Another result of the previous analysis is of general interest: for reactions influenced by the polarity of the medium, the free energy of activation, ΔG^+, should, at least in solvent mixtures, be a more simple parameter than ΔH^+ and ΔS^+, since these always contain contributions from the thermal expansion of the liquid, which are not reaction-specific. Special attention is, therefore, required when a solvent mixture exhibits two regions of validity of equation (4) (cf. also Section 4.2).

4.2. Nonlinear Winstein Relationships

The results just mentioned lead to other applications of equation (4) to mechanistic studies: Linear correlation of a process with the Winstein relationship is often used as a mechanistic criterion, by analogy to other linear free energy (LFE) relationships (*e.g.* see [32, 60–64]). In the first place, the value m, the slope of the straight line, is interpreted as a measure of the sensitivity of the reaction studied to solvent polarity effects, and is often related to increase or decrease of charge separation leading to the transition state. Furthermore, a linear correlation over a large range of solvent polarity is used as an indication of a uniform reaction mechanism in different solvents. In order to obtain a sufficient number of measurements, reactions are usually studied using solvent mixtures, often ethanol-water.

As the polarity of these mixtures is governed by equation (4), it seems worthwhile to redefine the previously mentioned mechanistic criteria on the basis of equation (4).

From equation (4), the slope m of a relationship between two polarity-dependent processes P_{G1} and P_{G2} is described by equation (5).

$$m = \frac{dP_{G1}}{dP_{G2}} = \frac{E_{D1}(c_p + c_2^*)}{E_{D2}(c_p + c_1^*)} \tag{5}$$

A good linear relationship between P_{G1} and P_{G2} requires that the slope m in equation (5) is independent of c_p, and hence, one of the following three conditions must be fulfilled:

1. The c^*-values of both processes are similar ($c_1^* \approx c_2^*$). The logarithmic term in equation (4) has an approximately equal numerical value in both cases for a given value of c_p. Consequently, P_{G1} and P_{G2} are linearly dependent.
2. The c^*-values are different in both cases, but considerably larger than c_p^{max} ($c_1^*, c_2^* \gg c_p^{max}$). Equation (4) can be expanded in both cases as a Taylor series, which as usual is terminated. A linear relationship between P_G and c_p results and, likewise, a linear relationship between P_{G1} and P_{G2}.
3. The c^*-values are different, but both very small. In each case P_G and $\ln c_p$ are linearly dependent and, therefore, also P_{G1} and P_{G2}.

Often, one of these three conditions is fulfilled. However, if a nonlinear relationship is found, *e.g.* with the Winstein scale, it does not necessarily follow that there is a change in mechanism, or even that a continuous transition from one mechanism to another occurs upon varying the medium (cf. also [65]). This information is obtained only by estimating the c^*-values.

Even more complicated is the influence of the solvent and its dependence on c_p when mixtures with critical transition points (double lines) are used. These are observed particularly when solvolysis reactions are carried out in frequently-used binary mixtures such as acetone-water, 1,4-dioxane-water and ethanol-water (see Table 2)[29, 40]. An example for the mixture ethanol-water is described here.

Brown et al.[66] studied the solvolysis of isopropyl, cyclohexyl, and 2-adamantyl tosylates in ethanol-water. The free energies of activation show good linear correlation with the *Y*-scale up to a water content of *ca.* 50%. At higher water contents, substantial deviations are observed, which represent a regular break in the LFE relationship (Fig. 1 in [66]). Nucleophilic solvent participation with a change in reaction mechanism was discussed. This appears to be contradicted by the behavior of isopropyl tosylate, which, although hardly shielded and easily accessible to nucleophilic attack, shows the smallest deviations. These were finally attributed to a specific solvation of the leaving anion, since the corresponding mesylates show linear relationships with the *Y*-scale.

The solvolysis data can be analyzed on the basis of equation (4). The break in the LFE relationship is observed at a water content of *ca.* 50% and can be interpreted as a critical transition point (see Section 3.1.3). Since similar c^* values are found for the solvolysis of *tert*-butyl chloride and the various tosylates, a discussion of the E_D values according to equation (5) is sufficient. For *tert*-butyl chloride and cyclohexyl mesylate (Table 4, Nos. 1 and 2), the ratio of the E_D values is almost equal in regions I and II. Thus, an approximate LFE relationship is observed for the entire water concentration range. The relatively low E_{DII} value of No. 2 even explains the slight deviations at high water contents.

Table 4. Solvolyses [11, 66] in solvent mixture ethanol-water at 25 °C.

No.	Substrate	Region I			Region II		
		E_{DI} [a]	c_I^* [b]	$\ln k_{0I}$ [c]	E_{DII} [a]	c_{II}^* [b]	$\ln k_{0II}$ [c]
1	*tert*-Butyl chloride	6.7	11.6	−16.1	6.3	0.001	− 7.16
2	Cyclohexyl mesylate	4.7	10.8	−17.3	4.6	(0.001) [d]	—
3	2-Adamantyl tosylate	4.7	8.3	−21.6	9.9	0.001	−11.7
4	2-Propyl tosylate	3.2	12.9	−14.7	5.0	(0.001) [d]	—
5	Cyclohexyl tosylate	8.3	32.8	−16.8	7.7	0.001	− 9.1

[a] In $\ln k_{298}$ units. [b] In mol·L^{-1}. [c] Value for pure alcohol extrapolated from equation (4). [d] Estimated, since too few points available for calculation.

The tosylates, however, behave quite differently (Table 4, Nos. 1, 3, and 4). The much higher values of E_D in region II result in LFE relationships, whose slopes are almost twice as large as those in region I. Therefore, breaks in the relationships must exist at c_k (Fig. 1 in [66]). The c^* value of cyclohexyl tosylate (Fig. 4, Nos. 1 and 5) no longer coincides well with that of No. 1. Appropriately, the resulting LFE relationship is considerably inferior. In this case, a simple comparison of the E_D values is not sufficient. Detailed analysis, however, shows that No. 5 behaves in the same way as Nos. 3 and 4. The solvolysis reactions in acetone-water mixtures can be analyzed in an exactly analogous manner.

Sridharan and *Vitullo*[64] studied the solvolysis of geminal dihalides in 1,4-dioxane-water. Here, also, the LFE relationship with the *Y* scale turned out to be nonlinear, with two straight lines. This was attributed to a change of reaction mechanism and transition to nucleophilic solvent participation. It can be shown, however, that the critical transition point of the 1,4-dioxane-water mixture coincides with the point of intersection of the two lines.

The last examples show that the existence of an LFE relationship is a limited mechanistic criterion for studying solvent-dependent processes in solvent mixtures. Therefore, when examining such processes, binary mixtures should be checked for critical transition points.

4.3. Further Applications

Using equation (4) conclusions about the composition of binary liquid mixtures can be made by considering polarity-dependent phenomena[28,40,67]. Mixtures can be analyzed in this way. Suitable reference substances are solvatochromic dyes. The water content of organic solvents can be estimated by this method, since water has a greater polarity than most organic liquids. The use of solvatochromic dyes in practice was hitherto hampered by the nonlinearity of the calibration curve, which necessitated a great number of experimental points at low water concentrations[68]. Using equation (4) it is now possible to linearize these calibration curves, so that only a few points are necessary. Apart from this, the quasi-logarithmic relationship of equation (4) furnishes the advantage of an almost constant relative error in measurement over a wide concentration range[40]. For a rough estimation of water concentration, even visual comparison with a color scale is sufficient. Solvents such as dimethylformamide or dimethyl sulfoxide present no problems, in contrast to what is experienced with other methods. Colored solutions can be examined in an analogous manner using solvatochromic fluorescent dyes. A triple point method of measurement even dispenses with a fluorescence spectrometer[67].

Furthermore, the polarity of a solution can be adjusted accurately by means of equation (4). This is of interest, when a compound reacts by different mechanisms in polar and nonpolar media. An example is the thermolysis of percarboxylic esters[69] which in nonpolar media generally proceeds homolytically with radical formation; in polar media, however, heterolysis occurs according to the Criegee mechanism. If generation of radicals in a polar medium is desired, it is advantageous to adjust the polarity of the medium to a point at which homolysis just prevails.

In other cases, where the addition of a small amount of polar additive should enhance the solvent polarity as much as possible[44], c^* plays a key role. If $c_p < c^*$, the polarity is strongly dependent on c_p, but if $c_p > c^*$, only to a small extent (this relationship is roughly logarithmic). In order to markedly enhance the polarity by addition of only a small amount of polar additive, c_p should be adjusted to approximately c^*.

Furthermore, it can be concluded from equation (4) that addition of a small amount of polar additive to a solvent of low polarity can enhance the polarity substantially; on the other hand, introducing a nonpolar additive to a polar medium produces hardly any reduction of polarity. This observation corresponds to a considerable amount of empirical data, for example, in chromatography, where polar additives have far greater influence on elution behavior than nonpolar. Polymer chemistry is another field of application for equation (4), where it is not only valid for liquids, but even holds for solids[70]: on the one hand, it character-

izes the effect of polar components on copolymerizations and on the other, that of low-molecular weight additives (plasticizers). This is useful in devising procedures for manufacturing polymers with specific properties.

5. Outlook

Apart from the previously described areas of chemistry, equation (4) can be utilized in many others which can only be mentioned briefly here. In the study of reaction mechanisms, an opportunity is provided to characterize the influence of the medium on a chemical reaction, even when the polarity varies as the reaction progresses. Since equation (4) even describes the polarity of pure alcohols as a function of their chain length[71], it can be expected that the polarity of the pure substances can be composed of increments. The correlations are, however, nonlinear.

Polymer chemistry, offers yet another field of application. Not only can equation (4) be of use in adjusting the polarity of the polymer to a particular value, in the methodical determination of polar additives which enhance polarity even at low concentrations, and in obtaining information on the effect of residual monomer[70], but it also offers the possibility of obtaining information on copolymerization parameters and on interactions between polymers. Finally, preliminary studies on ternary liquid mixtures show that equation (4) can be extended to multi-component systems.

Gratitude is expressed to the Deutsche Forschungsgemeinschaft and the Bundesministerium für Forschung und Technologie for financial support and to my mentor Prof. Dr. C. Rüchardt for continuous encouragement. Calculations were run at the Rechenzentrum of Freiburg University using the computer program POLAR.

Oxygen Transfer from Inorganic and Organic Peroxides to Organic Substrates: A Common Mechanism?

By Hubert Mimoun*

In this progress report an attempt is made to rationalize, from a mechanistic point of view, the different ways in which oxygen is transferred from inorganic and organic peroxides to nucleophilic substrates, particularly olefins. Oxygen transfer from transition-metal peroxides, which is relevant to catalytic oxidations using O_2, H_2O_2 or ROOH, occurs *via* a cyclic or "pseudocyclic" peroxymetalation in which a dioxametallacycle is formed. Owing to the wide discrepancy between peroxymetalation and the conventional oxidation mechanism, *i.e.* nucleophilic attack of the substrate at the electrophilic "active oxygen", we propose an alternative mechanism involving dioxiranes as the reactive species. The generation of dioxiranes appears to be a common denominator in the reactions of most organic peroxides *e.g.* peroxy acids, the reaction of electrophilic ketones with H_2O_2, or ozonizations. Oxygen transfer from dioxirane reagents probably involves the formation of a charge-transfer π-complex between the substrate and the carbon atom of the dioxirane, and the subsequent formation of a cyclic peroxidic intermediate.

1. Introduction

Molecular oxygen, one of the most abundant elements on earth, has until now scarcely been used for the selective oxidation of organic substrates. The reason for this is that O_2 has a triplet ground state, whose direct interaction with singlet-state organic molecules is a spin-forbidden process. Oxygen-transfer reactions are, however, of importance in two areas:

In biochemistry, oxygenases effect monooxygenations *e.g.* hydroxylations of hydrocarbons, epoxidation of olefins and arenes, lactonization of ketones[1], or dioxygenations *e.g.* the oxidative cleavage of various arenes[2] at room temperature; these reactions occur with high selectivity. Since most oxygenases contain transition metals as their active center, the last few years have seen considerable progress in our understanding of the interaction of dioxygen with transition metal complexes[3], and many models have been found and discussed[4].

The second area is in industry where there is a need for mild, selective, single-step oxidations of hydrocarbons to produce valuable products. Most of the present commercial processes are, however, generally based on radical-chain reactions or heterogeneous catalysis[5]. It would be desirable, therefore, to fix molecular oxygen to transition metal catalysts capable of transferring it selectively to coordinated organic substrates.

The easiest and the cheapest way to activate molecular oxygen is to transform it into organic or inorganic reactive peroxides. This article attempts to rationalize, from a mechanistic point of view, the different ways in which oxygen can be transferred from peroxide reagents to organic substrates. This attempt was necessitated by our study of oxygen transfer from inorganic peroxides which indicated a surprising discrepancy with conventional mechanisms of oxygen transfer from organic peroxides. Thus, we observed that the behavior of dioxirane compounds appeared to be closely related to that of inorganic peroxides. Accordingly, we examined whether such species might be involved as reactive intermediates in oxidations by peroxy acids and other peroxides, and found that such a rationalization can be meaningful.

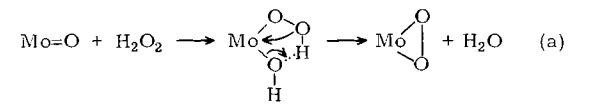
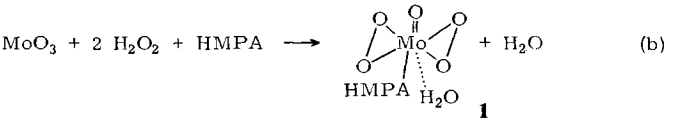
2. Oxygen Transfer from Inorganic Peroxides: Cyclic and Pseudocyclic Peroxymetalation

Our interest in transition-metal peroxide chemistry began in the late 1960s when, after frustrated attempts to isolate stable and well-defined alkylperoxo intermediates in the molybdenum-catalyzed epoxidation of olefins by hydroperoxides[6], we found a new family of peroxomolybdenum and -tungsten complexes of the general formula $MO(O{-}O)_2L^1L^2$ (M = Mo, W; L^1, L^2 = donor ligands such as pyridine, dimethylformamide (DMF), or hexamethylphosphoric triamide (HMPA)). These complexes were obtained from the reaction of molybdenum oxide with hydrogen peroxide in presence of the ligand [reactions (a), (b)][7].



(a)



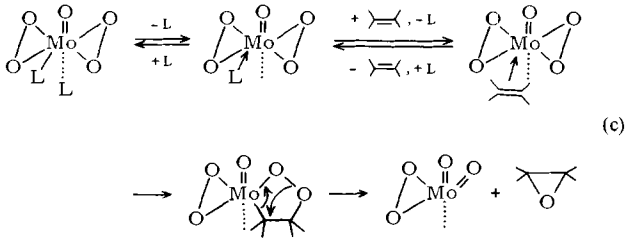
(b)

1

The X-ray structure determination of complex **1** revealed a pentagonal-bipyramidal structure, with HMPA occupying the equatorial position in the same plane as the two peroxo ligands[8]. **1** is easily dehydrated, producing $MoO_5 \cdot$ HMPA, which is highly soluble in organic solvents. $MoO_5 \cdot$ HMPA was found to be a highly effective reagent for the selective epoxidation of olefins at room temperature in aprotic solvents. The reaction is stereospecific (*cis*-

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/1010-0734 $ 02.50/0

olefins give *cis*-epoxides and *trans*-olefins give *trans*-epoxides) and the reactivity of olefins was found to increase with their nucleophilicity[9]. Kinetic studies, which were later reproduced[10], clearly indicated the reversible formation of an olefin-metal complex in the rate-determining step, followed by irreversible oxygen-transfer to the olefin. NMR spectroscopic monitoring of the reaction indicated that HMPA is displaced from the metal during the oxidation. Furthermore, addition of HMPA to the reaction mixture had a large inhibitory effect on the rate of epoxidation. The peroxidic origin of the transferred oxygen atom was later demonstrated using O^{18} labeling studies[11]. Accordingly, we proposed mechanism (c) to account for the general trends of this oxygen-transfer reaction.



(c)

2 3

The olefin-metal interaction is a pure Lewis acid/Lewis base association, since Mo^{VI} has no d electrons available for back-bonding to the olefin. We would therefore expect the olefin to lose its nucleophilic nature upon coordination, making possible the nucleophilic attack of the coordinated oxygen *via* an intramolecular 1,3-dipolar cycloaddition. The resulting five-membered dioxometallacycle (see **2**) then decomposes by 1,3-dipolar cycloreversion to produce the epoxide and the characterized molybdenum complex **3**. Since the equatorially bound HMPA is displaced by the olefin, it seems likely that the coordinated "dipolarophilic" olefin and the peroxo moiety occupy coplanar adjacent sites.

Although this mechanism disagrees with *Bartlett*'s widely accepted mechanism for the epoxidation of olefins by peroxy acids[12] (see Section 3.1) it is perfectly consistent with the π-σ rearrangement (*cis*-insertion) which occurs in most transition-metal catalyzed transformations of olefins[13]. This cyclic peroxymetalation is similar to the "dimerization" of two coordinated olefins at a metal center involving formation of metallacyclopentanes[14].

Asymmetric epoxidation of simple olefins (*e.g.* propene, *trans*-2-butene) has been achieved stoichiometrically using peroxo molybdenum complexes bearing chiral bidentate ligands[15a]. The X-ray structure determination of $MoO_5 \cdot (+)$-MeCHOH—$CONMe_2$ revealed that the chiral (*S*)-*N*,*N*-dimethyllactamide has bidendate coordination through the carbonyl group at the equatorial position, and through the hydroxyl group at the axial position (Fig. 1)[15b]. The complex was found to epoxidize *trans*-2-butene with enantiomeric excess (e.e.) of up to 35%. Since peroxomolybdenum complexes bearing chiral monodentate ligands exhibit no asymmetric induction, it was assumed that the origin of this asymmetric induction is that *N*,*N*-dimethyllactamide remains axially coordinated *via* the hydroxyl group during the reaction, while the equatorial carbonyl group is displaced by the olefin by analogy to reaction (c) and hence permits formation of the dioxametallacycle[16].

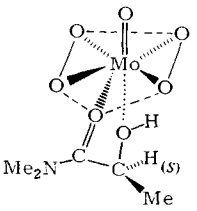


Fig. 1. Structure of the peroxo complex $[MoO(O_2)_2(MeCHOH—CONMe_2)]$.

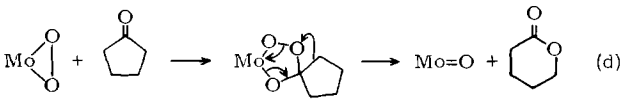
Peroxo molybdenum complexes have also been shown to α-hydroxylate enolizable ketones, probably *via* epoxidation of the enolate[17], and to cause Baeyer-Villiger lactonization of cyclic ketones *via* formation of five-membered trioxametallacycles [reaction (d)][18].

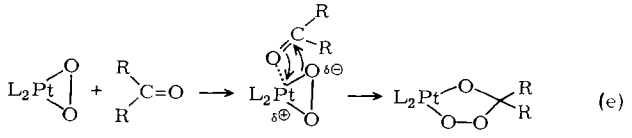


(d)

4

Since the discovery by *Vaska* in 1963 of adducts formed from the reversible addition of dioxygen to $IrCl(CO)(PPh_3)_2$[19] and the characterization of their structure as peroxo complexes[20], a great number of similar transition-metal dioxygen adducts have been reported[3]. Such compounds, *e.g.* $M(PPh_3)_2O_2$ (M = Ni, Pd, Pt) were found to be active catalysts for the oxidation of phosphanes[21] or isonitriles[22], but their use as catalysts for the oxidation of olefins by O_2 led to the same products as those obtained from free-radical chain autoxidations[23].

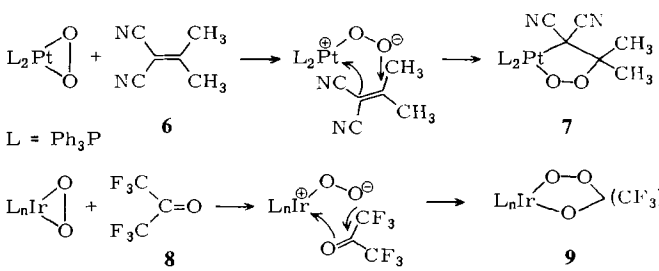
These dioxygen complexes form stable five-membered dioxametallacyclic adducts by reaction either with nucleophilic ketones[24], or electrophilic olefins[25] or fluoroketones[26]. The reaction of $(Ph_3P)_2PtO_2$ with nucleophilic ketones requires coordination of the substrate to the metal prior to the intramolecular nucleophilic attack of the peroxidic moiety at the electrophilic carbon atom bearing the carbonyl group [reaction (e)][24].



(e)

L = Ph_3P 5

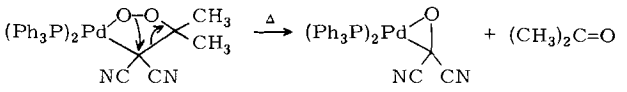
In the case of electrophilic substrates, the peroxo-metallic adduct results from the bimolecular 1,3 dipolar cycloaddition of the peroxo moiety to a cyanoolefin, such as **6**[25b], or a fluoroketone, such as **8**[26].



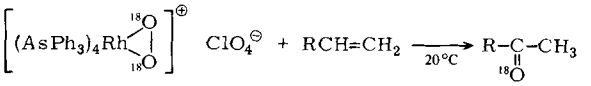
L = Ph_3P 6 7

8 9

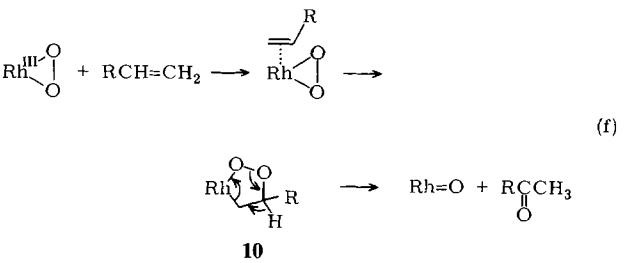
However, the thermal decomposition of the analogously obtained palladium adduct led to oxidative cleavage products instead of to the expected epoxide[25b].



The first evidence for an oxygen-transfer reaction from a dioxygen transition-metal complex to an unactivated olefin was provided by the selective formation of a methyl ketone from ^{18}O-labeled $[(AsPh_3)_4RhO_2]^+ClO_4^-$ and terminal olefins under O_2-free, anhydrous conditions (R = *n*-C_6H_{13}, 85% yield)[27].



This oxygen-transfer reaction was based on the important discovery of *Read et al.*, who found that rhodium complexes such as $RhCl(PPh_3)_3$ were able to promote the co-oxygenation of terminal olefins to afford methyl ketones and of PPh_3 to afford PPh_2O using conditions under which a Wacker-type oxidation (hydroxymetalation of the coordinated olefin by water) was disfavored[28]. Our results on the $RhCl_3/Cu(ClO_4)_2$- or $Rh(ClO_4)_3$-catalyzed oxidation of terminal olefins to methyl ketones by molecular oxygen also led to the conclusion that O_2-activation and O-transfer are involved in reaction (f)[29].



(f)

10

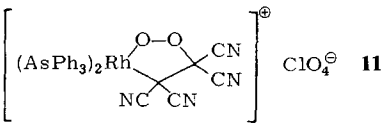
This catalytic reaction occurs under mild conditions with product selectivities, based on the terminal olefin and O_2 consumption, of up to 99%. The reaction is strongly inhibited by the presence of water and is accelerated when a dehydrating agent such as 2,2-dimethoxypropane is added to the reaction medium: competition between olefin and oxygen is observed. Higher O_2 partial pressure inhibits the oxidation of terminal olefins, whereas strongly complexing olefins, *e.g.* styrene or cyclooctene, were found to be less reactive. The reaction is strongly inhibited by ligands, *e.g.* phosphanes or strongly complexing diolefins, *e.g.* 1,5-cyclooctadiene, which compete with the substrate by occupying the vacant coordination sites at the metal.

The product pattern depends on the rhodium-olefin interaction. Terminal and internal olefins, *e.g.* cycloheptene, which form π-complexes with Rh^I, *e.g.* $[RhCl(olefin)_2]_2$, are selectively converted into ketones, whereas olefins which form π-allylic complexes with Rh^{III}, *e.g.* cyclopentene, afford alkenyl ethers *via* oxidative substitution of the olefin by the alcohol used as solvent[29].

The overall catalytic oxidation of terminal olefins to methyl ketones by molecular oxygen has been interpreted as resulting from two reaction steps: an oxygen activation path *via* cyclic peroxymetalation leading to consumption of one oxygen atom and a catalytic Wacker-type hydroxymetalation in which the second atom of O_2 is consumed.

The oxygen activation and transfer reaction depicted in reaction (f) involves coordination of both olefin and the oxygen atom to the same metal center, followed by the Markovnikov-directed peroxymetalation of the coordinated olefin. The decomposition of the dioxarhodacycle **10** occurs *via* a different mode from that of the dioxamolybdacyclo **2**; the less electrophilic nature of rhodium directs the electron transfer toward the β-carbon atom, and induces a β-hydrogen shift.

The dioxarhoda(III) adduct **11** has been isolated from the reaction of $[(AsPh_3)_4RhO_2]ClO_4$ with tetracyanoethylene. $[RhO_2(Ph_2P(CH_2)_2PPh_2)_2]ClO_4$, a peroxo rhodium complex containing bidentate phosphanes as ligands, was found to be inactive with terminal olefins, illustrating the necessity of vacant sites at rhodium[30].

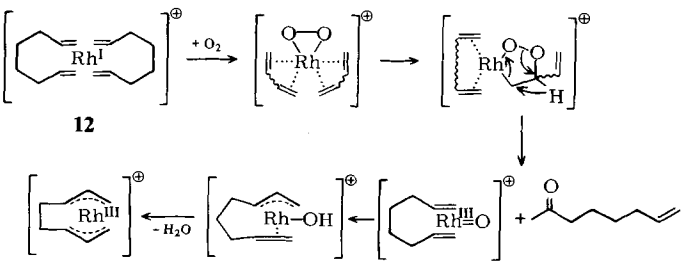


11

Further support for the oxygen activation process in the rhodium-catalyzed oxidation of terminal olefins to methyl ketones comes from the work of *Mares et al.*, who showed that in the presence of both $^{16}O_2$ and $H_2{}^{18}O$, 1-octene was oxidized to unlabeled 2-octanone using $RhCl(AsPh_3)_3$ as catalyst[31].

As shown in reaction (f), the intermediate **10** can be obtained from the reaction of a peroxorhodium(III) complex with the olefin. It may also result from the reaction of an olefinrhodium(I) complex with dioxygen. We succeeded in isolating $[Rh^ICl(1,7\text{-octadiene})]_2$, which reacted with $AgBF_4$ in the presence of 1,7-octadiene to afford the cationic complex **12** containing only olefinic ligands at Rh^I.

In anhydrous isopropanol, and even in the presence of excess 1,7-octadiene, **12** absorbs 1 mol of dioxygen per mol of rhodium, producing *ca.* 1 mol of 7-octen-2-one and 1 mol of water. Since no acetone was formed, we assume that the hydrogen source for H_2O was the olefin itself; the π-allylic complex of Rh^{III} is formed by opening the dioxarhodacyclo by a β-hydrogen shift.



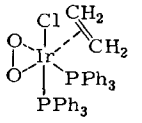
12

Anion: $BF_4^\ominus$

In the presence of 1 equivalent of HBF_4 and a large excess of 1,7-octadiene, more than 1 mol of O_2 was absorbed per mole of rhodium, whereas neither water nor acetone (from isopropanol used as solvent) were produced. Under these conditions, both atoms of O_2 were incorporated into 2 mol of the olefins, and the production of 7-octen-2-one is slightly catalyzed. This catalytic reaction interpreted as a peroxymetalation step followed by a Wacker-type hydroxymetalation of the coordinated olefin (*vide supra*).

It therefore appears that peroxo molybdenum complexes and dioxygen rhodium complexes exhibit similar behavior in transferring oxygen to olefins. Both involve coordination of the olefin to the metal, followed by intramolecular 1,3-dipolar cycloperoxymetalation of the substrate. The difference in the nature of the resulting oxygenated products (epoxides, ketones, or oxidative cleavage compounds) is due to the different mode of decomposition of the dioxametallacycle, and depends on the electrophilicity of the metal and the nature of the substrate. Such a directed transfer of oxygen to unactivated olefins cannot occur directly from other peroxo complexes, since this requires special coordination possibilities *i.e.* coplanar adjacent location of the substrate and the peroxy ligands at the metal. This is the case for $M(PPh_3)_2O_2$ complexes (M = Ni, Pd, Pt) as well as iridium complexes **13** containing both O_2 and ethylene[32].

$$[IrCl(C_8H_{14})_2]_2 + 2\ PPh_3 + C_2H_4 + O_2 \longrightarrow$$



13

This is also the case for some early peroxo transition-metal complexes having 18 electrons in the valence shell, *e.g.* $(C_5H_5)_2NbO_2Cl$[33] or a porphyrin ring, *e.g.* (tpp)$Mo(O_2)_2$[34] or (tpp)TiO_2[35] (tpp = tetraphenylporphyrin).

In the last mentioned oxygen-transfer reactions from peroxo complexes, the primary oxygen source is generally H_2O_2 in the case of early transition-metal complexes, or O_2 in the case of group VIII metals. However, there is another class of metal-catalyzed oxidations in which the reactive intermediates are M—O—O—R or M—O—O—H species. These involve molybdenum-, boron-, or aluminum-catalyzed epoxidation of olefins by alkyl hydroperoxides and palladium-catalyzed oxidation of terminal olefins to methyl ketones by alkyl hydroperoxides or hydrogen peroxide.

In the palladium-catalyzed ketonization of terminal olefins by *tert*-butyl hydroperoxide, our attempts to isolate the reactive intermediates led to the successful preparation of stable, well-defined *tert*-butyl peroxo palladium carboxylates of general formula $[Pd(RCO_2)(OO\mathit{t}Bu)]_4$ **14**; the structure of the derivative **14a** (with $R = CCl_3$) is depicted in Figure 2[36].

These palladium alkyl peroxides were found to be very efficient reagents for the selective transformation of terminal olefins into methyl ketones in anhydrous non-basic organic solvents at room temperature. The reactivity of these complexes toward terminal olefins decreases in the order $R = CF_3 > C_5F_{11} > CCl_3 > CH_3$. The reaction of *tert*-butyl

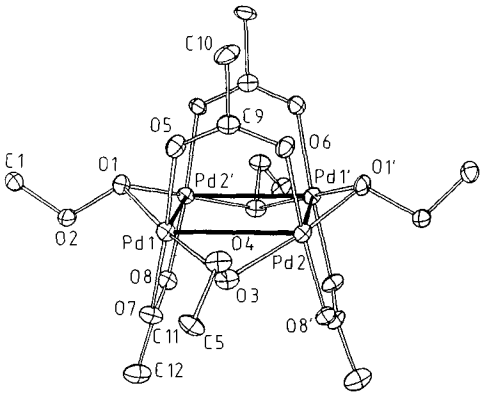


Fig. 2. Molecular structure of the tetrameric palladium complex $[Pd(Cl_3CCO_2)(OO\mathit{t}Bu)]_4$ **14a** in the crystal. In the interests of clarity, chlorine atoms and methyl groups have been omitted.

peroxo palladium trifluoroacetate **14b** with 1-hexene has been shown to proceed in two steps: oxygen transfer from the complex to the olefin affording the methyl ketone and the *tert*-butoxy palladium complex **15b**; rapid substitution of the *tert*-butoxy group on the metal by the olefin, gives rise to *tert*-butanol and a π-allylic complex [reaction (h)].

$$CF_3CO_2Pd{-}OO\mathit{t}Bu + \text{  } \xrightarrow{k_1}$$

14b (g)

$$CF_3CO_2Pd{-}O\mathit{t}Bu + \text{  }$$

15b

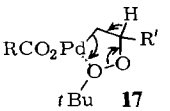
$$\textbf{15b} + \text{  } \xrightarrow{k_2} CF_3CO_2Pd\text{  } + \mathit{t}BuOH \quad \text{(h)}$$

$k_2 \gg k_1$

Only terminal olefins can be effectively transformed by the palladium reagent **14b**. Internal olefins produce the π-allylic complex directly, liberating *tert*-butyl hydroperoxide. A consideration of the general trends of this oxidation led us to propose the mechanism depicted in (i) for the oxygen-transfer reaction.

$$RCO_2Pd{-}OO\mathit{t}Bu \xrightarrow{+\ \text{ }} RCO_2Pd{-}OO\mathit{t}Bu \longrightarrow$$

14 **16** (i)



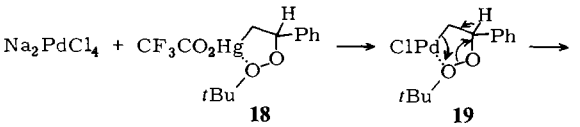
$RCO_2Pd{-}O\mathit{t}Bu$ +

17

The first step consists of coordination of the terminal olefin to palladium produces complex **16**. Intramolecular nucleophilic attack of the *t*BuOO group at the coordinated electrophilic olefin constitutes the "*cis*-peroxypalladation" step and gives rise to the formation of the five-membered pseudocyclic intermediate. Decomposition of **17** occurs by rupture of the O—O bond, followed by a β-

hydrogen shift, producing the methyl ketone and the *tert*-butoxy palladium complex **15**. This reaction step is similar to that of the dioxarhodacycle **10**.

It is noticeable that the pseudocyclic intermediate **17** strongly resembles the stable alkyl peroxymercury complex **18** prepared from the reaction of *t*-BuOOH with an olefin in the presence of mercury(II) carboxylate[37]. The recent X-ray structure determination of an adduct of this type, BrHg—CH(Ph)CH(Ph)—OO*t*Bu, has clearly shown the existence of an interaction between mercury and the oxygen atom adjacent to the *tert*-butyl group, forming the five-membered pseudocyclic structure[38]. Owing to the easy transmetalation of organomercury compounds with palladium chloride[39], we expected that the reaction of Na_2PdCl_4 with **18** would produce the unstable pseudocyclic intermediate **19**, which subsequently decomposes to afford the methyl ketone. Indeed, acetophenone was formed in 95% yield from this reaction at 20 °C in tetrahydrofuran (THF), together with insoluble $HgCl_2$[36].



18 **19**

$$PhCCH_3 + HgCl_2 + CF_3CO_2Na + ClPdO\,tBu$$

Methyl ketones can be produced catalytically when an excess of *t*-BuOOH is used for regenerating **14** from the resulting alkoxy complex **15** [reaction (i)]. In order to avoid formation of a π-allylic complex and hence lower selectivities, a large excess of *t*-BuOOH with respect to the olefin is required[40].

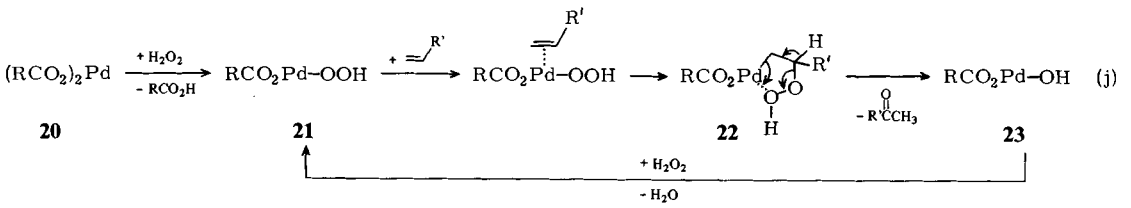
$$tBuOOH + RCH{=}CH_2 \xrightarrow{Pd(RCO_2)_2\ \mathbf{20}} tBuOH + RCCH_3 \quad (O)$$

We have also recently found that palladium(II) carboxylates are effective catalysts for the selective oxidation of terminal olefins to methyl ketones by H_2O_2[41].

$$RCH{=}CH_2 + H_2O_2 \xrightarrow{Pd(RCO_2)_2\ \mathbf{20}} RCCH_3 + H_2O \quad (O)$$

This reaction is best carried out between 20 and 80 °C in solvents such as *tert*-butanol or acetic acid. The best catalysts were found to be **20** or **14** (R = CH_3 or CF_3), whereas palladium complexes containing strongly coordinating bidendate ligands were found to be inactive in *tert*-butanol. For sufficiently high conversion of the substrate (>90%) to methyl ketone, a large excess of H_2O_2 with respect to the olefin is required (H_2O_2 : olefin ≧ 3 : 1).

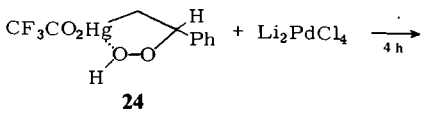
As expected, only terminal olefins, such as 1-hexene, 1-octene, 1-dodecene, and allyl acetate were oxidized to the corresponding methyl ketones with adequate conversion and selectivity (up to 90%). The efficiency of the catalyst is very high: one mol of $Pd(OAc)_2$ was found to convert about 400 mol of 1-octene into 2-octanone per hour (80 °C, olefin : $Pd(OAc)_2$ = 1500 : 1, H_2O_2 : 1-octene = 5 : 1). Partial decomposition of H_2O_2 was found to occur during the reaction, and *ca.* 2—3 mol of H_2O_2 were consumed per mol of 1-octene transformed. Oxidation of 1-octene in *tert*-butanol by $H_2{}^{16}O_2$ catalyzed by $Pd(OAc)_2$ in presence of a large excess of $H_2{}^{18}O$ resulted in formation of only unlabeled 2-octanone. This therefore indicates that the oxygen source for ketone formation is only H_2O_2, and *not* water as in the Wacker process. The following mechanism (j), similar to that previously shown for reaction (i), was suggested[41].



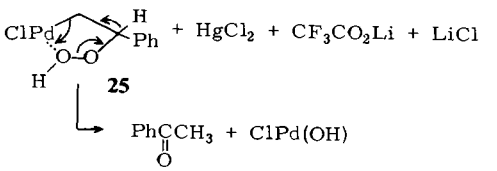
20 **21** **22** **23** (j)

As reactive species, this mechanism involves the hydroperoxide **21** resulting from the exchange of one carboxylate group of **20** at palladium. This compound transfers one oxygen atom to the coordinated olefin and, *via* a hydroperoxypalladation corresponding to mechanism (i), yields the methyl ketone and the palladium hydroxide **23**. Species **21** is regenerated from **23** by reaction with H_2O_2, liberating water. A large excess of H_2O_2 is necessary in order to avoid Wacker-type hydroxypalladation of the olefin by **23**, π-allyl complex formation, and to compensate for the decomposition of the unstable palladium hydroperoxide **21** (evolution of O_2). Despite many attempts, the isolation of such palladium hydroperoxide species was unsuccessful. However, there are several indirect indications of the involvement of such intermediates in the ketonization of terminal olefins:

1) The reaction of the stable hydroperoxyalkylmercury compound **24**[42] with Li_2PdCl_4 (20 °C, THF) produced acetophenone in 85% yield[43].



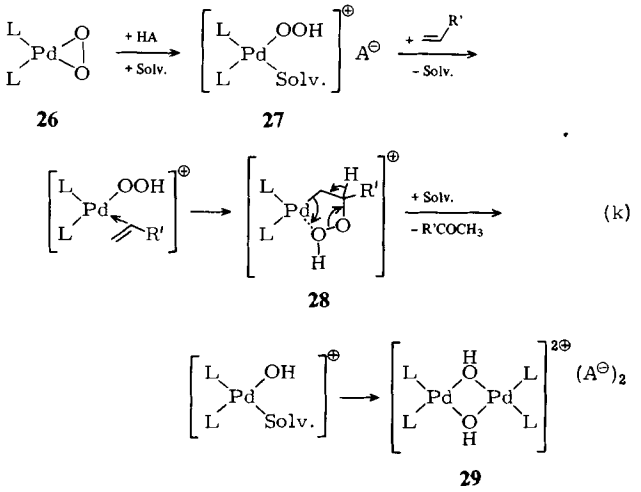
24



25

2) Cation **27** was generated by protonation of **26** by one equivalent of a strong noncoordinating acid, such as CH_3SO_3H, in a CH_2Cl_2/1-octene solution and afforded 2-octanone (50% yield based on palladium) together with Ph_3PO (36%). As shown by reaction (k), protonation of the

peroxo group in the inactive complex **26** creates a vacant site (**27**), which is occupied by a solvent molecule[43], and allows complexation of the olefin prior to the hydroperoxypalladation. The di-μ-hydroxy complex **29** has been isolated (A = BF_4). The addition of an acid with a strongly coordinating anion, such as CF_3CO_2H, results in almost complete inhibition of oxidation, since now the vacant site S is preferentially occupied by the CF_3CO_2 group, impeding coordination of the olefin. When the oxidation of 1-octene was carried out in presence of excess $H_2{}^{18}O$ only unlabeled 2-octanone was produced, indicating that the oxygen source for ketone formation is not water but molecular oxygen bound in the complex.



26 **27** **28** **29**

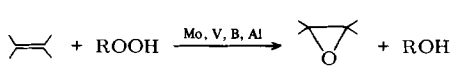
L = PPh_3, Solv. = CH_2Cl_2, $A^{\ominus}$ = $CH_3SO_3^{\ominus}$, $BF_4^{\ominus}$

The results indicate that under these conditions the internal *cis*-hydroperoxypalladation of the coordinated olefin prevails over external *trans*-hydroxymetalation by water (Wacker process). They also illustrate an additional possibility for oxygen activation and transfer to olefin at the coordination sphere of a metal, involving one monoanionic OOH group adjacent to a coordinated olefin, whereas in the case of the rhodium complex [see reaction (f)] the peroxo dianion adjacent to a vacant coordination site was required.

Platinum hydroperoxides, —Pt—OOH, obtained in the same way from the protonation of $(PPh_3)_2PtO_2$ by CH_3SO_3H, were found to be unreactive toward terminal olefins, probably due to the lower coordinating ability of platinum compared to palladium[43].

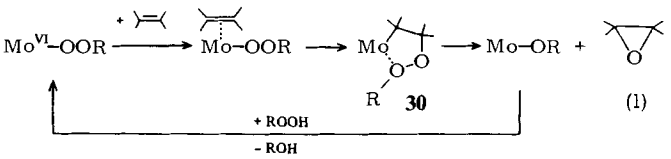
It therefore appears that oxygen can easily be transferred to olefins from group VIII dioxygen metal complexes, provided a suitable coordination site for the coordination of the olefin exists (rhodium complexes), or is liberated after protonation of the peroxo group (palladium complexes). If this condition is not fulfilled, no oxygen transfer to olefin can occur.

The concept of pseudocyclic peroxymetalation has also proved useful for interpreting the mechanism of the epoxidation of olefins by alkyl hydroperoxides catalyzed by molybdenum, vanadium, boron, and aluminum.

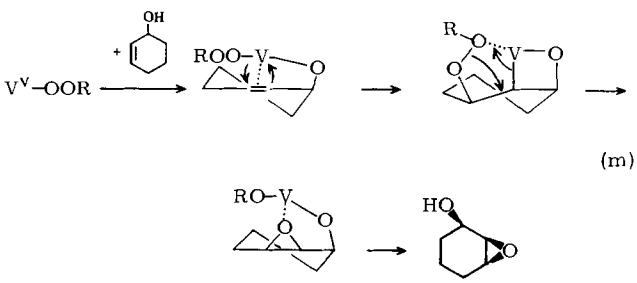


The molybdenum-catalyzed reaction has been developed on a large scale by Halcon for the production of propylene oxide by oxidation of propylene with *tert*-butyl hydroperoxide[45]. Many characteristics of this reaction are similar to those of the epoxidation of olefins by peroxo molybdenum complexes, *i.e.* high stereoselectivity and retention of configuration, increasing reactivity with increasing nucleophilicity of the olefin, and strong inhibition by coordinating σ-donor solvents and ligands[46]. Furthermore, the reaction is inhibited by the coproduct alcohol. Although not yet fully characterized, the reactive intermediates of this reaction have been shown by ^{18}O labeling studies to be the alkyl peroxo molybdenum complexes obtained by displacement of a ligand on Mo^{VI} by hydroperoxide[6].

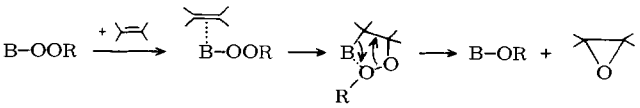
The suggested mechanism (l) satisfactorily accounts for the general trends of this catalytic oxidation.



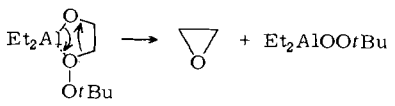
This involves coordination of the nucleophilic substrate to Mo^{VI} followed by a pseudocyclic alkyl-peroxymetalation of the coordinated olefin. The intermediate **30** strongly resembles the cyclic intermediate **2** postulated for the epoxidation of olefins by MoO_5·HMPA [reaction (c)]; **30** decomposes in the same way to give the epoxide and the molybdenum alkoxide. The coordinatively rigid structure of **30** also accounts for the high stereoselectivity of this reaction, exemplified by the vanadium-catalyzed epoxidation of allylic alcohols, which yields *syn*-epoxides almost quantitatively [reaction (m)][47].



In reactions (c) and (l) the metal-olefin association preceding the peroxymetalation reaction is a pure Lewis acid/Lewis base interaction, since Mo^{VI} and V^{V} are d^0 complexes. It would therefore be expected that compounds having alkylperoxy groups bonded to a Lewis acid center should be active for the epoxidation of olefins. This is indeed found for boron compounds, which are active as catalysts for the epoxidation of olefins by alkyl hydroperoxides[48]. Boron tris(alkyl peroxides) $B(OOR)_3$ have been shown to stoichiometrically epoxidize alkenes, presumably through alkyl-peroxyboration of the double bond.

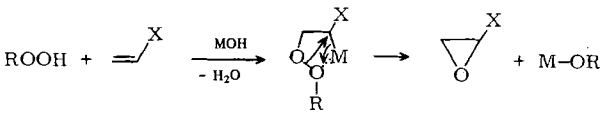


Aluminum compounds such as $(t\mathrm{BuO})_3\mathrm{Al}$ have also been shown to catalyze the epoxidation of olefins by alkyl hydroperoxides, and this reaction is also particulary selective for the transformation of allylic alcohols into *syn*-epoxides[50]. Related to the mechanism of this aluminum-catalyzed epoxidation is the decomposition of the aluminum compound **31** to give ethylene oxide[51].



31

Five-membered "pseudocyclic" peroxides such as **32** have also been assumed to be involved as reactive intermediates in the epoxidation of electron-poor olefins by H_2O_2 or ROOH in presence of alkali[52].



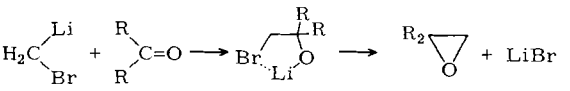
32

R = H or *tert*-alkyl

X = acceptor group. Reactivity of the olefin decreases along the series $X = NO_2 > SO_3R > CHO > COR > COOR > CN$

M = alkali metal. Activity of the base increases in the order $KOH < NaOH < LiOH$.

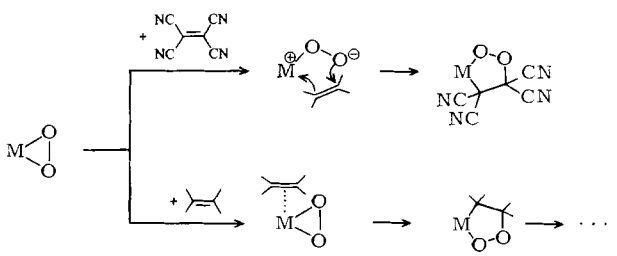
Epoxides have also been obtained from the reaction of carbonyl compounds with α-bromomethyllithium, presumably *via* decomposition of the pseudocyclic intermediate **33**[53].



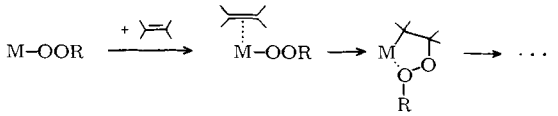
33

We can summarize the results from Section 2 as follows:

1) Peroxo metal complexes behave as 1,3-dipolar reagents $M^+—O—O^-$. The peroxo group reacts either bimolecularly with electrophilic substrates such as tetracyanoethylene or hexafluoroacetone, or else monomolecularly with coordinated nucleophilic olefins or ketones which become electrophilic in the metal-coordinated form. In both cases, the primary product is a cyclic five-membered dioxametallacycle. This reaction is called cyclic peroxymetalation.



2) Alkylperoxo or hydroperoxo metal complexes react with olefins *via* intramolecular nucleophilic attack of the —OOR or the —OOH group, respectively, at the coordinated olefin, which has become electrophilic due to coordination to the metal. As for cyclic peroxymetalation, this reaction obeys the general π-σ rearrangement procedure (*cis*-insertion) occurring in most transition metal-catalyzed transformations of olefins[13]. The primary product is a five-membered "pseudocyclic" alkyldioxyethylmetal compound.



3) In intramolecular cyclic and pseudocyclic peroxymetalations, the rate-determining step is generally the coordination of the olefin or the ketone to the metal. This requires the presence on the metal of vacant coordination sites adjacent to the peroxide group. Hence, increasing the electrophilicity of the metal and increasing the nucleophilicity of the substrate favor the reaction, whereas the presence of strongly coordinating ligands or basic solvents, in contrast, inhibit complexation of the substrate and, hence, the reaction.

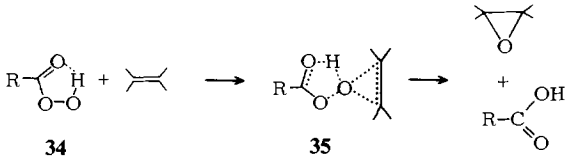
4) The decomposition of the cyclic and pseudocyclic peroxometallic adducts occurs *via* a concerted 1,3-dipolar cycloreversion. The nature of the products depends on the metal and the substituents on the substrate. With pure Lewis acids or d^0 transition-metals containing peroxide groups, epoxides are preferentially obtained from olefins, and esters result from the Baeyer-Villiger oxidation of ketones. In the case of less electrophilic group VIII metals predominantly β-hydrogen shift occurs; methyl ketones result from the oxidation of terminal olefins, whereas oxidative cleavage occurs with some electrophilic olefins.

5) Peroxymetalation requires the activation of both dioxygen and olefin at the same metal center: a) Oxygen can be used as a peroxide (H_2O_2 or ROOH), or can be reduced to a peroxide by donation of two electrons from the metal (*e.g.* Rh or Pd); b) the olefin loses its nucleophilic character upon complexing to the metal and becomes electrophilic, making possible intramolecular nucleophilic attack by the peroxide.

3. Oxygen Transfer from Organic Peroxides: 1,3-Dipolar Cycloaddition of Dioxiranes

3.1. Oxidation by Peroxy Acids

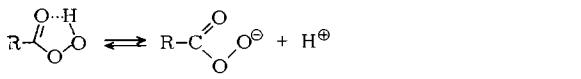
The mechanistic interpretation of organic oxidation reactions has long been, and still is, dominated by the concept of "electrophilic oxygen" characterizing the nature of the transferred oxygen atom in oxidations of organic substrates by peroxy acids[54]. The "butterfly mechanism" of the epoxidation of olefins by peroxy acids, first proposed by *Bartlett* in 1950, illustrates this concept [reaction (n)][55].



(n)

34 35

This mechanism involves nucleophilic attack of the olefin at the terminal "electrophilic" oxygen atom of the hydroperoxide group, followed by decomposition of the intermediate **35** into the epoxide and the carboxylic acid. Although this mechanism has long been very useful for interpreting many epoxidation reactions[56], and has recently received theoretical support[57], it suffers from the fact that the electrophilic nature of the transferred oxygen atom has never been clearly established. On the contrary, it would be expected that peroxy acids with acidity constants of pK = 3.7 (R = CF_3) or pK = 7.6 (R = CH_3) are dissociated in solution as shown in (o), and that a negative charge is located on the terminal oxygen atom.

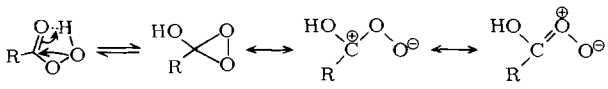


(o)

34

The rate of epoxidation is largely enhanced by the acidity of the peroxy acid, which increases with the introduction of electron-withdrawing substituents[58]. Furthermore, *Hjelmeland* and *Loew* have established by *ab initio* and semi-empirical MO calculations that neither of the peroxidic oxygen atoms of peroxy acids is electrophilic[59]. This makes the association (**35**) between olefin and peroxy acid unlikely in the sense of charge-transfer interactions. A nucleophilic attack on peroxy acids should therefore more probably occur at the electrophilic center of the molecule, *i.e.* the carbon of the CO_3H group, as shown by the hydrolysis by $H_2{}^{18}O$[60].

An alternative mechanism suggested later by *Kwart et al.* considers the intramolecularly hydrogen-bonded peroxy acid as a potential hydroxy-substituted dioxirane [reaction (p)][61,62].

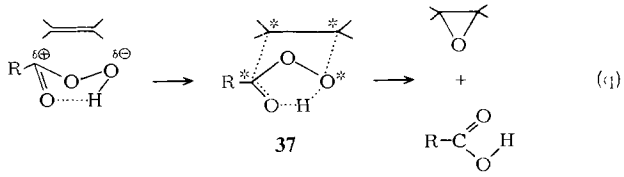


(p)

34 36a 36b 36c

The existence of peroxymethylene compounds **36** was first postulated by *Criegee* in 1949 for the ozonolysis of alkenes[63]. Although they have not yet been isolated, cumulative evidence has been provided which supports their involvement in many oxidation reactions. The dioxirane species **36a** has been identified in the gas-phase reaction of ozone with ethylene[64], and has been shown by theoretical studies to be far more stable than the zwitterion **36b**, the *cis*- and *trans*-carbonyl oxide **36c**, or the corresponding diradical[65]. Hence, dioxiranes are the products expected from the pericyclic rearrangement of peroxy acids **34** and from decomposition of the primary ozonides (see Section 3.3.3).

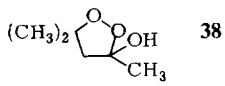
Kwart's epoxidation mechanism (q) involves the 1,3-dipolar cycloaddition of the peroxy acid in its zwitterionic form **36b** to the double bond, forming a cyclic peroxide **37** which decomposes to epoxide and carboxylic acid[62].



(q)

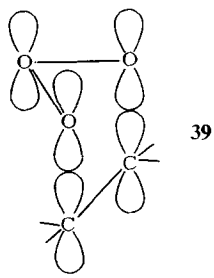
37

Since 1,2-dioxolanes such as **38** are unexpectedly stable, and upon thermolysis at 100 °C give only minor amounts of epoxide, it was concluded that this type of dioxolane never actually forms, but that "the very act of approach to bond formation produces rearrangement to epoxide by virtue of the conformation accomodation that produces O—O bond rupture, without intermediate formation of the 1,2-dioxolane (which would be the hypothetical nonplanar, stable product of the 1,3 dipolar cycloaddition)"[62].



38

The suggested alternative transition state **37** has been shown by molecular orbital considerations to require the coplanity of four (*) centers. It is worth pointing out that this envelope conformation is similar to the geometry of transition state **39** postulated for the *supra-supra* addition of ozone (4π) to olefins (2π)[66].



39

It should be recalled that coplanity of the peroxo ligand and the olefin is also required in the epoxidation of olefins by $MoO_5 \cdot$HMPA [reaction (c)].

The similarity between the mechanism of the epoxidation of olefins by peroxy acids and $MoO_5 \cdot$HMPA is further emphasized if we assume that the rate-determining step consists in the formation of a charge-transfer π-complex between the nucleophilic olefin and the electrophilic carbon atom of the peroxymethylene **36** prior to the nucleophilic attack of the terminal peroxidic oxygen atom at the "coordinated" electrophilic olefin (**40**) or the positively charged C atom (**41**) [reaction (r)].

This would explain why acceptor substituents in the peroxy acid increase the electrophilic nature of the C atom of the zwitterion, favor the formation of a charge transfer complex, and therefore increase the rate of epoxidation. Likewise, electron-rich olefins are more easily "coordinated", and are therefore more readily epoxidized[56].

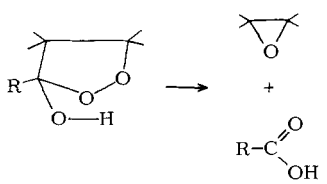
(r)



It is expected that the olefin would lose its nucleophilic nature upon complexation, enabling nucleophilic attack by the terminal oxygen atom, which should be Markovnikov directed. This is consistent with the results of measurements of secondary deuterium isotope effects carried out by *Hanzlik et al.* These studies revealed a clear distinction between the α- and β-positions of the olefin in the transition state[67]. The determination of the Hammet constants for epoxidation with peroxy acids[68,56] yielded a negative value of ρ and a large σ^+ contribution for olefins, and a positive ρ value for peroxy acids. These results are consistent with a charge separation in the transition state, which is partially positive on the olefinic moiety and partially negative on the peroxy acid moiety[67]. Recent kinetic studies of epoxidation with peracids in presence of nitrogen bases have also led to the conclusion that a charge-transfer complex between the peroxy acid and the olefin is formed prior to epoxide formation[69].

Solvent effects in peroxy acid epoxidations can also be accounted for by formation of a charge-transfer complex between peroxy acid and olefin. Basic solvents or ligands such as DMF, amine, phosphane, or arsane oxides inhibit epoxidation by disrupting the intramolecular hydrogen-bonded structure of the peroxy acid, thus preventing formation of the dioxirane species[70]. Stable crystalline complexes between peroxy acid and such ligands have been isolated[71]; the structure of the adduct **42** between *p*-nitro-

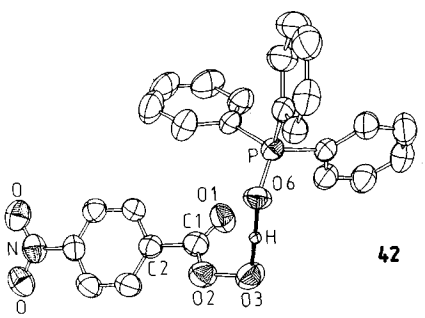
peroxybenzoic acid and triphenylphosphane oxide has been determined by X-ray crystallography and is reproduced in Figure 3[172].



42

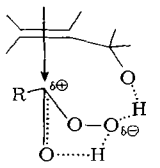
Fig. 3. Molecular structure of the complex **42** from *p*-nitroperbenzoic acid and triphenylphosphane oxide in the crystal [72].

The relatively lower rate of epoxidation in π-electron donor solvents, *e.g.* aromatic hydrocarbons, in comparison with in chlorinated non-aromatic solvents[56,57] could be explained by competition between olefin and solvent for the formation of charge-transfer π-complexes with the peroxy acid.

The smaller difference in reactivity of norbornene and cyclohexene toward peroxy acids ($k_1/k_2 = 1.2$) than toward 1,3-dipolar reagents such as phenyl azide ($k_1/k_2 = 6500$) has been used as an argument against Kwart's mechanism [five-membered transition state, see reaction (q)] and in favor of Bartlett's mechanism [three-membered transition state see reaction (n)][74,75].

These results, however, are consistent with mechanism (r). Since the rate-determining step is the formation of the π-complex **40** (three-membered transition state), the olefin reacts more according to its nucleophilic nature uninfluenced by its strain energy; this first becomes important in the next non-rate determining 1,3-dipolar cycloaddition.

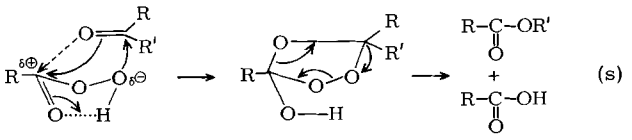
The directing effect of hydroxy, carboxy and carboxylate substituents on the olefin for formation of *cis*-epoxides[56] can also be interpreted by the modified Kwart mechanism (r), assuming the existence of a cyclic hydrogen-bonded intermediate **43**.



43

Hence, a modified Kwart mechanism, *i.e.* formation of a charge-transfer π-complex between the olefin and the peroxy acid as the rate-determining step followed by a 1,3-dipolar epoxidation is in accord with most of the data concerning this reaction.

The same mechanism would also be suitable for interpreting the Baeyer-Villiger oxidation of carbonyl compounds to esters by peroxy acids[76]. Great similarity exists

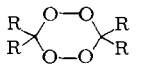


(s)

between this mechanism (s) and the formation of stable metal ozonides in the reaction of peroxo platinum complexes with ketones [reaction (e)], this also applies to the Baeyer-Villiger lactonization of cyclic ketones by peroxo molybdenum complexes [reaction (d)].

oxide **46a** which can be converted into bis(trifluoromethyl)dioxirane **47a** upon elimination of water (Table 1).

The formation of **47a** corresponds to the reaction of transition-metal oxides with H_2O_2 to form peroxo complexes **1** and is favored by the electrophilic character of the carbon atom of the dioxirane ring, caused by the electron-attracting effect of the two CF_3 groups. Dimeric (or trimeric) cyclic peroxides such as **48**, which can formally be treated as stable dioxirane oligomers, are commonly obtained from the reaction of carbonyl compounds with H_2O_2[83].

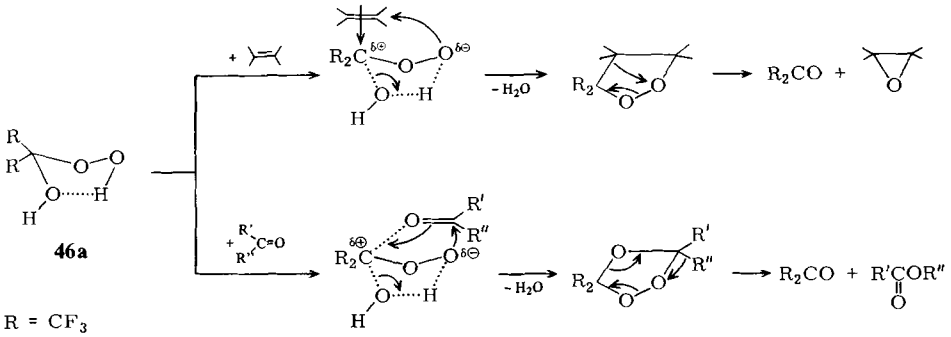


48

Oxygen transfer from a dioxirane (*e.g.* **47a**) to nucleophilic substrates such as olefins or ketones could, therefore, occur in an analogous way to that shown in mechanism (r) (rearrangement of peroxy acids).

It is noteworthy that the combination of alkyl hydroperoxides with hexafluoroacetone to afford **49** does *not* epoxidize olefins[78a], since dioxirane formation cannot occur!

The formation of epoxidation reagents from the reaction of H_2O_2 with dehydrating orthoesters such as



3.2. Oxidation by Dioxiranes

One of the most common striking features of the organic peroxides described in Table 1 is their ability to generate dioxiranes by sigmatropic rearrangement, which often results in the loss of water, alcohol, or N_2. Various oxygen sources are suitable for these dioxiranes, *i.e.* $^3O_2$, $^1O_2$ (singlet oxygen), ozone or hydrogen peroxide. Most of the reagents in Table 1 contain electron-acceptor substituents. All these peroxide species behave as oxidizing agents: they epoxidize olefins, transform ketones into esters (Baeyer-Villiger oxidation), oxidize organic sulfur and nitrogen compounds, and in part, hydroxylate nucleophilic C—H groups.

The use of an anhydrous mixture of hexafluoroacetone and hydrogen peroxide as a selective oxidant for the Baeyer-Villiger oxidation of ketones was first reported by *Chambers* and *Clark*[77]. Later it was shown to selectively epoxidize olefins[78], convert amines and sulfides into their corresponding oxides[79], and oxidize aldehydes to carboxylic acids[80]. Hexachloroacetone[81] and carbonylditriazole[82] in the presence of H_2O_2 were also found to be suitable for the epoxidation of olefins. The solvent is generally anhydrous CH_2Cl_2. Although it has not yet been isolated, the reactive species is most probably the hydroxyhydroper-

$MeC(OEt)_3$[84], might also be attributed to the generation of a reactive ethoxy-substituted dioxirane species **50** (Table 1).

Reactive dioxirane species may also be synthesized from O_2 or O_3 oxygenations in aprotic solvents. Epidioxyfurans such as **51** have been shown to cause epoxidation of olefins and Baeyer-Villiger lactonization of ketones, presumably *via* the transient formation of the intermediary dioxirane **52**[85].

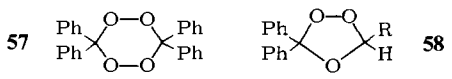
Ozonolysis of alkynes produces reactive intermediates capable of epoxidizing olefins[86]. It has been suggested that these reactive intermediates are probably the acyl-substituted dioxiranes **55** resulting from the rearrangement of the primary ozonide **53**[86] (Table 1).

It is noteworthy that the dioxirane species **55** can be obtained from the photosensitized oxygenation of benzoylphenyldiazomethane, *via* **54** (Table 1)[87].

49

The photolysis of diphenyldiazomethane in presence of oxygen (Table 1) affords diphenyldioxirane **56**[88], which

can be isolated as the cyclic dimer **57**, or can be trapped by aldehydes to form the ozonides **58**[89].



57 **58**

Dioxirane **56** produced in this photolysis is capable of epoxidizing olefins[129], hydroxylating alkanes[90] and naphthalene[91], and of oxidizing sulfides to sulfoxides and ketones to esters[87].

The epoxidation of highly nucleophilic olefins such as 2,3-dimethyl-2-butene by 3,3'-dibromobenzoyl peroxide[92] has been interpreted by *Kwart* as being due to the formation of a reactive acyloxy-substituted dioxirane **59** (Table 1)[61].

The peroxy acid-like reactivity of the N, S, Se, and As peroxides depicted in Table 1 might also be attributed to the transient formation of reactive heterodioxiranes.

Epoxidation of olefins by molecular oxygen in presence of tetramethyl-2-tetrazene and $ZnCl_2$ probably occurs *via* formation of the dimethylamino peroxide/$ZnCl_2$ complex **60**, in which zinc chloride exerts an electron-acceptor effect on the nitrogen atom (Table 1)[93].

The reaction of H_2O_2 with *S,S*-dialkoxy-2,1λ^4-benzoxathiol **61** at −78 °C produces a reactive species **62** (Table 1) capable of oxidizing sulfides and of epoxidizing olefins[94]. A 1,2,3λ^4-dioxathiirane **63** of this type has been trapped as a transient intermediate in the singlet oxygen oxidation of diethyl sulfide[95].

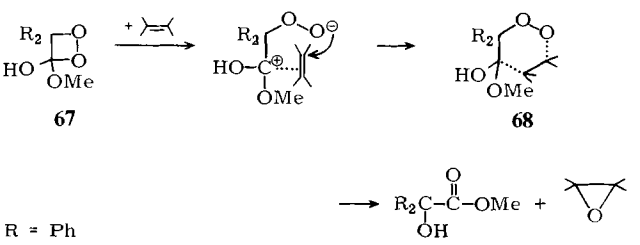
63

The same kind of reactive heterodioxirane may also arise in the rearrangement of peroxyselenic acids **64**[96,97] and peroxyarsonic acids **65** (Table 1)[98].

The involvement of reactive dioxirane intermediates in the ketone-catalyzed decomposition of potassium peroxomonosulfate, has been shown from ^{18}O-labeling experiments and kinetic studies[99].

Even weakly nucleophilic olefins are epoxidized under mild conditions in high stereoselectivity by dioxiranes of this type[99].

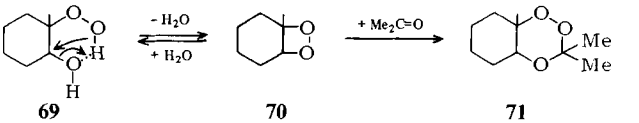
α-Hydroperoxy-ethers, -esters, (*e.g.* **66**) and -nitriles have recently been shown to epoxidize olefins[100]. These compounds rearrange to 1,2-dioxetanes (*e.g.* **67**) bearing electron-acceptor substituents on one carbon atom (Table 1). The epoxidation of olefins by the dioxetane could therefore occur by a 1,4-cycloaddition to form a six-membered peroxide intermediate **68**, which decomposes to epoxide and α-hydroxy ester.



67 **68**

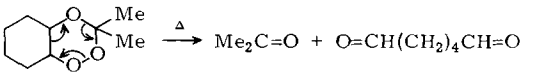
R = Ph

Such an insertion has been shown to occur in the reaction of the α-hydroxy hydroperoxide **69** with acetone, producing the ozonide **71**, probably *via* formation of the dioxetane **70**[83,101].



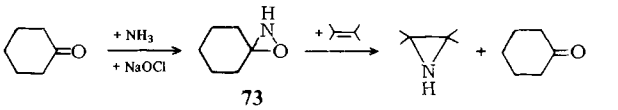
69 **70** **71**

Thermolysis of a similar perhydro-1,2,4-trioxane **72** at 160–180 °C produces acetone and adipaldehyde[102].



72

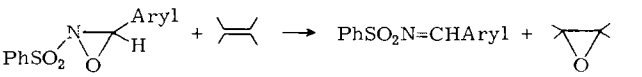
Finally, we should mention reactions of nucleophilic substrates with oxaziridines. The oxaziridine **73**, which is easily obtained from cyclohexanone, ammonia, and hypochlorite reacts with olefins to produce the corresponding aziridines[103].



73

This "epamination" of olefins by **73** has been shown to be very similar to epoxidation by peroxy acids.

Aryl(phenylsulfonyl)oxaziridines such as **74** have also recently been reported to cause asymmetric oxidation of sulfides to sulfoxides[104] as well as the epoxidation of olefins[130].



74

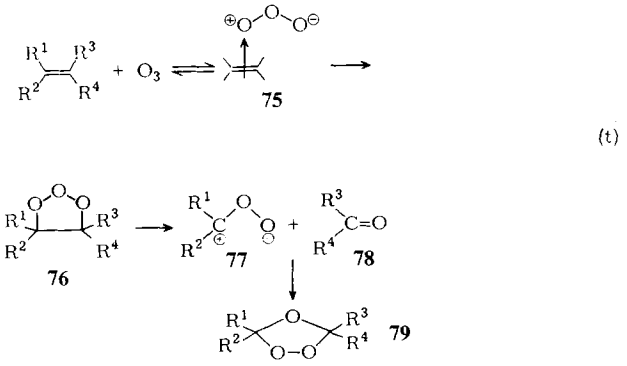
Hence, formation of dioxiranes (or 1,2-dioxetanes) as reactive intermediates appears to be a common denominator for most of the organic peroxide oxidizing agents. The various ways used for their preparation, the various oxygen sources from which they are formed ($^3O_2$, $^1O_2$, O_3, and H_2O_2), and the strong resemblance between these reagents and peroxy acids make possible a consistent rationalization of their reactivity in terms of intermediary dioxiranes.

3.3. Ozonization of Olefins

The reaction of ozone with olefins has been the subject of a great many investigations[105]. Here we will consider only selected aspects which are particularly relevant to oxidations by dioxirane reagents. The Criegee mechanism of ozonolysis, first proposed in 1949, is shown in (t)[63a].

3.3.1. Ozone-Olefin π-Complexes

Colored π-complexes such as **75** have been observed in the reaction of ozone with olefins such as 1-mesityl-1-phe-



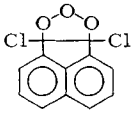
(t)

nylethylene at $-150\,^{\circ}C$[106], or in the reaction of ozone with arenes[107] or other olefins[108, 109] at low temperatures. The reversible formation of a π-complex between olefin and ozone as the rate-determining step was also suggested by *Cvetanovic et al.*[110] and *Fliszar et al.*[111] for interpreting the kinetic studies of ozonolysis of olefins; the analysis showed that electron-donor groups on the olefin have a rate-increasing effect, whereas electron-acceptor groups decrease the rate of ozonization. The relative rate constants for the ozonization of olefins are therefore similar to those previously shown for epoxidation by peroxy acids, MoO_5, and related dioxirane reagents.

3.3.2. Primary Ozonides (1,2,3-Trioxolanes)

Following the formation of the π-complex **75**, nucleophilic attack by the terminal oxygen atom occurs at the more substituted carbon of the olefin, producing the 1,2,3-trioxolane **76**. If the olefin has sterically very bulky groups at this site, as *e.g.* in 1-mesityl-1-phenylethylene[112] or adamantylideneadamantane[113], the π-complex **75** directly loses molecular oxygen and thus produces the epoxide.

The 1,2,3-trioxolane **80** has recently been isolated from the reaction of ozone with 1,2-dichloroacenaphthylene[114].



80

A crystalline compound obtained in the ozonization of *E*-2,2,5,5-tetramethyl-3-hexene ((*E*)-di-*tert*-butylethylene) at $-78\,^{\circ}C$, which can be reduced to racemic 2,2,5,5-tetramethyl-3,4-hexanediol (di-*tert*-butylethylene glycol), was previously also shown to be a 1,2,3-trioxolane[115].

3.3.3. Decomposition of Primary Ozonides to Carbonyl Compounds and "Carbonyl Oxide"

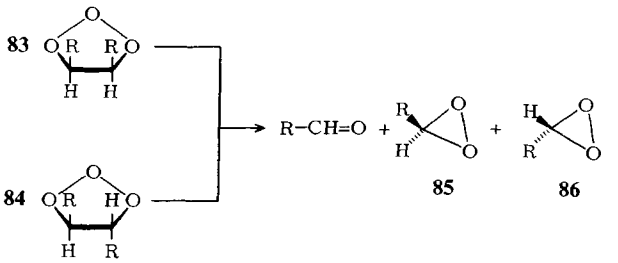
The trioxolane **76**, which results from the $[_{\pi}4_s + _{\pi}2_s]$ cycloaddition of ozone to an olefin *via* a transition state with envelope conformation **39**[66], decomposes by a concerted 1,3-dipolar cycloreversion mechanism to give the carbonyl oxide **77** and the carbonyl compound **78**.

However, the original Criegee mechanism (t) does not satisfactorily account for some data concerning the ozonolysis of olefins: The geometry of the olefin considerably influences the stereochemical composition of the ozonides **79**, particularly for olefins having bulky groups attached to the double bond. For example, (*E*)-di-*tert*-butylethylene in non-polar solvents mainly produces the *trans*-ozonide, whereas the (*Z*)-isomer gives a 70:30 mixture of *cis*-:*trans*-ozonides[117, 118]. This led *Kuczowski* et al.[66] and *Bailey et al.*[105a, 116] to propose a stereochemical refinement to the Criegee scheme which takes into consideration that the decomposition of the primary trioxolane **76** produces unequal amounts of *anti*- (**81**) and *syn*-isomer (**82**) of the carbonyl oxide **77** (cf. isomerism in oximes), which in turn recombine with the carbonyl compound stereoselectively to yield *cis*- and *trans*-ozonides **79**[116].

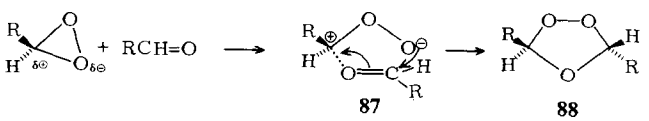
However, other observations cannot readily be incorporated into the Criegee scheme[119]. This applies particularly to solvent and stereochemical effects: the amount of ozonide produced from di-*tert*-butylethylene decreases in polar solvents[118], and the *cis*:*trans* ratio of the final ozonides depends on the solvent, olefin-concentration, and warming-up rate[120]. These results have been interpreted in terms of a nonconcerted addition of carbonyl oxide to the carbonyl compound[118b, 65a], whereas *Bailey et al.*[120] suggested an equilibration of the *syn*- and *anti*-forms of the carbonyl oxide. However, such an equilibration between **82** and **81** has recently been shown by theoretical considerations to be unlikely, since the barriers to rotation and inversion of **82** and **81** were found to be 31 and 41 kcal/mol, respectively[65c].

An alternative explanation on the basis of the rationale developed in this article could be made:

1) The decomposition of the *cis*- and *trans*-primary ozonides **83** and **84** occurs *via* a concerted 1,3-dipolar cycloreversion to give the carbonyl compound and unequal amounts of the two enantiomeric dioxiranes **85** and **86**, in which the C—O distances are different.



2) In the rate-determining step the carbonyl compound reacts with the dioxirane to form a charge-transfer π-complex **87**; this is followed by 1,3-dipolar cycloaddition to give the ozonide **88**.

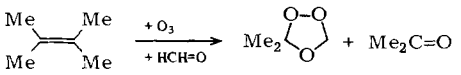


Theoretical investigations have shown dioxirane species to be the most stable form of the peroxymethylene com-

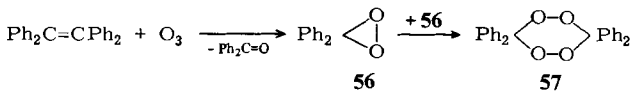
pounds resulting from the decomposition of primary ozonides[65], and they have been identified in the gas-phase ozonolysis of ethylene[64]. If the C—O distances are different, they can also exist in different enantiomeric forms. Since dioxiranes are isoelectronic with ozone, it is also expected that the carbonyl compound coordinates to the electron deficient carbon atom of the dioxirane ring. This coordination should be strongly inhibited by complexing agents which prevent ozonide formation, and should be strongly influenced by solvent effects and the bulkiness of the substituents attached both to the dioxirane ring and to the carbonyl compound. Note should be taken of the similarity between ozonide formation from dioxirane and carbonyl compound and the mechanism of both the Baeyer-Villiger oxidation [reaction (s)] of carbonyl compounds and the formation of stable metal-ozonides from peroxoplatinum complexes [reaction (e)].

3.3.4. Reactivity of Dioxiranes from the Ozonization of Olefins

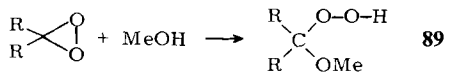
Dioxiranes can be trapped by "foreign" aldehydes, particularly when the ozonization of the olefin gives rise to the formation of ketones[105].



The ozonolysis of tetrasubstituted olefins produces dioxiranes, which can be isolated as cyclic dimers (*e.g.* **57**)[105, 121]; these are similar to the species obtained from the reaction of H_2O_2 with ketones[83].



When the ozonolysis of olefins is carried out in the presence of protic compounds (ROH, RCOOH, NH_3, HCN), hydroperoxides **89** are produced from the protonation of the dioxirane[105]. This reaction bears some similarity to the protonation of peroxo transition-metal complexes.

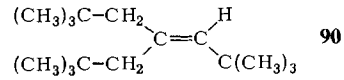


89

It would therefore be expected that dioxirane compounds produced by the ozonolysis of olefins, which resemble those in Table 1 obtained from various oxygen sources, should be able to epoxidize olefins and to cause the Baeyer-Villiger oxidation of carbonyl compounds to esters[61].

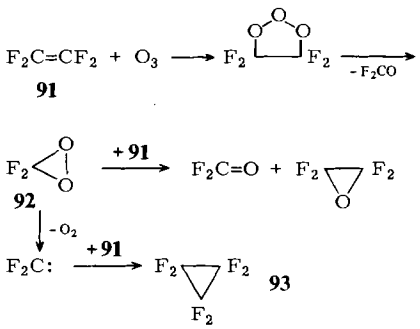
Of the many "anomalous" products of ozonolysis, epoxides and Baeyer-Villiger oxidation products should be mentioned as examples. Epoxide formation during ozonolysis of olefins occurs under two main circumstances:

1) When the olefin is sterically highly hindered, for example **90**[122], epoxide formation probably results from the direct decomposition of the olefin-ozone π complex **75** in which the nucleophilic attack by the negatively charged terminal oxygen atom is strongly inhibited [reaction (t)].



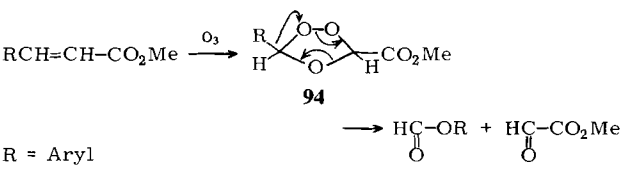
90

2) With electron deficient olefins[105], *i.e.* when ozonolysis produces dioxiranes having a strongly electrophilic carbon atom in the ring. A representative example is the ozonolysis of tetrafluoroethylene **91** yielding mainly $F_2C{=}O$ and epoxides[123], in which the difluorodioxirane **92** produced corresponds to the species **47a** obtained in the reaction of hexafluoroacetone with H_2O_2 (Table 1).

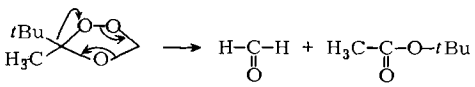


A small amount of **93** presumably results from the reaction of the carbene F_2C: (obtained from the decomposition of **92**) and tetrafluoroethylene **91**.

Baeyer-Villiger oxidation products have also been observed in the ozonolysis of cinnamic acid esters[124]. These products probably arise from the decomposition of the ozonide **94** (owing to the great migratory aptitude of the aryl substituents)[105].

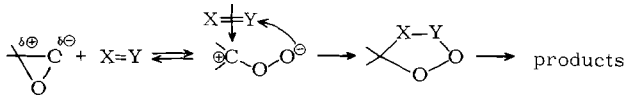


A decomposition reaction of this type has been shown to occur for the ozonide **95**[125].



4. Concluding Remarks

Oxygen transfer from organic peroxides to nucleophilic organic substrates can be described in terms of a two-step mechanism: Firstly, reversible formation of a charge-transfer complex between the nucleophilic substrate and the electrophilic carbon atom of the dioxirane ring in the rate-determining step, and secondly nucleophilic attack of the terminal oxygen atom at the "coordinated" substrate, forming a cyclic peroxide.



The formation of the charge-transfer complex is greatly accelerated as both the nucleophilicity of the substrate and the electrophilicity of the carbon atom of the dioxirane ring increase: it is strongly inhibited by complexing agents competing with the substrate. In the second step, nucleophilic attack occurs stereoselectively at the more substituted carbon atom of the substrate and is hindered by bulky substituents. The resulting cyclic peroxide is either stable (*e.g.* ozonides, X=Y ≙ C=O) or may decompose by 1,3-dipolar cycloreversion to produce the oxygenated substrate and the reduced peroxide reagent. This decomposition step, although not yet clearly elucidated, seems to be strongly dependent on the geometry of the cyclic intermediate (envelope conformation) and the nature of the substituents attached to the dioxirane and the substrate.

The structure and reactivity of the dioxiranes appear to be closely related to those of peroxo transition-metal complexes, which also form stable "metal-ozonides" (cf. **5**) with ketones and metallacycles (with group VIII metals) with electrophilic olefins (cf. **7**): their reactivity is also enhanced by the nucleophilicity of the substrate and by the electrophilicity of the metal, is inhibited by complexing agents, and is strongly dependent on the availability of vacant coordination sites at the metal. The decomposition of peroxometallacycles depends both on the substituents on the substrate and on the nature of the metal.

The reactivity of alkyl peroxide or hydroperoxide complexes with olefins differs from that of peroxo complexes: the second step is a *cis*-insertion instead of a 1,3-dipolar cycloaddition but the "pseudo"-dioxametallacycles decompose in the same way as the cyclic systems obtained from peroxo complexes, producing the same oxygenated products.

The aim of this article has been to provide a non-exhaustive approach to understanding selective oxygen-transfer reactions from inorganic and organic peroxides to organic substrates. We are aware of the fact that the joint treatment of two different fields may seem rather arbitrary and somewhat speculative, but we believe that both areas are sufficiently well developed to encourage communication between organic and inorganic chemists.

We are also aware that this article is incomplete, since it does not treat the relevant hydroxylation reactions which are common to organic[90, 127] and inorganic reagents[126]. Although a considerable amount of evidence suggests a unified view of oxygen-transfer reactions from peroxides, the most compelling proof will be hopefully given by the isolation of well-characterized, reactive organic dioxiranes.

In the inorganic area, much still has to be carried out to develop tailor-made syntheses for the selective oxidation of organic substrates. The recent use of $Ti(OiPr)_4$-diethyltartrate for the asymmetric epoxidation of allylic alcohols by *t*-BuOOH[131] is an example of the usefulness and superiority of peroxo transition-metal reagents in effecting a variety of selective transformations.

After this manuscript had been submitted for publication, several relevant contributions in this area appeared. In transition-metal oxidation reaction chemistry, these involve an important and useful book by *Sheldon* and *Kochi*[132], and articles on: titanium-catalyzed asymmetric epoxidation of allylic alcohols by *t*-BuOOH[131]; epoxidation of olefins by O_2+H_2[133], O_2+NaBH_4[134], PhIO[135], and NaOCl[136] catalyzed by manganese porphyrins; catalytic epoxidation of olefins by alkyl hydroperoxides[137]; ketonization of olefins catalyzed by group VIII transition-metal complexes[138], by Pd—NO_2 complexes (with the characterization of the five-membered metallocyclic intermediate)[139], by Pt—OO*t*Bu species[140], and by O_2+H_2 in the presence of iridium complexes[141, 145].

Oxygen-transfer reactions from organic peroxide reagents have also been the focus of recent investigations. Carbonyl oxides generated from the photolysis of diazo compounds have been shown to act as effective nucleophilic oxygen-atom transfer reagents[142], and decarboxylating agents of α-keto carboxylic acids[143]. It has also been shown that in the three step Criegee mechanism [reaction (t)], the carbonyl oxide determines the stereochemistry for lower olefins and the primary ozonide that for higher olefins[144].

I wish to thank my coworkers cited in references who have largely contributed to the work carried out in our laboratory. I am grateful to Professor Sir D. H. R. Barton, Professor H. J. Kagan, and Professor Harold Kwart for their interest in this work, and their remarks and criticism.

[145] *Note added in proof:* We have recently found that well-characterized covalent vanadium(v) peroxo complexes act as effective versatile oxidants for a) epoxidation of olefins in a non-stereoselective fashion (*e.g. cis*-olefins give *cis* + *trans* epoxide mixture), b) hydroxylation or aromatics (*e.g.* benzene to phenol) and c) hydroxylation of alkanes with a significant amount of epimerization at the functionalized carbon atom (*e.g. cis*-decalin gives a mixture of *cis* + *trans* 9-decalol). This behavior, which is very different from that of Mo peroxo complexes, was attributed to the reactive biradical $V^{IV}OO^{\cdot}$ species (generated from the homolytic cleavage of the V(v) peroxo group) which can add to olefins and aromatics and abstract hydrogen atoms from alkanes. It is noteworthy that some dioxirane species such as **56** (Table 1) exhibit a similar behavior and may therefore react as their homolytically dissociated $R_2C^{\cdot}-OO^{\cdot}$ form. This reactivity is reminiscent of that of enzymic cytochrome P_{450} monooxygenases. H. Mimoun, L. Saussine, E. Daire, M. Postel, J. Fischer, R. Weiss, *J. Am. Chem. Prostacyclin and Synthetic Analogues

By Wilhelm Bartmann* and Gerhard Beck

Dedicated to Professor K. Weissermel on the occasion of his 60th birthday

The prostanoids continue to attract a great deal of attention, particularly in the pharmacological sector. Many of the numerous biological studies on prostaglandins deal with their cardiovascular effects. The pronounced antihypertensive and platelet aggregation-inhibiting properties of prostacyclin (PGI_2) resulted in world-wide efforts to synthesize acid-stable analogues of the natural product. Whereas refined analytical procedures disproved the hypothesis that PGI_2 is a circulating hormone, exploratory human trials with PGI_2 confirmed the pharmacological findings obtained from animal experiments. Clinical studies of PGI_2 analogues have been started. *In vitro* studies on isolated vessels revealed that potent cardiovascular drugs stimulate prostacyclin synthesis; however, it has not as yet been possible to demonstrate whether these effects are also of therapeutic significance. A survey of the PGI_2 analogues synthesized so far is presented, and, with the aid of a few examples, the problems encountered during their synthesis are outlined; structure-activity relationships are also discussed.

1. Introduction

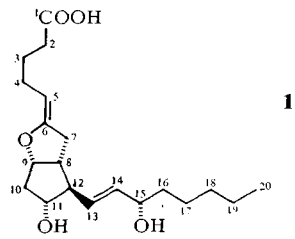
Since publication of the first reports on prostaglandins by *Goldblatt*[1,2] and *von Euler*[3] in 1933 and 1934, interest in this field, which remained dormant for a long time, has increased dramatically, particularly over the past 20 years. Numerous review articles[4–7] and monographs[8] on various aspects of prostaglandin research have now been published. The title of the last paper on this subject in Angewandte Chemie in 1978[4] "Synthesis and Biological Properties of Prostaglandin Endoperoxides, Thromboxanes and Prostacyclins" revealed that further biologically highly active members of the family of prostaglandins had been discovered.

Only one year later, at the 4th International Prostaglandin Conference in Washington[9], the introductory lecture by *Samuelsson*[10] no longer dealt with prostanoids, but rather with leucotrienes, thus opening a new field of study concerning the metabolism of polyunsaturated fatty acids in the mammalian organism.

The research results of the last 50 years are summarized in Schemes 1 and 2. Briefly, they demonstrate that unsaturated fatty acids of the arachidonic acid type are oxidized by two enzyme systems—cyclooxogenase and lipoxygenase—to oxygenated fatty acid derivatives. These natural products may be characterized biologically by their effect on smooth muscle—they contract or dilate smooth muscle organs. The two schemes also demonstrate that the article by *Nicolaou et al.*[7] may be considered to be the last attempt to provide the chemist not concerned with unsaturated fatty acids an overview of the entire field of research.

Prophylactic treatment of angiopathic patients with unsaturated fatty acids has been indicated for many years. The fact that we are now able to demonstrate the constitution and biological effect of the physiological oxidation products of unsaturated fatty acids using refined methods makes research in this field attractive. This is particularly true, for, after cancer, angiopathies have become the most important health risk for the population of the western world.

Since it has become very difficult to give a survey of the whole field of physiological metabolites of unsaturated fatty acids, in the present paper we shall concentrate on prostacyclin (PGI_2)[12] **1** and its synthetic analogues. Ever



1

since the time of its discovery prostacyclin has attracted a great deal of attention from the therapeutic viewpoint because of its blood pressure-lowering and platelet aggregation-inhibiting effects[13]. For the medicinal chemist it is still the most important representative of the prostanoids and—in a broader sense—of the physiological metabolites of unsaturated fatty acids.

2. Prostacyclin and its Biological Properties

One may differentiate the biological effects of prostacyclin as follows:

- Pharmacological effects induced by the administration of prostacyclin in animal and human studies.
- Physiological significance of prostacyclin PGI_2 **1** as a local hormone and its interaction with its physiological "opponent" thromboxane (Scheme 1).

2.1. Pharmacological Effects

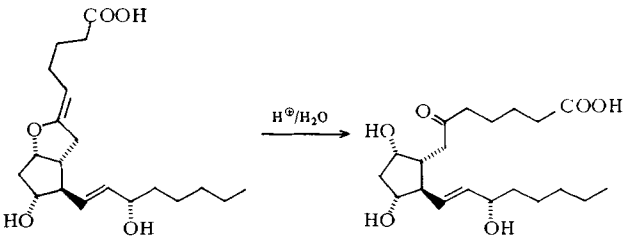
The platelet aggregating and vasodilating properties of prostacyclin observed in animal experiments were more rapidly confirmed in human trials than in the case of the "classic" prostaglandins. *Gryglewski* and *Szczeklik et al.*[14] reported in an article entitled, "Circulatory and Anti-Platelet Effects of Intravenous Prostacyclin in Healthy Man", that intravenous infusion of 2—50 ng/kg/min induced vasodilation in the skin of the head, the neck, and the palms. Whereas the diastolic blood pressure was lowered, the systolic pressure remained almost unchanged, and the heart rate was increased. In particular, platelet aggregation was suppressed. A further study at the Copernicus Academy for Medicine in Krakow[15] revealed that inhalation or infusion of prostacyclin in the above mentioned doses had no marked influence on the respiratory tract. This finding has since been confirmed in a review article on animal and human studies[16].

In 1981, a report was published on the side-effects observed during infusion of prostacyclin sodium in 27 volunteers under the title, "Intravenous Infusion of Prostacyclin Sodium in Man"[17]. This study showed that healthy volunteers could tolerate short-term infusion of prostacyclin sodium at rates of up to 10 ng/kg/min; higher doses cause headache, feelings of anxiety, nausea, and vomiting. The side-effects exhibited a linear relationship to the infusion rate. The maximum tolerated dose was a 24-hour infusion of 4 ng/kg/min. ADP-induced platelet aggregation was inhibited in a dose-dependent manner. The platelets showed increased levels of cyclic AMP. The authors concluded that the therapeutic index of the natural product is relatively small. Prostacyclin may, however, be administered safely in human trials if caution is applied. *O'Grady et al.*[18a] obtained analogous results. They established that the increase in stroke incidence, the reduction in diastolic blood pressure, the increase in heart rate, and increase in peripheral temperature are consistent with the vasodilating properties of prostacyclin.

Human trials thus confirm the hypothesis derived from animal studies that prostacyclin is a highly potent natural product possessing desirable cardiovascular activity.

Nevertheless, prostacyclin does not yet have the therapeutic index required to be administered without cardiovascular side-effects as, for example, in the case of pathologically increased platelet aggregation. The disadvantage of the relatively low therapeutic index is further exacerbated by the poor chemical stability of prostacyclin at physiological pH[18b]. Hydrolysis mainly leads to 6-oxo-$PGF_{1\alpha}$ **2**.

The activity of prostacyclin, in contrast to that of the E- and F-prostaglandins, seems to be more organ-specific, at least according to our present state of knowledge. *O'Grady et al.* investigated the effect of prostacyclin on renal function in man and found that it would seem to have no major effect on water and electrolyte excretion[19]. Whereas the effect of administered PGI_2 on the cardiovascular system



1 **2**

and platelet aggregation in man has been established, various other biological activities of prostacyclin could be investigated pharmacologically only in animal experiments. The finding that intravenous infusion of PGI_2 in anesthetized rats and conscious dogs induces a more pronounced antisecretory effect on the gastric mucosa than the infusion of PGE_2[20] (Scheme 1) may be of therapeutic interest.

The use of prostacyclin in humans seems to be promising for two instances, but further clinical evaluation is needed. In the extracorporeal circulation of blood, as is necessary in the case of artificial kidneys, the infusion of prostacyclin is designed to save heparin and to maintain normal platelet function. Moreover, prostacyclin is intended to avoid life-threatening hemorrhages in cardiopulmonary bypass operations where the coagulation time is affected by a reduction in the number of circulating platelets[21].

2.2. Physiological Properties

Whereas the pharmacological effects of prostacyclin in animal and human studies are reproducible, the question of the physiological significance of the natural product has not yet been sufficiently clarified.

There are several reasons for this: Reliable but difficult analytical methods for the detection of prostacyclin in body fluids have been developed only very recently (cf. Section 2.3), and, there is a great variety of interactions between unsaturated fatty acids in general, prostaglandins and prostacyclin in particular, and other biochemical control systems.

Even reducing the question to "Prostaglandins and the Cardiovascular System" (*i.e.* the subject of a symposium now available in book form[22]) has not solved the problems. Nor can a complete answer be provided by further limitation to the question of which prostaglandin regulates the release of renin[23] (*i.e.* a proteolytic enzyme of the kidney influencing the synthesis of vasopressor peptides).

The physiological importance of prostacyclin and its antagonist thromboxane (TXA_2) is a subject of controversy. According to *Vane et al.*[24] prostacyclin is a "circulating hormone", whereas *Christ-Hazelhof* and *Nugteren* state in a recently published article[25] that prostacyclin is *not* a "circulating hormone". *Gryglewski et al.*[26] are of the opinion that the lungs *in vivo* secrete prostacyclin into the cardiovascular system, which, as a circulating hormone, is then responsible for homeostasis, whereas thromboxane (TXA_2) is able to repair lesions in the vascular musculature by the induction of platelet aggregation under physiologi-

cal conditions, but under pathophysiological conditions contributes to the development of arteriosclerosis. This concept was taken up as a working hypothesis by *Vane* and *Moncada* in 1979 to develop new methods for the prevention and treatment of vascular diseases[27]. It cannot be conceded that prostacyclin continually circulates in an organism and is necessary for the maintenance of normal blood pressure but it is correct, that prostacyclin and thromboxane have a "repair function". The contradictory opinions are due to different results which were obtained from prostacyclin level determinations under physiological and pathophysiological conditions.

2.3. Analytical Procedures

The prostaglandins were discovered in biological experiments, and, using their pharmacological activity as a means of detection, they could be isolated and purified in crystalline form[4]. Initially, the biological experiment was also the only practicable analytical method in the search for unstable metabolites of arachidonic acid, such as the prostaglandin endoperoxides. *Ferreira* and *Vane*[28] combined individual biological experiments to create the so-called "superfusion bioassay technique" and have since developed it further. In combination with the platelet aggregometer, the superfusion technique led to the discovery of prostacyclin by *Moncada et al.*[13]. In his final remarks at the Symposium, "Clinical Pharmacology of Prostacyclin", *Dollery*[29] explained the high values obtained from the superfusion technique in terms of the possibility that prostacyclin might be formed from leukocytes during isolation.

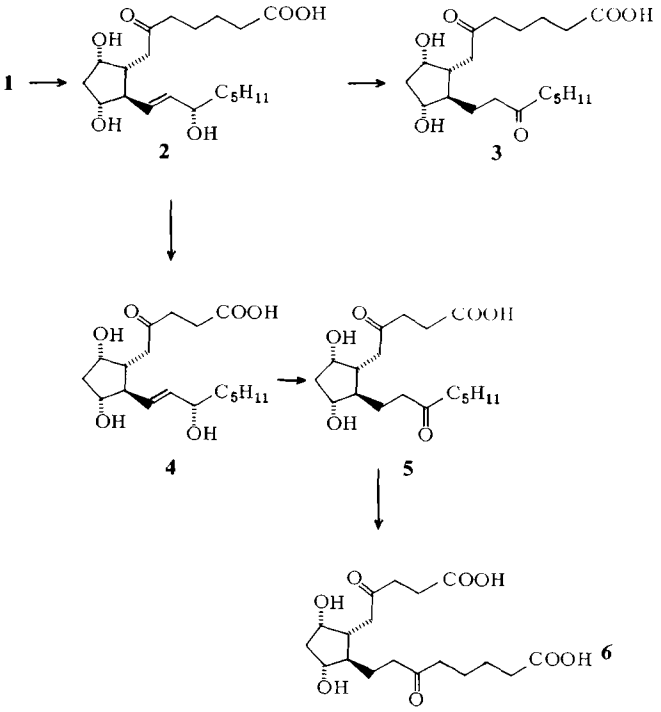
It is known that prostacyclin is, *inter alia*, hydrolyzed to 6-oxo-$PGF_{1\alpha}$ **2** at pH 7.2; therefore, prostacyclin determinations which are based on the measurement of this metabolite possibly yield values that are too high, for **2** has a longer half-life than prostacyclin itself and therefore accumulates[29].

The radioimmunoassay of **2** encounters similar difficulties to those observed during analysis of the classic prostaglandins because of possible cross-reactions with other prostaglandins and their metabolites.

A reliable determination of the prostacyclin level under physiological conditions can therefore presently only be obtained by means of the relatively difficult gas chromatography-mass spectrometry (GC-MS) technique or by gas chromatography combined with electron capture detection (GC-EC) after appropriate derivatization of the metabolite **2**. *Christ-Hazelhof* and *Nugteren*[25] concluded from GC measurements that neither human plasma nor whole blood contains more than 20 pG prostacyclin per mL. *Oates et al.* obtained similar results when determining the concentration of prostacyclin metabolites in urine[30].

In contrast to this, *Hensby*[31] reported markedly higher values: 130 pg/mL in healthy persons and 98 pg/mL in diabetics when he determined the concentration of **2** in plasma by means of quantitative GC-MS. For this reason, the presently most reliable method for measuring normal prostacyclin levels seems to be the determination of prostaglandin metabolites in the urine, as elaborated by *Frölich et al.*[32]. Using ^3H- and ^2H-labeled prostacyclin as well as ^3H-labeled 6-oxo-$PGF_{1\alpha}$, *Frölich et al.* identified dinor-6-oxo-prostaglandin-$F_{1\alpha}$ as the main renal metabolite of prostacyclin and 6-oxo-$PGF_{1\alpha}$ in man[33].

The metabolites of prostacyclin and 6-oxo-$PGF_{1\alpha}$ identified so far in man are summarized in Scheme 3 (after *Frölich et al.*)[34].



Scheme 3. Renal metabolization of prostacyclin (PGI_2) **1** and 6-oxo-$PGF_{1\alpha}$ **2** in man. **3**: 6,15-dioxo-13,14-dihydro-$PGF_{1\alpha}$; **4**: dinor-4-oxo-7,9,13-trihydroxyprosta-11-enoic acid; **5**: dinor-4,13-dioxo-7,9-dihydroxyprostanoic acid; **6**: dinor-4,13-dioxo-7,9-dihydroxyprostan-1,18-dicarboxylic acid.

2.4. Prostacyclin Biosynthesis under Pathophysiological Conditions

Disorders in prostacyclin biosynthesis are observed in arteriosclerosis[35], diabetes[36], and uremia[37]. In particular, numerous studies have established a connection between arteriosclerosis and a change in prostacyclin and/or thromboxane levels. This topic is dealt with in an informative article by *Szczeklik* entitled "Serum Lipoproteins, Lipid Peroxides, and Prostacyclin Biosynthesis in Patients with Coronary Heart Disease[38]. The statements regarding a change in prostacyclin levels under pathophysiological conditions need to be confirmed however, by reason of the above mentioned analytical problems.

3. Synthesis of Prostacyclin Analogues

Numerous hypotheses have been formulated about the biological significance and the therapeutic potential of prostacyclin[39,40]. Thus, *Moncada* and *Vane* have repeatedly postulated: "So far, prostacyclin is the most potent and comprehensive inhibitor of all forms of aggregation. This fact, together with the endogenous nature of prostacyclin, clearly suggests that the future of antithrom-

botic therapy for cardiovascular disease, including myocardial infarction, deep vein thrombosis, *etc.*, lies in the development of compounds with a prostacyclin type of action which are long acting, orally active and probably free from the cardiovascular effects of prostacyclin".

Owing to the pharmacological potential of prostacyclin, two principal possibilities for the future synthetic work of the medicinal chemist are conceivable: use of stable synthetic prostacyclin analogues (cf. Sections 3.1—3.4) or use of any cardiovascular compound which induces the same biochemical signals as prostacyclin (see Section 5). To our knowledge 24 prostacyclin analogues (Scheme 4) of different molecular structure were synthesized by various research groups between 1977 and March 1982.

3.1. Prostacyclin Analogues in which the Hydrolyzeable Enol Ether Double-bond is Stabilized

The prostacyclin isomer **7a**, in which the double bond has been shifted from the 5-*exo*- to the 6-*endo*-position, was synthesized by *M. Hayashi et al.*[41] and *Johnson et al.*[42] in 1978. The corresponding analogues with $X=CH_2$[43], **7b**, and $X=S$[44], **7c**, have also been synthesized recently by *Ikegami et al.*. **8**, a further double-bond isomer of prostacyclin, was synthesized by *Sih* and *Graber*[45] in 1978. *Pace-Asiak* and *Wolfe*[46] claimed to have isolated a substance with this structure in 1981. However, according to *Sih* and *Huang*[47] this natural product probably has another structure. *Ohno et al.*[48] also synthesized derivatives in which the double bond in the ring is shifted. **9**[48] contains in addition a conjugated double bond, in the 4-position, and **10**[49] an oxo-group in the 5-position. A hydrogenated analogue of **10**, the tetrahydrofuran derivative **11**, was prepared at about the same time by *Ayer et al.*[50].

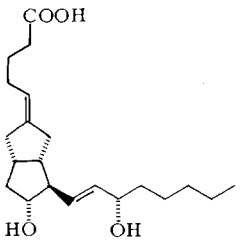
Sih et al.[51] applied the results of earlier studies and synthesized the phenyl derivatives **12**. Whereas the configuration at C-6 in **12** has not yet been clarified, the *cis*-configuration at the double-bond of the benzene ring linked to the tetrahydrofuran system by condensation has been established in the case of the analogue **13a** synthesized by *Ohno et al.*[52]. *Hayashi et al.*[53] reported in 1980 on the synthesis of **13b** which contains an annelated benzene ring and in which the oxygen atom in the 9-position is replaced by a CH_2-group. *Tömosközi et al.*[54] and *Bannai et al.*[55] have synthesized a 7-oxo- **14a** and a 7-hydroxy-derivative **14b**, respectively. In the analogue **15** prepared by *Vorbrüggen et al.*[56] the improved stability towards hydrolysis is achieved by a 5-cyano group.

3.2. Prostacyclin Analogues in which either O-9 is Replaced by Another Heteroatom or in which Additional Heteroatoms are Present

Aside from the already well-known thia-analogue **16**[57-60] and the aza-analogue **17**, in 1979 *Hayashi et al.*[62] were able to synthesize the trioxo-compound **18**; *Bartmann et al.*[63] reported compounds **19a—19c**, having the 5-membered ring and the 5-membered carbon chain in common with prostacyclin, and in addition carrying heteroatoms in various positions. The heteroprostacyclin analogues **20**, in which the sulfur is in a higher state of oxidation were prepared by *Nicolaou et al.*[64,65], *Wakatsuka et al.*[66], and by *Ikegami et al.*[67]. In the heteroanalogues **21a**[68a] and **21b**[68b], the tetrahydrofuran ring of prostacyclin has been replaced by a pyrrole ring. All these analogues have in common that C8 of the prostanoid structure is separated from the carboxy group by six atoms. This holds true also for the pyridazine-derivative **22** described by *Nicolaou*[69], as well as for **23**[70] and its isomer **24**[71,72] in which the tetrahydrofuran ring is expanded to a tetrahydropyran ring.

3.3. Carbacyclin

Among the prostacyclin analogues described since 1977, carbacyclin **25** deserves special attention. Initial results obtained in clinical trials after intravenous and oral administration of carbacyclin to man were reported by *Karim et al.*[73] in 1981. In these studies, intravenously infused carbacyclin (20 to 80 ng/kg/min) significantly inhibited the *ex vivo* ADP-induced platelet aggregation and, in contrast to PGI_2[74], was tolerated without any side-effects. According to initial results, oral doses were effective, but less well tolerated.

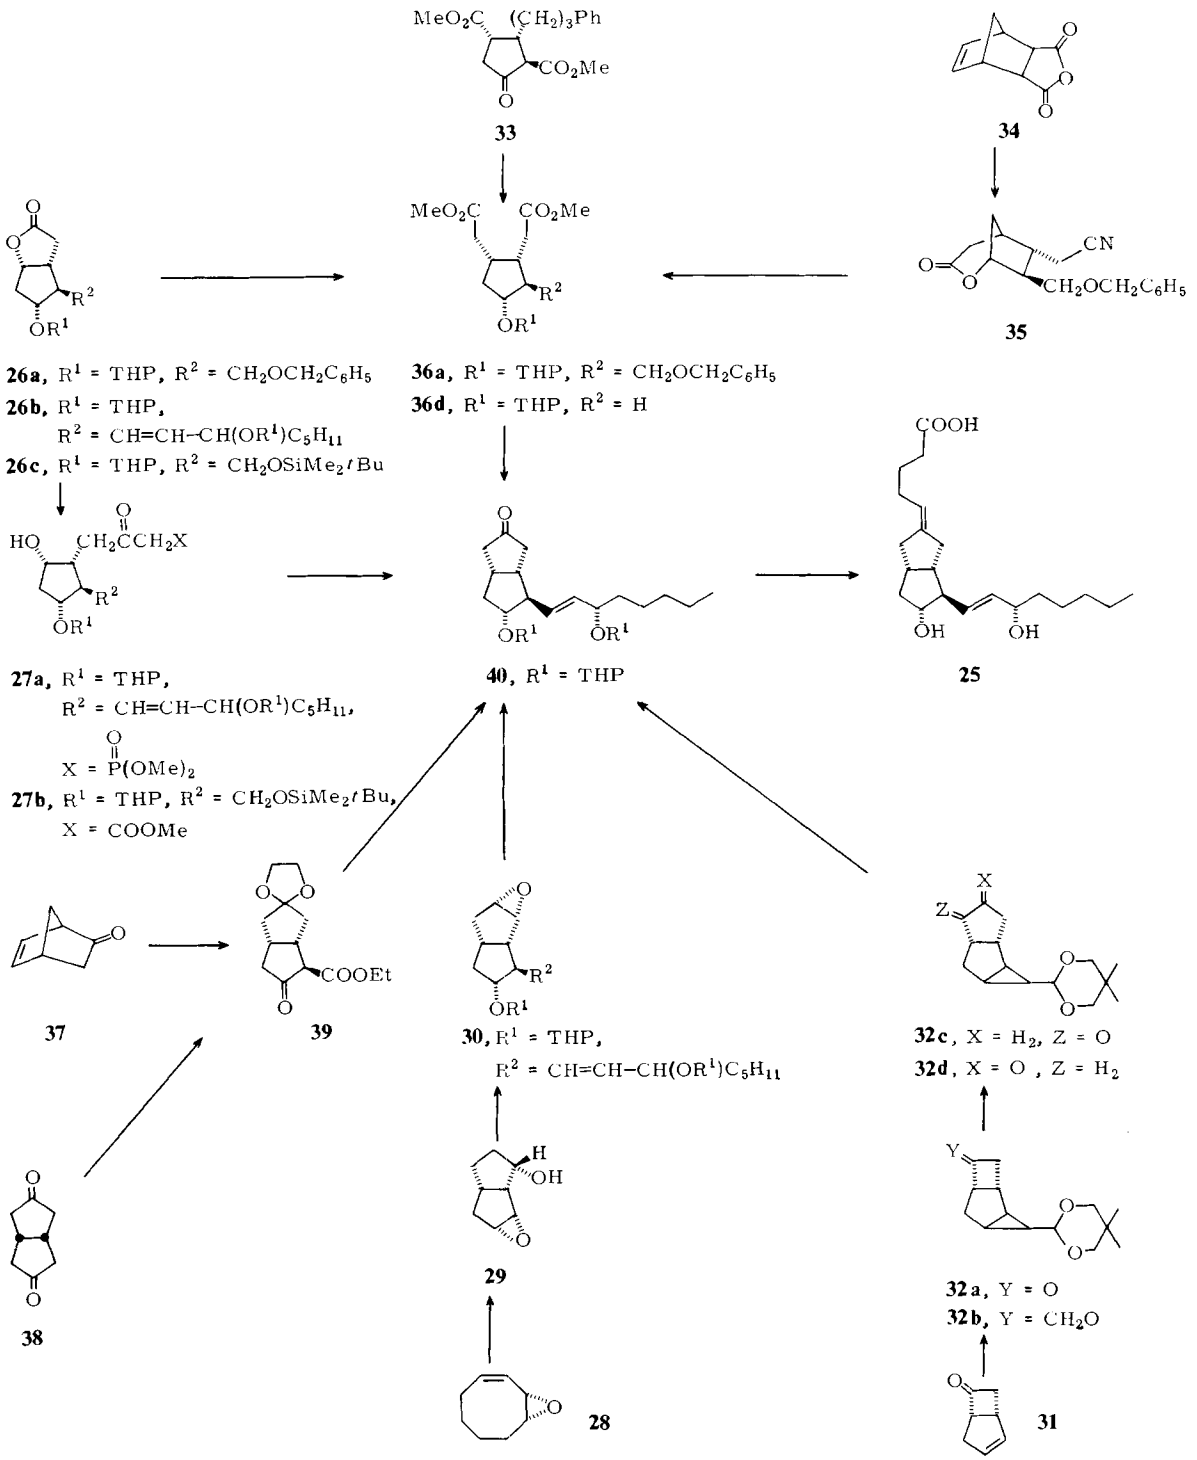


25

The total synthesis of carbacyclin was described almost simultaneously by several research groups[75,79,81,90]. They are in part a repetition of "classic" prostaglandin syntheses (Scheme 5). A detailed discussion of the multi-step synthetic routes is therefore considered unnecessary, and only important educts and relevant synthetic steps will be discussed.

The starting material in the total synthesis of carbacyclin and related isomers published by *Morton* and *Brokaw*[75] is the cyclobutanone derivative **32a** which was known from earlier studies. The product is transformed with dimethylsulfonium methanide into the isomeric spiroepoxides **32b**, using the method described by *Corey*[76] *et al.*. A major step in this carbacyclin synthesis is then a regioselective ring enlargement of this spiro compound[77], whereby a mixture of the isomeric cyclopentanones **32a** and **32d** is formed in a ratio of 1:9. The main product **32d** required for further synthesis may be crystallized from the crude reaction mixture in 60% yield. The subsequent reaction steps, *i.e.* formation of the ω-side chain and stereospecific hydroxylation at C-15, afford **40** and follow the known synthetic route of *Kelly et al.*[78].

The final synthesis step is a Wittig reaction with the *cis*-bicyclo[3.3.0]octan-3-one synthon **40**. This reaction has to be carried out with an excess of Wittig reagent, because the ketone shows a tendency towards enolization.



Scheme 5. Total synthesis of carbacyclin **25**. THP = tetrahydropyranyl.

The carbacyclin synthesis published slightly earlier by *Kojima* and *Sokai*[79] likewise employed the Wittig condensation with **40** as the final synthetic step; as in the case of the synthesis of *Kelly et al.*, the desired *cis*-isomer **25** is formed in a 1 : 1 ratio with the corresponding *trans* isomer. The stereospecific production of the *cis-trans* diester **33** and its transformation into **36d** by *Kojima* and *Sakai* is based on earlier work published by the same authors[80].

Gandolfi[81], *Nicolaou et al.*[90], and *Shibasaki et al.*[83] used *cis*-bicyclo[3.3.0]octan-3,7-dione **38** as starting material in their carbacyclin syntheses. An additional important intermediate in all three syntheses is the monoketal **39**. In order to circumvent the partial hydrolysis necessary for production of **39** from the diketal **38**, *Gandolfi*[82] described in 1980 a modified procedure starting from 5-norbornen-2-one **37**.

The ester group in **39** can be transformed into the ω-side chain by conventional methods and results in **40**, which is further converted under standard Wittig conditions into **25**.

In another synthesis of the carbacyclin **25**, *Shibasaki et al.* used 1,3-cyclooctadiene[83] as adduct; after epoxidation to **28**, the epoxide **30** is obtained *via* the endoepoxide **29**. Oxidative ring opening of epoxide **30** with Collins' reagent furnishes a mixture of the desired *cis*-bicyclo[3.3.0]octan-3-one derivative **40** and the isomeric *cis*-bicyclo[3.3.0]octan-2-one derivative in the ratio 1:2.

Two further total syntheses of the carbacyclin **25**[84,85], which also start from 1,3-cyclooctadiene, differ only in the transformation of the adduct into the *cis*-bicyclo[3.3.0]octan-3-one synthon **40**.

Sugie et al.[86] carried out a multi-step total synthesis based on previous studies with prostaglandins[87a]. This synthesis begins with the conversion of the 5-norbornene-2,3-dicarboxylic acid anhydride **34** into the lactone **35**. Hydrolysis of the lactone and the nitrile group in **35** with potassium hydroxide, and subsequent esterification of the resulting carboxylic acid with diazomethane affords diester **36a** which is then transformed in a Dieckmann condensation with subsequent decarboxylation and introduction of the ω-side chain into the carbacyclin precursor **40**.

Three further synthetic routes to carbacyclin **25** start from the derivatives **26a**—**26c** of the commercially available and optically active "Corey lactone". The key synthon **40** of all carbacyclin syntheses is then obtained by formal replacement of the oxygen atom in lactone by a methylene group.

In the first published synthesis according to the above principle[87b], sodium hydroxide is used to open lactone **26a**. The subsequent homologization of the oxoester obtained after oxidation with chromyl chloride leads to the tetrasubstituted cyclopentane derivative **36a**. This is then cyclicized by a Dieckmann condensation and transformed into **40** by subsequent introduction of the ω-side chain by known methods. *Aristoff*[88] opened **26b**, with dimethyl lithiomethylphosphonate to give **27b**, from which **40** is finally obtained *via* a substituted *cis*-bicyclo[3.3.0]octenone. In the recently published synthesis by *Skuballa* and *Vorbrüggen*[89], ring opening of **26c** is achieved with lithiated ethyl acetate; further transformation of the intermediate product **27b** leads *via* an intramolecular Michael addition to **40**.

A critical assessment of all synthetic routes must remain speculative, since each research group has used its own experiences which had been gained with prostaglandin chemistry over several years. Although the route from ketone **31** *via* the intermediate **40** to carbacyclin **25** described by *Kelly* and *van Rheenen*[78] may be tedious, it seems, due to synthetic "know-how", to be as practicable as the, apparently, more elegant syntheses starting from structures **37** and **38**[81-83,90].

The outstanding importance of *Corey*'s prostaglandin syntheses remains undisputed and the strategies developed at the end of the sixties could be applied to problems which did not appear until the advent of prostacyclin chemistry in the late seventies. For this reason, the synthetic route from **26b** *via* **27b** and **40** to **25** deserves special attention[88], all the more so because a precursor of **26b** may be obtained in optically active form from a commercially available intermediate.

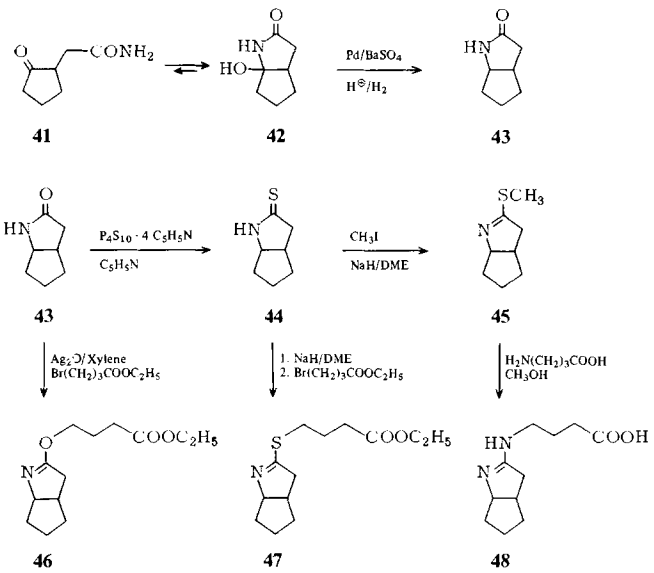
The synthetic routes summarized in Scheme 5 demonstrate quite clearly, even to the non-expert, that prostaglandin chemistry has begun, at least partially, to match steroid chemistry and has become attractive not only from the commercial standpoint, but also for experimental studies in the field of carbocyclic natural product chemistry.

3.4. Heteroiminoprostacyclins

Heteroanalogues of prostacyclin, in which the oxygen atom is replaced by a nitrogen atom or sulfur atom, have less favorable biological properties than prostacyclin[90,91].

In order to replace the enol-ether moiety by an isoelectronic group, the β-heteroiminoprostacyclins **19a**—**19c** were synthesized.

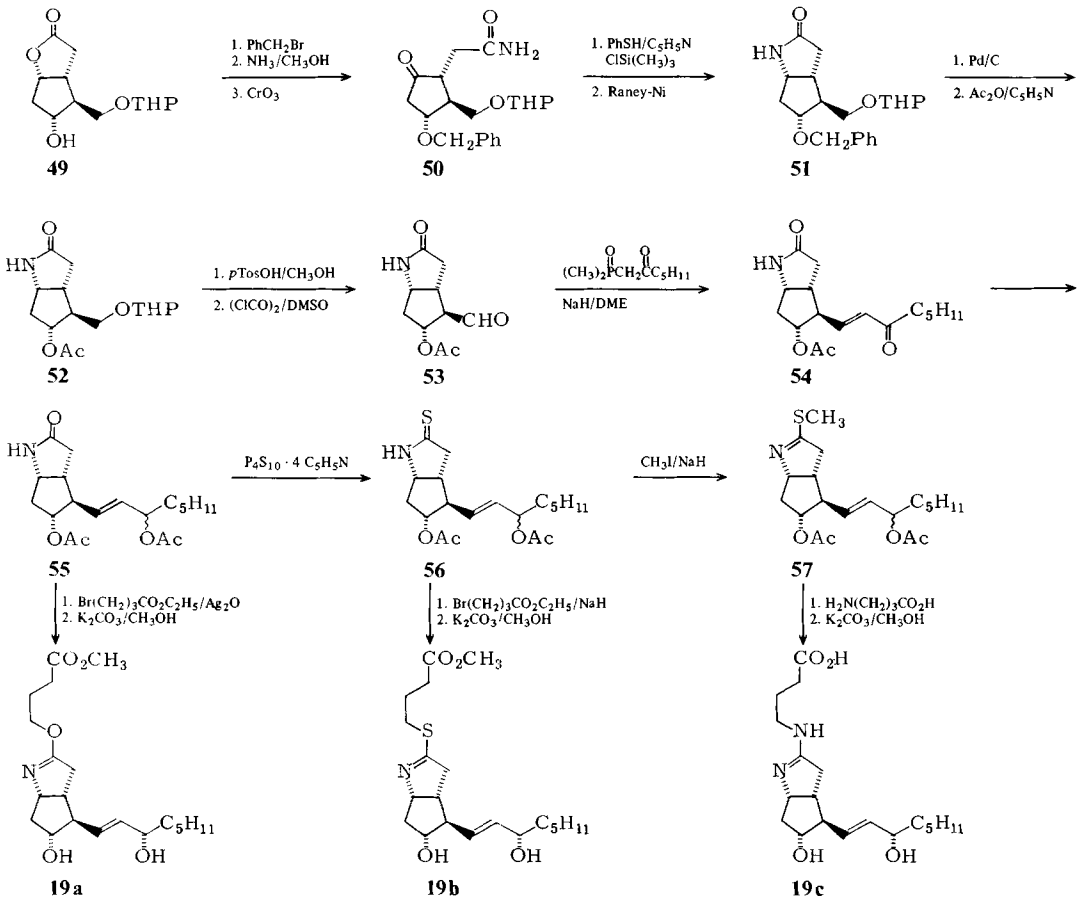
In addition, by simplification of the structure it was possible to investigate to what extent the electron-rich double bond of the enol ether was responsible for the biological properties of prostacyclin. They key reaction for obtaining such heteroiminoprostacyclins consists in tautomerizing 2-oxocyclopentylacetic acid amide **41** to the corresponding lactamol **42** (Scheme 6).



Scheme 6. DME = dimethoxyethane.

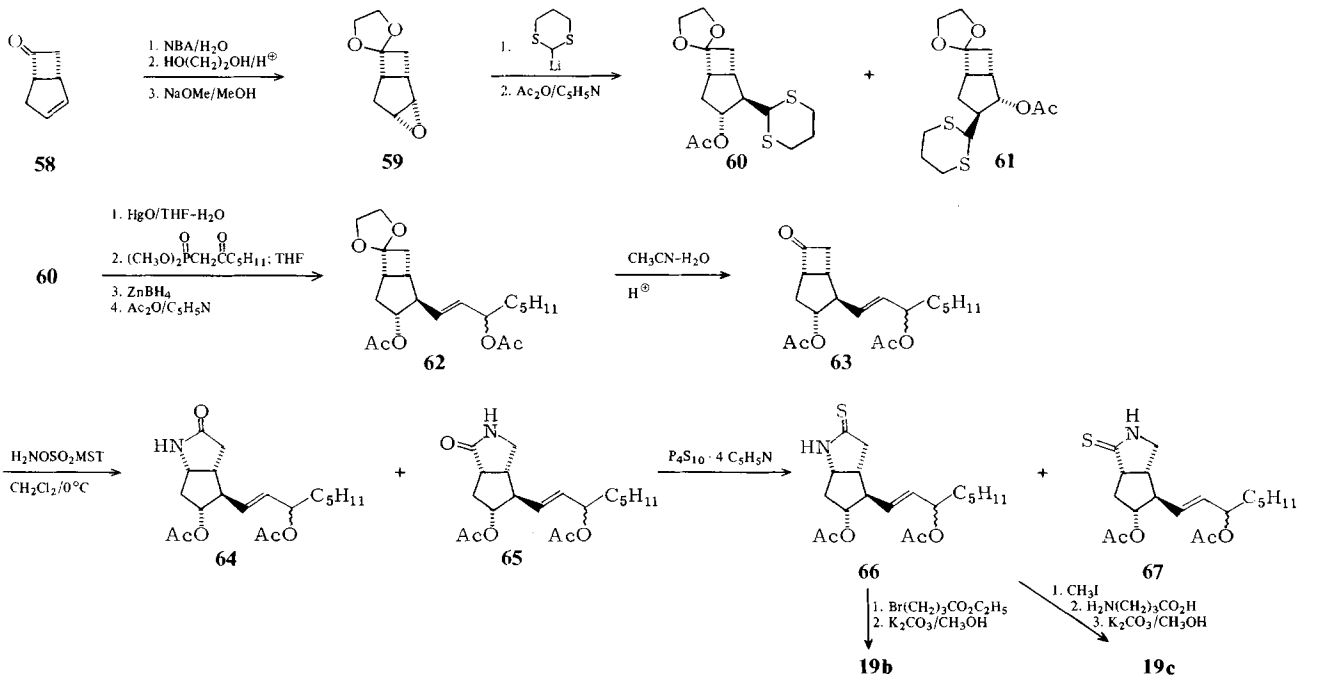
The OH-group can be eliminated from lactamol **42** by reduction, and the lactam **43** thus obtained converted into the corresponding thiolactam **44** by reaction with $P_4S_{10}\cdot 4\,Pyr$. Subsequent alkylation with ethyl ω-bromobutyrate leads to the desired β-thiaimino partial structure **47**. Alkylation of the thiolactam **44** with methyl iodide and addition of γ-aminobutyric acid affords the amidine derivative **48**. The lactim ether **46** is easily accessible by alkylating the lactam **43** with ethyl ω-bromobutyrate in the presence of silver oxide. Coumpound **47** proved to have both a platelet aggregation-inhibiting effect and vasodilating activity[92].

By coupling the synthesis of the heterocyclic ring with Corey's $PGF_{2\alpha}$ and prostacyclin syntheses it was possible to prepare β-heteroiminoprostacyclins **19a**—**19c**[63] from **49**, after selection of appropriate protecting groups for the individual synthetic steps (Scheme 7).

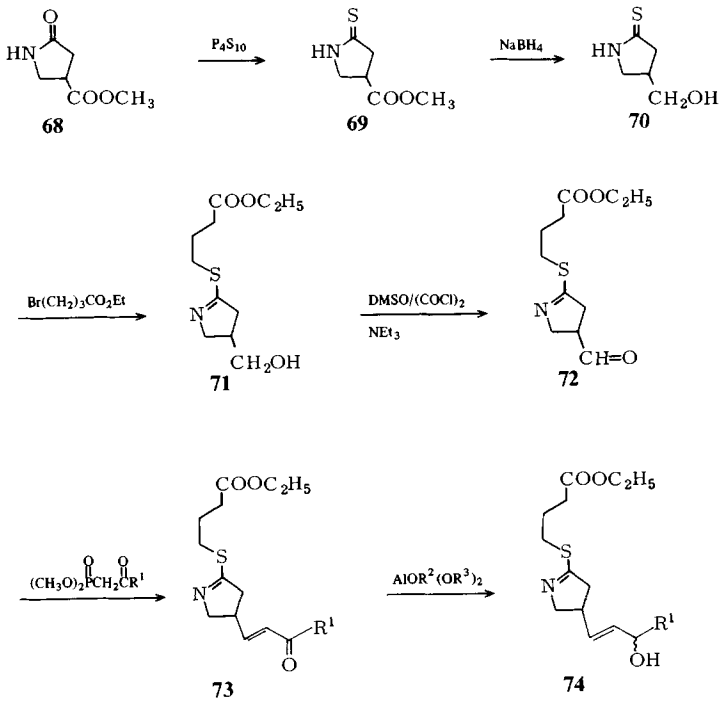


Scheme 7. DMSO = dimethyl sulfoxide; THP = tetrahydropyranyl.

An alternative route to the β-heteroiminoprostaglandins was elaborated, starting from easily accessible bicyclo[3.2.0]hept-2-en-6-one **58** (Scheme 8)[93]. The two key reactions of this synthesis—the nucleophilic attack of lithiodithiane on **59** and the Beckmann rearrangement of **63**—are not totally regioselective; however, the desired products **60** and **64**, respectively, can be easily separated from **61** and **65** by crystallization or column filtration through silica gel.



Scheme 8. NBA = *N*-bromoacetamide, THF = tetrahydrofuran, MST = mesityl.



Scheme 9.

It could also be demonstrated that β-thiaiminoprostacyclins **74** (Scheme 9), having a markedly simplified molecular structure[94], still possessed biological activity. In the synthesis both isomers are formed in the ratio 1 : 1. The Δ^1-pyrrolines obtained induced a decrease in blood pressure, depending on the ω-side chain, following intravenous administration to anesthetized rats ($ED_{25} = 30-100$ μg/kg). There was also an effect on platelet aggregation induced by arachidonic acid, but it was markedly weaker than in the case of PGI_2 (IC_{50}[*] $= 10^{-5}-10^{-6}$ mol/L).

4. Structure-Activity Relationships

Apart from the prostacyclin analogues in which the enol ether group is stabilized or simulated by chemical variations, numerous modifications of the natural prostacyclin and its analogues were prepared in which the ω-side chain is changed[95-97]. Examples of prostacyclins with modified ω-side chain that have an influence on plasma-renin activity, vasodilatation and inhibition of platelet aggregation have been described by *Schölkens et al.*[98,99]. Among such prostacyclin analogues the 10,10-difluoro-13,14-dehydro derivative deserves special mention, because of its increased chemical stability[100]. 12-Fluoro-analogues also exhibit good blood pressure-lowering and platelet aggregation-inhibiting properties[101].

In the series of β-thiaiminoprostacyclins, the following structure-activity relationships were established[102]:

1. An esterification of the carboxyl group in the α-chain generally does not affect the activity, at least *in vitro*.
2. A lengthening or shortening of the α-chain leads to a marked decrease in activity (intravenous studies in rats), which corroborates with the structure-activity relationships found with prostaglandins[2].
3. The ω-side chain can be subjected to various changes. Figure 1 shows that a number of derivatives maintain the blood pressure-decreasing and platelet aggregation-inhibiting effects. Some of the compounds, however, exhibit a greater difference between blood pressure-decreasing activity and platelet aggregation-inhibiting properties than prostacyclin or **19b**, a compound with a biological profile close to that of prostacyclin.

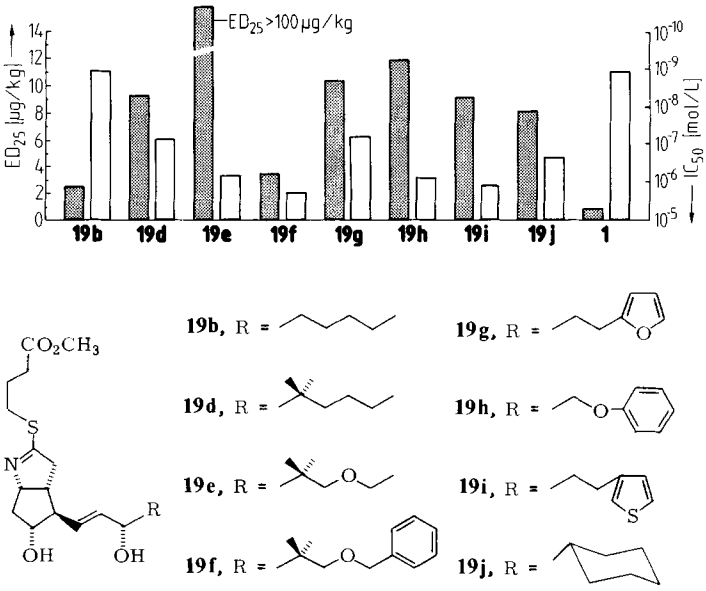


Fig. 1. Decrease in blood-pressure ED_{25} in anesthetized rats (black, left) and inhibition of arachidonic acid-induced platelet aggregation IC_{50} (white, right) by prostacyclin 1 and some β-thiaiminoprostacyclin analogues.

4. As observed with prostacyclin[97], 16,16-dimethyl analogues are usually less active than the basic molecule, in contrast to the corresponding 16,16-dimethyl prostaglandins.

5. Simulation of the Biological Activity of Prostacyclin by Other Compounds with Cardiovascular Activity

Numerous publications describe the pharmacological effects of well-known drugs as being attributable to their influence on prostaglandin, thromboxane, and prostacyclin levels. For example the influence of dipyridamol on prostacyclin biosynthesis[103], the action of antihypertensive agents like reserpine, α-methyldopa and propanolol on the biotransformation of the cyclic endoperoxide PGH_2 into prostacyclin[104], the effect of sodium nitroprusside on the formation of prostacyclin in isolated preparations of heart and vessels[105], and the influence of caffeine salicylate on the PGI_2-dependent inhibition of platelet aggregation[106] have been reported. The blood pressure-decreasing effect

[*] ED_{25} is the effective dose required to decrease the blood pressure by 25%; IC_{50} is the concentration at which the arachidonic acid-induced thrombocyte aggregation is reduced to 50%.

of angiotensin-converting enzyme inhibitors of the Captopril type and the cardiovascular activity of furosemide are possibly also connected with the biosynthesis of prostacyclin[107,108]. A recent article reported that pentoxifylline stimulates[109] microcirculation, which plays an important part in geriatric desease possibly by an increased prostacyclin release. Whether it is possible to stimulate prostacyclin release in patients undergoing chronic therapy still remains to be proven. The entire field of prostaglandin research is developing too rapidly to be able to make an exhaustive survey.

This paper has mainly considered the pharmacological properties and the synthesis of prostacyclin and its analogues. The question of the biochemical mechanism of action was consciously excluded because of its complexity. A detailed discussion would require a comprehensive report on thromboxane (TXA_2) (see Scheme 1), the platelet-aggregating, vasoconstrictive, physiological antagonist of prostacyclin (PGI_2). According to *Gorman*[122]:

The mechanisms responsible for the c-AMP regulatory activity of TXA_2 and PGI_2 are not known—and it is too early to establish the relative importance of the TXA_2 and PGI_2 regulatory systems in the general biochemical control of cells. In cells containing the prostacyclin synthetase, stimulation of the cyclooxygenase may result in an increase in the concentration of c-AMP (inhibition of Ca^{2+} mobilization). It is now of importance to characterize cell types on the basis of their ability to synthetize either TXA_2 or PGI_2. This would provide a much clearer understanding of both the role and mechanism of action of the local hormones, the prostaglandins.

However, great difficulties are encountered[123] when trying to classify the cell types as required by *Gormann*[122]; although it is known that prostaglandin synthesis takes place in discrete renal compartments, informational content of these findings is limited owing to the transport and exchange phenomena occurring mainly in the kidney.

6. Outlook and Conclusion

The above-cited attempt to correlate the function of a single organ—the kidney—with the arachidonic acid metabolism in general and the prostaglandins in particular shows how many factors influence the formation of arachidonic acid metabolites. For this reason, disturbances in the arachidonic acid metabolism are unlikely to be counteracted in general by a diet rich in unsaturated fatty acids, or by inhibition of cyclooxygenase or thromboxane isomerase. It remains to be seen whether a substitution therapy with prostacyclin analogues will be widely applicable and whether the hypothesis is confirmed that classic cardiovascular drugs reveal their effect through a prostacyclin release.

In a progress report on gastrointestinal peptides, *Creutzfeld*[124] has recently made the following statement: "Despite the "explosion" in gastrointestinal peptide research in recent years, clinical application has remained minimal. Such disappointments are not unusual but fairly typical of modern research and should therefore not be considered to be discouraging". This is also true for prostaglandin research.

The list of outstanding medical problems that may be understood through the study of arachidonic acid metabolism remains large, and so from the research point of view, further studies continue to be justified, especially regarding heart attack, stroke, malignant hypertension, deep-vein thrombosis, transplant preservation, vascular surgery, pregnancy-related hypertension, *etc.*

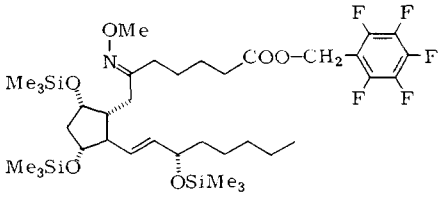
Prostaglandins are the subject of much intensive research work at university and industrial institutions because a knowledge of the metabolism of unsaturated fatty acids is expected to explain at least partially the origin of cardiovascular diseases and arteriosclerosis. A congress entitled "The Second Pharmacological Revolution", dealing, *inter alia*, with prostaglandins has recently come to a close in London. Such a title may sound somewhat euphoric to the prosaic chemist, but admittedly, the discovery of the fatty acid series in general and of prostaglandins in particular—with special consideration of the work on prostacyclin—has brought new developments in the fields of biochemistry and pharmacology. These studies seek a causal therapy of cardiovascular diseases.

7. Addendum

After this manuscript had been completed, the Fifth International Prostaglandin Congress in Florence provided an opportunity to verify the completeness of this review. The more than 800 individual contributions presented at the congress contained a profusion of chemical, biochemical, pharmacological and clinical data which, however, did not reveal any surprising new developments.

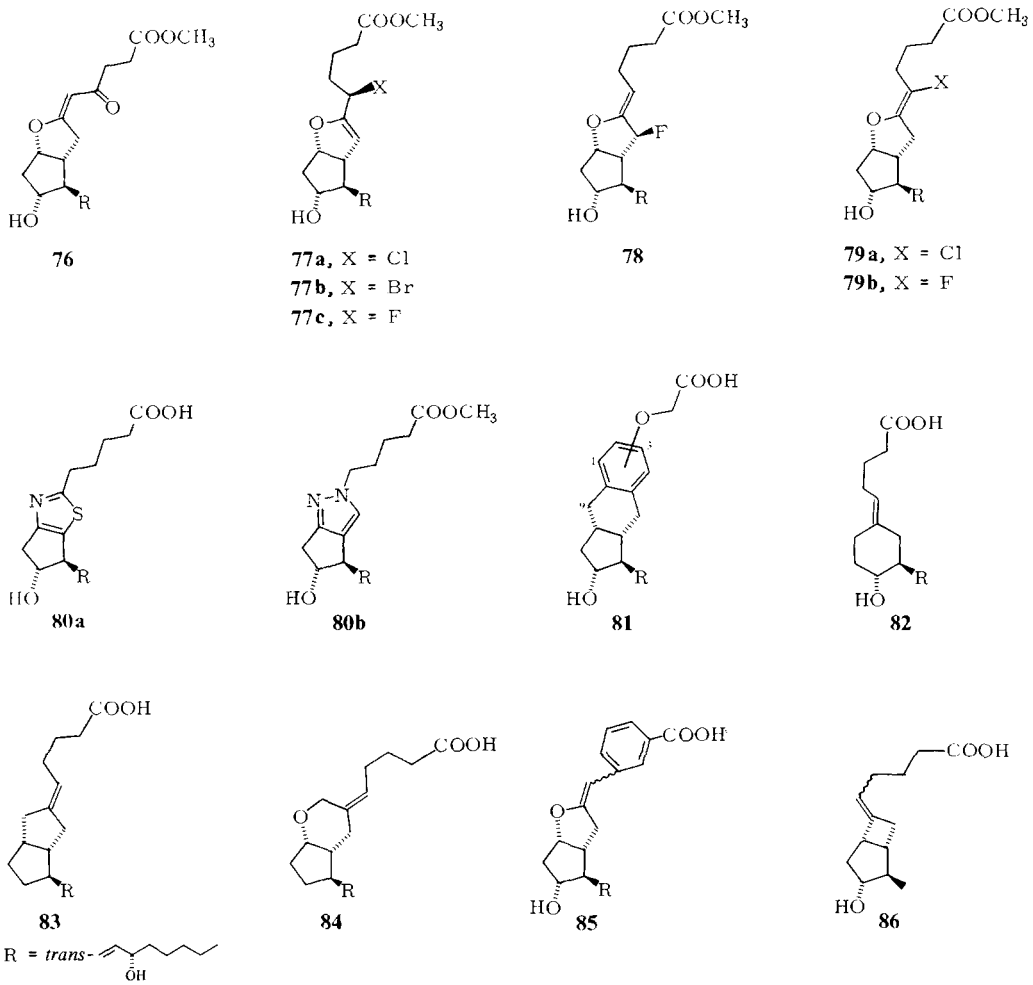
The most important results from the Florence meeting together with new publications which appeared whilst the manuscript was in preparation are summarized below under the appropriate headings.

Analytical Procedures: Most recent studies[110] have shown that the methods used up to now for determining PGI_2 in plasma are not specific enough. *Blair et al.*[111] have now reported a new highly selective method for the determination of 6-oxo-$PGF_{1\alpha}$, the stable metabolite of PGI_2 in plasma; the procedure is based on capillary column chromatography coupled with negative-ion chemical ionization mass spectrometry. The 6-oxo-$PGF_{1\alpha}$ is determined as its tris-trimethylsilyl ether **75**; the carboxy group is esterified with pentafluorobenzyl (PFB), the keto group is protected with *O*-methylhydroxylamine.



75

The mass spectrum of this derivative consists of one major ion m/z 614 = [M − PFB] carrying over 50 percent of the total ion current. The sensitivity of this new method is 0.5 pg/mL PGI_2 with 20 mL plasma samples. The assay was employed to determine the plasma level of 6-oxo-$PGF_{1\alpha}$ in



Scheme 10.

20 healthy volunteers. Concentrations in the range 0.5 to 2.49 pg/mL were found. On the basis of these results, *Blair et al.* conclude that PGI_2 does not function as a circulating hormone in man under normal physiological conditions.

Synthetic Prostacyclin Analogues: The following addendum (Scheme 10) gives the state of the art as of June 1982.

In Florence, *Galambos et al.*[112b] presented for the first time the 4-oxo-PGI_2 analogue **76** stabilized by conjugation, as continuation of earlier studies which had resulted in the 7-oxo-PGI_2 analogue **14a**. *Toru et al.*[113] reported the synthesis of stabilized prostacyclin analogues substituted with halogen at position 5 or 7 of the prostacyclin structure (**77a—77c**, **78**, **79a**, and **79b**). *Bradbury*[114] and *Noyori*[115] have meanwhile synthesized two further analogues—**80a** and **80b**—in which the tetrahydrofuran ring of prostacyclin has been replaced by a thiazole or pyrazole ring, respectively. *Aristoff et al.*[116] described the total synthesis of the benzo-annelated derivative **81** which has the side chain in the 1- or 3-position and may have an additional double-bond between positions 8a and 9. *Ceserani et al.*[117] presented a system simplified to the cyclohexane derivative **82**.

Finally, *Gandolfi et al.*[118] reported on a 11-deoxy analogue of carbacyclin **83** and *Dixon et al.*[119] on a further 11-deoxy analogue **84**. Two additional prostacyclin analogues **85** and **86** have been synthesized by *Seipp et al.*[120] and *Newton et al.*[121].

We are greatly indebted to Dr. R. Fickert for her help in editing. Special thanks are due to Mrs. E. Böhm and Mrs. U. Pöllath who labored long hours typing the manuscript. We also wish to thank the translators, Mrs. M. Bräuninger and Mrs. G. van Ooyen.

The Multiple-Path Mechanism for ^{13}C-^{13}C Long-Range Coupling Constants of Bicyclic Hydrocarbons

By *Martin Klessinger** and *Jung-Huyck Cho*

For the interpretation of the ^{13}C-^{13}C long-range coupling constants of cyclic hydrocarbons on the basis of a multiple-path mechanism we have recently assumed an algebraic additivity of the contributions of the various coupling pathways[1]. It should be possible to check this assumption particularly well on bicyclic hydrocarbons in which three coupling pathways are possible for the $J_{1,4}$-coupling between the bridgehead atoms. We have therefore synthesized the unlabeled compounds **1**—**10** and investigated their ^{13}C-NMR spectra. The $J_{1,4}$-coupling constants are collected in Table 1.

The coupling constants of the norbornane and bicyclo[2.2.2]octane series differ by about 5—7 Hz, as is to be expected on replacement of the two-bond coupling pathway *A* by the three-bond pathway *B* on the basis of the increments $^2J_A = -1$ Hz and $^3J_B = 4$ Hz[2]. A comparison of the data for **1**, **2**, and **3**, and for **6**, **7**, and **8**, shows, as expected, that the influence of a methyl group on ^2J_A and ^3J_B can be neglected, while an exocyclic methylene group (pathway C) reduces the coupling by about 2 Hz to $^3J_C = 2$ Hz. The comparison of the coupling constants of **4** and **2** and of **5** and **3**, as well as of **9** and **7** and of **10** and **8** shows that the introduction of a double bond into the norbornane series lowers the coupling by *ca.* 1 Hz, while in the bicyclo[2.2.2]octane series it increases it by *ca.* 1 Hz. This can be explained in terms of the valence angle dependence of the coupling *via* a three-bond pathway.

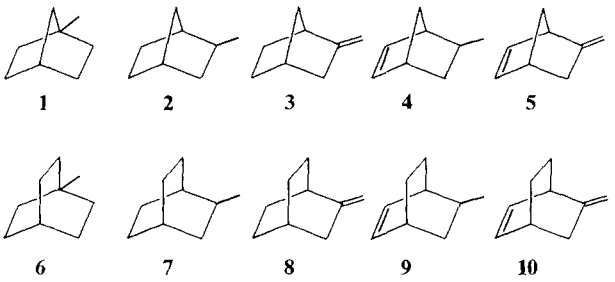

Table 1. Measured and calculated (according to the additivity rule) coupling constants $J_{1,4}$ [Hz] of bicyclic hydrocarbons.

Cpd.	$J_{1,4}$ (exp.) [a]	$J_{1,4}$ (calc.) [b]	Cpd.	$J_{1,4}$ (exp.) [a]	$J_{1,4}$ (calc.) [b]
1	6.8	7	**6**	12.9	12
2	5.9 (*endo*) 6.0 (*exo*)	7	**7**	12.8	12
3	4.4	5	**8**	11.1	10
4	5.5 (*endo*) 5.7 (*exo*)	6	**9**	13.4 (*endo*) 13.3 (*exo*)	13
5	4.0	4	**10**	11.3	11

[a] Measured in C_6D_6 (75%) with a Bruker WM-300 spectrometer at 75.47 MHz in the PFT method. [b] Calculated additively with the increments quoted in the text.

Quantum chemical calculations according to the INDO-SCPT method[4] show that for decreasing CCC valence angles the contribution to the coupling is expected to increase both for the coupling pathway *B* as well as for *D*, the effect in the case of *B* with about 3 Hz for a valence angle change of about 5° being almost twice as large as in the case of *D*[5]. As a result, in the norbornane series the valence angle effect dominates in the case of the saturated system, so that here $^3J_D < {}^3J_B$ and correspondingly a de-

crease of the coupling $J_{1,4}$ is observed in going from the saturated to the unsaturated system, whereas the opposite behavior is found in the bicyclo[2.2.2]octane series. If, in agreement with these results, one puts $^3J_D = 3$ Hz for the increment of the coupling pathway D for the norbornene derivative and $^3J_D = 5$ Hz for the bicyclo[2.2.2]octene derivative then excellent agreement is found between the measured data and the $J_{1,4}$-coupling constants calculated on the basis of a multiple-path mechanism, also given in Table 1.

Thus, on taking into consideration the ring strain effects an algebraic additivity of the contributions of the various coupling pathways to the coupling constant is strictly fulfilled also in the case of the bicyclic systems. Hence, on using suitable increments the long-range couplings of complicated systems can be estimated, while deviations of the additivity permit conclusions to be drawn regarding ring strain and similar effects.

Determination of the Structure of Dimethyldioctadecylammonium Chloride in Solution by Small Angle X-Ray Scattering; Reversible Phase Transition**

By *Hasko H. Paradies**

Phospholipid vesicles are of great importance as models for biological membranes. The use of surfactant vesicles, formed from simple amphiphiles upon sonication, can be anticipated as artificial vesicles mimicking cell membrane functions[1,2]. Dimethyldioctadecylammonium chloride (DODAC, $(CH_3)_2(n\text{-}C_{18}H_{37})_2N^+Cl^-$) and dihexyldecyl phosphate ($(n\text{-}C_{16}H_{33}O)_2P(O)OH$)[4] have been characterized by *Kunitake et al.*[1] and *Fendler*[2]. In spite of their potential for utilization in catalysis, energy conversion, and substrate partitioning no detailed information is available on the size and shape of DODAC surfactant vesicles in solution, nor on the factors which influence them. Unambiguous structural data have been obtained showing the formation of a lamellar bilayer structure as well as the internal structure of DODAC vesicles, including its phase transition behavior under varying pressures and temperatures.

The structural data of DODAC-vesicles (see Table 1) indicate that the amphiphile in aqueous solution is a random distribution of lamellas with a thickness of 4.4 ± 0.2 nm, which is consistent with a hollow vesicular structure with an outer diameter of 35.0 ± 0.1 nm (Fig. 1). The electron density profile perpendicular to the DODAC lamellar plane is shown in figure 1C.

[**] Part of this work was carried out in the Department of Chemistry, Cornell University, Ithaca, NY 14853 (USA).

Table 1. Morphological and hydrodynamic parameters of DODAC vesicles in aqueous solution; pH 7.0; 0.01 mol/L Tris-HCl.

Radius of gyration R_g [nm]	13.8 ± 0.5
Molecular weight $M_r \times 10^5$	33.5 ± 1.5
Thickness of double layer R_t [nm]	4.4 ± 0.05
Degree of hydration [g H_2O/g DODAC]	0.86
Maximum dimension D_{max} [nm]	35.0 ± 0.1
Partial specific volume Φ [mL/g]	0.8561
Diffusion coefficient $D \times 10^{-7}$ [cm^2/s]	1.72 ± 0.05
Mass per unit area [M_r/nm^2]	2510

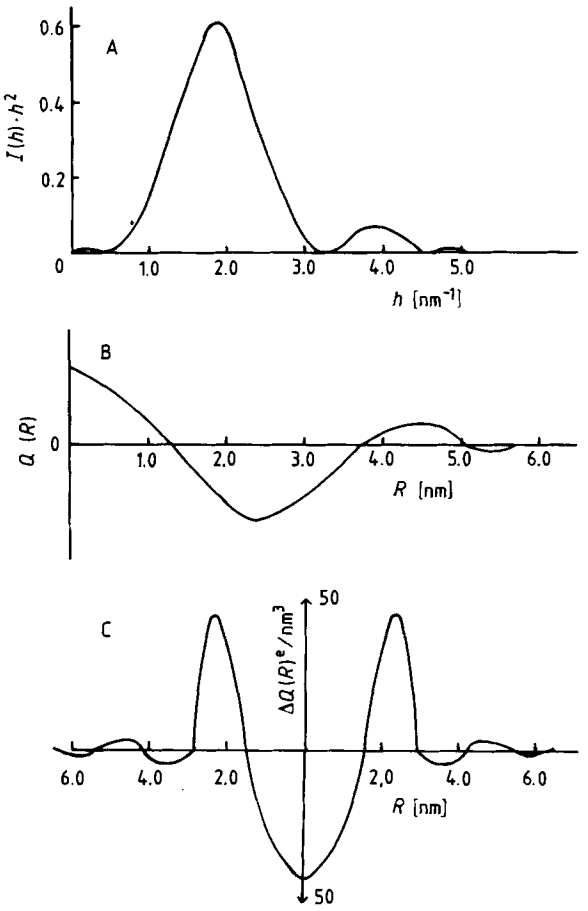

Fig. 1. A) Thickness factor, $I_t(h)h^2$ of DODAC vesicles obtained from the uncorrected data by assuming a one-dimensional cross section distance distribution function: $h = (4\pi/\lambda)\sin\theta$; $\lambda = 1.54$ Å, θ = scattering angle, and $I_t(h)$ = scattering intensity. B) Distance distribution function, $Q(R)$, obtained from the data in Fig. 1A. C) Electron density profile, $\Delta\rho(R)$, across the bilayer thickness obtained from the structure amplitudes.

The results obtained strongly support the view that a certain interdigitation of inner and outer DODAC molecules occurs since the thickness of 4.4 nm is shorter than the length of two octadecyl chains.

DODAC vesicles show a reversible transition at $T_m = 38$ °C at constant pressure and varying temperature, or *vice versa* (Fig. 2). The vesicle sizes changed from $D_{max} = 35$ nm to $D_{max} = 40$ nm, consistent with recent results by *Ceuterick et al.*[4] for dimyristoylphosphatidylcholine[3], but different from those of *Watts et al.*[5].

The changes in the effective hydrodynamic radii R_c ($D_{max}/2$) with pressure and temperature are due to changes in the isopotential partial specific volume from $\Phi = 0.8561 \pm 0.003$ mL/g at 293 K to 0.8361 ± 0.002 mL/g at 303 K. However, DODAC vesicles containing 11%

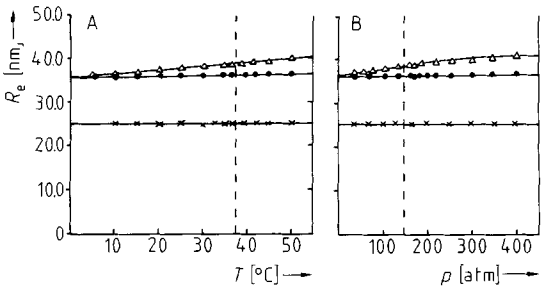

Fig. 2. Effective hydrodynamic radius, R_e, of DODAC-vesicles at 1 atm determined by dynamic light scattering. Temperature-induced phase transition. Broken line: phase transition. •—• DODAC vesicle, ×—× dimyristoylphosphatidylcholine vesicle; △—△ DODAC-vesicle containing 11% (w/w) cholesterol. $R_e = k_B T K^2/(3\pi\eta\Gamma)$; k_B = Boltzmann constant, $\Gamma = (1/\tau_c) = DK^2$ with $K = (4\pi n/\lambda)\sin(\theta/2)$, τ_c = time constant, D = diffusion coefficient: A) temperature-induced phase transition at 1 bar, B) pressure-induced phase transition at 22 °C.

(w/w) cholesterol reveal no changes in the radius of gyration, R_g, sedimentation constant, $S^0_{20,w}$, or diffusion coefficient, D, upon changing temperature or pressure, but in the isopotential partial specific volume from $\Phi = 0.8611$ mL/g to 0.8541 mL/g. Moreover, DODAC vesicles containing 11% (w/w) cholesterol are more stable with respect to pH and passage of ions than those without cholesterol, and they reveal a considerably higher melting temperature ($T_m = 42$ °C). The cholesterol is located close to the quaternary nitrogen.

Photocyclization of 2-Aryl-1,1-difluoroethylenes: Synthesis of Mono- and Difluorinated Polycyclic Arenes

By *René Lapouyade**, *Naïma Hanafi*, and *Jean-Pierre Morand*

Mainly due to their usefulness in biochemistry, the preparation of low-fluorinated compounds remains a problem of current interest[1]. More specifically, fluorinated hydrocarbons have proved to be important tools in defining the metabolic activation pathways responsible for the carcinogenic activity of polycyclic arenes. With the aim of obtaining new conducting radical-ion salts of polycyclic arenes, we were interested in introducing fluorine into these in order to modify their electron-donor properties without seriously affecting their molecular size.

F-33405 Talence (France)

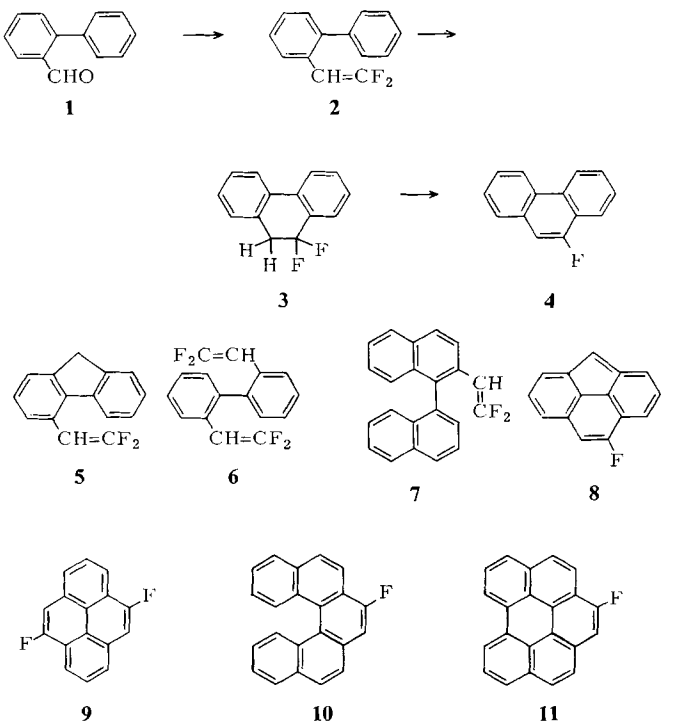
The synthesis of fluorinated polycyclic arenes was based on the first of the following two general methods: synthesis from fluorinated educts or fluorination of arenes. By this means we were able to synthesize arenes **4** and **8**—**10** in good yield and without isomeric impurities. The key step in this sequence is the photocyclization of 2-(2-biphenyl)-1,1-difluoroethylenes, which are accessible by difluoromethylenation of the corresponding aldehydes with the sodium salt of chlorodifluoroacetic acid and triphenylphosphane[2a], or with dibromodifluoromethane, triphenylphosphane and zinc dust[2b]. The final step is a dehydrofluorination carried out by filtration of the irradiated solution on a silica gel column or by reaction with $KOCH_3$ in boiling methanol.

We have now obtained the difluoro compounds **2** and **5**—**7**[3] in 50—80% yield, from which the cyclization products **4** and **8**—**10**[3] (*ca.* 60% yield) were obtained. We have also isolated the intermediate **3** and obtained **11** by oxidative photocyclization of **10**[3]. Since the photocyclization of 2-vinylbiphenyl derivatives is general[4], the reaction described provides a route to a large number of polycyclic arenes fluorinated in a specific position.



1 2 3 4 5 6 7 8 9 10 11

Electrochemical oxidation of **9** gave small black crystals of $\mathbf{9}_2 \cdot PF_6$, **12**[3]; a conductivity of 2 Ω^{-1} cm^{-1} at room temperature was measured along the needle axis using a conventional four probe technique.

Procedure

2: A solution of $ClCF_2CO_2Na$ (1.26 g, 8.3 mmol) in diglyme (6 mL) was added to a stirred hot (160 °C bath temperature) solution of **1** (0.91 g, 5 mmol) and triphenylphosphane (1.57 g, 6 mmol) in 2 mL of diglyme over a period of 35 min. The mixture was heated for 2 h at 160 °C, filtered, and evaporated to dryness and the residue formed was dissolved in CCl_4 and purified by chromatography on silica gel; yield **2** (0.54 g, 53%).

4: A degassed (N_2 stream) solution of **2** (0.092 g) in cyclohexane (85 mL) was irradiated for 24 h ($\lambda = 253$ nm,

Rayonet reactor). After evaporation, the residue was dissolved in 40 mL of a 3×10^{-3} M $KOCH_3/CH_3OH$ solution and refluxed for 1 h. The solution was extracted with ether. After drying, the solvent was removed and the oily residue chromatographed on silica gel with CCl_4. After crystallization from methanol 0.54 g of **4**[5] (60%) was obtained as white needles.

12: A 2×10^{-2} M solution of **9** in CH_2Cl_2, containing nBu$_4$NPF$_6$ (0.15 M) as conducting salt was anodically oxidized under argon at 5 °C with a current of 10 μA. After several hours shiny black crystals of **12** were collected and washed with CH_2Cl_2.

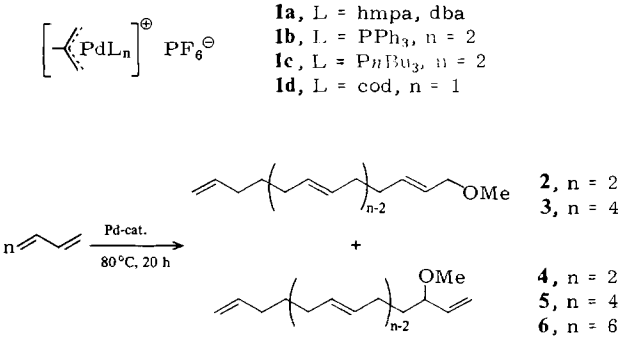
Higher Telomers in the Pd-Catalyzed Reaction of Butadiene with Alcohols**

By *Pierre Grenouillet, Denis Neibecker, Jacques Poirier,* and *Igor Tkatchenko**

Several reports have shown that zero-valent palladium compounds or divalent palladium compounds together with reducing agents are able to catalyze the telomerization of butadiene with a nucleophilic compound ZH (ZH = H_2O, ROH, ArOH, RCOOH, R^1R^2NH, *etc.*) leading to functionalized C_8-products[1]. In very few instances higher telomers containing three or four butadiene units were observed, *e.g.* on using bis[acetato(η^3-allyl)palladium][2a] or mixtures of bis[η^3-allyl(chloro)palladium] and silver salts[2b].



Scheme 1. hmpa = hexamethylphosphoric triamide, dba = dibenzylideneacetone, cod = cyclooctadiene.

We recently reported a method for the synthesis of cationic η^3-allylpalladium complexes which are stabilized by monodentate **1a**—**1c** or bidentate **1d** ligands[3]. On using complex **1a** as catalyst *in situ*, a mixture of $H(C_4H_6)_nOMe$ ethers is formed from butadiene and methanol. Telomers with even numbers n are practically the sole products, the C_{16}-derivative **5** being preferentially formed (Table 1, Scheme 1). Besides **5** and the expected 1- and 3-methoxyoctadienes (**2** and **4**, respectively), compounds **3** and **6** could also be detected. Higher telomers are presumably formed as judged from a preliminary HPLC analysis on μ-Styragel using a 100 Å column.

With the cationic complexes **1b** and **1c** as catalysts—both were isolated in pure form beforehand—mixtures of telomers and oligomers are formed. However, C_8 compounds are now preferred and, furthermore, the higher products do not contain linear oligobutadiene units. Conversely, reactions performed in the presence of complex **1d** give the expected product distribution observed for **1a**. An increase in the molar ratio MeOH : C_4H_6 leads to a greater selectivity for methoxy octadienes. Interestingly, the highest selectivity for C_{16}-derivatives is not observed for the anticipated ratio of 0.25, but for a ratio of *ca.* 0.5. The higher the methanol content the more of **5** is formed.

The temperature and the time of reaction also have a remarkable influence on the product selectivity. With **1a** as catalyst, more than 50% of C_{16}-derivatives is obtained if the reaction is carried out at 60 °C, 6 bar C_4H_6, with a reaction time of 6 h and a MeOH : C_4H_6 ratio of 0.5.

The catalytic reaction observed with methanol proceeds well with other aliphatic alcohols and with phenol; Table 1 shows, however, that the butadiene conversion decreases with increasing steric hindrance of the alkyl group, *i.e.*

Table 1. Telomerization of butadiene in the presence of alcohols ROH or phenol. Reaction conditions: [**1a**] = 0.25 mmol/L; [C_4H_6] = 300 mmol/L; [ROH] = 75 mmol/L; 80 °C 20 h. The upper indices (*e.g.* in C_8^3, C_{16}^5) denote the number of double bonds.

Me ≈ Et > *i*-Pr ≫ *t*-Bu[1]. 1-*tert*-Butoxy-2,7-octadiene, which was not obtained with conventional catalysts, is also formed. Higher telomers are formed in all cases except with *t*-BuOH. The presence of large amounts of phenoxy-C_{12}-derivatives may reflect an alteration in the reaction mechanism.

The reaction presumably proceeds *via* condensation of C_8-units, since almost only C_{8n}-products are formed. Indeed, 1-methoxy-2,7-octadiene **2** is converted *inter alia* into the ether **5**. The occurrence of two or even three vacant coordination sites may be a prerequisite for the formation of such higher telomers.

Procedure

All reactions are carried out under argon.
Solution of **1a**: A mixture of $Pd_2(dba)_3 \cdot CHCl_3$[4] (130 mg, 0.125 mmol) and $[(CH_2{=}C(CH_3)CH_2O)P(NMe_2)_3]^{\oplus}PF_6^{\ominus}$[5] (95 mg, 0.25 mmol) is placed in a 50 mL Schlenk tube and degassed by three vacuum-argon atmosphere cycles. Toluene (10 mL) is then added and the reaction mixture stirred under argon for 120 min.

Catalytic reaction: The pale yellow solution is filtered through Celite in order to remove traces of metallic palladium and then transferred *via* a syringe into a glass-lined 100 mL stainless steel autoclave. Methanol (3 mL, 75 mmol) and butadiene (16.2 g, 300 mmol) are then added. The autoclave is stirred magnetically and heated to 80 °C for 20 h; it is then cooled down and the excess butadiene is vented through a cold trap. The conversion is 94%. The products are analyzed by GC with dodecane and eicosane as internal standards.

Addition of Alkyl Radicals to Alkynes: Distinction between Radical and Ionic Nucleophiles**

By *Bernd Giese** and *Stephen Lachhein*

In radicals at least one orbital is singly occupied by an electron. This electron hole is filled in radical additions to alkenes by formation of a σ-bond; nevertheless, alkyl radicals are nucleophilic. The apparent contradiction is accounted for by Frontier Orbital theory, according to which the interaction between the highest, singly occupied orbital (SOMO) of the radical and the lowest, unoccupied orbital (LUMO) of the alkene is decisive for the reaction rate[1]. In consequence, the electron density is shifted from the radical to the alkene on the path leading to the transition state. The electron hole on the C-atom of the attacking radical is filled only when the transition state has been crossed. In contrast, with nucleophiles with lone pairs of electrons the negative charge is shifted both in the transition state and in the product to the alkene. This difference is discernible in the gradation in reactivity of alkenes and alkynes in radical and ionic[2] nucleophilic additions. Whereas nucleophiles having lone pairs of electrons attack alkynes markedly faster than alkenes[3], the alkynes in Table 1 react 3.0—5.2 times slower with the nucleophilic alkyl radicals than the corresponding substituted alkenes[4]. The values were obtained by the "mercury method", previously developed by us[1b].

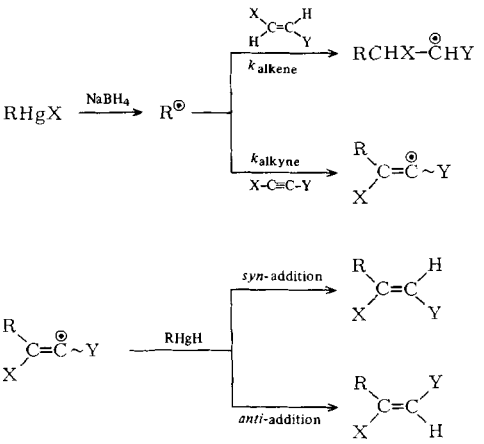

Table 1. Substrate selectivity ($k_{alkene}:k_{alkyne}$) and stereoselectivity (*syn* : *anti*-addition) of alkyl radicals $R^{\odot}$ at 293 K, as well as the overall yields of the addition reactions.

R	X	Y	$k_{alkene}:k_{alkyne}$	*syn* : *anti*	Yield [%]
c-C_6H_{11}	H	C_6H_5	3.5	30 : 70	8
t-C_4H_9	H	C_6H_5	—	7 : 93	10
n-C_6H_{13}	H	CO_2CH_3	—	69 : 31	10
c-C_6H_{11}	H	CO_2CH_3	3.0	56 : 44	35
t-C_4H_9	H	CO_2CH_3	—	28 : 72	41
c-C_6H_{11}	CO_2CH_3	CO_2CH_3	—	64 : 36	21
t-C_4H_9	CO_2CH_3	CO_2CH_3	5.2	42 : 58	54

The lower rate of addition of alkyl radicals to alkynes can be accounted for by the fact that the LUMO of an alkyne is energetically higher than the LUMO of an alkene[5a]. Application of Frontier Orbital theory indicates early transition states in additions of radical nucleophiles. In complete contrast to this, nonradical nucleophiles react faster with alkynes than with alkenes[3], because late transition states are involved and the rehybridization in reactions of alkynes is more energetically favorable than that of alkenes[5a].

Furthermore, the results indicate that, as in alkenes[5b], the *anti*-addition of radicals only predominates when R is highly bulky. This is consistent with the unsymmetrical shielding of the vinyl radical. The *syn*-approach of the H-donor is increasingly hindered as the size of the R group increases.

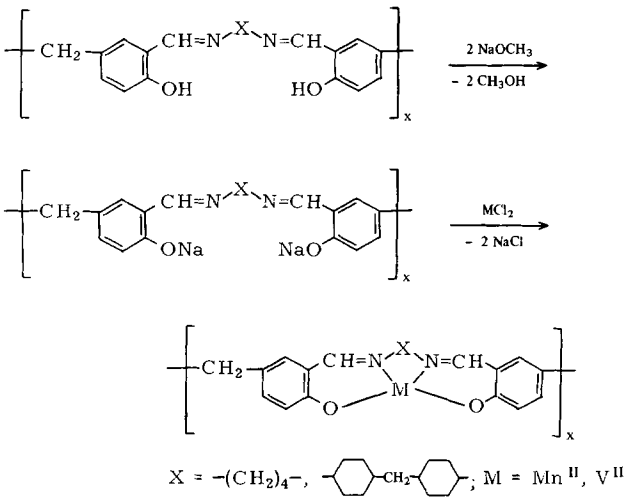
Reversible O_2-Addition to Polymeric Schiff-Base Complexes of V^{II} and Mn^{II} and Their Use as Oxidation Catalysts

By *Wolfgang Sawodny**, *Reinhard Grünes*, and *Helmut Reitzle*

In connection with our investigations on polymeric Schiff-base complexes[1-3] we have now also been able to synthesize such compounds with V^{II} and Mn^{II} as central ion. The complexation reaction proceeds more smoothly and productively *via* a novel route involving the Na-salt as intermediate (Scheme 1).



Scheme 1.

The V^{II}- and Mn^{II}-complexes synthesized according to Scheme 1 take up 0.4—0.5 mol O_2 per mol of complex (determined gravimetrically) at room temperature. The formerly high magnetic moments (*ca.* 5.5 μ_B in the case of the Mn^{II}-complex and 4.5 μ_B in the case of the V^{II}-complex) are reduced by the O_2-uptake. Accordingly, the O_2 is presumably incorporated as a peroxo-bridge between two metal ions. This assumption is supported by the observation that the same oxidized complexes are also formed by direct reaction of the M^{II}-complexes with H_2O_2.

O_2 is taken up reversibly. This is astonishing, especially in the case of the V^{II}-complexes. Thus, not only can the original M^{II}-complexes be recovered by reduction with $N_2H_4 \cdot H_2O$ in CH_3OH, but the O_2 is also liberated in a vacuum at temperatures above 200 °C. This would suggest that these complexes might be good catalysts for oxidation reactions. Preliminary investigations on unsaturated hydrocarbons have shown that the polymeric V^{II}- and Mn^{II}-Schiff-base complexes are as good as, if not even better than, the best previously known metal complex oxidation catalysts (Co^{II}-salene, Fe^{II}-porphyrin complexes)[7].

Table 3. Oxidation of cumene with Mn^{II}-complex (X = —$(CH_2)_4$—) as catalyst; concentration 10^{-3} mol/mol cumene. Reaction time: 15 h (at 30 °C: 65 h). The difference making up 100% consists of small amounts of methylstyrene (< 1%) together with unidentified products.

T [°C]	Cumene I [%]	2-Phenyl-2-propanol II [%]	Acetophenone III [%]	III : II
30	61.9	30.4	2.9	0.09
70	64.1	22.9	7.4	0.32
95	18.2	44	36.7	0.83
105	43.0	27.4	26.7	0.97
120	42.5	24.5	26.6	1.08
150	68.3	7.8	14.3	1.83

In the oxidation of cumene—addition of cumene hydroperoxide as initiator is not necessary here—only traces of the initially formed hydroperoxide[8] are found, evidence that its decomposition is likewise catalyzed by the complex. Generally, the Mn^{II}-complexes are more reactive than the V^{II}-complexes. Oxidation increases with increasing temperature, more and more acetophenone being formed besides 2-phenyl-2-propanol; methylstyrene is also formed in trace amounts. The most favorable temperature is *ca.* 100 °C. At higher temperatures cumene is already oxidized by O_2 without catalysts. Addition of polymeric Schiff-base metal complexes then has an inhibiting effect on the oxidation.

Electron Density Distribution in the Bonds of the Bridged Bicyclo[1.1.0]butane System 1,5-Dimethyltricyclo[2.1.0.$0^{2,5}$]pentan-3-one

By *Hermann Irgnartinger** and *Annette Goldmann*

The bond between the bridgehead atoms in the bicyclo[1.1.0]butane system is influenced by steric factors and substituent effects[1]. Its properties are considerably different from those of a normal C—C single bond. Using the X—X method[2] we have experimentally determined the electron density distribution in the bonds of the bridged bicyclo[1.1.0]butane system 1,5-dimethyltricyclo[2.1.0.$0^{2,5}$]pentan-3-one **1** from the X-ray data measured at −155 °C. As

previously found at room temperature[1a], the C3—C3′ bridge bond length (1.417 Å, Fig. 1d) is remarkably short.

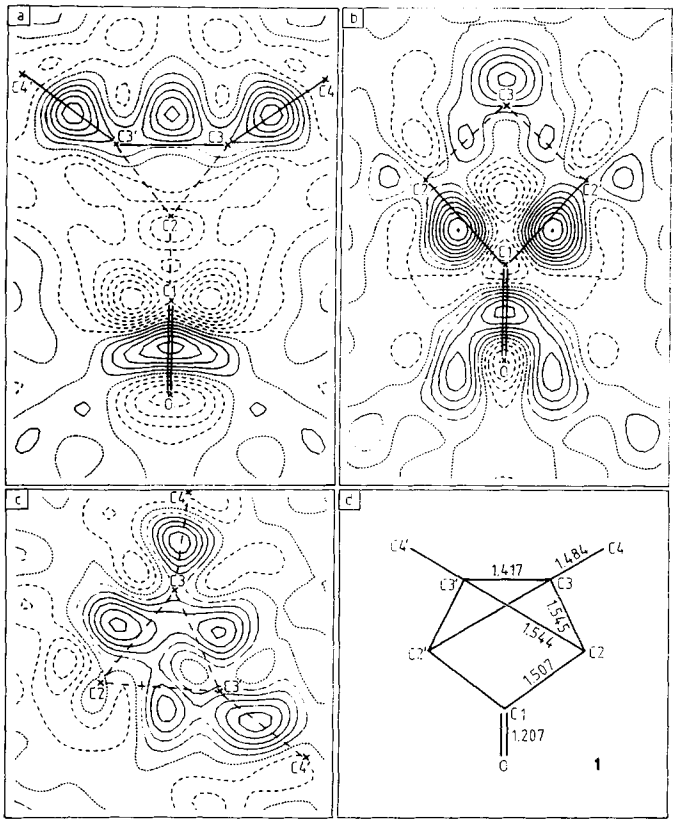

Fig. 1. Electron density distribution in the bonds of **1** and bond lengths [Å] at −155 °C. The contours are drawn at intervals of 0.05 eÅ^{-3} and the standard deviation of the bond lengths is 0.001 Å. The atoms are not numbered in accordance with IUPAC rules. Crystallographic data of **1** (C_7H_8O): for data at room temperature see [1]; at −155 °C: $a = 10.7598(7)$, $b = 6.8256(4)$, $c = 8.396(1)$ Å, $\beta = 110.999(5)°$; $C2/c$; $Z = 4$. Up to $\sin\theta/\lambda = 1.15$ Å^{-1} ($Mo_{K\alpha}$-radiation) 1968 independent, repeatedly measured reflections (248 of which were unobserved, $F_o < 2.5\sigma(F_o)$) were collected; the C and O atoms were refined with 1028 reflections of higher order ($0.70 < \sin\theta/\lambda < 1.15$ Å^{-1}, 27 reflections per variable); $R = 0.036$. The deformation densities are based on 753 ($F_o - F_c$) values taken from the range $\sin\theta/\lambda < 0.7$ Å^{-1}. The carbonyl group in the molecule is located on a crystallographic twofold axis. a) Section through the plane of atoms C1,C3,C3′,C4,C4′,O; b) Section through the plane of the atoms C1,C2,C2′,O; c) Section through the plane of the three density maxima of bonds C2-C3, C2-C3′, and C3-C3′; d) Bond lengths.

All the electron density maxima of the bonds of the tricyclopentane framwork of **1** are clearly displaced outwards from the bond axes, and hence this system consists only of bent bonds. In contrast to a [3.1.1]propellane derivative[3], which also contains the bicyclo[1.1.0]butane moiety —with, however, inverted C-atoms—the electron density in the bridge bond C3—C3′ of **1** clearly stands out, and is displaced by approximately 0.40 Å away from the bond axis (towards the top of Fig. 1a). The electron density exhibits a rotationally symmetric distribution in a section perpendicular to the bond axis (Fig. 1b); below the C3—C3′ bond axis it is equal to zero. Accordingly, no experimental evidence for π character in this bond is found, and it can best be described as a bent σ-bond. All three electron density maxima of the three-membered ring C2, C3, C3′ do *not* lie in the plane of the ring. The C atoms are 0.04 Å (C2) above, and 0.19 (C3) and 0.18 (C3′) Å below the plane through the three electron density maxima (Fig. 1c). The bonds are, therefore, not only bent within the plane of the three-membered ring, but are also twisted out of this plane. The electron densities of the exocyclic bonds, of the C=O bond, of the oxygen atom exhibit no unusual characteristics (Fig. 1).

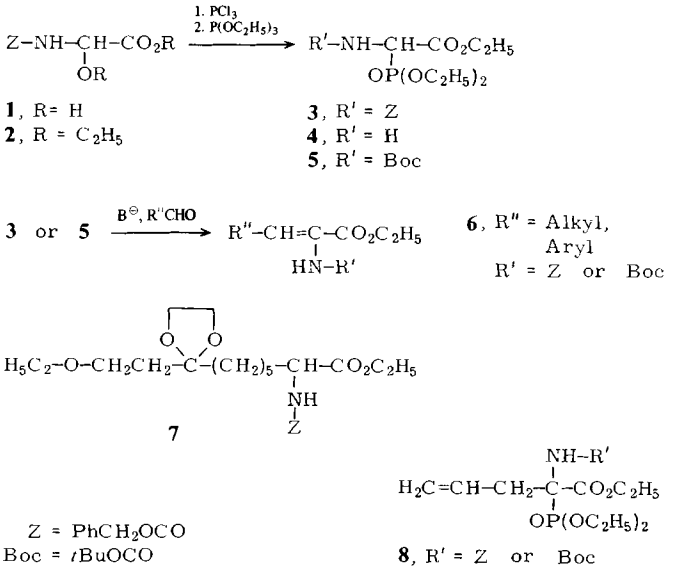
Facile Preparation of *N*-Acyl-2-(diethoxyphosphoryl)glycine Esters and Their Use in the Synthesis of Dehydroamino Acid Esters**

By *Ulrich Schmidt**, *Albrecht Lieberknecht*, *Ute Schanbacher*, *Thomas Beuttler*, and *Jochen Wild*

A phosphorylglycine ester serves as a synthetic building block in the syntheses of cephalosporins[1]. Many methods are known for the preparation of *N*-Acylphosphorylglycine esters; however, none of them are straightforward[1–3]. We describe an effective three-step synthesis of these compounds, which are suitable starting materials for preparation of dehydroamino acids; these in turn can readily be hydrogenated to amino acids with, in many cases, high optical induction. The route shown in Scheme 1 is, therefore, a novel synthesis of amino acids; starting from aldehydes, amino acid esters having two additional carbon atoms or *tert*-butoxycarbonylamino acid esters are formed under mild conditions and, in contrast to almost all other syntheses, an acid hydrolysis step is avoided.



Scheme 1.

[**] Amino Acids and Peptides, Part 36. Dehydroamino Acids, Part 16.—Part 35: U. Schmidt, M. Dietsche, *Angew. Chem. 94* (1982) 145; *Angew. Chem. Int. Ed. Engl. 21* (1982) 143. This work was supported by the Fonds der Chemischen Industrie and by BASF AG; Part 15: U. Schmidt, E. Öhler, J. Häusler, H. Poisel, *Fortschr. Chem. Org. Naturst. 37* (1979) 251.

Table 1. Synthesis of the dehydroamino acid esters **6**. Method *A*: NaH in THF, room temperature, method *B*: lithium diisopropylamide in THF, −60 °C.

	R″	R′	Method	Yield [%]
6a	C_6H_5	Boc	*A*	73
6b	C_6H_5	Z	*A*	81
6c	2-CH_3O—C_6H_4	Z	*A*	82
6d	2-CH_3O—5-Z-C_6H_3	Z	*A*	85
6e	*n*-C_3H_7	Z	*B*	80
6f	*i*-C_3H_7	Z	*B*	80

The α-hydroxyglycine **1**—readily accessible from glyoxylic acid hydrate and benzyl carbaminate[4]—was converted into the ethyl ether **2**. Successive reaction with PCl_3 and triethyl phosphite led to ethyl 2-benzyloxycarbonylamino-2-diethyloxyphosphorylacetate **3** (yield 80%). *N*-Acyl-2-(diethyloxyphosphoryl)glycine esters having various *N*-protecting groups are accessible by catalytic hydrogenolysis of the protecting group and acylation.

The phosphoryl ester **3** can be metalated by NaH in tetrahydrofuran (THF) and converted in high yields into *N*-benzyloxycarbonyldehydroamino acid esters **6a**–**6d** (Table 1) by condensation with aromatic aldehydes. Steric hindrance of the condensation by *o*-substituents is not observed. For the synthesis of aliphatic dehydroamino acid esters, metalation of **3** with lithium diisopropylamide and condensation with aliphatic aldehydes at −75 °C is the method of choice. By analogy, aromatic and aliphatic *N*-*tert*-butoxycarbonyldehydroamino acid esters are accessible from the phosphoryl ester **5**. The condensation products are formed as *E*/*Z*-mixtures and can be rearranged to afford mainly the (*Z*)-olefins.

The dehydroamino acid esters **6** can be catalytically hydrogenated to the corresponding amino acid esters in quantitative yield. Because of the very mild reaction conditions amino acids with acid-labile functional groups, such as *e.g.* 7 (yield from the corresponding aldehyde: 62%) can be synthesized in this way. The metalated phosphoryl esters **3** and **5** can also be smoothly *C*-alkylated, *e.g.* to **8**.

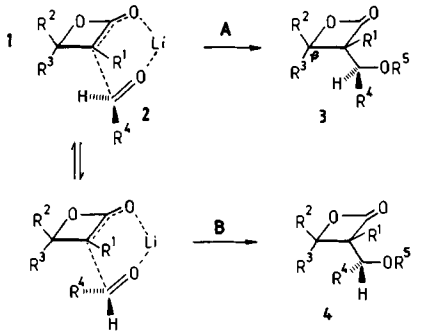
Three-Center Diastereoselective Aldol Additions of β-Lactone Enolates to Aldehydes**

By *Johann Mulzer** and *Alexander Chucholowski*

We term an aldol addition "three-center diastereoselective" if its course is directed by a chiral center already present in the enolate or carbonyl component. Thereby, the relative configurations of three chiral centers are determined in one addition step. Of the four possible diastereomers, one is formed selectively.

The addition of the β-lactone anions **1** to the aldehydes **2** proceeds with particularly high three-center diastereoselectivity. As a consequence of the rigid, planar ring-structure of **1**, R^2 almost completely shields the *syn*-ring plane against electrophilic attacks[1]. It remains to be clarified whether addition route **A** or **B** is preferred, *i.e.* which of the two possible enantiofacial modes of attacking **2** dominates (Scheme 1).



Scheme 1.

Table 1. Adducts **3** prepared as in Scheme 1. All compounds were characterized by elemental analysis, ^{1}H-NMR, and IR spectra. Yields are between 85 and 95%. R^1 = Ph.

3	R^2	R^3	R^4	R^5	M.p. [°C]	IR (KBr) ν(CO) [cm^{-1}]
a	*t*Bu	H	Ph	$SiMe_3$	174–175	1800
b	*t*Bu	H	Me	H	144–145	1805
c	*t*Bu	H	[a]	$SiMe_3$	204–205	1806
d	*t*Bu	H	[b]	$SiMe_3$	180–185 (decomp.)	1820 1806
e	*t*Bu	H	H	H	145–146 (decomp.)	
f	*i*Pr	H	Ph	$SiMe_3$	159.5–160	1805
g	*i*Pr	H	Me	H	131–132	1810
h	*i*Pr	H	H	H	110–111	1802
i	—$(CH_2)_4$—		Ph	$SiMe_3$	150–153	1792
j	—$(CH_2)_4$—		Me	H	141–145 (decomp.)	1785
k [c]	*t*Bu	H	Ph	$SiMe_3$	107–108	1807

[a] R^4 = [b] R^4 = [c] R^1 = Me

As shown in Table 1, in general up to >95% (^{1}H-NMR analysis of the crude product) of adduct **3** is formed[2]. Only in case **b** is isomer **4** detectable; a product ratio **3b**:**4b** = 85:15 was determined by ^{1}H-NMR spectroscopy. Until an X-ray structural analysis is performed only a tentative configurational assignment for **3b** and **4b** based on IR and ^{1}H-NMR spectroscopic data can be made. The broad OH band in the IR spectrum at 3400 cm^{-1} (CCl_4), which does not dissappear even at high dilution, indicates a hydrogen bonded quasibicyclic chelated structure. This indicates that only in **4b**, but not in **3b**, H^β may be shielded by the side-chain methyl group; this is consistent with the upfield shift of the singlet for H^β in **4b** (δ = 4.45, $CDCl_3$) compared to that in **3b** (δ = 4.71). By analogy, we assume the same configuration as in **3b** is adopted by the remaining adducts of **3**. If this assignment is correct, addition route **A** predominates and the repulsion between R^3 and R^4 outweights that between R^1 and R^4.

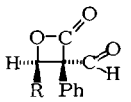
By means of the three-center diastereoselective aldol addition described, the β,β′-dihydroxycarbonyl structural element can be readily prepared in a stereocontrolled manner[3]. It is advantageous for further transformations of **3**



5a, R = *t*Bu
5b, R = *i*Pr

that one of the hydroxy groups is protected in the β-lactone and that the other is free in the side chain; consequently both can be treated differently. For example, we oxidized **3e** and **3h** with chromium trioxide in pyridine to afford the β-lactone aldehydes **5a** and **5b**, novel building blocks with considerable synthetic potential, in quantitative yield.

7-Azanorbornadiene**

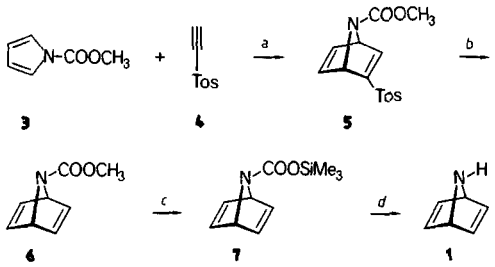
By *Hans-Josef Altenbach, Bernd Blech, Juan Alberto Marco*, and *Emanuel Vogel**

Dedicated to Professor Hermann Stetter on the occasion of his 65th birthday

7-Azanorbornadiene **1**, the parent compound of the multi-substituted 7-azanorbornadienes readily accessible by Diels-Alder reaction of *N*-substituted pyrroles with acetylenedicarboxylic acid esters, is a highly interesting molecule. Its first *C*-unsubstituted derivative, *N*-tosyl-7-azanorbornadiene, was recently synthesized *via* a laborious route by *Prinzbach* and *Babsch*[2]; however, conversion of the tosyl compound into **1** by cleavage of the protecting group proved to be problematic.

Parallels between the structures of **1** and 1,6-imino[10]annulene[3], and their possible chemical consequences stimulated us to synthesize **1**. The synthetic concept which enabled us to prepare **1** rather easily on a preparative scale is shown in Scheme 1.

Adduct **5** (m.p. = 95–96 °C) is formed from ethynyl-*p*-tolylsulfone **4**[4] and *N*-methoxycarbonylpyrrole **3**. Desulfonation of **5** with 6% sodium amalgam[5] affords **6** as a colorless liquid after chromatography on silica gel (ether/pentane) (b.p. = 39 °C/5 × 10^{-5} torr). A moderate yield for **6** (42%) is acceptable, since **5** can easily be prepared in larger amounts. Upon warming with trimethylsilyl iodide, smooth conversion of **6** into the silyl ester **7** occurs[6] (b.p. = 45 °C/5 × 10^{-5} torr) provided that trimethylamine is added to prevent the otherwise rapid acid-catalyzed isomerization of **6** to methoxycarbonylaniline. The silyl ester **7** reacts with methanol *via* the carbamic acid, which can be isolated below −30 °C, to afford the desired **1**, a colorless compound having an amine-like odor and being stable up to *ca.* 80 °C (b.p. = 39 °C/25 torr).



Scheme 1. *a*: 80–85 °C, 24 h; yield 60%. – *b*: 6% Na/Hg, Na_2HPO_4 in THF/CH_3OH (1:1), −78 °C, 3 h; yield 42%. – *c*: $(CH_3)_3SiI$, $(CH_3)_3N$ in $CHCl_3$, 60 °C, 3 h; yield 89%. – *d*: CH_3OH/CH_2Cl_2, reflux, 10 min, yield 80%.

The ^{1}H-NMR spectrum of **1** (90 MHz, $CDCl_3$) exhibits a singlet at $\delta = 2.63$ (N*H*) and two broad singlets at $\delta = 4.73$ (2 tert. H) and 7.06 (4 olef. H), and the ^{13}C-NMR spectrum ($CDCl_3$) signals at $\delta = 66.28$ (C-1,4) and $\delta = 145.57$ (C-2,3,5,6) with $J_{C\text{-}1,H} = 159$ Hz and $J_{C\text{-}2,H} = 180$ Hz. The anticipated fragmentation pattern is observed in the mass spectrum [70 eV: *m/z* 93 (M^+, 8%), 67 ($M^+ - C_2H_2$, 100), 39 ($M^+ - C_3H_4N$, 33)]. The UV spectrum [(CH_3CN), $\lambda = 220$ nm ($\varepsilon = 480$), 252 sh (120)] is very similar to that of 7-oxanorbornadiene.

In contrast to **6**, **1** is not acid sensitive and reacts with hydrogen chloride in ether to give a hydrochloride, which can be recrystallized from acetonitrile [m.p. = 200–201 °C (decomp.)]. **1** is stable to aqueous alkali. Attempts, however, to convert it with butyllithium in tetrahydrofuran (−78 °C) into the lithium salt and to trap this with methyl iodide failed. The expected retro-diene decomposition of **1** into pyrrole and acetylene makes itself noticeable only above 80 °C (half-life determined by NMR spectroscopy in DMSO at 100 °C: 7.5 h). This process is apparently so highly favored that the radical cleavage of one of the C—N-bonds, which would lead *via* benzene imine to 1*H*-azepine or secondary products thereof, has no chance. Conversion of **1** into the *N*-tosylate[2] can be brought about with tosyl chloride (molar ratio 1:1.5) in pyridine (room temperature, 24 h).

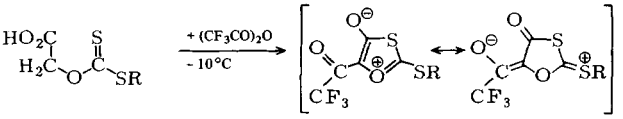
Stable 1,3-Oxathiolylium-4-olates—Synthesis and Cycloadditions of a Novel Class of Mesoionic Heteroarenes**

By *Hans Gotthardt*, Sabine Schoy-Tribbensee,* and *Ulrich Feist*

Mesoionic heteroarenes are valuable synthons for the synthesis of heterocycles[1]. We report here the preparation and cycloadditions of isolable 1,3-oxathiolylium-4-olates of type **2**.

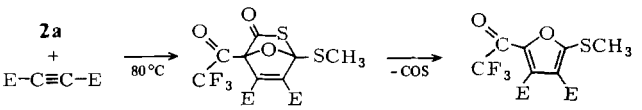
Reaction of methylthio(thiocarbonyloxy)acetic acid **1a** with trifluoroacetic acid anhydride (molar ratio 1:2.17) at −10 °C in ether results in formation of yellow crystals of **2a**[2] in 65% yield after recrystallization from benzene/*n*-hexane (1,3-dithiolylium-4-olate[3a] can be prepared analogously).



1 **2**

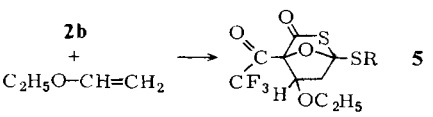
a, R = CH_3; **b**, R = $C(CH_3)_3$

1b reacts analogously to **1a** to afford the mesoionic heteroarene **2b** (37—40%)[2]. The constitutions of **2a** and **2b** are based on their mode of formation, spectroscopic data, and chemical reactions. Until now, mesoionic oxathiolylium derivatives had only been generated *in situ* in [3+2]-cycloadditions[3b].



E = CH_3CO_2 **3** **4**

The novel heteroarenes **2** undergo cycloadditions with activated alkynes and enol ethers. Hence, upon warming to 80 °C in benzene, **2a** reacts with dimethyl acetylenedicarboxylate *via* the non-isolable [3+2] primary adduct **3**, which undergoes elimination of carbon oxysulfide to afford the crystalline 2-trifluoroacetylfuran derivative **4** (68% yield), whose constitution is based on elemental analysis and spectroscopic data[4].



5

The bicyclic primary adduct **5b**[5] from **2b** and ethyl vinyl ether is isolable. Ethyl vinyl ether only forms an oily mixture of isomers with **2a**.

Synthesis of Cardiac Glycosides: Evatromonoside and its Anomer**

By *Joachim Thiem** and *Sabine Köpper*

Dedicated to Professor Hans Paulsen on the occasion of his 60th birthday

The cardiac glycosides used in the therapeutic treatment of cardiac insufficiency are still obtained from plant extracts. Due to their structure as oligosaccharides of deoxysugars, particularly of digitoxose, which are linked to a steroid aglycon, such as *e.g.* digitoxigenin, the synthesis of anomerically pure derivatives is more difficult than in the "normal" sugar series[1]. We describe here the glycosidations of novel, reactive derivatives of digitoxose with digitoxigenin.

Glycosidation of D-digitoxal diacetate **1**[2a] with digitoxigenin in acetonitrile using the N-iodosuccinimide (NIS) method[2b] results in exclusive formation of the α-D-glycoside **2**[3a], which can be reductively dehalogenated to afford **3**[3b], and deacetylated to give digitoxigenyl α-D-digitoxoside **4**[3c].

Since, however, the therapeutically more active β-D-anomer is not obtained using this method, we selected another route. Mild acetolysis of methyl α-D-digitoxoside **5** leads to a 1:1 anomeric mixture (72%) of 1,3,4-tri-*O*-acetyl-α- and -β-D-digitoxose, **6**[3d] and **7**[3e], respectively, which can be separated by chromatography. Conversion of this mixture with bromo(trimethyl)silane[4] under extremely mild conditions (R. T., 7 min) leads, for the first time, to the highly reactive 3,4-di-*O*-acetyl-α-D-digitoxosyl bromide **8**[3f] in quantitative yield; at longer reaction times this surprisingly reacts further to afford 4-*O*-acetyl-3-bromo-2,3,6-trideoxy-α-D-arabinohexopyranosyl bromide.

For the glycoside formation, α-acetobromodigitoxose **8** generated *in situ* was allowed to react with digitoxigenin under strict moisture exclusion in the presence of silver carbonate, silver carbonate/silver perchlorate (1:1), or silver silicate[1] in either dichloromethane or in more polar solvent mixtures (nitromethane/toluene/dichloromethane 1:4:2 or 3:7:1) at −40 to 20 °C: the anomeric mixture

3+**9** (from ^{1}H-NMR *ca.* 1:1.3) was formed in only 10–24% yield after chromatographic purification. The best yields were obtained when the components were treated with silver trifluoromethanesulfonate in nitromethane/toluene/dichloromethane (3:7:1)— the aglycon is just soluble in this mixture—at −78 °C and subsequently warmed to room temperature; in this way **3** and **9** were formed in

51% yield (ratio 2:3) after chromatography. Simple transesterification finally led to a chromatographically separable mixture of the free glycosides **4** and evatromonoside (digitoxigenyl β-D-digitoxoside) **10**[3g]. Previously, **4** and **10** were each obtained *via* a modified Fischer glycosidation in only 5% yield[5a]. Following the acid-catalyzed transacetalization reaction (cf.[5b]), however, we observed additional elimination of the tertiary 14-hydroxy group in the aglycon leading to formation of the undesired anhydrodigitoxigenin digitoxosides. Thus the procedure presented here provides a more convenient method for the synthesis of complex steroid glycosides of deoxy sugars.

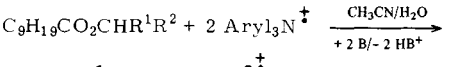
Oxidative Cleavage of Benzyl Esters with Triarylamine Cation Radicals—Selective Deblocking of Protected Carboxy Functions**

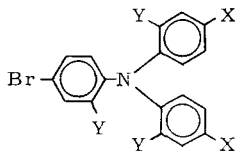
By *Steffen Dapperheld* and *Eberhard Steckhan**

We have been able to considerably extend the possibility of the selective cleavage of benzyl esters—of importance in protective group chemistry—with respect to current procedures[1]. By analog to benzyl ethers[3], benzyl esters are also oxidatively cleaved by stable triarylamine radical cations as electron-transfer agents; these can either be used in stoichiometric amounts as hexachloroantimonates[4] (method *A*) or generated and regenerated anodically in a divided cell from triarylamines (benzyl ester:triarylamine *ca.* 5:1, method *B*, indirect electrolysis). The driving force for the reaction is the deprotonation of the primary-formed ester radical cation.



1 **2**$^+$

3 **4** **2**



2a, X = Br, Y = H
2b, X = Y = Br
2c, X = NO_2, Y = H

4-Methoxybenzyl benzoate reacts with **2b** using method *B* in presence of Na_2CO_3 to afford benzoic acid (94% yield). 2,4-Dimethoxy- and 4-methoxybenzyl esters can readily be cleaved by **2a**$^+$, whereas because of their considerably higher oxidation potential benzhydryl esters are cleaved rapidly only by **2b**$^+$, or **2c**$^+$. Cleavage of unsubstituted benzyl esters is incomplete even by **2b**$^+$ (see also table 2).

The different reactivities of the esters towards **2a**$^+$—**2c**$^+$ can be exploited for the selective deblocking of pro-

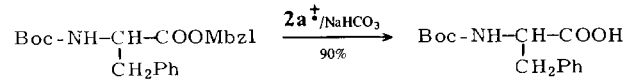
[**] Indirect Electrochemical Processes; Part 12. This work was supported by the Fonds der chemischen Industrie and the Forschungsgemeinschaft.—Part 11: R. Wolf, E. Steckhan, *J. Electroanal. Chem. 130* (1981) 367.

tected carboxy groups. In order to determine the selectivity, competitive experiments on 1:1 mixtures of differently substituted benzyl *n*-decanoates **1** were carried out using method *A*. Thereby it could be shown that not only the substituted benzyl esters (R^1 = 4-MeO—C_6H_4, R^2 = H; R^1 = 2,4-$(MeO)_2C_6H_3$, R^2 = H; $R^1 = R^2$ = Ph) can be deblocked in the presence of unsubstituted benzyl esters (R^1 = Ph, R^2 = H) by **2a**$^+$ or **2b**$^+$ with total selectivity, but that in contrast to previously known methods the acid labile 2,4-dimethoxybenzyl ester group can also be cleaved in the presence of the 4-methoxybenzyl and benzhydryl ester functions by **2a**$^+$, which are also acid labile, in high selectivity (>90%). In this way between 84 and 93% yields of carboxylic acids were obtained upon complete reaction of the more readily oxidizable component. In contrast, despite the large difference in oxidation potentials, no selectivity between 4-methoxybenzyl and benzhydryl esters is found.



Mbzl: 4-Methoxybenzyl–

The *tert*-butyl ester group and the *N*-Boc protecting group—both can be cleaved by acids—do not react with **2a**$^+$ and **2b**$^+$, and hence in presence of these protecting groups 4-methoxybenzyl, 2,4-dimethoxybenzyl, and benzhydryl esters can be selectively cleaved. Furthermore, the Z-protecting group is also stable towards **2a**$^+$/$NaHCO_3$, whereas it is slowly attacked by **2b**$^+$[7].

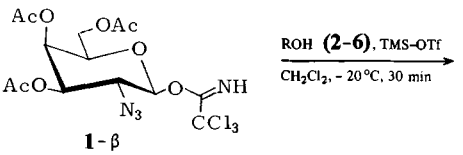
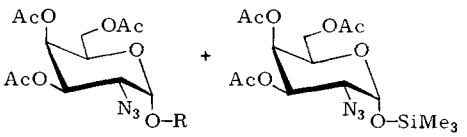
α-Linked Disaccharides from *O*-(β-D-Glycopyranosyl) Trichloroacetimidates using Trimethylsilyl Trifluoromethanesulfonate as Catalyst**

By *Richard R. Schmidt** and *Gerhard Grundler*

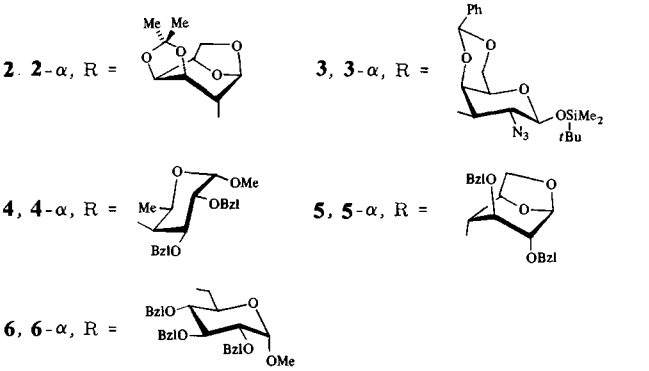
Stereoselective coupling of glycosidic bonds without the use of halogenoses or heavy metal salts as catalysts is of interest for the efficient syntheses of glycosides, and di- and oligosaccharides[1]. The readily accessible *O*-(α-D-glycosyl) trichloroacetimidates of benzyl-protected D-gluco-, D-galacto-, and D-xylopyranoses, as well as D-glucopyranuronic acid ester can be converted under acid-catalyzed conditions, predominantly or exclusively, into β-linked glycosides and β-linked di- and oligosaccharides in good yields[2].

We have now found that *O*-(β-D-glycosyl) trichloroacetimidates react with glycopyranosides containing a free OH group in presence of trimethylsilyl trifluoromethanesulfonate (TMS-OTf) as catalyst[3], to give α-linked disaccharides in good yields. The β-trichloroacetimidate **1**-β, directly accessible from 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-D-galactose[5] and trichloroacetonitrile (CH_2Cl_2, K_2CO_3, room temperature, 1.5 h; yield: 55%); $[\alpha]_{578}^{22}$ −4.8, c = 1, $CHCl_3$), reacts with the 2-, 3-, and 4-unprotected glycopyranosides **2**—**5** and TMS-OTf (imidate: alcohol: TMS-OTf = 1.1:1.0:0.04) to give exclusively the biologically important α-linked disaccharides **2**-α-**5**-α[6] (yield, $[\alpha]_{578}^{22}$; **2**-α: 53%, +95.2; **3**-α: 70%, +102.2; **4**-α: 56%, +151.6; **5**-α: 40%, +23.6). As expected, under the same conditions, the D-gluocopyranoside **6**, which contains one primary OH group, reacted to give a higher product yield but lower α-selectivity (yield: 80%; **6**-α:**6**-β = 4:1; **6**α: $[\alpha]_{578}^{22}$ + 112.2, c = 1, $CHCl_3$)[6]. Among others, the trimethylsilyl-α-D-galactopyranoside **7** occurs as a byproduct from which, however, 1-β can be re-isolated.





2-α - **6**-α **7**-α



It is of interest for the mechanism that TMS-OTf also catalyzes the reaction of α-trichlororacetimidate **1**-α (CH_2Cl_2, NaH, room temperature, 1 h; yield 80%, $[\alpha]_{577}^{22}$ + 103.6, c = 1, $CHCl_3$), obtained from 1-**β** by base catalysis, with **2** to afford exclusively the α-linked disaccharide **2**-α (yield: 50%).

(2,9 : 6,12-η-2,3,5,6-Tetrakis(methylene)-bicyclo[2.2.2]octane)zirconocene, an Isolable Bis(olefin)zirconium(II) Compound**

By *Gerhard Erker**, *Klaus Engel*, and *Pierre Vogel*

The equilibration between bis(olefin)transition-metal complexes and metallacyclopentanes is of great importance for the development of metal-catalyzed processes for the conversion of olefin substrates[1b]. Due to their rapid rearrangement to the more favorable metallacycles, bis(olefin) complexes of group IV transition metals, in contrast to those of other transition metals, have not been observed so far[3]. By using the olefinic ligand 2,3,5,6-tetrakis(methylene)bicyclo[2.2.2]octane **6**[7a], we have now been able to prepare, to our knowledge the first, bis(olefin)zirconocene complex isolable at room temperature.

Bis(η^5-cyclopentadienyl)zirconium(II), generated *in situ* from diphenylzirconocene by photochemically induced reductive elimination of biphenyl[5], reacts with **6** by coordination of the 1,4-diene unit to give the title compound **7**.

7, which is only moderately soluble in the aromatic solvents used, is very sensitive to air and moisture; like haloalkanes, oxygen also liberates the ligand **6**. Thermolysis of **7** (benzene, 60 °C, $\tau_{1/2} \approx 5$ min) leads to formation of its isomer **8**, in which one of the two conjugated diene-units of **6** is bound to the zirconocene group. The bis(olefin)zirconocene complex **7** can be quantitatively recovered upon irradiation (HPK 125, Pyrex filter) of **8** in benzene solution at room temperature.

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.

According to the NMR spectra (Tables 1 and 2) **7** is characterized by a markedly much more pronounced π-complex character than **8**. The similarity of the spectra of **7** and those of the previously known mononuclear (*s-trans*-η^4-diene)zirconocene complexes[6] is remarkable. From the finding that **7** can be readily and reversibly converted into a (η^4-diene)metal complex **8** of "normal" structure and stability it appears promising that the observation of other bis(olefin) complexes of early transition metals equilibrating with the isomeric metallacyclopentanes might also be possible.

Indirect Electrochemical Regeneration of NADH by a Bipyridinerhodium(I) Complex as Electron-Transfer Agent**

By *Rainer Wienkamp* and *Eberhard Steckhan**

Because of its significance in enzyme-catalyzed syntheses, there is considerable interest in straightforward and effective methods for the regeneration of NADH from NAD$^\oplus$. We report here preliminary results on the indirect electrochemical regeneration of NADH from NAD$^\oplus$.

The direct electrochemical reduction of NAD$^\oplus$ at −1.1 V *vs.* SCE leads essentially to inactive dimers and even at −1.8 V, active NADH is only formed in 50% yield[1].

We have now succeeded in reducing NAD$^\oplus$ to NADH using the electrochemically generated two-electron transfer agent [Rh(bpy)$_2$]$^\ominus$, which is generated cathodically from [Rh(bpy)$_3$]$^{3\oplus}$[5]. In this way an enzyme is not required for the transfer of two electrons[2] to the coenzyme. The regenerated NADH is oxidized by cyclohexanone under catalysis of horse liver alcohol-dehydrogenase (HLAD) [eq. (b)].

We performed the reactions in 40–60 mL tris-HCl buffer (pH 9) in divided cells using a graphite cathode, platinum anode, and a glass frit as diaphram at −850 to −950 mV *vs.* Ag/AgCl in discontinuous or continuous working mode [eq. (b)] (Table 1).

In experiment 3, 1.5×10^{-3} mmol of NAD dimer could be determined[1b] corresponding to 0.9% of NAD$^\oplus$ per cycle. At lower working potentials dimerization can be diminished. Using the discontinuous working mode NADH can be separated chromatographically and determined from its absorbance[1b].

The small number of regenerative cycles does not arise from the instability of the electron transfer agent or from that of the coenzyme or enzyme; it results solely from pas-

[a] In brackets: mmol. [b] R, R'=—$(CH_2)_5$—; in brackets mmol. [c] Discontinuous process; HLADH and cyclohexanone were added as substrates after electrolysis, cyclohexanol was determined by GC. [d] Continuous process; electrolysis was carried out in presence of cyclohexanone and HLADH.

sivation of the cathode and hence, from the reduction in current which falls off to such a level that the conversion becomes too low. The passivation is caused by formation of a layer which dissolves only slowly in the tris-HCl buffer; elemental analysis of this indicates that $[Rh(bpy)_2(H_2O)_2]Cl$ or $[Rh(bpy)_2(OH)_2]Cl$ is formed. Mechanically cleaning the electrode or using short pulses to positive potentials cause an increase in the current. A Rh^{I}-complex catalyzed hydrogenation of the ketone by cathodically generated hydrogen does not occur—as demontrated by control experiments.

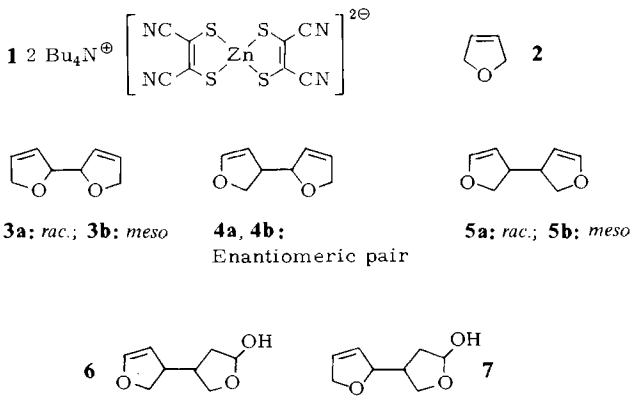
Zinc Sulfide as Catalyst for the Heterogenous Photoreduction of Water

By *Joachim Bücheler, Norbert Zeug,* and *Horst Kisch**

Metal dithiolenes such as **1** in the presence of mild reducing agents enable the hitherto most effective catalytic generation of hydrogen from water with UV light. The actual catalysts are formed in the first reaction step from the complexes. The best system proved to be that of **1** in H_2O/2,5-dihydrofuran **2**[1]. We report here on the mechanism of the reaction and identification of the catalyst as zinc sulfide.

Gas chromatographic analysis of the reaction solution[2] showed that the major products of the oxidation of **2** are **3a, 3b, 4a, b, 5a, 5b**. Their rate of formation correlates with the evolution of H_2 (Fig. 1). Separation of the products was accomplished by preparative GC; the structural assignment is based on GC-MS[3] and 270-MHz ^{1}H-NMR data including extended decoupling experiments. After short irradiation times, only **3a, b** and two new compounds are formed. On the basis of GC-MS and IR data we propose the structures **6** and/or **7** for the new compounds[3].



If the photoreduction is carried out with D_2O[2], pure D_2 is formed initially. However, with increasing conversion HD and H_2 are also formed, while the proportion of D_2 correspondingly decreases: 32% D_2, 50% HD, 18% H_2 after evolution of 2.2 L (0.1 mol) of hydrogen.

These findings point to intermediary OH radicals, which lead to formation of the products **3**—**7**. In the abstraction reaction water is regenerated, leading to formation of HOD and H_2O[4a] if D_2O is used. This explains the change in the isotopic composition of the gas phase. The products **3**—**7** are also obtained by radiolytic generation of OH radicals in H_2O/**2** or by photolysis of H_2O_2 in **2**. In competition experiments with the system **1**/**2**/H_2O/dioxane, the dioxane remains inert, whereas under radiolytic conditions (without **1**) the mixed dehydrodimers are also formed. This confirms the extraordinarily special reactivity of **2** (similarly as for tetrahydrofuran[1]) and indicates that the OH radicals in the catalytic system are not free.

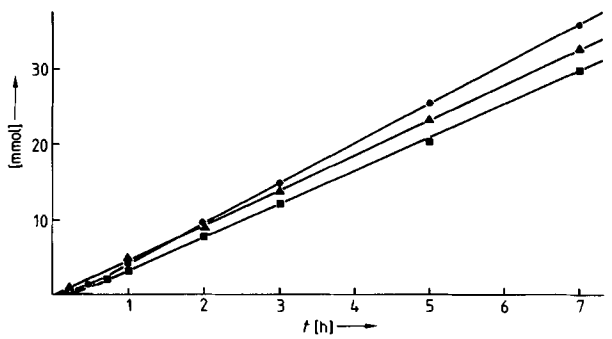


Fig. 1. ●—● hydrogen and ■—■ dehydrodimer formation in the presence of **1**, ▲—▲ hydrogen formation in the presence of 20 mg (0.20 mmol) ZnS [2].

[*] Priv.-Doz. Dr. H. Kisch, J. Bücheler, N. Zeug

Stiftstrasse 34—36, D-4330 Mülheim a. d. Ruhr 1 (Germany)

If the photoreduction is interrupted as soon as **1** is completely decomposed a colorless solid can be isolated by centrifugation. This is found to contain cubic zinc sulfide in a polymer formed from **2**[4b]. Irradiation of a suspension of this solid in $H_2O/2$ leads to the same catalytic photoreduction of water. Zinc sulfide, prepared from zinc sulfate and thiourea, exhibits somewhat the same activity in $H_2O/2$ or H_2O/tetrahydrofuran (Fig. 1). The photocorrosion of zinc sulfide in aqueous systems is apparently hindered by **2** and/or its polymer.

In the system zinc sulfide in $H_2O/2 = 1/14$ (v/v) the quantum yield of the hydrogen formation at 300 nm is 0.1, the reflections of the heterogeneous system not being taken into consideration. A measurable evolution of hydrogen already takes place however at 350 nm, the energy of the band gap (3.54 eV) of cubic zinc sulfide. Colloidal zinc sulfide[5] is much less active.

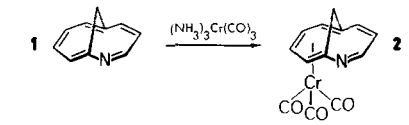
Tricarbonyl-2,7-methanoaza[10]annulenechromium(0)

By *Günter Hilken, Tonio Kinkel, Michael Schwamborn, Johann Lex, Hans Schmickler,* and *Emanuel Vogel**

2,7-Methanoaza[10]annulene **1**[1], which has to be considered as an aromatic 10π analogue of pyridine[2], is expected to afford complexes by σ and/or π coordination on reaction with carbonylchromium compounds. Complexation *via* the lone-pair of electrons of the nitrogen atom would correspond to the behavior of pyridine and quinoline, and would lead to a complex with σ bonding between chromium and nitrogen[3]. In contrast, if the 10π electron system acts as the donor, a π complex corresponding to the tricarbonyl-1,6-methano[10]annulenechromium(0) **3**[4] should be formed in which the $(CO)_3Cr$ group is highly probably bonded to the heteroatom-free part of the annulene ring as shown in **2**.

The π complex **2** was obtained as deep-red needles from **1** and triamminetricarbonylchromium (molar ratio 1 : 2) in



refluxing hexane (72 h) [after chromatography on alumina and recrystallization from hexane; sinters above 120 °C; yield 20% relative to amount of **1** reacted; IR (*n*-hexane): 1997, 1941, 1905 cm^{-1} (CO)]. To the best of our knowledge **2**, which is stable in air, is the first transition-metal π complex of an aza[4n + 2]annulene with $n > 1$[5].

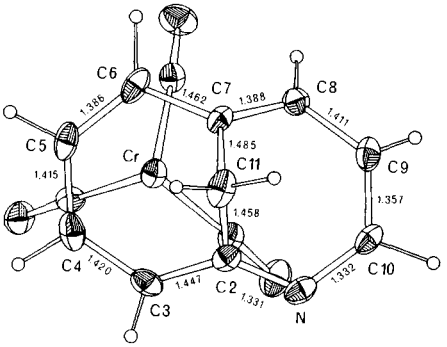


Fig. 2. Molecular structure of **2** in the crystal. Bond lengths in [Å]. C2—C11—C7 94.8 °; C2···C7 2.168 Å.

The unsymmetric bonding of the $(CO)_3Cr$ group to the heteroatom-free part of the annulene ring *anti* to the CH_2 bridge derived from the ^{1}H-NMR parameters of **2**, is corroborated by the X-ray structural analysis (Fig. 2). Whereas in complex **3**[4] the distances of the metal atom to C3, C4, C5, and C6 are almost equal (2.194 to 2.215 Å), in **2** they vary considerably (2.154 to 2.230 Å). The difference in the distances between chromium and C2 and C7 (2.69 and 2.40 Å, respectively) is even more striking. These and other relevant structural data suggest that the previously indicated twisting of the two halves of the annulene ring relative to each other in **1** is increased in the complex. The bond angle of the bridge in **2** (and hence the transannular distance between C2 and C7) is only slightly different from that in **1**, whereas in **3** this angle is markedly smaller than in the free ligand. The delocalization of the 10π electron system in **1** is maintained upon forming the complex, since no alteration of the bond lengths in the aza[10]annulene ring of **2** is observed, despite the fact that the lengths of the C8—C9 and C9—C10 bonds are considerably different. The C—C bond lengths in the complexed part of the ring are in good accord with the corresponding bond lengths in **3**, whereas the N—C bond lengths (as also in derivatives of **1**[2]) are almost identical and are of the pyridine-type. Hence, by analogy to **3**, **2** is characterized as aromatic.

The tendency of **1** to prefer π rather than σ complex formation may be due to the fact that the basicity of **1** is about two pK_a units less than that of pyridine of quinoline.

Synthesis of 2,3,7,8,12,13,17,18-Octamethylporphyrinogen in Almost Quantitative Yield

By *Bernd von Maltzan**

The mode of formation and chemical behavior of the porphyrinogens—including their conformational behavior—are of interest regarding simple syntheses of the porphyrins as well as their biosynthesis[1]. Thus, investigations of the influence of *meso*-substituents on the four strainless conformations of the porphyrinogen ring (Fig. 1)[2a,b] showed that reaction of protons with the four stereoisomers of the *meso*-tetramethyl-*meso*-tetraphenylporphyrinogen formed from acetophenone and pyrrole leads to a stable isomeric equilibrium in which the distribution of isomers is not random but is determined by the influence of the *meso*-substituents on the conformations[2a-c]. Whereas the thermodynamic stability of the uroporphyrinogens I—IV was only indirectly detected *via* the uroporphyrins I—IV[1c], in the reaction of acetophenone with pyrrole the cyclic tetracondensate proves to be the energetically preferred end-product.

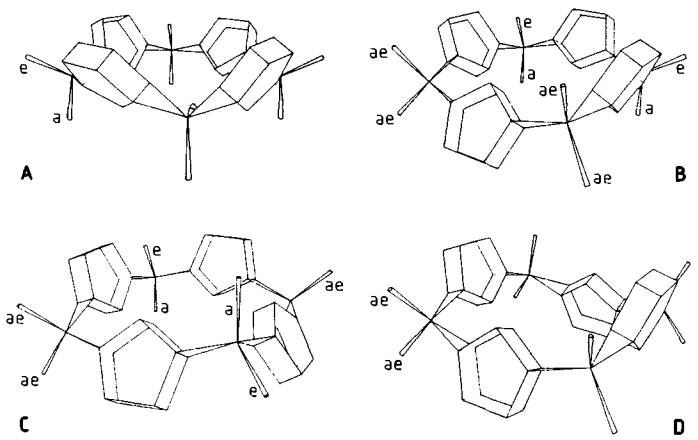

Fig. 1. The four fundamental conformations of the porphyrinogens: "bowl" (**A**), "chair" (**B**), "chaise longe" (**C**), and "saddle" conformation (**D**) (*meso*-substituents: a = axial, e = equatorial or ae = axial-equatorial). The conformations **B**—**D** have been detected X-ray crystallographically [2b].

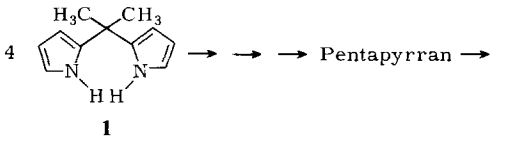
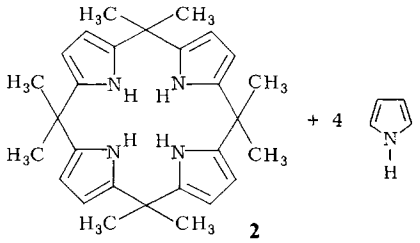
An additional indication of the preferred formation of porphyrinogens is provided by the ready autocondensation of *meso*-dimethyldipyrrylmethane **1** in boiling ethanol with HCl as catalyst or in CH_2Cl_2/0.1% CF_3COOH to give the known "acetonepyrrole" **2**[1b,c] in 36 and 53% yields, respectively. This must at least proceed *via* open penta- or higher-oligopyrrans, and with cleavage of pyrrole[3a]. Thus, this cyclization is no purely statistically faster[3b] head-to-tail reaction of an open-chain tetrapyrran. Furthermore, the cyclocondensation is also kinetically preferred: If acetone is added according to the dilution principle to pyrrole in boiling methanol with HCl as catalyst, only the porphyrinogen **2** is detectable, even at the beginning of the reaction.

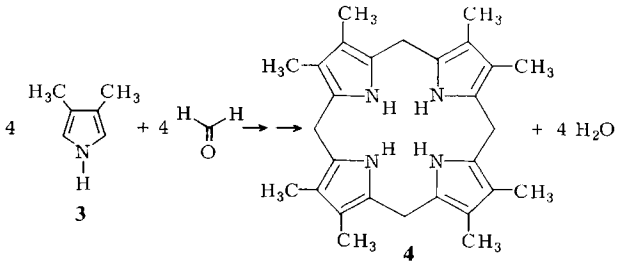


1



2

These findings do not rule out that the corresponding porphyrinogens can also be isolated in the reaction of β-substituted pyrroles with formaldehyde, which furnishes porphyrins in good yield[3c-e]; so far, however, this has been achieved only in the synthesis of the *meso*-tetraphenylporphyrins[3e]. β-Substituted porphyrinogens have had to be synthesized by hydrogenation of the corresponding porphyrins or by acid cyclization of the porphobilinogen-analogous 3,4-dialkyl-2-dimethylaminomethylpyrrole (40–60%)[4a] or of the 3,4-dimethyl-5-hydroxymethyl-2-pyrrolecarboxylic acid (57%)[4b].



3 **4**

Consistent with the strong tendency to undergo cyclization to porphyrinogens, 3,4-dimethylpyrrole **3** reacts with aqueous formaldehyde in methanol at 18 °C with acetic acid as catalyst to give 2,3,7,8,12,13,17,18-octamethylporphyrinogen **4**, which crystallizes chemically pure in practically quantitative (94%) yield (cf. [3c])[5]. **4** is not obtained if the reaction is carried out in boiling solution with conc. HCl or with formaldehyde-diethyl acetal[2d].

The IR spectrum of **4**[5] shows two associated N—H bands besides two "free" ones, even after most intensive drying. Surprisingly, no hydrogen bond forming species such as CH_3OH, H_2O or CH_3COOH were associated, which form strong H bonds above and below the porphyrinogen plane, especially in the "chair" and "chaise longe" forms, but only extremely labile bonds in the "saddle form"[2c]. This points to H-bonds between a pyrrole N—H and a pyrrole unit in a neighboring molecule with modified "chaise longe" or "saddle" form.

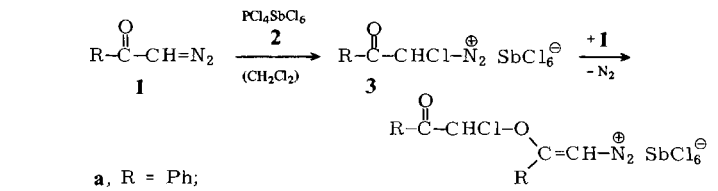
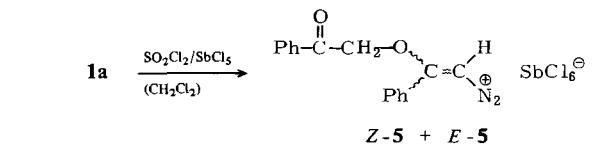
Alkylation of α-Diazoketones with Alkyldiazonium Ions: Facile Synthesis of β-Alkoxyethylenediazonium Salts

By *Kaspar Bott**

β-Alkoxyethylenediazonium salts **4** are readily accessible by allowing tetrachlorophosphonium hexachloroantimonate **2** to react with α-diazoketones **1**. The salts **4** are formed by *O*-alkylation of **1**, whereby the intermediate α-chlorophenacyldiazonium ions **3** resulting from **1** and **2** function as alkylation agents.



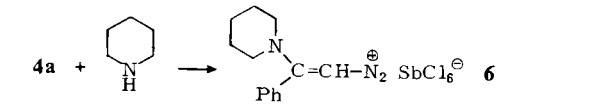
a, R = Ph;
b, R = *p*-$CH_3OC_6H_4$



Z-**5** + *E*-**5**

If instead of **2** a mixture of equimolar amounts of sulfonyl chloride and antimony pentachloride is allowed to react with diazoacetophenone **1a** in dichloromethane, the stereoisomeric olefindiazonium hexachloroantimonates *Z*-**5** and *E*-**5** can be isolated, which in contrast to **4** contain no carbon-bonded chlorine. The phenacyldiazonium ion required for the synthesis of **5** is formed from diazoacetophenone **1a** and hydrogen chloride, although its mode of formation remains to be clarified.

Corresponding to the strongly electrophilic character of olefindiazonium ions[4], **4a** reacts with piperidine, even below 0 °C, exchanging piperidine for the phenacyloxy group to afford the sterically uniform salt **6**. This reaction is associated with a significant shift of the diazo vibrational stretching frequency to longer wavelengths[5].



The preparative importance of the β-alkoxyethylenediazonium salts **4** and **5** lies in their remarkable reactivity, which can be exploited, *e.g.*, to generate unsaturated carbenes[6] or for the low temperature synthesis of triazoles and thiadiazoles[7].

Photoinitiated Hydrosilations in Presence of Tetrahedral Heterometallic Clusters: Catalysis by Intact Clusters**

By *Charles U. Pittman, Jr.**, *Michael G. Richmond*, *Ma'mun Absi-Halabi*, *Harald Beurich*, *Felix Richter*, and *Heinrich Vahrenkamp**

Many clusters fragment to mononuclear species upon optical irradiation or during thermal catalytic processes. However, there is no definitive evidence demonstrating conclusively that intact clusters serve as active, homogeneous catalysts—although strong evidence does exist in a few cases[1a]. To inhibit cluster fragmentation during catalysis, we advocated the use of transition metal clusters bound by stable, nonfluxional bridging ligands[1].

We have now investigated the photoinitiated hydrosilation of acetophenone with triethylsilane in the presence of the clusters **1**—**7**[2], all of which contain a μ_3-bridging ligand and these clusters have proven to be suitable catalysts for reaction (a) (Table 1).

Both irradiation ($\lambda = 254$ or 355 nm) as well as catalysts are necessary: No reaction occurs in the dark or in the absence of the cluster. Surprisingly, the quantum yields are

(a)

greater on using 254-nm radiation than 355-nm radiation. This is to be expected, if the catalytic mechanism requires the loss of carbon monoxide. Lower energy radiation leads to ligand field transitions with occupation of metal-metal σ^* orbitals and, thus, to metal-metal bond cleavage[3]. These bonds readily reform, so that optical absorption rarely leads to productive catalysis. Irradiation with short-wave light effects stronger metal-ligand charge transfer excitation[3], which, in turn, leads to more effective ligand (carbon monoxide) dissociation, and consequently higher catalytic quantum yields.

High performance liquid chromatography (HPLC)[4a] showed that the concentrations of the clusters **1**—**7** do not decrease during the course of the reaction within the limits of detection (*ca.* 0.5%). No other metal-containing complexes could be detected by HPLC or TLC[4b]. Furthermore, after photolysis the clusters **1**—**7** could be recovered in all cases (90—98%) by chromatography on neutral silica gel.

Asymmetric hydrosilation with (+)-**6** would provide irrefutable evidence for the intactness of the chiral FeCoMoS tetrahedron during the reaction. When this reaction was carried out under the conditions given in Table 1 ($\lambda = 355$ nm), after 12 d we were able to isolate a 48% yield of **9**, a 16% yield of racemic **8**, and racemic cluster **6**. We subsequently established that the photoracemization of (+)-**6** at $\lambda = 355$ nm proceeds substantially faster than the hydrosilation reaction.

Even though the asymmetric induction with (+)-**6** failed, the fact that all the clusters were recovered after photolysis strongly suggests that the clusters are indeed the active catalytic species. Moreover, since **1**—**7** all contain stable μ_3-bridging ligands they cannot easily dissociate to mononuclear species[5]. If such fragmentation was to occur, it is difficult to imagine how such fragments could reassemble to regenerate the initial cluster which is isolated at the end of the catalytic reaction.

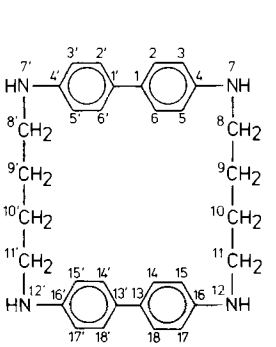
Stetter's Complexes are no Intramolecular Inclusion Compounds

By *Rolf Hilgenfeld* and *Wolfram Saenger**

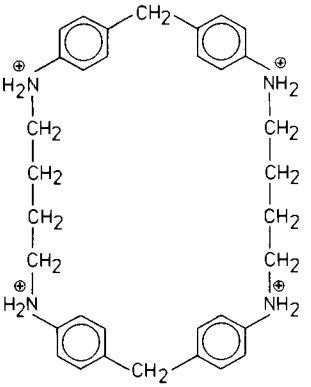
Dedicated to Professor Hermann Stetter on the occasion of his 65th birthday

Host molecules having hydrophobic cavities which can accommodate organic guest species are of interest because of their relevance as enzyme models and their usage for the stabilization and storage of unstable substances. The cyclodextrins, naturally occurring degradation products of starch, have been particularly thoroughly investigated in this field[1].

In recent years, molecules of the phane type have been studied as synthetic models for cyclodextrins[5]. As early as 1955, *Stetter* and *Roos* recognized compounds of this type as potential host molecules[6]. They synthesized bis(*N*,*N*'-tetramethylenebenzidine) **1** and observed that it tenaciously retained benzene or dioxane when crystallized



1



2

[*] Prof. Dr. W. Saenger, R. Hilgenfeld
Institut für Kristallographie der Freien Universität
Takustrasse 6, D-1000 Berlin 33 (Germany)

from these solvents. Based on this and on studies using molecular models, *Stetter* proposed an intramolecular inclusion of benzene (or dioxane) in the cavity of the ligand[6]. Since then, the Stetter complexes have been considered classical examples of intramolecular inclusion compounds[7].

We have now performed an X-ray structure analysis of the benzene complex of **1** and have found that the benzene molecules are *not* accommodated in the central cavities of the ligand molecules but fill interstices between them (Fig. 1). Thus the complex does not represent an intramolecular inclusion compound as hitherto assumed. Moreover, it contains only half a mole of benzene per mol of **1**, since the benzene molecule is localized on a crystallographic center of symmetry.

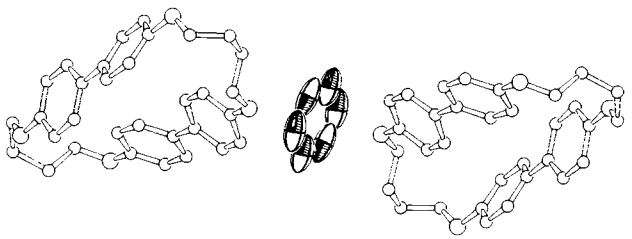


Fig. 1. Structure of the benzene complex of **1** in the crystal. The benzene molecule occupies a center of inversion between two ligand molecules.

The conformation of **1** in the crystal structure precludes intramolecular inclusion of a guest molecule: The benzidine moieties are not parallel but approximately perpendicular to one another and hence cannot function as the walls of an intramolecular cavity. As is usual for benzidines, the phenyl rings in both moieties are twisted about the biphenyl pivot bond by 23.1° and 28.0°, respectively. In contrast, inclusion of benzene in the molecular cavity corresponding to Stetter's model concept[6] would require strictly parallel alignment of the biphenyl skeletons. Moreover, each of the latter would have to adopt a non-twisted, coplanar conformation leading to unfavorable interactions between the *ortho* hydrogen atoms (H2,H2′; H6,H6′) of adjacent phenyl rings.

From these results we conclude that, in contrast to the opinion of *Faust* and *Pallas*[16], the structurally similar ligands employing binaphthyl instead of biphenyl spacers do not form intramolecular inclusion complexes either. However, in case of the related ligand **2**, *intra*molecular inclusion of a guest molecule has been established by X-ray structure analysis[17]. In this complex, a durene molecule is located at the center of the almost rectangular host cavity. This is due to subtle, but important differences in molecular structure: **2** contains diphenylmethane instead of biphenyl moieties. The methylene carbons of the former provide two of the four corners of the rectangular cavity—a configuration which could never be adopted by the biphenyl units of **1**. Moreover, in contrast to **1**, the amino nitrogens of **2** are protonated, rendering **2** not only water soluble but also more flexible than **1**, so that two of the amino groups can form the remaining two corners of the rectangular cavity. The effect of protonation of **1** on its conformational flexibility remains to be determined.

Our results show that subtle changes of molecular structure may result in a completely different inclusion behavior of a potential host molecule. This is due to the complicated interplay of weak intermolecular forces that govern host-guest interactions, which usually cannot be understood by simple studies using space-filling models.

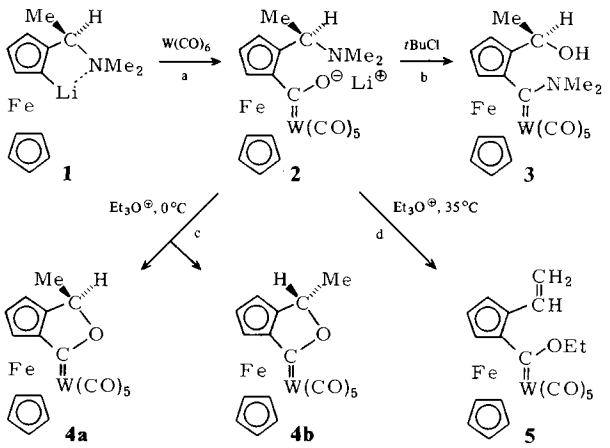
Chiral Binuclear Carbene Complexes from (*R,R*)-1-(1-Dimethylaminoethyl)-2-lithioferrocene and Hexacarbonyltungsten**

By *Rudolf Hermann* and *Ivar Ugi**

Dedicated to Professor Hermann Stetter on the occasion of his 65th birthday

The chiral binuclear carbene complexes **3**, **4a**, **4b** and **5** are obtained by reacting (*R,R*)-1-(1-dimethylaminoethyl)-2-lithioferrocene[6] with hexacarbonyl tungsten. The relative yields of the products depend on the reaction conditions and additives (Scheme 1). It is noteworthy that **1**, the reaction partner of hexacarbonyl tungsten, contains both functionalities which are needed for forming the carbene complex[1].



Scheme 1. a: Et_2O, 0 °C; b: yield *ca.* 25% **3**; c: $Et_3O[BF_4]$ or FSO_2Me, 20 h, yield *ca.* 15% diastereomeric mixture **4a/4b** (81:19); d: analogous to c, but heating under reflux, yield *ca.* 10% **4a/4b** together with 4% **5**.

The intermediate **2** is converted into **3** in the presence of proton donors like *tert*-butyl chloride. For such reactions an unusual mechanism seems to be plausible: the ex-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

change of the hydroxy group and the dimethylamino group is likely to proceed *via* the intermediacy of a carbyne complex. The Me_2N-group, which normally has no nucleofugual properties, serves here as the leaving group of an alkylating system.

The formation of the diastereoisomeric furanoid carbene complexes **4a** and **4b** (81:19, NMR) is favored at 0 °C in the presence of strong alkylating agents such as triethyloxonium tetrafluoroborate, whereas at 35 °C predominantly **5** is produced. The conversion of **2** into **4b** deserves special mention, since, to our knowledge, it is so far the only exception to the customarily retentive course of nucleophilic substitutions in α-ferrocenylalkyl compounds[11].

All the reaction products have been isolated, and have been identified by elemental analysis and spectroscopic data MS, IR NMR). The ^{13}C-NMR chemical shift of the "carbene carbon atom" of **3** has the comparatively low δ value of 213.36. The chemical shift and the coupling constant ($J_{183W\text{-}13C} = 126.4$ Hz) of the carbonyl carbon atoms of **4** and also of the other products are well within a range which is typical for carbene complexes[1].

"γ-$PW_{12}O_{40}^{3-}$", A Heteropolyanion with Clathrate Character

By *Joachim Fuchs**, *Axel Thiele*, and *Rosemarie Palm*

The majority of the numerous heteropolyanions of composition $XM_{12}O_{40}^{z-}$ (M = Mo, W; X = P, Si, B *etc.*), adopt the so-called Keggin structure (α-type)[1]: Four M_3O_{13} groups consisting of MO_6 octahedra tetrahedrally surround the heteroatom X (Fig. 1a). An isomeric β-type is also known in which one of the M_3O_{13} groups is rotated by 60°[2]. We have now discovered, in the course of structural studies on tetraalkylammonium tungstophosphates, a novel anion with centrosymmetric tungsten sites, for which we propose the designation γ-type.

Precipitation of commercial phosphotungstic acid with tetrabutylammonium bromide in aqueous solution results in formation of an α-dodecatungstophosphate, $[N(C_4H_9)_4]_3PW_{12}O_{40}$, which can be recrystallized from acetone: monoclinic, space group $P2_1/c$ with $a = 14.86(1)$, $b = 25.08(1)$, $c = 22.91(1)$ Å, $\beta = 93.37(8)°$, $V = 8526.3$ Å^3, $Z = 4$. The isomeric γ-compound is obtained in a secondary reaction. Acidification of an aqueous solution of Na_2WO_4 and Na_2HPO_4 (molar ratio 3:1) with glacial acetic acid and precipitation with tetrabutylammonium bromide results first in formation of $[N(C_4H_9)_4]_4H_3PW_{11}O_{39}$, which can be recrystallized, undecomposed, from isobutyl methyl ketone. In contrast, the γ-dodecatungstophosphate crystallizes from ethanol-acetone. The triclinic compound, space group $P\bar{1}$, has lattice parameters $a = 15.410(9)$, $b = 19.535(7)$, $c = 13.897(6)$ Å, $\alpha = 87.12(3)$, $\beta = 90.46(4)$, $\gamma = 84.89(4)°$, $V = 4161.3$ Å^3, $Z = 2$. Its anion is built up from WO_5 units (tetragonal pyramids) and consists of a neutral $W_{12}O_{36}$ moiety (Fig. 1b), in the cavity of which a PO_4^{3-} anion is incorporated.

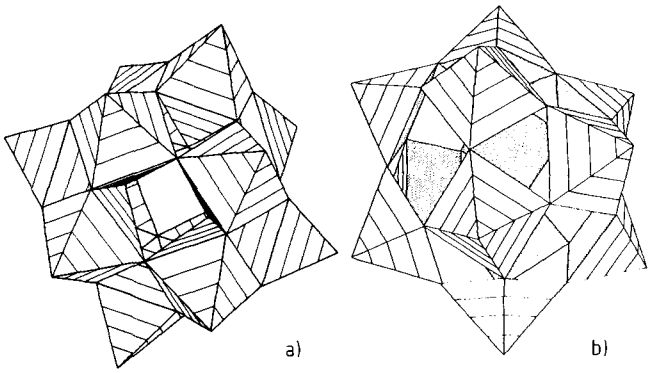

Fig. 1. a) $W_{12}O_{40}$ framework of α-$PW_{12}O_{40}^{3-}$; b) $W_{12}O_{36}$ framework of γ-$PW_{12}O_{40}^{3-}$.

In the unit cell the two anions with phosphorus atoms at 0, 0, 0 and ½, ½, ½ are differently orientated. It differs markedly from the α-type in the positions of the tungsten atoms, each of which occupies the corner of a cuboctahedron, which, however, in the case of the α-type is tetrahedrally distorted (Fig. 2a): the WW distances within the edge-bridged WO_6 octahedron (small dotted triangles) are, on average, 340 pm, within the vertex-linked (large dotted triangles) 369 pm. In contrast, in the γ-type (Fig. 2b) they are all *ca.* 356 pm. Here, the cavity has almost cubic symmetry and, hence, offers two equivalent positions for tetrahedra, which are statistically occupied in the crystal[3].

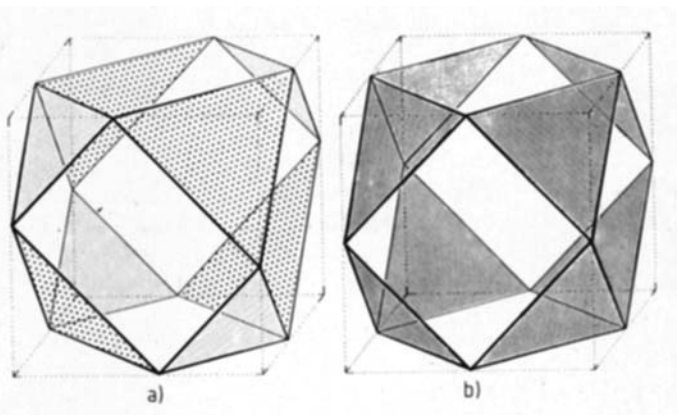

Fig. 2. Positions of the tungsten atoms in α-type (a) and γ-type (b) of $PW_{12}O_{40}^{3-}$.

The novel anion is to be considered as a clathrate; incorporation of the phosphate O atoms in the coordination sphere of the N atoms must lead to removal of the center of symmetry, because then, as in the α-type, vertex- and edge-linked octahedral groups, respectively, would face each other.

Fabeckstrasse 34-36, D-1000 Berlin 33 (Germany)

[**] *Note added in proof*: The isotypic γ-tungstoarsenate has also been prepared: H. Neubert, J. Fuchs, unpublished results.

In the γ-type every tungsten atom is bonded to a terminal (O_t) and to four bridging oxygen atoms (O_b). The distances W—O_t = 166 pm and W—O_b = 191 pm do not differ significantly from the analogous distances in the α-type. In contrast, the P—W distance of 355.8 pm is markedly shorter than in the α-form.

The isopolyanion $H_3W_{12}O_{40}^{5-}$[4a] has the α-structure, just as the heteropolyanions $CuW_{12}O_{40}^{7-}$ and $CoW_{12}O_{40}^{5-}$[4b], in which even Cu^+ and Co^{3+}, respectively, are forced to adopt the unusual tetrahedral coordination. The existence of the centrosymmetric γ-type with a heteroatom, which itself strives for tetrahedral cooordination is, therefore, all the more notable[**].

Novel Synthetic Building Blocks Activated by Ring Strain: General Entry to 2-Chloro-2-cyclopropylidene Acetates**

By *Thomas Liese, Gisela Splettstösser,* and *Armin de Meijere**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The cyclopropane ring is finding ever increasing use as functional and/or reactivity-increasing group in the design of organic syntheses[1]. Promisingly versatile are the esters **5**, for which we have now found a convenient and general synthesis.

When heated with potassium hydroxide and methanol, the 1-chloro-1-(trichlorovinyl)cyclopropanes **1**[2,3]—which are readily accessible from olefins and tetrachlorocyclopropene—afford the orthoesters **2** in good yields (see Table 1). On acid-catalyzed hydrolysis, the ortho esters **2** are smoothly and quantitatively converted into the 2-chloro-2-cyclopropylidene acetates **5**.

The first step of the surprising conversion **1** → **5** is evidently a nucleophilic substitution with allyl rearrangement (S_N2' reaction) to give an intermediate, which is successively substituted by methoxide ions to give **2**. Orthoesters **2** and esters **5** can be purified by 'Kugelrohr' distillation; the carboxylic acids **3** are accessible from **5** by alkaline hydrolysis (*e.g.* **1a** → **3a**, 74%, without isolation of **5a**).

[a] After gas-chromatographic isolation.

The cyclopropylidene acetic acid esters **5** are versatile ring strain-activated acrylic esters. In particular the unsubstituted compound **5g**, a chlorinated cyclic analogue of the senecionic acid ester, exhibits its excellent reactivity in cycloadditions and as Michael acceptor[4]. On heating, it undergoes [2+2]-cyclodimerization to the dichlorodispiro-[2.0.2.2]octanedicarboxylate; on heating with 1,3-dienes it affords the Diels-Alder adducts (*e.g.* with cyclopentadiene **6g**, 91%), and with methanol it forms the Michael adduct **4g** already at room temperature.

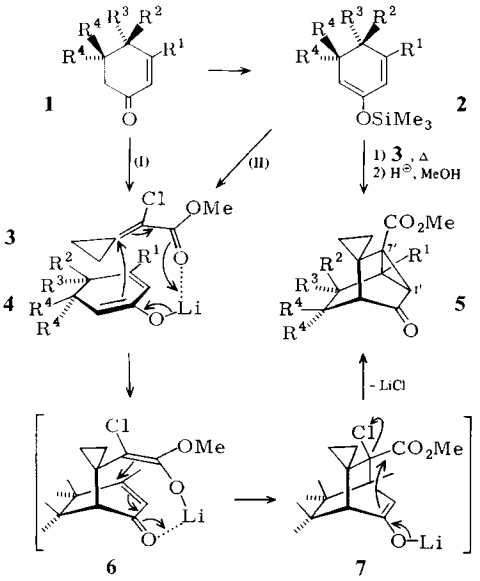
Reactivity by Ring Strain: Spirocyclopropyl-Annelated Tricyclic Skeletons by a One-Pot Three-Step Reaction**

By *Dietrich Spitzner**, *Anita Engler*, *Thomas Liese*, *Gisela Splettstösser*, and *Armin de Meijere**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The modified acrylic acid ester methyl 2-chloro-2-cyclopropylidene acetate **3**[1] owes its enhanced reactivity in cycloadditions and towards nucleophiles[1] to the electronic effects of ring strain. Aside from its utility as a dienophile, **3** is a particularly useful building block in Michael[2] and tandem Michael reactions.

In analogy to other acrylic acid esters[3,4] **3** reacts with lithium cyclohexadienolates **4**—prepared from the corresponding cyclohexenones **1** and lithium diisopropylamide or from the enoltrimethylsilyl ethers **2** and butyllithium—in the sense of a double Michael reaction to give the enolates of the oxobicyclo[2.2.2]octane-*endo*-carboxylic esters **7**, which spontaneously cyclize with loss of chloride to give the tricyclo[3.2.1.$0^{2,7}$]octane derivatives **5**[4] (see Table 1). The same products are also formed, along with others,



(I): LDA, THF, −60 °C; (II): *n*BuLi, THF/*n*-Hexane, −60 °C.

Table 1. 8′-Oxospiro[cyclopropane-1,6′-tricyclo[3.2.1.$0^{2,7}$]octane]-7′-carboxylic acid methyl esters **5** from **3** and lithium cyclohexadienolates **4**.

in the purely thermal Diels-Alder reaction of **3** with **2** and subsequent acid (hydrochloric acid/methanol) work-up, albeit in substantially poorer yields (*e.g.* **5a** from **2a**: 29%).

Products of type **5** are formed from **4** and **3** in distinctly higher yields than from **4** and α-bromocrotonates[4]. This can only be explained in terms of **3** being preoriented above the dienolate **4** with the lithium ion's assistance in the initial step of the three-step reaction and therefore in the second step predominantly **7** being formed with *anti*-chloro substituents, so that cyclization to **5** can take place by rear-side nucleophilic attack.

The three-membered ring in the skeleton of **5** can be reductively opened between $C^{1'}$ and $C^{7'}$ with lithium in liquid ammonia. If one further takes into account that, as a rule, a spirocyclopropyl is hydrogenated to a *gem*-dimethyl group[5], then this reaction sequence with **3** opens an entry to certain terpene skeletons, which are not obtainable with the far less reactive 3,3-dimethylacrylic acid esters (senecionic esters). For example, **5e** is a precursor of the diterpene eremolactone.

Generation and NMR-Detection of the Anions *N*-Methyl-1-benzazocinide, 1-Benzazocindiide, and Dibenz[*b*,*g*]azocindiide; A Family of Aromatic π-Excessive Compounds**

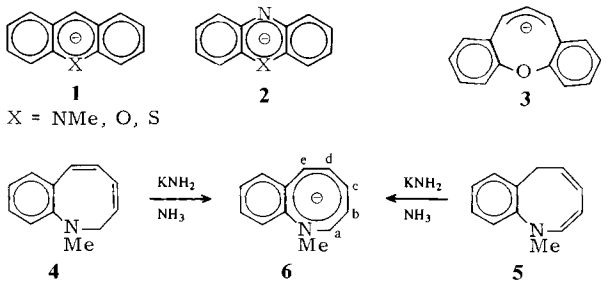
By *A. G. Anastassiou**, *H. S. Kasmai* and *D. Hauger*

In recent reports we recorded and interpreted information based on direct ^{1}H- and ^{13}C-NMR observation of certain novel π-excessive heterocyclic anions **1**[1a,d], **2**[1c] and **3**[1b] which led, rather surprisingly, to the classification of the "4n"-electron, potentially antiaromatic, π-excessives **1** and **2** as extensively delocalized and strongly paratropic, and the "4n + 2" counterpart **3** as largely localized and distinctly atropic. Further, having reasoned that the failure of **3** to realize its aromatic potential could be due, at least in large measure, to a skeletally-induced resistance of the central ring toward adopting the required planar geometry

[*] Prof. Dr. A. G. Anastassiou, Dr. H. S. Kasmai, D. Hauger
Department of Chemistry, Syracuse University
Syracuse, NY 13210 (USA)

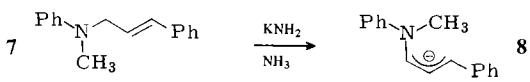
[**] This work was supported by the National Science Foundation.

we resolved to examine a monobenzo member of the family along similar lines. To this end, we chose the *N*-methyl benzazocinide shown in **6**, which we readily prepared on exposure of either of the two known cyclic anilines **4**[2] and **5**[2] to KNH_2 in liquid ammonia at *ca.* −30 °C.



1 **2** **3** **4** **6** **5**

Suitable analysis of the highly resolved ^{1}H-NMR spectrum of **6** reproduced in Figure 1a afforded the listed assignments and coupling constants, the latter being associated with a magnitude and uniformity normally reserved for π rings which are both flat (or very nearly so) and extensively delocalized. Further, comparison of the two key ^{1}H-NMR doublets of **6** ($\delta = 5.00$ and 5.62) with those of model anion **8** ($\delta = 3.92$ and 4.46) reveals a substantial



downfield shift of the former in relation to the latter, a fact which allows one to deduce that benzazocinide **6** is detectably diatropic. Equally implicative of the enhanced π mobility of the heteroatomic lone pair of **6** compared to that of the model **8** are the ^{1}H- and ^{13}C-NMR downfield shifts of the methyl appendages one observes on passing from **8** (δ, 3.15 and 38.14 ppm) to **6** (δ, 3.55 and 46.59 ppm).

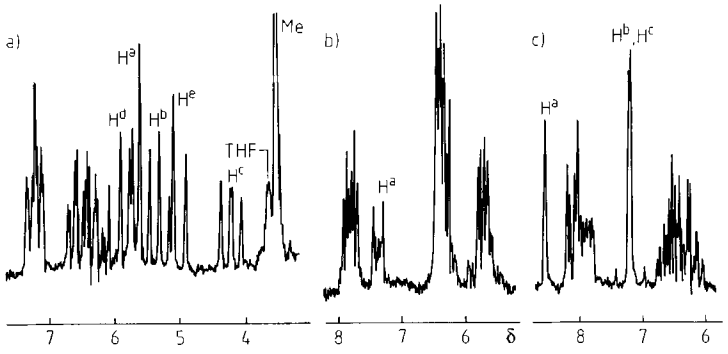


Fig. 1. 60 MHz-^{1}H-NMR spectra of the potassium salt of a) **6**, b) **13** and c) **15** in liquid NH_3 at *ca.* 34 °C with THF as internal standard. Coupling constants of **6**: $J_{a,b} = J_{b,c} = 8.5$; $J_{c,d} = 10.5$, $J_{d,e} = 11.0$ Hz.

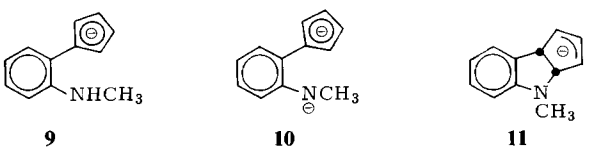
From a chemical viewpoint it is significant to note that despite its diatropic character, the eight-membered moiety of **6** is *not* thermally stable, cleanly rearranging ($t_{1/2} \approx 522$ min) to produce the two component mixture of monoanion **9** and dianion **10** [$\delta(^{13}C)Me = 39.10$ and 17.88, respectively] upon mild heating (34.9 °C); this reorganization is quite likely intermediated by the benzobicycle **11**[3].



9 **10** **11**

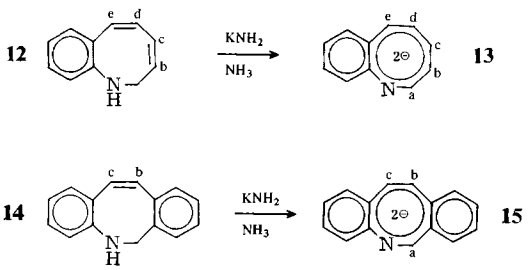
Furthermore, the related dianion **13** and the linearly fused dibenzo counterpart **15** were readily prepared upon exposure of annelated anilines **12** and **14** to an excess of KNH_2 in liq. NH_3 at *ca.* −35 °C. In turn, **12** and **14** were prepared by reduction of the corresponding lactams with $LiAlH_4$[2].

The well resolved ^{1}H-NMR spectra of **13** and **15**, reproduced in Figures 1b and 1c, respectively, are clearly indicative of frames which are endowed with a substantial degree of diatropic π mobility. Particularly revealing in this connection are, of course, (*i*) the distinctly low field resonance due to H^a of **15** (singlet at $\delta = 8.35$) and (*ii*) the low field position ($\delta = 7.4$) and relatively large coupling constant (9.5 Hz) of the H^a doublet in the spectrum of **13**; further, the ^{13}C-NMR characteristics of **13** and **15** are strongly implicative of the key geometric constraint imposed by π mobility, namely planarization of the molecule's eight-membered moiety. Specifically, one notes upon comparing the relatively strain-free, heavily buckled, eight-membered frames of **12** and **14** to those of dianions **13** and **15** in terms of C—H coupling constants (Table 1) that these uniformly become significantly smaller (10 to 25 Hz) on passing to the dianion. And bearing in mind that below-average C—H coupling constants associated with a medium-large π periphery are normally indicative of molecular flattening[1b,4] we interpret the data collected in Table 1 to

Table 1. ^{13}C-NMR data of C^b to C^e in **12** and **13** and of C^b and C^c in **14** and **15** in liquid NH_3 at *ca.* 34 °C, [D_8]tetrahydrofuran as internal standard. The δ values (referred to TMS) have not been assigned.

	12	13	14	15
δ	118.30	87.43	116.70	97.46
	120.49	91.14	118.15	102.80
	126.09	93.71		
	128.57	101.63		
$J_{C,H}$	162	146	164	140
[Hz]	157	142	154	147
	≈165	141		
	158	140		

mean that the formation of "4n+2" dianions **13** and **15** is attended by a significant degree of planarization. Also, the rather substantial upfield shift (14—30 ppm) experienced by the carbon centers of the eight-membered rings of **13** (C^b to C^e) and **15** (C^b, C^c) relative to their counterparts in **12** and **14** is fully consistent with the presence of substantial charge delocalization in the dianions.



The monoanions **6** and **9** and the dianion **13** gave the products to be expected, after quenching with water and hydrogenation; **15** was converted into **14** upon exposure to moist ether.

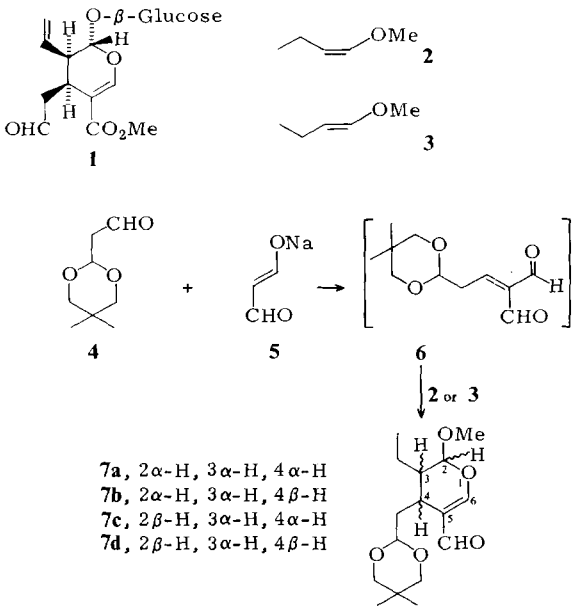
A Simple and Stereoselective Entry to the Secoiridoids by [4+2]-Cycloaddition of Alkylidene-1,3-dicarbonyl Compounds**

By *Lutz-F. Tietze*, Karl-Heinz Glüsenkamp,* and *Wolfgang Holla*

Secologanin **1**, a key-compound in the biosynthesis of numerous alkaloids[1], belongs to the secoiridoids, a widely occurring class of natural products derived biogenetically from geraniol. The synthesis of compounds of the secologanin type[2] is difficult because of the polyfunctionality, high reactivity, and the stereochemical requirements. We have now succeeded in obtaining the C_{10}-system in a one-pot synthesis from one C_4-moiety and two C_3-moieties; the crucial step is a [4+2]-cycloaddition with inverse electron demand.



7a, 2α-H, 3α-H, 4α-H
7b, 2α-H, 3α-H, 4β-H
7c, 2β-H, 3α-H, 4α-H
7d, 2β-H, 3α-H, 4β-H

When an aqueous solution of the sodium salt of malonic dialdehyde **5** is allowed to react with the monoacetal **4**[3] for 48 h at 5 °C and the reaction mixture is subsequently treated with (*Z*)- or (*E*)-1-methoxy-1-butene **2**, or **3** and sodium dihydrogen phosphate, **7** is formed directly; the reaction initially leads *via* the aldol adduct to the alkylidene compound **6**, which spontaneously reacts further with the enol ethers to give the cycloadducts. **2** affords 64% of a *ca.* 1:1 mixture of the two isomers **7a** and **7b**, while **3** furnishes 48% of the secologanin derivative **7c**, which at all chiral centers has the relative configuration typical for the secoiridoids[4]. 16% of the undesired stereoisomer **7d** is also formed; however, this can be separated chromatographically.

The high rate of reaction of the [4+2]-cycloaddition is due to the fact that the energy of the LUMO, and thus also the free activation enthalpy of the reaction, is considerably lowered by the electron acceptor group on the heterodiene. Similar results have also been obtained with other alkylidene-1,3-dicarbonyl compounds[5]. This simple entry to the secoiridoids is capable of wide variation by use of substituted C_3- and C_4-moieties.

Synthesis of S_{11} and S_{13}**

By *Torsten Sandow, Jürgen Steidel,* and *Ralf Steudel**

Sulfur homocycles are synthesized from chlorosulfanes in accordance with eq. (a)[1]. Thus, S_7 can be prepared from S_2Cl_2, and S_9 from S_4Cl_2. Larger rings S_n ($n = 11, 13, \ldots$) were hitherto not accessible in this way, since the corresponding chlorosulfanes could either not be prepared or, if at all, only with difficulty and in insufficient purity[2].

$$(C_5H_5)_2TiS_5 + S_mCl_2 \xrightarrow[0\,^\circ C]{CS_2} (C_5H_5)_2TiCl_2 + S_{m+5} \quad (a)$$

$$S_n + Cl_2 \xrightarrow[20\,^\circ C]{CS_2/CCl_4} S_nCl_2\ (n = 6, 8) \quad (b)$$

We have now synthesized S_6Cl_2 and S_8Cl_2 from the elements according to eq. (b)[3a], and then—analogously to the synthesis of S_7[3b]—prepared S_{11} and S_{13} according to eq. (a)[4]. An excess of sulfur (S_6 and S_8, respectively) is used in the chlorination, and unreacted sulfur is subsequently removed from the reaction mixture by evaporation, cooling, and crystallization. The mixture of cyclic sulfurs formed during the synthesis of S_{11} and S_{13} is partially precipitated as oil, S_{11} and S_{13} remaining dissolved in the mother liquor and only crystallizing out on further concentration and cooling[4]. After twofold recrystallization from $CHCl_3$, 7% of pure S_{11} and 5% of pure S_{13} were obtained; the identity and purity of the two sulfur rings were determined by HPLC[5]. S_{11} and S_{13} have previously been detected in rapidly cooled liquid sulfur and in other sulfur preparations[5].

S_{11} (m.p. 74 °C, dec.) forms rod-shaped crystals which grow in bundles; S_{13} (m.p. 114 °C, dec.) crystallizes in clear well-formed hexagonal platelets. Both species are readily soluble in CS_2 and moderately soluble in CCl_4, $CHCl_3$, CH_2Cl_2 and toluene. The EI mass spectra (70 eV; sample temperature up to 160 °C) show only fragment ions $S_n^{\oplus}$ ($n = 1-9$); the Raman spectra (Table 1) are different from those of all other known sulfur modifications[5]. Both species are about as thermally stable as S_6, which can be handled without decomposition for hours at room temperature.

Table 1. Raman spectra of crystalline cycloundecasulfur (S_{11}) and cyclotridecasulfur (S_{13}) at −100 °C ($Kr^{\oplus}$ laser, spectral slit width 3 cm^{-1}, wave numbers in cm^{-1}, rel. intensities in brackets, b broad, sh shoulder).

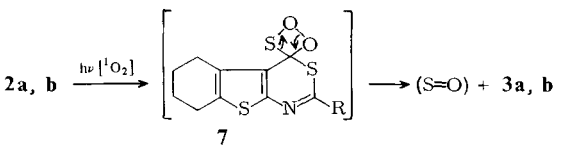
[**] Photochemistry of Heterocycles, Part 15. This work was supported by the Fonds der Chemischen Industrie and by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen. From the Dissertation by M. Ertas, Universität Bonn 1982; M. E. thanks the Konrad-Adenauer-Stiftung for a Promotionsstipendium.—Part 14: [1].

the ethyl 6-benzoylamino-3,4-dihydro-2*H*-thiopyran-5-carboxylate **4** are sulfurated to the novel deep-red 1,3-thiazin-6-thiones **2a**, **b** and **5**, respectively, on treatment with P_4S_{10} in boiling xylene[3]. **2a**: 83%, m.p. 200 °C; **2b**: 78%, m.p. 82 °C; **5**: 65%, m.p. 102 °C[4].

2a, b and **5** are converted rapidly, selectively and almost quantitatively into 1,3-thiazin-6-ones **3a**, **b** and **6**, respectively, by long-wave UV irradiation in the presence of oxygen. For example, a solution of **2a**, **b** (10 mmol) in benzene (200 mL) is irradiated (Pyrex filter) until the color changes from red to yellow (*ca.* 2—3 h) while oxygen is passed through the solution. The 5,6,7,8-tetrahydro-4*H*-[1]benzothieno[2,3-*d*][1,3]thiazin-4-ones **3a**, **b** are isolated after removal of the solvent (**3a**: 97%, m.p. 160 °C; **3b**: 95%, m.p. 133 °C[4]). In the case of **5** addition of methylene blue as sensitizer is necessary; after 4 h, **6** (92%, m.p. 124 °C[4]) is obtained by chromatography of the residue.

The oxidative photodesulfurization of heterocyclic thiones has only scarcely been described in the literature[5]. Hereby a cycloaddition of singlet oxygen to the CS double bond with subsequent (SO)-extrusion from the 1,2,3-dioxathietane **7** is discussed.



7

2a, **b** act simultaneously as sensitizers (**2a**: λ_{max} [nm] (lgε) 450, 344, 302 (3.73, 4.00, 3.97); **2b**: 425, 323 (3.63, 3.99)), whereas the UV excitation of **5** (395, 325 (3.84, 4.09)) is apparently not sufficient for the oxygen sensitization, which requires addition of methylene blue.

Characteristic in the broad-band decoupled ^{13}C-NMR spectrum of **2b** are the signals of thiocarbonyl C-4 (**2b**: $\delta = 200.10$; for comparison, **3b**: 177.68) and the neighboring C-4a (**2b**: $\delta = 130.10$; for comparison **3b**: 119.84).

This combination of a sulfuration and a photooxidation step represents a simple and elegant method for the synthesis of heteroannelated 1,3-thiazin-6-ones, which in turn can be used widely for the synthesis of heterocycles.

$[Mo_4^{III}S_4(CN)_{12}]^{8-}$, a Cluster with High Negative Charge and Cubane-Like Mo_4S_4-Moiety—On the Significance of Cyanothiomolybdates for the Prebiotic Evolution

By *Achim Müller**, *Werner Eltzner*, *Hartmut Bögge*, and *Rainer Jostes*

The occurrence of CN^-, S^{2-} and Precambrian Mo-S-phases on primordial earth suggests that cyanothiomolybdates could have been of importance for the evolution of Mo-enzymes (which were active at a very early stage in the phylogenesis of the prokaryotes through their presence in the oldest anaerobic organisms)[1-3]. We have found that in the system $Mo^{n+}/S^{2-}/CN^-$ cyanothiomolybdates with central di-, tri- and tetranuclear cluster moieties are formed, which, *inter alia*, compare with those in ferredoxins and exhibit properties which are relevant to the above mentioned subject of our studies. A typical example is $K_8[Mo_4S_4(CN)_{12}]\cdot 4H_2O$ **1**, generated by reaction of MoS_3 with aqueous CN^- solution, which could be isolated pure, and characterized by elemental analysis, TG/DTA, magnetic measurements, MO calculations, IR, Raman, NIR/VIS/UV and XPE spectroscopy, as well as by a complete single-crystal structure analysis.

The new compound **1** contains the remarkable eightfold negatively charged $[Mo_4S_4(CN)_{12}]^{8-}$ anion **2** (Fig. 1). The overall crystallographic symmetry of **2** is $\bar{4}2m$ (D_{2d}), the idealized $\bar{4}3m$ (T_d). The central cluster moiety is a distorted cube [Mo—S: 238.2(2), 238.1(2) pm (2×)]. The Mo and S atoms each form an almost regular tetrahedron [Mo—Mo: 285.5(1), 285.3(1) (2×); S—S: 375.5(3), 376.0(3) pm (2×)]. Each Mo is octahedrally surrounded by three CN^- and three S^{2-} [Mo—C: 219.0(10), 219.1(8) pm (2×)].

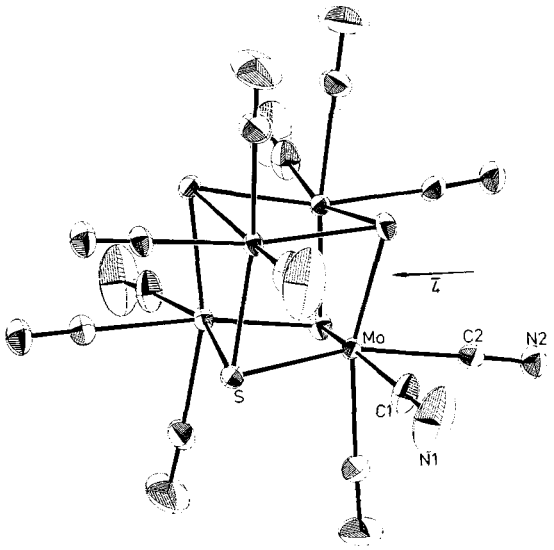

Fig. 1. Structure of **2** in crystals of **1** (space group $P4_2/nmc$, $a = b = 1236.1(5)$, $c = 1163.6(5)$ pm, $Z = 2$; $R = 0.051$ (880 observed reflections).

In **2** there are strong Mo—Mo interactions, since **1** is diamagnetic. Similar metal-metal distances are found in Mo-clusters with single bonds.

The ESCA bond energies [E_B(Mo-3p$_{3/2}$) = 395.1, E_B(Mo-3d$_{5/2}$) = 229.0 eV rel. E_B(C-1s$_{1/2}$) = 285.0 eV] are consistent with values expected for $Mo^{III}(d^3)$. According to a simple cluster rule, for this electron configuration a metal tetrahedron is to be expected, however, in contrast to the metal triangle (for d^2), this has seldom been found.

So far the following cyanothiomolybdates have been isolated: $[(CN)_4MoS_2Mo(CN)_4]^{6-}$, $[(CN)_4MoS_2Mo(CN)_4]^{4-}$, $[(CN)_6MoSMo(CN)_6]^{6-}$, and $[(Mo_3S_4(CN)_9]^{5-}$, which is also formed in the above mentioned reaction (the skeleton can formally be derived by removal of an $Mo(CN)_3$ corner from **2**)[8, 14, 17]. A significant observation is that complexes with various electron populations exist and, according to ESCA data, exhibit a large variation in bonding energy of the S-2p electrons (and thus can act as electron reservoirs).

The following steps seem plausible for the evolution of the Mo-enzymes: $MoS_x + CN^-$ ("solution process") → cyanothiomolybdates → Mo complexes with simple S-containing ligands (amino acids) → "early" enzymes.

Fixation of the Dithiosulfate Ion $S_3O_2^{2-}$; Preparation, Crystal Structure, and ESCA Spectrum of $(PPh_4)_2[(S_2)OMoS_2MoO(S_3O_2)]$

By *Achim Müller**, *Uta Reinsch-Vogell*, *Erich Krickemeyer*, and *Hartmut Bögge*

Previous attempts to isolate $S_3O_2^{2-}$ as the salt, or to stabilize it by complexation, have not met with success. We have now been able to fix by complexation the $S_3O_2^{2-}$ formed on oxidation of S_x^{2-} ligands in a metal complex with oxygen. Such reactions are relevant to the metabolism of phototrophic microorganisms which oxidize S^0 or S^{2-} and are effective in the sulfur cycle[1]. The reaction is, however, also of interest for an understanding of the oxidation of simple "sulfur species".

When a solution of $(PPh_4)_2MoOS_3$ and sulfur in acetonitrile [Reaction (a)] or of $(PPh_4)_2MoS_4$ in dimethylformamide [Reaction (b)] is exposed to oxygen, gradual formation of brown, crystalline $(PPh_4)_2[(S_2)OMoS_2MoO(S_3O_2)]$ **1** is observed. As shown by an X-ray structure analysis [Cc, $a = 2082.4(9)$, $b = 1364.6(8)$, $c = 1885.7(8)$ pm, $\beta = 108.98(3)°$, $V = 5066.9 \times 10^6$ pm^3, $Z = 4$; $R = 0.062$ for 4124 reflections] an S_2^{2-} as well as the bidentate dithiosulfate ligand $S_3O_2^{2-}$ are coordinated to the known central $OMoS_2MoO$ unit[2] in the complex anion of **1** (cf. Fig. 1 with atomic distances). As expected, the average SS distance in the dithiosulfate ligand is longer, the average SO distance somewhat shorter than in the "isolated" $S_2O_3^{2-}$ **2** (*ca.* 200 and 146 pm[1b], respectively). The OSS angles [110.5(7), 110.2(6), 110.6(6), 112.1(6)°] have values about the same as in the regular tetrahedron or as in **2**, whereas the SSS angle [96.2(2)°] is expectedly smaller and the OSO angle [115.6(9)°] correspondingly larger than the OSS bond angles. Asymmetrically coordinated complexes containing the $OMoS_2MoO$ moiety are already known.

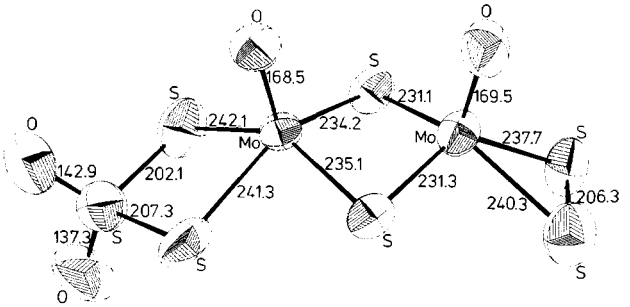

Fig. 1. Structure of the complex anion in crystals of **1**. Maximum standard deviations (in pm): Mo—S 0.5; S—S 0.7; Mo—O 1.1; S—O 1.5.

The $S_3O_2^{2-}$ ligand can be visualized nicely by the ESCA method: besides an S-2p signal at 162.7 eV (for a total of six "sulfidic" sulfur atoms in **1**, *i.e.* two from the dithiosulfate and four others) a signal is observed at 168.6 eV (for S^{+VI}) in the intensity ratio 6 : 1; E_B(Mo-3d$_{5/2}$) appears at 230.3 eV (all values relative to E_B(C-1s$_{1/2}$) = 285.0 eV). The ligand also shows characteristic IR bands in the solid state spectrum (KBr pellet) of **1**: $\nu_{as}(SO_2) = 1255$, $\nu_{as}(SS_2)/\delta(SO_2) = 598$, 557 cm^{-1}; ν(MoO) = 955 cm^{-1}.

Very little is known about the oxidation of S_x^{2-} ligands ($x = 1-5$). In the present case, $S_3O_2^{2-}$ *could* be schematically formed in reaction (a) (without considering redox processes[2a]; *i.e.* reduction of Mo^{VI}) according to

$$\{Mo(S^{2-})\} \xrightarrow{S_x} \{Mo(S_4^{2-})\} \xrightarrow[-S]{} \{Mo(S_3^{2-})\} \xrightarrow{O_2} \{Mo(S_3O_2^{2-})\}$$

(by activation of S_3^{2-} and stabilization of $S_3O_2^{2-}$ on Mo), since the complex $[(S_4)OMoS_2MoO(S_4)]^{2-}$ is formed (together with $[OMo(S_4)_2]^{2-}$) in the same reaction—but under N_2[2a]. In reaction (b), MoS_4^{2-} could furnish the fragment $\{Mo(S_3^{2-})\}$, which should react further according to (a)[3].

In the sulfur cycle, which is important for the biosphere and our ecosystem, microorganisms are effective which reduce SO_4^{2-} (by assimilatory reduction but also in "sulfate respiration"), or which oxidize reduced species such as S^{2-} or S^0, like the phototrophic prokaryotes Chromatiaceae and Chlorobiaceae. Possibly, not only sulfur-rich anions such as $S_2O_3^{2-}$ [1] are formed in the photosynthetic processes, but also previously undetected species such as $S_3O_2^{2-}$ (*e.g.* as intermediates).

[3] *Procedure:* $(PPh_4)_2MoS_4$ (0.6 g) was added to dimethylformamide (p.a.; 25 mL) in a 100 mL Erlenmeyer flask. The mixture was stirred at 20 °C under N_2 until dissolution was complete. After addition of 25 mL of anhydrous ethanol (p.a.) the mixture was heated at 60 °C for 15 min, whereupon reprecipitated $(PPh_4)_2MoS_4$ was essentially dissolved. The flask was stoppered and allowed to stand at 20 °C for 16 h (all operations were carried out under N_2). The solution was filtered in presence of air, and the filtrate stored in a closed vessel at 20 °C for 14 d. The reaction mixture was then treated with 75 mL of ethanol and once again allowed to stand for 16 h at 20 °C in a stoppered 250 mL Erlenmeyer flask. The precipitated reddish-brown crystals were filtered off, washed with anhydrous EtOH, CS_2, and Et_2O and dried in a vacuum (yield 0.15 g). **1** cannot be obtained in the pure state using reaction (a).—In a modified method (b), either the novel black "mixed valence" complex $(PPh_4)_2[(S_2)OMo^{V}S_2Mo^{V}O(Mo^{VI}S_4)]$ (characterized by crystal structure determination), or the monothiosulfate complex corresponding to **1** can be obtained.

BOOK REVIEWS

Kinetics and Mechanism. A Study of Homogeneous Chemical Reactions. By *J. W. Moore* and *R. G. Pearson*. 3rd edition, Wiley-Interscience, Chichester 1981. xv, 455 pp., bound, £ 23.70.

For the generation of chemists who first came into contact with chemical kinetics in the 'fifties and 'sixties "Frost-Pearson" was a standard introductory textbook and review of the field of homogeneous reaction kinetics[*]. A new edition of "Kinetics and Mechanism" by *J. W. Moore* and *R. G. Pearson* has now appeared after 20 years, and the expectations are naturally running high, in view both of the renown of the older work and the competition that has meanwhile arisen from other monographs in this field. It is a pleasure to say that these expectations can be regarded as having been satisfied. Through a far-reaching revision of the book (about four-fifths of it has been newly written) it has been possible to include the developments of the last 20 years so successfully that the new work constitutes an excellent review of the present state of kinetics and of its concepts, methods, and applications in the clarification of reaction pathways.

The classification of the material has remained substantially unchanged from the second edition. The number of detailed examples of elucidated reaction mechanisms has been drastically cut down to make room for the treatment of more recent theoretical and experimental developments, and the previous two concluding chapters have been eliminated. The book opens with a discussion of the empirical foundations for the treatment of rate constants, and goes on with a chapter on experimental methods and the analysis of kinetic measurements in which—as in a later chapter on complex systems—the appropriate use of computers in data analysis, numerical integration, and simulation with models is also briefly considered. The chapters "Collisions between Molecules" and "Potential Surfaces and the Theory of the Transition State" treat current theoretical concepts and principles for the analysis and calculation of homogeneous reactions under the common term of "elementary processes". Some important and topical aspects such as the pressure dependence of unimolecular processes or problems on energy transfer between and within molecules are discussed in the following chapter which, however, is mainly devoted to experimental examples from the standpoint of interaction between theory and experiment. This is followed by the treatment of neutral and ionic reactions in solutions. Formal and experimental aspects of composite reaction pathways are the subject of the next chapter, on "Complex Reactions". A longer chapter deals with homogeneous catalysis, and finally with chain reactions and—only very briefly—with photochemistry.

The text is unfailingly very clear and comprehensible and, with about 800 references (up to 1980!), it is prepared carefully with an eye to further study. The idea of communicating basic principles and central results so plainly that the reader acquires a sound basis for direct independent applications is everywhere in evidence. Thus, there are sound discussions on the prerequisites (*e.g.* the theory of the transition state or the concept of the steady state) and a detailed notation of equations and their derivations are given. All this is most helpful to the user. The high degree of balance between theoretical explanations and application-oriented preparation makes the book particularly suitable for the experimental scientist, even if only a potential one. Of course, one could always criticize this or that detail, but such objections pale into insignificance in comparison with the sheer solid worth of the book.

Summarizing, this new edition of "Kinetics and Mechanism" can be recommended without any reservations to the advanced student and to the practising scientist who from inclination or necessity wants a new general account and concrete access to kinetics. Those already experienced in kinetics will find it useful as a handy and rapidly accessible work of reference.

Klaus Luther [NB 567 IE]

Structure and Bonding in Crystals. Volume 1. Edited by *M. O'Keefe* and *A. Navrotsky*. Academic Press, New York 1981. xviii, 327 pp., bound, $ 48.00.

This is the first of two volumes containing the material of a conference on solid-state problems. It comprises 13 chapters—writen by 17 authors—each giving a unified account of one aspect of the solid state. The book must be praised for its sturdy appearance and many references, the latter enabling the interested reader to learn more about the background and the problems associated with the 13

[*] Cf. *Angew. Chem. 73* (1961) 719.

topics, whose treatment is far from being uniformly comprehensive. Five chapters are devoted to approaches to the description of the structure and bonding in solids on the basis of the pseudopotential theory, and of these *A. Zunger*'s particularly exhaustive and comprehensible contribution stands out from the point of view of the practical chemist. *Zunger* demonstrates using numerous examples the significance and usefulness of orbital radii, *e.g.* for classifying a large number of crystal structures, and shows how the orbital radii are connected with some classical concepts such as electronegativities and atomic radii. On the other hand, the description of the formalism for the elementary quantitative theory of the chemical bond is somewhat abstract and very difficult to follow, owing to the lack of detailed examples (this theory can be used for practical applications with the aid of a pocket calculator). *W. A. Harrison*'s own book on this topic must be considered the most important reference in this connection. The other chapters deal with ways of applying some semiquantitative methods of the MO theory to the question of bonding in solids, these methods being derived from molecular chemistry, where they have been used with great success. Such approaches will certainly gain importance in the future, even though the purists among the theoreticians do not entirely take them seriously. Reminiscences of the classical ionic model of chemical bonding in solids and a historical survey by *L. Pauling*, extremely enjoyable as vacation reading, complete the book, which on the whole creates a favorable impression. Despite the suggestion in the preface, however, the book cannot compete with *Pauling*'s own "Nature of the Chemical Bond" and will not become its successor in the literature. This is not so much because of its contents as because it necessarily lacks the didactically unified form of *Pauling*'s textbook, being a collection of 13 separate contributions (with another 13 to come in the second volume).

Hans-Jörg Deiseroth [NB 570 IE]

Bioorganic Chemistry. By *H. Dugas* and *C. Penney*. Springer-Verlag, Berlin 1981. xii, 508 pp., bound, DM 59.00.

It is probably true to say that few chemists know precisely the meaning of "bioorganic chemistry", and it was therefore wise to provide the subtitle (A Chemical Approach to Enzyme Action) and to give immediately (in the Preface) a definition of this recent discipline:

"Bioorganic chemistry" is the application of the principles, models, and methods of organic chemistry to the understanding of biological processes.

The field is sketched broadly with skilfully selected examples in an introductory chapter. Studies of enzymatic processes on natural systems are described side by side with investigations on simple synthetic models which make it possible to study effects without the disturbing influence of accompanying parameters. Knowledge of the complex-forming properties of molecules, on the one hand, and of enzymes and enzyme models on the other hand, should lead to structure-activity relationships invaluable for the directed synthesis of biologically active compounds such as pharmacological agents. Knowledge obtained on enzymes and models concerning reactivity, with the involvement of electronic, steric, and stereoelectronic effects and neighboring group effects, should make it possible to design tailor-made molecules whose catalytic activity at least approaches that of biological systems.

Not only the contents but also the similar classification of the next two chapters demonstrate the close correlation between the basic building blocks of life, nucleic acids and proteins.

The structure and chemical reactivity of the monomeric nucleotide and amino-acid units are compared with one another and brought into relationship with problems of the synthesis and biosynthesis of oligomers. What I believe to be particularly useful for students, at whom this book is also directed, is that analogies from "ordinary" organic chemistry are brought in again and again for the sake of clarification. The chapter on nucleic acids ends with an excellent digression on the chemical evolution of organic molecules, in which light is also thrown on the problem of the origin of chiral molecules.

Using all the tools of organic chemistry, *e.g.* conformational analysis and stereoelectronic control of reactions, the authors then acquaint the reader by means of selected examples with the problems of enzyme catalysis and prepare him for the chapter on enzyme models.

On the examples of chiral crown ethers, polymers, and micelles it is demonstrated here in what manifold ways these "artificial enzymes" perform selective complexing reactions, stereoselective transport, and catalytic functions. Also inspired by nature are biomimetic reactions, which are explained using phenol oxidations and terpene cyclizations.

The next chapter deals with the role of metal ions in enzyme reactions. The choice of the very well researched iron-containing hemoglobin and of vitamin B_{12}, and also of suitable synthetic models is very appropriate from the didactic point of view. Regrettably, there is no mention of photosynthesis as an important primary biochemical process.

The concept of comparing natural systems with artificial models is followed consistently in the last chapter on coenzymes with emphasis on chemoselectivity and stereoselectivity.

Summarizing, it may be said that whereas for students the book offers a good introduction into the field, the advanced reader will also find a wealth of suggestions and see many problems in new perspectives. A literature index which contains mainly review articles is useful for identifying the original literature. The book can also be recommended because of its relatively low price.

Franz Peter Montforts [NB 569 IE]

Polarographische Analyse. By *M. Geissler*. Verlag Chemie, Weinheim 1981. 194 pp., bound, DM 73.00.

This monograph is divided into seven chapters. After a brief historical introduction it covers as much of the theory of electrochemical kinetics as is needed by the practical analytical chemist. The principles of the various voltametric methods are discussed on the basis of the 1976 IUPAC recommendations for electrochemical analysis. From the point of view of practical trace analysis, the author does not put enough stress on the methods essential for this type of analysis. For example, inverse voltammetry, which is particularly important for trace analysis, should have been described in much greater detail, while a mere mention would have sufficed in the case of oscillopolarography, which is hardly ever used nowadays. The next chapter, on the theory of methods involving different types of polarization, will be a useful source of practical information.

However, when it comes to discussing the technical aspects, the analytical side again comes off inadequately. Thus, in the case of electrodes, the mercury film electrodes important for ultratrace analysis receive only sketchy treatment. There are also large gaps in the description of modern commercial polarographs and their analytical performance. In this respect the book lags behind practical developments, and indeed in some cases far behind them.

However, it is mainly in the last two chapters, dealing with analytical applications, that the book does not live up to the expectations suggested by its title in chemists engaged in trace analysis. It does not give a full account of the various possibilities and the many fields of application in the reliable and highly sensitive trace analysis of metals and organic substances. At best, it only gives impressions of these. From this point of view, the monograph does not do full justice to its title.

The forte of the work lies undoubtedly in its succinct and didactically successful treatment of the principles of polarographic methods and the theory of electrode processes. In this respect this highly readable book will be useful to analytical chemists not very familiar with electrochemistry and polarography.

Hans W. Nürnberg [NB 571 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Federal Republic of Germany).

Structure and Bonding. Vol. 51: Electron Nuclear Double Resonance of Transition Metal Complexes with Organic Ligands. By *A. Schweiger*. Springer-Verlag, Berlin 1982. vii, 128 pp., bound, DM 74.00.—ISBN 3-540-11072-0

The Role of Frontier Orbitals in Chemical Reactions (Nobel Lecture)**

By Kenichi Fukui*

Introduction

For more than a thousand years chemistry has been thought of as a complicated, hard-to-predict science. Efforts to improve even a part of its unpredictable character first bore fruit through the success of the "electronic theory". This was founded mainly by organic chemists, such as *Fry, Stieglitz, Lucas, Lapworth,* and *Sidgwick,* brought to a completed form by *Robinson* and *Ingold,* and later developed by many other chemists[1]. In the electronic theory, the mode of migration of electrons in molecules is considered under various aspects. For this purpose a criterion is necessary for the number of electrons which should be assigned to an atom or to a bond in a molecule. Therefore, it can be said that the concept of the sharing of electrons, proposed by *Lewis,* gave a firm basis to the electronic theory[2].

In the theory of organic chemistry the terms acid/base, oxidation/reduction, and so on have been profitably utilized for some time. Furthermore, there are terms centering more closely around the electron concept, such as electrophilicity/nucleophilicity and donor/acceptor.

It should be mentioned that these pairs of terms can be qualitatively related to the scale of electron density or electric charge. In the electronic theory, the static and dynamic behavior of molecules are explained by the electronic effects which are based solely on the distribution of electrons in a molecule.

The charge distribution in a molecule can be sketched to a certain extent using the electronegativity concept of atoms, in conjunction with chemical experience. It is given foundation, made quantitative, and supported by physical measurements and theoretical calculations based on quantum theory.

The distribution of electrons or electric charge—the result is the same irrespective of which is used—in a molecule is usually represented by the total number (generally non-integer) of electrons in each atom and each bond. This concept was easily acceptable, even to experimental chemists, as having a tolerably realistic meaning. Therefore, chemists used electron density as a fundamental concept for the explanation of various phenomena. In particular, in devising novel chemical reactions researchers usually rely upon analogy through experience, and here electron density was very effectively and widely used as the basic concept.

When the magnitude of the electron density is adopted as the criterion, the electrostatic attraction and repulsion caused by the electron distribution are taken into account. Therefore, it is reasonable to infer that an electrophilic reagent will attack the center of high electron density in a molecule, whereas a nucleophilic reaction will occur at the center of low electron density. In fact, *Wheland* and *Pauling*[3] explained the orientation of substitutions in benzene and its compounds along these lines, and analogous interpretations of the mode of many other chemical reactions followed in the same fashion.

However, the question as to why one of the long-known, simple reactions, such as the electrophilic substitution of naphthalene, *e.g.* by nitration, predominantly yields 1-substituted derivatives was not so easy to answer. This is because in many unsubstituted aromatic hydrocarbons both the electrophile and the nucleophile react at the same center. This point cast some doubt on the theory of organic reactivity, where exclusively the electron density was thought to be decisive.

The Concept of Frontier Orbital Interactions

The solution of this reactivity problem was attempted by many people from numerous angles. Above all, *Coulson* and *Longuet-Higgins*[4] investigated the change of electron density distribution under the influence of the approaching reagent. The explanation proposed by *Wheland*[5] was based on the calculation of the energy required to localize electrons at the site of reaction. But I myself tried to attack this problem in a way which was at that time slightly unusual. Bearing in mind the principal role played by the valence electrons in the formation of molecules from atoms, only the distribution of the electrons occupying the highest energy π orbital of aromatic hydrocarbons was calculated. The results were more successful than expected, and an almost perfect agreement between the actual position of electrophilic attack and the site of highest electron density calculated for the highest occupied π orbital was found, as shown in Figure 1[6].

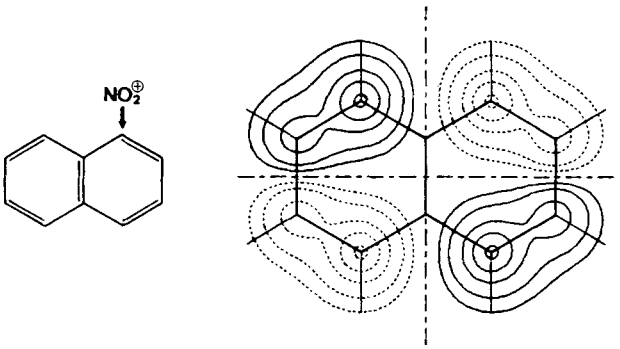

Fig. 1. Nitration of naphthalene.

The "orbital" concept, which was established and developed by many scientists—*Pauling, Slater, Mulliken, Roothaan, Löwdin, Hückel, Parr* and so on—had till then been used to construct wave functions of molecules by means of which molecular properties were usually interpreted[7]. It also seemed that the electron distribution in an orbital was directly connected to chemical observations, and this fact was certainly felt to be interesting by many chemists.

But the result of such an "extravagant" attempt was by no means readily accepted by the majority of chemists. The publication[6] received a number of controversial comments. This was in a sense understandable, because due to my lack of experience the theoretical foundation for our notable result was obscure or rather improperly presented. However, it was fortunate for me that the work of *Mulliken*[8] on charge-transfer complexes was published in the same year.

The model of *Mulliken et al.* for protonated benzene was very helpful[9]. Our work in collaboration with *Yonezawa, Nagata,* and *Kato* provided a simple and clear picture of the theoretical interpretation of reactions[10]. In a similar way the "overlap and orientation" principle proposed by *Mulliken* enabled the orientation in molecular complexes[11] to be clarified. Subsequent to electrophilic substitution, nucleophilic substitution was discussed and it was found that here the lowest unoccupied orbital was decisive[12]. In reactions with radicals, both of the two orbitals mentioned previously become the "essential" orbitals.

There was no reason to limit these essential orbitals to π orbitals, so that the method was applied not only to unsaturated but also to saturated compounds. The fact that it could be applied to saturated compounds was a substantial advantage compared to many theories of reactivity which were limited only to π electron compounds. The method displayed its particular usefulness in studying the abstraction of hydrogen from aliphatic hydrocarbons by radicals, the S_N2 and E2 reactions of halogenated hydrocarbons, the nucleophilic abstraction of α-hydrogen atoms from alkenes, and so forth[13].

The two molecular orbitals which play an essential role in a wide range of chemical reactions of saturated or unsaturated compounds were referred to under the general term "frontier orbitals", abbreviated frequently by HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital).

The validity of the theory gradually became clearer. The vein of ore discovered by chance was found to be more extensive than expected. But it was the role played by the symmetry of the "essential" orbital, pointed out in 1964 with regard to Diels-Alder reactions[14], that broadened the utility of our studies further. It was found, as seen in Figure 2, that the symmetries of the HOMO and LUMO of dienes and of the LUMO and HOMO of dienophiles, respectively, are in an extremely favorable situation for a concerted cyclic interaction.

This led to two important aspects: Firstly, it pointed out a possible correlation between the orbital symmetry and the rule determining the occurrence or non-occurrence of a chemical reaction, which may be called the "selection rule", in common with the selection rule in molecular spectroscopy. Secondly, it provided a clue to discuss what was the "concertedness" in a reaction which proceeds *via* a cyclic conjugation of electrons.

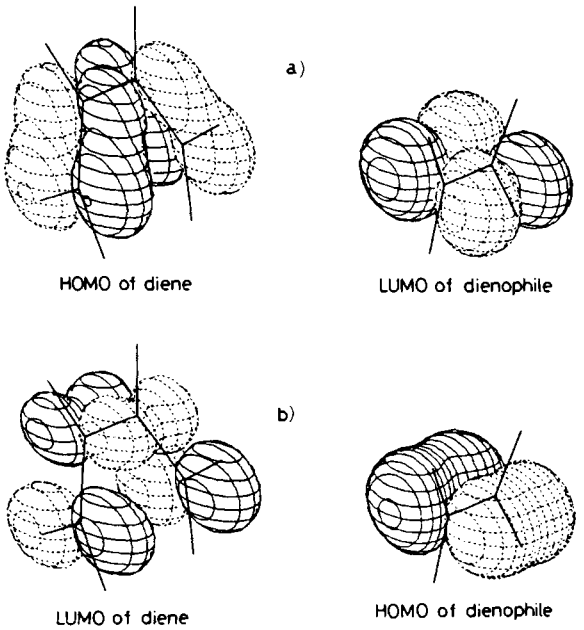

Fig. 2. The significance of orbital symmetry in the HOMO-LUMO overlap in Diels-Alder reactions.

In 1965 *Woodward* and *Hoffmann* proposed the stereoselection rules which are known today as the "Woodward-Hoffmann" rules[15,16]. An experimental result developed by *Havinga et al.*[17] was, herewith, extended immensely. It was only after the appearance of the brilliant work by *Woodward* and *Hoffmann* that I became fully aware that not only the electron density distribution but also the nodal properties of the essential orbitals have significance in a wide variety of chemical reactions. In fact, we previously studied the classical (4n+2) rule proposed by *Hückel*[8], and noticed that the sign of the bond order in the highest occupied orbital of an open-chain conjugation system should be closely related to the stabilization of the corresponding conjugated rings[19]. We did not imagine, however, that the discussion might be extended to the so-called Möbius-type ring-closure![20]

By considering the HOMO-LUMO interactions between the fragments of a conjugated chain divided into two parts[21], frontier orbital theory can yield selection rules which are absolutely equivalent to those obtained from the "conservation of orbital symmetry" principle of *Woodward* and *Hoffmann*. One point I may stress here is, as suggested by *Fujimoto, Inagaki,* and I[22], that the electron delocalization between the "essential" orbitals exactly expresses, in terms of orbital symmetries, the formation and breaking of chemical bonds which, I believe, should be of key importance for perceiving chemical processes.

In the cycloaddition of butadiene and ethylene shown in Figure 2, both the interaction between the HOMO of the diene and the LUMO of the dienophile, and that between the LUMO of the diene and the HOMO of the dienophile stabilize the reacting system. If one is interested in the spatial properties of interaction, however, one may recognize the clear distinction between the roles of the two types of orbital interactions. The HOMO of ethylene and the LUMO of butadiene are both symmetric with respect to the symmetry plane retained throughout the course of cycloaddition. This signifies that each of the carbon atoms of ethylene is bound to both of the terminal carbons of butadiene. The chemical bonding between the diene and dienophile thus generated may resemble that in a loosely bound complex, *e.g.*, protonation of an olefinic double bond. In contrast, the HOMO of butadiene and the LUMO of ethylene are antisymmetric. The interaction between these orbitals leads, therefore, to two separated chemical bonds, each of which links a carbon atom of ethylene and a terminal carbon atom of butadiene. Needless to say it is the interaction between the HOMO of the diene and the LUMO of the dienophile that is decisive for the occurrence of a concerted cycloaddition[22].

In the course of time it was discovered that the electron delocalization between the HOMO and LUMO is generally the principal factor determining the ease of a chemical reaction and its stereoselective path, irrespective of whether an intra- and intermolecular processes occurs (Fig. 3). Besides our work, a number of other research groups have made contributions to this area.

First of all, the general perturbation theory of HOMO-LUMO interaction between two molecules was built up by *Salem et al.*[23-25]. One of *Salem*'s papers[25] was in line with the theory of *Bader*[26], which specified the mode of

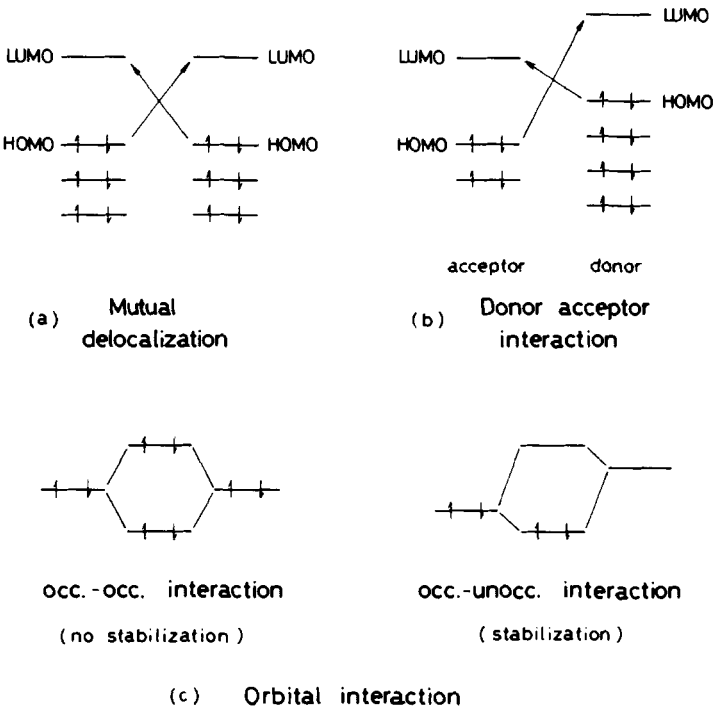

Fig. 3. The mode of interaction between orbitals of two molecules.

decomposition of a molecule or of a transition complex by means of the symmetry of the normal vibration. Furthermore, *Pearson*[27] investigated the relationship between the symmetry of reaction coordinates and that of the HOMO and LUMO.

The discussion so far may seem to overestimate the importance of these selected orbitals, HOMO and LUMO. This point was ingeniously modified by *Klopman*[28]. He carefully took account of the factors to be considered in the perturbation theory of reacting systems, and classified reactions into two types

- the first was the "frontier-controlled" case, in which the reaction was controlled by the "essential" orbital interaction, and
- the second was the "charge-controlled" case, where it was controlled by the electrostatic interaction of charges.

This classification was widely and successfully used. In this context, the review articles of *Herndon*[29] and of *Hudon*[30] proved to be very useful. The names of *Coulson*[4] and *Dewar*[31] should also be mentioned here as having made contributions to the development of theories of reactivity.

Returning to the subject again, let us imagine that two molecules approach each other and that orbital overlap takes place. Application of perturbation theory[32] to this sort of interaction indicates that the larger the orbital overlap and the smaller the energy level separation of the two overlapping orbitals, the larger is the contribution of the orbital pair to the stabilization of an interacting system. Accordingly, at least initially, a reaction will proceed with

a mutual nuclear configuration which is most favorable for the HOMO-LUMO overlap.

Now let us suppose that a flow of electrons occurs from the HOMO of molecule I to the LUMO of molecule II. In each molecule the bonds between the reaction center—the site at which the orbitals overlap with those of the other molecule—and the remaining part of the molecule are weakened. In this case, the bonding relationships in the HOMO of molecule I are weakened and the antibonding strengthened, while in molecule II the antibonding relationships in the LUMO are weakened and those bonding strengthened. Consequently, the HOMO of molecule I is particularly destabilized relative to the other occupied orbitals, and among the unoccupied orbitals the LUMO of molecule II is selectively stabilized, so that the HOMO-LUMO level separation between the two molecules is decreased. Such a set of circumstances is clearly seen in Figure 3.

When such bond weakenings have arisen the HOMO and the LUMO tend to become more localized at these weakened bonds in each molecule. In addition, the weakening of the bonds between the reaction center and the remaining part of the molecule causes an increase in the amplitudes of the HOMO and the LUMO at the reaction centers, resulting in a larger overlap of the HOMO and the LUMO[33]. Such a trend of the characteristic change in the orbital pattern is confirmed by numerical calculations. The role of the interaction between the HOMO and the LUMO turns out to become more and more important as the reaction proceeds.

A series of studies on chemical interactions was attempted in which the interaction of reactants was divided into the Coulombic, the exchange, the polarization, and the delocalization interactions, and their respective contributions to the interaction energy were quantitatively discussed[32, 34]. In this way the dimerization[35] and the addition of methylene to ethylene[36], the dimerization of BH_3[37], and also several donor-acceptor interactions, *e.g.* BH_3-NH_3[38], BH_3-CO[39], NH_3-HF[40], *etc.*, were discussed. The method was also applied to reactions of radicals, such as the abstraction of a hydrogen atom from methane by a methyl radical, the addition of a methyl radical to ethylene[41], and recombinations, disproportionations, and self-reaction of two radicals[42]. In these calculations, the configurational analysis proposed originally by *Baba et al.*[43] was also found to be useful. We were able to show numerically the increase in electron delocalization from the HOMO to the LUMO as the reaction proceeded, the increasing importance of the contribution of such a delocalization to the stabilization of the reaction system, and the driving force of the reaction in terms of orbital interactions, among others.

The question: "Why do the HOMO and the LUMO solely determine the reaction path?" was one which I was frequently posed by audiences at my lectures. The discussion so far should correspond, at least in part, to that answer. But one may not overestimate the importance of the HOMO and the LUMO. In one-center reactions, such as substitutions, in which the orbital symmetry plays no role, any occupied orbitals which are very close in energy to the HOMO should properly be taken into account[12]. In large alkane molecules a number of HOMO's (high-lying occupied MO's) and furthermore, as will be referred to later, in metal crystals even the "HOMO-band" must be taken into account. If the HOMO or the LUMO happens to be inadequate owing to its extension, symmetry, or nodal properties, the next orbital should be sought. One of the simplest examples of such an instance is the protonation of pyridine. In this case, the nitrogen lone-pair orbital is not the HOMO, but the addition of a proton to the nitrogen lone-pair so as not to disturb the π conjugation, will evidently be more advantageous than addition to higher occupied π orbitals, which may interrupt this. The reason why the proton dare not add to the positions of high amplitude of the π HOMO in this case is thus understood. It is not satisfactory to treat a disagreement between the HOMO-LUMO argument and an experimental result formally as an *exception* to the theory. A so-called exception has its own causes, and the investigation of these causes may possibly yield a novel result.

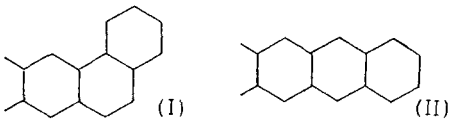
The HOMO-LUMO interaction argument was recently pointed out[44] to be useful, in an auxiliary sense, for interpreting the sign of a reaction constant and the substituent constant scale in the Hammett rule[45], which has made an immeasurable contribution to the study of substituent effects upon chemical reactivity. In cyclic additions, such as Diels-Alder reactions and 1,3-dipolar additions, the relative ease of occurrence of reactions, various subsidiary effects and interesting phenomena, such as regioselectivity and periselectivity, were interpreted with considerable success simply by knowing the height of the energy level of the HOMO and the LUMO, the mode of their extension, and their nodal structure, *etc.*[46]—I defined these as the *orbital pattern*.

Other topics that have been discussed in terms of HOMO-LUMO interactions are thermal formation of excited states[47], singlet-triplet selectivity[48], the chemical property of diradicals and excited states[49], the interaction of the central atom and ligands in transition-metal complexes[50], the interaction of three or more orbitals[51], and so forth. *Inagaki et al.* extended the theory to include the polarization effect on the HOMO and the LUMO due to mixing with other orbitals, and gave an elucidation of a number of problems in organic chemistry which were not always easy to explain: the unique stereoselectivity in transannular bond formation, the lone-pair effect, the d orbital effect, and the orbital polarization effect due to substituents[52].

As previously discussed, the method of orbital interaction was applied not only to the ground electronic state but also to excited states, giving rise to an explanation of the path of even complicated photochemical isomerizations[13, 21]. In the majority of cases the HOMO and the LUMO of the ground-state molecule were also found to be the essential orbitals. Even the ground-state reaction of a strong electron acceptor (or donor) causes a mixing with an ionized electron configuration or an excited electron configuration in another molecule. In consequence, a partial HOMO-HOMO or LUMO-LUMO interaction, which would be trivial without the influence of the acceptor (or donor), becomes important in stabilizing the interacting system[47].

The problems so far discussed have been limited to chemical reactions. However, the HOMO-LUMO interaction must also come into bearing in other chemical phenomena in almost the same way—with the exception that they usually do not bring about such a remarkable change in the nuclear configuration. Now let us examine the possibility of applying the theory to "aromaticity"—one of the simplest, but hardest-to-interpret problems. There seem to be few problems so frustrating to theoreticians as the explanation of this classical chemical concept. I greatly appreciate the contribution of *Dewar*'s theory[53, 54] based on quantitative energy calculations. Here, however, I want to give a qualitative comment from an entirely different point of view.

It is easily ascertained[55] from Figure 4 that in benzene, naphthalene, and phenanthrene, *etc.*, any conceivable division of the molecule into two fragments always produces segments whose HOMO and LUMO overlap in-phase at the original two junctions. But these circumstances are not observed in anthracene, which is usually viewed as one of the typical examples of an aromatic compound. *Hosoya*[55] pointed out from comparison with phenanthrene (see Fig. 4) that annelation of type (II) is less stable than that of type (I).



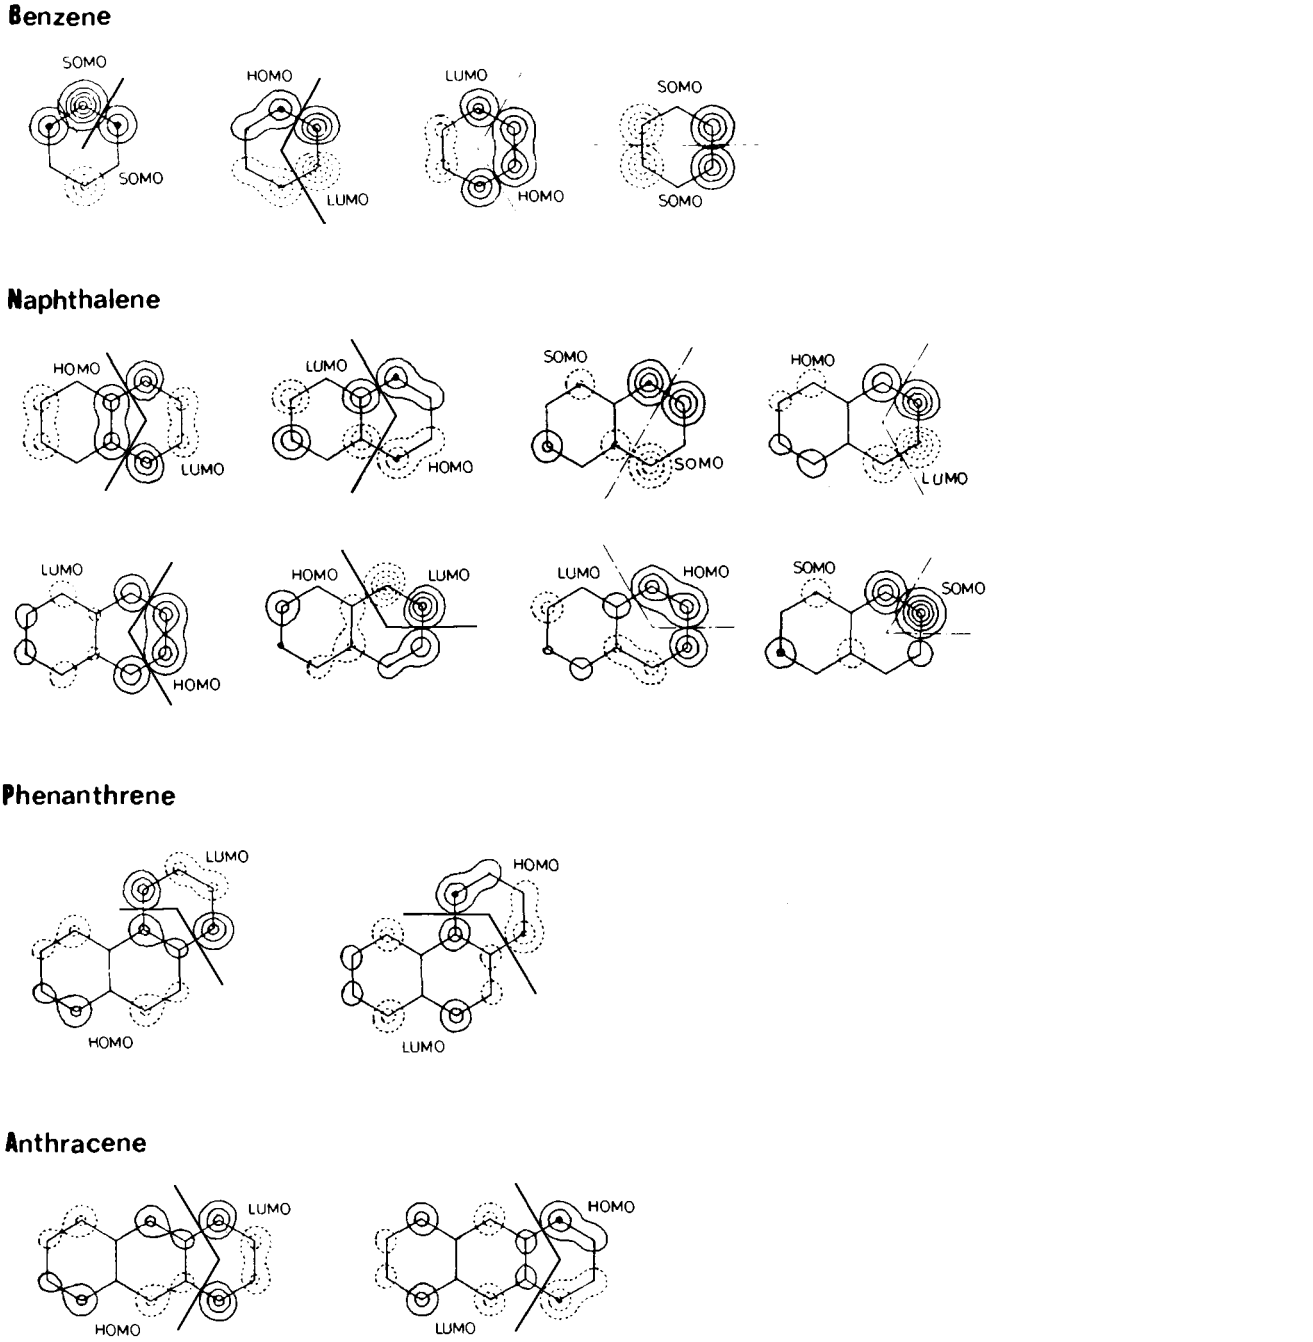


Fig. 4. The HOMO-LUMO phase relationship upon random division of aromatic hydrocarbons (SOMO = singly occupied MO of a radical).

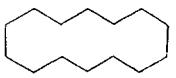
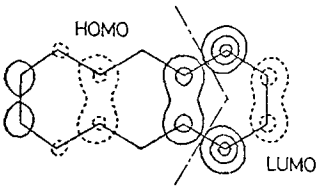
It is well known that anthracene occasionally undergoes reactions similar to additions to olefins.

According to *Hückel*'s (4n + 2)-rule, mentioned previously, the anthracene molecule has 14π electrons and fulfils the stability condition for "aromaticity". Actually, if one considers a molecule of anthracene with the two internal bridging bonds deleted,



it is readily seen that the HOMO and the LUMO of each fragment overlap in an in-phase manner at both of the junctions:



In this way, it is clear that the two bonds which were deleted exert an unfavorable influence on the aromaticity. Such an influence bears a close resemblance to that of impurity scattering of the wave of a free electron moving in a metal crystal.

This discussion seems to be a digression but, as a matter of fact, it is related to the crucial question as to how an electron delocalizes in a molecule. As will be mentioned later, *Anderson*[56] solved the question of how an electron localizes in a random system. In a molecule, there are potential barriers between atoms which must be overcome when certain conditions are satisfied, in order for an electron to move freely around it. Although the question of how valence electrons delocalize in a molecule may not yet have been solved satisfactorily for nonfixed nuclear configurations, the in-phase relationship of the HOMO and the LUMO at the junctions of the two molecular fragments seems to be at least one of the important conditions for the intramolecular delocalization of electrons.

Generally speaking, electron delocalization gives rise to stabilization due to "conjugation", which is an old concept in chemistry. If so, similar stabilization mechanisms must be detected in systems other than aromatic compounds. The discussion of this delocalization stabilization at the transition state or along the reaction path is nothing other than the reactivity theory discussed previously. The term "delocalizability" was attached to the reactivity indices we derived[10], and our reactivity theory itself was sometimes called the "delocalization approach"[14]. Various sorts of "hyperconjugation" can be explained in the same manner. Stabilization due to homoaromaticity or the bicycloaromaticity of *Goldstein*[57], the stability of spirocycles, pericycles[58], of the "laticycles" and "longicycles" of *Goldstein* and *Hoffmann*[59], that of the spirarenes of *Hoffmann* and *Imamura*[60], and so on are all comprehensible as examples of stabilization due to delocalization between HOMO and LUMO, although other explanations may also be possible.

One might ask to what extent such a qualitative consideration is reliable. In many cases, however, a considerably accurate nonempirical determination of the stable conformation of hydrocarbon molecules[61,62] results in a conclusion qualitatively not much different from expectations based on the simple orbital interaction argument mentioned here.

Chemical Reaction Pathways

It has already been pointed out that the detailed mechanism of a chemical reaction along the reaction path can be discussed on the basis of the orbital interaction argument. For this purpose, however, it is necessary that the problem of how the chemical reaction path is determined be solved. The evaluation of the route of a chemical reaction and its rate in terms of the potential energy surface is performed using a statistical-mechanical formulation established by *Eyring*[63]. Many other papers appeared in which the rate expression was derived wave-mechanically using the potential energy function. In addition, the problem of obtaining the trajectory of a given chemical reaction with a given initial condition was treated by *Karplus*[64].

The center line of the reaction path, so to speak, the idealized reaction coordinate—which I called the "intrinsic reaction coordinate" (IRC)[65]—seemed to have been, rather strangely, not specifically defined until then. For that reason, I began with the general mathematical equation which determines the driving force[34,66,67]. Although my papers themselves were possibly not very original, they later turned out to develop in a very interesting direction[68–74], and opened up the method of calculating the quasistatic change of nuclear configuration of the reacting system starting from the transition state and proceeding to a stable equilibrium point[66]. I termed the method of automatic determination of the molecular deformation accompanying a chemical reaction, "reaction ergodography"[34,67]. This method was applied to a few specific examples by *Kato* and I[67], and by *Morokuma*[72,73]: abstraction and substitution of methane hydrogen by hydrogen atoms[67], nucleophilic substitution of methane hydrogen by hydride anions[72], and isomerization of methyl isocyanide to acetonitrile[73]. All of these are very simple reactions, but there seems to be no principal difficulties in extending the applicability to larger systems. Once the IRC was determined in this way, the driving force of a chemical reaction was analyzed on the basis of the orbital interaction argument[66].

In a reacting system with no angular momentum it is possible to obtain the IRC by the use of a space-fixed Cartesian coordinate system. All of the calculated examples mentioned previously belong to this case. However, in a reaction in which rotational motion exists, it is necessary to discuss the IRC after separating the nuclear configuration space from the rotational motion[74–77]. For this purpose it is essential to derive the general classical Hamiltonian of the reacting systems and then to separate the internal motion, which is determined only by the internal coordinates. The nuclear configuration space thus separated

out is, in general, a Riemann space. The classical Lagrangian form obtained in this process of constructing the Hamiltonian is used to derive the IRC equation for the case of rotational motion. It is thus understood that the rotational motion of the reacting system generally causes a deviation from the IRC[74].

Once the method of determining unique reaction pathways is available, the next problem we are concerned with is to see if the pathways calculated can be interpreted in terms of frontier orbital interactions. A method referred to as "interaction frontier orbitals" or "hybrid molecular orbitals" has been developed very recently by *Fujimoto* and I in order, once and for all, to provide a lucid scheme of frontier orbital interactions with the accuracy of nonempirical calculations[78–80]. By properly including contributions from MO's other than the HOMO and the LUMO, we realized in terms of orbital diagrams how ingenious the empirically established chemical concepts—"reaction sites" and "functional groups"— and the empirical concept of reaction pathways could be.

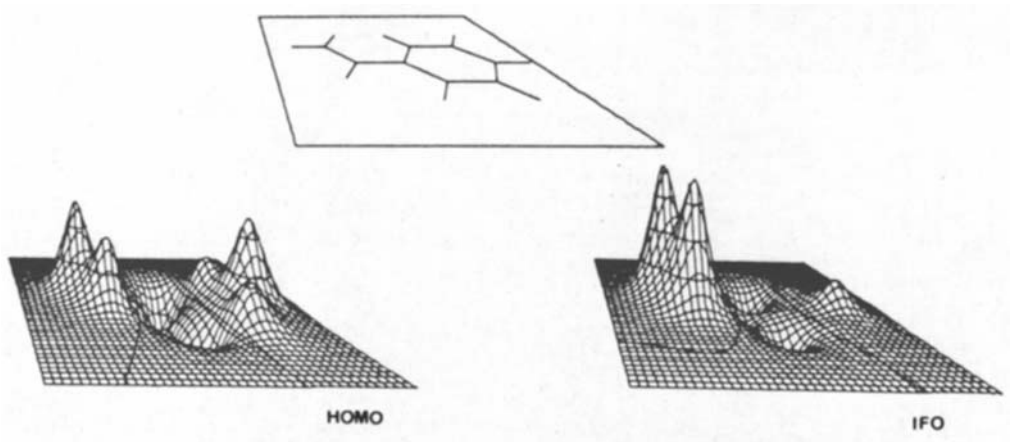


Fig. 5. Comparison of the HOMO and the IFO (interaction frontier orbital) for protonation of styrene.

Figure 5 compares the HOMO of styrene and its interaction frontier orbital (IFO) for protonation of the olefinic double bond. The latter is seen to be localized very efficiently at the site of chemical interaction. The double bond is evidently the functional unit in this case.

Innovation of the frontier orbital concept will hopefully be continued by young scientists to make it useful for one of our ultimate targets: theoretical design of molecules and chemical reactions.

Frontier Orbitals in Related Fields

Theoretical treatments of the properties of solid crystals, or chemisorption on a solid surface appear hitherto to have been almost a monopolistic domain of physics. But the orbital pattern technique has also advanced gradually into this field.

The "cluster approach"[81,82], in which a portion of the metal crystal in the form of a cluster of atoms is selected and its catalytic action or other properties investigated, has contributed to the development of the orbital pattern approach, because purely physical methods can hardly be applied to such large systems. It is expected that if clusters of various sizes and shapes are studied, the characteristic feature of their HOMO's (high-lying occupied MO's) and LUMO's (low-lying unoccupied MO's), the nature of chemisorption and catalytic action, the mode of surface chemical reactions, and several related subjects of interest will be able to be investigated theoretically.

As is the case with molecular interactions in normal chemical reactions, only the HOMO and LUMO bands lying in the range of several electron volts around the Fermi level can participate in the adsorption of molecules and surface reactions on solid crystals. You may recollect here that in the BCS (Bardeen-Cooper-Schrieffer) theory of superconductivity, too, only the HOMO's and LUMO's in close proximity to the Fermi surface are involved in the formation of electron pairs as the result of interactions with lattice vibrations. For solid catalysts the discrimination of particular orbitals and electrons from the others makes the situation much easier.

Consider a system composed of a regular repetition of a molecular unit, for instance, a one-dimensional high-polymer chain or a one-dimensional lattice, in which a certain perturbation is imposed at a definite location. Sometimes it is convenient to discuss the influence of this perturbation by transforming the orbitals belonging to the HOMO band to construct the orbitals localized at this site. One such technique was proposed by *Tanaka, Yamabe* and I[83]. This method is expected, in principle, to be applicable to a discussion of such "local" problems as the adsorption of a molecule on the two-dimensional surface of catalysts, surface reactions, and related matters. This approach may be a little more "chemical" than the method using the function of local density of states[84] or similar functions, in that the former can be used for the discussion of the reactivity of molecules on a catalyst surface in terms of the phase relationship of localized orbitals.

Low-dimensional semiconductors and some superconductors have also been the objects of application of the orbital argument. In these studies, the dimerization of S_2N_2 to S_4N_4[85] and its polymerization to high-polymeric $(SN)_x$[86] were discussed, and the energy band structure of the $(SN)_x$ polymer chain analyzed to investigate the stable nuclear arrangement and the mode of inter-chain interactions[87].

The modern techniques used in solid-state physics to interpret the interesting characteristic behavior of noncrystalline materials, in particular of amorphous materials in which the nuclear arrangements are not regular, are certainly striking. *Anderson* showed generally that in a random lattice system electron localization should take place[56]. *Mott* in his 1977 Nobel lecture, stated that he thought it the first prize awarded for the study of amorphous materials, and answered the question, "How can a localized electron become conducting?" using the concept of "hopping". Here, too, the HOMO-LUMO interaction—in this case the consideration of spin is essential—plays an important role.

In a few words I want to refer to the importance of virtual orbitals. The LUMO, which has held a key position in the orbital arguments hitherto discussed, is the virtual orbital which an external electron is considered to occupy if captured by a molecule to form an anion. Virtual orbitals always play an essential part in producing metastable states of molecules by electron capture[88]. To discuss such problems generally *Tachibana et al.*[89] systematized the theory of resonant states from the standpoint of the complex eigenvalue problem. The idea of resonant states will play a principal role in chemical reactions, particularly in high-energy reactions, which will be developed more in the future.

Prospects

In this article I have presented a series of recent results, largely from the studies carried out by our group, and have ventured to make those things the object of my talk which appear promising, but which are not yet completely established. In doing this my intention has been to stimulate the efforts of many younger chemists by specifying what fields I believe to be promising for the future.

In my opinion, quantum mechanics can make two different contributions to chemistry. Firstly, it permits nonempirical comprehension of experimental results. However, we should not overlook another important aspect: the promotion of empirical chemistry from the theoretical side. Here, also, reliable theoretical foundations and computational methods are required. The conclusions provided by theoretical considerations should be little affected by the degree of sophistication of the approximations used.

On the other hand, the contributions, made by theoreticians to the second aspect mentioned, in which predictions surpassing experimental accuracy are possible by very accurate calculations, are for the present limited to a very few, extremely simple molecules. In order to accomplish this objective for ordinary chemical problems, it is sometimes necessary to provide qualitative theories which can be used even by experimental chemists. If one can contribute nothing to chemistry without carrying out accurate calculations for each specific problem, one cannot be said to be making optimal use of quantum mechanics. It is certainly most favorable when the underlying concepts are as close to chemical experience as possible, but this sphere of experience is steadily expanding. Quantum chemistry has thus the task of furnishing useful concepts on a theoretical basis and of making them available to the experimental chemist.

Even the same atoms of the same element in different molecules show different behavior: the chemical symbol H seems to signify atoms of a completely different nature. In chemistry, this terrible individuality should never be avoided by "averaging", and, moreover, innumerable combinations of such atoms form the subject of chemical research, where it is not the "whole assembly of compounds of different kinds but each individual kind of compound" that is of chemical interest. As a consequence of this formidable complexity, chemistry inevitably depends on analogy through experience. This is in a sense the fate allotted to chemistry, and the source of its great difference from physics. Quantum chemistry, too, in so far that it is chemistry, is required to be useful in promoting experimental chemistry.

Acknowledgements

Lastly, I want to take this opportunity of mentioning the names of many members of my research group who have walked the same road as mine since my first paper (1952) on quantum chemistry, particularly Drs. *T. Yonezawa, C. Nagata, H. Kato, A. Imamura, K. Morokuma, T. Yamabe,* and *H. Fujimoto,* and also the scientists mentioned in the text who made contributions in opening up new aspects in this field. Among them, Prof. *T. Yonezawa* was helpful in performing calculations in our 1952 paper. It is to be mentioned with appreciation that the attractive title "frontier orbitals" of my lecture originated from the terminology I adopted in that paper upon the suggestion of Prof. *H. Shingu,* who as an organic chemist participated by classifying the relevant experimental results. Furthermore, many other young collaborators are now distinguishing themselves in other important fields of chemistry, which, however, have not been the object of this article.

It was the late Prof. *Yoshio Tanaka* of the University of Tokyo and Prof. *Masao Horio* of Kyoto University who recognized the significance of my early work. I owe such theoretical work, which I was able to carry out in the Faculty of Engineering, Kyoto University and in the Department of Fuel Chemistry, to the encouragement and kind attentiveness of Prof. *Shinjiro Kodama,* who fostered the Department. What is more, it was the late Prof. *Gen-itsu Kita,* my life-teacher and founder of the Department, who stimulated me to enter chemistry, one of the most attractive and promising fields of science. For all of these people no words of gratitude can be sufficient to express my thanks.

From Isocyanides *via* Four-Component Condensations to Antibiotic Syntheses**

By Ivar Ugi*

In memoriam Otto Bayer

The four-component condensation of amines and carbonyl compounds with isocyanides[***] and suitable acid components (water, thiosulfuric acid, hydrogen selenide, hydrogen azide, cyanic acid, thiocyanic acid, carboxylic acids, methyl hydrogen carbonate) to form α-amino acid derivatives was discovered in 1959. This reaction principle shares some features with the Strecker synthesis and the Passerini reaction. The four-component condensation affords easy and effective one-pot synthesis of complex molecules from simple building blocks. Only in recent years, however, have the preparative advantages of the four-component condensation been exploited by numerous authors in the synthesis of diverse natural products and related compounds, although many of the possibilities opened by this principle were recognized more than two decades ago. In this progress report some instructive syntheses of various antibiotics are reviewed. The design of each of these syntheses involves a four-component condensation as key step, by means of which lengthy sequences of reactions are avoided, which otherwise would be required to achieve the synthetic goal.

1. Introduction

The essential reactions of the simple functional groups have long been known. Almost all basic types of organic compounds were thoroughly studied by the classical organic chemists in the last century. The isocyanides **1** and the isocyanates **2**, close chemical relatives, are among the exceptions. For a long time, relatively little research was carried out on either class of compounds, and it was comparatively late that they received the attention they deserve.

1 **2**

The chemistry of the isocyanates began to gather momentum in the late thirties, when *Otto Bayer* initiated an intense exploration of these hitherto practically neglected compounds. With great vision he then created the conceptional foundations of polyurethane technology: this is based on isocyanate chemistry and the polyaddition principle, recognized by *Bayer* as a means of synthesizing macromolecules. *Bayer* thus triggered a unique development to which the isocyanates owe their present eminent scientific, technological, and commercial importance.

Systematic investigation of the isocyanides[1] began about 1960. Most of the isocyanide reactions on which synthetic methods are based were discovered only in the last decade. Examples are the reactions of the α-metalated isocyanides by *Schöllkopf et al.*[2], *van Leusen*'s "TosMIC chemistry"[3], and the aldehyde-ketone syntheses of *Walborski et al.*[4].

In the meantime, isocyanides have become a household word in preparative organic chemistry, although it is not long ago that they were seen as exotic compounds, useless for synthetic purposes. Just a few years ago the reviewer of an article about preparative uses of isocyanides[5] called it "intellectually rewarding"—probably a well-meant and courteous circumscription for "an academic topic without practical consequences". However, the isocyanides have finally come into their own as preparative reagents, as demonstrated by the syntheses reviewed in this article.

Why was it more than a hundred years from the discovery of the isocyanides[1a,6] to the true dawning of their chemistry, although many interesting reactions have long been known or predictable? The main reason was probably the lack of preparative access to pure isocyanides in high yield until the advent of modern methods for their preparation[1b]. The classical isocyanide syntheses—the "carbylamine reaction" of *A. W. Hofmann*[7] and the synthesis of isocyanides by alkylation of silver cyanide according to *Lieke*[6] and *Gautier*[8]—are of little use for the preparation of pure isocyanides. The efficient modern syntheses of the isocyanides are based on the dehydration of *N*-monosubstituted formamides. As early as 1867 *Gautier*[9] attempted to convert the latter into isocyanides by allowing them to react with P_4O_{10}. He did not succeed, because he had overlooked the fact that isocyanides are acid sensitive. The synthesis of isocyanides from *N*-monosubstituted formamides proceeds well only when the acid-forming dehydrating agents, such as arenesulfonyl chlorides[10], phosphorus oxychloride[11], sulfonyl chloride[12], or phosgene[13], are used in the presence of bases.

The "phosgene procedure", which is carried out in the presence of triethylamine, dimethylaniline or aqueous bases[14], is generally the method of choice. The phosgene can be substituted by "diphosgene"[15], which has recently

Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] Extended version of a lecture delivered at a scientific colloquium in honor of Professor *Otto Bayer* on November 4, 1982 in Leverkusen.

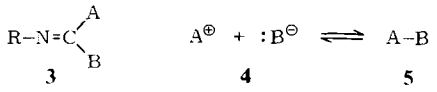
[***] Previously, isocyanides were almost always referred to as isonitriles. However, according to IUPAC Rule C-833.1 only the name "isocyanides" is permissible.

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/1111-0810 $ 02.50/0

become readily available[16]. Diprotonated carbonyldiimidazole is useful as a substitute for phosgene in the preparation of base-sensitive isocyanides in small quantities[17].

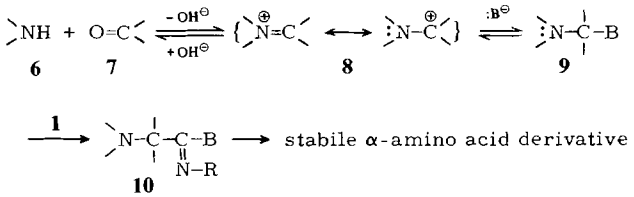
The formal divalency of the isocyanide carbon atom is responsible for the peculiarities of isocyanide chemistry. The formation of isocyanides is generally accompanied by conversion of tetravalent into divalent carbon, and most reactions of the isocyanides begin with an α-addition **1**→**3**, *i.e.* conversion of a divalent into a tetravalent carbon atom[1].

The pronounced ability of isocyanides to participate in multicomponent reactions is based on the α-addition of electrophiles and nucleophiles which may be involved in the equilibrium **4** ⇌ **5**.



3 **4** **5**

The majority of the classical multicomponent reactions, such as the Mannich condensation and the Strecker synthesis, are α-amino-alkylations[18]. These proceed *via* iminium ions, highly reactive electrophiles capable of existing as "equilibrium species" in media of low acidity. Thus, they qualify as reaction partners for the acid-sensitive isocyanides.

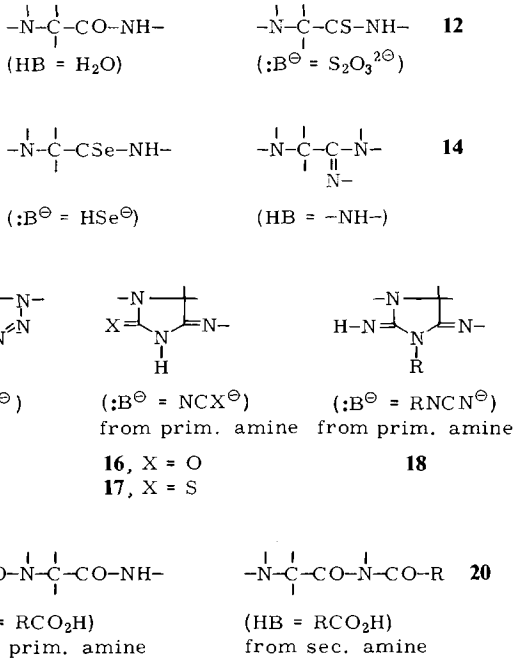


6 **7** **8** **9** **1** **10**

There are many nucleophiles ($:B^{\ominus}$) whose α-aminoalkylation, **8**→**9**, is reversible. Reversible α-aminoalkylation systems are generally able to react with isocyanides **1** to form labile α-adducts **10** which undergo spontaneous rearrangement to afford stable α-amino acid derivatives[1d, 19–29].

We use the term four-component condensation[22] for those reactions whose products are formed *via* α-addition of an iminium ion and a nucleophile to an isocyanide, followed by a secondary reaction of the α-adduct formed (cf. **21** + **22** + **23** + **24**). As a synthetic principle, four component condensation affords simple one-pot syntheses of a large variety of compounds, whose syntheses by alternative methods would generally require complex, multistep sequences of synthetic reactions[21]. Formulas **11**–**20** represent those classes of compounds available *via* four-component condensation of ammonia, primary and secondary amines, or hydrazine derivatives, and carbonyl compounds with isocyanides and suitable acidic components or their anions, such as water, thiosulfate, hydrogen selenide, dimethylamine[23], azide, cyanate, thiocyanate, carboxylic acids, and monoalkyl carbonates[1d, 21].

The nature of the products is primarily determined by the acidic component HB or its anion $:B^{\ominus}$. However, in the case of some acidic components (see **19** and **20**) the essential structural features of the product also depend on whether the amine component is primary or secondary.



11 (HB = H_2O) **12** ($:B^{\ominus}$ = $S_2O_3^{2\ominus}$)

13 ($:B^{\ominus}$ = $HSe^{\ominus}$) **14** (HB = –NH–)

($:B^{\ominus}$ = $N_3^{\ominus}$) **15**

($:B^{\ominus}$ = $NCX^{\ominus}$) from prim. amine **16**, X = O **17**, X = S

($:B^{\ominus}$ = $RNCN^{\ominus}$) from prim. amine **18**

19 (HB = RCO_2H) from prim. amine **20** (HB = RCO_2H) from sec. amine

The first four-component condensations, involving rather simple components, were carried out in methanol, and their products were isolated without recourse to chromatographic methods. Since these experiments generally resulted in high yields of products without significant detection of by-products, the initial impression was that all reversible side reactions were suppressed by a large thermodynamic driving force, and that hardly any irreversible side reactions occur[21]. Model experiments carried out later in which reactants and reaction conditions were widely varied indicated, however, that four-component condensations do indeed compete with a variety of irreversible side reactions which impair their yield[29]. Over the years, however, it was also found that the competing side reactions can, as a rule, be avoided with a good understanding of the reacting system. For a given four-component condensation, it is usually possible to find—through systematic model experiments—some conditions under which an excellent yield can be obtained. This optimum yield is, however, only obtained when the optimum conditions—including the precise concentrations of the reactants and additives[25]—are carefully observed. Most of the four-component condensations proceed in 75–95% yield, if the Schiff base of the enamine of the amine and carbonyl components, as well as the acid component are allowed to react in a 1 : 1 molar ratio in stirred concentrated methanolic solution with the isocyanide at 0 °C[1d, 27].

Based on the available data[25], mechanistic steps of third or higher order do not take part in the reaction mechanism of four-component condensations. Under a wide variety of conditions the mechanism of the four-component condensation is a complex system of consecutive and parallel first and second order reactions. Those steps in which only the amine, carbonyl and acid component participate are reversible, whereas those steps in which the isocyanide takes part are irreversible[25].

The scope and limitations of the four-component condensation and its reaction mechanism, as well as its de-

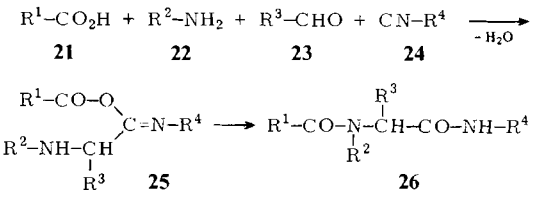
pendence on reaction conditions[1d,25,27] were, however, first studied systematically after 1962, when I moved from Universität München to the Wissenschaftliches Hauptlaboratorium of Bayer AG at Leverkusen, which was then under the directorship of *Otto Bayer*. His active interest in this topic, his critical participation in discussions, his constructive ideas, and the intellectually stimulating atmosphere of the laboratory, which was strongly determined by *Bayer*'s personality, not only profoundly influenced, helped, and stimulated the investigations of my research group in Leverkusen until 1968, but also far beyond: this period at Leverkusen is also the origin of other major research topics and areas of interest of the present author. They all began as auxiliary projects, corollaries and "fallout" from the four-component condensation, and its most obvious and important application, the synthesis of peptides[27-29]. This in turn is the source of the preparative[30] and theoretical investigations on stereochemistry[31-38] and chirality[34,35], as well as the later work on permutation isomers[36] and their mutual interconversions[37]. These led *via* hyperchirality[38] to the theory of the chemical identity group, a unified perspective of static and dynamic stereochemistry as a whole[39].

The computer assisted efforts towards understanding the mechanism of the four-component condensation[25], in order to make best use of it synthetically, led *Günter Kaufhold* and myself to design and implement the Leverkusen peptide synthesis planning program[40,41], an intellectual ancestor of the theory of the *BE*- and *R*-matrices[42], and to develop the concepts, algorithms, and computer programs for the deductive solution of a great variety of chemical problems[43], which are based on this unified theory of constitutional chemistry.

Last, but not least, some of our experimental work deserves mention, whose origin and motivation also stems from the four-component condensation: the chemistry of the α-ferrocenylalkylamines and related compounds[44], which serve as chiral auxiliary materials in the synthesis of peptide segments by the four-component condensation[29], the studies on functionalized polymers[45], and the development of new protective groups for the four-component synthesis of peptide segments. Later, this work led to the development of protective groups that can be selectively cleaved by Co^{I} phthalocyanine in neutral solution: these are used in peptide and oligonucleotide synthesis[47]. Even our work on phosphorus chemistry[48] is a consequence of the four-component condensations, *via* the related stereochemical studies[37].

2. Four-Component Condensation of Carboxylic Acids and Primary Amines with Aldehydes and Isocyanides

The reaction of primary amines **22** and aldehydes **23**—or better still, the Schiff bases of **22** and **23**—with carboxylic acids **21** and isocyanides **24** leads *via* the α-adducts **25** to the α-acylamino carboxylic acid amides **26**[1d,21,25-29] From a mechanistic standpoint (cf. [36]), and according to the essential structural features of the products **26**, this type of four-component condensation may be viewed as a "cross-breed of the α-aminoalkylation[18] with the Passerini reaction[1c].

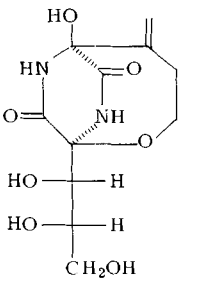


This variant of four-component condensation opens up new ways of synthesizing many natural products and their analogs, including numerous antibiotics and their precursors.

Various syntheses of antibiotics have recently been reported in which a four-component condensation of the last mentioned type plays a key role. These syntheses, with the exception of syntheses of peptide antibiotics, are reviewed in this article.

3. Bicyclomycin

Bicyclomycin, **27**, an antibiotic which is active against gram negative bacteria, has been isolated in crystalline form from culture filtrates of *Streptomyces sapporonensis*[49]. Its unusual structure, as elucidated by X-ray crystallography[50], and its promising antibiotic profile[51] make its synthesis a challenge[52,53].



27

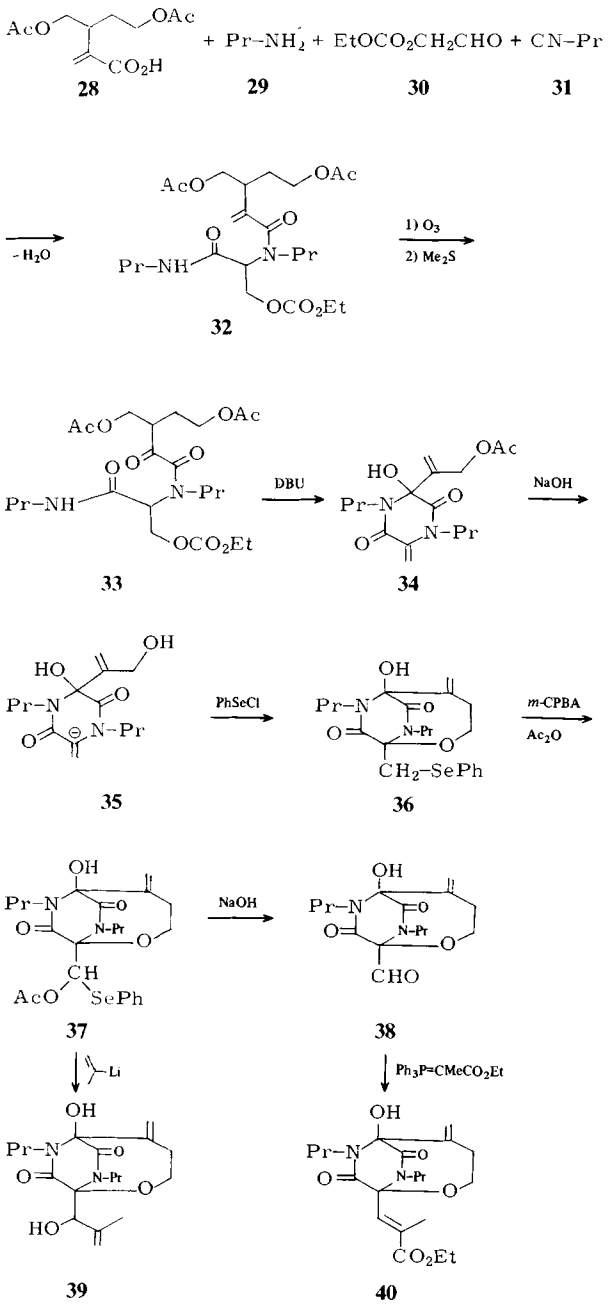
Fukuyama, Robins, and *Sachleben*[52] have recently performed an impressive synthesis of **39** and **40**, which can be seen as a model and a precursor of a total synthesis of **27**. The formation of **32** by four-component condensation of **28** to **31** to give the polyfunctional compound **32** is a key step (DBU = diazabicyclo[5.4.0]undecene[54], *m*-CPBA = *m*-chlorobenzoic acid).

According to *Fukuyama et al.*[52] this approach provides an access not only to bicyclomycin, but also to a variety of analogous compounds. Their structure is predetermined by the educts of the initial four-component condensation.

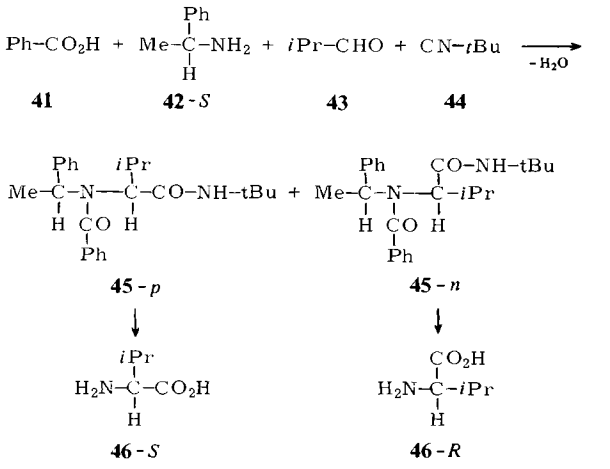
4. Asymmetrically-Induced Four-Component Condensation and the Synthesis of Furanomycin

As a model reaction for the asymmetrically-induced synthesis[35,55] of chiral amino acid and peptide derivatives, the formation of **45-*p*** and **45-*n*** by four-component condensation of **41** to **44** has been thoroughly studied[1d,25,27].

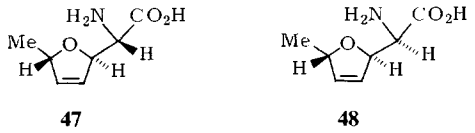
The ratio Q_{pn}[56] of the products **45-*p*** and **45-*n*** depends strongly on the reaction conditions[25,27]. Computer-assisted analysis of Q_{pn} as a function of the concentrations of



the starting materials **41** to **43** in methanol at 0 °C revealed that four competing pairs of corresponding reactions, *i.e.* pairs of reactions whose products and transition states are stereoisomeric, are involved. These four pairs of reactions differ with respect to their formal reaction order[25], and correspond to four competing reaction mechanisms. The observable overall stereoselectivity results from the concentration-dependent relative contribution of the individual pairs of corresponding reactions[31,32], each of which has its characteristic concentration-independent "intrinsic" stereoselectivity[41]. The relative yield of a given stereoisomer is maximized if conditions prevail under which that pair of corresponding reactions dominates whose "intrinsic stereoselectivity" most favors this stereoisomer. Moreover, the contributions of the unfavorable pairs of corresponding reactions must be minimized.

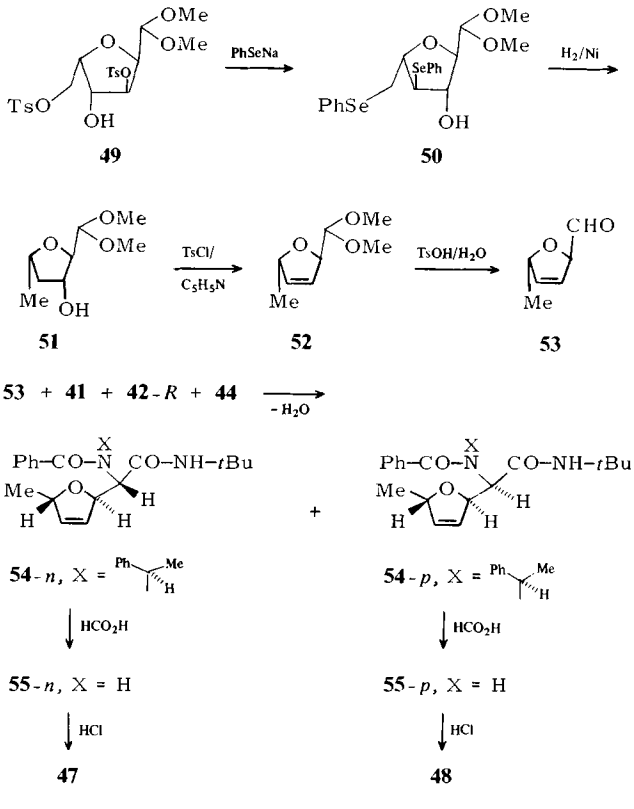


The results of the above model experiments were used by *Joullié et al.*[57b] in their synthesis of (+)-furanomycin **47** and related compounds. *Katagiri et al.*[58] isolated the



antibiotic furanomycin **47** from culture filtrates of *Streptomyces threomyceticus* and assigned to it the structure **48** based on spectroscopic data. Later, on the basis of NMR data[57-59] and preparative results[57,60], which were obtained partly *via* four-component condensations, the corrected structure, **47**, or (+)-furanomycin was obtained.

An elegant stereoselective four-component synthesis of (+)-furanomycin by *Joullie et al.*[57b], that was carried out in several variations, starts from D-glucose, which is converted into the aldehyde **53** *via* **49**. The four-component

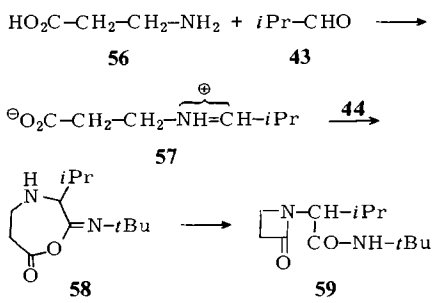


condensation of **53** with **41**, (*R*)-α-phenylamine **42-*R***, and *tert*-butyl isocyanide **44** yields **54-*n*** and **54-*p***. Acidolysis of **54-*n*** with formic acid leads to **55-*n***, whose hydrolysis affords **47**.

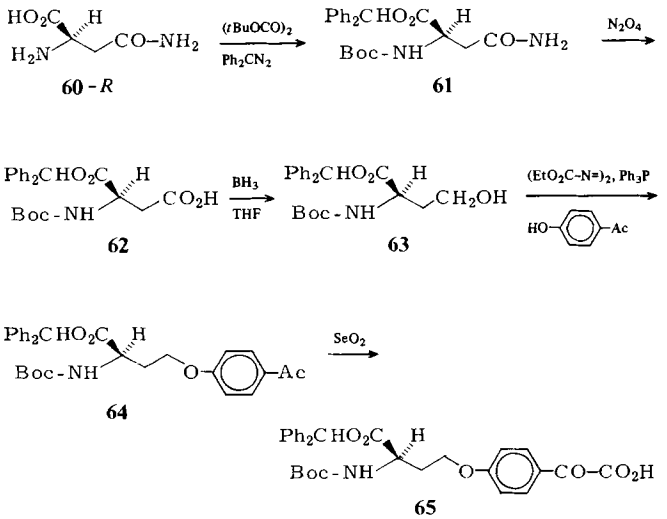
5. Nocardicin and Analogs

The recent literature indicates that interest in the β-lactams is still increasing[61], because of their outstanding antibiotic properties and few undesirable side effects. Even monocyclic β-lactams with noteworthy antibiotic activity have been found. In 1976 some Japanese authors[62,63] isolated nocardicin A, **75**, the first monocyclic β-lactam with potentially useful antibacterial properties. Together with six analogs, the nocardicins B—G[64], it occurs in the culture broths of *Nocardia uniformis*.

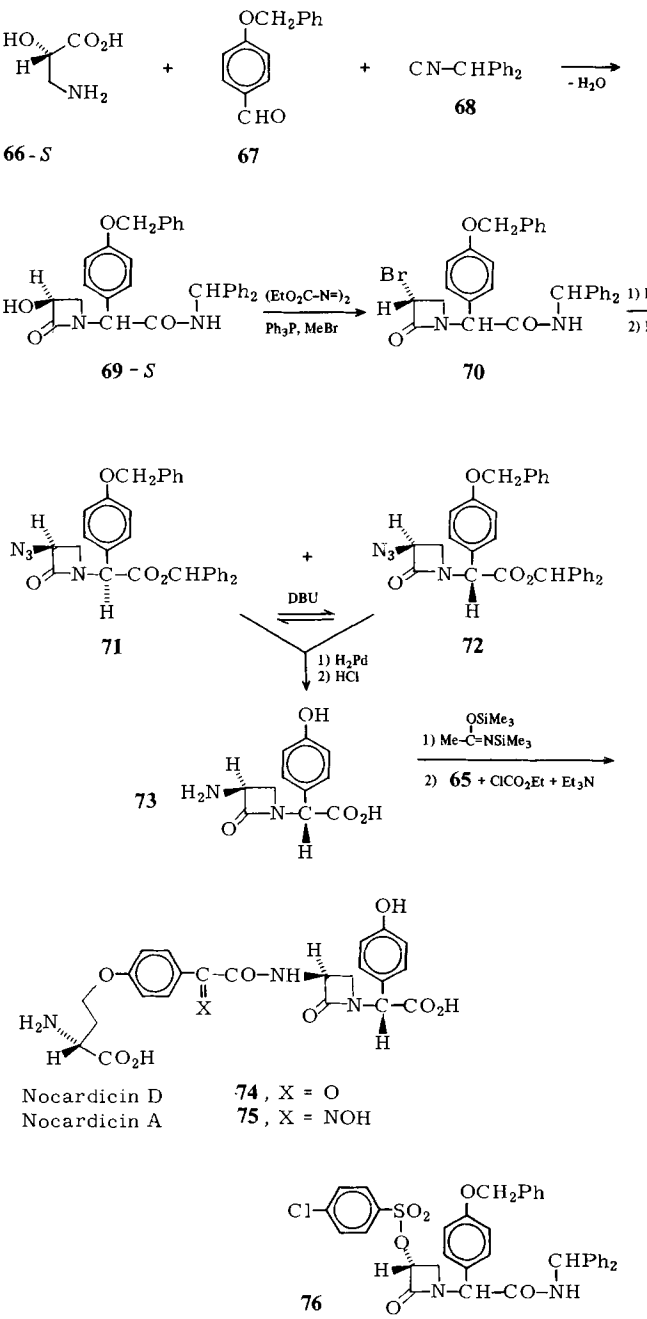
The formation of four-membered rings by cyclization of acyclic precursors is generally impeded by Baeyer strain and conformationnal effects; hence, formation of β-lactams from β-amino acids is not easy[65]. However, conversion of β-amino acids into β-lactams by four-component condensation proceeds smoothly, as a rule, in very good yields[1d,26,66]. For example, the difunctional **56** reacts smoothly with **43** and **44** in methanol to form **59**[1d,26].



In the synthesis of β-lactams by four-component condensation a seven-membered ring (cf. **58**) is formed, which closes relatively easily. The β-lactam system (cf. **59**) is obtained from the α-adduct by a secondary transannular *O,N*-acyl transfer.



Nocardicin A, **75**, has already been synthesized by conventional methods[67]. The advantages offered by four-component condensation for the synthesis of β-lactams were used impressively by *Isenring* and *Hofheinz*[68] at the Hoffmann-La Roche laboratories in their synthesis of 21

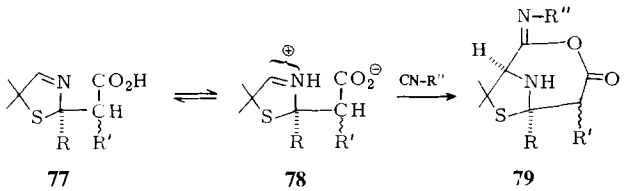


nocardicin analogs[68a]. As examples, we select the syntheses of nocardicin D, **74**, and A, **75**. The acid **65**, required for the last step, is first prepared from D-asparagine **60-*R***. An important step following the four-component condensation to **69-*S*** is the conversion of **71** into **72** by diazabicycloundecane[54]. **69-*R***, obtained analogously to **69-*S***, reacts *via* **76** to afford **71** and **72**.

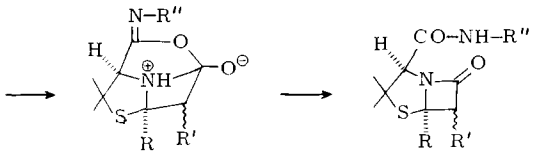
In this context the four component synthesis of 3-aminonocardinic acid by *Hatanaka et al.*[69] also deserves to be mentioned.

6. Penam Derivatives

The first preliminary studies towards the synthesis of penicillin derivatives by four-component condensation were carried out more than 20 years ago by *Ugi* and *Wischhöfer*[70]. 3-Thiazoline derivatives **78**, prepared by Asinger condensation[71] of β-oxoesters, ammonia and α-mercaptoisobutyraldehyde, and subsequent ester hydrolysis, were allowed to react with isocyanides in the two-phase system water/petroleum ether to afford the penam derivatives, **81**. Despite the general lability of penam derivatives, the products **81** could be purified by sublimation *in vacuo*. This four-component condensation proceeds *via* the bicyclic α-adduct **79**, in which, due to strain, the seven-membered ring can only be *cis*-annelated. Thus, in **81** the β-lactam moiety and the carbamoyl group must be *cis*-related.



77 **78** **79**



80 **81**

a, R = H, R′ = Me; **b**, R = Me, R′ = H

Using a similar route *Sjöberg*[72] obtained the amide of a stereoisomer of penicillin G, but in very low overall yield, because formation of the required 3-thiazoline derivative by Asinger condensation did not proceed satisfactorily.

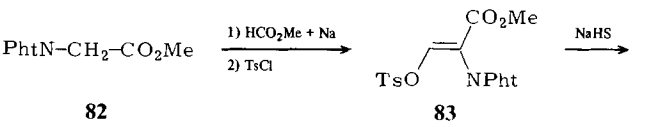
Schutz and *Ugi*[73] found the route **82** → **86** to 3-thiazoline derivatives, which can be converted into 6-aminopenam derivatives or their stereoisomers. Here, as also in the synthesis of cepham derivatives (see Section 8), the thienolate **84** is the key intermediate (Pht = phthaloyl).

Demethylation of **86** by LiI in dimethylformamide and pyridine gives **87**, whose four-component condensation with **44** in water/dioxane produces **88**. According to NMR results the asymmetric C-atoms in the β-lactam moiety of **88** have the same configurational relationship as in the natural penicillins.

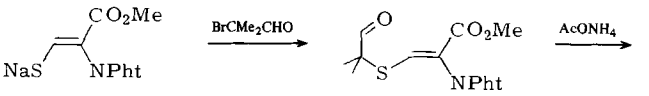
The conversion of **88** into penicillin G would require substitution of the phthalimido by a phenylacetamido group, as well as that of the *trans*-carbamoyl by a *cis*-carboxy group. All these operations are possible, but their execution on the penam system requires further model experiments. Analogous considerations apply to the synthesis of the cephalosporins (Section 8).

7. Carbapenem Derivatives

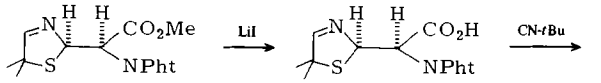
Thienamycin **90** and related carbapenem derivatives are distinguished by outstanding antibiotic activity[74]; accordingly, their syntheses deserve particular attention[75].



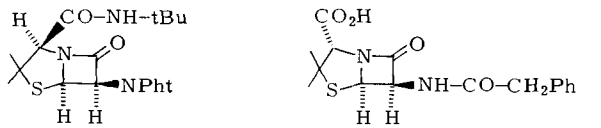
82 **83**



84 **85**

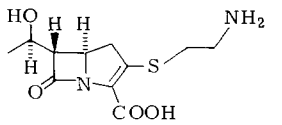


86 **87**

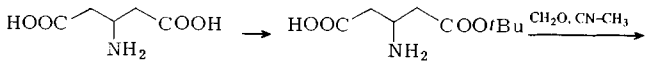


88 **89**

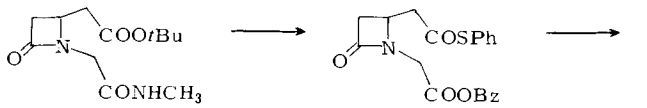
Hatanaka et al.[76] recently reported a synthesis of **96**. In its relative brevity, this synthesis sets new standards for the carbapenem field. The key step is a four-component con-



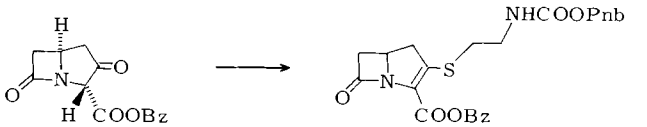
90



91 **92**



93 **94**



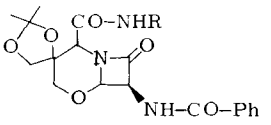
95 **96**

densation of **92** with formaldehyde and methyl isocyanide yielding **93**. A modified Dieckmann condensation **94** → **95** and subsequent condensation of **95** with protected cysteamine leads to **96** (Pnb = *p*-nitrobenzyl, Bz = benzyl).

The authors indicate that an analogous total synthesis of the thienamycin **90** is well underway.

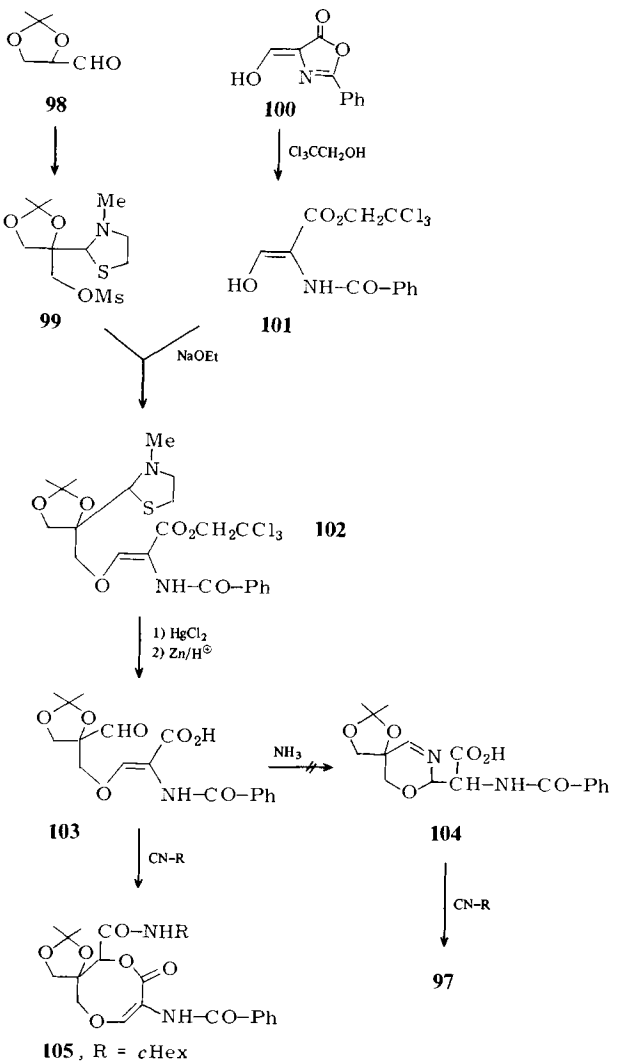
8. Cepham Derivatives and Related Compounds

Just et al.[77,78] attempted the synthesis of the oxacepham derivatives **97** as outlined below. This synthesis was planned as a model for analogous syntheses of cepham derivatives, and its conceptual design is ingenious and convincing.

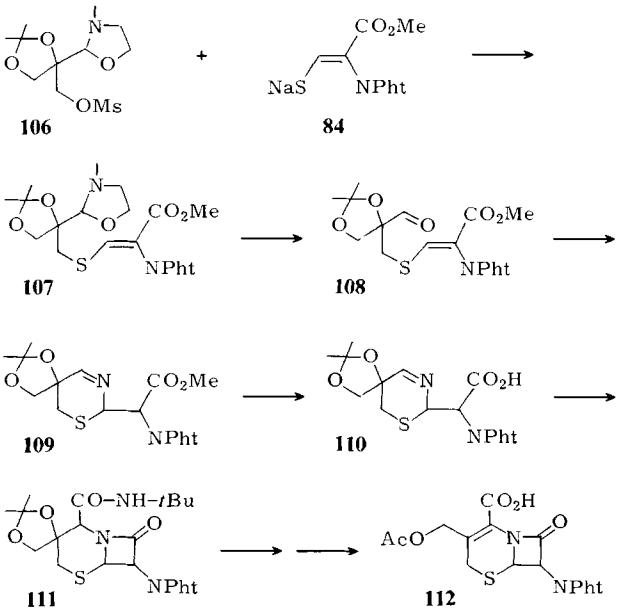


97, R = Et, *c*Hex

The synthesis starts from mannitol diacetonide, from which the glyceraldehyde acetonide **98** is obtained by oxidative glycol cleavage. The latter is converted into **99** by condensation with formaldehyde, subsequent protection of the aldehyde function with *N*-methyl cysteamine and, finally, reaction with methanesulfonyl chloride. The 4-hydroxymethylene-5-oxazolone **100** and trichloroethanol react to give **101**, whose sodium enolate reacts with **99**, yielding **102**. The labile aldehyde **103** is obtained by reductive cleavage of the trichloroethyl group and deblocking the aldehyde group by mercury(II) chloride. Aldehyde **103** was allowed to react *in situ* with ammonia and isocyanides in the hope that it would form a dihydroxazine derivative **104**, whose four-component condensation with an isocyanide ought to yield **97**. Instead, a Passerini reaction[1c] takes place between **103** and the isocyanide to form **105**[78].



Presumably discouraged by this result of their model study, *Just et al.*[78] seem to have abandond their planned synthesis of cepham derivatives. Their synthetic concept is by no means unrealistic, and after minor modification could well be realized (see **106**—**111**). After the successful synthesis of some penam derivatives we[79] took note of the concept of *Just et al.*[77,78] profiting considerably from their ideas and results. The thioenolate **84**, which had already proved its value in the penam synthesis[73], was allowed to react with the mesylate **106**, a reaction already described by *Just et al.*[77] in 1973. Treatment of the resulting product,



107, with aqueous acetic acid yields the aldehyde **108**, and when a slow stream of ammonia is passed over a stirred solution of this in tetrahydrofuran at 0 °C, the tetrahydrothiazine derivative **109** is formed: from this, **110** is obtained by demethylation. Its reaction with *tert*-butyl isocyanide leads to the cepham derivative **111**, whose essential configurational relations correspond to those of the natural cephalosporins, according to NMR data. It is intended to convert **111** or some analog obtained by four-component condensation into a cephalosporin **112**.

9. Perspectives

Although the four-component condensation, its versatility and most of its preparative advantages have been known for more than two decades[19], practitioners of organic synthesis have not made much use of it until recently. In many areas the required "supporting chemistry" has only been developed in recent years. For example, twenty years ago it was known that stereoselective four-component condensations are, in principle, useful for the synthesis of peptide segments[29]; however, syntheses of this type

did not become practicable until chiral α-ferrocenylalkylamines became accessible *via* the "Mannich condensation with exchanged roles"[44c], and subsequent resolution of the enantiomers with the aid of (−)-diisopropylidene-2-oxo-L-gulonic acid[80] became feasible. The facile recovery of the chiral amine components of such peptide syntheses[81] also had to be solved. Furthermore, were it not for the non-linear stereoselectivity effect of destructively selective reactions[33,35,83], discovered in 1975, stereochemically pure peptide segments could hardly have been synthesized by four-component condensation. The development of novel protective and auxiliary groups which can be removed by Co^{I} supernucleophiles[47] may also prove to be essential.

For some synthetic goals, four-component condensation has given rise to a shift in emphasis. In the synthesis of β-lactam antibiotics by conventional methods, construction of the β-lactam moiety is the central issue. However, in syntheses using the four-component condensation, the β-lactam part of an antibiotic only receives attention because of its lability towards acids and bases.

Progress in understanding the mechanism of the four-component condensation and its side reactions[29] will extend its applications. Studies of this type may lead to the selection of reaction conditions under which the formation of by-products is practically avoided, and the desired product—and if need be one of several stereoisomers—is obtained in maximum yield and purity.

It is foreseeable that the scope and efficiency of four-component condensations will grow with the development of new reagents and techniques. The following comments on the syntheses of antibiotics reviewed in this progress report may illustrate and support this statement.

Alkylamines and alkyl isocyanides, whose alkyl group can be selectively cleaved under mild conditions may, for example, be useful for the synthesis of bicyclomycin **27** and related compounds.

Straightforward syntheses of the nocardicins (*e.g.* **74**, **75**) would be possible if a derivative of L-α,β-diaminopropionic acid with a suitably protected α-amino group, such as **113**, where available.

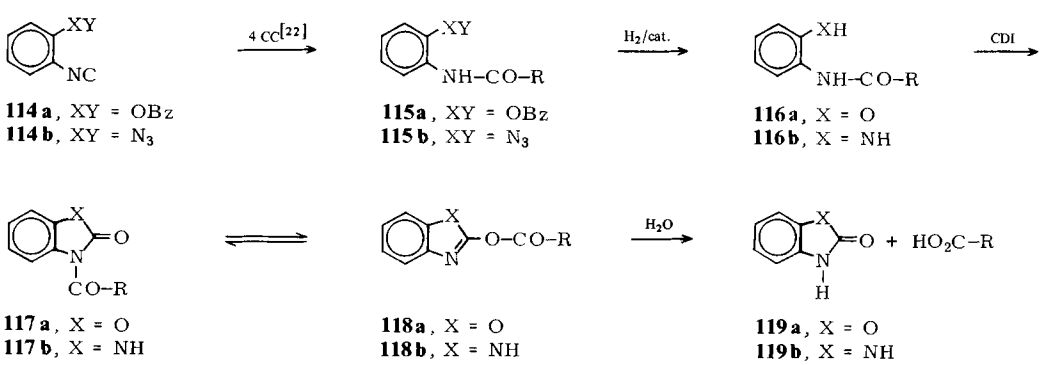
113

Since azidoacetaldehyde has recently become available[82], the synthesis of **113** should be feasible from a condensation product of the following four-components: *tert*-butyl monophthalate, azidoacetaldehyde, (*R*)-α-ferrocenyl-isobutylamine[44b], and an isocyanide with a selectively cleavable carbamoyl group.

The synthesis of furanomycin **47** and related compounds can probably be improved by using a chiral α-ferrocenylalkylamine as the asymmetrically inducing amine component, and by combining a productively stereoselective four-component condensation with a destructively stereoselective cleavage of the chiral auxiliary group[83].

The synthesis of β-lactam antibiotics by four-component condensation requires the conversion of the carboxylic acid amide group originating from the isocyanide component into a free carboxy group. Neither the cleavage of amides by nitrosation, used by *Isenring* and *Hofheinz*[68] in their synthesis of nocardicin nor the imidochloride method used by *Hatanaka et al.*[76] is universally applicable. Accordingly, the cleavability of the *o*-hydroxy- and *o*-aminoanilides **116a** and **116b**, respectively, by acylating derivatives of carbonic acid, such as carbonyldiimidazole (CDI)[84], is leading to novel β-lactam antibiotic syntheses *via* four-component condensation. *Kametani et al.*[85] have recently demonstrated that the racemate of an (α-branched) β-amino-β′-hydroxycarboxylic acid can be synthesized *via* diastereoselective 1,3-dipolar cycloaddition of a nitrone to some alkyl crotonates, and subsequent hydrogenolysis of the resulting isoxazoline derivative. This could serve as the starting material for a synthesis of racemic thienamycin **90** by a four-component condensation. If a chiral nitrone with powerful asymmetric inducing power were used in an analogous synthesis, a chiral β-amino-β′-hydroxycarboxylic acid would be formed, which in combination with the results of *Hatanaka et al.*[76] and amide cleavage according to **114** → **119** could be the basis of the conceivably most effective synthesis of thienamycin **90**. Since on the one hand it can be anticipated that thiemycin will not be produced microbiologically, and on the other that, because of the particularly favorable profile of this class of substances, one of its derivatives will find a place in the clinic, the thienamycin synthesis outlined could become the most important application of the four-component concensation in the near future.

Progress in isocyanide chemistry is dependent, to some extent, on the development of an "imbedding chemistry" as illustrated by the examples of advances in the area of antibiotics discussed here. Isocyanide chemistry still has ample virgin territory at its frontiers. Further advances will, however, only lead to optimum success if isocyanide chemistry and the rest of organic chemistry are well interfaced.



The financial support of the work of our group in this field by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Tricyclo[3.3.0.0^{2,8}]octan-3-ones: Photochemically Prepared Building Blocks for Enantiospecific Total Syntheses of Cyclopentanoid Natural Products

By Martin Demuth* and Kurt Schaffner*

Dedicated to Professor Oskar Jeger on the occasion of his 65th anniversary

Bi- and tricyclopentanoid natural products have been in the focus of synthetic interest in recent years. With widely applicable building blocks lacking, most work has been restricted in the past to specific approaches to single racemic target structures. A novel concept is now presented which uses for the first time a simple building block, tricyclo[3.3.0.0^{2,8}]octan-3-one, providing enantiospecific access to diverse cyclopentanoid structures. Tricyclooctanone is obtained in a few steps and in high yield from benzene, *via* the triplet-sensitized oxa-di-π-methane rearrangement of bicyclo[2.2.2]octenone as a photochemical key reaction. Smooth preparations of both enantiomers are possible by resolving the racemic mixture and of the bicyclooctenone. Owing to its structural properties the tricyclooctanone undergoes a wide array of regio- and stereoselective transformations in high yields, in compliance with the expectations for a synthetic key compound of general applicability. The total syntheses of boschnialactone, allodolicholactone, irido- and isoiridomyrmecin, and loganin aglucone 6-acetate provide the first examples of successful applications. Promising entries to coriolin, 6a-carbaprostacyclin and homologs, and 6,11-dehydroestrone complement this review of the potential of tricyclooctanone as a versatile building block for the enantiospecific total synthesis of polycyclopentanoids and related compounds.

1. Introduction

In recent years a remarkable number of natural products has been isolated which belong to the group of compounds containing a cyclopentanoid carbon skeleton. Several of these have proven to possess biological activities of pharmacological interest. This has stimulated interest to prepare such substances synthetically and to meet the methodological challenge of constructing bi- and tricyclopentanoid skeletons, and of achieving selective functionalizations of such systems. The area is relatively undeveloped and has therefore been in the forefront of research interest for several years.

Scheme 1 presents a characteristic selection of intermediates and building blocks which have so far been used in the synthesis of cyclopentanoid compounds. It is evident that, in general, building blocks with a broad range of applications have been lacking and that the synthetic goals have been restricted to racemic end products only—with exception of the single case ⑩, which, with an enantiomeric excess of merely 40%, is still far from satisfactory. In connection with ⑩ it should be noted that the Robinson annelation, which is a highly enantioselective alternative for six-membered ring systems in the presence of chiral bases, is not applicable to five-membered ring systems[17].

As shown by the transformations ① and ②, transannular reactions on eight-membered rings were used to construct bicyclo[3.3.0]octane derivatives[1,2]. The condensation ③[3] of ketoglutaric acid ester was utilized, *e.g.*, with biacetyl (R = CH_3)[4] in the synthesis of (±)-gymnomitrol, and with glyoxal (R = H)[5] for the synthesis of 6a-carbaprostacyclin[6]. A [2+2] ketene addition and subsequent extension of the four-membered ring ④ provided a route to (±)-hirsutene[7]. In far more cases, enones and enediones served as building blocks. Thus, the syntheses of (±)-hirsutene[8] (*via* ⑤[9]), members of the (±)-pentalenolactone group (*via* ⑥[10]), (±)-isocomene[11] (*via* ⑦[12]), (±)-quadrone (*via* ⑧, R = $CHCH_2$[13], R = CH_2CH_2Br[14]), and (±)-coriolin (*via* ⑨[15] and ⑩[16,18]) have been reported.

The examples given in Scheme 1 illustrate the general tendency, which is also shown by numerous other studies[19-23], to concentrate on synthetic approaches, each designed specifically for a single target structure. A more far-reaching concept which evolves from a central key reaction and is applicable to structurally diverse classes of compounds, is represented only by transformation ⑩.

2. The Concept

The following concept is the first to open an enantio*specific* access to the different structural variants of the cyclopentanoid natural products. In addition to this fundamental advantage, the new synthetic approach[24-28] is also superior, over the methods mentioned previously, regarding the flexibility in the set-up of the pattern of substitution. The objective was to prepare a basic set of simple building blocks with structural features which would allow for a multitude of transformations of predictable regio- and stereoselectivity, and for a smooth resolution into *both* enantiomers. The tricyclo[3.3.0.0^{2,8}]octan-3-ones **3** (see Scheme

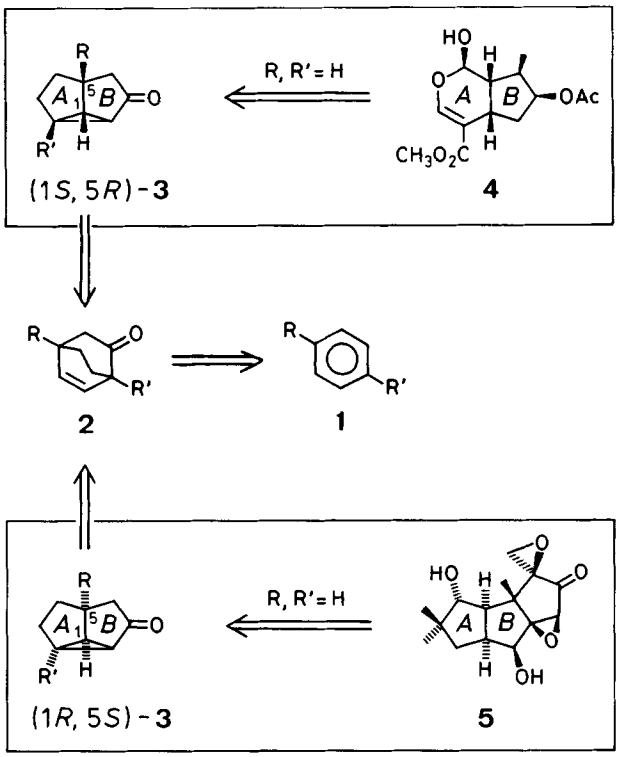
2 and Table 1) will be shown to satisfy these requirements to a large extent. They are readily accessible from the commercially available aromatic starting materials **1**, the key step being the photochemical rearrangement of the β,γ-unsaturated ketones **2**. The tricyclooctanones thus provide an optimum configurational and functional ensemble for economically attractive syntheses of cyclopentanoid target molecules.



Scheme 2. Retrosyntheses using tricyclo[3.3.0.0^{2,8}]octan-3-one **3a**: Loganin aglucone 6-acetate **4** from (1*S*,5*R*)-**3a**, and coriolin **5** from (1*R*,5*S*)-**3a**.

Scheme 2 uses two characteristic examples to illustrate the retrosynthetic analysis of cyclopentanoid natural products, based on the concept so far described.

3. Preparation of the Tricyclo[3.3.0.0^{2,8}]octan-3-ones

The tricyclooctanones **3** can be readily produced in high yields from benzene and derivatives thereof. Table 1 compiles the syntheses of compounds of this type which have been carried out so far. Birch reduction of the arenes, and subsequent isomerization of the resulting 1,4-cyclohexadienes **7** *in situ* by heating in the presence of trace amounts of hydroquinone afforded the 1,3-dienes, which were directly added to 2-chloroacrylonitrile. As expected, the Diels-Alder additions to the substituted dienes occurred with high regioselectivity. Only for the synthesis of **3a** was commercially available 1,3-cyclohexadiene **6** used. It was added to acrylonitrile, and the adduct was subsequently chlorinated.

Some time ago, *Givens et al.*[30] described the photochemical rearrangements of **2a** which are quite generally characteristic[34] for those of β,γ-unsaturated ketones: a

◀ Scheme 1. Selected examples of key steps in syntheses of cyclopentanoid compounds (cf. also Scheme 3). TMS = trimethylsilyl, DIOP = *P,P'*-[2,2-dimethyl-1,3-dioxolane-4,5-bis(methylene)]bis(diphenylphosphane).

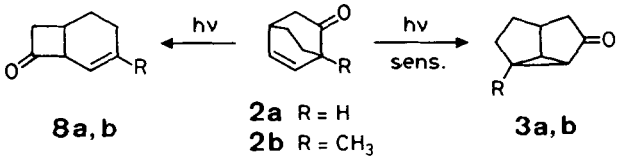
1,3-acyl shift forming the cyclobutanone **8a** on direct excitation, and an oxadi-π-methane rearrangement to **3a** on triplet sensitization.



In extensive studies of other β,γ-unsaturated ketones, the reaction mechanisms of both types of rearrangements have since been elucidated in more detail[35–37]. The 1,3-acyl migration is initiated by photolytic α-cleavage of the ketone to an acyl/allyl diradical which has the option of either regenerating the starting material or recombining in the alternative allylic position and forming the 1,3-shift product. The reaction occurs from the n,π* excited singlet and triplet states of the β,γ-enone, $S_1(n,\pi^*)$ and $T_2(n,\pi^*)$, respectively. In a similarly specific manner the lowest-lying triplet state, $T_1(\pi,\pi^*)$, is responsible for the oxadi-π-methane rearrangement (Fig. 1). In order to selectively secure the formation of the oxadi-π-methane product, excitation to S_1 on direct light absorption by the starting ketone has to be avoided. Also, the triplet energies of enone and sensitizer ought to be carefully adjusted. E_T of the sensitizer should be between T_1 and T_2 of the enone, so that the energy transfer can be directed specifically toward the lower-lying triplet.

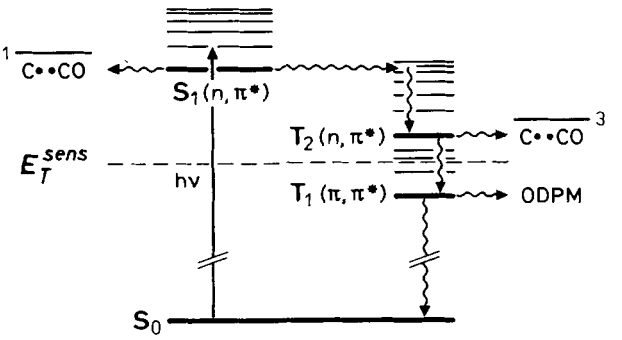


Fig. 1. Energy and excited state diagram of a β,γ-unsaturated ketone, with the optimum range of sensitizer triplet energy (E_T^{sens}) for the oxadi-π-methane rearrangement (ODPM) by selective energy transfer to T_1.

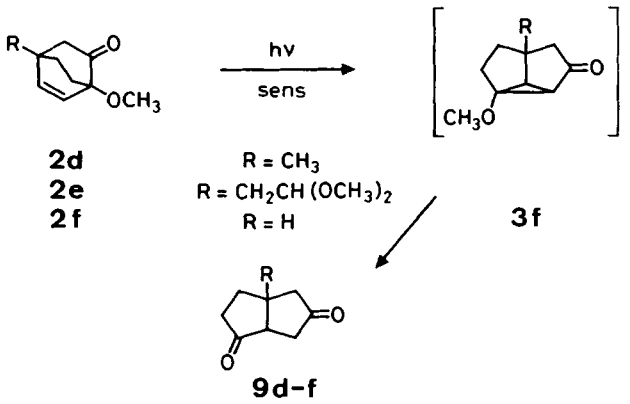
The original low yield of **3a** (34% in acetone upon irradiation with wavelength 254 nm[30]) could be improved considerably by optimizing concentration and irradiation wavelength[25]. Irradiation of 1% solutions of **2a** in acetone at 300 nm, which acts as both solvent and sensitizer, routinely affords **3a** in chemical yields of ≥85%. Only at concentrations above *ca.* 4% of **2a** does the undesired formation of **8a** become noticeable. The dependence of the formation of **8a** on concentration and wavelength (in 1—10% solutions of **2a** and wavelengths of 250—320 nm) points to residual direct absorption, due to insufficient light filtering by acetone, as the cause of the 1,3-shift.

The product distribution in irradiated acetone solutions of the methyl compound **2b** showed a qualitatively similar

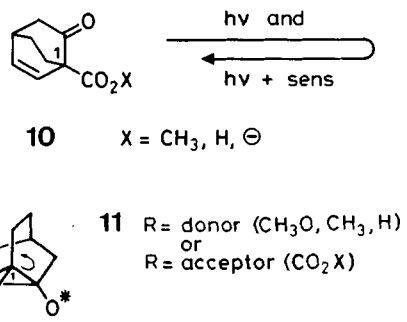
dependence on concentration. However, when the acetone-sensitized conditions which had proved most favorable for the oxadi-π-methane rearrangement of **2a** were applied to **2b**, an already considerable portion of **8b** (18%) was formed. Although the absorption spectra of **2a** and **2b** are essentially superimposable, the 1,3-shift of **2b** could not be suppressed by simply diluting the acetone solution. Only by using acetophenone as a triplet sensitizer and wavelengths $\lambda > 340$ nm could the formation of **8b** be completely avoided. Although this makes an additional purification process necessary, namely a column chromatographic separation of photoproduct and sensitizer, the procedure proved itself to be the more advantageous for all 1-substituted enones (Table 1).

The analogous photochemical behavior of the two enones, **2a** and **2b**, suggests also that the formation of **8b** is due to residual direct absorption. In other words, it is not a consequence of an additional population of the upper triplet of **2b** by acetone sensitization. Rather, the difference in the product formation can be attributed to the 1,3-acyl shift of the α-methylated ketone **2b** being more efficient than that of **2a** (see below).

In the cases of **2d–2f → 9d–9f** a structural variant of the photochemical rearrangement is available which in a very simple way furnishes a bicyclo[3.3.0]octane skeleton possessing experimentally distinguishable ketone groups in the two rings. In the primary product of type **3** the three-membered ring is opened either in a second photochemical step or thermally as a result of the destabilization by the donor-acceptor substitution[38]. Nevertheless, a small amount of the expected product **3f** could be isolated in the previously reported example of **2f**[39], in contrast to the cases of **2d** and **2e**.

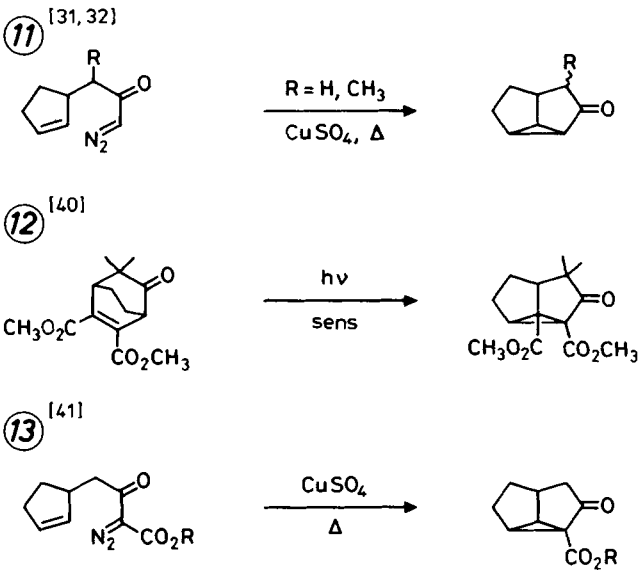


The examples in Table 1 already show the wide scope of the photochemical rearrangement of bicyclo[2.2.2]octenones. Only with the compounds of type **10** were members of this group found which could not be made to react, either by direct excitation ($\lambda = 300$ nm, in chloroform) or by triplet sensitization using acetone, benzene (both on irradiation at $\lambda \leq 300$ nm) or acetophenone (in acetone at $\lambda > 340$ nm). On comparison of these exceptional cases with the ketones **2a–e** it is apparent that photochemical reactivity and inertness parallel qualitatively the electron donor and acceptor properties of the bridgehead substituents in the α-position to the keto group (C1). While an



enhancement of the 1,3-acyl shift efficiency by α-donor substitution, as noted for **2b**, has been described[34] also for 3,4,5,6,7,8-hexahydro-2(1*H*)-naphthalenone (2-octalone) and its 1-methyl and 1,1-dimethyl homologues, investigations with β,γ-enones possessing α-acceptor groups have so far not been reported in the literature. The inhibition of both reaction paths in the case of **10** is possibly due to the electron density at C1 not being adequate enough either for the α-cleavage in the n,π*-excited state of **10**, or for the bond breaking in the intermediate **11** (R = CO_2X; * = ⊙/⊙ or ⊕/⊖) of the oxadi-π-methane rearrangement (cf. Scheme 5).

Tricyclo[3.3.0.$0^{2,8}$]octan-3-one **3a** has already been synthesized using the diazoketone method (Scheme 3, ⑪)[31,32]. This route to **3a** is, however, more costly, and



Scheme 3. Syntheses of tricyclo[3.3.0.$0^{2,8}$]octan-3-one **3a** and its derivatives by other methods.

step ⑪ renders the procedure unsuitable for larger-scale operations. The advantages of our concept become apparent not only when compared with the older synthetic route ⑪, but also even more ostensibly when compared with efforts[41] which have been limited to the more expensive access ⑬ and to a structural variant of smaller synthetic potential. Finally, reaction ⑫ is also worth mentioning, in which *Yates et al.*[40] employed, independently of us, the photochemical oxadi-π-methane rearrangement of bicyclo[2.2.2]octenone derivatives for the synthesis of racemic cedrenes.

4. The Resolution into the Enantiomers

In a first attempt to produce the ketone **3a** in optically active form, the possibility of using an enantioselective energy transfer was investigated. In acetone, the formation of **3a** occurs with the *maximum possible* quantum yield (Φ). As may be seen in Table 2, the Φ values and the rate constants k_q of the triplet energy transfer from the sensitizer to **2a** show the same trend with respect to the sensitizer energy (E_T^{sens}). Both Φ and k_q decrease with decreasing E_T^{sens} values in the range of *ca.* 69—75 kcal·mol^{-1}. The energy transfer from indanone is already clearly slower than diffusion-controlled. One can conclude that E_T of **2a** lies also in this energy range, as do the lowest-lying triplet energies of other β,γ-unsaturated ketones. As a consequence, the energy transfer will be reversible. Although speculative,

Table 2. Rate constants of sensitizer quenching by **2a** and quantum yields of the formation of **3a**; solvent: benzene.

Sensitizer	E_T^{sens} [kcal·mol^{-1}]	λ [nm]	τ^{sens}(exp.) [a] [μs]	k_q [b] [mol·L^{-1}·s^{-1}]	Φ_{max} [c]

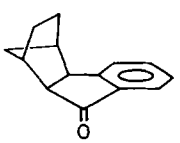
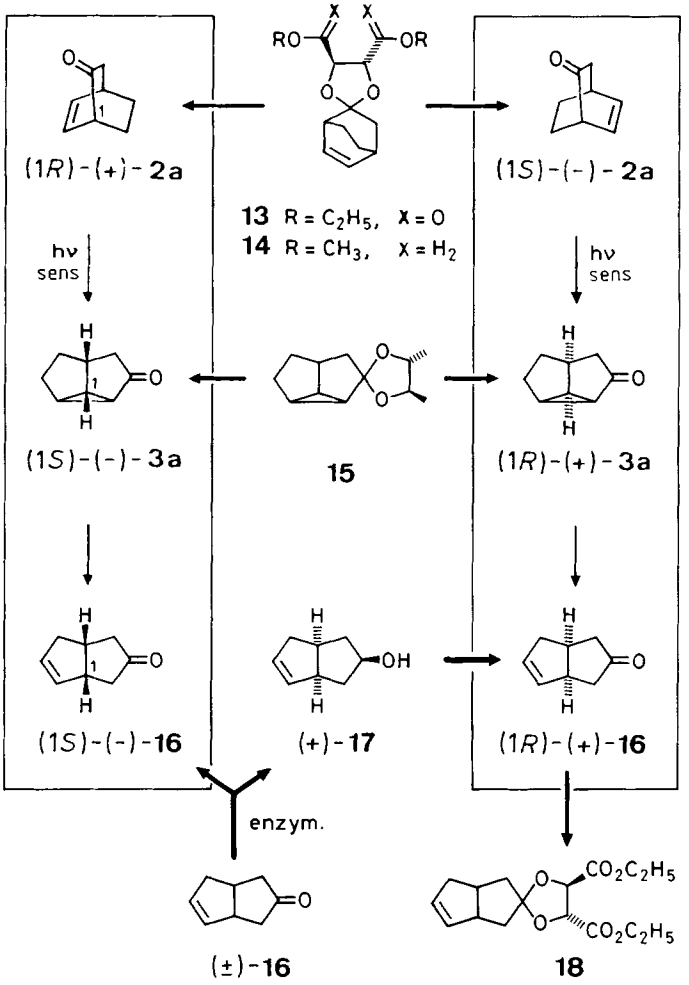
[a] Unpublished laser pulse experiments; for the experimental set-up see [42]. [b] Calculated from the Stern-Volmer slopes ($k_q\cdot\tau^{sens}$). [c] Reciprocal values of the intercept with the Stern-Volmer ordinate [25]. [d] Acetone is also the solvent. [e] Literature value: 0.13 [30]. [f] Estimated value from E_T^{phosph} in ether-isopentane-ethanol (5:5:2) at 77 K [44]. [g] This value may reflect, as a possible additional factor, a larger steric hindrance of the energy transfer than the k_q's of the other sensitizers.

such boundary conditions could be expected to be favorable for an enantioselective transfer from a chiral sensitizer, since control by steric factors should become better noticeable in this situation. However, these expectations were by no means satisfactorily fulfilled when (−)-**12**[44] was used as a sensitizer. The asymmetric induction of the rearrangement of (±)-**2a** was of the same order as in known cases[46] and was insufficient for any practical application. The enantiomeric excess of (−)-**3a** after 7—44% conversion of (±)-**2a** was only 4.5±0.7% in benzene and in ethyl acetate at room temperature, and 10±3% in ethyl acetate at −78 °C. Interestingly, the same order of induction was achieved when (±)-**12** was used to sensitize the rearrangement of **2a** at room temperature in diethyl (+)-tartrate solution.



(-)-12

Satisfactory results were, however, achieved in the production of the pure enantiomers by the resolution of racemic mixtures. This is possible at the stages of the bicyclooctenones **2** and the photoproducts **3** (Scheme 4). The sequence of acetalization, chromatographic separation of the diastereoisomers, and hydrolysis could always be carried out (**13**–**15**) essentially without losses.



Scheme 4. Preparation of the pure enantiomers by reduction of racemic bicyclo[2.2.2]octenone, (±)-**2a**, and tricyclo[3.3.0.0^{2,8}]octan-3-one, (±)-**3a**, and the enantioselective reduction of (±)-**16** with horse liver alcohol dehydrogenase (HLAD). **16** is numbered as in the parent compound **3a**.

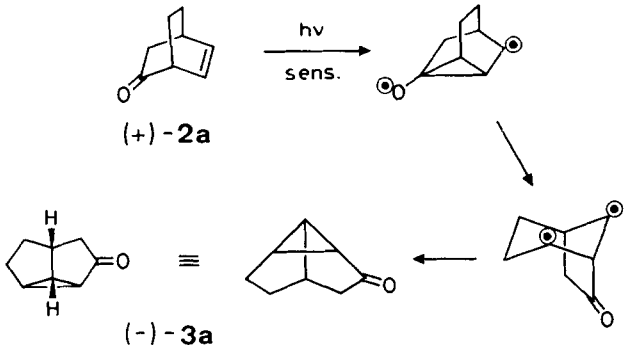
The route *via* the acetal **13** is especially advantageous using the cheapest of the optically active diols, diethyl (+)-tartrate. It also proved itself the best variant with respect to acetalization and chromatographic separation. Thus, (±)-**2a** in the presence of *p*-toluenesulfonic acid in refluxing benzene was quantitatively acetalized to a diastereoisomeric mixture **13**, whereas the transacetalization to **14** with (*S,S*)-(−)-4,5-bis(methoxymethyl)-2,2-dimethyl-1,3-dioxolane[47] reached a conversion of only *ca.* 80%. Chromatography of, *e.g.* 5 g of the mixture **13** using two Lobar C columns (Merck) in series and toluene as eluent, gave 1.9 g of a mixed middle fraction and 1.5 g each of the two components of >98% diastereoisomeric purity. The chromatography columns can be used for several runs.

The alternative route by way of **15** is impaired by the fact that the acetalization of (±)-**3a** with (−)-1,2-butanediol[48] can only be achieved with a conversion of *ca.* 80%. Also, chromatographic separation was not possible beyond a relatively large mixed middle fraction. The method is thus restricted to runs of only a few hundred milligrams.

The absolute configuration of the enantiomeric bicyclooctenones **2a** has been determined previously with sam-

ples obtained by fractional crystallization[49]. The configurational assignment of (+)- and (−)-**3a** is based on the CD Cotton effect of $\Delta\varepsilon_{max}^{306\,nm} = -2.02$ for the (+)-enantiomer, using the octant rule for bicyclo[3.1.0]hexan-2-ones[50].

The stereospecifity of the oxadi-π-methane rearrangement **2**→**3**, as shown by the mechanism given in Scheme 5 and established[37b,c] for other β,γ-unsaturated ketones, was fully confirmed by acetophenone-sensitized irradiations of (+)-**2a** and (−)-**2a** in benzene at room temperature ($\lambda > 340$ nm). The photoproducts, (−)-**3a** and (+)-**3a**, respectively, were formed with complete retention of the enantiomeric purity.



Scheme 5. Stereospecific mechanism of the photochemical oxadi-π-methane rearrangement of (+)-**2a**.

The enzymatic redox system of horse liver alcohol dehydrogenase, HLAD/NAD$^{\oplus}$/ethanol[51], promises to become an important extension of the methods suitable for separation of the enantiomers of this group of compounds. The ketones (±)-**2a**, **b** and (±)-**3a**, **b** could not be reduced enzymatically. In the case of **3** the result is compatible with the likewise negative findings reported[52] for other cyclopropyl ketones and for cyclopropyl aldehydes. However, the bicyclo[3.3.0]octenone (±)-**16**, a product obtained from **3a** in practically quantitative yield (see Section 5, Scheme 6), was reduced by HLAD/NAD$^{\oplus}$ with promising enantioselectivity. When, for example, after a conversion of 48% the reaction was stopped on silica gel and the mixture chromatographed, ketone (−)-**16** and alcohol (+)-**17** were isolated in enriched form, each in not yet optimized yields of 35—40%. The enantiomeric purity of the product of the enzymatic reduction, (+)-**17**, was determined by ^{1}H-NMR spectroscopy using an optically active europium shift reagent. The enantiomeric excess of 65% obtained so far is likewise not optimized. The acetalization of the enriched ketone (+)-**16**—obtained by Jones oxidation of (+)-**17**—with diethyl (+)-tartrate afforded a mixture of the diastereoisomers **18**. However, in contrast to **13**, a gas-chromatographic separation, and thus determination of the diastereomeric mixture, met in this case without success. The *endo*-configuration of the hydroxy group of **17** was assigned on the basis of the hydride mechanism of the enzyme reduction[52]. It is in accord with the sterically equivalent outcome of the $NaBH_4$ reduction of **16** in methanol at 0 °C.

5. Transformations of the Tricyclo[3.3.0.0^{2,8}]octan-3-ones

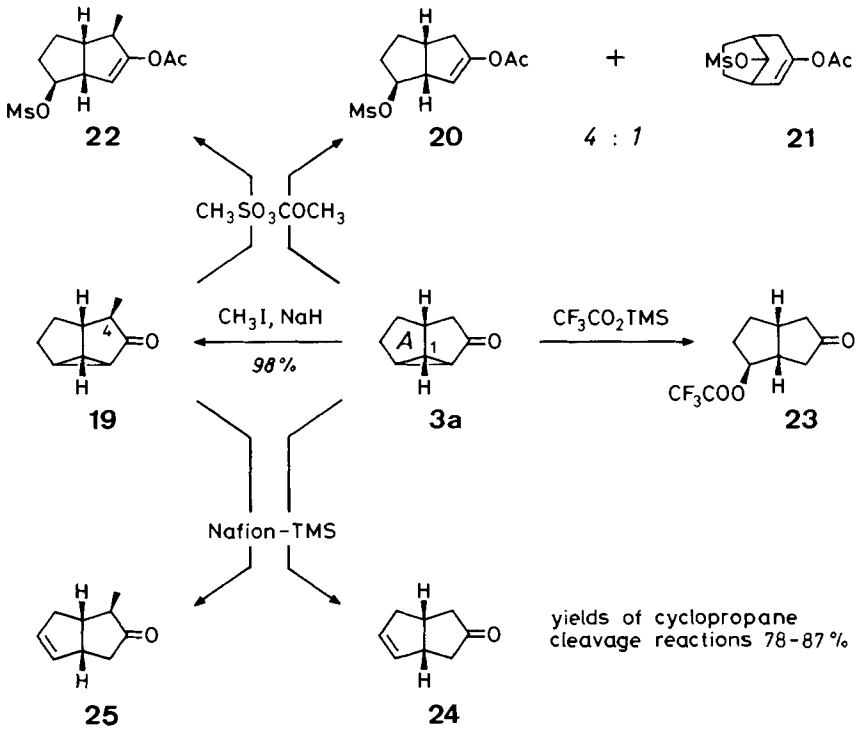
5.1. Functionalization of Ring A of 3a

Electrophilic opening of the three-membered ring of **3a** offers several variants of ready chemical access to the non-oxygenated five-membered ring A. The action of the electrophile can be assisted by a nucleophile which then is employed either in a mixture with the electrophile or in the form of a reagent combining groups with both properties[53,54]. In general, the desired cleavage of the C2—C8 cyclopropane bond is favored by the stereoelectronic control of the reaction. Thus, treatment of **3a** with acetyl methanesulfonate[55] gave product **20** in good yield, but still admixed with the isomer **21** formed by the alternative bond cleavage (Scheme 6[*])[53]. Complete regioselectivity of the reaction was achieved when **3a** was alkylated at C4 to form the homologue **19** with the methyl group exclusively in the *exo*-position (recently another, albeit sterically unselective synthesis of **19** has been described[32].) Reaction of the methyl compound **19** with acetyl methanesulfonate afforded exclusively **22**.

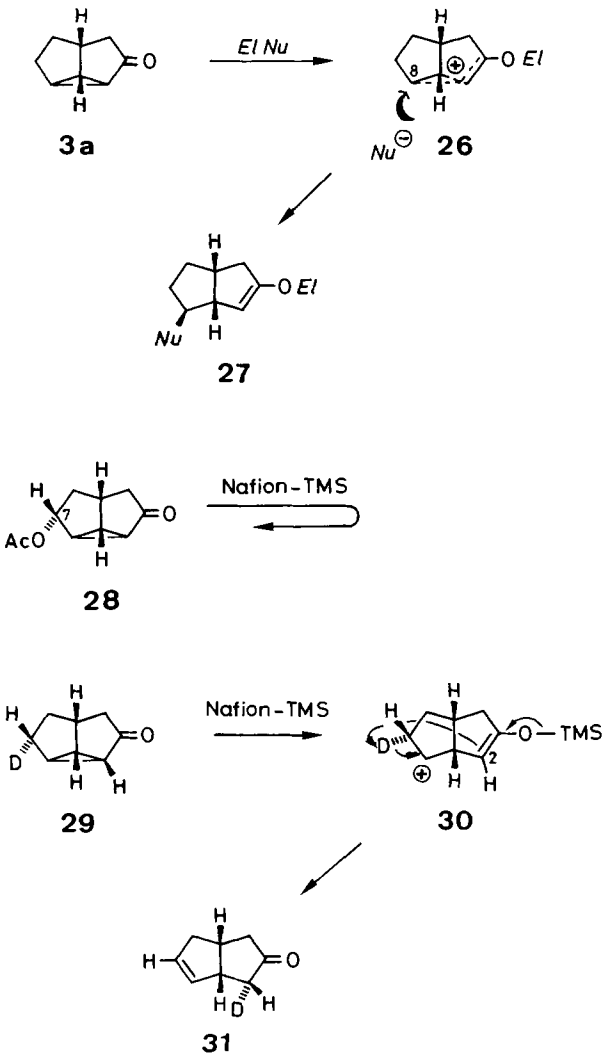
A similarly high stereoselectivity of the cyclopropane opening in the unsubstituted ketone **3a** could only be achieved at the expense of the enolate group which had been preserved in **20** and **22**. Treatment of **3a** with trimethylsilyl trifluoroacetate gave the trifluoroacetoxyketone **23**[54,56], while reaction with trimethylsilyl trifluoromethanesulfonate[56b] in chloroform at room temperature afforded the unsaturated isomeric ketone **24**[26,57]. The nucleophilicity of the trifluoromethanesulfonate is evidently insufficient to add the group to C8. Although analytically quite clean, the yield of this isomerization was substantially reduced upon chromatography. This draw-back could be avoided by the use of Nafion-TMS, a perfluorated trimethylsilyl sulfonate resin[58], in toluene at 80 °C, which yielded pure **24** almost quantitatively. The method can also be used for the isomerization of **19** (→**25**) with similar success[57]. The enone **24** has been prepared previously, employing a considerably less practicable procedure[59].

The sterically very uniform nucleophilic addition to C8 affording compounds such as **20**, **22**, and **23**, points to an S_N2-type mechanism (Scheme 7: **26**). The silyl enol ether **27** could be shown to be a precursor of **23** by gas chromatographic and IR spectroscopic monitoring of the reaction, but it escaped isolation. This is in accord with the previous observation[60] that such functional groups are very readily hydrolyzed to keto groups. The corresponding precursors of **24** and **25** are, however, not cleaved hydrolytically, but rather by way of an intramolecular transfer of the 7-*endo* proton to C2. A number of findings were in agreement with such a mechanism. Thus, the search for an intermediate in the reaction **3a**→**24** was unsuccessful, although the trimethylsilyl enol ether which had been prepared from **24** for comparison purposes, proved sufficiently stable under the conditions used. Also, the cyclopropane cleavage of **3a** with methyl trifluoromethanesulfonate (methyl tri-

[*] The compounds of Schemes 6–13 and 15–17 were prepared in racemic form only.



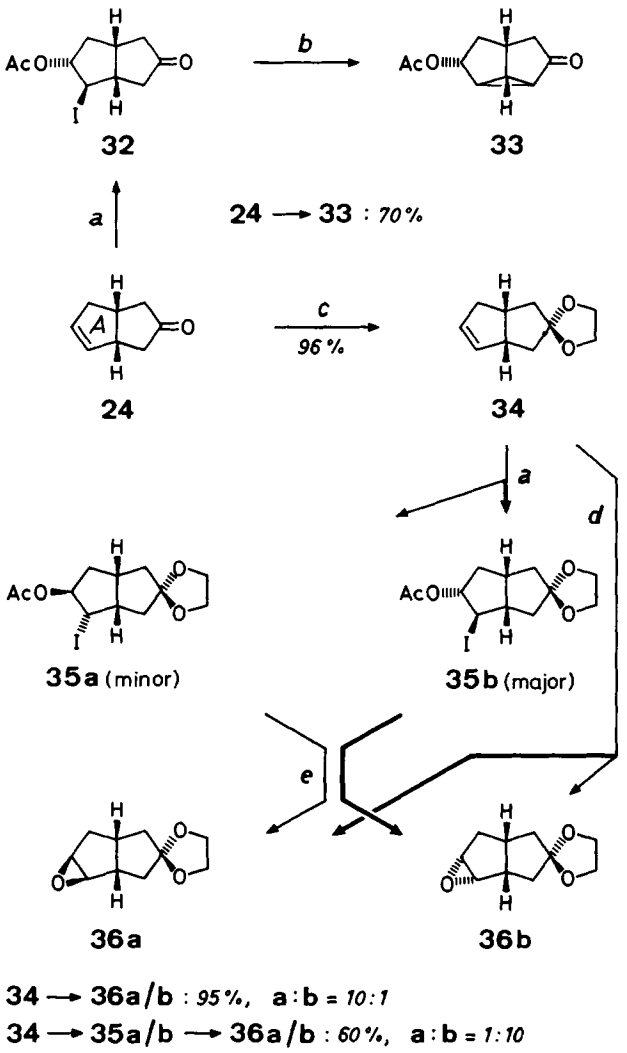
Scheme 6. Functionalization of ring A of **3a**: Cyclopropane cleavage by acetyl methanesulfonate, trimethylsilyl trifluoroacetate, and Nafion-TMS. TMS = trimethylsilyl.



flate) gave exclusively **24**. No methyl enol ether was produced, although it would have been much less susceptible to hydrolysis. Furthermore, the *endo*-7-acetoxyketone **28** remained unreactive under the conditions (Nafion-TMS in toluene at $\geq 80\,^{\circ}C$) under which **3a** was readily isomerized to **19**. This gave the first clue towards the participation of the *endo* proton at C7 in the reaction. Direct evidence for the protolytic cleavage of the enol ether by the intramolecular proton transfer shown in **30** was finally provided as follows: Upon treatment of **29** with Nafion-TMS in toluene at 80 °C the isomerization to **31** amounted to 85% in 6 h. The deuterium was fully incorporated into the 2-*endo* position. Only after an exposure to the reaction conditions for a period of about twice as long was an equilibrium between 2-*endo* and 2-*exo* deuterated stereoisomers established[57].

The Prévost addition of acetyl hypoiodite to the newly formed double bond of **24** occurred with extraordinary regio- and stereoselectivity (Scheme 8), as had already been noted previously with a lactone analogue of **24**[61]. The iodoacetate **32** was obtained in 80—85% yield. Treatment with base restituted the three-membered ring, furnishing **33**. The elimination of hydrogen iodide could be avoided in favor of epoxide formation when the keto group of **24** was acetalized first (→ **34**). The subsequent addition of acetyl hypoiodide occurred with undiminished selectivity. The iodoacetates **35a** and **35b** were formed in a ratio of about 1 : 10. They were directly converted by base into the epoxides **36a** and **36b**, which were readily separated by chromatography. The stereoselectivity of the formation of

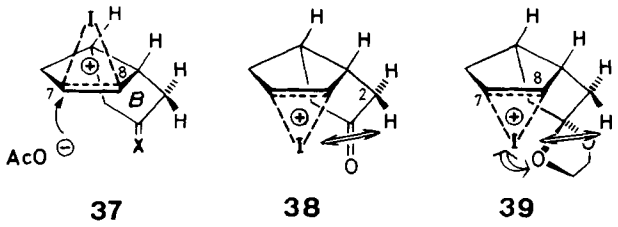
◀ Scheme 7. Mechanisms of the electrophile (*El*)-assisted cyclopropane cleavage with addition of a nucleophile (*Nu*) to C8 and with an intramolecular deuterium transfer from C7 to C2.



Scheme 8. Functionalization of ring A of **3a**: Oxidative additions to the double bond of **24** and restitution of the three-membered ring. *a:* AcOAg, I_2, toluene, 80 °C. *b:* 1,5-diazabicyclo[4.3.0]non-5-ene (DBN), room temperature. *c:* $HC(OCH_3)_3$, $(CH_2OH)_2$, TosOH. *d:* *m*-$ClC_6H_4CO_3H$, CH_2Cl_2, 0 °C. *e:* K_2CO_3, CH_3OH.

these products could also be reversed by epoxidizing **34** directly with *m*-chloroperbenzoic acid.

The configuration of the iodoacetate **32** was assigned on the basis of the facile ring closure **32** → **33**, which would not be expected to occur as readily with another configuration at C8[*], as well as model considerations of the course of the Prévost addition. As can be seen from Scheme 9, any addition at the double bond of **24** and **34** from the bottom, *i.e.*, from the side facing ring B (= *endo* attack), is sterically hindered. Thus, *endo* iodonium formation would encounter steric interactions with the *endo* methylene hydrogen at C2 (in **38** and **39**) and, additionally, with the *endo* acetal oxygen (in **39**). In contrast, the *exo* iodonium group **37** is sterically unhindered. The influence exerted by such steric interactions is illustrated by the finding that the substitution of iodine by bromine substantially reduces the stereoselectivity. The *endo* position of the acetoxy group in compounds of type **33** and **35b**, resulting from the *exo* arrangement of the iodonium group, was finally confirmed by an intramolecular ether ring closure (Scheme 15: **61** → **63**) and by the conversion of **35b** into the epoxide **36b**. The configuration of the latter had been established, together with that of **36a**, by ^{1}H-NMR spectroscopy using shift reagents.



Scheme 9. Stereo- and regioselective control of the Prévost addition of acetyl hypoiodite to **24** and **34** [*].

The preference for position C7 of **37** (X = O and $O(CH_2)_2O$) in the addition of the acetoxy anion can undoubtedly be attributed to the steric shielding of the *endo* side of C8) by the *endo* methylene hydrogen at C2. There remains the question concerning the regio(un)selective attack of the acetoxy anion on **39**. The molecular model does not reveal any significant difference between C7 and C8. The constitution of formula **35a** is therefore arbitrary. Only the *exo* arrangement of the acetoxy group is not in doubt, since the ratio of the epoxides **36a/36b** obtained from the mixture **35a** + **35b** is the inverse of that resulting from direct epoxidation (**34** → **36a**, **b**) by the predominant *exo* attack of the peracid.

5.2. Functionalization of Ring B of 19

The enol acetates of **20** and **22** which had been formed regiospecifically in the cyclopropane opening of **3a** and **19**, respectively (Scheme 6), constituted likely candidates for an extension of ring B into δ-lactones by oxidative cleavage of the double bond. For this purpose, **19** was

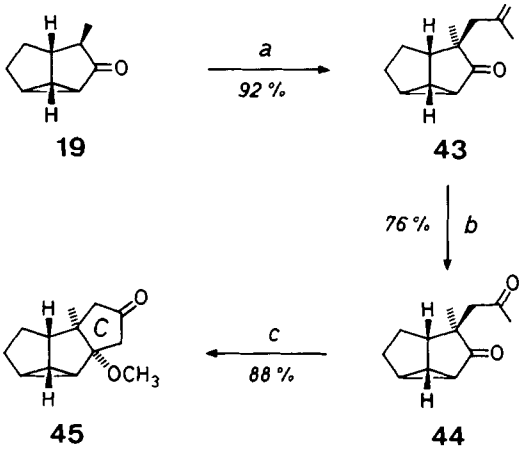
Scheme 10. [*] Numbering analogous to that of the precursor **3a**.

converted into the bromo and iodo compounds **40a** and **40b** using acetyl methanesulfonate and the appropriate tetramethylammonium halide (Scheme 10). The double bond was subsequently oxidized by treatment with OsO_4 and $NaIO_4$, the aldehydo function was reduced with $NaBH_4$, and the products were cyclized with acid to the corresponding lactones **41a** and **41b**. The total yield of the sequence **19**→**41** was 69%.

When the bromo compound **40a** was ozonized in methanol, the ozonide was cleaved by the solvent to form a methoxyhydroperoxide[62]. Reduction of the latter to the hemiacetal and acid-catalyzed ring closure gave the methoxylactone **42**.

5.3. Annelation of the Five-Membered Ring to 19

The pronounced steric control of the alkylation at C4 of **3a** could be exploited for the *anti* annelation of a third ring. The product of the first alkylation step, **19**, was converted in high yield into **43** by a second *exo* alkylation using methallyl bromide (Scheme 11). Oxidative cleavage of the CC-double bond of **43** gave the diketone **44**. The base-catalyzed ring closure in the presence of methanol finally afforded uniform tetracyclo[6.3.0.0^{2,4}.0^{3,7}]undecanone, **45**. The uniformity of the end product is due to the spontaneous addition of the alcohol to residual α,β-unsaturated ketone in the crude product mixture. The annelation of ring C was thus completed in three steps and with a total yield of 62%.

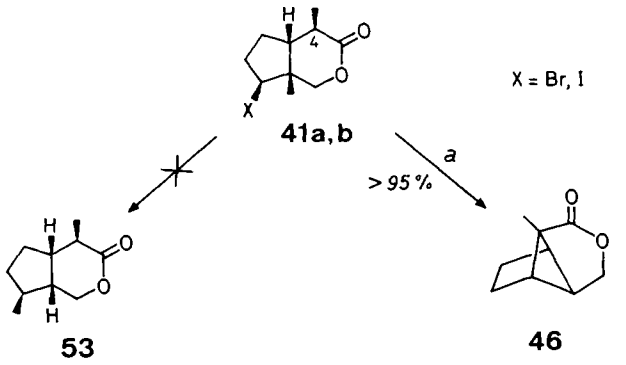


Scheme 11. Construction of the *cis-transoid-cis*-tetracyclic undecane **45** by annelation of the ring C to **19**. *a:* CH_2=$C(CH_3)CH_2Cl$, KBr, *t*BuOK, *t*BuOH, toluene, 80 °C. *b:* OsO_4, $NaIO_4$, tetrahydrofuran (THF), H_2O, room temperature. *c:* *t*BuOK, KOH, CH_3OH, reflux.

6. Applications in Natural Product Syntheses

6.1. Total Syntheses of Boschnialactone, Allodolicholactone, Iridomyrmecin, and Isoiridomyrmecin

The utility of the building block **3a** was tried for the first time in a six-step synthesis of the target molecule racemic isoiridomyrmecin (**53**, Scheme 12), a constituent of the defense secretion of ants. This natural product, which itself is of no practical importance, is a representative of the family of iridoid compounds, many of which exhibit activities of pharmacological interest[63]. The synthesis was initiated in order to confirm, in an early phase of this work, the *exo* steering of the alkylation at C4 of **3a** (→**19**) and of the substitution by nucleophiles at C8 in the cyclopropane cleavage **19**→**22**, **40** (Schemes 6 and 10). The steric course



Scheme 12. Preliminary experiments on the total synthesis of isoiridomyrmecin **53** from (±)-**3a** *via* **19** and **41a**, **b**. *a:* $(CH_3)_2CuLi$ or $(CH_3)_3ZnLi$.

of these reactions—which was expected on the basis of model considerations and supported by spectroscopic evidence from products such as **19**, **22**, and **40**—was finally established by an X-ray diffraction analysis of the bromolactone **41a** (Fig. 2)[26,64].

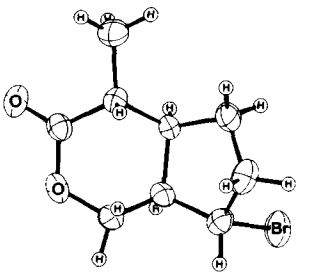


Fig. 2. Structure of bromolactone **41a** as determined by X-ray diffraction analysis [64].

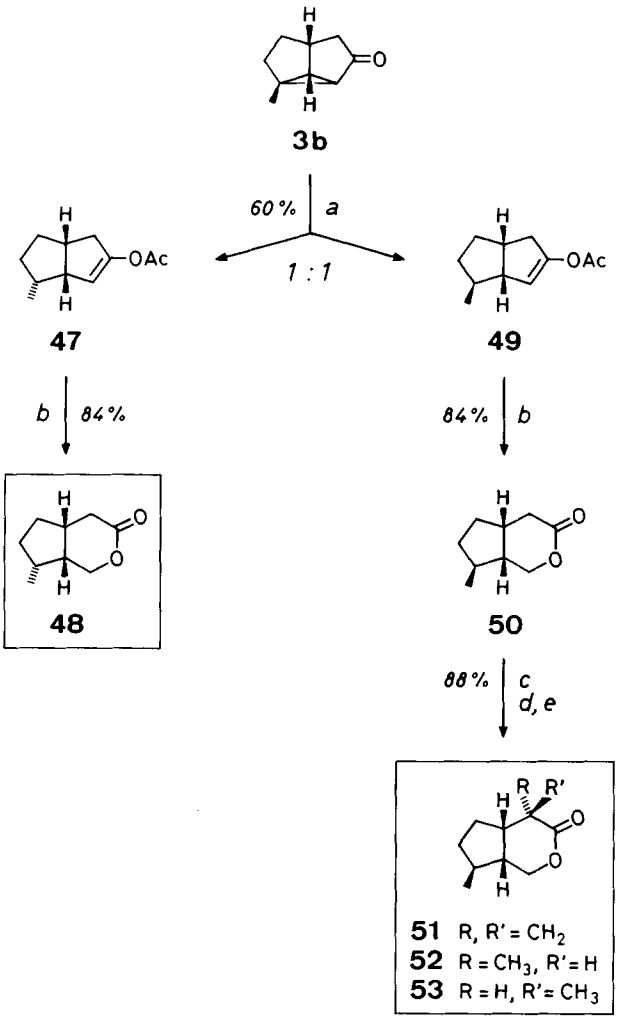
After completion of the sequence **3a**→**19**→**40a**, **b**→**41a**, **b** the project failed in the last step when an exchange of the halogen of **41** for methyl proved unfeasible. Instead, the unwanted lactone **46** was formed in almost quantitative yields, evidently as a consequence of predominant proton elimination from C4 by cuprate and zincate reagents, followed by cyclization upon intramolecular displacement of the halogen at C8. The structure of **46** was elucidated by an X-ray diffraction analysis[64].

The failure to introduce a methyl group at C8 of **41** called for a change in the synthetic strategy by starting with the methylated building block (±)-**3b**. The new route included a stereo*non*selective step, a disadvantage which was compensated for by the fact that a simultaneous access to altogether four natural products was gained. Birch reduction of **3b**, followed by addition of acetic anhydride, gave a readily separable 1:1 mixture of the epimeric enol acetates **47** and **49** (Scheme 13). The two products were converted—as described above—into the lactones **48** (boschnialactone) and **50**, respectively. The latter com-

pound, after treatment with lithium diisopropylamide (LDA)/dimethyl(methylene)ammonium iodide, methyl iodide, and diazabicyclononene (DBN), furnished the first synthetic allodolicholactone **51**[65]. Following published procedures[66], **51** can be hydrogenated to iridomyrmecin **52**[65], and the latter is isomerized by base to isoiridomyrmecin **53**[67].



Scheme 13. Total synthesis of boschnialactone **48**, allodolicholactone **51**, iridomyrmecin **52**, and isoiridomyrmecin **53**, in racemic form, from (±)-**3b**. *a:* Na, NH_3, *t*BuOH; Ac_2O. *b:* OsO_4, $NaIO_4$; $NaBH_4$; HCl, H_2O. *c:* $CH_2{=}N(CH_3)_2I$, LDA; CH_3I; DBN, benzene (→**51**). *d:* H_2, Pd/C (→**52**) [65]. *e:* CH_3OK (→**53**) [67].

The first synthesis of allodolicholactone **51** comprised 12 steps, starting with toluene, and a total yield of 16%. The syntheses of boschnialactone **48**, iridomyrmecin **52**, and isoiridomyrmecin **53**, which like that of **51** were all achieved *via* the key compound **3b**, compare quite favorably with the most efficient of the earlier methods (Table 3).

6.2. Enantiospecific Total Synthesis of Loganin Aglucone 6-Acetate

Loganin[74] is extracted from numerous different plant species. Used in earlier times as a bitter tonic in folk medicine[73], the iridoid glucoside has up to now not found any

Table 3. Comparison of the new total syntheses of boschnialactone **48**, iridomyrmecin **52**, and isoiridomyrmecin **53** (cf. Scheme 13) with previous syntheses.

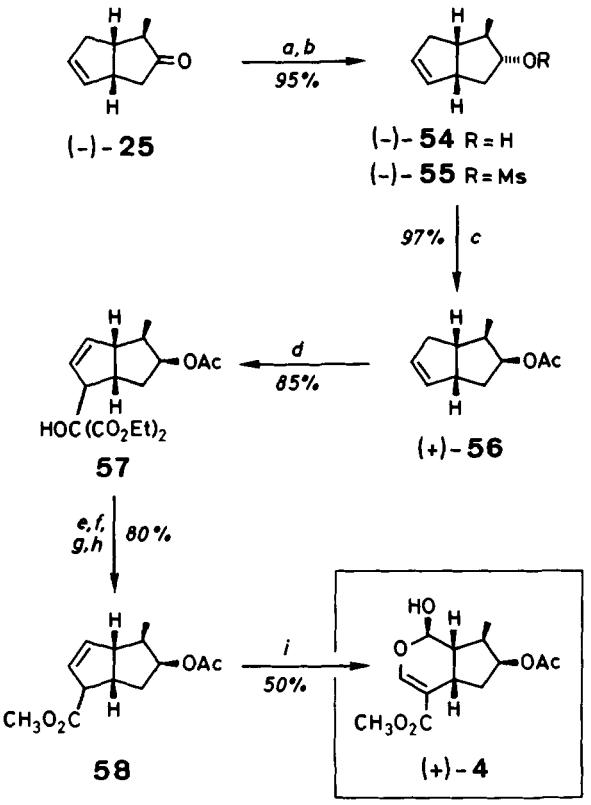
pharmaceutical use while other substances of this class are known[63] to exhibit interesting biological activities. With regard to biosynthesis, however, loganin plays a central role as a kay intermediate in the biosynthesis of indole and monoterpene alkaloids, and other natural products[75].

After the aglucone acetate **4** had already been transformed into loganin[73b] *via* the glucoside pentaacetate[76,77], the target of our synthesis could be confined to **4**. The access to the unsaturated ketone (−)-**25** *via* the steps (−)-**3a**→(−)-**19**→(−)-**25** (cf. Scheme 6) left in essence three more problems to be solved: the conversion of the keto group into an *exo* acetoxy group, the introduction of a methoxycarbonyl group with a concomitant allylic double bond shift, and the oxidative cleavage of the double bond to form the dialdehyde, which should cyclize spontaneously to **4** by way of the enolized β-aldehydoester group. Ample precedent for all three steps could already be found in the literature. In the synthesis of racemic loganin[77] by *Büchi et al.*, an *endo* hydroxy group was epimerized by way of an S_N2 substitution of the mesylate, furnishing the *exo* acetate. *Fleming et al.*[78] recently described a synthesis of (±)-**4** in which OsO_4 and $NaIO_4$ (in three steps) as well as ozonolysis (in two steps) were successfully tried in the cleavage of the β,γ-unsaturated ester. Finally, the ene synthesis with oxomalonate[79] proved to most

promising, in a somewhat modified version, for introduction of the ester group. *Fleming*'s loganin synthesis[78] had already applied an ene-synthetic step, resorting, however, to the detour of regiocontrolling the process by an allyl silane group.



Scheme 14. Enantiospecific total synthesis of loganin aglucone 6-acetate, (+)-**4**, from (−)-**3a** *via* (−)-**19** and (−)-**25** (cf. Scheme 6) [28]. *a:* $NaBH_4$, CH_3OH, 0 °C. *b:* CH_3SO_2Cl, $N(C_2H_5)_3$, CH_2Cl_2, 0 °C. *c:* $(C_2H_5)_4NOAc$, acetone, reflux. *d:* $OC(CO_2C_2H_5)_2$, $TiCl_4$, CH_2Cl_2, 0→25 °C. *e:* 10% KOH, room temperature. *f:* $NaIO_4$, pyridine (catalytic), room temperature. *g:* CH_2N_2, ether–CH_3OH. *h:* Ac_2O, pyridine, room temperature. *i:* OsO_4, benzene, room temperature; $Na_2S_2O_5$, C_2H_5OH, room temperature; $NaIO_4$, aqueous dioxane, 0 °C.

As was expected, the $NaBH_4$ reduction of (−)-**25** gave the *endo* alcohol (−)-**54** (Scheme 14), which was epimerized to the *exo* acetate (+)-**56** by treatment of the mesylate (−)-**55** with tetraethylammonium acetate. The subsequent ene synthesis with diethyl oxomalonate, when catalyzed with $TiCl_4$ in the temperature range from 0 to 20 °C, afforded better yields of **57** than when BF_3 or $SnCl_4$ were used[79]. The product (**57**) was sterically not uniform; this, however, is irrelevant with regard to the target structure. The degradation to the methyl ester **58** was carried out in high yield in four steps—alkaline hydrolysis, cleavage of the α-hydroxy diacid with periodate, esterification of the acid, and reacetylation of the hydroxy group. Finally, the double bond of the epimeric mixture **58** was oxidatively cleaved stepwise with OsO_4 and $NaIO_4$ to give (+)-**4**[78].

When comparing this new synthesis with previous ones (Table 4), that of *Uskoković et al.*[76] deserves special mention. Up to now, it has been the only asymmetrically induced synthesis, and is distinguished by its brevity. However, the total yield of (+)-**4** is but modest, and separation techniques are required which are hardly appropriate for larger than milligram-scale operations; this problem is not encountered in our new synthetic strategy leading to the natural aglucone enantiomer. In both *Uskoković*'s[76] and *Büchi*'s[77] syntheses the de Mayo photoannelation[81] has been chosen as the key reaction for the build-up of the skeleton of **4**. The [2+2] addition of a cyclopentene derivative to the enol of methyl diformylacetate led to the loganin framework, *via* retroaldol fission of the cyclobutane intermediate and subsequent ring closure. The two other syntheses[78,80] favored initial preparation of a bicyclopentanoid carbon skeleton, a strategy also adopted in our own work. In order to build up the second five-membered ring, the more successful of the two routes[78] employed a sequence reminiscent of method ④ (Scheme 1), *i.e.* dichloroketene addition and subsequent ring enlargement of the cyclobutanone.

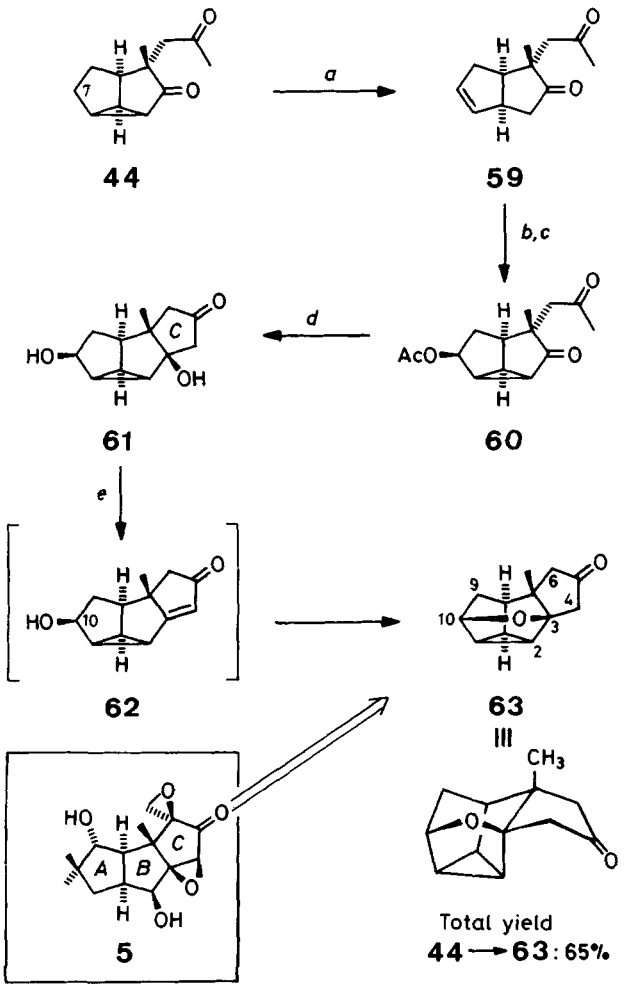
6.3. Preliminary Studies toward the Total Syntheses of Coriolin, 6a-Carbaprostacyclins, and 9,11-Dehydroestrone

6.3.1. Coriolin **5**

Products of type **61** (Scheme 15) should have a basic carbon skeleton sufficiently functionalized to serve as an attractive synthetic platform for the sesquiterpenoid coriolin **5**[82], an antibiotic with antitumor activity. For the preparation of **61**, the compound **19** was the obvious choice as a suitable intermediate. The previous studies summarized in Schemes 8 and 11 could serve as model cases for the introduction of an oxygen function at C7 and for the annelation of ring C. The actual reaction sequence comprised: Nafion TMS-induced isomerization (**44**→**59**), Prévost addition to the double bond, restitution of the three-membered ring (**59**→**60**), and cyclization by treatment of **60** for several hours with potassium *tert*-butoxide in *tert*-butyl alcohol and toluene at 80 °C.

The sequence could be carried out in an overall yield of 65% without the necessity of laborious work-up and purification procedures during the process. The primary product **61** of the ring C annelation could be intercepted when the aldol condensation of **60** was interrupted after only 5 min. The ether ring closure (**61**→**63**) could then be initiated by merely dissolving **61** together with catalytic amounts of *p*-

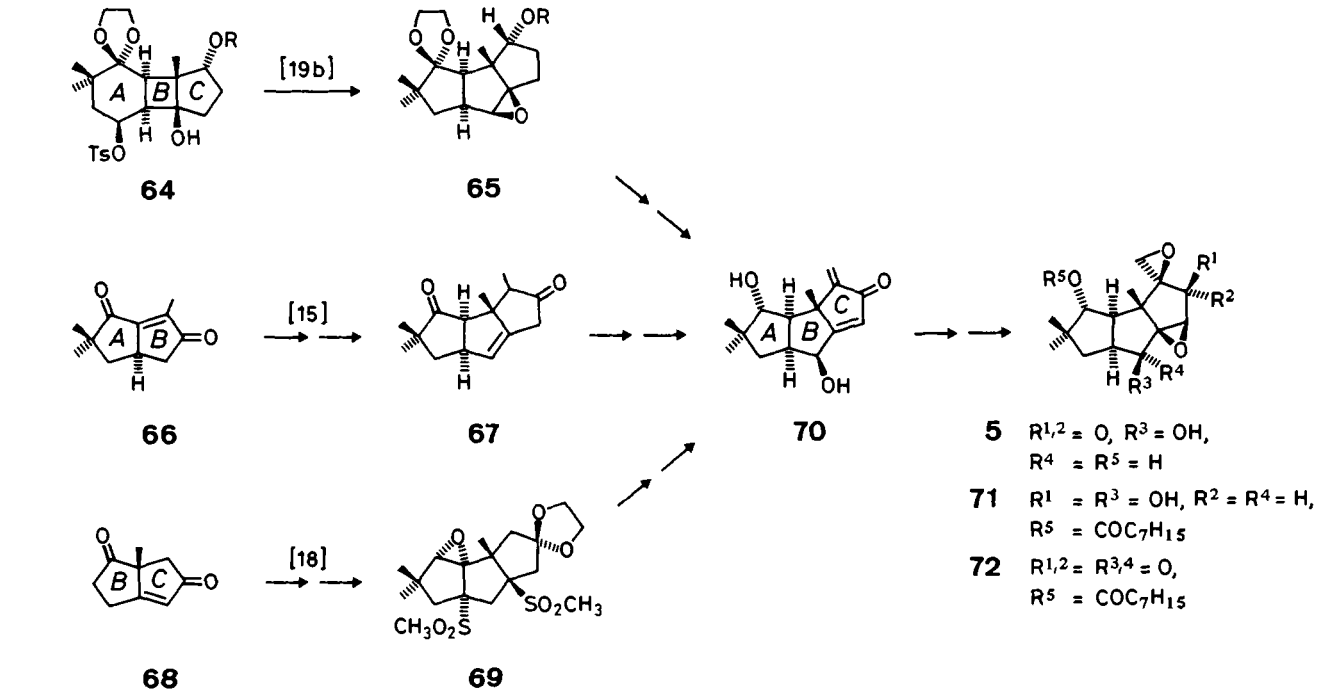


Scheme 15. First steps of an enantiospecific total synthesis of coriolin 5 from 3a *via* 19 and 44 (cf. Scheme 11). *a:* Nafion-TMS, toluene, 80 °C. *b:* AcOAg, I_2, toluene, 80 °C. *c:* DBN, toluene, room temperature. *d:* *t*BuOK, *t*BuOH, toluene, 80 °C, 5 min. *e:* as in *d*, but for 12 h, or cat. TosOH, CH_3OH, room temperature.

toluenesulfonic acid in methanol at room temperature. The α,β-unsaturated ketone **62**, presumed to be an intermediate, could not be detected. The facile cyclization is understandable upon inspection of the molecular model which shows the 10-*endo* oxygen to lie close above the enone β-carbon.

The synthesis of the diepoxyketone structure of ring C of **5** is currently in progress along routes which have been elaborated in other coriolin syntheses[15], and which take advantage of the potential $\Delta^{3,4}$-double bond and the C6 exocyclic methylene group in the α-positions to the ketone of **63**. There remain then the introduction of hydroxy groups at C2 and C9, the cyclopropane cleavage, and the *gem*-dimethylation at C10. The product **63** should possess the necessary degree of functionalization to allow selective execution of these individual steps.

Up to now, the syntheses of the racemates of coriolin **5**, coriolin B **71** and diketocoriolin B **72**, the natural enantiomers of which possess activities of pharmacological interest[82,83], have pursued the following strategies (Scheme 16). The terminal rings A and C can be joined, with concomitant formation of the centre ring B, either by a [2+2] photoaddition (→**64**)[19b] or in a metathetic sequence of thermal and photochemical steps[19d,84]. Alternatively, rings A and B can also be formed by the intramolecular addition of an aliphatic double bond to a trimethylenemethane-type diyl system contained in a starting ring C[85]. In most cases, however, the synthesis begins with bicyclic building blocks which serve as a basis for either rings A and B[15,19c,e] (*e.g.*, **66**) or rings B and C[18] (*e.g.*, **68**) (see also methods ⑨ and ⑩ in Scheme 1). The syntheses by *Tatsuta et al.*[19b] (→**64**→**65**) and *Danishefsky et al.*[15] (→**66**→**67**) converge to the intermediate **70**, which furnishes coriolin **5** on simultaneous epoxidation of both double bonds. However, the formation of the exocyclic epoxide is not stereoselective, and the yields of the last few steps range from 12[19b] to 29%[15] only. An improvement was achieved when—in



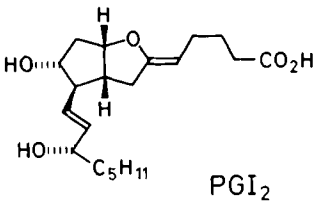
Scheme 16. Strategies of previously described syntheses of coriolin 5, coriolin B 71, and diketocoriolin B 72.

analogy to a previous synthesis of hirsutic acid[86]—first the cyclopentenone group of **70** was epoxidized stereoselectively, the keto group was reduced, and finally the exocyclic double bond was epoxidized according to the method of *Sharpless*. The overall yield of **5** after 24 steps was only 0.2%. The synthesis of **71** together with a previously described conversion of **71** into **72**[82b,87] also constitutes a formal total synthesis of the diketone.

Several other syntheses have been reported, all of which lead to the intermediate **70**[18,19c-e]. Among these, the work by *Trost et al.*[18] deserves special mention since it has been the only one so far exploring an enantioselective access to **70**, by way of **68** (e.e. 40%) and **69**[114]. The use of **44** (Scheme 15) promises to be the first satisfactory solution to the problem of enantiomeric resolution (with an enantiomeric excess of >98%), hopefully coupled with a practicable yield of the final product.

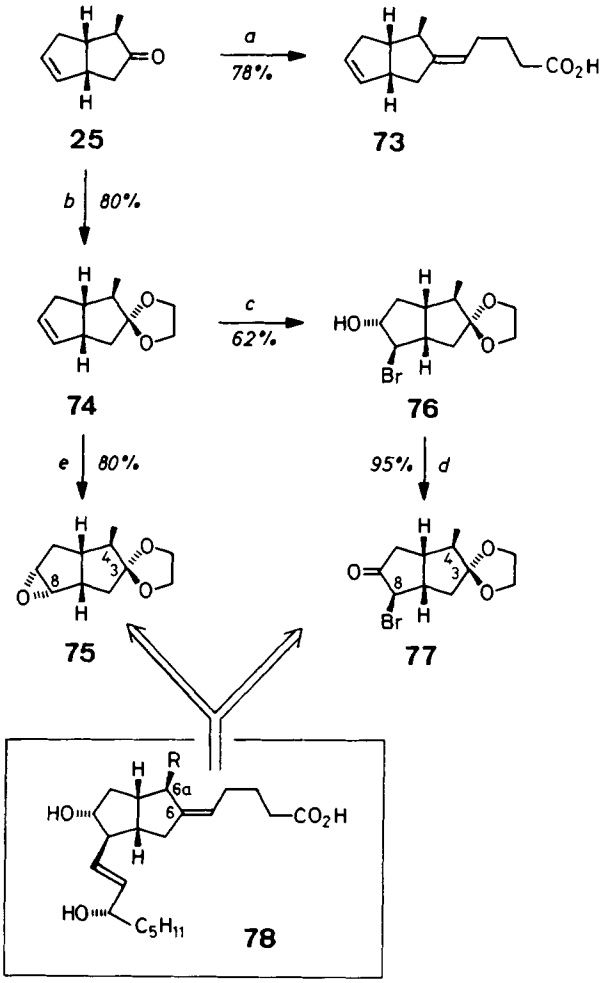
6.3.2. 6a-Carbaprostacyclins **78**

6a-Carbaprostacyclin **78** (R=H; other names: carba-PGI_2, carbacyclin, 9(O)-methanoprostacyclin) promises to eventually serve as a blood anticoagulant[88] in therapeutical applications as widely as do some naturally occurring prostaglandins[89]. Compound **78** (R=H) is the carbocyclic analogue of prostacyclin (=PGI_2)[90], the representative of greatest pharmacological importance among the prostaglandins. Such bicyclopentanoid analogues are more resistant to hydrolysis[91] than PGI_2, which is an essential advantage in therapy. This distinction has made the carbaprostacyclins a target of concerted synthetic efforts in the past few years[5,92-95].



PGI_2

Two combinations of functional groups, which are readily available *via* the unsaturated ketones **19** and **25** (Scheme 6), can now be envisaged to provide an improved synthetic access to 6a-carbaprostacyclin **78** (R=H) as well as—for the first time—to 6a-*exo*-alkylated derivatives (*e.g.*, **78**, R=CH_3): the ketone acetals with an *endo* epoxide such as **36b** (Scheme 8) and **75** (Scheme 17), and those with an α-bromoketone group such as **77**. The latter two intermediates were prepared as follows: On the one hand, oxidation of the unsaturated acetal **74** with *m*-chloroperbenzoic acid gave a 9:1 mixture of stereoisomeric epoxides (>95% yield). The major component **75**, with *endo* configuration, could be isolated by chromatography on a Florisil column (80% yield). On the other hand, treatment with *N*-bromosuccinimide in aqueous tetrahydrofuran converted **74** into a mixture of bromohydrins, from which the isomer **76** was separated by chromatography on silica gel. Although inferior to the highly selective step **74**→**75**, the yield of 62% **76** is sufficient to render this latter variant an alternative synthetic route worth further exploration. Similar transformations of the corresponding lactonic precursor of PGI_2 had proved non-selective[96]. The pure bromoketone **77** was obtained without further purification upon oxidation with *N*-chlorosuccinimide (NCS)/dimethyl sulfide[97].



Scheme 17. First steps of the enantiospecific total synthesis of a 6a-carbaprostacyclin **78** (R=CH_3) from **3a** *via* **19** and **25** (cf. Scheme 6). *a:* $Br(CH_2)_4CO_2H$, $(C_6H_5)_3P$, *n*BuLi, THF, room temperature. *b:* $HC(OCH_3)_3$, $(CH_2OH)_2$, TosOH. *c:* NBS, THF, H_2O, 0 °C. *d:* NCS, $(CH_3)_2S$, $(C_2H_5)_3N$, toluene, −30 °C. *e: m*-$ClC_6H_4CO_3H$, CH_2Cl_2, 0 °C.

The remaining tasks of the planned synthesis are restricted to the introduction of the side chains at C3 and C8 of **75** and **77**. For both, elaborate procedures are found in the literature. The δ-side chain is normally attached to C3 in a Wittig reaction, affording a mixture of isomers which differ with regard to the configuration of the double bond[5,93,94]. Since only the *E* isomer in formula **78** (R=H) exhibits the desired biological activity[5,94], we first began a synthesis of the as yet unknown methyl homologue **78** (R=CH_3). It was expected that the *exo* methyl group at C4 would direct the Wittig condensation with the adjacent keto group, still protected as the acetals in **75** and **77**, to selectively furnish the required configuration. And indeed, in an exploratory experiment with **25** exclusively the product **73**, with the correctly configurated double bond, was formed in high yield. The remarkably high degree of orienting influence on the Wittig reaction had not been exploited in previous work[5,93-95]. A likely obstacle was the

difficulty in carrying out stereoselective methylations on the bicyclo[3.3.0]octane systems used in these syntheses.

In the synthesis of PGI_2, *Corey et al.*[98] employed the Gilman reagent, lithium bisvinyl cuprate, to attach a ω-side chain precursor at C8 by opening of the *endo* epoxide with a high degree of the desired regioselectivity. The final build-up of the ω-chain was thus completed in three further steps. The same method should also be applicable to **36b** and **75**. A direct introduction of the entire ω-chain using a mixed cuprate reagent[99] which already contains the intact side chain, has been achieved so far only with 2,3-*endo*-oxidobicyclo[3.2.0]heptan-6-one acetal[96]. Although modest, the regioselectivity was still practicable. It is now of particular interest to note that in this special case the same combination of functional groups, epoxide and acetal was encountered as would be in **36b** and **75**. Moreover, the spatial arrangements are quite similar. The procedure may therefore be applicable to our intermediates as well. The overall synthetic enterprise may prove more simple in this case than the route involving the Gilman reagent.

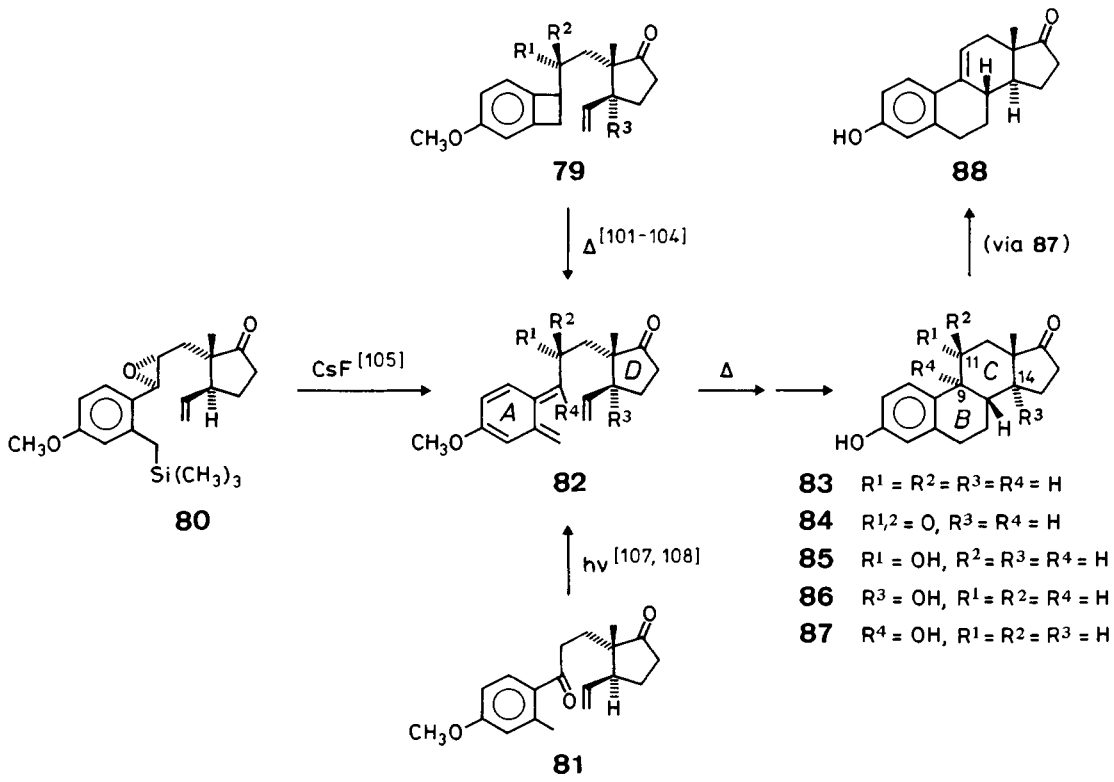
A possible alternative for the build-up of the ω-side chain begins with an alkylation step[5,93,95]. From among our set of intermediates, the bromoketone **77** should be an appropriate precursor.

Thus we are encouraginged to predict that the intermediates **36b**, **75**, and **77** will open up the hitherto most productive synthetic access to 6a-carbaprostacyclins **78** (R = H, alkyl) and 4,4-dialkyl derivatives, providing end products of high enantiomeric purity. For example, starting from benzene and using the mixed cuprate reagent, one may anticipate a total synthesis of **78** (R = H) in 12 steps, and of **78** (R = alkyl) in 13 steps. Employment of the bisvinylic cuprate would increase the sequences to 16 and 17 steps, respectively. In comparison with this prediction, the only completed synthesis of optically active **78** (R = H)[94] appears much less advantageous. It began with relatively expensive, optically active intermediates and led, *e.g.* starting from the Corey lactone[100], to a *E,Z*-mixture of **78** (R = H) in 17 more steps.

6.3.3. 9,11-Dehydroestrone **88**

Numerous novel and imaginative total syntheses of steroids have been developed in recent years mostly with the female sexual hormones estrone and estradiol as the target molecules. Both are widely used to regulate ovulation. The most pressing need at present is the development of more economic syntheses of optically active structural modifications of the estrogens in the hope of discovering analogues with fewer side effects on long-term application.

Most of the new syntheses use a building-up scheme in which the terminal rings A and D are linked first, and then the central rings B and C are simultaneously formed in a cyclization reaction: A + D → AD → ABCD (Scheme 18). This basic procedure has also been used for the generation of estrogens containing a functionalized ring C. The second step was accomplished either using purely thermal[101-105] or combined photochemical and thermal reaction sequences[107,108]. The double ring closure always proceeds *via* a regio- and stereoselectively well-controlled internal [2 + 4] cycloaddition of an *o*-quinodimethane-type precursor **82** which is generated *in situ*. This key intermediate can be generated by thermal isomerization of the appropriate benzocyclobutene **79**[101-104]. In two cases, the method led to oxygenated estrone derivatives: *Oppolzer*[101] prepared



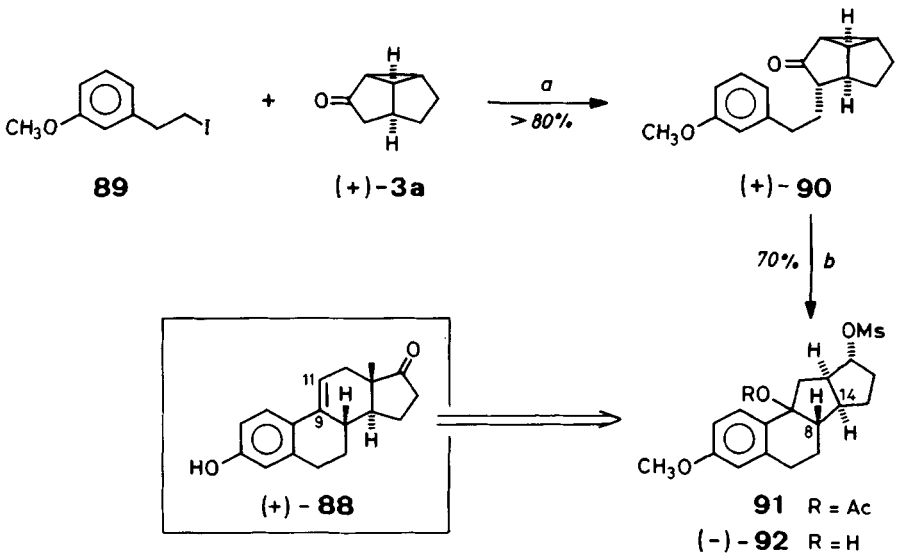
Scheme 18. Key steps of previously described enantiospecific total syntheses of estrone **83**, 11-oxoestrone **84**, 11α- **85**, 14α- **86**, 9α-hydroxyestrone **87**, and 9,11-dehydroestrone **88**.

the natural enantiomer of 11-oxoestrone **84**. The resolution of the racemate was carried out at the stage of the monocyclic (ring D) precursor of **79** (R^1, $R^2=O$, $R^3=H$). *Kametani et al.*[104] started from a 1,3-oxygenated ring D precursor (→ **79**, $R^1=R^2=H$, $R^3=OH$) in order to obtain the racemic form of a 14-hydroxy steroid **86**. In a synthesis aimed at racemic 11α-hydroxyestrone **85**, the *in situ* generation of an *o*-quinodimethane intermediate was achieved even at room temperature, when compound **80** was treated with cesium fluoride (→ **82**, $R^1=O^{\ominus}$, $R^2=R^3=R^4=H$)[105].

The photochemical variant consists of an intramolecular hydrogen abstraction by the optically active aromatic ketone **81** (Norrish type II photoreaction), leading to the *o*-quinodimethane **82** ($R^1=R^2=R^3=H$, $R^4=OH$). In this way, *Quinkert et al.*[107,108] opened up a novel access to 9α-hydroxyestrone **87**, 9,11-dehydroestrone **88**, and estrone **83**. For the synthesis of the oxygenated and unsaturated estrones 10 steps (formation of the racemates)[105] or 15 steps (formation of pure enantiomers)[101] are necessary if in each case the appropriate monocyclic ring D precursor is considered as starting material. With one exception only[108], these are rather costly cyclopentenone derivatives[101,104,105]. With regard to the number of steps—but not the overall yield—the earlier syntheses of 9,11-dehydroestrone **88** reported by *Crispin* and *Whitehurst*[106] and by *Cohen et al.*[109] still appear quite attractive, particularly in view of the fact that the starting material, an indane derivative of the Wieland-Miescher type, has become readily available in optically active form[110]. *Posner et al.*[111], in a more recent synthesis of **88**, underscored all previous efforts with respect to the number of reaction steps using a one-pot procedure which affords the end product in 5.5% yield starting from 6-methoxy-1-tetralone in an AB+D→ABD→ABCD sequence. The major drawback is that the method has so far been restricted to the synthesis of racemic material.

Our own work[112] assumes a route of the type A+CD→ACD→ABCD and it is founded on the prospect that, starting with an alkylation of (+)-**3a**, relatively few steps should lead to optically active 9,11-dehydroestrone **88** (Scheme 19). Treatment of the lithium enolate of (+)-**3a** with the phenylethyl iodide **89** at −20 °C smoothly furnished the *exo*-alkylated product (+)-**90**. Substituting bromide or tosyloxy derivatives for the iodide **89**, and sodium or potassium for lithium as the enolate counterion reduced the yields substantially, in accord with earlier experience[108,113]. The cyclization of (+)-**90** could be accomplished by treatment with acetyl methanesulfonate. The resulting tetracyclic acetoxymesylate **91** was hydrolyzed during the work-up to form the crystalline hydroxymesylate (−)-**92**. The mechanism of the ring closure is not yet clear. Undoubtedly the nucleophilic mesyloxy group was incorporated in the primary step of the cyclopropane cleavage[53,57], and the enol acetate (cf. **20**, Scheme 6) should have been formed at the same time. The subsequent closure of ring B corresponds to an acid-catalyzed cyclization, possibly a consequence of the difficulty to prepare the reagent without any contamination with acid.

Starting from benzene, the overall yield of optically active compound **92** (enantiomeric excess >98%) was 10%, with the last two (**3a**→**90**→→**92**) of altogether 8 steps not having yet been optimized. The only two asymmetric carbon atoms of synthetic importance, C8 and C14, were formed and retained, respectively, in the highly selective *exo* alkylation of (+)-**3a**. On continuing this project, attention will be focussed on the ring C enlargement, the introduction of the angular methyl group, and the epimerization of the secondary hydroxy function—reactions with ample precedent in steroid chemistry. This outlook hopefully justifies our optimism that the photoproduct **3a** in an application beyond the domain of polycyclopentanoid compounds, may open up a novel and economic route to optically active steroids possessing a functionalized ring C.



Scheme 19. First steps of an enantiospecific total synthesis of 9,11-dehydroestrone **88** from 3-methoxyphenylethyl iodide and (+)-**3a**. *a*: LDA, dimethoxyethane, −20 °C. *b*: $CH_3SO_3COCH_3$, $CHCl_3$, room temperature; yield of both steps not yet optimized.

7. Conclusions and Outlook

We have presented a synthetic concept with a photochemical key step which is particularly attractive with regard to its unusually wide versatility, and to the extraordinarily clean and selective reaction courses. Irradiation conditions have been used throughout which should pose no serious problems to scaling-up.

The parent building block, tricyclo[3.3.0.$0^{2,8}$]octan-3-one **3a**, is readily accessible from commercially available chemicals. Its resolution into both enantiomeric forms is quite simple, and it is amenable to a large variety of transformations. Compound **3a** is thus qualified as one of the most attractive starting materials for the total synthesis of optically active cyclopentanoid substances. Only the building blocks with a higher degree of substitution (**3b**, **c** and **9d**, **e**), although also readily accessible in their racemic forms, require further improvements of the optical resolution methods in view of their most promising potential as intermediates *en route* to non-linearly fused polycyclopentanoid natural products, such as isocomene (from **3c**) and the pentalenolactones (from **9e**).

In addition to the synthetic projects which have been taken up so far, one may consider probing into modifications of the basic concept in various ways, such as the following: Incorporation of heteroatoms may lead to, *e.g.*, alkaloid structures. Cleavage of the central 1,5-bond of **3** could open a route to medium-sized rings, with the ultimate goal of synthesizing sesterpenes such as the ophiobolins. Furthermore, a stereocontrolled access to acyclic elements appears feasible by way of oxidative bond fissions, and thus bring classes of macrolides and polyether ionophores within synthetic reach.

We have summarized the synthetic work of many notable young collaborators, Dr. A. Cánovas, Dr. C. Carter, Dr. S. Chandrasekhar, Mr. G. Mikhail, Mr. P. Ritterskamp, Dr. K. Nakano, Dr. U. Pati, Dr. P. R. Raghavan, Dr. K. Tsutsumi, and Mr. B. Wietfeld, supported by the able technical assistance of Mrs. H. Adams-Schulze. The results of their enthusiastic and intense collaboration have not yet been published in any detail, if at all. The authors of this account should therefore like to gratefully acknowledge for the first time the relentless efforts and contributions of the whole group.

Immobilized Biomaterials—Techniques and Applications

By Bhavender P. Sharma*, Lorraine F. Bailey, and Ralph A. Messing

The immobilization of enzymes, cofactors and whole cells offers the potential of economical exploitation of biomaterial activity. Enzymes or cells can be immobilized by binding to carriers through adsorption or covalent linkages or by entrapment in a polymer matrix or microencapsulation. The development of immobilized biomaterial systems requires the involvement of biochemical, kinetics and reactor design principles. Examples of commercial scale applications of immobilized biomaterial systems are the production of a fructose-rich syrup from starch and the synthesis of L-amino acids by selective hydrolysis of *N*-acyl-D,L-amino acids.

1. Introduction

The standard of living that the high-technology industrial nations have achieved during the first three-quarters of the twentieth century has led to increased demands for raw materials, energy, and, last but not least, food. In addition, the increased rate of industrial mechanization and activity has led to numerous ecological problems, which, in turn, appear to forecast diminishing supplies of raw materials.

The intent of this introduction is not a prediction of "gloom and doom" but rather to demonstrate the need of alternatives for conservation and of less wasteful approaches for the utilization of our natural resources. The immobilization of biomaterials is a useful technology for attaining these objectives. An overview of the techniques and applications in the immobilized biomaterials field is presented in this paper.

Modern man has ravaged the bowels of the earth for minerals; over-abundantly harvested vegetation; and wantonly spewed waste into the streams, water bodies, atmosphere, and upon the surface of the solid earth. These wastes have, in turn, putrified his environment. With this putrifaction he has destroyed much of his animal and plant resources.

Increased costs due to the diminishing supply of certain materials such as aluminum, copper, chromium, *etc.* have persuaded our society to initiate a recycling program. The light dawns!

Putrifaction pollution, however, does not arise from inorganic materials but rather from organic molecules that are subject to microbial attack. These waste organic molecules represent an additional rich source of raw materials. If this waste were to be harvested, the following items could be produced by a recycling process:

1) fuel in the form of methane or alcohol,
2) glucose, the major nutrient for the production by fermentation of antibiotics and other industrial commodities,
3) synthetic petroleum stocks for plastic production,
4) food and food supplements for livestock,
5) vitamins and hormones.

It is clearly apparent that waste will not exist if proper utilization of this squandered resource is adequately planned.

Plants, animals, and microbes are harvested for the production of biological catalysts, enzymes, which in turn are employed in processing foods and pharmaceuticals. Since these biological catalysts are soluble and generally employed in batch reactions they are used but once, and either they are destroyed in further processing, or they cannot be recovered from the reaction economically. An enzyme is a precious material harvested, sometimes, at the sacrifice of a precious life. Immobilization technology offers the opportunity to reuse the biological catalyst and thus reduce the consumption of life and the need for additional resources to produce that life.

The needs for the immediate future will probably be supplemented with methane or natural gas produced by immobilized cells. Although this gas is relatively clean, the preferred fuel which causes no atmospheric pollution is hydrogen. A hydrogen fuel economy, however, is at least fifteen years hence. Our society is neither geared to employ hydrogen nor prepared to transport this fuel over great distances in large quantities. The hydrogen economy of the future may well be supplied from solid-phase reactors which are capable of either splitting water to produce hydrogen and oxygen (biophotolysis) or stripping hydrogen from photosynthetically produced, organic molecules.

2. Immobilization[*]

The knowledge base accumulated on enzyme immobilization studies has grown to very large proportions and this wealth of information is one of the primary reasons for the advance in enzyme engineering that is being witnessed currently. The slower-than-predicted introduction of immobilized enzyme systems into commercial use has been the result of numerous factors. Some of these factors have been the development of more practical techniques of immobilization, frequently with nontoxic chemicals, the long term experiments required for approval of the total biological composite for use in food applications, learning to control microbial contamination in biological reactor systems, and

[*] For detailed reviews see *e.g.* [1-6].

enzymes possessing characteristics limiting their economic success, to name a few. The engineering of enzymes with more useful characteristics will overcome some problems encountered that have prevented commercial processes from developing.

2.1. Advantages to Immobilization

Besides reuse of biological catalysts and therefore reduced consumption, immobilization can offer numerous advantages in the operational handling of these materials. It can be employed to stabilize an otherwise labile substance by covalent multi-point attachment or by confinement in a stabilizing and protecting environment (Fig. 1)[7,8].

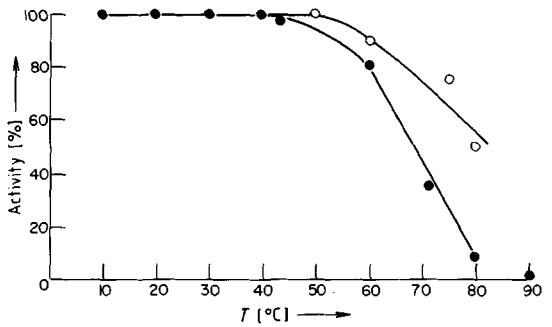

Fig. 1. Example of the increase in thermal stability of an enzyme by immobilization. This figure is a comparison of papain in soluble form (● — ●) and immobilized on porous glass (○ — ○) on storage at increasing temperatures for 30-minute periods. The activity remaining was measured at 25 °C (after [8]).

In so doing, chemical and physical properties can be selectively altered to one's choice of application. Not only are batch reactions possible, but continuous processes can be considered. Multiple enzyme immobilization can confer greater efficiency in consecutive multi-step reactions. Rate enhancement results because of an abnormally high local concentration of intermediates (the products of one enzyme which become substrates for the next one) relative to the conditions existing in a free solution. Multiple enzymes also mimic the cell environment where complex enzyme systems are common.

2.2. Immobilization of Microorganisms or Enzymes?

Many extracellular microbial enzymes are produced in large enough quantities to be used in industrial processes; however, the cost of isolating and purifying intracellular enzymes for commercial processes can dampen the profitability sufficiently for their use to become unattractive. Nonetheless, there are advantages to the isolated enzymes that must be balanced against cost based upon the nature of the conversion process. Isolated enzymes offer greater purity and the possibility of apparent modified kinetics which, in turn, may yield higher conversion of products less contaminated by miscellaneous materials. Immobilizing microorganisms containing the catalyst of interest combine the advantages inherent in the use of immobilized enzymes with those of microbial fermentation processes.

Immobilizing the whole cell should be considered when the extracted enzyme is unstable, since retaining the enzyme within its natural surroundings preserves its stability. Additional considerations for cell immobilization are: that no enzyme-catalyzing interfering side reactions be present within the cells (although often these can be deliberately inactivated); that the cells retain greater enzyme activity than is possible with immobilized enzymes; that the reactor volume per unit of product is much smaller for the continuous, immobilized cells method than for the conventional fermentation process. A conceivable short-coming could be encountered by substrate and product transport resistance of cell wall and cell membrane.

2.3. Effects of Immobilization

Upon immobilization, alterations in the properties of enzymes occur which result from cumulative reactions. An immobilized preparation placed into a solution of substrate, activators or other components at a given pH and ionic strength, does not assure that the conditions in the medium immediately surrounding the enzyme will be identical to those in the external bulk solution[9]. This phenomenon, referred to as the microenvironmental effect, can be the result of charges or physicochemical properties of the supporting matrix[8] or may be caused by diffusional limitations (Figures 2 and 3).

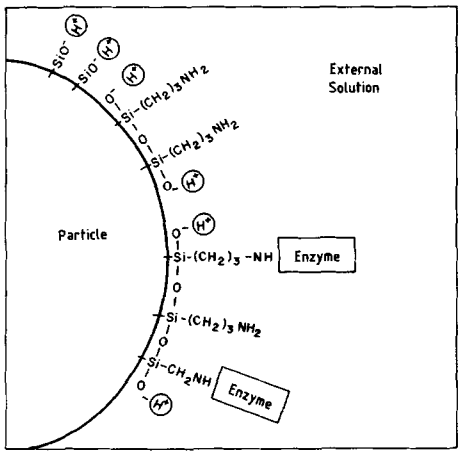

Fig. 2. Effect of pH upon the microenvironment of an immobilized enzyme on porous glass with primary amino groups (schematic). An accumulation of H^+ ions at the surface creates a more acidic environment than that of the external bulk solution (after [9]).

Kinetic constants and other enzyme parameters investigated on immobilized preparations are not true values equivalent to homogeneous reactions because of these factors, and measured values are referred to as apparent specific activity. Operational activity should be obtained under the specific process conditions under study.

In making a selection for a method and materials for immobilization of a whole cell, the choice must be dictated by the ultimate use of the cell and the effect of the immobilization procedure on the integrity of the cell. Whether or

not the enzyme of interest within a cell retains its activity only in viable cells, or only in intact cells, or is stable in non-growing cells will narrow the types of methods that

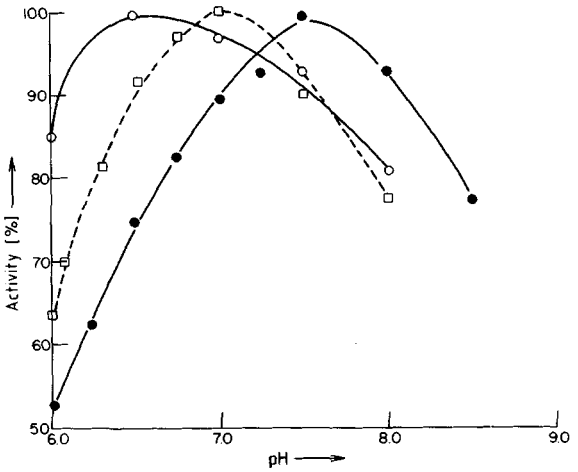

Fig. 3. The effect of increasing pH on the activity of soluble papain (O—O) and two papain immobilized samples on derivatized porous glass using heat-denatured casein as substrate. The carrier charge changed the profile as well as immobilization. □---□, negatively charged surface; ●—● positively charged surface (after [8]).

can be employed. In such cases as for the regeneration of cofactors, the system will be useful only as long as the cells are viable, thereby determining the life of the system. Under certain conditions, it may be necessary to supply a nutrient to retain the integrity and growth of the cell.

2.4. Methods of Immobilization

Briefly, enzymes or cells can be immobilized by binding to carriers through adsorption or covalent linkages or by entrapment within a matrix or microcapsule (Fig. 4).

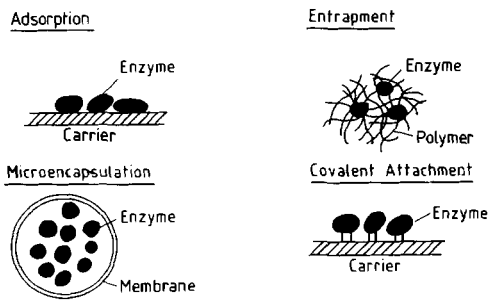

Fig. 4. Schematic representation of the general immobilization techniques.

Frequently, immobilization of a protein cannot be attributed to purely chemical or physical means, and quite often successful immobilization is dependent on both. The choice of carrier and the method of immobilization are nearly inseparable and dependent upon numerous factors which will be further elaborated as the discussion progresses.

2.4.1. Adsorption

Adsorption is the attachment of a protein to the carrier surface which has not been specifically functionalized for covalent bonding. The mechanism of adhesion may include simple ion-ion interactions, hydrogen bonding, hydrophobic interactions, or covalent bonding. The stability of the adsorbed protein will depend upon the additive strength of those bonds formed under the conditions of immobilization and those bonds maintained under the application conditions that are finally employed for the immobilized preparation. In theory, adsorption should be a reversible process; but in practice, it may or may not be. The degree of adsorption or desorption will be contingent upon a balance of parameters including pH and ionic strength of the medium, presence of substrate, protein concentration, time and temperature, as well as inherent characteristics of the enzyme and the support. The reversibility of adsorption may be of practical advantage, since intact recovery of both the enzyme and the carrier may be possible.

Operationally, adsorption is probably the simplest and most economical of the immobilization methods.

2.4.2. Covalent Attachment

Covalent bonding can involve the activation of the support material for reaction with protein groups, or the use of a coupling reagent for linkage of the protein and support matrix, or the activation of the protein for binding to the support. It is by far the most intensively studied of the immobilization techniques (Fig. 5). The overall configuration of a protein is designed to bring the residues of the active site into a precise arrangement of charge and microenvironment. Therefore, in the process of immobilization, care must be exercised to retain that active conformation. Failure to achieve an active, immobilized preparation may often be due to inactivation of the enzyme. If necessary, the active site can be protected by the presence of substrate or a competitive inhibitor during coupling. These protective molecules can be removed afterwards. For the most part, the chances of binding at the active site are slight, since the area of the active site is quite small in comparison to the overall area of the protein. Further, the active site is frequently located in a recessed portion with entrance dependent upon size, charge characteristics, and stereochemistry of the coupling agent. Sometimes, an increase in activity is observed after initial operation due to additional enzyme active sites opening up in the presence of substrate which may formerly have been bound to the carrier or adjoining protein molecule.

The amino acid groups suitable for binding are based upon their reactivity, their concentration within the protein, their location, and the microenvironment in which they are placed. The amino groups have been extensively used as sites for covalent binding, as they readily react with aldehydes, diazonium salts, isocyanates, acylating and alkylating agents.

Covalent attachment is considered the most permanent of the immobilization methods.

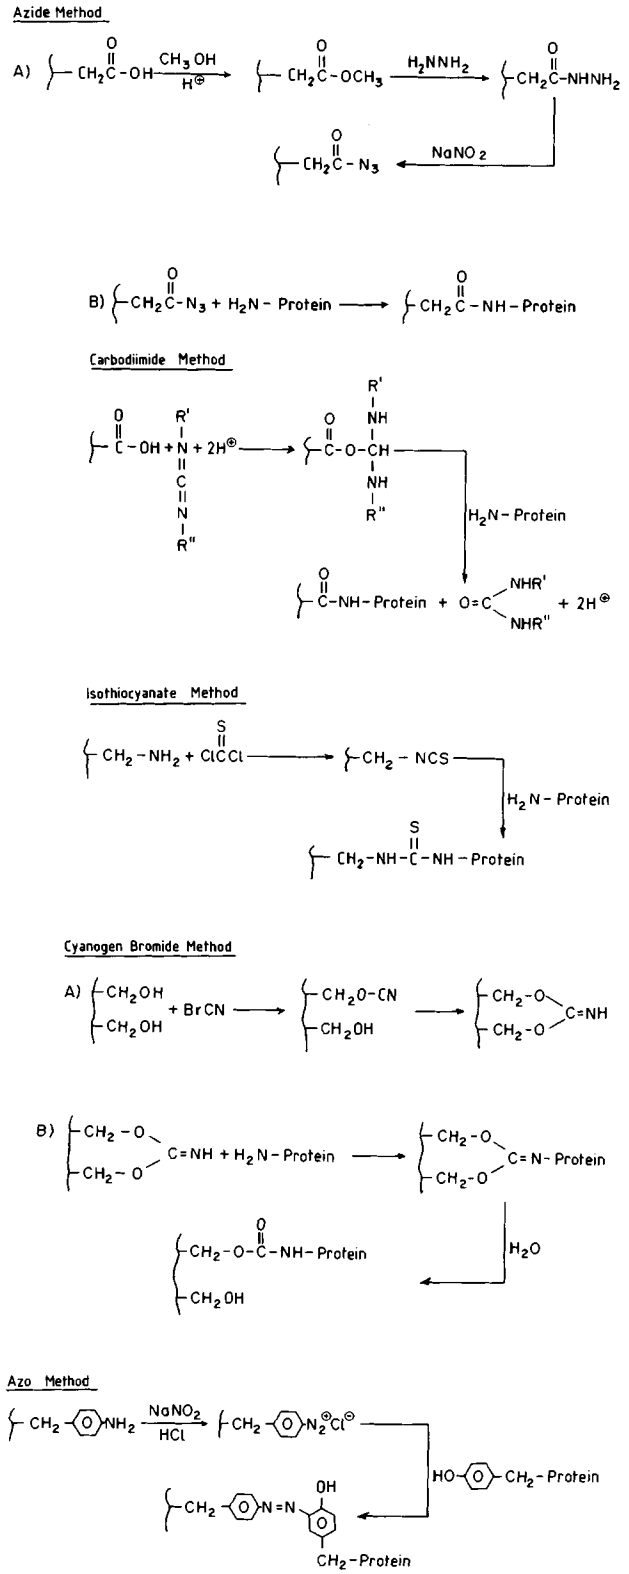

Fig. 5. Methods most commonly used for the immobilization of enzymes by covalent bonding.

2.4.3. Matrix Entrapment

To entrap an enzyme, either a cross-linked polymeric network is formed around the enzyme molecule, or the enzyme is placed inside a polymeric material, and the polymeric chains are then cross-linked. This is usually followed by disruption of the polymeric mass into the desired particle size. The most commonly used polymeric material is the polyacrylamide gel system; although silica gel, starch, and silicone rubber have also been employed for this technique. Entrapment is probably the most popular method of immobilization of microbial cells, although other methods have been successfully utilized. In recent years, materials like alginic acid and carrageenan have been employed which form beads of gel when the cell-containing solution of these materials is extruded into salt solutions such as $CaCl_2$. The advantage of this type of material is its nontoxicity to the cells—enzymes, also, are amiable to entrapment with these materials.

The end result is the confinement of the enzyme or cells within lattices of gels which permits the free diffusion of appropriate sized substrate and product molecules. These molecules are limited to low molecular weight due to the pore size requirement needed to prevent escape of the high molecular weight enzyme. The problem of enzyme release is always present because of the unequal pore distribution of the gels; however, it is possible to overcome this by cross-linking the entrapped enzyme with a bifunctional reagent such as glutaraldehyde.

The solubility of the enzyme within the entrapment medium may limit the maximum loading of the enzyme. The actual specific activity of the entrapped enzyme may be determined by such factors as microenvironmental effects of localized pH or ionic strength and unequal partitioning of the substrate, or inhibitors of the enzyme activity. In theory, this method of immobilization does not involve a disruption of the enzyme configuration.

2.4.4. Microencapsulation

Microencapsulation is only applicable to enzymes whose substrates and products are of rather low molecular weight. There are two methods of forming membrane microcapsules, one based upon coacervation (a physical phenomenon) and the other upon interfacial polymerization (a chemical process). The thickness and permeability of the membrane is influenced by the organic solvent composition, the concentrations and chemical components utilized to form the membrane, as well as the time of capsule formation. In principal, no chemical modification of the enzyme occurs, and thus, there should be no changes in the inherent properties of the enzyme. However, diffusional effects and enzymatically generated microenvironments can bring about apparent alterations in enzyme properties.

While this immobilization method is directed more toward medical use, there may be circumstances where the membrane protection would be beneficial and applicable to industrial processes.

2.5. Carrier Selection

The components comprising an immobilized enzyme system are the enzyme, the carrier, and the method of attachment. Other contributors such as pH, ionic strength, pressure, agitation, cofactor delivery, substrate delivery,

and product removal may affect the performance of the immobilized enzyme. The final system should be evaluated by the sum of the cost of the contributions of the individual components *versus* the performance value of the system. In making a carrier selection, the carrier properties of morphology, surface contributions, composition (see Table 1), and regeneration should be assessed. All should contribute synergistically to the enzyme activity in the application environment for optimum economic performance.

Table 1. Carriers for biomaterials (selection).

Controlled pore glass and ceramics (alumina, silica, titania)
Polystyrene
Ion-exchange resins
Agarose and Sephadex
Nylon
Collagen
Polysaccharide supports (cellulose, dextrose, starch, agar)
Acrylic copolymers
Silicone rubber
Silica gel
Bentonite
Clay
Magnetic supports

The morphology of the carrier is extremely important with respect to surface area and pore parameters. Superimposed upon this is the gross configuration of shape in a particulate, spherical, sheet, tube, fiber, or membrane form. Since the enzyme is attached to the surface, the surface area and thus the loading of the enzyme are greatly affected by whether or not the carrier is porous[3, 10]. Nonporous supports are very low in surface area; however, because of this characteristic diffusional constraints are minimal since the protein is located only on the external surface. While porous supports have much larger surface areas, much of the surface is internal; nevertheless, the potential for maximizing activity is greatly enhanced by this feature. In addition, the internal surface offers a protection from the turbulent and sometimes harsh, external environment as well as microbial attack. A variety of controlled pore (narrow pore distribution) and broad pore carriers are now available. These can be used to optimize biomaterial activity (Fig. 6—8).

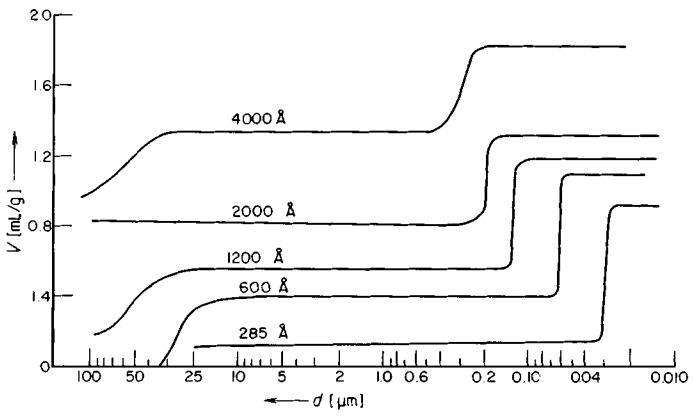

Fig. 6. Relationship between pore diameter d and pore volume V in glasses with controlled pore size. The midpoint of the vertical section in each curve represents the average pore diameter. The steeper the slope of the vertical section, the tighter is the pore control (after [10a]).

Also to be considered in carrier choice are the intrinsic features of whether the material is inorganic or organic. Inorganic carriers offer rigidity and lack of deformation. They can be expected to undergo abrasion in continuous stirred reactors but handle well in plug-flow reactors, and large pressure drops are not encountered. Organic carriers, on the other hand, are more flexible and elastic, which promotes the ease in which a variety of configurations can be produced, *e.g.*, a thin membrane. They resist abrasion

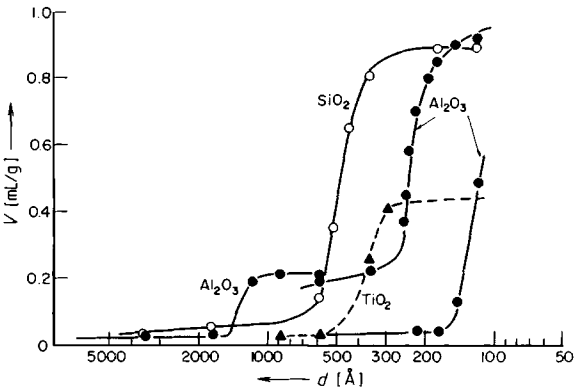

Fig. 7. Relationship between pore diameter d and pore volume V in controlled-pore ceramics as determined by mercury intrusion (after [10b]).

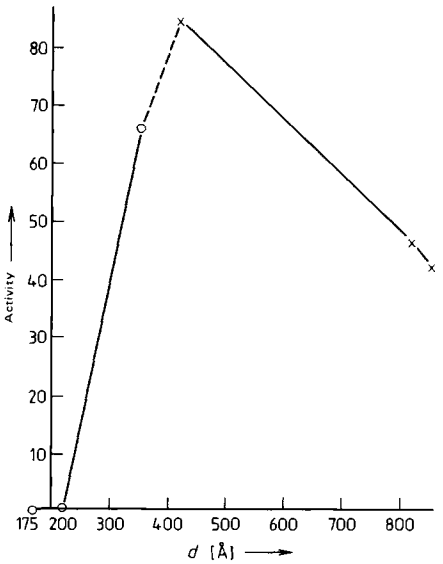

Fig. 8. Activity of glucose oxidase (in units/g) as a function of pore diameter d, cumulative data (after [7]).

in continuous-stirred reactors, but greater pressure drops will be experienced with their use in plug-flow reactors.

The ability to regenerate the immobilized enzyme system significantly effects its economics. The three approaches to regeneration are: 1) the reactivation of the immobilized preparation by removal through appropriate washing of the material plugging the pores that produced inactivation; 2) regeneration of the immobilized preparation by adding fresh enzyme to the system; and 3) regeneration of the carrier by removing old enzyme by chemical or physical means and initiating immobilization procedure anew.

3. Technical Application of Immobilized Biomaterials

3.1. Introduction[*]

Suppose the above-mentioned advantages in using immobilized biomaterials appear promising for a specific problem, the next step is the development of a suitable system. It is likely to be carried out in the context of questions relating to the selection of a carrier, the immobilization technique, and the reactor system. Ideally, these three facets should be considered simultaneously. This section will deal with the application of some concepts in developing an immobilized biomaterial system—the kinetic and mass transfer aspects, and the criteria and strategy in selecting, developing and operating a reactor system.

3.2. Kinetics of Reactions Catalyzed by Immobilized Biomaterials[**]

In general, the laws of conservation of mass and energy, as well as of physical transport phenomena, provide the framework for reactor calculations. Of course, immobilized biomaterials are *catalysts* which merely influence the rate of reactions without affecting the reaction equilibrium. Immobilized biomaterials often catalyze reactions under mild temperature conditions at a rate that exceeds that of solid, non-biological catalysts. Admittedly, comparable or better rates can be achieved with non-biological catalysts at elevated temperatures, while most biomaterials are denatured above 60 °C. An exception is the enzyme α-amylase (cf. Section 4.2.1).

The strategy for deriving rate expressions in chemical kinetics involves an appreciation of what elementary reactions might be involved in the system of interest. The reaction considered to be the slowest is the rate-limiting reaction, and it provides a reasonable rate expression. However, for immobilized biomaterial kinetics, the starting point most frequently used is a postulation developed in the early 20th Century by *Henri, Michaelis-Menten,* and *Briggs-Haldane,* namely Eq. (1).

$$-\frac{dS}{dt} = v = \frac{kES}{K_m + S} \tag{1}$$

[*] For detailed reviews see [11–16].

[**] The following abbreviations are used:

E Total concentration of biomaterial (enzyme), free and bound
F Flow rate
k Turnover number, a constant whose dimension is a reciprocal of time
K_i Product inhibition constant
K_m Michaelis constant with the dimension of concentration. Its numerical value corresponds to the substrate concentration at half-maximal reaction rate
P Product concentration
S Concentration of the non-bonded substrate at time t
S_0 Initial substrate concentration
S_t Total substrate concentrations if all product were converted to substrate
t Reaction time
v Reaction rate
V_{max} Maximum reaction velocity ($=kE$)
X Fractional conversion, $(S_0-S)/S_0$
X_e X_t at equilibrium
X_i $(S_t-S_0)/S_t$
X_t $(S_t-S)/S_t$

To many, this expression would be recognizable as being similar to that for a hyperbolic function, or Langmuir-Hinshelwood, or Houghon-Watson kinetics. The Michaelis-Menten equation [Eq. (1)] thus expresses kinetics between zero and first order. At low concentrations of the limiting substrate (reactant), the reaction is first order. If the substrate concentration is increased, the reaction order gradually diminishes to zero. There is also a direct dependence of the reaction velocity upon the total enzyme concentration. The parameters in the Michaelis-Menten equation can be estimated by rearranging the equation to yield a linear plot.

$$\frac{1}{v} = \frac{1}{V_{max}} + \frac{K_m}{V_{max}} \cdot \frac{1}{S} \tag{2}$$

Such a plot is referred to as the Lineweaver-Burke plot. Figure 9 is an example for a free as well as an immobilized protease enzyme[17]. That the data for the immobilized form are non-linear suggests mass transport effects, discussed later in this article (see Section 3.3). Other linearized and useful forms of the Michaelis-Menten equation are the Hanes-Woolf, Woolf-Augustinsson-Hofsfee, and Eadie-Scatchard plots.

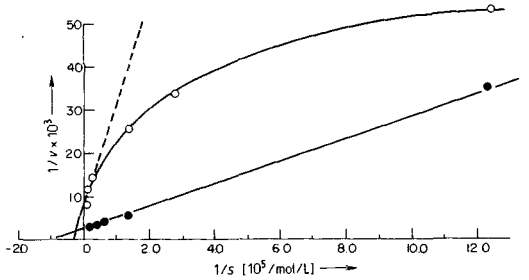

Fig. 9. A Lineweaver-Burke plot for a *B. subtilis* neutral protease with 1 percent sodium caseinate as the substrate. Zirconia coated silica glass was used as the support. The curvature in the plot for the immobilized enzyme indicates mass transfer effects. O—O: immobilized enzyme, $K_m = 3.3 \times 10^{-5}$ mol/L; ●—●: native enzyme, $K_m = 6.2 \times 10^{-6}$ mol/L (after [17]).

More often than not, the kinetic expression is more complex than Eq. (1). Frequently, inhibition or activation by the substrate or the product is observed, or the reaction involves multiple substrates, cofactor activation or multiple products. For immobilized biomaterials in particular, microenvironmental parameters such as pH, temperature and transport resistances are also factors to be considered. In the case of hydrolysis of lactose by β-galactosidase, a product, galactose, acts as an inhibitor. In this case, Eq. (1) may be modified as follows to include product inhibition by product, P:

$$v = \frac{kES}{S + K_m\left(1 + \frac{P}{K_i}\right)} \tag{3}$$

where K_i is the inhibition constant. The lower the value of K_i, the greater is the degree of inhibition (for a given S and P).

Since a knowledge of these kinetic parameters as well as the kinetics is extremely valuable in predicting the behavior of an immobilized biomaterial system, the subject has befittingly received much attention (improvement of kinetic studies, cf. [18–23]).

3.3. Effect of Heat and Mass Transport Resistance

Most reactions catalyzed by immobilized biomaterials have a low heat of reaction. So mass transport and not heat transport resistances happens to be the important consideration. The substrate(s) must be transported to the active site(s) of the attached catalyst and the product(s) away from it. This movement is guided by the rules of diffusion and convection. One should always remember to ensure that kinetic data are so obtained that reaction, and not diffusion, is controlling. In many cases, the kinetics observed are termed "apparent kinetics" when mass transport resistance could be significant. It should be noted, that "apparent K_m" is not an intrinsic property but is a function of the micro- and macroenvironment[24]. It is useful to know if the "intrinsic" or real kinetic parameters of a biomaterial system have changed as a result of immobilization. Such knowledge can be indispensible in the scale-up and design of industrial reactors.

It is convenient to think in terms of external mass transfer effects and internal mass transfer effects. The concern while considering the internal mass transfer has to do with transport resistance inside the porous particle or membrane to which the biomaterial is immobilized. External mass transfer problems involve transport resistances in the media surrounding the immobilized biomaterial particle or membrane. In such studies, chemical engineering concepts for determining controlling resistances in solid catalyzed reactions and for simultaneous diffusion and reaction are relevant[25].

Even when the kinetics for an immobilized biomaterial system can be described by a Michaelis-Menten type pattern, mass transfer effects can cause Lineweaver-Burke type plots to be curved or non-linear (cf. Fig. 9). While a non-linear Lineweaver-Burke plot[17,26,27] is not a definite indication of mass transfer problems, its presence is sufficient cause for a strong suspicion. A number of papers have presented mathematical analyses of non-linearity in such plots[28–31]. Both internal and/or external mass transfer limitation can cause this non-linearity. A significant difference between the K_m values for the soluble and the immobilized biomaterial, even in an otherwise linear kinetic plot[32], is also a suggestion that mass transfer resistances may be present.

The significance of internal mass transfer effects is often expressed in terms of an effectiveness factor η as defined below:

$$\eta = \frac{\left[\begin{array}{c}\text{Apparent or observed reaction rate with porous}\\ \text{particle or membrane}\end{array}\right]}{\left[\begin{array}{c}\text{Reaction rate without internal mass transfer}\\ \text{resistance}\end{array}\right]} \quad (4)$$

Another dimensionless variable that can be used to express the magnitude of the external mass transport effects is the Damköhler number Da:

$$\text{Da} = \frac{\left[\text{Maximum true or intrinsic reaction rate}\right]}{\left[\begin{array}{c}\text{Maximum mass transfer rate of substrate from}\\ \text{bulk to interface}\end{array}\right]} \quad (5)$$

Thus, when η is close to 1, and Da is much less than 1, a system may be said to have low mass transfer resistance and consequently to be relatively free of mass transfer problems. A few practical techniques available for ascertaining whether external mass transfer is a problem will be considered first, to be followed by a few ways of examining pore diffusion problems.

In general, the effect of external mass transfer resistance is to reduce the observed activity. If the apparent reaction rate remains unaffected by a sufficiently large variation in linear velocity, then external mass transfer is not the primary limiting factor in the system being considered. Experimentally, for packed-bed type reactors, considered later in this paper, this can be examined by operating with different bed heights but the same residence time. A more common approach is to measure the reaction rate for a series of flow rates as shown in Figure 10 for immobilized yeast invertase[33].

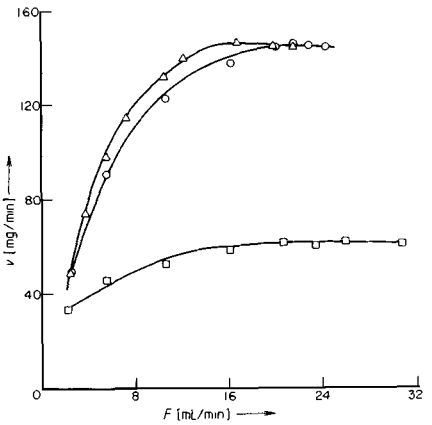

Fig. 10. Examination of external mass transfer effects. Invertase from *C. utilis* was immobilized onto porous cellulose beads. Bead size: □ 28 mesh, ○ 35 mesh, △ 48 mesh. Dependence of the reaction rate v (formation of invert sugar from saccharose) on flow through F (after [33]).

Such studies should be carried out under conditions of negligible internal or pore mass transfer resistance, as would be the case for non-porous supports. Estimates of actual rates of external mass transfer can be made with the help of several mass transfer correlations[12,16,34], originally arrived at in the chemical engineering literature. The external mass transfer rate can be compared with the rate of biochemical reaction to judge the relative importance of external mass transfer. A convenient, short-cut procedure is that of *Satterfield*[35,36]. The height of an immobilized biomaterial bed required to yield the observed degree of substrate conversion, assuming that film diffusion is controlling, can be calculated using *Satterfield*'s correlation. If the actual bed height being used in the system is significantly greater than the calculated bed height, external or film diffusion resistance is insignificant.

Pore diffusion effects, in general, also lower the observed activity as expressed by the effectiveness factor η [Eq. (4)]. A general idea of how significantly pore diffusion can influence reaction rates is provided by Figure 11[37]. As one might expect, the effectiveness factor increases as the substrate concentration increases. The relative increase

and the actual value of η also depend on the modified Thiele modulus Φ_0, a dimensionless number incorporating the shape and site of the biomaterial particle or membrane, the effective diffusivity, and the kinetic constants K_m and V_{max}. Larger particles or thicker membrane means larger Φ_0. For a substrate concentration about ten times the Michaelis constant and for a Thiele modulus of about two, the observed reaction rate is reduced by about 50%.

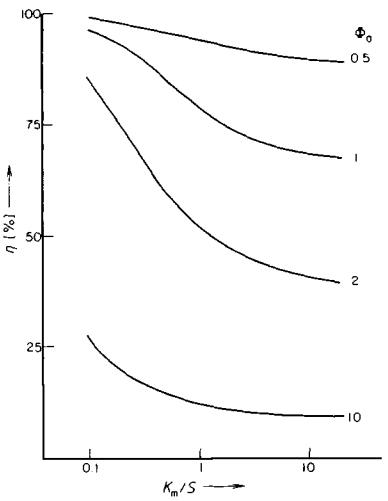

Fig. 11. Relationship between the internal effectiveness factor, η, the Thiele modulus, Φ_0, and dimensionless substrate concentration, K_m/S (after [37]).

As explained by *Levenspiel*[25], the existence of strong resistance to pore diffusion can be determined by at least the following three methods (assuming that resistance to external mass transfer is negligible):

1. *By estimating a value for the effective diffusion coefficient* within the enzyme particle or membrane. Appropriate test criteria[38] can be applied to see if strong pore resistance is present. In addition, the observed rate, the substrate concentration, support measurables, and the rate expression are required. A knowledge of the effective diffusion coefficient also permits one to utilize generalized plots for estimating the effectiveness factor, η[12,16,32]. However, since the estimation of the effective diffusion coefficient is not straightforward, the next two approaches are probably used more often.
2. *By measuring reaction rates for different particle sizes or membrane thicknesses.* If no increase is seen in the observed reaction rate by decreasing the membrane thickness or particle size, pore diffusion problems are not likely to be significant[39].
3. *By measuring reaction rates at different temperatures.* Reaction rates are significantly more temperature dependent than are diffusion rates. Reaction rate *versus* temperature data can be used to estimate an activation energy *via* an Arrhenius plot (see Fig. 12).

A non-linear or curved Arrhenius plot strongly suggests pore diffusion problems. However, a linear Arrhenius plot is only a partial proof of the absence of pore diffusion limitation. For example, for the case of β-amylase immobilized onto porous silica[40], the Arrhenius plot (Fig. 12) is linear. Despite that, the effectiveness factor for this system was estimated to be about 0.2, indicating slow intraparticle diffusion. A comparison between the activation energies (calculated by multiplying the slope of the Arrhenius plot by the ideal gas law constant and changing the sign) for the soluble and immobilized biomaterial also helps one to determine if pore diffusion is a problem[41]. The observed activation energy for an immobilized biomaterial system involving strong pore diffusion limitation is roughly one-half the true or intrinsic activation energy[25] ascertained for the reaction catalyzed by the native biomaterial.

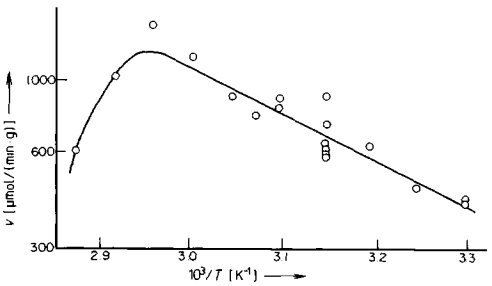

Fig. 12. An Arrhenius type plot for barley β-amylase immobilized onto porous silica particles. Dependence of the reaction rate v (formation of maltose (μmol) from starch referred to immobilized enzyme (g) and time (min)) on the temperature (after [40]).

Another practical method to define conditions where pore diffusion is not significant is the "e-test" suggested by *Yamane*[42]. According to this concept, utilized by others previously, reaction rate measurements with varied biomaterial loadings (amount per unit weight) are made. The data should exhibit a hyperbolic profile (Fig. 13), and the region where the rate increases linearly with loading can be identified for a high effectiveness factor.

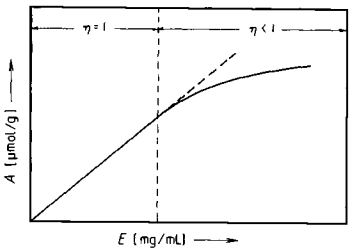

Fig. 13. Determination of the range of an enzyme reaction where the effectiveness factor, η, is equal to 1, assuming the biomaterial concentration itself does not affect the activity loss upon immobilization. Dependence of A (μmol substrate converted per g of immobilized enzyme) on the enzyme loading E (mg protein per mL of solution) (after [42]).

There are several other aspects of the effect of pore diffusion on immobilized biomaterial performance. For a biomaterial strongly susceptible to substrate inhibition, pore transport resistance might actually enhance the reaction. Such behavior has been observed with immobilized xanthine oxidase[43] and immobilized invertase[33]. It has also been suggested that the influence of pore diffusion alone is to enhance the temperature and pH stability of an immobilized biomaterial, *i.e.* the activity *versus* temperature or pH curve is broadened by the diffusion influence[44]. If the substrate molecules and/or the biomaterial support matrix carry a charge, then the electrostatic effects could be sig-

nificant; and the above observation does not apply in the case of pH stability. In such a case, one may instead observe a shift in the optimum pH (cf. Fig. 3).

3.4. Reactors for Immobilized Biomaterial Systems

Before discussing the considerations employed in choosing the reactor type, a brief review of the "idealized" types is in order. Performance equations for three types of "ideal" reactors have been well developed in the chemical engineering literature[45]. These three are: the batch reactor, the plug-flow reactor (also known as the slug flow, piston flow, ideal tubular and unmixed-flow reactor), and the mixed-flow reactor (or the back mix, the ideal stirred tank, the continuous flow stirred tank reactor or the CFSTR) (Fig. 14).

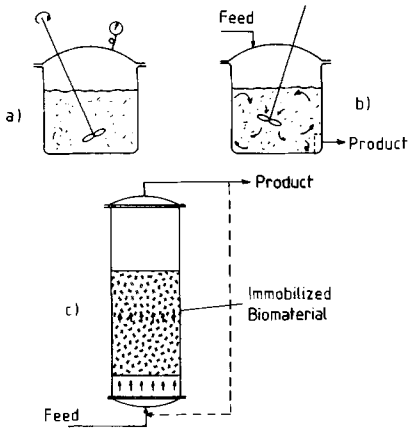

Fig. 14. Idealized reactor types: a) the batch reactor, b) the continuous flow stirred tank reactor, CFSTR, and c) the fixed bed reactor.

A fourth type, generally considered a hybrid of the plug-flow and the mixed-flow reactors, is the fluidized-bed reactor (Fig. 15a). In ideal plug flow, the substrate passes through the reactor as a slug, without any mixing with other slugs ahead or behind. In ideal mixed flow, the reactor substrate concentration is uniform throughout and is the same as the outflow substrate concentration. The flow pattern in a fluidized bed is not described as easily.

In a way, the fluidized-bed reactor, in which the immobilized biomaterial particles become suspended in an upward flowing substrate stream, is a "real" reactor. For preliminary experimental work, a differential recycle reactor (Fig. 15b), which allows a packed bed to be used in conjunction with a well-mixed reservoir of the feed and the product, is effective[25] and has been used extensively[46-49]. Most real reactors behave neither exactly like a plug-flow reactor nor like a CFSTR. However, once a particular real immobilized biomaterial reactor is judged to behave somewhat similar to an ideal reactor, performance equations can be derived from a knowledge of the material balances and the kinetics of the system. This can be an excellent starting point. Actually, the flow pattern of a real reactor can be analyzed by injecting at the inlet of the reactor a non-reactive tracer, and measuring the tracer concentration at the outlet as a function of time[50,51].

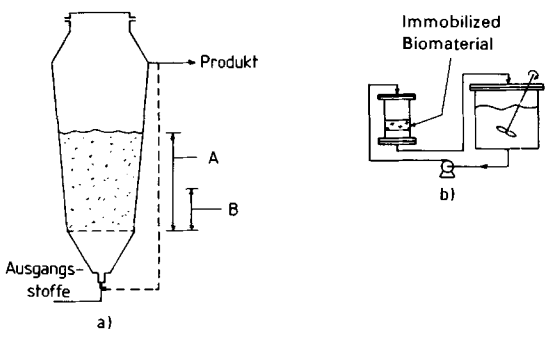

Fig. 15. a) The fluidized bed reactor, A: expanded bed, B: non-fluidized bed; b) differential bed recycle reactor.

The reactor performance equations applicable to the real immobilized biomaterial system of interest are one of the pivotal points of information during its development. Among other things, these equations permit an estimate of the biomaterial activity in the reactor at a given point in time. Often, it is desirable to arrange to have the reactor behave similarly to either the plug flow or the mixed flow, depending upon the kinetics. Performance equations for the batch, plug-flow, and the mixed-flow reactors, for modified or simple Michaelis-Menten kinetics, have been listed in several reviews[11-16,52]. Eq. (6) is valid, *e.g.*, for a plug-flow system exhibiting product inhibition, as is the case in the hydrolysis of lactose by immobilized lactase:

$$\frac{kE}{F} = S_0\left(1-\frac{K_m}{K_i}\right)(X_t - X_i) - \left(K_m + \frac{K_m S_t}{K_i}\right)\ln\left(\frac{1-X_e}{1-X_i}\right) \qquad (6)$$

3.4.1. Choice of Reactor Type

Perhaps somewhat facetiously, it may be said that *one wants the highest activity per unit reactor volume* (hence the least processing cost), *for the longest possible duration*, from an immobilized biomaterial reactor. One of the main advantages in immobilizing a biomaterial, as mentioned earlier in this article, is its convenient reuse. So in principle, any "closed"[15] system that would permit the biomaterial to be reused, at the same time yielding an "acceptable" degree of substrate conversion for an "acceptable" length of operating time is "acceptable". Some factors that influence the choice of reactor type are listed below:

1) Nature of the biomaterial support
2) Nature of the substrate to be processed
3) Reaction kinetics
4) Cost of reactor construction and operation
5) Ease of reactor scale-up
6) Method of regeneration or replacement of the immobilized biomaterial
7) Operational stability and requirements
8) Activity per unit volume or productivity required

Operational requirements should, of course, influence the reactor or system design. If pH or dissolved oxygen control is required, the well-mixed reactor may be favored.

This is because a direct addition of acid/base or a gas is easily possible. It should be pointed out that a fixed-bed reactor in conjunction with a recycle flow loop will allow acid/base/gas control external to the reactor. In a fixed-bed reactor, one has to be concerned with compressibility of the bed at high flow rates. Similarly, physical disintegration or solubilization of the support and/or the biomaterial may be an issue in any type of reactor under consideration.

One requirement that is very common to the immobilized biomaterial reactor system is that of microbial contamination control. In some cases, one may have to operate a sterile system. While that means the use of numerous precautions during the reactor operation, it also means the systems have to be sterilized. If autoclaving is the method chosen for sterilization, then the system components have to be capable of withstanding autoclave conditions (121 °C steam for 15 min to a few hours). In some cases, it may just not be practical to operate a sterile system. In that case, the operating protocol has to try to minimize the effects of unwanted microbial contaminants.

While it is generally perilous to generalize, a few comments concerning some features of the various reactor types (Table 2) will be made here. The Michaelis-Menten

Table 2. Reactor types and characteristics [11–16, 53].

Type	Comments
Batch (Fig. 14a)	Convenient to set up and operate. More efficient than a CFSTR for reaction kinetics of an order greater than zero.
Fixed bed, continuous (Fig. 14c)	Convenient and preferable for systems with kinetics of an order greater than zero, and for systems exhibiting product inhibition. Support material should have good particle strength and rigidity. Mass transfer problems can be a handicap for large carrier particles. Pressure drop can be a problem for small carrier particles.
Well-mixed, and fluidized bed (Fig. 15a)	Can handle feeds containing particulates; well mixed is preferable for systems exhibiting substrate inhibition; useful in circumventing mass transfer problems; support should have high abrasion resistance; scale-up of fluidized beds not well known.
Fixed or fluidized bed with recycle (cf. Fig. 15b)	Can be operated under conditions approximating plug flow at low or zero recycle; CFSTR behavior may be approached by operating at high recycle rates.

expression, with or without appropriate modifications, and material balances offer us a tool to estimate the packed-bed or well-mixed reactor volume required for a given degree of substrate conversion. The very nature of the Michaelis-Menten equation suggests that, for systems deviating not too significantly, it would be more efficient to have a reactor operate at substrate concentrations as high as possible relative to the K_m. This is the case in plug flow. On the other hand, in a well-mixed reactor, the substrate concentration is in effect diluted due to back mixing. Quantitative comparisons based on the kinetics and material balances clearly indicate that if a high degree of substrate conversion is desired, plug-flow operation is significantly better than well-mixed flow[11-16,54]. For obvious reasons, if a product formed in the system inhibits the reaction, the plug-flow reactor shows even greater promise. In general, a plug-flow reactor may also be expected to operate at a higher effectiveness factor than a well-mixed reactor at a given substrate concentration. However, for systems exhibiting severe substrate inhibition, backmixing is helpful as it would keep the reactor substrate concentration low. Then, a well-mixed reactor should be considered.

Conceptually, a fluidized-bed reactor offers a solution to some problems possible with fixed-bed, or plug-flow reactors. Smaller particles can be used to minimize mass transport resistance without significant plugging problems, and high biomaterial loadings per unit weight of the carrier can be employed. A fluidized-bed reactor can be operated so as to approach plug-flow behavior. The pressure drop in a fluidized-bed reactor, on the other hand, can be significantly less than a packed bed operated at a comparable flow velocity[54,55]. Until recently, workers in immobilized biomaterial catalysis tended to avoid working with fluidized-bed systems. Uncertainties in scaling-up and the difficulty of developing proper performance equations[56] may have played a part in this. Recently, however, pilot scale studies using a fluidized-bed system have been performed by *Coughlin et al.* for lactose hydrolysis[57] and corn starch hydrolysis[58], by *Tsao et al.* for glucose isomerization[59], and by *Emery* and *Cardoso* for soluble starch hydrolysis[51].

Among the well-known commercial scale applications of the plug-flow, fixed-bed system are: the production of High Fructose Corn Syrup or Isoglucose (HFCS or IGS) by the Clinton Corn Processing Co. and Corn Products International in the United States, and the Novo Industri A/S, Denmark, as well as amino acid production by the Tanabe Seiyaku Co., Japan. Mainly due to operational requirements, such as tight pH control, the well-mixed reactor has been used commercially by Beecham Pharmaceuticals, Squibb, and Astra AB for the acylation of benzylpenicillin by immobilized penicillin acylase[60]. Snamprogetti of Italy has employed lactase and penicillin acylase, entrapped in cellulose triacetate fibers, in both the well-mixed and the plug-flow arrangements[60]. The commercial fixed-bed reactors appear to be in the 1–9 m^3 (35–315 ft^3) range with bed diameters usually under 1.5 m (5 ft)[60]. The support material particles tend to be in the 0.2 to 4 mm range. Typical pore morphologies for porous inorganic carriers have been presented earlier (see Fig. 7 and 8).

Several other interesting types of reactors are awaiting commercial exploitation. These include reactors using membranes in tubular or rolled form[16,61], inorganic supports in the monolith form[62], and those employing magnetizable particles as the support material[63,64]. Reactors containing membranes rolled in a spiral offer a high surface area per unit volume and good substrate-biomaterial contact. Magnetizable particles, of course, permit fluidized bed operation with minimal loss of the immobilized biomaterial. Another promising development in Japan[65] has been that of biomaterial immobilization on polyvinyl alcohol fibers making available very high surface-to-volume ratios.

3.5. Operational Stability

Although not the only one, a critical parameter examined during the development of an immobilized biomater-

ial system is its operational stability. It may be emphasized here, that operational stability implies just that, *i.e.* stability when the system is under operation for its intended application (Fig. 16). Operational stability is to be distinguished from storage stability, *i.e.* stability when the immobilized biomaterial preparation is periodically tested for its activity while under storage. If available, information on operational stability is by far the more useful. Operational stability is usually expressed in terms of a half-life, $t_{1/2}$, which is the time elapsed during a 50% decline in activity. The causes of this decline in activity may be one or more, and the common ones are listed in Table 3. For comparison purposes, advantage is commonly taken of the fact that the decline in activity of an immobilized biomaterial often follows an exponential decay pattern. This permits a straight line fit between the logarithm of activity and time for data of the type of Figure 16. Frequently, an initial drop in activity due to a washout of the loosely bound biomaterial, or an initial increase due to some activation by a feed component, are observed.

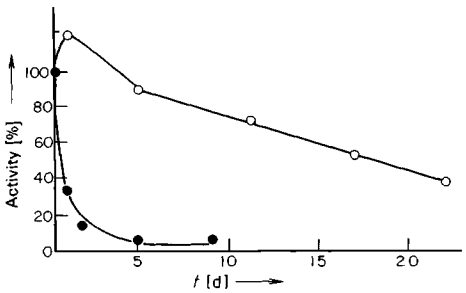

Fig. 16. Operational stability of immobilized aminoacylase for a relatively high concentration of the substrate (0.6 mol/L acetyl-DL-methionine) as a function of time. ●—●: tannin-aminohexylcellulose support; ○—○: DEAE-Sephadex support (after [94]).

Table 3. Possible factors affecting the operational stability of immobilized biomaterial systems.

Microbial growth
Desorption or leaching
Inactivation by trace metals or other inhibiting materials present in the feed
Coating of the biomaterial particle or membrane by proteins or other foreign materials
Thermal denaturation
Physical instability of the support material to withstand dissolution, attrition *etc.*
Variations in temperature and pH

As pointed out by *Pitcher*[66], operational stability studies should be performed as early as practical, with a feed as close as possible to that projected for commercial use. Half-lives could range from two days to over 100 days (in the case of immobilized lactase[66]) depending on the feed composition.

3.6. Processing Costs and Operating Strategy

The central concern in an industrial immobilized biomaterial system is the processing cost per unit of product, assuming major technical questions have been answered. At least a preliminary estimate of the processing cost can be made without much difficulty by including reasonable costs of the major components (Table 4). If possible, this should be followed with a sensitivity analysis to see how the processing cost is affected by the various components. Among the few cost estimating examples in the literature on immobilized biomaterials are those for lactase[67], glucoamylase[58,68], and penicillin amidase[101]. Overall conclusions for amino acid production at Tanabe Seiyaku Co., Japan, have been published[69] indicating that substantial savings were achieved *via* immobilization.

Table 4. Major cost components in an immobilized biomaterial system.

Raw materials including feed
Feed pretreatment, if any
Immobilized biomaterial
- support material
- amount of biomaterial required based on the efficiency of immobilization
- labor and materials required for the immobilization step
- replacement or regeneration of the immobilized biomaterial based on the operational stability
Product preparation
Labor, supervision and maintenance
Depreciation, taxes and insurance

While developing an immobilized biomaterial system, one may be able to arrive at a minimum half-life required for the system to be attractive. It should be possible to estimate the productivity per half-life, incorporating the actual level of biomaterial activity or loading. Thus, if one could significantly enhance the initial activity per unit reactor volume, a shorter half-life may be acceptable. It may be noted here, that doubling the initial activity may not double the reactor productivity[70a] and may increase the pressure drop problems[71]. The relative increase in biomaterial cost will depend on how the efficiency of immobilization varies in the range of interest.

The processing costs can be minimized by maximizing the production rate (the amount of product per unit time). This must be achieved within any constraints on temperature, pH, production rate, product quality, the number of half-lives for which a reactor may be operated, and the number of reactors available. The question of optimal op-

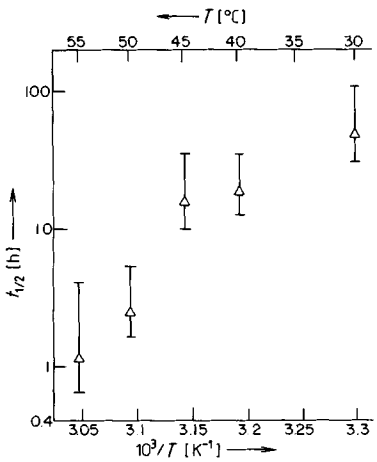

Fig. 17. Operational stability as a function of operating temperature for hog kidney mutarotase immobilized onto porous silica particles. The data indicate that the mechanism of activity decay is different for temperatures below and above 45 °C (after [70b]).

erating strategy in the face of such limitations has been addressed by *Pitcher*[12, 13, 66]. He has shown that given a knowledge of the effect of temperature and flow rate on reactor activity and half-life (Fig. 17), specific and practical operating strategies can be devised. Advantage can be taken, for example, of staggered start-up or regenerating schedules. Even more practical, an approach to maintaining the product quality or the extent of reaction, despite a gradual decay in the immobilized biomaterial activity, is to raise the operating temperature and/or to decrease the feed-flow rate[66, 72]. For any system under commercial development, the availability of the support as well as the biomaterial, in sufficient quantity and at an acceptable price and duration, must also be considered.

3.7. Health and Regulatory Aspects

In the application of immobilized biomaterial systems, health and regulatory considerations have been completely neglected in the literature. This is likely to change as more and more industrial applications are attempted. The following discussion is an admittedly incomplete representation of the many and complex aspects involved in assessing the safety of an immobilized biomaterial.

Enzymes, being proteins, can cause allergic reactions. Some enzymes, especially proteases, can have a non-allergic but highly noxious effect on people. In a skin prick test with papain on an allergic patient, *Flindt*[73] reports a 1 cm weal and 3 cm flare when only 0.3 nanograms of papain were introduced. He also reported a death by an asthma attack when a kilogram of papain powder was spilled into a protein hydrolysis pan, some ten meters from the victim. Thus, precautions will be required of workers to control hazards due to proteinaceous materials causing allergic reactions.

The support material and the chemical reagents, used for the immobilization of a biomaterial, must be proven to be safe unless already held so by the law. If the intended application is in the food or drug area, this demonstration may require considerable expense and effort. Animal feeding studies may have to be conducted. In this regard, biomaterials immobilized by adsorption onto "generally recognized as safe" (GRAS) substances will have an edge. Unless it is considered safe[74, 75], the absence of the enzyme from the product would, of course, have to be verified. Similarly, if microbial growth in the immobilized biomaterial system is a problem, and it is almost a perennial one, any biocides used should be legally considered safe for humans. A few reports on efforts at developing a practical system include information on control of microbial growth by sanitizing agents[76–78]. Sanitization procedures may also affect the system's half-life, *i.e.* enzyme deactivation or carrier deterioration are possible.

4. Applications of Immobilized Biomaterial Systems

4.1. Introduction

The objective of this section is to give the reader a perspective of the state of this technology. No attempt will be made to cover specific research efforts and their details for various applications. References may be consulted, if there is further interest. Keeping this in mind, the applications will be considered in three broad categories:

1) Commercial scale applications and those nearing commercial exploitation,
2) Applications which have been examined on a pilot scale,
3) Laboratory or research scale and potential applications.

Table 5 lists the firms using immobilized biomaterials on an industrial scale.

Table 5. Companies employing immobilized biomaterials on the industrial scale. Abbreviations: Pen. = penicillin, GI = glucose isomerase; Gal = galactosidase.

A. B. Astra (Pen. acylase)
A. E. Stanley Manufacturing Co. (GI[a]) [a]
American Maize (GI) [a]
Amstar Corporation (GI) [a]
Beecham (Pen. acylase)
CarMi (GI) [a]
Central Dairy of Milan (β-Gal) [a]
Clinton Corn Processing, a div. of Standard Brands (GI)
Corn Products International (GI) [b]
Gist Brocades NV (GI) [a]
Great Western Sugar Co. (α-Gal) [a, c]
H. J. Heinz Co. (GI) [a]
Imperial Chemical Industries (GI) [a]
Kyowa Hakko Co. (Fumarase)
Novo Industry, A/S (GI)

4.2. Commercial and Near-Commercial Applications

4.2.1. Production of High Fructose Corn Syrup[70, 71, 79–86]

A technology spurred by high sucrose prices in the early and mid-seventies, and now shackled by the low sucrose prices, is that of making "Isoglucose", "High Fructose Corn Syrup", or "High Fructose Glucose Syrup". It is perhaps the most significant and splendid commercial example of immobilized biomaterial technology. The enzyme glucose isomerase converts, far more specifically than its chemical alternative, aldo sugars into their keto isomers.

$$\text{D-glucose} \xrightarrow[\text{isomerase}]{\text{Immobilized glucose}} \text{D-fructose}$$

D-fructose competes with sucrose and can be 1.75 times as sweet as sucrose depending on the fructose concentration. The sweetness of HFCS can be varied by changing the fructose/glucose ratio without altering the calorie content. Canned fruits, carbonated and fruit-flavored beverages are some of the products that use the HFCS, which resists microbial growth by virtue of its high osmotic pressure. Syrups containing up to 90% fructose, on a dry basis, are commercially available in the United States.

HFCS technology has been a scene of intense industrial interest as evidenced by the patent activity[86]. Development efforts have not only been directed at improving the enzyme-based process, but also at using intact or

whole cells containing the enzyme[87]. Another improvement has been the availability of an α-amylase, from Novo Industries, which can withstand temperatures up to 105 °C for the initial 5—6 minutes during the starch liquifaction.

The United States estimate for 1979 was 1.6 million tons of HFCS[82]. The production in Europe was about 70000 tons in 1976, less than 1% of the sugar consumption in the EEC. As noted by *Barfoed*[82], the sugar surplus in the EEC, the lifting of a subsidy in 1977 on grain used for HFCS manufacture, and an additional production levy of about $69/dry ton during 1977—79 have virtually stalled the development of this technology in Europe. On the positive side for the HFCS makers in the EEC, an export subsidy was decided upon by the European commission[83].

Thus, immobilization of glucose isomerase has significantly reduced the cost of producing a sweetner from starch—the cost being low enough to completely change the sweetner market. Advantages, like decreased reactor volume, lower costs of adjustments in the product and the feed for the process, and, of course, lower enzyme costs, have played a significant role.

4.2.2. Production of L-Amino Acids[89–100]

The production of L-amino acids is big business worldwide because of their utilization for medicinal and food purposes. About 300 million dollars worth were produced in Japan alone in 1976[88,89]. Amino acids can be produced by isolation from protein hydrolyzate, by fermentation, or by chemical synthesis. The immobilized biomaterial technology has made chemical synthesis a viable option. Chemical synthesis yields an optically inactive racemic mixture of the L- and D-isomers of amino acids. Only the L-form can be incorporated into proteins; and, therefore, being the desired product, it has to be recovered from the racemic mixture. The Tanabe Seiyaku Co. has employed immobilized aminoacylase, since 1969, for this resolution step. This is also believed to be the first industrial application of an immobilized enzyme world-wide. In a continuous automatically controlled process, the racemic mixture of an amino acid is first acylated, then subjected to asymmetric hydrolysis by immobilized aminoacylase. A mixture of acyl-D form and the L-form of the amino acid is obtained, and the two can be separated because of solubility differences. The acyl-D form is racemized and reused.

Tanabe Seiyaku Co. has produced amino acids such as methionine, phenylalanine, alanine, tryptophan and valine on a large scale. Production of others such as L-Dopa, phenylglycine and hydroxyphenylglycine is said to be planned. Results from the extensive development studies on the immobilized aminoacylase system have been well documented by *Chibata et al.*[90–93].

The system employs *Aspergillus oryzae* derived aminoacylase, immobilized onto DEAE-sephadex by ionic binding in a packed-bed reactor. The DEAE-sephadex has proven to be stable over at least seven years of use.

Additional economies in immobilized aminoacylase utilization may be possible based on a recent report from Tanabe Seiyaku[94]. Laboratory scale studies have shown that a substrate three times more concentrated may be processed using a newer method of immobilization, *i.e.* adsorption onto tannin covalently bound to aminohexylcellulose (cf. Fig. 16).

Snamprogetti S.P.A. in Italy has achieved pilot scale application of immobilized aminoacylase for the production of L-tryptophan[95]. In their batch-recycle reactor system, the enzyme is not immobilized *per se*, but entrapped in cellulose triacetate fibers. Snamprogetti has also produced D-amino acids from hydantoins using a similarly entrapped calf liver enzyme[96].

For one amino acid, L-aspartic acid, the Tanabe Seiyaku Co. has found that using intact or whole cells in immobilized form is preferable to using the isolated aspartase enzyme. In their process, used commercially since 1973, the aspartase activity of *Escherichia coli* cells entrapped in a polyacrylamide gel catalyzes the formation of L-aspartic acid from ammonium fumarate[97].

$$\text{Fumaric acid} + \text{ammonia} \xrightarrow[\textit{E. coli}\ \text{cells}]{\text{Aspartase in Immobilized}} \text{L-Aspartic acid}$$

A striking feature of the immobilized biomaterial technology has to do with activation and inhibition of the biomaterial activity, in some cases with extraordinary significance. The entrapped cells exhibit an order of magnitude increase in activity from 130—180 to 1200—1700 moles per hour per mL of gel, when incubated in the substrate containing magnesium ions for 24—48 h at 37 °C. The system, employing a 1000 L packed-bed reactor, has excellent stability, about 120 d at 37 °C; and the product yields are in the 90—95% range. The exothermic reaction, causing a 6 °C increase for a 1 M substrate concentration, necessitates the reactor having a provision for heat removal.

Recently *Chibata et al.*[98] have reported an improved *E.-coli* immobilization scheme for L-aspartic acid production with carrageenan, a polysaccharide used as a gel-forming additive in foods, as the support material. The cells, following entrapment in the gel, are cross-linked with glutaraldehyde and hexamethylenediamine. Although the projected half-life of a laboratory scale column was 686 days, the stability after scale-up was still to be studied.

Production of two amino acid derivatives, L-citrulline[99] and glutathione[100], has also been studied at Tanabe Seiyaku. The glutathione production, based on entrapped *Saccharomyces cerevisiae* cells, was accomplished with continuous regeneration of the co-factor ATP. A continuous production of L-citrulline from L-arginine employed polyacrylamide gel entrapped *Pseudomonas putida* cells in a packed-bed reactor. A half-life of 140 days at 37 °C for the L-arginine deaminase activity in the laboratory scale reactor was observed. Although the optimum temperature was reported to change from 37 °C to 55 °C, this observation may well depend upon the conditions of the assay for activity.

4.2.3. Production of 6-Aminopenicillanic Acid

Another field where the immobilized biomaterial technology has had its impact is in the manufacture of semisynthetic penicillins. An important intermediate, 6-aminopenicillanic acid (6-APA), has been produced commer-

cially or at least on a pilot scale in Italy[101], Japan[102,103], Sweden[104], England, and the USA[60].

$$\text{Benzylpenicillin} \xrightarrow[\text{Penicillin Acylase}]{\text{Immobilized}} \text{6-APA} + \text{Phenylacetic Acid}$$

The stability of the enzyme, penicillin acylase or amidase, is significantly improved by immobilization. This coupled with the fact that the immobilized enzyme deployment in this case means lesser impurities in the product, is an explanation of the industrial interest in this technology.

Penicillin acylase covalently bonded to Sephadex G-200 is employed in the scheme used since 1973 at AB Astra, Sweden. Covalent binding onto Amberlite beads is used in the Beecham process. Both these companies and Squibb use a batch, stirred tank reactor mainly due to the operational requirement of alkali addition for pH control. Denaturation of the immobilized penicillin acylase by the alkali, unless its addition is controlled carefully, can be a problem resulting in low operational stability[105].

4.2.4. Production of Other Organic Compounds

Organic compounds such as L-malic acid and urocanic acid have been manufactured in Japan by exploitation of the immobilized biomaterial technology[88,106-109]. L-Malic acid, used in intravenous infusion mixtures and for treatment of hepatic ailments like hyperammonemia, is produced by the Tanabe Seiyaku Co. and the Kyowa Hakko Co. Urocanic acid, a sun-screening agent, is manufactured at Tanabe Seiyaku.

$$\text{Fumaric Acid} \xrightarrow[\textit{Brevibacterium ammoniagenes}]{\text{Fumarase in immob.}} \text{L-Malic Acid}$$

$$\text{L-Histidine} \xrightarrow[\text{in immob. } \textit{Achromobacter liquidum}]{\text{L-Histidine ammonia lyase}} \text{Urocanic Acid} + NH_3$$

The Tanabe Seiyaku studies reveal a problem characteristic with using intact or whole cells rather than the biomaterial in its isolated form. Immobilized whole cells often have bioactivity other than the one desired. In the case of L-malic acid the immobilized *B. ammoniagenes* cells contained the unwanted activity to form succinic acid in addition to the malic acid. Fortunately, it was found that suspending the polyacrylamide gel entrapped cells in substrate solution containing detergents such as deoxycholic acid or bile acid, not only suppressed the succinic acid formation it also enhanced the fumarase activity 6—7 times. Similarly, while *A. liquidum* cells were otherwise suitable for urocanic acid production, they also had urocanase activity. Thus, uroconic acid formed was further converted into oxoimidazolepropionic acid. In this case, heating the cells for 30 minutes at 70 °C eliminated the urocanase activity.

Another not too uncommon feature of immobilized biomaterial systems is the effect of metal ions on their stability (see Section 4.2.2). The inclusion of Mg^{2+} (1 mmol/L) improved the *A. liquidum* system half-life to an estimated 6 months, relative to 15 days for feed containing no Mg^{2+}[109].

4.2.5. Hydrolysis of Whey and Milk Lactose

Immobilized biomaterial technology appears poised to offer the dairy industry a new product *opportunity* out of the *problem* of whey utilization. It is estimated that nearly 35 million tons of whey is produced annually worldwide. Much of the sweet whey, from the manufacture of hard cheeses, is presently dried and blended in some animal and human processed food products. Utilization of acid whey, a by-product from the manufacture of soft cheeses like cottage cheese, on the other hand, poses a problem due to its acidity. The percent utilization of whey varies from about 60 percent in the US and Canada, and about 75 percent in France and the USSR, to about 95 percent in Denmark and Holland[110a]. This may leave as much as 10 to 12 billion pounds in the US that is not properly utilized. Because of its high biochemical oxygen demand and pollution regulations, most of the processed whey is either dried or concentrated. However, the increasing energy prices continue to have impact on the drying costs. Thus, the incentive to find a profitable way to upgrade the whey and improve its utilization is obvious.

Whey contains 4.5 to 5 percent lactose, 0.5 to 0.8 percent protein and about 0.7 percent salts. So the major components of commercial value are lactose and protein. The protein can be separated by ultrafiltration. As shown in Table 6, the sweetness of the permeate is significantly improved if the lactose could be hydrolyzed. This whey lactose utilization can be performed by an immobilized biomaterial (discussed here), or on a catalytic resin[112]. Other alternatives studied have been that of fermentation to make alcohol and methane[110a] and crystallization of lactose before protein recovery[110b].

Table 6. Relative sweetness of some sugars in 10% aqueous solution [111].

Sugar	Relative sweetness
Sucrose	100
Lactose	40
Glucose	75
Galactose	70

Immobilized lactase (β-galactosidase) can be used to hydrolyze lactose to glucose and galactose, thereby improving the sugar solubility in addition to sweetness. The hydrolyzed whey can then be used for its sweetness and nutritive qualities in dairy products. The hydrolyzed whey may also be used as a fermentation substrate for making baker's yeast[110c]. Figure 18 shows the process scheme of a system offered by Corning Glass Works.

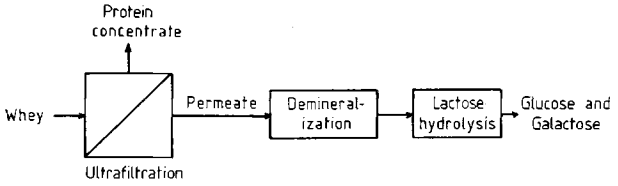

Fig. 18. A scheme for whey utilization. The protein is recovered by ultrafiltration and a sweetner is produced by hydrolyzing the demineralized permeate with immobilized β-galactosidase.

Demineralization of the permeate *via* ion-exchange or electrodialysis reduces the "salty" nature of the hydrolyzed syrup. The system employs a packed bed reactor in the down flow mode. The fungal lactase is immobilized onto 30/45 mesh controlled pore silica beads by chemical coupling using the aqueous silane-glutaraldehyde method. A pilot scale, fluidized bed reactor system was developed by *Coughlin et al.*[116,117] at Lehigh University in the United States. Development studies from Corning Glass Works and others on whey lactose hydrolysis have been documented in the literature[67,77,113-119].

A related problem is that of milk lactose hydrolysis for lactase deficient people. A 10 ton per day commercial plant for the hydrolysis of lactose in skim milk, based on a process developed by Snamprogetti, is in operation at the Central Dairy of Milan, Italy[78,120,121]. The enzyme, a yeast lactase, is entrapped in spun cellulose triacetate fibers and the fibers placed in a jacketed column. The fibers are first washed with sterile buffer and then lactose hydrolysis is carried out by batch recirculation of sterile, skim milk. The product "latte accadi" is said to have a pleasant sweetness and good shelf-life.

4.2.6. Analytical Applications

Analytical applications of immobilized biomaterials are many[122,123], but only mention of the successfully commercialized examples will be made here. Glucose analyzers, based on immobilized biomaterials, are marketed by Yellow Springs Instruments (YSI), Yellow Springs, Ohio; Technicon Instruments, Tarrytown, New York; and Leeds and Northrup Co., North Wales, Pennsylvania, from the US, and Radiometer Instruments, Copenhagen, from Europe. An instrument for the analysis of urea nitrogen in blood, employing immobilized urease, has been developed by Owens-Illinois[80].

The analyzer from YSI[124-127] can be utilized for a variety of analyses, depending upon which immobilized enzyme is used. As an example, glutaraldehyde coupled enzyme glucose oxidase is utilized to produce H_2O_2.

$$\beta\text{-D-Dextrose} + O_2 \xrightarrow[\text{glucose oxidase}]{\text{Immobilized}} H_2O_2 + \text{D-Glucono-}\Delta\text{-lactone}$$

The current flow is proportional to the H_2O_2 concentration. Sucrose can be analyzed by using a membrane containing immobilized invertase, mutarotase and glucose oxidase which together help to produce H_2O_2 from sucrose. Similarly, lactose can be analyzed when a membrane containing immobilized galactose oxidase is utilized.

Whichever immobilized enzyme(s) is utilized, the enzyme membrane is actually sandwiched between a cellulose acetate membrane (molecular weight cut off 100) and a polycarbonate membrane (0.03 micron pores). The former passes H_2O_2 but excludes other reducing agents which might be present in the sample. The polycarbonate membrane excludes unwanted cells or enzymes from the reaction zone (Fig. 19).

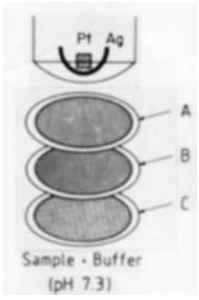

Fig. 19. A schematic representation of an analyzer based on immobilized biomaterials (Yellow Spring Instruments, USA). The immobilized enzyme membrane to be used depends on the analysis desired. The immobilized enzymes available and their intended applications (in parentheses) are: glucose oxidase (glucose analysis); invertase, mutarotase and glucose oxidase (sucrose analysis) and galactose oxidase (lactose analysis). A: cellulose acetate membrane, molecular cut off 100; B: membrane with immobilized enzyme(s); C: polycarbonate membrane 5 μm, pore diameter 0.03 μm.

4.3. Production of Glucose from Liquified Starch

An obvious temptation to use immobilized biomaterial technology exists in the saccharification of starch. In theory, an immobilized glucoamylase (amyloglucosidase) could be employed in the HFCS processes, in corn syrup production, or in the making of some alcoholic beverages. Soluble glucoamylase is used in these processes and its sales account for about 14 million dollars in the USA[128] and about 4 million dollars in Japan. At least three pilot scale studies with immobilized glucoamylase have been reported in recent years. The first[129] was based on a fixed bed process, while the other two[51,58] have examined fluidized bed operation. The latter two represent an advancement by virtue of evaluating the kinetics and operation of a pilot scale, fluidized bed immobilized biomaterial system. Although the list below is incomplete, a few key obstacles in the commercial development of this technology are mentioned.

1) Operational Stability: Microbial growth is a serious concern during the operation of immobilized glucoamylase systems. This is because the temperature range for stable enzymatic activity is usually around 40 to 45 °C, also favored by contaminating microbes. A continuous sterile operation at the plant scale is very difficult to maintain. A thermophilic glucoamylase may be the answer.
2) Costs: The cost per pound of the immobilized glucoamylase would have to be almost unrealistically low to replace the existing low cost soluble enzyme use. *Allen et al.*[58] estimate the total processing cost with a fluidized bed system to range from 42 to 62 cents per 100 pounds of solids, relative to 55 to 63 cents for the soluble enzyme process.
3) Yield: A commercial immobilized glucoamylase system would have to yield comparable product quality to the soluble enzyme process. The desirable range for corn processors, 94 to 97 DE, has been difficult to attain in continuous operation with the immobilized biomaterial.

Overall, in this case, the immobilized biomaterial performance and economics must be dramatically superior to justify change at the commercial scale. A possible exception would be the situation where the soluble enzyme must be removed after use and must not be present in the final product for regulatory or health reasons such as in the manufacture of low calorie beers.

5. Summary and Outlook

Perhaps the initial enthusiasm accorded the immobilized biomaterials in the nineteen sixties was somewhat exaggerated. Nevertheless, when one considers the variety of applications that have been examined at the research level and the continuing interest in this technology, a slow but steady growth in real applications can be predicted. A very brief account of the possibilities will be made here.

A statement must be made on the tremendous potential this technology offers with respect to renewable resource utilization (Table 7). To date, considerable work has been accomplished in the USA, the USSR, and other countries on the enzymatic hydrolysis of cellulose. In this case, the substrate cellulose can be considered to be the carrier as well as the substrate for the cellulases because the enzymes and the cellulose form a tight complex. Additional work in this area offers the promise of fuels and chemicals.

Table 7. Some potential applications of immobilized materials.

Utilization of renewable resources
Cofactor regeneration and synthesis
Production of maltose from starch
Disinfection of gaseous streams
Destruction of H_2O_2 in cold milk sterilization
Production of L-lysine from ε-aminocaprolactam
Milk coagulation
Production of cyclodextrin from starch
Flavor modification of ultra-high-temperature (UHT) processed milk
Steroid transformations
Waste conversion

That future practical systems should be capable of exploiting the benefits of co-immobilization seems reasonably clear. Co-immobilization of two or more biomaterials has an enourmous potential because of the synergistic effects that are possible.

This synergy may take many forms. Sequential reactions, protection from inhibitors, enhanced reaction rates, improved pH or thermal stability are only some of the obvious possibilities. One such example is co-entrapment of β-glucosidase and *Saccharomyces cerevisiae* in alginate for converting cellobiose and glucose into ethanol in a fluidized bed reactor[130]. In their bench scale studies, the authors obtained complete conversion to ethanol at dilution rates of about 0.25 per hour.

Improved thermal stability was the result when an alcohol dehydrogenase was co-immobilized with the coenzyme NAD(H) in agarose in another laboratory study[131]. The half-life improved from only a few minutes to just under 2 hours. Further work[132] in the same laboratory in Sweden has verified that the transition temperature, as observed by differential scanning colorimetry, is increased by immobilization.

The combined action of immobilized β-amylase and pullulanase for the hydrolysis of starch has been reported[133]. β-Amylase degrades the outer chains while pullulnase splits the branch points, in effect opening the starch structure for each other.

Biomaterials that participate in synthesis reactions often require cofactors such as ATP, FMN and NADP. Before any synthesis reactions can begin to look economically attractive, regeneration of "used" cofactors must be achieved because of their high cost. For example, ATP and NADP retail in the US for $ 1,500 to 2,900 and $ 57000 per mole, respectively. Immobilized biomaterials can be expected to have a role in bringing down the cost of making these co-factors and that of their regeneration.

As has been shown[134, 135], an immobilized coenzyme system would have to yield greater than 1000 redox cycles to be of practical interest. A recent effort[136] in this respect on the immobilization of NADH using water soluble copolymers may be noteworthy. The researchers obtained 1000–2500 turnovers with their preparations from the epoxide-combining monomer 3-[4-(2,3-epoxypropoxy)butoxy]-2-hydroxypropyl acrylate and *N*-(methacrylyl)-2-glucosamine. Immobilized coenzymes and multienzymes have been reviewed recently[135, 137, 138].

Although the system was not considered to be feasible on an industrial scale, workers in Italy showed[139] that synthesis of L-alanine was feasible by co-entrapping two enzymes and a coenzyme in cellulose triacetate fibers. The two enzymes were lactic dehydrogenase (LDH) and alanine dehydrogenase (AlaDH). The coenzyme, which was recycled as shown below, was 4-($NAD^{\oplus}$-N^6)-3-hydroxybutyrylpolyethyleneimine ($NAD^{\oplus}$-Pol).

$$CH_3CHOHCOOH + NAD^{\oplus}\text{-Pol} \xrightarrow{LDH} CH_3COCOOH + NADH\text{-Pol} + H^{\oplus}$$

$$CH_3COCOOH + NADH\text{-Pol} + NH_4^{\oplus} \xrightarrow{AlaDH} CH_3CH(NH_2)COOH + NAD^{\oplus}\text{-Pol} + H_2O$$

$$CH_3CHOHCOOH + NH_3 \rightarrow CH_3CH(NH_2)COOH + H_2O$$

We may note that fermentation systems are conceptually the ultimate in co-immobilization. Many enzymes and coenzymes, inside the cell, combine their action to achieve cell growth or other metabolic action. Thus, the immobilization of cells themselves is a logical extension of multienzyme-coenzyme immobilization.

The growing worldwide recombinant DNA effort represents additional opportunities as well as competition for the immobilized biomaterial technology. Analytical and medical applications, not covered in this paper, should continue to evolve from this technology. The feasibility of using immobilized biomaterials to detoxify or transform toxic substances in blood has been established[140, 141].

In summary, immobilization offers the potential of economical exploitation of biomaterial activity. The development of immobilized biomaterial systems requires the involvement of biochemical, kinetic, and reactor design principles. The immobilized biomaterial technology has passed its early stages, as evidenced by worldwide commercial applications. Additional applications may be expected but perhaps at a slower pace.

We would like to thank Dr. W. H. Pitcher, Jr. for his encouragement and help during the preparation of this manuscript. Thanks are also due to Ms. S. A. Harrau, Ms. F. J. Osekoski and Ms. N. L. Foster for their valuable assistance.

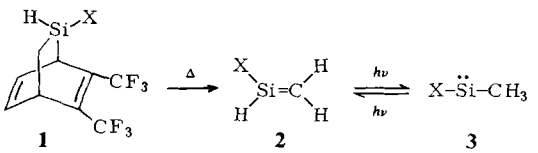
Reversible Photoisomerization between Silaethenes and Methylsilylenes (Methylsilanediyls)**

By *Hans Peter Reisenauer, Gerhard Mihm,* and *Günther Maier**

The energy hypersurface of $SiCH_4$ isomers is still the subject of intensive discussion[1]. In this connection the energetic relationship between silaethene and methylsilanediyl (methylsilylene)[***] plays a decisive role. Until now experimental results have been scarce[2], and only the photochemical formation of 1-methylsilaethene from dimethylsilanediyl at low temperature in the matrix has been demonstrated[2d]. We report for the first time the reversible photochemical conversion of silaethenes into methylsilanediyls.

The silaethenes **2a—2c** were generated by flash pyrolysis/matrix isolation from the precursors **1a—1c**, and isolated at 10 K in argon and nitrogen matrices[3]. Their characteristic spectroscopic data are shown in Table 1. The UV absorptions of the silaethenes completely disappear after being irradiated for a short period of time ($\lambda = 254$ nm, Hg low-pressure lamp); in contrast, the bands of the fragment (hexafluoro-*o*-xylene) remain unchanged. Simultaneously, new species are formed, which are characterized by a broad UV band shifted to long wavelength (intensity approximately 1/3 of the bands from **2a—2c**) with no structural features (Table 1). Similar changes occur in the IR spectra. In the case of **2a**, irradiation produces a marked shift of the Si—H stretching vibration to long wavelength. In the photoproducts from **2b** and **2c** a corresponding band is completely absent (Table 1).



1 **2** **3**

a, X = H; **b**, X = Cl; **c**, X = CH_3

Irradiation at the wavelength of the new UV absorptions (Hg high-pressure lamp with edge filters or monochromator) results in re-formation of silaethenes **2a—2c**. Subsequent short wavelength irradiation (254 nm) of these species again produces the above-mentioned isomerization. Forward and reverse reactions can be repeated several times. This revesibility of the photoconversion of **2** and the spectroscopic data suggest that the photoproducts are the methylsilanediyls **3a—3c**. The UV absorption of **3c** is identical with the value previously reported[2d]. The relatively low wavenumber of the Si—H stretching frequency

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der chemischen Industrie.

[***] According to IUPAC Rule D-6.12, silylenes should be termed silandiyls.

in **3a** is also consistent with the methylsilanediyl structure. Hence, bands at approximately 2030 cm^{-1} are observed for SiH_2[7]. Calculations also indicate that the Si—H stretching frequency in methylsilanediyl lies approximately 200 cm^{-1} lower than in silaethene[8].

Table 1. IR and UV absorption bands of silaethenes **2a—2c** and methylsilanediyls **3a—3c** in argon and nitrogen matrices at 10 K.

	Silaethenes			Silanediyls	
	IR [cm^{-1}]	UV [nm]		IR [cm^{-1}]	UV [nm]
2a	Ar: 2239 (m), 2219 (m), 1350 (w), 985 (w), 927 (w), 817 (s), 741 (s)	258	**3a**	Ar: 2004 (m), 1935 (w)	480
	N_2: 2235 (m), 2214 (m), 1350 (w), 985 (w), 927 (w), 817 (s), 747 (s)	258		N_2: 1986 (w), 1978 (w), 1971 (m)	330
2b	Ar: 2230 (w), 984 (m), 843 (s), 699 (w), 544 (m), 537 (w)	255	**3b**	Ar: 1223 (m), 485 (m), 480 (w)	407
	N_2: 2230 (w), 980 (m), 840 (s)	255		N_2: 1220 (m)	387
2c	Ar: 2182 (m) [a], 1255 (w), 991 (m), 879 (m), 811 (m), 711 (w)	260 [2d]	**3c**	Ar: 840 (m)	460
				N_2: —	425

[a] Consistent with values in [2d].

The strong dependence of the position of the band of the Si—H stretching vibration in **3a** on the type of matrix is notable. Instead of the expected single band, two absorptions of different intensity at 2004 and 1935 cm^{-1} are found in an argon matrix. In a nitrogen matrix **3a** even exhibits three bands between 1970 and 1990 cm^{-1}. The influence of the matrix material is also reflected in the UV spectra of silanediyls: in the nitrogen matrix all the absorption maxima are hypsochromically shifted, in **3a** by as much as 150 nm.

Although the matrix effects mentioned still leave some questions open, the following conclusion, however, can be drawn: silaethenes and the isomeric methylsilanediyls are separately existing species, but can readily be interconverted *via* a photochemically induced 1,2-H shift.

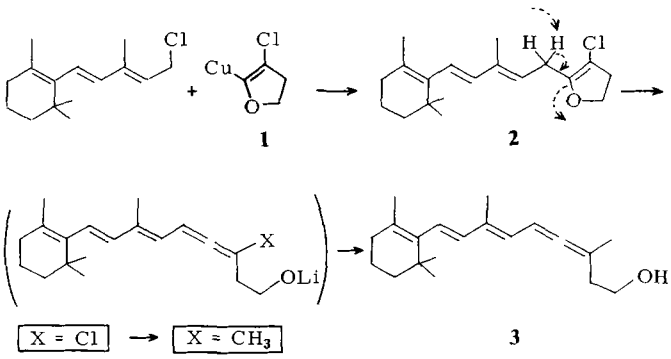
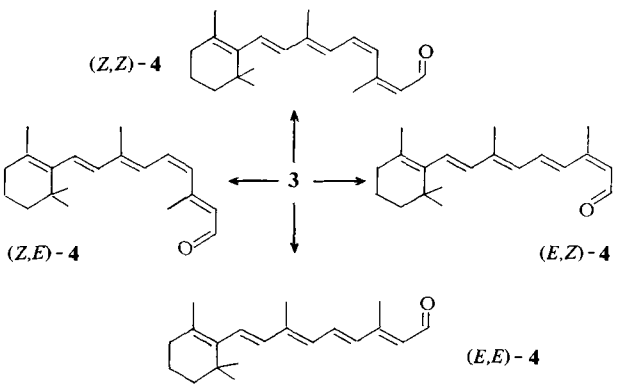
"Isoretinol" and Retinal: An Unorthodox, but Simple Entry to the Vitamin A Series

By *Renzo Ruzziconi* and *Manfred Schlosser**

Two equivalents of methyllithium react with 5-alkyl-4-chloro-2,3-dihydrofuran causing ring opening and substitution of the chlorine to give 3-methyl-3,4-dienols[1]. The chain of an alkyl halide (or alkyl toluenesulfonate) can be lengthened in this way by an unsaturated C_5-fragment which bears an OH-group and is branched at the appropriate position by a methyl group. Thus, a one-pot reaction using "2-β-ionylideneethyl chloride" as starting material leads *via* the dihydrofuran **2** to the "isoretinol" **3**[3] (55%). The key reagent is 3-chloro-4,5-dihydro-2-furylcopper **1**, accessible by treatment of the corresponding lithium compound[1] with copper(I) iodide.



The oxidation of **3** with dimethyl sulfoxide in presence of *N,N*-dicyclohexylcarbodiimide leads with concomitant double-bond shift to the four 11,13-stereoisomeric retinals (*Z,Z*)-, (*Z,E*)-, (*E,Z*)- and (*E,E*)-**4** (aldehyde proton: $\delta = 9.85$, 9.91, 10.13, and 10.01, respectively; ratio 1:1:4:5), which can be separated by liquid chromatography[7]. On addition of a trace of iodine the proportion of the *all-trans*-retinal (*E,E*)-**4** increases at the expense of the (*E,Z*)-isomer. The other two isomers disappear. In their place two new isomers are formed (each to the extent of *ca.* 10%) having (9*Z*,11*E*,13*Z*)- and (9*Z*,11*E*,13*E*)-configuration.



The wide applicability of the method was demonstrated by further natural product syntheses. Thus, 3,7,11-trime-

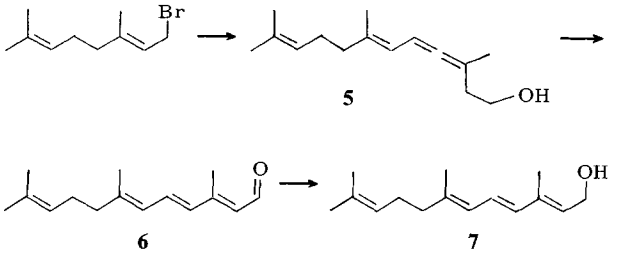
thyl-3,4,6,10-dodecatetraen-1-ol **5** was synthesized in 41% yield from geranyl bromide; **5** was then oxidized to the 4,5-dehydrofarnesal **6** (59%), which on reduction with $NaBH_4$ furnished the 4,5-dehydrofarnesol **7** (85%).



6 **7**

Most terpene syntheses are based on the coupling of appropriate isoprene building blocks. Only very seldom have other synthetic patterns, *e.g.* the condensation of a C_6-, C_{11}- or C_{16}-halide with (*Z*)-lithium-3-lithio-2-butoxide[11], been explored. The procedure now suggested here, namely separate incorporation of the linear C_4 moiety and the methyl group, has, *inter alia*, the advantage that the side chain can be varied within wide limits.

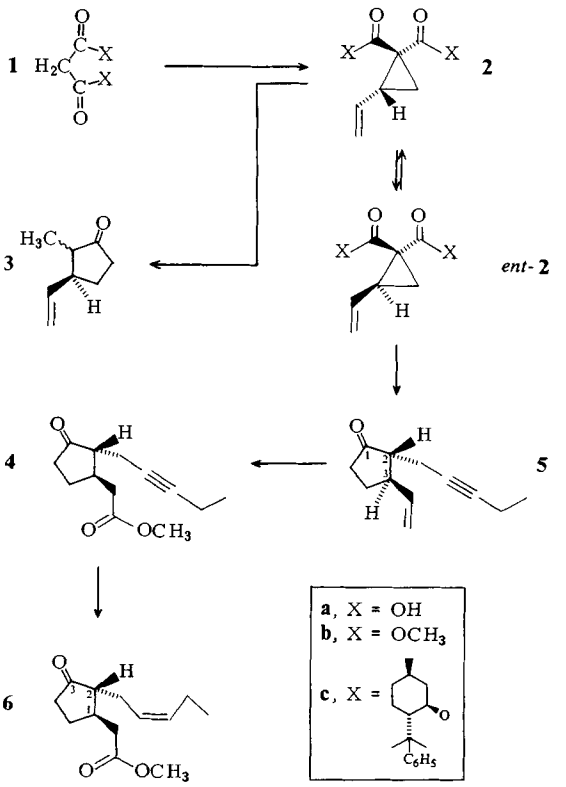
Asymmetric Synthesis of Methyl Jasmonate**

By *Gerhard Quinkert**, *Friedhelm Adam*, and *Gerd Dürner*

The cyclopropane derivative **2b** is a valuable synthetic building block: It has only one center of chirality, is readily available in an enantiomerically pure form[1], and for a total synthesis of 19-norsteroids has been transformed into ring D-building block **3** with complete inversion of configuration at the asymmetric center[2].

ent-**2b** is a potential building block for the synthesis of methyl jasmonate **6**[3], a valued perfumery ingredient. This enantiomer is, in principle, accessible by analogy to **2b**, *via* **2c**, with the latter obtained by an asymmetry inducing reaction of an (*E*)-1,4-dihalo-2-butene with **1c**[2], provided the alcohol component is not **1c**, but its enantiomer[6], which is only obtainable with difficulty.

However, a simpler route to *ent*-**2b** has now been found: refluxing a solution of **2c** in *p*-cymene leads to a separable



Scheme 1. **1c**→**2c**: $BrCH_2CH{=}CHCH_2Br$, $(C_8H_{17})_3(CH_3)NCl$, n-C_6H_{14}, NaOH, H_2O, 14 h, room temperature, 66.5%.—**2c**→*ent*-**2c**: *p*-cymene, 13 h, reflux, 57%.—*ent*-**2c**→*ent*-**2b**: C_2H_5OH, KOH, hydroquinone, reflux, 16 h; CH_2N_2, ether 72%.—*ent*-**2b**→**5**: $H_5C_2{-}C{\equiv}C{-}CH_2{-}CH(CO_2CH_3)_2$, CH_3OH, Na/CH_3OH, 10 min, 60 °C; removal of solvent; 1 h, 130 °C; CH_3OH, H_2O, 20 h, room temperature; 16 h reflux; conc. HCl; $NaH_2PO_4 \cdot 2H_2O$, 1 h, 0 °C; 4 h room temperature, 24%.—**5**→**4**: tetrahydrofuran, 9-borabicyclo[3.3.1]nonane, 2 h, room temperature; 30% H_2O_2, 3N NaOH; ether; Jones reagent, 14 h room temperature; CH_2N_2 65%.—**4**→**6**: petroleum ether, H_2/Lindlar catalyst, room temperature, 89%: chiroptical data for all the chiral compounds in Scheme 1 are shown in Table 2 of the Supplement.

equilibrium mixture (2.5 : 1) of the diastereomers **2c** and *ent*-**2c**. Hydrolysis of the latter, followed by esterification of the resulting dicarboxylic acid with diazomethane gives the desired compound *ent*-**2b**, which has been conventionally converted *via* **5** and **4**[8] into enantiomerically pure **6**. Previous syntheses of methyl jasmonate[9] have all led to mixtures of two racemates.

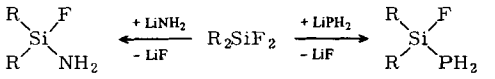
Synthesis of an *N*-Functionalized 1,3-Diaza- and a *P*-Functionalized 1,3-Diphospha-2,4-disilacyclobutane**

By *Uwe Klingebiel** and *Norbert Vater*

Reactions of dichlorodiorganosilanes with ammonia proceed with complete cleavage of hydrogen chloride to afford six- and eight-membered cyclosilazanes and higher condensation products[1]. Sterically demanding substituents lead to short-chain acyclic silazanes[2]. In this connection neither the formation of a four-membered ring $[R_2Si—NH]_2$ nor of an intermediate product $R_2SiCl—NH_2$ has been observed.

Cyclosilaphosphanes were obtained by reaction of dichlorodiorganosilanes with lithium phosphide or metalated organophosphanes[7]. The annelation can be attributed to the marked tendency of the initially formed unstable diphosphinosilanes to rearrange, although bis(*tert*-butylphosphino)dimethylsilane, $Me_2Si(PHtBu)_2$, has been isolated and after lithiation used in the synthesis of cyclosilaphosphanes[7].

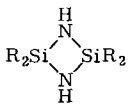
By allowing difluorodiorganosilanes to react with lithium amide or lithium phosphide, we obtained the surprisingly stable *N*-(fluorosilyl)amines **1** and **2**, and the *N*-(fluorosilyl)phosphane **3** (b.p. = 55 °C/18 torr, 38 °C/19 torr, and 70 °C/4 torr).



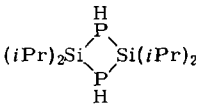
1, R = *t*Bu
2, R = *i*Pr

3, R = *i*Pr

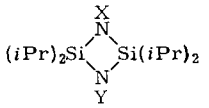
In an analogous fashion to the isoelectronic compound $(tBu)_2SiF(OH)$[9], **1** and **3** show no tendency to condense. **1**, **2** and **3** are readily *N*- and *P*-metalated by butyllithium, and in the absence of reactants form 1,3-diaza- (**7**, **8**) and 1,3-diphospha-2,4-disilacyclobutanes **9**, respectively (m.p. = 93 °C, b.p. = 55 °C/0.01 torr, and m.p. = 114 °C) upon cleavage of lithium fluoride.



7, R = *t*Bu; **8**, R = *i*Pr



9



10, X = Me_2FSi, Y = H
11, X = Y = Me_2FSi

Only one isomer was observed for **9** by NMR spectroscopy. The H atoms of the difunctional four-membered rings **7** and **8** can be mono- or dilithiated by C_4H_9Li, so that substitution reactions with elemental halides with retention of the ring framework are possible. For example, **8** forms *N*-mono- and *N,N'*-disubstituted products **10** and **11**, respectively (b.p. = 52 °C/0.01 torr, m.p. = 202 °C) with difluorodimethylsilane. All the novel compounds were characterized by NMR spectroscopy.

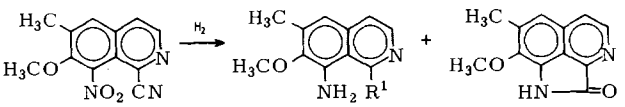
Catalytic Hydrogenation of 7-Methoxy-6-methyl-8-nitro-1-isoquinolinecarbonitrile to Unusual Products

By *Akinori Kubo**, *Naoki Saito*, *Shinsuke Nakahara*, and *Ryoichi Iwata*

There has recently been considerable interest in the crystal structures of 1,8-disubstituted naphthalenes with various nucleophilic groups ($N(CH_3)_2$, OH, OCH_3, NO_2) at one of the *peri*-positions and electrophilic groups (CO, CN) at the other, which exhibit intramolecular nucleophilic-electrophilic interactions[1]. However, few studies have been reported on the chemical properties of this class of compounds.

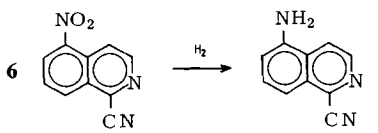
We now report the catalytic hydrogenation[2] of the title compound **1** in presence of 10% Pd/C (in anhydrous dimethylformamide (DMF), 3 h), which leads to formation of the novel heterocyclic lactam 8-methoxy-7-methylpyrrolo[2,3,4-*ij*]isoquinoline-2(1*H*)-one **4** (5.7%) in addition to the amines **2** (43%), **3** (13%)[3], and **5** (17%)[3]. Reduction of **1** in presence of PtO_2 (anhydrous DMF, 4 h) affords **2** (8.0%), **3** (22.0%), and trace amounts of **4** and **5**. Compound **4** was obtained in quantitative yield by treating **3** with conc. HCl (reflux, 30 min in ethanol).



1

2, R^1 = CN
3, R^1 = $CONH_2$
5, R^1 = H

4



6 **7**

The unexpected formation of lactam **4** can be rationalized by assuming that the oxygen atom of the nitro group of **1** is transferred to the carbon atom of the cyano group[2]. We, therefore, examined the catalytic hydrogenation of **2** and 5-nitro-1-isoquinolinecarbonitrile **6**. Under

the same conditions as the reaction of **1**[2], **2** resisted hydrogenation and was recovered in 81% yield, whereas **6** furnished 5-amino-1-isoquinolinecarbonitrile **7** in 72% yield, but no amide.

These results provided additional evidence in support of the proposed mechanism. Finally, we note that the orientation of nitration of 7-methoxy-6-methylisoquinoline derivatives is determined unambiguously without correlation methods or spectroscopic analysis[5].

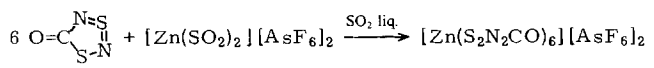
Synthesis and Structure of $[Zn(S_2N_2CO)_6][AsF_6]_2$—Sulfur-Nitrogen Rings as Ligands in Coordination Compounds**

By *Herbert W. Roesky**, *Manfred Thomas*, *Mathias Noltemeyer*, and *George M. Sheldrick*

Dedicated to Professor Rudolf Hoppe on the occasion of his 60th birthday

5-Oxo-1,3λ^4,2,4-dithiadiazole **1** can be prepared by reaction of $[(CH_3)_2SnN_2S_2]_2$ with carbonyl difluoride[1]. In order to clarify whether the coordination of the ligand to a metal atom takes place *via* oxygen, sulfur or nitrogen, we have investigated the reaction of **1** with the zinc complex **2** in liquid SO_2.



1 **2** **3**

After removal of SO_2, **3** precipitates as a colorless solid. **3** (m.p. 150 °C) is recrystallized from liquid SO_2; it is insoluble in CH_2Cl_2. Owing to their modest donor properties, the ligands **1** in **3** are very readily replaced by water molecules. In the IR spectrum of **3** the C=O stretching vibration is observed at 1560 cm^{-1}, *i.e.* it is shifted by 167 cm^{-1} to lower wave numbers compared to that of **1**. Thus, **1** should be coordinated to zinc *via* oxygen.

The X-ray structure determination shows that **3** crystallizes in the space group $P\bar{3}$ with $a = b = 1190.1(1)$, $c = 665.1(1)$ pm and $Z = 1$, $\rho_{calc} = 2.37$ Mgm^{-3}. The structure was solved by direct methods and refined to $R = 0.046$ and $R_w = 0.049$ for 1498 independent reflections with $F_0 > 3\sigma(F_0)$ and $Mo_{K\alpha}$-radiation.

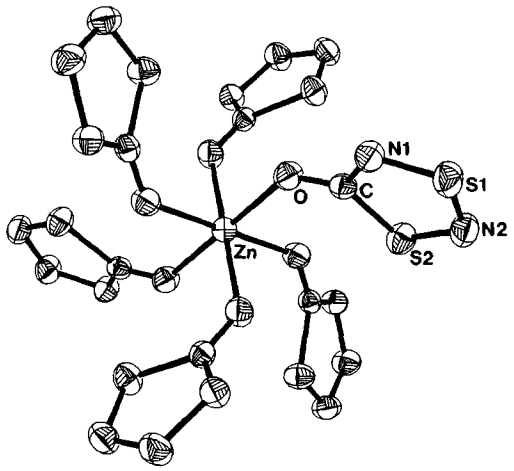


Fig. 1. Structure of $[Zn(S_2N_2CO)_6]^{2+}$, atom numbering and interatomic distances [pm], standard deviations in brackets: C—N(1) 134.7(3), N(1)—S(1) 157.6(3), S(1)—N(2) 157.0(3), N(2)—S(2) 161.7(2), S(2)—C 178.9(3), O—C 124.0(3).

In the $Zn(S_2N_2CO)_6^{2+}$ cation (Fig. 1) Zn is octahedrally coordinated: The maximum distortion from 90° is 1.4°. Zn lies on the special position with $\bar{3}$ symmetry and As on a threefold axis. The ligand **1**[2] is planar within experimental error, and possesses no crystallographic symmetry. The Zn—O—C angle is 134.2°. The C—O bond length in **3** (124.0(3) pm) is somewhat longer than in the free ligand (122.2(7) pm). The remaining bond lengths within the S_2N_2C ring show no significant change; the average S—N bond length in the uncoordinated ligand **1** is 159.5 and in **3** 158.8 pm.

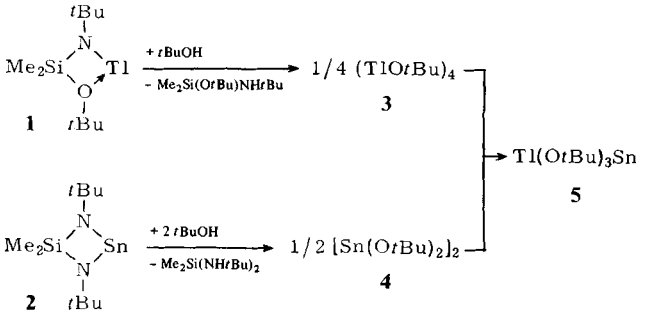
Institut für Anorganische Chemie der Technischen Universität
Pockelsstrasse 4, D-3300 Braunschweig (Germany)

[**] This work was supported by the Forschungsmittel of the Land Niedersachsen.

molecules. Hence, *e.g.* $TlOCH_3$[1] and *t*BuN=Sn[2] form tetramers, which consist of cubane-like Tl_4O_4 and Sn_4N_4 cages, respectively. In these compounds the main-group elements achieve a noble gas configuration through coordinative bonds.

We have now succeeded, for the first time, using Tl^I and Sn^{II}, in incorporating two low-valent elements from different main groups into a cage: for this purpose we made use of methods which we previously developed for the synthesis of Sn^{II} polycycles[2]. The pentatomic cage system **5** is obtained in high yield from the Tl^I and Sn^{II} molecular compounds **1**[3a] and **2**[3b] by allowing these to react with *tert*-butyl alcohol and subsequent reaction of the isolable intermediates of tetrameric **3**[4] and dimeric **4**.



5 is sublimable at 40 °C/0.001 torr, soluble in benzene, and displays only one signal ($\delta = 1.32$) in the ^{1}H-NMR spectrum, which indicates a highly symmetric molecule. The C_3 symmetry of the molecule is confirmed by X-ray structural analysis (Fig. 1). Tl and Sn are held together by three *t*BuO ligands, which results in a trigonal bipyramid: three oxygen atoms form the triangle, whereas the metal atoms are situated on the vertices.

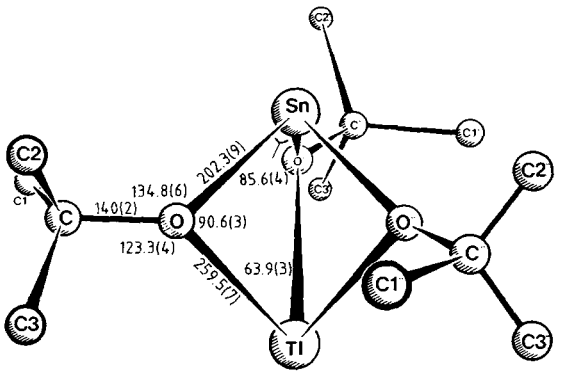


Fig. 1. Perspective representation of **5** with bond lengths [pm] and angles [°]. Crystal data: hexagonal, space group $P6_3/m$; $a = 994.4(5)$, $c = 1107(1)$ pm; $Z = 2$; $\rho_{exp} = 1.90$ g·cm^{-3}. 352 independent reflections, $R = 0.053$. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the following number CSD 50257, the name of the author, and the journal citation.

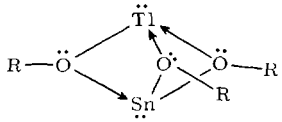
Due to the "encircling" the tin and thallium atoms come as close as 330.6(3) pm to each other. The relatively short SnO[2] and TlO distances[5] allow it to be presumed that an intramolecular ion pair, such as $Tl^{\oplus}[(OtBu)_3Sn]^{\ominus}$, is involved in **5**. This description, however, only corresponds to a mesomeric structure. The good solubility in benzene, ease of sublimation, and, above all, the crystal structure clearly indicate the nonpolar character of the molecule. In the crystal the molecules are arranged in a layer sequence AB, AB,..., in which a statistical defect along the hexagonal axis is observed (crystallographic point symmetry of **5**: C_{3h} (3/m)). The bonding behavior in the cage molecule **5** can be described thus:



According to the structural determination, the two-electron donor bonds are indistinguishable from the two electron single bonds.

Procedure

tert-Butyl alcohol (0.59 g, 0.008 mol resp. 1,2 g, 0.016 mol), is added dropwise to a solution of **1**[3a] (3.26 g, 0.008 mol) and **2**[3b] (2.58 g, 0.008 mol), respectively, in diethyl ether (20 mL) at −10 °C. Both solutions are stirred for 30 min and then combined. The reaction mixture is separated *in vacuo* whereby 3.9 g (90%) of colorless crystals of **5** sublime, which melt at 43 °C.

New Dihydropyrans: Lewis Acid Catalyzed Cycloadditions of α,β-Unsaturated Acyl Cyanides to Simple, Unactivated Olefins and Dienes: A Readily Accessible Route to Derivatives of Rose Oxide**

By *Zeinhom M. Ismail* and *H. M. R. Hoffmann**

Cycloadditions of α,β-unsaturated carbonyl compounds to electron-rich olefins[1] are classified as Diels-Alder reactions with inverse electron-demand and furnish 3,4-dihydropyrans: Typically, enol ethers react with α,β-unsaturated aldehydes on heating in an autoclave at 160—180 °C (see *e.g.* formation of **3a** in Table 1). Previously, intermolecular cycloadditions of simple alkenes to α,β-unsaturated carbonyl compounds were unknown[2].

We have recently prepared a variety of α,β-unsaturated acyl cyanides[3] and now report that they can be activated by $AlCl_3$ to react with simple olefins at room temperature, giving novel dihydropyrans, *e.g.* **3b—3e**, in good yield. Even isobutene, **1e**, reacts with **2a** to give **3e** having two quaternary centers.

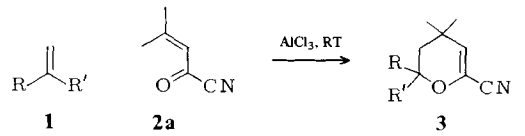
[**] This work has been presented in part at the EUCHEM Conference on Pericyclic Reactions in Ferrara, Italy, Sept. 27—Oct. 1, 1982. We thank the Niedersächsische Minister für Wissenschaft und Kunst and the Fonds der Chemischen Industrie for financial support.



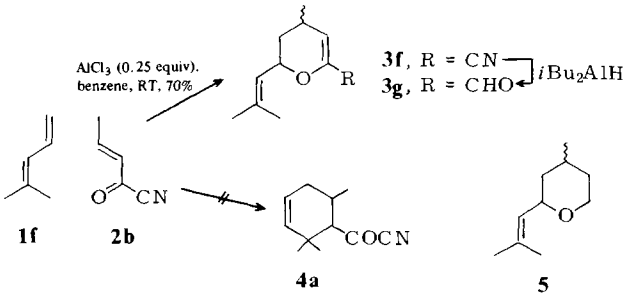
1 2a 3

Table 1. Dihydropyrans **3** from olefins **1** and 4-methyl-2-oxo-3-pentenenitrile **2a**.

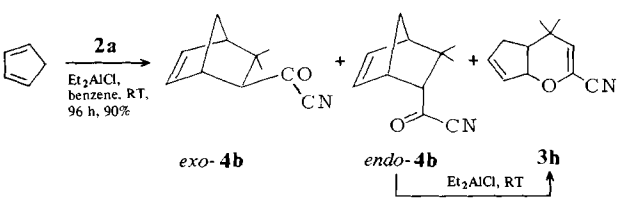
3	R	R'	$AlCl_3$: **2a**	Experimental conditions [a]	Yield [b] [%]
a	*i*PrO	H	—	160 °C, 10 h	76
b	Me_3SiCH_2	H	0.5	RT, 24 h	40
c	Ph	H	0.25	RT, 18 h	41
d	MeCH=CH	H	0.25	RT, 3 h	52 [c]
e	Me	Me	0.25	0—5 °C, 3 h	35

[a] For the preparation of **3a** neat reactants were used, otherwise reactions were conducted in benzene. [b] After Kugelrohr distillation. [c] 28% of the conventional Diels-Alder adduct is also formed.

Furthermore, 4-methyl-1,3-pentadiene **1f** and acyl cyanide **2b** furnish only **3f** in 70% yield (stereoisomeric ratio 59:41). Thus, a simple and convergent route has been opened to a variety of derivatives of rose oxide **5**[4], an important constituent of Bulgarian rose oil. The nitrile **3f** could also be converted into aldehyde **3g** in 70% yield.



Phenomenologically, the formation of these dihydropyrans can be regarded as a Diels-Alder reaction with inverse electron-demand, the LUMO of the heterodiene having been lowered by Lewis acid complexation. Mechanistically, Michael addition of the olefin to the activated α,β-unsaturated acyl cyanide, followed by formation of the second σ bond, must also be considered, especially when approach of the reacting termini is hindered (cf. **3e**).



With more reactive dienes, α,β-unsaturated acyl cyanides behave also as conventional dienophiles: from **2a** and cyclopentadiene **3h** is formed, in addition to *endo*-**4b** and *exo*-**4b**; *endo*-**4b** undergoes a facile Lewis acid catalyzed hetero-Cope rearrangement to give **3h** at room temperature.

$[Fe_3W_3S_{14}]^{4-}$, A Novel Hexanuclear, "Pure" Bimetal-Sulfur Cluster with $Fe_3(\mu_3\text{-}S)_2$ Center

By *Achim Müller**, *Winfried Hellmann*, *Hartmut Bögge*, *Rainer Jostes*, *Michael Römer*, and *Uwe Schimanski*

Dedicated to Professor Rudolf Hoppe on the occasion of his 60th birthday

Bimetal-sulfur clusters and complexes of Fe *and* Mo or W have generated extraordinary interest in relation to the active center of the MoFe protein of nitrogenase[1–4]; however, until now only a few different types of such compounds have been synthesized.

We have now succeeded in synthesizing the unusual bimetal cluster $[Fe_3W_3S_{14}]^{4-}$ **1** having a central $Fe_3(\mu_3\text{-}S)_2$ moiety, which displays remarkable structural details and is also interesting in relation to the recently discovered importance of Fe_3 centers in proteins[13]. **1** is formed from solutions of $[Fe(WS_4)_2]^{2-}$ **2**[1] and could be isolated in the crystalline state as $[(Ph_3P)_2N]_2(NEt_4)_2[Fe_3W_3S_{14}]$ **1a**, $(Ph_4P)(NEt_4)_3[Fe_3W_3S_{14}]$ **1b**, and $[(Ph_3P)_2N](NEt_4)_3[Fe_3W_3S_{14}]$ **1c** and characterized by elemental analysis, EH-SCCC-MO calculations, magnetic measurements, UV/VIS- [in CH_3CN: 630 (sh), 550 (sh), 465 (sh), 427, 365 nm], IR- [KBr pellet: 480 (st) (νWS_{term}), 443/435 (m) (νWS_{br}), 365 (w) ($\nu Fe\text{-}\mu_3\text{-}S$), 304 (m) cm^{-1} (νFeS)], resonance Raman-, and XPE-spectroscopy, as well as by complete X-ray structural analysis[**].

The three Fe atoms (Fe—Fe 272.1 pm) of the central unit form an equilateral triangle having a $\mu_3\text{-}S^{2-}$ ligand above and below this plane (Fe—S 229.4 pm). Each Fe atom is bidentately coordinated by a WS_4^{2-} ligand

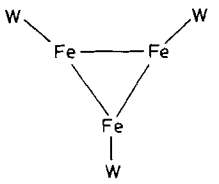
[**] Details of the crystal structure analysis can be obtained from the Fachinformationszentrum Energie—Physik—Mathematik, D-7514 Eggenstein-Leopoldshafen 2 by quoting the following number CSD 50287, the name of the author, and the complete citation of the journal.

(Fe—S_{br} 226.1, W—S_{br} 223.8, W—S_{term} 215.2, Fe—W 277.4 pm (average distances)). This results in a distorted tetrahedral environment for iron. The Fe_3W_3 moiety



is almost planar and exhibits metal-metal interactions[1] (the Fe atoms are strongly antiferromagnetically coupled). It is notable that the Fe_3S_2 cluster center is "held together" without the presence of doubly bridging ligands, which normally only occurs in electron-rich clusters with strong π-acceptors. This reconfirms the unusual properties of thiometalate ligands[1].

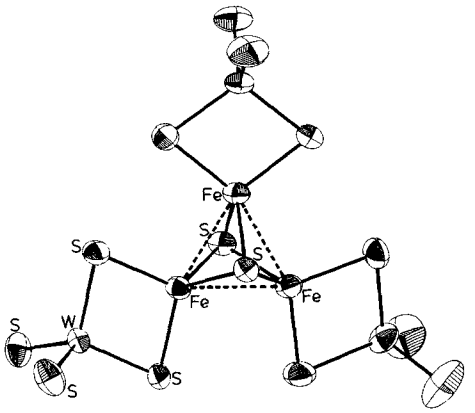


Fig. 1. Structure of the anion **1** (ORTEP plot) in crystals of **1b**. Space group $P\bar{1}$; $a = 1500.6(3)$, $b = 1475.4(3)$, $c = 1758.9(4)$ pm, $\alpha = 109.56(2)$, $\beta = 95.41(2)$, $\gamma = 106.10(2)°$; $Z = 2$; $R = 0.066$ for 8160 independent reflections ($F > 3.92\sigma(F)$); $Mo_{K\alpha}$ radiation.

It has recently been mentioned that apart from [2Fe-2S] and [4Fe-4S] moieties, Fe_3-sulfur cluster centers may also be widely distributed in proteins and enzymes[13]. For example, the 7Fe protein from *A. vinelandii*[13] not only contains a [4Fe-4S] but also a [3Fe-3S] cluster. Fe_3 groups perhaps occur *also in bimetal clusters* of proteins and enzymes (in nitrogenases *e.g.* a MoS_4 moiety could be considered to act as a bridging entity between two trinuclear clusters).

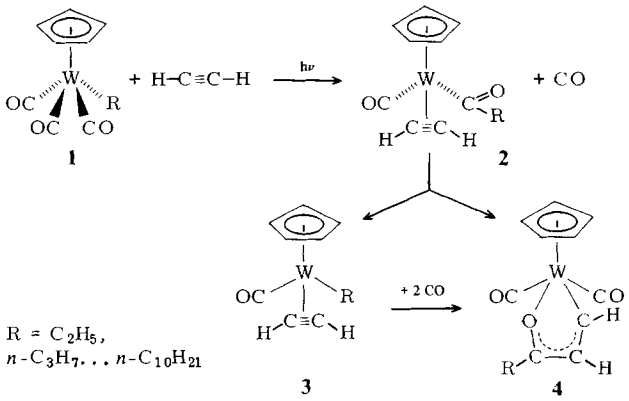
Novel Tungsten-Alkyl and Tungsten-Acyl Complexes with Acetylene as Four-Electron Ligand**

By *Helmut G. Alt**, *Manfred E. Eichner*, and *Brigitte M. Jansen*

Solutions of the alkyl complexes **1** are photochemically dealkylated by a rapid β-elimination[1]. The β-elimination also dominates over the photoinduced substitution of CO ligands when the complexes **1** are allowed to react with olefins or *n*-donors in solution. We have now observed that the reaction of **1** in pentane with acetylene leads to acetylene-acyl derivatives of the type **2**, photolytically generated carbon monoxide being inserted into the metal-alkyl σ-bond (cf. [4]). The complexes **2** can be smoothly converted in boiling toluene (110 °C, 4 min; without irradiation) into the CO-deficient compounds **3** and the CO-rich metallacycles **4**, which can be separated by column chromatography.

The alkyne complexes **2** and **3** are red, and, as expected, in the IR spectrum show one band for the terminal CO ligand, but no C≡C stretching vibrations in the region 2000—1500 cm^{-1}. In the ^{1}H-NMR spectrum the acetylene hydrogen atoms are strongly deshielded, and in the ^{13}C-NMR spectrum the acetylene carbon atoms are strongly deshielded; according to the mass spectra both types of complex are monomeric [*e.g.* **3**, $R = C_2H_5$: IR (pentane): $\nu(CO) = 1925$ cm^{-1}; ^{1}H-NMR ([D$_6$]acetone): $\delta = 5.48$ (s, 5), 12.44 (d, 1), 11.83 (d, 1) [J(H,H) = 1.2 Hz], 1.22 (m, 3), 0.96 (m, 1), 0.15 (m, 1); ^{13}C-NMR ([D$_6$]acetone): $\delta = 92.7$ (C_5H_5), 241.2 (CO), 191.3/185.7 (C_2H_5) [J(W,C) = 17.6 and 68.4 Hz], 26.6 (CH_3), 1.1 (W—CH_2) [J(W,C) = 94.7 Hz]; MS: $m/z = 332$ (M^+) referred to ^{184}W].



In acetylene complexes, in which the alkyne ligand clearly functions as a two-electron ligand, *e.g.* in $CpCr(CO)(C_2H_2)NO$[5], the corresponding C_2H_2 resonance signals in the ^{1}H-NMR ($\delta = 7.17/6.17$) and ^{13}C-NMR spectrum ($\delta = 89.8/75.8$; [D$_6$]acetone) appear far upfield. Such strongly deshielded alkyne resonance signals are also considered by other authors as an indication of the presence of alkynic four-electron ligands[6]. The unusually high rotation barrier around the tungsten-alkyne bond axis [*e.g.* **3**, $R = C_2H_5$: $\Delta G^{\neq} = 78.7$ (±4) kJ/mol] and the absence of a ν(C≡C) band in the IR spectrum about 1700 cm^{-1} also support this assumption. Extended Hückel calculations[8]

Laboratorium für Anorganische Chemie der Universität
Universitätsstrasse 30, D-8580 Bayreuth (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

on the model compounds $(C_5H_5)_2MoC_2H_2$, $Mo(CNH)_2(SH)_2(C_2H_2)$ and Mo(porphyrin)C_2H_2 confirm that both π-systems of the acetylene in **2** and **3** can interact with hybrid orbitals of the metal, so that the acetylene is to be regarded as a bidentate "biscarbene" ligand.

The complexes **3** are exceptionally stable towards UV light: **3**, R = *n*-C_3H_7, is changed to the extent of only 25% on irradiation ($\lambda > 300$ nm, 450 W) for one hour, when, according to the IR and ^{1}H-NMR spectra, the complex of type **2** is formed. This photochemical resistance of **3** further supports the assumption that the alkyne in **3** functions as a four-electron ligand, since otherwise β-elimination (in a 16-electron system) would be strongly favored as a result of the free coordination site on the metal, and would take place very rapidly.

The pentamethyl-substituted derivatives $C_5Me_5W(CO)_3R$ react analogously to complexes **1**; the products, however, are thermally more stable and crystallize better than **2**, **3**, and **4**. Substituted alkynes can also be employed instead of acetylene.

Preparation of Butatrienylamines from Butenynylamines

By *Lambert Brandsma**, *Peter E. van Rijn*, *Hermann D. Verkruijsse*, and *Paul von R. Schleyer*

Although the butatrienylamines (cumulenamines) **3** must occur as intermediates in the base-catalyzed rearrangement of the 3-buten-1-ynylamines (enynamines) **1** into the isomers **4**, all attempts to detect **3** have so far failed[1].

The isomerization **3** → **4** with potassium *tert*-butoxide in dimethyl sulfoxide or with potassium amide in liquid ammonia obviously proceeds much more rapidly than the formation of **3**. With a stronger base it should be possible to deprotonate **1** to **2** and to protonate **2** under kinetically controlled conditions to **3**. We report here on the isolation of the first butatrienylamine of type **3** (Table 1).

Henkestrasse 42, D-8520 Erlangen (Germany) (Guest Professor 1982 in Utrecht)

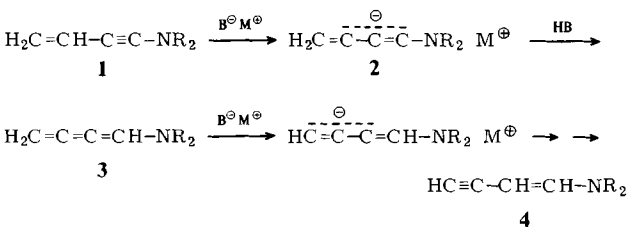

Table 1. Preparation of butatrienylamines **3** from butenynylamines **1**.

	2 R	B.p. [°C/torr]	n_D^{20}	Yield [%]	Contamination *trans*-**4** [%]
3a [a]	$2CH_3$	30/0.03 (70/10)	1.640	78	4
3b	$2C_2H_5$	45/0.03	1.598	66	3
3c	$2(CH_3)_2CH$	—	1.549	89	9
3d	$-(CH_2)_5-$	—	1.609	86	9
3e	$-(CH_2)_4O-$	—	1.613	82	8

[a] Spectral data of **3a** (representative for **3b**–**e**): ^{1}H-NMR (CCl_4, 20% solution TMS int.): $\delta = 2.73$ (CH_3, s), 3.90 (CH_2, m), 6.18 (CH, t, $^5J = 6.3$ Hz); ^{13}C-NMR (C_6D_6, TMS int): $\delta = 122.8$ (C1), 127.6 (C2), 162.2 (C3), 67.3 (C4), 40.0 (CH_3); IR (without solvent): 2065 s (C=C=C=C), 1635 s cm^{-1} (C=C).

Deprotonation of the readily accessible 3-buten-1-ynylamines **1**[2,3] with *n*-BuLi/*t*BuOK (1 : 1)[4] in hexane/tetrahydrofuran (THF) at low temperatures and protonation of the resulting species **2** (M = K) with *t*BuOH afforded butatrienylamines **3**. On work-up in the absence of water, **3a** and **3b** could be isolated[5]. In case of the higher boiling derivatives **3c**–**e** this methodology led to *cis*- and *trans*-**4** and to polymers. Very rapid aqueous work-up (water catalyzes the conversion **3** → *trans*-**4**), however, enabled the isolation of crude **3c**–**e**[5].

The butatrienylamines **3** are yellow liquids which rapidly turn brown at room temperature and form viscous polymers; the polymerization is catalyzed by oxygen. The refractive index is remarkably high: n_D^{20} for **3a** (96% pure) is 1.640; for comparison **1a**: 1.493, **4a**: 1.523[1].

[5] **3a**–**e**: A solution of **1** [1, 2] (0.05 mol) in THF (30 mL) was cooled to −100 °C, treated with 0.08 mol *n*BuLi in 56 mL hexane within 2–3 min, and then with 0.08 mol *t*BuOK in 20 mL THF within 1 min at −100 to −90 °C. After 5 minutes' vigorous stirring at −90 °C a solution of *t*BuOH (0.18 mol) in diethyl ether (30 mL) was added to the reaction mixture by means of a syringe. Subsequently, the temperature was raised to −25 °C. In the case of R = CH_3, 50 mL of paraffin oil and a few porcelain chips were also added to the mixture. After recondensation of the solvent at *ca.* 10 torr (bath temperature *ca.* 35 °C) into a flask cooled to −70 °C, **3a** was condensed together with a little *t*BuOH at 0.01–0.6 torr into a flask cooled to −60 °C. Renewed recondensation yielded **3a** (purity ≥ 96%).—In the other cases, after protonation with *t*BuOH the solvent was first removed at *ca.* 10 torr and the product recondensed at −70 °C. The residue was vigorously shaken with 120 mL pentane and the resultant suspension rapidly filtered through a G2 glass frit.—In the case of **3b**, 40 mL of paraffin oil was then added to the filtrate, pentane removed at *ca.* 20 torr, and the remaining paraffin oil-emulsion heated in a high vacuum. **3b** (97% pure) was isolated in the same way as **3a**. **3c**–**e** were obtained as crude products (purity 90–92%) after shaking the pentane solution

(−20 °C) for 30 s with 150 mL of an aqueous solution of 20 g K_2CO_3 cooled to 0 °C and subsequent drying over K_2CO_3, filtration, and evaporation of the solution to dryness at *ca.* 10 torr. The last traces of solvent and *t*BuOH were removed in a high vacuum (bath temperature <30 °C). Attempts to distill the compounds resulted in polymerization.

Tris(trimethylplumbyl)heptaphosphanortricyclene $P_7(PbMe_3)_3$[1]

By *Dieter Weber, Carlos Mujica,* and *Hans Georg von Schnering**

Molecular compounds containing phosphorus-lead bonds are still a rarity. The few known examples include the substituted phosphanes $P(PbR_3)_3$ and $R—P(PbR_3)_2$ described by *Schumann et al.*[2]. Entry to these P—Pb systems, however, is essentially thwarted by the lability of the P—Pb bond. It is well known that no binary lead phosphides exist, and that molten lead is even used for the crystallization of Hittorf's phosphorus. As regards ternary compounds, the only known examples are the polyphosphides of the type $HgPbP_{14}$ discovered by *Krebs et al.*[5]. We have now been able to prepare $P_7(PbMe_3)_3$ **3** from $P_7(SiMe_3)_3$ **1**[6] and $ClPbMe_3$ in a facile reaction. The reaction proceeds (presumably according to an S_N2 mechanism) practically quantitatively in monoglyme at −50 °C with cleavage of $ClSiMe_3$. In complete contrast to the very sensitive Si-compound **1**, the colorless crystals of the Pb-compound **3** can be stored for days in air without any notable change, until finally decomposition with darkening in color (precipitation of lead) takes place. The analogous Sn-compound $P_7(SnMe_3)_3$ **2** can be obtained in the same way by reaction with $ClSnMe_3$[7]. Finally, the analogous Ge-compound can also be synthesized, directly, in a heterogeneous reaction from Na_3P_7 and $ClGeMe_3$.

Mass spectroscopically, only fragment ions are detectable above 298 K, a clear indication of the thermal lability of the P—Pb bond. Thus, it is understandable that **3**, unlike **1**, cannot be sublimed. The formation of **3** is favored by its relatively sparing solubility and by the volatility of $ClSiMe_3$. The IR spectra of all four $P_7(MMe_3)_3$ compounds with M = Si, Ge, Sn, Pb are characterized on the one hand by the intense M—C vibrations, dependent upon the atomic weight, and on the other by two groups of almost invariant skeletal vibrations of the central nortricyclene system.

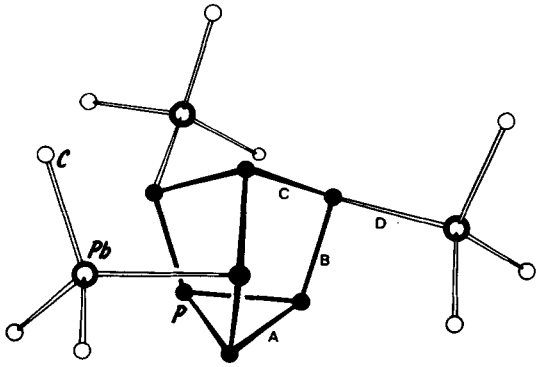

Fig. 2/3. Structure of $P_7(PbMe_3)_3$ **3**. Average bond lengths: A = 221.2, B = 217.6, C = 217.8, D = 261.1 pm ($\bar{d}$(Pb—C) = 219 pm). Crystal structure: $P2_1$ (No. 14); a = 990.8(2), b = 1819.1(3), c = 697.0(1) pm; β = 99.66(2)°; Z = 2; 2348 *hkl*; $Mo_{K\alpha}$ radiation; R = 0.052.

[*] Prof. Dr. H. G. von Schnering, Dr. D. Weber, C. Mujica
Max-Planck-Institut für Festkörperforschung
Heisenbergstrasse 1, D-7000 Stuttgart 80 (Germany)

The X-ray structure analysis (Fig. 2/3) reveals **3** as being isotypic with **1**[10]. The bond lengths d(P—Pb) average 261.1 pm ($\Sigma R_{cov.}$ = 258 pm). The bond lengths and angles in the nortricyclene framework closely resemble those in the other compounds[10]. The twisting of the P-skeleton about the threefold axis in **1**, determined by the steric interaction of the substituents with the free electron pairs on the bridge atoms, is also observed once again. The $P_7(MMe_3)_3$ molecules are chiral; in each case only one enantiomer is present in the crystal ($P2_1$). In the case of the Pb compound we were able to determine the absolute configuration. Since the crystals are relatively easy to handle there is the possibility of being able to separate the enantiomers.

Control of the Conformation of Transition States in Intramolecular Diels-Alder Reactions with Inverse Electron Demand**

By *Lutz-F. Tietze**, *Hartmut Stegelmeier, Klaus Harms,* and *Thomas Brumby*

In memoriam, Otto Bayer

Intramolecular Diels-Alder reactions permit the stereocontrolled synthesis of several chiral centers in one step[1a]; in this connection the configuration of at least two of the newly formed chiral centers is determined by the conformation of the chain linking the reacting π systems. We were able to demonstrate that 2-alkylidene-1,3-dicarbonyl compounds of type **1** lead exclusively, within a few minutes at 20 °C, to *trans*-annelated products **2** *via* an intramolecular Diels-Alder reaction with inverse electron demand[1b]. The chiral center in the chain of this system enables a stereoinduction with *de*-value >98% to be achieved[2].

Exclusively *cis*-annelated products are formed from arylidene compounds of type **3**, in which two C atoms are part of an aromatic ring. In this case the *endo*-transition state **3B** is energetically more favorable than the *exo*-transition state **3A**[3a]. The 2-benzylidene-1,3-dicarbonyl compounds **3** can be obtained by condensation of aldehydes **4** with 1,3-dicarbonyl compounds, *e.g.* **5** or **7**, in presence of

Table 1. Yields and melting points of the cycloadducts from **4a**—**4f** and **5** or **7**.

Educt	Cycloadduct	Yield [%]	M.p. [°C]
4a + **5**	**6a**	65	105 (decomp.)
4a + **7**	**8a**	69	225
4b + **5**	**6b**	73	131 (decomp.)
4b + **7**	**8b**	91	206
4c + **7**	**8c**	53	250
4d + **7**	**8d**	33 (65) [4]	253
4e + **7**	**8e** + **9e**	70; 4	184; 186
4f + **7**	**9f**	81	174

catalytic amounts of ethylenediammoniumdiacetate in CH_2Cl_2 or CH_3CN. They can only be isolated, however, in the case of the reaction of **4e** and **4f** with **5** or **7** (yield >90%). **4a** and **4b** react with **5**, and **4a**—**4d** with **7** (Table 1) within 5 h at 20 °C *via* intermediate arylidene compounds[4], which can be detected by ^{1}H-NMR spectroscopy (H—C≡C—CO: $\delta \approx 8.8$), to afford cycloadducts **6a**—**6b** and **8a**—**8d**, respectively[5a].

The presence of a heteroatom (X = O, N—Ms, S) instead of a CH_2 group in the chain adjacent to the aryl moiety has no product determining influence on the conformation of the transition state. This was expected for **3b** and **3c**, since substitution of a CH_2 group in carbocycles by an oxygen or a nitrogen atom causes only a slight conformational change. The substituents on the dienophile have considerable influence on the reaction rate and the type of transition state. Thus, **3e** (from **4e** and **7**) and **3f** (from **4f** and **7**) react first at 135 °C (12 h, xylene). A mixture of the annelated product **8e** and the bridged product **9e** (20:1) is obtained from **3e**, and, exclusively, the bridged product **9f** from **3f**; this selectivity is surprising, but is qualitatively consistent with the results expected from the HOMO coefficients of the dienophile. The bridged compounds are presumably formed from conformation **3C**[3b].

The conformation of the 2-benzylidene-1,3-dicarbonyl compounds **3** (from **4e** and **4f**, and **5** or **7**) in the crystal[5b], which are stable at 20 °C, however, precludes a Diels-Alder reaction in the solid state.

Engl. 19* (1980) 134.

[3] a) The (*E*)-heterodiene moiety in **3** is assumed to be the reacting system involved in the formation of the annelated products **6** and **8**. However, reaction of the (*Z*)-heterodiene moiety *via* an *exo*-transition state would yield the same products. But it has been shown that (*Z*)-heterodienes react sluggishly in intermolecular Diels-Alder reactions: G. Desimoni, G. Colombo, P. P. Righetti, G. Tacconi, *Tetrahedron 29* (1973) 2635; cf. also B. B. Snider, J. V. Duncia, *J. Org. Chem. 45* (1980) 3461. b) It must be assumed that either the (*Z*)-heterodiene moiety in **3** or a two-step mechanism is involved in the formation of the bridged products **9**, since otherwise a highly strained transition state would result.

[4] When the reaction of **4d** with **7** is quenched after 30 min and the mixture worked-up at low temperature, **3d** can also be isolated in 84% yield. **3d** forms the cycloadduct **8d** in boiling toluene (78% yield).

Erythro-Selective Aldol-Type Addition of Titanated Aldehyde-Hydrazones**

By *Manfred T. Reetz, Rainer Steinbach,* and *Kurt Kesseler**

In contrast to metal-enolates derived from ketones and esters the analogous reagents from aldehydes are not suitable for diastereoselective aldol-additions[1,2]. For example, lithium- and titanium-aldehyde-enolates exhibit practically no diastereoselectivity[3]. While lithiated aldehyde-hydrazones **2**[4] show no improvement (LDA = lithium diisopropylamide), their titanation with chlorotitanium triisopropoxide or bromotitanium tris(diethylamide) leads to the novel reagents **3**, which react *erythro*-selectively with aldehydes **4** to afford the adducts **5** and **6** (Table 1). Furthermore, the chemical conversion of **3** (X = isopropoxide) is higher than that of **2**. In the titanium series the alkoxides are generally markedly more efficient than the amides. The diastereomers **5** and **6** were isolated and separated by low-

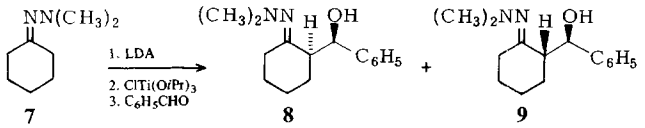
CH_3	O*i*Pr	$C(CH_3)_3$	**h** (70)	93 : 7

pressure liquid chromatography[1]. The product ratio was determined by analysis of the 400-MHz ^{1}H-NMR spectra.

The *erythro*-selectivity is also observed with titanated ketone-hydrazones (*e.g.* **7** → **8**), a finding which is to be compared with the *erythro*-selective behavior of titanium enolates from ketones[5].



> 98 : < 2

In the case of **3** ($R^1 = C_6H_5$, $X = N(C_2H_5)_2$) it was possible to record a ^{1}H-NMR spectrum which is in line with the *E*-configuration. The observed stereoselectivity is therefore surprising, because *E*-configurated ketone-enolates usually react *threo*-selectively[1,2]. In the case of a cyclic transition state, both chair and boat conformations are conceivable.

Aside from chlorotitanium triisopropoxide, titanium tetraisopropoxide can also be used for the titanation. However, in this case ate-complexes are formed which show less pronounced *erythro*-selectivity. Finally, titanated Schiff bases likewise behave *erythro*-selectively.

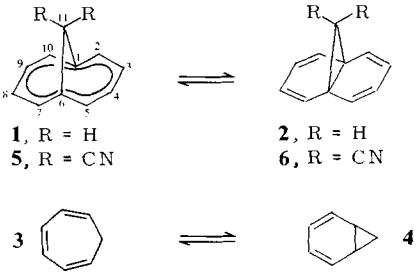
Theoretical Investigations on the Valence Tautomerism between 1,6-Methano[10]annulene and Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene

By *Dieter Cremer** and *Bernhard Dick*

1,6-Methano[10]annulene **1** must, on the basis of its physical and chemical properties, be described as a Hückel aromatic system with a delocalized π-electron decet[1a-d]. Investigations on C-11-substituted 1,6-methano[10]annulenes, however, suggest that **1** can transform into the valence tautomer tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene **2** in solution[1c,d]. There is the possibility of a rapid reversible valence tautomerism of the type **1** ⇌ **2**, similarly to that assumed for the system cycloheptatriene **3** - norcaradiene **4**[1e-g].



1, R = H
5, R = CN

2, R = H
6, R = CN

According to experimental and theoretical estimates[2], **4** is destabilized by about 4–12 kcal/mol compared to **3**. Accordingly, the equilibrium **3** ⇌ **4** is shifted far over to the side of the cycloheptatriene. However, detection of the norcaradiene component has so far only been possible in an indirect way. Thus, **3** reacts like **1** with dienophiles to give Diels-Alder products, indicating a previous rearrangement **3** ⇌ **4** or **1** ⇌ **2**. However, it cannot be ruled out that the norcaradiene component is first formed at the moment of reactive collision with the dienophile[2a].

To clarify this problem we have determined the energy profile of the valence tautomeric processes **1** ⇌ **2** and **3** ⇌ **4**, respectively, by *ab initio* calculations and therefrom obtained the energy differences $\Delta E = E(2) - E(1)$ and $\Delta E = E(4) - E(3)$[3]. After taking into account vibration and entropy effects values of 4.5 and 5.6 kcal/mol, respectively, result for the difference in the free energies ΔG^0, which corresponds to concentrations of about 0.05% **2** and 0.01% **4** at room temperature.

The valence tautomerization of **1**, like that of **3**, is characterized by an asymmetric double-well potential (Fig. 1). According to our calculations, an asymmetric single-well potential, as has been discussed for the 11-cyano-11-methyl derivative[4a], can be ruled out for the rearrangement **1** → **2**. For the energy barriers ΔE^+ of the forward and reverse reactions, we find values of 7.3 and 2.3 kcal/mol, respectively. These values are about 3 kcal/mol smaller than the barriers calculated for the equilibrium **3** ⇌ **4**. Appar-

[*] Priv.-Doz. Dr. D. Cremer, Dr. B. Dick
Lehrstuhl für Theoretische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

ently formation of the cyclopropane bond is favored as a result of the shorter 1,6-distance in **1** (2.26 Å as opposed to 2.50 Å in **3**[3]), whereas in **2** the interaction of the Walsh orbitals of the three-membered ring with the π-orbitals of the butadiene moieties indicates the far better π-conjugation in **1**.

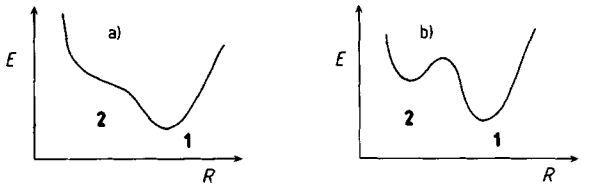


Fig. 1. Schematic representation a) of an asymmetric single-well potential and b) of an asymmetric double-well potential for the valence tautomeric equilibrium **1** ⇌ **2**. *R* is distance between C-1 and C-6.

According to experimental and theoretical investigations on cycloheptatrienes, substituents can shift the valence tautomeric equilibrium to the side of the norcaradiene[4b-e]. Thus, *Ciganek* synthesized 7,7-norcaradienedicarbonitrile as the first norcaradiene derivative in this way[4b].

The electronic influence of the two CN groups has been calculated to amount to about 10 kcal/mol[3] in the case of the cycloheptatriene. If this value is extended to the system **1** ⇌ **2**, then it can be predicted that tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene-11,11-dicarbonitrile **6** is more than 5 kcal/mol more stable than the valence tautomeric 1,6-methano[10]annulene-11,11-dicarbonitrile **5**. This prediction is confirmed by the synthesis of **6** and its spectroscopic and structural chemical characterization carried out by *Vogel et al.*[5].

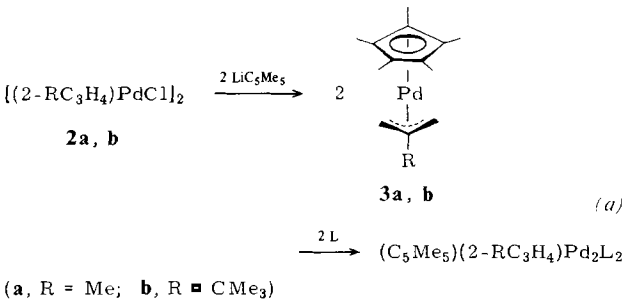
Synthesis of Pd(η²-CH₂=C₅Me₄)L₂: Formation of a Fulvene Ligand by Metal-Assisted H-Shift from Pentamethylcyclopentadienyl**

By *Hans-Jürgen Kraus* and *Helmut Werner**

Dedicated to Professor Rudolf Hoppe on the occasion of his 60th birthday

In connection with our studies on the chemistry of dinuclear palladium complexes of the type $(C_5H_5)(2\text{-}RC_3H_4)Pd_2L_2$ (**1**)[10] we attempted the preparation of the corresponding pentamethylcyclopentadienyl compounds *via* reaction sequence *(a)*. We expected these compounds to exhibit greater kinetic stability than the C_5H_5 complexes **1** regarding cleavage of the C_5Me_5—Pd_2 bond[12].



The reaction of **2a** or **2b** with LiC_5Me_5 in pentane (25 °C, 2 h) leads to **3a** and **3b**, respectively (*ca.* 85% yield, red crystals, m.p. 15—17 °C and 58 °C, respectively, correct elemental analysis, ^{1}H-NMR and mass spectra).

3b does not react with $P(iPr)_3$ or PPh_3, even on prolonged heating at 50—60 °C. Reaction with PMe_2Ph and $PMePh_2$ leads to cleavage of both the C_5Me_5—Pd as well as the allyl-Pd bond, with formation of the known palladium(0) compounds $Pd(PR_3)_4$. In contrast, the reactions with PMe_3 and $P(OMe)_3$ in toluene (50—60 °C, 5 h) afford the 1,2,3,4-tetramethylfulvene complexes **4** and **5** in 80—90% yield as bright yellow, air-sensitive solids which are readily soluble in all the common solvents and can be stored almost indefinitely at −30 °C under nitrogen.

The room-temperature ^{1}H-NMR spectra of **4** and **5** (in C_6D_6) indicate that the compounds have a fluxional structure in solution. Considerably broadened singlets are observed both for the protons of the exocyclic CH_2-groups as well as for the methyl protons of the ring. Signal sharpening occurs (in $(CD_3)_2CO$), and on cooling at −10 °C (**4**) and −25 °C (**5**), respectively, the splitting pattern to be expected for the constitution given in Scheme 1 is observed. From the large upfield shift of the signal of the C=CH_2 protons of $\delta = 5.47$ in the free tetramethylfulvene to $\delta = 2.54$ and 3.04 in **4** and **5**, respectively, the large PH-coupling constants, and the observation of two (and not of four) signals for the C—CH_3 groups, it can be concluded that the PdL_2 moiety is coordinated to the exocyclic C=C double bond. The palladium atom should lie in a plane with the two phosphorus atoms and the carbon atoms of the C=CH_2 bond. The platinum compounds $Pt(\eta^2\text{-}CH_2{=}C_5Ph_4)L_2$ (L = PPh_3, $PMePh_2$, PMe_2Ph, $AsPh_3$,

Scheme 1

CN*t*Bu) recently described by *Stone et al.*, which are formed from $Pt(\eta^2\text{-}CH_2{=}C_5Ph_4)C_8H_{12}$ and L, have an analogous structure[14].

The ^{13}C-NMR data are also consistent with the structure proposed for **4** and **5**. The signals of the carbon atoms of the $C{=}CH_2$ bond are each split into a doublet of doublets by coupling with two different ^{31}P-nuclei, and the signal of C^6 shows an additional triplet splitting in the off-resonance spectrum, due to CH coupling. The non-equivalence of the phosphane and phosphite ligands, respectively, is revealed in the ^{31}P-NMR spectrum by two doublets [**4**: $\delta = -21.47, -23.79$; $J(PP) = 28.3$ Hz. **5**: $\delta = 155.0, 152.34$; $J(PP) = 25.3$ Hz; in $(CD_3)_2CO$].

We assume that the formation of **4** and **5** primarily involves the addition of a phosphane or phosphite molecule, respectively, to the metal accompanied by a π/σ-rearrangement of the allyl group in **3b**, as has been demonstrated in the reaction of $C_5H_5Pd(2\text{-}RC_3H_4)$ with PR_3 and $P(OR)_3$[15]. A subsequent hydride-shift leads to a fulvene(hydrido)palladium(II) intermediate, from which, after elimination of 2,3,3-trimethyl-1-butene (detected ^1H-NMR spectroscopically) and addition of a second molecule of L, the fulvene complexes are formed.

That the formation of a 1,2,3,4-tetramethylfulvene ligand from C_5Me_5 is not restricted to palladium as metal atom has been shown by recent investigations on the synthesis of dinuclear $(\mu\text{-}C_5Me_4{-}CH_2)$ titanium complexes[16] as well as by NMR studies on the dynamics of $Ti(C_5Me_5)_2$[17].

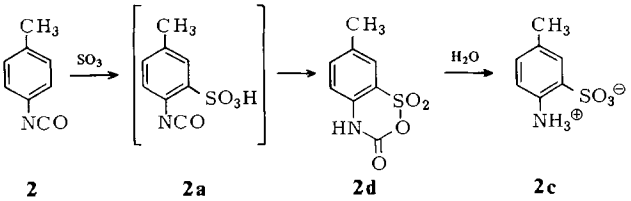
The Sulfonation of Aromatic Isocyanates: Sulfonated *p*-Tolyl Isocyanate—An X-Ray Structure Analysis

By *Gerhard Ballé, Liborius Born, Dieter Dieterich*, Marcel Petinaux,* and *Helmut Reiff*

Investigations on the sulfonation of aromatic mono- and polyisocyanates have shown that compounds containing isocyanate and sulfonic acid functions in one molecule are formed only in those cases in which the sulfo group enters the *ortho* position to the isocyanate group in the aromatic ring. We report here on the structure of sulfonation product **2d** derived from *p*-tolyl isocyanate **2**. Compound **2d** was formed by reaction of **2** with gaseous sulfur trioxide or with chlorosulfuric acid in dichloroethane. **2d** is a pale yellow powder which is practically insoluble in conventional inert organic solvents and is decomposed to the aminosulfonic acid **2c** with evolution of CO_2 on treatment with excess water. The IR spectrum of **2d** shows a sharply resolved group of bands in the region 1200–1400 cm^{-1} (sulfonic acid derivative) and one carbonyl band at 1780 cm^{-1}. Chemically, **2d** behaves like an isocyanatosulfonic acid, *i.e.* it gives the usual reactions of isocyanate and sulfo groups (urethane and urea formation, conversion into the isocyanatosulfonyl chloride or into the salt of the isocyanatosulfonic acid with a tertiary amine).



2 **2a** **2d** **2c**

The carbonyl band in the IR spectrum disappears in each case. The entry of the sulfo group in the *ortho* position to the NCO group can be confirmed by NMR spectroscopic investigations on derivatives. A complete structure elucidation *via* chemical routes seems impossible, since an important structural element characterized by the carbonyl band is destroyed in all reactions.

Since **2d** can be recrystallized from **2**, and also from $POCl_3$ and gives well-formed, sufficiently large crystals of m.p. 183 °C (dec.), the structure could be determined by X-ray diffraction. **2d** proved to be 7-methyl-2,1,4-benzoxathiazin-3(4*H*)-one-1,1-dioxide, a cyclic carbamic acid-sulfonic acid anhydride (Fig. 1). In contrast to the known open-chain carbamic acid-sulfonic acid anhydrides[2], this product is thermally fairly stable. Its formation is favored by the possibility of ring closure to the six-membered heterocycle. This ring system is new. The chemical behavior

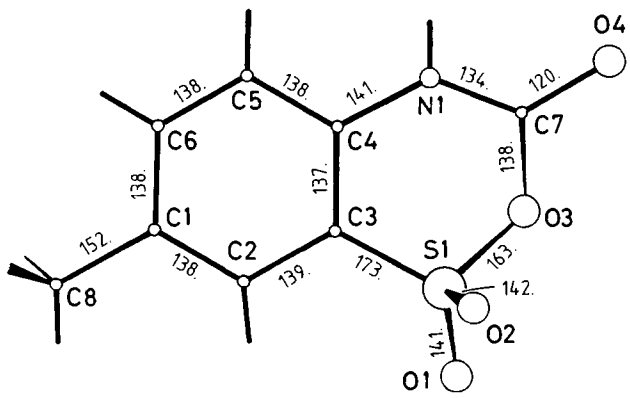


Fig. 1. Molecular structure of **2d** in the crystal including bond lengths in pm (standard deviations: 0.6 pm). Most important angles: C3—S1—O3 99.2(2), S1—O3—C7 120.2(7), O3—C7—N1 115.1(4), C7—N1—C4 126.3(7)°. Deviations from the plane of the aromatic ring: N1 5.5, C7: 47.4, O3: 76.4, S1: −11.8 pm. The annelated oxathiazine ring is thus present in a distorted half-boat form.—All data are average values from the two molecules of the asymmetric unit.

could be explained in terms of a temperature-dependent equilibrium between **2d** and the open form **2a**. Evidence for such an equilibrium is provided by the IR spectra recorded in solution at high temperatures.

First Metal Complexes of the Norcaradiene Form of 1,6-Methano[10]annulene

By *Peter Mues, Reinhard Benn, Carl Krüger, Yi-Hung Tsay, Emanuel Vogel,* and *Günther Wilke**

The sole transition metal complex of 1,6-methano[10]annulene **1** so far described in the literature is a tricarbonylchromium adduct[1], in which the annulene ligand, in complete contrast to complexes of cycloheptatriene, has benzenoid bonds similar to those in the free annulene **1**. Attempts to trap the norcaradiene derivative tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene, presumed to be in valence tautomeric equilibrium with **1**, by complexation to $Fe(CO)_3$ have hitherto remained unsuccessful[**], although recent *ab-initio* calculations indicate the aromatic system to be only 5 kcal/mol more stable than the tricyclic tautomer[2]. Complexation of the norcaradiene derivative by reaction of **1** with dicarbonyl(cyclopentadienyl)cobalt was also unsuccessful[**].

We have now found that reaction of **1** with η^5-cyclopentadienylbis(ethene)cobalt[3] leads to complexation. Reaction of the two components in pentane at room temperature affords the dark-red, crystalline air-stable complex **2** (35% yield, m.p. (dec.) 108–109 °C) and **3** (<1% yield).

[+] NMR spectroscopy.

[++] X-ray structure analysis.

[**] Experiments being carried out by Professor Dr. E. Vogel and his research group.

[***] More detailed information on the crystal structure investigation can be obtained on request from the Fachinformationszentrum Energie Physik Mathematik, D-7541 Eggenstein-Leopoldshafen, by quoting the following number CSD 50247, the name of the author and the journal citation.

Proof of the structure and composition is provided in particular by the ^{1}H-NMR spectra: in the case of **2**, in contrast to **3**, they show not only two different Cp groups but also two differently complexed butadiene moieties and bridge H-atoms. The disappearance of the aromaticity through valence isomerization to the norcaradiene derivative in the cobalt complexes manifests itself in the downfield shift of the bridge protons ($\delta = 0.95$ and 1.87 in **2**, $\delta = 1.33$ in **3**) of over 1 ppm in comparison with **1** and in their smaller geminal coupling ($^2J = 1.8$ Hz in **2**), as well as by their $^1J(^{13}C\text{-}H)$ coupling of about 164 Hz. Furthermore, the H,H couplings in the butadiene moieties of **2** and **3** are very similar to those observed for butadiene(Cp)Co[3]. (In **2**, AA′ = 3.8 and 3.7 Hz, and AB = 6.1 and 5.5 Hz, respectively, in **3**, AA′ = 4.2 and AB = 5.4 Hz.) All signals in **2** and **3** could be unequivocally assigned by nuclear Overhauser difference spectroscopy. The resulting structures derived therefrom for **2** and **3** are in complete agreement with the results of crystals structure investigations[***].

The distances between the bridgehead atoms are of particular interest: they are very much shorter than the C-1—C-6 distance in **1** (2.26 Å)[4] being only 1.512(5) Å in **2** and 1.499(5) Å in **3**. This clearly indicates that complexation of **1** is accompanied by cyclopropane ring-closure. The two isomers differ in the geometry of the tricyclic skeleton. In **2**, the diene systems are fixed *exo-endo*, whereas in **3** an *endo-endo* form is present. All CpCo groups π-bonded to this system have identical geometries. However, the molecule **3** has a number of special features and the extremely long CC bonds to the bridge atom C-11 (1.568(5) and 1.573(5) Å) indicate that the molecule is highly strained. In pentane, **2** reacts with atmospheric oxygen with partial decomplexation to give compound **4**. Presumably, **4** is the product of Berson-Willcott rearrangement, which is also observed under thermolytic conditions[5].

ab initio Calculation of Deformation Densities in Porphyrins

By *Marc Bénard**

Both experimental and theoretical studies of the electron deformation density[1] of organometallic compounds have become increasingly frequent. However, the first high resolution X-ray diffraction study on a porphyrin system (*meso*-tetraphenylporphinatocobalt(II), CoTPP) has only

[*] Prof. Dr. M. Bénard
E. R. no 139 du C.N.R.S. Laboratoire de Chimie Quantique
Université L. Pasteur, Institut Le Bel
4 rue Blaise Pascal, F-67000 Strasbourg (France)

recently been reported by *Stevens*[4]. We describe here preliminary results of *ab initio*-SCF calculations of the deformation density distributions in the "low-spin" cobalt(II) porphyrin (CoP) and the "intermediate-spin" iron(II) porphyrin (FeP), which are considered as models for CoTPP and FeTPP.

For CoP, the calculations were carried out on the $^2A_1$ configuration, which can be considered as the ground state. In FeP, the assignment of the ground state is still under discussion: conflicting experimental results indicate that the ground state might correspond either to a $^3A_{2g}$ configuration $(xy)^2(xz)^1(yz)^1(z^2)^2$[13], or to a ^3E_g configuration $(xy)^2(xz)^{1.5}(yz)^{1.5}(z^2)^1$[14], or to a spin-orbit coupling of these two states[15]. We report here the deformation density distribution for the $^3A_{2g}$ state only. Comparison of the computed distribution with that obtained from an X-ray study, which will appear shortly, should give some indication about the nature of the ground state.

The calculated deformation density map computed for CoP in the plane containing the metal atom and one pyrrole ring is displayed in Figure 1 (right). The corresponding map obtained by *Stevens* from the observed X-ray data, which is modeled using a multipole deformation refinement[4], is shown in Figure 1 (left). The difference between the two never exceeds 0.3 e Å^{-3}, except in the close vicinity of the nuclei. Such an agreement can hardly be improved within the framework of a static theoretical investigation.

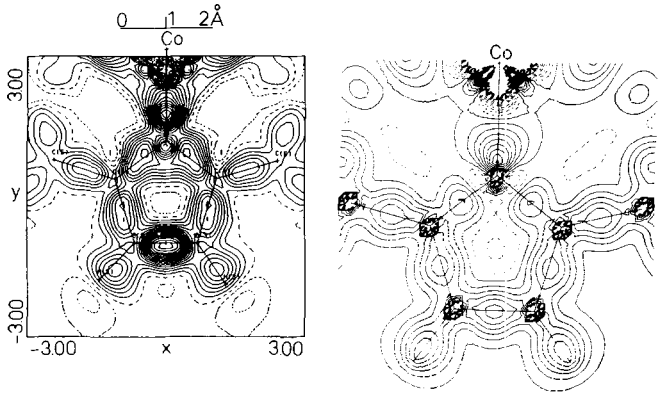

Fig. 1. Right: Computed deformation density for CoP plotted in the plane of the pyrrole ring. Contour intervals 0.10 eÅ^{-3}. Negative contours dashed.—Left: Observed deformation density (modeled) for CoTPP. Contours at 0.05 eA^{-3} with zero and negative contours dashed. Reproduced from [4] with permission of the author.

However, a map in the average molecular plane has little interest for the nature of the ground state of FeP, since the orbital populations in the xy-plane are similar for both the $^3A_{2g}$ and the ^3E_g configurations. Rather, one must consider the population of the d_{z^2} orbital in FeP, which is 2 for the $^3A_{2g}$ state and 1 for the ^3E_g state. The deformation density along the z-axis should therefore be quite different for these two states. A section through the computed deformation density distribution by a plane containing the z axis and bisecting two NFeN (or x0y) angles gave the following for the $^3A_{2g}$ state of FeP:

The computed distribution obtained shows four regions of accumulation. Two of them are localized along the z-axis and the other two along the line perpendicular to 0z bisecting the NFeN angles (in the xy-direction). These four regions of accumulation are similar in height and shape, and correspond to the filled d_{xy} and d_{z^2} orbitals in the $(xy)^2(xz)^{1.5}(yz)^{1.5}(z^2)^2$ configuration. This result is important with regard to the nature of the SCF ground state of FeP. One can reasonably infer that any mixing of the $^3A_{2g}$ state with the ^3E_g state $(xy)^2(xz)^{1.5}(yz)^{1.5}(z^2)^1$ will reduce the peak height along the z-axis, but not along the xy-direction. It can be therefore predicted that any significant dissymmetry between these two directions—should it be found experimentally—would represent a strong argument in favor of a spin-orbit coupling between the $^3A_{2g}$ and ^3E_g states.

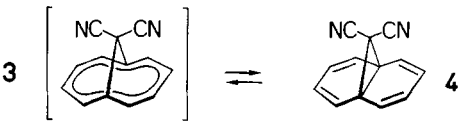
Norcaradiene Valence Tautomer of a 1,6-Methano[10]annulene: Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene-11,11-dicarbonitrile

By *Emanuel Vogel**, *Thomas Scholl*, *Johann Lex*, and *Georg Hohlneicher*

In memoriam, Otto Bayer

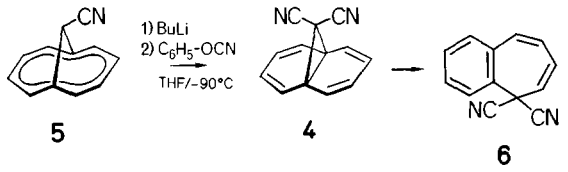
According to the *ab initio* calculations of *Cremer* and *Dick*[1], the Hückel aromatic 1,6-methano[10]annulene and its unknown norcaradiene valence tautomer (tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene) are separated by a free energy difference ($\Delta G = 4.5$ kcal/mol), which is practically equal to that between cycloheptatriene and norcaradiene. It is, therefore, to be expected that under the influence of π acceptor substituents on the methylene carbon atom[5] the postulated equilibrium 1,6-methano[10]annulene-tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene[4] should experience similar displacements to the side of the norcaradiene component as those observed for the cycloheptatriene-norcaradiene equilibrium.



The reaction of **5** with butyllithium and phenyl cyanate affords a transient dicyanide which, as evidenced by ^{1}H-NMR findings, must be **3** and/or **4**. Attempts at the isolation and full characterization of this species have until now been futile due to its pronounced tendency to undergo the Berson-Willcott rearrangement with formation of the known cycloheptatriene derivative **6**. We have now found

[*] Prof. Dr. E. Vogel, T. Scholl, Dr. J. Lex
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)
Prof. Dr. G. Hohlneicher
Lehrstuhl für Theoretische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

that the dicyanide can be isolated if the reaction product is worked-up below −10 °C and recrystallized at low temperature from dichloromethane; yield 27%. The compound, which occurs as colorless parallelepipeds, readily isomerizes in solution in chloroform [$t_{1/2}$(20 °C) = 28 min] to give **6**; in the crystal it is transformed into **6** only at 65–68 °C.



5 **4** **6**

The temperature independent ^{1}H-NMR spectrum (in CD_2Cl_2) of the dicyanide exhibits an AA'BB' system at $\delta = 6.27$ and 6.43 ($J_{1,2} = 9.64$ and $J_{2,3} = 6.20$ Hz), whose center is shifted by approximately 0.8 ppm to higher field relative to that of the AA'BB'-system of the vinylic protons in 1,6-methano[10]annulene. In the ^{13}C-NMR spectrum the C-1/C-6 signal of the dicyanide ($\delta = 54.5$) is shifted to high field by no less than 59 ppm relative to that of 1,6-methano[10]annulene ($\delta = 113.7$) and, hence, approaches the signal of C-1/C-6 in tricyclo[4.4.1.0^{1,6}]undeca-3,8-diene-11,11-dicarbonitrile ($\delta = 37.3$).

The NMR spectra of the dicyanide are consistent with the norcaradiene structure **4**, but leave open the possibility that the concentration of **3** at equilibrium is up to 10%.

A more precise statement on the maximum concentration of **3** is provided by the electronic spectrum. Whereas 1,6-methano[10]annulene displays the characteristic three band spectrum of a [4+2]annulene [with an intense ($\varepsilon = 68000$) band at 256 nm] the dicyanide exhibits a spectrum consisting of two bands [$\lambda = 243$ nm ($\varepsilon = 6450$), 283 (2400) (in 2-methyltetrahydrofuran)] which in its appearance resembles that of tricyclo[4.4.2.0^{1,6}]dodeca-2,4,7,9-tetraene. A weak shoulder in the region of the long wavelength band of the dicyanide probably arises from **3** ($\leq 1\%$).

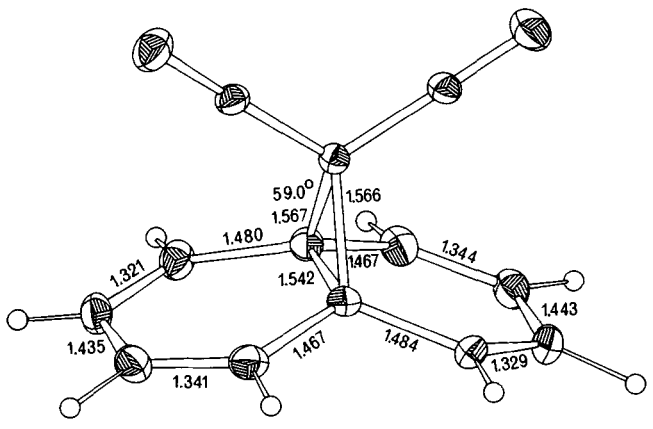


Fig. 2. Molecular structure of **4** in the crystal; bond lengths [Å].

The X-ray structural analysis (Fig. 2) of the dicyanide indicates that this also exists as **4** in the crystal. In contrast to the 11,11-dimethyl and 11-cyano-11-methyl derivatives of 1,6-methano[10]annulene[14], whose structural parameters lie between the values expected for the [10]annulene and norcaradiene structures (C-1–C-6 distance of 1.6–1.8 Å), the dicyanide exhibits a C-1–C-6 distance (1.542Å) corresponding to the length of a cyclopropane bond, and in consequence possesses 1,3-diene-type molecular segments C-2 to C-5 and C-7 to C-10.

The existence of **4**, as well as the recent synthesis of tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene transition-metal complexes by *Wilke et al.*[16] corroborate the statements, chiefly based on theoretical calculations, that the stability relationships in the "arene-olefin equilibrium" 1,6-methano[10]annulene-tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene and in the cycloheptatriene-norcaradiene equilibrium correspond to each other to a remarkable degree.

$[Ta_4F_{12}O_6]^{4-}$: A Tetranuclear Fluorooxotantalate(V) with Adamantane Skeleton

By *Jean Sala-Pala, Jacques-E. Guerchais**, and *Anthony J. Edwards*

As mentioned by *Van Wazer et al.*[1] about twenty years ago, "an outstanding challenge in chemistry is the preparation and characterization of families of compounds (ranging from the smallest molecule of the series—the *neso* molecule—to the infinitely large *macro* molecules) based on atoms other than carbon in the spine of the molecule". If we consider group V in this light, most work has been carried out since this date on compounds of the main group, mainly those of phosphorus[2]. With tantalum, and particularly fluorotantalate species, only few studies have been published[3], and in order to fill this gap we recently studied the hydrolysis of $Et_4N[TaF_6]$. The ^{19}F-NMR spectra[4] obtained are rather complicated and suggest formation of several anions made up from the following structural units: $[TaF_6]^-$ ("*neso* molecule"), $[TaF_5O_{1/2}]^-$ (end group), $[TaF_4(O_{1/2})_2]^-$ (middle group) and $[TaF_{3-x}(O_{1/2})_{3+x}]^-$ (x = 0...3; branch groups).

We report here on the complex $(Et_4N)_4[Ta_4F_{12}O_6]$, **1**, whose anion is made up of four *fac*-$[TaF_3(O_{1/2})_3]^-$ branch groups; the complex $(Et_4N)_2[Ta_2F_{10}O]$, **2**, built up from two end groups, has been described previously[4].

Complex, **1**, which was obtained by hydrolysis of **2**, is hygroscopic and its IR spectrum is not significantly different from that of **2** [880 cm^{-1}, vs, ν(TaOTa); 500 cm^{-1}, s, ν(TaF)]. In the ^{19}F-NMR spectrum only a sharp singlet is observed even at low temperature [($CDCl_3$), standard: CF_3CO_2H): $\delta = 50.0 \pm 0.5$] suggesting that all the fluorine atoms are equivalent. The results of an X-ray diffraction analysis of **2** are illustrated in Figure 1a[5]. $[Ta_4F_{12}O_6]^{4-}$ has an adamantane skeleton consisting of four Ta and six

O atoms (Fig. 1b), and therefore its structure may be compared with that of P_4O_{10} (H form)[2]. However, each Ta atom has three bridging O atoms in a *fac*-arrangement with the octahedron completed by three terminal F atoms. In contrast, the P atoms in P_4O_{10} are pseudotetrahedrally coordinated.

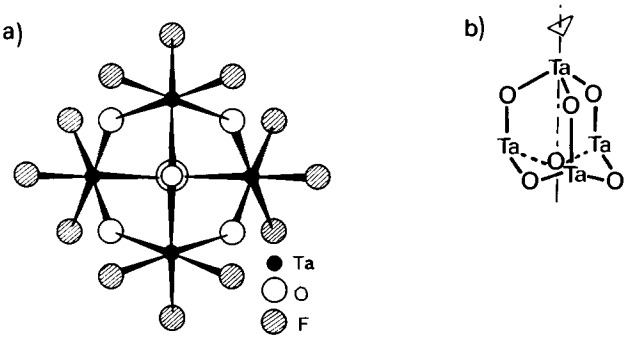

Fig. 1. a) Crystal structure of the anion of $(Et_4N)_4[Ta_4F_{12}O_6]$ **1** (projection along [001]). Interatomic distances and angles (average values): Ta—O 1.93, Ta—F 1.97, Ta...Ta 3.61 Å; Ta—O—Ta 139, O—Ta—O 91, F—Ta—F 87°; b) adamantane skeleton of Ta_4O_6.

Experimental

A solution of **2**[4] in CH_3CN (containing *ca.* < 1% water) under a nitrogen atmosphere is refluxed for 24 h. After cooling, colorless crystals of **1** slowly appear. These are filtered off, washed with ether, and dried *in vacuo*. Yield: 20%.

A Novel Route to Phloroglucinols – Synthesis, Structure, and Reactions of [n](2,4)Phloroglucinophanes**

By *Franz Effenberger**, *Karl-Heinz Schönwälder*, and *John J. Stezowski*

Dedicated to Professor Hermann Stetter on the occasion of his 65th birthday

Aldehyde enol ethers can be acylated to β-dicarbonyl- and 1,3,5-tricarbonyl-compounds in very good yields with reactive acid chlorides such as di- and trichloroacetyl chloride, phosgene or malonic acid dichloride **1**[1]. The ketone enol ethers **2** react—except with malonic acid dichloride—analogously; with **1**, the 4-hydroxy-2*H*-pyran-2-ones **6** and/or phloroglucinols **7** are obtained (Table 1). Since the pyranones **6** can be converted into the phloroglucinols **7**[2] the reaction of **2** with **1** enables a generally applicable synthesis of phloroglucinol and its derivatives in very good yields.

The extension of this reaction to enol ethers of cyclic ketones **8** leads to the bicycles **9** and/or **10** and/or the [n](2,4)phloroglucinophanes **11**, which allow interesting conclusions to be drawn about the structure and reaction behavior of metacyclophanes owing to the possibility of tautomerism in the arene moiety (Table 1). Aqueous work-

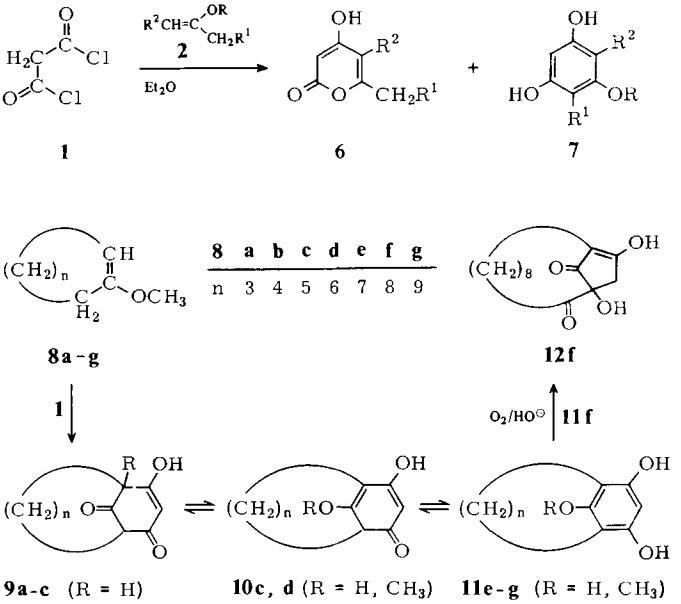

Table 1. 4-Hydroxy-2*H*-pyran-2-ones **6** and phloroglucinols **7** (selection).

2	R	R^1	R^2	**6** + (Yield [%])		**7**	
2a	CH_3	H	H	**5a**	(43)	**7a**	(52)
2b	C_2H_5	H	H	**6a**	(42)	**7b**	(43)
2c	$CH(CH_3)_2$	H	H	**6a**	(24)	**7c**	(65)
2d	$C(CH_3)_3$	H	H	—		**7d**	(79)
2e	CH_3	H	C_2H_5	**6b**	(11)	**7e**	(80)
2f	CH_3	CH_3	CH_3	**6c**	(30)	**7f**	(53)
2g	CH_3	C_2H_5	H	**6d**	(15)	**7e**	(16)

up of **8a—c** and **1** affords the bicycles **9a—c** (yields 84, 88, and 91%, respectively), while work-up of **8a**, **b** and **1** in methanol furnishes the 9,9- and 10,10-dimethylketals of **9a**, **b**, respectively. In the reaction of **8c—g** with **1** the hydrochlorides of the methyl ethers of **10c**, **d** and **11e—g** can be isolated (yields 70, 31, 18, 55, 28%).

The expected competition between the tautomers **9—11** can be deduced from the side views of the X-ray crystallographically determined structures of **9a** (n = 3), **9c** (n = 5), and **11g** (n = 9), where in each case R = H. In **9a** there is a strain-free coupling of 4-cyclohexene-1,3-dione and cyclohexanone in the chair form and in **9c** a combination of 4-cyclohexene-1,3-dione with cyclooctanone in the energetically less favorable chair-chair conformation. In **11g** the twelve-membered ring is almost strain-free and orthogonally coupled with the arene.

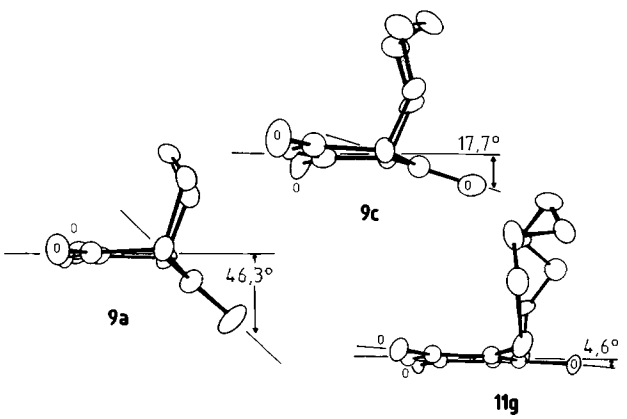
Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Frau Petra Kollat for assistance with the structure determinations.

The compounds **9**—**11** show different chemical behavior, depending on ring size and ring strain. The hydrochlorides of **10c** (R = CH_3) and **11f, g** (R = CH_3) with



n = 5, 8, 9 can be cleaved to the corresponding hydroxy compounds **9c** and **11f, g** (R = H) even with water, whereas in the case of **10d** (R = CH_3) and **11e** (R = CH_3), with n = 6, 7, no cleavage of ether takes place even under drastic conditions (conc. HBr). Comparable with the conversion of deoxyhumulone into humulone and its rearrangement to isohumulone[14] is the reaction of **11f** (R = H), whose autoxidation and rearrangement to the obviously more stable bicycle **12f**, however, takes place much more rapidly; this can be explained in terms of a decrease in strain on going from an 11- to a 12-membered ring.

^{13}C-^{13}C and ^{13}C-H Coupling Constants and the Electronic Structure of Cyclopropane, Cyclohexane, and Propane

By *Jürgen Wardeiner, Wolfgang Lüttke*, Rüdiger Bergholz,* and *Reinhard Machinek*

Dedicated to Professor Edgar Heilbronner on the occasion of his 60th birthday

The $^1J_{CC}$ and $^1J_{CH}$ coupling constants of saturated hydrocarbons are almost exclusively governed by the hybridization of the coupling C atoms *via* the Fermi contact term[1]. A complete set of $^1J_{CC}$ and $^1J_{CH}$ values should, therefore, give information about the electronic structure of a molecule, specifically about the hybridization of its C atoms. In order to obtain this information for cyclopropane **1**, cyclohexane **2**, and propane **3** we have determined the complete set of ^1J-values of isotopomers specifically labeled with ^{13}C and ^2H. We evaluated the data comparatively with respect to the different orbital properties arising from the various bond angles.

Table 1. ^{13}C-^{13}C and ^{13}C-H coupling constants [Hz] of **1**, **2**, and **3** [a].

	1	**2**	**3**
$^1J_{CC}$	12.4_0	32.7_0	34.6_5
$^1J_{CH}$	160.4_0	124.6_5	125.3_5 (CH_3) [b] 124.3_5 (CH_2) [b]
$^2J_{CH}$	−2.6	−4.0	—

[a] Mean deviation: ±0.1 Hz. [b] R. E. Wasylishen, T. Schaefer, *Can. J. Chem. 52* (1974) 3247.

Assuming that in CH bonds the non-contact terms hardly contribute to the coupling, the hybrid orbitals and the interorbital angles of all the C atoms can be calculated from the $^1J_{CH}$ data using the Muller-Pritchard equation[2a] and the sum rule[2b] for the s-character. From the orthogonality relationships[3] of molecular groups of type L_2ZL_2' the s-character of the individual C orbitals provides the values of the CCC- and HCH-interorbital angles in **1**, **2**, and **3**. The hybridizations thus obtained (Table 2) are in good agreement with the results of quantum chemical calculations[4].

Table 2. Hybridizations and interorbital angles of **1**, **2**, and **3**.

		1	**2**	**3**	
				CH_2	CH_3
s-Character	CH	0.3208	0.2492	0.2486	0.2506
	CC	0.1792	0.2508	0.2514	0.2483
Hybridization indices	CH	$sp^{2.12}$	$sp^{3.01}$	$sp^{3.02}$	$sp^{2.99}$
	CC	$sp^{4.58}$	$sp^{2.99}$	$sp^{2.98}$	$sp^{3.03}$
Interorbital angles	HCH	118.2°	109.4°	109.3°	109.6°
	CCC	102.6°	109.6°	109.7°	—

An almost ideal sp^3-hybridization is obtained for cyclohexane **2** and propane **3**. In contrast, the particular bonding characteristics of cyclopropane **1** are reflected in the considerably different s-character of the C orbitals of its CH and CC bonds; in consequence, the HCH and CCC interorbital angles deviate markedly from the values expected from ideally sp^3 hybridized C atoms: the cyclopropane CCC interorbital angle of 102.6° indicates that the axes of the hybrid orbitals of **1** are each bent by 21.3° relative to the direct line connecting the nuclei, corresponding to the *bent bonds* model of *Coulson*[4]. This result is experimentally confirmed by X-ray electron density determinations[5] as well as by quantum chemical calculations[4]. It is conspicuous that the experimentally determined CCC bond angles in **2** and **3** are *larger* (**2**: 111.4°, **3**: 112.4°) than the tetrahedral angle, but that the corresponding interorbital angles exhibit only minimal widening. In **1** an opposite deviation of a greater amount is noticeable: the forced reduction of the CCC bond angles from 109.5° to

[*] Prof. Dr. W. Lüttke, Dr. J. Wardeiner, Dr. R. Bergholz, R. Machinek
Organisch-chemisches Institut der Universität
Tammannstrasse 2, D-3400 Göttingen (Germany)

60° only causes a reduction of the CCC interorbital angle to 102.6°. Irrespective of whether the CCC bond angle is reduced or widened, the hybrid orbitals of all three hydrocarbons apparently have a strong tendency to retain the ideal tetrahedral angle as far as this is energetically possible, and to limit the orbital following to a minimum. This behavior, at least for saturated hydrocarbons, appears to be valid in general.

As we have found, the CCC coupling constants of aliphatic hydrocarbons can be represented well by the linear relationship (using the data of nine symmetric hydrocarbons).

$$^1J_{CC} = 658 \cdot s_1 \cdot s_2 - 7.9$$

If the s_{CC} data of Table 1 determined from the $^1J_{CH}$ values *via* the sum rule[2b] are inserted into this equation, $^1J_{CC}$ values of 13.2 for **1**, 33.5 for **2**, and 33.2 for **3** result. The (only slight) deviations of these data from the experimental ones (Table 1) provide a measure for the non-contact contributions to the $^1J_{CC}$. Hence, in **1**, **2**, and **3** the ^{13}C-^{13}C coupling actually arises almost completely from the Fermi contact mechanism.

BOOK REVIEWS

Modern Hot Atom Chemistry and its Applications. By *T. Tominaga* and *E. Tachikawa*, Inorganic Chemistry Concepts 5. Springer-Verlag, Berlin 1981. viii, 154 pp., bound DM 98.00.

The chemistry of hot atoms is dead, long live hot atom chemistry, in its modern and applied version, of course, at least that is what the title of the book suggests. On a closer inspection, however, the reader will inevitably come to the conclusion that the term "modern" means the beginning of the seventies and that the applications seem modest. This is not the fault of the authors. Already by the end of the sixties hot atom chemistry was no longer an individual and uniform field of endeavour, and what appeared to have a future has meanwhile been substantially taken over by physical chemistry, chemistry of the solid state, radiation biology, or radiolabelling chemistry.

One would certainly expect something new on experimental techniques, and it is precisely here that the book is disappointing. A modern book on hot atom Chemistry (HAC) should, for example, devote more than two pages to atomic and molecular beam techniques. Equally disappointing is the treatment of radiochemical separation techniques of the stable labelled molecules which are formed as a final manifestation of a nuclear recoil process. The chromatography has remained at the 1965 level; there is no mention of more sophisticated techniques, such as high-performance liquid chromatography.

The core of the book is the chapter "Characteristics of Hot Atom Reactions". On the whole, the parts on the reactions of hot tritium, halogen, carbon, silicon, germanium, and phosphorus atoms are didactically clear and coherent. A comparison with the reactions of the corresponding thermal atoms would have been useful here, especially as many thermochemical, photochemical, and radiation chemical investigations have now been published, which clearly show the similarities and the differences between the reactions of hot and thermal atoms. The part on "Solid Phase Hot Atom Reactions" is also too short.

In the chapter "Application of Hot Atom Chemistry and Related Topics" the emphasis is obviously on the related topics, since it is difficult to force subjects such as laser isotope separation or NEET (Nuclear Excitation by Electron Transition) into the HAC category. With this broadening of the concept of HAC in mind, it is difficult to see why muonium chemistry is discussed but positronium chemistry is not. Naturally, there are also HAC problems in energy research, but they play a minor role, and the examples confirm this. However, better choices could have

been made, particularly in the case of nuclear fusion. On the whole, the authors' aim to demonstrate the many-sided relationships of HAC with other research sectors is certainly praiseworthy, and has substantially been achieved. The importance of HAC is made obvious in topics such as the unimolecular decomposition of highly excited products, the study of the selectivity and reactivity of unsolvated decay ions, processes for rapid labelling with short-lived radionuclides, the chemical consequences of the radioactive decay and the Auger effect in biomolecules as the starting point for entry into novel areas of selective radiation biology. But all this is touched on only briefly, as if to give the reader no more than a taste. Few will quite get their money's worth (DM 98!), if any, hot atom chemists themselves. Either the book has come out five years too late or it is much too superficial.

Gerhard Stöcklin [NB 563 IE]

Elektrochemie (Electrochemistry) II (taschentext [pocket text] 42) by *C. H. Hamann* and *W. Vielstich*, Verlag Chemie, Weinheim 1981. xv, 428 pp., bound, DM 52.00.

A second volume on the subject of electrochemistry has now appeared in the "taschentext" series, building on Volume I (ionics, electrochemical thermodynamics) which appeared six years ago[*]. The extensive subjects of electrochemical kinetics and applied electrochemistry are now dealt with, each of them taking up about as much space as the whole of the first volume.

At the center of the kinetic treatment of electrode processes is, naturally, the current-voltage curve. The influence of the types of overvoltage on the course of this curve is discussed in detail. Not only simple metal electrodes but also mixed electrodes, semiconductor electrodes, and illuminated semiconductor electrodes are considered.

The chapter on electrochemical measurement techniques leads to the classical steady-state and nonsteady-state methods, the authors obviously being concerned to give a concentrated account of the theoretical foundations. Non-electrochemical techniques for surface analysis are also discussed, including such areas of topical interest as field desorption mass spectroscopy.

Among others, the processes at the hydrogen and oxygen electrodes are discussed as specific examples of electrode processes. The oxygen anode is considered somewhat too briefly; reference should perhaps have been made to a possible third mechanism of redox catalysis (decomposition of electrochemically formed oxides).

In the second part of the volume electrochemical syntheses, galvanic cells, and electrochemical surface techniques are discussed in extensive detail and the reader is acquainted with some modern developments. However, in the chapter on chlorine-alkali electrolysis one would like to find a somewhat more detailed account of the technical prerequisites for the vigorous development that set in 15 years ago with the advent of activated titanium anodes *(Beer)* and perfluorinated ion-exchange membranes, acknowledged perhaps in footnotes. The Monsanto process for the electrosynthesis of adiponitrile has for technical reasons been carried out in undivided cells since the end of the sixties, as has now become known through *Danly's* publications. Unfortunately, there is no mention of *Baizer*, the man who initiated this innovation.

In connection with a possible future hydrogen economy the electrolysis of water and the hydrogen/oxygen fuel cell are discussed in detail. The possibilities of secondary cells are outlined. These sections are particularly well arranged.

The authors' wish to present not only an accurate but also a clear account of the individual fields can be considered as largely achieved, and the few blemishes present hardly affect this over-all impression. (Thus, on p. 15—and then again on p. 39—it is expressly emphasized that the transfer reaction of electrons can be described as a quantum-mechanical tunnelling process. In spite of this, the Butler-Volmer equation on pp. 16—21 is derived precisely on this example with the aid of the Arrhenius equation.)

In spite of the necessary brevity, in most cases the authors succeed in formulating the problems precisely. On the whole, a readable and reliable account of electrochemistry has thus been achieved, which leads directly to the present situation in areas that are very much in a state of flux. The arrangement of the volume, and particularly the figures, is good. The book can be safely recommended to anyone who wishes to become acquainted with modern electrochemistry, and this also applies to the university level, although many students could be put off by the relatively high price.

Stabilization of Unusual Oxidation and Coordination States by the Ligands OSF_5, $OSeF_5$, and $OTeF_5$

By Konrad Seppelt*

Compounds with the ligands OSF_5, $OSeF_5$, and $OTeF_5$ are now known for most of the chemical elements. The ability of these ligands to stabilize the highest valency levels of the central atoms to which they are bound is unsurpassed by any other polyatomic ligand. Examples are $Xe(OTeF_5)_6$, $Te(OTeF_5)_6$, $W(OTeF_5)_6$, and $U(OTeF_5)_6$ or $I(OTeF_5)_5$ and $Br(OSeF_5)_3$. Because of the ligands' size and internal bonding they hardly ever form bridges, and in this respect they differ from fluorine, although they do share the latter's high electronegativity.

1. Introduction

The hexafluorides SF_6, SeF_6, and TeF_6 belong to the standard textbook repertoire. Their structure, bonding relationships, and lack of reactivity have meant that SF_6 in particular has become a typical example for perfluorinated compounds. Attempts to coax SF_6 into chemical reactions founder on its almost complete inertness. The coordination number of 6, relatively high for sulfur, precluded any attack by bases, which would have led to a temporary increase in coordination. Thus, SF_6 is stable to sodium hydroxide solutions up to temperatures of several hundred °C.

On the other hand, attack by acids, *e.g.* H^+ or AsF_5, should be easier because abstraction of fluoride would entail a reduction of the coordination number. There is hardly any experimental data, but it should be noted that substituted SF_6, *e.g.* CH_3—SF_5, is likewise completely inert to bases, but is immediately attacked by AsF_5, even at very low temperatures[1].

A comprehensive chemistry could not therefore be established starting from SF_6. But TeF_6, which can be substituted by bases, should be better because it can increase its coordination number beyond 6. However, the development of the above-mentioned ligands actually followed quite a different course:

Careful fluorinations of the elements or of the dioxides produced, quite unexpectedly, compounds such as $FOSF_5$[2], $FOSeF_5$[3], F_5SO—OSF_5[4], F_5SeO—$OSeF_5$[3], and F_5TeO-TeF_5[5]. It was not until the probably accidental discovery of pentafluorooxotelluric acid, $HOTeF_5$, by *Engelbrecht* and *Sladky*[7] and the similarly accidental discovery of its selenium analog $HOSeF_5$ by *Seppelt*[8] that the potential of the ligands was understood. It was only later that pentafluorooxosulfuric acid, $HOSF_5$, was shown to exist. This, however, has no preparative significance because of its instability[9].

2. The Acids $HOSF_5$, $HOSeF_5$, and $HOTeF_5$

New classes of compounds are usually discovered by chance. The reaction of barium tellurate with fluorosulfuric acid was ostensibly intended to yield the (still) unknown TeO_2F_2[7], in the same way that SeO_2F_2 is obtained in good yield from $BaSeO_4$ and FSO_3H[11]. However, in the tellurium system mainly $HOTeF_5$ was obtained[6, 7, 10]. This finding, which at the time was surprising, is now explained by the fact that hexavalent tellurium always strives to attain the coordination number 6. This tendency becomes still clearer when the hydrolysis of TeF_6[12, 13] or the solvolysis of $Te(OH)_6$ in HF are investigated[13–16]. Practically all the intermediate species $(HO)_xTeF_{6-x}$ have been detected.

$HOTeF_5$ is formed according to[7]

$$Te(OH)_6 + 5\,FSO_3H \rightarrow 5\,H_2SO_4 + HOTeF_5$$

The analogous selenic acid $HOSeF_5$ is formed, however, from SeO_2F_2 with an increase in the coordination number[8, 17, 18]:

$$3\,SeO_2F_2 + 4\,HF \rightleftharpoons 2\,HOSeF_5 + H_2SeO_4$$

This reaction establishes selenium as a true intermediate between sulfur and tellurium, because Se species with the coordination numbers 4 and 6 exist side by side. Sulfonyl fluoride SO_2F_2, on the other hand, is a strikingly inert compound with no tendency whatever to increase its coordination. Thus it is not surprising that $HOSF_5$ is unstable, releasing HF, and must be synthesized by more devious routes[9, 19]:

$$SOF_4 + ClF \xrightarrow{CsF} ClOSF_5 \xrightarrow[-Cl_2]{HCl} HOSF_5$$

The three compounds $HOXF_5$ are justifiably regarded as acids. On the one hand, a wide variety of XOF_5-salts is known (see Section 3), and on the other the acid strength of $HOTeF_5$ in glacial acetic acid has been measured directly and has been found to lie between those of HCl and HNO_3[20, 21]. The acid strength is certainly an expression of the inductive effect caused by the accumulation of fluorine atoms.

The octahedral structure of the molecules is most readily shown by their ^{19}F-NMR spectra of the AB_4 type (see Section 9). This indicates that the proton can rotate freely on the NMR time scale. Despite this, there is apparently a small fourfold torsion barrier of the proton as evident from satellite bands of the OH stretching and deformation vibrations in $HOSeF_5$ and $HOTeF_5$[19]. This phenomenon has not, so far, been subjected to a closer investigation. To the best of our knowledge no other example of a fourfold torsion barrier has been found (see Fig. 1).

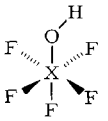

Fig. 1. Molecular model of $HOXF_5$. The similarity of OH and F results in an almost regular octahedral structure. This is reflected in many physical properties. The estimated intramolecular H...F distances are as follows: $HOSF_5$ 201, $HOSeF_5$ 232, $HOTeF_5$ 238 pm. No indication of an intramolecular H...F bridge has been established.

Formally derived from the chalcogen hexafluorides by replacement of one fluorine atom by an OH group, the pentafluorooxochalcogen(VI) acids are still virtually spherical molecules and consequently have both high melting points and vapor pressures. The melting points can be sharply depressed by the presence of impurities. Moreover, in the case of $HOSeF_5$ in particular, the vibrational spectra of the $OSeF_5$ skeleton degenerate almost to those of a regular octahedron, because the mass of the OH group and the strength of its bond to selenium do not essentially differ from those of the fluorine atoms[22]. The vibrational spectra of $HOTeF_5$ have a far greater number of bands[23].

The thermal stability of the three acids varies considerably[19]:

$$HOSF_5 \xrightarrow{-60\,^\circ C} HF + SOF_4$$

$$HOSeF_5 \xrightarrow{290\,^\circ C} HF + 1/2\,O_2 + SeF_4$$

$$HOTeF_5 \xrightarrow{>310\,^\circ C} HF + (TeOF_4)_n + TeF_6 + TeF_4 + \cdots$$

Below $-60\,^\circ C$ $HOSF_5$ is only kinetically stable to reduction of coordination. The somewhat lower stability of the hexavalent state of selenium limits the existence of $HOSeF_5$, whereas $HOTeF_5$ has none of these weaknesses and thus decomposes only at very high temperatures, and even then in uncharacteristic fashion.

These thermal stabilities also indicate, for example, the range of application of the ligands OSF_5, $OSeF_5$, and $OTeF_5$. Whereas $OTeF_5$ can be utilized most widely, closely followed in this respect by $OSeF_5$, OSF_5 compounds are only obtainable in a few selected cases.

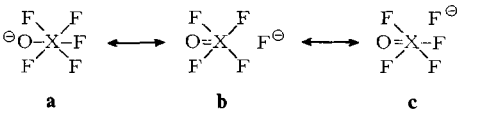
3. The Anions XOF_5^-, the Oxofluorides $O{=}XF_4$, and their Dimers $F_4XO_2XF_4$

It will come as no surprise that the strong acids $HOSeF_5$ and $HOTeF_5$ are easily converted into salts[24–28]. In the case of $HOSeF_5$ a degree of care must be exercised because of the high oxidizing power of the hexavalent selenium; for example, $K^+SeOF_5^-$ can only be obtained from potassium fluoride and not from potassium chloride[26]. Salts of $HOSF_5$ are obtained directly from SOF_4[29, 30]:

$$CsF + SOF_4 \rightleftharpoons Cs^+SOF_5^-$$

However, this reaction only proceeds with CsF, RbF, and KF. Presumably the lattice energy of sodium fluoride is too high, and that of the hypothetical $Na^+SOF_5^-$ too low, as is frequently the case with sodium salts of fluorinated anions.

The salts contain the isolated anion XOF_5^-, as can readily be shown by vibrational spectroscopy. The high frequency of the OX stretching vibration is striking, and a charge distribution



a **b** **c**

can thus be assumed[22, 26, 27, 30]. The low frequency of the axial X—F stretching vibration is particularly noticeable, so that the middle of the three mesomeric formulas **b** must have a high weighting.

The stronger mutual influence between the *trans*-atoms in the octahedral system is readily explained by the current bonding models: predominantly the T_{1u} molecular orbitals (*e.g.* in SF_6)—and thus the *p*-atomic orbitals of the central atom—form the bond. *trans*-Atoms share the same *p*-orbital. This *trans*-effect is also noticeable in the ^{19}F-NMR spectra (see Section 9). Here, mainly the signals of the axial fluorine atoms in XOF_5^- salts are shifted considerably relative to those of the free acids[26].

The alkali metal salts dissolve in acetonitrile without decomposition. $Ag^+TeOF_5^-$ forms ion-pairs in concentrated CH_3CN solution[27]. No exact structural data are as yet

available for these salts. Because of the cubic crystal symmetry (Fm3m) of the $SeOF_5^-$ salts, the anions must be statistically oriented[122]. *In the* $TeOF_5^-$ *salts the fluorine and oxygen atoms are likewise indistinguishable, although the crystal symmetry is rhombohedral in these cases*[28].

Due to the charge distribution in the anions, the oxofluorides $O{=}XF_4$ appear to be structurally preformed in the salts. In the case of sulfur there is a true equilibrium[29]. However, the oxofluorides cannot be released from the potassium, rubidium, and cesium salts of $SeOF_5^-$ and $TeOF_5^-$. This can only be achieved with $Na^+SeOF_5^-$ and $Li^+TeOF_5^-$, because of their lower lattice energies[31-33].

$$2\,K^+SeOF_5^- \xrightarrow[10^{-2}\ mbar]{400\ ^\circ C} 2\,KF + SeO_2F_2 + SeF_6$$

$$Na^+SeOF_5^- \xrightarrow[10^{-2}\ mbar]{150\ ^\circ C} NaF + SeOF_4$$

$$2\,Na^+TeOF_5^- \xrightarrow[10^{-2}\ mbar]{300\ ^\circ C} cis\text{-}Na_2TeO_2F_4 + TeF_6$$

$$2\,Li^+TeOF_5^- \xrightarrow[10^{-2}\ mbar]{130\ ^\circ C} 2\,LiF + (TeOF_4)_2$$

The salts of the lighter alkali metals have to be made by a more complicated method, *e.g.*[33]:

$$(CH_3)_3Si{-}OSeF_5 + Na^+OSi(CH_3)_3^- \rightarrow (CH_3)_3Si{-}O{-}Si(CH_3)_3 + Na^+SeOF_5^-$$

$SeOF_4$ has a similar structure to SOF_4, namely trigonal bipyramidal with the doubly bonded oxygen in the equatorial plane. Above $-100\,^\circ C$ it dimerizes spontaneously to $F_4SeO_2SeF_4$ and thus eludes the unfavorable coordination number 5[33,34]. Apparently the equilibrium

$$F_4SeO_2SeF_4 \rightleftharpoons 2\,SeOF_4$$

only occurs at higher temperatures[35]. Monomeric $TeOF_4$ is not obtained at all, but appears always as the dimeric $F_4TeO_2TeF_4$[32,33] or the polymeric $(TeOF_4)_n$[36,37].

The dimer $F_4TeO_2TeF_4$ is, moreover, formed in virtually quantitative yield from $B(OTeF_5)_3$ by vacuum pyrolysis[38]. The structure of the dimers has been closely examined by various methods[33,38,39]. A striking feature is the short distance between the chalcogen atoms, although no bonding between them can be assumed (see Fig. 2).

Whereas SOF_4 serves as the direct or indirect starting material for many OSF_5 compounds, $SeOF_4$ and $(TeOF_4)_2$ have not been studied under this aspect. Virtually all the $OSeF_5$ and $OTeF_5$ compounds are prepared directly or indirectly from $HOSeF_5$ and $HOTeF_5$.

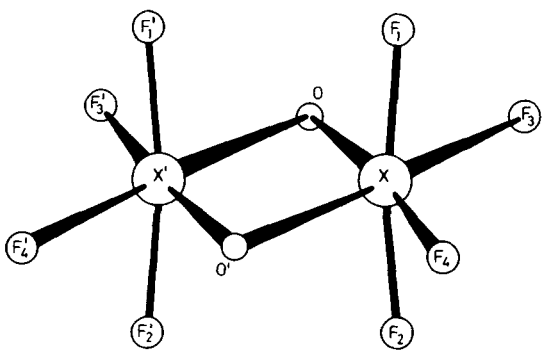


Fig. 2. Molecular model of $(SeOF_4)_2$ and $(TeOF_4)_2$ based on electron diffraction measurements. *In spite of the close proximity of the chalcogen atoms* (267 and 293 ppm) bonding interaction between them is not presumed (from [38]).

4. The Oxides $F_5X{-}O{-}XF_5$, the Peroxides $F_5XO{-}OXF_5$, and the Trioxide $F_5SO{-}O{-}OSF_5$

The oxides $F_5X{-}O{-}XF_5$ can be regarded as the anhydrides of the acids $HOXF_5$. But no reaction is known in which mutual conversion takes place in a manner even approaching the smoothness that the name "anhydride" suggests. According to another tradition, monodentate electronegative (see Section 5) ligands are named pseudohalides, and the peroxides $F_5XO{-}OXF_5$ would accordingly be the corresponding pseudohalogens. This name, too, has only formal significance. However, the two types of compounds have a structural significance in their own right. The oxides $F_5X{-}O{-}XF_5$ are, moreover, the initial members of a series of compounds, see below. Lastly, $F_5S{-}O{-}SF_5$, $F_5SO{-}OSF_5$, and $F_5SeO{-}OSeF_5$ were among the first compounds to have OXF_5 groups at all (see Section 1).

These compounds can be prepared in various ways:

$$SF_4 + SF_5OF \xrightarrow{h\nu} F_5S{-}O{-}SF_5\ [40,41]$$

$$SF_4 + OF_2 \xrightarrow{h\nu} F_5S{-}O{-}SF_5\ [42]$$

$$SF_5Cl + O_2 \xrightarrow{h\nu} F_5S{-}O{-}SF_5\ [43]$$

$$XO_2 + F_2/N_2 \longrightarrow F_5X{-}O{-}XF_5 \quad X = S\ [44],\ Se\ [45],\ Te\ [46]$$

$$Xe(OSeF_5)_2 \xrightarrow{>100\ ^\circ C} F_5Se{-}O{-}SeF_5\ [47]$$

$$SF_4 + SeF_5OF \longrightarrow F_5S{-}O{-}SeF_5\ [48]$$

$$SO_2(OTeF_5)_2 + K^+TeOF_5^- \longrightarrow F_5Te{-}O{-}TeF_5\ [6]$$

The oxides $F_5X{-}O{-}XF_5$ almost achieve the kinetic stability of the corresponding hexafluorides.

Little is known about the physiological action of $F_5S{-}O{-}SF_5$[49]: this seems of significance because $F_5S{-}SF_5$ is extremely toxic.

The structures of these fluorooxides were derived from electron diffraction measurements[42,50], since single crystal data have not yet been obtained because of the low melting points of the material. The bond angle at the oxygen ($140-145\,^\circ$) is relatively large, probably because of the repulsion between the fluorine atoms. The eclipsed arrangement of the fluorines, which contributes to the repulsion, has been interpreted in terms of a $(pd)_\pi$ bonding model[42,50].

These oxide fluorides are only the simplest members of a series, such as *e.g.* *cis*-$F_5SO{-}SF_4{-}OSF_5$[40,51], *cis*- and *trans*-$F_5TeO{-}TeF_4{-}OTeF_5$[52,53], *cis*- and *trans*-$F_2Te(OTeF_5)_4$[52,55], $FTe(OTeF_5)_5$[52,53], $Te(OTeF_5)_6$[52,53], and $(TeOF_4)_n$[36]. All heavy atoms in these compounds are six coordinated, are linked by oxygen bridges, and the remaining valences are filled by fluorine atoms. So far, $F_5S{-}O{-}SeF_5$ is the only known compound of this type with different chalcogen atoms[48].

The peroxides $F_5XO—OXF_5$ are, of course, substantially more reactive than the oxides. Interestingly, a few clean synthetic methods are available for their preparation: small quantities of F_5SOOSF_5 and $F_5SeOOSeF_5$ were originally prepared by fluorinating SO_2 and SeO_2, respectively.

$$2\,ClOXF_5 \xrightarrow{h\nu} Cl_2 + F_5XO—OXF_5 \quad X = S, Se, Te \;[56]$$

$$Xe(OXF_5)_2 \xrightarrow{h\nu} Xe + F_5X—O—O—XF_5 \quad X = Se, Te \;[17]$$

The structures of the peroxides have not been as closely investigated as those of the oxides[57]. One striking feature is that the OOX-angle is much smaller (102–110°) compared to the XOX angles in the compounds $F_5X—O—XF_5$ (140–145°). The peroxide bond can be regarded as unusually strong by virtue of the electron attraction of the XF_5 groups, the strength increasing in the sequence S < Se < Te, as indicated by the position of the peroxide stretching vibrations in the Raman spectra[22,58]. Despite this, in a few cases the peroxides act as transfer reagents for OXF_5 groups:

$$F_5SO—OSF_5 + SO_2 \longrightarrow F_5SO—SO_2—OSF_5 \;[51,59]$$

$$F_5SO—OSF_5 + SO_2 \xrightarrow{h\nu} F_5SO—SO_2F \;[51,60]$$

$$F_5SO—OSF_5 + C_6H_6 \longrightarrow C_6H_5—OSF_5 + SOF_4 + HF \;[61]$$

$$F_5SO—OSF_5 + CF_3O—OCF_3 \longrightarrow 2\,CF_3O—OSF_5 \;[51]$$

$$F_5SO—OSF_5 + FSO_2O—OSO_2F \longrightarrow 2\,FSO_2O—OSF_5 \;[51]$$

$$F_5SeO—OSeF_5 + F_2 \longrightarrow 2\,FOSeF_5 \;[3]$$

$$F_5SeO—OSeF_5 + FSO_2O—OSO_2F \longrightarrow 2\,FSO_2—OSeF_5 + O_2 \;[45]$$

There is little doubt that the majority of these reactions require radical cleavage of the peroxide bond, many take place upon UV irradiation. The ESR signals of the radicals $\cdot OSeF_5$ and $\cdot OTeF_5$ have been thoroughly analyzed[17].

$F_5SO—SF_4—O—OSF_5$ and $F_5SO—SF_4—O—O—SF_4—OSF_5$ can even be observed in the reaction of $FOSF_5$ with SF_4 in presence of ogygen[40].

The potential of the SF_5 group to stabilize unusual bonding is demonstrated by the preparation of the trioxide $F_5SO—O—OSF_5$, which can be obtained from SF_5OOH and F_2[62] or from SF_5Cl and O_2[63]. Kinetic studies of $F_5SO—O—OSF_5$ have led to an optimization of the preparative conditions[63–67].

The synthesis of the peroxoacid SF_5OOH and its halogen derivatives is highly unconventional:

$$ClOSF_5 + FCO—O—O—COF \xrightarrow{h\nu} FCO—O—OSF_5 \;[62]$$

$$FCO—O—OSF_5 + H_2O \longrightarrow HF + CO_2 + HOOSF_5 \;[63,68]$$

$$HOOSF_5 + ClF \longrightarrow ClOOSF_5 \;[62]$$

$$HOOSF_5 + F_2 \longrightarrow FOOSF_5 \;[62]$$

The last-mentioned compounds are thermally relatively unstable, and represent virtually unique systems. Only the analogues with CF_3 in place of SF_5 exist. Clearly SF_5OOCl and SF_5OOF are highly reactive compounds, which can undergo numerous reactions with retention of the SF_5OO group[68–70].

5. Electronegativity of the Ligands OSF_5, $OSeF_5$, and $OTeF_5$; Stabilities of Their Compounds

Recently the extraordinary stability of the xenon derivatives (see Section 7) has raised the question of the group electronegativity. However, electronegativity is an ambiguous concept, especially if it is applied to a group.

Several possibilities have been proposed for the determination of group electronegativity: the chemical shift of the ^1H-NMR of the methyl protons of $CH_3—OSeF_5$ relative to those of CH_3F, CH_3Cl, CH_3Br, and CH_3I[71], the difference between the chemical shifts of the methyl and methylene protons in $C_2H_5—OTeF_5$[72], the preference for equatorial positions in the substitution of IF_5 in the compounds $IF_x(OTeF_5)_{5-x}$ and $IF_x(OSeF_5)_{5-x}$[73,74], Mössbauer data, and ^{125}Te- and ^{129}Xe-NMR resonance measurements[75]. In all cases the electronegativity is found to be very high for OXF_5, and with two particular methods actually higher than that of fluorine[71,73,74]. It is quite possible that the accumulation of five fluorine atoms at the chalcogen atom produces an extreme electron deficiency there, extending as far as the oxygen and beyond. The electronegativity of this oxygen atom would then exceed that of the fluorine atom, because fluorine, despite its electron attraction is able to restore electron density *via* π bonds. This seems to be much less possible with oxygen in OXF_5 compounds. It is also conspicuous that the Lewis acidity of $B(OTeF_5)_3$ is greater than that of BF_3 or of $B(OR)_3$, but comparable with that of BCl_3[36].

It may well be that the OXF_5 groups are more electronegative than fluorine. However, the stability of corresponding fluorine compounds is unsurpassed (see Section 7):

$$XeF_4 \xrightarrow{300-600\,^\circ C} XeF_2 + F_2$$

$$Xe(OTeF_5)_4 \xrightarrow{72\,^\circ C} Xe(OTeF_5)_2 + F_5TeO—OTeF_5$$

To a first approximation it can be assumed that the Xe—F and Xe—O bond strengths in XeF_4, XeF_2, $Xe(OTeF_5)_4$, and $Xe(OTeF_5)_2$ are similar. The differences in stability thus result from the fact that the peroxide $F_5TeO—OTeF_5$ is formed much more readily than F_2. In fact, the peroxide bond is extremely strong (see Section 4).

OXF_5 compounds can undergo various decomposition reactions. Loss of the whole ligand with peroxide formation always takes place when the bond between the central atom Y and the ligand is weak. Here the tellurium compounds are slightly more stable than the others:

$$Y(OXF_5)_2 \rightarrow Y + F_5XO—OXF_5$$
Stability $OTeF_5 > OSeF_5 > OSF_5$

$$Y(OXF_5) \rightarrow YF + O{=}XF_4,\ 1/2(OXF_4)_2 \text{ or } 1/n(OXF_4)_n$$
Stability $OTeF_5 > OSeF_5 > OSF_5$

$Y(OXF_5)_2 \rightarrow Y{=}O + F_5X{-}O{-}XF_5$

$YF(OXF_5) \rightarrow Y{=}O + XF_6$

Stability $OTeF_5 > OSeF_5 > OSF_5$ (?)

$Y(OXF_5) \rightarrow YXF_5 + 1/2\,O_2$

Stability $OSF_5 > OSeF_5 > OTeF_5$

The elimination of $O{=}XF_4$, leaving one fluorine behind is encountered particularly with coordinatively unsaturated or very electropositive central atoms: $B(OTeF_5)_3$, $Ti(OSeF_5)_4$, $K^+SOF_5^-$. This decomposition is the weak point of many OSF_5 compounds, because $O{=}SF_4$ is particularly readily eliminated.

Coordinatively highly saturated compounds, such as $I(OTeF_5)_5$, and the hypothetical compounds $Os(OTeF_5)_6$, $Re(OTeF_5)_7$, and others, eliminate TeF_6 and $F_5TeOTeF_5$ with the formation of oxo derivatives such as $O{=}I(OTeF_5)_3$, $O{=}Os(OTeF_5)_4$, and $O_2Re(OTeF_5)_3$, respectively. The differences in stability between $OTeF_5$, $OSeF_5$, and OSF_5 derivatives are not known exactly because of the almost complete absence of the OSF_5 and the $OSeF_5$ compounds.

The elimination of oxygen is rare and so far only found in $F{-}OXF_5$, $F_5XO{-}OXF_5$, and $F_5SO{-}O{-}OSF_5$:

$F{-}OXF_5 \rightarrow XF_6 + 1/2\,O_2$

$F_5XO{-}OXF_5 \rightarrow F_5X{-}O{-}XF_5 + 1/2\,O_2$

Stability $OSF_5 > OSeF_5 > OTeF_5$ in both cases

$F_5SO{-}O{-}OSF_5 \rightarrow F_5SO{-}OSF_5 + 1/2\,O_2$

However, in these cases the OSF_5 ligand is the most stable, and $F_5SeO{-}O{-}OSeF_5$ and $F_5TeO{-}O{-}OTeF_5$ remain as yet unknown.

But in general, the $OTeF_5$ compounds usually prove to be the most stable, followed by the $OSeF_5$ and then, at some distance, by the OSF_5 compounds.

On the other hand, work with volatile $OTeF_5$ compounds is highly unpleasant from the physiological point of view. The body counters the incorporation of tellurium by expiring $Te(CH_3)_2$, which smells very strongly of garlic[76]. This process can persist for months. There is apparently a natural metabolism for incorporated selenium, because expiration of $Se(CH_3)_2$ subsides after only a few days. No problems of this type are encountered with OSF_5 compounds.

6. Main-Group Derivatives

Apart from the alkali metal salts which contain the ion XOF_5^-, an abundance of OXF_5 compounds are known; these are listed completely in Table 1. Nearly all these compounds can be formally produced by the replacement of F by OXF_5; practically all of these compounds are extremely volatile and some are astonishingly resistant to hydrolysis.

All this indicates that the OXF_5 groups cause very little intermolecular interaction. Whereas the small fluorine atom has a notorious tendency to form fluorine bridges (only in highly fluorinated compounds is this not observed), OXF_5 ligands virtually never form bridges. In particular, because of their spherical form and very weak intermolecular forces, compounds with several OXF_5 groups have a pronounced tendency to sublime, *i.e.* they have a rather high melting point together with a high volatility. This behavior culminates in the almost spherical compounds $HOXF_5$, $C(OSeF_5)_4$, $Si(OTeF_5)_4$, $Te(OTeF_5)_6$, $W(OTeF_5)_6$, and $U(OTeF_5)_6$. Thus, $Te(OTeF_5)_6$ already sublimes at 110 °C and melts at 242 °C, and is a pure molecular compound with a molecular weight of 1567[52,53]!

The only two main-group compounds in which OXF_5 groups may possibly form bridges are $Br(OSeF_5)_3$[47] (m.p. = 19 °C) and $I(OTeF_5)_3$[83] (m.p. = 44 °C). Both are highly viscous liquids above their melting points. In the fluorine analogues, bridging has been established for BrF_3 and is presumed for IF_3.

The methods of preparation of OXF_5 compounds are many. Although the acids $HOXF_5$ are certainly not always the most elegant starting materials, a few synthesic examples involving them may nevertheless be cited.

$HOTeF_5 + KCl \rightarrow HCl + K^+TeOF_5^-$ [24, 77]

$HOSeF_5 + KF \rightarrow HF + K^+SeOF_5^-$ [26]

$3\,HOTeF_5 + BCl_3 \rightarrow 3\,HCl + B(OTeF_5)_3$ [36, 37]

$2\,HOSeF_5 + XeF_2 \rightarrow 2\,HF + Xe(OSeF_5)_2$ [101]

$HOTeF_5 + SO_3 \rightarrow HOSO_2{-}OTeF_5 \xrightarrow{FSO_3H} FSO_2{-}OTeF_5$ [6, 10]

$2\,HOSeF_5 + 4\,SO_3 \rightarrow FSO_2{-}O{-}SO_2{-}OSeF_5 + 2\,HSO_3F + SeO_2F_2$ [81]

$HOTeF_5 + Sn(CH_3)_4 \rightarrow (CH_3)_3Sn{-}OTeF_5 + CH_4$ [82]

The high oxidation potential of hexavalent selenium restricts the usefulness of $HOSeF_5$ because it decomposes chlorides oxidatively, and thus only fluorides and oxides can be used. $HOTeF_5$, which has a lower tendency to oxidize, is decidedly better. This difficulty can partly be avoided by using $Hg(OSeF_5)_2$, which is itself prepared from HgF_2 and $HOSeF_5$ (see Section 7). This reacts gently with chlorides in inert solvents:

$O{=}SeCl_2 + Hg(OSeF_5)_2 \rightarrow HgCl_2 + O{=}Se(OSeF_5)_2$ [83]

$2\,AsCl_3 + 3\,Hg(OSeF_5)_2 \rightarrow 3\,HgCl_2 + 2\,As(OSeF_5)_3$ [86]

$CCl_4 + 2\,Hg(OSeF_5)_2 \rightarrow 2\,HgCl_2 + C(OSeF_5)_4$ [71]

The method is rather complicated because of the difficulties involved in the preparation of $Hg(OSeF_5)_2$ and $Hg(OTeF_5)_2$.

$OTeF_5$ compounds can be prepared particularly elegantly using the boron compound $B(OTeF_5)_3$[36,37]. Unfortunately, the analogues of selenium and sulfur are not available. Here are a few of the many possible examples:

$AsF_3 + B(OTeF_5)_3 \rightarrow BF_3 + As(OTeF_5)_3$ [82]

$3\,XeF_4 + 4\,B(OTeF_5)_3 \rightarrow 4\,BF_3 + 3\,Xe(OTeF_5)_4$ [99, 110]

$3\,SbF_5 + 2\,B(OTeF_5)_2 \rightarrow 2\,BF_3 + 3\,F_3Sb(OTeF_5)_2$ [90]

The advantage of this method is that the readily volatile and noncorrosive BF_3 can be easily removed from the reaction mixture. The use of the silyl compound can replace the unknown boron compound in the case of $OSeF_5$ to a limited extent.

Table 1. OSF_5, $OSeF_5$ and $OTeF_5$ compounds of the main-group elements.

Group 1 [a]	X

$O=Xe(OTeF_5)_4$ [75, 98, 99]	
$O=XeF_x(OTeF_5)_{4-x}$ [98, 99]	

[a] The salts $NH_4^+OSeF_5^-$ [26] and $C_5H_5NH^+OTeF_5^-$ [24, 77] can be included here.

$$[(CH_3)_3Si]_3N + 4HOSeF_5 \rightarrow NH_4^+SeOF_5^- + 3(CH_3)_3Si—OSeF_5$$ [33]

$$(CH_3)_3SiCl + HOTeF_5 \rightarrow HCl + (CH_3)_3Si—OTeF_5$$ [82]

$$(CH_3)_3Si—OSeF_5 + Na^+OSi(CH_3)_3^- \rightarrow (CH_3)_3Si—O—Si(CH_3)_3 + Na^+SeOF_5^-$$ [33]

To substitute chlorides by $OSeF_5$ one may also start from $ClOSeF_5$:

$$ICl_3 + 3ClOSeF_5 \rightarrow I(OSeF_5)_3 + 3Cl_2$$ [83]

Since HCl is not produced, there is no danger of reducing the hexavalent selenium.

On the other hand, $FOSF_5$ is one of the most important starting compounds for the introduction of the OSF_5 group, usually in the absence of a better alternative. $FOSeF_5$ can sometimes be used for the same purpose:

$$3FOSeF_5 + 2Br_2 \rightarrow BrF_3 + 3BrOSeF_5$$ [47]

$$FOSeF_5 + SF_4 \rightarrow F_5S—O—SeF_5$$ [48]

$$FOSF_5 + CH_2=CH_2 \rightarrow FCH_2—CH_2—OSF_5$$ [41]

$$FOSF_5 + CH_2=CF_2 \rightarrow CF_3—CH_2—OSF_5$$ [79]

The peroxide $F_5SO—OSF_5$ also serves as a source of the OSF_5 group:

$$2F_5SO—OSF_5 + 2SO_2 \rightarrow FSO_2—O—OSF_5 + SO_2(OSF_5)_2 + SOF_4$$ [51, 39]

$$F_5SO—OSF_5 + C_6H_6 \rightarrow C_6H_5—OSF_5 + SOF_4 + HF$$ [61]

Otherwise the incorporation of the OSF_5 group presents the greatest difficulties. SF_5Cl is actually often used as a starting material:

$$2SF_5Cl + O_2 \rightarrow Cl_2 + F_5SO—OSF_5$$ [33]

The synthesis of highly sensitive compounds containing the $OOSF_5$ group deserves particular consideration (see Section 4).

Most of the above-mentioned syntheses are simple substitution reactions. However, the reactions with $FOXF_5$ are also oxidations. Also the xenon derivatives can be used to introduce the OXF_5 group oxidatively:

$$TeF_4 + Xe(OTeF_5)_2 \rightarrow cis,trans\text{-}F_4Te(OTeF_5)_2 + Xe$$ [52, 53]

$$I(OTeF_5)_3 + Xe(OTeF_5)_2 \rightarrow I(OTeF_5)_5 + Xe$$ [73, 74]

The derivatives of the OXF_5 compounds often manifest the typical properties of the elements in very pronounced

form, such as the Lewis acidity of $B(OTeF_5)_3$ and the kinetic stability of $C(OSeF_5)_4$. Solid NO_2—$OSeF_5$ contains ions ($NO_2^+SeOF_5^-$), while in the gaseous state it is covalent (NO_2—$OSeF_5$). Besides CF_3O—O—OCF_3, F_5SO—O—OSF_5 is the only known trioxide. The valency of the stable halogen derivatives increases in a well known manner:

$$FOSeF_5 \triangleq ClOSeF_5 < Br(OSeF_5)_3 < I(OTeF_5)_5$$

7. Noble Gas Derivatives

The special position of the OXF_5 ligands is most striking in compounds of the noble gases. The corresponding compounds are the most stable covalent derivatives of XeF_2, and so far the only covalent derivatives of XeF_4, $XeOF_4$, and XeF_6.

The stable bivalent derivatives can be synthesized in several ways:

$$XeF_2 + HOXF_5 \rightarrow 2HF + Xe(OXF_5)_2 \quad X = Se, Te \quad [17, 100-102]$$

$$3XeF_2 + 2B(OTeF_5)_3 \rightarrow 2BF_3 + 3Xe(OTeF_5)_2 \quad [111]$$

$$3XeF_2 + 2SeOF_2 \rightarrow 2Xe + Xe(OSeF_5)_2 \quad [112]$$

The synthesis of $Xe(OSeF_5)_2$ from $SeOF_2$ and XeF_2 is of particular interest, since the difficult preparation of $HOSeF_5$ can be avoided in this way.

$Xe(OSeF_5)_2$ and $Xe(OTeF_5)_2$ are readily sublimable pale yellow solids stable up to 100 °C. The semisubstituted derivatives are yellow liquids and are formed in an equilibrium reaction.

$$XeF_2 + Xe(OXF_5)_2 \rightleftharpoons 2FXe—OXF_5 \quad X = Se, Te \quad [101, 104-106]$$

$$Xe(OSeF_5)_2 + Xe(OTeF_5)_2 \rightleftharpoons 2F_5SeO—Xe—OTeF_5 \quad [17, 104]$$

It is not surprising that it has also been possible to detect F_5SeO—Xe—$OTeF_5$ by ^{129}Xe-NMR spectroscopy. With the same method it has been shown that Lewis acids remove the fluorine atom and not the $OTeF_5$ group from $FXeOTeF_5$[109]:

$$FXe—OTeF_5 + AsF_5 \rightarrow XeOTeF_5^+AsF_6^-$$

The compounds of tetra- and hexavalent xenon are unique. They were prepared from XeF_4, XeF_6, and $XeOF_4$, in each case with $B(OTeF_5)_3$, and provide insight into the structural behavior of higher valent xenon.

$$3XeF_4 + 4B(OTeF_5)_3 \rightarrow 4BF_3 + 3Xe(OTeF_5)_4 \quad [99, 110]$$

$$XeF_6 + 2B(OTeF_5)_3 \rightarrow 2BF_3 + Xe(OTeF_5)_6 \quad [98, 99]$$

$$3XeOF_4 + 4B(OTeF_5)_3 \rightarrow 4BF_3 + 3O{=}Xe(OTeF_5)_4 \quad [98, 99]$$

Structurally the red, crystalline $Xe(OTeF_5)_6$ is a derivative of the monomeric, gaseous, lemon-yellow XeF_6 and not of the tetrameric or hexameric solid XeF_6, because the $OTeF_5$ ligands show little tendency toward bridge formation.

Since $Xe(OTeF_5)_6$ is isomorphous with rhombohedral $Te(OTeF_5)_6$, it is even possible to comment on the distortion of the octahedral environment of the xenon atom: this must be a C_{3v} or D_{3d} distortion, as postulated for gaseous XeF_6[99].

The colorless $O{=}Xe(OTeF_5)_4$ surpasses the yellow $Xe(OTeF_5)_4$ *in its thermal stability, whereas* XeF_4 *is more* stable than $XeOF_4$. These phenomena still require explanation.

All the intermediate members, $O{=}XeF_x(OTeF_5)_{4-x}$, between $O{=}XeF_4$ and $O{=}Xe(OTeF_5)_4$ can be detected by ^{129}Xe spectroscopy. This has not yet been possible for the systems XeF_6—$Xe(OTeF_5)_6$ and XeF_4—$Xe(OTeF_5)_4$.

$OTeF_5$ would also be the best candidate for a krypton-oxygen bond. Indeed, even at −196 °C cocondensation of KrF_2 and $B(OTeF_5)_3$ leads to an immediate reaction, but only Kr, BF_3, and F_5TeO—$OTeF_5$ are found[99]. Nevertheless, the clean occurrence of F_5TeO—$OTeF_5$ permits the conclusion that a krypton compound is formed, if only as an intermediate. An uncontrolled fluorination by the extremely aggressive krypton fluoride should yield at least a little TeF_6.

8. Transition-Group Derivatives

Table 2 lists all the known OXF_5 derivatives of the transition elements. Strikingly, no OSF_5 derivatives are known. Evidently the abstraction of fluoride from the ligand with formation of SOF_4 occurs too easy. The same decomposition reaction is also observed for many $OSeF_5$ compounds, for example in the systems $F_xTi(OSeF_5)_{4-x}$ and $F_xW(OSeF_5)_{6-x}$[113]. It thus happens that most of the derivatives originate from the $OTeF_5$ group. The ligand-transfer reagent here is nearly always $B(OTeF_5)_3$.

The elements of the first transition period have a tendency to adopt a coordination number of 4, even when fluorides such as VF_5 and CrF_5 are directly substituted.

$$3VF_5 + 4B(OTeF_5)_3 \rightarrow 3O{=}V(OTeF_5)_3 + 4BF_3 + 3TeF_6$$

$Ti(OTeF_5)_4$ is a rare example of a tetrahedral oxygen coordination to titanium. However, an increase in coordination is observed with $Cs_2Ti(OTeF_5)_6$[114]. The larger central atoms tungsten and uranium permit relatively simple formation of the heavy molecules $W(OTeF_5)_6$ and $U(OTeF_5)_6$, although in the case of the tungsten compound WF_5 must be used as the starting material[115, 118, 119].

Table 2. $OSeF_5$- and $OTeF_5$ compounds of transition metals.

Group 1+2	4	5	6	7+8
$Ag^+OTeF_5^-$ [27, 72]	$Ti(OTeF_5)_4$ [113, 114]	$O{=}V(OSeF_5)_3$ [113, 115]	$O_2Cr(OSeF_5)_2$ [113, 115]	O_3Re—$OTeF_5$ [120]
$Au(OTeF_5)_3$ [120]	$Cl_xTi(OTeF_5)_{4-x}$ [114]	$O{=}V(OTeF_5)_3$ [113, 115]	$O_2Cr(OTeF_5)_2$ [113, 115]	$O_2Re(OTeF_5)_3$ [115]
$Hg(OSeF_5)_2$ [17, 26, 77]	$Cs_2Ti(OTeF_5)_6$ [114]	$Nb(OTeF_5)_5$ [115]	$O{=}Mo(OTeF_5)_4$ [115]	$O{=}Os(OTeF_5)_4$ [115]
$Hg(OTeF_5)_2$ [17, 26, 77]		$Ta(OTeF_5)_5$ [115]	$O{=}MoF_3$—$OTeF_5$ [116]	
CH_3Hg—$OTeF_5$ [77]			$W(OTeF_5)_6$ [115]	$U(OTeF_5)_6$ [118, 119]
			$F_xW(OTeF_5)_{6-x}$ [115-117]	$F_xU(OTeF_5)_{6-x}$ [118]
			$ClW(OTeF_5)_5$ [113]	

$WF_5 + B(OTeF_5)_4 \rightarrow W(OTeF_5)_6 + "W(OTeF_5)_4"$
$WF_6 + B(OTeF_5)_3 \rightarrow F_xW(OTeF_5)_{6-x}$

Apparently the intermediate $W(OTeF_5)_5$ disproportionates readily, as is also known for WF_5, whereas WF_6 only undergoes substitution as far as $FW(OTeF_5)_5$[115-117].

It is surprising that molybdenum prefers the coordination number 5; $O{=}Mo(OTeF_5)_4$ is the end product detected[115]. It shares this property with rhenium, which gives $O_2Re(OTeF_5)_3$ as the only stable substitution product, a yellow liquid with still unknown geometry at the rhenium[115]. $O_2Re(OTeF_5)_3$ and $O_3Re{-}OTeF_5$ are the only OXF_5 compounds of a heptavalent central atom. Intermediate octavalent osmium(VIII) compounds tend to decompose to OsO_4, whereas heptavalent and hexavalent osmium fluorides and oxide fluorides all yield $O{=}Os(OTeF_5)_4$, a crystalline product that occurs in a wide variety of colors (black, amethyst, blue, green)[115]. Structure analysis of a uniformly green crystal revealed the composition $O{=}Os(OTeF_5)_4 \cdot 3\,TeF_4$ (see Section 12). In the systems $F_xOs^{VI}(OTeF_5)_y$ and $F_xOs^{VII}(OTeF_5)_y$, red and green intermediates are also found, but could not be isolated in pure form.

As is also observed in other aspects of the chemistry of these elements, the series of the highest-valence compounds is suddenly interrupted at iridium. Only the relatively "normal" derivatives of silver(I), mercury(II), and gold(III) have been found so far. $Au(OTeF_5)_3$ seems to be one of the rare cases with trigonal planar coordination of oxygen at gold: the X-ray structure analysis has not yet been performed. $Hg(OSeF_5)_2$ and $Hg(OTeF_5)_2$ apparently dissolve as molecules in nonpolar solvents but as ions in polar solvents, as has been demonstrated by ^{19}F-NMR spectroscopy[28,27] (see Section 9).

Of the actinoids only $U(OTeF_5)_6$ and its derivatives $F_xU(OTeF_5)_{6-x}$ are known (cf. Fig. 7).

9. NMR Spectroscopy

Of the routine analytical procedures ^{19}F-NMR spectroscopy of the OXF_5 compounds is the most important, since the ^{19}F nucleus has a high sensitivity, 100% natural abundance, and a wide chemical shift range. The OXF_5 ligands always give rise to AB_4 spectra (Fig. 3), recognized by two strong groups of lines (the B_4 part) and a dispersed and weaker group of lines (the A part). In $OSeF_5$ compounds ^{77}Se satellites with a coupling constant of *ca.* 1100 Hz are always observed as well, and in $OTeF_5$ compounds there are also ^{125}Te satellites (*J ca.* 3600 Hz) and very weak ^{123}Te satellites (*J ca.* 3300 Hz).

The spectra are nearly always highly resolved, *i.e.* all the individual transitions can be identified. Even when there is a very large separation between the A and the B_4 parts, the systems never degenerate into the trivial doublet-quintet pattern of a simple AB_4 spectrum.

The coupling constant $J(AB_4)$ varies only within narrow limits, *ca.* 150–160 Hz for OSF_5[121-124], *ca.* 215–230 Hz for $OSeF_5$[125], and *ca.* 175–195 Hz for $OTeF_5$[72,125,126]. Using a simple procedure it can be derived from any high-resolution spectrum[125]. Computer simulation is not really necessary, even though is does provide numerically somewhat more exact values. The signals of OSF_5 and $OSeF_5$ are always found at lower fields relative to $CFCl_3$. Those of homologous compounds (*e.g.* $ClOSF_5$, $ClOSeF_5$) are similar enough to be confused with one another if there were not the ^{77}Se satellites in the selenium compounds. The signals of the $OTeF_5$ groups are always found at higher field relative to $CFCl_3$.

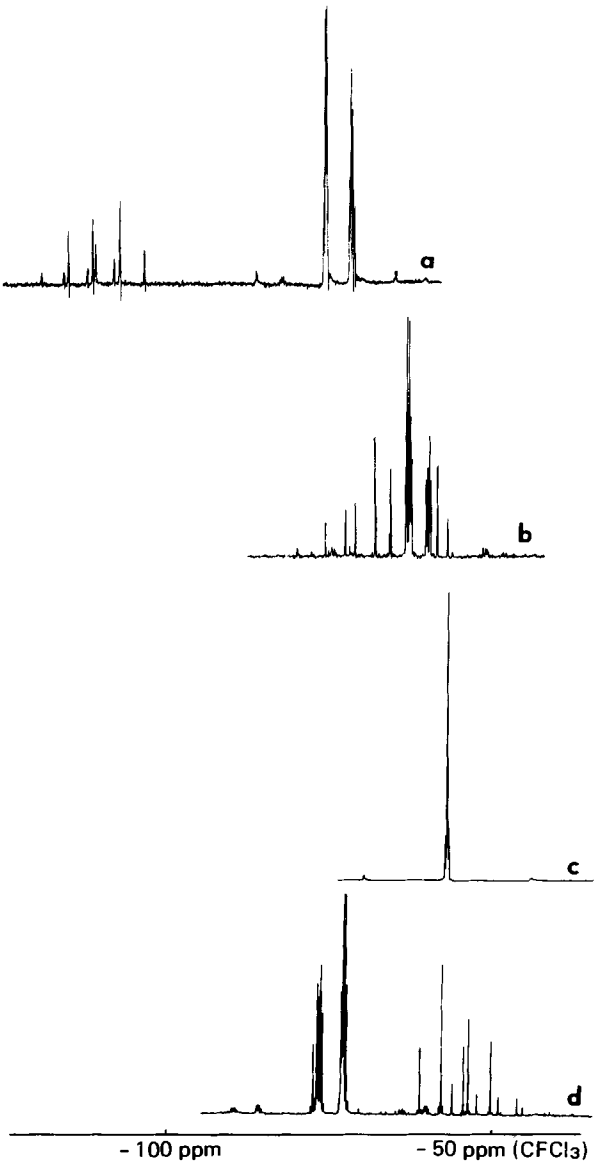

Fig. 3. Typical AB_4 spectra of OXF_5 compounds: a) $NO_2^+OSeF_5^-$ (in acetonitrile), A and B_4 parts are well separated; b) $HOSeF_5$ (in $CFCl_3$), a spectrum still easily recognizable as an AB_4 system; c) $F_5SeO{-}OSeF_5$ (pure liquid), the A and B_4 parts practically coincide; d) $CF_3CO{-}OSeF_5$ (pure liquid, C—*F* resonances at $\delta = +76$ have been omitted), part A eventually occurs to the right of part B_4.
The ^{77}Se satellites are clearly visible in all the spectra.

The chemical shift of the equatorial fluorines (B_4 part) of all three groups varies only little on oxygen substitution, whereas that of the axial fluorine atom varies very sensitively (see Fig. 3)[125]. For very simple $Z{-}OXF_5$ compounds the chemical shift of the axial fluorine correlates well with the electronegativity of Z[125]. In these simple derivatives the A part always occurs at lower field than the B_4 part. In more complicated compounds, such as $B(OTeF_5)_3$

and many others, the reverse is often the case. In a few borderline cases [F_5XO—OXF_5, $Br(OSeF_5)_3$, $CrO_2(OSeF_5)_2$, *etc.*] the A and B_4 parts coincide almost exactly (see Fig. 3). The spectrum then degenerates more or less to a single line. Since, however, the coupling constants of ^{77}Se or ^{125}Te to A and B_4 are different, these small satellite subspectra are sometimes more informative than the main spectra.

Coupling to nuclei outside the OXF_5 group is also observed. In such cases the coupling constant to the equatorial fluorine atoms is always much larger than that to the axial fluorine atom, and coupling to the latter is often not observed at all. The profusion of OXF_5 compounds also inspired NMR studies of other nuclei, such as ^{31}P[86], ^{129}Xe[75, 99, 104, 109, 115], and ^{125}Te[16, 75, 109]. Because of the importance of the OXF_5 group in xenon chemistry the development of ^{129}Xe-NMR spectroscopy was closely linked with preparative $OSeF_5$ and $OTeF_5$ chemistry (see Fig. 4).

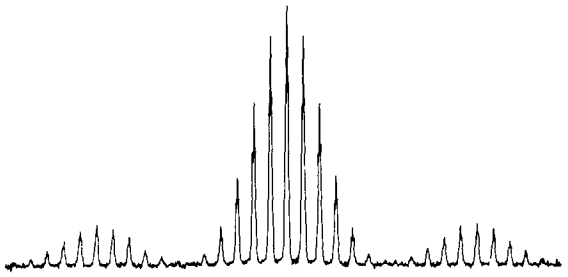

Fig. 4. ^{129}Xe-NMR spectrum of $O{=}Xe(OTeF_5)_4$. The ^{129}Xe nucleus couples with 16 equatorial fluorines, 4 axial fluorines, and 4 tellurium atoms of the isotope ^{125}Te: satellite spectrum (from [99]).

10. Mass Spectroscopy

The mass spectra of these compounds, which are mainly volatile, often reveal the molecular composition. Experimentally, the sample introduction path must be kept short. If, moreover, hydrolysis of the substance can be avoided the effort is rewarded by highly informative mass spectra (see Fig. 5). A weak molecular peak is nearly always observed, whereas loss of an entire OXF_5 group yields an intense fragment.

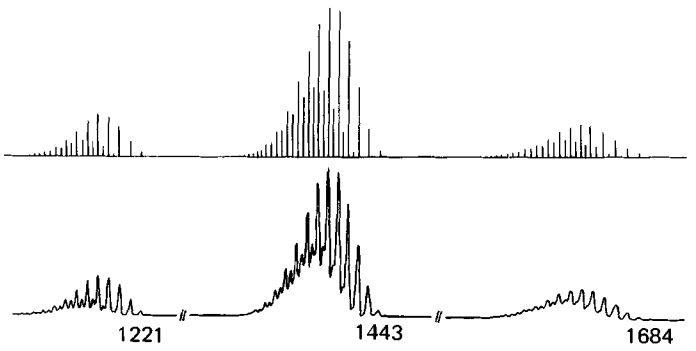

Fig. 5. Mass spectrum of $U(OTeF_5)_6$ (bottom). The section above $m/z = 1200$ shows the ions $FU(OTeF_5)_4^+$ (1221), $U(OTeF_5)_5^+$ (1443), and $U(OTeF_5)_6^+$ (1684). The isotope distribution in species with four, five, and six tellurium atoms extends theoretically over 50—70 mass units and can only be calculated by computer (top) (from [118]).

$O{=}XF_4$ is usually cleaved off next, so that, for example, the fragments $U(OTeF_5)_5^+$ and $FU(OTeF_5)_4^+$ are produced from $U(OTeF_5)_6$[118]. Presumably $ReO_2(OTeF_5)_3$ and $OsO(OTeF_5)_4$ undergo a different fragmentation: in these cases TeF_5-groups are subsequently split off, while Os—O or Re—O bonds are retained; this may perhaps be an indication of the special stability of the OsO and ReO bonds, even under mass-spectroscopic conditions[115].

The isotopic distribution of up to six tellurium atoms and up to four selenium atoms together with the isotopic distribution of the other elements, lead to extremely complicated peak groups, which often are superimposed on each other (see Fig. 5[118]) or refs [113, 116]. The simulation of this isotopic distribution is only possible with the aid of a computer, but it does have considerable informative value. High resolution mass spectroscopy is, however, rather useless, since virtually all the subpeaks originate from a multitude of isotope combinations.

The cumulative mass defect of several heavy atoms makes exact counting of the peaks difficult. The peaks are generally found several tenths of a mass unit too low; moreover, comparison spectra for species with $m/z > 1000$ are not exactly routine.

The mass-spectroscopic examination of nonvolatile compounds provided evidence of volatile decomposition products; thus the existence of the oxofluoride $SeOF_4$ and the nonexistence of $TeOF_4$ under similar conditions were demonstrated for the first time[31-33].

11. Other Analytical Methods

Mass spectra are often able to replace *elemental analysis* to some degree. The latter gets difficult because of the volatility and hydrolytic sensitivity of the substances and because of the difficulty of exactly determining selenium and tellurium in presence of fluorine and other heavy metals.

OXF_5 compounds can be readily detected by *vibrational spectroscopy* if they are neither too aggressive for the IR cell material nor too sensitive to laser light in the recording of Raman spectra, such as *e.g.* $Xe(OTeF_5)_6$. Often the Raman spectra are easier to obtain, because the substances can be sealed *in vacuo* into glass or quartz tubes. The selection of the typical OXF_5 bands on the basis of local C_{4v} symmetry then permits the assignment of less common stretching frequencies such as Xe—O, Br—O, U—O, or Au—O.

12. Crystal Structure Analyses

The molecular structure of the OXF_5 compounds can often be derived from the aforementioned physical methods. However, a few crystal structure analyses have been undertaken, namely for $Xe(OSeF_5)_2$[103], *trans*-$F_2Te(OTeF_5)_4$[54, 55], $Te(OTeF_5)_6$[52, 53], $U(OTeF_5)_6$[119], $O{=}Mo(OTeF_5)_4$[115], and $O{=}Os(OTeF_5)_4 \cdot F^- \cdot TeF_3^+ \cdot 2TeF_4$[115].

Single crystals susceptible to hydrolysis are best prepared by vacuum sublimation, though this process is notorious for the disorder it produces. This problem is enhanced in particular by the spherical shape of the ligands.

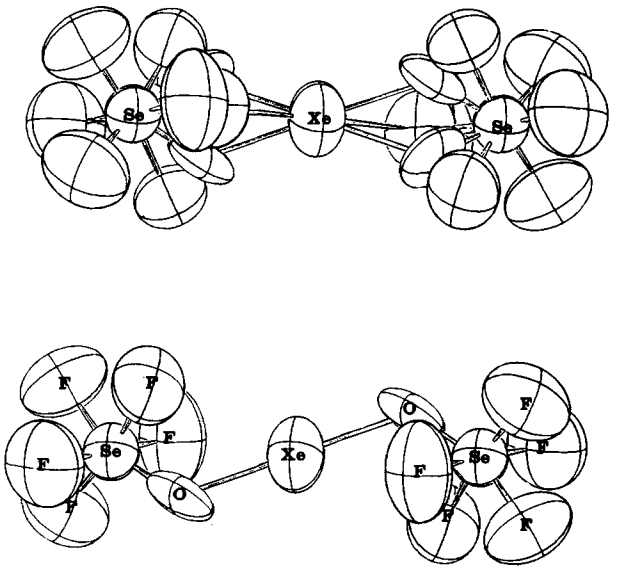

Fig. 6. Crystal structure analysis of $Xe(OSeF_5)_2$. The superimposition of the three molecular orientations, as they occur statistically in the crystal, is shown at the top. Below, one molecular orientation is shown. The assignment of the various fluorine atoms to individual molecular arrangements is arbitrary, but arises from the nearly regular octahedral shape of the $OSeF_5$ part (from [103]).

The disorder is sometimes systematic in nature, as in $Xe(OSeF_5)_2$ (see Fig. 6). Here three molecules are superimposed, but one molecule can be singled out. If the disorder is not so obvious, the whole X-ray analysis often fails, as with the $SeOF_5^-$ salts of the cations K^+, Rb^+, Cs^+, and NH_4^+[22]. The cubic symmetry Fm3m requires a completely disordered arrangement of the anion. In the case of $NO_2^+SeOF_5^-$ (likewise Fm3m) the cation and the anion are disordered[127]. Even in the absence of systematic disorder the peripheral fluorine atoms appear with very large vibrational parameters (see Fig. 7), caused certainly by a combination of molecular vibrations and disorder.

Another problem encountered in crystal structure analysis is the absorption by heavy atoms, which is only alleviated by the application of the usual absorption corrections. Nevertheless, the value of crystal structure analyses

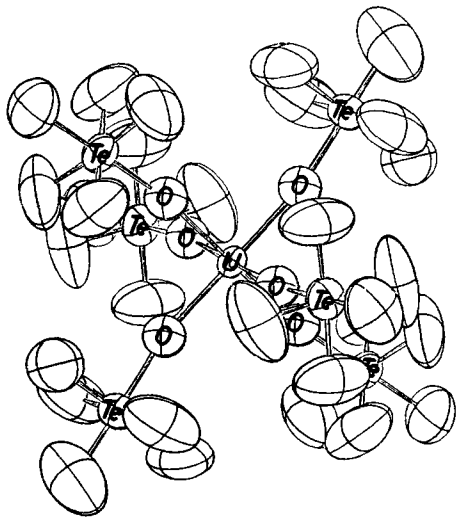

Fig. 7. Crystal structure of $U(OTeF_5)_6$. The peripheral fluorine atoms apparently exhibit large thermal motions, as indicated by the large vibrational ellipsoids. The U—O—Te bridge, with an angle of *ca.* 170°, is almost linear (from [119]).

is undisputed. For example, two precise structure analyses are available for the two modifications of $Te(OTeF_5)_6$[52,53]. Since $Xe(OTeF_5)_6$ has been proven to be isomorphous with the rhombohedral form of $Te(OTeF_5)_6$, valuable conclusions could be drawn about its molecular structure, although only powder diffraction data on $Xe(OTeF_5)_6$ were available[99].

A crystal structure analysis is also available for $U(OTeF_5)_6$ (see Fig. 7). The bond angle U—O—Te (*ca.* 170°) is much larger than the corresponding Te—O—Te angle (*ca.* 139°) in both crystallographic modifications of $Te(OTeF_5)_6$. This difference must reflect the different bonding relationships [(p—f)π bonding?]. Unfortunately, up to now no crystal structure analysis has been reported for $W(OTeF_5)_6$, because the crystals exhibit an almost plastic behavior.

$U(OTeF_5)_6$ and the two modifications of $Te(OTeF_5)_6$ have different crystal symmetries, although the molecular configurations are similar, indeed almost identical (Fig. 8).

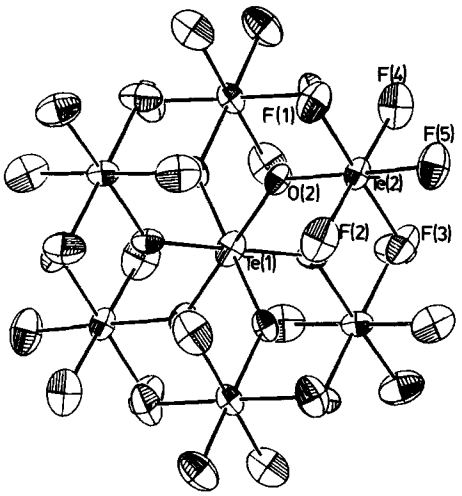

Fig. 8. Crystal structure of $Te(OTeF_5)_6$, rhombohedral modification. The complete enclosure of the core of the molecule by peripheral fluorines determines the stability of this compound to hydrolysis. The Te—O—Te angle (ca. 140°) is strikingly small (cf. Fig. 7) (after [53]).

The packing behavior of these giant spherical molecules is apparently governed by slight deviations from sphericity. All packings can, however, be derived from the hexagonal closest packing of spheres by slight displacements[53].

13. Summary and Outlook

The ligands $OSeF_5$ and $OTeF_5$ represent extremely interesting monovalent ligands which stabilize unusual oxidation states and coordination numbers. The OSF_5 has a limited applicability and can be well compared with the OCF_3 group, as shown by the instability of $HOSF_5$ and $HOCF_3$[128,129] but also by the existence of $SF_5—O—O—O—SF_5$ and $CF_3—O—O—O—CF_3$[130,131].

Hitherto the interest in these ligands has concentrated principally on "binary" compounds of the type $Y(OXF_5)_n$. The particular properties of these ligands have hardly been used for special purposes but it may be expected that, in future, more complicated systems will provide insight into unusual structure relationships. The crystal structure analysis of $O{=}Os(OTeF_5)_4 \cdot F^- \cdot TeF_3^+ \cdot 2\,TeF_4$ may be cited as

an accidental result (Fig. 9). This compound occurs as a by-product in the preparation of $O{=}Os(OTeF_5)_4$ and has been thoroughly studied because of its relatively good crystalline properties[115]. The $O{=}Os(OTeF_5)_4$ molecules are attached like lanterns on a string by F^- bridges to the polymeric $TeF_3^+(TeF_4)_2$ chain.

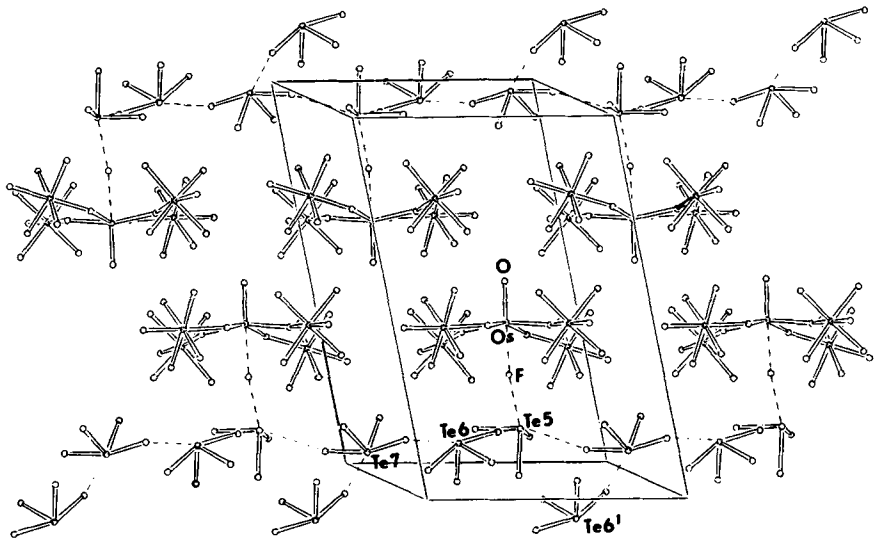

Fig. 9. Crystal structure analysis of $O{=}Os(OTeF_5)_4 \cdot F^- \cdot TeF_3^+ \cdot 2TeF_4$. The compound is formed as a by-product in the preparation of $O{=}Os(OTeF_5)_4$ [115]. The TeF_3^+ and TeF_4 units form a chain, similar to the arrangement in pure TeF_4, but with different bridging geometry [138]. The tetragonal pyramids of $O{=}Os(OTeF_5)_4$ are bonded to this chain by fluoride bridges. The central osmium atom is sheltered by the large $OTeF_5$ ligands, and the single remaining coordination site is occupied by the bridging fluorine atom (from [115]).

The principle of electronegative ligands can be extended to polydentate ligands. Recently, *cis*- and *trans*-$(HO)_2TeF_4$ have been reported[15, 132], and the first derivatives, including a xenon compound, are available. *trans*-$(FO)_2SeF_4$ was described as early as 1970[133], while *sym*-$(HO)_3TeF_3$ could actually function as a tridentate ligand[16].

The replacement of oxygen by nitrogen, as in $H_2N{-}SF_5$[133] and $H_2N{-}TeF_5$[134], opens up new prospects, especially for double-bonded $Y{=}N{-}XF_5$ systems. A bidentate nitrogen ligand occurs in *cis*-$[(CH_3)_3SiNH]_2TeF_4$, although the compound is explosive[136]. Taking the analogy a stage further, we arrive at the recently discovered CH_3SF_5[137]. The selenium and tellurium analogues have still not been synthesized. The promising chemistry of all these compounds is still very much in its early stages.

The author is indebted to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for supporting this work. Bayer AG, Leverkusen, Hoechst AG, Frankfurt-Höchst and Kali-Chemie, Hannover facilitated the investigations by providing special chemicals. Thanks are also due to my coworkers Dr. D. Lentz and Dipl.-Chem. P. Huppmann for painstakingly performaning many of the experiments.

[84] $P(OTeF_5)_3$ is formed from PCl_3 and $Hg(OTeF_5)_2$ in *cyclo*-C_4F_8 at 20 °C. Colorless hydrolysis-sensitive liquid, highly volatile at 10^{-2} mbar. Slowly decomposes with precipitation of tellurium. Identified by MS (M^+) and ^{19}F-NMR: $\delta_A = 48.9$, $\delta_B = 77.4$, $J(AB) = 185$, $J(^{31}P\text{-}^{19}F_A) = 3.3$, $J(^{31}P\text{-}^{19}F_B) = 12.5$ Hz; D. Lentz, K. Seppelt, *Z. Anorg. Allg. Chem.*, in press.
[85] $O{=}P(OTeF_5)_3$ is formed from PCl_5 and $ClOTeF_5$ at room temperature or from $P(OTeF_5)_3$ and $Xe(OTeF_5)_2$ in C_6F_{14} at room temperature. Colorless, hydrolysis-sensitive liquid volatile at 10^{-2} mbar. Identified by MS (M^+) and ^{19}F-NMR: $\delta_A = 52.8$, $\delta_B = 41.6$, $J(AB) = 181$ Hz; D. Lentz, K. Seppelt, *Z. Anorg. Allg. Chem.*, in press.
[86] K. Seppelt, *Chem. Ber. 110* (1977) 1470.
[87] $As(OTeF_5)_5$ is formed as a colorless solid in accordance with the reaction

$$As(OTeF_5)_3 + Xe(OTeF_5)_2 \rightarrow As(OTeF_5)_5 + Xe.$$

D. Lentz, K. Seppelt, *Z. Anorg. Allg. Chem.*, in press.
[88] *cis*-$SeF_4(OSeF_5)_2$ is produced by decomposition of the unstable $B(OSeF_5)_3$. D. Lentz, K. Seppelt, unpublished results.
[89] $Sb(OTeF_5)_3$ is prepared by the reaction

$$SbF_5 + 5/3\,B(OTeF_5)_3 \rightarrow Sb(OTeF_5)_5 + 5/3\,BF_3$$

in the absence of solvent: Colorless, hydrolysis-sensitivite solid, M.p = 39 °C, b.p = 67 °C/0.1 mbar. Identified by MS (M^+), Raman spectra, F analysis, and ^{19}F-NMR: $\delta_A = 41.6$, $\delta_B = 35.8$, $J(AB) = 186$ Hz.
$Sb(OTeF_5)_5$ was originally analyzed as $Sb(OTeF_5)_3$ [79]; it is formed by the reaction

$$SbF_5 + 5/3\ B(OTeF_5)_3 \rightarrow Sb(OTeF_5)_5 + 5/3\ BF_3.$$

Colorless, crystalline solid, which slowly decomposies at room temperature. D. Lentz, K. Seppelt, *Z. Anorg. Allg. Chem.*, in press.

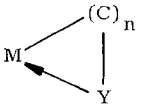
Organometallic Intramolecular π-Olefin-Metal Coordination Compounds

By Iwao Omae*

In this review article complexes of the type X_nM—R are dealt with in which a σ-bonded organic ligand R is additionally linked by a π-bond with the metal M. In other words, the complexes contain metallacycles with three and a half, four and a half, five and a half members, *etc.* Well-known five and a half membered ring systems are those with 4-pentenyl, 1,4-pentadienyl, norbornyl, norbornenyl, cyclooctenyl, and *endo*-dicyclopentadienyl ligands. Metallacycles of this size are strain-free and stable. Donor ligands such as amines and phosphanes can displace the coordinated double bond of the π-ligand from the metal. This C=C double bond is lengthened from *ca.* 133 pm to 136—146 pm by the coordination.

1. Introduction

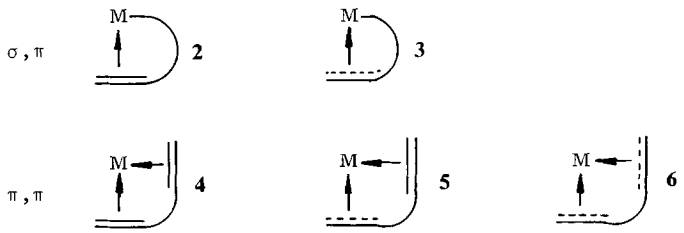
In 1955, *Bähr* and *Müller*[1] defined organometallic intramolecular coordination compounds as compounds of type **1**, in which $n = 3$ or 4. Later, the syntheses of several analogous compounds with $n = 1$, 2, 5 *etc.* were described in the literature, and the author[2-6c] proposed a further classification of such compounds with respect to the donor ligand Y, namely[2-5]: compounds with (i) oxygen ligands (carbonyl, alkoxy, phenoxy groups *etc.*); (ii) nitrogen ligands (amino groups *etc.*); (iii) ligands with multiple bonds (alkenyl, cyclopentadienyl, phenyl groups *etc.*); (iv) other ligands (with halogen, sulfur, phosphorus *etc.*).



1, M = Metall
Y = Donorligand
$n \geq 1$

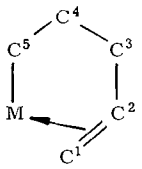
In this review article intramolecular coordination compounds with σ-metal bonded donor ligands Y are tentatively designated as "σ-coordination compounds" (examples of ligands: carbonyl, amino, halogen *etc.*), while analogues with π-metal bonded donor ligands are designated as "π-coordination compounds" (examples of ligands: alkenyl, cyclopentadienyl, and phenyl groups).

The σ-coordination compounds mainly contain elements of the 5th and 6th main groups, usually N, P, As, O or S, as donor atoms, and they tend to form five-membered ring structures, particularly if the donor atom, like nitrogen or sulfur, has no d-electron in the ground state[2-6a,c,d]. Almost all σ-coordination compounds also contain an authentic M—C single bond (for exceptions see [6a]). The π-coordination compounds may be classified into the five groups **2**—**6**. This review deals only with compounds of type **2**, *i.e.* with π-coordination compounds containing a M—C σ-bond. It will be demonstrated that organometallic compounds with intramolecular π-olefin-metal coordination mainly form five and a half membered rings, but in exceptional cases also four and a half and three and a half membered rings, as well as other rings. In addition, the classification, synthesis, reactivity and reaction mechanisms of these metallacycles are discussed.



2. Compounds with Five and a Half Membered Rings

Intramolecular σ-coordination compounds tend to form five-membered rings, while π-coordination compounds, especially those of type **2**, tend to form rings of similar size but with $n + 0.5$ members (n = integer). Thus, *e.g.*, a compound of type **7**[*] contains an almost strain-free five and a half membered ring. The C-atoms can be singly or doubly bonded to each other and also to parts of ring systems.



7

2.1. 4-Pentenyl Compounds

η^3-Allylcobalt complexes readily form the five and a half membered π-coordination compounds **8** by insertion of fluoroolefins into the η^3-allyl-cobalt bond[7,8].

The observation that η^3-allyl(tricarbonyl)cobalt complexes already react at room temperature, whereas the phosphane- and phosphite-complexes react only on heating is explained by the electrophilicity of cobalt being lowered on bonding to the phosphorus ligand. Monophosphane- and monophosphite-substituted products **8** can

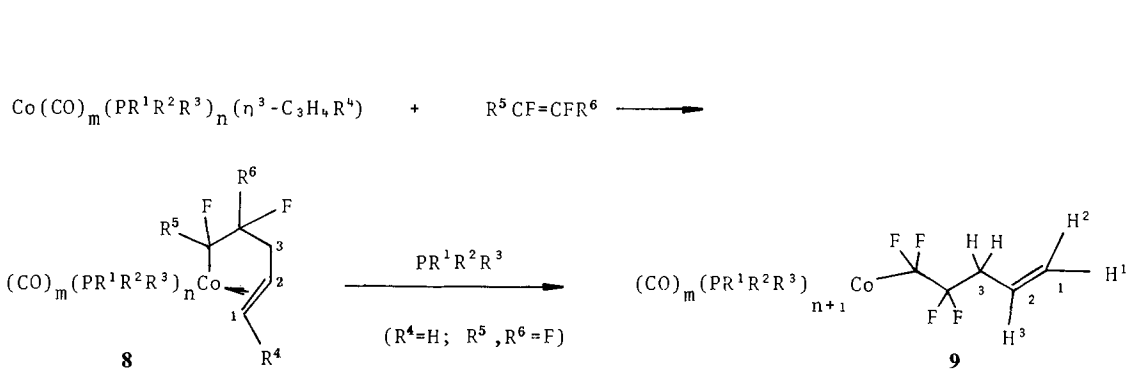
[*] The C-atoms of the ligands in **7**—**9**, **93**, **100**—**103** and in Figure 1 are not numbered systematically.

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/1212-0889 $ 02.50/0



R^1–R^3 = Me, Ph, OMe; R^4 = H, Ph, Me; R^5, R^6 = F, CF_3; n + m = 3; **8a**, R^1–R^3 = Me; R^4 = H; R^5, R^6 = CF_3; n = 1

react with further donor ligands with ring-opening to give **9** (dectected, *inter alia*, by ^{1}H- and ^{13}C-NMR).

Figure 1 shows the structure of the product **8a** formed on reaction of octafluoro-2-butene with η^3-allyldicarbonyl(trimethylphosphite)cobalt[7]. The Co—C^1 and Co—C^2 bond lengths in this trigonal-bipyramidal structure are almost identical, hence the terminal double bond is olefinically bonded. The pentenyl chain forms the characteristic five and a half membered ring structure incorporating the central metal.

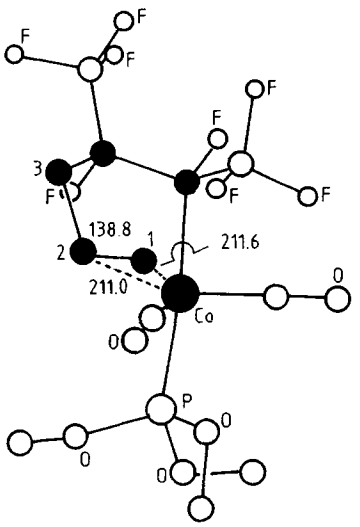


Fig. 1. Structure of **8a** in the crystal. Bond lengths in pm [7].

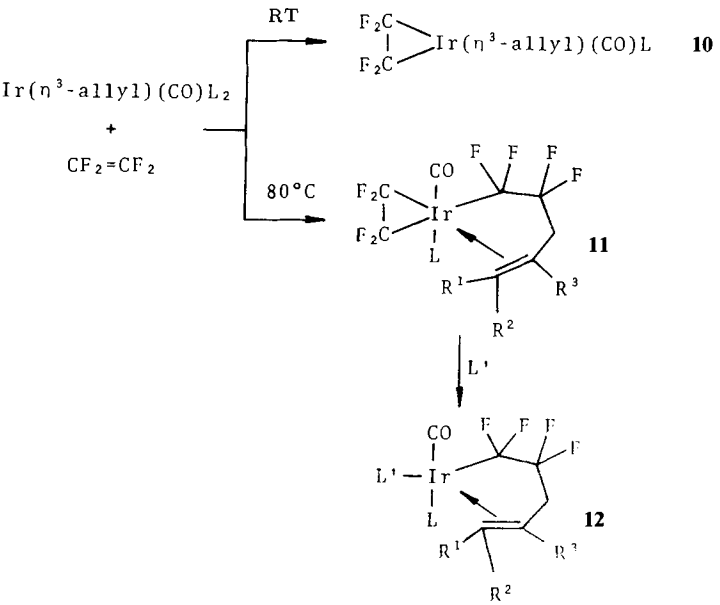
Triphenylphosphane- and triphenylarsane-substituted η^3-allylcarbonyliridium complexes also exhibit low activity towards tetrafluoroethylene. At room temperature, only one ligand is exchanged to give the complex **10**; on heating, however, the insertion products **11** are formed. The coordinated tetrafluoroethylene can subsequently be readily replaced by carbon monoxide or triphenylphosphane to give the substituted product **12** without ring-opening taking place[9].

Interactions between main-group metal atoms and CC double bonds have been investigated by *Oliver et al.*[10-16a] on compounds **13** bearing terminal olefins:

$M-(CH_2)_n-CH=CH_2$, M = Al [10, 11], Zn [10, 12, 13], $n = 2-4$

13

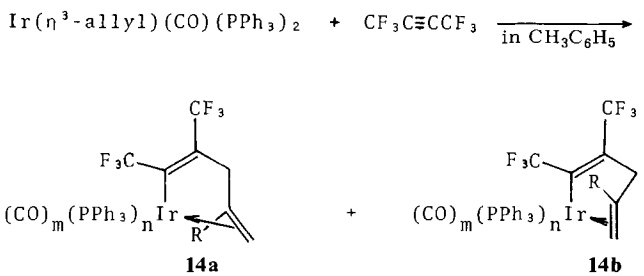
It was demonstrated that only 4-pentenyl compounds ($n = 3$) have a ring structure (NMR results). Such five and a half membered ring systems having the 4-pentenyl skeleton have also been prepared by reaction of ω-olefinic Grignard reagents with η^5-cyclopentadienyl derivatives[16b,c] and *via* other routes[16d,e].



η^3-allyl = 1-MeC_3H_4, 2-MeC_3H_4; L = PPh_3, $AsPh_3$; L' = PPh_3, CO; R^1–R^3 = H, Me

2.2. 1,4-Pentadienyl Compounds

Like olefins, acetylenes also react with η^3-allyliridium complexes to give *cis*-inserted diene compounds **14a** and **14b**, along with polymerization products of the acetylenes and small amounts of the open-chain *trans*-insertion products **15**[17].

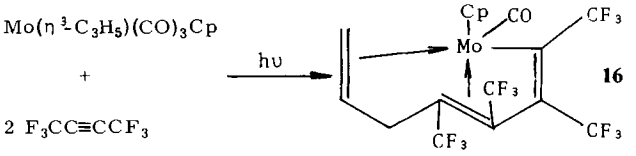


14a **14b**

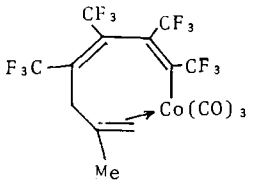
$Ir[(CF_3)C\overset{I}{=}C(CF_3)-CH_2-CHR=CH_2](CO)(PPh_3)_2$ **15**

η^3-allyl = C_3H_5, 2-MeC_3H_4;
R = H, Me;
m, n = 1,2; m + n = 3

Products analogous to **14** are also accessible photochemically from η^1-allylcarbonyl-iron[18] or -cobalt complexes[18b] and, *e.g.*, hexafluoro-2-butyne. A corresponding molybdenum complex substrate, however, afforded the bis-insertion product **16**.



16



17 Cp = (η^5-C_5H_5)

Double insertion of the fluoroalkyne into tricarbonyl-η^3-methylallylcobalt, on the other hand, leads to formation of the metallacycle **17** with a seven and a half membered ring structure (in low yields together with polymers)[8].

2.3. Norbornyl and Norbornenyl Compounds

Numerous η^3-allyl complexes **18** react with cyclic olefins, *e.g.* norbornene, norbornadiene and their derivatives, and bicyclo[2.2.2]octene, to give a variety of insertion products (**19–26**), all of which contain five and a half membered rings[19–22].

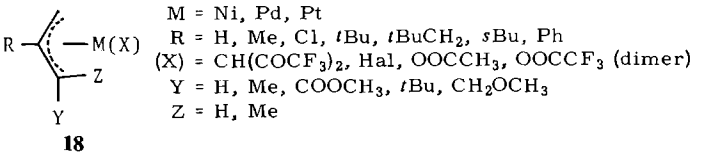
η^3-Allylnickel complexes **18**, *e.g.*, react under mild conditions with norbornene, presumably *via* initial formation of ordinary π-complexes, which then react with sodium acetate[23] or potassium acetate[24] to give the acetato-bridged nickel compounds **19**. The bond lengths in these norbornyl and norbornenyl complexes are indicative of a pronounced "*trans*-effect"[22,25–29].

2.4. Cyclooctenyl Compounds

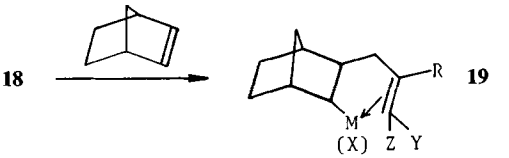
In 1957, *Chatt et al.* synthesized 1,5-cyclooctadieneplatinum(II) chloride **27a**[30,31], and *Schultz* prepared the dinuclear methoxy derivative **28a**[32]. **27a** can be prepared from 1,5-cyclooctadiene and Na_2PtCl_4, while **28a** can be obtained by methanolysis of **27a** in the presence of anhydrous sodium carbonate. Reactions of 1,5-cyclooctadiene complexes **27** with other alcohols[33], sodium methoxide[34], water[35], silver acetate[36], malonates[37], acetoacetates[37,38], and thallium β-dionates[39,40], analogously lead to compounds of type **28** to **36**. Complexes with amines have so far evaded isolation[41].

Hydride addition to tetracarbonyl-1,5-cyclooctadienemanganese(I) with $NaBH_4$ leads, *via* hydrogenation of one of the two CC double bonds of the educt, to formation of the metallacycle **37**. Reaction of the cation with sodium methoxide or sodium azide, respectively, affords methyl ethers or azides **38**[42].

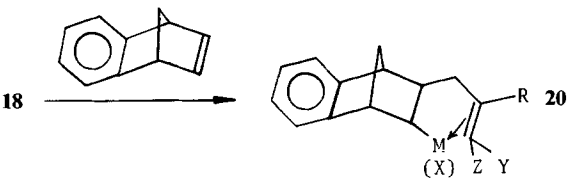
Bis(1,5-cyclooctadiene)metals react with cyclopentadiene (or methylcyclopentadiene[43]) or acetylacetone[44]



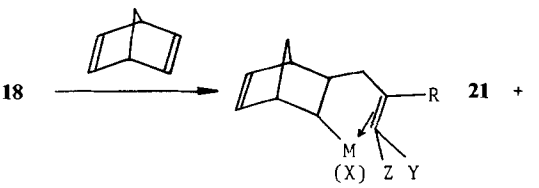
18



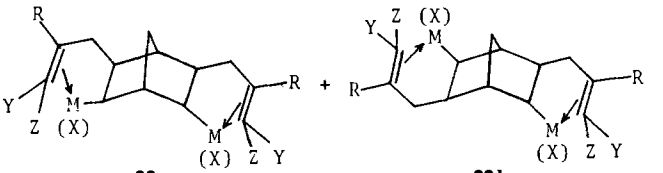
19



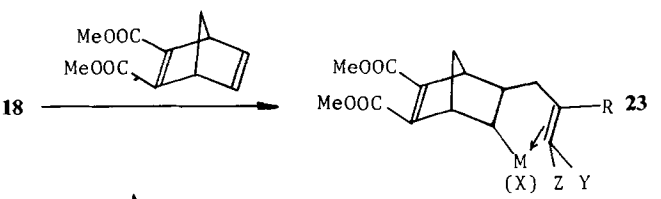
20



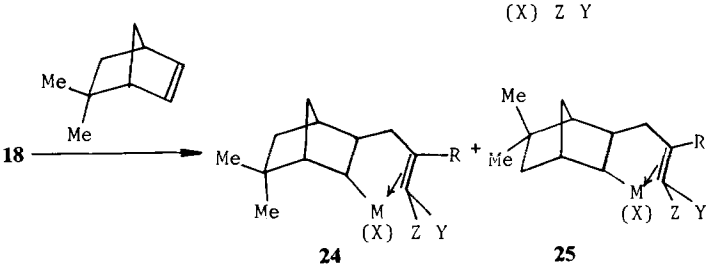
21 +



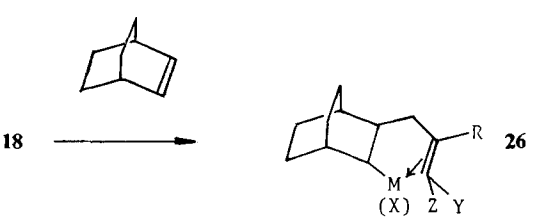
22a **22b**



23

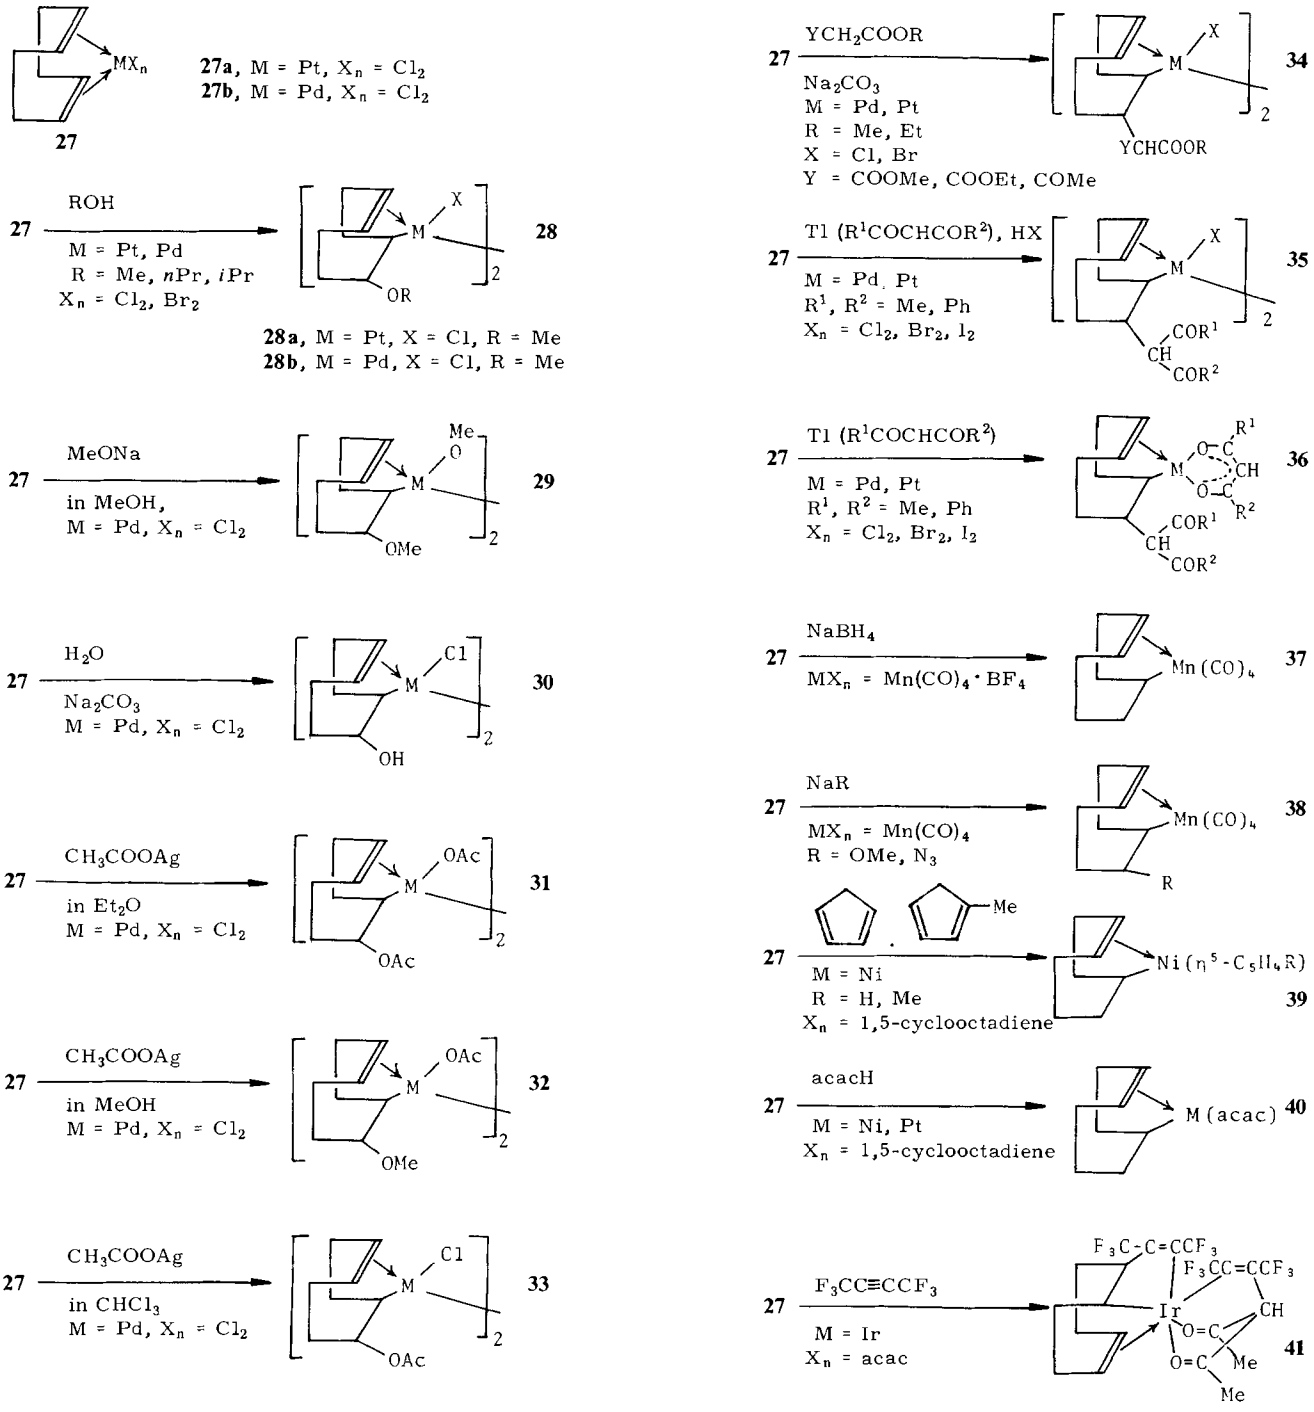


24 **25**



26

with exchange of one of the two ligands to give the complexes **39** and **40**, respectively. In **40** the coordination of the nickel is essentially square planar, and the length of the



CC double bond is surprisingly large (142 pm) even though it is 7 pm shorter than any other CC bond in the ring[44a].

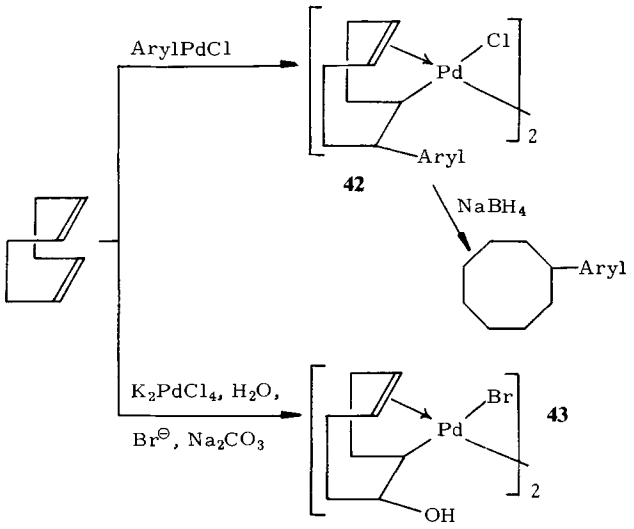
On reaction of 1,5-cyclooctadieneiridium acetylacetonate with hexafluoro-2-butyne the alkyne adds to both ligands to give the addition product **41** (X-ray structure analysis)[45].

Arylpalladium chlorides react directly with 1,5-cyclooctadienes, *i.e.* with circumvention of the monomeric 1,5-cyclooctadiene step, to give the dinuclear cyclooctenyl complexes **42**, which can be readily reduced to arylcyclooctanes[46]. K_2PdCl_4 likewise reacts directly with 1,5-cyclooctadiene and bromide ions to give **43**[47].

The stable dimer **44** is formed from *Z-cis*-bicyclo[5.1.0]octa-3-ene and bis(benzonitrile)dichloropalladium by transfer of chlorine from the palladium to the ligand[48].

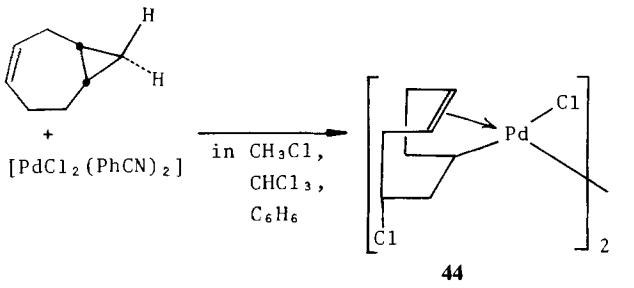
Halogen-bridged cyclooctenyl complexes of type **45** (examples: **28**, **30**, **33**—**35**, **43**) react with various kinds of donor ligands such as amines, phosphanes, phosphites and arsanes with cleavage of the halogen bridges to give the mononuclear complexes **46**[30,31,41,49–51].

The dimers **45** are also cleaved to the corresponding monomers on reaction with carbon monoxide. In the case of **45**, where Y = OR, the unstable carbonyl derivative **47** is first formed, which immediately reacts further with alcohols to give alkoxycarbonyl compounds **49**. Nucleophilic attack of the alcohol at the carbonyl group and subsequent

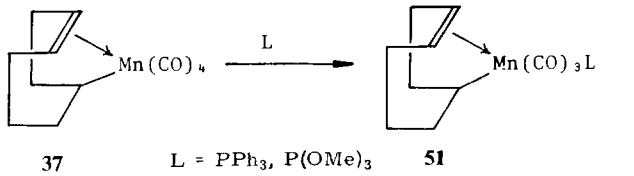


Aryl = C_6H_5, p-MeC_6H_4, p-$MeOC_6H_4$

cleavage of the alkoxy group Y leads to formation of the second coordinated CC double bond[33a,52].

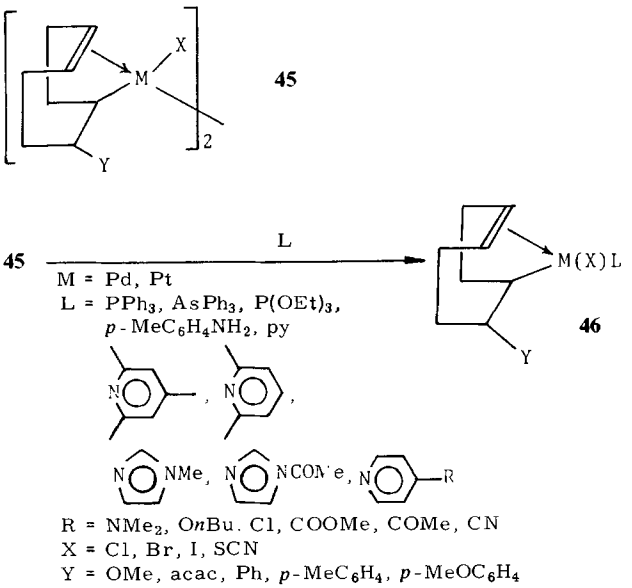


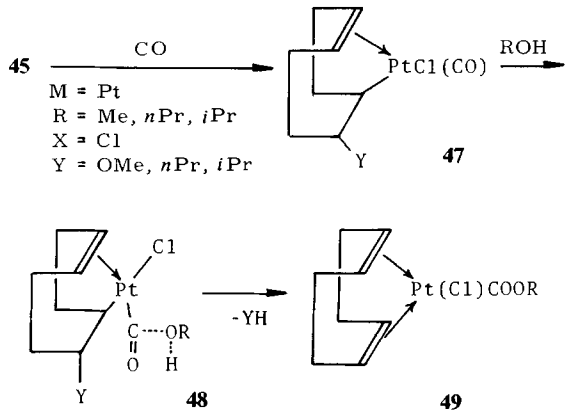
Thallium cyclopentadienide[47,53], 2,2,6,6-tetramethyl-3,5-heptanedionatothallium[47], and even ethylenediamine[54] likewise react with **45** with rupture of the halogen-bridge to give **50**. In contrast, in the case of **37** a simple ligand exchange takes place with donor ligands[42].

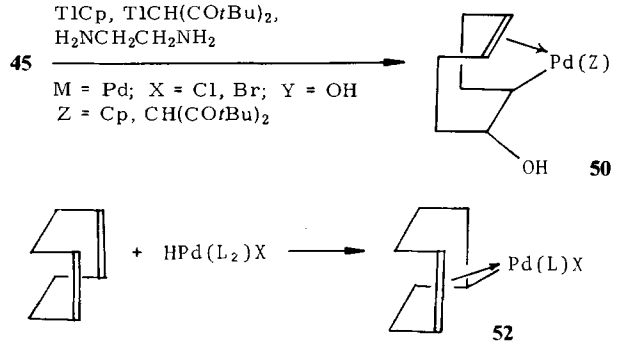


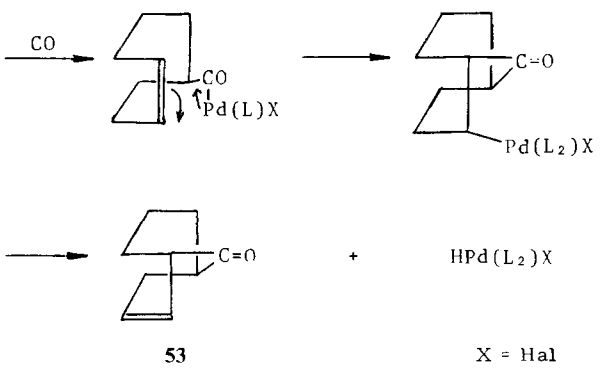
Brewis and *Hughes* were able to prepare bicyclo[3.3.1]non-2-en-9-one **53** by reaction of 1,5-cyclooctadiene with carbon monoxide in the presence of 1% diiodobis(triphenylphosphane)palladium(II) (150 °C, 1000 bar)[55]. Formation of the transannular addition product **53** suggested a reaction route involving formation of **52** with subsequent carbonyl insertion.

Methanolysis of dinuclear 2-methoxycyclooctenylpalladium complexes, *e.g.* of type **28** and **29**, leads to a broad spectrum of products (see [32,34]), while carbonylation of the analogous hydroxy derivative **30** yields exclusively the β-lactome, *trans*-(*Z*)-4-cyclooctene-1,8-carbolactone[35,56]. Basic methanolysis and methylation lead to the *trans*-(*Z*)-





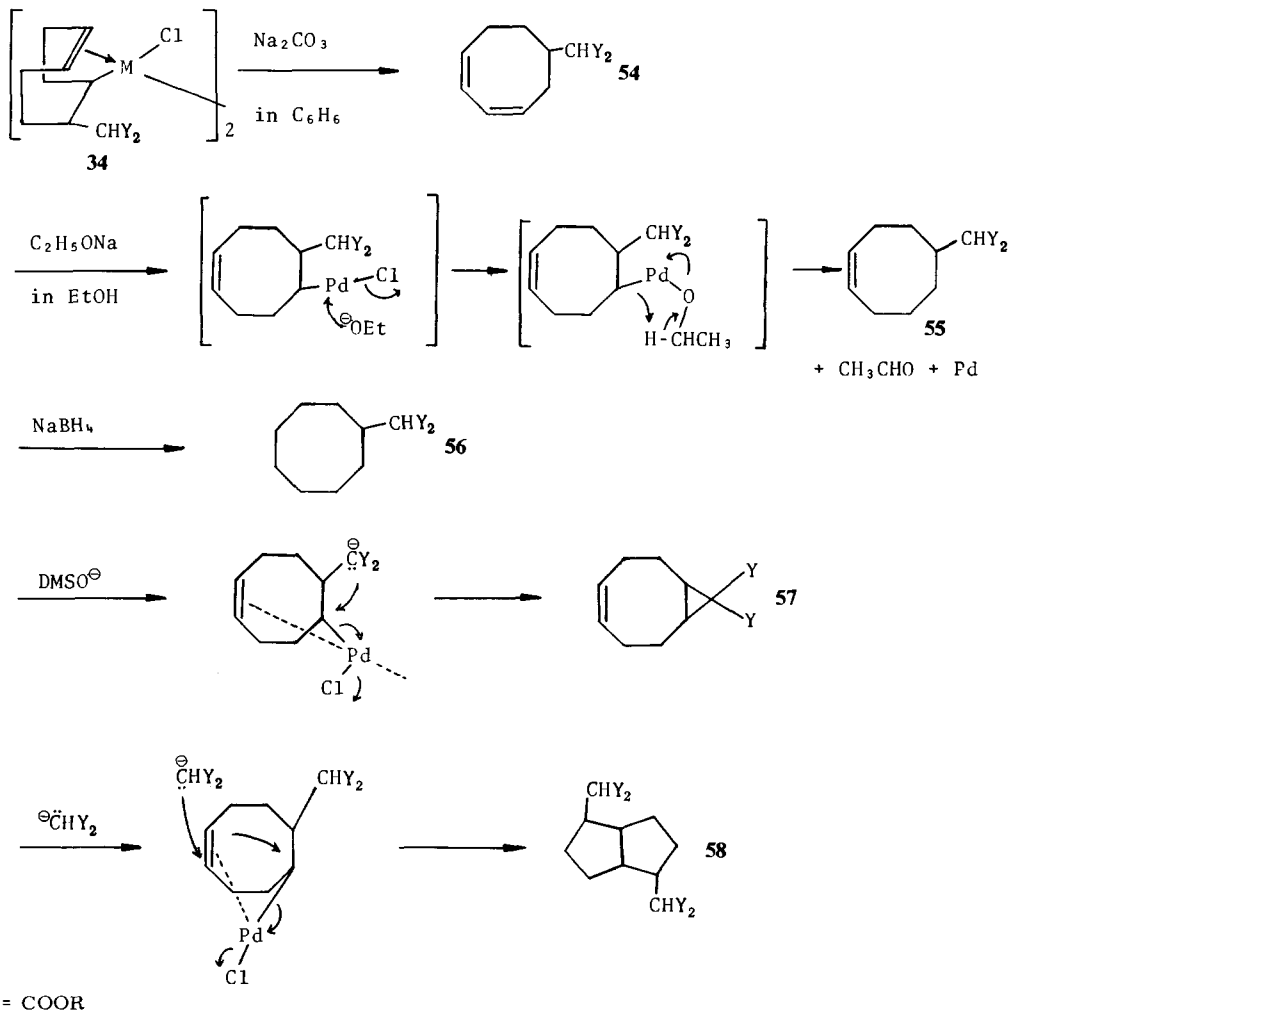




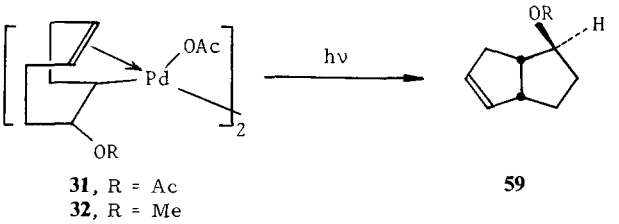
methoxy ester[57]. Thermolysis of **30** in acetone leads to formation of the γ,δ-unsaturated ketone, 4-cyclooctenone; this is the product expected from the Wacker oxidation of 1,5-cyclooctadiene, a reaction which has been demonstrated to proceed *via* a σ-bonded β-hydroxyalkylpalladium intermediate[58].

On heating under reflux with bases such as triethylamine or anhydrous sodium carbonate, the malonate-substituted cyclooctenyl complexes **34**[37,38] undergo cleavage, yielding the 3,5-cyclooctadienylmalonates **54**. On the other hand, treatment with sodium ethoxide leads to reductive cleavage of the Pd—C σ-bond to give the diethyl 4-cyclooctenylmalonate **55**.

Reduction of **34** with $NaBH_4$ in ether yields cyclooctyl malonates **56**. In contrast, stronger bases should abstract the activated hydrogen atom of the malonate group. Thus, **34** reacts with the dimethyl sulfoxide (DMSO) anion at room temperature to give bicyclo[6.1.0]non-4-ene-9,9-dicarboxylates **57**. Reaction of **34** with malonate leads in a transannular reaction to formation of bicyclo[3.3.0]octane-2,6-dimalonates **58**[37,38].



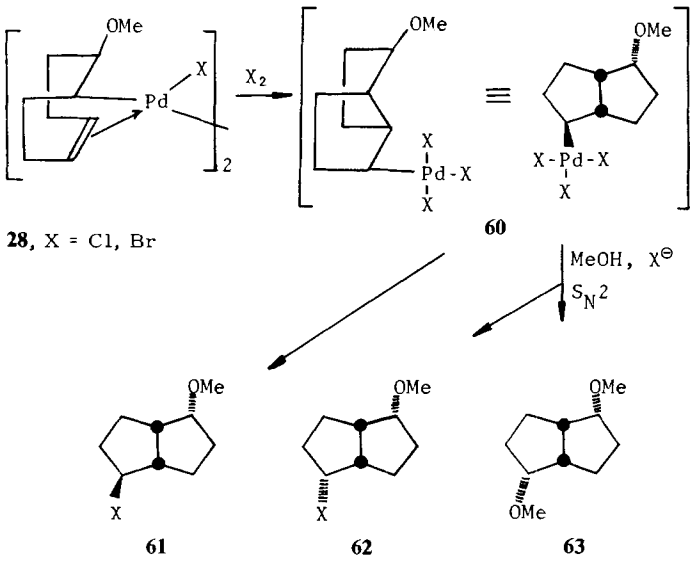
Photolysis of **31** likewise yields transannular reaction products; in addition to 55% of **59** also 10% of the saturated bicycle is formed. The methoxy compound **32** behaves similarly[59].



Halogenation of the complexes **28** leads to formation of the bicycles **61**—**63**. For the mechanism of this reaction *Wong* and *Stille*[60] proposed an oxidative addition *via* **60** with subsequent reductive elimination (for protonation and other reactions of cyclooctenyl complexes see [61]).

2.5. *endo*-Dicyclopentadiene Compounds

In 1908 *Hofmann* and *Narbutt*[62] prepared the first intramolecular coordinated dicyclopentadiene complex **65a** by direct reaction of *endo*-dicyclopentadiene with K_2PtCl_4 in aqueous methanol, and thus succeeded in circumventing the devious route *via* the diolefin complex **64**. However, they did not mention anything regarding intramolecular coordination. In 1957, *Chatt et al.* prepared the same compound from **64** and proposed that it has a structure with intramolecular coordination[30,31]. Later, in 1966, *Whitla et*

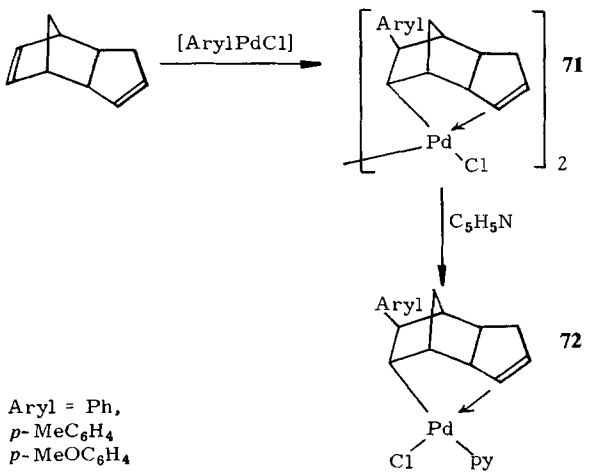


28, X = Cl, Br

61 **62** **63**

al. demonstrated by an X-ray structure analysis that the compound exhibits a very strong *trans*-effect (see Fig. 2)[63].

Numerous complexes with intramolecular coordination have been synthesized from **64**, *e.g.* complexes of type **65**—**70**[64-67].



Aryl = Ph, *p*-MeC_6H_4, *p*-$MeOC_6H_4$

In contrast, analogues of **69** and **70** with aromatic substituents on the ring are directly accessible from arylpalladium chloride and *endo*-dicyclopentadiene. On treatment with pyridine, **71** affords the pyridine-substituted monomer **72** without scission of the intramolecular σ,π-coordination[46].

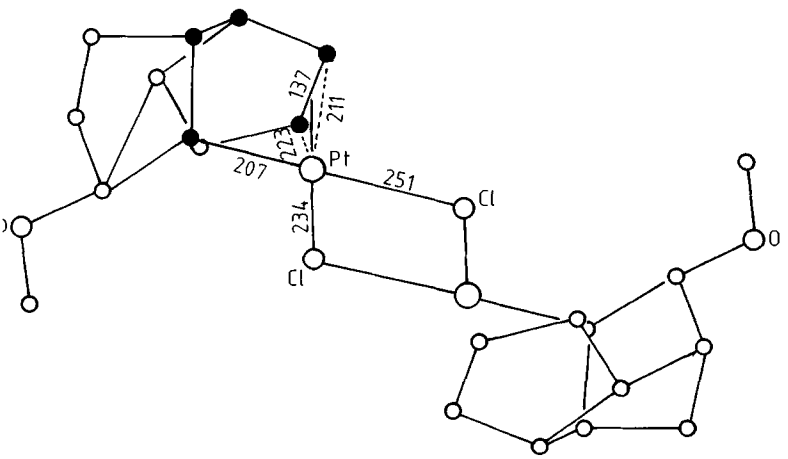


Fig. 2. Structure of **65a** in the crystal. Bond lengths in pm [63].

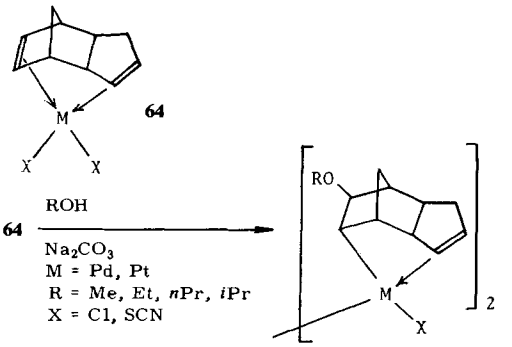
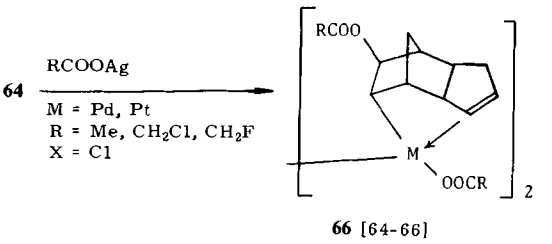
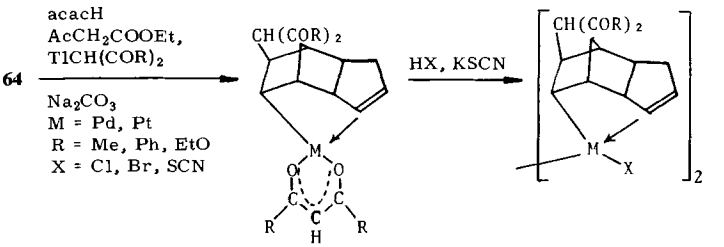


65

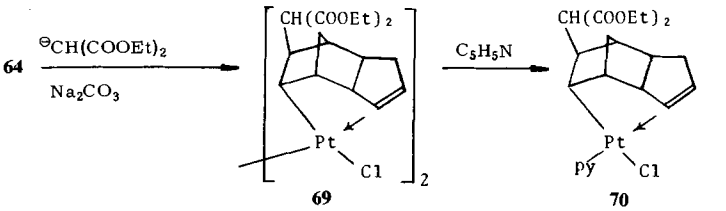
65a, M = Pt, R = Me, X = Cl



66 [64-66]



67 [40,67] **68**

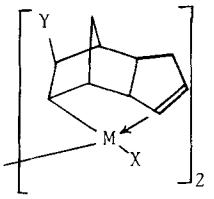


69 **70**

The bridged dimers **73** can generally undergo bridge-exchange reactions to give the products **74** on reaction with, *e.g.*, bromide, iodide, ethanethiolate or thiocyanate ions[30,31]. Amines, phosphanes, and isocyanates, on the other hand, induce cleavage of the bridge with formation of mononuclear complexes **75**[30,31,53,68-71].

Reaction of chloro-bridged **73** with the hyperoxide ion O_2^- leads to formation of the novel dioxygen complex **76**[72]. The fairly labile dioxygen bridge, however, is readily replaced by chlorine on warming in CH_2Cl_2, *i.e.* the starting compound **73** is obtained again, in quantitative yield. Treatment of **76** with methanol at room temperature leads to formation of the methoxo-bridged complex and hydrogen peroxide.

Reaction of **73** with cyclohexyl isocyanide initially yields the monomer, which after olefin displacement and



73, X = Cl, SCN

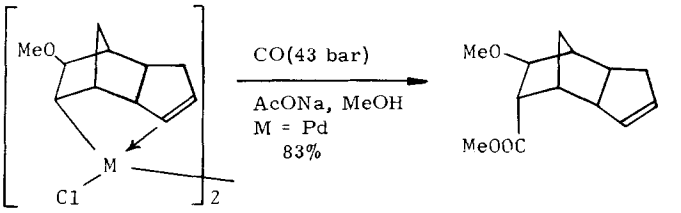
subsequent isocyanide insertion into the Pt—C σ-bond affords the *trans*-complex **77**[69] (cf. [73]).

73, M = Pt, readily undergoes carbonylation under mild conditions to give intramolecular coordinated species of type **75** (L = CO), whereas high-pressure carbonylation of **73**, M = Pd, leads to the metal-free esters **78**[57].



73 → **78**: CO(43 bar); AcONa, MeOH; M = Pd; 83%

73

78

Triphenylphosphane-substituted platinum complexes **79** react with carbon monoxide to give the carbonyl derivatives **80**[74]. In the case of **79**, M = Pd, the complex **80** cannot be isolated; however, it can be converted into the corresponding ketones **81a** or the aldehyde **81b**[75].

2.6. Cyclooctatriene-Dimetal Compounds

In 1963, *King* synthesized the compound $C_8H_{10}Fe_2(CO)_6$ by reaction of 1,3,5-cyclooctatriene with $Fe_3(CO)_{12}$ and suggested that it had the structure **82**[76]. Shortly afterwards, *Emerson et al.* concluded from a Mössbauer study that it has the structure **83** in the solid state[77]. However, in

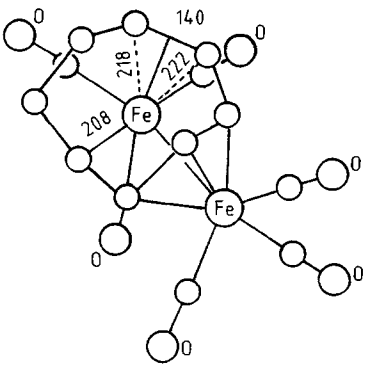


Fig. 3. Structure of **84** in the crystal. Bond lengths in pm [78].

80 → **81a**: MeI, LiR; M = Pd

80 → **81b**: HCl; M = Pd

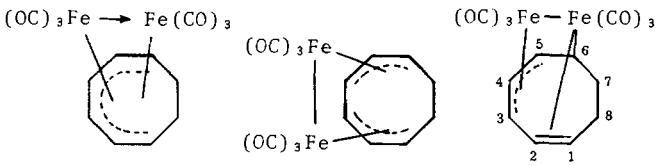
M = Pt, Pd
X = Cl, Me, Ph

81a

81b

1969 *Cotton* and *Edwards* carried out a three-dimensional X-ray crystallographic analysis on the compound and found that it has the unsymmetric structure **84** in the solid state[78]: The molecule does not have a plane of symmetry and the metal atoms are not structurally equivalent, one $Fe(CO)_3$ group being bonded allylically to C^3, C^4, and C^5, while the other coordinates the olefinic double bond and is coupled with C^6 by a single bond (Fig. 3)[78].

Dinuclear carbonyl compounds of similar structure are not only found with iron[78-86], but also with ruthenium[87-89] and rhodium[90]. The skeletal structure found in **84** also appears in *o*-annelated cyclooctatrienes (three-membered[84,85], four-membered[79,80], six-membered (benzene) rings[86], and other rings[88]).



82 **83** **84**

Cotton et al.[83] found by ^{13}C-NMR spectroscopic investigations that the molecular structure of **84** is markedly fluxional in solution. At temperatures below −65 °C, the ^{13}C-NMR spectrum is in complete accord with the skew structure observed in the solid state (Fig. 3). The first changes in the spectrum—observed between −65 and about 8 °C—result from a "twitching process" in which the two enantiomeric forms of the molecule interconvert by minimal movement of the $Fe_2(CO)_6$ moiety. At the same time a rapid scrambling of the CO-groups of the η^3-allyl-bonded $Fe(CO)_3$ moiety takes place. Above 8 °C, scrambling of the CO groups on the other iron atom commences.

The "twitching process".

2.7. Other Complexes with Five and a Half Membered Rings

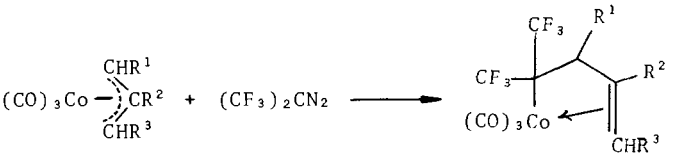
Of the acid chlorides $CH_2{=}CH{-}(CH_2)_n{-}COCl$ having a double bond at the terminal position, only 4-pentenyl chloride ($n=2$) reacts with $NaCo(CO)_4$[91a]. The stability of the five and a half membered ring structure is also apparent in some complexes which contain several CC double bonds and in which metal coordination to rings of other size would be possible[91b,c]. Further examples of compounds of this type are to be found in refs.[92-106].

3. Compounds with Four and a Half Membered Rings

These metallacycles, which are generally less stable than the five and a half membered analogues, are mainly obtained by insertion of alkynes; they are also accessible from norbornadiene-metal dihalides (cf. Sections 2.4 and 2.5).

3.1. 3-Butenyl and 1,3-Butadienyl Compounds

Olefins readily insert into allylic bonds of complexes, mainly giving five and a half-membered π-coordination compounds (see Section 2). Correspondingly, the insertion of a C_1-moiety (from hexafluoro-2-diazopropane) leads to four and a half membered metallacycles such as the extremely air-sensitive cobalt compounds **85**[107].

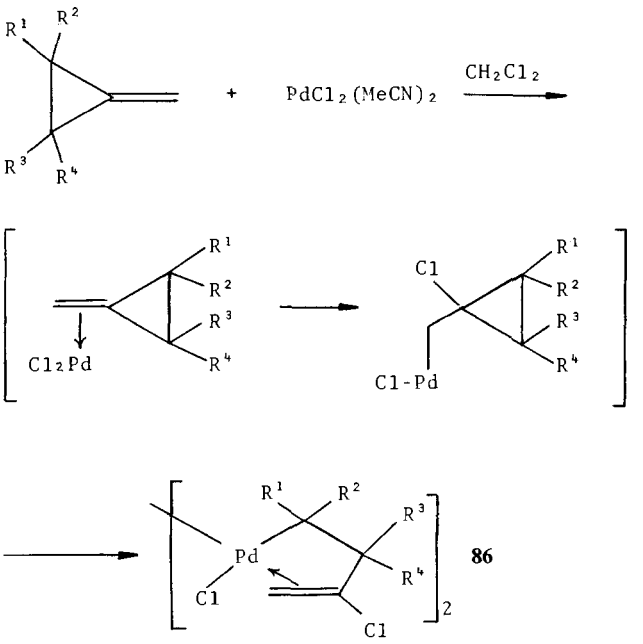


R^1 - R^3 = H, Me **85**

Alkynes likewise tend to insert into M—C, M—Hal and M—H bonds. Examples of this are the insertion of two molecules of RC≡CR (R = CF_3, COOMe) into the Ru—C σ-bond of $RuMe(PPh_3)_2Cp$, leading to the four and a half membered metallacycle

Analogously, $Pd(Cl)_2(PhCN)_2$ and *t*BuC≡CMe ("chloropalladation") afford complexes with the partial structure

Here, the insertion takes place into the M—Cl bond. If the $Pd(Cl)_2(PhCN)_2$ is allowed to react simultaneously with the alkyne PhC≡CR (R = mesityl) and the olefin $CH_2{=}CH(t\text{Bu})$ the mixed end product is formed[110].



R^1 - R^4 = H, D, COOMe, Ph

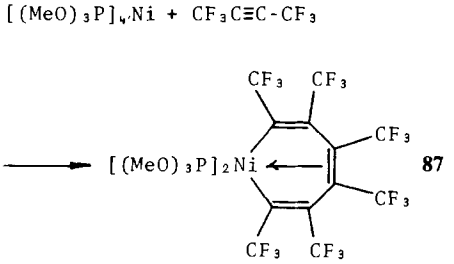
Equivalent insertions into M—H bonds are also possible. Reaction of $RuH(PPh_3)_2Cp$ and hexafluoro-2-butyne, *e.g.*, leads not only to formation of the bis-insertion product with a four and a half membered ring

but also of the acyclic mono-insertion product[111,112].

Methylenecyclopropane reacts with chloropalladium complexes with ring opening to give the dimer **86**[113-115].

A ruthenium complex with a four and a half membered ring structure is surprisingly formed by insertion of the alkyne into a Ru—H bond and not into the Ru—C bond[111,112,116].

As example of a cyclometalated alkyne trimer we have the complex **87**, which contains two four and a half membered rings[117]. Interestingly, pyrolysis of the cyclohexylphosphane analog of **87** yields hexakis(trifluoromethyl)benzene[118]. Ring-opening and other reactions of the 3-butenyl and 3-butadienyl compounds have been reported elsewhere[119-122].



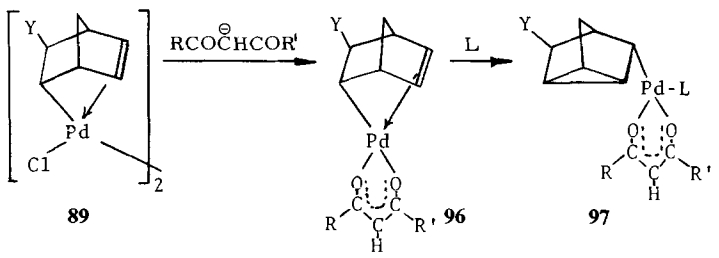
3.2. Norbornenyl Compounds

Norbornadiene-metal dihalides **88** similarly provide general access to intramolecular coordination compounds such as the cyclodiene-metal dihalides **27** and **64**.

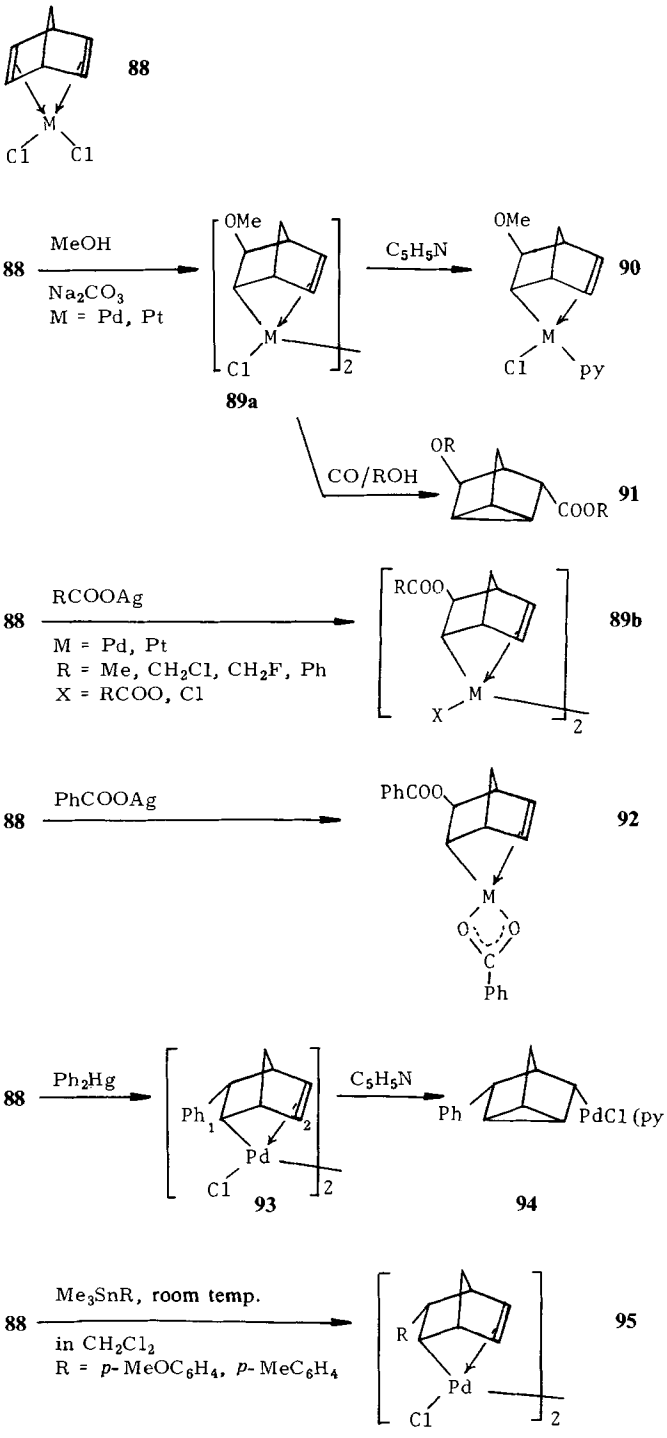
Thus, pyridine-substituted four and a half membered mononuclear complexes **90**[71] are obtainable from **88** *via* the dimeric methoxy-derivatives **89a**[53,57,123]; the same bridge-splitting occurs during carbonylation of **89a** (in methanol) to give the nortricyclane derivative **91**[124,57]. Reaction with silver carboxylate gives in most cases the species **89b** with carboxylato-bridges together with chloro-bridged $[AcOC_7H_8PdCl]_2$ and Pd- or Pt-carboxylates such as **92**[64].

Dichloro(norbornadiene)palladium also reacts with diphenylmercury[125,126] or aryltrimethyltin[127] to give the chloro-bridged dinuclear complexes **93** and **95**, respectively, which in contrast to **89a** have an *endo*-structure (X-ray analysis of **93** see [125]).

The dimeric norbornenyl complexes of type **89** react with multidentate ligands to give the cleavage products **96**.



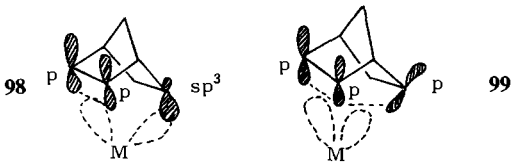
L = py, PPh_3, $PPhMe_2$, $SbPh_3$, $AsPh_3$; R, R' = CF_3, Ph;
Y = OMe, CH_3COO



Reactions of these with neutral donor ligands afford metalated nortricyclane derivatives **97**; reactions with monoolefins or 1,3-dienes lead to analogous derivatives[128] (cf. also [60,73]).

All these norbornenyl complexes contain four and a half membered rings, which can be expected to show relatively high ring strain. In fact the complexes should be unstable, since, according to model considerations, the CC double bond cannot coordinate orthogonally to the central atom. Nevertheless, almost all of these compounds can be prepared and isolated. *Green* and *Hancock* suggested that the π-homoallylic structure **99** is preferred over the four and a half membered metallacyclic form **98**[123]. However,

whether this is so or not has not yet been finally settled[125, 129].

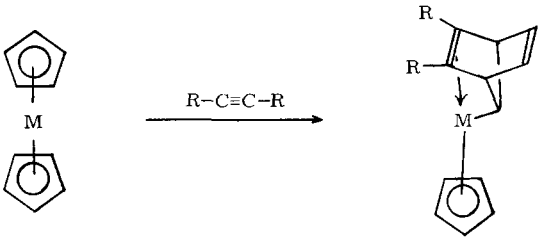


This argument was based on the significant deshielding of the C*H*Pd proton ($\delta = 4.20$) observed in the methoxynorbornenyl complex **89a**; for comparison: in the *endo*-dicyclopentadiene complex **65**, M = Pd, X = Cl, R = Me, the C*H*Pd proton absorbs at $\delta = 3.47$. Also the observation that norbornenyl complexes very readily form nortricyclanes (*e.g.* **91**, **94**, **97**) could serve as an argument in favor of the homoallylic π-coordination.

In this connection, *Hughes* and *Powell* have carried out ^{13}C-NMR spectroscopic investigations on the complexes **100**—**103**[129] (Table 1). They also preferred the π-homoallylic structure for **100**. Their arguments were as follows: J(Pt—C^1) of **100** is distinctly smaller than in the complexes **101**—**103**. This implies that the C^1—Pt bond has more "p-orbital character" than a typical norbornyl-Pt σ-bond. C^2 and C^3 in **100** must differ drastically in their interaction with the metal, for their coupling constants differ by about 160 Hz! Owing to the rigid carbon skeleton in the bicyclic system in **100** the C^2—C^3 axis must tilt away from the perpendicular, with the result that the coordination plane of the metal must intersect the C^2—C^3 axis at a point much closer to C^3 than C^2. Furthermore, the marked upfield shift of C^1 and C^2 in **100** in comparison to the corresponding signals of the enyl complexes **101**—**103** is indicative of more shielding of these two nuclei in **100**. The chemical shift of C^3 is of similar magnitude in all complexes. Aside from these findings in favor of homoallylic π-coordination of type **99** there are, however, a number of contradictory findings.

Segnitz, Bailey and *Maitlis* found that the C^1—C^2 bond length in **93** was 235 pm and considered this to be too long for homoallylic conjugation. They suggested the homoallylic form as being merely a transition state or metastable intermediate on the reaction path from **93** to **94**[125].

Sandwich compounds such as nickelocene react with alkynes to give the half-sandwich complexes **104**[130–138].



M = Ni, Mo, Pt; R = COOMe, CF_3 **104**

Four and a half membered π-coordination compounds are formed by Diels-Alder reaction of the alkyne with one of the cyclopentadiene rings (for the X-ray structure analysis of **104**, M = Ni, R = COOMe, see [131]). There are metal-ligand bonds not only to the η^5-cyclopentadiene ring, but also to the bridge C-atom (196.4 pm) and to the substituted CC double bond (distance to midpoint 183 pm). At 145.0 pm this ring double bond is significantly longer than a normal olefin bond (133.0 ± 2.1 pm)[131].

Table 1. ^{13}C-NMR data of the complexes **100**–**103**. X = hexafluoroacetylacetonate.

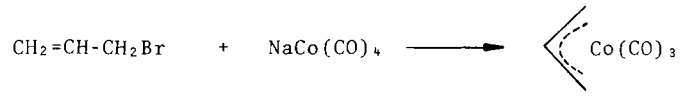
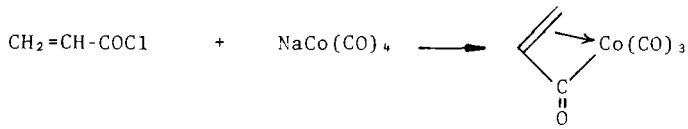
δ(C^3)	79.2	82.2	85.4	56.2
J(C^3—H) [Hz]	181	154	168	159
J(Pt—C^3) [Hz]	296	260	259	305

4. Compounds with Three and a Half Membered Rings

The η^3-allylcobalt complex **105** is readily accessible by reaction of sodium tetracarbonylcobaltate with allyl bromide. Reaction with acryloyl chloride, however, affords the complex **106** with a π-coordinated double bond[91a]. Of the other acryloyl compounds[139–141] special importance attaches to the complex **107**, in which the C^1—C^2 and C^2—C^3 bond lengths are almost equal[142]; the η^3-acryloyl moiety of this complex is thus considered as intermediate between an η^3-allyl system with oxygen atom and an η^2-olefin, η^1-acyl system.

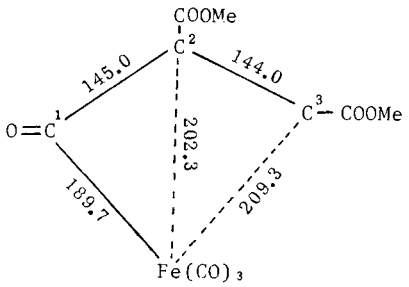


105

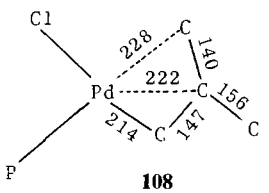


106

Reaction of methallylpalladium chloride with triphenylphosphane affords methallyl(triphenylphosphane)palladium chloride **108**. *Shaw et al.* also described this complex as being an intramolecular coordination compound, on the basis of NMR spectral data[143]. An X-ray structure analysis confirms their view[144]. The π-allyl character of **108** is much less pronounced than that of **107**.



107



108

Reaction of $Fe_3(CO)_{12}$ with octafluoro-1,3- or -1,4-cyclohexadiene leads to formation of a mononuclear iron complex[145]; an X-ray structure analysis of the complex suggested the presence of a σ,π-bond between metal and ligand and the conformation of the complexed cyclohexadiene shown in Figure 4[146]. Analogous compounds, not only with iron[147-150] but with ruthenium[151], cobalt[147, 152-158], chromium[159], molybdenum[160], tungsten[160] and rhodium[161] *etc.* are also known. These two types of examples demonstrate that three and a half-membered ring structures are better described as π-allylic systems; with normal σ,π-bonds the system would suffer far too much strain (for further examples see [162-166]).

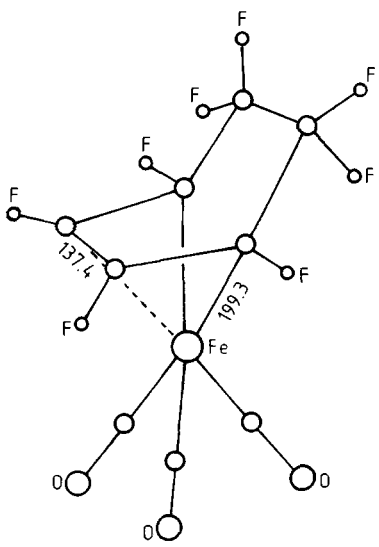


Fig. 4. Structure of tricarbonyl(octafluoro-1,3-cyclohexadiene)iron in the crystal. Bond lengths in pm [146].

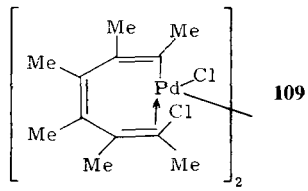
5. Other Metallacyclic Compounds

So far, very little has been published about complexes containing ring systems with more than five and a half members. As example might be mentioned the product obtained on reaction of dichloro(benzonitrile)palladium with



109

2-butyne. The dinuclear complex **109** would appear to contain a six and a half membered ring system[167, 168] (for larger metallacycles see [169-171]).

The author wishes to thank Dr. Ikuzo Tanaka and Dr. Sumio Chubachi for critical perusal of the manuscript.

The Leukotrienes, Highly Biologically Active Substances Involved in Allergy and Inflammation

By Bengt Samuelsson*

Arachidonic acid, a fourfold unsaturated C_{20}-fatty acid, has attracted interest over the last 15 years far beyond the bounds of nutritional research. It forms an essential acyl component of the phospholipids in all animal cells. The long known fact that certain unsaturated fatty acids must be contained in the diet in order to ensure normal function of the organism has been explained by the discovery of a broad palette of biologically highly active oxidation products of arachidonic acid, a cascade, as it is often referred to. Arachidonic acid is formed in organisms from linoleic and linolenic acids, which belong to the so-called essential fatty acids. As early as 1935 *Ulf von Euler* was able to detect a substance in semen which caused smooth muscles to contract. This factor, which was later isolated in pure form, was termed prostaglandin. The number of prostaglandins, including the synthetically obtained analogues, then rapidly increased. Prostaglandins are biosynthesized from arachidonic acid and similar C_{20}-fatty acids by enzymatic oxidation with a cyclooxygenase. Its activity is inhibited by acetylsalicylic acid, indomethazine, and other substances, because these relieve or cure inflammations arising from the action of certain prostaglandins. After the prostaglandins, the thromboxanes, which promote aggregation of blood platelets and thus cause thrombosis, were discovered as further metabolic products of arachidonic acid. In a well-balanced equilibrium the thromboxanes have a biological effect completely opposite to that

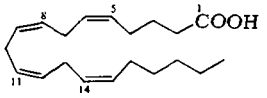
of prostacyclin, discovered soon after this, which inhibits platelet aggregation. Both of these biologically active substances are metabolites of arachidonic acid, and are formed in the course of the cyclizing oxidation. Aspirin and substances having a similar mode of action, therefore have an influence on thrombosis. There are, however, contraction processes and inflammation symptoms which do not respond to these substances, but to steroid hormones (cortisone). For symptoms of this type, to which asthma also belongs, the most recently discovered metabolic products of arachidonic acid are probably highly decisive; they are formed by another enzymatic route *via* a hydroperoxide of arachidonic acid. These compounds are formed in leukocytes and contain the triply unsaturated structural element of a triene and were, therefore, termed leukotrienes. Their astonishingly high histamine-like activity in producing contraction of lung capillaries, their marked property of making capillary vessels permeable to blood plasma, *i.e.* of generating oedema, the ability of leukotriene LTB_4 to cause adherence of human leukocytes and their adhesion to the endothelium, make the leukotrienes chemical mediators in allergies and inflammations, and produce biological effects when present at minute concentrations. In the following article one of the three scientists who were awarded this years Nobel prize for medicine and physiology, and who provided an explanation for this extraordinarily interesting class of natural products, gives an account of the conversion of arachidonic acid into the labile epoxide LTA_4 and further into the dihydroxy compound LTB_4 or the glutathione cysteinylglycine and cysteine conjugates LTC_4, LTD_4, and LTE_4, respectively, as well as of the physiological-pathological implications. The two other prize winners in this area of biologically active compounds, which are often referred to as eicosanoids, are *Samuelsson*'s teacher *Sune Bergström* and the Britain *John Vane*.

1. Introduction

Polyunsaturated fatty acids play a role as precursors of several biologically active derivatives. Thus, four main groups of derivatives, the prostaglandins, the thromboxanes, the prostacyclins, and the recently discovered leukotrienes, are formed by oxygenation and further transformation of various polyunsaturated fatty acids, particularly arachidonic acid **1**, a fourfold unsaturated C_{20}-fatty acid (5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid)[1,2]. These versatile, biologically active substances are also termed eicosanoids, after the number of C atoms they contain.



1

The leukotrienes exhibit three conjugated double bonds and usually form a thioether bond to cysteine: the latter type are of particular interest, since they are responsible for the biological activity referred to as "slow reacting substance of anaphylaxis" (SRS-A). These derivatives are potent bronchoconstrictors and seem to play a pathophysiological role in immediate hypersensitivity reactions. There is also evidence that both these compounds and a leukotriene with pronounced effects on leukocyte migration might function as mediators in inflammation. The present review summarizes the development of this new area of research.

2. Metabolism of Arachidonic Acid in Leukocytes

It is now well established that aspirin and other nonsteroidal anti-inflammatory drugs inhibit the enzyme cyclooxygenase responsible for conversion of arachidonic acid into prostaglandins, thromboxanes, and prostacyclins[3]. Anti-inflammatory steroids prevent formation of prostaglandins by a different mechanism, *i.e.* by inhibition of the release of arachidonic acid from the phospholipid stores[4,5]. In view of the pronounced differences in the anti-inflammatory effects of steroids and aspirin-type drugs it seemed conceivable to us that arachidonic acid might generate additional pro-inflammatory derivatives whose formation is independent of cyclooxygenase. To test this possibility, we studied the metabolism of arachidonic acid in polymorphonuclear leukocytes (PMNL).

Using PMNL obtained from the peritoneal cavity of rabbits it was found that (5*S*)-5-hydroxy(6*E*,8*Z*,11*Z*,14*Z*)-eicosatetraenoic acid (5-HETE) **2** was the major arachidonic

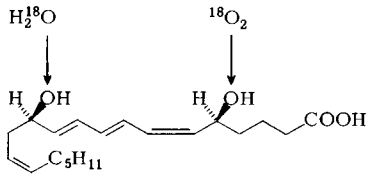
5,6-DHETE
Isomers **5a, b**

acid derived product[6]. Additional work showed that more polar products are also formed. These were identified as (5*S*,12*R*)-5,12-dihydroxy-(6*Z*,8*E*,10*E*,14*Z*)-eicosatetraenoic acid (major product), which was later termed leukotriene B_4, two additional (5*S*)-5,12-dihydroxy acids with (*E*,*E*,*E*,*Z*)-configuration (**4a**, **4b**), epimeric at C-12, and two isomeric 5,6-dihydroxy acids (**5a**, **5b**) with the same configuration of the 7,9,11,14-double bonds[7,8].

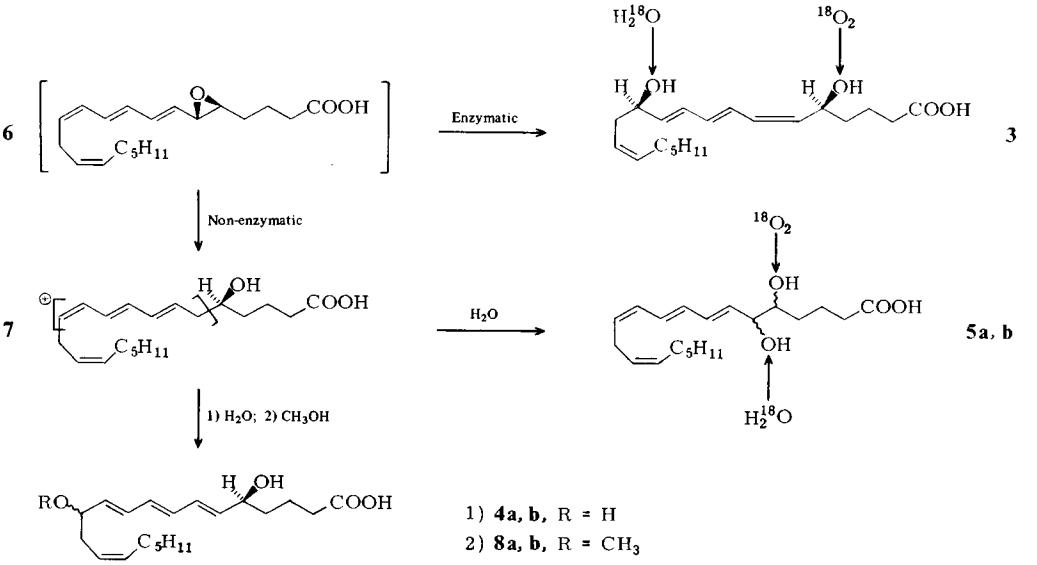
The occurrence of different double bond configurations in the products of the biological oxidation of arachidonic acid raised the question of the mechanism of their formation[8]. By means of ^{18}O labeling studies it could be demonstrated that the oxygen of the hydroxy group at C-5 originated from atmospheric O_2, whereas the oxygen of the hydroxy group at C-12 was derived from water[9]. On the basis of these observations, we postulated that the leukocytes generated an unstable intermediate which could undergo nucleophilic attack by water, alcohols, and other nucleophiles.



Rabbit PMNL were therefore incubated for 30 sec with arachidonic acid before addition of 10 times the volume of methanol or ethanol, or 0.2 volumes of 1 N hydrochloric acid. The products were analyzed by reversed-phase high performance liquid chromatography (RP-HPLC). The material formed upon trapping with methanol (or ethanol) contained two additional compounds (**8a** and **8b**) present in equal amounts in addition to compounds **2**–**5**. Their UV spectra indicated the presence of three conjugated double bonds, which were found to have an *E*-configuration as determined by IR spectroscopy. Gas chromatographic—mass spectrometric analyses of several derivatives of the two compounds showed that they were isomeric and carried hydroxy groups at C-5 and methoxy groups at C-12. Stereochemical analyses demonstrated that C-5 had an (*S*)-configuration. Although the configuration at C-12 was not determined it is clear that the compounds trapped with methanol are the C-12 epimers of (5*S*)-5-hydroxy-12-methoxy-(6*E*,8*E*,10*E*,14*Z*)-eicosatetraenoic acid. This indicated that a metabolite of arachidonic acid in leukocytes can undergo a facile nucleophilic reaction with alcohols. RP-HPLC analysis of samples obtained from trapping experiments performed under various conditions indicated that the amount of the 12-methoxy compounds **8a** and **8b** was always inversely proportional to the amount of 12-hydroxy acids **4a** and **4b**, thus suggesting that the latter are formed nonenzymatically from the same intermediate that gives rise to the alkoxy derivatives (cf. Scheme 1).

The stability of the intermediate was determined by incubating rabbit PMNL with arachidonic acid for 45 sec at pH 7.4 and 37 °C, suspending the resulting mixture in methanol and estimating the relative amounts of metabolites by RP-HPLC after various time intervals. The half-life of the intermediate was found to be 3—4 min. Simultaneously, the concentrations of compounds **4a**, **b**, **8a**, **b** and **5a**, **b** increased with time. The concentrations of **3** and **2** remained constant. This suggested that the other products are formed nonenzymatically by hydrolysis of a common unstable intermediate **6**, whereas **3** arises by enzymatic hydrolysis of the latter. Kinetic studies performed at various pH values indicated that the intermediate is acid-labile and is stabilized at alkaline pH.

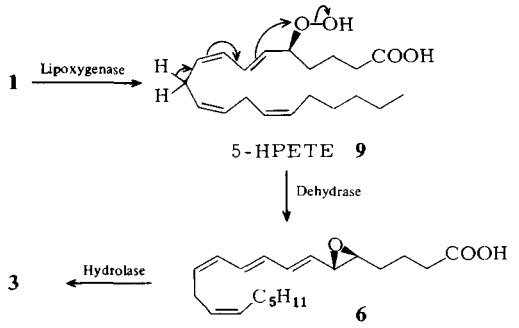
Based on these results, the structure (5*S*)-5,6-epoxy-7,9,11,14-eicosatetraenoic acid was proposed for intermediate **6**[9]. Hydrolysis of epoxides is acid catalyzed and opening of the rings of allylic epoxides is favored at allylic positions (C-6 in this case). This is consistent with the retention of ^{18}O at C-5 in the formation of the hydrolysis products **5a** and **5b** from the ^{18}O-labeled epoxide (formed by incubation of the leukocytes-arachidonic acid mixture with oxygen containing ^{18}O). The formation of all the hydrolysis products of the epoxide is shown in Scheme 1. Except for **3** these are formed by hydrolysis of the epoxide **6** *via* carbenium ion **7**. The latter adds hydroxyl anion preferentially at C-6 and C-12 to yield four isomeric products,



Scheme 1. Formation of dihydroxy derivatives from an unstable metabolite (epoxide **6**, LTA_4) of arachidonic acid.

which contain the stable conjugated triene structure. Compound **3** is formed enzymatically from the intermediate, since it has exclusively an (*R*)-configuration at C-12 and is only formed in nondenaturated cell preparations.

The pathway proposed for the biosynthesis of the epoxide **6** from arachidonic acid is shown in Scheme 2. It involves initial formation of 5-hydroperoxy-6,8,11,14-eicosatetraenoic acid (5-HPETE) **9**, from which the hydroxy compound **2** is formed by reduction. The epoxide **6** is formed from **9** by an intramolecular process, namely OH-elimination after abstraction of the proton at C-10, which is activated by two allyl groups.



Scheme 2. Formation of the unstable epoxide **6** (LTA_4) *via* the hydroperoxide **9** (5-HPETE).

The suggested structure of this 5,6-epoxide **6**, which is the same as that of leukotriene A_4 (LTA_4), has been confirmed by chemical synthesis whereby the stereochemistry was also elucidated[10]. The configuration of the three conjugated double bonds in leukotriene B_4 (LTB_4) was also determined using a synthetic approach[11]. LTA_4, the epoxide **6**, has recently been isolated from human polymorphonuclear leukocytes[12].

The recognition of the role of epoxide **6** in the transformation of arachidonic acid in leukocytes was a prerequisite for the work leading to elucidation of the structure and biogenesis of the "slow-reacting substance of anaphylaxis" (SRS-A)[9]. Thus, quantitative studies on the formation of the products of hydroxylation, **2** and **3**, from arachidonic acid by human PMNL demonstrated that the Ca-ionophore[*] A23187 stimulates the synthesis[13]. This was of particular interest since previous studies had shown that the ionophore also stimulates release of SRS-A from leukocytes[14]. Furthermore, the UV-absorption (λ_{max} about 270 nm) of the leukotrienes discovered in the leukocytes was similar to that reported for SRS-A[15,16]. The effects of the ionophore, the UV-absorbance data, and other considerations led us to develop the hypothesis that there was a biogenetic link between the unstable epoxide **6** and SRS-A[9].

3. Structure of the Slow-Reacting Substance of Anaphylaxis (SRS-A)

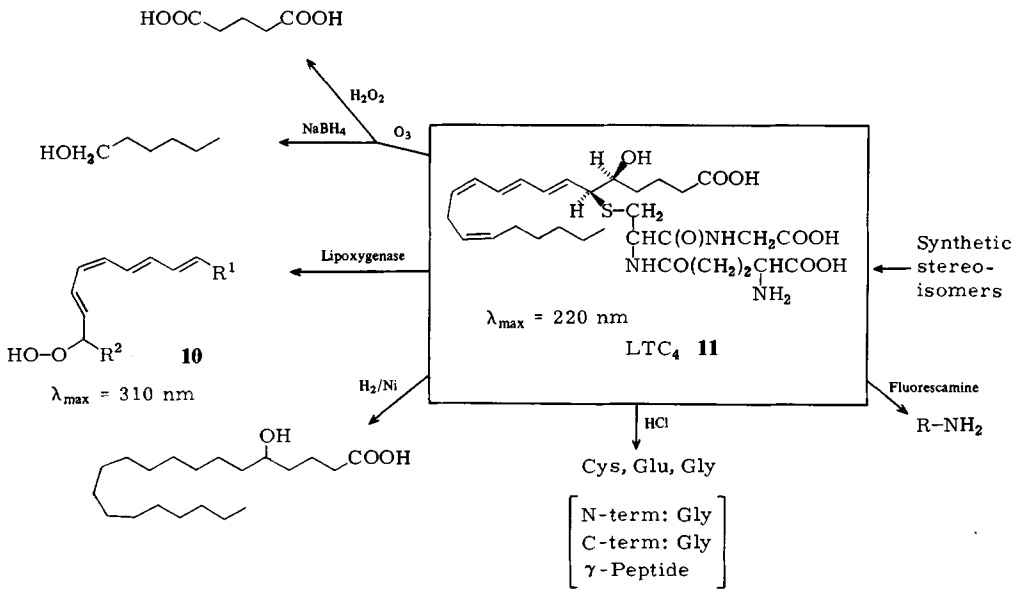
The term "slow-reacting substance" (SRS) was introduced in 1938 by *Feldberg* and *Kellaway* for a smooth muscle (guinea pig jejunum, part of the small intestine) contracting factor which appeared in the perfusate of guinea pig lung following treatment with cobra venom[17]. Subsequent studies have suggested that SRS is an important mediator in asthma and other types of immediate hypersensitivity reactions[18-21]. Immunologically released SRS is usually referred to as SRS-A (A for anaphylaxis), and is considered to be released together with other mediators (*e.g.* histamine and chemotactic factors) after interaction between immunoglobulin E (an antibody), bound to membrane receptors, *e.g.* to the bronchia, and antigens such as pollen *etc.* In the following, SRS and SRS-A are considered as practically identical. Previous structural work on SRS was severely limited by the difficulty in obtaining sufficient quantities of pure substance. However, it had been characterized as a polar lipid[16,22,23], possibly containing sulfur and having a UV spectrum with λ_{max} around 270 nm[15,16,24]. Studies with labeled arachidonic acid indicated that it was incorporated into SRS[25,26].

In preliminary studies employing different methods for production of SRS we found that murine mastocytoma cells treated with ionophore A23187 in presence of L-cysteine generated SRS in higher yields than previous procedures. This method also enabled formation of spasmogenic material antagonized by the SRS antagonist FPL 55712 and incorporation of isotopically labeled precursors[27]. The procedure used for isolation involved precipitation of protein with ethanol, alkaline hydrolysis, separation on Amberlite XAD-8 and silicic acid, and two steps of RP-HPLC. The material obtained by this procedure was essentially pure, showed a UV absorption maximum at 280 nm, and produced a characteristic contraction of guinea pig ileum which was reversed by FPL 55712[27]. The UV spectrum resembled those of the dihydroxy acids with three conjugated double bonds ($\lambda_{max} \approx 270$ nm) described in Section 2; however, the maximum was shifted 10 nm to higher wavelength. This is consistent with a sulfur substituent in the α-position to the conjugated triene. Experiments with labeled precursors showed that arachidonic acid and cysteine were incorporated into the products.

Degradation of SRS by desulfurization on Raney nickel afforded 5-hydroxyeicosanoic acid, which indicated that the arachidonic acid derivative and cysteine were linked by a thioether bond (cf. Scheme 3). The hydroxy group at C-5 in the fatty acid reinforced the hypothesis of a biogenetic relationship between the arachidonic acid metabolites and SRS, which we had found in leukocytes.

The positions of the double bonds in SRS biosynthesized from ^3H-labeled arachidonic acid were determined by reductive ozonolysis. This yielded [1-$^3H_1$] hexanol, demonstrating retention of the Δ^{14}-double bond of arachidonic acid. A unique method was used for locating the conjugated triene: Previous studies in our laboratory had shown that arachidonic acid and related fatty acids containing the homoconjugated system of two *cis*-double bonds at the terminal positions are peroxygenated by soybean lipoxygenase. Treatment of SRS with the lipoxygenase resulted in its conversion into the 15-hydroperoxide **10** of the conjugated tetraenoic acid, which was recognizable from a bathochromic shift of the UV maximum by 30 nm (Scheme 3). This indicated the presence of a Δ^{11}-(*Z*)-dou-

[*] Ionophores are molecules which channel ions, *e.g.* Ca^{2+}, through cell membranes.



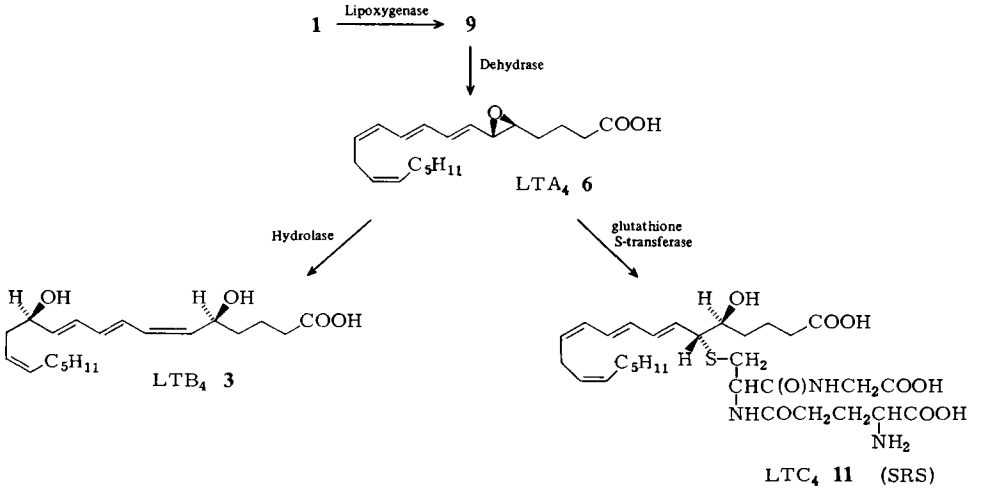
Scheme 3. Some reactions of SRS which account for its structure as leukotriene C_4 **11**.

ble bond and its conjugation with additional Δ^7- and Δ^9-double bonds. The structural studies at this stage showed that SRS was a derivative of 5-hydroxy-7,9,11,14-eicosatetraenoic acid with a cysteine-containing substituent linked in a thioether-manner at C-6.

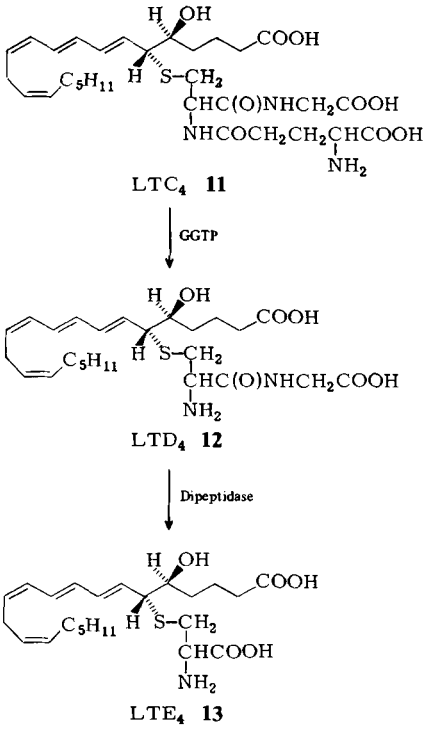
The fact that cysteine was bound was suggested by failure to isolate alanine after desulfurization. The cysteine-containing substituent was therefore referred to in the first publication as RSH[27-29]. Additional studies involving amino acid analyses of HCl-hydrolyzed SRS demonstrated that in addition to cysteine, glycine and glutamic acid were present in the ratio 1 : 1 : 1. The structure of the peptide, as determined by end group (dansyl method and hydrazinolysis) and sequence analyses (dansyl-Edman procedure), was γ-glutamylcysteinylglycine (glutathione). Accordingly, the structure of SRS obtained in murine mastocytoma cells from arachidonic acid and cysteine is 6-*S*-glutathionyl-5-hydroxy-7,9,11,14-eicosatetraenoic acid **11**, leukotriene C_4 (LTC_4)[30] (cf. Scheme 3).

The stereochemistry proposed for LTC_4 was confirmed and unambiguously assigned by its total synthesis, including preparation of stereoisomers, by *Corey et al.*[31]. The systematic name for LTC_4 is thus (5*S*,6*R*)-6*S*-glutathionyl-5-hydroxy-(7*Z*,9*Z*,11*E*,14*E*)-eicosatetraenoic acid. The previously proposed biogenetic relationship between the epoxide LTA_4 **6** and LTC_4 **11** has recently been confirmed by the conversion of synthetic LTA_4 into LTC_4 in human polymorphonuclear leukocytes[32]. The epoxide function of **6** is opened at the 6-position by the nucleophilic thio-function of glutathione to form a thioether (Scheme 4).

Note on Nomenclature: We chose the term "leukotriene" (LT), because the compounds were first detected in leukocytes and because their common structural feature is a conjugated triene[28]. Various members of the group have been designated alphabetically. Since the derivatives are formed not only from arachidonic acid (with 4 double bonds), but, in general, from C_{20}-fatty acids possessing the same 5,8,11-double bond system with more or less double bonds in the other half of the molecule, an additional numeration is needed[33]: referred to formula **6** LTA_n (n = 3, 4, or 5) are twofold to fivefold unsaturated 5,6-epoxy-7*Z*,9*Z*,11*E*-eicosanoic acids; LTB_n (5*S*,12*R*)-5,12-dihy-



Scheme 4. Formation of leukotrienes (LT) A_4, B_4, and C_4.



Scheme 5. Formation of leukotrienes (LT) D_4 and E_4.

droxy-(6*Z*,8*E*,10*E*)- (cf. **3**), LTC_n, (5*S*,6*R*)-6-*S*-glutathionyl-5-hydroxy-(7*E*,9*E*,11*Z*)-, LTD_n the corresponding *S*-cysteinylglycyl-, and LTE_n the simpler *S*-cysteinylpolyenoic C_{20} acids (cf. formulas **6**, **3**, **11**, **12**, and **13**, resp.).

The relationship of LTC_4, LTD_4 and LTE_4 is provided by the following observations. Studies with a different cell type, (rat basophilic leukemia cells, RBL-1), demonstrated that the major SRS species from this source was less polar than LTC_4 from leukocytes[34]. That the fatty acid part of this compound and LTC_4 were identical was indicated by their UV spectra, the products obtained after Raney nickel desulfurization, and the spectra changes observed after treatment with soybean lipoxygenase. Amino acid analyses, however, showed that the less polar product lacked glutamic acid. Edman-degradation indicated that glycine was C-terminal. Incubation of LTC_4 with γ-glutamyl transpeptidase (GGTP) provided additional proof for the structure. The product, the 6-*S*-cysteinylglycine compound LTD_4 (**12** in Scheme 5) was identical with the less polar product from RBL-1 cells. LTD_4 is more potent than LTC_4 in the guinea pig ileum bioassay and the contraction is faster[34].

The metabolism of LTC_3 has recently been studied using ^3H-labeled material of high specific activity, with the label in the fatty acid part of the molecule[35]. The results showed that guinea pig lung-homogenates rapidly converted LTC_3 to LTD_3. Liver and kidney homogenates did not catabolize LTC_3 appreciably. This was apparently due to high tissue concentrations of glutathione in the liver and kidneys. In accordance with these findings, labeled LTC_3 administered into the right atrium of male monkeys was rapidly transformed into LTD_3 and LTE_3[36]. The structures of leukotrienes have also been verified by chemical syntheses.

Leukotrienes have also been detected in the most varied of organs (Table 1). SRS-A is, therefore, a mixture of the sulfur-containing leukotrienes C_4, D_4, and E_4.

It has also been demonstrated recently that leukotrienes can be formed after initial oxygenation of arachidonic acid at C-15. Thus, the unstable 14,15-epoxy-5,8,10,12-eicosatetraenoic acid (14,15-LTA_4) is formed *via* the initially formed 15-hydroperoxide and is transformed into 14,15-dihydroxy-(14,15-LTB_4) and 8,15-dihydroxy-derivatives (8,15-LTB_4)[37,38]. A new isomer of LTB_4, (5*S*,12*S*)-5,12-dihydroxy-(6*E*,8*Z*,10*E*,14*Z*)-eicosatetraenoic acid, was recently isolated as a metabolite of arachidonic acid in human leukocytes[39]. This derivative is not formed *via* the leukotriene pathway and is therefore referred to as 5*S*,12*S*-DHETE.

4. Physiological Role of Leukotrienes

The "slow reacting substance of anaphylaxis" (SRS-A) has been characterized by some of its pharmacological effects. The classical contraction test on isolated guinea pig ileum relative to the analogous effect produced by histamine is a measure of the stimulating effect on smooth muscle, which is also responsible for the contraction of capillary blood vessels. An increase in the permeability of the blood vessels in guinea pig skin is recognized by the penetration of a dye into the tissue and formation of colored spots after the dye has been injected into the blood stream of the animal.

It has been suggested that SRS-A is an important mediator in asthma and other types of immediate hypersensitiv-

ity reactions. The pure leukotrienes LTC_4 and LTD_4 (0.1—1.0 nM) caused concentration-dependent contractions of guinea pig ileum[40]. It was found that on a mol/L basis, histamine was 200 times less active than LTC_4. Both leukotrienes also increased vascular permeability in guinea pig skin[40,41].

Comparative studies have indicated essential differences in the mode of action of the sulfur containing leukotrienes and LTB_4. Recent studies with the pure leukotrienes have provided more detailed information about the effects on the pulmonary and cardiovascular systems: the cysteine-containing leukotrienes have specific effects on the micro-circulation. LTB_4 influences leukocyte migration by causing leukocyte adhesion to the endothelium in post-capillary venules and by potent chemotactic effects. These results indicate that the leukotrienes might be of importance as mediators in host defense mechanisms, such as immediate hypersensitivity and acute inflammatory reactions.

When administered intravenously, both LTC_4 and histamine increase the tracheal insufflation pressure in anesthetized and artificially ventilated guinea pigs[40,41]. In this respect LTC_4 is at least 100 times as potent as histamine and causes a longer lasting increase in insufflation pressure. When administered as an aerosol, LTC_4 is at least 1000-fold more potent than histamine. The effects of LTD_4 and LTE_4 are practically identical to those of LTC_4. We have also recently studied the bronchoconstrictor activity of LTC_4 in artificially ventilated monkeys[42]. LTC_4 (20 nmol, 1 g) caused a severe bronchoconstriction, as evidenced by a marked rise in transpulmonary pressure and a simultaneous fall in the partial pressure of arterial oxygen. This lasted 45—50 min. The findings indicated that cysteinyl-containing leukotrienes preferentially affect the peripheral airways, as previously suggested for crude SRS-A.

Human and monkey airway preparations also contract when administered LTC_4[43]. Human bronchi were found to be particularly sensitive. LTC_4 elicited contractions in the same low-dose range as in guinea pigs and it was at least 1000 times more potent than histamine. Airway preparations from monkeys were less reactive to both substances, but LTC_4 elicited significant contractions in approximately 100 times lower concentrations.

When injected intradermally into guinea pigs, LTC_4 and LTD_4 mimic the effects of crude SRS-A by causing extravasation of Evans' blue[40,41]. We have recently studied the microvascular actions of leukotrienes *in vivo* in more detail using the hamster cheek pouch preparation[44] (Fig. 1). When applied topically to the cheek pouch for a 3 min period, LTC_4 and LTD_4 (in concentrations ranging between 0.3 and 20 nM) elicited an intense dose-dependent contraction in particular terminal arterioles. The vasoconstriction was short-lived, and it was consistently followed by a dose-dependent, reversible leakage of macromolecules, as indicated by extravasation of fluorescein-conjugated dextran. The plasma leakage induced by these leukotrienes appeared at postcapillary venules. LTC_4, LTD_4 and LTE_4 all induced a significant increase of vascular permeability at much lower concentrations than histamine: LTC_4 is approximately 5000 times more potent than histamine in this respect. Administration of a vasodilator together with leukotrienes potentiates the increase in plasma leakage caused by a submaximal dose of leukotrienes, as has been reported in guinea pigs for the prostaglandin PGE_2 and LTD_4[45], and in guinea pigs, rabbits and rats for PGE_2 and LTE_4[46,47]. However, macromolecular leakage induced by LTC_4 is not affected by indomethacin or mepyramine, indicating that leukotrienes, *per se*, are highly effective.

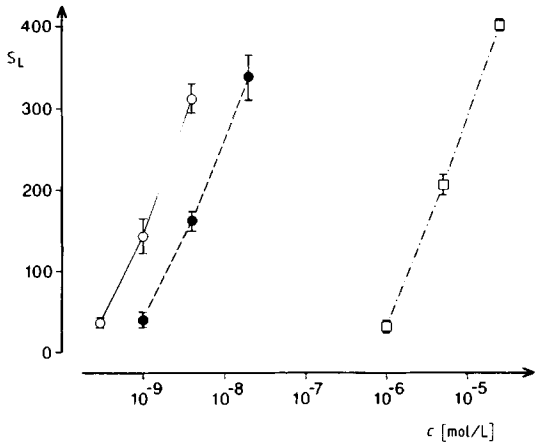

Fig. 1. Increase in vascular permeability of the hamster cheek pouch caused by leukotrienes (LTC_4 O—O, LTD_4 ●---●) and by histamine (□-·-□). S_L = number of plasma leakage outlets per cm^2.

Administration of LTB_4 to the hamster cheek pouch in the same dose-range as LTC_4 did not elicite vasoconstriction, and had no effects on plasma leakage. However, LTB_4 causes a dramatic increase in leukocyte adhesion to endothelium in small venules[44]. Upon addition of LTB_4, marginating leukocytes immediately started to roll slower and there was a pronounced increase in the number of leukocytes adhering to the endothelium. Increased adherence of human leukocytes caused by LTB_4 has also been demonstrated *in vitro* using a column of nylon fibers[48] (cf. Fig. 2).

The number of interstitial white cells increased during the superfusion with LTB_4 (6–10 min). This finding is consistent with the chemotactic stimulant property of LTB_4. The chemotactic effect of LTB_4 has been demonstrated, *in vitro*, using either the so-called Boyden chamber technique or migration under agarose[49–52]. This effect has been monitored, *in vivo*, by determining white cell accumulation in the peritoneal cavity of guinea pigs following intraperitoneal injection of LTB_4[53]. According to the results, LTB_4 might be a mediator in the migration of leukocytes from the blood to areas of inflammation. It is of interest in this context that the chemotactic peptide, formylmethionylleucylphenylalanine (fMLP) stimulates the formation of LTB_4 and other leukotrienes in human neutrophils[54].

Our results indicate that both leukotrienes and cyclooxygenase products of arachidonic acid, such as prostaglandins, are of importance in immediate hypersensitivity reactions and inflammation. The cysteine-containing leukotrienes, formed by another oxidation route, are potent stimulants of pulmonary smooth muscle with specific effects, *in vivo*, on peripheral airways. They also induce plasma leakage from postcapillary venules. These biologi-

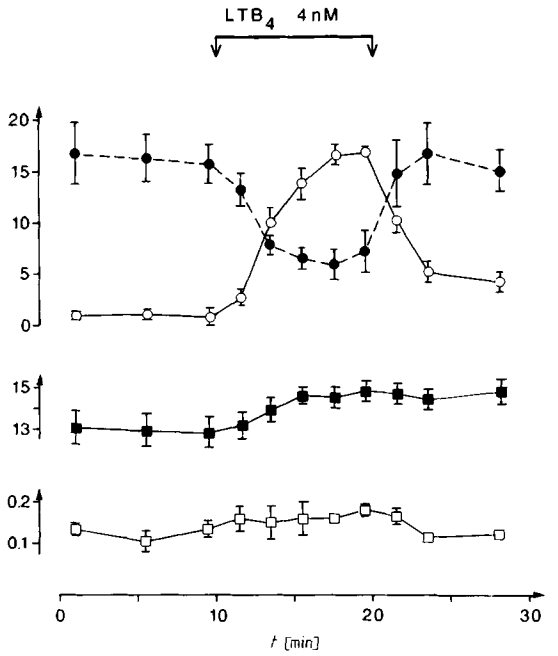

Fig. 2. Measurement of the activity of LTB_4 (4 nM) at a postcapillary venule of the hamster cheek pouch. Top: Leukocytes; number of cells marginating per minute (●) and number adhering to the endothelium (○). Middle: temporal change of the venule diameter (μm). Bottom: erythrocytes: velocity (mm/s).

cal effects indicate that they might function as mediators in airway and skin manifestations of immunological origin. However, the biological effects of these sulfur-containing leukotrienes and of LTB_4 indicate that they might be involved in inflammatory reactions of a more general character. The ability of LTB_4 to cause leukocyte adhesion to the endothelium in postcapillary venules and to stimulate leukocyte chemotaxis indicate that the leukotrienes participate in host defence reactions against various noxious stimuli. The combined effects of LTB_4 and LTC_4 and metabolites are reminiscent of the early phase of acute inflammation.

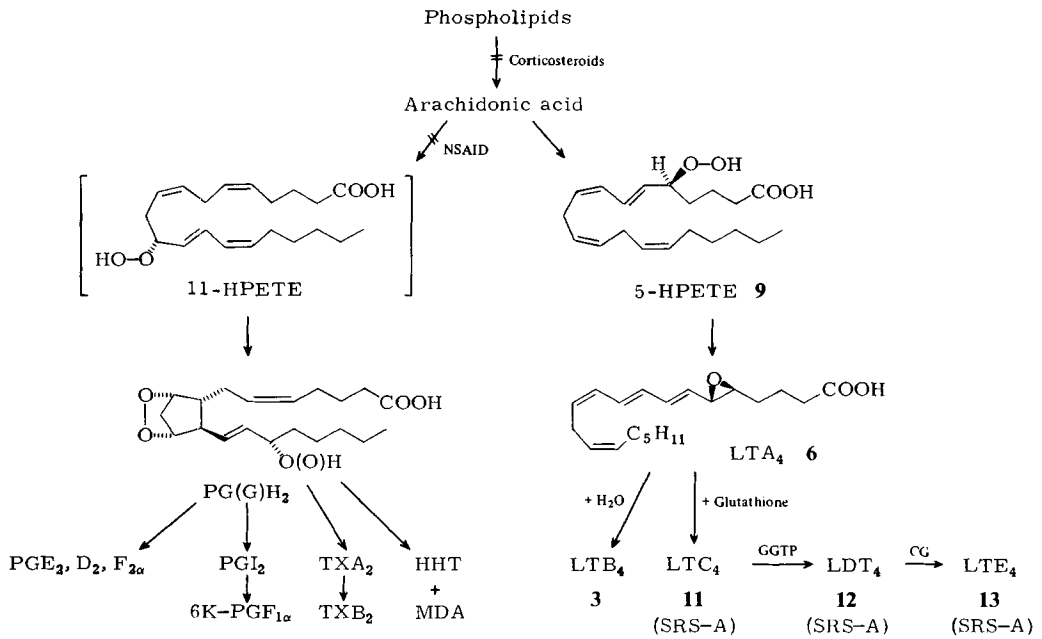
The leukotrienes and some metabolites resulting from the cyclooxygenase route from arachidonic acids have effects which are complimentary: prostaglandins, thromboxanes, prostacyclins. Hence the synergism between the leukotrienes, causing plasma leakage, and the vasodilators prostaglandin PGE_2 and prostacyclin PGI_2 might be of importance in the formation of oedema. Furthermore, synergistic effects between the leukotrienes, with bronchoconstrictor properties, and thromboxane A_2 are also conceivable. LTC_4 and LTD_4 cause release of TXA_2 in guinea pig lung[55]: TXA_2 is a potent constrictor of airways, and its release might contribute to the bronchospasm in allergic manifestations.

The interrelationship between the cyclooxygenase pathway (yielding prostaglandins and thromboxanes) and the leukotriene pathway is illustrated in Scheme 6.

Anti-inflammatory steroids prevent the release of the precursor arachidonic acid from the phospholipids of cell membranes, whereas cyclooxygenase inhibitors, such as aspirin, block the transformation of this acid into prostaglandins, thromboxanes, and prostacyclins. It has recently been proposed that anti-inflammatory steroids act by stimulating the synthesis of an inhibitor of phospholipase A_2[56,57]. By inhibiting the release of arachidonic acid, steroids prevent formation, not only of prostaglandins and thromboxanes, but also of leukotrienes and other oxygenated derivatives. The inhibition of leukotriene formation might be responsible for some of the therapeutic effects of steroids which are not shared by aspirin type drugs.

5. Outlook

The new knowledge about leukotrienes and their biochemical relatives[72] summarized in this article suggests



Scheme 6. Formation of prostaglandins (PG), thromboxanes (TX), prostacyclins (PGI_2), and leukotrienes (LT). NSAID: non-steroidal anti-inflammatory drugs; HHT: (12*S*)-12-hydroxy-(5*Z*,8*E*,10*E*)-heptadecatrienoic acid.

new possibilities for the development of novel and more specific therapeutic agents, particularly in diseases related to immediate hypersensitivity reactions and inflammation. Such drugs might be based on antagonism of end-products or inhibition of enzymes involved in the generation and further transformation of the key intermediate, LTA_4. Furthermore, compounds which have inhibitory effects involving both the cyclooxygenase pathway and the leukotriene pathway from arachidonic acid might be of significant importance.

The work form the author's laboratory was supported by the Swedish Medical Research Council (Project 03X-217).

$CrTe_3$—A Novel Transition-Metal Polytelluride

By *Kurt O. Klepp** and *Herbert Ipser*

We have been able to detect a previously unknown intermediate phase in the tellurium-rich field of the binary system chromium-tellurium[3]. This phase is formed in a peritectic reaction at 753 ± 3 K. Its composition, established as $CrTe_3$ from powder diffraction and thermoanalytical studies, indicated a polytelluride of chromium. Since higher polytellurides of 3d-elements were previously unknown, the structural characterization of this compound appeared to be particularly desirable. Single crystals for the structural investigation were obtained by annealing a stoichiometric mixture of the elements at 690 K for four months in the presence of Al_2Cl_6 and HCl as mineralizing agents.

As expected from its lamellar crystal habit, $CrTe_3$ crystallizes in a layered structure. Composite layers are formed (Fig. 1) which run parallel to the *bc*-plane. They consist of building groups of four edge-linked $CrTe_6$-octahedra which are connected according to $Cr_4Te_8Te_{8/2}$ *via* shared apical tellurium atoms to give a two-dimensional infinite arrangement. In addition these building groups are linked together *via* Te—Te bonds giving rise to the formation of Te_2 and Te_3 moieties. Only weak interactions, however, occur between the composite layers. $CrTe_3$ is a complex polyanionic compound which could be formulated ionically as $[Cr^{3+}]_2[Te^{2-}][Te_2^{2-}][Te_3^{2-}]$. The Te—Te distances of 282 pm are only slightly larger than the length of a Te—Te single bond (274 pm). The occurrence of Te_3-chains is surprising, since transition-metal compounds containing this polyanion were previously not known.

In common with the other chromium chalcogenides, whose structures can be derived from the NiAs-type, $CrTe_3$ shows octahedral coordination of the transition metal atom as well as the formation of close-packed chalcogen layers. These layers are slightly puckered and run—in contrast to the composite layers formed by chemical bonds—parallel to the *ac*-plane. Their stacking, however, no longer corresponds to a three-dimensional close-packing. This is due to the formation of the Te—Te bonds, which occurs between these layers and which causes them to be puckered. The Cr—Te distances (270—276 pm) are comparable with those in other chromium tellurides.

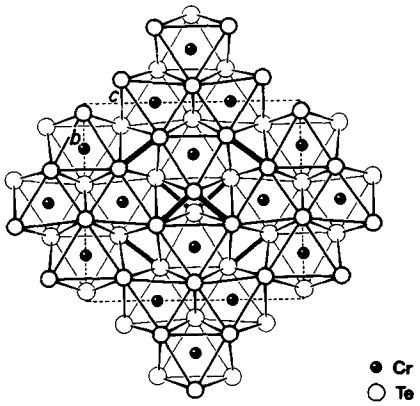

Fig. 1. Projection of the $^2_\infty[CrTe_3]$ composite layer on the *bc*-plane. Tellurium-tellurium bonds are indicated by thick lines. Crystallographic data: space group $P2_1/c$, $a = 788.7(6)$, $b = 1122(2)$, $c = 1156(1)$ pm, $\beta = 118.41(2)°$, $Z = 8$; $R = 0.054$, $R_w = 0.063$ (1063 reflections with $I > 3\sigma(I)$, 74 refined parameters). The Te—Te bond lengths are 281.6(3) pm for the Te_2 dumbbell, 281.7(3) and 282.4(3) pm for the Te_3 chains. The bond angle in the chain is 86.17(7)°. The Cr—Te distances lie between 270.0 (s) and 275.6(5) pm. Further details on the crystal structure determination can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50298, the name of the author and complete citation of the journal.

The building principle realized in the layered structure of $CrTe_3$ differs essentially from those of the previously known transition-metal trichalcogenides[12], which are predominantly formed by the elements of groups IVb and Vb. Here the transition metal atom is in a trigonal-prismatic environment; the polyanions are formed by chalcogen dumbbells which are coordinated "side on" to the transition-metal atom. In $CrTe_3$, however, as in pyrites, two homonuclearly bonded chalcogen atoms are coordinated to different transition metal atoms.

$CrTe_3$, apart from TiS_3[13] and VS_4[14], is the third higher polychalcogenide of a 3d-element whose crystal structure has been established. The formation of a metastable chromium polysulfide of composition Cr_2S_5 has been described[15]. A polytelluride of this stoichiometry is likely to exist as an equilibrium phase in the chromium-tellurium system[3]. Initial studies lead one to expect a close structural relationship to $CrTe_3$.

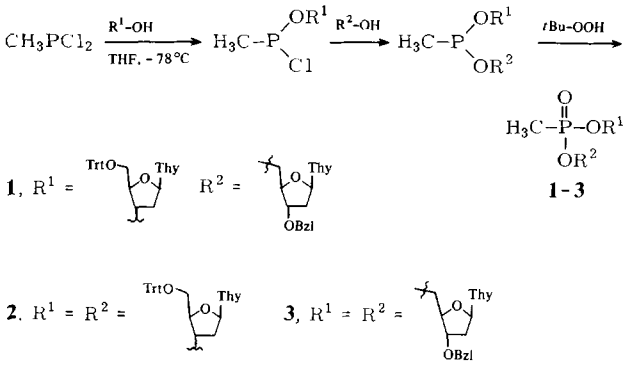
A Novel Synthesis of Nucleoside Methylphosphonates

By *Joachim Engels** and *Alfred Jäger*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Nonionic analogues of DNA are of interest in the study of DNA-DNA and DNA-protein interactions. In this connection, phosphonic acid esters of deoxyribonucleosides should be particularly suitable because of their chemical stability.

We report here a novel two-step route to nucleoside methylphosphonic acid esters, involving the direct synthesis of phosphonous acid esters and their subsequent oxidation[1]. Dichloro(methyl)phosphane is treated successively with two protected nucleosides in a one-pot reaction at −78 °C in tetrahydrofuran (THF). The resulting dinucleoside methylphosphonic acid diester is not isolated but oxidized to the corresponding methylphosphonate by addition of *tert*-butyl hydroperoxide (Scheme 1).



Scheme 1. Trt = trityl; Thy = thymine residue.

When CH_3PCl_2 is treated with two equivalents of 5′-*O*-tritylthymidine *or* 3′-*O*-benzoylthymidine, the symmetric 3′,3′- or 5′,5′-linked phosphonates **2** or **3** are accessible.

Reaction of 5′-*O*-tritylthymidine (R^1—OH) and 3′-*O*-benzoylthymidine (R^2—OH) with CH_3PCl_2 affords **1** (81%) with 3′,5′-methylphosphonate-internucleotide bonding. The 3′,3′-phosphonate **2** always occurs as a side product (8%), whereas formation of **3** (by reaction of 3′-*O*-benzoylthymidine with unconsumed CH_3PCl_2) can be avoided by using a slight excess (0.06 equiv.) of 5′-*O*-tritylthymidine.

1 consists of two diastereomers, which can be separated by thin layer chromatography: the P—CH_3 group exhibits two doublets in the ^{1}H-NMR spectrum. Although CH_3PCl_2 is not a sterically demanding reagent, the reaction nevertheless proceeds more stereoselectively than the synthesis of dinucleoside methylphosphonate derivatives by *Ts'o et al.*, which results in a 1 : 1.5 isomer ratio[2]; using the method described here we obtained the diastereomers of **1** in the ratio 4 : 1, whereby the major product is the isomer with the larger R_f value. Selectivity only occurs, however, when 5′-*O*-tritylthymidine is the first alcohol component. Each of the two isomers was converted into the corresponding dinucleoside methylphosphonate T*p*T[3] by debenzoylation with *tert*-butylamine and detritylation with $BF_3 \cdot OEt_2$. The NMR spectrum of the major deblocked product is identical with that of $(TpT)_1$, described by *Ts'o et al.*, and that of the other isomer with $(TpT)_2$[4].

The phosphonic acid ester intermediate also reacts smoothly with sulfur and selenium and, hence, opens up a route to the previously unknown thio- and selenophosphonate analogues. Because of the similarity with the phosphite method of *Letsinger et al.*[5], this synthetic route can also be combined with the Letsinger-DNA synthesis.

Novel Metastable Germanium Modifications *allo*-Ge and 4H-Ge from Li_7Ge_{12}

By *Andreas Grüttner, Reinhard Nesper*, and *Hans Georg von Schnering**

Dedicated to Professor Albrecht Rabenau on the occasion of his 60th birthday

A renewed investigation of the binary systems Li-Si[1] and Li-Ge[2,3] led to discovery of the phase Li_7Ge_{12}; it is formed as leaf-shaped metallic gray crystals on cooling a stoichiometric melt of the elements (Ta-crucible; ∅ up to 3 cm; $T_{max} = 1025$ K). The compound crystallizes orthorhombically with a structure (Fig. 1) containing a characteristic complex two-dimensional infinite polyanion $^2_\infty[Ge_{12}^{7-}]$[5]. One of the Li atoms is situated in a Ge cage, the other six are intercalated between the Ge layers [$Pmn2_1$ (No. 31); $a = 11.541(3)$, $b = 8.073(2)$, $c = 15.359(4)$ Å; $Z = 4$; 1788 *hkl*, $R = 0.07$]. The outstanding chemical property of Li_7Ge_{12} is the spontaneous evolution of H_2 on reaction with protic solvents, leading to topotactic formation of *allo*-germanium[5], a novel metastable Ge-modification[4]. The H_2 is extruded strictly parallel to the layers of the two-dimensional anion; at the same time, a linking of adjacent layers takes place with formation of a three-dimensional structure (Fig. 1). *allo*-Ge is formed in these reactions as gray shiny metallic frits or leaflets which can be ground like graphite. Single crystals of *allo*-Ge are formed on reaction of Li_7Ge_{12} single crystals with benzophenone in tetrahydrofuran, whereby strong topotactic demetalation of Li_7Ge_{12} leads to Li^+ and the radical anion of Ph_2CO. Mechanical strains in *allo*-Ge crystals are largely avoided under these mild conditions.

allo-Germanium is a diamagnetic semiconductor. It crystallizes orthorhombically with considerable stacking disorder [$Pmc2_1$ (No. 26): $a = n * 23.887(9)$, $b = 7.787(3)$,

$c = 16.304(5)$ Å; $Z = 128$]. The essential structural unit is the original two-dimensional polyanion of Li_7Ge_{12}, resulting from homonuclearly coupled four-, three- and two-bonded atoms of the type $(4b)Ge^0$, $(3b)Ge^{1-}$ and $(2b)Ge^{2-}$. The valences that become free on demetalation are saturated by new Ge—Ge bonds within the layers and between adjacent layers, so that only atoms of type $(4b)Ge^0$ are still present (Fig. 1).

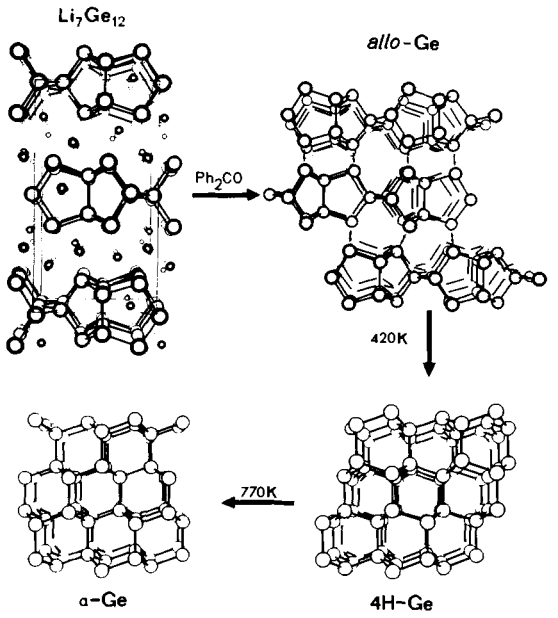

Fig. 1. Formation of the novel Ge modifications *allo*-Ge and 4H-Ge. *allo*-Ge (schematic) is formed in a strongly topotactic reaction from Li_7Ge_{12}; it is not converted directly into α-Ge, but firstly into 4H-Ge, which, so far, has only been obtained in this way. The slow transformation from the 4H-Ge into the α-Ge phase commences at 770 K.

On heating under inert conditions, *allo*-Ge is exothermally and irreversibly converted at 420 K into a further metastable Ge-modification. In this form, germanium crystallizes hexagonally with the known structure of the polymorphic compound 4H-SiC. The novel modification 4H-Ge[5] could previously be obtained only in the powdered form [$P6_3mc$ (No. 186); $a = 3.989$ Å, $c = 13.107$ Å; $Z = 8$; $c/a = 3.286$]. On further prolonged heating, the similarly exothermic conversion of 4H-Ge into the stable α-Ge commences at 770 K.

On rapid heating 4H-Ge melts at 1198 K, *i.e.* 10 K below αGe. The formation of *allo*-Ge from Li_7Ge_{12} encourages increased activity in the search for metastable forms of the elements.

Cyclobutadienes or Acetylenes from (2-Cyclopropen-1-yl)carbenes— A Question of Spin Multiplicity?**

By *Philipp Eisenbarth* and *Manfred Regitz**

Diazomethylcyclopropenes such as **1a**[1] or **1b**[2] are promising precursors for the synthesis of cyclobutadienes. Thus, on irradiation in pentane, they afford the tri-*tert*-butylcyclobutadienecarboxylates **5a**[1] (Table 1) and **5b**[2], respectively, together with the 3-hexyne **3** and the pentynoates **4a** and **4b**. The formation of alkynes in the photolysis of **1b**[2] was overlooked. In both cases, the ratio of cyclobutadiene formation to acetylene fragmentation is *ca.* 70:30 and is markedly dependent upon temperature and solvent.

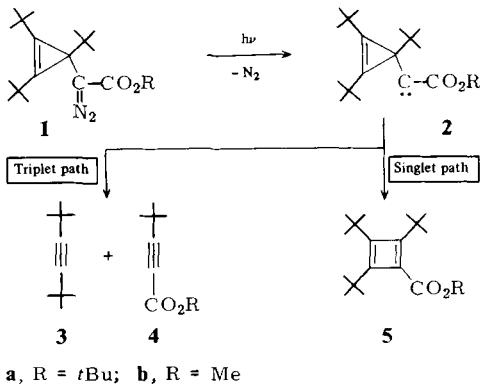

Table 1. (Selected data). Yields and physical and spectroscopic properties of **5a** and **6**.

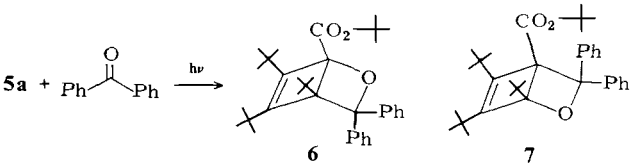
5a: 67%; orange crystals; m.p. = 56—57 °C; b.p. = 155—156 °C/0.1 torr; ^{1}H-NMR ($CDCl_3$): $\delta = 1.14$ (s, 18H), 1.16 (s, 9H), 1.46 (s, 9H)
6: 20%; colorless crystals; m.p. = 175—177 °C; ^{1}H-NMR ($CDCl_3$): $\delta = 0.87$, 1.15, 1.31, 1.44 (in each case s, in each case 9H), 7.10—8.20 (m, 10H)

What is the reason for this diversion in reaction behavior? By analogy to the Wolff rearrangement[3], singlet-**2** should rearrange (**2** → **5**) and triplet-**2** ought to fragment (**2** → **3** + **4**)[4]. Sensitization of the reaction with benzophenone should decisively influence the product ratio. The experiment with **1a** confirms this supposition (**5a** : **3** + **4a** = 20 : 70, 10% unidentified products). In any case, the excess of sensitizer reacts with **5a** in a [2 + 2]-cycloaddition to give the 2-oxabicyclo[2.2.0]hex-5-ene derivative **6** (7%)[5] (*Table 1*). *To our knowledge photochemical cycloadditions of cyclobutadienes have so far never been reported in the literature.*



The question as to whether **3** and **4a** could also be formed from **5a** by benzophenone-sensitized photolysis

[**] Carbenes, Part 29. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 28: [1].

can be answered in the negative. Under these conditions only the previously mentioned cycloaddition of the sensitizer is observed (20%); it does not take place if one forgoes the irradiation.

[4] There are only few confirmed examples of this reaction; *e.g.* a) M. Regitz, A. Heydt, B. Weber, *Angew. Chem. 91* (1979) 566; *Angew. Chem. Int. Ed. Engl. 18* (1979) 531; b) G. Maier, M. Hoppe, H. P. Reisenauer, C. Krüger, *ibid. 94* (1982) 445; *21* (1982) 437; *Angew. Chem. Suppl. 1982*, 1061.
[5] That the cycloaddition takes place at the electron-deficient double bond is revealed by the spectroscopic data of **6**. Evidence against the reversed orientation of the reaction partners in the cycloaddition (formation of **7**) is provided by the fact that a *tert*-butyl group is shifted markedly upfield ($\delta = 0.87$, anisotropic effect of a phenyl ring).

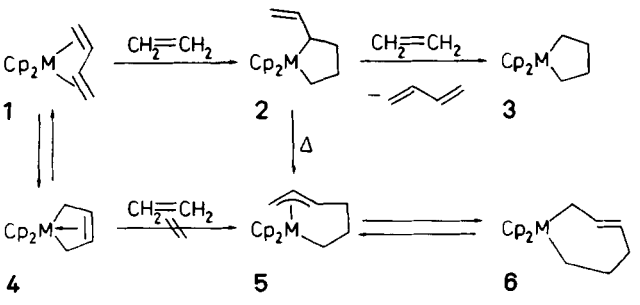
The Reaction of (Butadiene)zirconocene and -hafnocene with Ethylene**

By *Gerhard Erker**, *Klaus Engel*, *Ulrich Dorf*, *Jerry L. Atwood*, and *William E. Hunter*

In the coupling of olefinic substrates on early transition metals, reaction mechanisms *via* metallacycles can be favored over the conventional olefin-insertion mechanisms[1b]. Such likely competition should lead to (*s-trans*-butadiene)metallocene **1** and (*s-cis*-butadiene)metallocene **4**—isomers with markedly different σ-complex character[2]—exhibiting different reaction behavior towards ethylene.

We have now found that in the equilibrium mixture **1a** ⇌ **4a**, exclusively (*s-trans*-η^4-butadiene)zirconocene **1a** reacts with ethylene under mild conditions; the zirconacyclopentane **3a**[5] and (1-3:6-η-hexenylene)zirconocene **5a** (Fig. 1) are formed in a ratio which is temperature-dependent.

(*s-cis*-Butadiene)hafnocene **4b** does not react with ethylene at temperatures up to 120 °C. On the other hand, **1b** already reacts at −10 °C with ethylene in a 1:1 ratio to give the cyclic σ-allyl complex **2b**[6]. At room temperature, further reaction with ethylene leads to formation of **3b**[5b] and liberation of butadiene. At 25 °C, **2b** rapidly rearranges to the isomeric π-allyl complex **5b** in the absence of ethylene.



a, M = Zr; **b**, M = Hf; Cp = η^5-C_5H_5

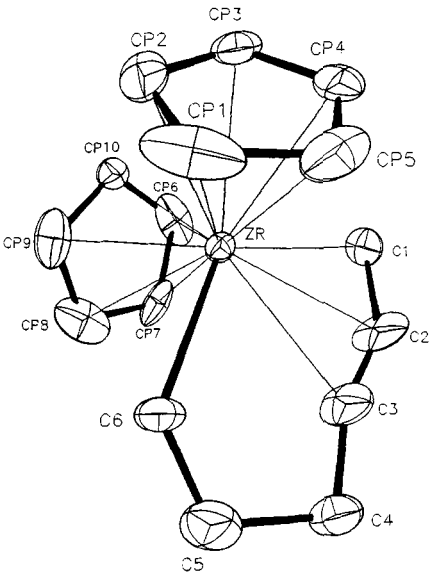

Fig. 1. Structure of **5a** in the crystal. Most important bond lengths: Zr—C1 246(1), Zr—C2 248(1), Zr—C3 264(1), Zr—C6 241(1), Zr—C_{Cp} (mean value) 251(3) pm.

The dynamic NMR spectra of the π-allyl complexes indicate equilibration with the σ-allyl compounds **6**. From the coalescence of the Cp resonances in the ^{1}H-NMR spectrum, a Gibbs activation barrier of $\Delta G^{\ddagger}_{50\,°C}(\mathbf{5b}) = 17.6$ kcal mol^{-1} [$\Delta G^{\ddagger}_{114\,°C}(\mathbf{5a}) = 21.0$ kcal mol^{-1}] has been determined for the automerization of **5** *via* **6**.

The finding that **5** is not accessible from **4** by direct insertion of ethylene but only from **1** *via* intermediate **2** demonstrates that a mechanism involving a metallacycle can also supersede the "classical" insertion mechanism in the coupling of ethylene with butadiene[8].

Catalyst Deactivation during Zirconocene- and Hafnocene-Induced Ethylene Dimerization**

By *Ulrich Dorf*, *Klaus Engel*, and *Gerhard Erker**

The factors leading to the termination of catalytic reaction cycles are generally very difficult to assess due to the

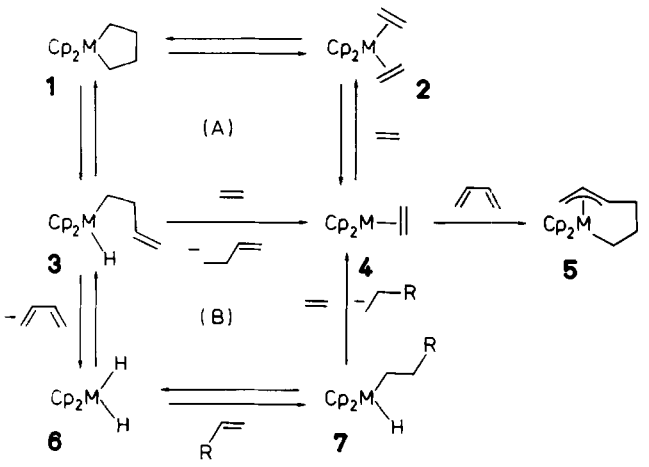
[*] U. Dorf, K. Engel, Priv.-Doz. Dr. G. Erker
Abteilung für Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (Germany)

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.

comparatively small amounts of active catalyst relative to other participating components. Zirconocene- and hafnocene-induced ethylene dimerization now provides a system in which the course of stoichiometric consumption of the catalyst can be monitored, because of comparable rates of propagation and termination of the chain.

When a solution of the zirconacyclopentane **1b** in ethylene-saturated toluene is heated to 60 °C, consumption of the olefin takes place slowly (≈1 equiv./Zr in 3 h). As organic products, 1-butene and ethane are formed at first, then on prolonged reaction, increasing amounts of *n*-butane. After 24 h at 60 °C there results a mixture of *n*-butane (0.94 equiv./Zr), 1-butene (0.66), and ethane (0.06). After this period of time the metal-induced transformation of ethylene has come to an end. The metallacycle **1b** has been quantitatively converted into the catalytically inactive (1—3:6-η-hexenylene)zirconocene **5b**[3]. A similar mixture is obtained on reaction of the oligomeric hydride $(Cp_2ZrH_2)_x$ with ethylene.

5b, which can be regarded as the product of the linkage of ethylene with butadiene on the zirconocene moiety, is formed in good yields under mild conditions, not only on reaction of (*s-trans*-η⁴-butadiene)zirconocene and ethylene[3], but also on reaction of the zirconacyclopentane **1b** or $(Cp_2ZrH_2)_x$ with butadiene.



a, M = Ti; **b**, M = Zr; **c**, M = Hf; Cp = η⁵-C_5H_5

The dimerization of ethylene induced by metallacyclopentane **1** can readily be explained in terms of a reaction sequence involving β-hydride elimination to give **3**, followed by reductive elimination to give **4**. Further reaction of **4** with ethylene leads to regeneration of the starting material **1** *via* the intermediate **2** (catalysis cycle (A)).

n-Alkanes are presumably formed by a competing reaction sequence starting with a further β-hydride elimination from **3**, affording butadiene, and leading to **6**[7]. After hydrogenation of alkene present in the solution by the hydride complex **6**, **4** is generated *via* **7**. According to our observations it may be assumed that the (olefin)metallocene complex **4** is very efficiently trapped by the butadiene formed in reaction cycle (B) with formation of the catalytically inactive **5**.

A corresponding reaction mechanism is observed in the case of the markedly less reactive hafnocene system. **1c** reacts with butadiene at 90 °C to give **5c**[3] and ethylene. At 110 °C, a slow dimerization of ethylene induced by **1c** can be observed. Thereby, a notable amount of **5c** is formed. Accordingly, in this system also, the active catalyst is consumed by a trapping reaction with a direct product of the reaction cycle[11].

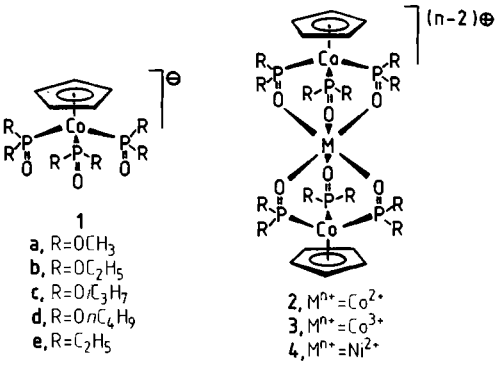
[11] In contrast to **1b** and **1c** the titanacyclopentane **1a** does not react with butadiene to give **5a**. With ethylene, a slow thermally induced reaction is in fact observed, but in competition a rapid unspecific decomposition of **1a** takes place (*ca.* 95% decomposition in ethylene-saturated toluene solution after 30 min at 70 °C). The resulting C_4 fraction (≈1.5 equiv./Ti) consists of *n*-butane (7.0%), 1-butene (15.4%), *cis*- and *trans*-2-butene (46.0%), and butadiene (31.6%); cf. G. P. Pez, *J. Chem. Soc. Chem. Commun. 1977*, 560.

Steric and Electronic Control of Ligand Field Strength in Octahedral Co^{3+} Spin-Crossover Complexes**

By *Werner Eberspach, Nabil El Murr,* and *Wolfgang Kläui**

In octahedral transition-metal complexes with d^4, d^5, d^6, or d^7 electron configuration a thermal equilibrium between the low-spin and high-spin form can be observed if the condition ligand field splitting ≙ spin pairing energy is fulfilled. All previously known Co^{3+}-d^6 complexes—with exception of the magnetically normal CoF_6^{3-} ion—are present in the diamagnetic "low spin" form. Recently, we were able to synthesize the organometallic oxygen ligand **1b**, which is weak enough and sufficiently hard[1] to induce a spin equilibrium in a Co^{3+} complex[2]. We have now found that the spin equilibrium can be so controlled by variation of the substituents R that at room temperature completely diamagnetic through to essentially paramagnetic Co^{3+} complexes of type **3** can be obtained. The synthesis of the Co^{3+} complexes **3a—e** was achieved by oxi-



dation of the Co^{2+} compounds **2a—e**—either electrochemically[3] or by means of tri(*p*-bromophenyl)ammoniumyl radical cations. Compounds of the cations **3a—d** (*e.g.* ClO_4- or PF_6-salts), which are dark green at room tempera-

ture, turn bright yellow on cooling, and *vice versa, i.e.* they are thermochromic. **3e** is yellow and shows no thermochromism. The change in color of the Co^{3+}-complexes with decreasing temperature is accompanied by a decrease in paramagnetism.

The magnetic moments of **3a—d** in the solid state lie between 1.2 and 5.3 μ_B at 300 K and between 0.3 and 0.9 μ_B at 4 K. In this temperature range, **3e** is diamagnetic. The change in low spin-high spin equilibrium with temperature can be followed in solution by ^{31}P-NMR spectroscopy (Fig. 1). Optimized thermodynamic parameters ΔG^0, ΔH^0, and ΔS^0 for the low-spin→high-spin transition can be determined from the measurements if the following temperature-dependence of δ is assumed[4] (Table 1):

$$\delta = \frac{C}{T(1+e^{\Delta G/RT})} + \delta_{ls}$$

Table 1. Equilibrium constants and thermodynamic parameters for the low-spin→high-spin transition in **3a—d**.

		3a	3b	3c	3d
ΔH^0	[kJ/mol]	25.1	24.8	14.1	23.3
ΔS^0	[J/mol K]	69	73	56	66
ΔG^0_{300}	[kJ/mol]	4.4	2.9	−2.7	3.5
K_{300} =	[hs]/[ls]	0.17	0.31	2.95	0.25
high spin fraction [%] at 300 K		15	24	75	20

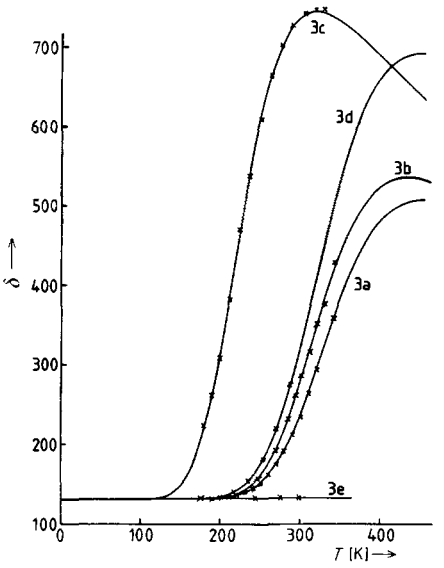

Fig. 1. Temperature dependence of the ^{31}P-NMR shift of **3a—e**, measured (×), and, in the case of **3a—d**, calculated using the parameters quoted in Table 1 (solvent: CD_2Cl_2/CD_3COCD_3).

The phosphinito complex **3e** is apparently diamagnetic over the whole temperature range under study. In contrast, in the case of the phosphito-complexes **3a—d** a temperature-dependent spin-equilibrium of the form $^5T_2(O_h) \rightleftharpoons {}^1A_1(O_h)$ at the central Co^{3+} is observed. The reason for this difference in behavior can be ascribed to the opposing inductive influences of the substituents R. Owing to the +I effect of the ethyl substituents, the two tripod ligands **1e** in the Co^{3+}-complex **3e** give rise to greater ligand-field splitting than the alkoxy-substituted ligands **1a—d** in **3a—d**. In the case of the phosphito complexes **3a—d** the high-spin/low-spin ratio increases markedly in the series R = OMe < OEt ≈ OBu ≪ O*i*Pr. This finding can be explained in terms of the increasing steric crowding of the ligands **1** in the Co^{3+}-complex **3**. The inter-ligand interactions due to this steric overcrowding lead to longer metal-donor atom bonds on going from **3a** to **3c**, and thus to diminishing ligand-field splitting[5]. This explanation is confirmed by the electronic spectra of the Co^{2+}-complexes **2a—d** and of the Ni^{2+}-complexes **4a—d**.

The magnetic measurements are consistent with the ligand-field spectra regarding the tripod ligands **1a—e**: The ligands **1a—d** are so weak and hard that an equilibrium exists between the d^6 high-spin and low-spin electron configuration in the Co^{3+}-complexes **3a—d**. The position of this equilibrium can be controlled to a large extent by the steric bulkiness of the alkoxy substituents. Ethyl substituents, on the other hand, make **1e** a distinctly stronger ligand than **1a—d**, for electronic reasons. The Co^{3+}-complex **3e** exists exclusively in the diamagnetic low-spin configuration. The steric and electronic effects of the substituents R in **1** thus allow a systematic fine tuning of ligand field strength in this novel class of oxygen ligands.

[4] This equation implies that the high-spin and low-spin forms are in rapid equilibrium on the NMR time scale and can be described in terms of a Boltzmann distribution. Moreover, it is assumed that the chemical shift of the low-spin species δ_{ls} is temperature-independent and that the paramagnetism shows a temperature dependence according to the Curie law (see [2]).
[5] Depending upon the model under consideration the theoretically expected dependence is $\Delta \approx 1/r^{5-6}$. See, *e.g.*, H. L. Schläfer, G. Gliemann: *Einführung in die Ligandfeldtheorie*. Akademische Verlagsgesellschaft, Frankfurt/M. 1967, p. 66.

Chloro(phenoxy)carbene—A Nucleophilic Carbene having Temperature-Dependent Selectivity**

By *Wolfgang Brück* and *Heinz Dürr**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Carbenes normally react as electrophiles. Electron donor substituents or coupling of the carbene center to a $(4n+2)\pi$ system leads to nucleophilic carbenes. Positive reaction constants for the Hammett correlation were obtained for the addition of such intermediates to substituted isocyanates, whereas the Moss technique for the experimental determination of the m-parameter for carbene additions failed here[6,7]. The Moss-Mallon equation predicts that CF_2 (m = 1.48) has electrophilic, CH_3OCCl (m = 1.59) ambiphilic, and chloro(phenoxy)carbene **2** either electrophilic or ambiphilic character (**2**; $m_{calc.} = 1.49$).

We have now studied the selectivity of **2** using the styrene technique[5] and report on 1) the addition of **2** to styrenes, 2) the determination of reaction constants, and 3) their temperature dependence.

[*] Prof. Dr. H. Dürr, W. Brück
FB 14—Organische Chemie der Universität
D-6600 Saarbrücken (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

α-Elimination of HCl from α,α-dichloroanisole **1** proceeds even at room temperature under phase transfer catalysis conditions with NaOH in presence of benzyltriethylammonium chloride (Fig. 1).

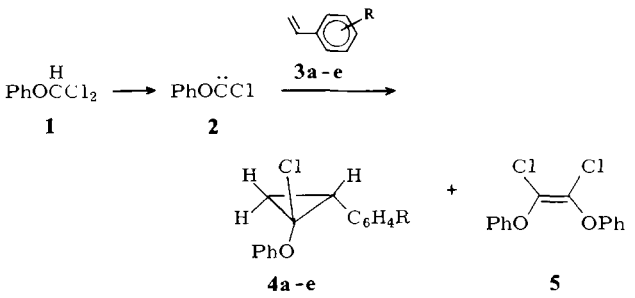

Fig. 1. **a**—**e**, see Table 1/2.

Reaction of **1** with the styrenes **3a**—**e** yields the cyclopropanes **4a**—**e** and the dimer **5** after chromatographic work-up. Products resulting from insertion into the olefin or aryl C—H bonds could not be detected.

The relative rate constants k_{rel} were determined by allowing **2** to react with styrene **3a** and a substituted styrene, **3b**—**e**, (molar ratio 1:5:5) at constant temperature; the values, which were obtained by gas chromatography, were evaluated using pseudo first order kinetics [eq. (1), simplified to (2)].

$$k_{rel} = \frac{k_B}{k_A} = \lg \frac{[B_0]/[B]}{[A_0][A]} \quad (1) \qquad k_{rel} = \frac{[B]}{[A]} \quad (2)$$

The selectivity of **2** is strongly temperature-dependent, and is consistent with the results of *Giese et al.*[13] for other carbenes. The reaction constants shown in Table 1/2 were obtained by plotting $\lg k_{rel}$ as a function of the Hammett σ-values (Fig. 2). The correlation coefficients lie between 0.98 and 0.99.

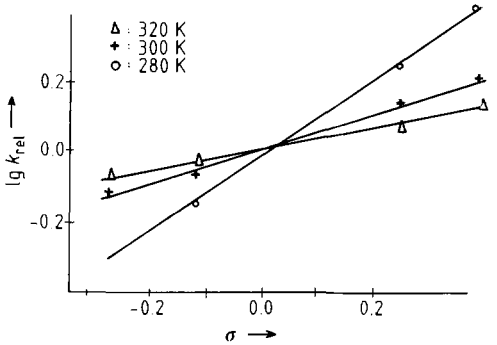

Fig. 2. Hammett correlation for the addition of **2** to styrenes **3**.

Table 1/2 (Selection). Yields [a] of cyclopropanes **4**, relative rate constants k_{rel} and ρ-values [k(**4a**, R = H) ≡ 1].

R		Yield 4 [%]	k_{rel} 280 K	300 K	320 K
p-OCH_3	*E*-**4b**	8	0.42	0.74	0.83
p-CH_3	*E*-**4c**	11	0.68	0.88	0.91
p-Cl	*E*-**4d**	6	1.77	1.12	1.02
m-Br	*E*- + *Z*-**4e**	7	2.39	1.53	1.24
ρ			1.11	0.40	0.23

[a] GC: 10% SE 30, Chromosorb PAW, 1.5 m, T = 190 °C.

The positive reaction constants prove that **2** is a nucleophilic carbene. According to MINDO/3 calculations on similar systems the electron density at the carbene center is certainly reduced by electron acceptor substituents, however, the resonance contribution of the lone pairs of electrons on oxygen produces an internal balancing of charge which leads to increased electron density in the p^0 orbital of the carbene. In contrast to chloro(phenyl)carbene[16a, 17], in **2** the temperature dependence of the selectivity is normal: *lowering* the temperature increases the *selectivity*.

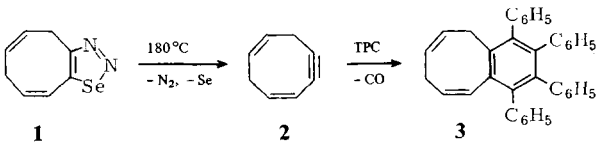
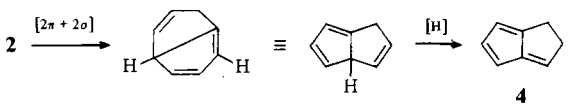
1,2-Dihydropentalene from 1,6-Cyclooctadien-3-yne**

By *Norbert Hanold, Thomas Molz,* and *Herbert Meier**

Cyclooctadienynes are highly strained hydrocarbons of the C_8H_8 series[1]. Their kinetic stability is essentially determined by thermal isomerizations on the C_8H_8 energy hypersurface[2]. Whereas 1,5-cyclooctadien-3-yne and 1,3-cyclooctadien-6-yne can be prepared in pure form, 1,3-cyclooctadien-5-yne is accessible only in solution. The latter, is also true for the 1,6-cyclooctadien-3-yne **2**, which can be obtained from the selenadiazole **1**[3].



In presence of tetraphenylcyclopentadienone (TPC), the trapping product **3** (m.p. = 217 °C) is formed in good yields. The preparation of pure **2** is thwarted by rapid isomerization to 1,2-dihydrocyclobutabenzene and styrene (22:78). On the other hand, under flash thermolysis conditions (450—640 °C, 0.3 torr) the 1,2-dihydropentalene **4**, first obtained by *Kaiser* and *Hafner*[6], is isolated as the main product.



The flash thermolysis of **2**, 1,3-cyclooctadien-5-yne, and 1,3-cyclooctadien-6-yne led to the following ratios of **4**,

1,2-dihydrocyclobutabenzene, and styrene: 60:3:37, 0:9:91, and 0:0:100, respectively.

1,2-Dihydropentalene **4** was identified and characterized, *inter alia*, by the 100.62 MHz ^{13}C-NMR spectrum [δ = 23.1 (C-1), 40.7 (C-2), 111.9 (C-6), 114.5 (C-4), 142.2 (C-3, C-5), 151.3, 153.9 (C-3a, C-6a)].

In order to confirm the assignment of the ^{1}H-NMR signals, double resonance experiments were carried out at 400 MHz. The signals appearing at highest field are H-1 (δ = 2.66) and H-2 (3.10). The olefinic protons H-6, H-4, H-3, H-5 give highly split multiplets at δ = 5.95, 6.21, 6.83, and 6.90, respectively. The coupling behavior in this AA'BB'WXYZ system is very complex owing to long-distance couplings.

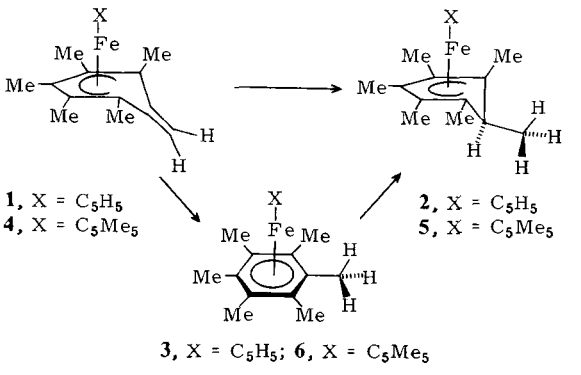
Cyclopentadienyl(peralkylarene) iron(I) Complexes as H Atom Reservoirs: Isolation of Semihydrogenated Species in the Pd/C Catalyzed Hydrogenation of Cyclopentadienyliron(II) Complexes of Exocyclic Olefins**

By *Pascal Michaud* and *Didier Astruc**

Concerted dihydrogen transfer in the heterogeneously catalyzed hydrogenation of olefins has been generally accepted for several decades[1a]. In some cases, however, the intermediacy of semihydrogenated species has been proposed on the basis of the stereochemistry of the reduction products, although they have never been isolated nor characterized spectroscopically[1b].

We report that stepwise double H atom transfer can occur when semihydrogenated species are stabilized.

The Fe^{II} complex $CpFe^{II}(\eta^5\text{-}C_6Me_5CH_2)$ **1**[2], in which neither of the olefinic C atoms is coordinated to the metal is hydrogenated by H_2/Pd/C to give **2** under ambient conditions in 2 h[2b,c]. The semihydrogenated Fe^I intermediate **3**[3] is a good candidate for the characterization of a stepwise double H atom transfer mechanism, since it bears one electron in an antibonding orbital of relatively low energy: **3** is stabilized by permethylation of the benzene ring. When **1** is hydrogenated (5% Pd/C, toluene, 20 °C, 1 bar H_2) the deep green color of **3** appears after 15 min; filtration and removal of the solvent *in vacuo* gives a black-green powder. The mass spectrum (*m/z* 283.114 M^+) and the Mössbauer doublet (IS = 0.73 mm s^{-1}; QS = 0.50 mm^{-1}) are characteristic of **3**[3]. From the Mössbauer absorption factors[4] of **1**, **2**, and **3** the relative abundance of **3** in the mixture is found to be 62.5%. The hydrogenation was also monitored by IR spectroscopy (decrease of the C=C band at 1660 cm^{-1} for **1** and the increase of the *exo*-stretching band at 2750 cm^{-1} for **2**). The maximum concentration of the Fe^I intermediate **3** is obtained after 20 min (Fig. 1). The second step, **3**→**2**, can also be effected starting with crystalline **3**[3b] under the same conditions: this is an oxidation of the metal $Fe^I \rightarrow Fe^{II}$ by H_2 whereas the first H atom transfer is a reduction $Fe^{II} \rightarrow Fe^I$.



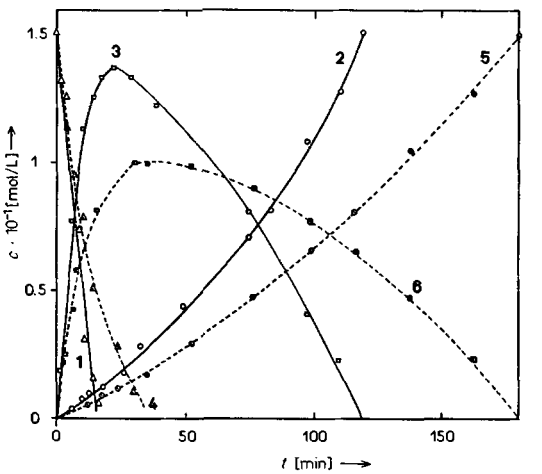


Fig. 1. Pd/C hydrogenation of **1** to **2** *via* **3** (—) and of **4** to **5** *via* **6** (---) at 20 °C; concentrations *c* followed by IR spectroscopy.

Like **1**, the pentamethylcyclopentadienyl analogue **4**[2c] is reduced to **5**[2c] *via* the intermediate **6**[3b] (Fig. 1). Finally the ethyl compound **7**[2c] reacts (5% Pd/C, 20 °C, 1 bar H_2, $t_{1/2}$ = 8 h) to give exclusively the d^7 complex **8**[3b] (Cp = η^5-C_5H_5).

$$CpFe^{II}(\eta^5\text{-}C_6Et_5CHMe) \underset{O_2(-H\cdot)}{\overset{H_2(+H\cdot)}{\rightleftharpoons}} CpFe^{I}(\eta^6\text{-}C_6Et_6)$$
7 **8**

Cleavage of H_2 upon hydrogenation can be homolytic or heterolytic[5], but in all known cases an H atom is transfered to a metal.

The complexes **3**, **6**, and **8** are not only reservoirs for electrons but also for H atoms. It should be noted that the exocyclic olefins **1**, **4**, and **7** are obtained from **3**, **6**, and **8** by H atom abstraction by O_2.

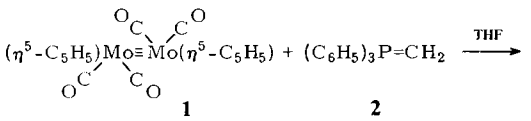
A μ_2-η^2-Styryl Complex by Reaction of $Cp_2Mo_2(CO)_4$ with the Wittig Reagent $(C_6H_5)_3P{=}CH_2$**

By *Klaus Endrich, Richard Korswagen, Thomas Zahn,* and *Manfred L. Ziegler*

Dedicated to Professor Georg Wittig on the occasion of his 85th birthday

$Cp_2Mo_2(CO)_4$ **1** reacts with nucleophiles as well as with electrophiles with formal addition to the MoMo triple bond[1]. Diphenyldiazomethane[2] and diazocyclopentadiene[3] also react with **1**, with formation of bridge complexes. In continuation of our studies on the reactivity of Wittig reagents towards organometallic substrates we have now carried out the reaction of **1** with the phosphorus ylide **2**, and, in accordance with the scheme,



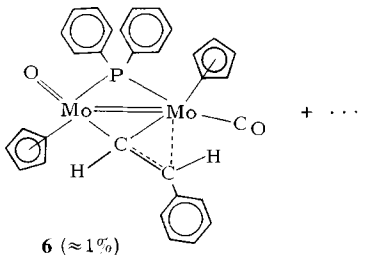
1 **2**

$(C_6H_5)_3P + CH_3(C_6H_5)_2P{=}O +$

3 (2%)

$[(\eta^5\text{-}C_5H_5)Mo(CO)_3]_2 + (\eta^5\text{-}C_5H_5)_2Mo_2(CO)_5[P(C_6H_5)_3] +$

4 (3%) **5** (10%)



6 (≈1%)

obtained the violet μ_2-η^2-styryl complex **6** as byproduct. This unusual compound was unequivocally characterized on the basis of IR, ^{1}H-NMR and mass spectra and by an X-ray structural analysis (Fig. 1).

6 is a doubly bridged Mo_2-complex with a diphenylphosphido bridge and an unsymmetrical (σ,π) η^2-styryl bridge. Both bridge-forming ligands are 3-electron donors, and, on the basis of the electron balance, a MoMo double bond must be present in **6**. Such a "degradation" of the MoMo triple bond in **1** to a double bond has so far not been reported in the literature; all other products would indicate presence of a MoMo single bond[1-3].

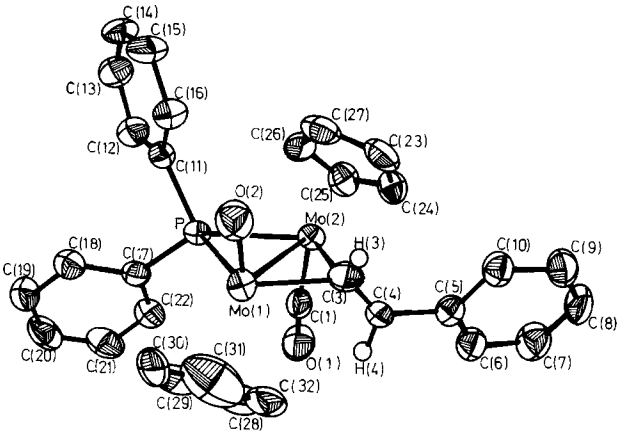


Fig. 1. Molecular structure of **6** in the crystal; the thermal ellipsoids correspond to a probability of 50%. Mo(1)—Mo(2) 288.5(1), Mo(1)—P 244.1(2), Mo(2)—P 234.9(2), Mo(1)—C(3) 205.7(9), Mo(2)—C(3) 215.8(10) pm. Further details about the crystal structure investigation can be obtained on request from the Fachinformationszentrum Energie-Physik-Mathematik, D-7514 Eggenstein-Leopoldshafen quoting Registry No. CSD 50256, the author, and the journal.

The spectroscopic data of **6** are consistent with the structural findings: Thus, the proton on the bridge carbon atom C(3), with $\delta = 9.91$, shows a chemical shift typical for μ-alkylidene complexes. The IR spectrum shows a band at 1820 cm^{-1} in the ν_{CO}-region, the ν_{MoO} bands appear at 910 cm^{-1}.

Synthesis of α-Vinyl-*P,P'*-ethylenebis(diorganophosphanes)

By *Wolf Jürgen Richter**

We recently reported the synthesis of substituted vinylphosphiranes, prepared by allowing organodichlorophosphanes ($RPCl_2$) to react with magnesium-butadiene[1]. Diorganochlorophosphanes (R_2PCl) react with butadiene to give phospholenium salts[2]: we report here on the 1,2-addition of 2 equivalents of R_2PCl **1** to magnesium-butadiene **2** to afford the novel α-vinyl-*P,P'*-ethylenebis(diorganophosphanes) **3** (Table 1)[3].

Table 1. Yields and selected physical data of the α-vinyl-*P,P'*-ethylene-bis(diorganophosphanes) **3a**—**3e**[3].

Compound	R	Yield [%]	B.p. [°C/torr]	^{31}P-NMR (C_6D_6) J_{PP} [Hz]	$\delta_{P(A)}$	$\delta_{P(B)}$
3a	C_6H_5	22	[a]	22.6	− 2.1	−20.4
3b	$CH(CH_3)_2$	58	96/0.01	26.6	+20.4	+ 1.8
3c	C_6H_{11}	64	145/0.01	26.9	+12.1	− 6.2
3d	$C(CH_3)_3$	28	140/0.01	30.8	+50.8	+22.5
3e [b]	Menthyl	52	[c]	16.4	−14.9	−29.6
				23.9	−17.9	−22.3

[a] Not determined. [b] Diastereometric mixture. [c] M.p. ≈ 173 °C.

Side reactions lead *inter alia* to formation of tetraorganodiphosphanes, particularly when aryl moieties are bonded to phosphanes. Thus, in the reaction of chlorodiphenylphosphane **1a** with **2**, apart from *ca.* 65% tetraphenyldiphosphane, only 22% of the bisphosphane **3a**, together with unidentified compounds were obtained.

The diorganochlorophosphanes **1b**—**1d** having branched alkyl moieties at phosphorus react to give the corresponding biphosphanes **3b**—**3d** in up to 64% yield, and only 3—5% of the respective tetraorganodiphosphanes. Chlorodimethylphosphane **1f** reacts with **2** to afford a diastereomeric mixture, in which the diastereomeric excess is only 16%. Even when less than the stoichiometric amount of **1** was used, monophosphino compounds could not be detected.

The ^{1}H-NMR and IR spectra of **3** indicate the presence of a vinyl group. The ^{31}P-NMR spectrum of **3** is particularly informative, since both phosphorus atoms have different substituents, thus giving rise to an AB system. The J_{PP} coupling constants and the chemical shifts are shown in Table 1; in this connection, the difference between the two diastereomeric menthyl compounds is notable. In the mass spectrum most compounds **3** exhibit the fragment ions at m/z $(M-R_2P)^{\oplus}$ as the base peak.

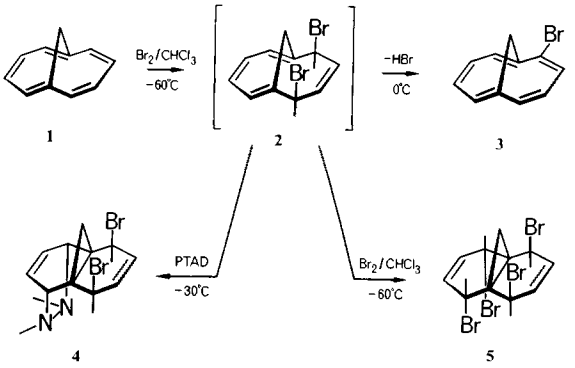
Stereochemistry of the Bromination of 1,6-Methano[10]annulene

By *Thomas Scholl, Johann Lex,* and *Emanuel Vogel**

The development of the chemistry of 1,6-methano[10]annulene **1** resulted, principally, *via* bromination reactions. In presence of either bromine at 0 °C or *N*-bromosuccinimide at 40 °C (in chloroform and dichloromethane, respectively), **1** is converted regioselectively and in high yield into 2-bromo-1,6-methano[10]annulene **3**. The findings of the bromination are consistent with those of extended Hückel and CNDO calculations[2].



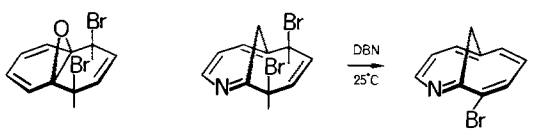
The substitution product **3** is highly probably formed *via* an addition-elimination mechanism, since in the reaction of **1** with bromine at −60 °C (in chloroform) a dibromo adduct (**2** or its isomer having reversed configuration of the bromine atoms), which is stable up to *ca.* −30 °C and results from a stereoselective *cis*-1,4-addition, can be detected by NMR spectroscopy. Upon warming to 0 °C the dibromo adduct is converted into **3**[1a].

Until now it was not known whether the bromine added to **1** in a *syn*- or *anti*-position relative to the CH_2-bridge. We report here on the solution to this interesting stereochemical problem.

In contrast to **1**, the parent hydrocarbon of **2**, 2,5-dihydro-1,6-methano[10]annulene, reacts very readily with dienophiles to form adducts derived from the norcaradiene valence tautomer[3]. In parallel to this, **2** could be trapped with 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD) at −30 °C (in chloroform) to yield the Diels-Alder adduct **4** possessing a cyclopropane ring. As indicated by the X-ray structural analysis, the bromine atoms in **4** are *syn*-oriented relative to the cyclopropane ring. This result therefore proves that the addition of bromine to **1** proceeds from the same side as the CH_2-bridge, although steric reasons would have led one to expect an attack from the opposite direction.

Renewed addition of bromine to **1** at −60 °C (in chloroform) also occurs in a *cis*-1,4-fashion to afford a tetrabromo adduct, which according to the results of previous ^{1}H-NMR investigations[1a] in conjunction with the identification of the dibromo adduct as **2**, must be the tricyclo[4.4.1.0^{1,6}]undeca-3,8-diene derivative **5** with a *syn-anti*-configuration of the two pairs of *cis*-1,4-positioned bromine atoms relative to the cyclopropane ring. This was confirmed by X-ray structural analysis.

The isolation by *Effenberger et al.*[2] of a dibromodichloro adduct analogous to **5** in the low-temperature bromination of **1** in presence of benzyltriethylammonium chloride is viewed as proof that **2** and **5**, respectively, are not formed by synchronous addition of bromine but *via* an intermediate σ-complex.



[*] Prof. Dr. E. Vogel, Th. Scholl, Dr. J. Lex
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

The same stereochemistry of bromination as observed for **1** could also be derived for 1,6-oxido[10]annulene. An X-ray structural analysis of the isolable dibromide **7**[1a] now indicated the *syn*-configuration of the two *cis*-1,4-positioned bromine atoms relative to the epoxide ring. Comparison of the NMR spectrum of the tetrabromo adduct[1a] with that of **5** suggests an analogous structure.

syn-Attack of bromine is apparently typical for 1,6-bridged[10]annulenes, since bromination of 2,7-methanoaza[10]annulene[4a] at −75 °C (in dichloromethane) leads to the labile bromo adduct **10**, which corresponds to **2** and **7** in the arrangement of the bromine atoms, and which upon standing, or more appropriately in presence of diazabicyclononene (DBN) in tetrahydrofuran (THF), undergoes regioselective dehydrohalogenation to yield the 3-bromo-2,7-methanoaza[10]annulene **11**[4b]. **10**, which did not afford a Diels-Alder adduct, could be subjected to an X-ray structural analysis despite its instability[4c].

The stereochemistry of the bromination **1** → **2** is interpreted in terms of MO theory in the following communication[5].

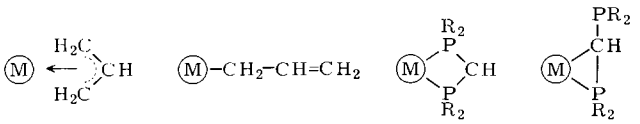
$Me_2PCHPMe_2^{\ominus}$ as Ambidentate Chelate Ligand**

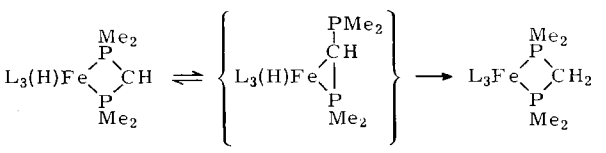
By *Hans Heinz Karsch**

Allyl transition-metal complexes are characterized by a special type of bonding isomerism (**A**, **B**).



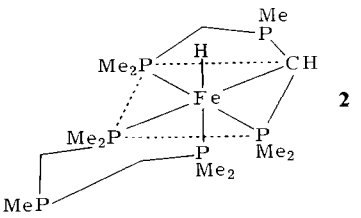
A **B** **C** **D**

In contrast, in mononuclear complexes of the "heteroallyl" anion $R_2PCHPR_2^{\ominus}$ only the form **C** (R = Ph) was previously known[1]. We consider the rearrangement **1a** → **1c** (L = PMe_3) as possible evidence for coordination of type **D** (R = Me)[2]. **1b** is, however, not detectable. Complex **2** is known to be coordinated according to type **D**[2], but the influence of the ring-strain in the bicycle is difficult to estimate.



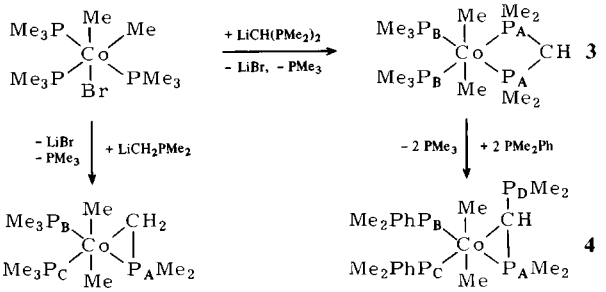
1a **1b** **1c**

We have now found an example in which a diphosphinomethanide complex of type **C** spontaneously rearranges to one of type **D**—without additional strain effects—as a result of only a slight change in the ligand periphery.



2

Complex **3** is present in solution as form **C**[3]. Substitution of the PMe_3 ligands in **3** by the sterically slightly more demanding PMe_2Ph leads to formation of **4**, with the "space-saving" configuration of type **D**[3,4]. This was confirmed by comparison with **5**, which also exhibits this structural element[3].



5 **3** **4**

The different mode of coordination of $R_2PCHPR_2^{\ominus}$ in **3** and **4** clearly indicates that the apparently slight energy difference considerably facilitates interconversion of the two coordination types, such as *e.g.* also in **1a** and **1b**. In this way, phosphorus and carbon in phosphinomethanides compete for complexed transition-metal centers just as for electrophilic main group compounds[5].

Synthesis under High Pressure: Mannich Reaction of Ketones and Esters with Dichloromethane and Secondary Amines**

By *Kiyoshi Matsumoto**

The Mannich reaction, which is also involved in the biosynthesis of alkaloids, can be used to yield a variety of aminomethyl derivatives (Mannich bases), which, *e.g.* have many synthetic and pharmacological applications[1]. This reaction is plagued by some shortcomings, *e.g.* highly branched carbonyl compounds such as diethyl alkyl- or arylmalonates do not respond to the classical Mannich reaction, although several modifications have appeared[2]. In the course of studies of Michael addition under high pressure[3], we discovered that CH_2Cl_2 underwent a Menschutkin reaction with Et_3N to give $(ClCH_2)\overset{\oplus}{N}Et_3 \cdot Cl^{\ominus}$. This prompted us to investigate possible transformations using CH_2Cl_2 as a C_1 synthon[4], and we report the Mannich reaction of carbonyl compounds with CH_2Cl_2 and secondary amines at a pressure of 6—9 kbar[5] (Table 1).

Table 1. Yields and reaction conditions in the synthesis of Mannich Bases from carbonyl compounds, CH_2Cl_2 and Secondary Amines [a].

Substrate [b]	Amine	P [kbar]	T [°C]	t [h]	Isolated yield [%] [c]
$PhCOCH_3$	pyrrolidine	9	20	72	34 (81)
$PhCOCH_3$	piperidine	8	40	24	86 (93)
$PhCOCH_2CH_3$	$(Et)_2NH$	9	22	43	30 (51)
$PhCOCH_2CH_3$	$(i\text{-}Pr)_2NH$	8	40	39	14 (78) [d]
$PhCOCH(CH_3)_2$	pyrrolidine	9	40	48	56 (83) [e]
$PhCOCH(CH_3)_2$	$(i\text{-}Pr)_2NH$	9	48	72	14 (100)
$t\text{-}BuCOCH_3$	$(Et)_2NH$	6	40	48	30 (65) [f]
$CH_3CH(CO_2Et)_2$	$(Et)_2NH$	6	48	61	71 (86)
$PhCH(CO_2Et)_2$	$(Et)_2NH$	9	48	48	12 (44)
CH_3CO_2—nBu	pyrrolidine	9	48	72	32 [g]
cyclohexanone	$(Et)_2NH$	9	22	48	26 [h]

[a] The Mannich bases were characterized by elemental analyses and spectroscopic data (^{13}C- and ^1H-NMR, and IR). [b] Aminomethylation occurs at the C atom shown in italics (in the case of cyclohexanone in the α-position to the carbonyl group). [c] Yields of isolated products; in parentheses yields based upon consumed substrates. [d] With CH_2I_2 1.6% yield was obtained [4]. [e] CH_2ClI gave only a trace of the Mannich base. [f] CH_2Br_2 gave tar-like material with complete consumption of the substrate [4]. [g] According to the method described in [4], this reaction fails. [h] Higher temperatures (*e.g.* 40 °C) lead to bis-aminomethylation.

In most cases the present method affords virtually pure Mannich bases after simple work-up; distillation, which causes poor yields due to the thermal instability of the products was unnecessary.

Mannich bases which are highly sensitive to heat, *e.g.* from pinacolone are readily accessible. The relatively bulky phenyl isopropyl ketone reacts readily with a base, and even with diisopropylamine produces the expected Mannich base.

Diethyl methyl- and phenylmalonates also underwent the normal Mannich reaction.

Thus, the present procedure is considered to be a mild as well as powerful method of the aminomethylation, and gives good yields even with sterically demanding educts.

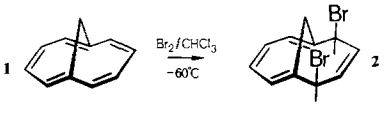
[5] *Experimental:* A mixture of the carbonyl compound (10 mmol), CH_2Cl_2 (20 mmol), and amine (30 mmol) is diluted with methanol in a 10 mL Teflon capsule which is stored for 24—72 h under high pressures (Table 1). The reaction mixture is diluted with 1 M HCl (100 mL) and extracted with several portions of hexane. The aqueous phase is made basic with NaOH, extracted with ether (20 mL × 3), washed with 2 M Na_2CO_3, brine, and water and then dried over $CaSO_4$. Evaporation of the solvent and unchanged amine under reduced pressure gives a virtually pure Mannich base.

MO Model for the Stereochemistry of Bromination of 1,6-Methano[10]annulene**

By *Rolf Gleiter**, *Michael C. Böhm*, and *Emanuel Vogel*

At low temperatures bromine adds to 1,6-methano[10]annulene **1** *syn* to the CH_2-bridge[1] to afford the labile dibromide **2**.



1 2

This result, which is surprising for stereochemical reasons, can be explained by π/σ interactions, which have

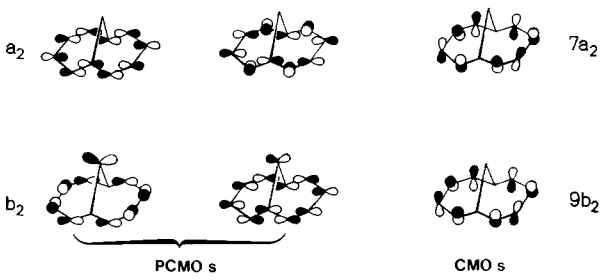

Fig. 1. Schematic representation of the most important precanonical MO's of **1** which interact with the π orbitals (left), as well as the resulting canonical π orbitals $7a_2$ and $9b_2$ (right).

been discussed for similar π/σ nonorthogonal systems[2]. Semiempirical MO calculations on **1** using a modified INDO method[3] predict a large σ/π interaction. A quantitative analysis according to ref.[4] indicates that each of the two high-lying π orbitals of the perimeter interacts considerably with two precanonical σ orbitals (PCMO's) (Fig. 1). The resulting canonical π orbitals (CMO's) $7a_2$ and $9b_2$[5] are also shown in Figure 1. The π/σ interaction causes rotation of the pπ atomic orbitals at the C(2)/C(5) and C(7)/C(10) centers.

Assuming that a bromine molecule approaches annulene **1** either parallel (**3a**) or perpendicular (**3b**) to the plane of the perimeter the antibonding interaction between the occupied levels of the halogen [for (**3a**) π and π*, for (**3b**) π* and σ] and $9b_2$ and $7a_2$ in *syn*-addition is smaller than that

in *anti*-addition. This is shown in Figure 2 for the approach parallel to the plane of the perimeter (**3a**). The main reason for the above mentioned difference is the smaller overlap[2b] between the π orbitals at the C(2)/C(5) or C(7)/C(10) centers of **1** and the corresponding orbitals of bromine in *syn*-addition compared to *anti*-addition. The rotation of the CMO's demonstrated in Figure 1 also occurs in the norcaradiene valence tautomer of **1**.

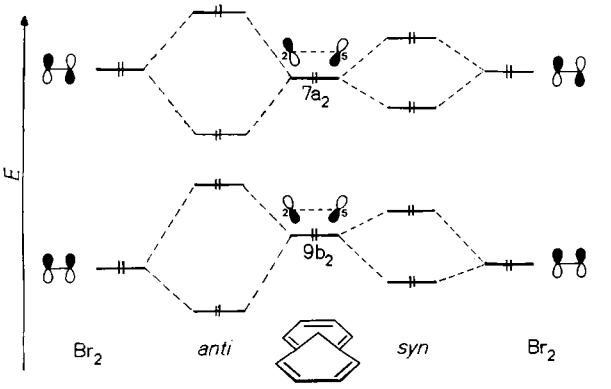

Fig. 2. Qualitative diagram for the interaction between the highest occupied molecular orbitals of Br_2 and the CMO's of **1** ($7a_2$ and $9b_2$) for *anti*- (left) and *syn*-addition (right), assuming that Br_2 approaches parallel to the plane of the perimeter (see **3a**).

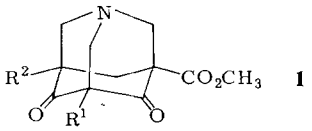
Synthesis of Specifically Substituted 1-Azaadamantanes

By *Nikolaus Risch** and *Wolfgang Saak*

1-Azaadamantanes[1] and related products are fascinating because of their interesting and, in part, surprising chemical and spectroscopic properties[2]. We have found a synthetic route, which for the first time provides a straightforward access to methyl 5,7-dialkyl-4,6-dioxo-1-azaadamantane-3-carboxylates **1** (Table 1), the first 1-azaadamantanes with completely C-substituted bridgehead atoms. The key step involves a triple Mannich reaction.



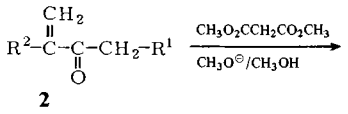
1

Table 1. Examples of Compounds **1** [a].

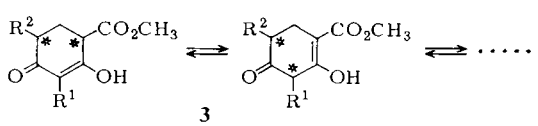
1	R^1	R^2	M.p. [°C]	Yield [%]
a	CH_3	CH_3	226	81
b	CH_3	C_2H_5	156	77
c	CH_3	n-C_8H_{17}	107	68
d	CH_3	$C_6H_5CH_2$—	192	70

[a] Spectroscopic characterization of **1a**, as example: ^{1}H-NMR (80 MHz, $CDCl_3$) 1.10 (s, 3H), 1.18 (s, 3H), 2.11 (AB, 2H), 3.08–3.66 (m, 6H), 3.80 (s, 3H). IR (KBr) 1739, 1723, 1692, 1269 cm^{-1}.

Michael addition and subsequent intramolecular Claisen condensation of the relatively easily available educts **2** and dimethyl malonate lead to the six-membered ring derivatives **3**, only a few of which have been described in the literature. A particular feature of **3** is the manifold possibilities of forming tautomers and stereoisomers.



2



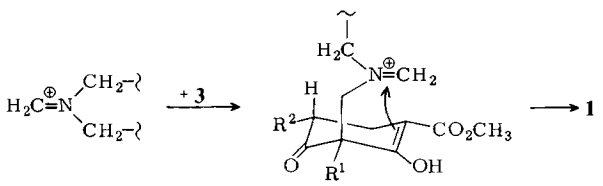
3

We have found that refluxing **3** with 1,3,5,7-tetraazaadamantane (hexamethylenetetramine) in methanol/dichloromethane produces the 1-azaadamantane derivative **1** as

[*] Dr. N. Risch, W. Saak
Fakultät für Chemie der Universität
Universitätsstrasse, D-4800 Bielefeld (Germany)

the sole product in high yield. Crystals were obtained after removal of the dichloromethane *in vacuo* and subsequent cooling, without further work-up. The structure has been confirmed by chemical and spectroscopic investigations[2].

We presume that the tetraazaadamantane framework is opened *via* an equilibrium with reactive intermediates of type **4**, which induce the Mannich-type reaction and form the intermediate **5**, which by analogy can react further. This formulation also accounts for the observation that **1** is the only product formed from each of the isomers **3**.



4 **5**

Compounds **1** are interesting, *inter alia*, as essential components of asymmetric catalysts, as models for reactions at fixed, sterically hindered systems, for solvolysis reactions[3], and for detailed spectroscopic investigations.

Tetra-*tert*-butylallene and Its Radical Cation**

By *Rudolf Bolze, Horst Eierdanz, Kaspar Schlüter, Werner Massa, Walter Grahn,* and *Armin Berndt**

Tetra-*tert*-butylallene **7** (m.p. = 43–44 °C) is the most highly sterically shielded and least chemically reactive allene derivative. It is formed as the sole product in the acid catalyzed dehydration of the readily accessible 1,1,3,3-tetra-*tert*-butylallyl alcohol **6**.

6 **7** R = *t*Bu

The steric shielding of the π system in **7** is clearly seen in the SCHAKAL plot[3] based on the results of an X-ray structure analysis (Fig. 1).

In accord with the large shielding, **7** displays practically no allene reactivity, and neither reacts with peroxy acids or ozone nor with chlorine or bromine, and is also inert to catalytic hydrogenation under pressure and to reaction with HI/phosphorus, or with strong aqueous acids. Only after being heated for several hours at temperatures above 100 °C with concentrated sulfuric acid does decomposition occur, which is observed as low as −60 °C with super acid.

[**] This work was supported by the Fonds der Chemischen Industrie and the Chemische Werke Hüls.

We attribute the low reactivity in addition reactions to the considerable steric hindrance, which affects all primary addition products. One-electron oxidation of **7** to generate the radical cation **10**, a reaction which is not accompanied by an increase in steric hindrance, can be smoothly achieved electrolytically or with $SbCl_5$ at −80 °C.

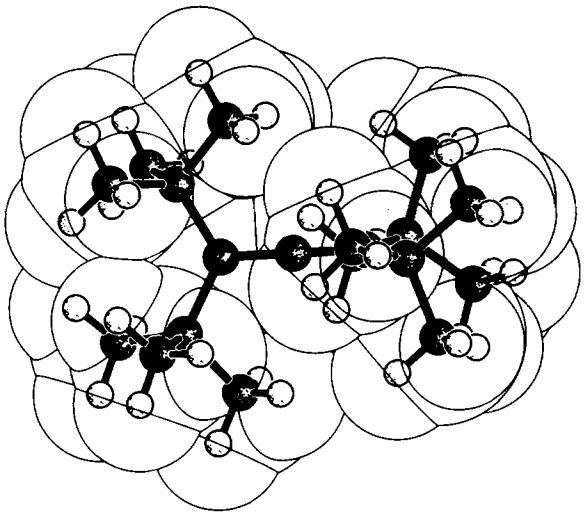

Fig. 1. SCHAKAL plot of the molecular structure of **7** (point symmetry 222 (D_2)) in the crystal. The space filling models are drawn with the van-der-Waals radii, and the ball-and-stick models arbitrarily with 1/5 of this value.

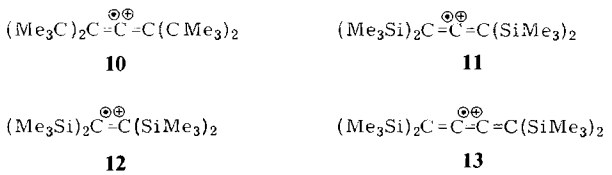
The radical cation **10** can be studied by ESR spectroscopy at temperatures up to −30 °C[6] in dichloromethane. The constitution of **10** is established by its ESR spectrum, which can be simulated using $a^H = 0.09$ mT for 36 equivalent H atoms and by the *g*-factor of 2.0028. The coupling constant of 0.09 mT for the sp^2-C atom, determined on **10** labeled with ^{13}C, precludes electronic structures in which either the unpaired electron or the positive charge is localized on the central sp-C atom. This establishes that the unpaired electron—and hence the positive charge—is distributed over all four p orbitals.

This electronic structure also occurs in the related radical cation **11**, which was generated by oxidation of tetrakis(trimethylsilyl)allene with $SbCl_5$ in CH_2Cl_2. The ESR spectrum of **11** can be simulated using $a^H = 0.022$ mT for 36 equivalent H atoms and $a^{Si} = 0.30$ mT for 4 equivalent ^{29}Si atoms (4.7% ^{29}Si).



10 **11**

12 **13**

The magnitude of the Si coupling constant in **11** is considerably smaller than that in **12** (1.775 mT)[11] and **13** (1.21 mT)[12], in which the unpaired electron occupies molecular orbitals consisting of only *two* p orbitals.

The small Si coupling constant in **11** is consistent with a distribution of the unpaired electron over all *four* p orbitals, since a^{Si} then contains a negative contribution arising from spin-polarization due to the spin density at the sp^2-C atoms (as in **12**) and a positive contribution arising from

hyperconjugation due to the spin density at the sp-C atom (as in **13**).

The $HCo_3(CO)_9$-Catalyzed Olefin Isomerization**

By *Giuseppe Fachinetti** and *Annibale Stefani*

In reactions involving catalytic amounts of $HCo(CO)_4$ **1**, $Co_2(CO)_8$ **2** is usually always involved[1]. Recently we found that **1** and **2** exist in equilibrium with the trinuclear 46e cluster $HCo_3(CO)_9$ **3** [eq. (a)][6].

$$\underset{\mathbf{1}}{HCo(CO)_4} + \underset{\mathbf{2}}{Co_2(CO)_8} \rightleftarrows \underset{\mathbf{3}}{HCo_3(CO)_9} + 3CO \qquad (a)$$

We now communicate that **3** is directly involved in olefin isomerization promoted by compounds **1** and **2**. Double-bond shift occurs very rapidly in neat *n*-hexenes at 0 °C in presence of **3** (molar ratio *n*-hexenes : **3** = 5×10^3 : 1). In this respect 1-hexene isomerizes fastest and (*Z*)-2-hexene faster than (*E*)-2-hexene, as expected if formation of π-complexes is assumed to be the first step of the reaction (Table 1).

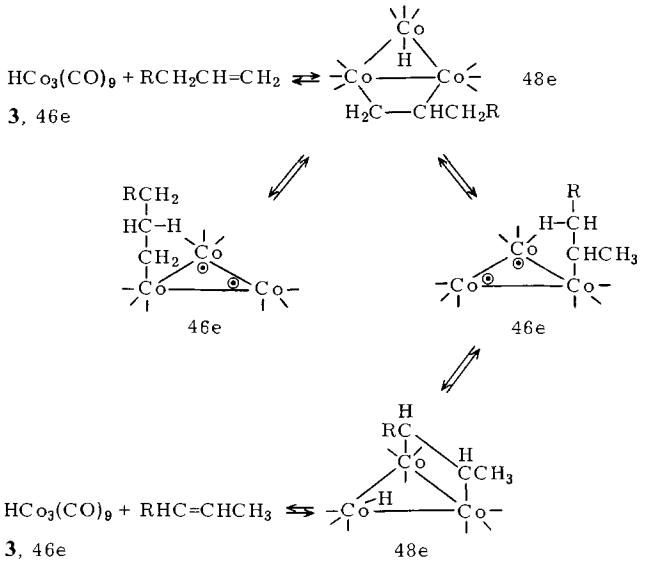
Table 1. $HCo_3(CO)_9$-catalyzed isomerization of neat *n*-hexenes at 0 °C (catalyst : substrate = $1 : 5 \times 10^3$).

Substrate	t [min]	Composition of the product mixture [a] 1-Hexene	(*Z*)-2-Hexene	(*E*)-2-Hexene	3-Hexene [b]
1-Hexene	*ca.* 0.5	3	30	59	8
(*Z*)-2-Hexene	3	<0.5	22	60	18
	18	<0.5	15	64	20
(*E*)-2-Hexene	3	<0.1	12	82	6
	10	<0.5	15	71	14
	40	<0.5	15	71	14
(*E*)-3-Hexene	3	<0.1	11	25	64
	10	<0.5	14	54	31
	40	<0.5	15	64	21

[a] Determined by gas chromatography. [b] Both (*Z*)- and (*E*)-3-hexene were always present in the mixture. The amount of (*Z*)-3-hexene in the mixture never exceeded 3%.

Experiments at $-35\,^{\circ}C$ in presence of **3** (molar ratio 2×10^3 : 1) show that (*Z*)- and (*E*)-2-hexenes are formed in equal amounts at 20% conversion within 3 min, despite the fact that the thermodynamic equilibrium lies very much in favor of (*E*)-2-hexene. When the reaction is carried out in cyclohexene, solvent and substrate compete in the first step of the reaction. The isomeric 2-hexenes can be obtained selectively at conversion rates up to 55% from 1-hexene.

Under these mild conditions neither **1** nor **2** show any catalytic activity, olefin isomerization being observed at higher concentrations of **1** in the presence of **2** and, at 0 °C, under an inert gas atmosphere. Since eq. (a) is operative under these conditions, the results suggest that cluster **3** might be the actual catalyst in the isomerization of olefins occurring in solutions containing **1** and **2**[11].



Scheme 2. Mechanism for olefin isomerization catalyzed by $HCo_3(CO)_9$.

It was previously demonstrated[8] that cobalt-catalyzed olefin isomerization occurs *via* consecutive metal-bonded hydrogen addition and elimination reactions. The observed C—H bond activations were explained in terms of 16e—18e additions of the mononuclear unsaturated hydridocarbonyl complex $HCo(CO)_3$ to the olefinic double bond, in accord with the hypothesis of *Heck* and *Breslow*[9]. Nevertheless, the trinuclear complex **3** could also react in this way (Scheme 2), whereby 46e—48e addition would occur[10], and the C—H bond activation would be promoted by two adjacent 17e cobalt atoms. The mechanism proposed in Scheme 2 is reminiscent of the Horiuti-Polanyi mechanism for the heterogeneously catalyzed olefin isomerization and, similar to heterogeneous catalysts, **3** is active even at $-50\,^{\circ}C$.

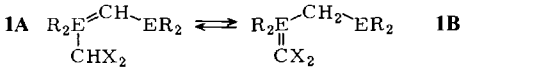
Stabilization of the Unstable Tautomers of Phosphino- and Arsino-Substituted Ylides by Coordination to Transition Metals**

By *Lothar Weber**, *Roland Boese*, and *Wolfgang Meyer*

Of the phosphino- and arsino-substituted ylides of type **1**, the tautomers **1A** and **1B** can be formulated, whereby the equilibrium for X = H at room temperature lies completely on the side of **1A**[1].



E = P, As; X = H, substituents capable of mesomerism
R = Alkyl, Aryl

Substituents X that are capable of mesomerism favor the tautomer **1B**, which can be fixed as complex ligand[2]. We have now been able to stabilize the tautomer **1B**, also when X = H, by coordination to transition metals. On reaction of the sulfur-ylide complexes **2**[9] or **6**[11] with the methylenebisphosphanes **4a—4c** and methylenebisarsane **4d** the unstable ylide tautomer is fixed as ligand to the transition metal. Formally, the $(CO)_4CrCH_2$ building block in **2** or **6** is transferred to **4a—4d** in a substitution reaction.

The ^{31}P-NMR spectra (200 MHz, 25 °C, $CDCl_3$, ext. H_3PO_4) of the yellow, briefly air-stable complexes **5a—5c** prove the presence of two different types of phosphorus atoms (**5a**: $\delta = 43.78$ (d), 65.47 (d), $J = 84$ Hz; **5b**: $\delta_A = 41.33$, $\delta_B = 43.09$, $J_{AB} = 81$ Hz; **5c**: $\delta = 90.58$ (d), 155.75 (d), $J = 105$ Hz). In **5d**, the methylene protons give rise to two singlets, in **5a—5c**, on the other hand, to two doublets of doublets. The X-ray structure analysis of **5d** (Fig. 1) confirms the presence of a five-membered metallacycle in envelope conformation (dihedral angle 36.7°).

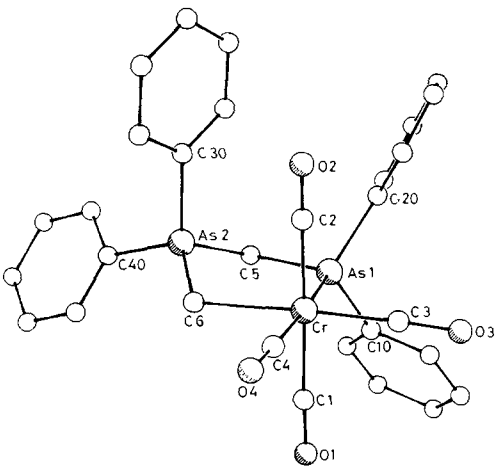


Fig. 1. Structure of the complex **5d** in the crystal. Monoclinic space group C2/c; $a = 2194.2(7)$, $b = 1418.5(4)$, $c = 2753.7(9)$ pm; $\beta = 138.87(2)°$; $V = 5.638(3) \times 10^9$ pm^3; $Z = 8$, $R = 0.035$.—Some selected bond lengths [pm] and angles [°]: Cr—As(1) 245.0(1), As(1)—C(5) 197.1(5), C(5)—As(2) 191.4(7), As(2)—C(6) 188.8(4), C(6)—Cr 222.1(6); CrAs(1)C(5) 109.8(2), As(1)C(5)As(2) 106.3(2), C(5)As(2)C(6) 107.6(3), As(2)C(6)Cr 113.6(2), C(6)CrAs(1) 88.1(1). Further details of the crystal structure investigation can be obtained on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2 (Germany), quoting CSD 50289, name of author, and full citation of Journal.

Synthesis of an Octasaccharide of the Basic Sequence of *N*-Glycoproteins**

By *Hans Paulsen** and *Rolf Lebuhn*

The oligosaccharide chain **9** is a basic sequence present as a building block in numerous *N*-glycoproteins[1], and is bonded at the reducing end to L-asparagine *via* a glucosamine moiety. Both lactosamine antennae having the nonreducing end groups are usually occupied by *N*-acetylneuraminic acids[1].

Until recently, the β-D-(1→4)-mannoside bond to the glucosamine in **9** could not be synthesized directly. Using a silver silicate catalyst[2] we recently were able to prepare saccharides **2** and **6**[3], which were required as educts for the oligosaccharides **5** and **9**.

Trisaccharide **3**, which is obtained from **2** (Scheme 1), can be selectively coupled with the lactosamine bromide **1**[4] in presence of silver trifluoromethanesulfonate (Ag-triflate, collidine, −40 °C) to afford the pentasaccharide **4** (75%, $[\alpha]_D^{20}$ −9.7, $c = 1.2$ in $CHCl_3$) with the desired β-D-glycosidic linkage. **4** could be deblocked as follows: Firstly it is deallylated (70%) with $PdCl_2$/AcOH/NaOAc. Deacetylation, hydrazine cleavage of the phthalimido group, acetylation, and subsequent hydrogenolytic cleavage of the benzyl groups, as well as reacetylation led to a to-

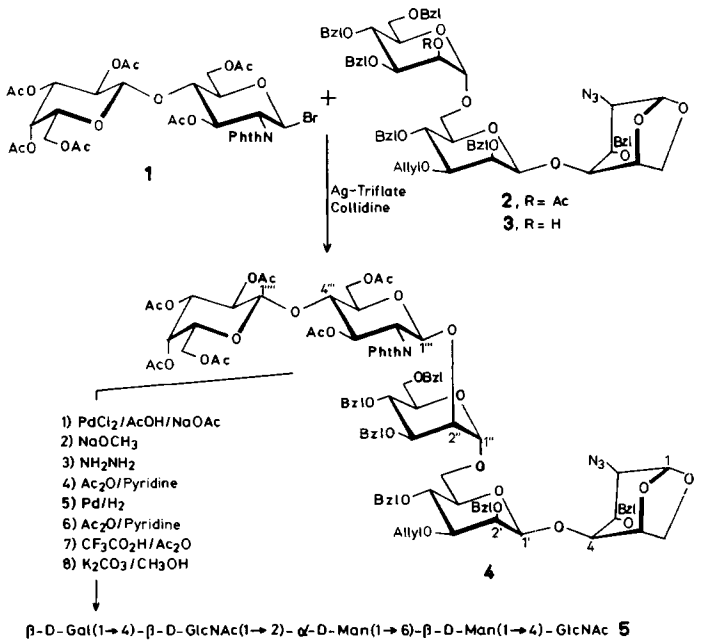
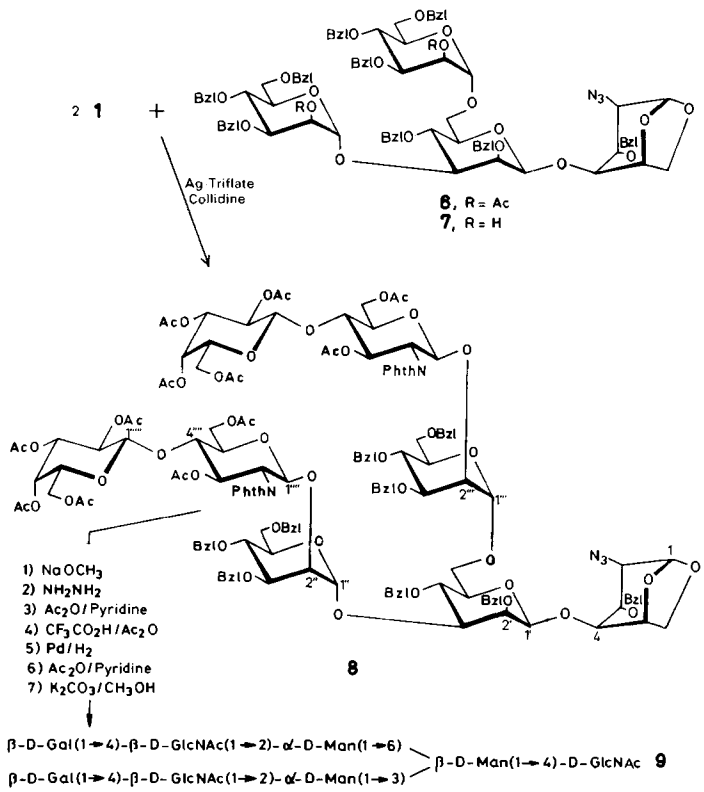


Scheme 1. Phth = phthaloyl.

tally acetylated compound (56%), which still only contains the 1,6-anhydro ring at the reducing moiety. This can be opened with CF_3CO_2H/Ac_2O (65%), and subsequent deacetylation with K_2CO_3/CH_3OH at 0 °C affords the free saccharide **5**[5] (90%, $[\alpha]_D^{20}$ +6.0, $c = 0.5$ in H_2O).

Tetrasaccharide **7**, which is obtained from **6**, reacts with **1** (molar ratio 1:2, Scheme 2) under the same conditions as the reaction of **1** with **3**. The octasaccharide **8** (70%, $[\alpha]_D^{20}$ −8.0, $c = 1.1$ in $CHCl_3$) is formed *via* stereoselective



Scheme 2. Phth = phthaloyl.

coupling of two β-D-glycoside bonds, and can be deblocked in three steps: After deacetylation, cleavage of the phthalimido group by hydrazine and reacetylation (77%) in the first step, follows 1,6-anhydro ring-opening, cleavage of the benzyl ether groups and reduction of the azido group by hydrogenation, as well as reacetylation (40%) in the second. Finally, the product is deacetylated by K_2CO_3 in methanol at 0 °C to afford the glycoprotein building block **9**[5] (90%, $[\alpha]_D^{20}$ +1.8, $c = 1.0$ in H_2O). The reducing glucosamine moiety is not converted into the *manno*-isomer under these conditions, which otherwise readily occurs in alkaline deacetylations of similar groups. The structure and linkage of all the oligosaccharides prepared were determined by analysis of the 400 MHz, ^{1}H-NMR spectra (in part, 2D spectra).

Synthesis of Trisaccharide Moieties from *N*-Acetylneuraminic Acid and *N*-Acetyllactosamine

By *Hans Paulsen** and *Holger Tietz*

Glycoproteins bound to L-asparagine by an *N*-glycosidic linkage contain a pentasaccharide core structure having a branched end section consisting of three mannoses. In the lactosamine type, lactosamine antennae carrying terminal α-D-(2→6)-glycosidic *N*-acetyl-D-neuraminic acid (NANA) are bonded there. We have now been able to synthesize the trisaccharide α-D-NANA(2→6)-β-D-Gal(1→4)-D-GlcNAC **11**, which is present as a functional terminal group in numerous glycoproteins.

Previous glycoside syntheses using neuraminic acid have caused severe problems[1]. We have studied the reactions of the chloride **7** and of the corresponding bromide, prepared by reaction of an acetylated *N*-acetylneuraminic acid ester with $TiCl_4$ or $TiBr_4$ under anhydrous conditions[2], in presence of numerous catalysts. With the bromide, predominantly elimination reaction occurs; only highly reactive monosaccharides having 6-OH groups react with **7** in presence of silver catalysts to afford disaccharides having α-D-glycosidic linkages. In compounds having less reactive OH groups, eliminations can be repressed by using $Hg(CN)_2/HgBr_2$ as catalyst; by this means disaccharides can be obtained in good yields, although, as a mixture of anomers. These conditions also proved to be suitable for a trisaccharide synthesis.

Bromide **1**[3] reacts with benzyl alcohol in presence of silver silicate[2] to give the benzyl glycoside **2**. After deacet-

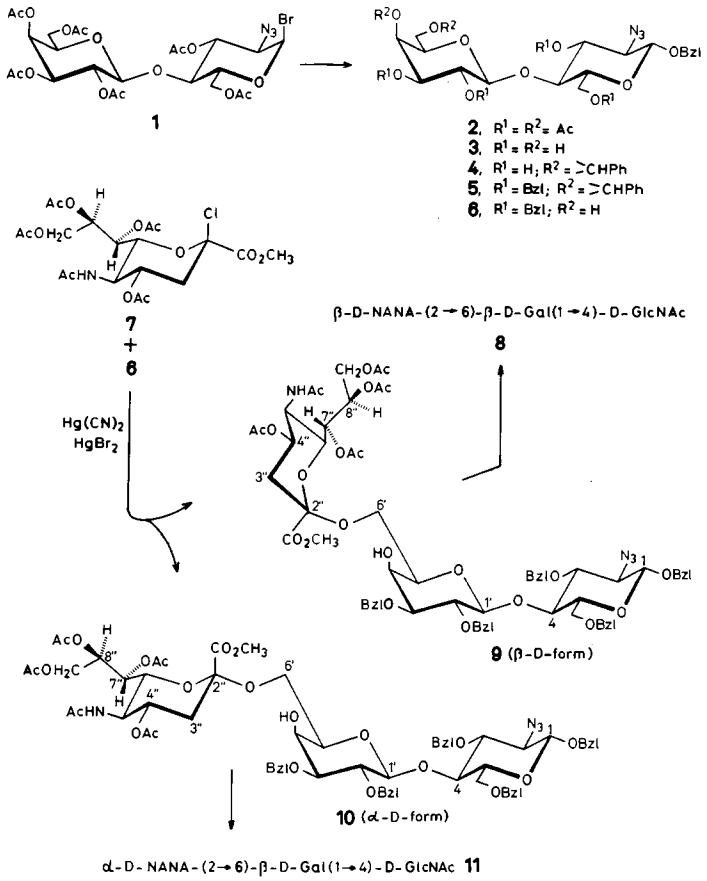
[**] Oligosaccharide Building Blocks, Part 43.—Part 42: H. Paulsen, R. Lebuhn, *Angew. Chem. 94* (1982) 933; *Angew. Chem. Int. Ed. Engl. 21* (1982) 926.

ylation to **3** this is converted by benzaldehyde dimethyl acetal into **4**, which after benzylation with benzyl bromide affords **5**. Subsequent acid hydrolysis furnishes **6**, which



can be used directly for glycoside synthesis, since 6′-OH is considerably more reactive than 4′-OH. **7** reacts with **6** in presence of $Hg(CN)_2/HgBr_2$ (3:1) in dichloromethane (20 °C, 3 d) to give the glycosides **9** and **10** (molar ratio 1:1) in approximately 50% yield. Column chromatography (chloroform/methanol) of the mixture results in isolation of 20% α-D-form **10** ($[\alpha]_D^{27}$ −12.8, $c=1.0$ in CH_2Cl_2) and 20% β-D-form **9** ($[\alpha]_D^{27}$ −4.0, $c=1.0$ in CH_2Cl_2). In order to deblock **10**, the N_3 group is first reduced by H_2S to the NH_2 group (62%), and both NH_2 and 4′-OH groups are subsequently acetylated (71%). The *O*-acetyl groups can then be cleaved using catalytic amounts of sodium methoxide in methanol and the methyl ester cleaved by NaOH (99%). Finally, the benzyl ethers are cleaved by hydrogenolysis leading to the free trisaccharide **11** ($[\alpha]_D^{26}$ −0.7, $c=1.0$ in H_2O)[4]. The β-D-form **9** can be analogously deblocked to afford the trisaccharide **8** ($[\alpha]_D^{27}$ −3.5, $c=1.0$ in H_2O)[4].

The assignment of the anomers was performed by comparison of the ^{1}H-NMR spectra of **8** and **11**. In the α-D-form **11**, the signal of 3″-H_e at $\delta=2.56$ (in D_2O) is characteristically[5] shifted to low field (3″-H_e of **8**: $\delta=2.31$). However, this rule does not apply to blocked *N*-acetylneuraminic acid oligosaccharides. Here we can state a new assignment rule for the case when the *N*-acetylneuraminic acid moiety is completely acetylated. In **10** and **9**, and in all intermediates the signal of 4″-H in the α-form at $\delta=4.89-4.93$ lies at higher field than in the β-form (4″-H, $\delta=5.68-5.81$). Furthermore, the $J_{7,8}$ coupling of 6.2—8.2 Hz in all the α-forms is large, and in contrast that in the β-forms of 2.4—2.6 Hz small, which suggests different conformations in the side chains.

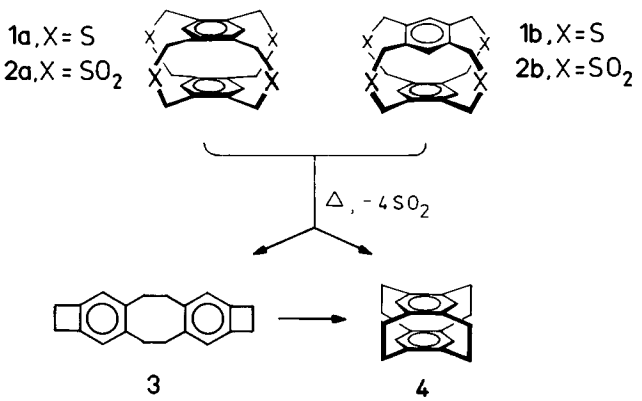
Novel Facile Synthesis of Multiply *ortho*-Bridged Phane-Hydrocarbons and of Dihydrocyclobutabenzenes

By *Brigitte Klieser* and *Fritz Vögtle**

We have now found that the cesium-catalyzed sulfide-cyclization recently developed by us enabled the one-step synthesis of multiply *ortho*-bridged benzene rings[1], *e.g.* of **1**; following on from that we have now succeeded by sulfone pyrolysis in synthesizing multiply 1,2-bracketed phane-hydrocarbons in a few simple steps, and—surprisingly—also of bridged dihydrocyclobutabenzenes. Multiply *ortho*-bridged phanes, unlike their *meta*-bridged analogs[3], were hitherto not accessible from sulfones[2].

Pyrolysis (600 °C/0.005 torr) of the mixture of sulfones **2a**, **b** (sublimation temp. 550 °C) obtainable from the mixture of the tetrasulfides **1a**, **b**[1], does not yield the desired fourfold bracketed phane **4**[4], but the doubly bridged 1,2-dihydrocyclobutabenzene **3**. The ^{1}H-NMR data of **3**[5] and **4**[4] are in complete accord with those quoted in the literature.



On pyrolysis of **2** at higher temperature (750 °C/0.15 torr; sublimation temperature 700 °C), however, we were able to isolate a 1:2 mixture of **3** and **4** in *ca.* 40% yield (unequivocal identification from ^{1}H-NMR signals and mass spectra).

[*] Prof. Dr. F. Vögtle, B. Klieser
Institut für Organische Chemie und Biochemie der Universität

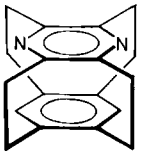
 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/1212-0928 $ 02.50/0

Our experimental findings that 1,2,4,5,7,8,10,11-octahydrobiscyclobuta[4,5]benzo[1,2-*a*:1′,2′-*e*]cyclooctene **3** is formed initially, and not the [2.2.2.2]cyclophane **4**, is very interesting, because **3** occurs as intermediate in the multistep synthesis of **4**[5], and **4** has already been obtained by thermolysis of **3**.

The novel synthetic route *via* an "ortho-sulfone pyrolysis" not only offers the advantage of a small number of rapid and simple steps, but also enables synthesis of dihydrocyclobutabenzene intermediates such as **3**, which are thus also conveniently accessible for other reactions. Furthermore, numerous unsymmetric phane-hydrocarbons such as the pyrazinobenzophane **5** should now be accessible in an analogous way from the corresponding unsym-



5

metrical sulfones, whereas previous methods were restricted to symmetrical compounds of type **3** and **4**. Fivefold and sixfold bracketed arenes—e.g. superphanes—including the corresponding dihydrocyclobutabenzene intermediates, should also be obtainable by this novel combination of cesium-catalyzed sulfide cyclization[1] and *ortho*-sulfone pyrolysis.

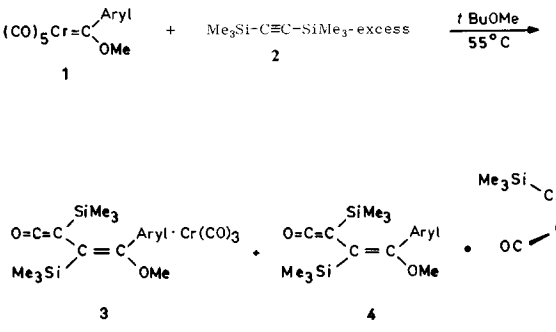
Bis[bis(trimethylsilyl)acetylene]dicarbonylchromium**

By *Karl Heinz Dötz** and *Jochen Mühlemeier*

Pentacarbonyl[aryl(methoxy)carbene]chromium complexes **1** react with equimolar amounts of bis(trimethylsilyl)acetylene **2** to give the metal-coordinated vinylketenes **3**, which can be formally described as products of a head-to-tail addition of the carbene and a carbonyl ligand to the alkyne[4]. In contrast, if the reaction is carried out with an excess of alkyne (*e.g.* in the ratio **1** : **2** = 1 : 2.2) in *tert*-butyl methyl ether, then, on heating, the uncoordinated vinylketene **4** and the title compound **5** are also obtained.

The deep-violet complex **5**, which is moderately sensitive to light and extremely sensitive to oxidation, was char-



Aryl = p-C_6H_4-R (R = H, Me, OMe, CF_3)

acterized by total analysis and by spectroscopic methods[5] [IR: ν(C=O) 1965, 1904 cm^{-1} (*n*-hexane), ν(C≡C) 1705 cm^{-1} (Nujol); ^{1}H-NMR: $\delta = 0.28$; MS: $m/z = 448$ (M^+), 392 ($M^+ - 2CO$), 222 ($M^+ - 2CO$—Me_3Si—C≡C—$SiMe_3$). In solution, bis(trimethylsilyl)acetylene is slowly cleaved from the complex if not kept in the dark, thus ruling out coupling of the alkyne ligands in the complex. Information about the coordination of the alkyne ligands is provided, in particular, by the ^{13}C-NMR spectrum: The signal of the C-atoms of the two CO-ligands appears at $\delta = 258.9$, that of the alkyne C-atoms at $\delta = 197.8$; such downfield shifts (free alkyne: $\delta = 115.4$) are regarded as a criterion for the alkynes functioning as four-electron ligands[6], thus leading to the noble gas configuration of the chromium in **5**. In contrast, the ^{29}Si chemical shift ($\delta = -7.4$) is unsuited for investigation of the electron-donor capability of the alkyne, as is revealed on comparison with the two-electron alkyne ligand in $(CO)_4Fe(Me_3Si—C≡C—SiMe_3)$ ($\delta = -8.5$)[9].

The bis(alkyne)dicarbonyl complex **5** constitutes the first satisfactorily characterized ternary alkyne-carbonyl compound of chromium, after the synthesis of the tris(alkyne)carbonyl complexes of molybdenum and tungsten could so far not be extended to the lightest homologue.

desulfurization occurs leading to the coordinatively unsaturated, diamagnetic nonelectrolytes **2**.

$$[Mo_3S_7(R_2PS_2)_3]^+[R_2PS_2]^- \underset{+S_8 \text{ or } +(R_2PS_2)_2}{\overset{+R_2^1P:\,-R_2^1PS}{\rightleftharpoons}} [Mo_3S_4(R_2PS_2)_4] \quad (1)$$

1 **2**

1a, **2a**: R = Et; **1b**, **2b**: R = *n*Pr, R′ = Ph

Consistent with this structure (Fig. 1), the $^{31}P\{^1H\}$-NMR spectrum of **2a** exhibits three resonances in the intensity ratio 1 : 2 : 1 (0.03 M in CH_2Cl_2; $\delta_P = 123.2$, 114.8, and 83.7, rel. to 85% H_3PO_4) and the FD-mass spectrum the molecular ion ($[M]^+$, *m/z* 1034, ref. to ^{98}Mo).

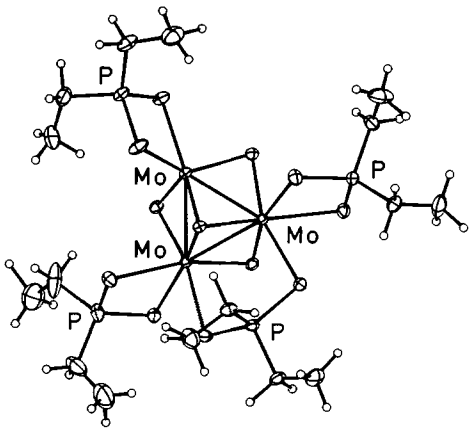

Fig. 1. Structure of the molybdenum(IV) cluster **2a** in the crystal.

The cluster contains the central unit Mo_3S_4[2–4]. As in **1a**, each of the Mo atoms, which form a triangle, is chelated by a dithiophosphinate moiety and capped trigonal-pyramidally by a sulfur atom. However, instead of the bridging S_2^{2-} ligands, single sulfide bridges now occur. Two of the Mo atoms are additionally linked to each other *via* a dithiophosphinato bridge, and hence sulfur fulfills four different bonding functions in the molecule. The formal oxidation state of the metal atoms in **2a** is the same as that in **1a**. However, in contrast to all other trinuclear MoS clusters the coordination number of the three Mo atoms in cluster **2a** is different: this is seven for one Mo atom and eight for the other two Mo atoms. In consequence, the coordinatively unsaturated compounds **2** can add, *e.g.* pyridine, to form $[Mo_3S_4(R_2PS_2)_4py]$ **3** (**3a**: R = Et; **3b**: R = *n*Pr) which upon heating is quantitatively released to give **2** again. The different coordination state in **3** is expressed *inter alia* by a distinct high-field shift of the resonances in the $^{31}P\{^1H\}$-NMR spectrum. Hence, **3a** also displays three resonances in the intensity ratio 1 : 2 : 1, however, at $\delta_P = 116.6$, 114.1, and 80.9 (0.03 M in CH_2Cl_2). As expected, the resonance of the chelate ligand bonded to the originally coordinatively unsaturated molybdenum atom is most strongly influenced: $\Delta\delta_P = 6.6$ ppm, relative to 0.7 and 2.8 ppm. Analogous situations are found when the resonances of **2b** and **3b** are compared.

Clusters **2** react with S_8 or $R_2P(S)S_2P(S)R_2$ (R = Et, *n*Pr) as sulfur donor to re-form **1**. Thus, reaction (1) reflects the redox process

$$S_2^{2-} \rightleftharpoons S + S^{2-}$$

The Mo_3 triangular plane remains intact both in the coordinative saturation of **2** and in reaction (1).

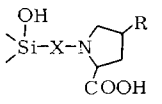
Chiral Silica Packings with L-Proline or L-Hydroxyproline Bonded *via* Alkyl or Alkylbenzyl Chains for the Separation of the Enantiomers of α-Amino Acids by HPLC

By *Panayiotis Roumeliotis, Klaus K. Unger*, Alexandre A. Kurganov,* and *Vadim A. Davankov*

The separation of enantiomers by means of column liquid chromatography has been the subject of numerous reports[1]. A favorite way of obtaining enantioselective supports consists in covalently bonding optically active ligands *via* a spacer to the surface of silica[2–4].

We synthesized silicon compounds of the type $(EtO)_3Si$—X-L-proline and $(EtO)_3Si$—X-L-hydroxyproline, which on reaction with LiChrosorb Si 100 ($d_p = 10$ μm; Merck) yielded chiral silica packings **1**–**4**.



1, X = $-CH_2-$
2, X = $-(CH_2)_3-$
3, X = $-(CH_2)_8-$
4, X = $-(CH_2)_2-C_6H_4-CH_2-$

a, R = H; **b**, R = OH

The concentration of surface functional groups amounted to 3—4 μmol/m^2. The supports were packed in columns by the slurry technique and loaded with Cu^{2+} (copper acetate solution). Table 1 shows examples of the separation of the enantiomers of α-amino acids[5].

The supports examined differ from each other in the type of hydrophobic spacer X that is employed. α-Amino acids with hydrophobic groups, *e.g.* Phe, Trp, Leu, Ile, Tyr, show increasing retention with increasing hydrophobic character of the spacer in the series of packings **4** > **3** > **2** > **1**. Accordingly, the retention is controlled by hydrophobic interactions. α-Amino acids with lower hydrophobicity exhibit a markedly complicated retention be-

The supports **1**—**4** show the same sequence of elution for all α-amino acids, *i.e.* for a given amino acid the D-form appears before the L-form or *vice versa* on all phases. Exceptions are Asp, Lys, Arg, Leu, Ile. The reason for this is still unclear. With hydrophobic α-amino acids such as Thr and Tyr, containing hydroxy groups, the D-form is always eluted before the L-form. α-Amino acids with additional groups capable of complexing behave somewhat differently.

The optically active supports offer good selectivity for all α-amino acids. Mixtures of several D,L-α-amino acids can also be separated on such columns (Fig. 1).

"μ-C_3" Trisphosphanes by Direct Phosphane/Allylphosphane Coupling**

By *Ertugrul Arpac* and *Lutz Dahlenburg**

Trisphosphanes with trimethylene bridges are valuable chelating ligands for the larger transition-metal ions. Until now, the most straightforward route to this class of compounds involved lithiated trimethylenebisphosphanes, $R_2P—(CH_2)_3—P(Li)R'$ (R' = Ph, Me), which first had to be synthesized from 3-chloropropylphosphanes, $R_2P—(CH_2)_3—Cl$, and then coupled with the latter[2,3]. The range of application of the method is limited, since the key compounds $R_2P—(CH_2)_3—Cl$, which can readily be quaternized, are known only with bulky substituents on phosphorus (R = C_6H_5, *cyclo*-C_6H_{11}).

1: R = Ph; **2**: R = Me

[**] Oligophosphane Ligands, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft. *E. A.* thanks the Friedrich-Ebert-Stiftung for financial support.—Part 1: [3].

We have found that the radical addition of PH functionalized mono- and bisphosphanes to allylphosphanes offers, in principle, a more variable synthetic method, and demonstrate its efficiency by means of the one-step preparation of the two chiral ligands **1** and **2**, as well as of the derivative **3** (2 h at 110 °C in presence of 2,2'-azobis(isobutyronitrile) having permethylated terminal phosphino groups[4].

After column chromatography, **1**, **2**, and **3** were obtained in yields of *ca.* 50% as colorless oils, which were characterized by their NMR data (Table 1).

The diastereotopicity of the Me_2P fragments is clearly evident in the ^{1}H-NMR spectra of **1** and **3**: in each compound the methyl protons display two doublets with a chemical shift difference of 0.02 ppm. In **2**, in contrast, the nonequivalence of the methyl protons cannot be detected, even at 270 MHz.

Since the synthetic building blocks required for the phosphane/allylphosphane coupling are readily obtainable, we expect that using this method a series of systematically variable ligands can be prepared, by means of which the reactivity of transition-metal complexes can be controlled.

Olefin Selectivities in the Addition of Carbenes**

By *Wolfgang W. Schoeller**, *Nevzat Aktekin*, and *Henniger Friege*

At variance with previous conceptions[1], according to the differential frontier model singlet carbenes can be divided into two classes depending on whether they follow a direct or inverse reactivity-selectivity relationship[2]. We have now experimentally tested this model for the electrophilic carbene series and placed it on a quantitative basis.

The following relationship applies to a change in reactivity of a carbene (C) with an olefin (O):

$$dE = \left[\frac{\partial E}{\partial \beta_{\varphi(O)\varphi(C)^*}} \frac{\partial E}{\partial \beta_{\varphi(C)\varphi(O)^*}} \frac{\partial E}{\partial E_{\varphi(O)}} \frac{\partial E}{\partial E_{\varphi(O)^*}} \frac{\partial E}{\partial E_{\varphi(C)}} \frac{\partial E}{\partial E_{\varphi(C)^*}}\right] \begin{bmatrix} d\beta_{\varphi(O)\varphi(C)^*} \\ d\beta_{\varphi(C)\varphi(O)^*} \\ dE_{\varphi(O)} \\ dE_{\varphi(O)^*} \\ dE_{\varphi(C)} \\ dE_{\varphi(C)^*} \end{bmatrix} \quad (a)$$

where E is proportional to the logarithm of the rate constant and dE corresponds to its (differential) change. From relationship (a), changes in the reactivity of a carbene (*i.e.* its selectivity), therefore result *additively* and *linearly* from changes in the individual quantities (*e.g.* orbital energies, frontier orbital coefficients, *etc.*).

With respect to (a) the following correlations were investigated: (1) π-ionization potentials of the olefins and the logarithms of the relative rate constants in addition reactions with CCl_2 [$\lg k_{rel} = a \cdot E_I(\text{olefin}) + c$] over as large a range of reactivity as possible[4] ($k_{rel} = 1$ to 1000; cf. Fig. 1); (2) *ditto* for all the carbenes studied under standard conditions[6], not only with (case a) but also without (case b) consideration of the different coefficients of the HOMO's of the various olefins [for case a) $\ln k_{rel} = a \cdot E_I(\text{olefin}) + b \cdot \text{coeff(olefin)} + c$ holds] (see Table 1). The coefficients were calculated using the CNDO/2 method.

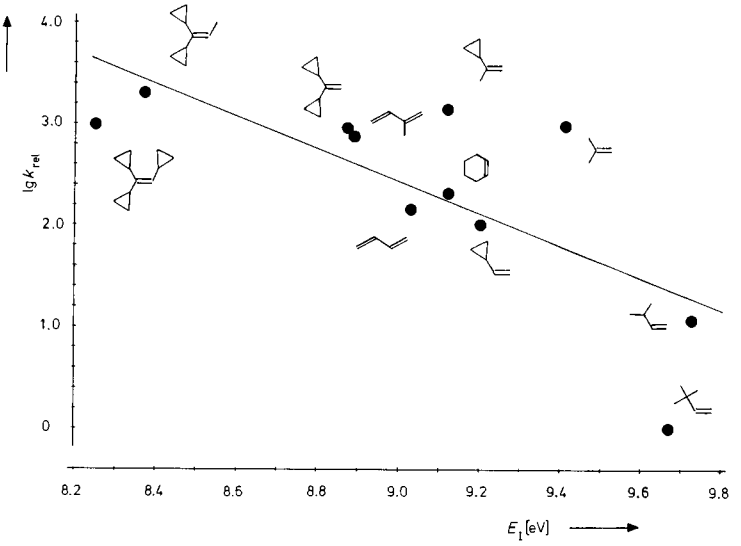

Fig. 1. Correlation of the logarithm of the relative rate constants with the π-ionization potentials of substituted olefins for the 1,2-addition of CCl_2.

As shown in Fig. 1, the relative reactivity of CCl_2 clearly increases as the π-ionization potential of the olefin decreases, however, a linear relationship is impaired by the large scattering of the points. On the other hand the correlations are greatly improved ($r^2 \approx 0.90$, case 2a) for the car-

benes investigated under standard conditions, if in the parameter equation the different coefficients of the HOMO's at the various olefins are taken into consideration (Table 1).

The parameters a of the linear equations (Table 1) are a quantitative measure of the change in reactivity of a carbene with the π-ionization potential of the olefin. For CCl_2 a relative selectivity scale is obtained, which is consistent with that reported by *Moss et al.*[6]. According to differential frontier orbital theory, it is therefore possible to predict the relative reactivity of a carbene with an olefin from the corresponding linear equations. This only requires knowledge of the π-ionization potential of the olefin and the orbital coefficients of its HOMO's.

Okamura, C. G. Overberger, T. Saegusa, G. V. Schulz, W. P. Slichter, J. K. Stille. Springer-Verlag, Berlin 1982. v, 145 pp., bound, DM 86.00.—ISBN 3-540-11774-1

Inorganic Syntheses. Vol. 21. Edited by J. P. Fackler Jr. John Wiley & Sons, Chichester 1982. xvii, 215 pp., bound, £ 29.25.—ISBN 0-471-86520-6

Correlation Analysis of Organic Reactivity. With particular reference to multiple regression. By J. Shorter. Research Studies Press, Chichester 1982. ix, 235 pp., bound, £ 18.50.—ISBN 0.471-10479-5

Reactivity and Structure. Vol. 13: Macrocyclic Polyether Syntheses. By G. W. Gokel and S. H. Korzeniowski. Springer-Verlag, Berlin 1982. xviii, 410 pp., bound, DM 238.00.—ISBN 3-540-11317-7

Topics in Current Chemistry. Vol. 104: Organotin Compounds. Edited by F. L. Boschke. Springer-Verlag, Berlin 1982. vii, 137 pp., bound, DM 76.00.—ISBN 3-540-11542-0

Reactive Intermediates. Vol. 2. Edited by R. A. Abramovitch. Plenum Press, New York 1982. xv, 599 pp., bound, $ 59.50.—ISBN 0-306-40594-6

Handbook of Carcinogens and Hazardous Substances. Chemical and Trace Analysis. Edited by M. C. Bowman. Marcel Dekker, Basel 1982. ix, 750 pp., bound, SFr. 284.00.—ISBN 0-8247-1683-3

Crystals. Growth, Properties, and Applications. Volume 7: Analytical Methods. High Melting Metals. Edited by H. C. Freyhardt. Springer-Verlag, Berlin 1982. vi, 148 pp., bound, DM 98.00.—ISBN 3-540-11790-3

Fachdidaktik: Naturwissenschaften Band 2. Schülereinstellungen und -leistungen im Unterrichtsfach Chemie. Ergebnisse empirischer Forschungen. By H.-J. Becker and G. Jüngel. Scriptor Verlag, Königstein/Taunus 1982. 208 pp., bound, DM 38.00.—ISBN 3-589-20770-1

Elektronenmikroskopie in der Festkörperphysik. Edited by H. Bethge and J. Heydenreich. Springer-Verlag, Berlin 1982. 564 pp., bound, DM 158.00.—ISBN 3-540-11361-4

Coal Science. Vol. 1. Edited by M. L. Gorbaty, J. W. Larsen, and I. Wender. Academic Press, New York 1982. x, 293 pp., bound, $ 32.50.—ISBN 0-12-150701-7

Advances in Chemical Physics. Vol. 51. Edited by I. Prigogine and S. A. Rice. John Wiley & Sons, Chichester 1982. ix, 289 pp., bound, £ 39.00.—ISBN 0-471-86439-0

Raman Spectroscopy. Linear and Nonlinear. Edited by J. Lascombe and P. V. Huong. John Wiley & Sons, Chichester 1982. xxxii, 834 pp., bound, £ 27.50.—ISBN 0-471-26241-2

Biochemical Applications of Raman and Resonance Raman Spectroscopies. By P. R. Carey. Academic Press, New York 1982. xi, 262 pp., bound, $ 34.00.—ISBN 0-12-159650-8

Analytical Profiles of Drug Substances. Vol. 11. Edited by K. Florey. Academic Press, New York 1982. x, 665 pp., bound, $ 39.00.—ISBN 0-12-260811-9

Batterien und Brennstoffzellen. Aufbau, Verwendung, Chemie. By K.-J. Euler. Springer-Verlag, Berlin 1982. xii, 206 pp., bound, DM 64.00.—ISBN 3-540-11378-9

Physikalische Organische Chemie. Band 1: Elektronenstruktur organischer Moleküle. Grundbegriffe quantenchemischer Betrachtungsweisen. Edited by M. Klessinger. Verlag Chemie, Weinheim 1982. xv, 331 pp., stitched, DM 78.00.—ISBN 3-527-25925-2

Tumor Immunity in Prognosis. The role of Mononuclear Cell Infiltration. Edited by S. Haskill. Marcel Dekker, Basel 1982. xiii, 426 pp., bound, SFr. 185.00.—ISBN 0-8247-1837-2

Inorganic Chemistry. A Modern Introduction. By Th. Moeller. John Wiley & Sons, Chichester 1982. viii, 846 pp., bound, £ 27.25.—ISBN 0-471-61230-8

The Chemistry of Heterocyclic Flavouring and Aroma Compounds. By G. Vernin. Ellis Horwood Publishers, Chichester 1982. 375 pp., bound, £ 32.50.—ISBN 0-85321-263-6

Inorganic Geochemistry. By P. Henderson. Pergamon Press, Oxford 1982. xv, 353 pp., stitched, £ 9.25.—ISBN 0-08-020447

Industrial Electrochemistry. By D. Pletcher. Chapman and Hall, London 1982. x, 325 pp., bound, £ 22.50.—ISBN 0-412-16500-7

Durgs and the Pharmaceutical Sciences Series. Vol. 13: Orphan Drugs. Edited by F. E. Karch. Marcel Dekker, Basel 1982. SFr. 148.00.—ISBN 0-8247-1681-7

Techniques of Chemistry. Vol. 17: Applications of Lasers to Chemical Problems. Edited by T. R. Evans. John Wiley & Sons, Chichester 1982. xi, 291 pp., bound, £ 42.50.—ISBN 0-471-04949-2

Fragrance Chemistry. The Science of the Sense of Smell. Edited by E. T. Theimer. Academic Press, New York 1982. xiii, 635 pp., bound, $ 89.50.—ISBN 0-12-695850-0

Electrons in Chemical Reactions. First Principles. Von L. Salem. John Wiley & Sons, Chichester 1982. x, 260 pp., bound, £ 27.25.—ISBN 0-471-08474-3

Analytical Methods for Pesticides and Plant Growth Regulations: Vol. 12: High-Performance Liquid Chromatography of Pesticides. Edited by J. F. Lawrence. Academic Press, New York 1982. x, 246 pp., bound, $ 35.00.—ISBN 0-12-784312-4

Organic Chemistry. Vol. 5-D: Oxidation in Organic Chemistry. Edited by W. S. Trahanovsky. Academic Press, New York 1982. xi, 360 pp., bound, $ 74.00.—ISBN 0-12-697253-2

Membrane Mimetic Chemistry. Characterization and Applications of Micelles, Microemulsions, Monolayers, Bilayers, Vesicles, Host-Guest-Systems and Polyions. By J. H. Fendler. John Wiley & Sons, Chichester 1982. xi, 522 pp., bound, £ 46.75.—ISBN 0-471-07918-0

Chemical Shift Ranges in Carbon-12 NMR Spectroscopy. By W. Bremser, B. Franke, and H. Wagner. Verlag Chemie, Weinheim 1982. xv, 971 pp., bound, DM 220.00.—ISBN 3-527-25908-2

Dem Ingenieur ist nichts zu schwer oder Technik und Industrie in Anekdoten. By G. Heindl and M. J. Higatsberger. Paul Neff Verlag, Wien 1982. 200 pp., bound, AS 160.00/DM 23.00.—ISBN 3-7014-190-X

Advances in Organometallic Chemistry. Vol. 20. Edited by F. G. A. Stone and R. West. Academic Press, New York 1982. ix, 369 pp., bound, $ 56.00.—ISBN 0-12-031120-8

Die Projektmethode. By K. Frey. Beltz Verlag, Weinheim 1982. 250 pp., stitched , DM 16.00.—ISBN 3-407-50106-4

Organic Reactions. Vol. 27. Edited by W. G. Dauben, G. A. Boswell, Jr., S. Danishefsky, H. W. Gschwend, R. F. Heck, R. F. Hirschmann, A. S. Kende, L. A. Paquette, G. H. Posner, B. M. Trost, R. Bittman, and B. Weinstein. John Wiley & Sons, Chichester 1982. vii, 405 pp., bound, £ 35.00.—ISBN 0-471-09657-1

Monographs in Modern Chemistry 14: Non-Formal Kinetics. By R. Schmid and V. N. Sapunov. Verlag Chemistry, Weinheim 1982. xi, 199 pp., bound, DM 98.00.—ISBN 3-527-25970-8

Reagents for Organic Synthesis. Vol. 10. By M. Fieser. John Wiley & Sons, Chichester 1982. 528 pp., bound, £ 31.00.—ISBN 0-471-86636-9

SUBJECT INDEX

(RA) = Review Article (SC) = Short Communication (NB) = Book Review

ACETOPHENONE, Asymmetric hydrosilylation of ~ with rhodium-complexes of optically active Schiff bases (SC) 377
Acetoxyalkyl radicals, Umpolung of carbonyl reactivity via ~ (SC) 130
1-Acetoxycarbapenems (SC) 537
Acetoxylation, Oxidation with palladium salts: Stereo- and regiospecific ~ of 4-vinylcyclohexene derivatives (SC) 366
β-Acetoxyphosphane oxides, Functionalization of α-methylenecarbonyl compounds to ~ and vinylphosphane oxides (SC) 537
N-Acetyldehydro-α-amino acids, A facile, generally applicable synthesis of ~ (SC) 203
Acetylene, Novel tungsten-alkyl and tungsten-acyl complexes with ~ as four-electron ligand (SC) 861
Cyclobutadienes or ~-s from (2-cyclopropen-1-yl)carbenes — A question of spin multiplicity? (SC) 913
N-acetyllactosamine, Synthesis of trisaccharide moieties from N-acetylneuraminic acid and ~ (SC) 927
Acetylneuraminic acid, Synthesis of trisaccharide moieties from ~ and N-acetyllactosamine (SC) 927
Acid chloride method, Coupling of sterically hindered peptide bonds—A renaissance of the ~ (SC) 630
Acidity, Kinetic ~ of methine protons and carbonyl-activated methylene protons (SC) 637
Activation volume, Influence of ring-size of cycloalkenes on the ~ in the high-pressure copolymerization of maleic anhydride (SC) 363
Active transport, of amino acid by a synthetic metal-complex carrier (SC) 304
Acylamination, Regioselective ~ by hetero-Cope-rearrangement (SC) 370
Acylaminomalonic ester synthesis, Reaction of acyliminomalonic esters with C-nucleophiles, an Umpolung in the ~ of α-amino acids (SC) 203
Acyl cyanides, The chemistry of ~ (RA) 36
Synthesis of ~ from acyl iodides (SC) 83
N-Acyl-2-(diethoxyphosphoryl)glycine esters, Facile preparation of ~ and their use in the synthesis of dehydroamino acid esters (SC) 776
Acyliminomalonic esters, Reaction of ~ with C-nucleophiles, an Umpolung in the acylaminomalonic ester synthesis of α-amino acids (SC) 203
Acyloxyimino-glycosyl bromides, Functionalization at proanomeric centers by photobromination: A novel access to oxo- and ~ (SC) 625
Acylsulfenyl iodides, Isolation of crystalline ~ — Intermediates in the I_2-oxidation of thiocarboxylic acids (SC) 150
Adamantane skeleton, $[Ta_4F_{12}O_6]^{4-}$: A tetranuclear oxofluorotantalate(V) with ~ (SC) 870
Addition, Diastereogenic ~ of crotylmetal compounds to aldehydes (RA) 555
Cationic prenylation of olefins (SC) 82
Alkylchromium(III) dichlorides, Highly selective reagents for the ~ of nucleophiles to aldehydes (SC) 144
Cyclopropenes as complex ligands: $Fe_2(CO)_9$-induced ring-opening of a spirocyclopropene and reversible CO-~ to the vinylcarbene ligand (SC) 205
~ of alkyl radicals to alkynes: Distinction between radical and ionic nucleophiles (SC) 768
Olefin selectivities in the ~ of carbenes (SC) 932
Albomycins, Constitution of the deferriform of the ~ δ_1, δ_2, and ε (SC) 527
Alcohols, Photo-induced reaction of ~ with tricarbonyl(η^5-cyclopentadienyl)ethyltungsten (SC) 205
tert-Alcohols, Alkylchromium(III) dichlorides, Highly selective reagents for the addition of nucleophiles to aldehydes (SC) 144
Aldehydes, Determination of the conformation of acyclic α,β-unsaturated ~ and ketones from their infrared and Raman spectra—Results and limitations of model calculations (SC) 639
Aldimines, Vacuum dynamic gas phase/solid-phase reactions: N-Chlorination of primary amines and α-elimination of the resulting chloramines; synthesis of reactive (E)- and (Z)-~ (SC) 690
Aldol addition, Competition between the aza-Cope rearrangement and ~ (SC) 198
Two-step sigmatropic rearrangement versus ~ of ammonioimides (SC) 199
Three-center diastereoselective ~ of β-lactone enolates to aldehydes (SC) 777
Erythro-selective aldol-type addition of titanated aldehyde-hydrazones (SC) 864
Aldosterone antagonist, Synthesis of spironerone—A novel highly active ~ (SC) 696
Algae, Signal substances and their reception in the sexual cycle of marine brown ~ (RA) 643
Alkaloid biosynthesis, Isoquinolines and naphthalenes from β-polyketones: Model reactions for an extraordinary ~ (SC) 200
Alkaloids, Photochemically generated 1,4-dihydroxypyridines and 2-hydroxytetrahydropyridines as precursors for benzo[a]quinolizidine ~ (SC) 539
Alkane mixtures, Liquid structures and thermodynamics of ~ (RA) 184
Alkanes, Selective hydroxylations of chiral and substituted paraffins (SC) 146
The conformational equilibrium of the lower ~ (SC) 146
Hydroxylation of acyclic ~ by oxygen atoms $O(^3P)$—Comparison of ozone and $O(^3P)$ oxidations of ~ (SC) 303
1-Alken-5-yne derivatives, One-pot synthesis of ~ (SC) 286
μ-Alkoxo-μ-hydridotungsten complexes, Photo-induced reaction of alcohols with tricarbonyl(η^5-cyclopentadienyl)ethyltungsten (SC) 205
β-Alkoxyethylenediazonium salts, Alkylation of α-diazoketones with alkyldiazonium ions: Facile synthesis of ~ (SC) 786
Alkylarenes, Synthesis of primary ~ without benzene via olefin metathesis (SC) 700
Alkylation, Lewis acid induced α-~ of carbonyl compounds (RA) 96
~ of α-diazoketones with alkyldiazonium ions: Facile synthesis of β-alkoxyethylenediazonium salts (SC) 786
α-tert-Alkylation, Lewis acid induced α-alkylation of carbonyl compounds (RA) 96
Alkylchromium(III) dichlorides, Highly selective reagents for the addition of nucleophiles to aldehydes (SC) 144
Alkylidenecarbenes, Geminal vinyl diazides: Potential precursors of functionalized ~; synthesis and reactions of 3,3-diazido-2-cyanoacrylic acid methyl ester (SC) 287
Alkynes, Cross-conjugated trienes by thermal isomerization of ~ (SC) 286
Alkynylcyclopropanes, Convenient general synthesis of ~ (SC) 65
Allenecarboxanilides, Intramolecular Diels-Alder reaction of ~ (SC) 620
Allene complexes, Metal-induced decarboxylation of diketene—A novel route to ~ (SC) 551
Allenes, Tetra-tert-butylallene and its radical cation (SC) 924
Allergy, The leukotrienes, highly biologically active substances involved in ~ and inflammation (FP) 902
Allyl group transfer, Unsymmetrical transfer of allyl groups in the reaction of $[(\eta^3\text{-}C_3H_5)_2M]$ (M = Pd, Ni) with bis(diphenylphosphino)maleic anhydride (SC) 356
Allylmetal compounds, Diastereogenic addition of crotylmetal compounds to aldehydes (RA) 555
Non-planar structures of ~ and pentadienylmetal compounds: Pleating to achieve a better charge distribution (SC) 145
Aluminum compounds, Novel chlorooxoaluminates (SC) 133
Aluminum fluoride, Preparation of a graphite fluoride film on aluminum (SC) 378
Aluminum iodide, Crystal structures of AlI_3, GaI_3, and InI_3—Isotypic relationship AlI_3/SO_3 (SC) 386
Amino acid esters, Facile preparation of N-acyl-2-(diethoxyphosphoryl)glycine esters and their use in the synthesis of dehydro-~ (SC) 776
Amino acids, Induction of asymmetry by ~ (RA) 584
Reaction of acyliminomalonic esters with C-nucleophiles, an Umpolung in the acylaminomalonic ester synthesis of α-~ (SC) 203
Resolution of D- and L-~ by HPLC using copper complexes of N,N-dialkyl-α-~ as novel chiral additives (SC) 218
Chiral silica packings with L-proline or L-hydroxyproline bonded via alkyl or alkylbenzyl chains for the separation of the enantiomers of α-~ by column liquid chromatography (SC) 930
2-Aminobenzothiazoles by oxidative cyclization of arylthioureas with sulfinyl chloride (SC) 541
Aminophosphane, Bis(trimethylsilyl)~ (SC) 62
Aminyl complex, $C_5H_5(CO)_2Mn$(m-Toluidinyl), An isolable ~ (SC) 691
Ammonioimides, Two-step sigmatropic rearrangement versus aldol addition of ~ (SC) 199
Ammoniomethanides, Dipolar intermediates in the [2,3]-sigmatropic rearrangement of ~ (SC) 198
Analysis, Polarographic ~ (NB) 798
Ancistrocladeine, Isoquinolines and napththalenes from β-polyketones: Model reactions for an extraordinary alkaloid biosynthesis (SC) 200
Anions, Generation and NMR-detection of the ~ N-methyl-1-benzazocinide, 1-benzazocindiide, and dibenz[b,g]azocindiide; a family of aromatic π-excessive compounds (SC) 791
Anomalies of liquid water (RA) 315
Anthracyclinone, Carbonyliron-assisted cycloaddition of a 1,3-diene to a CC double bond: Synthesis of an ~ precursor (SC) 430
Antiaromaticity, The effect of an annelated cyclobutene or cyclobutadiene ring on the norcaradiene—cycloheptatriene equilibrium (SC) 138
The question of the ~ of 1,3-cyclobutadiene: Thermal valence isomerization of the tricyclo[5.2.0.$3^{3,5}$]nona-1,6,8-triene system (SC) 139
Antibiotics, Constitution of the deferriform of the albomycins δ_1, δ_2, and ε (SC) 527

Antibiotic syntheses, From isocyanides via four-component condensations to antibiotic syntheses (RA) 810
Antimony compounds, Antimony homologues of dinitrogen and azobenzene as complex ligands: Preparation and structure of $[Sb{\equiv}Sb\{W(CO)_5\}_3]$ and $[PhSb{=}SbPh\{W(CO)_5\}_3]$ (SC) 215
Synthesis of an all-cis-organocyclotristibane and its pentacarbonylchromium complex (SC) 375
Arachidonic acid, The leukotrienes, highly biologically active substances involved in allergy and inflammation (RA) 902
Arachidonic acid hydroperoxide, Serial cyclizations of an ~ (SC) 217
Arene-metal clusters: Metal atom-bis(arene)metal solution phase chemistry (SC) 212
Support effects on the growth, stabilization, and agglomeration of low nuclearity transition metal clusters synthesized from metal atoms vaporized into liquid aryl-substituted polymers (SC) 550
Arenes, The thermal conversion of 1,5,9-triynes into ~ —[2+2+2]-cycloadditions or sigmatropic rearrangements? (SC) 685
Aromaticity, A bishomocyclooctatetraene dianion (SC) 301
Semibullvalenetetracarboxylates: Models for molecules with bishomoaromatic ground state (SC) 438
Generation and NMR-detection of the anions N-methyl-1-benzazocinide, 1-benzazocindiide, and dibenz[b,g]azocindiide; a family of aromatic π-excessive compounds (SC) 791
Theoretical invatigations on the valence tautomerism between 1,6-methano[10]annulene and tricyclo[4.4.1.$0^{1,6}$]undeca-2,4,7,9-tetraene (SC) 865
Norcaradiene valence tautomer of a 1,6-methano[10]annulene: Tricyclo[4.4.1.$0^{1,6}$]undeca-2,4,7,9-tetraene-11,11-dicarbonitrile (SC) 869
Arsenic ylides, Stabilization of the unstable tautomers of phosphino- and arsino-substituted ylides by coordination to transition metals (SC) 926
N-[1-(Arylcarbonyloxy)alkyl]pyridinium salts, Synthesis and properties of ~ (SC) 289
2-Aryl-1,1-difluoroethylenes, Photocyclization of ~: Synthesis of mono- and difluorinated polycyclic arenes (SC) 766
Arylthioureas, 2-Aminobenzothiazoles by oxidative cyclization of ~ with sulfinyl chloride (SC) 541
Asymmetric hydrosilylation of acetophenone with rhodium-complexes of optically active Schiff bases (SC) 377
Asymmetric iron atoms, Redox reactions of a ferrio-arsane and -stibane with chlorophosphanes: Synthesis of a diferrioarsonium chloride and a stiborane with ~ (SC) 549
Asymmetric reactions, Dependence of the enantioselectivity on the relative concentration of substrate in an NADH model reaction (SC) 433
Asymmetric syntheses, Induction of asymmetry by amino acids (RA) 584
The unambiguous specification of the steric course of ~ (RA) 654
Asymmetric synthesis of methyl jasmonate (SC) 856
H Atom reservoirs, Cyclopentadienyl(peralkylarene)iron(I) complexes as ~: Isolation of semihydrogenated species in the Pd/C catalyzed hydrogenation of cyclopentadienyliron(II) complexes of exocyclic olefins (SC) 918
Autoxidation, Formation of $^1O_2$ in the reversible ~ of enolates derived from carboxylic acids (SC) 75
1-Azaadamantanes, Synthesis of specifically substituted ~ (SC) 923
Azaborolinyl complexes, Azaborolinyl-iron and -cobalt sandwich complexes by metal atom synthesis (SC) 68
Aza-Cope Rearrangement, Competition between the ~ and aldol addition (SC) 198
7-Azanorbornadiene (SC) 778
Δ^3-1,2,5-Azasilaborolines, Novel BN ligand with six competing π electrons around the transition metal coordination center (SC) 207
Azobenzene, Phanes of ~ (SC) 373
Azulene, 1-Phenyl-~→2-Phenyl-~ rearrangement—Substituent migration or skeletal rearrangement? (SC) 440
Vacuum pyrolysis of 5,5,10,10-tetrachlorotricyclo[7.1.0.$0^{4,6}$]deca-2,7-diene: 1,5- and 2,6-Dichloro~-s (SC) 444
Simple transformation of the ~ system into the pentalene system (SC) 695
Cycloadditions of ~ at high pressure (SC) 708

BARBARALANES, A simple synthesis of di- and trihalo-~ (SC) 549
Benzamide, Controlled modification of crystal habit by "tailor-made" impurities: Application to ~ (SC) 631
Benzazocinide, Generation and NMR-detection of the anions N-Methyl-1-~, 1-benzazocindiide, and dibenz[b,g]azocindiide; A family of aromatic π-excessive compounds (SC) 791
Benzocyclobutadiene, The dianion 1,2-diphenylbenzocyclobutadienediide (SC) 132
The effect of an annelated cyclobutene or cyclobutadiene ring on the norcaradiene—cycloheptatriene equilibrium (SC) 138
The question of the antiaromaticity of 1,3-cyclobutadiene: Thermal valence isomerization of the tricyclo[5.2.0.$0^{3,5}$]nona-1,6,8-triene system (SC) 139
Benzocyclobutene, Thermal conversion of 1,3-cyclooctadien-5-yne into ~—A novel isomerization on the C_8H_8 hypersurface (SC) 66
1,4-Benzodiazepine derivatives, Light-induced decarboxylation of carbamoyloxyamino compounds (SC) 525
Benzopyrans, Synthesis and reactions of 4-chromanones (RA) 247
Benzo[a]quinolizidine alkaloids, Photochemically generated 1,4-dihydroxypyridines and 2-hydroxytetrahydropyridines as precursors for ~ (SC) 539
Benzoquinones, How similar are tropoquinones and ~? (SC) 76
o-Benzoquinone monoformylmethides, by sensitized photooxygenation of cis-β-methoxystyrenes (SC) 382
Benzothiazoles, 2-Amino~ by oxidative cyclization of arylthioureas with sulfinyl chloride (SC) 541
2,1,4-Benzoxathiazinone, The sulfonation of aromatic isocyanates: Sulfonated p-tolyl isocyanate—an X-ray structure analysis (SC) 867
η^3-Benzyl compounds, Reversible double deprotonation of hexamethylbenzene on ruthenium: Formation of a fluxional η^3-benzyl compound by protonation of an o-quinodimethane complex of ruthenium(0) (SC) 379
Benzyl esters, Oxidative cleavage of ~ with triarylamine cation radicals—Selective deblocking of protected carboxy functions (SC) 780
α-Benzylidene-γ-butyrolactone, Quantitative photodimerization of crystalline ~ (SC) 435
"Bichromocenylene": A sandwich with partly decoupled electrons (SC) 151
Bicycloalkylidenes, Is the unpaired electron in radical cations of sterically hindered alkenes localized or delocalized? (SC) 690
Bicyclo[1.1.0]butane, Electron density distribution in the bonds of the bridged ~-system 1,5-dimethyltricyclo[2.1.0.$0^{2,5}$]pentan-3-one (SC) 775
Bicyclo[4.4.2]dodeca-1-ene—The first "hyperstable" bridgehead olefin (SC) 306
Bicyclo[3.3.1]nonane derivatives, Synthesis of ~ under physiological conditions (SC) 306
Bicyclo[2.2.2]octanes, from allenecarboxylic acid esters and cyclohexadienolates (SC) 636
Bile pigments, Two mild, regioselective methods of degrading biliprotein chromophores (SC) 446
Biliprotein chromophores, Two mild, regioselective methods of degrading ~ (SC) 446
Bimetal-Sulfur cluster, $[Fe_3W_3S_{14}]^{4-}$, A novel hexanuclear "pure" bimetal-sulfur cluster with $Fe_3(\mu_3\text{-}S)_2$ center (SC) 860
Bioinorganic chemistry, The inorganic chemistry of biological processes (NB) 454
Bioorganic chemistry (NB) 798
Biosynthesis, Topical problems in the ~ of red blood pigment (RA) 343
2,2'-Bipyridyldichloroplatinum(II), Photochemical oxidative addition of chlorine from chloroform to ~ (SC) 209
Bis[bis(trimethylsilyl)acetylene]dicarbonylchromium (SC) 929
Bischelating ligand, A novel ~ with two tetradentate N,N,O,S subunits—Synthesis and properties of a dinuclear Cu^{II} complex (SC) 385
Bis(dinitrogen)-complexes, Bis(dinitrogen)- and diethylene-molybdenum(0) complexes (SC) 441
Bis(dithizone)hepta(diiodine), A branched chain of seven neutral iodine molecules in crystalline ~ (SC) 219
Bishomocyclooctatetraene dianion (SC) 301
Bishomodehydrobenzene, 2,3-Cyclooctadien-6-yne—An isolable ~ (SC) 67
Bis(isopropylidene)-1,2,4-trithiolane, Formation of ~ from 2-methyl-2-triphenylphosphoniodithiopropionate (SC) 291
Bis(methylene)phosphoranes, The first ~ of type $R{-}P[{=}C(SiMe_3)_2]_2$ with tricoordinated pentavalent phosphorus (SC) 80
Bismuthanes, Tetraethyldibismuthane: A dinuclear bismuth compound (SC) 439
Bismuth compounds, Structure of the octabismuth(2+) cluster in crystalline $Bi_8(AlCl_4)_2$ (SC) 445
Bis(pentafluoro-λ^6-sulfanyl)amines (SC) 355
Bis(pentamethylcyclopentadienyl)titana(IV)cyclotetrasulfane, metallacyclosulfanes: Synthesis of ~ (SC) 384
Bis(trimethylsilyl)aminophosphane (SC) 62
[2,3-Bis(trimethylsilyl)-2-cyclopropen-1-yl]diazomethane, Synthesis and properties of ~ (SC) 437
Black lipid membranes from polymerizable lipids (SC) 368
Blood pigment, Topical problems in the biosynthesis of red ~ (RA) 343
CC Bond formation, Diastereogenic addition of crotylmetal compounds to aldehydes (RA) 555
Cationic prenylation of olefins (SC) 82
C—H Bond activation, Selective ~ in ethane using photoexcited Cu atoms (SC) 211
Bonding isomerism, $Me_2PCHPMe_2^{\ominus}$ as ambidentate chelate ligand (SC) 921
Brefeldin A, 4-Oxo-2-cyclopentenyl acetate—A synthetic intermediate (RA) 480
Bridgehead olefin, Bicyclo[4.4.2]dodeca-1-ene—The first "hyperstable" ~ (SC) 306
Bridging ligands, A μ_3-CO_2 bridged, tetranuclear carbonylrhenium complex: $[(OC)_5Re(CO)_2Re(CO)_4]_2$ (SC) 526
Bromination, Stereochemistry of the ~ of 1,6-methano[10]annulene (SC) 920
MO model for the stereochemistry of ~ of 1,6-methano[10]annulene (SC) 922
Brown algae, Signal substances and their reception in the sexual cycle of marine ~ (RA) 643
Butadiene, Higher telomers in the Pd-catalyzed reaction of ~ with alcohols (SC) 767
(Butadiene)hafnocene, The reaction of (Butadiene)zirconocene and ~ with ethylene (SC) 913
(Butadiene)zirconocene, The reaction of ~ and (butadiene)hafnocene with ethylene (SC) 913
Butadiynylamines, A simple, highly variable route to (1,3-diynyl)amines (SC) 282
Butatrienylamines, Preparation of ~ from butenynylamines (SC) 862
Butenynylamines, Preparation of butatrienylamines from ~ (SC) 862

CAGE MOLECULE, $Tl(OtBu)_3Sn$: A small pentaatomic cage molecule (SC) 858
Carbacyclin, Prostacyclin and synthetic analogues (RA) 751
Carbamoyloxyamino compounds, Light-induced decarboxylation of ~ (SC) 525
Carbanions, Nucleophilic substitution of hydrogen in nitroarenes by phosphorus-stabilized ~ having "vicarious" leaving group (SC) 451
Carbapenems, 1-Acetoxy~ (SC) 537
Carbene complexes, Chiral binuclear ~ from (R,R)-1-(1-dimethylaminoethyl)-2-lithioferrocene and hexacarbonyltungsten (SC) 788
Carbenes, Geminal vinyl diazides: Potential precursors of functionalized alkylidene-~; Synthesis and reactions of 3,3-diazido-2-cyanoacrylic acid methyl ester (SC) 287
Chloro(phenoxy)carbene—A Nucleophilic carbene having temperature-dependent selectivity (SC) 916
Olefin selectivities in the addition of ~ (SC) 932
Carbocation, The norbornyl cation: Prototype of a 1,3-bridged ~ (RA) 87
Carbohydrates, Advances in selective chemical syntheses of complex oligosaccharides (RA) 155
Carbon dioxide, A μ_3-CO_2 bridged, tetranuclear carbonylrhenium complex: $[(OC)_5Re(CO)_2Re(CO)_4]_2$ (SC) 526
Carbonylation, Mechanistic aspects of the ~ of nitrobenzene with rhodium catalysis (SC) 687
Carbonyl compounds, Lewis Acid induced α-alkylation of ~ (RA) 96
Carbonylcyclopropanes (cyclopropylidenemethanones): Preparation and steric course of cyclodimerization to dispiro[2.1.2.1]octane-4,8-diones (SC) 83
Carbonylmetal complexes, Heterocyclic radical anions as ligands: An unexpected change of coordination in penta~ (SC) 700
C-Carboxylation, of nitroalkanes with 1-ethoxycarbonylbenzotriazole (SC) 139
Carboxylic acids, Formation of $^1O_2$ in the reversible autoxidation of enolates derived from ~ (SC) 75
Carbyne complex, $C_\alpha C_\alpha$-coupling of two $[(CO)_5CrCNEt_2]$ fragments by reductive dimerization of a cationic ~ (SC) 444
Carcinogenesis, Light-induced activation of 7-dehydrocholesterol (SC) 356
Cardenolide, 2β-2',3'-dideoxy-α,L-rhamnopyranosides, Synthesis of ~ (SC) 547
Cardiac glycosides, Synthesis of cardenolide 3β-2',3'-dideoxy-α,L-rhamnopyranosides (SC) 547
Synthesis of ~: Evatromonoside and its anomer (SC) 779
Catalysis, ETC: A mechanistic concept for inorganic and organic chemistry (RA) 1
Activation of silanes on a ruthenium cluster. Synthesis, characterization, and catalytic action of the cluster anion $[HRu_3(CO)_{10}(SiEt_3)_2]^-$ (SC) 73
Oxanickelacyclopentene derivatives from nickel(0), carbon dioxide, and alkynes (SC) 76
Preparation of an ethylene(hydrido)tungsten complex by photo-induceed β-elimination (SC) 78
Specific transfer of the H_{Si}-atom of succinate to the 5-deazaflavin analogue of succinate dehydrogenase (SC) 365
Electron spin resonance studies of the sulfur ~ of the industrial dichlorination of benzene (SC) 533
H_2S as a promotor for the water gas shift reaction (SC) 619
Palladium(0)-catalyzed [3 + 2]-cycloadditions of diphenylmethylenecyclopropanes to alkenes (SC) 622
cis-$[Ru(bpy)_2(CO)_2H]^+$—A possible intermediate in the photochemical production of H_2 from water catalyzed by $[Ru(bpy)_3]^{2+}$? (SC) 628
Mechanistic aspects of the carbonylation of nitrobenzene with rhodium catalysts (SC) 687
Higher telomers in the Pd-catalyzed reaction of butadiene with alcohols (SC) 767
Photoinitiated hydrosilylations in presence of tetrahedral heterometallic clusters: ~ by intact clusters (SC) 786
Catalytic hydrogenation of 7-methoxy-6-methyl-8-nitro-1-isoquinolinecarbonitrile to unusual products (SC) 857
Cyclopentadienyl(peralkylarene)iron(I) complexes as H atom reservoirs: Isolation of semihydrogenated species in the Pd/C catalyzed hydrogenation of cyclopentadienyliron(II) complexes of exocyclic olefins (SC) 918
Catalyst deactivation, during zirconocene- and hafnocene-induced ethylene dimerization (SC) 913
Catalysts, α-Linked disaccharides from O-(β-D-glycopyranosyl) trichloroacetimidates using trimethylsilyl trifluoromethanesulfonate as catalyst (SC) 781
Zinc sulfide as catalyst for the heterogeneous photoreduction of water (SC) 783
Cation radicals, Oxidative cleavage of benzyl esters with triarylamine ~—Selective deblocking of protected carboxy functions (SC) 780
Cellotetraoses, Synthesis of linear and branched ~ (SC) 72
Charge distribution, Non-planar structures of allyl- and pentadienylmetal compounds: Pleating to achieve a better ~ (SC) 145
Charge separation, Laser photolysis—A new route for ~ (SC) 436
Charge transfer, Intervalence transfer between hexaaminecobalt(III) and hexacyanoruthenate(II) (SC) 77
Chelate ligand, Triphenylstannanedithiocarboxylate, a novel ~ (SC) 364
A novel bischelating ligand with two tetradentate N,N,O,S subunits—Synthesis and properties of a dinuclear Cu^{II} complex (SC) 385
$K_2[Ni_2(N_2S_2)_2(CN)_2]$—A dinuclear Complex with the $S_2N_2^{2\ominus}$ ~ (SC) 633
Cleavage of the metal-metal triple bond by chelate-forming diazoalkane bridges (SC) 707
$[(S_3NNi)_3S_2]^\ominus$—A Ni_3S_2 cluster with $S_3N^\ominus$ ~-s (SC) 705
$Me_2PCHPMe_2^\ominus$ as ambidentate ~ (C) 921
Chelates, Coordinatively unsaturated trinuclear molybdenum-sulfur cluster with dithiophosphinato bridge (SC) 929
Chemical equilibrium, An introduction to ~ and kinetics (NB) 552
Chemical equivalence, Electrochemical oxidation of croconate salts; evidence of the ~ of the carbonyl oxygen atom and the dicyanomethylene Group (SC) 635
Chemical technology, Ullmanns Encycklopädie der technischen Chemie (NB) 553
Chiral additives, Resolution of D- and L-amino acids by HPLC using copper complexes of N,N,-dialkyl-α-amino acids as novel ~ (SC) 218
Chirality, Basic principles of the CIP-system and proposals for a revision (RA) 567
(Chloroacyl)diphenylphosphanes as sources of halogenated ketenes (SC) 355
2-Chloro-2-cyclopropylidene acetates, Novel synthetic building blocks activated by ring strain: General entry to ~ (SC) 790
P-Chloro(methylene)phosphane derivatives, $Ph(Me_3Si)C{=}PCl$ as educt for methylenephosphanes with alkyl-, amino-, phosphino-, alkoxy-, or alkylthio-groups on phosphorus (SC) 219
Chlorooxoaluminates, Novel ~ (SC) 133
Chlorophyll biogenesis, Evolution of hydrogen from photochemically reduced water-soluble tin(IV)-porphyrins (SC) 131
Chloro(phenoxy)carbene—A Nucleophilic carbene having temperature-dependent selectivity (SC) 916
4-Chromanones, Synthesis and reactions of ~ (RA) 247
Chromatography, Optimal parameters in high speed liquid ~ (RA) 50
Chromium compounds, "Bichromocenylene": A sandwich with partly decoupled electrons (SC) 151
Ferromagnetic interaction between orthogonal "magnetic" orbitals in dinuclear $Cu^{II}Cr^{III}$ complexes (SC) 624
$CrTe_3$—A novel transition-metal polytelluride (SC) 911
Bis[bis(trimethylsilyl)acetylene]dicarbonylchromium (SC) 929
CIP-system, Basic principles of the ~ and proposals for a revision (RA) 567
Clathrates, "Dodecasile"—A novel series of polytypic clathrate compounds of SiO_2 (SC) 206
A ternary clathrate from cryptand, hydroquinone and water—Selective formation and X-ray structural analysis (SC) 431
Stetter's complexes are no intramolecular inclusion compounds (SC) 787
"γ-$PW_{12}O_{40}^{3-}$", A heteropolyanion with clathrate character (SC) 789
Cleavage of water, Photochemical evolution of H_2 in the system methyl viologen/Mn^{II}-meso-tetraphenylporphyrintrisulfonic acid/mercaptoethanol/hydrogenase (SC) 434
Clusters, Organometallic aspects of the Fischer-Tropsch synthesis (RA) 117
Activation of silanes on a ruthenium cluster: Synthesis, characterization and catalytic action of the cluster anion $[HRu_3(CO)_{10}(SiEt_3)_2]^-$ (SC) 73
$[Fe_6S_9(SCH_2C_6H_5)_2]^{4-}$: A hexanuclear iron-sulfur cluster anion containing the square-pyramidal $[(\mu_4\text{-}S)Fe_4]$ unit (SC) 201
$(C_5H_5)_3CoMn_2(CO)_4(CS)PMe_3$—A heterotrinuclear complex with a μ_2-C, η^1-S-bonded thiocarbonyl group (SC) 202
Arene-metal ~: Metal atom-bis(arene)metal solution phase chemistry (SC) 212
λ^3-Phosphazenes as bridging η^1-ligands (SC) 297
A new type of iron-molybdenum-sulfur cluster: Synthesis and structure of $[Fe_2Mo_2(\eta^5\text{-}C_5H_5)_2(\mu_3\text{-}S)_2(\mu_3\text{-}CO)_2(CO)_6]$ (SC) 307
Structure of the octabismuth(2+) cluster in crystalline $Bi_8(AlCl_4)_2$ (SC) 445
$[Mo_4(NO)_4(S_2)_6O]^{2-}$, A novel highly symmetric polynuclear complex with two "handle-shaped" and four "roof-shaped" coordinated S_2^{2+} bridging ligands at a tetragonal Mo_4 disphenoid (SC) 535
Formation of metal-metal bonds and conversion of the metal aggregate $\{Mo_4(S_2)_4(S_2)_2\}$ by atom-transfer and redox reactions at nonequivalent ligands; $[Mo_4S_4(NO)_4(CN)_8]^{8-}$ an anion with a central cubane-like unit (SC) 536
$Cs_7Fe_4Te_8$, A compound with $[Fe_4Te_8]$ ~ (SC) 544
Support effects on the growth, stabilization and agglomeration of low nuclearity transition metal ~ synthesized from metal atoms vaporized into liquid aryl-substituted polymers (SC) 550
Designed synthesis of an alkylidyne-capped trinuclear (Mo, Mo, W) metal cluster (SC) 629
Cluster synthesis by exchange of bridge-forming carboxylate ligands (SC) 692
$(S_3NNi)_3S_2^\ominus$—A Ni_3S_2 cluster with $S_3N^\ominus$ chelate ligands (SC) 705
Photoinitiated hydrosilylations in presence of tetrahedral heterometallic ~: Catalysis by intact ~ (SC) 786
$[Mo_4^{IV}S_4(CN)_{12}]^{8-}$, a cluster with high negative charge and cubane-like Mo_4S_4-moiety—On the significance of cyanothiomolybdates for the prebiotic evolution (SC) 795
$[Fe_3W_3S_{14}]^{4-}$, A novel hexanuclear "pure" bimetal-sulfur cluster with $Fe_3(\mu_3\text{-}S)_2$ center (SC) 860
Coal utilization, Chemistry of ~ (NB) 640
Cobalt compounds, Steric and electronic control of ligand field strength in octahedral Co^{3+} spin-crossover complexes (SC) 915
The $HCo_3(CO)_9$-catalyzed olefin isomerization (SC) 925

Cobaltocene, Bridged $C_5Me_5Co^{II}$ complexes—Reactive intermediates in the cyclopentadienylation of cobalt(II) halides (SC) 131
Cobaltocenium salts, Cyclopentadienone complexes as synthons: Ring- and regiospecific nuclephilic additions to ~—Synthesis of substituted cyclopentadienes and cyclopentenones (SC) 617
Collisional activation mass spectrum, $HF{\rightarrow}CH_2^{\oplus\ominus}$: A novel, stable ion-dipole complex (SC) 528
Column liquid chromatography, Chiral silica packings with L-proline or L-hydroxyproline bonded via alkyl or alkylbenzyl chains for the separation of the enantiomers of α-amino acids by ~ (SC) 930
Competitive coordination, Novel BN ligand with six competing π electrons around the transition metal coordination center (SC) 207
Complex ligands, Cyclopropenes as ~: $Fe_2(CO)_9$-induced ring-opening of a spirocyclopropene and reversible CO-addition to the vinylcarbene ligand (SC) 205
Conductivity, Vehicle mechanism, a novel model for the interpretation of the ~ of fast proton conductors (SC) 208
Configurational identity (solid, liquid), (N→P)-Silatropism and rotamer detection in the methylenephosphane PhP=C(NArylSiMe$_3$)(PPhSiMe$_3$) (SC) 448
Conformation, and biological activity of cyclic peptides (RA) 512
Influence of conformational rigidity on the stabilization of α-ferrocenyl carbocations: A cis-fixed differrocenyl carbenium ion (SC) 293
Determination of the ~ of acyclic α,β-unsaturated aldehydes and ketones from their infrared and Raman spectra—Results and limitations of model calculations (SC) 639
Solid-state ^{13}C-NMR spectra of cyclotriprolines (SC) 689
Control of the ~ of transition states in intramolecular Diels-Alder reactions with inverse electron demand (SC) 863
Conformational equilibrium, The ~ of the lower alkanes (SC) 146
"Contra-steric" alkylation of the enolates of dioxolanecarboxylic acid esters (SC) 449
Conversion of energy, Chemically dissymmetrical, polymerized surfactant vesicles: Synthesis and possible utilization in artificial photosynthesis (SC) 81
Coordination, Stabilization of unusual oxidation and ~ states by the ligands OSF_5, $OSeF_5$, and $OTeF_5$ (FP) 877
Organometallic intramolecular π-olefin-metal ~ compounds (RA)
Manganese complexes with "end-on" and spirocyclic bonded σ^3,λ^5-phosphazene ligands (SC) 136
Ambivalent ~ behavior of lithium aluminium hydride in electron transfer reactions (SC) 141
Synthesis and structure of triply coordinated sulfur anions (SC) 153
A novel anionic five-coordinate tris(trichlorostannato)platinum(II) complex (SC) 284
Heterocyclic radical anions as ligands: An unexpected change of ~ in pentacarbonyl metal complexes (SC) 700
A μ_2-η^2-Styryl complex by reaction of $Cp_2Mo_2(CO)_4$ with the Wittig reagent $(C_6H_5)_3P{=}CH_2$ (SC) 919
$Me_2PCHPMe_2^{\ominus}$ as ambidentate chelate ligand (SC) 921
Stabilization of the unstable tautomers of phosphino- and arsino-substituted ylides by ~ to transition metals (SC) 926
Cope-rearrangement, Semibullvalenetetracarboxylates: Models for molecules with bishomoaromatic ground state (SC) 438
From cis,trans-cis-1,2,3,4-tetravinylcyclobutane to cyclododecatetraene—Two consecutive ~s (SC) 686
Copper atoms, Selective C—H bond activation in ethane using photoexcited ~ (SC) 211
Cu-H_2 Photochemistry in the matrix; ESR, FTIR, UV/VIS spectroscopic and kinetic studies (SC) 380
Copper compounds, CH_4 activation by photoexcited Cu_2 molecules (SC) 381
Ferromagnetic interaction between orthogonal "magnetic" orbitals in dinuclear Cu^{II}-Cr^{III} complexes (SC) 624
Corrin biosynthesis, Synthesis of a dicyanocobalt(III) D-didehydrocorrinate and its reduction to the dicyanocobalt(III) corrinate (SC) 152
(A→D) Ring closure to the nickel(II)-B,C,D-hexadehydrocorrinate (SC) 214
CC-Coupling, Lewis acid induced α-alkylation of carbonyl compounds (RA) 96
Alkylchromium(III) dichlorides, Highly selective reagents for the addition of nucleophiles to aldehydes (SC) 144
$C_\alpha C_\alpha$-Coupling of two $[(CO)_5CrCNEt_2]$ fragments by reductive dimerization of a cationic carbyne complex (SC) 444
Coupling constants, ^{13}C-^{13}C and ^{13}C-H coupling constants and the electronic structure of cyclopropane, cyclohexane, and propane (SC) 872
Croconate salts, Electrochemical oxidation of ~; Evidence of the chemical equivalence of the carbonyl oxygen atom and the dicyanomethylene group (SC) 635
Crotylmetal compounds, Distereogenic addition of ~ to aldehydes (RA) 555
Crown ethers, Complexes of ~ with uronium salts: Preparation and crystal structure of [18]crown-6 uronium nitrate(1/1) and benz-[27]crown-9 uronium perchlorate(1/1) (SC) 450
Double layer formation with a surfactant-type crown ether complex: Crystal structure of 15,15-bis(dodecyloxymethyl)[16]crown-5·NaSCN (SC) 627
Cryptands, A ternary clathrate from cryptand, hydroquinone and water—Selective formation and X-ray structural analysis (SC) 431
Crystal habit, Controlled modification of ~ by "tailor-made" impurities: Application to benzamide (SC) 631
Crystal structure, Structure and bonding in crystals (NB) 797
Cumulenamines, Preparation of butatrienylamines from butenynylamines (SC) 862
2-Cyano-3-ethoxyacrylamides—Selective synthons for the synthesis of heterocycles (SC) 540
α-Cyanophenylacetaldehydes, Reaction of with sulfonyl chloride (SC) 524
Cyanothiomolybdates, $[Mo_4^{III}S_4(CN)_{12}]^{8-}$, a cluster with high negative charge and cubane-like Mo_4S_4-moiety—On the significance of ~ for the prebiotic evolution (SC) 795
Cyclic peptides, Conformation and biological activity of ~ (RA) 512
Cyclization, (A→D) ring closure to the nickel(II)-B,C,D-hexadehydrocorrinate (SC) 214
Substituent-dependent competition between 1,5- and 3,5-~ in vinyl azides; 4H-triazoles from 3,3-diazido-2-cyanoacrylic acid methyl ester and primary amines (SC) 288
β,ε-Dioxophosphonates by reductive nucleophilic acylation of 1,3-dioxo compounds: Facile synthesis of jasmones (SC) 372
Anomalous reaction of hydrazine with β-aminovinyl ketones (SC) 548
2-Aminobenzothiazoles by oxidative ~ of arylthioureas with sulfinyl chloride (SC) 541
Regioselective 5-exo-trig-~ in the reaction of bis(ethylthio)vinylidenetriphenylphosphorane with heteroallenes (SC) 621
Catalytic hydrogenation of 7-methoxy-6-methyl-8-nitro-1-isoquinolinecarbonitrile to unusual products (SC) 857
Cycloaddition, Stereocontrolled synthesis of (+)-sarracenin via photochemical ~ (SC) 70
Efficient synthesis of 8-oxabicyclo[3.2.1]oct-6-en-3-ones, Preparatively useful [4+3]-cycloadducts (SC) 137
The ~ of carbonyl-flanked methylene bridges—A novel method for the synthesis of metallacycles (SC) 212
Stereo- and regioselective synthesis of enantiomerically pure (+)- and (−)-hexahydrocannabinol by intramolecular ~s (SC) 221
[4+1]-~s of isocyanides to 1,2,4,5-tetrazines: A novel synthesis of pyrazole (SC) 284
Evidence for intermediates in the ~ of singlet carbenes (SC) 310
λ^3-Phosphorins by [4+2]-~ of α-pyrones and cyclopentadienones with H_5C_6—C≡P (SC) 370
Reaction of 4-methyl-1,2,4-triazoline-3,5-dione with fulvenes: A 1,3-sigmatropic shift involving a dipolar intermediate (SC) 383
Carbonyliron-assisted ~ of a 1,3-diene to a CC double bond: Synthesis of an anthracyclinone precursor (SC) 430
1,3-Dipolar ~s to dialkyl-germanones and -germathiones (SC) 447
Palladium(0)-catalyzed [3+2]-~s of diphenylmethylenecyclopropanes to alkenes (SC) 622
The thermal conversion of 1,5,9-triynes into arenes: [2+2+2]-~s or sigmatropic rearrangements (SC) 685
~s of azulene at high pressure (SC) 708
A simple and stereoselective entry to the secoiridoids by [4+2]-~ of alkylidene-1,3-dicarbonyl compounds (SC) 793
New dihydropyrans: Lewis acid catalyzed ~-s of α,β-unsaturated acyl cyanides to simple unactivated olefins and dienes: A readily accessible route to derivatives of rose oxide (SC) 859
Cycloalkenes, Influence of ring-size of ~ on the activation volume in the high-pressure copolymerization of maleic anhydride (SC) 363
Cyclobutabenzene, The effect of an annelated cyclobutene or cyclobutadiene ring on the norcaradiene-cycloheptatriene equilibrium (SC) 138
The dianion 1,2-diphenylbenzocyclobutadienediide (SC) 132
The question of the antiaromaticity of 1,3-cyclobutadiene: Thermal valence isomerization of the tricyclo[5.2.0.0^{3,5}]nona-1,6,8-triene (SC) 139
Novel facile synthesis of multiply ortho-bridged phane-hydrocarbons and of dihydro-~ (SC) 928
Cyclobutadiene, The dianion 1,2-diphenylbenzocyclobutadienediide (SC) 132
The dianion 1,2,3,4-tetraphenylcyclobutadienediide (SC) 133
The effect of an annelated cyclobutene or ~ ring on the norcaradiene—cycloheptatriene equilibrium (SC) 138
The question of the antiaromaticity of 1,3-~: Thermal valence isomerization of the tricyclo[5.2.0.0^{3,5}]nona-1,6,8-triene system (SC) 139
Radical ion-pairs as intermediates in reactions of tetra-tert-butyltetrahedrane and tetra-tert-butyl~ (SC) 437
~: Mesomerism or valence isomerism? (SC) 693
~-s or acetylenes from (2-cyclopropen-1-yl)carbenes—A question of spin multiplicity? (SC) 913
Cyclobutadienediide, The dianion 1,2,3,4-tetraphenyl-~ (SC) 133
Cyclobutane, From cis,trans-cis-1,2,3,4-tetravinyl~ to cyclododecatetraene—Two consecutive Cope rearrangements (SC) 686
Cyclododecatetraene, From cis,trans-cis-1,2,3,4-tetravinylcyclobutane to ~—Two consecutive Cope rearrangements (SC) 686
2,4,6-Cycloheptatrienylidenemalondialdehyde (8,8-diformylheptafulvene) (SC) 65
Cyclonucleotide phosphodiesterase, 7-Deazaguanosine-3′,5′-phosphate — An isosteric cGMP analogue with high affinity for ~ (SC) 367
1,3-Cyclooctadien-5-yne, Thermal conversion of ~ into benzocyclobutene—A novel isomerization on the C_8H_8 hypersurface (SC) 66

1,3-Cyclooctadien-6-yne—An isolable bishomodehydrobenzene (SC) 67
1,6-Cyclooctadien-3-yne, 1,2-Dihydropentalene from ~ (SC) 917
Cyclopentadienes complexes as synthons: Ring- and regiospecific nucleohilic additions to cobaltocenium salts—Synthesis of substituted ~ and cyclopentenones (SC) 617
Cyclopentadienone, 4-Oxo-2-cyclopentenyl acetate—A synthetic intermediate (RA) 480
λ^3-Phosphorins by [4+2]-cycloaddition of α-pyrones and ~s with H_3C_6—C≡P (SC) 370
Cyclopentadienylation, Bridged $C_5Me_5Co^{II}$ complexes—reactive intermediates in the ~ of cobalt(II)halides (CS) 131
η^5-Cyclopentadienyl(η^5-1,3-diborolene)cobalt—A novel type of sandwich complexes with a pentacoordinated carbon atom (SC) 148
Cyclopentane derivatives, Tricyclo[3.3.0.$0^{2,8}$]octan-3-ones: Photochemically prepared building blocks for enantiospecific total synthesis of cyclopentanoid natural products (RA) 820
Cyclopentenone, 4-Oxo-2-cyclopentenyl Acetate—A synthetic intermediate (RA) 480
Cyclopentadiene complexes as synthons: Ring- and regiospecific nucleohilic additions to cobaltocenium salts—Synthesis of substituted cyclopentadienes and ~ (SC) 617
Cyclophanes, The chemical behavior of multibridged [2$_n$]~ (RA) 469
Fourfold bridging of the benzene ring in one step (SC) 618
Trifoliaphane—The trimer of a [2.2]paracyclophane with an ethyno-bridge (SC) 623
Cyclophosphanes, Chain and ring phosphorus compounds—Analogies between phosphorus and carbon chemistry (RA) 492
The first tetraphosphabicyclobutane (SC) 544
Tris(trimethylplumbyl)heptaphosphanortricyclene $P_7(PbMe_3)_3$ (SC) 863
Cycloprolines, Macrocycles of D- and L-proline residues (SC) 220
Solid state ^{13}C-NMR spectra of ~ (SC) 689
Cyclopropanes, Convenient general synthesis of alkynyl~ (SC) 65
Palladium(0)-catalyzed [3+2]-cycloadditions of diphenylmethylene~ to alkenes (SC) 622
Cyclopropenes as complex ligands: $Fe_2(CO)_9$-induced ring-opening of a spirocyclopropene and reversible CO-addition to the vinylcarbene ligand (SC) 205
Cyclopropenylcarbene, Synthesis and properties of [2,3-bis(trimethylsilyl)-2-cyclopropen-1-yl]diazomethane (SC) 437
Cyclopropylidene acetates, Novel Synthetic building blocks activated by ring strain: General entry to 2-chloro-2-~ (SC) 790
Cyclopropylidenemethanones, Carbonylcyclopropanes (~): Preparation and steric course of cyclodimerization to dispiro[2.1.2.1]octane-4,8-diones (SC) 83
[2+2]-Cycloreversions (RA) 225
Cyclosulfanes, Metalla~: Synthesis of bis(pentamethylcyclopentadienyl)titana(IV)-cyclotetrasulfane (SC) 384
Cyclotridecasulfur, Synthesis of S_{11} and S_{13} (SC) 794
Cyclotriprolines, Solid-state ^{13}C-NMR spectra of ~ (SC) 689
Cyclotristibane, Synthesis of an all-cis-organo~ and its pentacarbonylchromium complex (SC) 375
Cycloundecasulfur, Synthesis of S_{11} and S_{13} (SC) 794

5-DEAZAFLAVIN ANALOGUE of succinate dehydrogenase, Specific transfer of the H_{Si}-atom of succinate to the ~ (SC) 365
7-Deazaguanosine-3′,5′-phosphate—An isosteric cGMP analogue with high affinity for cyclonucleotide phosphodiesterase (SC) 367
Decamethylcobaltocene, Bridged $C_5Me_5Co^{II}$ complexes—Reactive intermediates in the cyclopentadienylation of cobalt(II) halides (SC) 131
Decarboxylation, Light-induced ~ of carbamoyloxyamino compounds (SC) 525
Metal-induced ~ of diketene—A novel route to allene complexes (SC) 551
Deformation densities, ab initio calculation of ~ in porphyrins (SC) 868
Dehydro-α-amino acids, A facile, generally applicable synthesis of N-acetyl~ (SC) 203
Dehydroamino acid esters, Facile preparation of N-acyl-2-(diethoxyphosphoryl)glycine esters and their use in the synthesis of ~ (SC) 776
7-Dehydrocholesterol, Light-induced activation of ~ (SC) 356
Dendralenes, Cross-conjugated trienes by thermal isomerization of alkynes (SC) 286
Deprotonation, Reversible double ~ of hexamethylbenzene on ruthenium: Formation of a fluxional η^3-benzyl compound by protonation of an o-quinodimethane complex of ruthenium(0) (SC) 379
1,4-Dialkylgermabenzenes—Generation and detection in the gas phase (SC) 221
Dialkylmagnesium compounds from magnesium, hydrogen, and 1-alkenes (SC) 199
O,O-Dialkylthiophosphonosulfenyl bromides—A new class of reactive organophosphorus compounds (SC) 135
Diantimony complexes, Antimony homologues of dinitrogen and azabenzene as complex ligands: Preparation and structure of $[Sb{\equiv}Sb\{W(CO)_5\}_3]$ and $[PhSb{=}SbPh\{W(CO)_5\}_3]$ (SC) 215
Diastereogenic addition of crotylmetal compounds to aldehydes (RA) 555
Diastereoselectivity, Diastereoselective synthesis of D,L-sphingosine (SC) 210
Diastereoselective homoaldol reaction with a (1-oxycrotyl)aluminum compound, a homoenolate equivalent of n-butanal (SC) 372
Highly diastereo- and regioselective homoaldol reactions with (1-oxyallyl)titanuum derivatives (SC) 372
Three-center diastereoselective aldol additions of β-lactone enolates to aldehydes (SC) 777
Erythro-selective aldol-type addition of titanated aldehyde-hydrazones (SC) 864
2,6-Diazasemibullvalene, A ~ (SC) 637
Diazasilacyclopropane, A stable ~ (SC) 301
3,3-Diazido-2-cyanoacrylic acid, Geminal vinyl diazides: Potential precursors of functionalized alkylidenecarbenes; synthesis and reactions of ~ methyl esters (SC) 287
Substituent-dependent competition between 1,5- and 3,5-cyclization in vinyl azides; 4H-triazoles from ~ methyl ester and primary amines (SC) 288
Diazoalkane bridges, Cleavage of the metal-metal triple bond by chelate-forming ~ (SC) 707
Diazonium salts, Alkylation of α-diazoketones with alkyldiazonium ions: Facile synthesis of β-alkoxyethylene~ (SC) 786
Dibenz[b,g]azocindiide, Generation and NMR-detection of the anions N-methyl-1-benzazocinide, 1-benzazocindiide, and ~: A family of aromatic π-excessive compounds (SC) 791
1,3(R):4,6(R)-Di-O-benzylidene-D-mannitol, Optically active glycerol derivatives from ~—The first structural analogues of moenomycin A (SC) 137
Diborolenes, η^5-Cyclopentadienyl(η^5-1,3-diborolene)cobalt—A novel type of Sandwich Complexes with a pentacoordinated carbon atom (SC) 148
μ,η^5-1,3-Diborolenyl tetradecker sandwich complexes (SC) 149
Synthesis of a pentadecker sandwich complex (SC) 453
Dichlorination of benzene, Electron spin resonance studies of the sulfur catalysis of the industrial (SC) 533
Dichloroazulenes, Vacuum pyrolysis of 5,5,10,10-tetrachlorotricyclo[7.1.0.$0^{4,6}$]deca-2,7-diene: 1,5- and 2,6-~ (SC) 444
1,4-Dichlorobenzene, Electron spin resonance studies of the sulfur catalysis of the industrial dichlorination of benzene (SC) 533
Dichloromethane, Synthesis under high pressure: Mannich reaction of ketones and esters with ~ and secondary amines (SC) 922
Dicyanocobalt(III) corrinate, Synthesis of a dicyanocobalt(III) D-didehydrocorrinate and its reduction to the ~ (SC) 152
Dicyanocobalt(III) D-didehydrocorrinates, Synthesis of a ~ and its reduction to the dicyanocobalt(III) corrinate (SC) 152
2β-2′,3′-Dideoxy-α,L-rhamnopyranosides, of cardenolides (SC) 547
Diels-Alder reaction, ~-s of [5]metacyclophane (SC) 298
Intramolecular ~ of allenecarboxanilides (SC) 620
Control of the conformation of transition states in intramolecular ~-s with inverse electron demand (SC) 863
Diethylene-molybdenum(0) complexes, Bis(dinitrogen)- and ~ (SC) 441
Diferrioarsonium chloride, Redox reactions of a ferrio-arsane and -stibane with chlorophosphanes: Synthesis of a ~ and a stiborane with asymmetric iron atoms (SC) 549
Diferrocenyl carbenium ion, Influence of conformational rigidity on the stabilization of α-ferrocenyl carbocations: A cis-fixed ~ (SC) 293
8,8-Diformylhaptafulvene, 2,4,6,-Cycloheptatrienylidenemalondialdehyde (~) (SC) 65
Dihydrocyclobutabenzene, Novel facile synthesis of multiply ortho-bridged phane-hydrocarbons and of ~-s (SC) 928
Dihydro-s-indacene, Phanes derived from 1,5- and 1,7-~ (SC) 304
Dihydropyrans, Alkyl substituted 3,4-Dihydro-2H-pyrans: Mass spectroscopy, synthesis, and identification as insect constituents (SC) 698
New ~: Lewis acid catalyzed cycloadditions of α,β-unsaturated acyl cyanides to simple unactivated olefins and dienes: A readily accessible route to derivatives of rose oxide (SC) 859
1,4-Dihydroxypyridines, Photochemically generated ~ and 2-hydroxytetrahydropyridines as precursors for benzo[a]quinolizidine alkaloids (SC) 539
2,7-Dihydro-2,2,7,7-tetramethylpyrene, Synthesis and valence isomerization of ~ (SC) 618
Diketene, Metal-induced decarboxylation of ~—A novel route to allene complexes (SC) 551
(R,R)-1-(1-Dimethylaminoethyl)-2-lithioferrocene, Chiral binuclear carbene complexes from ~ and hexacarbonyltungsten (SC) 788
3,3-Dimethylcyclopropene, Palladacycloalkanes by oxidative coupling of ~ with palladium(0) compounds (SC) 62
Dinitrogen-complexes, Bis(dinitrogen)- and diethylene-molybdenum(0) complexes (SC) 441
Dinuclear complex, $(\mu\text{-}H)_3[C_5H_5RhP(iPr)_3]_2^+$: A dinuclear (Rh—Rh) complex with three bridging hydrido ligands (SC) 296
$K_2[Ni_2(N_2S_2)_2(CN)_2]$—A ~ with the $S_2N_2^{2\ominus}$ chelate ligand (SC) 633
Dioxolanecarboxylic acid esters, "Contra-steric" alkylation of the enolates of ~ (SC) 449
β,ε-Dioxophosphonates, by reductive nucleophilic acylation of 1,3-dioxo compounds: Facile synthesis of jasmones (SC) 371
1,2-Diphenylbenzocyclobutadienediide, The dianion ~ (SC) 132
1,3-Diphospha-2,4-disilacyclobutane, Synthesis of an N-functionalized 1,3-diaza- and a P-functionalized ~ (SC) 857
Diphosphirane, A spirocyclic ~ (SC) 445
1,3-Dipolar cycloadditions to dialkylgermanones and -germathiones (SC) 447
Dipolar intermediates, in the [2,3]sigmatropic rearrangement of ammoniomethanides (SC) 198
Reaction of 4-methyl-1,3,4-triazoline-3,5-dione with fulvenes: A 1,3-sigmatropic shift involving a dipolar intermediate (SC) 383
Dipotassium sulfur diimide, K_2SN_2 (SC) 633
Dipyranopyrazines, Stereospecific synthesis of (S,S)-palythazine from D-glucose (SC) 141
Disaccharides, α-Linked ~ from O-(β-D-glycopyranosyl) trichloroacetimidates using trime-

thylsilyl trifluoromethanesulfonate as catalyst (SC) 781
Dispiro[2.1.2.1]octane-4,8-diones, Carbonylcyclopropanes (cyclopropylidenemethanones): Preparation and steric course of cyclodimerization to ~ (SC) 83
Disulfido ligands, $[Mo_4(NO)_4(S_2)_6O]^{2-}$, A novel highly symmetric polynuclear complex with two "handle-shaped" and four "roof-shaped" coordinated S_2^{2-} bridging ligands at a tetragonal Mo_4 disphenoid (SC) 535
Disulfur dinitride, Cleavage of S_4N_4 to S_2N_2 at room temperature: Formation and structure of $(AlCl_3)_2S_2N_2$ (SC) 634
Dithiadiazole, Synthesis and structure of $[Zn(S_2N_2CO)]_6[AsF_6]_2$—Sulfur-Nitrogen rings as ligands in coordination compounds (SC) 858
1,3-Dithian-2-yl-methoxycarbonyl, The ~-(Dmoc) moiety—A protecting group for the amino function in peptide synthesis (SC) 292
Dithiocarbonato complex, Synthesis and reactivity of metal complexes with the zwitterionic $Et_3P—CS_2$ ligand. Structure of the ~ [(triphos)Co(S_2CO)] (SC) 197
Dithiolenenickel complex, A 1,2-~ with different substituents—A novel type of mixed-valence compounds (SC) 77
Dithiophosphinato bridge, molybdenum-sulfur-cluster with ~ (SC) 929
Dithiosulfate ion, Fixation of the ~ $S_3O_2^{2-}$; preparation, crystal structure, and ESCA-spectrum of $(PPh_4)_2[(S_2)OMoS_2MoO(S_3O_2)]$ (SC) 796
(1,3-Diynyl)amines, A simple, highly variable route to ~ (SC) 282
DNA analogues, A novel synthesis of nucleoside methylphosphonates (SC) 912
Documentation, Natural versus indexing language in chemical ~ (RA) 608
DODAC vesicles, Determination of the structure of dimethyldioctadecylammonium chloride in solution by small angle X-ray scattering: Reversible phase transition (SC) 765
"Dodecasile"—A novel series of polytypic clathrate compounds of SiO_2 (SC) 206
PC Double bond, The first bis(methylene)phosphoranes of type $R—P[=C(SiMe_3)_2]_2$ with tricoordinated pentavalent phosphorus (SC) 80
Configurational identity (solid, liquid), (N→P)-Silatropism and rotamer detection in the methylenephosphane $PhP=C(NAryl-SiMe_3)(PPhSiMe_3)$ (SC) 448
SiC Double bond, Reversible photoisomerization between silaethenes and methylsilylenes (methylsilanediyls) (SC) 854
Double layer formation, with a surfactant-type crown ether complex: Crystal structure of 15,15-bis(dodecyloxymethyl)[16]crown-5·NaSCN (SC) 627

ELECTRICAL CONDUCTIVITY, A novel type of organic conductor: One-dimensionally polymerized phthalocyaninatoiron(II) (SC) 79
Electrochemical syntheses, The reactivity of primary free radicals and radical ions, mass transfer, and electrosorption—The fundamental factors for selectivity in ~ of organic compounds (RA) 256
Electrochemistry, Reversible electrochemical formation of graphite fluoride from aqueous hydrofluoric acid (SC) 69
Rotation of polymerized vesicles in an alternating electric field (SC) 134
Novel synthesis of octaalkyl- and octaisoalkylporphyrins (SC) 285
Electrochemical reduction of [2.2]paracyclophane (SC) 305
Electrochemical oxidation of croconate salts; Evidence of the chemical equivalence of the carbonyl oxygen atom and the dicyanomethylene Group (SC) 635
Indirect electrochemical regeneration of NADH by a bipyridinerhodium(I) complex as electron-transfer agent (SC) 782
Comprehensive treatise of ~ (NB) 313
Elektrochemie II (NB) 874
Electron conductor model, $S_6N_5O_4$, A compound with separately stacked cyclic radical cations $S_3N_2^+$ and cyclic anions $S_3N_3O_4^-$ (SC) 538
Electron density distributions in the bonds of the bridged bicyclo[1.1.0]butane system 1,5-dimethyltricyclo[2.1.0.0^{2,5}]pentan-3-one (SC) 775
Electronics, The resist technique—A chemical contribution to ~ (RA) 455
Electronic structure, ^{13}C-^{13}C and ^{13}C-H coupling constants and the ~ of cyclopropane, cyclohexane, and propane (SC) 872
Electron transfer, by Grignard reagents: Direct evidence for organomagnesium radical complexes (SC) 140
Ambivalent coordination behavior of lithium aluminum hydride in ~ reactions (SC) 141
Indirect electrochemical regeneration of NADH by a bipyridinerhodium(I) complex as ~ agent (SC) 782
Electron transfer catalysis, ETC: A mechanistic concept for inorganic and organic chemistry (RA) 1
Electrosynthesis, α,β-Unsaturated ketones by cathodic addition of benzotrichloride to ketones (SC) 79
Element modifications, Novel metastable germanium modifications allo-Ge and 4H-Ge from Li_7Ge_{12} (SC) 912
Elimination, Preparation of an ethylene(hydrido)tungsten complex by photo-induced β-~ (SC) 78
A pentakis(phosphane)iron(0) complex by reductive ~ (SC) 311
Vacuum dynamic gas phase/solid phase reactions: N-chlorination of primary amines and α-~ of the resulting chloramines; synthesis of reactive (E)- and (Z)-aldimines (SC) 690
Enantiomer separation, Resolution of D- and L-amino acids by HPLC using copper complexes of N,N-dialkyl-α-amino acids as novel chiral additives (SC) 218
Isocyanates as universal reagents for the formation of derivatives for gas chromatographic ~ (SC) 709
Enantioselective synthesis, 4-Oxo-2-cyclopentenyl acetate—A synthetic intermediate (RA) 480
Enantioselectivity, Dependence of the ~ on the relative concentration of substrate in an NADH model reaction (SC) 433
Enantiospecific total syntheses, Tricyclo[3.3.0.0^{2,8}]octan-3-ones: Photochemically prepared building blocks for ~ of cyclopentanoid natural products (RA) 820
Enolates, Easy rotation about the carbon-carbon bond in lithium cyclopentadienyl (ester-) ~ (SC) 688
Environmantal protection, Ullmanns Encyclopädie der technischen Chemie (NB) 553
Enzymatic catalysis, Specific transfer of the H_{Si}-atom of succinate to the 5-diazaflavin analogue of succinate dehydrogenase (SC) 365
Enzymes, The bacterial ribosome: A programmed enzyme (RA) 23
The hydrophobic and metal-ion coordinating properties of α-lipoic acid—An example of intramolecular equilibria in metal-ion complexes (RA) 389
Immobilized biomaterials—Techniques and applications (RA) 837
Epoxides, Regioselective opening of α- and β-alkoxy~ with trimethylaluminum (SC) 71
Ethanes, Sterically crowded ~ and ethenes from tri-tert-butylsilymethyl carbenoids (SC) 368
Ethenes, Sterically crowded ethanes and ~ from tri-tert-butylsilylmethyl carbenoids (SC) 368
1-Ethoxycarbonylbenzotriazole, C-Carboxylation of nitroalkanes with ~ (SC) 139
Ethylene, The reaction of (butadiene)zirconocene and -hafnocene with ~ (SC) 913
Ethylenediazonium salts, Alkylation of α-diazoketones with alkyldiazonium ions: Facile synthesis of β-alkoxy~ (SC) 786
Ethylene dimerization, Catalyst deactivation during zirconocene- und hafnocene-induced ~ (SC) 913
Ethylene(hydrido)tungsten complex, Preparation of an ~ by photo-induced β-elimination (SC) 78
Evatromonoside, Synthesis of cardiac glycosides: ~ and its anomer (SC) 779
Evolution, $[Mo_4^{III}S_4(CN)_{12}]^{8-}$, a cluster with high negative charge and cubane-like Mo_4S_4-moiety—On the significance of cyanothiomolybdates for the prebiotic ~ (SC) 795
Evolution of hydrogen from photochemically reduced water-soluble tin(IV)-porphyrins (SC) 131
π-Excessive compounds, Generation and NMR-detection of the anions N-methyl-1-benzazocinide, 1-benzazocindiide, and dibenz[b,g]azocindiide: A family of aromatic ~ (SC) 791
Exchange reactions, Cluster synthesis by exchange of bridge-forming carboxylate ligands (SC) 692

FAST PROTON CONDUCTORS, Vehicle mechanism, A novel model for the interpretation of the conductivity of ~ (SC) 208
Fatty acids, Serial cyclizations of an arachidonic acid hydroperoxide (SC) 217
Ferrabicycle, Ring contraction 6→5/3 by oxidative addition to a ferrobicycle having novel structural units (SC) 312
Ferrites, Hexagonal ~ from melts and aqueous solutions, magnetic recording materials (RA) 270
Ferrocene derivatives, Triferrocenylamine, NFc_3 (SC) 74
Chiral binuclear carbene complexes from (R,R)-1-(1-dimethylaminoethyl)-2-lithioferrocene and hexacarbonyltungsten (SC) 788
α-Ferrocenyl carbocations, Influence of conformational rigidity on the stabilization of ~: A cis-fixed diferrocenylcarbenium ion (SC) 293
Ferromagnetic interaction between orthogonal "magnetic" orbitals in dinuclear $Cu^{II}Cr^{III}$ complexes (SC) 624
Fischer-Tropsch synthesis, Organometallic aspects of the ~ (RA) 117
From a formyl to a methyl complex (SC) 150
Fluoroarenes, Photocyclization of 2-aryl-1,1-difluoroethylenes: Synthesis of mono- and difluorinated polycyclic arenes (SC) 766
Fluorooxotantalate(V), $[Ta_4F_{12}O_6]^{4-}$: A tetranuclear ~ with adamantane skeleton (SC) 870
Fluxional molecules, Reversible double deprotonation of hexamethylbenzene on ruthenium: Formation of a fluxional η^3-benzyl compound by protonation of an o-quinodimethane complex of ruthenium(0) (SC) 379
A simple synthesis of di- and trihalobarbaralanes (SC) 549
Formyl complex, From a formyl to a methyl complex (SC) 150
Free radicals, The reactivity of primary ~ and radical ions, mass transfer, and electrosorption—The fundamental factors for selectivity in electrochemical syntheses of organic compounds (RA) 256
Frontier orbitals, The role of ~ in chemical reactions (Nobel Lecture) (RA) 801
Four-component condensations, From isocyanides via ~ to antibiotic syntheses (RA) 810
Four-electron ligand, Novel tungsten-alkyl and tungsten-acyl complexes with acetylene as ~ (SC) 861
Fulvene ligand, Synthesis of $Pd(\eta^2-CH_2=C_5Me_4)L_2$: Formation of a ~ by metal-assisted H-shift from pentamethylcyclopentadienyl (SC) 866
Fulvenes, Reaction of 4-methyl-1,2,4-triazoline-3,5-dione with ~: A 1,3-sigmatropic shift involving a dipolar intermediate (SC) 383

GALLIUM IODIDE, Crystal structures of AlI_3, GaI_3, and InI_3—Isotypic relationship AlI_3/SO_3 (SC) 386
Gas chromatography, Isocyanates as universal reagents for the formation of derivatives for gas chromatographic enantiomer separation (SC) 709
Gas phase oxidation, 2-Oxopropanal (methylglyoxal) by oxidation of glycerin in the gas phase (SC) 540
Gas-phase reactions (NB) 222
Gas phase/solid-phase reactions, Vacuum dynamic ~: N-Chlorination of primary amines and α-elimination of the resulting chloramines; synthesis of reactive (E)- and (Z)-aldimines (SC) 690
Germabenzenes, 1,4-Dialkyl~—Generation and detection in the gas phase (SC) 221
Germanium compounds, 1,3-Dipolar cycloadditions to dialkylgermanones and -germathiones (SC) 447
Germanium modifications, Novel metastable ~ allo-Ge and 4H-Ge from Li_7Ge_{12} (SC) 912
Glasses, Polarity of organic ~ (SC) 432
N-Glycoproteins, Synthesis of an octasaccharide of the basic sequence of ~ (SC) 926
N-Glycosides, A ring building-up synthesis of ~: Dehydrogenation of glycosyltriazeno-1H-pyrazoles (SC) 698
Glycosyl bromides, Functionalization at pro-anomeric centers by photobromination: A novel access to oxo- and acyloxyimino-~ (SC) 625
Glycosyltriazeno-1H-pyrazoles, A ring building-up synthesis of N-glycosides: Dehydrogenation of ~ (SC) 698
Gold compounds, Methylene bridging of two gold atoms through double oxidative addition of methylene dihalides to a cyclic ylide complex (SC) 73
Graphite fluoride, Reversible electrochemical formation of ~ from aqueous hydrofluoric acid (SC) 69
Preparation of a ~ film on aluminum (SC) 378
Grignard reagents, Electron transfer by ~: Direct evidence for organomagnesium radical complexes (SC) 140
Guanosine-3′,5′-phosphate, 7-Deaza-~ —An isosteric cGMP analogue with high affinity for cyclonucleotide phosphodiesterase (SC) 367

HAFNOCENE, The reaction of (butadiene)zirconocene and -hafnocene with ethylene (SC) 913
Catalyst deactivation during zirconocene- and hafnocene-induced ethylene dimerization (SC) 913
Halobarbaralanes, A simple synthesis of di- and tri-~ (SC) 549
Halogenated ketenes, (Chloroacyl)diphenylphosphanes as sources of ~ (SC) 355
μ-Halogeno compounds, Bridged $C_5Me_5Co^{II}$ complexes—Reactive intermediates in the cyclopentadienylation of cobalt(II) halides (SC) 131
Heavy main-group elements, New possible applications of ~ in organic synthesis (RA) 410
Heme, Topical problems in the biosynthesis of red blood pigment (RA) 343
~ biosynthesis from isomeric uroporphyrinogens (SC) 215
Heptafulvene derivatives, 2,4,6-Cycloheptatrienylidenemalondialdehyde (8,8-diformylheptafulvene) (SC) 65
Polymethines with heptafulvenyl terminal groups (SC) 68
Heptaphosphanortricyclene, Tris(trimethylplumbyl)-~ $P_7(PbMe_3)_3$ (SC) 863
Heteroarene, 5-Pivaloyl-2H-isoindole—An isolable and crystallizable o-quinonoid ~ (SC) 621
Stable 1,3-oxathiolylium-4-olates—Synthesis and cycloadditions of a novel class of mesoionic ~-s (SC) 779
Hetero-Cope rearrangement, Regioselective acylamination by ~ (SC) 370
Heterocycles, A stable diazasilacyclopropane (SC) 301
$S_6N_5O_4$, A compound with separately stacked cyclic radical cations $S_3N_2^+$ and cyclic anions $S_3N_3O_4^-$ (SC) 538
2-Cyano-3-ethoxyacrylamides—Selective synthons for the synthesis of ~ (SC) 540
Synthesis of an N-functionalized 1,3-diaza- and a P-functionalized 1,3-diphospha-2,4-disilacyclobutane (SC) 857
Hetero-Diels-Alder reactions for the synthesis of thromboxane intermediates (SC) 302
Heterodimetallic complex, Synthesis and structure of a ~ containing a terminal hydrido ligand: $[(PPh_3)_2(H)PtMo(CO)_3(\eta^5\text{-}C_5H_5)]$ (SC) 308
Heteropolyanion, "γ-$PW_{12}O_{40}^{3-}$", A ~ with clathrate character (SC) 789
Hetero-trinuclear complex, $(C_5H_5)_3CoMn_2(CO)_4(CS)PMe_3$—A ~ with a μ_2-C,η^1-S-bonded thiocarbonyl group (SC) 202
Hexaazobenzene, Is hexazine stable? (SC) 64
Hexacarbonyltungsten, Chiral binuclear carbene complexes from (R,R)-1-(1-dimethylaminoethyl)-2-lithioferrocene and ~ (SC) 788
Hexahydrocannabinol, Stereo- and regioselective synthesis of enantiomerically pure (+)- and (−)-~ by intramolecular cycloaddition (SC) 221
Hexamethylbenzene, Reversible double deprotonation of ~ on ruthenium: Formation of a fluxional η^3-benzyl compound by protonation of an o-quinodimethane complex of ruthenium(0) (SC) 379
Hexaphenylcarbodiphosphorane, Synthesis, structure, and reactions of primary adducts of sulfur or selenium with ~ (SC) 310
Hexazine, Is ~ stable? (SC) 64
High performance liquid chromatography, Optimal parameters in high speed liquid chromatography (RA) 50
Resolution of D- and L-amino acids by HPLC using copper complexes of N,N-dialkyl-α-amino acids as novel chiral additives (SC) 218
Chiral silica packings with L-proline or L-hydroxyproline bonded via alkyl or alkylbenzyl chains for the separation of the enantiomers of α-amino acids by column liquid chromatography (SC) 930
High pressure chemistry, Liquid phase ~ (NB) 314
High-pressure copolymerization, Influence of ring-size of cycloalkenes on the activation volume in the ~ of maleic anhydride (SC) 363
High pressure reactions, Synthesis under high pressure: Mannich reaction of ketones and esters with dichloromethane and secondary amines (SC) 922
Homoaldol reaction, Diastereoselective ~ with a (1-oxycrotyl)aluminum compound, a homoenolate equivalent of n-butanal (SC) 372
Highly diastereo- and regioselective ~-s with (1-oxyallyl)titanium derivatives (SC) 372
Hormone-receptor interaction, Conformation and biological activity of cyclic peptides (RA) 512
Hot atom chemistry, Modern ~ and its applications (NB) 873
Hydrido ligand, $(\mu\text{-}H)_3[C_5H_5RhP(iPr)_3]_2^+$: A dinuclear (Rh—Rh) complex with three bridging ~-s (SC) 296
Synthesis and structure of a heterodimetallic complex containing a terminal ~: $[(PPh_3)_2(H)PtMo(CO)_3(\eta^5\text{-}C_5H_5)]$ (SC) 308
Hydrocarbons, Karplus curve for $^3J(^{13}C,^1H)$ in ~ (SC) 449
Novel facile synthesis of multiply ortho-bridged phane-~ and of dihydrocyclobutabenzenes (SC) 928
Hydrogen, Cu-H_2 photochemistry in the matrix; ESR, FTIR, UV/VIS spectroscopic and kinetic studies (SC) 380
cis-$[Ru(bpy)_2(CO)H]^+$—A possible intermediate in the photochemical production of H_2 from water catalyzed by $[Ru(bpy)_3]^{2+}$? (SC) 628
Hydrogenation, Catalytic ~ of 7-Methoxy-6-methyl-8-nitro-1-isoquinilinecarbonitrile to unusual products (SC) 857
Cyclopentadienyl(peralkylarene)iron(I) complexes as H atom reservoirs: isolation of semihydrogenated species in the Pd/C catalyzed ~ of cyclopentadienyliron(II) complexes of exocyclic olefins (SC) 918
Hydrogen sulfide, H_2S as a promotor for the water gas shift reaction (SC) 619
Hydroquinone, A ternary clathrate from cryptand, ~ and water—Selective formation and X-ray structural analysis (SC) 431
Hydrosilylations, Photoinitiated ~ in presence of tetrahedral heterometallic clusters: Catalysis by intact clusters (SC) 786
Hydroxoiron(III) complex, A mononuclear ~ of a porphinoid ligand system with bifacial steric hindrance (SC) 432
Hydroxylation, Selective ~ of chiral and substituted paraffins (SC) 146
~ of acyclic alkanes by oxygen atoms $O(^3P)$—Comparison of ozone and $O(^3P)$ oxidations of alkanes (SC) 303
3-Hydroxy-2-(1,2,4-triazol-1-yl)acrylic acid ethyl ester and Q-functional derivatives (SC) 546
Hyperstability, Bicyclo[4.4.2]dodeca-1-ene—The first "hyperstable" bridgehead olefin (SC) 306

IMINES, Vacuum dynamic gas phase/solid phase reactions: N-Chlorination of primary amines and α-elimination of the resulting chloramines; synthesis of reactive (E)- and (Z)-aldimines (SC) 690
Immobilization, Immobilized biometerials—Techniques and applications (RA) 837
Inclusion compounds, Selective inclusion of uncharged guest molecules by neutral hosts with fence-shaped side arms (SC) 147
Stetter's complexes are no intramolecular ~ (SC) 787
Indium iodide, Crystal structures of AlI_3, GaI_3, and InI_3—Isotypic relationship AlI_3/SO_3 (SC) 386
Inflammation, The leukotrienes, highly biologically active substances involved in allergy and ~ (FP) 902
Information storage procedures, Hexagonal ferrites from melts and aqueous solutions, magnetic recording materials (RA) 270
Insect constituents, Alkyl substituted 3,4-dihydro-2H-pyrans: Mass spectroscopy, synthesis, and identification as ~ (SC) 698
Intercalation compounds, Reversible electrochemical formation of graphite fluoride from aqueous hydrofluoric acid (SC) 69
Intermediates, Evidence for ~ in the cycloaddition of singlet carbenes (SC) 310
Intervalence transfer, between hexaamminocobalt(III) and hexacyanoruthenate(II) (SC) 77
Inverse electron demand, Control of the conformation of transition states in intramolecular Diels-Alder reactions with ~ (SC) 863
Iodine compounds, $[Ag_5I_6]^-$, A one-dimensional infinite anion with 10_5 mc symmetry (SC) 697
Iodine molecule chain, A branched chain of seven neutral iodine molecules in crystalline bis(dithizone)hepta(diiodine) (SC) 219
Iodine-Sulfur compounds, Isolation of crystalline acylsulfenyl iodides—Intermediates in the I_2-oxidation of thiocarboxylic acids (SC) 150
Ion-dipole complex, HF $CH_2^{\oplus\ominus}$: A novel, stable ~ (SC) 528
Iridium compounds, Synthesis of novel iridium and rhodium complexes containing diphenylphosphinito and dimethylphosphito ligands (SC) 452
Iron compounds, A pentakis(phosphane)-iron(0) complex by reductive elimination (SC) 311

Carbonyliron-assisted cycloaddition of a 1,3-diene to a CC double bond: Synthesis of an anthracyclinone precursor (SC) 430
$Cs_7Fe_4Te_8$, A compound with $[Fe_4Te_8]$ clusters (SC) 544
Iron-Molybdenum-Sulfur cluster, A new type of ~: Synthesis and structure of $[Fe_2Mo_2(\eta^5\text{-}C_5H_5)_2(\mu_3\text{-}S)_2(\mu_3\text{-}CO)_2(CO)_6]$ (SC) 307
Iron-Sulfur cluster anion, $[Fe_6S_9(SCH_2C_6H_5)_2]^{4-}$: A hexanuclear ~ containing the square-pyramidal $[(\mu_4\text{-}S)Fe_4]$ unit (SC) 201
Iron-Sulfur compounds, $[Fe_3W_3S_{14}]^{4-}$, A novel hexanuclear "pure" bimetal-sulfur cluster with $Fe_3(\mu_3\text{-}S)_2$ center (SC) 860
Isocyanates, as universal reagents for the formation of derivatives for gas chromatographic enantiomer separation (SC) 709
The sulfonation of aromatic ~: Sulfonated p-tolyl isocyanate—an X-ray structure analysis (SC) 867
Isocyanides, From ~ via four-component condensations to antibiotic syntheses (RA) 810
Synthesis of macromolecular ~ with general solvent compatibility—Novel polymer supports for solid phase syntheses (SC) 374
2H-isoindole, 5-Pivaloyl-~—An isolable and crystallizable o-quinonoid heteroarene (SC) 621
Isolobal-analogy, Building blocks between inorganic and organic chemistry (Nobel Lecture) (RA) 711
Isomerization, Thermal conversion of 1,3-cyclooctadien-5-yne into benzocyclobutane—A novel ~ on the C_8H_8 hypersurface (SC) 66
Cross-conjugated trienes by thermal ~ of alkynes (SC) 286
Orbital symmetry analysis of triplet-singlet spin-flip during thermal ~ of tetrahedral to planar nickel(II) complexes (SC) 288
Easy rotation about the carbon-carbon bond in lithium cyclopentadienyl (ester-)enolates (SC) 688
Preparation of butatrienylamines from butenynylamines (SC) 862
Isoquinolinecarbonitrile, Catalytic hydrogenation of 7-methoxy-6-methyl-8-nitro-1-~ to unusual products (SC) 857
Isoquinolines and naphthalenes from β-polyketones: Model reactions for an extraordinary alkaloid biosynthesis (SC) 200
"Isoretinol", and retinal: An unorthodox, but simple entry to the vitamin A series (SC) 855
Isotypic relationship, Crystal structures of AlI_3, GaI_3 and InI_3—~ AlI_3/SO_3 (SC) 386

JASMONATES, Asymmetric synthesis of methyl jasmonate (SC) 856
Jasmones, β,ε-Dioxophosphonates by reductive nucleophilic acylation of 1,3-dioxo compounds: Facile synthesis of ~ (SC) 371

KARPLUS CURVE, for $^3J(^{13}C,^1H)$ in hydrocarbons (SC) 449
Ketenes, Carbonylcyclopropanes (cyclopropylidenemethanones): Preparation and steric course of cyclodimerization to dispiro-[2.1.2.1]octane-4,8-diones (SC) 83
(Chloroacyl)diphenylphosphanes as sources of halogenated ~ (SC) 355
Ketones, α,β-Unsaturated ~ by cathodic addition of benzotrichloride to ketones (SC) 79
Determination of the conformation of acyclic α,β-unsaturated aldehydes and ~ from their infrared and Raman spectra—Results and limitations of model calculations (SC) 639
Kinetics and mechanism. A study of homogeneous chemical reactions (NB) 797

LASER PHOTOLYSIS—A new route for charge separation (SC) 436
Leaving groups, Nucleophilic substitution of hydrogen in nitroarenes by phosphorus-stabilized carbanions having "vicarious" ~ (SC) 451
Leukotrienes, The ~, highly biologically active substances involved in allergy and inflammation (RA) 902
Licences, Problems of economic exploitation of basic research findings (discoveries, inventions, patents, ~) (RA) 109
Ligands, Transition metal complexes with cyclo-triphosphorus (η^3-P_3) and tetrahedro-tetraphosphorus (η^1-P_4) ~ (RA) 330
Stabilization of unusual oxidation and coordination states by the ~ OSF_5, $OSeF_5$, and $OTeF_5$ (RA) 877
Synthesis and reactivity of metal complexes with the zwitterionic $E_3P\text{-}CS_2$ ~. Structure of the dithiocarbonato complex [(triphos)-$Co(S_2CO)$] (SC) 197
Cyclopropenes as complex ~: $Fe_2(CO)_9$-induced ring-opening of a spirocyclopropene and reversible CO-addition to the vinylcarbene ligand (SC) 205
Antimony homologues of dinitrogen and azobenzene as complex ~: Preparation and structure of $[Sb{\equiv}Sb\{W(CO)_5\}_3]$ and $[PhSb{=}SbPh\{W(CO)_5\}_3]$ [SC] 215
Novel BN ligand with six competing π electrons around the transition metal coordination center (SC) 207
2-Methyl-2-triphenylphosphoniodithiopropionate—A photosensitive complex ligand with labile P—C bond (SC) 290
λ^3-Phosphazenes as bridging η^1-~ (SC) 297
Triphenylstannanedithiocarboxylate, a novel chelate ligand (SC) 364
Stereospecific synthesis of palladium(II) complexes of macrocyclic tetradentate phosphane ~ (SC) 375
A novel bischelating ligand with two tetradentate N,N,O,S subunits—Synthesis and properties of a dinuclear Cu^{II} complex (SC) 385
Synthesis of novel iridium and rhodium complexes containing diphenylphosphinito and dimethylphosphito ~ (SC) 452
$K_2[Ni_2(N_2S_2)_2(CN)_2]$—A dinuclear complex with the $S_2N_2^{2\ominus}$ chelate ligand (SC) 633
Heterocyclic radical anions as ~: An unexpected change of coordination in pentacarbonylmetal complexes (SC) 700
Synthesis and structure of $[Zn(S_2N_2CO)_6]$-$[AsF_6]_2$—Sulfur-Nitrogen rings as ~ in coordination compounds (SC) 858
Novel tungsten-alkyl and tungsten-acyl complexes with acetylene as four-electron ligand (SC) 861
Synthesis of $Pd(\eta^2\text{-}CH_2{=}C_5Me_4)L_2$: Formation of a fulvene ligand by metal-assisted H-shift from pentamethylcyclopentadienyl (SC) 866
$Me_2PCHPMe_2^{\ominus}$ as ambidentate chelate ligand (C) 921
"μ-C_3" trisphosphanes by direct phosphane/allylphosphane coupling (SC) 931
Ligand field strength, Steric and electronic control of ~ in octahedral Co^{3+} spin-crossover complexes (SC) 915
Light-induced carcinogenesis, Light-induced activation of 7-dehydrocholesterol (SC) 356
Light-induced dermatoses, Topical problems in the biosynthesis of red blood pigment (RA) 343
Ligand-Metal Ion interactions, The hydrophobic and metal-ion coordinating properties of α-lipoic acid—An example of intramolecular equilibria in metal-ion complexes (RA) 389
CC-Linking reactions, A stereocontrolled synthesis of the pheromone 4-methyl-3-heptanol: Novel and selective ~ (SC) 309
Lipid membranes, Black ~ from polymerizable lipids (SC) 368
α-Lipoic Acid, The hydrophobic and metal-ion coordinating properties of ~—An example of intramolecular equilibria in metal-ion complexes (RA) 389
Liquid mixtures, Polarity of binary ~ (RA) 724
Liquid structures and thermodynamics of alkane mixtures (RA) 184
Lithium aluminum hydride, Ambivalent coordination behavior of ~ in electron transfer reactions (SC) 141
Lithium compounds, $Li_{12}Si_7$: Theoretical interest aroused (SC) 632
$^{13}C\text{-}^{13}C$ Long-range coupling constants, The multiple-path mechanism for ~ of bicyclic hydrocarbons (SC) 764

MACROCYCLES, of D- and L-proline residues (SC) 220
Stereospecific synthesis of palladium(II) complexes of macrocyclic tetradentate phosphane ligands (SC) 375
Macrotetrolides, Monomolecular membranes from synthetic ~ (SC) 440
Magnesium compounds, Electron transfer by Grignard reagents: Direct evidence for organomagnesium radical complexes (SC) 140
Dialkyl-~ from magnesium, hydrogen, and 1-alkenes (SC) 199
"Magnetic" orbitals, Ferromagnetic interaction between orthogonal ~ in dinuclear $Cu^{II}Cr^{III}$ complexes (SC) 624
Magnetic pigments, Hexagonal ferrites from melts and aqueous solutions, magnetic recording materials (RA) 270
Main-group elements, New possible applications of heavy ~ in organic synthesis (RA) 410
Maleic anhydride, Influence of ring-size of cycloalkenes on the activation volume in the high-pressure copolymerization of ~ (SC) 363
Manganese compounds, Manganese complexes with "end-on" and spirocyclic bonded σ^3,λ^5-phosphazene ligands (SC) 136
From a formyl to a methyl complex (SC) 150
$C_5H_5(CO)_2Mn$(m-Toluidinyl), An isolable aminyl complex (SC) 691
Mannich reaction, Synthesis under high pressure: ~ of ketones and esters with dichloromethane and secondary amines (SC) 922
Mass spectrometry, $HF{\rightarrow}CH_2^{\oplus\oplus}$: A novel, stable ion-dipole complex (SC) 528
Matrix photochemistry, Cu-H_2 photochemistry in the matrix; ESR, FTIR, UV/VIS spectroscopic and kinetic studies (SC) 380
Membrane models, Active transport of amino acid by a synthetic metal-complex carrier (SC) 304
Membranes, Synthetic ~—Preparation, structure, and application (RA) 660
Monomolecular ~ from synthetic macrotetrolides (SC) 440
Mesoionic heteroarenes, Stable 1,3-oxathiolylium-4-olates—Synthesis and cycloadditions of a novel class of ~ (SC) 779
Mesomerism, Cyclubutadiene: ~ or valence isomerism? (SC) 693
[5]Metacyclophane, Diels-Alder reactions of ~ (SC) 298
Metalated carbon, Doubly ~ by metal-induced vinyl-ethylidene rearrangement (SC) 204
Metal atom-Bis(arene)metal chemistry, Arene-metal clusters: Metal atom-bis(arene)metal solution phase chemistry (SC) 212
Metal atom synthesis, Azaborolinyl-iron and -cobalt sandwich complexes by ~ (SC) 68
Metal atoms, Support effects on the growth, stabilization, and agglomeration of low nuclearity transition metal clusters synthesized from ~ vaporized into liquid aryl-substituted polymers (SC) 550
Metal complexes, First ~ of the norcaradiene form of 1,6-methano[10]annulene (SC) 868
Metal hexametholides (SC) 142
Metal-ion complexes, The hydrophobic and metal-ion coordinating properties of α-lipoic acid—An example of intramolecular equilibria in ~ (RA) 389
Metallacycles, Organometallic intramolecular π-Olefin-metal coordination compounds (FP) 889
The cycloaddition of carbonyl-flanked methylene bridges—A novel method for the synthesis of ~ (SC) 212
Metallacyclosulfanes: Synthesis of bis(pentamethylcyclopentadienyl)titana(IV)-cyclotetrasulfane (SC) 384

Metal-Metal bonds, Formation of ~ and conversion of the metal aggregate $\{Mo_4(S_2)_4(S_2')_2\}$ by atom-transfer and redox reactions at nonequivalent ligands; $[Mo_4S_4(NO)_4(CN)_8]^{8-}$ an anion with a central cubane-life unit (SC) 536
Metal-Metal interactions, "Bichromocenylene": A sandwich with partly decoupled electrons (SC) 151
ThI_3, A Janus amongst compounds with ~ (SC) 525
Metal-Metal triple bond, Cleavage of the ~ by chelate-forming diazoalkane bridges (SC) 707
Methane activation, by photoexcited Cu_2 molecules (SC) 381
1,6-Methano[10]annulene, Theoretical investigations on the valence tautomerism between ~ and Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene (SC) 865
First metal complexes of the norcaradiene form of ~ (SC) 868
Norcaradiene valence tautomer of a ~: Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene-11,11-dicarbonitrile (SC) 869
Stereochemistry of the bromination of ~ (SC) 920
MO model for the stereochemistry of bromination of ~ (SC) 922
2,7-Methanoaza[10]annulenechromium(0), Tricarbonyl-~ (SC) 784
Methine protons, Kinetic acidity of ~ and carbonyl-activated methylene protons (SC) 637
7-Methoxy-6-methyl-8-nitro-1-isoquinolinecarbonitrile, Catalytic hydrogenation of ~ to unusual products (SC) 857
cis-β-Methoxystyrenes, o-Benzoquinone monoformylmethides by sensitized photooxygenation of ~ (SC) 382
Methyl complex, From a formyl to a ~ (SC) 150
N-Methylene-tert-butylamine, A new route to pyridine derivatives: Reaction of ~ with enamines (SC) 213
Methylenecyclopropanes, Palladium(0)-catalyzed [3+2]-cycloadditions of diphenyl-~ to alkenes (SC) 622
Methylenephosphane derivatives, $Ph(Me_3Si)C{=}PCl$ as educt for methylenephosphanes with alkyl-, amino-, phosphino-, alkoxy-, or alkylthio-groups on phosphorus (SC) 219
Configurational identity (solid liquid), (N→P)-silatropism and rotomer detection in the methylenephosphane $PhP{=}C(NArylSiMe_3)(PPhSiMe_3)$ (SC) 448
Methylene protons, Kinetic acidity of methine protons and carbonyl-activated ~ (SC) 637
Methyl esters, Geminal vinyl diazides: Potential precursors of functionalized alkylidenecarbenes; synthesis and reactions of 3,3-diazido-2-cyanoacrylic acid ~ (SC) 287
Substituent-dependent competition between 1,5- and 3,5-cyclization in vinyl azides; 4H-triazoles from 3,3-diazido-2-cyanoacrylic acid ~ and primary amines (SC) 288
Methylglyoxal, 2-Oxopropanal (~) by oxidation of glycerin in the gas phase (SC) 540
4-Methyl-3-heptanol, A stereocontrolled synthesis of the pheromone ~: Novel and selective CC-linking reactions (SC) 309
Methyl jasmonate, Asymmetric synthesis of ~ (SC) 856
Methylsilanediyls, Reversible photoisomerization between silaethenes and methylsilylenes (~) (SC) 854
Methylsilylenes, Reversible photoisomerization between silaethenes and ~ (methylsilandiyls) (SC) 854
2-Methyl-2-triphenylphosphoniodithiopropionate—A photosensitive complex ligand with labile P—C-bond (SC) 290
Formation of bis(isopropylidene)-1,3,4-trithiolane from ~ (SC) 291
Mixed-valence compounds, A 1,2-dithiolenenickel complex with different substituents—a novel type of ~ (SC) 77
Model calculations, Determination of the conformation of acyclic α,β-unsaturated aldehydes and ketones from their infrared and Raman spectra—Results and limitations of ~ (SC) 639
Modifications, Novel metastable germanium ~ allo-Ge and 4H-Ge from Li_7Ge_{12} (SC) 912
Moenomycin A, Optically active glycerol derivatives from 1,3(R):4,6(R)-Di-O-benzylidene-D-mannitol—The first structural analogues of ~ (SC) 137
Molybdenum compounds, Bis(dinitrogen)- and diethylene-molybdenum(0) complexes (SC) 441
Designed synthesis of an alkylidyne-capped trinuclear (Mo, Mo, W) metal cluster (SC) 629
Fixation of the dithiosulfate Ion $S_3O_2^{2-}$; preparation, crystal structure, and ESCA spectrum of $(PPh_4)_2(S_2)OMoS_2MoO(S_3O_2)$ (SC) 796
Molybdenum-sulfur cluster chelate, Coordinatively unsaturated trinuclear ~ with dithiophosphinato bridge (SC) 929
Molybdenum-sulfur compounds, $[Mo_4(NO)_4(S_2)_6O]^{2-}$, A novel highly symmetric polynuclear complex with two "handle-shaped" and four "roof-shaped" coordinated S_2^{2+} bridging ligands at a tetragonal Mo_4 disphenoid (SC) 535
Formation of metal-metal bonds and conversion of the metal aggregate $\{Mo_4(S_2)_4(S_2')_2\}$ by atom-transfer and redox reactions at nonequivalent ligands; $[Mo_4S_4(NO)_4(CN)_8]^{8-}$ an anion with a central cubane-like unit (SC) 536
$[Mo_4^{III}S_4(CN)_{12}]^{8-}$, a cluster with high negative charge and cubane-like Mo_4S_4-moiety—On the significance of cyanothiomolybdates for the prebiotic evolution (SC) 795
MO model, for the stereochemistry of bromination of 1,6-methano[10]annulene (SC) 922
Multiple-path mechanism, The ~ for ^{13}C-^{13}C long-range coupling constants of bicyclic hydrocarbons (SC) 764

NADH, Dependence of the enantioselectivity on the relative concentration of substrate in an ~ model reaction (SC) 433
Indirect electrochemical regeneration of ~ by a bipyridinerhodium(I) complex as electron-transfer agent (SC) 782
Naphthalenes, Isoquinolines and ~ from β-polyketones: Model reactions for an extraordinary alkaloid biosynthesis (SC) 200
Natural products, 4-Oxo-2-cyclopentenyl acetate—A synthetic intermediate (RA) 480
Tricyclo[3.3.0.0^{2,8}]octan-3-ones: Photochemically prepared building blocks for enantiospecific total syntheses of cyclopentanoid ~ (RA) 820
From isocyanides via four-component condensations to antibiotic syntheses (RA) 810
Nickel compounds, Oxanickelacyclopentene derivatives from nickel(0), carbon dioxide, and alkynes (SC) 76
A 1,2-dithiolenenickel complex with different substituents—a novel type of mixed-valence compounds (SC) 77
Nickel(II)-B,C,D-hexadehydrocorrinate, (A→D) ring closure to the ~ (SC) 214
Orbital symmetry analysis of triplet-singlet spin-flip during thermal isomerization of tetrahedral to planar nickel(II) complexes (SC) 288
Nickel-Sulfur compounds, $[(S_3NNi)_3S_2]^{\ominus}$—A Ni_3S_2 cluster with $S_3N^{\ominus}$ chelate ligands (SC) 705
Nitroalkanes, C-Carboxylation of ~ with 1-ethoxycarbonylbenzotriazole (SC) 139
Nitrobenzene, Mechanistic aspects of the carbonylation of ~ with rhodium catalysts (SC) 687
NMR Spectroscopy, The multiple-path mechanism for ^{13}C-^{13}C long-range coupling constants of bicyclic hydrocarbons (SC) 764
^{13}C-^{13}C and ^{13}C-H coupling constants and the electronic structure of cyclopropane, cyclohexane, and propane (SC) 872
Nobel Lecture, Building blocks between inorganic and organic chemistry (~) (RA) 711
The role of frontier orbitals in chemical reactions (~) (RA) 801
Nomenclature, Basic principles of the CIP-system and proposals for a revision (RA) 567
Non-planar structures, of allyl- and pentadienylmetal compounds: Pleating to achieve a better charge distribution (SC) 145
Norbornyl cation, Prototype of a 1,3-bridged carbocation (RA) 87
Norcaradiene-cycloheptatriene equilibrium, The effect of an annelated cyclobutene or cyclobutadiene ring on the ~ (SC) 138
Norcaradiene form, First metal complexes of the ~ of 1,6-methano[10]annulene (SC) 868
Norcaradiene valence tautomer of a 1,6-methano[10]annulene: Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene-11,11-dicarbonitrile (SC) 869
Nucleophilic acylation β,ε-Dioxophosphonates by reductive ~ of 1,3-dioxo compounds: Facile synthesis of jasmones (SC) 371
Nucleophilic addition, Alkylchromium(III) dichlorides, highly selective reagents for the addition of nucleophiles to aldehydes (SC) 144
Addition of alkyl radicals to alkynes: Distinction between radical and ionic nucleophiles (SC) 768
Nucleophilic substitution, of hydrogen in nitroarenes by phosphorus-stabilized carbanions having "vicarious" leaving groups (SC) 451
Nucleophilic trifluoromethylation, Trialkylsilyl(trifluoromethyl)diazenes as tailored reagents for ~ (SC) 443
Nucleoside methylphosphonates, A novel synthesis of ~ (SC) 912
Nucleotide analogs, Synthesis and biological function (NB) 84

OCTAALKYLPORPHYRINS, Novel synthesis of octaalkyl- and octaisoalkylporphyrins (SC) 285
Octabismuth(2+) cluster, Structure of the ~ in crystalline $Bi_8(AlCl_4)_2$ (SC) 445
Octaisoalkylporphyrins, Novel synthesis of octaalkyl- and ~ (SC) 285
Octamethylporphyrinogen, Synthesis of 2,3,7,8,12,13,17,18-~ in almost quantitative yield (SC) 785
Octasaccharide, Synthesis of an ~ of the basic sequence of N-glycoproteins (SC) 926
Olefin isomerization, The $HCo_3(CO)_9$-catalyzed ~ (SC) 925
π-Olefin-metal coordination, Organometallic intramolecular π-olefin-metal coordination compounds (FP) 889
Olefin metathesis, Synthesis of primary alkylarenes without benzene via ~ (SC) 700
Olefins, Synthesis of trisubstituted ~ via trimethylsilylated phosphorus ylides (SC) 545
Olefin selectivities, in the addition of carbenes (SC) 932
Oligosaccharides, Advances in selective chemical syntheses of complex ~ (RA) 155
Synthesis of linear and branched cellotetraoses (SC) 72
Synthesis of an octasaccharide of the basic sequence of N-glycoproteins (SC) 926
Synthesis of trisaccharide moieties from N-acetylneuraminic acid and N-acetyllactosamine (SC) 927
Orbitals, The role of frontier ~ in chemical reactions (Nobel Lecture) (RA) 801
Orbital symmetry, Building blocks between inorganic and organic chemistry (Nobel Lecture) (RA) 711
Orbital symmetry analysis, of triplet-singlet spin-flip during thermal isomerization of tetrahedral to planar nickel(II) complexes (SC) 288
Organic conductors, A novel type of organic conductor: One-dimensionally polymerized phthalocyaninatoiron(II) (SC) 79
Organic glasses, Polarity of ~ (SC) 432
"Organic metals", (Oxamidoximato) (oxamidoxime)platinum(II) 7,7,8,8-tetracyanoquinodimethanides: A crystal structure with segregated parallel stacks (SC) 524
all-cis-Organocyclotristibane, Synthesis of an ~ and its pentacarbonylchromium complex (SC) 375

Organoelement groups, New possible applications of heavy main-group elements in organic synthesis (RA) 410
Organomagnesium radical complexes, Electron transfer by Grignard reagents: Direct evidence for ~ (SC) 140
Organomercury compounds, High-field conditioned NMR spin decoupling in ~ (SC) 295
Organometal compounds, Organometallic aspects of the Fischer-Tropsch synthesis (RA) 117
Organometallic intramolecular π-Olefin-metal coordination compounds (RA) 889
Organophosphorus fluorine compounds, Novel application of sulfonyl chloride fluoride in the synthesis of ~: Direct conversion of >P(O)H and >P(O)OH groups into >P(O)F groups (SC) 294
Organotitanium reagents, Stereoselectivity and relative reactivity in the reaction of organotitanium and -zirconium reagents with carbonyl compounds (SC) 135
Organozirconium reagents, Stereoselectivity and relative reactivity in the reaction of organotitanium and -zirconium reagents with carbonyl compounds (SC) 135
8-Oxabicyclo[3.2.1]oct-6-en-3-ones, Efficient synthesis of ~, Preparatively useful [4+3]-cycloadducts (SC) 137
(Oxamidoximato)(oxamidooxime)platinum(II) 7,7,8,8-Tetracyanoquinodimethanide, A crystal structure with segregated parallel stacks (SC) 524
Oxanickelacyclopentene derivatives from nickel(0), carbon dioxide, and alkynes (SC) 76
1,3-Oxathiolylium-4-olates, Stable ~—Synthesis and cycloadditions of a novel class of mesoionic heteroarenes (SC) 779
1,3-Oxazin-6-ones, Selective sulfuration and photooxidation of heteroannelated ~ to 1,3-thiazin-6-ones (SC) 794
Oxidation, Serial cyclizations of an arachidonic acid hydroperoxide (SC) 217
Hydroxylation of acyclic alkanes by oxygen atoms O(^{3}P)—Comparison of ozone and O(^{3}P) ~-s of alkanes (SC) 303
~ with palladium salts: stereo- and regiospecific acetoxylation of 4-vinylcyclohexene derivatives (SC) 366
Electrochemical ~ of croconate salts; evidence of the chemical equivalence of the carbonyl oxygen atom and the dicyanomethylene group (SC) 635
Oxidation catalysts, Reversible O_2-addition to polymeric Schiff-base complexes of V^{II} and Mn^{II} and their use as ~ (SC) 775
Oxidative addition, Methylene bridging of two gold atoms through double ~ of methylene dihalides to a cyclic ylide complex (SC) 73
Photochemical ~ of chlorine from chloroform to 2,2'-bipyridyldichloroplatinum(II) (SC) 209
Oxidative coupling, Palladacycloalkanes by ~ of 3,3-dimethylcyclopropene with palladium(0) compounds (SC) 62
Oxidizing Agents, Sulfuric acid derivatives as ~ for phosphorus(III) compounds (SC) 542
Oxiranes, Reaction of α-cyanophenylacetaldehyde with sulfonyl chloride (SC) 524
Oxocarbon dianions, Novel pseudo-~ of the C_4-series (SC) 283
4-Oxo-2-cyclopentenyl acetate—A synthetic intermediate (RA) 480
5-Oxo-1,3λ^4,2,4-dithiadiazole, Synthesis and structure of $[Zn(S_2N_2CO)_6]$ $[AsF_6]_2$—Sulfur-Nitrogen rings as ligands in coordination compounds (SC) 858
Oxofluorotantalate(V), $[Ta_4F_{12}O_6]^{4-}$: A tetranuclear ~ with adamantane skeleton (SC) 870
Oxo-glycosyl bromides, Functionalization at proanomeric centers by photobromination: A novel access to oxo- and acyloxyimino-glycosyl bromides (SC) 625
α-Oxonitriles, The chemistry of acyl cyanides (RA 36)
Synthesis of acyl cyanides from acyl iodides (SC) 83
2-Oxopropanal (methylglyoxal), by oxidation of glycerin in the gas phase (SC) 540
Oxygen addition, Reversible O_2-addition to polymeric Schiff-base complexes of V^{II} and Mn^{II} and their use as oxidation catalysts (SC) 775
Oxygen atoms, Hydroxylation of acyclic alkanes by ~ O(^{3}P)—Comparison of ozone and O(^{3}P) oxidations of alkanes (SC) 303
Oxygen transfer from inorganic and organic peroxides to organic substrates: A common mechanism? (RA) 734
Ozone, Hydroxylation of acyclic alkanes by oxygen atoms O(^{3}P)—Comparison of ~ and O(^{3}P) oxidations of alkanes (SC) 303

PALLADACYCLOALKANES, by oxidative coupling of 3,3-dimethylcyclopropene with palladium(0) compounds (SC) 62
Palladium compounds, Oxidation with palladium salts: Stereo- and regiospecific acetoxylation of 4-vinylcyclohexene derivatives (SC) 366
Palladium(II) complexes, Stereospecific synthesis of ~ of macrocyclic tetradentate phosphane ligands (SC) 375
(S,S)-Palythazine, Stereospecific synthesis of ~ from D-glucose (SC) 141
[2.2]Paracyclophane, Electrochemical reduction of ~ (SC) 305
Patents, Problems of economic exploitation of basic research findings (discoveries, inventions, ~, licences) (RA) 109
Penicillanic acid analogues, Synthesis of bicyclic β-sultams (SC) 548
Pentacoordinated carbon atom, η^5-Cyclopentadienyl(η^5-1,3-diborolene)cobalt—A novel type of sandwich complexes with a ~ (SC) 148
Pentadecker sandwich complex, Synthesis of a ~ (SC) 453
Pentadienyl compounds, Non-planar structures of allyl- and pentadienylmetal compounds: Pleating to achieve a better charge distribution (SC) 145
N-(Pentafluoro-λ^6-sulfanyl)iminosulfur tetrafluoride by reaction of thiazyl trifluoride with fluorine (SC) 354
Pentakis(phosphane)iron(0) complex, A ~ by reductive elimination (SC) 311
Pentalene, 1,2-Dihydropentalene from 1,6-cyclooctadien-3-yne (SC) 917
Pentalene system, Simple transformation of the azulene system into the ~ (SC) 695
Pentamethylcyclopentadienyl, Synthesis of $Pd(\eta^2\text{-}CH_2{=}C_5Me_4)L_2$: Formation of a fulvene ligand by metal-assisted H-shift from ~ (SC) 866
Pentamethylcyclopentadienyl(pyridine)tin trifluoromethanesulfonate, $[(CH_3)_5C_5Sn(C_5H_5N)]^+$: Synthesis, structure and bonding (SC) 70
Peptide bonds, Coupling of sterically hindered ~—A renaissance of the acid chloride method (SC) 630
Peptide formation, by activation with phenyltetrazolinethione/isocyanide (SC) 143
Peptides, Conformation and biological activity of cyclic ~ (RA) 512
Peptide synthesis, The 1,3-dithian-2-ylmethoxycarbonyl (Dmoc) moiety—A protecting group for the amino function in ~ (SC) 292
Peroxides, Oxygen transfer from inorganic and organic ~ to organic substrates: A common mechanism? (RA) 734
Phanes, The chemical behavior of multibridged [2$_n$]Cyclo-~ (RA) 469
~ derived from 1,5- and 1,7-dihydro-s-indacene (SC) 304
Azobenezene ~ (SC) 373
Fourfold bridging of the benezene ring in one step (SC) 618
Trifoliaphane—The trimer of a [2.2]paracyclophane with an ethyno-bridge (SC) 623
A novel route to phoroglucinols—Synthesis, structure, and reactions of [n](2,4)phloroglucino-~ (SC) 871
Novel facile synthesis of multiply ortho-bridged phane-hydrocarbons and of dihydrocyclobutabenzenes (SC) 928
Phenylazulene, 1-~→2-~ rearrangement—Substituent migration or skeletal rearrangement? (SC) 440
Phenylenebis(dichlorophosphane), o- and m-~—Versatile, useful synthetic building blocks (SC) 638
1-Phenylethanol, Asymmetric hydrosilylation of acetophenone with rhodium complexes of optically active Schiff-bases (SC) 377
Phenyltetrazolinethione, Peptide formation by activation with ~/Isocyanide (SC) 143
Pheromones, Signal substances and their reception in the sexual cycle of marine brown algae (RA) 643
A stereocontrolled synthesis of the pheromone 4-methyl-3-heptanol: Novel and selective CC-linking reactions (SC) 309
Phloroglucinols, A novel route to ~—Synthesis, structure, and reactions of [n](2,4)phloroglucinophanes (SC) 871
Phosphane/allylphosphane coupling, "μ-C_3" trisphosphanes by direct ~ (SC) 931
Phosphanes, Chain and ring phosphorus compounds-Analogies between phosphorus and carbon chemistry (RA) 492
(Chloroacyl)diphenyl-~ as sources of halogenated ketenes (SC) 355
Unsymmetrical transfer of allyl groups in the reaction of $[(\eta^3\text{-}C_3H_5)_2M]$ (M=Pd, Ni) with bis(diphenylphosphino)maleic anhydride (SC) 356
Triphosphaalkanes $R_2P{-}CH_2{-}PR{-}CH_2{-}PR_2$ (R=Cl, CH_3) (SC) 376
Functionalization of α-methylencarbonyl compounds to β-acetoxyphosphane oxides and vinylphosphane oxides (SC) 537
o- and m-Phenylenebis(dichlorophosphane)—Versatile, useful synthetic building blocks (SC) 638
Synthesis of α-Vinyl-P,P'-ethylenebis(diorgano~-s) (SC) 919
$Me_2PCHPMe_2^{\ominus}$ as ambidentate chelate ligand (SC) 921
Phosphane ligands, Stereospecific synthesis of palladium(II) complexes of macrocyclic tetradentate ~ (SC) 375
Phosphazene ligands, Manganese complexes with "end-on" and spirocyclic bonded σ^3,λ^5-~ (SC) 136
λ^3-Phosphazenes as bridging η^1-ligands (SC) 297
Phosphinito ligands, Synthesis of novel iridium and rhodium complexes containing diphenylphosphinito and dimethylphosphito ligands (SC) 452
Phosphiranes, Synthesis of 2-vinyl-~ (SC) 292
A spirocyclic diphosphirane (SC) 445
Phosphito ligands, Synthesis of novel iridium and rhodium complexes containing diphenylphosphinito and dimethyl-~ (SC) 452
Phosphonates, β,ε-dioxo-~ by reductive nucleophilic acylation of 1,3-dioxo compounds: Facile synthesis of jasmones (SC) 371
Phosphoniovinamidinium salts (SC) 543
Phosphoranes, The first bis(methylene)-~ of type $R{-}P[{=}C(SiMe_3)_2]_2$ with tricoordinated pentavalent phosphorus (SC) 80
Regioselective 5-exo-trig cyclization in the reaction of [bis(ethylthio)vinylidene]triphenyl-~ with heteroallenes (SC) 621
Phosphorane oxide anion, A stable tetraalkoxy(hydroxy)phosphorane and ~ by hydrolysis of tetraalkoxy(halogen)phosphoranes (SC) 208
λ^3-Phosphorins by [4+2]-cycloaddition of α-pyrones and cyclopentadienones with $H_5C_6{-}C{\equiv}P$ (SC) 370
Phosphorus-Carbon bond, The heterocyclic chemistry of phosphorus. Systems based on the ~ (NB) 153
Phosphorus cation, A diphos-complex of $P^{\oplus}$: The 1,1,3,3-tetraphenyl-1λ^5,2λ^3,3λ^5-triphospholenyl cation (SC) 63
Phosphorus chemistry, Chain and ring phosphorus compounds—Analogies between phosphorus and carbon chemistry (RA) 492

Phosphorus compounds, O,O-Dialkylthiophosphonosulfenyl bromides—A new class of reactive organo-~ (SC) 135
Synthesis and structure of the first transition metal complex of a phosphorus compound with a direct λ^3P—λ^5P bond (SC) 379
Sulfuric acid derivatives as oxidizing agents for phosphorus(III) compounds (SC) 542
Phosphorus-stabilized carbanions, Nucleophilic substitution of hydrogen in nitroarenes by ~ having "vicarious" leaving group (SC) 451
Phosphorus ylides, Synthesis of trisubstituted olefins via trimethylsilylated ~ (SC) 545
Stabilization of the unstable tautomers of phosphino- and arsino-substituted ylides by coordination to transition metals (SC) 926
Photoacoustic spectroscopy, Photoacoustics and ~ (NB) 223
Photobromination, Functionalization at proanomeric centers by ~: A Novel access to oxo- and acyloxyimino-glycosyl bromides (SC) 625
Photochemical oxidative addition of chlorine from chloroform to 2,2'-bipyridyldichloroplatinum(II) (SC) 209
Photochemistry, Tricyclo[3.3.0.0^{2,8}]octan-3-ones: Photochemically prepared building blocks for enantiospecific total syntheses of cyclopentanoid natural products (RA) 820
Evolution of hydrogen from photochemically reduced water-soluble tin(IV)-porphyrins (SC) 131
Photo-induced reaction of alcohols with tricarbonyl(η^5-cyclopentadienyl)ethyltungsten (SC) 205
Selective C—H bond activation in ethane using photoexcited Cu atoms (SC) 211
Novel synthesis of spiro[1,8a]dihydroindolizines; A new photochemically reversible system (SC) 216
Cu—H_2-~ in the matrix; ESR, FTIR, UV/VIS spectroscopic and kinetic studies (SC) 380
CH_4 activation by photoexcited Cu_2 molecules (SC) 381
cis-[Ru(bpy)$_2$(CO)H]$^+$—A possible intermediate in the photochemical production of H_2 from water catalyzed by [Ru(bpy)$_3$]$^{2+}$? (SC) 628
Photocyclization, of 2-aryl-1,1-difluoroethylenes: Synthesis of mono- and difluorinated polycyclic arenes (SC) 766
Photodimerization, Quantitative ~ of crystalline α-benzylidene-γ-butyrolactone (SC) 435
Photoelectron spectroscopy, How similar are tropoquinones and benzoquinones? (SC) 76
Photo-induced cleavage of water, Photochemical evolution of H_2 in the system methyl viologen/Mn^{II}-meso-tetraphenylporphyrintrisulfonic acid/mercaptoethanol/hydrogenase (SC) 434
Photoinitiated hydrosilyations, in presence of tetrahedral heterometallic clusters: Catalysis by intact clusters (SC) 786
Photoisomerization, Reversible ~ between silaethenes and methylsilylenes (Methylsilanediyls) (SC) 854
Photolysis, Laser ~—A new route for charge separation (SC) 436
Photooxidation, Selective sulfuration and ~ of heteroannelated 1,3-oxazin-6-ones to 1,3-thiazin-6-ones (SC) 794
Photooxygenation, o-Benzoquinone monoformylmethides by sensitized ~ of cis-β-methoxystyrenes (SC) 382
Photoreduction, Zinc sulfide as catalyst for the heterogeneous ~ of water (SC) 783
Photoresists, The resist technique—A chemical contribution to electronics (RA) 455
Photosensitive complex ligand, 2-Methyl-2-triphenylphosphoniodithiopropionate—A ~ with labile P—C-bond (SC) 290
Photosynthesis, Chemically dissymmetrical, polymerized surfactant vesicles: Synthesis and possible utilization in artificial ~ (SC) 81
Evolution of hydrogen from photochemically reduced water-soluble tin(IV)-prophyrins (SC) 131
Phthalocyaninatoiron(II), A novel type of organic conductor: One-dimensionally polymerized ~ (SC) 79
Physiological conditions, Synthesis of bicyclo[3.3.1]nonane derivatives under physiological conditions (SC) 306
5-Pivaloyl-2H-isoindole—An isolable and crystallizable o-quinonoid heteroarene (SC) 621
Platinum compounds, (Oxamidoximato) (oxamidoxime)platinum(II) 7,7,8,8-tetracyanoquinodimethanides—A crystal structure with segregated parallel stacks (SC) 524
Polarity, of binary liquid mixtures (RA) 724
~ of organic glasses (SC) 432
Polarographic analysis, Polarographische Analyse (NB) 798
Polymer alloys, Single-phase ~ of polyvinyl chloride and new polymers (RA) 174
Polymeric matrix, Support effects on the growth, stabilization and agglomerization of low nuclearity transition metal clusters synthesized from metal atoms vaporized into liquid aryl-substituted polymers (SC) 550
Polymerizable lipids, Black lipid membranes from ~ (SC) 368
Polymerization, Influence of ring-size of cycloalkenes on the activation volume in the high-pressure co-~ of maleic anhydride (SC) 363
Higher telomers in the Pd-catalyzed reaction of butadiene with alcohols (SC) 767
Polymerized vesicles, Rotation of ~ in an alternating electric field (SC) 134
Polymers, Chemically dissymmetrical, polymerized surfactant vesicles: Synthesis and possible utilization in artificial photosynthesis (SC) 81
Polymer supports, Synthesis of macromolecular isocyanides with general solvent compatibility—Novel ~ for solid-phase syntheses (SC) 374
Polymethines, with heptafulvenyl terminal groups (SC) 68
Polytelluride, $CrTe_3$—A novel transition-metal ~ (SC) 911
Polyunsaturated fatty acids, Serial cyclizations of an arachidonic acid hydroperoxide (SC) 217
Polyvinyl chloride, Single-phase polymer alloys of ~ and new polymers (RA) 174
Porphyria, Topical problems in the biosynthesis of red blood pigment (RA) 343
Porphyrinogen, Synthesis of 2,3,7,8,12,13,17,18-octamethyl-~ in almost quantitative yield (SC) 785
Porphyrins, Evolution of hydrogen from photochemically reduced water-soluble tin(IV)-~ (SC) 131
Novel synthesis of octaalkyl- and octaisoalkyl-~ (SC) 285
A mononuclear hydroxoiron(III) complex of a porphinoid ligand system with bifacial steric hindrance (SC) 432
ab initio Calculation of deformation densities in ~ (SC) 868
Prenylation, Cationic ~ of olefins (SC) 82
Primary adducts, Synthesis, structure, and reactions of ~ of sulfur or selenium with hexaphenylcarbodiphosphorane (SC) 310
L-Prolinamide, Dependence of the enantioselectivity on the relative concentration of substrate in an NADH model reaction (SC) 433
Proline residues, Macrocycles of D- and L-~ (SC) 220
Prostacyclin, and synthetic analogues (RA) 751
Prostaglandin derivatives, Prostacyclin and synthetic analogues (RA) 751
The leukotrienes, highly biologically active substances involved in allergy and inflammation (RA) 902
Protective groups, The 1,3-dithian-2-ylmethoxycarbonyl (Dmoc) moiety—A protecting group for the amino function in peptide synthesis (SC) 292
Oxidative cleavage of benzyl esters with triarylamine cation radicals—Selective deblocking of protected carboxy functions (SC) 780
~ in organic synthesis (NB) 640
Protein biosynthesis, The bacterial ribosome: A programmed enzyme (RA) 23
Provitamin D_3, Light-induced activation of 7-dehydrocholesterol (SC) 356
Pseudooxocarbon Dianions, Novel ~ of the C_4-series (SC) 283
Pyrans, Alkyl substituted 3,4-dihydro-2H-~: Mass spectroscopy, synthesis, and identification as insect constituents (SC) 698
New dihydro-~: Lewis acid catalyzed cycloadditions of α,β-unsaturated acyl cyanides to simple, unactivated olefins and dienes: A readily accessible route to derivatives of rose oxide (SC) 859
Pyrazole, [4+1]Cycloadditions of isocyanides to 1,2,4,5-tetrazines: A novel synthesis of ~ (SC) 284
Anomalous reaction of hydrazine with β-aminovinyl ketones (SC) 548
Pyrene, Synthesis and valence isomerization of 2,7-dihydro-2,2,7,7-tetramethyl-~ (SC) 618
Pyridine derivatives, A new route to ~: Reaction of N-methylene-tert-butylamine with enamines (SC) 213
Pyridinum Salts, Synthesis and properties of N-[1-(arylcarbonyloxy)alkyl]-~ (SC) 289
Pyrolysis, Vacuum ~ of 5,5,10,10-tetrachlorotricyclo[7.1.0.0^{4,6}]deca-2,7-diene: 1,5- and 2,6-Dichloroazulenes (SC) 444
α-Pyrones, λ^3-Phosphorins by [4+2]-cycloaddition of ~ and cyclopentadienones with H_5C_6—C≡P (SC) 370

QUINODIMETHANE COMPLEX, Reversible double deprotonation of hexamethylbenzene on ruthenium: Formation of a fluxional η^3-benzyl compound by protonation of an o-~ of ruthenium(0) (SC) 379
o-Quinone methide, o-Benzoquinone monoformylmethides by sensitized photooxygenation of cis-β-methoxystyrenes (SC) 382
o-Quinone structure, 5-Pivaloyl-2H-isoindole—An isolable and crystallizable o-quinonoid heteroarene (SC) 621

RADICAL ANIONS, Laser photolysis—A new route for charge separation (SC) 436
Heterocyclic ~ as ligands: An unexpected change of coordination in pentacarbonylmetal complexes (SC) 700
Radical cations, Tetra-tert-butylallene and its radical cation (SC) 924
Radical complexes, Electron transfer by Grignard reagents: Direct evidence for organomagnesium ~ (SC) 140
Ambivalent coordination behavior of lithium aluminum hydride in electron transfer reactions (SC) 141
Radical ion-pairs as intermediates in reactions of tetra-tert-butyltetrahedrane and tetra-tert-butylcyclobutadiene (SC) 437
Radicals, The reactivity of primary free ~ and radical ions, mass transfer, and electrosorption—The fundamental factors for selectivity in electrochemical syntheses of organic compounds (RA) 256
Which factors determine the reactivity and regioselectivity of free radical substitution and addition reactions? (RA) 401
Umpolung of carbonyl reactivity via acetoxyalkyl ~ (SC) 130
Addition of alkyl ~ to alkynes: Distinction between radical and ionic nucleophiles (SC) 768
Raman spectroscopy, Determination of the conformation of acyclic α,β-unsaturated aldehydes and ketones from their infrared and Raman spectra—Results and limitations of model calculations (SC) 639
Reaction mechanisms, ETC: A mechanistic concept for inorganic and organic chemistry (RA) 1
Which factors determine the reactivity and regioselectivity of free radical substitution and addition reactions? (RA) 401
Oxygen transfer from inorganic and organic peroxides to organic substrates: A common mechanism? (RA) 734

Reaction of 4-methyl-1,2,4-triazoline-3,5-dione with fulvenes: A 1,3-sigmatropic shift involving a dipolar intermediate (SC) 383
Mechanistic aspects of the carbonylation of nitrobenzene with rhodium catalysts (SC) 687
Kinetics and mechanism. A Study of homogeneous chemical reactions (NB) 797
Reactivity, Which factors determine the reactivity and regioselectivity of free radical substitution and addition reactions? (RA) 401
Rearrangement, Competition between the aza-Cope-~ and aldol addition (SC) 198
1-Phenylazulene→2-phenylazulene ~—Substituent migration or skeletal ~? (SC) 440
The thermal conversion of 1,5,9-triynes into arenes: [2+2+2]-Cycloadditions or sigmatropic ~-s (SC) 685
1,2-Dihydropentalene from 1,6-cyclooctadien-3-yne (SC) 917
Reductive dimerization, $C_\alpha C_\alpha$-Coupling of two $[(CO)_5CrCNEt_2]$ fragments by ~ of a cationic carbyne complex (SC) 444
Regioselective acylamination, by hetero-Cope rearrangement (SC) 370
Regioselective homoaldol reactions, Highly diastereo- and ~ with (1-oxyallyl)titanium derivatives (SC) 372
Regioselectivity, Which factors determine the reactivity and ~ of free radical substitution and addition reactions? (RA) 401
Regioselective 5-exo-trig cyclization in the reaction of [bis(ethylthio)vinylidene]triphenylphosphorane with heteroallenes (SC) 621
Relaxation studies, on the stabilization of trityl cations by acids (SC) 295
Resist technique, A chemical contribution to electronics (RA) 455
Retinal, "Isoretinol" and ~: An unorthodox, but simple entry to the vitamin A series (SC) 855
Rhenium compounds, A μ_3-CO_2 bridged, tetranuclear carbonylrhenium complex: $[(OC)_5Re(CO)_2Re(CO_4]_2$ (SC) 526
Rhodium compounds, $(\mu\text{-}H)_3[C_5H_5RhP(iPr)_3]_2^+$: A dinuclear (Rh—Rh) complex with three bridging hydrido ligands (SC) 296
Asymmetric hydrosilylation of acetophenone with rhodium-complexes of optically active Schiff-bases (SC) 377
Synthesis of novel iridium and rhodium complexes containing diphenylphosphinito and dimethylphosphito ligands (SC) 452
Indirect electrochemical regeneration of NADH by a bipyridinerhodium(I) complex as electron-transfer agent (SC) 782
Ribosome, The bacterial ~: A programmed enzyme (RA) 23
Ring closure, (A→D) -~ to the nickel(II)-B,C,D-hexadehydrocorrinate (SC) 214
Ring contraction, 6→5/3 by oxidative addition to a ferrobicycle having novel structural units (SC) 312
Ring opening, [2+2]-Cycloreversions (RA) 225
Regioselective Opening of α- and β-alkoxyepoxides with trimethylaluminium (SC) 71
Ring size, Influence of ~ of cycloalkenes on the activation volume in the high-pressure copolymerization of maleic anhydride (SC) 363
Ring strain, Novel synthetic building blocks activated by ~: General entry to 2-chloro-2-cyclopropylidene acetates (SC) 790
Reactivity by ~: Spirocyclopropyl-annelated tricyclic skeletons by a one-pot three-step reaction (SC) 791
Rose oxide, New dihydropyrans: Lewis acid catalyzed cycloadditions of α,β-unsaturated acyl cyanides to simple unactivated olefins and dienes: A readily accessible route to derivatives of ~ (SC) 859
Rotamers, Configurational identity (solid, liquid), (N→P)-silatropism and rotomer detection in the methylenephosphane $PhP{=}C(NArylSiMe_3)(PPhSiMe_3)$ (SC) 448
Rotation, of polymerized vesicles in an alternating electric field (SC) 134
Easy ~ about the carbon-carbon bond in lithium cyclopentadienyl (ester-)enolates (SC) 688
Ruthenium cluster, Activation of silanes on a ~: Synthesis, characterization, and catalytic action of the cluster anion $[HRu_3(CO)_{10}(SiEt_3)_2]^-$ (SC) 73
Ruthenium compounds, Reversible double deprotonation of hexamethylbenzene on ruthenium: Formation of a fluxional η^3-benzyl compound by protonation of an o-quinodimethane complex of ruthenium(0) (SC) 379

SANDWICH COMPLEXES, η^5-Cyclopentadienyl(η^5-1,3-diborolene)cobalt—A novel type of ~ with a pentacoordinated carbon atom (SC) 148
μ,η^5-1,3-Diborolenyl tetradecker ~ (SC) 149
"Bichromocenylene": A sandwich with partly decoupled electrons (SC) 151
Synthesis of a penta-decker sandwich complex (SC) 453
(+)-Sarracenin, Stereocontrolled synthesis of ~ via photochemical cycloaddition (SC) 70
Schiff base complexes, Asymmetric hydrosilylation of acetophenone with rhodium complexes of optically active Schiff bases (SC) 377
Reversible O_2-addition to polymeric ~ of V^{II} and Mn^{II} and their use as oxidation catalysts (SC) 775
Seawater desalination, Synthetic membranes—Preparation, structure, and application (RA) 660
Secoiridoids, A simple and stereoselective entry to the ~ by [4+2]-cycloaddition of alkylidene-1,3-dicarbonyl compounds (SC) 793
Segregated stacks, (Oxamidoximato)(oxamidoxime)platinum(II) 7,7,8,8-tetracyanoquinodimethanides: A crystal structure with segregated parallel stacks (SC) 524
$S_6N_5O_4$, A compound with separately stacked cyclic radical cations $S_3N_2^+$ and cyclic anions $S_3N_3O_4^-$ (SC) 538
Selective alkylation, Alkylchromium(III) dichlorides, Highly selective reagents for the addition of nucleophiles to aldehydes (SC) 144
Selective C—H bond activation, in ethane using photoexcited Cu atoms (SC) 211
Selective hydroxylations, of chiral and substituted paraffins (SC) 146
Selective inclusion, of uncharged guest molecules by neutral hosts with fence-shaped side arms (SC) 147
Selectivity, The reactivity of primary free radicals and radical ions, mass transfer, and electrosorption—The fundamental factors for ~ in electrochemical syntheses of organic compounds (RA) 256
Addition of alkyl radicals to alkynes: Distinction between radical and ionic nucleophiles (SC) 768
Chloro(phenoxy)carbene—A nucleophilic carbene having temperature-dependent selectivity (SC) 916
Olefin selectivities in the addition of carbenes (SC) 932
Selenium-fluorine compounds, Stabilization of unusual oxidation and coordination states by the ligands OSF_5, $OSeF_5$, and $OTeF_5$ (RA) 877
Semibullvalene, A 2,6-Diaza-~ (SC) 637
Semibullvalenetetracarboxylates: Models for molecules with bishomoaromatic ground state (SC) 438
Semiconductor circuits, The resist technique—A chemical contribution to electronics (RA) 455
Separation of enantiomers, Chiral silica packings with L-proline or L-hydroxyproline bonded via alkyl or alkylbenzyl chains for the separation of the enantiomers of α-amino acids by column liquid chromatography (SC) 930
Sesquiterpenoids, A short route to 7,7-dimethyl-6-methylenetricyclo[6.2.1.0^{1,5}]undeca-9-ene and the zizaene class of ~ (SC) 442
Side arms, Selective inclusion of uncharged guest molecules by neutral hosts with fence-shaped ~ (SC) 147
Sigmatropic rearrangement, Dipolar intermediates in the [2,3]-~ of ammoniomethanides (SC) 198
Two-step ~ versus aldol addition of ammonioimides (SC) 199
1,3-Sigmatropic shift, Reaction of 4-methyl-1,3,4-triazoline-3,5-dione with fulvenes: A 1,3-~ involving a dipolar intermediate (SC) 383
Signal substances, and their reception in the sexual cycle of marine brown algae (RA) 643
Silacyclopropane, A Stable Diaza-~ (SC) 301
Silaethenes, Reversible photoisomerization between silaethenes and methylsilylenes (methylsilanediyls) (SC) 854
Silicon compounds, $Li_{12}Si_7$: Theoretical interest aroused (SC) 632
Silver compounds, $[Ag_5I_6]^-$, A one-dimensional infinite anion with 10_5mc symmetry (SC) 697
A novel three-dimensional tellurium array: High-pressure synthesis and crystal structure of $AgTe_3$ (SC) 706
Silylenol esters, Lewis acid induced α-alkylation of carbonyl compounds (RA) 96
Silyl ether, Activation of silanes on a ruthenium cluster. Synthesis, characterization, and catalytic action of the cluster anion $[HRu_3(CO)_{10}(SiEt_3)_2]^-$ (SC) 73
Silylmethylphosphinium salts, Synthesis of trisubstituted olefins via trimethylsilylated phosphorus ylides (SC) 545
Single-phase polymer alloys of polyvinyl chloride and new polymers (RA) 174
Singlet carbenes, Evidence for intermediates in the cycloaddition of ~ (SC) 310
Singlet oxygen, Formation of $^1O_2$ in the reversible autoxidation of enolates derived from carboxylic acids (SC) 75
Skeletal rearrangement, 1-Phenylazulene→2-phenylazulene rearrangement—Substituent migration or ~? (SC) 440
Small angle X-ray scattering, Determination of the structure of dimethyldioctadecylammonium chloride in solution by ~: Reversible phase transition (SC) 765
Solar energy, Evolution of hydrogen from photochemically reduced water-soluble tin(IV)-porphyrins (SC) 131
Novel synthesis of spiro[1,8a]dihydroindolizines; A new photochemically reversible system (SC) 216
Photochemical evolution of H_2 in the system methyl viologen/Mn^{II}-meso-tetraphenylporphyrintrisulfonic acid/mercaptoethanol/hydrogenase (SC) 434
Solid-phase syntheses, Synthesis of macromolecular isocyanides with general solvent compatibility—Novel polymer supports for ~ (SC) 374
Solid-state problems, Structure and bonding in crystals (NB) 797
Solid state reactions, Quantitative photodimerization of crystalline α-benzylidene-γ-butyrolactone (SC) 435
Solid-state ^{13}C-NMR spectra of cyclotriprolines (SC) 689
Solvents, Polarity of binary liquid mixtures (RA) 724
Solvolysis, The norbornyl cation: Prototype of a 1,3-bridged carbocation (RA) 87
Spectroscopy, in heterogeneous catalysis (NB) 387
ESCA spectroscopy, Preparation of a graphite fluoride film on aluminum (SC) 378
ESR spectroscopy, Electron spin resonance studies of the sulfur catalysis of the industrial dichlorination of benzene (SC) 533
IR spectroscopy, Determination of the conformation of acyclic α,β-unsaturated aldehydes and ketones from their infrared and Raman spectra—Results and limitations of model calculations (SC) 639
NMR spectroscopy, Karpulus curve for $^3J(^{13}C,^1H)$ in hydrocarbons (SC) 449

Two-dimensional dynamic ^{13}C-~—An investigation of $(\eta^3\text{-}C_3H_5)_4Cr_2$ (SC) 626
^{13}C-NMR spectra, Solid-state ~ of cyclotriprolines (SC) 689
D,L-Sphingosine, Diastereoselective synthesis of ~ (SC) 210
Co^{3+} spin-crossover complexes, Steric and electronic control of ligand field strength in octahedral ~ (SC) 915
NMR Spin decoupling, High-field conditioned ~ in organomercury compounds (SC) 295
Spin-flip, Orbital symmetry analysis of triplet-singlet ~ during thermal isomerization of tetrahedral to planar nickel(III) complexes (SC) 288
Spin multiplicity, Cyclobutadienes or acetylenes from (2-cyclopropen-1-yl)carbenes—A question of ~? (SC) 913
Spiro compounds, Manganese complexes with "end-on" and spirocyclic bonded σ^3,λ^5-phosphazene ligands (SC) 136
Spirocyclopropyl compounds, Reactivity by ring strain: Spirocyclopropyl-annelated tricyclic skeletons by a one-pot three-step reaction (SC) 791
Spiro[1,8a]dihydroindolizines, Novel synthesis of ~; A new photochemically reversible system (SC) 216
Spirorenone, Synthesis of ~—A novel highly active aldosterone antagonist (SC) 696
Stabilization, Influence of conformational rigidity on the ~ of α-ferrocenyl carbocations: A cis-fixed diferrocenyl carbenium ion (SC) 293
~ of the unstable tautomers of phosphino- and arsino-substituted ylides by coordination to transition metals (SC) 926
Stereochemistry, Basic principles of the CIP-system and proposals for a revision (RA) 567
The unambiguous specification of the steric course of asymmetric syntheses (RA) 654
"Contra-steric" alkylation of the enolates of dioxolanecarboxylic acid esters (SC) 449
~ of the bromination of 1,6-Methano[10]annulene (SC) 920
MO model for the ~ of bromination of 1,6-methano[10]annulene (SC) 922
Stereocontrolled synthesis, A ~ of the pheromone 4-methyl-3-heptanol: Novel and selective CC-linking reactions (SC) 309
Stereoselectivity and relative reactivity in the reaction of organo-titanium and -zirconium reagents with carbonyl compounds (SC) 135
Stereospecific acetoxylation, Oxidation with palladium salts: Stereo- and regiospecific acetoxylation of 4-vinylcyclohexene derivatives (SC) 366
Stereospecific synthesis, of palladium(II) complexes of macrocyclic tetradentate phosphane ligands (SC) 375
Sterically crowded ethanes and ethenes from tri-tert-butylsilymethyl carbenoids (SC) 368
Steric hindrance, A mononuclear hydroxo-iron(III) complex of a porphinoid ligand system with bifacial ~ (SC) 432
Stetter's complexes, are no intramolecular inclusion compounds (SC) 787
Stibobenzene complexes, Antimony homologues of dinitrogen and azabenzene as complex ligands: Preparation and structure of $[Sb{\equiv}Sb\{W(CO)_5\}_3]$ and $[PhSb{=}SbPH\{W(CO)_5\}_3]$ (SC) 215
Stiborane, Redox reactions of a ferrio-arsane and -stibane with chlorophosphanes: Synthesis of a diferrioarsonium chloride and a ~ with asymmetric iron atoms (SC) 549
μ_2-η^2-Styryl complex, A ~ by reaction of $Cp_2Mo_2(CO)_4$ with the Wittig reagent $(C_6H_5)_3P{=}CH_2$ (SC) 919
Substituent migration, 1-Phenylazulene→2-phenylazulene rearrangement—Substituent migration or skeletal rearrangement? (SC) 440
Succinate dehydrogenase, Specific transfer of the H_{Si}-atom of succinate to the 5-deazaflavin analogue of ~ (SC) 365
Sulfenyl iodides, Isolation of crystalline acyl-~—Intermediates in the I_2-oxidation of thiocarboxylic acids (SC) 150
μ_4-Sulfido compounds, $[Fe_6S_9(SCH_2C_6H_5)_2]^{4-}$: A hexanuclear iron-sulfur cluster anion containing the square-pyramidal $[(\mu_4\text{-}S)Fe_4]$-unit (SC) 201
Sulfonation, The ~ of aromatic isocyanates: Sulfonated p-tolyl isocyanate—an X-ray structure analysis (SC) 867
Sulfonyl chloride fluoride, Novel application of ~ in the synthesis of organophosphorus fluorine compounds: Direct conversion of >P(O)H and >P(O)OH groups into >P(O)F groups (SC) 294
Sulfur, Synthesis of S_{11} and S_{13} (SC) 794
Sulfur anions, Synthesis and structure of triply coordinated sulfur anions (SC) 153
Sulfuration, Selective ~ and photooxidation of heteroannelated 1,3-oxazin-6-ones to 1,3-thiazin-6-ones (SC) 794
Sulfur catalysis, Electron spin resonance studies of the ~ of the industrial dichlorination of benzene (SC) 533
Sulfur diimide, Dipotassium ~, K_2SN_2 (SC) 633
Sulfur-Fluorine compounds, Stabilization of unusual oxidation and coordination states by the ligands OSF_5, $OSeF_5$, and $OTeF_5$ (RA) 877
Sulfuric acid derivatives as oxidizing agents for phosphorus(III) compounds (SC) 542
Sulfur-Nitrogen chelate ligand, $K_2[Ni_2(N_2S_2)_2(CN)_2]$—A dinuclear complex with the $S_2N_2^{2\ominus}$ chelate ligand (SC) 633
Sulfur-Nitrogen compounds, N-(Pentafluoro-λ^6-sulfanyl)iminosulfur tetrafluoride by reaction of thiazyl trifluoride with fluorine (SC) 354
Bis(pentafluoro-λ^6-sulfanyl)amines (SC) 355
Cleavage of S_4N_4 to S_2N_2 at room temperature: Formation and struture of $(AlCl_3)_2S_2N_2$ (SC) 634
Sulfur-Nitrogen-Oxygen compounds, $S_6N_5O_4$, A compound with separately stacked cyclic radical cations $S_3N_2^+$ and cyclic Anions $S_3N_3O_4^-$ (SC) 538
Sulfur-Nitrogen rings, Synthesis and structure of $[Zn(S_2N_2CO)_6][AsF_6]_2$—Sulfur-Nitrogen rings as ligands in coordination compounds (SC) 858
β-Sultams, Synthesis of bicyclic ~ (SC) 548
Supercooled aqueous solutions, Anomalies of liquid water (RA) 315
Surfactant-type crown ether complex, Double layer formation with a Crystal structure of 15,15-bis(dodecyloxymethyl)[16]crown-5·NaSCN (SC) 627
Surfactant vesicles, Chemically dissymmetrical, polymerized ~: Synthesis and possible utilization in artificial photosynthesis (SC) 81
Synthetic methods, The chemistry of acyl cyanides (RA 36)
Lewis acid induced α-alkylation of carbonyl compounds (RA) 96
New possible applications of heavy main-group elements in organic synthesis (RA) 410

TANTALUM COMPOUNDS, $[Ta_4F_{12}O_6]^{4-}$: A tetranuclear oxofluorotantalate(V) with adamantane skeleton (SC) 870
Tellurium array, A novel three-dimensional ~: High-pressure synthesis and crystal structure of $AgTe_3$ (SC) 706
Tellurium-Fluorine compounds, Stabilization of unusual oxidation and coordination states by the ligands OSF_5, $OSeF_5$, and $OTeF_5$ (RA) 877
Tellurium compounds, $Cs_7Fe_4Te_8$, A compound with $[Fe_4Te_8]$ clusters (SC) 544
$CrTe_3$—A novel transition-metal polytelluride (SC) 911
Telluroferrates, $Cs_7Fe_4Te_8$, A compound with $[Fe_4Te_8]$ clusters (SC) 544
Telomers, Higher ~ in the Pd-catalyzed reaction of butadiene with alcohols (SC) 767
Template Effect, Stereospecific synthesis of palladium(II) complexes of macrocyclic tetradentate phosphane ligands (SC) 375
Tensides, Synthesis of primary alkylarenes without benzene via olefin metathesis (SC) 700
Terminal hydrido ligand, Synthesis and structure of a heterodimetallic complex containing a ~: $[(PPh_3)_2(H)PtMo(CO)_3(\eta^5\text{-}C_5H_5)]$ (SC) 308
Tetraalkoxy(halogen)phosphorane, A stable tetraalkoxy(hydroxy)phosphorane and phosphorane oxide anion by hydrolysis of ~ (SC) 208
Tetraalkoxy(hydroxy)phosphorane, A Stable ~ and phosphorane oxide anion by hydrolysis of tetraalkoxy(halogen)phosphoranes (SC) 208
Tetra-tert-butylallene, and its radical cation (SC) 924
Tetra-tert-butylcyclobutadiene, Radical ion-pairs as intermediates in reactions of tetra-tert-butyltetrahedrane and ~ (SC) 437
Tetra-tert-butyltetrahedrane, Radical ion-pairs as intermediates in reactions of ~ and tetra-tert-butylcyclobutadiene (SC) 437
Tetradecker sandwich complexes, μ,η^5-1,3-Diborolenyl ~ (SC) 149
Tetraethyldibismuthane: A dinuclear bismuth compound (SC) 439
Tetrahedrane, Radical ion-pairs as intermediates in reactions of tetra-tert-butyl-~ and tetra-tert-butylcyclobutadiene (SC) 437
~-s, Synthesis and properties of [2,3-bis(trimethylsilyl)-2-cyclopropen-1-yl]-diazomethane (SC) 437
Tetrakis(methylene)bicyclo[2.2.2]octane)zirconocene, (2,9:6,12-η-2,3,5,6-~, an isolable bis(olefin)zirconium(II) compound (SC) 782
Tetraphenylcyclobutadienediide, The dianion 1,2,3,4-~ (SC) 133
Tetraphosphabicyclobutane, The first ~ (SC) 544
tetrahedro-Tetraphosphorus, Transition metal complexes with cyclo-triphosphorus (η^2-P_3) and (η^1-P_4) ligands (RA) 330
Tetrasulfur Tetranitride, $S_6N_5O_4$, A compound with separately stacked cyclic radical cations $S_3N_2^+$ and cyclic anions $S_3N_3O_4^-$ (SC) 538
Cleavage of S_4N_4 to S_2N_2 at room temperature: Formation and struture of $(AlCl_3)_2S_2N_2$ (SC) 634
Tetravinylcyclobutane, From cis,trans-cis-1,2,3,4-~ to cyclododecatetraene—Two consecutive Cope rearrangements (SC) 686
Thallium compounds, $Tl(OBu)_3Sn$: A small pentaatomic cage molecule (SC) 858
Thermodynamics, Liquid structures and thermodynamics of alkane mixtures (RA) 184
1,3-Thiazin-6-ones, Selective sulfuration and photooxidation of heteroannelated 1,3-oxazin-6-ones to (SC) 794
Thiazyl trifluoride, N-(Pentafluoro-λ^6-sulfanyl)iminosulfur tetrafluoride by reaction of thiazyl trifluoride with fluorine (SC) 354
Thiiranimines, A novel method for the synthesis of ~ (SC) 694
μ_2-C,η^1-S-Thiocarbonyl compound $(C_5H_5)_3CoMn_2(CO)_4(CS)PMe_3$—A heterotrinuclear complex with a μ_2-C,η^1-S-bonded thiocarbonyl group (SC) 202
Thiosulfenyl bromides, O,O-Dialkylthiophosphonosulfenyl bromides—A new class of reactive organophosphorus compounds (SC) 135
Thorium(III) iodide, ThI_3, A Janus amongst compounds with metal-metal interactions (SC) 525
Three-Center-diastereoselective aldol-additions of β-lactone enolates to aldehydes (SC) 777
Thromboxane intermediates, Hetero-Diels-Alder reactions for the synthesis of ~ (SC) 302
Tin-cluster-adduct, $[(CH_3)_5C_5Sn(C_5H_5N)]^+$: Synthesis, structure and bonding (SC) 70
Tin compounds, A novel anionic five-coordinate tris(trichlorostannato)platinum(II) complex (SC) 284

Triphenylstannanedithiocarboxylate, a novel chelate ligand (SC) 364
$Tl(OtBu)_3Sn$: A small pentatomic cage molecule (SC) 858
Tin(IV)-porphyrins, Evolution of hydrogen from photochemically reduced water-soluble ~ (SC) 131
Titanium compounds, Stereoselectivity and relative reactivity in the reaction of organo-titanium and -zirconium reagents with carbonyl compounds (SC) 135
Highly diastereo- and regioselective homoaldol reactions with (1-oxyallyl)titanium derivatives (SC) 372
Metallacyclosulfanes: Synthesis of bis(pentamethylcyclopentadienyl)titana(IV)-cyclotetrasulfane (SC) 384
Erythro-selective aldol-type addition of titanated aldehyde-hydrazones (SC) 864
Titanium tris(tetrahydridoborate), The molecular structure of gaseous ~ as determined by electron diffraction (SC) 534
Transition metal clusters, Support effects on the growth, stabilization, and agglomeration of low nuclearity ~ synthesized from metal atoms vaporized into liquid aryl-substituted polymers (SC) 550
Transition metal complexes, with cyclo-triphosphorus (η^3-P_3) and tetrahedro-tetraphosphorus (η^1-P_4) ligands (RA) 330
Unsymmetrical transfer of allyl groups in the reaction of $[(\eta^3\text{-}C_3H_5)_2M]$ (M = Pd, Ni) with bis(diphenylphosphino)maleic anhydride (SC) 356
Synthesis and structure of the first transition metal complex of a phosphorus compound with a direct λ^3P—λ^5P bond (SC) 379
Transition states, Control of the conformation of ~ in intramolecular Diels-Alder reactions with inverse electron demand (SC) 863
Triacylmethanes, 2-Cyano-3-ethoxyacrylamides —Selective synthons for the synthesis of heterocycles (SC) 540
Triazoles, Substituent-dependent competition between 1,5- and 3,5-cyclization in vinyl azides; 4H-~ from 3,3-diazido-2-cyanoacrilic acid methyl ester and primary amines (SC) 288
3-Hydroxy-2-(1,2,4-triazol-1-yl)acrylic acid ethyl ester and O-functional derivatives (SC) 546
Tri-tert-butylsilylmethyl carbenoids, Sterically crowded ethanes and ethenes from ~ (SC) 368
Tricarbonyl(η^5-cyclopentadienyl)ethyltungsten, Photo-induced reaction of alcohols with (SC) 205
Tricarbonyl-2,7-methanoaza[10]annulenechromium(0) (SC) 784
Tricyclo[7.1.0.0^{4,6}]deca-2,7-diene, Vacuum pyrolysis of 5,5,10,10-tetrachloro-~: 1,5- and 2,6-dichloroazulenes (SC) 444
Tricyclo[5.2.0.0^{3,5}]nona-1,6,8-triene, The question of the antiaromaticity of 1,3-cyclobutadiene: Thermal valence isomerization of the ~ system (SC) 139
Tricyclo[3.3.0.0^{2,8}]octan-3-ones: Photochemically prepared building blocks for enantiospecific total syntheses of cyclopentanoid natural products (RA) 820
Tricyclo[2.1.0.0^{2,5}]pentan-3-one, Electron density distribution in the bonds of the bridged bicyclo[1.1.0]butane system 1,5-Dimethyl-~ (SC) 775
Tricyclo[6.2.1.0^{1,5}]undeca-9-ene, A short route to 7,7-Dimethyl-6-methylene-~ and the zizaene class of sesquiterpenoids (SC) 442
Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene, Theoretical investigations on the valence tautomerism between 1,6-methano[10]annulene and ~ (SC) 865
Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene-11,11-dicarbonitrile, Norcaradiene valence tautomer of a 1,6-Methano[10]annulene: ~ (SC) 869
Triethylphosphoniodithiocarbonate ligand, Synthesis and reactivity of metal complexes with the zwitterionic Et_3P—CS_2 ligand. Structure of the dithiocarbonato complex [(triphos)Co(S_2CO)] (SC) 197
Triferrocenylamine, NFc_3 (SC) 74
Trifluoromethylation, Trialkylsilyl(trifluoromethyl)diazenes as tailored reagents for nucleophilic ~ (SC) 443
Trifluoromethyldiazenes, Trialkylsilyl(trifluoromethyl)diazenes as tailored reagents for nucleophilic trifluoromethylation (SC) 443
Trifoliaphane—The trimer of a [2.2]paracyclophane with an ethyno-bridge (SC) 623
Trimethylsilyl trifluoromethanesulfonate, α-Linked disaccharides from O-(β-D-glycopyranosyl) trichloroacetimidates using trimethylsilyl trifluoromethanesulfonate as catalyst (SC) 781
Triphenylstannanedithiocarboxylate. A novel chelate ligand (SC) 364
Triphosphaalkanes
R_2P—CH_2—PR—CH_2—PR_2 (R = Cl, CH_3) (SC) 376
Triphospholene derivatives, A diphos-complex of P$^{\oplus}$: The 1,1,3,3-tetraphenyl-1λ^5,2λ^3,3λ^5-triphospholenyl cation (SC) 63
cyclo-Triphosphorus, Transition metal complexes with ~ (η^3-P_3) and tetrahedro-tetraphosphorus (η^1-P_4) ligands (RA) 330
CC Triple bond, Trifoliaphane—The trimer of a [2.2]paracyclophane with an ethyno-bridge (SC) 623
PC Triple bond, λ^3-Phosphorins by [4+2]-cycloaddition of α-pyrones and cyclopentadienones with H_5C_6—C≡P (SC) 370
Trisaccharide, Synthesis of ~ moieties from N-acetylneuroaminic acid and N-acetyllactosamine (SC) 927
Trisphosphanes, "μ-C_3" ~ by direct phosphane/allylphosphane coupling (SC) 931
Tris(trichlorostannato)platinum(II) complex, A novel anionic five-coordinate ~ (SC) 284
Tris(trimethylplumbyl)heptaphosphanortricyclene $P_7(PbMe_3)_3$ (SC) 863
1,2,4-Trithiolane, Formation of bis(isopropylidene)-~ from 2-methyl-2-triphenylphosphoniodithiopropionate (SC) 291
Trityl cations, Relaxation studies on the stabilization of ~ by acids (SC) 295
Triynes, The thermal conversion of 1,5,9-~ into arenes: [2+2+2]-Cycloadditions or sigmatropic rearrangements (SC) 685
Tropoquinones, How similar are ~ and benzoquinones? (SC) 76
Tungsten compounds, Designed synthesis of an alkylidyne-capped trinuclear (Mo, Mo, W) metal cluster (SC) 629
Novel tungsten-alkyl and tungsten-acyl complexes with acetylene as four-electron ligand (SC) 861
Two-dimensional dynamic ^{13}C-NMR spectroscopy—An investigation of (η^3-$C_3H_5)_4Cr_2$ (SC) 626
Twofold metalation, Doubly metalated carbon by metal-induced vinyl-ethylidene rearrangement (SC) 204

ULLMANNS ENCYKLOPÄDIE der technischen Chemie (NB) 387, 553
Umpolung, of carbonyl reactivity via acetoxyalkyl radicals (SC) 130
Reaction of acyliminomalonic esters with C-nucleophiles, an ~ in the acylaminomalonic ester synthesis of α-amino acids (SC) 203
Synthesis and properties of N-[1-(arylcarbonyloxy)alkyl]pyridinum salts (SC) 289
α,β-Unsaturated ketones, by cathodic addition of benzotrichloride to ketones (SC) 79
Uranium-235 enrichment, Metal hexamethoxides (SC) 142
Uranium hexamethoxide, Metal hexamethoxides (SC) 142
Urea, Complexes of crown ethers with uronium salts; Preparation and crystal structure of [18]crown-6 uronium nitrate(1/1) and benzo[27]crown-9 uronium perchlorate(1/1) (SC) 450
Uronium Salts, Complexes of crown ethers with ~; Preparation and crystal structure of [18]crown-6 uronium nitrate(1/1) and benzo[27]crown-9 uronium perchlorate(1/1) (SC) 450
Uroporphyrinogens, Heme biosynthesis from isomeric ~ (SC) 215
Topical problems in the biosynthesis of red blood pigment (RA) 343

VACUUM PYROLYSIS, of 5,5,10,10-tetrachlorotricyclo[7.1.0.0^{4,6}]deca-2,7-diene: 1,5- and 2,6-dichloroazulenes (SC) 444
Valence isomerism, Cyclobutadiene: Mesomerism or valence isomerism? (SC) 693
Synthesis and valence isomerization of 2,7-dihydro-2,2,7,7-tetramethylpyrene (SC) 618
Valence tautomerism, Theoretical investigations on the ~ between 1,6-methano[10]annulene and tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene (SC) 865
First metal complexes of the norcaradiene form of 1,6-methano[10]annulene (SC) 868
Norcaradiene valence tautomer of a 1,6-methano[10]annulene: Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene-11,11-dicarbonitrile (SC) 869
Vehicle mechanism, A novel model for the interpretation of the conductivity of fast proton conductors (SC) 208
Vesicles, Chemically dissymmetrical, polymerized surfactant ~: Synthesis and possible utilization in artificial photosynthesis (SC) 81
Rotation of polymerized ~ in an alternating electric field (SC) 134
Determination of the structure of dimethyldioctadecylammonium chloride in solution by small angle X-ray scattering: Reversible phase transition (SC) 765
"Vicarious" leaving groups, Nucleophilic substitution of hydrogen in nitroarenes by phosphorus-stabilized carbanions having "vicarious" leaving groups (SC) 451
Vinamidinium salts, Phosphonio-~ (SC) 543
N-Vinylamides, New method for the synthesis of ~ (SC) 630
Vinyl azides, Substituent-dependent competition between 1,5- and 3,5-cyclization in ~; 4H-triazoles from 3,3-diazido-2-cyanoacrylic acid methyl ester and primary amines (SC) 288
Vinylcarbene ligand, Cyclopropenes as complex ligands: $Fe_2(CO)_9$-induced ring-opening of a spirocyclopropene and reversible CO-addition to the ~ (SC) 205
4-Vinylcyclohexene derivatives, Oxidation with palladium salts: Stereo- and regiospecific acetoxylation of ~ (SC) 366
Vinyl diazides, Geminal ~: Potential precursors of functionalized alkylidenecarbenes; synthesis and reactions of 3,3-diazido-2-cyanoacrylic acid methyl ester (SC) 287
Vinyl-ethylidene rearrangement, Doubly metalated carbon by metal-induced ~ (SC) 204
Vinylketenes, Bis[bis(trimethylsilyl)acetylene]-dicarbonylchromium (SC) 929
Vinylphosphanes, Synthesis of α-Vinyl-P,P'-ethylenebis(diorganophosphanes) (SC) 919
Vinylphosphane oxides, Functionalization of α-methylenecarbonyl compounds to β-acetoxyphosphane oxides and ~ (SC) 537
2-Vinylphosphiranes, Synthesis of ~ (SC) 292
Vitamin A series, "Isoretinol" and retinal: An unorthodox, but simple entry to the vitamin A series (SC) 855
Vitamin B_{12}, Synthesis of a dicyanocobalt(III) D-didehydrocorrinate and its reduction to the dicyanocobalt(III) corrinate (SC) 152
(A→D) ring closure to the nickel(II)-B,C,D-hexadehydrocorrinate (SC) 214

WATER, Anomalies of liquid ~ (RA) 315
cis-$[Ru(bpy)_2(CO)H]^+$—A possible intermediate in the photochemical production of H_2 from ~ catalyzed by $[Ru(bpy)_3]^{2+}$? (SC) 628
Zinc sulfide as catalyst for the heterogeneous photoreduction of ~ (SC) 783
Water Gas Shift Reaction, H_2S as a promotor for the ~ (SC) 619
Wittig reagent, A μ_2-η^2-Styryl complex by reaction of $Cp_2Mo_2(CO)_4$ with the ~ $(C_6H_5)_3P$=CH_2 (SC) 919

YLIDES, Synthesis of trisubstituted olefins via trimethylsilylated phosphorus ~ (SC) 545
Stabilization of the unstable tautomers of phosphino- and arsino-substituted ~ by coordination to transition metals (SC) 926
Ylide complex, Methylene bridging of two gold atoms through double oxidative addition of methylene dihalides to a cyclic ~ (SC) 73
Ynamines, A simple, highly variable route to (1,3-diynyl)amines (SC) 282

ZINC SULFIDE, as catalyst for the heterogeneous photoreduction of water (SC) 783
Zirconocene derivatives, (2,9:6,12-η-2,3,5,6-Tetrakis(methylene)bicyclo[2.2.2]octane)zirconocene, an isolable bis(olefin)zirconium(II) compound (SC) 782
The reaction of (Butadiene)zirconocene and -hafnocene with ethylene (SC) 913
Catalyst deactivation during zirconocene- and hafnocene-induced ethylene dimerization (SC) 913
Zizaene, A short route to 7,7-dimethyl-6-methylenetricyclo[6.2.1.$0^{1,5}$]undeca-9-ene and the ~ class of sesquiterpenoids (SC) 442
