °C) with a line shape analysis (100 to 160 °C) to give $\Delta H^{+} = 20.39$ kcal/mol and $\Delta S^{+} = -1.49$ eu. In addition to these multi-temperature studies, there have been other Fourier transform investigations at only a single temperature that reported rate constants but not activation parameters[60]. Saturation transfer involving $^{13}$C nuclei has also been used to study ligand migration mechanisms[61].

The *Forsén-Hoffman* method provides a very useful procedure for studying kinetics at the upper end of the barrier range for line shape methods. To date, most of the studies, however, have relied upon a combination of *Forsén-Hoffman* and line shape methods in order to produce the largest possible dynamic range of rate constants. It should nonetheless be possible to use saturation transfer to provide kinetics for systems that do not attain the fast exchange line shape extreme. For most Fourier transform applications, however, the *Forsén-Hoffman* method requires that $T_{1A} = T_{1B}$, since the independent measurement of $T_1$ only yields a true value under these conditions (Section 4.2). Also, many NMR-spectrometers are not designed to deliver selective irradiation of a single $^{13}$C resonance under Fourier transform conditions: they provide selective $^1$H irradiation but nonselective $^{13}$C irradiation. This drawback should disappear with future development of instrumentation. For the upper end of the barrier range, the *Forsén-Hoffman* approach is the method of choice for exchanging spins of equal spin-lattice relaxation time. It ought to be used not only to expand line shape kinetics but also to study non-coalescing systems.

### 4.2. The Coalescence of Relaxation Times

Saturation of one of the component resonances in an exchanging system leads to simplification of the differential equation [eq. (19)] for the change in magnetization and hence to a simple exponential solution [eq. (22)]. If saturation is nonselective, there must be a term (in the case of the A magnetization) both for loss of magnetization by A and gain from B [eq. (24)].

$$-\frac{dM_z^A(t)}{dt} = \frac{(M_z^A(t) - M_z^A(0))}{T_1^A} + \frac{M_z^A(t)}{\tau_A} - \frac{M_z^B(t)}{\tau_B} \tag{24}$$

The solution to this equation takes the form of eq. (25).

$$M_z^A(t) = M_z^A(0) + C_1 \exp(-t/T_I) + C_2 \exp(-t/T_{II}) \tag{25}$$

The constants in this expression have been defined elsewhere[62-65].

The major difference between this solution and that for the more restrictive *Forsén-Hoffman* conditions is the double exponential that is present in eq. (25). In contrast, *Forsén-Hoffman* data are controlled by a single time constant $\tau_{1A}$ (the reciprocal sum of $T_{1A}$ and $\tau_A$). In a normal spin-lattice relaxation measurement (inversion or saturation recovery) for a non-exchanging system, the data are also controlled by a single time constant $T_1$. The double exponential form of eq. (25) means that exchanging systems gives rise to nonlinear behavior in the usual magnetization plot ($\ln M_z$ *vs.* $t$), similar to the behavior of systems exhibiting cross-correlation[25].

The physical interpretation of the pair of time constants [$T_I$ and $T_{II}$ in eq. (25)] depends on the relative values of the lifetimes and relaxation times. We can consider three kinetic regions. At the slow exchange limit (low temperatures, long lifetimes compared to relaxation times), $T_I$ corresponds to $T_{1B}$ and $T_{II}$ to $T_{1A}$. The values of the coefficients are such that the $C_1$ term drops out for A-magnetization and the $C_2$ term drops out for B-magnetization. Thus, each resonance line gives single exponential decay (or growth) of magnetization, and the time constants are the true relaxation times[62,65].

At the fast exchange limit (high temperatures, short lifetimes compared to relaxation times), the first term (with time constant $T_I$) goes to zero. The result is single exponential decay or growth of magnetization, and the reciprocal of the time constant $T_{II}$ is the weighted average of the reciprocals of the true relaxation times, $T_{II}^{-1} = 0.5(T_{1A}^{-1} + T_{1B}^{-1})$ for equal population or $T_{II}^{-1} = p_A T_{1A}^{-1} + p_B T_{1B}^{-1}$ in general. Thus, under conditions of rapid exchange, the usual inversion recovery experiment for $T_1$ does not give a true relaxation time, but a weighted average for the various sites[65]. It should be emphasized that "slow exchange" and "fast exchange" in the present context do not have the same meaning as for line shape analysis. In the latter context, the terms refer to the presence or absence of line collapse. In the present context, they refer to the relative values of the lifetimes and the relaxation times. At the beginning of the fast exchange limit, in terms of relaxation, distinct resonances still appear for the two exchanging species. Thus, fast exchange for relaxation ($T_1$ coalescence) is still slow exchange for line shapes ($\Delta\nu$ decoalescence). At higher temperatures line shape coalescence would eventually take place. In the region of fast relaxation exchange and slow line shape exchange, relaxation times can be measured for both the A and the B resonances. The result would apparently be equal relaxation times, but the numbers are averaged ($T_{II}$) rather than true ($T_{1A}$, $T_{1B}$) relaxation times. We refer to this phenomenon as relaxation time coalescence, which precedes line shape coalescence as the temperature is raised[65].

The coalescence of relaxation times occurs in the intermediate kinetic region between fast and slow relaxation exchange, when the lifetimes and relaxation times have comparable values. In this region, the magnetization exhibits double exponential (nonlinear) behavior, and the time constants $T_I$ and $T_{II}$ correspond to a complex mixture of the lifetimes ($\tau_A$ and $\tau_B$) and the true relaxation times ($T_{1A}$ and $T_{1B}$) (see eq. (5) in [65]). Single exponential analysis of inversion recovery data in this region will give false values for the relaxation times.

There have been two approaches to exploit relaxation behavior in the coalescence region in order to obtain exchange lifetimes (reciprocal first order rate constants). *Strehlow* and *Frahm*[64] obtained closed solutions when $T_{1B} \ll T_{1A}$ (in a ratio of at least 1:5). They applied this method to the exchange of water between the inner hydration sphere of nickel ions and the bulk solution. A large inequality between the two relaxation times might be expected to occur if paramagnetic relaxation has a greater influence on one of the relaxation times, if there is a large difference in the size of A and B, or if relaxation is quadrupolar-determined and the two species have considerably different symmetries. Thus, this approach is severely limited by the necessity of unequal relaxation times.

In the second approach to exploiting relaxation time coalescence to study kinetics, we developed a nonlinear regression analysis to solve the complete differential equation[65]. This approach gives the mean lifetimes ($\tau_A$ and $\tau_B$) and the true relaxation times ($T_{1A}$ and $T_{1B}$) in the intermediate (coalescing) region. Applied to amide rotation in dimethylformamide, this method gives lifetimes (and hence barriers) very close to those from extrapolated line shape analysis. Regression analysis of the nonlinear change in magnetization has the main advantage over other high barrier techniques that it is not constrained by the relative values of the true relaxation times. They need not be equal or very unequal. It offers the most general approach, but its accuracy must be further tested.

## 5. Final Comments

Measurement of spin-lattice relaxation times can expand both the high and the low extremes of the barrier range available to line shape experiments (see the summary in Figure 1; the limits are tentative).

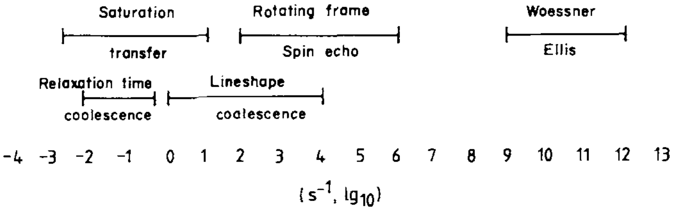


Figure 1. The dynamic range of rate constants ($s^{-1}$ on a logarithmic scale of base 10) for NMR methods.

For very fast rotational processes, the *Woessner* method provides the semiquantitative determination of barriers in systems whose relaxation is dominated by dipole-dipole or quadrupole relaxation. The method has numerous systematic errors, but relative rates within an homologous series appear to be reliable. For systems whose relaxation is dominated by spin rotation, the *Ellis* procedure offers an alternative to the *Woessner* method. This procedure is highly parametrized and as yet has not been applied to very many undetermined cases. Both of these methods are presently restricted to $CH_3$ or $CH_2X$ rotation. For slightly higher barriers, the $T_{1\rho}$ method can be applied to systems that fail to decoalesce at very low temperatures, without restriction on the symmetry of the exchanging species. It is less prone to systematic errors than the *Woessner* method, and offers outstanding promise for measurements of the kinetics in systems with low-to-intermediate barriers. Saturation transfer (the *Forsén-Hoffman* method) similarly offers outstanding promise in the intermediate-to-high barrier region. The lifetimes and relaxation times for the exchanging sites A and B can be measured regardless of the relative values of $T_{1A}$ and $T_{1B}$, provided that the spectroscopist has equipment for selective irradiation and rapid repetitive scans. Otherwise, the relaxation time is measured independently, and the result is only valid when $T_{1A} = T_{1B}$. Exchange rates in the high barrier region can be measured by the analysis of relaxation time coalescence. The usual inversion recovery method for determining $T_{1A} \neq T_{1B}$ gives false values when the lifetimes and relaxation times have comparable magnitudes. For nonselective irradiation without saturation transfer, rates can be measured relatively easily if the true relaxation times are considerably different in magnitude ($T_{1B} \leqslant T_{1A}$). Regression analysis within the region of relaxation time coalescence can give the lifetimes and true relaxation times, regardless of the relative magnitudes of the true relaxation times. This last method has not been tested in a variety of situations, although potentially it offers a general approach to the measurement of barriers that are near or above the limit to line shape coalescence.

Relaxation time methods span the barrier range from close to 0 kcal/mol to possibly above 30 kcal/mol, corresponding to a dynamic range of 15 orders of magnitude in the rates (Figure 1). They offer both alternatives to and extensions of the classical line shape coalescence/decoalescence approaches. The field is still rapidly developing, so that new methods, new restrictions, and new expansions can be expected.

*The authors wish to thank the National Science Foundation and the National Institutes of Health for support of this work. We are indebted to Dr. Donald E. Woessner and to Professor Horst Kessler for valuable comments.*

# Molecular Self-Organization and the Origin of Life[**]

## By Hans Kuhn and Jürg Waser[*]

The sequence of many small physically and chemically plausible steps that lead to self-organization of matter are considered. These are governed by periodic temperature changes and a multi-faceted spatial environment, both of which occurred in suitable locations on the primordial planet. The specific model described reveals the logical framework of this process, the nature and locations of fundamental difficulties as well as the means by which they might be overcome. The barriers that must be surmounted are mostly related to an accumulation of copying errors. An early stagnation barrier was hurdled by aggregate formation, by means of which erroneous copies are rejected; a further barrier was overcome by the evolution of machinery capable of synthesizing "cellular" envelopes which confine the building components. A system evolved which produced a primitive "replicase" that stabilized a rudimentary genetic code. A later stagnation phase ended when the functional system was reorganized by the evolution of separate machinery for replication and for translation of genetic information. - The purpose of this account is to stimulate experiments and theoretical efforts towards the improvement, refinement, and expansion of the model described. It also demonstrates the fruitfulness of the present style of approach that leads to assertions about the prerequisites, logical framework, and organizational structure of evolutionary processes.

## 1. The Genetic Blueprint and its Translation

A feature of all living systems is their ability to produce copies of themselves. They consist of macromolecules functioning together as an entity in a similar way to the interacting parts of a machine. Living individuals contain their own blueprint along a nucleic acid strand, in the form of a specific sequence of four kinds of nucleotides. During multiplication of an individual this information is copied by replication of the nucleic acid strand. The blueprint can be translated into proteins, that is, linear sequences of twenty kinds of amino acids. This step is accomplished by means of *adapter* or *transfer ribonucleic acid* molecules. For every amino acid $a_1, a_2, a_3 \ldots$ at least one specific molecule of this type, to which it can become attached exists, which also carries a specific *anticodon* nucleotide triplet. Adapter molecules can in turn couple by complementary base pairing to a nucleic acid strand that contains the blueprint for the protein in question *(messenger ribonucleic acid).* Attachment of the base triplet of an adapter molecule to a base triplet on a messenger nucleic acid strand can only occur if corresponding base pairs are *complementary.* The four bases G (guanine), C (cytosine), A (adenine), and U (uracil) are pairwise complementary; bases G and C can readily form three hydrogen bonds with each other, while bases A and U can readily form two hydrogen bonds with each other. Put more simply, if there is a C on the messenger strand there must be a G in the corresponding place on the adapter molecule, *etc.*; for example, the first *codon* triplet ACU on the messenger strand (read in the 5'3'-direction) must correspond to an adapter molecule with the *anticodon* triplet UGA (read in the 3'5'-direction), which carries *e.g.* the amino acid $a_1$ (Fig. 1). Amino acids

are therefore linked into protein chains with an amino acid sequence that is determined by the blueprint. These proteins then form the functional structure of the organism.

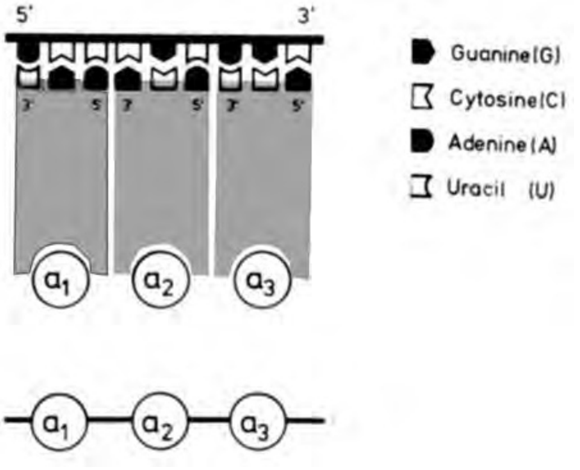

Fig. 1. Simplified version of present-day protein synthesis, guided by a blueprint nucleic acid strand (top), to which adapter molecules carrying the amino acids $a_1$, $a_2$, $a_3$ are attached. Once in favorable juxtaposition the amino acids can form polypeptide bonds (bottom).

Errors during the copying of the blueprint may cause changes in the proteins. Such errors are usually disadvantageous, but in rare cases lead to improved survival chances of the changed individuals. Individuals survive that are best adapted to the environment. Such progressive adaptation to the environment represents a process of *"learning"* for the system that requires many generations.

## 2. The Method of Model Paths

How could simple systems of this kind, that learn by evolution arise? How could machinery for the translation of genetic information that contains proteins as essential translation products arise? How can this chicken-and-egg problem, be solved? Can the laws of physics be applied towards its understanding?

The appearance of the first system capable of learning represented a jump in quality, in which a fundamental property of matter suddenly manifested itself. Systems began to be carriers of information, of a meaningful message, with a content capable of growing as the learning process advanced. Prior to this not even the faintest trace of this property existed, but once the breakthrough had occurred, the process of learning went on inexorably *via* the continued confrontation of evolving systems with their surroundings and their adjustment to environmental changes by multiplication, mutation and selection.

Experimental data capable of directly showing how this manifestation—the sudden appearance of learning machines and the slow evolutionary process leading to the genetic apparatus of present-day biological systems could have come about—is not available. The search for such model paths is important not only as an aid in recognizing these astonishing phenomena as a consequence of plausible physical processes, but also to indicate particularly important steps and in this way to stimulate experiments that might be fruitful. The task of indicating promising experiments is an important aspect of the ideas discussed here, and it is therefore of value to describe the models in a concrete and specific manner.

In more general considerations of self-organization it is easy to overlook the crucial difficulties, and the detailed consideration of an imaginable path constitutes a method of avoiding this problem. However, it cannot be expected that the model steps considered furnish an accurate description of the events that actually occurred.

It is also important not to lose sight of the logical relationship between the different steps, a relationship that is easily buried in the necessarily cumbersome details required for an adequate description of the steps. Each step only leads to the next, and so the overall logical structure of the model is not apparent until the very end (see Section 14, Fig. 24). It is this overall structure that represents the essence of the model, a structure that is not affected, even if some of the details in the steps may have to be changed.

The methodological program for recognizing and understanding the grand connections in the process of self-organization, which we describe here, therefore involves consideration of specific paths consisting of many simple steps[1,2]. A good illustration is the description of how a translation apparatus might have arisen. The presentation is kept simple in order to point out decisive relationships in the clearest possible way.

A machine is constructed by fitting its parts together *via* external directed action. In a similar way, molecular functional cooperatives can be produced artificially, and this is the aim of the Abteilung für Molekularen Systemaufbau in the Max-Planck-Institut für Biophysikalische Chemie. Molecules are forced together in a planned way by directed external action. For example, if suitable molecules on the surface of liquids are pushed together, the monomolecular layers thus formed aggregate, to produce the functional cooperative[3]. On the primordial planet the role of the experimentalist is replaced, in a way, by the enormous variety of environmental influences.

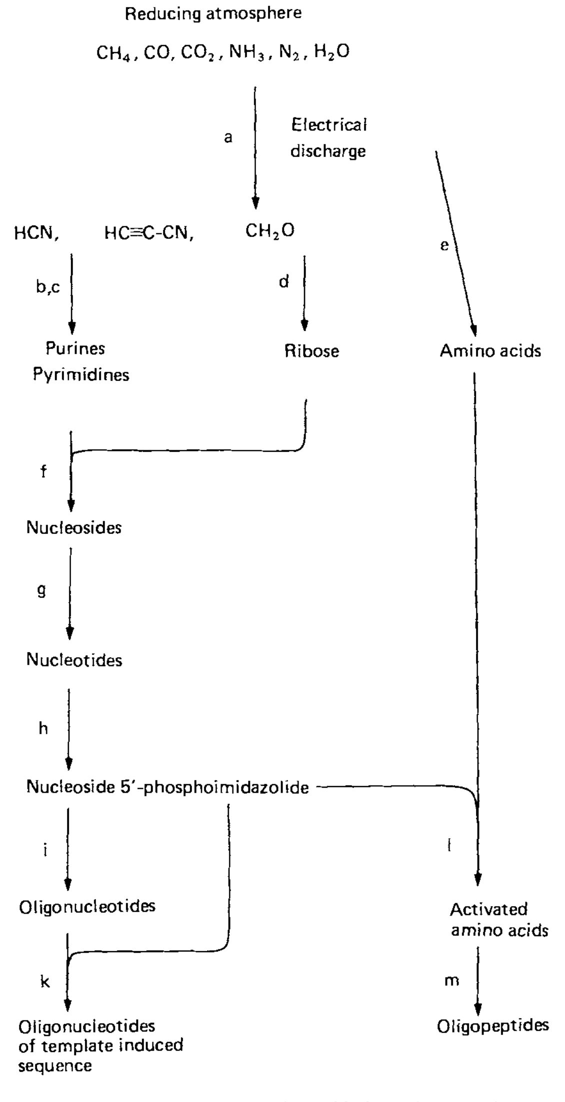
## 3. Some Results of Prebiotic Chemistry

The most important components of our model for the origin and the earliest steps of life are amino acids, ribose, and the nucleotide bases G, C, A, and U. These substances were presumably present on the primordial planet and might have accumulated in particular regions by natural concentration processes, such as evaporation of an aqueous solution and redissolution of the residue, or by adsorption and desorption. Using simulations of conditions thought to have existed on prebiotic earth, many researchers[4-28] have been able to obtain nucleotide bases, sugars, and amino acids from the gases $CH_4$, $CO_2$, $H_2O$, $N_2$, and $NH_3$ which presumably formed the reducing atmosphere of the planet[*]. It has also been possible to demonstrate that these compounds can be made to yield nucleotides

---

[*] It is also quite possible that meteorites, known to contain nucleobases and amino acids, were the initial sources of these building blocks [26—31]. They could have accumulated in particular locations by adsorption and desorption [32].

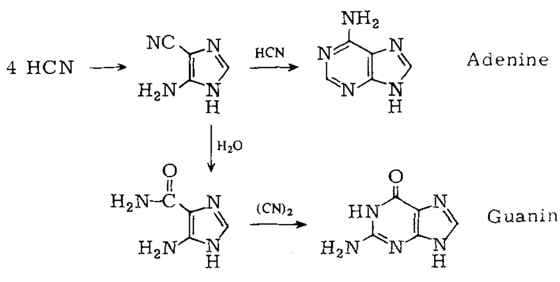
and oligonucleotides, on the one hand, and activated forms of amino acids on the other, under conditions believed to be realistic. Moreover, *Orgel*[21] has recently succeeded in the enzyme-free polymerization of nucleotides on nucleic acid templates, more than 90% of the nucleotides of the replicate strands being complementary to those on the template strands. Some important results of this work are summarized in Scheme 1, in steps a—m.



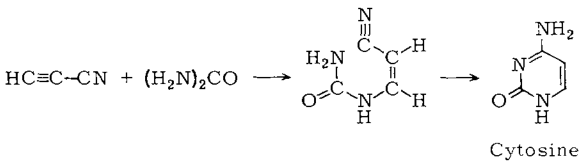
Scheme 1. Possible processes on the prebiotic earth. a) to m) see text.

a) Electrical discharges in mixtures of these gases have led to HCN, $H_2$, $CH_2O$, propynenitrile, and hydrocarbons[4-6].

b) Adenine and guanine have been obtained by cyclic oligomerization of HCN and hydrolysis[7-9].

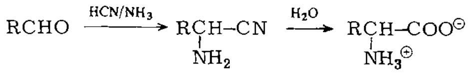


c) Cytosine has been prepared by the reaction of propynenitrile and urea[10].



d) Ribose has been obtained from formaldehyde in the presence of alumina and kaolinite[11].

e) 14 of the 20 amino acids that are protein components could be obtained by electrical discharge and Fischer-Tropsch synthesis in the presence of solid catalysts (nickel-iron, magnetite, clays), and by Strecker synthesis[12-13].

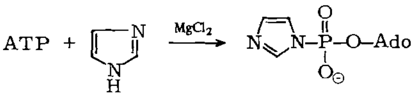


$$\mathrm{RCHO} \xrightarrow{\mathrm{HCN/NH_3}} \mathrm{R\underset{NH_2}{C}H{-}CN} \xrightarrow{\mathrm{H_2O}} \mathrm{R\underset{NH_3^{\oplus}}{C}H{-}COO^{\ominus}}$$

f) Nucleosides have been prepared by the evaporation of aqueous solutions of purines and ribose (or 2-deoxyribose) containing magnesium chloride[14].

g) Heating nucleosides with inorganic phosphates and urea, in the presence of magnesium salts, has yielded mononucleotides (5′-triphosphates). In the absence of $Mg^{2+}$ a mixture of 5′-, 3′-, and 2′-phosphates was produced[15].

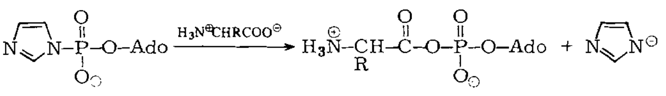
h) Adenosine-(Ado-)oligophosphates such as ATP could be converted into nucleoside 5′-phosphoimidazolides by the evaporation of aqueous solutions containing $MgCl_2$[16].



i) Adenosine and uridine 5′-phosphoimidazolides have been shown to form oligonucleotides with five and more chain members in a reaction catalyzed by $Pb^{2+}$ ions[17].

k) Several cases of template-induced polymerizations of nucleotide derivatives have been observed. Of particular interest are those of nucleoside 5′-phosphoimidazolides, presumed to be available under prebiotic conditions (see h). Guanosine 5′-phosphoimidazolide (ImpG) has been polymerized on a polycytidylic acid template in the presence of $Zn^{2+}$, forming chains of 30-40 members that are predominantly connected in the 3′-, 5′-positions, in an analogous way to the bonding in biological nucleic acids.
When a mixture of ImpC and ImpG and a polycytidylic acid template are used, ImpG (that is, the compound containing the base complementary to the base in the template) is incorporated with high selectivity into the growing strand[18-21].

l) Adenosine(Ado-) 5′-phosphoimidazolide has been demonstrated to form aminocyl adenylates[16].



m) Aminoacyl adenylates have been polymerized in aqueous solution in the presence of specific clays[23-25].

The results in Scheme 1 support the assumption that short strands are able to replicate under special conditions, and it therefore seems promising to search for such conditions. Attempts to achieve template-induced polymerization using deoxyribose instead of ribose were unsuccessful[21], a result that supports the assumed model *i.e.* that the first carrier of genetic information was RNA and that DNA came into the picture at a later stage, when a genetic apparatus for producing enzymes became available.

The results demonstrate that prebiotic synthesis of energy-rich nucleotide derivatives, oligonucleotides, and activated amino acid derivatives required solid-state reactions as well as reactions in aqueous solution and in the gas phase. It is plausible that such substances could have accumulated on primeval earth only in particular locations where a multitude of special conditions were fulfilled, that allowed a succession of very different reactions to occur, requiring highly diversified and structured regions.

## 4. First Steps in the Origin of Life

Chain molecules consisting of two kinds of complementary monomers in a random sequence are considered here as examples of very simple systems with the property of producing copies of themselves. Suppose that such strands may have arisen occasionally by the accidental condensation of monomers. Such strands can then replicate by serving as templates (Fig. 2). Monomers in the solution can attach themselves to complementary monomers along the given strand. The monomers become interlinked and form a second strand, the replicate or (−)-strand. The two strands separate; on the new strand a new replicate forms that is identical with the original or (+)-strand. Repeated strand replication can, of course, take place only with suitable kinds of monomers and requires appropriate conditions, such as highly specific periodic temperature changes. Since the primordial planet exhibited an immense variety of environmental conditions, it is almost certain that the required temperature variations existed in small localized regions.

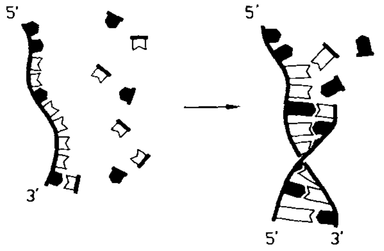


Fig. 2. Replication along a template strand. The template strand and its replicate form a double helix.

We may thus imagine a short nucleic acid strand on primordial earth containing the two complementary bases guanine and cytosine that are anchored together in the strand by ribose and phosphate groups and are capable of interlinking by three hydrogen bonds. It is further supposed that this short strand has diffused into one of the special regions mentioned, after having been formed elsewhere by accidental condensation during the drying of a solution of monomers. In this strand, all of the monomers are presumed to be linked in such a way that the strand can serve as a precise template for replication, the chain members being associated by 3′5′-linkages. During replication, a double helix is formed, as in all nucleic acids present in biosystems. The special aspects of such a template strand are that its monomers are spatially situated in a way that is appropriate for the attachment of replicate monomers, which are then in a favorable position to interlink into the daughter strand. A helical arrangement favors rapidity and precision of chain replication, because the environment of each new building block that is to be attached is the same as that of the preceding block, resembling the situation of a sequence of steps in a spiral stairway. The bases of neighboring nucleotides along the template and growing daughter strands are stacked, increasing with each added nucleotide the energetic stability of the growing double helix that involves interaction between solvent molecules as well as the stacked bases. The template-directed polymerization runs along the 3′5′-direction of the template strand, while the direction of the daughter strand is in the opposite sense, its 5′-end being at the 3′-end of the template strand.

All of this requires monomers of the same chirality. It is accidental which chirality the original strand has, since the process would work just as well if the mirror images of all monomers were used. However, the appearance of an appropriate template strand is decisive for the chirality of all subsequent daughter strands. Hence, it is not surprising that the chirality of the building blocks in all living systems of a given kind is the same.

By considering a solution of the different monomers that may have existed on earth at the location considered (see[2] Section 18.1.4.1.), it is possible to estimate the probability with which the very special original template strand can be formed through accidentally correct condensation. In this way, the plausibility of such a step can be justified for strands containing, for example, ten monomeric units. There should be one correct strand in approx. 0.1 mmol of strands of randomly condensed monomers, *i.e.* in one of $10^{20}$ strands (cf. also Section 17). For longer strands the probability that all monomers are linked in the correct way is much smaller, so that model considerations must begin with short strands.

The probability of the spontaneous appearance of a correct strand of 10 monomers may be compared with that of obtaining an unbroken sequence of 26 sixes when throwing dice. The latter probability is $(1/6)^{26}$ or also about $10^{-20}$. The example may clarify the proposition that by trying one's luck with a sufficient number of dice even such an exceedingly improbable event can be made to occur with near certainty. Thus, when $10\times6^{26}=10^{21}$ dice are used simultaneously the event is expected to occur for about $10^{-20}10^{21}=10$ dice. It can therefore be assumed with a probability close to unity that at least one of the dice used shows a six in each of 26 successive throws (more exactly with a probability of $1-[1-(1/6)^{26}]^{10\cdot 6^{26}} \simeq 1-(1/e)^{10} \simeq 0.99995$).

By continued replication many such strands are formed, once an appropriate template strand has arisen and has accidentally diffused into a favorable location in which the conditions required for replication prevail. Disregarding processes of loss there should be 2 strands after one generation, $4=2^2$ strands after 2, and $2^n$ strands after n generations. Eventually, a stationary state is reached in which as many strands are created by replication as disappear by losses *e.g.* by strand diffusion from the favorable region.

## 5. Barrier Caused by Too Many Errors

Every so often, strands become lengthened by the accidental condensation of two short strands. This can readily occur, in contrast to the spontaneous formation of a longer strand by the direct linkage of monomers. Longer strands diffuse more slowly and thus have better chances to stay in the favorable region than short ones. As time passes, ever longer strands are made and the shorter ones disappear. However, with growing strand length the probability increases that, during replication, a monomer is built into a "lethal" daughter strand, preventing renewed replication of the new strand, *e.g.* because some monomer contains an incorrect sugar. Hence there is an upper limit to feasible chain length extension and as shown by quantitative considerations this is reached with about 50 monomers (see [2], Section 18.1.4.1. therein).

It can also happen that a non-complementary nucleotide (*e.g.* G instead of C) is incorporated as monomer during replication. The new strand can still be used as a template for replication, but its nucleotide sequence is different from that of the parent strand. In time, strands with all possible sequences are therefore formed.

Strands may fold into specific conformations by internal pairing of complementary bases, provided the base sequence is appropriate[*]. Such conformations can confer selective advantages upon existing *forms*, as the common aspects of similar strands will be called. Some conformations make strands resistant against chemical attack, for example, by the mutual protection of adjoining regions. However, any given conformation, such as that of a partial hairpin (Fig. 3), is tied to an exact sequence of nucleotides and is therefore lost by almost any new error. If a favorable folding conformation has arisen, by accident, it is soon lost because of the high level of replication errors with 50 monomers, the approximate number for any reasonable sophisticated folding conformation.

The model thus leads to difficulties at this point. An insurmountable limit of the amount of information that can be transferred by replication appears to have been reached. It is hard to see how an accumulation of errors can be avoided in such first self-reproducing systems, how a form does not "forget" what it has "learned".

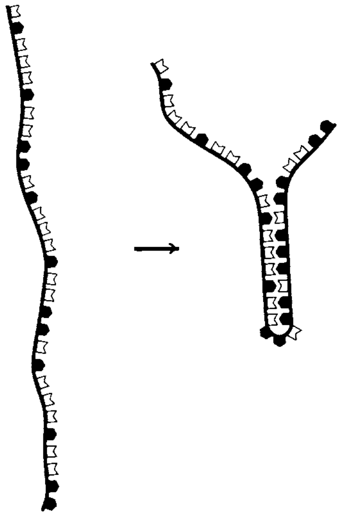

Fig. 3. Nucleotide sequence that permits a partial hairpin conformation.

## 6. Faulty Replicates Rejected During Aggregate Formation

This barrier can, however, be surmounted by a very simple mechanism that nonetheless has far-reaching consequences within the model. Consider a strand, that is capable of assuming the conformation of a hairpin along its entire length, with the hairpin bend at the middle of the strand because of an appropriate sequence of nucleotides (Fig. 4). A strand that arises by the template replication of

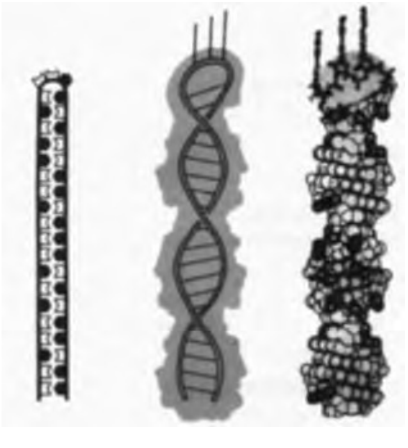

Fig. 4. Left: Possible arrangement of bases G and C that permits a hairpin conformation along the entire strand. The supposition that early strands contained, mainly or exclusively, just these two nucleotides is made plausible by comparative studies of nucleotide sequences of different transfer ribonucleic acids by *Eigen* and *Winkler* [41]. Middle: Schematic drawing of hairpin strand conformation in which the "legs" of the hairpin form a double helix. The outline is that expected for the van der Waals radii. Right: Molecular model of hairpin strand. For clarity the upper portion is shown as a ball- and stick model, the lower portion as a space-filling model. Double helix is left-handed as recently found by *Rich et al.* [35] and *Dickerson et al.* [36] in an X-ray crystal analysis of guanine-cytosine oligonucleotides, and by *Arnott et al.* [37] in GC DNA fibers. A left-handed double helix had been discussed by *Pohl* and *Jovin* [38] as the result of a phase transition at high salt concentration.

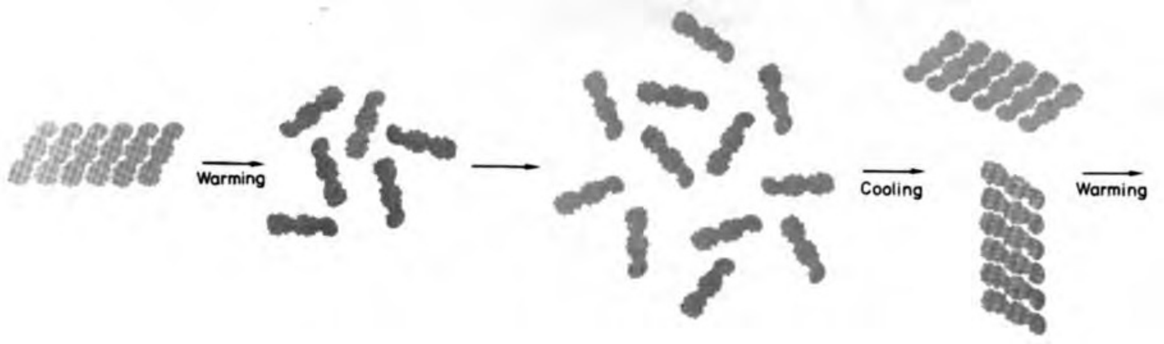
---

[*] For transfer RNA, such conformations have been established by X-ray structure determinations [33]. The melting of different regions of single strands, upon temperature increase, has been investigated by examining high-resolution $^1$H-NMR spectra that reveal gradual transitions from folded to unfolded conformations [34]. Upon cooling, the original folding conformations establish themselves error-free. The change between the unfolded single-stranded and the double-stranded forms of nucleic acids occurs between about 30 and 100 °C, and one may count on the existence of such temperatures on prebiotic earth.



a hairpin is automatically capable of again assuming a hairpin conformation (cf. Fig. 13). From detailed examinations of space-filling models it turns out that in a suitable medium, such hairpin strands can form aggregates with amazing precision (Fig. 5). The precision of aggregation is such that faulty hairpins are rejected during aggregate formation, so that in this way an all-important error-filtering mechanism is brought into being. The aggregates may be stabilized by suitable bivalent cations, such as $Ca^{2+}$ ions, that hold together negatively charged phosphatidyl groups on the outside of neighboring hairpin strands. The number of monomers considered to comprise such hairpin strands roughly corresponds to that of today's transfer ribonucleic acids (70—80 monomers), a point that is significant and to which we will return.

Fig. 5. Aggregation of two convoluted hairpin strands.

The survival chances of strands in an aggregate are increased by their mutual protection against chemical attack, or because it may be less easy for aggregated strands to leave the favorable region. Aggregates may undergo self-reproduction. Suitable temperature and other environmental changes may cause their disassembly into component strands. The individual strands may replicate and again assume folded conformations. They are thus able to diffuse and again aggregate through favorable accidental collisions, hence, increasing the number of aggregates. All of this requires a very specific and highly detailed program of temperature changes that must be periodically repeated for repetition of the process described. Convolution of strands and aggregation are favored by cooling, disassemblage of aggregates and deconvolution of strands by warming. However, a myriad of cyclic temperature programs existed on the primordial planet (Fig. 6), and it is almost certain that an appropriate program was realized at least once, in a region that need not have been larger than about 1 mm across (see [2], Section 18.1.4.2).

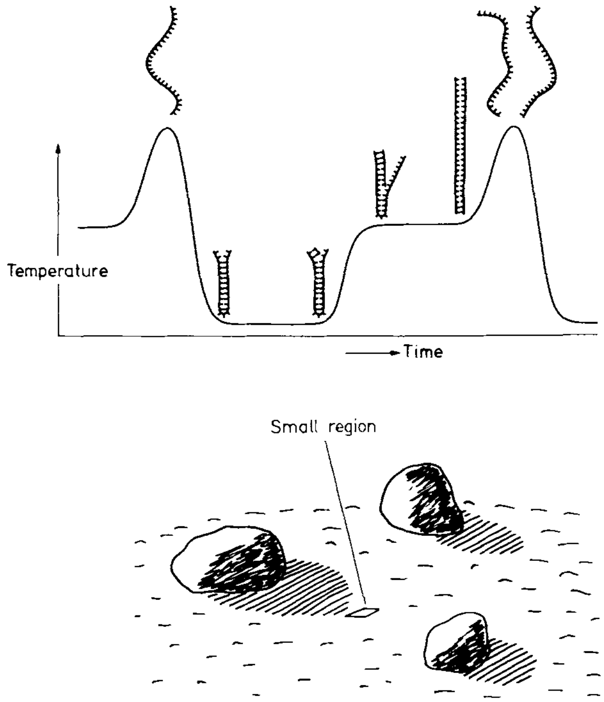


Fig. 6. a) Multiplication of aggregates by disassembly into strands, replication of the strands, and reaggregation. b) Schematic temperature variation required for strand replication. At the highest temperatures the strands are uncoiled. As the temperature decreases, internal base-pairing occurs and the strands convolute, taking up *e.g.* the conformation of a hairpin. In this conformation, replication could only start at an end of the hairpin and progressed from there as the temperature rose and internal base pairing began to weaken. The aggregation of convoluted strands and the later disassembly of aggregates requires an additional superimposed cyclic temperature variation. c) Realization of periodic changes in temperature by shadow-casting rocks in a region of small linear dimensions (*e.g.* 1 mm). The rocks are immersed in a broth of energy-rich monomers.

It is of importance that the component strands do not diffuse too far from each other during the multiplication phase, because they would be lost and reaggregation could no longer occur. The phenomena discussed must therefore have taken place in a confined space, such as in small pores of a rock formation. The pore walls kept the strands together during their diffusion, so they were able to locate each other again and could form new aggregates. The rock formation is presumed to be inundated by a solution of suitable energy-rich monomers that could easily diffuse through the pore channels, while the strands formed were largely retained by them (Fig. 7). Neighboring pores are invaded by strands, and the descendents of the aggregates formed in the original pore slowly spread through the porous material. Detailed considerations lead to a pore diameter of about 500 *nm* or 5000 Å (see [2], Section 18.1.4.2d). For purposes of comparison, this is of the order of magnitude of a bacterium.

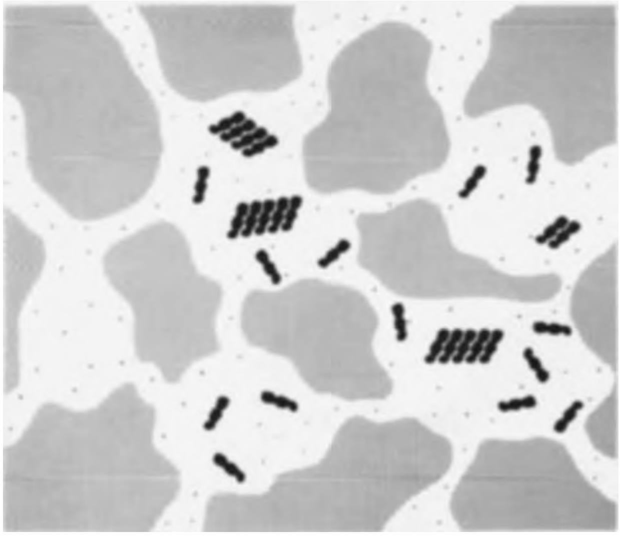

Fig. 7. Pores with channels, into which monomers can readily diffuse while strands capable of forming aggregates and serving as templates for replication are mostly held back.

Aggregates such as those described, offer crucial selective advantages because they are capable of invading larger pores than single strands. Additionally such advantages would result from machinery that facilitated the assembly of convoluted strands into aggregates. Both the disassembly of aggregates and their later reassembly must have come about easily and quickly. Linear aggregates consisting of essentially identical component parts are especially favored by these requirements, because they can fall apart suddenly (as would not be the case for three-dimensional aggregates), and any one of the component parts can reaggregate with any other one. The requirements would be met by the aggregates of hairpin strands just discussed.

## 7. The Assembler

A large selective advantage would be inherent in machinery that speeds the assembly of convoluted hairpin strands. A model of a simple mechanism, that would serve this purpose, consists of an extra unfolded strand that has become attached to one of the hairpin strands (Fig. 8, left). The extra strand is assumed to be capable of acting as a *collector strand* that guides other hairpin strands to the location of growth of the aggregate; in essence, the collector strand converts the spatial diffusion of folded strands to be aggregated into a one-dimensional diffusion along the open strand (Fig. 8, middle). They may, for example, migrate from one place of attachment on the collector strand to the next. The carrier of the collector strand acts as an initial *nucleation site* in the formation of the picket fence-like aggregate, serving also as its endpost (Fig. 8, right). The orientation of the hairpin strand forming this endpost is opposite to that of the other hairpin components of the aggregate.

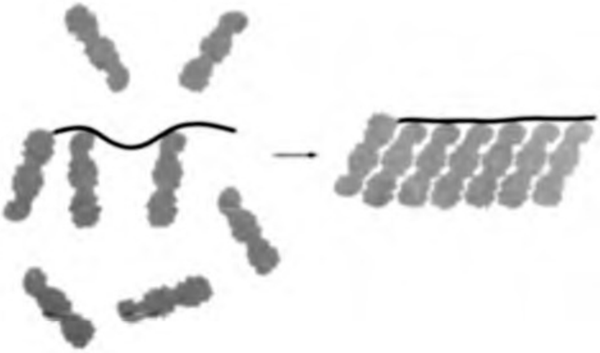

Fig. 8. Mechanism facilitating the aggregation of hairpin strands. Left: The hairpin strand on the far left is turned upside down and has an unfolded strand attached to it that can function as collector strand. Right: Picket fence-like aggregate formed in this way.

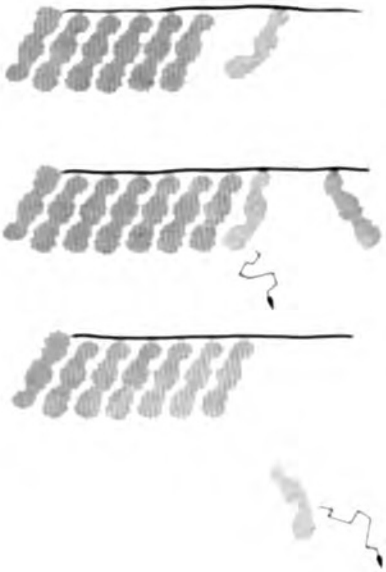

Fig. 9. Mechanism facilitating aggregation acts as an error filter. Top: Strand with error that convolutes to faulty hairpin which diffuses along the collector strand. Middle: Faulty hairpin does not fit into the aggregate and is rejected, a correct copy taking its place (bottom).

Figure 9 shows, in detail, how the aggregate formation by the *assembler* just described causes the all-important rejection of erroneous copies and in this way prevents the accumulation of replication errors. The consequence of this error-filtering action is that the hairpin components of an aggregate are essentially error-free. Without it, a hairpin formed by accident would lose the information "hairpin" within a few generations. The components of an aggregate "co-exist" in this sense; they form a functional cooperative that survives or dies as a whole and that evolves as an entity.

In the proposed *molecular* model the hairpin strands are attached to the collector strand by base-pairing of triplets of complementary nucleotide pairs, as shown schematically (Fig. 10). The model exhibits an astonishingly precise fit between neighboring hairpin strands (Fig. 11 and 12).

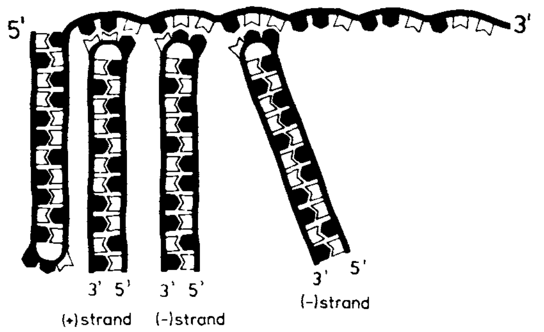

Fig. 10. Details of base pairing in aggregate being formed. Note attachment of hairpin strands to collector strand by triplets of complementary bases.

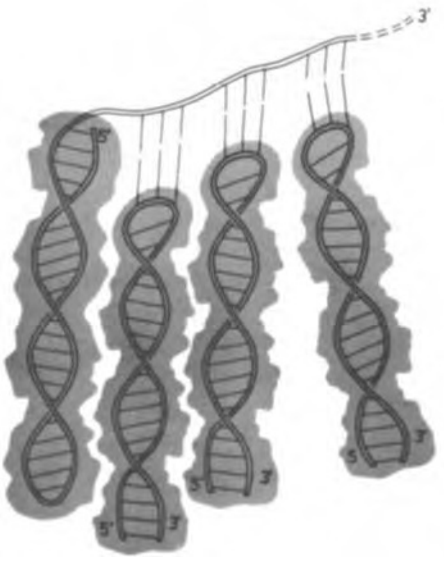

Fig. 11. Spatial arrangement of strands shown in Fig. 10. Hairpin "legs" are twisted into double helices and outlines are as expected for van der Waals contacts.

Equally precise is the fit among the stacked bases in the triplets of complementary base pairs just mentioned. The excellent fit shown in the figures appears to be ruined in models in which the hairpin strands are attached by more than three bases to complementary bases on the collector strand. On the other hand, at least three nucleotides are needed to form the 180° bend of a hairpin. Finally, there is an excellent fit between the hairpin strand of opposite orientation at the beginning of the aggregate and the first hairpin strand adjoining it. All fits appear to require that the 3'5'-strand directions are as indicated in Figure 10.

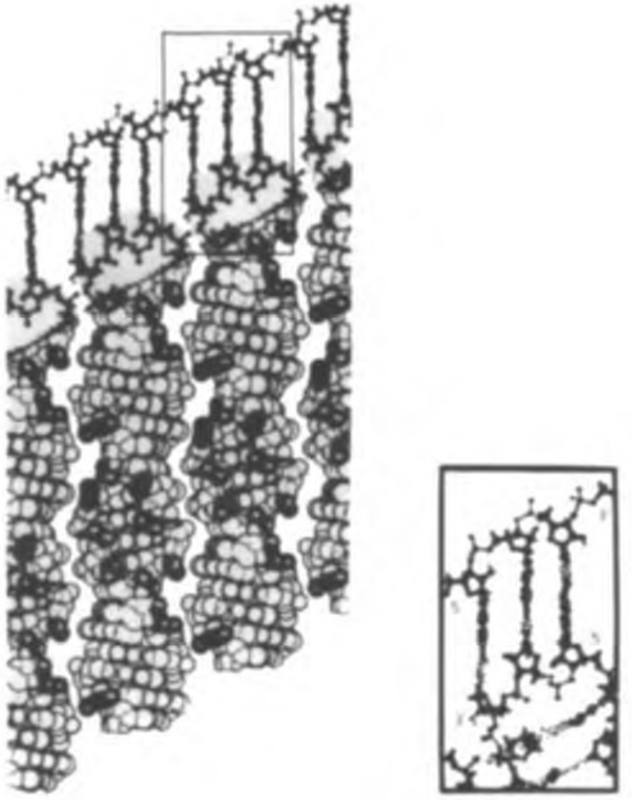

Fig. 12. Details of the excellent fit between the different hairpin strands in a picket fence-like aggregate and between the base triplets at the hairpin bends and complementary triplets along the collector strand (inset). No equally good fits seem to be possible with hairpin strands in the usual right-handed helical conformation.

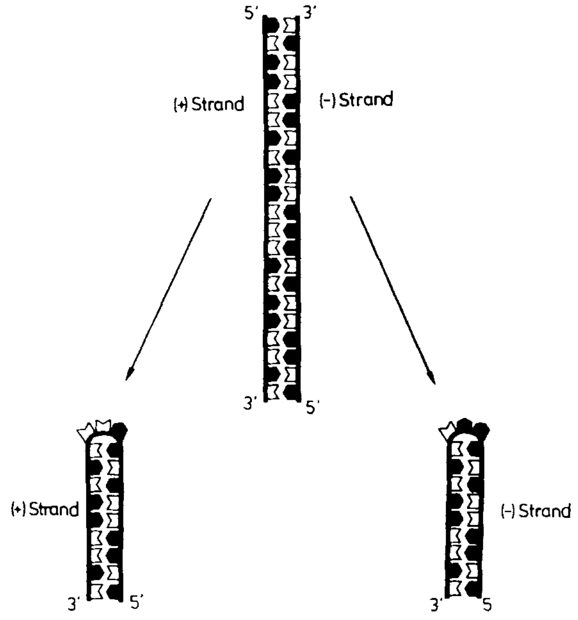

Fig. 13. (+)- and (−)-hairpin strands. Middle: Upon completion of replication, with bases paired. Left: (+)-Strand in hairpin conformation. Right: (−)-Strand in hairpin conformation.

An important feature of this model is that both (+)- and (−)-strands can be used as components. This feature permits great economy in the use of strand material and in the assembly of aggregates. Except for the bases in the middle, which are complementary to each other, the (+)- and (−)-strands are identical (Fig. 13).

The nucleotide in the first position of the triplet at the hairpin bend could, for example, be C in (+)-, as well as, (−)-strands; in the third position it then has to be G in both strand types. At the corresponding first positions of the collector strand there would then always have to be G and at the third positions C. The midpositions can be randomly occupied by G or C. If a midposition of the collector strand contains G, then a (+)-strand can attach itself, and in the other situation a (−)-strand. In this way, a simple "reading frame" would be established. A "word" on the collector strand would always begin with G and end with C.

The bonding energies of base pairing are insufficient at room temperature to establish stable bonding between two triplets of bases. It is therefore reasonable to imagine that a hairpin strand is first attached only very loosely to the collector strand. Each newly acquired hairpin strand can then move back and forth along the collector strand until it reaches the growth region of the aggregate, where its attachment is stabilized by close fit to the hairpin strand preceding it on the aggregate. The model therefore permits the postulated one-dimensional diffusion along the collector strand. The new hairpin strand is firmly incorporated if its triplet contains the appropriate bases that must be complementary to the corresponding bases on the collector strand; it is discarded if this is not the case. Each newly incorporated hairpin strand provides additional stabilization to the portion of the aggregate that already exists. If this mechanism is to function as described, the binding energy for the lateral interactions between a newly incorporated hairpin strand and the one preceding it must be approximately equal to the binding energy of its base triplet and the corresponding triplet on the collector strand. If this energy were smaller, there would be no firm incorporation at room temperature. If it were larger, any hairpin strand would be firmly incorporated regardless of whether its base triplet were complementary to the corresponding triplet on the collector strand or not.

The direction in which the triplets are read along the collector strand is the same 5′3′-direction in which today's genetic blueprint, the strand of messenger ribonucleic acid, is read. Similarly, the triplets of the hairpin strands of the aggregate are in the opposite 3′5′-direction, as are the anticodon triplets of today's transfer ribonucleic acids. It is quite striking that the excellent fit of the hairpin strands in the aggregate is just as one would wish from the model, and it is therefore easy to imagine that the collector strand is the primordial form of today's messenger ribonucleic acid. The hairpin strands would be the primordial forms of the adapter or transfer ribonucleic acid molecules mentioned at the beginning. As mentioned earlier, they would contain about the right number of nucleotides. The aggregates would represent the primordial forms of the translation apparatus.

The experimental realization of such aggregates is of considerable importance, and the search for conditions (high ionic strength or suitable solvent) that would favor the folding of strands of GC ribonucleic acid into the hairpin conformation of our model, the *Arnott-Rich-Dickerson* left-handed double helix would be of interest[*]. The conditions (strand length and medium) must be chosen in such a way that stabilization by the lateral fit of neighboring hairpin strands would be of exactly the correct magnitude. Under these circumstances formation of the described aggregates is predicted[**]. It can also be imagined that the interlocking of just two hairpin strands and their attachment to the collector strand results in an aggregate of sufficient stability to facilitate further aggregation. The nucleation center at the end of the collector strand would then be unnecessary and could be omitted. Such systems would also represent fruitful research targets.

The view that the collector strand is the primordial form of the carrier of genetic information is supported by sequence analyses of the DNA of viruses, procaryotes, and eucaryotes by *Shepherd*[40]. The clear periodic correlation found, indicates that the reading frame PuNPy (Pu = purine, like G; Py = pyrimidine, like C; N = purine or pyrimidine) originally existed, vestiges of which are still in evidence.

The concept that the hairpin strands are the primordial forms of transfer ribonucleic acids is supported by the most recent studies of *Eigen* and *Winkler*[41], who have found a great similarity in the sequences of the different transfer nucleic acids they compared. These findings led them to an *ancestral* sequence that is therefore derived from empirical data. It exhibits a certain symmetry in the sense that it permits a strand with this sequence to convolute into a hairpin conformation (or into the cloverleaf conformation considered by *Eigen*). This result makes the model so far described even more attractive, but the question still remains as to how the machinery described could undergo the astonishing transformation into an apparatus capable of translating nucleic acid sequences into amino acid sequences or proteins.

## 8. Catalytic Activity of Aggregates

Let us proceed to develop the model further and see where our considerations lead. How could the aggregates

---

[*] Recently, *J. H. von De Sande* and *T. M. Jovin* of the Max-Planck-Institut für Biophysikalische Chemie, Göttingen, have found evidence of a conformational change in GC ribonucleic acids, that suggests a transition to a left-handed helix, as postulated. In an aqueous solution of GC-RNA, containing $NaClO_4$ and 20% ethanol, a concentration increase of the salt from 4.8 mol liter$^{-1}$ to 6 mol liter$^{-1}$ causes a change in the sign of the circular dichroism (DC) maximum at 284 nm (from + to −), while the maximum is shifted to 294 nm. The CD spectrum of GC-RNA at the higher salt concentration is very similar to the spectrum of the left-handed *Arnott-Rich-Dickerson* form of GC-DNA. The change in conformation is associated with a marked increase in tendency towards aggregation just as would be expected on the basis of our model (personal communication). In the methylated polynucleotide (poly(dG-m$^5$ dC) the transition into the left-handed helix conformation can be induced at a $Mg^{2+}$ concentration three orders of magnitude lower than that required for the unmethylated polymer, *i.e.* close to usual physiological conditions (*M. Behe* and *G. Felsenfeld*, Proc. Natl. Acad. Sci. USA *78*, 1619 (1981)).

[**] Current views of possible DNA and RNA double helix conformations and their dependence on the nucleotide sequences are still in considerable flux and further stable conformations may well be found (cf. *e.g.* the DNA conformation recently proposed by *Hopkins* [39]). What is of importance to our model is the close fit of neighboring hairpin strands, and it makes no difference whether a good fit can be achieved by left-handed or right-handed double helices or by yet another conformation.

consisting of collector strand and hairpin strands develop catalytic properties for use in protein synthesis?

It was noted earlier that errors in the nucleotide sequence of a hairpin strand can affect its conformation and in this way prevent it becoming part of an aggregate (cf. Fig. 9). However, not all errors are important in this regard, only those that affect lateral contacts between neighboring strands in an aggregate. Errors at the hairpin ends are of little or no consequence with regard to aggregation, and these ends can easily open-up when replication errors disturb the pairing of the first and last two bases (Fig. 14).

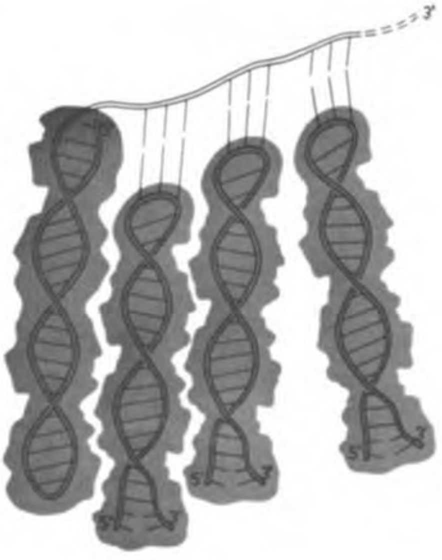

Fig. 14. Hairpin strands in which the last few bases at the strand ends are not complementary and for this reason are not paired. The open hairpin ends do not affect the precision with which the hairpin strands fit together in the aggregate.

In fact, even in the earliest hairpin strands these ends could have remained open: Open ends would only be of help in permitting the start of replication at a strand end (cf. Fig. 6b), and would impart selective advantages upon such strands by preventing the confusion that would arise if strand replication began simultaneously in several locations.

We now postulate that amino acids, linked to appropriate activating groups, became attached to these open ends. The existence of amino acids on the primordial planet can readily be assumed, because they are easily obtained in simulations of prebiotic conditions (Section 3). Once attached to the hairpin ends of an aggregate these amino acids are assumed to readily form mutual polypeptide bonds, being held in close proximity by the hairpin ends and satisfying other steric conditions. The polypeptide chains formed are then released and the entire process repeated (Fig. 15).

In our model, polypeptides consisting of glycine and alanine, the two amino acids that are produced in the largest amounts in prebiotic simulations, bestow great advantages upon forms producing them: Being hydrophobic and capable of agglomeration they formed impediments in pore channels and in this way slowed down diffusion, making possible the colonization of pores with wider channels

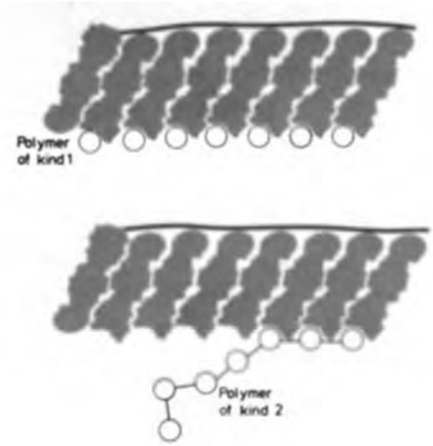

Fig. 15. Catalysis of polypeptide formation. Top: Hairpin ends exhibit an affinity towards activated amino acids that, once attached, can form polypeptide bonds. Bottom: The completed polymer is released.

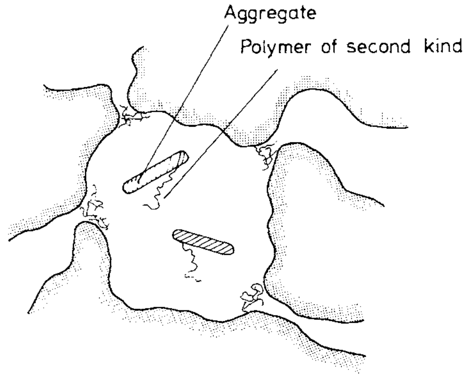

Fig. 16. Polypeptides serving as impediments to diffusion in pore channels.

than before (Fig. 16). At a later stage, they coalesced into some sort of "cellular" envelopes that again furthered the propagation of forms producing them (Fig. 17). The envelopes presumably acted as nets, allowing mononucleotides to enter and preventing nucleic acid strands from leaving[*]. This requirement can be fulfilled by agglomerated polypeptides, but not by lipids, which therefore are expected to be useful and to become cell membrane constituents only at the time a specific semipermeability is required[**].

---

[*] The significant function of a polymer envelope as a barrier against diffusion has already been recognized by *Oparin* [42], who investigated coacervates. Coacervates form a pre-existing structure, as is the case for the porous rocks in the present model. Note, however, that in our model the polymer envelopes have the function of liberating the evolving system from the pre-existing porous structure. Their position in the logical framework of our model is thus completely different from that of the coacervates in *Oparin*'s picture. If one assumes (together with *Oparin*) that polypeptide envelopes were available even at the beginning, then no selective advantages would have accrued in aggregates that might have accidentally arisen with catalytic properties towards the formation of envelope components. No selective pressure in the direction of envelope producing systems would have existed in such a situation.

[**] The polypeptide envelope could also be endowed with certain catalytic properties towards the hydrolysis of nucleic acid strands, accelerating the degradation of erroneous copies that are not included in aggregates. The liberated mononucleotides would be available for strand synthesis and selective advantages would be gained.

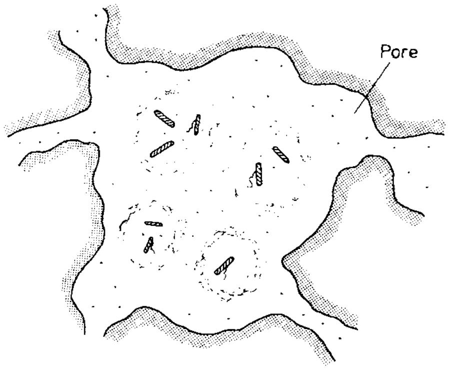

Fig. 17. Polypeptides serving as "cellular" envelopes.

Note that the formation of stable structures such as impediments and envelopes requires monomers, such as amino acids, with properties that differ from those of the monomers that make up the strands. The reason is that these structures must remain intact during the environmental changes that drive the replication of aggregates and strands.

Any change that permits a liberation from the region of small pores, increases the possibilities for multiplication because the changed form does not face competition in the new region. This effect, the advantage of the more complex form in the colonization of new domains, leads to continued evolution in the direction of more complex forms. The increase in refinement of evolving forms is a necessary consequence of the variety and the multi-faceted wealth of environmental conditions. Without such variety, no selective gradients would have existed and there would have been no evolution.

## 9. The Translation Apparatus

The evolution of polypeptides, that serve as impediments and later as envelopes of increasing complexity, leads to another important development. To see this, it should be remembered that both (+)- and (−)-hairpin strands, both of which are always present, can be built into the aggregate side by side. The two strand types are identical except that they have complementary bases in the midposition and in corresponding positions at the ends of the strands (Figs. 13 and 18). If the ends of a (+)-strand are occupied by the bases G, for example, then there must be bases C at the ends of a (−)-strand. The two kinds of strands could then have different affinities for two kinds of activated amino acids. At the same time, the two kinds of strands have different bases in the midposition in the middle of their anticodon triplets. In this way an automatic correlation would exist between amino acids and bases in the middle of the anticodon triplet, and as a consequence of this, a correlation between the sequence of nucleotides on the collector strand and that of amino acids in the polypeptide. The hairpin strands would serve the function of adapter molecules.

A possible explanation of how a specific linkage of an amino acid to a nucleotide could have arisen is illustrated for (+)-strands at the very bottom of Figure 18. The amino acid $a_1$ is activated by a purine nucleotide (G) (cf. Scheme 1, step 1). Intercalation and complementary base pairing would then mediate specific linkage and place the amino acid in such a position that reaction with the 2′-OH group of the ribose of the terminal nucleotide of the strand could occur. Our molecular model shows that the whole sequence of steps described would be sterically quite plausible, permitting reaction with the 2′- as well as the 3′-OH

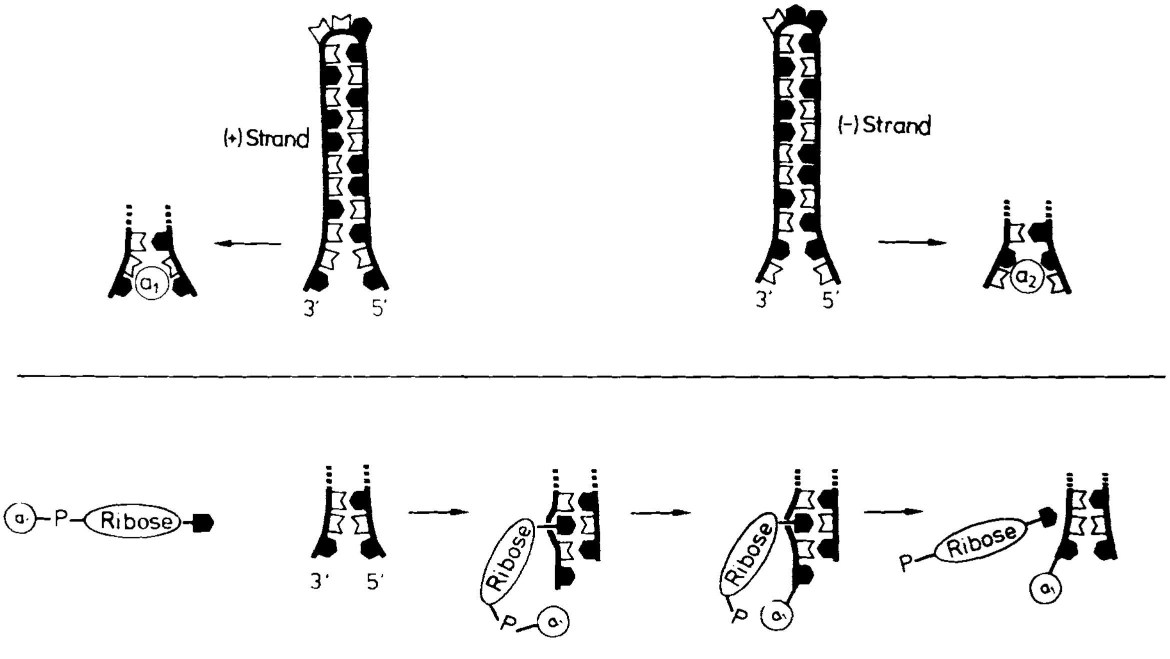

Fig. 18. (+)- and (−)-hairpin strands as adapters for amino acids $a_1$ and $a_2$. Note that the two strands are identical expect for the nucleotides in the middle and the ends of each strand. Top (left and right): Attachment of amino acids in highly schematic view. Bottom: possible mode of attachment of an amino acid $a_1$ that has been activated by a purine nucleotide to the end of a (+)-strand.

group of the ribose in question. This would correspond to the same linkage that is found in today's charged tRNA. Amino acid $a_2$ could be activated in a corresponding way by a pyrimidine nucleotide (C) and then linked to the terminus of a (−)-strand. A specific enrichment in activated amino acids in special locations of the prebiotic planet can readily be imagined[*].

The nucleotide sequence on the collector strand changes slowly with time, and periodically a sequence can occur that corresponds to a polypeptide exhibiting traces of enzymatic properties, which acts as a primitive *"replicase"*, *i.e.* as an enzyme that accelerates replication and reduces the number of replication errors. This primitive replicase would have to decrease the frequency of these errors sufficiently, so that the information coding for it would not be lost during the number of generations required to fix it by selection. Without replication, improvements of this kind would be "forgotten" by the form within a few generations.

A quantitative estimate shows that these conditions can be achieved even by quite weak enzymatic activity. For example, if the survival rate is increased by just 10% by the advent of a "replicase" consisting of ten amino acids, a reduction of the replication error rate per base from 1/100 to 1/300 is sufficient for fixation by selection (see [2], Section 18.1.4.3).

It can be imagined that such replicase activity can be achieved, for example, by a short polypeptide that fits into a notch of a double helix which exists in the region where the new strand is formed during strand replication, and which slips along in the notch, remaining in the region of replication as the new strand is lengthened[**]. Its presence would stabilize the double helix conformation during replication and improve the contact between the two strands in that region. Replication would be accelerated and there would be fewer errors in base pairing during replication.

If the conditions for the formation of the aggregates described were known, attempts could be made to produce the postulated polypeptides from activated glycine and alanine or perhaps from two other amino acids. Once the circumstances of aggregation and template-directed strand synthesis are understood, they could be used to formulate an appropriate periodic temperature program that could be used to direct the reproduction of aggregates, with a view to the gradual appearance of a replicase.

The attainment of a replicase represents a major breakthrough; the development of machinery for reading and translating a code. It permits the evolution of systems with further enzymes. Progress could now proceed at a rapid pace. Additional bases and positions in the codon triplet became incorporated into the code and the code translator became more sophisticated. No difficulties arose in this regard in computer simulations in which codes first for two, and later for up to six amino acids were allowed to evolve[44]. Cooperation develops between the different components inside the envelope, and the whole grows into a functional cooperative. The evolution of ever more refined replicases permits the genetic transmission of ever larger amounts of information between parent and daughter systems.

This, in principle, is the answer to the question posed originally of how a translation apparatus, that consists of translation products, could arise. In our model a very simple process is decisive; the astonishingly precise fitting together of building blocks consisting of a nucleation unit, a collector strand, and hairpin adapter strands.

## 10. Further Details of the Primordial Translation Process

Even the earliest concept of the present model of a translation apparatus[1] at first featured the middle position of the nucleotide triplet used in the attachment of the collector strand as the only position employed for coding. If it is further assumed that, in the beginning, only the bases G and C were used in strand nucleotides, then the first and third bases of the anticodon triplets mentioned would always be G and C, respectively, or reversed C and G (because of the symmetry properties of (+)- and (−)-hairpin strands discussed earlier). These two positions would thus, at first only have been used to fix the "reading frame" for code triplets. The actual code words for amino acids would then either have been CCG and CGG, or GGC and GCC. *Eigen* and *Schuster*[45] have opted for the second possibility, since GGC codes for glycine in all biological organisms, and GCC for alanine, the two most prominent amino acids of prebiotic chemistry. A reading frame of the form PuNPy is also favored by *Shepherd*'s results mentioned in Section 7[40]. After the invasion of the midposition by A and U, the triplets GAC and GUC became available. These triplets code for aspartic acid and valine, respectively, also among the most abundant amino acids in simulations of prebiotic terrestrial conditions. Aspartic acid is hydrophilic and it can well be imagined that with its availability the development of polypeptides with enzymatic activity became possible.

*Crick, Brenner, Klug,* and *Pieczenik*[46] have developed a model of an early primordial translation apparatus, that also consists of a strand of messenger RNA and adapters; however, they have not indicated how such an apparatus might have evolved. The difficulty that three base pairs are insufficient for stable attachment of adapters to a messen-

---

[*] Aside from chemical differences that may cause one kind of amino acid to be activated by a purine nucleotide and another by a pyrimidine nucleotide, physical differences between the activated molecules may also exist. It is conceivable, for example, that there is little difference between the two modes of activation of a given amino acid at the site at which activation takes place, but that separation of different species occurs by a physical effect, *e.g.* by differences in chromatographic properties. It can readily be imagined that a mixture of activated amino acids is adsorbed on a substrate such as montmorillonite clay and then eluted by an aqueous solution of inorganic salts, separate zones being formed with $a_1$-G in one location, $a_1$-C in another, *etc.*; the zones serving as physically separated reservoirs of activated species. The pores in which the crucial action takes place would then be in the vicinity of suitable reservoirs, so that *e.g.* $a_1$-C and $a_2$-G would be able to trickle into the porous region. It is easy to separate nucleotides in cationic as well as anionic exchange columns, using aqueous salt solutions as eluants [32].

[**] Investigations of specific binding of proteins on nucleic acids have shown that a section in a polypeptide of, say, ten amino acids can form a two-stranded antiparallel β-sheet that fits into the groove of a double helix [43]. It would be of great interest to search for Gly-Ala-polypeptides with, for example ten amino acids that facilitate a template-directed polymerization of nucleic acid strands and act as primitive replicases in this fashion.

ger strand is overcome in their model by postulating that five base pairs are used in the bonding and are, moreover, involved in a flip-flop mechanism actuated by the state of bonding into a polypeptide of the attached amino acids. (This model was discussed and modified by *Eigen* and *Schuster*[45].) There is no evidence that a similar mechanism is involved in present-day ribosomes[47]. The difficulty that three base pairs are insufficient for stable attachment is overcome in our model by the inter-linkage of neighboring adapters in the picket fence-like aggregate; an interlinkage that contributes decisively to the stability of this cooperative system of close-fitting components (cf. Section 7).

## 11. Ancestral and Primordial Sequences

The important results of *Eigen* and *Winkler*[41] on the sequence analysis of known tRNA's were used in Section 7 to support our model considerations. Their analysis established a probable common *ancestral sequence* of all transfer ribonucleic acids (Fig. 19). Two nucleotides U in positions 60 and 65 and one of the three nucleotides C in positions 61—63 were deleted here to improve the complementary base pairing in the hairpin conformation (*Eigen* and *Winkler* preferred to delete the C triplet, just mentioned, as having probably been added at a later time). *Eigen* and *Winkler*[41] attempted to derive an even earlier *primordial sequence* from this ancestral sequence by assuming that the template coding for the very first polypeptide was identical with the original adapter subunit, the primordial transfer ribonucleic acid. They thus obtained their primordial sequence by changing the ancestral sequence in such a way that along the entire strand, read in the 5′3′-direction, there is a sequence of guanine-N-cytosine triplets (where N denotes any one of the four bases). In Figure 19, these triplets are indicated by brackets; purines (G or A) are shown by filled, pyrimidines (C or U) by open symbols (cf. Fig. 1). Positions in which there is agreement between ancestral and primordial sequences are marked by (+) symbols while (−) symbols indicate disagreement. No distinction was made between different purines or between different pyrimidines.

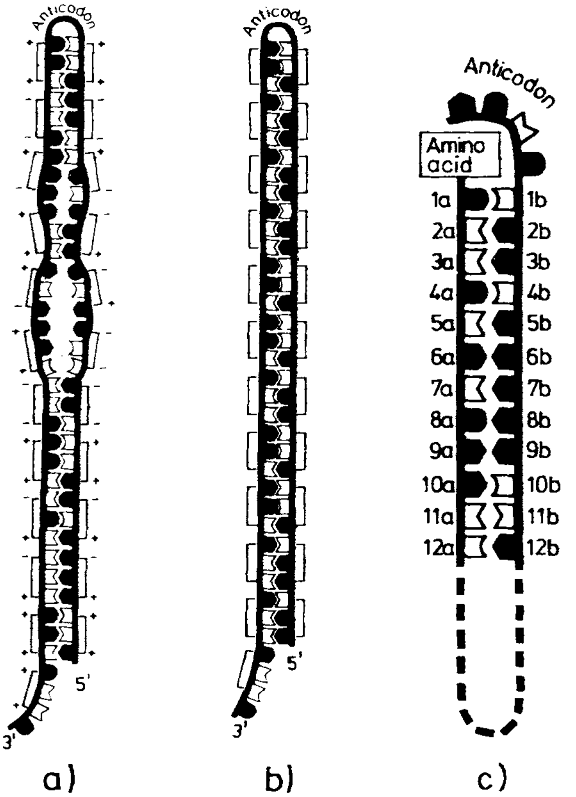

Fig. 19. Ancestral and primordial tRNA sequences. a) Ancestral sequence derived by *Eigen* and *Winkler* from a consideration of known nucleotide sequences of tRNA, shown in hairpin conformation. Three nucleotides, in positions 60, 61 and 65 have been deleted. b) Primordial sequence of *Eigen* and *Winkler* (after [22]). c) Primal tRNA according to *Hopfield* [48]. Nucleotide sequence is that of Val-tRNA of *E. coli*. The primal nucleotide strand contains only half of the present-day tRNA nucleotide sequence, folded in a manner that brings the 3′-terminus (charged here with an amino acid) into proximity of the anticodon triplet.

If we only distinguish between purines and pyrimidines, we find 27 agreements (at 15 "first" and 12 "third" locations) and 19 disagreements, a difference that is considered to be relevant to *Eigen*'s model. In our model a more accidental sequence of the complementary nucleotides along the "legs" of the hairpin is expected, so that the deviation from the average value should be close to that expected for a statistical fluctuation. For a random sequence, agreement would be expected in 23 cases with a standard deviation of $\pm\sqrt{23/2}=3.4$. The value of 27, therefore, does not deviate significantly from the average value. For a random distribution, the chance of finding the observed or a larger deviation from the mean is 30% $\left(2\sum_{i=27}^{46}\binom{46}{i}\Big/2^{46}\right)$.

There might nevertheless be a preference for the sequence PuNPy (where Pu = purine base and Py = pyrimidine base). To investigate this possibility, the frequencies with which the sequences PuNPy, PuNPu, PyNPy, and PyNPu should occur in a random arrangement, in which 15 of the 23 "first" locations are occupied by Pu and 12 "third" locations by Py, are calculated. The probability of the sequence PuNPy is then $15\times12/23^2$ and those of the other sequences $15\times11/23^2$, $8\times12/23^2$, and $8\times11/23^2$, respectively.

The situation, for all of the 23 triplets, is therefore as follows:

| | | | | |
|---|---|---|---|---|
| PuNPy | from Fig. 19a, b: | 9 | statistically | 8±2 |
| PuNPu | | 6 | | 7±2 |
| PyNPy | | 3 | | 4±2 |
| PyNPu | | 5 | | 4±2 |

Again there is no statistically significant difference between the experimental values and those expected in a random situation.

A comparison of the sequences of 20 known tRNA's of *E. coli*[49] that code for 14 amino acids has lead *Hopfield*[48] to another model for primal tRNA. It rests on the assumption that the strand conformation was such that the anticodon and the amino acid of the charged primal tRNA were in direct contact (Fig. 19c). The nucleotide strand of the proposed model only contains the portion of today's tRNA that runs from its acceptor terminus (to which an amino acid can be bonded) to the anticodon triplet. The conformation of the proposed primal tRNA would therefore be different from that of its supposed descendant and the nucleotides shown in juxtaposition in Figure 19c would nowadays be quite distant from each other. *Hopfield* derives support for his model from a statistical analysis of the nucleotide pairs in positions 1a, 1b to 6a, 6b. If these pairs were to exhibit more than *a priori* complementarity, this would constitute evidence in favor of the posited model.

For a random occupation of the six pairs of positions considered by the four kinds of nucleotides one would expect an average of $6 \times \frac{1}{4} = 1.5$ complementary base pairs; while observed values run as high as 5 in the example shown in Figure 19c, the average over the 20 tRNA's is 2.5. While *Hopfield* argues from a number of considerations, that the difference between the values of 2.5 and 1.5 is statistically significant, it appears that a comparison with a random sequence of nucleotides is not pertinent, because the 20 observed sequences are far from random, as can be seen from columns 2 through 5 of Table 1 based on the collection of nucleotide sequences by *Barrell* and *Clark*[49]. Thus, the three nucleotides at the 3'-terminus are always ACC, and most other values in the table differ considerably from the average value of $20/4 = 5$. It is evident that the details of these occupancies are related to different nucleotide functions in the positions in question. What are the probabilities of finding complementary nucleotides in the pairs of positions of interest? From Table 1 the probabilities of finding nucleotides A, C, U and G in position 6a are 2/20, 11/20, 0, and 7/20 respectively, while for 6b the probabilities are 1/20, 2/20, 1/20, and 16/20, respectively. The probability of finding complementarity is the sum of the probabilities for the base pairs AU, UA, GC, and CG:

$$\left(\tfrac{2}{20} \times \tfrac{1}{20}\right) + \left(0 \times \tfrac{1}{20}\right) + \left(\tfrac{7}{20} \times \tfrac{2}{20}\right) + \left(\tfrac{11}{20} \times \tfrac{16}{20}\right) = 0.48\,.$$

If an event has an *a priori* probability $p = 0.48$, then the result from 20 attempts is approximately $Np = 20 \times 0.48 = 9.6$, with a standard deviation $\pm\sqrt{Np(1-p)} = \pm 2.2$.

Table 1: Analysis of 20 tRNA's of *E. coli* [a].

| Position | Number of tRNA's with A | C | U | G | Number of base pairs observed | statistical |
|---|---|---|---|---|---|---|
| 1a | 20 | | | | 6 | |
| 1b | 12 | 2 | 6 | 0 | | |
| 2a | | 20 | | | | |
| 2b | 3 | 3 | 4 | 10 | 10 | |
| 3a | | 20 | | | 8 | |
| 3b | 0 | 11 | 1 | 8 | | |
| 4a | 10 | 1 | 2 | 7 | 8 | 6.3±2.1 |
| 4b | 3 | 8 | 6 | 3 | | |
| 5a | 3 | 14 | 3 | 0 | 7 | 8.1±2.2 |
| 5b | 5 | 3 | 2 | 10 | | |
| 6a | 2 | 11 | 0 | 7 | 10 | 9.6±2.2 |
| 6b | 1 | 2 | 1 | 16 | | |
| 7a | 2 | 10 | 3 | 5 | 5 | 5.7±2.0 |
| 7b | 3 | 5 | 5 | 7 | | |
| 8a | 4 | 10 | 3 | 3 | 4 | 7.4±2.2 |
| 8b | 4 | 0 | 4 | 12 | | |
| 9a | 0 | 11 | 3 | 6 | 5 | 6.8±2.1 |
| 9b | 3 | 1 | 5 | 11 | | |
| 10a | 4 | 7 | 2 | 7 | 8 | 5.1±2.0 |
| 10b | 0 | 6 | 12 | 1 | | |
| 11a | 2 | 13 | 5 | 0 | 1 | 1.3±1.1 |
| 11b | 2 | 16 | 1 | 1 | | |
| 12a | 0 | 6 | 9 | 5 | 11 | 5.7±2.0 |
| 12b | 3 | 4 | 2 | 11 | | |

[a] In Met-tRNA the base in position 10b is unknown, so that for the pair of positions 10, the calculations include 19 rather than 20 cases. For purposes of calculation the rare bases pseudouridine and 3-(3-amino-3-carboxypropyl)uridine were counted as U and $N^7$-methylguanine as G.

The expectation value for the number of complementary base pairs is therefore 9.6±2.2. The statistical value is close to the observed value of ten base pair complementarities. Analogous conclusions apply to positions 5a and 5b as well as 4a and 4b (columns 6 and 7 of Table 1). If there had been base complementarity in primordial tRNA in the region concerned, statistical values significantly higher than those observed would be expected. This is not the case[*].

While *Hopfield* limited his statistical considerations to the pairs of positions 1 to 6, it is of interest to include the additional pairs 7 to 12. Again approximate agreement is found between the numbers of observed complementary base pairs and the numbers based on statistical analysis just described (Table 1, columns 6 and 7). There is, however, one exception; the pairs of positions 12a, 12b for which the number of observed complementary pairs is eleven, almost double the statistical value. The reason for this discrepancy is that in eight of the eleven present-day tRNA's positions involved, 12a and 12b are actually paired, forming the beginning of loop I. Only the pairs 7a, 7b to 11a, 11b are therefore significant in this context. If *Hopfield*'s model were correct, significantly more complementary base pairs would be expected in these positions than corresponds to the calculated statistical values (Table 1, columns 6 and 7). In fact, for these five position pairs the number of observed complementary pairs is smaller also than would be expected for an *equal a priori* distribution of the four kinds of nucleotides over the ten positions. From Table 1 the total of observed complementary pairs is 23, giving an average of $23/20 = 1.15$, while the expected avarage number of complementary base pairs is $5 \times \frac{1}{4} = 1.25$. In summary, *Hopfield*'s model cannot be supported by means of the observed complementarities.

---

[*] The statistical test used here cannot be applied to the pairs of positions 1 to 3b, because positions 1a, 2a and 3a are always occupied by the same respective nucleotides in the sequence ACC. If *Hopfield*'s model were correct, one would expect positions 1b to 3b to be preferentially occupied by the sequence UGG. However, in position 1b, for example, A is found twice as often as U.

## 12. DNA Takes Over the Storage of Genetic Information

The example of the emergence of a translation apparatus illustrates the method of procedure in our model. Further important steps are considered here in a more cursory fashion. A question that is initially extremely puzzling is how and when the translation apparatus described was restructured into the genetic apparatus of today's biological systems, which have a completely different organizational structure. The methodological program used previously leads, however, to the view that a restructuring of precisely this kind almost certainly had to occur.

Systems containing translation devices invaded regions of ever larger pores and, related to these events, increased in complexity and sophistication. However, the achievable degree of complexity is limited at this level by congestion. That is, while (+)-collector strands contain the codes for useful polypeptides, the corresponding (−)-strands are either useless for the synthesis of polypeptides or, even worse, effect the production of nonsense polypeptides that add to the confusion inside the envelope and use up amino acids. These complications increase with the sophistication and variety of devices that synthesize different polypeptides. An individual can therefore manufacture only a limited number of different enzymes, and a quiescent phase of evolution is thus reached.

A possible way out is the following: The "replicase" can sustain minor changes because of erroneous base couplings, and eventually "replicases" with slightly different properties can evolve in the same envelope. Let such an enzyme $E_1$ be one that favors, to a small degree, mononucleotides containing deoxyribose rather than ribose in the synthesis of strands and $E_2$ an enzyme that in turn favors such deoxyribose-rich strands as templates in the synthesis of strands rich in ribose. By chance let enzyme $E_2$ be slightly more efficient than $E_1$ (Fig. 20). The $E_1$-catalyzed replication of a (+)-strand of RNA (denoted by $R^+$) then yields a deoxyribose-rich (−)-strand (denoted by $D^-$) that in turn can serve as template for the rapid production of a number of copies $R^+$, assisted by the efficient enzyme $E_2$. The strands $R^+$ can convolute into hairpins and aggregate into enzyme-synthesizing devices. Thus, a few $D^-$ strands now produce many $R^+$ strands. Directional selection oc-

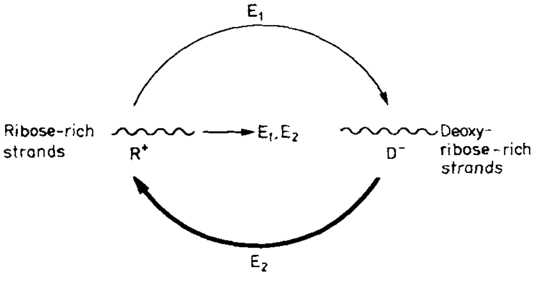

Fig. 20. Emergence of deoxyribose-rich ($D^-$)-strands. Short deoxyribose-rich (−)-strands ($D^-$) are synthesized on ribose-rich (+)-strands ($R^+$), catalyzed by enzyme $E_1$, while $E_2$ catalyzes the synthesis of $R^+$ on $D^-$. Enzyme $E_2$ is more efficient than $E_1$.

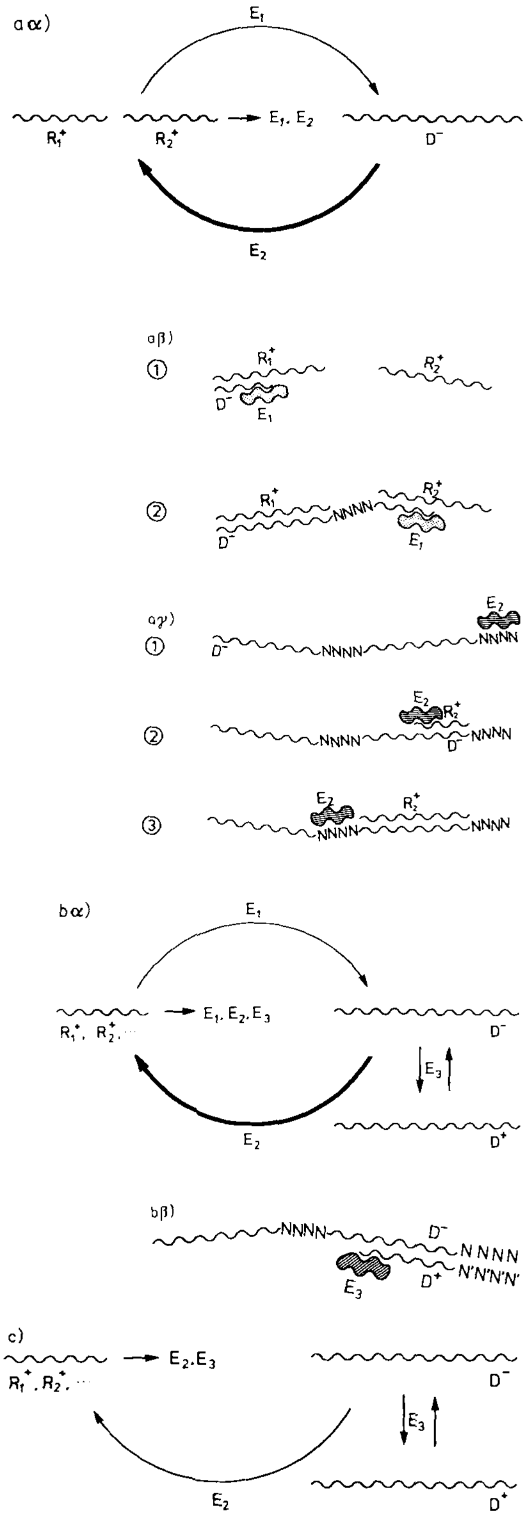

Fig. 21. Organizational structure of the processes that permit the separation of the machinery for replication and enzyme synthesis. a) $D^-$ becomes longer and serves as template for short strands $R_1^+, R_2^+, \ldots$; α) schematic representation of the catalytic action of enzymes $E_1$ and $E_2$; β) strands $R_1^+$ and $R_2^+$ serve as templates in the formation of $D^-$, catalyzed by enzyme $E_1$. The stretch NNNN is formed without the benefit of a template; γ) formation of $R_2^+$ with $D^-$ serving as template, catalyzed by enzyme $E_2$. The NNNN portions of the $D^-$ strand are not replicated but serve as recognition regions where replication is to begin ① and end ③. b) Enzyme $E_3$ catalyzes the replication of $D^+$ on $D^-$ strands and *vice versa*; α) schematic representation of the catalytic action of the enzymes $E_1$, $E_2$, and $E_3$; β) formation of $D^+$ with $D^-$ acting as template strand, catalyzed by enzyme $E_3$. The portion N'N'N'N' on $D^+$ is formed by replication of the analogous portion NNNN on $D^-$. c) Enzyme $E_1$ is no longer needed; schematic representation of the catalytic actions of the enzymes $E_2$ and $E_3$.

curs, favoring genetic machinery in which mechanisms for replication and enzyme synthesis become separate. The difficulty that arose through the accumulation of unproductive strands and of nonsense polypeptides is thus solved by a reorganization of the system, and the appearance of a third sort of polymers rich in deoxyribose nucleotides.

The cooperation of enzymes $E_1$ and $E_2$ permits, for a while, growth of the functional cooperative by the emergence of additional enzymes. However, linked to the increase in complexity of this macromolecular society, there is an increase in organizational problems, since the blueprints of the organisms are distributed over many $R^+$ strands ($R_1^+, R_2^+ \ldots$). The difficulty can be overcome by combining the complementary strands $D_1^-, D_2^- \ldots$ into fewer longer strands and eventually into just one long $D^-$ strand (Fig. 21a α) that then serves as template for new strands $R_1^+, R_2^+ \ldots$. Apart from the decrease in organizational problems thus brought about, there is also less tendency for a long strand to escape by diffusion.

The process of lengthening the $D^-$ strands would be aided by an enzyme acting as *"ligase"*. It can be imagined that enzyme $E_1$, slipping along as replication proceeds, protrudes from its slot as the end of the strand is reached. The protruding end may then assist in the occasional attachment of a second strand that happens to be nearby. The result is a $D^-$ strand, that is lengthened by the new piece, which contains the information of the two $R^+$ strands separated by a short piece of strand NNNN that was polymerized template-free (Fig. 21a β)[*].

Enzyme $E_2$, involved in the synthesis of the short strands $R_1^+, R_2^+, \ldots$, must contain recognition sites for the locations along the $D^-$ strand at which replication of $R^+$ strands must start and end. Perhaps the short pieces along $D^-$ that arose through non-template polymerization can act in a special way (Fig. 21a, γ).

A further necessary step is the modification of an earlier "replicase" into an enzyme $E_3$ (Fig. 21b, α) that catalyzes the formation of $D^+$ strands from $D^-$ templates and the converse. Since only $D^-$ should be used as template for producing strands $R_1^+, R_2^+, \ldots$, enzyme $E_2$ should be able to interact with the recognition sites of $D^-$ only, which would therefore have to be special. They might *e.g.* consist of the sequence NNNN, to which the "non-recognition" piece N′N′N′N′ on $D^+$ would correspond, where N′ is the nucleotide complementary to N (Fig. 21b β).

Such a system of enzymes would confer great selective advantages and initiate the evolution of machinery for replication operating with increased efficiency and accuracy. The mechanism would lead to a situation in which DNA strands became the carriers of information. $E_1$ would degenerate and $E_2$ evolve into *"transcriptase"* (Fig. 21c). (Since *inverse transcriptase* is endowed with the same function as $E_1$ it is conceivable that it evolved from such a precursor.)

At an early stage, another apparatus must have evolved that improved the contact between the collector strand and the hairpin adapters, suppressing "reading" errors. This surmise is strongly suggested by the fact that today's ribosomes are the only functional cell elements (enzyme systems) that are largely composed of nucleic acids and may therefore have evolved from such an apparatus.

At this stage all essential elements of the present-day genetic machinery, as known from molecular biology, have been accounted for and their evolution appears to be a necessity.

## 13. Exchange of Genetic Information

As the systems considered grew ever more complex, the information passed from one generation to the next increased. Let W be the probability that during replication an error occurs in the choice of a new base, so that the base incorporated into the daughter strand is not complementary to the corresponding base on the template strand. This probability must consequently decrease as the number, $N_{total}$, of monomers involved in information storage and transfer increases, and it can be shown that the relation $N_{total}\ W = 1$ must approximately be satisfied (cf. [2], Section 18.1.4.7). This condition theoretically assures that there is a sufficient number of error-free copies in each generation so the form does not become extinct. There is also some experimental evidence for this approximate relationship. It has, for example, been found by *Weissmann et al.*[51] that $W \simeq 1/3000$ for Qβ-bacteriophage, for which the number of nucleotides is 4500.

As $N_{total}$ increases, W must decrease, *e.g.* by the appearance of improved "replicases". However, a new difficulty arises, caused by the requirement that there must be a certain minimum error frequency to permit the continuous adaptation of the systems to an ever-changing environment, when $N_{total}$ reaches approximately $10^6$. The required approximate value of W is $10^{-6}$. Once the corresponding approximate value of $N_{total} = 10^6$ has been reached, it becomes impossible to increase $N_{total}$ further without violating one of these two limiting conditions (Fig. 22). A phase of stagnation is reached in the model and a new fundamental organizational change, a new breakthrough is required to overcome this barrier.

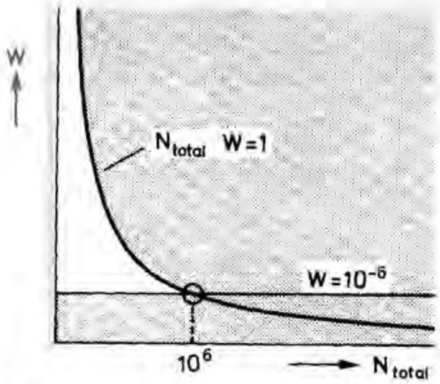

Fig. 22. Conditions for W. The value of $10^6$ on the horizontal axis represents an upper limit for $N_{total}$. Gray region is in violation of the two boundary conditions described in the text.

---

[*] It is known, that under certain conditions Qβ replicase can cause the template-free replication of strands [50].

In the model, this breakthrough consists in the exchange of genetic information between individuals. An evolution of sexual machinery that permits the mutual exchanges of pieces of strand takes place, *i.e.* there is recombination of genetic material that may confer advantages upon the recipients. The approximate requirement that $W = 10^{-6}$ is thereby relaxed, and $N_{total}$ can grow, as long as accidental improvements in the replication machinery lower W to a level at which the condition $N_{total}\ W \simeq 1$ is again satisfied. The gain in flexibility through recombination must, of course, outweigh the loss caused by the decline in the replication error rate. An improvement of the mechanism for the recombination of genetic material and a decrease in W and increase in $N_{total}$ are thus strongly coupled to each other.

The stage of information under discussion corresponds approximately to that of a bacterium, for which the total number of nucleotides in the DNA lies between $3 \times 10^6$ and $6 \times 10^6$, only a fraction of which carry information coding for proteins, *i.e.* constitutes $N_{total}$. The portion of DNA that carries such information is probably quite large in bacteria, so that a value of about $10^6$ for $N_{total}$ would seem justified. For *E. coli* it is found experimentally[52] that $W \simeq 10^{-8}$; indeed *E. coli* sometimes exchanges genetic material by conjugation.

The interchange of genetic material strongly accelerates the accumulation of genetic information and therefore determines the direction of further evolution. At the stage considered, a division into organisms that remained simple and others that became more and more complex must have occurred. Simplicity of organization (non-development of sexual machinery or limitation to very primitive such machinery) yields selective advantage in some ecological niches—the organisms remained at the stage of procaryotes.

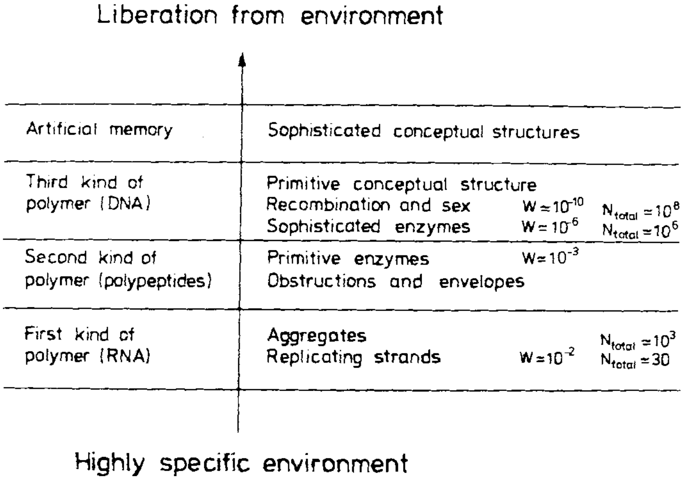
A decisive improvement in the sexual machinery presupposes an increase in complexity. The increase in sophistication caused organizational problems that could only be solved by the subdivision of the cell interior, hence improving the regulation of molecular traffic. The cell architecture became more complicated—eucaryotes evolved. In regions, in which the procurement of nutrients required the development of more and more complicated devices, only further structuring by multicellularity was left as a means of escape into new living spaces.

The question of the emergence of primitive sexual mechanisms, a necessity in the model considered, must not be confused with the question, commonly discussed by evolutionary ecologists, of the present-day selective forces maintaining sexual reproduction. Asexual reproduction must have repeatedly arisen in different evolutionary lineages as a derivation of primitive sexual reproduction.

## 14. Thermal Barriers to Information Storage and Transfer

It is not possible, however, to increase $N_{total}$ beyond a certain limit, because new difficulties arise in the model. The new barrier arises because errors caused by ever-present thermal fluctuations cannot be avoided, a fact that implies the existence of a minimum value below which W cannot be decreased.

This barrier can only be hurdled once machinery is available that uses larger than molecularly dimensioned symbols and in this manner permits the storage of much greater quantities of information than is possible by the genetic apparatus. Such machinery is available in written language, and more recently, in computers. Information in artificial memories, such as instructions for the manufacture of some device, is transmitted over many generations and modified and supplemented by material that is subject to a selection process. The revolutionary breakthrough of artificial storage systems is comparable to the revolution associated with the separation of the machinery for replication from that for protein synthesis, during which DNA became the receptacle of genetic information. As then, a change in the system of information transmission led to a huge increase in the information that could be transferred from one generation to the next.



| | | | |

Fig. 23. Increased complexity of information storage led to increased independence from specific environments.

Some of the breakthrough phases described are summarized in Figure 23. This depicts, in our view, the main line of evolution—a sequence of many minute steps that lead to an ever-increasing liberation from an environment that was, in the beginning, very special. This development is related to a large increase in complexity, of which $N_{total}$ is a measure, and to a decrease in the probability W of replication errors. At first only one kind of polymer, ribonucleic acid, was of importance. Replication set in, followed by the formation of aggregates. A second kind of polymer, the polypeptides, became important. Envelopes developed and a genetic translation apparatus evolved. A third kind of polymer, deoxyribonucleic acid, permitted, the complete reorganization of the system of information transfer. A refined translation apparatus evolved and sexuality became important. Finally, artificial memory systems became carriers of information.

While individual steps can always be replaced by others that are somewhat different, without thereby destroying the logical connections between the steps, the fundamental

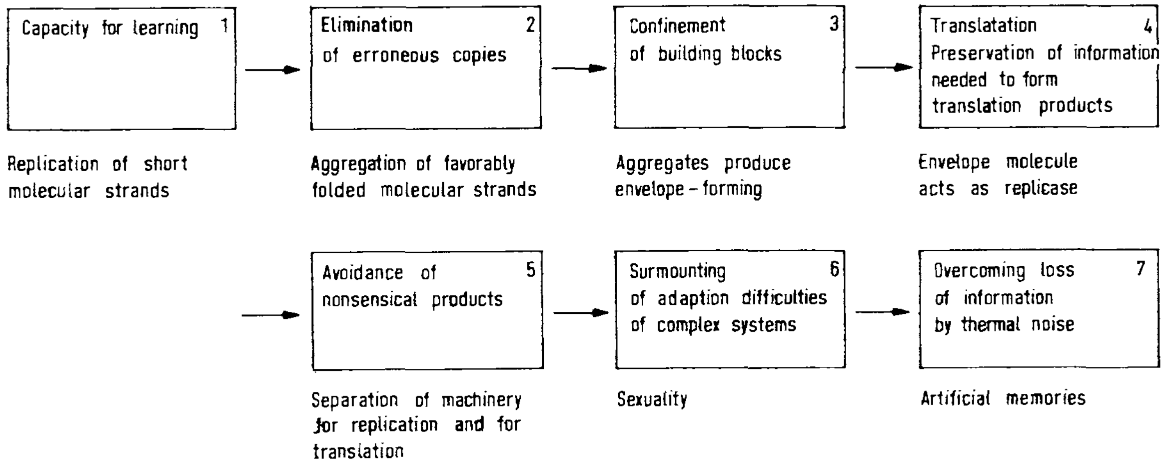

Fig. 24. Organizational framework of the evolution process. Logical requirements (boxes) and their realizations.

changes in the system structure of the explored model seem to be fixed necessities. Under appropriate circumstances, a system appears that is capable of learning (Fig. 24, step 1). The complexity increases but stagnation sets in, because of the accumulation of replication errors. To overcome it, machinery for the discarding of erroneous copies is needed and is achievable (step 2). The complexity of the systems again increases, until stagnation occurs, because they are tied to pre-existing compartmentation. To conquer this barrier machinery is needed and achievable that permits a containment of building blocks that is independent of external structure (step 3). Given appropriate conditions this machinery develops, by necessity, into machinery for code translation and machinery that permits the preservation of information needed to form translation products (step 4). This development in turn allows an increase in complexity until stagnation sets in at a certain level, because of the accumulation of nonsense products. The conquest of this hurdle (step 5) requires machinery that permits the bypassing of meaningless production and can be achieved by reorganization of the systems. Further evolution leads to increasingly complex, and thus ever more delicate systems, ending again in stagnation because of inadequate adaptability of the systems. The barrier can again be hurdled by a fundamental reorganization of the systems (step 6). This change permits the achievements of a level of complexity that cannot be raised further because of thermal noise, until another fundamental restructuring of the organization permits a conquest of this barrier (step 7).

## 15. Knowledge as a Measure of the Usefulness of Information

The process of evolution can be described as a phenomenon that, at some place and at some time in the development of any suitable planet (Fig. 25), starts with a bang. All of a sudden a strand arises that can replicate, thereby creating a system that adapts itself again and again to a changing environment, in many steps of replication and selection. This process of evolution proceeds in jumps: Nothing of importance happens for long periods, until a reorganization of the system ushers in a rapid new development. In a corresponding way there are discontinuous increases in the contents of the message of which the systems are carriers. An important function that is a measure of and increases with the degree of the evolution of the systems will be termed the *knowledge* of the systems. We roughly define this function as the information (measured in bits or yes-no decisions) contained in the totality of the blueprints that had to be rejected by necessity until the stage of evolution considered was reached (see [53] and [2], Section 18.1.5). Knowledge is a measure of the usefulness of the information accumulated during the course of evolution. (*Shannon*'s well-known measure for information[54] represents the *amount* of information, the number of bits, and not its *usefulness*.)

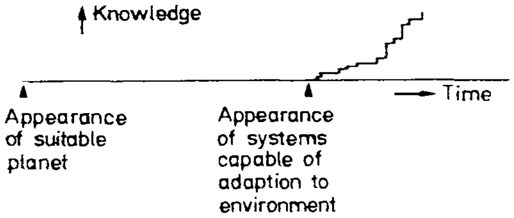

Fig. 25. Emergence of life. Learning systems suddenly appear, without prior traces of this new quality. *Knowledge* of evolving systems increases discontinuously.

## 16. Comparison with Another Approach

Our model differs in a cardinal point from an often-presented viewpoint—adhered to, for example, by *Prigogine*[55], *Eigen*[56], and others[57]—in which it is asserted that a model for the origin of life can be described in terms of the spontaneous formation of structure in a solution far from equilibrium, to which suitable reactants are supplied and reaction products removed in a steady-state situation.

In *Eigen*'s view a translation apparatus, that is, an apparatus in which tRNA molecules can attach themselves to a strand of messenger RNA, serving as adapters can spontaneously appear in a suitable solution of nucleotides, the result being the synthesis of polypeptides that can act as "replicase". Here, this apparatus must form before an effective mechanism for the removal of replication errors has become available. After *Eigen* and *Schuster* (see [45], Section XV therein), such a filtering mechanism is only formed later by the cyclic coupling of two or more reaction cycles. For example, in the case of two cycles 1 and 2 that produce the replicases $R_1$ and $R_2$, respectively, cycle 1 is catalyzed by $R_2$ and cycle 2 by $R_1$, so that cooperation between the two cycles exists in this way. The resulting *hypercycle* then dominates the solution.

In our opinion, the fundamental enigma is the mechanism that caused the emergence of a translation apparatus. The degree of intricacy is such, that a device of this kind could only have developed after the evolution of an effective mechanism for the removal of replication errors.

The only conceivable error-filtering mechanism (rejection of erroneous copies in the formation of an aggregate) requires pre-existing external spatial and temporal structure as *sine qua non* for the coming together of convoluted strands—for their aggregation, for the disassemblage of aggregates and replication of aggregate components, and for the correct reconstruction of functionally new, and at times improved, aggregates.

Our conception is in conflict with the view that a fundamental event in the origin of life was the spontaneous appearance of structure, caused by an inner instability (an occurrence that is the basis of many natural phenomena). Instead, we consider the question of how life originated *primarily* as a problem of finding the logical framework and organizational structure of evolutionary processes: By what principles can systems emerge that are capable of learning? What fundamental barriers confront such systems that can learn once they exist? What fundamental possibilities exist to overcome these barriers? *Secondly* we consider it as a problem of physical chemistry: What fundamental possibilities satisfying the organizational requirements exist in physical chemical models, that is, by remaining within the framework of physical and chemical laws? Given such a starting position questions about the thermodynamic conditions for the appearance of dissipative structures in a homogeneous solution, in a stationary state far removed from equilibrium, do not arise. Instead, pre-existing spatial and temporal structure is recognized as a fundamental requirement, and therefore a homogeneous, stationary system cannot serve as a suitable starting point. Thus, one does not ask for the conditions for the existence of a cyclic reaction sequence that must be satisfied everywhere in the solution, but for conditions that must prevail in a specific location so that aggregates consisting of a small number of macromolecules as components can appear and multiply; such aggregates have the qualities of a simplest translation apparatus, and can develop, by mutation and selection, ever more complex capabilities in their interaction with a multifaceted environment.

With this initial position, the appearance of a translation apparatus contributes the decisive breakthrough: A mechanism for the production of ever more complex enzymes has become available. A cyclic coupling of systems that produce replicases contributes nothing at this level. Cooperation arose earlier in our model, with the formation of aggregates, while in *Eigen*'s approach the first appearance of cooperation is the mutual interaction of cycles that produce replicases. As we have seen, a certain cyclic coupling between replicase-producing systems becomes important, in our model, at a later stage of evolution when deoxyribonucleic acid began to play a role. The type of coupling developing at that time is different from the one involved in *Eigen*'s hypercycle.

According to *Eigen*, hypercycles are the only possibile way of surmounting the informational crisis that arises through the proliferation of replication errors, because they simultaneously satisfy the following three conditions[58]:

1) Each replicative unit must selectively maintain its information content in competition with its own error distribution.
2) Competition between replicative units that belong to the same functional cooperative must cease to operate.
3) The functional unit as an entity must be capable of competition against alternative units.

These three conditions are, however, also satisfied by the systems, which we have considered; *i.e.* molecular strands that form aggregates (condition 1, because erroneous copies are rejected by the aggregate; condition 2, because of cooperation among the components of the aggregate; and condition 3, because of the special survival properties of the aggregate as a whole). On the other hand, this system does not constitute a hypercycle. In the case of a single kind of strand (for example, functionally equivalent (+)- and (−)-hairpin strands), autocatalytic replication of a kind of strand simply occurs, while aggregation serves to increase its viability.

The cardinal problem concerning the origin of life is how one can imagine the development of the simplest systems that could adapt to their environment—systems consisting of a few macromolecules capable of mutual cooperation. An essential requirement for this process is the existence of a spatially and temporally structured environment, which is needed to keep the potential building blocks of such systems from diffusing away from the region of importance and to drive the replication, assemblage, and disassemblage of the aggregates. The presence of structure is thus the condition for the appearance of life by molecular self-organization[*], that is, for the build-up of the information content of a learning system. How such temporal and spatial structure arose on the primordial planet is a question to be answered by planetary science.

## 17. Answers to Frequent Questions and Questionable Statements Concerning the Origin of Life

Questions and erroneous statements one often hears are the following:

---

[*] In our usage of the concept of self-organization, we exclude extra-physical influences.

1) *The geological time span available for the appearance of even the simplest forms of life was insufficient, thus requiring seeding of the planet or extra-physical phenomena to explain the emergence of life.*

Evolution up to the period at which genetic machinery appeared must have occurred rapidly, because of the large error frequency that dominated the early stages. It was most rapid at the beginning, until the frequency of errors was enormously decreased by the formation of aggregates. The development of a genetic apparatus again enormously decreased the error frequency in the correct pairing of bases. The time requirement for all steps up to the development of the genetic apparatus must therefore be small compared to the time required for the instruction of the about 1000 proteins of a bacterium. We can estimate the latter time using the assumption that proteins are inserted consecutively into the functional cooperative of the form existing at the time, and through this the DNA strand lengthened by $10^3$ nucleotides for each new protein.

The nucleotide sequence on the newly added piece of strand changes by random errors in the matching of bases, and in this way the protein adjusts to its appropriate function. For simplicity we assume that each protein is instructed by approximately 100 optimization steps, and that between each of these steps the situation must be awaited in which a random distribution of the occupancies of the non-instructed locations of amino acids, produces yet another step in the optimization. This implies $1/W = 10^6$ generations per step (one base change has occurred on the average in each position during this period) or $10^6 \times 10^2$ generations per protein, and therefore a total of $10^6 \times 10^2 = 10^8$ generations. Following this, the DNA strand is again lengthened by a piece of $10^3$ nucleotides and the process repeated. The $10^3$ proteins therefore require about $10^8 \times 10^3 = 10^{11}$ generations. This amounts to approximately $10^8$ years, assuming one day *per* generation; compared to the approximately $10^9$ years available for the process in geological history.

The reason for making this estimate is to answer the question posed and is not intended to give accurate information about the time needed for the evolution of a bacterium. It may well be an overestimate by an order of magnitude, because all proteins appear to consist of about 100 *domains* that were independently instructed and then developed further by gene duplication[59].

2) *The probability of the spontaneous emergence of the simplest systems that could develop into living organisms is much too small for a physical explanation of this phenomenon.*

Here, it is important to consider the probabilities of very many minute and detailed steps. For a small number of larger steps the probabilities soon become infinitesimally small. This can even be seen in the simple case of the spontaneous appearance of the first self-replicating strand, consisting of monomers that became accidentally linked.

Each monomer must contain the correct sugar, correctly linked to a nucleotide base and to a phosphate group. The probability of this is about 1/100, or around about $1/100)^{10} = 10^{-20}$ for a strand of ten monomers. This value is within acceptable limits, as indicated in the earlier dicussion. However, for a strand of 50 members the corresponding probability is $(1/100)^{50} = 10^{-100}$, a value so small that it would take an entire universe filled with strands, at a density of one strand per $nm^3$, so that just one of them could be assumed to be accidently correct. That is, for all practical purposes, the probability that such a strand could have spontaneously been formed is zero. Our considerations imply that in general relatively large steps do not occur.

3) *Biological systems behave in a holistic, purpose-oriented fashion that is in conflict with the way in which systems describable by physical laws behave.*

In fact, no conflict exists with the laws of physics, because the described behavior is the result of the survival of the systems considered in an environment in which survival may be difficult, while a large number of slightly less suitable systems were rejected. It is the result of the well-known mechanism of evolution: multiplication, mutation, and selection.

Replication errors are disadvantageous in most cases, but lead in rare cases to an improvement of the survival chances of the changed form. Those forms, that are better adapted to the surroundings, remain. Biological evolution leads in this way to an ever improved adaptation to the surroundings. It represents a learning process that extends over great numbers of generations. Adaptation and learning, however, are in essence holistic, purpose-directed processes that are therefore seen to be derivable from physical laws.

## 18. Concluding Remarks

The methodology followed in our approach to the origin of life is intended to overcome the mental difficulties in understanding this astonishing phenomenon on a physical basis. The many small model steps that are considered have not been devised with the hope of describing the actual path followed by nature, but rather with the intention of understanding the fundamental aspects and difficulties as tangibly as possible. It is therefore remarkable that, using this method, a successful description of the development of systems endowed with a genetic apparatus is possible, as a consequence of many small plausible steps that follow each other with an almost inescapable inner logic. Given sufficient time, all of the individual steps have probabilities near unity. Even more remarkable is that one of the results of these considerations, is a detailed description of a molecular model of this apparatus. In many details, including the possible hairpin conformation of the adapter molecules, this model is identical with that described some years ago[1], at a time when many of the experimental results used here were not as yet known.

# *N*-Methyl Inversion Barriers in Six-membered Rings[**]

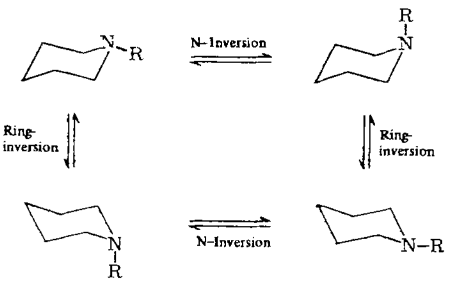
**By Alan R. Katritzky, Ranjan C. Patel, and Frank G. Riddell[*]**

Conformational conversions of *N*-methylazacyclohexanes are of particular interest: they can proceed either *via* ring- or nitrogen-inversion processes. In both procedures an equatorial *N*-methyl group is converted into an axial one, and the converse. It is appropriate to dissociate the energy barriers for *N*-methyl inversion into two "half-barriers" for the steps, axial form → transition state and equatorial form → transition state, and to report both values separately.—In this article the *N*-methyl inversion barriers of numerous methylated oligoazacyclohexanes, including species with oxygen or nitrogen atoms in the ring, are discussed.

## 1. Introduction

Since the fifties, conformational analysis has revolutionized our treatment of saturated ring systems. At first it was applied mainly to carbocyclic systems, but its influence has long been felt in saturated and partially saturated heterocyclic ring systems.

The substitution of a nitrogen or oxygen atom for a carbon atom in cyclohexane does not fundamentally change the geometry. However, a trivalent nitrogen atom displays the phenomenon of N-inversion. The *N*-substituent in a piperidine, for example, can occupy either the equatorial or axial position, and there are two possible ways of these conformations interconverting, either by ring- or N-inversion.



In the case of piperidine itself, the *position* of the equilibrium was long controversial, but this matter has now been largely cleared up and the general view accepted that the *N*-equatorial conformer predominates by a rather small factor[1]. For *N*-alkylpiperidines, it has long been accepted that the *N*-equatorial form predominates, but the *magnitude* of the N-inversion barrier in this compound and that for other *N*-alkyl groups in other azacyclohexanes has proved a fascinating and contentious problem.

The problems raised by studies of N-inversion barriers in six-membered rings such as *N*-methylpiperidine *(1)* have been a subject of dispute between the authors' laboratories[2]. Since the dates of the original communications on this subject, much further work has been carried out by each of our groups and by others and the principal points of controversy now appear to have been resolved. This review outlines our agreed assessment of the current situation.

An important basic point is that the N-inversion barrier cannot be measured by current NMR techniques for the simplest six-membered derivative *N*-methylpiperidine *(1)*. This arises because the free energy difference between the two conformations *(1e)* and *(1a)* is *ca.* 2.7 kcal/mol[3], making it impossible to record peaks from the minor conformer *(1a)* below the anticipated coalescence temperature, even with the most sophisticated modern instrumentation[*].

The only current technique that would appear to be available for the measurement of the barrier in *N*-methylpiperidine is ultrasonic relaxation; this has recently been used with success, *e.g.* in studies of rotation in ethanes[4]. An ultrasonic relaxation study on *N*-methylpiperidine by *Wyn-Jones et al.*[5] in 1975 yielded a barrier of 6.0 kcal/mol for the *ax*→*ts* barrier[**]. Although $\Delta G^0$ measured by this

[**] Conformational Analysis of Saturated Heterocycles, Part 98.—Part 97: *A. R. Katritzky, R. C. Patel, F. G. Riddell*, J. Chem. Soc. Chem. Commun. *1979*, 674.

[*] Given $\Delta G^0 = 2.7$ kcal/mol and an optimistic upper temperature limit of −150° C at which N-inversion might be frozen out, the equilibrium constant *K* is *ca.* 65000 (*i.e. ca.* $2^{16}$). Therefore, if a piece of information from the (preferred) *(1e)* completely filled one 16 bit word of store, only one bit would be recorded in a word of store containing the corresponding information from *(1a)*. Moreover these values would be superimposed on noise certainly greatly exceeding 1 bit in magnitude and would have no statistical significance. The problem is therefore beyond any 16 bit FT computer and probably beyond the dynamic range of the FT routines of all current FT computers utilizing larger word sizes.

[**] The following abbreviations are used: *ax*=axial, *eq*=equatorial, *ts*=transition state; *N*-Methyl orientation: *a*=axial, *e*=equatorial.

*0570-0833/81/0707-0521 $ 02.50/0*

technique was found to be 0.9 kcal/mol, a value much lower than that currently accepted[3], it is agreed that $\Delta H^0$ values from spectroscopic methods are more reliable than those from ultrasonic relaxation techniques, whereas $\Delta G^{+}$ determinations compare well with reliable values from other methods[4]. This suggests a $\Delta G^{+}$ value of 6.0 kcal/mol for the *ax→ts* barrier in *N*-methylpiperidine *(1)*.

## 2. Measurement of Individual Half-Barriers by NMR

A fundamental point arises in the interpretation of NMR coalescence data. The rate constant obtained from an NMR experiment is always the sum of the forward and reverse rate constants, but three cases can be distinguished:

1. If the process being observed is the freezing out of a biased equilibrium where $K$ is *e.g.* $\geq 10$, the observed rate constant is effectively the greater of the two and therefore corresponds to the conversion of the least stable conformer in the transition state. This applies in all applications of dynamic $^{13}$C-NMR line-broadening (Anet equations).

2. If there are appreciable concentrations of the two conformers of which the equilibration is being observed, the individual activation energies can be obtained from the average $\Delta G^{+}$ measured, and the $\Delta G^0$ for the system, using the equations derived by *Bovey et al.*[6].

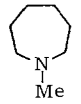
3. If the equilibrium under study is between two identical (or mirror image) conformers, then the measured rate constant is for ground state → transition state, and this applies regardless of the possible occurrence of minor amounts of other conformers along the reaction coordinate.

It is obviously necessary to state clearly which "half-barrier" is referred to and the neglect of this has led to much of the confusion in the literature.

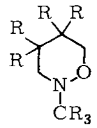
## 3. Previous Interpretation of N-Inversion Barriers

It is now clear that our viewpoints[2] can in many features be reconciled, if the work from Norwich[2a] is referred to the change axial to transition state (*ax→ts*), whereas the work from Stirling[2b] is referred to the change equatorial to transition state (*eq→ts*). This viewpoint emphasizes the fact that each nitrogen inversion barrier has to be formally regarded as made up of two half-barriers (*ax→ts* and *eq→ts*). Clearly, the difference between the two half-barriers represents the conformational energy difference of the *N*-substituent[*].

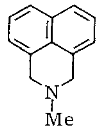
In their original preliminary communication, the Norwich group took the measured $\Delta G^{+}$ of 6.8 kcal/mol, for nitrogen inversion in the seven-membered *N*-methylhomopiperidine *(2)*[7], as a model (Table 1) to obtain empirical increments for the quantitative interpretation of changes in N-inversion barriers in terms of changes in steric and electronic factors resulting from insertion of heteroatoms in six-membered rings[2a]. It was concluded that β-heteroatoms significantly increased the atomic inversion barrier (positive β-heteroatom effect) and that α-heteroatoms had still greater barrier enhancing effects. The barrier observed for 2-methyl-1-oxa-2-azacyclohexane *(3)*, originally assigned to N-inversion[8], was suggested to be due to ring inversion because the derived empirical increments predicted the N-inversion barrier to be much lower than that observed.



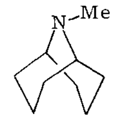
*(2)*



*(3)*, R = H
*(4)*, R = D



*(5)*



*(6)*

Table 1. Model compounds used in incremental analyses

| Compound | *(2)* | *(5)* | *(6)* | *(7)* | *(8)* |
|---|---|---|---|---|---|
| $\Delta G_c^{+}$ [kcal/mol] | 6.8 | 9.7 | 8.1 | 8.4 | 6.5 |
| Ref. | [7] | [11] | [14] | [13] | [15] |

This work was criticized by *Riddell* and *Labaziewicz*[2b], who noted that the seven-membered ring model *(2)* for N-inversion in *N*-methylpiperidine *(1)* was inadequate because it lacked the constraints imposed upon nitrogen inversion by a six-membered ring[*]. The barrier in 2-methyl-1-oxa-2-azacyclohexane *(3)* was reasserted to be due to N-inversion and this has been verified recently[9,10]. It is now clear that this barrier of *ca.* 13.7 kcal/mol (14.4 kcal/mol[10]) applies to *eq→ts*, whereas the *ax→ts* barrier is ≤ 10.0 kcal/mol, thus explaining the misassignment by the Norwich group. The Stirling workers suggested[2b] an alternative empirical analysis, which led to a barrier of 9.63 kcal/mol for the N-inversion barrier in *N*-methylpiperidine *(1)*. It was concluded that β-heteroatoms have a marked barrier decreasing effect and the N-inversion barriers reported[11,12] for compounds *(5)* and *(6)*, which at the time appeared to fall close to this derived value, were cited to support this analysis.

However, these supplementary results for *(5)* and *(6)* quoted by *Riddell et al.* can no longer be regarded as satisfactory. The N-inversion barrier of 9.7 kcal/mol in the naphthalene derivative *(5)* was considered by *Anderson* and *Oehlschlager*[11] to reflect a distorted saturated six-membered ring, for which N-inversion rates are measurable, because strain forces the C—N—C angle apart in the transition state and leads to distortion of the aromatic rings. We conclude that *(5)* represents a strained model for *eq→ts* N-inversion, with probably more strain in the *ts* than the ground state; hence, the unstrained *eq→ts* barrier

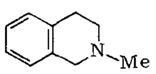
---

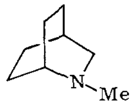
[*] In this analysis, the two observable quantities $\Delta G^0$ and $\Delta G^{+}$ are represented by three parameters. This situation would clearly be better defined if in future authors clearly specified to which direction their barriers referred. Preferably *both* half barriers should be quoted.

[*] *N*-Methyl homopiperidine *(2)* is expected to be biased to the conformation with the *N*-methyl group pseudo-equatorial.

in $N$-methylpiperidine should be significantly less than 9.7 kcal/mol. A study[13] of the tetrahydroisoquinoline *(7)* gives 8.4 kcal/mol for N-inversion. In this compound, strain that arises from opening of the C—N—C angle in the transition state is less than for *(5)*; compound *(7)*, therefore, probably provides a closer estimate of the *eq*→ *ts* barrier in *(1)* than *(5)* permits.

*(7)*





*(8)*

The barrier for the bicyclo[3.3.1]nonane derivative *(6)* has been accurately measured by *Nelsen et al.*[14] as 8.11±0.04 kcal/mol, whereas *Lehn*'s previously "unpublished" proton data for *(6)*[12] (determined at −80±10°C), $\Delta G_c^{+} = 9.5 \pm 1.0$ kcal/mol, was quoted by *Riddell* as support for his results[2b]. The variance with *Nelsen*'s $^{13}$C-NMR result was probably due to difficulties in accurately determining data from the strongly coupled proton spectra. Moreover, we now agree that *(6)* is not a good model since the methyl group is equatorial in one ring but axial in the other. The barrier in the bicyclo[2.2.2]octane *(8)* has been measured[15] by *Nelsen* to be 6.5 kcal/mol. *Nelsen* concluded that *(6)* has a higher barrier than *(8)* due to the difficulty in expanding the C—N—C angle to 120° for nitrogen inversion in *(6)* because of the rigid bicyclic system.

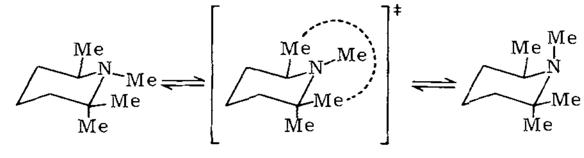
Taking the best of the available data from other workers, and considering results from our own laboratories, we suggest that the best estimations for the barriers to N-inversion in $N$-methylpiperidine are $\Delta G^{+}(ax \rightarrow ts) = 6.0$ kcal/mol and $\Delta G^{+}(eq \rightarrow ts) = 8.7$ kcal/mol. These conclusions take into account the *ca.* 2.7 kcal/mol $\Delta G^0$ in favor of the equatorial form of $N$-methylpiperidine[3].

A general but basic point, that needs consideration before discussion of the various systems, is the applicability of $\Delta G^{+}$ values from coalescence data in any comparative analysis. The barriers we are discussing range from *ca.* 6 to *ca.* 15 kcal/mol over a correspondingly large temperature range. If a nitrogen inversion process had an entropy of activation appreciably different from zero, $\Delta G^{+}$ would vary with temperature, making comparison of data obtained at different temperatures inappropriate. However, all recent carefully determined[10, 16-18] values of $\Delta S^{+}$ for nitrogen inversion processes fall in the range $0 \pm 2.5$ cal mol$^{-1}$ K$^{-1}$ rendering $\Delta G^{+}$ values a relatively good and reliable means of comparing activation energies. Finally, it was not clear that incremental schemes of the type proposed by us are at all satisfactory for the analysis of substituent effects in anything but a qualitative sense. *Riddell et al.*[19] have shown how dependent these schemes can be on one selected piece of data and that additivity of substituent effects does not hold in certain cases.

The data presently available on N-inversion barriers in $N$-methylated six-membered nitrogen-containing rings are collected in Table 2. Where possible, both *ax*→ *ts* and *eq*→ *ts* half barriers are given: there is generally an experimental error of ±0.2 kcal/mol in coalescence determinations of $\Delta G^{+}$.

## 4. Strained Piperidines

Although the equatorial conformation of 1,2,2,6-tetramethylpiperidine *(9)* is only favored by $\Delta G_c^0 = 1.9$ kcal/mol (*cf.* $\Delta G^0 \approx 2.7$ kcal/mol for $N$-methylpiperidine), both half-barriers are considerably higher than those of $N$-methylpiperidine. Destabilization of the transition state with three eclipsed methyl groups is evidently much greater than the destabilizing torsional and van der Waals interactions of the three adjacent equatorial methyl groups in the equatorial conformation (Scheme 1).



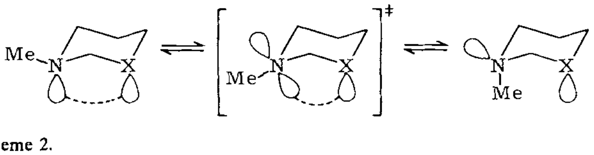
Scheme 1.

For the piperidines with fused benzene rings, [2-methyltetrahydroisoquinoline *(7)* and the naphthalene derivative *(5)*], only the *eq*→ *ts* barriers are known. Compared with 1-methylpiperidine this is marginally lower in *(7)*, but considerably raised in *(5)* by the strain involved in expanding the C—N—C bond angle to the 120° required for pyramidal N-inversion.

The bridged azabicyclononane *(6)* has its $N$-methyl group axial with respect to one ring and equatorial with respect to the other in each conformer: the measured barrier should therefore be compared to *ax*→ *ts* for piperidine, and is considerably raised by the strain in the transition state. For $N$-methyltropane *(10)* the strain is still greater in the transition state and the *ax*→ *ts* barrier is raised by 3.2 kcal/mol: however, some strain is now found in the *eq* ground state and thus *eq*→ *ts* is only raised by 1.4 kcal/mol. The barrier found for the azabicyclooctane *(8)* is near that for *ax*→ *ts* in $N$-methylpiperidine: this molecule, with boat-rings, is not strictly comparable with the others but evidently differential strains cancel in ground and transition states.

## 5. 1,4-Di- and 1,3,5-Triheteracyclohexanes

Compared with $N$-methylpiperidine, the axial conformation ground state of 1,3-heteraazacyclohexanes is stabilized by (i) removal of a β-*syn*-axial proton, (ii) the generalized anomeric effect and (iii) for the S—N-heterocycles, by further alleviation of *syn*-axial van der Waals interaction, by the greater S—N transannular distance. The equatorial conformation is destabilized by the anomeric effect and, in the case of sulfur-nitrogen heterocycles, also by torsional effects[20]. The transition state is also probably destabilized by N(p)−X(sp$^3$) lone pair—lone pair interaction (see Scheme 2).



Scheme 2.

Taken together, these interactions should increase the *ax*→*ts* barrier (positive β-heteroatom effect) but decrease the *eq*→*ts* barrier (negative β-heteroatom effect), compared to corresponding values for *N*-methylpiperidine. This conclusion amalgamates ideas from both the original analyses[2], and is amply borne out by the barriers for the three parent compounds *(11)*, *(12)* and *(13)*: *ax*→*ts* = 7.0—7.8 and *eq*→*ts* = 7.9—7.1 kcal/mol (Table 2); for 1-methylpiperidine *ax*→*ts* = 6.0 and *eq*→*ts* = 8.7 kcal/mol). A similar trend observed for 1-oxa-2-aza-4-heteracyclohexanes when compared with 2-methyl-1-oxa-2-azacyclohexane *(3)*, is discussed below.

For methylated 1,3,5-triheteracyclohexanes, the interconversion path must be defined. Two intermediates are possible: 1. the conformer with no axial methyl groups (*ee*) or 2. the conformer with two axial methyl groups (*aa*). Which intermediate is involved has no effect on the interpretation, since the measured barrier is that for *aee*→*ts* [for *(14)*] or *ae*→*ts* [for *(15)*]. However, there are also two possible transition states (Fig. 1): $t_x$ should have a higher energy than $t_y$, due to greater electronic interactions; thus pathway (2), *via* intermediate *aa*, is more likely. It follows that the measured barriers are *eq*→*ts*, and once again we clearly see the effects of the β-heteroatoms in lowering the *eq*→*ts* barriers (Table 2). The *ax*→*ts* barriers are not experimentally accessible, but they must be *lower* than those for *eq*→*ts* (see Fig. 1); however, in these cases the axial ground state has two *syn*-axial methyl groups and is hence itself of rather high energy.

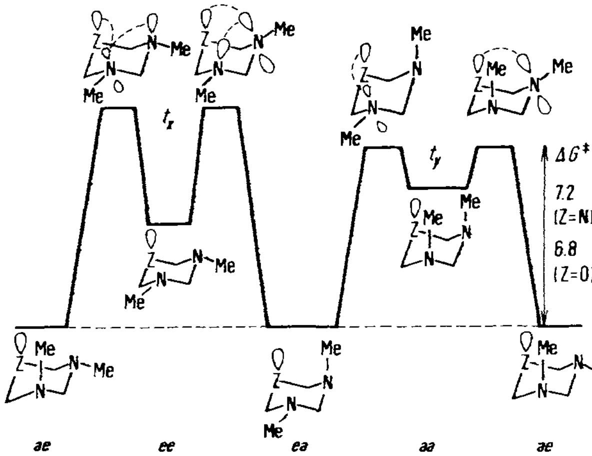


Fig. 1 Conformational equilibria of 1,3,5-trimethyl-1,3,5-triazacyclohexane *(14)* (Z = NMe) and 3,5-dimethyl-1-oxa-3,5-diazacyclohexane *(15)* (Z = O). Values in kcal/mol.

The high N-inversion barriers for *trans*-1,4,5,8-tetraazadecalin *(17)*, a '1,3-diazacyclohexane'[*], reflect additional transition state strain from (i) eclipsing methyl-methyl, (ii) p-$sp^3$ lone pair—lone pair ('passing') interactions, and (iii) rigidity of the *trans*-ring junction. Still higher barriers are found for the bicyclo[2.2.2]octylhydrazines *(26)*[15] ($\Delta G_c^{\ddagger}$ =

## 6. 1,3-Diheteracyclohexanes with Equatorial *C*-Methyl Groups in α-Position to *N*-Methyl Groups

The data in Table 2 lead to the following conclusions: (i) provided there are not more than two adjacent methyl groups, the effect of *C*-methyl on the equilibria and kinetics of *N*-methyl is small [cf. *(20)* and *(21)* with *(12)*]: (ii) three adjacent methyl groups raise *ax*→ *ts* barriers by 1.0–1.3 kcal/mol [cf. *(18)* and *(19)* with *(11)*, and *(22)* with *(12)*]: (iii) three adjacent methyl groups can considerably affect *eq*→ *ts* barriers, but the effect is variable (−0.8 to +0.5 kcal/mol for the two comparisons available).

Conclusions (ii) and (iii) can be rationalized in the following way: upon insertion of an α-equatorial *C*-methyl group leading to three adjacent methyl groups, the energy of the ground state for an equatorial *N*-methyl group is raised, as well as that for the transition state ('passing Me—Me interactions'); the effect is least for the axial *N*-methyl ground state. Comparison of the data (Table 2) for 1,3-dimethyl- *(11)* and 1,2,3-trimethyl-1,3-diazacyclohexane *(18)* shows that *ts* is raised by 1.0 and *eq* by 1.8 kcal/mol more than the *ax* ground state. A similar comparison of 3-methyl- *(12)* and 2,3,4-trimethyl-1-oxa-3-azacyclohexane *(22)* gives the *ts* and *eq* raised by 1.2 and 1.8 kcal/mol, respectively, more than the *ax* ground state. Finally, comparison of the tricyclic derivative *(19)* with *(18)* gives 0.3 and 1.3 kcal/mol respectively.

## 7. 1,2-Diazacyclohexanes

The conformational analysis of these compounds, including their N-inversion barriers, has been authoritatively reviewed by *Nelsen*[21] and only a brief account will be given here. The Norwich group originally pointed out[2a,22] that there were two different *N*-inversion barriers for these compounds and this has now been amply confirmed[21] with a distinction being made between (i) low 'non-passing' barriers for *N*-methyl inversion when the adjacent *N*-methyl group is *axial* and (ii) high 'passing' barriers when the adjacent *N*-methyl group is *equatorial*. It was originally believed[22] that the high energy of the transition state for the 'passing' barriers arose from steric methyl-methyl interactions, but later realized[2a] that the lone pair-lone pair interaction is mainly responsible (see detailed discussion in [21,23]).

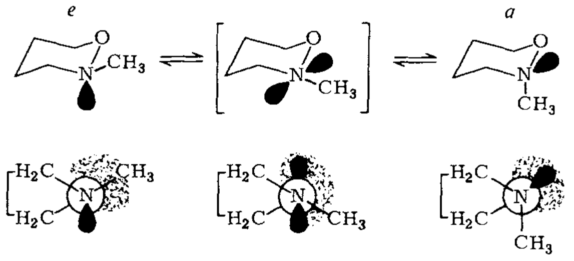
*Nelsen*'s work[24] on the bicyclic derivative *(25)*, for which ring inversion is not possible, allows accurate determination of the 'passing' *ax*→ *ts* and *eq*→ *ts* barriers as 12.6 and 12.9 kcal/mol, respectively; *i.e.* they are raised by 6.6 and 4.2 kcal/mol respectively, compared to *N*-methylpiperidine. For the parent compound *(23)*, only lower limits are available for these barriers because of ambiguity with ring inversion, but they are in good accord. For the unsaturated compound *(24)* a high passing barrier of 12.0 kcal/mol cannot be unambiguously assigned, hence the passing N-inversion barrier (*ax*→ *ts*) is ⩾12.0 kcal/mol.

The non-passing *eq*→ *ts*-barriers determined for the parent compounds *(23)* and *(24)* are, at 7.6 and 8.1 kcal/mol, respectively, significantly lower than *eq*→ *ts* for *N*-methylpiperidine; compound *(30)*, with a single adjacent *C*-methyl group, falls in the same range.

Only upper estimates for the non-passing *ax*→ *ts* barriers can be given for *(23)*, *(24)*, and *(30)*, as no signals were detected for the *aa*-conformers at low temperature: they may not be very different from *ax*→ *ts* in *N*-methyl piperidine. Only high passing N-inversion barriers are observed for *(31)* and *(32)*: the non-passing N-barrier for *(32)* is thought to be ⩽7.6 kcal/mol[23] owing to destabilization of the *ae*-ground state by axial *C*-methyl groups.

## 8. 1-Oxa-2-azacyclohexanes

We now agree that $\Delta G^{+} = 14.4$ kcal/mol found for the parent *N*-methyl compound *(3)*[2b,10] arises from N-inversion, that it should be assigned to *eq*→ *ts* (following NMR criterion (iii), see Section 2), that the $\Delta G^0$ is ⩾3.7 kcal/mol[19], and that the *ax*→ *ts* half-barrier is hence ⩽10.7 kcal/mol. Therefore, compared to *N*-methylpiperidine, the *ax*→ *ts* and *eq*→ *ts* half-barriers are raised by ⩽4.7 and 5.7 kcal/mol, respectively. Clearly, the transition state for inversion in *(3)* is raised by lone pair-lone pair interactions, which are qualitatively similar to those found for the passing N-inversion in 1,2-dimethyl-1,2-diazacyclohexane *(23)* (see Section 7) (Scheme 3).



Scheme 3.

The non-passing *N*-methyl inversion in 1,2-diazacyclohexane *(23)* has half-barrier energies not vastly different from those of *N*-methylpiperidine *(1)*: this indicates that an α-equatorial lone pair has little effect on the transition state energy. Hence, the major differences in half-barrier energies between 1,2-diazacyclohexane *(23)* and 1-oxa-2-azacyclohexane *(3)* are probably due to ground state energy variations. Quantitative comparison indicates that the equatorial ground state in *(3)* is stabilized relative to *(25)* by 1.5 kcal/mol and the axial ground state is destabilized by ⩾1.9 kcal/mol. The former effect is probably mainly steric: loss of methyl-methyl interaction. The latter is certainly due to gain in unfavorable lone pair-lone pair interactions. Barriers in the unsaturated analogue *(28)* are rather similar to those of *(3)*. Manifestations of these effects are also observed in the bicyclooctanes *(8)* and *(27)*, and *(26)* and *(29)*: lone pair-lone pair interactions and torsion effects in *(27)* lead to an increase of 1.4 kcal/mol for the barrier to *N*-methyl inversion relative to *(8)*. A similar but greater increase (+2.7 kcal/mol) is found on proceeding from *(26)* to *(29)*.

## 9. 1,2,4-Triheteracyclohexanes with Two Adjacent *N*-Methyl Groups

The 1,2,4-triheteracyclohexanes *(33)*, *(34)*, and *(35)* have high passing barriers of > 13 kcal/mol: however, the passing N-inversion barriers cannot be distinguished unambiguously from the similar energy, passing ring inversion barriers. The non-passing N-inversion barriers in these compounds have been unequivocally determined and will be discussed at length.

The relevant conformational equilibria for 1,2,4-trimethyl-1,2,4-triazacyclohexane *(33)* are shown in Figure 2[*]. The measured barrier of 7.5 kcal/mol relates to the $\Delta G^{\ddagger}$ for the conversion of conformers *ae* and *ea*, where conformer *ae* is more stable by $\Delta G^0 = 1.0$ kcal/mol (this is discussed in detail in [25]). Conformers *ae* and *ea* are interconverted *via* the still less stable conformer *aa*, and thus $\Delta G^{\ddagger}$ could either refer to *ea→aa/ea* or to *ea→ae/aa*, depending on whether *aa/ea* or *ae/aa* has the higher energy. However, we can equate the energy difference (*ae/aa* − *ae*) to the 7.6 kcal/mol barrier measured for the *N*-inversion of 1,2-dimethyl-1,2-diazacyclohexane *(23)*[21], because the γ-effect is known to be small *(vide infra)*. Hence, the observed $\Delta G^{\ddagger}$ must refer to *ea→aa/ea*, and by difference, the β-effect is calculated as a 1.1 kcal/mol *raising* of the *ax→ts* barrier *aa→aa/ea*. The barrier *aa→ae/aa* is presumably the same as in 1,2-dimethyl-1,2-diazacyclohexane, for which we only have an upper limit ≤6.0 kcal/mol. We can now calculate $\Delta G^{0\prime}$ for the minor conformer *aa* as ≥0.9 kcal/mol. Similar conclusions follow for 3,4-dimethyl-1-oxa- *(35)* and 3,4-dimethyl-1-thia-cyclohexane *(34)*. Figure 2 includes the values of $\Delta G^{\ddagger}$ and $\Delta G^0$ measured for both of these compounds. The β-effects of the O and S heteroatoms *raise* the *ax→ts* barrier *aa→aa/ea* by 1.0 and 0.5 kcal/mol respectively. $\Delta G^{0\prime}$ for the minor conformers *aa* are estimated as ≥1.1 and ≥0.7 kcal/mol, respectively. β-Effects are observed for the *N*-2- and *N*-3-inversion, respectively for *(33)*, *(34)*, *(35)*, as expected.

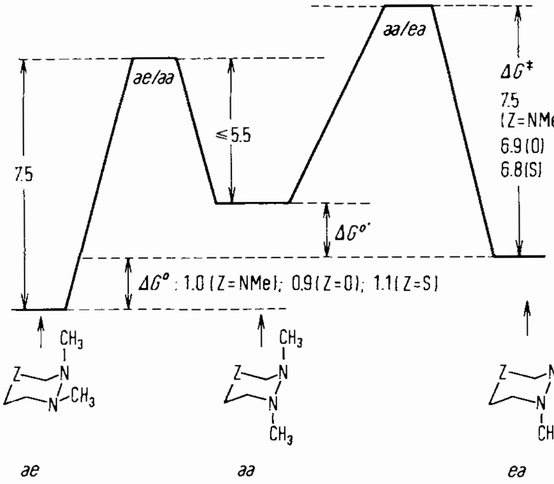


Fig. 2. Conformational equilibria for 1,2,4-trimethyl-1,2,4-triazacyclohexane *(33)* [Z=NMe (*eq*)]; 3,4-dimethyl-1-oxa-3,4-diazacyclohexane *(35)* [Z=O]; and 3,4-dimethyl-1-thia-3,4-diazacyclohexane *(34)* [Z=S]. Values in kcal/mol.

## 10. 1,2,4-Triheteracyclohexanes without Two Adjacent *N*-Methyl Groups

We consider first the compounds with a single N atom. The barriers in 2-methyl-1,4-dioxa-2-azacyclohexane *(39)* and 2-methyl-1-oxa-4-thia-2-azacyclohexane *(40)* can be compared with those of *(12)* and *(13)* to demonstrate that the effect of an α-oxygen atom is to raise the *ax→ts* and *eq→ts* barriers by 2.9 and 3.9—4.5 kcal/mol, respectively. This can be compared with the value of ≤4.7 and 5.7 kcal/mol for the effect of an α-oxygen on the barrier in *N*-methylpiperidine [cf. *(1)* and *(3)*]: additivity is evidently not maintained. A further comparison can be made with 2-methyl-1-oxa-2-azacyclohexane to determine the effect of a β-heteroatom: this is found to *lower* the *eq→ts* barrier by 3.0 and 2.9 kcal/mol for oxygen and sulfur, respectively [compare *(3)* with *(39)* and *(40)*]; corresponding effects on the *ax→ts* barrier are certainly much smaller and probably in the other direction, but cannot be calculated exactly.

The effects of adjacent geminal *C*-methyl groups on the N-inversion in *(39)* and *(40)* is shown by compounds *(41)* and *(42)* to raise *ax→ts* and *eq→ts* barriers by 0.6—1.0 and 0.3—0.4 kcal/mol, respectively.

The N-2-inversion process in 2,5-dimethyl-1-oxa-2,5-diazacyclohexane *(43)* shows that the γ-nitrogen atom has no noticeable effect: the *eq→ts* barrier is identical with that of *(3)*: in the *C*-methyl derivatives *(45)* and *(46)*, analogously high barriers are found for the N-2-inversion (13.1—13.9 kcal/mol) showing the small effect of α-C-methyl groups.

Comparison of the N-2-inversion processes in 2,4-dimethyl-1-oxa-2,4-diazacyclohexane *(44)* and 1,3-dimethyl-1,3-diazacyclohexane *(11)* shows that the α-oxygen atom increases the *ax→ts* and *eq→ts* barriers by 4.1 and 4.8 kcal/mol, respectively. Comparison with 2-methyl-1-oxa-2-azacyclohexane *(3)* indicates that the β-nitrogen atom in *(44)* raises the *ax→ts* barrier by ≥0.4 and lowers the *eq→ts* barrier by 1.7 kcal/mol (see Fig. 3).

The N-5-inversion barrier for 2,5-dimethyl-1-oxa-2,5-diazacyclohexane *(43)* and the N-4-inversion barrier for the 2,4-analogue *(44)* are, within 0.2 kcal/mol, identical to the corresponding barriers in *(12)* and *(11)*, respectively, showing that the γ-oxygen and γ-nitrogen effects are negligible. The effect of a 6-methyl group in *(45)* or 6,6-*gem* dimethyl groups in *(46)* is almost zero for the *ax→ts* barrier but raises the *eq→ts* barriers of *(43)* by 0.7 kcal/mol: the former agree, but the latter is significantly greater than those found in the corresponding pair *(12)/(20)*.

---

[*] We do not consider any conformers with an axial *N*-4-Methyl group: the lowest energy of these (1*e*2*e*4*a*)- and (1*e*2*a*4*a*)-conformers still have energies *above* both *ae* and *ea*, and will not be involved in the *ae→ea* interconversion.

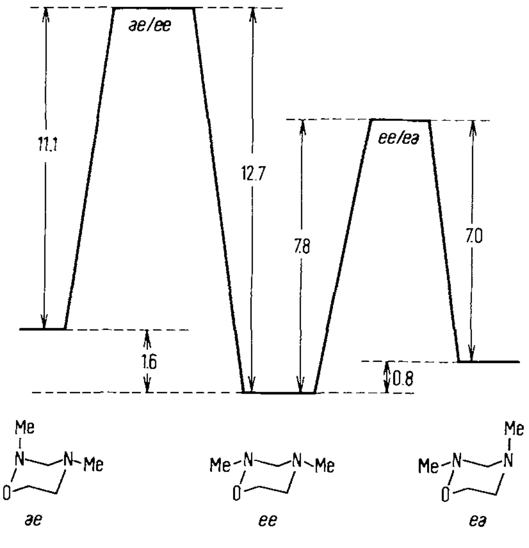

Fig. 3. Conformational equilibria and kinetics for 2,4-dimethyl-1-oxa-2,4-diazacyclohexane *(44)*. Values in kcal/mol.

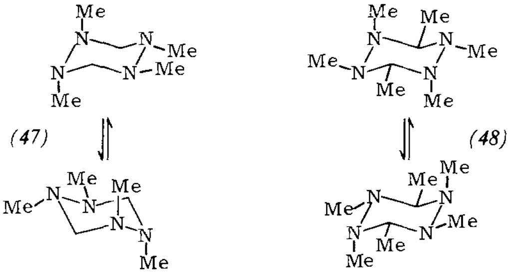
## 11. Tetraheteracyclohexanes

Interconversion of the mirror image form of *sym*-tetramethyltetrazacyclohexane *(47)* (Scheme 4, left) involves either (i) passing ring inversion and non-passing N-inversion or (ii) passing N-inversion. We therefore know that the passing N-barrier *eq→ts* in *(47)* is ⩾11.8 kcal/mol. It would be expected to be similar to that for the 1,2,4-triaza-analogue *(33)* (12.0 kcal/mol).



Scheme 4.

In the hexamethyl analogue *(48)* (Scheme 4, right), the non-passing *eq→ts* barrier is 7.7 kcal/mol, almost identical to the corresponding barrier of 7.9 kcal/mol for *trans*-1,2,3,6-tetramethyl-1,2-diazacyclohexane *(30)*.

## 12. Summary

Due to substantial and variable conformational bias, N-inversion barriers in six-membered rings must be discussed in terms of the half-barriers *ax→ts* and *eq→ts*. For *N*-methylpiperidine we have decided that $\Delta G^{+}(ax\rightarrow ts)=6.0$ kcal/mol and $\Delta G^{+}$ $(eq\rightarrow ts)=8.7$ kcal/mol.

γ-Heteroatoms have negligible effects on both half-barriers (⩽0.2 kcal/mol). β-Heteroatoms *increase* the *ax→ts* (positive β-heteroatom effect), but *decrease* the eq→ts (negative β-heteroatom effect) barriers. These β-heteroatom effects are rather regular: an equatorial β-*N*-methyl group increases the *ax→ts* barrier by 1.0 kcal/mol, whereas β-oxygen and β-sulfur atoms have greater effects (+1.6 and +1.8 kcal/mol respectively). Similarly, the β-heteroatom effects on the *eq→ts* barrier are respectively −0.8, −1.2, and −1.6 kcal/mol for *eq* *N*-Me, -O and -S. The effects of α-heteroatoms are less regular: axial α-*N*-methyl groups significantly *decrease* the *eq→ts* barrier (*ca.* −1.1 kcal/mol), their effect on the *ax→ts* barrier is probably small. By contrast, equatorial α-*N*-methyl groups and α-oxygen atoms *increase* both the *ax→ts* and *eq→ts* barriers by 2.9−6.6 kcal/mol: the effect of an equatorial α-*N*-methyl group is greatest on the *ax→ts* and that of an α-oxygen is greatest on the *eq→ts* barrier.

α-*C*-methyl groups show small effects on the barriers, unless either three methyl groups on adjacent ring atoms result or a geminal dimethyl group is involved. In the former case, the *ax→ts* barriers are considerably increased, but the effect is less regular on *eq→ts*. In the latter case the reverse applies.

These effects are rationalized in terms of steric and electronic interactions.

## 13. General Significance of Results

The concept of using "half-barriers" to describe conformational changes does not appear to have been much utilized in the past, but it is clearly of general applicability. In principle, for any biased equilibrium the energy of the transition state relative to the ground state depends on which of the two (or more) ground states is considered as reference. This applies, for example, to the conformational equilibria of carbocyclic compounds, to inversion barriers for acyclic pyramidial compounds containing a chiral center, and to many rotational barriers.

Underlining the importance of realization of this concept is the fact that different experimental measurements are related to different ground states. General adoption of the quotation of equilibrium interconversions in terms of half-barriers, as described in the present paper, would be helpful in avoiding ambiguity and confusion.

# Benzvalene—Properties and Synthetic Potential

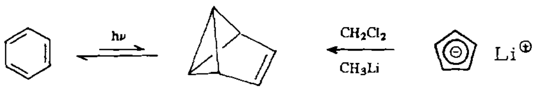
## By Manfred Christl[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

Today, thanks to the versatile synthesis developed by *Katz et al.*, benzvalene is not only the most extensively studied valence isomer of benzene but also one of the most easily synthesized bicyclo[1.1.0]butane derivatives. The double bond in this highly strained hydrocarbon is particularly reactive owing to interactions between the σ system and the double bond. Benzvalene is one of the most reactive olefins toward electron deficient substrates. Furthermore, the compound is bifunctional, since after addition to the π system the ring strain of the σ system provides the driving force for rearrangement or further addition reactions. This paper summarizes the spectroscopic properties and the reactivity of benzvalene. In order to demonstrate the importance of benzvalene and its derivatives as building blocks in organic synthesis the chemistry of compounds arising from benzvalene is also discussed. The article concludes with a summary of substituted benzvalenes.

## 1. Introduction

For the research chemist to be interested in a particular compound, three important requirements must be met: first, it must be easily accessible, it should be highly reactive, and the reaction products must show interesting properties. Cyclooctatetraene, norbornene and without doubt benzvalene *(1)* are examples of compounds satisfying these conditions.



*(1)*

The substituted derivatives *(243)*[1] and *(245)*[2] (Section 4) were already known when in 1967 *Wilzback et al.*[3] identified benzvalene *(1)* as a photoproduct of benzene. Four years later, *Katz et al.*[4,5] reported a versatile synthesis starting from lithium cyclopentadiene, dichloromethane, and methyllithium, which made it possible to obtain 20 g quantities of *(1)*. This opened up the way for intensive studies of its physical and chemical properties and also

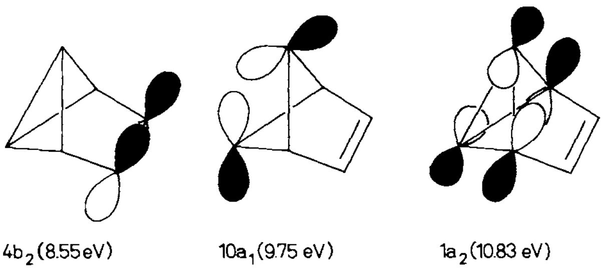
permitted an experimental evaluation of theoretical predictions[6,7].

## 2. Spectroscopy of Benzvalene

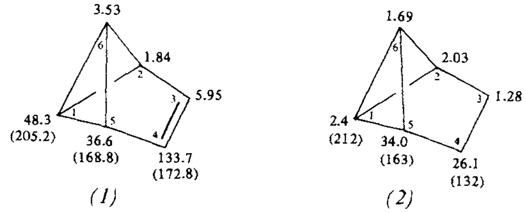
The presence in benzvalene *(1)* of two functionalities in close proximity, namely the olefinic double bond and the bicyclo[1.1.0]butane system, leads to strong interactions. This results in a UV absorption band with a maximum at $\lambda = 217$ nm ($\varepsilon \approx 2500$)[8]. In contrast, 1,2-dialkylethylenes and bicyclo[1.1.0]butane[9] show no significant absorption above 200 nm. This relatively longwave band is due, at least in part, to the increased energy of the double bond $\pi$ orbital ($4b_2$) as a result of interaction with an occupied orbital of the proper symmetry in the bicyclo[1.1.0]butane system. This follows from the photoelectron spectrum where the first ionization potential appears at 8.55 eV[10-12] (for comparison: cyclopentene 9.01, 9.18 eV[13a]; norbornene 8.97 eV[13]). Scheme 1 shows the three highest occupied orbitals of *(1)*. The ordering is based on calculations[6,10], according to which the second absorption band at 9.75 eV is due to the orbital ($10a_1$) localized almost exclusively in the central bond of the bicyclo[1.1.0]butane system. The $1a_2$ orbital (corresponding to the third ionization band at 10.83 eV) is an important contributor to the four peripheral bicyclo[1.1.0]butane bonds. The second and third ionization potentials of *(1)* are increased and decreased, respectively, in comparison with those of the unsubstituted bicyclo[1.1.0]butane (9.39 and 11.30 eV[12]). This is a consequence of the decreased angle between the two three-membered rings due to the etheno bridge[10]. It is interesting to note that in homobenzvalene *(118)* the order of the two highest occupied orbitals is interchanged: here, the HOMO is the $\sigma$ orbital of the central bicyclo[1.1.0]butane bond[12,14].



Scheme 1. The three highest occupied orbitals of benzvalene *(1)*.

The structural parameters of *(1)* were established using microwave spectroscopy[15] and electron diffraction[16]. The results are in agreement with the exception of the CH bond lengths (1.08 Å[15] and 1.14 Å[16], resp.). The dihedral angle is reduced from 121.7° in bicyclo[1.1.0]butane[17] to 106° in *(1)*. Therefore, the central bond arising from atomic orbitals possessing more than 90% p-character is shortened, from 1.497 Å in bicyclo[1.1.0]butane (C1—C3)[17] to *ca.* 1.45 Å in *(1)* (C1—C6). This trend is even more evident in the case of the bicyclo[1.1.0]butanes where the dihedral angles are even smaller[18]. The dipole moment of *(1)*, 0.88 D[19], obtained from the Stark effect in the microwave spectrum, is somewhat larger than that of bicyclo[1.1.0]butane (0.68 D)[17]. Calculations[6] show that for both molecules the negative end of the dipole is on the *endo* side of the bicyclo[1.1.0]butane system, *i.e.* in *(1)* at the site of the C=C double bond, which itself, however, contributes only 20% to the dipole moment.

The IR[20] and Raman spectra[21] of *(1)* have been thoroughly analyzed. The exceptionally low frequency (1556 cm$^{-1}$) of the C=C stretching vibration as well as the NMR spectra (Scheme 2) undoubtedly reflect the conjugation between the double bond and the strained $\sigma$ system. The signal for the allylic protons (2,5-H) appears at $\delta = 1.84$, *i.e.* at considerably higher field than the protons in the 1,6-position ($\delta = 3.53$)[3]. The unusually low field absorption of 1,6-H compared to the saturated system *(2)*[22] is also reflected in the corresponding $^{13}C$ chemical shifts: *(2)* shows signals at $\delta = 2.4$ and 34.0 which are typical values for the central and lateral hydrogen atoms in bicyclo[1.1.0]butanes[22,23]. In *(1)* the sequence is inverted. Although the position of the C2,5 signal is more or less unchanged, the C1,6 signal appearing at $\delta = 48.3$ is shifted by 45.9 ppm to lower field[24,25]. This low field shift arises from the interaction between the $\pi^*$ orbital of the double bond and the $a_2$ orbital of the bicyclo[1.1.0]butane system. This is also found in other rigid envelope-shaped cyclopentenes, the magnitude depending on the degree of ring strain[24]. Also the $^{13}C—^1H$ coupling constants in *(1)* and *(2)* show significant differences.

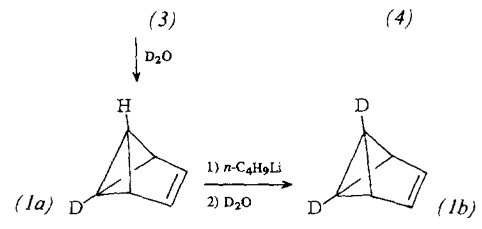


Scheme 2. $^1H$- (at positions 6,2,3) and $^{13}C$-NMR data (at positions 1,5,4, in brackets $J_{^{13}C^1H}$ in Hz) of benzvalene *(1)* and dihydrobenzvalene *(2)*. $\delta$ values, measured in $C_6H_6$ and $CDCl_3$, respectively.

## 3. Reactions of Benzvalenes

### 3.1. Metalation

As in other bicyclo[1.1.0]butanes[26] the bridgehead hydrogen atoms 1,6-H in *(1)* are comparatively acidic and therefore react easily with butyllithium to give the metalated product 1-benzvalenyllithium *(3)*[27]. This in turn reacts with methyl iodide to give 1-methylbenzvalene *(4)*[28] or with heavy water to give 1-deuteriobenzvalene *(1a)*. The



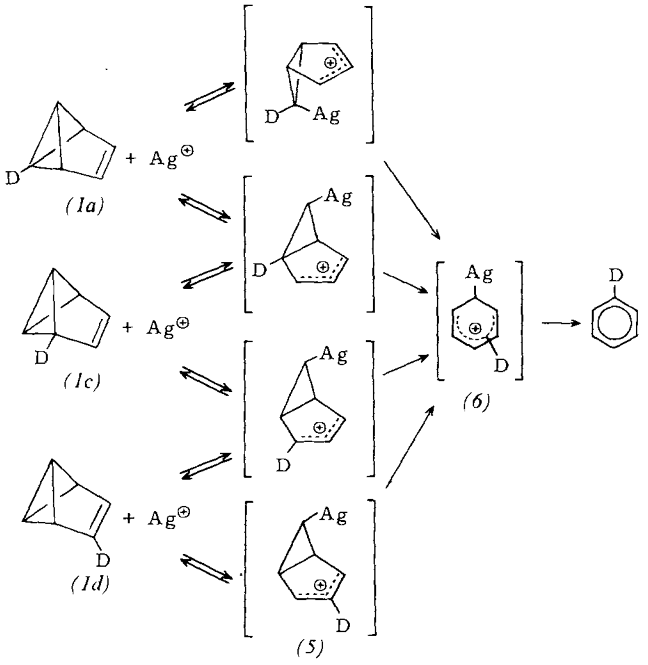
latter can undergo a further metalation, followed by treatment with $D_2O$, giving 1,6-dideuteriobenzvalene *(1b)*[27]. *(1a)*, which can also be obtained from $CD_2Cl_2$ by the Katz synthesis[29], as well as *(1b)* are highly useful in mechanistic studies.

### 3.2. Isomerization and Formation

*Hückel*[30] mentioned the formula for tricyclo[3.1.0.0$^{2,6}$]hex-3-ene already in 1937. The trivial name, benzvalene, is, however, due to *Viehe*[1,31] who wished to convey not only the relationship with benzene, but also the possibility of degenerate valence isomerism (automerization)—*e.g.* through a 1,3-shift of the C6—C2 bond. According to the principle of the conservation of orbital symmetry[32], at the time unknown, the process is thermally forbidden and also unobserved due to the migration being forced to occur suprafacially and with retention of configuration at the migrating C atom.

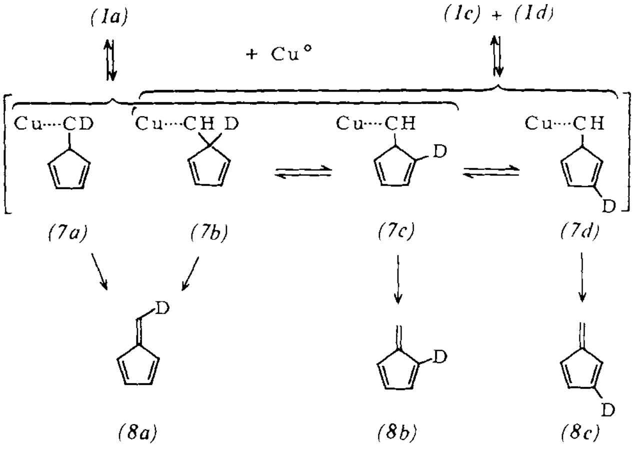
#### 3.2.1. Silver Ions and Metals

*Burger* and *Mazenod* have shown that silver(I) ions[33] and copper(0)[34] catalyze an automerization of *(1)*[25]. $Ag^{\oplus}$ ions catalyze the isomerization of *(1)* to benzene. When the isomerization of *(1a)* is interrupted after one half-life, the deuterium label is found distributed over positions 1, 2 and 3 [*(1a)*, *(1c)*, and *(1d)*]. The fact that the starting benzvalene is labeled in only *one* position means that a reversible reaction, involving *two* cations of the type *(5)*, must be involved[33]. This mechanism also explains the formation of *o*-, *m*-, and *p*-dideuteriobenzene when *(1b)* is treated with silver salts[35]. The end product of the *(1a)* isomerization reaction, deuteriobenzene, is probably formed from the cation *(5)* *via* argentobenzenium ions of the type *(6)*. The *endo* attack by $Ag^{\oplus}$ on *(1a)*, *(1c)*, and *(1d)* is analogous to protonation (see Section 3.3.1), where the stereochemical course of the reaction has been established. The $Ag^{\oplus}$-catalyzed rearrangement of tricyclo[4.1.0.0$^{2,7}$]heptane to 1,3-cycloheptadiene derivatives (the so-called α-rearrangement) is analogous to the benzvalene isomerization[36].



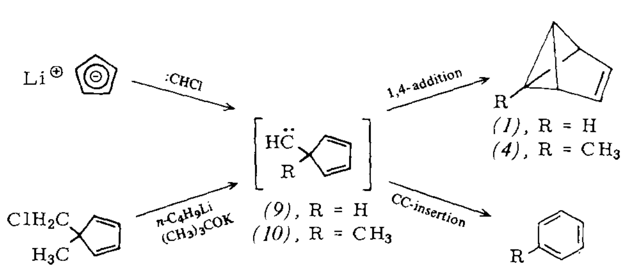
Whereas metallic silver and iron transform *(1)* into benzene, platinum, palladium, gold, nickel, and copper[3] catalyze the isomerization to fulvene *(8)*[34]. When *(1a)* reacts with copper, after *ca.* 100 sec at 25 °C, the benzvalene derivatives *(1a)*, *(1c)*, and *(1d)* are isolated in the ratio: 81 : 12 : 7. It was postulated in this case that the reaction proceeds by reversible 1,2- or 1,4-retrocarbene addition *via* the copper cyclopentadienylcarbene complexes *(7a)*–*(7c)*.

A second scrambling process must be involved because the ratio of the fulvene products *(8a)* : *(8b)* : *(8c)* (56 : 24 : 20), deviates strongly from that of *(1a)* : *(1c)* : *(1d)*. This second process must be a [1,5]-H migration leading to an equilibrium between *(7b)*, *(7c)*, and *(7d)*. The irreversible [1,2]-H shift to the exocyclic carbon atom completes the formation of the fulvene. The gas chromatography of *(1a)* on a copper column reportedly gives a quantitative yield of *(8a)*[37a].



#### 3.2.2. The Mechanism of the Katz Benzvalene Synthesis

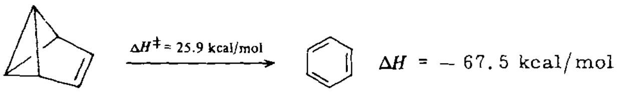
The above processes do not play a role in the Katz synthesis of *(1)* because when labeled dichloromethane is used, the resulting benzvalene is labeled in the 1-position only[29], and benzene is the only side product. A likely intermediate is the cyclopentadienylcarbene *(9)* which undergoes ring expansion to benzene, however, in the main reaction cyclizes to *(1)*, the latter process being an extremely rare 1,4-addition of a carbene.



The fact that, apart from toluene and spiro[2,4]hepta-4,6-diene only 1-methylbenzvalene *(4)* is formed in the reaction of *(10)* (formed from 5-chloromethyl-5-methylcyclopentadiene), excludes participation of the equally possible 1,2-addition as shown by *Burger* and *Gandillon*[28]. Early reports of benzvalenes labeled in all possible positions[15,37b] in the synthesis with D- or $^{13}$C-labeled dichloromethane do not, therefore, concern the synthesis itself, but rather the subsequent metal-catalyzed automerization.

### 3.2.3. Thermolysis and Thermochemical Data

The half-life of the thermal isomerization of *(1)* to benzene in ether at 30 °C is 48 h[28]. In *n*-heptane an enthalpy of activation of 25.9 kcal/mol was measured. The reaction enthalpy for the Ag$^{\oplus}$-catalyzed process is −67.5 kcal/mol[38]. Since the transformation to benzene is so exothermic, and the activation energy so low, it is not surprising that pure *(1)* is susceptible to detonation[4]. Yet, it can be safely handled in dilute solution.



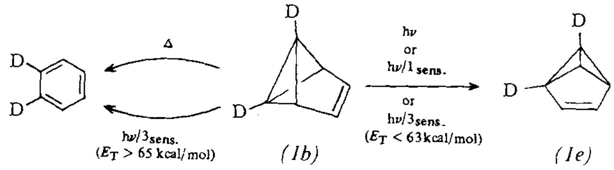
An approximate value of the heat of formation of *(1)* (87.3 kcal/mol) can be calculated from the standard heat of formation of benzene (19.8 kcal/mol)[39]. Group increments[39] yield a $\Delta H_f^0$ value of 10.4 kcal/mol for strain free *(1)*. In other words, the strain energy of *(1)* is *ca.* 77 kcal/mol, or a little higher than the sum of the strain energies of bicyclo[1.1.0]butane (67 kcal/mol) and cyclopentene (5.9 kcal/mol)[39].

According to MINDO/3 calculations the value of $\Delta H_f^0$ was at first estimated to be 114[40] and then 102 kcal/mol[10,41]. When this is compared with the MINDO/3 value of $\Delta H_f^0$ for benzene, then a reaction enthalpy which is slightly too high, *i.e.* 73 kcal/mol[41] for the transformation of *(1)* into benzene, is found. Although a one-step thermal transformation of an *endo,endo*-bridged bicyclo[1.1.0]butane into a *cis,cis*-butadiene is forbidden[32], not only MINDO/3[42], but other calculations[43,44] as well, favor a *concerted* thermal transformation of *(1)* into benzene. This is because the double bond is involved in a six-electron process. The calculated[42] activation energy of 21.5 kcal/mol is somewhat too low.

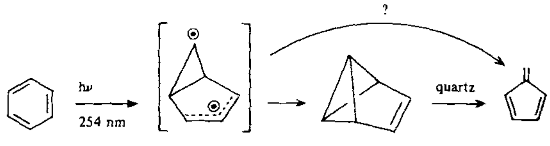
Experimental findings are also in agreement with the idea of a one-step process. Two plausible intermediates in the stepwise processes are the diradical *(11)* and Dewar benzene formed *via cis,cis,trans*-cyclohexatriene[45]. When the activation energy is compared with those of the thermal rearrangements of dihydrobenzvalene *(2)* and homobenzvalene *(118)*[46], or with the $\Delta H_f^0$ calculated for *(11)* using group increments[39], then the activation enthalpy of 25.9 kcal/mol does not seem to be large enough to generate *(11)* from *(1)*. The benzene formed in the thermolysis of Dewar benzene (by a forbidden process)[32] is chemiluminescent[47]. That formed from *(1)* is not[38], in spite of the fact that the energy liberated from the transition state (ca. 93 kcal/mol) would be more than sufficient for creation of the triplet state of benzene (*ca.* 82 kcal/mol). It follows, therefore, that Dewar benzene cannot be an intermediate in this reaction. The lack of chemiluminescence in pericyclic reactions is taken as evidence for a concerted reaction, since theory predicts the crossing of the energy surfaces for ground and triplet states and hence chemiluminescence in forbidden pericyclic reactions. As expected for a one-step reaction, the thermolysis of *(1b)* gives *o*-dideuteriobenzene[38].

### 3.2.4. Photochemistry and Photochemical Formation

In contrast to the above, direct irradiation as well as photolysis in the presence of singlet (pyrene) or triplet sensitizers (triplet energy, $E_T$, between 53 and 63 kcal/mol) leads to automerization, *i.e.* formation first of *(1e)* and then benzvalenes with two statistically scrambled deuterium atoms[48].



This is the [1,3] shift already mentioned, which *Viehe*[1,31] had in mind when naming the compound. A second benzvalene triplet state is populated using higher energy triplet sensitizers. The second triplet does not significantly decay to the first, but rather to the triplet state of benzene. The end product is *o*-dideuteriobenzene, formed with a quantum yield of *ca.* 4[48], presumably because triplet benzene sensitizes the isomerization of *(1)* to benzene[51], thereby inducing a chain process.



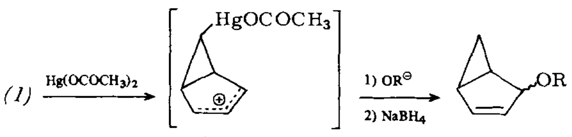
*(11)* *(1)* *(8)*

As mentioned in the introduction, *(1)* was first obtained by photolysis of benzene[3], a process in which fulvene *(8)* had already been discovered[49]. Neither of these isomers can be obtained in a yield higher than 300—500 mg per liter of pure benzene on direct irradiation at 254 nm[45]. The yields of *(1)* and *(8)* can be increased by dilution of the benzene with alkanes[3]. As common intermediate, the diradical *(11)* has been proposed[45,50]. However, *(8)* is possibly derived from *(1)* in a quartz-catalyzed reaction[45,51]. *(1)* is obtained in a measurable concentration in the direct gas-phase photolysis of benzene only in the presence of additives, which facilitate the vibrational relaxation of *(1)* and inhibit its benzene-sensitized reverse reaction[51]. The irradiation of liquid benzene at 160—200 nm gives a mixture of *(1)* and *(8)* and Dewar benzene[52].

### 3.3. Stepwise Additions to Benzvalene

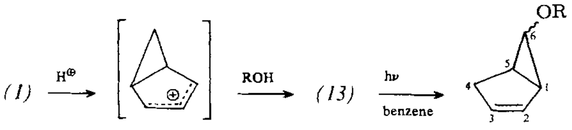
#### 3.3.1. Oxymercuration and Action of Acids

A possible intermediate in the oxymercuration[53] of *(1)* is the cation *(12)* which is analogous to the intermediate *(5)* in the Ag$^{\oplus}$-catalyzed isomerization. The cation *(12)*, however, is trapped by nucleophiles such as acetate or methanolate ions (R = CO—CH$_3$ or CH$_3$). Work-up with sodium borohydride gives low yields of the bicyclo[3.1.0]hexenyl acetates or the methyl ethers *(13)*.



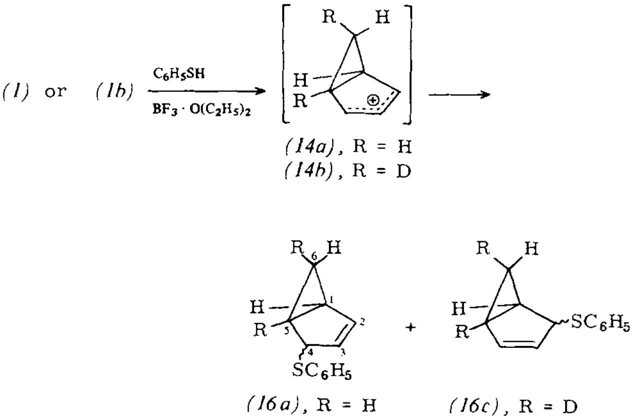
*(12)* *(13)*

Acids also react with *(1)* to give bicyclo[3.1.0]hexene derivatives. Even before the intermediate formation of *(1)* was clarified, compounds of the type *(13)* were isolated when benzene was photolyzed in acidified hydroxylated solvents (ROH = CH$_3$CO$_2$H, CF$_3$CH$_2$OH, CH$_3$OH, H$_2$O)[54]. The 6-substituted bicyclo[3.1.0]hexene derivatives *(15)* also formed originate from the benzene-sensitized vinylcyclopropane-cyclopentene rearrangement of *(13)*.



*(14)* *(15)*

Using deuterium-labeled substrates[4,54] it has been established that, in analogy to other bicyclo[1.1.0]butanes[55], a proton attacks at the bridgehead carbon, with retention, from the *endo* side. Whether or not the nucleophile ROH enters in the *exo* or *endo* position of the bicyclo[3.3.0]hexenyl cation *(14)* depends on the acidity of the medium. In a strongly acidic medium "free" *(14)* is present; thus, the nucleophiles can attack from the more sterically favorable *exo* side. On the other hand, in weakly acidic media the proton transferring, and hence *endo* oriented nucleophile has a better chance of attacking; the result is that up to 50% *endo-(13)* is formed[54].



*(14a)*, R = H
*(14b)*, R = D

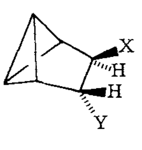
*(16a)*, R = H
*(16b)*, R = D
*(16c)*, R = D

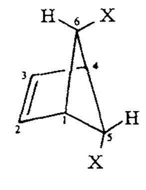
Thiophenol reacts with *(1)* in the presence of boron trifluoride etherate like an acid, giving a high yield of predominately *exo-(16a)*[56]. In agreement with the above, the use of *(1b)* as starting material leads to the specific appearance of one deuterium atom in the *exo*-6 position; the other deuterium atom is evenly distributed over positions 1 and 5, thus giving a 1 : 1 mixture of *(16b)* and *(16c)*[57]. The presence of a deuterium atom at one bridgehead carbon means that in contrast to *(14a)*, *(14b)* is unsymmetrical. Hence, there are two different but equivalent centers for attack by the sulfur nucleophile.

#### 3.3.2. Halogens

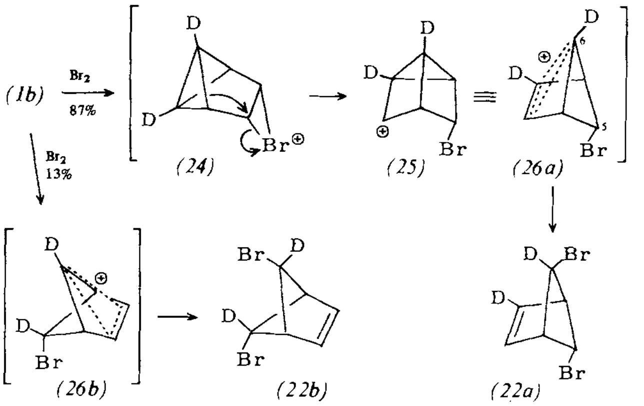
The behavior of *(1)* toward the halogens is dependent both on the nature of the halogen and the reaction conditions employed. With ether as solvent, iodine in CHCl$_3$, iodine and tetrapropylammonium bromide or tetraethylammonium chloride in acetonitrile, all react with *(1)* to give the *trans* adducts *(18)*—*(20)*[58]. Under these conditions, the initially formed iodonium ion is opened by an iodide, bromide, or chloride ion. Only a small quantity of the *trans* adduct *(17)*[58] is formed with either pyridinium hydrobromide perbromide or the dimethyl sulfide-bromine complex. The main product is the *endo,anti*-5,6-dibromobicyclo[2.1.1]hexene *(22)* which in the reaction of *(1)* with bromine in CCl$_4$ is the only product, isolated in quantitative yield[27,59,60]. Similarly, with chlorine in CCl$_4$, or iodine in acetonitrile, only the compounds *(21)*[59,60] and *(23)*[58], respectively, are isolated. Formally, the compounds *(21)*—*(23)* are adducts of the halogens to the C1—C6 bond of *(1)*. Mechanistically, however, this is only partially correct as seen in the bromination or chlorination of *(1b)*[27,60]. 87% of the bromine attacks the double bond. The resulting bromonium ion *(24)* undergoes a Wagner-Meerwein rearrangement to give *(25)* which is none other than the 6-bicyclo[2.1.1]hexenyl cation *(26a)* written in the classical form. The backside attack of a bromide ion at the C6 atom leads to *(22a)*. *(22b)* is probably formed from *(1b)* by bromine ca-

(17), X = Y = BR
(18), X = Y = I
(19), X = I, Y = BR
(20), X = I, Y = Cl





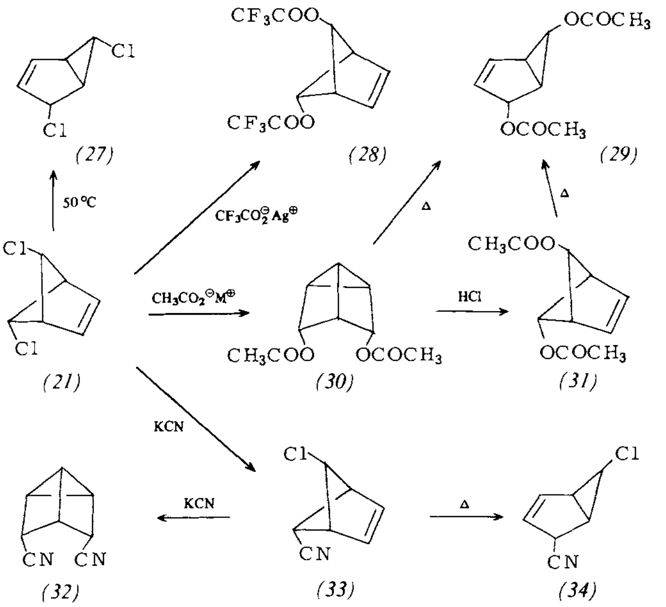
(21), X = Cl
(22), X = Br
(23), X = I



*(24)* *(25)* *(26a)*
*(26b)* *(22b)* *(22a)*

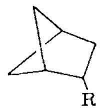
tion attack at C1. The central bond of bicyclo[1.1.0]butane is then thought to rupture through inversion to give the non-classically stabilized cation *(26b)*. The final step giving *(22b)* is analogous to that for *(26a)*→*(22a)*.

The fact that the halogen adducts are reactive is synthetically useful in the cases of *(21)* and *(22)*. Already at 50 °C, *(21)* is transformed into the bicyclo[3.1.0]hexene *(27)*. *(22)* reacts four times faster[60]. When *(21)* reacts with silver trifluoroacetate in benzene, the bistrifluoroacetate *(28)* is isolated[58]. On the other hand, with potassium acetate in acetonitrile or silver acetate in benzene, the bicyclo[2.2.0.0$^{2,6}$]hexane derivative *(30)* is formed, which can transform either into *(29)* on heating, or into *(31)* on treatment with HCl[59,60]. The bicyclo[2.1.1]hexene derivative *(31)* also rearranges thermally to *(29)*. In acetonitrile, with an excess of potassium cyanide, *(21)* gives *(32)*. When only one equivalent of potassium cyanide is used, the intermediate *(33)* is isolable; this in turn isomerizes thermally to *(34)*. The detailed study of the rearrangements of the bicyclo[2.1.1]hexene derivatives *(21)*, *(22)*, *(31)*, and *(33)* led to the discovery of a manifold of unexpected complex reaction mechanisms[60].



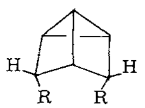
The double bond in the bicyclo[2.1.1]hexene derivative *(22)* was catalytically hydrogenated; subsequent replacement of the bromine atoms by hydrogen using triphenyltin hydride afforded bicyclo[2.1.1]hexane *(35)*[27,60].

A proof of the bicyclo[3.1.0]hexene structure was obtained when the hydrocarbon *(36)* was isolated after stepwise debromination of the bromo analog of *(27)*, first with LiAlH$_4$ and then with sodium in *tert*-butyl alcohol/tetrahydrofuran.



*(35)*, R = H
*(39)*, R = Br

*(36)*



*(37)*, R = H
*(37a)*, R = D

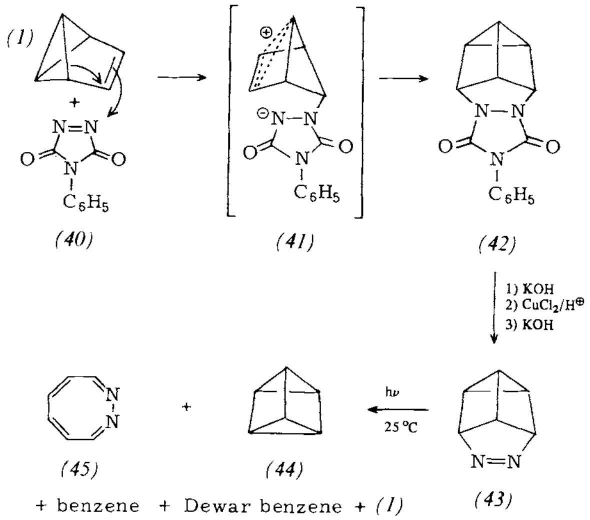
*(38)*

The reaction of *(22)* with an excess of LiAlH$_4$ afforded an economical pathway[27] to the known, but difficultly accessible C$_6$H$_8$ hydrocarbon *(37)*; *(36)* is the side product. *(37a)* is obtained when LiAlD$_4$ is used. Thus, both deuterium atoms are *endo*, which suggests the bicyclo[2.1.1]hexenyl cation as a plausible intermediate[37b]. *(22)* gives *(39)* when less than a fivefold excess of LiAlH$_4$ is used[27]. Both silver salts and [Rh(CO)$_2$Cl]$_2$ catalyze the isomerization of *(37)* to bicyclo[3.1.0]hexene *(36)* and 4-methylenecyclopentene *(38)*; with Ag$^\oplus$ formation of *(36)* is favored, with Rh(I) *(38)* is the main product.

### 3.3.3. 4-Phenyl-1,2,4-triazoline-3,5-dione *(40)* and Chlorosulfonyl Isocyanate

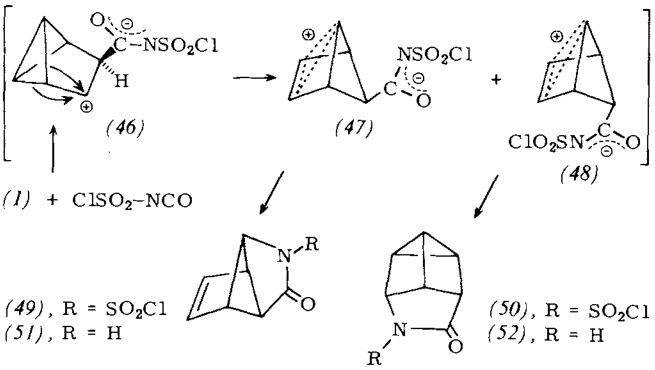
The mechanism of the addition of the triazolinedione *(40)* to benzvalene *(1)* is similar to that of the addition of bromine to *(1)*[61]. This assumption is supported by the observation made when *(40)* reacts with *(1b)*. It is possible that the non-classical zwitterion *(41)* is formed in an electrophilic addition followed by a Wagner-Meerwein rearrangement. The final step leads to *(42)*. This compound allows the preparation of the azo compound *(43)* which is also obtainable in an alternative synthesis[62]. Compound *(43)* affords only benzene on thermolysis[63a,64], but its photolysis represents the only route to the unsubstituted prismane *(44)*[61], which detonates when pure but in solution isomerizes slowly to benzene at 90 °C.

The direct irradiation of *(43)* at 25 °C gives mainly Dewar benzene and benzene, as well as small amounts of *(1)*, *(44)* and 1,8-diazacyclooctatetraene *(45)*[63a]. The low temperature photolysis, on the other hand, gives apart from benzene and *(45)*, only small amounts of *(1)* and Dewar benzene; *no (44)* is formed[64]. In the presence of the sensitizer acetophenone, *(43)* decomposes to *(45)* in 67% yield, together with benzene and nitrogen in 33% yield.



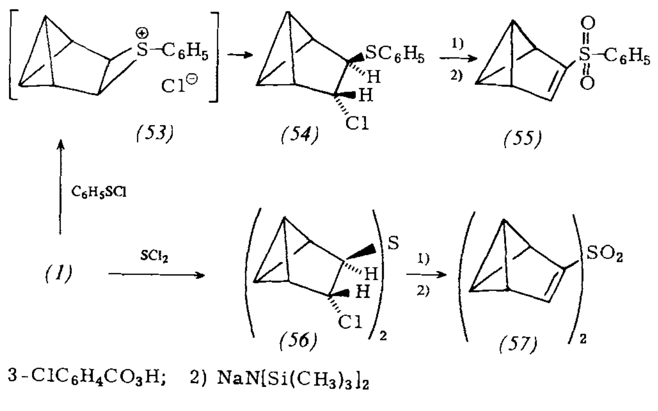
A secondary decomposition of *(45)* gives rise to the latter two products[63,65]. The synthesis and properties of *(45)* have been described in detail[65]. *(45)* is probably derived from the first triplet state of *(43)*, whereas the C$_6$H$_6$ isomers arise from the singlet state through cleavage of a C—N bond. The dependence of the product pattern on temperature and solvent observed in the direct photolysis of *(43)* is evidence for a competition between singlet-triplet transition and C—N bond cleavage; this bond breaking process requires thermal activation[63a].

Chlorosulfonyl isocyanate (CSI) attacks the strained σ bond system in bicyclo[1.1.0]butane derivatives[66], whereas it adds to the double bond in *(1)*. The reaction of *(1b)* with CSI supports the postulated mechanism[67]. The first intermediate is probably the zwitterion *(46)* containing the tricyclo[3.1.0.0$^{2,6}$]hexyl cation structure. In this intermediate both the *cis* and *trans*—with respect to the substituent—oriented bicyclo[1.1.0]butane bonds (C5—C6 and C1—C5) will migrate to the neighboring cationic center. This should give a mixture of the zwitterions *(47)* and *(48)* which cyclize to the *N*-chlorosulfonyllactams *(49)* and *(50)*. These are hydrolyzed by sodium hydroxide to the *N*-unsubstituted lactams *(51)* and *(52)*, whereas dimethylformamide transforms them into *(33)* and an isomer thereof.



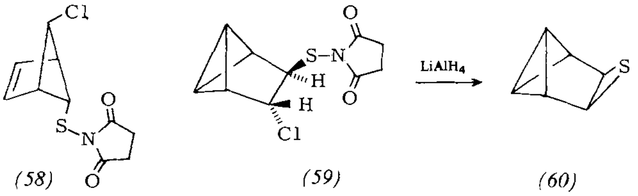
### 3.3.4. Sulfenyl Chlorides and Mercaptans

The mechanism of the addition of sulfenyl chlorides to olefinic double bonds is controversial. The participation of a free episulfonium ion such as *(53)* is not uncontested[68]. At any rate, the quantitative formation of the *trans* adduct *(54)*[67] from *(1)* and benzenesulfenyl chloride shows that rearrangement does not occur and therefore proves that an open carbocation analogous to *(46)* cannot be involved.

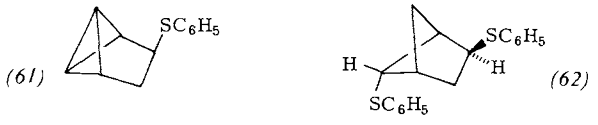


1) $3\text{-}ClC_6H_4CO_3H$; 2) $NaN[Si(CH_3)_3]_2$

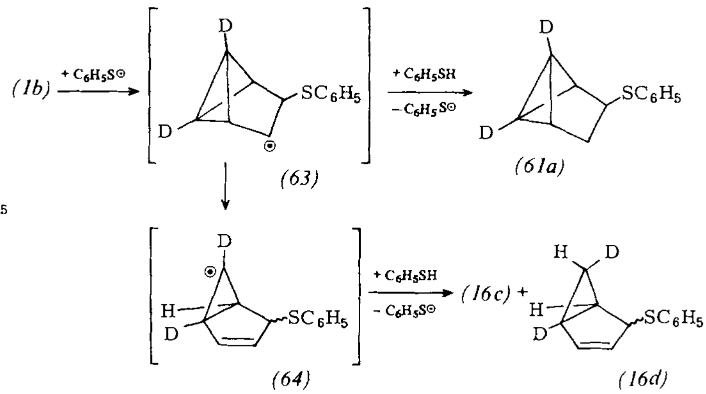
Sulfur dichloride reacts with two molecules of *(1)* to give *(56)*. *m*-Chloroperbenzoic acid oxidizes the thioethers *(54)* and *(56)* to the corresponding sulfones. From these, 3-benzvalenylphenyl sulfone *(55)*, as well as the explosive bis-3-benzvalenyl sulfone *(57)*, can be obtained by HCl elimination using sodium bis(trimethylsilyl)amide.



Benzvalenothiirane *(60)*[70] can be prepared using a new general method for the synthesis of thiiranes[69]. *N*-(chlorothio)succimide reacts with *(1)* giving a mixture of *(58)* and *(59)*. The succinimide moiety probably improves the leaving group ability of the sulfur in the intermediate episulfonium ion, thereby causing partial rearrangement to *(58)*. The main product *(59)* reacts smoothly with $LiAlH_4$ to give *(60)*, a stable isomer of the unknown parent thiepin.



The addition of thiophenol to *(1)* gives four products: *exo-* and *endo-(16a)* in a ratio of 6 : 1, together with *(61)* and *(62)*[56]. The formation of the bis-adduct *(62)* is the result of a slow secondary reaction between *(61)* and thiophenol following rapid addition of $C_6H_5SH$ to *(1)*; there is precedence for such reactions[71,72]. *(16a)* is also formed in the acid catalyzed reaction between *(1)* and $C_6H_5SH$ (see Section 3.3.1). In the uncatalyzed reaction, however, it is formed by a different mechanistic route as has been shown using *(1b)*[56,57].

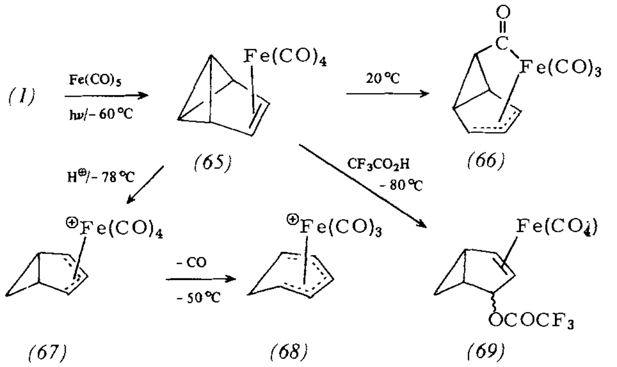


The reaction proceeds *via* a radical chain mechanism[73], in which the phenylthio radical, formed by air-oxidation of thiophenol, adds to the double bond in *(1b)*. The resulting *(63)* can react in two ways: hydrogen abstraction from thiophenol gives *(61a)*; a cyclopropylmethyl-homoallyl radical rearrangement gives *(64)*, which abstracts a hydrogen atom from thiophenol, non-stereospecifically, giving *(16c)* and

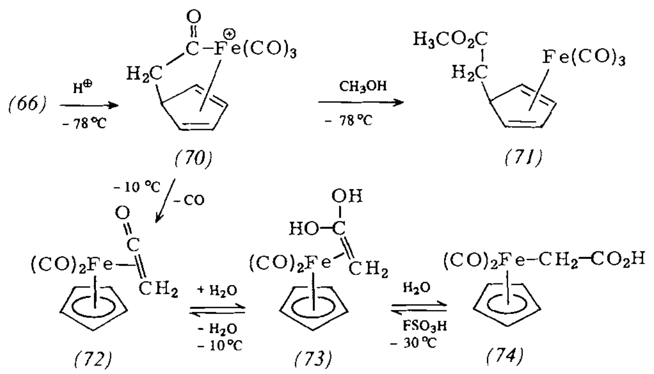
*(16d)* in the ratio 1:3[57]. The dependence of the ratio *(16a)*:*(61)* on the thiophenol concentration supports the above mechanistic scheme. This means that it is possible, starting from *(1)* with suitable choice of reaction conditions, to obtain *(16)*, *(61)* or *(62)* in essentially pure form and high yields[56]. Methylthiol reacts with *(1)* in the same way as thiophenol, giving the methyl analogs of *(16)* and *(61)*[57].

### 3.3.5. Carbonyliron Complexes

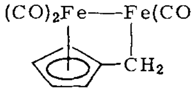
Low temperature photolysis of pentacarbonyliron in the presence of *(1)* gives the π complex *(65)*, which rapidly isomerizes to the acyl complex *(66)* above 10 °C[74]. Excess trifluoroacetic acid protonates *(65)* at −78 °C into the complexed bicyclo[3.1.0]hexenyl cation *(67)*. Above 50 °C, *(67)* looses a molecule of CO and undergoes ring expansion to the complexed cyclohexadienyl cation *(68)*.



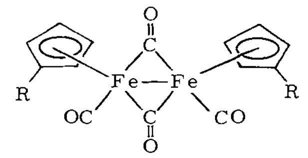
*(65)* reacts with only one equivalent of trifluoroacetic acid to give the neutral complex *(69)* with an *endo*-oriented trifluoroacetoxy group. At −10 °C an equilibrium is established between *exo*- and *endo-(69)* in which the *exo* isomer predominates. At the same time decay of *(69)* to *(68)* is also observed.



Protonation of *(66)* with fluorosulfonic acid in $SO_2ClF$ at −78 °C gives the cation *(70)* which reacts with methanol to the tricarbonyliron complex *(71)* of cyclopentadienylacetic acid methyl ester. *(70)* looses a molecule of CO at −10 °C giving the cationic ketene complex *(72)*. Thus, *(1)* has been transformed into the cyclopentadienyl ligand while coordinated to the iron atom. *(72)* is hydrolyzed by acid to *(74)*, presumably *via* the ketene hydrate complex *(73)*. This complex is regenerated from *(74)* at −30 °C through the action of fluorosulfonic acid, and at −10 °C is further dehydrated to *(72)*. The thermolysis of *(66)* in methanol at 40 °C gives benzene and the methyl ester of *(74)*.



*(75)*



*(76)*, R = H; *(77)*, R = $CH_3$

In contrast to the photochemically induced reaction of *(1)* with $Fe(CO)_5$ no primary product can be obtained in the thermal reaction with $Fe_2(CO)_9$ at 20 °C[74,75]. The hexacarbonylfulvenediiron *(75)* is obtained together with the two-center cyclopentadienyl and methylcyclopentadienyl complexes *(76)* and *(77)*, presumably *via* the common precursor *(66)*.

### 3.3.6. Orientation of Electrophilic Attack

So far, in all the reactions described for *(1)*, the reaction partners have been electrophiles; even the thio radicals can be so described. Most electrophiles selectively attack the double bond in *(1)*: 4-phenyl-1,2,4-triazolinedione, chlorosulfonyl isocyanate, sulfenyl chlorides, thio radicals, and carbonyliron complexes. Halogens also transfer a cation to the double bond in most cases, although with bromine and chlorine an *endo* attack on C-1 with inversion appears to compete to a small extent.

Protons, mercuric acetate and probably also silver ions attack C-1, as is usual for bicyclo[1.1.0]butanes, from the *endo* side. Retention of configuration is, however, observed.

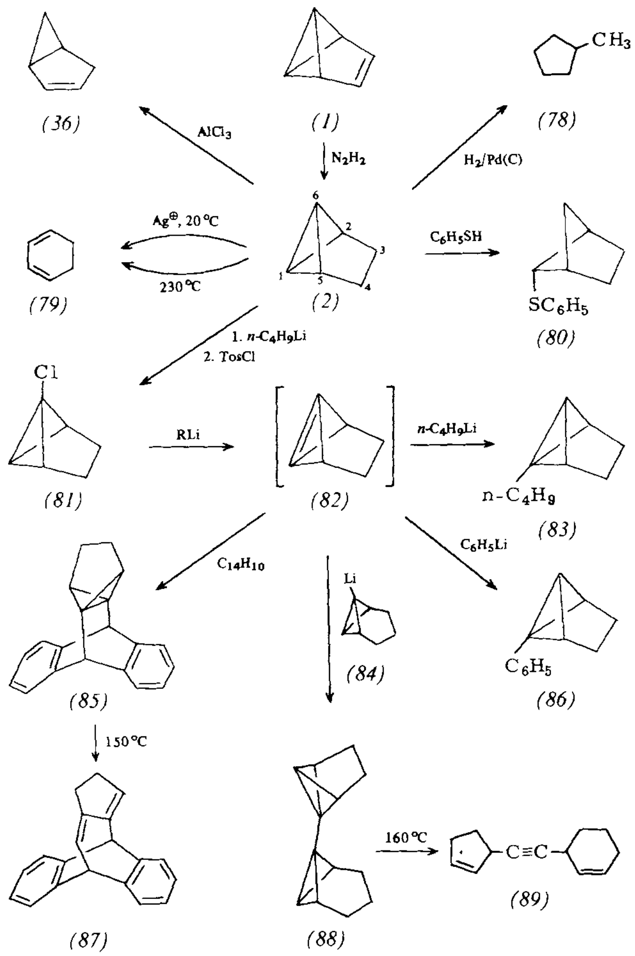
The reactions at the double bond of *(1)* are probably HOMO controlled, since the HOMO is represented by the π orbital (see Section 2). The *endo* addition to the σ system of *(1)* might be favored by the partial negative charge on the *endo* side. These ideas are opposed by the fact that mercury and silver ions are soft electrophiles.

## 3.4. Concerted Additions to the Benzvalene Double Bond

Electrophiles adding to *(1)* in multistep reactions can do so by attack at either the σ or π system. In contrast, the σ system is not capable of undergoing concerted additions. Consequently, all products arising from a concerted reaction retain the tricyclo[3.1.0.0$^{2,6}$]hexane framework *(2)*.

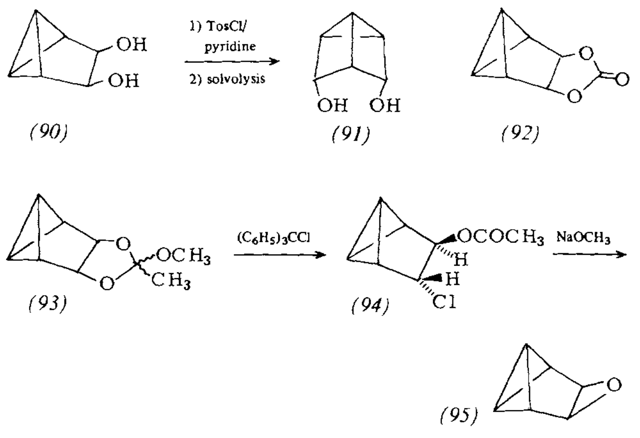
### 3.4.1. Hydrogenation with Diimine and *cis*-Hydroxylation

The double bond in *(1)* cannot be selectively saturated by catalytically activated hydrogen, since under these conditions dihydrobenzvalene *(2)* is transformed into methylcyclopentane *(78)*[76]. Furthermore, *(1)* should rearrange to fulvene in the presence of the usual hydrogenation catalysts (see Section 3.2.1) more rapidly than hydrogen is added. In contrast, diimine smoothly transfers two hydrogen atoms to the double bond of *(1)*[22]. Thus, *(2)*, which is also formed in low yield together with other $C_6H_8$ isomers on irradiation of 3-cyclopentenyldiazomethane[76], can be obtained in 10 g quantities for use in a variety of reactions (cf. Scheme 3).



Scheme 3. Products derived from tricyclo[3.1.0.0$^{2,6}$]hexane *(2)*.

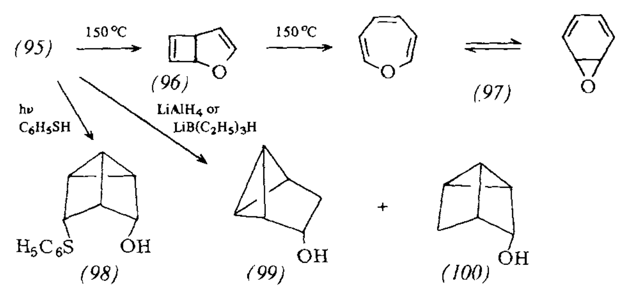
At 20 °C silver ions catalyze the isomerization of *(2)* to 1,3-cyclohexadiene *(79)*[22]. This reaction requires at least 230 °C in the absence of a catalyst. The kinetics of the latter reaction has been studied[46]. Aluminum chloride transforms *(2)* into bicyclo[3.1.0]hexene *(36)*. Thiophenol adds to *(2)* giving the bicyclo[2.1.1]hexane derivative *(80)*[71,72]. In analogy to *(1)*, *(2)* is also metalated with *n*-butyllithium. Treatment with $D_2O$ causes deuteration and a repetition of this procedure gives the 1,6-dideuterio derivative[22]. Using lithiated *(2)* and tosyl chloride *Szeimies et al.*[77] synthesized the 1-chloro derivative *(81)*; this in turn reacts with organolithium compounds, to the reactive intermediate *(82)* which is an isomer of *(1)*. As a highly strained bridgehead olefin, *(82)* readily adds *n*-butylltihium, phenyllithium, and tricyclo[4.1.0.0$^{2,7}$]hept-1-yllithium *(84)*, giving the hydrocarbons *(83)*, *(86)* and *(88)*, respectively. The latter compound isomerizes at 160 °C to give a quantitative yield of the substituted acetylene *(89)*. When *(82)* is generated in the presence of anthracene, a Diels-Alder addition occurs giving the propellane *(85)* which rearranges to the diene *(87)* at 150 °C.



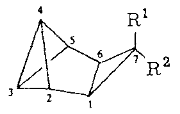
The *cis*-glycol *(90)* can be prepared from *(1)* and $KMnO_4$ using standard reaction conditions, or even better with *tert*-butyl hydroperoxide and $OsO_4$ as catalyst[78]. The ditosylate is formed when tosyl chloride in pyridine is employed. This in turn is solvolyzed in buffered aqueous acetone to the tricyclic diol *(91)* isomeric with *(90)*[70]. The cyclic carbonate *(92)* is formed from *(90)* and phosgene in pyridine. A mixture of two ortho esters *(93)* is formed from *(90)* and trimethyl orthoacetate when benzoic acid is used as a catalyst. The chlorohydrin acetate *(94)* can be prepared by reaction of *(93)* with trityl chloride and transformed into benzvalene oxide *(95)*[78].

### 3.4.2. [2 + 1]-Cycloaddition Reactions: Epoxidation and Halocarbene Additions

Attempts at the direct epoxidation of *(1)* using the usual peracids have so far met without success. Benzoylperoxycarbamic acid is the only reagent which affords *(95)* in good yield[78] together with benzamide und carbon dioxide. Preliminary thermolyses in solution at 150 °C indicate a rearrangement to the oxepin-benzene oxide system *(97)* *via* the 2-oxabicyclo[3.2.0]hexa-3,6-diene intermediate *(96)*[70]. On irradiation, thiophenol adds to *(95)* to give the rearranged tricyclic compound *(98)*; *(95)* is reduced by complex hydrides to give a 1 : 1 ratio of the isomeric alcohols *(99)* and *(100)*.



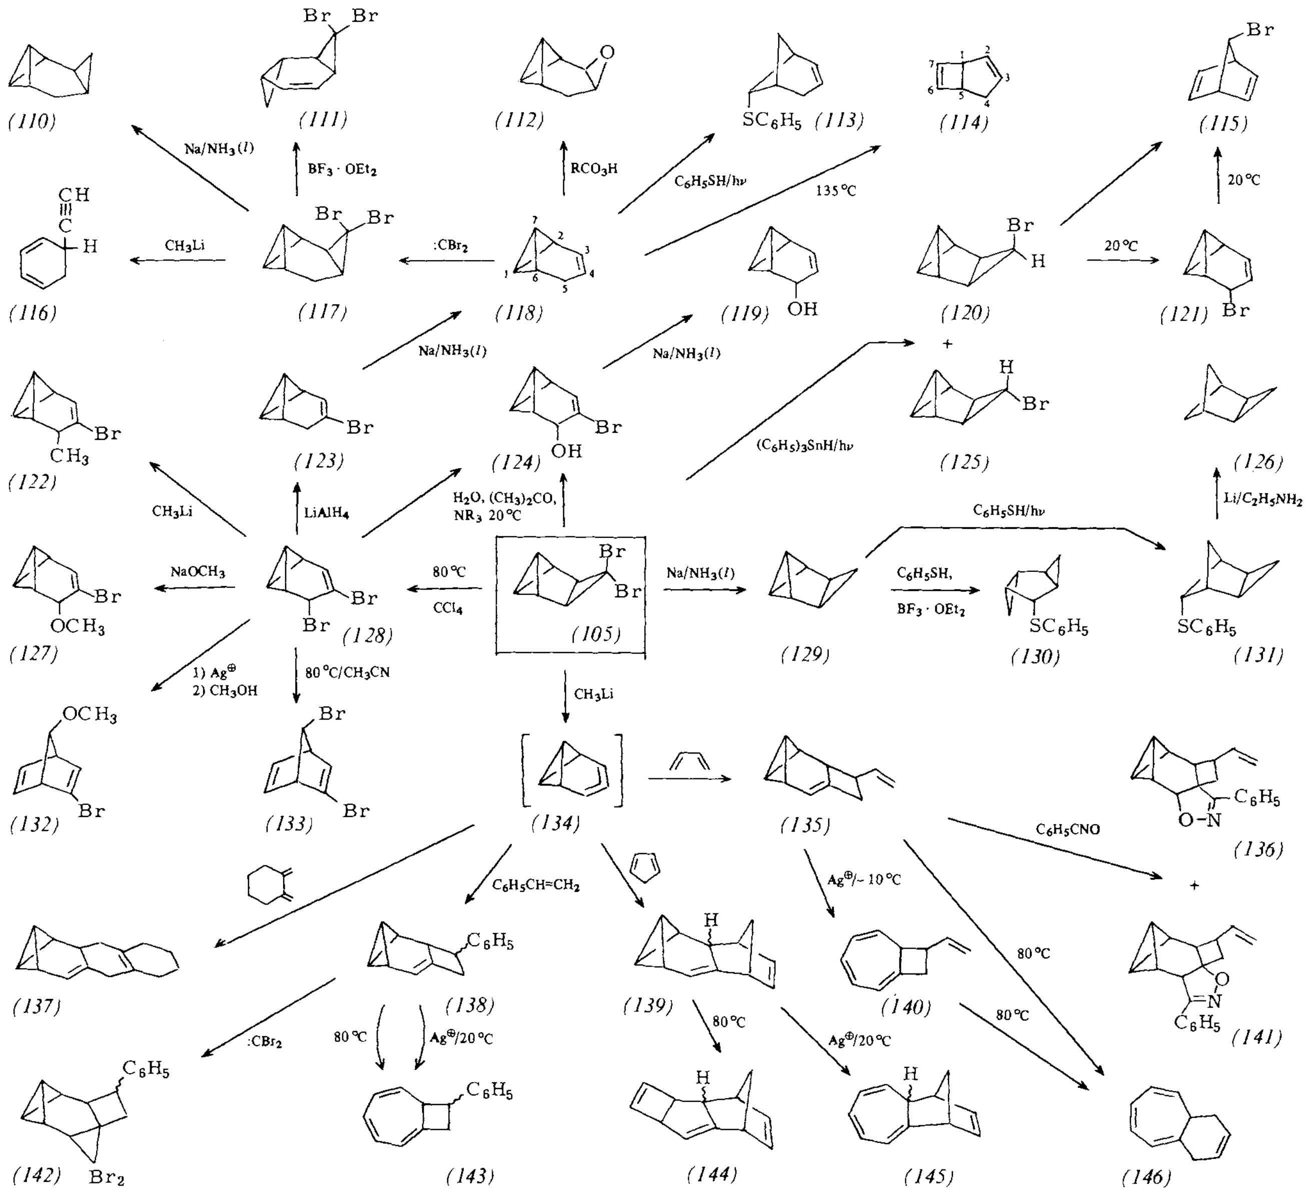
The synthesis of a large variety of new small-ring polycycles is made possible by the addition of halocarbenes to *(1)*. Difluoro-, chlorofluoro-, dichloro-, dibromo-, chloro-, chlorophenyl-, and bromophenylcarbene all react with *(1)* to give the tetracyclo[4.1.0.0$^{2,4}$.0$^{3,5}$]heptane derivatives *(101)*–*(107)*[79] as well as *(108)* and *(109)*[80].



| | (101) | (102) | (103) | (104) | (105) | (106) | (107) | (108) | (109) |
|---|---|---|---|---|---|---|---|---|---|
| $R^1$ | F | F | Cl | Cl | Br | Cl | H | $C_6H_5$ | $C_6H_5$ |
| $R^2$ | F | Cl | F | Cl | Br | H | Cl | Cl | Br |

The known reactions of *(105)* and products derived from it are summarized in Scheme 4. As in the case of *(104)*, reduction with sodium in liquid ammonia furnishes the parent hydrocarbon *(129)*[79]. The $^{13}$C-NMR spectra of this compound, as well as those of the heterocyclic analogs *(60)*, *(95)* and *(207)*, are remarkable because of the large difference in the chemical shifts of C-3 and C-4[24]. The thermal isomerization of *(129) via* tricyclo[3.2.0]hepta-2,6-diene *(114)* to cycloheptatriene only occurs at temperatures above 180 °C. The mechanism has been the subject of kinetic and deuterium labeling studies[46]. Cycloheptatriene is formed by the rapid isomerization of *(129)* caused by an $Ag^{\oplus}$-catalyst already at 0 °C. A simple synthesis of 3,4-dideuteriocycloheptatriene is available by using [3,4-$D_2$]-*(129)* as the starting material[79]. Thiophenol can add to *(129)* in two different ways: in the presence of boron trifluoride etherate it adds to one of the lateral bonds of the bicyclo[1.1.0]butane molecule to give *(130)*. Irradiation causes addition to occur at the central bond with formation of *(131)*, which can be desulfurized to the unsubstituted tricyclo[3.1.1.0$^{2,4}$]heptane *(126)*[72].

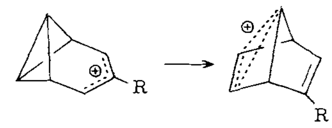
Partial dehalogenation of *(104)* and *(105)* using triphenyltin hydride with irradiation leads to the formation of



Scheme 4. Products derived from 7,7-Dibromotetracyclo[4.1.0.0$^{2,4}$.0$^{3,5}$]heptane *(105)*.

the monochloro compounds *(106)* and *(107)* and the monobromo derivatives *(120)* and *(125)*, respectively. Similarly, *(102)* and *(103)* are reduced with sodium in liquid ammonia, giving the monofluorine analogs. The *endo*-bromo derivative *(120)* is, like the corresponding chloride *(106)*, thermally labile. Already at 20 °C, it is transformed into the 7-bromonorbornadiene *(115)*. The probable intermediates in this reaction are the tricyclo[4.1.0.$0^{2,7}$]heptenyl cation *(147)* and the 7-norbornadienyl cation *(148)*. NMR spectroscopy shows evidence of a dead end equilibrium with *(121)*[81].

*(147)*, R = H
*(149)*, R = Br



*(148)*, R = H
*(150)*, R = Br

The transformation of *(105)* into *(128)*[81] and *(124)*[82], as well as that of *(128)* into *(124)*, proceed *via* the intermediate cation *(149)*, which is trapped by either bromide ions or water before rearranging to give *(150)*. Starting from *(128)* this rearrangement can be initiated either by heating to 80 °C in acetonitrile[81], giving norbornadiene *(133)*, or Ag$^{\oplus}$-catalyzed[82], whereby on work-up with methanol *(132)* is the product. With sodium in liquid ammonia, *(124)* gives the debrominated alcohol *(119)*[82] which can also be obtained by an alternative route[83]. The reaction of the alcohol *(119)* with fluorosulfonic acid at $-120$ °C[84], as well as the solvolysis of its 3,5-dinitrobenzoic acid ester[82] provide evidence for the rearrangement *(147)*→*(148)*.

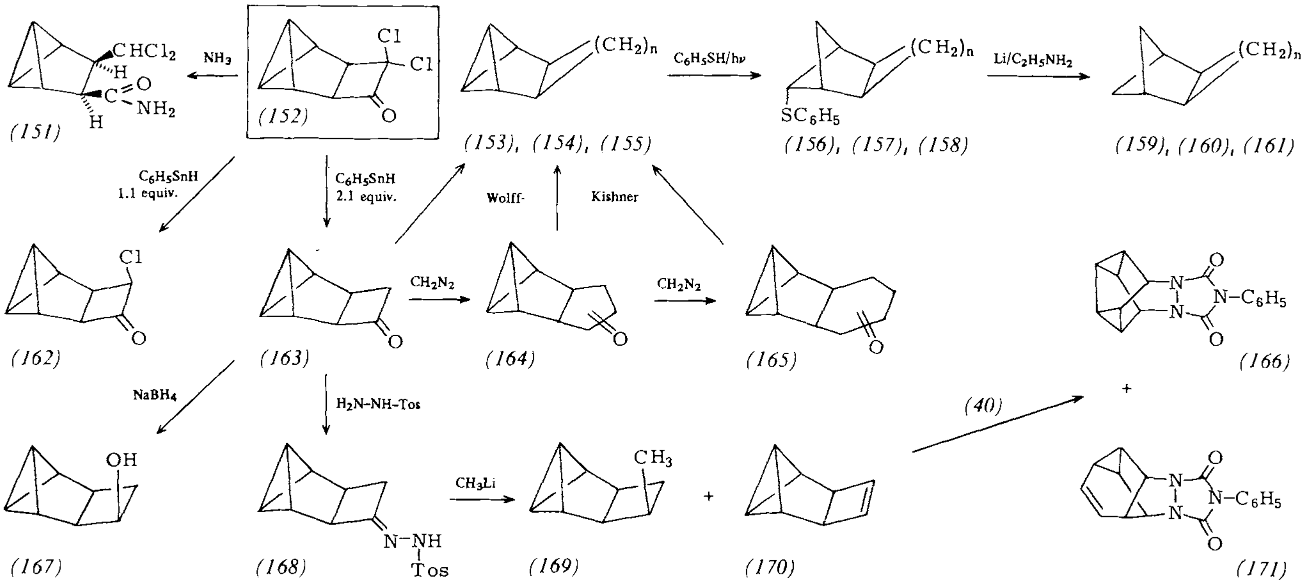
There are no skeletal changes involved when *(128)* reacts with methyllithium, sodium methylate, or LiAlH$_4$, giving *(122)*[57], *(127)*[82], and *(123)*[81], respectively. *(103)* and *(104)* rearrange in a series of reactions analogous to that of *(105)*→*(128)*→*(123)*. The unsubstituted tricyclo[4.1.0.$0^{2,7}$]hept-3-ene *(118)* is obtained in good yield by dehalogenation of *(123)* and the corresponding chloro compound with sodium in liquid ammonia[81], or else by reduction of the dichloro compound analogous to *(128)* with sodium and *tert*-butyl alcohol[57]. This synthesis from benzvalene is useful for preparing *(118)* in quantity; there are, however, two other albeit less productive routes[85,86].

When *(118)* is heated at 135 °C (half-life ≈ 1 h), it is transformed *ca*. 500 times quicker than the isomer *(129)*[46]; the only product formed is *(114)*. Use of 1,7-dideuteriated *(118)* leads selectively to *(114)* labeled in positions 6 and 7. On the other hand, the Ag$^{\oplus}$-catalyzed reaction already occurs at room temperature, giving 2,3-dideuteriocycloheptatriene[81]. In contrast to benzvalene (see Section 3.3.4), *(118)* adds thiophenol exclusively at the bicyclo[1.1.0]butane central bond to give the norpinene derivative *(113)*[56]. The reaction is accelerated by irradiation. The different nature of the HOMO's of *(1)* and *(118)* is regarded as responsible for the rather different reactions of these two substrates. The epoxidation of *(118)* with benzoylperoxycarbamic acid gives the epoxide *(112)*[87]; dibromocarbene addition gives the dibromocyclopropane *(117)*[88]. The latter is much more stable than *(105)* and when heated gives the dibromo-*trans*-bishomobenzene *(111)*[57,89]. This rearrangement is said to be concerted[89] although there is strong evidence that it is acid-catalyzed, *e.g.* by traces of HBr[57]. Indeed, *(117)* is transformed into *(111)* in the presence of boron trifluoride etherate[57]. The isomerization of *(110)* to the *trans*-bishomobenzene is also acid-catalyzed[90]. Compound *(110)* can be prepared by reaction of *(117)* with sodium in liquid ammonia[88] or *via* a shorter, more efficient route[90]. On the other hand, *(110)* rearranges thermally at 210 °C to give *trans*-tricyclo[4.2.0.$0^{2,4}$]oct-7-ene as the main product[88].

The homologous dibromocyclopropanes *(105)* and *(117)* behave very differently with methyllithium. It is probable that *(117)* first gives rise to a cyclopropylidene which stabilizes itself through skeletal rearrangement to the acetylenic compound *(116)*[88]. Both isotope labeling[88] and methyl substitution[91] enabled clarification of the mechanism of this reaction. The cyclopropylidene arising from *(105)* undergoes ring expansion to give the new reactive intermediate *(134)*, a strained allene, which can be trapped by activated alkenes in what are probably two-step [2+4]- and [2+2]-cycloaddition reactions. *(134)* reacts with 1,2-bismethylenecyclohexane to give the pentacyclic compound *(137)*[87], and with styrene to give two isomers of the tetracyclic molecule *(138)*[92]. The double bond in *(138)* is highly reactive; it can be epoxidized[87], smoothly hydrogenated by diimine[92], and adds dibromocarbene to give the spiro compound *(142)*. The cycloheptatriene *(143)* is obtained from *(138)* using Ag$^{\oplus}$ catalysis[87] and also by an alternative route[93]. Furthermore, *(143)* is formed by purely thermal means at 80 °C from *(138)*; in comparison to the rearrangement *(118)*→*(114)* this is very unusual. Presumably, this is due to the lability of the cyclobutane moiety[87]. The 1,1-diphenylethylene adduct[92] analogous to *(138)* exhibits the same behavior[87]. In contrast, the two isomers of the cyclopentadiene adduct *(139)* formed from *(134)*[92] rearrange thermally to *(144)*[87] in a manner analogous to *(118)*. Ag$^{\oplus}$ catalyzes the formation of the two cycloheptatrienes *(145)*. The products which are formed from *(134)* and furan, or 1,3-cyclohexadiene are analogous both in structure[92], and thermal decay[87] to *(139)*. The butadiene adduct *(135)* behaves abnormally but similarly to *(138)*[92]. Heating at 80 °C leads not only to the formation of the cycloheptatriene system but also to a vinylcyclobutane-cyclohexene rearrangement[87] which gives rise to *(146)*. When Ag$^{\oplus}$ is used, the bicyclo[1.1.0]butane skeleton isomerizes at $-10$ °C, and the resulting compound *(140)* rearranges also to *(146)* on heating at 80 °C. The reactivity of the methylenecyclobutane double bond manifests itself in the benzonitrile oxide addition of *(135)* to give *(136)* and *(141)*. In spite of its greater substitution it is more reactive than the vinyl group.

### 3.4.3. [2+2]-Cycloadditions: Dichloroketene and Singlet Oxygen

As yet, only the addition of one ketene to benzvalene *(1)* is known: dichloroketene gives 8,8-dichlorotetracyclo[4.2.0.$0^{2,4}$.$0^{3,5}$]octan-7-one *(152)* in high yield[94]. Monochloroketene does not react with *(1)*. Scheme 5 summarizes the reactions of *(152)* which have so far been carried out.

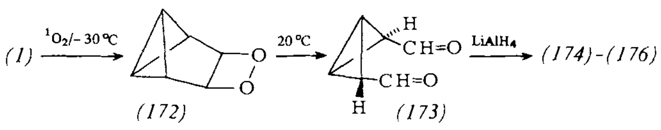


Scheme 5. Products derived from 8,8-Dichlorotetracyclo[4.2.0.$0^{2,4}$.$0^{3,5}$]octan-7-one *(152)*, *(153)*, *(156)* and *(159)*, $n=2$; *(154)*, *(157)* and *(160)*, $n=3$; *(155)*, *(158)* and *(161)*, $n=4$.

Ammonia opens the dichlorocyclobutanone ring to give the amide *(151)*; dimethylamine and hydrazine react analogously. The partial or complete dehalogenation of *(152)* can be carried out with triphenyltin hydride; this gives *(162)* or *(163)*. The ketone *(163)* is reduced with $NaBH_4$ to the *endo* alcohol *(167)*; the tosylate of the latter compound does not undergo a β-elimination to the olefin *(170)*. However, the ketone *(163)* permits access to the desired new $C_8H_8$ isomer *(170) via* the tosylhydrazone *(168)*. Here, the use of lithium 2,2,6,6-tetramethylpiperidide as a base afforded the best yield. The reaction of *(168)* with methyllithium gives a mixture of *(169)* and *(170)*, the ratio of which is solvent dependent. *(170)* isomerizes to cyclooctatetraene in $Ag^{\oplus}$-catalyzed, photochemical, or purely thermal ($>140°$) reactions. 4-Phenyl-1,2,4-triazoline-3,5-dione *(40)* adds to *(170)* in a stepwise manner. In an initially formed zwitterion, the cationic part rearranges and then reacts with the anionic nitrogen atom of the heterocycle giving the known *(166)* as the main product. One of the side products was identified as *(171)*. A Wolff-Kishner reduction of *(163)* leads smoothly to the saturated hydrocarbon *(153)*, which in the gas phase at 430 °C decomposes to a mixture of known $C_8H_{10}$ isomers and products derived therefrom.

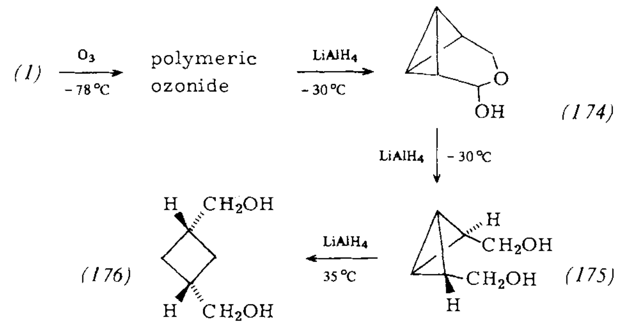
*(163)* undergoes two successive ring expansions with diazomethane, giving cyclopentanone *(164)* and cyclohexanone *(165)*. The positions of the carbonyl groups are uncertain[72]. Wolff-Kishner reduction of these ketones allows the preparation of the corresponding hydrocarbons *(154)* and *(155)*. Thiophenol adds photochemically to the central bond of the bicyclo[1.1.0]butane system in *(153)*—*(155)*; the resulting tricycloalkylphenyl thioethers *(156)*—*(158)* undergo reductive desulfurization with lithium in ethylamine to give the tricyclic hydrocarbons *(159)*—*(161)* possessing annelated four-, five- and six-membered rings. These compounds, together with *(126)*, and the corresponding tricyclo[3.1.0.$0^{2,6}$]hexane derivatives *(129)* and *(153)*—*(155)*, were the subject of a study of the effect of annelation on $^{13}C$-NMR chemical shifts of strained cyclopentanes[95].

The mechanism of the addition of singlet oxygen to olefins with dioxetane formation is still controversial[96]. Whereas norbornene reacts sluggishly with $^1O_2$[97], *(1)* reacts already at $-30$ °C in a [2+2]-cycloaddition giving the dioxetane *(172)*[78]; this is probably due to the higher energy HOMO (see Section 2). As is characteristic for compounds of this type, *(172)* decomposes to the dialdehyde *(173)* in a [2+2]-cycloreversion accompanied by chemiluminescence[70]. Proof of the structure of the dialdehyde *(173)* is provided by its reduction with $LiAlH_4$ to give, depending on reaction conditions, the products *(174)*—*(176)* (see Section 3.4.4).



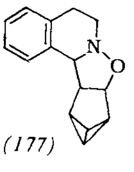
### 3.4.4. [2+3]-Cycloadditions: 1,3-Dipolar Cycloadditions

A polymeric ozonide is formed from *(1)* and $O_3$ at $-78$ °C[22]. Successive 1,3-dipolar cycloaddition to the

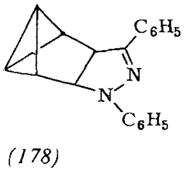


double bond, cycloreversion, and finally another cycloaddition reaction should leave the bicyclo[1.1.0]butane skeleton intact in accord with the findings after reductive workup with LiAlH$_4$[78].

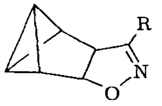
When three equivalents of LiAlH$_4$ are employed in tetrahydrofuran at $-30\,^\circ$C, a 1:3 mixture of the hemiacetal *(174)* and the diol *(175)* is obtained. In the reaction using six equivalents of LiAlH$_4$, *(175)* is the only product. Surprisingly, when the reaction temperature is raised to 35 °C, the bicyclo[1.1.0]butane central bond in *(175)* is broken to give the known cyclobutane derivative *(176)*.



*(177)*

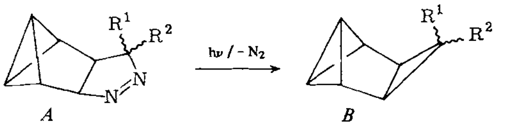


*(178)*



*(179)*, R = C$_6$H$_5$
*(180)*, R = 2,4,6-(CH$_3$)$_3$C$_6$H$_2$

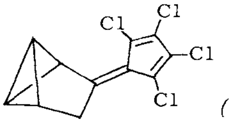
The nitrone 3,4-dihydroisoquinoline *N*-oxide reacts with *(1)* to give the hexacyclic adduct *(177)*; *(1)* and diphenylnitrile imine combine to give the 2-pyrazoline derivative *(178)*[98]. Benzonitrile oxide and its 2,4,5-trimethyl analog react with *(1)* giving the isoxazolines *(179)* and *(180)*, respectively.



| A | *(181)* | *(182)* | *(183)* | *(184)* | *(185)* | *(186)* | *(187)* |
|---|---|---|---|---|---|---|---|
| R$^1$ | H | CH$_3$ | C$_6$H$_5$ | biphenylylene | CH$_3$ | C$_6$H$_5$ | CH$_3$ |
| R$^2$ | H | CH$_3$ | C$_6$H$_5$ | | H | H | CO$_2$CH$_3$ |
| B | *(129)* | *(188)* | *(189)* | *(190)* | *(191)* | *(192)* | *(193)* |

The addition of diazoalkanes to *(1)* has been more thoroughly investigated. Symmetrical compounds such as diazomethane, 2-diazopropane, diphenyldiazomethane and diazofluorene all react with *(1)* to give the homogeneous 1-pyrazolines *(181)*[98]—*(184)*[99]. Unsymmetrical substrates such as diazoethane and phenyldiazomethane each give a mixture of the two possible isomers *(185)* and *(186)*. Ethyl diazoacetate is no longer reactive enough to compete with the isomerization of *(1)* to benzene[99]. On the other hand, methyl 2-diazopropionate does react with *(1)* to give the mixture *(187)*[100].

Tetrachlorodiazocyclopentadiene reacts only very slowly with *(1)* and the unobserved primary addition product eliminates nitrogen already at room temperature to give the fulvene *(193a)*[99].

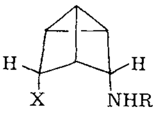


*(193a)*

Besides the additions of halocarbenes to *(1)* (see Section 3.4.2) a second synthesis of tetracyclo[4.1.0.0$^{2,4}$.0$^{3,5}$]heptanes is the result of the photochemical nitrogen extrusion from the 1-pyrazolines *(181)*—*(187)*. The parent substrate *(129)* is best obtained *via* the dichloro compound *(104)* where the yield is higher, but for the 7-alkyl [*(188)* and *(191)*][99] and the 7-aryl compounds [*(189)*, *(190)*, *(192)*][99], as well as the 7-carboxylic acid methyl esters *(193)*[100], the photolysis of the 1-pyrazolines is by far the method of choice.

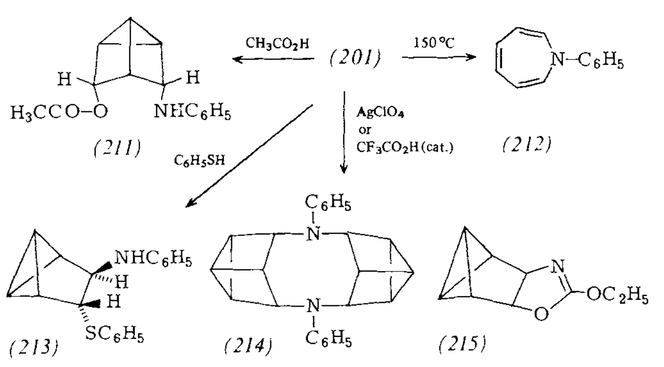
| | R | |
|---|---|---|
| *(194)* | C$_6$H$_5$ | *(201)* |
| *(195)* | 4-NO$_2$–C$_6$H$_4$ | – |
| *(196)* | 2,4,6-(CH$_3$)$_3$C$_6$H$_2$ | *(202)* |
| *(197)* | CH$_2$–C$_6$H$_5$ | *(203)* |
| *(198)* | CO$_2$C$_2$H$_5$ | *(204)* |
| *(199)* | CO$_2$C(CH$_3$)$_3$ | *(205)* |
| *(200)* | 4-CH$_3$–C$_6$H$_4$–SO$_2$ | *(206)* |
| – | H | *(207)* |

In view of the high reactivity of azides toward norbornene, their ready addition to *(1)* was not entirely unexpected. Phenyl, *p*-nitrophenyl, mesityl, and benzyl azides, as well as ethyl and *tert*-butyl azidoformate react with *(1)* to give the triazolines *(194)*—*(199)*[70,101] in acceptable yields. Tosyl azide reacts with *(1)* to give as the immediate product 7-*p*-toluenesulfonyl-7-azatetracyclo[4.1.0.0$^{2,4}$.0$^{3,5}$]heptane *(206)*, which is probably derived from the initially formed triazoline *(200)* by nitrogen elimination. *(201)*—*(203)* can be synthesized photochemically from *(194)*, *(196)*, and *(197)*, respectively; in the thermal reaction, the triazolines *(198)* and *(199)* give rise to *(204)* and *(205)*, respectively. The unsubstituted aziridine *(207)* is obtained by LiAlH$_4$ reduction of *(204)*, or from *(206)* with naphthalene- or, even better, biphenyl-sodium. It reacts *via* the *N*-metalated derivative to give the benzylated and sulfonated compounds *(203)* and *(206)*, respectively.



*(208)*, X = OH, R = CO$_2$C(CH$_3$)$_3$
*(209)*, X = O–COCH$_3$, R = 4-CH$_3$–C$_6$H$_4$–SO$_2$
*(210)*, X = S–C$_6$H$_5$, R = 4-CH$_3$–C$_6$H$_4$–SO$_2$

When *(199)* is treated with aluminum oxide of activity grade I, the aziridine *(205)* is obtained. When aluminum oxide of activity grade III is employed, nitrogen elimination also occurs. However, after rearrangement, probably *via* cationic intermediates, and addition of water, the *endo,endo*-disubstituted tricyclo[2.2.0.0$^{2,6}$]hexane *(208)* can be isolated[102]. *(206)* reacts with acetic acid and thiophenol to give also compounds of the type *(208)*[70]. Presumably, the nitrogen is protonated; this is followed by C—N bond cleavage and Wagner-Meerwein rearrangement to give a cation of the type *(41)*, which then adds a nucleophile to give *(209)* or *(210)*.

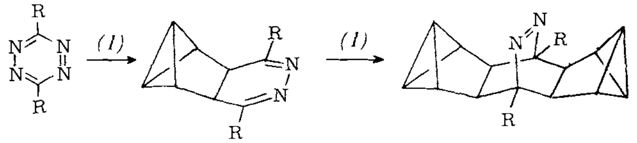


Whereas the *N*-phenyl compound *(201)* reacts with acetic acid to give the rearranged compound *(211)*, with thiophenol it gives the unrearranged molecule *(213)*. Apparently the aziridinium ion formed from *(201)* does not rearrange as easily as protonated *(206)* because $NHC_6H_5$ is a poorer leaving group than NHTos. Therefore, thiophenol directly opens the three-membered ring giving *(213)*. In contrast, in the presence of the less nucleophilic acetic acid, the rearrangement of protonated *(201)* occurs faster than the nucleophilic attack. With still weaker nucleophiles, the anilino group competes with the nucleophile, and dimerization to *(214)* results; this is the case, for example, on treatment of *(201)* with a catalytic amount of silver perchlorate or trifluoroacetic acid.

The thermolysis of *(201)* at 150 °C leads to cleavage of three σ bonds and the formation of three π bonds giving *N*-phenylazepine *(212)*[101] which can also be prepared *via* an alternative route. As is general for *N*-acylaziridines, *(204)* undergoes an expansion only of the aziridine ring on heating to 120 °C; this gives the oxazoline derivative *(215)* with retention of the tricyclo[3.1.0.$0^{2,6}$]hexane moiety.

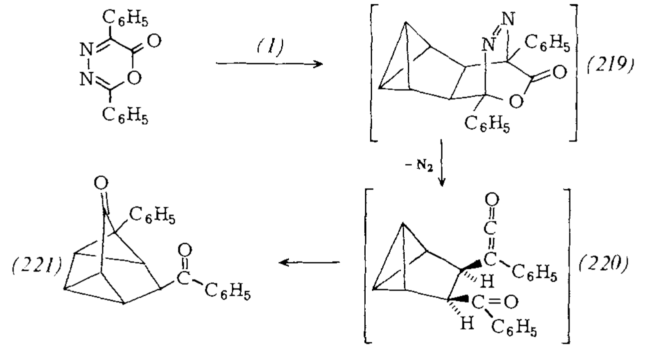
### 3.4.5. [2+4]-Cycloadditions: Diels-Alder Additions

Due to the high energy of the π orbital, benzvalene is predestined to be a good dienophile in Diels-Alder additions with inverse electron demand. 3,6-Bismethoxycarbonyl- and 3,6-diphenyl-1,2,4,5-tetrazine add to *(1)* in a manner typical of these dienes. A subsequent nitrogen elimination gives the dihydropyridazines *(216)* and *(217)*[103]. With excess *(1)*, *(216)* undergoes also a Diels-Alder addition leading to the octacyclic azo compound *(218)*[103], the configuration of which has been established by X-ray analysis[18].

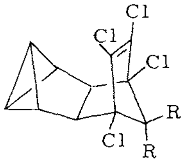


*(216)*, R = $CO_2CH_3$ *(218)*, R = $CO_2CH_3$
*(217)*, R = $C_6H_5$

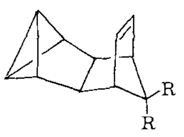
The newly reported 2,5-diphenyl-1,3,4-oxadiazin-6-one can be used as a diene[104]. Here, the reaction with *(1)* presumably gives *(219)* as the primary product, from which the ketene *(220)* is formed in a $[_{\sigma}2+_{\sigma}2+_{\sigma}2]$ cycloreversion, accompanied by nitrogen elimination; the ketene then further rearranges to the tetracyclic compound *(221)*[105]. This latter step involves a novel addition of a ketene function to the neighboring bicyclo[1.1.0]butane bond.



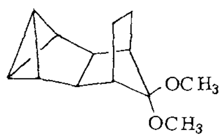
Although cyclopentadiene is unreactive toward *(1)*, hexachlorocyclopentadiene and tetrachlorocyclopentadienone dimethylketal react in accord with Alder's *endo* rule to give the pentacycles *(222)*[103] or *(223)*[106a] in good yields. On reaction with sodium in liquid ammonia or sodium and *tert*-butanol the chlorine atoms in these products are replaced by hydrogen with formation of *(224)* and *(225)*, respectively. The double bond in the ketal *(225)* is reduced with diimine to form *(226)*.



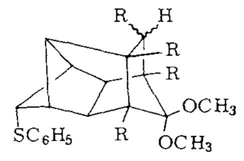
*(222)*, R = Cl
*(223)*, R = $OCH_3$



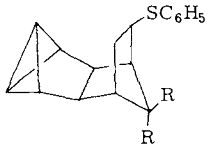
*(224)*, R = H
*(225)*, R = $OCH_3$



*(226)*

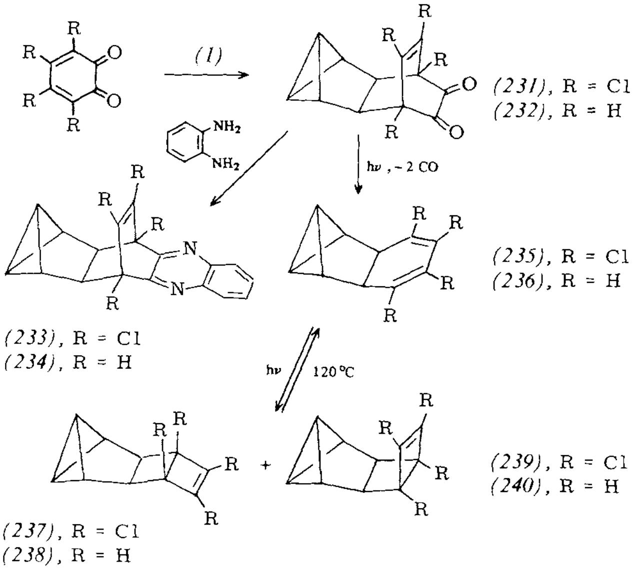


*(227)*, R = Cl
*(228)*, R = H

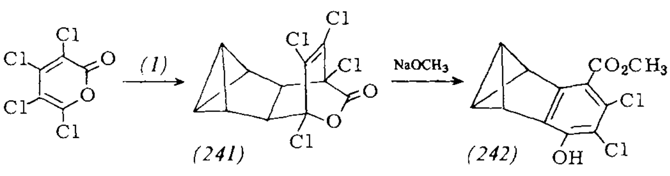


*(229)*, R = H
*(230)*, R = $OCH_3$

It is worth noting the thiophenol additions to *(223)*–*(225)* which probably involve radical chain process[106a]. Triggered by the phenylthiolyl radical the reaction of *(223)* begins at the bicyclo[1.1.0]butane ring, continues in a transannular ring closure with participation of the double bond, and finally gives the pentacyclic thioether *(227)*. When the starting compound is *(225)*, only about half the molecules follow this pathway giving *(228)*. The other half of the starting molecules add thiophenol to the double bond to give *(230)*. The analogous product *(229)* is formed as the sole product on reaction of *(224)* with thiophenol. Freed from steric hindrance due to the *syn*-methoxy group in *(223)* and *(225)*, and from the inductive effect of the chlorine atoms in *(223)*, the double bond in *(224)* is far more reactive toward thiophenol than is the case for the central bond in the bicyclo[1.1.0]butane system. This can be understood when one considers the energies of the highest occupied orbitals in tricyclo[3.1.0.$0^{2,6}$]hexane *(2)*[10] and norbornene[13b], which serve as models for the different functionalities of *(224)*.

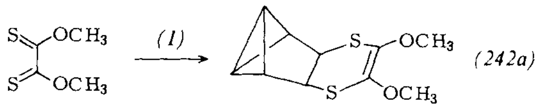


Tetrachloro-*o*-benzoquinone reacts instantaneously with *(1)*, whereas the addition of *o*-benzoquinone itself needs 15 h at 20 °C[103]. The configuration of the pentacyclic α-diketones *(231)* and *(232)* was established from the NMR spectra of the quinoxalines *(233)* and *(234)* which are easily obtained on treatment with *o*-phenylenediamine. Photochemical elimination of two CO molecules from the α-diketones *(232)* and *(231)* gives the new $C_{10}H_{10}$ hydrocarbon *(236)* and its tetrachloro derivative *(235)*, respectively. Further irradiation now at shorter wavelengths leads to an electrocyclization forming the isomeric cyclobutene derivatives *(238)* and *(240)*, or *(237)* and *(239)*, respectively. At 120 °C they isomerize back to *(236)* and *(235)*, respectively[57]. The double bonds in *(236)* each accept two hydrogen atoms from diimine, thus providing a second synthetic pathway to *(155)*[72] (see Section 3.4.3).



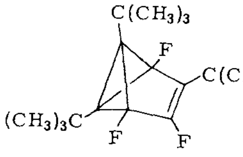
α-Pyrone does not react with *(1)*; tetrachloro-α-pyrone, on the other hand, gives a high yield of a lactone, for which configuration *(241)* is proposed[106a]. At 150 °C in solution, it looses $CO_2$, and *(235)* is formed. With sodium methylate in methanol *(241)* undergoes opening of the lactone ring and elimination of HCl, to give the first substituted naphthvalene *(242)*.

Dimethyl dithionooxalate—a 1,4-dithia-1,3-butadiene—reacts with *(1)* to give the Diels-Alder adduct *(242a)*[106b].

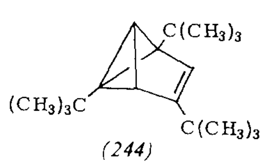


## 4. Substituted Benzvalenes

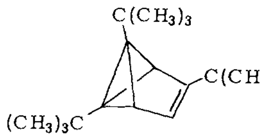
Despite the fact that substituted benzvalenes are not as easily accessible as *(1)*, they are of great importance because of their sometimes extremely varied properties. The first benzvalene derivative, tri-*tert*-butyltrifluorobenzvalene *(243)*, was found, by *Viehe et al.*[1], along with other products in the spontaneous trimerization of *tert*-butylfluoroacetylene. 1,2,4-Tri-*tert*-butylbenzvalene *(244)* is formed when 1,3,5-tri-*tert*-butylbenzene is photolyzed[107]; on further irradiation it partially rearranges to the 1,3,6-isomer *(245)*, which is also formed in the photolysis of 1,2,4-tri-*tert*-butylbenzene[2].



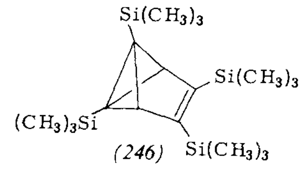
*(243)*



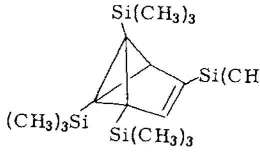
*(244)*



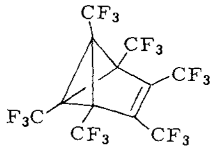
*(245)*



*(246)*



*(247)*

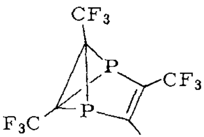


*(248)*

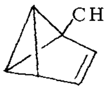
When 1,2,4,5-tetrakis(trimethylsilyl)benzene is irradiated, the substituted benzvalenes *(246)* and *(247)* as well as other isomers, are obtained[108]. Irradiation of hexakis(trifluoromethyl)benzene causes isomerization to the benzvalene *(248)*[109, 110], in quantitative yield. This product has been the subject of extensive studies.

Thermolysis of *(248)* causes reverse rearrangement to hexakis(trifluoromethyl)benzene[109]. This process has a considerably higher activation enthalpy (38.0 kcal/mol)[111], than the isomerization of *(1)* (see Section 3.2.3). *(248)* reacts analogously to *(1)* with phenyl azide to give the corresponding triazoline[112]. Because of the change in electronic properties due to the trifluoromethyl groups, *(248)* reacts with other dienes than does *(1)*: cyclopentadiene[112], pyrrole[112], butadiene[113] and its methyl substituted derivatives[114], furan and methylfuran[114] as well as cyclobutadiene[115, 116]. 1,3-Cyclohexadiene does not add to *(248)*; instead the double bond is hydrogenated[114].

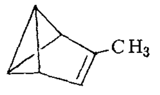
Also in contrast to *(1)*, *(248)* forms the monomeric ozonide[117] with which a variety of interesting reactions are made possible[118]. Acetone-sensitized irradiation of *(248)* in the presence of dialkylacetylenes leads to [2+2]-cycloaddition[119].



*(249)*

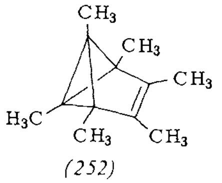


*(250)*

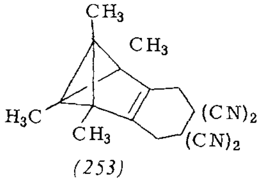


*(251)*

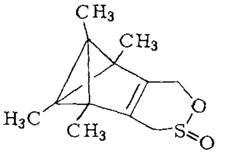
The $CF_3$-substituted 2,5-diphosphabenzvalene *(249)* is formed when tetrakis(trifluoromethyl)-1,4-diphosphabenzene is irradiated[120]. The 2- and 3-methylbenzvalenes *(250)* and *(251)*, as well as some toluene, are the products formed when methylcyclopentadienyllithium reacts with dichloromethane and methyllithium[28]. Although 1-methylbenzvalene *(4)* is not formed in this reaction, it can be synthesized by other methods (see Sections 3.1 and 3.2.2).



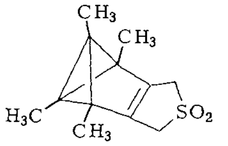
*(252)*



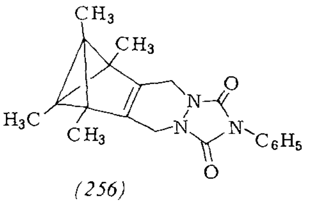
*(253)*



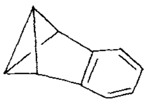
*(254)*



*(255)*



*(256)*

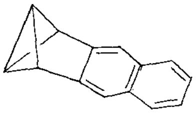


*(257)*

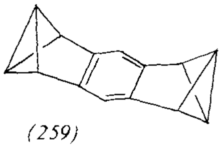
Hexamethylbenzvalene *(252)* is the proposed intermediate in the thermal isomerization of hexamethylprismane to hexamethylbenzene[121]. Its derivatives *(253)*[122], *(254)*[123], *(255)*[123], and *(256)*[124], were synthesized by *Hogeveen et al.* by reaction of 1,2,5,6-tetramethyl-3,4-bismethylenetricyclo[3.1.0.0$^{2,6}$]hexane with tetracyanoethylene, sulfur dioxide, and the triazolinedione *(40)*, respectively.

Analogously to *(1)*, benzobenzvalene (naphthvalene) *(257)* is synthesized from the indenyl anion and chlorocarbene[4]. The mechanism of its formation[29], as well as the $Ag^{\oplus}$- or Cu-catalyzed rearrangement[34] to naphthalene and benzofulvene have been investigated. *(257)* is thermally more stable than *(1)*; in $CCl_4$ at 80 °C it rearranges to benzofulvene with a half-life of *ca.* 30 h[4]. Acids add to one of the lateral bonds of the bicyclo[1.1.0]butane system[4]. Under radical reaction conditions, thiophenol does not react with *(257)*[57,71].

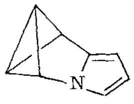
The anthracene isomers *(258)* and *(259)* are formed from the *s*-indacene dianion and chlorocarbene in a manner analogous to *(257)*[125]. The heterocyclic compound *(260)* can also be prepared by this method using 4-azapentalenyl anion[126]. On thermolysis, *(258)* rearranges to fulveno[*b*]naphthalene. *(259)* reacts *via* benzvalenobenzofulvene to give a mixture of 1,5- and 1,7-bismethylenedihydro-*s*-indacene[125]. Other substituted benzvalenes can be synthesized from *(1)*: the benzvalene sulfones *(55)* and *(57)* (see Section 3.3.4) and the naphthvalene *(242)* (see Section 3.4.5).



*(258)*



*(259)*



*(260)*

## 5. Conclusion and Outlook

The findings presented in this paper should give ample evidence that although benzvalene was first discovered only about a decade ago, it is more than a curiosity among the hydrocarbons. Its ready availability and high reactivity allows the synthesis of a multitude of new small-ring polycyclic compounds. Furthermore, the rearrangements and intermediates encountered are of mechanistic interest. Spectroscopic measurements on benzvalene and products derived therefrom provide information on σ-π and σ-σ interactions. A deeper understanding of these effects may contribute to the overall knowledge of the chemical bond.

This work is not a final review, however. The synthetic utilization of the new compounds has certainly not been exhausted, and so far benzvalene has mainly been treated with classical double bond reagents only. It is possible that new substrates will be found which are inert to normal olefins but reactive toward the benzvalene double bond.

Only a small number of reagents attack the bicyclo[1.1.0]butane moiety in benzvalene and related molecules. This is probably due to the fact that the chemistry of the bicyclo[1.1.0]butane system as such is little explored, the required starting materials, apart from a few exceptions, being difficultly accessible. *Via* benzvalene a variety of bicyclo[1.1.0]butane derivatives is available, therefore this area has been opened for more active study.

The chemistry of benzvalene demonstrates that the study of small-ring hydrocarbons is more than a playground for old-fashioned esoterics. Advances in the understanding of chemical properties have often been made by means of small and simple molecules.

# Intermolecular Forces—An Example of Fruitful Cooperation of Theory and Experiment

By Peter Schuster[*]

New experimental techniques and extensive *ab initio* calculations have rendered it possible to gain a detailed knowledge of aggregates of atoms, small ions and/or small molecules in the vapor phase which are held together by intermolecular forces. Theory and experiment are often complementary regarding reliable predictions. The results obtained for complexes of three or more constituents are still fragmentary; nevertheless, they can be used to explain some properties of the condensed phase.

## 1. Introduction

For more than two decades most theoretical chemists have been engaged in developing and testing various numerical methods in quantum chemistry. An enormous amount of effort has been expended, involving many millions of hours of electronic computing time. The primary goal in this field has been and still is the calculation of precise approximations of the Schrödinger equation for the stationary states of atoms, molecules and molecular complexes. The limitations of the numerical methods available are already apparent: the computational problems concerning ground states of molecules have more or less been solved[1]. This is true for most molecular properties. The major obstacle opposing general applicability of *ab initio* calculations is the size of the molecules and molecular associations. The computer time required increases enormously with the size of the molecular structures to be studied.

The central role of intermolecular forces in any theory of the three states—gaseous, liquid and solid—is readily understood: in a world free of attractive forces between molecules or atoms there exists only ideal gases. Consequently, the investigation of intermolecular forces represents an extremely important but difficult chapter of chemical physics. The theory of intermolecular forces fits very well into the requirements and possibilities of quantum chemistry. Experimental data which are easy to interpret can be expected for very small and structurally simple molecular associates only. These systems, however, are notoriously difficult to investigate by conventional experimental techniques. Enormous experimental efforts and developments of new spectroscopic methods, *e.g.* "molecular beam electric resonance" spectroscopy[2] or high-pressure mass spectrometry[3] were necessary in order to obtain reliable experimental data on simple aggregates of small molecules. These small systems, however, are amenable also to precise numerical computation. The progress recently achieved in this field was a direct result of theoretical "predictions" and "precalculations" eventually being accurate enough for use by the experimentalist.

The interactions most commonly studied at present are those between rare gas atoms or between unpolar mole-

cules. Nevertheless, this review will concentrate on the forces acting between polar molecules and between polar molecules and ions because they commonly attract the interest of a broader audience and because they are closer to our own field of research. They are more difficult to study theoretically but they lead to a much richer variety of ag-

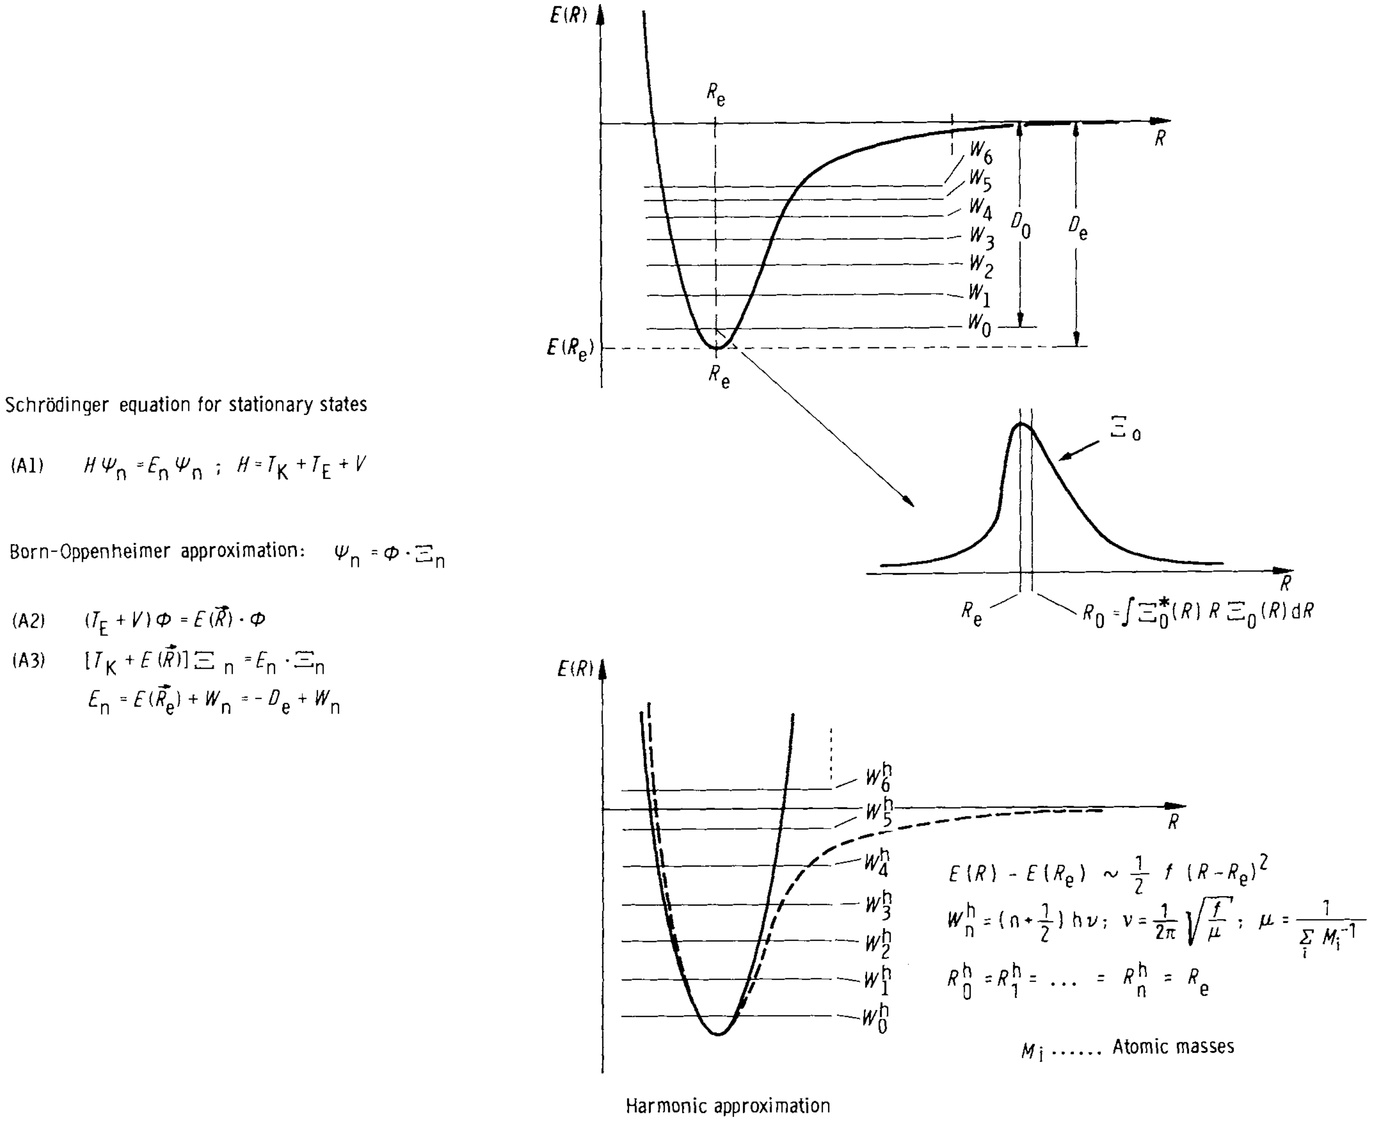

Fig. 1. Born Oppenheimer approximation and energy surface. The mathematical separation of the states of motion of a molecule or a molecular complex into fast motions of electrons and slow motions of the atomic nuclei is known as Born-Oppenheimer approximation. This approximation actually represents the basis of molecular spectroscopy. The nuclei are assumed to stay at fixed positions in comparison to the rapidly moving electrons. The wave function is approximated by a product, $\psi = \phi \cdot \Xi$ and the Schrödinger equation for stationary molecular states(A1) is separated into two equations, one for the electronic motion (A2) and one for the nuclear motion (A3). $H$ is the Hamilton operator or Hamiltonian of the molecule or the molecular complex. $T_E$ and $T_K$ are operators, which describe the kinetic energy of electrons and nuclei respectively. $V$ is the potential energy and it is calculated by Coulomb's law from the electric charges of nuclei and electrons as well as their mutual distances. Equation (A2) has to be solved point by point for different relative positions of the nuclei. Thereby we obtain the energy surface $E(\vec{R})$ of the molecule or the molecular complex. $\vec{R}$ represents the set of all internal degrees of freedom. The states of nuclear motion are described by equation (A3). The eigenvalues $W_k$ correspond to the stationary states of the molecules or molecular complexes. Their differences $(W_j - W_k)$ are measured in the vibrational spectra—apart from modifications due to rotational states. For the purpose of illustration we consider a system with a single degree of freedom only, *e. g.* a diatomic molecule, AB. The energy curve $E(R)$ shown is characteristic of a bound state. In general there will be many bound states of a molecule. In this overview we restrict ourselves to the energetically lowest electronic state or the electronic ground state of the molecule or the molecular complex. Therefore we omit any index referring to the electronic state and write simply $\phi$ and $E(R)$ respectively. The position of the energy minimum of the curve $E(R)$ corresponds to the "equilibrium geometry" $\vec{R}_e$—in our one-dimensional example this is simply the "equilibrium distance" $R_e$. The depth of the trough of the curve $E(R)$ represents the "equilibrium dissociation energy",

$$D_e = -\Delta E_{AB}(R_e) = -\{E_{AB}(R_e) - (E_A + E_B)\}$$

For each vibrational state $n$ we have a pair of values $R_n$ and $D_n = D_e - W_n$. In general, $R_n$ is only slightly longer than $R_e$ for small values of $n$. The vibrational ground state, $n=0$, is of particular importance since it represents the lowest experimentally accessible state. Accordingly, $R_0$ is the interatomic distance of the molecule which is measured at absolute zero (0 K). $D_0$ is the corresponding experimentally accessible energy of dissociation. In most cases higher vibrational levels are scarcely populated only at room temperature ($T \approx 300$ K). The avarage atomic distance, $\bar{R}$, therefore, is close to $R_0$ at these temperatures and the enthalpy of dissociation of the process $AB \rightarrow A + B$, $\Delta H_{300}^0$, is only slightly different from $D_0$.
In the case of molecules the harmonic approximation plays an important role. The potential curve is approximated by a parabola. Then, the Schrödinger equation (A3) can be solved easily. For the atomic distance and the dissociation energy in the vibrational ground state we obtain: $R_0^h = R_e$ and $D_0^h = D_e - W_0^h = D_e - 1/2\,h\nu$. The harmonic approximation is indicated by the superscript "h". In the case of some intermolecular complexes the potential curve $E(R)$ is so flat that there are only very few stationary vibrational states. In these cases, as we shall see later, the harmonic approximation does not provide a sufficient description of the molecular vibrations.

gregates in appearance and properties. Examples of aggregates of non-polar constituents will be mentioned only insofar as is inevitably unavoidable. Some new and comprehensive reviews on intermolecular forces are collected in Ref. [4].

## 2. Numerical Computation of the Structures and Properties of Molecules and Molecular Aggregates

Apart from some rare exceptions molecular systems have been studied within the framework of the Born-Oppenheimer approximation (Fig. 1). This approximation makes use of the difference in mass between electrons and nuclei, which amounts to more than three orders of magnitude, and assumes that the electrons move "infinitely fast" in the field of the slowly moving nuclei. This simplifying assumption is not only the starting point of quantum mechanical calculations but also represents the basis of practically all theories on intermolecular forces, chemical reactions and of molecular spectroscopy in general. The cardinal concept of all these theories is the energy surface. Because of its high dimensionality—the energy surface of a general aggregate of $N$ atoms has $3N-6$ degrees of freedom—it is often called the "energy hypersurface". It represents the energy of a molecule or a molecular association as a function of the positions of the nuclei. The minima of the energy surface, as far as they are deep enough (Fig. 1), correspond to stable stationary states with defined nuclear geometries. The curvatures or second derivatives of the energy surface at the minimum are the harmonic force constants of the molecule or the molecular aggregate in a given state. They contain the basic information of the vibrational spectrum.

Small molecules can be calculated theoretically as well as studied spectroscopically with incredible accuracy (Table 1). At present there are two generally accepted levels of

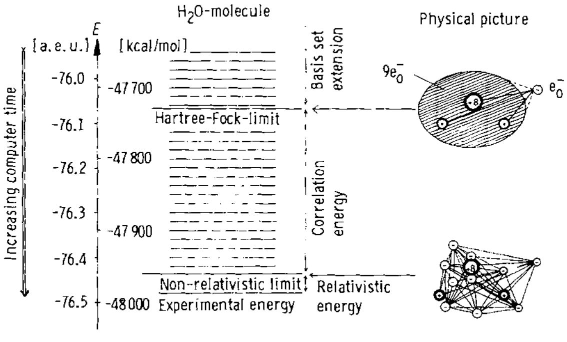

Fig. 2. The steps of the approximate solution of the electronic Schrödinger equation of the water molecule. Within the framework of the Hartree-Fock approximation the equation of motion of the individual electron is solved in the average potential of all other electrons. Explicit consideration of the motions of the individual electrons leads to the "non-relativistic" approximation. A computation of the relativistic energy leads beyond the frame of conventional quantum mechanics and is accompanied by enormous methodical difficulties. Experience, however, has shown that almost all important properties of molecules and molecular complexes containing light atoms ($Z < 36$) are described accurately within the non-relativistic approximation. For systems of atoms with heavy nuclei the calculations become extremely time consuming in any case and hence relevant predictions on the importance of relativistic corrections are not possible at present. Some molecular properties—equilibrium geometries, electron density distributions *etc.*—are reproduced very well already at the Hartree-Fock limit. For other quantities like force constants, vibrational spectra or bond energies the corrections due to electron correlation are substantial.

Table 1. Some properties of small polar molecules [a].

| HF | Geometry | | Force constant(s) | Dipole moment | | Quadrupole moment [b] unit: $10^{-26}$ esu cm$^2$ | | Electric polarizability unit: $10^{-25}$ cm$^3$ | | | |

[a] References are given in [55]. The original literature contains further hints on the accuracy of calculated and experimental data. In general, the error limits hardly exceed 2 or 3 units of the last digit shown. The coordinate system of $H_2O$ has been chosen such that the z-axis coincides with the $C_2$-axis of the molecule. The H-atoms lie in the xz-plane. In HF $\parallel$ denotes the direction of the $C_\infty$-axis. The index "e" refers to the equilibrium geometry, the index "0" to the vibrational ground state. [b] The quadrupole tensor was calculated relative to the center of gravity of HF and $H_2{}^{16}O$. [c] We give the available results of the SCF-calculation with the most extended basis set as the best approximation to the Hartree-Fock limit. Electron correlation was taken into account either by CEPA (coupled electron pair approximation) or by MBPT (many-body perturbation theory) techniques. For technical details see *W. Kutzelnigg, I. Shavitt* in [1]. The experimental results were taken from the references given in [55].

approximate solutions to the electronic Schrödinger equation:

1) the so-called Hartree-Fock limit, which represents the "best" approximation within the model of independently moving electrons (Fig. 2) and

2) the non-relativistic limit.

With the exception of some molecular systems with extremely flat energy troughs like the cation $H_5O_2^+$[4a,b] molecular geometries are computed fairly accurately in calculations close to the Hartree-Fock limit. This is not true for many other molecular properties. Force constants, in particular those of bond stretching vibrations, contain systematic errors: the calculated values are too high, the calculated energy surface is curved too much around the minimum. The origins of this deficiency is well understood (Fig. 3). Explicit consideration of the correlation of electron motion satisfactorily eliminates this failure. Within the framework of the non-relativistic approximation energy surfaces can be predicted with high accuracy. The non-relativistic approximation presumably fails only in the case of molecular systems with atoms of the fourth, fifth and sixth row of the periodic table—Rb, Sr and heavier atoms—where we can easily recognize the substantial relativistic contributions already in the atomic spectra. It must be admitted, however, that there are, as yet, no accurate numerical results available on the influence of relativistic corrections on computed properties of chemical bonds and intermolecular forces.

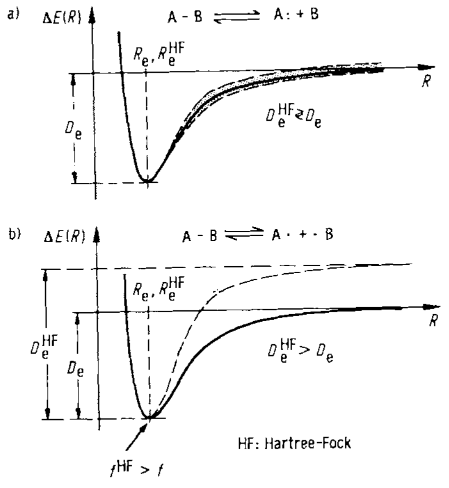

Fig. 3. Dissociation of a molecule or a molecular complex into a) two "closed shell" subsystems or b) into two "open shell" subsystems. In the first case the Hartree-Fock method is able to reproduce the dissociated state very well. In the latter example, however, this is not the case: the Hartree-Fock approximation fails to describe the homolytic dissociation of a chemical bond. This is also the cause, why bond energies and force constants can be predicted accurately only when electron correlation is considered explicitly. The scales for $E(R)$ and $R$ were chosen such that the correlation energy vanishes at the energy minimum. Hence, the minima of the curves $E(R)$ and $E^{SCF}(R)$ coincide at the energy minima. —— $\Delta E(R)$: non-relativistic limit; $\Delta E^{HF}(R)$: Hartree-Fock limit.

The wave functions of molecules and molecular associations are obtained together with the energy surfaces by *ab initio* calculations. They are also functions of the nuclear coordinates. The spatial electron density distribution (1)

$$\int \ldots \int \Psi^*(1,2,\ldots,n)\,\Psi(1,2,\ldots,n)\,ds_1\,d\tau_2 \ldots d\tau_n = \rho(x,y,z)^{[5]} \qquad (1)$$

is computed from the wave function by integration. In principle, the electron density distribution can be determined experimentally, *e.g.* by electron diffraction studies in the gaseous state. The electron density distribution is a function in three-dimensional space. For the purpose of illustration one commonly uses two-dimensional sections, *e.g.*$\rho(x, y = y_0, z)$ as shown in Figure 4. The choice of a flexible enough basis set and the explicit consideration of electron correlation often have a pronounced effect on the quality of the wave function, as we shall see in detail when we compare calculated and measured electric properties of molecules.

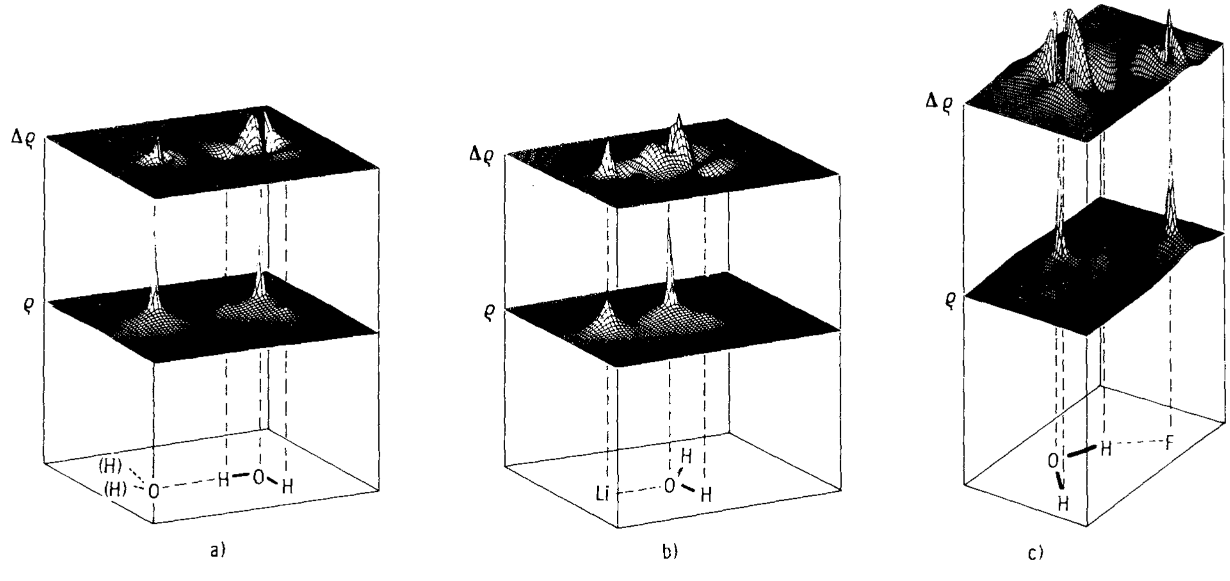

Fig. 4. Electron density- ($\rho$) and electron density difference functions ($\Delta\rho$) [see eq. (4)] of three examples of intermolecular complexes: a) $(H_2O)_2$, b) $Li^+ \cdot OH_2$ and c) $F^- \cdot HOH$. We show cuts through the three-dimensional functions in the xz-planes ($y = 0$). The maxima of the electron density functions coincide with the positions of the atomic nuclei. In case of the water dimer the two protons of the water molecule on the left-hand side cannot be recognized since they lie above the xy-plane. The density difference function $\Delta\rho$ shows the polarization of the electron densities as a consequence of intermolecular interactions. The decrease in electron density at the central proton of the two hydrogen bonds (a and c) can be recognized particularly well. The same decrease through polarization can be observed with protons in the complex $Li^+ \cdot OH_2$ (b).

Electron density distributions are troublesome in comparisons of different systems and do not contribute very much to an intuitive understanding of intermolecular forces. Therefore, it is very popular to use multipole expansions of electron density distributions. The coefficients of these expansions are the electric multipole moments of molecules. In most cases electric multipole moments are reproduced satisfactorily by accurate *ab initio* calculations. Sometimes electron correlation effects are important (cf. Table 1). The changes of electron density distributions in the electric field are known as polarization or induction effects. A homogeneous electric field ($\vec{\mathfrak{E}}$) induces a dipole moment ($\vec{\mu}_{\text{ind}}$), which can be described by the electric polarizability $\boldsymbol{\alpha}$ as long as the linear approximation is valid, *i.e.* at low field strengths:

$$\vec{\mu}_{\text{ind}} = \boldsymbol{\alpha} \cdot \vec{\mathfrak{E}} \tag{2}$$

Table 1 lists some results of *ab initio* calculations. It is worth mentioning that the anisotropy of the polarizability tensor, which is very difficult to measure in non-linear molecules, can be obtained easily and with high reliability by numerical computation.

Interactions between molecules cause changes in electron density distributions as well. These changes can be understood as relaxations in the fields of the molecular partners. The accuracy, with which the electric moments and polarizabilities of isolated molecules are predicted by calculations, can be considered as a proper criterion for the suitability of the method of calculation for describing intermolecular forces.

*Ab initio* calculations of magnetic properties of molecules, in particular those of magnetic susceptibilities and chemical shifts, cause more difficulties than the calculations of all other properties discussed so far[6]. The change in chemical shift will not be discussed in detail here.

So far we have not differentiated between molecules and molecular associations. There was no need for such a differentiation, since molecules and molecular complexes are treated in precisely the same way by *ab initio* methods (see Fig. 1). The results of these calculations are the energy surface and the wave function of the complex as an entity, and quantities are derived from them like the vibrational spectra and the electric and magnetic properties of the complex, respectively. For heuristic reasons we are much more interested in differences in the case of molecular associations than in the case of isolated molecules. We are not interested so much in the complete high-dimensional energy surface but in that part which is characteristic for the formation of the complex from its constituents. We do not intend to analyze the total electron density but rather its changes as a result of complex formation. In the case of weak interactions between the partners in the complex an approximation called the "frozen geometry" approach turned out to be very useful for approximative studies: we assume that the nuclear coordinates of the subsystems do not change on complex formation. The mutual approach of the molecules thus leads only to changes in electron density distributions. In this case the "intermolecular" energy surface of a binary complex

$$\Delta E(\vec{R}) = E_{\text{AB}}(R) - (E_{\text{A}}^{0} + E_{\text{B}}^{0}) \tag{3}$$

depends on a few coordinates only. Depending on the symmetries of the subsystem we have from one to six degrees of freedom (Fig. 5). Within the framework of the "frozen geometry" approach electron density difference functions (see Fig. 4) can be defined without any difficulty, since the nuclear geometries of the subsystems in the complex and in the isolated molecules are congruent.

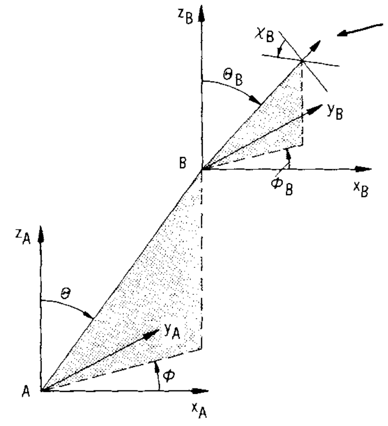

Fig. 5. Degrees of freedom of intermolecular energy surfaces within the "frozen geometry" approximation. The centers of gravity of both molecules A and B are chosen as the origins of Cartesian coordinate systems: $A = (x_A^0, y_A^0, z_A^0)$ and $B = (x_B^0, y_B^0, z_B^0)$. Depending on the nature of the two subsystems we need a different number of geometrical quantities in order to fix the relative position and orientation of A and B:

| Nature of A | Nature of B | Degrees of freedom |
|---|---|---|
| Atom | atom | 1: $R$ |
| Linear molecule (z-axis) | atom | 2: $R$, $\Theta$ |
| General molecule | atom | 3: $R$, $\Theta$, $\Phi$ |
| Linear molecule (z-axis) | linear molecule | 4: $R$, $\Theta$, $\Theta_{\text{B}}$, $\Phi_{\text{B}}$ |
| General molecule | linear molecule | 5: $R$, $\Theta$, $\Phi$, $\Theta_{\text{B}}$, $\Phi_{\text{B}}$ |
| General molecule | general molecule | 6: $R$, $\Theta$, $\Phi$, $\Theta_{\text{B}}$, $\Phi_{\text{B}}$, $\chi_{\text{B}}$ |

$R = \sqrt{(x_A^0 - x_B^0)^2 + (y_A^0 - y_B^0)^2 + (z_A^0 + z_B^0)^2}$. The arrow (above, right) points to an axis in the molecule B ($\Theta_{\text{B}}$, $\Phi_{\text{B}}$); rotation about ($\Theta_{\text{B}}$, $\Phi_{\text{B}}$): $\chi_{\text{B}}$.

$$\Delta\rho(x,y,z) = \rho_{\text{AB}}(x,y,z) - (\rho_{\text{A}}^{0} + \rho_{\text{B}}^{0}) \tag{4}$$

This electron density difference function describes the change in electron density as a result of forces of interaction in the aggregate.

For a deeper understanding of intermolecular forces a partitioning of the energy of interaction into individual contributions was found to be very useful:

$$\Delta E = \Delta E_{\text{COU}} + \Delta E_{\text{POL}} + \Delta E_{\text{DIS}} + \Delta E_{\text{EX}} + \Delta E_{\text{RES}} \tag{5}$$

The individual contributions have the following meaning:
1) $\Delta E_{\text{COU}}$ represents the electrostatic energy of interaction between both subsystems caused by their charge density distributions in the isolated state,
2) $\Delta E_{\text{POL}}$, the polarization- or induction-energy describes the additional stabilization of the aggregate by relaxation of electron densities in the field of the partner,
3) $\Delta E_{\text{DIS}}$ is the dispersion energy, a universal attractive contribution, which is caused by correlation of electron motions in both subsystems,

4) $\Delta E_{EX}$, the exchange energy, represents an interaction which is caused by mutual overlap between both subsystems and is always repulsive between two "closed-shell" molecules, and

5) $\Delta E_{RES}$, the residual contribution, which is frequently subdivided further into the charge transfer energy $\Delta E_{CHT}$ and additional terms. We restrict ourselves here to those complexes in which this residual contribution is small. Molecular aggregates with a high percentage of charge transfer energy, like the anion $[FHF]^-$, are considered more appropriately as uniform molecular entities with chemical bonds[7] and not as intermolecular complexes.

The partitioning of energies of interaction results from calculations of intermolecular forces by means of perturbation theory[8]. Thereby, the energy of interaction between the two subsystems is obtained as a sum of individual contributions, which are closely related to those mentioned above. In the case of *ab initio* calculations based on the molecular orbital method, energy partitioning can be performed exclusively by means of certain model considerations[9]. Without going into details we might merely mention that the individual contributions to the energy of interaction are not free from arbitrariness when the wave functions of the two subsystems overlap significantly. The overlap increases considerably with decreasing intermolecular distance. The source of arbitrariness is actually the same, both in calculations by perturbation theory and by molecular orbital methods. The exchange energy, $\Delta E_{EX}$, and the charge transfer or residual energy, $\Delta E_{RES}$, become very small at large intermolecular distances. At the same time, the three residual contributions, $\Delta E_{COU}$, $\Delta E_{POL}$ and $\Delta E_{DIS}$ approach asymptotically the well known "semiclassical" expression of the series expansion in $R^{-n}$ (Table 2). The coefficients of this series expansion are determined by the multipole moments and polarizabilities of the interacting subsystems as well as by their mutual orientation. The multipole expansion of intermolecular energies is of great practical value for approximation calculations in the case of large intermolecular distances. Nevertheless, it is not free of problems for the theorist: the series expansion is semi-convergent, *i.e.* the series converges only until a certain minimum term; the higher terms become larger again and ultimately the series diverges. Convergence is achieved only in the limit $R \rightarrow \infty$[10].

Table 2. Expansion of the intermolecular energy as a power series of $R$ as used in the "semiclassical" theory: $\Delta E = \sum_{n=1}^{\infty} C_n R^{-n}$.

| n | Type of interaction | Nature of interaction | Effective components [a] A | B |
|---|---|---|---|---|
| 1 | ion - ion | electrostatic | $q_A$ | $q_B$ |
| 2 | ion - dipole | electrostatic | $q_A$ | $\vec{\mu}_B$ |
| 3 | ion - quadrupole | electrostatic | $q_A$ | $\Theta_B$ |
|  | dipole - dipole | electrostatic | $\vec{\mu}_A$ | $\vec{\mu}_B$ |
| 4 | dipole - quadrupole | electrostatic | $\vec{\mu}_A$ | $\Theta_B$ |
|  | ion - polarizability | polarization (induction) | $q_A$ | $\boldsymbol{\alpha}_B$ |
| 5 | quadrupole - quadrupole | electrostatic | $\Theta_A$ | $\Theta_B$ |
| 6 | dipole - polarization | polarization (induction) | $\vec{\mu}_A$ | $\boldsymbol{\alpha}_B$ |
|  | polarizability - polarizability | dispersion | $\boldsymbol{\alpha}_A$ | $\boldsymbol{\alpha}_B$ |

[a] The expansion coefficients $C_n$ are functions of the angles $\Theta$, $\Phi$, $\Theta_B$, $\Phi_B$, $\chi_A$, $\chi_B$ as well as of the components of multipole moments and polarizabilities. $q_A$, $q_B$: charges $\vec{\mu}_A$, $\vec{\mu}_B$: dipole moments: $\vec{\mu} = (\mu_x, \mu_y, \mu_z)$; $\Theta_A$, $\Theta_B$: quadrupole moments; these are tensors which have only the components $\Theta_{xx}$, $\Theta_{yy}$ and $\Theta_{zz}$ different from zero after transformation to principal axes, moreover the relation $\Theta_{xx} + \Theta_{yy} + \Theta_{zz} = 0$ is fulfilled; $\boldsymbol{\alpha}_A$, $\boldsymbol{\alpha}_B$: polarizabilities, these are tensors with the components $\alpha_{xx}$, $\alpha_{yy}$, $\alpha_{zz}$ after transformation to principal axes.

The partitioning of intermolecular energies for a number of stable binary associations at the energy minimum is presented in Table 3. As expected, the electrostatic contribution, $\Delta E_{COU}$, dominates the energy of interaction in polar systems, which represent the main subject of this review. At the other end of this series of interacting systems we find the dimers of rare gas atoms, which are held together exclusively by the dispersion energy ($\Delta E_{DIS}$).

The essential limitation of the applicability of *ab initio* calculations in the study of intermolecular forces is not a major issue: calculations cannot be performed with the accuracy required in the case of systems that are too large—that is aggregates involving too many electrons. High com-

Table 3. Energy partitioning in some intermolecular complexes, AB, around the energy minimum. All energies are given in kcal/mol. The SCF energy of interaction is the sum of four contributions, which were obtained by means of Hartree-Fock energy partitioning.

$$\Delta E_{SCF} = \Delta E_{COU} + \Delta E_{EX} + \Delta E_{POL} + \Delta E_{RES}$$

| Atom, molecule or ion A | B | Hartree-Fock method $\Delta E_{COU}$ | $\Delta E_{EX}$ | $\Delta E_{POL}$ | $\Delta E_{RES}$ | $\Delta E_{SCF}$ [a] | Electron correlation $\Delta E_{DIS}$ | $\Delta E$ [a] | Ref. |
|---|---|---|---|---|---|---|---|---|---|
| He | He |  |  |  |  | 0.0168 | −0.0379 | −0.0211 | [24] |
| Ne | Ne |  |  |  |  | 0.1022 | −0.1841 | −0.0819 | [24] |
| Ar | Ar |  |  |  |  | 0.2682 | −0.5100 | −0.2418 | [24] |
| $H_2$ | $H_2$ |  |  |  |  | 0.0920 | −0.1651 | −0.0731 | [24] |
| He | HF |  |  |  |  | −0.015 | −0.136 | −0.151 | [25] |
| $H_2$ | HF |  |  |  |  | −0.667 | −0.867 | −1.534 | [25] |
| HF | HF | −4.77 | −1.89 | −0.59 | −0.33 | −3.80 |  |  | [44] |
| $H_2O$ | $H_2O$ | −7.3 | 4.5 | −0.7 | −1.2 | −4.7 | −1.5 | −6.2 | [4b] |
| $H_2O$ | $Li^+$ | −41.5 | 15.3 | −12.8 | 5.2 | −33.7 |  |  | [4b] |
| $H_2O$ | $Na^+$ | −30.3 | 7.0 | −5.1 | 1.1 | −27.4 |  |  | [4b] |
| $F^-$ | $H_2O$ | −34.7 | 26.0 | −7.2 | −7.2 | −23.1 |  |  | [4b] |
| $Cl^-$ | $H_2O$ | −14.6 | 7.0 | −1.6 | −5.7 | −14.9 |  |  | [4b] |

[a] We use the notation "SCF" = "self-consistent field" in order to indicate that the basis set used was not sufficient to approach the Hartree-Fock limit very closely (cf. Fig. 2) in all cases. The total energy of interaction $\Delta E$ is obtained as the sum of the dispersion energy and the SCF energy of interaction: $\Delta E = \Delta E_{SCF} + \Delta E_{DIS}$ [cf. eq. (5)].

putational accuracy, however, is inevitably necessary, since the energies of interaction are obtained as small differences between large quantities. Experience with actual calculations revealed two sources of errors in calculations of low accuracy:

1) Calculations with small basis sets are not able to reproduce the properties of the isolated subsystems, atoms or molecules correctly, and this leads to errors in the energies of interaction, as can be seen immediately from an estimate by means of the conventional approximation formulas (Table 2). The consequences of this deficiency are almost always errors in equilibrium geometries and force constants.

2) The superposition of the basis sets of the subsystems in the association is the second source of errors: the individual systems are described better by the larger basis set of the complex. Consequently, we have smaller, *i. e.* more negative energies for the parts in the complex than at infinite intermolecular separation. The calculation thus predicts too great a stability for the aggregates. This artificial binding disappears when the calculations are performed with large basis sets[11].

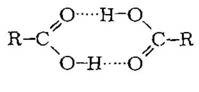
Electron correlation likewise provides essentially two contributions: the first contribution corresponds entirely to the effects described above under item (1). It accounts for the changes in calculated molecular properties as a consequence of electron correlation. In this class of erroneously calculated quantities we have, *inter alia,* the force constants of stretching vibrations, which are calculated too large at the Hartree-Fock limit and thereby lead to substantial differences between calculated and experimentally determined frequencies of the normal vibrations. The dispersion energy, $\Delta E_{DIS}$, is an electron correlation phenomenon and cannot be obtained by Hartree-Fock calculations. It represents the most important intermolecular contribution of electron correlation. In the case of polar systems the relative contribution of the dispersion energy to the total energy of interaction is fairly small. Therefore, most calculations on systems of this kind have been performed close to the Hartree-Fock limit.

If necessary, dispersion energies are added to the Hartree-Fock potentials by means of simple approximation formulas.

## 3. Binary Complexes in the Vapor Phase

*Ab initio* calculations on small aggregates of molecules yield a variety of results, which we will now correlate with the corresponding experimental data. The most interesting quantities which can be derived from intermolecular energy surfaces are the equilibrium geometries and dissociation energies of vapor phase aggregates. Both quantities can be easily calculated, but their experimental determination often leads to substantial difficulties.

Until a few years ago very little was known about the structures of stable intermolecular complexes in the vapor phase. Electron diffraction[12] is the conventional technique used in the study of molecular structures in the vapor phase. However, in only a few exceptional cases has this technique been applied to molecular associations. The best studied examples are the dimers of carboxylic acids[13].



R = H, $CH_3$, $C_2H_5$

No wonder, these systems, in particular the dimer of formic acid, were, now more than tens years ago, the first intermolecular complexes which were studied systematically. At that time semiempirical MO-methods were applied[14]. Later on, more accurate calculations were performed. One of the most recent, and at the same time, most extensive *ab initio* study of formic acid dimer[15] yielded essentially the same results as electron diffraction studies. Systems with as many electrons as formic acid dimer cannot, however, be calculated with a high degree of accuracy by *ab initio* techniques, at least with regard to presently available capacities for computation.

The experimental techniques which are used for the study of charged and of uncharged associations in the vapor phase are naturally very different. We shall therefore divide our survey of these into two sections.

### 3.1. Complexes of Atoms and Molecules

Such a variety of theoretical and experimental investigations have been performed on the vapor phase during the last two decades that we shall have to restrict ourselves to some characteristic examples. We have chosen the dimers formed from noble gas atoms and/or hydrogen halides and water, respectively, since these associations have been studied in great detail. Moreover, they are very well suited for demonstrating the universal manifestation of the underlying problems.

All noble gas dimers except $He_2$ are stable (Table 4). Only in this particular case is the trough of the potential curve $\Delta E(R)$ so shallow, and the vibrating mass so small,

Table 4. Experimental data and results of accurate calculations [a] of noble gas dimers in the electronic ground state.

| Dimer | Potential curve | | Vibrations | | Ref. |
|---|---|---|---|---|---|
| | $R_e$ [Å] | $-\Delta E(R_e) = D_e$ [cal/mol] | $D_0$ [cal/mol] | Number of states [b] | |
| HeHe | 2.97 (2.98) | 21.00 (21.1) | | 0 | [24] |
| HeNe | 3.01 (3.02) | 43.1 (40.7) | 5.3 | 1; $n=0$ | [24, 16, 56] |
| NeNe | 3.10 (3.08) | 83.5 (81.9) | 46.6 | 2 (3); $n=0$, 1 (2) | [24, 16, 56] |
| ArAr | 3.76 (3.83) | 284.6 (241.8) | 242 | | [24, 56] |
| | | | 220 | 6; $n=0,\ldots,5$ | [16] |

[a] We give the results of *ab initio* Hartree-Fock calculations combined with an empirical calculation of the dispersion energy [24] (calculated results are given in parantheses). [b] Vibrational states which have been found experimentally [16]. Isotopes: $^4$He, $^{20}$Ne and $^{40}$Ar.

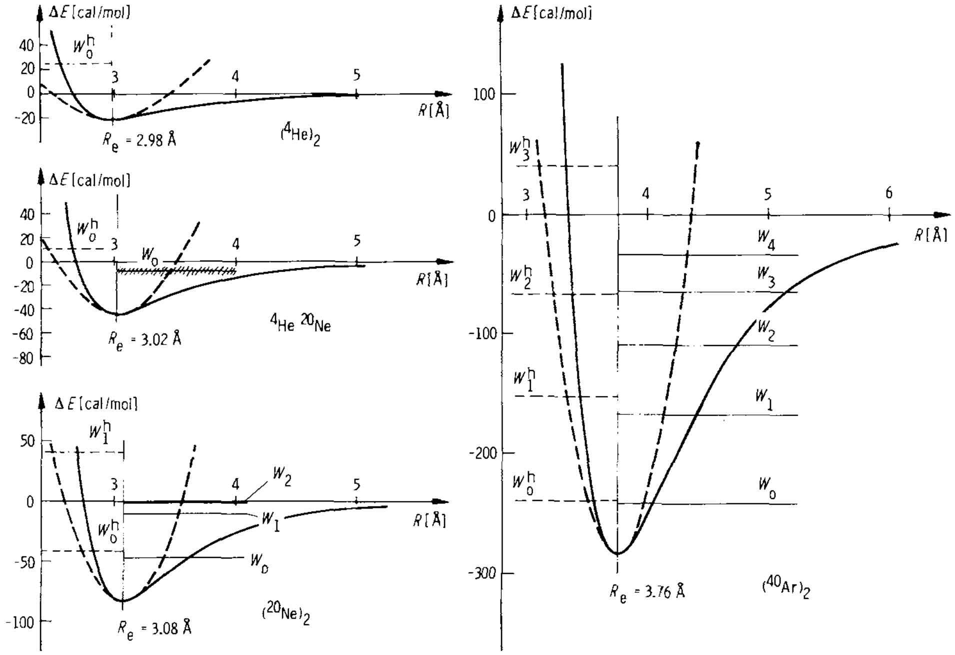


Fig. 6. Some potential curves and vibrational states of noble gas dimers. $(^4\mathrm{He})_2$ has no bound state. The potential curve of $^4\mathrm{He}^{20}\mathrm{Ne}$ supports just one stationary state. In the case of $(^{20}\mathrm{Ne})_2$ there are certainly two vibrational states, presumably there exists also a third one ($n=2$). $(^{40}\mathrm{Ar})_2$ has already a whole variety of stationary vibrational states. The best fits of harmonic potentials and the vibrational levels within the harmonic approximation are given as broken lines. The deeper the potential trough or, in other words, the more stationary states exist, the better the harmonic potential describes the actual vibrations of the dimer. In the whole series presented here the harmonic approximation predicts satisfactorily only the ground state of $(^{40}\mathrm{Ar})_2$.

that there is no stationary vibrational state of the dimer. The two next heavier "van der Waals-molecules" formed from noble gas atoms are stable: HeNe has one stable vibrational level, $\mathrm{Ne}_2$ at least two (Figure 6). The experimental information on noble gas dimers comes from different sources:

1) *Tanaka, Yoshino et al.*[16] succeeded in recording vacuum UV absorption spectra in pure noble gases and noble gas mixtures at 77 K and at pressures between 1 and 200 torr. The spectral lines were assigned to electron excitation processes in the dimers. The rotational and vibrational fine structures of these bands were used for determining the depths of the potential wells and the interatomic distance.

2) The most detailed results on noble gas dimers were obtained from molecular beam experiments mainly performed by *Lee* and his group[17]. So far, refinement of the measurements and further development of the techniques of evaluation have lost little of their primary importance[18]. In these experiments one measures the elastic, differential cross-sections (DCS) of the scattering process between crossed atomic beams which escape from supersonic nozzles into a high vacuum chamber ($p \approx 10^{-7}$ torr; see Fig. 7). The potential curve is calculated by inversion of the angular dependence of the DCS. Generally, certain analytical model potentials—the most simple functions are Lennard-Jones- and Morse-van-der-Waals potentials[19]—have to be applied.

3) Another technique, which has been used in the study of noble gas dimers, consists in the combination of the molecular beam method and a spectroscopic or structure determining method (Fig. 7). Under suitable conditions dimers and higher aggregates are formed by adiabatic cooling when the atomic beam escapes the nozzle and expands

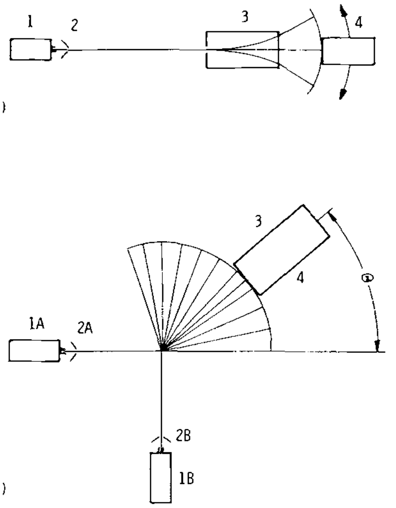

Fig. 7. Schematic setup of molecular beam experiments on intermolecular complexes. a) Single beam apparatus, b) crossed molecular beams technique. The molecular beam can be generated in both cases from a source (1, 1 A, 1 B) through expansion from a supersonic nozzle (2, 2 A, 2 B) [66]. The advantage of his technique consists essentially in a uniform translational energy of the atoms or molecules. The energy distribution function becomes narrower with increasing Mach number. During the expansion into high vacuum dimers and higher aggregates are formed which can be studied directly in the analyzer (3) (a) or which are scattered at a second molecular beam (from the source 1B) (b). In the latter case product analysis is performed as a function of the scattering angle $\Theta$. Thereby one obtains the "differential scattering cross section", $S(\Theta)$, from which conclusions on the potential surface can be drawn. A mass spectrometer generally serves as detector (4) for the species formed. Additional information may be obtained by other analytical techniques. Studies by means of "electric resonance-spectroscopy" [67] turned out to be particularly useful for intermolecular complexes. Examples are discussed in the text.

into the vacuum. *Audit*[20] determined the interatomic distances in $Ar_2$ and $Xe_2$ by means of electron diffraction in such an apparatus.

4) An important, but indirect source of information on intermolecular potentials in homodimers are the equations of state of gases in appropriate ranges of pressure and temperature[21]:

$$\frac{pV}{nRT} = 1 + \frac{B_2(T)}{V} + \frac{B_3(T)}{V^2} + \cdots \tag{6}$$

The second virial coefficient, $B_2(T)$, can be calculated from the potential curve $\Delta E(R)$ by integration. Again we need an assumption on the analytical shape of the potential curve in order to adjust energetic parameters and equilibrium distances to the $p, V, T$-data available.

In the case of noble gas dimers there is a great variety of experimental data available with which to determine a fairly simple one-dimensional energy curve. It is not surprising, therefore, that theory could not contribute much more than the shape of the potential curve and an independent verification of the experimental data. A very accurate potential curve of $He_2$ was obtained from extensive *ab initio* calculations with almost complete correlation of electron motion[22]. Because of the higher number of electrons a comparable calculation of $Ne_2$ is extremely time consuming and involved[23]. Hence, there is no completely *ab initio* calculated curve of $Ne_2$ available, which is of the same accuracy as that of $He_2$.

Another theoretical approach turned out to be extremely useful in calculations of potential curves for noble gas dimers. One calculates the energy of interaction within the framework of the Hartree-Fock approximation ($\Delta E^{HF}$). As we mentioned in the previous section $\Delta E^{HF}$ does not contain the dispersion energy and, consequently, is always repulsive. This dispersion energy, $\Delta E_{DIS}$, is calculated by means of the series expansion shown in Table 2. In order to improve the agreement with experimental data the computed dispersion energies are multiplied by an empirical factor at medium distances[24]:

$$\Delta E(R) = \Delta E^{HF}(R) - \left\{\frac{C_6}{R^6} + \frac{C_8}{R^8} + \frac{C_{10}}{R^{10}}\right\} f(R) \tag{7}$$

$$\begin{array}{lll} \text{where } f(R) = \exp\{-[1.28\,R_e/R - 1]^2\} & & \text{for } R < 1.28\,R_e \\ \text{and } f(R) = 1 & & \text{for } R \geq 1.28\,R_e \end{array}$$

$R_e$ denotes the equilibrium distance (Fig. 3). The HFD (Hartree-Fock-Dispersion) potential curves obtained thereby are considered to be the most reliable theoretical energy curves for all noble gas dimers.

The investigation of associations of noble gas atoms (E) and polar molecules is theoretically and experimentally substantially more difficult and involved than the investigation of noble gas dimers. This is also true for the most simple aggregates in which the polar molecule is diatomic. Extensive studies have been performed on complexes with hydrogen halides (HX). Some results are summarized in Table 5. Accurate *ab initio* calculations and experimental investigations are, to some extent, complementary: exact calculations are available for some representative parts of the energy surface of the He·HF[25], whereas extensive experimental data are available only for the complexes of Ne, Ar and Kr with HCl[26]. All these three systems are too large for extensive *ab initio* studies, at least at present.

Energy partitioning in case of He·HF (Table 5) demonstrates that we have stabilizing contributions to the Hartree-Fock energy of interaction in complexes of the type E·HX, in contrast to nobel gas dimers where $\Delta E^{HF}$ is repulsive. These complexes are already stable without the contribution of dispersion energy. This stabilization can be identified with a non-vanishing contribution of polarization energy, $\Delta E_{POL}$, in the semiclassical approach. An electrostatic contribution in the classical sense does not exist in the case of atom-molecule complexes.

At first we consider the complexes E·HX as general triatomic molecules. Consequently, the energy surface has three degrees of freedom. The "frozen geometry" approximation fixes the intramolecular distance $\overline{HX}$, and we are left with the problem of determining the two-dimensional energy surface $\Delta E(R, \Theta)$ (Fig. 5 and 8).

The justification of this approximation, which is essential for the interpretation of the experimental data, will be discussed later when we study the associations of polar molecules.

An elegant combination of molecular beam techniques and microwave spectroscopy corresponding schematically to the experimental setup in Figure 7a was used by *Klemperer et al.*[2,26] in their investigations on the energy surface $\Delta E(R, \Theta)$ of Ar·HCl. The complex is formed by adiabatic expansion of a mixture of Ar and HCl vapor from a supersonic nozzle. Excess of noble gas hinders the formation of

Table 5. Some complexes of noble gas atoms (E) and hydrogen halide molecules (HX) [a].

| Noble gas atom E | Hydrogen halide HX | Ground state geometry $R_0$ [Å] | $\Theta_0$ [b] | Equilibrium geometries $R_e$ [Å], $\Theta=0°$ | $R_e$ [Å], $\Theta=180°$ | Energies of interaction [cal/mol] $\Delta E\,(\Theta=0°)$ | $\Delta E\,(\Theta=180°)$ | $\Delta(\Delta E)$ | Ref. |
|---|---|---|---|---|---|---|---|---|---|
| He | HF | | | (3.17) | (2.93) | (−151) | (−111) | (40) | [25] |
| Ne | HCl | (3.7–3.9) [c] | — | | | | | | [26] |

[a] Calculated or estimated values are given in parantheses. Isotopes: $^{1}H$, $^{40}Ar$, $^{82}Kr$, $^{132}Xe$, $^{19}F$, $^{35}Cl$, and $^{79}Br$. [b] The value of $\Theta_0$ corresponds to an average of $\cos^2\Theta$. [c] An estimate which is based on a comparison of interatomic distances in E·Ar and E·HCl für E = Ne, Ar, Kr und Xe.

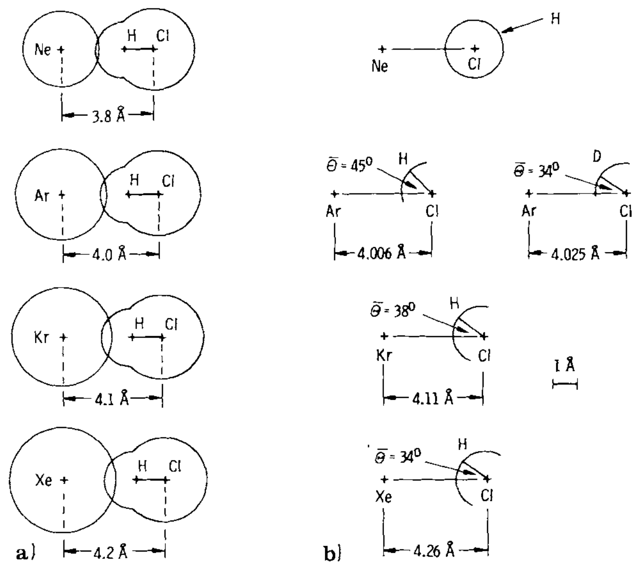

Fig. 8. a) Equilibrium- and b) ground-state geometries of some complexes of noble gas atoms and hydrogen halide molecules [26]. Note the extreme mobility of the hydrogen atom which leads to free rotational states of the HCl molecule in the complex Ne·HCl. The $\overline{\text{NeCl}}$ distance was estimated by an extrapolation from closely related systems (Table 5). In case of the best studied complex (Ar·HCl) we show the ground state geometries of two isotopic substitutions ($^{40}$ArH$^{35}$Cl and $^{40}$ArD$^{35}$Cl). Interestingly, the replacement of H by D leads to a substantial change in the geometry. In a) we have drawn spheres around the individual atomic nuclei which correspond to van der Waals radii ($R_H^w = 1.2$, $R_{Cl}^w = 1.8$, $R_{Ne}^w = 1.6$, $R_{Ar}^w = 1.9$, $R_{Kr}^w = 2.0$ Å and $R_{Xe}^w = 2.2$ Å). The values for H and Cl were taken from [68]. In the case of noble gas atoms we use one half of the atomic distance in the dimer (or in the crystal, see Table 10) as van der Waals-radius.

self-associations of hydrogen chloride, $(HCl)_n$. The constants of the rotational-vibrational spectrum of the four isotopic molecules Ar·H$^{35}$Cl, Ar·H$^{37}$Cl, Ar·D$^{35}$Cl and Ar·D$^{37}$Cl are determined. This information is sufficient to determine a substantial part of the energy surface, because the complex has a low frequency—large amplitude vibration. This normal mode corresponds to a deformation of the angle $\Theta$ at an almost constant interatomic distance $\overline{\text{ArCl}}(R)$. The large difference in the frequencies of the normal modes allows an approximation analogous to the Born-Oppenheimer approach, which separates the angular deformation—or hindered rotation of the HCl molecules within the complex—from the remaining vibrations[27].

The low frequency vibration with large amplitude mentioned above has an interesting consequence regarding the properties of the complex Ar·HCl: In contrast to most other molecules or molecular associations, equilibrium and zero-point geometries differ greatly. According to the energy surface the complex Ar·HCl has a linear equilibrium geometry ($\Theta = 0°$). The energy surface also shows a second local energy minimum at somewhat higher energy which corresponds to an arrangement Ar—Cl—H ($\Theta = 180°$). Qualitatively, these relative energies at $\Theta = 0°$ and $\Theta = 180°$ are in agreement with the data calculated on the system He·HF (Table 5). However, the second trough is extremely flat, and, accordingly, the evaluation of the experimental data is relatively uncertain. In both examples we find a somewhat larger distance between the two heavy atoms in the structure with the hydrogen atom between them. There is no doubt that the structure E·HX with $\Theta = 0°$ has the lower energy and, in other words, is more stable. We may interpret this result in terms of the stronger field effects at the H-end of the hydrogen halide compared to those at the X-end.

As a consequence of the zero-point contribution of this angular deformation vibration, the ground state of Ar·HCl appears to be bent when the geometry is determined by means of the nuclear quadrupole coupling constants of $^{35}$Cl or $^{37}$Cl. By this method the angle is obtained as an average of $\cos^2 \Theta$. The deviation from linearity ($\Theta = 41.5°$) demonstrates the mobility of the hydrogen atom in the vibrational ground state. Large vibrational amplitudes have the consequence that the mean geometries of the ground states depend strongly on the isotopic composition of the molecule (Fig. 8).

An analogous investigation was performed on the complex Kr·HCl[26]. The method used differs from that mentioned above, mainly by a pulse technique which is applied to the molecular beam ejected from the supersonic nozzle. This pulse technique is used to record the microwave spectrum by the Fourier method. The structure of Kr·HCl is closely related to that of Ar·HCl, only the amplitude of the angular deformation vibration is somewhat smaller (Fig. 8).

A molecular beam-microwave investigation of the complex Ne·HCl gave a remarkable result: The association is non-polar[26]. The lack of a permanent dipole moment in Ne·HCl has been interpreted in the following way: The HCl molecule bound to the Ne atom rotates essentially freely. In other words, the very flat potential curve observed for the angular deformation in the complexes Ar·HCl and Kr·HCl is still flatter in Ne·HCl. Consequently, there exists no vibrational state in the region around a certain value of $\Theta$, say $\Theta = 0°$. The hydrogen atom is delocalized on a sphere around the chlorine atom (Fig. 8).

The family of complexes, E·HCl, discussed above represents an illustrative example for demonstrating the usefulness of the partitioning of intermolecular energies according to eq. (5). We consider the angular dependence of the individual contributions at a constant or essentially constant intermolecular distance $R$ in order to provide an explanation for the different mobility of the HCl molecule in the three associations. $\Delta E_{\text{COU}}$ does not contribute at all, $\Delta E_{\text{RES}}$ is small, and $\Delta E_{\text{EX}}$ does not depend strongly on the angle $\Theta$. Accordingly, we restrict our estimation to the two contributions $\Delta E_{\text{POL}}$ and $\Delta E_{\text{DIS}}$. The semi-classical series expansion in $R^{-n}$ yields a first non-vanishing term with $n = 6$. We consider only this term which is assumed to be the largest:

$$\Delta E_{\text{POL}}(\text{E}\cdot\text{HX}) = -\frac{\alpha_E}{2R^6}\mu_{\text{HX}}^2(3\cos^2\Theta + 1) - \cdots \tag{8}$$

$$\Delta E_{\text{DIS}}(\text{E}\cdot\text{HX}) =$$

$$-\frac{\alpha_E}{4R^6}\cdot\frac{I_{\text{E}}\cdot I_{\text{HX}}}{I_{\text{E}}+I_{\text{HX}}}\{5\,\alpha_{\text{HX}}^{xx} + \alpha_{\text{HX}}^{zz} + 3\,(\alpha_{\text{HX}}^{zz} - \alpha_{\text{HX}}^{xx})\cos^2\Theta\} - \cdots \tag{9}$$

$I_{\text{E}}$ and $\alpha_{\text{E}}$ refer to the first ionization potential and the electric polarizability of the noble gas atom. $I_{\text{HX}}$, $\mu_{\text{HX}}$, $\alpha_{\text{HX}}^{zz}$ and $\alpha_{\text{HX}}^{xx}$ denote the first ionization potential, the electric dipole moment, and the electric polarizability parallel and perpendicular to the molecular axis of the HX molecule. Both contributions together yield the following angular dependence of the energy of interaction:

$$\Delta E_{\mathrm{POL}}+\Delta E_{\mathrm{DIS}} = -\frac{1}{R^6}\{A+B\cos^2\Theta\}-\cdots \qquad (10)$$

$$A=\frac{\alpha_{\mathrm{E}}}{2}\left\{\mu_{\mathrm{HX}}^2+\frac{1}{2}\cdot\frac{I_{\mathrm{E}}\cdot I_{\mathrm{HX}}}{I_{\mathrm{E}}+I_{\mathrm{HX}}}\left(5\,\alpha_{\mathrm{HX}}^{xx}+\alpha_{\mathrm{HX}}^{zz}\right)\right\}-\cdots$$

$$B=\frac{3}{2}\,\alpha_{\mathrm{E}}\left\{\mu_{\mathrm{HX}}^2+\frac{1}{2}\cdot\frac{I_{\mathrm{E}}\cdot I_{\mathrm{HX}}}{I_{\mathrm{E}}+I_{\mathrm{HX}}}\left(\alpha_{\mathrm{HX}}^{zz}-\alpha_{\mathrm{HX}}^{xx}\right)\right\}$$

A calculation of the numerical value of B for different noble gas atoms shows, that the first ionization potential $I_E$ has only little influence, and $B$ increases essentially with the polarizability $\alpha_E$ (Table 6). Consequently, $B$ makes an appreciable jump between Ne and Ar. This increase by a factor of four is not compensated by the somewhat larger intermolecular distance in Ar·HCl compared to in Ne·HCl and we expect a higher barrier for the rotation of the HCl molecule in the complex Ar·HCl, in qualitative agreement with the experimental results.

Table 6. A crude estimate of relative rotational barriers in complexes of noble gas atoms and hydrogen chloride according to eq. (10).

| E | Nobel gas atom | | Relative rotational barrier for E·HCl | |
|---|---|---|---|---|
| | $I_E$ [eV] | $\alpha_E$ [$10^{-25}$ cm$^3$] | $B_E/B_{Ar}$ | $\frac{B_E}{B_{Ar}}\left(\frac{R_{Ar}\cdot Cl}{R_E\cdot Cl}\right)^6$ |
| He | 24.6 | 2.2 | 0.14 | – |
| Ne | 21.6 | 4.0 | 0.25 | 0.3–0.4 [a] |
| Ar | 15.8 | 16.3 | 1 | 1 |
| Kr | 14.0 | 24.8 | 1.51 | 1.3 |
| Xe | 12.1 | 40.1 | 2.42 | 1.7 |

[a] Estimate based on the value of $R_{NeCl}$ taken from Table 5.

Investigation on complexes of two polar molecules turned out to be much more sophisticated than those discussed to far. This is true for theoretical studies because of the inevitably larger number of atoms in associations of polar molecules as well as for experimental investigations. We shall concentrate our interests on the complexes $(HF)_2$, $(H_2O)_2$ and $H_2O \cdot HF$ as well as on structures of the type $R_2O \cdot HF$. Apart from accurate *ab initio* calculations we have essentially four experimental techniques at our disposal for studies on polar aggregates:

1) Molecular beam electric resonance spectroscopy,
2) direct microwave spectroscopy,
3) IR-spectroscopy, and
4) $p, V, T$ measurements.

The combination of molecular beam techniques and microwave spectroscopy[28] led to the most reliable and most accurate results on the structure of the homodimers $(HF)_2$ and $(H_2O)_2$ (Fig. 9). Sufficiently large concentrations of dimers are again obtained by adiabatic expansion of HF or $H_2O$ molecular beams from supersonic nozzles. It has been shown by mass spectroscopic techniques that the dimer is the only polar oligomer in the case of hydrogen fluoride.

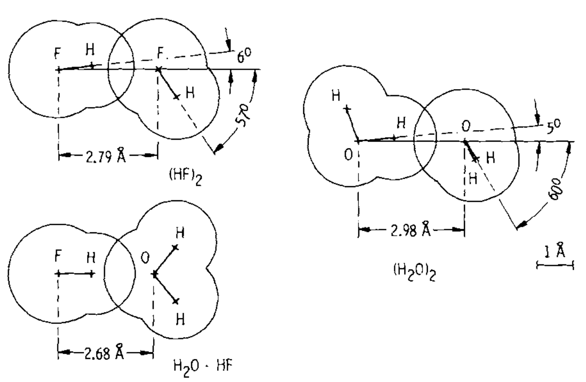

Fig. 9. Equilibrium geometries of the complexes $(HF)_2$, $H_2O \cdot HF$ and $(H_2O)_2$. The spheres around the atomic nuclei correspond to van der Waals-radii ($R_H^w = 1.2$, $R_O^w = 1.4$, and $R_F^w = 1.35$ Å). Because of the strong electrostatic dipole-dipole force the two molecules are pressed upon each other more strongly than in the case of pure dispersion forces. This shortening of the intermolecular distance is characteristic of complexes with hydrogen bonds.

All the other higher aggregates (see Section 4) apparently have cyclic structures and are non-polar. The same is true for higher aggregates of $H_2O$. The molecular beam is analyzed in an "electron resonance"-spectrometer[29] in the radio and microwave range of frequencies. Thereby one gains information on transitions between rotational levels and eventually between the energy levels of low frequency vibrations. The evaluation of the moments of inertia of as many isotopic complexes as possible provides information on the structures of the aggregates. The Stark effect in the rotational spectrum may be used to determine electric dipole moments of complexes. Despite this multitude of data the molecular structure of the simplest association of polar molecules, mainly that of $(HF)_2$, can be reconstructed only with simplifying assumptions. Generally, one uses the "frozen geometry" approximation.

Hydrogen fluoride dimer was found to be a very mobile aggregate: the complex is bent and the two protons switch

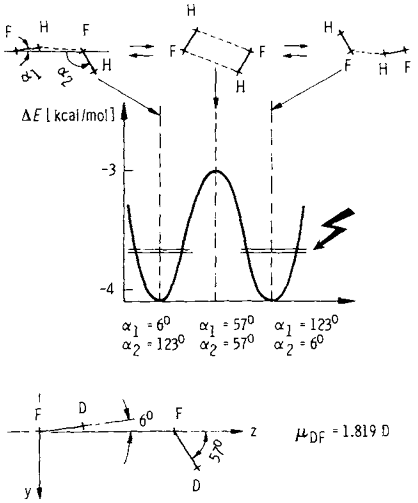

Fig. 10. Tunneling motion of the two protons in hydrogen fluoride dimer (arrow: cleavage by tunneling effect) and the superposition of the electric moments of the two monomers. Extensive calculations [29] have shown that the cyclic structure of the dimer corresponds to a saddle point of the energy surface.

Superposition: $\mu_z = 2.80$ D; $\mu_y = 1.34$ D
Experiment [28]: $\mu_z \sim \mu_a = 2.987$ D; $\mu_y \sim \mu_\perp = 1.6$ D

back and forth between two equivalent positions by a tunneling mechanism (Fig. 10). From the splitting of the rotational levels one calculates an energy barrier of 1.4 kcal/mol. The distance between the two heavy atoms ($R_{FF} = 2.79 \pm 0.05$ Å) can be determined with a high degree of accuracy. From the Stark coefficients of the rotational transitions we obtain the components of the dipole moment along the direction of the main axis of inertia (Fig. 10; note that it almost coincides with the $\overline{FF}$ bonding direction) and perpendicular to it. These two components confirm that the complex is, on average, bent. Moreover the dipole moment is larger than it would be in the case of a simple vectorial superposition of dipoles of two free HF molecules in the same geometry (Fig. 10).

Because of its relative smallness the system $(HF)_2$ has also been studied by theoretical methods for some time[30]. Long before the experimental determination of the equilibrium geometry, calculations predicted essentially the correct results. Later on, the theoretical studies were refined more and more and now complete the experimental data in some important details. The accuracy of the "frozen geometry" approximation, an indispensable constituent of the model for the evaluation of the experimental data, can be tested directly by means of accurately calculated equilibrium geometries (Fig. 9): Actually the bond distances in both HF molecules increase on complex formation. The changes, however, are very small and amount to a few thousandths of an Ångstrøm only. The hydrogen bond is not entirely linear: the central proton lies slightly displaced from the $\overline{FF}$ connecting line. The increase in dipole moment reflecting changes in electron density distributions on complex formation is a consequence of the mutual polarization of both molecules in the association.

In the case of the water dimer, $(H_2O)_2$, we encounter a completely analogous situation, although the theoretical calculations and the evaluation of the experimental data are much more difficult because of the greater number of atoms. Experiment and accurate *ab initio* calculations confirm and complement each other[28,31]. At the equilibrium geometry the dimer is not planar but has a plane of symmetry (Fig. 9). The hydrogen bond OH...O is not completely linear. The electric dipole moment increases substantially on complex formation. This increase in polarity in the two subsystems can be explained easily by means of the calculated differences in electron density distribution which are shown graphically in Figure 4.

Harmonic force constants were calculated for both dimers, and from these the vibrational spectra were predicted[30,31]. The calculations reproduce very well the shifts towards lower frequencies observed with the experimental HF and HO bond stretching vibrations[32]. Obviously, the *ab initio* calculations of vibrational spectra still suffer from some deficiencies. As we shall see in the next example, a profound interpretation of the experimental data requires also explicit consideration of the harmonic coupling force constant between HX bond stretching and intermolecular motion as well as the anharmonic correction to the HX stretching mode. Both constants were not taken into account in the calculations mentioned above.

Table 7. Energies and enthalpies of interaction in the dimers of hydrogen fluoride and water.

| Dimer | Energy of interaction [kcal/mol] | | $-D_0 = \Delta H_0^0$ [a] [kcal/mol] | $\Delta H_{298}^0$ [a] [kcal/mol] | Ref. |
|---|---|---|---|---|---|
| | $\Delta E_{SCF}$ | $\Delta E$ | | | |
| $(H_2O)_2$ | $-4.55$ | $-5.63$ | $-3.21$ | $-3.64$ | [31, 33] |
| | $-3.87$ | $-4.75$ | $-2.45$ | $-2.88$ | [b] |
| | | $-5.76$ | $-3.31$ | $-3.65$ | [c] |
| $(HF)_2$ | $-3.8$ | $-4.1$ | $-2.1$ | $-2.9$ | [29, 33] |

[a] $\Delta H_T^0$ is the enthalpy of dimerization at $T$ K under standard conditions. [b] Estimation based on the presently most accurate *ab initio* calculation. The Hartree-Fock energy was taken from [57], the value of the correlation energy from [31]. The total energy of interaction appears to be somewhat too small in absolute value. The same is true for the most accurate calculations on $(HF)_2$. Both calculations are of similar quality. [c] Empirical potential from [58] together with the vibrational corrections from [33].

The dissociation energy of vapor-phase dimers is of particular importance. Unfortunately, this quantity is neither easy to calculate[4d,33] nor accessible by direct experimental measurements. The difficulty with *ab initio* calculations lies in the sensitivity of the energy difference to the choice of the basis set and to electron correlation effects (Table 7). The binding energy of $(H_2O)_2$ has been evaluated from the second virial coefficient $B_2(T)$[34]. Theory and experiment converge at a value of $D_0[(H_2O)_2] = 3$–$4$ kcal/mol.

Heterodimers from polar molecules have been neglected for a long time since it was generally accepted that they are extremely difficult to study in the vapor phase. With the exception of some calculations, publications on such complexes hardly appeared in the literature until the mid-sixties. Searching for a simple hydrogen bonded system in the vapor phase *Millen et al.*[35] discovered, about 15 years ago, that the association constant in the system $(CH_3)_2O + HCl$ is large enough to allow direct recording of the infrared spectrum of the association $(CH_3)_2O \cdot HCl$ in the vapor phase. Meanwhile, these investigations have been extended to many other systems of the type $R^1R^2O \cdot HX$ and to other spectroscopic techniques — microwave and Raman spectroscopy as well as investigations in the far and near infrared[36]. For the sake of simplicity we shall consider here the systems $H_2O \cdot HF$ and $(CH_3)O \cdot HF$.

The complex $H_2O \cdot HF$ is best studied as far as theoretical calculations and experimental measurements are concerned. The microwave spectrum can be recorded directly in the vapor phase since the association constant is large enough. We therefore know the structure and the dipole moment of this complex very well (Fig. 9). The aggregate $H_2O \cdot HF$ is either planar ($C_{2v}$-symmetry) or it vibrates between two equivalent equilibrium geometries which are separated by an extremely small barrier only. In other words we have either a single minimum potential or a very flat double minimum potential for the corresponding bending vibration. The dipole moment of the complex ($\mu_a = 3.82 \pm 0.02$ D) is larger than the sum of the dipole moments of the two free molecules ($\mu_{HF} + \mu_{H_2O} = 3.68$ D). Thus, we find an increase in the dipole moment of $\Delta\mu_{H_2O \cdot HF} = 0.14$ D for the planar equilibrium geometry. In the case of a vibrating system with a planar average structure $\Delta\mu$ would be even larger. Because of the simple geometry of the association $H_2O \cdot HF$ we have here a direct experimental proof for the increase in polarity as a consequence of mutual polarization of the two subsystems in the complex.

The energy surface of $H_2O\cdot HF$ has also been the subject of extensive *ab initio* calculations[37]. An essentially correct equilibrium geometry was already predicted in the first theoretical investigation on this system. Recent, very extensive studies favor a double minimum potential with an extremely low barrier for the bending mode. There is no doubt that the complex is extremely flexible with respect to the out-of-plane bending vibration (Fig. 9).

Further details on the energy surfaces of $H_2O\cdot HF$ and $(CH_3)_2O\cdot HF$ can be derived from infrared spectra in the vapor phase. The associations with isotopes H and D have been studied in great detail. In the case of $(CH_3)_2O\cdot HF$ and $(CH_3)_2O\cdot DF$ the first overtones were recorded as well. An analysis of the observed frequencies and intensities clearly shows that a satisfactory description of the vibrational spectrum of the complex is possible only if the anharmonicity of the HF bond stretching vibration and the harmonic force constant for the coupling between HF and OF vibration are considered explicitly. Unfortunately, however, just these terms have so far been neglected in most *ab initio* calculations of vibrational spectra of associations with hydrogen bonds. An exception is a very recent study on $H_2O\cdot HF$ and $(CH_3)_2O\cdot HF$[37c] in which the force constants mentioned were calculated from the energy surface as well. This calculation still requires some refinement before definitive conclusion of the vibrational frequencies can be drawn. The authors of this latter mentioned publication, ***Bouteiller, Allavena*** and ***Leclercq,*** found that the higher force constants cannot be predicted with sufficient accuracy unless *all* degrees of freedom of the complex are subject to variation. Such a complete study of the energy surface, however, requires an enormous computational effort and has not yet been performed.

Accurate calculations and a careful analysis of the vibrational spectra agree very well with respect to equilibrium dissociation energies of the complex $H_2O\cdot HF$. *Thomas*[36] obtained a value of $D_e = 7.1$ kcal/mol. This corresponds to a zero-point dissociation energy of $D_0 = 6.2$ kcal/mol.

Considering the partitioning of intermolecular energies for some characteristic examples of associations of polar molecules (Table 3) we observe primarily a dominance of the electrostatic contribution. Indeed, the orientation of the molecules in the equilibrium geometries of the complexes is essentially determined by the angular dependence of the electrostatic energy. Electron density distributions in molecules in general have low symmetry and, hence, the angular dependence is a much more sophisticated function than the pure interaction of two point dipoles.

### 3.2. Ion-Molecule Complexes

*Ab initio* calculations do not fundamentally differentiate between molecule-molecule and ion-molecule associations, even though the dissociation energies of the complexes may differ by more than an order of magnitude. Equilibrium geometries and energy surfaces are obtained with about the same accuracy in both cases.

Naturally, the low volatility of ions makes the experimental investigation of ion-molecule associations an extraordinarily difficult problem. Since the sixties a new experimental technique, "high pressure-mass spectroscopy"[3], has become a generally accepted method. This technique provides direct access to the equilibrium constants of associations between ions and molecules. Reaction enthalpies and entropies are calculated in the conventional way from the temperature dependence of the equilibrium constants.

The ions, *e.g.* the cations $A^+$, react in the reaction chamber with molecules B and form ion-molecule aggregates $A^+B_n$. Collision partners M remove excess translational energy:

$$\begin{aligned}
&A^+ + B + M && \xrightleftharpoons{K_{0,1}} A^+B + M \\
&A^+B + B + M && \xrightleftharpoons{K_{1,2}} A^+B_2 + M \\
& && \quad\vdots \\
&A^+B_{n-1} + B + M && \xrightleftharpoons{K_{n-1,n}} A^+B_n + M
\end{aligned} \tag{11}$$

As a rule, equilibrium is already established after a fraction of a millisecond. The equilibrium constants are then calculated according to

$$K_{n-1,n} = \frac{[A^+B_n]}{[A^+B_{n-1}][B]} = \frac{I_n}{I_{n-1}[B]} \tag{12}$$

from the relative "peak intensities" of the ions $A^+B_n$ and $A^+B_{n-1}$, $I_n$ and $I_{n-1}$, as well as from the pressure of the monomer [B]. In the actual measurements, pressures up to

Table 8. Calculated and experimental (high pressure mass spectroscopy) enthalpies and entropies for the vapor phase hydration of some small ions [3, 38]. $\Delta H$ in kcal/mol, $\Delta S$ in cal $K^{-1}$ $mol^{-1}$.

| Ion | Number of water molecules $n-1$, $n$ | Calculated results | | | Exp. results | |
|---|---|---|---|---|---|---|

| | 1, 2 | | | | −16.6 | −18.7 |
| | 2, 3 | | | | −13.7 | −20.4 |
| | 3, 4 | | | | −13.5 | −36.9 |
| | 4, 5 | | | | −13.2 | −30.7 |
| $Cl^-$ | 0, 1 | −12.4 | −10.8 | −11.4 | −13.1 | −16.5 |
| | 1, 2 | | | | −12.7 | −20.8 |
| | 2, 3 | | | | −11.7 | −23.2 |
| | 3, 4 | | | | −11.1 | −25.8 |

a few mbar are commonly employed. The results for the "step by step" hydration of small ions are summarized in Table 8.

Accurate *ab initio* calculations on 1:1 complexes[38] reproduce the experimental enthalpies of the complex formation with remarkable precision (Table 8). For accurate comparisons the differences in zero-point energies and the temperature dependent contribution to $\Delta H$ have to be taken into account explicitly.

In contrast to the comprehensive thermodynamic data on ion-molecule complexes almost no experimental information on equilibrium geometries is available. Hence, in this context, we have to rely on *ab initio* calculations[38]. The results of the most accurate investigations performed so far on some simple hydrated ions are summarized in Figure 11. Associations of metal cations and water have planar equilibrium geometries with $C_{2v}$-symmetry. A deformation of the water molecule in the complex becomes recognizable only with cations which carry charges greater than +1. Associations between water molecules and halide ions are characterized by more complicated equilibrium geometries: $F^- \cdot H_2O$ has a hydrogen bond like structure with an almost linear arrangement of the atoms F, H and O. In the equilibrium geometry of $Cl^- \cdot H_2O$ the deviation from a linear arrangement of the three atoms Cl, H and O is much larger. More remarkable, however, is the fact that the potential curve for a partial rotation of the water molecule in the complex (Fig. 11) is surprisingly flat. We may conclude, therefore, that the water molecule in $Cl^- \cdot H_2O$ is highly mobile, like the hydrogen chloride molecule in the complex $Ar \cdot HCl$. The ions $H_5O_2^+$ and $H_3O_2^-$ are characterized by very flat potential curves for the motion of the central proton along the connection line $\overline{OO}$. This unusual mobility of the proton in these systems is responsible for a variety of properties in solution[39]. The two latter mentioned examples are cases in which the "frozen-geometry" approximation is no longer applicable. It would seem more appropriate therefore to consider the ions $H_5O_2^+$ and $H_3O_2^-$ as unique "chemical individuals" having a "four-electron three-center" bond which has close similarity to that in polyhalide ions like $I_3^-$.

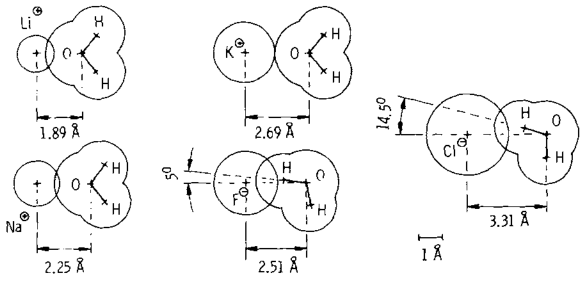

Fig. 11. Equilibrium geometries of the monohydrates of some monovalent ions [38]. The spheres around the atomic nuclei correspond to van der Waals-radii [68] ($R_H^w = 1.2$, $R_O^w = 1.4$ Å) as well as to ionic radii [69] ($R_{Li^+}^i = 0.78$, $R_{Na^+}^i = 0.95$, $R_{K^+}^i = 1.33$, $R_{F^-}^i = 1.36$ and $R_{Cl^-}^i = 1.81$ Å). In the case of anion-water complexes strong mutual penetration of the van der Waals spheres is observed as a consequence of hydrogen bond formation.

Energy partitioning in ion-molecule complexes (Table 3) shows the expected dominance of the electrostatic contribution. In comparison to the associations of polar molecules we find that $\Delta E_{COU}$ is roughly larger by one order of magnitude in the charged aggregates. The differences in intermolecular energies are essentially determined by this difference in the electrostatic contribution. The polarization of the electron density distribution in the molecules is much greater as a consequence of the strong field of the ions. Consequently, the polarization energy, $\Delta E_{POL}$, is larger in absolute value than in the case of molecule-molecule complexes. Electron density difference functions (Fig. 4) reveal the polarization of the water molecule in the field of the ions very well.

If we are able to define an appropriate surface boundary between the subsystems it is possible to calculate a charge transfer in the complex directly from the electron density distribution. For all systems discussed here except $H_5O_2^+$ and $H_3O_2^-$ this charge transfer is very small: The shifts are of the order of 0.001 $e_0$ to 0.01 $e_0$[4b].

## 4. Higher Aggregates in the Vapor Phase

A profound knowledge of the properties of higher aggregates—*i.e.* associations of more than two atoms, molecules or ions—is of particular importance for a better understanding of interactions in condensed phases. Recalling the problems we encountered in the preceding section we realize that investigations on higher aggregates are by no means easy to perform. Because of the large numbers of degrees of freedom and the inevitable size of the entire system, *ab initio* calculations are extremely time consuming. Accurate calculations can be performed only for small parts of the energy surface. Experimental investigations are in no way less involved: In general, it is very difficult to obtain defined higher aggregates in concentrations high enough for experimental studies. Should this however be the case it is nevertheless by no means granted that a few spectroscopic data are sufficient to provide conclusive information on the structure of something as complicated as an oligomer of molecules. Exceptions are provided only by molecular beam experiments and high pressure mass spectroscopic studies. Additional, although indirect, information on the energies of aggregate formation is available from an analysis of higher virial coefficients. At first we might mention some experimental results, primarily on polar systems, and consider the theoretical aspects later on.

Studies on clusters of noble gas atoms are comparatively simple because of the structural simplicity of these aggregates. We mention here two characteristic investigations[40] in which small and medium size clusters of Ar atoms were produced by escapement of a molecular beam from a supersonic nozzle. The structure of the cluster has been studied by electron diffraction. Despite these data, information on the structures of higher aggregates of noble gas atoms is rather fragmentary.

Aggregates of polar molecules have been studied experimentally by the "molecular beam electric resonance" technique[41]. The conditions were so chosen that higher aggregates were formed on expansion of the beam from the supersonic nozzle. The molecular weight of the clusters is determined in the mass spectrometer. The most important conclusion that can be drawn from these studies is of a negative nature: most higher aggregates cannot be focussed in the "electric-resonance" spectrometer and hence are nonpolar. In other words the clusters are characterized by a structure in which the electric moment vanishes because of symmetry reasons. Most probably the individual molecules are arranged cyclically in the aggregates (Fig. 12). Some years ago cyclic higher aggregates were postulated to explain the properties of hydrogen fluoride in the vapor phase: *Janzen* and *Bartell*[42b] proved the existence of cyclic hexamers $(HF)_6$ by means of an elegant combination of molecular beam electron diffraction techniques. These oligomers are very flexible, as can be seen from the large vibrational amplitudes. The thermodynamics of higher ion-molecule aggregates can be studied very well by high-pressure mass spectroscopy[3] (see Section 3.2).

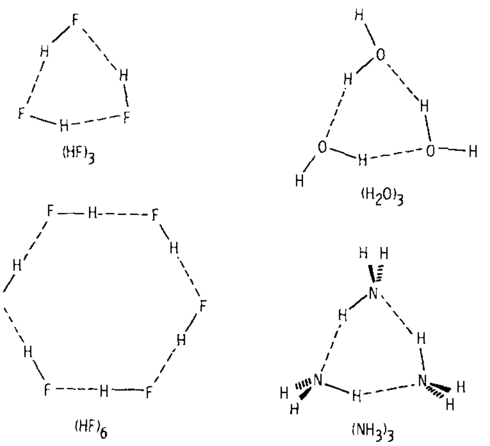

Fig. 12. Cyclic HF, $H_2O$ and $NH_3$ oligomers with hydrogen bonds.

*Ab initio* calculations have been performed on higher aggregates of polar molecules as well. In particular, the trimers of HF, $H_2O$ and $NH_3$ have been studied extensively[43]. Because of the size of these systems the accuracy of these calculations has to be evaluated critically. There is uncertainty concerning relative stabilities of open chain and cyclic oligomers. In contrast to some calculations on $(H_2O)_3$ with rather small basis sets extensive *ab initio* calculations led to the result that the sequential open chain trimer (Fig. 12) is more stable than the cyclic conformation of the complex. The most accurate studies performed so far, however, yield a lower energy for the cyclic trimer of water. There is no doubt, that theoretical investigations have not, as yet, reached the accuracy which would allow definite conclusions to be drawn regarding this question. It is hoped that future studies will clarify the influence of further basis set extension and electron correlation effects on the results of such calculations. Despite all uncertainties of the experimental data, it seems well established that trimeric water has no permanent electric dipole. This fact is most easily accounted for by a cyclic equilibrium geometry. In the case of $(NH_3)_3$ a cyclic equilibrium geometry was found in a calculation using a fairly large basis set.

*Ab initio* calculations on aggregates of $Li^+$, $Na^+$, $K^+$, $F^-$ and $Cl^-$ with water molecules[38] show good agreement with the corresponding hydration enthalpies determined by high-pressure mass spectroscopy (Table 8). In the case of the higher associations a systematic error is observed: with increasing number of water molecules, $n$, we find too large a stabilization energy. The origin of this error is to be seen in increasing contributions of the artificial basis set superposition stabilization of higher associations (see Section 2).

To obtain a better understanding of the forces acting in the molecular clusters we consider the partitioning of intermolecular energies. For the formation of an aggregate of the three subsystems A, B and C

$$A + B + C \rightleftharpoons ABC \qquad (13)$$

we find

$$\Delta E = E_{ABC} - (E_A^0 + E_B^0 + E_C^0) = \Delta E_{AB} + \Delta E_{BC} + \Delta E_{CA} + \Delta E_{ABC} \qquad (14)$$

Apart from binary interactions or pair potentials $\Delta E_{AB}$, $\Delta E_{BC}$ and $\Delta E_{CA}$ there is also the contribution of three-body forces, $\Delta E_{ABC}$. In higher clusters there are four-body, five-body and, in general, many-body interactions which are defined analogously.

Similarly, as in the case of interactions between two subsystems three-body forces can also be analyzed by means of energy partitioning[44].

$$\Delta E_{ABC} = \Delta E_{ABC}^{COU} + \Delta E_{ABC}^{POL} + \Delta E_{ABC}^{DIS} + \Delta E_{ABC}^{EX} + \Delta E_{ABC}^{RES} \qquad (15)$$

Using the definitions given in Section 2 we find that the electrostatic contributions of three- and many-body forces are zero:

$$\Delta E_{ABC}^{COU} = 0, \quad \Delta E_{ABCD}^{COU} = 0, \ldots \qquad (16)$$

In clusters of noble gas atoms there are two contributions to the "non-additivity" of intermolecular potentials, which originate from exchange and dispersion energy. By non-additivity we characterize that total contribution to the energy of interaction which comes from three-body and higher many-body forces. In the case of the trimers of the light noble gas atoms, $He_3$ and $Ne_3$, the exchange contribution $\Delta E_{ABC}^{EX}$ is obtained, as mentioned previously, within the Hartree-Fock approximation. It is of particular importance at small interatomic distances. The non-additivity of the long-range contribution, the dispersion energy, can be estimated by means of the approximation introduced by *Axilrod* and *Teller*[46]:

$$\Delta E_{ABC}^{DIS} \approx \frac{3}{2} \frac{(I_A + I_B + I_C)\, I_A\, I_B\, I_C}{(I_A + I_B)(I_B + I_C)(I_C + I_A)} \alpha_A \alpha_B \alpha_C \frac{3 \cos\alpha \cos\beta \cos\gamma + 1}{R_{AB}^3 R_{BC}^3 R_{CA}^3} \qquad (17)$$

$I_A$, $I_B$ and $I_C$ are the first ionization potentials, and $\alpha_A$, $\alpha_B$ $\alpha_C$ are the electric polarizabilities of the subsystems concerned. The definition of the angles $\alpha$, $\beta$ and $\gamma$ is shown in Figure 13. Both contributions, $\Delta E_{ABC}^{EX}$ and $\Delta E_{ABC}^{DIS}$, show a

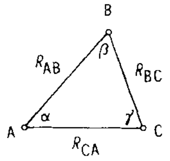

Fig. 13. Diagram for calculation of the non-additive contribution to the dispersion energy according to *Axilrod* and *Teller* [46].

pronounced dependence on the geometrical arrangement of the three atoms A, B and C: The long-range three-body dispersion forces are attractive in the linear arrangement ($\beta = 180°$, $\alpha = \gamma = 0°$) and repulsive in an equilateral triangle geometry ($\alpha = \beta = \gamma = 60°$). The three-body exchange forces which dominate at short distances have opposite sign: they lead to an attractive, *i. e.* negative contribution to the total energy in an equilateral triangle geometry and destabilize linear arrangements of the three atoms. In the neighborhood of the equilibrium geometries we find very small contributions of three-body forces to the energies of noble gas trimers.

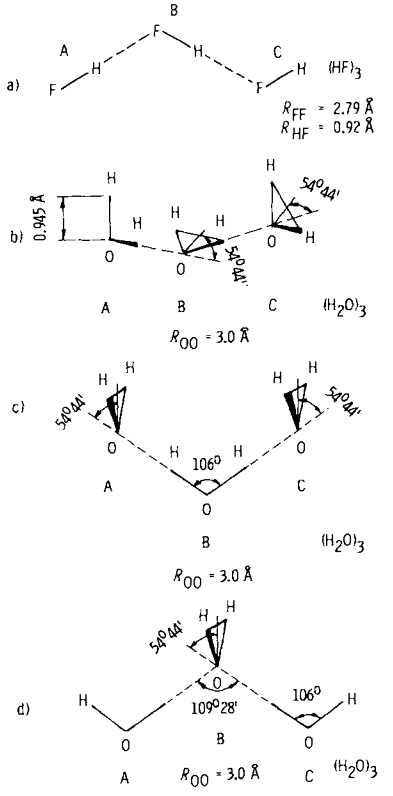

Fig. 14. Non-additivity of the energy of interaction in the trimers of hydrogen fluoride and water.

a) $(HF)_3$, sequential trimer:

$\Delta E^{EX}_{ABC} = -0.07$ kcal/mol
$\Delta E^{POL}_{ABC} = -0.42$ kcal/mol
$\Delta E^{RES}_{ABC} = -0.10$ kcal/mol

---

$\Delta E^{SCF}_{ABC} = -0.58$ kcal/mol
$\Delta E^{DIS}_{ABC} \approx 2 \times 10^{-3}$ kcal/mol
$\Delta E_{ABC} \approx \Delta E^{SCF}_{ABC} = -0.58$ kcal/mol

b) $(H_2O)_3$, sequential trimer

$\Delta E^{DIS}_{ABC} \approx 5 \times 10^{-3}$ kcal/mol
$\Delta E_{ABC} \approx \Delta E^{SCF}_{ABC} = -0.57$ kcal/mol

c) $(H_2O)_3$, double donor-trimer:

$\Delta E_{ABC} \approx \Delta E^{SCF}_{ABC} = 0.60$ kcal/mol

d) $(H_2O)_3$, double acceptor-trimer:

$\Delta E_{ABC} \approx \Delta E^{SCF}_{ABC} = 0.37$ kcal/mol

Energy partitioning in $(HF)_3$ shows that the non-additivity of the polarization energy is the largest contribution. The non-additive contributions of dispersion calculated by means of eq. (17) are very small compared to the non-additivity of polarization [43].

There are no electrostatic contributions to the three- and higher many-body forces. Hence we expect to find only one important contribution in addition to exchange and dispersion three-body energies in aggregates of polar molecules: This is the non-additivity of the polarization energy. The polarization term is already the largest contribution to the three-body energies in clusters of polar molecules like $(HF)_n$ or $(H_2O)_n$. In higher aggregates of ions and molecules the three-body polarization energy is the dominant contribution, compared to which the other terms are negligible. Several characteristic examples are summarized in Figure 14. The three-body dispersion energies were estimated by means of the Axilrod-Teller equation.

Qualitative hints on the nature of the non-additivity of polarization energies are easy to find. Let us consider the "sequential" trimer of hydrogen fluoride as a characteristic example (Fig. 15a). The electron density distribution in the central HF molecule is shifted in the direction C→A by the action of the electrostatic fields of its neighbors. As we already know from the shift in the electron density distribution in various dimeric aggregates, the hydrogen atom becomes more acidic and the basicity of the lone pair increases at the same time. Both interactions, AB and BC, are thus strengthened by the charge shift. We find a negative, *i. e.* a stabilizing contribution of the three-body polarization energy to the total energy of interaction. In general, sequential arrangements of polar molecules—*i. e.* those in which electric moments point approximately in the same direction—are favored (Fig. 14). In the case of the three possible open chain associations of three water molecules the "sequential" trimer is more stable than the "double do-

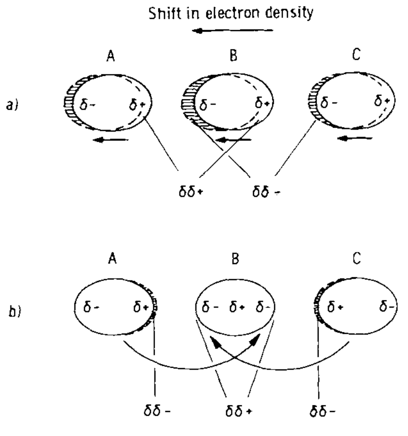

Fig. 15. Qualitative interpretation of the non-additivity of polarization energies in polar systems. The shift in electron densities in the potential field of the neighboring molecules leads a) to an increase or b) decrease of intermolecular forces. This qualitative picture largely corresponds to the concept of inductive forces used in physical organic chemistry which, *inter alia*, has been extended to general intermolecular interaction by *Gutmann* [70].

Table 9. Contributions to the non-additivity of energies of interaction in ion-molecule clusters [59]. Energies in kcal/mol [a].

| Cluster | $\Delta E$ | $\Delta E_{AB}+\Delta E_{BC}+\Delta E_{CA}$ | $\Delta E_{ABC}$ | $\Delta E^{EX}_{ABC}$ | $\Delta E^{POL}_{ABC}$ | $\Delta E^{RES}_{ABC}$ |
|---|---|---|---|---|---|---|
| $H_2O\cdot Li^+\cdot OH_2$ | −64.05 | −66.47 | 2.42 | −1.04 | 3.79 | −0.33 |
| $Li^+\cdot\overset{H_2}{O}\cdot OH_2$ | −46.40 | −43.84 | −2.55 | −0.28 | −2.61 | 0.33 |
| $Li^+\cdot\overset{H_2}{O}\cdot HOH$ | −24.08 | −25.61 | 1.54 | −0.23 | 2.33 | −0.56 |
| $HOH\cdot F^-\cdot HOH$ | −43.00 | −45.40 | 2.40 | −0.94 | 2.25 | 1.10 |
| $F^-\cdot\overset{H}{HO}\cdot\overset{H}{HO}$ | −32.94 | −30.39 | −2.54 | −0.04 | −2.24 | −0.27 |
| $F^-\cdot HOH\cdot OH_2$ | −20.91 | −23.03 | 2.12 | 0.13 | 1.62 | 0.38 |

[a] The numerical values are taken from Hartree-Fock calculations with large basis sets [59]. The non-additive contribution of the dispersion energy has been calculated by means of the formula by *Axilrod* and *Teller* [eq. (17)]. This contribution is negligibly small [43, 54].

nor" or the "double acceptor" arrangement. Cyclic oligomers are always of the sequential type. Moreover, they have one bond more than their open chain conformers. These various polarization effects can be evaluated quantitatively by means of the three-body forces discussed above.

Ion-molecule aggregates can be studied completely analogously (Table 9). Again the non-additivity of the polarization energy may be considered as the cause for weaker ion-ligand binding in the 1 : 2 complex. The ion-ligand bond energy per molecule is smaller in absolute value for the 1 : 2 aggregate compared to the energy for the 1 : 1 complex. Molecules in the second hydration shell are bound more strongly if the arrangement of the electrostatic field is sequential. This is clear to see in the two examples $Li^+\cdot(OH_2)_2$ and $F^-\cdot(H_2O)_2$. We do not intend to exaggregate here the importance of the polarization effect discussed. Other contributions play their role as well. Nevertheless, it should be pointed out that the sign and the geometrical dependence of non-additivities in complexes of the type discussed here can be predicted easily and correctly by the simple arguments presented above. Apart from a few exceptional cases three- and higher many-body forces contribute comparatively little to the total interaction. It would seem therefore that a quantitative correction to the sum of binary energies by means of semiclassical model calculations of the non-additivity of polarization is promising.

An important, though not completely solved problem concerns the role of higher contributions, namely those of four-body forces. In clusters of noble gas atoms, in characteristic intermolecular associations of polar molecules or simple ions and molecules the contributions of four-body energies are certainly very small. An entirely different situation is encountered in aggregates of atoms with partially filled electron shells ($1s^2\ldots ns^2$) like Be or Mg which form metals in the condensed phase. In these systems the three-body contributions are large and non-negligible four-body energies can be expected[47].

## 5. A World of Additive Binary Potentials and the Role of Three- and Many-body Forces

In the introduction to the preceding section we stressed the fact that a precise experimental analysis of three- and many-body forces in the vapor phase is very difficult if not impossible, as yet. Information on three-body energies obtained from higher virial coefficients is uncertain and very debatable. We shall now try to derive positive indications of the importance of these contributions from the molecular structures in condensed phases. Let us first imagine a world without three- and many-body forces, and begin with non-polar systems. The pair potential is of the Lennard-Jones type[19]:

$$\Delta E_{AB}=D_e\left\{\left(\frac{R_e}{R}\right)^{12}-2\left(\frac{R_e}{R}\right)^{6}\right\} \qquad (18)$$

$D_e$ is the depth of the trough in the potential curve and $R_e$ is the equilibrium distance. In the case of pairwise additivity of the potential the equilibrium distance is the same in the dimer, the trimer and the tetramer. The equilibrium geometry of the trimer is an equilateral triangle, that of the tetramer a tetrahedron. In the crystal we expect to find a hexagonal closed packed (hcp) arrangement of atoms. The equilibrium distance in the solid state will be shorter than that in the vapor phase dimer. The difference between both, however, should be negligibly small (Fig. 16).

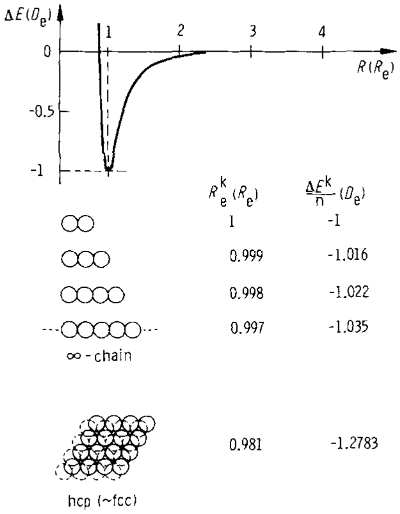

Fig. 16. Additivity of intermolecular energies in unpolar systems. The estimate presented is based on a pair potential of Lennard-Jones type: $\Delta E(R)=A\,R^{-12}-B\,R^{-6}$ [see eq. (18)]. Other potential functions for the interaction of unpolar systems lead to identical conclusions. As examples for the condensed phase we consider an infinite chain as well as a face centered cubic (fcc) or a hexagonal closed packed (hcp) lattice [71]. For the purpose of comparison we calculate the dimensionless quantities $R^k_e/R_e$ and $\Delta E^k/n\,D_e$. The superscript "k" denotes a certain cluster. $R_e$ and $D_e$ are the constants of the Lennard-Jones potential and correspond to the dimer in the vapor phase. The energy of cluster formation, $\Delta E^k$, is divided by the number of bonds to nearest neighbors ($n$). The atomic distance in the solid state appears to be only insignificantly smaller than in the vapor phase. The energy of interaction is increased by a few percent due to the presence of further atoms in the crystal.

In the case of polar systems we consider a linear chain in order to avoid sophisticated calculations caused by different orientations of the dipoles. The following simple expression is obtained for the electrostatic energy in a chain in which all dipoles point in the same direction:

$$\Delta E_{AB}^{COU} = -\mu_A \mu_B \frac{2}{R^3} \tag{19}$$

This contribution has to be added to the simple model potential given in equation (18). Summation of pair potentials yields a stronger contraction of the equilibrium distance than we find with non-polar systems when we compare the infinite linear chain with the isolated dimer in the vapor phase (Fig. 17). Nevertheless, this contraction is still small if we consider dipole moments in the range of those of ordinary polar molecules ($1\,D < \mu < 3\,D$). The stronger effect observed with polar systems has its origin in the longer effective range of dipole forces: the energy of interaction decreases with $R^{-3}$ instead of $R^{-6}$ in non-polar systems.

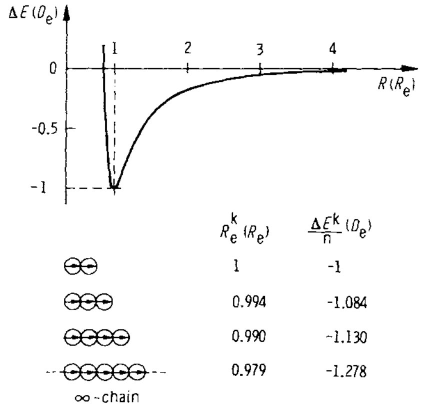

Fig. 17. Additivity of intermolecular energies in polar systems. In polar systems dipole-dipole forces (and further electrostatic and polarization forces of higher order) are superimposed upon the Lennard-Jones type interaction. In the limit of a very strong dipole-dipole force the potential approaches the function $\Delta E(R) = A \cdot R^{-12} - B \cdot R^{-3}$. For this limiting case we made similar considerations as those discussed in Figure 16. As a model for strong interaction in the solid state we consider a linear chain with parallel oriented dipoles. In this case the superimposed electrostatic fields are strongest. The effects observed strengthen the forces in condensed matter and are stronger than those found with non-polar systems: the intermolecular distance decreases by about 2%, the energy of interaction increases by 28% when the condensed phase is formed.

We shall now compare our ideas of a world of additive potentials with the actual experimental data on structures (Table 10). In the case of solids formed by noble gas atoms we find very small contractions indeed. The differences in equilibrium distances between vapor phase and crystal amount to only a few hundreths of an Ångstrøm or even less. A minute energetic effect which, nevertheless, has been debated extensively, is observed in crystal structures: Instead of the hexagonal closed packed (hcp) structure the face centered cubic lattice (fcc) is found to be the most stable arrangement[48]. The only exception is solid helium which prefers hcp structure.

Table 10. A comparison of interatomic or intermolecular distances in the vapor-phase dimers and crystals.

| Monomer | Dimer in the vapor-phase | | Crystal | | |
|---|---|---|---|---|---|
| X | $R_e^{xx}$ [Å] | Ref. | $R_e^{xx}$ [Å] | Structure [b] | Ref. |
| He | 2.97 | [56] | 3.0 | hcp | [60] |
| Ne | 3.15 | [56] | 3.156 | fcc | [61] |
| Ar | 3.758 | [56] | 3.755 | fcc | [61] |
| Kr | 4.03 | [56] | 3.992 | fcc | [61] |
| Xe | 4.36 | [56] | 4.335 | fcc | [61] |
| Li | 2.673 | [56] | 3.04 | bcc | [62] |
| | | | 3.09 | hbc | [62] |
| | | | 3.11 | fcc | [62] |
| Na | 3.079 | [56] | 3.72 | bcc | [62] |
| Be [a] | (4.3–4.5) | [63] | 2.29 | hcp | [62] |
| Mg | 3.891 | [56] | 3.21 | hcp | [62] |
| HF (X = F) | 2.79 | [28] | 2.49 | [c] | [64] |
| $H_2O$ (X = O) | 2.98 | [28] | 2.74 | ice I [c] hexagonal | [65] |

[a] The values in parantheses are results of *ab initio* calculations on $Be_2$. For this system there are no experimental data available. [b] Abbreviations hcp = hexagonal closed packed, bcc = body centered cubic and fcc = face centered cubic. [c] For the solid phase of HF and $H_2O$ see Figure 18.

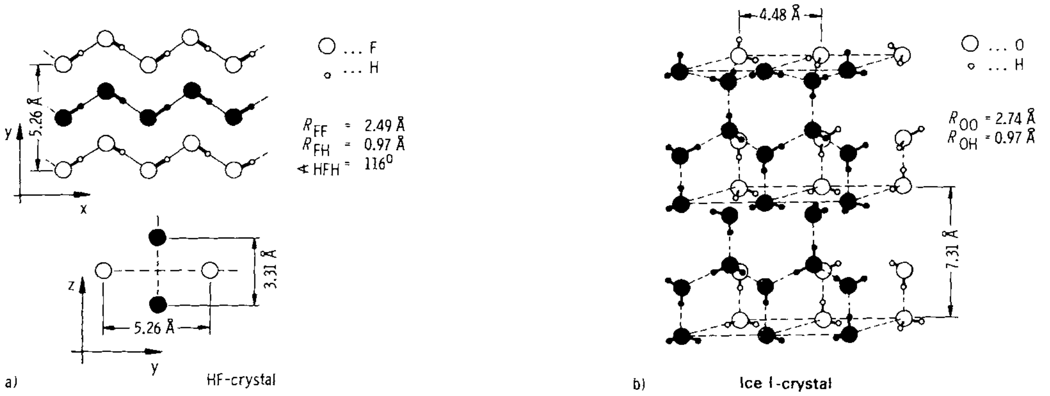

Fig. 18. The crystal structures of a) hydrogen fluoride and b) ice I (hexagonal). The HF crystal consists of loosely packed one-dimensional zig-zag chains of HF molecules. Apart from the tilt the electrostatic fields of the molecular dipoles are superimposed in optimal manner. All trimeric subsystems in the chain are of the sequential type. Therefore, all three-body forces are stabilizing and we expect a maximum effect with respect to contraction of the intermolecular distance relative to the vapor phase (Table 10). The water molecules in the ice I crystal are characterized by different orientations of their electric dipoles. In order to utilize all possibilities to form hydrogen bonds we have trimeric subunits of sequential, double-donor and double-acceptor type (see Figure 14). Consequently, there are three-body contributions of different sign. The contraction of the OO-distance relative to the vapor phase is smaller than in the HF crystal.

Simple metals, *i. e.* alkaline and alkaline-earth metals behave very differently in the solid state. The differences in equilibrium distances between vapor phase and crystal are large and very different. The dimers of alkaline metal atoms in the gas phase, $Li_2$ and $Na_2$, are characterized by a weak covalent bond. This bond is markedly stretched in the solid state. Accordingly, we find a repulsive contribution of three- and many-body forces. Alkaline earth metals behave completely differently: $Mg_2$ is a typical van der Waals molecule similar to the noble gas dimers $Ne_2$ and $Ar_2$. The data on $Be_2$ are uncertain. Attempts to prove the existence of a bonded ground state by spectroscopic techniques have so far failed. The most accurate calculations also favor a very flat potential curve with a shallow trough. Despite the smallness of the system—eight electrons only—the calculation of the electron correlation energy was found to be particularly problematical. Theoretical predictions should therefore be considered very carefully. It is, nevertheless, certain that in the case of Mg and Be the equilibrium distance in the crystal is much smaller than in the vapor phase. Both systems represent examples of stabilization through three-body forces. An extensive discussion of the role of three-body forces in various, covalently bound clusters of atoms including $Be_n$, has been presented by *Murrell*[49].

Let us now consider the systems formed by polar molecules which have been studied in most detail, namely hydrogen fluoride and water. The hydrogen fluoride crystal contains one-dimensional chains between which relatively weak mutual interactions take place (Fig. 18a). Despite the bent arrangement in the zig-zag chains the fields of the individual dipoles are strengthened by induction. All trimeric substructures are of the sequential type. Accordingly, a marked contraction in the equilibrium distance ($\Delta R_{FF} \approx 0.30$ Å) is observed on formation of the solid phase. Ice I has a fairly complicated three-dimensional structure (Fig. 18b). Apart from sequential trimer subunits we also observe "double donor" and "double acceptor" structures. The contraction of the equilibrium distance in the solid state is somewhat smaller ($\Delta R_{OO} \approx 0.24$ Å). In both cases the stabilizing contributions of the three-body forces originate essentially from the non-additivity of the polarization energy, as is known from an analysis of the vapor-phase trimers. The collection of data presented here enables us to conclude that an accurate description of condensed phases formed from polar molecules requires a proper consideration of the deviations from pairwise additive intermolecular potentials.

## 6. Polar Liquids

Needless to say, even a brief and superficial discussion of the various problems encountered with polar liquids would be beyond the scope of this review. What we intend to present, however, is an attempt to show how we can use our knowledge of intermolecular forces in the vapor phase in order to facilitate a description of polar liquids. The liquid state is notoriously difficult to characterize. It has so far been impossible to extend quantum mechanical calculations directly to the condensed liquid phase. Nevertheless, remarkable progress in the theory of liquids has been achieved during the last few years by proper application of the concepts of classical statistical mechanics. Calculations in "molecular dynamics" make an attempt at solving Newton's equations of motion for an ensemble of up to thousands of molecules. The dynamics of such a huge cluster is computed from a given potential function. In order to describe the situation in condensed matter properly the ensemble is embedded into a periodic lattice of equal ensembles (Fig. 19). The initial results of these calculations are

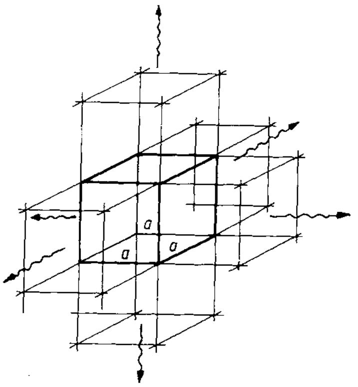

Fig. 19. Periodic boundary conditions applied with computer simulation experiments of liquids. In order to simplify the numerical calculations one assumes that a volume element of the liquid consisting of 200—1000 molecules is repeated periodically in the liquid phase. The most simple geometry of such an element is that of a cube. In each volume element ($a \cdot a \cdot a$) (arrow) "ghost particles" carry out the same motions as in the central box. This continues periodically *ad infinitum*.

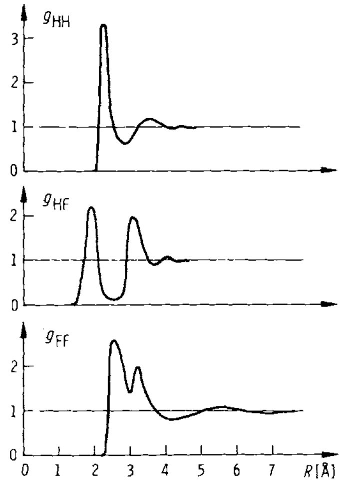

Fig. 20. The three atom-atom pair distribution functions, $g_{FF}$, $g_{FH}$ and $g_{HH}$ in liquid hydrogen fluoride under the conditions $\rho = 1$ g/cm³ and $T = 269$ K (curves taken from [50]). The pair distribution function $g_{AB}(R)$ counts the number of atoms B ($n_B$) which in the time average surround an atom A at a distance $R$.

$$\delta n_B = 4\pi R^2 \mathrm{d}R\, g_{AB}(R) \rho$$

Generally, the pair distribution function starts at $g_{AB}(0) = 0$ (at the position of one atom the probability of finding a second atom is zero), passes through several maxima and minima which are determined by the structure and local order in the liquid, and finally approaches a value of 1, which means that there is no far-reaching order in the liquid. A comparison of curves at different temperatures shows that the local order in the liquid disappears gradually with increasing temperature.

correlation functions which provide an abstract picture of the dynamic and static properties in a liquid. The static properties are obtained as time averages. A simple example of such a correlation function is the distance pair correlation (Fig. 20). It represents the average structure of the liquid, and its numerical value for a certain distance is the probability of encountering a particle of a certain class at this distance from the center.

"Monte Carlo" calculations are an alternative technique for simulating the liquid state. In this method one tries to calculate a representative set of most probable geometric arrangements of molecules. In principle, only static properties of liquids can be obtained by this approach. For example, one can calculate distance correlation functions, but not velocity correlation functions. As in molecular dynamics, Monte-Carlo calculations are based on our knowledge of the intermolecular potential.

All "computer simulation experiments" (*i.e.* Monte Carlo and molecular dynamics calculations) which have been carried out so far use intermolecular potentials which are either derived from the semiclassical theory and have model character or have been fitted to the results of *ab initio* calculations. The main interest, of course, centered on the associated liquids water, hydrogen fluoride and ammonia[50].

Two particular difficulties are encountered in simulation experiments on polar systems: For technical reasons it has not yet been possible to incorporate three-body potentials into actual calculations. As we have seen in the preceding sections, however, it is impossible to obtain correct average distances between neighboring molecules without considering three-body forces. One way of circumventing this problem is to use an effective pair potential which accounts globally for the stabilizing contribution of three- and many-body forces. The second problem, not yet solved satisfactorily, is concerned with the long effective range of potentials between dipole molecules. Correct summation of all contributions is extremely time consuming. Very popular, stringent simplifications like the "cut off" of potential curves at a certain distance introduce characteristic and crucial errors into the calculated dielectric properties[51].

The structures of liquids are amenable to experimental investigation by X-ray and neutron-scattering techniques. Combination of both methods provides the most detailed results obtained so far[52]. The quantities that can be compared best with the vapor phase are the HX stretching frequencies. With respect to these data the liquid state lies between the vapor phase and the crystal and resembles more closely the latter. Here, we may glean an indirect indication of the action of three-body forces (see Section 7).

At the moment there is very close collaboration between theorists and experimentalists regarding the physics of liquids. Experience in dynamics, gained by computer simulation experiments, helps the experimentalist in the evaluation of his data.

## 7. Crystals of Polar Molecules

In contrast to the liquid, the crystal is directly accessible to quantum mechanical investigations. In principle, *ab initio* calculations can be performed on molecular crystals if one makes use of the translational symmetry[53]. As we have already mentioned in the case of calculations on molecules, the number of electrons in the elementary cell must not be too large in order to ensure the computational accuracy required. A problem not yet solved is concerned with an economic and efficient consideration of electron correlation effects. The principles of the procedure are in complete analogy to calculations on molecules. An energy surface is calculated within the framework of the Born-Oppenheimer approximation, and from there one derives equilibrium geometries and force constants. Here, we consider exclusively the hydrogen fluoride crystal, since it is particularly well suited for *ab initio* calculations[54]. Solid hydrogen fluoride forms bent chains which are in relatively weak contact; in other words, the distance between these chains is large (Fig. 18). This quasi one-dimensional structure facilitates the theoretical investigation enormously. Large basis sets can be applied which guarantee highly accurate results. The computational efforts in real three-dimensional calculations are much larger, and so far only very small basis sets could be used in the elementary cells.

In the previous section we observed a basic feature of hydrogen bonded systems which consists in a contraction of the intermolecular distance on transition from the vapor phase dimer to the crystal. We shall now consider this difference in more detail (Table 11). The contraction of the intermolecular distance is accompanied by an increase in the HF bond length which is already present, albeit to a far less extent, in the dimer. Similarly, the shift in the HF stretching frequency between monomer and dimer in the vapor phase is very small compared to that between monomer and HF crystal. The substantial differences between the dimer and the infinite chain originate from two causes. At first we have the stabilizing effect of three-body forces

Table 11. A comparison of calculated and experimental data of hydrogen fluoride in the gaseous, liquid and solid state. References: Vapor phase: [28, 29]; liquid: [50]; crystal: [54, 64]; the calculations were performed on an ∞-chain of HF molecules as a model of the solid state.

[a] Negative heat of vaporization at $T = 293$ K [50]. [b] Energy of interaction per monomer in the HF chain. [c] Results of calculations using a smaller basis set and a linear chain [54]. [d] The numerical values correspond to the symmetric and asymmetric HF stretching vibration.

which strengthen the interaction between the subsystems. Secondly, we have a kind of symmetry in the infinite system which does not exist in the dimer. This symmetry has an additional influence on the properties of the chain. Let us go beyond the "frozen geometry" approximation and consider the energy curve for proton transfer (Fig. 21). The potential curve for simultaneous transfer of all protons along the infinite chain shows two equivalent minima, whereas the potential curve for proton transfer in the dimer has a single minimum only. Consequently there is an elongation of the HF bond length and a decrease in the curvature of the potential curve at the energy minimum which leads to a shift towards lower frequencies of the corresponding normal mode. *Ab initio* calculations and experiment agree completely within the expected error limits. The difference between the absolute values of calculated and experimentally measured HF stretching frequencies is explained by the lack of correlation effects in the calculation on the crystal.

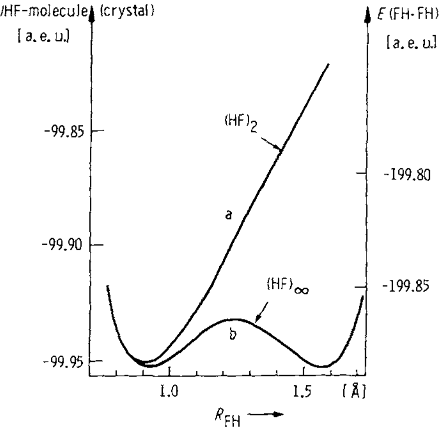

Fig. 21. The potential curve of proton displacement along the hydrogen bond in dimeric hydrogen fluoride (a) and of the synchronous, collective proton motion in the infinite hydrogen fluoride chain (b) [54]. Because of the symmetry in the solid state structure there exists a second minimum of the potential curve which has the same energy as the ordinary minimum and which corresponds to equivalent positions of all protons. Accordingly, the HF bond distance in the chain is longer than in the dimer. The curvature of the potential curve at the minimum and the harmonic force constant of the HF stretching vibration are smaller in the solid state than in the vapor phase dimer. 1 a.e.u. = 627.5 kcal/mol.

All three effects of the condensed phase, the contraction of the intermolecular distances, the elongation of the HX bonds, and the shift of the HX vibrational frequencies towards lower frequencies are observed with ice I, in exactly the same way as with solid hydrogen fluoride. Because of the essentially three-dimensional structure of ice the *ab initio* calculation is extremely complicated. No accurate data are available at present, so we shall dispense with enummerating the plethora of literature on this system.

In this brief section we were able to consider only those aspects of crystals of polar molecules which are directly related to the results obtained in the vapor phase.

## 8. Concluding Remarks

The data summarized in this review are the results of simultaneous efforts by theorists and experimental researchers. Thanks to their work our present knowledge of some intermolecular complexes is as complete as that of small molecules. The dimers of hydrogen fluoride and water count among the complexes which have been studied in more detail. This is of particular importance, because the forces acting in these dimers are essentially the same as those which determine the properties of these substances in the condensed state. Liquid water in particular has already attracted a great deal of interest for some time. This is fully justified in view of its primary importance. Unfortunately, associated liquids are the least understood systems at present. Simultaneous progress of theory and experiment obtained by computer simulation experiments and further combined X-ray and neutron scattering studies will inevitably provide further insights into the problem at hand.

The theorists found a powerful method for unifying a description of intermolecular associations and chemical bonds by means of numerical computations. The fundamental concept of (inter)molecular energy surface is the common basis also for a deeper understanding of the properties of all three states of aggregation. In retrospect one point appears to be worth mentioning: Concepts, based on unobservable indices and weakly defined quantities like bond orders, atomic charges, charge transfer *etc.* have contributed less to a better understanding of intermolecular forces than the consequent although tedious and sometimes boring calculation of quantities, which, in principle, are accessible to experimental observation.

No doubt, many systems will be studied by *ab initio* techniques during the next years. On the other hand, a clear limitation to the problems that can be treated in this way can be seen as well. The high degree of accuracy which is inevitably necessary in investigations of intermolecular forces requires enormous amounts of computer time and hence only small systems can be treated with the present day computational capacities. To go beyond this limitation would require a kind of revolution in electronic computers leading to an enormous increase in computational speed which is rather unlikely. Simulation experiments on liquids are similarly involved and they will face the same problem of technical limitation in the not too distant future. Nevertheless, in this field, the development of numerical techniques is in a state of rapid progress so that we may expect a variety of interesting results in the coming years.

*All my colleagues and coworkers have contributed a great deal to this review through their work, their advice, and their enthusiastic discussions. I should like to mention some by name: Prof. Dr. Werner Kutzelnigg, Prof. Dr. Volker Staemmler, Prof. Dr. Hans Lischka, Dr. Alfred Karpfen, Dr. Othmar Steinhauser and Dr. Anton Beyer. Dr. Bohumila Schreiber and Mrs. Judith Jakubetz worked hard with the typing of the manuscript. The Österreichische Fonds zur Förderung der wissenschaftlichen Forschung kindly provided financial support, and the Interuniversitäre Rechenzentrum Wien generously allotted computer time. I wish to take this opportunity of sincerely thanking all of them.*

[5] The wave function of a system containing *n* electrons depends on 4*n* coordinates, $x_1 y_1 z_1 s_1 x_2 y_2 \ldots s_n$. Here $x_i, y_i$ and $z_i$ denote space coordinates of the "*i*"-th electron. The spin state is characterized by $s_i$. All four coordinates of an electron are summarized by the symbol $\tau$: $\tau_i = x_i y_i z_i s_i$. The spatial electron density distribution is derived from the square of the absolute value of the wave function by integration over all coordinates of $n-1$ electrons and over the spin-coordinate of the remaining *n*-th electron.

Klemperer, ibid. 60,* 3208 (1974); Ar·HBr: *K. C. Jackson, P. R. R. Langridge-Smith, B. J. Howard,* Mol. Phys. *39,* 817 (1980).

[27] *S. L. Holmgren, M. Waldman, W. Klemperer,* J. Chem. Phys. *67,* 4414 (1977); *69,* 1661 (1978).

[28] $(HF)_2$: *T. R. Dyke, B. J. Howard, W. Klemperer,* J. Chem. Phys. *56,* 2442 (1972); $(H_2O)_2$: *T. R. Dyke, K. M. Mack, J. S. Muenter, ibid. 66,* 498 (1977); *J. A. Odutola, T. R. Dyke, ibid. 72,* 5062 (1980).

[29] Most accurate calculation of $(HF)_2$ around the equilibrium geometry: *H. Lischka,* Chem. Phys. Lett. *66,* 108 (1979); most extended study of a large region of the $(HF)_2$ energy surface: *D. R. Yarkony, S. V. O'Neil, H. F. Schaefer III, G. P. Baskin, C. F. Bender,* J. Chem. Phys. *60,* 855 (1974). Both investigations were preceded by numerous papers of several groups of authors. Calculation of an extensive force field based on ten harmonic force constants and the corresponding normal frequencies: *L. A. Curtiss, J. A. Pople,* J. Mol. Spectrosc. *61,* 1 (1976).

[30] Analysis of the wave function of $(HF)_2$ on the basis of a somewhat less accurate *ab initio* calculation: *P. A. Kollman, L. C. Allen,* J. Chem. Phys. *52,* 5085 (1970).

[31] Most extensive investigation of the energy surface of $(H_2O)_2$: *A. Matsuoka, E. Clementi, M. M. Yoshimine,* J. Chem. Phys. *64,* 1351 (1976); somewhat earlier paper with explicit consideration of electron correlation effects: *G. H. F. Diercksen, W. P. Kraemer, B. O. Roos,* Theor. Chim. Acta *36,* 249 (1975); calculation of an extensive force field of water dimer and the corresponding vibrational spectrum: *L. A. Curtiss, J. A. Pople,* J. Mol. Spectrosc. *55,* 1 (1975).

[32] The experimental data on the vibrational spectra of $(HF)_2$ and $(H_2O)_2$ are not very good. In the former case we have to rely on a somewhat older analysis of pressure and temperature dependence of the infrared spectrum of HF vapor which were interpreted by means of a monomer-dimer equilibrium: *D. F. Smith,* J. Mol. Spectrosc. *3,* 473 (1959). The infrared spectrum of water dimer was recorded only by matrix isolation technique: *A. J. Tursi, R. E. Nixon,* J. Chem. Phys. *52,* 1521 (1970). The influence of the matrix, commonly one uses Ar or $N_2$ crystals, on the spectra recorded is frequently debated.

[33] *B. Hobza, P. Carsky, R. Zahradnik,* Int. J. Quantum Chem. *16,* 257 (1979).

[34] The second virial coefficients and the transport coefficients at low pressures ($p \leq 8$ atm) and temperatures up to 500 °C were used to calculate an empirical potential surface of $(H_2O)_2$: *J. P. O'Connell, J. M. Prausnitz,* Ind. Eng. Chem. Fundam. *8,* 453 (1969); *9,* 579 (1970). An interesting more recent publication is that by: *C. Braun, H. Leidecker,* J. Chem. Phys. *61,* 3104 (1974), in which the authors calculated the complete rotational-vibrational spectrum in order to compare calculated and measured thermodynamic data.

[57] The most accurate calculation of the interaction between two water molecules by means of perturbation theory was performed by *B. Jeziorski, M. van Hemert*, Mol. Phys. *31*, 713 (1976). This publication reports a very accurate Hartree-Fock calculation on the water dimer as well. The contribution of dispersion energy was calculated with the aid of an expression derived from perturbation theory. Other contributions of electron correlation like the changes in the properties of the monomers were neglected. These contributions, however, have a non-negligible influence on the total energy of interaction.

[58] An empirical, six-dimensional potential function of the water dimer has been proposed by *L. L. Shipman, H. A. Scheraga*, J. Phys. Chem. *78*, 909 (1974). This function was subjected to extensive testing and is able to reproduce the well known results from *ab initio* calculations [31] as well as the data from microwave spectroscopy [28]: *L. L. Shipman, J. C. Owicki, H. A. Scheraga, ibid. 78*, 2055 (1974).

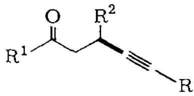
## Michael Addition of Lithium Acetylides to Propenyl Trityl Ketone

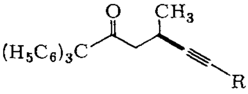
By *Rita Locher* and *Dieter Seebach*[*]

The synthetically valuable 4-alkyne-1-ones *(1)* can only be prepared indirectly from enones and terminal acetylenes, *i.e.* by formation of the prominant C—C bond in formula *(1)*[1]. To our knowledge, the direct 1,4-addition of alkali metal- or alkaline earth-acetylides[2] to simple enones has not been previously observed.

We have now found, that between −45 and +25 °C, lithium acetylides in tetrahydrofuran (THF) add to 1,1,1-triphenyl-3-penten-2-one to give good yields of the alkynones *(2)* (Table 1). This result and the Michael addition of other lithium compounds to trityl enones[3a] show that the a$^3$-reactivity of enones can be *purely sterically*[3b] controlled, independent of the mechanism (radical[4a], charge- or orbitalcontrol[4b]), the structure of the nucleophile[5a] or solvent[5b] and temperature effects[5c].

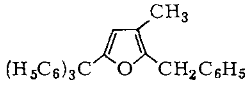
*(1)*



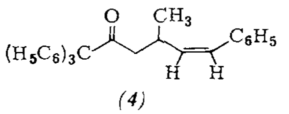


*(2)*

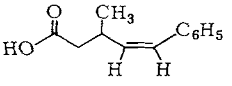
This C—C bond forming process is only synthetically useful when cleavage of the bond between the carbonyl carbon and the trityl carbon is possible under mild conditions. The Haller-Bauer-type cleavage with potassium *tert*-butoxide/H$_2$O in THF[6] used previously[3a], could not be successfully applied to *(2)*, R = C$_6$H$_5$, the furan *(3)* being formed[7]. However, hydrogenation of the triple- to a *cis* double-bond [*(2)*→*(4)*, Lindlar catalyst/H$_2$, quantitative], permits hydrolysis of the trityl ketone [*(4)*→*(5)*] in 76% yield. Moreover, we have now found that trityl ketones are smoothly cleaved by LiBHEt$_3$[8], in THF upon warming from −45 °C to room temperature, to triphenylmethane and primary alcohols. Thus, the alkynone *(2)*, R = C$_5$H$_{11}$, reacts in 77% yield to the alkynol *(6)* without interference from the triple bond. The IR- and mass-spectra, as well as the $^1$H- and $^{13}$C-NMR spectra are in accord with the given structures. Applications[9] for the described Michael additions are currently being investigated.



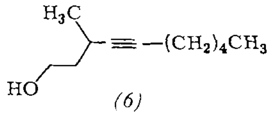
*(3)*



*(4)*



*(5)*



*(6)*

Table 1. Yields and melting points of the products *(2)* purified by chromatography on silica gel and/or by recrystallization.

| R | Yield [%] | M.p. [°C] |
|---|---|---|
| C$_6$H$_5$ | 89 | 109—110 |
| (CH$_2$)$_4$CH$_3$ | 86 | 59 |
| C(CH$_3$)$_2$OH | 32 | 128 |
| Si(CH$_3$)$_3$ | 66 | 102 |
| CH$_2$OCH$_3$ | 66 [a] | 86 |
| CH$_2$N(CH$_2$CH$_3$)$_2$ | 65 | oil [b] |

[a] In addition to 15% unreacted starting material. [b] After chromatography (SiO$_2$/EtOEt : MeOH 19 : 1).

### *Procedure*

A solution of the Li-acetylide at −50 °C in 15 cm$^3$ THF, prepared from heptyne (0.61 cm$^3$, 4.6 mmol) and butyllithium (4.7 mmol, ≈1.6 N in hexane) under argon (−45° to −10 °C), is added to a solution of 1,1,1-triphenyl-3-penten-2-one (1.32 g, 4.2 mmol) in 50 cm$^3$ THF stirred at −50 °C. After warming to room temperature overnight, the mixture is poured into water and extracted with ether. "Flash" chromatography[10] of the crude product over SiO$_2$ (5 cm diameter column, CH$_2$Cl$_2$/hexane 3 : 1) yielded 1.46 g (86%) *(2)*, R = C$_5$H$_{11}$ (4-methyl-1,1,1-triphenyl-5-undecyn-2-one).—A solution of this ketone (190 mg, 0.46 mmol) in 8 cm$^3$ THF at −45 °C is treated with 1.4 cm$^3$ of a 1 N solution of LiBHEt$_3$ in THF. After warming-up and stirring (40 h), the mixture is treated with 3 cm$^3$ 1 N hydrochloric acid and worked-up with ether. Triphenylmethane is removed on a short SiO$_2$ column and the 3-methyl-4-decyn-1-ol purified by Kugelrohr distillation [60 mg (77%); b.p. = 60 °C (oven)/10$^{-2}$ torr; $^{13}$C-NMR (75.5 MHz, CDCl$_3$): $\delta$ = 84.14 (s), 81.53 (s), 61.58 (t), 39.93 (t), 31.12 (t), 28.87 (t), 23.18 (d), 22.22 (t), 21.74 (q), 18.72 (t), 13.96 (q)].

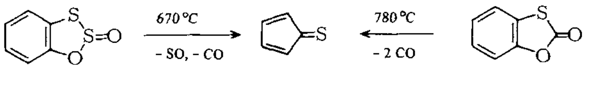
## Cyclopentadienethione[**]

By *Reinhard Schulz* and *Armin Schweig*[*]

We report here the first synthesis of cyclopentadienethione *(2)*[1]. It is formed by gas phase pyrolysis (VTPES method[2], reactor *ca.* 20 × 0.5 cm, 0.05 mbar pressure) of 1,2,3-benzoxadithiol 2-oxide *(1)* and 1,3-benzoxathiol-2-one[3] *(3)*.



*(1)* *(2)* *(3)*

*(2)* is unambiguously characterized from its photoelectron spectrum (Fig. 1b and d). Band ① (at 8.87 eV), due to its shape, position and energy-dependence of the intensity[4], is unequivocally the $^2B_2(n_S)$-band. Band ② (at 9.18 eV) is, because of its position (expected at 9.2 eV from the position of the corresponding band in cyclopentadienone[5] and from the *ca.* 0.2 eV smaller inductive effect of the thiocarbonyl group[6]), assigned as an $^2A_2(\pi)$-band. Band ③ (at 10.35 eV) is identified from a relationship[7] for the $^2B_1(\pi)$-ionization energy of fulvene-type molecules—again in excellent agreement with the measured value—expected at 10.4 eV, as a $^2B_1(\pi)$-band. These conclusions are corroborated by CNDO/S-[8a], MNDO-[8b] and PERTCI[8c]-calculations (Fig. 2).

Thermal fragmentation of *(1)* and *(3)* probably proceeds[9] *via* the monothiobenzoquinone *(4)*[10]. From MNDO-calculations, the valence isomeric benzoxathiete *(5)* is considerably more energy-rich than *(4)*; the thiocarbonyl compounds *(2)* and *(4)* have *ca.* 50 kcal/mol more energy than the carbonyl compounds cyclopentadienone and 1,2-benzoquinone. In fact, when *(1)* is pyrolyzed be-

[**] Theory and Application of Photoelectron Spectroscopy, Part 92. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 91: *A. Schweig, N. Thon, S. F. Nelsen, L. A. Grezzo,* J. Am. Chem. Soc., *102,* 7438 (1980).

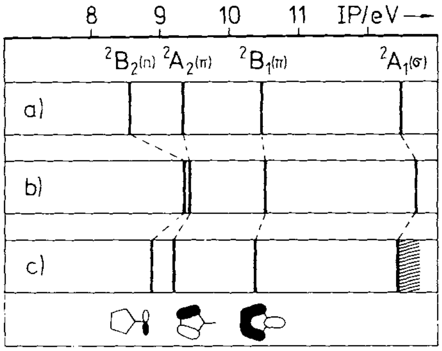

Fig. 2. Calculated a) MNDO-PERTCI, b) CNDO/S-PERTCI and c) measured vertical ionization energies (IP) of cyclopentadienethione *(2)*.

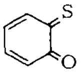
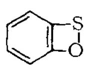
tween 550 °C and 600 °C, a compound is obtained as intermediate whose photoelectron spectrum indicates the monothiobenzoquinone *(4)* (bands at 8.85, 9.45 (high intensity) and 11.6 eV; from qualitative rules, MNDO- and CNDO/S-PERTCI-calculations, expected at $^2A'(n_S)$ 8.9, $^2A'(n_O)/^2A''(\pi)$ *ca.* 9.4 and $^2A''(\pi)$ *ca.* 11.5 eV). Because of the high temperature (>700 °C) required for the cleavage of *(3)*, this intermediate cannot be observed. Other possible products, fulven-6-one *(6)* and fulven-6-thione *(7)*, whose photoelectron spectra are known[11], do not appear.

The thermal behavior of *(1)* and *(3)* has parallels in the electron-impact induced fragmentation of the cations. $SO_2$-cleavage from $(1)^{\oplus}$ and $CO_2$-cleavage from $(3)^{\oplus}$ only takes place to a minor extent; the principle fragmentation route is the formation of the $C_5H_4S$ ion ($m/e=96$) [MS[12] (70 eV): *(1)*: $m/e=172$ $M^{\oplus}$ (100%), 124 (16), 108 (14), 96 (57); *(3)*: $m/e=152$ $M^{\oplus}$ (20%), 124 (4), 108 (12), 96 (100)].



*(4)*



*(5)*

*(6)*

*(7)*

From the results of preliminary theoretical investigations (π-conjugation energy, π-charge-transfer and bond length equalization) *(2)* can be assigned an electronic structure between that of cyclopentadienone and fulvene.

### *Procedure*

*(1)*: Solutions of 2-mercaptophenol (9 g) and $SOCl_2$ (8.5 g), each in 100 cm$^3$ $CS_2$, are simultaneously dropped into a stirred solution of pyridine (11.5 g) in 200 cm$^3$ $CS_2$ under $N_2$ at 0–5 °C. After heating under reflux (15 min), the mixture is filtered, the filtrate concentrated to *ca.* 5 cm$^3$ and taken up in 100 cm$^3$ $CCl_4$. After filtration, concentration and distillation *in vacuo* (bath 150 °C; 0.8 torr), *(1)* is isolated as a yellow oil, which crystallizes upon standing. Yield 1.4 g (9.8%); m.p. = 46.5 °C; IR: $\nu=3070$, 1450, 1180 cm$^{-1}$; $^1$H-NMR ($CDCl_3$): $\delta=7.37$ (m); $^{13}$C-NMR[12] ($CDCl_3$): $\delta=114.9$, 121.5, 123.3, 125.4, 127.0, 153.9. *Photoelectron spectroscopic data for (1) and (3)*: *(1)*: 8.77 (π), 9.48 (π), 10.14, 10.97 eV; *(3)*: 8.84 (π), 9.55 (π), 10.80 ($n_O$), 11.12 (π) eV.

## 4,13-Diaza[$2_4$](1,2,4,5)cyclophane and 4,16-Diaza[$2_4$](1,2,4,5)-cyclophane[**]

By *Hee Chol Kang* and *Virgil Boekelheide*[*]

The pyrolysis of *o*-chloromethyltoluenes to give *o*-xylylenes and their thermal dimerization, either inter- or intramolecularly, has proved to be an extremely useful synthetic sequence for preparing [$2_n$]cyclophanes[1]. We have now investigated the extension of this method to heterocycles and find that it provides convenient, seven-step syntheses to the title compounds *(11)* and *(12)*.

As outlined in the reaction scheme shown below, treatment of diethyl 2,6-dimethylpyridine-3,5-dicarboxylate *(1)* with 2 equiv. lithium aluminum hydride in tetrahydrofuran (THF), followed by heating the product with methanol to effect ester interchange, gave *(2)*[2]. Conversion of *(2)* to *(3)* was accomplished with $SOCl_2$; sublimation of *(3)* at $10^{-2}$ torr into the hot zone (775 °C) of an empty quartz tube gave a colorless oil whose spectroscopic properties [$^1$H-NMR ($CDCl_3$): $\delta=7.70$ (s, aryl-*H*), 3.83 (s, —$CO_2CH_3$), 3.27–3.41 (m, —$CH_2$—), 2.97–3.11 (m, —$CH_2$—), 2.73 (s, —$CH_3$); UV (EtOH), $\lambda=228$ ($\varepsilon=5271$), 283 nm (6410)] are in accord with structure *(4)*.

Although intermolecular dimerizations of *o*-xylylenes to [2.2]orthocyclophanes have previously been carried out in boiling diethyl phthalate[1,3], we have recently found that

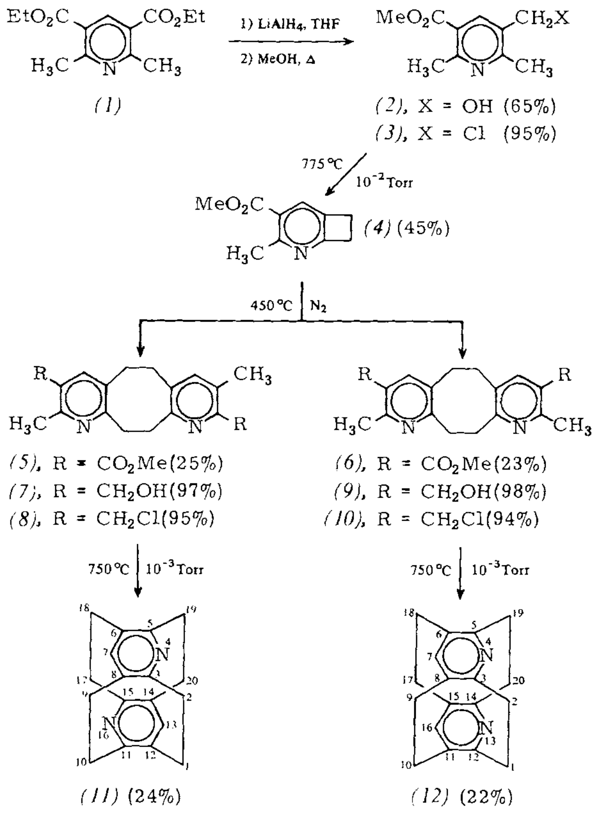
Department of Chemistry, University of Oregon
Eugene, Oregon 97403 (USA)

[**] This work was supported by the National Science Foundation. We thank Dr. *A. W. Hanson* for the X-ray structure analysis.



they can be accomplished much more conveniently, and in higher yield, in the gas phase at 450 °C at atmospheric pressure using $N_2$ as carrier gas[4]. When *(4)* was subjected to these conditions, both possible dimers, *(5)* (m.p. = 220–221 °C) and *(6)* (m.p. = 191–192 °C), were formed in approximately equal amounts. Structures *(5)* and *(6)* could readily be distinguished by their $^1$H-NMR spectra, *i.e.* the bridging protons of *(6)* appear as two singlets of four protons each at $\delta = 3.13$ and 3.39, whereas the bridging protons of *(5)* appear as a symmetrical multiplet of eight protons at $\delta = 3.06-3.46$. Silica gel chromatography followed by fractional crystallization from ethyl acetate cleanly separates isomers *(5)* and *(6)*.

Conversion of *(5)* to the corresponding hydroxymethyl derivative *(7)* (m.p. = 290–291 °C) was readily accomplished using lithium aluminum hydride in ether. Similarly, treatment of *(7)* with $SOCl_2$ easily gave the chloride *(8)* (m.p. = 252 °C, decomp.). In a similar manner, *(6)* could be converted first to *(9)* (m.p. = 284–285 °C) and then to *(10)* (m.p. = 238 °C decomp.). Gas phase pyrolysis of *(8)* at 750 °C and $10^{-3}$ torr gave the desired cyclophane *(11)* [m.p. > 350 °C (decomp.); $^1$H-NMR ($CDCl_3$), $\delta = 6.63$ (s, aryl-*H*), 2.80–3.66 (m, —$CH_2$—); UV (EtOH), $\lambda = 298$ ($\varepsilon = 4369$), 307 nm (5243)]. Similarly, gas phase pyrolysis of *(10)* at 750 °C and $10^{-3}$ torr gave *(12)* [m.p. > 310 °C (decomp.); $^1$H-NMR ($CDCl_3$), $\delta = 6.24$ (s, aryl-*H*), 3.12–3.58 (m, —$CH_2$—), 2.68–2.87 (s, —$CH_2$—); UV (EtOH), $\lambda = 300$ ($\varepsilon = 6166$), 307 nm (6143)].

The geometries of *(11)* and *(12)* were determined by *Hanson* by single crystal X-ray analysis, and these are very similar to each other as well as to $[2_4](1,2,4,5)$cyclophane[5]. In each case, the aromatic rings have boat conformations in which the tips are inverted to the outside. For $[2_4](1,2,4,5)$cyclophane, the distance between "decks" is 2.688 Å, whereas for both *(11)* and *(12)* it is approximately 2.64 Å. In *(11)*, the N4 to C13 distance is 2.868 Å, whereas for *(12)* the N4 to N13 distance is only 2.84 Å.

The cyclophanes *(11)* and *(12)* are relatively strong bases and should serve as ligands in transition metal complexes. Since cyclophanes behave as a single π-electron system, *(11)* is the cyclophane analogue of pyrazine. In view of the classic work of *Creutz* and *Taube* on the mixed-valence, bis-ruthenium complex of pyrazine[6], it would be of interest to prepare a similar mixed-valence, bis-ruthenium complex of *(11)* and examine its properties.

## Non-planar Double Bonds and Increased Reactivity in Olefins with Low Strain

By *Ulrich Burkert*[*]

In highly strained olefins, nonplanar double bonds with an increased reactivity occur frequently[1]. In this connection deplanarization of double bonds as a consequence of torsion, such as in tetra-*tert*-butylethylene[2], and of *out-of-plane bending*, such as in 9,9′,10,10′-tetrahydrodianthracene[3], should be distinguished. On the other hand, the double bonds in slightly strained olefins are considered to be planar. We have now found from *molecular mechanics* calculations[4], however, that pure torsional strain in otherwise slightly strained olefins can cause deplanarization of the double bonds.

According to *ab initio* calculations by *Wipff* and *Morokuma* (geometry optimization with an STO-3G basis set), norbornene *(1)* and norbornadiene *(2)* have nonplanar double bonds with the olefinic hydrogen atoms on the *endo*-side of the molecule[5]. In the structure calculated for *(1)*, the angle that the plane C1—C7—C4 makes with the plane of the olefin bridge (C1—C2—C3—C4) is larger than the angle which it makes with the saturated bridge (C1—C6—C5—C4). These structural details were explained by a repulsion between the methylene bridge and the $\pi_{23}$-orbital[5]. Experimental investigations do not, as yet, permit definite statements to be made concerning the planarity of these double bonds[6]. Bearing in mind the tendency of STO-3G calculations to underestimate the magnitude of bond angles, and hence, to spuriously produce a nonplanar geometry at the trigonal atoms[7], the results of the *ab initio* calculation were tested with the molecular mechanics method, which permits a very precise calculation of hydrocarbon geometries.

Fig. 1. Nonplanar olefins: Deviation $\Delta\omega$ of the CCCH-torsion angle from 180°, and (in brackets) magnitude of $\omega^*$. (Cycloheptene ring of *(4)* in chair conformation. Boat conformation is 1.16 kcal/mol higher in energy [4b].)

The geometries of *(1)* and *(2)* obtained from the molecular mechanics[4b] and *ab initio* methods[5], as well as those from electron diffraction experiments[6a], are in excellent agreement with each other[8]. The molecular mechanics calculations indicate that the double bonds in *(1)* and *(2)* are nonplanar; the deviation of the olefinic hydrogen atoms to the *endo*-side, amounting to around 1.7° in *(1)* and 2.2° in *(2)*, is significant in view of the high precision of the method. In addition, both computational methods yielded the same angle between the three bridging planes. The argument that the deplanarization of the double bond stems primarily from orbital repulsion is therefore invalid, since this concept does not exist within the formalism of molecular mechanics calculations. An exhaustive analysis of the individual interaction terms shows that the torsion angle $\omega^*$ between the olefinic H-atoms and the bridgehead H-atoms (at C1 and C4), is increased by the bending and hence leads to reduction of unfavorable torsional strain with the bridgehead H-atoms (Fig. 2). Such torsional strain has previously been discussed in connection with the increased reactivity of *exo*- relative to *endo*-norbornyl derivatives[9] and the preferred *exo*-orientation of cycloadditions to *(1)* and *(2)*[10], but not its effect on the geometry of *(1)* and *(2)* (or of the norbornyl cation, which also evades torsional strain in this way).

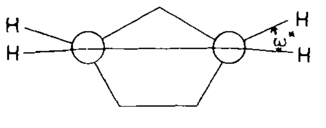

Fig. 2. Newman projection of *(1)* along the bonds C1—C2 and C3—C4 (C5 and C6 below, C7 above).

The explanation of the nonplanarity of *(1)* and *(2)* *via* torsional strain permits the prediction of the same effects in other cyclic olefins. Nonplanarity should occur in those olefins in which the methyl groups of *cis*-2-butene are bridged such that a conformation, where these groups are rotated away from the energy minimum of the *cis*-2-butene ($\omega^* = 60°$, Fig. 2) in a disrotatory manner, is fixed. This has been confirmed by molecular mechanics calculations on various species (Fig. 1). Thereby, a maximum value of the deplanarization occurs at intermediate values of $\omega^*$; if the torsion angle is small, the torsional potential is very flat, *i. e.* the deplanarization costs more energy than is gained in torsional energy. The double bonds in cycloheptene *(5)* and bicyclo[2.2.2]octene *(6)* are therefore planar. In contrast, the deplanarization increases in the case of alkylated double bonds, as in *(7)* and *(9)*.

A correlation appears to exist between the nonplanarity of double bonds and their reactivity. *Huisgen et al.* found that the rate of cycloaddition reactions in a series of planar olefins can be adequately explained by the reduction in strain caused by conversion of the olefin into a saturated product; in comparison, cycloadditions to *(1)* occur considerably more rapidly than is expected from the strain energy[10]. Effects such as the unequal extension of the π-orbitals above and below the double bond[5,10,11], which have been suggested as additional reaction-accelerating factors are, however, to be expected in all olefins having *out-of-plane* bent double bonds. In fact, the same increased reactivity as in *(1)* is found for cyclopentene *(3)*. In contrast to the olefins investigated by *Huisgen et al.*[10], the strain increases on hydrogenation of *(3)* (calculated strain energies[4b]: *(3)* 7.13 kcal/mol, cyclopentane 8.12 kcal/mol), and hence, using strain arguments, *(3)* must be less reactive than cyclohexene. In fact, it reacts approximately a hundred times faster[12] and when the various strain effects in *(1)*[10] and *(3)* are considered, the additional reaction acceleration factors in *(1)* and *(2)* are of the same order of magnitude.

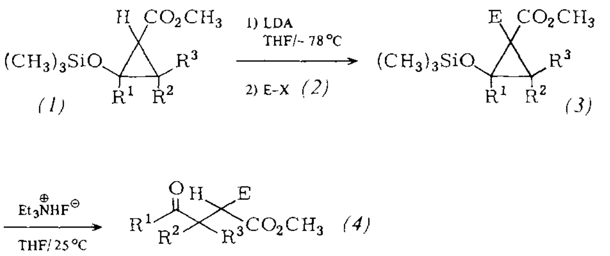
# Alkylation of Donor-Acceptor Substituted Cyclopropanes: A Flexible Route to 4-Oxocarboxylic Acid Esters[**]

By *Ingrid Böhm, Elisabeth Hirsch,* and
*Hans-Ulrich Reissig*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

We recently reported on the synthesis of the donor-acceptor substituted cyclopropanes *(1)* from silylenol ethers and methyl diazoacetate[1]. Their smooth ring-opening with fluoride ions leads to the methyl 4-oxocarboxylates *(4)* (E = H), which are useful precursors for cyclopentane, furan and lactone systems. The preparation of substituted derivatives of *(1)* and *(4)* with E = alkyl was therefore also of interest.

The use of higher diazoalkane carboxylic acid esters for the cyclopropanation of silylenol ethers is conceivable in principle, however the required diazoalkanes are generally not readily available[2]. Nonetheless, we anticipated that the subsequent alkylation of the cyclopropanecarboxylic acid ester *(1)* would lead to a better route to highly substituted derivatives of *(4)*.



In fact, solutions of the ester *(1)* in tetrahydrofuran (THF) can be smoothly deprotonated at –78 °C by lithium diisopropylamide (LDA). The ester enolate ions react with reactive alkyl halides *(2)*[3] to give the substituted cyclopropanecarboxylic acid esters *(3)* in excellent yields (Table 1)[4]. Whereas 1-iodobutane reacts without complications, 2-iodopropane cannot be used, even under different reaction conditions; presumably an elimination reaction occurs with secondary halides.

[a] Non-optimized yields of isolated products after Kugelrohr distillation; all novel compounds gave appropriate spectra and satisfactory combustion analyses. [b] Degree of alkylation after GC analysis > 95%.

To our knowledge, the reaction *(1)*→*(3)* represents the first alkylation of a cyclopropanecarboxylic acid ester[5]. The ester enolate ions of *(1)* can also be considered as homoenolates; after hydrolysis, compounds are obtained in which an electrophile has been introduced in the β-position to the keto- or aldehyde functionality, respectively, which was originally masked in our version of the "cyclopropane trick"[6].

Using the readily available triethylammonium fluoride[7], ring opening of *(3)* proceeds under mild, almost neutral conditions to give the 2-substituted methyl 4-oxoalkanecarboxylates *(4)* in good yield. Even the methyl 3-formylpropionates *(4j)* and *(4k)* can be synthesized without difficulty.

Since the starting silylenol ethers are readily accessible and can be manifoldly varied[8], the reaction sequence described is one of the most flexible routes to highly substituted 4-oxo-carboxylic acid esters as far as both R¹- to R³-moieties and the group E are concerned[9]. Ring opening reactions with strong electrophiles (*e.g.* halogens or carbonyl compounds/$TiCl_4$) indicate that siloxy-substituted cyclopropanecarboxylic acid esters are valuable building blocks for use in other syntheses[10].

## *Procedure*

A solution of *(1a)* (1.00 g, 4.10 mol) in 1 cm³ THF is dropped into a solution of LDA (4.9 mmol) in 10 cm³ THF at –78 °C and the mixture stirred for 1 h at this temperature. The clear, pale yellow solution is treated with 1-iodobutane (1.51 g, 8.2 mmol), left first for 5 h at –78 °C and then slowly warmed up to room temperature within 15 h. The usual work-up conditions ($NH_4Cl$, diethyl ether) gave, after Kugelrohr distillation at 80 °C/0.01 torr, 1.12 g (91%) analytically pure *(3b)*.

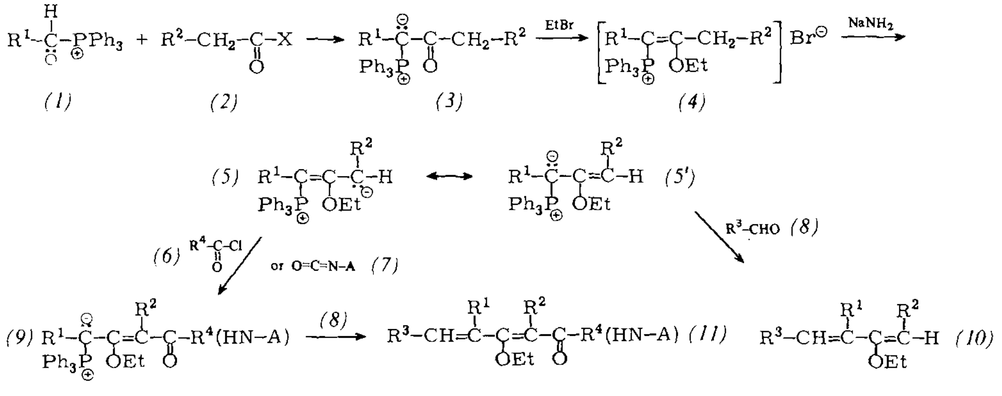
# A Novel Route to 2-Ethoxybutadienes; Diels-Alder Reaction of 1,2-$\lambda^5$-Oxaphosphorines

By *Hans-Jürgen Bestmann* and *Kurt Roth*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

2-Ethoxybutadienes are, as enol ethers of α,β-unsaturated carbonyl compounds, versatile and useful synthons. We describe here, a variable synthetic method for this class of compounds starting from primary alkyl halides, carboxylic acids and aldehydes.

Alkylidenetriphenylphosphoranes *(1)*, whose ylide substructure is formed from a primary alkyl halide or alcohol, can be transformed by treatment with the carboxylic acid derivatives *(2)* to acyl ylides *(3)*[1]. The ambidentate[2] phosphoranes *(3)* are *O*-alkylated[3], by treatment with ethyl bromide, to the phosphonium salts *(4)*, from which a γ-proton can be abstracted by sodium amide[4]. The 2-ethoxyallylidenetriphenylphosphoranes, which are described in the mesomeric limiting structures *(5)* and *(5′)* are thus formed, and formally react as *(5′)* with aldehydes *(8)* in a Wittig reaction to the 2-ethoxybutadienes *(10)* (Table 1); as enol ethers they are readily converted into α,β-unsaturated ketones by known methods.



On the other hand, the ylides *(5)* react with acid chlorides *(6)* at the γ-position to the P atom[5]. Thus, apart from 1 mole of the phosphonium salt ($Cl^{\ominus}$ instead of $Br^{\ominus}$), the acylphosphoranes *(9)* are formed from *(5)* and *(6)* (2 : 1 molar ratio). Isocyanates *(7)* also attack the allyl ylides *(5)* at the γ-position to form, after proton rearrangement, the carbamoyl-substituted compounds *(9)*[6]. Wittig reaction of *(9)* with *(8)* produces the 1-acyl-2-ethoxybutadienes *(11)* (Table 1), from which, *inter alia*, γ,δ-unsaturated 1,3-dicarbonyl compounds and derivatives of the 2,3-dihydro-4-pyrones can be obtained[7].

*(9)*, which is describable *via* mesomeric limiting structures, should exist in several different conformations. It therefore follows, in particular when $R^2 \neq H$, that reaction of *(8)* with *(9)* should lead to formation of compound *(11)* having a mixture of *Z*,*E*-isomers at the 1-position. In contrast, carbonyl olefination forms a new double bond having *E*-geometry which is in accord with our concepts of the mechanism of the Wittig reaction[8a].

It should be possible to cyclize *(9′)* to the 1,2-$\lambda^5$-oxaphosphorines *(12)*, in which the oxygen atom primarily occupies the apical position[8]. In the $^{31}$P-NMR spectra, particularly that of *(9)* ($R^2 \neq H$), two broad signals appear at $\delta = +10$ to $+16$ and $-20$ to $-50$ ($H_3PO_4$ as external standard); these indicate an equilibrium between *(9)* and *(12)*. In polar solvents such as $CDCl_3$, this lies more on the side of *(9)*, while in nonpolar solvents, such as benzene and toluene, *(12)* is more predominant. If solutions of *(9)*/*(12)* $R^1 = H$ in toluene are treated with *N*-methylmaleimide *(13)*, the substituted *N*-methylphthalimides *(17)*[9] and triphenylphosphane oxide *(15)* can be isolated whose formation we account for by the following mechanism: *(12)*, in a Diels-Alder reaction with *(13)*, yields the bicycle *(14)*. After ligand rearrangement to *(14′)*, the bridgehead C-atom bonded to the phosphorus occupies an apical position in the trigonal bipyramid, permitting cleavage of the C—P bond[8], which is cleaved in a cycloreversion to *(15)*. The dihydrophthalimide derivative *(16)* is formed, which is dehydrated in the work-up to *(17)*. In principle, a cycloaddi-

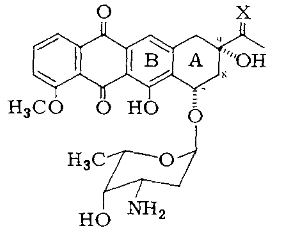
# Synthesis of (±)-13-Deoxo-11-deoxydaunorubicinone[**]

By *Karsten Krohn*[*]

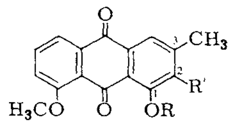
*Dedicated to Professor Albert Mondon on the occasion of his 70th birthday*

In the search for novel anthracycline antibiotics *Acramone et al.*[1] succeeded in isolating 13-deoxo-11-deoxydaunorubicin *(1)* and 11-deoxydaunorubicin *(2)*, which proved to have particularly useful antitumor effects in animals.

The synthesis of anthracyclinones, having only one hydroxy group at ring B, derived from the chromophore 1,8-dihydroxy-9,10-anthraquinone, has been reported to be difficult using existing methods[2]. We have, however, been able to prepare the naturally occurring 13-deoxo-11-deoxydaunorubicinone *(11)* for the first time, using a novel variation of the cyclization of doubly alkylated anthraquinones[3].



*(1)*, X = $H_2$
*(2)*, X = O



| | R | R' |

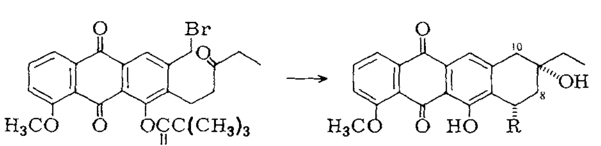
| *(4)* | H | $CH_2OH$ |
| *(5)* | H | $CH_2Cl$ |
| *(6)* | H |  |
| *(7)* | H |  |
| *(8)* | OCO–C$(CH_3)_3$ |  |



*(9)*

*(10)*, R = H
*(11)*, R = OH

The starting material was the readily accessible 8-*O*-methyl ether of chrysophanol *(3)*[4]. Hydroxymethylation of *(3)* in the *o*-position using formaldehyde, in a modification of the Marschalk reaction[5], gave the benzyl alcohol *(4)* in 82% yield (decomp. above 190 °C). Reaction of *(4)* with thionyl chloride led, quantitatively, to the chloromethyl

[**] Synthetic Anthracyclinones, Part 17. Part 16: [4].

compound *(5)* (m.p. = 135 °C), which could be converted into the β-keto ester *(6)* (m.p. = 130 °C; 97%) by treatment with ethyl 2-oxovalerate (EtONa, 50 °C, 1 h). Saponification to the acid and decarboxylation (160 °C, 15 min) produced the ketone *(7)* (m.p. = 155–156 °C, 94%) as the main intermediate. To ensure that the planned reaction with *N*-bromosuccinimide selectively functionalized only the C-3 methyl group, the α-position to the keto group was protected by formation of the ethylene acetal (m.p. = 154—155 °C, 96%). The competing benzyl site on the side chain at C-2 was sterically shielded by formation of the pivolate *(8)* (m.p. = 143 °C, 94%). In the subsequent light-induced bromination of *(8)* with *N*-bromosuccinimide, the monobromo-product *(9)* (m.p. = 141–142 °C, 70%) was the major product formed. The ring-closure to the anthracyclinone *(10)* (m.p. = 185—186 °C) proceeded in 63% yield by treatment of *(9)* with magnesium, which had previously been activated with 1,2-dibromoethane. As in previous instances[5b], the cyclization of *(10)* could be easily recognized from the coupling constants of the C-8 protons in the $^1$H-NMR spectrum[6].

Introduction of a hydroxy group at the C-7 position of *(10)* was carried out *via* photolytic bromination; the labile products were dissolved in 0.5 N NaOH. Apart from aromatization products, only the racemic 7,9-*cis*-diol *(11)* (m.p. = 216 °C), formed in a stereoselective reaction, could be isolated in 62% yield. It's chromatographic and spectroscopic properties are in accord with the naturally occurring substance[7]. – Starting from *(9)*, it should also be possible to synthesize the pharmacologically important class of akalavinones[8].

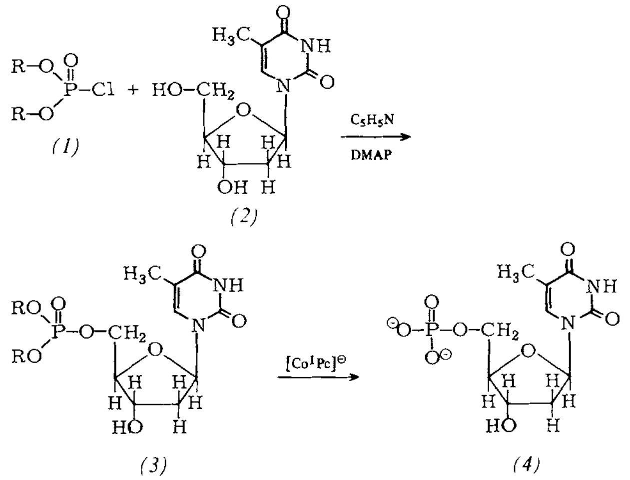
## Bis(2,2,2-trichloro-1,1-dimethylethyl) Monochlorophosphate, a Selective Reagent for the Phosphorylation and Protection of the 5′-OH Group of Nucleoside Derivatives[**]

By *Herbert A. Kellner, Ruth G. K. Schneiderwind, Heiner Eckert*, and *Ivar K. Ugi*[*]

*Dedicated to Professor Helmut Zahn on the occasion of his 65th birthday*

5′-Phosphorylated oligonucleotides, required for enzymatic nucleotide syntheses, are normally obtained by deblocking the 5′-trityl- or 5′-dimethoxytrityl-derivatives followed by enzymatic or conventional preparative 5′-phosphorylation[1].

In a preliminary investigation, we found that of the many reagents studied, bis(2,2,2-trichloro-1,1-dimethylethyl) monochlorophosphate *(1)*[2] [bis(trichloro-*tert*-butyl) monochlorophosphate = bis-2-TCB monochlorophosphate] was the only one able to simultaneously selectively phosphorylate and protect the terminal 5′-OH group in the synthesis of 5′-phosphorylated oligonucleotides. This reagent attacks the 5′-OH group, in the presence of a free 3′-OH group, just as selectively as trityl chloride and its analogues. The TCB-phosphate group survives all the necessary steps in the oligonucleotide synthesis, but can readily be removed by the cobalt(I)-phthalocyanine anion $[Co^IPc]^{\ominus}$[3].



R = $Cl_3C{-}C(CH_3)_2{-}$

The synthetic principles are illustrated in the following example:

Thymidine *(2)* reacts with *(1)* in pyridine, in the presence of ≥ 10 mol% 4-dimethylaminopyridine (DMAP)[4], to give *(3)* in 72% yield. The latter product when treated with $[Co^IPc]^{\ominus}$ releases thymidine 5′-phosphate *(4)*. The DMAP-catalysis of the reaction *(1)* + *(2)* → *(3)* depends on the intermediate formation of *(5)* from *(1)* and DMAP[5].

*(5)*

Deblocking with $[Co^IPc]^{\ominus}$, in which the first TCB-moiety is cleaved considerably more rapidly that the second, proceeds almost quantitatively at sufficiently long reaction times. For example, from a molar solution, 84% *(4)* and 16% of the mono-TCB derivative were obtained after 2 d at 20 °C, while after 4 d the ratio was 90 : 10.

### *Procedure*

Improved synthesis of *(1)* (cf.[2a]): A solution of dry 2-trichloromethyl-2-propanol (177.5 g, 1 mol) and pyridine (80.5 cm$^3$, 1 mol) in 300 cm$^3$ pentane is treated with $PCl_3$ (43.5 cm$^3$, 0.5 mol) in 150 cm$^3$ pentane at 0 °C under an $N_2$-atmosphere; the mixture is stirred for 1 d at room temperature and finally stirred and refluxed for 2 h. The precipitate of pyridine hydrochloride is filtered off, the

Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

solvent removed and the residue fractionally distilled *in vacuo*. 150 g (71%) of bis(2,2,2-trichloro-1,1-dimethylethyl) monochlorophosphite (m.p. = 46 °C, b.p. = 134°/0.015 torr) is obtained. A cooled solution of the phosphite (109 g, 259 mmol) in 200 $cm^3$ chloroform is added in the dark under an $N_2$-atmosphere to a suspension of (diacetoxyiodo)benzene[6] (91 g, 294 mmol) in 500 $cm^3$ chloroform cooled to −15 °C. The mixture is allowed to warm up slowly to room temperature and is stirred for 2 d. After evaporation of the solution and covering the residue with pentane, 74 g (65%, relative to the phosphite) of crystalline *(1)* is obtained (m.p. = 81 °C).

*(3):* A mixture of *(2)*[7] (0.24 g, 1 mmol), *(1)* (0.87 g, 2 mmol) and DMAP (0.02 g, 0.2 mmol) is stirred for 24 h at 50 °C. The solvent is then removed, the residue taken up in a little chloroform and precipated with 100 $cm^3$ pentane. The precipate is dissolved in 50 $cm^3$ chloroform, filtered, washed twice with citrate buffer (pH 6) and twice with water, and then dried over $Na_2SO_4$. Chromatography on silica gel (Merck $60\,F_{254}$) using chloroform/methanol (9 : 1) as eluent gives *(3)* (0.46 g, 72%) (m.p. = 186 °C).

*(4):* A solution of $Li^I[Co^IPc]\cdot 4.5$ tetrahydrofuran (2.51 g, 2.8 mmol) and *(3)* (0.39 g, 0.6 mmol) in 20 $cm^3$ acetonitrile is stirred in the absence of oxygen at room temperature for 48 h. The green mixture is treated, at 0 °C, with 40 $cm^3$ $H_2O$ and $CO_2$ and air immediately passed in for 5 min. The violet precipate is centrifuged off (5 min, 3000 r.p.m.) and washed three times with water. The combined centrifugates are treated with 1 N hydrochloric acid until decomposition of the $LiHCO_3$ at pH 6.5 occurs, concentrated and the product converted to the Na salt on a Lewatit S100 G1 ion exchanger: 300 mg *(4)*, which contains 16% of the mono-TCB-derivative as impurity, is obtained.

## Redox Reltionship between Carbeneiron and σ-Alkyliron Porphyrins[**]

By *Doris Lexa, Jean-Michel Savéant, Jean-Paul Battioni, Marc Lange,* and *Daniel Mansuy*[*]

Porphyrin complexes with Fe—C bonds are likely to be involved in the enzymatic reactions of cytochrome P450 hemoproteins of the monooxygenase systems responsible for the detoxification of exogenous compounds by living organisms. In this connection, evidence has been given for the formation of iron-carbene bonds during the oxidation of 1,3-benzodioxole derivatives by the active oxygen cytochrome P450 complex[1]. Involvement of σ-alkyliron complexes as intermediates in this reaction has also been proposed[1c]. On the other hand, carbeneiron complexes are formed upon reduction of various polyhalogenated compounds by cytochrome P450-$Fe^{II}$[2] or by reacting the polyhalogenated substrates with iron(II)-porphyrins under reducing conditions[3]. These reactions may involve the intermediacy of σ-halogenated alkyliron porphyrins of the same type as those recently observed in a pulse radiolysis study of the reaction of halogenated alkyl radicals with $Fe^{II}$-porphyrins[4]. It is noteworthy that only one σ-alkyl[5a] and very few σ-aryliron porphyrins[5] have been reported so far: they have all been obtained as $Fe^{III}$ σ-derivatives, prepared by reaction of a Grignard reagent with $Fe^{III}$-porphyrins.

We report here the preliminary results of a study based on an electrochemical investigation of the reduction of carbeneiron(II)-porphyrin complexes in aprotic media[6], which establishes a redox relationship between carbeneiron and σ-alkyliron porphyrins and opens a new route to σ-alkyliron porphyrins both at the $Fe^{II}$ and $Fe^{III}$ oxidation levels.

The three *meso*-tetraphenylporphyrin complexes (TPP[7])

$(TPP)FeC{=}X$ *(1a):* $X = C(p\text{-}C_6H_4Cl)_2$
*(2a):* $X = C(C_6H_5)_2$
*(3a):* $X = S$

were prepared according to previously described procedures[8]; the reaction medium was a 0.1 M solution of $Bu_4NBF_4$ in DMF[9]. Typical cyclic voltammograms obtained under these conditions are shown in Figure 1.

The $Fe^{II}$-carbene complex is reduced in two successive one-electron steps. While the first one-electron reduction gives rise to products [*(1b)*, *(2b)* or *(3b)*] which are stable for *ca.* 1 s, the second reduction product undergoes irreversible decomposition leading to new types of complexes [*(1d)*, *(2d)* or *(3d)*] which can be electrochemically reoxidized between −0.4 and −0.6 V. This process is reversible for complexes *(1d)* and *(2d)* and irreversible for *(3d)* at low sweep rates. In the latter case, reversibility can, however, be restored by raising the sweep rate. The standard potentials for this new redox couple are: *(1c/d)* −0.62 V, *(2c/d)* −0.64 V and *(3c/d)* −0.44 V (*vs.* SCE). The second wave can also be rendered reversible by drastically raising the sweep rate to *ca.* 100—1000 $vs^{-1}$. Addition of water de-

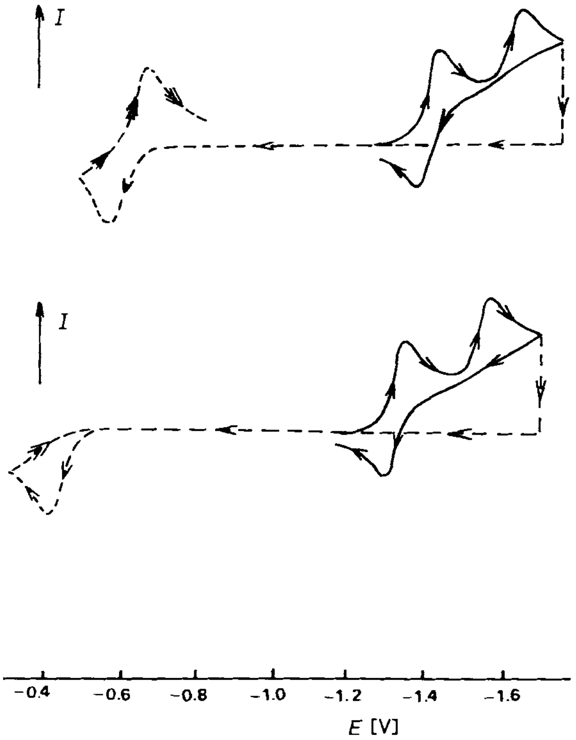

Fig. 1. Cyclic voltammograms of the carbeneiron(II) porphyrins *(1a)* and *(2a)* (top) as well as *(3a)* (bottom) at low sweep rate (0.2 V s$^{-1}$). (——): reduction of complexes; (-----): reoxidation of complexes obtained by 2e-reduction of *(1a)*—*(3a)*.

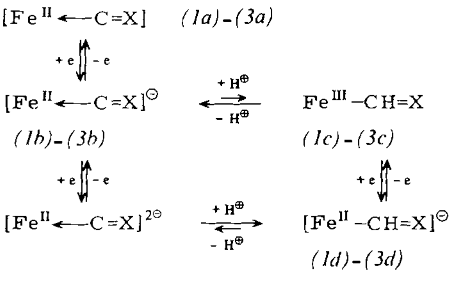
creases the reversibility of the wave. Coulometric investigations of the second wave, under standard electrolysis conditions, shows the exchange of two Faradays per mole.

These results suggest the redox mechanism shown in Scheme 1 for the observed reactions, which involves formation of the σ-alkyl Fe(II) complexes *(1d)*—*(3d)* by (2e + H$^{\oplus}$)-reduction of *(1a)*—*(3a)*.



Scheme 1. *(1)*, X = C($p$-$C_6H_4Cl)_2$; *(2)*, X = C($C_6H_5)_2$; *(3)*, X = S.

That a σ-alkyliron(II) complex is actually formed was demonstrated for *(2d)* by independent synthesis. The σ-vinyl Fe(III) complex *(2c)* was prepared as a purple crystalline air-sensitive solid by reaction of BrMgC=CPh$_2$ with (TPP)FeClO$_4$ in THF[10]. Its elemental analysis and mass spectrum are in accord with the suggested structure. Furthermore, the UV-spectrum [λ = 529 (ε = 9100), 426 nm (11 500)] is very similar to that of (TPP)Fe$^{III}C_6H_5$[5c]. The nature of the axial ligand of iron was further confirmed by reaction of *(2c)* with HCl which leads quantitatively to (TPP)Fe$^{III}$Cl and 1,1-diphenylethene. *(2c)* gives rise to a cyclic voltammetric one-electron reversible wave at exactly the same potential as the reoxidation wave from the (2e + H$^{\oplus}$)-reduction of the carbeneiron(II) complex *(2a)*. Moreover, the UV/VIS spectrum obtained upon one electron reduction of *(2c)* is the same as that of the product obtained by (2e + H$^{\oplus}$)-reduction of *(2a)* [λ = 795 (ε = 4700), 511 (12 600), 428 (75 000), 356 nm (31 500)]. The complex resulting from this reduction decomposes upon addition of 1 M HCl with quantitative formation of diphenylethene. Very similar reduction patterns were obtained with the carbene complexes of octaethylporphyriniron(II), the characteristic potentials being more negative by *ca.* 100 mV.

In conclusion, the results show that σ-alkyliron(II) porphyrins are formed upon (2e + H$^{\oplus}$)-reduction of the corresponding carbeneiron(II) complex. The σ-alkyliron(III) complexes can then be obtained by a 1e-reoxidation reaction. In the case of *(3a)* this redox relationship can be reversed. This is shown by the chemical irreversibility of the reoxidation wave of the σ-alkyliron(II) complex [Fig. 1, *(3a)*] and by the fact that upon slow reoxidation it forms the carbene complex *(3a)* again. This type of reversibility could not be observed in *(1a)* and *(2a)* where the σ-alkyliron(III) derivative slowly cleaves off the carbon ligand rather than deprotonate and reoxidize to the carbeneiron(II) complex.

[8] *D. Mansuy, M. Lange, J. C. Chottard,* J. Am. Chem. Soc. *100*, 3213 (1978); *D. Mansuy, J. P. Battioni, J. C. Chottard, ibid. 100*, 4311 (1978).

[9] No special precautions were taken to remove traces of water, which was present in concentrations of 0.1-0.5%.

[10] Standard procedure: A solution of 0.5 mmol (TPP)FeCl in THF was successively treated with one equivalent of AgClO$_4$ and three equivalents ($C_6H_5)_2$C=CHMgBr (0.5 M in THF). The reaction mixture was filtered, the THF removed, benzene added and washed with degassed water; the benzene was partially removed. Upon addition of pentane, the complex *(2c)* was obtained as a fine, purple powder. The crystals retain 1 mol water, as shown by the elemental analysis.

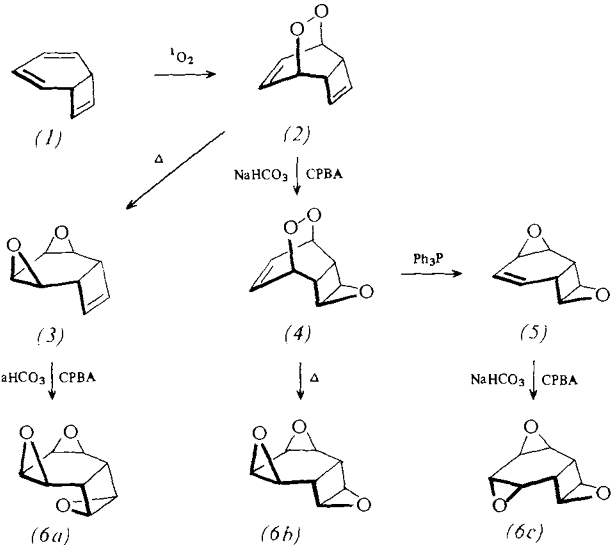
# Triepoxides of Bicyclo[4.2.0]octa-2,4,7-triene[**]

By *Waldemar Adam, Omar Cueto, Ottorino De Lucchi,*
*Karl Peters, Eva-Maria Peters*
and *Hans Georg von Schnering*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

A total of six diastereomeric triepoxides, *(6a)—(6f)* of the bicyclo[4.2.0]octa-2,4,7-triene *(1)*, a valence isomer of cyclooctatetraene, are possible. Here, we report on the diastereoselective synthesis of the triepoxides *(6a)—(6c)*. The starting material, the endoperoxide *(2)*, was prepared[2] by [4+2]-cycloaddition of singlet oxygen to the thermally labile triene *(1)*[1].

On heating a benzene solution of the endoperoxide *(2)* at 100 °C for 1 h, the diepoxide *(3)* was isolated in 80% yield[3]. Treatment of *(3)* with *m*-chloroperbenzoic acid (CPBA) in dichloromethane (25 °C, 48 h) in the presence of solid $NaHCO_3$ as buffer, afforded the triepoxide *(6a)* in 70% yield[4]. The NMR spectra did not permit an unequivocal assignment of the stereochemistry of the cyclobutane epoxide ring. X-ray structure analysis revealed, however, that the epoxidation had led to the *(6a)* isomer (Fig. 1). Dreiding models show that an *exo*-attack by CPBA should be preferred. Presumably stereoelectronic reasons must come into play to rationalize the unexpected *endo*-attack.



Epoxidation of the endoperoxide *(2)* with CPBA (25 °C, 36 h) gave the expected epoxy-endoperoxide *(4)* in 70% yield[5]. Steric reasons preclude *endo*-attack on the double bond of the four-membered ring. On heating a benzene solution of *(4)* (80 °C, 12 h) the triepoxide *(6b)* was obtained in 60% yield[6]. An X-ray structure analysis confirms the given configuration (Fig. 1).

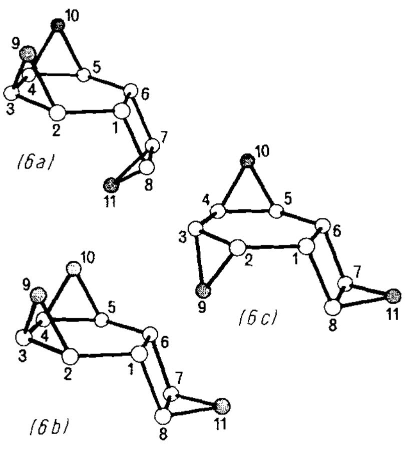


Fig. 1. Structures of *(6a)*, *(6b)* and *(6c)* in the crystal.

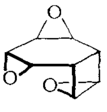
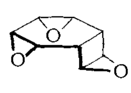
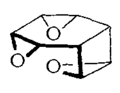
*(4)* also served as precursor in the stereoselective synthesis of the triepoxide *(6c)*; a chloroform solution of *(4)* reacts with triphenylphosphane (0 °C, 0.5 h and 25 °C, 1 h) to give the diepoxide *(5)* in 42% yield[7]. Epoxidation with CPBA (25 °C, 40 h) afforded the triepoxide *(6c)* in 60% yield[8]. An X-ray structure analysis of *(6c)* corroborated the proposed structural assignment (Fig. 1).



*(6d)*



*(6e)*



*(6f)*

By means of these diastereoselective syntheses the novel triepoxides *(6a)—(6c)* could be conveniently prepared from the endoperoxide *(2)*. For the remaining diastereomers *(6a)—(6f)* other strategies must be developed[9].

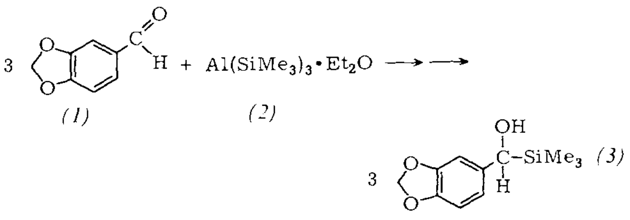
# Facile Nucleophilic Silylation Reactions at Carbonyl Functionalities Using Trimethylsilylaluminum Compounds[**]

By *Lutz Rösch, Gerald Altnau* and *Wolfgang Helmut Otto*

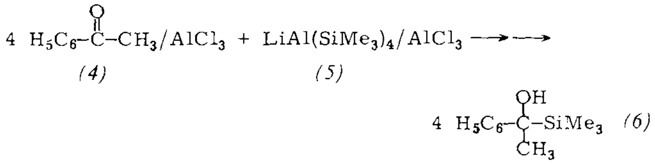
Silylated organic compounds are valuable starting materials in numerous syntheses. Hereby, the organosilyl group can assume both the function of a protecting group and in addition steer the course of the reaction. The trimethylsilyl group is most frequently used for this purpose[1]. While many effective methods for the electrophilic transfer of this group exist[2], directed nucleophilic silylation is generally only feasible with difficulty. Until now, the reagents available for this purpose—solutions of trimethylsilyl(alkali metal)[3] or bis(trimethylsilyl)mercury[4]—have been difficultly accessible and/or are only stable for short times; sometimes, the reactions are accompanied by side-reactions[5]. In contrast, trimethylsilylaluminum compounds are conveniently prepared, even in large amounts, and can be stored for long periods at room temperature under an inert gas.

It has already been shown that the reaction of such Si—Al compounds with inorganic substrates can be used to transfer trimethylsilyl groups[6]. In order to test to what extent they are also suitable for nucleophilic silylation in organic chemistry, the reaction of ether-coordinated tris(trimethylsilyl)aluminum *(2)*[7] and of lithium tetrakis(trimethylsilyl)aluminate *(5)*[8] with an aldehyde (piperonal) *(1)*, a ketone (acetophenone) *(4)*, and an ester (methyl benzoate) *(8)* was investigated. The reactions were performed in an analogous way to $LiAlH_4$ reductions, since silylation reactions of this type are readily comparable to these.

Reduction of aldehydes with $LiAlH_4$ produces primary alcohols. Reaction of piperonal *(1)* with *(5)* in diethyl ether firstly results in formation of a yellow solution; after decomposition with methanol/hydrochloric acid, removal of acid by washing and extraction, a green oil is obtained. Examination of this by thin layer chromatography reveals four products. The expected product, 3,4-methylenedioxy-α-(trimethylsilyl)benzyl alcohol *(3)*, can be isolated in 48% yield, in addition to 6.7% *(1)*, 5.8% 3,4-methylenedioxyphenyl trimethylsilyl ketone and 1.9% 3,4-methylenedioxybenzyl alcohol, by column chromatography. If the reaction is carried out with ether-coordinated tris(trimethylsilyl)aluminum *(2)*, the thin layer chromatogram reveals only one product, the desired α-silylalcohol *(3)*, which can be isolated in practically quantitative yield without recourse to separation procedures. All three trimethylsilyl groups *(2)* are transferred.



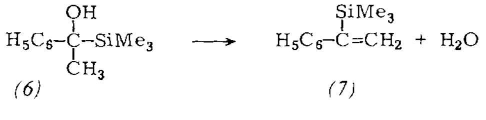
Ketones are converted to secondary alcohols by treatment with $LiAlH_4$. Acetophenone *(4)* does not react with *(5)*. This is, however, not astonishing, since *(4)* is a member of a group of ketones which are difficult to reduce and which cannot be simply reduced by $LiAlH_4$[9]. In these situations "mixed hydrides", for example the mixture $LiAlH_4$/$AlCl_3$, have been successfully used[10]. By analogy, *(4)* was coordinated with aluminum chloride and dropped into a "mixed silyl", in an ethereal solution of *(5)* and $AlCl_3$ (1:1).



$$4\ H_5C_6-\overset{O}{\overset{\|}{C}}-CH_3/AlCl_3\ +\ LiAl(SiMe_3)_4/AlCl_3 \longrightarrow 4\ H_5C_6-\underset{CH_3}{\underset{|}{\overset{OH}{\overset{|}{C}}}}-SiMe_3$$

*(4)* *(5)* *(6)*

Under these conditions the desired final product, 1-phenyl-1-(trimethylsilyl)ethanol *(6)* is formed. However, this compound is not particularly stable and decomposes quantitatively with loss of water to give α-(trimethylsilyl)styrene *(7)*.

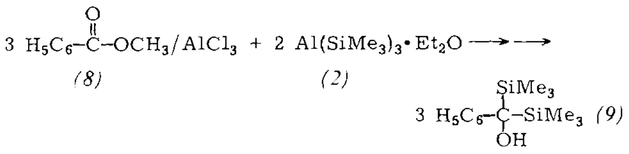


$$H_5C_6-\underset{CH_3}{\underset{|}{\overset{OH}{\overset{|}{C}}}}-SiMe_3 \longrightarrow H_5C_6-\overset{SiMe_3}{\overset{|}{C}}=CH_2\ +\ H_2O$$

*(6)* *(7)*

After drying with magnesium sulfate, the vinylsilane *(7)* can be isolated practically quantitatively. This is a particularly facile route to *(7)*. The analogous reaction of *(4)*/$AlCl_3$ with *(2)* leads to the same result.

Carboxylic acid esters are reduced by $LiAlH_4$ to primary alcohols. However, methyl benzoate *(8)* does not react with *(2)* or *(5)* or with *(5)* and $AlCl_3$. In contrast, if $AlCl_3$-coordinated *(8)* is reacted with *(2)* in boiling diethyl ether, the desired α,α′-bis(trimethylsilyl)benzyl alcohol *(9)* is obtained as the only silylated product in 79% yield after work-up.



$$3\ H_5C_6-\overset{O}{\overset{\|}{C}}-OCH_3/AlCl_3\ +\ 2\ Al(SiMe_3)_3\cdot Et_2O \longrightarrow 3\ H_5C_6-\underset{OH}{\underset{|}{\overset{SiMe_3}{\overset{|}{C}}}}-SiMe_3$$

*(8)* *(2)* *(9)*

These model reactions show that trimethylsilylaluminum compounds can be used for the nucleophilic silylation of carbonyl functionalities.

## *Procedure*

All reactions with *(2)* and *(5)* must be carried out in the abscence of air and moisture (argon as inert atmosphere).

Dr. W. H. Otto, Institut für Organische Chemie der Technischen Universität Berlin (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Products were characterized by IR-, $^1$H-NMR- and mass spectroscopy.

*(3), (6), (9): (2)* or *(5)* are added to 20—30 mL $Et_2O$ and the organic component, dissolved in approximately the same volume of $Et_2O$, dropped into the mixture. (When $AlCl_3$-coordinated substances are used, the calculated quantity of $AlCl_3$ is added to the cooled substance dissolved in $Et_2O$.) After addition, the mixture is heated for 3—4 h under reflux. The mixture is subsequently cooled to room temperature, treated with 2 mL methanol and finally *ca.* 2 mL dilute HCl added until the precipitate just starts to dissolve. The solution is extracted with $Et_2O$ washed with saturated $NaHCO_3$ solution until free of acid and with saturated NaCl solution until neutral. The solution is then dried with $MgSO_4$, filtered and the solvent removed on a rotary evaporator; the desired substance remains as residue (see Table 1).

## Trimethylsilylaluminium Compounds as Catalyst Components in the Polymerization of Ethene[**]

By *Lutz Rösch* and *Gerald Altnau*[*]

From the broad definition of the patent specifications, the Ziegler-Natta polymerization catalyst consists of a mixture of an alkyl-main group metal compound and a transition metal salt[1]. The combination of alkylaluminum and titanium compounds has proved to be particularly effective. Depending on the composition, the catalyst is obtained in soluble, insoluble or colloidal forms. Having recently found simple preparative routes to a series of trimethylsilylaluminum compounds, we investigated whether they were suitable for use as co-catalysts, in place of the homologous alkylaluminum derivatives, for the polymerization of ethene.

A soluble system results when dicyclopentadienyltitanium(IV) compounds are used as the metal component. Reactions with this system, however, proceed unsatisfactorily (Table 1). Uptake of ethene, in the presence of tris(trimethylsilyl)aluminum[2] or bis(trimethylsilyl)aluminum chloride[3], could not be observed, either at 20 or −25 °C. The $Cp_2Ti(Cl)Et/Al(SiMe_3)_2Cl$ and $Cp_2Ti(Cl)SiMe_3/AlEt_2Cl$ systems show only a small degree of activity; this appears to confirm the general hypothesis that for polymerization it is necessary to have a transition metal-carbon bond as the active center[4]. In the last mentioned system, it is assumed that the trimethylsilyl- and ethyl-groups exchange between the titanium[5] and aluminum compounds. The results obtained with a heterogenic catalyst system[6] of the Solvay type are also indicative of this hypothesis (Table 2). Only the $MgOTi/EtAl(SiMe_3)_2$ system, which can form a titanium-carbon bond, shows polymerization activity.

Table 1. Investigation of the polymerization of ethene with soluble catalyst systems [a].

| System | $T$ [°C] | $t$ [min] | PE [g] |
|---|---|---|---|
| $Cp_2TiCl_2/Al(SiMe_3)_2Cl$ | 20 | 60 | — |
| $Cp_2TiCl_2/Al(SiMe_3)_2Cl$ | −25 | 60 | — |
| $Cp_2TiCl_2/Al(SiMe_3)_3$ | 20 | 60 | — |
| $Cp_2TiCl_2/Al(SiMe_3)_3$ | −25 | 60 | — |
| $Cp_2TiCl/EtAl(SiMe_3)_2$ | 20 | 60 | — |
| $Cp_2Ti(Cl)Et/Al(SiMe_3)_2Cl$ | 20 | 30 | 4 |
| $Cp_2Ti(Cl)SiMe_3/AlEt_2Cl$ | 20 | 150 | 6 |

[a] PE = isolated polyethylene. Cp = cyclopentadienyl. All experiments in toluene, titanium component $10^{-3}$ mol/L, aluminum component $2\times10^{-3}$ mol/L.

Table 2. Investigation of the polymerization of ethene with heterogeneous catalyst systems [a].

| System [6] | $T$ [°C] | $t$ [min] | PE [g] |
|---|---|---|---|
| MgOTi/Al(SiMe$_3$)$_3$ | 80 | 120 | — |
| MgOTi/EtAl(SiMe$_3$)$_2$ | 40 | 120 | 52 |
| MgOTi/Al(SiMe$_3$)$_2$Cl | 40 | 120 | — |

[a] All experiments in toluene, titanium component $10^{-3}$ mol/L, aluminum component $10^{-2}$ mol/L.

In previous investigations, the aluminum component was always used in excess. *Razuvaev et al.* reported, that tetrakis(trimethylsilyl)titanium, which decomposes at 0 °C[7], is formed from titanium tetrachloride and trimethylsilyllithium. We obtained similar results with the $TiCl_4/Al(SiMe_3)_3 \cdot Et_2O$ system. However, on the basis of the steric shielding of the four trimethylsilyl groups, a tetrakis(trimethylsilyl)titanium species should not be suitable as a catalyst. An olefin species would be offered better attacking possibilities by a partially silylated titanium compound. For this reason, an excess of titanium tetrachloride was used and because of the anticipated thermolability of the trimethylsilyl-titanium-chlorine compounds, the reactions were carried out at −30 °C. In order to avoid persilylation, the titanium tetrachloride was first placed in the flask and the aluminum component added to this in a dropwise fashion. Under these conditions uptake of ethene is observed, even in the absence of an alkylating reagent (Table 3). The activity depends on the ratio $TiCl_4/Al(SiMe_3)_3 \cdot Et_2O$, the best result to date being reached with a ratio of 5 : 2. This is the first catalyst in which, at least in the first polymerization step, a transition metal-silicon bond, instead of a transition metal-carbon bond, is present. In contrast to the usual Ziegler-Natta systems, the aluminum component is used in excess. The low temperature of the polymerization is also of note.

Table 3. Investigation of polymerization of ethene with the $TiCl_4/Al(SiMe_3)_3 \cdot Et_2O$ system [a].

| $TiCl_4$ [mol] | $Al(SiMe_3)_3 \cdot Et_2O$ [mol] | $t$ [min] | PE [g] |
|---|---|---|---|
| $1.5 \times 10^{-3}$ | $10^{-3}$ | 90 | 0.05 |
| $10^{-2}$ | $3 \times 10^{-3}$ | 120 | 1.4 |
| $10^{-2}$ | $5 \times 10^{-3}$ | 60 | 13 |
| $5 \times 10^{-3}$ | $2 \times 10^{-3}$ | 60 | 7 |
| $10^{-2}$ | $4 \times 10^{-3}$ | 60 | 23 |

[a] All experiments in pentane at −30 °C.

### *Procedure*

a) Soluble catalyst system: A solution of the titanium component in toluene is placed in a 1 L polymerization flask, a solution of the aluminum component in toluene added and ethene, at a pressure of 150 mbar, passed in. The polymerization is stopped by addition of methanol. After filtration, the polymerizate is washed with methanol, containing a few mL conc. hydrochloric acid, and dried using an oil pump vacuum.

b) Heterogenic catalyst system: Both catalyst components are allowed to pre-react under a protective gas atmosphere in a 50 mL flask. After 30 min, the mixture is added to a 1 L polymerization flask and treated as described in a).

c) The $TiCl_4/Al(SiMe_3)_3 \cdot Et_2O$ system. A solution of $TiCl_4$ in pentane is placed in a 300 ml cold-jacketed flask, the mixture cooled to −30 °C and saturated with ethene. Finally, a solution of $Al(SiMe_3)_3 \cdot Et_2O$ in pentane is injected into the flask *via* a serum cap. The ethene pressure is 150 mbar. Termination and work-up follows, as described in a).

## Novel Molecules of the Phane-type with *p*-Benzoquinone and Oxahomobenzene Moieties[**]

By *Ihsan Erden, Peter Gölitz, Reinhard Näder,*
and *Armin de Meijere*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

In the search for organic compounds with electrical conductivity[1], attention has recently been focussed on molecules having intramolecular charge-transfer interactions[2]. In the known syntheses of phane-type bridged donor-acceptor complexes, the functional groups have frequently been introduced at a precursor stage. We describe here a three-step synthesis of the [2.2]paracyclophanedienemonoquinone *(5)* *via* functionalization of the hydrocarbon *(1)*[3]. The key intermediate, the endoperoxide *(2)*, also serves as starting material for bridged oxahomobenzenes such as *(8)* and *(9)*, which are also suitable as model compounds for the study of intramolecular interactions.

In view of the fact that singlet oxygen[4a] or other dienophiles[4] add to cyclophanes with sufficiently deformed benzene rings, the conveniently accessible [2.2]paracyclophanediene *(1)*[3] was photooxygenated ($CHCl_3$ solution, tetraphenylporphyrin (TPP), Na-vapor lamp) at 30—40 °C. After 16 h, *(1)* had completely reacted[5]; pure *(2)* was isolated in 74% yield by chromatography on silica gel. Table 1 contains the $^1$H-NMR data of all new compounds.

| *(9)* | (CD$_2$Cl$_2$): 2.79, 2.80 (2s, 12(13,15,16)-H); 6.11 (d, 1(10)-H, $^{3}J$=10.0); 7.07, 7.19 (2 d, 4(5,7,8)-H); 7.29 (d, 2(9)-H, $^{3}J$=10.0) |

*(2)* is stable at room temperature; however, above 100 °C it cleaves to give the starting material *(1)*. Reaction of *(2)* with potassium hydroxide in methanol[4a] produced the ketol *(3)* in 65% isolated yield, which was oxidized by freshly prepared manganese dioxide in chloroform to the quinone *(5)* (yield 90%).

In the presence of catalytic amounts of cobalt-*meso*-tetraphenylporphyrin (Co-TPP), a solution of the endoperoxide *(2)* in dichloromethane, even at −10 °C, completely rearranges within a few minutes to the bisepoxide *(4)*[6]. *(4)* could be unequivocally characterized by $^{1}$H-NMR spectroscopy (see Table 1), however, it isomerizes rapidly at room temperature ($\tau_{1/2}$ (20 °C) ≈ 80 min) to the dioxocin *(6)*, in a process known for dioxa-bis-σ-homobenzene[7], so that only pure *(6)* could be obtained by column chromatography at room temperature.

*(2)* can be smoothly epoxidized with *p*-nitroperoxybenzoic acid in dichloromethane, in the presence of sodium carbonate, to a mixture of *(7)* and *(8)* (ratio 1 : 9 from $^{1}$H-NMR). Treatment of the major product *(8)* with Co-TPP at room temperature leads, practically quantitatively, to the phane-type bridged *cis*-benzene trioxide, *cis*-trioxa-tris-σ-homobenzeno-[2,2]paracyclophane-1,9-diene *(9)*. The $^{1}$H-NMR spectrum (see Table 1) of the product *(9)*, which is either insoluble or only slightly soluble in all common organic solvents, shows only six signals, as expected. Like the unbridged *cis*-benzene trioxide[8], *(9)* is stable up to 150 °C; however, it does not melt without decomposition, and attempts to purify it by chromatography on silica gel also lead to its decomposition. In its general appearance, the UV spectrum of *(5)* with maxima at 275, 295 and 340 (sh) nm is similar to that of the already known quinone derived from [2.2]paracyclophane[9]. The UV spectrum of the bridged dioxocin *(6)* shows an absorption at 276 nm with a long wavelength branch out to ≈ 390 nm.

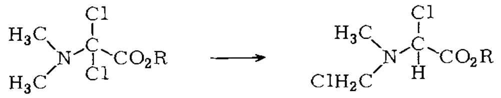
## A Novel Method of CC-Bond Formation: Thermolytic Elimination of Sulfur and Hydrogen Halides from α-Halosulfides[**]

By *Jean-Claude Pommelet, Claire Nyns, Francis Lahousse, Robert Merényi*, and *Heinz G. Viehe*[*]

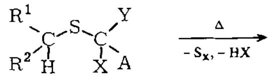
In a previous communication we reported an unusual 1,3-migration of chlorine atoms bonded to C atoms bearing *capto-dative (cd)* substituents[1]. The intramolecular Cl,H-disproportionation of *(1)* to *(2)*[2] may proceed in a similar manner to the reaction of oxamide chloride to the trichloroimidazolium salt[3]. We now describe attempts to extend this type of reaction to α-halosulfides *(3)*; hereby the acrylic acid derivatives *(4)* were unexpectedly obtained *via* HX- and $S_x$-elimination reactions.

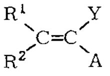
*(1)*



*(2)*

*(3)*





*(4)*

The educts *(3)* were obtained by reaction of the thiols (or thiolates) *(5)* with the halogen compounds *(6)* to give the sulfides *(7)*, and their subsequent halogenation with $SO_2Cl_2$ or $Br_2$ (Table 1).

$$\underset{(5)}{R^1R^2CH{-}SH} + \underset{(6)}{XCH_2{-}A} \longrightarrow \underset{(7)}{R^1R^2CH{-}S{-}CH_2{-}A} \xrightarrow[\text{or } Br_2(h\nu)]{SO_2Cl_2} (3)$$

Table 1. Yields and $^1$H-NMR data for the sulfides *(3)*.

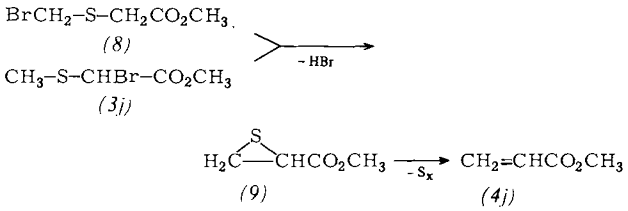
1-oxides). Furthermore, α-chlorodibenzyl- or α-chlorobis(benzoylmethyl)sulfides also yield the corresponding olefins upon treatment with bases[5].

The transformation of *(3)* into *(4)* may proceed *via* a thiirane such as *(9)*, which then loses a sulfur atom[6]. These thiiranes are either directly formed from *(3)* by elimination of HX or *via* a prior disproportionation step from compounds such as *(8)*: both *(8)* and *(3j)* react thermally to give the methyl acrylate *(4j)*.



It is interesting to note further the formation of 1,1-dichloroethene from trichloromethyl(methyl) sulfide (3k), $R^1 = R^2 = H$, $X = Y = A = Cl$.

*Procedure*

Solutions or pure samples of the sulfides *(3)* were vaporized at the top of an electrically heated quartz column filled with quartz beads. The temperature was held constant during the pyrolysis; the pressure at the foot of the column was maintained between $2 \times 10^{-2}$ and 16 torr. Products were condensed at −195 °C and analyzed both before and after distillation and separation.

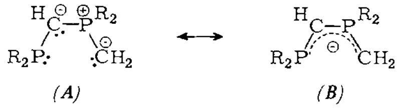
## A Novel Ylidic Organophosphorus Ligand[**]

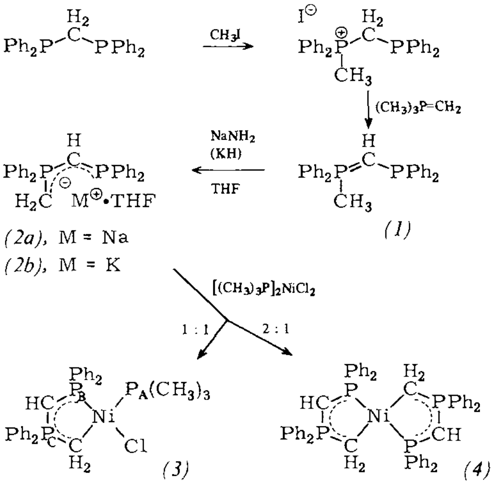
By *Hubert Schmidbaur, Ulrich Deschler*, and
*Beatrix Milewski-Mahrla*[*]

Coordination chemistry, using organophosphorus ligands in their numerous variations, has retained its interest for over 40 years[1a,b]. We now wish to report on a chelate system in which the traditional donor function of a tertiary phosphane is intimately bound to the structural elements of a phosphorus ylide. As represented in a simplified way in formula *(A)*, a particularly robust ensemble is formed by the alternate attachment of two carbanions and a phosphonium center at the phosphane, which can be better described by the charge delocalization shown in *(B)*.



*(A)* *(B)*

In this arrangement the preferred donor properties of phosphanes[1] and ylides[1c] are particularly effectively combined, because the charge density on phosphorus is increased *via* the bridging carbanion without affecting the terminal carbanion function. Methyl(diphenyl)phosphonio(diphenylphosphino)methanide *(1)*, which is readily accessible by several different methods[2], can be converted into the alkali metal complexes *(2)* by treatment with $NaNH_2$ or KH in tetrahydrofuran (THF) with concomitant formation of $NH_3$ or $H_2$, respectively. These complexes crystallize as 1 : 1-adducts with the solvent and are characterized in solution by $^1$H-, $^{13}$C- and $^{31}$P-NMR spectroscopy[3]. Their structure in solution can be described as ion-pairs which show clear influence of the metal cation on the anion[4a]; in the solid state it should correspond to the principle recently determined by X-ray crystallography for benzylphosphonio-analogues[4].



*(2a)*, M = Na
*(2b)*, M = K
*(1)*
*(3)*
*(4)*

The alkali metal precursors *(2)* for the synthesis of the transition metal complexes do not have to be isolated, but can be reacted *in situ* with metal halides. Thus, the reaction with dry $[(CH_3)_3P]_2NiCl_2$ in the molar ratio 1 : 1 first gives, after separation of NaCl (KCl) and release of one of the two $(CH_3)_3P$-ligands, the orange brown complex *(3)*, m.p. = 192 °C, which is somewhat air and moisture sensitive. The broadening of the signals for $P_A$ and $P_B$, in the $^{31}$P-NMR spectrum of solutions of *(3)* in THF, indicates a $(CH_3)_3P$-exchange process ($\delta P_A = -13.5$, br; $\delta P_B = 28.7$, br. d, $^2J(P_BP_C) = 164.8$ Hz; $\delta P_C = 48.6$, d)[5].—Reaction of *(2)* with $[(CH_3)_3P]_2NiCl_2$ in the molar ratio 2 : 1 yields the complex *(4)* directly, which when formed from *(2a)* tenaciously retains NaCl; in contrast, it is readily obtained free

of salt as lemon yellow crystals m.p. = 247 °C from *(2b)*. *(4)* is practically insensitive to air and moisture, but rapidly decomposes in methanol. The EI-mass spectrum shows the ion of highest mass at $m/z = 853$ ($M^+ - {}^{59}Ni$) which supports a monomeric formulation. The complex $^{31}P$-NMR spectrum, which can only be simulated with a set of data taking into account a strong *trans*= $P_AP_{A'}$ coupling through the nickel atom, indicates that *(4)* has a *trans*-structure (Fig. 1).

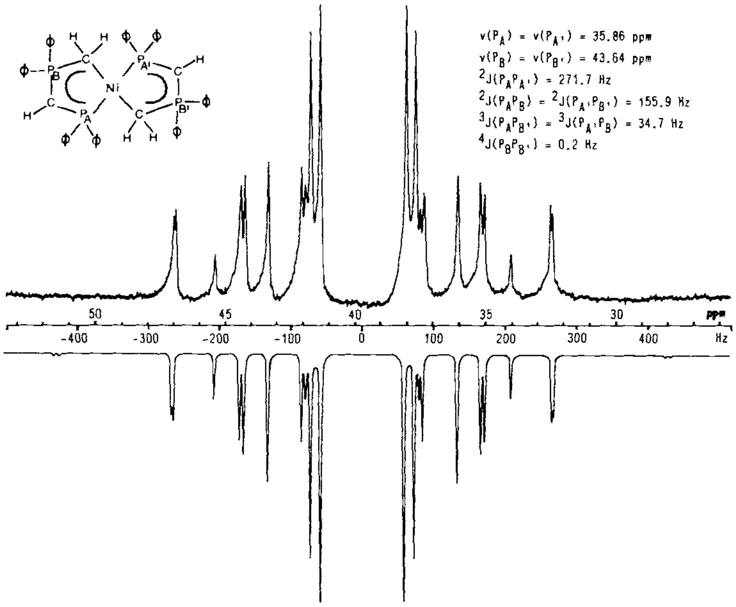

Fig. 1. Experimental and calculated $^{31}P\{^1H\}$-NMR spectra of *(4)* (in THF at 30 °C).

The X-ray structure analysis[6] confirms the square planar environment of the Ni atom in the diamagnetic complex *(4)* and provides important bond length criteria, which substantiate the concept of extensive charge equalization in the ligands. All three PC bond lengths in the ring (170—177 pm, standard deviation 0.6 pm) correspond to double bond character (standard values are 165 pm for P=C and 188 pm for P—C[7]). All PNiC-angles are approximately 90°. The unusually small PCP-angles of 108.1(3)° are caused by deformation of the five-membered rings in the centrosymmetric molecule, due to the square planar configuration of the metal center.

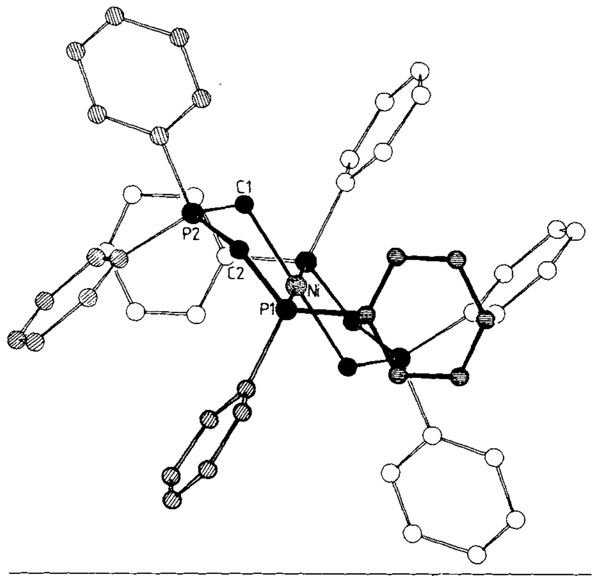

Fig. 2. Molecular structure [6] of the nickel complex *(4)*. Most important bond lengths [pm] and angles [°]: Ni—P1 221.0(2), P1—C2 174.1(6), C2—P2 170.3(6), P2—C1 177.2(7), C1—Ni 201.2(6); C1—Ni—P1 90.1(2), Ni—P1—C2 108.3(2), P1—C2—P2 108.1(3), C2—P2—C1 106.6(3), P2—C1—Ni 109.3(3).

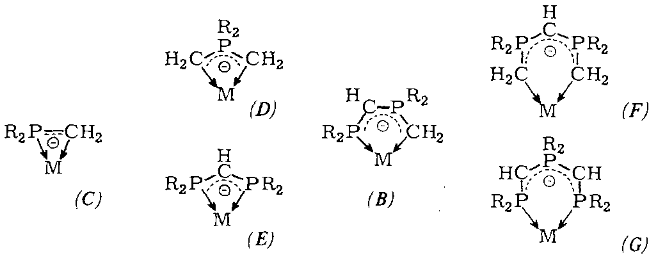
Ni(II) complexes with two phosphanes and two alkyl or aryl ligands are considerably less stable than *(4)* and rapidly decompose both thermally and by the action of oxygen and water[8]. The chelate system *(B)* extends the known series of $P_mC_n$-ligands *(C)*—*(F)*[1c, 9].



### Procedure

$CH_3(C_6H_5)_2P{=}CHP(C_6H_5)_2$ (2 g, 5 mmol) is dissolved in 30 cm³ THF and heated under reflux with $NaNH_2$ (0.4 g, 10 mmol) for 3 d. After filtration, concentration of the filtrate to 10 cm³ and addition of pentane, 2.1 g *(2a)* (85%) precipitates. By analogy, 2.3 g *(2b)* (90%) is formed using KH.—The filtered reaction mixtures can be further reacted directly. Thus, 1.7g of complex *(3)* (60%) is formed from $[(CH_3)_3P]_2NiCl_2$ (1.41 g, 5 mmol) after heating for 5 h at 65 °C in 25 cm³ THF. *(4)* (1.9 g) (45%) is produced from 10 mmol *(2b)* and 1.41 g $[(CH_3)_3P]_2NiCl_2$. In contrast 10 mmol *(2a)* first gives 2.8 g yellow crystalline product (57% from THF/pentane), containing exactly 2 equivalents NaCl; repeated recrystallization from THF/toluene gives pure *(4)*.

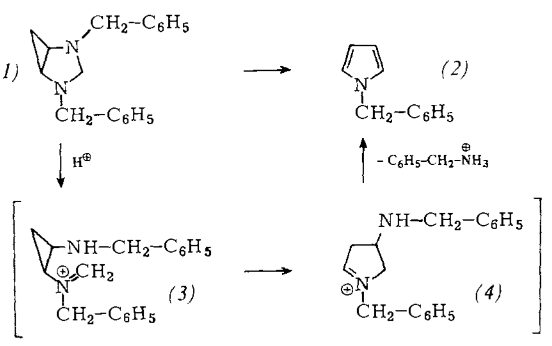
## A Simple Pyrrole Synthesis *via* an Unusually Facile 1,3 Shift in *N*-Benzyl-*N*-(2-benzylaminocyclopropyl)-*N*-benzylideneammonium Ions[**]

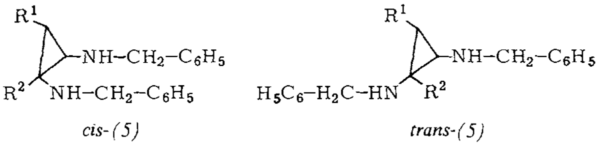
By *Helmut Quast, Wolfgang von der Saal*, and *Josef Stawitz*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

1,2-Cyclopropanediamines *(5)* retain their configuration in aqueous mineral acids even at elevated temperatures. In striking contrast, apart from slow ring-cleavage affording about 1 mole alkylamine, in aqueous neutral solution *(5)* undergoes rapid *cis-trans* equilibration, even at 25 °C[1]. We have now found that *(5)* and aromatic aldehydes *(6)* readily react to give pyrroles. The present experiments were stimulated by the very rapid, almost quantitative formation of 1-benzylpyrrole *(2)* and benzylamine upon hydrolysis of 2,4-diazabicyclo[3.1.0]hexane *(1)*[1] with dilute acetic acid or aqueous copper sulfate solution at 20 °C. Most probably, the pyrrolinium ion *(4)* was formed by opening of the imidazolidine ring of *(1)*, induced by protonation[2], and subsequent 1,3-shift in the methyleneammonium ion *(3)*. It, therefore, appeared reasonable to generate the analogous benzylideneammonium ions *(12)* by condensation of *(5)* with aldehydes *(6)* and to test their 1,3-shift propensity.

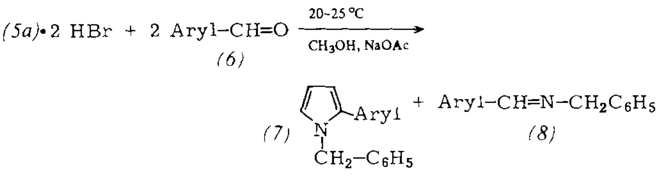


The ammonium bromides *(5)*·2HBr were obtained in good yields by Curtius degradation of diastereomerically pure dimethyl 1,2-cyclopropanedicarboxylates *via* the hydrazides[3]. The 1,2-bis(benzyloxycarbonylamino)cyclopropanes formed in benzyl alcohol were selectively alkylated at both N atoms by benzyl bromide in the presence of NaH and then cleaved with HBr in acetic acid. The configuration of all the cyclopropanediamines *(5)* and their precursors was established from LAOCOON III optimized $^1$H-NMR data.



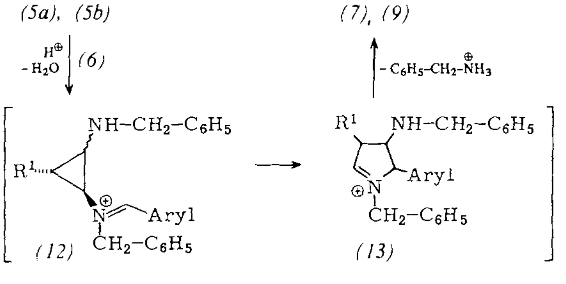
*(a)*, $R^1 = R^2 = H$; *(b)*, $R^1 = CH_3$, $R^2 = H$;
*(c)*, $R^1 = H$, $R^2 = CH_3$

When *(5a)*·2 HBr was reacted with 2 moles of aromatic aldehydes *(6)* in methanol or ethanol in the presence of 13 moles of sodium acetate, the 2-arylpyrroles *(7)* and the Schiff bases *(8)* were obtained after 15 h [3 d in the case of *(6d)*] at 20–25 °C. While *(7c)* crystallized directly from the reaction mixture, the other pyrroles *(7)* were isolated by preparative layer chromatography (alumina/petroleum ether (50–70 °C)) (Table 1). Irrespective of the configuration of the starting cyclopropane diamines *(5)* both *cis-(5a)* and *trans-(5a)* afforded the same pyrrole *(7c)* upon reaction with *(6c)*. This preparative advantage obviates the separation of the *cis-trans* diastereomeric cyclopropanedicarboxylates.



Aryl: *(a)* $C_6H_5$; *(b)* 4-$NO_2$–$C_6H_4$; *(c)* 4-$(CH_3)_2N$–$C_6H_4$;
*(d)* 2,4,6-$(CH_3)_3C_6H_2$; *(e)* 2-Pyridyl

The structures assigned to the pyrroles are based on elemental analyses, IR and mass spectra and, in particular, $^1$H-NMR spectra (Table 1). *(7a)* was identical with an authentic sample obtained by reaction of 3-chloropropene with benzoyl chloride in dichloromethane in the presence of aluminum chloride and heating the product under reflux for 4 h in benzyl amine (28% yield)[4].



The substituted cyclopropanediamines *(5b)* and *(5c)* react analogously: from *trans-(5b)* and 4-nitrobenzaldehyde *(6b)*, only *(8b)* and *(9)* were formed, while *trans-(5c)* and *(6b)*, as well as *trans-(5c)* and *(6d)*, afforded a 6 : 4 ratio of the pyrroles *(10a)* and *(11a)* and a 7 : 3 ratio of the pyrroles *(10b)* and *(11b)*, respectively. Steric factors therefore lead to a low regioselectivity of the reaction.

Am Hubland, D-8700 Würzburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The results are part of the dissertation of *J. S.*, Universität Würzburg 1978, and the prospective dissertation of *W. v. d. S.*

Even at 20 °C the benzylideneammonium ions *(12)* generated from *(5)* and aromatic aldehydes, ring-expand to the pyrrolinium ions *(13)*, which on loss of benzylamine, stabilize by formation of the pyrroles *(7)* [or *(9)*—*(11)*]. The ring-expansion of *(12)* probably proceeds equally rapidly and analogously to *N*-benzylidene(1,2,2-triphenylcyclopropyl)amines *via* trimethylene intermediates[5]. The present pyrrole synthesis provides an impressive example of the great acceleration of 1,3-shifts in vinylcyclopropanes by amino and alkoxide groups (LiO—, KO—)[6] attached to the migrating carbon atom. Despite the abundance of known pyrrole chemistry, novel and simple pyrrole syntheses are of timely interest[7].

## An Unusual Double Intramolecular Cyclization—Structural Analysis of 2,6-Dibromo-4,8-dimethyltetracyclo[3.3.0.0$^{2,8}$.0$^{4,6}$]octane-3,7-dione[**]

By *Krystina Kratzat, Franz W. Nader*, and *Thea Schwarz*[*]

*Dedicated to Professor Karl Freudenberg on the occasion of his 95th birthday*

In our investigations of the structural chemistry of cumulenes[1], we sought a route to bisallene-1,6-dicarboxylic acid derivatives. The most promising appeared to be the classic synthesis of allenes from 1,1-dihalocyclopropanes after *Doering*[2]. By means of this route, pentatetraenes[3b], in addition to numerous allene derivatives[3a], were first synthesized; furthermore, both acyclic-[4a] and cyclic-bisallenes[4b] have been prepared. A synthetic route to the bisallene-dicarboxylic acid diester *(5)* starting from the tetrabromobicyclopropyl dicarboxylic acid esters *(2)* and *(3)* should therefore also be feasible.

Double dibromocarbene addition to dimethyl (*Z,Z*)-2,5-dimethylmuconate[5] *(1)* occurred in approximately 20% total yield under phase-transfer catalysis at 50-70 °C. In addition to the expected stereoisomers *meso*-*(2)* and (±)-*(3)*, two further diastereomeric adducts, which were formed as a consequence of partial isomerization of (*Z,Z*)-*(1)* to (*E,E*)-*(1)*, could be obtained in pure form by column chromatographic separation. Configurational assignments were carried out by spectroscopic and chemical methods[6].

Reaction of *(3)* with *tert*-butyllithium (*t*BuLi) or lithium diisopropylamide at −60 °C in ether produced a crystalline compound, which after elemental analysis and mass spectroscopy, proved to have the empirical formula $C_{10}H_8Br_2O_2$. On the basis of the NMR spectroscopic data, this compound must have a symmetrical structure. The $^1$H-NMR spectrum contains only two singlets in the ratio 1:3,

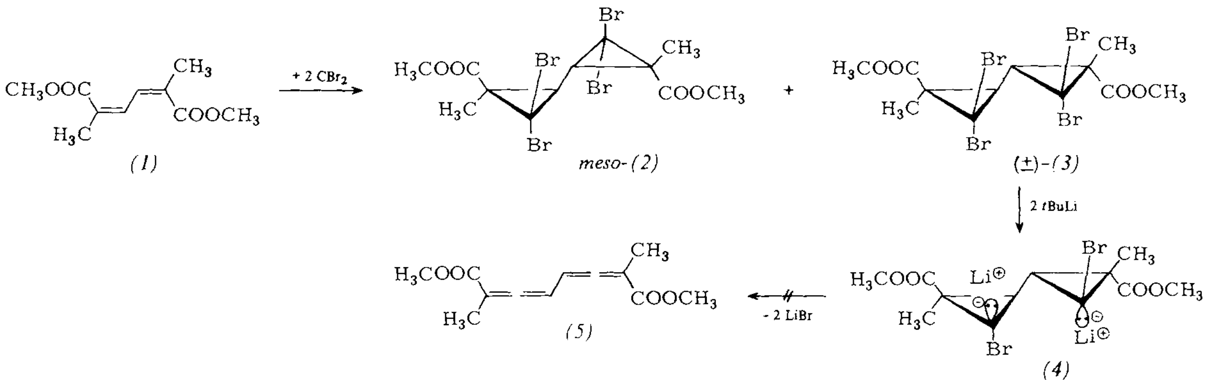
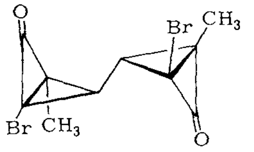
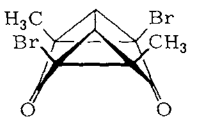
[**] This work was supported by the Deutsche Forschungsgemeinschaft.



which are indicative of aliphatic methine protons ($\delta = 3.15$) and methyl groups ($\delta = 1.48$); the signals are similar to those of the corresponding educt *(3)*. The $^{13}C$-NMR spectrum shows signals arising from five different C atoms. By virtue of their position and off-resonance decoupling, the following assignments could be made: $C{=}O$ ($\delta = 196.75$), methine $C{-}H$ (40.21), $CH_3$ (13.46), in addition to two aliphatic, quaternary C atoms (43.66 and 37.19). Metalation of *(3)* leading to formation of an allene system can therefore be excluded. On the contary, the product must result from an intramolecular condensation of the intermediate dicarbanions, formed by metalation of *(3)* with both ester functionalities. If this condensation occurs on the α-bromocarbanion intermediate *(4)*, the two structures *(6)* and *(7)* could result; if the carbanion attacks the ester group on the same respective cyclopropyl moiety the highly strained bisbicyclobutanone *(6)* is formed, while attack at the other ester group results in formation of the tetracycle *(7)*.

*(6)*





*(7)*

The structure *(6)* can most probably be excluded from its $C{=}O$ vibrational frequency of 1748 $cm^{-1}$ (*ca.* 1850 $cm^{-1}$ would be expected for a cyclopropanone) and from the investigation of analogous reactions on a model compound[7].

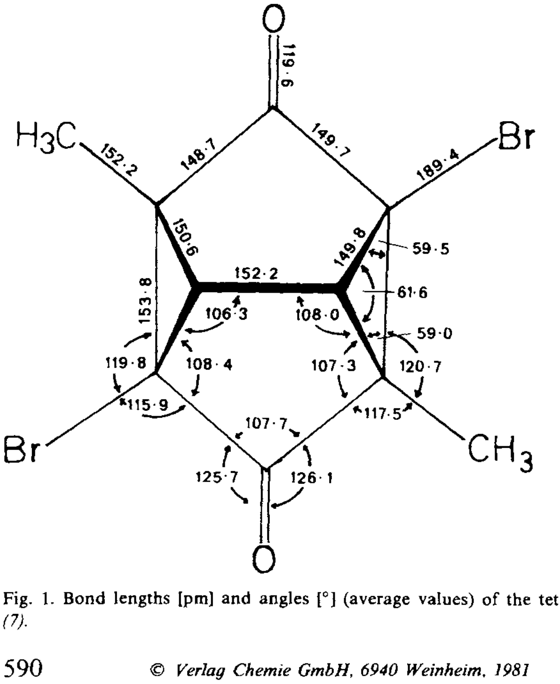


Fig. 1. Bond lengths [pm] and angles [°] (average values) of the tetracycle *(7)*.

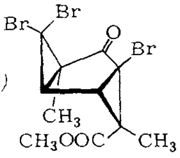
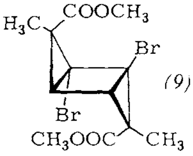
An X-ray structure analysis[8] of the product confirmed the suggested structure *(7)*, which has approximate $C_2$ symmetry. Due to the influence of the β-ester function[7], the carbanionic intermediate *(4)* is so stable—even at high temperatures—that it does not spontaneously α-eliminate to the carbene; furthermore, although sterically hindered, it can react *via* double intramolecular cyclization to give *(7)*.

The structural analysis also proves that the stereochemical assignment of the starting material *(3)* was correct, since only in the (±)-diastereomer do the ester functions occupy positions from which double intramolecular cyclization is possible. In contrast, the *meso*-compound *(2)* can only cyclize to the tricyclic cyclopentanone *(8)*. In this latter compound both cyclopropane rings are *trans* to each other and hence the second coupling step is, for steric reasons, impossible. In fact, *(8)* can be obtained by metalation of *(2)*; an allene is not formed here either.

*(8)*





*(9)*

Metalation of *(3)* with *t*BuLi at 0°C in cyclohexane results, in addition to the tetracycle *(7)*, in isolation of a second crystalline compound, which on the basis of analytical and spectroscopic data[9], is assigned the structure of the tricyclo-[3.1.0.0$^{2,4}$]hexane derivative *(9)*; under these conditions a second coupling variation—coupling of both $CBr_2$ groups of *(3)*—is possible, which leads to the formation of cyclobutane and hence to the "chair-analogous" structure *(9)*.

[7] As a model compound, 2,2-dibromo-1-methylcyclopropanecarboxylic acid was reacted with *t*BuLi under the same conditions. Only one stereospecific Br/H-exchange process, leading to ethyl *trans*-2-bromo-1-methylcyclopropanecarboxylate, occurred. This shows that an extraordinary stable carbanion is formed *syn* to the ester function, a fact which is in accord with the stereochemistry of both cyclization products *(7)* and *(9)*.

[8] Space group $P2_1/c$; $a=801.4$, $b=1073.7$, $c=1221.4$ pm, $\beta=97.55°$; $Z=4$, $\rho_{calc.}=2.04$ g·cm$^{-3}$. The structure was solved by direct methods with a multi-solution technique. [*G. Germain, M. M. Woolfson*, Acta Crystallogr. *B 24*, 91 (1968); see also *H. W. Kaufmann, L. Leiserowitz, ibid. B 26*, 442 (1970)]. The positions of the H atoms were obtained from the $|F_o - F_c|$ difference map. The refinement with 2531 reflections (of which 589 were unobserved) converged to an *R*-factor of 5.2%.

[9] Elemental Analysis and mass spectrum (molecular peak at $m/e=380$) gave the summation formula $C_{12}H_{12}Br_2O_4$. $^1$H-NMR: $\delta=1.35$ (s, 3H, CH$_3$), 2.69 (s, 1H), 3.81 (s, 3H, OCH$_3$); $^{13}$C-NMR: $\delta=169.40$ (C=O), 52.19 (OCH$_3$), 49.60 (quart. C), 45.71 (quart. C), 39.02 (CH), 19.01 (CH$_3$).

## A Diorganotin Oxide with a Planar Tin-Chalcogen Six-Membered Ring[**]

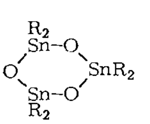
By *Heinrich Puff, Willi Schuh, Rolf Sievers,* and *René Zimmer*[*]

*Dedicated to Professor Rolf Appel on the occasion of his 60th birthday*

The properties of most diorganotin oxides would indicate polymeric structures[1]. Although molecular weight determinations indicated presence of trimers in solution in the case of di-*tert*-butyltin oxide[2] *Chu* and *Murray* assumed a polymeric structure in the solid state on account of the sparing solubility of the sample.

On reaction of $tBu_2SnCl_2$ with sodium hydroxide in boiling toluene we were able to obtain a form of the di-*tert*-butyltin oxide which is readily soluble in organic solvents in the cold and is therefore obviously of low molecular weight.

The compound crystallizes hexagonally in the space group $R\bar{3}c$-$D_{3d}^{6}$, $a=1035$, $c=5144$ pm[3]. The unit cell contains six molecules $(tBu_2SnO)_3$. As shown by the X-ray structure analysis[4] ($R=0.045$), tin and oxygen atoms are coupled to a planar six-membered ring.



R = C(CH$_3$)$_3$

| Bond length [pm] | | Angle [°] | |
|---|---|---|---|
| Sn—O | 196 | O—Sn—O | 106.9 |
| Sn—C | 219 | Sn—O—Sn | 133.1 |
| | | C—Sn—C | 119.9 |

Such a planar arrangement has so far not been detected in the case of diorganotin-chalcogen compounds; in the analogous sulfur, selenium, and tellurium compounds there are either puckered six-membered[5a] or four-membered[5b] rings, or open chains[5c]. The Sn—O bond lengths are of about the same order of magnitude as in comparable compounds with distinctly tetravalent tin, *e.g.* $Ph_3Sn{-}O{-}SnPh_3$ (195 to 196 pm)[6]. In contrast to other SnO-compounds[7], an association of the molecules with an increase in the bond numbers of tin and oxygen is not observed; the shortest intermolecular Sn—O distance is 644 pm.

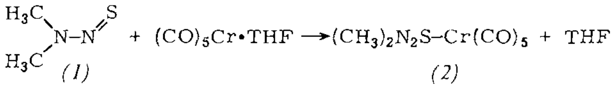
## Coordination of Dimethyl(thionitroso)amine to Pentacarbonylchromium *via* the Sulfur Atom[**]

By *Herbert W. Roesky, Ralf Emmert, William Clegg, Wilhelm Isenberg* and *George M. Sheldrick*[*]

*Dedicated to Professor Josef Goubeau on the occasion of his 80th birthday*

In all complexes of acyclic sulfur-nitrogen compounds known so far the N—S ligands are coordinated to the metal *via* nitrogen atoms[1]. Reaction of the unstable dimethyl(thionitroso)amine *(1)*[2]—prepared from dimethylhydrazine and sulfur—with $(CO)_5Cr\cdot THF$ in tetrahydrofuran (THF) affords the 1:1 complex *(2)*, which we isolated as ruby-red crystals, stable at room temperature. As shown by an X-ray structure analysis[3], the SN ligand in *(2)* is bound to chromium *via* the sulfur atom (Fig. 1).



$$(H_3C)_2N{-}N{=}S + (CO)_5Cr\cdot THF \longrightarrow (CH_3)_2N_2S{-}Cr(CO)_5 + THF$$

*(1)* *(2)*

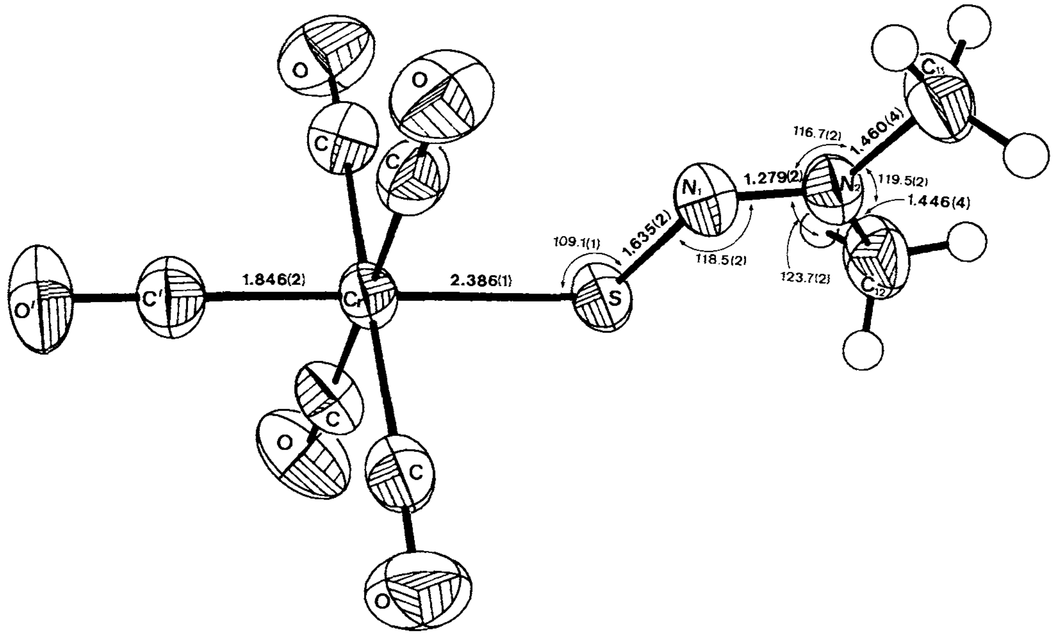

Fig. 1. Molecular structure of the complex *(2)*, showing the bond lengths [Å] and bond angles [°] (standard deviations in brackets). Mean values for 5 C—O 1.138(3), Cr—C(*cis*) 1.903(5) Å, S—Cr—C(*cis*) 89.8(4), S—Cr—C(*trans*) 178.2(1)°.

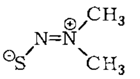
For the CO group in the *trans* position to the sulfur atom the Cr—C distance is shortened to 1.846(2) Å compared to the mean value of 1.903(5) Å for the remaining carbonyl ligands. The atoms Cr, S, N2 and C″ are coplanar within 0.012 Å, and the coordination octahedron about Cr is almost ideal. The S—N distance of 1.635(2) Å corresponds to a single bond, while the N—N bond (1.278(2) Å) is markedly shortened compared to that in hydrazine derivatives (1.45 Å). The bonding in the ligand can best be described in terms of the resonance structure *(1a)*.



In the mass spectrum of *(2)* the molecular ion appears at $m/z = 282$ with a relative intensity of 37%. The fragmentation follows a stepwise cleavage of the CO groups, so that $\mathrm{Cr[SNN(CH_3)_2]^+}$ appears at $m/z = 142$—and with a relative intensity of 100%.

### *Procedure*

*(1)* (0.57 g, 6.3 mmol) is treated at *ca.* $-15\,^\circ\mathrm{C}$ with a solution of $\mathrm{(CO)_5Cr \cdot THF}$ (7.5 mmol) in THF (100 ml). The mixture is allowed to warm to room temperature, then stirred for 1 hour, the solvent removed, and the residue taken up in 25 ml $CH_2Cl_2$. After filtration and cooling, $\mathrm{Cr(CO)_6}$ is removed from the resulting crystalline mixture by vacuum sublimation. Yield 0.4 g (24%) *(2)*, decomp. ≈ 100 °C.

# 1,5-Bis(dimethylamino)tetrasulfur Tetranitride—A Cage Molecule with a Non-Symmetric Nitrogen Bridge[**]

By *Herbert W. Roesky, M. N. S. Rao, Cornelia Graf, Alfred Gieren,* and *Erich Hädicke*[*]

*Dedicated to Professor Marianne Baudler on the occasion of her 60th birthday*

"Substitution products" of $S_4N_4$ with amino groups have so far not been reported in the literature. We have now found that $S_4N_4Cl_2$ *(1)* reacts with dimethyl(trimethylsilyl)amine *(2)* in the molar ratio 1 : 2 to give the dimethylamino derivative *(3)*.

*(3)* could be isolated in good yields as pale yellow, transparent crystals. $S_4N_4$ is formed as by-product. Crystals of *(3)* and their solution in $CH_2Cl_2$ or $CHCl_3$ undergo decomposition and turn red at room temperature. However, the crystals can be stored for months at 0 °C without decomposition.

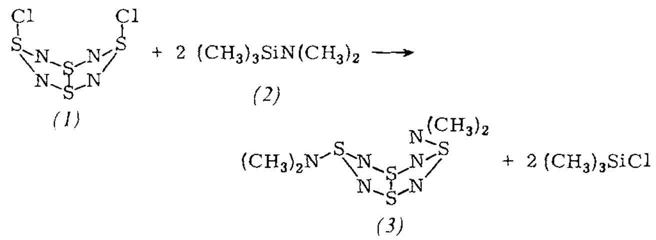
[**] Studies on the structure of $S^{IV}N_3$ Groups, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft. – Part 4: *A. Gieren, B. Dederer, I. Abelein,* J. Anorg. Allg. Chem. *465*, 191 (1980).



The molecule *(3)* (Fig. 1) exhibits only $C_s$ symmetry, and not the possible ($C2_v$ symmetry. The two $(CH_3)_2N$-groups are stereochemically non-equivalent. One (containing N6) occupies an *exo*-position on the $S_4N_4$ ring with trigonal-planar, the other (containing N5) an *endo*-position with pyramidal ligand arrangement. The bond lengths in the two $SN_3$ groups are markedly different. The group containing S3 contains one shorter exocyclic and two longer endocyclic S—N bonds, the group with S1 one longer exocyclic and two shorter endocyclic S—N bonds. The $C2_v$ symmetry is also destroyed with respect to the usual S—N bond lengths. The bonds from S2 (and S4) to N1 and N2 (and N4 and N3, respectively) are different in length. The average S—N bond length in the $S_4N_4$ ring (1.62 Å), however, has almost the same size as in the $S_4N_4$ eight-membered ring of $S_4N_4$[1a], $S_4N_5^-$[1b], $S_4N_5^+$[2a], $S_4N_5O^-$[2b], $S_4N_4\cdot 2C_7H_8$[3], $S_5N_6$[4], $S_5N_6(CH_2)_4$[5], $S_5N_6(CH_3)_2$[6a] and $S_5N_7Si(CH_3)_5$[6a], but distinctly greater than in the Lewis acid adducts of $S_4N_4$ with $BF_3$[6b], $SO_3$[7a], $FSO_2NCO$[7b] and $AsF_5$[8] (1.588–1.599 Å).

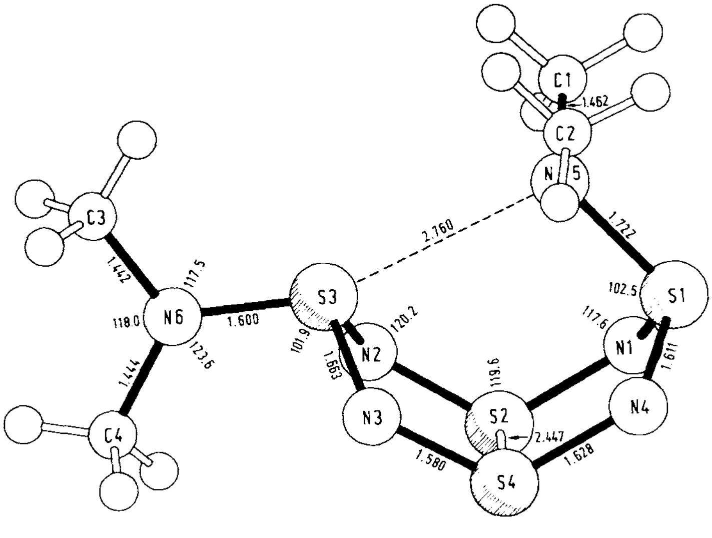


Fig. 1. Molecular structure of $S_4N_4[N(CH_3)_2]_2$ *(3)* with bond lengths [Å] and angles [°] determined *via* the molecular mirror symmetry. Further bond angles are: C1—N5—S1 111.8, C1—N5—C2 112.9, N1—S1—N4 106.5, N2—S3—N3 100.4, N1—S2—S4 92.4, N2—S2—S4 92.0°. Standard deviations of the determined values: bond lengths: S—S 0.002, S—N 0.005–0.008, C—N 0.007—0.013 Å; angles 0.2—0.7°.—*(3)* crystallizes in the triclinic space group $P\bar{1}$ with $a=7.559(5)$, $b=8.496(5)$, $c=9.480(6)$ Å, $\alpha=104.19(5)$, $\beta=93.4(5)$, $\gamma=103.13(5)°$, $Z=2$; diffractometer data: $Cu_{K\alpha}$ radiation, 1274 observed reflections ($I>2\sigma_I$), corrected for absorption, measured at −60 °C, $\Theta_{max}=57.5°$, $R=0.079$.

The conformation of the $S_4N_4$ ring in *(3)* corresponds to that of $S_4N_4$; however, one transannular S—S bond is opened, while the other is shortened by *ca.* 0.14 Å to 2.447 Å. The opened S—S bond becomes unsymmetrically bridged by a $(CH_3)_2N$-group: N5 in the substituent forms an S—N single bond to S1 and at the same time a strong transannular interaction with S3 (N5—S3: 2.760 Å); as a consequence the coordination number of S3 increases to four. N5 adds nucleophilically *via* the lone electron pair S3. The molecular geometry can be explained in terms of a frozen-in intramolecular rearrangement of an $(CH_3)_2N$-group from S1 to S3. Two sharp signals are observed in the $^1$H-NMR spectrum recorded at room temperature ($\delta=2.53$ for the *exo*- and $\delta=2.35$ for the *endo*-dimethylamino group). At −70 °C the exchange of the *exo*-methyl group is frozen-in, and two broad signals appear instead of the singlet. The signal of the *endo*-dimethylamino group remains sharp and in exactly the same position.

### *Procedure*

A suspension of *(1)*[9] (2.55 g, 10 mmol) in $CH_3CN$ (80 mL) is cooled, with stirring, to −35 to −40 °C and treated dropwise within 2.5 h with a solution of *(2)* (2.57 g, 22 mmol) in $CH_3CN$ (70 mL). The resulting solution is then warmed within 2 h to room temperature. A deep-red clear solution is obtained. After removal of solvent in a vacuum a red oil remains. This is extracted portionwise with 100 mL *n*-hexane, and the *n*-hexane solution is evaporated down to 60 mL. On cooling (in a deep-freeze) *(3)* (decomp. pt. 70–72 °C) is obtained as pale-yellow crystals in 40% yield. Further amounts of *(3)* can be obtained by concentration of the mother liquor. The residue insoluble in *n*-hexane contains $S_4N_4$ as identifiable product.

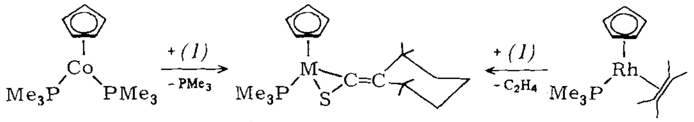
the complexation of $CO_2$[2]. We recently reported the synthesis of $C_5H_5(PMe_3)Co(\eta^2\text{-}CS_2)$[3] and $C_5H_5(PMe_3)Co(\eta^2\text{-}SCSe)$[4], which are formed by attack of the strong metal base $C_5H_5Co(PMe_3)_2$[5] at the electrophilic carbon atom of $CS_2$ and SCSe, respectively. 1,1,3,3-Tetramethyl-2-thiocarbonylcyclohexane *(1)*, which in contrast to other dialkylthioketenes is remarkably stable, also reacts with this metal base (in benzene, 25 °C), rapidly and quantitatively to give the cobalt complex *(2)*. The corresponding rhodium complex *(3)* is formed from $C_5H_5Rh(PMe_3)C_2H_4$[6] and *(1)* in benzene on warming to 60 °C for a day.



*(2)*, M = Co
*(3)*, M = Rh

The air-stable solids *(2)* and *(3)* are readily soluble in the usual organic solvents. The characteristic stretching frequency at 1750 cm$^{-1}$ for the S=C=C group in *(1)* is no longer observed in the IR spectra of the complexes. The *di-hapto*-($\eta^2$)coordination thus indicated for the thioketene is confirmed by the crystal structure analysis of *(2)*[7].

Table 1. Spectroscopic data of the new thioketene-metal complexes *(2)* and *(3)*.

*(2)*: $^1$H-NMR ([D$_6$]benzene): $\delta=4.70$ ($C_5H_5$; s), 1.96, 1.75, 1.65, 1.62 (4$CH_3$; s), 0.84 ($PMe_3$; d, $J_{PH}=9.8$ Hz), $CH_2$-signals of the six-membered ring masked by methyl resonances. MS (70 eV): $m/z$ ($I_r$) = 382 (13; $M^+$), 366 (2; $M^+-CH_4$), 334 (3; $M^+-3\,CH_4$), 306 (1; $M^+-PMe_3$), 200 (100; $C_5H_5CoPMe_3^+$), 189 (7; $Co(C_5H_5)_2^+$), 124 (15; $CoC_5H_5^+$).

*(3)*: $^1$H-NMR ([D$_6$]benzene): $\delta=5.16$ ($C_5H_5$; d×d, $J_{PH}=1.5$, $J_{RhH}=0.7$ Hz), 1.81, 1.66, 1.58, 1.57 (4$CH_3$; s), 1.05 ($PMe_3$; d×d, $J_{PH}=10.4$, $J_{RhH}=1.0$ Hz), $CH_2$-signals masked. MS (70 eV): $m/z$ ($I_r$) = 426 (35; $M^+$), 410 (3; $M^+-CH_4$), 244 (100; $C_5H_5RhPMe_3$), 168 (37; $RhC_5H_5^+$).

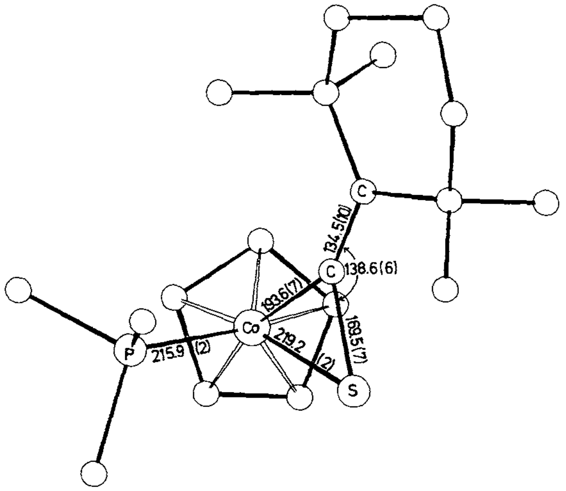


Fig. 1. Molecular structure of *(2)*, projected perpendicular to the plane of the $C_5H_5$-ring.

The bond lengths and angles between the Co atom and the S=C=C group of the thioketene ligand verify presence of a CoSC three-membered ring. Whereas the CoS bond length corresponds to that of a single bond, partial multiple bonding cannot be ruled out in the case of the Co—C bond[8]. Thus, similarly to $CS_2$, SCSe and other heteroallenes, *(1)* could also exhibit considerable π-acceptor character. The hypothesis of comparable ligand properties of $CS_2$ and dialkylthioketenes such as *(1)* is, moreover, supported by the very similar bond angles S—C—C = 138.6° in *(2)* and S—C—S = 141.2° in $C_5H_5(PMe_3)Co(\eta^2\text{-}CS_2)$[3].

Very few mononuclear thioketene-metal complexes have so far been mentioned in the literature. *Behrens et al.*[9a] describe a complex in which *(1)* is presumably bound only *via* the S atom to $Cr(CO)_5$. Iridium(I) and platinum(0) complexes with $\eta^2$-coordinated bis(trifluoromethyl)thioketene have been synthesized by *Stone et al.*[9b], not however from $(CF_3)_2C{=}C{=}S$ as starting material, but from heterocyclic, $CF_3$-substituted sulfur compounds.

## Bis(tetraphenylphosphonium) Hexadecaphosphide, a Salt Containing the Novel Polycyclic Anion $P_{16}^{2-}$[1]

By *Hans Georg von Schnering, Victor Manriquez*, and *Wolfgang Hönle*[*]

We have recently shown[2] that the molecular compounds $P_7R_3$, $P_{11}R_3$ and $As_7R_3$ ($R=SiMe_3$) are formed in surprisingly high yields on reaction of the salts $Na_3P_7$, $Na_3P_{11}$ and $Rb_3As_7$ with chlorotrimethylsilane. In the mass spectra of $P_{11}R_3$ and $P_7R_3$, besides a series of fragments which differ by $P_2$- or $P_4$-units there also appear small amounts of $P_{16}R_2^+$. We have now been able to trap the $P_{16}^{2-}$ anion corresponding to this species by reaction with salts of large cations.

*$(Ph_4P)_2P_{16}$:* $Na_3P_7$[3] (3.16 g, ≈ 11 mmol) is suspended in 500 ml of tetrahydrofuran (THF) which has previously been freed of oxygen by treatment with K/benzophenone.

---

[*] Prof. Dr. H. G. von Schnering, Dipl.-Chem. V. Manriquez,
Dr. W. Hönle
Max-Planck-Institut für Festkörperforschung
Heisenbergstr. 1, D-7000 Stuttgart 80 (Germany)

A suspension of tetraphenylphosphonium chloride (12.43g, ≈33 mmol) in THF (100 ml) is added dropwise with stirring to the yellow suspension at 220 K. After warming to 298 K the suspension is stirred for *ca.* 20 h at 298 K. Red, rod-shaped crystals (length ≈0.4 mm) crystallize out from the filtrate within a week. Later, yellow amorphous "higher phosphanes" also separate out. However, the red crystals of $(Ph_4P)_2P_{16}$ can easily be separated mechanically from the by-products.

Compared to salts like $Na_3P_7$, $Na_3P_{11}$ and their derivatives, the hexadecaphosphide is remarkably stable. The crystals, which are practically insoluble in anhydrous solvents, hydrolyze and turn brown within two days on exposure to air. They decolorize within minutes in $H_2O$/ethanol mixtures, but their morphology is preserved. The phosphane odor typical for such reactions does not occur. Up to 570 K the mass spectrum (QMS) shows only the fragments of the cation and of $P_4$. In the presence of $Me_3SiCl$ the fragment $P_{16}R_2^+$ ($m/z=642$) is observed.

The X-ray structure analysis[4] gave a surprising result: The compound does not contain the anions $P_7^{3-}$, as would be expected in the synthesis, but the novel polycyclic hexadecaphosphorus dianion $P_{16}^{2-}$ (Fig. 1). Its skeletal structure, with mm2 symmetry, is made up of two $P_7$ units which are coupled *via* a common $P_2$ dumbbell; it can also be described in terms of the combination of a $P_7$-unit with a $P_9$-unit. The bond lengths show some peculiarities: The P—P distance *a* of 232 pm is very long. Here the strain caused by the 3m symmetry of the nortricyclic unit and the ψ-tetrahedral configuration of the bridgehead atoms linked directly to the $P_2$-dumbbell is effective. The shortest bond lengths (*h* and *i*) occur at the two divalent $P^{1-}$ atoms. The height 312 pm of the nortricyclene moieties lies directly between those in $P_7^{3-}$ and those in the neutral $P_7R_3$[5].

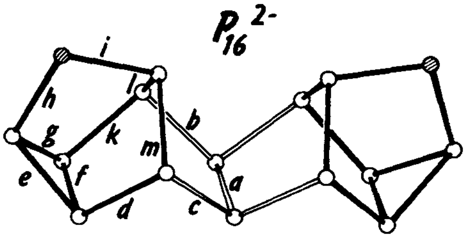

Fig. 1. The dianion in the $(Ph_4P)_2P_{16}$ structure. The bonds of the $P_7$-fragment are shown in bold lines. Bond lengths P—P in pm ($\sigma \leq 0.6$): $a=232.0$, $b=219.7$, $c=220.6$, $d=219.6$, $e=222.3$, $f=223.6$, $g=221.4$, $h=217.0$, $i=214.1$, $k=220.2$, $l=220.4$, $m=219.7$.

The slow crystallization of the sparingly soluble salt would indicate slow formation of the $P_{16}$-system. A number of disproportionation reactions are conceivable, which, *e.g.*, start with $P_7^{3-} \rightarrow P_3^{3-} + P_4$ and then lead from $2P_7^{3-}$ and $P_4$ directly or *via* $P_9^{3-}$ as intermediate to $P_{16}^{2-}$ and $P_2^{4-}$. The $P_9$-fragment of the dianion is isomeric with the framework of the prismane derivative $P_9R_3$ discussed earlier[2], into which it can be converted *via* a simple route by a double 1,2-bond shift.

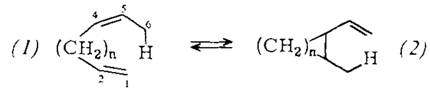
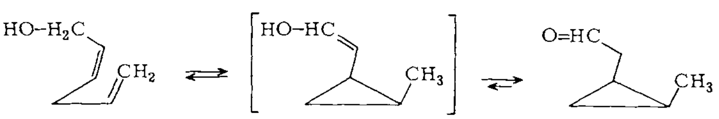
## Stereoselective Cyclopropane Syntheses by "Oxy-Homodienyl Hydrogen Shifts"[**]

By *Frank-Gerrit Klärner, Wolfgang Rüngeler*, and *Werner Maifeld*[*]

The thermally induced 1,5-homodienyl hydrogen shift *(1)*⇌*(2)* ($n=1$) belongs to the intramolecular ene reactions, which are of importance in the stereoselective synthesis of cyclic compounds[1]. With $n>2$, the equilibrium *(1)*⇌*(2)* lies on the side of the carbocycle, whereas with $n=1$ ring strain effects shift the equilibrium in favor of the acyclic diene[2].



Application of the reaction, despite its homogeneous course, has so far been limited to stereoselective olefin syntheses (*e.g.* 1,4,7-cyclononatriene[3a] or Cecropia juvenile hormone[3b]). The reaction should, in principle, be suitable in a reverse sense for stereoselective cyclopropane syntheses if it were possible to shift the equilibrium to the cyclic side, *e.g.* by an effect of substituents. A strong effect in this direction can be expected if during the reaction a CO-double bond can form at the expense of a less stable CC-double bond[4]. We have therefore studied the thermal behavior of the *cis*-2,5-hexadiene-1-ols *(1a)*—*(1e)*. The initial product of the hydrogen shift of *(1a)* should be the enol *(2a)*, which can be stabilized by enol-keto tautomerism to the aldehyde *(3a)*. According to an evaluation of the enthalpies of formation with the aid of Benson increments[5]



*(1a)* *(2a)* *(3a)*

the enol-keto tautomerism affords a gain in energy, hence the rearrangement *(1a)*→*(3a)* is *exo*-thermic ($\Delta\Delta H_f^0 = -8.8$ kcal/mol). The rearrangement *(1)*→*(2)* ($n=1$), on the other hand, is endothermic ($\Delta\Delta H_f^0 = +6.4$ kcal/mol).

*(1b)*—*(1e)* can be prepared analogously to the synthesis of *(1a)*[6a] starting from propargyl alcohol and substituted alkyl halides in two steps by basic $Cu^{\oplus}$-catalyzed CC-coupling and subsequent selective catalytic *cis*-hydrogenation of the CC-triple bond. Thermolysis of *(1a)*—*(1e)* in the gas

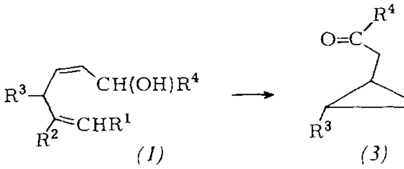
Abteilung für Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

phase[7] at *ca.* 260 °C leads to the air-sensitive aldehydes *(3a)*—*(3d)*[8] and the ketone *(3e)* in yields between 75 and 90% (Table 1). Only small amounts of side products (< 3%; not isolated) are formed.



*(1)* *(3)*

| | $R^1$ | $R^2$ | $R^3$ | $R^4$ |
|---|---|---|---|---|
| *a* | H | H | H | H |
| *b* | H | H | $CH_3$ | H |
| *c* | $CH_3$ | H | $CH_3$ | H |
| *d* | H | $CH_3$ | H | H |
| *e* | H | H | H | $CH_3$ |

Table 1. Results of the thermolysis of *(1a)*—*(1e)* at 263.3° in the gas phase.

| Reaction | Half-life [min] | $\Delta G^{\neq}$ [kcal/mol] | Yield of *(3)* [%] [a] |
|---|---|---|---|
| *(1a)* → *(3a)* | 569 | 43.5 | 82 |
| *(1b)* → *(3b)* | 40 | 40.7 | 90 |
| *(1c)* → *(3c)* | 286 | 42.8 | 85 |
| *(1d)* → *(3d)* | 490 | 43.4 | 75 |
| *(1e)* → *(3e)* | 203 | 42.5 | 85 |

[a] The yields were determined gas-chromatographically (35 m glass capillary column "Marlophen", 1 mL He/min, flow division 1 : 60, 90 °C) against *p*-diethylbenzene as standard. The values refer to unreacted educt after two half-lives.

The structural and stereochemical assignment of the products follows mainly from the 250-MHz $^1$H-NMR spectra (Table 2). Especially characteristic are the coupling constants $^3J_c$ and $^3J_t$ of the vicinal, *cis* and *trans* cyclopropane hydrogen atoms, which were determined by double resonance experiments. As expected[9] one finds $^3J_c$ (8.2—8.7 Hz) > $^3J_t$ (4.4—4.8 Hz) in each case for *(3a)*—*(3e)*. The *cis*-position of the 1-$CH_2$-$COR^4$- and 2-$CH_3$-groups could also be demonstrated independently by conversion of *(3a)*[10] into the *cis*-1-methyl-2-vinylcyclopropane (*cis*-*(2)*[2]).

Table 2. $^1$H-NMR data of *(3a)*—*(3e)* (250 MHz, $C_6D_6$).

*(3a)*: $\delta = -0.44$ (q, 3-$H^s$ [a]$= {}^2J_{\text{gem.}} = -4.4$ Hz, $^3J_{t,1\text{-H},3\text{-H}^s} = J_{t,2\text{-H},3\text{-H}^s} = 4.4$ Hz), 0.56 (m, 3-$H^a$ [b], $^3J_{c,1\text{-H},3\text{-H}^a} = {}^3J_{c,1\text{-H},3\text{-H}^a} = 8.7$ Hz), 0.67 (m, 1,2-H), 0.80 (d, $CH_3$), 1.85 (m, $CH_2$—CHO), 9.38 (t, —$CH_2$—CHO).

*(3b)*: $\delta = -0.09$ (m, 3-$H^s$, $^3J_{t,1\text{-H},3\text{-H}^s} = {}^3J_{t,2\text{-H},3\text{-H}^s} = 4.4$ Hz, $^3J_{3\text{-H}^s,3\text{-CH}_3} = 6.0$ Hz), 0.44 (m, 1,2-H), 0.82 (d, 3-$CH_3$), 0.96 (d, 2-$CH_3$), 1.89 (m, $CH_2$—CHO), 9.40 (t, $CH_2$—CHO).

*(3c)*: $\delta = -0.05$ (m, 3-$H^s$, $^3J_{t,1\text{-H},3\text{-H}^s} = {}^3J_{t,2\text{-H},3\text{-H}^s} = 4.8$ Hz, $^3J_{3\text{-H}^s,\text{CH}_3} = 6.3$ Hz), 0.33 (m, 2-H, $J_{C,1\text{-H},2\text{-H}} = 8.2$ Hz), 0.52 (m, 1-H), 0.91 (t, $CH_2$—$CH_3$), 0.99 (d, 3-$CH_3$), 1.06 (m, $CH_2$—$CH_3$), 1.90 (m, CH—CHO), 9.40 (t, $CH_2$—CHO).

*(3d)*: $\delta = -0.20$ (t, 3-$H^s$, $^2J_{\text{gem.}} = -4.5$ Hz, $^3J_{t,1\text{-H},3\text{-H}^s} = 4.5$ Hz), 0.37 (dd, 3-$H^a$, $^3J_{c,1\text{-H},3\text{-H}^a} = 8.2$ Hz), 0.83 (s, 3-$CH_3^s$), 0.95 (s, 3-$CH_3^a$), 1.87 (m, $CH_2$—CHO), 9.46 (t, $CH_2$—CHO).

*(3e)*: $\delta = -0.35$ (q, 3-$H^s$, $^2J_{\text{gem.}} = -4.6$ Hz, $J_{t,1\text{-H},3\text{-H}^s} = J_{t,2\text{-H},3\text{-H}^s} = 4.6$ Hz), 0.65 (m, 3-$H^a$, $J_{c,1\text{-H},3\text{-H}^a} = J_{c,2\text{-H},3\text{-H}^a} = 8.5$ Hz), 0.76 (m, 1,2-H), 0.89 (d, 2-$CH_3$), 1.77 (s, $CH_2$—$COCH_3$), 2.0 (m, $CH_2$—$COCH_3$).

[a] s = *syn*. [b] a = *anti* (relative to the $CH_2COR^4$ group).

Owing to its high degree of stereoselectivity the hydrogen shift observed here provides a method for the synthesis of *cis*-1,2-disubstituted cyclopropanes. As the rearrangements *(1b)*→*(3b)* and *(1c)*→*(3c)* show, only the sterically less hindered transition states *(4b, c)* are utilized. The more unfavorable transition states *(5b, c)* would have led to *all-cis*-trisubstituted cyclopropanes. Thus, with this method variously substituted cyclopropane systems can also be prepared stereospecifically. Because of the analogy to the "oxy-Cope rearrangement"[11], we propose the designation "oxy-homodienyl hydrogen shift" for this reaction. As in the oxy-Cope rearrangement[12a], the 1,3-sigmatropic carbon shift[12b], or the [4+2]-cycloreversion[12c], a metalation of the hydroxy group could lead to the thermolysis already taking place at considerably lower temperatures.

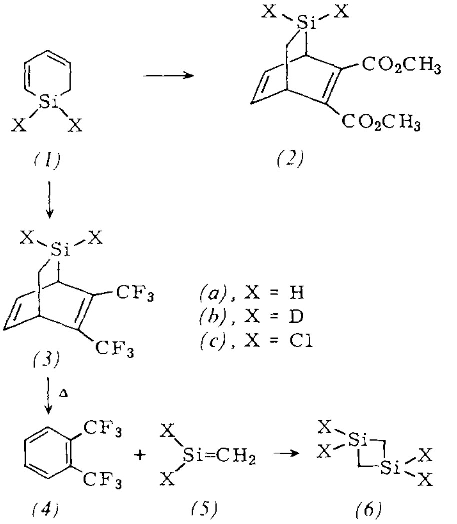
## Silaethene[**]

By *Günther Maier, Gerhard Mihm,* and
*Hans Peter Reisenauer*[*]

Encouraged by the successful matrix isolation of silabenzene[1], we ventured to approach unsubstituted silaethene[2]. While derivatives[3] are known, unequivocal evidence[4] for the parent compound, which is especially important in order to experimentally test theoretical predictions[5], was still awaited. We report the preparation of silaethene *(5a)* by retrodiene cleavage and its detection by IR and UV spectroscopy.

1,1-Dichloro-1-sila-2,4-cyclohexadiene *(1c)*[1a] and dimethyl acetylenedicarboxylate react to produce the adduct *(2c)* (Table 1), whose flash pyrolysis at 400 °C in the presence of benzene with nitrogen as the carrier gas, led to dimethyl phthalate and phthalic anhydride.

Attempts to trap the presumed intermediate product, 1,1-dichloro-1-silaethene *(5c)*, by carefully freezing the fragments formed by vacuum flash pyrolysis (650 °C, $10^{-4}$ torr)[6] in argon at 10 K, resulted in the detection of IR absorption bands at $\tilde{\nu} = 1008$, 732 and 593 $cm^{-1}$, in addition to those of the previously mentioned arenes. The same bands are also recognizable when the bicyclooctadiene *(3c)*[7] (Table 1), readily accessible from *(1c)* and perfluoro-2-butyne, is similarly cleaved. This observation and the fact that the normal flash pyrolysis (650 °C, 0.2 torr, product trapped at 77 K) of *(3c)* only yields *o*-bis(trifluoromethyl)benzene *(4)* and tetrachlorodisilacyclobutane *(6c)*[8], suggest that the absorptions measured in the matrix are assignable to *(5c)*.



The thermal behavior of the unchlorinated silaethene precursors *(3a)* and *(3b)*, which are readily obtained from *(1a)*[1a] and the silacyclohexadiene *(1b)*—prepared from *(1c)* and $LiAlD_4$—is even more assertive.

When *(3a)* or *(3b)* are heated to 420 °C with $N_2$ as the flow gas, in the presence of cyclohexane[7], *(4)* is smoothly formed together with the hydrogenated or deuterated 1,3-disilacyclobutanes *(6a)* or *(6b)*, respectively[8].

Table 1. Synthetic conditions together with physical and spectroscopic properties of compounds *(2c)*, *(3a)*, *(3b)* and *(3c)*. IR (film) [$cm^{-1}$]; NMR: $\delta$-values relative to TMS (in $CDCl_3$, unless otherwise specified).

*(2c)*: 6 h reflux in toluene; 57%; B.p. = 130 °C/$10^{-2}$ torr.—IR: 1740, 1730, 1718 (C=O), 1635, 1600 (C=C), 562 (Si—Cl).—$^1$H-NMR ($CCl_4$): 1.00 (2 H, d), 3.40—4.30 (2 H, m, +2 $CH_3$), 6.13—6.54 (2 H, m).—$^{13}$C-NMR: 15.00, 37.12, 38.31, 51.81, 51.93, 128.72, 131.78, 136.46, 139.32, 164.31, 165.26.—Correct elemental analysis.

*(3a)*: autoclave; 5 h, 90 °C; 52%; B.p. = 90 °C/100 torr.—IR: 2160 (Si—H), 1655, 1605 (C=C).—$^1$H-NMR: 0.82 (2 H, q), 3.53 (2 H, d), 3.94 (1 H, d), 4.20 (1 H, m), 5.90—6.33 (2 H, m).—$^{13}$C-NMR [a]: 6.94, 29.23, 35.19, 116.37, 127.28, 129.85, 130.38.—MS: *m/e* = 258.0299 (calc.), 258.0291 (found).

*(3b)*: as *(3a)*, 50%; B.p. = 90 °C/100 torr.—IR: 1655, 1605 (C=C), 1585, 1565 (Si—D).—$^1$H-NMR: 0.82 (2 H, d), 3.92 (1 H, d), 4.20 (1 H, m), 5.88—6.28 (2 H, m).—$^{13}$C-NMR [a]: 6.85, 29.26, 35.18, 116.46, 127.33, 129.85, 130.42.—MS: *m/e* = 260.0425 (calc.), 260.0425 (found).

*(3c)*: as *(3a)*, 71%; B.p. = 75 °C/5 torr.—IR: 1660, 1610 (C=C), 570 (Si—Cl).—$^1$H-NMR: 1.01 (2 H, q), 3.94 (1 H, d), 4.14 (1 H, d), 6.01—6.56 (2 H, m).—$^{13}$C-NMR [a]: 14.26, 36.03, 37.56, 114.78, 128.98 [b], 132.04.—MS: *m/e* = 325.9520 (calc.), 325.9515 (found).

[a] The C-atoms of the $CF_3$ groups are not observable under the recording conditions. [b] Two olefinic C-atoms coincidently show the same chemical shift.

By means of a combination of vacuum flash pyrolysis (650 °C, $10^{-4}$ torr) and matrix isolation techniques, apart from the bands originating from *(4)*, the IR absorptions shown in Table 2 can also be measured. The latter disappear upon irradiation ($\lambda = 254$ nm) of the condensate[9]. This also occurs upon thawing of the argon matrix at 35 K. Hereby, the corresponding 1,3-disilacyclobutanes *(6a)* and *(6b)* are formed.

Table 2. IR and UV absorption bands of the silaethenes *(5a)*, *(5b)* and *(5c)*, together with those of the dimerization products *(6a)*, *(6b)* and *(6c)*.

| | Silaethenes *(5)* | | | 1,3-Disilacyclobutanes *(6)* |
|---|---|---|---|---|
| | IR [$cm^{-1}$] | UV [nm] | | IR [$cm^{-1}$] |
| *(5a)* | 2239 (m), 2219 (m), 985 (w), 927 (w), 817 (s), 741 (s) | 258 [a] | *(6a)* | 2160—2140 (m), 961 (s), 899 (s) |
| *(5b)* | 1635 (m), 1600 (m), 952 (w), 759 (s), 719 (s), 396 (w) | 259 [a] | *(6b)* | 1677 (m), 1654 (m), 786 (s), 689 (s) |
| *(5c)* | 1008 (m), 732 (s), 593 (m) | 246 [a] | *(6c)* | [b] |

[a] The extinction is considerably greater than that of the $\alpha$-band of *(4)*. [b] The low intensity of the bands from *(6c)* do not permit unambiguous identification.

Of the bands observed, the antisymmetric and symmetric Si—H and Si—D vibrational frequencies are of considerable diagnostic use. These frequencies are found above 2200 $cm^{-1}$ in silabenzene (2217 $cm^{-1}$)[1a]. The still higher wavenumbers (2239 and 2219 $cm^{-1}$) suggest that the product obtained from *(3a)* is in fact a compound with a hydrogen atom on an $sp^2$-hybridized silicon atom[3f]. These experimentally determined frequencies lie between the values obtained by calculation (2480[5c] and 2160[4] $cm^{-1}$). The correctness of the assignment follows from the shift of the bands mentioned above to much lower wavenumbers (1635 $cm^{-1}$ and 1600 $cm^{-1}$) in the product prepared from the deuterated precursor *(3b)*.

Comparison of the matrix UV spectrum of separately matrix isolated arene *(4)* with the matrix spectra obtained by pyrolysis of *(3a)*, *(3b)* and *(3c)*, indicates that the silaethenes *(5a)*, *(5b)* and *(5c)* are characterized by distinct UV

maxima (Table 2)[10]. These disappear, as do the corresponding IR bands, upon irradiation or thawing of the matrices.

It should be noted that the most commonly used route to silaethenes, *i.e.* the pyrolysis of the corresponding silacyclobutanes[2,4], cannot be transferred to the parent compound. Instead of *(5a)* only propene, ethene and acetylene can be detected as cleavage products after vacuum flash pyrolysis[11].

The following conclusions can be drawn: 1) Unsubstituted silaethene *(5a)* and its derivatives *(5b)* and *(5c)* are species capable of existence and can be identified by IR and UV spectroscopy. 2) They are only stable under conditions of matrix isolation at 10 K. 3) On thawing of the matrix they dimerize to 1,3-disilacyclobutanes.

# Silaethene: Highly Correlated Wave Functions and Photoelectron Spectroscopic Evidence[**]

By *Pavel Rosmus, Hans Bock, Bahman Solouki, Günther Maier*, and *Gerhard Mihm*[*]

*Dedicated to Professor Edgar Heilbronner on the occasion of his 60th birthday*

*Ab initio* quantum mechanical calculations, which account for large portions of the electron correlation[1,2], yield reliable theoretical predictions of experimentally unknown molecular properties[3]. Thus, ionization energies can be calculated to an accuracy of *ca.* 0.1 to 0.3 eV, *i.e.* to a degree of accuracy sufficient to identify unknown molecules by photoelectron spectroscopy. We have used such a combination of theory and experiment in the search for thermal dissociation reactions through which silaethene could be formed[4,5].

The quality of the wave function plays an important role in calculations of energy differences: the total energies for silaethene calculated by us, are, to date, the most accurate for this molecule[6]. For all electronic states treated, we have obtained 70 to 80% of the valence electron correlation energies. The vertical energy differences are shown in Table 1.

Table 1. Vertical energy differences between the ground state of the neutral molecule $H_2Si{=}CH_2$ and the doublet state of the radical cation $H_2Si{=}CH_2^{\cdot\oplus}$.

| Method of calculation | | $\tilde{X}(^2B_1)$ | $\tilde{A}(^2B_2)$ | $\tilde{B}(^2A_1)$ | $\tilde{C}(^2B_2)$ | $\tilde{D}(^2A_1)$ | $\tilde{E}(^2A_1)$ |
|---|---|---|---|---|---|---|---|
| $\Delta E^{SCF}$ | [eV] | 7.40 | 12.6 | 12.3 | 14.7 | 18.0 | 23.0 |
| $\Delta E^{PNO-CEPA}$ | [eV] | 8.59 | 12.5 | 12.7 | 14.2 | 16.9 | 21.1 |
| "$IE_n$" | [eV] | 8.95±.1 | 12.5±.1 | 12.9±.1 | 14.1±.1 | 16.5±.2 | 20.4±.3 |

The ionization energies "$IE_n$" are estimated from the energy differences $\Delta E^{SCF}$ and $\Delta E^{PNO-CEPA}$, using the assumption that approximately 75% of the correlation contributions are covered.

It should be possible to detect silaethene by photoelectron spectroscopy, in particular from the predicted first ionization energy at 8.95±0.1 eV. However, in numerous pyrolysis experiments on promising precursors, such as 1,3-disilacyclobutane, no reproducible bands in the expected region were observed[4,5]. Finally, in the thermal retrodiene cleavage of the bis(trifluoromethyl)-substituted bicycle[5], a novel band with vibrational fine structure (Fig. 1) appears, whose intensity increases upon addition of argon to the flowing gas. Higher ionization bands are masked by the superimposed PE spectrum of the cleaved off component 1,2-bis(trifluoromethyl)benzene (Fig. 1).

The following additional arguments corroborate the assignment of silaethene as a retrodiene dissociation product[5]: The first ionization energy is observed in the pre-cal-

[**] For previous work on highly correlated wave functions see: *H. J. Werner, P. Rosmus*, J. Chem. Phys. *73*, 2319 (1980). Also Part 25 on Analysis and Optimization of Gas Phase Reactions.—Part 24: *H. Bock, T. Hirabayashi, S. Mohmand*, Chem. Ber., in press.

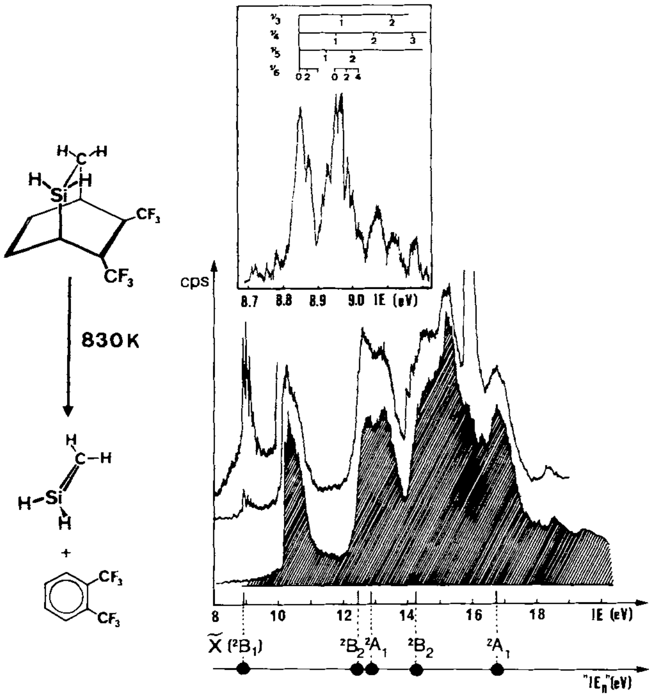

Fig. 1. He(I)-PE spectrum of the thermal retrodiene dissociation products of 5,6-bis(trifluoromethyl)-2-silabicyclo[2.2.2]octa-5,7-diene at 850 K (hatched: 1,2-bis(trifluoromethyl)benzene) as well as the expanded vibrational fine structure of the ground state of the silaethene radical cation with the following suggested assignments (from top to bottom: $\tilde{\nu}_3(a_1, \delta_{CH_2}) = 1010 \pm 40\ cm^{-1}$, $\tilde{\nu}(a_1; \nu_{Si=C} + \delta_{SiH_2}) = 840\ cm^{-1}$; $\tilde{\nu}_5(a_1; \nu_{Si=C} + \delta_{SiH_2}) = 620\ cm^{-1}$ and $\tilde{\nu}_6(a_2; \tau) \approx 200\ cm^{-1}$).

culated energy region; mixing with the inert gas argon apparently inhibits secondary reactions and the pronounced vibrational fine structure of the first PE band (Fig. 1) resembles that of the iso(valence)electronic ethene[7]. In particular, the vibrational progressions assigned (cf. Fig. 1: $\nu_4$ and $\nu_5$ $(\delta_{SiH_2} + \nu_{Si=C})$) preclude, with a high degree of probability, the presence of isomers[4] such as $CH_3$—Si—H or $H_3Si$—C—H. The PES-values of the analogously generated $D_2Si{=}CH_2^{\cdot\oplus}$ amount to 770 and 550 $cm^{-1}$.

The resolved fine structure of the first PES band indicates a twisted equilibrium structure in the ground state for the radical cation $H_2Si{=}CH_2^{\cdot\oplus}$: both the lowest doublet states (cf. Table 1, $\tilde{X}(^2B_1)$ and $\tilde{A}(^2B_2)$) are coupled *via* the torsional vibration $\nu_6(a_2)$. In addition to the totally symmetric vibrations, it becomes excited and is assigned to the frequencies observed at $\approx 200\ cm^{-1}$ (Fig. 1: $2n \cdot \nu_6$; for $D_2Si{=}CH_2^{\cdot\oplus} \approx 120\ cm^{-1}$). Furthermore, such an interpretation supports the twisted equilibrium structure deduced for the iso(valence)electronic radical cation $H_2C{=}CH_2^{\cdot\oplus}$, which has a similar PES-vibrational fine structure[7]—a classic example of structure alteration upon oxidation or reduction of molecules[8].

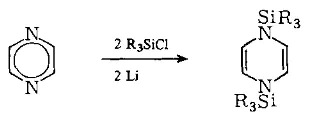
## The "Antiaromaticity" of 1,4-Dihydropyrazines[**]

By *Wolfgang Kaim*[*]

1,4-Dihydropyrazines, as cyclic 8π-electron systems, are potential antiaromatic compounds[1,2a]. Until now, the only known organic derivatives have been highly substituted[2]; however, the reductive silylation of pyrazine offers a straightforward route to the very reactive compound *(1)*[3].



*(1)*, R = $CH_3$

From the X-ray structure analysis of a 1,2,4,6-tetraaryl-1,4-dihydropyrazine, the central six-membered ring exists in a flat boat conformation; the cyclic conjugation appears to be markedly impaired by the bending of the aryl substituent on N-1[4]. Since silyl substituents are able to flatten the pyramidal configuration at the amine nitrogen atom[5], sufficient conjugation of *all* eight π-electrons should occur in a molecule such as *(1)*. As a criterion of "antiaromatic" behavior, the paramagnetic ring current concept is used[6], which—*cum grano salis*[7]—is specifically suitable for

[**] The author acknowledges the award of a Liebig-Stipendium from the Fonds der Chemischen Industrie.

monocyclic compounds[6], and has been of particular heuristic value for comparative studies[8].

For this reason, in addition to the model compound *(1)*, the three isomeric dimethyl derivatives *(2)*—*(4)* were prepared[9a]; the 1,2,3,4-tetrahydropyrazine *(5)*[9b] and the 1,4-dihydropyridine *(6)*[9c] are given for comparison with non-conjugated systems. The $^1$H-NMR data of these compounds are collected in Table 1.

| *(5)* | 5.38 | 3.14 | 0.08 | — |
| *(6)* [a] | 5.97 (2, 6)<br>4.62 (3, 5) | 3.17 | | — |

[a] In $C_6D_6$, $\delta_{SiCH_3}$ is not reported [9c]. [b] Pyrazine. [c] 2,5-Dimethylpyrazine. [d] 2,3-Dimethylpyrazine. [e] 2,6-Dimethylpyrazine.

Comparison of the data of *(5)* and *(6)* with that of *(1)* clearly shows the effect of the 8π-electron conjugation, which, on the basis of the paramagnetic ring current, leads to a high-field shift of the olefinic protons of *ca.* 0.75 ppm (Fig. 1). Similar high-field shifts have been observed in other "antiaromatic" molecules[8], however *aromatic* compounds have often been used for purposes of comparison[8c-e].

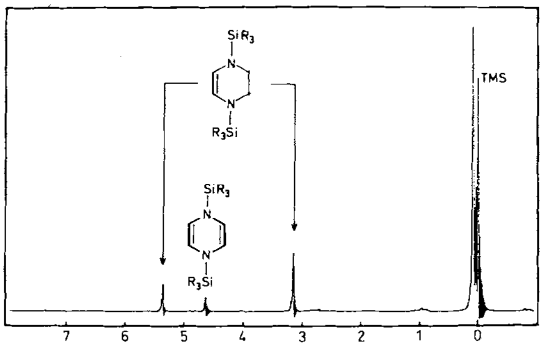

Fig. 1. $^1$H-NMR spectrum (60 MHz, $CDCl_3$) of the mixture of *(5)* and *(1)* obtained by partial hydrogenation of *(1)*. Signal at δ=2.8: *N,N'*-bis(trimethylsilyl)piperazine.

Investigation of the dimethyl derivatives *(2)*—*(4)* yields a remarkable result: In all of these compounds, both the olefinic and methylsilyl protons are shifted to *low field*, relative to the unsubstituted molecule *(1)*, although the methyl group normally exerts the opposite effect (cf. Table 1, pyrazines). The chemical shifts of the CH-protons follow a characteristic series: While a small paramagnetic ring current can still be determined upon 2,5-substitution, the 2,3- and 2,6-dimethyl derivatives exhibit no significant difference from the non-conjugated compound *(5)*.

These substitution effects are probably caused by steric interactions; as shown by the X-ray structure analysis[4], 2,6-substitution deforms the 1,4-dihydropyrazine framework so effectively, that the π-electron conjugation is interrupted. Similarly, the steric interaction of neighboring 2,3-substituents is expected to reduce the conjugation because of a more pronounced boat structure. Only 2,5-substitution still allows sufficient π-electron conjugation.

It is therefore comprehensible why all known organic 1,4-dihydropyrazine derivatives bear aryl substituents in the 2,3-[2a] or 2,6-[2b-d] positions; according to the NMR data[2] ($\delta_{CH} > 5.32$), these compounds have, in fact, no paratropic[6c] character.

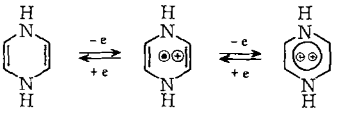
Niederurseler Hang, D-6000 Frankfurt am Main 50 (Germany)

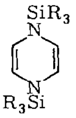
[**] The author thanks the Fonds der Chemischen Industrie for a Liebig-Stipendium.

bital and consequently should be highly reactive[1]. Until now *(1)* has not been synthesized, but the one- and two-electron oxidation products *(1)*$^{+\cdot}$ and *(2)*$^{2+}$ have been detected[2]:

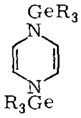


*(1)* *(1)*$^{+\cdot}$ *(1)*$^{2+}$

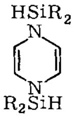
Reductive silylation of pyrazine[3] yields 1,4-bis(trimethylsilyl)-1,4-dihydropyrazine *(2)*, which, in contrast to the highly substituted organic derivatives of *(1)*, exhibits considerable conjugation of *all* eight π-electrons[4] and is a suitable model compound for *(1)*[5]. The photoelectron (PE) spectra of *(2)* and of four other 1,4-dihydropyrazine derivatives *(3)*—*(6)*[6] provide information on the radical cation states of the compounds; these states are advantageously described using molecular orbitals[7]. The first three ionization energies of the compounds *(2)*—*(6)*, together with the corresponding orbital assignments, are shown in Table 1.



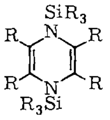
*(2)*



*(3)*



*(4)*



*(5)*

*(6)*

R = $CH_3$

Table 1. PE spectroscopically determined vertical ionization energies $IE^v_{1-3}$ [eV] of the 1,4-dihydropyrazine derivatives *(2)*—*(6)*.

| Compound | $IE^v_1$ | $IE^v_2$ | $IE^v_3$ |
|---|---|---|---|
| *(2)* | 6.16 $b_{3u}(\pi_S^*)$ [a] | 9.5 $b_{1g}(\pi_S)$ | 9.5 $b_{2g}(\pi_A)$ |
| *(3)* | 5.87 $b_{3u}(\pi_S^*)$ | 9.15 $b_{1g}(\pi_S)$ | 9.50 $b_{2g}(\pi_A)$ |
| *(4)* | 6.33 $b_{3u}(\pi_S^*)$ | 9.7 $b_{1g}(\pi_S)$ | 9.7 $b_{2g}(\pi_A)$ |
| *(5)* | 6.48 $b_{3u}(\pi_S^*)$ | 8.10 $b_{2g}(\pi_A)$ | 8.70 $b_{1g}(\pi_S)$ |
| *(6)* | 6.50 $b_1$ | 8.25 $a_2$ | 9.00 $b_1$ |

[a] For denotion of orbitals the symmetry groups $D_{2h}$ and $C_{2v}$, which are valid for planar structures, were used for *(2)*—*(5)* and *(6)* respectively; coordinates according to [8].

The PES data demonstrate:

1) Compounds *(2)*—*(6)* are extraordinarily electron rich[9]; their ionization potentials are similar to those of tetrakis(dialkylamino)ethenes or phosphorus ylides[10]. Of particular note is the extremely low first ionization potential (5.87 eV!) of the trimethylgermyl derivative *(3)* (Fig. 1).

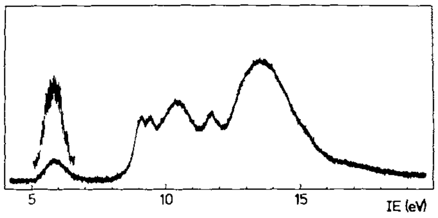


Fig. 1. He(I)-PE spectrum of *(3)* over the region 4 to 20 eV, first band amplified ($R = CH_3$).

2) Variation of the *N*-substituents in *(2)*—*(4)* leads to characteristic shifts of the ionization energies and hence permits assignment of the orbitals to the individual radical cation states. While one ionization remains approximately constant at *ca.* 9.6 eV, and the associated state $\tilde{B} = {}^2B_{2g}$ can therefore be described by a $\pi_A$ molecular orbital[1,8], the first two ionization energies are influenced to approximately the same extent and decrease along the series *(4)*> *(2)*> *(3)* *i.e.* with decreasing "electronegativity" of the nitrogen centers; accordingly these $\tilde{X} = {}^2B_{3u}$ and $\tilde{A} = {}^2B_{1g}$ states correspond to $\pi_S^*$ and $\pi_s$ molecular orbitals[1,8].

3) Unexpectedly, the four methyl groups at the 2,3,5,6-positions do not lead to a reduction[11] but to an increase of the ionization energy of *(5)* relative to *(2)*; apparently, the $CH_3$-electron donor effect is more than compensated by reduction of the cyclic conjugation caused by considerable steric interactions[4]. Benzannulation, as in the quinoxaline derivative *(6)* also increases the ionization potential relative to *(2)*; here, apart from steric interactions, the lowering of the occupied antibonding molecular orbital by a process of charge delocalization[1] into the condensed ring, is also significant[9].

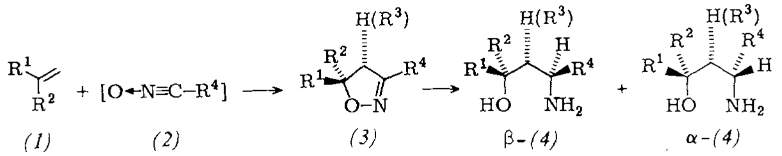
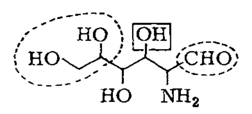
[**] Syntheses with Isoxazolines, Part 9. Part of the Dissertations by *V. B.* (1979) and *W. S.* (1981). This work was supported by the Deutsche Forschungsgemeinschaft.—Part 8: *H. Grund, V. Jäger,* J. Chem. Res. (S) *1979*, 54; (M) *1979*, 649.

sphingolipid bases or amino sugars. *Simple* γ-aminoalcohols *(4)* can be constructed from alkene and nitrile oxide building blocks *(1)* and *(2)* *via* isoxazolines *(3)*, which are equivalent to aldols (β-hydroxyketones)[1]. In addition, the reduction by $LiAlH_4$/ether[2] in many cases can be effected with preparatively useful diastereoselectivity ($\gtrsim 3:1$[3]). In this connection unusually high 1,3-asymmetric induction was stated. In the reduction of *cis/trans*-4,5-dimethylisoxazolines *additivity* of the individual substituent effects ($\Delta\Delta G^{+}$ values) is observed[1].





(5)

It therefore seemed obvious to examine the potential of the isoxazoline route with respect to the synthesis of more complex natural aminoalcohols. With aminodeoxyhexoses such as *(5)* set as a long-term objective, first of all it is required to introduce and carry along further *O*-functions in *(3)*.

The requisite *O*-functions in the *side-chains* of *(3)*—encircled by a dotted line in *(5)*—can be provided in free or protected form by appropriate choice of the cycloaddition components[1d,4]; for derivatives with a *central* hydroxy group—OH group shown in a box in *(5)*—access is given by hydroxylation of isoxazoline-4-anions[5]. In order to solve the problem posed, it then remains essential to determine the influence of free and protected hydroxy groups at the positions stated regarding the stereoselectivity of the reduction step. The most important results relating to this point are listed in Table 1.

Table 1. Aminoalcohols *(4)* from isoxazolines *(3)* by $LiAlH_4$ reduction [a].

[g] After hydrolysis to *(4e)* with $CH_3OH—CHCl_3/H_2SO_4$, then treatment with $^{\ominus}OH$-form of Lewatit M 600 G-3. [h] Yield of β-*(4h)*: 61%. [i] Not very stable; correct elemental analyses of hydrochloride (m.p. 205—210 °C) and triacetate (m.p. 91—97 °C) were obtained.

$LiAlH_4$-reduction of the 5-tetradecyl derivatives *(3a)*—*(3d)*, which served as models for the synthesis of phytosphingosine[5], for the simplest case *(3a)* afforded an 88 : 12 mixture of the diastereomeric 2-amino-4-octadecanols β-*(4)*/α-*(4)*. A 3-hydroxymethyl group, as in *(3b)*, decreases the diastereoselectivity of the process (Table 1). This could be avoided by blocking the hydroxy group, *e.g.* as 2-tetrahydropyranyl (THP) or *tert*-butyl ether as in *(3c)* or *(3d)*, to the extent that useful diastereomer ratios are achieved once again (Table 1).

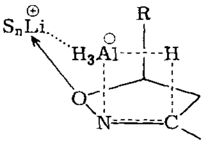
In the reduction of *(3e)* the 5-hydroxymethyl group causes the hydride transfer to occur preferentially from the substituent face of the ring: In the case of *(4e)* we found a β/α ratio of 37 : 63, thus a reversal—even though preparatively unsatisfactory—of the main direction of attack compared to the parent compounds with $R^1 = CH_3$ (β/α = 85 : 15; $\Delta\Delta G^{+}_{308} = 1.06$ kcal/mol[1]). In the THP derivative *(3f)* this hinge effect[6] is still exerted, if only weak (Table 1). The high diastereoselectivity desired is found when the "haptophilicity"[6] of the OH-group is made void by tritylation: After reduction of *(3g)* and deblocking to give *(4e)*, a β/α ratio of 92 : 8 was recorded; the predominant isomer, *erythro*-4-amino-1,2-pentanediol β-*(4g)* could be isolated in 61% yield[7].

The direction of hydride addition to the C═N double bond of *(3h)* is influenced by *both* 5-substituents, methyl *and* hydroxymethyl. The diastereoisomer ratio of β-*(4h)*/α-*(4h)* (88 : 12) again reflects the additivity of the individual substituent effects[8,9]: According to the calculated differences in the free enthalpies of activation for 5-$CH_3$[1] and 5-$CH_2OH$ one would expect a difference of −1.4 kcal/mol, corresponding to a β/α ratio of 90.5 : 9.5 for the hydride transfer from the two different ring faces in *(3h)*. The deviation from the value of 88 : 12 actually observed lies within the limits of experimental error of the $^1H$- and $^{13}C$-NMR spectroscopical determination of diastereomer ratios.

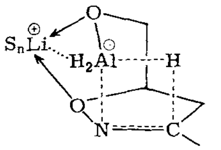
The most powerful directing effect in these reductions was observed in the case of 4-hydroxyisoxazoline *(3i)*[5]: A 69 : 31 mixture of the aminoalcohols was obtained upon reaction of 4-methyl-3-phenylisoxazoline with $LiAlH_4$[1a,c];

in contrast, according to $^1$H-NMR analysis the reduction of *(3i)* furnishes a crude product containing $>90\%$ of one diastereomer of *(4i)*. The relative configuration of the main product could not be deduced from NMR data; however, the inductions stated in the case of 5-methyl- and 5-hydroxymethylisoxazolines suggest formation of the *erythro* diastereomer β-*(4i)*. This interpretation is supported by the results of the phytosphingosine synthesis[5].

The stereochemical outcome of most of these reductions can be satisfactorily accounted for by the following assumptions: in substrates bearing alkyl or phenyl substituents, inducing (*anti*-directing) by size[8] only (cf. *(6)*[10]), solvated lithium cations are coordinated to the free electron pairs of the isoxazoline oxygen atom[1c,d] on both faces of the ring to a different degree. Hence different transition states for the hydride transfer from the respective aluminate counter-ions associated follow.



*(6)* → α-*(4)* (unfavorable)



*(7)* → α-*(4)* (preferred)

In the case of substrates with OR functions, other or additional coordination complexes are involved. If hydroxy groups are present, such as in *(3e)* and *(3i)*, hydride transfer preferably will result from the corresponding intermediate alkoxyaluminate species such as *(7)*; substituents of this kind are *syn*-directing.

The effects described here complement and extend the possibilities to direct cation-assisted nucleophilic additions by means of hydroxy groups, *or* to preclude their action, and thus to exert steric control in the synthesis of acyclic compounds[1d,6,7,11]. In particular, this allows for regio- and stereocontrolled syntheses of *erythro*-aminodiols and many other aminopolyols.

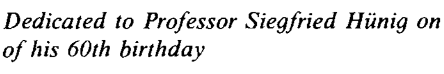
# 4-Hydroxylation of Isoxazolines; Synthesis of *rac*-Phytosphingosine (*ribo*-2-Amino-1,3,4-octadecanetriol)[**]

By *Wilfried Schwab* and *Volker Jäger*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

4-Hydroxyisoxazolines are potential precursors for the synthesis of many natural aminopolyols and amino sugars[1]. However, they are not available by nitrile oxide cycloaddition to enol ethers or esters, since 5-alkoxy- and 5-acyloxyisoxazolines are then formed[2]. We have now found an access to *trans*-4-hydroxyisoxazolines by reacting isoxazoline 4-anions[3] with borates, followed by oxidative work-up[4]. The latter constitutes the crucial step of this process: Although anion formation proceeds almost quantitatively[3], incomplete conversion was observed; we attributed this to the competing protolysis of the intermediate boronates. The best results then were achieved by applying concentrated oxidizing agents (hydrogen peroxide or *tert*-butyl hydroperoxide) in the presence of amine or ammonia. *(1)* and *(2)* were thus isolated in yields of 67% (m.p. 96 °C) and 78% (m.p. 102—105 °C), respectively[5]. In the case of *(2)* only the *trans*-isomer ($>90:10$) was formed, according to the $^{13}$C-NMR spectrum of the crude product.



*(1)*, $R^1$ = H
*(2)*, $R^1$ = $CH_3$

1) Lithium diisopropylamide (LDA), tetrahydrofuran (THF)/hexamethylphosphoric triamide (HMPA), -78°C.
2) $B(O\text{-}i\text{-}C_3H_7)_3$ for *(1)*, $B(OCH_3)_3$ for *(2)*, -78 °C.
3) $H_2O_2$, $NEt_3$ für *(1)*, $NH_3$ for *(2)*, -78 °C → RT.

The synthesis of $C_{18}$-phytosphingosine *(6a)*, the long-chain base characteristic of plant sphingolipids[6], was attempted then, with 1-hexadecene and 2-nitroethanol *(3a)* serving as suitable building blocks. For the cycloaddition

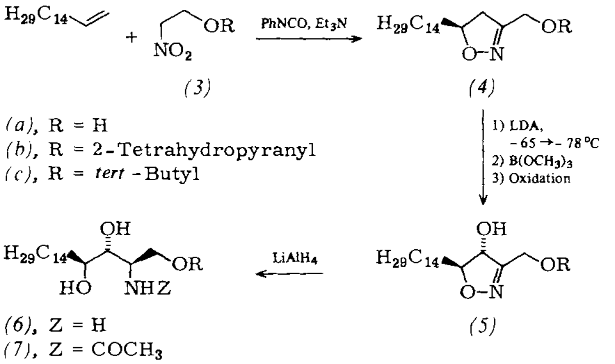
[**] Syntheses *via* Isoxazolines, Part 10. Delivered in part in lectures at Würzburg (3. 7. 1979) and Berlin (GDCh Hauptversammlung, 14. 9. 1979); part of the Dissertation by *W. S.*, Giessen 1981. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 9: [1].

according to the method of *Mukaiyama*[2a], *(3a)* was used as the 2-tetrahydropyranyl ether *(3b)*[1]. The metalation/hydroxylation of the cycloadduct *(4b)* was carried out similarly as with the model compounds. *(5b)* was isolated in up to 55.5% yield, either by lengthy fractional crystallization or by crystallization and chromatographic purification of the mother liquors. Here, too, the hydroxylation proceeded in a highly stereoselective manner: The $^{13}C$-NMR spectra of *(5b)* and of its solvolysis product *(5a)* (with $CH_3OH$/HCl; 98%, m.p. 74—78 °C) did not show any of the signals expected for the *cis*-isoxazoline[7]. Reduction of *(5b)* with $LiAlH_4$[1], followed by removal of the THP group with $HCl/CH_3OH$ produced the hydrochloride of *(6a)*. The broad-band decoupled $^{13}C$-NMR spectrum once again indicated none of the other diastereomers nor impurities to be present. This is consistent with the stereochemical outcome of the reduction of the model compound *(1)*[1]. *rac*-Phytosphingosine *(6a)* was recovered on treatment with basic ion-exchange resin (yield *ca.* 33% with respect to nitroethanol); it was pure according to elemental and $^{13}C$-NMR analyses. The synthetic product *(6a)* was converted into the *N*-acetyl derivative *(7)*; a comparison of its $^{13}C$-NMR spectrum with that of authentic D-*(7)*[8] confirmed the identity of the relative configuration of the synthetic product, as was shown also by GC comparison[9] of the silylated derivatives.



In a modified version of this route, *(6a)* was obtained from the *tert*-butyl ether *(3c)* in similar over-all yield (29%). Here the 4-hydroxyisoxazoline *(5c)* was isolated after crystallization *without* subsequent use of chromatography (oxidative work-up with *tert*-butyl hydroperoxide/triethylamine, or 85% hydrogen peroxide/conc. aqueous ammonia).

Compared with previous syntheses of phytosphingosine (7—9 steps, over-all yields 2—6%[6b,d]), the efficiency of the isoxazoline route for the straightforward synthesis of such aminopolyols is evident. Stereo-controlled syntheses of important amino sugars of this and other configurations are the subject of further work, key steps of which have already been successful[10].

## Procedure

*(6a)*[5] *Cycloaddition:* Hexadecene (14.4 cm³, 50 mmol) and *(3b)* (50 mmol) (crude product of the reaction of *(3a)* with 2 equivalents of dihydropyran/50 mg of *p*-toluenesulfonic acid) are allowed to react as described in Ref. [1]; yield of *(4b)* 13.46 g (70.5%), in fractions with m.p. 28—30 to 34—36.5 °C (mixtures of diastereomers). *(4c)* was obtained analogously as a colorless liquid in 74.1% yield from *(3c)* (20 mmol; crude product of the reaction of *(3a)* with 2-methylpropene/conc. $H_2SO_4$ in $CH_2Cl_2$).—*Hydroxylation: (4b)* (381 mg, 1 mmol), dissolved in THF (2 cm³), was added by means of a syringe to a solution of LDA (1.5 mmol) in 15 cm³ THF/0.7 cm³ (4 mmol) HMPA at −65 °C; 30 min later the mixture was cooled to −78 °C and, after 2 h, treated with $B(OMe)_3$ (0.23 cm³, 2 mmol) and kept for 2.5 h. 0.83 cm³ (6 mmol) $Et_3N$/1 cm³ *tert*-butyl hydroperoxide (10 mmol, 80% with *tert*-butyl peroxide) was then added. The resulting mixture was allowed to warm, stirred at room temperature for 60 h and treated successively with 5 cm³ of $H_2O$, after 30 min with 5 cm³ of conc. $NH_4Cl$ solution and kept for 15 min, then 1 g $NaHSO_3$ was added. After a further 15 min the mixture was extracted four times with ether. Washing (1 N NaOH, half-saturated solution of $NH_4Cl$; three times half-saturated solution of NaCl), drying ($Na_2SO_4$), evaporating and crystallization from cyclohexane/pentane afforded 138 mg of *(5b)* with m.p. 68—73 °C together with a further 79 mg *(5b)*, m.p. 47—50 °C (major part; rest up to 69 °C) after chromatography ($SiO_2$ column, Merck, eluent $CH_2Cl_2/Et_2O$ 4 : 1) and crystallization as above; total yield 55.5%.—*(5c):* From *(4c)* (3 mmol) in an analogous way, however oxidative work-up with 0.9 cm³ (*ca.* 12 mmol) of conc. aqueous ammonia/0.78 cm³ 85% $H_2O_2$; repeated crystallization from cyclohexane afforded analytically pure fractions of 375 mg (m.p. 63—64 °C), 103 mg (m.p. 60—65 °C), and 85 mg (m.p. 60-63 °C; according to $^{13}C$-NMR together with a trace of starting material); total yield 50.8%.—*Reduction:* a) *(5b)* was reduced as detailed in [1]; THP-ether cleavage with $CH_3OH$/HCl in 1.5 h at 60 °C. From 360 mg of *(5b)*, 89.5% of analytically pure *(6a)*·HCl of m.p. (dec.) 200 °C was obtained (isomerically pure according to $^{13}C$-NMR), from which the base *(6a)* (95%) was liberated by means of Lewasorb A 50 ($^{\ominus}$OH form); melting range 68—76 °C (amorphous according to Debye-Scherrer photographs). Recrystallization, from $CH_3CN$/ether gave a product of m.p. 138—144 °C (with sintering above *ca.* 85 °C; lit. m.p. 149—151 °C)[6d]. For identification, 265 mg of *(6a)*·HCl was treated with acetic anhydride/3 N NaOH; after recrystallization from acetone, 250 mg (93%) of *(7)* were obtained as colorless, analytically pure product of m.p. 118—123 °C (sintering at 96—98 °C; lit. m.p. 110—111 °C for D,L-*(7)*[6d]; m.p. 113—123 °C for natural D-*(7)*[8]). $^{13}C$-NMR ($CDCl_3/CH_3OH$ *ca.* 4 : 1; values for D-*(7)* in brackets[8]): $\delta = 33.4$ [C-5 (33.3)], 52.5 [C-2 (52.3)], 61.3 [C-1 (61.3)], 72.8 [C-4 (72.7)], 75.9 [C-3 (75.9)] for the most important signals.—b) Reduction of *(5c)*: From 323 mg of *(5c)*, 308 mg (95%) of colorless crystalline *(6c)* were isolated, m.p. 80—83.5 °C. After removal of the *tert*-butyl group from 115 mg of *(6c)* with 0.4 cm³ of $BF_3 \cdot OEt_2$ in 4 cm³ $CH_2Cl_2$ at room temperature the product was treated and stirred for 15 min each with 2 cm³ of $CH_3OH$, then 3 cm³ of conc. aqueous ammonia, then mixed with 10 cm³ of semi-saturated $NH_4Cl$ solution, and extracted three times with $CH_2Cl_2$. After washing ($H_2O$, then twice with semi-saturated NaCl solution), drying, and removal of the solvent, 77 mg (81%) of *(6a)* was obtained as above.

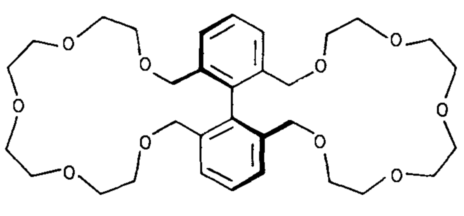
## Allosteric Effects: Binding Cooperativity in a Subunit Model[**]

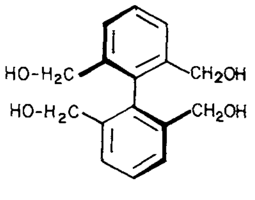
By *J. Rebek, Jr. R. V. Wattley, T. Costello, R. Gadwood* and *L. Marshall*[*]

The binding cooperativity shown by hemoglobin toward oxygen is one of the most intriguing manifestations of allosteric effects. These effects—interactions between remote sites—result from conformational changes induced by binding; in general they provide a means by which the catalytic activity of enzymes can be regulated[1]. We have recently shown that processes involving "small" molecules in solution can also be subjected to such control[2] and we report here the first example of a model system which shows binding cooperativity between two remote sites.

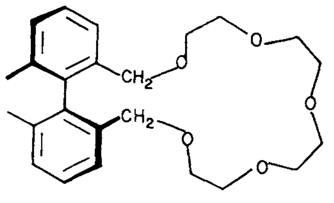
The macrobicyclic structure *(1)* incorporates the minimum requirements for such behavior: symmetrically disposed binding sites and a conformational mechanism by which binding at one polyether site can increase the receptivity of the other. Specifically, that distance between the benzylic C-atoms which is optimum for ion binding to one site is faithfully reproduced at the other site by the rigidity of the biphenyl system. This predictable, mechanical action of *(1)* is precisely the feature which distinguishes it from the host of other known macrobicyclic polyethers.



*(1)*



*(2)*



*(3)*

Polyether *(1)* was obtained as a low-melting solid (m.p. = 70—72 °C)[3] in 20—30% yield, through the action of NaH and tetraethylene glycol ditosylate on the tetra-alcohol *(2)*. The latter is readily available from pyrene through ozonolysis followed by reduction[4]. The monocyclic counterpart *(3)* was also prepared for purposes of comparison.

Analysis of the binding behavior of subunit systems such as *(1)* requires measurements over a large range, *i.e.* from a few percent of the sites occupied to near saturation. High resolution NMR spectroscopy proved to be ideal for this purpose and Figure 1 summarizes the changes observed in the spectra of the downfield aromatic protons, in positions 3,5 and 3′,5′ of the benzyl skeleton, when *(1)* was titrated with $Hg(CN)_2$ in $(CD_3)_2CO/C_6D_6$ (1 : 1, v/v) at 15 °C.

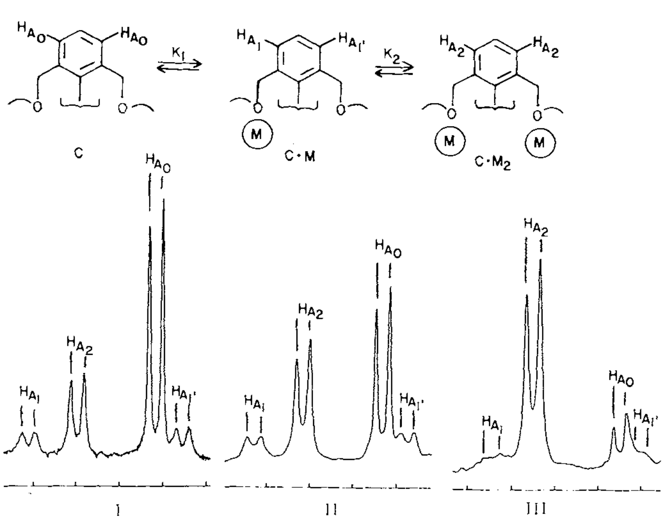


Fig. 1. Changes in the aromatic proton region of the $^{1}$H-NMR spectrum of *(1)* (600 MHz) upon addition of $Hg(CN)_2$. I, 38% sites occupied; II, 50% sites occupied; III, 74% sites occupied.

[**] This research was supported by the National Institutes of Health. Additional funds from the same agency maintain the 600-MHz NMR facility at the Mellon Institute of Carnegie-Mellon University.

The concentration of the various species—free *(1)* (C), the 1 : 1 complex (C·M), and the 2 : 1 complex ($C\cdot M_2$) could be determined by integration of the well resolved 600-MHz $^1H$-NMR spectrum. The excellent resolution is due to the relatively slow rates of exchange involved in complexation of $Hg(CN)_2$ with these ethers. In contrast, alkali metals showed rapid exchange rates and resulted in averaged spectra for the various species.

The ratio $K_2/K_1=[C\cdot M_2]\cdot C/[C\cdot M]^2$ of the macroscopic association constants $K_1=[C\cdot M]/[C]\cdot[M]$ and $K_2=[C\cdot M_2]/[C\cdot M]\cdot[M]$ can be determined directly from the $^1H$-NMR-spectrum. It is found that $K_2=(2.5\pm0.2)\,K_1$. However, these constants must be corrected for statistical effects. The corrected (intrinsic) association constants are $K_2^i\approx 10\,K_1^i$ *i.e.* the system shows *positive cooperativity*. The *Hill* plot of the data[5] produces a slope of $n=1.5$, with mid-point at a free metal concentration of *ca.* 0.03 M. This corresponds to $K_1^i=10\,\text{M}^{-1}$, in good agreement with that observed for the monocyclic polyether *(3)* ($K=13\,\text{M}^{-1}$).

The receptivity of the ether toward a second $Hg(CN)_2$ is enhanced 10-fold by the binding of the first $Hg(CN)_2$. The conformational restrictions imposed on the open site by binding of the first metal are modest—only one of the many internal rotations are removed, yet receptivity is increased by an order of magnitude[6]. This suggests that even greater cooperativity should be available to systems composed of less flexible subunits.

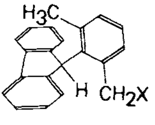
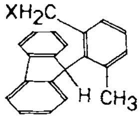
## Contrasting Behavior in the Substitution Reactions of 9-(2-Bromomethyl-6-methylphenyl)fluorene Rotamers[**]

By *Shigeru Murata, Seiichiro Kanno, Yo Tanabe, Mikio Nakamura,* and *Michinori Ōki*[*]

We wish to report that the *sp-* and *ap*-rotamers of 9-(2-bromomethyl-6-methylphenyl)fluorene *(1)* behave quite differently in substitution reactions. *sp-(1)* and *ap-(1)* were prepared by bromination of 9-(2,6-dimethylphenyl)fluorene[1] and separated by preparative high pressure liquid chromatography ($SiO_2$/hexane). Since the activation parameters for interconversion of both rotamers are known ($E_A=27.1$ kcal/mol, $\log A=11.4$), the time necessary for conversion of 5% ($^1H$-NMR detection limit) of one isomer, into the other by internal rotation can be calculated *e.g.* 27.2 h at 62 °C. In order to detect the differences in reactivities of the respective rotamers, the reactions must be carried out under conditions which will not permit isomerization to a detectable degree. At the outset we focused our attention on $S_N2$-type reactions in dimethyl sulfoxide. Preliminary experiments with methanol indicated that, while *sp-(1)* reacted with measurable rates at 57 °C, *ap-(1)* was almost inert. Since methanolysis produces hydrogen bromide, the reaction is autocatalyzed and hence, to compare the rates of clean $S_N2$ reactions, we used 2-methylpyridine as a nucleophile[2]. The pseudo-first order rate constants of the reactions in acetone in the presence of 2-methylpyridine at 34 °C were $1.4\times10^{-2}$ and $4.0\times10^{-4}$ $\text{min}^{-1}$ for *sp-(1)* and *ap-(1),* respectively. Thus *sp-(1)* is *ca.* 35 times more reactive than *ap-(1),* under the conditions used. The products were the corresponding 2-methylpyridinium salts: *sp-(2)* (m.p. = 226—227 °C (decomp.)) and *ap-(2)* (oil)[3]. The poorer reactivity of the *ap*-form may be attributed to the blocking of the back-side of the leaving group $Br^{\ominus}$ by the fluorene moiety.

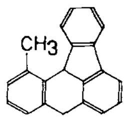
*sp-(1),* X = Br
*sp-(2),* X = $\overset{\oplus}{N}C_5H_4CH_3$



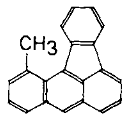


*ap-(1),* X = Br
*ap-(2),* X = $\overset{\oplus}{N}C_5H_4CH_3$

For an investigation of $S_N1$ reactions, we chose trifluoroacetic acid as solvent which has a high dielectric constant but low nucleophilicity. Heating a solution of *ap-(1)* in $CF_3CO_2H/CDCl_3$ (1 : 1) at 61.2 °C caused a decrease in intensity of the methyl and methylene signals in the $^1H$-NMR spectrum of *ap-(1)* from which a rate constant of *ca.* $7\times10^{-4}$ $\text{min}^{-1}$ for the reaction involved was obtained. In sharp contrast, *sp-(1)* did not react with a measurable rate under the same conditions. The enhanced reactivity of the *ap*-form may be ascribed to the interaction of the π-electrons of the fluorene ring with the carbenium ion formed; the inertness of the *sp*-form is due to the lack of such participation.



*(3)*



*(4)*

The product of the reaction of *ap-(1)* in $CF_3CO_2H$/$CDCl_3$ (1 : 1) was a mixture of polymers which could be formed by an intermolecular Friedel-Crafts reaction. However, when the reaction was carried out in dilute solution, identifiable products were obtained *i.e.* heating 33 mg of *ap-(1)* in 1.5 $cm^3$ of $CHCl_3$ and 25 $cm^3$ of $CF_3CO_2H$ afforded 8 mg of 12-methyl-8,12b-dihydrobenz[a]aceanthrene *(3)* (m.p. = 180—181 °C)[5] and 3 mg of 12-methylbenz[a]aceanthrene *(4)* (yellow-orange oil)[6]. The yield of *(4)* decreased if the reaction was carried out under $N_2$, indicating that *(4)* is formed from *(3)* by dehydrogenation of *(2)* by $O_2$. Formation of *(3)* is expected if ionization occurs at the $CH_2$—Br site and intramolecular Friedel-Crafts cy-

clization follows. The reason why the concentrated solution of *ap-(1)* only gave polymeric product may be, that for the cyclization, rotation about the C9—C1′-bond has to take place: since the barrier to rotation is high, polymerization is preferred.

In conclusion, the rotamers *sp-(1)* and *ap-(1)* exhibit remarkable differences in nucleophilic substitution reactions. In $S_N2$ reactions *sp-(1)* is—predominantly for stereochemical reasons—more reactive, however, in $S_N1$ reactions *ap-(1)* is—predominantly because of electronic interactions—more reactive.

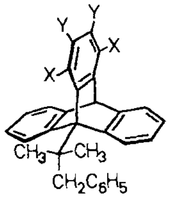
## *peri*-Substituent Effects on the Rotational Barrier of 9-(1,1-Dimethyl-2-phenylethyl)triptycene[**]

By *Gaku Yamamoto, Masahiko Suzuki*, and *Michinori Ōki*[*]

Substitution at the *peri*-position of 9-substituted triptycene derivatives generally raises the barrier to rotation about the 9-substituent-to-bridgehead bond, when the 9-substituent is a primary or a secondary alkyl group[1]. In 9-(1-cyano- or 1-methoxycarbonyl-1-methylethyl)triptycene, introduction of a chloro or a methyl group into the *peri*-position has been found to decrease the rotational barrier[2]. In order to see if this is a general phenomenon in 9-*tert*-alkyl substituted triptycene derivatives, and to investigate the effects of some other *peri*-substituents, we studied the rotational barriers in 9-(1,1-dimethyl-2-phenylethyl)triptycenes with a variety of *peri*-substituents and found an interesting dependence of the barrier on the nature of the substituents.



*ap-(1)-ap-(5)*

*(1)*, X = H, Y = Cl
*(2)*, X = Y = F
*(3)*, X = OCH$_3$, Y = H
*(4)*, X = Y = Cl
*(5)*, X = CH$_3$, Y = H

Previously we reported the stereoselective synthesis and high rotational stability of 2,3-dichloro-9-(1,1-dimethyl-2-phenylethyl)triptycene *(1)*[3]. Reaction of 9-(1,1-dimethyl-2-phenylethyl)anthracene with dehydrobenzene derivatives gave, stereoselectively, the *ap*-rotamers of *(2)*—*(5)*[4]. A study of the kinetics of the *ap*→ ± *sc* isomerization was carried out by NMR spectroscopy (by $^{19}$F- for *(2)* and $^1$H-NMR for the others) in 1-chloronaphthalene solutions between 160—280°C (Table 1). The ±*sc*-rotamers were isolated upon chromatographic separation of the equilibrated mixture[4].

Table 1. Equilibrium and kinetic parameters for *ap*→ ± *sc* isomerization in 1-chloronaphthalene.

$$ap\text{-rotamer} \underset{k_{-1}}{\overset{2k_1}{\rightleftharpoons}} \pm sc\text{-rotamer}$$

$$K = 2k_1/k_{-1} = [\pm sc]/[ap]$$

| Compound | *peri*-Substituent [a] | | $K$ | $T$ [°C] | $\Delta H^{+}$ [kcal/mol] | $\Delta S^{+}$ [eu] | $\Delta G^{+}_{500\,K}$ [kcal/mol] |
|---|---|---|---|---|---|---|---|

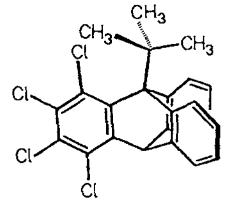
| *(4)* | Cl | (1.80) | 0.48 | (208) | 34.7 | − 7.0 | 38.2 |
| *(5)* | CH$_3$ | (2.0) | 0.41 | (212) | 31.6 | − 13.9 | 38.6 |

[a] In parentheses are the van der Waals radii after Pauling [5] (in Å). [b] van der Waals radius of an oxygen atom.



*(6)*

Table 1 reveals that relatively small *peri*-groups (F or OCH$_3$) considerably increase the barrier relative to that for the *peri*-unsubstituted derivative *(1)*, while bulkier groups (Cl or CH$_3$) *decrease* the barrier. Since the barrier is the energy difference between the ground and the transition states, the effects of *peri*-substitution on both should be examined.

9-*tert*-Butyltriptycene was used as a model compound for these investigations. The crystal structure of its 1,2,3,4-tetrachloro derivative *(6)* reveals the effects of *peri*-substitution on the ground state geometry[6]. The most prominent feature is the tilting of the *tert*-butyl and the *peri*-chloro groups away from each other, due to steric compression. This feature may be found to a greater or less extent in any of the *peri*-substituted derivatives and can be represented by the Newman projection *(8)*; the *peri*-unsubstituted compound is shown in *(7)*. The bulkier the *peri*-group, the greater the degree of tilting of the axis bond and the greater the ground state energy level.

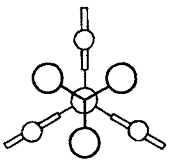
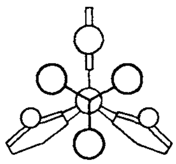
[**] Restricted Rotation Involving the Tetrahedral Carbon, Part 32. This work was supported by the Japanese Ministry of Education.—Part 31: [2b].

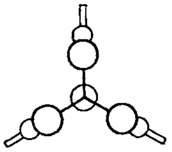
(7)

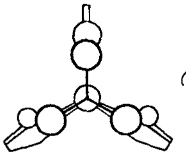




(8)

(9)





(10)

The *peri*-unsubstituted derivative adopts conformation *(9)* as the transition state for rotation, where the $CH_3/H$ eclipsing interaction simultaneously becomes maximal at the three sites, assuming that the geometry of the *tert*-butyl group in the ground state is also maintained in the transition state. In the *peri*-substituted derivatives, however—because of the tilting of the *tert*-butyl group—only one methyl group and the substituent X are eclipsed at a time; the other two methyl groups become eclipsed before or after the maximal $CH_3/X$-interaction. If the *peri*-group is relatively small (F or $OCH_3$), the tilting of the axis-bond is not large and the time lags for the eclipsing process will be small. Since the steric interaction between $CH_3$ and X in *(10)* should be larger than in *(8)*, the destabilization of the transition state should exceed that of the ground state, resulting in an increase of the barrier. Further increase of the bulkiness of the *peri*-substituent causes even larger tilting of the axis-bond and the time lags for eclipsing become larger. Thus, in spite of the large $CH_3/X$-interaction the destabilization of the transition state may be less than that of the ground state, and result in a decrease of the rotational barrier.

It may be argued that the above discussion is an oversimplification of the transition state for rotation, because it neglects the changes in bond lengths and angles. However, we believe that the differential timing of the maximal eclipsing interaction between the *peri*-groups and the side chains of the 9-substituent contributes, at least partially, to the origin of the unusual dependence of the barrier on *peri*-substitution.

## *P*-Functionalized Diferriophosphonium Salts and Complex-Stabilized Derivatives of Phosphinic Acid[**]

By *Hans Schäfer*[*]

A cationic $PH_2$-bridged iron complex *(1)* has been prepared for the first time in the following way:

$$2\ \mathrm{Cp(CO)_2FeX} + \mathrm{Me_3SiPH_2} \xrightarrow[-\ \mathrm{Me_3SiX}]{\mathrm{C_6H_5CH_3},\ 20\,^{\circ}\mathrm{C}} [\mathrm{Cp(CO)_2Fe}]_2\mathrm{PH_2}^{\oplus}\mathrm{X}^{\ominus}$$

*(1a)*, X = Cl; *(1b)*, X = Br; *(1c)*, X = $BPh_4$

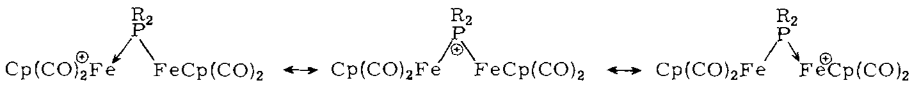
Using similar Si—P cleavage reactions we were previously able to synthesize neutral, open-chain[1] and cyclic[2] $PH_2$-complexes of some transition metals.

$$(1)\ \xrightarrow[\mathrm{CD_3OD}]{\mathrm{D_2O\ or}} [\mathrm{Cp(CO)_2Fe}]_2\mathrm{PD_2}^{\oplus}\mathrm{X}^{\ominus}$$

*(2a)*, X = Cl; *(2b)*, X = Br; *(2c)*, X = $BPh_4$

*(1a)* and *(1b)* can be converted into the tetraphenyl borate *(1c)* by reaction with $NaBPh_4$ in acetone. The salts are air-stable in the crystalline state; *(1a)* and *(1b)* dissolve without decomposition in water and methanol, *(1c)* in acetone, tetrahydrofuran (THF), and dichloromethane. The solutions can be stored indefinitely under an inert gas atmosphere in the dark at room temperature (20 °C). When treated with $D_2O$ or $CD_3OD$ a selective H/D exchange takes place with formation of salts *(2)* containing a *P*-deuterated cation.

The diferriophosphonium ion—the nomenclature corresponds to the central one of the three possible mesomeric resonance formulas—



$$\mathrm{Cp(CO)_2^{\oplus}Fe}\overset{\overset{\mathrm{R_2}}{\mathrm{P}}}{\diagup\ \diagdown}\mathrm{FeCp(CO)_2} \longleftrightarrow \mathrm{Cp(CO)_2Fe}\overset{\overset{\mathrm{R_2}}{\mathrm{P}}}{\diagup^{\oplus}\diagdown}\mathrm{FeCp(CO)_2} \longleftrightarrow \mathrm{Cp(CO)_2Fe}\overset{\overset{\mathrm{R_2}}{\mathrm{P}}}{\diagup\ \diagdown}\mathrm{Fe^{\oplus}Cp(CO)_2}$$

is isoelectronic with the neutral $SiH_2$ complex $[Cp(CO)_2Fe]_2SiH_2$ prepared by *Aylett*[3a]. SiH-[3] and PH-bonds[2a] are so activated by double transition-metal substitution that hydrogen-halogen exchange is observed with

[**] Transition Metal Phosphido-Complexes, Part 5: This work was supported by the Deutsche Forschungsgemeinschaft.—Part 4: [1].

halogenated hydrocarbons even at 20 °C. This enables a gentle halogenation, and thus functionalization of the bridging $PH_2$-group without altering the basic structural moiety. *(1c)* can be converted into salts containing bishalogenated cations using $CBr_4$ or $CCl_4$ in acetone. However, side reactions with the $BPh_4$ anion lead to the formation of a mixture of ionic products. On reaction of *(1a)* or *(1b)* with $CBr_4$ or $CCl_4$ in methanol at 20 °C the hydrogen atoms attached to phosphorus are first replaced by halogen atoms and those consecutively by methoxy groups. The reactions involving several intermediates finally yield the salts *(3a)* and *(3b)* with the first $P(OCH_3)_2$-bridged complex cation, which can be precipitated as the $BPh_4$-salt *(3c)*.

$$(1a,b) + 2\,CX_4 + 2\,CH_3OH \xrightarrow[-2\,CHX_3,\,-2\,HX]{CH_3OH,\ 20\,^\circ C} [Cp(CO)_2Fe]_2P(OCH_3)_2^{\oplus}X^{\ominus}$$

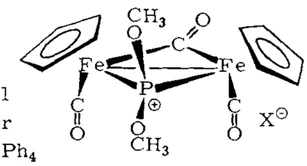
*(3a)*, X = Cl; *(3b)*, X = Br;
*(3c)*, X = $BPh_4$

Reaction of *(1a, b)* with $CBr_4$ in aqueous solutions affords a complex from which *(4c)* can be obtained; *(4c)* is a complex-stabilized derivative of phosphinic acid in which for the first time a $P(OH)_2$ group functions as a bridge.

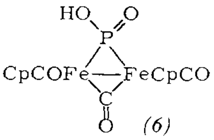
$$(1a,b) + 2\,CBr_4 + 2\,H_2O \xrightarrow[-2\,CHBr_3,\,-2\,HBr]{(CH_3)_2CO,\ H_2O,\ 20\,^\circ C} [Cp(CO)_2Fe]_2P(OH)_2^{\oplus}X^{\ominus}$$

*(4a)*, X = Cl; *(4b)*, X = Br;
*(4c)*, X = $BPh_4$

The IR spectra of solutions of compounds *(1c)*—*(4c)* in acetone each show three CO stretching vibrations of about equal intensity (Table 1). The diferriophosphonium ions of salts *(1)*—*(4)* are presumably sterically fixed in solution and have $C_{2v}$ symmetry[4]. This assumption is supported by the observation that only the salt *(5c)*, in which the cation is present as *cis*-isomer, is formed with cleavage of CO if *(3c)* is irradiated with UV light in acetone.



*(5a)*, X = Cl
*(5b)*, X = Br
*(5c)*, X = $BPh_4$



*(6)*

The structure of the cation of *(5)*, with both Cp groups on the same side of the $Fe_2P$ ring, follows from the $^1H$-NMR spectrum (Table 1), since the two $CH_3O$-groups have a different environment only in this isomer.

A single relatively sharp OH-stretching vibration in the IR spectrum of *(4c)* at 3400 $cm^{-1}$ indicates that the OH-groups of the cation of *(4)* are not associated[5].

*(4c)* is extremely sensitive to light. Upon UV irradiation of an aqueous solution of the bromide *(4b)*, CO is evolved and red crystals are precipitated which, according to the IR spectra, consist of a neutral, cyclic diferriophosphinic acid derivative *(6)*.

In the crystalline state *(6)* is air-stable and only moderately soluble in THF. On addition of bases (NaOH, $NEt_3$), *(6)* is soluble in water, methanol, acetone, THF, and dichloromethane. The IR spectra of the crystals of *(6)* show bands at 2740, 2330 and 1240 $cm^{-1}$ typical for associated P(O)OH-groups. An X-ray structure analysis carried out by *B. Deppisch* on a single crystal shows that *(6)* is associated to give dimers *via* hydrogen bonding of the P(O)OH groups. The two Cp groups are coordinated exclusively in the *cis* position, just as in *(5)*.

### *Procedure*

All reactions up to the isolation of the crystalline products must be carried out under an inert gas atmosphere in anhydrous and degassed solvents and, with the exception of the photolysis, in the absence of light.

*(1b)* and *(1c)*: $Me_3SiPH_2$ (2.34 g, 22 mmol) is condensed under reduced pressure into a mixture of $Cp(CO)_2FeBr$ (10.27 g, 40 mmol) and toluene (100 $cm^3$) cooled with liquid nitrogen. After warming to room temperature (20 °C) the mixture is stirred for 6 h under reduced pressure. The yellow precipitate is filtered, washed with toluene, and dried at $10^{-3}$ torr. This crude product *(1b)* can be used directly for further reactions. Recrystallization from $CH_3OH$ at −78 °C affords 4.76 g (51%) of yellow-brown, air-stable crystals of *(1b)*. Treatment of the crude product with excess $NaBPh_4$ in excess acetone and recrystallization from ace-

tone at $-20\,^{\circ}C$ yields 8.5 g (60%) of golden-yellow, air-stable crystals of *(1c)*.

*(2b)* and *(2c)*: *(1b)* (0.2 g) is recrystallized twice from $CD_3OD$ at $-78\,^{\circ}C$. 0.12 g (60%) of *(2b)* are isolated. *(1c)* (0.5 g) is stirred twice for 1 d with a mixture of acetone and a few drops of $CD_3OD$ or $D_2O$ at $20\,^{\circ}C$ and recrystallized from acetone at $-20\,^{\circ}C$; 0.4 g (80%) of *(2c)* are obtained.

*(3c)*: *(1b)* (1.5 g, *ca.* 3 mmol) is dissolved in $CH_3OH$ (20 $cm^3$), treated with 2.32 g (7 mmol) of $CBr_4$, and the mixture stirred for 8 d. All volatile components are distilled off under reduced pressure at $20\,^{\circ}C$. The residue is re-dissolved in $CH_3OH$ (20 $cm^3$), and the solution is stirred further for 2 d. On addition of excess $NaBPh_4$ *(3c)* precipitates as a yellow powder, which is recrystallized from acetone at $-20\,^{\circ}C$; *(3c)* (1.38 g, *ca.* 60%) is obtained as yellow, air-stable crystals.

*(5c)*: *(3c)* (1 g, 1.3 mmol) is dissolved in acetone and irradiated with UV light (HANAU TQ 150, externally through DURAN 50 glass) for 6 h at $20\,^{\circ}C$ and *ca.* 300 torr. The solution is filtered, concentrated under reduced pressure at $20\,^{\circ}C$, and brought to crystallization at $-78\,^{\circ}C$; *(5c)* (0.62 g, 65%) is obtained as red-brown, air-stable crystals.

*(4c)* and *(6)*: A crude sample of *(1b)* (2.5 g, *ca.* 5 mmol) is dissolved in a mixture of distilled water (100 $cm^3$) and acetone (100 $cm^3$), treated with $CBr_4$ (4 g, 12 mmol) and the final mixture stirred for 24 h. A little more than 100 $cm^3$ of the solution is distilled off (most of the acetone) at $20\,^{\circ}C$. The remaining solution is diluted with 100 $cm^3$ of distilled water, filtered, and divided into two parts. To one half of the solution excess $NaBPh_4$ is added and the resulting yellow powder is filtered off, washed with distilled water, and dried for 12 h at $20\,^{\circ}C$ and $10^{-3}$ torr; *(4c)* (1.48 g, 80%) is isolated as a yellow powder, which is sensitive to light and air.

The other half of the solution is irradiated with UV light (for conditions see above) at $20\,^{\circ}C$ and *ca.* 300 torr until the evolution of CO ceases (*ca.* 6 h). The red crystals are filtered off, washed with acetone, and dried at $20\,^{\circ}C$ under reduced pressure; *(6)* (0.68 g, *ca.* 70%) is obtained as red, air-stable crystals.

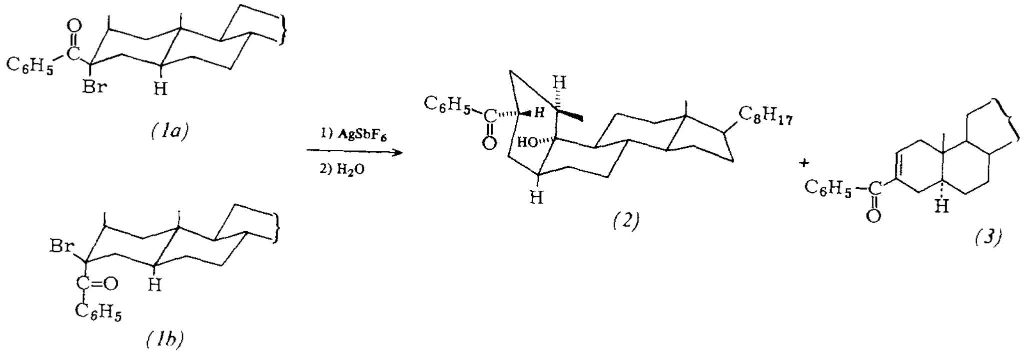
## Regio- and Stereoselective "Long-Range" Hydroxylation of Cholestanes—A Novel Route to 5α-Steroids with *cis*-Coupled A,B-Rings

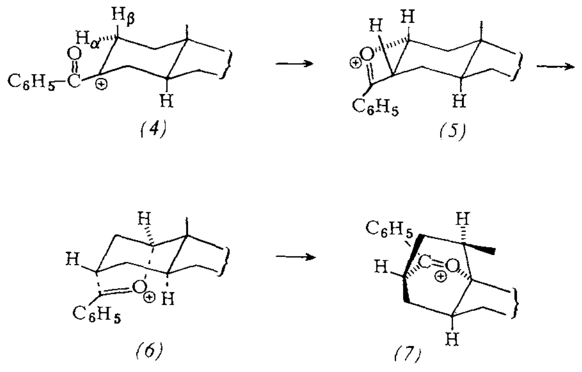
By *Jean-Pierre Bégué*[*]

For some time we have investigated whether compounds can be regio- and stereoselectively hydroxylated, *via* α-acylcarbenium ions, at positions far removed from the carbenium ion center[1]. We have now succeeded in applying this method, which had previously been successfully used on cyclohexane systems, to steroids; the intermediate formation of oxonium ions should prevent backbone rearrangements, and, hence, stereoselective hydroxylation can be anticipated.



The bromides *(1a)* and *(1b)*, prepared from cholestanone[2], were dehalogenated with $AgSbF_6$ (1.5 equivalents) in $CH_2Cl_2$ and, following hydrolysis and thin layer chromatography (silica gel), the hydroxyketone *(2)* [yield: 45 or 32%] and the unsaturated ketone *(3)* [yield: 35 or 25%] were isolated. *(2)* (m.p. = 155 – 160 °C) was identified by means of an X-ray structure analysis[3] and spectroscopic data[4].

The formation of *(2)* and *(3)* can be explained by the initial formation of the α-acylcarbenium ion *(4)*[5]; *(4)* can then undergo two competitive reactions: either by hydride- and methanide-shifts *via (5)* and *(6)* to the oxonium ion *(7)*, resulting in formation of *(2)*, or directly to *(3)* *via* proton elimination. *(3)* is the expected elimination product of a C-3-substituted 5α-steroid[6].



---

[*] Dr. J. P. Bégué
Groupe de Recherche No. 12 (CNRS)
2 rue Henri-Dunant, F-94320 Thiais (France)

The transformation (1)→(2), which is novel for steroids, consists of the following individual steps: (5) is formed by hydride-shift of 2-$H_\beta$ to C-3[7] and successive migration of the 1-H and 19-Me groups—the last step is accompanied by an inversion of the configuration at C-10—leads to the 5-$H_\alpha$ steroid (2).

In educt (1b), the 2-$H_\beta$ and Br are *cis* to each other, this corroborates an earlier observation that dissociation of the C—Br bond and the 1,2-hydride shifts occur sequentially[2]. The fact that in both possible reactions of (4), only 2-H and not 4-H is involved, indicates that analogous intermediate conformations occur in both cases[8].

We have therefore succeeded in the regio- and stereoselective "long-range" hydroxylation of the C-10 position of steroids. Furthermore, the unusual isomerization of an A/B-*trans* to an A/B-*cis* steroid (5-H) has been observed.

## Synthesis of a Novel Biscarbene Type of Complex[1]

By *Ernst Otto Fischer, Werner Röll, Ulrich Schubert*, and *Klaus Ackermann*[*]

The direct reaction of carbonyl transition metal monocarbenes with nucleophiles LiR to give biscarbene complexes is, with few exceptions[2], thwarted by the strong electrophilic character of the carbene carbon atom; the addition does not take place at one of the CO ligands, but at the carbene carbon.

We have now succeeded in synthesizing 1,4-chelated *cis*-bis[alkoxy(aryl)carbene] complexes by reaction of *o*-dilithiobenzene[3] with hexacarbonylchromium, -molybdenum or -tungsten and alkylation of the adducts with triethyloxonium tetrafluoroborate.

The biscarbene complexes (1)—(3) are stable in the solid state at room temperature, crystallize from pentane as permanganate-colored to black leaflets, and dissolve in most common organic solvents to give dark-red solutions.

If the complex is assumed to have quasi-octahedral structure, then the four $\nu_{CO}$ bands of the IR spectra are in agreement with theory; the short-wavelength vibration corresponds to the species $A_1^{(2)}$, the long-wavelength vibration to the species $B_2$.

The insertion of a second carbene function leads to a significant shielding of the carbene carbon atom compared to in $(CO)_5M[C(OR^1)R^2]$[4], whereas a downfield shift is observed for $^{13}$C{$^1$H}-NMR signals of the CO groups, in agreement with investigations by *Todd et al.*[5]. The resonances of the remaining aromatic and aliphatic carbon atoms of (1)—(3) lie in the usual range for carbene complexes.

The X-ray structure analysis[6] of (1) shows that the presence of two *cis*-carbene ligands in the complex has only a

slight effect on the bonding of the carbene carbon atom, but that the coordination octahedron of the metal is markedly distorted. The $C_{carbene}$—Cr and $C_{carbene}$—$C_{phenylene}$ bond lengths are comparable with those found in other alkoxy(aryl)carbene complexes of chromium, only $C_{carbene}$—O is slightly shorter (cf.[7]). The angles at $C_{carbene}$ are not unduly affected by the ring formation. The phenylene ring is essentially coplanar with the atoms of the two carbene groups and, within the standard deviations, shows no bond-length alternation.

The coordination octahedron is distorted in two respects by the chelate effect of the biscarbene ligand ($C_{carbene}$—Cr—$C_{carbene}$ angle of 81.3°) (cf. [8]): 1. Since the *trans*-$C_{carbene}$—Cr—$C_{CO}$ groups in the plane of the carbene ligands with 179.0 and 178.5° are almost linear and no bending of this plane takes place, the $C_{CO}$—Cr—$C_{CO}$ angle of 82.3° is likewise very small, while the *cis*-$C_{carbene}$—Cr—$C_{CO}$ angles of 98.5 and 97.9° are distinctly widened.—2. The CO ligands perpendicular to the carbene plane are bent in towards the chelate ring and form an angle of 171.7(3)° with each other.

## *Procedure*

A suspension of $Cr(CO)_6$ (2.5 g, 11.3 mmol) in 150 ml tetrahydrofuran is treated at 0 °C with 80 ml of a 0.15 M solution of *o*-dilithiobenzene in ether and the mixture stirred for 1 h. The solvent is then removed and the residue is taken up in 100 ml of dichloromethane (−10 °C). A solution of triethyloxonium salt in $CH_2Cl_2$ is now added dropwise until the mixture no longer reacts alkaline, and, after 15 minutes' stirring, the mixture is evaporated to dryness. The crude product is chromatographed at −25 °C with pentane/$CH_2Cl_2$ (5 : 1) on silica gel. The eluate of the almost black zone is evaporated down, dissolved in pentane, and allowed to crystallize at −78 °C; m.p. 115 °C *(1)*. *(2)* and *(3)* are obtained analogously; m.p. 104 °C and 114 °C, respectively.

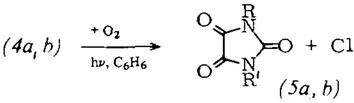
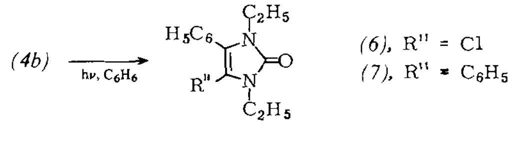
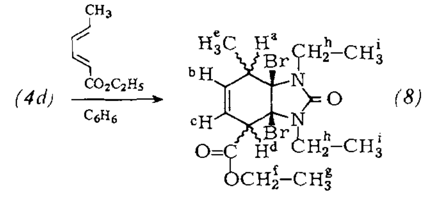
fluoroborate in high yields to the crystalline, stable, high-melting imidazolium salts *(3a—d)*. On treatment with dilute sodium hydroxide the salts *(3a—d)*, readily soluble in dimethylformamide, exchange their 2-halogen substituents for hydroxy groups selectively and almost quantitatively. With NaOH the intermediary 2-hydroxyimidazolium salts in turn split off $NaBF_4$ to afford the 4,5-dihalo-2(3*H*)-imidazolones *(4a—d)* (cf. Table 1)[8]. The chloro-derivatives *(4a, b)* are stable, whereas the bromo-derivatives *(4e, d)* decompose even with traces of moisture or on exposure to light.

UV irradiation (benzene, filter $\lambda = 350$ nm) of *(4a, b)* without carefully excluding oxygen (or far more rapidly on passing through $O_2$) leads in high yields to the dialkylparabanic acids *(5a, b)*[9a], most probably *via* the intermediary endoperoxides[10], which spontaneously eliminate chlorine. If oxygen is completely excluded, *e.g.* in argon atmosphere, *(4b)* is photoarylated (benzene, filter $\lambda = 320$ nm); *(6)* and *(7)* can be detected (each 3% yield) with the aid of mass spectrometry.







The sole isolable Diels-Alder adduct *(8)* of *(4d)* is formed with ethyl sorbate on heating for 8 h in benzene under inert gas. Careful work-up affords colorless crystals which rapidly decompose. *(8)* is characterized spectroscopically (see Table 1); the mass spectrum shows a molecular ion (triplet) of weak intensity at $m/e = 436$.

### *Procedure*

*(2a—d):* A suspension of anhydrous potassium carbonate in a solution of *(1a, c)* (100 mmol) in anhydrous acetone (300 $cm^3$) is treated with 100 mmol dialkyl sulfate and the mixture heated for 2 h under reflux. After filtration, evaporation of the filtrate to dryness, and treatment of the residue with ethanol, *(2a—d)* are precipitated with water. Yield/m.p. (b.p.): *(2a):* 78%/79 °C; Ref. [6] 75 °C. *(2b):* 83%/56 °C/0.07 torr; Ref. [6] 53 °C/0.05 torr. *(2c):* 75%/93 °C; Ref. [9b] 93—94 °C. *(2d):* 87%/61—62 °C; Ref. [9b] 61—62 °C.

*(3a—d):* *(2a—d)* (60 mmol) are suspended in anhydrous $CH_2Cl_2$ (50 $cm^3$). After addition of trialkyloxonium tetrafluoroborate (60 mmol) the mixture is briefly refluxed. The crystals which precipitate on cooling are recrystallized from a little methanol. Yield/m.p.: *(3a):* 84%/305 °C. *(3b):* 81%/268 °C. *(3c):* 76%/293—296 °C (dec.). *(3d):* 81%/285—288 °C (dec.).

*(4a—d):* A solution of *(3a—d)* (10 mmol) in dimethylformamide (40 $cm^3$) is stirred into 40 $cm^3$ of 2 N NaOH. The reaction mixture is immediately extracted with *n*-hexane and filtered through sodium sulfate. The products *(4a—d)* are isolated by evaporating down in a stream of inert gas. Yield/m.p.: *(4a):* 88%/88—91 °C. *(4b):* 82%/35—37 °C. *(4c):* 93%/87—88 °C (dec.). *(4d):* 94%/105—106 °C (dec.).

## The Unusual Stereochemistry of the Cycloaddition of Vinyl Ethers with Sulfonyl Isothiocyanates

By *Ernst Schaumann, Hans-Günther Bäuch,* and *Gunadi Adiwidjaja*[*]

The stereochemistry of the products formed in synchronous reactions can be predicted on the basis of the rules for the conservation of orbital symmetry[1]. In the case of two-step cycloadditions a knowledge of the conformation of the intermediate would be necessary. The reaction of vinyl ethers *(1)* with the isothiocyanates *(2)* has now opened an insight into this otherwise difficultly accessible area of research.

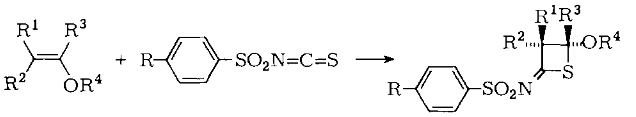
*(1a)*, $R^1 = R^2 = R^3 = H$, $R^4 = C_2H_5$
*(1b)*, $R^1 = R^3 = H$, $R^2 = CH_3$, $R^4 = C_2H_5$
*(1c)*, $R^1 = CH_3$, $R^2 = R^3 = H$, $R^4 = C_2H_5$
*(1d)*, $R^1 = R^2 = CH_3$, $R^3 = H$, $R^4 = C_2H_5$
*(1e)*, $R^1 = R^2 = H$, $R^3 = C_6H_5$, $R^4 = CH_3$



*(2a)*, R = H
*(2b)*, R = $CH_3$
*(3)*

Table 1. Ylides and physical data of the 2-thietaneimines *(3)*.

| *(3)* | R¹ | R² | R³ | R⁴ | R | Yield [%] | M.p. [°C] | IR (KBr) $\tilde{\nu}$(C=N) |
|---|---|---|---|---|---|---|---|---|
| *(a)* | H | H | H | $C_2H_5$ | $CH_3$ | 60 | 71–72.5 | 1600 |
| *(b)* | H | $CH_3$ | H | $C_2H_5$ | $CH_3$ | 76 | – | 1590 |
| *(c)* | $CH_3$ | H | H | $C_2H_5$ | $CH_3$ |  | 76–78 | 1590 |
| *(d)* | $CH_3$ | $CH_3$ | H | $C_2H_5$ | $CH_3$ | 69 | 73–74 | 1595 |
| *(e)* | H | H | $C_6H_5$ | $CH_3$ | H | 50 | 90–92 | 1595 |

The alkenes *(1)* react with the heteroallenes *(2)* at 50 °C to give 1 : 1 adducts (Table 1). Intense $\tilde{\nu}_{C=N}$ bands in the IR spectrum and signals at $\delta = 180.7$ *(3a)* and 190.2 *(3d)* in the $^{13}$C-NMR spectrum are indicative of the 2-thietane imine structure of the products and hence of a [2+2]-cycloaddition of the vinyl ethers *(1)* with the C=S double bond of *(2)*. The X-ray structure analysis[2] provides final proof of the structure of *(3c)* (Fig. 1). In contrast to the parent compound[3] and other thietanes with sp²-hybridized C2[4], the four-membered ring in *(3c)* is completely planar. Also remarkable for a four-membered ring is the extremely long S1—C4 distance.

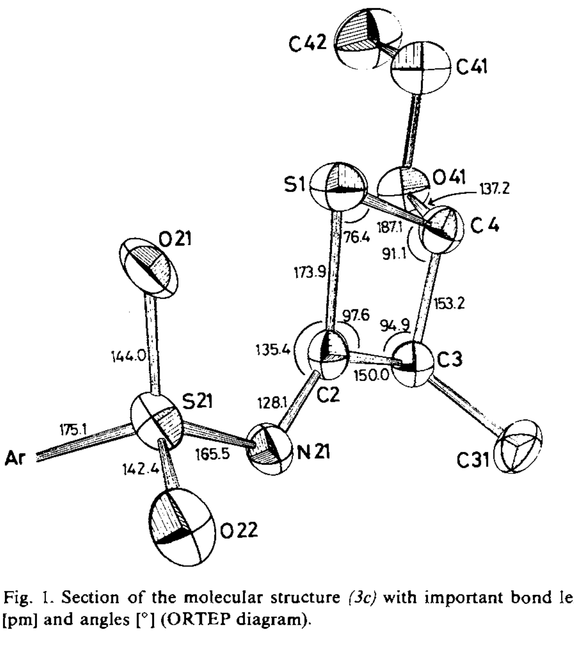


Fig. 1. Section of the molecular structure *(3c)* with important bond lengths [pm] and angles [°] (ORTEP diagram).

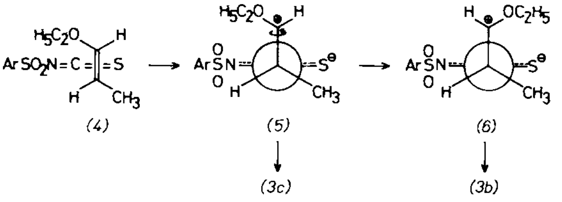
The cycloaddition of *(1)* with *(2)* can be readily monitored and kinetically evaluated by means of ¹H-NMR spectroscopy. The slight influence of solvent on the rate of the reaction of *(1d)* with *(2b)* $[k(CD_3CN)/k(CCl_4) = 24\,(37\,^{\circ}C)]$ could indicate a concerted cycloaddition. Inconsistent with this, however, is the finding that the cycloaddition with *(2b)* is only threefold faster on going from the *trans*-vinyl ether *(1c)* to the *cis*-compound *(1b)*; thus, the effect is of the same order of magnitude as in the reaction of *(1)* with tetracyanoethylene, the example *par excellence* for a cycloaddition with zwitterionic intermediate[5].

The configuration of the cycloadducts obtained from *(1b)* and *(1c)* can—on the basis of the X-ray crystallographically determined stereochemistry of *(3c)*—be determined *via* the vicinal ¹H-NMR coupling constants of the protons on the four-membered ring. As in the case of 2-azetidinones[6] $^2J_{cis}$ with a value of 6 Hz is greater than the value of $^2J_{trans}$ of 2.5 Hz. It thus follows that the *cis*-vinyl ether *(1b)*—otherwise especially susceptible to change of configuration—affords 98±2% of the *cis*-product *(3b)*; isomerization to the *trans*-product *(3c)* occurs only secondarily, thus affording evidence for a kinetically controlled reaction. Surprisingly, however, when the *trans*-vinyl ether *(1c)* is used as starting material (in $CCl_4$), the *cis*-cycloadduct *(3b)* is formed, depending upon the temperature, in 33 to 42% yield.



*(4)* *(5)* *(6)*
*(3c)* *(3b)*

The difference in the selectivity of the cycloaddition of the *cis*- and the *trans*-vinyl ethers *(1b)* and *(1c)* cannot be explained in terms of a concerted multicenter process or a dipolar intermediate in "U conformation"[7]. We therefore assume, in analogy to the $[_{\pi}2_s+_{\pi}2_a]$-process[1], an orthogonal approach of the reactants as in *(4)*, in which the steric interactions of *(2)* with the substituents on the β-C atom of *(1)* are slight. With the *trans*-vinyl ether *(1c)* as starting compound the zwitterion *(5)* is formed, in which, however, the orientation of ethoxy- and sulfonyl-groups to each other is sterically and electrostatically unfavorable. Hence, rotation about the original π-bond of *(1)* competes with ring closure to the *trans*-product *(3c)*; *(6)* is formed as intermediate and, hence, finally the *cis*-product *(3b)*. This model could be of general importance for dipolar cycloadditions of heteroallenes[8], whereas for two-step cycloadditions between cumulated π-electron systems the orientation corresponding to a $[_{\pi}2_s+_{\pi}2_s]$-process is theoretically required[9] and has been proven experimentally[5].

## BOOK REVIEWS

**Comprehensive Biochemistry.** By *M. Florkin* and *E. H. Stotz.* Section VI: A History of Biochemistry, Part V: The Unravelling of Biosynthetic Pathways. Vol. 33 A, xx, 433 pp., 45 figs.; Vol. 33 B, xix, 320 pp., 30 figs. Elsevier Scientific Publishing Company, Amsterdam 1979. Vol. 33 A, bound, Dfl. 140.00, Vol. 33 B, bound, Dfl. 108.00.

After more than 15 years this monumental work[*] which has itself become almost historical, is now alledgedly approaching its conclusion. As its crowning achievement, a wide-ranging history of biochemistry was intended to form a historical finale summarizing all the developments. But both it, and therefore the whole work, will remain incomplete—Professor *Florkin* died shortly after these two volumes had appeared, and whether the material collected for the last volume, containing the physiological and biological ideas on the origin of life, can be properly synthesized by a different hand without the experienced and systematizing driving force of the original author remains an open question. Indeed, even now one can discern an increasing uncertainty and disinclination for this overwhelming self-imposed task. Though far-reaching, the account given of how and by whom our present generally accepted knowledge on the biosynthetic steps and chains that lead to the building blocks of cells have come about is an aggregation of isolated facts rather than a synoptic whole. In contrast to the preceding volumes, which presented the origins of biochemical thinking stretching back to chemistry and biology, the development of the concept of integrating cellular reactions into general physical chemistry, and the investigation of the material world side by side with organic chemistry, and in which the authors' personal involvement with these developments and investigations and their personal knowledge of the research workers, circumstances, and controversies made the course of development clear, here we have a bare account, subdivided in accordance with the chapter titles, of the events up to around the mid-sixties. It is a textbook of intermediate metabolism, with emphasis on the development of methods and theorems, after an entrance into the cell interior had been achieved near the turn of the century by processes for the preparation of active cell extracts and, with glycolysis as an example, the foundations of the isolation of enzymes and of their chemistry and thermodynamics had been laid. The beginning consists of the energetics of biosyntheses and the activation of substrates by phosphates and thiols. Sugsequently there is a critical description of the possibility—discovered and considered to be effective on the basis of simplified ideas concerning the influence of the law of mass action on the cell situation—of obtaining peptides and polysaccharides, without sufficient reference to the serious fallacy and without a sufficiently clear treatment of the concepts of regulation, compartmentalization, and circumvention of energetically unfavorable equilibria by the synthesis of labile intermediates. Then follow alternative pathways of the glucose metabolism, photosynthesis with a hint of the (truly "revolutionary") concept of multienzyme complexes, and the formation of complex carbohydrates, fatty acids, isoprenoids, tetrapyrroles, heterocycles, and amino acids of various genealogies. All this is well-considered and excellently done, although the compilation is on the dull side and bloated with facts. The treatment is thoroughly competent, and often adopts a remote standpoint to distribute merit and priority, with a critical detachment from tales of favor and hatred. All this is very fitting and proper for the doyen of comparative biochemical research. And yet the whole has a certain lifelessness and mere dutifulness about it—after all, this should be an epic history of a heroic period of biochemistry, a period dominated by personalities. What does become impressively clear is that for a generation the investigation of biosynthetic metabolic pathways was one of the most successful domains of biochemical research, which was made possible by the methods acquired in connection with catabolic reactions and by the reductionistic concepts of chemists who had devoted themselves to this promising field. With their tendency to strive toward an over-all view, medics and biologists had given a picture of the details with a blurred outline, but had pointed out earlier the necessity for regulation and integration. Here again it is clear that only the interplay of all life sciences can give us a picture approximating to reality. The work is illustrated by portraits of many of the protagonists and is thus made more personal, perhaps not always justifiably.

These two volumes have not only increased the long Russian green series by two handsome and comprehensive parts, but have transformed it into an interesting and valuable work of history. Regretfully, we must now wait long for the conclusion, for who is there—precisely for what remains to be done—to replace *Florkin*, the co-founder of comparative biochemistry, a man who was as interested in the biological substrate as in the chemical product?

It is almost superfluous to mention that in both production and form the books do credit to the publishers (though this is reflected in their price) and that they may be recommended to any scientist interested in history both as a collection of material and as an aid in the formulation of his own opinions.

# The Philosophy of Science: Its Possibilities and Limits[**]

By Wolfgang Wieland[*]

Science in the modern world has long since become a factor in the production and reproduction of goods and a condition of life in this world. At the same time, however, it is more than this. Science has therefore become caught-up in an orientation crisis ever since scientists became aware that science can no longer be pursued merely for the sake of pure knowledge, the ideal from ancient times which had been held to be the proper guide for science in its quest for self-understanding. Is the philosopher of science capable of providing the researcher with an answer to the questions what it is he does, and whether or not he is deceiving himself in regard to science and his relationship to it? The philosophy of science has revealed areas which demonstrate that our science is never the smooth and elegant construction composed of observation, experiments, and mathematical and formal techniques which it has often been held to be. It is not the least of the modern philosophy of science's achievements to have demonstrated that science cannot teach man what he should do with it and its results.

Upon being requested to expound upon the possibilities and limits of the philosophy of science[1-3], a professional philosopher does well to begin by considering the fact that the modern philosophy of science has met with a growing interest which has long since ceased to be restricted to specialized institutes. Nowadays one speaks of the falsification principle, of scientific revolutions, of paradigms and their shifts, even outside professional circles; and the conviction is that an approach has been found which might enable scientists to adequately understand and represent what they do. Of course, this manner of speaking often remains at the level of mere slogans, but it must also be taken seriously. Whenever a certain discipline's basic concepts have finally crossed the threshold to becoming mere slogans, the reasons behind this symptom are worth investigating.

Just twenty-five years ago, the situation was very different. The philosophy of science was cultivated in Germany only in a few, seemingly almost esoteric circles. The general public no more took notice of it than did the specialized academic public. An information deficit existed, which was difficult to overcome. The German edition of the book, which is without doubt the most important in the modern philosophy of science, *Popper*'s "The Logic of Scientific Research"[6], published in 1934, had long since been out of print and there was no prospect of a new edition. There is, then, all the more reason to inquire how a general interest came to be directed towards those who had begun to make scientific methods and science itself the object of their inquiry and research.

In order to understand this, one must recall that, during the past two decades, the role that science has played, in the eyes of the general public and in its own eyes, has

Philosophisches Seminar, Abteilung I, der Universität
Werthmannplatz, D-7800 Freiburg (Germany)

[**] Originally given as a lecture at the presentation of the Goedecke-Preis der Universität Freiburg i. Br. on December 5, 1980.

*0570-0833/81/0808-0617 $ 02.50/0*

changed. It has ceased to play a role which, within the functional context of the modern world, might be compared with that of a mere ecological niche. The military use of knowledge gained in nuclear physics had, at an earlier date, precipitated a clear and general awareness that science is not as harmless with respect to human life on earth as had long been presumed. Nonetheless, this instance in particular seemed at first to indicate that this had basically been just a regrettable accident in the history of science and its application. The conviction at the time—a conviction which is often still expressed—was that what appeals to the scientist's sense of responsibility could prevent similar mishaps in the future[4]. Such appeals are usually well-meant and ill-founded. They proceed for the most part from a false estimation of the nature of scientific work and of the opportunities an individual scientist has to exercise his influence. Certainly, every person is responsible to a certain degree for the remote consequences and side-effects of his actions, even if he did not intend them. But there is hardly another area in which the possible consequences of human actions are less predictable and more difficult to calculate than in the realm of science and of cognitive conduct in general. Knowledge, especially as the result of scientific research, takes its own course once it has been expressed and published. The initiator has no more influence upon this course than anyone else.

Today, it is at least evident that an old dream has come to an end. For, the founders of modern science in the seventeenth century had hoped that their new science might one day be so highly developed that it would be able to provide man with a clear answer to the ancient question: what must be done in order to optimally further both the well-being of each individual and the common good? A radical change in attitude has occurred here. Modern science has perhaps transformed human life to a degree for which there is no comparable example in history, but this has taken place in a manner which no one could have predicted. Today, science can provide man with counsel concerning a multitude of special problems. Nevertheless, in the essential questions of life, it is far from able to provide guidance or instruction for our actions. On the contrary, we have suddenly realized that the reliable guides, which we need in order to deal with science and its consequences, are lacking.

It is a platitude to say that science today has become a political issue. Certainly, the individual scientist must still, just as always, cultivate the attitude of theoretical aloofness; he must have learned to disregard himself, his wishes, expectations, and hopes in his work. At the same time, however, science as a whole has been integrated into the system of human needs, their administration, and satisfaction. Science encounters great difficulties in attempting to maintain or to obtain anew a small portion of that latitude without which it never could have originated or developed. Today, all over the world, science is no longer supported by the state and society in just a few areas and is thus confronted with obligations. A rough estimate has indicated that there are more scientists living in the world today than during the whole development of science over the past few millenia. Science has long since paid the price for the possibilities of expansion which it has been granted. It is also confronted with the demand to relinquish an increasing portion of that freedom which was taken for granted by researchers before science became enmeshed in the system of human needs, as one of its functional elements. If the scientist nevertheless demands a certain degree of freedom, this is, in contrast to a popular prejudice, no defence of a position which is now untenable. It is not a struggle for special privileges. Whoever wishes to paralyze science and its work could accomplish this most effectively by allowing it to be perfectly administrated and completely regulated. If, then, in spite of everything, there is still a willingness to grant science a certain degree of freedom, then this is less an act of generosity than the consequence of an insight into an elementary necessity for scientific work.

This necessity is based on the fact that the results of scientific research can never be exactly predicted. Expressed in this manner, this is obviously common knowledge. If the results could be prognosticated in every detail, the researcher's painstaking labor would be superfluous. However, in reality scientific research is constantly subject to the law of trial and error. Every scientific activity worthy of the name, therefore, entails the risk of possible failure, and the only guarantee for science's freedom is the impossibility of banishing risk. Truth can never be a secure, incontrovertible possession for all time. A modern scientist's dilemma becomes apparent here. Unless he is extremely naive, he knows that he is integrated into the modern world's system of needs and their satisfaction; he also knows that he is hardly granted the opportunity to undertake research in his particular field just because of an interest in a fundamentally unavailable and functionless truth for its own sake. But, at the same time, he is well aware of another fact: if he abandoned his science as science, then he would allow himself to be integrated into this system of needs with no reservations whatsoever.

In the modern world, science has long since become a factor in the production and reproduction of goods and a condition of the possibility of living in this world. At the same time, however, it is more than this; the question is where to draw the line. In any case, science has become caught up in an orientation crisis ever since scientists became aware that science is no longer pursued solely for its own sake. In previous eras, scientists believed that this ideal could serve as a guide in their self-interpretation. But when the discrepancy between science's traditional self-interpretation and its factual existence under the conditions of the modern world became apparent, it is not surprising that there is a search for bearing-points.

Can the modern philosophy of science provide such bearing-points? The researcher who concerns himself with the philosophy of science's questions cannot expect any assistance in fulfilling the tasks which present themselves to him within his specific field. His concern with the philosophy of science, then, cannot be motivated by a purported optimization of his daily work, but by the aspiration to gain an insight into what he really does and whether or not he is deceiving himself with respect to science and his relationship to it. Thus, it is no mere coincidence that the philosophy of science, a discipline which has been in existence for a long time, succeeded in gaining the attention of a large public at that moment in which the entanglement of science in the modern world's system of needs and their satisfaction became apparent.

**What is the philosophy of science?** I shall characterize this discipline by tracing the **major stages of its development.**

**The first stage** in this development was marked by the already legendary **"Vienna Circle"**[5]. This circle included a number of prominent researchers who had come together in the period immediately after the First World War and collaborated with each other closely. Their intention was to bring philosophy into a close and lasting union with the exact sciences. Especially important among them were *Moritz Schlick* and, after his violent death, *Rudolf Carnap.* It was only after the political situation had forced the majority of its members to emigrate that the circle began to exercise a greater influence. At first, it attracted little attention; wherever it was taken notice of, it was not usually taken very seriously. In the final analysis this may have arisen since the members of this circle often exhibited a certain awkwardness whenever they departed from the philosophy of science proper and became involved in polemics with the representatives of other contemporary philosophical movements.

The Vienna Circle intended, above all, to apply the principle of empiricism. Their plan to base all valid knowledge upon experience had, of course, been proclaimed repeatedly throughout the history of human thought and knowledge: beginning with *Epicurus* and his school in ancient times up to *John Stuart Mill.* The Vienna Circle, however, dedicated itself to the task of also finally realizing the principle of empiricism in detail. Thus, the members of the Vienna Circle were not content with the application of mere fundamental theoretical considerations aimed at emphasizing the role of experience in the construction of human knowledge. Rather, they attempted to demonstrate something in detail that no one had ever been able to show before, *i.e.*, the way in which a certain particular piece of knowledge, for instance, the insight into the validity of a natural law, can be traced back step by step to experience and conclusively founded on this.

Whenever the members of this circle dealt with the knowledge found in the empirical sciences, they were less interested in the way in which such knowledge is discovered in a particular instance. Instead, they inquired how knowledge, which was already factually present, can be provided with a foundation, legitimized, and systematized. But here they encountered difficulties of a special nature. These are related to the indisputable fact that natural science, in the end, aims to find and found propositions with a high degree of universality. In this respect, singular real facts, as such, are less important than the universally valid laws to which these facts are subject. However, in natural science the pathway to these laws always proceeds from observations and experiments, and observations and experiments are always immediately directed to singular facts. Natural laws—one might consider, for instance, the laws of conservation in physics cannot, at least as such, be observed. The problem presented here is whether there is a method which makes it possible to base an insight into the existence of universally valid natural laws upon the observation of singular facts at all. This difficulty is involved in every empirical science: inasfar as it is founded upon experience, it refers to particular facts; inasfar as it is a science, it orients itself upon the ideal of supra-individual, universal validity. The difficulty that is known as the problem of "induction" presents itself here. Is there a methodologically incontestable way to proceed from singular facts to the deduction of propositions which can lay claim to strict universal validity, such as the natural laws?

The Vienna Circle attempted to find the pathway which leads from singular observable facts to universal natural laws, and then to survey and map it out, so to speak. That such a pathway must exist at all, is by no means obvious; nevertheless, the success of modern natural science seems to guarantee the existence of a corresponding pathway. The first step upon the way has far-reaching consequences but seems at first to be quite insignificant. The point of departure was not sense-data, not observations and experiments as such, but rather statements concerning them. At first, the Vienna Circle viewed the foundation of empirical science to be these statements and not the observations to which they refer. These are the famous "protocol sentences" which only contain what has actually been perceived. For instance, "The researcher $R$ observed at time $t$ using the measuring apparatus $A$ that the needle moved $x$ units." An extensive discussion dealt with the question: what kind of information it is that a protocol sentence must or may contain? Without proceeding any further on this point, we should emphasize the basic thought involved here: protocol sentences should be such that, if one wishes to attain those universally valid statements of laws which are the goal of natural sciences, the only additional requirement should be the techniques supplied by logic and mathematics.

This is without doubt a new approach that takes seriously the idea that the foundation of all scientific knowledge must be sought in experience. In spite of this, logic and mathematics are by no means interpreted as empirical sciences. Although formal logic occupied a central position in the work of the Vienna Circle, experience remained the essential basis for all knowledge of reality. It thus became necessary to redefine the boundaries between these domains; for, if one does not wish to accept anything as well-founded knowledge that is not based upon experience, and if, on the other hand, one must admit that logic and mathematics are not founded upon experience, then the only alternative is simply to deny these two disciplines the ability to provide knowledge. In this case, one need only stipulate the proper normative connotations for the concept of knowledge. In accordance with the view developed by the original Vienna Circle, logic and mathematics consequently cannot lead to knowledge in the normative sense of the word indicated above because they purportedly deal only with analytical statements, with tautologies. They were thus interpreted as mere organizational systems consisting of signs and symbols; their function was to regulate the operations and transformations within the realm of these symbolic systems. According to the presuppositions of such an interpretation, the high estimation of logic and mathematics within the Vienna Circle was not necessarily impaired by the fact that both of these disciplines were denied the capability to provide knowledge in the normative sense of the word.

Only those statements that can be empirically verified or falsified were recognized as meaningful sentences, again in a sense determined by a suitable normative definition of the term. This is the Vienna Circle's famous criterion of meaning. A statement's ability to be empirically verified and falsified is, according to this norm, not only a condition for recognizing the correctness or falsity of the statement itself, but also for its having any meaning at all. According to this criterion, the meaning of a sentence can only be understood by someone who knows what must be done in order to verify or falsify it through experience. If this criterion is not fulfilled, then the statement is meaningless.

We have thus established the following: according to the conception of a philosophy of science originally developed by the Vienna Circle, certain observational statements, the protocol sentences, are the foundation of all empirical knowledge. It is from them, and only from them, that more general statements up to and including natural laws may be deduced by means of mathematical and logical techniques. More general statements are to be verified as well as falsified on the basis of these statements.

**Karl R. Popper**, in his earlier mentioned book [6], marks the beginning of **the second stage** in the development of the modern philosophy of science. He called attention to the fact that those statements which scientific research is most interested in discovering, the statements of laws, can and must be repeatedly corroborated by experience, but that it is never possible for them to be verified in a strict sense by experience. It is trivial to say that natural laws, as such, are never the objects of direct observation; however, according to *Popper*'s thesis, they can also never be deduced by means of formal techniques if our only available basis is composed of observational statements. Of course, the problem of induction is then irresolvable if the universal validity which science aims at in general statements cannot be attained on the sole basis of observation and experimentation. *Popper* realized that no logical or mathematical procedure can exist which would allow one to proceed from singular observational statements and lead to the deduction of natural laws which would fulfill a claim to strict universal validity thereby passing the final test, so to speak, of enabling events that will occur in the future to be prognosticated.

The considerations upon which *Popper* bases his theory are surprisingly simple. In fact, he did nothing other than consider the formal difference between singular, empirical statements, on the one hand, and universal, law-like statements, on the other. A natural law is universal precisely because, according to its very idea, it is valid for an indefinite, unlimited number of single cases, as long as certain initial conditions are fulfilled. The unlimited number of singular cases can never be exhausted by observation. On the other hand a claim to universal validity, which is made by a general statement and holds for an indefinite number of cases, can be rejected even if only one counter-example is found. Similarly, textbooks of logic used to cite the statement "All swans are white", which can be refuted by the discovery of a single black swan. This illustrates the meaning of *Popper*'s famous falsification principle. This principle holds that statements concerning the validity of a natural law can never be verified in a strict sense, though they can indeed be falsified. Precisely in the case of general statements of law, the symmetry between verification and falsification, that was often presupposed earlier, does not exist.

Of course, one does not have to forego searching for natural laws on this account. *Popper*'s solution, or better, his dismissal, of the problem of induction by no means prevents researchers from orienting themselves upon natural laws and the statements which express them. *Popper*'s new turn affects only the formal status of laws. Under the presupposition of the falsification principle, the only function they can ever fulfill is that of a hypothesis. Regardless of how well and how often they have been corroborated anew, they still never cease to function as hypotheses, as far as their fine logical structure is concerned. They are suppositions which are never valid for more than the time being, so to speak, which are always subject to revocation; for, they are constantly accompanied by a risk that can never be completely overcome, the risk that they might someday be falsified after all by future experiments or observations. Hence, complete security can never be attained in this area. At the very most, within the restrictions of ordinary language, where there are no clear-cut boundaries, one may say that a hypothesis has been proved whenever it has been corroborated in a great number of instances. In truth, all general statements of law, as far as their logical status is concerned, are suppositions which, on principle, can never be absolved from the compulsion to succeed. In accordance with this status, they can never clearly represent the final goals of science's efforts for knowledge. Their character is like that of a tool, in that their construction demonstrates the researcher's ingenuity. To this extent, there can be no final decision about their "truth", though one can indeed say something about their ability to perform certain tasks. For, by means of them, observations and experiences should be able to be explained, but it is impossible to deduce the assumptions, which are presupposed in the explanation, from the state of affairs they are supposed to explain.

*Popper*'s conception does much more justice to the unique dynamics proper of scientific research than does the Vienna Circle's conception. His theory is based on the idea of an open-ended science, which in principle can never come to an end in its work, since the supply of hypotheses which can be tested is and remains inexhaustable. For, at any moment there are only a finite number of hypotheses which have been eliminated by falsification, that is, by counter-examples from experience. *Popper*'s philosophy of science also accounts for the risk of failure which is inseperable from any research enterprise. It is no coincidence that *Popper*'s main work is entitled "The Logic of Scientific Discovery"[6]. The theme here is not merely logical relationships such as those that may hold between propositions. The question is not just how statements that express universally valid knowledge can be founded and deduced, that is, how their validity can be legitimized; but also how such statements can be found at all and how they are to be dealt with. Here, we have a conception that is not content merely to organize and provide a foundation for knowledge that is already present. For, this conception is oriented to the same degree upon the scientific researcher's concrete activity. *Popper*'s conception also attempts to do it justice.

If statements of law are such that they cannot be verified, but, at most, falsified, then there is of course always the possibility that one and the same empirical finding may be interpreted and explained on the basis of very different hypotheses that compete with one another. Therefore, the question arises whether there are rules which enable us to make a reasonable choice between such competing hypotheses. For what reason does one explanatory model prevail over the other, when there are a number of models available that have not yet been falsified? There is no answer to such questions which could be satisfactorily explained by *Popper*'s conception.

**Thomas S. Kuhn,** however, has proposed an answer in his essay on "The Structure of Scientific Revolutions"[7], which appeared in 1962 and marks the **beginning of the third stage** in the modern philosophy of science. This work is a challenge not only to the contemporary philosophy of science, but also to the modern scientist's whole self-understanding, and it is no mere coincidence that, at first, it provoked some reactions which were primarily emotional. *Kuhn* proposes a conception according to which the competition among theories and the competition among hypotheses is ultimately decided by situations whose estimation and evaluation lie less within the domain of the logician and epistemologist, than in that of the historian and sociologist. The occurrences which define an epoch in the history of science are precisely the ones which no longer permit an explanation that is purely scientific in nature, at least according to this conception. In this case, the only answer that remains for the theorist of science is: "This can only be explained historically". *Popper* had defended the thesis that it is impossible to verify general statements of laws; he had not called into doubt the possibility of falsifying them. *Kuhn* now goes a decisive step further. He asserts that, in the history of science until now, there has not been a single instance in which a general hypothesis has been falsified in a manner corresponding to *Popper*'s model of falsification. By means of a number of case studies from the history of physics and astronomy, as well as from chemistry and biology, *Kuhn* tries to illustrate that theories and hypotheses of laws are not discarded as soon as a particular experience cannot be brought into agreement with them. *Kuhn* demonstrates that, according to all historical experience, theory prevails when a collision between theory and individual experience occurs. As a rule, the purported counter-example is reinterpreted so that it fits into the theory from which one proceeded in the first place.

On a smaller scale, we are familiar with similar experiences from the course of everyday experimental research: if a certain measurement or observation deviates too strongly from the general context, no researcher will immediately conclude that hei on the track of previously undiscovered laws. At first, he supposes instead that the particular result which deviates from the general context is due to a measuring error that must be recognized as such and corrected. The hypotheses from which one proceeds thus possess a unique capability to persevere. The stability which *Kuhn* ascribes to established theories is of a similar nature. It merely seems that such theories are tested by experience. In reality, experience is from the outset interpreted or, if necessary, reinterpreted so that it is commensurable to a theory which from the outset is assumed to be valid.

*Kuhn* himself has peculiar reservations in regard to the term "theory". He prefers to speak instead of "paradigms", which refer to theoretical patterns that determine whole directions of research and even whole scientific epochs. Geocentric and heliocentric astronomy, phlogiston and oxygen chemistry may illustrate what *Kuhn* means by paradigms. These paradigms are most closely comparable to the precedent-setting or model cases upon which a lawyer orients himself in his work. They establish the framework within which specialized research takes place. They specify within their domain what can be accepted as a possible object of experience. In view of them, a decision is often made about which questions can be meaningly posed within a science and which ones cannot. Whenever conflicts between paradigms and experience arise—according to *Kuhn*'s findings, which are not discovered by the philosophy but rather by the history of science—experience will, as a rule, be disregarded. In spite of this, a paradigm's power is not completely unlimited. After all, *Kuhn* must account for the fact that scientific theories one day come to be replaced by other theories. There are phases in the development of a science during which experience is no longer merely adjusted to the paradigm dominant at the time; in such phases, paradigms compete with one another. These are the phases *Kuhn* calls scientific revolutions. But even here, he is not prepared to grant rational criteria a decisive influence; the explanatory ability of a new paradigm is generally of a different sort, but not always greater than that of the paradigm it replaces. The competition among theories, up until now, has never been resolved in a manner which would fulfill the requirements of rational foundation. Logic and experience may play a role in the shifts from an old theory to a new one, but they do not suffice by themselves to explain the dynamics of a theory. The only fact that can be registered is that one theory has prevailed over other competing theories. According to *Kuhn*'s conception, it is a mere myth that successful theories distinguish themselves over the theories they replace by a greater capability to explain and interpret phenomena. A theory's performance can only be spoken of in a very different sense; its performance can be measured only historically by the number of adherents it has been able to find who are committed to it. *Max Planck* coined the phrase that scientific theories do not cease to be discussed because they have been refuted, but because their proponents finally die out. Basically, what *Kuhn* does is merely to provide a theoretical conception that is a skillful variation of this statement.

*Kuhn*'s conception not only renounces the possibility of verifying the statements of laws, as *Popper*'s conception does, but also of falsifying them. For *Kuhn*, the researcher's painstaking labor based on observation and experimentation is by no means absurd; but he believes he has demonstrated that observation and experimentation alone can neither prove nor disprove a certain theory. Nor would *Kuhn* deny that there is a connection between experience, on the one hand, and theory on the other; however, according to his conception, this connection is much looser than the practicing researcher or the philosopher of science has previously supposed.

The way in which *Kuhn* interprets scientific research shows very little similarity to the ideals which were traditionally attached to it. At times, it may even seem as if he wished to deprive the researcher of his self-confidence in the rationality of his actions. But at least his conception is able to account for the conditions in which science is actually pursued. If the faith in an absolutely certain "method" for science, which would be capable of providing indisputable decisions, is an illusion, then the human side of the scientific enterprise appears in a completely different light. It becomes understandable that, within science, certain schools emerge which orient themselves upon particular methods or models of explanation and that scientists try to gain recognition for them. It is understandable that the researcher strives for recognition and that this endeavour is by no means merely the result of personal vanities which have no bearing upon science. It is understandable that there are conflicts concerning priorities in science—in short, it is understandable that science is regularly pursued by groups of people and that the internal structure of these groups is not fundamentally different from that of other groups. That scientific labor is tied to and oriented upon a group, remains ultimately a kind of organizational principle which is capable of regulating this work. In the end, it is symptomatic that *Kuhn* avoids the term "truth" except in quoting others.

This third stage in the modern philosophy of science might represent a temporary conclusion to its history, but, as is proper for a genuine trilogy, a satire follows. Its author is **Paul K. Feyerabend,** the bold warrior "Against Method"[8], which is the title of one of his works. In reading his recent publications, one occassionally has the impression that *Palmström*[*] has landed among the philosophers of science. Fortunately, *Feyerabend,* who has long since proven himself as a philosopher and as a historian of science, can allow himself the luxury of an ironically aloof attitude. Besides, he is only drawing the final conclusion in the development traced here when he rejects *Kuhn*'s group principle as the organisational principle's last gasp, so to speak, and propagates total methodological anarchy, in which each approach initially has equal justification. This first principle in his theory rapidly gained fame; it is: "Anything goes." Here modern science appears as one of many forms of mythical thought if there is no sure method of giving scientific statements a foundation and allowing them to distinguish themselves from other statements. According to this conception, it is categorically impossible to clearly delineate the realm of science from other realms of human activity. Whoever performs scientific work in the usual sense can claim no superiority over those who try to cure illnesses by faith-healing or to influence the weather by rain dances, at least in *Feyerabend*'s estimation. According to this conception, science has at its disposal no rules or results that a free person is obliged to recognize.

These very brief comments suffice to indicate what high demands are placed upon the reader's sense of irony here. Regardless of how one might judge *Feyerabend*'s attempt, it can be instructive for everyone who comes to deal with it. There is no doubt that the image of science sketched here sometimes exhibits the traits of a caricature, but a good caricature does not consist merely in the distortion of its object; instead, it renders certain characteristics extremely prominent and distinct compared to others. *Feyerabend* basically draws the final conclusion in a development whose turning point must be sought at that point where the orientation upon the concept of truth is abandoned as a guide for comprehending the meaning and task of the scientific enterprise. *Feyerabend*'s conception is especially suited to illustrate the extent to which modern science has already become a functional part of a comprehensive system for mastering and transforming reality. Contemporary science is indeed confronted with obligations both with regard to truth and to its role in helping master our existence, without being able to resolve the tension between these two obligations or merely establish an equilibrium between them.

It would be a misunderstanding to suppose that this sketch intends to reduce the modern philosophy of science to absurdity regarding its development. On the contrary, much can be learned from this development because it is so logically consistent, and with the onesidedness characteristic of self-consistent thought, it carries things to an extreme. Certain elements of science are screened out of this development; extrapolations are made possible on this basis, and these allow traits of science to be illustrated which might otherwise easily be overseen. For this reason, other important developments which are closely related to the modern philosophy of science have not been dealt with. These include hermeneutics, which concerns itself with problems that are especially relevant to the human sciences; as well as evolutionary epistemology, a conception from which much can be expected as soon as it has gone through the teething stage in which it now finds itself. A further conception, the so-called Critical Theory, has not been dealt with because up until now it has been unable to attain the minimal degree of conceptual clarity and distinctness necessary for a productive occupation with any philosophical proposal. The ambiguity with which critical theory still amalgamates political wishes and epistemological claims makes it impossible to accept its representatives as partners in a philosophical discussion oriented towards the ideal of conceptual clarity.

At the outset, we spoke of the orientation crisis which afflicts current science. This crisis reveals itself, among other things, in the fact that faith in science, a sceptical attitude towards science, and even a certain superstition towards science all find proponents; and that these proponents include many who live and work within the charmed circle of science. However, the philosophy of science, which encounters such a great interest today, cannot resolve this orientation crisis, although it can contribute something else. It can develop concepts which are necessary to represent the crisis and it can, above all, illustrate

---

[*] A poem from "Galgenlieder" by Christian Morgenstern.

the great extent to which science as it is actually undertaken in our world conflicts with the projections and ideals with which it is often confused.

**The lessons which can be learned from the development of the philosophy of science** do not make it possible to define precisely and finally what science is. But it can provide an indication what science certainly is not. Hence, first of all, science's work does not consist merely in the accumulation of knowledge about facts or laws. It is simply not the case that science's business consists in reaping new harvests which, so to speak, can be stored up in its warehouses for all time. In the domain of science, one must always reckon with the possibility that a result which seemed to be completely certain may be reinterpreted and relativized during the further course of research, and perhaps even declared invalid. The basic, epoch-making discoveries, are those which compel us ever anew to reinterpret that which was previously known and only apparently secure for all times. The accumulation model is obviously not suited to the true development of science. The science we possess is an open-ended science which permits no predictions regarding its further course.

Secondly, the philosophy of science, in contrast to the original intentions it attached to its work, has been forced to place a stronger emphasis upon the active role played by the thought and conduct of the researcher. Whatever scientific research might achieve does not just consist in a simple copy of reality. Whatever confronts us as the result of research is no mere image of reality; it is the result of our intervention into reality and our processing of it. The philosophy of science has shown that the researcher not only intervenes in reality with his experiments and measuring apparatus, but also in a much more subtle but effective manner with his entire theoretical and mental arsenal, that is, with his concepts and questions, with his definitions and hypotheses. Obviously, no discovery which deserves the name is exclusively the object of convention. It would nonetheless be impossible to make such discoveries if one did not settle upon conventions at a variety of levels. The philosophy of science, in any case, has rightfully and persistently put its finger on those points which illustrate that science, even in the ideal case, is never the smooth and elegant construction composed of observation, experimentation, and mathematical and formal techniques which it is often held to be. Here, one cannot even take recourse to the well-known argument that everyone who utilizes the technical applications of modern science has implicitly, by means of his action, recognized the underlying theory's correctness; at most, the mere possibility that it may be correct has been recognized. If an effect can be explained by a certain theory, the possibility is still not excluded that it might perhaps be explained just as well by another, completely different theory. This is due to a simple logical fact: theories are, by their very nature, at best sufficient, but never necessary conditions for the effects and applications which are subsumed under them. As far as the technical applications of science are concerned, the factual possibility of things always has priority over the theories that are offered as their explanation.

Thirdly, the philosophy of science has also had to account for the fact that the scientist's actions always remain enmeshed in the organization of the human community in general. The researcher is also a part of modern society's system of needs; nonetheless, he can exercise his activities meaningfully and with good prospects of success only if he is at least practically suspended from this system. For this reason, the latitude which a scientist claims for his work is not a superaddition or special privilege but rather an elementary necessity for science's very existence.

The question still remains what we wish to do with science and its results and what we should do with them. Furthermore the question of whether or not we can determine which of those knowable objects science deals with are at the same time worth knowing about, also remains. But these are questions of practical nature and cannot be answered within the realm of science itself. A great portion of science's success in its work is due to the fact that it ignores such questions before it has begun its work. In any case, it is not the least of the modern philosophy of science's achievements to have demonstrated that science cannot instruct man what he should do with it and its results.

# Mass Spectrometry of Negative Ions[**]

**New analytical methods (22)**

By Herbert Budzikiewicz[*]

"It appears that negative ion mass spectra measured with a commercial instrument and the electron energies used (20—70 eV) are not suitable either for molecular weight or for structure determination—". This was the conclusion of a paper appearing in 1965 which expressed the then almost universal opinion on the importance of negative ion mass spectrometry in the structure analysis of organic compounds[8]. The fact that quinones and aromatic nitro compounds were exceptions to this rule was rather taken as substantiation of this opinion. The potential value of the work originating from the laboratories of *Manfred von Ardenne* was first realized with the development of chemical ionization. This technique gave a firm foundation to negative ion spectrometry in the area where it is complementary to that of positive ions.

## 1. Introduction[***]

Whereas positive ion mass spectrometry is an integral part of modern instrumental analysis, the importance of its negative ion counterpart is still considered with some uncertainty. Statements like "unimportant in structure analysis of organic molecules", "important complementary method to positive ion mass spectrometry", or "much more sensitive than the positive ions", indicate that, since only a few research groups are investigating this area systematically, the subject is still not widely understood or appreciated. However, this did influence the instrument manufacturers. Whereas in the sixties several mass spectrometers had dual polarity facilities, these were abandoned and have only recently been reintroduced.

In this paper we shall discuss the principal differences between positive and negative ion mass spectrometry as well as the importance of the latter in structure elucidation and the analysis of mixtures. Since our knowledge in certain areas is incomplete, in particular as regards chemical ionization, general conclusions are not warranted. We shall not consider the details of instrumentation here[****], nor purely physical aspects, *e.g.* the determination of electron affinities[2], electron capture cross sections[3], or appearance potentials[4].

## 2. Theoretical Foundations

### 2.1. Definitions and Units

Like in many areas of physics, there is a problem of sign here too. According to modern definition, ionization is a transition in which the number of negative charges decreases or that of the positive charges increases. This means, that not the formation of the molecular anion [eq. (a)],

$$\mathrm{AB} + \mathrm{e} \rightarrow \mathrm{AB}^{\ominus} \qquad \text{(a)}$$

but rather the reverse process [eq. (b)]

$$\mathrm{AB}^{\ominus} \rightarrow \mathrm{AB} + \mathrm{e} \qquad \text{(b)}$$

is considered as ionization.

All energy expressions are based on this definition.

The electron affinity *(EA)* of AB is defined as the minimum energy required for an electron to be released from the system $\mathrm{AB}^{\ominus}$. Consequently, this is also the first ionization potential of $\mathrm{AB}^{\ominus}$, *i.e.* $I(\mathrm{AB}^{\ominus})$[*]. From this it is possible to define the appearance potentials of fragment ions, $A(\mathrm{A}^{\ominus})$, for dissociative electron capture according to eq. (c), and for ion pair formation according to eq. (d), where $D(\mathrm{AB})$ is the dissociation energy and $E$ the excitation energy (vibration and rotation energy) of $\mathrm{A}^{\ominus}$, which, for example, are determined from the activation energy for decomposition (see Section 2.2)

$$\mathrm{A}^{\ominus} \rightarrow \mathrm{AB} - \mathrm{B} + \mathrm{e} : A(\mathrm{A}^{\ominus}) = EA(\mathrm{A}) - D(\mathrm{AB}) - E \qquad \text{(c)}$$

$$\mathrm{A}^{\ominus} \rightarrow \mathrm{AB} - \mathrm{B}^{\oplus} : A(\mathrm{A}^{\ominus}) = EA(\mathrm{A}) - I(\mathrm{B}) - D(\mathrm{AB}) - E \qquad \text{(d)}$$

Unfortunately, even in the recent literature, there is no agreement on sign usage. It should be made clear, however, that in bond homolysis, energy must be consumed, like in the process $\mathrm{B} \rightarrow \mathrm{B}^{\oplus}$. In the formation of stable negative ions ($\mathrm{A}^{\ominus}$) from A, energy must be released[**].

### 2.2. Ionization Processes

#### 2.2.1. Resonance Capture ($\mathrm{AB} \rightarrow \mathrm{AB}^{\ominus}$)

Resonance capture is a prerequisite for the formation of molecular anions ($\mathrm{AB}^{\ominus}$) capable of detection by mass spectrometry. This is possible only if $EA(\mathrm{AB}) > 0$. Thereby an electron is accepted by a low lying unoccupied orbital. The electron capture cross-section, *i.e.* the probability of ioni-

[**] Mass Spectrometry of Negative Ions, Part 3.—Part 2: [36].

[***] Abbreviations: EI = electron impact ionization, CI = chemical ionization, NCI = negative chemical ionization, NI = negative ionization, $EA$ = electron affinity, $I$ = ionization potential, $A$ = appearance potential.

[****] See [1] and the construction details of modern apparatus. The problem of high negative entry voltage of secondary electron multipliers, which prevent negative ions of too low acceleration voltage from reaching the first dynode has meanwhile been solved by the introduction of a conversion dynode. The latter works at a potential of +2—4 kV, transforming $M^{\ominus}$ into $M^{\oplus} + 2\mathrm{e}$.

[*] Definitions commonly used in mass spectrometry are to be found in [5].

[**] Conversion factors for energy units: 1 eV = 23.0 kcal = 96.14 kJ.

zation, can vary over a wide range for organic compounds (*e.g.* by a factor of $10^6$ between hexane and $CCl_4$)[*]. The phenomenon of resonance capture is also used with electron capture detectors in gas chromatography.

During resonance capture $AB^\ominus$ is formed as an excited species with an excitation energy of at least $EA$(AB). Provided that this species ($AB^\ominus$) is not deactivated by radiative emission of its excess energy[7], or through collision at higher pressures, then it can lose the electron again (autoionization). In small molecules this process occurs very rapidly ($\approx 10^{-13}$ s). In larger molecules, where the excess energy can be distributed over many internal degrees of freedom, the process is slow enough ($> 10^{-6}$ s) for $AB^\ominus$ to be observed in the mass spectrometer. If the excitation energy is sufficient according to eq. (c) (see Fig. 1a), then fragments can be formed (cf. Section 2.2.2). In general, resonance capture is observed at electron energies of 0 to a maximum of 2 eV (*e.g.* for $SF_6^\ominus$, the ion yield curve has its maximum at 0 eV and falls to zero again at 0.3 eV).

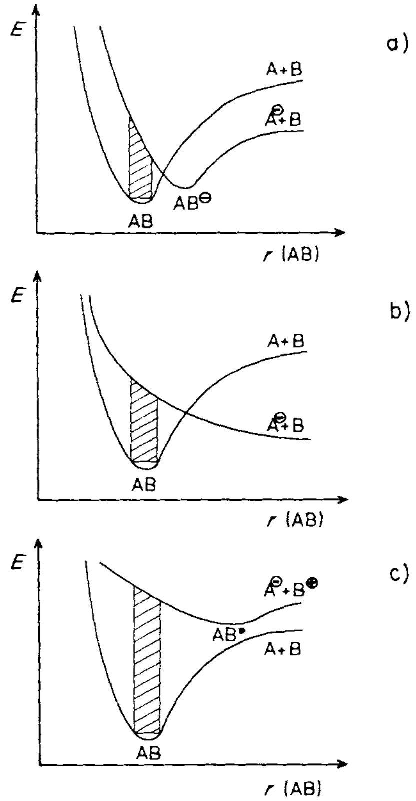

Fig. 1. Typical potential curves for the formation of negative ions from diatomic molecules. a) Resonance capture, b) dissociative resonance capture, c) ion-pair formation.

2.2.2. Dissociative Resonance Capture ($AB \rightarrow A^\ominus + B$)

During electron capture, $AB^\ominus$ attains either a repulsive (Fig. 1b) or an attractive state, in which the dissociation threshold is lower than that of AB by at least the amount of $EA$(B): $AB^\ominus$ decomposes within the subsequent vibrational period. This process is observed at energies between 2 and 15 eV. The ion yield curve for $A^\ominus$ is normally structured (Fig. 2); the maxima correspond to different excited states (see Section 3.4.1).

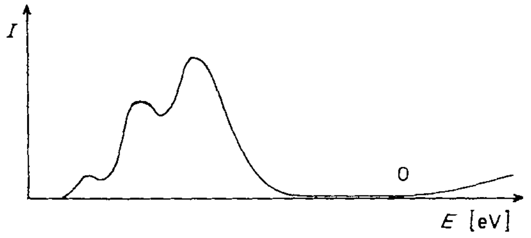

Fig. 2. Typical ion-yield curve for negative fragment ions; $I$ = ion current.

2.2.3. Ion Pair Formation ($AB \rightarrow A^\ominus + B^\oplus$)

In the majority of cases, no intermediate of the type $AB^\ominus$, but rather an excited molecule AB* is formed which then dissociates heterolytically (Fig. 1c). Ion pair formation begins at energies above *ca.* 15 eV (the point marked by 0 on the ion yield curve in Fig. 2).

## 3. Electron Impact Ionization

### 3.1. General

It follows from the discussion in Section 2.2 that molecular ions ($M^\ominus$) are formed only at the lowest electron energies. Under normal electron impact conditions (70 eV), therefore, one would expect only fragment ions to be formed under NI-conditions. Investigation of a series of typical organic compounds[8] appeared to confirm this (Fig. 3)[*], though there is some evidence, in particular in the work of *Bowie*[9], that intensive $M^\ominus$ ions can also be observed at 70 eV. In the case of nitrobenzene[10], it was even found that the relative intensity of $M^\ominus$ with respect to $NO_2^\ominus$ increased by a factor of 150 when increasing the electron energy from a nominal value of 3 to 20 eV. This apparent contradiction can be explained[11-13]: The generation of positive ions is accompanied by thermal secondary elec-

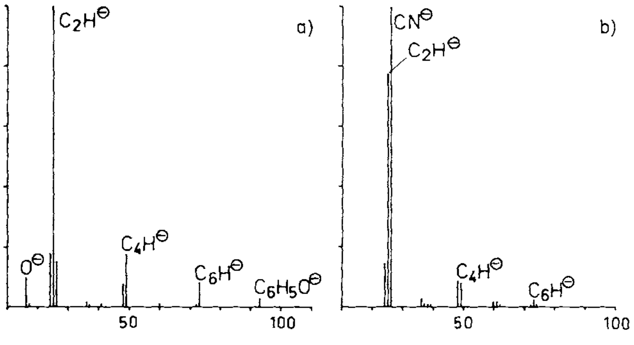

Fig. 3. NI spectra of a) anisole, b) aniline (CH-4, 70 eV).

---

[*] A table of the most important classes of compounds is found in ref. [6].

[*] It has been suggested that the mass spectra of negative ions (negative spectra) be represented in icicle form [8] (mass scale on top, ion intensities toward the bottom). This has been followed up by only a few authors and so will not be considered here.

trons ($e_s$), which then allow the formation of $M^{\ominus}$ ions [eq. (e)]. This makes it understandable that the formation of $M^{\ominus}$ commences at the ionization potential of $C_6H_5NO_2$ and that the ion yield curve of $M^{\ominus}$ follows that of $M^{\oplus}$. Further proof is found in the observation that in the addition of $SF_6$, which has a high electron capture cross section for thermal electrons, the formation of $M^{\ominus}$ at higher electron energies is suppressed. Thus we are dealing with a secondary process, as confirmed by the observed pressure dependence (see the following Section).

$$M + e_p \rightarrow M^{\oplus} + e_s + e'_p \qquad \text{(e1)}$$
$$M + e_s \rightarrow M^{\ominus} \qquad \text{(e2)}$$

### 3.2. Dependence of Spectra on Ionization Energy, Temperature, and Pressure

The typical energy ranges for the various ionization processes have been mentioned already in Section 2.2, those for the formation of energy deficient secondary electrons according to eq. (e) in Section 3.1. The special importance of the ionization energies for dissociative resonance capture will be treated in Section 3.4.1.

The excitation energy $E$ of an ion depends on the energy of the ionizing electron as well as the internal energy of the molecule to be ionized; it follows from the discussion in Section 2 that the extent of fragment formation will increase with the inlet or source temperature, as is indeed observed[14].

The pressure dependence of the various ion-source processes is more complicated. Here, only the rate of formation of the ions will be considered and not their further reactions. At higher pressures it is possible that, *e.g.* through ion-molecule reactions, the ion current becomes independent of the sample pressure. Occasionally, one uses this situation to achieve more reproducible spectra[14].

The simplest case is that of ion pair formation, since (see Section 2.2.2) the electrons only supply energy for the excitation of the molecule (AB*), which is the rate determining step. The rate of formation, and hence the intensity of the ion current of $A^{\ominus}$ is linearly dependent on the sample pressure and the density of emitted primary electrons $Ne_p$ [eq. (f)].

$$AB + e_p \rightarrow AB^* + e'_p; \quad AB^* \rightarrow A^{\ominus} + B^{\oplus} \qquad \text{(f1)}$$
$$\frac{d[A^{\ominus}]}{dt} = k[AB]\,Ne_p \qquad \text{(f2)}$$

By analogy, eq. (f2) applies to the dissociative capture at low pressures and electron energies, when the primary electrons are responsible for the formation of $AB^{\ominus}$. At higher pressures and electron energies, capture of secondary electrons takes place according to eq. (e2). The number of these electrons is also a function of the pressure of AB according to eq. (g1)[*]. Thus, the final equation shows a second order pressure dependence [eq. (g2)]. Similar considerations apply to slowed down primary electrons, $e'_p$.

$$Ne_s = k' \cdot Ne_p \cdot [AB] \qquad \text{(g1)}$$
$$\frac{d[A^{\ominus}]}{dt} = k'' \cdot Ne_s \cdot [AB] = k \cdot Ne_p \cdot [AB]^2 \qquad \text{(g2)}$$

The resonance capture of $e_p$ to give $AB^{\ominus}$ is described analogously by eq. (f2) that of $e_s$ by eq. (g2). If, however, the life of the molecular anions is sufficiently long only when they can be deactivated through two-body collisions we have again second-order pressure dependence, according to eq. (h1). If at higher primary electron energies, secondary electrons are captured, then it follows from eq. (g1) that the pressure dependence rises to the third power [eq. (h2)].

$$2\,AB + e_p \rightarrow AB^{\ominus} + AB^*: \frac{d[AB^{\ominus}]}{dt} = k \cdot Ne_p \cdot [AB]^2 \qquad \text{(h1)}$$
$$\frac{d[AB^{\ominus}]}{dt} = k \cdot Ne_p \cdot [AB]^3 \qquad \text{(h2)}$$

If the pressure is high enough that the deactivation step is no longer rate determining, then the exponent decreases by one (pseudo-$(n-1)^{th}$ order). Of course, fractional orders can be found at intermediate pressures; this is also borne out by measurement[15].

In this section we have shown in a comprehensive manner the critical dependence of the spectra on instrumental parameters as compared to the spectroscopy of positive ions. In situations where it is impossible to find reaction conditions where only single processes can be selected (see Section 3.4), chances are that the spectra obtained are barely reproducible.

### 3.3. Stability of Molecular Anions[16]

The question of structural requirements for the existence of long-lived molecular anions has inspired a whole range of studies and hypotheses. What is surely essential is the presence of a low-lying unoccupied molecular orbital (this explains why, for example, alkanes cannot form stable $M^{\ominus}$ ions). An attempt at correlating the probability of the occurrence of long-lived molecular anions with the dipole moments measured in the gas phase[17] met without success in this case: Acetone ($\mu = 2.84\,D$) afforded no $M^{\ominus}$ ion[8] whereas *p*-benzoquinone ($\mu = 0\,D$) furnished an intense $M^{\ominus}$ ion[18]. In particular through the work of *Bowie et al.*, supported by the theoretical studies of *Christophorou et al.*, it became clear that intense molecular anions can be expected when, after resonance capture the system can stabilize itself through resonance *via* a π-system. Some typical examples are quinones such as *(1)*[18-21], simple diketones such as *(3)*[18] and their monoximes[22], as well as compounds such as maleic anhydride and its derivatives[23], aromatic nitro compounds such as *(5)*[24,25] and related systems like aromatic azoxy compounds[26], aryl-$SO_2$—X compounds[27], and highly conjugated nitriles[28,29].

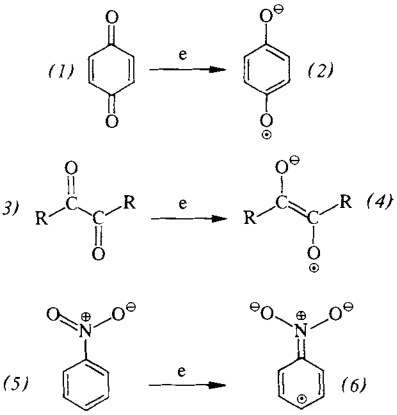
Substituent effects have been investigated, in particular, in the case of aromatic nitro compounds. It would appear that it is inductive effects (apart from possible *ortho*-effects

---

[*] Eq. (g1) holds for the stationary state in which the capture of $e_s$ in the reaction $AB + e_s \rightarrow AB^{\ominus}$ [Eq. (e2)] is independent of [AB], *i.e.* the capture step is not rate determining ($e_s$ is formed according to Eq. (e1)).

$$\frac{dNe_s}{dt} = k_p \cdot [AB] \cdot Ne_p - k_s \cdot Ne_s = 0$$

in the fragmentation[30]) rather than mesomerism which play an important role[31,32]. Resonance stabilization involving an aromatic system is, however, essential in many cases: aliphatic nitro compounds[33], as well as ketones[8], show no $M^{\ominus}$ ions, whereas $C_6H_5NO_2$ and benzophenone do[34].

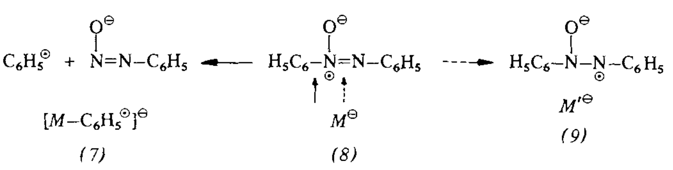


Phosphoric acid derivatives[35] and thiocarboxylic acid esters[36] can be counted in this group. So far, it has not been possible to clarify just how important a role the unoccupied d-orbitals play in this case. Owing to lack of complete data the discussion concerning sulfur compounds[18,37-39] as well as compounds containing other heteroatoms such as Si[40], is not yet closed. It is possible to obtain stable anions from unsubstituted arenes[41] and fluorocarbons[42]. One particularly interesting group is that of the metal complexes, in which the electron can be bound by the metal cation by changing the valence (see Section 3.4.3). It can be concluded that—apart from quinone systems and metal complexes—only nitrobenzene derivatives are expected with certainty to give intense $M^{\ominus}$ ions. Thus, nitrobenzoic acid derivatives are recommended for the analysis of alcohols[43] and of amino acid esters[44]. The importance of NI-mass spectrometry in the analysis of explosives should also be mentioned[45].

### 3.4. Fragment Formation

#### 3.4.1. General Considerations

Over the years there has been no lack of attempts deriving general rules from the diverse observations made on the fragmentation of negative ions. One attempt[46], applying the concept of localized charge also to molecular anions, led to rather general rules (*e.g.* "slow electrons prefer to position themselves at the positive end of a dipole"; "if, due to excess energy, a π bond adjacent to a negative center is ruptured with electron pairing [*(8)*→*(9)*], then $M^{\ominus}$ is stabilized. If, however, rupture of a σ-bond occurs [*(8)*→*(7)*], then fragmentation rapidly follows", *etc.*).



$$C_6H_5^{\bullet} + \overset{O^{\ominus}}{\overset{|}{N}}{=}N{-}C_6H_5 \longleftarrow H_5C_6{-}\overset{O^{\ominus}}{\overset{|}{\underset{\oplus}{N}}}{=}N{-}C_6H_5 \dashrightarrow H_5C_6{-}\overset{O^{\ominus}}{\overset{|}{N}}{-}\underset{\oplus}{N}{-}C_6H_5$$

$[M-C_6H_5^{\bullet}]^{\ominus}$ *(7)* $M^{\ominus}$ *(8)* $M'^{\ominus}$ *(9)*

Two observations were the prerequisite for a more detailed discussion: a) some exothermic processes $AB \rightarrow A^{\ominus} + B$ require an activation energy[47,48]; b) orbital symmetry arguments play an important role[48,49]. This means, for example, that formation of $Cl^{\ominus}$ from $C_6H_5Cl^{\ominus}$ in the lowest excited state does not simply correspond to the reverse of the approach of $Cl^{\ominus}$ to $C_6H_5^{\bullet}$, because the lowest unoccupied orbital of $C_6H_5Cl$ is an aromatic π* orbital, whereas in $C_6H_5^{\bullet}$ the unpaired electron occupies a σ orbital. Hence, dissociation must take place either from a state in which the added electron occupies a non-bonding orbital of the Cl (this requires higher excitation)[*], or after reorientation (*e.g.* by two body collision)[48]. Thus, different mass spectra are obtained at different ionizing energies (cf. the structured ion yield curve in Section 2.2.2). For example, at 1 eV $CH_3SCH_3$ gives only $CH_3S^{\ominus}$ ions, at 4.5 eV both $S^{\ominus}$ and $CH_3^{\ominus}$ but no $CH_3S^{\ominus}$ ions, at 7.5 eV all three types of ion *etc.*[49]. Further examples may be found in a review article[50]. These results led *Khvostenko et al.*[51] to formulate some rules which we shall consider in a somewhat extended form:

1) Whereas in positive ion spectrometry each fragment can carry the charge, in the case of NI a prerequisite for this is a positive *EA*. That is why, for example, no $N^{\ominus}$ or $N_2^{\ominus}$ ions are formed from azo compounds. Similarly, no $C_2H_5^{\ominus}$ ions are observed (even when $[M-C_2H_5]^{\ominus}$ is formed); anions which would have to be formed by simple breakage of a non-activated σ bond of a longer alkyl chain are usually absent.

2) Other factors being equal, the probability of anion formation roughly parallels the *EA* of the uncharged species in question. This is seen in the often observed very intense halogen ions, $CN^{\ominus}$, $O^{\ominus}$, $HC{\equiv}C^{\ominus}$, *etc.* (see Fig. 3).

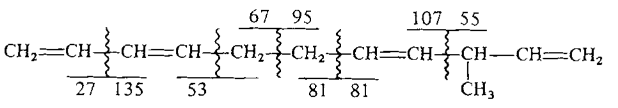
3) It should be possible to correlate the orbital symmetries of the daughter and parent ions. Even so, distinguishable mass spectra, at different excitation energies are only obtainable when one employs monoenergetic electrons. Otherwise, (*e.g.* using a hot filament or secondary electrons according to Eq. (e1)) the decompositions arising from the various energy levels will overlap. Their importance depends on the energy distribution of the electrons concerned.

4) The fact that, in the case of anions, autoionization (emission of e) competes with fragment formation, means that rapid decay reactions (in particular those involving simple bond cleavages) are preferred over more complex rearrangements. The portion of ions formed by rearrangement increases with increasing lifetime of the decaying ion (see Section 2.2.1). This is true for molecular as well as for fragment ions. Thus, in the case of negative ion spectra, it should be easier to make a simple correlation with the structure of the substrate molecules. For example, the two compounds 9-methylundeca-1,3,7,10-tetraene *(10)* and 3,8-dimethyldeca-1,4,6,9-tetraene *(11)*, have positive ion spectra which are almost indistinguishable. In their NI spectra (Fig. 4), all fragments can be interpreted in terms of simple bond breakages. Similarly the negative ion spec-

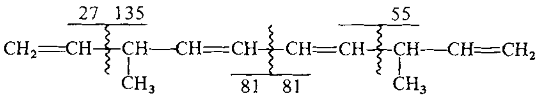
---

[*] Using the values given in Ref. [47-48], $EA(Cl) = 3.7$ eV and $D(C_6H_5Cl) = 2.9$ eV, the formation of $Cl^{\ominus}$ according to Eq. (c) is calculated to be exothermic by −0.8 eV. However, the $E_a$ was measured as 0.76 eV.

trum of 1-heptene contains an ion at $m/z=27$ ($CH_2{=}CH^{\ominus}$) which is absent in the case of 2-heptene[52].



$CH_2{=}CH{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}\underset{CH_3}{CH}{-}CH{=}CH_2$ *(10)*



$CH_2{=}CH{-}\underset{CH_3}{CH}{-}CH{=}CH{-}CH{=}CH{-}\underset{CH_3}{CH}{-}CH{=}CH_2$ *(11)*

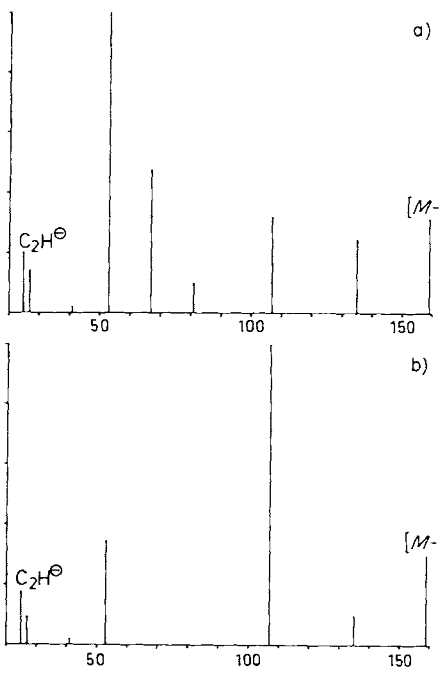


Fig. 4. NI spectra of a) 9-methylundeca-1,3,7,10-tetraene and b) 3,8-dimethyl-deca-1,4,6,9-tetraene (MKh 13-03, 2.5—8 eV) (after [59]).

5) The fact that autoionization can occur, thereby causing only those ions with a relatively low energy and thus a long enough lifetime to be recorded ($>10^{-6}$ s), leads to a very important difference from that of the fragmentation processes in the case of positive ions. In particular, ions requiring a high activation energy are formed. Thus, 1,2-diphenylethane *(12)* affords $C_6H_5CH{=}CH^{\ominus}$; this ion, however, is not present in the spectrum of 1,2-diphenylethylene *(14)*, despite the fact that it could arise here through simple bond breaking. Instead, the ion formed after $H_2$ elimination is in fact $H_5C_6C{\equiv}C^{\ominus}$[51]. $H_2$-Elimination of this kind is very frequently observed in the case of negative ions.

$$\underset{(12)}{H_5C_6{-}CH_2{-}CH_2{-}C_6H_5} \xrightarrow{e} \underset{(13)}{H_5C_6{-}CH{=}CH^{\ominus}} + H_2 + C_6H_5^{\odot}$$

$$\underset{(14)}{H_5C_6{-}CH{=}CH{-}C_6H_5} \xrightarrow{e} \underset{(15)}{H_5C_6{-}C{\equiv}C^{\ominus}} + H_2 + C_6H_5^{\odot}$$

The rules outlined above explain several important observations:

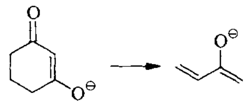
a) The 70-eV spectra of compounds which cannot form stable molecular anions frequently consist of merely "molecular debris", *i.e.* particularly stable species such as acetylide ions, ($C_2^{\ominus}$, $C_2H^{\ominus}$, $C_4H^{\ominus}$ *etc.*), or $O^{\ominus}$, $CN^{\ominus}$, $NO_2^{\ominus}$ *etc.* (Fig. 3)[8].

b) In particular, when using electrons of lower energy (see Section 3.4.2), an $[M-H]^{\ominus}$ ion is frequently observed in place of $M^{\ominus}$ (Fig. 4). The relatively high dissociation energy of, *e.g.*, C—H and O—H bonds plus the high *EA* of the resulting anions, explains these observations.

c) Fragments specific to the substrate structure can be expected for compounds forming stable $M^{\ominus}$ ions. Fragments can also be formed in rearrangement reactions. "Molecular debris" will not occur in such cases (cf. Fig. 7). The rule that consecutive elimination of two radicals will not occur[24] applies particularly to these ions. This often cited rule is the pendant to the "even electron rule" for positive ions[53]. There are, however, many exceptions[18,54], *e.g.*, *p*-methylbenzoic acid methyl ester (see Section 3.4.3).

A comparison of biacetyl, 1,2- and 1,3-cyclohexanedione may serve as an illustration[18,39]: in biacetyl the negative charge is well stabilized—as shown in *(4)* (Section 3.3); only minor amounts of $C_2H^{\ominus}$ ($m/z=25$) and $HC{\equiv}C{-}O^{\ominus}$ ($m/z=41$) ions are formed in addition to $M^{\ominus}$. 1,3-Cyclohexanedione can form a resonance stabilized enolate ion *(16)*; as a result $[M-H]^{\ominus}$ furnishes the base peak (Fig. 5a).

*(16)*



*m/z* 69

1,2-Cyclohexanedione, on the other hand, exists largely as the enol. Therefore, resonance stabilization of $M^{\ominus}$, as was the case for biacetyl, will not occur here, and furthermore the enolate ion is less stabilized than in the case of the 1,3-dione. The result is $M^{\ominus}$ and $[M-H]^{\ominus}$ ions of low intensity, as well as $H_2$-elimination from the latter, and intense peaks at $m/z=25$ and 41 (Fig. 5b).

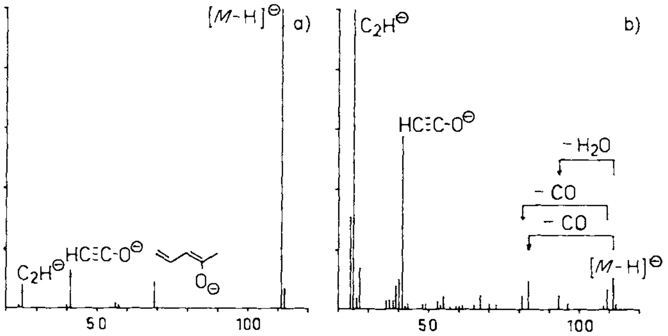


Fig. 5. NI-spectrum of a) 1,3-cyclohexanedione, b) 1,2-cyclohexanedione (CH-4, 70 eV).

### 3.4.2. Stable Molecular Anions

The importance of stable molecular anions for the interpretation of negative ion spectra has been emphasized by *Bowie et al.* (see Section 3.3) as well as *Rullkötter et* *al.*[18,39]. The concentration of the thermal electrons may be increased by appropriate adjustment of experimental parameters in cases where no stable molecular ions are obtained under normal electron impact ionization conditions (70 eV, $10^{-4}$ Pa)[8]. There are several such possibilities:

1) *Decreasing the electron energy.* The work of *Khvostenko et al.*[50] has shown that characteristic negative ion spectra can be obtained using low excitation energies. Natural products such as sugars, steroids, or glycosides also furnish intense $[M-\mathrm{H}]^{\ominus}$ ions under such conditions[55] (see Section 3.4.1). Yet, the electron energies required ( < 10 eV) are not always accessible with commercial mass spectrometers. The use of energies of above 10 eV is of no advantage but rather causes a decrease of ion intensities compared to 70 eV spectra[39].

2) *Decreasing of the drawout potentials*[18,39]. This effect is illustrated in Figure 6. Whereas methyl propyl sulfide *(17)* gives mainly $C_2H^{\ominus}$, $S^{\ominus}$, and $SH^{\ominus}$ ions under the normal operating conditions of 6—8 V of the Varian CH-4 mass spectrometer, these ions are superceded by the structurally significant $CH_2S^{\ominus}$ and $CH_3S^{\ominus}$ ions at 0 V.

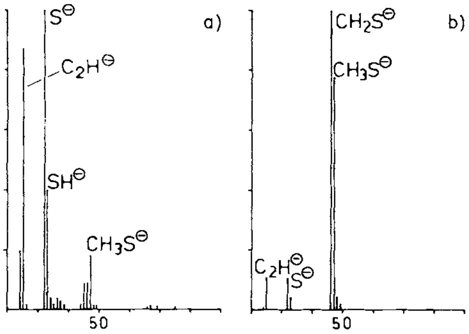

Fig. 6. NI-spectra of methyl propyl sulfide *(17)*; drawout potential a) 8 V, b) 0 V (CH-4, 70 eV).

*(17)* $CH_3—S—CH_2—CH_2—CH_3 + e \longrightarrow$
$[CH_3—S—CH_2—CH_2—CH_3]^{\ominus} \longrightarrow CH_3S^{\ominus}$ *m/z* 47

3) *Increasing the source pressure.* In this case too, the number of low-energy electrons increases; this holds for both secondary (Eq. (e1)) and slowed down primary electrons arising from plasma discharges. In the case of nitrobenzene a pressure increase by a power of ten causes a corresponding increase in the relative intensity of $M^{\ominus}$[10]. The usual electron impact sources limit the increase in sample pressure attainable. Therefore *Knof et al.* constructed a source capable of supporting pressures of up to $10^{-1}$ Pa[56]. Since almost all modern commercial mass spectrometers are equipped with CI sources, such modifications of the EI source are no longer necessary. An increase in sample pressure in the source can result in ion-molecule reactions; thus alcohols, aldehydes, acids, amines, *etc.* form cluster ions of the composition $[n\cdot M-\mathrm{H}]^{\ominus}$ ($n$=2—4). Furthermore, so-called auto-CI can occur (see Section 3.5) as in the formation of $CHCl_4^{\ominus}$ from $CHCl_3$. In order to circumvent such difficulties, it has been suggested the source pressure be increased by introduction of an additional gas ($N_2$, Ar, $H_2$, $CH_4$)[57-58]. At any rate, this is an area bordering on CI which is true also of the work of *Manfred von Ardenne* as discussed in Section 3.5.

### 3.4.3. Special Classes of Compounds

This section presents a selection of results where simple structure fragment correlations are possible. The following abbreviations are used: N = normal conditions spectrometery ($\approx$70 eV, $10^{-4}$ Pa), L = low electron energy, P = increased source pressure.

1) Aliphatics and Cycloaliphatics

*Olefins:* $[M-\mathrm{H}]^{\ominus}$, single bond breakage. There is no simple correlation between ion intensity and the nature of the bond to be cleaved (*e.g.* alkylic, vinylic, *etc.*) (L)[52,59].

*Alcohols:* $[M-\mathrm{H}]^{\ominus}$, $[M-3\,\mathrm{H}]^{\ominus}$; an unambiguous correlation between fragments and substrate structure is not possible. Cluster formation may occur (P)[56,60].

*Ethers:* $RO^{\ominus}$ (L)[52].

*Mercaptans:* $[M-\mathrm{H}]^{\ominus}$, $S^{\ominus}$, $SH^{\ominus}$. NI Mass spectrometry of mercaptans is of importance in crude oil analysis (P)[60]. *Thioethers:* $RS^{\ominus}$, $S^{\ominus}$ (L)[49-50]. $RS^{\ominus}$ becomes uncharacteristic in the case of long chain compounds (N)[18,39].

*Aldehydes, Ketones:* $[M-\mathrm{H}]^{\ominus}$, $HC{\equiv}C—O^{\ominus}$, $CH_3COCH_2^{\ominus}$ or the corresponding homologs (L)[50-52]. $[M-\mathrm{H}]^{\ominus}$ (P)[60]. *1,2-Diketones:* $M^{\ominus}$ (cf. Sections 3.3 and 3.4.1). *1,3-diketones:* $[M-\mathrm{H}]^{\ominus}$ (N)[18,34,39].

*Acids:* $[M-\mathrm{H}]^{\ominus}$ (P)[60]. *Dicarboxylic acids;* $[M^{\ominus}]$, $[M-\mathrm{H}]^{\ominus}$, $[M-\mathrm{COOH}]^{\ominus}$ and when sterically possible $[M-\mathrm{H_2O}]^{\ominus}$ (N)[61].

*Esters:* In some unsaturated esters $[M-\mathrm{H}]^{\ominus}$, $CH_3O^{\ominus}$, $^{\ominus}CH_2COOCH_3$, as well as $[M-\mathrm{CH_3OH}]^{\ominus}$ were found (L)[62-63]. $CH_2(COOC_2H_5)_2$ similarly gave $[M-\mathrm{H}]^{\ominus}$ and $^{\ominus}CH_2COOC_2H_5$ (P)[60]. Dithiocarboxylic acid methyl esters give $M^{\ominus}$ and $[M-\mathrm{CH_3}]^{\ominus}$ (N)[36].

*Dinitriles:* $[M-\mathrm{H}]^{\ominus}$, $^{\ominus}CH_2CN$, $CN^{\ominus}$ (N)[64].

*Nitrites:* $RO^{\ominus}$, $[M—NO—H_2]^{\ominus}$, $HNO^{\ominus}$ L[157].

2) Aromatic Compounds.

*Unsubstituted aromatics:* $C_6H_6$ gives $[M-\mathrm{H}]^{\ominus}$, whereas in higher annelated aromatics the importance of $M^{\ominus}$ increases. The situation is analogous for heteroaromatic compounds (L)[16,41,50,55,65]. $[M]^{\ominus}$ and $[M-\mathrm{H}]^{\ominus}$ are observed in higher condensed aromatics and heteroaromatics in particular; occasionally $[M-2\,\mathrm{H}]^{\ominus}$ (thermally) is also observed (P)[57,60,66,67].

*Aralkanes and heteroaralkanes* show $[M-\mathrm{H}]^{\ominus}$ together with $[M-\mathrm{C}_n\mathrm{H}_{2n+1}]^{\ominus}$. Either aryl$^{\ominus}$ or aryl-$CH_2^{\ominus}$ may predominate depending on the nature of the compound. Different structures are discussed for the ion $C_7H_7^{\ominus}$ depending on the precursor. In view of the discussion in Section 3.4.1 it is interesting to note that the $C_7H_7^{\ominus}$ ion is virtually absent in the spectrum of *tert*-butylbenzene, from which it cannot be formed without rearrangement (L)[50,68].

*Ketones:* $[M-\mathrm{H}]^{\ominus}$, $C_6H_5^{\ominus}$ (both weak) for acetophenone and its homologs; $M^{\ominus}$, $[M-2\,\mathrm{H}]^{\ominus}$, $C_6H_5CO^{\ominus}$, $C_6H_5^{\ominus}$ have a high to medium intensity for benzophenone (N)[18,34,39].

*Benzoic acids and thiobenzoic acid esters:* $[M-H]^\ominus$, $[M-R]^\ominus$, $[M-COOR]^\ominus$ and to an important extent $C_2H^\ominus$ and $C_4H^\ominus$ for benzoic acid alkyl esters. $C_6H_5COO^\ominus$ is apparently formed through ion pair formation. Thioesters and dithioesters give rise to $M^\ominus$ and $[M-CH_3]^\ominus$ (the latter ion has a relative intensity of 100% when a COSR group in contrast to a CSOR group is present) as well as $RS^\ominus$ (N)[18,36]. $[M-H]^\ominus$, $[M-COOCH_3]^\ominus$, $OCH_3^\ominus$ as well as an intense $[M-H-CH_3]^\ominus$ (splitting off of two radicals!) for $p$-$CH_3$—$C_6H_4COOCH_3$ (L)[54]. Multiply unsaturated aliphatic esters give complicated spectra[141,142].

*Quinones:* Unsubstituted quinones give rise to intense $M^\ominus$; anthraquinone esters fragment by elimination of $^\circ R$ and $^\circ COOR$ radicals. In 1-alkoxycarbonyl derivatives $^\circ OR$ is also lost as a result of an *ortho* effect (N)[18,19].

*Nitrobenzene and Derivatives* (N): As a result of the extensive work carried out by *Bowie et al.*[9], these compounds are among the most thoroughly studied. However, since they are not of general importance they will only be dealt with here in a limited manner. Apart from $NO_2^\ominus$, intense $M^\ominus$ and $[M-NO]^\ominus$ are observed. In compounds with an *ortho* substituent containing an H atom ($CH_3$, $NH_2$ *etc.* by operation of an "*ortho*-effect"[30]) $[M-OH]^\ominus$ is also found[13,69]. Whereas $p$-nitrobenzoic acid methyl ester hardly fragments at all[18], esters of longer chain alcohols give $O_2N$—$C_6H_4$—$COO^\ominus$ ions[43]. Neighboring group interactions between the $NO_2$ group and an *ortho* substituent is also important in the isomeric nitrobenzoic acid phenyl esters[31]: only the *ortho* isomer *(18)* easily eliminates $C_6H_5O^\ominus$, leading to the formation of a cyclic structure. (The subsequent elimination of $CO_2$ supports the presence of such a structure (Fig. 7).)

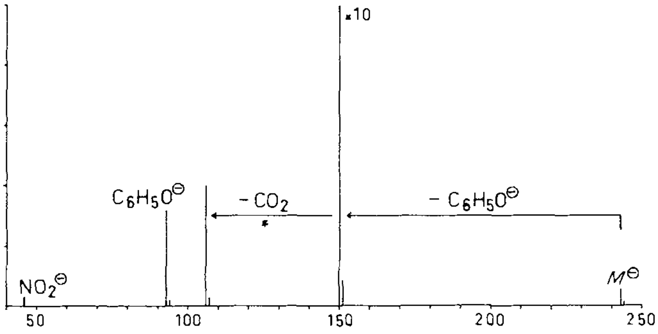

Fig. 7. NI-spectrum of $o$-nitrobenzoic acid phenyl ester *(18)* (RMU-6D, 70 eV) (after [31]).

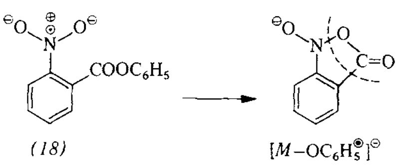
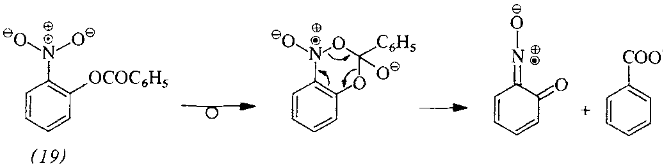
More complicated rearrangement reactions are also observed: whereas $p$-nitrophenyl benzoate gives $[M-C_6H_5CO]^\ominus$ as the principal fragment, the $o$-isomer *(19)* eliminates $C_6H_4NO_2^\ominus$. $^{18}O$-labeling shows that one of the O atoms in $C_6H_4NO_2^\ominus$ comes from phenol. Neighboring group interaction is important here too[31].

*Silyl Compounds* (N): Benzoic acid trimethylsilyl esters give a weak $M^\ominus$; the base peak is $C_6H_5COO^\ominus$. The analogous $p$-nitrobenzoic acid ester gives almost only $M^\ominus$[18,70], whereas for the $m$-compound, $[M-(CH_3)_3Si]^\ominus$ is the base peak. The $o$-compound is again special in that it shows $[M-(CH_3)_3SiOH]^\ominus$[70]. *Ortho* effects are also found for the trimethylsilyl ether of $o$-nitrophenol[70].



*(18)*



*(19)*

3) Organometallic Compounds (N)

Intense $M^\ominus$ peaks are usually obtained from β-alkenedionates[71,135,136], dithiocarbonates[72], salicylaldehyde derivatives[73,74] and metallocenes[75,76]. The ligand anion is usually also observed. In general, further fragmentation is of little importance and, therefore, in contrast to the situation for positive ion spectra, the question whether valence changes of the metals influence the fragmentation pattern cannot be studied[77,78]. The high intensities of $M^\ominus$ have, however, been used in the trace analysis of metals[138].

4) Natural Products

Nitrobenzamides of glycine and alanine give intense $M^\ominus$ peaks. Poorer ion yields are obtained from the trifluoroacetates. The fragments observed in these two examples are more characteristic of the derivative groups than of the amino acids themselves. The paucity of data available gives no indication of a special advantage of the NI technique (N)[44]. The situation is similar for the $N$-acetyl-$p$-nitrobenzyl esters of alanine, valine and proline which give $[M-{}^\circ CH_2C_6H_4-NO_2]^\ominus$ ions (L)[79]. Alkylated itaconic acid anhydrides give intense $M^\ominus$ ions; elimination of the alkyl groups with concomitant hydrogen migration also occurs (N)[23].

Two acetylated diterpene diols give $[M-H]^\ominus$, cleavage of the acetoxy group, and $CH_3COO^\ominus$ as the most intense ion (L)[80]. The preferred formation of carboxylate ions permits identification of the esterified acids in a diterpene of the *Euonymus* family; furthermore, small amounts of homologs are seen; these are indicated by arrows in Figure 8a. The corresponding $RCO^\oplus$ ions in the positive spectra (Fig. 8b) are obscured by the large number of fragment ions in this region (L)[55]. $[M-H]^\ominus$ ions were obtainable from some hydroxysteroids (L)[55]. Arabinose also yields an $[M-H]^\ominus$ together with $O{=}CH$—$CH{=}CH$—$O^\ominus$ ($m/z=71$) as the base peak (L)[55]. Sugar acetates form $[M-CH_3CO]^\ominus$ (cf. Fig. 8a) and eliminate $CH_3COOH$ as well as $CH_2CO$ (L)[81].

5) Pesticides

A series of carbamates of aromatic hydroxy compounds has been examined; the phenolate ion usually appears with high intensity. Some thiophosphoric acid esters and chlorinated compounds were also studied (N)[82].

6) Inorganic Compounds

NI-spectra may be obtained from inorganic compounds as well (regarding $SF_6$ see Section 2.2.1) when they are sufficiently volatile and their *EA* is positive. The investigations are not so much of importance for analyses but rather for the determination of physical data[162].

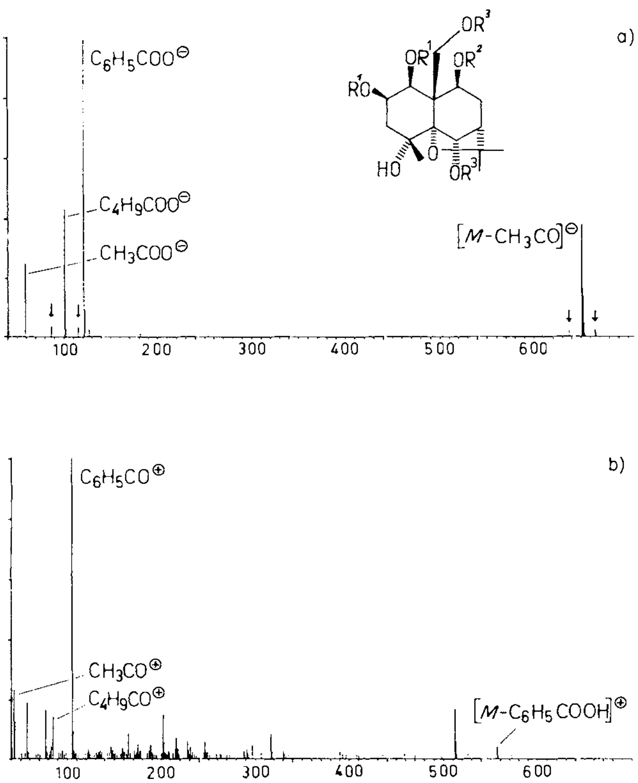


Fig. 8. a) NI-spectrum of Euolaline (ester B-5) from *Euronymus europaeus* (MAT-731, 5 eV). $R^1=C_6H_5CO$; $R^2=C_2H_5CHCH_3CO$, $R^3=CH_3CO$; b) positive spectrum (MAT-731, 100 eV).

### 3.5. The Work of *Manfred von Ardenne*

For many years the majority of the NI spectra relevant to the structure analysis of organic molecules came from the research institute Dresden-Weisser Hirsch. In the apparatus constructed by *Manfred von Ardenne,* the primary electrons are deprived of most of their energy through collision with Ar at a pressure of *ca.* 1 Pa. The electrons produced in this way give rise to $M^\ominus$ or, more frequently, $[M-H]^\ominus$ ions, which often undergo subsequent characteristic decomposition. Before the introduction of field desorption mass spectrometry, *Ardenne*'s instrument was the only one allowing usable spectra of involatile compounds to be obtained. This method played an important role in *Reichstein*'s work on cardenolide glycosides. The literature up to 1968 is reviewed in [83]; accordingly, only a short overview and description of newer work is given here. It appears that only one instrument of the *Ardenne* type is in existence in Dresden. Nevertheless, many of the results are relevant in studies using CI mass spectrometry, and in some areas can even be considered as pionieering work (see Section 4).

Inasmuch as this technique involves pure electron attachment (see also Section 4.2.1), the results extend those in Section (3.4.3); aromatics give $[M-H]^\ominus$ together with $M^\ominus$, the latter increasing with the number of rings. Acids give $[M-H]^\ominus$ but may also undergo fragmentation; thus phenylacetic acid gives $C_7H_7^\ominus$ as the base peak. In esters, both $[M-H]^\ominus$, $RCOO^\ominus$, and $R'O^\ominus$ are to be expected although the relative intensities may vary; thus for butyl butyrate the ratio of carboxylate to alcoholate ion equals *ca.* 3 : 1; in ethyl benzoate the carboxylate ion predominates; in phenyl benzoate the alcoholate ion. More complicated fragments may also be observed, however: butyl butyrate gives $[M-29]^\ominus$. Aliphatic alcohols give $[M-H]^\ominus$ and intense $[M-3H]^\ominus$, and ketones give $[M-H]^\ominus$ ions. The three isomeric nitrobenzoic acids give widely different negative ion spectra (*p:* $[M-NO]^\ominus$, $[M-HNO_2]^\ominus$; *m:* $[M-OH]^\ominus$; *o:* a combination of the *m* and *p* spectra.

Natural product studies are also important: usually, $M^\ominus$ or $[M-H]^\ominus$ are of high intensity. Steroid glycosides lose their sugar moiety with the formation of alcoholate ions[83]; esters behave as described above[83,84]. Gibberellins split off $H_2O$, HCOOH, and CO, but show only few skeletal fragments[85]. Amino acids give rise to $[M-H]^\ominus$, $[M-R]^\ominus$ and $R^\ominus$[86]. Glucose esters[87], terpenes[133] and lichen constituents[134] have also been throughly studied.

*von Ardenne* systematically examined the occurrence of ion-molecule reactions[83], a problem also relevant to CI mass spectrometry (several of these processes are discussed in Section 4). Molecular ions react either with the residual gases $H_2O$ and $O_2$ or with non-ionized molecules of the same material (auto-CI). The most important processes are presented in Table 1.

Table 1. Ions in the $M^\ominus$ region formed in ion-molecule reactions (ionization with electrons slowed down by collision with an auxiliary gas).

| Ion | Class of compound | Remarks |
|---|---|---|
| $[M+OH]^\ominus$ | alkanes, cycloalkanes<br>alkenes | only ion in $M^\ominus$ region |
| $[M+O]^\ominus$ | aromatics | |
| $[M-H+O]^\ominus$ | hydrocarbons | |
| $[M-2H+O]^\ominus$ | compounds with allylic $CH_2$-group | $[M+14]^\ominus$ can be confused with homologous compounds [85]. |
| $[nM-H]^\ominus$ | alcohols, acids | see Section 3.4.2 |
| $[M+CF_3]^\ominus$ | trifluoroacetates | |
| $[M+Cl]^\ominus$ | chlorine compounds | [88], see text. |

Apparently, traces of halogen compounds are easily retained in the source so that $[M+Cl]^\ominus$ ions may be found in later measurements[83]. All these reactions may complicate the analysis of unknown substances.

## 4. Chemical Ionization (CI)

### 4.1. General

The principles and instrumental techniques of CI are described in refs.[89] and [90], respectively. The reactant gas can have three functions:

1) Slowing down the primary electrons to give thermal electrons.
2) Charge transfer; this requires that *EA* (reactant gas) < *EA* (substance).
3) True CI; here, there is a chemical reaction between an ion of the reactant gas and a molecule of the substance to be examined[164].

The first two processes lead to resonance capture with or without dissociation. The findings of *von Ardenne* (Section

3.5) and the possibility of raising the source pressure using an auxiliary gas could be included here[57,58] (Section 3.4.2). For practical reasons, in this section we shall discuss those studies carried out using commercially available CI sources.

Similarly as in work with EI sources (see Section 3.2), instrumental parameters play an important role here also. General problems related to CI such as the influence of the repeller potential on the residence time in the source, optimum reactant gas pressure, *etc.*, will not be further dealt with here (for further information see [89,90] and references cited therein). In this case also, it is true that with increasing source temperature, the relative proportion of $M^{\ominus}$ and quasi-$M^{\ominus}$ decreases while the fragment ions increase or even in some cases appear for the first time[83,91]. In extreme cases, this can lead to a situation where quasi-$M^{\ominus}$ is formed only when the source is cold, *e.g.* $[M+OH]^{\ominus}$ for alkanes (see Section 4.2.4)[55]. Because of the high pressure of the reactant gas (up to $10^2$ Pa), processes such as the formation of low energy electrons and collisional deactivation of excited ions occur exclusively by way of reactant gas molecules, *i.e.* eqs. (g1) and (h1) no longer play a role. One could expect, therefore, that as a first approximation, there is a linear dependence of ion formation on substance pressure (see, however, Section 4.3).

## 4.2. Specific Reactant Gases

### 4.2.1. Formation of low energy electrons ($CH_4$, $i$-$C_4H_{10}$, $NH_3$, $H_2$, and occasionally $CH_2Cl_2$)

(Compare also Section 3.5 and ref. [57,58] as well as Section 4.2.2 regarding $H^{\ominus}$ and 4.2.3 regarding $CH_2Cl_2$.)

In general, the results of *von Ardenne* (Section 3.5) apply here also. Studies using $CH_4$ and $i$-$C_4H_{10}$[55] have shown that alkanes give no $M^{\ominus}$ ions, whereas benzil does, and esters fragment to carboxylate ions; aromatic nitro compounds behave as expected from the results of *Bowie et al.* (Section 3.4.3). Oligosaccharides give $M^{\ominus}$ ions of moderate intensity[92]. Bile acids give $[M-H]^{\ominus}$ from which water splits off[93]. First results[55] indicate that the use of different reactant gases gives rise to electrons of varying energy content. Thus, for a chloro compound (aldrin) it was found that, when $i$-$C_4H_{10}$ is used, fewer fragments are formed than with $CH_4$[94]. Systematic studies are still called for in this area.

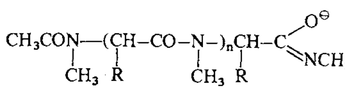
Because of their importance as pesticides and also following the Seveso catastrophy, chlorinated cycloaliphatic and aromatic compounds have been particularly well investigated[91,94-96]. $M^{\ominus}$ ions, and occasionally $[M-H]^{\ominus}$, are almost always observed. The most important fragmentation reactions are those where Cl, HCl, and possible combinations of these, are lost. $RO^{\ominus}$ is observed in ethers but often only at higher source temperatures. By auto-CI, $[M+Cl]^{\ominus}$ is formed, as well as smaller amounts of $[M+Cl_3]^{\ominus}$. When $CH_2Cl_2$ is used the formation of the former ion is somewhat lower. It would appear that this is due to $CH_2Cl_2$ having a greater affinity for $Cl^{\ominus}$; $CH_2Cl_3^{\ominus}$ appears at the expense of $[M+Cl]^{\ominus}$[94]. Traces of $O_2$ and/or $H_2O$ (see Section 3.5) in the source lead to nucleophilic displacement of Cl by $O^{\ominus}$ ($[M-Cl+O]^{\ominus}=[M-19]^{\ominus}$ and $[M-HCl-Cl+O]^{\ominus}=[M-55]^{\ominus}$). This occurs to a greater extent with $CH_4$ than with $i$-$C_4H_{10}$[94]. It has been suggested, because of the bad reproducibility of the intensities of these ions, that some $O_2$ be added to the reactant gas ($CH_4$) in order to achieve constant ratios[91,96]. When hydrocarbons are used as reactant gases, one occasionally observes addition of alkyl residues giving $[M+CH_3]^{\ominus}$, $[M+C_2H_5]^{\ominus}$ and $[M-H+CH_3]^{\ominus}$. Since the ions $CH_3^{\ominus}$ and $C_2H_5^{\ominus}$ do not occur in the plasma, it may be assumed that alkylation precedes ionization[55,139,140,163].

A series of alkylated cyclic pharmaceuticals (phenothiazines, barbiturates and others) was examined[97-100,156]. Whereas the use of $N_2$[97], $NH_3$[98] and $i$-$C_4H_{10}$[156] normally allows the observation of $[M-H]^{\ominus}$ ions, the use of $CH_4$[98] can lead to $H^{\ominus}$ transfer giving intense $[M+H]^{\ominus}$ ions (see Section 4.2.2). Important fragments are always formed by elimination of the whole side chain; longer chains are preferred over smaller, and unsaturated over saturated ones.

A series of chelates has been reported to give abundant $M^{\ominus}$ (or $[M—H]^{\ominus}$) as well as the ligand anions[163]. Several derivatives of primary amines have also been investigated[155].

### 4.2.2. Acid-Base Reactions

Several reactant gases give anions which can abstract $H^{\oplus}$ from another molecule in an acid-base reaction. For example, $CH_3O^{\ominus}$ can be used as the reagent anion (obtained from a reactant gas mixture consisting of *ca.* 0.1% of $CH_3ONO$ in $CH_4$). $CH_3O^{\ominus}$ reacts with ketones abstracting the α-H-atom, yielding intense $[M-H]^{\ominus}$ ions. The formation of $[M-H]^{\ominus}$ and ions of the type *(20)* from the reaction of an acetylated tripeptide ester with $CH_3O^{\ominus}$ has also been described[97].



*(20)*

$$CH_3CO\underset{\underset{CH_3}{|}}{N}—(\underset{\underset{R}{|}}{C}H-CO-\underset{\underset{CH_3}{|}}{N}-)_n\underset{\underset{R}{|}}{C}H-C\genfrac{}{}{0pt}{}{\nearrow O^{\ominus}}{\searrow\!\!\!= NCH_3}$$

Using $H_2$ as the reaction gas the stronger base $H^{\ominus}$ may be obtained[101,102]. Ketones, acids and esters possessing α-H-atoms, as well as acids, amines, alcohols and phenols give $[M-H]^{\ominus}$; fragment ions are absent or of low intensity except when strongly stabilized species such as $RCOO^{\ominus}$ can be formed, *e.g.* from esters. Nitroarenes give rise to $M^{\ominus}$ ions. Compounds which do not form stable $M^{\ominus}$ or $[M-H]^{\ominus}$ ions, *e.g.* aliphatic ethers, give intense fragment ion peaks (*e.g.* $RO^{\ominus}$ and $ROCH_2^{\ominus}$).

However, $H^{\ominus}$ can also add as a nucleophile to neutral molecules. Thus, ketones give $[M+H]^{\ominus}$ ions, especially when α-H-atoms are lacking (*e.g.* benzophenone)[102]. It should be mentioned that $H^{\ominus}$ can also be formed from both $CH_4$ at 10 eV[97] and isobutane[94], thus giving rise to formation of $[M+H]^{\ominus}$ ions (see Section 4.2.1). $H^{\ominus}$ reacts with traces of $H_2O$ to give $OH^{\ominus}$, which then leads to $[M+OH]^{\ominus}$ and $[M+H_2O+OH]^{\ominus}$ ($[M+35]^{\ominus}$) (particularly with alcohols and ketones; cf. also the formation of cluster ions $[ROH_n+RO]^{\ominus}$, Section 3.4.1). 1-Pentanol is reported to give $[M-H]^{\ominus}$ (15%), $[M+OH]^{\ominus}$ (44%), and $[M+H_2O+OH]^{\ominus}$ (40%)[102]. Less basic reactant gas ions can be generated from the plasma of $H^{\ominus}$ or $CH_3O^{\ominus}$ by addition of $CH_3NO_2$, $CH_3COCH_3$, $C_6H_5CH_3$, $C_2H_2$, $CH_3CN$, cyclopentadiene, *etc.*, until the original ions disappear[97,101]. However, a practical use of such ions of varying base strength has not yet been studied.

### 4.2.3. Cl$^{\ominus}$ and F$^{\ominus}$ as Plasma Ions

$CH_2Cl_2$ forms Cl$^{\ominus}$ together with some $HCl_2^{\ominus}$ and $CH_2Cl_3^{\ominus}$. The ratio of the three ions is strongly dependent on pressure and temperature. Reasonably constant values are, however, obtained at a pressure of $\approx$100 Pa and 210 °C[103]. Intense $[M+Cl]^{\ominus}$ ions are obtained from compounds capable of forming strong hydrogen bonds (acids, amides, amino acids, aromatic amines and phenols[103], but also polyols[104] and thiophosphoric acid esters[137]). Aliphatic amines and alcohols give low intensity $[M+Cl]^{\ominus}$ ions. This is also observed for ketones, esters, and ethers where attack of Cl$^{\ominus}$ on a substituted carbon atom in $S_N$-like transition states has been postulated. Cl$^{\ominus}$ is of little importance as a reactant ion for this group of compounds. Hydrocarbons, tertiary amines, and nitriles do not react at all. Nitroarenes give $M^{\ominus}$ and sometimes $[M+HCl]^{\ominus}$. Alkyl bromides and iodides give Br$^{\ominus}$ and I$^{\ominus}$, respectively[103].

Apart from the addition of Cl$^{\ominus}$, one may also add $HCl_2^{\ominus}$ and $CH_2Cl_2^{\ominus}$, especially at low source temperatures. When Cl$^{\ominus}$ is just weakly bound in a quasi-M$^{\ominus}$, drastic temperature effects are observed. Thus, the intensity ratio of $[M+Cl]^{\ominus}$ to Cl$^{\ominus}$ decreases by $10^2$ when increasing the temperature from 65 °C to 200 °C.

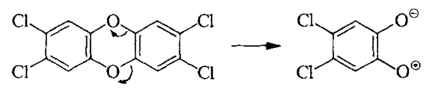
$CF_2Cl_2$ gives only Cl$^{\ominus}$. $[M+Cl]^{\ominus}$ and, more rarely $[M-H]^{\ominus}$ ions have been observed in a series of natural products (oligosaccharides, testosterone, reserpine, tetracycline); apart from the elimination of water there are hardly any fragments observed[92,93]. The Cl$^{\ominus}$ spectra should find application in particular in trace analysis, *e.g.* of acids, in materials which are not easily ionized with Cl$^{\ominus}$[103].

Little is known about F$^{\ominus}$. As reactant gases $CHF_3$, $CF_4$, $NF_3$, and perhaps also $SF_6$ may be used. Cyclic diols give $[M+F]^{\ominus}$[104]. $RSi(CH_3)_3$ can undergo cleavage of activated C—Si bonds with the formation of R$^{\ominus}$ and $FSi(CH_3)_3$[105]. Furthermore, the behavior of a series of metal complexes with Schiff bases toward reactant gases such as $CF_4$, $SO_2F_2$ and $SF_6$ has been investigated[106].

### 4.2.4. O$^{\ominus}$, $O_2^{\ominus}$, OH$^{\ominus}$ and $S_x^{\ominus}$ as Plasma Ions

When used as a reactant gas, $O_2$ leads to the formation of O$^{\ominus}$, $O_2^{\ominus}$ and a large number of low-energy electrons although it is somewhat aggressive toward the hot filament[97,101,102,107,108]. Alcohols, even tertiary ones, and free acids give $[M-H]^{\ominus}$ and $[M+O_2]^{\ominus}$ ions although few fragments. Polycyclic aromatic hydrocarbons give rise to $M^{\ominus}$ and $[M-H+O]^{\ominus}$ (phenolate ions), sulfur containing aromatic compounds (*e.g.* dibenzothiophene) $M^{\ominus}$ and intensive $[M+O_2]^{\ominus}$ (sulfone?). Of importance in pollution analysis is the formation of *(22)*, $m/z=176$ (80% TIC) ($M^{\ominus}$ from dichloro-*o*-benzoquinone, cf. Section 3.3), from tetrachlorodibenzodioxine *(21)*, which permits its detection in the presence of other chloro compounds.

*(21)*



*(22)*

O$^{\ominus}$ is also formed through decay of $N_2O^{\ominus}$; the observed formation of NO$^{\ominus}$ ($O^{\ominus}+N_2O\rightarrow NO^{\ominus}+NO$), particularly at high pressures, can be suppressed by addition of inert gases. Alkyl substituted aromatic compounds give $[M-H+O]^{\ominus}$, usually together with $[M-H]^{\ominus}$; $[M-R]^{\ominus}$ and $[M-R+O]^{\ominus}$ are formed with varying intensities. $[M-H+N_2O]^{\ominus}$ ($[M+43]^{\ominus}$), and $[M-H+N_2O-H_2O]^{\ominus}$ ($[M+25]^{\ominus}$) may be very intense[98,100,109]. Aliphatic alcohols give $[M-H]^{\ominus}$ (loss of the hydroxyl-H) and/or $[M-3H]^{\ominus}$ (elimination of hydrogen from both the α- and the β-position whereby an enolate anion $R-CH=CH-O^{\ominus}$ or $R-CH=CR'-O^{\ominus}$ is formed; this explains why $[M-3H]^{\ominus}$ is found only with primary and secondary alcohols). Characteristic fragments are formed by α-cleavage (bigger residues are lost preferentially) and additional loss of two H-atoms, one of which stems from the carbon of the second chain neighboring the hydroxylated carbon atom, thus yielding again an enolate anion[158]. $[M-17]^{\ominus}$ is thus $[M-CH_3-H_2]^{\ominus}$ in the case of 2-alkanols![100,109]. Acid chlorides give besides $[M+O-Cl]^{\ominus}$, $[M+O-Cl-H_2]^{\ominus}$[110]. As regards $[M-H]^{\ominus}$ and $[M-2H]^{\ominus}$ from ketones, unsaturated hydrocarbons, nitriles and some aromatics see refs.[111-114].

OH$^{\ominus}$ can be obtained from $H_2O$[158]. More frequently, however, it is generated by a different process: If $N_2O$ is mixed with $H_2$, $CH_4$, $i$-$C_4H_{10}$ and similar gases, then the primary product O$^{\ominus}$ reacts further to give OH$^{\ominus}$, which in turn can react with a whole range of compounds. The formation of OH$^{\ominus}$, side-reactions, and pressure and temperature dependence have been throughly studied[109] and have shown that the highest proportion of OH$^{\ominus}$ in the overall ion current is obtained at pressures of *ca.* 100 Pa, temperatures above 150 °C, and a mixing ratio of *ca.* 1:1. On the other hand, a high source temperature can be critical in measurements: only when the source is cold do alkanes give $[M+OH]^{\ominus}$, $[M-H]^{\ominus}$ and $[M-3H]^{\ominus}$ ($C_4H_{10}/N_2O$); in addition, $[M+NO]^{\ominus}$ and $[M+N_2O]^{\ominus}$ ($CH_4/N_2O$) are formed. At higher temperatures absolutely no ions are obtained from the hydrocarbons[55]. The stability of $[M+OH]^{\ominus}$ increases with increasing molecular size[115]. In general, it is possible to say that, alkenes[55,116], acids, alcohols, ketones, and esters give $[M-H]^{\ominus}$ as an intense ion (frequently accompanied by $[M-3H]^{\ominus}$)[109,117]; in the case of alcohols one H comes from the α- and one from the β-position[158]. This is also true for steroids and terpenoids, which have been examined in detail[118,160]. Fragmentation is usually of little importance; RCOO$^{\ominus}$, and to some extent R'O$^{\ominus}$, is found for esters (RCOOR'). Ethers and amines give hardly any quasi-molecular ions; RO$^{\ominus}$ and $[RO-H_2]^{\ominus}$ dominate for ethers; the fragment ($m/z=42$) formed from aliphatic amines seems to be independent of the structure[109]. Acid chlorides give similar results with OH$^{\ominus}$ and O$^{\ominus}$; however, the subsequent loss of $H_2$ is less apparent in the former case[110]. Alkyl substituted aromatics give $[M-H]^{\ominus}$ together with $[M+43]^{\ominus}$ and $[M+25]^{\ominus}$[109]. In general, the formation of these ions formed by attack of $[M-H]^{\ominus}$ on $N_2O$ is of lesser significance when $i$-$C_4H_{10}$ (or higher alkanes)/$N_2O$ is employed as the reactant gas[55]. See also the results reported in refs. [109] and [119]. The fact that OH$^{\ominus}$ does not give any ions with saturated hydrocarbons, particularly at higher tempera-

Table 2. Summary of the possible Uses of NCI.

| Reactant gas | Reagent ions | Class of compound | Ios in the $M$ region | Remarks |
|---|---|---|---|---|

| | | amines | scarcely ions | |
| | | RCOCl | $[M-Cl+O]^{\ominus}$, $[M-H_2Cl+O]^{\ominus}$ | |
| S | $S_x^{\ominus}$ | alkanes | $[M-H+S_x]^{\ominus}$ | intense $S_x^{\ominus}$-spectrum |
| | | dinitriles | $[M-H]^{\ominus}$, $[M+S_x]^{\ominus}$, | |
| | | ferrocene | $C_5H_5S_x^{\ominus}$ | |

tures, means that it is possible to determine the presence of aromatics in crude oil fractions[119].

If a mixture of $N_2O$ and $D_2$ is used, one can observe an interesting exchange reaction: in simple alcohols neither $[M-H]^{\ominus}$ nor $[2M-H]^{\ominus}$ exchange, whereas this is observed for both ion types in diols. A special bridging mechanism is conceivable in this case[143].

Alkanes react with sulfur to give intense ions of the composition $C_nH_{2n+1}S_x^{\ominus}$ ($x=1-4$)[83] (besides of course the normal sulfur spectrum up to $S_8^{\ominus}$). Dinitriles give, in addition to $[M-H]^{\ominus}$, also $[M+S_x]^{\ominus}$ ions[64]; ferrocene gives $[C_5H_5S_x]^{\ominus}$[76].

### 4.2.5. Pulsed Positive-Ion Negative-Ion Chemical Ionization (PPINICI)

With quadrupole instruments it is possible to quickly switch the measuring set-up for positive and negative ions, thus making it possible to measure both spectra alternately[97]. In this way, it is easy to get complementary information; *e.g.* since aromatic compounds give $M^{\oplus}$ and $[M-H+O]^{\ominus}$ when $O_2$ is used as reactant gas, and sulfur-containing arenes give $M^{\oplus}$ and $[M+O_2]^{\ominus}$ (see Section 4.2.4), it is possible to distinguish very quickly between these two classes. Reactant gas mixtures such as $CH_4$ with $CH_3ONO$ (which give $CH_5^{\oplus}$ and $CH_3O^{\ominus}$) can be employed[97]. This procedure will prove useful in cases where both positive and negative ion spectra cannot separately be measured owing to lack of either substance or time. The price to be paid for this advantage is that the same reactant gas must be used for both methods; consequently the possible range of CI is curtailed. Furthermore, the time required for the double scan, together with that of switching systems, is critical since the time available is limited by the width of the gas chromatography peaks, and finally the optimal adjustment of the source is not possible for both types of ionization.

### 4.3. Sensitivity of the Method

On the whole, only scattered data are available here. For barbiturates, anthracene and benzil, for example, it is reported that the total ion current (TIC) for NCI is about equal to that for positive EI but up to a factor of 50 higher than that for positive CI. For chlorinated dibenzodioxins the NCI sensitivity is higher by a factor of about 1000 than that for either positive EI or positive CI. In addition, quasi-molecular ions carry the major part of the total ion current in NCI[100, 145, 159].

In an analysis of the problem *Hunt et al.*[120] established the formation of $M^{\ominus}$ should occur about 400 times more frequently than that of $[M+H]^{\oplus}$ on using $CH_4$ as the reactant gas ($\approx 100$ Pa) and low substance pressures, causing the ionization to be diffusion controlled (addition of $H^{\oplus}$ or capture of a thermal electron). This value was experimentally verified for some highly fluorinated compounds. A requirement is, however, that each collision leads to a stable (quasi) molecular ion, *i.e.* processes such as autoionization of $M^{\ominus}$, dissociative resonance capture, *etc.* could lead to a drastic decrease in the yield of $M^{\ominus}$.

Furthermore, impurities, particularly halogen compounds (*e.g.* solvents), which might be retained in the source (see Section 3.5) can lead to a strong reduction in the number of thermal electrons. *Hunt et al.* suggested derivatization with *e.g.* $C_6F_5COOH$ or $C_6H_5CHO$, which, using single ion detection, allows access to the fg-region ($10^{-15}$ g). One should be aware, however, that the derivatization of a pure substance and the preparation of dilution series is not the same as the identification of a trace impurity.

## 5. Further Ionization Methods and Techniques

As in all ionization methods giving mainly (quasi) molecular ions, the collision induced fragment formation[121] has been used, whereby charge reversal can also occur ($M^{\ominus} \rightarrow M^{\oplus} \rightarrow$ positive fragments)[122]. The opposite process, namely the formation of $M^{\ominus}$ from $M^{\oplus}$ through collision, has likewise been observed[123]. Negative ions both from organic and inorganic compounds can also be obtained using special methods such as atmospheric pressure ionization (API)[124], laser desorption[125, 144, 161], secondary ion mass spectrometry (SIMS)[126], or $^{252}Cf$ plasma desorption[127, 144]. All these methods are confined to specialized laboratories and will not, therefore, be further treated here. Judging from the few results available, two methods of ionization may develop into generally applicable procedures, namely the direct chemical ionization (DCI) and field desorption (FD). Under DCI conditions, substances of low volatility or thermal sensitivity are placed directly in the reactant gas plasma with the aid of a special probe. It is still an open question whether ionization takes place in the condensed phase, followed by emission of ions from the surface, or whether ionization follows the vaporization of the molecules. At any rate, examples have shown that negative ions can also be produced in this manner. Thus, an $OH^{\ominus}$ plasma ($CH_4+N_2O$, see Section 4.2.4) interacts with glycosides to give $[M-H]^{\ominus}$ as well as the sugar sequence[146], and with non-derivatized glucuronides to give, in part $[M-H]^{\ominus}$ and in part, by electron capture, $M^{\ominus}$, together with the anions of the glycosidic alcohols. The general appearance of the spectra is strongly dependent on the recording conditions; *e.g.* at strong heating currents, the $[M-H]^{\ominus}$ peak is barely visible[147]. Using $CH_4$ as a retarding gas (cf. Section 4.2.1) it was possible to observe $M^{\ominus}$ or $[M-H]^{\ominus}$ as well as a series of fragment ions of some penicillin derivatives[148]. Using field desorption (FD), the $M^{\ominus}$ ion of a ubiquinone, and the $[M-H]^{\ominus}$ ions (often accompanied by $[nM-H]^{\ominus}$) of sulfonic acids and oligopeptides could be generated[153]. The $[M-H]^{\ominus}$ ions of compounds possessing acidic hydrogen atoms can be generated by placing a mixture of the substance with water and polyethylene oxide on an FD-emitter. The addition of LiCl can lead to $[M+Cl]^{\ominus}$ ions, as observed, for example, in the case of cholesterol[128].

Using the same procedure, the anions of organic and inorganic salts can be identified, often together with cluster ions, *e.g.* $LiCl_2^{\ominus}$ and $Li_2Cl_3^{\ominus}$ (organic examples are sodium naphthalenesulfonate and the salts of fatty acids; in the case of dibasic inorganic acids the anions are obtained only after cation exchange)[128, 154]. Alternatively, a freshly broken tungsten rod has been employed as the field desorption cathode for inorganic salts, and polyvinyl alcohol was used as the electrolyte (this, however, undergoes partial fragmentation of its own to give ions such as $CH^{\ominus}$, $C_2H^{\ominus}$, *etc.*)[149]. Chloride[150], bromide[151], and less easily fluoride ions[152] can be liberated from their salts using thermal ionization (hot rhenium ribbon). This procedure is useful in the trace analysis of halides in minerals according to the isotope dilution method[150], and in environmental analysis[152].

## 6. Closing Remarks

The possibilities offered by modern CI sources will probably restrict in future the practical use of the generation of negative ions from organic molecules using electron impact ionization to some special classes of compounds and to studies on the formation and decomposition of ions, determination of physicochemical data, *etc.* Usually, the generation of thermal electrons by slowing down of the primary electron current in CI sources leads to characteristic and more reproducible spectra. Examples are known where the fragmentation pattern of the negative ion spectrum gives information not available from the positive ion spectrum. The major importance appears, however, to lie in the paucity of fragments, which—given the necessary sensitivity—facilitates the analysis of mixtures, particularly when using single or multiple ion detection. The advantages and disadvantages compared with fragment poor positive CI spectra—obtained by specific ionization of certain compound classes—must be evaluated from case to case. Only a first step towards the use of reactant gases in the identification of particular structural elements has been taken. A vast area remains to be explored.

When using NI mass spectrometry in practice it should not be forgotten that it is much easier to interpret the spectra of a known compound than to derive structurally relevant information from the spectrum of an unknown substance. In particular, the numerous ion-molecule reactions observed in NCI lead, among other things, to several different quasi-molecular ions, the interpretation of which requires some experience.

It cannot be the purpose of a review article to give a complete evaluation of the literature. Instead, an attempt has been made to select from the available data those aspects which are of special importance for a general understanding of the special features of NI mass spectrometry, in particular those of interest to the organic and analytical chemist. The literature has been surveyed up to the middle of 1981 in so far as the journals have been directly available. It was considered important to select references which facilitate the location of further information (older reviews[50,83,129-132], tabulated works[2,4,16], and recent contributions in series publications[9,71]). Also less widely available publications and those indicating research groups specializing in NI mass spectrometry have been quoted.

*I wish to thank Dr. J. Rullkötter (now at KFA Jülich) and D. Stöckl, Dipl.-Chem., who in their doctoral theses collected and sorted extensive literature material. The Landesamt für Forschung Nordrhein-Westfalen is gratefully acknowledged for generous support of our work on negative ions.*

# Structure and Decay of Gaseous Organic Radical Cations Studied by Their Radiative Decay, Exemplified by the 1,3-Pentadiyne Cation

By John P. Maier[*]

*Dedicated to Professor Edgar Heilbronner on the occasion of his 60th birthday*

The radiative decay of over a hundred open-shell organic radical cations has now been established. As a result, the spectral structure of such cations in their ground and excited electronic states can be probed with resolutions of the order of $\leqslant 1\ \mathrm{cm}^{-1}$. This is achieved by means of emission and laser-induced fluorescence techniques. The analysis of the emission and excitation spectra provides the vibrational frequencies of many of the totally symmetric fundamentals of the cations in the two electronic states. In order to study the relaxation behavior of these cations under "isolated conditions", the lifetimes and fluorescence quantum yields can be obtained by means of photoelectron-photon coincidence measurements. These data yield the radiative and non-radiative rate constants as a function of the internal energy of the cations. The structural and decay information obtained from each of these techniques is illustrated using the 1,3-pentadiyne radical cation as example.

## 1. Introduction

Molecular ions have attracted a great deal of interest in the past decade. This has arisen with the realization of their importance in various environments and physicochemical phenomena. These include stellar, cometary and interstellar media as well as plasma, laser and radiation chemistry[1]. The application of spectroscopic methods enables the species to be identified and, for example, the physical conditions (*e.g.* temperature, particle densities) prevailing in the medium to be inferred. Furthermore, the dynamic aspects (*e.g.* radiative lifetimes, collision-cross-sections) are essential for the quantitative evaluation of the pertinent chemical processes. A good example of these aspects is the key role ions and ion-molecule reactions appear to play in interstellar space[2], producing large organic species (*e.g.* cyanopolyacetylenes)[3].

For all these investigations and evaluations, the spectroscopic structure and relaxation behavior of ions have to be well characterized in the laboratory. The knowledge acquired for polyatomic species is, however, still nevertheless scarce. The present article deals with our contributions in obtaining the spectroscopic and relaxation data for open-shell organic cations.

Open-shell, or radical cations of organic molecules in the gas phase have, for some time, only been experimentally accessible by mass-spectroscopic techniques. In the latter, however, neither the internal energy nor the state of the cations can usually be specified. The first generally applicable technique to provide a detailed insight into the energetics and electronic structure of radical cations was photoelectron (PE) spectroscopy[4]. By means of this technique ionization energies leading to the doublet states of radical cations, which could be reached in the photoionization process, can be measured. An example of this is given in Figure 1, which shows how the ground and lowest excited states of an organic cation are located with respect to the ground state of the molecular species. These results can be viewed on two levels; simply as a means of locating the doublet cationic states $^2\tilde{X}$ (ground), $^2\tilde{A}$ (first excited state), $^2\tilde{B}$, $^2\tilde{C}$..... $^2\tilde{J}$..... (*i.e.* successive excited states) or the symmetry of the states can be deduced as well, by associating each with a configuration based on the molecular orbital description. These aspects have been extensively discussed and reviewed[5].

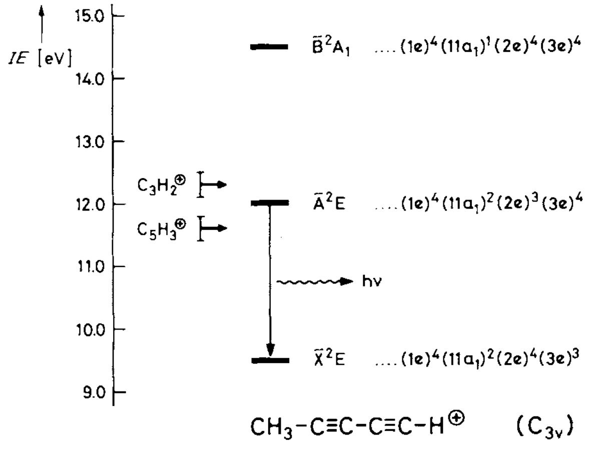

Fig. 1. Location and assignments of the lowest doublet electronic states of the 1,3-pentadiyne radical cation (under assumed $C_{3v}$ symmetry) taken from the PE study [14]. Adiabatic ionization energies (I.E.) are used. The appearance potentials of the $C_5H_3^{\oplus}$ and $C_3H_2^{\oplus}$ fragment-ions are also indicated [19]. The detected radiative decay of the 1,3-pentadiyne cation enables the $\tilde{X}^2E$ and $\tilde{A}^2E$ states to be probed in detail using the techniques described in the text.

In order to observe the finer spectroscopic structure, and to follow the relaxation dynamics of such radical cations under collision-free conditions, other approaches, or tech-

niques, had to be developed or applied. These invariably involve the absorption or emission of electromagnetic radiation. Historically the most important high resolution technique for molecular systems[6] and radicals[7] was emission spectroscopy. This is also the case for di- and triatomic cations[8]. With the advent of tunable lasers alternative methods, often leading to even finer details, have flourished.

Complementary studies on polyatomic organic radical cations in the gas phase are only now beginning to follow. The purpose of this article is to present an overview of the structural and dynamic data that is obtained from methods relying on the radiative decay of such electronically excited cations[9]. The techniques used are emission, laser-induced excitation and photoelectron-photon coincidence spectroscopy[10].

Emission (or fluorescence) spectroscopy is one of the oldest techniques for molecular structure investigations, whereby photons emitted following electron impact, as in a discharge tube (or photon impact excitation), are wavelength dispersed while their intensity is measured[8].

In the laser-induced fluorescence technique on the other hand, the wavelength of a tunable narrow bandwidth light source (dye-laser) is scanned and the excitation spectra are obtained by monitoring the resultant fluorescence[11]. The latter is detected, provided the exciting laser wavelength coincides with a molecular transition (*i.e.* resonance) and the excited species decays radiatively. Thus, the technique is specific and the resolution is given by the bandwidth of the laser. In addition it is rather sensitive, since ion densities of $10^6-10^9$ cm$^{-3}$ are adequate for such measurements. The photoelectron-photon coincidence method[12] is also specific, as it is partly based on the principle of PE spectroscopy and selects the internal energy of an electronically excited cation. If such a "prepared" cation decays by emission of a photon, this will yield a true coincidence if the sampled electron and photon both originate from the same level and from the same cation.

Table 1. Summary of the characteristics of the three techniques used to study the structure and decay of radical cations in the gas phase.

| Technique | Information | Resolution |
|---|---|---|
| Electron impact induced emission spectroscopy | Ground state vibrational frequencies, rotational structure, lifetimes of lowest levels of excited states | 0.004 nm<br>6 ns |
| Laser-induced fluorescence spectroscopy | Excited state vibrational frequencies, rotational structure, lifetimes of excited state levels | 0.02 or 0.002 nm<br>5 ns |
| Photoelectron-photon coincidence spectroscopy | Fluorescence quantum yields and cascade-free lifetimes of excited state levels. | 50-100 meV<br>10-15 ns |

Table 1 summarizes the information provided by these measurements, as well as the energy and time characteristics of the techniques. As can be seen for the cations decaying radiatively, the structure of the two electronic states involved in the transition ($^2\tilde{X}$ and $^2\tilde{A}$ or $^2\tilde{B}$) can be probed with a resolution $10^2-10^3$ better than can be achieved with PE spectroscopy, because photons can be wavelength-selected much more precisely than it is possible to energy-analyze photoelectrons. On the other hand, the coincidence determinations are necessarily carried out with lower resolution because electron energies have to be analyzed. The essence of the coincidence experiment is that the energy of the outgoing photoelectron serves to define the internal energy of the cation. Since the electrons and photons can be individually counted, absolute measurements of fluorescence quantum yields of radical cations in selected vibrational levels are possible.

The starting point of such studies was the search for the radiative decay of electronically excited radical cations, because prior to 1973 only a handful of open-shell triatomic radical cations[8] and the butadiyne radical cation[13] were known to yield emission spectra. Thus, in our earliest experiments, the emission spectra of organic radical cations were studied using an electron beam apparatus. As a result, the emission spectra of over a hundred such cations have now been reported[9, 10]. In all cases, the band systems were assigned to the $^2\tilde{A}$(or $^2\tilde{B}$)$\rightarrow$$^2\tilde{X}$ electronic transitions of these cations on the basis of their PE spectra, and lie in the 300—800 nm wavelength region.

Table 2. Main classes of organic radical cations found to decay radiatively: $\tilde{A}$ (or $^2\tilde{B}$)$\rightarrow$$^2\tilde{X}$. For a complete listing see [10].

| | |
|---|---|
| $X-C\equiv NNQ^{\oplus}$<br>$X-C\equiv C-H^{\oplus}$<br>$X-C\equiv C-X^{\oplus}$ | X = Cl, Br, I |
| $X(C\equiv C)_2H^{\oplus}$ | X = Cl, Br, I, CN, $CH_3$, $C_2H_5$ |
| $X(C\equiv C)_2X^{\oplus}$ | X = Cl, Br, I, CN, F, $CF_3$, $C_2H_5$ |
| $H_3C-C\equiv C-X^{\oplus}$ | X = Cl, Br, CN |
| $H_3C(C\equiv C)_2X^{\oplus}$ | X = Cl, Br, CN, $CH_3$, H |

Table 2 summarizes the main classes of organic cations which undergo radiative decay. Rather than try to present a comprehensive review of the emission, laser-induced fluorescence and photoelectron-photon coincidence studies of radical cations, the 1,3-pentadiyne cation (and its deuterated derivatives) will be taken as an example. This will serve to illustrate the structural and decay data that can at present be obtained.

## 2. Electronic States

The electronic states of the 1,3-pentadiyne radical cation were first investigated by *Heilbronner et al.* using He(Iα) PE spectroscopy[14]. The bands were attributed to various ionization processes by means of which a link to the molecular orbital description of 1,3-pentadiyne was established. This is summarized in Figure 1, where the measured energetic data for the lowest electronic states of 1,3-pentadiyne cation, their symmetries and corresponding configurations are depicted. The configurations shown are those which, by far, dominate these lowest electronic states. On the other hand at higher levels in the energy manifold such a simple description is often inadequate, as configurational interaction can be considerable. A consequence of this is the appearance of additional PE bands in the higher valence ionization region[15].

It should again be pointed out that the labelling

$^2\tilde{X}, {}^2\tilde{A}, {}^2\tilde{B}, \ldots {}^2\tilde{J} \ldots\ldots$

of the states of radical cations, inferred in conjunction with the PE spectral data, is not entirely a true sequence of the doublet states. The "non-Koopmans' states", *i.e.* those differing in the location of two electrons from the molecular ground state configuration, are usually not accessible by the photoionization process. The lowest of these may, in favorable cases, be located using techniques such as matrix absorption-[16] or photodissociation-[17] spectroscopy where the cation in its ground state is the absorbing species. Nevertheless, the $^2\tilde{A}$ state of organic radical cations labelled according to their photoelectron spectra is, with a few exceptions, the lowest excited electronic state. The corresponding quartet states of organic radical cations

$^4\tilde{a}, {}^4\tilde{b}, {}^4\tilde{c}, \ldots {}^4\tilde{j} \ldots\ldots$

have, to date, not been experimentally located; however, in most cases the lowest state of this multiplicity, $^4\tilde{a}$, is expected to lie energetically above that of $^2\tilde{A}$, having a similar geometry to the cationic ground state.

Further structural information suggested by the PE spectrum of 1,3-pentadiyne is that the linear configuration of the carbon atoms is probably retained for the $\tilde{X}^2E$ and $\tilde{A}^2E$ cationic states. This is based on the Franck-Condon profile of the first two bands (cf. Fig. 2) for which the adiabatic, $(0_0^0)$, transitions are intense. On the basis of the separation of the ionization energies leading to the $\tilde{X}^2E$ and

$$H_3C{-}C{\equiv}C{-}C{\equiv}C{-}H^{\oplus}\ \tilde{A}^2E \longrightarrow \tilde{X}^2E(C_{3v})$$

$\tilde{A}^2E$ states, the emission band system detected on electron impact excitation of 1,3-pentadiyne could be identified as the electronic transition of its radical cation[18]. The radiative decay is manifested in spite of the fact that the $C_5H_3^{\oplus}$ fragment ion appearance potential lies about 0.5 eV below the lowest level of the $\tilde{A}^2E$ state (cf. Fig. 1)[19].

## 3. Vibrational Frequencies

In this section the vibrational structural data which can be deduced from the emission and laser-induced excitation spectra of radical cations in their $^2\tilde{X}$ and $^2\tilde{A}$ (or $^2\tilde{B}$) states will be discussed. Previously, the only source of vibrational frequencies of organic cations in the gas phase has been PE spectroscopy[4], and in a few cases photoionization mass spectroscopy or spectroscopy of Rydberg states[20]. These techniques, however, provide only a few values for larger organic cations and are of limited accuracy. To illustrate these aspects, a "high resolution" recording (electron band pass of 160 cm$^{-1}$) of the first two photoelectron bands of 1,3-pentadiyne is reproduced in Figure 2. Discernible are vibrational peaks corresponding to the excitation of two, and three, modes of the $\tilde{X}^2E$ and $\tilde{A}^2E$ cationic states, respectively. The accuracy of the frequencies deduced from such measurements is, at best, ±40 cm$^{-1}$. The inferred values are included in Table 3, where they can be compared with the emission and excitation data.

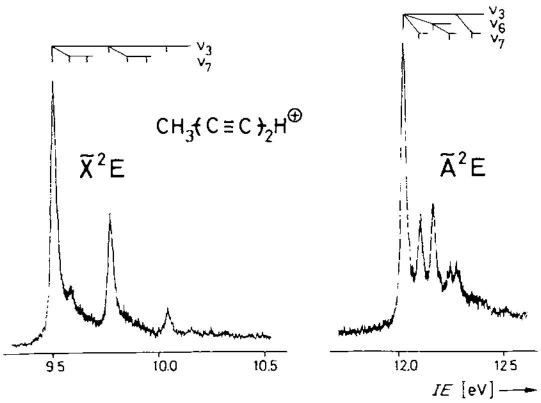

Fig. 2. The first two bands in the He(Iα)-PE spectrum of 1,3-pentadiyne recorded with a band pass of ≈20 meV. A vibrational assignment is indicated (cf. Table 3).

### 3.1. Emission Spectra

The emission spectra of the 1,3-pentadiyne cation and of its three deuterated derivatives are shown in Figure 3.

Table 3. Vibrational frequencies of the totally symmetric fundamentals ($A_1$) of the 1,3-pentadiyne and of 5,5,5-trideutero-1,3-pentadiyne cations (under $C_{3v}$ classification) in their $\tilde{X}^2E$ and $\tilde{A}^2E$ states, inferred from their emission (em) and excitation (ex), spectra; values ±10 cm$^{-1}$. The PE spectral (PE) values are ±40 cm$^{-1}$. The ground molecular state frequencies and the approximate description of the modes are taken from [22].

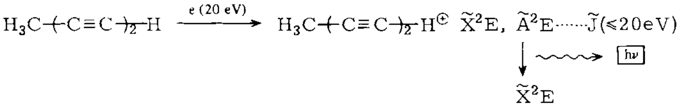
These spectra were recorded with an optical resolution of 7 $cm^{-1}$ using a crossed electron sample beam apparatus[18]. Using this apparatus, the radical cations are produced under clean and reasonably well-defined conditions. A collimated electron beam of chosen energy is directed at an effusive sample beam entering the interaction region at right angles to it, and the sample is efficiently removed by means of a liquid nitrogen trap. In the case of the 1,3-pentadiynes, the electron beam energy was tuned to about 20 eV, which in general is an advantageous energy range for the ionization cross section and yet the excitation of fragments is still not overwhelming. Thus, the various accessible states of the 1,3-pentadiyne cation are produced, *e.g.*:



$$H_3C\text{-}(C\equiv C)_2\text{-}H \xrightarrow{e\,(20\,eV)} H_3C\text{-}(C\equiv C)_2\text{-}H^{\oplus}\ \tilde{X}^2E,\ \tilde{A}^2E\cdots\cdots\tilde{J}(\leq 20\,eV)$$

$$\downarrow \rightsquigarrow \boxed{h\nu}$$

$$\tilde{X}^2E$$

as well as excited molecular states of 1,3-pentadiyne, and of some of its fragments (*e.g.* $C_2^*$, CH*, H*) as a result of inelastic electron processes. The photons emitted from the ionization region are wavelength-dispersed and detected by a single photon counting technique. Computerized on-line data acquisition is used[21].

The primary information that can be inferred from the structure of the emission spectra, such as shown in Figure 3, are vibrational frequencies, mainly the totally symmetric modes of the cationic ground states. Usually these can be obtained with an accuracy of 5—10 $cm^{-1}$, limited usually by the width of the bands. In addition, when the resolution is reduced to about 1 $cm^{-1}$, or better, the bands are often split into sub-bands, which are usually attributed to sequence transitions. Excited vibrational levels in the $^2\tilde{A}$ states are known to decay radiatively, in view of the excitation spectra and the photoelectron-photon coincidence measurements *(vide infra).*

In the 1,3-pentadiyne cation, excitation of four of the totally symmetric fundamentals, $A_1$ (under $C_{3v}$ symmetry classification), in the $\tilde{X}^2E$ state is indicated from the emission spectra (Fig. 3). In addition, a degenerate mode ($\nu_{13}$) is doubly excited.

The assignment of most of the intense bands of the emission band systems is shown in Figure 3. The numbering of the fundamentals follows the ground state molecular values[22] given in Table 3. Most of the assignments are to transitions from the lowest vibrational level of the $\tilde{A}^2E$ state to the various excited levels in the $\tilde{X}^2E$ state, which possess $A_1$ symmetry. A few bands are also observed at higher energy than the $0_0^0$ bands, the emitting levels corresponding to the excitation of the $\nu_5$-, $\nu_6$- and $\nu_7$-modes in the $\tilde{A}^2E$ electronic state. The study of the isotopically labeled derivatives serves as a means of corroborating the assignments, as is usual in other forms of spectroscopy. The inferred vibrational frequencies for the 1,3-pentadiyne and 5,5,5-trideuterio-1,3-pentadiyne cations are summarized in Table 3.

In a similar fashion, the ground state vibrational frequencies of many of the cations listed in Table 2 have been obtained. For the smallest, or high symmetry species, the frequencies of all the totally symmetric modes could often be inferred. In contrast, for the largest, or low symmetry species, the number of vibrations that can be excited is large but usually only a few of the modes are strongly excited.

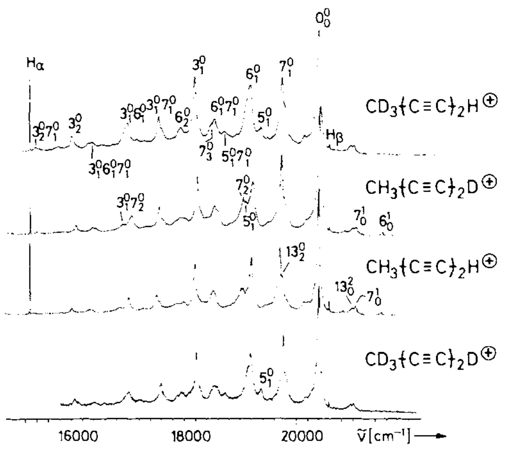


Fig. 3. The $\tilde{A}^2E \rightarrow \tilde{X}^2E$ emission band system of the 1,3-pentadiyne radical cation recorded with an optical resolution of 0.16 nm. The vibrational assignment of the bands was made using the numbering in Table 3.

### 3.2. Laser-Induced Excitation Spectra

One method of obtaining the complementary vibrational frequency data for the cations in their excited electronic states is *via* their absorption or excitation spectra. Although the primary excitation process in the absorption and excitation techniques is the same, the principle of monitoring the induced changes differs. In the absorption experiment the change in intensity of the incident light is measured, whereas for the excitation spectra the total (*i.e.* wavelength-undispersed) fluorescence is detected. Consequently, the latter technique is much more sensitive but depends on the excited species decaying radiatively. The relative intensities of the bands in the absorption and excitation spectra will naturally differ but the same spectroscopic information (vibrational, or rotational) is available.

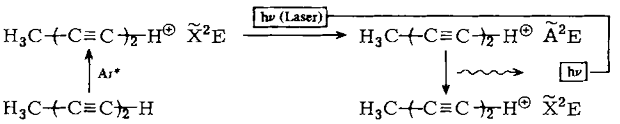
As yet, absorption spectra of organic radical cations in the gas phase have not been measured due to the inherently low densities associated with their generation. However, the excitation spectra can be obtained for the radical cations which relax by emission of photons (cf. Table 2) even at low cation concentrations because of the availability of tunable dye-lasers.

The laser-induced fluorescence technique is well established for spectroscopic studies on molecular systems[23], but only in recent years has its application to cations evolved. The technique was first applied to the $N_2^+$ cation[24], and since then has been used to probe a few of the organic radical cations whose radiative decay has been observed (Table 2)[25]. Table 4 summarizes the results obtained to date on the organic cations investigated by this approach, usually using a laser bandwidth of the order of 1 $cm^{-1}$. A large part of the effort has been devoted to the study of Jahn-Teller effects (*i.e.* of the spectroscopic consequences of the removal of the degeneracy of electronic states, which according to the Jahn-Teller theorem, are inherently unstable) in the ground states of the hexafluoro-, 1,3,5-trifluoro-, and 1,3,5-trichlorobenzene cations[29,30]. Conventional high resolution emission spectroscopy has also been applied to the latter problem[33].

Table 4. Organic radical cations studied by the laser-induced fluorescence technique in the gas phase. The isotopic species are not listed.

| Cation | | Ref. |
|---|---|---|
| $Cl{+}C{\equiv}C{+}X^{\oplus}$ | X = H, Cl | [26] |
| $H_3C{+}C{\equiv}C{+}_2H^{\oplus}$ | | [27] |
| $H_3C{+}C{\equiv}C{+}_2CH_3^{\oplus}$ | | [27, 28] |
| Fluorobenzenes$^{\oplus}$ | | [29] |
| 1,3,5-trichlorobenzene$^{\oplus}$ | | [30] |
| 1,3,5-trichlorotrifluorobenzene$^{\oplus}$ | | [31] |
| Fluorophenols$^{\oplus}$ | | [32] |

The laser-induced excitation spectra of the $\tilde{A}^2E \leftrightarrow \tilde{X}^2E$ transition of the cations of 1,3-pentadiyne and of 5,5,5-trideuterio-1,3-pentadiyne are reproduced in Figure 4[27]. The process whereby the spectra are obtained is shown in Scheme 1.



Scheme 1

In essence, the apparatus used to record the spectra consists of a source of rare gas metastables which on collision with the sample molecules yield the molecular radical cations (*i.e.* Penning ionization), a nitrogen pumped dye-laser, a detection system and on-line data accumulation. The latter consists of a micro-computer controlled transient digitizer which samples the photo-multiplier signals[27]. Thus, the total fluorescence is monitored as a function of the laser wavelength, which is driven by the computer. The spectra shown consist of three separate recordings using appropriate dye solutions. Due to the relatively high pressure of the rare gas carrier, the radical cations formed in the Penning ionization process are thermalized by collisions. By this means, a sufficient concentration of radical cations in the lowest vibrational level of the $\tilde{X}^2E$ state is produced.

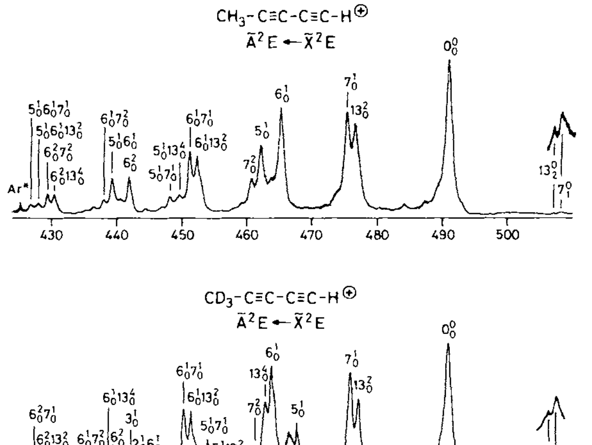


Fig. 4. The $\tilde{A}^2E \leftrightarrow \tilde{X}^2E$ laser-induced excitation spectra of 1,3-pentadiyne and 5,5,5-trideuterio-1,3-pentadiene radical cations recorded with a 0.02 nm bandwith. The vibrational numbering of the assigned bands corresponds to the modes listed in Table 3.

Analysis of the excitation spectra of the 1,3-pentadiyne cations (Fig. 4) yields the vibrational frequencies of five $A_1$ modes, as well as of the $\nu_{13}$ mode of the excited state. The sequence bands are not resolved, though asymmetry for most of the bands is apparent.

The inferred vibrational frequencies are also given in Table 3. Thus, sets of frequency values are available for these radical cations in the $\tilde{X}^2E$ and $\tilde{A}^2E$ states, and can be compared to the molecular state values. The respective changes can in turn be related to the molecular orbital description of the structure (cf. Fig. 1) as the electrons are removed from orbitals of different nodal characteristics. The $\tilde{X}$ and $\tilde{A}$ cationic states are generated by removal of electrons from π-molecular orbitals, $2e^{-1}$ and $1e^{-1}$, which are antibonding and bonding between the triple bands, respectively[14]. These features are reflected to an extent in the changes in frequencies of the various vibrations (cf. Table 3).

## 4. Non-Radiative Decay

The preceding sections have been concerned with structural aspects of radical cations which have become accessible using the described spectroscopic techniques. The dynamic features, that is the relaxation behavior of electronically excited radical cations under collision-free conditions, will now be briefly considered. The discussion is restricted to those cations decaying radiatively, albeit that the numerous studies of cations which do not reveal a detectable radiative relaxation provide ancillary information about the rates of the non-radiative decay pathways. The implications of such "negative" observations have already been previously summarized[9].

The non-radiative pathways open to organic radical cations in their lowest excited electronic states are internal conversion, $[^2\tilde{A} \rightsquigarrow {}^2\tilde{X}]$, isomerization and fragmentation $[^2\tilde{A} \rightsquigarrow \cdots \rightarrow F_1^{\oplus}, F_2^{\oplus} \ldots]$ if the latter are allowed energetically. In the majority of cations listed in Table 1, only the radiative and internal conversion channels to the $^2\tilde{X}$ state are accessible. Fragmentation thresholds usually lie higher in energy[34] (but for exceptions see Section 4.2), as do the lowest states of higher multiplicity, $^4\tilde{a}$, as discussed earlier. Thus, the study of the internal conversion process is simpler than with molecular species, for which the $S_1 \rightsquigarrow T_1$ (intersystem crossing) process is always a competing, and sometimes dominant decay process[35]. Furthermore, for molecular systems the determinations of absolute fluorescence quantum yields are fraught with difficulties, relying on comparison with suitable standards and careful calibration of the apparatus[36]. In contrast, flourescence quantum yields, $\phi_F(\upsilon')$ of state selected levels, *e.g.* $^2\tilde{A}(\upsilon')$, can be directly determined for radical cations using the photoelectron-photon coincidence technique.

### 4.1. Lifetimes

The lifetime $\tau(v')$ of an electronically excited cation in a selected vibrational level can be determined by following the intensity of the emitted photons as a function of time. Thus, if the bands in the emission spectrum have been assigned, the decay curves corresponding to the various levels in the excited state, from which the emission bands originate, can be obtained.

However, in practice, such determinations are mainly restricted to the lowest vibrational level, 0°, of the excited state as most of the strong bands identified originate from this level (cf. Fig. 3). The lifetimes of some of the low excited levels can sometimes be obtained because of the weak bands at higher energy levels of the $0_0^0$ bands. These limitations are dictated in the emission experiment by the necessary compromise between optical resolution and practical measuring times. Clearly, the way to obtain the lifetimes of such cations in excited vibrational levels at high resolution is by the laser-induced fluorescence technique. This is one of the aims for the near future.

In the case of the emission technique, the lifetimes are deduced from decay curves accumulated using the single photon delayed coincidence approach (*i.e.* by measuring the time interval between formation of the cation and the arrival of the fluorescence photon) when the electron beam is pulsed, typically at frequencies up to 500 kHz[21]. The level is selected by tuning the monochromator to an appropriate emission band. The advantage of this method is that high quality statistics can be reasonably rapidly obtained[37]. An example of such a decay curve is given in Figure 5 for the 1,3-pentadiyne cation in the $\tilde{A}^2E$ $0^0$ state. The inferred $\tau(0^0)$ value is $48 \pm 3$ ns.

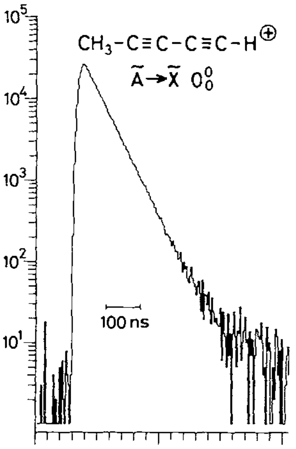

Fig. 5. Decay curve for the $\tilde{A}^2E$ $0^0$ level of the 1,3-pentadiyne cation accumulated using pulsed electron beam excitation and a 0.8 nm band pass for the $0_0^0$ band. The data are plotted using a semilogarithmic scale and the background has been subtracted.

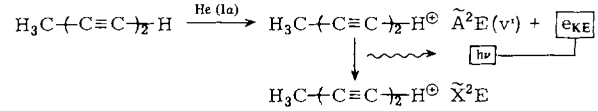
The measured lifetime, $\tau(v')$, yields the overall rate constant, $k_T(v')$, for the selected level. It is composed of the sum of the rate constants of the radiative channel, $k_r(v')$, and of all the non-radiative channels, $k_{nr}^i(v')$, accessible *i.e.*

$$\tau(v')^{-1} = k_T(v') = k_r(v') + \sum_i k_{nr}^i(v') .$$

On the other hand, when the radiative decay is not detected, a lower limit for the non-radiative rate can be given. Typical $k_r(v')$ values for organic radical cations are $\approx 10^7$ $s^{-1}$, the sensitivity of the apparatus implies that $\sum_i k_{nr}^i(v') \geq 10^{12}$ $s^{-1}$.

### 4.2. Photoelectron-Photon Coincidences

The principle of the measurements relies on the detection of energy selected photoelectrons in coincidence with undispersed photons following photoionization with a monochromatic source, *e.g.*, He(Iα)[12] or synchrotron radiation[38]. This is again illustrated by the recent results on 1,3-pentadiyne cations in the $\tilde{A}^2E$ state[39] (Scheme 2).



Scheme 2

Thus, the internal energy (or vibrational level) $v'$ within the $\tilde{A}^2E$ state is determined by the kinetic energy, $e_{KE}$, of the ejected photoelectron. The spread in the electron energy, typically 100 meV for 10 eV electrons, means that, in effect, internal energies within this bandwidth are sampled. The detection of true photoelectron-photon coincidences proves that the fluorescence process occurs only when the cations are initially prepared in the selected state, *i.e.* if they themselves decay to a lower electronic state or if an excited isomer cation or fragment relaxes by photon emission. Since in the case of the cations investigated, the radiative decay has been established, there is no ambiguity.

The fluorescence quantum yield is obtained from the coincidence statistics[40]. The rate of true coincidences, $N_T$, obtained from the area encompassed by the decay curve superimposed on the background of random coincidences (cf. Fig. 6), and the rate of detection of energy selected electrons, $N_e$, are required since it can be shown that

$$N_T / N_e = f_{h\nu} \, \phi_F(v')$$

In this relationship $f_{h\nu}$ is the photon detection probability (determined entirely by experimental factors) and this can be absolutely calibrated as a function of wavelength using cations for which $\phi_F(v') = 1$. These include $N_2^{\oplus}(\tilde{B}^2\Sigma_u^+ \, v' = 0)$, $N_2O^{\oplus}(\tilde{A}^2\Sigma^+ \, 0^0)$ and $CO_2^{\oplus}(\tilde{A}^2\Pi_u \, 0^0)$. The nature of the experiment is such that long counting periods are required, typically a day for each curve, in order to infer the $\phi_F(v')$ and $\tau(v')$ values with an error of 5%.

Figure 6 shows the relevant part of the He(Iα) PE spectrum of 1,3-pentadiyne, recorded under the coincidence conditions, showing the four energy locations within the $\tilde{A}^2E$ state (arrows) where coincidences were detected. Qualitatively, these observations show directly, as does the excitation spectrum (Fig. 4), that the radiative channel depletes vibrational levels up to $\approx 0.5$ eV above the zeroth level in the $\tilde{A}^2E$ state. One such photoelectron-photon coincidence curve is depicted in Figure 6; in this case for

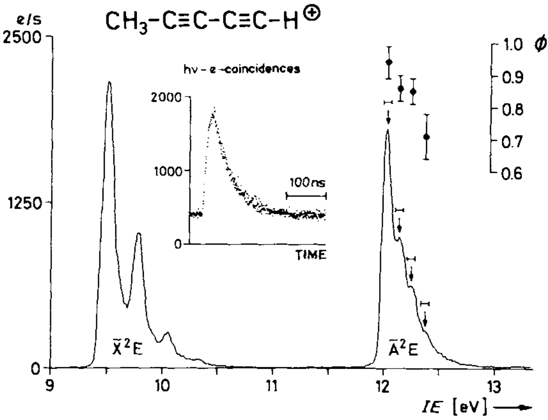


Fig. 6. Photoelectron-photon coincidence curve for the $\tilde{A}^2E$ $0^0$ level of the 1,3-pentadiyne cation accumulated over 17 h. The decay curve of true coincidences is superimposed on the background of random coincidences. The lifetime is extracted from the decay-part of the curve and the fluorescence quantum yield from the rate of true coincidences and the electron count rate. The He(Iα)-PE spectrum was recorded under the coincidence conditions. The fluorescence quantum yields determined are plotted at the internal cation energies selected.

the $\tilde{A}^2E$ $0^0$ level of the 1,3-pentadiyne cation. This consists of a uniform background of random coincidences upon which is superimposed a curve whose decay-part is characteristic of the excited state and from which the cascade-free lifetime is extracted. The determined $\phi_F(v')$ values are plotted above the vibrational bands in the photoelectron spectrum.

The radiative, $k_r(v')$, and non-radiative, $k_{nr}(v')$ $(\equiv \sum_i k^i_{nr}(v'))$, rate constants can then be evaluated from the measured quantities *via*

$$k_r(v') = \phi_F(v')/\tau(v')$$

and

$$k_{nr}(v') = [1-\phi_F(v')]/\tau(v').$$

For the 1,3-pentadiyne cation and its isotopic derivatives it is found that, within the error limits, the radiative rates are the same and constant over the internal energy sampled. In contrast, the $k_{nr}(v')$ rates increase with excess energy and vary among the isotopes. Similar trends in the $k_{nr}(v')$ dependence on excess energy are apparent for the isotopic cations as well as other organic radical cation studied hitherto (Table 5).

The availability of such data enables one to consider the decay of organic cations in terms of the developed theoretical models of radiationless transitions[35,44]. In the example of 1,3-pentadiyne cation, the $^2\tilde{A}\rightsquigarrow{}^2\tilde{X}$ internal conversion process falls within the statistical limit category, since the density of vibrational levels of the $^2\tilde{X}$ state is sufficiently high $(\rho(\tilde{X}) \approx 10^{10}/\text{cm}^{-1})$. This situation, $\tau(\tilde{A}) \ll \hbar\rho(\tilde{X})$, is characterized by non-unity fluorescence quantum yields, mono-exponential decay and, for a large energy gap situation, by a decrease in the $k_{nr}(0^0)$ rate on deuteration[35,44]. In addition, with excess vibrational energy the $k_{nr}(v')$ rates often increase either exponentially, or linearly, depending on the cation. The applications of the radiationless decay models to organic cations have already been considered in some detail in connection with the average fluorescence quantum yields and lifetimes for the excited state[45]. Such data have been obtained by the photoion-photon coincidence approach for the cations of the fluorinated benzenes[46] and of chloro- and dichloro-acetylene[47].

Table 5. Organic radical cations for which fluorescence quantum yields and lifetimes of selected levels have been obtained by the photoelectron-photon coincidence technique. All the isotopic species are not included.

The non-radiative decay of 1,3-pentadiyne cations in the $\tilde{A}^2E$ state leads ultimately to the $C_5H_3^{\oplus}$ fragment ion[18]. As depicted in Figure 1, the appearance potential of this fragment ion is found at about half an electron volt below the lowest level of the $\tilde{A}^2E$ state[19]. This species thus belongs to the relatively small category of organic radical cations for which both the radiative $(^2\tilde{A}\rightarrow{}^2\tilde{X})$ and fragmentation $(^2\tilde{A}\rightsquigarrow\cdots\rightarrow M^{\oplus}, F_1^{\oplus}, F_2^{\oplus}\cdots)$ pathways occur, following their preparation in an excited state[9]. The organic cations for which this decay behavior has been demonstrated are collected together in Table 6. Because fragment ions are produced, mass spectroscopic approaches can be used to probe this decay channel of state selected cations. Two such methods are photoelectron-photoion coincidence[53] and photodissociation spectroscopies[17].

Table 6. Organic radical cations for which the radiative $(^2\tilde{A}\rightarrow{}^2\tilde{X})$ and fragmentation $(^2\tilde{A}\rightsquigarrow\cdots\rightarrow M^{\oplus}, F_1^{\oplus}\cdots)$ decay channels are both detected. The isotopically labeled derivatives studied are not listed.

The fragmentation processes of 1,3-pentadiyne cations have consequently been studied by *Heilbronner et al.* using the photoelectron-photoion coincidence technique[19]. In these measurements, mass-selected ions are detected in coincidence with energy-selected photoelectrons, and yield the branching ratios of the ions detected as a function of the internal energy of the parent cation. For example, the branching ratio of the $C_5H_4^{\oplus}$ parent ion decreases in a parallel fashion to the $\phi_F(v')$ value (cf. Fig. 6) across the PE band corresponding to the $\tilde{A}^2E$ state. Furthermore, it was concluded on the basis of the results on the deuterated derivatives that prior to the loss of H (or D) extensive scrambling and/or ionic carbon skeletal isomerization takes place[19]. This is consistent with the interpretation, that the $k_{nr}(v')$ rates determined from the photoelectron-photon coincidence data correspond to the $\tilde{A}^2E \rightsquigarrow \tilde{X}^2E$ internal conversion process[40]. The 1,3-pentadiyne cations are then highly vibrationally excited, and in due course fragment. The results and inferences from all the different measurements are summarized schematically in Figure 7.

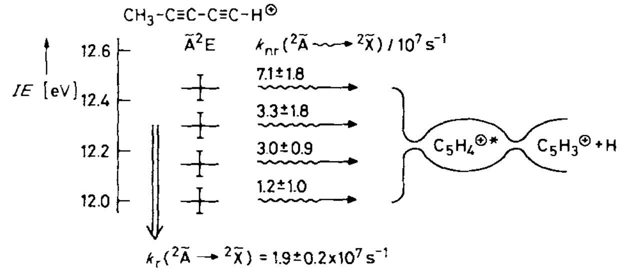

Fig. 7. Schematic view of the relaxation behavior of the $\tilde{A}^2E$ state of the 1,3-pentadiyne cation. The radiative and non-radiative rate constants as a function of the vibrational excitation have been obtained from the photoelectron-photon coincidence measurements. The radiationless decay leads ultimately to the $C_5H_3^{\oplus}$ fragment ions but prior to that, sufficient time is available for structural rearrangements of the vibrationally excited $C_5H_4^{\oplus *}$ cation.

Such a mechanism can be quantitatively followed for some of the cations listed in Table 6 because the slowest step in the fragmentation rate could also be determined. An example is the *cis*-1,2-difluoroethylene cation in the lowest level of the $\tilde{A}^2A_1$ state; the fragmentation rate is an order of magnitude slower than the non-radiative rate (presumably $^2\tilde{A} \rightsquigarrow {}^2\tilde{X}$ step), which competes directly with the radiative decay ($^2\tilde{A} \rightarrow {}^2\tilde{X}$)[42,48].

## 5. Concluding Remarks and Outlook

In this article, the recent spectroscopic studies on 1,3-pentadiyne radical cation in its ground and first excited doublet states have been chosen to illustrate the sort of structural and dynamic information that has become accessible. The techniques developed for this purpose rely on the radiative decay of the excited cations, which is also their limitation. However, since to date the emission spectra of over a 100 organic radical cations have been recorded, these approaches can be applied to them.

The advantage of the emission and laser-induced fluorescence methods is that the states of the cations involved in the transition can be probed with resolutions of 1 $cm^{-1}$. Improvements in resolution by a further factor of ten have already been achieved (cf. Table 1) and in the future this should enable not only more precise data on the vibrational frequencies of cations to be obtained, but also the resolution of rotational fine structure in smaller species[10].

It is fair to say that the spectroscopic data from electronic spectra are usually invaluable in ultra-high resolution studies which probe details such as hyperfine interactions. This has already been demonstrated by the recent laser-ion beam experiments on some diatomic and triatomic cations[54]. A further step in this direction will undoubtedly be the development of double resonance techniques (*e.g.* microwave-optical) relying on the laser-induced fluorescence decay of such organic cations. The latter property is also of potential interest in monitoring ion-molecule collisions and as a diagnostic tool for the investigation of internal energy partitioning. Knowledge of the energetic and dynamic processes of the open-shell cation is a prerequisite for this purpose.

Complementary data on the relaxation characteristics of radical cations can be obtained from studies of their lifetimes and from fluorescence quantum yields. To this end the photoelectron-photon coincidence technique is employed. Consequently, the rates of the radiative and non-radiative relaxation channels can be followed as function of excess internal energy of the cation. Observations of this type will be extended to individual vibrational levels, and in some cases to rotational levels, when their lifetimes have been measured by the laser-induced fluorescence approach. As sets of such data become available on structurally related cations, a more detailed description of the relaxation behavior of organic radical cation should emerge.

Undoubtedly the understanding of the interdependence between the spectroscopic features and relaxation characteristics of molecular species and their ions will, in time, become more firmly established. One of the ultimate goals of studies of this sort is, of course, the investigation of "state to state chemistry" and as outlined in this article there are some advantages in also trying to achieve these aims *via* studies of open-shell organic cations.

*I would like to take this opportunity of thanking Professor E. Heilbronner, not only for his continual support throughout but also for providing a congenial environment for me in Basel. Furthermore, the work described in this article was only made possible by the efforts of my co-workers over the past few years; Dr. Michael Allan, Fritz Burger, Dr. Oskar Marthaler, Dr. Manijeh Mohraz, Liubomir Misev and Fritz Thommen, and by the continual financial support of the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung (Project No. 2-622-0.80). Ciba-Geigy, Sandoz and F. Hoffmann-La Roche, Basel are also thanked for financial support.*

# Methods of Fluorination in Organic Chemistry

By Michael R. C. Gerstenberger and Alois Haas[*]

Since the days of the "Manhattan Project" our knowledge of the chemistry of fluorine-containing compounds has increased tremendously. At first only considered out of curiosity, this area of research bordering between inorganic and organic chemistry has developed from modest beginnings to such a complexity of interesting ramifications that it would be very difficult to review all aspects in detail. The motivating force behind the developments in this field were, above all, the unusual properties the numerous compounds acquire on introduction of fluorine substituents. The spectrum of unusual modes of behavior extend from extreme stabilization in fluorine-containing polymers and blood-substitutes to drastic increases in reactivity in pharmacologically and phytomedicinally active substances and in dyes. Moreover, one physical peculiarity of the fluorine atom, its magnetic moment, opens a new route to the decyphering of metabolic processes.—Parallel to the ever increasing number of fluorinated compounds there has been a concomitant increase in the variety of methods of synthesis and reagents, which is frequently difficult to overview in entirety, even for the specialists. Older, simple methods such as halogen metathesis with metal fluorides and electrofluorination are being refined as far as higher selectivity is concerned, and completely new, very reactive substances such as hypofluorites and noble-gas fluorides enable fascinating reactions on complex substrates, *e.g.* steroids and nucleobases. The present review is an attempted documentation and classification of the methods as well as a critical appraisal, not least from the standpoint of efficiency and economic aspects.

## 1. Historical Note

The entire course of development of the chemistry of fluorinating agents for organic compounds has been determined and motivated by the industrial importance of the resulting products. *F. Swart's* studies of simple metathesis reactions[1]

$$R{-}X + MF \rightarrow R{-}F + MX\,; \quad X = Cl,\ Br,\ I$$

mainly with $SbF_3$ and $HgF_2$, have led to the use of $CCl_2F_2$ as an inert, nontoxic, and readily accessible coolant that could replace $NH_3$ and $SO_2$. The usefulness of highly fluorinated compounds as resistant materials was first recognized during the Manhattan Project in the manipulation of the extremely aggressive $UF_6$[2]. The prerequisite for the synthesis of substances of this kind had been provided a few years earlier with the introduction of $CoF_3$ as a reagent for the exhaustive fluorination of hydrocarbons[3] and by the discovery of polytetrafluoroethylene[4]. The development of electrofluorination aimed in the same direction[5,6]. The significance of low-fluorinated compounds for biochemistry was initially based on toxicological research with fluoroacetic acid and the concept of "lethal synthesis" that developed from it[7], and also on the use of fluorinated nucleic acids as cytostatics[8].

## 2. Uses of Fluorinated Compounds

Two classes of fluorine-containing substances must essentially be distinguished, on the basis of their preparation and their uses. The first class comprises compounds in which all or at least most of the hydrogens initially bonded to carbon atoms have been replaced by fluorine (highly fluorinated compounds); in the second class this applies to only some of the hydrogen atoms (low-fluorinated compounds). In what follows we shall present a selection of fields in which these two classes are used[9].

### 2.1. Highly Fluorinated Compounds

#### 2.1.1. Coolants for Cooling Systems and Aerosol Propellants

Chlorofluoroalkanes and cycloalkanes are used in these two domains, especially the short-chain ones, on account of the low boiling points required, for example $CCl_2F_2$, $CF_2Cl{-}CFCl_2$, $CFCl_3$, and *cyclo*-$C_4F_8$.

#### 2.1.2. Fire Extinguishers

The compounds of choice here are the bromine-containing fluoroalkanes, *e.g.* $CF_3Br$ and $CF_2ClBr$.

#### 2.1.3. Inhalation Anaesthetics

The best known example is halothane, $CF_3{-}CHClBr$, although oxygen heterocycles such as the tetrahydrofuran derivative *(1)* and the dioxane derivative *(2)* have given very promising results.

Postfach 102148, D-4630 Bochum (Germany)

0570-0833/81/0808-0647 $ 02.50/0

### 2.1.4. Surfactants

Typical examples in this field are the perfluoroalkanesulfonic acids $R_fSO_3H$ ($R_f$ = *e.g.* $C_7F_{15}$ to $C_{10}F_{21}$) and their derivatives. Because of its extremely low surface energy, the perfluorinated chain reduces the surface tension in aqueous systems at concentrations at which analogous non-fluorinated compounds are practically ineffective. These compounds are used as fire-extinguishing foams, as emulsifiers in polymerization reactions, and as wetting and dispersing agents.

### 2.1.5. Polymers

The best known example is of course polytetrafluoroethylene, whose unusual properties (high melting point, form stability (lack of flow) above the melting point, insolubility in all conventional solvents, and high thermal and chemical resistance) make this class of compounds suitable for a wide range of applications. Further developments have led to copolymers of tetrafluoroethylene (TFE) and perfluoropropylene (reduced tendency toward crystallization in spite of shorter chain lengths), of TFE and ethylene (better mechanical strength), and of TFE and perfluorinated alkyl vinyl ethers (better thermal resistance).

### 2.1.6. Blood Substitutes[10]

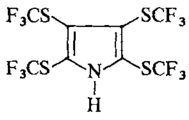
Although this sphere of application is still in its infancy, spectacular results have already been achieved with some classes of compounds (perfluorinated cycloalkanes, amines, and oxygen heterocycles). The specific requirements are: similarity to normal blood as regards osmotic pressure, rheological properties, transport, and exchange of $CO_2$ and $O_2$, as well as the possibility of new production of erythrocytes and other blood constituents.

### 2.1.7. Summary of the Uses of Highly Fluorinated Compounds

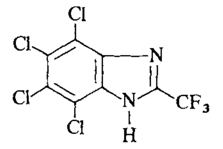
The fundamental precondition for all the above-mentioned spheres of application is high chemical (and by extension biological) inertness of the compounds used. This requirement is very largely satisfied by substances containing C—F bonds, a lack of any chemical interaction with biological systems being observed above all in the perhalogenated compounds. The absence of interaction means that the compounds have a very low toxicity, a property required particularly for the blood substitutes. Interestingly enough, the common structural feature of anaesthetics, *i.e.* substances that must interact with the organism to some extent (weakly) if they are to fulfill their function, is an incomplete replacement of the H-atoms by the halogen. The specific action of these compounds correlates with the remaining *C*-bonded hydrogens[11,12]. Pronounced biological activity is thus encountered predominantly in the compounds with a low fluorine content. Examples behaving contrary to this rule, such as the perfluoroalkylsulfonyl-substituted urea *(3)* (strongly hypocholesterolemic and anorectically active)[13], the highly substituted pyrrole *(4)* (strong fungicidal and insecticidal action)[14], and benzimidazole *(5)* (strongest known respiratory-chain decoupler)[15] are exceptions.

$C_8F_{17}SO_2NHCONH_2$

*(3)*



*(4)*



*(5)*

## 2.2. Low-Fluorinated compounds

### 2.2.1. Pharmaceuticals

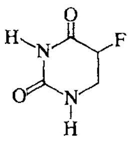
As a rule, a specific interaction of a fluorinated compound with a living organism is only possible when not all the *C*-bonded hydrogen atoms have been replaced by halogens. This may be attributed to the fact that a biologically active substance must bear a certain similarity to the structures with which it is to interact. Many of the fluorine-containing drugs do in fact show a close analogy to natural products, *e.g.* nucleobases, steroids, and amino acids. The future significance of such classes of compounds, which can hardly be overestimated, stems from the following properties of elementary fluorine[16]:

1. The highest electronegativity of all the elements in the periodic table. The difference between fluorine and chlorine, the closest homolog, is substantially greater than the differences between any other two successive halogens, and is reflected in the term "superhalogen"[17] used to describe fluorine. The unusually strong polarization of the C—F bond is explained by a strong negative inductive effect which can gradually alter and even invert the reaction behavior of adjacent centers.

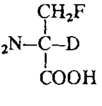
2. Fluorine is the halogen whose van der Waals radius is most like that of hydrogen (F = 1.35; H = 1.1 Å). The steric requirements of the two atoms are so similar that formal replacement of H by F can be regarded as an "isogeometric transformation".

3. The high energy of the C—F bond (107 kcal/mol) is responsible for the difficult metabolization of fluorine-containing compounds which can lead to competitive enzyme inhibition. The term "lethal synthesis" is used[18] if an intermediate stage of this kind is produced in the organism from a precursor (*e.g.* fluoroacetic acid → fluorocitric acid, competitive inhibition of aconitase in the tricarboxylic acid cycle, and its inactivation by fluoroacetic acid[19]).

This last point in particular has given rise to the concept of "antimetabolites", *i.e.* fluorine analogs of natural products which are incorporated in their stead and give rise to lethal synthesis. An important example is 5-fluorouracil *(6)*[20], which as a competitive inhibitor of thymidylate synthetase constitutes one of the most potent antineoplastic agents. 5-Fluorouracil is used in particular in the treatment of breast cancer, leukemia and Hodgkin's disease.

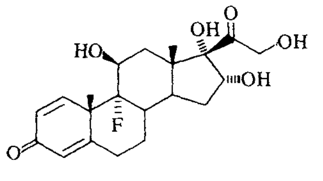


*(6)*



$$H_2N-\overset{\displaystyle CH_2F}{\underset{\displaystyle COOH}{C}}-D$$

"DFA" *(7)*



*(8)*

2-Deuterio-3-fluoro-D-alanine (DFA) *(7)*[21] belongs to the group of "cell-wall active antibiotics". As an inhibitor of alanine racemase, in combination with cycloserine it represents a broad-spectrum bactericidal agent with a pronounced activity against virtually all microorganisms known to be pathogenic in man[22].

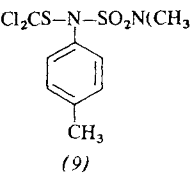
A very different situation prevails in another group of pharmacologically active substances, the fluorinated corticosteroids. Whereas the preparations discussed so far are antagonists of their H-analogs, the antiphlogistic and antirheumatic activity common to the corticosteroids is intensified or modified in the fluorinated derivatives. Triamcinolone *(8)*[23] has a markedly stronger action than cortisone in the treatment of rheumatic arthritis; on the other hand, the undesirable sodium retention (mineralocorticoid activity) observed with many halogenated steroids is suppressed.

### 2.2.2. Study of Metabolic Processes
### ("Reporter Group Technique")

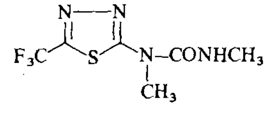
The fluorine atom has a nuclear spin ($I = 1/2$), and $^{19}$F-NMR studies[24] are therefore possible. They are facilitated by the fact that fluorine is an element of 100% natural abundance; the apparatus necessary resembles that customary in proton resonance spectroscopy. The spectra-accumulation technique with the use of the Fourier transformation allows reliable detection of even very small concentrations. The substantially greater absorption range of several hundred ppm in comparison with the $^{1}$H-NMR spectrum and the comprehensive and well-systematized literature on reference compounds[25] are further factors favoring the use of fluorinated compounds in biochemistry. The bonding behavior of inhibitors such as *N*-trifluoroacetyltryptophan and *N*-trifluoroacetylphenylalanine on chymotrypsin has thus been examined[26]. The prosthetic group of the xanthine oxidase of milk could be discerned by $^{19}$F-NMR spectroscopy[27]; similar investigations have been carried out on the enzyme-inhibitor complex of thymidylate synthetase with fluorodeoxyuridine monophosphate[28].

### 2.2.3. Pesticides

Fluorine-containing compounds have also gained application in the realm of plant protection, *i.e.* some of them are distinguished by fungicidal, insecticidal, and herbicidal action. There is no universal theory on the significance of fluorine in these compounds; the mere heterogeneity of the structures is enough to make this difficult.



*(9)*



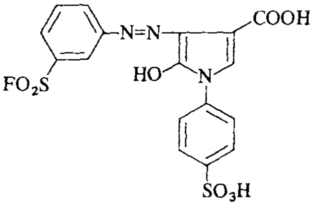
*(10)*

Two arbitrarily cited examples are *N*-dichlorofluoromethylsulfenyl-*N*-dimethylaminosulfonyl-4-methylaniline *(9)*[29] (tradename Euparen), a broad-spectrum fungicide, and *N,N'*-dimethyl-*N*-(5-trifluoromethyl-1,3,4-thiadiaz-2-yl)urea *(10)*[30] (Thiazafluron), a herbicide.

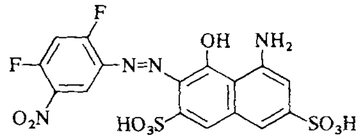
### 2.2.4. Dyes

Fluorine-containing components are used in reactive dyes for two essential reasons:

Fluorine acts as a nucleofugal group in the process of fixing the dye to the fibers, *e.g.* in the azo compounds *(11)* and *(12)*[31,32].



*(11)*



*(12)*

Fluorine increases the dye's reactivity with respect to the nucleophilic groups of the fibers without itself being the leaving group. Examples are found in the series of halogenated pyrimidine derivatives[33].

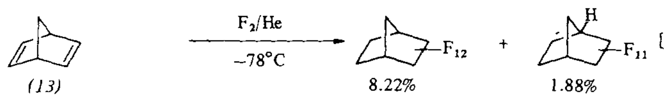
## 3. Production of Highly Fluorinated Compounds

Essentially there are three possible methods for the synthesis of this class of compounds: fluorination with elementary fluorine or with fluorine-active metal fluorides, and electrofluorination.

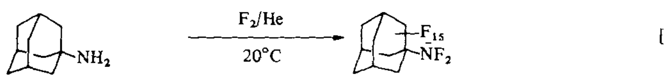
In all these techniques oxidative fluorination (*i.e.* fluorination of CC double and triple bonds; increase of the oxidation number of hetero-atoms such as sulfur and phosphorus) and metathesis (replacement of other halogens and hydrogen with fluorine) take place side by side. The common characteristic feature of these methods, their lack of selectivity, is rather regarded as positive in view of the high degree of fluorination desired.

### 3.1. Elementary Fluorine

Fluorinations with gaseous fluorine are among the oldest methods. Originally the reactions were carried out at several hundred degrees Celsius; the reaction partners, *e.g.* longer-chain, branched, or ring alkanes, were thus present in the gas phase. However, the heat of reaction released gave rise to fragmentations, *i.e.* product mixtures difficult to sort out were frequently produced. More recently the process has been modified[34] in that the fluorine is diluted with $N_2$ or He; the fluorine fraction of the gas mixture should be well below 10% at the start. Careful control of the reaction temperature in specially designed reactors is a further important condition. Highly fluorinated products are obtained in all cases. The reactions are metathetic as regards the H-atoms and oxidative in the presence of multiple bonds and hetero-atoms in low oxidation stages. Functional groups remain partly intact. The fluorinations of the compounds *(13)*—*(23)* can serve as examples.



(13) [35]



(14) [36]

$$\underset{(15)}{(CH_3)_2SO_2} \xrightarrow[20^\circ C]{F_2/He} \underset{34\%}{(CF_3)_2SO_2} + \underset{15\%}{CF_3SO_2F} + \underset{40\%}{SO_2F_2} \qquad [37]$$

$$\underset{(16)}{(CH_3)_4Ge} \xrightarrow[-100 \rightarrow -20^\circ C]{F_2/He} \underset{63.5\%}{(CF_3)_4Ge} \qquad [38]$$

$$\underset{(17)}{(CH_3)_2Hg} \xrightarrow[-78^\circ C]{F_2/He} \underset{6.5\%}{(CF_3)_2Hg} \qquad [39]$$

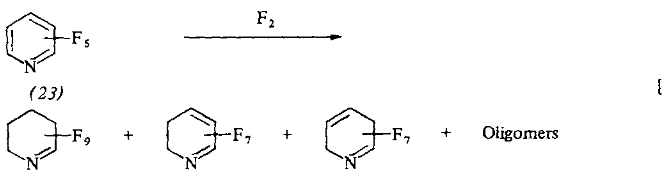
$$\underset{(18)}{(CH_3)_4Si} \xrightarrow[-100 \text{ bis } -110^\circ C]{F_2/He} \underset{\text{(mixture)}}{\text{Polyfluorinated tetramethylsilanes}} \qquad [40]$$

$$\underset{(19)}{CS_2} \xrightarrow[-120^\circ C]{F_2/He} \underset{60\%}{F_3S{-}CF_2{-}SF_3} \qquad [41]$$

$$\underset{(20)}{ICF_2{-}CF_2I} \xrightarrow[-78^\circ C]{F_2/CFCl_3} F_2ICF_2{-}CF_2IF_2 \qquad [42]$$

$$\underset{(21)}{CH_3COOC_2H_5} \xrightarrow[-78^\circ C]{F_2/He} \underset{5\%}{CF_3COOC_2F_5} + \underset{20\%}{CF_3COOCHFCF_3} \qquad [43]$$

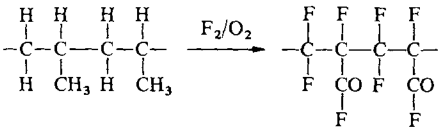
$$\underset{(22)}{CH_3(OCH_2CH_2)_nOCH_3} \xrightarrow[-78^\circ C]{F_2/He} CF_3(OCF_2CF_2)_nOCF_3,\ n = 1,2 \qquad [44]$$



(23) [45]

The majority of these reactions were performed at low temperatures. Fragmentation took place in the reactions carried out close to room temperature with the formation of secondary products[46,47].

Reactions of this kind proceed by a radical mechanism, as has been demonstrated by studies at low temperatures[48]. The simultaneous fluorination and functionalization of polypropylene surfaces is of potential industrial significance[49]:



$$-CH_2-CH(CH_3)-CH_2-CH(CH_3)- \xrightarrow{F_2/O_2} -CF_2-CF(COF)-CF_2-CF(COF)-$$

The fluorination of polyesters and polyamides with elementary fluorine improves the wetting characteristics[50] of the products.

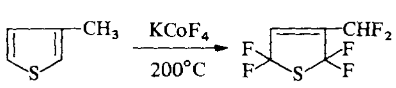
## 3.2. Fluorine-Active Metal Fluorides

At elevated temperature fluorides of metals in the highest oxidation state release a part of their fluorine in free form, the metal thus being reduced. Familiar examples are $AgF_2$, $MnF_3$, $CeF_4$, $PbF_4$, and $BiF_5$. $CoF_3$ and $KCoF_4$ are used most often. The fluorination can be described by the following simple equation:

$$CoF_3 \rightleftharpoons CoF_2 + 0.5\,F_2$$

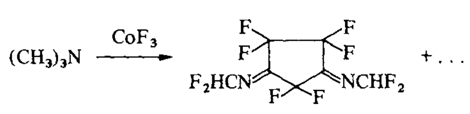
$CoF_3$ can be prepared[51] by the reverse reaction, the equilibrium being displaced to the left. Fluorides of this kind are thus generally regarded as the solid "transport form" of elementary fluorine. The reaction is therefore related to that of free fluorine: metathesis and oxidation take place side by side, resulting in highly fluorinated compounds. Complex product mixtures are isolated even from the fluorinations of ethane[52] and 2-methylpropane[53], but the percentage distribution of the products is clearly temperature-dependent, allowing a measure of control over the reaction.

The oxidative fluorination of double bonds likewise does not yield consistent products[52]; the stereospecificity is low, as has been demonstrated on cycloalkenes[54]. The use of aromatic substrates, *e.g.* naphthalene, shows that even with the relatively mild $CsCoF_4$ some saturated systems are formed[55]. The theory of the fluorination of arenes[56] with the fluorine-active metal fluorides assumes intermediary formation of radical cations, whose rearrangement then leads to a wide variety of products. A reaction with a clearly defined course, such as that of *(24)*→*(25)*, is therefore an exception[57]:



*(24)* *(25)*

The presence of functional groups in the reactants does not cause any fundamental change in this picture. Fluorinations of linear[58] and ring[59-61] ethers give the usual wide ranges of products, the corresponding dioxolane derivatives[59] being regarded as potential inhalation anaesthetics. For the oxygen heterocycles studied, ring-opening reactions have not been described. Conversely, the reaction of trimethylamine leads to ring products such as *(26)*[62].



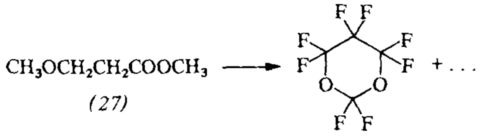
*(26)*, 13%

Short-chain nitriles ($CH_3CN$, $C_2H_5CN$) are largely monosubstituted in the α position, both with $CoF_3$ and with $KCoF_4$; the C≡N group remains intact. Longer-chain and unsaturated compounds react less specifically[63].

## 3.3. Electrofluorination

Like the two methods described in the preceding sections, electrofluorination is regarded as a classical technique[5], although it is also cited frequently in more recent publications. The substrate to be fluorinated is introduced into liquid hydrogen fluoride to which a small percentage of water or a conducting salt (*e.g.* $NH_4F$) has been added to increase the electrical conductivity. The electrolysis vessel is made of steel or copper, the cathode is iron or copper, and the anode is usually nickel. The voltage used for the electrolysis must be below the discharge potential of elementary fluorine to avoid its evolution. The organic substrate serves as a depolarizer[6,64], reacting with the $F^-$ probably in the form of radical cations. The anodic current density must be adjusted to the individual reaction; a high anodic current density favors ring-cleavage products in the fluorination of tertiary aromatic amines[65], a low one increases the yield of the five-membered ring product in the fluorination of *N*-alkylated piperidines[66].

Electrochemical fluorination is in many respects the least selective process compared with the processes in Sections 3.1 and 3.2, and this applies above all to the compounds containing functional groups. Thus, while the conversion of $CH_3CN$ into $CF_3CN$ takes place without destruction of the nitrile group[67], in trifluoromethylbenzonitriles this group is split off as $NF_3$[68]. Aromatic carbocycles[68] and heterocycles[69] are "fluorinated up" oxidatively. Ring cleavage is likewise observed, as in the saturated or partially saturated ring compounds: from oxane derivatives[70] perfluorinated linear ethers are produced; sulfolane[71] is converted into $C_4F_9SO_2F$ in a high yield (30 to 50%). Conversely, in the electrofluorination of methyl β-methoxypropionate *(27)*[72] a ring product is isolated in addition to many others[73].



(27)

In the reaction of carboxylic acids[74-76] elimination of $CO_2$ is observed above all, resulting in the formation of fluorinated alkanes. Alcohols give carboxylic acid fluorides[77] or cyclic ethers[78]. Hetero-elements, *e.g.* sulfur, are raised by fluorination to the highest state of oxidation[79,80]. Exclusive halogen exchange has not been observed[81]. In conclusion, reference may be made to a more recent finding, that the selectivity may be favorably influenced, at least in the fluorination of arenes, by the choice of a different anode material (platinum) and a different solvent ($CH_3CN$)[82]. Directed *p*-substitution[83] and disubstitution[84] in substituted benzenes is thus made possible. In the case of 1,1-diphenylethylene the fluorine can be added smoothly to the olefinic double bond[85], whereas with 1,2-isomers[86] several products are obtained.

The above three methods have the common feature that they give rise to mixtures of highly fluorinated compounds, *i.e.* their selectivity is low. Their usefulness therefore stands or falls with the availability of appropriate separation methods, such as fractional condensation and distillation or chromatographic techniques.

## 4. Preparation of Low-Fluorinated Compounds

The reactions leading to substances of this class represent the true domains of fluorination agents. Three such compounds have already been mentioned in Section 2.2.1: 5-fluorouracil *(6)*, 2-deuterio-3-fluoro-D-alanine *(7)*, and triamcinolone *(8)*, all potent fluorine-containing pharmaceuticals. There are two fundamentally different ways in which the fluorine atom can be introduced:

1. Fluorination at an early stage of conventional synthesis with possible modification of subsequent steps while adhering to the basic principle. This method requires much time and effort, because fluorine often produces a drastic change in the reaction, especially in the case of small molecules. The laborious development of a completely new synthetic sequence is thus frequently necessary[87].

2. Incorporation of the F-atom into the compound in question at the end of conventional synthesis, which in the above examples *(6)*, *(7)*, and *(8)* amounts to the fluorination of a nucleobase, an amino acid, and a corticosteroid, respectively. During this process any functional groups and multiple bonds already present in the molecule should as far as possible remain undisturbed, unless the intention is to substitute one of them deliberately.

Given the availability of suitable fluorination agents and techniques, the second method is more elegant than the first, quicker, and more economic. The demands on a fluorinating agent are thus clearly defined:

*selectivity,* the most important condition;
*efficiency, i.e.* high conversions and yields in as short a time as possible; this requirement is often directly associated with the first;
*Simplicity of the technical implementation of the preparation* and *economy* of the process.

Reactions with extremely aggressive gaseous substances, reactions under pressure, and difficultly accessible reagents must be regarded as less favorable.

In what follows, the classical and modern reagents and methods will be compared with one another. The three aspects of selectivity, efficiency, and simplicity underlie the emphasis on the preparational aspect in this review. Mechanistic considerations will be taken into account only insofar as they prove indispensable for understanding a reaction or if they occupy a large area in the researched literature; nevertheless, they provide a simple scheme of ordering for the very heterogeneous group of fluorinating agents in the confusing host of publications.

Fundamentally, two possibilities are available for classification purposes:

1. Classification by the *mode of fluorination.* The key question is: "Which function in the molecule is altered?"

   The most important reaction types are as follows:

   *Metathetic fluorination*

   $-H_{\text{aliphat.}} \rightarrow -F$
   $-H_{\text{aromat.}} \rightarrow -F$
   $-H_{\text{aldehyd.}} \rightarrow -F$
   $-Cl$, $-Br$ or $-I \rightarrow -F$
   $-OH \rightarrow -F$
   $-SH \rightarrow -F$
   $>C{=}O \rightarrow >CF_2$
   $-COOH \rightarrow -CF_3$
   $-NH_2 \rightarrow -F$

   Special cases: $-NO_2$, —tosyl, or $-O-SO_2CF_3 \rightarrow -F$
   Epoxide and aziridine ring opening.

*Oxidative Fluorination*

$—CH{=}CH— \rightarrow —CHF—CHX—$ $X = H, Cl, Br, I, NO_2, F$

$—C{\equiv}C— \rightarrow —CF{=}CX—$

$\gtreqless E \rightarrow \gtreqless EF_2$ E = heteroatom *e.g.* phosphorus

2. Classification by *fluorinating agents*. The key question is: "What can the fluorinating agents do?"
The most important reaction types and reagents are as follows:

*Nucleophilic F-transfer*
metal fluorides, $MF_n$
hydrogen fluoride, HF
tetrafluoroboric acid, $HBF_4$
halogen fluorides, $XF_n$
sulfur tetrafluoride, $SF_4$
fluorophosphoranes, $R_nPF_{5-n}$

*Electrophilic F-transfer*
perchloryl fluoride, $ClO_3F$

*Nucleophilic and electrophilic F-transfer*
fluorine-containing nitrogen compounds

*Electrophilic and radical F-transfer*
fluorine, $F_2$
trifluorofluoroxymethane, $CF_3OF$
noble-gas fluorides

In what follows the second type of classification will be used, for the purpose of clarity and to illustrate the order of importance.

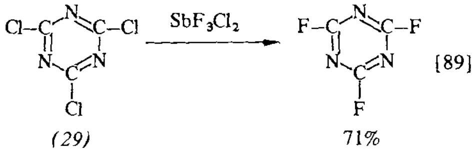
## 4.1. Nucleophilic F-Transfer

### 4.1.1. Metal Fluorides

*Classical process:* Of the reactions with metal fluorides, two well known metatheses will first be presented: Because of the easy availability of the metal fluorides, this type of substitution of chlorine, bromine, or iodine by fluorine continues to enjoy great popularity, in spite of the lower activity in comparison with more modern variants, which gives rise to lower conversions and, owing to the high temperatures required, to a variety of side reactions. Insensitive compounds thus constitute favorable substrates: highly fluorinated aliphatics[90] and arenes[91], hexachlorobenzene[92], and highly halogenated pyridines[93]. Metal fluorides are also used for halogen exchange on heteroelements such as silicon ($KF$[94], $AgF$[95]), germanium ($PbO/SbF_3$[96]), phosphorus (in cyclic phosphazenes with Swarts' reagent $SbF_3/SbCl_5$[97]), sulfur ($SO_2Cl_2$: $PbF_2$[98], aminosulfenic acid halides: $CsF$[99]), tungsten ($AsF_3$[100]), and osmium (tridodecylammonium fluoride[101]).

$$CH_3(CH_2)_5\text{—}Cl \xrightarrow[175\text{–}185°C]{KF/Glycol} CH_3(CH_2)_5\text{—}F \qquad [88]$$

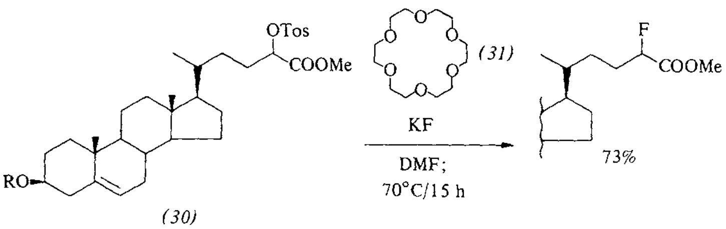
*(28)* 54%



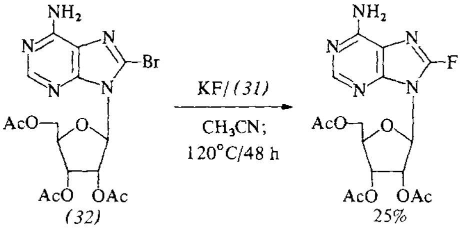
*(29)* 71% [89]

This simple method can also prove successful with complicated derivatives of natural products, as shown by the examples of prostaglandins ($KHF_2$[102], $(C_4H_9)_4N^+F^-$[103], sugars ($CuF$[104]), and nucleosides ($KF$[105]). In all these cases it is not a halogen that is exchanged but, for reasons of the easier accessibility, a tosyl group (obtained from the alcohol by esterification). The unusual substitution of a chlorine atom in the vinyl position with $AgF$[106] and the exchange of an $NO_2$ group in the aromatic ring for F with $KF$[107] are noteworthy special cases.

*Activation by crown ethers:* In the overwhelming majority of the above reactions an aprotic polar solvent such as sulfolane or $CH_3CN$ was used as the medium. By an exclusive solvation of the cations a degree of anion activation is assured, without which nucleophilic substitution takes place only slowly. The process is enhanced by the use of a chelating crown ether whose solvate complex with the cation of the metal fluoride has a high formation constant. The unsolvated fluoride ion ("naked fluoride") is strongly nucleophilic. In this way the substitution of Cl, Br, or I by F on singly or multiply bound carbons can take place in acceptable yields under mild conditions. Two examples of the use of [18]crown-6 *(31)* in the reaction of the steroid *(30)*[108] and the nucleoside *(32)*[109] may serve as an illustration of this method (DMF = dimethylformamide, R = tetrahydropyranyl).



*(30)*



*(32)*

The action of the crown ether *(31)* can be seen from comparisons on less spectacular examples: without an addition of *(31)* halogen-fluorine-substitutions in aliphatics and aromatic carbocycles proceed under mild conditions (boiling acetonitrile) to an extent of less than 5%; in the presence of catalytic quantities of *(31)* the degrees of conversion are between 40 and 90%[110]. The nucleophilic substitution on pentachloropyridine with *(31)* at 65 °C leads in 2 hours quantitatively to 3,5-dichloro-2,4,6-trifluoropyridine[111]; in the absence of *(31)* the same reaction proceeds at 200 °C in 6 h to an extent of only 65%[112]. Similarly clear results have been obtained with other crown ethers[113, 114].

The method has been used successfully on a variety of substrates, among them pyrimidine derivatives (nucleophilic exchange in the ring)[115], 2,3-dichloro-1,4-dioxane[116], carbonic esters, and carbamoyl compounds (substitution of chlorine on sp$^2$-hybridized carbon of the C=O group)[117], substitution of chlorine in the difficultly accessible vinyl position[118,119], on a β-oxolactone (tertiary position)[120], and in nitroamines (74—85% yields; no reaction in the absence of catalyst!)[121,122]. The method also finds application for metathesis reactions on a heteroatom (silicon[123], sulfur[124]). In virtually all cases [18]crown-6 *(31)* is selected as the catalyst, owing to its excellent complexing properties for the potassium ion and its commercial availability. The molar ratio of the substrate to the catalyst *(31)* is *e.g.* 10 : 1[125,126].

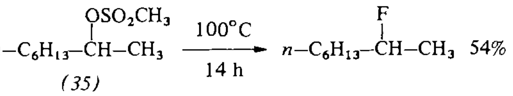
*Phase-transfer catalysis:* In the halogen-fluorine exchange reactions this popular method of preparative organic chemistry offers the particular technical advantage of the use of readily separable aqueous fluoride solutions. In addition, the yields may be high and the selectivity good, as in the reactions of *(33)—(35)*[127] (using $(KF)_{aq}/(C_{16}H_{33})(C_4H_9)_3P^+Br^-$).

$$n\text{-}C_8H_{17}Cl \xrightarrow[7\text{ h}]{160^\circ C} n\text{-}C_8H_{17}F \qquad 82\%$$

*(33)*

$$PhCH_2Cl \xrightarrow[7\text{ h}]{120^\circ C} PhCH_2F \qquad 95\%$$

*(34)*



$$n\text{-}C_6H_{13}\text{-}\overset{OSO_2CH_3}{CH}\text{-}CH_3 \xrightarrow[14\text{ h}]{100^\circ C} n\text{-}C_6H_{13}\text{-}\overset{F}{CH}\text{-}CH_3 \qquad 54\%$$

*(35)*

The reaction of the diazomethane derivative *(36)* constitutes a special application[128].

$$Ph_2C{=}N_2 \xrightarrow[(KHF_2)_{aq}]{Bu_4N^{\oplus}ClO_4^{\ominus}} Ph_2CHF \quad 50\%$$

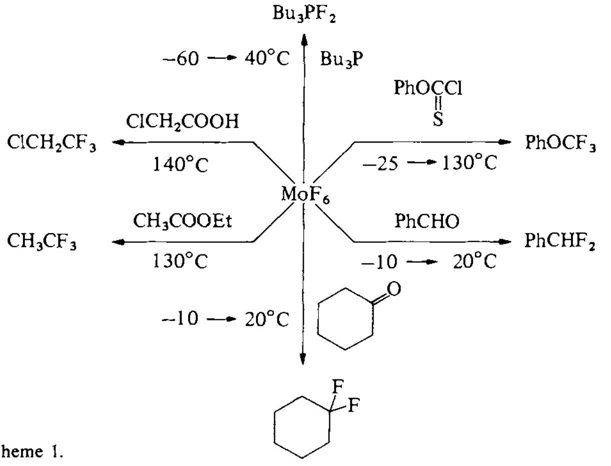
*(36)*

*Polymer-supported reagents:* In this case a basic ion-exchanger is charged with fluoride ions and reacted with the compound to be fluorinated in an organic solvent. Examples of this method are offered by the reactions of *(33)—(35)* to the corresponding fluorine compounds with resin-$\overset{+}{N}(CH_3)_3F^-$ in *n*-pentane under reflux (30, 24, and 20 h).

Noteworthy about these examples are the very mild reaction conditions and the outstanding yields (92, 100, and 70%). A further preparative advantage lies in the ease of removal of the exchanged halide which, being fixed to the resin, is simply filtered off. Other applications[130] have recently been reported.

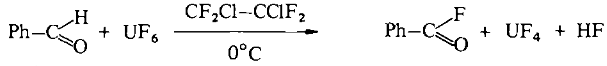
*New metal fluorides:* For some years now, molybdenum hexafluoride has found a variety of applications both for the metathetic and for the oxidative fluorinations (Scheme 1)[131-136].

The many known reactions also permit an estimation of the relative reactivities in multifunctional molecules.

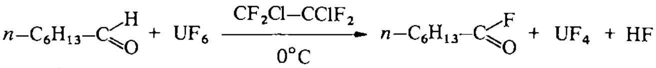


Scheme 1.

Uranium hexafluoride is an unusual fluorinating agent. This strongly aggressive substance, whose handling on a large scale made it necessary to develop highly resistant perfluorinated polymers[2], can substitute fluorine for aldehyde hydrogen under mild conditions, *e.g.* in *(37)* and *(38)*, with a high degree of selectivity[137]. This reaction does not take place with any other fluorinating agent.



*(37)* 40%



*(38)* 47%

*Organo-substituted metal fluorides:* The substitution of some of the fluorines bound to a metal atom by organic groups (*e.g.* phenyl groups) reduces the reactivity of the original fluorinating agent, as shown by the following sequence[138], found experimentally for antimony compounds:

$$PhSbF_4 > Ph_2SbF_3 > SbF_3 > Ph_3SbF_2$$

The phenylantimony compounds were obtained as follows:

$$Ph_2SbF \xrightarrow{XeF_2} Ph_2SbF_3 \quad [139] \quad 98\%$$

$$Ph_3Sb \xrightarrow{XeF_2} Ph_3SbF_2 \quad [139] \quad 95\%$$

$$PhSb(O)(OH)_2 \xrightarrow{SF_4} PhSbF_4 \quad [140] \quad 87\%$$

An example of the use of $Ph_2SbF_3$ is the partial fluorination of benzotrichloride *(39)*.

$$PhCCl_3 \xrightarrow[CH_2Cl_2/50^\circ C]{Ph_2SbF_3} PhCClF_2 \quad [138] \quad 65\%$$

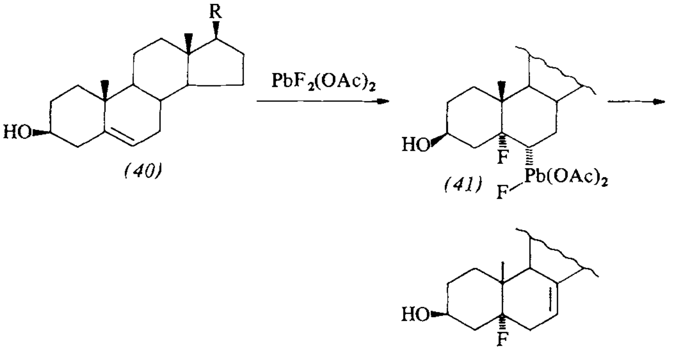
*(39)*

Diphenylantimony(III) fluoride has also been carefully studied[141], but so far nothing is known of its properties as a fluorinating agent. It will probably prove to be less active than $SbF_3$. This has been demonstrated for PhHgF, whose fluorinating power is too low for the reaction with 1-bromopentane. In contrast, the adduct $PhHgF \cdot HF$ permits the fluorination of $PhCCl_3$ *(39)* to $PhCFCl_2$ or $PhCF_3$, depending on the reactant ratios used[142].

The combination $Tl(OCOCF_3)_3/KF$[143] is suitable for the introduction of fluorine into activated arenes:

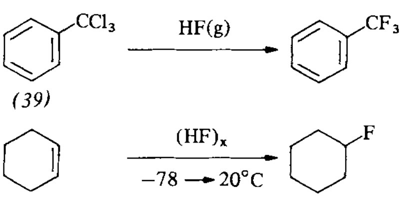
$$\text{Aryl-H} \xrightarrow{Tl(OCOCF_3)_3} \text{Aryl-}Tl(OCOCF_3)_2 \xrightarrow{KF} \text{Aryl-}TlF_2 \xrightarrow{BF_3} \text{Aryl-F}$$

In this reaction the thallium(III) reagent exerts an oxidizing and fluorinating action.—A parallel from the field of aliphatic chemistry is represented by the fluorination of a steroid of the type of *(40)* with $PbF_2(OCOCH_3)_2$[144,145]. The intermediate *(41)* has been isolated ($R = CH_3CO—$).



### 4.1.2. Hydrogen Fluoride

*Classical reactions:* HF can both replace a halogen on $sp^3$-hybridized carbon by fluorine and add to double or triple bonds; examples are the reactions with *(39)* and *(42)*.

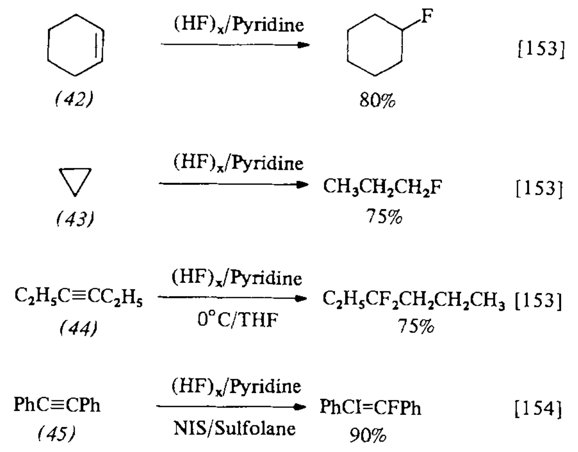


95% [147]

70% [146]

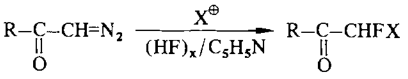
The use of anhydrous HF is also significant with complicated substrates. The exchange of esterified OH-groups in various sugars[148,149] can be carried out in this way, but the ionic mechanism leads to rearrangements[150]. Pure hydrogen fluoride is also used for the fluorination of small molecules such as KOCN or KSCN (formation of $H_2N—CXF$; $X = O, S$)[151], and in steroid chemistry[152]. However, the tendency to alkyl shifts in the protonated substrate is a constant perturbing factor.

*$(HF)_x$/pyridine:* A clear improvement of the situation has been brought about by *Olah*[153,154] with the introduction of the HF/pyridine mixture. Pyridine is an excellent solvent for hydrogen fluoride: a 70% solution does not lose any HF up to 50 °C, which obviously facilitates the handling of the reagent. Moreover HF is a weaker acid in pyridine than in the pure form, so that cationically induced polymerizations and rearrangements are strongly suppressed. On the other hand, the nucleophilic activity of the fluoride ion is enhanced. The reactions with *(42)*—*(45)* have been selected as examples (THF = tetrahydrofuran, NIS = *N*-iodosuccinimide).



The last of these reactions, the combined addition of fluorine and another halogen to a double-bond, is an example of "halofluorination". In alkenes the reaction follows Markovnikov's rule[155], but it can also be performed selectively in the presence of other functional groups (*e.g.* aryl[156] and ester groups[157]), and subsequent HX elimination permits the production of vinyl fluorides[158].

Nucleophilic substitution also proceeds with $(HF)_x$/pyridine. OH-groups are exchanged above all, *e.g.* in steroids[159] or in organosilicon and organogermanium compounds[160]. Interestingly, in a chlorinated alcohol reacting with Olah's reagent the halogen remains intact[161]. α-Diazoketones of the type *(46)* can likewise be used as educts[162]. This reaction has a very wide applicability. For procedural details and for the preparation of the HF/pyridine mixture, reference is made to a comprehensive recent publication[163].



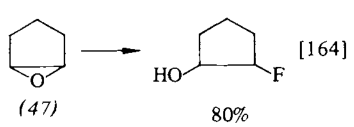
$$\underset{\underset{O}{\|}}{R-C}-CH{=}N_2 \xrightarrow[(HF)_x/C_5H_5N]{X^{\oplus}} \underset{\underset{O}{\|}}{R-C}-CHFX$$

*(46)*

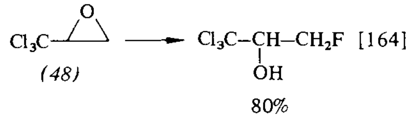
$R = C_6H_5, c\text{-}C_6H_{11}, C_2H_5, OC_2H_5$; $X = H, Cl, Br, I$

*Ring-opening reactions:* Olah's reagent makes it possible to open epoxide and aziridine rings as in *(47)*—*(49)* at 20 °C by nucleophilic attack and to arrive selectively at fluorinated alcohols and amines in high yields.

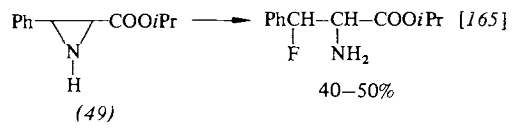
The ring opening in *(49)* shows that fluorinated amino acids are also accessible in this way. Further examples of the epoxide reactions are the fluorinations of "glycerol entities" for the synthesis of potential cancerostatics[166], of epoxidized sugars[167], and of simple oxiranes, although in the latter case with the similarly active reagent $(HF)_x/(CH_3)_3N$[168]. There are also other applications with aziridines[169,171]. Under the given conditions azirines react in a similar fashion; the product is an α-fluoroketone[170].



(47)



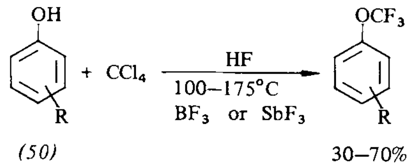
(48)



(49)

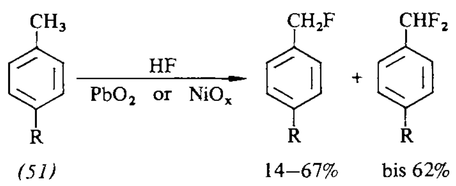
*Special processes:* The aim of this section is to present a few "spectacular" processes and some special features.

There are few proven methods for the introduction of the $CF_3O$ group (cf. Section 5.3) into arenes. Multistage syntheses are generally performed, but these can be used only on a very limited number of substrates. One recently published[172] method is based on phenols such as *(50)*. The



(50)

reaction is a "single-vessel process", which reduces the expenditure on apparatus. A variety of groups with different inductive and mesomeric effects have been tried as the substituent R. Although the yields are different, the basic process remains practicable. The reaction of *(51)* could be of similar significance[173,174].



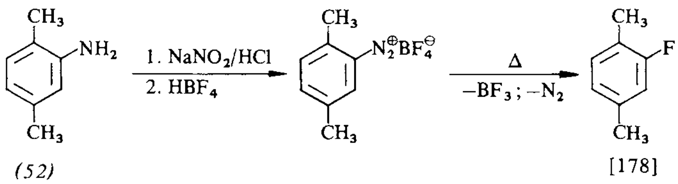
(51)

R *e.g.* $NO_2$, CN

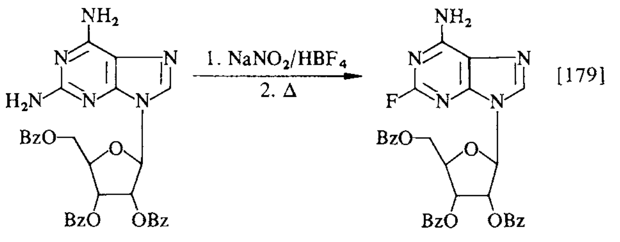
Other interesting reactions are fluorination in the *p*-position to an azide group in arenes (from amino groups by diazotization and reaction with $NaN_3$)[175], the conversion of aryltriazenes into aryl fluorides[176], and the monofunctional diazotization of 2,3-diaminosuccinic acid in the presence of HF, in which one $NH_2$ group is replaced by fluorine[177].

### 4.1.3. Boron Trifluoride, Tetrafluoroboric Acid and Their Salts

*Classical reactions:* The most common process in this group is the "Balz-Schiemann" reaction, in which an aromatic $NH_2$ group as in *(52)* and *(53)* is replaced by fluorine. The $NH_2$ group is first diazotized in the presence of tetrafluoroboric acid, and this is followed by thermal decomposition of the isolated intermediate product, diazonium tetrafluoroborate (Bz = benzyl).



(52)

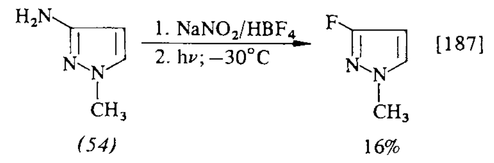


(53)

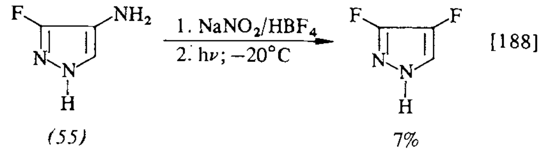
Other interesting more recent applications are the fluorination of the carcinogenic benz[*a*]anthracene[180] and of some aminopyrimidine derivatives used in the treatment of leukaemia[181]. The latter example also demonstrates the high decomposition temperature of the intermediate stage: 225 °C.

*Modifications of the classical reactions:* In a number of cases catalysis with crown ethers dramatically reduces the decomposition temperature of the intermediate tetrafluoroborate[182]. Within certain limits the $HBF_4$ can be replaced by $HPF_6$[183,184]. Fluorine can be introduced into alkyl compounds *e.g.* with $NO^+BF_4^-$ (substitution of the azide group)[185] and with $AgBF_4$ (substitution of bromine α to the keto group)[186].

*"Photo-Schiemann reaction":* If, for example, the aromatic carbocycle *(52)* is replaced by heterocycles such as *(54)* and *(55)*, the intermediate diazonium salt becomes so unstable that its isolation, the precondition for controlled thermal decomposition, becomes impossible. Here the answer lies in the "photo-Schiemann reaction", in which the intermediate is not isolated but decomposed photolytically *in situ*.



(54)



(55)

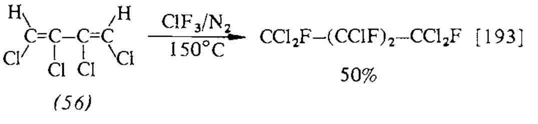
The method has also proven successful in the conception of antiviral agents, namely in the fluorination of an imidazole ring bound to a ribose molecule[189].

*Fluorinations with $BF_3$:* Similarly to hydrogen fluoride, boron trifluoride can split epoxide rings nucleophilically.

A vicinal fluoroalcohol is formed during the subsequent hydrolysis. This reaction has so far been used only in a few instances in steroid chemistry[190–192]; it has proved not to be very selective.

### 4.1.4. Halogen Fluorides

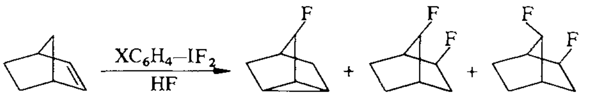
*Classical reactions:* Some interhalogen compounds were tried out early as fluorinating agents, *e.g.* for *(56)* and *(57)*. The reactions are metatheses, although additions to double bonds have also frequently been observed[195,196], especially with reactive reagents such as $BrF_3$. This ambivalent behavior is of course synonymous with low selectivity. In the classical methods halogen fluorides are thus more successful with simple substrates, *e.g.* for the preparation of $SeF_4$ from $SeCl_4$ (ClF)[197]. The addition of "IF" (AgF + $I_2$) to the double bond of a nucleoside sugar[198] is highly selective, but this is not a typical example.



*(56)*

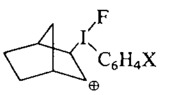
$$(57)\ CI_4 \xrightarrow[90-100°C]{IF_5} CF_3I\ [194]$$

*Organohalogen fluorides:* During the systematic further development of the halogen fluorides the effect of substituting one or more fluorines by organic groups has been studied, just as in the metal fluorides. The whole has so far been limited to iodine. The common intermediate stage in the reaction of norbornene *(58)* is the cation *(59)*. $CH_3IF_2$ has similar fluorinating properties to those of $XC_6H_4$—$IF_2$[201]; a noteworthy point here[202], as in the case of the phenyl derivatives[203], is the careful product analysis. All the organo-derivatives mentioned fluorinate double bonds on an exclusive basis. Metathesis occurs only with the compound *(60)*. The reaction of *(60)* with PhMgBr affords PhF in 90% yield.



*(58)* 6–18% 74–88% 5–13%

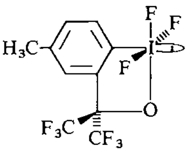
X = *p*–$OCH_3$, *m*–$OCH_3$, H, *m*–Cl, *m*–$NO_2$ [199]



*(59)*

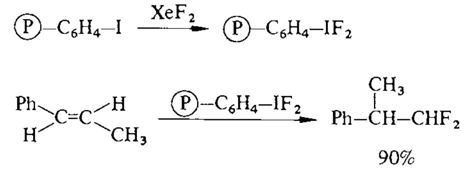
$$R{-}I \xrightarrow[R = C_6H_5,\, C_6F_5,\, C_3F_7]{XeF_2} R{-}IF_2 \xrightarrow[R = C_6F_5]{XeF_2} R{-}IF_4\ [200]$$

60–82% 100%



*(60)*

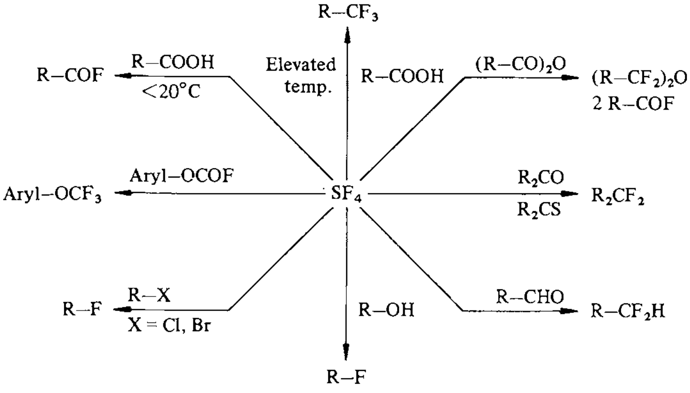
*Polymer-supported reagents*[205]: Again as in the case of the metal fluorides, it is possible with iodine fluorides to make use of the preparative advantage of the easy separation of a polymeric resin by appropriate derivatization:



However, the distinctly cationic reaction mechanism in all organoiodine fluorides leads to a predominance of rearranged products.

### 4.1.5. Sulfur Tetrafluoride and Analogues

*Classical reactions:* $SF_4$ is one of the most common fluorinating agents. Its action mechanism is metathetic in character (Scheme 2[206]).



$$R{-}OH + SF_4 \xrightarrow{(\text{Lewis acid})} R{-}OSF_3 + HF$$
$$R{-}OSF_3 \longrightarrow R{-}F + SOF_2$$

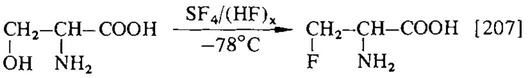
Scheme 2.

The above reaction path[207] can be regarded as definite. Although the manipulation of the sulfur tetrafluoride is not without problems (boiling point −40 °C, toxicity like that of phosgene), the reagent is still often used, especially with more inert substrates. A popular application is for the conversion of carboxyl groups into the $CF_3$ or the acid fluoride. Acetylenedicarboxylic acid is converted smoothly into the acid fluoride[208]. Fluorocarbonic esters are converted into the $CF_3O$-substituted compounds by $SF_4$[209]. $SF_4$ plays a particularly outstanding role in the introduction of the $CF_3$ group into aromatic systems. This applies both to carbocycles[210] and to heterocycles like thiazoles[211], and even to the very sensitive furans[212-214]. It is also possible to replace COOH by $CF_3$ in perfluorinated adamantanes[215].

The likewise customary conversion of a keto group into $CF_2$ has been demonstrated on anthraquinone[216] and on adamantanones[217,218]. Biologically active compounds (*e.g.* lysine derivatives[219]) frequently contain amino groups that are sufficiently nonreactive in the case of tertiary perfluorinated compounds[220] or have to be protected *e.g.* by the $CF_3CO$ group[221]. The carbonyl groups of acid amides are inert[222]. The replacement of the OH-group by F is possible in 3-*O*-acetyldigitoxigenin in moderate yields, with KF as an HF-receptor. An interfering competitive reaction in this process is the elimination of $H_2O$ with the formation of a double bond in the steroid skeleton[299].—$SF_4$ can also replace Cl, Br, or I with F, as shown by an example from adamantane chemistry[223]. The reaction conditions are mild (85—140 °C; 3—8 h). The epoxide ring is already opened at room temperature, though in rather uncontrolled fashion[224]. Even tertiary hydrogens have been substituted by fluorine with the aid of $SF_4$ (substrate: adamantane)[225].

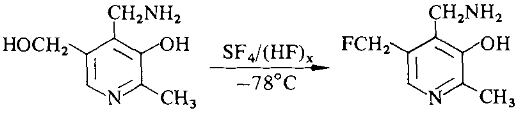
*Hydrogen fluoride as a catalyst and a solvent:* In the reactions with $SF_4$ hydrogen fluoride is primarily used as a catalyst, allowing the reaction temperature to be reduced and thus preventing side reactions from taking place. In addition, the reaction times become shorter and the conversions more complete. In many cases the applications are covered by the examples already cited: replacement of the COOH bound to the benzene ring by a $CF_3$-group[226,227] and analogous reactions on the furan[228-230] and adamantane[231] skeletons, tertiary H-atoms being also exchanged for F, apparently owing to the high temperature. The CO-group in aromatic trifluoroacetic acid esters is smoothly fluorinated to $CF_2$[232-234].

Hydrogen fluoride plays a particularly important role as solvent in "fluorodehydroxylations" (—OH→—F) and "fluorodesulfurizations" (—SH→—F)[235]. In amino acids such as *(61)* the amino groups are protonated by HF and thus made incapable of perturbing side reactions.



$$\underset{\mathrm{OH}}{\mathrm{CH_2}}{-}\underset{\mathrm{NH_2}}{\mathrm{CH}}{-}\mathrm{COOH} \xrightarrow[-78^\circ\mathrm{C}]{\mathrm{SF_4/(HF)_x}} \underset{\mathrm{F}}{\mathrm{CH_2}}{-}\underset{\mathrm{NH_2}}{\mathrm{CH}}{-}\mathrm{COOH}\ [207]$$

*(61)* 51%



49%

The extremely mild reaction conditions are particularly worthy of note. A variety of compounds can be made to react in this way, *e.g.* 2-amino-3-hydroxybutyric esters[236], quinine, hydroxyphenylalanine, thiamine chloride, ephedrine, and pseudoephedrine[237].

*Amino derivatives:* Formal substitution of one or more fluorine atoms in $SF_4$ by secondary amino group or groups leaves the character of the fluorinating agent unchanged[238]. "DAST" *(62)* boils at 46—47 °C/10 torr.

$$\mathrm{SF_4 + Et_2N{-}SiMe_3 \xrightarrow{CCl_3F} Et_2N{-}SF_3 + Me_3SiF}$$

"DAST" *(62)*, 84%

$$\text{“DAST”} + \mathrm{Et_2N{-}SiMe_3 \xrightarrow{CCl_3F} (Et_2N)_2SF_2 + Me_3SiF}$$

*(63)*

The advantages of modified compounds such as *(62)*—*(64)* over $SF_4$ are as follows:

| | |
|---|---|
| chemically: | less reactive; more selective reactions; fewer rearrangements or eliminations |
| technically: | less volatile, reactions under pressure or elaborate cooling are not necessary |

$$\mathrm{CH_3CH{=}CHCH_2OH \xrightarrow[(64)]{Me_2N{-}SF_2{-}NEt_2} CH_3CH{=}CHCH_2F + CH_3CHFCH{=}CH_2}$$

57% 15%

$$\mathrm{(CH_3)_3C{-}CHO \xrightarrow[CCl_3F/25^\circ C]{\text{“DAST”}} (CH_3)_3C{-}CHF_2}$$

78%

The selective fluorination of acid-sensitive substrates such as crotyl alcohol and pivalaldehyde, achieved with these reagents with clear suppression of the otherwise common dehydration, rearrangement, and oligomerization reactions, indicates a shorter lifetime of the ionic intermediates and illustrates the importance of this development. Other preparation processes have been given for the two aminosulfur fluorides *(62)* and *(63)*[239], and analogous compounds with other substituents on the sulfur (*e.g.* piperidine[238], morpholine[240], or those of the type $(R_2N)_3S^+(CH_3)_3SiF_2^-$[241]) have been synthesized, but in preparative fluorination chemistry diethylaminosulfur trifluoride "DAST" *(62)* has been used almost exclusively, among other reasons probably because it is available commercially. Apart from special applications such as the fluorination of the keto groups in spirocyclic four-membered rings[242], substitution in optically active compounds[243], or the skeleton-fluorination of carcinogenic hydrocarbons such as benzanthracene[244] and benzpyrene[245], "DAST" is used primarily in the chemistry of natural products. Pregnadiene derivatives[246] have been fluorinated as also have androstanes[247,248], cholesterol[249], gibberellins[250,251], vitamin $D_3$[252,253], and sugars[254-256]. However, in the face of all these successes it should not be forgotten that even with "DAST" dehydration reactions may occasionally predominate[257]. The reaction with halogenated compounds with halogen fluorine exchange, which is sometimes used for preparative purposes[258], can in other cases prove to be a perturbing influence[259]. Lastly, explosions with the use of "DAST" have been reported[260,261].

*Organo-derivatives:* Phenylsulfur trifluoride[262] has already been in use for some considerable time. Diphenylsulfur difluoride *(68)* is a new development[263] which according to the preliminary data exhibits fluorinating properties. Since the compound is solid, it has become known as "solid $SF_4$". The reactions with *(65)*, *(37)*, and *(67)* are

$$\mathrm{Ph{-}S{-}S{-}Ph + 6\,AgF_2 \xrightarrow{CClF_2{-}CFCl_2} 2\,Ph{-}SF_3 + 6\,AgF}$$

*(65)* *(66)*, 60%

$$\mathrm{Ph{-}CHO \xrightarrow[20^\circ C]{Ph{-}SF_3} Ph{-}CF_2H}$$

*(37)* 71—80%

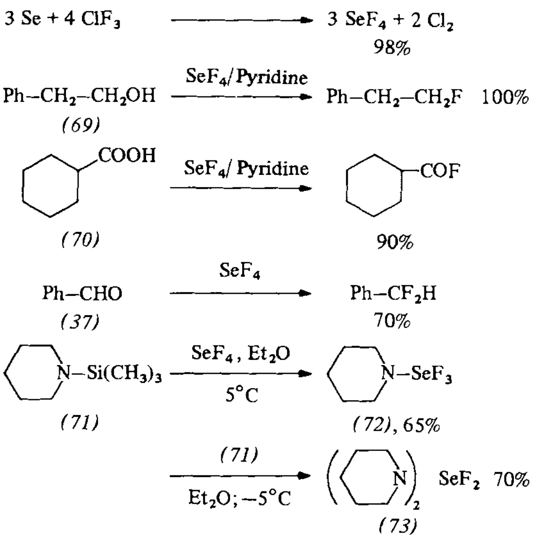
$$\underset{(67)}{\mathrm{Ph{-}S{-}Ph}} \xrightarrow{\mathrm{F_2/Ar}} \underset{(68)}{\mathrm{Ph_2SF_2}}$$

$$\underset{(37)}{\mathrm{Ph{-}CHO}} \xrightarrow{\mathrm{Ph_2SF_2}} \mathrm{Ph{-}CF_2H}$$

examples. The main advantage of *(68)* ("solid sulfur tetrafluoride") over $SF_4$ is the higher boiling point.

### 4.1.6. Selenium Tetrafluoride and Its Amino Derivatives

The fluorination properties of $SeF_4$, b.p. 106 °C, are similar to those of $SF_4$. The compound can be prepared from selenium and $ClF_3$ in very good yield. Pyridine is recommended as a solvent for the reactions to moderate the activity[264]. The reactions with *(69)—(71)* have been selected as examples.

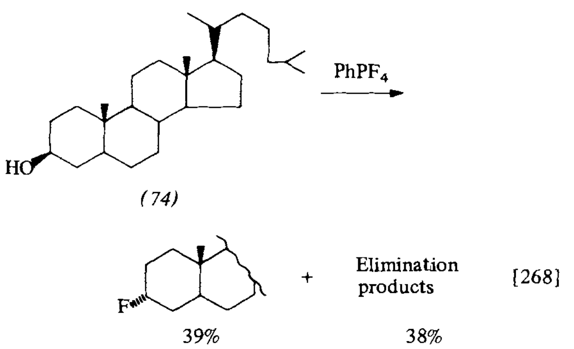


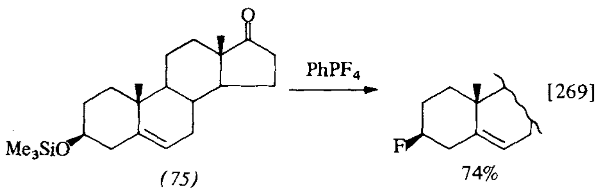
The amino derivatives *(72)* and *(73)* of $SeF_4$[265] (morpholine compounds are also accessible in this way) have not yet been tried out as fluorinating agents.

### 4.1.7. Fluoro(phenyl)phosphoranes

The compounds $Ph_nPF_{5-n}$, $n = 1-3$, can replace OH-groups with fluorine. The fluoro(phenyl)phosphoranes are prepared by reacting their chlorine analogs with $AsF_3$ or $SbF_3$[266] or by reacting chlorophosphanes with $XeF_2$[267]; $Ph_2PF_3$ is available commercially. In general, the reactivity decreases with increasing number of organic groups, a feature also observed with other fluorinating agents. The reaction mechanism, demonstrated here on the steroids *(74)* and *(75)*, probably resembles that of $SF_4$.

In nonesterified alcohols such as *(74)* the elimination process is significant. The use of silylated compounds such as *(75)* suppresses the competing reaction. This method has also become established in the presence of ester groups and arene-bound halogens[270].





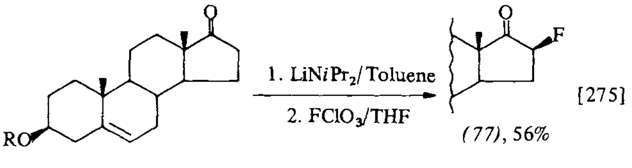
## 4.2. Electrophilic F-Transfer: Perchloryl Fluoride

4.2.1. *Classical applications:* Fluorinations with $FClO_3$ proceed only in the presence of anionic substrates; the primary production of a carbanion with a sufficiently strong base is thus a necessary precondition. The fluorine atom in the $FClO_3$ can be regarded as carrying a partial positive charge, probably in consequence of the high electronegativity of $Cl^{VII}$. However, the problems associated with this method of fluorination are manifested in the reaction with malonic ester *(76)*[271].

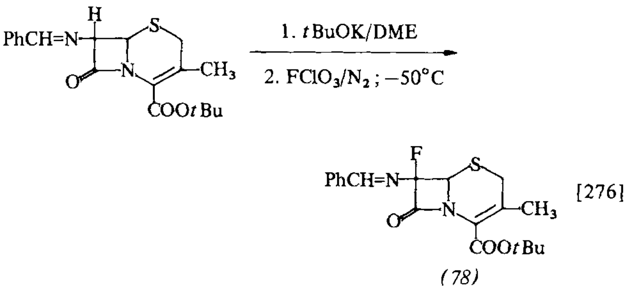
$$\underset{(76)}{\mathrm{CH_2(COOEt)_2}} \xrightarrow{\mathrm{Na/EtOH/FClO_3}} \begin{array}{ll} \mathrm{FCH(COOEt)_2} & 8.7\% \\ \mathrm{F_2C(COOEt)_2} & 36.1\% \\ \mathrm{EtCH(COOEt)_2} & 25.2\% \\ \mathrm{EtCF(COOEt)_2} & 15.3\% \\ (76) & 14.4\% \end{array}$$

The range of products characterizes $FClO_3$ as a nonselective reagent; some of the substances obtained make it necessary to postulate $EtOClO_3$ as an intermediate. The method has nevertheless proved useful with substrates offering a narrow choice of reaction possibilities, as in the fluorination of 4,4-dimethyl-2-cyclopentenone[272] and in the synthesis of tricyanofluoromethane[273] and 2-fluorothiophene[274].

*New variants:* The decisive development is based on the knowledge of how to separate the production of the car-



*(77)*, 56%



*(78)*

banion and the fluorination process and to obtain the carbanion irreversibly[275]. Possibilities are thus opened up for the fluorination of multifunctional compounds, *e.g.* of natural products, frequently in the position α to a keto group (fluorination of an enolate; DME = dimethoxyethane, R = tetrahydropyranyl).

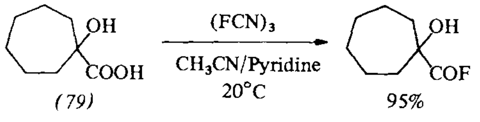
Similar examples are the fluorination of a pregnenone[277] and of a norbornane derivative (86% yield; prostaglandin precursor)[278]. Care must always be exercised when using $FClO_3$, for at higher temperatures this very reactive compound tends towards explosive decomposition on contact with organic substances[279].

## 4.3. Nucleophilic and Electrophilic F-Transfer

The fluorine-containing nitrogen compounds to be discussed here represent a very heterogeneous group of substances with various modes of reaction. The F-atom to be transferred need not be bound to the nitrogen. Since all the reagents are comparatively recent, the classification into classical and modern reactions is superfluous.

### 4.3.1. Cyanuric Fluoride

This compound, easily prepared by chlorine-fluorine metathesis (see Section 4.1.1), converts carboxylic acids such as *(79)* and *(80)* mildly and selectively into the acid fluorides[280].



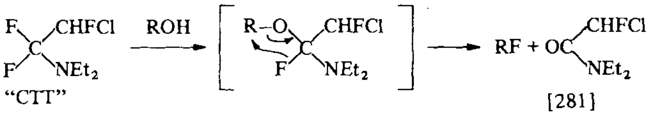
$$\underset{(80)}{\text{PhCH=CHCOOH}} \xrightarrow[\text{CH}_3\text{CN/Pyridine}]{(\text{FCN})_3} \underset{95\%}{\text{PhCH=CHCOF}}$$

As the examples show, CC- and CO-double bonds, alcohol groups, and aryl groups remain unaffected.

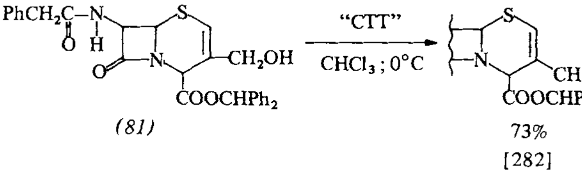
### 4.3.2. 2-Chloro-1,1,2-trifluorotriethylamine, "CTT"

This partly halogenated amine has gained the widest application of the fluorine-containing nitrogen compounds. It is particularly suitable for the fluorination of natural products, since even under mild conditions it replaces alcoholic OH-groups, *e.g.* in the cephalosporin derivative *(81)*.

$$\text{CFCl=CF}_2 + \text{Et}_2\text{NH} \longrightarrow \underset{\text{"CTT", 61\%}}{\text{HClFC–CF}_2\text{–N(C}_2\text{H}_5)_2}$$



[281]

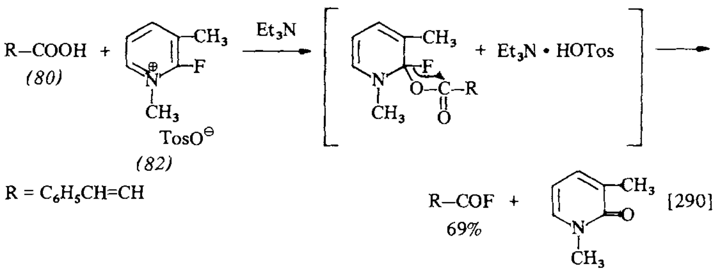


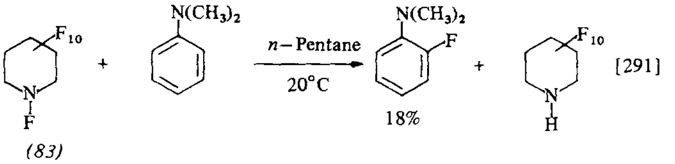
*(81)* 73% [282]

"CTT" fluorinates OH-groups at the bridge-head positions of bicyclic compounds[283] and selectively in the 7-position of norbornadiene[284]. The reagent has proved suitable for the fluorination of complicated substances such as brefeldin A[285] and gibberellin[286], and for the fluorination of kaurenoids[287]. "Bromofluorination" (addition of formal BrF to a double bond in steroids[288]) with "CTT" and *N*-bromoacetamide represents an exception. A "CTT"-analog has recently been obtained from perfluoropropene and diethylamine[289]. This reagent fluorinates cholesterol in a yield of 83%.

### 4.3.3. 2-Fluoro-1,3-dimethylpyridinium Tosylate *(82)* and Perfluoropiperidine *(83)*

The action mechanism of these rather exotic reagents may be demonstrated on one example of each.

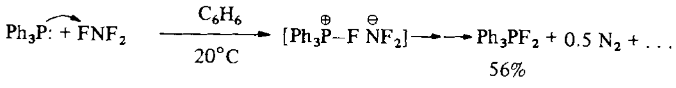




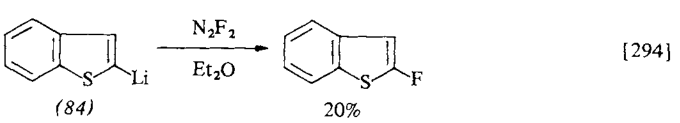
With the piperidine derivative *(83)* the ESR spectra indicate a free radical mechanism. It was already known in 1964 that *(83)* can transfer *N*-bound fluorine to a carbanion[292].

### 4.3.4. Nitrogen Trifluoride and Dinitrogen Difluoride

In conclusion, reference may be made to two remarkable curiosities: even such an inert compound as $NF_3$ can fluorinate suitable substrates, and the same is true of $N_2F_2$.



$$(\text{Me}_2\text{N})_3\text{P} + \text{NF}_3 \xrightarrow[20\text{–}45^\circ\text{C}]{} \underset{80\%}{(\text{Me}_2\text{N})_3\text{PF}_2 + 0.5\ \text{N}_2 + \ldots} \quad [293]$$

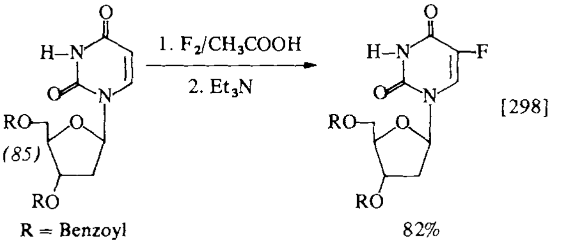


## 4.4. Electrophilic and Radical F-Transfer

### 4.4.1. Elementary Fluorine

*Classical reactions:* The conventional use of $F_2$ has already been discussed in Section 3.1. A characteristic feature of all these reactions is their radical mechanism, with the typically wide range of products. For this reason elementary fluorine has long been considered unsuitable for selective fluorinations.

*Modern techniques:* At the beginning of the 'seventies *Meinert et al.*[295] reported selective fluorination of (partially protected) uracil, uridine, and 2'-deoxyuridine *(85)* in the reactive 5-position of the pyrimidine ring, using an $F_2$-pyridine adduct. The adduct is obtained in the form of a colorless solid which is stable up to $-2\,^\circ C$ by passing fluorine diluted with $N_2$ into a solution of pyridine in a chlorofluorohydrocarbon at $-78\,^\circ C$[296]. The adduct is believed to have an ionic structure, the fluorination being apparently ionic (electrophilic). In the case of uracil the reaction is quantitative. Extension of the investigations to other solvents[297] revealed that glacial acetic is most advantageous, although only if it is saturated with $F_2$ before the addition of the substrate (nucleobase or nucleoside) ("fluorinated acetic acid"). In contrast, complex reactions occur if the $F_2$ is introduced into the reactant-solvent mixture. It has not yet been clarified whether this means that the actual fluorinating species is not $F_2$ itself but a reactive intermediate of a reaction between fluorine and acetic acid (*e.g.* "$CH_3COOF$"). "F" and "$CH_3COO$" probably first add to the CC-double bond of the nucleobase. In the case of nucleosides the corresponding adducts could be detected at an early stage[297], and they have since also been isolated from uracil[299]. The second step of the reaction consists in the elimination of acetic acid which often has to be induced by a base, resulting over-all in an apparently direct replacement of a vinyl hydrogen by fluorine. Other nucleosides have also been fluorinated by the described process[300,301].

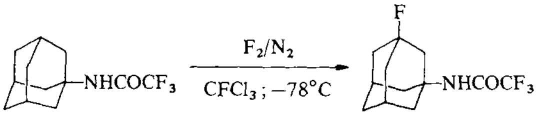


*(85)*

R = Benzoyl

82%

Another method of selective fluorination with elementary fluorine was discovered by *Barton et al.*[302]. In the presence of radical receptors, in suitable solvents, and at low temperatures fluorine diluted with $N_2$ selectively substitutes tertiary hydrogen in steroids[303] and adamantane derivatives such as *(186)*[304].



*(86)*

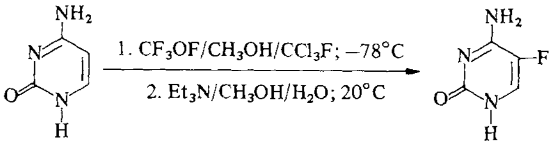
83%

Fluorinations with elementary fluorine have also been successfully tried out in carbohydrate chemistry[305]; the method is suitable for the selective oxidative halogenation of heteroatoms in organic compounds without affecting the C—H, C—halogen, or C=C bonds[306,307]. The fluorination of arenes with elementary fluorine (H→F substitution) has already also been the subject of careful mechanistic studies[308]. Moreover, the reaction of $F_2$ with carbanionic centers has established conclusively the transfer of positively polarized fluorine[309].

### 4.4.2. Trifluorofluoroxymethane and other Fluoroxy Compounds

A classification into classical and modern techniques is again superfluous for $CF_3OF$, since all the results discussed here have been published in the last decade. Trifluorofluoroxymethane ("trifluoromethyl hypofluorite") has two fundamentally different possible reactions: electrophilic and radical F-transfer. In turn, among the ionic reactions a distinction must be drawn between electrophilic addition to double-bond systems and electrophilic substitution of a hydrogen atom at an $sp^3$-hybridized carbon.

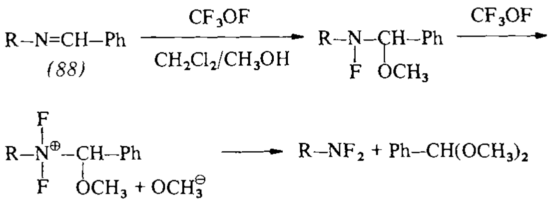
*Addition to double-bond systems (ionic mechanism):* When mixed with $CF_3OF$ in a suitable solvent mixture at low temperature, and after working-up under alkaline conditions, cytosine *(87)* gives a high yield of 5-fluorocytosine[310].



*(87)*

85%

This process had already been used earlier in the synthesis of 5-fluorouracil *(6)*[311,312], pharmacologically a highly interesting substance, and the corresponding complete uracil nucleotide[313]. Though the replacement of a vinyl hydrogen by fluorine is apparently direct, in truth—similarly to the situation with the analogous examples with $F_2$ described above—this is an addition-elimination reaction. Positively polarized fluorine first opens the CC double bond and the carbenium ion formed can then react with the nucleophiles present ($CF_3O^-$, $F^-$, or $CH_3O^-$) to give a saturated compound. Elimination of the same nucleophile in combination with the H-atom geminal to the fluorine (*e.g.* as $CH_3OH$) yields the final product. This reaction pathway is confirmed by results from arene chemistry. $CF_3OF$ can introduce fluorine into aromatic systems[235] and thus simulate direct H-substitution. Careful investigations into the fluorination of specially carcinogenic arenes (reaction in the K region)[314,315] show that here too the primary reaction is an addition with loss of aromaticity of the ring in question. A similar situation applies in the reaction of benzofuran and indole with $CF_3OF$[316]. The fluorination of griseofulvin[317] is also a clearly understandable process, whereas in steroid chemistry limits are revealed: nonactivated double bonds add $CF_3OF$ to give complex product mixtures[319]. Unsaturated sugars can likewise be fluorinated with $CF_3OF$[320-324]. Not only the CC- but also the CN-double bond, *e.g.* in *(88)*, reacts with $CF_3OF$ in the manner described but with subsequent cleavage[324a].



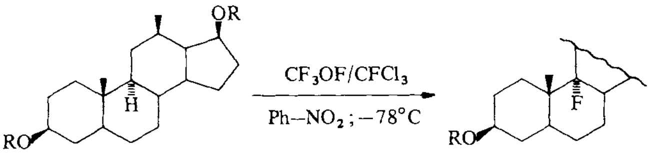
$$R{-}N{=}CH{-}Ph \xrightarrow[CH_2Cl_2/CH_3OH]{CF_3OF} R{-}N(F){-}CH(OCH_3){-}Ph \xrightarrow{CF_3OF} R{-}N^{\oplus}F_2{-}CH(OCH_3){-}Ph + OCH_3^{\ominus} \longrightarrow R{-}NF_2 + Ph{-}CH(OCH_3)_2$$

(88)

R = Adamantyl

The fluorination of α-diazoketones, which can lead to α,α-difluoroketones or to α-fluoro-α-trifluoromethoxyketones[325,326] represents an exceptional case of electrophilic addition to CN double bonds.

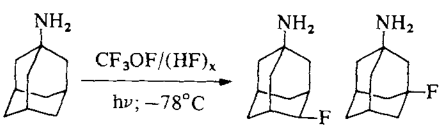
*Substitution at an $sp^3$-hybridized carbon (ionic mechanism):* $CF_3OF$ reacts with adamantane in $CFCl_3$ or $CH_2Cl_2$ at −25 °C to give mainly 1-fluoroadamantane[304]. On the basis of the influence of polar substituents on the reaction rate, of the high selectivity, and the pronounced tendency toward monosubstitution on tertiary carbons, an electrophilic reaction mechanism must be assumed. The reaction starts with an electrophilic attack of positively polarized fluorine on the C—H-σ bond. An analogous reaction occurs with complicated substrates, *e.g.* the steroid *(89)*[303]. Once again a tertiary H-Atom is here substituted.



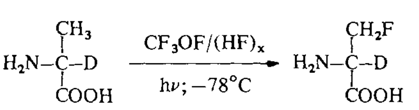
*(89)* 34%

R = $CF_3CO$

*Photofluorination with $CF_3OF$ (radical mechanism):* With 1-aminoadamantane *(14)*[327], as a substrate, radical fluorination with $CF_3OF$ in the liquid phase [$(HF)_x$] yields only two monofluorinated products *(90)* and *(91)* in more or less comparable quantities; the pharmacologically interesting 2-deuterio-3-fluoro-D-alanine *(7)* ("DFA") is formed directly from the nonfluorinated compound in an acceptable yield[21].



*(14)* *(90)*, 27% *(91)*, 25%



$$H_2N{-}C(CH_3)(D){-}COOH \xrightarrow[h\nu;\,-78^\circ C]{CF_3OF/(HF)_x} H_2N{-}C(CH_2F)(D){-}COOH$$

"DFA" *(7)*, 59%

The remarkable fact is that neither the unprotected amino group nor the carboxylic acid group is attacked, which at least in part explains the importance of hydrogen fluoride as a solvent. In place of H-atoms SH-groups are also replaced by F in mercaptoamino acids during photofluorination[328], a reaction pathway known as "fluorodesulfurization". The reaction can be carried out with $CF_3OF$, but only when readily oxidizable secondary and tertiary SH-groups are present; $F_2$ must be used in the case of primary thiols[235].

### 4.4.3. Other Fluoroxy Compounds

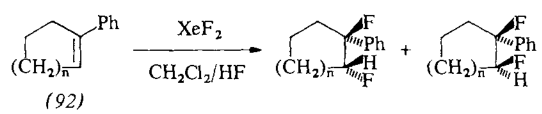
The next higher homolog of $CF_3OF$, $C_2F_5OF$, is formed in addition to $CF_3CF(OF)_2$ in the reaction of $F_2$ with $CF_3COONa$ at low temperatures. The compound can be used to prepare α-fluoroketones from enol acetates *in situ*[329]. The process is also useful in steroid chemistry[330,331]. $CF_2(OF)_2$ fluorinates steroids in the tertiary position[331a] and exchanges N-bound hydrogen for fluorine similarly to $CF_3OF$[331b]. The inorganic parent compound of the fluoroxy compounds described here, oxygen difluoride $OF_2$, itself has fluorinating properties and acts quite selectively under mild conditions (substrate: barbituric acid)[299].

### 4.4.4. Noble-Gas Fluorides[332]

$XeF_2$ and its homologs are also a recent class of fluorinating agents. The first systematic investigations reach back less than 9 years, and only very recently has a dramatic increase in relevant publications taken place. The fact that fluorinations with $XeF_2$ proceed *via* radical cations can be taken as certain, which explains the significance of acid catalysts (HF, $CF_3COOH$). Xenon difluoride, which is available commercially, enters into essentially three types of reaction: it can fluorinate CC-double bonds oxidatively and it can replace aliphatic or aromatic H-atoms with F.

The oxidizing fluorinations on heteroatoms in organic compounds deserve a brief mention because new fluorinating agents are often thus obtained. From experimental findings it can be concluded that when an arene and alkene are present at the same time, the alkene is the more reactive. The comparison of aliphatic and aromatic hydrogen, on the other hand, is less clear.

*Reactions of alkenes and alkynes with $XeF_2$:* The reaction of $XeF_2$ with a cyclic alkene of the type of *(92)* in the presence of traces of HF[333] gives a mixture of products whose composition varies with the ring size of the alkene. The proportion of *cis*-isomers increases with increasing *n*. The cationic reaction mechanism is based on investigations on

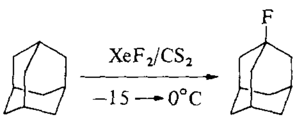


*(92)*

phenyl-substituted ethylenes[334-337] and norbornenes[338,339]. From the preparative standpoint, the rearrangements observed constitute a restriction. Halogen-substituted alkenes react in a similar fashion[340,341]. Lewis acids such as $BF_3$ can also catalyze the reaction[342]. Finally, mention should be made of the bromofluorination of alkenes with $XeF_2/Br_2$[343] and the addition to an alkyne to give a tetrafluorinated product[344].

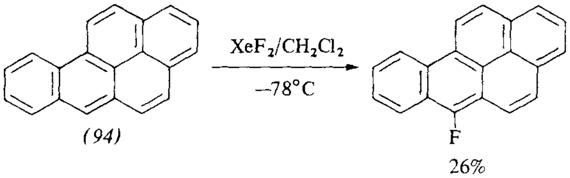
*Reactions of saturated compounds with $XeF_2$:* One noteworthy example is the fluorination of adamantane *(93)*[345].

Further uses of this method relate to linear and cyclic sulfanes[346] and to hexamethylbenzene[347].



(93)

*Reactions of arenes with $XeF_2$:* The fluorination of benzene with $XeF_2$ has been studied in detail[348]: the products formed are mono- and difluorinated benzenes and fluorinated biphenyls. Single and multiple substitution has also been observed with naphthalene[349]. Oxidative fluorination also occurs with anthracene and phenanthrene[350-352]. Besides the monofluorination of pyrene[353], the reaction with carcinogenic arenes such as *(94)* is of primary interest[354].

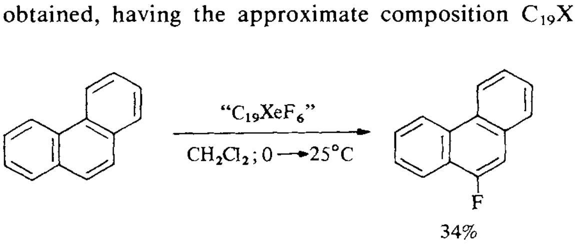


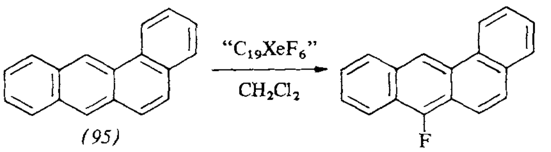
(94)

$OCH_3$- and OH-substituted benzene and naphthalene can even be reacted without catalysis by HF[355]; acenaphthylene reacts at the 1,2-double bond[356]; indane only in the aromatic part of the molecule[357]. It is worth noting that $XeF_2$ fluorinates bromopentafluorobenzene oxidatively with $BF_3$ catalysis[358] and oxidizes hydroquinone to the quinone[359]. Heterocycles such as pyridine and quinoline react smoothly at low temperatures[360], amino groups also remaining intact.

*Fluorination on heteroatoms with $XeF_2$:* A simple reaction leads to the production of $Ph_2SF_2$ *(68)*[361,362] ("solid $SF_4$"; cf. Section 4.1.5, reaction of $Ph_2S$ with $XeF_2$). Arene-bound $CF_3S$- and $CF_3Se$-groups are converted by $XeF_2$ quantitatively into the corresponding $CF_3XF_2$ groups (X = S, Se)[363]. With $XeF_2$, inorganic halides and carbonyl compounds give fluorides of elements in higher states of oxidation[364,365].

*Other noble-gas fluorides:* the aggressive xenon hexafluoride can be "tamed" by its addition to graphite to such an extent that a compound with a limited stability in air is obtained, having the approximate composition $C_{19}XeF_6$.





(95)

The adduct exerts a fluorinating action and can fluorinate phenanthrene[366] and the carcinogen benzanthracene *(95)*[367].

$XeOF_4$ in combination with graphite ("$C_{8.7}XeOF_4$") behaves in a similar fashion[368]. Interestingly enough, "$C_{19}XeF_6$" fluorinates uracil in 90% yield to 5-fluorouracil *(6)*[369]. Mention should also be made of the difficultly accessible krypton difluoride[370], though this has not yet been used in organic chemistry. $KrF_2$ converts a number of elements into fluorides of the highest oxidation state, *e.g.* $I_2$ into $IF_7$ and Au into $AuF_6^-$.

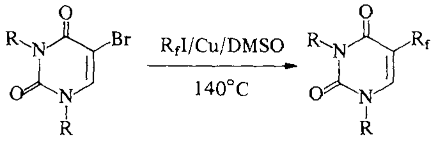
## 5. Preparation of Compounds with Highly Fluorinated Functional Groups

A distinction should be drawn between the methods for the monofluorination of complicated molecules discussed in Section 4 and methods in which fluorine-containing—usually highly fluorinated—groups are introduced into organic compounds. In particular, one should distinguish the preparations of $CF_3$- (and $R_f$-), —$CF_2$-, $CF_3O$- (and $R_fO$-), $CF_3S$- (and $R_fS$-) and $CF_3Se$-substituted species (here $R_f$ denotes a highly fluorinated group).

### 5.1. $CF_3$-(and $R_f$-)Substitution

#### 5.1.1. Nucleophilic Substitution and Related Reactions

Halouracils such as *(96)* react with $R_fI$ in the presence of copper in the sense of a Wurtz reaction[371] (DMSO = dimethyl sulfoxide). Analogous reactions take place with 2-bromobenzofuran[213] and with alkyl halides[372]. Vinyl hydrogens can also be replaced by $R_f$-groups. Similarly, 5-$R_f$-uracil can be produced from uracil [in place of the bromine compound *(96)*] and $R_fCu$ (prepared from $R_fI$ and a specially activated Cu bronze)[373].



(96)

$R = CH_3, C_6H_5CH_2; R_f = C_3F_7$

This reaction is also possible with the complete deoxyribonucleoside[374]; its mechanism has still not been clarified. Some of the products are cytostatic. With $CF_3I$ in the presence of $Ph_3P$, nickelocene gives $CF_3$-substituted cyclopentadiene in 55—60% yield[375].

#### 5.1.2. Radical Reactions

The homolytic cleavage of $CF_3I$ by ultraviolet light with subsequent addition of the radicals to olefinic double bonds[376] is, so to speak, mentioned here only to be dismissed, because of the triviality of the method. The processes with electrolytic production of $CF_3$ radicals are more interesting. These radicals are produced by anodic discharge and decarboxylation of $CF_3CO_2^-$ and add readily to ethylene and 1,1-difluoroethylene to give $CF_3$-substituted oligomers[377]. A variety of other alkenes react in a similar fashion[378]. $CF_3$ radicals can also enter into substitution reactions. Electrolytically produced, they substitute vinyl hydrogen atoms, *e.g.* in the 5-position of uracil[379].

$CF_3$ radicals produced in plasma substitute halogens in aliphatic and aromatic systems[380]. Finally, the following reaction is worth mentioning[381]:

$$R{-}NH_2 \xrightarrow{CF_3{-}NO} \underset{(97)}{R{-}N{=}N{-}CF_3} \xrightarrow{h\nu} R{-}CF_3$$

This reaction is possible with a great number of linear and polycyclic alkylamines. The diazo compound *(97)* can be isolated and in highly viscous solvents reacted by photolysis in the sense of a "cage recombination".

### 5.1.3. Other Reactions

The reaction between arenecarboxylic acid chlorides *(98)* and perfluoropropene is initiated by fluoride ions[382]:

$$\underset{(98)}{Aryl{-}CO{-}Cl} + CF_3CF{=}CF_2 \xrightarrow{F^{\ominus}} Aryl{-}CO{-}CF(CF_3)_2$$

The yields vary between 3 and 66%, depending on the nature and the substituents of the arene. Polyfluorinated acetone derivatives react with the Wittig compounds of steroids to give fluorinated desmosterols[383].

## 5.2. Introduction of the $CF_2$ Group

The $CF_2$ group (or CFX, X = halogen) is produced as a carbene and adds preferentially to double bonds. Ring opening of the cyclopropane produced then allows access to alkenes, which are often biologically important[87]. The carbenes are obtainable from chlorofluoromethanes (*e.g.* $CCl_2F_2$) with bases (*e.g.* $LiCH_3$)[384,385]. Phosphonium salts yield $:CF_2$ in a simple manner[386,387]

$$Ph_3P^{\oplus}CF_2\,Br\;Br^{\ominus} + KF \rightarrow Ph_3PFBr + KBr + :CF_2$$

The carbene can be generated *in situ* from $Ph_3P$ and $CF_2X_2$ (X = Cl, Br).

## 5.3. Introduction of the $CF_3O$ Group

The direct path of introducing the $CF_3O$ group into arenes, reaction with $CF_3OF$, yields no more than about 10% of the desired products[235]. The "single-vessel reaction" of hydroxyarenes + $CCl_4$ + HF, already mentioned in Section 4.1.2, is an elegant method that remains applicable in the presence of many substituents[172]. Partly fluorinated methoxy groups are obtained by condensation of a phenolic OH, *e.g.* with $CH_2F_2$ (performed on pyrimidine derivatives)[388].

## 5.4. Introduction of the $CF_3S$ Group and its Analogues

### 5.4.1. Electrophilic Substitution

The starting compound is a sulfenic acid chloride, for example $CF_3SCl$. This reacts in the sense of a Friedel-Crafts acylation in the presence of acid catalysts, *e.g.* with substituted benzenes[389]. The electrophilic route is by far the most frequently used[390], because of the reactivity and the easy accessibility of the sulfenyl chlorides.

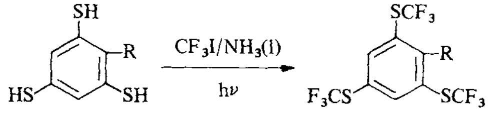
Heterocycles such as furan[13,391], pyrrole[14], imidazole[13,392], and (as an organometallic compound) pyridine[393] can be reacted. Partly halogenated sulfenyl chlorides[393a] and $C_6F_5SCl$[394] react similarly.

### 5.4.2. Nucleophilic Substitution

Suitable aromatic systems such as pyridine[395], quinoline[396], and appropriately activated benzene derivatives[397] can be reacted in the form of their halogen compounds with $CF_3S$-metal compounds (usually $CuSCF_3$).

### 5.4.3. Radical Substitution

This unusual reaction route will be illustrated using the example of photochemical reaction of the trithiol *(99)*[398] with illumination by a mercury vapor lamp. The reaction, which is carried out in liquid ammonia, apparently proceeds *via* a radical-ionic mechanism[399]. Similar reactions are possible with pyrimidines[400] and mercaptoacetic acid[401].



*(99)*

R = OH, $NH_2$, $CH_3$, Cl

37–90%

## 5.5. Introduction of the $CF_3Se$ Group

The processes resemble those for the introduction of the $CF_3S$ group, but much less work has been done on $CF_3Se$ than on $CF_3S$.

### 5.5.1. Electrophilic Substitution

$CF_3SeCl$ reacts with arenes similarly to $CF_3SCl$[402]. $CF_3SeBr$ reacts analogously to $CF_3SCl$ with furan and thiophene[13].

### 5.5.2. Radical Substitution

Like the homologous sulfur compounds, the aromatic selenols react with $CF_3I$ in liquid $NH_3$ under ultraviolet light to give the corresponding $CF_3Se$-compounds[403].

## 6. Summary and Outlook

The significance that fluorinated compounds have now gained in clinical medicine, in phytomedicine and in technology in general was already indicated at the beginning of this review, and there is little doubt that this significance will increase further in the future. In parallel with this, the search for selective, efficient, and "simple" fluorinating agents must inevitably gather momentum.

New methods and techniques will certainly be developed by trying various modifications of the known reagents, as shown by "organo-substitution" (*e.g.* in $SbF_5$ and $SF_4$) and "homologization" ($SF_4 \rightarrow SeF_4$). On the other hand, it pays to explore completely "new" and unusual compounds or substance classes, as has been demonstrated in the cases of $UF_6$, the fluoroxy compounds, and the noble-gas fluorides.

It must be admitted that not all the reactions presented in this review can automatically be generalized, for it is precisely biologically important substrates that are often multifunctional. The group to be fluorinated cannot, therefore, be considered in isolation, and—*e.g.* in the case of cholesterol—one cannot talk simply of "fluorination of an alcohol". At present there are virtually no universal recipes; every new compound is a new challenge that must be faced with a sound experimental attitude. "Instant successes" are rare. Thus, the present review should be regarded only as an aid to orientation, hopefully helping one to formulate the initial strategy for the solution of a particular problem.

The application of known fluorinating agents to untried substrates and thorough documentation of the results may appear to be dull work but it makes an immensely important contribution to opening up this interesting borderland between classical inorganic and organic chemistry.

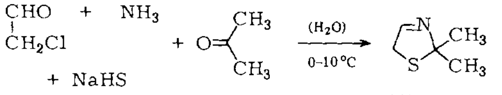
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

## Facile Synthesis of Racemic Cysteine

By *Jürgen Martens*, *Heribert Offermanns*, and
*Paul Scherberich*[*]

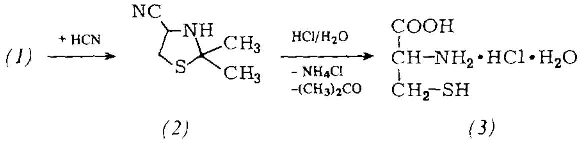
Until now racemic cysteine has only been synthetically accessible *via* expensive multi-step syntheses[1].

In the course of our investigations on the synthesis of natural and unnatural amino acids[2] and amino acid derivatives[3] we have now found a facile and efficient synthesis for DL-cysteine hydrochloride · $H_2O$ *(3)*. The key intermediate, 2,2-dimethyl-3-thiazoline *(1)*, can be obtained in 92% yield in a one-pot reaction from chloroacetaldehyde, sodium hydrogen sulfide, ammonia and acetone. This reaction is based on the fundamental studies of *Asinger et al.*[4].



*(1)*

Anhydrous hydrocyanic acid adds to the azomethine group of *(1)* to give the 2,2-dimethylthiazolidine-4-carbonitrile *(2)* in almost quantitative yield.



*(2)* *(3)*

The crude thiazolidine *(2)* can be directly further reacted. Using aqueous hydrochloric acid, the desired *(3)* is obtained in 70% yield (relative to *(1)*) in a one-pot reaction[5].

*Procedure*

*(1)*: 350 mg of a 45% aqueous solution of chloroacetaldehyde (2.0 mol) is added between 0 and 10 °C, over 45 min, to a suspension of sodium hydrogen sulfide (135 g, 2.4 mol) in acetone (450 mL, 6.1 mol), 235 g water, and ammonia (93 g, 5.5 mol). After 25 min at 5—10 °C, the organic and aqueous phases are separated. Fractional distillation of the organic phase (88—89 °C/100 mbar) gives 106 g *(1)* (92%) as a colorless liquid.

*(2)*: Hydrocyanic acid (50 mL, 1.3 mol) is added over 60 min to a stirred solution of *(1)* (115 g, 1 mol) in 100 mL methanol at 5—10 °C. After 30 min at 15—20 °C, the solution of *(2)* obtained is directly further reacted.

*(3)*: A solution of *(2)*, as prepared above, is dropped over 60 min into 1000 mL (*ca.* 11 mol) conc. hydrochloric acid at 20—30 °C. After 3 h stirring at 40—50 °C the mixture is diluted with 600 mL water, the methanol and acetone distilled off, the resulting solution refluxed for 4—5 h, clarified with activated charcoal and the solvent removed. Ammonium chloride, which does not dissolve upon digestion of the residue in 400 mL methanol, is filtered off. The methanolic filtrate is evaporated to dryness and the residue recrystallized from 20% hydrochloric acid; *(3)* forms thick colorless crystals. The latter are suction-filtered, washed with cold 20% hydrochloric acid, and dried in a fluidized bed dryer at 20—40 °C. 122.9 g (70%) of *(3)* is obtained from two crystallization fractions; the product is found to be pure by thin layer chromatography.

## New Tungsten-Iridium Dinuclear Complexes Containing Cyclopentadienyl and Hydrido Bridges

By *Paul S. Pregosin*, *Antonio Togni*, and
*Luigi M. Venanzi*[*]

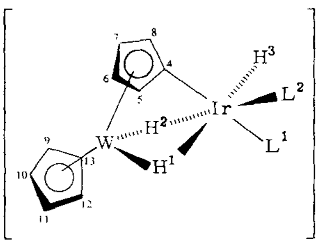
We have previously shown that neutral monomeric hydrido complexes of platinum(II)[1a] and iridium(III)[1b] react with cationic species to form dimeric complexes containing one or more bridging hydrido ligands.

As an extension of this work we report here the new dinuclear complex *(1a)* obtained by reacting *(2)* with *(3a)*.

---

[*] Prof. Dr. L. M. Venanzi, Dr. P. S. Pregosin, A. Togni (Ciba-Geigy-Fellow)
Laboratorium für Anorganische Chemie
ETH-Zentrum, Universitätstrasse 6, CH-8092 Zürich (Switzerland)

Cation (3a) is produced *in situ* as previously described for the formation of (3b) and (3c)[2].



$PF_6$ (1a), L = $PEt_3$

$[WH_2(\eta^5\text{-}C_5H_5)_2]$ (2)

$[IrH_2L_2(EtOH)_2]PF_6$
(3a), L = $PEt_3$; (3b), L = $PMePh_2$;
(3c), L = $PPh_3$

Compound (1a) is a green solid and is stable in air for several days. It is moderately soluble only in polar organic solvents and the solutions obtained decompose rapidly in the presence of oxygen.

Support for the proposed structure for (1a) stems from its $^1H$-, $^{13}C$- and $^{31}P$-NMR spectra (in $CD_2Cl_2$):

$^1H$-NMR: $\delta = -17.57$ [H1, $^2J(H1,H2) = 3.7$ Hz, $^1J(W,H1) = 95.2$ Hz]; $-18.86$ [H2, $^2J(H1,H2) = {}^2J(H2,H3) = {}^2J(H2,P1) = 3.7$ Hz, $^2J(H2,P2) = 47.6$ Hz, $^1J(W,H2) = 92.4$ Hz]; $-23.78$ [H3, $^2J(H3,P1)$, $^2J(H3,P2) = 16.8$, 28.4 Hz]; 6.42 [(1H), 6.36 (1H), 5.09 (2H), H5—H8, 5.34 (5H), H9—H13; $^{13}C$-NMR: $\delta = 85.5$ [C9—C13]; 110.3 [C4, $^2J(P1,C4) = 84.2$ Hz, $^2J(P2,C4) = 8.3$ Hz]; 95.1 [C5 or C8, $^3J(P1,C) = 7.4$ Hz]; 93.6 [C8 or C5, $^3J(P1,C) = 5.5$ Hz]; 91.2 [C6 or C7]; 89.9 [C7 or C6]; 20.3, 19.8, [$PCH_2$, $^1J(P,C) = 25$ Hz]; 8.0, 7.8 [$PCH_2CH_3$]. $^{31}P$-NMR: $\delta = 6.2$ [P1, $^2J(P1,P2) = 11.8$ Hz]; 4.7 [P2].

The $^{31}P\{^1H\}$-NMR spectrum of the two non-equivalent tertiary phosphorus atoms appears as an AB pattern. The magnitude of $^2J(P1,P2)$ is consistent with a *pseudo-cis*-orientation of the phosphorus atoms. The $^1H$-NMR spectrum between $\delta = -17$ and $-24$ ppm comprises three groups of resonances, which may be assigned to H1, H2 and H3. The two lower field signals are assigned to H1 and H2 since they show $^{183}W$-satellites (natural abundance of $^{183}W = 14.3\%$) with $J(W,H) \approx 90$ Hz, consistent with one-bond interactions. Reported $^1J(W,H)$ values in related complexes are 107 Hz for (4)[3] and 60.3 and 59.7 Hz for (5a) and (5b)[4] respectively. A further relatively large splitting of the H2 signal stems from P2, and hence it can be concluded that these two atoms occupy a *pseudo-trans* arrangement. H3 couples to two *cis*-phosphorus atoms and H1 but, interestingly, the *trans*-coupling $^2J(H1,H3)$ is quite small (< 1.5 Hz).

$[(\eta^5\text{-}C_5H_5)_2W(\mu\text{-}H)_2Rh(PPh_3)_2]PF_6$ (4)
$[(\eta^5\text{-}C_5H_5)_2W(\mu\text{-}H)_2PtR(PEt_3)_2]BF_4$ (5a), R = H
(5b), R = $C_6H_5$

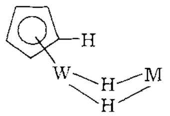
The assignment of C5 and C8 in the $^{13}C\{^1H\}$-NMR spectrum follows from the suggestions of *Davison* and *Wreford*[5], while the signal at $\delta = 110.3$ may be assigned on the basis of its position[6], spin-lattice relaxation time and $^{31}P$ coupling pattern.

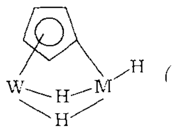
Complex (1a) appears to be a member of a general class of compounds of type (1); (1b) and (1c) can be prepared in a similar way to (1a) (L = $PMe_2Ph$ or $PMePh_2$).

To our knowledge, the complexes of type (1) are the first examples of compounds containing both "$C_5H_4^{2-}$" and "$H^-$" bridging ligands. Although ($\eta^5:\eta^1$-$C_5H_4$) bridges have been observed in complexes of zirconium[6], molybdenum and tungsten[7,8], when bridging hydrides are present[5,8], the cyclopentadienyl moiety is present as a bridging $\eta^5:\eta^5$-fulvalene.

The mechanistic pathway leading to (1) is likely to involve the initial formation of $[(\eta^5\text{-}C_5H_5)_2W(\mu\text{-}H)_2\text{-}Ir(PEt_3)_2]^+$, which is analogous to (4) and contains the structural unit (A), followed by the oxidative addition of a cyclopentadienyl C—H bond, resulting in the formation of structural unit (B). (Hydrogen-abstraction reactions occur easily and often irreversibly in $Ir^I$ complexes[9].) A species of type (B) (M = Rh) has been postulated to explain the H/D-exchange observed in compound (4)[3].

(A)





(B)

## *Experimental*

A vigorously stirred deep-red suspension of $[Ir(cod)(PEt_3)_2]PF_6$ (0.539 g, 0.79 mmol) (cod = 1,5-cyclooctadiene) in 25 mL EtOH at 0 °C was treated with $H_2$ for 15 min. A solution of (2) (0.250 g, 0.79 mmol) in 15 mL EtOH was added to the resulting clear pale-yellow solution and stirring continued for an additional 0.5 h. Solvent was evaporated (with cooling) until precipitation began and this was followed by rewarming to room temperature and subsequent recrystallization at −22°. The green microcrystalline (1a) formed was recrystallized again from EtOH to afford the product: yield 0.218 g (31%).

# Double Ring-Opening of Bicyclic Oxaziridines to *N*-(3-Oxopropyl)amides by Iron(II) Sulfate

By *David St. C. Black* and *Lynn M. Johnstone*[*]

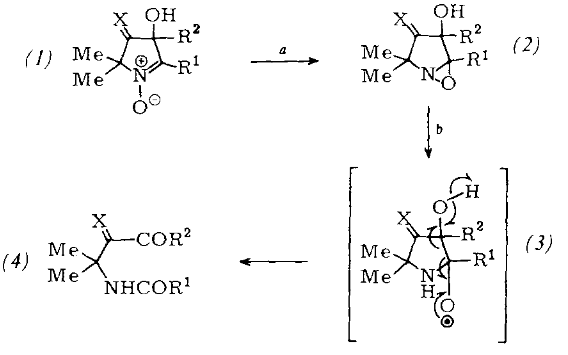
*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

Iron(II) sulfate has been shown to cleave *C*-alkyl-, *C*-aryl-[1, 2] and *C*-cyano-[3] substituted oxaziridines, the nature of the products depending on the particular substitution pattern. We now report that oxaziridines of type (2),

---

[*] Dr. D. St. C. Black, L. M. Johnstone
Department of Chemistry, Monash University
Clayton, Vic. 3168 (Australia)

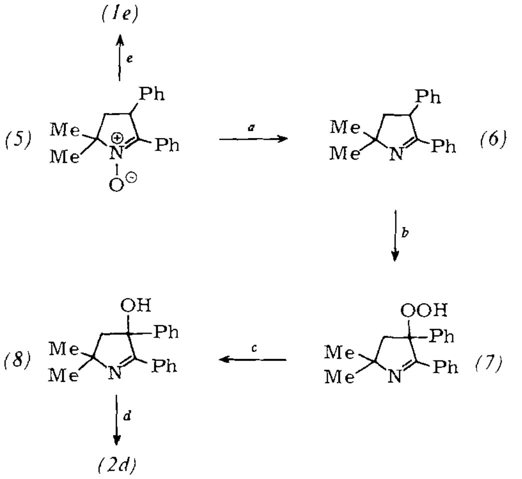
whose *C*-hydroxymethylene substituents form part of a pyrrolidine ring, undergo a reaction with iron(II) sulfate which results in opening of both rings to afford the oxoamides *(4)* (Scheme 1). An isolated example of a similar reaction which has, however a different outcome, has been previously reported by *Bischoff*[4].



| (1)—(4) | X | R¹ | R² |
|---|---|---|---|
| *a* | H, H | *t*Bu | Me |
| *b* | H, H | Ph | Me |
| *c* | H, H | Ph | Et |
| *d* | H, H | Ph | Ph |
| *e* | O | Ph | Ph |

Scheme 1. *a)*: hν, benzene, 1—12 h. *b)*: $FeSO_4$, aqueous EtOH, 2 h.

The oxaziridines *(2a—e)* are formed as isomeric mixtures by photorearrangement ($\lambda_{max}$ = 254 or 300 nm, benzene) of the related cyclic nitrones *(1a—e)*. The known nitrones *(1a—d)*[5] can be prepared by Grignard reactions from the corresponding 3-oxo-derivatives. However, oxaziridine *(2d)* is more readily available from the method shown in Scheme 2. It is noteworthy that, on attempted recrystallization from hexane in air, the 1-pyrroline *(6)* was rapidly transformed into the stable hydroperoxide *(7)*. Unlike the 3*H*-indolyl hydroperoxides[6], *(7)* did not undergo thermal CC-bond cleavage, but afforded the alcohol *(8)* in low yield. Yields were improved by addition of triethyl phosphite. Peracid oxidation of *(8)* yielded isomerically pure *(2d)* (with *cis*-phenyl groups).—The 4-oxonitrone *(1e)* ($\nu_{max}$ = 1776 $cm^{-1}$ (CO)) can be prepared in 36% yield as shown in Scheme 2.



Scheme 2. *a:* $Fe(CO)_5$/*n*$Bu_2O$, reflux, 24 h. *b:* $O_2$, hexane, reflux, 2 h. *c:* $(EtO)_3P$, tetrahydrofuran, room temperature, 1 h. *d:* 2% $CH_3CO_3H$ in $CH_3CO_2H$, room temperature, 16 h. *e:* $HNO_3$, $CH_3CN$, reflux, 1 h.

The oxoamides *(4)* show infrared absorptions characteristic of the ketone and amide groups. Some other physical data are presented in Table 1.

Table 1. Selected physical data of compounds *(4)*, *(7)* and *(8)*.

| Cpd. | Yield [%] | M.p. [°C] | ¹H-NMR ($CDCl_3$), δ-values *gem*-$Me_2$ | —$CH_2$— |
|---|---|---|---|---|
| *(4a)* | 92 [a] | 54—55 | 1.40 | 2.92 |
| *(4b)* [7] | 88 [a] | 98—100 | 1.53 | 3.00 |
| *(4c)* | 83 [a] | [e] | 1.53 | 2.95 |
| *(4d)* | 50 [b] | 82—84 | 1.63 | 3.51 |
| *(4e)* | 55 [a] | 135—136 | 1.77 | — |
| *(7)* | 74 [c] | 139—142 | 1.28, 1.41 [f] | 2.10, 2.90 ($J_{AB}$ = 14 Hz) |
| *(8)* | 74 [d] | 147—148 | 1.40, 1.47 | 2.33 |

[a] From nitrones *(1)*. [b] From oxaziridine *(2d)*. [c] From the 1-pyrroline *(6)*. [d] From the hydroperoxide *(7)*. [e] B.p. = 70—82 °C/1 torr (air bath temp.). [f] In [$D_6$]DMSO.

It is proposed that the conversion *(2)*→*(4)* involves the intermediate formation of oxyl radicals *(3)* (cf. [1]). The reactions proceed to completion only when stoichiometric amounts of iron(II) sulfate are used. The reaction proceeds much more slowly when iron(II) sulfate is replaced by iron(III) chloride; furthermore, it is not catalyzed by trifluoroacetic acid. These observations support the proposed radical mechanism.

### *General Procedure*

A solution of $FeSO_4 \cdot 7H_2O$ in water is added to a solution of *(2)* in ethanol (1 : 1 molar ratio) and the resulting mixture stirred and heated under reflux for 2 h. The mixture is concentrated, the aqueous residue extracted with chloroform, and the extracts dried and concentrated to give *(4)*, which is purified by recrystallization or distillation.

## Three-Atom Ring Expansion of Cyclic Ketones *via* Nitrones and Oxaziridines

By *David St. C. Black* and *Lynn M. Johnstone*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

Ring-opening of bicyclic *C*-hydroxymethylene-substituted oxaziridines on treatment with iron(II) sulfate leads to *N*-(3-oxopropyl)amides[1]. This reaction can also be applied to tricyclic oxaziridines *(6)* and thus opens up a good route to a variety of eight- and nine-membered oxolactams

---

[a] From *(1)* [b] From *(2)*. [c] From *(5)*. [d] From *(9)*. [e] B.p.=92—96 °C/0.05 torr. [f] $^1$H-NMR (242 K): $\delta$=1.33 (s, 3 H), 1.66 (s, 3 H), 1.33—3.03 (br. m, 9 H), 3.76 (d, $J$=3 Hz, 1 H), 5.67 (br. s, 1 H).

*(10)* (Scheme 1). Two distinct routes from the γ-nitroketones *(2)* to the oxaziridines *(6)* have been developed. In route I the nitroketones *(2)* are converted by reductive cyclization into the bicyclic nitrones *(3)*, which on treatment with benzoyl chloride undergo *O*-benzoylation and allylic rearrangement[2] to the benzoyloxy-1-pyrrolines *(4)*, and can readily be saponified to the alcohols *(5)*. Treatment of *(5)* with peracetic acid affords isomerically pure oxaziridines *(6)* having *cis*-coupled rings (assignment of the structures was confirmed by $^1$H-NMR spectroscopy). In route II, the γ-nitroketones *(2)* are converted *via* the enol acetates *(7)* and their epoxides into the α-hydroxy-γ-nitroketones *(8)*, which undergo reductive cyclization to the bicyclic nitrones *(9)*. Photorearrangement of *(9)* affords *cis*- and *trans*-*(6)*.

Both routes are suitable for the synthesis of lactams *(10a)* and *(10b)* (see Table 1). *(10c)* is only accessible *via* route II since *(3c)* rapidly decomposes. It is significant that the stability of the hydroxynitrones *(9)* is, in general, much greater than that of the nitrones *(3)*; route II is generally preferable to route I, where both are applicable. Route I, however, was chosen for the synthesis of the benzylidene-substituted lactam *(10d)* because of the expected lack of selectivity in the peracid oxidation of the benzylidene-enol acetate *(7d)*. The C=N-double bond in *(5d)* can be oxidized, without concomitant epoxidation of the C=C-double bond, to form *(6d)* in high yield.

Isolation of *(6)* is not required in either route I or II. Indeed, nitrones *(9)* can be irradiated in ethanol and the concentrated reaction solution treated directly with iron(II) sulfate to afford the lactams *(10)*. The $^1$H-NMR spectra of the latter compounds at room temperature generally consist of broad signals, which indicates that the systems are considerably flexible. The low temperature spectra are, however, much sharper.

The overall reaction *(1)*→*(10)* permits a three-atom condensative ring-expansion of cyclic ketones.

## Formation of Oxiranes from Methyl(phenyl)selenoniomethanide and Aldehydes or Ketones

By *Ken Takaki, Masateru Yasumura,* and
*Kenji Negoro*[*]

Organoselenium compounds have been widely investigated in the last decade[1]. Selenium ylides, in which carbanions are stabilized by a carbonyl group, react with α,β-unsaturated ketones to give cyclopropanes[2]. However, their reactivities, especially those of non-stabilized ylides,

---

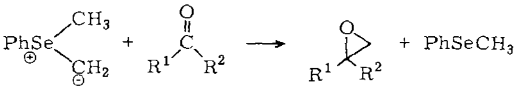
Hiroshima University, Sendamachi-3, Hiroshima 730 (Japan)

have not been as completely investigated as sulfonium and phosphonium ylides.

We report here on reactions of methyl(phenyl)selenoniomethanide *(1)* with carbonyl compounds *(2)*, which afford oxiranes *(3)* in good yields (Table 1).



*(1)* *(2)* *(3)* *(4)*

Table 1. Selected data of the oxiranes *(3)* obtained from methyl(phenyl)selenoniomethanide *(1)* and carbonyl compounds *(2)*. *(3a)*, *(3b)*, *(3e)* and *(3f)* show molecular ions in the mass spectrum.

| *(3e)* | 0.77—1.87 (t and m, $J$ = 7.0 Hz, 14 H), 2.20—2.67 (m, 2 H) |
| *(3f)* | 0.83—2.06 (m, 10 H), 2.33—2.60 (m, 2 H) |

[a] The products *(3)* were identified by comparison with authentic samples prepared from dimethylsulfoniomethanide and the corresponding carbonyl compounds [3]. [b] Yields were determined by NMR. [c] M.p. = 83—85 °C.

The ylide *(1)* was generated *in situ* from dimethylphenylselenonium methyl sulfate and sodium hydride in the presence of carbonyl compounds *(2)*, since selenium ylides are relatively unstable and undergo fission of the ylide bonds[4]. Generally, these reactions are mild and result in good yields of ketones and aromatic aldehydes. In the reaction with heptanal *(2c)* GC analysis of the reaction mixture showed a small peak, in addition to those of the educts, which may be assigned to the expected oxirane *(3c)*, the isolation of which was, however, difficult. These epoxidations are the first examples, to our knowledge, of reactions of non-stabilized selenium ylides with "enolizable" carbonyl compounds.

### *General Procedure*

A solution of dimethyl(phenyl)selenonium methyl sulfate[5] (12 mmol) and the aldehyde or ketone (10 mmol) in dry dimethylformamide (30 mL) is added dropwise over a period of 30 min to a stirred suspension of NaH (12 mmol) in dry tetrahydrofuran (30 mL); all operations were conducted under nitrogen and the mixture was cooled on an ice bath. The mixture was then warmed to room temperature for 4 h and held at 50 °C for 30 min. After cooling, 10% aqueous $NH_4Cl$ (20 mL) was added and the organic layer extracted with ether, washed with NaCl solution, and dried over $Na_2SO_4$. Evaporation of the solvent *in vacuo* gave a residue which contained the oxirane *(3)*, methyl phenyl selenide *(4)*, and a small amount of unreacted *(2)*. Distillation of the residue afforded analytically pure *(3)*.

## Experimental Evidence for the $[H_2SSH_2]^{+\cdot}$ Radical Cation in Solution

By *Shamim A. Chaudhri* and *Klaus-Dieter Asmus*[*]

The $H_2S$ molecule and radical species derived from it have been the subjects of numerous investigations. The ionization and excitation energies, as well as geometrical parameters, for example, have been calculated using various theoretical models[1] and the results compared with experimental values[2]. Recently, *Clark*[3] has used theoretical calculations (HF/4-31G, MP2/4-31G and MNDO) to consider some thermodynamic and optical characteristics of an $[H_2SSH_2]^{+\cdot}$ radical cation.

A significant feature of $[H_2SSH_2]^{+\cdot}$ is assumed to be a three-electron bond; two p-electrons forming a σ-bond and the third, unpaired electron being promoted into an antibonding σ*-orbital. A corresponding three electron bond has been experimentally well established in the analogous $[R_2SSR_2]^{+\cdot}$ radical cations formed as intermediates in the oxidation of thioethers[4,5]. We are now able to present experimental evidence on the formation, stability and optical absorption spectrum of $[H_2SSH_2]^{+\cdot}$ for purpose of comparison with *Clark*'s calculations.

The experiments were carried out using a pulse radiolysis technique. $^\cdot$OH and H$^\cdot$ react with $H_2S$ according to

$$H_2S + {}^\cdot OH/H^\cdot \rightarrow HS^\cdot + H_2O/H_2$$

to yield HS$^\cdot$ radicals ($k_{^\cdot OH} \approx 10^{10}$ and $k_{H^\cdot} \approx 10^9$ mol$^{-1}$ L s$^{-1}$)[6]. The HS$^\cdot$ radicals exhibit no detectable optical absorption in the UV/VIS-region as is apparent from, for example, pulse radiolysis investigations (aqueous solutions, pH = 3, $10^{-4}$ mol/L $H_2S$). At higher $H_2S$ concentrations, (*e.g.* $10^{-2}$ mol/L and lower pH values (*e.g.* with 0.2 mol/L $HClO_4$), however, a well characterized transient optical absorption band can be observed in the UV ($\lambda_{max}$ = 370 nm; Fig. 1a).

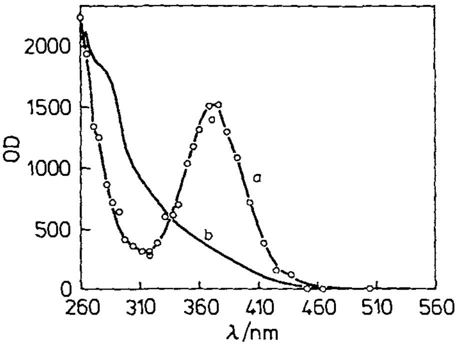

Fig. 1. a) UV/VIS-absorption spectrum of the $[H_2SSH_2]^{+\cdot}$ radical cation, measured immediately after a 4 μs pulse in an aqueous solution of $10^{-2}$ mol/L $H_2S$ and 0.2 mol/L $HClO_4$, b) UV/VIS-absorption spectrum after decay of $[H_2SSH_2]^{+\cdot}$(*ca.* 0.5 ms after pulse).—Optical density (OD) in arbitary units.

[*] Prof. Dr. K.-D. Asmus, Dr. S. A. Chaudhri
Hahn-Meitner-Institut für Kernforschung Berlin GmbH,
Bereich Strahlenchemie
Postfach 39 01 28, D-1000 Berlin 39 (Germany)

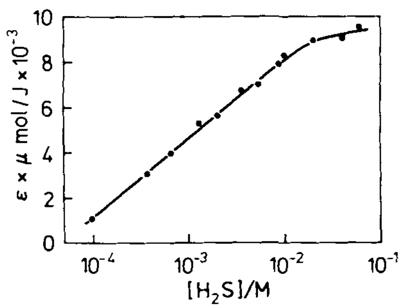

Fig. 2. Yield of $[H_2SSH_2]^{\dot{+}}$ measured from the absorption at 370 nm as a function of $H_2S$ concentration in aqueous solutions containing 0.2 mol/L $HClO_4$.

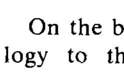
The absorption is fully developed at the end of the 4 µs pulse. This species decays with a first half-life of *ca.* 60 µs to a non-identified product (Fig. 1b). The decay kinetics follow a second order decay process *i.e.* a radical-radical reaction, with a rate constant of $2k = (3.0 \pm 1.0) \times 10^9$ mol$^{-1}$ L s$^{-1}$, based on the assumption of quantitative conversion of each ˙OH and H˙ into this transient absorbing species.

The yield of the 370 nm transient depends markedly on the $H_2S$ concentration as can be seen from the plot in Figure 2 (all solutions contained 0.2 mol/L $HClO_4$); a saturation value was reached first at *ca.* 0.1 mol/L $H_2S$[7].

The yield of the species absorbing at 370 nm is practically constant at high proton concentrations ($> 10^{-2}$ mol/L $HClO_4$). At lower proton concentrations its yield decreases and the already known $[HSSH]^{\dot{-}}$ radical anion ($\lambda_{max} = 380$ nm)[6b] appears. The latter is formed by complexation of HS˙ by $HS^-$ and thus its yield strongly depends on the actual $HS^-$ concentration and on the pH-value of the solution. At pH = 3, for example, the yield of $[HSSH]^{\dot{-}}$ is low, as indicated by a short-lived "spike" absorption which practically decays already during the 4 µs pulse. To further distinguish between our new 370 nm-species and the $[HSSH]^{\dot{-}}$ absorption we also performed corresponding experiments in methanol as solvent, in which the pK of $H_2S$ is considerably higher. As anticipated, no absorption attributable to $[HSSH]^{\dot{-}}$ was observed. The absorption at 370 nm also appeared in methanolic solutions containing $HClO_4$. (In methanol HS˙ radicals are formed in the reaction of $H_2S$ with $^{\bullet}CH_2OH$ radicals.)[6b]



On the basis of our experimental findings and by analogy to the $[R_2SSR_2]^{\dot{+}}$ radical cations obtained from thioethers, the 370 nm absorption (Fig. 1a) is assigned to the complex radical cation $[H_2SSH_2]^{\dot{+}}$ formed in the overall reaction:

$$HS^{\bullet} + H_2S + H^{+}_{aq} \rightarrow [H_2SSH_2]^{\dot{+}}$$

The stabilization of the three-electron bond structure in $[H_2SSH_2]^{\dot{+}}$ and in $[R_2SSR_2]^{\dot{+}}$ is considered to be facilitated by the symmetrical resonance structures which are provided by charge- and spin-delocalization over both sulfur atoms. A similar situation would also explain the relative stability of the radical anions $[HSSH]^{\dot{-}}$, $[RSSR]^{\dot{-}}$. The radical cation $[H_2SSH_2]^{\dot{+}}$ should result from addition of two protons to $[HSSH]^{\dot{-}}$, and this is indicated by the corresponding pH-dependent decay of the absorption of $[HSSH]^{\dot{-}}$.

We exclude the possibility of an asymmetrical $[H_2SSH]^{\bullet}$ radical, since one of the resonance forms would require charge separation formed by addition of HS˙ addition to $H_2S$. Such a conclusion is also in accordance with the fact that the analogous $[R_2SSR]^{\bullet}$ radicals apparently cannot be stabilized in solution. Evidence for the latter has only been found in some low temperature (77 K) rigid matrices and with electron withdrawing substituents R[8]. The lower stability of the asymmetrical radical can also be understood from a MO picture. Thus, the separation of the energy levels should be smaller in $[H_2SSH]^{\bullet}$ than in $[H_2SSH]^{\dot{+}}$ ESR data on analogous $[R_2SSR]^{\bullet}$ radicals further support this picture by invoking a much weaker sulfur-sulfur bond in such species relative to the symmetrical $[R_2SSR_2]^{\dot{+}}$ radical cations[8b].

The optical absorption of the $[R_2SSR_2]^{\dot{+}}$ radical cation has been attributed to a $\sigma \rightarrow \sigma^*$ transition[5] and this should, in principle, also apply to absorptions of the $[RSSR]^{\dot{-}}$, $[HSSH]^-$, and $[H_2SSH_2]^{\dot{+}}$ species. *Clark* has essentially substantiated this assignment in his theoretical calculations on $[H_2SSH_2]^{\dot{+}}$[3]. He indicated, however, that the newly established $a_g(\sigma)$ level may interact with the $a_g(n^-)$ level of the non-bonding s-electrons of the two sulfur atoms leading to a split into $a_g(\sigma - n^-)$ and $a_g(\sigma + n^-)$ levels. The optically excited electron would then be a σ-electron with more or less non-bonding character. Using the MP2/4-31G-method *Clark* has calculated the $\sigma \rightarrow \sigma^*$ transition ($a_g(\sigma - n^-) \rightarrow b_n(\sigma^*)$) to be 3.25 eV or 380 nm and this is in excellent agreement with our experimental value of 3.35 eV or 370 nm. Finally, the extinction coefficient of $[H_2SSH_2]^{\dot{+}}$ is estimated to be $\varepsilon = 1600 \pm 300$ mol$^{-1}$ L cm$^{-1}$, based on our experimental results.

## An *ab initio* Investigation of the Mechanism of Ester Reduction[**]

By *Pietro Cremaschi, Gabriele Morosi,* and
*Massimo Simonetta*[*]

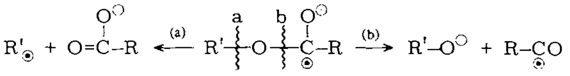
The dissolving metal reduction of alkyl carboxylic esters affords, predominantly, the corresponding alkanes rather

---

[*] Prof. Dr. M. Simonetta, P. Cremaschi, G. Morosi
Centro del CNR e Istituto di Chimica Fisica
Via Golgi 19, I-20133 Milano (Italy)

[**] We are indebted to Prof. *D. H. R. Barton* for communicating his results prior to their publication.

than the parent alcohols[1]; in this connection it has been established that the main products are formed *via* scission of the $C_{Alkyl}$—O bond in the ester radical anion. The experimental data have been rationalized by a mechanism in which cleavage of the $C_{Alkyl}$—O bond [pathway (a)] is favored with respect to $C_{Carbonyl}$—O fragmentation [pathway (b)].



We present here *ab initio* calculations on the ester radical anion and the products in which only the relative stability of reagent and different products are compared.

Methyl formate was used as a model system ($R'=CH_3$, $R=H$) for the *ab initio* calculations (restricted HF-SCF calculations) using a STO-3G[2a] and a 4—31 G basis set[2b]. All the geometrical parameters of the four products were optimized, while the CH bond lengths and the HCH bond angles of the methyl group of the methyl formate anion were assumed to be equal to the corresponding optimized values of $CH_3O^{\ominus}$, and the remaining CH bond length corresponds to the value of optimized $HCOO^{\ominus}$.

Table 1. Geometrical parameters and energies of the methyl formate radical anion and its products [a].

| | STO-3G | 4—31 G | | |
|---|---|---|---|---|
| | Energy | Geometrical parameters | | Energy |
| $H\overset{\odot}{C}O$ | −111.72947 | C—O | = 1.176 | −113.06497 |
| | | C—H | = 1.088 | |
| | | H—C—O | = 128.5 | |
| $CH_3O^{\ominus}$ | −112.70359 | C—O | = 1.364 | −114.21840 |
| | | C—H | = 1.122 | |
| | | H—C—O | = 115.7 | |
| $HCOO^{\ominus}$ | −185.45627 | C—O | = 1.252 | −187.90198 |
| | | C—H | = 1.112 | |
| | | O—C—O | = 130.4 | |
| ${}^{\odot}CH_3$ | − 39.07701 | C—H | = 1.067 | − 39.50179 |
| | | H—C—H | = 120.0 | |
| $HCOOCH_3^{\ominus}$ | | C═O | = 1.303 | −227.34175 |
| | | C—O | = 1.473 | |
| | | O—$CH_3$ | = 1.427 | |
| | | H—C═O | = 126.2 | |
| | | H—C—O | = 110.6 | |
| | | C—O—$CH_3$ | = 113.1 | |

[a] Bond lengths in Å, bond angles in °, and energies in Hartree. (1 Hartree = 27.21 eV = 627.71 kcal/mol.)

The results are shown in Table 1. Using the STO-3G basis set, $HCOO^{\ominus} + \overset{\odot}{C}H_3$ ($E = -224.53328$ Hartree) is more stable than $H\overset{\odot}{C}O + CH_3O^{\ominus}$ ($E = -224.43306$ Hartree) by 0.10022 Hartree (62.9 kcal/mol). With the 4—31 G basis set the corresponding values are −227.40377, −227.28337, 0.12040 Hartree (75.6 kcal/mol) and $HCOO^{\ominus} + \overset{\odot}{C}H_3$ is, hence, more stable than $HCOOCH_3^{\ominus}$ by 0.06202 Hartree (38.9 kcal/mol). Preliminary calculations on pathway (a) indicate a barrier to stretching of the $H_3C$—O bond $(HCOO...CH_3)^{\ominus}$, the height of which has not yet been determined.

In conclusion, $HCOO^{\ominus} + {}^{\odot}CH_3$ is the most favored system energetically. The relative amount of products cannot, however, be predicted theoretically since the barrier heights for the pathways have not been determined. Furthermore, entropy and solvation effects could be of paramount importance, and other reaction mechanisms, *e.g.* those involving nucleophiles could occur under the majority of experimental conditions[1c].

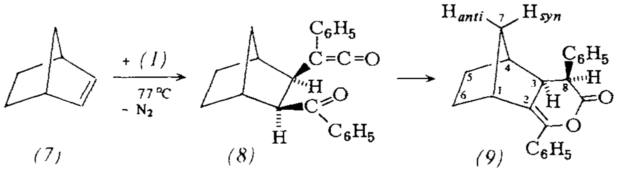
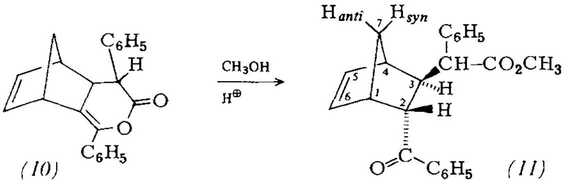
tions with 1-diethylaminopropyne and with dehydrobenzene. The initial Diels-Alder addition is followed by a cycloreversion with elimination of nitrogen and formation of an α-pyrone. We report here on reactions of olefins with *(1)*, which enable simultaneous addition of a benzoyl- and a phenylketenyl group to a CC double bond.

In an ether solution of benzvalene *(2)*, an olefin of high activity in Diels-Alder additions with inverse electron demand[2], *(1)* is converted within 24 h at 20 °C into the tetracyclic diketone *(6)*, which can be isolated in 75% yield. Probably in a $[_{\sigma}2+_{\sigma}2+_{\sigma}2]$-cycloreversion with elimination of nitrogen and cleavage of the lactone bond the primary adduct *(3)* forms (4-benzoyltricyclo[3.1.0.0$^{2,6}$]hex-3-yl)phenylketene *(4)*. The electrophilic ketene function then adds intramolecularly in a novel cycloaddition to the nucleophilic bicyclo[1.1.0]butane system, finally resulting in the formation of the tetracycle *(6)*, possibly *via* the zwitterion *(5)*. For assignment of the structure of *(6)* the $^{13}$C-NMR spectrum is decisive: The direct $^{13}$C-H coupling constants show that five of the six CH groups belong to cyclopropane moieties, but the sixth to a cyclopentane.

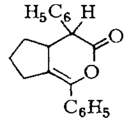
Norbornene *(7)* reacts with *(1)* only in boiling tetrachloromethane. Here, in contrast to the addition of *(2)*, the ketene intermediate containing a benzoyl function *(8)* is detected in solution by IR bands at 2100 and 1680 cm$^{-1}$, but after 10 hours reaction time it has completely disappeared again. The enol lactone *(9)*, which is presumably formed by enolization and intramolecular addition of the enol hydroxy group to the ketene function of *(8)*, is then isolated in 35% yield. This slow process takes place because the bridged cyclopentane in *(8)* is far less nucleophilic than the bicyclo[1.1.0]butane system in *(4)*.



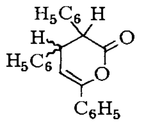
The $^{1}$H-NMR spectrum of *(9)* (Table 1) provides arguments for the configuration at C-3 and C-8. Since $J_{3,4}$ is not resolved, 3-H should be in the *endo* position, indicating the expected *exo* attack of *(1)* on *(7)*. The large difference between the chemical shifts of the two 7-H atoms shows that 7-H$_{syn}$ protrudes into the shielding region of the 8-phenyl group, thus suggesting the *exo* arrangement of the latter.



A 43% yield of *(10)* is obtained from *(1)* and norbornadiene in tetrachloromethane after 4 d at 45—50 °C. The reaction of *(10)* with methanol in the presence of sulfuric acid as catalyst leads to the opening of the lactone ring. In the $^{1}$H-NMR spectrum of *(11)* (73% yield) the coupling constants of 2-H and 3-H show that the benzoyl function occupies the *endo* position and the phenylacetate group the *exo* position. The stereochemistry at C-3 proves the *exo* addition of *(1)* to norbornadiene.



(12)



(13)

Reaction of cyclopentene with *(1)* in tetrachloromethane at 100 °C in an autoclave affords only 4% of the enol lactone *(12)* after 10 d. Nonetheless, the two diastereomeric dihydrotriphenyl-α-pyrones *(13)* are formed in 24% yield when *(1)* and styrene are heated in tetrachloroethane for 24 h at 121 °C. Proof of the structure in this case was provided by comparison with the authentic[3] substances *(13)*. Thus, the addition of *(1)* to styrene proceeds regioselectively, just as that to 1-diethylaminopropyne[1].

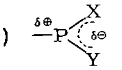
## Valence Isomerization of an Imino(methylene)phosphorane to a 1,2λ$^{3}$-Azaphosphiridine: A Novel Rearrangement in the Phosphorus System[**]

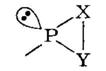
By *Edgar Niecke, Anette Seyer*, and
*Dirk-Andreas Wildbredt*[*]

*Dedicated to Professor Marianne Baudler on the occasion of her 60th birthday*

Phosphorus compounds of the ylide- *(A)*[1] and of the tricyclic-type *(B)*[2] have found great interest recently because of their unusual bonding properties and their suitability as valuable synthetic building blocks.



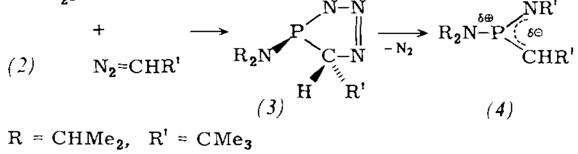
(A)



(B)

Having recently shown that both these classes of compounds could be generated from the same isoelectronic precursor[3], we attempted the preparation of both isomers *(A)* and *(B)* in one system. We report here on a valence isomerization of an imino(methylene)phosphorane *(A)* to a 1,2λ$^{3}$-Azaphosphiridine *(B)* (X = N—, Y = C<)[8].

Diisopropylamino(*tert*-butylimino)phosphane *(1)* reacts with 1-diazo-2,2-dimethylpropane *(2)* to give the crystalline [2+3]-cycloadduct *(3)*. The elimination of N$_2$ from the λ$^{3}$-Triazaphospholine *(3)*, which commences at 40 °C, leads to the corresponding imino(methylene)phosphorane *(4)*; this can be isolated in pure form by rapid distillation.



R = CHMe$_2$, R' = CMe$_3$

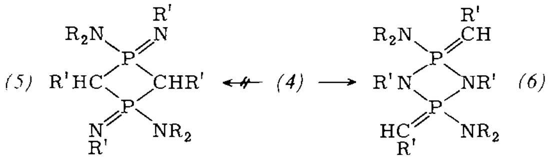
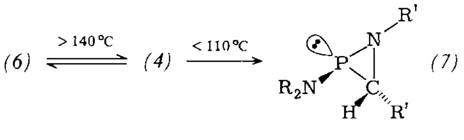
[**] Phosphazenes of Coordination Number 2 and 3, Part 20. This work was supported by the Fonds der Chemischen Industrie.—Part 19: *E. Niecke, M. Engelmann, H. Zorn, B. Krebs, G. Henkel*, Angew. Chem. *92*, 738 (1980); Angew. Chem. Int. Ed. Engl. *19*, 709 (1980).

By-product of this reaction is the cycloadduct *(6)*, which can also be isolated from aged samples of *(4)*. The previously observed formation of a diphosphetane *(5)*[4] in the case of the kinetically labile imino(methylene)phosphoranes, does not take place here; due to steric effects, the [2+2]-cycloaddition leading to the diazaphosphetidine system *(6)* is favored.



Surprisingly, the thermally induced ring-opening of *(6)* leads not to the expected product of a cycloreversion *(4)*, but to a thermostable compound, which could be identified as the unknown $\lambda^3$-azaphosphiridine *(7)*, an isomer of *(4)*.

Proof of the valence isomerization *(4)*→*(7)* was obtained experimentally by $^{31}$P-NMR controlled temperature-studies on toluene solutions of imino(methylene)phosphorane, where we observed the formation of the tricyclic phosphorus compound already below the decomposition temperature of *(6)*.



Compounds *(3)*, *(4)*, *(6)* and *(7)* were characterized by elemental analysis, mass spectra, and by IR and NMR data (Table 1).

Table 1. $^{31}$P-, $^{1}$H- and $^{13}$C-NMR-data of the compounds *(3)*, *(4)*, *(6)* and *(7)* [a].

[a] 30% solution in $C_6D_6$ or $C_7D_8$; $H_3PO_4$ as external ($^{31}$P) and TMS ($^{1}$H, $^{13}$C) as internal standard. [b] Anisochronous methyl groups in a prochiral unit. [c] $^{3}J_{HH}=6.9$ Hz. [d] $|J_{HP}+J_{HP'}|$ and $|J_{CP}+J_{CP'}|$, resp.

The constitution of *(7)* as the cyclic valence isomer of *(4)* was proved beyond doubt by comparing their NMR-data. The $^{31}$P-NMR-spectrum of *(4)* shows a downfield shift, typical of sp$^2$-hybridized $\lambda^5$-phosphorus, while in the $^{13}$C{$^1$H}-NMR-spectrum the position of the resonance signal of the methylene carbon atom corresponds to the values observed for the imino(methylene)phosphoranes. The change in hybridization of the phosphorus and methylene-carbon atoms and also the development of the strained $\lambda^3$-azaphosphiridine-system *(7)* leads to the expected strong shielding of the phosphorus and methylene-carbon atoms, and is connected with a drastic reduction in the P—C-coupling constant [199.5 Hz in *(4)*, 9.8 Hz in *(7)*]. In accordance with this valence isomerization at the phosphorus atom, we found a doubling of the methyl resonances of the isopropyl group in the now prochiral unit. The phosphorus ylide structure of the [2+2]-cycloadduct *(6)* manifests itself in the similar absolute value of the P—C-coupling constants of *(4)* and *(6)*. An examination of molecular models indicates the sterically favored *trans*-form with a *Z*-configuration in the $R_2N—P{=}CHR'$-fragment.

The low absolute value of $^2J_{PCH}$ in *(3)* and *(7)* indicates a *trans* relation of the lone pair at the phosphorus atom to the hydrogen atom, because of the significant dependence of this interaction on the interplanar angle[5].

This investigations show that in the C—P—C-system as well as in the C—P—N-system, the formation of the cyclic is energetically favored over the acyclic dipolar form. While the previously described amine-silylated amino(imino)methylenephosphorane derivatives avoid the formation of a $\lambda^3$-azaphosphiridine by thermally induced 1,3-silyl group rearrangement to a diiminophosphorane[6], in the alkylated system the reaction is directed to a valence isomerization[7].

### *Procedure:*

*(3)*: To a stirred solution of about 50 mmol of *(2)* in 20 ml of tetrahydrofuran (THF) is added dropwise 8 g (40 mmol) of *(1)* at a temperature of −30 °C. After 2 h stirring at −30 °C, half of the solvent is removed at −30 °C, giving a crystalline solid, which is isolated at −30 °C and washed with a little cold THF. Yield: 7.3 g (63%) *(3)*; decomp. above *ca.* 45 °C.

*(4)*: *(3)* (6 g, 20 mmol) is pyrolized at 50 °C, until no more N$_2$-formation is observed. The resulting bright-yellow, crude liquid product (about 85%) is at once purified by short-path distillation and the distillate is frozen out at −30 °C in the collector. Yield: 3.8 g (70%) *(4)*; b.p. 52—53 °C/0.01 torr.

*(6)*: After 6 h at 0 °C *(4)* (1.5 g, 5 mmol) affords the corresponding [2+2]-cycloaddition product *(6)* as a colorless crystalline solid in almost quantitative yield. M.p. 147—149 °C (dec.).

*(7)*: *(4)* (3 g, 10 mmol) is heated at 140 °C for a short time (about 5 min). Subsequent distillation yields 1.7 g (57%) of *(7)* as a colorless liquid. B.p. 53—55 °C/0.01 torr.

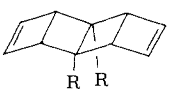
## Pterodactyladiene (Tetracyclo[4.4.0.0$^{2,5}$.0$^{7,10}$]deca-3,8-diene)[**]

By *Hans-Dieter Martin, Bernhard Mayer, Marianne Pütter*, and *Hans Höchstetter*[*]

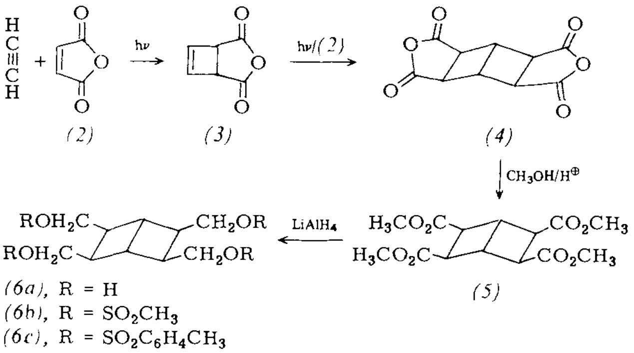
*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

Pterodactyladiene derivatives *(1)*, highly strained members (strain energy about 110 kcal/mol) of the (CH)$_{10}$-family, have hitherto been accessible by two different routes: Diels-Alder reaction of electrophilic alkynes with two equivalents of cyclobutadiene[1] or by reaction of 3,6-disubstituted 1,2,4,5-tetrazines with cyclobutadiene, followed by photoelimination of nitrogen[2], respectively, allowed the preparation of the 1,6-disubstituted tetracyclics *(1b)*–*(1d)*. Pterodactyladiene *(1a)* cannot be synthesized in this way. We now report on a third synthetic route, by means of which *(1a)* can also be obtained.



*(1a)*, R = H
*(1b)*, R = COOCH$_3$
*(1c)*, R = CH$_3$
*(1d)*, R = C$_6$H$_5$

Maleic anhydride *(2)* adds photochemically to acetylene yielding *(4)*[3] (conditions of photolysis: acetone, benzophenone, 700 W high-pressure Hg lamp, Solidex filter, *(3)*: −30 °C, *(4)*: room temperature).



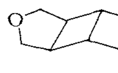
*(2)* *(3)* *(4)*

*(6a)*, R = H
*(6b)*, R = SO$_2$CH$_3$
*(6c)*, R = SO$_2$C$_6$H$_4$CH$_3$

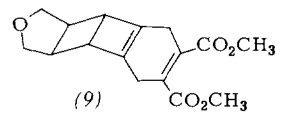
*(5)*

Treatment with CH$_3$OH/H$^{\oplus}$ gives the all-*exo*-ester *(5)* [$^{13}$C-NMR (CDCl$_3$): $\delta$ = 37.4 (C-1, C-4), 45.8 (C-2, C-3, C-5, C-6)] which can be reduced by LiAlH$_4$/tetrahydrofuran (THF) to *(6a)*, m.p. = 134 °C. In the preparation of the sulfonate *(6c)*, m.p. = 147 °C, from alcohol *(6a)*, the bisether *(7)*, m.p. = 62 °C, could be isolated as a by-product. On treatment with potassium *tert*-butoxide in dimethyl sulfoxide (DMSO) the sulfonate *(6b)*, m.p. = 134 °C, was converted into the diene *(8)* [$^1$H-NMR (CDCl$_3$, 60 MHz): $\delta$ = 2.75 (cm; 2 H, C*H*—CH$_2$), 2.85 (s; 2 H, C*H*—C=), 3.19—4.00 (m; 4 H, C*H*$_2$—O—), 4.68 (s; 2 H, =C*H*$_2$), 5.10 (s; 2 H, =C*H*$_2$)] which reacted with dimethyl acetylenedicarboxylate to afford the Diels-Alder adduct *(9)*, m.p. = 152 °C. On treatment with anhydrous sodium sulfide in DMSO, *(6c)* cyclized to the bisthioether *(10)*, m.p. = 126 °C, which was easily oxidized by H$_2$O$_2$/sodium tungstate to the sulfone *(11)*, m.p. = 288 °C. Since direct chlorination of sulfone *(11)* proved to be problematic, bisthioether *(10)* was chlorinated using *N*-chlorosuccinimide (NCS). The doubly chlorinated bisthioether is moisture-sensitive and was not isolated but directly oxidized with *m*-chloroperbenzoic acid (MCPBA) to the chlorinated sulfone *(12)*, m.p. = 214 °C (dec.). The double Ramberg-Bäcklund ring contraction to *(1a)* could be successfully achieved by treatment with potassium *tert*-butoxide in THF. *(1a)*, which is present in a mixture with four non-identified other products could be purified by preparative gas chromatography (OV 17, 105 °C), affording a colorless liquid with characteristic odor [$^1$H-NMR (CDCl$_3$, 90 MHz): $\delta$ = 2.40 (m; 2 H, 1-H, 6-H), 3.10 (m; 4 H, allylic), 6.35 (m; 4 H, olefinic). — $^{13}$C-NMR (CDCl$_3$): $\delta$ = 45.3 (C-1, C-6), 48.6 (C-2, C-5, C-7, C-10), 141.2 (C-3, C-4, C-8, C-9). — $^1J_{\text{C-1,H}}$ = 153 Hz, $^1J_{\text{C-2,H}}$ = 156 Hz, $^1J_{\text{C-3,H}}$ = 171 Hz. — MS (70 eV): m/e = 130 (5%, M$^{\oplus}$), 129 (39%, M − H), 128 (68%, M − H$_2$), 52 (100%, M − C$_6$H$_6$)].

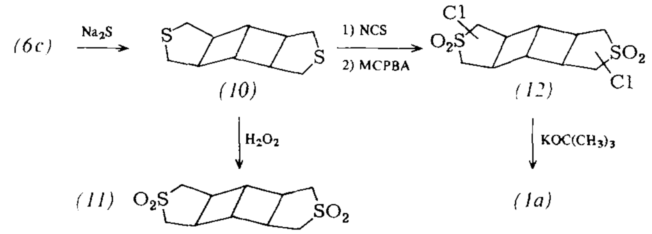
*(7)*



*(8)*



*(9)*



*(6c)* *(10)* *(12)* *(11)* *(1a)*

$^{13}$CH-coupling constants yield information on the hybridization state of the corresponding C—H bonds. The values for C-1 (30% s-character) and C-2 (31% s-character) are considerably different from the coupling constant of cyclobutane ($^1J_{^{13}\text{CH}}$ = 134 Hz, 26% s-character) and are in better accord with that of cubane ($^1J_{^{13}\text{CH}}$ = 153 Hz, 30% s-character[4]). Force-field calculations[5] predict a heat of formation of 141 kcal/mol and a strain energy of 113 kcal/mol for *(1a)*. The thermal lability of *(1a)* is apparent even at 130 °C, the most stable thermolysis product being naphthalene[6].

## Periodated Cyclosilanes

By *Edwin Hengge* and *Dieter Kovar*[*]

Hitherto, periodated silanes were little known and mostly inadequately described; iodated cyclosilanes were completely unknown. We have now been able to prepare and characterize for the first time the periodated cyclosilanes $Si_4I_8$, $Si_5I_{10}$, and $Si_6I_{12}$[1]. As starting material we used the perphenylated cyclosilanes $(SiPh_2)_n$, $n=4$, 5, and 6, which are obtainable by reaction of dichlorodiphenylsilane with Na/K alloy or Li *via* a kind of Wurtz synthesis. The separation of the individual components of the reaction mixture was possible owing to the differences in solubility: $(SiPh_2)_5$ is readily soluble, $(SiPh_2)_4$ sparingly soluble and $(SiPh_2)_6$ very sparingly soluble in benzene.

Treatment of a benzene solution or suspension of $(SiPh_2)_n$ with anhydrous and iodine-free aluminum iodide and passage of hydrogen iodide into the mixture leads to quantitative replacement of the phenyl groups by iodine and formation of the corresponding iodosilanes.

$$(SiPh_2)_n + 2n\,HI \xrightleftharpoons{AlI_3} (SiI_2)_n + 2n\,PhH$$

Presence of free iodine leads to cleavage of the ring and formation of chain-like products—as is evident from the $^{29}$Si-NMR data.

The catalyst $AlI_3$ is absolutely necessary. In the case of the readily soluble $(SiPh_2)_5$ only half of the phenyl groups are cleaved in the absence of $AlI_3$ (in a bomb-tube with liquid HI); $Si_5Ph_5I_5$ and its derivatives $Si_5Ph_5X_5$ (X = H, OMe) have been synthesized in this way[2]. The sparingly soluble educts $Si_4Ph_8$ and $Si_6Ph_{10}$ react to an even a lesser extent with HI in the absence of $AlI_3$. The cleavage of phenyl moieties, which can be regarded as an electrophilic reaction[3], is consequently very much favored by aluminium halides.

The products $(SiI_2)_n$, $n=4$, 5, 6, are yellow and extraordinarily sensitive to moisture. The color becomes distinctly more intense and slightly shifted bathochromically on going from $Si_6I_{12}$ to the smaller rings. The solubilities correspond to those of the cyclosilanes. The five-membered ring is the most readily soluble, while $Si_4I_8$ and, in particular, $Si_6I_{12}$ are sparingly soluble.

Only the $^{29}$Si-NMR spectrum of $Si_5I_{10}$ could be recorded. The measured value fits very well in the series of values of the remaining cyclopentasilanes $Si_5X_{10}$ [X = Cl ($\delta=-1.67$), Br ($-28.08$), Ph ($-34.41$), Me ($-42.12$), I ($-98.55$), H ($-105.53$)].

Molecular weight determinations were not possible, even mass spectroscopically. However, vibration spectroscopic findings (number and frequency of the vibrations, see Table 1) would indicate the cyclic structure. On using the force constants $f_{SiSi}=1.5\times10^2$ N m$^{-1}$, $f_{SiI}=1.4\times10^{-2}$ N m$^{-1}$ and the expected symmetries, normal coordinate analysis[4] enables very good reproducibility of the measured frequencies.

Table 1. Raman and IR vibrations of $(SiI_2)_n$, $n=4$, 5, 6.

### *Procedure*

$Si_4Ph_8$ (4 g, 5.4 mmol) is treated with benzene (150 mL) and a spatula tip of $AlI_3$. HI (free of $H_2O$ and iodine) is then passed through the solution until it is no longer warm due to heat of reaction. Yellow $Si_4I_8$ already precipitates out during the passage of HI. It is filtered off and dried in a vacuum; yield 5.4 g (87%). $Si_4I_8$ starts to decompose on melting at 184 °C (uncorrected)—$Si_5I_{10}$ and $Si_6I_{12}$ are synthesized analogously; yields (from 4 and 3 g of educt, respectively), 4.7 g (83%) and 4.1 g (89%), m.p. (uncorr.) 205 °C (dec.) and 258 °C (dec.), respectively.

## The First Lithium Fluorosilanolate—A Building Block for Directed Siloxane Synthesis[**]

By *Uwe Klingebiel*[*]

A route currently used for the synthesis of acyclic and cyclic polysiloxanes is the condensation of silanols $R_3SiOH$ and silanediols $R_2Si(OH)_2$[1]. The thermal stability of the silanols increases with increasing size of the substituents. Thus, *e.g.* di-*tert*-butylsilanediol condenses only under drastic conditions[2,3]. Cyclic condensation products have so far not been obtained[3].

A favorable method for the synthesis of di-*tert*-butylsilanediol is the reaction of di-*tert*-butyldifluorosilane *(1)* with

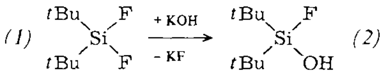
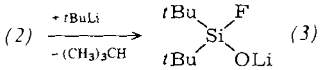
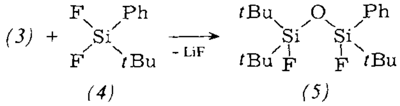
KOH in the molar ratio 1:2. If a molar ratio of 1:1 is used, then the stable fluorosilanol *(2)* is formed in high yields[4]. At room temperature it forms colorless, readily sublimable crystals.



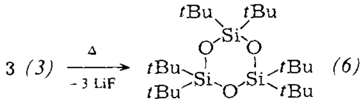
*(2)* reacts quantitatively with *tert*-butyllithium with cleavage of isobutane to give the unexpected stable lithium di-*tert*-butylfluorosilanolate *(3)*[5], which melts at 238 °C with partial decomposition.



As the reaction of *(3)* with *tert*-butyl(difluoro)phenylsilane *(4)* to give unsymmetrically substituted *(5)* demonstrates[6], lithium fluorosilanolates are valuable building blocks for the synthesis of siloxanes.



The hitherto sterically most overcrowded silicon-oxygen ring *(6)*[7] is preparable from *(3)* by thermal cleavage of LiF.



*Procedure*

*(2)*[4]: KOH (0.1 mol) in pellet form is gradually added to a stirred solution of *(1)* (0.1 mol) in 100 mL of petroleum ether (PE) at room temperature. After dissolution of the KOH pellets (*ca.* 8 h) the petroleum ether is removed by evaporation *in vacuo* and *(2)* is sublimed at room temperature and 0.01 torr. *(2)* also slowly sublimes under normal pressure in a glass flask; yield *ca.* 80% [by-product: $(tBu)_2Si(OH)_2$]; m.p. 40 °C.

*(3)*[5]: *tert*-$C_4H_9Li$ (0.1 mol, 15% solution in pentane) is added dropwise with stirring to a solution of *(2)* (0.1 mol) in PE (50 mL) at room temperature. The liberated isobutane is condensed in a cold trap. *(3)* can be purified by recrystallization from hexane or by vacuum sublimation; yield 95%, m.p. 238 °C (dec.).

*(5)*[6]: A stirred solution of *(4)* (0.1 mol) in PE (50 mL) is treated with a suspension of *(3)* (0.1 mol) in hexane (100 mL). *(5)* is purified by distillation; yield 95%; b.p. 115 °C/0.5 torr.

*(6)*[7]: *(3)* (0.1 mol) is heated at 230—240 °C for 1 h. Sublimation from the melt is then carried out at 0.1 torr. *(6)* sublimes, together with unreacted *(3)*, and is purified by recrystallization from PE (80—100 °C); yield 30%, m.p. 297 °C.

## $RuCo_2(CO)_{11}$ and $Ru_2Co_2(CO)_{13}$, Two New "Pure" Carbonylmetal Clusters[**]

By *Eckehart Roland* and *Heinrich Vahrenkamp*[*]

About 50 "pure" carbonylmetal compounds have so far been documented; the last time that the synthesis of such a complex was described in Germany was some 38 years ago[1]. Interest in this sector has recently reawakened, but important developments are taking place mainly in the case of carbonylmetal derivatives. There are only a few heterometal complexes which hold out promise as new parent compounds, two of which are presented here.

We found an entry to the chemistry of the carbonylruthenium-cobalt compounds *via* the trinuclear cluster *(1)*, which is accessible *via* several routes, the most favorable having proven to be the reaction of $[Ru(CO)_3Cl_2]_2$ with $KCo(CO)_4$. *(1)* shows a high reactivity towards inorganic and organic donor reagents[2]. In solution, *(1)* also reacts with itself in the sense of a disproportionation to give the two tetranuclear clusters *(2)* and $Co_4(CO)_{12}$. *(2)* is markedly less reactive than *(1)* and is air-stable in the solid state.

| $RuCo_2(CO)_{11}$ | $Ru_2Co_2(CO)_{13}$ |
|---|---|
| *(1)* | *(2)* |

*(1)* and *(2)* were identified by EI mass spectra, which show the molecular ions and stepwise loss of all CO groups. The CO stretching vibrations prove *(1)* (in $C_6H_{12}$ [cm$^{-1}$]: 2126 vw, 2069 s, 2056 sh, 2050 vs, 2018 w, 2005 w, 1820 w) to be a homologue of $OsCo_2(CO)_{11}$ with a bridging carbonyl ligand[3]. In the case of *(2)* (in $C_6H_{12}$ [cm$^{-1}$]: 2103 vw, 2068 vs, 2059 vs, 2050 vs, 2035 m, 2025 s, 1922 sh, 1895 w, 1843 w) they likewise indicate CO bridges, but do not provide any further structural information. Therefore, the structure of *(2)* was determined crystallographically[4]. Figure 1 shows the observed distorted $Ru_2Co_2$-tetrahedral arrangement with unsymmetrical distribution of terminal and bridging ligands, which can only roughly be related to those in $Co_4(CO)_{12}$[5] or $Ru_3Co(CO)_{13}^-$[6]. The polyhedron formed by the O atoms of the CO groups is however the [13]-polyhedron of lowest energy[7]. The structure of *(2)* thus complies with the previous finding, that the spatial distribution of the ligands rather than the localization of bonding relationships determines the structure of many polynuclear carbonyl complexes[7,8].

[*] Prof. Dr. H. Vahrenkamp, Dipl.-Chem. E. Roland
Institut für Anorganische Chemie der Universität
Albertstr. 21, D-7800 Freiburg (Germany)

[**] We thank Dr. *K. Steinbach* (Marburg) and Dr. *P. Merbach* (Erlangen) for recording the mass spectra, Heraeus GmbH (Hanau) for a gift of ruthenium chloride and the Rechenzentrum der Universität Freiburg for computer time.

Both ruthenium and cobalt are catalytic elements. The bimetallic character of the two new clusters and the proven reactivity of *(1)* open up numerous possibilities here. With the parent compounds *(1)* and *(2)* as starting materials, ligand substitution, metal exchange and electron transfer provide access to a wide field of derivative chemistry.

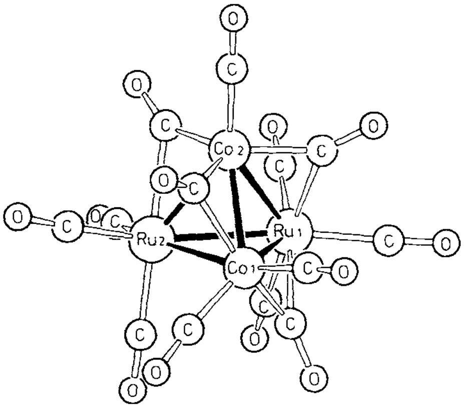

Fig. 1. Molecular structure of *(2)* in the crystal. Bond lengths [pm]: Ru1—Ru2 278.3(3), Ru1—Co1 273.1(2), Ru1—Co2 266.0(2), Ru2—Co1 270.3(3), Ru2—Co2 261.4(3), Co1—Co2 248.7(3).

### *Procedure*

A suspension of $[Ru(CO)_3Cl_2]_2$ (300 mg, 0.59 mmol) in 50 mL of an aqueous solution of $KCo(CO)_4$ (500 mg, 2.38 mmol) is stirred for 1 h at room temperature. The black precipitate which is formed is filtered off, dried in vacuum, taken up in hexane, filtered, and cooled to −35 °C. *(1)* separates out as black crystals; 470 mg (76%), m.p. 208 °C (dec.).

A solution of *(1)* (200 mg, 0.38 mmol) in hexane (30 mL) is stirred for 3 d at 35 °C and then chromatographed on a silica gel column (65 × 2.5 cm). Hexane elutes $Co_4(CO)_{12}$ and some $Ru_3(CO)_{12}$. Elution with benzene/hexane (1 : 7) affords 60 mg (46%) of balck *(2)*, m.p. 182 °C (dec.).

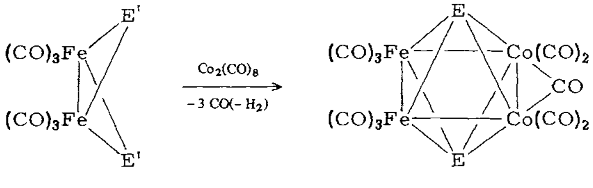
## Cluster-Construction: Synthesis and Structure of $Fe_2Co_2(CO)_{11}(PC_6H_5)_2$ and $Fe_2Co_2(CO)_{11}S_2$[**]

By *Heinrich Vahrenkamp* and *Edward J. Wucherer*[*]

The principle of ligand bridging for the stabilization of organometal-clusters has been realized on numerous occasions[1,2]. Its application as a synthetic concept calls for cluster precursors containing appropriate functional ligands. For the synthesis of RP- or S-bridged clusters, suitable precursors are, *e.g.*, those with P—H or S—S bonds, which can react directly with carbonylmetal complexes[2,3].

We have been able to use this concept for the first time for the directed synthesis of tetranuclear clusters from two dinuclear precursors. The reactive educts were the dinuclear complexes *(1a)* and *(1b)*, which are predestined by their functionality and folded structure[4] for the addition of further carbonylmetal units. As expected, their reactions with carbonylcobalt led smoothly to the new clusters *(2a)* and *(2b)*, respectively.



*(1a)*, E' = PPhH
*(1b)*, E' = S (with S–S bonding)
*(2a)*, E = PPh
*(2b)*, E = S

The relationship between the two complexes *(2)* manifests itself in the needle-like shape and black color of their crystals and in their IR spectra in the νCO region (in $CH_2Cl_2$ [cm⁻¹], *(2a)*: 2080 vw, 2041 vs, 2020 s, 1950 m, 1862 m; *(2b)*: 2090 vw, 2050 vs, 2039 sh, 2021 sh, 1953 m, 1875 m). They were characterized by crystal structure analyses[5]. The molecular structures and most important bond lengths are shown in Figure 1 and Table 1, respectively.

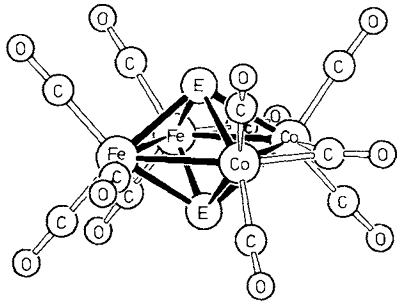


Fig. 1. Molecular structures of *(2a)* (E = phosphorus atom of the $PC_6H_5$ group) and *(2b)* (E = S) in the crystal.

Table 1. Values (average) of the most important atomic distances [pm] in the clusters *(2)*.

| Bond | *(2a)* | *(2b)* |
|---|---|---|
| Fe—Fe | 272.4(3) | 260.4(2) |
| Fe—Co | 262 ± 2 | 258 ± 0.03 |
| Co—Co | 251.5(3) | 249.5(2) |
| Fe—E | 223 ± 0.5 | 227 ± 0.5 |
| Co—E | 227 ± 2 | 231 ± 2 |

*(2a)* and *(2b)* belong to the relatively small group of tetranuclear clusters containing planar metal frameworks[6]. Their metal-metal and metal-bridge atom bond lengths lie in the normal range for such compounds. For both complexes, there exist "pure" cobalt analogues, the clusters $Co_4(CO)_{10}E_2$ (E = PPh, S), which were formed by non-specific syntheses and whose structures are known[7]. These clusters also contain rectangular planar arrays of metal atoms; their $Co_2(CO)_5E_{2/2}$-halves are very similar to those

---

[*] Prof. Dr. H. Vahrenkamp, E. J. Wucherer
Institut für Anorganische Chemie der Universität
Albertstr. 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and by Rechenzentrum der Universität Freiburg. We thank Frl. *D. Steiert* for her valuable help with the preparative work.

of the complexes *(2)*, and their M—M and M—E bond lengths show the same trend as in *(2a)* and *(2b)*.

The intrinsic novelty of the clusters *(2)* is, therefore, their systematic preparation. Since numerous functional dinuclear complexes having the butterfly structure shown in *(1a)* and *(1b)* and suitable simple carbonylmetals for reaction exist, the route described here to planar tetranuclear clusters should not be merely limited to *(2a)* and *(2b)*.

### *Procedure*

Equimolar amounts (1—2 mmol) of *(1a)* or *(1b)* and $Co_2(CO)_8$ are added to 50 ml of hexane. For the formation of *(2a)* the mixture is stored in the dark for 20 d at room temperature, then chromatographed on silica gel, and finally the product obtained from the third fraction is crystallized from hexane at −30 °C. The complex *(2b)* precipitates from the reaction mixture in analytically pure form after 12 h at 0 °C. The yields of *(2a)* (m.p. 134 °C, dec.) and *(2b)* (dec. at 100—200 °C without recognizable m.p.) are 20—25%.

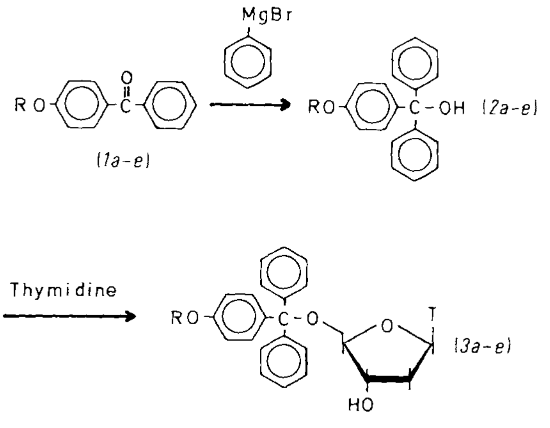
## New Hydrophobic Protecting Groups for the Chemical Synthesis of Oligonucleotides[**]

By *Hans-Helmut Görtz* and *Hartmut Seliger*[*]

In the chemical synthesis of polynucleotide fragments by the triester procedure[1,2], chromatographic methods are important for the purification of protected intermediates and for the isolation of the unprotected final product[2,3]. The chromatographic behavior of the oligomers can be varied within certain limits by protecting groups, generally producing an unspecific change in the total polarity of the molecule. We have introduced 4-alkoxytrityl groups as a novel type of hydrophobic protection for the 5′-end of oligonucleotides[4]. For this purpose, the 4-alkoxytritanols *(2a—e)* were prepared by Grignard reaction from *(1a—e)* and the trityl chlorides reacted with thymidine to produce *(3a—e)*.



| (1)-(3) | a | b | c | d | e |
|---|---|---|---|---|---|
| R = | $C_8H_{17}$ | $C_{10}H_{21}$ | $C_{12}H_{25}$ | $C_{14}H_{29}$ | $C_{16}H_{33}$ |

As expected, the $R_f$-values of the 5′-*O*-(4-alkoxytrityl)thymidines *(3a—e)* on silica gel are somewhat higher and on RP-2 somewhat lower than the $R_f$-values of 5′-O-(4,4′-dimethoxytrityl)thymidine. These changes reflect the reduction in total polarity. The behavior of *(3a—e)* upon RP (reversed phase) chromatography on a $C_{18}$-phase is, however, different: here, an apparently specific interaction between the alkyl chains of the sorbent and sorbate leads to a dramatic reduction of the $R_f$-values with increasing chain length upon thin layer chromatography (Fig. 1) and increasing retention times in HPLC (Fig. 2).

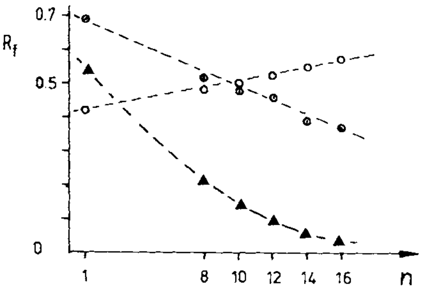


Fig. 1. Dependence of the $R_f$-values on the alkyl chain length n of compounds *(3)* [n = 8, 10, 12, 14, 16 ≡ *(3a, b, c, d, e)*]. ○: silica gel 60 (Merck), chloroform/methanol 9:1; ●: silica gel RP-2 (Merck), acetone/water 75:25; ▲: silica gel $KC_{18}$ (Whatman), acetone/water 75:25.

The 4-hexadecyloxytrityl ($C_{16}$Tr-) derivatives [*(6), (8), (11), (13)* and *(16)*] among the oligonucleotide phosphotriesters *(4)—(16)* (Table 1) exhibit the same characteristic behavior as the monomers *(3)* upon RP-18 chromatography. Of prime interest for preparative application is the magnitude of the $R_f$-difference between the $C_{16}$Tr-derivatives and the corresponding compounds having free 5′-OH groups, which indicates an easy and complete HPLC separation of both types of components irrespective of the chain length and sequence. This is in contrast to separations of the 4-methoxy- or 4,4′-dimethoxytrityl (DMTr) derivatives used so far, in which the starting components with 3′-terminal phosphate charge can readily be separated from the reaction mixture arising from nucleotide condensations, however, good separation of the oligonucleotides

[**] Syntheses with Nucleic Acid Constituents, Part 9.—Part 8: *H. Seliger, B. Haas, M. Holupirek, T. Knäble, G. Tödling, M. Philipp*, Nucleic Acids Res. Symp. Ser. *7*, 191 (1980).

with free 5'-OH groups requires a complicated after-treatment[5]. For purposes of clarification, the $R_f$-values of the nucleotide sequences having a terminal $C_{16}$Tr-[*(8)*, *(13)*, *(16)*] or DMTr-group [*(7)*, *(12)*, *(15)*] shown in Table 1, should be compared with their precursors *(4)*, *(9)* and *(14)*.

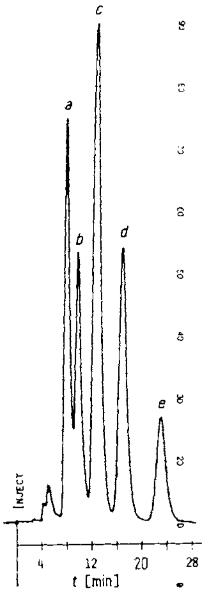

Fig. 2. HPLC separation of compounds *(3a–e)*. Column: μ-Bondapak $C_{18}$ (Waters), eluent: 2-propanol/methanol/water 6:2:2, flow rate: 1 mL/min, pressure: 130 bar, detection: $UV_{254}$.

Table 1. $R_f$-values of compounds *(4)–(16)* [a] in systems A, B and C [b].

| | Cpd. | A | B | C |

| *(14)* | $\mathrm{dTpC^{bz}pTpC^{bz}_{Bz}}$ | 0.73 | 0.89 | 0.96 |
| *(15)* | $\mathrm{DMTrdG^{ibu}pA^{bz}pG^{ibu}pA^{bz}pTpC^{bz}pTpC^{bz}_{Bz}}$ | 0.56 | 0.86 | 0.87 |
| *(16)* | $\mathrm{C_{16}TrdG^{ibu}pA^{bz}pG^{ibu}pA^{bz}pTpC^{bz}pTpC^{bz}_{Bz}}$ | 0.72 | 0.33 | 0.21 |

[a] p = *p*-chlorophenylphosphoryl; CE = β-cyanoethyl; DMTr = 4,4'-dimethoxytrityl, $C_{16}$Tr = 4-hexadecyloxytrityl. [b] A: silica gel 60 (Merck); chloroform/methanol 9:1; B: silica gel RP-8 (Merck); acetone/water 85:15; C: silica gel RP-18 (Merck); acetone/water 85:15. [c] Diastereomeric pairs.

Bearing in mind that the advantage of the triester method rests mainly upon the rapid and simple removal of the reaction precursors, the possibility of also separating the hydroxy component in a selective way should substantially increase the efficiency of the process. In this context the analogy of the $C_{16}$Tr- to the 4-methoxy-group with respect to the introduction and cleavage conditions requires no change in the synthetic strategy.

## *Procedure*

*(1e)*: 4-Hydroxybenzophenone (39.6 g, 0.2 mol), 1-bromohexadecane (61.1 g, 0.2 mol) and a trace of KI are added to a solution of 0.2 mol sodium ethoxide in 200 mL ethanol. After refluxing the mixture for 5 h, the ethanol is removed *in vacuo* and the residue is taken up in 100 mL $CH_2Cl_2$/1 N NaOH. The aqueous phase is separated, extracted twice with $CH_2Cl_2$, the combined organic phases washed with a little water, dried over sodium sulfate and the solvent removed. Vacuum distillation of the residue (air condenser!) gives 45.6 g (54%) of a light beige liquid, b.p. = 255 °C/1 torr, which solidify on cooling (m.p. = 73 °C)[6].

*(2e)*: A solution of *(1e)* (42.2 g, 0.1 mol) in 50 mL tetrahydrofuran (THF) is dropped into a solution of 0.125 mol phenylmagnesium bromide in 50 mL ether over 30 min. After the addition, the mixture is boiled for 1 h and upon cooling poured onto an ice/hydrochloric acid slush. The organic phase is separated and the aqueous phase extracted with THF (2 x 50 mL). After being washed with water, $NaHCO_3$ solution and water again, the combined organic phases are dried over sodium sulfate and the solvent removed. The oily residue is taken up in pentane and recrystallized at −20 °C; yield 37.6 g (75%), m.p. = 56–58 °C[6].

*(3e)*: A solution of *(2e)* (750 mg, 1.5 mmol) in 10 mL benzene and 3 mL acetyl chloride are heated for 1 h under reflux, concentrated and evaporated to dryness three times with benzene (3 x 10 mL). The residual oil is taken up in 3 mL anhydrous pyridine, and thymidine (242 mg, 1 mmol) and 2 mg 4-dimethylaminopyridine are added. At the end of the reaction (*ca.* 2 h, monitored by thin layer chromatography) and after addition of 10 mL 5% $NH_4HCO_3$ solution, the mixture is extracted twice (2 x 10 mL) with chloroform. The dried organic phase is concentrated, successively twice evaporated to dryness with toluene, ethanol and chloroform, dissolved in a little chloroform and chromatographed on silica gel (Merck 7733, 1.5 x 7 cm column, chloroform eluent). The product fractions are concentrated and solid *(3c)* obtained by concentrating twice with pentane; yield 545 mg (75%)[6].

## Specific Separation of Products in Supported Oligonucleotide Syntheses Using the Triester Method[**]

By *Hartmut Seliger* and *Hans-Helmut Görtz*[*]

In the search for simplified syntheses of oligonucleotides having a specific sequence, methods involving polymeric supports are of considerable interest. However, incomplete lengthening of the chains immobilized on the carrier leads to formation of a mixture of homologous sequence fragments from which the desired product can only be obtained in sufficient purity with considerable expenditure of effort. Earlier we described procedures to separate the product chain, *i. e.* generally the longest sequence, from all by-products by selective affinity labelling[1]. We have now applied this scheme to supported oligonucleotide syntheses using the triester method[2]. This aspect has not been considered in other triester carrier syntheses[3].

As new support materials we prepared "popcorn" copolymers[4] from styrene and the 5′-tritylated deoxynucleoside-3′-*p*-vinyl benzoates *(1)* [styrene :*(1)* ≅ nucleoside loading of support material = 0.09 mmol/g *(2a)* and 0.02 mmol/g *(2b)*] (Scheme 1).

With this support a chain-lengthening step was performed in which, *1)* the 5′-OH protecting group was removed by treatment with acid, *2)* the product was condensed with *ca.* a threefold excess of 5′-O-(4,4′-dimethoxytrityl)thymidine-3′-*p*-chlorophenyl phosphate and *3)* the unreacted chain-ends were blocked by reaction with acetic anhydride in pyridine. This chain-lengthening step was repeated. Subsequently, the chains were further lengthened by block condensation with a trithymidylate moiety, which was protected at the 5′-end by a hexadecyloxytrityl group[5]. Following ammoniacal cleavage from the support, the product mixture was separated by HPLC. By this means the hexanucleotide $C_{16}TrdT(pT)_5$ was specifically separated (Fig. 1, fraction P); after cleavage of the $C_{16}Tr$-group it proved to be chromatographically homogeneous and identical with authentic material synthesized by a support-free method[5]. The yields, relative to the immediate precursor, were determined to be 51, 57 and 58% respectively, following VIS spectroscopic investigation of the acid-treated carrier samples. By means of the support-method described here, the advantages of the triester method—generally increased yields at shortened reaction times and with only a slight excess of one reactant—can be used in solid phase synthetic procedures.

Scheme 1. Synthesis of $dT(pT)_5$ on support. *A:* 1) "Popcorn" copolymerization, 2) H$^+$; *B:* 1) DMTrTp$^-$, mesitylenesulfonyl tetrazolide, 2) acetic anhydride, pyridine, 3) H$^+$, 4) Repeat of 1)–3); *C:* $C_{16}Trd(Tp)_3^-$, mesitylenesulfonyl tetrazolide; *D:* 1) aqueous $NH_3$/pyridine, 2) HPLC on $C_{18}$-phase, 3) H$^+$. p=*p*-chlorophenylphosphoryl, DMTr=4,4′-dimethoxytrityl, $C_{16}Tr$=4-hexadecyloxytrityl.

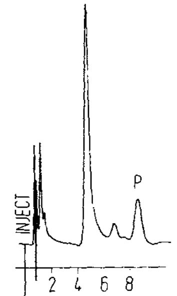

Fig. 1. Separation of the sequence $C_{16}TrdT(pT)_5$ (P) from the by-products of the supported synthesis by HPLC. Column: μ-Bondapak $C_{18}$ (Waters), eluent: 2-propanol/methanol/water 50 : 15 : 35, flow rate: 2 ML/min, pressure: 110 bar, detection: UV$_{254}$.

### *Procedure*

*(1a):* 5′-*O*-(4-Hexadecyloxytrityl)thymidine[5] (725 mg, 1 mmol) is dissolved in 5 mL anhydrous pyridine and the solution mixed with 4-vinylbenzoyl chloride[6] (500 mg, 3 mmol). After stirring for 30 min, 10 mL of a 5% $NH_4HCO_3$ solution is added to the mixture which is then extracted with chloroform (2 x 15 mL). After drying over sodium sulfate, the organic phase is separated, the pyridine removed by azeotropic distillation with toluene, and the residue chromatographed (Merck 7734, column 1.5 x 7 cm, eluent chloroform). Approximately 700 mg (80%) of a light yellow oil, $R_f$ = 0.73 (educt: 0.43; silica gel, chloroform/methanol 9 : 1); UV: $\lambda_{max}$ = 265 nm.—*(1b)* is synthesized analogously.

[**] Polymer supported synthesis, Part 9.—Part 8: see [1].

*(2):* Nucleoside *(1)* is lyophilized from benzene and then dissolved in the stoichiometric amount of freshly distilled styrene. After addition of 0.2% divinyl benzene and some popcorn-polystyrene-seeds, the mixture is maintained at 50 °C until the reaction had ceased (*ca.* 4 to 8 h). The polymer is thoroughly washed with benzene and ether and dried *in vacuo* (yield almost quantitative). Cleavage of the 5′-*O*-protecting group follows by treatment with a 2% solution of benzenesulfonic acid in chloroform/methanol (7 : 3; 1 h, 0 °C). After washing with methanol, chloroform and ether and repeated drying, the support is ready for use.

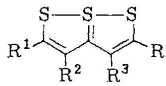
## Catalytic Lithiation of 1-Olefins

By *Borislav Bogdanović* and *Bernd Wermeckes*[*]

In 1967 *D. L. Skinner et al.*[1] described the reaction of 1-olefins with lithium to give 1-lithio-1-alkynes and lithium hydride, whereby (*E*)-1-lithio-1-alkenes are formed as by-products. In 1975, *V. Rautenstrauch*[2] reported that small amounts of 1-lithioethylene and 1,4-dilithiobutane are formed in the reaction of lithium with ethylene in dimethoxymethane or tetrahydrofuran (THF) in the presence of biphenyl and naphthalene. Direct lithiation, however, has so far been limited to "acidic" hydrocarbons such as 1-alkynes[3a], triphenylmethane[3b] or cyclopentadiene[3c,d].

In our studies on the catalytic properties of the poly(alkali metal) complexes[4a] obtainable from 1,6,6a$\lambda^4$-trithiapentalenes *(1)* or related compounds and alkali metals, we found catalysts for a direct reaction of 1-olefins with lithium to give organolithium compounds of the vinyl- and allyl-type, respectively, and lithium hydride[4b].

For the catalytic lithiation, the 1-olefins were allowed to react with lithium sand in THF at 0 °C in the presence of a catalytic amount of a 1,6,6a$\lambda^4$-trithiapentalene *(1)* (or a related compound) and a metal salt[5]. Combinations of 2,5-[6] or 2,4-diphenyl-1,6,6a$\lambda^4$-trithiapentalene[6b] [*(1a)* and *(1b)*, respectively], anhydrous zinc- or iron(III) chloride, and lithium have proven to be particularly effective catalysts for the lithiation of olefins.



*(1a)*, $R^1 = R^4 = C_6H_5$, $R^2 = R^3 = H$
*(1b)*, $R^1 = R^3 = C_6H_5$, $R^2 = R^4 = H$

Lithiation of ethylene with the catalysts prepared from *(1a)*, $ZnCl_2$ and lithium affords vinyllithium in 70—75% yield, together with lithium hydride and small amounts (2—3%) of 1,ω-dilithioalkanes[2]. The course of the reaction with time is illustrated in Figure 1.

$$H_2C{=}CH_2 + 2\ Li \xrightarrow[THF]{cat.} H_2C{=}CHLi + LiH$$

After completion of reaction $H_2C{=}CHLi$ can be separated from the precipitated LiH and isolated in crystalline form as $C_2H_3Li \cdot THF$.

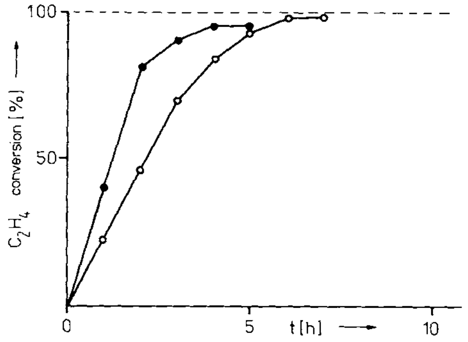


Fig. 1. Plot of the lithiation of ethylene at 0 °C/1 bar in THF with time; (—●—) Li : *(1a)* : $ZnCl_2$ = 100 : 1 : 2, [*(1a)*] = 0.04 mol/L; (—○—) Li : *(1a)* : $ZnCl_2$ = 200 : 1 : 2, [*(1a)*] = 0.02 mol/L.

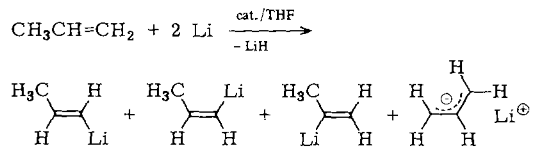
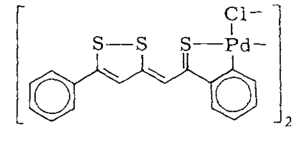
In the catalytic lithiation of propene the four isomeric $C_3H_5Li$ compounds *(2)*—*(5)* are formed along with LiH. On using the catalyst of combined *(1a)*, $ZnCl_2$ and Li, the $C_3H_5Li$ compounds are obtained in a total yield of 75—85%. The (*E*)-propenyllithium *(2)* is present up to 85—90% in the mixture; it can be enriched to 98.5% by double recrystallization from THF/pentane (1 : 1).



*(2)* *(3)* *(4)* *(5)*

When combinations of *(1a)* or *(1b)*, palladium(II)- or platinum(II) chloride and lithium are used as catalysts the main product is *(5)*. The highest selectivity for the formation of *(5)* (80—90%) has so far been achieved with the complex *(6)*[7], preparable from *(1a)* and $PdCl_2$, as catalyst.



*(6)*

Analogously to propene, higher 1-olefins also react with the catalyst from *(1a)*, $ZnCl_2$ and lithium to give (*E*)-1-lithio-1-alkenes. Moreover, the selectivity is higher than in

Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr 1 (Germany)

the case of propene; thus, 1-butene, 1-hexene and 1-octene can be catalytically lithiated to the products *(7)* with selectivities of 90—95, 95, and 94—97%, respectively.
