
2, X = H; **5**, X = F

2 and **5** have planar S_2NX frameworks with large SNS angles (134.8 ± 1° and 138.3 ± 1.0°, resp.). The SN distances increase with increasing electronegativity of the substituents, *e.g.* **2** < **5** < F_5SNF_2[5], but in all cases are shorter than the Schomaker-Stevenson value (1.74 Å). The average SF distances show an opposite trend.

The two latter mentioned findings can be qualitatively explained by a simple electrostatic model.

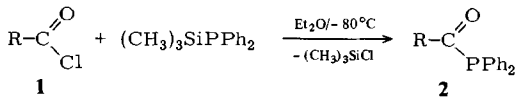
(Chloroacyl)diphenylphosphanes as Sources of Halogenated Ketenes**

By *Ekkehard Lindner*, Michael Steinwand, and Sigurd Hoehne*

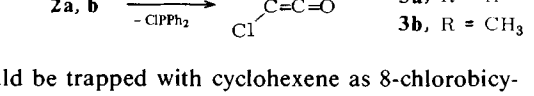
Because of their polar cumulative double-bond system, chloroketenes are highly reactive compounds, which add to olefins, and thus are of special preparative interest[4]. We have now succeeded[7] in isolating and characterizing the pure chloroketones **3a** and **3b**, hitherto unknown in substance. Thermolysis of the (chloroacyl)diphenylphosphanes **2a** and **2b**, which were synthesized for the first time by reaction of $(CH_3)_3SiPPh_2$ with the acyl halides **1**, afforded **3a** and **3b**, which were isolated and characterized by freezing out at −80 °C, and by ^{13}C-NMR spectroscopic measurements at −60 °C.



1 **2**

a, R = $HCCl_2$; **b**, R = CH_3CCl_2; **c**, R = CCl_3

The crystalline acylphosphanes **2a—2c**, which are readily soluble even in slightly polar solvents, were identified by elemental analyses and by their ^{13}C-, $^{31}P\{^1H\}$-NMR, IR, and mass spectra; in the case of **2a**, also by an X-ray structure analysis (Fig. 1). **2a—2c** are thermally labile and decompose even under mild conditions into $ClPPh_2$ and ketene derivative.



3a, R = H
3b, R = CH_3

3a could be trapped with cyclohexene as 8-chlorobicyclo[4.2.0]octan-7-one. Various products are formed on decomposition of **2c**, depending on the temperature: Between 0 and 40 °C, Cl_3PPh_2 is formed; on briefly heating to 80 °C, $ClPPh_2$ can be observed $^{31}P\{^1H\}$-NMR spectroscopically and is found to be further chlorinated to Cl_3PPh_2 after a short while. This would suggest that dichloroketene occurs as intermediate. The signals of the Cl atoms in the ^{13}C-NMR spectra of **3a** and **3b** are shifted upfield compared to the corresponding signals of ketene and methylketene[11] [$^{13}C\{^1H\}$-NMR ($CDCl_3$) **3a**: $\delta = 166.2$; **3b**: $\delta = 168.9$]; consistent with this finding the C2 atoms in **3a** and **3b** are less shielded [^{13}C-NMR ($CDCl_3$) **3a**: $\delta = 70.1$ (d, $^1J_{CH} = 184.4$ Hz); **3b**: $\delta = 85.0$ (q, $^2J_{CH} = 4.5$ Hz)].

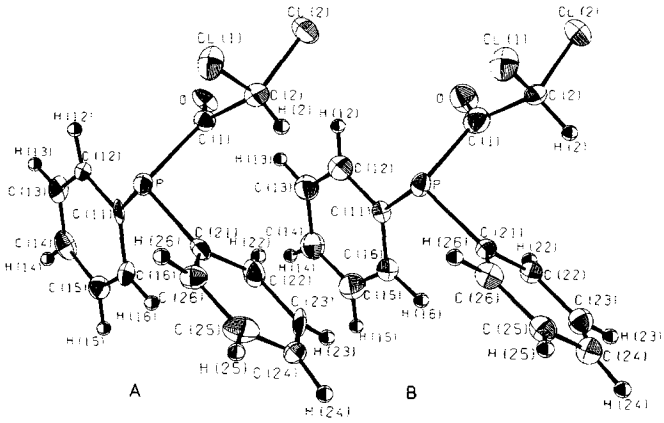

Fig. 1. ORTEP diagram of the structure of **2a** in the crystal.

The crystal lattice[12] of **2a** accomodates two sets of mutually symmetry-independent molecules (A, B). In accord with the $^{31}P\{^1H\}$-NMR spectrum, the X-ray structure analysis of **2a** also indicates an interaction between Cl1 and the lone pair of the phosphorus, which favors the thermal decomposition (Cl1—P distance = 327 pm). The PCl bond, of *ca.* 188 pm, is longer than the PC_{alkyl} bonds; this is important, since cleavage of this bond is an important prerequisite for the formation of **3a**.

Light-Induced Activation of 7-Dehydrocholesterol

By *Karlheinz Schmitt-Rau** and *Manfred Wilk*

It has long been presumed that autoxidation products of cholesterol and its derivatives participate in carcinogenesis[1]. We have been able to show[5] that 7-dehydrocholesterol (7-DHC) and ergosterol can be oxidized to reactive alkylating species which could possibly react as precarcinogens with cell nucleophiles. 7-DHC is present as provitamin D_3 in high concentrations in the skin. Should it likewise be activated in this way by irradiation such that it reacts with a model nucleophile—1-methylimidazole—this could give an indication of the mechanism of light-induced carcinogenesis.

[*] Dr. K. Schmitt-Rau

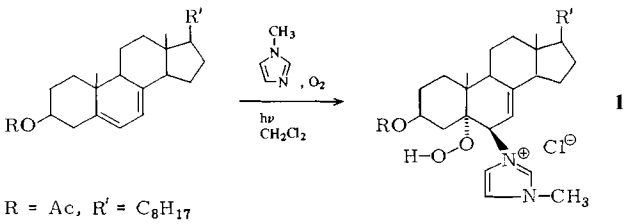
Koellikerstrasse 2, D-8700 Würzburg (Germany)
Prof. Dr. M. Wilk
Institut für Organische Chemie der Universität
Sandhofstrasse, D-6000 Frankfurt am Main (Germany)

After 120 hours irradiation of the acetate of 7-DHC (or of 7-DHC itself) and 1-methylimidazole in dichloromethane, a 1 : 1 adduct of the steroid and nucleophile could be isolated following the purification steps described in [5]. Elemental analysis revealed the presence of two additional oxygen atoms in the molecule. The adduct reacts—on a thin-layer chromatographic plate—with *N,N,N',N'*-tetramethyl-*p*-phenylenediamine, giving a blue coloration indicative of formation of a hydroperoxide. On subsequent treatment with a saturated aqueous solution of Na_2SO_3 the hydroperoxy group is reduced to a hydroxy group. The cisoid-conjugated double bond system of 7-DHC is no longer present in the product, as indicated by the absence of a band at 270–280 nm in the UV spectrum. The adduct was ^{1}H-NMR spectroscopically identical with the product of the Fenton reaction of 7-DHC[5]. According to all the above data the adduct formed in the photoreaction has the structure **1**. The ^{13}C-NMR spectrum is also consistent with this proposed structure[7].



1

R = Ac, R' = C_8H_{17}

Photoactivated 7-DHC is thus indeed capable of alkylating nucleophiles such as 1-methylimidazole. *Black et al.*[13] found that 5α,6α-epoxycholesterol, a well-known carcinogen, is formed on UV irradiation of skin preparations. It appears plausible that irradiation of 7-DHC *in vivo* leads to similar metabolites, which can be effective as "ultimate carcinogens". Hence, the reaction described here can be considered as a model reaction for the initiation of light-induced cancer illnesses.

Unsymmetrical Transfer of Allyl Groups in the Reaction of $[(\eta^3\text{-}C_3H_5)_2M]$ (M = Pd, Ni) with Bis(diphenylphosphino)maleic Anhydride**

By *Dieter Fenske** and *Petra Stock*

Phosphino derivatives of maleic anhydride are able to form complexes with transition metals in which the metal has formally more than 18 valence electrons[1,3]. Compounds of this type have a tendency to undergo subse-

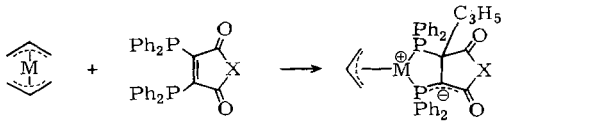
quent reactions[4–6]. We now report the reaction of the bis(η^3-allyl) complexes of Pd and Ni, **1** and **2**, respectively, with bis(diphenylphosphino)maleic anhydride and bis(diphenylphosphino)-*N*-methylmaleimide. **1** and **2** react with the maleic acid derivatives *via* transfer of a π bonded C_3H_5 group to afford the diamagnetic compounds **3** and **4**, respectively.



1, M = Pd X = O, NCH_3 **3**, M = Pd, X = O
2, M = Ni **4**, M = Ni, X = NCH_3

A short-lived intermediate free radical, which from the hyperfine structure and coupling constants must be a maleic acid derivative, can be detected in this reaction by ESR spectroscopy. An X-ray structure analysis of **3** (Fig. 1) indicates that Pd is bonded to two PPh_2 groups and to a C_3H_5 group in a *trihapto* fashion. Because of the allyl

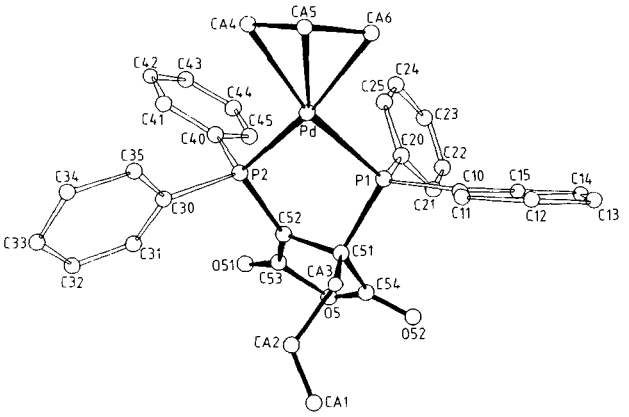


Fig. 1. Molecular structure of **3** in the crystal.

group on C51, the complex is chiral. Both electrons of the double bond in the free maleic acid derivative are formally localized on C52 in the complex; the charge of the carbanion thus formed is compensated by Pd^{1+}.

Spectroscopic data (^{31}P-NMR: $\delta = -19.2$ and -66.0; IR (KBr): ν(CO) = 1756 and 1705 cm^{-1}) and bond lengths, however, suggest delocalization of the lone pair of electrons into the neighboring CO and PPh_2 groups.

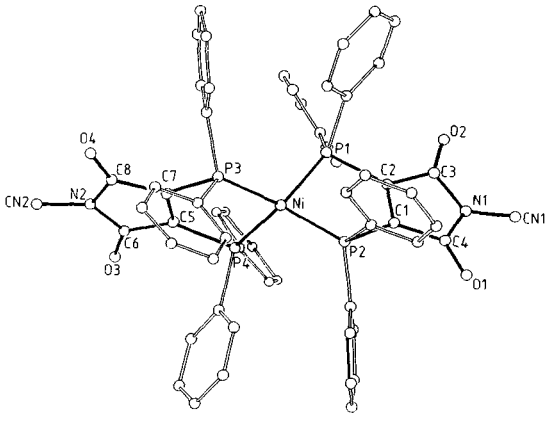

Fig. 2. Molecular structure of **5** in the crystal.

Reaction of $[(\eta^3\text{-}C_3H_5)_2Ni]$ with bis(diphenylphosphino)-*N*-methylmaleimide results, in addition to **4**, in formation of nickel complex **5**, in which both η^3-C_3H_5 groups are exchanged by bis(diphenylphosphino) ligands. An X-ray structure analysis of **5** (Fig. 2) indicates that the Ni is coordinated in a distorted tetrahedral manner by four PPh_2 groups.

Influence of Ring-Size of Cycloalkenes on the Activation Volume in the High-Pressure Copolymerization of Maleic Anhydride

By *Gérard Jenner**, *Mohamed Kellou*, and *Mihalis Papadopoulos*

Recently we reported on the high pressure kinetics of the free radical copolymerization of maleic anhydride with mono- and polysubstituted alkenes[3] in order to quantify the variations of activation volume $\Delta V^{\neq}$ with increasing steric demands of substituents (alkyl or aryl) located at the reaction center of the alkene. We introduced a new parameter, the *steric activation volume* $\Delta V_\sigma^{\neq}$, which was shown to be related to the mode and the degree of substitution, and hence may be used to predict steric effects in reaction series.

Cycloalkenes may be regarded as simple internal alkenes, since both polar and resonance factors can be considered as constant and their relative reactivities are governed mainly by steric factors. Previously, we observed that in the high-pressure copolymerization of maleic anhydride and cyclohexene, the resulting $\Delta V^{\neq}$ is more negative than expected[4]. We were therefore prompted to investigate more closely the possible $\Delta V^{\neq}$-variations with the ring size of the cycloalkene.

Table 1. Activation volumes $\Delta V^{\neq}$, steric activation volumes $\Delta V_\sigma^{\neq}$, and strain activation volumes $\Delta V_\tau^{\neq}$ for the copolymerization of maleic anhydride with cycloalkenes, as well as strain energies (SE) of the cycloalkenes.

Cycloalkene [a]	$-\Delta V^{\neq}$ [b] [cm^3/mol]	$-\Delta V_\sigma^{\neq}$ [c] [cm^3/mol]	$-\Delta V_\tau^{\neq}$ [d] [cm^3/mol]	SE [kcal/mol]
cyclopentene	30	3.7	12.3	6.9
cyclohexene	23	5.4	3.6	2.6
norbornene	28	7.5	6.5	23.6
cis-cyclooctene	32	7.4	10.6	8.8

[a] No reproducible results could be obtained in the corresponding reaction with cycloheptene. The rate of the copolymerisation with *cis*-cyclodecene is too low to be measured accurately. [b] Precision is estimated to 1–2 cm^3/mol, depending on the monomer pair. [c] Calculated. [d] Estimated.

[*] Dr. G. Jenner, Dr. M. Kellou, Dr. M. Papadopoulos
Laboratoire de Chimie Organique Appliquée (ERA CNRS 826),
Ecole Nationale Supérieure de Chimie
1, rue Blaise Pascal, F-67008 Strasbourg (France)

Table 1 shows that the activation volume ($\Delta V^{\neq}$) is not constant, although the copolymerization mechanism is the same in each case[3,4]. This change may be the result of two main factors controlling the reactivity of cycloalkenes: the strain energy of the alkene and steric hindrance due to the ring skeleton.

The activation volume ($\Delta V^{\neq}$) can be formulated as a sum[3], in the presence case as

$$\Delta V^{\neq} = \Delta V_0^{\neq} + \Delta V_\sigma^{\neq} + \Delta V_\tau^{\neq}$$

$\Delta V_0^{\neq}$ is the activation volume of the standard reaction (maleic anhydride + ethylene: -14 cm^3/mol), $\Delta V_\sigma^{\neq}$ is the steric activation volume[3], and the third term $\Delta V_\tau^{\neq}$ is the *strain activation volume* corresponding to strain associated with the ring. $\Delta V_\tau^{\neq}$ is related to a "tighter" transition state resulting from the steric interaction between monomer substituents and the propagating polymer end. $\Delta V_\tau^{\neq}$ may be roughly approximated by considering a cycloalkene as an α,β-disubstituted alkene[7] and calculating $\Delta V_\sigma^{\neq}$ from the following relationship[3]:

$$\Delta V_\sigma^{\neq} = -\omega \Psi_\sigma; \quad \Psi_\sigma = \sum_{i=1}^{n} Z_i$$

where ω is a substitution parameter, Ψ_σ a steric parameter, and Z_i is the steric value for substituent i[3].

The apparently anomalous pressure effect of $\Delta V^{\neq}$ on these copolymerizations[4] is very probably the result of ring strain. However a correlation between $\Delta V^{\neq}$ and strain energy is hard to assess (see Table 1).

Steric effects are large when adjacent parts of molecules are forced into close neighborhood by rigid groups and the possibilities of evasion are reduced to a minimum; this has an effect on the activation volume. The steric demands of substituents and/or enhanced strain energy should thus be measurable (at least for the reactions described here) as activation volume components of $\Delta V^{\neq}$. $\Delta V_\tau^{\neq}$ can be regarded as an additional volume term which gives information on the position of the transition state; steric congestion produces "late" transition states (Hammond's postulate[10]).

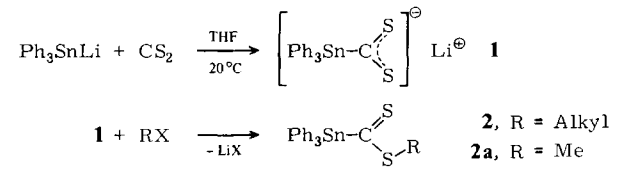
Triphenylstannanedithiocarboxylate, a Novel Chelate Ligand**

By *Thomas Hättich* and *Udo Kunze**

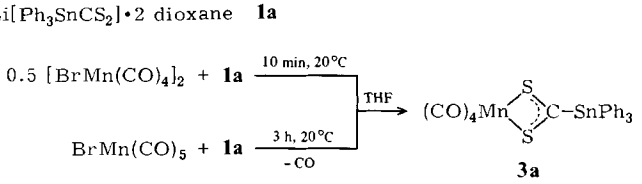
We were recently able to detect the nucleophilic addition of triphenylstannyllithium to carbon disulfide and trap the initially formed lithium salt **1** by reaction with alkyl halides[1].



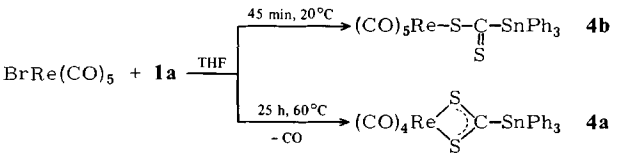
Following purification by chromatography, the alkyl stannanedithiocarboxylates **2** can be isolated as air-stable, red-violet crystals. The tin-carbon bond was verified by X-ray structure analysis.

Previously it was not possible, however, to prepare tin-functionalized dithiocarboxylato complexes from **1** and metal halides. We therefore attempted to stabilize the lithium salt **1** as a solvent adduct[2]. When the addition of CS_2 is performed in presence of dioxane, the bis(dioxane) adduct **1a** (Table 1) is obtained following removal of tetrahydrofuran (THF)[3]. **1a** crystallizes to form air- and moisture-sensitive, golden-yellow prisms (m.p. = 81–85 °C (decomp.)), which can be stored under protective gas for a few days. Using the same method we were also able to prepare the sodium **1b** and potassium salts **1c**, which are thermally more stable.

Reaction of a solution of **1a** in THF at room temperature with $[BrMn(CO)_4]_2$ or $BrMn(CO)_5$ affords, after purification by column chromatography, the stannanedithiocarboxylato(*S,S'*)-tetracarbonylmanganese complex **3a**[3] as yellow air-stable crystals (decomp. > 119 °C, m.p. = 129–131 °C).



At room temperature the pentacarbonyl complex **4b**[3] with monodentate ligand, which can be isolated as a light-pink solid (m.p. = 100 °C (decomp.)), is initially formed from $BrRe(CO)_5$. At 60 °C the analog of **3a**, the yellow chelate complex **4a**[3] (decomp. > 141 °C, m.p. = 152 °C) is obtained.



To the best of our knowledge, **3a** and **4a**, **b** are the first main-group metal substituted dithiocarboxylato complexes and are to be viewed as bonding isomers of the unstable metalodithiocarboxylates, *e.g.* $(CO)_5ReCS_2SnPh_3$, described by *Ellis et al.*[5].

The IR spectra of **3a** and **4a** (Table 1) display the four absorptions expected for a *cis*-$(CO)_4$ arrangement (C_{2v} symmetry); the antisymmetric CS stretching vibration is displaced to longer wavelengths than that of the alkyl esters **2** in consequence of the four-ring bonding scheme. Similarly, the signal of CS_2 in the ^{13}C-NMR spectrum is shifted to high field. In the mass spectrum the complete fragmentation series is observed. The IR spectrum of **4b** in CCl_4 exhibits three CO absorptions (2134 w, 2035 vs, 1999 m cm^{-1}; C_{4v}: $2A_1 + [B_1] + E$).

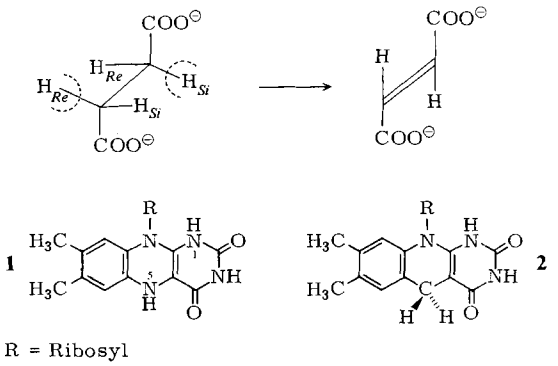
Specific Transfer of the H_{Si}-Atom of Succinate to the 5-Deazaflavin Analogue of Succinate Dehydrogenase**

By *Hans-Joachim Strobel* and *János Rétey**

Succinate dehydrogenase from porcine heart mitochondria catalyzes the abstraction of an H_{Re} *and an* H_{Si}-atom of succinate[1]. Assuming an antiperiplanar conformation, this corresponds to an *anti*-elimination.

The prosthetic groups of the enzyme are covalently bound flavin and iron-sulfur clusters which transfer the electrons to ubiquinone and cytochromes. The fate of the protons abstracted is less certain. They exhibit different intramolecular kinetic isotope effects[2a], but are both washed out into the solvent. This can be explained by the fact that in the reduced form **1** of riboflavin the incoming H-atoms are bound to N-5 and N-1 and can therefore be exchanged. In 5-deazariboflavin (see **2**) an exchange of this type can be avoided[3a]. Flavin cannot be removed from succinate



dehydrogenase without denaturing the enzyme. 5-Deazaflavin was thus incorporated *via* a biosynthetic route using the flavin auxotrophic yeast mutant (HK 857b[4]). This does not grow on 5-deazariboflavin, but incorporates it into the mitochondria during aerobic incubation. Following the method of *Singer et al.*[3b], we allowed the yeast mutant to grow in the presence of riboflavin under strict anaerobic conditions. After thoroughly removing the nutrient medium, the aerobic incubation was performed in the presence of 5-deazariboflavin, whereby the yeast mitochondria were fully developed. The subsequently isolated mitochondria contained only 5-deazaflavin, manifested by their fluorescence emission spectrum and by the fact that they did not catalyze the oxidation of succinate with oxygen and artificial electron acceptors (*N*-methylphenazinium sulfate, $K_3Fe(CN)_6$).

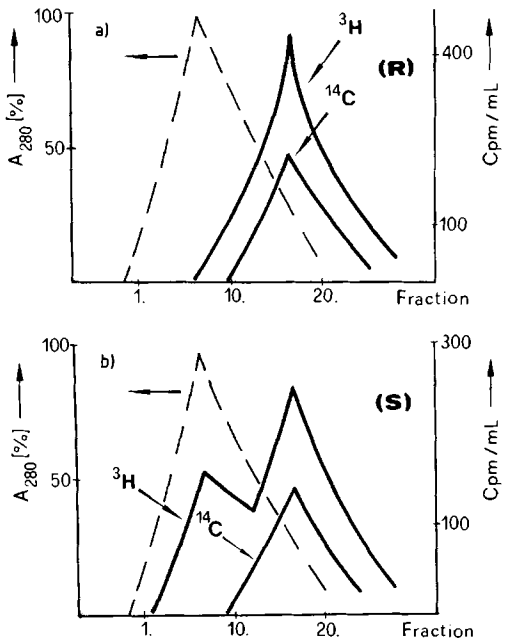


Fig. 1. Radiochromatography (—) of the 5-deazaflavin analogue of succinate dehydrogenase on Bio-Gel P-2 after incubation a) with (*R*)-[2-^{3}H, U-^{14}C] succinate and b) with (*S*)-[2-^{3}H, U-^{14}C] succinate.—The protein content was determined by absorption spectrometry (- - -).

The 5-deazaflavin-containing succinate dehydrogenase was isolated from the mitochondria by the same procedure[5] used for the natural enzyme. Natural and modified dehydrogenases from yeast exhibited similar migration rates in disc electrophoresis but different fluorescence emission spectra (λ_{max} = 520 nm and 480 nm, respectively).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. *I. D. Spenser* for helpful discussions and Prof. *F. Lingens* for the yeast mutants.

The enzyme analogue was catalytically inactive with artificial electron acceptors.

Investigation of the stereospecificity of natural succinate dehydrogenase from yeast mitochondria indicated considerable agreement with that of the enzyme from porcine heart mitochondria. Hence, the same initial ratio (2 : 1)[2a] of mono- and dideuterated succinate was found upon anaerobic incubation in D_2O. Partial oxidation of (*R*)-, (*RS*)-, and (*S*)-[2-^{3}H]succinate led to similar tritium enrichments in the unreacted substrates[2b], corresponding to a large isotope effect ($k(H_{Re})/k(T) \approx 10$) for the abstraction of H_{Re}, and to a smaller effect ($k(H_{Si})/k(T) \approx 1.5$) for the abstraction of H_{Si}.

After these preliminaries, 5-deazaflavin-containing succinate dehydrogenase was incubated with (*R*)- and with (*S*)-[2-^{3}H, U-^{14}C]-succinate. Subsequently, the main portion of the excess radioactive substrate and the stoichiometrically formed product were removed by dialysis. The residual low-molecular weight material was separated by gel chromatography of the radioactive protein on Bio-Gel P-2.

From the radioactivity (^{3}H and ^{14}C) and the protein content of the individual fractions (Fig. 1) it could be deduced that tritium was only transferred from (*S*)-[2-^{3}H]succinate to the protein. The ^{3}H/^{14}C ratio of the later fractions corresponds to that of the substrate.

The main portion of the radioactive acids was then isolated from the dialysis water using anion exchanger. Following chromatographic separation the radioactivity of the samples of succinic and malic acids (the initially formed fumaric acid was largely converted by the contaminating fumarase into L-malic acid, which, however, should not alter the radioactivity, in particular the ^{3}H/^{14}C ratio) was measured. As expected[2b], the ^{3}H/^{14}C ratio following dehydrogenation with succinate dehydrogenase decreased to approximately half the original value irrespective of the sense of chirality of the [^{3}H]succinic acid used.

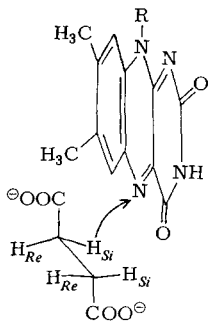

Fig. 2. Relative position of substrate and coenzyme in the active center of succinate dehydrogenase.

The steric behavior at the active center can therefore be represented as shown in Fig. 2.

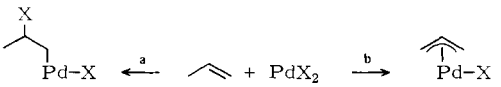
Oxidation with Palladium Salts: Stereo- and Regiospecific Acetoxylation of 4-Vinylcyclohexene Derivatives**

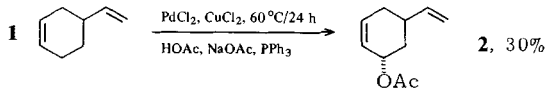
By *Andreas Heumann, Marius Reglier,* and *Bernard Waegell**

The Pd-catalyzed reaction of alkenes can proceed *via* direct addition of PdX_2 to the double bond (route a) or by abstraction of an H-atom α to the double bond (route b)[1]. It has so far remained unclear which factors determine the reaction path[2].



In the case of the catalytic oxidation of non-conjugated mono- and bicyclic alkadienes, exclusively route a has been reported[3]. We now report on the oxidation of related alkadienes such as **1** and **8**, which under similar conditions ($PdCl_2$ as catalyst in buffered glacial acetic acid, varying amounts of $CuCl_2$ or $CuCl_2$-LiCl-O_2) react—regioselectively and, in part, stereoselectively—according to route b.

Reaction of 4-vinylcyclohexene **1** under these conditions in the presence of excess triphenylphosphane (or "diphos") leads to formation of the allylic acetate **2**, whose structure is confirmed by ^{1}H- and ^{13}C-NMR spectroscopy, and by conversion into the unsaturated and the saturated alcohols [**2**, ^{1}H-NMR: $\delta = 1.4$—2.6 (m, 5H), 2.05 (s, 3H, OAc), 4.95, 5.04, 5.12 (m, m, m, 2H), 5.25 (m, 1H, C*H*OAc), 5.6—6.1 (m, 3H)].



The formation of the *trans*-isomer **2** and the high regioselectivity can be explained in terms of a homogeneous catalytic mechanism. The palladium(0) formed in the reaction is reoxidized by $CuCl_2$.

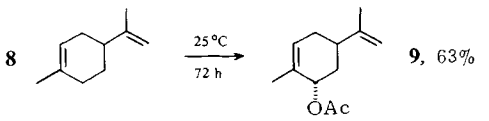
[**] We thank Hüls (Marl) for a supply of 4-vinylcyclohexene, and Shell-Chimie (Fos) for 1,4-dimethyl-4-vinylcyclohexene.

The question as to why the oxidation of **1** leads to allylic end products (route b) is difficult to answer. According to models it would seem that the course of reaction is determined not only by steric effects (proximity of the abstracted H-atom to the metal in the intermediary $PdCl_2$-**1** complex) but also by stereoelectronic effects. That the *trans*-isomer **2** is formed is understandable: The better ligand triphenylphosphane, present in excess, blocks the metal center in **7**, so that the poorer acetate-ligand can attack only from "outside"[6].

As can be seen from the mechanistic scheme, the vinyl group in **1** is decisive for the steric course of the reaction, though additional phosphane ligands appear to be necessary for the stabilization of the intermediates **6** or **7**. On increasing the nucleophilicity of the vinyl group, for example by introduction of a methyl group, the catalytic acetoxylation should take place, even in the absence of phosphanes. Indeed, reaction of limonene **8** without additional phosphane ligands (25 °C, 72 h) leads stereospecifically to α-carvyl acetate **9** (63% yield).



After modification of the limonene structure, as in 1,4-dimethyl-4-vinylcyclohexene, the acetoxylation is less selective: both isomeric acetates are formed in about equal amounts.

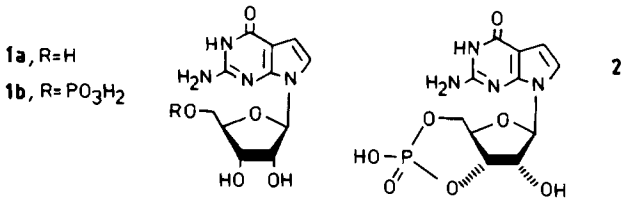
7-Deazaguanosine-3′,5′-phosphate—An Isosteric cGMP Analogue with High Affinity for Cyclonucleotide Phosphodiesterase**

By *Quynh-Hoa Tran-Thi, Doris Franzen*, and *Frank Seela**

Guanosine-3′,5′-phosphate (cGMP), like adenosine-3′,5′-phosphate (cAMP), occupies a key position in the regulation of hormone activity, but exhibits partial antagonistic functions; furthermore it activates a series of enzymes, *e.g.* protein kinases. This provided entry to the synthesis of a series of cyclonucleotide analogues[2]. Recently it has been established that cGMP is also of great importance in vision: photoactivation of one rhodopsin molecule leads to enzymic hydrolysis of 10^5 cGMP molecules[3]. Incubation of intact cells with cyclonucleotides produced no or only slight activity; because of their negative charge they can only penetrate the cell membrane with difficulty. In consequence, cyclonucleotides with lipophilic groups, *e.g.* butyryl residues, were synthesized. We report here the synthesis and properties of the first 7-deaza-cGMP analogue.

Pyrrolo[2,3-*d*]pyrimidine nucleosides are more lipophilic than the corresponding purine compounds, since they do not contain an N atom in the 7-position. Furthermore, the 7-deaza derivative of guanosine is the only ring-modified guanosine analogue of which naturally occurring derivatives have been found. We recently synthesized 7-deazaguanosine **1a** by phase transfer catalysis[6]. In contrast to guanosine, the more lipophilic compound **1a** shows no tendency to aggregate, thus increasing its availability in aqueous solution.



Phosphorylation of **1a** with PCl_3O in trimethyl phosphate leads regioselectively to the 5′-monophosphate **1b** [^{31}P-NMR (D_2O): $\delta = 3.17$], which can be cyclized with *N,N*-dicyclohexylcarbodiimide in pyridine yielding the cyclophosphate **2**. Subsequent anion-exchange chromatography and lyophilization produces pure **2** [^{31}P-NMR (D_2O): $\delta = 9.40$] as the amorphous triethylammonium salt. The structure of **2** is confirmed by its ^{1}H-NMR spectrum. The fused cyclophosphate ring results in angular distorsion of the β-D-ribofuranosyl residue and hence the 1′-proton does not participate in vicinal coupling, a result which is also found with cGMP.

Cyclophosphate-specific phosphodiesterase cleaves the cyclonucleotide **2** to afford the 5′-monophosphate **1b**. Table 1 shows that **2** is hydrolyzed more rapidly than cGMP. The 7-purine nitrogen is thus not a requirement for the binding of cGMP[8] and its analogues to the phosphodiesterase and their hydrolysis by this enzyme, a phenomenon which is also found with tubercidin-3′,5′-phosphate[10a].

Table 1. Relative initial rates of the enzymic hydrolysis of purine and 7-deazapurine nucleoside-3,5′-phosphates with cyclonucleotide phosphodiesterase from bovine heart.

Compound	Relative initial rates of hydrolysis
7-deazaguanosine-3′,5′-phosphate **2**	3.2
cGMP	1.9
tubercidin-3′,5′-phosphate	1.4
cAMP	1.0

In contrast to cGMP, **2** does not aggregate in aqueous solution; we presume that this is due to the absence of the 7-purine nitrogen, avoiding Hoogsteen base-pairing, which causes the aggregation in guanidine nucleotides.

The higher rate of hydrolysis of **2**, which is not achieved by other cGMP derivatives, may be due to the following: 1) increased availability of **2** due to diminished aggregation, 2) increased affinity of the more hydrophobic substrate to the active center of the phosphodiesterase, and 3) increased ring strain in the cyclophosphate residue in-

Sterically Crowded Ethanes and Ethenes from Tri-*tert*-butylsilylmethyl Carbenoids**

By *Manfred Weidenbruch** and *Hermann Flott*

Ethanes[1] and ethenes[2] with bulky substituents are suitable as models for the investigation of unusual bonding situations, which manifest themselves for example, in large atomic distances, widened bond angles, unexpected conformations, and twisting of the CC double bond. We have found a facile entry to 1,2-disilyl derivatives of this class of compounds *via* reaction of methyllithium with tri-*tert*-butyl(dihalomethyl)silanes.

Thus, reaction of tri-*tert*-butyl(dibromomethyl)silane **1**[3] with methyllithium leads, *via* the carbenoid **2** to (*E*)-bis(tri-*tert*-butylsilyl)ethene **3** together with 1,2-dibromo-1,2-bis(tri-*tert*-butylsilyl)ethane **4** and (bromomethyl)tri-*tert*-butylsilane **5**[4].

$$(t\text{-}C_4H_9)_3SiCHBr_2 + LiCH_3 \longrightarrow \underset{\mathbf{2}}{\{(t\text{-}C_4H_9)_3SiCHBrLi\}} + CH_3Br$$
1

$$\xrightarrow[-2\ LiBr]{\times 2} (t\text{-}C_4H_9)_3SiCH{=}CHSi(t\text{-}C_4H_9)_3 \quad \mathbf{3}$$

$$\mathbf{2} \xrightarrow[-LiBr]{+\mathbf{1}} (t\text{-}C_4H_9)_3SiCHBrCHBrSi(t\text{-}C_4H_9)_3 \quad \mathbf{4}$$

$$\longrightarrow (t\text{-}C_4H_9)_3SiCH_2Br \quad \mathbf{5}$$

A further route to **3** is the partial lithiation of **4** with intramolecular elimination of LiBr. Repeated reaction of methyllithium with **5** yields 1,2-bis(tri-*tert*-butylsilyl)ethane.

Unlike **1**, which exclusively exchanges Br for Li, its dichloro analog[3] reacts with methyllithium preferably with H/Li exchange *via* the carbenoid **8** to give (*E*)-1,2-bis(tri-*tert*-butylsilyl)-1,2-dichloroethene **9**.

$$(t\text{-}C_4H_9)_3SiCHCl_2 + LiCH_3 \rightarrow \underset{\mathbf{8}}{\{(t\text{-}C_4H_9)_3SiCCl_2Li\}} + CH_4$$

$$2\ \mathbf{8} \rightarrow \underset{\mathbf{9}}{(t\text{-}C_4H_9)_3SiCCl{=}CClSi(t\text{-}C_4H_9)_3}$$

[**] Silicon Compounds with Strong Intramolecular Steric Interactions, Part 12. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 11: M. Weidenbruch, R. Rankers, *J. Organomet. Chem. 198* (1980) 29.

The X-ray structure analysis (Fig. 1) of **4** illustrates quite nicely the unusual bonding features in the sterically congested ethanes and ethenes prepared so far.

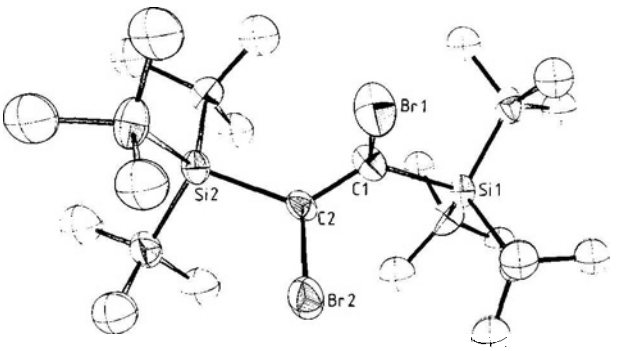

Fig. 1. Structure of **4** in the crystal.

As in other highly-branched C_t—C_t hydrocarbons[1] the molecule **4** exists in the D,L-*gauche* form. Consistent with empirical force field calculations[7] the tri-*tert*-butylsilyl groups have C_3 local symmetry. The C1—Si1 and C2—Si2 bonds of 196 and 200 pm, respectively, are markedly longer than the normal value (187 pm), whereas the central C1—C2 bond is only *ca.* 150 pm in length. The bond angles Si1C1C2 and Si2C2C1 of 128.6 and 126.9°, respectively, are much greater than those found in all previously known highly-branched hydrocarbons.

Black Lipid Membranes from Polymerizable Lipids**

By *Roland Benz, Werner Prass,* and *Helmut Ringsdorf**

The stabilization of model membranes *via* polymerization of lipid molecules has been investigated up to now in monolayers and liposomes[6]. Polymerizations in planar bimolecular black lipid membranes (BLMs), another model system for membranes, have not yet been described. The great disadvantage of BLMs as model membranes is their lack of long-term stability: depending on the lipid and the

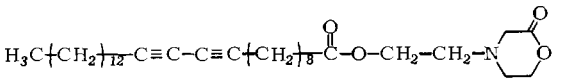
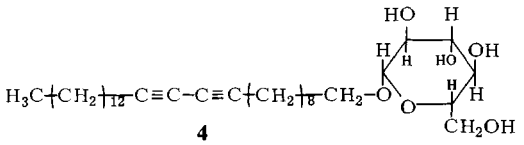
[**] Polyreactions in Oriented Systems, Part 25.—Part 24: H. Ringsdorf, H Schupp, *J. Macromol. Sci. Chem. A 15* (1981) 1015

conditions used for their preparation, they are stable only for minutes or hours. We report here efforts to stabilize BLMs by polymerization of lipid molecules in planar bilayer membranes.

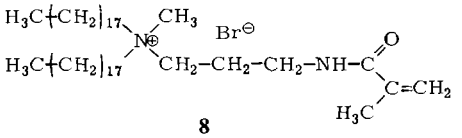
In a preliminary study, several synthetic lipids and lysolipids containing polymerizable acrylic, butadiene, or diacetylenic units either in the hydrophobic part or in the hydrophilic part of the molecule were observed to form BLMs. The membrane resistance and capacitance of the BLMs formed from **3**, **4**, and **8**, which are stable for more than 5 min, are shown in Table 2. The measured values are compared with values obtained for BLMs from purified egg lecithin[13].



3



4



8

Table 2. Lifetime, electrical resistance, and capacitance of black lipid membranes from polymerizable lipids **3**, **4**, and **8**.

Compound	T [°C]	Lifetime	Resistance [Ω cm²]	Capacitance [μF/cm²]
Egg Lecithin	20	2—3 h	10^7-10^8	0.33 ± 0.02
3	25	1—3 h	10^7-10^8	0.31 ± 0.02
4	40	1—2 h	10^7	—
8	21	5—10 min	10^6	0.38 ± 0.04

Attempts to achieve UV-sensitized polymerization of BLMs from the two diacetylenic compounds **3** and **4** were unsuccessful. This can be explained by the fact that the formation of stable black lipid membranes is possible only in the liquid-analogous state. On the other hand, polymerization of diacetylene-containing lipids is topochemically controlled, and thus takes place only in the solid-analogous state[16]. Furthermore, methacrylamide derivatives do not only polymerize in the solid-analogous state[6]. The free-radical polymerization of **8** was initiated by UV irradiation of methyl azoisobutyrate dissolved in the membrane.

The progress of the reaction can be followed by measuring the change in the charging current (capacitance). This is shown schematically in Figure 3.

During UV irradiation, optical changes were not observed in the membranes: nevertheless, their capacitance rose from 0.38 μF/cm² to the very high value of 2 μF/cm². This was observed on the oscilloscope trace as a slower current-decrease, corresponding to a higher capacitance (see Fig. 3b). The current did not return to zero after 0.5—2 min, and the plateau value increased slowly over *ca.* 20 min (see Fig. 3c). The resistance of the membrane, which had still not undergone an optical change, therefore, decreased markedly. In the final stage of the polymerization—after *ca.* 20 min—the measured resistance was only *ca.* 20% more than that of the electrolyte solution itself. These results can be explained by changes in the structure

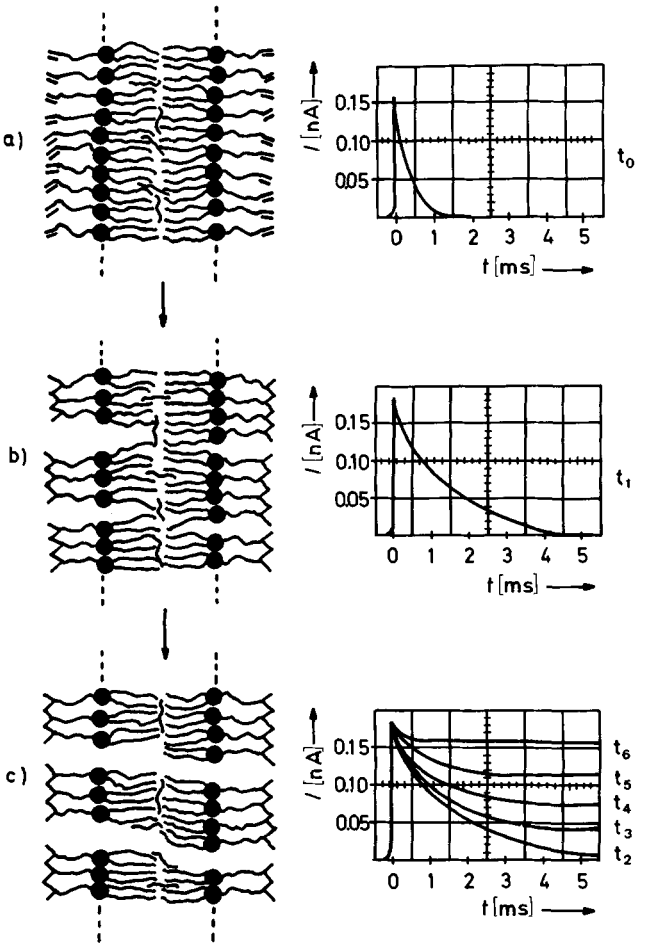


Fig. 3. Schematic representation of the structural changes in the membrane and course of charging currents (measurement of capicitance) during polymerization: a) monomeric membrane before UV irradiation ($t = t_0$); b) membrane at the beginning of the polymerization ($t = t_1 = 0$ min); c) polymeric membrane and change in current across the membrane with time ($t_2 = 1$ min, $t_6 = 20$ min).

of the polymeric black lipid membrane (shown schematically in Fig. 3). Because the polymerization occurs at the surface of the bilayer, the lipid head-groups are drawn together. Thus, the membrane becomes "thinner" at some points and water can enter the hydrophobic part of the bilayer. This causes an increase in the dielectric constant (ε_M) of the membrane, leading to a higher capacitance.

The strain on the membrane surface during polymerization finally leads to formation of holes in the polymer membrane (see Fig. 3c) and hence to the low electrical resistance of the polymerized bilayer. The product of the reaction is a bilayer net, which still has remarkable mechanical stability and has a lifetime of up to 50 min after the polymerization. In contrast to this slow membrane collapse, the rupture of a typical monomeric BLM after its induction is complete within a fraction of a second.

Regioselective Acylamination by Hetero-Cope Rearrangement**

By *Richard Höfelmeier* and *Siegfried Blechert**

The direct amination of substituted arenes can be accomplished in some cases with electrophilic aminating reagents or by rearrangement reactions, but often presents problems as a result of unsatisfactory regioselectivity or poor yields[4]. We therefore searched for a generally applicable method void of these disadvantages. Numerous [3,3]-sigmatropic rearrangements have proven useful for *o*-alkylation; however, corresponding hetero-Cope rearrangements for *o*-amination have, to our knowledge, previously never been investigated. From the results of *Sheradsky et al.*[8] and also of *Coates et al.*[9] it can be concluded that *N*-aryl-*O*-vinylhydroxylamines are suitable for [3,3]-sigmatropic rearrangements.

We found that the hydroxamic acids **1**, readily obtainable from *N*-phenylhydroxylamines[11], are good educts for regioselective acylaminations: Reaction of the sodium salts **2** with imidoyl chlorides **3** directly affords the *o*-phenylenediamine derivatives **6** (**1**→**2**: suspension of NaH in tetrahydrofuran; **2**→**6**: after addition of **3**, 2–6 hours stirring at room temperature).

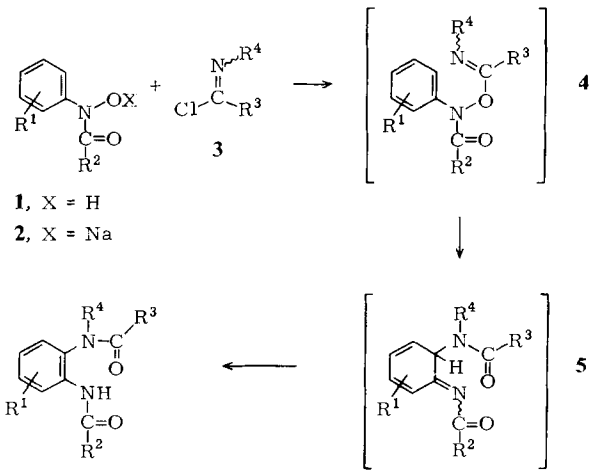

Table 1. Synthesized *o*-phenylenediamine derivatives **6**. $R^3 = p\text{-}O_2NC_6H_4$ (in the case of **6c**: C_6H_5).

	R^1	R^2	R^4	Yield [%]
6a	H	$OCH_2C_6H_5$	CH_3	75
6b	H	$OCH_2C_6H_5$	C_2H_5	80
6c	4-CH_3	CH_3	CH_3	65
6d	4-CH_3	CH_3	C_2H_5	60
6e	4-CH_3	CH_3	C_6H_5	15
6f	4-OCH_3	CH_3	CH_3	65
6g	4-Cl	CH_3	CH_3	80

In no case were the plausible intermediates **4** isolable. However, in HPLC studies of the reaction we were able to observe the formation of an apolar product, also unstable at −25 °C, which is rapidly converted into **6**. Our findings so far point to a [3,3]-sigmatropic rearrangement, which, however, differs somewhat from the rearrangement of the "heteroanalogous" **4**, =O instead of $=NR^4$, and **4**, $-SO_2R^3$ instead of $-C(NR^4)R^3$[12].

[**] This work was supported by the Forschungsmitteln des Landes Niedersachsen.

The method described here thus enables an arene to be regioselectively substituted under mild conditions with acylamino groups. But the method is unsuitable for the incorporation of an acylamino group (see **6e**).

λ^3-Phosphorins by [4+2]-Cycloaddition of α-Pyrones and Cyclopentadienones with $H_5C_6—C{\equiv}P$

By *Gottfried Märkl**, *Gui Yu Jin*, and *Ernst Silbereisen*

Until now only a few or no [2+2]- or [2+4]-cycloaddition reactions, respectively, involving the participation of the —P=C-group have been described for λ^3-phosphaalkenes and aromatic λ^3-phosphorus heterocycles. To the best of our knowledge the first cycloaddition of an open-chain phosphaalkene was achieved by *Bickelhaupt et al.* in the reaction of *P*-mesityl(diphenylmethylene)phosphane with mesityl nitrile oxide as 1,3-dipole[8,9].

We now report for the first time the [2+4]cycloadditions of *P*-chloro(α-trimethylsilylbenzylidene)phosphane **1**[13] or of the benzylidynephosphane (2-phenylphosphaethyne) **5** to α-pyrones **2** and cyclopentadienones **8**.

α-Pyrones react with **1** in the presence of KF/[18]crown-6 at 220 °C in a bomb tube (undiluted or in *o*-dichlorobenzene) to afford the λ^3-phosphorins **3**.

The reaction conditions allow us to presume that the Diels-Alder adduct **4** is not formed, but rather that **1** is firstly converted into **5**, which was recently synthesized by *Appel et al.*[14] by thermolysis of **1** at 800 °C, and is stable up to −50 °C. **5** and **2** react *via* the cycloadduct **6** to yield

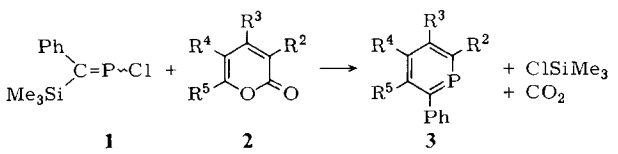

Table 1. λ^3-Phosphorins **3** from methylenephosphanes **1** (*via* **5**) and α-pyrones **2** (molar ratio 1 : 1) [22] (selection).

Comp.	R^2	R^3	R^4	R^5	M.p. [°C]	Yield [%] [a]

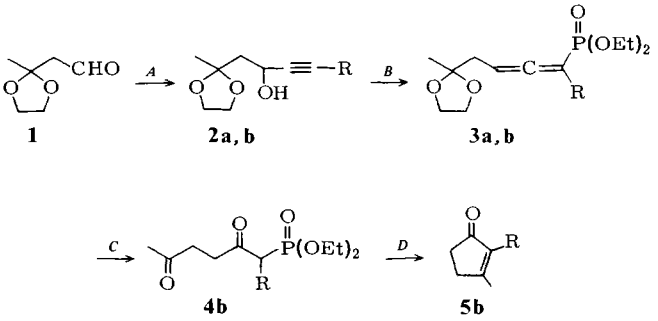
β,ε-Dioxophosphonates by Reductive Nucleophilic Acylation of 1,3-Dioxo Compounds: Facile Synthesis of Jasmones**

By *Hans-Josef Altenbach** and *Rainer Korff*

The cyclization of 1,4-diketones is still the widest applicable method for the synthesis of cyclopentenones; in place of the classical aldol condensation, Wittig- and Wittig-Horner-reactions have also found application for the ring closure. A method developed by us to provide easy excess to β-oxophosphonates by reductive nucleophilic acylation of ketones or aldehydes[4] stimulated attempts to prepare the β,ε-dioxophosphonates (type **4**), suitable as educts for such cyclizing olefination reactions, from partially protected 1,3-dioxo compounds (type **1**). The method is outlined here, using the synthesis of dihydrojasmone **5b** and dehydrojasmone **5c** as examples.

The protected 3-oxobutanal **1**[6], easily accessible from ethyl acetoacetate, served as educt for **5b** and **5c**. For the synthesis of the dihydrojasmone **5b**, **1** is transformed into the alkynol **2b**, from which the α-pentyl-substituted allenephosphonate **3b** is formed *via* the phosphorous acid ester by propargyl rearrangement[7]. The addition product obtained from **3b** on reaction with sodium ethoxide is hydrolyzed with hydrochloric acid to the β,ε-dioxophosphonate **4b**, previously prepared *via* another route[3a]. The intramolecular olefination of **4b** to **5b** can be realized (yield 60%) with sodium hydride in tetrahydrofuran (THF), as already mentioned by *Heathcock et al.*[3a].

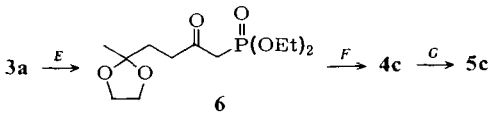


1 **2a, b** **3a, b** **4b** **5b**

a, R = H; **b**, R = *n*-C_5H_{11}; **c**, R = $CH_2C{\equiv}CC_2H_5$

A 1) LiC≡CR in THF, −78 °C, 2) NH_4Cl; *B* $ClP(OEt)_2$, Et_3N, CH_2Cl_2 (14 h, room temperature) [**3b**: short-path distillation 120 °C/0.1 torr, yield 88%]; *C* 1) 2 h reflux with NaOEt in EtOH, 2) 10% HCl (0.5 h, room temperature); *D* NaH in THF (12 h, room temperature).

In the synthesis of the dehydrojasmone **5c**, the unsaturated side chain was not incorporated during the alkynation step, but at a later stage. This is possible, since the allenephosphonate **3a** can by hydrated to the β-oxophosphonate **6** by reaction with diethylamine in ether followed by hydrolysis, without the ketal function being cleaved.



6

$R=CH_2C{\equiv}CC_2H_5$

E 1) $HNEt_2$ in Et_2O (12 h, room temperature), 2) 30% aqueous NH_4Cl solution, Et_2O (4 h, room temperature) [**6**: b.p. 134–136 °C/0.3 torr, yield 62%]; *F* 1) NaH or $KN(SiMe_3)_2$, 2) RBr, 3) 10% HCl, Et_2O (24 h, room temperature) [chromatography: silica gel/ethyl acetate; **4c**: short-path distillation 90–100 °C/0.4 torr, yield 48%]; *G* $NaN(SiMe_3)_2$ in THF (2 h, room temperature).

The anion of **6** is (partially) dialkylated by 1-bromo-2-pentyne. The desired compound **4c** can, however, be isolated by column chromatography after hydrolysis of the ketal function, and then cyclized with sodium bis(trimethylsilyl)amide to give **5c** (yield 62%).

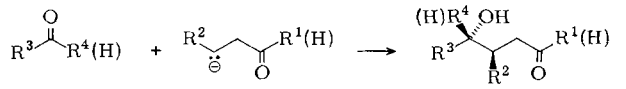
Diastereoselective Homoaldol Reaction with a (1-Oxycrotyl)aluminum Compound, a Homoenolate Equivalent of *n*-Butanal**

By *Dieter Hoppe** and *Florian Lichtenberg*

We recently reported[1] the first more general preparative solution to the transformation aldehyde- or ketone-homoenolate **2** + carbonyl compound **1** → homoaldol **3**.



1 **2** **3**

Stereocontrolled homoaldol reactions[4] have been successfully performed using the *E*-(1-carbamoyloxy)crotylaluminum derivative **8**[15]: **8**, obtained by transmetalation of the lithium compound **5a** with excess **7**, adds to aldehyde **1** at −78 °C to afford δ-hydroxyenol carbamates **9** and **10**. Of the four possible diastereomers, the homofacial[10b] (*threo*-configurated[10]) adducts *E*- and *Z*-**9** (rel. yields 83—97%) predominate; only 2—16% of the heterofacial[10b] (*erythro*)-diastereomers *E*-**10** are formed (cf. Table 1).

[**] Metalated Nitrogen Derivatives of Carbonic Acid in Organic Synthesis, Part 21. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 20: [1].

Enol esters **9** and **10** are stable to acid; esters **9** and methanol/methanesulfonic acid react under mercuric acetate catalysis (1 mol%) to form lactol ethers **19**. Thus, **19c** is formed in 79% yield from *E*-**9c** after 4 h at 25 °C. Analogously the acetates **17** deliver the dimethyl acetals **18**; *e.g.* *E*-**17c** affords **18c** in 86% yield after 12 h at 25 °C. **18** and **19** are easy to handle, protected derivatives of γ-hydroxyaldehydes **3**. Hence, **8** acts as a diastereoselectively-reacting synthetic equivalent for the unknown homoenolate of *n*-butanal **2** (R^1 = H, R^2 = CH_3).

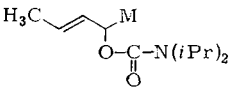
Highly Diastereo- and Regioselective Homoaldol Reactions with (1-Oxyallyl)titanium Derivatives**

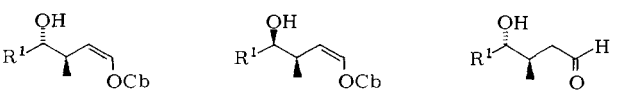
By *Rudolf Hanko* and *Dieter Hoppe**

We have reported the stereoselective addition of the crotylaluminum derivative **3** to aldehydes **6**[1], and now describe a particularly effective variant of the homofacial (*threo*-selective)[1] homoaldol reaction. Allowing the lithium compound **2**, obtained (as are in general homoenolate equivalents of this type) by deprotonation of the *E*-crotyl carbamate **1** with *n*-butyllithium (*n*-BuLi)[2], to react with chlorotris(diethylamino)titanium **5**[3] afforded the crotyltitanium derivative **4**[4]. At −78 °C **4** adds to aldehyde **6** to form almost exclusively the *Z*-configurated



$ClTi(NEt_2)_3$ **5** $R^1CH{=}O$ **6**

1, M = H, **2**, M = Li
3, M = Al(*i*Bu)$_2$ **4**, M = $Ti(NEt_2)_3$



Z-**7** *Z*-**8** **9**

Cb = $C(=O)N(iPr)_2$

(*threo*)-δ-hydroxyenol carbamate[5] *Z*-**7** (cf. Table 1), in addition to 0—3.0% of *Z*-**8** (*erythro*)[1] in the crude product; the fraction of the remaining regio- and stereoisomers is

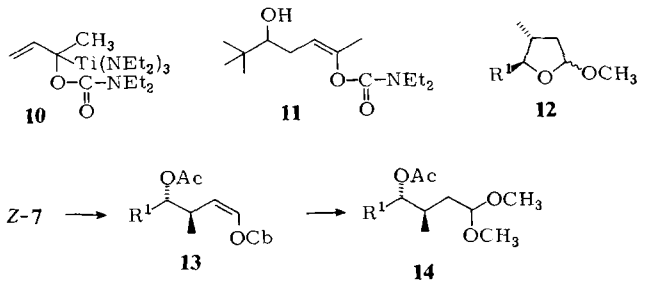
Table 1. Synthesis of esters *Z*-7 [a, b] by addition of the crotyltitanium compound **4** to aldehydes **6**.

	R¹	Yield [%] [c]	*Z*-7 : *Z*-8 [d, e]	^{1}H-NMR of *Z*-7 [f] H-4 [δ-values]	$J_{3,4}$ [Hz]
a	$(CH_3)_3C$	92	99.5 : <0.5	3.08	2.5
b	CH_3	92	97.6 : 2.4	3.58	6.0
c	$(CH_3)_2CH$	96	97.5 : 2.5	3.00	5.0
d	$(CH_3)_2C{=}CH$	96	97.0 : 3.0	4.10	5.5

[a] Satisfactory CH analyses obtained. [b] Racemic mixtures. [c] Crude product homogeneous according to ^{1}H-NMR and thin layer chromatography. [d] Determined by capillary gas chromatography [1]. [e] Poorest value from two or three experiments. When freshly prepared **5** was used, the fraction of *Z*-**8** decreased to approx. half these amounts. [f] In CCl_4.

less than 1% (detected by gas chromatography[1]). A high regioselectivity of the carbonyl addition is also observed with 1-alkylated derivatives; thus, **10** and 2,2-dimethylpropanal **6a** react to form the γ-adduct **11** free of isomers (yield 87%). Methanolysis of the enol ester *Z*-**7** (methanol, 1 equiv. methanesulfonic acid, 1 mol% Hg(II) acetate, 25 °C)[1] affords the lactol ether **12**. Dimethyl acetals **14** were obtained analogously *via* acetates **13**[1]. **12** and **14**



are versatile, useful derivatives of homoaldol **9**. Hence, a method is thus available for the homoaldol reaction (to our knowledge the only[1]) which is just as efficient as the best variants of the aldol reaction.

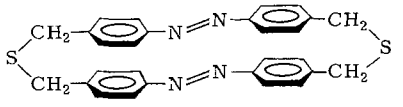
[5] *General procedure. Z*-7: 1.1 equiv. of **5** as a *ca.* 1 M solution in hexane is added to a *ca.* 0.3 M solution of **2** [2] in ether/hexane under N_2 at −78 °C, the mixture stirred for 1 h at −78 °C, and 1.0–1.1 equiv. of **6** then added. After 30 min at this temperature, the cold reaction mixture is poured into 10 mL (per mmol **2**) of 2 N hydrochloric acid/ether (1:1 v/v), the aqueous layer extracted with ether, the ether removed, and the combined extracts washed with $NaHCO_3$ and KCl solutions. After drying ($MgSO_4$) and removal of the solvent *in vacuo*, almost pure *Z*-**7** is obtained (Table 1).

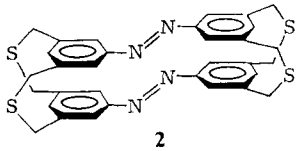
Azobenzene Phanes**

By *Dieter Gräf, Helmut Nitsch, Dieter Ufermann, Gisela Sawitzki, Helmut Patzelt,* and *Hermann Rau**

We have synthesized 2,19-dithia[3.3](4,4′)-*trans*-diphenyldiazeno(2)phane **1** and 2,19,36,39-tetrathia[3.3.3.3]-(3,3′,5,5′)-*trans*-diphenyldiazeno(4)phane **2**, the first azobenzene phanes, in order to study the interactions of the azobenzene electron systems and to investigate the *trans-cis* isomerization. **1** and **2** are potential precursors of molecules containing the tetraazacyclobutane moiety.



1



2

Cyclization of 4,4′-bis(bromomethyl)azobenzene with Na_2S (high dilution)[1] afforded **1** as a yellow powder in 40% yield (crude yield 80%)[2a]. Likewise[1], alkaline condensation of 3,3′,5,5′-tetrakis(mercaptomethyl)azobenzene with 3,3′,5,5′-tetrakis(bromomethyl)azobenzene under high dilution conditions furnished **2** (crude yield 60%)[2b]. X-ray structure analysis[3] indicated that **1** has point symmetry and parallel *trans*-azo groups; the benzene rings are inclined *ca.* 20° relative to one another. Bond-lengths and -angles are similar to those of azobenzene. The separation of the azo groups is 386 pm and that of the center of gravity of the benzene rings 357 pm (only slightly more than the "thickness" of the aromatic π-system[4]).

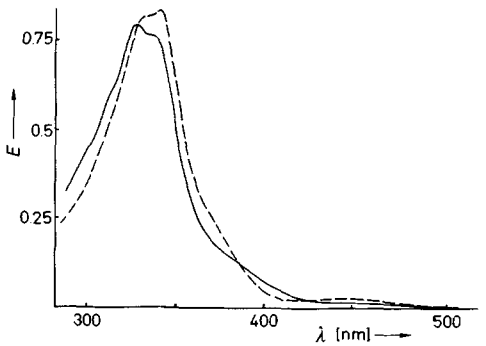


Fig. 1. Absorption spectrum of **1** (---), $c = 1.6 \times 10^{-5}$ mol/L in benzene and **2** (—), *c* not determined, in toluene.

In contrast to 4,4′-dimethylazobenzene **3**, the UV π→π* bands of **1** and **2** (Fig. 1) are split: increasing hypsochromic shift of the intense short wavelength component band (0—0 transition in **3**: 360 nm; **1**: 344 nm; **2**: 339 nm) and bathochromic shift of the typically weak phane band (**1**: *ca.* 380 nm; **2**: *ca.* 395 nm) are observed. The vibrational structure of the short wavelength component band is

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

characteristic of phanes (used as a criterion in the isolation procedure) and can be interpreted as arising from the increased rigidity of the molecular framework relative to that of simple azobenzenes. The long wavelength $n \rightarrow \pi^*$ bands at 450 nm become weaker with increasing planarity of the azobenzene units in the series **3**→**1**→**2**; interactions between the n orbital systems cannot be established with certainty.

1 and **2** isomerize under the action of light[5]. This is experimental proof that *trans-cis*-photoisomerization of azobenzenes can occur by inversion of the bond angle at nitrogen.

By means of kinetic analysis of irradiation experiments in highly dilute solutions we have obtained evidence for the possible formation of tetraazacyclobutane: Apart from the *trans-cis* isomerizations an additional reaction, which is not very important compared to the isomerizations, is observed that leads to a molecule forming the phanes quantitatively, unless $\lambda_{exc} < 320$ nm whereupon the azo groups are destroyed (azobenzene and bis-(*p*-benzeneazotolyl)sulfide are stable under these conditions). At present we are investigating the irradiation of powders (analysis by photoacoustic spectroscopy) and of crystals (X-ray structure analysis).

Synthesis of Macromolecular Isocyanides with General Solvent Compatibility—Novel Polymer Supports for Solid-Phase Syntheses**

By *Reza Arshady** and *Ivar Ugi*

Polymer-supported reagents and solid-phase techniques have assumed an important role in many areas of chemistry, *e.g.* in the synthesis of peptides and oligonucleotides, as well as in catalysis by enzymes and transition-metal compounds[6].

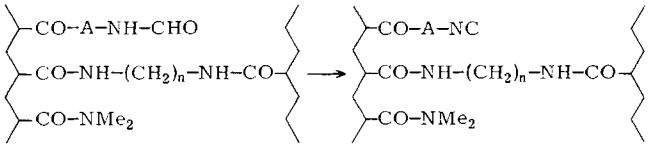
[+] Present address:
Department of Chemistry
Imperial College, London SW7 2AZ (England)

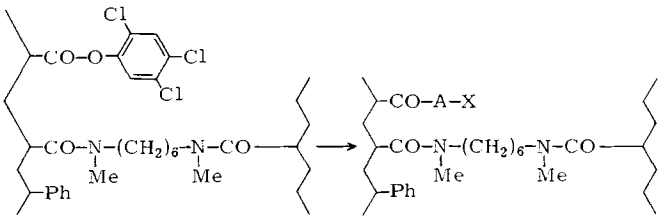
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We describe here several novel macromolecular isocyanides of type **2** and **5** (see Table 1).

These polymers afford the combination of the versatile reactivity of the isocyanide group[7a] with the advantages of solid-phase techniques. In contrast to isocyanomethylpolystyrene, our new isocyanide resins have excellent solvent compatibility. The new resins have a swellability of 5—10 mL/g in a wide range of solvents, including water, methanol, dimethylformamide, dichloromethane, benzene, and pyridine.



1 **2**



3

4, X = NH-CHO
5, X = NC

Table 1. Examples of resins of type **2** and **5**.

Resin	n	A—NC	Functionality [mmol/g] [a, b]
2a	1	O—$(CH_2)_3$—NC	1.0
2b	2	O—$(CH_2)_3$—NC	0.6
2c	6	O—$(CH_2)_3$—NC	2.6
2d	1	O—CH_2—$C(Me)_2$—NC	1.9
5a		O—$(CH_2)_6$—NC	3.4
5b		NH—$(CH_2)_2$—C_6H_4—NC(*p*)	3.3 [b]
5c		N(Me)—$(CH_2)_2$—OCO—$(CH_2)_5$—NC	2.8

[a] The data are based on the initial polymer compositions; all of the polymers were subjected to quantitative analysis and showed isocyanide contents of 100 ± 10% of the theoretical values. [b] The isocyanide content of some of the polymers stored at room temperature was found (by IR spectroscopy $\nu(NC) = 2150$ cm^{-1}) to gradually decrease, most rapidly for **5b**, whose isocyanide absorption disappeared completely within 2—3 months.

The macromolecular isocyanides **2** and **5** are obtained by dehydration of the formamides **1** and **4**, respectively. Here, tosyl chloride in pyridine is the reagent of choice[11].

The formamide bead polymers **1**[12] are directly available *via* suspension polymerization, whereas the formamides **4** are derived from the copolymer **3**[13]. The monomers needed for **4** are not compatible as comonomers for suspension polymerizations.

Synthesis of an all-*cis*-Organocyclotristibane and its Pentacarbonylchromium Complex**

By *Jochen Ellermann** and *Adolf Veit*

Dedicated to Professor Wolfgang Beck on the occasion of his 50th birthday

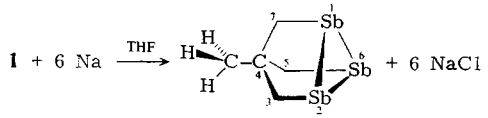
To our knowledge, apart from polymers only two stibanes of general formula $(RSb)_n$[1], the organocyclo*hexa*stibane $(C_6H_5Sb)_6 \cdot C_6H_6$[2a] and the organocyclo*tetra*stibane $(t\text{-}C_4H_9Sb)_4$[2b,c], have so far been reported in the literature. We have now succeeded in synthesizing the first all-*cis*-organocyclo*tri*stibane.

Reaction of tris(dichlorostibane) **1** ($R = C_6H_5$)[3], which is accessible in two steps according to

$$CH_3C(CH_2Br)_3 + 3\,NaSbR_2 \xrightarrow{\text{liq. } NH_3} CH_3C(CH_2SbR_2)_3 + 3\,NaBr$$

$$CH_3C(CH_2SbR_2)_3 + 6\,HCl \xrightarrow{CH_2Cl_2} \underset{\mathbf{1}}{CH_3C(CH_2SbCl_2)_3} + 6\,RH$$

with sodium in tetrahydrofuran (THF), leads to the crystalline 4-methyl-1,2,6-tristibatricyclo[2.2.1.$0^{2,6}$]heptane **2**.

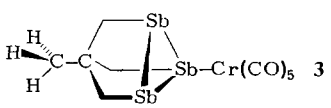


2

The composition and structure of **2** are confirmed by elemental analysis, osmometric molecular weight determination and by mass spectra (FD, EI)[4].

The cyclotristibane **2**, which is very sensitive to oxidation, is sublimable, readily soluble in THF, moderately soluble in diethyl ether, CH_2Cl_2 and $CHCl_3$, and very sparingly soluble in petroleum ether, methanol, and benzene. Its ^{1}H-NMR spectrum ($CDCl_3$, TMS int.) shows two singlets at $\delta = 1.42$ (CH_2) and 1.65 (CH_3) in the intensity ratio 2:1. The strongest band at 210 cm^{-1} in the Raman spectrum of the solid is assigned to the stretching vibration A_1 of the antimony three-membered ring; the $\nu(Sb_3)$-vibration (E) also to be expected for **2**, assuming C_{3v} molecular symmetry, is assigned by us to the medium-strong Raman band at 151 cm^{-1} [FIR spectrum: 147 (m) cm^{-1}].

$Cr(CO)_5 \cdot THF$, prepared from hexacarbonylchromium(0) by UV irradiation in THF, reacts with **2** in the molar ratio 1:1 to give the complex **3** (molecular symmetry: C_s)[5].



2

In the case of η^1-coordination of **2** to $Cr(CO)_5$, $\nu(Sb_3)$(E) in the Raman spectrum at 151 cm^{-1} is split (154 and 140 cm^{-1}, A′ + A″); at the same time a new band appears at 227 cm^{-1}, which we assign to the Cr—Sb stretching vibration.

[**] Contributions to the Chemistry of Polyfunctional Ligands, Part 72. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by Hoechst AG.—Part 71: J. Ellermann, M. Lietz, K. Geibel, *Z. Anorg. Allg. Chem.*, in press.

Procedure

All operations were carried out under nitrogen and in anhydrous solvents.

2: Granulated sodium (1 g, 43.50 mmol) is added to a stirred solution of **1** (0.73 g, 1.13 mmol) in anhydrous THF (30 mL). The mixture is heated under reflux for 0.5 h, and then cooled. As soon as the solution turns orange in color it is filtered free of excess sodium, undissolved NaCl and decomposition products, and evaporated to dryness. The residue is washed three times with 10 mL of THF and the solvent removed at room temperature *in vacuo*. The crude product can be purified by sublimation (100 °C/0.5 torr): yield 285 mg (61%) **2**, yellow crystals, subl. 216–218 °C.

A stirred solution of $Cr(CO)_6$ (32 mg, 0.145 mmol) in THF (3 mL) is irradiated with UV light for 2 h, and then added dropwise within 5 min to a solution of **2** (63 mg, 0.145 mmol) in THF (15 mL). After 2 h at 20 °C the solvent is removed and the dark-red oily residue is taken up in 4 mL CH_2Cl_2, filtered, and treated with 20 mL petroleum ether. After 2 d at −78 °C, analytically pure **3** separates out; yield 65 mg (72%), dark-red crystals, decomp. 231–234 °C.

The isotopic pattern was as expected.

Stereospecific Synthesis of Palladium(II) Complexes of Macrocyclic Tetradentate Phosphane Ligands**

By *Rainer Bartsch, Sibbele Hietkamp, Stephen Morton,* and *Othmar Stelzer**

As analogs of crown ethers, polydentate macrocyclic phosphanes are of current interest[1–3]. The syntheses previously described require several steps and result in formation of these ligands or their complexes as diastereomeric mixtures in less than satisfactory overall yields. By exploitation of the "template effect" we have now successfully prepared chiral Pd^{II} complexes with tetradentate macrocyclic phosphane ligands in a stereospecific manner in *one* synthetic step.

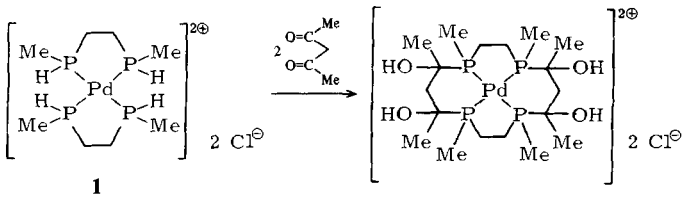
[**] Reactions of Coordinated Ligands, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.—Part 10: R. Bartsch, S. Hietkamp, S. Morton, O. Stelzer, *J. Organomet. Chem. 222* (1981) 263.

The bisphosphane complex **1**—readily accessible from K_2PdCl_4 and $MeHP(CH_2)_2PHMe$—undergoes reaction with two equivalents of acetylacetone in ethanol to form two isomeric cycloadducts **2** and **3** of composition $C_{18}H_{40}Cl_2O_4P_4Pd$. Isomer **2** is only slightly soluble in ethanol, and precipitates out of the reaction mixture. **2** and **3** can be isolated in pure form by recrystallization from water and ethanol/tetrahydrofuran, respectively.



1

2 (20%), **3** (70%)

The novel Pd^{II} complexes **2** and **3** are completely stable in water, and the conductivity of dilute solutions (*ca.* 10^{-4} M) establishes that they are 1:2 electrolytes. Very broad bands at 3180 and 3200 cm^{-1}, respectively, are seen in the IR spectra of **2** and **3**, and these are assigned to OH stretching vibrations. Interestingly, the $^{31}P\{^1H\}$-NMR spectra of each isomer exhibits only a singlet ($\delta = 63.4$ and 60.6, respectively).

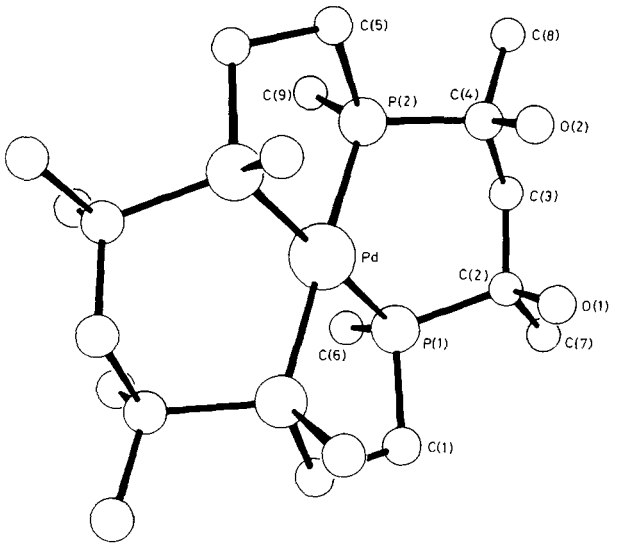


Fig. 1. Structure of the dication of **2** (without H-atoms).

Recrystallization of **2** from water results in isolation of the hydrate $C_{18}H_{40}Cl_2O_4P_4Pd \cdot 4H_2O$. The four P atoms in **2** (Fig. 1) together with the Pd atom form an almost undistorted square-planar arrangement. The *P*-methyl groups are arranged pair-wise in *"cis"* positions. In the chelate six-membered rings, the OH groups are located in axial, and the *C*-methyl groups in equatorial sites. The chelate five-membered rings are in the twist form, and the chelate six-membered rings in the chair form. This also applies to isomer **3**.

Complex **3** has distorted square-pyramidal geometry at the Pd^{II} center (Fig. 2). The Pd atom lies 26 pm above the plane through the four P atoms.

Isomer **2** can be derived from the (*RSSR*)-form and isomer **3** from the (*RSRS*)-form of the starting compound **1**. In aqueous solution the dissociation equilibrium

$$[Pd(L)Cl]^+ \rightleftharpoons [Pd(L)]^{2+} + Cl^-$$

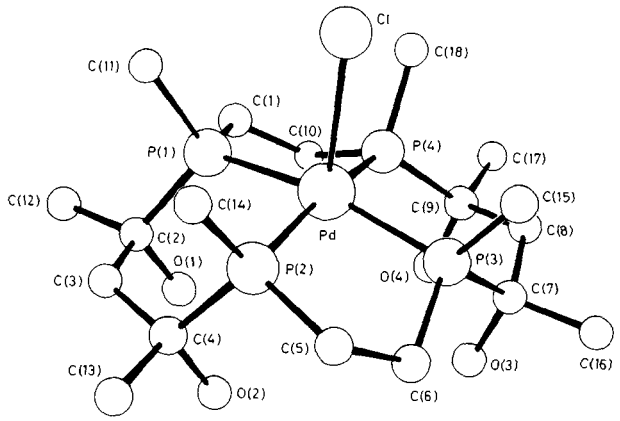

Fig. 2. Structure of the monocation of **3** (without H-atoms).

occurs, as indicated by conductivity measurements (nonlinear $\sqrt{C}/\Lambda_m$ plot). As we have already found for Pd^{II} and Ni^{II} complexes of acyclic chiral tetraphosphaalkanes, this leads to equilibrium of both sides of the surfaces defined by the four P atoms[8]. Therefore, in **2** and **3**, only one $^{31}P\{^1H\}$-NMR signal, respectively, is observed.

Triphosphaalkanes $R_2P—CH_2—PR—CH_2—PR_2$ (R = Cl, CH_3)**

By *Sibbele Hietkamp, Herbert Sommer,* and *Othmar Stelzer**

Until now[1] only one example of a tritertiary methylene bridged triphosphaalkane, the 1,1,3,5,5-pentaphenyl-1,3,5-triphosphapentane described by *Appel et al.*[2] was known.

In an investigation of the synthesis of methylenebis(dichlorophosphane) **1** from dichloromethane, trichlorophosphane, and aluminum after *Novikova, Prishchenko,* and *Lutsenko*[3], we have now found that by extraction of the residue (petroleum ether 40/60) after the usual work-up the triphosphapentane **2** can be obtained (*ca.* 16% yield relative to that of **1**). Apart from **2**, the chloromethyl-substituted bisphosphane **3** can be isolated in low yield (*ca.* 8% yield relative to that of **1**).

Products **1** and **3** can be largely separated by distillation (100 °C/0.01 mbar); further purification of **2** by fractional distillation was unsuccessful due to an as yet unexplained decomposition reaction. In contrast, **3** can be isolated in pure form in this way (b.p. = 51 °C/0.15 mbar).

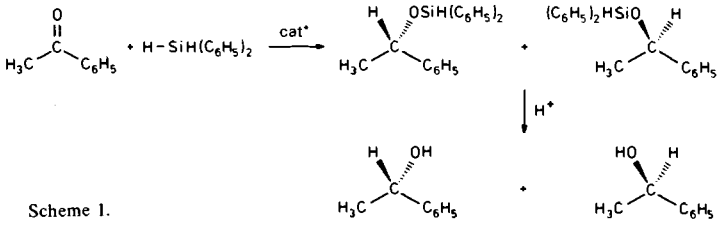
Asymmetric Hydrosilylation of Acetophenone with Rhodium-Complexes of Optically Active Schiff Bases**

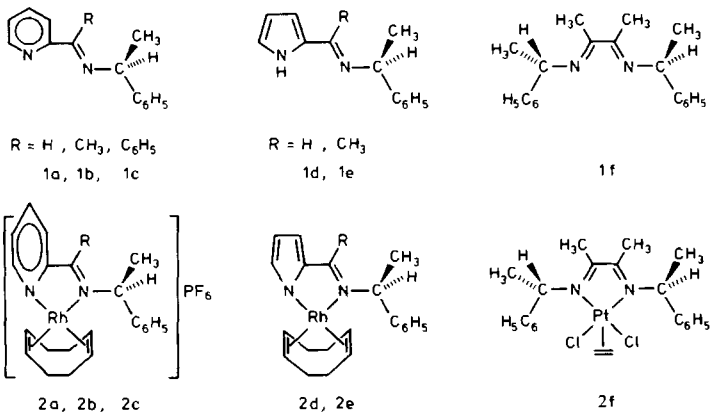
By *Henri Brunner** and *Georg Riepl*

Besides chiral Grignard reagents[1a] and $LiAlH_4$ derivatives[1b], homogeneous catalytic hydrogenations[2] and hydrosilylations[3] with optically active catalysts have been used in recent years for the reduction of prochiral ketones to optically active alcohols. Hitherto, the asymmetric hydrosilylation catalysts, as a rule rhodium or platinum complexes, have without exception contained optically active phosphanes or phosphinites as ligands.



Scheme 1.

We have found that rhodium- and platinum-complexes containing optically active nitrogen ligands are also catalytically active in the model system (Scheme 1) acetophenone/diphenylsilane → 1-phenylethanol[3]. Suitable ligands **1a**—**1f** were obtained by Schiff-base condensation of the corresponding carbonyl compounds with (*S*)-(−)-1-phenylethylamine.



The stoichiometric complexes **2a**—**2f**, though catalytically active, give only slight optical inductions of between 0 and 2% *ee* (Table 1). On the other hand, if the hydrosilylation catalysts are synthesized *in situ* from $[(cod)RhCl]_2$ or $K[PtCl_3(C_2H_4)]H_2O$ with a large excess of ligand, the optical induction increases considerably, in all cases. In the system $[(cod)RhCl]_2$/**1a** with a Rh/ligand ratio of 1 : 13, almost complete hydrosilylation is obtained with an optical induction of 57% *ee*, which surpasses the maximum optical induction of 55% *ee*[4] achieved so far with rhodium complexes of optically active phosphorus ligands on the same model substrate acetophenone/diphenylsilane.

Table 1. Asymmetric hydrosilylation of acetophenone with diphenylsilane (pyridinimine-, pyrrolimine- and diazadiene-noble metal catalysts).

Catalyst system	Rh/ ligand	Rh/ substrate	Reaction time	% Hydrosilylation	% *ee*
2a	1/1	1/320	23 h	38	0.0
2b	1/1	1/380	41 h	35	0.0
2c	1/1	1/350	22 h	59	0.0

[*] Prof. Dr. H. Brunner, G. Riepl
Institut für Anorganische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

A disadvantage of the Rh/pyridinimine catalysts compared to the Rh/phosphane catalysts is the almost tenfold higher ligand concentration, necessary for generation of the catalytically active species. However, this is no great setback, because the optically active Schiff bases, in contrast to the optically active phosphanes previously used in asymmetric catalysis, are inexpensive and easy to prepare. Considering that the components of the Schiff bases **1a**—**1f** and similar compounds—carbonyl compound and optically active primary amine—are variable within very wide limits, there is an almost inexhaustible potential for new catalysts.

A striking feature of the results in Table 1 is the surprising effect of various groups R in the pyridinimine series. In the case of **1a** (R = H), the (*R*)-configuration predominates (57%) in the resulting 1-phenylethanol, whereas in the case of **1b** ($R=CH_3$), the (*S*)-configuration (9%) predominates, and for **1c** ($R=C_6H_5$) the (*R*)-configuration is once again predominant (18%), though all three Schiff bases derive from (*S*)-(−)-1-phenylethylamine. This confirms the dominating role of the substituents R on the azomethine C-atom regarding the arrangement of the optically active group on the neighboring N-atom, which had already manifested itself in the optical induction of the metal configuration[5] and which obviously also exerts a decisive influence on the configuration of the product in asymmetric hydrosilylations.

Preparation of a Graphite Fluoride Film on Aluminum

By *Hiroaki Yamada, Tsuyoshi Nakajima,* and *Nobuatsu Watanabe**

When a mixture of sheet aluminum and graphite fluoride powder $[(CF)_n]$[1,2,5] is heated at 450–600 °C in F_2 (0.1–1.0 bar) a graphite fluoride film is formed on the surface of the aluminum. This film can be prepared more conveniently by allowing aluminum metal to react with natural graphite powder (1 bar F_2, 600 °C).

[*] Prof. Dr. N. Watanabe, Dr. H. Yamada, T. Nakajima
Department of Industrial Chemistry, Faculty of Engineering
Kyoto University
Sakyo-ku, Kyoto-shi, 606 (Japan)

X-ray microanalysis showed that the film contained almost 50% fluorine and 30% carbon, but almost no oxygen. X-ray diffraction studies indicated the absence of aluminum oxide, but that both α- and γ-aluminum fluoride were present[10].

The ESCA spectra of the film yield C1s and F1s binding energies (E_B) of 290.0 ± 0.2 and 689.0 ± 0.2 eV, respectively, which were assigned to graphite fluoride[9] $[(CF)_n]$ (Fig. 2A).

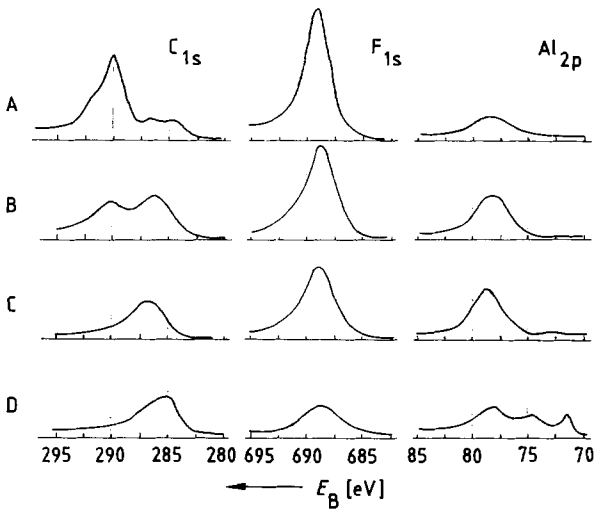

Fig. 2. ESCA spectra of the graphite fluoride film on aluminum obtained by heating aluminum with graphite fluoride under F_2 (450 °C, 1 bar F_2, 48 h), $Mg_{K\alpha}$ radiation. A) Film surface; B)–D) after successive polishing of the surface with sandpaper. E_B = binding energy. Standard: contaminating carbon, E_B (C1s) = 285.0 eV.

The peak for Al2p binding energy located at 78.5 ± 0.2 eV suggests that the aluminum atom is bonded to fluorine or to a fluorocarbon. Removal of the surface layer from the film resulted in a rapid decrease in the C1s maximum at 290 eV and an increase in that at 286.5 ± 0.2 eV (Fig. 2B–D). The latter maximum is characteristic of this film and its chemical shift is assigned to a carbon atom of part structure Al—C—F.

The film is gray to grayish black in color and has a smooth lustrous surface; it could not be detached mechanically from the aluminum support. The thickness of the film is about 3 μm. The contact angle of distilled water on the film is 120°, and the specific resistance is greater than $4\times10^{10}\ \Omega\cdot$cm at room temperature. In addition, the film has high corrosion-resistance to acidic and alkaline solutions, and its thermal decomposition temperature is 600 °C in air.

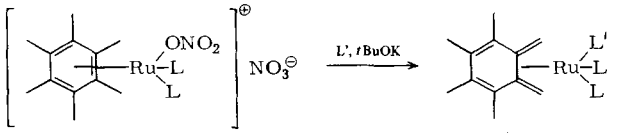
Reversible Double Deprotonation of Hexamethylbenzene on Ruthenium: Formation of a Fluxional η^3-Benzyl Compound by Protonation of an *o*-Quinodimethane Complex of Ruthenium(0)

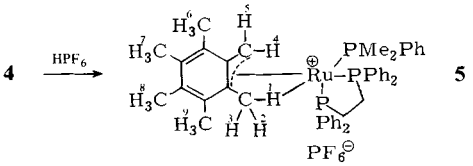
By *Martin A. Bennett**, *Ian J. McMahon*, and *Terence W. Turney*

Ruthenium(0) complexes **1**—**4** containing 1,2,3,4-tetramethyl-5,6-bis(methylene)-1,3-cyclohexadiene (*o*-quinodimethane) are formed by abstraction of two protons from a η^6-hexamethylbenzeneruthenium(II) complex, the metal atom being coordinated to the exocyclic diene.



1, L = L' = $P(OMe)_3$
2, L = L' = $P(OCH_2)_3CMe$
3, L = L' = PMe_2Ph
4, L_2 = diphos; L' = PMe_2Ph

The double deprotonation is reversible: complex **1** reacts with an excess of HBF_4 or HPF_6 to give $[Ru\{P(OMe)_3\}_3(\eta\text{-}C_6Me_6)]X_2$ and there is NMR spectroscopic evidence for a mono-protonated intermediate when a deficiency of acid is employed at 0 °C. In contrast, **4** reacts even with an excess of 60% aqueous HPF_6 to give a yellow, air-stable, monoprotonated salt **5**.



The cation **5** is formulated as a fluxional η^3-benzyl complex in which the added proton bridges the metal atom and a methyl carbon atom[14, 15]. Exchange between this proton (H^1) and the two protons H^2, H^3 on the carbon atom is rapid on the NMR time scale, even at −90 °C [^{1}H-NMR (CD_2Cl_2, −30 °C): δ = −2.31 (m, $H^{1,2,3}$), 1.42, 1.58, 2.17 (s, s, s, each 3H, $H^{6,7,9}$), 2.40 (s, 3H^8), 3.17 (m, H^5), *etc.*]. Above −30 °C a $\eta^3 \rightleftharpoons \eta^1$ benzyl interconversion[16, 17] takes place which interchanges $H^{1,2,3}$ with H^6, and H^7 with H^9, but leaves H^8 unaffected. In the range 28—80 °C all the ring methyl protons begin to become equivalent, probably owing to successive C—H cleavages and formation of Ru—H bonds (cf. $Mn(CO)_3(\eta^3\text{-}C_6H_9)$[14]), which allow the $L_2L'Ru$ group to traverse the substituents on the six-membered ring.

The formation of **5** from **4** is clearly analogous to the generation of η^3-allyliron(II) complexes by protonation of $FeL_3(\eta^4$-diene) compounds[9], and supports the formulation of **1**—**4** as η^4-dieneruthenium(0) in preference to the alternative α,α'-*o*-xylenediylruthenium(II) complexes.

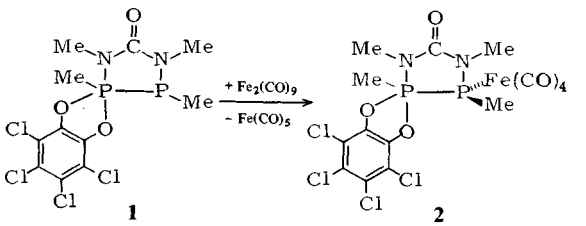
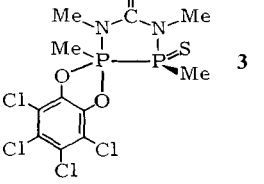
Synthesis and Structure of the First Transition Metal Complex of a Phosphorus Compound with a Direct λ^3P—λ^5P Bond

By *John W. Gilje*, *William S. Sheldrick*, *Norbert Weferling*, and *Reinhard Schmutzler**

Although many complexes of triply coordinated phosphorus with transition metals have been known for some time, there are few cases involving λ^3P-λ^3P diphosphane ligands, and only one example of a complex in which the free ligand contains a λ^4P-λ^3P structural unit is known[3]. We have now studied the donor properties of the λ^5P-λ^3P diphosphorus compound **1**, which we had previously prepared[4]. The first representatives of this novel class of compounds were only recently synthesized and structurally characterized[5]. Reaction of an equimolar amount of **1** with $Fe_2(CO)_9$ affords, quantitatively, the tetracarbonyliron complex **2** (Fig. 1), which is stable towards atmospheric oxygen and moisture.





An X-ray structure analysis of **2** indicated that this unusual molecule contains both a pentacoordinated metal (Fe) as well as a pentacoordinated nonmetal (P2). The iron atom has trigonal bipyramidal coordination, while the coordination at P2 is largely square pyramidal.

Both angles O1P2P1 and O2P2N2 (150.8(1) and 151.7(1)°, respectively) closely approach that expected for

a square pyramid (150°). The difference in the P201 (169.8(3) pm) and P202 (173.5(2) pm) bond lengths, however, indicate that P2 exhibits some residual trigonal-bipyramidal character. Analysis of the interplanar dihedral angles for the normalized bond lengths shows that in **2** P2

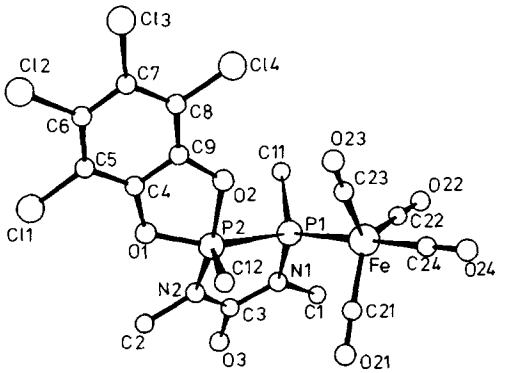

Fig. 1. Molecular structure of **2** in the crystal. Details of the crystal structure can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen (F.R.G.) by quoting the number CSD 50 175, the name of the author, and the complete citation of the article.

has more than 80% square pyramidal character. In contrast, **3** exhibits only *ca.* 56% C_{2v} distortion towards this geometry[9]. The SP1P2 angle in **3** (112.8(1)°) is considerably smaller than the FeP1P2 angle in **2** (120.3(1)°). Possibly the different coordination at P2 in **2** and **3** has its origin in steric interactions *e.g.* between C12 and atoms of the $Fe(CO)_4$ group. The P1P2 distance (224.5(1) pm) in **2** is in the expected range (218—225 pm). In both **2** and **3** the two methyl groups C11 and C12 have *trans*-orientations; a *cis* arrangement would be sterically much less favorable.

Cu-H_2 Photochemistry in the Matrix; ESR, FTIR, UV/VIS Spectroscopic and Kinetic Studies**

By *Geoffrey A. Ozin**, *Steven A. Mitchell*, and *Jamie García Prieto*

In this communication we wish to report that photoexcited copper atoms react with molecular hydrogen in a krypton matrix to yield CuH and H atoms.

The UV/VIS spectrum of Cu atoms isolated in a Kr/H_2 matrix at 12 K ($Cu:Kr:H_2 = 1:10^4:10^3$) closely resembled that observed for Cu atoms in a pure Kr matrix[7], although the effects caused by 310 nm photoexcitation of the entrapped Cu atoms ($4^2P \leftarrow 4^2S$) were markedly different. Whereas in the case of the pure Kr matrix loss of Cu atoms was characterized by approximately second order kinetics, consistent with the bimolecular dimerization $2Cu \rightarrow Cu_2$, the photoinduced decay of Cu atoms in the Kr/H_2 matrix was much faster, and was characterized by first order kinetics; such decay kinetics would be expected for a reaction of the type $Cu + H_2 \rightarrow$ products, where H_2 is in great excess. Only minimal growth of Cu_2 was observed under the conditions mentioned. Furthermore, the photodecay rates of Cu atoms in Kr/H_2 and Kr/D_2 matrices were found to be identical.

Direct evidence for a chemical reaction involving photoexcited copper atoms and molecular hydrogen was obtained by means of *in situ* ESR and FTIR studies of $Cu/Kr/H_2$ matrices[8].

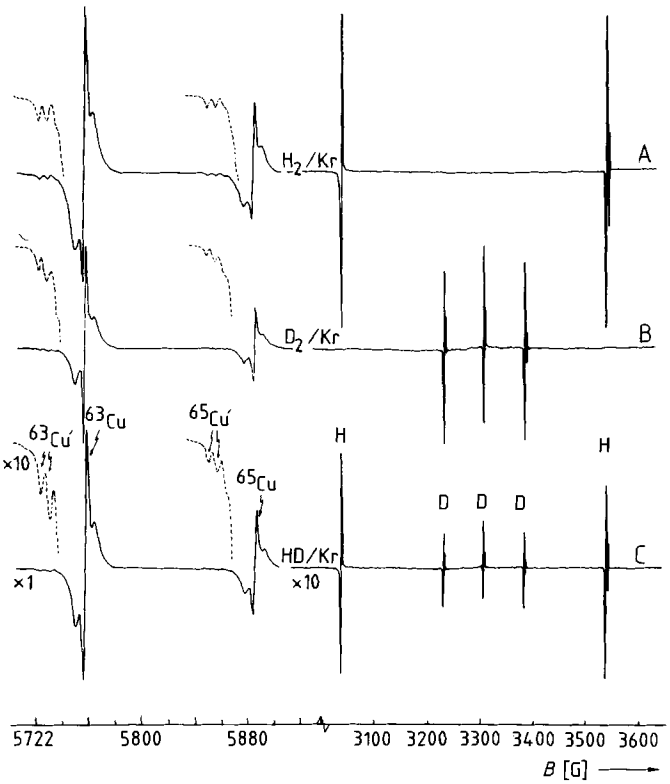

Fig. 1. Left: Part of the ESR spectra (Varian E4, 9.278 GHz) showing the high field doublet associated with ^{65}Cu and ^{63}Cu atoms isolated in freshly deposited Cu-containing Kr/H_2 (A), Kr/D_2 (B), and Kr/HD (C) matrices (ratios $1:10^4:10^3$) at 12 K. Right: Spectra showing the presence of H and D atoms in the various matrices after ≃ 1 h photolysis at 310 nm. No H or D atoms were detected prior to photolysis.

In each case the ESR spectra of the $Cu/Kr/H_2$, $Cu/Kr/D_2$, and Cu/Kr/HD matrices showed only the known[9a] spectrum of Cu atoms, and no H or D atoms. The high field doublet associated with ^{63}Cu and ^{65}Cu atoms is reproduced in Figure 1. Photoexcitation (310 nm) of the entrapped Cu atoms caused decay of their resonance lines with concurrent appearance and rapid growth of resonance lines due to H and/or D atoms (Fig. 1, right). No lines attributable to Cu^{II} species, *e.g.* CuH_2 were observed in these experiments in contrast to similar studies with CH_4[1] and C_2H_6[5] in which the primary products H_3CCuH and H_5C_2CuH, respectively, were detected in addition to

the major secondary photolysis channel $^{\circ}CH_3 + CuH$ and $^{\circ}C_2H_5 + CuH$, respectively. Interestingly, in Kr/HD matrices there was a pronounced intramolecular isotope effect and H atoms were approximately twice as favored over D atoms. This isotope effect and the identical copper atom photodecay rates in Kr/H_2 and Kr/D_2 matrices are similar in both direction and magnitude to those found for the reactions of $^3P_{0,1}$-Cd and -Hg atoms with HD, H_2, and D_2 in the gas phase. These reactions are known to produce the metal hydride, H, and D atoms, respectively, and have been postulated to occur by a direct insertion-dissociation mechanism involving side-on attack of H_2 or D_2 by the excited metal atom. However, to make definitive statements on the Cu/H_2 system, further experiments are necessary.

The formation of CuH and CuD, respectively, as products of the photochemical reaction of Cu atoms in a Kr/H_2, Kr/D_2 or Kr/HD matrix was detected by FTIR studies [intense bands in the IR spectra at 1852 ($Cu/Kr/H_2$) and 1336 cm^{-1} ($Cu/Kr/D_2$)][13].

An interesting possibility is that the much less intense band at 1907 ($Cu/Kr/H_2$) or 1388 cm^{-1} ($Cu/Kr/D_2$), respectively, is associated with a dicopper monohydride species, formed by a reaction of the type $Cu + CuH \rightarrow Cu_2H$.

In summary, the photochemical reaction of copper atoms with molecular hydrogen in Kr matrices can be written as follows:

$$Cu + H_2 \xrightarrow[\text{Kr matrix, 12 K}]{\text{UV/310 nm}} CuH + H$$

We found no evidence for formation of a copper dihydride HCuH intermediate.

CH_4 Activation by Photoexcited Cu_2 Molecules**

By *Geoffrey A. Ozin**, *Steven A. Mitchell*, and *Jamie García-Prieto*

We report here our observations concerning the first example of alkane activation using a selectively photoexcited M_2 species: the matrix reaction of Cu_2(B) with CH_4.

Evidence for this photochemical reaction stem from a number of sources, including UV/VIS absorption, fluorescence emission/excitation and ESR spectroscopy. In a typical UV/VIS absorption trace of a Cu/CH_4 matrix ($1:10^3$, 12 K) the freshly desposited sample shows the presence of Cu atoms which coexist with small amounts of Cu_2. Prolonged resonance excitation of the Cu atoms [15 minutes, 320 nm intensity at the sample: 80 μwatt cm^{-2}; $Cu(^2P) \leftarrow Cu(^2S)$] causes rapid bleaching of all the Cu atom absorptions, and formation of $^{\circ}CH_3$ and CuH as the major photoproducts (absorbing at $\lambda = 200-250$ nm) with very little alteration of the concentration of Cu_2 (Fig. 1)[1].

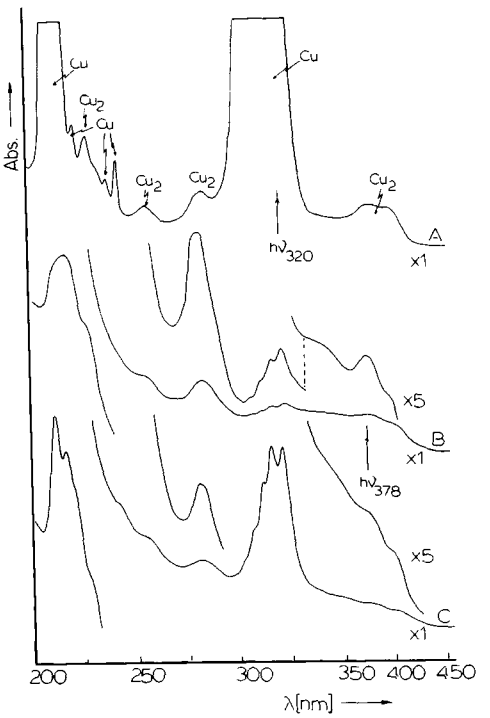

Fig. 1. UV/VIS absorption spectrum of Cu atoms in a CH_4 matrix ($Cu:CH_4 \approx 1:10^3$) at 12 K. A) Directly after deposition, B) after irradiation for 15 min at 320 nm, and C) after irradiation for 5 min at 378 nm (cf. text).

Subsequent photoexcitation of Cu_2 (5 min, $\lambda = 378$ nm) results in rapid bleaching of the Cu_2 absorptions, with concurrent ten-fold growth in the intensity of the Cu atom resonance absorption bands. This observation should be sharply contrasted with the minor net photodissociative yield (10% after 30 min) following similar photoexcitation of Cu_2 in rare gas matrices[7]. Furthermore, the $Cu(^2D) \rightarrow Cu(^2S)$ emission observed in rare gas matrices after photoexcitation of Cu_2 is completely quenched in the corresponding spectra of CH_4 matrices[5]. ESR spectroscopy clearly revealed significant production of $^{\circ}CH_3$ radicals (quartet centered around $g = 2$) following excitation of Cu_2 in CH_4. Trace amounts of H atoms (doublet centered around $g = 2$) were observed in these experiments; however, no evidence for the insertion product H_3CCuH was obtained, although because of the low Cu_2 concentration employed in these experiments the amount of H_3CCuH could have been below the detection limit of the ESR measurements. This observation should be contrasted with the reaction of $Cu(^2P)$ formed by directed resonance excitation of $Cu(^2S)$ with CH_4 in the matrix, which leads to efficient generation of H_3CCuH in the primary step[1].

These results point to very efficient photodissociation of Cu_2 excited in CH_4 matrices; this appears to have its origin in the chemical quenching of the $Cu(^2D)$ photofragment:

$$Cu(^2D) + CH_4 \rightarrow {}^{\ominus}CH_3 + CuH$$

This eliminates the competing cage-assisted recombination pathway which predominates in rare gas matrices[5,7]. This proposal is entirely consistent with our observation of a large, net Cu_2 photodissociative yield of the immobilized ground state [$Cu(^2S)$] of Cu atoms, which occurs in addition to the excited state [$Cu(^2D)$].

These results may be significant as they point to the possibility of excited state selectivity in the condensed phase photosensitization reactions of Cu atoms with CH_4:

$$Cu(^2P) + CH_4 \xrightarrow{\text{insertion}} H_3CCuH$$

$$Cu(^2D) + CH_4 \xrightarrow{\text{abstraction}} H_3C^{\ominus} + CuH$$

$$Cu(^2S) + CH_4 \xrightarrow{\text{no reaction}} Cu + CH_4$$

In conclusion, photochemistry of metal atoms and dimetal species opens up the possibility of activating saturated hydrocarbons and performing selective alkane transformations[1,3]; in this connection certain M_2 species can be photoexcited with visible light.

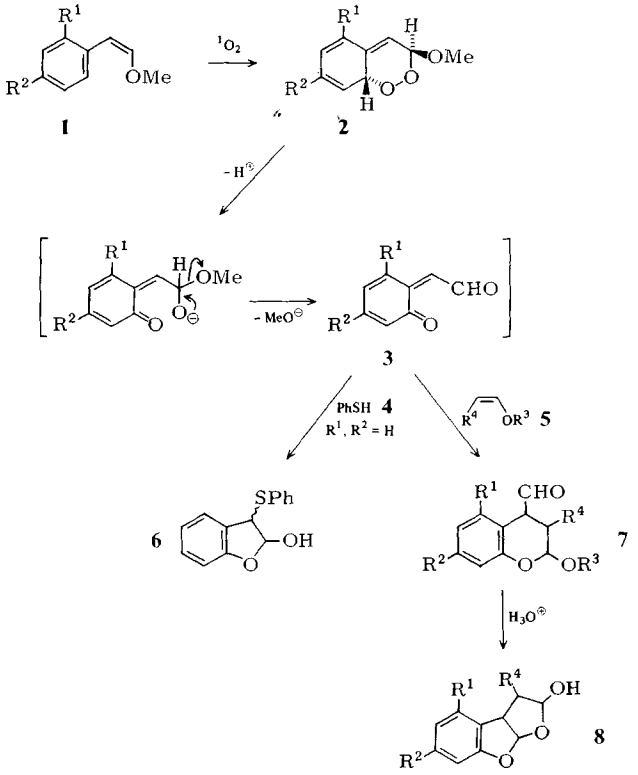
o-Benzoquinone Monoformylmethides by Sensitized Photooxygenation of *cis*-β-Methoxystyrenes

By *Masakatsu Matsumoto* and *Keiko Kuroda**

A reactive *o*-quinone methide[1] is often generated as a reaction intermediate by dehydration[2] or by pyrolysis[3] at high temperature. Mainly because of these forcing conditions, generation of quinone methides possessing labile functional groups has hardly been attempted so far. We report here an effective generation of new *o*-quinone methides **3**, which have a formyl group at the exocyclic carbon, from cyclic peroxides **2** of cis-β-methoxystyrenes **1** under mild conditions. These quinone derivatives **3** react with enol ethers **5** affording 4-formylchromans **7**, which are utilized as versatile intermediates in the synthesis of furobenzofuran-type mycotoxins.

Sensitized photooxygenation of *cis*-β-methoxystyrene **1a** at low temperature gives quantitatively an unstable 1,4-endoperoxide **2a**[4a], which decomposes into a complex mixture at room temperature[4b,c]. However, decomposition of



1	R^1	R^2	5	R^3	R^4	7
1a	H	H	+ **5a**	*i*Bu	H	→ **7a**
1a	H	H	+ **5b**	—CH_2CH_2—		→ **7b**
1a	H	H	+ **5c**	Me	Ph	→ **7c**
1b	H	MeO	+ **5a**	*i*Bu	H	→ **7d**
1c	$PhCH_2O$	MeO	+ **5a**	*i*Bu	H	→ **7e**

2a was found to proceed cleanly in the presence of excess isobutyl vinyl ether **5a**; chromatographic purification of the reaction mixture afforded a 4-formylchroman **7a** in 68% yield[5]. In this reaction, the peroxide **2a** is believed to decompose initially into the quinone methide **3a** and methanol. Diels-Alder addition of **3a** to **5a** then leads to the product **7a**. Intermediary **3a** was further confirmed by reaction of **2a** with a nucleophile such as thiophenol **4**, which affords a stereoisomeric mixture of lactols **6** in 45% yield.

The addition of **3a** to 2,3-dihydrofuran **5b** and *cis*-β-methoxystyrene **1a** (≡ **5c**), respectively, afforded the 4-formylchromans **7b** (13%) and **7c** (54%). Ring-substituted *cis*-β-methoxystyrenes **1b** and **1c** gave the chromans **7d** (29%) and **7e** (39%), respectively, when allowed to react with **5a**. On the other hand, reaction of the peroxide from the *trans*-isomer of **1a** with vinyl ethers gave unfavorable results.

The formylchromans **7** are useful synthetic intermediates. For example, under acid catalysis with H_2SO_4 they give furobenzofurans **8**. The reaction sequence described here is suitable for the synthesis of some mycotoxins possessing a furobenzofuran skeleton such as sterigmatocystin and aflatoxins[4d].

[5] **7a**: A solution of *cis*-β-methoxystyrene **1a** (0.67 g, 5 mmol) and tetraphenylporphyrine (5 mg) in CH_2Cl_2 (20 mL) was irradiated with visible light under O_2 at −78 °C until an equimolar amount of oxygen was consumed (*ca.* 4 h). Isobutyl vinyl ether **5a** (5 g) was added to the mixture which was allowed to stand for 15 h at 5 °C. The reaction mixture was condensed *in vacuo* and chromatographed on SiO_2 (Wako C-200). Elution with CH_2Cl_2 gave **7a** [747 mg, 68% yield based on the consumed **1a**]; b.p. *100 °C/0.24* torr; ^{1}H-NMR (CCl_4): δ = 0.78 (d, J = 6.5 Hz, 3H), 0.81 (d, J = 6.5 Hz, 3H), 1.52–2.00 (m, 1H), 2.00–2.20 (m, 2H), 3.12–3.60 (m, 2H), 3.57–3.80 (m, 1H), 5.05–5.16 (m, 1H), 6.66–7.18 (m, 4H), 9.56 (d, J = 3.5 Hz, 1H).

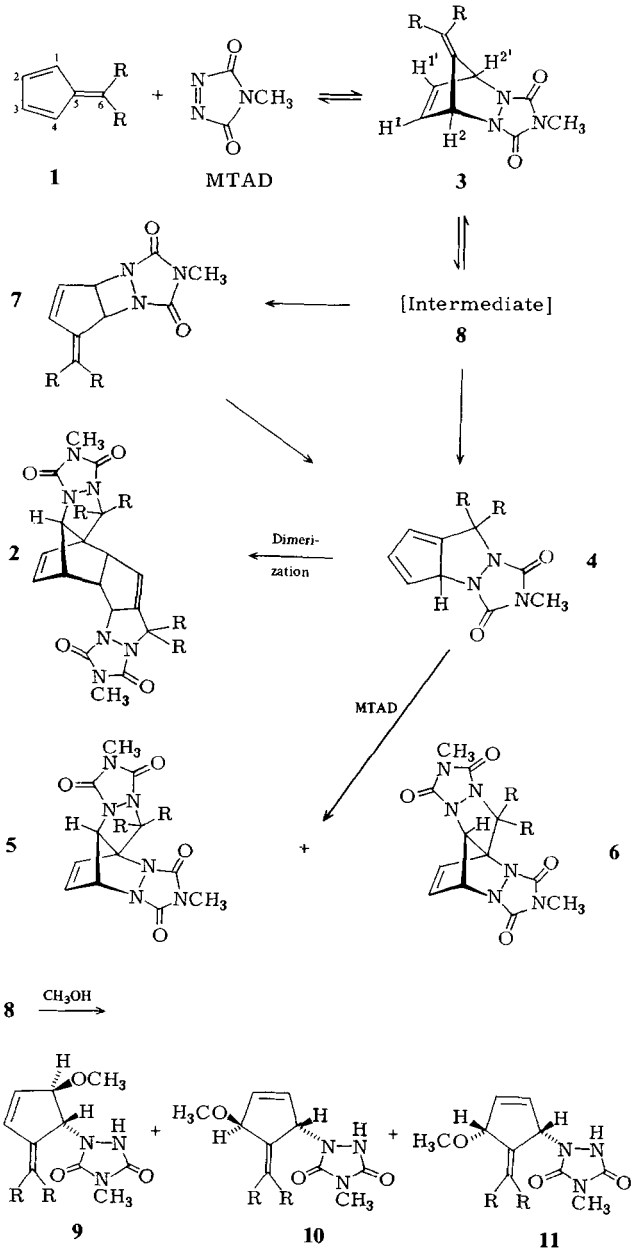
Reaction of 4-Methyl-1,2,4-triazoline-3,5-dione with Fulvenes: A 1,3-Sigmatropic Shift involving a Dipolar Intermediate**

By *Henrik Olsen**

The Diels-Alder reaction of azodicarbonyl compounds and fulvenes has led to a wide variety of polycyclic *N*-heterocycles. We have now found that the reaction between 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) and fulvenes **1a** and **1b** provides novel products, the heptacycles **2a** and **2b**, respectively, formally derived by successive [6+2]- and [4+2]-cycloadditions. Since a $[_\pi 6_s + _\pi 2_s]$-cycloaddition contravenes the Woodward-Hoffmann rules, the mechanistic details of this reaction were examined more closely.

Surprisingly, the reaction between **1a** and MTAD at room temperature did not furnish the expected Diels-Alder adduct **3a**. The ^{1}H-NMR spectrum of the isolated product (72% yield) is in complete agreement with the structure of the *bis*-adduct **2a**. In addition to six singlets for the methyl groups (δ = 3.00, 2.98, 1.78, 1.65, 1.44, 1.41) eight groups of signals for the eight other protons are observed. On the other hand, reaction of MTAD and **1b** under analogous conditions furnished *bis*-adduct **2b** (86% yield). Formation of heptacycles **2** strongly suggests that MTAD reacts initially with **1** to give the 1,6-addition products **4**. When the cycloaddition reaction between **1a** and **1b** and MTAD was performed (in the ratio 1:2) the 1:2 adducts **5a** (49%) and **6a** (36%) or **5b** (88%), respectively, could be isolated. Clearly the Diels-Alder reaction of **4a** and **4b** with MTAD must be considerably faster than the dimerization.

In order to establish whether the pathway leading to **4** from **1** and MTAD could proceed *via* initial [4+2]-cycloaddition followed by a formal [1,3]-sigmatropic shift or directly *via* a [6+2]-cycloaddition, MTAD was added to a CD_2Cl_2 solution of dimethylfulvene **1a** (1:1) in an NMR tube at −78 °C. ^{1}H- [(100 MHz), δ = 6.57 (AA′ part of an AA′XX′ system, 1- and 1′-H), 5.41 (XX′ part, 2- and 2′-H), 2.94 (s, NCH_3), 1.72 (s, CH_3)] and ^{13}C-NMR spectra indicate that the [4+2]-cycloadduct **3a** is formed initially.



a, R = Me; **b**, R = Ph

Scheme 1.

At −10 °C **3a** rearranged to afford isomers **4a** and **7a**. In the final stages of the reaction only signals corresponding to **2a**, **5a**, **6a**, and **1a** could be observed. Similarly, the reaction between **1b** and MTAD at −78 °C furnished **3b**, *which rearranged at −10 °C to furnish* **2b**.

In preliminary investigations of the mechanism (concerted, diradical, or zwitterionic), remarkably low-energy barriers for the conversion **3b**→**4b** (ΔH^{+} = 21.7 ± .2 kcal/mol, ΔS^{+} = 6.5 ± .6 cal/mol K in [D_8]THF) were estimated. Evidence for a true intermediate on the potential energy surface was provided by performing the cycloaddition reaction between **1b** and MTAD in CH_2Cl_2/MeOH (1:5) at −45 °C. NMR spectroscopy (at −45 °C) indicates the initial formation of **3b**; however, warming the solution to room temperature results in the formation of the metha-

nol adducts **9b**, **10b**, and **11b**, consistent with the intervention of intermediate **8**, which has a zwitterion-like character[17]. However, since the rate of transformation **3b**→**4b** is by and large insensitive to solvent polarity ($k_{CD_3CN}/k_{[D_8]THF}=2.2$), the intermediate has to be mediated on the continuous scale between biradical and zwitterion[21]. We consider **8** to be a resonance hybrid of zwitterion and biradical mesomeric structures[23].

The interrelationship of the various adducts is depicted in Scheme 1. One possibility is that **8** may collapse to produce both **7** and **4**. The former (**7**) would then have to rearrange subsequently to **4**, either by a concerted [1,5]-sigmatropic shift or by a stepwise process. Alternatively, formation of **4** could result from **7** and not directly from **8**. This is in accord with the reported behavior of the [2+4]-cycloadduct between tetracyanoethylene and dicyclopropylfulvene, which consecutively forms [2+2]- and [2+6]-cycloadducts *via* zwitterionic intermediates[22]. Since in the NMR study of the reaction of **1a** with MTAD the signals of **1a**, **5a**, and **6a** remained constant with respect to an internal standard as soon as **3a** had disappeared from the reaction mixture, the existence of an equilibrium **1** + MTAD⇄**3** is supported; an analogous equilibrium has also been reported in the literature[26]. An alternative would be dissociation of intermediate **8** into **1** and MTAD.

Metallacyclosulfanes: Synthesis of Bis(pentamethylcyclopentadienyl)titana(IV)cyclotetrasulfane**

By *Peter H. Bird, James M. McCall, Alan Shaver**, and *Upali Siriwardane*

Since the report of the complex $(C_5H_5)_2TiS_5$[1a], a number of metallacyclosulfanes *i.e.* compounds containing an MS_x ring have been prepared[1b]. Except for the special case of disulfide complexes only rings with x = 4 or 5 have been characterized. Recently, we prepared the complexes $(C_5H_5)_2ME_5$ (M = Zr, Hf and E = S, Se) and compared the ring flipping activation energies of the pentasulfides to that reported for $(C_5H_5)_2TiS_5$[2a]. Here we report that attempted preparation of the analogous pentamethylcyclopentadienyl complexes led to the isolation of the first confirmed examples of metallacyclotetrasulfanes $(Me_5C_5)_2MS_3$, M = Ti, Zr[2b].

In the solid state the TiS_3 ring in $(Me_5C_5)_2TiS_3$ is nonplanar, with S(2) being significantly displaced in the direction of one Me_5C_5 ring (pseudoaxial). The dihedral angle between the two planes formed by atoms TiS(1)S(2) and S(1)S(2)S(3) is 49°. The Ti—S(2) distance (2.77 Å) seems short but it would only lengthen to about 3.0 Å if the ring were planar. Thus, it is not possible to rule out a substantial interaction between Ti and S(2)[3a] (for further information see Fig. 1).

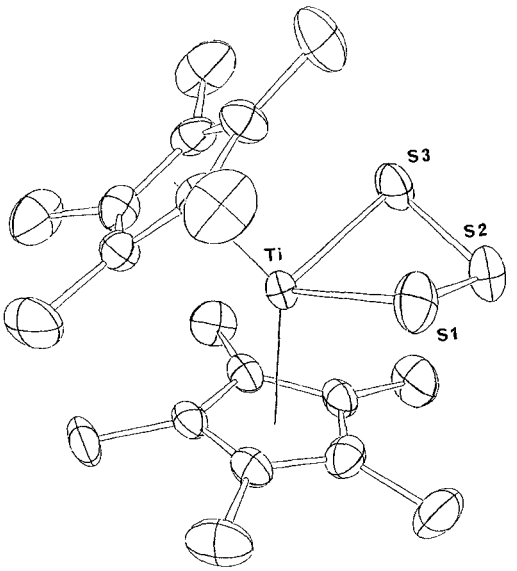

Fig. 1. Structure of $(Me_5C_5)_2TiS_3$ in the crystal (ORTEP representation, methyl protons omitted). $P2_1/c$, $a=8.770(8)$, $b=13.885(6)$, $c=17.20(1)$ Å, $\beta=103.75(6)°$. Single crystal diffractometer (Picker FACS-1, software from National Research Council of Canada), $Mo_{K\alpha}$ irradiation, graphite monochromator, θ-2θ scan, $3.5° < 2\theta < 45°$, 1829 reflections with $I > 3\sigma(I)$, direct methods, R = 5.8%. Most important bond lengths [Å] and angles [°] (averaged where appropriate; values in square brackets apply to $(C_5H_5)_2TiS_5$ [3b]): TiS 2.413(4), SS 2.041(5), $(Me_5C_5)Ti(Me_5C_5)$ 136.85(3) [$(C_5H_5)Ti(C_5H_5)$ 133.7], STiS 84.44(9) [94.6], TiSS 76.34(1) [108.00(8)], SSS 105.3(1) [104.9(1)].

Both $(Me_5C_5)_2TiS_3$ and $(Me_5C_5)_2ZrS_3$ exhibit variable temperature ^{1}H-NMR spectra. At room temperature one peak is observed for the methyl protons. Upon cooling this peak broadens, collapses (−80 to −90 °C) and reappears as two peaks (overlapping for Ti, resolved for Zr) which continue to sharpen until at lower temperatures they also broaden, collapse and in the case of the Ti complex begin to reappear as a number of small peaks (< −105 °C). The changes at higher temperatures are assigned to the slowing of ring reorientation ("ring-flipping"[4]) until the peaks due to the Me_5C_5 protons in the pseudoaxial and equatorial environments are resolved. We feel that the low temperature changes are due to the slowing of the Me_5C_5 ring rotation about the ring-metal axis. The barriers to "ring-flipping" are 40 ± 2 kJ mol^{-1} for both complexes. These values are smaller than those for the pentasulfides, and within the latter series the TiS_5 ring has a much higher barrier than its congeners.

The "natural" ring size for the metallacyclosulfanes of the $(C_5H_5)_2M$ system, where M is a group IVa metal, is six. Apparently, the ring size for the $(Me_5C_5)_2M$ system is four, even in the presence of excess sulfur.

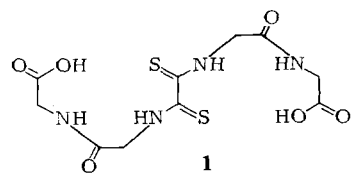
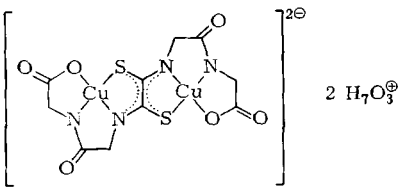
A Novel Bischelating Ligand with Two Tetradentate *N,N,O,S* Subunits—Synthesis and Properties of a Dinuclear Cu^{II} Complex

By *Jean Jacques Girerd* and *Olivier Kahn**

The synthesis of new bischelating ligands is of considerable current interest[1]. These ligands and the related dinuclear complexes have potentially a wide range of application in homogeneous catalysis, in the activation of small molecules, in electrochemistry, or as models for bioinorganic systems. Furthermore, they have provided an insight into the mechanism of the exchange interaction between metal ions[2]. In this connection, bischelating ligands able to propagate the electronic effects between metal ions far removed from each other are of particular importance. We have shown recently that an appropriate strategy to obtain such systems consisted in the design of ligands with sulfur atoms in the bridging network[3].



1



2

We report here the synthesis of the dicarboxylic acid **1** obtained from dithiooxamide $C_2S_2(NH_2)_2$ and glycylglycine $H_2NCH_2CONHCH_2COOH$ (1:2). Upon losing six protons, this molecule can function as a novel bischelating ligand with two tetradentate moieties. Indeed, the reaction of **1** and $CuSO_4 \cdot 5H_2O$ results in the dinuclear Cu^{II} complex **2**, which is insoluble in the usual protic solvents but which dissolves in basic media to give bright green solutions. The UV/VIS spectrum exhibits bands at $\lambda = 540$ ($\varepsilon = 400$) and 420 nm (1100) which are assigned to d-d and $\sigma(s)$-$d_{x^2-y^2}$ transitions, respectively.

The temperature dependence of the molar magnetic susceptibility (χ_M) between 50 and 300 K is shown in Figure 1.

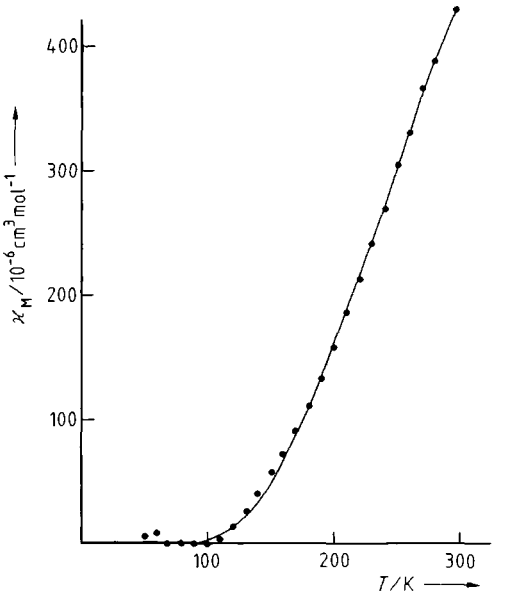


Fig. 1. Experimental and theoretical temperature dependence of the molar magnetic susceptibility (χ_M) of **2**: (•) points corrected for the non-coupled Cu^{II} impurity; (—) theoretical curve [4].

The curve is characteristic of a complex Cu^{II} dimer with very strong intramolecular antiferromagnetic coupling. The singlet-triplet energy difference J determined by a least squares fitting procedure is found to be -630 cm^{-1}[4]. This magnetic behavior is quite similar to that exhibited by the dinuclear complexes of *N,N'*-bis(2-hydroxyethyl)dithiooxamide[3]. **2** contains no COOH and NH protons, as determined by IR spectroscopy. Both the magnetic behavior and the spectroscopic properties of **2** confirm the structure of the dimeric entity shown in the formula.

[4] The observed molar magnetic susceptibility (χ_M) was corrected for diamagnetic contributions (-370×10^{-6} cm^3 mol^{-1}) and for a small proportion of noncoupled Cu^{II} impurity, the molar magnetic susceptibility χ_M of which was assumed to follow the Curie Law $N\beta^2g^2/4kT$. The corrected susceptibility was then fitted using the expression:

$$\chi_M = \frac{2N\beta^2g^2}{kT}\left[3+\exp\left(-\frac{J}{kT}\right)\right]^{-1} + N\alpha$$

g is 2.02 and $N\alpha$ can be neglected. The "agreement factor" defined in [3] is equal to 0.8×10^{-4}.

Crystal Structures of AlI_3, GaI_3 and InI_3—Isotypic Relationship AlI_3/SO_3**

By *Rüdiger Kniep*, Peter Blees,* and *Wolfgang Poll*

Our present state of knowledge of the crystal structures of the "simple" title compounds (and their halogen homologues) is epitomized by the citation in Wells' "Structural Inorganic Chemistry"[1]: "In contrast to crystalline $AlCl_3$ (YCl_3-type structure, Al occupies octahedral holes) $AlBr_3$ has a molecular structure (Al_2Br_6 molecules, Al occupies pairs of adjacent tetrahedral holes). The same type of molecule is found in crystalline $GaCl_3$ and InI_3 with which AlI_3 and GaI_3 are (probably) isostructural". In a communication presented at a conference, held some years earlier[2], it had been stated however that GaI_3 should have an orthorhombic octahedral layer structure, and this statement has so far never been challenged. Since no complete crystal structure analysis of AlI_3 has so far been available we have carried out crystal structure analyses on both GaI_3 and AlI_3, and at the same time have also re-determined[4] the crystal structure of InI_3[3]. The results are collected in Figure 1.

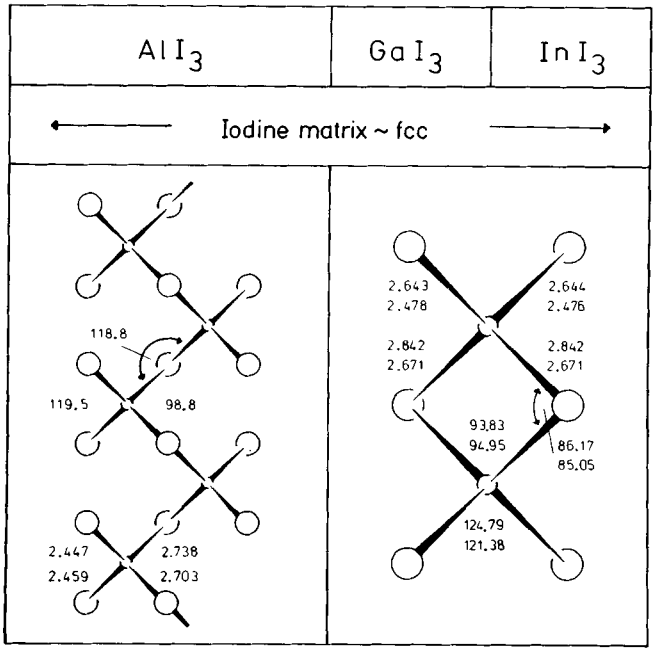

Fig. 1. Structural units in the crystal structures of AlI_3, GaI_3, and InI_3. *AlI_3*: standard deviations 0.009 Å and 0.4°, resp.; angles at Al not listed: 107.2–110.3°.—*GaI_3*: lower numerical values; standard deviations 0.002 Å and 0.07°, resp.; angles at Ga not listed: 108.90–109.76°.—InI_3: upper numerical values; standard deviations 0.002 Å and 0.06°, resp.; angle at In not listed: 107.50–109.33°.

Institut für Anorganische Chemie und Strukturchemie der Universität
Universitätsstr. 1, D-4000 Düsseldorf (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

A feature common to all three structures is the distorted cubic close packed iodine matrix, with the metal atoms accomodated in the tetrahedral holes. GaI_3 and InI_3 are isotypic and contain dimeric molecules M_2I_6. In contrast AlI_3 has a $1/\infty$ chain structure, which is isotypic to the "asbestos-like" SO_3[5]; the concept of expected structural relationships in isoelectronic compounds[6] also proves its use here, when taking into consideration differences in electronegativity and the ratios of atomic or ionic radii.

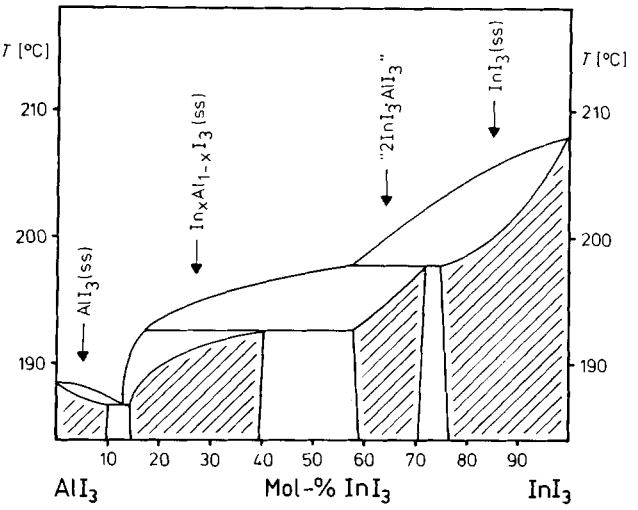

Fig. 2. Phase relationships on the quasi-binary section AlI_3-InI_3.

The structural relationships also correspond to the phase relationships on the quasi-binary sections GaI_3-InI_3 (unlimited mixed-crystal formation with minimum melting point), AlI_3-InI_3 (cf. Fig. 2), and AlI_3-GaI_3 (almost analogous to AlI_3-InI_3). With increasing InI_3 content the dimeric structure $In_xAl_{1-x}I_3$ (ss) is preferred over the chain structure AlI_3 (ss); an ordered superstructure phase "$2\,InI_3 \cdot AlI_3$" seems to occur between the isotypic substitution mixed-crystal phases $In_xAl_{1-x}I_3$ (ss) and InI_3 (ss).

Ullmanns Encyklopädie der technischen Chemie (Ullmann's Encyclopedia of Industrial Chemistry). Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (deceased), *W. M. Weigert* (deceased), and *E. Weise*. Vol. 5: *Analysen- und Messverfahren* (Analytical and Measurement Techniques). Volume editor: *H. Kelker*. Verlag Chemie, Weinheim 1980, 4th edition, xvi, 1010 pp., bound, DM 670.00.

This volume on analytical and measurement techniques which forms part of the general series of Ullmann's Encyclopedia[*] is unusual in its size: whereas the average number of pages of the previous volumes was about 700, this volume, including the German and English subject indexes, contains more than 1000 pages. Yet even at this size the editor has had difficulty in accommodating the wealth of analytical and measurement techniques relevant to the problems of industrial chemistry. The surpassing way in which he has achieved this will be seen in what follows.

Industrial measurement technology, including process analysis, *i.e.* one half of the overall topic, takes up a bare 150 pages. (Control technology was covered in Volume 4.) The present volume is thus predominantly devoted to analysis as such. Apart from the many essentially instrumental analytical methods, various general and fundamental problems and methods are dealt with. This is especially true of the introductory chapter on "Aims and methods of analysis" (25 pp.), which is also concerned with chemical analytical methods; for example in the field of organic chemistry it deals with elementary analysis and functional group analysis. It is emphasized that, despite the very high level of development of physical methods today, chemical methods are still of great importance and in many cases are irreplaceable. The other general chapters deal with digestion methods (27 pages), balances and weighing in the laboratory (8 pages), evaluation of measurements (9 pages), and the use of computers in analysis (24 pages). The instrumental techniques described are distillation (16 pages), chromatographic methods (142 pages, broken down into fundamentals, gas chromatography, thin-layer chromatography, and electrophoresis), structural analysis by crystal diffraction (34 pages), spectroscopic methods (249 pages, broken down into ultraviolet and visible, infrared and Raman spectroscopy, microwave gas spectroscopy, NMR and ESR, atomic absorption spectroscopy, emission spectroscopy, and X-ray spectral analysis), surface studies (58 pages), mass spectrometry (28 pages), electron microscopy (19 pages), polarimetry (16 pages), refractometry (10 pages), electrochemical techniques (34 pages), activation analysis (23 pages), radionuclides in analytical chemistry (8 pages), particle measuring techniques (29 pages) rheometry (23 pages), and thermal calorimetry (18 measuring techniques. All such problems can be very quickly resolved with the aid of the detailed (14 pages) subject index.

As is customary for Ullmann's Encyclopedia, the authors of the individual chapters are recognized practical experts. The overall appearance of this volume meets the quality standards to which we have grown accustomed. The editor states that his aim has been to provide a guide to the subject, and this must rank as a definite understatement. The reviewer would rather call this volume a standard work (over and above its position within the narrower framework of the encyclopedia) that will prove indispensable to any chemist who needs to make use of the techniques of instrumental analysis.

Ulfert Onken [NB 561 IE]

Spectroscopy in Heterogeneous Catalysis. By *W. N. Delgass, G. L. Haller, R. Kellerman.* and *J. H. Lunsford,* Academic Press, New York 1979, x, 341 pp., 117 figs., bound, $ 35.00.

Spectroscopic methods for the study of solid surfaces and states of chemisorption are currently in a state of such rapid development, both in numbers and in refinement, that it is often far from easy to select and use the most suitable and effective method for a given problem. This is where the present compilation should help those working in research or industry; at the same time it should act as a spur to fresh research and as an introduction to advanced students. The topics covered are infrared spectroscopy and Raman spectroscopy *(Haller),* diffuse reflection spectroscopy, including photoacoustics *(Kellerman),* Mössbauer spectroscopy *(Delgass),* electron spin resonance and nuclear magnetic resonance *(Lunsford),* and X-ray photoelectron spectroscopy *(Delgass).* With the exception of the X-PES, the methods chosen can thus be applied under the conditions of temperature and pressure usual for heterogeneous catalysis.

Each of the seven chapters comprises between 30 and 50 pages and begins with a short introduction outlining the ranges, conditions of application, and limitations of the method. There follow an introduction into the theoretical fundamentals, a presentation of the experimental layout and instrumentation, and a report on characteristic applications illustrated with examples selected from the literature. A distinction is always made between information on catalyst structures in bulk, on the surface, and on chemisorbed structures or complexes. Apart from the static state of these structures particular stress is laid upon the deter

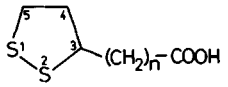
The Hydrophobic and Metal-Ion Coordinating Properties of α-Lipoic Acid— An Example of Intramolecular Equilibria in Metal-Ion Complexes

By Helmut Sigel*

Hydrophobic interactions as structure determining factors for macromolecules are well-known in biochemistry. Considerably less recognized is the fact that these low-energy interactions may also determine the structure of low-molecular species. The same applies for weak ligand-metal ion interactions. That both these factors may lead to intramolecular, concentration-independent equilibria between isomeric metal-ion complexes is demonstrated with α-lipoic acid as ligand. This cofactor offers metal ions two different binding sites: the carboxylate group and the disulfide linkage. The carboxylate group dominates the coordinating properties of this ligand towards the biologically important metal ions, but a disulfide-metal ion interaction is still possible and under sterically favorable conditions may become very important; this could also be true under enzymic conditions where the carboxyl group is no longer free but amide-linked to the protein. Furthermore, due to the valeric acid side chain, the lipoyl moiety is ideally suited to undergo hydrophobic ligand-ligand interactions in mixed-ligand complexes. Such hydrophobic interactions seem to be ideal to allow migration, *e.g.*, of the 14 Å long lipoyllysyl moiety, and also to facilitate the correct 'fixation' at the surface of the enzyme.

1. Introduction

α-Lipoic acid (1,2-dithiolane-3-valerie acid) — also known as 6,8-dithiooctanoic acid — is widely distributed in animals and plants[1]. It was discovered about 35 years ago; shortly thereafter its growth-promoting effect on certain microorganisms was recognized[2–4] and its chemical structure established[5,6] (Fig. 1)[**]. α-(+)-Lipoic acid[7] is an important protein-bound coenzyme, which *e.g.* occurs as the transacylating cofactor of several multienzymic α-keto acid dehydrogenase complexes[8–10]. Evidence that lipoic acid plays an important role in oxidative phosphorylation has also been given[11].



n = 4 : Lipoic acid (LP)
n = 2 : Bisnorlipoic acid (BL)
n = 0 : Tetranorlipoic acid (TL)

Fig. 1. Structure of α-lipoic acid and two of its analogs.

Enzyme systems that catalyze the oxidative decarboxylation of pyruvic and α-ketoglutaric acids mediated by lipoic acid have been isolated from microbial and eukaryotic cells as functional units with molecular weights in the millions[8]. For example, the pyruvate dehydrogenase multienzyme complex has been isolated from *Azotobacter, Strepto-*

coccus, yeast, potatoes, and the hearts of mammals[1,9]. The corresponding enzyme system isolated from *Escherichia coli* and several organs of mammals has been especially well studied[8-10]. Fascinating in this connection is the question of the organization of the structure and of the reaction sequence in such a multienzyme complex. The appearance of hydrophobic interactions or the participation of labile metal ions seems possible, at least as a hypothesis.

The kinetics and regulation of pyruvate dehydrogenase kinase and pyruvate dehydrogenase phosphatase from bovine kidney and heart are partly known.[8]. Pyruvate is the substrate for pyruvate dehydrogenase and also inhibits noncompetitively the kinase which functions as regulatory subunit of pyruvate dehydrogenase. The half-maximal activity of the phosphatase is reached when the concentration of Mg^{2+} is *ca.* 2 mM; this is approximately 100 times the concentration of $Mg(ATP)^{2-}$ (*ca.* 0.02 mM) which is required to achieve half-maximal activity of the kinase[8]. Ca^{2+} is also required in addition to Mg^{2+} for pyruvate dehydrogenase phosphatase activity[12,13]. In the presence of Ca^{2+} the phosphatase binds to the transacetylase, thereby facilitating the Mg^{2+}-dependent dephosphorylation of the phosphorylated pyruvate dehydrogenase[12]. Half-maximal activity of the phosphatase is observed at a free Ca^{2+} concentration of about 1 μM. It is possible that Ca^{2+} serves as a bridge between the phosphatase and the transacetylase. Alternatively, Ca^{2+} may bind to either the phosphatase or the transacetylase, producing a conformational change that facilitates binding of the phosphatase[8]. In any case, it is clear that metal ions have some importance in these lipoic acid dependent systems.

In this connection it is also of interest that heavy-metal poisoning has been treated with lipoic acid[1,14,15], which indeed forms complexes, *e.g.* with Hg^{2+} [16,17]. The inhibition of microsomal-membrane ATPase of pigeon brain by Cu^{2+} is also reversed by lipoic acid[18]. These observations, the widespread occurrence of lipoic acid[1,7,9] and of metal ions[19] in biological systems, as well as the therapeutic use of this disulfide, stimulated investigations on the basic coordinating properties of this coenzyme.

From the structure of α-lipoic acid given in Figure 1 it is evident that this molecule has two possible binding sites for metal ions: the carboxylate group and the disulfide bridge. The coordination tendencies of these two groups in solution are now summarized and discussed in relation to their biochemical significance. Where appropriate, intramolecular hydrophobic ligand-ligand interactions in ternary complexes will also be considered.

2. Carboxylate Group: Basicity and Formation of Metal-Ion Complexes

The acidity constant of α-lipoic acid [Eq. (1)] and the stability constants of the corresponding binary complexes [Eq. (2)] have been determined by potentiometric pH-titrations (25 °C).

$$HL \rightleftharpoons H^+ + L^- \qquad K^H_{HL} = [HL]/([H][L]) \qquad (1)$$

$$M^{2+} + L^- \rightleftharpoons ML^+ \qquad K^M_{ML} = [ML]/([M][L]) \qquad (2)$$

The acidity constants obtained[20] in 50% aqueous dioxane (v/v; $I = 0.1$, $NaClO_4$) for (±)-lipoic acid ($pK^H_{HL} = 6.37$), (±)-bisnorlipoic acid (6.05), and (±)-tetranorlipoic acid (4.84) show that the acidity increases with decreasing chain length. This is in accord with the results obtained for simple carboxylic acids: valeric ($pK^H_{HL} = 6.44$)[21] < propionic (6.29)[22] < acetic (6.01)[22] ≪ formic acid (4.75)[22]. The electron withdrawal by the disulfide moiety is especially evident from a comparison of the acidity constants of acetic acid (6.01) and (±)-tetranorlipoic acid (4.84)[20]; the latter is considerably more acidic[23].

The stability of the binary 1:1 complexes of Mn^{2+}, Cu^{2+}, Zn^{2+} (cf.[20]), Cd^{2+}, or Pb^{2+} (cf.[24]) with α-lipoate is solely governed by the basicity of the carboxylate group. This is indicated by the fact that a straight line results when $\lg K^H_{HL}$ values of a series of complexes with structurally related ligands are plotted against the pK^H_{HL} values of the ligands (Fig. 2)[26,27]. It is evident that the α-lipoate complexes fit the straight "reference lines" of the binary complexes, ML^+ [Eq. (2)], of monodentate carboxylates: formate, acetate, propionate, and valerate[20-22]. As expected, there is no significant difference between the data for the (+)- and (−)-isomers of α-lipoate, or its (±)-mixture[20]. Obviously, if a metal-ion interaction with the disul-

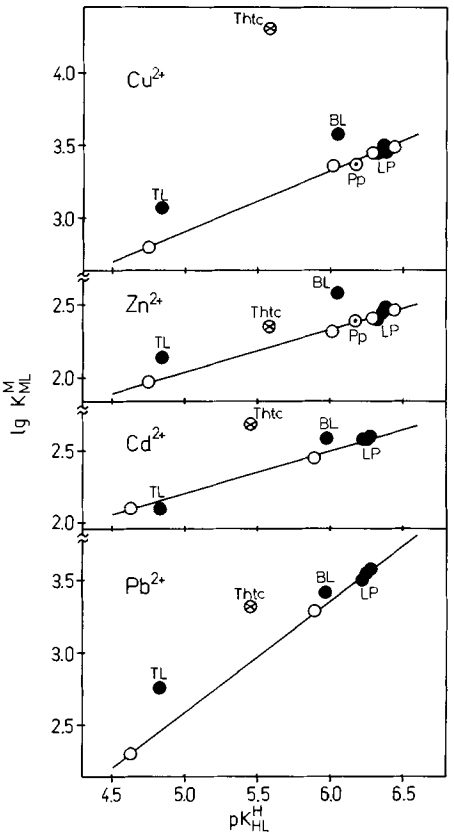

Fig. 2. Relationship between $\lg K^M_{ML}$ [Eq. (2)] and pK^H_{HL} [Eq. (1)] for the binary ML^+ complexes of α-lipoate (LP; the three points refer to (+)-, (−)-, and (±)-LP), (±)-bisnorlipoate (BL) and (±)-tetranorlipoate (TL) (●), or tetrahydrothiophene-2-carboxylate (Thtc, ⊗) and 3-phenylpropionate (Pp, ⊙; see Section 5 and Fig. 3). The reference lines are due to the corresponding complexes of the monodentate carboxylates (○) (from left to right): formate, acetate, propionate, and valerate. The plotted data ($I = 0.1$, $NaClO_4$, or $NaNO_3$; 25 °C; 50% aqueous dioxane) for the Cu^{2+} and Zn^{2+} complexes ($NaClO_4$) are taken from Table 1 of [20] and Table 2 of [25], and for the Cd^{2+} and Pb^{2+} complexes ($NaNO_3$) from Table 1 of [24].

fide moiety of α-lipoate should occur, it does not significantly increase complex stability.

However, the metal-ion complexes of the two chain-shortened lipoate analogs and of tetrahydrothiophene-2-carboxylate are clearly more stable, at least in a number of cases (Fig. 2), than expected on the basis of the basicity of the carboxylate groups alone. Here, the disulfide and the thioether groups participate in complex formation; the stability of the resulting chelates is discussed in Section 3.2.

It should be pointed out that the pK-value [Eq. (1)] of lipoic acid and the lg K-values [Eq. (2)] of the corresponding $M(LP)^+$ complexes are approximately 1.5 lg units smaller in aqueous solution. This can be estimated from the following data for acetic acid and its complexes ($I=0.1$; 25 °C). In 50% aqueous dioxane it holds that[20-22]:

$$pK^{H}_{H(Ac)} = 6.01 \pm 0.01,$$

$$\lg K^{Cu}_{Cu(Ac)} = 3.36 \pm 0.03, \quad \lg K^{Zn}_{Zn(Ac)} = 2.32 \pm 0.03$$

and in aqueous solution[28]:

$$pK^{H}_{H(Ac)} = 4.54 \pm 0.01,$$

$$\lg K^{Cu}_{Cu(Ac)} = 1.81 \pm 0.02, \quad \lg K^{Zn}_{Zn(Ac)} = 0.86 \pm 0.06.$$

The constants for (±)-lipoic acid in 50% aqueous dioxane are[20]:

$$pK^{H}_{H(LP)} = 6.37 \pm 0.01,$$

$$\lg K^{Cu}_{Cu(LP)} = 3.50 \pm 0.02, \quad \lg K^{Zn}_{Zn(LP)} = 2.47 \pm 0.02.$$

It appears safe to predict that the stability of the complexes of lipoate in water will also be solely determined by the basicity of the carboxylate group; in fact, this has already been demonstrated in the case of (+)-biotinate[29]. That the stability of complexes formed with O ligands increases as the water activity decreases is a general experience, and probably of significance for biological systems[30].

In conclusion, the dominance of the metal-ion binding properties of the carboxylate group does not mean that the disulfide moiety of lipoate does not have coordinating capacity, but only that this is not apparent under the conditions described. Moreover, it must be noted that coordination of a metal-ion to carboxylate could play a role only during the biosynthesis and metabolism[7,31-34] of lipoic acid, but not during its enzymic action since then the lipoyl moiety is amide-linked[1,8] to the enzymes and hence no longer available for coordination to a metal-ion.

3. Disulfide Coordination

3.1. Stability of Disulfide Complexes

The stability of complexes of this type with biologically important metal ions is expected to be small, but the determination of the stability constants of such weak complexes recently became possible by ^{1}H-NMR spectroscopy[35]: diamagnetic metal ions upon coordination induce a downfield shift of the resonance signals of nearby protons. The simplest ligand for such studies, which is also soluble enough in water, is dimethyl disulfide (Dmds). The stability constants of some of its complexes, according to Eq. (3), are given in Table 1.

$$M^{n+} + L \rightleftharpoons ML^{n+} \qquad K^{M}_{ML} = [ML]/([M][L]) \tag{3}$$

Table 1. Comparison of the stability of several dimethyl disulfide (Dmds) complexes with that of the corresponding dimethyl sulfide (Dms) complexes (34 °C) [a].

M^{n+}	$\lg K^{M}_{M(Dmds)}$ (D_2O)	$\lg K^{M}_{M(Dms)}$ (H_2O)	I [b]
Ca^{2+}	−1.4	−1.6	2-4.5 ($NaClO_4$)
Zn^{2+}	−1.4	−1.4	2-4.5 ($NaClO_4$)
Cd^{2+}	−1.4	−0.3 ± 0.2	2-4.5 ($NaClO_4$)
Pb^{2+}	−1.5	−1.05 ± 0.2	2-3 ($NaNO_3$)
Ag^{+}	2.01 ± 0.09	3.7 ± 0.3	0.1 ($NaNO_3$)

[a] Taken from Table 1 in [35]. Most of the given stability constants are rough estimations; unless mentioned, the lower error limit for the values is −0.5 and the upper limit +0.2 lg units. [b] The primary electrolyte is given in parenthesis.

Indeed, the stability of the complexes with the biologically important metal ions Ca^{2+} and Zn^{2+} is very low; the same is true for the heavy metal ions Cd^{2+} and Pb^{2+}.

Of course, soft[36] metal ions like Cu^+, Ag^+, or Hg^{2+} have a greater tendency to coordinate with the disulfide group, and crystal structures of disulfides, *e.g.* with Cu^+, have been determined[37,38], although coordination of these metal ions often causes cleavage of the disulfide bond[39,40]. In order to determine the stability constant of the $Ag(Dmds)^+$ complex in Table 1, the pD-value of the D_2O solution was adjusted to about 2 with DNO_3 so as to prevent cleavage of the disulfide link, a reaction which occurs at higher pH[41]. Under the conditions used, the Ag^+-Dmds solution was stable for 24 hours[35]. Attempts to study the Hg^{2+}-Dmds system failed, since a white precipitate formed[35]; this could be the nitrate salt of an $Hg(Dmds)_x^{2+}$ complex or the result of fission of the disulfide bond[42]. Furthermore, Hg_2^{2+} seemed to undergo disproportionation in the presence of dimethyl disulfide[35], in accord with earlier results[43].

All these results[35] agree well with those obtained for lipoic acid[17]: addition of lipoic acid in 95% ethanol to $Hg(NO_3)_2$ in dilute HNO_3 results in immediate formation of a heavy white precipitate which was assigned the formula $Hg(LP)(OH)_2$. From IR measurements it was concluded that the carboxylate group of lipoic acid in this compound is protonated and that Hg^{2+} coordinates to the disulfide moiety. With Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} and Pb^{2+}, lipoic acid did not form isolable solids[17]; photolytic or thermal cleavage of the disulfide link was necessary before any isolable products with these cations were formed. All these metal ions, including Hg^{2+}, form insoluble solids with dihydrolipoic acid[17].

Comparison of the stability constants listed in Table 1 reveals[35] that the ligating properties of the disulfide and the thioether groups appear to be about the same for hard metal ions (*e.g.* Ca^{2+} [36]), while for several of the 'borderline' metal ions (*e.g.* Cd^{2+} [39,44] and Pb^{2+}) they are somewhat different: this means the disulfide complexes are less stable than the corresponding thioether complexes (despite the fact that the disulfide complexes with two S atoms are

statistically favored). With the soft Ag^+ these properties are even more evident: the Ag^+ complexes of dimethyl disulfide and dimethyl sulfide differ in stability by a factor of 50. This may indicate that the S_2R_2 group is somewhat less soft than the SR_2 moiety.

It may be concluded that the results shown in Table 1 are in accord with what might have been predicted[35]. Due to the $p_\pi - d_\pi$ interaction in a disulfide[1,45-47] the electrons are less available for coordination than at the thioether sulfur, hence complexes with S_2R_2 are expected to be somewhat less stable than those with SR_2.

The results described can also be viewed as a further example of the so-called α-effect, *i.e.* the observation that OH^-, for example, is a better base than OOH^-, or NH_3 than NH_2NH_2, and indeed this is also true for $S(CH_3)_2$ and $S_2(CH_3)_2$[48]. The disulfide group is less basic than the thioether sulfur, which is itself an extremely weak base ($pK_a = -6.8$)[49]. Estimations of basicity suggested the order $(CH_3)_2S > (CH_3)_2S_2 \approx CH_3SH$[48], which indicates $pK_a < -6.8$ for the disulfide moiety.

Of further interest in the present connection is a comparison of the coordinating properties of the 1,2-dithiolane moiety and those of the thiolane (tetrahydrothiophene) group. This can be carried out by comparing the stability of, for example, the Cu^{2+} complexes of tetranorlipoate and tetrahydrothiophene-2-carboxylate: as shown in Figure 2, the stabilities are respectively around 0.23 and 1.16 lg units greater than expected from the basicity of the carboxylate group (reference line). Hence, the coordination tendency of the thiolane ring is about 8-fold greater than that of the 1,2-dithiolane moiety. This indicates that this result and the corresponding observations for other metal ions (see Table 2 of Section 3.2) are in good accord with the conclusions of Table 1.

The $p_\pi - d_\pi$ interaction in disulfides is most pronounced in simple aliphatic disulfides, where the dihedral angle, *i.e.* the angle between the planes defined by RSS and SSR, is *ca.* 90° [45-47]. The SS bond length depends therefore on this angle[50,51]: for $\sphericalangle CSSC \approx 90°$ the bond length is *ca.* 202 pm, and for $\sphericalangle CSSC \approx 0°$ it is *ca.* 210 pm[52]. In the 1,2-dithiolane ring the same angle is only about 27° [1] to 35° [53], and the S—S bond length is 205.3 pm[53], *i.e.* the $p_\pi - d_\pi$ interaction is somewhat diminished[1], but the electron density available for the coordination of the metal ion at one of these sulfurs is still less than at the sulfur of the tetrahydrothiophene ring, and therefore is in agreement with the observed complex stabilities[*].

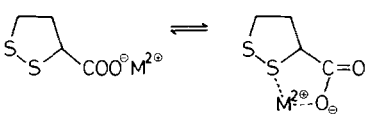
For the interaction between hard metal ions and thioethers it is known[29,44,59] that a decrease in the activity of water, *e.g.* on proceeding from water as solvent to 50% aqueous ethanol, promotes formation of the corresponding complex. The same may be surmised for the disulfide-metal ion interaction. For biological systems, this is of interest, because one may expect that at the surface of a protein the activity of water is reduced and thus a metal ion-disulfide interaction should be favored.

3.2. Formation of Chelates Involving the Disulfide Group

It is evident from Section 3.1 that the complexes formed between disulfides and those hard or 'borderline' metal ions which are important in biological systems, such as Mg^{2+}, Ca^{2+}, Mn^{2+}, Zn^{2+}, or Cu^{2+} are not very stable. However, this must not lead to the conclusion that these interactions are unimportant since, as already indicated, under conditions of reduced water activity, complex stability may increase and, more importantly, a weak interaction is enough to create specific structures, as will now be shown.

In α-lipoate the disulfide bridge and the carboxylate group are too far apart to expect a stable chelate, and this is in accord with the results of Section 2. With the chain-shortened catabolites[31,34] bisnorlipoate and tetranorlipoate (Fig. 1) the situation is different because here seven- and five-membered chelates could be formed. Indeed, the Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} complexes of (±)-tetranorlipoate and (±)-bisnorlipoate are all, with the single exception of $Cd(TL)^+$, more stable by 0.08 to 0.31 lg units than expected from the basicity of the carboxylate group of these ligands (Fig. 2). This increased stability demonstrates that the disulfide group participates in complex formation and that chelates are formed. A comparison of this increase in stability with that of the corresponding tetrahydrothiophene-2-carboxylate complexes (Fig. 2) shows that, in general, the thioether interaction is more favorable. This, however, also indicates—without any calculation being required—that the extent of chelate formation differs in these complex systems.

This implies that an intramolecular equilibrium between an 'open' and a 'closed' form exists. This is illustrated using the example of the complexes with tetranorlipoate in Eq. (4):



(4)

If the chelated isomer in which an O of the carboxylate group and an S of the disulfide moiety are coordinated is depicted as $M(L)^+_{O,S}$, and the simple carboxylate-coordi-

[*] One might be tempted to speculate that in the tetrahydrothiophene moiety the sulfur is hybridized in a more sp^3-like manner (corresponding to angles of *ca.* 109°) than S2 in the 1,2-dithiolane ring of lipoic acid. However, such a supposition would not be in agreement with the results of crystal structure determinations, where it was found that the angle around the sulfur in the tetrahydrothiophene ring (of the biotin moiety) [54] is 89.4° and the angle around the corresponding S2 in the 1,2-dithiolane ring of lipoic acid [53] is 92.8°. Hence, assuming that the angles are not different in solution, one cannot rationalize why the coordination tendency of the thioether is favored over the disulfide group. Nevertheless, it should also be added that in lipoic acid the angle at S1 is 95.5°, while at S2 it is 92.8° [53]. Hence, from the view of an orientated electron density (*i.e.* more sp^3-like) S1 should be somewhat favored [for steric reasons, only the somewhat less suitable S2 is accessible for chelate formation in tetranorlipoate (see also Section 3.2)]. In agreement with this, and possibly further favored by the steric conditions, *i.e.* the greater distance to the side chain, is the observation that S1 is the preferred reaction site in electrophilic reactions, where the steric restrictions present in chelating reactions are not imposed. For example, chemical oxidation of lipoic acid and lipoate metabolism in *Pseudomonas putida* occur preferably at S1 to form the monoxide [34]; similarly, acetylation [55] and photoreductive acylation [56, 57] at position 1 are also favored. This contrasts with a natural enzymic system [55—57] from which 6-acetyl-thio-8-mercaptooctanoic acid was isolated (see, *e.g.* also [58]); hence in enzymic systems other effects guide the reaction.

nated isomer as $M(L)_O^+$, the position of Eq. (4) may be described by the corresponding equilibrium constant K_{Ch}:

$$K_{Ch}=[M(L)_{O,S}]/[M(L)_O] \quad (5)$$

This intramolecular equilibrium constant is dimensionless and therefore independent of the absolute concentration of ML^+ [Eq. (2)]. As shown earlier[35,60], K_{Ch} may be calculated from Eq. (6),

$$K_{Ch}=\frac{K^M_{ML}}{K^M_{M(L)O}}-1 \quad (6)$$

where K^M_{ML} [Eq. (2)] is the experimentally determined constant of the isomeric complex system considered, and $K^M_{M(L)O}$ is the stability constant for the formation of the simple carboxylate-coordinated species. The crucial parameter is

$$\lg\Delta=\lg K^M_{ML}-\lg K^M_{M(L)O} \quad (7)$$

$\lg\Delta$ may be estimated from the difference between the experimentally determined value of $\lg K^M_{ML}$ for a given complex system and the corresponding "reference line" in Figure 2. Once K_{Ch} is known, the amount of $M(L)^+_{O,S}$ in Eq. (4) may also be easily obtained.

Table 2. Extent of chelate formation in binary metal-ion complexes of carboxylate ligands (L^-) with an additional sulfide or disulfide residue (in 50% aqueous dioxane; $I=0.1$; 25 °C) [a].

L^-	M^{2+}	$\lg K^M_{ML}$ [Eq. (2)]	$\lg\Delta$ [Eq. (7)]	K_{Ch} [Eq. (5)]	Amount of $M(L)^+_{O,S}$ [b] [%] [Eq. (4)]

[a] The entries for the first two ligands are the slightly modified results from [35]. The other results were calculated from the data published in [20] and [24]; see also Fig. 2. The error limits given for $\lg K^M_{ML}$ are *three* times the standard deviation of the mean value. [b] The error limits were calculated from the given errors for $\lg K^M_{ML}$. The values given in parenthesis were calculated by adding 0.02 log units to the errors given with $\lg K^M_{ML}$; this accounts for a possible error in the 'reference lines' which is estimated to be ≤0.02 lg units (possibly apart from the Mn^{2+} systems), because this line is based on several independent systems (Fig. 2). Hence, the values given in parenthesis can be considered as upper error limits, which might still be justified.

The results calculated for the intramolecular equilibrium constant, K_{Ch}, and the amount of 'closed' isomer $M(L)^+_{O,S}$ for the tetrahydrothiophene-2-carboxylate, (±)-tetranorlipoate, and (±)-bisnorliponate complex systems are listed in Table 2. It is evident that the percentage of the chelated isomer depends strongly on the metal ion involved: the whole range from traces to amounts close to 100% is covered. These results clearly demonstrate that the disulfide moiety does not only participate in complex formation, but *may even fix a structural arrangement* if the sulfur atom is in a sterically favorable position.

A comparison of the complexes with the sterically very similar ligands tetranorlipoate and tetrahydrothiophene-2-carboxylate shows that in the M^{2+}-Thtc$^-$ systems the amount of chelated isomer $M(L)^+_{O,S}$ is usually larger than in the M^{2+}-TL^- systems, thus confirming the somewhat better coordinating properties of thioethers compared to the disulfides (cf. Section 3.1). In addition, closer examination reveals the similar coordination tendency of Zn^{2+} towards SR_2 and S_2R_2, or the tendency of Cd^{2+} to favor SR_2. Surprisingly, the necessity of forming a seven-membered chelate does not significantly disfavor the participation of the disulfide group in bisnorlipoate complexes, compared with those of tetranorlipoate where a five-membered chelate can be formed.

Summarizing, the coordinating properties of the disulfide group favor soft metal ions, whereas their tendency to coordinate with the biochemically important hard or 'borderline' metal ions is obviously slight and apparently rather unspecific (Table 1). However, it must be emphasized that these seemingly negligible coordinating properties may lead to enhanced complex formation with ligands which have these weakly coordinating groups located close to stronger binding sites (Table 2). The most important point with regard to biological systems is that equilibration between isomers of certain complexes may be attained rather easily; a factor which could well be a key to the observed selectivity.

4. Hydrophobic Interactions in Mixed Ligand Complexes

4.1. Stability of Ternary Complexes

For the ternary complexes formed by Cu^{2+} or Zn^{2+} and 2,2′-bipyridyl (bpy) and α-lipoate or one of its chain-shortened derivatives (Fig. 1), a similar picture to that described for the binary metal ion systems (Section 2) is obtained [Eq. (8)] to a first approximation.

$$M(bpy)^{2+}+L^- \rightleftharpoons M(bpy)L^+ \quad (8)$$

$$K^{M(bpy)}_{M(bpy)L}=[M(bpy)L]/([M(bpy)][L])$$

Plots of $\lg K^{M(bpy)}_{M(bpy)L}$ against pK^H_{HL} for the ternary systems with the simple carboxylates formate, acetate, *etc.* furnish "reference lines" (Fig. 3); the values of many other systems lie relatively close to this line (usually about 0.3 lg units above it), indicating that the stability of these complexes is also determined to a large part by the basicity of the carboxylate group of the ligands.

The fact that in Figure 3 the reference line of the ternary Cu^{2+} complexes lies somewhat above the line of the binary complexes, while in the Zn^{2+} systems it lies somewhat below, is in accord with general experience[28,61-64]. In the absence of steric restrictions a *positive* value[65] for $\Delta\lg K_{Cu}$ [Eq. (9)] is obtained for the combination of a heteroaromatic N base and an O donor ligand with Cu^{2+}, *i.e.*

the mixed ligand complex [Eq. (8)] is somewhat more stable than the binary one [Eq. (2)]:

$$\Delta \lg K_M = \lg K^{M(bpy)}_{M(bpy)L} - \lg K^{M}_{ML} \quad (9)$$
$$= \lg K^{ML}_{ML(bpy)} - \lg K^{M}_{M(bpy)}$$

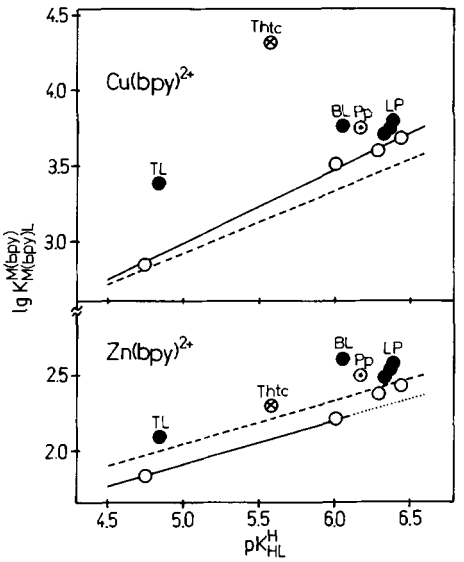

Fig. 3. Relationship between $\lg K^{M(bpy)}_{M(bpy)L}$ [Eq. (8)] and pK^{H}_{HL} [Eq. (1)] for the ternary M(bpy)L^+ complexes of α-lipoate (LP; the three points refer to (+)-, (−)- and (±)-LP), (±)-bisnorlipoate (BL) and (±)-tetranorlipoate (TL) (●), or tetrahydrothiophene-2-carboxylate (Thtc, ⊗) and 3-phenylpropionate (Pp, ⊙; see Section 5 and Fig. 2). The reference lines are due to the corresponding complexes of the monodentate carboxylates (○) (from left to right): formate, acetate, propionate, and valerate; for Zn(bpy)L^+ the reference line is only drawn through the data of formate and acetate (solid part) and then tentatively extrapolated (dotted part; cf. Section 4.2 and 4.3). The broken lines refer to the binary 1:1 complexes (Fig. 2) and are given for comparison. All the data plotted ($I = 0.1$, $NaClO_4$; 25 °C; 50% aqueous dioxane) are taken from Tables 1 and 2 of [20] and Table 2 of [25].

The same ligand combination with Zn^{2+} and other metal ions of the second half of the 3d series also leads to an enhanced stability, compared with the statistical expectation[66], but usually to a less pronounced one[28,61-64].

From the data plotted in the lower part of Figure 3 it is evident that the values for the ternary Zn(bpy)$^{2+}$ complexes with propionate and valerate, because of their enhanced stability, deviate markedly from the reference line of the corresponding complexes with formate and acetate. Similarly, for the ternary Cu(bpy)$^{2+}$ complexes of propionate and valerate a slight stability enhancement is indicated by the increased slope of the reference line (upper part of Fig. 3). The ternary complexes of both metal ions with α-lipoate and 3-phenylpropionate are *ca.* 0.2 lg units more stable than would be expected from the basicity of the carboxylate group of these ligands. Since all of these carboxylate ligands have no, or at least no easily accessible, additional binding sites, the slight but significant stability increase in the ternary lipoate and aliphatic carboxylate complexes can *only* be attributed to an intramolecular hydrophobic interaction within the mixed ligand complexes between the aromatic 2,2'-bipyridyl and the aliphatic residues of the carboxylate ligands.

For bisnorlipoate and tetranorlipoate the situation is clearly more complicated, since the disulfide groups now also become available for coordination, as is known from the corresponding binary complexes (Section 3.2). The stability and structure of the ternary complexes of these ligands will therefore be discussed separately in Section 5.

4.2. Further Evidence for Intramolecular Hydrophobic Ligand-Ligand Interactions

It is now well established that aromatic-ring stacking and hydrophobic interactions between aromatic and aliphatic groups[67] may be promoted by the formation of a metal-ion bridge between these groups, provided that suitable metal binding sites are also available[64,68-70]. Aromatic-ring stacking within mixed ligand complexes has not only been shown to occur in solution[25,64,71-75] but also in the solid state[76-79]. For the complexes considered here it is worthwhile to point out that intramolecular ligand-ligand interactions also occur in the ternary complexes of Zn(phen)$^{2+}$, or Cu(phen)$^{2+}$ and valerate[80], as indicated from the corresponding stability data.

An ideal method to establish such hydrophobic interactions more directly is ^{1}H-NMR shift measurements. Protonation or coordination of a metal ion shifts the signals of the ligand protons close to the binding site *downfield*. However, in a complex in which the aliphatic side-chain of a carboxylate is located above or below the plane of an aromatic ring, the signals of the aliphatic protons should be shifted *upfield*, relative to those of the free carboxylate, due to the ring current of the aromatic system[81]. Using NMR spectroscopy the coordination, *e.g.* of the diamagnetic Zn^{2+} (cf. also Section 3.1), and especially the ligand-ligand interaction in a ternary complex containing one ligand with an aromatic group and another with an aliphatic residue can be studied.

It is obvious that the extent of the intramolecular hydrophobic interaction in the Zn(bpy)L^+ and Zn(phen)L^+ ter-

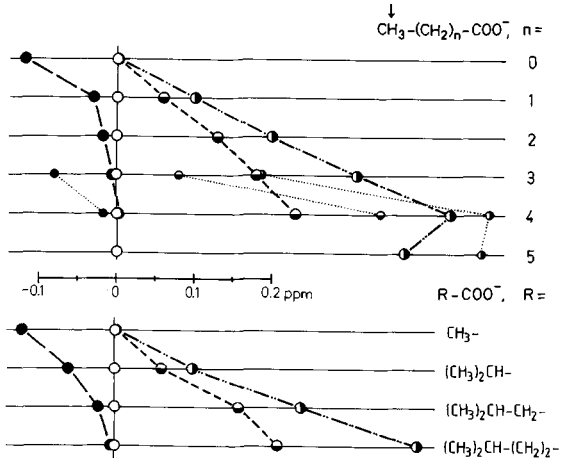

Fig. 4. Up- and down-field shifts of the terminal methyl group(s) in the ^{1}H-NMR spectra of straight-chain (upper part) and of branched-chain aliphatic carboxylates (lower part) for the Zn^{2+} (●), Zn(bpy)$^{2+}$ (◒), or Zn(phen)$^{2+}$ (◑) coordinated carboxylate ligands, relative to the resonance position of the uncoordinated carboxylates (○). For pentanoate (valerate, n = 3), hexanoate (n = 4) and heptanoate (n = 5) the resonance position of the methylene group adjacent to the terminal methyl group is also shown (smaller symbols, dotted lines). Extention of the two series was prevented by ligand insolubility. The measurements were carried out in H_2O at 35 °C. The plotted values are from [69]. Upfield shifts are positive, downfield shifts negative.

nary complexes should be dependent on the length and possibly also on the volume of the aliphatic residue of the carboxylate ligand. The results of NMR spectroscopic measurements of these complexes[69] are summarized in Figure 4: the effect which the coordination of Zn^{2+}, $Zn(bpy)^{2+}$, or $Zn(phen)^{2+}$ has on the aliphatic residue of the carboxylate ligands is quantified by plotting the *relative* position of the signal of the terminal methyl group(s) of the ligands as a function of Zn^{2+}, $Zn(bpy)^{2+}$, and $Zn(phen)^{2+}$. As expected, Zn^{2+} leads to a downfield shift and the shift difference decreases with increasing distance between the methyl group and the site of coordination. Actually, the effect is large only with acetate and falls off rapidly with increasing chain length, being already small for four-carbon chains (butyrate and 3-methylbutyrate) and negligible for longer chains. However, the upfield shift caused by $Zn(bpy)^{2+}$ and by $Zn(phen)^{2+}$ increases rapidly with increasing chain length. The larger upfield shifts due to $Zn(phen)^{2+}$ are in agreement with the larger π system of 1,10-phenanthroline and thus its larger ring current, compared to that of 2,2'-bipyridyl.

In pentanoate (valerate; n = 3 in Fig. 4), the resonance signal of the methylene group adjacent to the terminal methyl group is also shifted upfield by $Zn(bpy)^{2+}$ and $Zn(phen)^{2+}$, although less than the methyl signal itself (Fig. 4). For hexanoate (n = 4 in Fig. 4) the shifts of the methylene group adjacent to the methyl group are already larger for both ternary complexes, and for heptanoate (n = 5) $Zn(phen)^{2+}$ shifts the signal of the methylene group significantly more than the signal of the methyl group, but the signals of both groups are now shifted less than those of hexanoate. For the structure of these ternary complexes with the linear carboxylates this suggests that the "best fit" probably occurs for $Zn(phen)^{2+}$ with hexanoate and for $Zn(bpy)^{2+}$ with valerate or hexanoate[69]. A tentative structure of such a ternary complex is shown in Figure 5 for $M(bpy)(valerate)^+$ complexes.

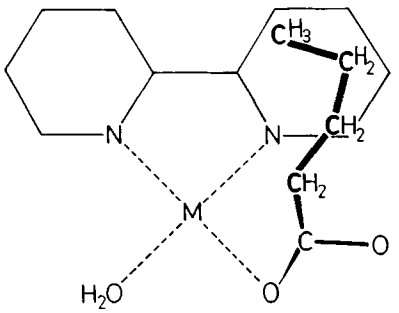

Fig. 5. Possible (schematic) structure of $M(bpy)(valerate)^+$ for the isomer with the hydrophobic ligand-ligand interaction between the alkyl residue of valerate and the aromatic ring system of 2,2'-bipyridyl.

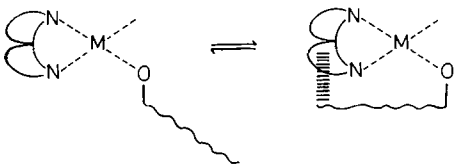
It is interesting to note[69] that the upfield shift of the branched-chain carboxylates by $Zn(bpy)^{2+}$ and by $Zn(phen)^{2+}$ is similar to, but somewhat higher than that of the linear carboxylate of the same chain length (Fig. 4). The reason for this is probably that a somewhat higher proportion of the complex exists in the 'closed' form (see Section 4.3) due to the increased hydrophobicity of the isopropyl moiety (compared with an ethyl group).

It is possible by ^{1}H-NMR measurements to show that the aliphatic residues of such carboxylate ligands interact with 2,2'-bipyridyl and 1,10-phenanthroline also in the *absence* of metal ions. However, as expected, the adduct formation is very weak and stability constants could only be estimated[69]: $K^{(bpy)}_{(bpy)L} \simeq 1\ M^{-1}$ and $K^{(phen)}_{(phen)L} \simeq 2\ M^{-1}$ (in water). Similar results were obtained for the interaction between the isopropyl residue of L-leucine and bpy or phen[70]: $K^{(bpy)}_{(bpy)(H\cdot Leu)} = 0.6 \pm 0.4\ M^{-1}$ and $K^{(pben)}_{(phen)(H\cdot Leu)} = 1.4 \pm 0.9\ M^{-1}$ (in 25% methanol). These estimates agree well with theoretical calculations[67] for the hydrophobic interaction between leucine and phenylalanine in aqueous solution at 25 °C: $K^{(Phe)}_{(Phe)(Leu)} \simeq 2\ M^{-1}$.

4.3. Extent of the Intramolecular Ligand-Ligand Interactions

Based on the results of Section 4.2 it can readily be understood why the $M(bpy)(lipoate)^+$ complexes show enhanced stability: the valerate side chain of α-lipoate is ideally suited for hydrophobic ligand-ligand interactions. The occurrence of a complex with a structure similar to that shown in Figure 5, which is responsible for the slight increase in stability (Fig. 3) and the observed upfield shifts in the ^{1}H-NMR spectra (Fig. 4), does not imply that all the $M(bpy)(L)^+$ ternary species exist in this "folded" form. In solution there is certainly an intramolecular, and therefore concentration independent, equilibrium between an 'open' and a 'closed' form, *i.e.* between the two isomers indicated in equilibrium (10).



(10)

If these two isomers are designated as $M(bpy)(L)^{\pm}_{O}$ and $M(bpy)(L)^{\pm}_{Hy}$, the dimensionless constant of this equilibrium is defined by Eq. (11):

$$K_{Hy} = [M(bpy)(L)_{Hy}]/[M(bpy)(L)_{O}] \tag{11}$$

Values of K_{Hy} may be calculated from Eq. (12) (for details see[70]),

$$K_{Hy} = \frac{10^{\Delta \lg K_{M/exp}}}{10^{\Delta \lg K_{M/op}}} - 1 \tag{12}$$

provided values for $\Delta \lg K_{M/exp}$ and $\Delta \lg K_{M/op}$ are known [for the definition of $\Delta \lg K_M$ see Eq. (9)].

For the present cases $\Delta \lg K_{M/exp}$ for the ternary complexes of M^{2+}, bpy, and an aliphatic carboxylate or lipoate have been determined experimentally[20]. Since in $M(bpy)(HCOO)^+$ and $M(bpy)(Ac)^+$ complexes, intramolecular interaction does not occur, or is insignificant (Figs. 3 and 4)[69,80], we can use the corresponding (experimentally determined)[20] values of $\Delta \lg K_M$ for $\Delta \lg K_{M/op}$, and hence calculate K_{Hy} for the $M(bpy)(L)^+$ complexes. The K_{Hy} values in turn allow the calculation of the amount of 'closed' isomer, *i.e.* of the complex with the intramolecular hydrophobic interaction (Fig. 5). These data are assembled in

Table 3 for ternary complexes containing aliphatic carboxylates or α-lipoate.

Table 3. Estimates of the intramolecular dimensionless equilibrium constant K_{Hy} [Eqs. (11) and (12)] and of the amount of "closed" isomer [Eq. (10)] for the ternary complexes M(A)(B), with an intramolecular ligand-ligand interaction between a heteroaromatic N ligand (A) and a second ligand (B) with an aliphatic moiety (50% aqueous dioxane; $I = 0.1$, $NaClO_4$; 25 °C) [a].

[a] The constants for $\Delta\lg K_{M/exp}$ were taken for No. 1–14 from [20] and for No. 15–24 from [80]. Part of the results concerning the simple carboxylates are also given in Table 3 of [29]. [b] $\Delta\Delta\lg K_M = \Delta\lg K_{M/exp} - \Delta\lg K_{M/op}$ (see text); *i.e.*, this value is the decisive parameter of Eq. (12).

It must be emphasized that the values of K_{Hy} and the resulting amounts given in Table 3 can only be considered as estimates, because they are derived from differences between stability constants which are connected with a certain experimental error. On the other hand, it should also be pointed out that by using the difference $\Delta\Delta\lg K_M$ (see footnote [b] in Table 3) in these calculations, systematic errors cancel to a large part[70]. Indeed, the trends indicated by the results are highly reasonable, *i.e.* the amount of 'closed' isomer increases with increasing chain length of the aliphatic carboxylate: propionate < valerate < α-lipoate. Similarly, an increase in the size of the aromatic ring system also favors hydrophobic interaction, provided the chain of the aliphatic carboxylate is long enough, *e.g.* for valerate $M(bpy)^{2+}$ (No. 4,11) < $M(phen)^{2+}$ (No. 18,23) holds. That an increase in the size of the alkyl group of the aliphatic carboxylate also favors the 'closed' isomer is to be expected: clearly, the hydrophobic interaction of $M(phen)^{2+}$ with 2-cyclohexylacetate (No. 19,24) is more pronounced than with valerate (No. 18,23).

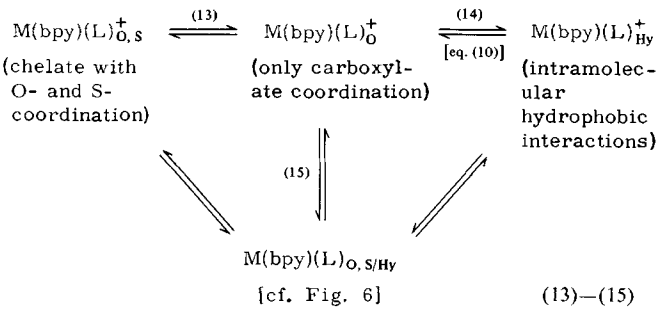
No significance should at present be attached to the seemingly different extents of intramolecular hydrophobic interactions in the ternary complexes containing the optical isomers of α-lipoate; here, very careful investigations of the indicated trends would be necessary before any conclusions should be drawn. But it may be added that the amounts given in Table 3 for the $M(bpy)(lipoate)^+_{Hy}$ complexes are very similar to those calculated recently[29] for the corresponding complexes with (+)-biotin: 29 and 31% for $M(bpy)((+)\text{-biotinate})^+_{Hy}$ with $M^{2+} = Cu^{2+}$ or Zn^{2+}, respectively. This result is gratifying because both the ligands lipoate and biotinate contain a valerate side chain.

That the properties of the Cu^{2+} and Zn^{2+} complexes may differ somewhat is to be expected because Cu^{2+} prefers a square-planar (or grossly distorted octahedral) coordination sphere, while that of Zn^{2+} is octahedral (or tetrahedral). These different geometries could, in certain cases[70], lead to a somewhat different intramolecular ligand-ligand interaction, though it appears for the systems in Table 3 that this is not very significant.

It is instructive to compare the results of Table 3 from an energetic point of view with the theoretical calculations of *Scheraga*[67], who calculated that at 25 °C $\Delta G° = -1.7$ kJ/mol for the hydrophobic interaction between the phenyl residue of phenylalanine and the isopropyl moiety of leucine in aqueous solution. By considering the whole range of the $\Delta\Delta\lg K_M$ values (0.04–0.24 log units) listed in Table 3 a value of $\Delta G° = -0.23$ to -1.4 kJ/mol is calculated. This means that the agreement between the theoretical and experimental data is highly reasonable, especially if it is considered that in the present examples the aliphatic group is often not branched, and that the theoretical calculation of *Scheraga* is based on a maximal interaction; it is obvious that in the ternary complexes the mobility of the ligands is restricted and, therefore, that the interaction is often not sterically ideal.

5. Are There Isomeric Equilibria Involving the Coordination of Disulfide *and* a Hydrophobic Interaction?

In binary complexes of the chain-shortened catabolites of α-lipoate, namely bisnor- und tetranorlipoate (Fig. 1), the disulfide group participates in complex formation by forming seven- and five-membered chelates, respectively (Section 3.2). However, these ligands also have aliphatic moieties of five and three carbon atoms; from the results outlined in Sections 4.2 and 4.3 it is clear that this is sufficient for a hydrophobic interaction with the aromatic system of 2,2′-bipyridyl in ternary $M(bpy)L^+$ complexes. Hence, at least from a theoretical point of view, the following intramolecular equilibria become possible[*]:



[*] Assuming that equilibria (13) and (14) operate, Eq. (8) may be rewritten as Eq. (16):

$$M(bpy)^{2+} + L^- \rightleftharpoons [M(bpy)(L)^+_{O,S} + M(bpy)(L)^+_{Hy} + M(bpy)(L)^+_O]$$

$$K^{M(bpy)}_{M(bpy)L} = ([M(bpy)(L)_{O,S}] + [M(bpy)(L)_{Hy}] + [M(bpy)(L)_O])/([M(bpy)][L] \quad (16)$$

Bearing this scheme in mind we may now consider the increased stabilities (see Fig. 3) of the ternary complexes $M(bpy)L^+$, where L is bisnorlipoate, tetranorlipoate, tetrahydrothiophene-2-carboxylate, or 3-phenylpropionate. In ternary complexes of the last mentioned ligand only aromatic-ring stacking is possible because, apart from the carboxylate group, this ligand offers no metal-ion binding site[**]. A comparison of the increase in stability of $M(bpy)(Pp)^+$ with that of $M(bpy)(BL)^+$ reveals for both Cu^{2+} and Zn^{2+} that the ternary bisnorlipoate complexes are more stable (Fig. 3). Since intramolecular hydrophobic interactions are somewhat less pronounced than aromatic-ring stacking interactions, *i.e.* they contribute less to the overall stability[70], it follows that in the ternary $M(bpy)(BL)^+$ complexes a metal ion-disulfide interaction must also exist, which is responsible for this additional increase in stability.

Another relatively clear-cut case is that of $Cu(bpy)(Thtc)^+$, where due to the square-planar coordination sphere of the metal ion a chelated tetrahydrothiophene-2-carboxylate cannot simultaneously undergo a ligand-ligand interaction with the 2,2′-bipyridyl, which is also coordinated. Furthermore, a Cu^{2+}-thioether interaction is expected[62] to be of about the same extent in binary and ternary complexes, *i.e.* $\Delta\lg K_{Cu} \simeq 0$. Indeed, *e.g.* for $Cu(bpy)(CH_3CH_2—S—CH_2COO)^+$, $\Delta\lg K_{Cu} = -0.01$[82] and for $Cu(bpy)(Thtc)^+$, $\Delta\lg K_{Cu} = 0.01$[21]. Hence, the whole increase in stability observed for this ternary complex in (Fig. 3) may be attributed solely to a Cu^{2+}-thioether interaction: the complex is present in 92% as the chelated isomer $Cu(bpy)(Thtc)^+_{O,S}$ (Table 4); in fact, this percentage is, within the error limits, identical to the 93% calculated for the binary $Cu(Thtc)^+_{O,S}$ species (Table 2).

Reconsidering $Cu(bpy)(BL)^+$ ($\Delta\lg K_{Cu} = +0.18$[20]), for which it was already concluded that in addition to the metal ion-disulfide coordination a hydrophobic ligand-ligand interaction must also occur, it may be assumed—based on the results with $Cu(bpy)(Thtc)^+$—that the Cu^{2+}-disulfide interaction is also about the same in $Cu(BL)^+$ and $Cu(bpy)(BL)^+$. The values given in Table 4 for $Cu(bpy)(BL)^+_{O,S}$, $Cu(bpy)(BL)^+_{Hy}$, and $Cu(bpy)(BL)^+_O$ were tentatively estimated using this assumption. The corresponding arguments may be advanced for the $Cu(bpy)(TL)^+$ system ($\Delta\lg K_{Cu} = +0.31$[20]) by taking into account the results for $Cu(bpy)(benzoate)^+$; again it can be concluded that both types of interactions exist, *i.e.* that equilibria (13) and (14) are important. The tentatively estimated amounts of the isomers are also given in Table 4.

There is one further aspect to be mentioned for $Cu(bpy)(BL)^+$ and $Cu(bpy)(TL)^+$. Assuming that an apical Cu^{2+}-disulfide coordination occurs, a simultaneous hydrophobic interaction becomes possible (*vide infra;* Fig. 6). Apical (axial) coordination of the disulfide bridge of this type has recently been shown to occur in crystals of the Cu^{2+} complex of oxidized glutathione[83]: the long Cu—S distance of 3.22 Å indicates that this interaction is weak and probably non-existent in aqueous solution. However, occurrence of the isomers $Cu(bpy)(BL)^+_{O,S/Hy}$ and $Cu(bpy)(TL)^+_{O,S/Hy}$ in trace amounts cannot be excluded at present.

[**] Eq. (19) therefore simplifies to $K_{I(tot)} = K_{Hy}$.

Table 4. Intramolecular isomeric equilibria in the ternary complexes, $M(bpy)(L)^+$, which involve *S*-coordination and/or interactions (50% aqueous dioxane; $I = 0.1$, $NaClO_4$; 25 °C)[a, b].

$M(bpy)(L)^+$	$\lg K^{M(bpy)}_{M(bpy)L}$ [Eq. (8, 18)]	$\lg\Delta$ [c]	$K_{I(tot)}$ [Eq. (19, 20)]	Amount of $M(bpy)(L)^+_{I(tot)}$ [%]	$M(bpy)(L)^+_{O,S}$ [Eq. (13)] [%] [b]	$M(bpy)(L)^+_{Hy}$ [Eq. (10, 14)] [%] [b]	$M(bpy)(L)^+_{O,S/Hy}$ [Eq. (15)] [%] [b]	$M(bpy)(L)^+_O$ [%]
$Cu(bpy)(Thtc)^+$	4.32 ± 0.03	1.07	11	92 ± 1 (1)	92			8
$Cu(bpy)((\pm)\text{-}TL)^+$	3.38 ± 0.04	0.44	1.8	64 ± 3 (5)	*41*	*23*		36
$Cu(bpy)(Bnz)^+$	3.58 ± 0.03	0.18	0.51	34 ± 5 (8)	—	34	—	66
$Cu(bpy)((\pm)\text{-}BL)^+$	3.76 ± 0.02	0.32	1.1	52 ± 2 (4)	*41*	*11*		48
$Cu(bpy)(Pp)^+$	3.75 ± 0.02	0.26	0.82	45 ± 3 (5)	—	45	—	55
$Zn(bpy)(Thtc)^+$	2.30 ± 0.03	0.23	0.70	41 ± 4 (7)			*41*	59
$Zn(bpy)((\pm)\text{-}TL)^+$	2.09 ± 0.03	0.23	0.70	41 ± 4 (7)			*41*	59
$Zn(bpy)(Bnz)^+$	2.40 ± 0.03	0.17	0.48	32 ± 5 (8)	—	32	—	68
$Zn(bpy)((\pm)\text{-}BL)^+$	2.61 ± 0.04	0.40	1.5	60 ± 4 (6)			*60*	40
$Zn(bpy)(Pp)^+$	2.50 ± 0.01	0.25	0.78	44 ± 1 (4)	—	44	—	56

[a] These results were calculated from the data published in [20–22, 25]; see also Fig. 3. The error limits given for $\lg K^{M(bpy)}_{M(bpy)L}$ are *three* times the standard deviation of the mean value; see also footnote [b] of Table 2. [b] The percentages printed in *italics* are assigned tentatively. [c] This is the crucial parameter of Eq. (20). For the ternary Cu^{2+} complexes the difference between the experimental value and the reference line of the *binary* complexes (see Fig. 3; upper part) was taken and 0.10 lg units (= average of $\Delta\lg K_{Cu}$ of $Cu(bpy)(HCOO)^+$ and $Cu(bpy)(Ac)^+$; cf. Table 3) were deducted to account for the formation of the ternary complexes. For the ternary Zn^{2+} complexes, $\lg\Delta$ corresponds to the difference between the experimental value and the reference line (Fig. 3; lower part).

With Eq. (16), $K^{M(bpy)}_{M(bpy)(L)O}$ (*i.e.* the formation constant of the simple carboxylate coordinated species), K_{Hy} [Eq. (11)], and $K_{O,S}$ [Eq. (17); cf. Eq. (13)] equation (18) may be derived [35, 60, 70]:

$$K_{O,S} = [M(bpy)(L)_{O,S}]/[M(bpy)(L)_O] \quad (17)$$

$$K^{M(bpy)}_{M(bpy)L} = K^{M(bpy)}_{M(bpy)(L)O}(1 + K_{O,S} + K_{Hy}) \quad (18)$$

The difficulty will certainly be to determine, independently of one another, the intramolecular constants $K_{O,S}$ and K_{Hy}, while it should be easier to determine their sum, *i.e.* the constant due to the *total* intramolecular interaction:

$$K_{I(tot)} = K_{O,S} + K_{Hy} \quad (19)$$

Obviously, $K_{I(tot)}$ is also the equilibrium constant for Eq. (15) if the *total* disulfide and hydrophobic interaction occurs within the same ternary species, *i.e.* if Eq. (13) and (14) do not exist. Should equilibria (13), (14) *and* (15) exist simultaneously, then the situation is even more complicated.

From Eq. (18) and (19), Eq. (20) can be derived:

$$K_{I(tot)} = \frac{K^{M(bpy)}_{M(bpy)L}}{K^{M(bpy)}_{M(bpy)(L)O}} - 1 \quad (20)$$

Eq. (20) may now be used analogously to Eq. (6) for calculations.

It has already been concluded that both types of interactions must be present in the ternary complex $Zn(bpy)(BL)^+$ and the corresponding arguments also hold for $Zn(bpy)(TL)^+$ and $Zn(bpy)(Thtc)^+$; the observed increased stabilities (Fig. 3; Table 4) cannot be *solely* attributed to hydrophobic interaction *or* to disulfide coordination (cf. Table 2). However, with the octahedral (or tetrahedral) coordination sphere of Zn^{2+} a disulfide coordination (approximately normal to the ring)[29,46,84] and a hydrophobic ligand-ligand interaction are simultaneously possible (as may also be seen from molecular models); this situation is depicted in Figure 6. Since this structure, which allows both kinds of interactions, seems energetically favored relative to $Zn(bpy)(L)^+_{O,S}$ and $Zn(bpy)(L)^+_{Hy}$, it was assumed in Table 4 that these isomers occur only in trace amounts, whereas $M(bpy)(L)^+_{O,S/Hy}$ is the predominant isomer.

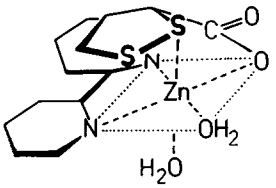


Fig. 6. Possible (schematic) structure of the isomer with a Zn^{2+}-disulfide coordination and a hydrophobic ligand-ligand interaction of the ternary complex-system formed by Zn^{2+}, 2,2'-bipyridyl, and tetranorlipoate.

In conclusion it is clear that the mixed ligand complexes containing bisnorlipoate or tetranorlipoate exist in isomeric equilibria and that both metal ion-disulfide and hydrophobic ligand-ligand interactions are important. However, it is also clear that at present the amounts of the several isomers may only be assigned tentatively.

6. Conclusions Concerning the Properties of the Lipoyl Residue

If lipoic acid is linked to an amino group in a protein as an amide[1,8], the 1,2-dithiolane moiety will remain rather flexible. So far, it is not known whether a metal ion-disulfide interaction occurs during the biochemical reactions in which the lipoyl group is involved, but the results (Section 3) show that this possibility should be considered. A weak disulfide-metal ion interaction of this type could create the active enzyme-substrate complex. Furthermore, taking into account that the electron density at the two sulfur atoms is apparently not equivalent (Section 3.1)[52], this would allow coordination of a metal ion (if sterically possible) at S1, thereby creating an electron deficiency at S2. This could stimulate hydride transfer from an appropriate substrate. The result would be rupture of the S-S bond and formation of the reduced species, dihydrolipoic acid. Obviously, instead of a hydride any other suitable group could be transferred to such a metal ion-activated species.

It should also be added that, in agreement with general observations[85], reduction of the disulfide bond of the lipoyl moiety results in two RS^- groups, which are much stronger binding sites for most metal ions[17]. This is probably the reason why lipoic acid could be used[1,14,15,17] in the treatment of heavy-metal poisoning.

The sterically correct 'fixation' of the lipoyl moiety at the surface of the protein might be further promoted, or even solely achieved (*i.e.* without a metal ion-sulfur coordination), by hydrophobic interactions. From Section 4 (and 5) it is evident that an intramolecular ligand-ligand interaction of this type occurs in mixed-ligand metal-ion complexes containing an aromatic moiety and the lipoyl group. In enzymic systems a corresponding interaction, *e.g.* between a tryptophanyl residue and the valeric acid side chain of the lipoyl moiety, also appears to be possible. Moreover, the need for a sterically correct 'fixation' of the lipoyl moiety seems apparent: In the pyruvate and α-ketoglutarate dehydrogenase complexes of *Escherichia coli*[8] the carboxyl group of lipoic acid is amide-linked to the ε-amino group of a lysyl residue of the protein, providing a flexible arm of about 14 Å for the reactive dithiolane ring; the lysyl residue also has hydrophobic properties[29]. A schematic representation of the possible rotation of such a lipoyllysyl moiety within a multienzyme complex is shown in Figure 7.

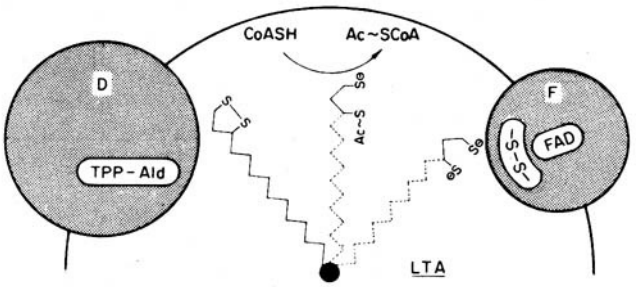

Fig. 7. Schematic representation (after *Reed* [8]) of the possible rotation of a lipoyllysyl chain between α-hydroxyethylthiamine pyrophosphate (TPP-Ald) bound to pyruvate dehydrogenase (D), the site for acetyl transfer to CoA (coenzyme A), and the reactive disulfide of the flavoprotein (F). The lipoyllysyl moiety is an integral part of dihydrolipoyl transacetylase (LTA). Reproduced by permission of the author and the American Chemical Society.

It appears that the dynamic features which are involved in the lipoyl-enzymic process require distinct structural conditions (Fig. 7). But it also seems clear that these structural conditions should readily be brought about to allow the 'cyclic' transformations of the dithiolane ring. The disulfide-metal ion coordination and the hydrophobic interactions described appear to meet this condition from an energetic point of view. The values of $\lg\Delta$ (Tables 2 and 4) and $\Delta\Delta\lg K_M$ (Table 3) range from 0.04 to 0.44 lg units, corresponding to $\Delta G^0 = -0.23$ to -2.5 kJ/mol. In summing up it becomes clear that the lipoyl moiety is very versati'e in its ability to interact with other molecules or ions.

7. Outlook

What have we learned, aside from the special case of 'lipoic acid'? In other words, can the results described be generalized?

Certainly, metal ions are abundant and clearly play an important role in biology[19], and *Wood*, in a slight overstatement, formulated[86]: "If you think that biochemistry is the organic chemistry of living systems, then you are

misled; *biochemistry is the coordination chemistry of living systems*". Indeed, it appears that an interaction between metal ions and disulfide or thioether groups is inevitably to be expected, since these groups are also rather abundant, occurring, *e.g.* in cystine[39], lipoic acid, the oxidized form of glutathione[40], methionine[39,87], *S*-methylcysteine[39,87], penicillin[87], and (+)-biotin[29]. The most well-known example is presumably the coordination of Cu^{2+} to the thioether group of a methionyl residue in plastocyanin, a 'blue' copper protein[88].

It is evident from the results summarized in this article that an interaction is also to be expected between such S donors and other biologically important, but compared to Cu^{2+} less coordinating[30,89] metal ions like Zn^{2+} or Mn^{2+}, possibly even Mg^{2+} and Ca^{2+}. The crucial point is that the *stability of a complex* may well be determined, *e.g.* by the coordination to a carboxylate group, but that the *structure of the complex* is governed by a sterically favorably positioned thioether or disulfide group. This additional interaction then causes *intra*molecular equilibriation between isomers, the position of these equilibria being independent of the concentration! Assuming that an isomer of this type has a structure which makes it the 'reactive' substrate for a particular reaction, a 'flowing' or a 'cyclic' process may be relatively easily sustained, because the energy needed for the interconversion of the isomers is small. For an alteration of the position of such an equilibrium, a change in the water structure is already enough, as it occurs *e.g.* at the surface of a protein. It will not be simple to detect such weak interactions between metal ions and thioether or disulfide groups, but a specific search now appears possible and rewarding.

This also holds for the structuring action of the hydrophobic interactions between aliphatic or aromatic groups, including aliphatic-aromatic interactions[67]. For these interactions, *e.g.* the purine bases of nucleotides[72-76,90], the indole residue of tryptophan[72,75], or the isopropyl moiety of leucine are especially suitable[70]. Indeed, it has already been established that the corresponding ligand-ligand interactions occur in ternary complexes and the positions of the intramolecular equilibria have been estimated[64,70,91]. That such hydrophobic interactions can lead to stereoselectivity has been demonstrated recently with Cr^{3+} and Co^{3+} complexes[92].

The interplay between high- and low-molecular weight ligands *via* the interactions described is evident from the following example. Carbonic anhydrase is a zinc-metalloenzyme whose active site is in a protein cavity having hydrophobic properties[93,94]. This enzyme is inhibited by the monoanions of sulfonamides[93,95,96], those with an aromatic residue being especially effective, and this indicates the occurrence of hydrophobic interactions[96]. It is also remarkable that the apoenzyme binds sulfonamides, *e.g.* acetazolamide (2-acetylamino-1,3,4-thiadiazole-5-sulfonamide) but the affinity is approximately a factor of 1000 less than that of the native Zn^{2+}-enzyme[95]; indeed monoanions[93,94], including those of sulfonamides[97], also coordinate to the metal ion[96]. The cooperative effect observed here may be explained by observations obtained with low-molecular ternary complexes: *firstly*, the combination of donor atoms bound to a metal ion is important, whereby imidazole groups, in particular, may increase stability[61-63][*]; such groups are coordinated to Zn^{2+} in carbonic anhydrase[62,93]. *Secondly*, the hydrophobic interactions[70,91] as described here, also enhance the stability of the complex. Both points are certainly responsible for many of the cooperative effects observed in biological systems.

The support of this research by the Swiss National Science Foundation is gratefully acknowledged.

[*] The combination of heteroaromatic N-bases with O-donors (or groups with O-donor-like properties, *e.g.* nitrogen in R—C(O)NH$^-$ [62]) results in increased stability of the ternary complexes with Mn^{2+}, (Fe^{2+}), Co^{2+}, Ni^{2+}, Cu^{2+}, or Zn^{2+} [61—65].

[66] For the coordination of a bidentate ligand followed by a monodentate ligand in a regular octahedral coordination sphere statistical considerations [65] indicate that $\Delta \lg K_{sh} = \lg(4:1/6:1) = -0.18$; assuming Zn^{2+} has not an octahedral but rather a tetrahedral coordination sphere in these ternary complexes, then it holds that $\Delta \lg K_{th} = \lg(2:1/4:1) = -0.3$. For the distorted octahedral coordination sphere of Cu^{2+} a statistical value is more difficult to assess[65]: $\Delta \lg K_{Cu/dl} \simeq -0.3$, but the value might be as large as 0.0 or as low as -0.48 lg units.

Which Factors Determine the Reactivity and Regioselectivity of Free Radical Substitution and Addition Reactions?

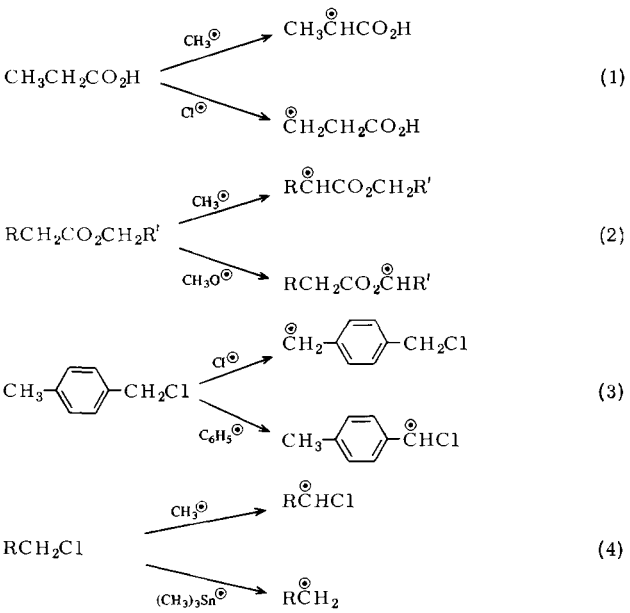
By John M. Tedder*

The relative importance of bond strength, steric effects, and polarity in determining the rate and orientation of free radical substitution and free radical addition reactions is considered. The factors which control substitution reactions (radical transfer reactions) are gathered together as five "rules", and a similar five "rules" are proposed for addition reactions. These "rules" are shown to be special cases of two "laws" which govern all free radical reactions.

1. Introduction

At first sight we might expect it would be easier to unravel the directive effects which control free radical reactions than it would be to elucidate the factors which control ionic reactions in solution. In the long run this will probably prove to be so. However, when we first look at free radical reactions we find them, in many ways, to be more complicated than heterolytic processes in solution. For example, in electrophilic aromatic substitution a substituent (*e.g.* methyl) will be *ortho-, para*-directing and activating—no matter what electrophile (*e.g.* $NO_2^{\oplus}$ or $CH_3CO^{\odot}$ or SO_3) is involved.

There are however many examples of radical substitution (*i.e.* transfer) reactions where different radicals attack different sites:



(1)

(2)

(3)

(4)

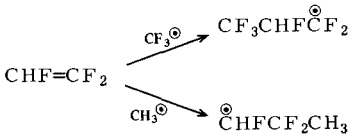
Scheme 1.

Scheme 1 contains examples of four different regioselectivities exhibited in radical transfer reactions; the regioselectivity is dependent on the attacking radical.

[*] Prof. Dr. J. M. Tedder
Department of Chemistry, University of St. Andrews
The Purdie Building, St. Andrews KY16 9ST (Scotland)

Examples (1) to (3) are reactions in which the different radicals (or atoms) abstract hydrogen atoms from the same substrate, whereas in example (4) the different radicals abstract different atoms (methyl radicals abstract hydrogen while trimethyltin radicals abstract chlorine).

Similarly, the orientation of electrophilic addition to unsymmetric olefins is the same regardless of the electrophile, but in free radical addition different radicals add preferentially to different sites of the substrate.



(5)

Scheme 2.

Scheme 2 shows the predominant orientation of addition of methyl and trifluoromethyl radicals to trifluoroethylene

2. Factors which Control the Regiospecificity and Relative Rate of Free Radical Transfer Reactions[3]

We will first discuss radical reactions which lead to substitution, more particularly reactions in whose product-determining step, a hydrogen atom is transferred from substrate to the radical.

$$R{-}H + X^{\odot} \rightarrow R^{\odot} + H{-}X$$

Table 1 shows the logarithm of the pre-exponential factors (A) and the activation energies for the abstraction of H

Table 1. Arrhenius parameters for H-abstraction from methane by various atoms and radicals $R^{\odot}$ [1]. D(R—H) = bond dissociation energy [2].

$CH_4 + R^{\odot} \rightarrow CH_3^{\odot} + R{-}H$

$R^{\odot}$	log$A$ [L mol^{-1} s^{-1}]	E_A [kcal mol^{-1}]	D(R—H) [kcal mol^{-1}]
$F^{\odot}$	11.1	1.2	136
$Cl^{\odot}$	10.4	3.9	103
$Br^{\odot}$	11.0	18.6	87
$CH_3^{\odot}$	8.8	14.3	104
$CF_3^{\odot}$	9.2	11.5	106
$CH_3O^{\odot}$	8.8	11.0	104

from methane. The pre-exponential terms for the radicals are approximately two orders of magnitude less than for the atoms because of the loss of rotational entropy in forming the transition state. Table 1 also shows there is no simple relationship between the strength of the bond being formed (D(R—H)) and the activation energy (E_A).

The first factor we will consider is the strength of the bond being broken.

2.1. Strength of the Bond Broken and the Evans-Polanyi Relationship

Table 2 shows that A varies very little with the site of attack (marked with asterisk). The changes in rate constant k are entirely due to differences in the activation energy term. Plotting the determined activation energies against the strength of the C—H bond being broken leads to a straight line. Such relationships are called Evans-Polanyi equations:

$$E_A = \alpha[D(\text{R—H})] + \beta$$

Table 2. Arrhenius parameters for H-abstraction from alkanes by methyl radicals at 164 °C [1c].

Alkane	log$A$ [L mol^{-1} s^{-1}]	E_A [kcal mol^{-1}]	log$k$ [L mol^{-1} s^{-1}]
$\overset{*}{C}H_4$	8.76	14.23	1.65
$CH_3\overset{*}{C}H_3$	8.83	11.83	2.96
$CH_3\overset{*}{C}H_2CH_3$	8.82	10.13	3.75
$(CH_3)_3\overset{*}{C}H$	8.38	8.03	4.36

Similar straight line plots have been observed for the reaction of other radicals with the alkanes listed in Table 2 (see Table 3).

Table 3. Evans-Polanyi parameters for the reaction of radicals and atoms with alkanes (RH) [2].

$$RH + X^{\odot} \rightarrow R^{\odot} + HX$$

$X^{\odot}$	α	β [kcal mol^{-1}]
$CH_3^{\odot}$	0.49	74
$CF_3^{\odot}$	0.53	84
$Br^{\odot}$	0.86	83
$I^{\odot}$	0.91	69

The existence of Evans-Polanyi relations emphasizes the importance of the strength of the bond being broken. However, no linear relationship of this kind is to be expected when the polarity changes from reaction to reaction. The constant α would be expected to increase as the reaction became more endothermic (*i.e.* more selective), and Table 3 shows that α increases with the endothermicity of the reactions from methyl radicals, to bromine atoms, to iodine atoms. The constant α for trifluoromethyl radicals, however, is greater than that for methyl radicals even though the trifluoromethyl radical reactions are exothermic. The difference is that trifluoromethyl radicals are "electrophilic" and hydrogen abstraction is facilitated at the more electropositive centers (*i.e.* *tert* > *sec* > *prim* > CH_4). This is one of the many examples we will find in which the most reactive radical is also the most selective[4].

Later we will discuss the effect of polarity on the transition state, but in any discussion of bond strength it is important to remember that an unsymmetric bond is usually stronger than a similar symmetric bond (*i.e.* $D(\text{ABX—XAB}) < D(\text{A}_2\text{X—XB}_2)$); this is due to the presence of some ionic character in the unsymmetric bond. It is necessary to distinguish this ground state effect on bond dissociation energy from the polar effect in the transition state of a radical transfer reaction.

2.2. Steric Effects and Their Influence on Radical Transfer Reactions

There are three types of steric effects which are likely to be important in radical transfer reactions: steric hindrance, which inhibits the primary radical approaching a particular reaction site; steric inhibition of resonance, which prevents the incipient radical from being stabilized by electron delocalization; and finally steric compression, which is partly released in forming the new radical. All three types of steric effect are important in free radical reactions, but some release of steric compression must occur in every abstraction reaction. The familiar decrease in C—H bond strengths from primary to secondary to tertiary, can be attributed partly to steric compression which is released when the incipient radical forms[5,6]. The relative strength of C—H bonds has also been attributed to stabilization of the incipient radical by hyperconjugation, but, as we shall see, there is good evidence that resonance stabilization is only of minor importance.

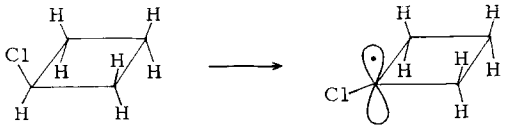
Table 4 lists the Arrhenius parameters for H-abstraction from cyclopentane, cyclohexane, and cycloheptane. It is seen that the activation energy for H-abstraction from cyclohexane is always greater than for that from either cyclopentane or cycloheptane. This difference in E_A between cyclopentane and cycloheptane, on the one hand, and cyclohexane on the other is attributed to the presence of torsional strain in the former two compounds, which is released when the corresponding radical (or cation) is formed. In contrast, cyclohexane is free from torsional strain.

Table 4. Arrhenius parameters for H-abstraction from cyclopentane, cyclohexane, and cycloheptane by $Br^{\odot}$ and other radicals (A in L mol^{-1} s^{-1}, E_A in kcal mol^{-1}) [7].

	$Br^{\odot}$		$CF_3^{\odot}$		$C_2F_5^{\odot}$		$CH_3^{\odot}$		$CCl_3^{\odot}$	
	log$A$	E_A	log$A$	E_A	log$A$	E_A	log$A$	E_A	log$A$	E_A
Cyclopentane	11.6	9.4	9.3	6.2	8.6	5.7	8.9	9.5	9.0	10.7
Cyclohexane	12.2	11.5	9.1	6.3	8.6	5.8	9.1	9.9	8.8	10.7
Cycloheptane	11.4	8.0	9.4	6.0	9.0	5.7	9.9	9.3	9.1	9.9

Another example of the release of steric compression comes from the chlorination of chlorocyclobutane[8]. The rate of H-abstraction from the α-position of this compound by chlorine atoms is five times faster than abstraction from the α-position of chlorocyclohexane, notwithstanding the effect of Walsh orbitals (which lead to a strengthening of the cyclobutane exocyclic bonds). Again,

the formation of the (1-chlorocyclobutyl) radical is accompanied by the release of steric strain.



2.3. Electron Delocalization and its Influence on Bond Strength

Electron delocalization plays a large part in any theoretical account of heterolytic reactions. It is natural, therefore, that the concept should be applied to homolytic processes. Table 5 lists the Arrhenius parameters for H-abstraction from substituted methanes (R—CH_3), where substituent R provides varying possibilities of delocalizing an unpaired electron.

Table 5. Arrhenius parameters for H-abstraction from substituted methanes by methyl radicals at 164 °C [1c].

$RCH_3 + \overset{\odot}{C}H_3 \rightarrow R\overset{\odot}{C}H_2 + CH_4$

RCH_2—H	Resonance	log$A$ [L mol^{-1} s^{-1}]	E_A [kcal mol^{-1}]	k [L mol^{-1} s^{-1}]
CH_3CH_2-H		8.1	10.4	8.0×10^2
FCH_2-H		8.2	11.8	2.0×10^2
$CH_3CH{=}CHCH_2$-H		8.1	7.6	2.0×10^4
$C_6H_5CH_2$-H		8.6	9.5	7.1×10^3
CH_3COCH_2-H		8.5	9.7	4.5×10^3
CH_3OCH_2-H		8.6	10.0	4.0×10^3
		8.4	8.9	8.9×10^3

The surprising feature of the data in Table 5 is not the evidence for "resonance stabilization", but how small the effect turns out to be. There is a wider variation of reactivity in H-abstraction from the series CH_3—H to $(CH_3)_3C$—H (see Table 2) than for those compounds in Table 5. In other words, although electron delocalization of the unpaired electron in the incipient radical affects the strength of the bond undergoing fission, the effect is much smaller than might be expected from our knowledge of heterolytic processes.

"Resonance stabilization" of the unpaired electron requires that the half-filled orbital of the radical center possesses a symmetry such that it can overlap with an adjacent p-AO or π-MO. Overlap of this type may be restricted by steric factors.

A related phenomenon is the stereoelectronic effect, *i.e.* the steric requirements for the delocalization of non-bonding electrons[9]. For example, hydrogen abstraction by *tert*-butoxyl radicals from the two dioxanes **A** and **B** proceeds more than ten times faster from **A**, than from **B**. The important difference is that the axial hydrogen atom in **A** is antiperiplanar to the shaded sp^2 orbitals on the oxygen atoms allowing orbital interaction. No such interaction is possible with **B**.

2.4. Strength of the New Bond being Formed

If the strength of the bond broken is important, it follows that the strength of the bond being formed will also be important. Table 6 shows the relative selectivities for H-abstraction from simple alkanes by the four halogen atoms. The transition from the very exothermic fluorine atom reaction to the almost equally endothermic iodine atom reaction is associated with a change in rate constant (at 150 °C) of nearly fifteen orders of magnitude. As shown in Section 2.5, the polarity of the transition state plays an important role in determining selectivity. In the present case, however, the halogen atoms are all electronegative species and hence polarity only makes a small contribution to the very dramatic changes in selectivity observed in Table 6.

Table 6. Relative selectivities for H-abstraction from ethane, propane, and isobutane by halogen atoms in the gas phase [1].

Atom	T [°C]	CH_3—	$CH_2<$	$CH\leqslant$	D(X—H) [kcal mol^{-1}]
$F^\odot$	25	1	1	2	136
$Cl^\odot$	25	1	4	7	103
$Br^\odot$	150	1	80	2000	87
$I^\odot$	150	1	1000	97000	71

It is often asserted that free radical reactions are unselective, particularly when compared to reactions like aromatic nitration. Table 6 shows that free radical substitution can be extremely selective; for example, bromination of *iso*-butane leads almost exclusively to 2-bromo-2-methylpropane.

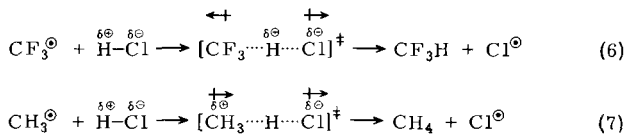
2.5. Importance of Polarity in Radical Transfer Reactions

Table 7 shows the activation energies for a series of radical transfer reactions in which the heat of reaction (ΔH) is very small, *i.e.* the reactions are nearly thermoneutral. The very striking feature of these data is the low energy barrier

Table 7. Activation energies for nearly thermoneutral radical transfer reactions involving small molecules (Forward reaction: (1); reverse reaction: (2); E_A in kcal mol^{-1}) [1, 2].

Reaction	E_A (1)	E_A (2)	ΔH_1
$CH_3^\odot + CH_4 \rightleftharpoons CH_4 + CH_3^\odot$	14.0	14.0	0
$CF_3^\odot + CH_4 \rightleftharpoons CF_3H + CH_3^\odot$	11.2	11.5	−0.3
$CH_3^\odot + HCl \rightleftharpoons CH_4 + Cl^\odot$	2.5	3.5	−1.0
$CF_3^\odot + HCl \rightleftharpoons CF_3H + Cl^\odot$	5.0	8.0	−3.0

for the reactions involving hydrogen chloride. The lowering of the energy barrier is due to polar forces in the transition state. It is very significant that while the activation energy for H-abstraction from methane by trifluoromethyl radicals is lower than that for abstraction by methyl radicals, the order is reversed in the H-abstractions from hydrogen chloride. This is because in the latter reactions the "electronegative" ("electron attracting") trifluoromethyl radical resists formation of a polar transition state, while the "electropositive" ("electron supplying") methyl radical facilitates the formation of a polar transition state:

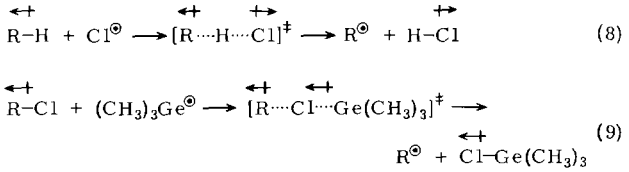


Scheme 3.

Evidence for the importance of polar forces in determining the course of radical transfer reactions is well documented. Relationships of the Hammett $\sigma\rho$-type have been thoroughly investigated for H-transfer reactions involving halogen atoms[10]. Perhaps one of the most convincing arguments for the importance of polarity in radical reactions is that groups which facilitate hydrogen abstraction by one radical retard H-abstraction by another.

2.6. Reversal of the Polarity Effect

If we consider a molecule R—H, in which R contains electronegative substituents close to the hydrogen atom to be abstracted by a chlorine atom, the R—H bond will be polarized and the formation of the hydrogen chloride will be opposed.



Scheme 4.

If we now consider a similar molecule R—Cl in which R again contains an electronegative substituent close to the chlorine atom, which this time is to be abstracted by trimethylgermyl radicals, the polarization of the R—Cl bond will now assist the formation of trimethylgermyl chloride (Scheme 4, examples (8) and (9)). This "reversal" of the polarity effect is illustrated in Table 8.

Other examples of the "reverse" polarity effect have been reported, especially Hammett relationships with positive ρ values[12].

Table 8. Relative rate constants of Cl-abstraction from R—CCl_3 molecules by trimethylgermyl radicals in the gas phase at 25 °C [11].

$(CH_3)_3Ge^{\odot} + R—CCl_3 \rightarrow (CH_3)_3GeCl + RCCl_2^{\odot}$

R	CH_3	CH_2Cl	$CHCl_2$	CF_3
k_{rel}	1	3.1	7.5	9.2

2.7. Combination of Steric, Resonance, and Polar Effects

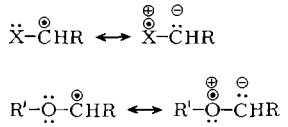
The relative reactivity of different sites in an alkane towards attack by a radical, *i.e.* tertiary, secondary, or primary, is best interpreted in terms of release of steric compression.

Resonance stabilization *via* hyperconjugation is of minor importance. An electron-repelling inductive effect will augment the effect of steric compression when the attacking atom or radical is "electrophilic". Thus, attack on branched chain alkanes by bromine will be enhanced by the inductive effect of adjacent alkyl substituents, whereas the more or less "nucleophilic" methyl radicals will be retarded. Table 9 shows that the polar effect is larger than we might have expected. The H-abstractions by methyl radicals are slightly exothermic, whereas the abstractions by bromine atoms are endothermic (even for *iso*-butane). We would therefore expect bromine to be the more selective although, because of the higher pre-exponential factors (A) associated with atom reactions, the differences in rate constants might not be large. In fact, as Table 9 shows, the rate of H-abstraction from molecular hydrogen by bromine atoms is two orders of magnitude less than abstraction by methyl radicals. In sharp contrast, bromine atoms abstract hydrogen from *iso*-butane two orders of magnitude faster than methyl radicals. Once again we have polarity overriding bond strengths.

Table 9. Arrhenius parameters for H-abstraction from simple alkanes by methyl radicals and bromine atoms ($\log A$ in L mol^{-1} s^{-1}; E_A in kcal mol^{-1}) [1].

R	$CH_3^{\odot}$		$Br^{\odot}$		$\frac{\log k(Br^{\odot})}{\log k(CH_3^{\odot})}$
	$\log A$	E_A	$\log A$	E_A	
H—H	8.6	10.5	10.7	17.5	−2.4
CH_3—H	8.8	14.2	10.6	18.6	−0.5
CH_3CH_2—H	8.8	11.8	10.9	13.4	+1.3
$(CH_3)_2CH$—H	8.8	10.1	10.7	10.1	+1.9
$(CH_3)_3C$—H	8.3	8.0	10.3	7.5	+2.5

As reagents, *i.e.* as attacking atoms, the halogens are "electrophilic" species, but as substituents, in addition to being "electronegative", they can also behave as electron donors.



Exactly the same is true for the alkoxy group, both as a radical (*e.g.* $CH_3O^{\odot}$) and as a substituent. There is comparatively little data about ethers or alkoxyl radicals, but there are considerable good kinetic data about chlorine and fluorine as substituents.

Table 10 shows that although we can rationalize the experimental data, prediction of the relative reactivities using qualitative arguments is very difficult. Very electronegative substituents have the effect of strengthening adjacent C—H bonds, and in the case of fluorine this is in opposition to any delocalization of the unpaired electron which may be possible. The introduction of one fluorine atom substituent into methane (*e.g.* CH_3F) lowers the activation

Table 10. Arrhenius parameters for H-abstraction from methane and its chloro- and fluoro-derivatives by $CH_3^{\odot}$, $CF_3^{\odot}$, and $Br^{\odot}$ ($\log A$ in L mol^{-1} s^{-1}; E_A in kcal mol^{-1}) [1].

Substrate	$CH_3^{\odot}$		$CF_3^{\odot}$		$Br^{\odot}$	
	$\log A$	E_A	$\log A$	E_A	$\log A$	E_A
CH_3—H	8.8	14.2	9.2	11.5	11.0	18.6
FCH_2—H	8.2	11.8	9.1	11.2	10.7	16.1
F_2CH—H	8.0	10.4	8.9	11.2	10.4	15.6
F_3C—H	7.4	13.6	—	—	10.1	22.3
$ClCH_2$—H	—	— [a]	9.1	10.6	10.9	14.7
Cl_2CH—H	—	— [a]	9.1	10.6	10.0	10.9
Cl_3C—H	—	— [a]	8.1	6.6	9.4	9.3

[a] No reliable data available.

energy for H-abstraction, the effect being greatest for methyl radicals where polarity enhances reactivity. A second fluorine atom substituent (CH_2F_2) further enhances H-abstraction by methyl radicals, but retards abstraction by trifluoromethyl radicals to a small extent (clearly a polar effect). The third fluorine atom substituent, as in fluoroform, greatly strengthens the C—H bond. It is noticeable however that in bromination the bond strength effect is supplemented by a deactivating polar effect, whereas in attack by methyl radicals the polar effect is activating (*i.e.* in bromination, CF_3H is less reactive than CH_4, whereas in attack by methyl radicals the reverse is true). The reactivity of chloroform is in sharp contrast to fluoroform. It is by far the most reactive of the chloromethanes and this is undoubtedly attributable to release of steric strain as the trichloromethyl radical is formed.

3. Summary of Section 2; Five Rules for Radical Transfer Reactions

Free radical substitution is a two stage process involving two discrete atom (or group) transfers. In the examples discussed, the overall reaction is determined by the initial atom transfer. In terms of simple rate theory the reaction is governed by two terms, the pre-exponential factor (A) and the activation energy (E_A). The A-factor varies by nearly three orders of magnitude depending on whether the primary species is an atom or a radical. However, A-factors vary very little from radical to radical or to changes in the substrate molecule. We can thus reduce the variables which control free radical substitution reactions, to two, apart from the almost constant pre-exponential factor. These are the relative strengths of the bonds being broken and formed, and polarity in the transition state. The way in which these two interrelated factors operate can best be summarized in *"Five Rules of Radical Substitution"*.

Rule 1

If there is little polarity in the transition state (or if polarity is constant in the reaction series) the relative rates of atom transfer by a particular radical will depend on the strengths of the bonds being broken (the Evans-Polanyi relationships). The strength of the bond being broken can be regarded as being affected (apart from polarity) by: a) resonance stabilization of the incipient radical, and b) the extent to which steric compression is released in forming the new radical.

Rule 2

The strength of the bond formed will largely control the selectivity of the reaction. If there is no polarity in the transition state the selectivity of a particular radical will depend on the heat of reaction (ΔH large and positive indicates a very selective reaction, ΔH large and negative means a very unselective reaction).

Rule 3

In thermoneutral reactions the rate of atom transfer is very dependent on the degree of polarity in the transition state.

Example: nonpolar transition state

$$H^{\odot} + CH_4 \rightarrow H_2 + CH_3^{\odot}$$
$\Delta H \simeq -1$ kcal mol^{-1}; $E_A = 11.9$ kcal mol^{-1}

Example: polar transition state

$$CH_3^{\odot} + HCl \rightarrow CH_4 + Cl^{\odot}$$
$\Delta H \simeq -1$ kcal mol^{-1}; $E_A = 2.5$ kcal mol^{-1}

Rule 4

Radicals (or atoms) which lead to polar transition states can be regarded as "electronegative" (e.g. the halogens) or "electropositive" (e.g. trimethylgermyl radicals). Electron withdrawing substituents will enhance transfer reactions by electropositive radicals and retard reactions with electronegative radicals. In reactions where ΔH is small this can mean that the more reactive radical is also the more selective

Example: reversal of substituent effects (X = H or F)

$$X—CCl_2—H + Br^{\odot} \xrightarrow{k_x} X—CCl_2^{\odot} + HBr$$
$k_H/k_F = 25$

$$X—CCl_2—Cl + (CH_3)_3Ge^{\odot} \xrightarrow{k_x} X—CCl_2^{\odot} + (CH_3)_3GeCl$$
$k_H/k_F = 0.1$

Rule 5

In exothermic reactions the transition state is "early" and although polarity may be important, neither release of steric strain nor delocalization of the unpaired electron in the incipient radical are important. In contrast in endothermic reactions, polarity will still be significant but both release of steric strain and delocalization of the unpaired electron are important

Example: exothermic reactions (early transition state, influence of polarity neutralizes the bond strength)

$$Cl^{\odot} + CHCl_3 \xrightarrow{a} HCl + CCl_3^{\odot}$$

$$Cl^{\odot} + CH_4 \xrightarrow{b} HCl + CH_3^{\odot}$$

$k_a/k_b = 1.0$ (164 °C)

Example: endothermic reactions (late transition state, steric release overrides polarity)

$$Br^{\odot} + CHCl_3 \xrightarrow{a} HBr + CCl_3^{\odot}$$

$$Br^{\odot} + CH_4 \xrightarrow{b} HBr + CH_3^{\odot}$$

$k_a/k_b = 1000$ (164 °C)

$D(CCl_3—H) = 95.7$ kcal·mol^{-1}; $D(CH_3—H) = 104$ kcal·mol^{-1}

4. Factors which Control the Regiospecificity and Relative Rate of Free Radical Addition Reactions[3, 7]

The activation energies for radical addition to ethylene are usually substantially lower than those for H-abstraction from methane. As in radical transfer reactions the pre-exponential term (A) is two to three orders of magnitude larger for reactions of atoms than for reactions of radicals, because of the loss of rotational entropy when the radicals start to form a new bond.

Table 11. Arrhenius parameters for the addition of $H^{\odot}$, $CF_3^{\odot}$ and $CH_3^{\odot}$ to ethylene at 164 °C [1b].

	log$A$ [L mol^{-1} s^{-1}]	E_A [kcal mol^{-1}]	k [L mol^{-1} s^{-1}]
$H^{\odot}$	11.0	2.8	3.9×10^9
$CF_3^{\odot}$	8.0	2.9	3.5×10^6
$CH_3^{\odot}$	8.5	7.7	4.5×10^4

4.1. Strength of the Bond Being Formed and Steric Compression

In radical transfer reactions we saw that release of steric compression played an important role in determining the strength of the bond being broken, and hence the ease of H-abstraction. In radical addition, exactly the reverse process occurs and we would therefore expect the relative magnitude of the steric compression to be important.

The big difference between ionic and radical addition reactions is illustrated in Table 12. Cationic addition occurs preferentially at the CH_2-end of propene and at the CF_3CH-end of 3,3,3-trifluoropropene, *i.e.* at opposite ends of the double bond. No such reversal is observed in free radical addition, and indeed there is as yet no well-established report of preferential addition to the substituted end of a monosubstituted olefin (*i.e.* for the olefins in Table 12, addition is always preferentially at the α-position). This includes an enormous range of substituents and is clearly associated with steric compression in the adduct radical.

We commented on the relative strengths of symmetric and similar unsymmetric bonds in our discussion on radical transfer reactions in Section 2.1. The same applies to CC double bonds; thus, the π-bond in 1,1-difluoroethene is stronger than that in either ethene or tetrafluoroethene. The activation energies and relative rates of addition reflect this (cf. relative rates at 164 °C:

$$CF_3^{\odot} + CH_2{=}CH_2 \qquad k_{rel} = 1$$

$$CF_3^{\odot} + CH_2{=}CF_2 \qquad k_{rel} = 0.15$$

$$CF_3^{\odot} + CF_2{=}CF_2 \qquad k_{rel} = 0.12$$

$$CF_3^{\odot} + CH_2{=}CF_2 \qquad k_{rel} = 0.006$$

Table 12. Relative rates and regioselectivity in the addition of $CH_3^{\odot}$ und $CF_3^{\odot}$ to some substituted ethylenes 164 °C [3]; k_c = rate constant for addition to ethylene.

Olefin $\overset{\alpha}{CH_2}{=}\overset{\beta}{CH}—X$	Regioselectivity (α : β)		k_α/k_c	
	$CH_3^{\odot}$	$CF_3^{\odot}$	$CH_3^{\odot}$	$CF_3^{\odot}$
$CH_2{=}CH—CH_3$	1 : 0.2	1 : 0.1	0.7	2.3
$CH_2{=}CH—CF_3$	1 : 0.3	1 : 0.02	0.9	0.4
$CH_2{=}CH—F$	1 : 0.2	1 : 0.09	0.9	0.5
$CH_2{=}CH—CH{=}CH_2$	1 : 0.01	1 : > 0.01	8.1	20

4.2. Electron Delocalization in the Adduct Radical

Electron delocalization plays an important role in any treatment of directive effects in ionic reactions. This is usually attributed to resonance stabilization (*i.e.* to lowering of the electronic energy of the adduct ion), but it seems likely that in solution dispersion of the charge associated with the resonance is more important than the electronic energy. Table 12 shows that radicals attack the unsubstituted end of vinyl fluoride preferentially, because attack at the substituted end is retarded (*i.e.* steric compression) and not because attack at the unsubstituted end is enhanced. Table 13 lists the Arrhenius parameters for trifluoromethyl radical addition to a wide variety of monosubstituted olefins, and also indicates possible delocalization of the electron in the adduct radical. In practice the

Table 13. Possible resonance stabilization of adduct radicals at 164 °C [7]; k_c = rate constant for addition to ethylene.

$CF_3^{\odot} + CH_2{=}CHX \rightarrow CF_3CH_2C^{\odot}HX$

X	Resonance structures	k/k_c	log$A$ [L mol^{-1} s^{-1}]	E_A [kcal mol^{-1}]
H	$CF_3CH_2\overset{\oplus}{C}H_2$	1	8.0	2.9
F	$CF_3CH_2\overset{\oplus}{C}H{-}F \leftrightarrow CF_3CH_2\overset{\ominus}{C}{-}\overset{\oplus}{F}$	0.5	7.9	3.3
Cl	$CF_3CH_2\overset{\oplus}{C}H{-}Cl \leftrightarrow CF_3CH_2\overset{\ominus}{C}{-}\overset{\oplus}{Cl}$	1.3	7.8	2.3
Br	$CF_3CH_2\overset{\oplus}{C}H{-}Br \leftrightarrow CF_3CH_2\overset{\ominus}{C}{-}\overset{\oplus}{Br}$	1.2	7.8	2.2
—CN	$CF_3CH_2\overset{\oplus}{C}H{-}C{\equiv}N \leftrightarrow CF_3CH_2CH{=}C{=}\overset{\oplus}{N}$	0.7	7.4	2.1
$\overset{O}{\overset{\|}{C}}{-}CH_3$	$CF_3CH_2\overset{\oplus}{C}H{-}C(CH_3){=}O \leftrightarrow CF_3CH_2CH{=}C(CH_3){-}\overset{\oplus}{O}$	2.1	7.9	1.8

rates of addition are almost identical to each other, and the exclusive addition of $CF_3^{\odot}$ to the unsubstituted end of some of the olefins is entirely due to deactivation (attributable to steric compression) at the substituted end.

As shown in Table 12, the addition to butadiene is appreciably faster than addition to any of the other olefins and this is clearly attributable to electron delocalization.

We conclude that electron delocalization involving CC π-orbitals can play an important part in determining the rate and regiospecificity of radical addition reactions. On the other hand, unsymmetrical π-orbitals in the nitrile group or the carbonyl group are less willing to donate electrons from the more electronegative nitrogen or oxygen atoms and therefore have little activating effect. Electron delocalization involving non-bonding electrons also only plays a minor role, probably because such delocalization involves separation of charge, *e.g.*

4.3. Steric Requirements of the Attacking Radical

If our picture of increasing steric compression as the attacking radical forms a bond with one end of an olefin is correct, the actual "bulk" of the radical will affect the regiospecificity of the reaction. Table 14 shows that rate constants for addition of alkyl radicals to ethylene decrease as the bulk of the radical increases.

Table 14. Relative rate constants for the addition of alkyl radicals to ethylene at 164 °C [7].

Radical	$CH_3^{\odot}$	$CH_3CH_2^{\odot}$	$(CH_3)_2CH^{\odot}$	$(CH_3)_3C^{\odot}$
k_{rel}	1.0	0.8	0.5	0.2

The effect of the bulk of the attacking radical on the regiospecificity is shown in Table 15.

Table 15. Regiospecificity and rate of the addition of fluoroalkyl radicals to vinyl fluoride at 164 °C [7]; k_c = rate constant for addition to ethylene.

Radical	$\overset{\alpha}{C}H_2=\overset{\beta}{C}HF$	
	α : β	$2k_\alpha/k_c$
$CF_3^{\odot}$	1 : 0.1	0.5
$CF_3CF_2^{\odot}$	1 : 0.06	0.6
$(CF_3)_2CF^{\odot}$	1 : 0.02	0.5
$(CF_3)_3C^{\odot}$	1 : 0.005	0.5

The constant values of $2k_\alpha/k_c$ show that the strong preference for attack at the α-position can be attributed to specific hindrance towards attack at the β-position (*i.e.* to the =CHF group).

4.4. Polarity in the Transition State

Convincing evidence for a polarity effect comes from the addition of the methyl and the fluoromethyl radicals to ethylene.

Table 16. Ratio of the rates of addition of methyl and fluoromethyl radicals to ethylene and tetrafluoroethylene at 164 °C [7].

Radical	$k(CF_2=CF_2)/k(CH_2=CH_2)$
$CH_3^{\odot}$	9.5
$CH_2F^{\odot}$	3.4
$CHF_2^{\odot}$	1.1
$CF_3^{\odot}$	0.1

Figure 1 shows that the difference in relative rates of addition is entirely attributable to the difference in the activation energy terms.

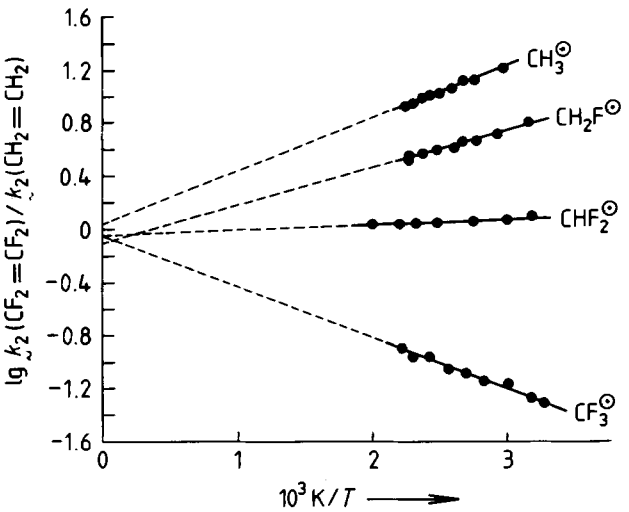


Fig. 1. Arrhenius plots for the relative rates of addition of methyl and fluoromethyl radicals to ethylene and tetrafluoroethylene [7] (see Table 16).

Methyl radicals are thus "nucleophilic" and their rate of addition is accelerated by electronegative substituents in the olefin, while trifluoromethyl radicals are "electrophilic" and their rate of addition is retarded by electronegative substituents. The addition of trifluoromethyl radicals is accelerated by electron—repelling alkyl groups, while attack at the substituted site is progressively inhibited (Table 17).

Table 17. Regioselectivity and rate of addition of trifluoromethyl radicals to olefins at 164 °C.

	$\overset{\alpha}{C}H_2=\overset{\beta}{C}H_2$	$\overset{\alpha}{C}H_2=\overset{\beta}{C}HCH_3$	$\overset{\alpha}{C}H_2=\overset{\beta}{C}(CH_3)_2$
α : β	1 : 1	1 : 0.1	1 : 0.08
$2k_\alpha/k_c$	1	2.3	6.0

4.5. Regiospecificity in Free Radical Addition

The regioselectivity for the addition of trichloromethyl radicals to propene and vinyl fluoride is almost the same, but the rates are very different. The methyl-group substituent enhances the rate of addition of the electrophilic trichloromethyl radical to propene, while the fluorine atom as substituent retards addition to vinyl fluoride. If we now compare the addition of the same radical to trifluoroethylene and 2-chloro-1,1-difluoroethylene, we find the rates of addition are about the same, but that the regioselectivi-

Table 18. Regioselectivity and rate of addition of trichloromethyl radicals to olefins at 164 °C.

	$\overset{\alpha}{C}H_2=\overset{\beta}{C}H-CH_3$	$\overset{\alpha}{C}H_2=\overset{\beta}{C}H-F$	$\overset{\alpha}{C}F_2=\overset{\beta}{C}H-F$	$\overset{\alpha}{C}F_2=\overset{\beta}{C}H-Cl$
$\alpha:\beta$	1:0.07	1:0.08	1:3.5	1:0.04
$2k_\alpha/k_c$	9.0	0.7	0.22	0.21

ties are very different (Table 18). The polar effects of chlorine and fluorine are very similar but the bulk of the chlorine atom is much greater than that of fluorine. These results show that the influence of any substituent must be considered separately in steric and electronegativity terms.

Table 19. Regioselectivity and rate of addition of methyl and fluoromethyl radicals to fluorinated ethylenes [3, 7].

Radical	$\overset{\alpha}{C}H_2=\overset{\beta}{C}HF$		$\overset{\alpha}{C}H_2=\overset{\beta}{C}F_2$		$\overset{\alpha}{C}HF=\overset{\beta}{C}F_2$	
	k/k_c	$\alpha:\beta$	k/k_c	$\alpha:\beta$	k/k_c	$\alpha:\beta$
$CH_3^\odot$	1.1	1:0.2	—	—	5.8	1:2.1
$CH_2F^\odot$	0.4	1:0.3	—	1:0.4	—	1:2.0
$CHF_2^\odot$	0.4	1:0.2	0.1	1:0.1	0.3	1:0.9
$CF_3^\odot$	0.5	1:0.1	0.2	1:0.04	0.05	1:0.5

Table 19 shows the relative rates and regioselectivities of the addition of methyl and fluoromethyl radicals to fluoroethenes. The "nucleophilic" methyl radicals add fastest to trifluoroethylene and the "electrophilic" trifluoromethyl radicals add fastest to monofluoroethylene. All four radicals add preferentially to the unsubstituted end of vinyl fluoride, confirming that the steric effect overrides any polarity influence. Nonetheless, the polar effect is clearly present as shown by the increasing regioselectivity for the addition to 1,1-difluoroethene as the attacking radical becomes more electrophilic. In the addition to trifluoroethylene we find that the polar effect predominates. The "nucleophilic" methyl radicals add preferentially to the CF_2-end of the olefin, whereas the "electrophilic" trifluoromethyl radical adds preferentially to the CHF-end. The total polarity difference between the α- and β-positions in trifluoroethylene is no greater than the difference between the α- and β-positions in vinyl fluoride. However, there is much evidence to show that the steric "hindrance" associated with a CF_2-group is not double that associated with a CHF-group. This means the steric compression involved in forming a new bond at a CF_2-group is also less than twice that involved in forming a new bond at the CHF-group; hence, the polar effect, which is doubled, becomes the predominant factor.

5. Summary of Section 4; Five Rules for Radical Addition Reactions

Free radical addition is a two stage process involving an addition step followed by atom transfer. In all the examples discussed, the overall reaction is assumed to be determined by the initial addition step. The rate expressions can be considered to be comprised of two terms, a preexponential factor (A) and the activation energy (E_A). Just as with the radical transfer reactions, A varies by nearly three orders of magnitude depending on whether an atom or radical is involved; otherwise A varies only slightly, and the major changes in reactivity can be attributed to changes in the activation energy. We can thus reduce the variables which control free radical addition, apart from the relatively small changes in factor (A), to two: the relative strengths of the bonds being broken and formed, and the polarization of the transition state. These are the same factors which govern free radical substitution reactions. The big difference is that addition reactions are reversible and we have, therefore, not included any endothermic reactions. This has meant that the strength of the π-bond broken is relatively (but not entirely) unimportant and the crucial term controlling orientation of addition is the strength of the bond formed. We can summarize the factors which control radical addition by a similar *"Five Rules of Radical Addition"*.

Rule 1

The preferred orientation of addition of a free radical to a monosubstituted olefin will invariably be to the unsubstituted end of the double bond. This can be attributed to the degree of steric compression associated with the formation of the new bond, which overrides other influences on the regioselectivity.

Rule 2

Substituents with CC π-orbitals (e.g. $CH_2=CH-$, C_6H_5-), which can overlap the half-filled atomic orbital of the incipient radical center, enhance the rate of addition at the remote end of the double bond, but vinyl substituents with non-bonding pairs of electrons (e.g. F—, Cl—, CH_3O—) have only a very small "resonance" effect. Most radical additions are exothermic and have early transition states i.e. delocalization of the unpaired electron in the adduct radical is of small importance.

Example: relative rates of addition to butadiene and vinyl chloride (taking ethylene as standard)

$$R^\odot + CH_2=CH-CH=CH_2 \longrightarrow [RCH_2-\overset{\odot}{C}H-CH=CH_2 \longleftrightarrow RCH_2-CH=CH-\overset{\odot}{C}H_2]$$

$$R^\odot + CH_2=CH-Cl \longrightarrow [RCH_2-\overset{\odot}{C}H-Cl \longleftrightarrow RCH_2-\overset{\ominus}{\underset{\cdot\cdot}{C}}H-\overset{\oplus}{Cl}]$$

$R^\odot$	$k(C_4H_6)/k(C_2H_4)$	$k(C_2H_3Cl)/k(C_2H_4)$
$CH_3^\odot$	8.1	4.2
$CF_3^\odot$	20	1.3

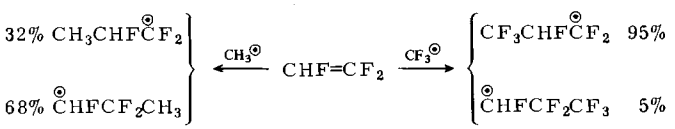
Rule 3

Polarity can have a major effect on the overall rate of addition of radicals to olefins. Methyl radicals behave as "nucleophiles" and their addition is facilitated by electron withdrawing substituents on the olefin, whereas trifluoromethyl radicals behave as "electrophiles", whose addition is retarded by electron withdrawing and assisted by electron repelling substituents.

Rule 4

The regioselectivity of free radical addition to polysubstituted ethenes is controlled principally by the degree of steric compression associated with forming the new bond. If the steric effects are mutually opposed, polarity can be the deciding factor.

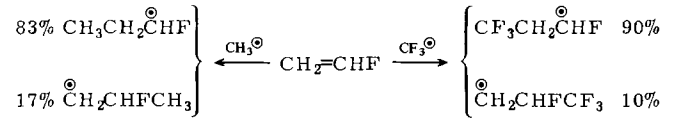
Example: addition of $CH_3^{\odot}$ and $CF_3^{\odot}$ to $CHF{=}CF_2$ at 164 °C.



Rule 5

Even when the regioselectivity of addition to a polysubstituted ethene is determined principally by steric compression, polarity can influence the magnitude of the regioselectivity, making it larger or smaller depending on the relative electronegativity of the radical and the substituents in the olefin. The net effect may be that the more reactive radical is also the more selective.

Example: addition of $CH_3^{\odot}$ and $CF_3^{\odot}$ to vinyl fluoride at 164 °C; the more reactive $CF_3^{\odot}$ radical is also the more selective.



6. Laws of Free Radical Reactions

In addition to the five rules which govern the rate and regiospecificity of free radical substitution reactions we have now proposed five more rules to govern the rate and regioselectivity of free radical addition to olefins. The similarity of the two sets of rules suggests that they are special cases of laws which govern free radical reactions as a whole. This turns out to be the case and we can formulate two laws which comprise all ten rules.

1st Law of Free Radical Reactions (Thermochemistry)

If the heat of reaction ΔH of a free radical process is large and negative, the transition state is early and the reaction will be fast and unselective; if ΔH is large and positive the transition state will be late and the reaction slow and selective; but if ΔH is small (positive or negative) the relative rate and selectivity will depend on other factors, especially polarity.

The relative heats of reaction of free radical processes are largely controlled by the increase (addition reactions) or release (transfer reactions) of steric compression associated with the formation of the incipient radical and by the extent of electron delocalization in the new radical (interactions involving substituents with CC π-orbitals, *e.g.* $CH_2{=}CH{-}$, will have a large effect, but substituents with non-bonding electron pairs, *e.g.* $CH_3O{-}$, only have a small effect). The effects of steric compression and electron delocalization are only fully manifest in a late transition state.

2nd Law of Free Radical Reactions (Polarity)

Polarity, i.e. the difference in relative electronegativity, cannot be completely separated from bond dissociation energies, but dipole-dipole interactions, i.e. opposing or complementing electrostatic forces, in the transition state can substantially raise or lower the energy barrier in both radical substitution and radical addition reactions.

These polar forces can be manifest quite early in a reaction (*i.e.* polarity is important in both exothermic and endothermic reactions), and in cases where ΔH is small (positive or negative) this means that the more reactive radical can also be the most selective.

7. Conclusions and Outlook

The purpose of proposing "rules" and "laws" serves to summarize a very wide collection of empirical data in a concise and coherent form. The "laws" are also applicable to homolytic dissociation reactions, *i.e.* those involving the rupture of a single bond to form two radicals. It seems likely that the "laws" will also apply to radical dimerizations, although as yet there is insufficient data available about the dimerization of very bulky radicals. (The heat of reaction of dimerization of small radicals is large and negative and hence, according to the first law, the reactions are fast and unselective.)

The second purpose in proposing "rules" and "laws" is to stimulate further research aimed at verifying or disproving these laws. It is to be hoped that the rules will also stimulate theoretical studies. The concepts used in formulating the rules and laws will appear in a different guise in any sophisticated theoretical treatment. Nonetheless steric compression and dipole-dipole interactions will be inherent in any comprehensive theoretical treatment. The simple qualitative ideas used here cannot be expected to completely account for small differences in rate or regioselectivity. For example, 1,1-difluoroethene is particularly unreactive towards radicals due to a high π-bond dissociation energy, which cannot be explained in our qualitative picture. Similarly over-simplified theoretical treatments (*e.g.* "extended Hückel" calculations) are even less comprehensive, and for example do not account for the destabilization attributable to steric compression. Full calculations will eventually render the use of rules and laws less necessary. However, there will always be a need for qualitative treatments summarizing empirical data and which are consistent with sophisticated theoretical ideas; it is to be hoped that this review article will provide the basis for such a treatment.

This article is based on a lecture delivered at the 3rd International Symposium on Organic Free Radicals at Freiburg (September 1981); the author was able to acknowledge some of the many organic chemists on whose work the proposed "rules" were based. The importance of polarity in radical transfer was developed particularly by Walling, Russell, and Minisci; the importance of steric effects was emphasized by Rüchardt, and in a very different way by Beckwith; factors controlling addition were thoroughly studied by Haszeldine and the problem of selectivity was recognized by Giese. At

the Symposium further examples of the importance of steric effects (E. Vismara) and polar effects (P. Boldt) were given. The author hopes that those not specifically mentioned above will accept this general acknowledgment. He must however acknowledge his own colleagues and in particular J. C. Walton.

New Possible Applications of Heavy Main-Group Elements in Organic Synthesis**

New synthetic methods (36)

By Thomas Kauffmann*

Dedicated to Professor Leopold Horner on the occasion of his 70th birthday

Aside from elements of the 2nd row, and one element of the 3rd row of the periodic system—Si, P, S, and Se, respectively, whose organoelement groups such as Me_3Si and $Ph_3P^{\oplus}$ have proven useful in numerous organic syntheses—other elements of the 3rd as well as 4th and 5th row (Ge, As, Sn, Sb, Te, Pb, Bi) can also be used as components of synthetically useful organoelement groups, the elements As, Sn, and Pb, in particular, offering certain advantages over the others. Some of these organoelement groups are suitable equivalents for Li- or halogen-substituents attached to carbon; they stabilize carbanionic centers (minimum of this effect at the 3rd-row elements), and owing to their suitability as leaving groups in β-eliminations, also open up interesting synthetic possibilities. The thermally induced *syn*- and silica-gel induced *anti*-elimination of Ph_3Sn, Ph_2Sb, Ph_3Pb, together with β-OH, are novel. With the newly synthesized compounds $Ph_nEl—CH_2—Li$ (El = Sn, Pb, As, Sb, Bi) and other α- and β-lithiated R_nEl- and $Ph_2As(O)$-reagents such organoelement groups can be introduced into organic compounds and exploited in organic and organoelement syntheses.

1. Organoelement Functional Groups

Organic chemistry largely concerns the chemistry of functional groups. More and more "organoelement functional groups"[2] containing elements previously not considered by the organic chemist are presently acquiring importance in organic synthesis. There are some groups of this type whose central atom is a transition metal (examples: 3rd row in Scheme 1); however, groups with a main group element are presently of much more importance: for instance, regarding hydroboration, Wittig reaction, organoselenium reagents. Unlike classical functional groups such as —OH, $—NH_2$, —CO—, —COOH, the organoelement functional groups are cleaved off again during the course of the synthesis. The designation "mobile functional groups"[3], however, would raise objections in that such a designation frequently also holds for the classical functional groups Cl—, Br—, I—.

HO—	H_2N—	—CO—	Hal—

Main group elements that have proven particularly useful as constituents of novel functional groups are to be found in the region of the periodic system shown in Scheme 2. Hitherto, their use has almost been restricted to the light elements B, Si, P, S, and Se; only Sn (see Section 2.1) constitutes an exception. This prompted the question as to what extent the heavier elements Ge, As, Sb, Te, Pb, and Bi are suitable[4] as constituents of new functional groups.

In general, we examined compounds with singly-bonded groups of the type Ph_nEl-, which are less volatile and so presumably less poisonous than their Alk_nEl-analogues. Such groups can be replaced by Li-, halogen-, or H-atoms; they are electron-withdrawing, and some can be readily eliminated together with a β-O- or β-H-atom. The attractiveness of these groups largely lies in the fact that-with limitations in the case of P, Bi, Te-the C—El bond is just as stable as a C—N, C—O or C—Hal bond towards H_2O and O_2. Hence, when using them the organic chemist can keep to conventional methods and apparatus.

	(Sn)	Sb	Te
	Pb	Bi	

Scheme 2. The main group elements so far frequently used in organoelement groups are circled.

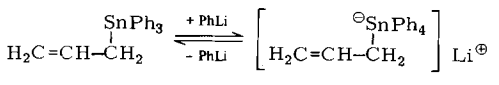
Our interest in organoelement functional groups was awakened when it was shown that the scope of application of 1,3-anionic cycloadditions[5] can be considerably extended by cleavable electron-withdrawing organoelement groups (see Section 4.2.2).

2. Organoelement Groups as Li-Equivalent

2.1. Organoelement/Li Exchange

The activation of C-atoms by Li-substituents enables the coupling of a large variety of electrophilic moieties. Aside from H/Li exchange, the most important method for introduction of Li into organic compounds is by halogen/Li exchange—which permits carbanionic centers to be generated at sites where this is impossible by H/Li exchange owing to relatively low CH-acidity.

The third possibility, namely "organoelement/Li exchange"[6], is much less known[7]. Of these reactions, in which the intermediary occurrence of ate-complexes is rarely questionable[8], *Seyferth et al.*[9] have mainly used stannyl/Li exchange on a preparative scale, *e.g.* for the very convenient synthesis of allyllithium compounds (Scheme 3)[9].



Scheme 3.

The possibilities offered by seleno/Li exchange have been exploited, in particular, by *Seebach et al.*[10] and by *Krief et al.*[11].

The following features are common to both halogen/Li and organoelement/Li exchange: a) The reactions usually proceed rapidly, even below −50 °C. b) Since equilibria are established, good yields are achieved only when the negative charge in the organolithium compound that is formed is stabilized better than in the Li-reagent (exceptions: shift in equilibrium, *e.g.* precipitation of a sparingly soluble product). c) With the exception of boron (sextet → octet on formation of the ate-complex), the exchange takes place only in the case of elements having valence electron shells that can be expanded to a decet; *the exchange takes place markedly easier with 4th- and 5th-row elements than with 2nd- and 3rd-row elements.*

Organoelement/Li exchange has the advantage that at least nine elements (Scheme 4) can be conveniently used, as opposed to only two elements in the case of halogen/Li exchange (Cl is very seldom suitable).

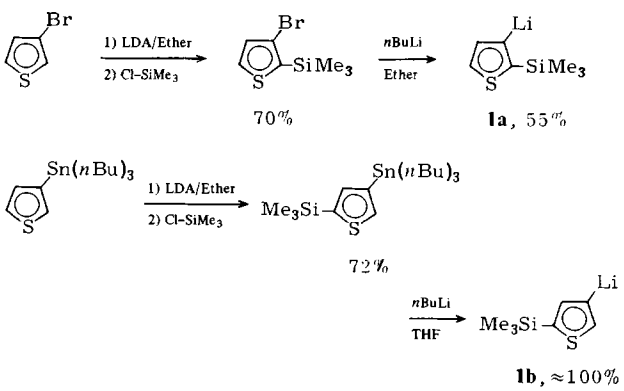
	B				(Cl)
			(As)	Se	Br
		Sn	Sb	Te	I
Hg	Tl	Pb	Bi		

Scheme 4. Elements suitable for organoelement/Li (A) and halogen/Li-exchange (B).

A further advantage is that a reactive, and, in the case of stannyl- and plumbyl-groups, coordinatively saturated compound *e.g.* tetraphenylstannane (Scheme 3) is usually formed as by-product. Therefore, other than in the case of halogen/Li exchange, which leads to alkyl or aryl halides, undesirable secondary reactions of the lithiated product (see Section 2.2.2) are rarely encountered.

All the elements amenable to organoelement/Li exchange are less electronegative than the halogens Cl, Br, and I. Scheme 5 shows how this can be favorably exploited: Whereas H/Li exchange with the Li-equivalent Br— (1st reaction step) takes place at the 2-position of the thiophene, the Li-equivalent *n*-Bu_3Sn directs the Li into the 5-position, resulting in the isomer **1b** being formed instead of **1a**[12]. This reaction could have wider synthetic utility.



Scheme 5. All reactions at −60 °C [12]; LDA = lithium diisopropylamide, THF = tetrahydrofuran.

A further reason for organoelement/Li exchange being preferred over halogen/Li exchange could lie in the better accessibility of organoelement educts. This holds true, *e.g.*, for some of the compounds $(Ph_nEl)_2CH_2$ **3** dealt with in Section 2.2.

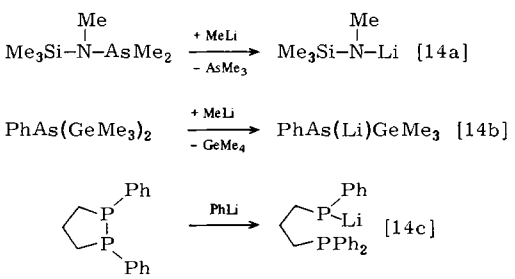
As expected, the suitability of an organoelement group for organoelement/Li exchange strongly depends on the electronegativity of the site of attachment: for example, a Ph_2As group attached to an sp^3 or sp^2 C-atom can be replaced by Li only with difficulty, whereas arsino/Li exchange takes place rapidly, even at 0 °C, in the case of the arsinoethynes **2** (Scheme 6)[13]; this is also of preparative interest because of the thermal instability of stannyl- or plumbylethynes and the much higher thermal stability of arsinoethynes.

$$\underset{\mathbf{2}}{Ph_2As{-}{\equiv}{-}G} \xrightarrow[0\,^\circ C,\ THF]{n\text{BuLi}} \underset{\approx 100\%}{Li{-}{\equiv}{-}G}$$

Scheme 6. G = $AsPh_2$, $SiMe_3$ [13].

Finally, it should be mentioned that organoelement/Li exchange is not just restricted to *C*-bonded organoelement groups: whereas groups such as R_3Si—, R_3Ge—, and R_2P—, which attach to carbon are not as a rule amenable to this exchange, they can be exchanged if they are attached to a relatively electrophilic heteroatom (examples: Scheme 7).

Regarding the *stereochemistry* it was established that stannyl/Li exchange at vinyl compounds takes place with complete retention of configuration[15], which could recently be demonstrated also for the exchange at an sp^3 C-atom in the synthesis of an α-lithiated ether[16].



Scheme 7. Organoelement/Li exchange at heteroatoms.

Organoelement/Li exchange offers still further inexhaustible possibilities. Some of these are outlined in the following Sections.

2.2. Organoelement/Li Exchange at G_2CH_2

2.2.1. Synthesis of G—CH_2—Li by Organoelement/Li and, for Comparison, by Halogen/Li Exchange

To the reagents which have proven useful in organic synthesis belong anions of the type G—$CH_2^{\ominus}$, where G (as throughout this review) symbolizes an organoelement group. Some of these reagents have been synthesized in the form of compounds G—CH_2—Li **4** by organoelement/Li exchange from disubstituted methanes **3** (G = PhSe, PhTe[10, 17]), or G—CH_2—G′ **10** (*e.g.* G = PhS—, G′ = PhSe—[11b]).

We checked whether the methyllithium derivatives **4** listed in Table 1 are accessible by organoelement/Li exchange (Scheme 8) from the symmetrically disubstituted methanes **3**, which, with exception of the Bi-compound **3f**[18, 24n], were all well known[*].

$$\underset{}{Hal_2CH_2} \xrightarrow{2\,M\text{-}G} \underset{\mathbf{3}}{G_2CH_2} \xrightarrow{RLi} \underset{\mathbf{4}}{G{-}CH_2{-}Li}$$

Scheme 8. M = Li, Na, K.

Table 1. Synthesis of G—CH_2—Li **4** from **3** by organoelement/Li exchange in THF according to Scheme 8.

	G	RLi	**4**, Yield [%]
a	Ph_3Ge	*n*BuLi or PhLi	0 [a, c] [23f]
b	Ph_3Sn	PhLi	36 [a], 52 [b] [24n, e]
c	Ph_3Pb	PhLi	89 [a], 100 [b] [24m, n]
d	Ph_2As	*n*BuLi	72 [c] [23d, 25a]
e	Ph_2Sb	PhLi	100 [a] [25b]
f	Ph_2Bi	PhLi	70 [a] [24n]

Molar ratios: [a] **3** : PhLi = 1 : 1; [b] **3** : PhLi = 1 : 1.5; [c] **3** : *n*BuLi = 1 : 4.

The synthesis of **4b** and **4c** appeared particularly problematical, since it was not expected that the electropositive, heavy elements Sn and Pb would stabilize a carbanionic center. Moreover, secondary reactions were expected to take place. Some stannyl- and plumbylmethyllithium derivatives had indeed already been described in the literature, but they were of type **5**, with carbanion-stabilizing substituents Z and Z′.

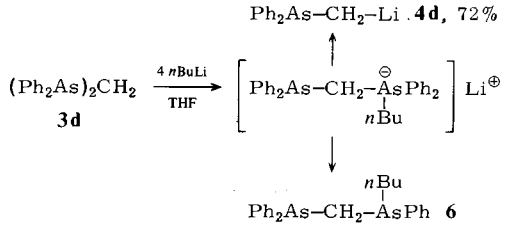
$$R_3El{-}\overset{\displaystyle Z}{\underset{\displaystyle Z'}{C}}{-}Li$$

5, El = Sn, Pb

Z = Z′ = Hal [19]
Z = Z′ = SR′ [20a, b]
Z = Z′ = $B(OR')_2$ [21]
Z = SMe, Z′ = $SiMe_3$ [20c]

More interesting in this connection was the synthesis of PhTe—CH_2—Li **4h** by phenyltelluro/Li exchange (yield ≈ 100%) described by *Seebach et al.*[17]; Te is, of course, markedly more electronegative than Sn and Pb.

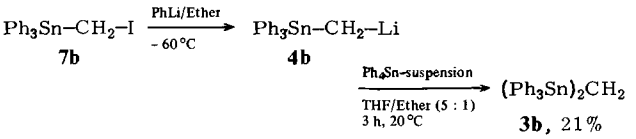
With exception of **4a** the desired methyllithium derivatives **4** are formed in preparatively satisfactory yields (Table 1)[2, 4, 22]. Whereas PhLi could generally be used—in which formation of a mixture cannot occur by ligand exchange—the more reactive *n*BuLi was required in excess for the synthesis of **4d**. Small amounts of **6** are formed by ligand exchange *via* an ate-complex (Scheme 9).



Scheme 9. [23d, 25a].

[*] In compounds **3**, **4**, **7**, **12**, **13**, **34**, **35**, **57** with G = Ph_nEl, **a** means: Ph_nEl = Ph_3Ge, **b**: Ph_3Sn, **c**: Ph_3Pb, **d**: Ph_2As, **e**: Ph_2Sb, **f**: Ph_2Bi, **g**: PhSe, **h**: PhTe.

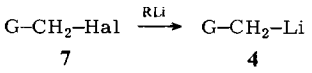
The reaction **3b→4b** was examined more closely: Demonstration of the back reaction shown in Scheme 10 reveals that, as expected, an equilibrium is set up[24e]. Accordingly, the yield of **4b** can be increased by increasing the concentration of PhLi (Table 1). The reaction analogous to **4b→3b** (Scheme 10) using Pb instead of Sn could likewise be demonstrated (yield 19%)[24m].



7b **4b** **3b**, 21%

Scheme 10. [24e].

For comparison, the methyllithium derivatives **4** were also synthesized from halogen compounds **7** by halogen/Li exchange[2,4,26] (Table 2). With exception of **4a**[27], none of the compounds **4** in Tables 1 and 2 had hitherto been described in the literature.



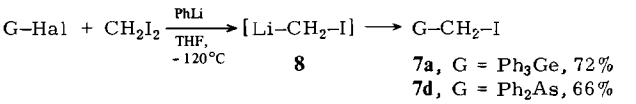
7 **4**

Table 2. Synthesis of G—CH_2—Li **4** from **7** by Hal/Li exchange.

	G	4, Yield [%]
a	Ph_3Ge	≈ 100 [a, b] [23f]
b	Ph_3Sn	98 [a] [24k], 86 [b] [24e]
c	Ph_3Pb	≈ 70 [a] [24k], ≈ 100 [b] [24m]
d	Ph_2As	≈ 100 [a, b] [24i]
i	Me_3Sn	92 [a] [24k]
j	$(n-Bu)_3Sn$	≈ 100 [a] [24k]

[a] In ether, molar ratio **7** : *n*BuLi = 1 : 1; [b] in THF, **7** : PhLi = 1 : 1.

Educts **7a** and **7d** were synthesized by using the reagent **8**, which is stable for only a short time at −100 °C (Scheme 11). The trick[24j] for achieving good yields is to add the organoelement halide at the same time as the CH_2I_2, and not later[28].—The rest of the halides **7** (Table 2) are accessible by means of the Simmons-Smith reagent[29], whose nucleophilicity is inadequate for the synthesis of **7a** and **7c**.

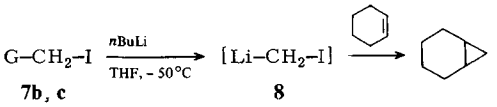


8

7a, G = Ph_3Ge, 72%
7d, G = Ph_2As, 66%

Scheme 11. CH_2Br_2 can also be used instead of CH_2I_2 [24j].

Since the lithium compounds **4** are distinctly more reactive in THF than in ether (see Section 2.2.2), they were also prepared by halogen/Li exchange with PhLi in THF (Table 2). By way of contrast, *n*BuLi in THF proved to be unsuitable in the cases investigated (Scheme 12), since competing organoelement/Li exchange takes place: After addition of cyclohexene, norcarane could be detected, thus indicating that the reaction follows the course formulated in Scheme 12[24e].



7b, c **8**

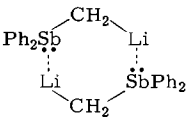
Scheme 12. Yield of norcarane in the case of **7b**, G = Ph_3Sn, 28%, in the case of **7c**, G = Ph_3Pb, 49% [24e].

In contrast to most of the organoelement/Li exchange reactions listed in Table 1[30], no sparingly soluble product separates out in the reactions given in Table 2, *i.e.* establishment of equilibrium is not disturbed. From these reactions, therefore, it can be concluded that the relatively electropositive, heavy main-group elements Sn, Pb, As, Sb, Bi readily stabilize a neighboring carbanionic center; this was confirmed by H/Li exchange reactions (see Section 4.1). Experiments with the tri*alkyl*stannyl compounds **7i** and **7j** (Table 2) show that phenyl ligands on the element are not decisive for this stabilization.

The reagents **4** synthesized can be used for indirect nucleophilic lithio- (El = Sn, Pb, Sb; Section 2.2.3) and halomethylation (El = As, Sb, Bi; Section 3.3.1) and for carbonyl olefination (El = Ge, Sn, Pb, Sb; Section 5.1.1).

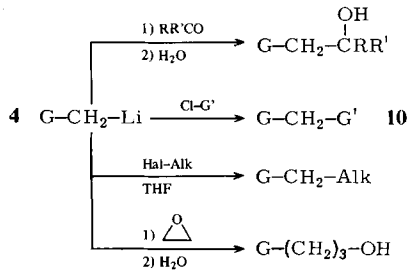
2.2.2. *Stability and Reactivity of G—CH_2—Li*

Seebach and *Beck*[17] were surprised at the stability of the phenyltelluromethyllithium **4h** which they synthesized (no decomposition after 24 h in THF at 0 °C under inert gas). Triphenylstannyl- **4b**, triphenylplumbyl- **4c**, diphenylarsino- **4d**, and diphenylstibino-methyllithium **4e** are likewise astonishingly stable: **4b** (in ether) or **4c-e** (in THF) could still be detected to the extent of 20, 17, 100 and 96%, respectively, after 24 h at 20 °C[24k,h]. Free electron pairs on the heteroatom would thus appear to effect additional stabilization (cf. *e.g.* **9**). However, the Bi-compound decomposes relatively rapidly in THF at ≈20 °C; only ≈20% was still detectable after 30 min[24i].



9

4a—f[2,4,26,31,24e,h-k,m,n] and **4h**[17,24a] react with aldehydes, ketones (see Table 10), organoelement halides, and—as far as tested—with oxiranes in moderate to good yields according to Scheme 13[32].



Scheme 13 (see also Tables 3 and 10).

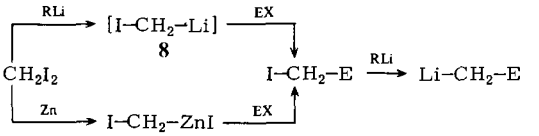
Reactions with alkyl halides proved more critical: As a rule, only **4a** undergoes reaction in ether; in THF, on the other hand, use of **4a-d** leads to CC-coupling in prepara-

Table 3. Synthesis of G—CH_2—Alk from **4** and alkyl halides in THF at −30 to +20 °C. Yields based on **4**.

	G	Hal—Alk	Yield [%] [a]	[b]
4a	Ph_3Ge [24j]	Iodomethane	92	(34)
		Iodoethane	85	46 (35)
		1-Iodopropane	86	
		1-Iodobutane	86	
4b	Ph_3Sn [24e]	1-Iodopropane	75	
		1-Iodobutane		72
		1-Iodopentane	78	
4c	Ph_3Pb [24m]	Iodomethane	68	67
		Bromoethane	69	
		1-Iodobutane	89	
		Benzyl bromide	19	
4d	Ph_2As [24i, 25a, 31]	1-Iodopropane	93	30
		1-Brombutane	85	2
		1-Bromoctane	57	0
		1-Iodobutane		48
4e	Ph_2Sb [26, 31]	1-Iodopropane	15	
		1-Brompropane	12	

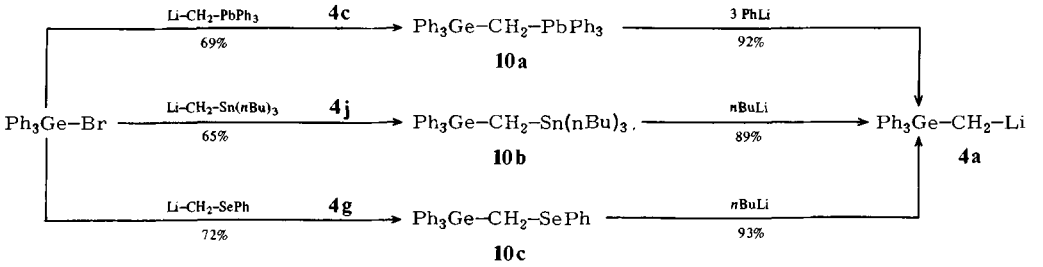
[a] **4** prepared by organoelement/Li exchange (in the case of **4a** see Section 2.2.3). [b] **4** generated by bromine/Li (values in brackets) or iodine/Li exchange.

and the analogous Br-compound (extensive decomposition even after a few minutes at −100 °C) (Scheme 15) is very limited, despite the variant involving generation of the halomethyllithium immediately in the presence of the electrophile (see Scheme 11) indicating a potential improvement in this connection. Moreover, possible indirect lithiomethylation with the Simmons-Smith reagent in the case of strong electrophiles (*e.g.* Ph_3SnCl[29]) (Scheme 15) also fails, even with compounds like Ph_3SiCl or Ph_3GeBr[24j].



Scheme 15. EX = electrophile.

A favorable extension to the methodology is provided by organoelement/Li exchange: Like PhSe—CH_2—Li **4g**[10], the new reagents **4b**, **4c**, **4j**, and—to a lesser degree—**4e** can also be used for nucleophilic lithiomethylation (Schemes 16 and 17). Of importance is that these compounds are thermally considerably more stable than bromomethyllithium or **8** (see Section 2.2.2). Compared to **10a** and **10c** the intermediate **10b** has the disadvantage of not being crystalline. Disadvantageous in the case of **10a** is that 2—3 moles of PhLi are required per mole of educt for the organoelement/Li exchange.

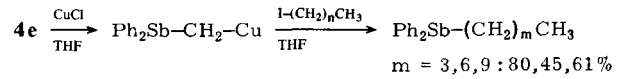


Scheme 16 [24j].

tively satisfactory yields (Table 3). **4e**, **4f**, and **4h** (G = Ph_2Sb, Ph_2Bi and PhTe, respectively), however, also react only slowly or not at all (**4e**) in THF. This would suggest that these compounds form stable, less reactive aggregates of type **9** with participation of the free electron pairs.

As follows from Table 3, the method adopted for the synthesis of the reagent **4** also influences the yields of the products obtained in its reactions with alkyl halides: The halobenzene formed as byproduct during synthesis of **4** by halogen/Li exchange with PhLi deactivates the reagent **4** by complexation, while the by-product *n*-butyl halide can undergo CC-coupling with **4**.

The very moderate yields obtained on reaction of **4e** to give alkyl(diphenyl)antimony could be noticeably increased by transmetalation to the copper(I) compound (Scheme 14)[24,31].

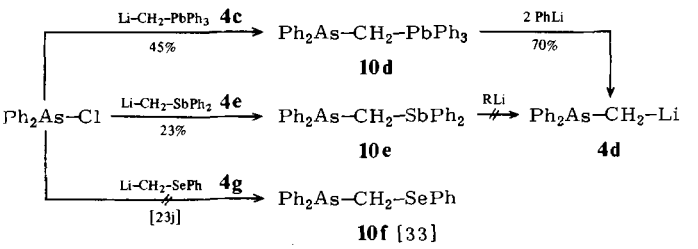


Scheme 14. [24h, 31].

2.2.3. *Indirect Nucleophilic Lithiomethylation with G—CH_2—Li*

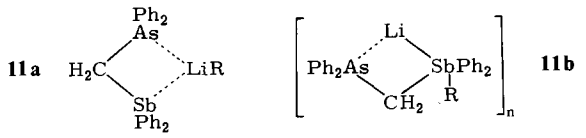
The possibility of carrying out indirect lithiomethylations with the extremely thermolabile iodomethyllithium **8**

Free electron pairs on the heteroatoms of reagent and educt can have an unfavorable effect in such reactions, as shown in Scheme 17: Although PhLi reacts smoothly with methylenebis(diphenylstibane) **3e** with organoelement/Li exchange (Table 1), the analogous compound **10e** can be quantitatively recovered after reaction with PhLi or *n*BuLi and hydrolysis with water[24b].



Scheme 17 [24b].

Either LiR is deactivated by complexation in accordance with **11a**, or an aggregated energy-deficient ate-complex is formed, *e.g.* **11b**, which yields the educt again during the hydrolysis.

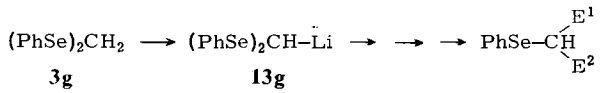


11a **11b**

2.3. Organoelement/Li Exchange at G_3CH

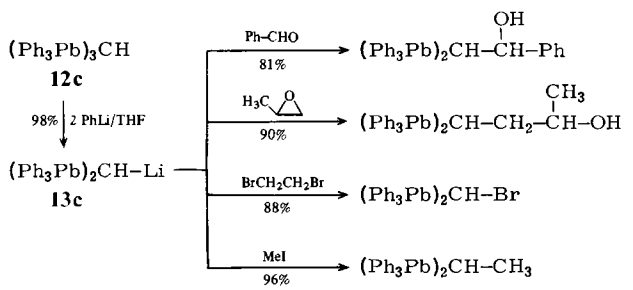
2.3.1. Bis(triphenylplumbyl)methyllithium

Numerous organoselenium compounds can be synthesized from **3g** by H/Li exchange to give **13g**, reaction with an electrophile, seleno/Li exchange, and renewed reaction with an electrophile (Scheme 18)[10,11].



Scheme 18.

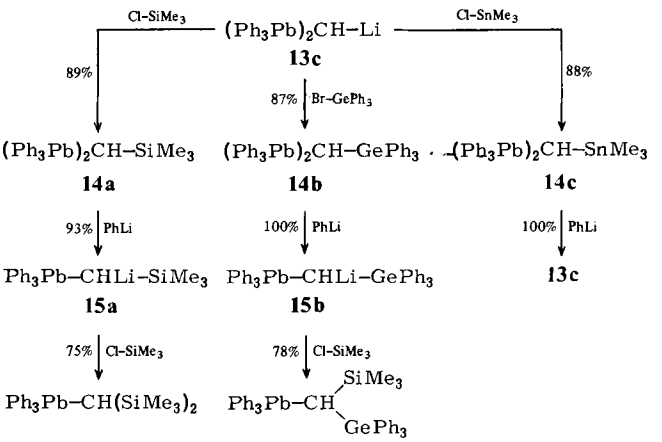
The compounds $(Ph_nEl)_2CH_2$ (El = Sn, Pb, As, Sb) **3b—e** can also be lithiated by H/Li exchange to **13b—e**, but only under conditions which lead to strongly deactivated Li-compounds (see Section 4.1.1). In the case of **3c**, El = Pb, this difficulty could be overcome by using organoelement/Li exchange on a compound of the type G_3CH **12**: The well-known tris(triphenylplumbyl)methane **12c**, which can be conveniently prepared from chloroform and Ph_3Pb—Li[34], and whose yield could be increased from 66 to 91%[23h], reacts quantitatively with PhLi to give **13c**[35], which proved to be surprisingly stable (45—50% still existing after 5 h in boiling THF) and to be very versatile, owing to its exceptional reactivity and selectivity and its exchangeable plumbyl groups (see Schemes 19, 20): On reaction with non-enolizable aldehydes and ketones[36] it forms β-hydroxybis(plumbyl)compounds (57—81%)[24m], which can be decomposed to plumbyl- and lithio-alkenes (see Section 5.1.3). Primary alkyl halides (secondary and tertiary do not react) are converted into alkylidenebis(plumbanes) (25—96%)[24m], from which α-plumbylalkyllithium compounds can be prepared (see Section 5.1.4).



Scheme 19 [24m].

13c reacts with organoelement halides to give derivatives **14**, which contain a further organoelement group besides two plumbyl groups and which can be decomposed to a daughter generation of Li-reagents **15** containing only one plumbyl group, also replaceable by Li (examples: Scheme 20[24,35]). Isolation of the pure product is, as a rule, easy, since plumbyl compounds very readily crystallize. A disadvantage is that plumbyl/Li exchange usually requires 2 moles of PhLi per mole of **14**, which in turn necessitates the use of 2 moles of electrophile in subsequent reactions.

On reaction with PhLi, the tri*methyl*stannyl compound **14c** exchanges exclusively the trimethylstannyl group for Li. In the corresponding triphenyl compound, on the other hand, exchange of all three groups takes place to the same extent[24m].

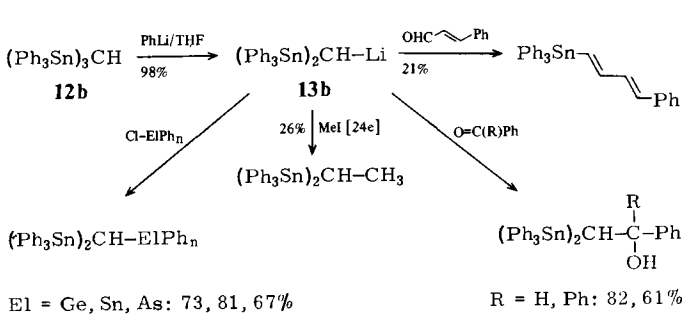


Scheme 20. Use of **15a**: Scheme 61 [24].

$(PH_3Pb)_4C$ is not attacked by LiR (R = Me, *n*Bu, Ph)[25c].

2.3.2. Bis(triphenylstannyl)methyllithium

Other than quoted in the literature[37], the heteroanalogue tris(triphenylstannyl)methane **12b** of **12c** is currently only available by an involved synthesis (see Section 4.1.1). The Li-compound **13b**, which is obtainable in almost quantitative yield from **12b**, is a promising educt, but very few reactions have been tried out (Scheme 21)[23e].



El = Ge, Sn, As: 73, 81, 67%

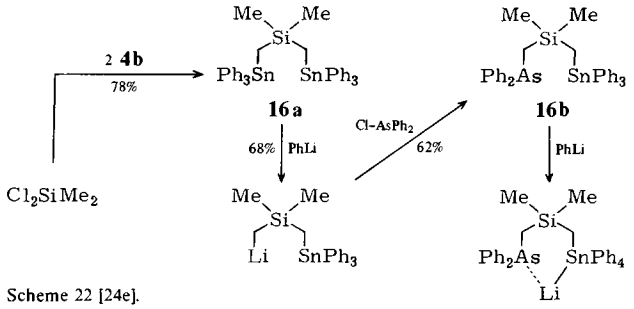
R = H, Ph: 82, 61%

Scheme 21 [23e].

2.4. Compounds of Type G—CH_2—G′—CH_2—G

Compounds of type **16** would be convenient educts for the synthesis of more complex organoelement molecules, if they would allow the peripheral groups to be exchanged for Li without the central group being attacked. However,

preliminary investigations (Scheme 22) have shown that limitations are soon encountered. Though **16a** could be relatively easily lithiated, further reaction in preparatively satisfactory yield was possible only with Ph_2AsCl, and the product **16b** did not undergo stannyl/Li exchange (almost quantitative recovery after addition of water). Presumably the resulting ate-complex is stabilized to such an extent by the diphenylarsino group that $SnPh_4$ is not eliminated[24e].

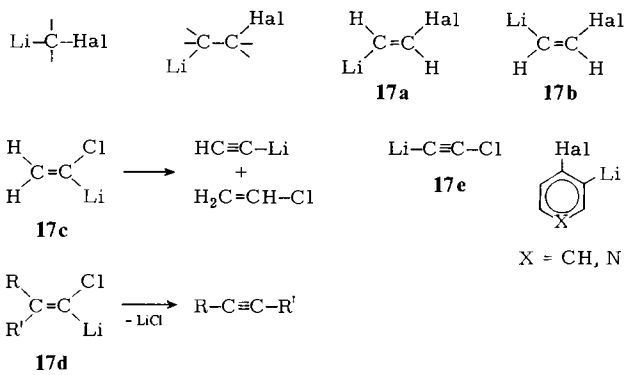


Scheme 22 [24e].

3. Organoelement Groups as Halogen Equivalents

3.1. Motivation and Previous Uses

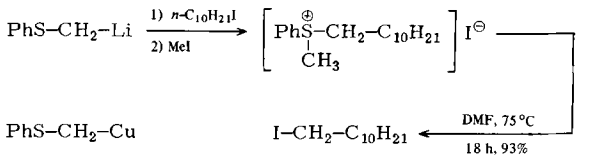
Halogen substituents are important functional groups, since they can be readily exchanged, often stereospecifically, for other functional groups and C- and metal-atoms. However, there are limits to their use, in that a negative charge in the α- or β-position to the halogen has a strong destabilizing effect. Thus, the groups and compounds depicted in Scheme 23 can be used as nucleophiles only at very low temperatures, if at all[38]. **17e** is explosive.



Scheme 23.

It is meaningful, therefore, to search for equivalents for *C*-bonded halogens. These equivalents should, first of all, tolerate a neighboring negative charge or partial charge, and, moreover, be strongly nucleophilic.

Corey et al.[39] were the first to use methylmetal reagents (Li, Cu) containing an organoelement group (= PhS) as halogen-equivalents for nucleophilic halomethylations. Disadvantages of their method (Scheme 24) are long reaction times, limitation to introduction of iodine, and, above all, that practically only alkyl halides can be used as substrates. If instead phenylthiomethyllithium is allowed to react with aldehydes, ketones or oxiranes, then the hydroxy group of the product in the "onium cleavage" with MeI/NaI is, according to our observations[25a], partially methylated.



Scheme 24 [39]. "Onium Cleavage".

Krief et al.[40] carried out analogous but more rapid reactions with the Se compound **4g** and also described indirect nucleophilic α-bromoalkylations with Se reagents (see Section 3.3.2). *Brown et al.*[41] likewise used an organoelement group as halogen-equivalent in the indirect anti-Markownikoff addition of HHal to olefins *via* borane addition and halogenolysis. The same can be achieved by hydrozirconation and subsequent halogenolysis at 0 °C[42].

3.2. Organoelement/Halogen Exchange at C-Atoms

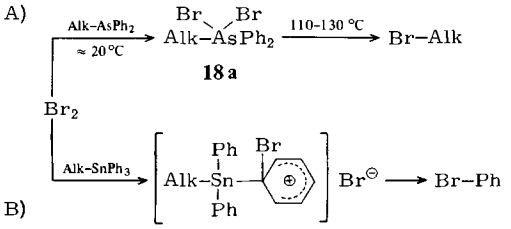
Prerequisites for the use of halogen equivalents in organic synthesis are easy introduction of the equivalent and favorable exchange of halogen. Should organoelement groups function as halogen substitutes in carbanionic reagents, high thermostability and nucleophilicity of these anions is also desirable.

As a rule, the coupling of organoelement groups with C-atoms is unproblematical, since both nucleophilic as well as electrophilic introduction is possible. Moreover, on using suitable organoelement groups (see Sections 2.2.2; 2.3.1; 3.3.1—3.3.3) carbanions exhibiting satisfactory stability and nucleophilicity can be generated. However, difficulties are encountered on exchange of the organoelement group for halogen.

3.2.1. Alkyl-Bound Organoelement Groups

Since halogens attached to sp^3 C-atoms are generally far more versatile than those attached to sp^2 or sp C-atoms there is mainly a demand for equivalents for alkyl-bound halogen. In the case of the organoelement groups which represent potential candidates for this purpose, exchange for halogen is most difficult if the group is attached to a *primary* sp^3 C-atom.

The disadvantages of the "onium cleavage" used by *Corey*[39] and *Krief*[40] were pointed out in section 3.1. "Halogenolysis" with halogen or SO_2Cl_2 might as a rule be more favorable (example: Scheme 26). As in the "onium cleavage", an element with a free pair of electrons is also required. The electrophilic attack of the halogen leads in these cases to "dihalides" such as **18a** (Scheme 25A),



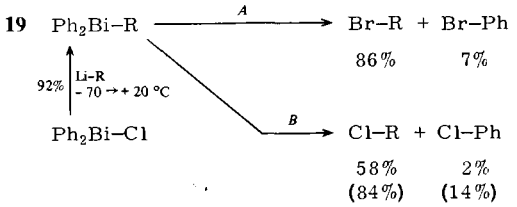
Scheme 25.

which eliminate alkyl halides on heating. The remaining valences of the element (as *e.g.* in the diphenylarsino group) are more appropriately blocked with phenyl ligands, which do not participate in the exchange reactions.

If the central atom of the organoelement group does not bear a free electron pair, all the alkyl moieties participate in the exchange reactions, or the halogen initially attacks a phenyl ligand (if present), which leads to undesirable cleavage of this moiety (Scheme 25 B). Such groups are thus unsuitable as halogen-equivalents on sp^3 C-atoms.

The formation of alkyl halides by halogenolysis of organo-arsenic, -antimony, and -selenium compounds is already well known[43]. But this approach has only recently been used for the directed synthesis of *primary* alkyl halides, while *Krief et al.*[40] had already previously synthesized *secondary* and *tertiary* alkyl halides by productive halogenolyses of organoselenium compounds.

Alkyldiphenylbismuthanes such as **19**, and thus also their halogenolysis, were previously unknown. We synthe-

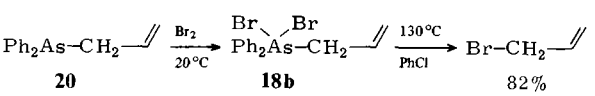


Scheme 26 [18, 24n]; R = *n*-C_5H_{11}. *A*: Br_2, ether −70→+20 °C; *B*: analogous to *A* with SO_2Cl_2 or with Cl_2/THF, 0 °C.

sized them according to Scheme 26—the stratagem here being the use of alkyllithium compounds at low temperatures instead of Grignard compounds at elevated temperatures[43a]—and found that bromolysis and chlorolysis already take place below 0 °C (Scheme 26).

Table 4 enables a comparison of the methods and groups for organoelement/Br and organoelement/I exchange at a primary sp^3 C-atom. On bromolysis, Ph_2As and Ph_2Bi give the highest yields; the air-sensitive group Ph_2Bi is only used at low exchange temperatures. In the "onium cleavage" the yields with PhS, PhSe, PhTe are more favorable than with Ph_2As and Ph_2Sb; surprisingly, however, the lowest exchange temperature was with Ph_2Sb.

In the bromolysis of allyldiphenylarsane **20** with bromine in the molar ratio 1:1 the CC bond remains intact (Scheme 27), while in the case of cyclopropyldiphenylarsane the exchange is accompanied by ring opening[4, 23g].



Scheme 27 [4, 23g].

Organoelement/halogen exchange by halogenolysis at *secondary and tertiary sp^3 C-atoms* is unproblematical. When attached to such C-atoms the otherwise unfavorable PhSe and PhTe groups can be exchanged for bromine already at room temperature in moderate to good yields; on the other hand, "onium cleavage" fails in this case[40]. On using Ph_2As, halogenolysis with Br_2 or I_2 is practically quantitative but requires a temperature of 110—130 °C.

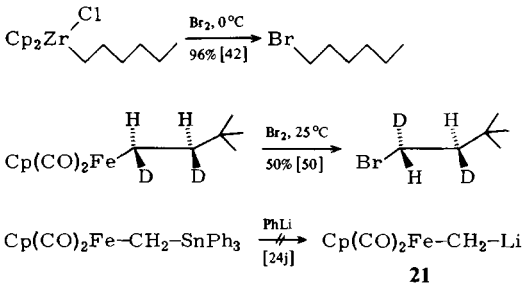
Table 4. Synthesis of *n*-$C_6H_{13}Br$ by bromolysis of *n*-$C_6H_{13}G$ with Br_2 and of *n*-$C_6H_{13}I$ by "onium cleavage" of *n*-$C_6H_{13}G$ with MeI/NaI. Cleavage temperatures and yields.

G	*n*-$C_6H_{13}Br$		*n*-$C_6H_{13}I$	
	T [°C]	Yield [%]	*T* [°C]	Yield [%]
Ph_2As	130	86 [46, 47]	20	<3 [25a]
Ph_2Sb	220	65 [24h, 25b]	20	41 [25b] [a]
Ph_2Bi	−10	84 [24n, 18]		
PhS			80	93 [39]
PhSe	80	44 [23a, 46]	80	80 [40]
PhTe	80	27 [24a]	66	77 [24a]

[a] Since methylation with MeI was not possible, ethylation was carried out with $[Et_3O]BF_4$.

To our knowledge the only comment made so far in the literature about the stereochemistry of organo/halogen exchange at sp^3 C-atoms is that PhSe/Br exchange largely proceeds with inversion[48]. In the diphenylarsino/halogen exchange studied by us there is little prospect of an optically active arsane being converted into an optically active halide, since secondary or tertiary halides rapidly racemize at 110—130 °C[49].

Organo-transition metal groups can be cleaved just as readily as Ph_2Bi from alkyl moieties by halogens (examples: Scheme 28). The possibilities of using such groups as halogen equivalents are however very limited, since all attempts to synthesize reactive carbanions containing organo-transition metal groups have so far failed. Thus, the synthesis of **21** could not be achieved[24j].

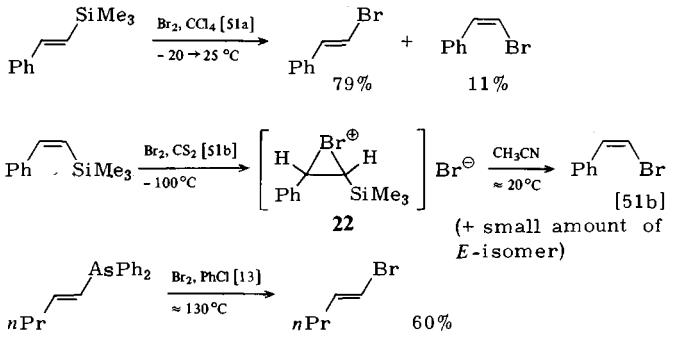


Scheme 28.

3.2.2. *Vinyl-Bound Organoelement Groups*

Groups such as Me_3Si, $(nBu)_3Sn$ (central atom without free electron pair, alkyl ligands), which are attached to an alkyl moiety are unsuitable as halogen equivalents. On the other hand, when bound to a vinyl group or a nucleophilic arene they are very useful: In the case of 1-alkenylsilanes, Me_3Si/Br exchange already takes place specifically at room temperature with rupture of the sp^2 C—Si bond and with retention, whereupon intermediary bromonium ions, *e.g.* **22**, are formed (Scheme 29)[51]. Stannyl groups are exchanged for bromine even more readily than are silyl groups (Scheme 40)[13, 52].

We have found that PhSe and Ph_2As groups attached to vinyl are exchanged for Br in high yields without the double bond being attacked. In contrast to Ph_2As/Br exchange (Schemes 29, 41, 42)[13, 23b], PhSe/Br exchange (Scheme 38) already takes place at 20 °C[4, 47b].



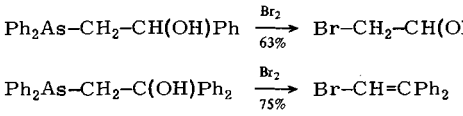
Scheme 29.

3.3. Nucleophilic Reagents with Halogen-Equivalent Groups

3.3.1. Indirect Nucleophilic Halomethylation

Diphenylarsinomethyllithium **4d**: Nucleophilic halomethylations of alkyl halides previously required the four-step process Alk—Hal → Alk—CN → $AlkCO_2H$ → Alk—CH_2OH → Alk—CH_2Hal. With organoelement groups as halogen equivalents the process nowadays involves rather Alk—Hal → Alk—CH_2G → Alk—CH_2—Hal. Besides the well-known reagents $PhSCH_2Li$ and $PhSCH_2Cu$ (Scheme 24) and **4g**, whose disadvantages have been mentioned in Section 3.1, the As-reagent **4d** is particular suitable for this purpose. The Bi-analogue **4f** is less suitable, since on reaction with electrophiles it yields difficultly separable mixtures (so far a pure product has been obtained only from benzophenone), while on using the analogous Sb reagent **4e** (or the analogous Cu(I) compound) organoelement/halogen exchange is relatively unfavorable (see Table 4).

Since reaction of **4d** with aldehydes and ketones or oxiranes yields β- or γ-hydroxyalkylarsanes (yields: 53—94%), it should be pointed out that a γ-hydroxy group causes little interference in diphenylarsino/bromine exchange, whereas a β-hydroxy group may markedly reduce the yield of halide, or, in certain cases, lead to cleavage of water (Scheme 30). In cases where cleavage of water interferes with halogenolysis, it can be profitable to esterify the hydroxy group with acetyl chloride beforehand[24g].

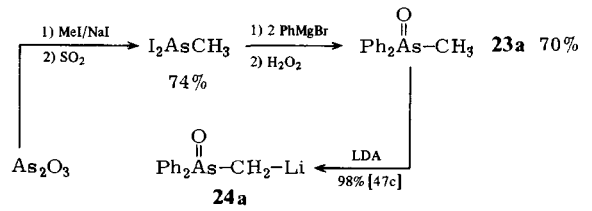


Scheme 30 [44, 45, 47a].

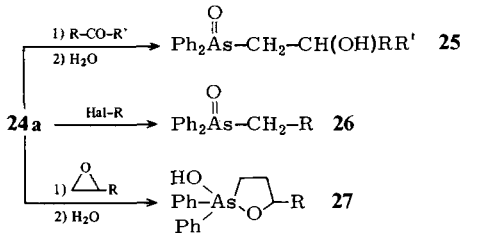
For reactions with aldehydes, ketones, and oxiranes, **4d** can be prepared by iodine/Li exchange (Table 2). For reactions with alkyl halides, on the other hand, the uneconomical synthesis (larger excess of *n*BuLi necessary) by organoelement/Li exchange according to Scheme 9, which leads to reactive **4d** (Table 1), is necessary.

Diphenylarsinoylmethyllithium **24a**: An alternative to **4d** is the more reactive and somewhat more conveniently accessible arsane oxide derivative **24a**[44,45,47c] (Scheme 31: avoidance of the volatile poisonous intermediate Ph_2AsCl and the low temperature synthesis formulated in Scheme 11), which reacts with electrophiles according to Scheme 32.

The main advantage of **24a** is its strongly acidifying diphenylarsinoyl group, which enables coupling of a total of three residues in the α-position (see Section 3.3.2). The disadvantage that a $LiAlH_4$-reduction is necessary after the



Scheme 31.



Scheme 32.

Table 5. Reaction of **24a** with electrophiles in THF at −40→+20°C in the molar ratio 1:1 according to Scheme 32.

Electrophile		Product R	R'	Yield [%]
Butyraldehyde	**25a**	H	*n*Pr	60 [47a]
Benzaldehyde	**25b**	H	Ph	82 [47a]
Cyclohexanone	**25c**	—$(CH_2)_6$—		53 [47a]
Benzophenone	**25d**	Ph	Ph	81 [47a]
Ethyl bromide	**26a**	Et		56 [24h]
n-Propyl bromide	**26b**	*n*Pr		69 [24h]
n-Butyl bromide	**26c**	*n*Bu		72 [47a]
Allyl bromide	**26d**	CH_2—CH=CH_2		70 [47a]
Benzyl bromide	**26e**	CH_2—Ph		72 [24h]
Oxirane	**27a**	H		74 [24g]
Methyloxirane	**27b**	Me		68 [24g]
Ethyloxirane	**27c**	Et		70 [24g]

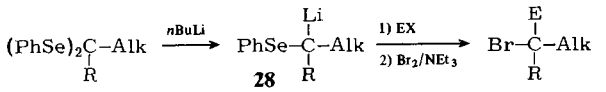
CC-coupling, is not so serious, since the reduction proceeds quantitatively and can be combined with the CC-coupling in a one-pot process.

In reactions with carbonyl compounds and oxiranes the arsinoyl reagent **24a** does not lead to better yields (Table 5) than the arsino reagent **4d**. On the other hand, the yields in reactions with alkyl halides are essentially better (Table 5) than when using **4d** (Table 3), in that the more convenient route *via* Ph_2As—CH_2—I **7d** was chosen for the preparation of **4d**.

Reaction of **24a** with oxiranes and then with water does not lead to γ-hydroxyalkylarsane oxides but to 2-hydroxy-1,2λ⁵-oxarsolanes **27**[24g], which, however, are smoothly reduced by $LiAlH_4$ to γ-hydroxyalkylarsanes, *i.e.* the readily accessible compounds of halogenolysis (cf. Scheme 36).

3.3.2. Indirect Nucleophilic α-Haloalkylation

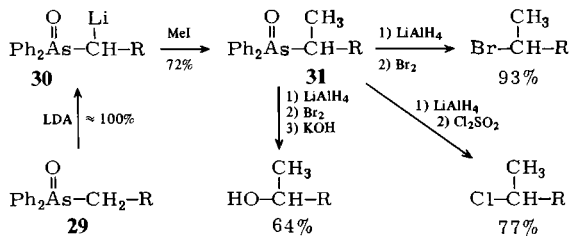
For the introduction of α-bromoalkyl groups into electrophiles (Scheme 33) *Krief et al.*[40,53] used the reagents **28**, which are obtainable by PhSe/Li exchange (cf. *e.g.* Scheme 18).



Scheme 33. EX = electrophile.

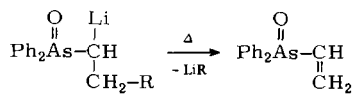
In our method (example: Scheme 34), on the other hand, *α-lithioalkylarsane oxides, e.g.* **30**, are used, which are also readily accessible by H_2O_2-oxidation and lithiation after reaction of PhAsCl with carbanions or of Ph_2AsLi with alkyl halides. The halogenolysis can be combined with a nucleophilic substitution in a one-pot process, whereupon hydroxy compounds or thioethers are immediately formed[24h,54]. The α-lithioalkylarsane oxides thus offer a variety of possibilities for the synthesis of functionalized hydrocarbons.—Also secondary alkylarsane oxides, *e.g.* **31**, can be lithiated with LDA; further reaction with electrophiles, however, is more difficult than with compounds of type **30**.

Owing to their high thermostability (in contrast to corresponding selenium oxides, which already decompose below 20 °C[55]) and tendency to crystallize, the alkylarsane oxides, *e.g.* **29**, necessary as precursors or intermediates



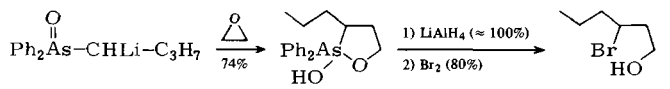
Scheme 34 [24h, 54]; R = C_2H_5.

can easily be isolated. Also their α-lithiation products are usually so thermally stable that they can be heated during reaction with electrophiles. Exceptions are the compounds listed in Scheme 35, and similar compounds: They fragment by LiR elimination[24h,56].



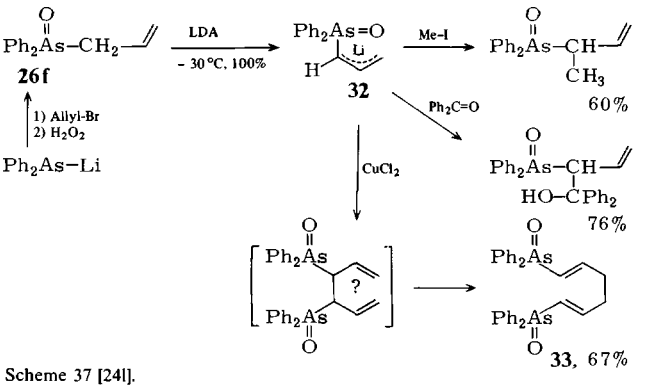
Scheme 35 [24h, 56]. Fragmentation of the educts with R = Ph, Ph_2As, $Ph_2As(O)$ at > −55, <20, and <20 °C, respectively.

Like **24a**, α-lithioalkylarsane oxides also react with oxiranes to give 2-hydroxy-1,2λ^5-oxarsolanes, which can be readily decomposed to open-chain bromides[24g] (Scheme 36).



Scheme 36 [24g].

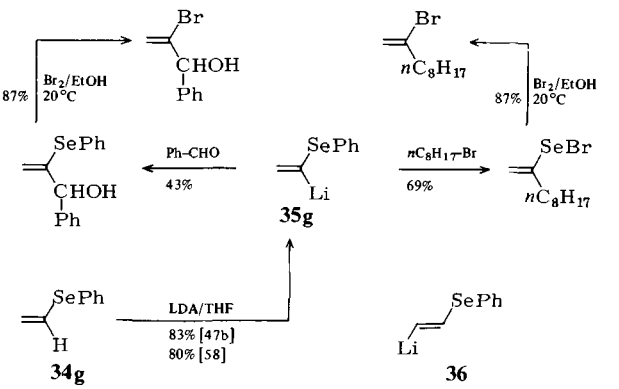
Of the *specific* α-lithioalkylphenylarsane oxides prepared[4], the allyl compounds **32** deserve special mention. Since they react with electrophiles—in analogy to allyllithium compounds with sulfinyl, sulfonyl or phosphonate groups[57]—exclusively in the α-position (Scheme 37), and the CC double bond remains intact during diphenylarsino/bromine exchange at allyldiphenylarsane **20** (Scheme 27), **32** is in all probability suitable for the indirect nucleophilic introduction of α-haloallyl groups into electrophiles. Also worthy of mention is the oxidative coupling of **32** in good yields to give **33**, a diene containing two halogen-equivalent substituents. In the synthesis of **26f** according to Scheme 37 it is advisable to oxidize the very unstable allyldiphenylarsane **20** with 30% H_2O_2 immediately after its formation[24l].



Scheme 37 [24l].

3.3.3. *Indirect Nucleophilic α- and β-Halovinylation*

The thermal instability of **17c** and **17d**[38] (Scheme 23) considerably lowers the value of these reagents for syntheses. A substitute for **17c** is 1-phenylselenovinyllithium **35g**: According to independent observations by *Krief et al.*[58] and by us[4,47b] the electron-withdrawing phenylseleno group of **34g** enables H/Li exchange, to give the sufficiently thermostable and nucleophilic reagent **35g**. Moreover, according to our findings[4,47b] on the products obtained by reaction of **35g** with electrophiles (examples: Scheme 38), phenylseleno/Br exchange in ether or chlorobenzene proceeds quite smoothly already at room temperature, even if a hydroxy group is in the β-position to the phenylseleno group. **35g** is therefore a suitable reagent for *indirect nucleophilic α-halovinylation.*

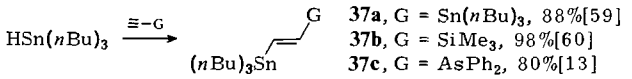


Scheme 38 [4, 47b].

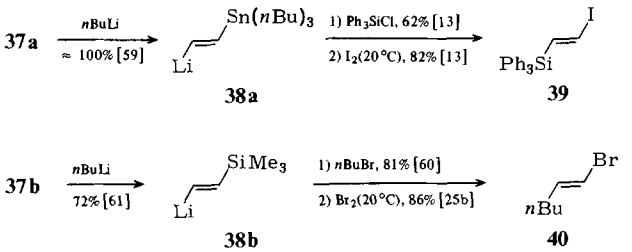
When using **35g**, account should be taken of its tendency to undergo elimination of PhSeLi—particularly in

the presence of hexamethylphosphoric triamide (HMPA)[58]. A small HMPA content is, however, advantageous for reaction with alkyl halides[58].—The tellurium analogue **35h** (see Section 4.1.3) is no alternative on account of its poorer accessibility and lower nucleophilicity.

The thermolability is greater when halogen and lithium, as in **17a** and **17b**, are attached *vicinal* to a CC double bond than when attached at the *geminal* position (Scheme 23). Whereas a substitute organoelement reagent for *cis*-compounds of the type **17b** is to our knowledge unknown, there are equivalents for the *trans*-compound **17a**: Unlike the extremely unstable Se-compound **36**[25a], the Li-compounds **38a** and **38b** synthesized for another purpose by *Corey et al.*[59] and *Cunico et al.*[60], respectively, are suitable in this respect, as is demonstrated by synthesis of the halides **39** and **40** (Schemes 39 and 40). The Sn-reagent **38a** is, of course, hardly recommendable, since it is extremely difficult to separate the desired product from the tetrabutyltin and other products that are always formed.

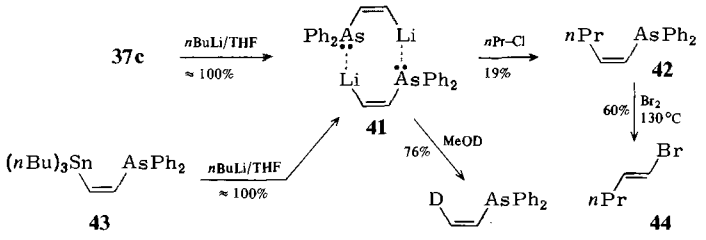


Scheme 39.



Scheme 40.

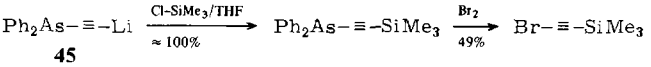
In the case of the As-reagent **41** synthesized by us, the *Z*-configuration is presumably stabilized by the complexation formulated in Scheme 41. Unfortunately, the Ph_2As/Br exchange requires such severe conditions that inversion of configuration occurs[62].—The educts for **41** are accessible by hydrostannation according to Scheme 39, where up to ≈10% of the *Z*-isomer **43** is formed as well as **37c**.



Scheme 41 [13].

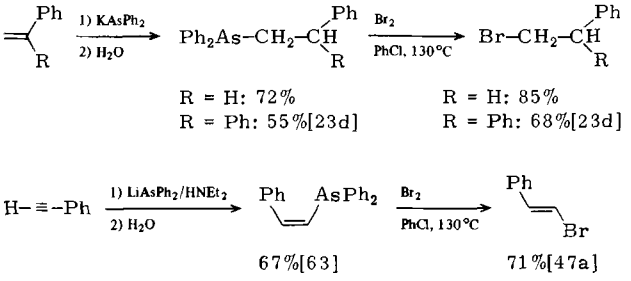
3.3.4. *Indirect Nucleophilic Haloethynylation*

Such conversions have rarely been investigated. An As-reagent, namely **45**, is also suitable for this purpose; it is conveniently accessible by H/Li or Ph_2As/Li exchange (Scheme 6). That the diphenylarsino- and not the trimethylsilyl-group of the intermediate is exchanged for bromine is surprising.



3.3.5. *Strongly Nucleophilic Equivalents for Hal⊖*

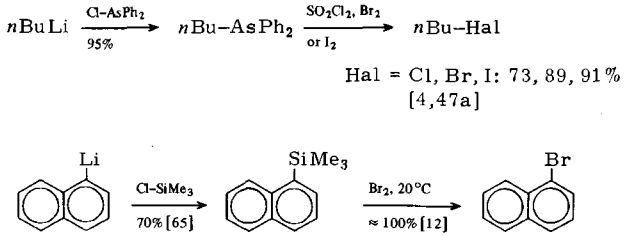
When halide ions with extremely high nucleophilicity are desirable in synthetic operations, reaction with $Ph_2As^{\ominus}$ (Ph_2As—Cl or Ph_2As—$AsPh_2$ + Li, Na, K) or $PhSe^{\ominus}$ (PhSe—SePh + $NaBH_4$) with subsequent organoelement/halogen exchange is recommended. Here, the diphenylarsenide ion generally has the higher nucleophilicity. If in such a reaction the organoelement group is coupled with a *primary* C-atom, $Ph_2As^{\ominus}$ might, as a rule, also be more suitable than $PhSe^{\ominus}$, since the yield on organoelement/halogen exchange is better (see Table 4). Scheme 42 shows some applications.



Scheme 42.

3.4. Electrophilic Reagents with Halogen-Equivalent Groups

In attempts to halogenate carbanions with halogens, CC-linkage by oxidative coupling is not rarely the main reaction. As a rule, better results are obtained with CCl_4 or CBr_4[64]. If the Li atom attaches to an sp^3 C-atom a favorable alternative is arsanation with chloro(diphenyl)arsane followed by diphenylarsino/halogen exchange. In the case of alkenyl- and aryllithium compounds, silylation with trimethylchlorosilane followed by trimethylsilyl/halogen exchange is more favorable (examples: Scheme 43).



Scheme 43.

Organoelement equivalents for vinyl halides are mentioned in Section 4.2.1.

4. Electron-Withdrawing Effect of Organoelement Groups and Synthetic Uses

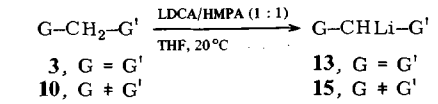
4.1. Acidification by Heavy Main-Group Elements

4.1.1. H/Li-Exchange at G_2CH_2

According to the findings in Section 2.2.1, Ph_nEl-groups with E = Sn, Pb, As, Sb, Bi stabilize a lithiated C-atom directly attached to them. Moreover, the reactions with the tri*alkyl*stannyl compounds **4i** and **4j** (Table 2) showed, in the case of tin, that phenyl ligands are not decisive for this stabilization. The question now arose, whether heavy main-group elements in general could detectably acidify an attaching CH-group.

We initially investigated the effect of bases on bis(triphenylstannyl)methane **3b**, whose tendency to undergo stannyl/Li exchange precluded the use of organolithium compounds as base. After a number of fruitless attempts[66a], lithiation was finally accomplished with the aid of the bulky lithium dicyclohexylamide (LDCA) in presence of up to 92% HMPA[23e]. Analogous compounds were also lithiated under the same conditions, at room temperature according to Scheme 44[67] (Table 6); in the case of the Bi-compound **3f**, decomposition reactions prevent detection of lithiation.

That the acidifying action of heavy main-group elements has only just been discovered might be due to the high electrophilicity of the corresponding organoelement groups. This promotes direct attack at these groups by bases such as *n*BuLi or PhLi, which effect organoelement/Li exchange (cf. Scheme 51).



Scheme 44.

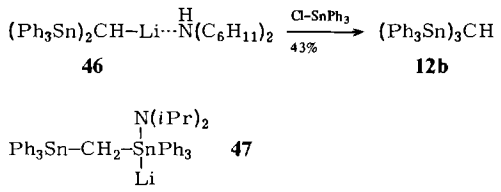
Table 6. Lithiation of **3** and **10** to **13** and **15**, respectively, according to Scheme 44 [67].

	G	Yield [%]		G	Yield [%]
13l	Ph_3Si	0 [24n]			
13a	Ph_3Ge	0 [23f]	**13d**	Ph_2As	63 [24e]
13b	Ph_3Sn	92 [23e]	**13e**	Ph_2Sb	68 [24h]
13c	Ph_3Pb	67 [25a]	**13f**	Ph_2Bi	decomp. [24n]
15c	Ph_3Sn—CHLi—$AsPh_2$, yield 67% [24b]				
15d	Ph_3Pb—CHLi—$AsPh_2$, yield 32% [24b]				

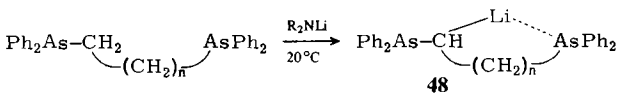
The Li-compounds **13** obtained by H/Li exchange disappointingly showed little reactivity towards carbonyl compounds and other electrophiles: For example, the most investigated of such compounds, namely bis(triphenylstannyl)methyllithium **13b**, reacted in preparatively useful yields, if D_2O or H_2O is ignored, only with Ph_3SnCl, whereby tris(triphenylstannyl)methane **12b**[23e,67] was obtained for the first time[37].

If, on the other hand, **13b** is synthesized by organoelement/Li instead of H/Li exchange, it is very reactive (see Section 2.3.2). As experiments with **13b** in the presence of dicyclohexylamine or HMPA have shown, deactivation is effected by the amine and not by HMPA[23e]. Probably the 1 : 1 complex **46** is formed, whose nucleophilic center is strongly shielded by bulky residues.

Since LDA has a greater tendency to undergo nucleophilic addition than the bulky LDCA, it was surprising that **3b** could be recovered largely unchanged after reaction with LDA (practically no lithiation). Presumably the ate-complex **47** is formed, which decomposes on addition of water, with generation of **3b**.



In compounds **3**, *two* organoelement groups acidify the methylene group. It could be shown with the aid of the reactions outlined in Scheme 45, that even *one* diphenylarsino group makes the α-methylene group capable of lithiation if a second group of the same kind supports it by chelation[23c].

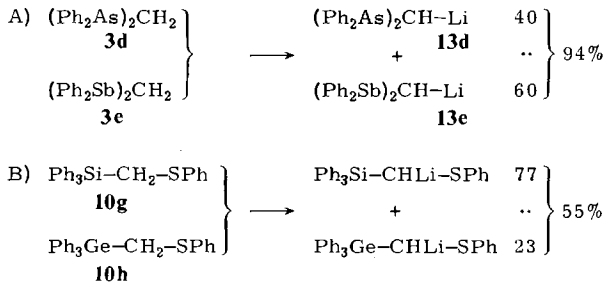


Scheme 45 [23c, 24b, 24c].

Conditions	**48**, n =	Yield/[%] 1	2	3	4	5	6
LDA/THF		0	36	36	32	21	0
LDCA/HMPT		63	49	60	54		

4.1.2. Influence of Element and Ligand on the Acidification

We have compared the acidifying effect of heavy and of light main-group elements by H/Li exchange on the compounds **3** under competing conditions, the experimental conditions having to be varied for practical reasons[66b]. Scheme 46 A shows a typical competition experiment. The results are collected in Scheme 47.

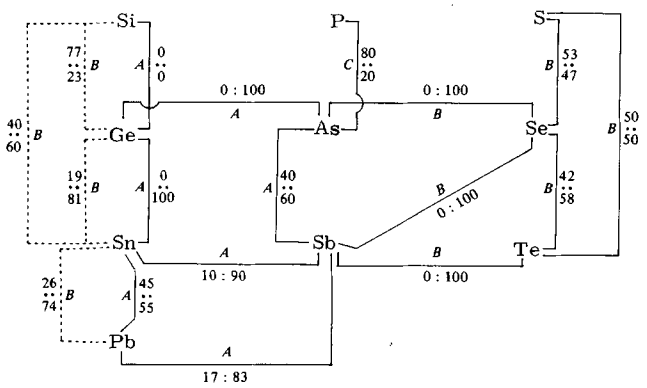


Scheme 46. Conditions: A) LDCA/HMPA (1 : 1), THF, 20 °C, 0.5 h; B) LDA/THF, −50 → −10 °C, 2.5 h.

Since a comparison of the groups Ph_3El in which El = Si, Ge, Sn, Pb was either impossible, or possible to only a lim-

ited extent, owing to the very low acidity of compounds **3**, El = Si and Ge [**3a**], these groups were combined with the distinctly acidifying phenylthio group to give, *e.g.*, compounds **10g** and **10h**, respectively. The results of competition experiments with these compounds[24j] (example: Scheme 46 B) are given alongside the dotted brackets in Scheme 47. The degrees of lithiation were determined by deuterolysis with D_2O and ^{1}H-NMR analysis of the products.

From the molar ratios of the lithiation products it is concluded that the elements of the 4th row (Sn, Sb, Te) are more strongly acidifying than the homologous elements of the 3rd row (Ge, As, Se), and equally as strongly acidifying as the homologous elements of the 2nd row. Furthermore, a marked increase in acidifying action was observed on going from the 4th row element Sn to the 5th row element Pb, and—as expected—on going from the 4th→5th→6th group.—Since the molar ratios of the lithiation products did not change in experiments carried out over prolonged periods, thermodynamic acidity must be involved.



Scheme 47. For explanation see text. Lithiation conditions: *A* as in Scheme 46 A [24j, 24n]; *B* as in Scheme 46 B [24a, 24j]; *C* *n*BuLi + 2 TMEDA, THF, 20 °C, 0.5 h [24g].

Since bis(tri*methyl*silyl)methane **3k** is lithiated largely at the methylene group by *n*BuLi + HMPA[68a], whereas all attempts at lithiation on the analogous hexaphenyl compound **31**[24n] failed, it would appear that phenyl ligands in comparison to methyl ligands reduce the acidifying effect of the element[4]. Individual and competition experiments, mainly performed on compounds **10**, in which the group under examination is combined with a phenylthio- or phenylseleno-group, later showed a reverse pattern in the ratios (examples: Table 7).

3k $(Me_3Si)_2CH_2$ **3l** $(Ph_3Si)_2CH_2$

Table 7. Competing lithiation of G—CH_2—G' **10** for determining the influence of ligands on the acidifying action of main group elements.

Substrates		Yield G—CHLi—G' rel.	abs. [%]
Me_3Si—CH_2—SPh/Ph_3Si—CH_2—SPh	[a]	6 : 94	80 [47a]
Me_3Si—CH_2—SePh/Ph_3Si—CH_2—SePh	[b]	23 : 77	53 [24j]
Me_3Ge—CH_2—SPh/Ph_3Ge—CH_2—SPh	[a]	12 : 88	≈ 100 [24j]
Me_3Ge—CH_2—SePh/Ph_3Ge—CH_2—SePh	[b]	0 : 100	56 [24j]

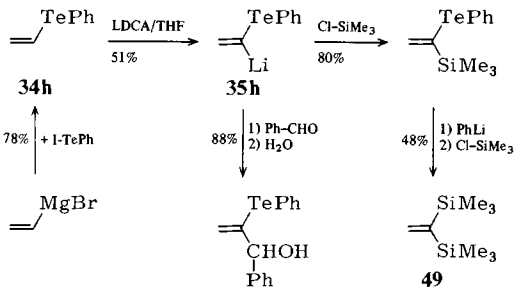
[a] LDA, THF, −50→−10 °C, 2.5 h; [b] LDCA/HMPA (1 : 1), ether/THF (3.5 : 1), 20 °C, 2 h.

Accordingly, the failure of attempted lithiation of **31** can only be explained thus: Owing to the small C—Si bond length of ≈ 1.93 Å (corresponding bond lengths in the case of Ge, Sn, Pb: ≈ 1.98, 2.18, ≈ 2.29 Å)[69] the methylene group of **31** is so strongly shielded that, other than in the case of the corresponding Sn- or Pb-compound (see Section 4.1.1) or **3k**, it cannot be attacked by lithiating reagents.

4.1.3. H/Li Exchange at Phenyltelluroethene

Since the PhTe group is superior rather than inferior to the PhSe group in the acidifying action[24a] (Scheme 47), and since phenylselenoethene **34g** is amenable to H/Li exchange (see Section 3.3.3), it was of interest to us whether this also holds for phenyltelluroethene **34h**. The question at hand was also whether organoelement/Li exchange can be suppressed in favor of H/Li exchange.

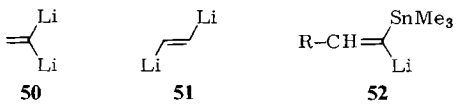
Whereas reaction of *n*BuLi with the recently prepared compound **34h**[24a] (Scheme 48) leads to formation of only ≈ 10% α-lithio(phenyltelluro)ethene—as expected the main reaction is organoelement/Li exchange—the yield increases to ≈ 50% on using the bulky bases lithium dicyclohexylamide (LDCA) or lithium-2,2,6,6-tetramethylpiperidide in THF at −70 °C. A further increase in yield was not possible[24a].



Scheme 48 [24a, 47a].

In view of the very good yields obtained for organotelluro-compounds on reaction of **35h** with benzaldehyde or trimethylchlorosilane (Scheme 48), the failure of the reaction with allyl bromide or 1-iodopropane was surprising.

The products to be expected, and actually synthesized from **35h** and electrophiles, contain the phenyltelluro group, which is readily exchangeable for Li; hence, the vinyl group can be coupled with a second electrophile to give, *e.g.*, **49**[68b]. **35h** may therefore be regarded as equivalent for 1,1-dilithioethene **50**, similarly to **38a**[59] (Scheme 40) as equivalent for *E*-1,2-dilithioethene **51**.—



50 **51** **52**

Equivalent reagents for 2-substituted 1,1-dilithioethenes are the recently described compounds **52**, which are accessible by stannyl/Li exchange[70].

4.1.4. What Causes the Stabilization of Carbanions by Heavy Main-Group Elements?

This stabilization of carbanions is proven by the exchange reactions (organoelement/Li, halogen/Li, H/Li exchange) outlined. The question as to the cause, however, cannot as yet be answered unequivocally: According to *ab initio* calculations on REl—$CH_2^{\ominus}$ anions (El = S, Se) the stabilization of carbanions by thio- or seleno-groups is due to the polarizability of S and Se, and to a stereoelectronic effect[71]. If polarizability does in fact play an essential role, then stabilization by the "soft" elements of the 4th and 5th row is readily understandable.

The relatively high acidity of C—H bonds alpha to 2nd-row elements Si, P, S is still usually explained, even today, in terms of a (p→d)π orbital overlapping in the respective anions. A corresponding overlapping is unlikely in the case of a 4th- or 5th-row element, owing to the distinctly longer C—El bond. That long pd hybrid orbitals of 4th- and 5th-row elements participate, as has been discussed for explanation of the strong ring current effect of arsa- and stiba-benzene[72], is, however, also worth considering here. It might also be possible that alkyllithium compounds containing a heavy main-group element in the α-position form particularly stable aggregates and are thus thermodynamically favorable. Here, the formation of ate-complexes, *e.g.* **53**, is the first likelihood, provided that the heteroatom has no free electron pair.

$$\underset{\textbf{4c}}{2\ Ph_3Pb{-}CH_2{-}Li} \longrightarrow \underset{\textbf{53}}{Ph_3Pb{-}\overset{\overset{Li}{|}}{C}H_2{-}Pb(Ph)_3{-}CH_2{-}Li}$$

4.2. Nucleophilic Addition and Cycloaddition to Organoelement-Substituted Ethenes

4.2.1. Chain Expansion of Carbanions

It was known from the literature that R_nEl-substituted ethenes **34**, El = SiP, S, Ge, add to the double bond of alkyllithium compounds[73] because of the electron-withdrawing action of these elements. Since As and Se are likewise electron-withdrawing (cf. Section 4.1.2), and since alkyl-bound Ph_2As- and PhSe-groups are favorable halogen equivalents (Section 3.2.1), we checked whether the chain-lengthening of carbanions with diphenylarsino- **34d** and phenylseleno-ethene **34g** formulated in Scheme 49 could be realized, and found our expectations confirmed.

$$\underset{\textbf{34}}{Alk{-}Li + \overset{G}{=\!\!\diagup}} \longrightarrow \underset{\textbf{54}}{Alk{-}\overset{\overset{Li}{|}}{C}H_2{-}CH{-}G} \xrightarrow{H_2O} \underset{\textbf{55}}{Alk{-}(CH_2)_2{-}G} \xrightarrow{Br_2} \underset{\textbf{56}}{Alk{-}(CH_2)_2{-}Br}$$

d, G = Ph_2As
g, G = PhSe

Scheme 49. Yields: Table 8.

Table 8. Synthesis of **55** and **56** from **34** and alkyllithium compounds (molar ratio 1 : 1) according to Scheme 49. Yields based on Alk—Li.

Alk	G	Yield [%] 55	56	G	Yield [%] 55	56
C_2H_5	Ph_2As	37 [a]		PhSe		
n-C_4H_9	[24o]	95 [a]	82	[23a]	72 [b]	32
s-C_4H_9		71 [b]	84		25 [b]	28
t-C_4H_9		57 [b]			25 [b]	

[a] Reaction in THF; [b] reaction in ether [46].

In each case, diphenylarsinoethene **34d** gave far better yields than phenylselenoethene **34g** (Table 8) in the addition and the halogenolysis (see Section 3.2.1). The drawback of using **34g** as substrate for the addition may be due to the fact that α-lithiation to **35g** (see Section 3.3.3) and phenyl/alkyl exchange to give alkylselenoethene compete with the addition[58].—The reactions formulated in Scheme 49 reveal **34d** as equivalent for vinyl halides, which cannot add carbanionic compounds because of polymerization.

α-Lithiated alkyldiphenylarsanes **54d** have been made accessible for the first time *via* the reaction of **34d** formulated in Scheme 49. With these, as with diphenylarsinomethyllithium **4d** (see Section 3.3.1), α-arsino-, and thus α-haloalkyl-groups (see Section 3.3.2) can be incorporated into electrophiles (example: Scheme 50).—Electrophiles have also been reacted with Se derivatives **54g**[58].

$$\underset{\textbf{54d}}{Alk{-}\overset{\overset{Li}{|}}{C}H{-}AsPh_2} \xrightarrow[2)\ H_2O]{1)\ Ph\text{-}CHO(THF)} \underset{68\%}{Alk{-}\overset{\overset{HO{-}CH{-}Ph}{|}}{C}H{-}AsPh_2}$$

Scheme 50 [24o]. Alk = *n*-C_5H_{11}.

According to our observations, R_nEl-substituted ethenes **34** do not react with 4th- and 5th-row elements according to Scheme 49, most likely due to organoelement/Li exchange. Thus, there is a clear line of demarcation between suitable elements (area circled in Scheme 51) and unsuitable elements for such reactions. The same applies for cycloadditions (Section 4.2.2).

Si	P	S
Ge	As	Se
Sn	Sb	Te
Pb	Bi	

Scheme 51. The group of elements circled can react according to Scheme 49.

4.2.2. Organoelement Groups as Removable Auxiliary Groups in 1,3-Anionic Cycloadditions

The scope of the "1,3-anionic cycloaddition" type of reaction[5] is considerably limited by the fact that, for stabilization of the heteroallyl anions and activation of the substrates, aromatic moieties are required which can be removed after reaction.—This problem was remedied by the observation that organoelement groups like PhS, PhSe, Ph_2P and Ph_2As, which are readily removable after the cycloaddition, so activate olefinic double bonds that cycloaddition of 2-azaallyllithium compounds according to Scheme 52 is possible[74] (yields: Table 9). The cleavage of these auxiliary groups can be accomplished by hydrogen-

ation with Raney-nickel (PhS, PhSe, Ph_2As) or by bromolysis (Ph_2As, PhSe) (examples: Scheme 53). The Ph_2P group may be removable after oxidation by Horner reaction.

Me_3Si, Ph_3Si[75] and Ph_3Ge groups are likewise activating (Table 9), but they are difficultly removable, while corresponding groups containing the 4th- and 5th-row elements Sn, Sb, Te, Pb, Bi are unsuitable because of organoelement/Li exchange (see Scheme 51).

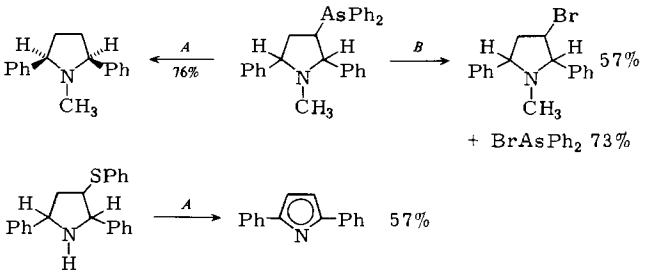
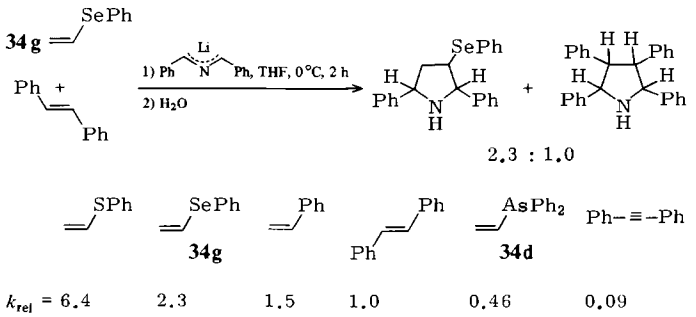


Scheme 53 [24o]. *A:* Raney-nickel/EtOH, 20°C; *B:* 1) Br_2/CCl_4 0°C, 2) 120°C.

In competition experiments, in which two olefins were allowed to react with 1,3-diphenyl-2-azaallyllithium in the molar ratio 1:1:1, we determined the relative rate constants quoted in Scheme 54. The gradation in readiness to



Scheme 54.

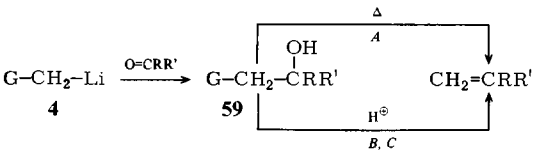
undergo cycloaddition along the series PhS> PhSe> Ph_2As directly corresponds to the relative acidifying effect of these groups revealed in Scheme 47. Thus, as expected, the tendency to undergo cycloaddition depends on the degree of stabilization of a negative partial charge in the α-position to the organoelement group. The comparison phenylthioethene : phenylethene (styrene)—about four times more rapid reaction and easily removable activating groups of the sulfur compound—clearly demonstrates the improvement achieved.

5. Organo Heavy-Metal Groups as Leaving Groups in β-Eliminations

5.1. Novel Reagents for Carbonyl Olefination

5.1.1. Synthesis of Terminal Olefins

The reagents **4** listed in Table 10 (synthesis: Sections 2.2.1 and 2.2.3) react with aldehydes and ketones to give β-hydroxy compounds of the type **59**[2,4,26,31].



Scheme 55. Methods *A, B, C* see text.

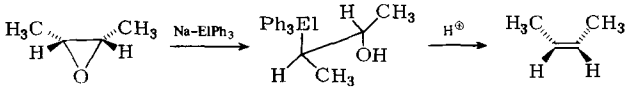
[a] Yield based on **59**. [b] Yield based on **4**, since **59** not isolated. [c] Method *A:* Heating to 110°C.

With exception of the Ge-derivatives and the Bi-compound obtained by reaction with benzophenone, the products **59** undergo β-elimination on heating to give terminal olefins (Scheme 55, Method *A*)[4,26,76]. The decomposition temperature in the case of the Sn-compounds (100—120°C) is lower than in the case of the Pb-, Sb-, and As-

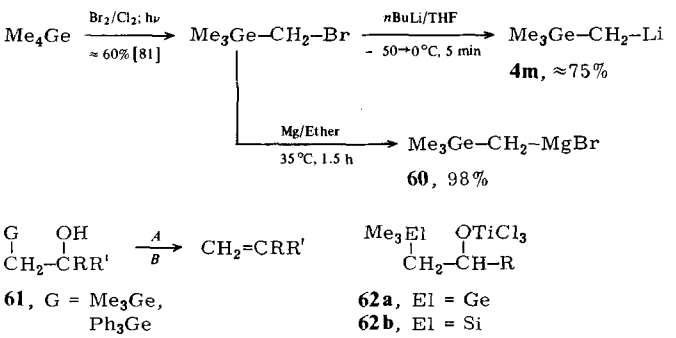
compounds (160—180 °C). Accordingly, the yield of olefin is usually somewhat better in the former case; the As-compounds give the lowest yields of olefin. Apart from by heating (in toluene at 110 °C, in chlorobenzene at 130 °C, or without solvent at 180 °C; Method *A*) the formation of olefin can also be achieved by reaction with $HClO_4$ (Method *B*)[76]. A much simpler and more gentle method is to pass the THF-solution of **59** through a short silica-gel column (Method *C*)[76,77]. Method *C* fails in the case of Ge- and As-compounds and is thus apparently limited to compounds **59** containing organoelement groups of 4th- and 5th-row elements. Table 11 shows the yields obtained in carbonyl olefinations for the example of benzaldehyde (yields on the use of other carbonyl compounds: [4,26,31,76]). The Bi-compound obtained from benzophenone gave 0, 61, and 91% yields of 1,1-diphenylethene on using Methods *A*, *B*, and *C*, respectively[24m].

Prior to our investigations β-hydroxy compounds of type **59**, G = Ph_3Sn, Ph_3Pb, were synthesized by *Davis* and *Gray*[78] by nucleophilic ring-opening of oxiranes according to Scheme 56, followed by decomposition with acid to the olefin. Since the overall reaction proceeds with retention, and the C—O bond is undoubtedly opened by attack from the rear, the olefin is formed by *anti*-elimination. This is of interest in connection with the findings described in Section 5.1.2.



Scheme 56. El = Sn, Pb [78].

Aside from **4a**, the first Ge-reagent used for carbonyl olefinations[23f,24j,76] (Tables 11 and 12), the analogous anionoid tri*methyl*germyl compounds **4n** and **60** are also suitable for this purpose (Scheme 57)[24j]. They have the advantage over **4a** in that the β-hydroxyalkylgermanes **61** (cf. **59**) obtained by reaction with aldehydes and ketones, like the analogous Si-compounds[79,80], are also decomposed to olefins by KH (presumably *syn*-elimination) as well as by acids (presumably *anti*-elimination), the yields being very good in each case (Table 12). These findings can possibly be exploited for stereospecific carbonyl olefinations (cf. Section 5.1.2). In comparison to the analogous, less-expensive Si-reagents, it would appear to be advantageous in the case of the Ge-reagents **4a**, **4m**, **60**—as well as **63a** and **63b** (Table 13)—that the nucleophilicity is somewhat higher as a result of the particularly low stabilization of carbanions by Ge (see Scheme 47).



Scheme 57 [24j]. *A*, *B* see Table 12.

In the synthesis of organic compounds the organoelement functional groups must be removed again. Carbonyl olefination with Ge-reagents (see also Section 5.1.4) thus also deserves attention, since it is the mildest method for the removal of organogermanium groups from C-atoms[82].

Table 12. Carbonyl olefinations according to Scheme 57 with $Me_3Ge—CH_2—Li$ **4m** and $Ph_3Ge—CH_2—Li$ **4a** as well as $Me_3Ge—CH_2—MgBr$ **60** to give terminal olefins. Decomposition of the β-hydroxy compounds **61** obtained by hydrolysis with H_2O; Method *A*: with $HClO_4$ at ≈ 20 °C; *B*: with KH at ≈ 20 °C [24j].

	Carbonyl compound	Olefin yield [%] *A* [b]	*B*
4m [a]	Heptanal	90 (91)	88

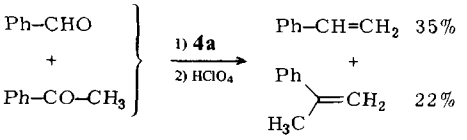
	Benzaldehyde	94 (87)	81
	4-(*tert*-Butyl)-cyclohexanone	91 (79)	90
	Acetophenone	91 (63)	95
4a [c]	Heptanal	99	no olefin formation
	Phenylacetaldehyde	96	
	Benzaldehyde	94	
	Acetophenone	96	

[a] Molar ratio **4m** : carbonyl compound = 1.5 : 1. [b] Values in brackets: Yields on analogous reaction with **60**. [c] Molar ratio **4a** : carbonyl compound = 1.3 : 1.

4a, 4n, 60 and the analogous Si-reagents are unsuitable for aldehyde-selective carbonyl olefinations, since they also react rapidly with ketones (example: Scheme 58). On the other hand, we were able to carry out *"highly aldehyde-selective" carbonyl olefinations* for the first time with the transition-metal reagents quoted in Table 13. These were generated *in situ* from **60** and the analogous Si-compounds prepared by reaction with $TiCl_4$ in ether or with $CrCl_3$ in THF (examples: Table 13)[83].



Scheme 58 [24j].

Table 13. Yields [%] of terminal olefins on using aldehyde-selective carbonyl olefinating reagents **63** (molar ratio **63** : carbonyl compound = 3 : 1) [83].

	[a] Heptanal [b] Nonanal [c] Benzaldehyde	[a] 5-Nonanone [b] Acetophenone [c] 4-(*tert*-Butyl)-cyclohexanone
$Me_3Ge—CH_2—TiCl_3$	[a] 88	
63a [24j]	[b] 76	
	[c] 76	[c] 0
$Me_3Ge—CH_2—CrCl_2$	[a] 67	
63b [24j]	[b] 58	[c] 0
$Me_3Si—CH_2—TiCl_3$	[a] 65	[a] 0
63c [47a, 84]	[b] 61	[b] 3
	[c] 59	[c] 8
$Me_3Si—CH_2—CrCl_2$	[a] 47	[a] 0
63d [47a, 84]	[b] 45	[b] 0
		[c] 0

The mechanism of carbonyl olefination with the reagents **63** varies considerably. When Ti-reagents **63a, c** are employed, olefination already occurs before hydrolysis[85], whereas when the Cr-reagents **63b, d** are used it occurs only after the neutral hydrolyzate has been treated with mineral acid. The intermediates **62** obviously decompose rapidly with formation of olefin.

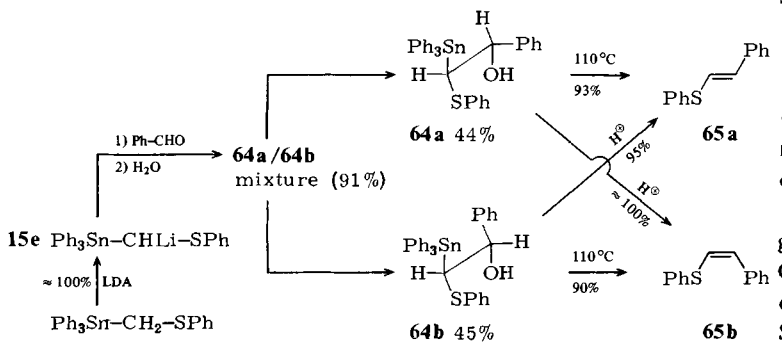
5.1.2. Stereospecific Carbonyl Olefination to the Z- or E-Olefin

In highly stereoselective olefinations a distinction is made between methods "without isolation of intermediates" (*e.g.* influencing the steric course of the Wittig reaction according to *Schlosser* and *Christmann*[86]) and methods "with isolation of intermediates". Of the latter the Peterson carbonyl-olefination[79] is, in principle, especially advantageous: Since the intermediary β-hydroxalkyltrimethylsilanes can be decomposed at choice by *syn-* or by *anti*-elimination (action of KH or acid)[80], an aldehyde or an unsymmetric ketone can be converted selectively and in high yield into an *E-* or *Z*-olefin, provided the *threo-* and *erythro*-form of the β-hydroxyalkylsilane can be separated. In contrast, in the case of other carbonyl olefinations either only *syn-* (Wittig-like reactions) or only *anti*-elimination (use of Se-reagents[87]) is possible.

In principle, however, the scope of the Peterson carbonyl-olefination is considerably limited. In the case of the readily accessible Si-reagents with an electron-withdrawing moiety on the carbanionic center, the alcoholic intermediates are isolable in only very low yields or not at all, owing to the instability of their anion (see Scheme 63).

According to our findings, stereospecific carbonyl olefinations to give either the *E-* or the *Z*-olefin are also possible with stannyl- and plumbyl-stabilized carbanions[4,24k,25a,88]. Since the alcoholic intermediates can almost always be isolated when using these reagents (exception: Scheme 62) it would appear that they have broader scope than those of the trimethylsilyl derivatives (Peterson carbonyl olefination).

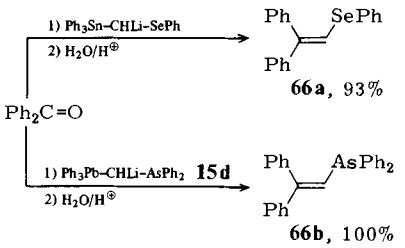
The synthesis of the β-phenylthiostyrenes **65a** and **65b** from benzaldehyde according to Scheme 59[4,88] has been investigated in most detail[4,88]: The action of perchloric acid in methanol on the *threo*-intermediate **64a**, separated quantitatively by HPLC from the isomer **64b**, led exclusively to the *Z*-olefin, while heating gave exclusively the *E*-olefin. The former reaction is, according to *Davis* and *Gray*[78] (see Section 5.1.1), an *anti*-elimination; hence, *syn*-elimination takes place on heating. The *erythro*-isomer **64b** was decomposable in the same way. Accordingly, benzaldehyde can be converted at choice with *phenylthio(triphenylstannyl)methyllithium* **15e** into the *E*-olefin **65a** (83%) or the *Z*-olefin **65b** (84%). Under analogous conditions the Pb-analogue of **15e** gave either pure **65a** or a 1:2 mixture of **65a** and **65b**. Thus, Sn-reagents would seem to be more suitable than the Pb-analogues for stereospecific syntheses of *Z*-olefins from carbonyl compounds.



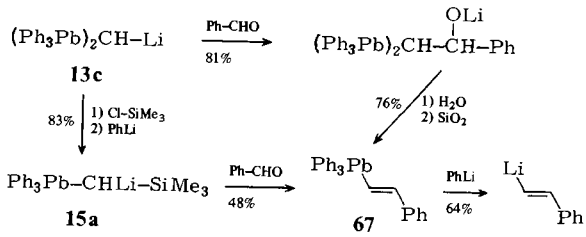
Scheme 59. For simplicity only one enantiomer of each of the alcoholic intermediates **64** is formulated.

5.1.3. Other Syntheses of Organoelement-Substituted Olefins by Carbonyl Olefination

Organoelement-substituted ethenes, *e.g.* of type **34**, have a variety of uses in organic synthesis. Some of the more useful reactions (examples: PhS group: indirect nucleophilic acylation with 1-phenylthiovinyllithium[89]; PhSe, PhTe, Ph_2As groups: Schemes 38, 48, 49, 52) may be extended to correspondingly substituted higher olefins. The synthesis of such compounds—also using the stereospecific method presented in Section 5.1.2—is one convenient use of carbonyl olefination reagents containing stannyl- or plumbyl-leaving groups. Some such syntheses are outlined in Schemes 60 and 61.



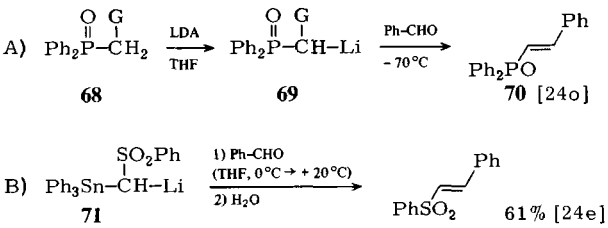
Scheme 60 [24m]. The yields of **66a** and **66b** on elimination by heating are 74 and 75%, respectively.



Scheme 61 [24m].

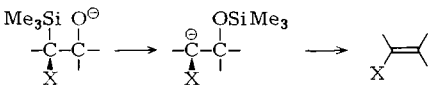
The yields obtained on synthesizing the plumbyl olefin **67** *via* two routes (Scheme 61) show that Ph_3Pb can be more favorable than Me_3Si as leaving group. In each case only the *E*-olefin is formed.

In analogous experiments, the organo heavy-metal groups behaved surprisingly: the Li-compounds **69**, G = Ph_3Sn, Ph_3Pb, Ph_2Sb, PhTe, did not react with benzaldehyde in the sense of a Horner reaction but according to Scheme 62, even at −70°C, with immediate cleavage of the organo heavy-metal group to give β-(diphenylphosphinoyl)styrene **70**[24o,90].



Scheme 62. Yield of **70** from **68**, G = Ph_3Sn, Ph_3Pb, Ph_2Sb, PhTe = 92, 71, 25, 41% [90].

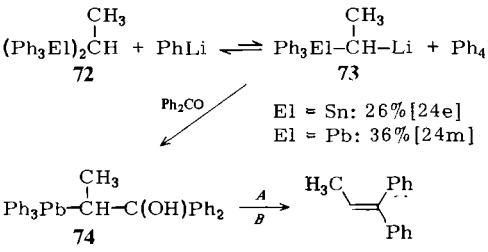
Thus, in this case even the phenyltelluro-group which is otherwise unsuitable for this purpose is relatively suitable as leaving group. The observed promotion of β-elimination by a strong electron-withdrawing group is reminiscent of the analogous circumstances in the Peterson carbonyl olefination, where a rearrangement of the silyl group (Scheme 63) is assumed for explaining the observed effect[91].—The triphenylstannyl group was also eliminated even at low temperature in the reaction of **71** with benzaldehyde[24e].



Scheme 63.

5.1.4. *Synthesis of Non-Terminal Olefins*

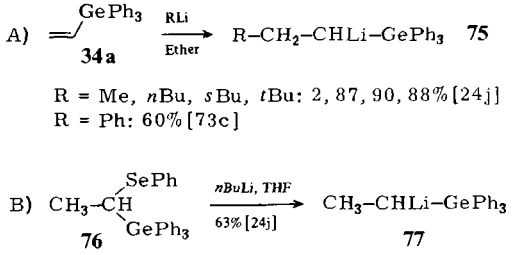
Extension of the carbonyl olefination with Sn- and Pb-reagents mentioned in Section 5.1.1 to the synthesis of non-terminal olefins appears less worthwhile, since compounds **72**, El = Sn, Pb, are relatively difficultly accessible (see Schemes 19 and 21) and the equilibria set up in the organoelement/Li exchange (Scheme 64) lie distinctly more unfavorably than in the corresponding methane-derivatives as a result of poorer charge-stabilization in **73** (see Table 1).



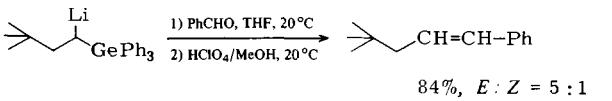
Scheme 64. *A*: 110°C, toluene, 22 h, 15% [24m]; *B*: $HClO_4$, ≈90% [24m].

Moreover, the β-hydroxy compounds, *e.g.* **74**, formed from carbonyl compounds and **73**, are thermally more stable than the corresponding compounds **59** (Scheme 55).

α-Lithiated triphenylgermylalkanes such as **75** and **77** are far more easily accessible than the analogous Sn- and Pb-compounds, namely by addition of organolithium compounds to triphenylgermylethene **34a** (Scheme 65 A) or *via* Se-compounds (*e.g.* according or analogous to Scheme 65 B; **76** is synthesized according to Scheme 18). Whether they offer advantages over the corresponding more cheaply available α-lithiated triphenyl- and trimethylsilylalkanes is still undecided. Presumably they—as well as the corresponding transition metal compounds of type **63** (cf. Table 13)—show enhanced nucleophilicity. The only carbonyl olefination carried out so far (Scheme 66) is promising with regard to yield and stereoselectivity.



Scheme 65.



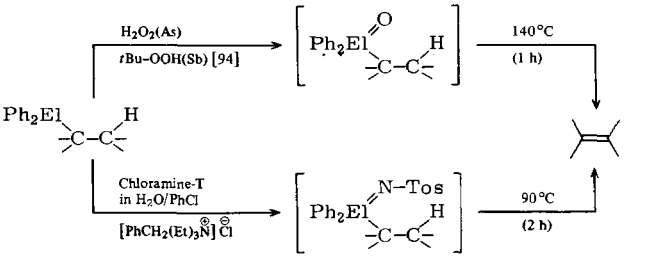
Scheme 66 [24j].

The synthetic routes formulated in Scheme 65 cannot be extended to the Sn- and Pb-analogues[92].

5.2. Elimination of Organoarsenic- and Organoantimony Groups together with β-H Atoms

The importance of organoselenium reagents in organic synthesis is largely based on the fact that selenium oxide groups are rapidly eliminated together with a β-H atom with formation of olefin, even at room temperature[55]. When the cleavage of seleno groups *via* the oxide (primary seleno groups) is rendered difficult, the phase-transfer reaction with chloroamine-T *via* selenium tosylimine has proven useful[93].

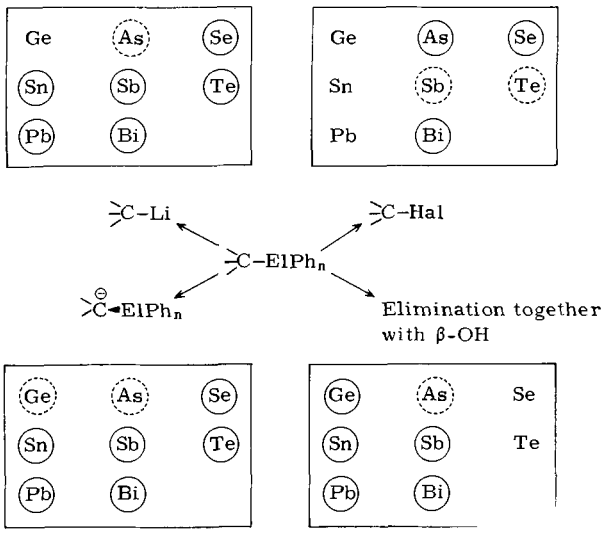
We extended both methods to primary diphenylarsino- and diphenylstibinoalkanes (Scheme 67) and found that the route *via* the oxide leads to olefin formation (*ca.* 21—23%) only in the case of the Sb-compounds, whereas the expected olefins are formed in both cases *via* the tosylimine. However, since the yields were unsatisfactory[24h] (El = As, 41-45%; El = Sb, 53-56%) and the required decomposition temperature (90°C) was relatively high, this method cannot be fully recommended. Surprisingly, in analogous reactions with a secondary arsane and stibane (2-diphenylarsinooctane[25a], 2-diphenylstibinopentane[12]) only minimal amounts of olefin could be detected.



Scheme 67, El = As, Sb [24h].

6. Conclusion and Outlook

On examining heavy main-group elements for possible uses in organic synthesis we found, in the case of the elements marked with a circle in Scheme 68, that there are four possible modes of reaction. As shown in Scheme 68, none of the elements investigated is completely unsuitable for synthetic application. Moreover, each element—even the inconvenient bismuth[18]—revealed special characteristics and useful features arising from a combination of various properties. The element Te, *e.g.*, is exceptionally good in that it has a strong acidifying effect in the functional group PhTe, it is the most amenable to organoelement/Li exchange, and it forms essentially more thermally stable α-hetero-substituted carbanions (cf. **4h** and **35h**) than the comparable elements Br and I (cf. **8**).



Scheme 68. Four possible reactions of organoelement compounds >C—ElPh$_n$.

The author is convinced that all the elements investigated here (selection criterion: see Section 1) will at some later date become trusted and profitable "heteroatoms" for the practising synthetic chemist. The element As, which, unlike the neighboring elements Si, P, S, Se in the Periodic System is rarely taken into consideration, has proven particularly useful for our research group. Because of its suitability as air-stable donor atom in transition-metal ligands it still plays a major role in new investigations being carried out by our group[95].

For the results presented here I am grateful to all those enthusiastic and capable colleagues who have been engaged in this work and who have also shown their professional prowess at handling toxic substances. I sincerely thank all colleagues cited in the references and hope that this report might bring back memories of their having joined in the combined effort as members of our research team studying organoelements. I also wish to thank Herrn H. Niewind, Organisch-chemisches Institut der Universität Münster, for the synthesis of numerous starting substances, as well as the Deutsche Forschungsgemeinschaft (Ka 144/34 and Ka 144/35-1), the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen (Project "Unreaktivierung durch Ummetallierung") and the Fonds der Chemischen Industrie for very helpful financial support.

[32] Pure products could not be isolated according to the reaction of **4f** with aldehydes and organoelement halides, although **4f** was completely consumed.

[33] **10f** could be obtained (66%) from PhSeNa and **7d**. Reaction with *n*-BuLi leads to **4d** (45%) [24i]. – While organolithium compounds are activated by chelate ligands with hard donor centers, *e.g.* tetramethylenediamine (TMEDA), from our experience the reverse is the case with chelate ligands with soft donor centers.

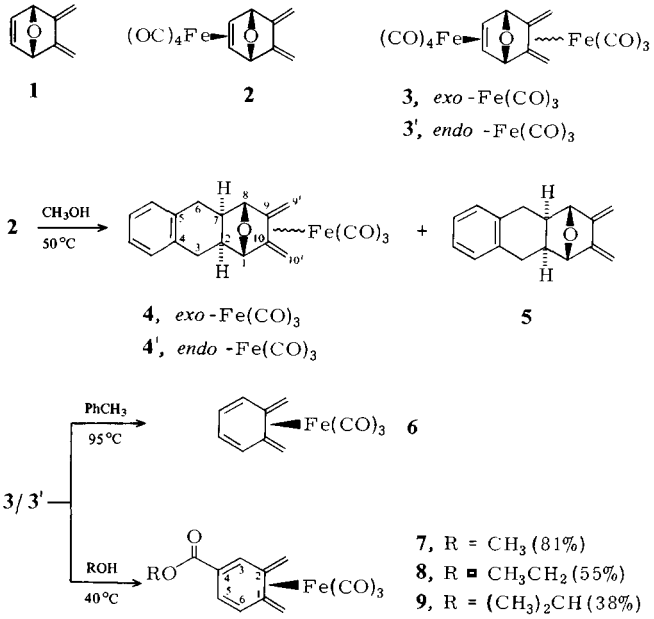
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Carbonyliron-Assisted Cycloaddition of a 1,3-Diene to a CC Double Bond: Synthesis of an Anthracyclinone Precursor**

By *Philippe Vioget, Pierre Vogel,* and *Raymond Roulet**

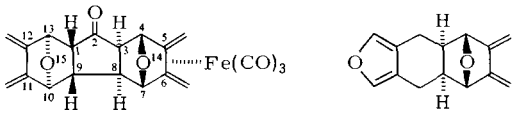
The cycloaddition of a 1,3-diene to a monoolefin coordinated to a transition metal has not been reported so far. The reaction is unfavored as the final cyclohexene complex would be coordinatively unsaturated[1]. It can occur, however, if the required extra ligand is incorporated into the dienophile[2] or if the dienophile is a CC triple bond[3]. We report the first case of a formal [4+2] cycloaddition in which the dienophile is complexed by carbonyliron, namely the cyclodimerization of 5,6-bismethylene-7-oxabicyclo[2.2.1]hept-2-ene **1** in presence of $Fe_2(CO)_9$, the extra ligand being probably the oxygen bridge of the oxanorbornene system.

The reaction between **1** and $Fe_2(CO)_9$ in pentane yields the mono- and dimetallic complexes **2**, **3** and **3'**[4]. In methanol at 50 °C, the complexes **4** and **4'** (30%, yellow crystals, m.p. = 128–129 and 175–177 °C, respectively), the diene **5** (9.3%; colorless crystals; m.p. = 130–131 °C; ^{1}H-NMR (360 MHz, $CDCl_3$, TMS): δ = 7.13 (m, 4H), 5.22/4.98 (2s, 2×2H, =CH_2), 4.61 (s, 2H, H-1,8), 2.90/2.57/2.16 (3 m, 3×2H, ^2J = 13.5 Hz, ^3J = 5.0 and 9.0 Hz); ^{13}C-NMR (90.55 MHz, $CDCl_3$, TMS): δ = 148.0/138.4 (2s), 126.9 (dd, ^1J(CH) = 154 Hz, ^3J = 5 Hz); 126.3 (dd, ^1J = 159 Hz, ^3J = 9 Hz), 101.0 (t, 160 Hz), 86.7 (d, 154 Hz), 44.8 (d, 137 Hz), 32.3 (t, 128 Hz)), and the *ortho*-quinodimethane complexes **6** (6.5%) and **7** (3%) were formed. Heating **2** in methanol (50 °C) gave **4** (33%), **5** (11%), and **6** (14%). Thermolysis of **3** in toluene gave **6** (60%)[4]. Heating **3** in methanol, ethanol, and 2-propanol gave the esters **7**–**9**. Control experiments confirmed that the cyclodimerization



1 **2** **3**, *exo*-$Fe(CO)_3$ **3'**, *endo*-$Fe(CO)_3$ **4**, *exo*-$Fe(CO)_3$ **4'**, *endo*-$Fe(CO)_3$ **5** **6** **7**, R = CH_3 (81%) **8**, R = CH_3CH_2 (55%) **9**, R = $(CH_3)_2CH$ (38%)

occurred only with the monometallic complex **2**. Oxidation of **4** and **4'** by $(CH_3)_3NO$ in acetone furnished **5** (98%, relative to **2**: 41%). The coupling constant $J_{1\text{-H},2\text{-H}} \simeq 0$ Hz in **4**, **4'**, and **5** confirmed the *exo*-annelation.



10 **11**

Irradiation of **1** in CH_3OH in presence of $Fe_2(CO)_9$ at −20 °C results in formation of the cyclopentanone derivative **10**: reaction of **1** and $Ru_3(CO)_{12}$ in toluene (65 °C, 7 d) results in isolation of the furan **11** in 10% yield, in addition to 10% of **5**.

The reaction sequence **2**→**4**→**5** gives a simple route to the synthesis of bismethylene compounds **5**, a potential precursor for the preparation of antitumor agent 4-demethoxydaunomycinone[8].

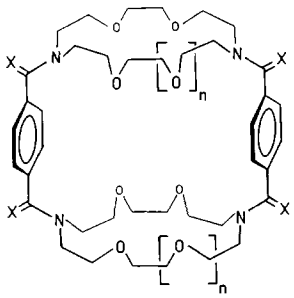
A Ternary Clathrate from Cryptand, Hydroquinone and Water — Selective Formation and X-Ray Structural Analysis**

By *Fritz Vögtle**, *Heinrich Puff*, *Edmund Friedrichs*, and *Walter M. Müller*

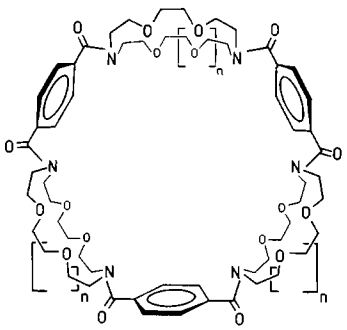
Dedicated to Professor Hermann Stetter on the occasion of his 65th birthday

In the last few years it has been possible to prepare numerous (neutral) complexes of crown ethers with uncharged guest molecules[1]. We describe here for the first time the synthesis and X-ray structural analysis of a ternary neutral complex of an uncharged cryptand compound - with hydroquinone and water.

The host molecules **1a** (m.p. = 216—220 °C)[2a] and **2a** (m.p. = 89—93 °C), which are similar to cyclodextrins in their cavity size and water solubility, were obtained by reaction of terephthaloyl dichloride with 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane under conditions of high dilution.



1a: X=O n=1
1b: X=H_2 n=1



2a: n=1
2b: n=2

The 32-membered tetralactam **1a**, which was recrystallized from water, still retained water after being dried for 12 h (12 torr, 50 °C), forms a 1 : 1 : 4 complex in water with hydroquinone[4] (**1a**: hydroquinone:H_2O; m.p. = 185—187 °C) even if the ratio of hydroquinone: cryptand in water is 2 : 1. The ready solvation of hydroquinone in hot chloroform ("neutral phase transfer"[4]) and the stabilization of the hydroquinone solutions from oxidation by **1a** indicate that complexation occurs even in solution.

Hydroquinone was isolated from aqueous solutions of quinhydrone *via* complexation with **1a**. **1a** also yields a crystalline complex with resorcinol, although more slowly, and with pyrocatechol even more slowly. From the mixture of these three benzenediols with 0.3 equivalents **1a**, only the hydroquinone complex precipitates. This can be exploited for a preparative separation.

The X-ray structure analysis of the 1 : 1 : 4 complex (Fig. 2) indicates that the hydroquinone is not incorporated into the cavity of the cryptand, although in this position it could complex with the crown ether moieties[4]. Apparently the bonding of the hydroquinone molecules outside the cryptand *via* H bonds involving water molecules leads to a more stable crystal lattice. Of note is the fact that the H bonds are formed exclusively with the carbonyl oxygen atoms of the cryptand.

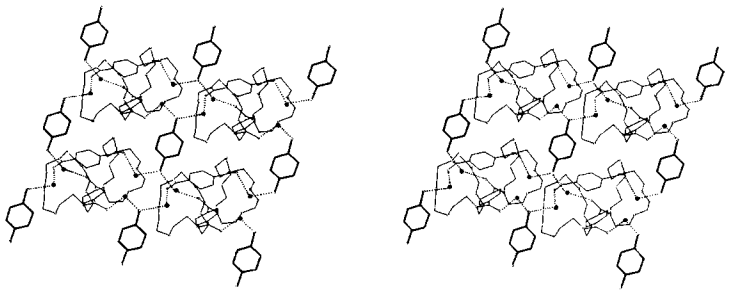


Fig. 2. Structure of the **1a**-hydroquinone-H_2O clathrate (1 : 1 : 4) in the crystal; section of one layer (stereoscopic view).

The lattice consists of layers of hydroquinone, water, and cryptand. The triclinic unit cell with $a = 10.427(6)$, $b = 12.842(5)$, $c = 18.908(7)$ Å, $\alpha = 91.99(3)$, $\beta = 98.83(4)$, $\gamma = 94.44(4)°$, and space group $P\bar{1}$ contains 2 molecules of hydroquinone and cryptand, respectively, and 8 molecules of water[5a].

Guest molecules such as 1,2,4-, 1,3,5-, and 1,2,3-benzenetriols as well as 2,7-naphthalenediol, which have similar spatial demands as hydroquinone, also yield stable isolable 1 : 1 : n H_2O-complexes; 2,6-naphthalenediol, 4-nitrophenol, 4-hydroxybenzyl alcohol, and similar compounds do not form crystalline complexes.

The water-insoluble amine **1b** (m.p. = 111—113 °C), as well as water-soluble and -insoluble analogues of **1a** do not afford complexes of this type under the same conditions.

The 48-membered hexalactam **2a**, which is also water-soluble, has a larger cavity than γ-cyclodextrin. In this case, aqueous solutions of 1,3,5-benzenetricarboxylic acid and benzenehexacarboxylic acid are suitable guest compounds; crystalline complexes (m.p. 237—245 °C and 166—173 °C, respectively) could be isolated, but their structures have not yet been determined.

From these results it can be concluded that even with cyclodextrin-analogous uncharged and water-soluble host compounds such as **1a** a guest molecule which fits into the cavity must not necessarily be incorporated even when H-bonding contributes to stabilization. As shown in the example of the 1 : 1 : 4 complex, the lattice-clathrate formation—which also occurs in cyclodextrins—competes successfully.

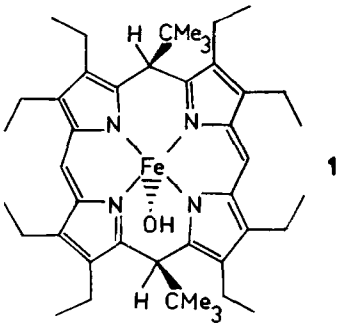
A Mononuclear Hydroxoiron(III) Complex of a Porphinoid Ligand System with Bifacial Steric Hindrance**

By *Johann W. Buchler**, *K. Lam Lay*, *Young J. Lee*, and *W. Robert Scheidt**

Mononuclear hydroxoiron(III) porphyrins are normally unstable, the ease of condensation of isolated FeOH groups to FeOFe bridges preventing their isolation[2]. Recently, a variety of mononuclear hydroxohemins have been mentioned, the stability of which is attributed to bifacial steric hindrance, *i.e.* to bulky substituents on both sides of the porphinato plane[2,4]. The published data of these compounds do not yet allow full characterization.

We report here a well-defined mononuclear hydroxoiron(III) complex of a porphinoid ligand system: [α,γ-bis(*tert*-butyl)-octaethyl-α,γ-dihydroporphinato]hydroxoiron(III) **1**, an iron α,γ-dialkylporphodimethene.

The synthesis of **1** is achieved by reductive *tert*-butylation of octaethylporphinatozinc, demetalation of the product, iron insertion, and exhaustive chromatography on alumina by analogy to [5] (for details see [6c]).



1

Under basic conditions, condensation of **1** to afford a μ-oxo complex does not occur. However, even traces of alcohols lead to formation of the previously disregarded[4] alkoxo complexes, which are recognized by rhombic ESR spectra, whereas **1** has an axial spectrum ($g_\perp = 5.84$, $g_\parallel = 2.00$).

The configuration of **1** as its dimethylacetamide solvate was determined by X-ray structure analysis (Fig. 1). The essential structural parameters (Fe—O, 188.6(1.0), Fe—N, 204.4(3.0) pm, and the displacement of the Fe atom from the plane of the four N atoms by 40 pm in the direction of the OH group) are consistent with those expected for a high-spin iron(III) porphinate[9]. The two halves of the macrocycle are folded in a roof-like manner (dihedral angle 42.9°). The two *tert*-butyl groups occupy "chimney positions" on the ridge of the roof, similar to the positions of the methyl groups in the previously characterized α,γ-dimethylporphodimethene derivatives[2].

A quite surprising feature is the *anti*-axial configuration of the two *tert*-butyl groups and the hydroxo ligand. Obviously, the two *tert*-butyl groups prevent any binding of a ligand to the *syn*-axial position, although in some related α,γ-dimethylporphodimethene complexes of pentacoordinate metal ions, *e.g.* the titanyl ion, the *syn*-axial position is preferred[2].

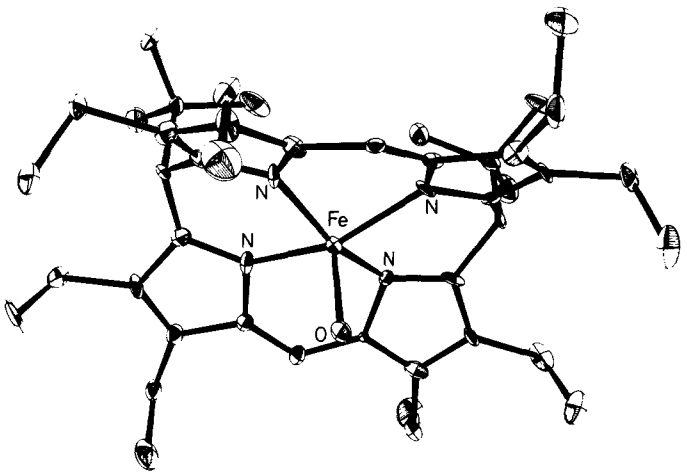


Fig. 1. *Anti*-axial configuration of the mononuclear hydroxoiron(III) porphodimethene **1** in the crystal [8] (viewed from below the roof).

Since the condensation of two molecules of **1** to afford a μ-oxo complex does not occur, although the *tert*-butyl groups do not impede the hydroxo ligand, it follows that the α,γ-bis(*tert*-butyl)porphodimethene skeleton provides bifacial steric hindrance, resulting, on the one hand, from the bulky *tert*-butyl groups and, on the other from the folding of the macrocycle: this does not even permit formation of a greatly over-extended Fe—O—Fe bridge at the *endo*-side. This type of steric hindrance provides interesting modifications to reactions of small molecules with hemes derived from **1**, and this is presently being investigated.

Polarity of Organic Glasses**

By *Heinz Langhals**

Empirical polarity scales are usually used for the quantitative description of solvent polarity, since purely physical solvent properties such as refractive index or dielectric

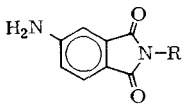
[*] Dr. H. Langhals
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the BMFT (Project ET 4428 A).

constant are unsatisfactory parameters for most chemical applications[2].

The empirical *Y*-scale developed by *Winstein*, which is based on solvolysis reactions, presently serves as a general reference system. However, it is limited to polar media, whereas the secondary polarity scales derived from spectroscopic data and linearly correlating with the *Y*-scale, *e.g.* the $E_T(30)$ scale of *Dimroth* and *Reichardt*, can also be applied in low polarity media.

The empirical polarity quantities are defined only for the liquid phase; it should be checked, however, as to how far an extension to solids is possible (see also [4]). The phthalimides **1** and **2**, which are also readily soluble in



1, R = CH_3; S_1
2, R = H; S_2

low polarity media and, with their strong solvatochromism in the fluorescence, are sensitive to polar solvation effects, can be used as models here.

$$S = 28\,590\ [\text{kcal}\cdot\text{nm}\cdot\text{mol}^{-1}]\ \lambda_{max}^{-1} \qquad (1)$$

The molar emission energy S is calculated analogously to the E_T values, from λ_{max} of the fluorescence using eq. (1); S correlates linearly with the $E_T(30)$ scale.

$$E_T(30) = -1.93\,S_1 + 160.4$$
$$E_T(30) = -1.81\,S_2 + 155.7$$

Organic glasses, *e.g.* polymethylmethacrylate (Plexiglas) are suitable model solids for the investigation of polarity, since their spatial isotropism favors accuracy of measurement. We found that pure Plexiglas prepared by melting granules shows only low polarity ($E_T(30) = 37.3$) at 25 °C, comparable to 1-chloropropane. Even a small residual content of monomer noticeably increases the polarity; it can be increased into the polarity range of 2-butanol ($E_T(30) = 47.5$) by addition of *ca.* 10% methanol.

Accordingly, solvatochromic dyes are just as influenced by the medium in organic glasses as in liquids. That the solvatochromism of the fluorescence of **1** or **2** in the glasses investigated actually reflects the polarity of the medium can be shown with eq. (2),

$$S = E_D \ln(c_p/c^* + 1) + S^0 \qquad (2)$$

which quantitatively describes the polar behavior of binary liquid mixtures[10]. c_p is the molar concentration of the more polar component and S^0 the S-value of the less polar component (here pure Plexiglas). E_D and c^* are the parameters of the equation.

Equation 2 also describes the polar behavior of solid mixtures and holds both for solid copolymers (examples see Fig. 1) as well as for low molecular additives to polymers (1,2-propanediol and 1,3-butanediol).

This finding is of interest for the directed preparation of polymers having definite properties, for an understanding of the action of softeners, and for the analysis of polymers. It follows from these findings that the polarity of solid matrices can be defined empirically in the same way as the polarity of liquids (for a summary of previous works see[13]).

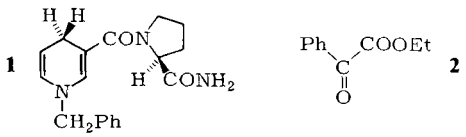
Dependence of the Enantioselectivity on the Relative Concentration of Substrate in an NADH Model Reaction**

By *Naomichi Baba*, *Jun'ichi Oda*, and *Yuzo Inouye**

Recently we found[1] that the NADH model system **1**, which contains L-prolinamide as a chirality-inducing center, reduced ethyl 2-oxo-2-phenylacetate **2** (in presence of $Mg(ClO_4)_2$ at 50 °C in anhydrous CH_3CN) to give (*R*)-ethyl mandelate in high enantiomeric excess (*e.e.* = 83%)[1] and that the *e.e.* increased as the reaction proceeded. A similar increase has also been reported in other examples[2] and was accounted for in terms of the feedback effect of the oxidized nicotinamide, which accumulates during the



conversion (Scheme 1): the oxidized form **4** interacts ("feedback interaction") with the reductant **3** *via* chelative mediation of metal ion and/or charge transfer interaction. This may bring about specific blocking of one of the diastereotopic faces of the dihydropyridine ring (chiral selection), permitting easier access of the substrate carbonyl

[*] Prof. Dr. Y. Inouye, Dr. J. Oda, Dr. N. Baba

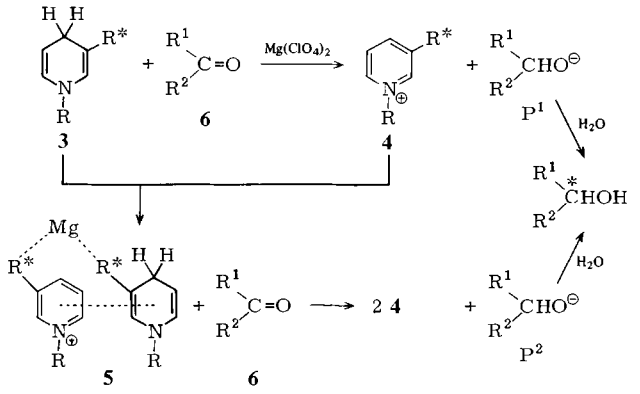
[**] We wish to express our thanks to Dr. Nobuyuki Sugita and Dr. Tadashi Okamoto for their helpful advice on the kinetic treatments.

compound to the other face, and thereby contributing much towards increasing the enantiomeric excess in the later stages of the reduction.



Scheme 1. Hypothetical pathway of the asymmetric reduction with nicotinamide derivatives **3** using a feedback interaction between **3** and **4**.

The feedback mechanism can be described by eqs. (a)—(c):

$$A + S \xrightarrow{k_1} C + P^1 \quad (a)$$

$$B + S \xrightarrow{k_2} 2C + P^2 \quad (b)$$

$$A + C \xrightarrow{k_3} B \quad (c)$$

where A = Mg^{2+}-activated[6], chiral NADH model **3**; C = oxidized species **4**; B = hypothetical intermediate **5**; S = substrate **6**; P = product. The *e.e.* can be calculated using eq. (d):

$$e.e. = \frac{(m-n)K + m - (n-m)JK(1-[S]/[S_0])^{-1}\ln[([S]/[S_0]+K)(1+K)^{-1}]}{} \quad (d)$$

where, m and n represent the optical yield of P^1 and P^2, respectively, with the assumption that $n > m$; $J = k_1(k_1-k_3)^{-1}$ and $K = k_3(k_1-k_3)^{-1}$. Eq. (d) shows that the *e.e.* should increase monotonically with increasing initial concentration of the substrate ($[S_0]$); moreover, as is found, an increase in *e.e.* is also to be expected with decreasing $[S]$ towards the end of the reaction.

In accord with predictions, a significant increment in *e.e.* (from 46 to 76%) was observed in the reduction of **2** upon increase of the substrate initial concentration from 10^{-2} to 10^{-1} M.

This constitutes the first example in which the enantioselectivity is dependent on the initial concentration of substrate. It seems very likely that a similar feedback interaction between products and reactants may sometimes be operative in other asymmetric systems. Accordingly, it might possibly be used as a probe for studying the mechanisms of other reactions.

Photochemical Evolution of H_2 in the System Methyl Viologen/Mn^{II}-*meso*-Tetraphenylporphyrintrisulfonic Acid/Mercaptoethanol/Hydrogenase**

By *Ichiro Okura**, *Nguyen Kim-Thuan*, and *Makoto Takeuchi*

Aside from zinc porphyrin complexes[2] almost exclusively ruthenium complexes have been used as sensitizers in studies on the photo-induced cleavage of water[1]. We report here on the use of the manganese(II) *meso*-tetraphenylporphyrintrisulfonic acid complex (Mn^{II}-TPP(SO_3H)$_3$) as photosensitizer for the photo-induced reduction of methyl viologen (*N,N'*-dimethylbipyridinium dichloride, MV^{2+}); photochemically facile redox reactions are possible with manganese porphyrin and phthalocyanin complexes[3]. Since the reduced form of methyl viologen (MV^+) in the presence of a catalyst liberates H_2 from water, we attempted carrying out this reaction with the system Mn^{II}-TPP(SO_3H)$_3$/MV^{2+}/mercaptoethanol/hydrogenase.

Mn^{II}TPP(SO_3H)$_3$ was generated *in situ* from the corresponding Mn^{III} complex, which was synthesized from TPP(SO_3H)$_3$ and Mn(OAc)$_3$ in CH_3OH. The hydrogenase from *D. vulgaris* was purified according to *Yagi*'s method[4]; the hydrogenase solution had the ability to generate 8.5×10^{-7} mol of hydrogen using the reaction system: hydrogenase (0.1 mL) + MV^{2+} (8.1×10^{-7} mol) + $Na_2S_2O_4$ (2×10^{-5} mol) in 3 mL of a 0.02 M phosphate buffer (pH 7) at 30 °C for 20 min. Irradiation (150 W tungsten lamp, $\lambda > 390$ nm) of a buffered (Tris-HCl, pH 7) aqueous solution of Mn^{III}-TPP(SO_3H)$_3$, MV^{2+}, and mercaptoethanol under anaerobic conditions at 30 °C led to formation of MV^+ (characteristic absorption at 395 and 605 nm); as shown in Figure 1 the formation of MV^+ first sets in after an induction period, and then increases with time. During the induction period the concentration of Mn^{III}-TPP(SO_3H)$_3$ drops rapidly (rapid decrease in intensity of the band at $\lambda = 467$ nm), with concomitant formation of Mn^{II}-TPP(SO_3H)$_3$, which shows a strong absorption at $\lambda = 435$ nm: Aeration (introduction of oxygen) leads to immediate reconversion of the Mn^{II}-complex into the Mn^{III}-complex.

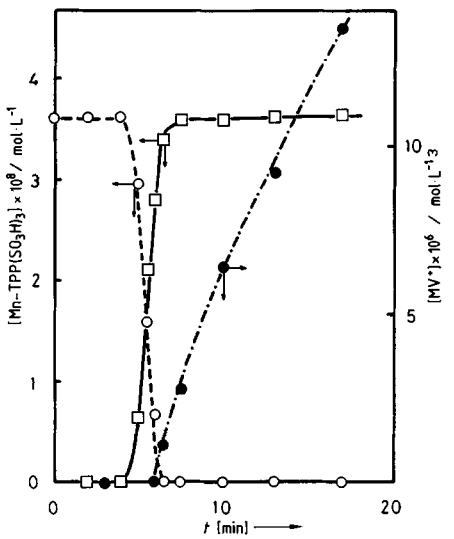

Fig. 1. Change of concentration of Mn^{III}-TPP(SO_3H)$_3$ (○), Mn^{II}-TPP(SO_3H)$_3$ (□), and MV^+ (●) on irradiation of 6 mL of an aqueous solution of 1.31×10^{-9} mol Mn^{III}-TPP(SO_3H)$_3$, 8.12×10^{-7} mol MV^{2+}, and 5.43×10^{-4} mol mercaptoethanol at 30 °C.

Department of Chemical Engineering, Tokyo Institute of Technology
Meguro-ku, Tokyo, 152 (Japan)

[**] We thank Prof. *T. Keii* and Prof. *Y. Ono* for stimulating and helpful discussions.

When hydrogenase (0.5 mL) was added to the buffered aqueous (6 mL) system Mn^{III}-TPP$(SO_3H)_3$ (4.64×10^{-9} mol), MV^{2+} (7.26×10^{-6} mol) and mercaptoethanol (5.43×10^{-4} mol), evolution of hydrogen was observed on irradiation: the amount of hydrogen evolved after 2 h and 4 h was 1.23 μmol and 1.89 μmol, respectively. No evolution of hydrogen was observed when any component of the system was omitted. Hydrogen evolution (1.08 μmol H_2 in 4 h) was also observed on irradiation with sunlight instead of with a tungsten lamp.

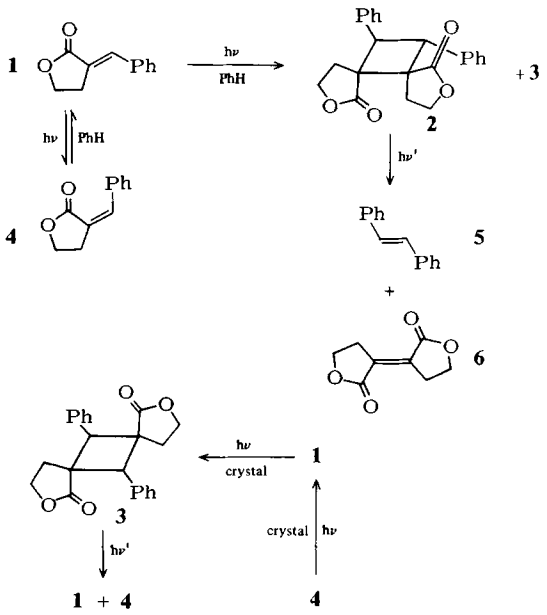
Quantitative Photodimerization of Crystalline α-Benzylidene-γ-butyrolactone**

By *Gerd Kaupp**, *Ernst Jostkleigrewe*, and *Hans-Jörg Hermann*

The lactone **1** (m.p. = 115–116 °C), which is readily accessible from γ-butyrolactone and benzaldehyde[1], is of importance as a fungicide and plant growth regulator[2]. The photochemistry of **1** (*trans/cis*-isomerization; solvent addition) has given rise to extensive theoretical speculations[3]. We have now found that **1** photodimerizes in solution and in the crystalline state.

Irradiation of **1** in benzene (Hg high-pressure lamp, Hanovia, 450 W; Solidex filter, N_2, 1 g, 3 d, 37% conversion) results in formation of **4** (16%), **2** (12%; isolated *via* preparative thin layer chromatography on SiO_2 with CH_2Cl_2, m.p. = 170 °C), **3** (4%), and an unidentified compound (*ca.* 5%; ^{1}H-NMR analysis). On the other hand, photolysis of crystalline **1** proceeds rapidly and quantitatively (1 g is converted in 5 h) without the formation of **4** (cf. [4]). The head/tail *anti*-dimer **3** is formed exclusively under these conditions, and is obtained analytically pure after one crystallization from CCl_4 (m.p. = 242 °C). In accordance with the *cis*-effect[5], photolysis of the dimers **2** and **3** (253.7 nm, 83 K) results predominantly in formation of **5**[5a] and **6**[5b], and of **1** and **4** (both orientations!), respectively. The symmetry of the stereoisomers **2** and **3** was established from the 250 MHz ^{1}H-NMR spectra[6].



The perfectly regio- and stereospecific as well as rapid and quantitative course of the photolysis of the crystalline lactone **1** is noteworthy, since other benzylidene compounds can give rise to several photodimers without melting[4]. The specificity is so pronounced here, that upon photolysis (as above) of crystalline **4**, (m.p. = 90 °C[3]; rarely observed *Z/E*-isomerization in the crystal!) even intermediately generated and ^{1}H-NMR-spectroscopically detected **1** dimerizes exclusively to give **3**.

In addition to the crystallochemical aspects, the particularly facile preparative accessibility to **3** appears attractive. Corresponding to the procedure in [4], the crystal film of the educt **1** may be generated, without particular precautions, by evaporation of its solutions (*e.g.* in dichloromethane) or by solidification of its melt, and may be irradiated without exclusion of air. Therefore, exposing finely divided crystal films of the biologically active[2] **1** to sunlight (the short wavelength portion of which is absorbed by **1**[3]) appears worthy of more detailed studies.

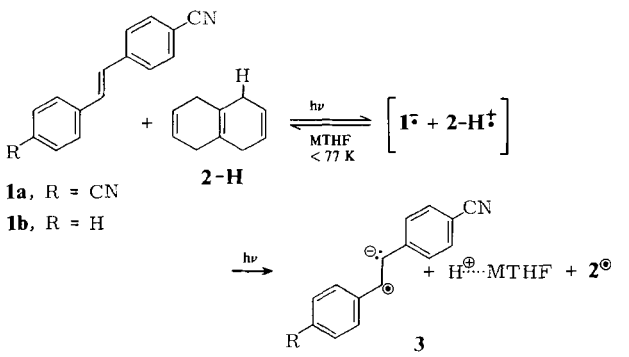
Laser Photolysis— A New Route for Charge Separation**

By *Gerd Kaupp** and *Ernst Jostkleigrewe*

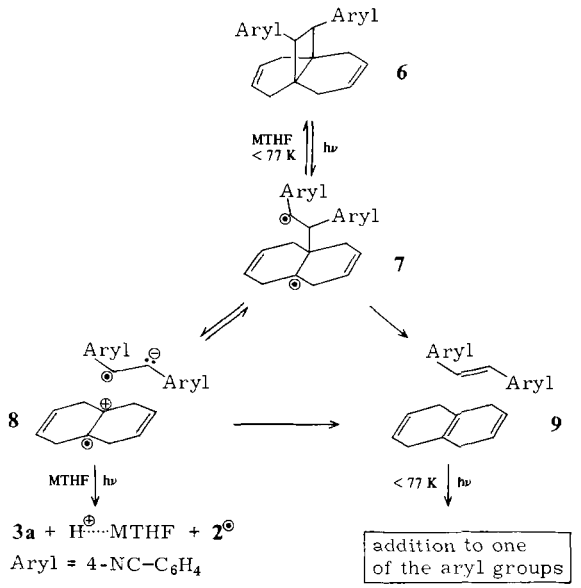
While photoionization to give stable radical cations causes no problems, photochemical charge-separation to give stable radical anions and (secondary) cations, which is potentially useful for storage of light energy, has met with enormous difficulties[2]. We report on a new technique, which successfully forms charge separations *via* photodeprotonation of radical-ion pairs.

Upon irradiation of **1** at 15—77 K in a polar 2-methyltetrahydrofuran (MTHF) glass, preferentially in presence of additional electron donors such as **2-H** (or toluence, or triethylamine), the VIS-spectra of the radical anions **3** are obtained only if pulsed short-wavelength light sources (60—250 or ≥ 10 mJ nanosecond pulses from an excimer laser at 248 or from the stimulated Raman emission of H_2 at 277 nm) are used. Under these conditions the radical cation **2-H**$^+$, which is formed *via* electron transfer and is paired with **1**$^-$, can immediately absorb light[4] and thus undergo photodeprotonation. **3a** ($\lambda_{max} = 567$, 545 (sh), 505 (sh) nm) and **3b** ($\lambda_{max} = 517.5$, 485, 440 nm) are not formed upon pulsed excitation at 355 nm (*ca.* 10 mJ, dye laser) or upon continuous irradiation with 15 W low-pressure Hg lamps.



Evidently, "spontaneous" deprotonation of **2-H**$^+$ (or the radical cations of toluene and triethylamine) with channeling of the proton out of the ion-pair cage[2b] is too slow here for successful competition with the back-transfer of the electron (to give **1** + **2-H**). Correspondingly, the spectrum of the radical anion of 4,4'-dicyanoacetylene ($\lambda_{max} = 499$, 481.5 nm) is obtained only after pulsed laser excitation (248 nm, with **2-H** in MTHF glasses).

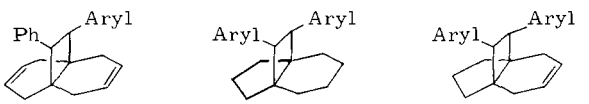
The new charge-separation technique also permits the spectroscopic detection of stable radical anions in cycloreversions (as competing reaction). Thus, only pulsed laser excitation (248; 277 nm) of **6** in MTHF at 15—77 K yields the VIS spectrum of **3a**. Here also, the "removal" of the positive charge has to be accelerated by additional absorption of light and photodeprotonation of the radical cation, if stable **3a** is to be formed in competition with cycloreversion of **7** (which is reformed in part from **8**) and charge transfer in **8**.



The radical anions **3a** and **3b** generated from **1**, **6**, or **10** are stable below the softening range of the glass at 95—100 K. However, short wavelength irradiation (253.7 nm or over-irradiation with the laser) rapidly bleaches the red color (presumably *via* "photodetachment"[5]), but even intense long wavelength excitation (high-pressure Hg lamp at $\lambda = 546$, or pulsed at 567, 517.5, or 427 nm) does not cause electron transfer in the polar glass. The radical anion of 4,4'-dicyanoacetylene behaves similarly.

The charge separation is not due to specific properties of exciplexes: Thus, irradiation ($\lambda = 365$ or pulsed at 377 or 360 nm) of the charge-transfer complex **9**, which is obtained at 15—77 K upon irradiation of **6** at $\lambda = 253.7$ nm, does not produce **3a** but rapidly diminishes the bathochromically shifted UV spectrum of **1a** in favor of new absorptions at $\lambda_{max} = 300$ and 280 nm. This corresponds to a shortening of the chromophore in **1a** by one 4-cyanophenyl group (*via* H_2 transfer from or cycloaddition with **2-H**).

The cycloreversion variant of the charge-separation technique gives the better yields of **3**, particularly upon excitation at 277 nm. In accordance with the formulated



10 **11** **12**

Aryl = 4-NC-C_6H_4

mechanism, the radical anions form with increasing ease along the series **10**, **11**, **12**, and **6**.

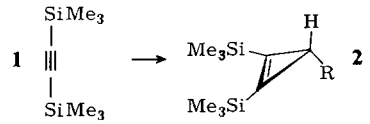
Synthesis and Properties of [2,3-Bis(trimethylsilyl)-2-cyclopropen-1-yl]-diazomethane**

By *Günther Maier**, *Manfred Hoppe*, *Hans Peter Reisenauer*, and *Carl Krüger*

Substituted cyclopropenyldiazomethanes — potential precursors of tetrahedranes — have been studied many times. So far, it is not known how a cyclopropenylcarbene behaves in argon at 10 K. In order to reduce the synthetic difficulties we have chosen the trimethylsilyl analogues, in the hope that the protecting groups could be removed at the end of the synthetic sequence[4].

The CuBr-catalyzed thermolysis of methyl diazoacetate in presence of bis(trimethylsilyl)acetylene **1** affords the cyclopropenecarboxylic acid ester **2a**[6]. Reduction with diisobutylaluminium hydride leads to alcohol **2b** and subsequent oxidation with silver carbonate/celite to aldehyde **2c**. Condensation with tosylhydrazide smoothly yields tosylhydrazone **2d** (Table 1), which reacts with butyllithium to furnish salt **2e**.



2a, R = CO_2Me; **2b**, R = CH_2OH; **2c**, R = CHO;
2d, R = CH=N–NHTos; **2e**, R = CH=N–NLiTos; **2f**, R = CHN_2

Table 1. (Selection) **2a—2d**: Yields, physical and spectroscopic properties; ^{1}H-NMR ($CDCl_3$; δ-values rel. to TMS). All substances gave correct elemental analyses.

2a: 18%, oil [6]; ^{1}H-NMR: 0.23 (s, 18H), 1.86 (s, 1H), 3.64 (s, 3H)

2b: 90%; oil; b.p. = 100°C/15 torr; ^{1}H-NMR: 0.20 (s, 18H), 1.47 (t, 1H, J = 5 Hz), 1.0—1.5 (br. s, OH), 3.41 (d, 2H, J = 5 Hz)

2c: 73%; oil; b.p. = 97°C/15 torr; ^{1}H-NMR: 0.13 (s, 18H), 2.15 (d, 1H, J = 8 Hz), 8.57 (d, 1H, J = 8 Hz)

2d: 69%; m.p. = 138—140°C (*E*/*Z*-mixture); ^{1}H-NMR: 0.13 (s, 18H), 1.84/2.00 (d, 1H, J = 8 Hz), 2.43 (s, 3H), 5.87/6.52 (d, 1H, J = 8 Hz), 7.15—8.00 (AA'BB', 4H)

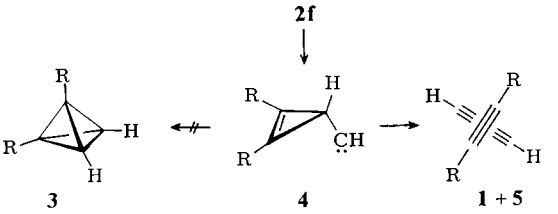
[**] Small Rings, Part 43. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 42. G. Maier, T. Sayraç, H. P. Reisenauer, *Chem. Ber.*, in press. - Details of the crystal structure study of **2f** can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the number CSD 50189, the name of the author and a complete citation of the article.

Heating **2e** to 110°C in an oven flanged onto the vacuum mantel of a cryostat results in formation of the diazo compound **2f**, which can be condensed with argon onto a window at 10 K and subsequently cleaved photochemically (λ = 366 nm). The experiment shows that the initially formed carbene **4** does not participate in intramolecular addition to afford tetrahedrane **3** but decomposes even under the matrix conditions to yield the fragments **1** and **5**. Desilylated **2d** could not be converted into the corresponding diazomethane.



R = $SiMe_3$

In the CuBr-catalyzed reaction of **1** with methyl diazoacetate, apart from **2a** a colorless solid product is formed which decomposes only above 110°C and is shown from the X-ray structure analysis to be a π complex between CuBr and **1**. **1**·CuBr can be obtained without difficulty as long, colorless needles; this is consistent with the considerable readiness of **1** to form complexes with other transition metals[10].

Radical Ion-Pairs as Intermediates in Reactions of Tetra-*tert*-butyltetrahedrane and Tetra-*tert*-butylcyclobutadiene**

By *Günther Maier**, *Klaus-Albert Schneider*, *Klaus-Dieter Malsch*, *Hermann Irngartinger*, and *Andrea Lenz*

Under normal conditions tetra-*tert*-butyltetrahedrane **1** is stable in air[1], whereas tetra-*tert*-butylcyclobutadiene **3** reacts readily with oxygen or water[2]. However, as soon as an acceptor is added **1** becomes very reactive. This effect can be illustrated by the two following examples.

Formation of the "Diels-Alder type" adduct **2** *via* a radical ion pair: Whereas **3**, despite the large steric hindrance, undergoes a diene addition with acetylenedicarboxylic ester[8], **1** remains unchanged under these conditions. When

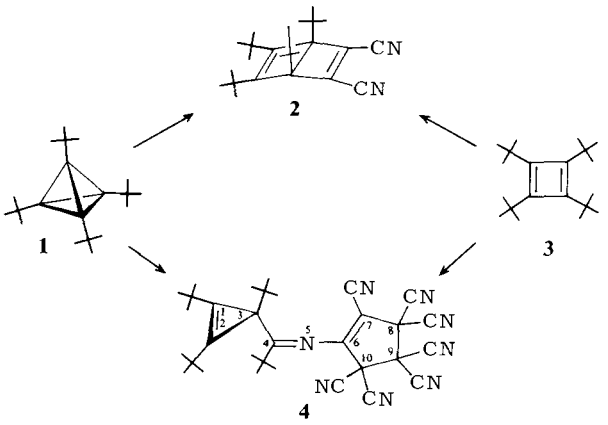
[**] Small rings, Part 44. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 43: G. Maier, M. Hoppe, H. P. Reisenauer, C. Krüger, *Angew. Chem. 94* (1982) 445, *Angew. Chem. Int. Ed. Engl. 21* (1981) 437.



dicyanoacetylene is used, however, both **1** and **3** yield the formal Diels-Alder adduct **2**. The following explanation is proposed: the oxidation potential of dicyanoacetylene is sufficient to generate the radical cation **5** from **1** and **3**. Recombination with the radical anion **6** thus formed leads to zwitterion **7**, which cyclizes to **2** (Table 1).

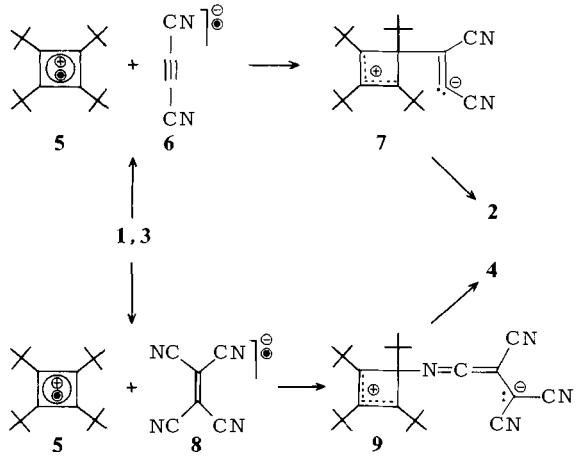


Table 1. (Selection). **2** and **4**: Yields, physical and spectroscopic properties; IR (KI) [cm^{-1}]; NMR ($CDCl_3$, δ-value rel. TMS, p = primary, q = quaternary). Both substances gave correct elemental analyses.

2: 74% from **1**, 63% from **3**; m.p.: 229 °C; IR: 2210 (C≡N), 1610 (C=C); ^{1}H-NMR: 1.41 (s, 18 H), 1.38 (s, 18 H)

4: quant. from **1** or **3** (NMR-spectroscopic; considerable losses on purification), m.p. = 100 °C (decomp.); IR: 2255, 2215 (C≡N), 1755 (sst, br.), 1525 (m); ^{1}H-NMR: 1.43 (s, 18 H), 1.39 (s, 9 H), 1.11 (s, 9 H); ^{13}C-NMR (−40 °C): 195.9 (C4), 141.9 (C6), 126.6/123.6 (C1/2), 64.8 (C7), 50.2 (C3), 47.9 (C10), 46.7 (C9), 45.7 (C8) *etc.*

Formation of adduct **4**, which has an unusual structure, *via* a radical ion-pair: It is to be expected that tetracyanoethylene (TCNE) should be capable of oxidizing **1** and **3**. However, 1:1-adducts analogous to **2** are not formed, rather unexpectedly the 1:2-adduct **4** (Table 1) instead, whose structural elucidation has involved considerable effort: on the one hand, no olefin which reacts analogously is known, and, on the other, the ^{13}C-NMR spectrum (C1 and C2 are magnetically non-equivalent) and IR spectrum appear at first sight to be inconsistent with **4**. The X-ray structure analysis, however, clears up any doubt.

Surprisingly the IR spectrum of **4** has a very intense band at 1755 and a moderately intense band at 1525 cm^{-1}. These can presumably be explained by the particular properties of the fixed structural element C4N5C6C7. C4N5C6, as a consequence of coupling, can give rise to an asymmetric and a symmetric stretching vibration, which must both be IR-active[14]. The conspicuously short wavelength absorption of the asymmetric vibration at 1755 cm^{-1} is consistent with the postulated coupling phenomenon, which at the same time shifts the symmetric stretching vibration to long wavelength (1525 cm^{-1}).

For the formation of **4** it can be assumed that the radical anion **8**, which is more bulky than **6**, attacks the radical cation **5** using a nitrogen atom as "spear point". The zwitterion **9** thus formed, in which direct ring-closure is unfavorable for geometrical reasons, finally forms the product **4** *via* ring contraction and addition of a second molecule of TCNE.

Semibullvalenetetracarboxylates: Models for Molecules with Bishomoaromatic Ground State**

By *Rudolf Gompper** and *Marie-Luise Schwarzensteiner*

The rate of Cope-rearrangement is drastically increased by polar substituents such as, *e.g.*, donor-acceptors[1]. In semibullvalene, which rearranges extremely rapidly, donor groups on C-1,5, acceptor groups on C-2,8 and C-4,6 or the replacement of CH by N at the 2,6 or 3,7 centers should, according to MO calculations by *Dewar*[6] and *Hoffmann*[7], increase the energy barrier of the Cope rearrangement to such an extent that a bishomoaromatic ground state results. This prediction could hitherto not be confirmed experimentally. We report here on a synthetic route which leads to semibullvalenetetracarboxylates such as **4** and **5** and should make further acceptor-substituted semibullvalenes accessible[***].

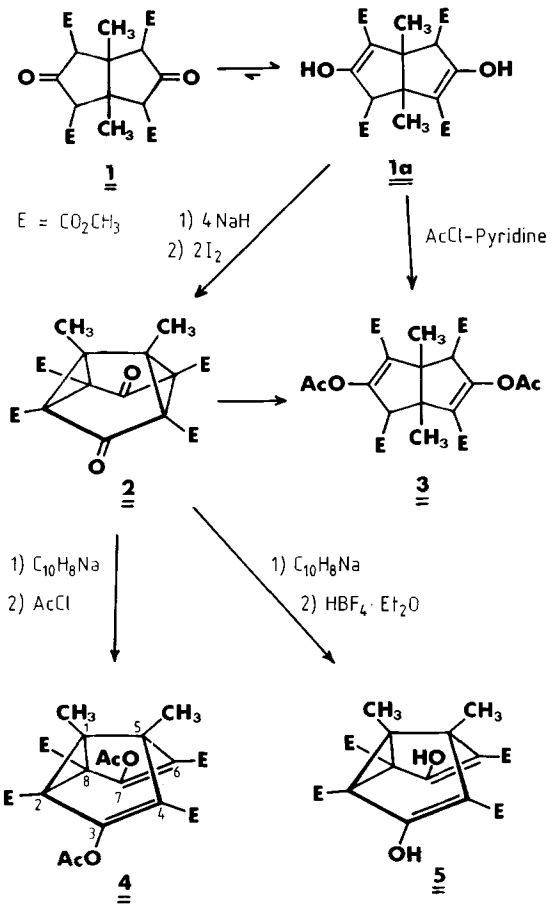
The bicyclooctane derivative **1**[13], existing as dienol **1a**, can be converted by reaction with sodium hydride and iodine into the tetramethyl 1,5-dimethyl-3,7-dioxotetracy-

[*] Prof. Dr. R. Gompper, M.-L. Schwarzensteiner
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

[***] *Note added in proof during publication of the short version* (February 12, 1982): In the meantime, tetramethyl 1,5-dimethyltricyclo[3.3.0.0^{2,8}]octa-3,6-diene-2,4,6,8-tetracarboxylate has also been prepared from **1** *via* **2** using another method [L. S. Miller, R. Grohmann, J. J. Dannenberg, L. Todaro, *J. Am. Chem. Soc. 103* (1981) 6249]. Like **4**, the compound does not have a delocalized structure.—The X-ray structure analysis of **4** gives C2—C8 = 1.643, C4—C6 = 2.352 Å (Dr. H. Lotter, Dr. H.-U. Wagner); in the case of **2**, C2—C8 = 1.566, C4—C6 = 1.563 Å (Dr. U. Nagel).

clo[3.3.0.0^{2,8}.0^{4,6}]octane-2,4,6,8-tetracarboxylate **2** (55%, m.p. 185 °C). Reduction of **2** with zinc/glacial acetic acid and with zinc/acetic anhydride respectively afford 1,5-dimethylbicyclo[3.3.0]octane-3,7-dione and the bisenol acetate **3** (m.p. 130 °C), which is also accessible from **1** and acetyl chloride/pyridine. Reduction of **2** with sodium dihydronaphthylide, however, and treatment of the reaction mixture with acetyl chloride, leads to tetramethyl 1,5-dimethyl-3,7-diacetoxytricyclo[3.3.0.0^{2,8}]octa-3,6-diene-2,4,6,8-tetracarboxylate **4** (25%, colorless needles, m.p. 117 °C). The IR spectrum of **4** resembles that of **3**; thus, there is little likelihood that **4** has a delocalized structure. Average ^{1}H-NMR spectra (singlets of the CO_2CH_3- and 1,5-CH_3-protons) are observed at room temperature and down to −111 °C. The ^{13}C-NMR spectra also point to a rapid Cope-rearrangement. The signal of C-2,4,6,8 first begins to broaden below −110 °C (in $CHClF_2$); at −131 °C it has almost disappeared (so far, a lower temperature could not be reached).



Hydrolysis of the mixture obtained on reaction of **2** with sodium dihydronaphthylide affords colorless crystals of the compound **5**, whose ^{1}H-NMR spectrum indicates that the dienol predominates. Remarkably, as in the ^{1}H-NMR spectrum of **4**, the 1,5-CH_3 protons yield one singlet, while the CO_2CH_3-protons give two singlets. This could be explained in terms of the OH-groups and ester groups forming chelate rings which remain intact during a rapid Cope-rearrangement.

Tetraethyldibismuthane: A Dinuclear Bismuth Compound

By *Hans Joachim Breunig* and *Ditmar Müller**

All previous attempts[1] to prepare tetraorganodibismuthanes have met without success[**] or led at most to traces of non-analyzable products. Hence, the characterization of compounds containing a Bi—Bi bond was limited to multinuclear bismuth cluster-cations[2a] and -anions[2b] and a polymer $(PhBi)_x$[1c]. These species contain a variety of homoatomic bonds. So far, however, only one isolable compound containing a Bi—Bi bond, a chelate complex, has been described in the literature[3a]. In view of this lack of knowledge about such compounds it was surprising to find how easy tetraethyldibismuthane can be generated by a method based on a synthesis of distibanes[3b].

Reaction of triethylbismuthane with sodium in liquid ammonia led to formation of a deep-red solution of sodium diethylbismuthide, which, after destruction of the ethylsodium, reacts with 1,2-dichloroethane with decoloration to give tetraethyldibismuthane[5] [eqs. (a)—(c)]:

$$Et_3Bi + 2\,Na \rightarrow Et_2BiNa + EtNa \quad (a)$$
$$EtNa + NH_4Br \rightarrow EtH + NH_3 + NaBr \quad (b)$$
$$2\,Et_2BiNa + ClCH_2CH_2Cl \rightarrow Et_2BiBiEt_2 + C_2H_4 + 2\,NaCl \quad (c)$$

Et_4Bi_2 is a red, oily liquid at room temperature. Solutions in benzene are likewise red, those in cyclohexane yellow. On cooling, neat Et_4Bi_2 first turns dark-red, and below −30 °C it appears almost black. However, similarly to Me_4Sb_2[1a], Et_4Bi_2 also assumes a yellow color once again at −196 °C.

Et_4Bi_2 proves to be more stable than expected. Although it begins to decompose to Et_3Bi and black solids, $(EtBi)_x$, and Bi already at 0 °C, it is still detectable in such samples even after a few days. Above 40 °C, however, it decomposes completely; only Et_3Bi can be isolated after distillation at reduced pressure [eqs. (d)—(e)]:

$$Et_4Bi_2 \rightarrow Et_3Bi + 1/x\,(EtBi)_x \quad (d)$$
$$3\,Et_4Bi_2 \rightarrow 4\,Et_3Bi + 2\,Bi \quad (e)$$

Decomposition according to eq. (d) was also observed in the case of the non-isolated Ph_4Bi_2[1c].

The existence of Et_4Bi_2 is confirmed by elemental analysis and by the mass spectrum[5], which contains a prominent intense molecular ion at 25 eV. At 70 eV the successive cleavage of the ethyl groups down to the Bi_2-fragment can also be observed. Et_3Bi is formed by thermal decomposition and by fragmentation, as was analogously demonstrated in the case of a distibane[4]. The ^{1}H-NMR spec-

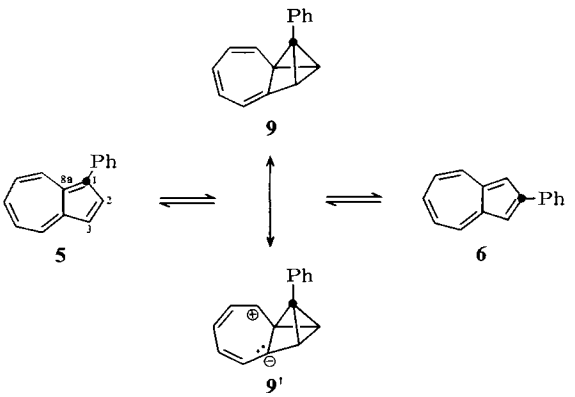
1-Phenylazulene→2-Phenylazulene Rearrangement—Substituent Migration or Skeletal Rearrangement?**

By *Klaus-Peter Zeller**

The thermal rearrangements of 1-substituted azulene derivatives into the 2-substituted isomers were previously[1] regarded as substituent migrations. After studies on the thermolysis of ^{13}C-labeled azulene[2] revealed thermal automerization of the azulene, the assumption of a skeletal rearrangement also seemed justified.

Using the reversible conversion of 1-phenylazulene into 2-phenylazulene[1] as example, we have studied the mechanism by means of a ^{13}C-labeling experiment. The 2-phenylazulene **6** formed on gas-phase thermolysis (400 °C) of 1-phenyl-[1-^{13}C]azulene **5** contains all the ^{13}C-enrichment on C2—thus, a skeletal rearrangement must take place.

From the labeling experiment and from older findings, according to which substituents on the seven-membered ring retain their position during such rearrangements[1], an interpretation of the reaction mechanism requires that 1) no changes should occur at the seven-membered ring; 2) C1 must be coupled with C3, and C2 with C8a; 3) the bonds C1—C8a and C2—C3 must be broken.



Rearrangement *via* the bicyclo[1.1.0]butane intermediate **9** fulfills these conditions. However, the postulation of **9** is at first problematic, because an *endo,endo*-bridged bicyclo[1.1.0]butane should thermally isomerize to a *cis,trans*-1,3-butadiene, irrespective of whether the reaction is regarded as a concerted $[_\sigma 2_s + _\sigma 2_a]$-mechanism or a two-step process *via* a biradicaloid intermediate[5]. Interestingly, however, thermal opening of benzvalene to benzene is premitted, since a favorable six-electron process takes place here through participation of the double bond[6]. In the case of the reaction sequence **5** ⇌ **9** ⇌ **6** it would be necessary to check whether an electron distribution as in the resonance structure **9'** with participation of a free electron pair renders possible the thermal conversion of the bicyclo[1.1.0]butane system into a *cis,cis*-1,3-butadiene structural moiety.

Monomolecular Membranes from Synthetic Macrotetrolides**

By *Jürgen-Hinrich Fuhrhop**, *Karin Ellermann*, *Hans Herrmann David*, and *Joachim Mathieu*

Long-chain hydrophobic molecules, in which two α,ω-sited hydrophilic heads can be introduced, are useful for the synthesis of specific monomolecular membranes with different head groups. If this "hydrophilation" proceeds in high yield, the hydrophobic educts and amphiphilic products can be separated by straightforward crystallization. We now report the first synthesis of maleic acid macrotetrolides which with sulfides and sulfites give good yields of readily isolable membrane components.

Maleic anhydride reacts with 1,12-dodecanediol to afford the dicarboxylic acid **1** (100%), which can be cyclized with a further 1,12-dodecanediol to form the 36-membered *Z,Z*-macrotetrolide **2**; isolation (40%) follows by single crystallization from ethyl acetate[4, 5]. Photochemical isomerization results in the presumed wedge-shaped *E,Z*-stereoisomer **3** (70%)[5], and the action of heat on an ethanolic solution in presence of piperidine gave the *E,E*-diastereomer[5].

Reaction of macrotetrolide **2** in isopropanol-water 4:1 with sodium hydrogen sulfite yielded the analytically pure

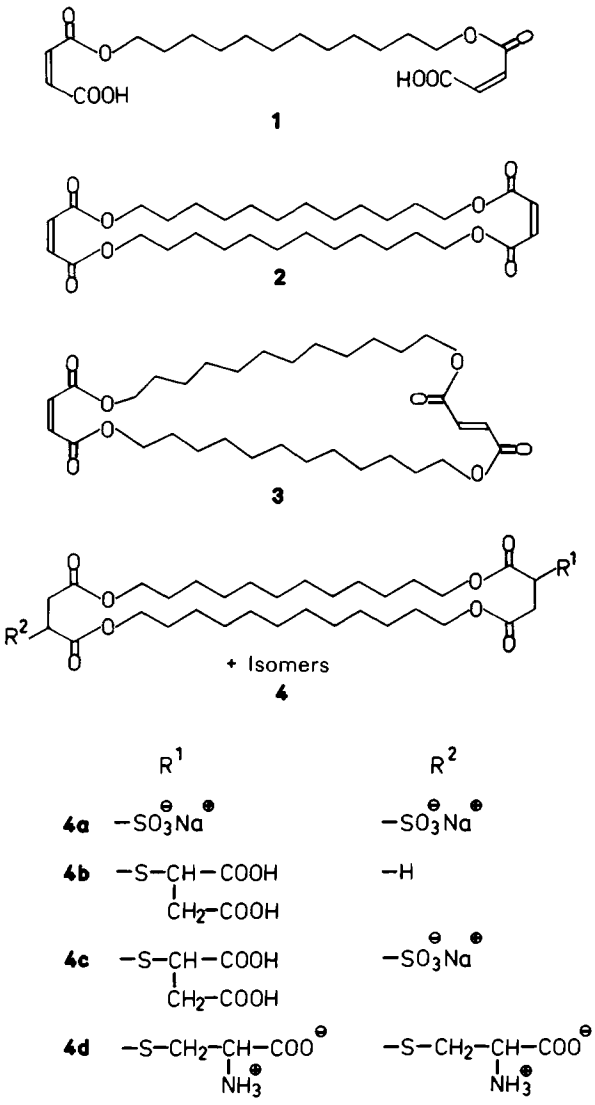
disulfonic acid **4a**[6], after crystallization from methanol-water. Addition of thiosuccinic acid to **2** led to the mono-adduct **4b**[6] (90%), which reacts with sodium hydrogen sulfite to furnish the unsymmetrically substituted macrotetrolide **4c** (80% total yield). **4d** was obtained from **2** and cystein.



4c, which is insoluble in water, yielded vesicles upon ultrasonication; with **4a**, formation of vesicles was observed after addition of cyclohexylamine and ultrasonication. Molecular models indicate that the monolayer membranes should be only 20 Å thick.

Bis(dinitrogen)- and Diethylene-molybdenum(0) Complexes**

By *Ernesto Carmona*, José M. Marín, Manuel L. Poveda, Jerry L. Atwood, Robin D. Rogers,* and *Geoffrey Wilkinson*

Although a large number of dinitrogen complexes[1] of Group 6A metals containing tertiary phosphane ligands have been isolated, for monodentate trialkylphosphanes, apparently only *cis*-$[Cr(N_2)_2(PMe_3)_4]$ is known. The complex $[MoCl_3(PMe_3)_3]$, when treated with dispersed sodium and PMe_3 in tetrahydrofuran (THF), gives *cis*-$[Mo(N_2)_2(PMe_3)_4]$ **1**, in yields better than 60%. With sodium amalgam, the corresponding *trans* isomer is formed, also in good yields. The IR spectrum of the *cis* complex (Nujol) contains two strong bands at 2010 and 1950 cm^{-1}, that of the *trans* isomer a strong band at 1930 cm^{-1} and a very weak band at 2000 cm^{-1}.

Reaction of **1** with C_2H_4 in petroleum ether (ambient temperature and pressure) affords *trans*-$[Mo(C_2H_4)_2(PMe_3)_4]$ **2** as an amber-colored, very air-sensitive crystal line substance, whose structure was determined by X-ray diffraction (Fig. 1)[5]. The ^{1}H-NMR, spectrum shows bands due to the C_2H_4- and the PMe_3-protons [$(C_6H_6)\delta = 1.4$ (s) and 1.0 (s)], respectively.

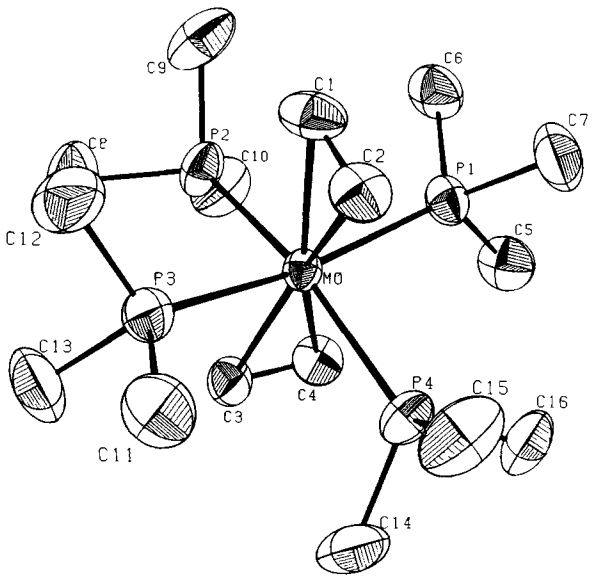

Fig. 1. ORTEP diagram of the structure of **2** in the crystal.

2 is essentially octahedral with the ethylene molecules staggered with respect to one another and eclipsing the *trans*-P—Mo—P bonds[7]. This conformational preference has been predicted from quantitative calculations[9]. The

four phosphorus atoms lie almost in the same plane; the average MoP distance is 249.2(8) pm. Both ethylene molecules are symmetrically bound to the Mo atom, the mean distance for the C=C bonds being 140(1) pm (6 pm longer than in free ethylene).

In hydrocarbon solutions of **2**, the following equilibrium appears to exist:

$$\underset{\mathbf{2}}{[Mo(C_2H_4)_2(PMe_3)_4]} + N_2 \rightleftarrows \underset{\mathbf{3}}{[Mo(N_2)(C_2H_4)_2(PMe_3)_3]} + PMe_3$$

This was demonstrated by molecular weight determinations under He and N_2 and by IR and NMR spectra. Prolonged interaction with N_2 followed by reduction in volume in a vacuum leads to a bright yellow crystalline solid which redissolves on admission of N_2. The sequence is reversible and may be described in terms of the following equation:

$$2\underset{\mathbf{3}}{[Mo(N_2)(C_2H_4)_2(PMe_3)_3]} \underset{+N_2}{\overset{-N_2}{\rightleftharpoons}} [Mo_2(\mu\text{-}N_2)(C_2H_4)_4(PMe_3)_6]$$

That the dinitrogen in **3** is weakly bound is also indicated by the high value[11] of ν_{N_2} (2070 cm^{-1}) and by its facile displacement by CO to give colorless crystalline $[Mo(CO)(C_2H_4)_2(PMe_3)_3]$, a compound in which the C_2H_4-ligands are likewise *trans*-oriented.

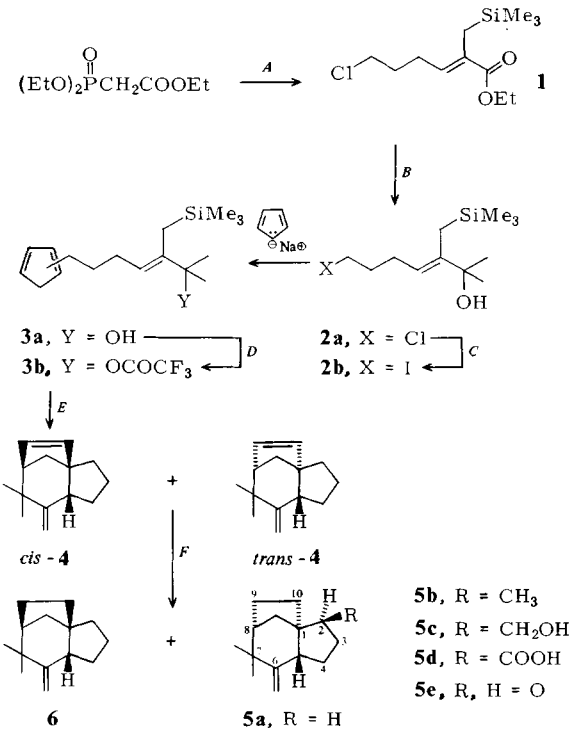
A Short Route to 7,7-Dimethyl-6-methylenetricyclo[6.2.1.0^{1,5}]undeca-9-ene and the Zizaene Class of Sesquiterpenoids**

By *H. M. R. Hoffmann, Rolf Henning*, and *Olgierd Romuald Lalko**

Zizaene **5b** and its oxygenated derivatives **5c–e** are important olfactory constituents of vetiver oil and, as has just been reported, also excellent insect repellents[1c]. Despite a number of published syntheses[1a,b], practical approaches to **5** remain a special challenge. We have now found a short route to racemic **5a**, in which the tricyclic skeleton is constructed by intramolecular cycloaddition of an allyl cation in a single step.—This work extends previous syntheses of 3-methylenebicyclo[3.2.1]oct-6-enes[2].

The functionalized acrylic ester **1** was obtained in a single flask reaction in 30% yield by (*i*) deprotonation of triethyl phosphonoacetate with sodium hydride in solvent 1,2-dimethoxyethane, (*ii*) alkylation with iodomethyl(trimethyl)silane, (*iii*) renewed deprotonation and (*iv*) Horner-Wittig reaction with 4-chlorobutyraldehyde. Methylation of **1** with an excess of methyllithium at −30 °C gave allylic alcohol **2a** (90% yield), which was converted into **2b** (Cl/I exchange 86%) by refluxing with sodium iodide in solvent acetone. Treatment of **2b** with cyclopentadienylsodium afforded the mixture of the 1- and 2-alkylated 1,3-cyclopentadienes **3a**, isolated in 87% yield by chromatography.

The key intramolecular double cyclization was carried out after developing methodology for generating highly alkylated allyl cations, which are prone to proton loss, from sensitive precursors at low temperature[3]. For example, esterification of **3a** with trifluoroacetic anhydride/ethyldiisopropylamine at −70 to −30 °C followed by chromatography of the reaction mixture at −30 °C gave the title compound **4** (*trans*-**4** : *cis*-**4** = 1.15 : 1; 16% yield with respect to **3a**) as a colorless liquid, having a fresh characteristic odor reminiscent of camphene. Addition of **4** to a concentrated solution of *ca.* 1.3 equivalents of silver nitrate in deoxygenated water gave an immediate precipitate of the silver nitrate complex, stable at −20 °C. Recovery of **4** by treatment with moist ether or pentane was quantitative. Hydrogenation of **4** with diazene occurred selectively at the endocyclic double bond, giving **6** and 2-norzizaene **5a** in quantitative yield (Scheme 1).



Scheme 1. *A*) 1. NaH in 1,2-dimethoxyethane; 2. Me_3SiCH_2I, 70 °C, 3 h; 3. NaH, 0 °C → RT; 4. $Cl(CH_2)_3CHO$, 0 °C → RT; *B*) >2 equiv. MeLi, Et_2O, −30 °C; *C*) NaI, acetone, reflux, 48 h; *D*) $(CF_3CO)_2O$, $EtN(iPr)_2$, CH_2Cl_2, −70 → −40 °C; *E*) chromatography on neutral Al_2O_3 (activity I) coated with $ZnCl_2$, CH_2Cl_2/pentane, −30 °C; *F*) N_2H_2, MeOH, RT.—NaC_5H_5 from cyclopentadiene and Na-dispersion on neutral Al_2O_3 (activity I) in tetrahydrofuran.

The new route to functionalized tricyclo[6.2.1.0^{1,5}]undeca-9-enes is short and flexible. The strained endocyclic

bond in **4** fulfills several useful functions by (*i*) providing a site for silver nitrate complexation, thus allowing easy separation, purification and storage of oily **4**; (*ii*) introducing tricyclic strain, thus holding the labile methylene double bond in the *exo*-position, without danger of isomerization into the otherwise more stable endocyclic 5,6-position[1b,4]; (*iii*) allowing access to new analogues of zizaene which have not yet been encountered in any natural products.

Trialkylsilyl(trifluoromethyl)diazenes as Tailored Reagents for Nucleophilic Trifluoromethylation**

By *Uwe Hartkopf* and *Armin de Meijere**

The search for novel methods of introducing trifluoromethyl groups into organic molecules continues[1]. Nucleophilic transfer of trifluoromethanide carbanion was, until quite recently, unknown[2]. We therefore designed the novel trialkylsilyl(trifluoromethyl)diazenes **2** which should be suitable candidates for the generation of $CF_3^\ominus$ ions under extremely mild conditions because of the exceptional electrophilicity of trialkylsilyl groups bound to heteroatoms.

Trialkylsilylamines proved to be inadequately nucleophilic for reaction with trifluoronitrosomethane, which converts primary alkylamines into trifluoromethylazo-compounds[1]. The lithium silylamides **1**, however, react smoothly with CF_3NO. Thus, reaction of lithium bis(trimethylsilyl)amide **1a** and of lithium *tert*-butyldimethylsilylamide **1b** with CF_3NO in diethyl ether afforded pale-red solutions of **2a** and **2b**, respectively; however, only **2b** could be enriched to a purity of up to 95% by preparative gas-chromatography (Table 1). **2a** decomposes very rapidly on attempted isolation, while **2b** is extremely sensitive to hydrolysis: Traces of moisture initiate autocatalyzed decomposition to the respective disiloxanes and silanols, trialkylsilyl fluorides, and other trialkylsilyl derivatives. Ethyl- and phenylsubstituted compounds **2** were lacking hydrolytic and/or thermal stability as well, and accordingly, could only be generated in solution and detected by combined GC/MS.

Such diazenes **2** with adequately bulky groups on the silicon, as in **2g** and **2i**, however, are completely stable. The tri-*tert*-butylsilyl derivative **2g** is a violet solid (m.p. 37–38 °C), the raspberry-red crystalline dimethyl [tris(trimethylsilyl)methyl]silyl derivative **2i** (m.p. ≈200 °C (dec)) can be heated under atmospheric conditions up to ≈200 °C without decomposition (Table 1). Accordingly, **2g** and **2i** provide a means of investigating the bonding properties of this new class of compounds.

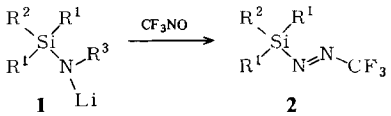

Table 1. Trialkylsilyl(trifluoromethyl)diazenes **2** from lithium silylamides **1** and trifluoronitrosomethane at −80 °C.

	R^1	R^2	R^3	Solvent	Yield [%] [a]	λ_{max} (ε_{max})
a	Me	Me	$SiMe_3$	Et_2O: Bu_2O	—	—
b	Me	*t*Bu	H	Et_2O	6	520 (6)
g	*t*Bu	*t*Bu	H	Et_2O	11	548 (24)
i	Me	$C(SiMe_3)_3$	H	Et_2O	33	504 (15)

[a] Gas-chromatographically isolated yields.

The observed sensitivity of the other compounds **2** towards hydrolysis was regarded as an indication that they fragment, as expected, with liberation of $CF_3^\ominus$ ions. Indeed, it was possible to carry out fragmentation of **2a** *in situ*, even at −100 °C, and to trap the $CF_3^\ominus$ ions thus liberated with carbonyl compounds. A solution of sodium bis(trimethylsilyl)amide in tetrahydrofuran was added dropwise at −100 °C to a solution of CF_3NO and carbonyl compound in the same solvent. Thus, trifluoroacetophenone **4a** and cyclohexanone **4b** afforded the tertiary alcohols **5a** and **5b** (^{1}H-, ^{13}C-NMR, MS) in 34 and 30% yield, respectively (isolated gas-chromatographically).

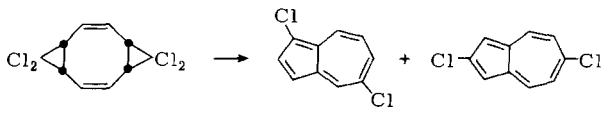
[2] According to a recent report, CF_3I reacts with zinc metal in dimethylformamide when exposed to ultrasonic sound, forming a reagent which transfers $CF_3^\ominus$ to carbonyl compounds. Cf. T. Kitazume, N. Ishikawa, *Chem. Lett. 1981*, 1679, and references cited therein.

Vacuum Pyrolysis of 5,5,10,10-Tetrachlorotricyclo[7.1.0.0^{4,6}]deca-2,7-diene: 1,5- and 2,6-Dichloroazulenes**

By *Eckehard V. Dehmlow** and *Marion Slopianka*

The dehalogenation of tetrahalotricyclo[7.1.0.0^{4,6}]decadienes with organolithium compounds leads *via meso*-1,2,4,6,7,9-cyclodecahexaene to naphthalene[1]. However, nothing has been described in the literature about the thermolysis and dehydrohalogenation of such compounds, whereas the related bicyclo[6.1.0]nonatrienes found much interest.

Cleavage of HCl takes place to a small extent on sublimation of the title compound **1** in a "poor" vacuum (250 °C/100—200 torr); on heating to 170 °C in quinoline, it undergoes polymerization. **1** behaves similarly in the presence of $NaOCH_3$ in $HOCH_3$[2].

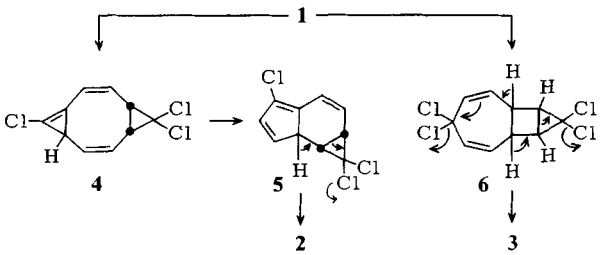


1 **2** **3**

We have now carried out a flash pyrolysis of **1** at *ca.* 700 °C/10^{-4} torr in the apparatus described by *Seybold*[3]. The blue product was free of educt. Preparative thin-layer chromatography on silica gel with petroleum ether as eluent afforded a deep-blue zone and a blue-violet zone, from which two $C_{10}H_6Cl_2$-isomers were obtained. In addition, traces of 2,6-dichloronaphthalene (but not the 1,5-isomer!) were detectable. A diffuse, deep polar-blue zone could not be obtained in a pure state.

The blue compound was shown by analysis and spectral data to be 1,5-dichloroazulene **2**[4a] the blue-violet compound to be 2,6-dichloroazulene **3**[4b].

These compounds, the first azulenes with halogen-substituents in both rings, are potentially interesting educts for further syntheses.



4 **5** **6**

For the formation of **2**, we suggest dehydrochlorination to **4**, subsequent rearrangement to **5**, and renewed dehydrochlorination. **3** can be formed *via* Cope-rearrangement to **6** and double dehydrochlorination. A reaction analogous to the intermediate formation of **6** is known in the well-investigated bicyclo[6.1.0]nonatriene series[5].

$C_\alpha C_\alpha$-Coupling of Two $\{(CO)_5CrCNEt_2\}$ Fragments by Reductive Dimerization of a Cationic Carbyne Complex[1]

By *Ernst Otto Fischer**, *Dieter Wittmann*, *Dieter Himmelreich*, and *Dietmar Neugebauer*

Addition of nucleophiles to the carbyne carbon atom of the cationic aminocarbyne complex $[(CO)_5CrCNEt_2]BF_4$ **1**[2] leads to numerous aminocarbene complexes $[(CO)_5Cr\{C(NEt_2)Nu\}]$ not usually accessible *via* conventional routes. Thus, *e.g.*, reaction of **1** with potassium diphenylarsenide affords the C_α-arsene-substituted aminocarbene complex $[(CO)_5Cr\{C(AsPh_2)NEt_2\}]$ **4**[5].

A completely different type of reaction course is observed on reaction of **1** with lithium dimethylarsenide: Instead of the expected addition of nucleophile with formation of the complex analogous to **4**, reductive $C_\alpha C_\alpha$-coupling of two $\{(CO)_5CrCNEt_2\}$ fragments takes place to give the μ-bis(aminocarbene)-complex **5** (*ca.* 30% yield, elemental analysis, MS, IR, NMR, X-ray structure analysis).

$$\underset{\mathbf{1}}{2[(CO)_5CrCNEt_2]BF_4} + 2\,LiAsMe_2 \xrightarrow[-60\,^\circ C]{Et_2O} [\{(CO)_5CrCNEt_2\}_2] + As_2Me_4 + 2\,LiBF_4$$
$$\mathbf{5}$$

The tetramethyldiarsane formed concomitantly as oxidation product can be detected mass spectrometrically in the form of the complex pentacarbonyl(tetramethyldiarsane)chromium(0). As a result of hindered rotation about the C_α—C'_α bond in **5**, two conformational isomers are formed whose existence in solution is demonstrated both by IR data as well as ^{1}H-NMR data.

An X-ray structure analysis of **5** showed that the two $\{(CO)_5CrCNEt_2\}$ fragments are crystallographically connected *via* a C_2-axis. The μ-bis(aminocarbene)-complex, however, with the longest Cr—$C_{carbene}$ bond length (219.0(7) pm)[6] found so far, shows no shortening of the C_α—C'_α (148.0(9) pm) and C_α—N (130.6(9) pm) bonds. The angle of 97.6° between the two carbene fragments Cr—C_α—N—$C_{\alpha'}$ and Cr*—$C_{\alpha'}$—N*—C_α rules out a bridging delocalized π-system[7]. Each metal atom balances its charge by a significant shortening of its bond distance to the *trans*-carbonyl group (Cr—C1 184.8(10) pm).

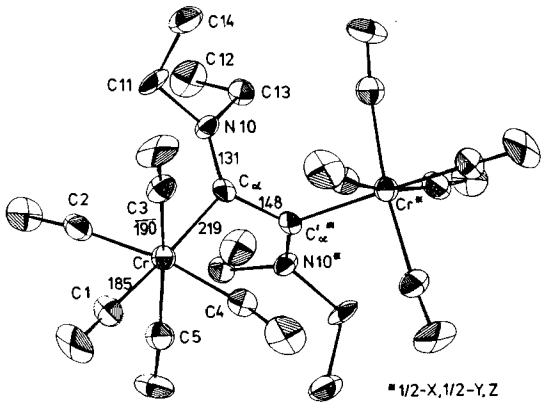

Fig. 1. Molecular structure of μ-[1,2-bis(diethylamino)ethanediylidene]-bis(pentacarbonylchromium) **5** in the crystal.

In the meantime we have also been able to demonstrate the formation of **5** in the reaction of **1** with lithium acetylacetonate; the compound is likewise formed as by-product in the aforementioned synthesis of **4**.

This novel type of reaction—reductive dimerization of a cationic carbyne complex with $C_\alpha C_\alpha$-coupling—can thus become the dominating reaction competing against addition of the nucleophile to the carbyne carbon atom when using strongly reducing nucleophiles.

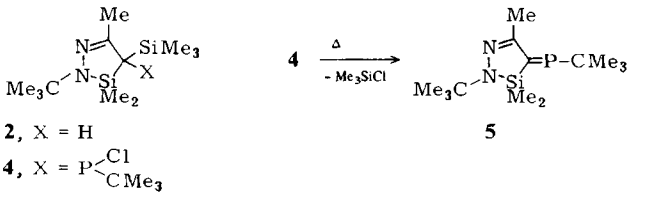
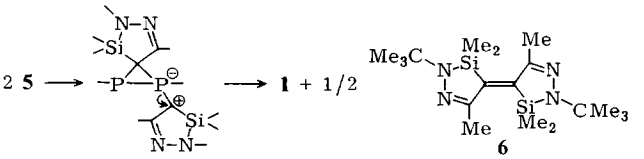
Apart from **1** only the intense red-orange compound **6** is isolated, whose structure was determined by X-ray diffraction.



We presume that by analogy with the [2+1]cycloaddition of 1,2-bis(*tert*-butyl)iminophosphane[9], two molecules of **5** react to give **1** and a carbene diazasilacyclopentenylidene, which dimerizes to **6**.



The carbene-analogous behavior of the phosphorus in **5** could result from its increased nucleophilicity produced by the *tert*-butyl group.

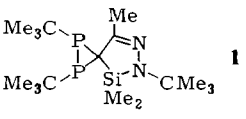
A Spirocyclic Diphosphirane**

By *William Clegg, Martin Haase, Michael Hesse, Uwe Klingebiel,* and *George M. Sheldrick**

Stable cyclotriphosphanes, as well as mono- and diphosphiranes[2] are known. We describe here the spirocyclic diphosphirane **1** obtained by a novel route[10].



1

In the reaction of lithiated **2** with *tert*-butyldichlorophosphane, phosphino-substituted **4** can be detected in solution. Attempts to distil **4** result in continuous loss of chlorotrimethylsilane; the expected[7,8] methylenephosphane **5** could not, however, be detected.

Structure of the Octabismuth(2+) Cluster in Crystalline $Bi_8(AlCl_4)_2$

By *Bernt Krebs**, *Marita Hucke,* and *Claus Jörg Brendel*

Three unusual polycations of the heavy main group element bismuth—Bi_5^{3+}, Bi_8^{2+}, and Bi_9^{5+}—have so far been described in the literature[3-7], of which only the Bi_9^{5+} cluster ion has been unequivocally characterized by X-ray structure determinations on $Bi_{10}Hf_3Cl_{18}$[6] and $Bi_{24}Cl_{28}$[4]. Although solid compounds of the composition $Bi_5(AlCl_4)_3$[5,7] and $Bi_4(AlCl_4)$[5] have been isolated, preparative difficulties with respect to the synthesis of pure single crystal phases have prevented a similar structural proof of the postulated pentameric and octameric cations. The Bi_8^{2+} cluster (22 valence electrons, Bi with the very low oxidation number +0.25), whose degree of association in the chemistry of the "naked" metal cluster is still without example, seems particularly interesting. We have now been able to prepare this species in the form of pure $Bi_8(AlCl_4)_2$

[*] Prof. Dr. B. Krebs, Dipl.-Chem. M. Hucke, C. J. Brendel
Anorganisch-Chemisches Institut der Universität
Corrensstrasse 36, D-4400 Münster (Germany)

single crystals by reaction of Bi with $BiCl_3+4AlCl_3$ (33 mol-% excess of $AlCl_3$ over a "neutral" melt), and to prove unambiguously the existence and the degree of association of the cluster cation Bi_8^{2+} from an X-ray structure analysis.

The synthesis of $Bi_8(AlCl_4)_2$ was successful with a modification of the method of *Corbett*[5], however, without using $NaAlCl_4$ as a solvent. The acidities of the melts must be controlled independently of the $Bi/BiCl_3$ ratio, by changing the amount of $AlCl_3$. After subliming off the excess of $AlCl_3$, the solidified melt is deep-black and interspersed with small quantities of a second, red-brown crystalline phase.

$Bi_8(AlCl_4)_2$ forms column-shaped diamagnetic black crystals. The electronic spectrum and X-ray powder diagram are similar to those of $Bi_4(AlCl_4)$[5] and indicate both phases to be identical.

$Bi_8(AlCl_4)_2$ crystallizes hexagonally [$a=17.854(4)$, $c=12.953(3)$ Å, $\rho_{calc}=5.60\ g\cdot cm^{-3}$, $Z=6$, Laue symmetry 6/m]. The crystal structure (four-circle diffractometer, 1957 reflections, $R=0.087$) can be described in terms of space group $P6_3/m$. As an important novel structural feature the compound contains octameric Bi_8^{2+} cluster cations as shown in Figure 1 with a molecular structure of square antiprisms. The clusters are on mirror planes in the crystal and deviate only slightly from the idealized D_{4d} symmetry. The average of the observed Bi—Bi distances is 3.100 Å, which corresponds approximately to the value in metallic bismuth. The Bi—Bi—Bi bond angles in the square and triangular planes of the Bi_8^{2+} polyhedra are between 88.1(3) and 91.8(3)°, and between 59.3(3) and 60.7(3)°, respectively. Apart from two distances of 3.34(2) and 3.42(2) Å, all other intermolecular Bi...Cl distances are larger than 3.60 Å. Comparison with the Bi_9^{5+} clusters[4,6] reveals a weaker cation-anion interaction for Bi_8^{2+} (valence electron concentration of $22/8=2.75$ per Bi atom compared to $22/9=2.44$ per Bi atom in Bi_9^{5+}).

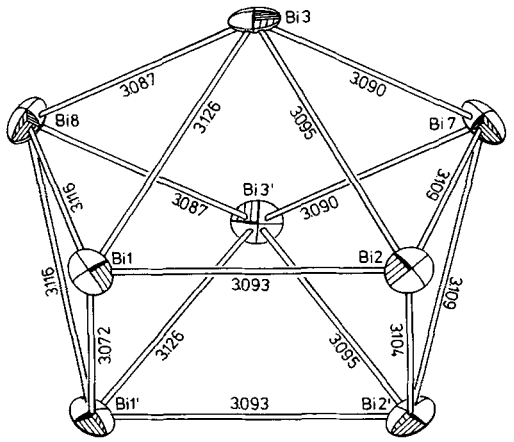

Fig. 1. Bi_8^{2+} cluster cation in crystalline $Bi_8(AlCl_4)_2$ with interatomic distances (in Å, standard deviations 0.005—0.006 Å) and vibrational ellipsoids.

The Bi_8^{2+} clusters are only incompletely shielded from each other by the relatively small anions. Remarkably short intermolecular Bi...Bi distances of 3.900(6) (Bi1...Bi3') and of 4.109(6) Å (Bi2...Bi2') seem to indicate weak inter-cluster interactions.

The structural relationship of Bi_8^{2+} to the Bi_9^{5+} cluster, which is richer by one Bi^{3+} unit, is of special interest as it may give some indication of possible paths of interconversion between the two species. The square-pyramidal Bi_8^{2+} can be transformed by very slight shifts of the atoms plus addition of one Bi^{3+} into the trigonal-prismatic tricapped Bi_9^{5+}.

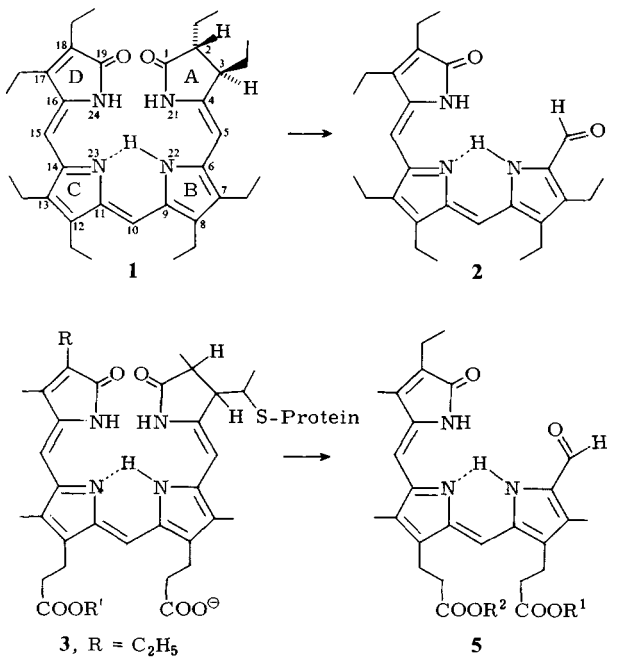
Two Mild, Regioselective Methods of Degrading Biliprotein Chromophores**

By *Werner Kufer, Corinna Krauss,* and *Hugo Scheer**

Biliproteins—receptor proteins in photosynthesis and photomorphogenesis—consist of bile pigments, which are covalently bound *via* a thioether bond at ring A to a protein; a second bond is disputed (see Discussion in [2]). We describe here two mild degradation precedures for free and protein-bound bile pigments. These methods, unlike chromic acid degradation[5], result in the retention of substantial information on the substituents at the α-pyrrolic and methine positions.



Scheme 1. (Part). **3**: R' = H or protein, **5a**: $R^1=R^2=H$; **5d**: R^1, R^2 = H, protein.

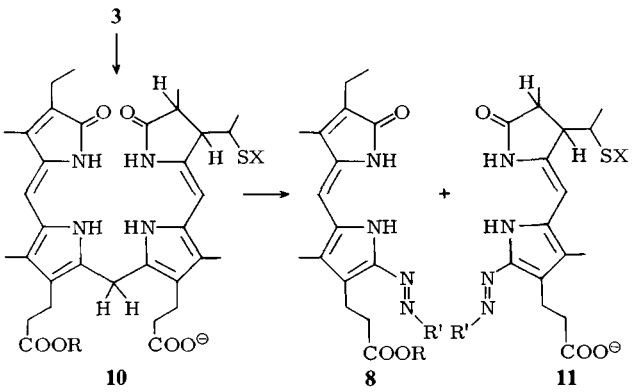
[**] Studies of Plant Bile Pigments, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft. Prof. C. T. Soeder, Jülich, is thanked for a sample of *Spirulina platensis*. Part 9: C. Krauss, H. Scheer, *Photochem. Photobiol. 34* (1981) 385.

In the first method (Scheme 1), regioselective cleavage of the C-5 methine bridge occurs. Under mildly basic conditions the zinc complex of A-dihydrobilindione **1** loses the hydrogenated ring A to form **2**[6]. The biliprotein phycocyanin **3** is cleaved in an analogous manner.

3, obtained from *Spirulina platensis* (0.05 mM) was unfolded with urea (8 M). Addition of zinc acetate (0.05 mM) and titration with NaOH to pH 9.5 yielded the characteristic intermediate[6] ($\lambda_{max}=720$ nm), which afforded the zinc complex of **5a** and/or **5d** within 8 min. Using **3**, which had been degraded by trypsin, the free tripyrinone **5a** could, in addition, be isolated.

Since trypsin is not only able to cleave proteins but also ester or amide bonds to the chromophore, this result would be evidence for the existence of one of these bonds to rings B, C, or D, whereby, however, possible artifacts (partial hydrolysis, complex binding[10] *via* Zn^{++}) make an unequivocal statement difficult.



Scheme 2. (Part). R^1 = 2-ethoxycarbonylphenyl, X = protein; **8a**: R = H; **10**: R = H or protein.

In the second method (Scheme 2) regioselective cleavage between rings B and C occurs. The denatured phycocyanin **3** was reduced with $NaBH_4$ to afford the rubin **10**[13], which after gel filtration was treated with a diazonium salt *e.g.* diazotized ethyl anthranilate in 5- to 10-fold excess[11]. By means of gel filtration or extraction with organic solvents the product mixture can be separated into two fractions, of which the low molecular and less polar ($\lambda_{max}=522$ nm) is identical with authentic **8a** (rings C and D of **3**).

The high molecular and more polar fraction ($\lambda_{max}=480$ nm) should contain **11**.

A preliminary quantitative analysis of the reaction mixture indicated that approximately 14% of the extinction at 520 nm in the crude mixture disappears after extraction with organic solvents or gel filtration. Consequently, apparently at least a part of the chromophore does not contain a protein binding site at rings C or D.

1,3-Dipolar Cycloadditions to Dialkyl-germanones and -germathiones

By *Hélène Lavayssière, Gabriel Dousse, Jacques Satgé*, Jacques Barrau*, and *Moussa Traoré*

Dialkyl-germanones $R_2Ge{=}O$ and -germathiones $R_2Ge{=}S$, novel sp^2-bonded germanium intermediates, have been characterized recently in our laboratory[1-4]. We report here new cycloaddition reactions of these unsaturated dipolar species with 1,3-dipolar reagents (nitrilimines and nitrones).

The precursor of the germanium species (see Table 1) and 2,5-diphenyltetrazole (precursor of nitrilimine) are heated in a Carius tube. Fractional distillation results in isolation of only the cycloadduct **1** (oxa- or thiadiazagermoline). **1** could also be prepared from diorganogermanium diamides and *N'*-phenylbenzo- or -thiobenzo-hydrazide.

The part structure —X—C=N— in **1** was established by IR and ^{13}C-NMR spectroscopy. The regioselectivity of these reactions is analogous to that observed with ketones and thioketones[5].

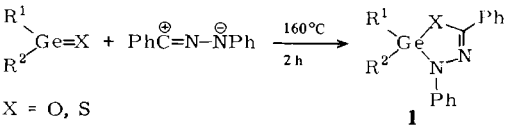

Table 1. 1,3,4,2-Oxa(or thia)diazagermolines **1**.

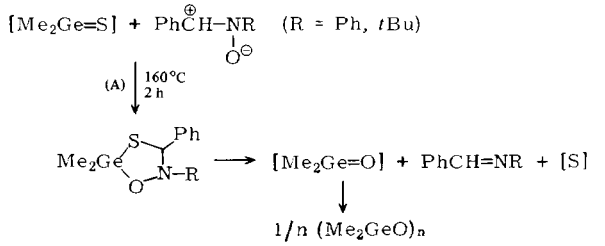
Dimethylgermathione reacts with the nitrone *N*-benzylidenephenylamine *N*-oxide at 160 °C in a Carius tube (Scheme 1, reaction A) to form an oxathiazagermolidine, which was characterized by ^{1}H-NMR spectroscopy (in C_6D_6, $\delta = 3.90$ (CH)). In the reaction with *N*-benzylidene-*tert*-butylamine *N*-oxide only thermolysis products of the cycloadduct were detected.



Scheme 1. (Selection)

An attempt to synthesize the unstable cycloadduct (R = *t*Bu) from $Me_2Ge{=}S$ and 2-*tert*-butyl-3-phenyloxaziridine (60 °C, 9 h, Et_3N) led only to the products of thermal decomposition (type 5→2+2+1). Similarly, the stable cycloadducts **1** decompose slowly above 220 °C.

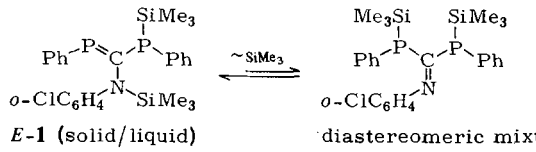
Configurational Identity (Solid, Liquid), (N→P)-Silatropism and Rotamer Detection in the Methylenephosphane $PhP{=}C(NArylSiMe_3)(PPhSiMe_3)$**

By *Rolf Appel**, *Hans Förster*, *Benno Laubach*, *Fritz Knoll*, and *Ingo Ruppert*

The transformation of *E*/*Z* stereoisomers at a specific CC-double bond during dissolution has recently been described[1]. We have now found that the spatial arrangement of the substituents at the PC double bond of methylenephosphane **1**[2] is not only stable in the crystalline state but also in solution.

According to an X-ray structure analysis the yellow crystalline *C*-amino-*C*-phosphinomethylenephosphane **1**, which can be prepared from disilylphosphane and isocyanide dichloride, has *E*-configuration[2].



E-**1** (solid/liquid) diastereomeric mixture **2**

The $^{31}P\{^1H\}$-NMR spectra recorded at room temperature in solution (AB-type, Fig. 1a–d) and on the solid substance show equal shift values for the phosphorus atoms. An *E*→*Z* isomerization during the process of dissolution can thus be ruled out.

The solution spectrum, however, contains an additional peak (Fig. 1b, c) in the shift region of the triple-bonded P-atom, which on slow cooling yields two AB patterns of different intensity (Fig. 1d–f). According to position and

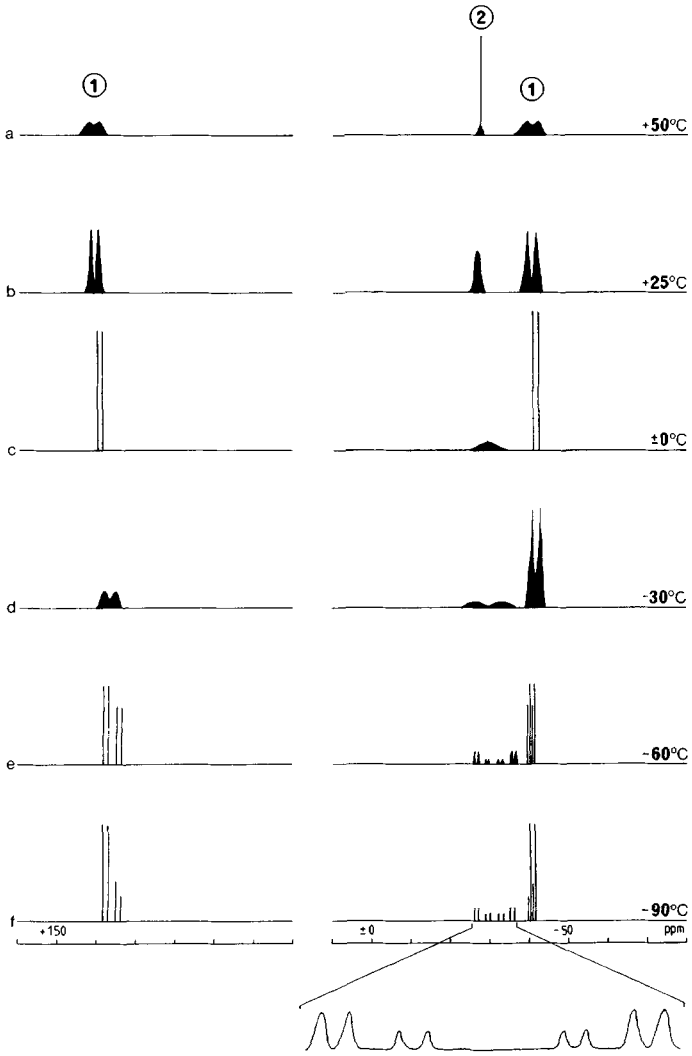


Fig. 1. $^{31}P\{^1H\}$-NMR spectra of an equilibrium mixture of **1** and **2** at various temperatures. a–f, see text.

[**] Lower Coordination Phosphorus Compounds, Part 13. This work was supported by the Deutsche Forschungsgemeinschaft and by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.

spectral habit they can be assigned to a 3 : 1 mixture (integration) of diastereomeric forms of the diphosphaguanidine **2** with fixed CN double bond. Formation and equilibrium behavior of the two silatautomers **1** ⇌ **2** were substantiated by the following findings.

When solid **1**, cooled to −90 °C, is dissolved in CD_2Cl_2 and measured without interruption of the cooling track at −90 °C, its isomer **2** is detectable in the $^{31}P\{^1H\}$-NMR spectrum below 0 °C, *i.e.* still no silyl migration occurs up to this temperature. The signal of **2** appears at $\delta = -23$ only above this limiting temperature. The temperature-dependent sequence of spectra is reversible. Moreover, on comparison of Figure 1a with 1b and 1c, the reverse broadening of the signals of **1** and **2** indicates the presence of a dynamic equilibrium within the NMR time scale.

In the spectrum of the methylphosphane **1** below −30 °C, an increasing differentiation of the original AB multiplet (Fig. 1e, f) can be recorded which could be due to a previously unobserved, special conformational characteristic at the methylene carbon. By comparative investigations on authentic *E*/*Z* pairs of similarly structured phosphaalkenes[2] we might possibly establish that this signal doubling is not just caused by the *Z* isomer, but by rotamers—presumably at the CN bond[3].

The silatropism is reminiscent of the equilibrium behavior of siloxy-substituted derivatives of **1**[4]; both phenomena—silatropism and hindrance to rotation—are known for (silyl)-carboxamides[5].

Karplus Curve for $^3J(^{13}C,^1H)$ in Hydrocarbons**

By *Rafet Aydin, Jean-Pierre Loux*, and *Harald Günther**

Of the various NMR spin-spin coupling constants, particularly those between vicinal nuclei are of importance for conformational analysis, due to their torsional angle dependence postulated by *Karplus* and verified experimentally. Whereas the Karplus curve for $^3J(^1H,^1H)$[1] has been thoroughly investigated, this is not the case for $^3J(^{13}C,^1H)$[2]; specifically, until now hydrocarbons have not been studied. We therefore synthesized the deuterated norbornanes **1**–**4** and calculated the $^{13}C,^1H$ coupling constants from the measured $^{13}C,^2H$ coupling constants[3] using the well-known relationship

$$^nJ(^{13}C,^1H) = 6.5144\ ^nJ(^{13}C,^2H)$$

The $^3J(^{13}C,^1H)$ values of interest here are shown in Table 1 together with the CCCH torsion angles ϕ determined by

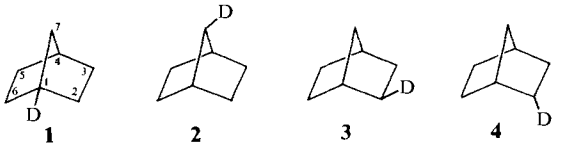

Table 1. $^3J(^{13}C,^1H)$ [Hz] in norbornane; pertinent CCCH torsion angles ϕ [°] in parentheses.

electron diffraction measurements[4]. The dependence of $^3J(^{13}C,^1H)$ values on ϕ can be described by the function

$$^3J(^{13}C,^1H) = 3.81 - 0.90\cos\phi + 3.83\cos 2\phi \qquad (a)$$

which is displayed graphically in Figure 1. Excellent agreement with the results of calculations on propane is found[5]. Hence, bearing in mind the known reservations[1], eq. (a) can be used for the conformational analysis of hydrocarbons and serves as a basis for the study of substituent effects on $^3J(^{13}C,^1H)$.

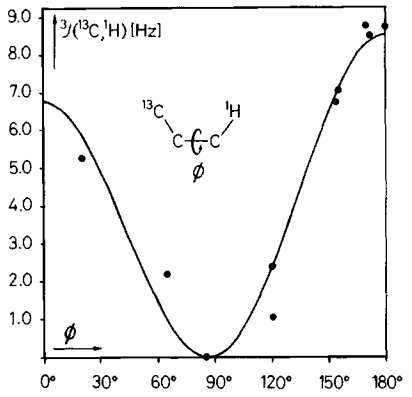

Fig. 1. Dependence of $^3J(^{13}C,^1H)$ in norbornane on the torsion angle; • experimental, — calculated from eq. (a).

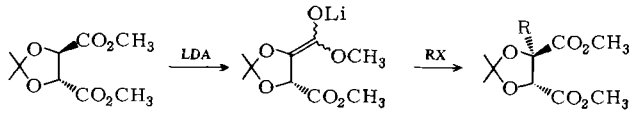
"Contra-Steric" Alkylation of the Enolates of Dioxolanecarboxylic Acid Esters

By *Wolfgang Ladner**

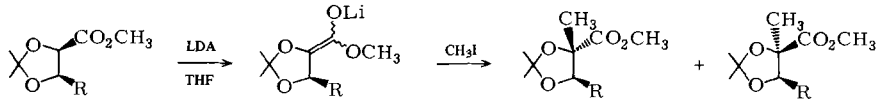
The deprotonation of the *trans*-substituted dioxolanes (tartrate acetonides) **1** to yield the enolates **2** has recently been described[1]. On reaction with electrophiles these enolates gave preferentially the isomers **3**. Hence, the substitution **1**→**3** corresponds stereochemically to a retention.

[*] W. Ladner
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)



1 2 3

In the context of another investigation we generated the enolates **5** from the *cis*-substituted dioxolanes **4**. Methylation of **5** led preferentially to the isomer **6**. Hence, the conversion **4**→**6** corresponds stereochemically to an inversion. Obviously the terms inversion or retention are not relevant here, rather the enolates **2** and **5** exhibit a tendency to undergo "contra-steric"[2] alkylation *cis* to the neighboring substituents on the dioxolane ring (CO_2CH_3 in **1**[1] and R in **5**, respectively).

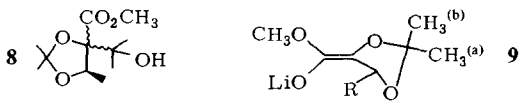


4 5 6 7

a R = CH_3–	66%	88 : 12	
b R = CH_3–CH_2–	83%	91 : 9	
c R = CH_2–$\underset{\diagdown O \diagup}{CH}$–	33%	>95 : <5	

The sterically homogeneous **4a** was obtained in 72% yield from methyl *trans*-2,3-epoxybutyrate[3] by reaction with $SnCl_4$ and acetone (molar ratio 1 : 0.2 : 1) in CCl_4 at −35 °C. After deprotonation of **4a** at −78 °C with lithium diisopropylamide (LDA) in tetrahydrofuran, methyl iodide was added (molar ratio 1 : 1.1 : 1). In the mixture of **6** and **7** obtained after warming to room temperature in all cases the diastereoisomer **6** with *cis*-orientated methyl groups (^{13}C-NMR at $\delta = 19$ ppm) predominated over the isomer **7** with *trans*-orientated methyl groups (^{13}C-NMR at $\delta = 22$–23 ppm). These structures were additionally confirmed by comparison with **7b**[4] and **7c** prepared by other routes. The stereochemical result of the alkylation should be independent of whether **4** or its *trans*-isomer is used as starting material. Thus, as expected, a sample of **4b** (ethyl ester), which contained 20% of the *trans*-isomer, afforded 90% of **6** and **7** in the same ratio 91 : 9, obtained for stereochemically homogeneous **4b** (ethyl ester).

Enolate **5a** could be hydroxyalkylated by acetone to yield **8** in 85% yield. In this case only one isomer, whose relative configuration has still to be determined, was obtained with a diastereoselectivity of >98%.



8 9

The reason for the "contra-steric" course of the alkylation is not certain. It is likely that the enolate **5** has the conformation **9** in which the methyl group (a) and the R-residues are maximally separated from each other so that the direction of alkylation is determined by the methyl group (b).

Complexes of Crown Ethers with Uronium Salts: Preparation and Crystal Structure of [18]Crown-6 Uronium Nitrate (1/1) and Benzo[27]crown-9 Uronium Perchlorate (1/1)

By *Jos W. H. M. Uiterwijk**, *Sybolt Harkema*, *David N. Reinhoudt*, *Kari Daasvatn*, *Herman J. den Hertog Jr.*, and *Jan Geevers*

As part of our work aimed at the synthesis of molecular receptor molecules for urea we have recently described the first crystalline complex of urea with a macrocyclic polyether, *viz.* [18]crown-6 **1**[1,2].

In order to check whether the stability of urea complexes can be enhanced by protonation (at the oxygen atom[5]), we synthesized complexes of **1** with uronium nitrate (1 : 1), uronium picrate (1 : 1) and uronium *p*-toluenesulfonate (1 : 2) and a complex of benzo[27]crown-9 **2** with uronium perchlorate (1 : 1). The two title compounds were investigated by X-ray structure analysis at 168 and 269 K, respectively.

In neither of the two cases is the site of protonation affected by complexation. A very interesting feature of the structure of **1**·uronium nitrate (1/1) is the rather unusual conformation of the polyether ring ($ag^+a\ ag^-a\ ag^+g^+\ ag^+a\ ag^-a\ ag^+g^+$) which differs both from the centrosymmetric conformation of the macro-ring in the **1**·urea (1/5) complex ($ag^+a\ ag^+a\ g^+g^+a$) and from the centrosymmetric conformation of the crown in the **1**·*S-tert*-butylthiouronium perchlorate (1/2) complex ($ag^+a\ ag^-a\ ag^+a$)[11].

In the **1**·uronium nitrate (1/1) complex there are three N—H···O hydrogen bonds, namely between the uronium cation and the O(1), O(2), and O(4) oxygen atoms of the macro-ring. The guest molecule lies outside of the plane of the crown ether (Figure 1).

In the **2**·uronium perchlorate (1/1) complex the binding between host and guest is completely different from the situation described above. The cation is totally encapsulated within the crown ether with its molecular framework almost coincident with the best plane defined by the crown oxygens. The polyether ring has the conformation *asa* $ag^-g^-\ ag^+a\ ag^-a\ ag^-g^-\ ag^+a\ ag^-a\ ag^-g^-\ g^-g^-a$, where "*s*" (synperiplanar) denotes the torsion angle of almost 0°, imposed by the benzo-substituent.

All five uronium hydrogen atoms are used for hydrogen bonding to crown oxygens (Fig. 2). Although the conformation of the polyether ring is rather different from the conformation in the isoelectronic **2**·guanidinium perchlorate (1/1) complex[16] (*asa* $ag^+a\ g^-g^-g^-\ ag^-a\ ag^-g^-$

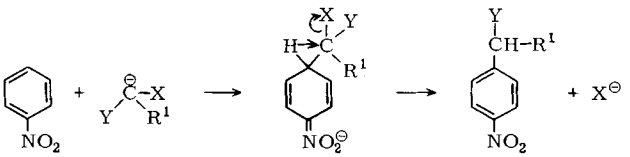
Nucleophilic Substitution of Hydrogen in Nitroarenes by Phosphorus-Stabilized Carbanions having "Vicarious" Leaving Groups

By *Mieczysław Mąkosza, Jerzy Goliński*

We have previously described the vicarious nucleophilic substitution of hydrogen in nitroarenes by carbanions containing leaving groups at the carbanionic center[1]. This principle is shown in Scheme 1.



Scheme 1. Y = stabilizing group, X = leaving group [1].

We have now found that stabilization by phosphorus-containing groups offers particular advantages. As model compounds dimethyl α-chlorobenzylphosphonate **1** and chloromethyl(diphenyl)phosphane oxide **2** were selected.

1 reacts with nitrobenzene in dimethylformamide in presence of sodium hydride to give dimethyl 4-nitrobenzhydrylphosphonate **4a** in 39% yield. In contrast, a 78% yield was obtained when the reaction was carried out in liquid ammonia in presence of powdered sodium hydroxide. For the reactions with **2**, potassium hydroxide in dimethyl sulfoxide (DMSO) was the most efficient system.

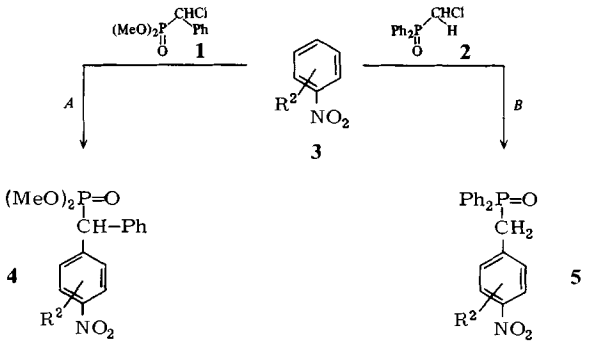


Table 1 shows examples. From these results it should be noted that the carbanions generated from **1** and **2** react with *o*- and *p*-chloronitrobenzenes *exclusively at unsubstituted positions*. No appreciable replacement of chlorine is observed, although it is strongly activated toward nucleophilic substitution by the nitro group. This is strong evi-

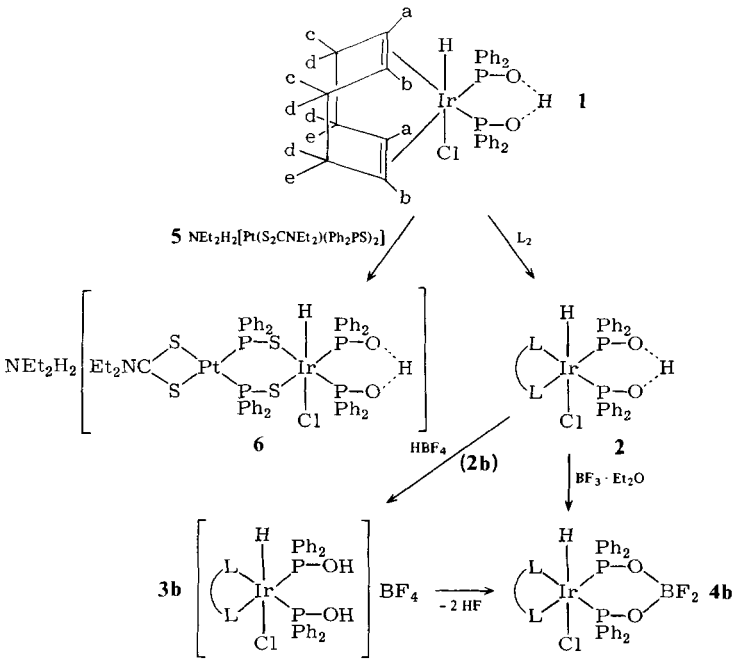
Synthesis of Novel Iridium and Rhodium Complexes Containing Diphenylphosphinito and Dimethylphosphito Ligands**

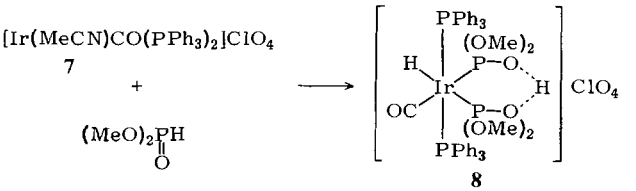
By *J. Andrew S. Duncan, David Hedden, D. Max Roundhill, T. Anthony Stephenson**, and *Malcolm D. Walkinshaw*

In recent years, a number of transition metal compounds containing the hydrogen-bonded $R_2POHOPR_2$ ligands (R = Ph, OMe, OEt) have been synthesized and some reactions of these compounds reported[1]. To date, however, the majority of these studies have been confined to complexes of palladium(II) and platinum(II). In this preliminary communication we now wish to report our attempts to synthesize related complexes of rhodium and iridium[2].

Thus, treatment of $[\{IrCl(cod)\}_2]$ (cod = cycloocta-1,5-diene) with an excess of Ph_2PCl in aqueous methanol (1:7; v/v) at ambient temperature [*i.e.* $Ph_2P(O)H + HCl$ mixture] gave as the major product, the neutral, monomeric iridium(III) complex **1**. In solution, **1** readily loses diene and therefore on treatment with bidentate ligands L_2 forms compounds **2a—c** in high yields, which show no tendency to undergo further ligand dissociation. Reaction of **2b** with HBF_4 gave the cationic complex **3b**, which readily rearranged to **4b** when redissolved in $CHCl_3$. **4b** can also be synthesized by reaction of **2b** with $BF_3 \cdot Et_2O$. Preliminary studies indicate that reaction of **1** with the platinum species **5** leads to formation of the unusual mixed metal complex **6**[4]. The synthesis of a range of such mixed metal complexes is now in progress.



a, $L_2 = Ph_2P(CH_2)_2PPh_2$; **b**, $L_2 = Ph_2As(CH_2)_2AsPh_2$; **c**, $L_2 = PhS(CH_2)_2SPh$



Similarly, treatment of the iridium complex **7** with $(MeO)_2P(O)H$ gave an almost quantitative yield of the closely related cationic complex **8**, whose configuration was determined ^{1}H-NMR spectroscopically.

In contrast, related (diene)-rhodium(I) compounds react with various $R_2P(O)H$ ligands, undergoing facile diene displacement to generate quite different species. Furthermore, the nature of the product from the reaction of $[\{RhCl(cod)\}_2]$ with an excess of Ph_2PCl in aqueous methanol depended critically on the water to methanol ratio. At low water : methanol ratios (1 : 15, v/v) the only products formed were the well-known cations $[Rh(Ph_2POMe)_4]^+$

and $[RhH(Cl)(Ph_2POMe)_4]^+$, which were isolated as PF_6 salts[5]. However, at higher water:methanol ratios (1:7, v/v), short reaction times at ambient temperature, followed by addition of various large cations, gave high yields of the novel dinuclear, triple chloride bridged *anionic* complexes $M[Rh_2Cl_5([Ph_2PO]_2H)_2]$ ($M = AsPh_4$, $Ph_3(PhCH_2P)$, Cs). In the $AsPh_4$ salt (Fig. 1) the O...O distances of 2.4 Å are consistent with those found in other symmetrically hydrogen-bonded $R_2POHOPR_2$ complexes[1].

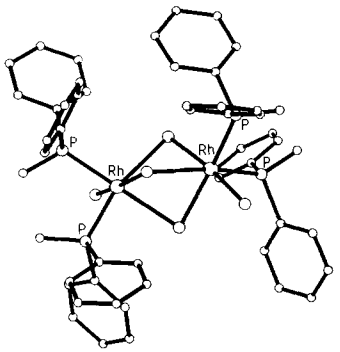

Fig. 1. Structure of the anion of $AsPh_4[Rh_2Cl_5([Ph_2PO]_2H)_2]$ in the crystal. $P\bar{1}$; $a = 12.157(4)$, $b = 16.191(5)$, $c = 20.523(8)$ Å, $\alpha = 96.02(3)$, $\beta = 99.88(2)$, $\gamma = 96.10(2)°$, $U = 3926$ Å^3, $Z = 2$. The structure has been refined to $R = 0.084$ for 4400 independent reflections ($Mo_{K\alpha}$) with $I > 2.5\sigma(I)$. Rh atoms with anisotropic temperature factors, idealized phenyl rings. Disordered CH_2Cl_2 solvent molecules not yet fully refined.

Finally, reaction of various $[Rh(diene)L_2]ClO_4$ salts with hydrogen, followed by treatment with $(MeO)_2P(O)H$ (molar ratio 1:2) led to the isolation of various air-sensitive cationic rhodium(I) complexes $[RhL_2(P(OMe)_2OH)_2]ClO_4$ ($L_2 = 2\,PPh_3$, $2\,PMePh_2$, $Ph_2P(CH_2)_2PPh_2$) in which the *tricoordinate* form of the dimethylphosphite ligand has been stabilized.

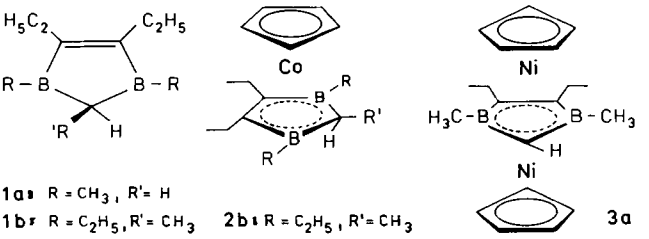
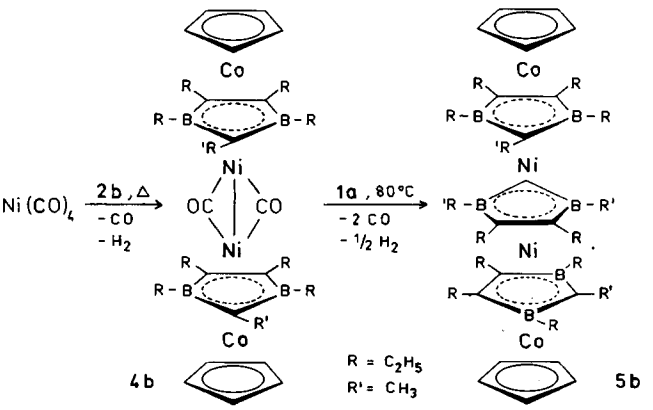
Synthesis of a Penta-decker Sandwich Complex**

By *Mark W. Whiteley, Hans Pritzkow, Ulrich Zenneck,* and *Walter Siebert**

Complexes **2**[1] with a *penta*coordinated carbon atom and an axial hydrogen atom are formed from Δ^4-1,3-diborolenes **1** and η^5-cyclopentadienylbis(ethene)cobalt. This novel type of sandwich is suitable for the synthesis of polynuclear complexes[1,2] since the formal dianion $\mathbf{1}^{2-}$ in **2** reacts with carbonylmetal complexes *via* H-elimination, in a manner analogous to the isoelectronic cyclopentadiene. We report here the directed synthesis of the CO bridged tetranuclear complex **4b** and its reaction with **1a** to afford the penta-decker complex **5b**.



Heating **2b** and tetracarbonylnickel in toluene to 80 °C results in formation of red-violet diamagnetic **4b**[3]. [$\delta^1H(C_6D_6)$: 4.07 (s, 5), 2.2 (m, 2), 2.1 (m, 2), 1.78 (s, 3), 1.5 (m, 4), 1.4 (m, 6), 1.20 (t, 6); $\delta^{11}B$: 14.8; MS (FD): *m/z* 798 (M^+, 100% rel. int.); IR: $\nu_{CO} = 1852$ cm^{-1} (in petroleum ether); yield 88%; m.p. = 256–258 °C]. **4b** has 58 valence electrons (VE) and is thus the electronic and chemical analog of $[(C_5H_5)Ni(CO)]_2$, from which **4b** can formally be prepared by inserting two 12 VE fragments of 1,3-diborolenylcobalt into the C_5H_5—Ni bonds.



Just as **1a** reacts with $[(C_5H_5)Ni(CO)]_2$ to afford the 33 VE triple-decker **3a**[4], **1a** replaces the CO bridges in **4b** to form **5b**. This first example of a penta-decker sandwich complex has 57 VE and is paramagnetic [δ^1H (D_8-THF): 30.8, 14.6, 7.7, 6.6, 5.7, 3.8, 3.1, 2.4, −3.5, −4.6, −58.9, −60.6; MS (FD): *m/z* 889 (M^+, 100% rel. int.); yield 45%; m.p. = 182–185 °C].

The unsymmetrical 30 VE triple-decker sandwich complex $[(C_5H_5)Co(\mathbf{1b}\cdot)Ni(\mathbf{1a}\cdot)]$, in which **1a**· and **1b**· signify the ligands **1a** and **1b** after elimination of H, is formed as a side product [MS(FD): *m/z* 518 (M^+, 100% rel. Int.); yield 7%; m.p. = 89–91 °C].

The constitution of **5b** is based on analytical and spectroscopic data. The ^1H-NMR spectra of **5b** and $\mathbf{5b}^{\ominus}$ (generated by reducing **5b** with potassium in [D_8]-tetrahydrofuran) and of mixtures of both species behave completely analogously to those of the triple-decker complex pairs $\mathbf{3a}/\mathbf{3a}^{\ominus}$[4]; however, in **5b** the cyclopentadienyl ligands are barely influenced by the paramagnetism. The analogy be-

[**] Oligo-decker Complexes, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF-AG. Dr. *S. Berger* and Dr. *K. Steinbach*, Fachbereich Chemie der Universität Marburg, as well as Dr. *P. Kunzelmann* and *G. Rissmann*, Organisch-chemisches Institut der Universität Heidelberg are thanked for the NMR and mass spectra.

tween **3a** and **5b** is also valid for $[(C_5H_5)Ni(CO)]_2$ and **4b**.

The X-ray structural analysis [crystal data of **5b**: space group $P2_1/c$, $a = 18.411(3)$, $b = 14.411(2)$, $c = 18.860(2)$ Å, $\beta = 116.93(9)°$, $V = 4461.3$ Å^3, $Z = 4$; 4553 reflexions ($I \geq 2\sigma_I$), Syntex R3 ($Mo_{K\alpha}$ irradiation, θ-scan), $R = 0.052$ (without H atoms, anisotropic temperature factors)] confirms the penta-decker structure. Two neighboring 1,3-diborolenyl ligands are, as in analogous tetra-deckers[2], mutually *trans*-orientated, whereas the third ligand is rotated by approximately 70°. The distances of the best ring-planes to the metal centers are 1.69, 1.69 [(C_5H_5)—Co], 1.61, 1.63 [(C_2B_2C)—Co], 1.73, 1.73, 1.75, 1.73 [(C_2B_2C)—Ni]; Ni···Ni 3.48 Å.

BOOK REVIEWS

The Inorganic Chemistry of Biological Processes. By *M. N. Hughes*. John Wiley & Sons, Chichester 1981. 2nd edition, ix, 338 pp., paperback, £ 9.90.

Although this monograph, now appearing in its second edition, was first published in 1972, in spite of the wealth of new material its size has increased by only 10% as a result of judicious pruning. The paperback edition is thus still within the reach of advanced students.

After a short and useful physiological-chemical introduction (Chapter 1) and a discussion of the properties of transition-metal ions (Chapter 2), the following main themes are treated in eleven chapters: Chapter 3—physicochemical characterization of metalloproteins and other metal-containing biologically active molecules; Chapter 4—metalloenzymes in hydrolysis and group-transfer reactions; Chapter 5—transition metals in biological redox reactions; Chapter 6—the fixation of nitrogen and the nitrogen cycle in nature; Chapter 7—oxygen transport; Chapter 8—transport and storage of iron; Chapter 9—alkali metals and alkaline earth metals in physiological-chemical processes; Chapter 10—metal ions and chelating agents in medicine; and Chapter 11—nonmetals as trace elements in the animal and plant world. More than 700 literature references, some as late as 1980, provide an up to date extension of the text.

The breadth of the material deserves a somewhat more detailed list of contents and a larger index. Thus, under "nucleic acids" one is referred to DNA and RNA, but these are not listed. In the text, the metal complexes of adenosine triphosphate and nucleic acids are treated somewhat too briefly (Chapters 1 and 9), though it must be admitted that this area of inorganic biochemistry is still very complicated. The other chapters—almost in the nature of review articles—give good introductions to the above-mentioned special fields. There are occasional false notes in the interpretation of special results, but they are not very important (p. 147: cytochromes are not hematins; p. 149: an increase in the length of the Fe—S bond in the oxidation of cytochrome c is by no means expected; p. 233: indeed, simple hemes with coordination number 5 may be prepared).

In a later (desirable!) new edition there should be illustrations of whole macromolecules that have meanwhile become known through X-ray structure analysis (*e.g.* hemoglobin, cytochrome c, carboxypeptidase, and yeast-phenylalanine transfer-ribonucleic acid) and their discussion from the point of view of inorganic chemistry, since only an attempt at a complete overview of this kind can broaden the understanding of the problems of inorganic biochemistry. Some details of the coordination chemistry and organometallic chemistry in Chapters 2 and 6 could be left out to make room.

The book, otherwise written with great sensitivity, is highly recommended to advanced students. Every chemical library should have a copy.

The Resist Technique— A Chemical Contribution to Electronics

By Hartmut Steppan, Gerhard Buhr, and Hansjörg Vollmann*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Besides its technical meaning, the word "electronics" signifies another industrial revolution. The driving force behind this development is the very rapid progress in the field of integrated semiconductor circuits. An ever-increasing number of structures of ever-decreasing size must be accommodated on the same surface of the semiconductor crystal. This trend towards miniaturization embraces not only the integrated circuit but also its mounting panel, the printed circuit board; integrated circuits with 65536 storage spaces, *i.e.* more than 100000 individual functions, on a semiconductor die of less than 1 cm^2 are already standard today in industry. This micro-world, the potential of which can hardly be fully appreciated even today, has a direct appeal to all those of scientific inclination. However, the role of chemistry in the creation of this world becomes clear only on closer examination of the manufacturing processes: no mechanical tool is fine enough and no machine is sufficiently precise and rapid to work out complicated structures in the micron range with the required perfection. Chemistry first made possible the mass production of electronic components and consequently their widespread use today, and it is chemistry which will also play a decisive role in the future. Whether in the field of photoresists for the production of printed circuit boards with conductor widths of less than 100 μm, or in overcoming the 1 μm barrier in the manufacture of semiconductors using electron beam- and X-ray-resists, photochemistry, radiation chemistry, and polymer chemistry will have to develop new manufacturing processes and provide industrially utilizable materials.

1. Introduction

On April 14, 1981 a young man is sitting in his room in Frankfurt am Main; he presses a button, and in the next instant a runway in California appears in true-to-life colors on the screen of his television set. In the clear sky a small point appears, becomes larger, and in a few minutes the observer witnesses the space shuttle "Columbia" returning from its first space flight, gliding-in majestically and precisely, touching down on the runway, and taxiing to a standstill as though nothing in the world were more normal. The young man in Frankfurt sees the touch-down of the space shuttle at the very moment at which the landing actually takes place in California, although the runway is about nine thousand kilometers away from him. The information reaches him *via* a communications satellite "parked" in space, over the Atlantic.

What is astonishing here is the detailed functioning of a technology which today is termed electronics in the widest sense. For many of us today, electronics is a magic word which is regarded both as a promise and as a threat.

We come into contact with applied electronics to an increasing extent in many areas of life, for example in toys, in watches, in the automobile, in calculators, in computers, in the area of television and radio, or in the heart pacemaker. Thus, not only communications technology, but also control and regulation technology are predominantly affected.

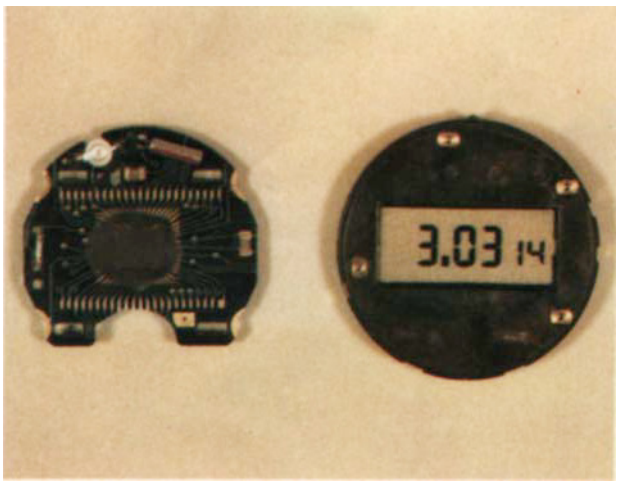

Fig. 1. View of the interior of a digital quartz watch. Left: Integrated circuit (chip coated with plastic) and other components mounted on a printed circuit board which also carries the contacts for the display. Right: Digital liquid crystal display (LCD).

Examination of the interior of a quartz watch (Fig. 1) shows the few, but important, components of this electronic device.

The actual core, the integrated circuit, is a small silicon platelet (chip), into whose surface of *ca.* 5×5 mm a large number of transistors, diodes, resistors, capacitors and other electronic functions are incorporated.

The integrated circuit also carries an extensive network of conductors, which connect the individual elements on the chip, and end in small contact points. Thin metal wires connect these points in turn with contacts on the small printed circuit board, which forms the contact with the remaining components.

The printed circuit board thus has a double function: on the one hand it is the base *i.e.* the mounting panel for the components, and on the other it contains the circuits between these components.

In this article, a closer examination will be made only of the so-called phototechniques and the chemistry on which they are based; techniques which first made possible the modern processes for the manufacture of integrated circuits and of printed circuit boards.

The discovery of the transistor effect in 1947 by *Bardeen, Barttain,* and *Shockley* was the prerequisite of our present microelectronics. In the meantime, the transistor has practically completely replaced the valve.

The second milestone in the technical development of electronic components was the introduction of the monolithic integrated circuit ten years later by *Kilby* and *Noyce*; the associated manufacturing process, planar technology, introduced the age of microelectronics.

2. Manufacturing Techniques

2.1. General

Chemistry plays a key role both in the mass production of semiconductors containing integrated components and in the production of printed circuit boards.

In this article resist is to be understood as a material which, when applied to a substrate surface, masks that part of the surface it covers *i.e.* protects it from attack by any agents, for example etching media, chemical or electrochemical metallization baths. The *resist* must therefore be *resistant* to the agents in question.

Using the resist technique, the whole component, a part of whose surface is protected by a resist layer, may be subjected to the undifferentiated action of the processing media, a technique which is indispensable for mass production.

Resist techniques have been known for some time in other areas, *e.g.* the production of letterpress and gravure printing forms by chemigraphic etching processes may be mentioned.

2.2. Masking Techniques

Resist masks having relatively coarse detailed structures (in general > 0.3 mm) can be printed onto the surface to be masked, either using the screen-printing process (Fig. 2) or magnetographically (Fig. 3).

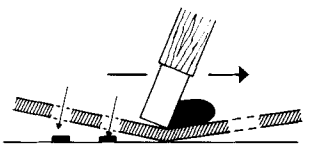

Fig. 2. Application of a resist mask by screen printing. The resists used are viscous solutions or pastes which exhibit the required resistance after printing (and drying, if they contain solvent), or achieve this resistance by subsequent crosslinking [1].

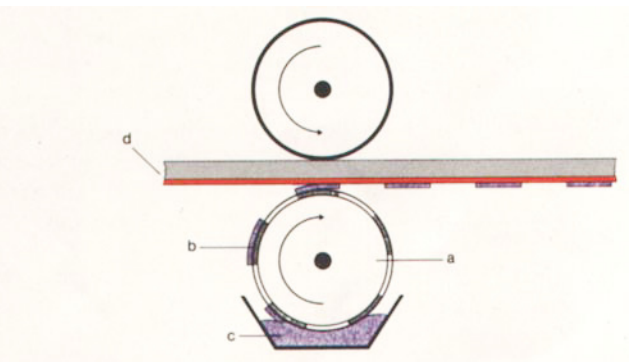

Fig. 3. Application of a resist mask by magnetographic printing [2]. The printing drum (a) has a magnetic printing form (b)clamped around it and this selectively takes up, in its magnetic areas, a pulverized magnetic resist material (c), and transfers this to the substrate (d). The powder image is then coalesced by thermal shock to give a pore-free resist layer.

Resist masks having finer structural elements are produced in most cases by the so-called photoprinting process, using photoresists (Fig. 4).

By analogy to screen printing, the term photoprinting is commonly used to describe the masking of surfaces by photoresists, although this is not a printing process.

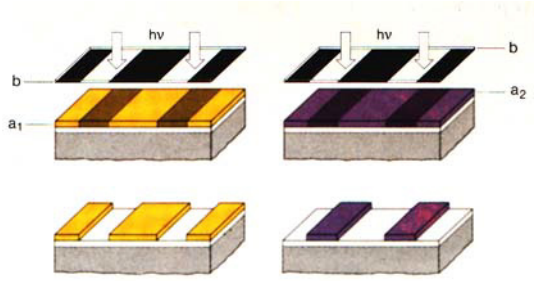

Fig. 4. Application of a resist mask by photoprinting. The total substrate surface is first completely coated with a positive (a_1) or negative photoresist (a_2). A radiation mask (b) carrying an image of the structures to be transferred in the form of areas which are permeable or impermeable to radiation, is superimposed on the photoresist layers. The irradiation changes the solubility of the resist layer under the transparent zones of the mask. After the mask has been removed, the substrate is treated with a liquid, the developer, which selectively removes the more soluble areas of the resist layer baring the substrate surface there and making it accessible to further selective treatment. The unprotected substrate areas correspond to the transparent regions of the irradiation mask of positive photoresists (a_1), and to the masked structures that are impermeable to radiation for negative photoresists (a_2).

Photoresists[3,4], in general, are understood as radiation-sensitive, in particular, photosensitive materials which undergo a change in their solubility when irradiated. According to whether the solubility is increased or decreased when irradiated, the material is termed a "positive" or "negative" photoresist, respectively. As described in more detail in Section 3, photochemical or radiochemical reactions are exploited to create a decrease or an increase in the molecular weight (polymerization or crosslinking with formation of a three-dimensional network), or cause a change in the polarity or the molecular interactions of the resist constituents.

The photoresist layer is principally applied by two processes: Either by applying a solution of the radiation-sensitive material to the surface, followed by a drying step in which the solvent is evaporated—this process is used particularly for applying thin layers—or so-called dry film resists[3g,h,5,6] are used. A dry film resist consists of a support film and a thermoplastic photosensitive layer, which in turn is covered by a protective film.

Dry film resists are commercially available as rolls. For coating, the protective film of the resist assembly is peeled off and the laminate comprising an active layer and a temporary support film is applied, under the action of heat and pressure, to the surface to be coated. Simultaneous lamination on both sides is also a technique much used today. The active layer of dry film resists is relatively thick, in general between 25 and 50 μm, but can also be up to 100 μm. The thick dry film resist layers open up a number of interesting possibilities which will be considered in more detail under the individual manufacturing processes.

2.3. Manufacture of Integrated Circuits

Today, very highly integrated circuits already contain up to 100000 or more individual components, such as transistors, diodes, resistors, capacitors, *etc.* on a semiconductor die of less than 1 cm^2 area, the chip: it essentially consists of monocrystalline silicon, the most frequently used semiconductor material.

Starting from silicon disks, the so-called wafers—those used industrially have a diameter of up to 12.5 cm—hundreds of integrated circuits are produced simultaneously in a multistage process. Depending on the process and on the type of circuit, between five and, in some cases, more than ten different resist masking steps must be used. The wafers are cut out of single crystals of silicon[7].

2.3.1. Monocrystalline Silicon

Impure silicon is produced from sand by reduction with charcoal in an electric arc furnace. The resulting material, whose principal impurity is iron, is converted into trichlorosilane, which is then purified by multistage distillation. The pure trichlorosilane decomposes on silicon rods at temperatures of $>1000\,^{\circ}C$ in the presence of hydrogen to give pure polycrystalline silicon. This is then melted in a quartz crucible, a seed crystal of the desired crystal orientation immersed in the melt, and the crystal rotated and slowly withdrawn upwards (temperature program). In this procedure, the silicon solidifies in monocrystalline form, in the predetermined orientation of the seed crystal. As a rule, before the single crystal is drawn the ultra-pure silicon is doped with impurity atoms which impart certain conducting characteristics to the single crystal (Fig. 5).

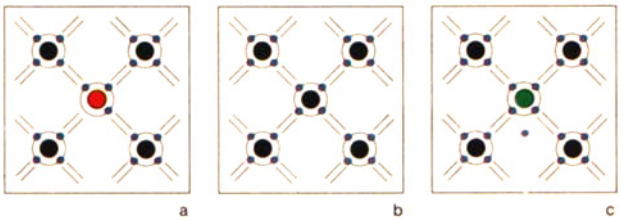

Fig. 5. Schematic details of the crystal lattice of a *p*-doped (a), undoped (b), and *n*-doped silicon crystal (c). The incorporation of atoms which, like boron, have one valence electron less than silicon produces holes, and these are filled by electrons of the neighboring atoms during the conduction process. A doped silicon crystal of this type is *p*-conducting (hole current). Incorporation of atoms with one valence electron more than silicon, for example phosphorus atoms makes the silicon *n*-conducting, electrons as charge carriers transporting the current.

The silicon single crystals are then divided into disks using special diamond saws; the disks are ground and finally polished to produce wafers.

2.3.2. The Planar Technique[3b,c,e,i,4b–d,8]

The manufacture of an integrated circuit containing a large number of individual elements begins with the design produced by the electronics engineer, generally with the aid of a computer (CAD = *C*omputer *A*ided *D*esign). Since every integrated circuit contains a large number of structures juxtaposed together, some inside others and some on top of others, and these are built up consecutively (Fig. 6), a particular radiation mask is required for each of the required photolithographic structuring steps (Fig. 7).

The production of the radiation masks, which consist of layers of silver halide emulsion on special glasses, will not be described here in more detail. However, it may be emphasized that photoresist techniques are employed for the manufacture of non-emulsion masks (chromium, chromium oxide, and iron oxide masks on glass or quartz, "hard-surface masks")[9] used in the manufacture of highly integrated circuits.

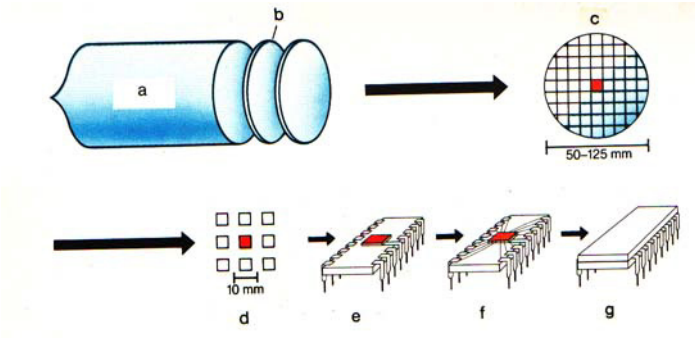

Fig. 6. Production of integrated circuits (schematic). a) Single crystal of silicon, b) wafer, c) integrated circuits (ICS) on the wafer, d) individual ICS or chips, e) chips mounted on supports, f) bonded, and g) encapsulated.

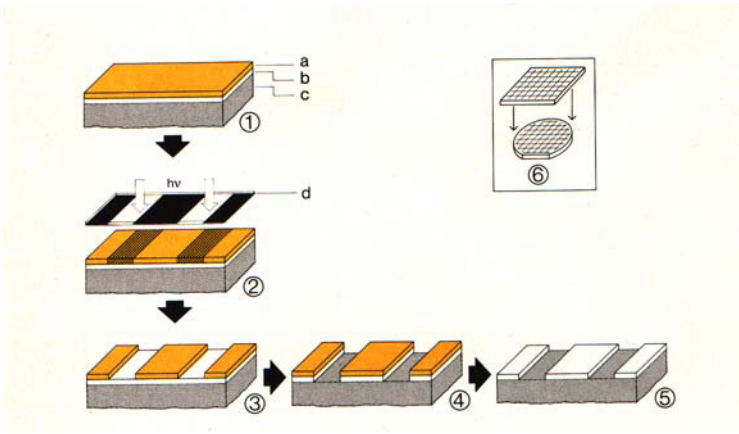

Fig. 7. Photolithography using a positive liquid resist. ① A substrate (c) is provided with an intermediate layer (b) and coated with a positive resist layer (a). ② Exposed under a photomask (d). ③ Areas of the resist layer which are exposed to light become detached in the subsequent development process. ④ In these non-protected zones, the intermediate layer is etched away. ⑤ After removing (stripping) the photoresist, the substrate is only partially covered by the intermediate layer; "windows" have been opened which made the substrate accessible to further treatment at these sites. The substrate can, for example, be the wafer and the intermediate layer silicon dioxide. However, metallic circuit paths and contacts are also produced from a metallic intermediate layer using this technique. ⑥ Represents the total photolithographic process from the application to the removal of the photoresist (see Fig. 8).

To transfer the information contained on the radiation mask, the latter is placed directly on the photoresist layer (contact exposure), or is held at a small precisely defined distance above the surface of the wafer (proximity exposure); alternatively, exposure is effected by projection using lenses or mirrors[10]. All these processes use radiation masks which contain the total information to be transferred to one manufactured plane, for all integrated circuits on the waver.

The most modern exposure method, step and repeat exposure, is used particularly for wafers of large surface area. Here, the information for each individual chip area, or for small groups of areas of this type are successively projected onto the wafer coated with the photoresist. This very precise but, compared to the area or scanning exposure processes, time-consuming method achieves an accuracy that represents the limits possible by photooptical methods.

The production of a simple transistor by the planar technique, using photolithographic processes, may be illustrated by the production of a *p*-MOSFET (*M*etal *O*xide *S*emiconductor *F*ield *E*ffect *T*ransistor, see ⑨, Fig. 8). A tiny section (25×25 μm) of an integrated circuit is shown in Figure 8.

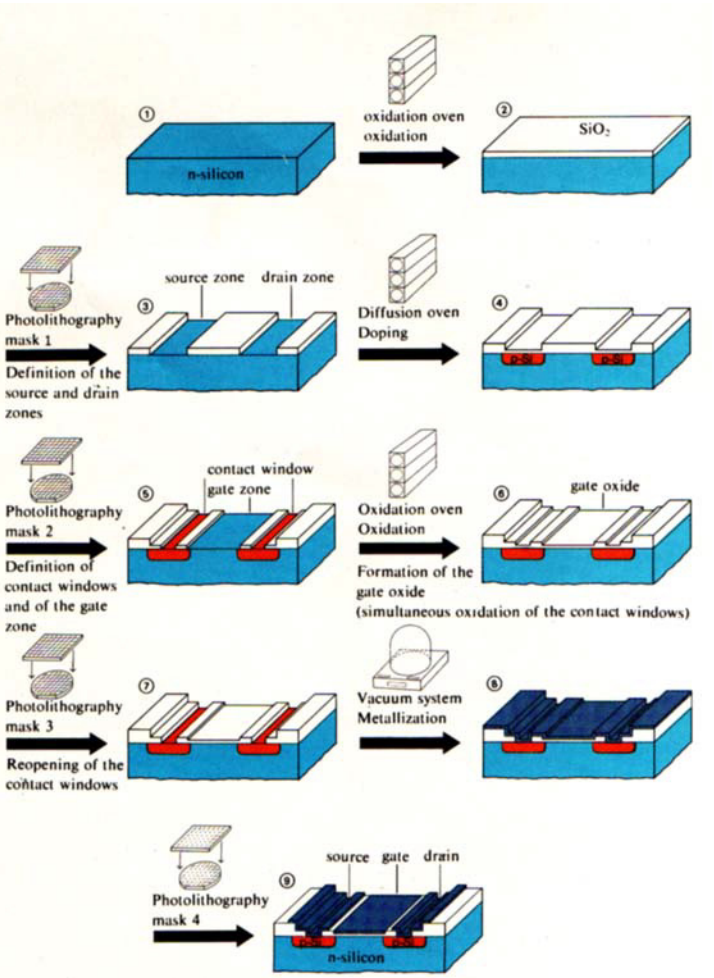

Fig. 8. Planar technology: Manufacturing scheme for an individual MOSFET in 9 stages. In ⑨, a negative voltage applied across the gate controls the current flow between source and drain. For further details see text.

The base material for the *p*-MOSFET is an *n*-doped wafer ①. A thin silicon dioxide layer ② is first grown on this wafer in an oxidation oven. This is followed by the photolithographic step 1 (see Fig. 7), which defines the source and drain zones ③ *i.e.* the silicon surface is exposed in these areas, and subsequent doping takes place only at these sites. All other areas are protected by the silicon dioxide mask manufactured by photolithography.

If atoms carrying only three valence electrons are allowed to diffuse into the source and drain zones, these zones become *p*-doped. The process is terminated by slight oxidation of the *p*-doped areas ④.

In the photolithographic step 2, the contact windows in source and drain are opened, and the gate zone is formed ⑤. Another oxidation step produces a thin, well-defined silicon dioxide layer, the so-called gate oxide ⑥. Since the contact windows in the source and drain areas have again been closed in this step, they must be opened again in photolithographic step 3 ⑦.

After metallization ⑧ in photolithographic step 4, the metal contacts for source, drain, and gate are established ⑨.

The entire integrated circuit is further coated with a passivating layer in whose edges windows are opened *via* a

further photolithographic step. This later enables the circuit to be contacted and connected with the appropriate pins used to plug it into the printed circuit board and for subsequent soldering steps (see Fig. 6).

To produce structures of this type on the μm scale, the highest requirements are made on the quality of the processing tools, on the consistency of the photoresist, and on the reproducibility of the total processing method[11].

2.3.3. Future Developments

The smallest windows which are currently opened by the photolithographic process in the mass production of integrated circuits are 2 to 5 μm in diameter (Fig. 9)[12]. The last decade has seen a progressive miniaturization of the structures down to these dimensions. By 1985, a further reduction in the diameter of the smallest reproduced structures to between 1 and 2 μm is expected[12]. Structures in the submicron scale have already been realized in the labo-

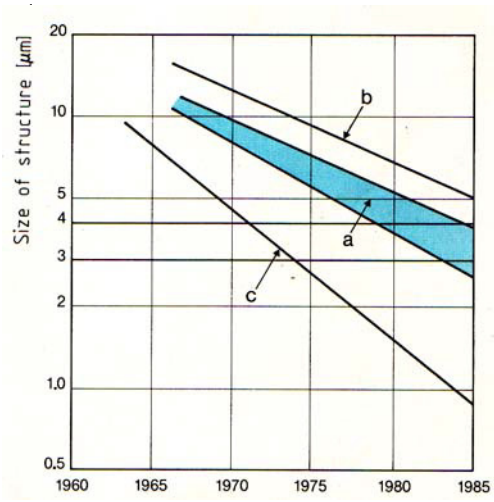

Fig. 9. Sizes of structures, development in the years 1960—1985. a) Range of structural dimensions which can be mass produced; b) sizes of structures in components with low resolution requirements, and c) limits achievable by demanding manufacturing techniques.

In order to make progress with photolithographic processes in these dimensions, a basic restriction has to be overcome. Currently, high pressure mercury lamps, which have an intense emission between 366 and 436 nm, are predominantly used in photolithography. Structures whose dimensions are smaller than these wavelengths cannot be reproduced by photooptical processes. To overcome this limit, light of shorter wavelength must be used for the imaging process *e.g.* short wavelength UV light, so called "deep UV" ($\lambda = 200-300$ nm)[13, 14b]. More far-reaching possibilities are offered by electron beams, ion beams, and X-rays[14a-c,e, 15-17].

At the present time, electron beam lithography is already widely used for the production of photomasks having very fine structures. A particular advantage of electron and ion beams is that they can be steered in a simple controlled manner. By this means using the beam it is possible to directly produce an image on a radiation-sensitive layer without a mask.

X-ray lithography has the advantage that it makes possible the irradiation of a large area in a simple manner, but is associated with the disadvantage of masks which are complicated to produce and radiation sources which today are still of low intensity. Which process will finally be used predominantly for the reproduction of small structures has not yet been decided.

The use of all these high energy radiation techniques requires resists that are sensitive and can be differentiated *i.e.* there must be sufficiently great differences in the properties of irradiated and non-irradiated areas, *e.g.* solubility. Of course, the chemistry of resists of this type differs completely from that of the conventional resists used for producing images with long wavelength UV light[4d,e, 8c, 13b].

Progressive miniaturization is accompanied by a demand for increasingly finer processing techniques: for example, the progressive replacement of wet etching processes, which give rise to pronounced under-etching because of their isotropic mode of action, by dry processes[14d, 18] (plasma and ion etching processes). These may be performed such that the etching is anisotropic, *i.e.* underetching of the resist layer is avoided.

Of course, resists may only be employed for dry etching processes of this type when removal of material from them is kept within reasonable limits of removal of material from the substrate.

A logical development of these considerations leads to the recently published photoresist techniques by means of which the development, the etching of the bared areas, and the removal of the resist mask are effected by a combination of thermal steps using plasma etching processes[19, 20].

The reduction in lateral size of the structures on a chip does not result in a proportionate decrease in the thicknesses of the structures. Thus, it is frequently necessary to differentiate resist layers whose height is substantially greater than the width of the structures to be resolved and which, moreover, are located on structured surfaces. Here, good results are obtained using so-called multilayer resist systems[14b, 20], which consist of at least two different resist layers but which can also be separated by an inert intermediate layer. A first non-radiation sensitive resist or a resist which in comparison to the second resist is sensitive to other radiation, serves as a leveling filling material for the vertical profile of the chip. The first resist layer is covered by an essentially planar second resist layer, which is very thin and thus permits high resolution; after structuring, this second layer represents an ideal mask in intimate contact with the layer below. The unprotected areas of this layer are solubilized by irradiation or are removed by an anisotropic plasma.

2.4. Production of Printed Circuit Boards

2.4.1. Subtractive and Additive Techniques

As already mentioned in the introduction, the printed circuit board has a double function: on the one hand it is the mounting base for all components and on the other it must carry the circuits between all components which are insulated from one another. A very large number of conductors have to be juxtaposed in close proximity to each other. In order to produce the conductor density required today in the more demanding printed circuit boards, it is

no longer possible to accommodate the circuitry on one level: Two or more levels are required, and these are insulated from one another and only have a conducting connection at certain points, *i.e.* "through-hole plating" is necessary (Fig. 10). Today multilayer boards contain up to about 30 circuit levels.

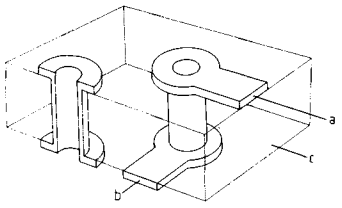

Fig. 10. Schematic view of "through-hole plating": A metal sleeve connects the circuit level (a) above the insulating board (c) and the circuit level (b) below the insulating board.

The production of a printed circuit board commences with its design, which today involves CAD methods, both for complicated printed circuit boards and integrated circuits. Using an electronically controlled photoplotter, the design in its original size is transferred onto a silver film, which can then serve as the photomask for the photoprinting process[21].

A large number of techniques for the production of printed circuit boards are known[22,23]. Three important ones are the *subtractive technique*[23], the *semi-additive technique*[23,25], and the *fully additive technique*[23,24].

In all these techniques, the production of printed circuit boards starts from a base material, in most cases an insulating sheet clad in the subtractive technique, for example, with a 35 μm thick copper film; with additive techniques the sheet carries a 20–30 μm thick insulating, adhesion-promoting layer, the so-called adhesive.

In the *substractive technique*, in the simplest case, a conductor is produced by applying a resist mask corresponding to the circuit onto the copper-laminated base material, followed by a process which etches away the unprotected copper. In the *fully additive technique*, for example, the adhesive layer is provided with a resist mask having apertures only in those areas of the adhesive surface on which the metallic, in most cases, copper circuit is to be formed. The circuit is selectively built up to the desired thickness exclusively by means of chemical deposition from copper baths[23].

In the *semi-additive technique* base material coated with adhesive is first provided with a thin conductive copper layer over the total surface of the adhesive in an electroless copper bath, and this copper layer is frequently reinforced electrochemically to a few μm. As in the case of the fully additive technique, a resist mask is now applied through whose apertures the conductors are then built up—in this case—electrochemically to the desired thickness *e.g.* 30–40 μm. After removal of the resist mask by treatment with an etching agent, the thin conductive copper layer is etched away in the so-called differential etching process; however, the height and width of the conductors are both reduced to roughly the same extent by the isotropically-acting etching medium. Typically, a complete series of process combinations and mixed processes characterize the steps in the various groups of procedures.

In many processes, non-conducting surfaces, *e.g.* adhesive layers and walls of drilled holes must also be coated with copper. This is achieved by roughening and subsequent activation processes using Pd or Cu catalysts for the electroless deposition of copper. The catalyst can also be incorporated into the adhesive and the insulating material of the base (core-catalyzed base material).

Table 1. Production of a through-hole plated printed circuit board having two circuit levels.

	Subtractive technique	Semi-additive technique	Fully additive technique
Base material	Insulating board laminated on both sides with copper (copper base)	Insulating board coated on both sides with adhesive	Insulating board core-catalyzed coated on both sides with adhesive containing catalyst
Drilling holes where through-hole plating is intended	+	+	+
Application of catalyst to the walls of the holes and, if appropriate, to the adhesive surface for electroless deposition of metal	+	+	–
Electroless deposition of copper (thin conductive copper layer), if appropriate, electrochemical reinforcement to a few μm of copper	+	+	–
Masking with a resist (photoprinting, screen printing, magnetography)	+	+	+
Activation of the catalyst in the adhesive and in the base material for electroless deposition of copper	–	–	+
Building-up the conductors by metal deposition			
electrochemical:			
copper	+	+	–
lead/tin	+	–	–
electroless:			
copper	–	–	+
Removal (stripping) of the resist mask	+	+	+
Copper etching	+	+	–
Solder reflow	+	–	–
Application of a solder mask	+	+	+
Hot air leveling	–	+	+

Table 1 gives a schematic comparison of the operations conventionally employed in the respective processes for the production of a through-hole plated printed circuit board having two circuit levels. For each process, one facet has been selected and described in a highly simplified manner. A large proportion of printed circuit boards are

produced today by resist techniques, predominantly by means of negative dry film resists. Printed circuit boards having circuit path diameters of between 250 and 150 μm and less and similar spacings—as predominantly used in the industrial electronics' sector (computers, telecommunications, *etc.*)—are almost without exception produced by this technique.

At first sight, comparison of the processes shown in Table 1 suggests that the fully additive technique is attractive, since copper is selectively deposited only where it is required. However, it has not yet been widely adopted in practice, because particular stages of the process are somewhat complex. To a lesser extent, the same also applies to the semi-additive technique. Today more than 90% of printed circuit boards are produced by subtractive techniques. Because of its great importance, a subtractive process is illustrated schematically once again for the very widely used metal resist technique (Fig. 11).

A special feature of this process is that the conductor regions, after the copper base has been masked with a resist, are built up electrochemically, firstly with copper and, on top of this, with a lead-tin layer that is stable to ammoniacal copper etching agents. After the resist mask has been stripped, the copper base is etched away and the lead-tin covering thus serves as an etch resist.

It is now customary, and, in the case of printed circuit boards having a high conductor density, also necessary to provide the printed circuit board with a solder mask which only leaves bare the lands at which the contacts of the components, *e.g.* integrated circuits, are soldered. The solder mask must therefore withstand a temperature of 260 °C for a few seconds. It remains a part of the printed circuit board. Solder masks, also, are now produced to an increasing extent by photoprinting process, *i.e.* a light-sensitive solder resist, *e.g.* a dry film resist, is applied to the whole surface, exposed imagewise, developed, and post-cured[26].

The subtractive process described in Figure 11 illustrates the advantages associated with the use of a rather thick dry film resist: on the one hand the drilled holes are covered over during lamination, and the resist does not penetrate these holes, from which it could only be removed with difficulty, and on the other, the regions in which the conductors are electrochemically built up are comparable to steep-walled ravines. As long as the electrochemical metal deposition takes place within the trough, spreading, and hence the danger of short-circuiting between conductors lying close together, is precluded.

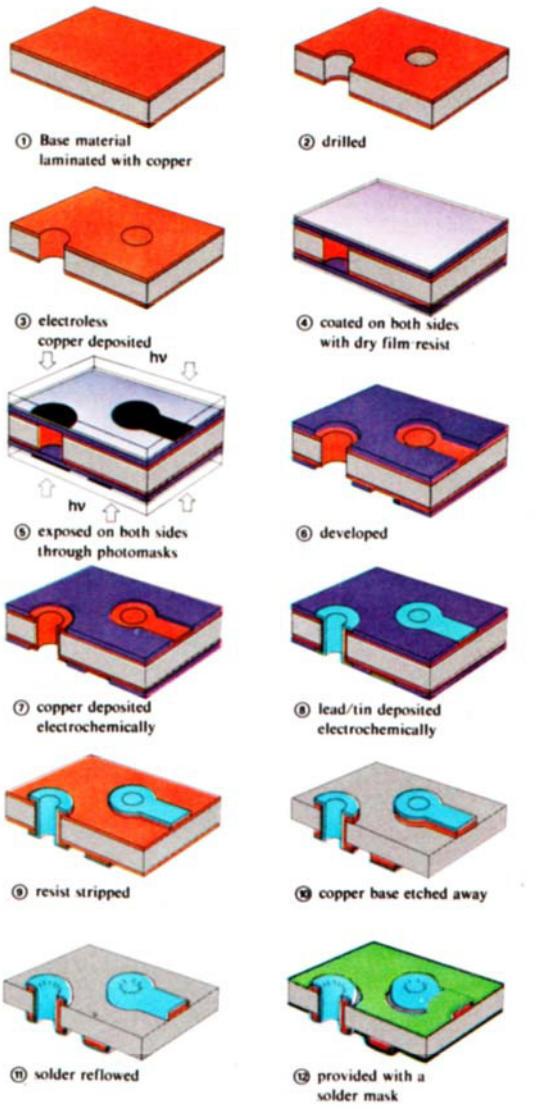

Fig. 11. Production of a through-hole plated printed circuit board by the metal resist technique, using a negative dry film resist. Through-hole plating is effected by drilling ②, at the desired points, through base material covered on both sides with 35 μm thick copper ①. The walls of the drilled holes are activated for electroless metal deposition, and a thin conductive copper layer ③ deposited using a chemical copper bath; this copper layer is frequently reinforced electrochemically by a few μm. After the component has been coated on both sides with a negative dry film resist ④, both sides are exposed through the appropriate photomasks, which are impermeable to light in the areas corresponding to the conductors and holes ⑤. After the support film has been peeled off and the photoresist developed ⑥ (dissolving away unexposed resist, the conductors in the planes and in the holes between the upper and lower sides are formed by electrochemical metal deposition: For example, with 30 μm copper ⑦ and on top of this *ca.* 10 μm lead-tin alloy ⑧. After removing (stripping) the resist mask ⑨, which is now no longer required, the bared copper base is first removed by means of an ammoniacal copper etching agent ⑩, and the solder on the conductive elements finally reflowed ⑪, *i.e.* after application of a so-called flux, the printed circuit board is heated to above the melting point of the lead-tin alloy, which then encases the conductors. In order to save solder and to prevent short circuiting between conductors in close proximity to each other, the printed circuit board is also provided with a solder mask ⑫, which covers the printed circuit board, apart from the lands.

2.4.2. Future Developments

The miniaturization trend in microelectronics has also extended to printed circuit boards. Thus, an ever-increasing number of contacts and conductors have to be accommodated on the same area. For the simple through-hole plated printed circuit board, this implies a transition from fine-circuit to ultrafine-circuit technique; conductor widths and spacings of 150 μm have already been produced, work on widths and intervals of 100 μm is in progress, and even smaller dimensions of down to 50 μm are under discussion.

This requires improved base materials and manufacturing techniques, and implies a still greater contribution from photoprinting in the future, together with increased use of the solder mask and possibly—owing to their better resolution—increased use of liquid resist techniques in the printed circuit board sector, which is presently dominated by negative to dry film resist methods.

Positive photoresists may also become important in future, since these not only have a particularly good resolution capacity but, in addition, produce resist coatings in the first photoprinting step which are still photosensitive and thus permit, in further photoprinting steps, other areas of the surface to be opened step by step for processing.

Increased use of additive techniques in the production of printed circuit boards may also be predicted, since the circuit path width and intervals decrease in size. Advantages in this respect are already provided by the semi-additive technique, because of the particularly low degree of lateral under-etching of the conductors when the conductive copper layer, which is only a few μm thick, is etched away. The fully additive technique is even more advantageous, since it involves no removal of material by etching steps, and thus no under-etching.

Currently, a number of processes are already being developed, which may one day substantially replace the classical printed circuit board. For example, one possible method uses a combination of photoprinting processes with electroless and electrochemical metal deposition to build up, step by step, three-dimensional circuit systems in which the originally photosensitive material remains a part of the finished element.

Similar to the procedure used in microlithography, in which the stored circuit design can be directly "inscribed" in a photoresist layer on the waver, it has also become possible in printed circuit board technology to directly transfer stored designs of circuit path levels from an electronic memory into a photoresist using a laser beam, *i.e.* without the intermediate stage of a film original[27]. Analogous techniques for the production of printing forms without the use of films have recently been reported[28].

3. Function and Chemistry of Photoresists

3.1. Introduction

In the majority of cases, photoresists are specifically designed multi-component systems which attain the required properties only when the individual components function cooperatively. Table 2 gives an idea of the variety of different requirements made of a photoresist.

Table 2. Important properties of industrial photoresists.

Solubility in suitable solvents
Long shelf-life in the absence of light
Good processing properties
Good adhesion to substrate
High sensitivity to differentiating radiation
Rapid development by non-toxic solutions
Exact transfer of the original, and reproducible, well-defined flanks upon development
Resist mask which is stable to etching, plating, and heat
Resist mask readily removable when no longer required

It is striking that no *single* resist or masking process is able to fulfill simultaneously all these requirements, which have to be further extended for special techniques; a large number of resists are required, each of which may be employed optimally in its own field. In this article it is only possible to select a number of systems in actual use, and describe their chemistry and mode of action. This review is supplemented by a few interesting novel chemical systems or application processes, whose practical relevance cannot yet be fully appreciated.

According to their change in solubility the systems are classified as "positive- or negative-working resists". This division into positive and negative systems is also limited to the photochemical systems which use light in the wavelength range from 300 to about 500 nm, and is, in addition, arbitrary in some cases, since systems are known which, depending on the procedure, can undergo "umpolung".

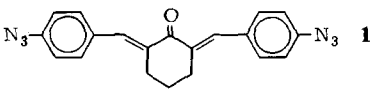
Resists that are sensitive to short wavelength UV light, electron beams, ion beams, and X-rays are summarized in Section 3.4, without regard to positive or negative function.

3.2. Negative-Working Photoresist Systems

The majority of photoresists used today are negative photoresists, *i.e.* systems whose solubility is reduced upon irradiation. A long road leads from the beginnings (*Niepce:* Syrian asphalt, 1826; *Talbot:* bichromate gelatins, 1852) to the photoresists which are now employed for the most demanding work. Only a few of the large number of systems which are theoretically suitable, and which have previously been reviewed many times[29], have proved useful industrially.

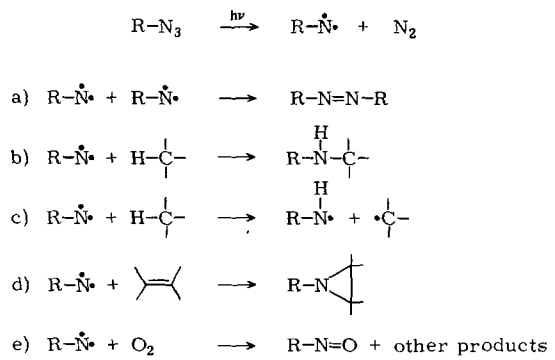
3.2.1. Photo-Crosslinking Systems

Diazide-Polydiene Systems: Today, negative photoresists for the production of integrated circuits use, almost without exception, partially cyclized polyisoprene as the crosslinkable component and a diazido compound as the photosensitive bifunctional crosslinking agent. A diazide of structure **1** is very commonly used: sulfazides are also used as crosslinking agents.



1

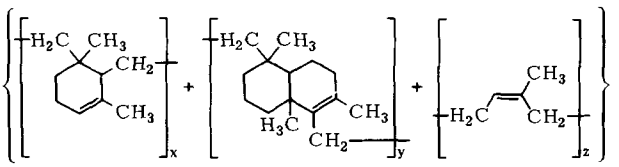
Upon irradiation, nitrogen cleaves off and the azide groups form very reactive nitrenes (R—Ṅ·) in both singlet and triplet states. The course of reaction given in Scheme 1 has been discussed[29i].



Scheme 1.

Singlet *and* triplet nitrenes undergo reactions a) and d); insertion reaction b) is a typical singlet reaction and reaction c) a typical triplet reaction.

The partially cyclized polyisoprene **2** is an ideal reactant for reactions b), c), and d) and is, in addition, a resist constituent which has a pronounced influence on the adhesion to substrates, and the mechanical and chemical properties, *i.e.* essential characteristics of the quality of the photoresist. Recently, photoresists based on partially cyclized polybutadiene and diazides have also become commercially available[30].



2

In reaction e), the ever-present atmospheric oxygen competes with the crosslinking reactions[31]. Photoresists of this type are therefore frequently irradiated under nitrogen.

Photodimerization Systems: Today a large number of photoresists use photodimerization for the crosslinking reaction. These include the now classical cinnamic acid derivatives and the structurally related chalcones. The particularly extensively investigated crosslinking reaction of cinnamic acid derivatives proceeds essentially as a photoinduced [2+2]-cycloaddition, and leads to formation of cyclobutanes[29c,32].

The systems are of industrial interest as photoresists when a polymer chain carries a large number of photodimerizable groups. For polyvinyl cinnamate, which is used industrially, these groups are produced by esterification of polyvinyl alcohol with cinnamoyl chloride. The direct free-radical polymerization of vinyl cinnamate is unsuccessful, owing to the tendency of this compound to undergo cyclopolymerization. Cationic polymerization of vinyloxyethyl cinnamate is possible[33]. Free-radical polymerization is also possible for compounds in which the cinnamoyl group and the reactive double bond cannot be directly linked[34]. Of particular industrial significance is the possibility of sensitizing cinnamic acid derivatives to relatively long wavelength light (up to *ca.* 500 nm) by triplet energy transfer[29c].

Recently, a type of photodimerizable epoxide resin **3**, which has been known for a relatively long time, has also been used as a photoresist[35,36].

The resins not only carry groupings capable of photocycloaddition, for example chalcone structures, but also epoxy groups, which permit suitably catalyzed thermal crosslinking. Systems of this type thus permit a resist mask to be initially produced in a photoprinting step, and then to be further crosslinked by heating. A typical application is the production of solder masks.

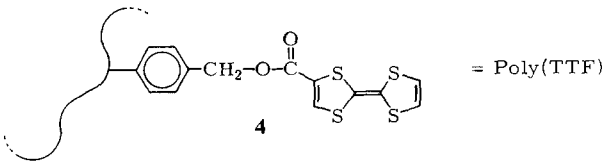
3.2.2. Systems Based on Photochemically Induced Polarity Changes

In the systems described in the previous section, preformed polymer chains crosslink to form a three-dimensional network upon irradiation.

Development is carried out using an organic solvent which not only dissolves the unexposed material but also swells the crosslinked areas to a greater or lesser extent.

The undesirable swelling can be substantially suppressed by converting the non-polar structural elements into, for example, ionic ones.

These systems are soluble in solvents of low polarity, such as ethers or ketones, before being irradiated but insoluble after irradiation[37]. An example is the combination of a polymer bearing tetrathiafulvalene groups **4** with tetrabromomethane **5**. The photochemical reaction is represented as a redox process leading to polar salt structures **6** in the polymers.



4

$$\mathbf{4} + CBr_4 \xrightarrow{h\nu} \text{Poly(TTF)}^+\ Br^- + \ldots$$

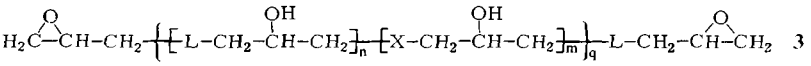
5 **6**

3.2.3. Photoinitiated Systems

The photoreactions mentioned in Sections 3.2.1 and 3.2.2 have quantum yields ≤ 1. To produce adequate crosslinking density, high intensity radiation and long irradiation times must be used. In order to use acceptable irradiation times, extremely thin resist layers (< 10 μm) are used in these systems.

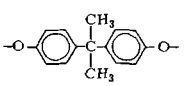
In photoinitiated processes a photoinitiator, which is present in low concentration, is electronically excited to form a reactive species, which initiates a chain reaction leading either to an increase in the size of the molecule or to crosslinking.

Photoinitiated Polymerization: Photoinitiated, polymerization processes, particularly those of the free radical type, which have been extensively investigated since the 1940's, are of industrial importance: The technical aspects and chemical principles of these processes have been treated in numerous reviews and monographs[29a,b,d-g,i,j,l,m].

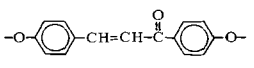


3

Scheme 2. X represents, *e.g.*



and L represents a photodimerizable moiety, *e.g.*



Systems of this type are used, in particular, as dry film resists[6,26]. Photopolymer materials used for this purpose contain a photoinitiator system, monomers, which are polymerizable by free radicals, and polymeric binders as the most important constituents. Furthermore, they may contain thermal polymerization inhibitors and modifying additives such as plasticizers, dyes, and adhesion promoters.

A very large number of photoinitiators or photoinitiator systems are known, which upon irradiation produce polymerization-initiating free radicals[38,39].

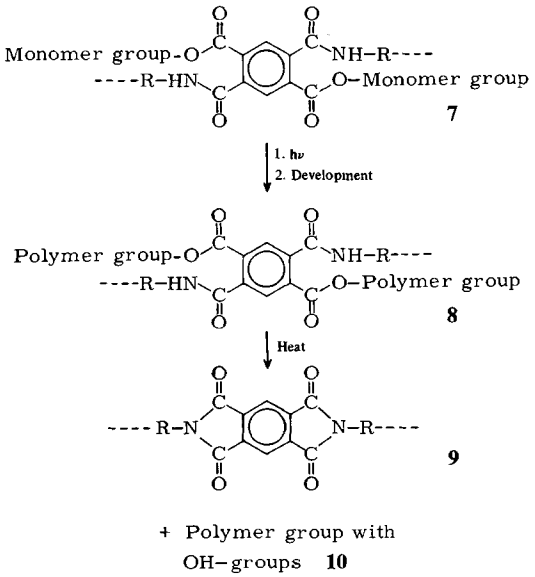
Radicals are formed by photofragmentation (benzoin ether), by transfer of electrons (benzophenone/aliphatic amine) or hydrogen atoms (anthraquinone/aliphatic ether). A few photoinitiator systems can be sensitized to light of relatively long wavelength[40,41].

As monomers predominantly esters or amides of acrylic and methacrylic acids with polyhydric alcohols or amines, respectively, are used, *i.e.* compounds which are frequently liquids.

In addition to monomers, the solid layers must also contain compatible polymeric binders: these serve, however, not only as thickeners, but rather contribute some of the properties which the photo-hardened material should finally possess. The choice of binder also determines which type of developer (organic solvent or aqueous alkali) is to be used to develop the unexposed regions of the layers.

Since the photoinitiated free-radical polymerization is inhibited by oxygen, it is necessary to exclude oxygen as far as possible.

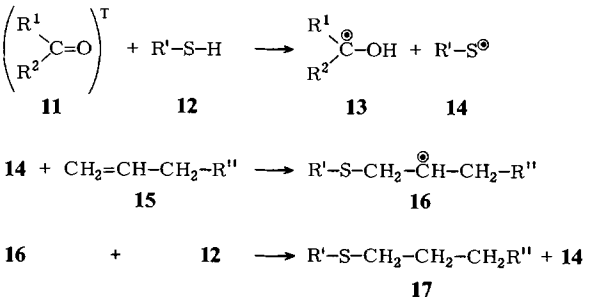
The systems based on photoinitiated polymerization also embrace the recently described principle for producing masks stable at high temperatures[42]. As shown in Scheme 3, the unexposed material contains soluble polyamide precursors **7** carrying polymerizable groups. During processing, the layers are first differentiated in a photo-



Scheme 3. R is, *e.g.* 
and the monomer group is, *e.g.* $-CH_2-CH_2-O-\overset{O}{\overset{\|}{C}}-\overset{CH_3}{\overset{|}{C}}=CH_2$

printing step, *i.e.* non-crosslinked photoresist which has not been exposed to light is removed. Thereafter, the resist mask **8** is thermally converted into polyimide **9**; the polymerized groups **10** being split off. This type of photoresist is of particular interest for microelectronic applications.

Thiol-Ene Systems: In a photoinitiated free-radical chain reaction, thiols **12** form adducts with alkenes **15**, forming thioethers **17** (Scheme 4)[29i,43]. Examples of suitable photoinitiators are ketones.



Scheme 4. R^1, R^2 = aryl; R', R'': alkyl.

The radicals **13** can also initiate or interrupt chains, either by direct reaction or by abstracting hydrogen from the substrate.

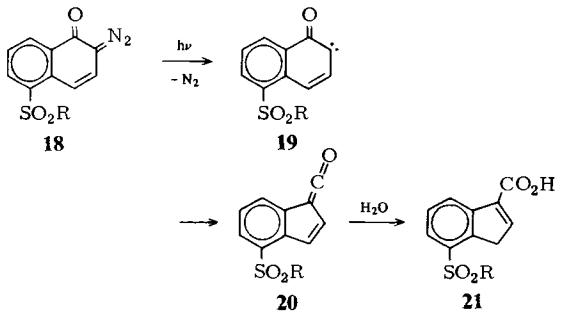
In order to obtain a high crosslinking density, thiols and alkenes containing numerous SH groups and CC double bonds, respectively, are used.

3.3. Positive-Working Photoresist Systems

In contrast to negative photoresist systems, the photochemical reaction does not change the original properties of the resist in positive resists; a change in solubility occurs only in the areas of the resist layer removed in the subsequent development step. The protective resist mask thus produced, if not deactivated thermally or by illumination, is still photochemically reactive and can, after undergoing a process step, be re-exposed and converted into a differently structured mask for a subsequent process. For this purpose, however, the resist must, at the outset, also possess all those properties required for the protective function, *e.g.* adhesion and "resistance", in addition to good, defect-free film formation and adequate photosensitivity. These requirements are obviously not easy to fulfill, since of the large number of systems proposed only a few appear to have prospects of industrial use: up to the present time, only one system is in use, of course in a variety of modifications.

3.3.1. Diazonaphthalenone Systems

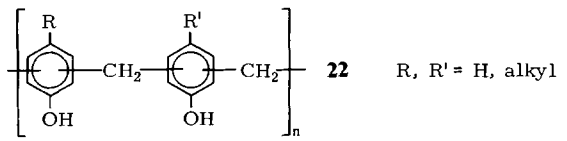
All positive photoresists used industrially on a relatively large scale are liquid systems which exploit the photoinduced Wolff rearrangement[44] of diazonaphthalenone derivatives (2-diazo-1-naphthalenones) **18**. According to more recent investigations the end product of the Süs reaction[45] is not 1-indenecarboxylic acid but 3-indenecarboxylic acid **21**[46]; ketenes, such as **20** have been confirmed as educts of the hydration, but it has not been possible to date[47] to detect carbenes **19**.



Scheme 5.

In addition to compounds of type **18**, only derivatives of diazooxonaphthalene-4-sulphonic acids are used in photoresists[5e] (R predominantly represents aryloxy groups, and occasionally substituted amino groups).

Scheme 5 illustrates a differentiation principle based on the conversion of the oleophilic compound **18**, which is insoluble in aqueous systems, into the alkali-soluble **21**; however, the situation becomes complicated in industrial resist formulations containing a binder of the novolac type (non self-hardening phenolic resin) **22**, in addition to the photosensitive component **18**.



22 R, R' = H, alkyl

In Figure 12 the situation is considered with respect to the solubility properties of this resin, which, owing to its phenolic hydroxyl groups, is partly soluble in dilute aqueous alkali solutions; its solubility is changed in a characteristic manner by certain additives.

The possibility of aqueous-alkaline development of photoresists of this type is one of the essential reasons for using this system to produce very fine structures on semiconductor surfaces and mask substrates: the hydrophobic nature of the unexposed resist elements prevents them from swelling during development. Troughs, whose widths are equal to the thickness of the resist layer, can still be produced.

For negative photoresists, a minimum value of the ratio of trough-width to layer-thickness of 3 : 1[4e] currently applies; for a given resist-layer thickness, the resolution obtainable with positive systems is therefore higher. A further advantage is that the photochemically unchanged resist mask can be more easily removed when it has fulfilled its function.

3.3.2. Photocatalytic Systems

Although positive photoresists based on diazonaphthalenone derivatives proved suitable for industrial use some time ago and are increasingly gaining ground over negative photoresists for the production of integrated circuits, they suffer from the same principal disadvantage as the systems mentioned in Sections 3.2.1 and 3.2.2: Since they are based on photochemical one-quantum

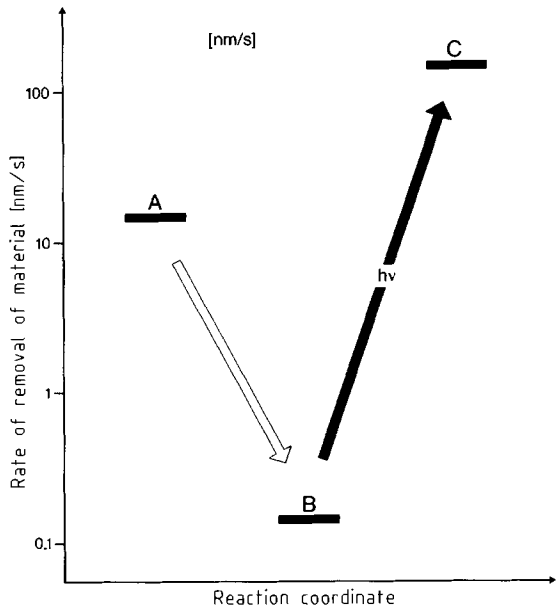


Fig. 12. Solubility changes of phenolic resins caused by additives. A layer of the phenolic resin **22** is removed at a rate A by an aqueous-alkaline developer of particular concentration. The incorporation of a diazonaphthalenone derivative into the resin layer reduces the rate of removal considerably (B), presumably *via* an association in which the phenolic hydroxyl groups of the resin participate. Photolysis cancels out this association; acid **21** formed in the ubiquitous water is neutralized by the developer, and increases the solubility drastically (C). The numerical values [48] of the ordinate are very dependent on the experimental conditions [49] and are intended only to represent the order of magnitude of the solubility changes.

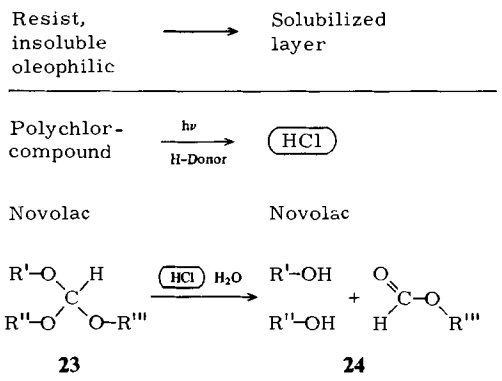
processes, their photosensitivity can be manipulated only within relatively narrow limits. This problem is particularly evident with relatively thick layers, since the photochemical reaction must also involve the lower regions of the layer close to the substrate to ensure that the resist becomes soluble throughout. In addition to the amount of light required, the absorption properties of the layer constituents must, therefore, also be taken into account. These restrictions may be removed by using systems which, like photoinitiated processes in negative systems, produce a catalyst upon irradiation of a photoreactive, absorbing compound present only in low concentration; this catalyst in turn initiates the modification of a second, photochemically inert compound which does not absorb in the actinic region. Thus, the important functions in diazonaphthalenone derivatives, namely photoreactivity and inhibition of solubility, are separated. Suitable catalysts are hydrohalic acids which may be readily generated photochemically from photosensitive polyhalogen compounds; suitable modifiable solubility inhibitors are *e.g.* acetals of aromatic hydroxy compounds or *O,N*-acetals of *N*-alkylarylsulfonamides[50a], aliphatic polyacetals[50c], orthoester—and amide acetals[50b], polymeric orthoesters[50f], enol ethers[50d], and acyliminocarbonates[50e] all of which readily undergo acid-catalyzed hydrolysis[51].

While in some of these compound classes hydrolysis products of relatively high acidity—phenols and *N*-alkylarylsulfonamides are formed, which themselves are soluble in alkali—the aliphatic polyacetals and orthoesters are hydrolyzed to neutral alcohols. However, the photosolubilizing process described in Section 3.3.1 may, in principle, be extrapolated without restriction if the decrease in the rate

of removal of material (B) in Figure 12 is caused by a hydrophobic inhibitor instead by a diazonaphthalenone derivative, and the increase (C) is caused by a hydrophilic hydrolysis product instead by an indenecarboxylic acid derivative (Scheme 6). The inhibition of the solubility by the educts may be explained by assuming that the phenolic hydroxyl groups of novolak are blocked by hydrogen bonds to the ether oxygen atoms of the inhibitors. In contrast, the hydrophilic low-molecular weight hydrolysis product **24** acts as a cosolvent for the aqueous alkaline developer. Scheme 6 clarifies the relationships.



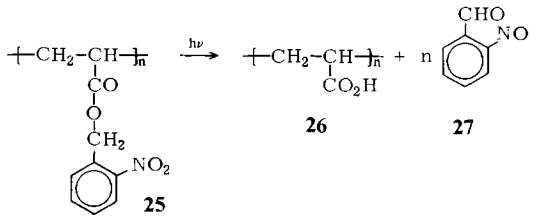
Scheme 6.

Particularly suitable polyhalo compounds are 2-styryl-[52a] and 2-aryl-4,6-bis(trichloromethyl)-*s*-triazines[52b], whose UV absorption maxima span the wide range from <300 nm to >440 nm, depending on the substituents on the aryl moiety. Of the large number of substances from which acids can be produced photolytically, this class of compounds fulfils the requirement of high effectiveness particularly well, *i.e.* of high resist "photosensitivity", together with thermal and solvolytic stability; this is necessary to prevent premature solvolysis of the inhibitor. The substituents R of the orthoester **23** shown in Scheme 6 can be parts of polymer chains, so that the hydrolysis has the effect of reducing the molecular weight at the same time.

Using the principles described, positive-working dry resists may be produced which, even for layer thicknesses of >50 μm, can still be solubilized with industrially acceptable amounts of light. Thick layers of this type, containing diazonaphthalenone derivatives are less photosensitive by at least one order of magnitude.

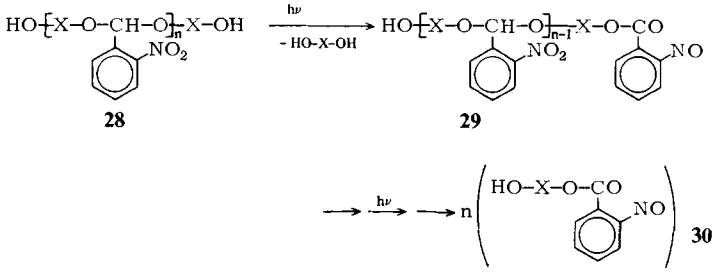
3.3.3. *o*-Nitrobenzyl and -Benzal Systems

How advantageously even classical photochemical reactions[53] can be used in modern photoresists may be illustrated by the following three systems, all of which utilize the migration of an oxygen atom from an electronically excited nitroarene to the α-C atom of a side chain in the *ortho*-position. The compounds most likely to be used industrially, particularly for dry film resists, appear to be polymers **25** containing *o*-nitrobenzyl acrylate moieties, which can be split photochemically[54] into acrylic acid units **26** and *o*-nitrosobenzaldehyde **27** (Scheme 7). Because the free carboxyl groups produced, those parts of the layer exposed to light may be removed by alkaline solvents.



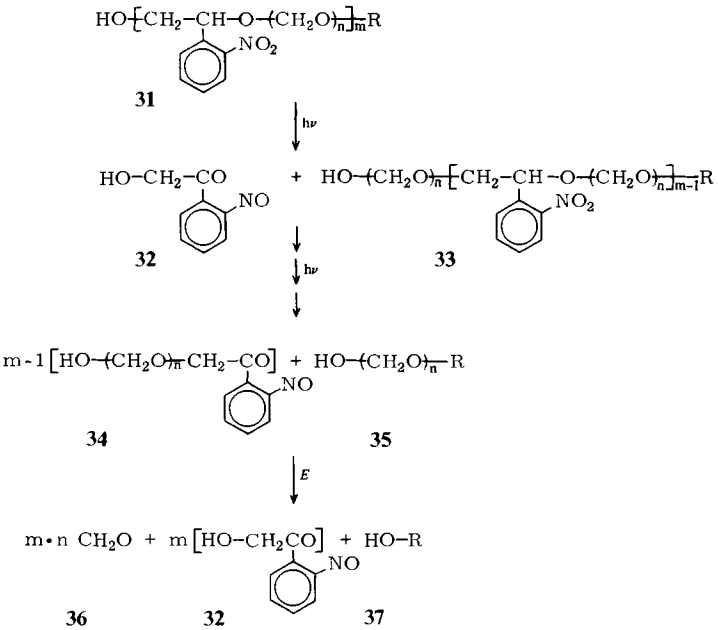
Scheme 7.

Another system[55] (Scheme 8) uses polyacetals **28** obtained from aliphatic diols and *o*-nitrobenzaldehyde. Since in this case no acid groups are formed photolytically, development must be carried out using organic solvents *e.g.* 2-ethoxyethanol. The differentiation is based on solubility differences between the unexposed layer areas containing intact polymer units and the more readily soluble fragments **30** at the exposed points.



Scheme 8.

In Scheme 8, X represents the alkylene group of a diol, *e.g.* 1,4-cyclohexanedimethanol. In principle, the third system[56] (Scheme 9) even offers the possibility of "dry", solvent-free development. The exposed areas can be developed by treatment with organic or inorganic bases, or simply by heating; this leads in **34** and **35** to depolymerization of the polyoxymethylene partial chain which is no



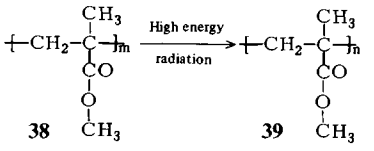
Scheme 9. *E:* Development by action of heat or basic solvents.

longer end-capped after photofragmentation. 1,2-Glycol or 1,3-propanediol moieties, which carry an *o*-nitrophenyl group on at least one of the terminal C atoms, are inserted into the polyoxymethylene chains. In polymer **31**, R represents a unit which blocks the polyoxymethylene chain, *e.g.* an acyl group or even an *o*-nitrophenyl(hydroxyethyl) unit.

3.4. Resists Sensitive to Short Wavelength UV Irradiation, Electron Beams, X-Rays, and Ion Beams

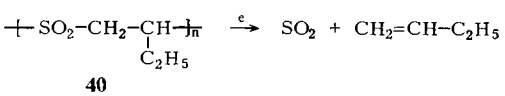
The photochemistry of photoresists sensitive to electromagnetic radiation of wavelengths $\lambda > 300$ nm is, in general, well understood. Selective reactions cause clearly predictable solubility changes in the resist material. However, relatively high-energy radiation excites isolated double bonds, nonbonding electron pairs and σ bonds, in addition to conjugated π bond systems. Ionizing radiation, *i.e.* electron beams, X-rays, and ion beams, produces reactive intermediates, whose secondary reactions are not very selective and which are more similar to thermal than photochemical processes. Structural differences in the irradiated compounds, which at first sight appear small, steer the reaction in the direction of fragmentation or depolymerization (positive procedure), or towards graft polymerization and crosslinking processes (negative procedure). Frequently both processes occur side by side, and can be influenced by the radiation dose.

High-molecular weight polymethyl methacrylate **38** is a resist which can be differentiated by all four types of radiation mentioned. Short wavelength UV radiation, in the range 230 nm to 280 nm, which today is largely accessible industrially, induces, *via* $n \rightarrow \pi^*$ excitation of the carbonyl group, fragmentation to lower-molecular weight fragments **39** that are more readily soluble than the starting polymers. The same result may be obtained using ionizing radiation and X-rays, whose action is based on the photoelectrons emitted after absorption of the primary radiation.



38 high molecular, sparingly soluble — **39** low molecular, readily soluble

Owing to its high-resolution potential and its good processing properties, the readily obtainable polymethyl methacrylate is used industrially as a positive electron beam resist, although its sensitivity to radiation leaves something to be desired[57]. Another more sensitive positive electron beam resist is polyethylethylene sulfone ("polybutene sulfone, PBS") **40**.



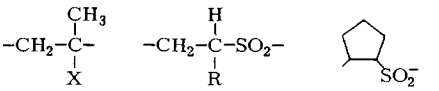
40

Irradiation of **40** with electrons causes at least partial depolymerization into the volatile comonomers SO_2 and 1-butene. It is therefore possible in certain applications to produce the resist relief directly, *i.e.* "dry" and without a special developing step[58]. Positive electron-beam resists also include diazonaphthalenone-based resists, which are, however, of low sensitivity[4e,59].

The copolymer of glycidyl methacrylate and ethyl acrylate is an example of a negative-working electron beam resist.

The structural characteristics that control the positive and negative behavior in a polymeric electron-beam resist are shown in Scheme 10.

Positive electron-beam resists



X = CO_2R, COR, CN, phenyl etc.

R = alkyl

Negative electron-beam resists

alkyl-, haloalkyl- and aryl-group

Scheme 10.

Similar structural units, which in most cases also contain elements of higher atomic number, *e.g.* halogen atoms to increase the absorption coefficient, are also found in X-ray resists[4e,60,61].

To date, the field of ion beam resists[15e] has been investigated only to a small extent, but as already mentioned the pertinent chemical principles should be similar to those for resists that are sensitive to X-rays and electron beams. However, ion beams also make it possible to produce inorganic-organic or pure inorganic resist-masks by selectively implanting ions in certain regions of an organic polymer layer or of a silicon dioxide layer. The less resistant, untreated zones are etched away in a subsequent plasma process.

It is not yet possible to foresee what resists will finally be used in the new, fascinating processes and to what extent these processes themselves will be employed in the production of electronic components. It is possible that the use of short wavelength UV radiation, as a "photooptical" process closely related to known technologies, will dominate in the medium term. However, in spite of a large number of systems which are in principle suitable, there is a lack of resists which fulfill all the requirements[13b,62]. The concept of combining the binder and the photoreactive component, which is successful in the long wavelength region, is greatly limited by self-absorption (below $\lambda = 300$ nm) of the binders suitable for classical photoresists and which have proved useful in the manufacturing processes.

4. Prospects

The very rapid advance of microelectronics in the industrial, public, and private sectors is illustrated by the data in Table 3[63], which applies exclusively to the market in "integrated circuits" (in millions of dollars).

Table 3. Size of the integrated circuit market (in million dollars).

	1981	1982 (estimate)	Increase [%]
USA	5351	6558	22.6
Japan	3797	4603	21.2
Europe	1498	1690	12.8

Although predictions[64] should be treated with reservation, even conservative estimates up to 1991 assume an inflation-corrected average growth of 8–9% per year.

Miniaturization of circuits has not yet reached insurmountable physical barriers; however, to utilize the remaining margin, new materials and processing methods must be developed. The service function of photolithography—the term includes the use of generally radiation-sensitive resists—will continue to have an important position for a long time. It will also certainly not be possible to dispense with the conventional semiconductor materials in the immediate future. In spite of all efforts, "molecular circuits"[65] based on proteins or non-biological polymers, such as polyacetylene, are still things of the future. The dimensions of circuit elements of this type could shrink to that of the molecular scale (*ca.* 100 nm).

It is uncertain as to whether attempts of this type will finally mature into a practicable technique. In a technique of this type, classical photolithography, if at all, would play only a peripheral role, but chemistry would continue to play a key role, even if in a different way.

The Chemical Behavior of Multibridged [2$_n$]Cyclophanes**

By Jürgen Kleinschroth and Henning Hopf*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Multibridged [2$_n$]cyclophanes comprise a novel class of aromatic compounds, in which two benzene rings are connected by three up to a maximum of six ethano bridges. Compared to classical nonannelated arenes, their most distinct chemical property is the ease with which, particularly the higher-bridged homologs, take part in addition reactions (Diels-Alder additions, hydrogenations, and ionic additions). On the other hand, the typical regenerative behavior of aromatic molecules is not fully suppressed in the [2$_n$]cyclophanes as evidenced by such typical electrophilic aromatic substitution reactions as bromination, Friedel-Crafts acylation, and nitration. Besides these reactions in which the benzene rings are either destroyed or retained, reactions at and with the ethano bridges, *e.g.* their cleavage, isomerization, and functionalization can also occur.

1. Introduction

On extraction of polymeric compounds produced by high-temperature pyrolysis (900 °C) of *p*-xylene, *Brown* and *Farthing* in 1949 isolated minute amounts of a hydrocarbon to which they assigned the structure tricyclo[8.2.2.2^{4,7}]hexadeca-4,6,10,12,13,15-hexaene (**1**, Scheme 1) from an X-ray structural analysis[1,2]. Since "conventional methods", not described in further detail, failed to reproduce this compound with the trivial name di-*p*-xylylene, the authors concluded that the ring-strain evidently present in the molecule could only be overcome by the extreme reaction conditions of the pyrolysis. That this is, in fact, not at all the case was shown, however, only two years later by *Cram* and *Steinberg*, who prepared **1** by Wurtz-coupling 1,2-bis-(4-bromomethylphenyl)ethane, although the total yield did not surpass 2.1%, even under high-dilution conditions[3]. After *Cram*, **1** and its homologs, which may be prepared by similar (and other conventional) methods, are termed [m.n]paracyclophanes with m and n symbolizing the number of CH_2 groups bridging the benzene rings, the prefix describing the anchoring points of the bridges, and the stem of the name resulting from a contraction of *cyclo*, *ph*enyl, and alk*ane*[4]; according to this nomenclature, hydrocarbon **1** is designated [2.2]paracyclophane[5].

In this first publication *Cram*[3] not only laid the basis for a new group of aromatic compounds but also mentioned most of the reasons that make cyclophanes even today, thirty years later, a much studied class of compounds: The transannular interactions between the benzene rings, which are particularly pronounced when the molecular bridges are short and when one arene-half carries electron donor, the other electron acceptor substituents[6]; the deformation of the benzene rings, which—depending on the type of phane molecule—may be either boat- or chair-like[7a,b]; bond lengths and angles deviating from the norm, and, finally, the many possibilities of generating molecular asymmetry using derivatives of **1**[8]. Phane molecules, in

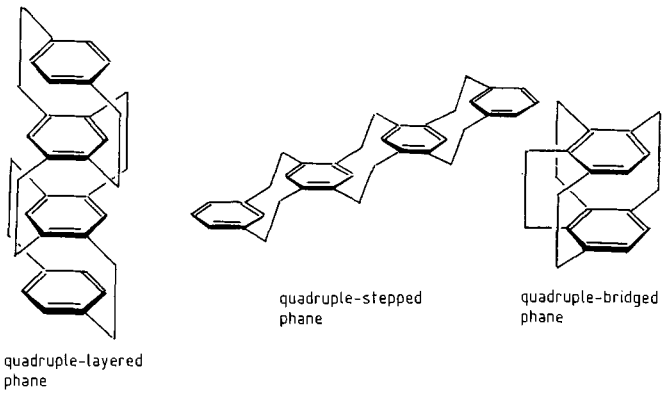
[**] Cyclophanes, Part 15.—Part 14: S. H. El-tamay, H. Hopf, *Tetrahedron Lett. 1980*, 4901.

which all types of aromatic subunits are bridged by polymethylene chains but also by functionalized bridging units are known today in large numbers[9].

As far as the parent systems, which only contain benzene rings and ethano and propano bridges, are concerned present research activities are focused on multilayered[5, 10], multistepped[9e, 11], and multibridged cyclophanes[9e, 12].



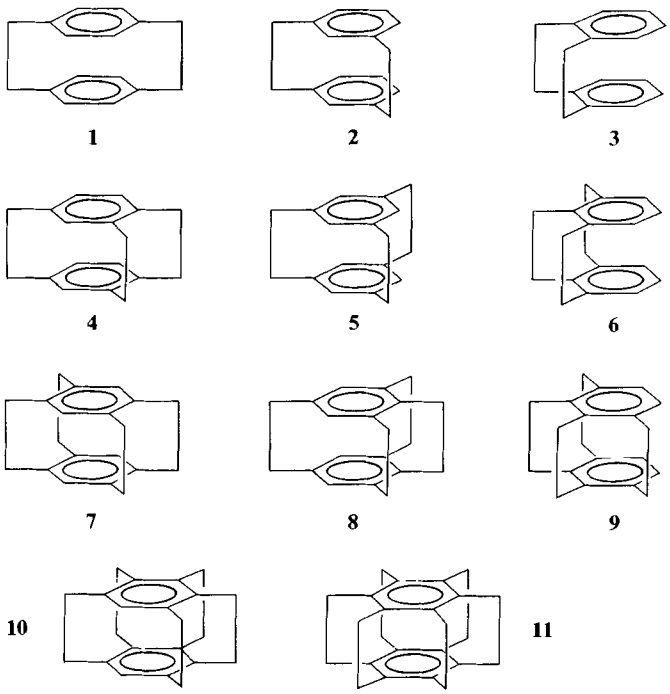
Whereas the first phane-type is of interest because its stacked or columnar structure allows electronic interactions over unusually large distances, and the relatively flexible multistepped phanes have been studied because of their dynamic properties, the multibridged phanes are structurally remarkable since they possess a "hollow" interior, into which in principle other chemical species, be they atoms or complete molecules, may be incorporated. Among the multibridged cyclophanes, the [2$_n$]cyclophanes "with parallel bridges" (see Section 2) represent the simplest type; for a comparative study of chemical reactivity it is important that during the last few years it has been possible to synthesize the complete series of all possible hydrocarbons of this type.

This review summarizes the chemical properties of these unusual arenes for the first time. The syntheses leading to these substances will, however, not be described again, since all the pertinent information may be found in a recent review article[12].

2. Multibridged Cyclophanes

2.1. Some Remarks on Nomenclature

All hydrocarbons composed of at least two aromatic systems held together by three or more ethano bridges will be called multibridged [2$_n$]cyclophanes. Evidently, the maximum number of the bridges depends on the size of the aromatic subunits. The bridges may either be in "parallel" or in "non-parallel" alignment. Whereas in the former case they are anchored to identical positions of the aromatic nuclei, in the latter they are not. The number of all possible cyclophanes with two benzene rings and parallel ethano bridges is easily determined: it corresponds to the number of the identically substituted benzene derivatives. Hence, there exist three [2$_2$]cyclophanes: [2.2]para- **1**, [2.2]meta- **2**, and [2.2]orthocyclophane **3** (dibenzocyclooctadiene); three [2$_3$]cyclophanes: [2.2.2](1,2,4)- **4**, [2.2.2](1,3,5)- **5**, and [2.2.2](1,2,3)cyclophane **6**; three [2$_4$]phanes: [2.2.2.2](1,2,4,5)- **7**, [2.2.2.2](1,2,3,5)- **8**, and [2.2.2.2](1,2,3,4)cyclophane- **9**, and, of course, one five- and one sixfold bridged molecule: [2.2.2.2.2](1,2,3,4,5)- **10**, and [2.2.2.2.2.2](1,2,3,4,5,6)cyclophane **11** ("superphane").



Scheme 1. [2$_n$]Cyclophanes with parallel ethano bridges.

2.2. Possible Reactions

The whole series of hydrocarbons **4**—**11** is in the meantime known[12]. The maximum number of systems with non-parallel bridges[13] may also be readily derived. However, it is more difficult to predict which of these molecules is stable under normal laboratory conditions; according to molecular models some of the "skew" phanes are very strained; they should therefore be much more reactive than the occasionally sluggish cyclophanes **4**—**11**.

Formally the [2$_n$]cyclophanes consist of the building blocks methylene bridge and benzene ring, and in principle two types of reactions could be discussed: those that take place at and with the ethano bridges, and those occuring at the benzene rings. The clear separation of these centers of reactivity is convenient to organize the experimental results; however, some reactions like the Lewis-acid catalyzed isomerizations (see Section 3.2) involve both parts of the molecule. The chemical behavior of the parent molecule **1** is discussed only in a cursory fashion on the following pages, since the whole spectrum of reactions of this hydrocarbon and its simple derivatives has been the subject of several review articles[9].

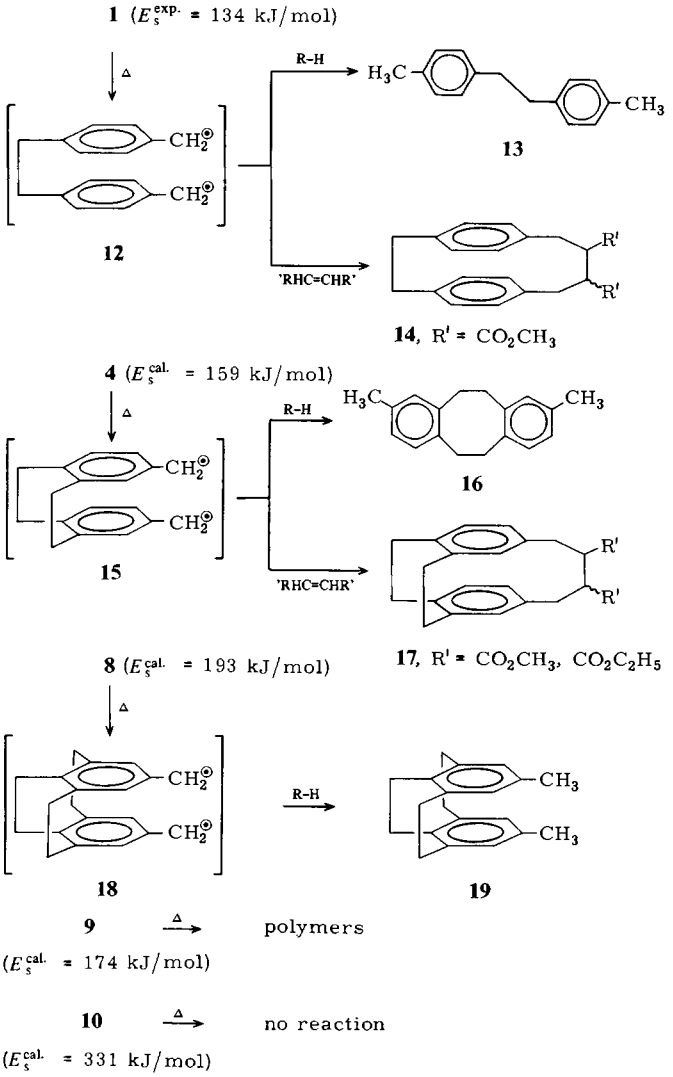
3. Reactions at the Ethano Bridges of [2$_n$]Cyclophanes

So far three types of reactions involving the ethano bridges have been observed: cleavage, shift, and functionalization. The cleavage reaction principally takes place between the benzene ring and the ethano bridge or between the methylene groups.

3.1. Radical Cleavage

Homolysis of the C_2-bridges may be initiated thermally or photochemically. In the simplest case of [2.2]paracyclophane **1**, pyrolysis at temperatures above 200 °C in the presence of hydrogen donors like *p*-diisopropylbenzene or thiophenol leads to 4,4′-dimethylbibenzyl **13** (21 and 74% yields, respectively). Evidently the diradical **12**, which may also be trapped by dimethyl maleate or dimethyl fumarate yielding the ring-expanded cyclophane **14** (200 °C, 40 h, 60%) serves as a precursor[8,14]. Interestingly—and supporting the diradical nature of the intermediate—both the yield of **14** and its isomeric composition are practically independent of the configuration of the trapping reagent.

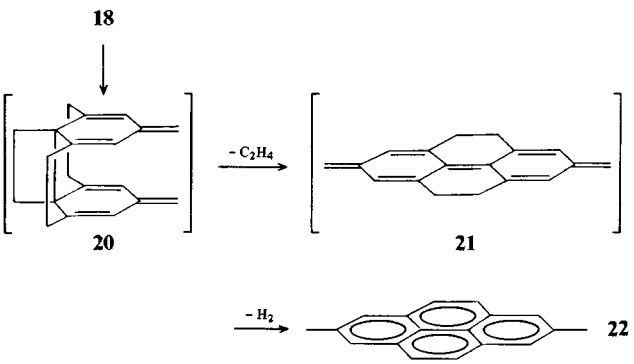
The next higher homologs **4** shows a similar behavior:



Scheme 2. Pyrolysis reactions of [2$_n$]cyclophanes.

The pyrolysis in thiophenol (22 °C, 73 h) or *p*-diisopropylbenzene (270 °C, 40 h) affords only 2,9-dimethyldibenzo[*a*,*e*]cyclooctadiene **16** (88 and 63%, respectively), and trapping experiments with diethyl maleate (220 °C, 43 h, 42%) and diethyl fumarate (220 °C, 72 h, 51%), or dimethyl maleate (250 °C, 40 h, 74%) lead to mixtures of the isomeric [2.2.4]cyclophane diesters **17**, although the reaction conditions are slightly more vigorous than for the homolysis of **1**[15]. That of the three possible ethano bridges the one indicated in Scheme 2 breaks, has been attributed to the greater strain release in the formation of diradical **15** than for alternative pathways[15a].

At first glance the [2.2.2.2]cyclophane **8** does not show any novel behavior: heating for 65 hours at 290 °C in *p*-diisopropylbenzene cleaves it to give the [2.2.2](1,2,3)cyclophane **19** (31%), *i.e.* the isolated ethano bridge is again cleaved[16]. However, only a slight increase in temperature and reaction time (300 °C, 75 h) suffices to force the pyrolysis along a completely different pathway. Under these more extreme conditions **18** is transformed into 4,9-dimethylpyrene **22**, the only solid reaction product of the pyrolysis[17].



Recyclization of the diradical **18** could now lead to the polycycle **20** which, *via* successive loss of ethene (formation of **21**) and hydrogen to yield **22**, finds a new way of stabilizing itself. **9** is considerably more thermally stable than **8**: after 65 h at 290 °C, and even 12 h at 400 °C this hydrocarbon is recovered unchanged from the pyrolysis-trapping experiment. Only above 470 °C (12 h) does **9** begin to decompose to polymeric products, possibly *via p*- or *o*-quinodimethanoid intermediates[16]. The pinnacle of thermal resistance is finally reached with superphane **11**, which is neither reductively cleaved nor undergoes ring expansion with diethyl maleate after 24 hours at 350 °C[18].

Scheme 2 also lists the strain energies of the [2$_n$]cyclophanes[19] (calculated except for **1**). The data show that both thermal stability and strain energy increase with the number of ethano bridges, indicating that the steady increase in ground state energy on proceeding from **1** to **11** is outmatched by the increase in the energy of the transition states leading to the various diradicals. This seems reasonable, since the spatial separation of the diradical centers to a distance that allows a chemical reaction to take place, whether this is hydrogen abstraction or addition to a double bond, necessarily must become more difficult if the two molecular halves undergoing separation are held together by additional molecular clamps. In other words: in molecules of this type—and presumably in other

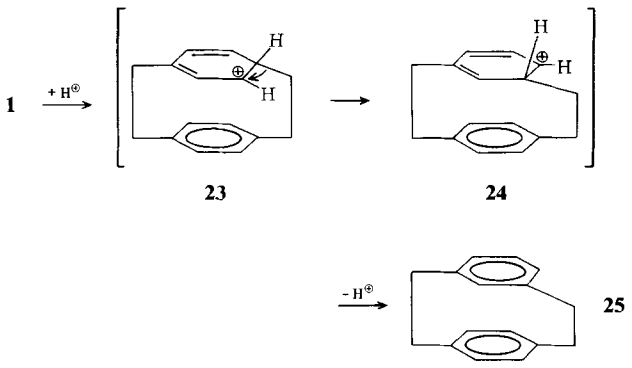
highly symmetrical hydrocarbons as well—several, and in the limiting case possibly all of the appropriate C—C bonds have to be stretched to the bond breaking distance to generate an interceptable intermediate. It may well be that the ring expansions mentioned are also of preparative value in other areas of hydrocarbon chemistry; *e.g.* pyrolysis of cubane in an unsaturated ester might well afford derivatives of basketane.

Both **12** and **18** have been generated and observed directly by irradiation of **1** and **8**, respectively, in a glassy matrix of 2-methyltetrahydrofuran at 77 K; the UV/VIS and fluorescence spectra of both species measured under these conditions constitute the first spectroscopic evidence for the formation of diradicals in photocycloreversions[20].

Irradiation of **1** in acetone, which serves both as solvent and sensitizer, at room temperature with a medium pressure mercury lamp leads to *p*-ethylbibenzyl exclusively, *i.e.* under these conditions scission between the benzene ring and the methylene group occurs[21].

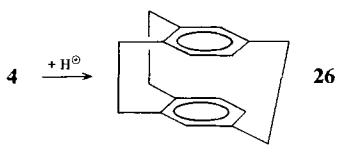
3.2. Ionic Cleavage

The experimental results on the ionic cleavage of the ethano bridges in [2_n]cyclophanes are presently rather heterogeneous, in particular hardly any comparative studies have been performed. The Lewis-acid catalyzed isomerizations belong to the better studied reactions. Treatment of

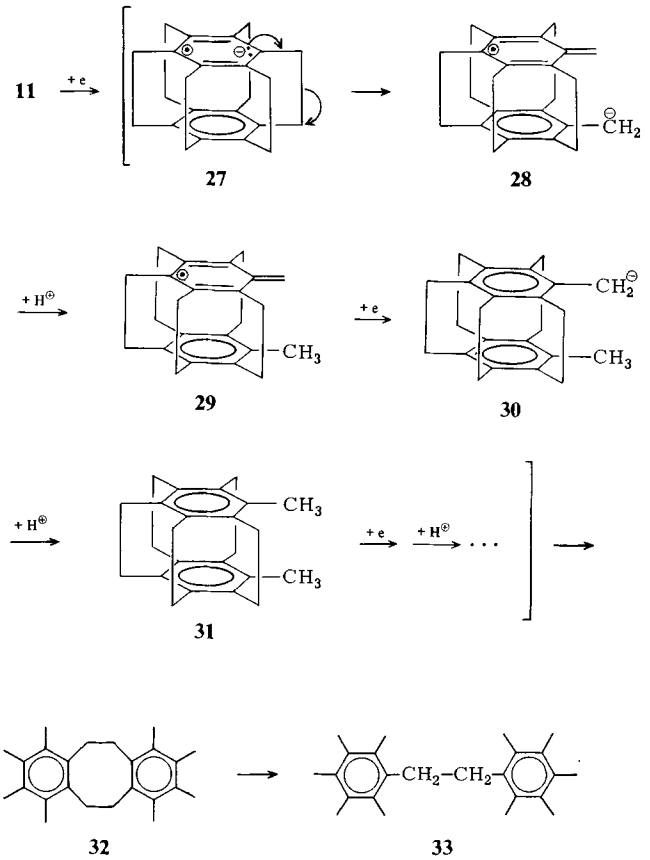


the parent compound **1** with $AlCl_3$/HCl in CH_2Cl_2 at 0 °C provides a mixture of hydrocarbons, from which *inter alia* [2.2]metaparacyclophane **25** may be separated in 44% yield[13].

The driving force for this reaction, which presumably takes place *via* the σ-complexes **23** and **24** is most likely provided by the reduction of the strain energy (E_s of **1**: 134 kJ/mol; E_s of **25**: 100 kJ/mol[19]). Among the higher bridged [2_n]cyclophanes only **4** has so far been induced to undergo a similar isomerization: after 30 min at −10 °C (CH_2Cl_2, $AlCl_3$/HCl) it affords the "skew" hydrocarbon [2.2.2](1,2,4)(1,2,5)cyclophane **26** (44%). Under the reaction conditions no further rearrangement takes place[16]. In



contrast, **8** and **9** do not even isomerize under more severe conditions (3 h, 25 °C). Although the intense red color that forms when HCl is added to the reaction mixture signalizes that a σ-complex is formed, a Wagner-Meerwein rearrangement evidently does not take place[22]. Molecular models indicate that in the triply-bridged cyclophane **4** the two benzene rings may be displaced towards each other during the migration of the ethano bridge, causing a reduction in molecular strain, whereas in the case of **8** and **9** such a displacement would cause a prohibitively large increase in strain. Related to these isomerizations is the first step of the *ipso*-substitution of **8** discussed in Section 4.

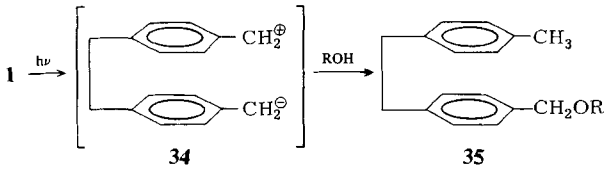


Scheme 3. Reductive cleavage of the ethano bridges of superphane **11**.

An anionic cleavage of the C_2-bridges takes place when superphane **11** is reduced with lithium/ethylamine in *n*-propylamine to form **32** (57%) and **33** (7%) (Scheme 3)[18a].

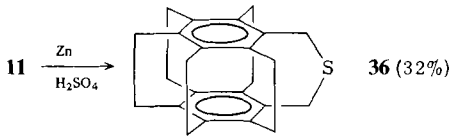
A plausible mechanism for this reaction is shown in Scheme 3. Radical anions like **27** correspond to the intermediates commonly discussed for the Birch reduction (see Section 4.2), and the cleavage of a bridging bond in [2.2]paracyclophane **1** by sodium/ammonia/ethanol to afford 4,4'-dimethylbibenzyl is well known[23]. The hexamethylbenzene dimer **33** is presumably formed by reduction of **32**.

The only report of a heterolytic destruction of a C_2-bridge in one of the molecules **1**—**11** concerns [2.2]paracyclophane itself, which on irradiation ($\lambda = 253.7$ nm) in alcohol is converted into the ether **35** *via* zwitterion **34**[21]:



34 35

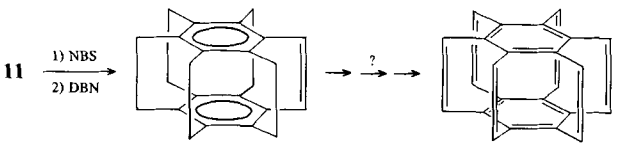
An unusual ring expansion is observed when **11** is treated with zinc in concentrated sulfuric acid (1 h). This reaction, of unknown mechanism, seems to be typical of superphane, since none of the other multibridged cyclophanes investigated so far yields products comparable to the thioether **36** if subjected to similar reaction conditions[18b].



36 (32%)

3.3. Functionalization

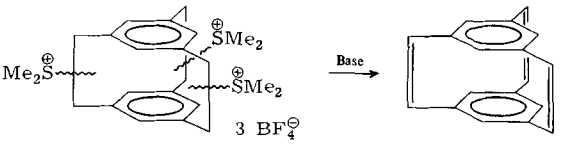
[2_n]Cyclophanes which are bridge-functionalized, *e.g.* with olefins, ketones, or epoxides, are of preparative, mechanistic, and spectroscopic interest; unfortunately, however, there exists a wide gap between attractive target molecules and their synthetic realization. For example, the monoolefin **37**, prepared from **11** by routine methods—bromination with *N*-bromosuccinimide (NBS) and subsequent elimination with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) might be regarded as the first step towards the hexaene **38**. But the low yield of only 20% is certainly not encouraging[18].



37 (20%) **38**

Hydrocarbon **38** is an electronically very unusual molecule since it is formally composed of a "core" containing 12 π-electrons (the two aromatic π-systems penetrate each other) and an orthogonal "sheath" possessing the same number of π-electrons. Overlap between the p-orbitals of the six olefinic double bonds could take place as in barrelene (bicyclo[2.2.2]octatriene).

The synthesis of the triene **40**, which corresponds to **5**, was accomplished by threefold Hofmann elimination of the trissulfonium salt **39** using *n*-butyllithium in tetrahydrofuran[24].



39 **40** (71%)

4. Reactions at the Benzene Rings

Even in their first publication *Brown* and *Farthing* discussed the non-planar geometry of the benzene rings in [2.2]paracyclophane **1**[2]. As shown by a later, more detailed X-ray structural analysis by *Lonsdale et al.*[25], at 291 K the bridgehead carbon atoms are displaced by 16.9 pm (14°) from the plane that passes through the remaining four aromatic carbon atoms. In other words, the benzene rings of **1** have a boat configuration. In the meantime, similar deformations have also been observed for **6**[26], **7**[27], **8**[28], **9**[29], and **10**[30]. Independent of the type and degree of the "deformation"[9b], the overlap of the six p-orbitals in a nonplanar benzene ring cannot be as effective as in benzene itself. In turn, a perturbation of the cyclic conjugation should affect the chemical and physical, and in particular the spectroscopic properties of these molecules[9]. It may, therefore, be asked whether the regenerative behavior so characteristic of the "classical" $(4n+2)\pi$-systems is displaced by an additive tendency in non-planar arene compounds, whether there is a competition between these two reaction modes, or whether the normally strongly disfavored addition is at least facilitated. Considering this background, which is also of theoretical interest[31], it is not surprising that most reactions performed with **4**—**11** have been addition reactions.

4.1. Diels-Alder Additions

In contrast to the readiness of conjugated di- and trienes to participate in [2+4]cycloadditions as diene components, simple aromatic 6π-electron systems are normally extremely sluggish in Diels-Alder additions—one reason for the use of benzene, toluene, the various xylenes, and halobenzenes as solvents in these reactions. Despite the low reactivity of *e.g.* benzene, 6π-arenes can react as dienes if the reaction is performed at high temperatures or in presence of Lewis acid catalysts; reactive dienophiles also add[32]. Nevertheless, the "superdienophile" 4-*N*-phenyl 1,2,4-triazoline-3,5-dione **41** does not add to benzene or any of the polymethylbenzenes at room temperature after several weeks[33]. If these molecules are incorporated into a [2_n]cyclophane system, however—*i.e.* [2.2]paracyclophane **1** as a formal dimer of *p*-xylene, superphane **11** as a dimer of hexamethylbenzene—then, in certain cases a drastic increase in the rate of addition is observed. As the data in Table 1 show[33], **1** and **41**, for example, react to afford the 1:2-cycloadduct after *ca.* six days at room temperature (the positions of the new bonds are marked with arrows).

The incorporation of further bridges—cf. **4** and especially **7**—then causes an extreme increase in reaction rate: in the presence of [2_4](1,2,4,5)cyclophane **7** the intense red color of **41** vanishes within a few seconds—in other words, in its ability to add this double 6π-system it can compete with acyclic polyolefins! Comparable trends are noted for the additions of **1**, **4**, and **7** to tetracyanoethylene **42** and dicyanoacetylene **44**, respectively—and in as far as the corresponding experiments have been carried out—to maleic anhydride **43**, perfluoro-2-butyne **45** and dimethyl acetylenedicarboxylate **46**. Only the comparatively unreac-

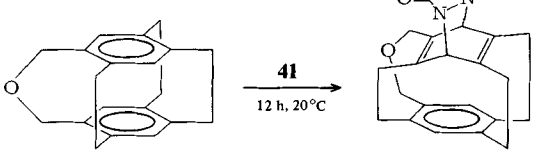
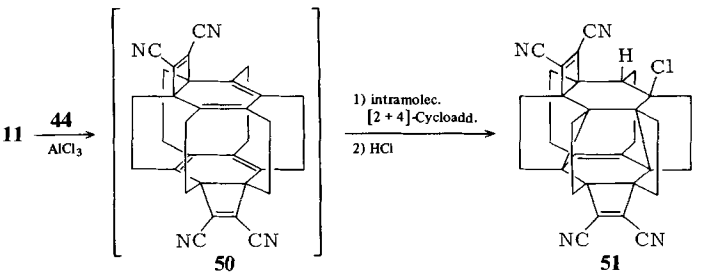
tive dimethyl maleate **47** does not undergo cycloaddition to **1** and **4**. That large ring strain in the educt alone does not suffice to induce a Diels-Alder addition in multibridged cyclophanes, however, is demonstrated by hydrocarbons **8**, **9**, and **11**[18a], none of which reacts with the various dienophiles (Table 1). Apparently in order to participate in a [2+4]-cycloaddition as a diene, a multibridged cyclophane must have a pair of *para*-hydrogen atoms. During the Diels-Alder reaction, which is accompanied by a rehybridization from sp^2 to sp^3, the methylene groups in **8**, **9**, and **11** have to be disposed towards the interior of these molecules, whereas in **1**, **4**, and **7** only hydrogen atoms are relocated. Furthermore, the substitution patterns in **8**, **9**, and **11** lead one to expect a compression of the C—C-bonds in the ethano bridges. The built-up of strain in the σ-framework of the expected Diels-Alder adducts hinders the addition reactions. The only hydrocarbon that does not fit into this scheme is the [2$_5$]cyclophane **10**, which surprisingly reacts with both dicyanoacetylene **44** (60 °C, 3 d, 44%) and perfluoro-2-butyne **45** (100 °C, 7 d, 100%), to afford 1 : 1-adducts[18b].

The important influence of ring-strain in these cycloadditions is impressively demonstrated by cyclophane **7**, which reacts faster than any of the other multibridged systems[36]. As shown by the data in Table 1, **7** initially forms a monoadduct with **44**; however, this is reactive enough to either produce the 2 : 1-product or to form a "mixed" adduct with tetracyanoethylene **42** within a matter of seconds[36]. If, on the other hand, the ring-enlarged, and hence probably less strained, ether **48** is treated with **41** the addition stops at the 1 : 1-stage **49**[17].



48 **49** (100%)

That **44** and superphane **11** do not undergo [2+4]cycloaddition has already been pointed out (Table 1). If, however, these two components are exposed to the catalytic influence of aluminum trichloride, then even at room temperature (3 d, dichloromethane) the polycycle **51** is



produced (40%), whose complicated structure was determined by X-ray crystallography[18a].

To explain the formation of **51** it has been proposed that **11** is first transformed into the 2 : 1 adduct **50** by double [2+2]cycloaddition, that this stabilizes itself by an intramolecular [2+4]cycloaddition, and that the resulting tetraene is trapped in an ionic reaction by the HCl formed during the process to provide the isolated product **51**—a reaction cascade involving three of the most important types of addition reactions.

Summarizing the results presented so far, it can be stated that the Diels-Alder additions of [2$_n$]cyclophanes are controlled by strain effects in both the educt and product molecules. Thus [2.2.2](1,2,4)(1,2,5)cyclophane **26** prepared

from **4** by Lewis-acid catalyzed isomerization (see Section 3.2), and hence is less strained than **4**, does not take up **41** or **42**, even as a π-complex[37]. In this case, the high strain energy of the conceivable cycloadduct most probably hinders the addition. On the other hand, the strain in **1** is just high enough to allow cycloaddition. These arguments are necessarily rather qualitative; however the experimentally determined strain energies of **4**—**11** are presently not available. It would also be desirable to extend the type of dienophiles employed, heteroatom-containing addends being of special interest. One of the few known reactions of this kind involves the sensitized photooxidation of **7**, which leads to the expected *endo*-peroxide[36]. Derivatives like this may be used as starting materials for further oxygenated cyclophanes[38].

4.2. Hydrogenations

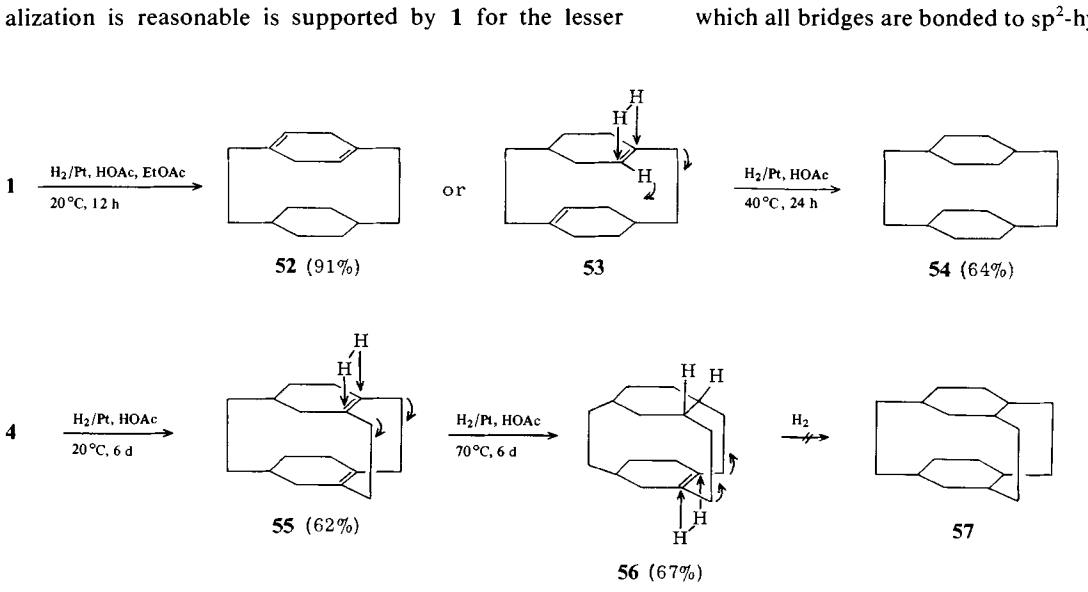
The behavior of [2$_n$]cyclophanes in catalytic hydrogenations may be compared to their Diels-Alder additions in more than one respect. The parent compound **1** is transformed under mild conditions into a diene that either has structure **52** or **53**, whereas slightly more rigorous reaction conditions yield perhydro[2.2]paracyclophane **54**[39]. The incorporation of an additional bridge—as in **4**—is of no immediate consequence: in presence of platinum in glacial acetic acid, four equivalents of hydrogen are added rapidly, and the diene **55** is formed[15a]. Further hydrogenation of **55**, however, requires even more drastic conditions: only after 6 d at 70 °C[15a] or 5 d at room temperature at 5 bar[40] is the monoolefin **56** produced, which is resistant to further hydrogenation under the above conditions.

The low rate of conversion of **55** into **56**, which proceeds considerably more slowly than the hydrogenation of **4** to **55**, can again be attributed to strain effects: the hydrogen necessarily has to attack **55** from the "outside", causing a "compression" of the vicinal ethano bridges and hence increases the strain in the polycycle (bent arrows in **55**). For **56**, rehybridization from sp^2 to sp^3 carbon atoms is opposed by even stronger strain effects, and the perhydro-derivative **57** is therefore not formed. That this rationalization is reasonable is supported by **1** for the lesser bridged cyclophanes, and by **8** (no uptake of H_2 after 7 d at 70 °C and 2.5 bar[22]), **10**[18b], and superphane **11**, which is unreactive towards hydrogen in the presence of Adams' catalyst[18a] for the higher bridged molecules.

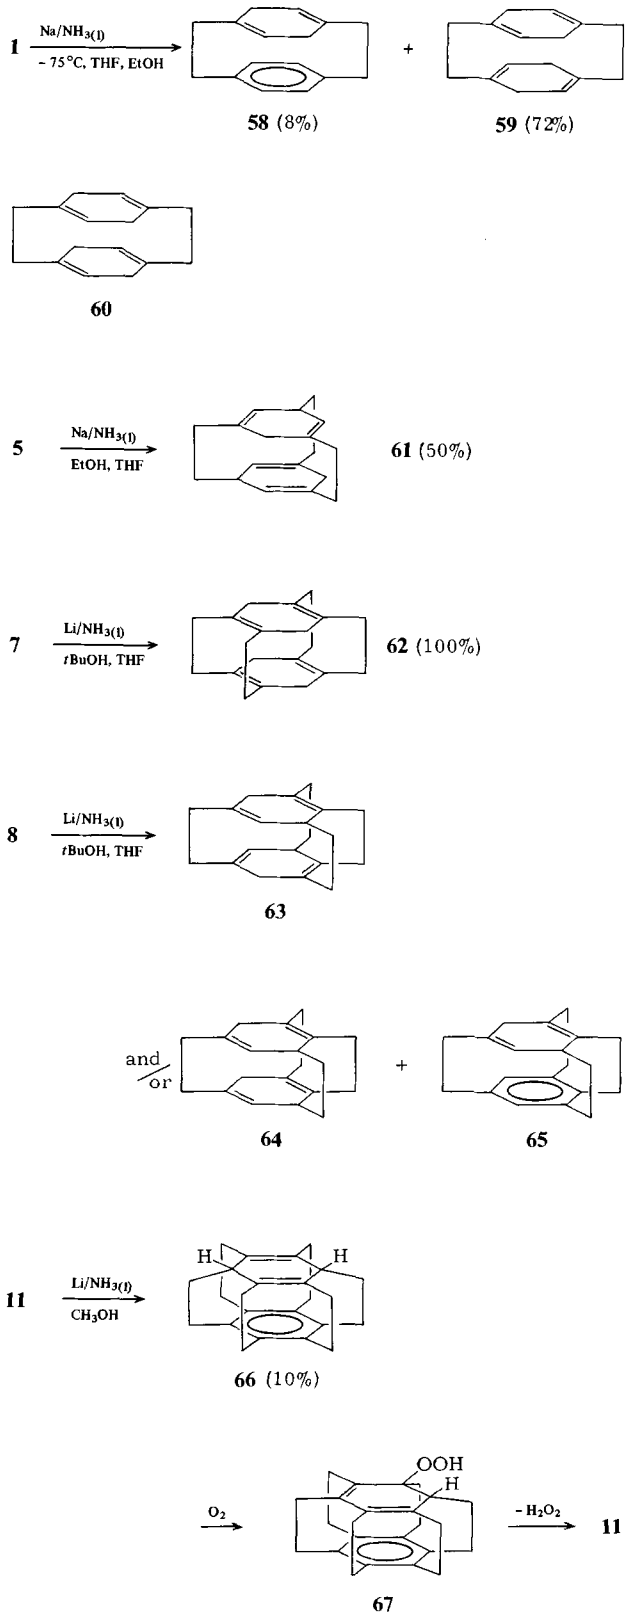
Qualitative indications on the behavior of the benzene rings of [2$_n$]cyclophanes during reduction may also be gathered from Birch reductions, which so far have been carried out with **1**, **5**, **7**, **8**, **10**, and **11** (Scheme 4). This reaction should take place particularly readily, since a substantial reduction in strain is expected for the transformation of non-planar aromatic nuclei into boat-configurated 1,4-cyclohexadiene units.

Under the conditions given in Scheme 4, [2.2]paracyclophane **1**, besides providing small amounts of the dihydro compound **58**, mainly affords the tetrahydro derivative **59**, the "crossed" arrangement of its double bonds being inferred from subsequent reactions and the spectroscopic properties of the products formed[23,41]. Differentiation between **59** and the tetraolefin **60** with "parallel" double bonds, can only be carried out with difficulty using spectroscopic methods alone. Heating **59** to 150—160 °C in a closed system leads to **58**[41a]. The known[42] strong dependence of the product composition in Birch reductions on small variations in the reaction conditions is also observed for **1**; whereas addition of a solution of **1** in tetrahydrofuran (THF) to a refluxing solution/suspension of sodium in liquid ammonia, followed by addition of ethanol yields 4,4'-dimethylbibenzyl **13** in 94% yield[23], slow addition of **1** in tetrahydrofuran/ethanol to a solution of sodium in refluxing ammonia leads quantitatively to **59**[41b]. Birch reduction of the higher homologs of **1** should again be partially governed by the same factors that control the diene reactivity of the [2$_n$]cyclophanes (cf. Section 4.1). Examination of molecular models indicates that the six-ring sp^3-carbon atoms of **59** are strongly tilted "outwards", *i.e.* the cyclohexadiene rings have a boat configuration. An ethano bridge anchored at these positions would probably have to be stretched considerably, causing a severe increase in strain energy in the system.

It is therefore not surprising that in the Birch reduction of **7**, exclusively and quantitatively the energetically more favored tetrahydro[2$_4$](1,2,4,5)cyclophane **62** is formed, in which all bridges are bonded to sp^2-hybridized ring carbon



atoms[36]. The observation that **5** is readily reduced to **61**[24] does not contradict this explanation since a *meta*-arrangement of the bridges, as in substrate **5** and tetraene **61**, tolerates ring-strain more easily. It was hence even more interesting to study the Birch reduction of **8**, a formal hybrid of a [2.2]para- and a [2.2]metacyclophane.



Scheme 4. Birch reduction of [2$_n$]cyclophanes.

Reaction with lithium in liquid ammonia/*tert*-butanol yields a mixture of **63** and/or **64**, and **65**[22]. It is difficult to decide which of the two tetrahydro compounds is present from the spectroscopic evidence—as in the tetrahydro derivative of **1** *(vide supra)*. Steric arguments favor **63**, since sp^3-hybridization of both bridgehead carbon atoms of one ethano bridge (cf. **64**) probably cannot be realized. If the reaction mixture is studied by thin layer chromatography immediately after the reduction has been terminated, **63/64** is found to be practically the only primary product. Hydrocarbon **65** is only present in trace amounts, and substrate **8** has been completely consumed. After purification of the products by column chromatography, however, **65** (6%) and **8** (6%), besides **63/64** (83%) are isolated. The severely strained **63/64** hence begins to rearomatize during work-up at room-temperature; it is stable for several days only at $-20\,^{\circ}C$. The dihydroderivative **65** is somewhat more stable than **63/64**; however, purification by either recrystallization or sublimation fails again, **8** being reisolated.

In its reduction behavior superphane **11** fits neatly into this series: it yields the Birch product **66** (although only in 10% yield) but this rearomatizes rapidly at room temperature to **11**[18a]. Mechanistically this dehydrogenation could proceed as a thermal, symmetry-allowed process as known for other, simple 1,4-cyclohexadiene derivatives[43], or alternatively as an ene-reaction *via* **67** initiated by atmospheric oxygen[18a] and subsequent elimination of H_2O_2. Interestingly enough, hydrocarbon **10** also plays a special role in this reaction: it survives the Birch-reduction unchanged[18b].

The bridge-cleaving hydrogenation of **11** has already been discussed in Section 3.2: Birch reduction of **5** to a dimethyl[2.2]metacyclophane has also been accomplished[24].

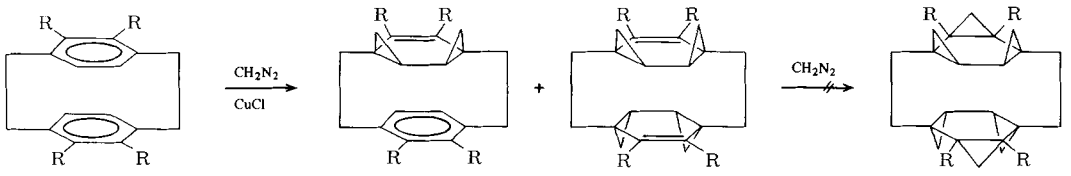
4.3. Various Addition Reactions

Considering the great ease with which some [2$_n$]cyclophanes participate in such typical polyene reactions as the Diels-Alder addition (Section 4.1), it is obvious to submit these hydrocarbons to other classical olefin reactions.

Indeed, the tetraester **68** reacts at room temperature with diazomethane/copper(I) chloride to yield a complex product mixture, from which the methylenation products **69** and **70** could be separated by column chromatography[44].

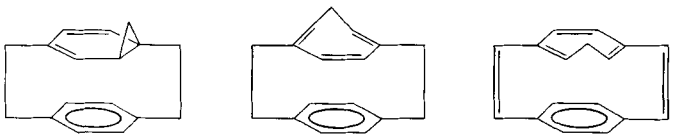
On the other hand, further carbene addition to afford a derivative of the so far unknown *all-cis*-trishomobenzene (*e.g.* **71**) no longer takes place[45]. The electron-withdrawing effect of the methoxycarbonyl groups is not responsible for this inertness, since the tetramethyl[2.2]paracyclophane **72** also yields only bis- **73** and tetra-adduct **74**, respectively[45]. [2.2]Paracyclophane **1** can also be cyclopropanated under the above conditions, providing the norcaradiene **75** in 10% yield, and the ring-enlarged cyclophane **76** in the same yield[46,47].

Surprising in the [2.2]cyclophane series is the observation that [2.2]paracyclophane-1,9-diene is preferentially at-



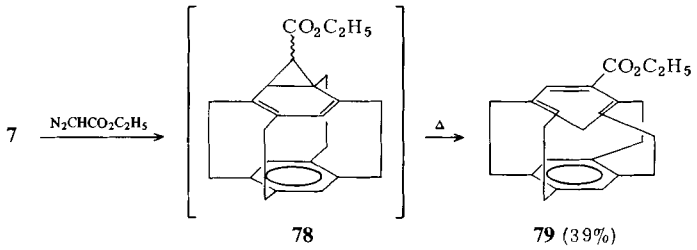
68, R = CO_2CH_3 **69**, R = CO_2CH_3(4%) **70**, R = CO_2CH_3(8%) **71**
72, R = CH_3 **73**, R = CH_3(3%) **74**, R = CH_3(8%)

tacked at one of the benzene rings, hydrocarbon **77** being isolated as the product[47]. As a rule, olefinic double bonds are cyclopropanated more readily than aromatic ones[48].



75 **76** **77**

The norcaradiene derivative, **78**, also ought to be the most likely primary product in the reaction of **7** with ethyl diazoacetate; under the reaction conditions, however, it isomerizes spontaneously to the seven-membered ring system **79**[36].

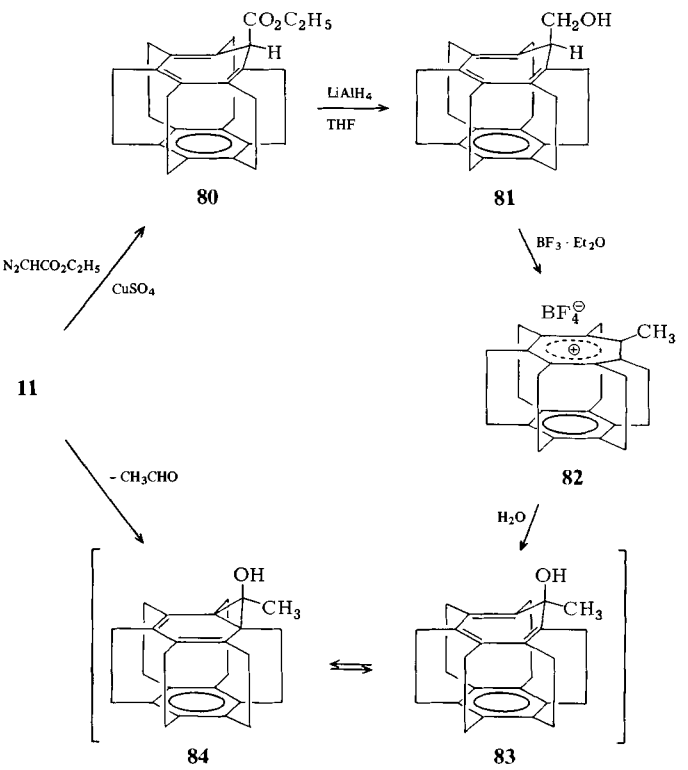


78 **79** (39%)

Tropilidenes like **76**, **77**, and **79** are of interest primarily as starting materials for phane systems in which an uncharged aromatic nucleus, like the benzene ring, is connected to a tropylium ion by ethano bridges and fixed in a stereochemically unambiguous position. Indeed, it has been possible to prepare the simplest molecule of this class of compounds, [2]paracyclo[2](1,4)tropyliophane, from **76** by hydride abstraction, and to study the interaction between the π-systems of its aromatic subunits[46,49]. Recently, a tropyliophane has been obtained from **79**[36]. If the preparative methodology developed in these syntheses is applied to **11**, the "circular process" shown in Scheme 5 results[18a].

As in the case of **7**, addition of ethyl diazoacetate first leads to a tropilidene ester **80**; its reduction with $LiAlH_4$ provides the alcohol **81**, which with boron trifluoride etherate isomerizes (presumably by a hydride shift) to the tropyliophane **82**. When this salt is either recrystallized from methanol/water or allowed to stand exposed to the atmosphere it is reconverted into **11**. This remarkable decomposition could occur *via* alcohol **83**, which after it undergoes valence isomerization to **84** by acetaldehyde cleavage, rearomatizes to **11** (52%)[18a].

Exploratory epoxidation experiments with *m*-chloroperbenzoic acid lead for **1** and **72** to oxidative degradation of the benzene rings, whereas the less electron-rich tetraester **68** yields a bisepoxide in 21% yield[45].

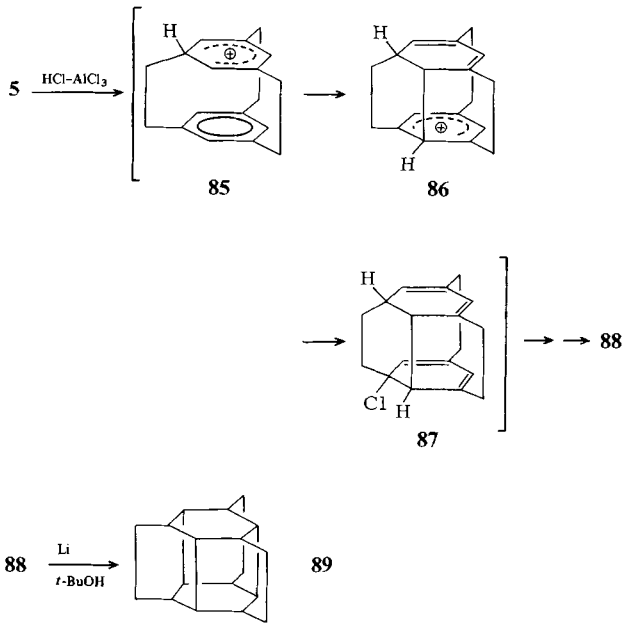


80 **81** **82** **11** **84** **83**

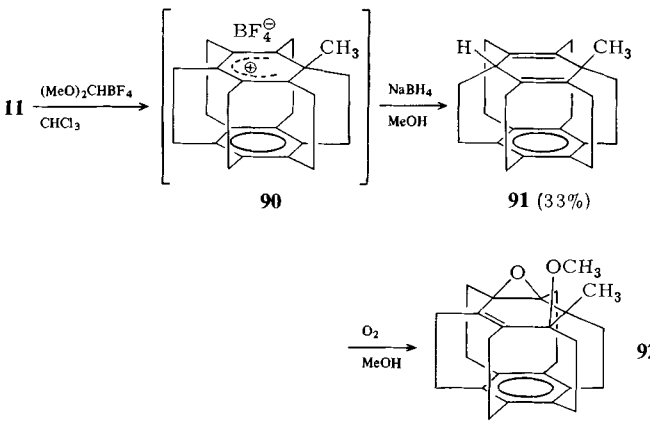
Scheme 5. Preparation and properties of a tropylium system derived from **11**.

Ionic additions to the benzene rings of the multibridged cyclophanes would certainly hint at a reduced aromatic character of these molecules, and in fact there are several reports in the literature describing this type of reaction: for example, **5** is transformed into a complex product mixture of composition $C_{18}H_{18}\cdot H_xCl_{6-x}$ (**88**) when treated with $HCl/AlCl_3$ in CH_2Cl_2 for 10 min at 0 °C. The separation and identification of the different chlorides was unsuccessful; however, **88** could be reduced to a homogeneous hydrocarbon $C_{18}H_{24}$, which—according to spectral data—has the cage structure **89**[24].

A plausible precursor for **88** is the HCl-adduct **87**, formed from **5** *via* the σ-complexes **85** and **86**. Monochloride **87** is well-suited for a multiple repetition of this ionic addition.



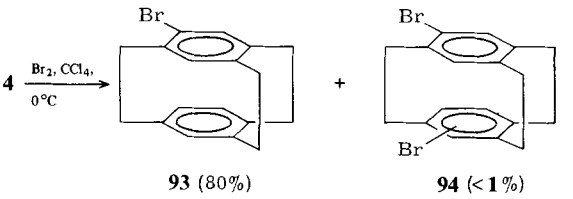
In another ionic process, **11** is alkylated with the Meerwein reagent dimethoxymethylium tetrafluoroborate to give the cation **90**, which may be intercepted by hydride ions to afford **91**. When this hydrocarbon is recrystallized from methanol it reacts to furnish epoxide **92** or a positional isomer thereof[18a].



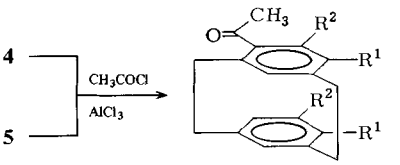
Polymethylated [2.2]paracyclophanes also react very rapidly with HCl to yield various chlorides, of as yet unknown structures[50].

4.4. Reactions in which the Benzene Rings are Conserved

The method of choice for the preparation of simple derivatives of [2.2]paracyclophane **1** is electrophilic aromatic substitution. Bromination, Friedel-Crafts acylation, nitration, and other reactions have all been reported[9] and are normally carried out under conditions characteristic for this type of substitution reaction. It can hence be assumed that in the majority of cases the standard reaction mechanism is also followed. However, precise mechanistic studies are rare and are, furthermore, primarily concerned with the mode of secondary- and polysubstitutions, and not with the primary process. *A priori* there is no reason to preclude substitutions that take place by an addition-elimination mechanism.



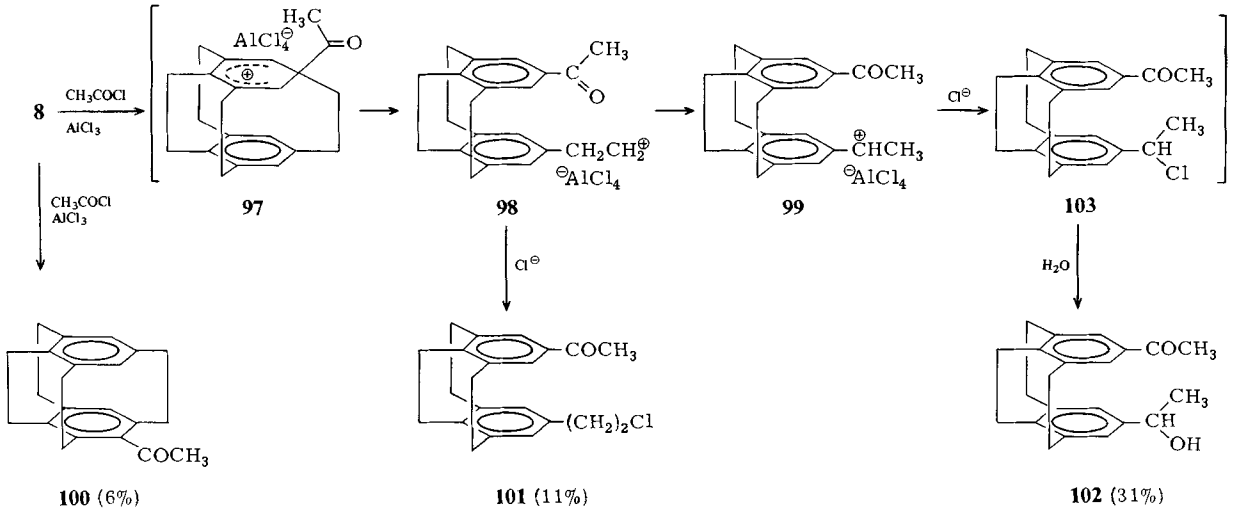
Bromination of the multibridged phane **4** provides the expected monobromide **93** as well as traces of the dibromide **94**[15a]. **4** is more reactive than **1**, and the fourfold bridged phane **8** cannot compete with **4** either: under the above conditions it does not react with bromine, and the addition of iodine or an increase of the reaction time is at first also of no consequence. Only when the reaction times become very long (16 h) does the bromine solution decolorize; however, from the resulting multi-product mixture, no monosubstituted derivative could be isolated[22]. Possibly addition of the electrophile occurs, as in the case of **5** in the presence of HCl.



95, R^1–R^1 = CH_2CH_2, R^2 = H(79%)
96, R^2–R^2 = CH_2CH_2, R^1 = H(59%)

Friedel-Crafts acylation of **4** and its isomer **5** proceeds as expected to form **95** and **96**, respectively[15]. The methyl ketones **95** and **96** do not undergo further acylation. The (1,2,3,5)cyclophane **8** provides the ketone **100** upon acylation, but only in low yield. The main products—besides reisolated **8** (16%)—are the two (1,2,3)cyclophanes **101** and **102**, respectively (Scheme 6)[22]. The formation of these two ketones requires the breaking of an ethano bridge between the benzene ring and a methylene group, and it seems reasonable to propose an *ipso*-substitution mechanism for this process[51]. The initial intermediate could hence be the σ-complex **97**, which removes part of its strain by isomerizing to the primary carbenium ion **98**. This, in turn, is either intercepted by chloride ions (formation of **101**) or stabilized by hydrogen migration to form the secondary cation **99**. Reaction of this species with chloride ions, however, leads to **103**, a secondary and benzylic halogen-derivative that is hydrolyzed to alcohol **102** during work-up.

Formylation after *Rieche*[52] (Cl_2CHOCH_3, $TiCl_4$, CH_2Cl_2, 0 °C) converts **8** in excellent yield (94%) into the expected aldehyde **104**, whereas nitration (fuming nitric acid, glacial acetic acid, 70 °C, 2 min) yields only traces of the nitro compound **105**[22].



Scheme 6. *Ipso*-substitution of [2$_4$](1,2,3,5)cyclophane **8**.

Both bromination (Br_2/iron) and Rieche formylation transform [2$_5$](1,2,3,4,5)cyclophane **10** into the expected monosubstitution products in excellent yields[18b].

5. Concluding Remarks

Although the homologous series of [2$_n$]cyclophanes with parallel ethano bridges has only been known for about two years[12], many results already exist on the chemical behavior of this new class arenes. Compared to classical monocyclic arenes their most distinct chemical property is the ease with which several of these phane systems participate in addition reactions. This behavior has been termed cyclohexatrienoid[33,35].

At most, however, this term describes the formal course of these additions. A "real" cyclohexatriene must show alternating single and double bonds—but just this property is not observed in any of the [2$_n$]cyclophanes that have been investigated by X-ray structural analysis[25-30].

The chemical reactions of **4**—**11**, as already mentioned in the text, need to be studied in greater detail. This is particularly true of photo-processes, which have been neglected so far. To put the mechanistic discussions on a quantitative level it would be desirable to compare the rates for the above reactions with those for their corresponding "halves", *i.e.* the various methylbenzenes. The direct observation of several reactive intermediates, like the various σ-complexes, would also be of mechanistic importance.

A *conditio sine qua non* for these and other investigations is synthetic methods that provide larger amounts (*i.e.* gram quantities) of the different [2$_n$]cyclophanes. In closing it should be mentioned that several of the synthetic pathways leading to the new hydrocarbons do not yet fulfill this all-decisive condition.

We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the van't Hoff Funds, and the Stiftung Volkswagenwerk for financial support; BASF AG, Bayer AG, and Hoechst AG are thanked for the continuous supply of chemicals.

4-Oxo-2-cyclopentenyl Acetate—A Synthetic Intermediate[1]

By Michael Harre, Peter Raddatz, Rainer Walenta, and Ekkehard Winterfeldt*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The present day importance of cyclopentenone derivatives in preparative organic chemistry and especially in natural product chemistry is demonstrated by the stereoselective synthesis of substituted and annelated cyclopentanone derivatives. It has been found that 4-oxo-2-cyclopentenyl acetate ("4-acetoxy-2-cyclopenten-1-one") can be used in many reactions as a substitute for cyclopentadienone, which is itself too unstable to be isolated. A large variety of polyfunctionalized cyclopentanone derivatives, as well as carbocyclic and heterocyclic annelation products, can thus be obtained in a simple way. Various stereoselective transformations of the adducts so formed are presented, using the total synthesis of brefeldin A—a typical natural product of this series—as example. Several methods for the synthesis of 4-oxo-2-cyclopentenyl acetate are outlined and, in addition, the more important methods for the enantioselective synthesis of other 4-substituted 2-cyclopenten-1-ones are discussed.

1. From Prostaglandin to Dodecahedrane—Cyclopentanes

The chemistry of the cyclopentenes, cyclopentanones and cyclopentenones has developed with increasing rapidity in the last twenty years. One of the major reasons for this has been the search for synthetic routes to the prostaglandins (*e.g.* $PFG_{2\alpha}$ **1**[2]), prostacyclins (*e.g.* PGJ_2 **2**[3]), and thromboxanes (*e.g.* A_2 **3**[4]), and to the macrolide antibiotic brefeldin A **4**[5], which exhibits some of the structural features of **1**—**3**.

Additional impetus was given to this development through the interest in cyclopentanoid terpenes, *i.e.* the acoranes **5**[6], iridoids **6**[7], spirovetivanes **7**[8], hydroazulenes **8**[9], and, particularly, the pseudoguajanolides[10] and steroids **9**, as well as in the total synthesis of hirsutic acid **10**[11], pentalenolactone **11**[12], isocomene **12**[13], and modheptene[14].

12

Finally, substances such as pentalene **13**[15,16], triquinacene **14**[16] and the tetraquinanes, pentaquinanes and hexaquinanes leading to dodecahedrane **15**[16], which have been studied primarily because of their theoretical and stereochemical interest, have also greatly enriched our understanding of the chemistry of the cyclopentanes.

13

14

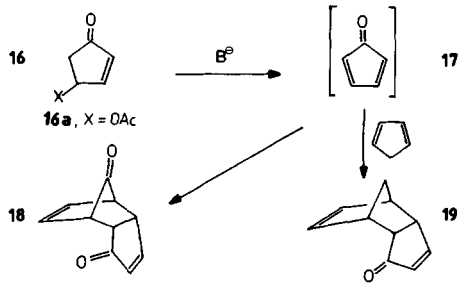
15

Many important intermediates have been prepared, interesting synthetic strategies for the synthesis of cyclopentanoid compounds have been developed, and many of the idiosyncratic and characteristic properties of the cyclopentane system have been revealed.

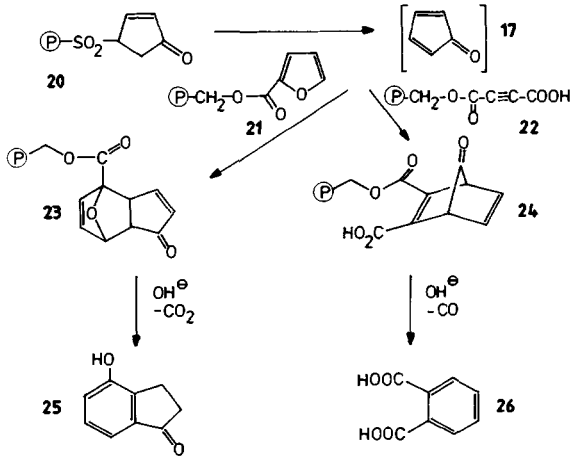
2. The Starting Material of Choice: Reactive but Tamable, Versatile but Docile

Our interest was especially aroused by the promising reactivity of substituted cyclopentanones of type **16** containing a good leaving group. These substances tend to undergo rapid elimination with formation of the unstable and highly reactive cyclopentadienone **17**[17], which, under normal conditions, generally dimerizes to **18** and cannot be isolated or manipulated in the monomeric state.

As early as 1964 *DePuy et al.*[18] were able to prevent this dimerization by addition of cyclopentadiene, which reacts



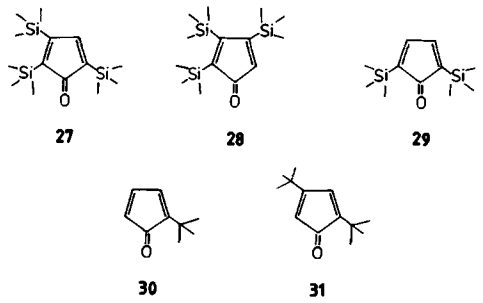
with cyclopentadienone as dienophile to give the cycloadduct **19**. In this reaction the dienone **17** thus functions exclusively as 2π component, whereas in the very fast dimerization, which excludes detection of the monomer, it obviously reacts both as dienophile as well as diene. Last year, all lingering doubts as to the actual existence of the monomer in solution were removed by a so-called three-phase test[19] (P in a circle signifies polymer).



The solid phase bound cyclopentadienone precursor **20** generates cyclopentadienone **17**, which then reacts with either the 2π-partner **22** or the 4π-partner **21**, which are also bound to the solid phase. Subsequent hydrolysis releases the cycloadducts **24** and **23**, respectively, from the polymer, and their stable end products **26** and **25** can be isolated.

The generation of the dienone **17** by pyrolysis or flash pyrolysis in the gas phase has been reported by various groups[20]; *Maier et al.*[21] recently succeeded in carrying out the first matrix isolation of this substance, in the vacuum discharge pyrolysis of the acetate **16a**. It was in connection with this experiment that *Maier et al.* also synthesized the first cyclopentadienone equivalent that proved to be stable at room temperature: The 2,3,5-trisilylated compound **27** can be handled as the monomer at room temperature, whereas the 2,3,4-isomer **28** dimerizes completely within a week. A disilylated analogue **29** has been described by *Vollhardt et al.*[22]; however, like **28**, this compound dimerizes at room temperature.

Even earlier, it had been demonstrated on several occasions that multiple substitution dramatically changes the behavior of the dienone **17**[23]. As long ago as 1966, *Garbisch et al.*[24] prepared the rapidly dimerizing *tert*-butyl derivative **30** by elimination, as well as the di-*tert*-butyl



compound **31**, which also has a short half-life at room temperature.

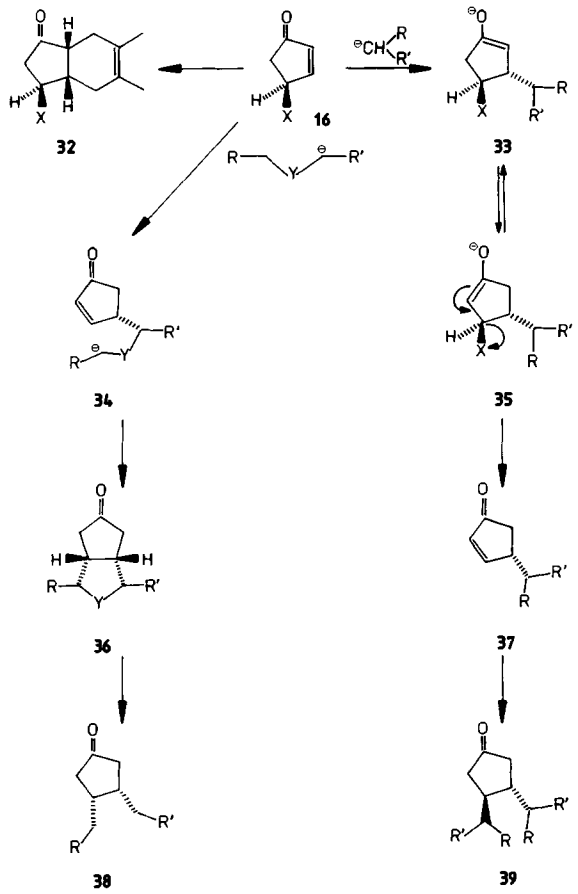
For the preparation of **31** *DeSelms* and *Schleigh*[25] carried out the *o*-quinone decarbonylation reaction described by *DeJong et al.*[26] and by *Chapman et al.*[27] on 3,5-di-*tert*-butyl-*o*-benzoquinone and were able to confirm that the product had a great tendency to dimerize[24].

The special electronic structure of compounds of this type suggested the *a priori* possibility that the high reactivity and tendency to dimerize were a result of the presence of the intact carbonyl group; thus, it appeared purposeful to seek a remedy in carbonyl derivatives having an sp^3-hybridized center. The relevant ketals[28], however, were also found to dimerize very rapidly, even more rapidly than the parent cyclopentadiene itself.

In view of these findings it seemed unlikely that cyclopentadienone **17** itself could ever be used as a synthon, so we searched for a synthetic equivalent designed to generate reaction products expected from **17** without the disadvantages of the highly reactive 4π-system.

It is one of the intellectually stimulating features of goal oriented total synthesis that the utility of a synthon is not just dependent upon its structural characteristics but on its inherent synthetic potential, *i.e.* upon the products into which it can be converted. Why try to experiment with an awkward and reactive substance when it is possible to find a stable, well behaved and reliable substitute? It seemed possible, for instance, that the acetate **16a** might be a substitute for cyclopentadienone **17**, since Michael additions, for example, should yield the same products from **16a** as from **17** (Scheme 1).

If Michael donors with CH-activities higher than that of the ring CH_2-group of the cyclopentenone derivative **16** are used, Michael addition will lead to formation of the enolate **33** without interference by transprotonation and subsequent elimination and dimerization. Under suitable reaction conditions **33** should be in transprotonation equilibrium with **35**, from which **37**—a compound which can be regarded as the mono-Michael adduct of cyclopentadienone—is formed by elimination. A further addition would be *trans*-directed, thus yielding a *trans*-disubstituted cyclopentanone such as **39**. If a bidentate donor having a short linkage chain Y is used, then *cis*-addition *via* **34** to give **36** is to be expected. If Y were designed to be preferentially cleaved, then this would also open up access to *cis*-disubstituted cyclopentanones such as **38**. It should also be possible to utilize **16** as a dienophile and to form products of the type **32**. Owing to its structure, only the role of 4π-reagent remains impossible for **16**.



Scheme 1.

The applicability of the different Michael donors, which depends on the electronic properties and bulkiness of the acceptors R and R', the influence of the chain length of Y on the configuration of the annelated ring system, and the method of bond cleavage at Y, had to be clarified in detail.

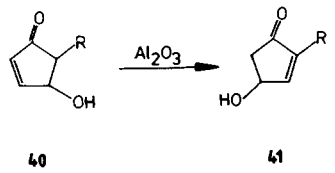
3. Enantiomer-Selective Preparation of the Intermediate

Fortunately, in contrast to cyclopentadienones, compounds of type **16** have the added advantage that they are accessible in a variety of ways and in adequate quantities, and, at the same time, exhibit the stability desirable for a starting material. A number of possible routes which should enable preparative access to 1,3-bifunctionalized cyclopentanes and cyclopentenes are listed in Table 1.

The alcohols and esters thus obtained can be used either directly or, after partial hydrolysis, esterification, or etherification, they can be oxidized to the cyclopentenones.

Table 2 lists the routes leading directly to ketones of type **16**.

It is also worth mentioning that compounds of type **40**, which can be synthesized directly from furans, can be easily isomerized to **41**, thus broadening the range of possibilities. This isomerization to the more highly substituted olefin can also be readily carried out in the absence of a hydroxyl group.



40 41

Table 1. Examples of the synthesis of 1,3-bifunctionalized cyclopentanes and cyclopentenes.

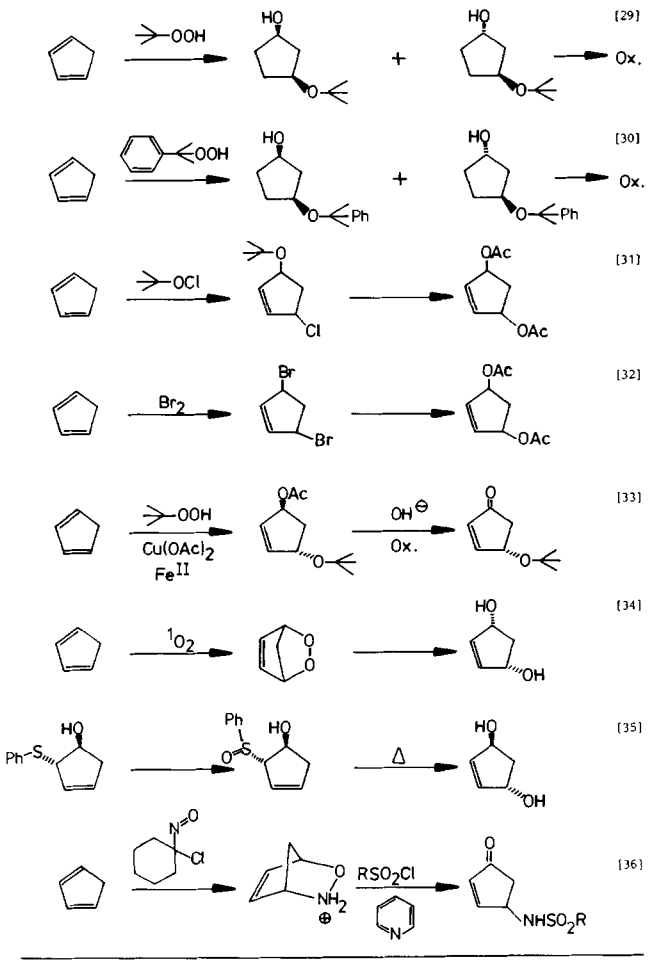


Table 2. Examples of the synthesis of bifunctionalized cyclopentenones of type **16**. NBS = *N*-bromosuccinimide.

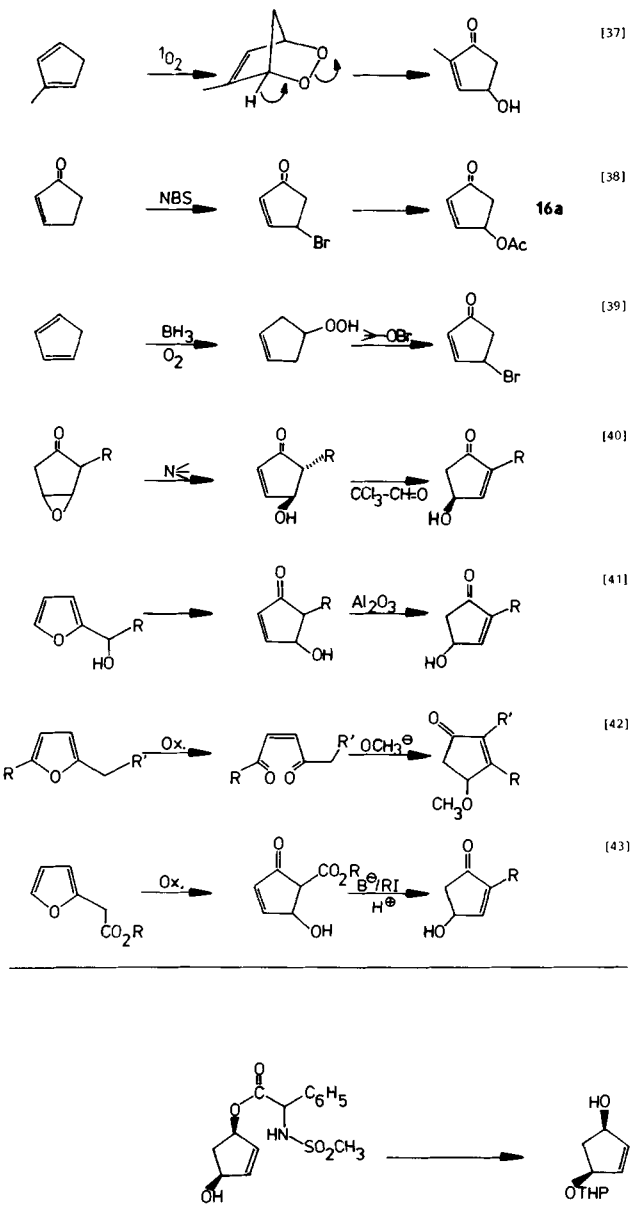
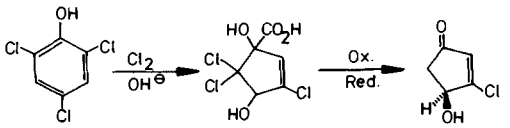


Scheme 2. Reaction sequence: 1) Diastereomerization, 2) reaction with dihydropyran, 3) alkaline hydrolysis (THP = tetrahydropyranyl).

Considering the numerous interesting classes of substances which can be synthesized with the aid of these substituted cyclopentenones it is not surprising that concerted efforts have also been made at preparing the pure enantiomers. After *Fischli et al.*[44] had introduced the concept of economic enantioselective synthesis, it was logical to apply it also to cyclopentene derivatives[45] (Scheme 2). Separation of the diastereoisomeric sulphonamides is not an easy task, and carrying out the reaction sequence in our laboratories gave cause for reflection on its utility on a larger scale.

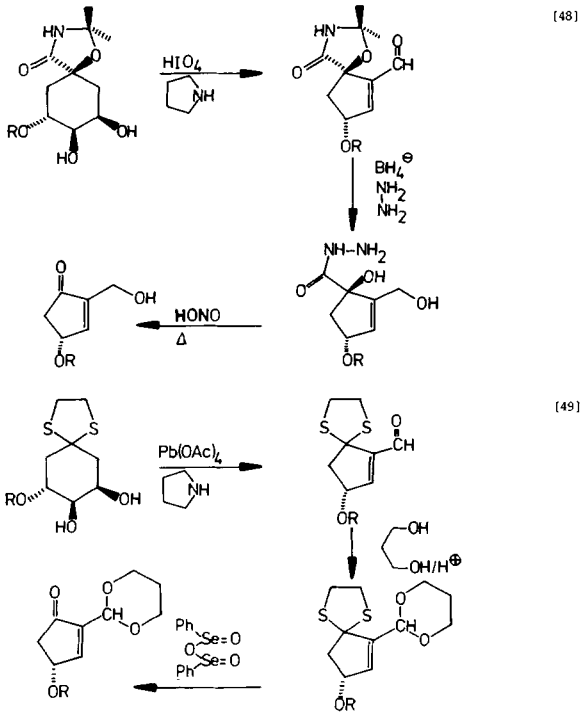
The method starting from trichlorophenol, as described by *Gill, Rickards et al.*[46] (Scheme 3), is also not unproblematical. One stage of the process is the separation of a α-hydroxycarboxylic acid racemate obtained by ring contraction of the chlorophenol. Resort to this process revealed it as being far from ideally suited for large-scale preparation: here also there was much left to be desired for the "production" of starting material.—Since the halogen atoms at the sp^3 hybridized center can be removed by selective reduction, an intermediate vinylogous acid chloride can be obtained, which can easily be converted into a substituted hydroxycyclopentenone[47].



Scheme 3.

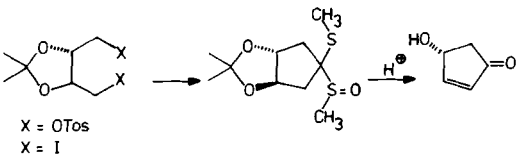
Substituted chiral alkoxycyclopentenones of this kind have also been prepared *via* two routes[48,49] from the chiral pool (quinic acid), without the need for resolution (Scheme

4). In the case of the second method it is remarkable that the configuration of the decisive chiral center is not changed at the unsaturated aldehyde stage and also that the aldehyde as well as the corresponding acetal can be obtained in good optical yield.



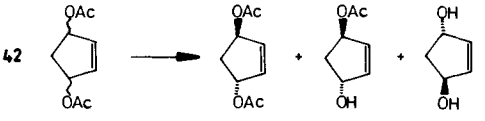
Scheme 4.

The method developed by *Ogura et al.*[50] also makes use of the chiral pool. The commercially available ditosylate obtained from D-tartaric acid is converted *via* the diiodide and alkylation into the thioketal monosulfoxide, which on acid hydrolysis affords the chiral hydroxycyclopentenone (Scheme 5).



Scheme 5.

The possibility of hydrolysis with bakers' yeast[51] was studied on a stereoisomeric mixture of **42**. The chiral *trans*-monoacetate can be isolated from the resulting mixture of compounds and oxidized to **16a**.

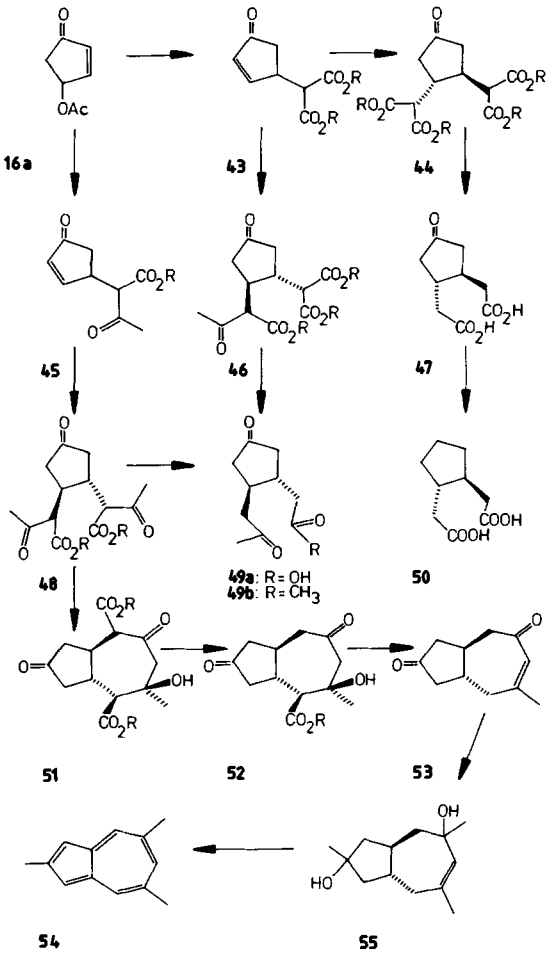


Without wishing to denigrate in any way the advances made in the field of enantioselective synthesis, experimental studies of the methods available up to now have, nevertheless, revealed the need for improvement, especially when it comes to scaling them up.

4. The Importance of Choosing the Correct Leaving Group

Whatever preparative gaps may still have to be closed in the case of the chiral starting material, the desired cyclopentenones are widely accessible using the methods outlined in Tables 1 and 2, and the problem now is which leaving group X best fulfills the requirements of Scheme 1. This is not a trivial question. A critical analysis of the scheme reveals that the margin of safety is small, and that there are many pitfalls to be avoided. If a very good leaving group is employed then there is a danger of premature elimination before the Michael addition has taken place, leading to the formation of the cyclopentadienone, which would then dimerize. Even if, against all likelihood, the high donor concentration made the Michael addition competitive with the dimerization, then the achiral nature of this intermediate would vitiate the effect of any prior chiral synthesis. This danger is also present if X itself possesses acceptor properties, for the increased acidity at the chiral center would lead to a rapid racemization in alkaline media. Too weak a leaving group X, on the other hand, would lead to various difficulties with the primary enolate anion. Since the charged group could not be ejected rapidly there would be the possibility of secondary reactions, of undesired transprotonation, and of an unfavorable addition equilibrium.

Preliminary trials using acetoacetic ester and malonic ester as donors quickly indicated that 4-oxo-2-cyclopentenyl



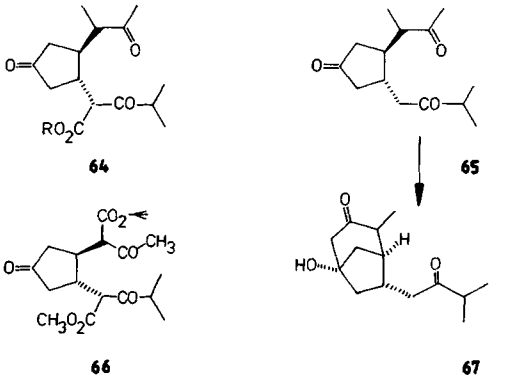
acetate **16a** is a suitable starting material[52]. Monoadducts (**43**, **45**) and bisadducts (**44**, **46**, and **48**) can be generated from malonic and acetoacetic esters. **44**, $R=CH_3$, could be shown by decarboxylation and reduction to **50** to have a *trans*-configuration, while **48**, $R=CH_3$, rapidly underwent cyclization to give the hydroazulene **51**.

Stepwise decarboxylation and dehydration of **51** furnished the unsaturated ketone **53**, an interesting intermediate product in this series which can easily be transformed by reaction with methyllithium and dehydration into trimethylazulene **54** – a further proof of the hydroazulene structure.

5. The Correct Leaving Group is not Everything!

Longer chain β-keto esters can also add to cyclopentenone derivatives **16**, to give **56**[53], from which the triketones **57** can be prepared; substituted malonic esters can also be added, followed by β-keto esters, so that, *e.g.*, the triester **58a** can be prepared and then decarboxylated in good yield to **58b**. However, the limits of the method also become apparent in this study; thus, **58a** cannot be synthesized by reversing the order of the nucleophiles. If valerylacetic ester is used in the first stage it gives **59** in 65% yield, but attempts to add the dimethyl ester of *n*-butylmalonic acid to **59** were unsuccessful. Attempts to force the second addition quickly exposed the weaknesses of this method. The two main weaknesses are a possible retro-Michael addition with dimerization of the cyclopentadienone so produced, and the great tendency of compounds of type **59** to isomerize to stable more highly substituted olefins. Thus, the range of applicability of the reaction is drastically narrowed.

These difficulties also occur on addition of substituted or branched acetoacetic esters. **60** is thermally converted into **61**, and **62**, which is formed in quantitative yield on treatment of **60** with trifluoroacetic acid, smoothly isomerizes to **63** on distillation, if all traces of acid are not carefully removed beforehand[54]. This behavior of cyclopentenones has, in principle, been known for some time, but fortunately it is unimportant for the second addition since no acid is used here. At this stage the retro-Michael reaction is a much more serious handicap, for it leads to undesired side-reactions during the treatment with base that is necessary in the case of hydroazulene cyclization.

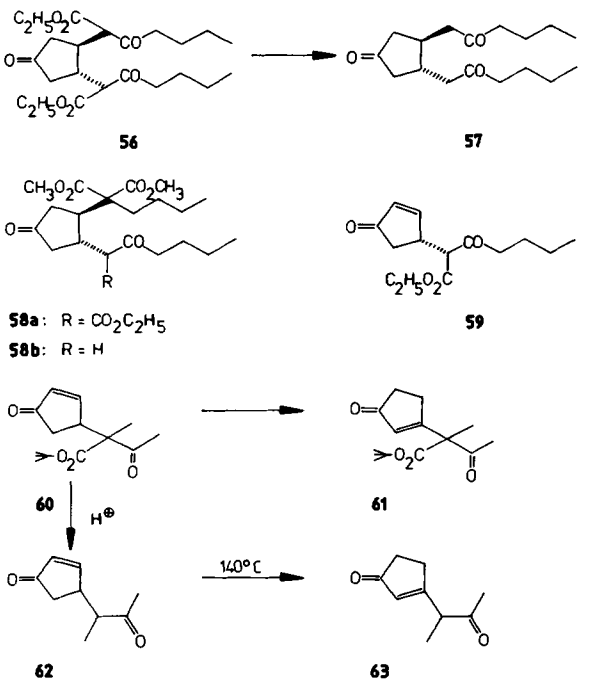


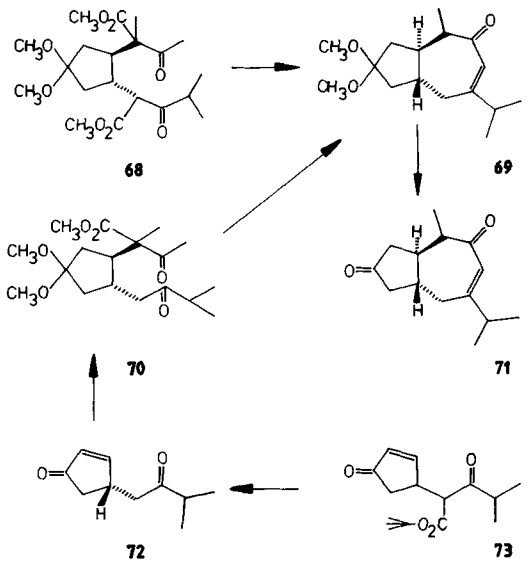
64 **65** **66** **67**

Thus, for example, **64** is accessible in good yield, but it is not possible to cyclize it to the hydroazulene. If **64** is decarboxylated to **65**, cyclization occurs even under very mildly basic conditions. However, the product can, on the basis of spectroscopic evidence (disappearance of the five-membered ring carbonyl band) be assigned the bicyclic diketone structure **67**[55]. Attempts to cyclize β-ketoester Michael adducts of general type **66** to hydroazulenes are also bedevilled by reverse reactions. It is, however, of special importance to find a reliable method for cyclization of these hydroazulene precursors having the typical terpenoid substitution pattern seen in so many natural products. The results obtained up to now suggest that it might be useful to ketalize the keto group in the five-membered ring prior to cyclization of the bisadducts **66** or **68**.

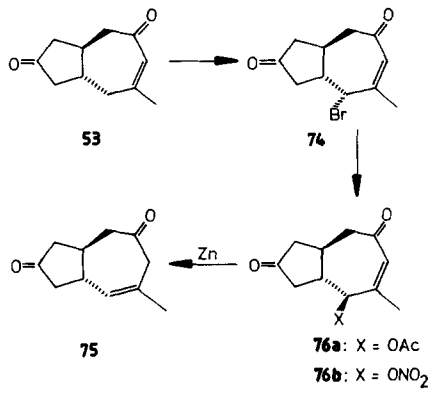
6. Cyclizations

The ketalization suggested above—easily performed with methanol/methyl orthoformate under conditions of proton catalysis—succeeds miraculously. Cyclization and decarboxylation to **69** take place without difficulty, and subsequent deprotection yields the desired diketone **71**[54]. The overall yield can be improved by using the *tert*-butyl ester **73**, which can be transformed into the monoadduct **72** by mild decarboxylation and careful distillation without isomerization. Second addition and ketalization, which take place with excellent selectivity in spite of the presence of three ketone groups, yield the cyclizable intermediate **70**, which can be transformed in high yield into **69** and **71**. Analysis of the product mixture after removing the ketal shows that **71** is always accompanied by a small quantity of the corresponding deconjugated ketone. Such a deconjugation can be achieved in high yield by reduction of γ-substituted derivatives. Investigations of this type have been made using a simple model **53**. Reaction of **53** with *N*-bromosuccinimide leads with high regio- and stereose-





lectivity to the bromoketone **74**[56]. Nucleophilic substitution yields the acetate **76a** or the nitrate **76b**, which upon reduction with zinc smoothly gave rise to the β,γ-unsaturated ketone **75**.

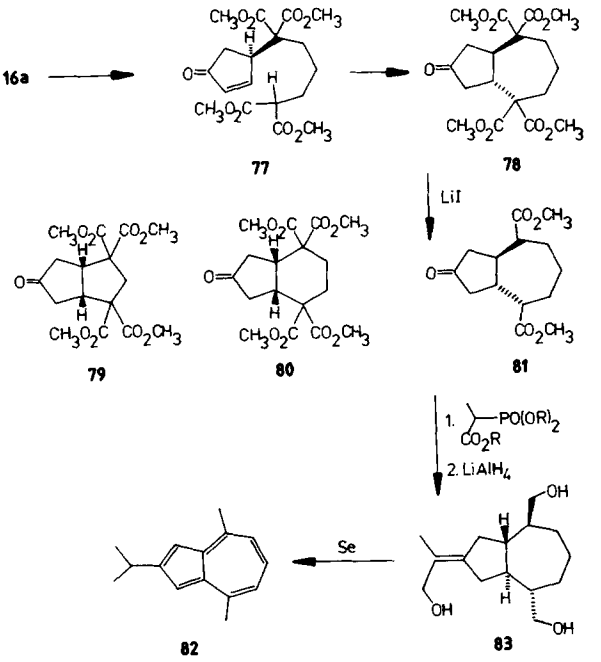


7. Annelation

As can be seen from Scheme 1, annelation with double donors is possible; the hydropentalene- and hydroindene-derivatives **79** and **80**, as well as hydroazulenes **78** can be formed. This stimulated an investigation of the stereochemistry of the reaction as a function of the length of the chain Y, the configuration being determined from NMR data of the particularly easily prepared dimethyl ketals[57]. While **79** and **80** are expectedly *cis*-annelated, *trans*-annelation occurs on formation of hydroazulenes **78** and **81**. The fact that the dimethyl ketals of **79** and **80** show very different signals, as can be expected for a *cis*-system, while in the case of the dimethyl ketal of **78** the resonances were absolutely identical, is in accord with the configurational assignment.

An intermediate product, namely **77**, could only be isolated in the case of **78**. In the case of **79** and **80**, on the other hand, the cyclization takes place immediately after addition; monocyclic addition products could not be detected.

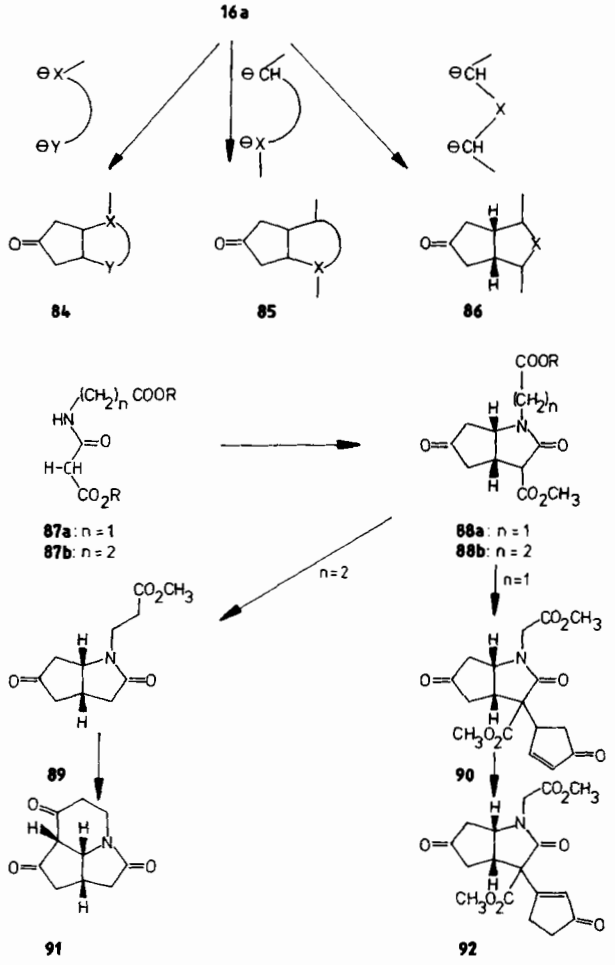
The diester **81** obtainable from **78** by nucleophilic ester cleavage has structural features that make a simple synthesis of vetivazulene **82** possible; it can be transformed by olefination and aluminate reduction into the triol **83**, which, on treatment with selenium, yields vetivazulene.



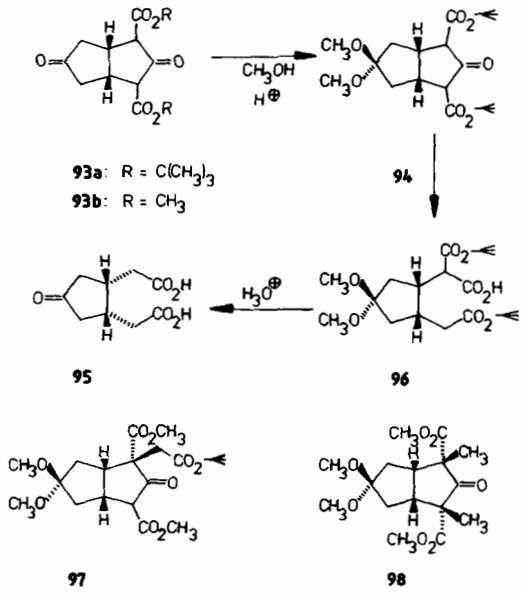
Annelations of this type can, in principle, be carried out with heteroatoms where either both donor centers, as in **84**, are heteroatoms, or, as in **85**, only one is a heteroatom and the other a carbanion. The incorporation of an heteroatom into the chain joining the two donors is another a possibility. In this case any additional carbon acidity that may be conferred by the heteroatom could be of synthetic value, while, additionally, such a center X could be a point of cleavage and lead, *via* intermediates of type **86**, to *cis*-disubstituted compounds. An example of the mixed variant is the addition of malonamides, which leads to compounds of the type **85**[57].

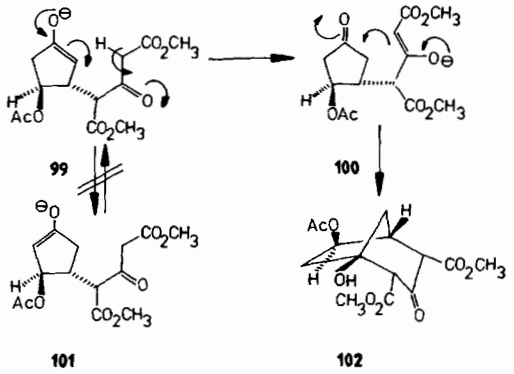
Esters **87a** and **87b** add smoothly and in good yields to **16a**; indeed, an excess of Michael acceptor must be avoided, since otherwise **88a** reacts further to give **90**, which is converted into the thermodynamically more stable unsaturated ketone **92** on treatment with acid. Cleavage of the double bond of this stable product can yield valuable intermediates. Decarboxylation of the homologous compound **88b** affords easy access to the tricyclic lactam **91** *via* a Dieckmann cyclization. Attack at the lactam carbonyl group leads to ring opening with formation of a *cis*-disubstituted cyclopentanone. The potential of this strategy was first studied on ketones of the type **93**, which are readily accessible with acetonedicarboxylic esters[57].

In order to direct the nucleophilic attack of the base at the carbonyl group flanking the ester the *tert*-butyl ester was chosen, and, in order to avoid retro-Michael reactions, the other carbonyl group was ketalized. After ring opening, in the case of the simple compound **96** hydrolyzation and decarboxylation afforded the *cis*-dicarboxylic acid **95**, whose constitution and configuration were established by comparison with authentic material. Various mono- and di-alkylated compounds can be prepared from **93a** and



93b, for example **97** and **98**, which on β-dicarbonyl cleavage yield branched analogues of **96**, from which symmetrical and/or unsymmetrical *cis*-disubstituted cyclopentanones of type **95** can be obtained. In all the additions mentioned so far, the chirality center formed in the first nucleophilic attack excellently directs the second addition; the question now remains whether the chiral center in 4-oxo-2-cyclopentenyl acetate **16a** effects steric direction even in the primary step. This point is of some importance regarding the use of optically-active **16a** as a starting material and the extent of the chirality transfer to be expected. This question can be investigated by suitable manipulation of the acetonedicarboxylate addition.

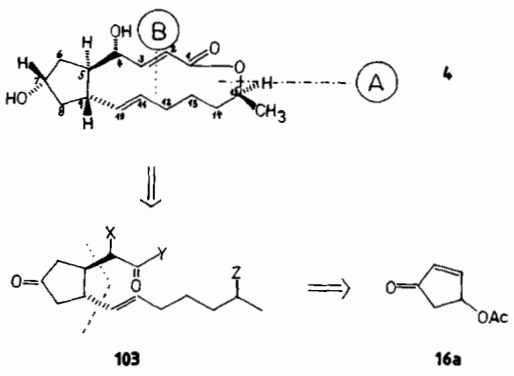




In the formation of products **93a** and **93b** with NaH in tetrahydrofuran (THF), this Michael donor reacts as postulated in Scheme 1. If the reaction is carried out in glyme with potassium *tert*-butoxide as the proton acceptor then proton transfer from the side chain competes with transprotonation in the five-membered ring, which would lead to elimination. The enolate **100** is formed, the ring carbonyl group is regenerated, there is no elimination, and nucleophilic attack at this carbonyl group leads to the bicyclo[3.2.1]octanone derivative **102**. The NMR data obtained for this compound confirm the given configuration, in which the acetoxy group is oriented *trans* to the newly generated C—C bond. There is high steric control, so the chances for chiral transfer seem good. This problem is currently under investigation.

8. Additions—The Route to Brefeldin A

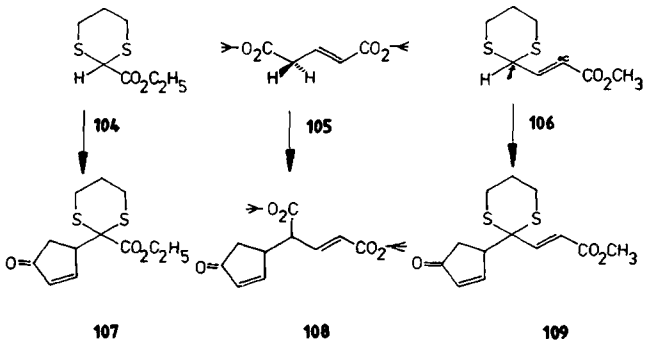
Up to now the Michael donors used have almost exclusively been 1,3-dicarbonyl compounds, and it remains to be seen whether other Michael donors can be successfully employed. The best test of the utility of a synthetic method is its employment in the stereoselective total synthesis of a complex natural product. To test the effectiveness of our preliminary steps and the flexibility of the additions on a specific and important molecule with complicated structure we have chosen the antifungal and cytostatically ac-



tive antibiotic brefeldin A **4**[5]. Its synthesis has already been accomplished by several research groups.

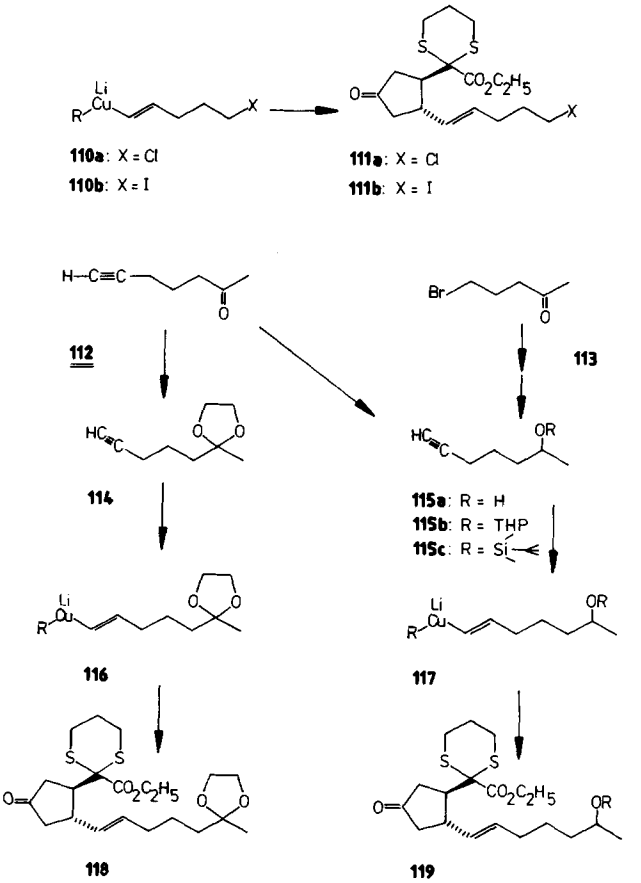
If the lactonization (line A) or the Wittig-Horner cyclization (line B) is envisaged as the ring closure step, then **103** can be regarded as tailor-made for a retrosynthetic analysis to our cyclopentenone synthon **16a**. The task in the retrosynthetic analysis is to break the target molecule up into strategically convenient parts that can be easily synthesized and brought together stereoselectively using reactions with good precedent already reported in the literature or analogous reactions which have been tested in the laboratory on model systems.

Starting from **16a** the "upper" chain would be incorporated as an α-functionalized acetic acid or possibly (in this case) as a γ-functionalized crotonic acid, while a suitably functionalized vinyl cuprate could be visualized for the "lower" chain, thus allowing the necessary 1,4-addition.



Donors **104**, **105**, and **106** looked like promising precursors for the upper chain[58]. **104** smoothly affords the adduct **107** in good yields. Its synthesis on a large scale is also reproducible. Compound **108** can be obtained in high yield by deprotonizing the di-*tert*-butyl ester **105** of glutaconic acid (avoiding self-condensation) with lithium tetramethylpiperidide, but the selectivity of the second addition to the cyclopentenone is disappointing; the acrylic ester group, competing very efficiently for the nucleophile, created selectivity problems[59]. Similar problems are encountered with **109**, which is, in addition, difficult to prepare because the Michael addition shows poor regioselectivity. Even in the nonpolar solvent toluene at −78 °C the required γ-addition product (70%) is accompanied by 30% of the α-addition product. In THF the α-addition product even preponderates, to such an extent that it can be obtained on a preparative scale under these conditions[60].— Thus, the thioketal **107** is, without doubt, the monoadduct of choice, since it fulfills all the requirements as intermediate for the synthesis of the target molecule.

The use of a Gillman reagent[61] for the "lower" chain was decided upon from the beginning. Such reagents, which can be prepared from the corresponding vinyllithium derivatives by reaction with pentynylcopper, are highly nucleophilic, and very readily undergo 1,4-addition. Although on paper there are a large number of possibilities, in practice only a small number of vinyl cuprates generated in this way are suitable[62]. Compounds **110a** and **110b**, which are easily prepared from 5-chloro-1-pentyne by addition of diisobutylaluminum hydride (DIBAH), iodination followed by iodine/lithium exchange, and reaction with 1-pentynylcopper, give good yields of **111a** and **111b**, respectively, and the selectivity with which the intermediary vinyl iodide reacts with butyllithium without attacking the iodine attached to the sp^3 hybridized center is remarkable—particularly in the case of **110b** (Scheme 6).

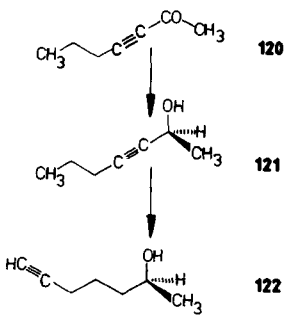


Scheme 6. R = C≡C—CH_2—CH_2—CH_2.

The complete "lower" side chain can be very conveniently incorporated using the acetylene ketone **112**. This can be prepared from methylcyclohexenone by Eschenmoser fragmentation[63]; on reduction it yields the alcohol **115a**, and on ketalization **114**. The alcohol **115a** and its derivatives **115b** and **115c** can also be obtained from the bromoketone **113** by reduction, incorporation of protecting group, and coupling with lithium acetylide.

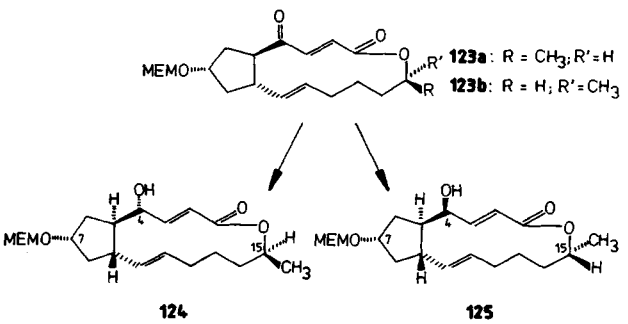
However, in these cases it is not advisable to prepare the vinyl iodide, required for production of the vinyl cuprate, by DIBAH reduction, since side-reactions, such as reductive cleavage of the ketal, occur. Instead tributyltin hydride[64] is used and the resulting intermediate reacted with iodine[65]. The additions of the ketal **116** and of the silyl ether **117c** to **107** are of particular synthetic interest. The tetrahydropyranyl ether **117b**, however, was disappointing; the yield of **119b** is poorer than that of the alcohol **119a** obtained from **117a** *via* the dianion. Although **111a** and **111b** as well as **118** and **119c** are about equally well accessible, the silyl ether **119c** was chosen for further synthesis, since, because of the sp^3 hybridization at the carbon which becomes C 15, all results can be extended di-

rectly to the corresponding chiral silyl ether. Chiral **119c** can also be obtained from ketone **120** by enantioselective reduction with *Mosher*'s reagent[66], whose special merits in the case of acetylene ketones were recognized in a comparative study by *Brinkmeyer* and *Kapoor*[67]. Isomerization of **121** with Kapa[*] using a slightly modified version of the method described by *Brown et al.*[68] drives the triple bond to the end of the chain, thus producing the chiral alcohol **122**, from which the silyl ether can be prepared in the usual way.



119c is an attractive intermediate for the synthesis of brefeldin A; since the configurations at C7 and C15 can be changed it is also useful for the investigation of several selectivity problems peculiar to this ring system.

The observation by *Corey* and *Wollenberg*[69] that the 7-MEM ether[**] of the C15 epimeric ketone **123** can be reduced with excellent stereospecificity, has always proven useful in attempts to synthesize brefeldin A. **123a**, with natural configuration at C15, yields overwhelmingly the alcohol **124**, and thus, finally, brefeldin A, whereas the 4-*epi*-15-*epi* compound **125** can be generated with about the same selectivity from the 15-*epi* compound **123b**.

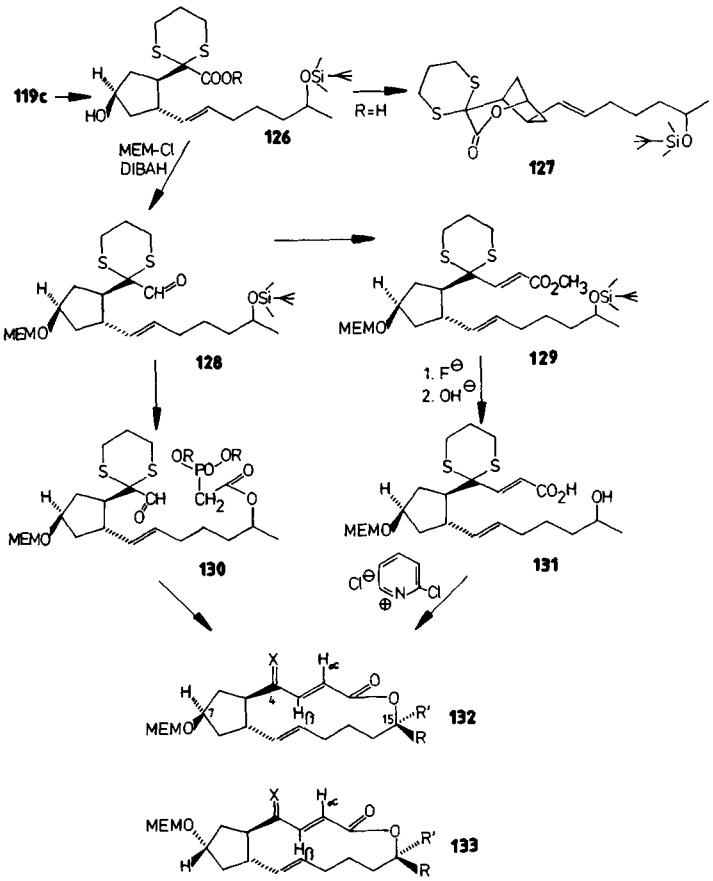


It is unlikely that the distant C15 asymmetric center steers the reduction directly; more plausible is that the configuration at C15 forces the lactone ring to assume a conformation in which the substituents on the ring do not, if possible, enter the ring cavity. *Still*[70] has recently demonstrated typical examples of such conformational stereoselectivity.

The C15 configuration not only affects the reduction but also has a considerable influence on the rate of lactonization[69]. The 4,7-bis-MEM etherated alcohol with natural configuration at C15, cyclizes more rapidly than its epimer. Again different lactone conformations might be responsible. With cyclization, generally product-close transition-states are to be expected, carrying all the strain inherent in the product ring.

To further clarify this point we synthesized both C7 epimeric alcohols and cyclized them using two completely different methods, so that the transition states would be as dissimilar as possible. The influence of C15 on ring conformation ought to be greater than that of C7. We then reduced the C4 ketones in both series, in order to check whether C7 in the close neighborhood really has less effect than the more distant but conformation-dictating C15. This was accomplished in a few stages starting from the easily accessible silyl ether **119c**.

The bulkiness of the dithioketal ensured high stereoselectivity in the production of the β-hydroxy compound **126** by selective reduction of the 7-keto group in **119** with selectride (lithium tri-*sec*-butylhydridoborate). The configuration was confirmed by formation of the lactone **127**[71]. If the carboxy group in **126** is present as MEM ester and the hydroxy group as MEM ether **126** can be reduced directly to the aldehyde **128** using DIBAH in toluene. **128** can be cyclized by both techniques. A Wittig reaction yields the unsaturated ester **129**, which after generation of the free hydroxy acid **131** can be cyclized, using *Mukaiyama*'s[72]



Scheme 7. Substituents of **132** and **133**:

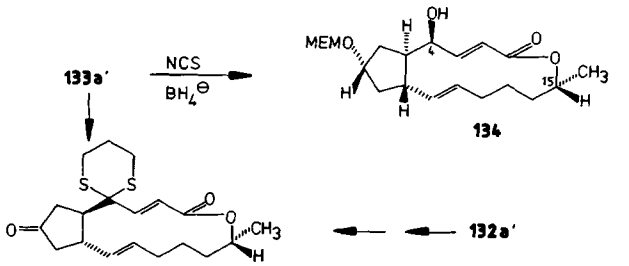
pyridinium salt, to the lactone mixture **132a/132a'**. Under these conditions, in the case of the educt **131** the configuration at C 15 has no influence on the lactonization rates: The two C 15-epimeric lactones **132a** and **132a'** are formed in equal proportions (Scheme 7). The situation is quite different for the Wittig-Horner cyclization[73] of phosphonate **130**, which is easily accessible from aldehyde **128** *via* cleavage of the silyl ether and DCCI esterification with phosphonoacetic acid. The cyclization was initiated at room temperature by the slow, controlled addition of a proton acceptor into the solution [$LiOC(CH_3)_3$] or the suspension [NaH], by means of a dosing pump. After 15 hours, almost 50% of the starting material had reacted. The product formed consisted mainly ($\approx 10:1$) of the stereoisomer **132a'**, whose configuration could easily be established[58]. If the configuration at C 7 of the alcohol **126** is inverted, using *Mitsunobus'* reagent[*][74], it can be cyclized like its epimer *via* the aldehyde and phosphonate; here also only one stereoisomer is produced in overwhelming preponderance, namely **133a'** (Scheme 7). This configuration was easily confirmed. Since thioketal cleavage with *N*-chlorosuccinimide (NCS) and reduction with tetrahydroborate leads to **134**, which, after MEM ether-cleavage, yields 4,15-*epi*-brefeldin A, there can be no doubt that the Wittig-Horner cyclization has in this case yielded the 15-*epi*-thioketal **133a'** stereoselectively.



The fact that both cyclization products **133a'** and **132a'** lead to the same ketone **135** after MEM ether-cleavage and oxidation shows that the same stereoselectivity controls the cyclization of the 7β-MEM ether series[58]. The C 15 configuration-dependent conformations in both C 15-epimer series can be seen by comparison of the proton magnetic resonance spectra of **132a** and **133a** with **132a'** and **133a'**. In the series having a "natural" C 15-configuration the signal of the β-proton of the acrylic ester group is observed at $\delta = 7.16$, while in the spectrum of the Wittig-Horner cyclization product having an "unnatural" configuration this is shifted to $\delta = 6.72$. Such a large difference is difficult to explain in terms of the spatial differences caused by a proton or methyl group, and a configuration-dependent conformation with different relative positions and a different degree of immersion into the π system of the double bond between C 10 and C 11 is a much more satisfactory explanation. This suggestion is supported by the fact that such an interaction with the π system can be recognized in the C4,C15-epimeric alcohols **133c** and **133d** on account of the very different signals of H 10 and H 11. In the case of the natural C 15-configuration **133d** the signals of these protons are noticably split, whereas the protons in **133c** exhibit a normal two proton multiplet. Here again a transannular conformational effect is perceptible. To summarize, it emerges that the configuration at C 15 has no effect on the lactonization rate if a dithioketal is present on C 4. *Bartlett et al.*[75] have reported a similar finding for the C 4 ketone. The Wittig-Horner cyclization, on the other hand, unambiguously favors the 15-*epi*-configuration (**132a'**, **133a'**), independent of the configuration at C 7. Hence, one now has a stereoselective cyclization process for both configurations at C 15[76].

Finally, the 4-keto group is reduced. In the case of the C 15-epimeric ketones (**133b** and **133b'**) this leads to brefeldin A and 4,15-*epi*-brefeldin A, respectively[77]. Additionally, the 7β-MEM ethers of type **132** too yield exclusively two alcohols (**132c** and **132d**), the stereoselectivity of the reaction again being determined by the configuration at C 15. Everything points to a conformational effect. It is hardly possible to explain in any other way the fact that the comparatively distant C 15 has a greater influence on the reduction of the ketone group at C 4 directly adjacent to the five-membered ring than the spacial configuration of an MEM-ether group in its close neighborhood.

9. Outlook

The results referred to here, even though they are restricted to a narrow field, give some impression of the many possibilities offered by 4-oxo-2-cyclopentenyl acetate **16a** for the stereoselective and enantioselective synthesis of cyclopentanoid compounds and natural products. The broad field of heteroatom-activated donors and double donors, which lead stereoselectively to various nonaromatic heterocyclic ring systems, has hardly been explored. Such double additions can either lead directly to polycyclic systems or, the heteroatom, *e.g.* sulfur, can serve for further functionalization and/or as a built-in cleavage point. In the case of the monoadducts the main emphasis is on the manifold possibilities of intermolecular and intramolecular cycloadditions guaranteeing regioselectivity. Products such as **72**, **107**, **108** and **109**, open up interesting synthetic pathways, and in this connection it is worth remembering the smooth isomerization to more highly substituted cyclopentenones (see **40**→**41**) in order to correctly assess the flexibility of the methodology. If the correctly substituted product is not available directly as a cyclization product then functionality transformations as they are being intensively studied at the moment can be brought into play. In view of this considerable potential it would appear that 4-oxo-2-cyclopentenyl acetate is a very promising and versatile synthetic building block.

The results obtained in Hannover have been taken from the diploma or doctoral theses of Vera Osterthun, Heinrich Schneider, Yetkin Köksal, Peter Raddatz, Michael Harre, Rainer Walenta and Karl-Heinz Marx. Andreas Meier and Martin Bohnenpoll also provided important contributions as part of their practical research studies at the Institute of Or-

[*] *Mitsunobus'* reagent = triphenylphosphane/dimethylazodicarboxylate.

ganic Chemistry.—The enthusiastic cooperation and skillful approach of our co-workers in performing the experiments is gratefully acknowledged. We wish to thank Dr. H. Rudolf, Bayer AG, Leverkusen, for generous gifts of cyclopentenones, Degussa Hanau for gifts of silver acetate, Hoechst AG and other companies for generous gifts of chemicals. Thanks are also due to the Deutsche Forschungsgemeinschaft (Wi 206/34, Wi 206/35—6) and the Fonds der Chemischen Industrie for their financial assistance.

Chain and Ring Phosphorus Compounds—Analogies between Phosphorus and Carbon Chemistry**

By Marianne Baudler*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Up to about 15 years ago compounds with a skeleton of phosphorus chains or rings were regarded as "exotic" in the field of nonmetal chemistry. Aside from a number of examples of molecules with two P atoms directly bonded to each other and a few sporadically discovered monocyclic ring compounds, only solids of undefined composition and structure were known. Since then the state of our knowledge in this sector has made considerable progress: between PH_3 and its derivatives on the one hand, and the high-molecular modifications of elementary phosphorus on the other, an unexpected variety of well defined compounds have been discovered, showing many similarities to the analogous compounds of carbon. However, surprises can still occur even with "small" phosphorus-containing molecules, as shown by the likewise recently discovered field of phosphorus three-membered ring compounds.

1. Introduction

Compounds with a skeleton of trivalent phosphorus atoms are generally very reactive: they can easily be attacked by oxidation on the free electron pair of the P atoms, and disproportionate like other nonmetal compounds containing homonuclear element-element bonds. Thus, until recent times only a limited number of such compounds were known[1], except for the much earlier investigated tetraorganodiphosphanes $R_2P—PR_2$. In the last decade advances in preparative techniques[2] and in the ability of spectroscopic methods to characterize reactive species led to a considerable broadening of our knowledge of chain and ring-type phosphorus compounds, and concomitantly some striking analogies to carbon chemistry have come to light:

The existence of constitutional and configurational isomers;
valence tautomerism in phosphorus compounds;
stable phosphorus three-membered ring compounds;
the existence of phosphorus compounds with annelated ring systems.

In this review article we shall demonstrate the similarities between phosphorus and carbon chemistry, discussing the various classes of compounds with P_n skeletons from several points of view.

2. Phosphorus Hydrides (Phosphanes)

All compounds having a skeleton of trivalent phosphorus atoms can be regarded as derivatives of the corresponding phosphorus hydrides (phosphanes). Since 1965 an unexpectedly wide variety of binary phosphorus-hydrogen compounds have been found, in addition to the already long-known hydrides PH_3 and P_2H_4, in the volatile hydrolysis products of calcium phosphide or in the thermolyzates of diphosphane[3a-d]. The present situation is shown in Table 1.

The general formula of the individual phosphanes can be deduced with certainty from their mass spectra. To exclude disproportionation as far as possible during the investigation, the specimens of the substances are introduced directly into the ion source of the mass spectrometer at various vaporization temperatures (−196 °C to +50 °C) by means of a special injection system[7,8]. The ionization takes place by bombardment with 10—12 eV electrons or by field ionization. The identification of the low-hydrogen phosphanes relies on the dependence of the field ionization spectra on the vaporization temperature of the specimens and the different proportions of the individual compounds present in different fractions. The correlation is fully confirmed by means of electron bombardment excitation, by the constant intensity ratios of the corresponding peaks with respect to those of other molecule-ions when

Table 1. Phosphorus hydrides (phosphanes) with more than two P-atoms in the molecule

Phosphanes	P_nH_{n+2}	P_nH_n	P_nH_{n-2}	P_nH_{n-4}	P_nH_{n-6}	P_nH_{n-8}	P_nH_{n-10}	P_nH_{n-12}	P_nH_{n-14}
Triphosphanes	P_3H_5	P_3H_3							
Tetraphosphanes	P_4H_6	P_4H_4	P_4H_2						
Pentaphosphanes	P_5H_7	P_5H_5	P_5H_3	P_5H					
Hexaphosphanes	P_6H_8	P_6H_6	P_6H_4	P_6H_2					
Heptaphosphanes	P_7H_9	P_7H_7	P_7H_5	P_7H_3	P_7H				
Octaphosphanes	P_8H_{10}	P_8H_8	P_8H_6	P_8H_4	P_8H_2				
Nonaphosphanes	P_9H_{11}	P_9H_9	P_9H_7	P_9H_5	P_9H_3				
Decaphosphanes		$P_{10}H_{10}$	$P_{10}H_8$	$P_{10}H_6$	$P_{10}H_4$	$P_{10}H_2$			
Undecaphosphanes			$P_{11}H_9$	$P_{11}H_7$	$P_{11}H_5$	$P_{11}H_3$			
Dodecaphosphanes			$P_{12}H_{10}$		$P_{12}H_6$	$P_{12}H_4$	$P_{12}H_2$		
Tridecaphosphanes						$P_{13}H_5$			
Tetradecaphosphanes						$P_{14}H_6$	$P_{14}H_4$	$P_{14}H_2$	
Pentadecaphosphanes							$P_{15}H_5$		
Hexadecaphosphanes							$P_{16}H_6$	$P_{16}H_4$	$P_{16}H_2$
Heptadecaphosphanes								$P_{17}H_5$	
Octadecaphosphanes								$P_{18}H_6$	$P_{18}H_4$

By analogy with the boranes, the individual compounds are characterized by the number of phosphorus and hydrogen atoms, for example P_3H_5 is triphosphane(5), P_3H_3 is triphosphane(3), *etc.*

The phosphanes make up a number of homologous series with general formulas P_nH_{n+2}, P_nH_n, P_nH_{n-2}, ... up to P_nH_{n-14}. The first series comprises the open-chain phosphanes, the second series the monocyclic compounds (and with more than five P atoms, probably also single rings with side chains), while the other series comprise the low-hydrogen hydrides with condensed ring systems. As can be seen from the synopsis in Table 1, as the phosphorus content of the compound increases, the tendency to form chain-type phosphanes P_nH_{n+2} as opposed to ring compounds shows a marked decrease. From $n=5$ upwards first the monocyclic phosphanes P_nH_n, and from $n=7$ upwards the polycyclic hydrides P_nH_{n-2m} ($m=1-7$) are clearly preferred.

Up to now it has been possible to prepare triphosphane(5)[4], pentaphosphane(5)[5], and heptaphosphane(3)[6] in pure form. The other hydrides have only been isolated and studied in the form of sometimes strongly enriched mixtures. The reason for this is that the very similar properties of the individual compounds, and particularly their marked tendency to disproportionate, makes them very difficult to separate.

the ionization voltage is reduced from 70 eV to the appearance potential. The occasional complete absence of low-phosphorus disproportionation products such as PH_3, P_2H_4, P_3H_3, and P_3H_5 shows that the phosphorus-rich compounds are not formed thermally or by electron bombardment within the mass spectrometer itself. If the measurement conditions mentioned are observed, then clearly the results will hardly be influenced by any simultaneous disproportionation of the phosphanes in the mass spectrometer. In contrast, if the specimen temperature is increased to above 100 °C, or if the ionization voltage is raised above 15 eV, rearrangement or decomposition reactions clearly become predominant.

In addition to this, triphosphane(5), tetraphosphane(6), pentaphosphane(7), and pentaphosphane(5) have been characterized by a complete analysis of their phosphorus nuclear magnetic resonance spectra (see Sections 2.1 to 2.4). Compared to mass spectroscopy, this method has the advantage that the phosphane specimens can be investigated below room temperature and possibly in solution, so that disproportionation reactions can be reliably excluded. However, in the case of compounds with high phosphorus and low hydrogen contents, the applicability of nuclear magnetic resonance spectroscopy for characterization purposes is often limited by unduly low solubilities[9]. Satisfactory agreement is generally obtained between the composi-

tions determined for phosphane mixtures by mass spectrometry and by NMR spectroscopy.

The higher phosphanes with more than two phosphorus atoms in the molecule are generally relatively volatile. Their spontaneous combustibility in air gradually decreases with increasing phosphorus content. In contradiction to many statements in the literature and in textbooks, diphosphane and its higher homologs are not explosive: they burn quietly in atmospheric oxygen, giving a white smoke of phosphorus pentoxide. However, explosions with phosphanes can arise in two ways: the product mixture contains hydrogen at the same time, as is possible in the volatile hydrolysis products of metal phosphides; then, in presence of oxygen an explosive gas mixture is produced, which is ignited by the spontaneously flammable phosphane. Also, when phosphanes disproportionate one of the end products is PH_3, whose boiling point lies at $-88\,^{\circ}C$; thus, sealed glass ampoules containing phosphane specimens can suddenly be destroyed by explosion, even when cooled in dry ice, owing to the build-up of PH_3 pressure. On the other hand, the disproportionation, which takes place to an appreciable extent already above $-30\,^{\circ}C$, and which is greatly accelerated by heat and light, gives rise to phosphorus-rich, solid, yellow decomposition products. The phosphanes of the series P_nH_{n+2} and P_nH_n from $n=3$ upwards can be dissolved in diphosphane, molten white phosphorus, cyclooctatetraene, and the hydrocarbon mixtures 1-methylnaphthalene/phenanthrene and toluene/phenanthrene[7,8]. While the phosphorus-rich hydrides are clearly stabilized in the white phosphorus and the aromatic solvents, the solutions in diphosphane are extremely unstable and tend to decompose spontaneously. A violent reaction sometimes takes place with chlorinated hydrocarbons.

2.1. Triphosphane(5)

The first indication of the existence of triphosphane(5) **1** was given by the presence of an excessive number of lines in the Raman spectrum of diphosphane, P_2H_4[10]. The increase in the intensity of these attendant lines when the specimen was illuminated or warmed, with simultaneous evolution of PH_3, led to the conclusion that the diphosphane was undergoing disproportionation with **1** as the product:

$$2\,P_2H_4 \rightarrow \underset{\mathbf{1}}{P_3H_5} + PH_3$$

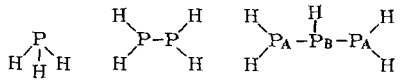
Mass-spectrometric identification of the compound was achieved by *Royen et al.* in 1964, who decomposed small amounts of Mg_3P_2 and Ca_3P_2 mixed with the corresponding arsenides, nitrides, or germanides with dilute hydrochloric acid, directly at the mass spectrometer[11]. Shortly afterward fractions strongly enriched in **1** could be isolated on a preparative scale during the separation of the reaction products of commercial calcium phosphide[12] with pure water[3a,b]. At approximately the same time, *Fehlner*[13] detected the formation of **1** mass spectrometrically in the thermolytic and photolytic decomposition of diphosphane.

In 1968 *Fehlner* described a process for the gas-phase photolysis of diphosphane in a closed-circuit apparatus, by means of which about 10 mg of 95%-pure **1** was obtained in 100 min[14,15]. The chain structure of **1** was established in 1972, by analysis of the $^{31}P\{^1H\}$-NMR spectrum[16].

In recent years we were able to develop a reproducible process for the production of nearly pure **1** in milliliter quantities by the thermolysis of liquid diphosphane at normal pressure followed by fractionation of the thermolyzate[4]. In a typical experiment 81 mL[17] of highest-purity P_2H_4 was subjected to thermolysis for 25 h at 35 °C, yielding in the first instance 63 mL of clear yellow thermolyzate with a content of **1** amounting to about 20% of the total phosphorus in the reaction mixture (P-%). At this stage the thermolysis was stopped to avoid any further reaction of **1** and formation of solid phosphorus hydrides, which initiate autocatalytic decomposition of the thermolyzate. Compound **1** was then isolated by cocurrent distillation in a mixture with P_2H_4 (pressure 10^{-4} torr, bath temperature -40 to $+90\,^{\circ}C$) followed by fractional condensation. At $-40\,^{\circ}C$ 9.1 ml of a condensate of highly enriched **1** (86.9 P-%) was obtained, which still contained some P_2H_4 and P_4H_6, and at $-196\,^{\circ}C$ 45 mL of P_2H_4. By repeated distillation, the purity of **1** was improved to 96%. The degree of difficulty of the process is comparable to that of the preparation of diphosphane[18].

1 is a colorless liquid which in the absence of air and light remains stable for many days at $-80\,^{\circ}C$. At room temperature and in diffuse daylight it rapidly turns yellow and later decomposes to give yellow solid products.

The triphosphane **1** can be regarded as a derivative of monophosphane **2** and diphosphane **3**, in which individual hydrogen atoms have been replaced by the bulkier PH_2 group. This substitution increases the bond angle at the



2 **3** **1**

phosphorus, as shown by the parameters of the ^{31}P-NMR spectrum[4] (see Table 2): the δ-downfield shift in the sequence **2**—**3**—**1** and the increase in the absolute value of the negative $^1J(PP)$ coupling constant following the transformation of **3** into **1** are, according to current experience[20], attributable to a change in the hybridization of the phosphorus—increasing s-character of the bonding orbitals. The relative high-field position of the P_B signal of **1** provides evidence that the hydrogen in the PH group is more acidic.

Table 2. ^{31}P-NMR parameters of P_3H_5 (**1**), P_2H_4 (**3**), and PH_3 (**2**), solvent-free, **1** and **3** at 213 K, **2** at 183 K [a].

Phosphane	δ	$^1J(PP)$	Ref.
1	P_A: −156.7 P_B: −173.2	−146.6	[4]
3	−205.0	−108.2 [b]	[16]
2	−235.1		[16]

[a] δ-Values with *negative* sign for *upfield* shift; coupling constants in Hz. [b] Determined from the ^1H-undecoupled room-temperature spectrum [19].

Table 3. Raman spectrum of P_3H_5 (**1**), solvent-free, 193 K. Frequencies, relative intensities (0 to 100) with polarization filter (parallel to the E-vector of the laser light), degree of depolarization $\rho_{p\perp}$, state of polarization, and assignment of the bands.

Frequency [cm^{-1}]	Int.	Degree of depolarization State of polarization	Assignment

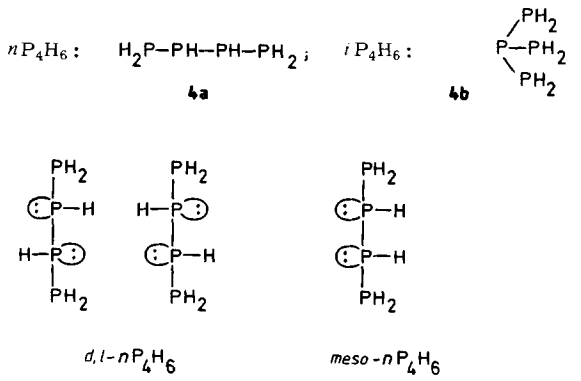
The broadening of the angle at the central phosphorus atom has been confirmed from the Raman spectrum of **1**[4] (see Table 3). If the molecule is treated to a first approximation as a three-mass model of the C_{2v} point group[21], the PPP valence angle is obtained as 104.5° ($\sphericalangle$HPH in **2**: 93.8°[22]; $\sphericalangle$HPP in **3**: 95.2°[23]). The valence force constant of the P—P bond amounts to 1.77 mdyn/Å and the deformation constant of the PPP valence angle to 0.15 mdyn/Å.

2.2. Tetraphosphane(6)

Heating of liquid diphosphane and triphosphane(5) gives rise to phosphane mixtures containing varying amounts of tetraphosphane(6) **4**[3,7,8]. Initially, the diphosphane and triphosphane thermolyzates consist only of chain-type hydrides, which, when the thermolysis is continued, react further in part to form pentaphosphane(5) **5**. Clearly, the formation of the cyclopentaphosphane is thermodynamically more favorable, and is in any case accelerated by autocatalysis. Phosphane mixtures with a content of **4** of 35—40 P-% in addition to **1** (about 55 P-%), **3** (5—10 P-%), and **5** (<5 P-%) are obtained from diphosphane thermolyzates (see Section 2.1) by removal of **2** and **3** at −40 °C under high vacuum[8]. In this way 100 mL of **3** can be made to yield about 15 mL of a markedly tetraphosphane-rich, solid-free, yellow phosphane mixture of medium viscosity. Further enrichment of **4** by distilling off **1** is impossible, because this causes further disproportionation, with the formation of **5**. The highest content of **4**, amounting to 48 P-%, has been obtained by the thermolysis of pure **1** at +10 °C under high vacuum[7].

Beginning with tetraphosphane(6), the structural problem of the chain-type phosphanes becomes increasingly complex as a result of isomerism. If an unbranched phosphorus chain is present, **4** should be characterized in the $^{31}P\{^1H\}$-NMR spectrum by an AA'BB' system for the two different types of P atoms (in the middle and at the ends of the chain). However, the spectrum obtained in practice contains considerably more lines (Fig. 1). According to the complete analysis of the spectrum[24], there are two reasons for this: in the first place, when either **3** or **1** is subjected to thermolysis, **4** is always formed as a mixture of the two constitutional isomers, with unbranched and branched



phosphorus chains (**4a** and **4b**). To the branched isomer **4b**, which can be regarded as tris(phosphino)phosphane, there corresponds an A_3B spin system (Fig. 1e).

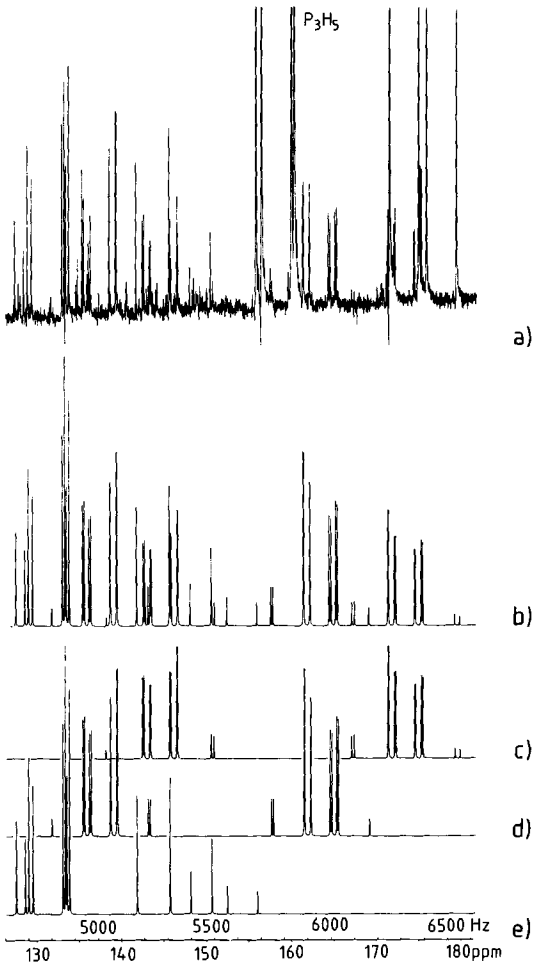


Fig. 1. $^{31}P\{^1H\}$-NMR spectrum of a P_3H_5/P_4H_6 mixture at 190 K (36.434 MHz). a) Observed spectrum; the eight intense signals correspond to the A_2B system of P_3H_5. b) Calculated spectrum of P_4H_6. c)—e) Separate simulation of the individual isomers (*d,l-n*P_4H_6, *meso-n*P_4H_6, *i*P_4H_6).

On the other hand, in isomer **4a** both of the middle P atoms are chiral centers, since each of them has three different substituents and a free electron pair. Assuming that the inversion at the P atoms is slow in comparison with the NMR timescale, which is plausible in the case of chain-type phosphanes below room temperature[25], there will

then be two configurational isomers that can be distinguished by NMR spectroscopy, namely the *d,l*- and the *meso*-forms. Both diastereomers are characterized by an AA'BB' system (Fig. 1c and d, respectively), that of the *meso*-isomer being shifted somewhat downfield[26]. Superimposition of the calculated individual spectra (Fig. 1b) reproduces the experimental P_4H_6 spectrum very satisfactorily. At the same time, this provides a clear indication of the existence of isotetraphosphane(6) and of the two configurational isomers of *n*-tetraphosphane(6). The relevant ^{31}P-NMR parameters and the relative isomer frequency are summarized in Table 4[24].

Table 4. ^{31}P-NMR parameters of iP_4H_6 (**4b**), *meso*-nP_4H_6 (*meso*-**4a**), and *d,l*-nP_4H_6 (*d,l*-**4a**) in a P_3H_5/P_4H_6 mixture at 190 K; *J* in Hz.

$(H_2P_A)_3P_B$	$H_2P_B—P_AH—P_{A'}H—P_{B'}H_2$	
4b	*meso*-**4a**	*d,l*-**4a**
30.2%	41.7%	28.1%
$\delta_A = -131.3$	$\delta_A = \delta_{A'} = -137.5$	$\delta_A = \delta_{A'} = -144.6$
$\delta_B = -147.6$	$\delta_B = \delta_{B'} = -163.0$	$\delta_B = \delta_{B'} = -173.0$
$J_{AB} = -178.7$	$J_{AB} = J_{A'B'} = -163.8$	$J_{AB} = J_{A'B'} = -168.2$
	$J_{AA'} = -168.5$	$J_{AA'} = -181.2$
	$J_{A'B} = J_{AB'} = +24.2$	$J_{A'B} = J_{AB'} = +25.7$
	$J_{BB'} = -3.0$	$J_{BB'} = +7.1$

The ratio of **4a** to **4b** is influenced by the method of production of (**4**): in the thermolyzates of **1** the fraction of **4b** is always smaller than that in the thermolyzates of **3**. Very probably **4a** is formed preferentially according to reaction (a), and **4b** according to reaction (b).

$$\underset{\mathbf{1}}{P_3H_5} + \underset{\mathbf{1}}{P_3H_5} \rightarrow \underset{\mathbf{4a}}{H_2P—PH—PH—PH_2} + \underset{\mathbf{3}}{P_2H_4} \quad (a)$$

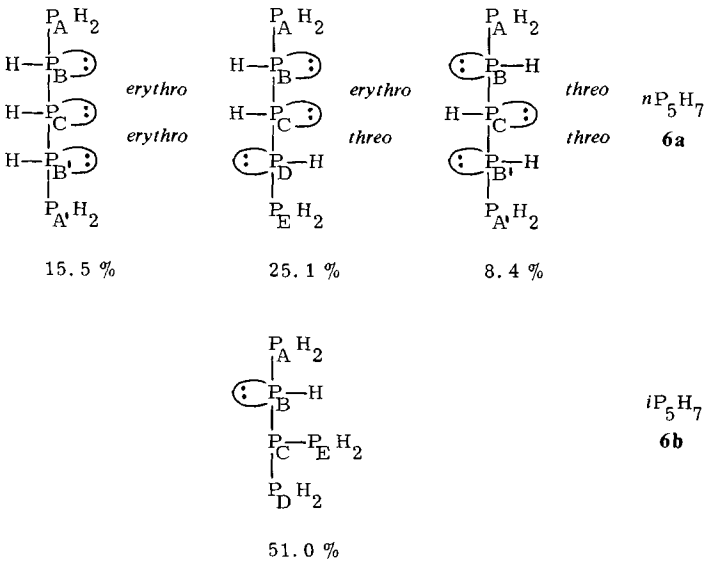
$$\underset{\mathbf{3}}{P_2H_4} + \underset{\mathbf{1}}{P_3H_5} \rightarrow H_2P—\underset{\displaystyle PH_2}{\underset{|}{P}}—PH_2 + \underset{\mathbf{2}}{PH_3} \quad (b)$$

4b

2.3. Pentaphosphane(7)

Phosphane mixtures of P_2H_4 thermolyzates or fractions of the diphosphane preparation with a high content of **1** and **4** show, in their $^{31}P\{^1H\}$-NMR spectra, additional low-intensity signal groups between -100 and -180 ppm, which correspond to pentaphosphane(7), **6**[27]. The proportion of **6** is at the most 5—10 P-%. Any further enrichment leads to decomposition with the formation of cyclophosphanes. **6** is not stable for long periods even at $-70\,^\circ C$. Clear proof of the existence of **6** and of its structural arrangement is based on a complete analysis of the $^{31}P\{^1H\}$-NMR spectrum[27,28]. According to the latter, all four of the possible isomers distinguishable by NMR spectroscopy, namely *d,l*-isopentaphosphane(7) **6b** and the three diastereomers of *n*-pentaphosphane(7) **6a** (*erythro/erythro*, *erythro/threo*, and *threo/threo*) coexist; of these, **6b** shows the highest relative frequency.

Together with the data concerning the low-phosphorus homologs, the ^{31}P-NMR parameters of **6** make it possible to derive general relationships for the chemical shifts and the ^1J(PP)-coupling constants of chain-type phosphanes as



a function of their structural parameters (*a, b, c:* number of phosphorus atoms in the α, β, and γ positions)[29]:

$$\delta(^{31}P) = -224.7 + 26.4a + 33.7b - 6.0c$$
$$^1J(PP) = -110.5 - 31.6a - 13.0b + 1.9c$$

Clearly, the chemical shifts depend strongly on the chain length and the extent of the branching: α and β PH_2 groups bring about a strong downfield shift, the β-effect being still greater than the α effect. γ PH_2 groups bring about a slight upfield shift. It should be noted that in alkanes, though the displacement increments for α, β, and γ carbons[30] are quantitatively smaller, they are of the same sign as, and of similar magnitude ratios to the corresponding increments in the case of the chain-type phosphanes. These relationships allow predictions concerning the appearance of the ^{31}P-NMR spectra of the various structurally isomeric phosphanes P_nH_{n+2} with $n = 6$—9. This offers the prospect of being able to characterize these extremely unstable homologs, obtainable only in low concentrations, not only by mass-spectrometry but also by ^{31}P-NMR spectroscopy.

2.4. Pentaphosphane(5)

When phosphane mixtures with a high content of **1** and **4** are subjected to mild thermolysis ($-20\,^\circ C$, high vacuum), the main product formed is cyclopentaphosphane **5**[5].

$$\underset{\mathbf{1}}{P_3H_5} + \underset{\mathbf{4}}{P_4H_6} \rightarrow \underset{\mathbf{5}}{P_5H_5} + 2\,\underset{\mathbf{2}}{PH_3}$$

$$\underset{\mathbf{4}}{P_4H_6} + \underset{\mathbf{4}}{P_4H_6} \rightarrow \underset{\mathbf{5}}{P_5H_5} + \underset{\mathbf{3}}{P_2H_4} + \underset{\mathbf{2}}{PH_3}$$

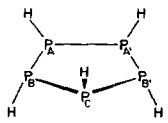
Since **2** and **3** are removed continuously from the reaction system, the final residue of a low-temperature vacuum thermolysis of this type consists of highly enriched **5** (about 80 P-%), in addition to **2**, **3**, **1**, **4**, and other phosphorus hydrides, which give ^{31}P-NMR signals between $\delta = +50$ and -80 and very probably also have cyclic

structures. Largely pure **5** (96 P-%) can then be obtained as a dilute and relatively stable solution by extraction with aromatic hydrocarbons and subsequent removal of the more volatile hydrides under vacuum[5]. The methanolysis of tetrakis(trimethylsilyl)cyclotetraphosphane **7** also leads to **5** *via* a complex reaction, the product being obtainable in 97% purity[31,32].

$$\underset{\mathbf{7}}{(Me_3SiP)_4} \xrightarrow[-Me_3SiOMe]{+MeOH} \underset{\mathbf{5}}{P_5H_5}$$

The compound is positively identified from the mass spectrum (20 eV, 23 °C) with a high relative intensity of the M^+ ion ($m/z = 160$; rel. int. 97%), and in particular from the AA'BB'C spin system in the $^{31}P\{^1H\}$-NMR spectrum (Fig. 2, Table 5)[7].

Table 5. ^{31}P-NMR parameters of P_5H_5 (**5**) in 1-methylnaphthalene/phenanthrene (≈ 1%) at 300 K; J in Hz.



$\delta_A = \delta_{A'}$	=	− 36.4
$\delta_B = \delta_{B'}$	=	− 31.7

$J_{AA'}$	=	−234.6
$J_{AB} = J_{A'B'}$	=	−220.6
$J_{BC} = J_{B'C'}$	=	−219.4
$J_{AB'} = J_{A'B}$	=	+ 27.5
$J_{AC} = J_{A'C}$	=	+ 31.6
$J_{BB'}$	=	+ 44.3

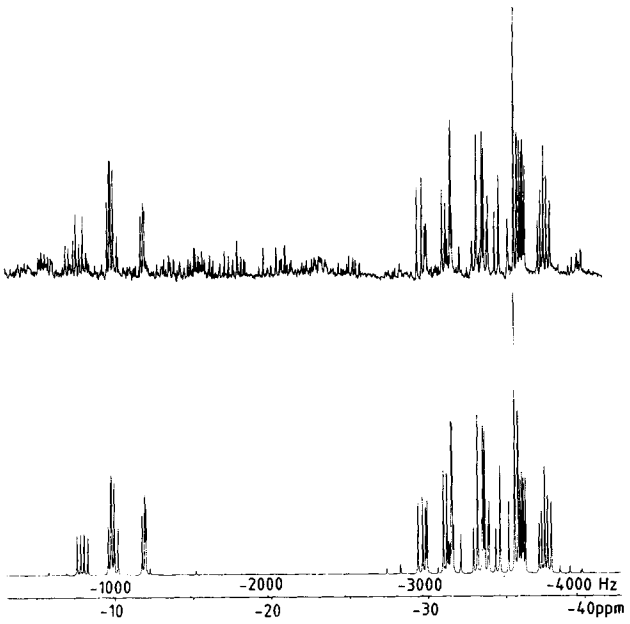

Fig. 2. Observed (upper) and calculated (lower) $^{31}P\{^1H\}$-NMR spectrum of P_5H_5 in 1-methylnaphthalene/phenanthrene (≈ 1%) at 300 K (101.25 MHz).

From the calculated ^{31}P-NMR parameters it is evident that the configurational isomer obtained is the one with the maximum *trans*-arrangement of the adjacent free electron pairs or hydrogen atoms. **5** is the basic compound of the long-known pentaorganocyclopentaphosphanes, $(PR)_5$[1], which according to the results of X-ray structure analysis show the same configuration for $R = CF_3$[33] and C_6H_5[34].

2.5. Heptaphosphane(3)

Heptaphosphane(3) **8** is one of the phosphorus-rich hydrides with a particularly high tendency of being formed. Thus, it can always be detected in considerable concentrations by mass spectrometry in fractions from the preparation of diphosphane and in P_2H_4 thermolyzates[3b]. According to *von Schnering*[35], it is also observed as the main product in the mass spectrum of the hydrolysis products of Ba_3P_{14} and Ba_2P_7Cl. Preparative amounts of pure **8** can be obtained[6] by mild solvolysis of the trimethylsilyl compound **9**[36,6].

$$\underset{\mathbf{9}}{(Me_3Si)_3P_7} \xrightarrow[-3\,Me_3SiOMe]{+3\,MeOH} \underset{\mathbf{8}}{P_7H_3}$$

In this case **8** occurs in the form of white flakes which turn pale yellow on drying and persistently retain traces of the solvent. On contact with atmospheric oxygen there appears to be no change, but subsequent mass spectrometry reveals the presence of P_7H_3O[37]. On prolonged exposure to water a number of phosphorus acids are formed. The X-ray amorphous substance is completely insoluble in aliphatic and aromatic hydrocarbons, alcohols, ethers, acetonitrile, carbon disulfide, dimethylformamide, dimethyl sulfoxide, hexamethylphosphoric acid triamide, as well as in **3** and in molten white phosphorus. This phenomenon is attributable to a still unexplained process of physical aggregation, which is also observed in substituted polycyclic phosphanes P_nR_m ($m < n$) with small organic groups R (see Section 6). The aggregation forces are relatively weak, since **8** occurs with a high intensity in the mass spectrum (12 eV) already at a vaporization temperature of 60 °C, and can be transformed by metalation directly into derivatives with discrete $P_7H_2^-$, P_7H^{2-}, and P_7^{3-} anions (see Section 3). The compound **8** has a remarkable thermal stability; it decomposes and turns red at about 300 °C.

The tricyclic structure of **8** can be reliably ascertained by analogy of the molecular vibration spectra[6] with those of metalated derivatives of known structures (see Section 3).

3. Metalated Phosphanes

Since the structures of metal phosphides have already been reviewed in recent years[35,38], in what follows we shall only deal with the compounds obtained by direct metalation of phosphanes. In common with the entire chemical behavior of the higher PH_3 homologs—except for their self-ignition in air and their easy disproportionation—their metalation has also never been studied until very recently.

3.1. Trilithium Heptaphosphide

3 reacts with *n*-butyllithium or lithium dihydrogen phosphide with simultaneous disproportionation to give trilithium heptaphosphide **10** and phosphane **2**; in the first case *n*-butane is also formed[6].

$$9\,P_2H_4 + 3\,n\text{BuLi} \xrightarrow[-20\,^\circ C]{\text{THF}} \underset{\mathbf{10}}{Li_3P_7} + 11\,PH_3 + 3\,n\text{BuH}$$
$$\mathbf{3} \qquad\qquad\qquad\qquad \mathbf{2}$$

$$9\,P_2H_4 + 3\,LiPH_2 \xrightarrow[-20\,^\circ C]{\text{Monoglyme}} Li_3P_7 + 14\,PH_3$$

The first step is undoubtedly the metalation of **3** to lithium trihydrogen diphosphide **11**, which immediately reacts further with an excess of **3** with disproportionation and transmetalation to give the triphosphide **12**. The latter under-

$$\underset{\mathbf{11}}{LiH_3P_2} + \underset{\mathbf{3}}{P_2H_4} \rightarrow \underset{\mathbf{12}}{LiH_4P_3} + PH_3$$

goes an analogous transformation to that of **11**, so that tetraphosphides, pentaphosphides, *etc.* are produced in succession. Since the PH groups in phosphanes are generally more acidic than PH_2 groups[4,24], and are therefore also preferentially metalated, not only do chain branchings occur preferentially but also polycyclic compounds can be formed in addition to monocyclic ones.

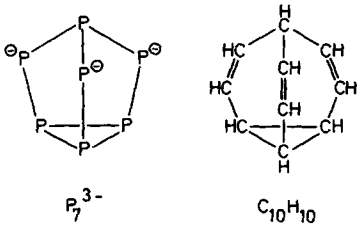
A similar complex reaction results in the nucleophilic cleavage of white phosphorus with lithium dihydrogen phosphide, in which once more **10** is produced as the end product in a yield of 95%[39].

$$3\,P_4 + 6\,LiPH_2 \rightarrow \underset{\mathbf{10}}{2\,Li_3P_7} + 4\,PH_3$$

10 is stabilized by the addition of three solvent molecules (tetrahydrofuran, monoglyme), whose removal leads to decomposition. With chloro(trimethyl)silane the silyl compound **9**, obtained by *Fritz et al.* in another way[36], and with methyl bromide the methyl derivative P_7Me_3 **13**[40], are produced.

The structure of the P_7 skeleton has already been elucidated by *von Schnering* by X-ray structure analysis in the case of the compounds Sr_3P_{14}[41], Ba_3P_{14}[42], and **9**[43]: it is a tricyclic cage, analogous to P_4S_3.

The low-temperature ^{31}P-NMR spectrum of **10**[6] (Fig. 3) shows three separate groups of signals at $\delta = -57$, -103, and -162 in the intensity ratio of 1 : 3 : 3, corresponding to the three different types of phosphorus atoms (at the apex, in the negatively charged bridges, and in the three-membered ring). According to the result of a complete spectrum analysis[44], the finely split "doublet" in the high-field region and the low-field "quartet" correspond respectively to the P atoms in the three-membered ring and to the single atom at the apex, while the pseudo-triplet is produced



P_7^{3-} $C_{10}H_{10}$

by the P-nuclei bound to the lithium. Surprisingly, increasing line-broadening sets in above $-35\,^\circ C$, until at room temperature the only remaining observable feature is a nonspecific broad signal. A further rise of the temperature produces at $+50\,^\circ C$ as the average spectrum a singlet at $\delta = -119$, which becomes completely sharp at $+80\,^\circ C$ (in monoglyme). The low-temperature spectrum reappears on cooling.

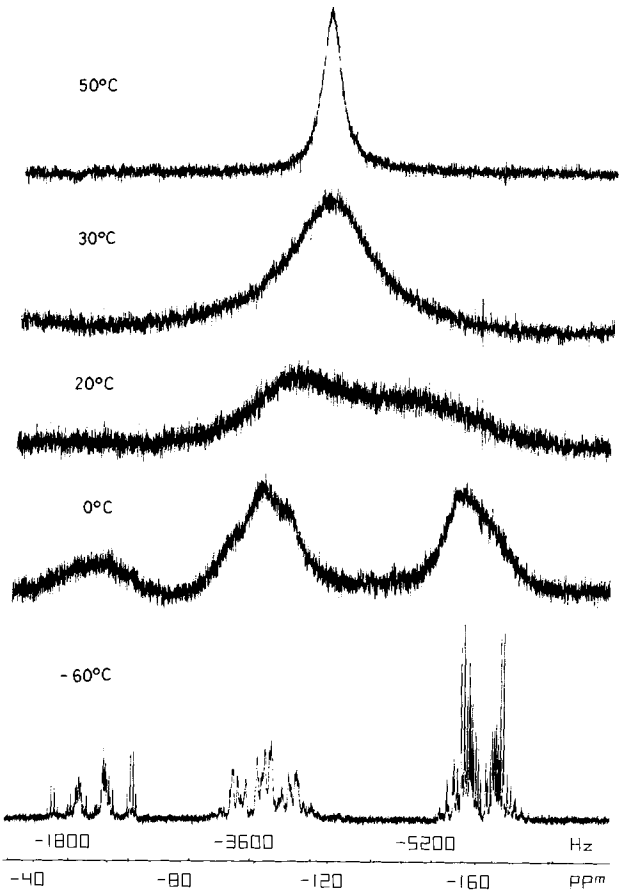


Fig. 3. ^{31}P-NMR spectrum of Li_3P_7 in [D_8]-tetrahydrofuran (saturated at 195 K) as a function of temperature (36.434 MHz).

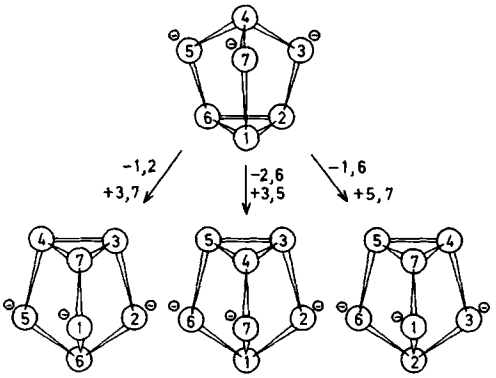
The reversible temperature variation of the ^{31}P-NMR spectrum of **10** is caused by a dynamic process known as reversible valence tautomerism (degenerate Cope rearrangement)[45] and has been thoroughly investigated in carbon chemistry in the case of bullvalene[46a-c]. In fact, the P_7^{3-} ion and the $C_{10}H_{10}$ hydrocarbon have three essential structural elements in common: they each contain a three-membered ring which markedly reduces the activation energy for the Cope rearrangement, and in addition a threefold symmetry axis and three easily-movable electron pairs.

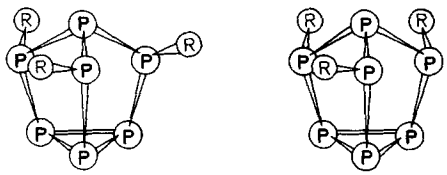
In the course of the intramolecular rearrangement of the P_7^{3-} ion P—P bonds are continually broken and new ones formed, and on account of the threefold symmetry axis, the anion is repeatedly re-formed.

By means of three reversible Cope rearrangements of equal statistical weight, each involving the breaking of one bond in the three-membered ring ($-1,2$ or $-2,6$ or $-1,6$) and the formation of a new P—P bond ($+3,7$ or $+3,5$ or $+5,7$), the P atoms in the three-membered ring are successively transformed into bridge phosphorus atoms, while the original bridge atoms change into three-membered ring



atoms with migration of the electron pairs. Each of the seven phosphorus atoms can end up in any of the possible positions by appropriate further rearrangements, so that in all there are $7!/3 = 1680$ valence-tautomeric forms. At room temperature this dynamic process is rapid in comparison with the NMR time scale, so that all seven P atoms are equivalent. The activation enthalpy ($\Delta H^{\neq} = 59.12$ kJ/mol) calculated by *Gleiter et al.*[47] agrees well with the temperature-dependent ^{31}P-NMR studies, and is of the same order of magnitude as in bullvalene ($\Delta H^{\neq} = 53.53$ kJ/mol)[48]. Accordingly, the P_7^{3-} ion is a typical fluctuating molecule.

The valence tautomerism is naturally limited to the heptaphosphide *ion*. In the methyl compound **13** the substituents are fixed by covalent bonds at the bridge phosphorus atoms. Since the configuration of the latter is not specific in the methylation of **10**, **13** is obtained as a mixture of

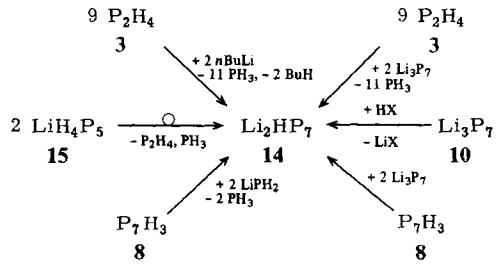


13a **13b**

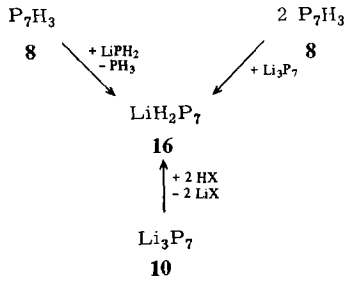
two isomers (**13a** and **13b**), of which, for steric reasons, **13a** is preferred over a statistical frequency distribution[40].

3.2. Dilithium Hydrogen Heptaphosphide and Lithium Dihydrogen Heptaphosphide

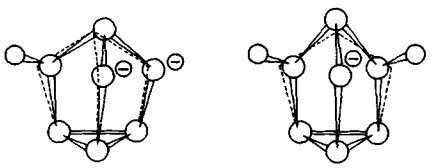
In the metalation of **3** with *n*-butyllithium a red-orange oil appears before the formation of **10**; this consists essentially of dilithium hydrogen heptaphosphide **14**[49]. Pure **14** can be obtained by reacting **3** with Li_3P_7 (4.5 : 1), and is isolated by low-temperature crystallization as a bright orange solvent adduct[49]. **14** is also formed in the partial metalation of P_7H_3 **8** with $LiPH_2$ or **10**, and in the decomposition of lithium tetrahydrogen cyclopentaphosphide **15** and the partial protolysis of **10**[49].



Lithium dihydrogen heptaphosphide **16** is also produced under modified stoichiometric conditions in the lithiation of **8** or the protolysis of **10**[50]. The best way to prepare it is by reacting **8** with Li_3P_7 at $-78\,^{\circ}C$, when it is obtained as a bright orange, amorphous solvent adduct[50].



The composition and the structure of **14** and **16** are established by a complete analysis of their ^{31}P-NMR spectra. In the case of **16** it was only possible to analyze the spin system for the symmetric isomer **16a** (see Table 6)[49,50]. As shown by the NMR parameters, the P_7 cage in **14** and **16**



14 **16**

is clearly distorted compared with **10** (shown by the broken lines), as a result of the partial hydrogen substitution.

Like dihydrobullvalene, **14** should be capable of a degenerate Cope rearrangement between two valence tautomers. According to temperature-dependent ^{31}P-NMR studies[49] coalescence signals develop as the temperature is raised, thus confirming such a process.

At room temperature **14** and **16** decompose with the formation of dilithium hexadecaphosphide **17**, which can be isolated in the form of large octahedral crystals as a solvent adduct. The P_{16}^{2-} ion shows the constitution recently determined by *von Schnering et al.*[38,51] in the case of the Ph_4P^+ salt by X-ray structure analysis, as is evident from the six signal groups (intensity ratios 2 : 1 : 1 : 1 : 1 : 2) in the ^{31}P-NMR spectrum of **17** (Fig. 4).

Table 6. ^{31}P-NMR parameters of Li_3P_7 (**10**) [44], Li_2HP_7 (**14**) and LiH_2P_7 (symmetrical isomer **16a**), in each case in tetrahydrofuran (saturated), **10** and **14** at 213 K, **16a** at 193 K; J in Hz.

3.3. Lithium Tetrahydrogen Cyclopentaphosphide, Lithium Trihydrogen Diphosphide, and Lithium Tetrahydrogen Triphosphide

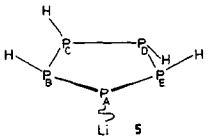
In the low-temperature metalation of **3** with *n*BuLi or $LiPH_2$ (−70 °C), the first reaction product that can be detected by ^{31}P-NMR spectroscopy is lithium tetrahydrogen cyclopentaphosphide **15**[52]. Its formation undoubtedly takes place in a rapid series of metalation and disproportionation reactions in which the highly reactive monolithiated chain-type phosphanes LiP_nH_{n+1} are first formed, which cannot exist in the presence of **3**. As in the case of the hydrides, when the chain length is $n=5$ cyclization to the thermodynamically more favorable five-membered ring compound takes place.

$$\underset{\mathbf{11}}{LiH_3P_2} \xrightarrow[-PH_3]{+P_2H_4} \underset{\mathbf{12}}{LiH_4P_3} \xrightarrow[-PH_3]{+P_2H_4} LiH_5P_4 \xrightarrow[-PH_3]{+P_2H_4} LiH_6P_5$$

$$\underset{\mathbf{3}}{LiH_6P_5} + P_2H_4 \rightarrow \underset{\mathbf{15}}{LiH_4P_5} + 2\,PH_3$$

15 can be obtained pure in solution, and by analysis of the ^{31}P{^{1}H}-NMR spectrum it has been clearly characterized as the monolithium salt of pentaphosphane(5) **5** (Table 7)[52].

Table 7. ^{31}P-NMR parameters of LiH_4P_5 in tetrahydrofuran (saturated) at 203 K; J in Hz.



5

$\delta_A = -101.9$	$J_{AB} = -360.8$
$\delta_B = -\ 7.4$	$J_{AE} = -352.0$
$\delta_C = -\ 79.3$	$J_{BC} = -240.3$
$\delta_D = -\ 50.6$	$J_{CD} = -237.4$
$\delta_E = +\ 15.7$	$J_{DE} = -219.6$
	$J_{AC} = +\ 5.5$
	$J_{AD} = +\ 12.8$
	$J_{BD} = +\ 25.9$
	$J_{BE} = +\ 80.0$
	$J_{CE} = +\ 3.9$

Above −30 °C **15** disproportionates to form **14**, for which the marked stability of the tricyclic P_7 skeleton is responsible.

$$\underset{\mathbf{15}}{2\,LiH_4P_5} \rightarrow \underset{\mathbf{14}}{Li_2HP_7} + P_2H_4 + PH_3$$

If further amounts of the metalation agent are added to the reaction system, also small quantities of lithium trihydrogen diphosphide **11** ($\delta_A = -167.0$, $\delta_B = -271.7$, $J_{AB} = -205.3$ Hz) and lithium tetrahydrogen triphosphide **12** ($\delta_A = -123.0$, $\delta_B = -251.7$, $J_{AB} = -266.8$ Hz; all at 203 K) are detectable by ^{31}P-NMR spectroscopy[52].

4. Homocyclic Phosphorus Three-Membered Ring Compounds

Ever since the mass-spectrometric detection of the existence of triphosphane(3)[3a] as the first member of the

monocyclic phosphane series P_nH_n, the synthesis of isolable compounds with a phosphorus three-membered ring skeleton has become a challenge for preparative nonmetal chemistry. Although P_3H_3 can be separated in small amounts from phosphane mixtures by gas chromatography[53], its preparation on a preparative scale is made difficult by the extremely high rate of rearrangement into the five-membered ring compound **5**. However, since the reactivity of phosphorus hydrides can generally be reduced by suitable substitution of the hydrogens, the possibility of synthesizing relatively stable triorganocyclotriphosphanes $(PR)_3$ did not seem to be excluded.

The first derivative of P_3H_3, the pentafluoroethyl compound **18**, was described by *Cowley et al.*[54a] in 1970. In the reaction of the diiodophosphane **19** with mercury a mixture of the corresponding cyclotriphosphane and cyclotetraphosphane was obtained, which could be separated by fractional condensation. **18** was then identified by mass spectrometry and by gas density-molecular weight determination.

$$\underset{\mathbf{19}}{C_2F_5PI_2} \xrightarrow{Hg} \underset{\mathbf{18}}{(PC_2F_5)_3} + (PC_2F_5)_4$$

However, a little later *West et al.*[54b] reported that in the reaction taking place the five-membered ring compound $(PC_2F_5)_5$ was produced in place of **18**. This controversy persisted for over half a decade, until in 1976 *Mills et al.*[54c] were able to ascertain the identity of **18** by ^{31}P-NMR spectroscopy.

At the same time and independently, our Cologne group succeeded after prolonged efforts[55] in synthesizing the phenyl compound **20**, whose formation during the cyclocondensation of the diphosphane **21**[56] with phenyldichlorophosphane was unambiguously demonstrated by ^{31}P-NMR spectroscopy[57]. However, **20** cannot be isolated in the pure state, since even in solution and below room temperature it transforms relatively rapidly *via* the cyclotetraphosphane **22** into the thermodynamically stable five-membered ring compound **23**.

$$\underset{\mathbf{21}}{Me_3Si(Ph)P{-}P(Ph)SiMe_3} + PhPCl_2 \xrightarrow[-2\,Me_3SiCl]{} \underset{\mathbf{20}}{(PPh)_3}$$

$$\xrightarrow{o} \underset{\mathbf{22}}{(PPh)_4} \xrightarrow{o} \underset{\mathbf{23}}{(PPh)_5}$$

4.1. Syntheses

It has been shown in recent years that triorganocyclotriphosphanes may have considerable kinetic stability, depending on the substituent R on the three-membered ring, so that they are formed in various reactions and can often be isolated in the pure state[3c].

A general route for the generation of a phosphorus three-membered ring skeleton is the [2+1]-cyclocondensation of a bifunctional 1,2-diorganodiphosphane with an organodihalophosphane. This reaction path leads to uniformly or mixed-substituted cyclotriphosphanes.

$$X(R^1)P{-}P(R^1)X + R^2PY_2 \xrightarrow[-2XY]{} (PR^1)_2PR^2$$

Up to now the following possibilities have been verified: a) for $X=SiMe_3$, $Y=Cl$: $R^1=R^2=Ph$[57]; $R^1=Ph$, $R^2=Et$[57b]; $R^1=Ph$, $R^2=Me$[57b]; $R^1=Ph$, $R^2=iPr$[58]; $R^1=Ph$, $R^2=iBu$[58]; b) for $X=K$, $Y=Cl$: $R^1=R^2=tBu$[59]; $R^1=Ph$, $R^2=iPr$[58]; $R^1=tBu$, $R^2=iPr$[60].

A comparison of the leaving groups X on the diphosphane shows that the formation of potassium chloride generally takes place already at considerably lower temperatures than does the cleavage of chloro(trimethyl)silane. The latter is sterically hindered, particularly with bulky substituents R^1, and can thus be achieved only above 0 °C or room temperature, which is a disadvantage for the generation of thermally labile cyclotriphosphanes. On the other hand, the basic phosphide attacks the already-formed three-membered ring compound and favors a rearrangement into the comparatively more stable cyclotetra- and cyclopentaphosphanes. Thus, the cyclocondensation of the salts can only be successfully achieved in practice if the action of the educt on the reaction product is prevented by carrying out the reaction heterogeneously in a nonpolar solvent.

A synthetic route for cyclotriphosphanes that is nonspecific for the size of the ring is the dehalogenation of an organodihalophosphane by a metal.

$$RPX_2 + M^{II}(2\,M^I) \rightarrow \frac{1}{n}(PR)_n + M^{II}X_2(2\,M^IX)$$
$$n=3,\ 4,\ 5$$

The same reaction has long been used for the preparation of organo cyclophosphanes with $n>3$[1]. Thus, it is only preparatively efficient for cyclotriphosphanes when these possess a considerable stability and show an appreciable tendency to form. This is the case for $R=C_2F_5$[54a], *t*Bu[61,59], *s*Bu[62], *i*Pr[62], *c*Hex[63], and iC_3F_7[64]. In spite of this, one always obtains a mixture of oligomers of various ring sizes, which has to be separated by fractional distillation or crystallization[61-64]. However, this process is particularly suitable for making kinetically stable cyclotriphosphanes on a preparative scale.

Not significant from the preparative standpoint, but interesting on systematic grounds, is the cyclization of 1,3-dihalo-1,2,3-tri-*tert*-butyltriphosphanes **24** which have recently become available[65] to the *tert*-butyl compound **25**[66]. This reaction corresponds fully to the classical synthesis of cyclopropanes by dehalogenation of 1,3-dihalogenpropanes; the use of lithium hydride instead of a metal is advantageous, merely because of the temperature-sensitivity of **24**.

$$\underset{\mathbf{24},\ X=Hal}{X(tBu)P{-}P(tBu){-}P(tBu)X} + 2\,LiH \rightarrow \underset{\mathbf{25}}{(PtBu)_3} + 2\,LiX + H_2$$

Surprisingly, the cyclohexyl compound **26** is obtained in good yield by the action of carbon disulfide on the corresponding tetraphosphide **27**. The first step in this complex

reaction is very probably the insertion of a CS_2 molecule into the metal-phosphorus bond.

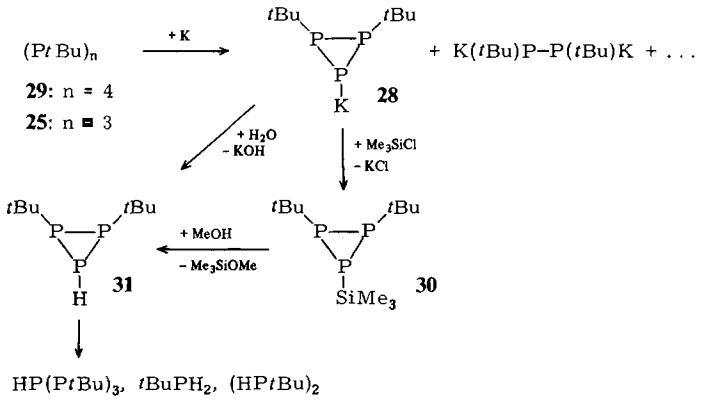
$$\underset{\mathbf{27}}{K(c\text{Hex})P\text{—}(Pc\text{Hex})_2\text{—}P(c\text{Hex})K} \xrightarrow{CS_2} \underset{\mathbf{26}}{(Pc\text{Hex})_3} + (Pc\text{Hex})_4 + \cdots$$

Finally, triorganocyclotriphosphanes are also formed in the thermolysis of cyclophosphanes with $n > 3$, as has been demonstrated for R = Et[57a,67] and for R = Me[20a,68].

$$(PR)_5 \xrightarrow{\Delta} (PR)_3 + (PR)_4 + (PR)_6 + \cdots$$

In agreement with the known stabilization of small ring systems by bulky substituents, it has been possible so far to isolate in pure form the uniformly and mixed-substituted cyclotriphosphanes $(Pt\text{Bu})_3$[59,61], $(Ps\text{Bu})_3$[62], $(Pi\text{Pr})_3$[62], $(Pc\text{Hex})_3$[63], $(PiC_3F_7)_3$[64] and $(Pt\text{Bu})_2(Pi\text{Pr})$[60], all as compounds stable at room temperature.

Of particular interest as a synthon is the monometalated cyclotriphosphane **28**. This is formed—together with other open-chain and cyclic *tert*-butyl phosphides—in the ring cleavage of the cyclophosphanes **29**[69] or **25**[70] with potassium. By direct protolysis or—which is better from the preparative standpoint—*via* the silyl derivative **30**, earlier obtained by *Fritz et al.*[71] in another way, this compound can be converted into the partially hydrogen-substituted cyclotriphosphane **31**[70]. Compared with **25**, **31** is kinetically destabilized and even below room temperature a rearrangement takes place to form the four-membered ring compound **32**, with simultaneous partial decomposition.



4.2. Properties and Structural Characteristics of Triorganocyclotriphosphanes

The triorganocyclotriphosphanes made on the preparative scale up to now are colorless, somewhat viscous liquids or crystalline solids oxidizing easily in air. They are readily to very readily soluble in ethers and in aliphatic and aromatic hydrocarbons, polar solvents favoring the rearrangement into cyclophosphanes with $n > 3$. Decomposition takes place with halogenated hydrocarbons.

All cyclotriphosphanes are characterized in their $^{31}P\{^1H\}$-NMR spectra by chemical shifts at high fields compared to open-chain triphosphanes or to cyclophosphanes of other ring sizes[72]. Accordingly, the $\delta(^{31}P)$ values are influenced by the three-membered ring structure in the same direction as the $\delta(^{31}C)$ values of the cyclopropanes[73]. The even more marked "small ring effect" observed with phosphorus compounds can be attributed to the predominant s-character, and the consequently enhanced shielding effect of the free electron pairs on the phosphorus atoms of the cyclotriphosphanes[57b].

The uniformly substituted cyclotriphosphanes $(PR)_3$ show in each case an A_2B spin system (Table 8), which means that the substituents are undoubtedly arranged on both sides of the ring plane. More precisely, the $\delta(^{31}P)$ values are determined not only by the endocyclic bond angles but also by the exocyclic angles, the dihedral angle between the free electron pairs of adjacent P atoms, and the β-effect[20a].

The configuration of the triorganocyclotriphosphanes has been confirmed by crystal structure analysis of the *tert*-butyl compound **25**[74]. Figure 5 shows the arrangement of the substituents of the two independent molecules in the crystal association.

In the mixed-substituted cyclotriphosphanes $(PR^1)_2PR^2$ there are two diastereomers. The symmetric isomer **a** with identical substituents on one side of the ring shows an A_2B system in the $^{31}P\{^1H\}$-NMR spectrum, and the asymmetric isomer **b** an ABC system (Table 9). If R^1 and R^2 are not

bulky groups, both isomers will be formed in the statistical ratio of **a** : **b** = 1 : 2[3c].

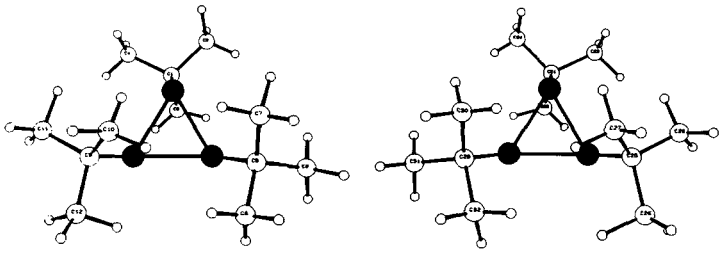

Fig. 5. Structure of the two independent molecules of $(PtBu)_3$ in the crystal [74].

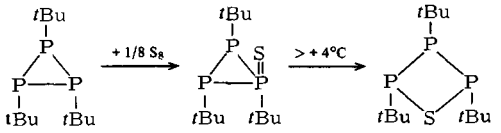
4.3. Reactions of Triorganocyclotriphosphanes

Insofar as the reaction behavior of triorganocyclotriphosphanes is known at all, one can distinguish between reactions in which the P_3 ring skeleton is preserved and ones in which it is changed.

4.3.1. Reactions in which the P_3 Ring Skeleton is Preserved

As a rule, additions on the λ^3 phosphorus in cyclotriphosphanes proceed with opening of the three-membered ring structure. However, it has proved possible to make the monothiocyclotriphosphane **33** by the action of sulfur on the *tert*-butyl compound **25** under mild reaction conditions, and to enrich this compound up to 50 mol-% in the reaction mixture[75]. The compound is thermally unstable and rapidly rearranges at room temperature into the heterocyclic four-membered ring compound **34**[75].



25 **33** **34**

Trivalent phosphorus compounds are generally outstanding ligands in the chemistry of complexes. Thus, cyclotriphosphanes react as expected with metal carbonyls, to form mononuclear and binuclear cyclotriphosphanecarbonylmetal complexes (**35** and **36**), which are remarkably stable both thermally and to oxidation[76] (Fig. 6[77]). The P_3 ring here functions—as in hexamethyltetraphosphatrisilanortricyclene[78] but differently from the triphenylcyclotriphosphane complex **37** obtained in another way[79]—as a 2- or a 4-electron donor[80].

35	**36**	**37**
$R = iPr$; $M = Cr$, *Mo*, W	$R = iPr$; $M = Cr$, W	
$R = tBu$; $M = Cr$, W		

4.3.2. Reactions in which the P_3 Ring Skeleton is Changed

Triorganocyclotriphosphanes are only metastable in comparison with the corresponding cyclophosphanes with $n > 3$. Thus, depending on the substituents R and the polarity of the solvent, they undergo rearrangements at various rates to form the stable four-membered or five-membered ring phosphanes[82]. The individual reaction steps do

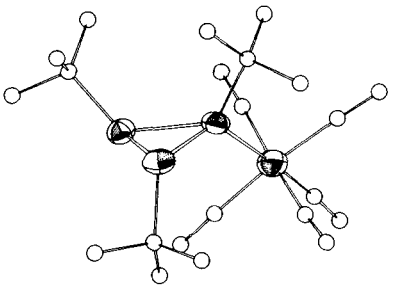

Fig. 6. Structure of $(PtBu)_3Cr(CO)_5$ [77].

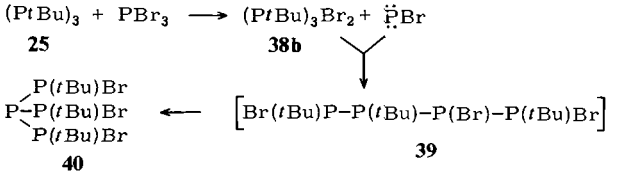
not proceed radically *via* free phosphinidenes $\ddot{P}R$, but rather, most probably, by a four-center mechanism between two P—P groups[57b,60], as has also been assumed for the formation of the mixed-substituted cyclopentaphosphanes[83]. The corresponding transition state requires a *trans* arrangement of the free electron pairs on the phosphorus atoms of the participating P—P bonds. The resultant dimerization which takes place first leads to a six-membered ring compound, which is not, however, observed to be the main rearrangement product of the cyclotriphosphanes. Enrichment of this species is opposed by its comparatively high reactivity, which is a result of the conformational mobility and hence the ability of the free electron pairs on adjacent P atoms to assume a *trans* position. The same is true of cyclophosphanes with $n > 6$. Thus, subsequent reactions first produce still larger rings, such as cyclonona- and perhaps also cyclododecaphosphanes, which then break up again into smaller oligomers. In the course of these rearrangements there is a progressive enrichment of the thermodynamically favored four-membered or five-membered ring compounds[82].

Mild halogenation of the *tert*-butyl compound **25** leads to 1,3-dihalo-1,2,3-triorganotriphosphanes **38**, which are of considerable interest as synthetic reagents for the preparation of new open-chain and ring-type *tert*-butylphosphanes[65]. **38a** is a remarkably stable open-chain triphosphane.

$$(PtBu)_3 + X_2 \rightarrow X(tBu)P{-}P(tBu){-}P(tBu)X$$

25 — **38a**: X = Cl; **38b**: X = Br; **38c**: X = I

If phosphorus(III) bromide is used for ring-opening with halogenation, the subsequent reaction consists in the insertion of the intermediate bromophosphanediyl into **38b** with the formation of the mixed-substituted tetraphos-



phane **39**. As expected, the latter is unstable and rearranges to form the constitutional isomer **40**[84].

The light-sensitive compound **40** is the first derivative of isotetraphosphane(6) that is stable at room temperature in the absence of air[85] (see Section 2.2).

5. Heterocyclic Phosphorus Three-Membered Ring Compounds of the Types $(PR^1)_2ER^2_n$ and $(PR)_4E$

Three-membered ring compounds with only one phosphorus atom in the ring have been known since the work of *Goldwhite et al.*[88] in the 'sixties and have already been reviewed in recent times[89]. In contrast, three-membered phosphorus heterocycles with two P atoms have generally been thought to be extremely reactive and hence not preparatively accessible because of the thermal instability of heterocyclopropanes with elements of the second short period[90]. However, in recent years it has become possible to make a broad spectrum of three-membered ring heterocyclophosphanes with carbon, silicon, germanium, tin, boron, nitrogen, arsenic, antimony, sulfur, and selenium as the heteroatoms, and in large part also to isolate them in the pure state[3c,d,91].

A suitable route for the generation of a P_2E ring skeleton (E = heteroatom) is the [2+1]-cyclocondensation of a bifunctional 1,2-diorganodiphosphane with a geminal nonmetal or metal compound. Assuming, that the leaving groups on the phosphorus and on the heteroatom will all cause the requisite polarization of the remainder of the molecule and will combine to form a stable leaving compound, this reaction has a very broad field of application. The *tert*-butyl-substituted diphosphanes **41**[69] and **42**[92] are particularly well suited synthetic reagents for the preparation of kinetically stable phosphorus three-membered ring heterocycles.

$$X(R^1)P{-}P(R^1)X + R^2_nEY_2 \xrightarrow[-2XY]{} (PR^1)_2ER^2_n$$

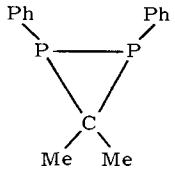
42

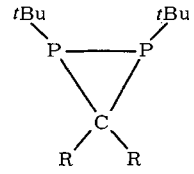
5.1. Diphosphiranes (Diphosphacyclopropanes)

Among the three-membered ring heterocyclophosphanes the diphosphiranes are of particular interest. Their successful synthesis completes an unbroken transition in the series of three-membered ring compounds from cyclopropane to cyclotriphosphane.

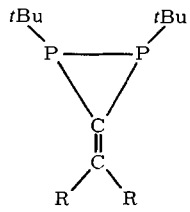
The first spectroscopic detection of the diphosphirane **43**[93] stimulated efforts to synthesize kinetically more stable representatives. The reactions of **41** with dichloromethane, 1,1-dichloroethane, or 2,2-dichloropropane give the diphosphiranes **44a—c**, which can be isolated by distillation as oxidation-sensitive liquids[94a,b]. While **44c** is surprisingly stable in the absence of air, and can even be heated to 200 °C for a short time without decomposition, **44a** dimerizes already quantitatively to **45** within a few days at room temperature. With 1,1-dichloroolefins the



43



44a: R = H
44b: R = H, Me
44c: R = Me



46a: R = H
46b: R = Me
46c: R = 4-ClC$_6$H$_4$

44a **45**

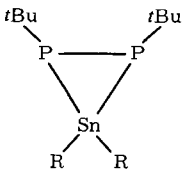
methylenediphosphiranes **46a—c** are formed, but because of their enhanced reactivity only **46b** and **46c** can be prepared in the pure state[3c,95]. The diphosphirane structure of all these compounds is ascertained unambiguously from the high-field position of their ^{31}P-NMR signals, which occur in the cyclotriphosphane region (see Table 10).

5.2. Diphosphasiliranes, Diphosphagermiranes, and Diphosphastanniranes

The reactions of **41** with diorganodichlorosilanes, diorganodichlorogermanes, and diorganodichlorostannanes lead to the heterocyclic compounds **47—49**[3c,d,96,97]. The reactivity of the compounds increases with increasing covalent radius of the heteroatom and with decreasing bulk of its substituents. Thus, the diphosphasilirane **47a** is appreciably less stable than the diphosphirane **44c**, and the diphosphastannirane skeleton can only be stabilized sufficiently by *tert*-butyl groups on the tin atom, while with smaller substituents dimerization takes place at once.

47a: R = Me
47b: R = Ph

48a: R = Et
48b: R = Ph



49: R = *t*Bu

As has been shown by the investigation of the crystal structure of **47b**[98], the replacement of a $>PtBu$ ring member in the cyclotriphosphane **25** by a $>SiPh_2$ group leads

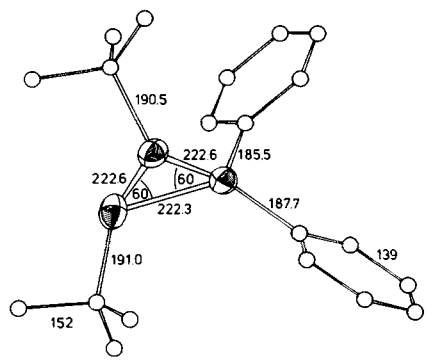


Fig. 7. Structure of $(PtBu)_2SiPh_2$ [98].

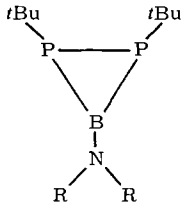
to little if any distortion of the ring skeleton, so that the endocyclic bond angle at the phosphorus and silicon is in each case 60° (Fig. 7). This is surprising, since silicon generally shows a considerably greater tendency than phosphorus to keep the tetrahedral angle constant.

In diphosphagermirane **48a** the greater covalent radius of the germanium atom compared to phosphorus results in a reduction of the interior ring angle at the heteroatom to 58°, but the deviations compared to an equilateral three-membered ring are not large[3c, 99].

5.3. Diphosphaboriranes

41 reacts with diorganoaminodichloroboranes to give the diphosphaboriranes **50a—50g**, while with organodihaloboranes only larger phosphorus-boron rings are produced[100].



50a: R = Et
50b: R = *i*Pr
50c: R = Me, *n*Bu
50d: R = Me, *t*Bu
50e: R = Me, *c*Hex
50f: R = Me, Ph
50g: R = Ph

The P_2B heterocycles are stable at room temperature if the substituent on the boron contains two secondary C-atoms or one primary and one tertiary C-atom in α position to the nitrogen (**50b** and **50d**). If both of the alkyl groups are unbranched (**50a** and **50c**), or if the electron density on the nitrogen is lowered by phenyl substitution (**50f** and **50g**), dimerization will take place relatively rapidly. The occurrence of an AB-spin system in the ^{31}P-NMR spectra of **50c—50f** indicates the presence of a partial double bond between the boron and the nitrogen atoms. In contrast, corresponding to the high-field position of the signals, there is no appreciable phosphorus-boron π interaction in the ring (see Table 10). According to the results of X-ray structure analysis carried out on **50a**, the endocyclic bond angle is 54° at the phosphorus, and 72° at the sp^2-hybridized boron (Fig. 8)[101].

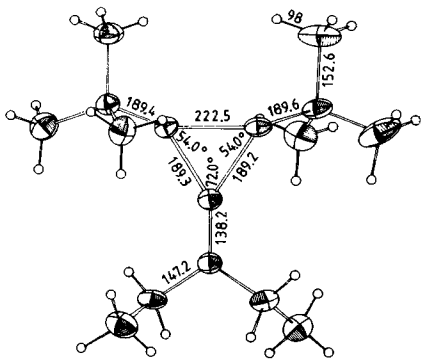


Fig. 8. Structure of $(PtBu)_2BNEt_2$ [101].

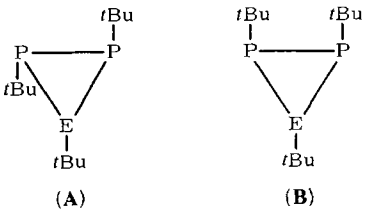
The diphosphaboriranes are at the same time the first-known monocyclic three-membered ring boron compounds, since no boracyclopropane has been known up to now.

5.4. Diphosphaarsiranes and Diphosphastibiranes

The heterocycles **51**[102] and **52**[3d, 103] obtained by reacting **41** with *tert*-butyldichloroarsane or *tert*-butyldichlorostibane are both formed as mixtures of the diastereomers **A** and **B**, of which the isomer **A**, with *trans*-oriented *tert*-butyl groups at the phosphorus atoms, is more stable. While **51** can be isolated in the form of colorless, light-sensitive crystals, **52** rearranges already at −78 °C into larger phosphorus-antimony rings.

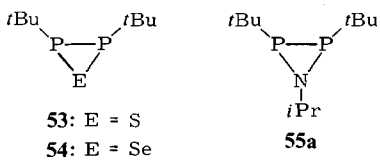


51: E = As
52: E = Sb

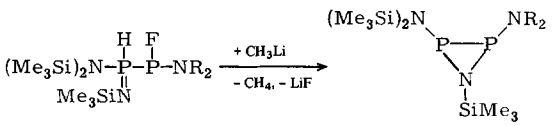
The remarkable stability of **51** also stimulated the synthesis of phosphadiarsiranes[104] and of tri-*tert*-butylcyclotriarsane[105], so that in the series of three-membered ring compounds from cyclotriphosphane to cyclotriarsane examples are known for each stage.

5.5. Thia-, Selena-, and Azadiphosphiranes

Heterocyclic phosphorus three-membered ring compounds with the electronegative ring members sulfur, selenium, and nitrogen have been obtained by the condensation of the diphosphane **42** with the stannyl compounds of the corresponding elements[106, 107]. The thiadiphosphirane **53** is also produced in the thermolytic ring contraction of larger phosphorus-sulfur heterocycles, and in the reaction of sulfur dichloride with 1,2-di-*tert*-butyldiphosphane or with the diphosphasilirane **47b**[106]. Azadiphosphiranes with bulky amino groups on the phosphorus have been prepared by *Niecke et al.*[108], by the dehydrohalogenation of a phosphorane with a P—P bond.



53: E = S
54: E = Se
55a



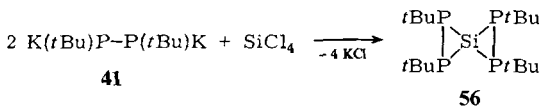
55b: R = $SiMe_3$
55c: R = $CHMe_2$

Collectively, these heterocyclic compounds can be isolated by distillation and show considerable kinetic stability. In contrast to the aziridines, the appearance of their $^{31}P\{^1H\}$-NMR spectra down to −140 °C is not temperature-dependent, so that the nitrogen has a planar surrounding, most probably because of the formation of dative π-bonds to the phosphorus atom.

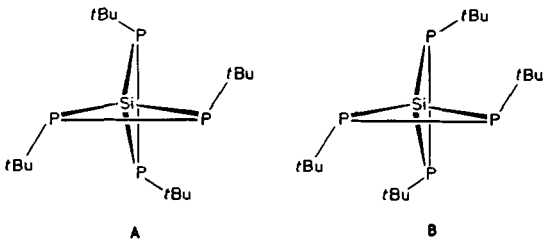
5.6. A Spirocyclic Phosphorus Three-Membered Ring Compound

As early as in 1896 it had proved possible to link two cyclopropane rings at a common carbon atom to form spiro[2.2]pentane[109]. It was therefore a challenge for preparative chemists to combine two P_2E rings at the common heteroatom E into a spirocyclic compound.

The synthesis of the tetraphosphasilaspiro[2.2]pentane **56** could be recently achieved in our group by cyclocondensation of silicon tetrachloride with the diphosphide **41**[110]. At the same time, **56** is the first spirocyclic compound made from two three-membered rings with silicon as the central atom.



41 **56**



The compound **56** is formed as a mixture of the isomers **A** and **B**, which can be isolated separately and which differ from each other in the relative arrangement of the *trans*-oriented *tert*-butyl groups at the two three-membered rings. The sterically less favored isomer **B** slowly rearranges at room temperature into the more stable isomer **A**. According to the results of X-ray structure analysis[111], in the individual, mutually perpendicular P_2Si rings the endocyclic bond angles at the phosphorus and silicon atoms are *ca.* 60°.

5.7. ^{31}P-NMR Parameters of the Phosphorus Three-Membered Ring Heterocycles $(PR^1)_2ER^2_n$ and $(PR)_4E$

As in the case of the homocyclic phosphorus three-membered ring compounds, so with the heterocyclic compounds the signal positions in the ^{31}P-NMR spectra are determined mainly by the size of the ring.

Table 10, which is arranged according to substance classes, illustrates the dependence of the $\delta(^{31}P)$ values on the individual heteroatoms. The dominant influence is that of the covalent radius, while the electronegativity is only of secondary significance: an increase in the P—E bond length widens the endocyclic bond angles at the phosphorus atoms and thus produces a shift in the downfield direction; at the same time, the absolute value of the negative $^1J_{PP}$ coupling constant increases. Moreover, the $\delta(^{31}P)$ values of the three-membered ring heterocycles are influenced by the same parameters as those of the homocyclic compounds.

Table 10. ^{31}P-NMR parameters of the three-membered ring phosphorus heterocycles $(PR^1)_2ER^2_n$ and $(PR)_4E$; J in Hz.

6. Polycyclic Organophosphanes

Phosphorus compounds with the compositions P_7R_3, P_8R_6, and P_9R_3, in which the hydrogens of polycyclic hydrides have been replaced by alkyl or phenyl groups, have already been observed several times in the thermolysis of open-chain or cyclic phosphane derivatives and identified by mass spectroscopy[40, 60, 112]. However, their isolation and structural characterization are opposed by considerable preparative difficulties. Since a better knowledge of these compounds was expected to yield the decisive key to understanding the complex structures of the polycyclic hydrides P_nH_{n-2m} ($n \geq 4$, $m = 1-7$), the Cologne group has, for some time, devoted considerable attention to this class of compounds.

6.1. Syntheses

The first polycyclic organophosphane prepared was trimethylheptaphosphane(3) **13**, obtained by the reaction of trilithium heptaphosphide **10** with methyl bromide[6, 40]. The formation of the P_n skeleton of **10** takes place—as in

the case of the polycyclic hydrides in Table 1—by uncontrolled disproportionation (see Section 3.1).

$$\underset{\textbf{10}}{Li_3P_7} + 3\,MeBr \xrightarrow[-3\,LiBr]{} \underset{\textbf{13}}{P_7Me_3}$$

The breakthrough in the production of polycyclic organophosphanes on a preparative scale came with the discovery of directed and generally applicable synthetic methods. Since organodichlorophosphanes give monocyclic phosphorus compounds on dehalogenation[1], in order to obtain polycyclic organophosphanes it is necessary to introduce into the reaction additional phosphorus atoms not substituted with organo-groups. Corresponding to this concept, substances of the general composition $P_{x+y}R_x$ can be made by any of the reaction paths (c) to (e).

$$x\,RPCl_2 + y\,PCl_3 + \frac{2x+3y}{2}\,Mg \longrightarrow P_{x+y}R_x + \frac{2x+3y}{2}\,MgCl_2 \qquad (c)$$

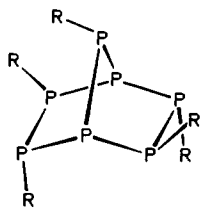
$$\frac{x}{n}(PR)_n + y\,PCl_3 + \frac{3y}{2}\,Mg \longrightarrow P_{x+y}R_x + \frac{3y}{2}\,MgCl_2 \qquad (d)$$

$$x\,RPCl_2 + \frac{y}{4}P_4 + x\,Mg \longrightarrow P_{x+y}R_x + x\,MgCl_2 \qquad (e)$$

Other dehalogenating agents, such as lithium hydride, can be used instead of magnesium[113]. In all cases the overall composition of the reaction product, *i.e.* the number of organo-substituted P atoms compared to the number of P atoms connected only to other phosphorus atoms, can be established from the molar ratio of the two starting phosphorus-containing compounds. However, whether the stoichiometry observed corresponds to a definite organophosphane or only to a mixture of substances with the same overall composition will depend on the thermodynamic and the kinetic stability of the compounds involved. Since the stoichiometric composition of various polycyclic organophosphanes can be very similar to one another, a product mixture of several compounds is always obtained which must be separated chromatographically.

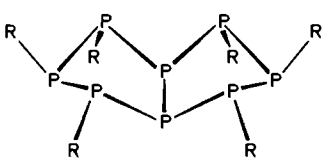
6.2. Bicyclophosphanes: P_7R_5, P_8R_6, P_6R_4

Dehalogenation in accordance with (c) or (d) at moderate temperature leads to heptaphosphanes(5)[114] or octaphosphanes(6)[115], of which **57a**, **57b**, **58b**, and **58c** have been isolated as oily liquids.



P_7R_5

57a: R = Me
57b: R = Et
57c: R = *i*Pr



P_8R_6

58a: R = Me
58b: R = Et
58c: R = *i*Pr

The structures of these compounds have been determined by NMR spectroscopy and confirmed by a complete analysis of the $^{31}P\{^1H\}$-NMR spectra of **57a**, **57b**, and **58b**[116]. According to this, the compounds **57** are 2,3,5,6,7-pentaorganobicyclo[2.2.1]heptaphosphanes with a skeleton analogous to that of norbornane, while the **58**-type compounds are 2,3,4,6,7,8-hexaorganobicyclo[3.3.0]octaphosphanes with a structure analogous to pentalane. In the case of **57a—c**, apart from the dominant configurational isomer with the maximum *trans* arrangement of the substituents other isomers occur with a lower relative frequency.

The compounds **58a—c** are always formed together with the corresponding compounds **57**, in spite of the maintenance of the required stoichiometry. This can clearly be attributed to the fact that both the octaphosphanes(6) and the heptaphosphanes(5) contain a bicyclic molecular skeleton consisting of two phosphorus five-membered rings. It follows from the product distribution in each case that with small substituents (Me, H) the P_7-skeleton with a one-atom bridge has an appreciably greater tendency to form than the P_8-skeleton with a zero bridge. With increasing bulk of the substituents (Et, *i*Pr), however, the stability difference between the two bicyclophosphane skeletons is changed, since the steric interactions of the substituents on P^6 and P^7 in **57** are considerably greater than those of the *cis* substituents in **58**, so that the **58** : **57** ratio increases.

On going over to R = *t*Bu both the norbornane and the pentalane skeletons are destabilized: while no corresponding heptaphosphane(5) has so far been obtained[117], the relatively stable octaphosphane(6) shows the unusual structure of a 2,2',3,3',4,4'-hexa-*tert*-butyl-1,1'-bicyclotetraphosphane **59**[118] (Fig. 9). All the P—P bond lengths within the nonplanar four-membered rings and in the bridge are approximately the same. Rotation around the exocyclic P—P bond is already frozen-in at room temperature[119]. The mixed bicyclic compound $P_6As_2tBu_6$ **60**, accessible according to reaction (c) with arsenic trichloride instead of phosphorus trichloride, has the same structure, with arsenic atoms in the bridgehead positions[120].

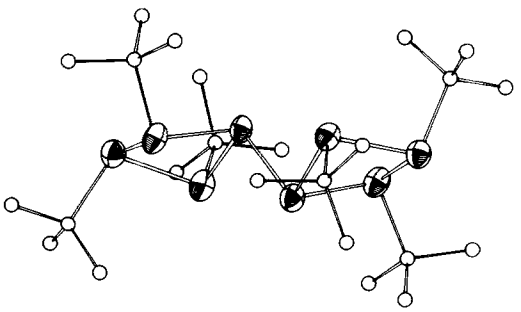


Fig. 9. Structure of P_8tBu_6.

Together with **59**, a further bicyclic compound, namely a hexaphosphane(4), is produced in accordance with reaction (c) in a wide range of mixture ratios of *tert*-butyl dichlorophosphane and PCl_3; surprisingly, this compound has a phosphorus skeleton comprising a three-membered ring and a five-membered ring. It is therefore a 2,3,4,6-tetra-*tert*-butylbicyclo[3.1.0]hexaphosphane **61**[121a,b] (Fig.

10). The slightly distorted three-membered ring is nearly perpendicular to the relatively flat five-membered ring. In spite of this unusual structure, **61** is remarkably stable toward heat and atmospheric oxygen.

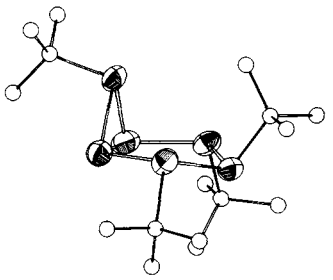

Fig. 10. Structure of P_6tBu_4.

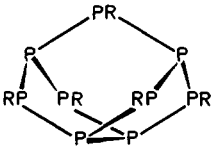
6.3. Tricyclophosphanes: P_7R_3, P_9R_5

If the dehalogenation according to reaction (d) is carried out at an elevated temperature (boiling tetrahydrofuran), then in addition to phosphorus-richer polycyclics the heptaphosphanes(3) with R = Me, Et, *i*Pr are preferentially formed[122]. The methyl compound **13** is identical with the reaction product obtained from **10** and methyl bromide in all its properties, including the distribution of the isomers[6,40]. The compounds are 3,5,7-triorganotricyclo-[2.2.1.$0^{2,6}$]heptaphosphanes, with a skeleton analogous to that of nortricyclene (see Section 3.1), as has been ascertained by a complete analysis of the $^{31}P\{^1H\}$-NMR spectra of the two configurational isomers of **13**[123].

Under suitable conditions of stoichiometry, reaction temperature, and reaction time, nonaphosphanes(5) are formed predominantly according to reactions (c) or (d), of which the compounds **62a** and **62b** have been isolated as analytically pure, high-viscosity oils[114,124].



P_9R_5

62a: R = Me
62b: R = Et
62c: R = *i*Pr

Their structure has been clearly shown from the $^{31}P\{^1H\}$-NMR spectra to be 2,4,6,8,9-pentaorganotricyclo[3.3.1.$0^{3,7}$]nonaphosphanes with a P_9 skeleton analogous to that of noradamantane. Since the >PR ring members in these molecules are all separated from one another by unsubstituted P atoms, a deviation from the all-*trans* arrangement of the substituents does not lead to any drastic destabilization. As a result, in all cases mixtures of various configurational isomers with comparable frequency are formed (*e.g.* **62a**: 3 isomers in the ratio 40:40:20); this constitutes the reason for the low tendency of these compounds to crystallize.

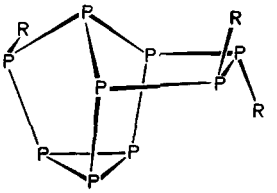
Furthermore, a constitutional isomer of **62b** is formed in accordance with reaction (e), and has been separated in the pure form[125]. Since its $^{31}P\{^1H\}$-NMR spectrum shows no signal groups in the three-membered or four-membered ring region, the P_9 skeleton should have a structure analogous to the hydrocarbons brendane or brexane. A definitive clarification of this question is difficult, because the spectrum is extremely complex owing to the presence of configurational isomers.

6.4. Tetracyclophosphanes: P_9R_3, $P_{11}R_5$

Of the phosphorus hydrides with nine P atoms, nonaphosphane(3) is outstanding because of its marked stability and tendency towards formation[3b]. In agreement with this, organo-substituted nonaphosphanes(3) are generally formed in the thermolysis of open-chain or ring-type phosphane derivatives[40,60,112,121a].

According to reaction (c) considerable portions of nonaphosphanes(3) are produced under suitable reaction conditions (excess of PCl_3, prolonged reaction time at elevated temperatures), often together with corresponding heptaphosphanes(3)[126]. Separation of the product mixture is difficult owing to the poor solubilities, but has recently been achieved in the case of the *tert*-butyl compound **63d**.

63a: R = Me
63b: R = Et
63c: R = *i*Pr
63d: R = *t*Bu



P_9R_3

According to data from the $^{31}P\{^1H\}$-NMR spectra of **63b** and **63d**, these compounds are 5,8,9-triorganotetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]nonaphosphanes with a P_9 skeleton analogous to that of the hydrocarbon deltacyclane. Corresponding to the observed nonequivalence of all nine P-atoms, the symmetry is of the C_1 type, while the symmetric triasterane structure assumed by other authors[38,112] is inconsistent with the spectroscopic findings. As expected, there are two configurational isomers of different frequencies, which differ in their spatial arrangements of the substituent on P^5. The deltacyclane skeleton is also present as a structural element in the P_{16}^{2-} ion (see Section 3.2).

Together with the tricyclic nonaphosphanes(5), varying amounts of the corresponding undecaphosphanes(5) are formed in most cases[114,125]. This suggests that the stabilities of the two classes of compounds are similar and that their structures are closely related. In agreement with this, the results so far obtained on enriched $P_{11}Et_5$[125] suggest that the structure is associated with the noradamantane (or brendane or brexane) analogous $P_9(5)$ skeleton in a similar manner as the $P_9(3)$ skeleton is associated with the $P_7(3)$ skeleton, namely by an additional two-atom bridge, giving a new five-membered ring.

6.5. General Properties of Polycyclic Organophosphanes

The polycyclic organophosphanes so far obtained on a preparative scale are colorless to yellow oily liquids or solids, which only crystallize when they do not consist of diastereomeric mixtures. Their solubilities in the usual solvents become lower with increasing number of phosphorus atoms and decreasing number of organo groups. Within a

given class of compounds, the solubility increases with increasing number of C-atoms in the substituents. In the ethyl, and particularly methyl, compounds there is often a marked reduction of the solubility on allowing the solution to stand or after complete removal of the solvent. This physical aggregation process, which is limited to small substituents and which is still unexplained, is also responsible for the extremely sparing solubility of the underlying polycyclic phosphorus hydrides. The stability of the organophosphanes to atmospheric oxygen increases with increasing phosphorus content and with increasing bulk of the substituents.

7. General Structural Principles of Polycyclic Phosphanes and their Derivatives

The structures established for the organophosphanes with condensed ring systems constitute an essential key to understanding the structures of the polycyclic phosphorus hydrides, which because of their low solubilities and poor crystallizability have not yet proved amenable to NMR or X-ray investigation. As shown by the synopsis in Figure 11, a variation of the substituents in the range of relatively small alkyl groups brings about no alteration of the phosphorus skeleton, so that even when the organo groups have been replaced by hydrogens a structural change can be reliably excluded. This leads to definitive conclusions for a whole range of phosphorus hydrides:

P_7H_5 is a bicyclo[2.2.1]heptaphosphane;
P_7H_3 is a tricyclo[2.2.1.$0^{2,6}$]heptaphosphane;
P_8H_6 is a bicyclo[3.3.0]octaphosphane;
P_9H_5 is a tricyclo[3.3.1.$0^{3,7}$]nonaphosphane;
P_9H_3 is a tetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]nonaphosphane.

Small differences between the hydrogen- and the methyl-substituted phosphanes are only expected in the frequency distribution of the various configurational isomers, since with trimethylheptaphosphane(3) **13** there is already a sterically determined deviation from the statistical distribution (see Section 3.1).

Significant changes in the skeleton structures characteristic for the individual compound classes—as in the case of P_8tBu_6 **59**—may be compelled by special steric conditions; however, these only represent nature's emergency measure, as shown by the fact that the element-homologous compound As_8tBu_6 has the same structure as the sterically unhindered octaphosphanes(6)[118a, 127]. Whether the unusual skeleton in P_6tBu_4 is only limited to bulky substituents will be shown by further investigation of the compounds P_6R_4 (R = Et[124], Me[117], H[3b]) already identified by mass spectroscopy. In general, the formation of different skeleton structures within one and the same class of compounds should mainly be reckoned with in the bicyclophosphanes, where steric interactions between the substituents play a far greater role than in tri-, tetra- or pentacyclic compounds.

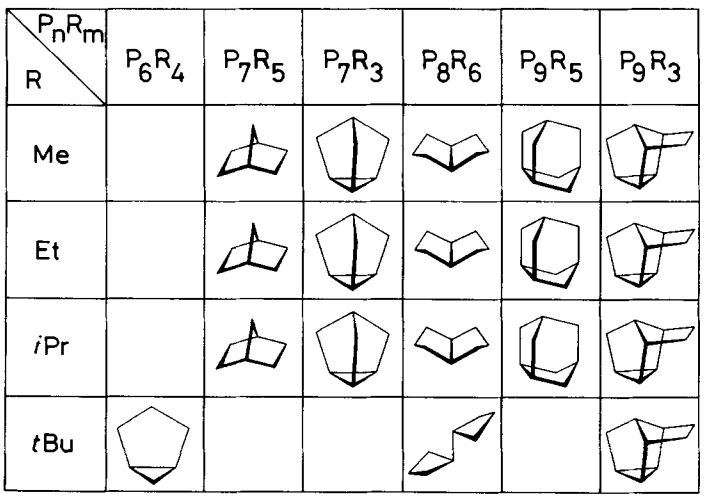


Fig. 11. Phosphorus skeleton in polycyclic organophosphanes.

The P_n skeletons of the various classes of compounds show close family relationships. For example, the double ring in P_6tBu_4 can be obtained formally from the tricyclic $P_7(3)$ cage if one of the three one-atom bridges is removed. The $P_7(5)$ skeleton analogous to norbornane and the $P_9(5)$ skeleton analogous to noradamantane differ from the $P_7(3)$ cage only by the opening of one bond in the three-membered ring or by the substitution of the three-membered ring by a five-membered ring. The tetracyclic $P_9(3)$ skeleton can be obtained from the $P_7(3)$ skeleton by the condensation of a five-membered ring onto the latter structure with the aid of a two-atom bridge. Moreover, the $P_7(5)$, $P_8(6)$, and $P_9(5)$ skeletons are essential structural unit groups of Hittorf phosphorus[128]. It is these structural relationships that are responsible for the easy reciprocal transformations and the simultaneous genesis of the various species.

If the class of structurally ascertained molecular polycyclic phosphane derivatives is also taken to include the "inorganically" substituted $P_{11}(SiMe_3)_3$, which according to *von Schnering et al.*[129] contains a symmetric skeleton of six condensed five-membered rings, the outstanding significance of the formation of five-membered ring structural elements in polycyclic phosphane skeletons becomes clearly evident. This is an essential difference from carbon chemistry, and among other things it explains why it has not yet been possible to prepare a molecular decaphosphaadamantane[38, 130]. The mass-spectroscopically identified compounds $P_{10}R_6$ (R = *i*Pr[115], H[3d]) must have some other structure. In contrast to several three-membered and six-membered partial frameworks, structure elements made up of four-membered rings or from rings of more than six P-atoms have not so far been encountered in sterically unhindered polycyclic phosphanes.

Summarizing, according to our present state of knowledge the structures of polycyclic phosphanes and their sterically unhindered derivatives are determined by the following criteria:

1. In accordance with the empirical formula, fundamentally the same formally derivable polycyclic structures may exist as in hydrocarbons of analogous composition, each P-atom substituted by a monofunctional residue corresponding to a CH_2 group and each P-atom bound only to phosphorus corresponding to a CH group.

2. Of the constitutional isomers possible according to point 1 above, those with the maximum number of five-membered ring elements are formed.

3. If the stoichiometric composition requires other

structure elements in addition to five-membered rings, then additional three-membered and six-membered rings are incorporated in the phosphane structure, but not four- or seven-membered rings.

4. Phosphane skeletons with three-membered rings are generally more thermally stable than ones with six-membered rings.

5. The structures of higher-condensed phosphanes are derived from those of lower-condensed phosphanes with two fewer P-atoms, often by the condensation of a new five-membered ring onto the latter structure *via* a two-atom bridge with *trans* substituents.

6. Particularly phosphorus-rich structures are built up by the linking of large partial frameworks (P_7-, P_8-, P_9-, P_{11}-), either by an exocyclic P—P bond or *via* the zero bridge of a commonly formed bicyclo[3.3.0]octaphosphane partial structure.

7. Constitutional isomers may be produced if several skeletons of similar structure and hence comparable stabilities are possible for one and the same empirical formula.

8. Of the various possible configurational isomers, the one produced is always that with the maximum *trans* arrangement of the substituents. The formation of further isomers is determined by the steric interactions when the structure deviates from the "all-*trans*" arrangement.

Thus, whilst the formulas of the polycyclic phosphorus hydrides listed in Table 1 may at first sight show no rhyme or reason, the application of these structure principles makes them largely comprehensible.

8. Summary and Future Prospects

Research in the last 15 years has led to the realization that compounds with a skeleton of phosphorus chains and rings are not in any way "exotic" in the field of nonmetal chemistry. With modern preparative techniques such compounds can be handled with little or no problem and in their structures they show many similarities to the corresponding hydrocarbons. This must be attributed to the equal numbers of valence electrons in the $-CH_2-$ and $-\ddot{P}H-$, and in the $\geqslant CH$ and $\geqslant P:$ groups. Analogous framework structures can therefore be produced. Certain differences do exist, due mainly to the following special features of phosphorus:

1. $\ddot{P}-\ddot{P}$ bonds enter easily into four-center reactions owing to their free electron pairs. Disproportionations and ring-rearrangement reactions therefore take place under considerably milder conditions than in the case of hydrocarbons or of hydrogen-silicon compounds.

2. Phosphorus tends to form smaller bond angles than carbon, and this can lead to different stability sequences among the cyclic compounds of the two elements.

3. As a result of the trivalence of phosphorus, chiral centers occur appreciably more often in open-chain and ring-type phosphorus compounds than in the corresponding compounds of carbon.

The present review should make it clear that we just stand at the beginning of an era of new and highly promising developments in the field of chain-type and ring-type phosphorus compounds. If we consider the number of phosphorus hydrides and organophosphanes that have already been identified by mass spectroscopy but not yet been made on a preparative scale, and whose structures still have to be confirmed experimentally, the scope and diversity of work ahead of us in the near future becomes very evident. Further stimulating investigations will arise from the question whether one could carry out aimed isomerizations from which information could be derived about the relative stabilities of the individual constitutional isomers and about the mechanism of these reactions. Another particularly fascinating subject is the valence tautomerism in phosphorus compounds. Furthermore, the reactive potential of the phosphorus three-membered ring compounds could prove to be useful in various preparative contexts. Studies in the various areas mentioned are currently under way in our laboratories.

Special thanks are due to my co-workers cited in our own contributions, for their dedicated and always friendly collaboration, and to Dr. M. Fehér and Dr. K. Glinka for valuable technical assistance. The work of our research group was kindly supported by the Deutsche Forschungsgemeinschaft, the Minister for Science and Research of the Nordrhein-Westfalen province, the Fonds der Chemischen Industrie, and Hoechst AG, Frankfurt am Main.

Conformation and Biological Activity of Cyclic Peptides**

By Horst Kessler*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Cyclic peptides containing biologically active hormone sequences are suitable models for studying conformation-activity relationships. In such models the usual flexibility of peptide chains is reduced by their cyclic arrangement. However, conformational analysis of such systems by experimental means is possible only if a single conformer predominates at equilibrium, and criteria for this are put forward. NMR spectroscopic methods, including many recent advances, are discussed in relation to their ability to contribute to peptide conformational analysis.

Apart from consideration of the hydrogen bond, we organic chemists have really paid little attention to linkages other than the purely covalent. I believe that it will be the duty of organic chemists in the furture to study the weak non-bonding interactions which are of enormous importance in the large natural macromolecules. Such studies will lead to a new blossoming of organic chemistry in the future. *Lord Alexander R. Todd*[1]

1. Introduction

The planned synthesis of a totally selective drug with no side effects is the ambition of every pharmacologist and drug chemist. Efforts towards realizing this goal of drug design have been many[2–6], and the search for relationships between structure and activity has been the principal subject of activity in many industrial and academic laboratories. At the same time, the search for refinement of present-day concepts of the structure of organic compounds is reflected in the work of chemists, biochemists, and pharmacologists alike. Initial efforts at finding a connection between structure and activity equated structure with constitution, but it soon became evident that configuration was at least of equal importance. As a result, special emphasis has been placed in recent years on stereospecificity in the synthesis of active substances. The importance of molecular conformation in both chemistry and biochemistry has been evident ever since the pioneering work of *Barton*[7]; yet only hesitant efforts have since been made to establish a link between conformation and activity[8].

Perhaps it is not difficult to see why. Conformers are generally not isolable as stable compounds and therefore cannot be tested separately for biological activity. The cyclic tetrapeptide [Sar^1]-Tentoxin appears to be the only molecule known so far[9b] whose two conformers have been separately examined—and here in fact they have been found to differ in activity. Generally it is difficult enough even to determine the most stable conformation in solution, and all the more to follow changes in conformation in biological media[10, 11]. The only way out of this problem appears to be to effect *conformational* changes by altering the *constitution* and/or *configuration* of an active substance, but it would then be highly difficult to distinguish between the separate effects on biological activity of the various changed parameters.

2. Hormone—Receptor Interaction

An alternative way out of this dilemma could be the study of certain physiologically active peptides which have recently been the center of interest as hormones and neuropeptides[12][*].

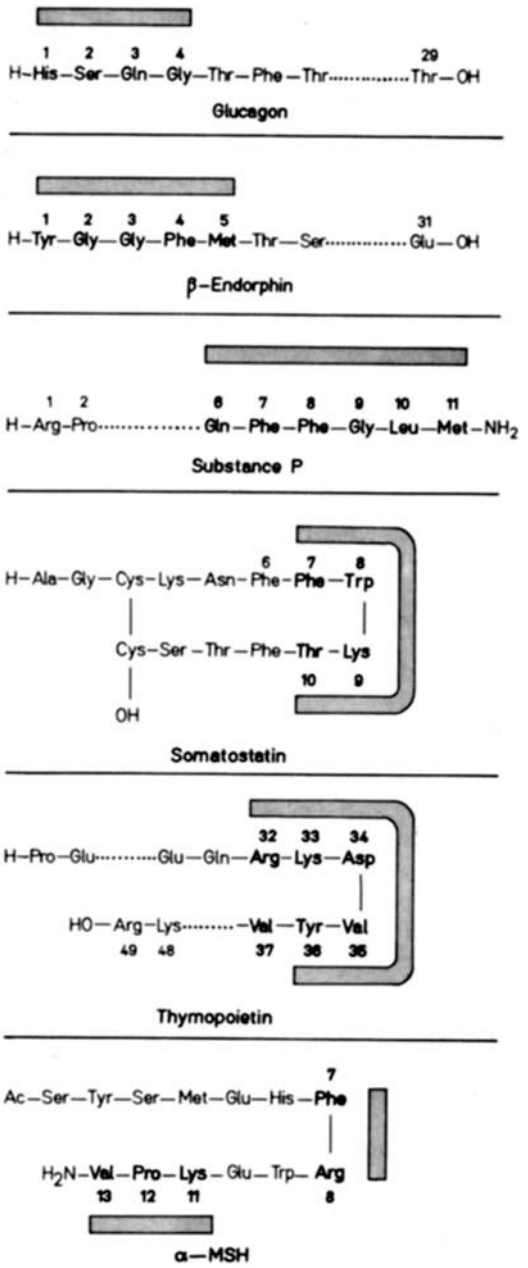

Fig. 1. Sequences of the active parts of peptides: glucagon [13, 14], β-endorphin [15], substance P [16, 17], somatostatin [18], thymopoietin [19], α-MSH [20].

In many of these compounds the "active region" is relatively small and comprises a sequence of only four to five amino acids (Fig. 1). Structural modifications in this region lead to particularly pronounced changes in biological activity. This should raise the question of whether the rest of the molecule merely serves to hold the active part in the "right" conformation. If so, changes in this "scaffolding" should lead to conformational changes which might be directly correlatable to changes in biological activity.

One possible way to put this idea into practice could be through models of hormone-receptor interaction. *Emil Fischer*'s "lock and key" principle, based on the binding[21] of the hormone to the receptor, and thus on "molecular recognition" is generally recognised as valid to this day. An encounter of this type is assumed to lead to conformational change in the receptor, which in turn causes "transduction" of a signal (Fig. 2). Complex formation and signal transduction are not necessarily interconnected. Hence, substrates which might complex with the receptor and yet fail to induce a signal (competitive inhibition) have been sought.

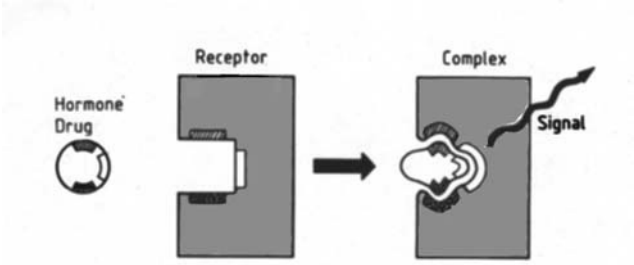

Fig. 2. Model of hormone- or drug-receptor interaction.

Complexation can also lead to conformational change in the hormone itself. In fact, the concept of "induced fit" is now thought to apply equally to the hormone and to the receptor (Fig. 3)[22]. It is immaterial for the purposes of the subsequent discussion whether a predetermined equilibrium or a change of conformation induced only during complexation is the more important factor. To begin with, it is appropriate to assume that the most stable conformation of the hormone in solution is the same as that in the complex with the receptor but that this may subsequently change. However, the structure of no invidual hormone receptor has been elucidated yet[23], and currently there are no methods to determine directly the relevant conformation of a hormone in association with the receptor. Hence, indirect methods must be sought.

One possible approach lies in determining the conformation of biologically active molecules by assuming that the more similar the conformation of the hormone in contact with the receptor is to its most stable conformation in

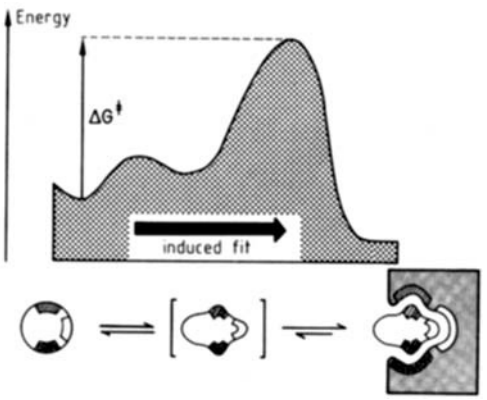

Fig. 3. Induced fit of conformations upon binding to the receptor.

[*] A matter of current interest is the synthesis of hormone agonists or antagonists (*e.g.* competitive inhibitors), which may lead to drugs for the treatment of hormonal disorders.

solution, the greater is the hormone's biological activity (Fig. 4). At the back of this is the argument that conformational change ensuing upon complexation would entail additional energy consumption at the expense of binding energy. There appears to be little force for this argument when it is considered that, in general, the energy change involved in changing conformation is of a much lower order of magnitude than the binding energies[*]. Nonetheless, the basic hypothesis of correlating the most stable conformation in solution with that at the receptor site does appear to justify the study of active molecules in solution; and it also seems safe to assume that at least some of the systems studied will indeed behave according to this hypothesis, in that conformational change upon complexation will not be unduly excessive.

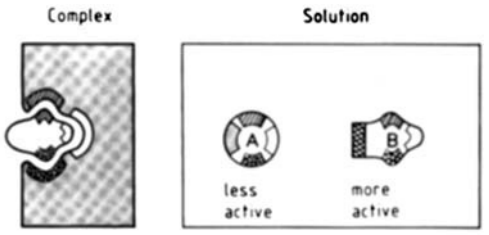

Fig. 4. Possibility I for determination of the conformation at the receptor. Hypothesis: The most active molecule already prefers a conformation in solution which is similar to the conformation in the complex.

Another possibility of obtaining information on the conformation at the receptor site is by introducing conformational restraint. This is illustrated schematically in Figure 5 by placing a "girdle" on the molecule. If the process of "girdling" leads to a geometry which does not suit the receptor, then no biological activity can be expected. If the girdling is in the right position then, on the other hand, activity should remain unchanged or even be enhanced. In practice, such modification of conformation can be achieved by cyclization, which restricts freedom of conformational movement, particularly in the case of smaller rings. In other words, this indicates that cyclic peptides should first be studied[25-27].

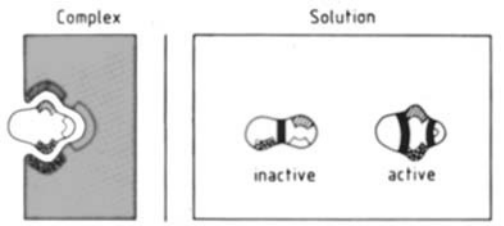

Fig. 5. Possibility II for determination of the conformation at the receptor by conformational restraint.

It seems appropriate to conduct such studies of conformational effects in the order indicated by the following headings:

[*] Typical binding energies of biologically active peptides are of the order of 12—17 kcal/mol [24], whereas energy changes of only fractions of a kcal/mol are sufficient to induce considerable conformational change.

1. Search for the active sequence in the hormone

This can be carried out using the classical procedure of varying the constitution and configuration of the amino acids in the peptide chain, until that part of the molecule has been located where minimal changes lead to maximal effect.

2. Conformational studies of biologically active molecules

First and foremost this involves studying conformational integrity under various conditions (*e.g.* in the crystalline state and dissolved in various solvents). In solution, in particular, the coexistence of several different conformations has to be taken into account; clear-cut results can, in general, be expected only in cases of proven conformational homogeneity. The less conformational transition occurs in solution, the more chance will there be that this will also be minimal on complexation with the receptor.

3. Conformational studies of model peptides

These, with variations in both constitution and configuration, should help to predict the conformations of analogous novel peptides.

4. Introduction of an active amino acid sequence into cyclic structures for simulation of conformation at the receptor site

On the basis of results with models, the non-active fragments have to be selected such that through their influence the molecule as a whole will be likely to assume the probable "active" conformation deduced from other studies on biologically active hormones. Thus, synthesis, conformational analysis, and biological activity measurements proceed hand in hand.

The study of *cyclic* peptides involves an important side aspect. In the organism, the breakdown of a peptide chain proceeds most easily starting at a C- or N-end group; hence the degradation of cyclic peptides is markedly slower, and their biological activity is more sustained[18,28-31]. Another aspect concerns reversed turns in cyclic structures. In linear peptides and proteins such loops are occasioned by the tendency to form intramolecular hydrogen bonds. Best known is the β-loop[32], which facilitates the antiparallel hairpin bending of peptide molecules and enables hydrogen bonding between C=O and NH groups of the first and fourth amino acids in a peptide sequence. In smaller acyclic or cyclic peptides the γ-loop, whose function is to facilitate analogous hydrogen bonding between the first and third amino acid in the sequence, is also encountered (see Fig. 17). The importance of these turns in the transmission of information can be rationalized thus:

It can be assumed in the following that the "lock and key" principle in nature will keep the transportable hormone "key" as small as possible, and that to ensure maximal information transfer this "key" will be sheathed three-dimensionally to the fullest possible extent. The receptor, on the other hand, can be relatively large in view of its fixed immobility (*e.g.* in the cell membrane). Such "sheathing" of the "region of encounter" would be most effective at chain terminals or helical loops which could efficiently penetrate inside a receptor pocket (cf. Fig. 1). It

thus seems reasonable to assume that active sequences locally concentrated within a peptide chain will indeed incorporate such looping. As for the rest of the molecule, its function would then be to ensure the proper conformation of the active region and the reinforcement of its connection with the receptor (see Section 2).

In this essay a short account of the experimental methods presently available for determining conformation will be presented. Here, NMR spectroscopy occupies a special place since this method is greatly superior to all others for supplying detailed information on conformation in solution[25-27,33-42]. The present discussion does not of course preclude supplementing our fount of knowledge by additional means, whether experimental[43-48] or theoretical, such as by molecular mechanical calculations[49].

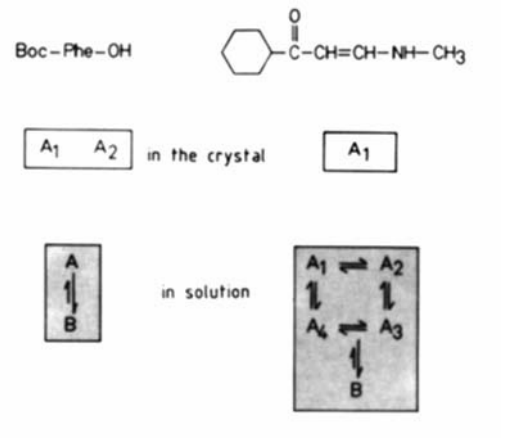

Fig. 6. Conformational changes upon dissolution of crystals (see text).

3. Conformation in the Crystal and in Solution

X-ray crystallography has now reached such a high state of development that, provided good crystals are available, structure determination of small molecules, in particular, has become a routine matter. No other method can rival it as regards accuracy and the advantages of direct pictorial representation. However, the information obtained is restricted to the crystalline state, and attempts frequently and thoughtlessly made to extend the validity of such information to the situation in solution are, on the whole, quite improper.

For those cases where the energy barrier between the most stable conformation in solution and that in the crystalline state is $>ca.$ 10—15 kcal/mol it is possible to follow the conformational change involved by dissolving the crystal at low temperature and following the change in the NMR spectrum after different time intervals and/or after raising the temperature[50-54]. This method frequently permits the assignment of discrete signals to particular conformations. In many other cases, however, energy barriers are so low that rapid conformational equilibria are established on dissolution. This problem can now be circumvented by the recently routinized CP-MAS (cross polarization magic angle spinning) technique[55], which yields high resolution ^{13}C-NMR spectra of solids and can thus provide a bridge to the results obtained from NMR spectroscopic studies of such substances in solution[55-60]. Undoubtedly this approach will also be of value in those cases where single crystals suitable for X-ray crystallography cannot be prepared. An example of the application of this method is the protected amino acid Boc-Phe-OH (*N-tert*-butoxycarbonyl phenylalanine) which exists in two discrete conformations in the crystal[54,59,61]. On dissolution, these equilibrate rapidly even at low temperatures and their separate NMR spectra cannot then be measured[54,62]. However, in solution there is a subsequent transition, with a relatively high energy barrier ($\Delta G^{\neq}_{298} = 16.0$ kcal/mol), to a third conformation which is more stable in solution than the other two[54,62] (Fig. 6).

In the vinylogous amide shown in Figure 6, there is only a single conformer in the crystalline state, and this rapidly undergoes equilibration on dissolution to give four other unstable conformations. After a little time these are almost completely transformed into yet another conformer, which is the most stable one[59]. A further interesting case is that of the cyclic tripeptide *cyclo*[Pro$_2$-NBGly] (NBGly = N(o-nitrobenzyl)glycyl)[63]. This crystallizes from CCl_4 and from MeOH in two different crystalline forms[64], and X-ray crystallography has shown that in both of these the ring has a boat conformation[53,65,66], in each case in a different spatial environment. However, in MeOH solution a crown conformation appears to predominate[63]. This at any rate was found by ^{1}H-NMR studies of first fractions obtained by crystallization from this solvent at low temperatures and redissolution at $-50°$, whereas crystals which had separated more slowly and were identical with those used for the above-mentioned X-ray work gave a spectrum indicative of a boat conformation[63].

The coexistence of several conformations appears to be the case in general in both solution and in the amorphous state. In the latter they are apparently "frozen"; in the high-resolution solid state ^{13}C-NMR spectrum broad signals, resulting from many conformers and from packing (molecular disorder) effects, are observed. In solution, on the other hand, rapid equilibration between numerous conformations must be assumed, and it is only when energy barriers separating these are between 5 and 25 kcal/mol that detailed information on the molecular processes involved in these conformational transitions can be expected from NMR spectroscopy[67-69]. Thus, generally speaking, conformational rigidity will be restricted to certain portions of the molecule, and conformational mobility will be inherent in other parts such as side chains. Even with molecules assumed to be relatively rigid, the question of conformational homogeneity is the one that has to be considered first. Frequently a "median" conformation has been proposed as a working hypothesis for flexible molecules, but as *Jardetzki* has clearly pointed out[70] this is physically meaningless in the majority of cases since there is no linear relationship between NMR data and geometrical parameters (see Section 4).

Before going into the means at our disposal for demonstrating conformational homogeneity it seems appropriate to discuss the type of information available in this field from NMR spectra.

4. NMR Spectroscopic Methods for Conformational Analysis of Peptides

The conformation of the peptide "backbone" can be expressed in terms of the angles ϕ, ψ, and ω, while the side chain can be characterized by the angles χ (Fig. 7)[71].

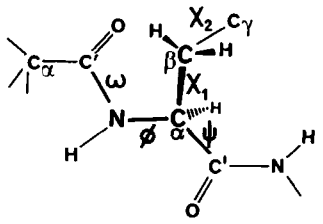

Fig. 7. Definition of the angles in peptides. The eclipsed orientation of the bonds along the peptide framework $-C_\alpha-C'-N-C_\alpha-$ corresponds in this sequence to a dihedral angle of 0°. The right-handed helical orientation is taken as positive.

The following parameters can be deduced from NMR spectra:

- Chemical shift δ
- Scalar coupling J (indirect through-bond coupling)
- Intensities
- Exchange broadening
- Dipolar through-space coupling evident by relaxation phenomena, *e.g.* spin-lattice relaxation times (T_1) and nuclear Overhauser effects (NOE).

After *extracting* these parameters from the spectra one has to *assign* them to molecular structures. *Interpretation* of the parameters, in turn, leads to the desired structural information (see Fig. 8). Although it seems obvious, it is just with relatively complex peptide structures that erroneous extraction and indiscriminate assignment of data have led to conclusions which turned out to be dubious, even though arrived at *via* critical interpretation. In fact, many previously reported literature data would seem to bear reexamination.

For the purpose of assigning signals to amino acids the search for coupling patterns[72,73] has been enormously simplified by the use of modern two-dimensional NMR techniques[74-76], such as homonuclear[73,77-79] and heteronuclear[76,80,81] 2 D-*J*-resolved spectroscopy[82], ^{1}H-^{13}C-2 D-shift correlation[76,80,81,83-85], and homonuclear 2D-shift correlated[11,78,80,81,83-85] spectroscopy. By means of NOE-difference spectra[85,88,89] or of 2D-NOE spectroscopy[90-94] it is now possible to sequence peptides without the need for tedious synthesis of selectively deuterated derivatives[97-99]. In cases where two conformers coexist in moderately rapid equilibrium, the exchange of individual nuclei between them can be demonstrated directly by saturation-transfer[53,65,99,100] or by 2D-exchange[94,101-106] spectroscopy.

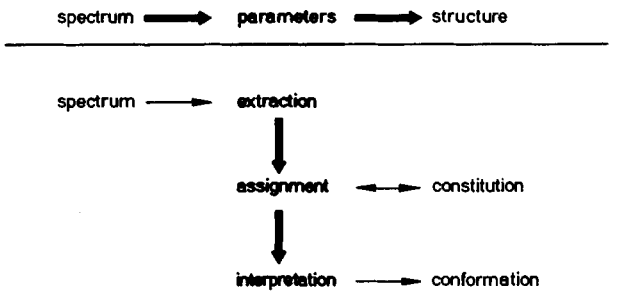

Fig. 8. Interpretation of NMR spectra.

Table 1 serves to summarize all currently available NMR techniques for determining peptide conformation.

Important first indications concerning molecular structure are provided by knowledge of the orientation of amide linkages, which on the whole is defined by hydrogen bonding (intra- or intermolecular or by interaction with the solvent). Intermolecular hydrogen bonds and those to the solvent are readily cleaved with increasing temperature, because the decrease in entropy, which goes hand in hand with solvent bonding, is increasingly evident at higher temperatures (Fig. 9). This is true for all hydrogen bonding solvents, and the most numerous and meaningful results have been obtained for solutions in DMSO[25,26,97,107-112]. In this solvent, generally speaking, temperature gradients for the chemical shift of the N*H*-signal in excess of 4×10^{-3} ppm/K are considered evidence of external NH-orientation, while values of under 2×10^{-3} ppm/K point to solvent shielding[*][97].

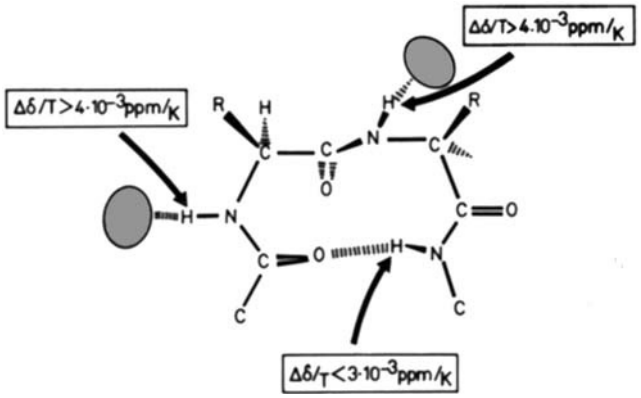

Fig. 9. Temperature gradients $\Delta\delta/T$ of the N*H* signals in dimethyl sulfoxide (DMSO) using the example of a β-loop.

Within the framework of conformational studies it is possible to interpret solvent effects only after ascertaining that a change of solvent does not induce a conformational change. Replacement of the strongly H-bonding solvent DMSO by $CDCl_3$ leads to a considerable shift to higher field of NMR signals of exposed N*H*-groups (Fig. 10)[113,114]. This effect is evident in mixtures containing more than 50% $CDCl_3$, because the interaction between this solvent and residual DMSO leaves insufficient of the latter to bond to the peptide[97]. Conversely, solvents which can act as H-donors for hydrogen bonding, such as trifluoroethanol (TFE), can shift the NMR signals of the neighboring N*H*-proton to lower field *via* "protonation" at

[*] Use of the δ-scale for chemical shifts necessarily leads to negative values for the temperature gradient defined by $\Delta\delta/T$. In the literature on the other hand, values are encountered which are positive for historical reasons (use of the τ-scale), and this review holds to the latter convention, *i.e.* a positive value indicates shift of the N*H*-signal to higher field with increasing temperature.

Table 1. Possible methods of determining the conformation of peptides by NMR spectroscopy.

Cause	Observed Spectral Parameter		Typical Information
Interaction with the environment	N*H*-shift as a function of: solvent, temperature		Orientation of the amide bond, H bonds
	Paramagnetically-induced spectral changes		Distinction between peripheral and inner nuclei
Interactions through-bonds	Scalar couplings:	vicinal coupling	Angles ϕ, ψ, χ
		geminal coupling of glycine H_α	Angle χ
		direct coupling ^{13}C-H	$C_\alpha CO$ angle
		direct coupling ^{15}N-H	*cis/trans*-Isomers of the amide bond
	^{15}N chemical shift		H bonds to neighboring CO
Interaction through space	Chemical shift:	^1H (anisotropic)	Orientation of aromatic side-chains
		^{13}C (steric and electronic effects)	*cis/trans*-Isomerization at proline
	Dipolar coupling:	NOE effect (^1H)	Intramolecular proton distances
Mobility	Line Coalescence		Processes with relatively high barriers
	Relaxation times ^{13}C (T_1 and NOE)		Mobility of side chains
Chemical exchange	H/D Exchange rates		Extent of exposure of the NH groups

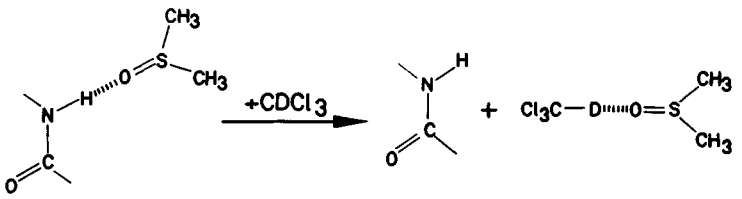

Fig. 10. Effect of titrating a DMSO solution of a peptide with $CDCl_3$. The removal of H bonds to the solvent at $CDCl_3$ levels of > 50% leads to a strong high-field shift of the N*H* signal.

the carbonyl oxygen (Fig. 11)[113, 114]; this effect however is more difficult to evaluate, since the addition of protic solvents also causes conformational changes.

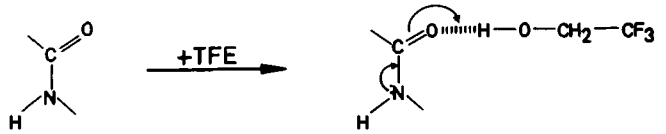

Fig. 11. Effect of adding a protic solvent (here: TFE) to a peptide. A shift of the N*H* signal to low field is observed because of "carbonyl protonation".

Vicinal coupling constants ^3J, whose dependence on dihedral angle is expressed by the Karplus equations, are of great importance in conformational analysis. As these functions are highly dependent on the type of substituent involved, special expressions derived empirically from a wealth of experimental data have been proposed for various different bond types[115–117]. Of particular importance is the easily measurable homonuclear $^3J_{HNC_\alpha H}$ type of coupling, which is dependent on the angle ϕ. However, it is difficult to achieve unambiguous results with such measurements, because of the ambiguity of the Karplus curve (most measured coupling constant can correspond to four different bond angles!) and the range of experimental error. The ambiguity problem can be solved in principle by evaluation of additional coupling constants for a particular bond (Fig. 12). This entails either special instrumental conditions, or the tedium of synthesizing peptides specifically enriched by ^{13}C and/or ^{15}N, since it is difficult to deduce heteroatom—proton coupling from a spectrum directly. For this reason there are only few instances where exhaustive treatment of multicoupling have been described[116, 117]. However, a recent development describing the use of two-dimensional NMR spectroscopy in dealing with heteronuclear coupling over more than one bond[118] should greatly improve the availability of such data.

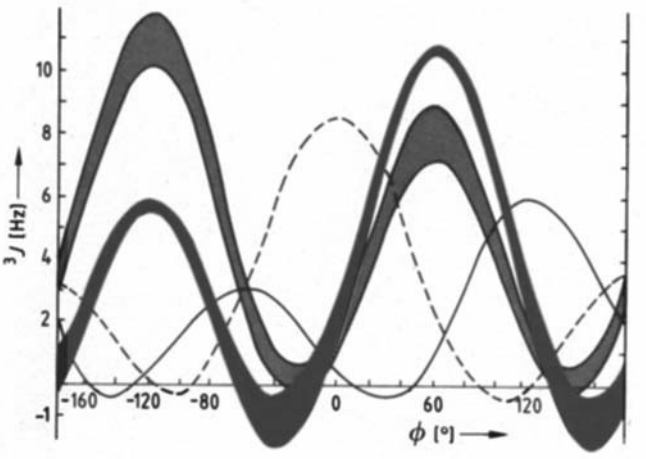

Fig. 12. Interpretation of the vicinal coupling constants for the determination of the ϕ angle (after *Bystrov et al.* [116]). ▨: $^3J(H—NC_\alpha—H)$; ■: $^3J(^{13}C'—NC_\alpha—^1H)$; —: $^3J(^1H—NC_\alpha—^{13}C_\beta)$; ---: $^3J(^1H—NC_\alpha—^{15}C')$. See Figure 7 for the definition of the angle ϕ (ϕ refers to the L-form).

The situation is different with conformations of side chains (angle χ). Here it almost always necessary to make the prior assumption of a rapid equilibration between several conformations which is analyzable by interpreting vicinal coupling constants (such as between the α-proton and the two diastereotopic β-protons within an amino acid residue)[115, 119, 120]. Proline is of special significance in this respect[27, 78, 121, 122] in view of its importance in the specific construction of peptide structures and the manner of folding of peptide chains in proteins[123, 124]. Here, on the one hand, the flexibility of the "side chain" is undoubtedly restricted by its attachment to a five-membered ring, but on the other, since this is a pyrrolidine ring, a rapidly established equilibrium between many conformations in such a system has to be taken into account. Originally, the discussion on the conformation of proline was based on the assumption of two rapidly equilibrating Ramachandran conformations[125], but later more exact analysis indicated that a greater range of pseudorotation must be taken into ac-

count[126-128]. Since, *e.g.* for the C_β—C_γ bond a total of four vicinal coupling constants (two *cis*- and two *trans*-couplings) is available for determining the angle, it is possible to arrive at a complete analysis of the equilibrium between several conformations by a series of iterative calculations[128, 129].

From the more easily available vicinal coupling data it is not generally possible to arrive at direct information on the angle ψ (N—C_α—C′—N), though in the case of glycine the value of ψ has been found to be related to the geminal coupling between the two α-protons[115, 130-132]. More recently, measurement of the direct ^{13}C-^1H coupling constant has been suggested as a means of determining the angles ψ and ϕ[133, 134].

A *trans*-conformation of the amide linkage ($\omega = 180°$) can now be deduced[85, 115] from the value for $^1J_{^{15}N-H}$, which has recently become more accessible by use of the INEPT technique[*][135, 136]. In linear and macrocyclic peptides such *trans*-peptide linkages (*Z*-conformations) have been observed in every case examined so far.

In a few instances it has been possible to use the long range coupling between α-protons in two neighboring amino acid residues[137] or between and α-proton and the δ-protons in a proline residue for sequence determination[78].

Chemical shifts *per se* are generally more difficult to exploit. One phenomenon which may possibly prove useful is that of the downfield shift of a ^{15}N-NMR signal encountered when the carbonyl group adjacent to the amino group participates in hydrogen bonding[85, 138-140]. Prior to this, information of this kind had not been available.

In using ^1H-NMR spectroscopic chemical shifts, anisotropy effects from neighboring carbonyl groups or aromatic side chains must be singled out first and foremost as a source of information on molecular geometry. Thus, the orientation of an α-proton of one amino acid residue in the plane of the carbonyl group of the adjacent amino acid leads to a considerable shift to lower field (Fig. 13, cf. [78, 85, 141, 142]). A characteristic example of the effect exerted by aromatic side chains is the upfield shift of the α-protons of lysine 9 by the neighboring indole ring of tryptophan 8 in the biologically active sequence of the peptide hormone somatostatin[143-146]. This effect of course prescribes a specific folding of the peptide chain and can therefore be used for diagnostic purposes with synthetic somatostatin analogues having potential biological activity[147].

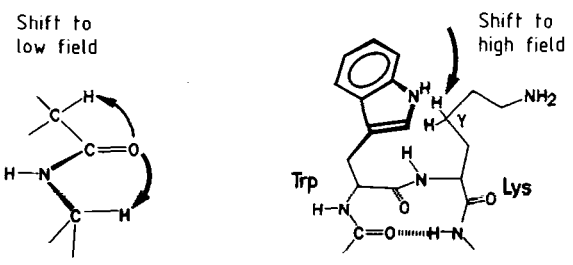

Fig. 13. Anisotropy effect on the chemical shifts of the γ-protons of lysine 9 of somatostatin due to the neighboring carbonyl groups and the aromatic side chain of tryptophan 8.

[*] INEPT = insensitive nuclei enhanced by polarization transfer.

As previously mentioned, amide linkages in peptides generally assume the *trans* (*Z*-) conformation. However, in peptides containing *N*-alkyl amino acid the presence of both conformations has to be reckoned with. The ^{13}C-chemical shift of C_β and C_α in proline rings, in particular, can give clear information on the stereochemistry at this bond[27, 37, 148] (Fig. 14).

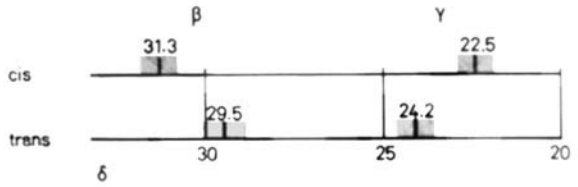

Fig. 14. Typical chemical shifts of the C_β- and C_γ-atoms for *cis*- and *trans*-Xxx-Pro-amide bonds in proline-containing peptides.

Siemion et al.[149] have put forward a quantitative relationship between the *difference* in chemical shifts between C_β and C_γ in proline and the angle ψ, and have also applied this to conformational analysis in a number of cases, but in our opinion their conclusions do not stand up to the test of critical examination[98].

Recently, the experimental determination of nuclear Overhauser effects (NOE)[150] has been facilitated by a number of improvements[88-94]. In one-dimensional NMR these effects manifest themselves by changes in signal intensity following irradiation at the resonance frequency of a nearby nucleus. Since homonuclear intramolecular NOE's between protons are caused by a dipolar relaxation mechanism there is a correlation between them and the distance between these protons. In most cases, however, NOE's can be observed only if that distance is not greater than 3—4 Å. In smaller molecules (in our case up to cyclic hexapeptides) NOE's are positive at medium field strength (*e.g.* when using a 270 MHz spectrometer) and under normal conditions (room temperature, DMSO as solvent). In proteins and at higher field strengths they are negative. In the latter case, the problem of spin diffusion[151-152] may arise, so that time dependence of NOE build-up is an additional factor to be considered[91, 153-155]. For further details the reader is referred to the literature cited.

NMR spectroscopy can also provide information on molecular dynamics phenomena. With exchange phenomena, *e.g.* the transition between several conformations or the exchange of NH-protons with the solvent, line broadening and signal coalescence are encountered when the energy barriers involved are in the range 5—25 kcal/mol[67-69]. Such conformational equilibria occur mainly because of rotation around the amide bond in peptides containing proline units[156] (rotational barrier *ca.* 20 kcal/mol), and in smaller cyclic peptides[50-53, 65, 66, 141, 142, 157, 158] where the ring reduces conformational freedom of movement. More rapid processes, such as the mobility of side chains in larger peptide molecules, can be followed by measuring ^{13}C spin lattice relaxation times (T_1) in cases where a dipolar relaxation mechanism is confirmed by the simultaneous measurement of a heteronuclear NOE[37, 41, 159, 160].

Only limited conclusions can generally be drawn on thermodynamic stability by following the course of a

chemical reaction, and this also applies to the information obtained in some instances on the "exposure" of NH-groups within a conformation by following the rate of exchange with deuterons (from added D_2O)[161, 162] or by saturating the H_2O signal and following the saturation transfer[99, 163] to the NH-signal[164–166]. In all likelihood, 2D-exchange spectroscopy will in future be used more frequently for studies of this kind[167]. In situations where any one conformation is strongly favored in a cyclic peptide, one would expect that NH protons directed outwards would be exchanged much more rapidly than those directed inwards, which are also more likely to participate in intramolecular hydrogen bonding. Admittedly, such arguments would fail in cases of rapid equilibration with another conformation (albeit less populated), where perhaps an even faster exchange of such "inner" NH protons might occur. This is merely one example to illustrate that in this approach to interpreting exchange rates one has to proceed with caution.

We have seen that NMR spectroscopy is a most versatile method for obtaining information on peptide conformation in solution. Of course, this review cannot cover the various techniques employed in more detail, but it does aim to provide a guide for the reader to the various options open to him.

5. Conformational Homogeneity in Solution

In Section 3 it was stressed that it must first be ascertained whether one is dealing with conformational homogeneity in tackling the problem of peptide conformation in solution. The reason why this principle was violated in this survey by treating this subject in Section 4 is because a familiarity with the NMR techniques in conformational analysis is desirable before detailed questions of conformational homogeneity are dealt with. Whereas as previously mentioned rapidly established equilibration between various conformations has to be considered as the norm for peptides in solution, it can also be assumed that the mobility can differ greatly in different parts of the peptide molecule. Thus, in smaller cyclic peptides we can expect greater rigidity from the peptide framework "backbone", and greater relative mobility for the side chains.

Strictly speaking, everything mentioned in Section 4 about using NMR spectroscopic techniques is valid only when the molecule assumes a single conformation, or where one conformation is so dominant at equilibrium that the effect of others on spectroscopic parameters is negligible. Statements on so-called "median" or "average" conformations should be treated with the greatest caution[70]. The problem is that all evidence on conformational homogeneity is indirect in nature. It is only the sum total of many different items of evidence which ensure a reasonable extent of certainty on this point.

In general, differences in chemical shifts, coupling constants, and temperature dependence between different amino acids in the peptide sequence can be used as indicators of conformational homogeneity; the smaller these differences, the greater the likelihood that a rapidly established conformational equilibrium will cause an averaging-out of these parameters. An example is provided by the cyclic pentapeptides. These are of special interest because they are the smallest cyclic peptides in which all amide linkages can have an unstrained *trans*-conformation, and in which we can expect a relatively strong inhibition of mobility. *cyclo*[Gly_5] and *cyclo*[Phe_5] show only a single set of glycine and phenylalanine signals, respectively, in the ^1H- and ^{13}C-NMR spectrum[97, 168]. The explanation could either be an inherent C_5-symmetry of the molecule, or a five-fold degenerate, rapidly established equilibrium of one or more conformation types[*] (median C_5-symmetry)[170, 171]. Evidence for the latter assumption is provided by the average temperature gradients for the NH-signal chemical shifts: $\Delta\delta/T = 2.96 \times 10^{-3}$ ppm/K (Gly), and 3.71×10^{-3} ppm/K (Phe). Introduction of a "symmetry distortion" in such compounds, *e.g.* by replacing the *pro-S* proton of the glycine unit by a methyl group (*i.e.* forming *cyclo*[Ala-Gly_4])[98] leads to pronounced differences in NH-shift temperature gradients for the separate amino acids units (see Fig. 15). Here, the methyl group appears to occupy a preferred position (thermodynamically) within its conformation(s). In *cyclo*[Phe-Gly_4], which has an even larger side

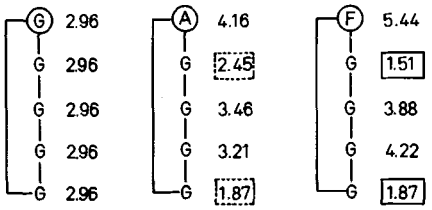

Fig. 15. Temperature gradients of the N*H* signals of three cyclic pentapeptides of type *cyclo*[Xxx-Gly_4] in DMSO [10^{-3} ppm/K] (see text); G = Gly, A = Ala, F = Phe (international single-letter symbols).

chain (benzyl groups)[97, 98, 168], the differentiation in the NH-shift temperature gradients is even more pronounced, as are those of the chemical shifts and coupling constants of the two diastereotopic α-protons in the glycine units[168]. Here, we can conclude that one conformation is predominant at equilibrium. After assignment of signals had been performed by synthesizing specifically deuterated deriva-

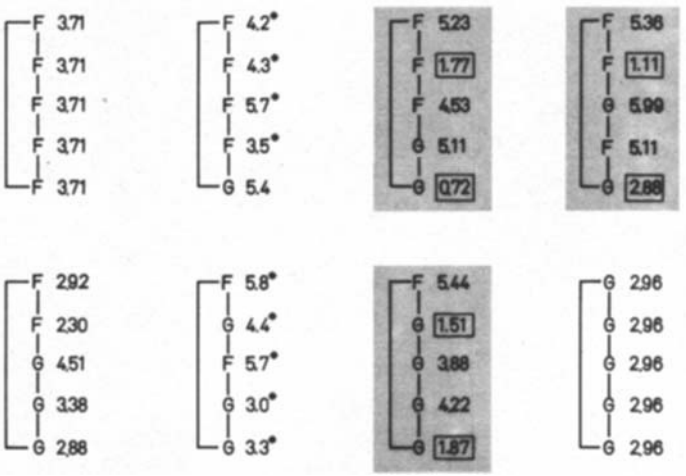

Fig. 16. Temperature gradients of the N*H* signals of all the cyclic pentapeptides of L-Phe(F) and Gly (G) in DMSO [10^{-3} ppm/K]. The three peptides on the shaded background are probably conformationally homogeneous. The values with asterisk were not assigned sequentially.

[*] In [168] it has been demonstrated that, *e.g.*, the transformations: $\beta_1\gamma_2 \rightleftharpoons \gamma_1\gamma_2 \rightleftharpoons \gamma_1\beta_2$ *etc.* occur easily and involve no great barrier.

tives, it was concluded[98] that an γ,γ-conformation (cf. Fig. 17)[109,111] is the most probable. Similar evidence of possible conformational homogeneity has been found in three of the eight possible pentapeptides containing only L-phenylalanine and glycine units (Fig. 16). The remaining five are thus to be considered as conformational mixtures and are unsuitable for conformational studies.

Altogether *ca.* 20 cyclic pentapeptides have so far been found likely to be conformationally homogeneous[85,97,109-111,172-180]. In these molecules two basic types can be distinguished, each with two intramolecular hydrogen bonds: the β,γ- and the γ,γ-conformation shown in Figure 17. The main aim of these studies was to find out

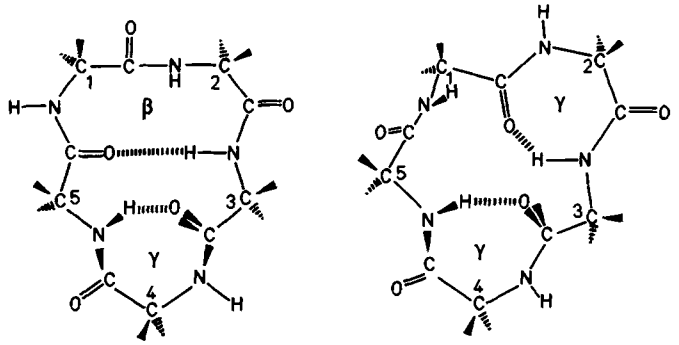

Fig. 17. The two most important conformations of cyclic peptides.

whether specific amino acid units tend to occupy specific sites within a given conformation. The results obtained so far can be summarized as follows[109,111]:

- Position 3 (Fig. 17) is usually occupied by glycine or a D-amino acid
- Position 4 in the γ-loop is generally taken up by a sterically demanding unit (Pro, Val, Phe, Aib)
- Proline preferentially occupies position 1 or 4

These and other results should make it possible to predict the most stable conformation of a peptide with a given amino acid sequence, or alternatively to forecast the best sequence to fit a desirable conformation. These results also show that for predominance of any particular peptide conformation, the exact nature of a side chain is of less importance than the absolute configuration. Thus, the four cyclic peptides shown in Figure 18, which have in common a sequence of three L-amino acids and two glycine units, have the same conformation in DMSO solution, whereas replacing L-Phe in position 2 in the cyclic peptide *cyclo*[Phe_3-Gly_2] by D-Phe leads to a marked change in the NMR parameters. In Figure 18 the N*H*-shift temperature gradients are used as the principle criteria[98,111], but other NMR parameters behave similarly.

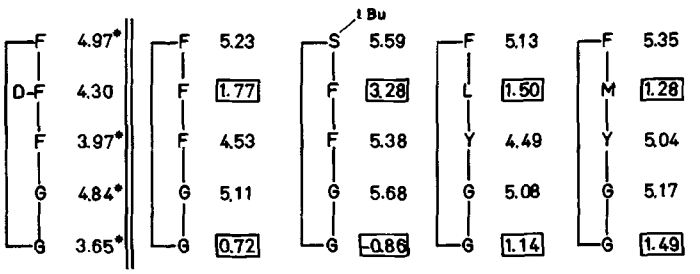

Fig. 18. Temperature gradients of the N*H* signals of some cyclic pentapeptides in DMSO [10^{-3} ppm/K]. The two first peptides from the right are cyclic enkephalins. F = L-Phe, D-F = D-Phe, G = Gly, L = Leu, M = Met, S-tBut = Ser(O-*t*Bu), Y = Tyr.

Of course, the minimal extent of side-chain influence on preferred peptide conformation is not encountered in every case. For example, replacing phenylalanine by serine in the i + 2-position of a β-loop is found to enhance the instability of that loop[110,181], and serine, in particular, is known to cause breakdown of β-structures[182,183].

The main indicators for conformational homogeneity are summarized as follows:

- Strong differentiation of temperature gradients of the N*H*-signals between separate amino acid units
- Similarly strong differentiation between chemical shifts of like amino acid units within the sequence
- Large chemical shift differences between geminal diastereotopic glycine protons
- Strong differentiation between vicinal coupling constants of diastereotopic protons (N*H* to both α-protons in glycine, and $C_\alpha H$ to both diastereotopic β-protons in other amino acid units)
- Large differences between N*H* $C_\alpha H$ coupling constants (a value of *ca.* 7.5 Hz can be interpreted as the mean for free mobility).

In additions to the absence of the above, the following can be taken as indicative of conformational heterogeneity:

- Non-linearity of N*H*-shift temperature gradients
- Change in coupling constants following change of solvent.

6. Conformation of Cyclic Peptides with Biologically Active Amino Acid Sequences

The need to restrict the mobility of peptide molecules in order to obtain information on their conformation has been discussed on a number of occasions[27-31,97]. So far, structure-activity relationships have been studied mainly on the basis of changes in constitution. Noteworthy contributions, which also take conformation into account, are *e.g.* those of *Hruby et al.* in connection with oxytocin[21], and above all those of *Veber*'s group on somatostatin[28-30,190]. The various steps leading to the development of the biologically highly active minisomatostatin are exemplary in illustrating this kind of study and are therefore summarized here.

Somatostatin[184], a tetradecapeptide containing a disulfide bridge between Cys-3 and Cys-14 (see Fig. 1) is formed in the hypothalamus and other endocrine glands (*e.g.* pancreas D-cells)[185,186]. It acts by inhibiting the release of peptide hormones such as glucagon, insulin, gastrin, secretin, and the growth hormone[185,186]. Activity studies on derivatives had previously shown that amino acids Ala-1 and Gly-2, which are not part of the ring, could be omitted without loss of activity, and that replacing tryptophan 8 by its enantiomer (D-Trp) resulted in an eightfold

increase in activity[187-189]. Together with numerous NMR studies on somatostatin[*] itself, these results were explained[143-146] by assuming that the sequence Phe^7-Trp^8-Ly^9-Trp^{10} is part of a β-loop. *Veber*'s group then synthesized somatostatin derivatives in which ethylene replaced the disulfide bridge[28,29,31], as well as bicyclic analogs with decreasing ring size[29,30]. These studies have ultimately led to the highly active cyclic hexapeptide "minisomatostatin"[147,190,191] in which only the sequence 7—10 of the original hormone is retained and the rest has been replaced by phenylalanine and proline. In this work NMR results on bicyclic intermediates and computer calculations on bridging in the conservation of a biologically active conformation were of paramount importance in setting the right course. Above all, the combination of instrumental and computational work made it possible to effect a drastic reduction in the number of derivatives which had to be synthesized and tested biologically.

Similarly, cyclic derivatives of enkephalins[111,192-200] and other cyclic peptides containing any biologically active sequences will also help to clarify the relationship between conformation and activity.

7. Conclusion and Outlook

NMR spectroscopy is an excellent probe for recognizing molecular conformation, because it responds to individual atoms in their specific environment. Since it can be used favorably to study molecules in solution, it fulfills the requirements for the investigation of intra- and intermolecular interactions. In addition it also provides considerable information on molecular dynamics.

Considerable advances in resolution and sensitivity in NMR spectroscopy have been brought about by the use of superconducting magnets and the discovery of 2D-NMR techniques. However, they also had a significant effect on the rapid, ever continuing development of NMR techniques to solve more and more complicated problems. Even the spectra of complicated natural products can now be reliably analyzed and assigned.

Apart from their roles in the transport of energy and material, natural products have an important function in information transfer. This involves weak interactions with the environment (*e.g.* hormone-receptor interaction, enzyme-substrate interaction, intercalation in nucleic acids, incorporation into membranes).

Individual weak interactions, because of their small magnitude, are difficult to detect *energetically*; however, they find their *geometrical* expression in conformational changes in the molecules involved. The order in the crystalline state, which can be represented by X-ray structure analysis, is contrasted in solution by considerable conformational multiplicity. The conformation can be changed by the influence of the solvent, by complex formation with metal ions, or by a biological receptor. Even these changes can be followed by NMR spectroscopy by incorporating molecules into membranes. Studies of this type, which I consider to be a prerequisite for "conformative drug design" will be of the greatest significance in the future.

The author's own work cited in this survey was performed by his coworkers as listed, to whom he wishes to express his gratitude. Special thanks are due to Professor R. Geiger (Hoechst AG) for his suggestions and for generally providing a stimulus for our work. Stimulating discussions on the English translation with Prof. H. J. E. Löwenthal (Technion, Haifa) are gratefully acknowledged. Financial support and gifts of chemical were provided by Hoechst AG, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.

(Oxamidoximato)(oxamidoxime)platinum(II) 7,7,8,8-Tetracyanoquinodimethanide: A Crystal Structure with Segregated Parallel Stacks**

By *Helmut Endres**

The organic acceptor 7,7,8,8-tetracyanoquinodimethane ("tcnq", 2,2'-(2,5-cyclohexadiene-1,4-diylidene)bispropanedinitrile) is known as a component of "organic metals", which contain segregated parallel stacks of tcnq and planar organic donor molecules[1]. Attempts to obtain compounds crystallizing in this type, in which one of the two organic components is replaced by a planar metal complex, have been unsuccessful until now. Only the crystal structures of a few bis(arene)metal-tcnq salts with segregated stacks of the two components are known[2]. Such a structural type with a planar transition metal complex should be favored by hydrogen bonds between the two components. Bis(oxamidoximato)platinum(II) appears to be a suitable metal complex, since the α,β-dionedioximato complexes of the Ni triad crystallize in stacked structures[4] and oxamidoxime ("diaminoglyoxime", $oaoH_2$) with its amino groups readily forms H bonds.

The blue-black title compound was prepared by mixing methanolic solutions of Li(tcnq) and $Pt(oaoH_2)_2Cl_2$. The X-ray crystal structure analysis[11] (Fig. 3) indicates that the salt crystallizes in the desired structural type. Since the compound is paramagnetic, and is not obtained when neutral tcnq instead of Li(tncq) is used, it is assumed that tcnq is present in monoanionic form. This is also in accord with the CN stretching frequency, which is observed as a doublet at 2165 and 2200 cm^{-1} (cf. Li(tcnq): 2180 and 2210 cm^{-1}, tcnq: 2225 cm^{-1}). The metal complex must be a monocation, since the ratio metal complex: tcnq = 1 : 1; hence, only one of the two oxime ligands has lost a proton. Although the positions of the H atoms could not be determined, the structural analysis gives a clue about the position of the "surplus" H atom: the intermolecular O-O distance (255 pm) between the oxime oxygen atoms of the neighboring metal complexes in the *y*-direction indicates an intermolecular H bond between these; in addition, the usual intramolecular H bonds in bis(dioximato) complexes occur. The "additional" proton, therefore, links neighboring metal complexes; this has also been observed *e.g.* in the complex $Ni(oaoH)_2 \cdot HCl \cdot H_2O$, in which the position of this H atom could be determined.

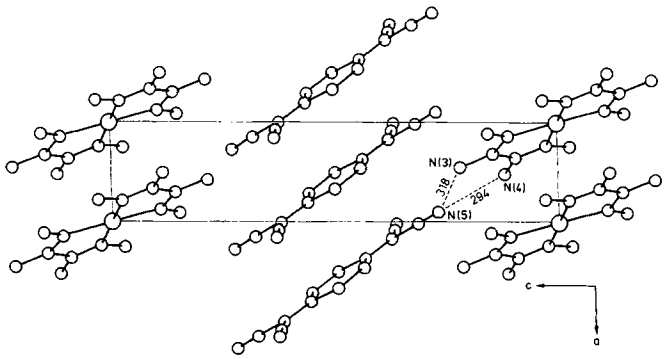

Fig. 3. Projection of the structure of the title compound in the *ac*-plane. Some of the H bonds between the metal complex and tcnq are indicated. Pt is located at the origin of the centric unit cell, and the midpoint of tcnq at the inversion center at 1/2, 1/2, 1/2.

Cations and anions form regular parallel stacks in the *x*-direction; the interplanar distances are 341 pm in the metal complex and 320 pm in the $tcnq^{\ominus}$ stack. This structure, in which every tcnq molecule carries a complete negative charge, leads one to expect semiconductor behavior for the compound[10]. Consistent with this is the fact that the conductivity of the compound is approximately a factor of 50 higher than that of Li(tcnq). Thus we have synthesized the first compound with segregated parallel stacks of a planar metal complex and tcnq, and have characterized it by X-ray structure analysis.

Reaction of α-Cyanophenylacetaldehyde with Sulfonyl Chloride

By *Ulrich Hertenstein**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

α-Cyanophenylacetaldehyde **1** reacts[1] with sulfonyl chloride in CCl_4 to afford the novel 3-chloro-2-cyano-2-phenyloxirane **2** (85%)[2a]. In contrast, in benzene the reaction proceeds to give α-cyano-α-chlorophenylacetaldehyde **3** (88%)[2b]; both **2** and **3** are strong lacrymatory agents and allergens. **2** is cleaved by secondary amines such as

After 20 min the mixture is distilled, b.p. = 132–134 °C/0.005 torr; m.p. = 98 °C; ^{1}H-NMR ($CDCl_3$): δ = 0.25 (s, 9H), 5.55 (s, 1H), 7.45 (m, 5H), 8.05 (s, 1H), 8.20 (s, 1H).

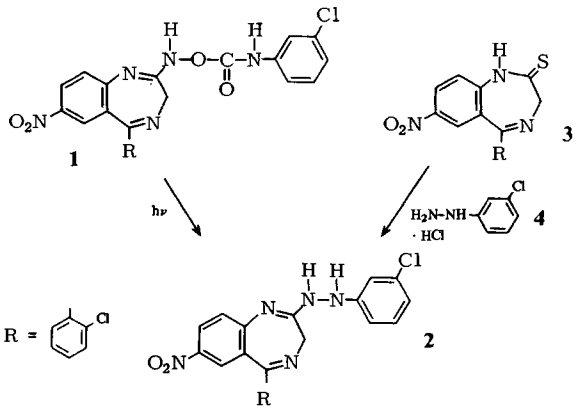
Light-Induced Decarboxylation of Carbamoyloxyamino Compounds

By *Gregory M. Shutske* and *Manfred Försch**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

In the search for novel anxiolytic compounds we found carbamoyloxyamino-1,4-benzodiazepines with an interesting profile[1], but which, in part, slowly decompose in light. Hence, *e.g.* a pale orange coloration, which increases with the exposure time, is observed when the solid nitro derivative **1** is exposed to sunlight. A novel compound was detected in the thin layer chromatogram of the mixture. The MS (*m/z* 239 (M^+)) allows a light-induced cleavage of CO_2 to be assumed. Proof that the decomposition product is **2** was provided by synthesizing it from the known thione **3**[2] and 3-chlorophenylhydrazinium chloride **4**.

Until now, light-induced decarboxylations of carbamoyloxyamino compounds were unknown. The thermal decarboxylation of *in situ* formed 2-ethoxycarbonyloxyamino-1,4-benzodiazepines to 2-amino-3-ethoxy-1,4-benzodiazepines has recently been described[3].



Procedure

2: A solution of **3**[2] (3.3 g, 10 mmol) in 20 mL of dimethylformamide at 50 °C is treated with **4** (1.8 g, 10 mmol) and $NaHCO_3$ (2.0 g, 24 mmol). After being stirred for 1 h at 50 °C and subsequent TLC control, the oil is extracted with CH_2Cl_2/water; the organic phase is separated off, dried, and concentrated *in vacuo* using a rotary evaporator. After purification by column chromatography (silica gel; CH_2Cl_2/EtOH (9 : 1), orange needles of analytically pure **2** (0.6 g) are obtained (decomp. = 159–160 °C, isopropyl alcohol)[4].

ThI_3, A Janus amongst Compounds with Metal-Metal Interactions**

By *Horst P. Beck** and *Cornelia Strobel*

In the thorium-iodine system, ThI_2[1a] and ThI_4[1b] have been unambiguously characterized and their structures are known. Until now, the only indication that ThI_3 exists was based on thermoanalytical studies of the phase diagram[2]. X-ray powder diagrams of samples of this composition could not be interpreted[2]. We now report the preparation and single crystal structure determination of ThI_3.

Starting from ThI_4, which was synthesized directly by reaction of the elements in Duran ampules at 350 °C and multiple sublimation *in vacuo*, we obtained samples of ThI_3 *via* a symproportionation reaction with Th metal at 680 °C in sealed tantalum ampules. Two different forms of the product are obtained in this reaction: After short reaction times (2–3 d) thin, shiny-black, cylindrical rods were observed ["α-ThI_3", space group B2/b or Bb with pseudoorthorhombic metrics (a = 787.0, b = 2699.1, c = 3149.2

pm, $\gamma \approx 90°$); at low diffraction angles X-ray diffraction gave a pseudohexagonal reflection pattern]. After longer tempering (4—6 weeks) compact, dark crystals having a slight green to brass colored luster on smooth surfaces were formed ["β-ThI_3, for crystal data[3] see Table 1]. This

modification of ThI_3 is an interesting variation of the "one-dimensional metals", which should be compared[5] with the structures derived from the TiI_3 type[4]. Th(1) has a cubic and Th(2) and Th(3) have a square-antiprismatic coordination of I atoms in β-ThI_3. The average Th—I distances are 330, 322, and 325 pm, respectively, and are very similar to those in ThI_4 (313—329 pm) and in ThI_2 (320—322 pm). The formulations $Th^{4+}(2e^-)I_2$ and $Th^{4+}(e^-)I_3$ indicate that the valence electrons are delocalized in a quasi-metal bond or are engaged in Th—Th interactions. The first of these possibilities applies to ThI_2 in which metallic conductivity was detected. In contrast, in ThI_3 both principles are combined. In Figure 1, only the framework of the

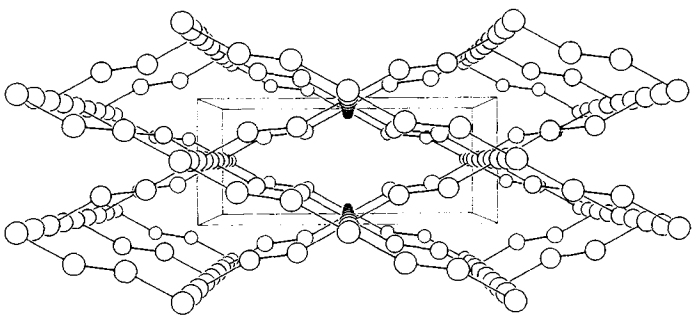

Fig. 1. Framework of the Th atoms in ThI_3 ("β-modification"). Viewed along [001].

metal atoms is shown. A strictly equidistant (366.5 pm) linear arrangement of Th atoms with alternating cubic and square-prismatic coordination by I atoms is found parallel to [001]. At the site of the cubically coordinated metal atoms, the strands are crosslinked by slightly wavy Th chains as "cross-connections" parallel to [110] and [1$\bar{1}$0]. In these chains, longer (380.0 pm) and extremely short (346.0 pm) Th—Th distances alternate. The distances in the Th_2 dumbells are *ca.* 4% shorter than in Th metal (360 pm): the distance between the dumbell atoms and the atoms in the linear chain is only around 5.5% longer, and is still shorter than the Th—Th distances in the metallic conducting ThI_2 (397 pm). The alternatives—equidistant *versus* dumbell-shaped atomic arrangement—are also known in other compounds with metal-metal interactions in chains. Often a transition from delocalization to localization of the valence electrons occurs at a critical temperature. This β-modification of ThI_3 is a "Janus" amongst compounds of this type, since one part of the metal framework appears to be in a state above and the other part, in contrast, in a state below such a critical temperature.

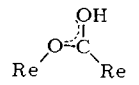
[5] The metrics of the non-characterized α-modification suggest a relationship with other superstructures derived from the TiI_3 variations. The intensity distribution in the observed X-ray reflections cannot, however, be interpreted on the basis of this model.

A μ_3-CO_2 Bridged, Tetranuclear Carbonylrhenium Complex: $[(OC)_5Re(CO_2)Re(CO)_4]_2$**

By *Wolfgang Beck**, *Klaus Raab*, *Ulrich Nagel*, and *Manfred Steimann*

Pentacarbonyl(tetrafluoroborato)rhenium is a particularly reactive starting compound for reactions with σ- and π-donors[1]. Reaction of $(OC)_5ReFBF_3$ with aqueous alkali (20 °C, molar ratio $(OC)_5ReFBF_3/NaOH \approx 1$) results in the precipitation of a colorless product of analytical composition "$Re(CO)_5OH$" **1** (yield 95%), which slowly turns pale jellow in light; the reaction—as determined by potentiometric titration—involves the consumption of one equivalent of OH^- per Re. From its IR spectrum (νCO_2: 1458 s, 1180 s, 1165 sh cm^{-1} in KBr; deuteration only shifts these bands by a maximum of *ca.* 5 cm^{-1}) **1** contains the structural element



The carboxy group in **1** is formed *via* the well known "base reaction"[2] of the metal carbonyl *i.e.* by nucleophilic attack of hydroxide ion at one of the carbon monoxide ligands. Thermolysis (100—150 °C) of **1** affords $[Re(CO)_3OH]_4$[3] and CO; rapid heating to above 200 °C gives CO_2 as detected in the mass spectrum. The action of hydrochloric acid on **1** affords, practically quantitatively, $(OC)_5ReCl$.

The crystalline, colorless, air-stable compound **2** (yield 56%) was obtained from the solution of **1** in acetone (20 °C). IR: 2148 m, 2088 m, 2039 vs, 1992 sh, 1983 s, 1965 sh, 1936 s, 1891 w cm^{-1} (νCO) in THF; 1380 s, 1295 m, 1260 w cm^{-1} (νCO_2) in KBr. In the mass spectrum (140 °C) of **2** the highest mass fragment found was $[Re_2(CO)_{10}O]^+$ ($= [(OC)_4Re(CO_2)Re(CO)_5]^+$). X-ray structural analysis of **2** shows a tetranuclear framework with CO_2 bridges, with every atom of the two CO_2 ligands being bonded to a rhenium atom having a noble gas configuration (Fig. 1).

[**] Organometallic Lewis Acids, Part 10.—Part 9: B. Olgemöller, H. Bauer, H. Löbermann, U. Nagel, W. Beck, *Chem. Ber. 115* (1982) 2271.

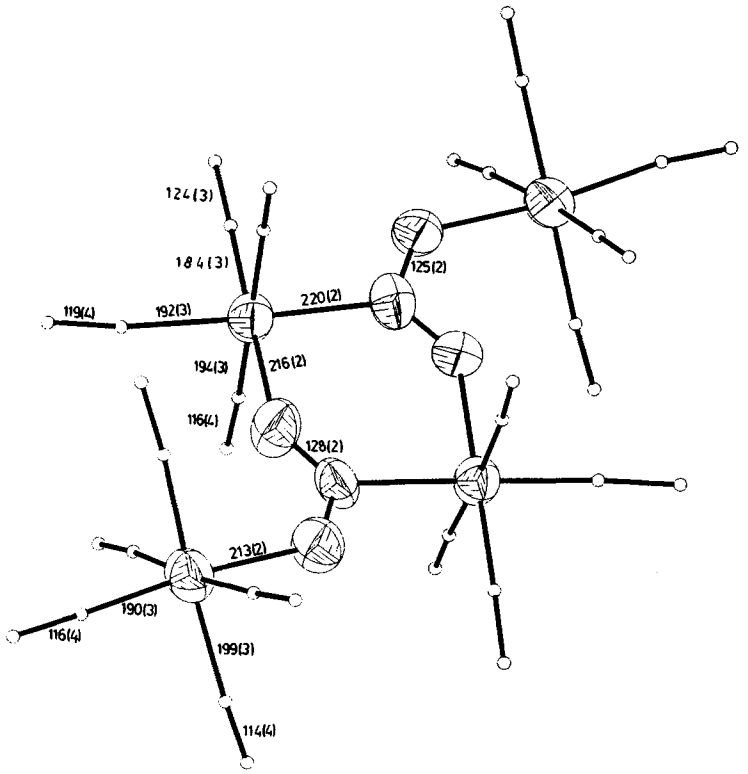

Fig. 1. Molecular structure of complex **2** in the crystal (50% probability thermal ellipsoids). The carbonyl groups are represented schematically and the given bond lengths are averages for the respective equivalent bonds. Space group $P2_1/c$, $a = 1402.3(6)$, $b = 1121.8(4)$, $c = 1954.2(5)$ pm, $\beta = 92.83(3)°$, $\rho_{calc} = 2.89$, $\rho_{exp} = 2.87$ (± 0.05) g·cm^{-3}, $Z = 4$; 4392 reflections ($I > 1.5\sigma(I)$), 215 parameters (measurement: Syntex P3, solution: Shel XTL), $R_1 = 0.084$.

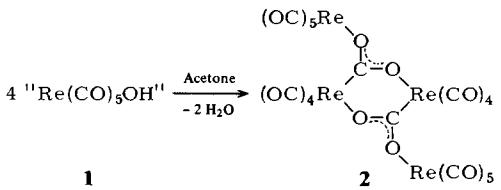
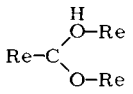
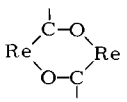
The trinuclear complex $Re_3(CO)_{14}COOH$ with the structural element



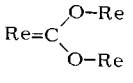
1 **2**



has recently been isolated[4]. As in this compound, the $ReCO_2$ moiety in **2** is planar. The entire six-membered ring



is also almost planar. The CO distances of the CO_2 group correspond to those in the carboxylate anion, and the Re—C bond is almost a σ single bond; hence, **2** can best be considered as a metal carboxylate. A carbene structure



has little weighting. In the $Re(CO)_4$ and $Re(CO)_5$ moieties a shortening of the Re—C bond and a lengthening of the CO bond *via* the *trans*-sited donor atoms of the CO_2 group can clearly be recognized.

2 is of interest since it represents a novel type of coordination of carbon dioxide in CO_2 complexes[5]. For the CS_2 ligand, for which numerous types of coordination are known[6], covalent bridging of three metal atoms has, to the best of our knowledge, not been observed to date.

The bond between a carbonylrhenium group and oxygen donors is apparently very stable, and we were able to obtain the very stable complexes $(OC)_5ReOCHO$, $(OC)_5Re(O_2CCO_2)Re(CO)_5$, $(OC)_5Re(C_4O_4)Re(CO)_5$, $(OC)_5ReONO$, $(OC)_5ReNO_2$ (mixture of isomers) and $(OC)_5ReONO_2$ by allowing $(OC)_5ReFBF_3$ to react with formate, oxalate, squarate, nitrite, and nitrate, respectively.

Constitution of the Deferriform of the Albomycins δ_1, δ_2, and ε**

By *Günter Benz*, Theo Schröder, Jürgen Kurz, Christian Wünsche, Wolfgang Karl, Gerd Steffens, Jörg Pfitzner,* and *Delf Schmidt*

Dedicated to Professor Grünewald on the occasion of his 60th birthday

From the strain *Streptomyces spec.* WS 116 (DSM 1692) three sulfur-containing antibiotics were isolated whose physico-chemical properties were identical in all respects with those of the albomycins δ_1, δ_2, and ε isolated by *Maehr et al.*[2].

The constitution published in 1965[5] (ferriform) for the albomycin δ_2 was later thrown into doubt[2,6].

According to our spectroscopic investigations (CD, UV, MS, ^{1}H-NMR, ^{13}C-NMR) albomycin δ_2 has the constitution **2a**. Mild basic hydrolysis (pH = 8—9, 90 °C, 2 h) of **2a** leads to formation of the albomycins ε and δ_1, which according to their UV spectra have the constitution **2b** and **2c**, respectively.

3) The constitution of the nucleoside moiety is proven by the peracetate of the albomycin δ_2, **4**, and the derivatives **5**—**7**, whose constitution is confirmed by UV, ^{1}H-NMR and MS spectra and, in the case of **4**—**6** by ^{13}C-NMR spectra. The ^{1}H-NMR spectra indicate the furanose form. The 4'-thiofuranose partial structure follows from a comparison of the mass spectrum of **5** (fragment *m/z* 223, high resolution $C_9H_9N_3O_2S$; base + C_2HS)[10] and of the ^{13}C-NMR spectrum of **4** with the corresponding spectra of 4'-thiocytidine[11]. The nucleoside-peptide coupling is proven by the serine-containing nucleosides **6** and **7**.

Mass spectra of the whole molecule are obtained only by the fast atom bombardment (FAB) technique[12]. The $(M+H)^{\oplus}$ mass lines of albomycin δ_2 (*m/z* 993) and δ_1 (*m/z* 951) confirm the proposed constitutions **2a** and **2c**, respectively.

$HF \rightarrow CH_2^{\odot\oplus}$: A Novel, Stable Ion-Dipole Complex**

By *Herman Halim, Bernhard Ciommer,* and *Helmut Schwarz**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Unusual molecules, which because of intermolecular reactions are inaccessible in the condensed phase, can be generated and studied in an ideal way in the gas phase[1]; this applies particularly to ions, whose inherent properties can only be determined experimentally in the gas phase[2]. We report on the first complex of $CH_2^{\odot\oplus}$ with a fluorine derivative. Dissociative ionization of fluoroacetic acid **1** in the gas phase (electron impact ionization, 70 eV) affords, *via* elimination of CO_2, an ion *m/z* 34 (CH_3F) whose collisional activation (CA) mass spectrum differs characteristically from that of $CH_3F^{\odot\oplus}$ **2**, which in turn was generated by ionization of fluoromethane (cf. Table 1). Of the many alternative species $[\mathbf{1} - CO_2]^{\odot\oplus}$ of **2** we propose structure **3**, which provides an explanation why the $[M - CO_2]^{\odot\oplus}$ ions from **1**, in contrast to **2**, do not give signals for $CH_3^{\oplus}$ under CA conditions but those for $HF^{\odot\oplus}$ and very intense signals for $CH_2^{\odot\oplus}$[3].

Table 1. Collisional activation mass spectra of *m/z* 34 for $CH_3F^{\odot\oplus}$ **2** and the $[M - CO_2]^{\odot\oplus}$ ion **3** for CH_2FCO_2H **1** [a].

m/z	**2**	**3**
32	100	100
31	15.8	36.9
20 ($HF^{\odot\oplus}$)	—	1.8
15 ($CH_3^{\oplus}$)	0.4	—
14 ($CH_2^{\odot\oplus}$)	2.1	22.3
13	0.6	3.8

[a] The intensities expressed as % are relative to the base peak = 100%. In the CA spectra of **2** and **3** an intense fragment also occurs at *m/z* 33, which however—in contrast to all the other CA fragments—is also formed by unimolecular dissociation of *m/z* 34.

Molecular orbital calculations at the MNDO[4a] and *ab initio* levels (4—31G/STO-3G[4b]) support our interpretation. **2** and **3** exist in potential minima, whereby the ion-dipole complex **3** is calculated by both methods to be the more stable. Experience with calculations on other ion-dipole complexes[5a] indicates that the *ab initio* results are more reliable, although it cannot be excluded that the use of a 6—31G* basis set would reduce the discrepancy between MNDO- and 4—31G/STO-3G results[5a].

The MNDO and STO-3G geometric data (Scheme 1 contains the MNDO values, bond-lengths [Å], and angles [°]) are very similar in **3**; the only difference involves the

Table 2. Calculated enthalpies of formation (MNDO, kcal/mol), total energies (in Hartrees), and relative energies (kcal/mol) for $CH_3F^{\oplus\ominus}$ **2** and $HF{\rightarrow}CH_2^{\oplus\ominus}$ **3**.

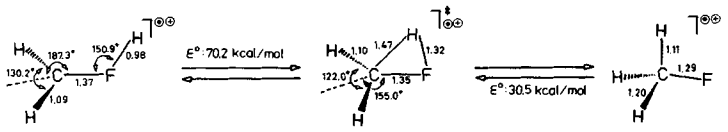
	MNDO	4–31G/STO-3G [a]	
	ΔH_f^0	E_{tot}	E_{rel}
2	223.2	−138.429312	7.1
3	183.5	−138.440611	0

[a] 4–31G/STO-3G indicates complete optimization of geometry at an STO-3G-level and single point energy calculation using 4–31G.

C—F bond lengths (according to STO-3G, 1.47 Å). Comparison of the data for **3** with that for **2**, $CH_2F^{\oplus\ominus}$, and HF leads to the following interpretation: **3** is a slightly bent complex of $CH_2^{\oplus\ominus}$ with HF, in which the C—F bond is formed by interaction of an empty sp^2-hybridized orbital of $CH_2^{\oplus\ominus}$ with one of the nonbonding electron pairs of HF; it is approximately 0.08 Å longer than the C—F bond in **2**. The C—H and F—H bond lengths in **3** are hardly (<0.01 Å) different from those in $CH_2^{\oplus\ominus}$ and HF.

Complex formation does, however, have a considerable effect on the charge distribution; whereas in $CH_2^{\oplus\ominus}$ 60% of the charge is located on the carbon atom and 20% on each of the hydrogen atoms, only 14% of the charge is located on the carbon atom in **3**. The greatest amount of charge is distributed on the hydrogen periphery: the H atom of the HF component accepts 49%, whereas each of the H atoms carry 16%; the F atom only accepts 4%. The unpaired electron of radical cation **3** is, on the whole, localized in a carbon atom $2p_y$ orbital. Complexation of $CH_2^{\oplus\ominus}$ with HF provides a stabilization of at least 43 kcal/mol (estimated from the known experimental ΔH_f^0 values of **2**, $CH^{\oplus\ominus}$, and HF assuming that **3** is at least 7 kcal/mol more stable than **2**).

That **2** and **3** exist as discrete, non freely-interconverting species, follows directly from the MNDO barrier for [1,2]-H migration: the transition state **4** (one and only one negative eigenvalue of the force-constant matrix) lies approximately 70.2 and 30.5 kcal/mol higher than **3** and **2**, respectively. Therefore, if **2** and **3** are generated, they should be considered as stable isomers, which according to their spectral data (*e.g.* the CA spectra) must be distinguishable. This is exactly what is observed (Table 1). The existence of **3** and other more stable ion-dipole complexes $X{\rightarrow}CH_2^{\oplus\ominus}$ ($X=CH_3Cl$[5a], $CH_2=O$[5b], H_2O, H_2S, HCl, and HBr[6c]), which are in part, however, only obtainable *via*



3 **4** **2**

Scheme 1

more complicated and less efficient routes, indicates that a general structural type is involved: the high stability and formally straightforward mode of formation (complexation of the ubiquitous $CH_2^{\oplus\ominus}$ with polar neutral molecules) indicate that this could be significant also in interstellar processes.

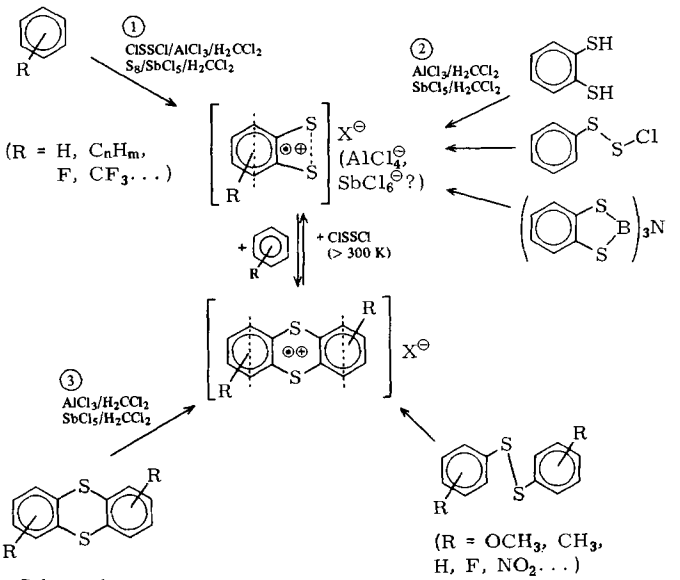
Electron Spin Resonance Studies of the Sulfur Catalysis of the Industrial Dichlorination of Benzene**

By *Hans Bock**, *Udo Stein*, and *Peter Rittmeyer*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

In the dichlorination of benzene in suspensions with 1.5% $FeCl_3$ it is known[1] that the addition of sulfur (or sulfur compounds such as dichlorodisulfane or thianthrene[2]) considerably improves the selectivity: the yield of 1,4-dichlorobenzene increases from 47% to approximately 75% and that of the *ortho*-isomer decreases from 37% to *ca.* 22%[1,2].

The conditions of the industrial chlorination suggest a radical cation intermediate. ESR spectroscopy with its high sensitivity, (concentration *ca.* 10^{-5} M, temperatures up to 180 K) therefore offers a possibility of obtaining information on the course of the sulfur-catalyzed, selective dichlorination of benzene. Preliminary results are summarized in Scheme 1:



Scheme 1

1. If dichloromethane solutions of benzene, or its alkyl- or fluoro-derivatives containing two *ortho*-hydrogens at

[**] Radical Cations, Part 53. This work was supported by the Land Hessen, the Deutsche Forschungsgemeinschaft, the Fonds der chemischen Industrie, and the Schlosser-Stiftung (*P. R.*).—Part 52: J. Giordan, M. Eiser, H. Bock, H.-W. Roesky, *Phosphorus Sulfur 12* (1982), in press.

180–200 K are treated with S_2Cl_2 and $AlCl_3$ or with S_8 and $SbCl_5$, the ESR spectra of the radical cations generated, displaying hyperfine structural details, are observed. Based on ^{33}S, ^{13}C, and ^{2}H isotopic labeling, the parent compound (R = H) can be assigned a structure with C_{2v} symmetry: Presumably a ring-closed benzodithiete radical cation is present in solution. Upon warming to room temperature, the known[2] ESR signals of stable thianthrene radical cations appear in addition at high field (R = H: $g = 2.0153 \rightarrow 2.0084$).

2. Oxidation of numerous benzene derivatives[2]—1,2-benzenedithiol, chloro(phenyl)disulfane, and tris(1,3,2-benzodithiaborolyl)amine are shown as examples in Scheme 1—using the tested anhydrous and oxygen-free oxidation systems $AlCl_3/H_2CCl_2$[3b] or $SbCl_5/H_2CCl_2$[3a] also results in solutions in which the ESR signals of the unknown *o*-phenylenedithio radical cation and of the known thianthrene radical cation can be measured.

3. The oxidation of thianthrene and diphenyldisulfanes bearing the same substituents led in each case to identical thianthrene radical cations[2,3]. Addition of dichlorodisulfane and increasing the temperature result in the appearance of additional ESR signals of the substituted *o*-phenylenedithio radical cations.

Information on the preferred 1,4-dichlorination of benzene can be drawn from the ESR result that no signals are observed for substituents R in the "nodal planes" indicated in Scheme 1 by dotted lines, i.e. only a small positive charge and hence the highest electron density for an electrophilic attack is found here[2,3].

Gas phase pyrolyses, optimized by photoelectron spectroscopy[2]—*e.g.* the cleavage of propene from 2-methyl-2,3-dihydro-1,4-benzodithiane—suggest that benzodithiete can be isolated preparatively[4] and hence its chlorination investigated. Further ESR experiments with the aim of detecting reactive sulfur species, such as $ClSS^{\oplus}AlCl_4^{\ominus}$, *via* their reaction products show that the oxidation in presence of sulfur can also be applied to other π-systems. For example under the conditions shown in Scheme 1, substituted phenylacetylenes do not react to give *o*-phenylenedithio and thianthrene radical cations, but[2,4] to 3-phenyl-1,2-dithiete and further to 2,5-diphenyl-1,4-dithiin radical cations.

The Molecular Structure of Gaseous Titanium Tris(tetrahydridoborate) as Determined by Electron Diffraction**

By *C. John Dain, Anthony J. Downs**, and *David W. H. Rankin*

The tetrahydridoborate group is remarkable for the versatility of its ligation to metal centers which may entail triple[1a], double[1a], or even single[1b] hydrogen bridges. To date direct methods of structural analysis have been applied to only one gaseous molecule in which the tetrahydridoborate groups function as tridentate ligands, namely zirconium tetrakis(tetrahydridoborate), $Zr(BH_4)_4$[1c]. Here we wish to report the structure of the gaseous titanium tris(tetrahydridoborate) molecule which we have deduced by analyzing its electron diffraction pattern. The results have added significance in view of the dearth of structural information about molecular titanium(III) derivatives with a trigonal disposition of ligands around the metal atom.

$Ti(BH_4)_3$ was prepared by the passage of a slow stream of $TiBr_4$ vapor through a bed of powdered, freshly recrystallized $LiBH_4$ held at room temperature, the volatile products being removed under continuous pumping and trapped at 77 K. Fractionation *in vacuo* gave samples of $Ti(BH_4)_3$ which were judged to be pure on the evidence of analysis (*via* methanolysis) and of the IR[2a] and UV photoelectron[2b] spectra of the vapor; the preparative procedures previously reported[3] appear, by contrast, to have yielded only impure products. The purified product is a green solid highly susceptible to attack by traces of oxygen or moisture and with a vapor pressure at room temperature in the order of 1 torr; changes in the color and IR spectrum of the solid at lower temperatures imply the existence of more than one solid phase.

The electron diffraction pattern of gaseous $Ti(BH_4)_3$ at room temperature was measured photographically using the Edinburgh/Cornell gas-diffraction apparatus[4] over a range of 22–140 nm^{-1} (scattering variable s). Since the IR and UV photoelectron spectra of the vapor were found to exhibit the patterns characteristic of tri-hydrogen bridged tetrahydridoborate ligands[2a–c], we based the analysis of the electron scattering pattern on a model of the type $Ti[(\mu\text{-}H)_3BH]_3$ involving five independent geometrical parameters and five amplitudes of vibration; data reduction[4b] and least-squares refinement[5a] followed established procedures. Convergence of the structural refinement proceeded satisfactorily, the optimum refinement achieved to date corresponding to $R_G = 0.051$ ($R_D = 0.037$).

[**] We thank the Science Research Council for the award of research grants and of a research studentship (to C. J. D.).

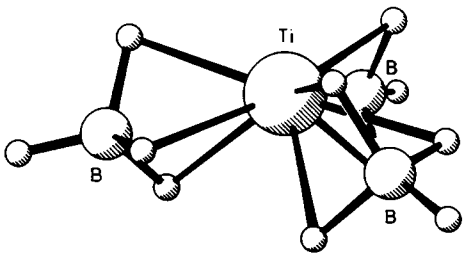

Fig. 1. Molecular structure of gaseous $Ti(BH_4)_3$. The distances correspond to r_a. The sixth parameter is the semi-vertical angle subtended by the Ti—B bonds with respect to the C_3 axis.

Parameter	Bond distance [pm] Bond angle [°]	Amplitude [pm]
r(Ti—B)	221.8(1.5)	9.8(1.2)
r(Ti—H_b)	206.7(1.7)	8.5(2.0)
r(B—H_b)	123.0(0.8)	4.5(1.9)
r(B—H_t)	110.7(2.1)	4.5 tied to u(B—H_b)
r(B···B)	375.8(1.5)	9.1(1.4)
angle	78.0(1.6)	

The two most notable features of the structure of gaseous $Ti(BH_4)_3$ (Fig. 1) are: (i) the triply bridged BH_4 groups generating ninefold coordination of the titanium atom and (ii) the non-planar geometry of the TiB_3 skeleton in which the Ti—B units depart by about 12° from a planar configuration to give a B—Ti—B angle of 115.8(0.7)°. In other respects the structural features resemble those deduced for the $Zr(BH_4)_4$ molecule[1c]. Although the departure from planarity could be an artifice of shrinkage effects, we have reasons for believing it to be an authentic feature of the equilibrium geometry of $Ti(BH_4)_3$. Thus, the molecule naturally invites comparison with $Al(BH_4)_3$, which appears on the evidence of its electron diffraction pattern to contain bidentate BH_4 groups completing a *planar* AlB_3 skeleton[5b]; unless the vibrational properties of $Al(BH_4)_3$ and $Ti(BH_4)_3$ are very different, the electron diffraction patterns admit little alternative to the conclusion that the geometries of the AlB_3 and TiB_3 skeletons are at variance. The same conclusion is reached from an analysis of the IR and Raman spectra of $Ti(BH_4)_3$ contained either in a noble-gas matrix at 15 K or in trichlorofluoromethane solution at *ca.* 250 K[2a]. Hence it appears that the vibrational fundamentals approximating most nearly to the Ti—B stretching modes conform to the selection rules and frequency pattern of a TiB_3 skeleton possessing not D_{3h} but C_{3v} symmetry. Whether the shallow pyramid of the TiB_3 skeleton stabilizes the odd electron by permitting it to be accommodated in a molecular orbital derived from the blending of $3d_{z^2}$ and $4p_z$ AO's of the titanium must at this stage be a matter of speculation; on the other hand, preliminary extended Hückel MO calculations give no grounds for anticipating anything but a planar TiB_3 skeleton[2d].

$[Mo_4(NO)_4(S_2)_6O]^{2-}$, A Novel Highly Symmetric Polynuclear Complex with Two "Handle-Shaped" and Four "Roof-Shaped" Coordinated S_2^{2-} Bridging Ligands at a Tetragonal Mo_4 Disphenoid**

By *Achim Müller**, *Werner Eltzner*, *Hartmut Bögge*, and *Sabyasachi Sarkar*

Molybdenum-sulfur chemistry is full of surprises. This applies in particular, to complexes with S_2^{2-} ligands[1a,c]. Thus, for example, in $[Mo_4(NO)_4(S_2)_5S_3]^{4-}$ **1** it is noticeable that the S atoms are found in five different bonding states[1a,c] (structural data in [1c]).

In the complex $[Mo_4(NO)_4(S_2)_6O]^{2-}$ **2**, which we have now isolated, a (metal)$_4$aggregate (tetragonal disphenoid) is linked *via* a novel bridging system. Indeed, **2** has a very similar stoichiometry to **1**, but has, however, a completely different structure (cf. Fig. 1) with two other types of S_2^{2-} ligands (among which the "handle-shaped", previously found only in one complex[2]). Consequently, **1** and **2** contain four (!) different types of S_2^{2-} ligands (cf. [3]).

The isostructural compounds $(NH_4)_2[Mo_4(NO)_4(S_2)_6O]\cdot 2H_2O$ **2a** and $NH_4K[Mo_4(NO)_4(S_2)_6O]\cdot 2H_2O$ **2b** can be obtained by passing H_2S through an aqueous alkaline solution which contains the reaction product of MoO_4^{2-} and $NH_2OH\cdot HCl$ (unidentified hydroxylamine complex).

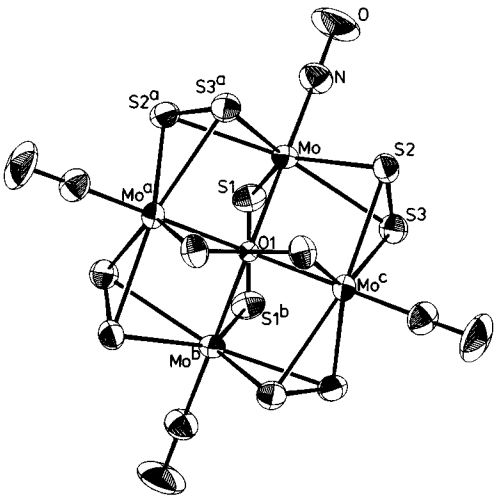

Fig. 1. Molecular structure of **2** in crystals of **2a** and **2b** (S2—S3 ≙ "roof-shaped"; S1—$S1^b$ ≙ "handle-shaped". **2a**: Space group $I4_1/a$; $a = 10.396(3)$, $c = 22.912(5)$ Å; $Z = 4$; 1171 observed reflections; $Mo_{K\alpha}$ radiation; $R = 0.057$.

Fakultät für Chemie der Universität
Postfach 8640, D-4800 Bielefeld 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Minister für Wissenschaft und Forschung (NRW), and the Fonds der Chemischen Industrie.

The black crystals of **2a** and **2b** were characterized by elemental analysis, vibrational spectroscopy, magnetic measurements, as well as by X-ray crystallography.

In the anion **2** (Fig. 1) the Mo atoms form a tetragonal disphenoid (Mo—Mo (short): 3.309(1), Mo—Mo (long): 3.942(2)), over whose edges two handle-shaped (S—S: 2.079(5) and four roof-shaped S_2^{2-} ligands (S—S = 2.061(3)) are situated. An O atom (Mo—O: 2.163(1)) is located at the center. Since an NO ligand (Mo—N: 1.772(8); N—O: 1.205(10) Å; Mo—N—O: 179.0(9)°) is, in addition, coordinated to each Mo atom, every metal center has a pentagonal-bipyramidal environment. **2** is diamagnetic and has the electronic configuration $\{MoNO\}^4$. The 18 electron rule is formally fulfilled for Mo if each bond to the other ligands provides an electron pair. It should be noted that the anion **2**, despite its construction from four kinds of atoms, has the high S_4 symmetry. Comparison of the structures of **1** and **2** indicates that due to steric effects, the μ_4-S atom in **1** is located outside, and the μ_4-O atom in **2** inside the Mo_4 system.

Formation of Metal-Metal Bonds and Conversion of the Metal Aggregate $\{Mo_4(S_2)_4(S_2')_2\}$ by Atom-Transfer and Redox Reactions at Nonequivalent Ligands; $[Mo_4S_4(NO)_4(CN)_8]^{8-}$ an Anion with a Central Cubane-Like Unit**

By *Achim Müller**, *Werner Eltzner*, *William Clegg*, and *George M. Sheldrick*

Reactions of molybdenum-sulfur compounds with CN^- have been discussed in connection with the evolution of Mo enzymes[1] and general prebiotic problems[2]; the reaction of Mo-η-S_2^{2-}-groups is of bioinorganic interest[3]. Thio(cyano)metalates were possibly important in chemical evolution[2].

We report here on the reactions of nonequivalent S_2^{2-} bridging ligands in the tetranuclear anion $[Mo_4(NO)_4(S_2)_4(S_2')_2O]^{2-}$ **1**[4]. The Mo in **1** form a tetragonal disphenoid (without Mo—Mo bonds) with two bridging "handle-shaped" and four "roof-shaped" S_2^{2-} ligands. **1** reacts with KCN to give red crystalline $K_8[Mo_4S_4(NO)_4(CN)_8]\cdot 4H_2O$ **2** in low yield[5], which contains the cubane-like cluster anion **3**. Atom-transfer and redox processes are involved in this reaction, whereby two Mo—Mo bonds are formed. **2** was characterized by crystal structure analysis (Fig. 1), magnetic measurements, as well as by IR, Raman, and XPS spectroscopy.

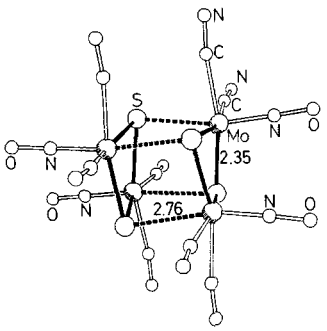

Fig. 1. Structure of **3** in crystals of **2**. Space group $P4_2/nmc$; $a = 12.333(6)$, $c = 11.553(4)$ Å; $Z = 2$; 864 reflections with $F > 4\sigma(F)$; $R = 0.060$ ($R_g = 0.056$). **3** adopts a special position with point symmetry D_{2d} ($\bar{4}2$ m) and has three orientations in the lattice.

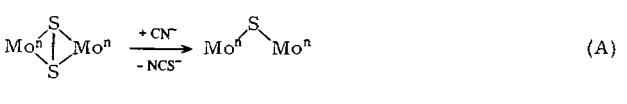
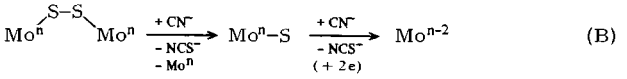
Each Mo atom of the central Mo_4S_4 system in **3** is coordinated by one NO ligand (Mo—NO = 1.76(2)) and two CN^- ligands (Mo—CN = 2.21(2)). The Mo—S bonds (2.76(2)) *trans* to NO are considerably longer than those in the *cis*-positions (2.35(2)), and hence the central unit of **3** can also be described as two linked Mo_2S_2 quadrilaterals with metal-metal bonds (Mo—Mo = 2.99(3); Mo—Mo (long *i.e.* between the two units = 3.67(4) Å). The values given are averages (with estimated standard deviations) for the three disordered positions of **3**. The large negative charge of the diamagnetic anion **3** produces a high electron density on the NO ligands and, hence, an extremely low ν(NO) frequency (1450 cm^{-1} in KBr disc) is observed.

Apart from **3** there are only few polynuclear nitrosyl complexes. Of particular note is the reaction of **1** containing the $\{Mo_4(S_2)_4(S_2')_2\}$ moiety to yield **3** containing the Mo_4S_4 unit. The four "roof-shaped" S_2^{2-} ligands probably react as in (A) (without changing the oxidation staten of



(A)



(B)

Mo) and the two "handle-shaped" as in (B)). In addition, reaction (B) (reduction of two Mo centers by formal addition of 2·2 electrons) leads to the formation of two Mo—Mo bonds. After S transfer as in (A) the bridging S^{2-} ligand of the MoSMo linkage is, as expected, inert towards further nucleophilic attack by CN^-. The trivalency of the sulfur (as originally in the "roof-shaped" ligands) is then

[5] The main product is a yellow species (very probably the less interesting binuclear complex $[Mo_2(NO)_2S_2(CN)_6]^{6-}$ with an additional CN^- ligand *trans* to NO), which is not obtained using the preparative procedure described for **2** because of its higher solubility.

1-Acetoxycarbapenems

By *Wolfgang Koller, Adolf Linkies, Hartmut Pietsch, Herbert Rehling,* and *Dieter Reuschling**

Dedicated to Professor Weissermel on the occasion of his 60th birthday

Since the discovery of thienamycin **1**[1] numerous 1-unsubstituted carbapenem derivatives have been synthesized[2]; in contrast, little is known about 1-substituted systems **2**[3]. We report here on a simple method for the preparation of 1-acetoxycarbapenems.

4-Vinylazetidin-2-one **3** is converted into the *N*-protected compound **4** (77%), which is then subjected to ozonolysis in CH_2Cl_2/CH_3OH (2:1); after reductive work-up the resulting hemiacetal of the 4-formylazetidin-2-one is allowed to react with lithium acetylide. The hydroxyalkynyl compound **5a** (56%) is isolated as the acetate **5b** (55%). Deblocking leads to the azetidin-2-one **5c** (89%), which can be hydrogenated to **6a** (82%) and hydrated to give **7a** (80%). The glyoxylic acid derivatives **6b** and **7b** were prepared from **6a** and **7a** in 81% and 63% yield, respectively (PNB = *p*-nitrobenzyl). Conversion of **6b** and **7b** into the phosphoranes **6c** (60%) and **7c** (87%) was accomplished by the usual methods ($SOCl_2/NEt_3$; Ph_3P/NEt_3). Ozonization of the phosphorane **6c** in the presence of trifluoroacetic acid[9] followed by reductive work-up and neutralization directly afforded the carbapenem **8a** (52%). The intramolecular Wittig-reaction of the ketone **7c**, on the other hand, required much more severe conditions: 32 hours' heating in toluene in presence of propylene oxide led to **8b** (53%). All attempts to cleave the *p*-nitrobenzyl esters **8a** and **8b** hydrogenolytically led to pyrrole derivatives, and not to the expected acids.

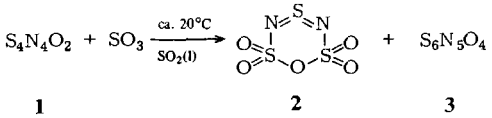
$S_6N_5O_4$, A Compound with Separately Stacked Cyclic Radical Cations $S_3N_2^+$ and Cyclic Anions $S_3N_3O_4^-$**

By *Herbert W. Roesky**, *Michael Witt*, *Jürgen Schimkowiak*, *Martin Schmidt*, *Mathias Noltemeyer*, and *George M. Sheldrick*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Reaction of tetrasulfur tetranitride with sulfur trioxide or other Lewis acids generally leads to formation of 1:1 adducts[1]. In these compounds a nitrogen atom of S_4N_4 is bound to the electrophilic center of the reaction partner, thus changing the structure of the educt S_4N_4 (with all four nitrogen atoms in one plane) to a saddle conformation in which the sulfur atoms form an approximate square. As a consequence, the transannular sulfur-sulfur interaction in S_4N_4 is removed.

If the *S,S*-dioxide $S_4N_4O_2$[4a] **1** is allowed to react with SO_3 in the molar ratio 1:2 in liquid SO_2 the novel compound $S_6N_5O_4$ **3** (20%) is formed, as well as the well-known $S_3N_2O_5$[4b] **2** (80%).



The greenish-black crystals of **3** are extremely sensitive towards oxygen and moisture; they cannot be dissolved again without decomposition.

As shown by the X-ray structure analysis [monoclinic single crystal, space group $P2_1/n$, $a = 700.7(3)$, $b = 1216.8(4)$, $c = 1154.2(3)$ pm, $\beta = 103.61(2)°$; $Mo_{K\alpha}$ radiation, 1140 symmetry-independent reflections with $F > 4\sigma(F)$, $R = 0.0611$, $R_w = 0.0563$], **3** is composed of the $S_3N_2^+$ radical cation and the $S_3N_3O_4^-$ anion (Fig. 1). Structures containing the anion[8] and cation[5], in each case with other counter-ions, are known. In **3**, however, we observed for the first time separated stacks of anions and of radical cations.

The cations in **3** are present as loosely bound centrosymmetric dimers: two S...S distances of 294.7 pm between two radical cations are clearly shorter than the van-der-Waals distance of 350 pm. The structural makeup of **3**

Photochemically Generated 1,4-Dihydroxypyridines and 2-Hydroxytetrahydropyridines as Precursors for Benzo[*a*]quinolizidine Alkaloids**

By *Lutz-F. Tietze** and *Klaus Brüggemann*

Dedicated to Professor Weissermel on the occasion of his 60th birthday

Owing to their reactivity, as a result of enamine-imine(iminium-salt) tautomerism, dihydropyridines[1] are of great importance as intermediates in the synthesis of complex nitrogen-containing natural products; besides, they are formulated as intermediates in the biosynthesis of numerous alkaloids. The 2-hydroxytetrahydropyridines, which form the corresponding iminium salts by acid-catalyzed reaction, are even more reactive. We have recently been able to show that 1,4-dihydropyridines and 2-hydroxytetrahydropyridines can be obtained by photochemical addition of enaminoaldehydes to olefins[2]; we now describe the use of this method for the synthesis of derivatives of benzo[*a*]quinolizidine, the parent compound of the ipecacuanha alkaloids.

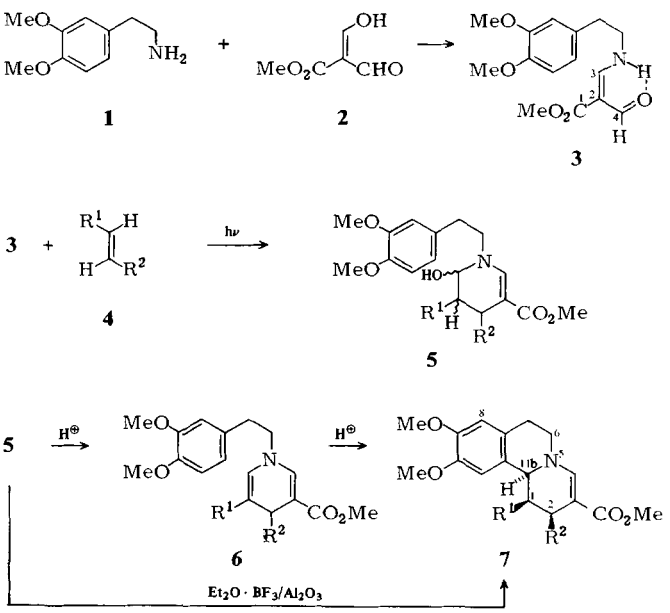
[*] Prof. Dr. L.-F. Tietze, K. Brüggemann
Institut für Organische Chemie der Universität
Tammannstrasse 2, D-3400 Göttingen (Germany)

[**] Dihydropyridines, Part 2. This work was supported by Forschungsmitteln des Landes Niedersachsen.—Part 1: [2].

Condensation of 2-(3,4-dimethoxyphenyl)ethylamine **1** with methyl diformylacetate **2** (toluene, Na_2SO_4, 20 °C, 3 h) affords the enaminoaldehyde **3** in 82% yield, which at 20 °C in $CDCl_3$ is present up to 95% in the *Z-s-Z* conformation. Irradiation of a mixture of **3** (1 molar equivalent) and olefin **4a—4e** (10—100 molar equivalents) in CH_2Cl_2 ($\lambda \geq 300$ nm) at −20 °C furnishes the unstable diastereomeric 2-hydroxytetrahydropyridines **5** in the ratio 1 : 2[3]. The photochemical [2+2]-cycloaddition proceeds completely regioselectively[4]. Presumably a cyclobutane system is formed as intermediate by attack of the olefin **4** at C-2 and C-4 in **3** (cf. mesomeric resonance form/tautomer of **3**); hetero-retro-aldol cleavage then yields a new enaminoaldehyde, which recyclizes to **5**.

Olefins containing electron-acceptor groups, **4a—4d**, react with **3** to give the 2-hydroxytetrahydropyridines **5a—5d** having acceptor groups in the 4-position, while olefin **4e**, which contains a donor group, yields the 3-substituted compounds **5e**. Acid-catalyzed reaction of **5a—5d** furnishes the dihydropyridines **6a—6d**. Thus, with catalytic amounts of trifluoroacetic acid in CH_2Cl_2 at 20 °C, **5a** affords **6a** in 85% yield within a few minutes; prolonged reaction leads to the quinolizidine derivative **7a** (80%)[5].

The quinolizidine derivatives **7a—7e**[5] can, however, be synthesized much more simply by reaction of the crude tetrahydropyridines **5a—5e**[6], obtained after removal of solvent and excess olefin, with $EtO_2 \cdot BF_3$ on aluminum oxide[3] (CH_2Cl_2, 20 °C, 5 min). Primarily, the iminium salt is formed, which reacts further in a kind of Pictet-Spengler



4–7	a	b	c	d	e	f	g
R^1	H	H	CH_3	H	OMe		
R^2	CN	CO_2Me	CO_2Me	$COCH_3$	H		
Yield [%] 3→7	88	71	93	83	45	0	0

reaction. In each of the cases **7a—7e** only one diastereomer is obtained. Presumably the reaction, except for **7c** and **7e**, is thermodynamically controlled, since on reaction of **6a** the epimer of **7a** is also formed. However, on prolonged reaction this is converted into **7a**, the thermody-

namically more stable product containing a pseudoequatorial cyano group. Reaction with cyclopentene or (*Z*)-2-butene yields respectively the 2-hydroxytetrahydropyridines **5f** and **5g**, and the 1,4-dihydropyridines **6f** and **6g**; a cyclization to the benzo[*a*]quinolizidines fails, presumably on account of steric hindrance.

[3] Typical reaction conditions: A solution of enaminoaldehyde **3** (2.00 mmol) and olefin **4** (80.0 mmol) in CH_2Cl_2 (200 mL) is irradiated for 1.3—2.5 h (**3d**: 14.5 h) at −20 °C with a Hg high-pressure lamp (500 W; Hanau) in a Duran ring reactor (cf. Tietze/Eicher: *Reaktionen und Synthesen in organisch-chemischen Praktikum*, Thieme, Stuttgart 1981, p. 13). After removal of solvent and excess olefin **4** (except in the case of **4d**) the residue is taken up in CH_2Cl_2 (200 mL) and the stirred solution is treated with 200 mg of $Et_2O \cdot BF_3/Al_2O_3$ (1:2 mol-%) at 20 °C (**7e**: −60 °C → 0 °C). This previously unknown reagent gives better yields than the reaction with $Et_2O \cdot BF_3$ alone.
[4] L.-F. Tietze, A. Bergmann, unpublished results.
[5] **7d**: ^{1}H-NMR (200 MHz, $CDCl_3$): $\delta = 7.62$ (s, 1 H, 4-H), 6.64 (s, 1 H, 8-H), 6.60 (s, 1 H, 11-H), 4.39 (br. d, $J = 11$ Hz, 1 H, 11b-H), 3.87 (s, 6 H, O—CH_3), 3.72 (m, 1 H, 2α-H), 3.67 (s, 3 H, O—CH_3), 3.63—3.38 (m, 2 H, 6-H), 3.02 (m, 1 H, 7-H), 2.68 (m, 1 H, 7-H), 2.46 (ddd, $J = 13$ Hz, $J = 6$ Hz, $J = 3$ Hz, 1 H, 1α-H), 2.12 (s, 3 H, CH_3), 1.72 (dt, $J = 13$ Hz, $J = 11$ Hz, 1 H, 1β-H).
[6] The diastereomeric semiaminals **5** react at various rates. Small amounts of the dihydropyridines **6** (< 1%) are also formed; these likewise cyclize to **7**, but more slowly, under the reaction conditions.

2-Oxopropanal (Methylglyoxal) by Oxidation of Glycerin in the Gas Phase

By *Herbert Baltes* and *Ernst Ingo Leupold**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

2-Oxopropanal **2** and its acetals are important industrial intermediates, *e.g.* for the production of pyrethrum insecticides[1]. On an industrial scale, **2** is primarily produced from 1,2-propanediol[2].

A novel simple entry to **2** is the gas-phase oxidation of glycerin **1** at 300—350 °C on specially developed heterogeneous catalysts[3].
Presumably, the initial product is 1,3-dihydroxyacetone, which immediately rearranges with elimination of water to give **2**[4].

$$\underset{\mathbf{1}}{HOCH_2—CH(OH)—CH_2OH} + 1/2\,O_2 \rightarrow \underset{\mathbf{2}}{CH_3—CO—CHO} + 2\,H_2O$$

A suitable form of reactor consists of an externally heated glass tube (diameter: 2 cm; length 15 cm), arranged vertically and packed with catalyst (15 cm^3) covered by a layer of glass beads (vaporization zone). A mixture of glycerin and water is pumped into the vaporization zone from the top. The resulting vapor is mixed with pre-heated nitrogen and oxygen or air and passed through the catalyst. The residence times are 0.2 to 0.5 s. The products are condensed in a cold trap and analyzed by HPLC.

Vanadium, molybdenum, silver, and tin (in particular, combinations of vanadium and silver) are suitable as catalytically active elements. The elements are deposited from solutions of their salts onto surface area-deficient aluminosilicate supports, dried, and oxidized in a stream of oxygen[3].

Two typical examples are given in Table 1. The main byproducts and secondary products formed are acrolein, formaldehyde, and carbon dioxide.

Table 1. Oxidation of glycerin **1** to 2-oxopropanal **2** in the gas phase. Catalyst carrier: aluminosilicate (BET surface area *ca.* 1 m^2/g; water uptake 30 wt-%).

2-Cyano-3-ethoxyacrylamides—Selective Synthons for the Synthesis of Heterocycles

By *Klaus-Dieter Kampe**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

In contrast to the triacylmethanes, which are readily cleaved by nucleophiles, the 3-alkoxy-2-acylacrylic acid derivatives **1**, as capped triacylmethanes, are useful synthetic building blocks. We have now investigated some reactions of 2-cyano-3-ethoxyacrylamides **3** (*E* > *Z* mixtures or pure *E*-isomers[12]) with bisnucleophiles regarding their selectivity.

The amides **3** react with amidines **4**, **5** and guanidines **6—9** in glyme/*i*-PrOH at 82 °C to give 4-amino-5-pyrimidinecarboxamides **10—15**. The amide group remains intact during the condensation.

Unlike the amides **3**, the *E*,*Z*-ester **16** reacts with amidines non-selectively at the enol ether function and one of

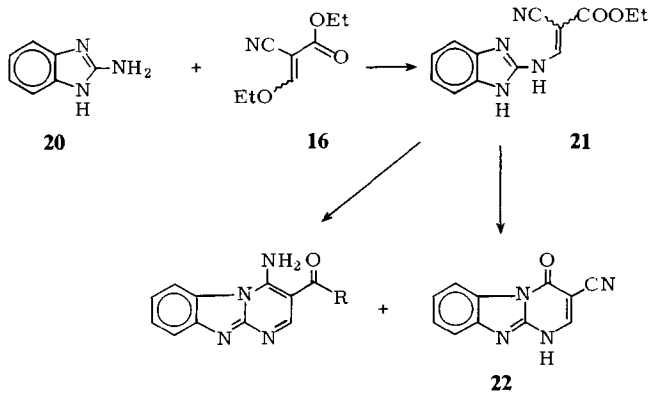
the two acyl groups. The formation of **22** and **23** (2.5 : 1) from **16** and **20** is well known[3]. From **16** and **20** in glyme at 75 °C, *i.e.* under conditions under which reaction of **20** with **3c** gives only **24**, we obtained almost equal amounts of **21**, **22**, and **23**.



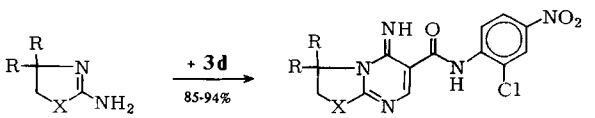
20 16 21

22

23, R = EtO

20 + 3c ⟶ (94%) **24**, R = 3-$F_3CC_6H_4NH$

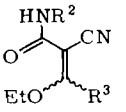
Amides (example **3d**) also react with 2-amino-2-azolines **26** and **27** to give only a single product, namely **28** and **29**, respectively.



26	X = O, R = CH_3	**28**
27	X = S, R = H	**29**

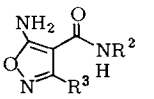
The 3-alkyl homologues of **3**, *e.g.* **30a**, react with the guanidines **6**—**9** with cleavage of R^1H to give pyrimidinones or oxazines (as yet unclear) and with benzamidine **5** to give pyrimidinones.

Compounds **3** (*e.g.* **3c**) and **30** (*e.g.* **30b**) react with hydroxylamine in ethanol/NEt_3 at 80 °C to give 5-amino-4-isoxazole-carbanilides **38** and **39**, respectively.



3c, R^3 = H (>75% *E*)
30a, R^3 = CH_3 (70% *Z*)
30b, R^3 = C_2H_5 (*Z*)

R^2 =



38, R^3 = H
39, R^3 = C_2H_5

In contrast to **16** the new 2-cyano-3-ethoxyacrylamides **3** are thus very effective, regioselectively reacting synthons for the synthesis of heterocycles with functional groups. Amino- and carbamoyl-groups, aside from other functions, can be incorporated in one step.

2-Aminobenzothiazoles by Oxidative Cyclization of Arylthioureas with Sulfinyl Chloride

By *Theodor Papenfuhs**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Arylthioureas **4** can be oxidized with sulfinyl chloride. Donor-substituted educts **4** react cleanly with an excess of sulfinyl chloride in the absence of solvent to give 2-aminobenzothiazoles **5**[9]. With sulfinyl chloride used in high dilution and initially in substoichiometric amounts, and especially with acceptor-substituted educts (**4**, R = NO_2, halogen, CN, COOR) the guanidines **6** are also formed; these are cleaved by water to 2-aminobenzothiazoles **5** and arylureas **7**.

6 7

[*] Dr. T. Papenfuhs
Hoechst AG
D-6230 Frankfurt am Main 80 (Germany)

The following analytically confirmed empirical equation was determined for the solvent-free reaction of **4** with sulfinyl chloride in excess:

$$2\ \mathbf{4} + 2\ OSCl_2 \rightarrow 2\ \mathbf{5}\cdot HCl + S + SO_2 + 2\ HCl$$

In order to ascertain the scope of application of this novel entry to the benzothiazole series not only the reactions of **10** but also those of multi-*N*-substituted arylthioureas **12** and **14** were examined (Table 1-3).

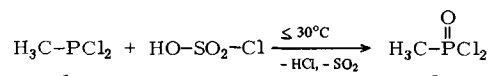
Sulfuric Acid Derivatives as Oxidizing Agents for Phosphorus(III) Compounds

By *Jürgen Grosse**, *Werner Pieper*, and *Hubert Neumaier*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

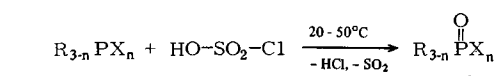
The importance of dichloro(methyl)phosphane **1** in organophosphorus chemistry has recently been outlined in a comprehensive review[1]. However, the problem of oxidizing **1** to methanephosphonic acid dichloride **2**, a versatile intermediate for organophosphorus syntheses, had previously not been satisfactorily solved.



1 **2**

Oxidation of **1** with chlorosulfuric acid[1,5] has proven superior to the conventional methods. The exothermic reaction starts spontaneously on dropwise addition of the reactants, if necessary into previously formed **2**, at room temperature with vigorous evolution of gas. After removal of the dissolved gaseous reaction products *in vacuo* highly pure **2** (>99%) is obtained in practically quantitative yield referred to chlorosulfuric acid. A purification by distillation is unnecessary.

Chlorosulfuric acid can also be used successfully for the oxidation of other phosphorus(III) derivatives to **3—13**[5].



3-13

R = Alkyl, Aryl, OR', SR''; X = halogen; $n = 0-3$

Particularly good results are obtained with compounds where R = Alkyl, Aryl; X = Cl; $n = 1$ and 2 (content of product after degassing *in vacuo*, 90 to 99%; yields after distillation ≥95%).

Sulfuric acid monoesters are suitable for the oxidation of dichloro(organo)phosphanes[8] to chlorophosphonic acid esters **14—19**.

14-19

R = CH_3, C_2H_5, C_6H_5; R' = Alkyl, Aryl

[*] Dr. J. Grosse, Dr. W. Pieper, Dr. H. Neumaier

The yields are up to 60%. Apart from the phosphorus being oxidized, a chlorine atom is replaced by an ester group.

Sulfuric acid itself can also be used as oxidizing agent. The oxidation of dichloro(organo)phosphanes in ethers with conc. sulfuric acid leads to mixtures of condensed phosphonic acids **23-25** in high yields[9].

$$n\ RPCl_2 + n\ H_2SO_4 + H_2O \xrightarrow[-2n\ HCl,\ -n\ SO_2]{40^\circ C} (RPO_2)_n \cdot H_2O$$

23-25

$R = CH_3, C_2H_5, C_6H_5$

The chain length *n* is influenced to a certain extent by the amount of water present during the oxidation reaction.

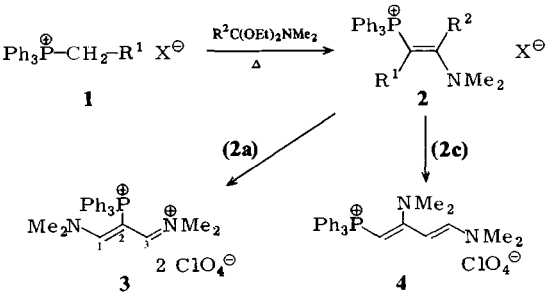
Phosphoniovinamidinium Salts**

By *Rudolf Gompper**, *Eckard Kujath*, and *Hans-Ulrich Wagner*

Dedicated to Professor Hermann Stetter on the occasion of his 65th birthday

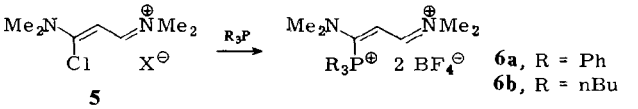
Acceptor moieties in the 1-position of vinamidinium salts increase the positive charge density on C-3 and thus enhance the reactivity of this position towards nucleophiles in accord with the allopolarization principle[1]. Carbonyl groups have been used as acceptors. We have now turned our attention to the scarcely investigated vinamidinium salts bearing cationic substituents; phosphoniovinamidinium salts were hitherto unknown.

Analogously to the preparation of vinamidinium salts from β-aminovinyl ketones, 2-phosphoniovinamidinium salts ought to be accessible from β-dialkylaminovinylphosphonium salts **2**[2]. Surprisingly, they are obtained quite smoothly from the "non-activated" phosphonium salts **1**[3] by heating (≈130 °C) with amide acetals (**2a**, 92%, m.p. 153–156 °C; **2c**, 74%, m.p. 268–269 °C). Reaction of dimethylformamide/phosphoryl chloride/$NaClO_4$ with **2a** at 60–70 °C yields the sought after 2-phosphoniovinamidinium salt **3** (82%, m.p. 233–234 °C, UV/VIS ($CHCl_3$): λ_{max} = 327.5 nm). **2c** does not react at C-1, but at the methyl group to give a 1-phosphoniomethylvinamidinium salt, which can be converted with sodium carbonate into the phosphonium salt **4**.

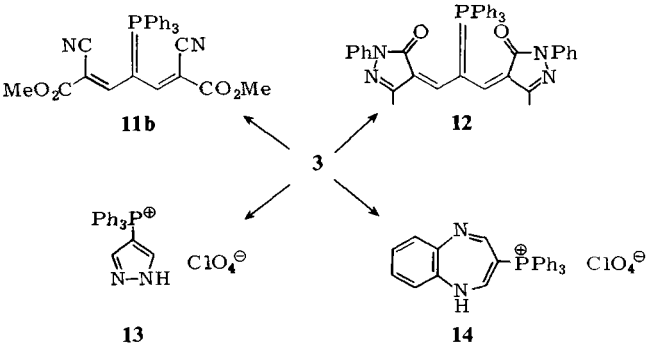


a, $R^1 = R^2 = H$, X = Br; **c**, $R^1 = H$, $R^2 = CH_3$, X = I

The 1-phosphoniovinamidinium salt **6** (**6a**: 31%, m.p. 230–232 °C, $\lambda_{max}(CH_2Cl_2)$ = 375 nm; **6b**: 56%, m.p. 130 °C, λ_{max} = 375 nm (CH_2Cl_2)) is obtained by heating **5** with phosphanes in ethanol in presence of $NaBF_4$. 1-Pyridiniovinamidinium salts are obtainable in a similar way.—It is worth mentioning that **6** absorbs at longer wavelength than **3** in the UV/VIS, while both absorb at longer wavelength than the parent compound (λ_{max} = 312.5 nm). Other acceptor moieties such as 1-ethoxycarbonyl and 1-pyridino (λ_{max} = 327 and 320 nm, resp.) give rise to no such long-wavelength absorption.



The 2-phosphoniovinamidinium salt **3** reacts with numerous nucleophiles. Scheme 1 shows some examples.



Scheme 1 (selection). **3** + methyl cyanoacetate (KOH, MeOH, reflux) → **11b** (90%, m.p. 219–223 °C, $\lambda_{max}(CH_2Cl_2)$ = 438 nm); **3** + methylphenylpyrazolone (NaH, THF, 20 °C) → **12** (32%, m.p. 270–272 °C, $\lambda_{max}(CH_2Cl_2)$ = 510 nm). The compounds **12** exist as internal salts. **3** + hydrazine (in acetonitrile) → **13** (78%, m.p. 240–245 °C); **3** + *o*-phenylenediamine (in acetonitrile, ≈80 °C) → **14** (71%, m.p. >360 °C).

$Cs_7Fe_4Te_8$, A Compound with $[Fe_4Te_8]$ Clusters

By *Welf Bronger**, *Manfred Kimpel*, and *Dieter Schmitz*

Dedicated to Professor Friedrich Asinger on the occasion of his 75th birthday

The crystal structures of the previously known alkali metal thioferrates and selenoferrates are characterized by edge-linked tetrahedra, whose corners are occupied by chalcogen atoms centered by iron atoms. Hence, compounds of general composition $AFeX_2$ (A = K, Rb, or Cs; X = S or Se) crystallize in chain structures with a $^1_\infty[FeX_{4/2}]$ framework of tetrahedra[1], whereas the sodium compounds Na_3FeX_3 contain isolated $[FeX_2X_{2/2}]_2$ double tetrahedra[2].

We have now prepared the first alkali metal telluroferrate as anthracite colored needles with a metallic luster by allowing a mixture of iron and cesium carbonate to react in a stream of hydrogen charged with tellurium at 1050 K. Its composition is $Cs_7Fe_4Te_8$. The structure was determined from single crystal X-ray data ($Ag_{K\alpha}$ radiation, graphite monochromator; 1595 symmetry-independent reflections with $F_0^2 > 3\sigma(F_0^2)$ in the range $1° < \theta < 30°$; $R = 0.038$).

Isolated $[Fe_4Te_8]$ clusters, in which the iron atoms are tetrahedrally surrounded by tellurium atoms, occur as the characteristic units. The four tetrahedra are mutually linked such that each is joined to the others *via* three edges, corresponding to $[FeTeTe_{3/3}]_4$ (cf. Fig. 1). The $[Fe_4Te_8]$ cluster has approximate T_d symmetry, although only a twofold axis is provided by the space group. Corresponding to this, values for the FeFe distances were found which vary within the threefold standard deviation of the average value 2.847(2) Å. The coordination of the cesium atoms is determined from the atomic arrangement $Cs_7(Fe_4)Te_8$, which corresponds to that in cesium chloride.

The $[Fe_4Te_8]$ cluster represents the first tellurium analog of the active sites of the 4 Fe4S ferredoxins. Of note is that the oxidation number of iron atoms in $Cs_7Fe_4Te_8$ of

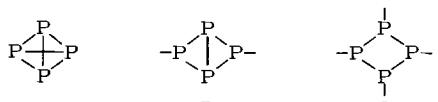
The First Tetraphosphabicyclobutane**

By *Edgar Niecke**, *Reinhold Rüger*, and *Bernt Krebs*

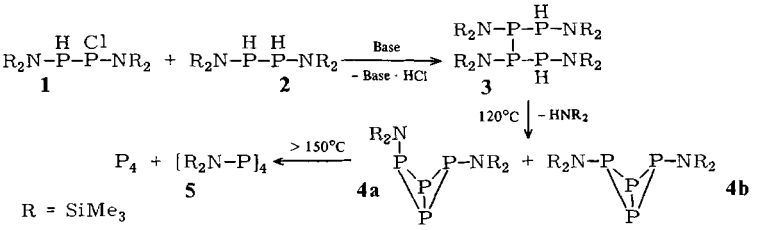
The previously unknown bicyclobutane analogue **B** of the series of phosphorus homocycles **A**–**C** is of vital importance regarding mechanistic aspects of the reactions of the elemental phosphorus[1].



[*] Prof. Dr. E. Niecke, Dr. R. Rüger
Fakultät für Chemie der Universität
Postfach 8640, D-4800 Bielefeld 1 (Germany)
Prof. Dr. B. Krebs
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Starting from the diaminodiphosphanes **1** and **2**[2a] we have now succeeded in synthesizing the tetraphosphabicyclobutane system (**4a**, **b**) by PP-coupling to give the tetraphosphane **3** and subsequent cyclizing amine-elimination.



4a, **b** are pyrophoric, thermally remarkably stable compounds, of which **4b** is obtained in pure form from the isomeric mixture by crystallization. Its composition is confirmed by correct elemental analysis and by the mass spectrum (field ionization, $M^+ = 444.1$).

The $^{31}P\{^1H\}$-NMR spectrum of **4a**, **b** (30% in CD_2Cl_2, H_3PO_4 ext.) shows the resonance absorptions of the bridgehead atoms, as expected, at very high field [$\delta = -222.5$ (**4a**), -287.3 (**4b**)]. The signal pattern for the resonance absorptions of the peripheral phosphorus atoms, shifted about 200 ppm downfield, affords proof of the *cis,trans*-form for **4a** ($\delta = -19.7$, -43.4, $^1J_{PP} = \pm 242$, ± 255 Hz, $^2J_{PP} = \pm 31.5$ Hz) and is consistent with a C_{2v} symmetry[3] for **4b** ($\delta = -79.1$, $^1J_{PP} = 225$ Hz), where model considerations support the sterically favored *trans,trans*-arrangement. This could be confirmed by a complete X-ray structure analysis (Fig. 1).

The P—P bond lengths of the peripheral phosphorus atoms being 2.22—2.23 Å correspond to a "normal" single bond. A surprising feature, however, is the extremely short bridgehead bond, which, with a value of 2.13 Å (P_4: 2.21 Å) indicates considerable double bonding. According to calculations[2b] this "π-bonding" arises from an effective charge transfer of the equatorially arranged bis(trimethylsilyl)amino groups (angle between the normals to the planes Si_2N and NPPN: 92°) to the central P—P bond. Also worthy of note is the transannular P—P distance of only 2.81 Å (bonding angle 95.2°).

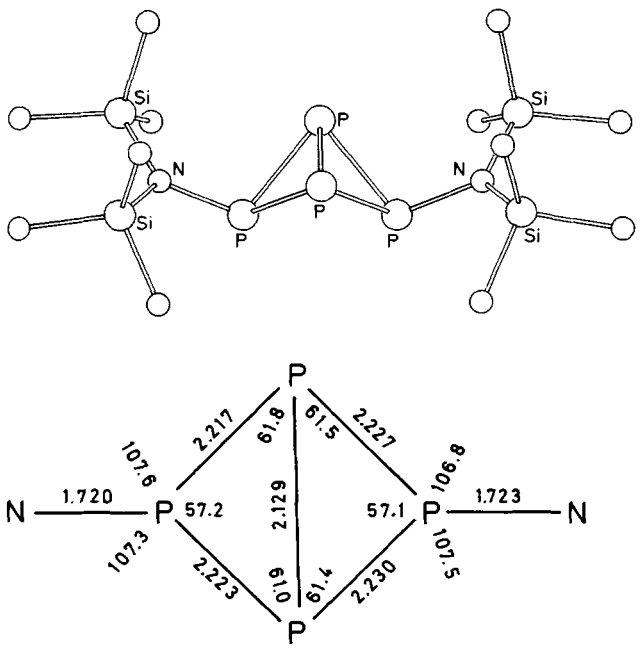


Fig. 1. Top: Molecular structure of **4b** in the crystal; bottom: most important bond lengths and angles ($\sigma < 0.005$ Å and 0.04°, respectively). **4b** crystallizes monoclinically, space group $P2_1/c$, $a = 11.872(2)$, $b = 18.058(3)$, $c = 12.259(2)$ Å, $\beta = 105.34(2)°$, $\rho_x = 1.17$ g cm^{-3}, $Z = 4$ (measured at -115 °C). The crystal structure was determined by direct methods (MULTAN) from 2933 single-crystal diffractometer data and refined to $R = 0.065$.

The instability to be expected for the tetraphosphabicyclobutane system **B** compared to a decomposition into **A** and **C** manifests itself in the fragmentation into phosphorus and **5** above 150 °C[2a].

Procedure

A mixture of **1** (0.005 mol), **2** (0.05 mol) and quinoline (20 mL) was stirred for 24 h at 60 °C/10 torr under an inert gas. Extraction of the reaction mixture with 100 mL of *n*-pentane furnished essentially only **3**[4] and unreacted **2**. After removal of solvent from the extract, vacuum short-path pyrolysis at 130—135 °C/0.5 torr afforded 8 g of the crude product (**4a**, **b**) as a red, highly viscous oil, which still contained *ca.* 5% of **2**, **5** and P_4. **4b** could be isolated in pure form as ebony colored needles (2.5 g ≙ 11%) by recrystallization from a little *n*-pentane.

Synthesis of Trisubstituted Olefins *via* Trimethylsilylated Phosphorus Ylides

By *Hans Jürgen Bestmann** and *Andreas Bomhard*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The synthesis of phosphorus ylides **6** with $R^1 \neq R^2$ (R^1, $R^2 \neq H$) causes problems, since the reaction of secondary alkyl halides with triphenylphosphane to afford phosphonium salts also leads to elimination. Secondary reactions afford a mixture of isomeric phosphonium salts, which can only be separated with difficulty. The alkylation of ylides **1** with alkyl halides **5** also produces mixtures[1].

We have found that the pure ylides **6** can be synthesized and immediately converted *via* the following route: reaction of **1** and **2** (molar ratio 2:1) yields, *via* transylidation[1a], the salt **4** and the silylated ylides **3**[2,3], which react with the halogen compounds **5** to afford the phosphonium salts **7**[3]. Desilylation of **7** with cesium fluoride[4] (with tetra-*n*-butylammonium fluoride yields are, in general, poor) results in formation of the disubstituted ylides **6**. Addition of aldehydes **8** (best in dimethylformamide) after the desilylation leads to trisubstituted olefins **9** *via* a Wittig reaction[3].

Wittig reactions with ylides such as **6d** and **6i** (see Table 1), which can hardly be prepared from the corresponding

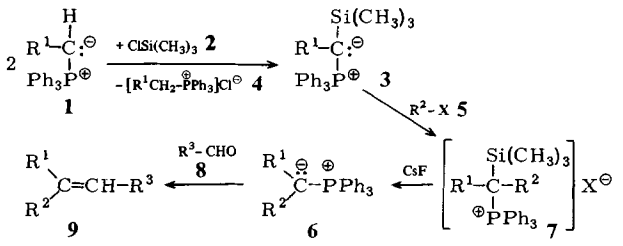
Henkestrasse 42, D-8520 Erlangen (Germany)



droxy-2-(1,2,4-triazol-1-yl)acrylic acid ester **4** is obtained in good yields. **2** reacts with chlorotrimethylsilane to give the trimethylsilyl enol ether **3**, whose hydrolysis, which already occurs on removal of the sodium chloride formed in presence of moist air, likewise gives **4**, in quantitative yield.

The ^{1}H-NMR spectrum of the ester **4** in $CDCl_3$ and dimethyl sulfoxide (DMSO) shows that only the enols are present. In the case of **4** it was found by ^{1}H-NMR and

phosphonium salts because of simultaneous Hofmann degradation, can also be carried out in this way[5a].

Our conceptions of the mechanism of the Wittig reaction[5b] do not lead us to expect high stereoselectivity in the formation of trisubstituted olefins **9** from **6** with substituents R^1 and R^2 having similar steric and electronic structure. This is conformed by the results in Table 1.

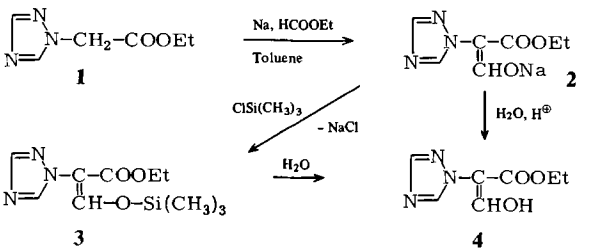
3-Hydroxy-2-(1,2,4-triazol-1-yl)acrylic Acid Ethyl Ester and *O*-Functional Derivatives

By *Thomas Maier** and *Friedrich Cavagna*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The triazolylacetic ester **1** can be formylated with ethyl formate[1]. On acidifying the sodium enolate **2**, the 3-hydroxy-2-(1,2,4-triazol-1-yl)acrylic acid ester **4** is obtained in good yields. **2** reacts with chlorotrimethylsilane to give the trimethylsilyl enol ether **3**, whose hydrolysis, which already occurs on removal of the sodium chloride formed in presence of moist air, likewise gives **4**, in quantitative yield.

The ^{1}H-NMR spectrum of the ester **4** in $CDCl_3$ and dimethyl sulfoxide (DMSO) shows that only the enols are present. In the case of **4** it was found by ^{1}H-NMR and ^{13}C-NMR spectroscopic investigations that only the *Z*-form exists in DMSO, whereas both the *Z*- (*ca.* 88%)



and the *E*-form (*ca.* 12%) are present in $CDCl_3$ [^3J(H, CO_{trans}) = 8 Hz, *E*-form; ^3J(H, CO_{cis}) = 2 Hz, *Z*-form]. In $CDCl_3$ the OH protons of the *Z*-form form hydrogen bonds with N2 of the triazole moiety, and those of the *E*-form form such bonds with the oxygen of the carbonyl group.

[1] a) Review on the formylation of methylene groups: J. Mathieu, J. Weill-Raynal: *Formation of C—C Bonds, Vol. I, Introduction of a Functional Carbon Atom*, Thieme, Stuttgart 1973, p. 176; b) **2**: A mixture of ethyl formate (144.3 g, 1.95 mol), ethanol (38.3 g, 0.83 mol), and **1** (201.5 g, 1.3 mol) is added dropwise within 15 min to a suspension of sodium (31.05 g, 1.35 mol) in toluene. The mixture is briefly warmed to 30 °C, whereupon an exothermic reaction sets in. The internal temperature remains at 31 °C for 2 h, and solid separates out. After 12 h a thick, yellowish mass has formed. The mixture is then stirred for a further 6 h at 60–70 °C, cooled, the solvent removed by suction, and the residue washed with diisopropyl ether. After drying, 262.5 g (98.5%) of **2** (m.p. 232–235 °C) is obtained.

[2] General procedure for **6**: A solution of **2** (0.1 mol) in DMF (*ca.* 50 mL) is treated dropwise within *ca.* 5 min with 0.1 mol of the halogen compound (in the case of solids with a concentrated solution of the halogen compound in DMF). The mixture is stirred for 60 min at room temperature (in the case of an exothermic reaction the mixture is allowed to warm and then cooled to room temperature again) and 90 min at 60–70 °C. After cooling, the sodium halide is removed by suction and the DMF solution is evaporated to dryness in a vacuum and treated with acetone; undissolved sodium halide is removed by suction and the acetone is distilled off from the filtrate. The crude products are, in the case of solids, washed with diisopropyl ether and water, in the case of oils they are treated with H_2O/chloroform (1:1); the product is isolated from the chloroform phase.

Synthesis of Cardenolide 3β-2′,3′-Dideoxy-α,L-rhamnopyranosides**

By *Ulrich Stache**, *Kurt Radscheit*, *Werner Haede*, and *Werner Fritsch*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

We had previously synthesized a series of 3β-(2′,3′-didehydro-2′,3′-dideoxy-α-L-rhamnopyranosyloxy)-cardenolides with positive inotropic activity[2a] from 3,4-di-*O*-acetyl-1,2,6-trideoxy-L-arabino-1-hexenopyranose (diacetyl-L-rhamnal) and cardenolide aglycons, *e.g.* 3β,14-dihydroxy-5β,14β-card-20(22)-enolide (digitoxigenin) according to the "glycal method" of *Ferrier et al.*[1]; owing to the 2′,3′-double bond in the sugar moiety they already hydrolyze at pH 5, and thus are unsuitable as cardiac glycosides. Hydrogenation of the 2′,3′-double bond should confer a better acid-stability on the glycosidic coupling.

During the catalytic hydrogenation of **1a**[2a]—Pd/$CaCO_3$ (10%), C_2H_5OH, 760 torr, 20 °C; 92% yield after filtering off the catalyst, evaporation to dryness, and recrystallization from ethanol—the 2′,3′-double bond in the glycoside moiety is reduced regioselectively. As proven by the UV spectrum [(C_2H_5OH) $\lambda_{max}=217$ nm, $\varepsilon=15800$], IR spectrum [(KBr) $\nu=1775$, 1735 cm^{-1}], mass spectrum [$m/z=530$, M^+], and ^{1}H-NMR spectrum [($CDCl_3$) $\delta=5.9$ (t, 22-H), 4.9 (AB system, 21-H_2)] of the resulting **2a** [m.p. = 229 °C; $[\alpha]_D^{20}=-54$ ($HCCl_3$, $c=0.5$)], the 20(22)-double bond of the butenolide ring is not attacked. Mild hydrolysis of the 4′-acetate group of **2a**—$KHCO_3$ in methanol/water (11:1), 25 min reflux—affords 3β-(2′,3′-dideoxy-α-L-rhamnopyranosyloxy)digitoxigenin **2b**[5] in 80% yield [m.p. 218 °C; $[\alpha]_D^{20}=-41$ (CH_3OH, $c=0.5$)]. In diverse animal experiments[3], **2b** proved to be three times more active than digoxin with respect to the inotropic action, for almost quantitative oral resorption; it has a duration of effect like the non-orally active k-strophanthin as well as a therapeutically acceptable acid-stability (stable at 20 °C in ethanolic solution up to *ca.* pH 1). **2b** could find use as an "oral strophanthin"[3]. In analogy to the reaction sequence **1a**→**2a**→**2b** the 3β-2′,3′-dideoxy-α-L-rhamnopyranosides of the k-strophanthidin, **3b** [m.p. 226–228 °C; UV (CH_3OH): $\lambda_{max}=217$ nm, $\varepsilon=15800$; $[\alpha]_D^{20}=-14.2$ (CH_3OH, $c=0.5$)], and of the 5,19-(epoxycarbonylmethyleno)digitoxigenin, **4b**[2a] [m.p. 184–186 °C; UV (CH_3OH): $\lambda_{max}=214$ nm, $\varepsilon=22300$; $[\alpha]_D^{20}=-28.0$ (CH_3OH, $c=0.5$)], can also be obtained.

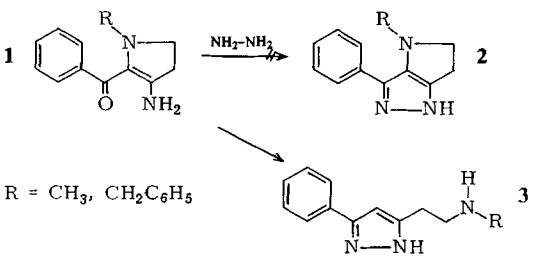
Anomalous Reaction of Hydrazine with β-Aminovinyl Ketones

By *Rudolf Kunstmann** and *Erich F. Paulus*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

There are numerous examples of the synthesis of pyrazoles from β-aminovinyl ketones or 1,3-dicarbonyl compounds and hydrazine or hydrazine derivatives[1]. It was therefore unexpected that 3-amino-2-benzoyl-3,4-dihydropyrroles **1** do not give the desired 1,4,5,6-tetrahydropyrrolo[3,2-*c*]pyrazoles **2**, but 5-(2-aminoethyl)-3-phenyl-1*H*-pyrazoles **3** on reaction with excess hydrazine.



The potential structural isomers of **3** could not be distinguished from one another by ^{1}H-NMR and mass spectroscopy. X-ray crystal structure analysis of **3**, R = $CH_2C_6H_5$, confirmed the proposed structure.

The balance of the reaction of **1** with hydrazine indicates that a reduction step is involved in the formation of **3**; in the course of the reaction 1/2 mol nitrogen per mol of **1** is eliminated. It has not yet been established whether the intermediate **2** is formed.

Procedure

A mixture of hydrazine hydrate (2 mL), ethanol (15 mL), and **1**, R = $CH_2C_6H_5$ (2.78 g, 10 mmol) is heated for 2 h under reflux. The resulting solution is diluted with water, extracted with ethyl acetate, and the organic phase dried and concentrated. The residual oil is crystallized from isopropyl alcohol and subsequently converted into the hydrochloride; yield 1.9 g (63%) **3**·HCl, R = $CH_2C_6H_5$, m.p. = 213–215 °C. In an analogous manner **3**, R = CH_3, was obtained as the dioxolate in 52% yield; m.p. = 187 °C.

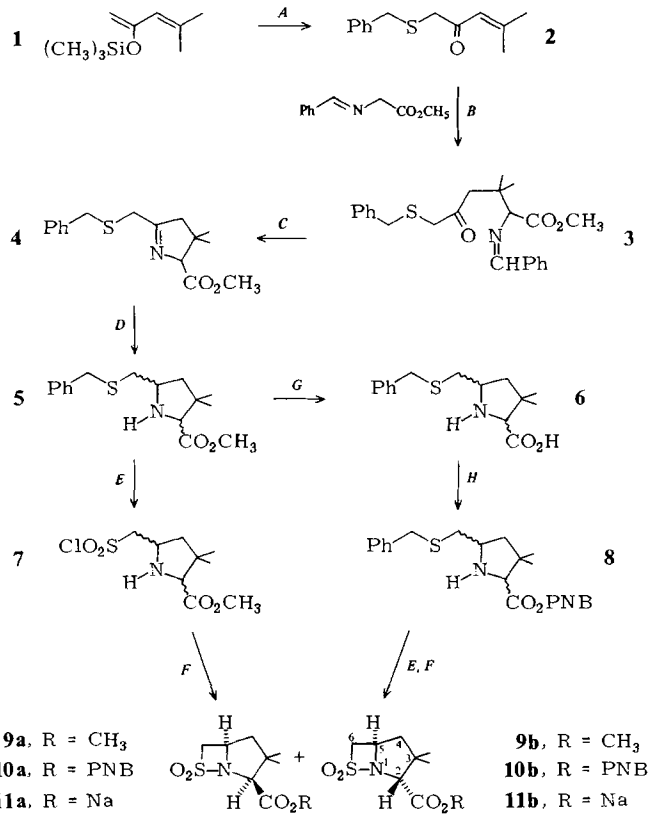
Synthesis of Bicyclic β-Sultams

By *Friedrich Cavagna, Wolfgang Koller**, *Adolf Linkies, Herbert Rehling*, and *Dieter Reuschling*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

It is generally assumed that the biological activity of β-lactam antibiotics depends on the reactivity of the β-lactam ring. Substitution of the CO group of the β-lactam by an SO_2 group leads to the more reactive β-sultams. We report here on the synthesis of bicyclic β-sultams (Scheme 1), whose structure resembles that of the penicillins.



Scheme 1. PNB = *p*-nitrobenzyl. *A:* 1. Br_2, CH_2Cl_2, −65 °C; 2. $PhCH_2SH$, Et_3N, CH_2Cl_2, RT.—*B:* KOH, tetrahydrofuran, Bu_4NBr, RT, 20 h.—*C:* 1. 2N HCl; 2. K_2CO_3.—*D:* $NaBH_3CN$, MeOH, citric acid, CH_2Cl_2.—*E:* Cl_2, CH_2Cl_2, EtOH, 10 °C.—*F:* Et_3N, CH_2Cl_2, 0 °C.—*G:* KOH, MeOH, H_2O, 18 h.—*H:* *p*-$NO_2C_6H_4OH$, $CHCl_3$, *p*-$CH_3C_6H_4SO_3H$, 30 h.

Mesityl oxide is converted by regioselective bromination of the silylenol ether **1**[2] and subsequent reaction with benzylthiol into the benzylthiomesityl oxide **2**, which on reaction with the *N*-benzylidene derivative of glycine methyl ester[3] forms the adduct **3**; this can be cleaved by treatment with 2N hydrochloric acid into the amine and benzaldehyde. After extraction of the aldehyde from the acidic solution, addition of K_2CO_3 leads to spontaneous cyclization of the amine to give the pyrroline **4**, which is reduced to the pyrrolidine **5** with $NaBH_3CN$. Both possible diastereomers are formed in a ratio of 4:1. Oxidation of **5** with chlorine in the presence of ethanol affords the sulfonic acid chloride **7** and benzyl chloride; **7** is converted without purification into the non-hydrolyzable β-sultam ester **9**. The *p*-nitrobenzyl ester **10** cannot be prepared in this way, since the benzylidene derivative of glycine *p*-nitrobenzyl ester does not react with **2**. However, the pyrrolidine **5** can be hydrolyzed to **6**, and then reesterified with *p*-nitrobenzyl alcohol to **8**. As expected, the reactions of **8** lead to a mixture of the diastereomers **10**, which can be separated by column chromatography. Finally, catalytic hydrogenation of **10a** and **10b** affords the sodium salts **11a** and **11b**, respectively. The sodium salt **11b**—like the analogous β-lactam penicillanic acid[4] too—is devoid of any significant antibacterial activity.

The stereochemistry of the diastereomers **9**—**11** was determined ^{1}H-NMR spectroscopically, in particular by comparison with analogous β-lactams[5]. In the case of **9b**, unequivocal assignment of the relative configuration of the protons in the 2-position and 5-position was possible by means of FT-NOE (nuclear Overhauser effect) difference spectroscopy: saturation of the protons of the methyl group at $\delta = 1.05$ and at $\delta = 1.45$ led to a marked nuclear Overhauser effect at H-5 and H-2, respectively.

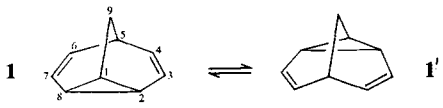
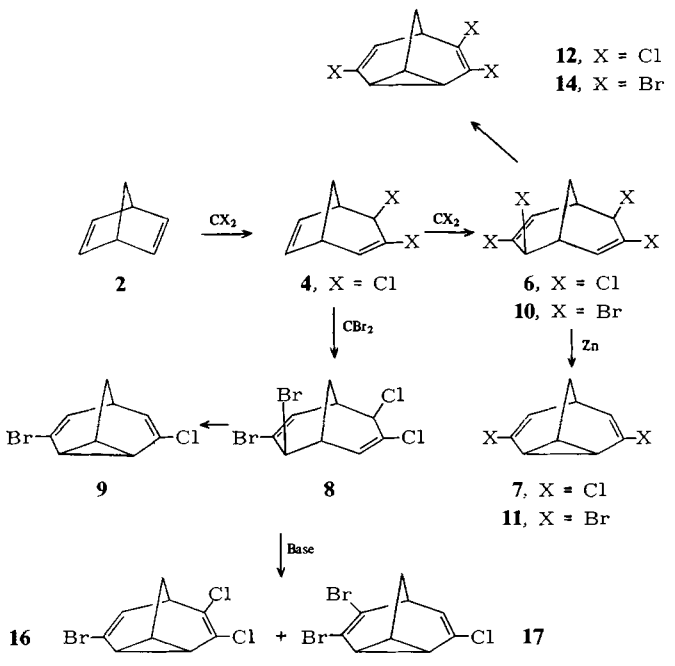
A Simple Synthesis of Di- and Trihalobarbaralanes

By *Charles W. Jefford*, Jean-Claude Rossier,* and *Jacques A. Zuber*

Fluxional molecules such as barbaralane **1** ⇌ **1'** are not easily accessible[3]. We now present a short synthesis of di- and trihalobarbaralanes (**7**, **9**, **11** and **12**, **14**, **16**, **17**, respectively) from norbornadiene **2**.



When excess dichlorocarbene, generated by the phase transfer method[4], is allowed to react with **2** several products are obtained. The product of interest **6** is formed as a result of double addition. It is easily separable from the product mixture, but can also be conveniently obtained stepwise from **4**. Compound **6** possesses two *exo*-Cl atoms which are easily removed by zinc dust to give 3,7-dichlorobarbaralane **7**. By analogy, addition of dibromocarbene[7] to **4** gives **9** *via* **8**. Double addition of dibromocarbene to **2** gives, among others, the expected tetrabromo derivative **10**, which (analogously to **6**→**7**) can be converted into **11**. The NMR spectra of all three 3,7-dihalobarbaralanes **7**, **9**, and **11** at room temperature show them to be fully fluxional molecules just like the parent molecule **1** [*e.g.* **7**: 100.1 MHz ^{1}H-NMR ($CDCl_3$): $\delta = 1.14$ (t, 2 H-9), 2.54 (H-1,5), 4.16 (H-2,4,6,8)].



The trihalo derivatives are also easily prepared from **2** *via* **6**, **8**, and **10**. Dehydrohalogenation of **6** and **10** with base gives **12** and **14**, respectively. However, the action of base on **8** gives a mixture of **16** and **17**.

Unlike **7**, **9**, and **11** all the trihalo derivatives are either nonfluxional or strongly weighted in favor of the structures indicated at room temperature [*e.g.* **12**: $\delta = 1.26$ (H-9m (points towards C-7)), 1.48 (H-9d), 2.22 (H-1), 2.45 (H-8), 2.61 (H-2), 3.13 (H-5), 5.95 (H-6)]. The synthetic procedure described may offer a good route to homoaromatic barbaralanes[9].

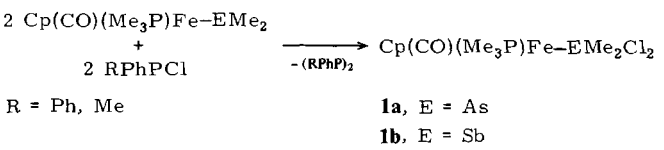
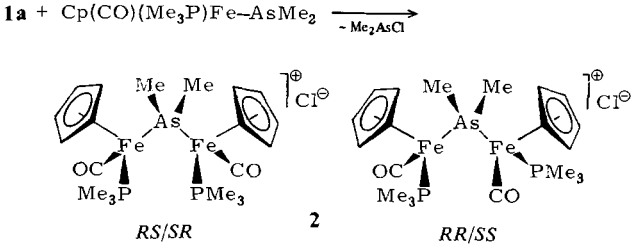
[+] X-ray structure analysis.

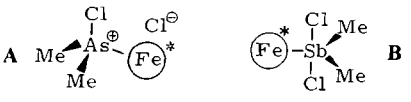
spectively, exhibit pronounced Lewis basicity; thus the compounds can be quaternized with alkyl halides, whereupon salts containing the chiral cations $[Cp(CO)(Me_3P)Fe—EMe_2R]^{\oplus}$ are formed[2]. As has now been found, their reaction with the chlorophosphanes Ph_2PCl and PhMePCl proceeds quite differently: The arsane or stibane is oxidized to a dichloroarsenic(v) or dichloroantimony(v) species, namely **1a** or **1b**; simultaneously the chlorophosphanes are converted into the diphosphanes $(RPhP)_2$.



1b is stable under normal conditions, whereas **1a** is a short-lived intermediate which immediately reacts further *via* $Me_2AsCl/Cp(CO)(Me_3P)Fe—AsMe_2$-exchange to give the diferrio-arsonium salt **2**. Compound **2** has two identical chiral centers and is therefore obtained as the *meso*-form (*RS/SR*) and a diastereomerically related pair of enantiomers (*SS/RR*), which are distinguishable by NMR spectroscopy.



The instability of **1a** can be explained in terms of the ionic arsonium structure **A**[5]. **1b**, which is barely air-sensitive, moderately soluble in benzene, very soluble in nitromethane, and dissolves without decomposition, has a covalent structure—as is reflected in its low conductivity. Thus, **1b** is the first transition metal derivative of pentavalent antimony, which, in addition, for the first time bears three different substituents.



The X-ray structure analysis of **1b** (Fig. 1) shows two independent molecules with almost identical conformation. In accordance with the polarity rule[7], the chiral ferrio group and the two methyl groups assume the equatorial positions, the electronegative chloro-atoms the axial positions at the trigonal-bipyramidally configurated Sb atom. Whereas the SbC bond lengths in **1b** agree quite well with those in known Sb^V compounds, the SbCl bond lengths are distinctly longer [Me_3SbCl_2[10]: 2.13 (Sb—C) and 2.49 Å (Sb—Cl), respectively]. The bulkiness of the $Cp(CO)(Me_3P)Fe$ group implies a wide opening of the FeSbCl angle and a closing of the H_3CSbCH_3 angle compared to the ideal values of 90 and 120°, respectively.

1b represents the first confirmed example of a simply constructed transition metal substituted 5B-element compound with coordination number 5. An analogous structure had already previously been proposed on the basis of spectroscopic findings for the stiboranes $Cp(CO)_3M—SbMe_2Br_2$ (M = Mo, W)[17]. Since the diastereotopic methyl groups in **1b** give only one ^{1}H-NMR signal it is uncertain whether the structure **B** is also preferred in solution. According to previous experiences a rapid inversion of configuration at the metal is not responsible for this NMR finding; it can only be explained in terms of a rapid pseudorotation process at the antimony or a coincidental NMR equivalence of the methyl groups.

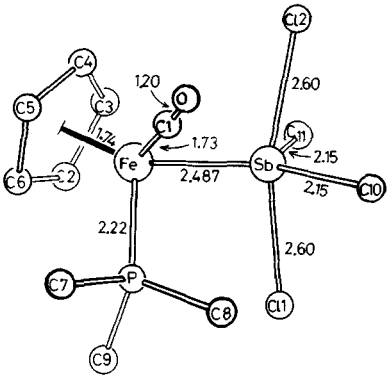


Fig. 1. Molecular structure of **1b** in the crystal. The bond lengths (Å) are the mean values for two crystallographically independent molecules.

Support Effects on the Growth, Stabilization, and Agglomeration of Low Nuclearity Transition Metal Clusters Synthesized from Metal Atoms Vaporized into Liquid Aryl-Substituted Polymers**

By *Geoffrey A. Ozin** and *Mark P. Andrews*

In this study, we report the effect of liquid aryl-substituted polymers on the growth, stabilization, and agglomeration behavior of arene transition-metal cluster complexes of catalytic interest[1]. Only species of the type $(arene)_mM_n$ (m = 2, n = 1, 2) are formed when atomic metal vapors of groups 4A to 6A are cocondensed with arenes under various conditions[2-4]. Complexes containing up to three metal atoms can be stabilized in liquid α,ω-diphenyloligo(ethylene oxides) containing from five to eleven ether oxygen atoms. In the presence of liquid poly(methylphenyl-

[*] Prof. G. A. Ozin, M. P. Andrews

[**] This work was supported by the Natural Sciences and Engineering Research Council (Canada), Strategic Energy Programme.

co-dimethylsiloxane) (DC 510) the cluster size (n = 4, 5), the rate of cluster formation, and stabilization are substantially enhanced. For example, when vanadium atoms are cocondensed with benzene or toluene (matrix, 12—77 K) two species are formed: $(arene)_2V$ showing a metal-ligand charge transfer (MLCT) absorption at $\lambda = 323$ nm, and $(arene)_2V_2$ absorbing at 455 nm. Homo- and heterodimetallic compounds can be produced by direct addition of a transition metal atom to bis(arene)metal (n = 1) sandwich complexes[5] in solution.

Deposition of atomic Mo into liquid α,ω-diphenyloligo(ethylene oxides) at 275—290 K gives rise to mono-, di-, and trimetal compounds ($\lambda_{max} = 318$, 415, and 502 nm, respectively). Clusters having nuclearity $n > 3$ cannot be prepared in these reaction media. Reaction of Mo with DC510 (250 K) gives rise to two additional species: a tetra- and a pentanuclear cluster ($\lambda_{max} = 578$ and 640 nm, respectively). However, only $(arene)_2Mo_2$ is produced when $(arene)_2Mo$ dissolved in phenyl-free, liquid poly(dimethylsiloxane) DC200 is titrated with Mo atoms. Stable, low nuclearity clusters could not be grown in the absence of free arene or arene functionalities in liquid media.

Kinetic analysis of the growth curves for Mo_n in DC510 appears to confirm a stepwise aggregation model. Further studies (viscometry, NMR, ESR) on the DC510/M system indicate (among other factors) the role played by inter- and intramolecular crosslinking *via* $(arene)_2Mo$ complex formation in stabilizing tetranuclear and higher metal clusters: for $(arene)_mM_n$ this decreases from n = 2 to n = 5. Loss of the binuclear $(arene)_2Mo_2$ species supported on DC510, through diffusion-controlled aggregation follows second order kinetics, the rate and activation energy of diffusion being functions of metal loading (variation in crosslink density). Thus the activation energy for the dimerization of $(arene)_2Mo_2$ supported on DC510 (290 K) at low metal loading levels is 4.2 kcal/mol compared to a high loading value of 14.2 kcal/mol: the respective diffusion coefficients of 32.6×10^{-16} and 18.7×10^{-16} cm^2/s reflect the microscopic mobility of the polymer support, which is constrained by increasing crosslinking.

These data together with results of ESR, EXAFS, SIMS, and Raman spectroscopic studies collectively indicate that the growth/agglomeration characteristics in the polymer are determined by a number of effects: 1) the presence or absence of covalently bound arene groups; 2) changes in the microenvironment in the vicinity of the metal aggregate, where cluster size and stability are seen as determined, in part, by the dimensions and arene density of "solvating" cavities. 3) Steric interaction between the immobilized metal aggregate, the polymer support, and the diffusant (metal atom, covalently bound arene, or nucleation site); diffusional encounters are controlled by polymer microdynamics which are dependent both on temperature and crosslink-density. 4) Diffusional limitations which affect the rate of penetration of metal atoms into the polymer (to contribute to cluster growth or be "removed" by a colloid sink), cluster aggregation is also diffusion controlled. 5) Structural changes or constraints imposed on metal aggregates or polymer as a result of binding or stabilization of macromolecules by crosslinking; such changes will control both the number and size distribution of clusters, determining a maximum metal loading limit beyond which colloid formation becomes the favored process for metal atom consumption.

The bis(arene)metal complexes are viewed as "crosslinking" and/or chain propagating agents, as well as metal nucleation sites for the production of clusters. The aggregates are, in part, "solvated" by the ether oxygen atoms of the oligomer or polymer backbone. Evidence suggests that this interpretation is more likely than the alternative involving crown ether or cryptand-like ligand-M_n interactions, without participation of the phenyl substituents.

Metal-Induced Decarboxylation of Diketene—A Novel Route to Allene Complexes[1]

By *Wolfgang A. Herrmann**, *Josef Weichmann*, *Manfred L. Ziegler*, and *Heike Pfisterer*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The synthetic potential of the readily accessible and industrially important[2] diketene **2** has so far been overlooked in organometallic chemistry. We report here on the metal-induced decarboxylation of this compound, which reaction enables the facile and convenient synthesis of allene complexes.

Whereas breakdown of the diketene skeleton requires temperatures around 550 °C and yields besides ketene only traces of allene[2], its decarboxylation takes place under surprisingly mild conditions in the presence of carbonylmetal compounds that are labile towards ligand substitution; concomitantly, allene is incorporated into the organometal substrate. Thus, reaction of the tetrahydrofuran complex **1** with excess diketene **2** in the temperature range −30 to +25 °C leads cleanly, under vigorous evolution of CO_2, primarily to the mononuclear η^2-allene complex **3** (characterized by total elemental analysis, and by IR, ^1H-

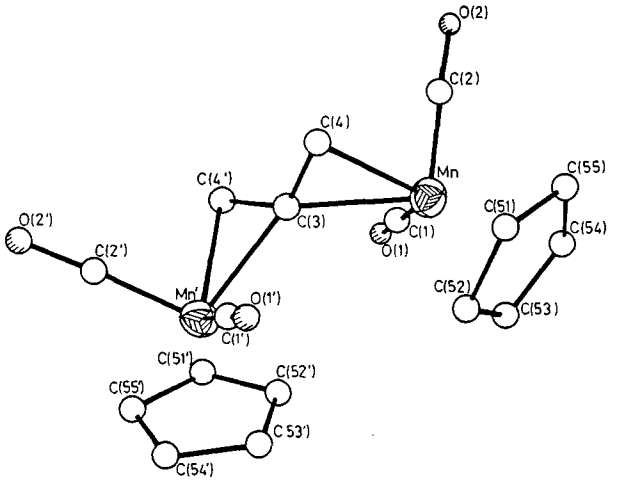

Fig. 1. Structure of the $\mu(\eta^2:\eta^2)$-allene complex **5** in the crystal. $R_w = 0.029$. The angle between the plane of the V-shaped allene bridge and the Mn—Mn vector is 48.6°. The $\eta^2:\eta^2$-coordination rules out a metal-metal bonding with the present stoichiometry on electronic grounds; as expected the Mn—Mn distance is greater than 380 pm.

Table 2 (selected data). Some important bond lengths [pm] and angles [°] in **5**.

MnC(1) 177.8(6), MnC(2) 175.9(6), MnC(3) 214.6(3), MnC(4) 211.9(6), C(3)C(4) 140.8(7), C(1)O(1) 116.2(7), C(2)O(2) 117.1(8); C(4)C(3)C(4') 129.5(0.8), C(1)MnC(2) 87.1(0.3), MnC(4)C(3) 71.8(0.3), MnC(3)Mn' 131.3(0.4)

NMR and mass spectra). The η^2-allene ligand does not fluctuate with respect to the metal-ligand bond [^{1}H-NMR (270 MHz, [D$_8$]THF, 25 °C): $\delta CH_2 = 6.19$ (1 H), 5.66 (1 H), 2.53 (2 H); $\delta C_5H_5 = 4.68$ (5 H)]. Besides **3**, the dinuclear derivatives **4** (< 3%, already known[7]) and **5** (< 10%) with symmetrically bonded V-shaped $\eta^2:\eta^2$-allene bridges (Fig. 1, Table 2) are formed.

The high-yield secondary complexation of the free C=C bond of **3** to the $(\eta^5\text{-}C_5H_5)Mn(CO)_2$ fragment with clean subsequent decarbonylation (**1**+**3**→**5**; **5**→**4**+CO) can be used in general for the straightforward synthesis of previously rarely encountered dinuclear complexes with allene bridges[7-9, 12].

As a test-case, the reaction of diketene **2** with $Fe_2(CO)_9$ may be cited here. Analogously to **3** and **5**[9], the complex $Fe_2(CO)_7(C_3H_4)$ with an $\eta^1:\eta^3$-allene bridge is formed almost quantitatively already at 25 °C; this particular compound was hitherto accessible only by reaction of allene and $Fe_2(CO)_9$ at elevated temperatures (50 °C) and pressures[8]. Our synthetic route to bridged allene complexes also opens up the possibility of synthesizing derivatives containing different metal centers.

BOOK REVIEWS

An Introduction to Chemical Equilibrium and Kinetics. By *L. Meites*. Pergamon Press, Oxford 1981, xiii, 549 pp., price £ 8.95.

This book was written to serve the new type of beginners' chemistry course at Clarkson College of Technology. The course comprises a first semester of lectures on structure and bonding, and a second semester of lectures based on the present book, both running in parallel with a one-year "integrated" practical course. The book is divided into the following chapters: Chemical Thermodynamics and Equilibrium, Chemical Kinetics, Non-electrolyte Equilibria, Solubility of Ionic Compounds, Acid-base Equilibria, Complex Reactions, Redox Processes, Analytical Chemistry and Stoichiometry, Precipitation, Titration Curves, Errors in Measurement, Activities and Activity Coefficients, Potentiometry, and Spectroscopy. Thus, almost nothing has been left out from the field embraced by classical chemistry.

As a physical chemist I found myself fluctuating between laughter and tears while reading this book. The laughter was a reminder of my own student days, when I heard a world-famous organic chemist announce to his students that "a real chemist has little use for physical chemistry". The tears were provoked by the way this book treats the fundamentals of physical chemistry as "black box" concepts. Thermodynamics are dealt with in 23 pages, and free energy occupies a page or two. Students of chemistry are already reluctant to interrupt chemistry practicals to attend lectures on physical chemistry, and were they to take Mr. *Meites'* book seriously, this trend could not but be reinforced. It is inconceivable to me that a course of study written in this superficial style can possibly produce scientifically creative chemists. No doubt the book can be explained in terms of the widely differing standards encountered in colleges in the United States, not all of which aim to foster a new generation of researchers. The book can be recommended: for physical chemists in search of illustrative examples; for teachers of advanced inorganic or organic chemistry who wish to bridge over into physical chemistry; for undergraduate students who

wish to relate the contents of lectures in physical chemistry to other branches of chemistry.

However, the book cannot be recommended for beginners. To avoid presenting beginners' lectures in this style, the course of study would have to be redesigned to put the physical-chemistry content at the start. However, this presupposes considerable mathematical knowledge, which would have to be acquired at school level and/or in introductory pre-semester courses. — The book should stimulate us all to give careful thoughts to new ways of educating our future chemists.

Ullmanns Encyklopädie der technischen Chemie. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley †, W. M. Weigert †*, and *E. Weise*. Verlag Chemie, Weinheim 1981. 4th edition, Vol. 6: Umweltschutz und Arbeitssicherheit [Environmental Protection and Works Safety]. Volume editor: *E. Weise*. xvi, 830 pp., bound, DM 640.00.—Vol. 20: Radionuklide bis Schutzgase [Radionuclides to Protective Gases], xvi, 705 pp., bound, DM 525.00.

With the appearance of these two volumes the 4th edition of Ullmann has come appreciably closer to completion: all the volumes of the general part are now available and of the alphabetical part only four volumes are still lacking[*].

Volume 6 covers two areas in which considerable changes have taken place in the last ten years. Whereas these areas have always been of great importance to industrial chemists, the newly developed public sensitivity to questions of ecology and safety have led to the situation that the government has become increasingly involved in this field by means of laws and decrees. As this development is still in full swing, it requires no particular foresight to state that volume 6 of Ullmann will probably be the first one to become out of date. This applies particularly to those sections in which the legal prescriptions form the starting point of the account of the subject, as in the chapter on safety techniques (110 pp.). In contrast to this, in the majority of the chapters on environmental protection the problems and their possible technical solution are in the foreground. Particular mention must be made of the chapter on ecologically unobjectionable production processes (67 pp.). After a short introduction, the volume begins with four chapters on some general matters, namely ecology (22 pp.), legal principles (19 pp.), endangering of the environment (14 pp.), and toxicology (90 pp.). The already mentioned chapter on ecologically unobjectionable processes is followed by individual areas of environmental protection, namely prevention of atmospheric pollution (96 pp.), effluents (144 pp.), soil (61 pp.), wastes (99 pp.), and noise prevention (56 pp.). Corresponding to its importance, a relatively broad account is given of the biological treatment of effluents; for example, nine different plants that have been realized in practice are described. In comparison with this, the anaerobic treatment of effluents, which is finding increasing interest, is discussed relatively briefly. Here a reference to "Methane" in vol. 16 would have been appropriate.

The coordination of the contributions to this volume was particularly difficult because of the great breadth and complexity of the field. It can nevertheless be stated that, in spite of the very large number of participating authors (about 100), the editors have succeeded well in this task.

Volume 20, the second volume to be reviewed here, belongs to the alphabetical part of Ullmann. Accordingly, it contains headings from a wide diversity of areas, for example nitric acid and related compounds (58 pp.), hydrochloric acid (12 pp.), oxygen and ozone (25 pp.), rhenium, rubidium (including their compounds), resorcinol, salicyclic acid, saponins, and radionuclides (90 pp.), of which, however, the most important—plutonium, thorium, the transuranics and uranium—have their own headings. In addition to these chemically oriented entries there are application-oriented ones: rocket fuels (22 pp.), reactive dyestuffs (11 pp.), reduction (21 pp.), cleaning agents (without detergents) (10 pp.), reproduction technology (22 pp.), reprography (10 pp.), scents and aromas (89 pp.), rodenticides used for plant protection, foam suppression, foamed plastics (18 pp.), hypnotics (16 pp.), abrasion, abrasives agents, and lubricants (215 pp.), chocolate (16 pp.), shoe-cleaning agents, and protective gases. These application-oriented entries obviously also contain a large amount of chemistry; thus, under the heading of scents and aromas some hundreds of compounds are described.

In the quality of presentation and in their arrangement these two volumes are equivalent in every respect to those already in existence. The amount of work that the authors, editors, and publishers have put into them is shown by the fact the preliminary work on the next (5th) edition of Ullmann has already been started, even though the present edition will not be completed before the end of next year. The new edition will, moreover, be in English.

Diastereogenic Addition of Crotylmetal Compounds to Aldehydes**

By Reinhard W. Hoffmann*

Dedicated to Professor Georg Wittig on the occasion of his 85th birthday

In an ideal synthesis, the formation of the CC bonds as well as the creation of the chiral centers and of the final functionality would be carried out simultaneously in each step. Accordingly, stereoselective CC bond forming reactions are required. Instead of a pair of diastereomers, a synthesis should yield only one of the two possible diastereomers. Such selectivity is often achieved in the addition of crotylboron, -aluminum, -tin, -titanium, and -chromium compounds to aldehydes. Depending on whether one starts from *E*- or *Z*-crotyl compounds, one diastereomeric adduct is formed preferentially. In this case the newly formed CC bond carries a methyl substituent. However, the synthetic goal is often a compound carrying an oxygen function at the site of the new CC bond. Compounds of this type can be obtained through addition of heteroatom-substituted allylboronic acid esters or analogous reagents to aldehydes.

1. Introduction

For several decades stereoselective synthesis belonged to the domain of alicyclic and heterocyclic chemistry, being concerned in particular with the generation of chiral centers having the desired configuration during the synthesis of sugars, steroids, or alkaloids. In contrast, stereoselective synthesis of open-chain systems has been intensely investigated only during the last few years. This surge in interest was caused by new efforts to synthesize macrolide and polyether antibiotics, as well as some pheromones containing stereochemically defined β-methyl alcohol or *vic*-diol functionalities. Many improvements have been reported within a short span of time and numerous methods are now available[1].

As an example, consider some syntheses of *exo*-brevicomin **3**, which is a sex-attractant of the bark beetle *Dendroctonus brevicomis*. Being a bicyclic acetal, brevicomin can be prepared from the ketodiol **2**. Diastereomerically pure **2**[***] is needed in order to obtain isomerically pure **3**. Following a classical synthetic strategy[2] the carbon skeleton would be constructed first. In the case of **1** this would involve the synthesis of the stereochemically uniform *cis*-substituted double bond constituting the two adjacent prochiral centers. Further steps—epoxidation with *m*-chloroperbenzoic acid and opening to the *trans*-diol **2**—give rise to the two neighboring chiral centers with the desired relative configuration *via* "internal asymmetric induction"[1].

In such a typical reaction sequence the carbon skeleton is first formed, followed by creation of uniform prochirality, and finally of the chiral centers themselves. In princi-

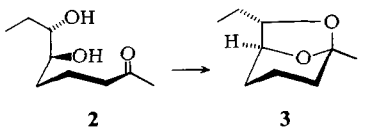
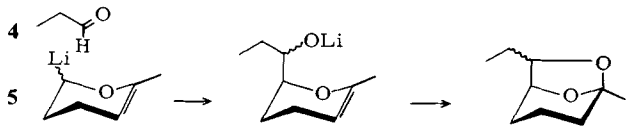
1



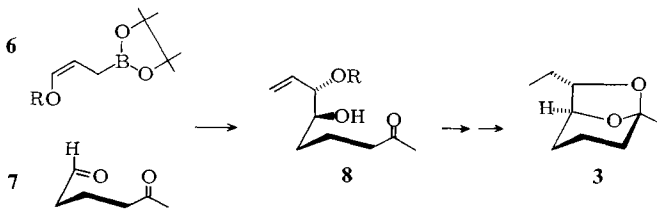
2 3

ple, it would be more economical if the carbon atom skeleton and the chiral centers were formed in a single step. For this purpose, two prochiral C atoms would have to be linked to each another, *e.g.* the negatively charged C atom in the organolithium compound **5** and the C atom of the carbonyl group in the aldehyde **4**. However, this reaction sequence did not give the desired diastereomer only, but rather a mixture of the two possible diastereomers in the ratio 1 : 1.3[3].



3 + Diastereomer

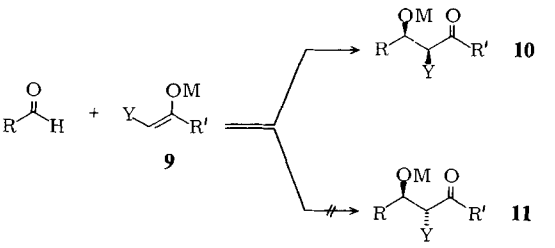
CC bond forming reactions of much greater diastereoselectivity are, therefore, required. This holds, for example, for the addition of the allylboronic acid esters **6** to the aldehyde **7**, which resulted in a diastereoselectivity of 15 : 1 in favor of the required adduct **8**. This, in turn, was easily converted into *exo*-brevicomin **3**[4].



8 **3**

This example illustrates the trend in present day stereoselective synthesis to form not only a new CC bond *but also* the relative (and possibly also the absolute) configuration of the newly formed chiral centers in a single reaction step. Thus, by avoiding refunctionalization steps one approaches the "ideal synthesis"[5] in which individual segments of the molecular skeleton are linked in such a way that the final functionality and steric structure are formed simultaneously. Because of the high selectivity (> 100 : 1)[10, 11] in the aldol addition of metal enolates **9** to aldehydes, this diastereogenic CC bond forming reaction[6, 7] is of particular current interest[1, 7-9].

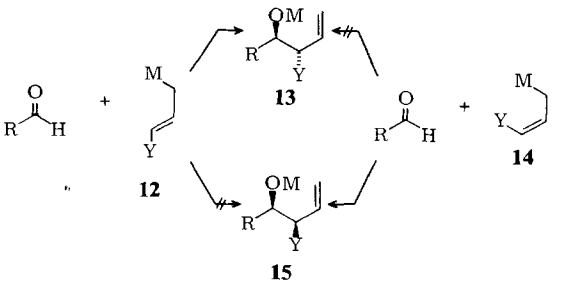
It took a considerable length of time, however, before the early observations of *Dubois et al.*[12] and *House et al.*[13] were developed so that the aldol addition could be carried out in such a way that of the two possible diastereomeric adducts **10** and **11**, only one—*e.g.* **10**, and not **11**—is formed (Scheme 1).



9 **10** **11**

Scheme 1. Y = alkyl or a heteroatom-bonded group, M = metal.

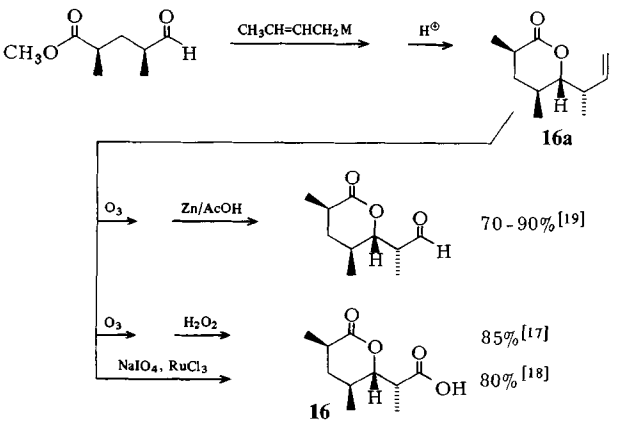
The addition of allylmetal compounds to aldehydes (Scheme 2) is structurally and, probably also, mechanistically analogous to the aldol addition (Scheme 1). Accordingly, in the case of the reaction of aldehydes with allylmetal derivatives **12** or **14**, a high degree of diastereoselectivity is achieved. Because reactions of this kind are only marginally covered in reviews of aldol additions[1, 7-9] it is appropriate at this point to review them in their own right[14].



12 **13** **14** **15**

Scheme 2. Y = alkyl or a heteroatom-bonded group, M = metal.

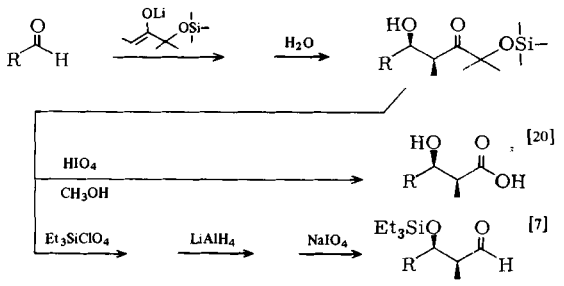
These reactions are not only structurally, but also synthetically equivalent to the aldol addition since the adducts **13** and **15**, being homoallylic alcohols, can be transformed into aldol derivatives. The newly formed alcohol group is often protected by esterification in these reactions. The double bond is cleaved by ozonolysis and transformed into



Scheme 3.

an alcohol or an aldehyde by reductive work-up[15]. Oxidative work-up, on the other hand, leads to formation of carboxylic acids[16]. Typical examples are given by the transformations of a cyclic lactone-olefin[17-19] **16a** which led to the Prelog-Djerassi lactone **16** (Scheme 3).

These refunctionalizations turned out not to be more bothersome than the corresponding reactions required after aldol addition of special enolate reagents to aldehydes (Scheme 4).



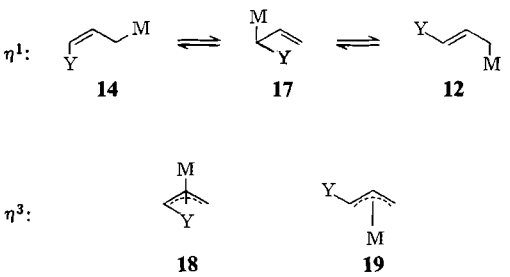
Scheme 4.

At this point a word on the stereo-nomenclature of diastereomeric pairs, such as **10/11**, is in order. If one attempts to read the original literature on aldol additions quoted in the reviews[1,7-9], one is confronted with a Babylonic confusion. The unambiguous *R*,S**-nomenclature is too cumbersome for easy reading of formulas and for verbal communication. Research groups concerned with the aldol addition predominantly use the terms *threo* for **11** and *erythro* for **10**[7,20]. Unfortunately, this designation is just the opposite of what would result from the usual Fischer projection. Therefore, when using the terms *erythro* and *threo* it is first necessary to establish to which nomenclature forms the audience is accustomed. Because of this dilemma, other designations have been suggested. These are derived either from structures of the products, such as *u/l*[21], *syn/anti*[22], *p/n*[23], or from the structures of the educts, such as *lk/ul*[21], *rere/resi*[7,24,25], or heterofacial/homofacial[24]. Although none of these descriptions is ideal, the *syn/anti* nomenclature will be used here for the sake of ease of communication, because in the most frequently encountered simple cases structures can be recognized or assigned at a glance. Thus **10** would be a *syn* compound, because in the "sawhorse" formalism the groups of interest, OM and Y, are on the same side of the main backbone (the newly formed CC bond).

2. Configurational Stability of Allylmetal Compounds

In the addition reactions in Scheme 2, the basic idea is the production of a specific relative configuration in the product by transformation of the prochirality of the allylmetal compound, *e.g.* *E* in **12**, or *Z* in **14**, in a stereoselective reaction. Therefore, a preparative application is usually possible only when each *E/Z* stereoisomer of the γ-substituted allylmetal compound is independently accessible. Furthermore, each of these should be configurationally stable under the reaction conditions and, ideally, also on storage.

Allylmetal compounds can exist as either *monohapto*-(η^1-) or *trihapto*-(η^3-) bound forms, each of which should be configurationally stable. However, *E/Z* isomerization is possible for the *monohapto*-compounds **12** and **14** *via* a metallotropic rearrangement to **17**. Typical examples of this are the fluxional dialkyl(allyl)boron compounds[26,27]. The transition states for these rearrangements should resemble the *trihapto*-structures **18** and **19** ($M=BR_2$). *E/Z*-isomerizations are also conceivable with the *trihapto*-compounds **18** and **19**, if the *monohapto*-structure **17** is accessible from them. For example, this is the case in allyllithium compounds[28,29] where rapid *E/Z* isomerization occurs[30,31].



In a simplified discussion it is not necessary to consider the ion-pair character of allylmetal compounds. Rather, it suffices to state that, in order to be of use for diastereoselective CC bond formation, only allylmetal compounds possessing an energy barrier >20 kcal/mol for the mutual interconversion of the *monohapto*- and *trihapto*-forms can be used. Examples of *trihapto*-compounds fulfilling this requirement are dicarbonyl(cyclopentadienyl)iron derivatives[32], a wide range of nickel complexes[33], or dicyclopentadienyltitanium compounds[34]. Allylpotassium compounds should also be mentioned here[29,35]. Among the *monohapto*-allylmetal compounds, the silanes should have the lowest tendency to metallotropic isomerization[36]. The configurational stability decreases on going from the germanium to the tin compounds[37,38], which often undergo *E/Z* isomerization below 100 °C or in the presence of Lewis bases.

Of the allyl compounds of the third group elements, those of boron are the best known. In such compounds the tendency to metallotropic rearrangement can be controlled through proper choice of the other substituents at boron: dialkyl(allyl)boron compounds rearrange rapidly at room temperature[26,27] and can be handled without isomerization only below −78 °C[39]. π-Donor substituents at boron raise the energy of the vacant boron p orbital to such an extent that rearrangement to the *trihapto*-structure is rendered difficult or does not occur. Although a single OH group at boron is insufficient to suppress the borotropic shift at −20 °C[40], an amine substituent renders the compounds stable up to 150 °C[41].

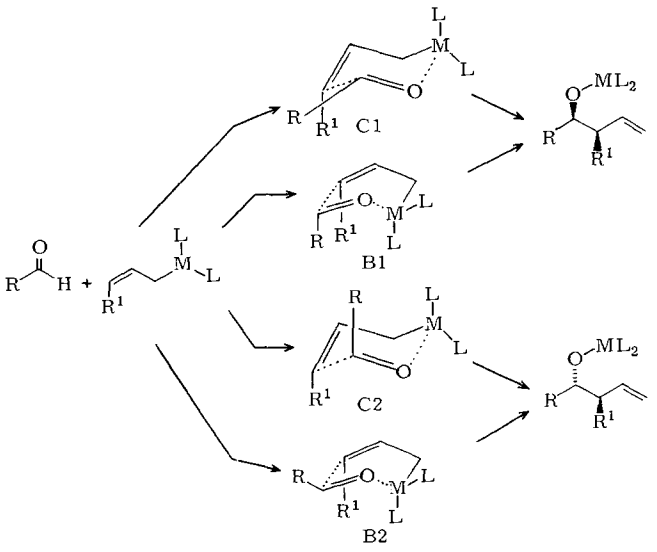
Allylboron derivatives with two oxygen functions at boron, *e.g.*, the crotylboronic acid esters **25** and **26**, are sufficiently thermally stable that the *E*- and *Z*-derivatives are separately manipulable at room temperature[42-44]. Consequently, allylboron compounds containing one oxygen and one nitrogen substituent, or even two nitrogen substituents,

are particularly resistant to borotropic rearrangement[44,45]. On the other hand, with these compounds and the allylboronic acid esters as well, the tendency to isomerize like other organometallic compounds in the presence of Lewis acids[44-46] becomes apparent; this, of course, limits the choice of conditions for their preparation.

Allylmagnesium, like the organozinc compounds—and by inference also the organocadmium compounds—undergo rapid metallotropic shifts **12** ⇌ **14**, even at low temperatures[30,47]. Thus, apart from special cases[48,49], they are hardly useful as reagents in diastereoselective additions to aldehydes[50,51]. The same holds[52] for the allyllithium compounds[30,53], particularly if not only one of the stereoisomers **12** or **14** is to be used. Consequently, further discussion will be limited to allylmetal compounds which are configurationally stable *per se* at room temperature and also under the conditions of reactions with the aldehydes. *Monohapto* bonded allylchromium[54,55], allylzirconium[56], and allyltitanium compounds[57,58] also belong to this class.

3. Stereochemistry of the Addition Reaction

An allylic rearrangement is always observed in reactions between allylmetal compounds such as **12** or **14** and aldehydes under kinetically controlled conditions (Scheme 2). Thus, it is reasonable to propose a six-membered cyclic transition state, especially when the metal can coordinate to the carbonyl group of the aldehyde as a Lewis acid due to the presence of a low-lying vacant orbital, *i.e.* when it is able to form ate-complexes[59]. In order to delineate the occurrence and the limits of diastereoselectivity one can refer to the concepts used in the interpretation of the aldol reaction[8,9]. As in the aldol addition, the transition state comprises a cyclic arrangement of the reacting atoms with conformations similar to that of cyclohexane, *i.e.* chair or boat. Thus, diastereoselectivity depends on the relative energies of the diastereomeric transition states and these can be influenced by conformational factors in the same way as in cyclohexane. This is illustrated (cf. [8]) for the addition of a *Z*-allylmetal derivative to an aldehyde. Both, the chair-like transition states C1 and C2, as well as boat-like transition states B1 and B2 are considered in Scheme 5.



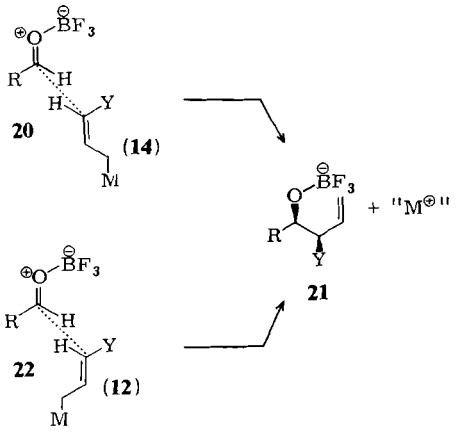
Scheme 5. C1, C2 = chair-like, B1, B2 = boat-like transition states.

In the simplest case the addition is diastereoselective when one of the transition states is approximately >2 kcal/mol more stable than the others. For the discussion of the factors determining the relative energies of the transition states it is necessary to assume that at least two more ligands, L, are bound to the metal. The steric requirements of R and L are of decisive importance for the diastereoselectivity, because in the chair-like transition state C2 a 1,3-diaxial interaction exists between them. If this interaction is larger than the *gauche*-interaction between R and R^1 in the transition state C1, then C1 will be preferred. Of the three conceivable boat-like conformations, the one having the aldehyde-oxygen and the allyl-CH groups in the bow and stern positions are preferred. Only these transition states (B1 and B2) are considered here. Of these, transition state B2 should be significantly more stable than B1 as a result of the 1,3-diaxial R/L and R/R^1 interactions. However, because of the eclipsing groups, boat transition states are inherently disfavored with respect to the chair transition states. However, the energy difference between boat and chair transition states should not be very large, since studies of the Claisen rearrangement, which takes place *via* similar transition states, have shown that the boat-like transition states are only 2—3 kcal/mol less stable than the corresponding chair forms[60]. Therefore, boat-like transition states may well represent the principal path of the Claisen rearrangement as a result of steric interactions between substituents[1]. Consequently, boat-like transition states should also be considered in the additions of allylmetal compounds discussed here.

These conclusions were derived for the reactions of the *Z*-allylmetal compounds **14**. A similar analysis may be made for the reactions of the corresponding *E*-compounds of type **12**.

Further points to be noted include: a high degree of diastereoselectivity may be expected in additions to aldehydes, but not to ketones, because the diastereoselectivity stems from different steric interactions between the groups R and the aldehydic H with the metal ligands. Therefore, the size of L should be significant for the degree of diastereoselectivity. Fortunately, the size of L can be chosen at will (see *e.g.* [61]). The R/L-interaction and, hence the diastereoselectivity are at a maximum when the length of the oxygen-metal bond in the transition state is at a minimum. This will be the case in endothermic or weakly exothermic reactions in which the transition state occurs late on the reaction coordinate[62]. However, the ultimate attainable metal-oxygen bond length is the most decisive factor. According to this criterion, as shown by *Evans et al.*[8], diastereoselectivity should decrease along the series, metal = B (B—O ≅ 1.4 Å), Si (Si—O ≅ 1.6 Å), Ti (Ti—O ≅ 1.7 Å), Sn (Sn—O ≅ 2.1 Å), Zr (Zr—O ≅ 2.1 Å). The above considerations refer to metals which can coordinate to the aldehydic carbonyl group as Lewis acids. It is questionable whether or not this is possible for M = $R_3B^{\ominus}$ [63]. If so, this reaction would imply a nucleophilic substitution with retention at a saturated first row element (boron).

The addition of allylmetal compounds to aldehydes can, according to the nature of the metal, occur even at low temperatures, or, in the case of trialkyltin derivatives, only at temperatures above 100 °C[64]. Such additions are catalyzed by Lewis acids such as boron trifluoride etherate[65]. Essentially only the Lewis acid catalyzed addition is known for allyltrialkylsilanes[66]. The catalysis may derive from an activation of the carbonyl group through coordination of the Lewis acid with the oxygen atom. In these cases it is not certain whether the reactions still take place *via* cyclic transition states since the aldehyde group is already complexed with the catalyst. In these cases open-chain transition states as in S_E2'-reactions may well be more favorable than cyclic ones[67]. Support for this interpretation comes from the fact that allylic rearrangement is no longer the rule in catalyzed additions of crotyltin compounds to quinones[68], because both S_E2' and S_E2 reactions are possible for open-chain transition states[68]. Of such open-chain transition states (see **20** and **22**) the most



favorable will be those in which the least steric interaction occurs along the newly formed bond. Stereoconvergence can occur in such cases, so that predominantly one and the same diastereomeric product **21** arises from the two stereoisomeric allylmetal compounds **12** and **14**.

4. Diastereogenic CC Bond Formation

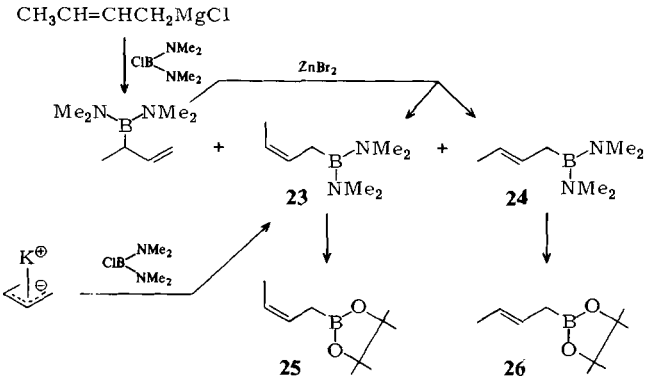
In this section we will describe the preparative aspects of the addition of crotylmetal compounds to aldehydes, considering the synthesis of the stereochemically pure reagents as well as the diastereoselectivity in their reactions with aldehydes.

4.1. Boron as Key Atom

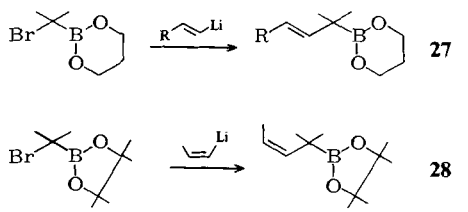
4.1.1. Crotylboronic Acid Esters

The crotylboronic acid esters **25** and **26** can be prepared from the reaction of crotylmagnesium chloride with chlorobis(dimethylamino)borane, which gives a mixture of isomeric methylallylboronic acid amides[45]. Isomerization with $ZnBr_2$ at 120 °C gives a mixture of **23** and **24**, which can be separated by distillation at 100 torr using a spinning band column.

Pure *Z*-crotylbis(dimethylamino)borane **23** has also been obtained from *Z*-crotylpotassium; the yields were *ca.* 40%[44]. The boronic acid amides **23** and **24** could be converted *in situ* with a 1,2-diol into the reactive but thermally only slightly stable boronic acid esters **25** and **26**[44]. Analogous chiral crotylboronic acid esters (e.g. **67** and **69**) are



obtainable using optically active 1,2-diols[69]. The dimethyl ester of *Z*-crotylboronic acid can be advantageously generated *in situ* from *Z*-crotylpotassium[70] and allowed to react directly with aldehydes. *E*- and *Z*-Boronic acid esters such as **27** and **28** carrying two α-alkyl groups, *e.g.* CH_3, can be obtained in good yields from α-bromoisopropylboronic acid esters[42,44].



The crotylboronic acid esters thus obtained undergo virtually quantitative addition to aldehydes below 0 °C[71]. Cleavage of the boric acid esters formed using triethanolamine gives rise to the homoallylic alcohols **29** and **30**, the 1,2-diol, and the boratrane **31**. In favorable cases the homoallyl alcohol and the diol can be separated by distillation. If this is not possible, the homoallyl alcohol must be separated by gas or column chromatography.

In the addition of the *Z*-crotylboronic acid ester **25** to aldehydes, the diastereoselectivity obtainable was directly related to the isomeric purity of **25** (see Table 1)[44,70]. In each case the diastereomer of type **29** predominated; this is formed *via* the chair-like transition state C1. This stereoselective CC bond formation has been applied in the preparation of the pheromone **33** of the drugstore beetle, whereby the *syn*-isomer **32** was obtained in 70% enantiomeric excess (e.e.)[*] using the chirally modified crotylboronic acid ester **69**[16] (Scheme 6).

[*] e.e., enantiomeric excess is a measure of the enrichment of one enantiomer relative to a racemic mixture. A 70% e.e. corresponds to a 85% content of the enantiomer concerned. Here, diastereomeric purity refers to the amount of the appropriate diastereomer in the isomeric mixture isolated.

The addition of the *E*-crotylboronic acid ester **26** to aldehydes also took place in a diastereoselective manner *via* transition state C1 (see Table 1). Thus, the complementary

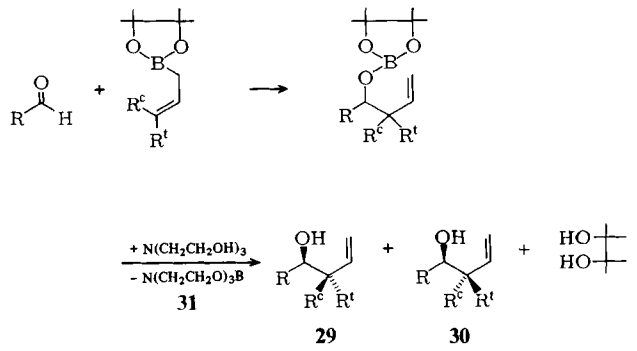


Table 1. Diastereoselectivity in the formation of the homoallylic alcohols **29** and **30**.

Aldehyde R	Boronic Acid Ester	R^c	R^t	Yield [%]	**29** : **30**	Ref.

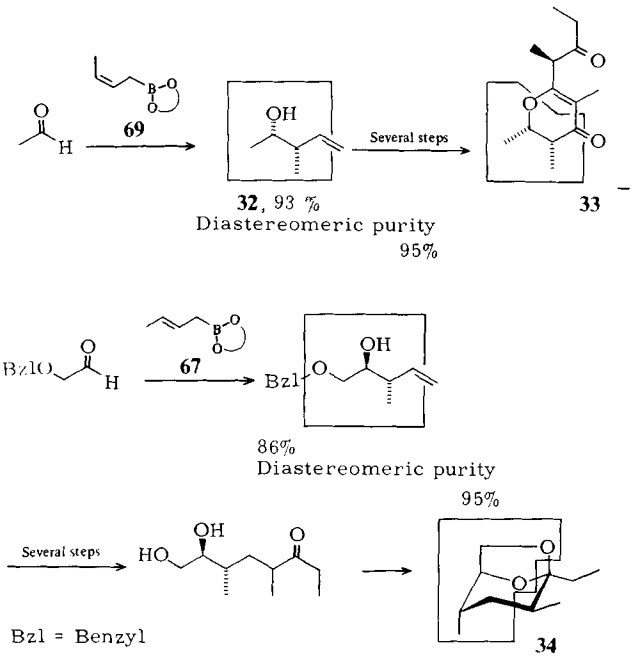
$AcO(CH_2)_8$				92	>98 : <2	[74]

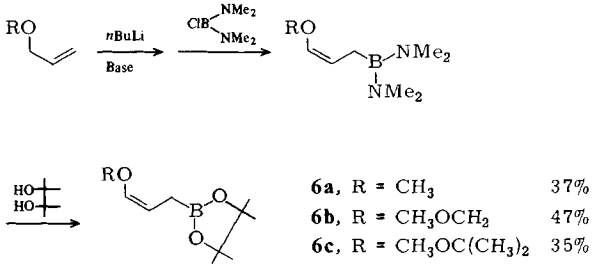
diastereoselectivity afforded the homoallyl alcohols with *anti*-configuration. This CC bond formation step was used in a synthesis of δ-multistriatin **34**, whereby 52% e.e. (= 76% of the corresponding enantiomer) was achieved using the chirally modified crotylboronic acid ester **67**[15] (Scheme 6). Furthermore, the α,α-disubstituted boronic acid ester **28** also added to benzaldehyde with 97% diastereoselectivity[44].



Scheme 6.

4.1.2. Substituted Boronic Acid Esters

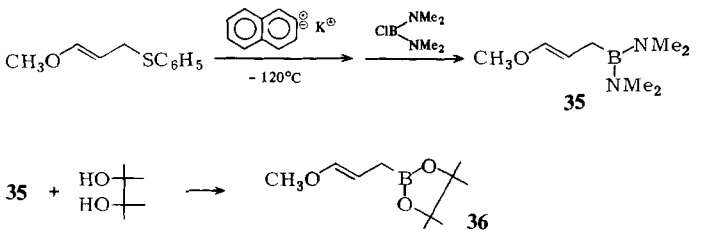
Diastereoselective CC bond formation also occurs using γ-alkoxy-substituted allylboronic acid esters: the *Z*-allylboronic acid esters **6**, prepared according to Scheme 7, add to aldehydes at room temperature (cf. Table 1)[4, 72, 75].



Scheme 7. Tetramethylethylenediamine or potassium *tert*-butoxide is used as a base.

An application of this reaction has already been given in Section 1 (the synthesis of *exo*-brevicomin **3**). However, the reaction between **6a** and isobutyraldehyde took place with somewhat lower diastereoselectivity than in the reactions with benzaldehyde, acetaldehyde, and propionaldehyde. This decrease in diastereoselectivity is even more pronounced in the addition of the allylboronic acid esters **6b** and **6c** possessing larger γ-substituents, particularly in the reaction with sterically hindered aldehydes. These limiting factors can be understood in terms of transition states C1 and C2: sterically demanding groups R and R^1 destabilize C1 in particular, and to a lesser extent C2. In the latter case, the two groups are farther removed from each other. As a consequence, a significant portion of the reaction will take place *via* transition state C2 when steric hindrance is present. The results do not preclude the possibility that the boat-like transition state B2 can also be involved in the reaction.

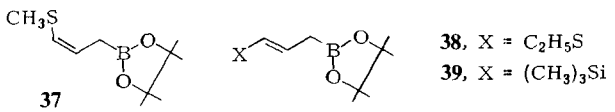
In the addition of boronic acid esters of *E*-configuration such as **36**, the same steric factors which decrease the diastereoselectivity with sterically demanding aldehydes, such as in reactions of **6**, should now increase the diastereoselectivity. Scheme 8 shows the synthesis of **36**.



Scheme 8.

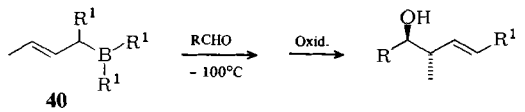
E-Methoxyallylpotassium generated at $-120\,^{\circ}C$ can be trapped *in situ* giving **35**. Under these conditions, isomerization to the *Z*-conformer is largely suppressed: the product **36** was formed in 60% total yield and with 90% *E*-configuration. Since **36** reacts more rapidly with aldehydes than the *Z*-isomer **6a**, crude **36** was mixed with 0.9 equivalents of the aldehyde, whereby virtually only **36** reacted. The data in Table 1 demonstrate the high diastereoselectivity obtainable in these reactions, particularly in the addition to isobutyraldehyde.

γ-Alkylthioallylboronic acid esters **37** and **38** can be prepared analogously and also add with high diastereoselectivity to aldehydes[73]. Using a mixture of **38** and its *Z*-isomer, the more reactive *E*-isomer **38** reacted selectively with a slight deficiency of the aldehydes[73]. The silyl-substituted boronic acid ester **39** also adds diastereoselectively to aldehydes[74].



38, X = C_2H_5S
39, X = $(CH_3)_3Si$

With respect to reactions of other crotylboron compounds, the reaction between **40** and aldehydes is worthy of mention since a borotropic isomerization can be avoided when the reaction is carried out at $-100\,^{\circ}C$[39].

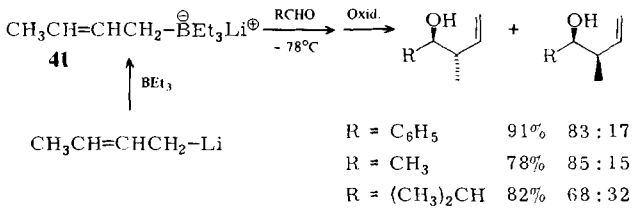


R = C_6H_5, R^1 = *n*Bu		84%
R = C_6H_5, R^1 = Et		67%
R = $C_6H_5CH_2CH_2$, R^1 = Et		52%

As expected, dialkylcrotylboranes which are not configurationally stable at room temperature react with aldehydes in a nonstereospecific manner[76].

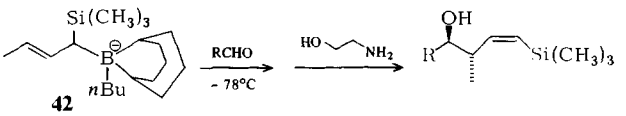
4.1.3. Crotylborate Complexes

The situation is different in the reaction of the trialkylcrotylborate complex **41**. Due to the method of preparation, this complex probably contains *ca.* 80% *E*-crotyl residues. This was also the maximum diastereoselectivity observed[63,77].



R = C_6H_5	91%	83 : 17	
R = CH_3	78%	85 : 15	
R = $(CH_3)_2CH$	82%	68 : 32	

The higher degree of isomeric purity in educt **42** (and its stannyl analogues) led to very high diastereoselectivities in the addition to aldehydes; however, due to side reactions the chemical yields were only 50—70%. On the other hand,

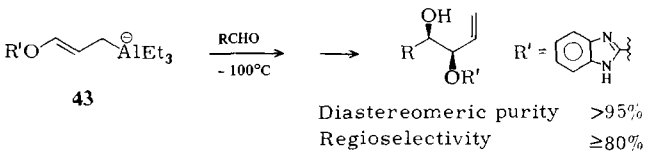


R = C_6H_5	50%	Diastereomeric	>98%
R = *n*Bu	62%	purity	>98%

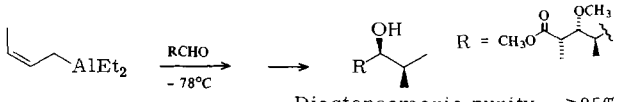
42 (pyridinium instead of butyl) gave very high chemical yields and diastereomeric purities of between 85 and 90%[78].

4.2. Crotylaluminum Compounds

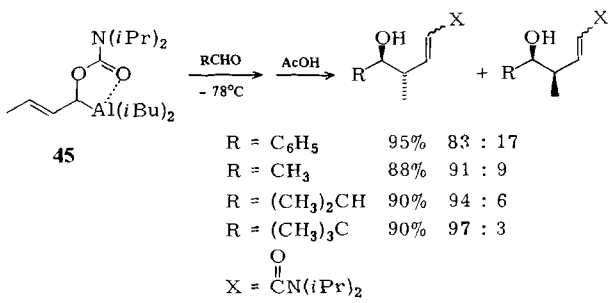
Aluminate complexes can be obtained by analogy to **41**. However, the reaction of these complexes with aldehydes did not give rise to a particularly high degree of diastereoselectivity[63,77]. This is probably due to the fact that the double bond in crotyl- and heterosubstituted allylaluminates[79] does not possess a uniform configuration; however, diastereoselective addition to aldehydes has been achieved with some heterosubstituted allylaluminates, *e.g.* **43**[14,80].



Diastereomeric purity >95%
Regioselectivity ≥80%



Diastereomeric purity >95%



R = C_6H_5	95%	83 : 17	
R = CH_3	88%	91 : 9	
R = $(CH_3)_2CH$	90%	94 : 6	
R = $(CH_3)_3C$	90%	97 : 3	

X = $\overset{O}{\overset{\|}{C}}N(iPr)_2$

Crotylaluminum compounds with uniform double bond configuration, *e.g.* **44**[81], can be prepared at low temperatures from stereochemically pure crotylalkali metal compounds and react with aldehydes *in situ* in a highly stereoselective manner. In the spectacular synthesis of monensin[81], use was made of this procedure to form one of the CC bonds.

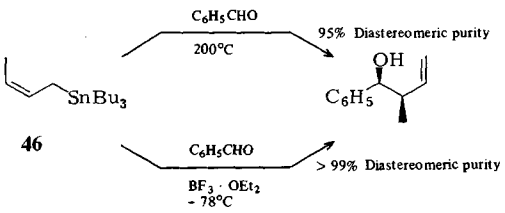
Heterosubstituted allylaluminates and allylaluminum compounds have been examined also: differing regioselectivities were observed in the addition reactions of **43**[80] and **45**[82] with aldehydes. This is possibly due to a metallotropic equilibrium in which the aluminate exists in the extended form, because of coulombic repulsion, and the aluminum compound **45** is present in an intramolecularly complexed form.

4.3. Crotylsilicon Compounds

Z-crotyl(trimethyl)silane is obtainable from butadiene[83] and *E*- and *Z*-crotyl(triphenyl)silane from the isomeric crotyl chlorides, respectively[38] (for further syntheses of trialkyl(crotyl)silanes, see [84,85]). Trialkyl(allyl)silanes of this type give good yields in the addition reaction with aldehydes only when Lewis acid catalysis ($TiCl_4$) is used[66]. The fluoride ion catalyzed addition also takes place in low yields[86]. Little information has been given about diastereoselectivity in these cases[67].

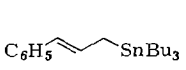
4.4. Crotyltin Compounds

Stereochemically pure crotyltin compounds can be prepared from the corresponding crotyl chlorides by reaction with trialkyl-[87] or triaryltin lithium compounds[38]. For example, **46** adds diastereoselectively to benzaldehyde at 200 °C[88]. Chloral reacts even at 20 °C[85,88].

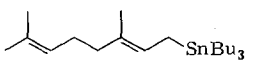


Use of the more reactive trihalotin compounds[89,90] allows a decrease in the reaction temperature. Diastereoselectivity is preserved in some cases[91]. In other cases, the dibutyl(crotyl)tin chloride adds to aldehydes in such a manner that the *E*/*Z*-ratio of the crotyl residues is no longer reflected in the *syn*/*anti* product ratio[92].

The addition of trialkyl(crotyl)tin compounds to aldehydes can also be facilitated using Lewis acid catalysts: **46** adds diastereospecifically to benzaldehyde in presence of $BF_3 \cdot OEt_2$[85]. High diastereoselectivity was also reported for the Lewis acid catalyzed addition of other γ-substituted allyltin compounds such as **47** and **48** to aldehydes[93].

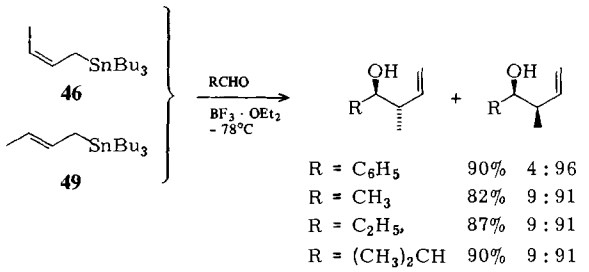


47



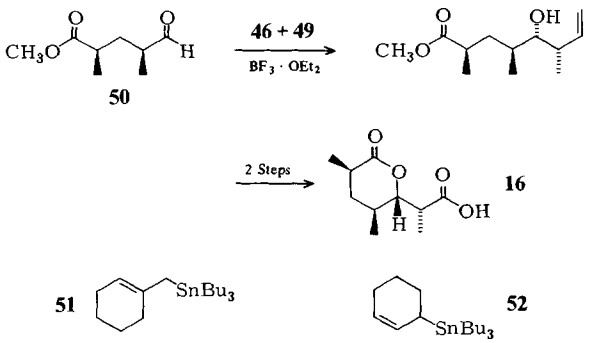
48

The *stereoconvergence* in the BF_3-catalyzed reaction was surprising: both **46** and the corresponding *E*-isomer **49** added with predominant formation of one and the same diastereomeric product[17,67]. The preparative advantage of stereoconvergence is obvious: instead of using configurationally pure starting materials, **46** or **49**, the more readily available mixture of isomers may be used. The stereoconvergence is not due to an initial rearrangement of **49** to **46**; rather, open-chain transition states have been considered as possible causes.



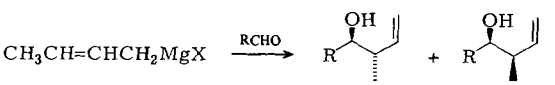
R = C_6H_5	90%	4 : 96
R = CH_3	82%	9 : 91
R = C_2H_5,	87%	9 : 91
R = $(CH_3)_2CH$	90%	9 : 91

The stereoconvergent reaction of **46** + **49** with **50** was applied to a stereoselective synthesis of the Prelog-Djerassi lactone **16**[17]. However, not all crotyltin compounds react diastereoselectively with aldehydes; thus, **51** and **52** gave mixtures of diastereomeric products[93].



4.5. Crotylmagnesium and Crotylcadmium Compounds

The addition of crotyl-Grignard compounds to aldehydes gave rise to low diastereoselectivity and are thus of little preparative interest[50,51,94]. Nontheless, some work with heterosubstituted allylcadmium compounds[48,49] indicates the possibility of diastereoselective CC bond formation.



R = C_6H_5	38 : 62
R = CH_3	50 : 50
R = C_2H_5	50 : 50
R = $(CH_3)_2CH$	57 : 43

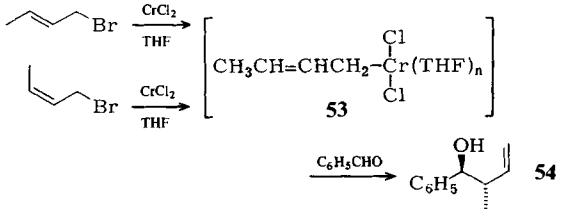
4.6. Crotyllithium Compounds

No diastereoselectivity worth mentioning has been achieved in the addition of crotyllithium to aldehydes[52].

Most likely, this is due to the fact that the lithium (like magnesium) compounds exist as equilibrating *E*/*Z*-isomers. A high degree of diastereoselectivity has occasionally been observed in the addition of γ-substituted allyllithium compounds to aldehydes[95,96]; this probably arises because the *E*/*Z*-equilibrium lies far to the side of one of the geometric isomers.

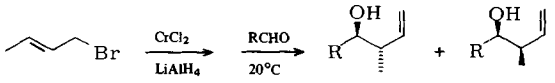
4.7. Crotylchromium Compounds

The addition of allyl bromides to aldehydes in the presence of $CrCl_2$ has been known for some time. When *E*-crotyl bromide is used, only diastereomer **54** is produced[55].



54

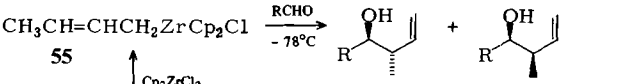
Surprisingly enough, this reaction is also stereoconvergent[54]. It is not known whether this stereoconvergence is due to an equilibration of the intermediate crotylchromium compound **53** to the *E*-isomer. The diastereoselectivity attainable depends both on the solvent (tetrahydrofuran is best) and on the aldehydic residue R[54].



R = C_6H_5	96%	100	: 0
R = n-C_3H_7	59%	93	: 7
R = $(CH_3)_2CH$	55%	95	: 5
R = n-C_5H_{11}	70%	97	: 3
R = CH_3–CH=CH	73%	83	: 17
R = $(CH_3)_3C$	64%	35	: 65

4.8. *Monohapto*-Crotylzirconium Compounds

A fair degree of diastereoselectivity is shown in the addition of the crotylzirconium compound **55** to aldehydes[56]. This may be due to the fact that the reagent, because of the method of preparation, is an *E*/*Z*-mixture.

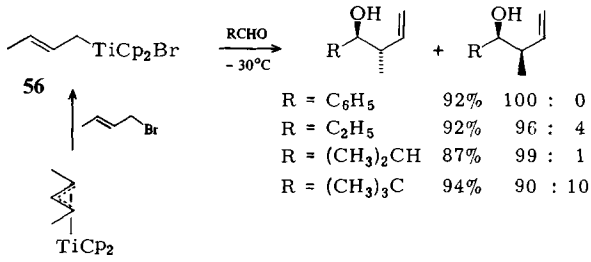


R = C_6H_5	90%	81	: 19
R = CH_3	85%	73	: 27
R = C_2H_5	88%	86	: 14
R = $(CH_3)_2CH$	90%	88	: 12
R = $CH_3O\overset{O}{\overset{\|}{C}}(CH_2)_2$	90%	94	: 6

Cp = Cyclopentadienyl

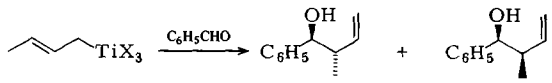
4.9. *Monohapto*-Crotyltitanium Compounds

The titanium compound **56**, which corresponds to **55**, is expected to have the *E*-configuration. Excellent diastereoselectivity was achieved in the addition of both **56** and the corresponding iodo but not the chloro complex[58].



R = C_6H_5	92%	100	: 0
R = C_2H_5	92%	96	: 4
R = $(CH_3)_2CH$	87%	99	: 1
R = $(CH_3)_3C$	94%	90	: 10

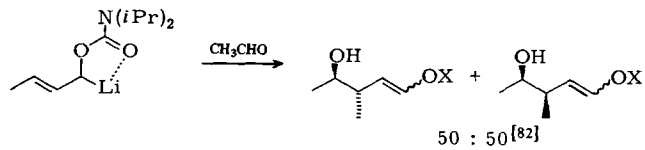
Very good yields were also reported for the addition of the triamino(crotyl)- or trialkoxy(crotyl)titanium compounds **57**—**60**[61,97]. The degree of diastereoselectivity appears to depend on both the spatial demands and the electronegativity of the residues at titanium.



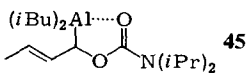
57, X = NMe_2	48 : 52[97]
58, X = NEt_2	70 : 30[97]
59, X = $OiPr$	80 : 20[61,97]
60, X = OC_6H_5	85 : 15[61]

The amino compound **58** exists as the pure *E*-compound[97]. In all likelihood, this is also true for the alkoxy-compound **60** which gave selectivities of >90% in several reactions with α-branched aliphatic aldehydes, favoring formation of the *anti*-adducts[61].

The results shown in Scheme 9 indicate that also in the case of heterosubstituted allyl derivatives, the titanium compounds are the superior reagents.



50 : 50[82]



45

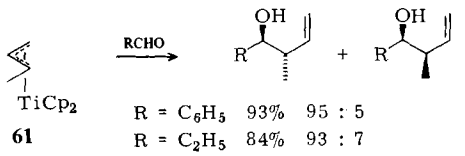
97.5 : 2.5[98]

X = $\overset{O}{\overset{\|}{C}}N(iPr)_2$

Scheme 9.

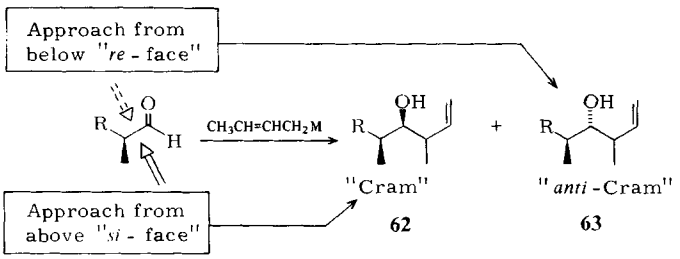
4.10. *Trihapto*-Crotyltitanium Compounds

Although stereoisomeric *trihapto*-crotylmetal derivatives are known[32,99], only titanium compounds **61** with *E*-configuration have been reacted with aldehydes to date[34]. The additions took place with good diastereoselectivity and yields.



5. Cram/*anti*-Cram Selectivity

Up until now, only those diastereogenic reactions have been discussed in which a prochiral allyl or crotylmetal compound was added to the prochiral carbonyl group of an aldehyde. The *relative* configuration of the two newly formed chiral centers was of particular interest. If the aldehyde is not achiral then the upper and lower faces of this group will no longer be an enantiotopic, but rather diastereotopic. Different diastereoisomeric adducts will be formed in CC bond formations taking place on the *re*- and *si*-faces. An example is the addition to an aldehyde containing a chiral center, such as an α-methyl group, leading to a pair of isomers such as **62**/**63** (Scheme 10) with three chiral centers. The isomers now differ as regards the configuration of the newly formed chiral center (with the hydroxy group) relative to the chiral center carried over from the aldehyde.

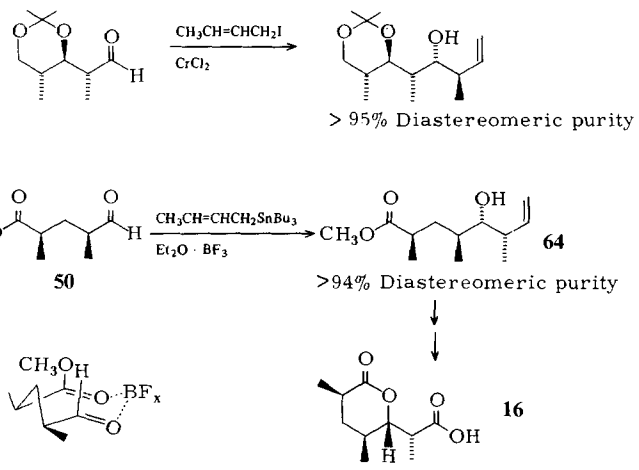


Scheme 10. The configuration of the second newly formed chiral center is not considered.

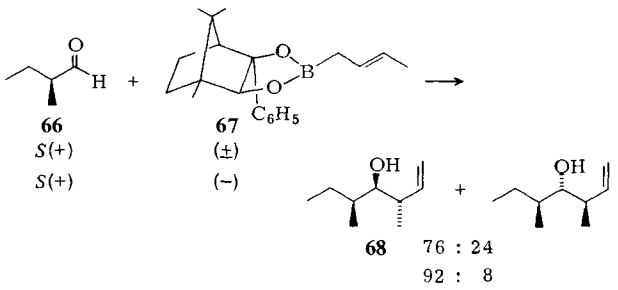
The chiral center in the α-position of the aldehyde causes a 1,2-asymmetric induction. As a result, the two diastereomers are formed in different yields. Of course, reactions leading in high selectivity to only one diastereomer are desirable. The extent of 1,2-asymmetric induction in the addition to α-chiral carbonyl compounds has been examined, in particular, by *Cram et al.*[100]. According to Cram's rules the isomer **62** should be formed preferentially. Compounds **62** and **63** are, therefore, also designated as Cram and *anti*-Cram products, respectively.

The Cram/*anti*-Cram selectivity problem is of course relevant to the addition of crotyl- and allylmetal compounds to α-chiral aldehydes. Examples of surprisingly high diastereoselectivity are found in the syntheses of rifamycin by *Kishi et al.*[89] and the Prelog-Djerassi lactone **16** by *Maruyama et al.*[117].

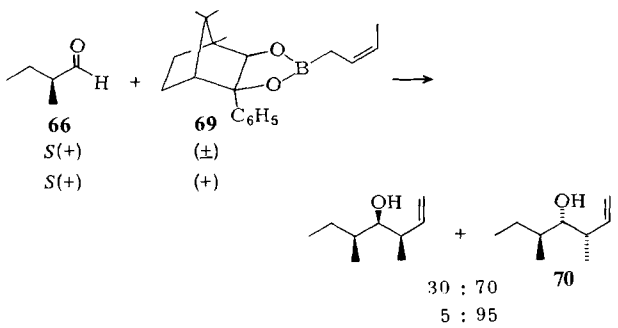
In the last example, the preferred attack at the *re*-side of the aldehyde **50** forming **64** is probably due to complexation (cf. **65**). Unfortunately, the Cram/*anti*-Cram selectivities are often only in the range 2—5 : 1 in the addition of crotylmetal compounds[54-56,69,81,104] and substituted allylmetal compounds[101,102] to α-chiral aldehydes. The reason is that the asymmetric induction is due to only one of the



reaction partners, namely the aldehyde. A higher degree of selectivity is attainable when the two faces of the crotylmetal compounds are made diastereotopic as well. This is possible *e.g.* through a chiral modification of the reagent **26** to give **67**.



A proper combination of the chiralities of aldehyde (+)-**66** and reagent (−)-**67** results in a mutual reinforcement of the individual stereodifferentiations; this "double stereodifferentiation"[6] has proved of value in the aldol addition[8,9,22,103], and could thus be used to improve the selectivity to 92 : 8 in favor of the diastereomer **68**[69]. For comparison, the addition of *rac*-**67** to (+)-**66** gives a selectivity of 76 : 24, because this reaction is only subject to single stereodifferentiation from the aldehyde. Surprisingly, the *anti*-Cram isomer **70** predominated in the addition of the *Z*-crotylboronic acid ester *rac*-**69** to the aldehyde (+)-**66**. In this case, (+)-**69** has the "correct" chirality to increase the selectivity in favor of **70** through double stereodifferentiation.



Similarly, the reaction of **50** with (+)-**69** occurs with a diastereoselectivity of ≥81 : ≤19 thanks to the double

stereodifferentiation[69]. The Prelog-Djerassi lactone **16** was easily obtained from the adduct, although in this case the stereoselectivity was not as high as in the addition of chiral enolates[10,22] to **50**.

6. Conclusion

When an *anti*-adduct such as **13** is desired, of the many possibilities for diastereoselective addition of crotyl residues to aldehydes, the reaction of the *monohapto*-chromium **53** or -titanium compounds **56**—**60** should be the method of choice. In order to obtain the other diastereomer **15**, the use of the crotyltin compound **46** or the *Z*-crotylboronic acid ester **25** is the most advantageous. If alkyl groups other than methyl are desired as appendages at the new CC bond, the requisite tributylstannyl or the chromium(II) derivatives are probably most readily prepared. The diastereoselective positioning of heteroatoms, *e.g.* oxygen, sulfur, or silicon at the branching point, is particularly well achieved using allylboronic acid esters.

It is clear, therefore, that crotylmetal compounds such as **12** or **14** are equal or even superior to the enolate reagents **9** (Scheme 1) with respect to both structural variety and diastereoselectivity in addition reactions to aldehydes (Scheme 2). Another advantage is the high chemoselectivity of the allylboronic acid esters and the allylchromium reagents[54,55], both of which react selectively at the aldehyde function of a ketoaldehyde (cf. **7**→**8**). The chemoselectivity of allylsilicon[66], allyltin[65], and *trihapto*-crotyltitanium[34] reagents is less pronounced, since these react with aldehydes and ketones under comparable conditions. Allylboronic acid esters are also the reagents of choice for asymmetric induction through chiral modification[15,16,69]. However, these have not yet reached the standard set by the enolate reagents using chirally modified enolborinates[8-10].

The work described here originating from our own group is due, in particular, to the initiative and persistence of Dr. H.-J. Zeiß, W. Ladner, and Dr. B. Kemper to whom I express my thanks. Thanks are also due to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for continued support.

Basic Principles of the CIP-System and Proposals for a Revision

By Vladimir Prelog* and Günter Helmchen

Dedicated to the memory of Robert Sidney Cahn (June 9, 1899—September 15, 1981) and of Sir Christopher (Kelk) Ingold (October 28, 1893—December 8, 1970)

"From Configurational Notation of Stereoisomers to the Conceptual Basis of Stereochemistry" is the title of a lecture [V. Prelog, ACS Symp. Ser. No. 12 (1975) 179] in which the chronologically and alphabetically third member of the CIP-triumvirate discusses the history of the CIP-system. The experience accumulated in the meantime, particularly the efforts to teach computers to use the system as described in 1966 by Cahn, Ingold and Prelog, has shown that certain of its aspects must be more strictly formulated and others modified. Questions dealing with stereoisomers (and stereotopicity), which previously have been treated predominantly in a pragmatic manner, are now discussed in a systematic way.

1. Introduction

The last publication in this journal on this topic appeared in 1966[1]. Although in general the CIP-(*Cahn-Ingold-Prelog*) system has served its purpose well, even for special cases not taken into account sixteen years ago, accumulated experience has since shown that there is a need for revision, or at any rate for a more precise formulation of some of its aspects. Contributory to such experience have been our own work, discussions with other colleagues active in this field, and the work of *Meyer* and *Custer*[4] on adaptation of the CIP-system to computer use. Apart from its contribution to the field of stereoisomerism, the CIP-system has come to serve as the basis for the specification of stereotopicity[5,6] to which it has bequeathed its own shortcomings. This and other aspects unforeseen sixteen years ago have made it necessary now to deal in a systematic way with questions which earlier had been answered on a pragmatic basis only.

One serious constraint is necessary in any kind of revision of the CIP rules: previously assigned descriptors should remain unchanged as far as at all possible and should be altered only for compelling reasons, or in problematic cases to which the system has not yet been applied. To this we would add a second limitation: the need for self-restraint in introducing yet more to the already existing surfeit of new stereochemical terms, many of which could well be replaced by established concepts of elementary geometry. We feel that, particularly for educational reasons, economy in coining new terms should be the order of the day.

[*] Prof. Dr. V. Prelog

Before going into detail concerning our proposals for revision we would like to reiterate the basic tenets of the CIP-system in order to demonstrate its logical construction and self-consistency, notwithstanding the arbitrary nature (mainly for historical reasons) of some of its conventions. We feel that this is necessary in view of certain, in our view, unjustified criticisms[7,8].

2. Basic Principles of the CIP-System

2.1. Stereomodels

One of the important aims of static stereochemistry is the specification of the geometry and topography of stereoisomers[9]. We define stereoisomers as different molecular species of equal constitution (same atomic makeup and atomic bonding), which are separated by intervening energy barriers[11]. Since for the purpose of the specification of stereoisomers the order of magnitude of these barriers and the physical nature of the bonding, as well as time-dependent properties are immaterial, we assign to molecules rigid stereomodels; geometrical figures, which should contain only the information necessary for that purpose.

The model which is our point of departure is a rigid framework of fixed points connected by straight lines. The points define the spatial arrangement of the atomic nuclei and the lines the chemical bonds.

2.2. Chiral, Helical, and Tripodal Four-Point Figures and their Chirality Sense

For the description of stereomodels one can advantageously use internal ("chemical") coordinates, bond lengths, and bond and torsion angles, since they are invariant towards translation and rotation of the model as a

 © *Verlag Chemie GmbH, 6940 Weinheim, 1982* *0570-0833/82/0808-0567 $ 02.50/0*

whole. Models of nonplanar stereoisomers contain at least one chiral arrangement of four distinguishable points (a chiral three-dimensional simplex) of which two enantiomorphic versions are possible. Since enantiomorphic[13] arrangements are not defined by the absolute values of internal coordinates they have to be specified[15].

As *Möbius*[18] already showed in 1827, this can be expressed by the algebraic sign of the volume of the corresponding chiral tetrahedron as calculated from the coordinates of its specified vertices in a given Cartesian coordinate system[19]. There are, of course, many other equivalent procedures for specification of a chiral four-point figure by an algebraic sign. If we start with internal coordinates it is convenient to use instead of Cartesian coordinates of four points the three bond vectors $\vec{x}$, $\vec{y}$, $\vec{z}$ connecting them. If the bond vectors $\vec{x}$, $\vec{y}$, $\vec{z}$ constitute a right-handed system, then the algebraic sign of the volume of the corresponding tetrahedron in a right-handed Cartesian coordinate system is positive: if they constitute a left-handed system it is negative.

In principle, there are two possible arrangements of three bonds connecting four points: helical and tripodal (Fig. 1). In the helical arrangement the sequence of points

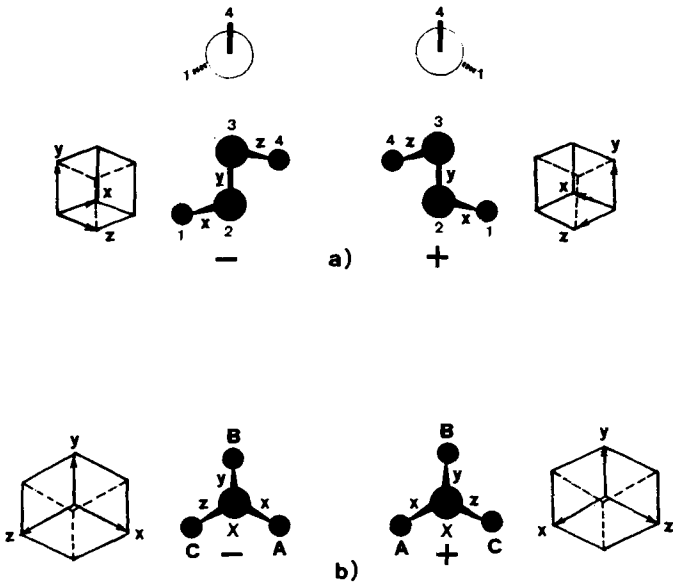

Fig. 1. Fundamental three-dimensional chiral figures (simplices): a) Helical arrangements of four points, their bond vectors and torsion angles. b) Tripodal arrangements of four points and their bond vectors.

can be deduced from the direction of bond vectors as defined by their topological sequence ($1>2>3>4$ or $4>3>2>1$). The bond vector directions are then $\vec{x}=\overrightarrow{12}$, $\vec{y}=\overrightarrow{23}$, $\vec{z}=\overrightarrow{34}$. In the tripodal arrangement the sequence of three topologically equivalent points A, B, and C and the bond vector directions must be defined by a non-topological criterion *i.e.* by conventional rules, for example $A>B>C$ and $\vec{x}=\overrightarrow{XA}$, $\vec{y}=\overrightarrow{XB}$, $\vec{z}=\overrightarrow{XC}$.

In chemistry instead of algebraic signs, expressions such as "right" and "left" or synonymous words and descriptors are used: these, as well as the algebraic signs, signify the *chirality sense* of that arrangement, a useful concept when dealing with stereoisomorphism and stereoisomerism. The chirality sense is unaffected by deformations of the stereomodel; it remains the same provided that the four points do not move into a plane. It is synonymous with the classical concept of "absolute configuration" and at the same time is better defined. Finally, the concept of chirality sense enables one to deal with both tripodal and helical structures within the same general framework. We would like to point out that the distinction between helical and tripodal arrays of four points can serve, according to *Gerlach*[20], as the basis for a rational definition of frequently used concepts, such as conformation and configuration, for which no generally accepted definitions exist[21]. Structures and stereomodels which differ in their tripodal arrangements have different configurations, those which differ in their helical arrangements are of different conformation.

2.3. Two-Dimensional Chirality, Heterotopy

It is possible to apply the concepts of chirality and chirality sense to spaces whose dimension is either less or more than three. In fact, discussion of two-dimensional chirality can lead to a better understanding of three-dimensional stereoisomerism.

The internal coordinates of a planar stereomodel are bond lengths and bond angles. The simplex of two-dimensional space is a three-point figure, the triangle. When this has three distinguishable vertices, it is two-dimensionally chiral, just as the tetrahedron with four distinguishable vertices is three-dimensionally chiral.

The simplest stereomodel containing a two-dimensional chiral triangle is the bipodal arrangement of three atom points (Fig. 2), from which the two topologically equiv-

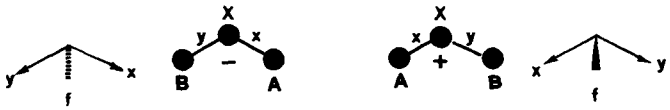

Fig. 2. Two-dimensionally chiral simplex: dipodal arrangements of three points, and their bond vectors.

alent arrangements, A and B, have to be differentiated by conventional rules. In two-dimensional space such an arrangement can exist in two enantiomorphic non-congruent versions which, however, become congruent in three-dimensional space by rotation. Their enantiomorphism is due to the fact that in two-dimensional space they are "orientated". In three-dimensional space their two-dimensional chirality is manifested by the fact that a chiral triangle has two distinguishable faces[22].

In an analogous way to three-dimensional tripodal arrangements it is possible to specify two-dimensional enantiomorphic models or the faces of chiral triangles by the algebraic sign of the area calculated from the Cartesian coordinates of their vertices, or through the algebraic sign of the vector product $\vec{f}=\vec{y}\times\vec{x}$ of the two bond vectors $\vec{x}$ and $\vec{y}$ (Fig. 2).

The plane which contains a two-dimensional chiral simplex divides the three-dimensional space into two distin-

guishable half-spaces, which can be specified by the algebraic sign (or by a corresponding descriptor) of the adjacent face of the chiral triangle. Atoms, ligands, and other objects which are located within such distinguishable half-spaces have been termed heterotopic by *Mislow* and *Raban*[23].

2.4. Factorization of Complex Stereomodels into Stereogenic Units

Non-planar stereomodels with chiral regions containing more than four connected points can be factorized into four-point regions which can be either tripodal or helical. However, factorization down to regions of four directly connected points is performed only in the case of helical arrangements. For historical and practical reasons, stereomodels which contain three-dimensionally chiral tripodal as well as two-dimensionally chiral dipodal regions are subdivided into units containing more than four or three atoms, respectively, which following a suggestion by *McCasland*[24] we term "stereogenic units". It is essential for such a unit to be composed of an achiral core (atom or a skeleton of atoms) with distinguishable ligands, whose constitution-preserving interchange leads to a stereomorphic figure.

2.5. Chirality Elements: Stereogenic Units of the CIP-System

In this paper we wish to restrict ourselves to proposals for revision of the CIP-system concerning stereoisomers with atoms having no more than four ligands. However, subject to appropriate modification, these proposals will also be found applicable to an eventual revision of the rules specifying stereoisomers containing atoms of higher ligancy.

For stereomodels of molecules with at most tetraligant atoms, three types of tetrahedral stereogenic units (three chirality elements) are used in the CIP-system: the chirality center, the chirality plane, the chirality axis, and the analogous pseudoasymmetric units. These we shall discuss and analyze as far as the stage of elementary tripodal and helical regions. Apart from these we shall also consider as stereogenic units planar diastereomorphic arrangements of four ligands of planar tetraligant atoms or double bonds which are commonly described as *cis,trans*-isomers[25].

2.5.1. Chirality Center: The Tetrahedral "Asymmetric Atom"

Among three-dimensional stereomodels with more than four points we shall first discuss the five-point figure shown in Figure 3. This is in fact the model for tetrahedral atoms with four distinguishable ligands, which are of overriding importance in organic stereochemistry. A five-point figure of this type can be converted in four different ways into tripodal four-point figures by omission of one conventionally chosen ligand atom point and its bonds. The chirality sense of each of the four-point figures thus obtained would define unambiguously that of the five-point figure. There is, however, a fifth possibility of mapping such a

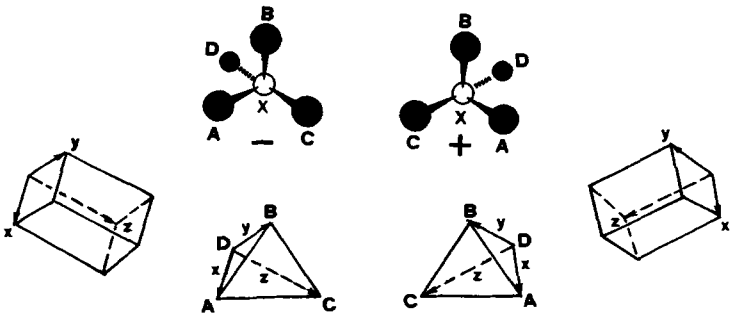

Fig. 3. Chirality center: enantiomorphic tetrahedral "asymmetric" atoms, corresponding T_d-tetrahedra, and their bond vectors.

five-point figure onto a homomorphic complementary four-point simplex. In this, the topologically unique central atom point and its four bonds are omitted, and the remaining four points are placed at the vertices of a regular tetrahedron with point symmetry T_d[26]. The resulting four-point model, unambiguously derived from the original five-point model, is in fact the "asymmetric atom" of *Le Bel* and *van't Hoff*, and at the same time the "chirality center" of the CIP-system.

By such a conversion of a chiral five-point figure into a four-point stereogenic center, considerable simplification of the specification process is achieved. Moreover, the concept of the "asymmetric atom" is so deeply rooted in the mind of the organic chemist that a specification system based on more fundamental tripodal four-point units would have had little chance of acceptance.

In the CIP-system, even a chiral tripodal triligant atom is converted into a tetrahedral one by adding a "phantom" atom. If the directions of the bond vectors are determined in the conventional manner, then the algebraic signs specifying corresponding tripodal and tetrahedral systems are the same. Such a conversion has the advantage of making it possible to specify the chirality sense of both tripodal four-point models of triligant atoms and of tetrahedral five-point models of tetraligant atoms in an analogous manner.

2.5.2. Chirality Plane and Chirality Axis: Their Specification Based on Preferred Helical Regions

To specify the chirality of certain stereoisomers which do not possess centers of chirality (stereoisomeric allenes, atropisomeric biphenyls and *ansa*-compounds) two additional stereogenic units were introduced in 1956: chirality planes and chirality axes.

Figure 4 shows two enantiomorphic five-point figures which are fundamental for representing a chirality plane. In each there is a planar two-dimensionally chiral trigonal atom X, with its proximal atoms or ligands A, B, Y and an additional atom Z connected to Y and lying outside the ABY plane (chirality plane). Such figures can be mapped unambiguously onto four-point simplices. As pointed out in 1972[6] one can omit the planar trigonal atom X and its three bonds and then connect the remaining four atom-points with straight lines. This will lead to the formation of a tetrahedral model of point symmetry C_s with two topologically equivalent vertices which have to be differentiated by conventional rules in order to obtain a tetrahe-

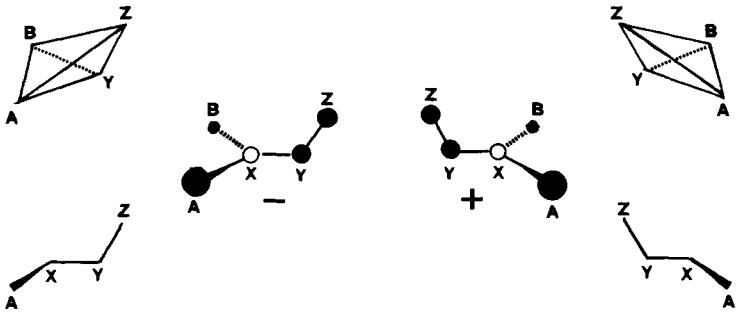

Fig. 4. Chirality plane: enantiomorphic five-point figures, corresponding C_s-tetrahedra, and preferred torsion angles A—X—Y—Z.

dral stereogenic unit, which is then specified in the usual way.

In an analogous manner Figure 5 shows the enantiomorphic figures needed to represent a chirality axis: two nonplanar combinations of planar-trigonal atoms Z_1 and Z_2 with their respective proximal ligating atoms. Such a six-point figure can likewise be mapped unambiguously onto a four-point simplex, a tetrahedron with point symmetry D_{2d}, by omitting atoms Z_1 and Z_2 and their bonds followed by interconnecting the remaining four ligand atom points by straight lines. If the ligand atoms occupying the topologically equivalent positions are distinguishable, the resulting figures are representations of tetrahedral stereogenic units, which again can be specified by an algebraic sign in the same way as the other two chirality elements. The line of intersection of the two planes of the trigonal atoms constitutes an axis, hence this stereogenic unit was termed "chirality axis".

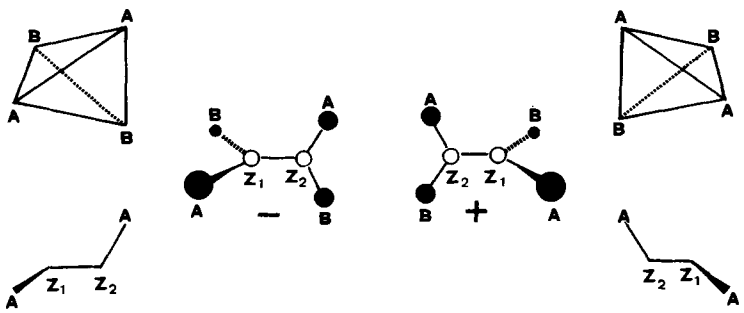

Fig. 5. Chirality axis: enantiomorphic six-point figures, corresponding D_{2d}-tetrahedra, and preferred torsion angles A—Z_1—Z_2—A.

It had previously been recognized[1] that planes and axes of chirality can also be specified by the algebraic sign (or the corresponding descriptor) of the torsion angle of a helical array of four atoms chosen by a conventional rule. We now suggest that this simple and unambiguous method should be applied generally in place of the less convenient specification procedures based on tetrahedral simplices. For chirality planes the preferred sequence of atoms is A—X—Y—Z (Fig. 4), and for chirality axes A—Z_1—Z_2—A (Fig. 5), as already proposed previously. Since stereoisomers with chirality planes and chirality axes are in fact atropisomeric conformers, their specification *via* the algebraic sign of a preferred torsion angle is particularly appropriate (cf. [17]).

Between points X and Y in a chirality plane and points Z_1 and Z_2 in a chirality axis it is possible to insert various linear atom-sequences (*e.g.*, =C=, —C≡C—) which thus do not influence the specification process. An example of practical significance is that of the chiral allenes containing the linear grouping =C=.

The fact that there are molecules with several chirality planes or axes has been mentioned previously[1]. If such stereogenic units are interdependent, then of the possible unambiguous specifications the one chosen should be in accord with *Einstein*'s advice: "Keep it as simple as possible but not simpler than that". A multitude of redundant descriptors[28] will only confuse rather than elucidate. In case of doubt one should clarify the affiliation of a descriptor by giving the systematic numbering of an appropriate atom, as is customary for differentiating several chirality centers or double bonds; and this atom should advantageously be that among those termed Z_1, Z_2 or X or Y, with the lower systematic number.

Among stereomodels with more than six atoms we should briefly mention a seven-point figure comprising a planar trigonal and a tetrahedral atom (Fig. 6). This can be

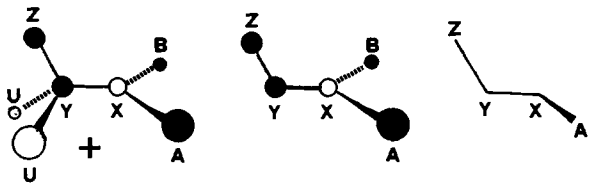

Fig. 6. A seven-point figure, the corresponding chirality plane, and the preferred torsion angle.

unambiguously mapped onto the five-point figure shown in Figure 4, by the choice of one of three topologically equivalent ligands of atom Y or, in other words, it can be treated as a plane of chirality. The choice of the ligand has to be made in accord with criteria derived from the specification of conformations[17].

2.5.3. *"Pseudoasymmetric" Stereogenic Units*

The concept of the stereogenic unit comprises not only the elements of chirality mentioned so far, but also the analogous elements of pseudoasymmetry: pseudoasymmetric centers, planes, and axes. These always exhibit two ligands which differ only in their topography, *i.e.* which are enantiomorphic. In a tetrahedral stereogenic unit such ligands are situated within heterotopic half-spaces; the chirality sense of such enantiomorphic ligands and of the half-spaces can be combined in two geometrically different ways [(+ +, − −) or (+ −, − +)]. This leads to two geometrically different models and to two diastereomers.

Formally, such stereoisomers can be specified analogously to those comprising chirality elements with four

distinguishable ligands. In contrast to the algebraic sign (or corresponding descriptor) of a chirality element, the algebraic sign of a pseudoasymmetric unit obtained in this way is reflection invariant, because diastereoisomerism is based on a geometrical property. Upon reflection, the chirality sense of both enantiomorphic ligands and their halfspaces are reversed; the two inversions cancel each other out.

2.5.4. *The Two-Dimensionally Chiral Triligant Atom. Two-Dimensional Diastereomorphism: "Geometrical" Isomerism*

A planar four-point figure (Fig. 7a), representing the model of a triligant central atom with three distinguishable ligands, can be unambiguously mapped onto a regular triangle in which the central atom and its three bonds have been omitted. This gives the model of the planar "two-dimensional asymmetric atom", analogous to the tetrahedral "asymmetric atom". Previously we showed how one can change the model of a tripodal array into a tetrahedral stereomodel by adding a "phantom" atom: in the same way a bipodal array can be transformed into a trigonal "two-dimensional asymmetric" atom.

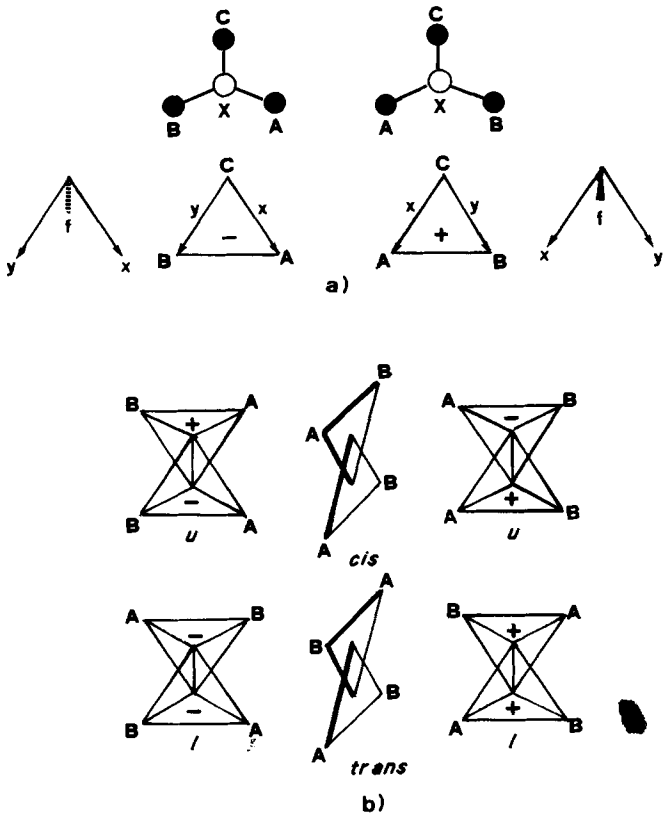

Fig. 7. a) Two-dimensionally enantiomorphic trigonal "atoms" and their bond vectors. b) Two planar diastereomorphic six-point figures composed of two trigonal two-dimensionally chiral atoms; *cis-trans* isomerism.

As indicated in Section 2.3, enantiomorphic "two-dimensional asymmetric atoms" are congruent in three-dimensional space but non-congruent in the plane because of their different "orientations". From two such orientated "two-dimensional asymmetric" atoms two pairs of planar figures can be constructed: one from two differently and one from two equally orientated atoms. Two pairs are diastereomorphic not only in two-dimensional but also in three-dimensional space (Fig. 7b). They are interconvertible by a constitution-preserving interchange of two ligands. A planar combination of two two-dimensional chiral simplices thus represents a stereogenic unit by definition. The two diastereomorphic figures just mentioned are models of *cis-trans* isomers containing planar tetraligant atoms or double bonds.

2.6. Differentiation of Ligands

To establish the chirality sense of a stereogenic unit it is necessary to determine the rank of its ligands by comparing their properties. Since ligands can differ in several types of properties and the rank of ligands must be determined by a single property, this requires a clear-cut hierarchy of relevant properties and an unambiguous prescription for the order in which they are compared. Moreover, the comparison must be performed in a finite number of steps[8].

The properties used in the CIP-system for differentiation of ligands (see Scheme 1) can be divided into material and structural. Material properties are atomic number and (with isotopes) mass number, whereas structural properties include those based on topology (connectedness), geometry, or topography (cf. Section 2.1[9]). Material and topological differences, which in organic chemical usage are termed constitutional differences, are considered first, followed by geometrical differences (either two- or three-dimensional ligand diastereomorphism); topographical differences (ligand enantiomorphism) are treated last. The relative status of the three types of properties is apparent from the sequence (top to bottom) shown in Scheme 1.

constitutional (material and topological)	reflection-invariant
geometrical (diastereomorphic)	
topographical (enantiomorphic)	reflection-variant

Scheme 1. Hierarchical order of ligand properties.

It is essential to examine the relevant properties of ligands in the hierarchical sequence outlined—exhaustively for each type—before proceeding to the next lower rank. This can be formulated also in the following way: equality with respect to a certain type implies equality relative to that of the higher but not lower rank. For example, geometrically equivalent ligands must be equivalent topologically but can be different topographically. The importance of

the precept was recognized only after 1966; nonetheless the Sequence Rules[1] as originally formulated did already follow the correct hierarchical order, a fact that was due to pragmatic recognition of the consequences of not following such an order in a number of cases (see examples *(21)—(23)* in [1]). In spite of this, several cases have since been found where the CIP-system appeared to fail because geometrical and topographic properties had not been properly kept apart. In fact, differentiation is always feasible so long as one keeps in mind that differences in topography are based on the reflection-variant enantiomorphism of two ligands, *i.e.* on their chirality sense, whereas all other properties, geometrical and constitutional, are reflection-invariant. Here it is advisable to point out that a relevant property of a particular ligand used for specification must not be based on its relationship to the stereogenic unit to be specified. This caveat has been discussed in [1] with special reference to the configuration of the inositols. Finally it should be pointed out that two ligands which are ordinarily equivalent but heterotopic, and thus chemically and physically distinguishable, are of the same rank order: their heterotopy alone is not a sufficient distinction criterion for determining their order of precedence.

3. Hierarchical Digraphs

So far we have consistently used the term ligand, without defining it. Its meaning is quite clear in the case of monodentate ligands. On the other hand, for polydentate and cyclic "ligands", especially as parts of polycyclic structures, the term appears to lose its clear connotation. This can be rectified by converting the polydentate and cyclic ligands into equivalent acyclic structures: their hierarchical digraphs.

The hierarchical digraph of the whole stereogenic unit is a directed chromatic acyclic graph, a "tree-graph" representing the connectedness (topology) and make-up of atoms: its edges, originating from the root of the tree-graph—the core of the stereogenic unit—point towards the branch ends.

3.1. Hierarchical Digraphs of Acyclic Molecules

The non-directed graph of an acyclic molecule is obtained from its constitutional formula by addition of duplicate and phantom atoms. The digraph of a stereogenic unit within this molecule is then obtained by assigning directions to the edges, starting from the core and pointing towards the branch ends (Fig. 8). Frequently it is not only sufficient but also advantageous, especially with larger molecules, to use simplified instead of complete hierarchical digraphs. In these simplified versions the nonrelevant hydrogen and phantom atoms are omitted and carbon atoms replaced by their systematic numbering. In developing such a graph one need only proceed to the extent of determining the rank order of all ligands. The spatial arrangement of the proximal atoms of the core of the tetrahedral stereogenic unit is shown advantageously in such simplified digraphs by using Fischer projections.

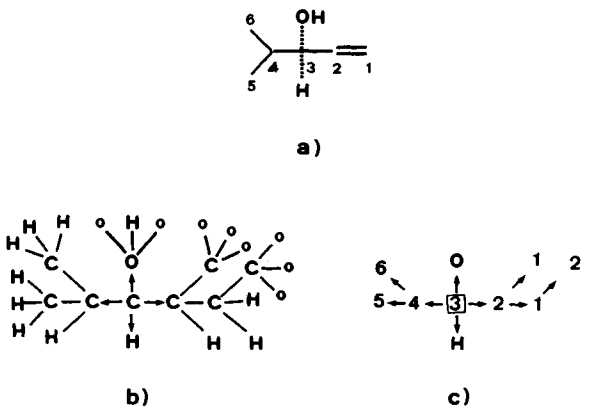

Fig. 8. a) A constitutional formula in which the configuration of stereogenic atom C-3 is represented by Fischer projection. b) Complete hierarchical digraph of a. c) Simplified hierarchical digraph of a.

In the case of an acyclic molecule containing several stereogenic units the hierarchical digraphs of all these units are derived from one and the same non-directed molecular graph (Fig. 9).

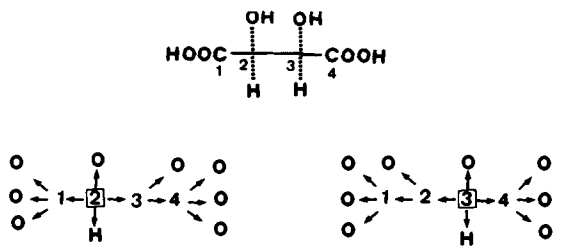

Fig. 9. An acyclic molecule: derivation of the hierarchical digraphs of both stereogenic atoms C-2 and C-3 from the same molecular non-directed graph.

3.2. Hierarchical Digraphs of Cyclic Molecules

In order to transform the constitutional formula of a cyclic molecule into an acyclic "tree-graph" all rings have to be opened in such a way that the resulting acyclic graph contains all the necessary but no redundant information. This procedure has so far not been properly described, and we shall do so in the following sections.

3.2.1. Stereogenic Units with Polydentate Ligands

In order to obtain the acyclic digraph of a stereogenic unit the n-dentate ligand is transformed into n monodentate ligands, by leaving intact in each case one bond with the core and breaking the remaining n − 1 bonds. At each end of n branches thus obtained a duplicate atom of the core is attached (as in the case of broken multiple bonds) (Fig. 10).

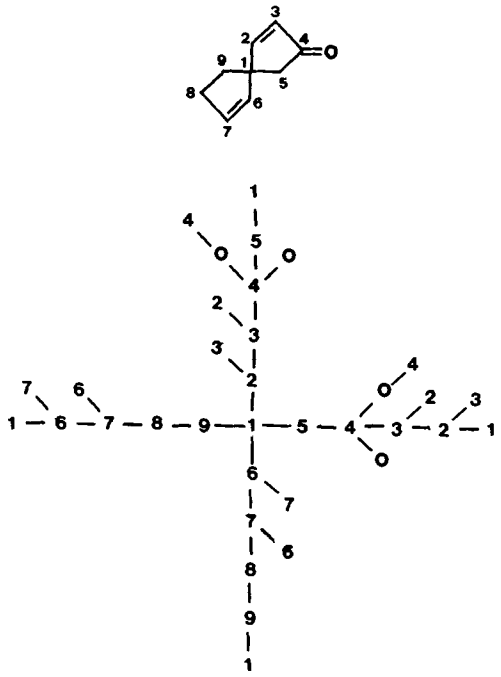

Fig. 10. Hierarchical digraph of a stereogenic atom with two bidentate ligands.

3.2.2. *Stereogenic Units with Ligands Containing Rings*

In ligands of a stereogenic unit containing rings these are opened twice after the first ring atom encountered from the core: one bond remains intact and the other is broken; a duplicate of the first encountered ring-atom is attached at the end of the two branches thus obtained (Fig. 11). If the first-encountered ring atom of the ligand turns

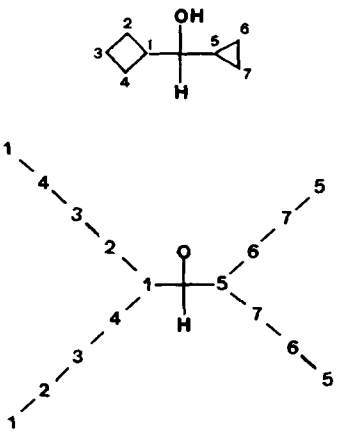

Fig. 11. Hierarchical digraph of a stereogenic atom with two cyclic (three- and four-membered) ligands.

out to be the quaternary common atom of a bicyclic system, one of the three ring bonds is kept intact and the other two are broken. Three branches of the tree graph, which are provided at their ends with requisite duplicate atoms, are therefore produced (Fig. 12).

A characteristic difference between hierarchical digraphs of stereogenic units in acyclic and cyclic molecules is that in the former the non-directed graph is the same, as

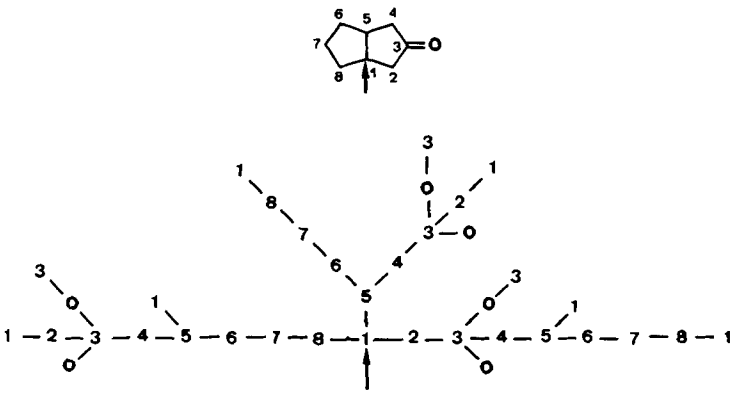

Fig. 12. Hierarchical digraph of a ligand which includes branching due to a bicyclic ring system.

mentioned previously, whereas the digraph of the latter may be derived from the same or from a different non-directed graph, depending on the position of the stereogenic units relative to the ring (see Fig. 13).

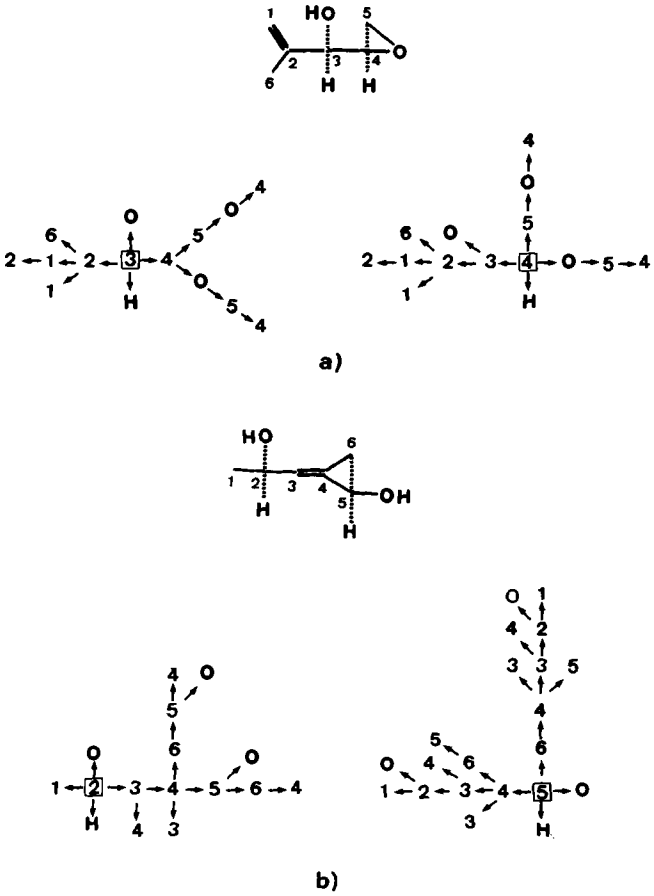

Fig. 13. Hierarchical digraphs of two cyclic molecules with two stereogenic atoms each: a) both digraphs derivable from the same molecular non-directed graph, b) each digraph requiring its own molecular non-directed graph.

3.3. Examination of Hierarchical Digraphs. The Precedence of Atoms as a Result of their Topology

To establish the order of precedence of ligands, their atoms are rearranged in such a way that their rank is ap-

parent both from their topological distance (number of bonds), from the core of the stereogenic unit, as well as from their evaluation by the sequence rules.

Atoms of equal topological distance can be said to lie in the same sphere. Atoms occupying the n-th sphere have precedence over those in the (n + 1)th sphere.

The ranking of each atom within an n-th sphere depends in the first place on the rank of the atom within the (n − 1)th sphere to which it is bonded, and only then on its rank according to the sequence rules. The first sphere is occupied by the proximal atoms p, p′ (Fig. 14). Those in the second sphere are numbered 1,2,3,..., and those in the

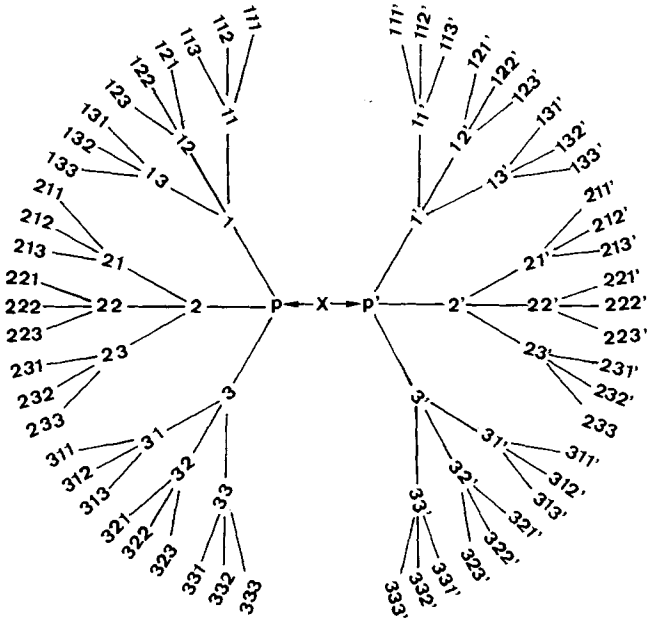

Fig. 14. Rank order of two ligands with proximal atoms p and p′.

third sphere 11, 12, 13, 21, 22, 23 ... *etc.*; the smaller the number, the higher the relative ranking.

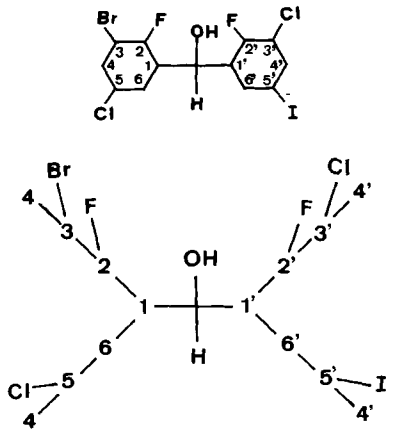

Fig. 15. Illustration of the precept that a branch rank, once determined, has subsequent priority: to determine order of sequence of both cyclohexyl groups the rank order 3-Br > 3′-Cl is used, and not 5′-I > 5-Cl because the former atom-pair is attached to branches of higher rank due to 2-F and 2-F′, respectively.

Those atoms in the n-th sphere which are of equal rank with respect to those in the (n − 1)th sphere to which they are bonded are graded by means of the sequence rules—and these are applied exhaustively in turn: first the entire hierarchical graph is examined by sequence rule 1. If a clear precedence over other ligands can be established, the examination of that particular ligand is concluded. If ligands remain whose rank is not provided by sequence rule 1, then one uses sequence rule 2, once again exhaustively, and so forth. While this procedure is in accordance with precepts published earlier[1] it now makes clear, we hope, that a rank established for a sphere nearer to the core remains valid with respect to atoms in more distant spheres (Fig. 15).

4. Descriptors

In principle, one could specify stereoisomers by the algebraic sign of their stereogenic units as shown in Figures 1 to 5, wherein vector directions are defined as proceeding from points of lower to those of higher precedence.

There are, however, good reasons for using letters (descriptors) instead of algebraic signs for such specification: 1) (+) and (−) have for long been employed to signify the direction of rotation of polarized light of enantiomers, 2) use of these signs does not clearly establish whether they are reflection-variant or -invariant (cf. Section 2.5.4), 3) use of a multitude of algebraic signs is also not conductive to oral or written transmission of information.

Scheme 2 gives a complete summary of descriptors employed in the revised CIP-system, wherein reflection-variant descriptors are marked by capital and -invariant descriptors by lowercase letters.

The descriptors are:

Re,Si[a)b)]; *re,si*[a)b)]; *R,S*; *r,s*[c)]; *P,M*[d)]; *p,m*[e)]. Abbreviations for descriptor pairs: *lk, Lk, l* for like, *ul, Ul, u* for unlike. *ReRe, SiSi=lk*[f)]; *ReSi=ul*[f)]; *reRe, siSi=Lk*[g)]; *reSi, siRe=Ul*[g)]; *RR, SS, MM, PP, RM, SP=l*; *RS, MP, RP, SM=u*.

a) *re, si* have been suggested by *Hanson*[5] for specifying the lateral faces of planar chiral trigonal atoms. No suggestions were put forward for differentiating between reflection-invariant and -variant faces.

b) We have used *Re, Si, re,* and *si*[6] to specify two-dimensional stereogenic units and heterotopic half-spaces; here, reflection-variant units were denoted by *Re, Si,* and -invariant units by *re, si.*

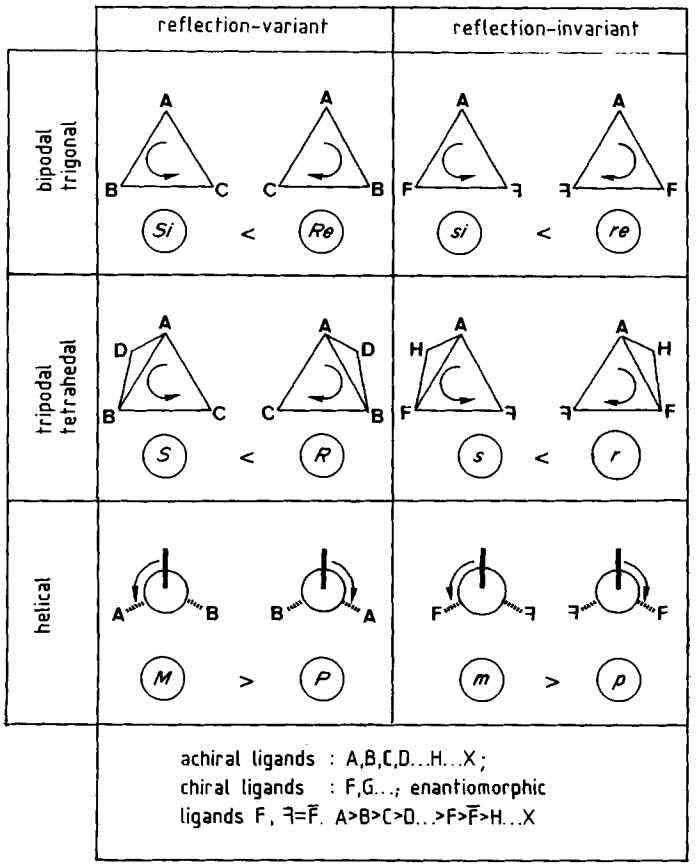
c) *R, S, r,* and *s* were first introduced in [2].

d) *P* and *M* were suggested in [1] and are based on a convention put forward in [17].

e) *p* and *m* are suggested in this paper as symbols for the specification of reflection-invariant "pseudo-asymmetric axes" and "pseudo-asymmetric planes".

f) It might be possible to specify *cis-trans* diastereomers of compounds containing planar tetraligant atoms or double bonds by use of descriptor pairs *ReRe, SiSi=lk* or *ReSi, SiRe=ul,* respectively. However, these offer no advantages over the more graphic *seqcis=Z* or *seqtrans=E* usually employed. On the other hand, the expressions *lk* and *ul* do appear to be particularly suitable

for specifying the steric course of asymmetric syntheses involving reactions between planar triligant atom centers, a suggestion which is dealt with in greater detail elsewhere[29].



Scheme 2. Descriptors of stereogenic units.

g) For the sake of consistency one can use the reflection-variant terms *Lk* and *Ul* for the descriptor pairs *reRe*, *siSi*, and *reSi*, *siRe* for the specification of "geometrically enantiomorphic" stereoisomers (see Section 6.4).

Further to what was said earlier about the convention of vector directions one could equate descriptors *P*, *p* with the algebraic sign +, and *M*, *m* with the sign −. However, for historical reasons *R*, *r*, *Re*, *re* are equivalent to −, and *S*, *s*, *Si*, *si* to +: in 1956 the symbols *R*, *S*, *r*, and *s* were chosen so that most D-sugars and L-amino acids would be allocated descriptors *R* and *S*, respectively.

In cases where stereomodels contain elements of symmetry it may be advisable to subject their descriptors to a test of symmetry consistency. Stereogenic units denoted by reflection-variant terms *R* or *S* can never lie in a symmetry plane. The latter can only accommodate units with reflection-invariant descriptors *r* or *s*. No tetrahedral stereogenic unit should ever coincide with a center of inversion. If the stereomodel contains a plane of symmetry or a center of inversion, every stereogenic unit in that model which can be specified by a reflection-variant descriptor *R* should be accompanied by another enantiomorphic unit specifiable by descriptor *S* and *vice versa*.

A reflection-variant stereogenic atom can conceivably be situated on a two-fold or three-fold axis of rotation. Such relatively rare cases will be discussed, with appropriate examples, in Section 6.3. It is clear that in a stereomodel every n-fold axis of rotation requires at least n stereogenic units having equal descriptors which lie outside this axis.

Here the difference between hierarchical digraphs of cyclic and acyclic molecules should once again be emphasized. With the latter, in which all digraphs are derived from the same nondirected graph, the descriptors of all stereogenic atoms present are definitive—this is not the case with cyclic molecules. Whenever, for the sake of discussion, it is necessary to use such auxiliary descriptors we shall differentiate between these and the definitive descriptors by marking the former with the subscript o.

5. Sequence Rules

5.1. Sequence and Assignment Rules 1966

The Sequence Rules (standard sub-rules) were formulated in 1966 as follows[1]:

(0) Nearer end of axis or side of plane precedes further
(1) Higher atomic number precedes lower
(2) Higher atomic mass number precedes lower
(3) *Seqcis* precedes *seqtrans*
(4) Like pair *R,R* or *S,S* precedes unlike pair *R,S* or *S,R*; and *M,M* or *P,P* precedes *M,P* or *P,M*; and *R,M* or *S,P* precedes *R,P* or *S,M*; and *M,R* or *P,S* precedes *M,S* or *P,R*; also *r* precedes *s*.
(5) *R* precedes *S*; and *M* precedes *P*.

If it is possible to denote the order of precedence of the four ligands a > b > c > d present in a tetrahedral array by application of the Sequence Rules, then stereogenic units are assigned descriptors according to the "chirality rule":

> Among ligands of highest precedence the path of their sequence is followed from the preferred side of the model, that is, the side remote from the group of lowest precedence, and, depending on whether the path turns to right or left, the chirality unit will be assigned the chiral label *R* or *S*, or, if pseudoasymmetric, *r* or *s*.

With a helical array the "helicity rule" applies:

> Depending on whether the identified helix is left- or right-handed, it is designated "minus" and marked *M*, or "plus" and marked *P*.

Although both assignment rules can each be expressed in different ways[30] there is no reason for changing the original versions, which have found their way into elementary textbooks. It might be worth pointing out, however, that they are exchangeable. After having determined the rank

of proximal atoms a>b>c>d, one can determine and specify the stereogenic unit as a right or left helix according to the helicity rule. Alternatively one could construct a tetrahedron from four helically arranged points 1—2—3—4 and specify it according to the chirality rule. Between the descriptors thus obtained the following simple relationships apply: $P \leftrightarrow R$; $M \leftrightarrow S$; $p \leftrightarrow r$; and $m \leftrightarrow s$ (Fig. 16).

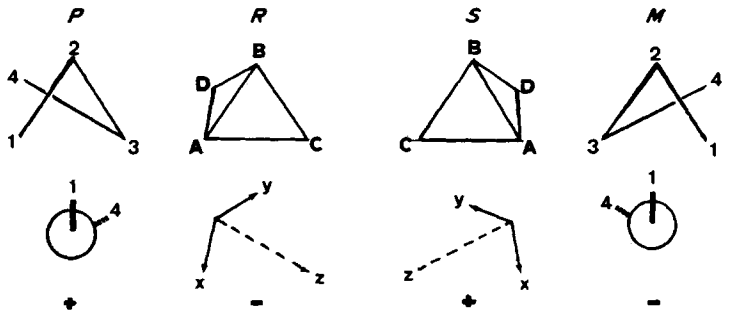


Fig. 16. Equivalent assignments of descriptors by the chirality and by the helicity rule.

5.2. Sequence Rules 1 and 2

In the majority of cases the relative rank of ligands is established on the basis of material differences, *i.e.* by application of rules 1 and 2. These constitute the solid basis on which the CIP system rests and there is no reason for revising them.

5.3. Revision of Sequence Rule 3

In contrast there is a need, in view of more recent developments, for revision of rule 3, dealing as it does with certain of the geometrical differences of ligands. The following will differentiate between ligands which differ in *cis-trans* isomerism due to planar tetraligant atoms or double bonds, and ligands which differ in *cis-trans* isomerism in rings.

5.3.1. cis-trans Isomers Associated with Double Bonds

When two ligands, materially and topologically identical, differ in their geometry at double bonds, rule 3, as applied up till now, has assigned to first encountered double bonds descriptors *seqcis* = *Z* or *seqtrans* = *E*, respectively, followed by establishing precedence through the precept *seqcis* > *seqtrans*. When this rule was put forward, molecules in which assignment of *seqcis* and *seqtrans* is not possible, even though their stereogenic units contain ligands with double bonds differing in *cis-trans* isomerism, were unknown. A simple example is that shown in Figure 17. We therefore suggest the following minor modification of rule 3 in order to specify cases of this type: When two ligands (indistinguishable by rules 1 and 2) differ by one having the atom or the atom-group of the higher rank in a *cis*-position to the core of the stereogenic unit, and the other in a *trans*-position, then the former has precedence over the latter. The original precept in its abbreviated form, *cis* > *trans*, is still valid, but now these terms apply to the location of an atom or atom group of higher rank in relation to the core of a stereogenic unit, rather than to the configuration the double bonds themselves. The way this revised rule applies in the case of Figure 17 is shown by the adjacent hierarchical graph.

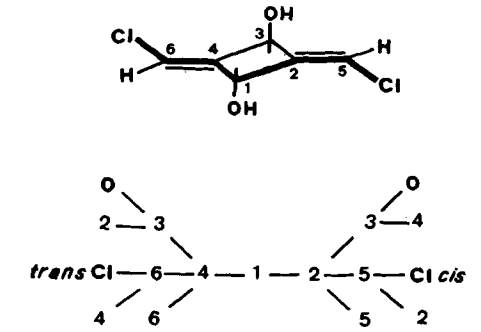

Fig. 17. Stereogenic atoms C-1 and C-3 with geometrically distinguishable unsaturated ligands which cannot be specified using *seqcis* or *seqtrans*, respectively.

Figure 18 should serve to demonstrate that if the modified rule 3 is used in cases where double bonds could be specified alternatively by *seqcis* or *seqtrans*, it would lead

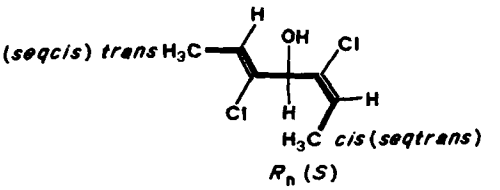

Fig. 18. A stereogenic atom with two geometrically different unsaturated ligands, whose specification by the previous and by the revised rule 3 gives different descriptors (*S* and R_n, respectively).

to a situation in which the previous and the modified rules lead to different descriptors. Hence, even though cases of molecules with stereogenic units whose ligands differ as a result of double bond isomerism are rare[31], and have not hitherto been specified using the CIP-system, we would suggest adding the subscript n (for new) for all descriptors assigned by the modified rule 3.

5.3.2. cis-trans Isomerism in Ring Compounds

Here it is necessary to introduce a substantial change. In principle, *cis-trans* isomerism in ring compounds is three-dimensional diastereomerism. The stereomodels of such diastereoisomers should reveal ligands with at least one pair of three-dimensional stereogenic units specifiable by descriptors such as *R, S etc.* The geometrical differences should be specifiable by either an unlike or like pair of descriptors, respectively. In other words, this type of diastereoisomerism ought to be specified using rule 4 as in the case of analogous acyclic molecules and not rule 3.

Up to now it has frequently been possible to determine the rank of ligands by either rule 3 or rule 4. Any ambiguity had been forestalled by the requirement that each rule had to be applied exhaustively before proceeding to the next one. Nonetheless it seems unreasonable to use two overlapping rules for one and the same type of three-dimensional diastereoisomerism, while at the same time using rule 3 to specify both two- and three-dimensional diastereoisomerism.

Apart from a point of principle there are good practical reasons for modifying rule 3. In the case of multi-membered, polycyclic, or *spiro* ring systems it is often not at all easy to ascertain (even using a computer) which ligands belonging to distant stereogenic atoms are in a *cis*- or a *trans*-position to each other; a point which is especially pertinent when one tries to find an answer to this question on the basis of structural coordinates determined by X-ray analysis.

Unfortunately, and unavoidably, there are cases where descriptors assigned to stereogenic units by the new rule may differ from those established by rule 3 in its original form: to forestall misunderstanding, such descriptors of the "new" type should receive the subscript n.

5.4. Sequence Rule 4

Whereas the actual wording of this rule remains practically unchanged, in view of its applicability to the specification of *cis-trans* isomerism in cyclic molecules its general scope has been considerably extended. Hence it may be necessary to spell out more accurately how one should use it to arrive at an unambiguous specification.

Before applying rule 4 it is useful to derive from the first hierarchical digraph a second one, in which stereogenic centers (or generally units) which had initially been specified using rules 1 to 3 are now replaced by descriptors *R* and *S* (or *M* and *P*) (cf. Fig. 19). One now systematically examines pairs of ligands containing two or more stereogenic units for geometrical differences arising from various alternative combinations of their descriptors. The comparison of such descriptor pairs should proceed in such a way that all relevant but no redundant information is used. This can be achieved by the following procedure based on general CIP principles: Before pairing, the descriptor chosen as first is that highest in rank according to rules 1 to 3. One now forms the descriptor pairs by pairing the one chosen as first in each ligand with one of the (n − 1) remaining descriptors in the order prescribed by the scheme shown in Figure 14. This is then followed by comparing corresponding pairs in both ligands. As soon as a difference is found, rule 4 is used in order to establish the sequence of ligands. The whole procedure is illustrated by examples in Figure 19a—c. In a) the "first" descriptor is the one found in a topologically preferred location, in b) it is the one seen in the highest ranked branch of the hierarchical digraph, and in c) it is the descriptor that occurs twice in the highest ranked triad. The descriptor thus established as first is now paired with other descriptors in the sequence of their order numbers (11, 21, 31, 111, 211 *etc.*), and the descriptor pairs thus formed are in turn evaluated as like (*l*) or unlike (*u*). The first different pair determines the sequence of these ligands.

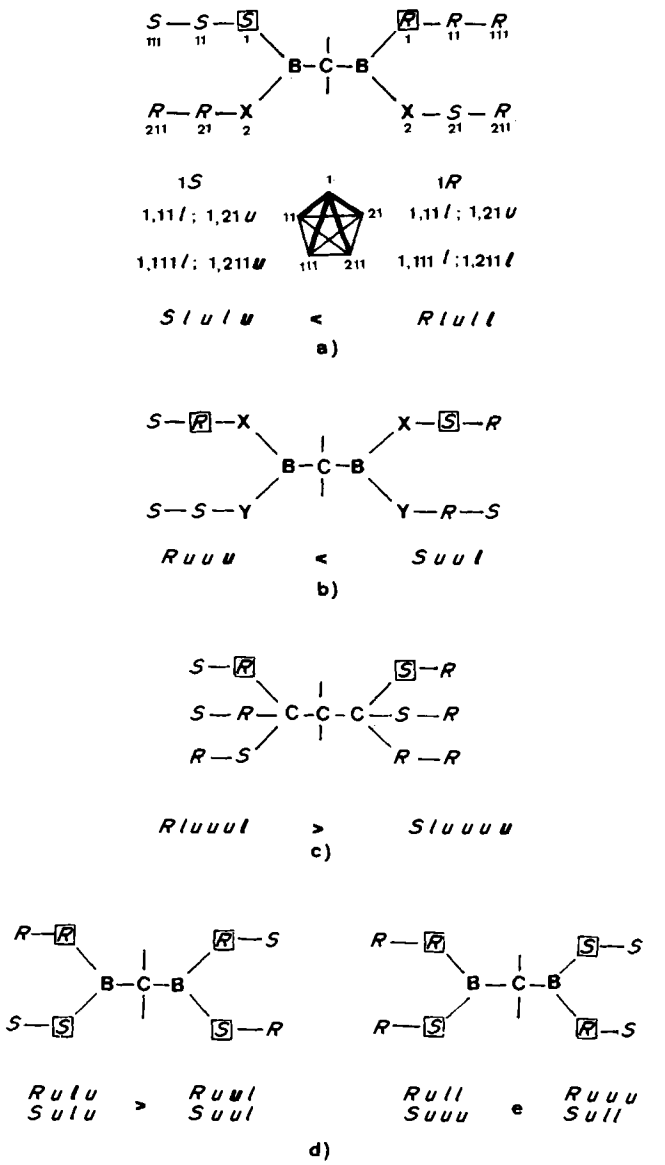

Fig. 19. a) b) c) d) Descriptor assignment in stereogenic atoms whose ligands contain different descriptor pairs.

The rationale of this procedure can be stated as follows: A complete graph whose n vertices represent the descriptors and whose edges represent the n(n − 1)/2 descriptor pairs can be unequivocally mapped onto a spanning tree-graph whose root is the first descriptor. The (n − 1) edges of this spanning tree-graph, shown in Figure 19a as bold lines, contain all the relevant descriptor pairs.

A special case is that of ligands containing enantiomorphic stereogenic units and consequently inverse descriptor pairs in positions of highest rank. Here one forms all relevant descriptor pairs using both the *R*- as well as the *S*-descriptor, after which one compares all pairs situated at the same rank level (Fig. 19d). The highest-ranked difference is then used for establishing sequence. Had only one of the two enantiomorphic ones (*e.g.*, *R*) been used as first de-

scriptor, this would have led to the evaluation of enantiomorphic ligands as geometrically different.

Figure 20 shows the specification of the six stereogenic atoms in (+)-inositol, as an example of sequence determination on the basis of differences between descriptor pairs in a cyclic molecule. The procedure is shown in detail for carbons C-1 and C-2 with the aid of their hierarchical digraphs; the other four atoms can be specified in the same manner. As in the case of acyclic compounds one uses the first-encountered different descriptor pairs in order to evaluate the two branches of the bidentate ligand using rule 4.

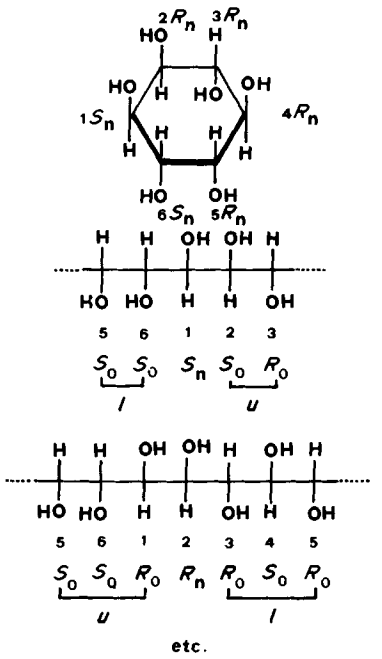

Fig. 20. Descriptor assignment of stereogenic atoms in (+)-inositol.

5.5. Sequence Rule 5

Here, too, the wording of this rule remains unchanged but a few further remarks clarifying its use are necessary.

After having failed to discover any geometrical differences between ligand pairs pertaining to stereogenic units containing descriptors, one proceeds to compare corresponding descriptors in two ligands. If they are inverse, then one uses those of the highest rank for determining sequence.

A pair of enantiomorphic ligands together with two other ligands which are not enantiomorphic together constitute a "pseudoasymmetric" stereogenic unit, which is specified according to rule 5 using reflection-invariant descriptors *r* or *s*.

It should be noted that a stereogenic unit containing two different pairs of enantiomorphic ligands (cf. [32]) is not pseudoasymmetric, but is a chirality element which has to be specified by the reflection-variant descriptors *R* or *S*.

A special case is that of stereogenic units with ligands, whose sole difference is that they contain two different "pseudoasymmetric" stereogenic atoms. The CIP-system recognizes such chirality elements only after all the other stereogenic atoms have been specified by applying rules 1 to 5 (Fig. 21a). The subrule of rule 4, *r* precedes *s*, can thus be applied only after rule 5 has been used to determine descriptors *r* or *s*, respectively. In order to keep to our precept that each rule be employed exhaustively before proceeding to the next one, we suggest that this subrule ($r > s$), even though based on a geometrical difference, become a second part of rule 5.

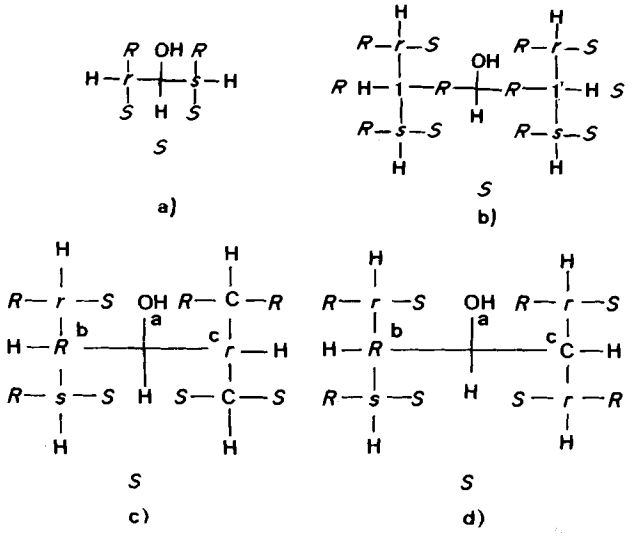

Fig. 21. Graphs with descriptors assigned according to rule 5. The descriptor for the central stereogenic atom in case b) can be assigned only by subsequent reapplication of rule 4 ($l > u$).

It is thus not difficult to envisage structures such as that shown in Figure 21b, in which we meet with the following situation: topological differences engender geometrical differences, which in turn lead to new topological differences. It appears, however, that such compounds have not yet been prepared.

Stereogenic units are conceivable[4b] which contain constitutionally equivalent ligands, differing only in that one of them comprises a chiral and the other a pseudoasymmetric stereogenic unit (Fig. 21c). A ligand with a chiral or pseudoasymmetric stereogenic unit could also be juxtaposed to a constitionally equivalent ligand without the corresponding stereogenic unit (Fig. 21d). In such cases we propose that the chiral stereogenic unit should preceed the pseudoasymmetric one, and the ligands with a chiral or pseudoasymmetric unit should preceed the one without a corresponding stereogenic unit.

5.6. Summary of Revised Sequence Rules

If, as we have recommended, specification of chirality planes and chirality axes is carried out on the basis of preferred helical domains, rule 0 becomes superfluous. Rules 1 and 2 and their application remain unchanged. Rule 3 should henceforth be restricted to ligands which differ in *cis-trans* isomerism of planar tetraligant atoms or double bonds. It should then read as follows: When two ligands differ only in that one has an atom or atom-group of higher rank in a *cis*-, and the other in a *trans*-position to the core of a stereogenic unit, then preference is given to the former.

Revised rule 4 is as follows: When two ligands have different descriptor pairs, then the one with the first-chosen

like descriptor-pair has priority over one with a corresponding unlike descriptor-pair. Like descriptor-pairs are: *RR, SS, RRe, SSi, ReRe, SiSi, MM,* and *PP,* and also by corollary *RM, SP, ReM,* and *SiP.* Unlike pairs are: *RS, ReSi, SRe, ReSi, MP*; and by corollary *RP, SM, ReP,* and *SiM.* The rule stating that a ligand with descriptor *r* has preference over one with descriptor *s* is used as rule 5b, since it will only be used following rule 5a.

Rule 5a reads exactly as the original rule 5: A ligand with descriptor *R* or *M* has priority over its enantiomorph with descriptor *S* or *P.*

6. Parerga and Paralipomena

In the preceding sections we have endeavoured to describe the revised CIP-system in concise form, and to this end we have used only simple and lucid examples to illustrate our arguments. The purpose of this section is to show that the revised system also lends itself to the treatment of more complicated cases, in particular those which various workers in this field have considered unspecifiable.

6.1. The "Finiteness" of the Specification Process

In 1966[11] a statement, supported by two examples, was published to the effect that examination using the Sequence Rules must be terminated when the specifiable chirality center has been reached. In spite of this *Schubert* and *Ugi* stated in 1979 with reference to the molecule shown in Figure 22[8] that "no matter how many iteration steps are performed it is impossible to put the ligands into order. Here the CIP-Sequence Rule fails". They gave another four examples where, in their view, ligands could not be put in sequence and came to the devastating conclusion that the CIP-system "is fundamentally incapable of ordering ligands".

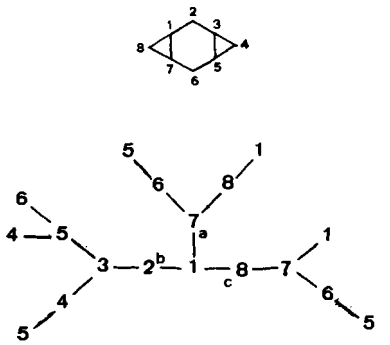

Fig. 22. Hierarchical digraph of C-1 in tricyclo-[5,1,0,$0^{3,5}$]-octane

The hierarchical digraphs of two of the structures used as a negative example (Figs. 22 and 23) demonstrate that this conclusion is completely unwarranted; and the remaining three structures quoted by them can be specified in an analogous manner.

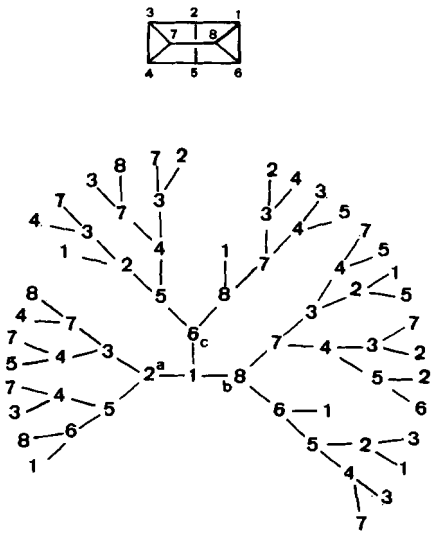

Fig. 23. Hierarchical digraph of C-1 in cuneane.

6.2. Compounds with Hitherto Unspecifiable Stereogenic Atoms

6.2.1. Achiral Cyclic Stereoisomers

A systematic utilization of hierarchical digraphs of cyclic compounds makes it possible to specify "pseudoasymmetric" stereogenic units, which up to now required the use of the *cis-* and *trans*-descriptors. Well-known examples are the stereogenic atoms in 1,3-disubstituted cyclobutanes, in *cis-* and in *trans*-decalin, in all-*cis-* and in all-*trans*-inositols, and in many of their homologues and analogues.

For example, let us consider stereogenic atoms C-1 and C-2 in *cis*-1,3-cyclobutanediol (Fig. 24), which the unre-

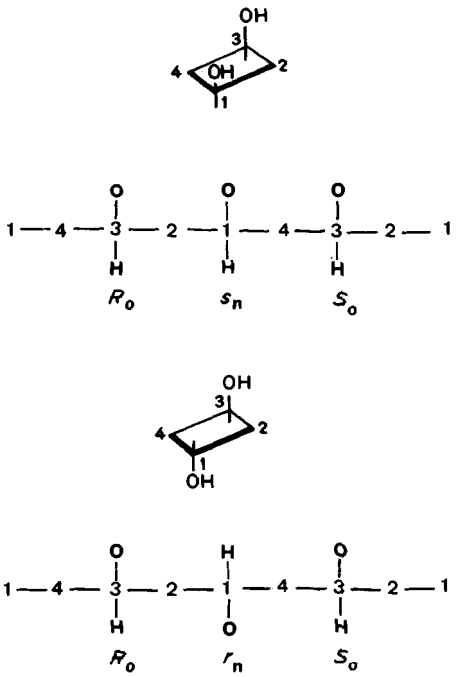

Fig. 24. Hierarchical digraphs of C-1 in diastereomeric cyclobutane-1,3-diols.

vised CIP-system could not specify. In the hierarchical digraph of C-1 we now see that C-3 is a specifiable stereogenic atom in both of the branches corresponding to the ring. In the left branch it is assigned descriptor R_0 and in the right descriptor S_0. Hence C-1 is a pseudoasymmetric

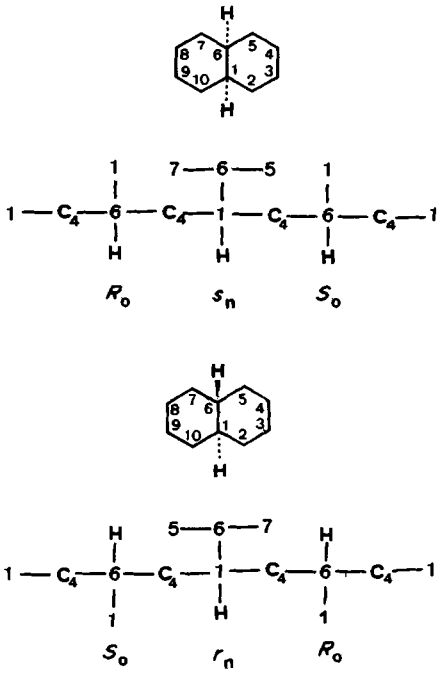

Fig. 25. Hierarchical digraphs of C-1 in diastereomeric decalins.

atom, which by rule 5 is specified by descriptor *s*. The fact that C-3 has different descriptors in each branch demonstrates that this atom is topographically different (enantiomorphic) with respect to C-1. These C-3 descriptors are auxiliaries which do not appear in the final specification. The definitive descriptor of C-3 has to be ascertained by examining its own hierarchical digraph; and this shows that for this atom, too, the descriptor is *s*, in accord with the C_2 point symmetry of the molecule as a whole. By the same procedure one obtains descriptors 1*r*, 3*r* for *trans*-1,3-cyclobutanediol (Fig. 24), 1*s*, 6*s* for *cis*-decalin 1*r*, 6*r* for *trans*-decalin (Fig. 25), and 1*r*, 2*r*, 3*r*, 4*r*, 5*r*, 6*r* for all-*trans*-inositol (Fig. 26).

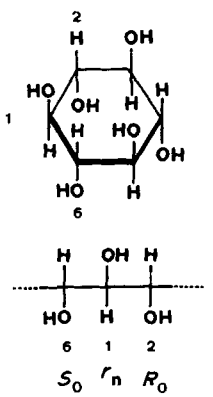

Fig. 26. Hierarchical digraph of C-1 in all-*trans*-inositol.

6.2.2. *2,6-Adamantanediol*

In this molecule we find two stereogenic atoms which until now could not be specified. This particular example shows how one can establish the rank of ligands in the case of a highly symmetrical (T_d) polycyclic framework.

Since obviously O > C, C > H, what one has to tackle is the problem of the proximal ligand atom pairs (C-1, C-3)

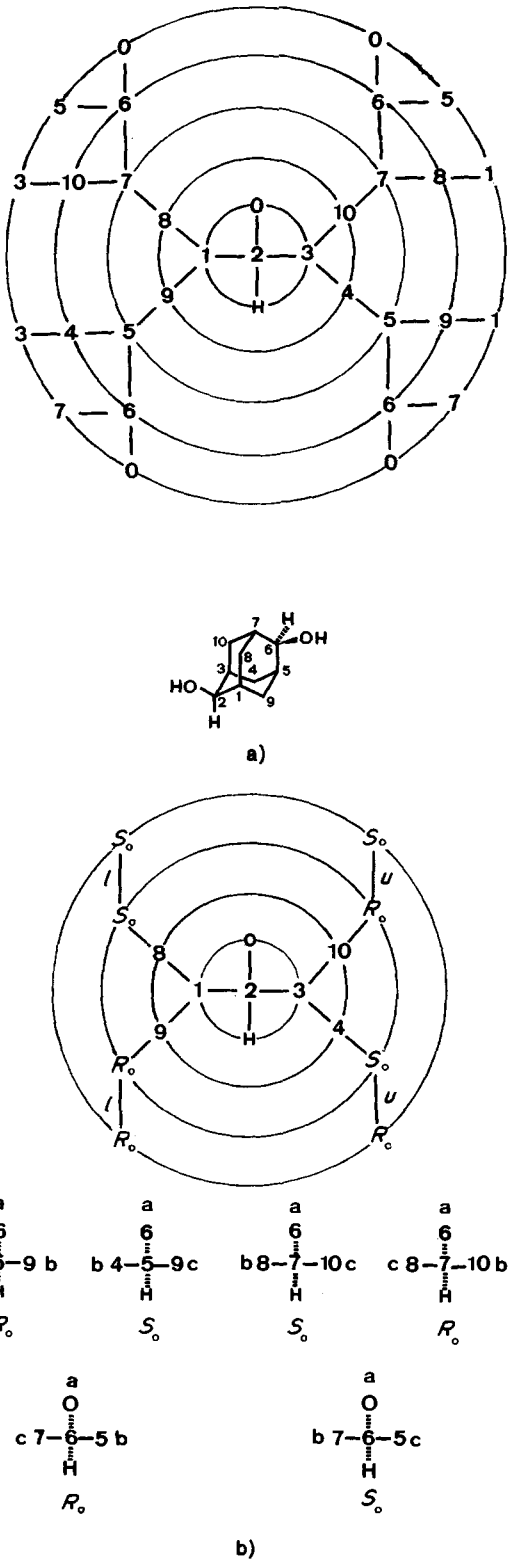

Fig. 27. Hierarchical digraphs and auxiliary descriptors of C-2 in (*S*)-2,6-adamantanediol.

at C-2 and (C-5, C-7) at C-6. Figure 27a shows the hierarchical digraph of stereogenic carbon atom 2. Ligands at C-1 and C-3 exhibit no constitutional differences and they must be different geometrically. On the basis of constitutional differences one first assigns auxiliary descriptors to stereogenic atoms C-5, C-7, and C-6. It then follows from Figure 27b that the ligand at C-1 contains two like (*l*) auxiliary descriptor pairs, and that at C-3 two unlike (*u*) ones, from which it follows that C-1 > C-3 and the descriptor is 2*S*. In accordance with the molecule's C_2-symmetry one then arrives at the descriptor 6*S*.

6.2.3. *R. S. Cahn's Cyclobutane Derivatives*

Among molecules with mutually interdependent stereogenic atoms of different type the four test cases suggested by *Cahn* (cf. [7,33]) (Fig. 28) deserve special mention. After

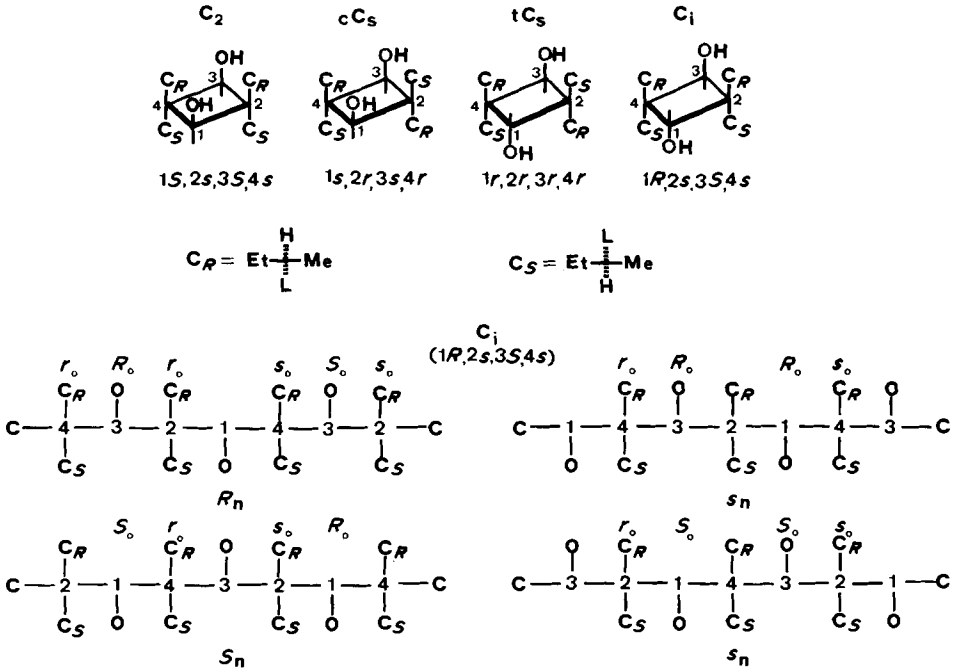

Fig. 28. Descriptors of the four diastereomeric cyclobutane derivatives. Hierarchical digraphs of stereogenic atoms in C_i diastereoisomer.

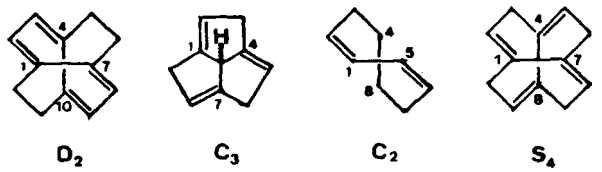
and then evaluating the others through their topological distance from this atom on the hierarchical digraph. The examples in Figure 29a—c show how the ligands can be thus ranked clearly and simply. The chiral molecule with point symmetry D_2 has a stereogenic central atom with four rotationally equivalent proximal atoms; the chiral molecule with point symmetry C-3 has three such proximal atoms. In the chiral molecule with point symmetry C_2 we find a stereogenic central atom with two rotationally equivalent proximal atom pairs.

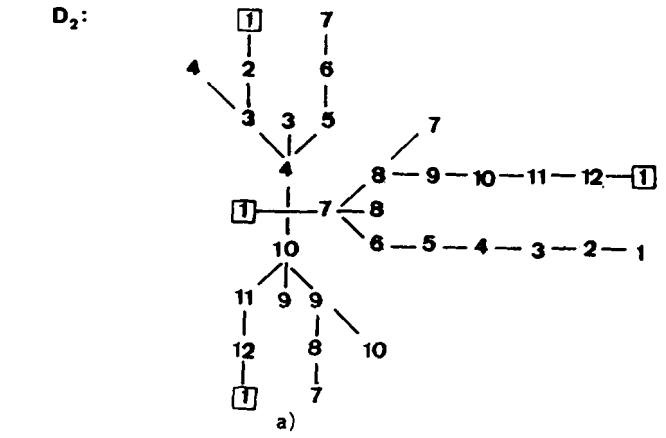
The fourth example in Figure 29d is of interest since it deals with an achiral molecule with S_4-point symmetry. The central atom is not stereogenic. Going through the above exercise using atoms C-1 and C-7 as reference atoms one arrives at a sequence leading to descriptor *R*, and using atoms C-4 and C-11 as reference one obtains descriptor *S*. These descriptors cancel each other out. This result constructing the requisite hierarchical digraphs it emerges that in all four examples the stereogenic atoms are all specifiable using symmetry-concordant descriptors; this is exemplified *in extenso* by digraphs with the stereoisomer having C_i point symmetry.

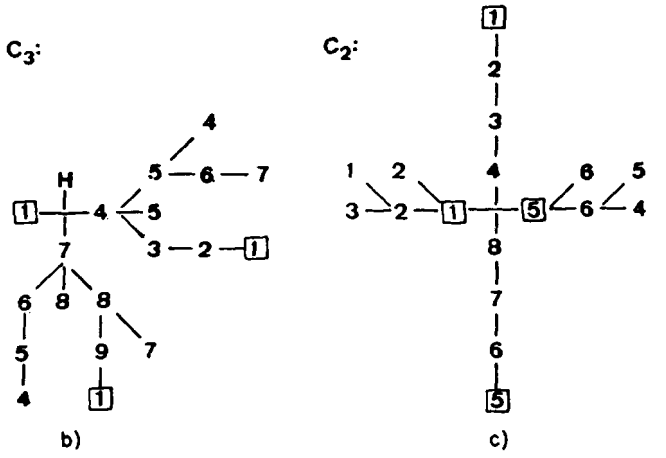
6.3. Ligands of Rotationally Symmetric Stereogenic Atoms which are Topologically Distinguishable

Proximal atoms in a polydentate ligand of a tetrahedral stereogenic atom need not necessarily be different; they may be rotationally equivalent and yet be distinguishable by their location relative to each other within the polydentate ligand. As demonstrated in 1966 such stereogenic atoms can be specified by arbitrarily allocating highest rank to one of the rotationally equivalent proximal atoms has been arrived at merely by consideration of the relative topological ranking of proximal atoms discernable from the hierarchical digraph, without any foreknowledge of the symmetry of the molecule. This should serve to illustrate the requirement that for determining order of sequence based on relative topological differences *all* proximal atoms must be used as reference atoms. The ligand sequences thus obtained lead to pairs of the same descriptor only in the case of chiral molecules, whereas with achiral molecules one obtains pairs of enantiomorphic descriptors.

This criterion of topological differentiation of ligand atoms attached to a central stereogenic atom in relation to one chosen freely and arbitrarily from the rank-highest equivalent (homotopic) among them can be used to specify stereogenic atoms in many different types of rotation-symmetric molecules, such as that shown in Figure 30[34] and







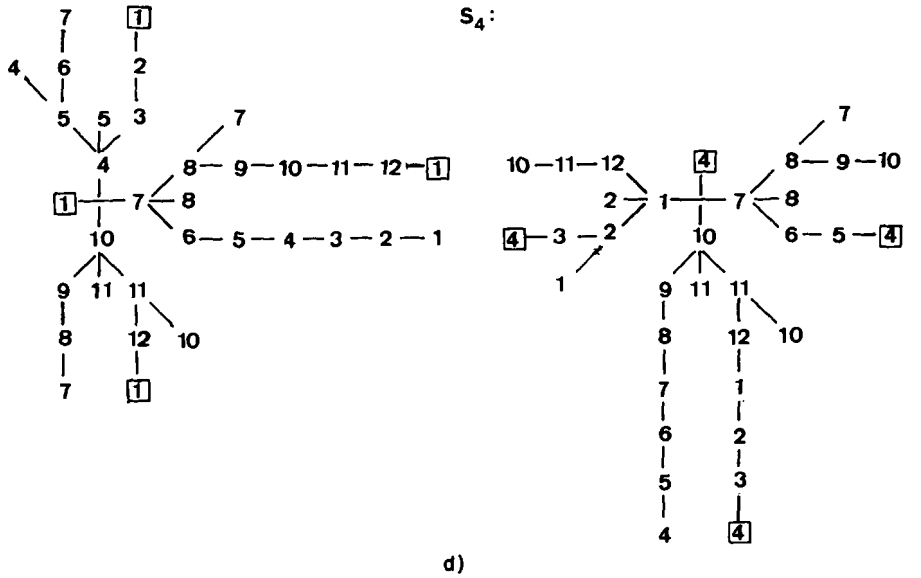


Fig. 29. Hierarchical digraphs of four molecules with rotation-symmetric topologically distinguishable ligands.

its many stereoisomers and analogues. For specifying C-1 one can use either sequence $a_1 > a_2 > b_1 > b_2$ or $a_2 > a_1 > b_2 > b_1$. Both sequences will lead to descriptor R for this and consequently for the other four stereogenic rotationally equivalent atoms.

6.4. Geometrical Enantiomorphism

Lyle and *Lyle*[35] have used the term "geometrically enantiomorphic stereoisomers" for enantiomers with constitution (A,B)X=Y(F,$\bar{F}$), where A and B are two different chiral ligands, and F and $\bar{F}$ represent an enantiomorphic ligand-pair.

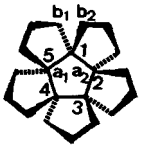

Fig. 30. A molecule with C_5 axis.

Hirschmann and *Hanson*[7] have suggested using the reflection-variant descriptors *seqCis* and *seqTrans* (note capitals!) for such enantiomers. Our example in Figure 31 shows that the enantiomer on the right can be specified using the "like" descriptor pairs *reRe* or *siSi*, and that on the left by the "unlike" pairs *siRe* or *reSi*. Since these are reflection-variant descriptor pairs, the logical abbreviations for these are *Lk* and *Ul*, respectively.

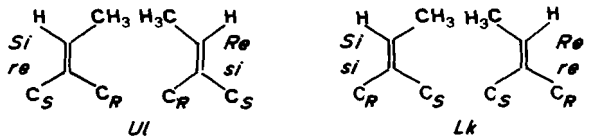

Fig. 31. Specification of "geometrically enantiomorphic" stereoisomers. C_R and C_S as in Fig. 28.

7. Epilogue

An ancient Chinese proverb states that a picture can often obviate a thousand words. One can, however, obviate thousands of pictures by means of a right word (descriptor) at the right place and a left word at the left place.

[9] Concerning the exact definition of the terms geometry and topography *Klein* [10] wrote the following comments, which have already been quoted in [6] and which, in view of their importance for understanding the subject, we requote (translated from the original German): "Geometry deals only with those relationships between coordinates which remain unaltered during substitution operations such as mentioned under 1 (*i.e.* parallel displacements, rotation about the coordinate origin, reflection and similarity transformations). In other words, geometry is the invariant theory of these operations. On the other hand, all non-invariant relationships between coordinates, *e.g.* the statement that a certain point has coordinates 2,5,3, refer to a system of coordinates which has been fixed once and for all—they belong to a science which individualizes each point and deals with the properties of each separately, namely the science of topography ...". It follows from this that chirality (orientability in Euclidean space) of a figure is a geometrical property, whereas chirality sense (the orientation of that figure and its algebraic sign) is a topographical one.
[10] F. Klein: *Elementarmathematik von höherem Standpunkt aus*, 2. ed., Springer-Verlag, Berlin 1925 (reprint 1968), p. 141.
[11] Although in principle, static stereochemistry could dispense with the use of the rather ill-defined term chemical bond, we would not consider such a move as appropriate and agree with the pointed remarks made by a mathematician, H. Weyl [12] who writes (translated from original German): "one should not take arbitrary relational representations such as valence diagrams too seriously even though they have their use in serving as a rough guide through a seemingly chaotic accumulation of facts. One cannot expect a rough sketch purporting to represent reality to contain all possible shades of that reality. Nonetheless the sketcher should have the courage of his convictions and draw the lines firmly".
[12] H. Weyl: *Philosophie der Mathematik und Naturwissenschaft*, 4th ed., Oldenbourg, München, 1976, p. 352.
[13] In order to stress the difference between molecules and models we restrict the expressions "enantiomer" and "diastereomer" to molecules and compounds only (cf. [6]). When referring to geometric and topographic interrelationships between models, ligands, or other objects we use the terms "enantiomorphic" and "diastereomorphic" (cf. [14]).
[14] K. R. Hanson, *Ann. Rev. Biochem. 45* (1976) 307.
[15] The CIP-system does not take into account diastereomers whose models are differentiated only by the magnitude of their internal coordinates (but not by their algebraic sign). Stable diastereomers of this type are exemplified by "cogwheel" stereoisomers [16]. These can be specified by using the descriptors *sp*, *sc*, *ac*, and *ap*, proposed by *Klyne* and *Prelog* [17], which indicate the approximate magnitude of torsion angles.

[24] In a pamphlet issued by Chemical Abstracts Service (*A New General System for the Naming of Stereoisomers*, Columbus, Ohio, 1953, p. 2) G. E. McCasland suggested the following definitions of a stereogenic atom: "a) An atom (usually carbon) of such nature and bearing groups of such nature that it can have two different configurations. b) An atom bearing several groups of such nature that an interchange of any two groups will produce an isomer (stereoisomer)."
[25] This kind of stereoisomerism is usually denoted by the too general and hence misleading term "geometrical isomerism". In fact every diastereoisomerism is a geometrical isomerism.
[26] *J. H. van't Hoff*, the originator of the model of the "asymmetric atom", at first placed the atoms and atom groups proximal to the central atom on the faces of a tetrahedron (cf. [27]). This is feasible because replacing the vertices of a tetrahedron by its faces and *vice versa* produces an "inverse" tetrahedron. At a later stage *van't Hoff* relinquished this original idea; much later still it was taken up again as the basis of modern space-filling models.

Induction of Asymmetry by Amino Acids

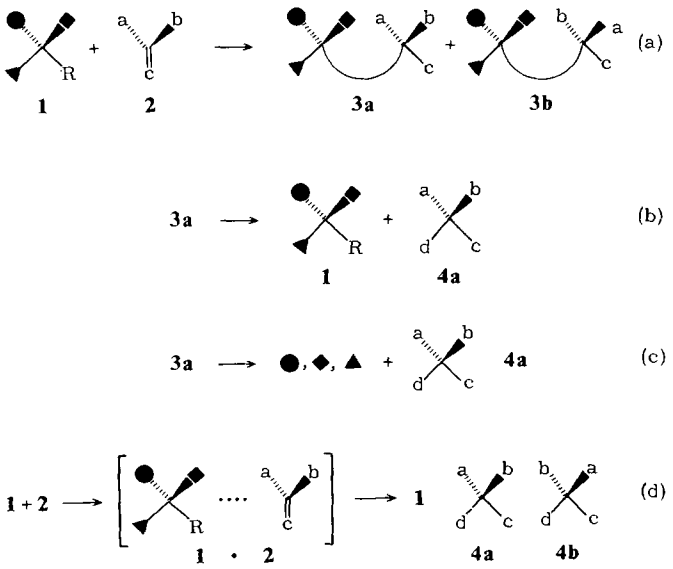
By Karlheinz Drauz, Axel Kleeman, and Jürgen Martens*

Dedicated to Professor Friedrich Asinger on the occasion of his 75th birthday

Since the stereoisomers of molecules with one or more asymmetric centers often exhibit different biological activities (*e.g.* thalidomide, pheromones), stereoselective synthesis as a method of preparative chemistry is rapidly attaining importance. Of the numerous drugs prepared by total synthesis that contain at least one asymmetric center, only about 20% have so far been used in sterically pure form. Amino acids constitute the greatest "chiral pool" of compounds whose enantiomers can be obtained commercially in large amounts; they are gradually being used more and more frequently as auxiliary agents or educts in asymmetric syntheses.

1. Introduction

The individual reaction steps of a multistep synthesis should proceed as selectively as possible, since normally the desired result is either *one* or *predominantly one* product. Depending on the nature of the synthesis, a distinction is drawn between regioselective (formation of compounds with defined constitution), diastereoselective (formation of compounds with defined relative configuration), and enantioselective reactions (formation of compounds with definite absolute configuration). The last two terms can be included under the common term of stereoselective reactions. If a compound has one chiral center, a reaction at a prochiral center with the formation of a second center of chirality leads, in principle, to two diastereomers.



When prochiral molecule **2** reacts with chiral molecule **1** to form a new center of chirality, two diastereomers, **3a** and **3b** [eq. (a)], are formed. The *de* value (%) (de = diastereomeric excess) is used as a measure of the diastereoselectivity of the reaction:

$$de = \frac{[\mathbf{3a}]-[\mathbf{3b}]}{[\mathbf{3a}]+[\mathbf{3b}]} \times 100\%$$

If only one of the two diastereomers **3a** or **3b** is formed, the reaction is said to be diastereospecific ($de = 100\%$). In the subsequent course of the synthesis **3a** or **3b** may be cleaved with the formation of a new enantiomer **4a** or **4b**, whereby chiral **1** is either recovered [eq. (b)] or not [eq. (c)].

If equivalent or catalytic amounts of a chiral molecule **1** react with a prochiral molecule **2**—the complex **1**·**2** is formed as intermediate—to give the new chiral compounds **4a** or/and **4b**, one speaks of an enantioselective reaction [eq. (d)]. The enantioselectivity of such a reaction is given by the enantiomeric excess (*ee*) or by the optical yield:

$$ee = \frac{[\mathbf{4a}]-[\mathbf{4b}]}{[\mathbf{4a}]+[\mathbf{4b}]} \times 100\%$$

$$\text{optical yield} = \frac{\alpha}{\alpha_0} \times 100\%$$

α = measured rotation of the product
α_0 = rotation of the pure enantiomer

General considerations and earlier results of stereoselective syntheses have been summarized in some recent reviews[1]. Other review articles describe special aspects: educts[2], types of reactions[3], spontaneous crystallization of one enantiomer[4], and absolute asymmetric syntheses[5]. The enantiomerically pure educts of asymmetric syntheses, the chiral[6] units **1**, can either be prepared in the laboratory or be isolated from natural products. As a rule, nature transforms prochiral[6] educts enantioselectively[6] into chiral products. Thus, the chemist has at his disposal a large number of chiral units among the natural products. In particular, carbohydrates[2c,3a,7], α-hydroxycarboxylic acids[8], and amino acids have found application as building blocks for asymmetric syntheses. The disadvantage of carbohydrates, which can rarely be obtained in several enantio-

meric forms, does not exist in the case of α-hydroxycarboxylic acids such as lactic[9], mandelic[9], malic[9], and tartaric acids[9].

This is the first review on the induction of asymmetry for the case in which the compound **1** is represented by *amino acids* or their derivatives. Only those works are considered in which the formation of a *new* center of asymmetry is induced. This can take place with the simultaneous incorporation of the enantiomerically pure amino acid (or a derivative thereof) in the target molecule or by the action of catalytic amounts of this amino acid on a prochiral molecule. Reactions in which only the asymmetric center of the amino acid is modified, without the stereoselective appearance of a new chiral center, have not been considered. Enzymatically catalyzed transformations[10] of molecules are not treated here.

The (*S*)-amino acids used most frequently[11] are obtained by fermentation, extraction of protein hydrolyzates, or enzymatic cleavage of racemates. There are also specific preparation processes for the nonnatural (*R*)-amino acids[12]. All important amino acids can be obtained commercially in at least 1000-kg quantities in the two enantiomeric forms.

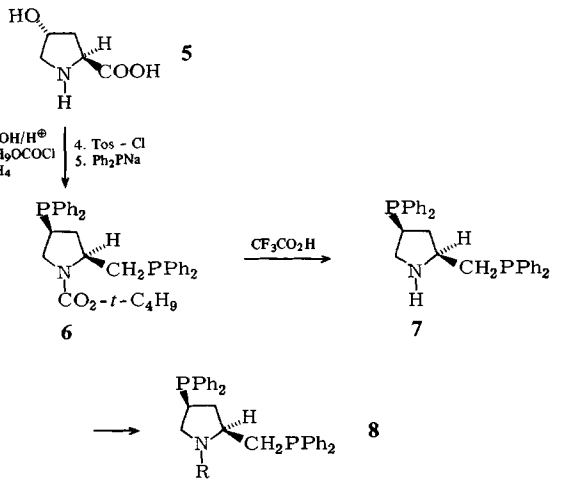
2. Induction of Asymmetry by Catalytic Amounts of Amino Acids or their Derivatives

If the chiral educts are used only as catalysts the reactions closely resemble an enzymatic process, *i.e.* an optimal process in which a small amount of chiral information is sufficient to direct a large number of molecules through the desired transformations in accordance with eq. (d).

2.1. Homogeneous Asymmetric Hydrogenation

2.1.1. Preparation of the Catalysts

A preparatively useful transfer of hydrogen to π-systems by soluble rhodium(I)-phosphane complexes such as



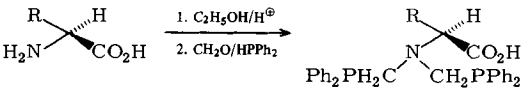
R = $OCOC_{27}H_{45}$, $COCH_3$, CO-t-C_4H_9, COC_6H_5, CO–NHC_6H_5, CONH(4-Br–C_6H_4), CONH(4-Cl–C_6H_4), CO–NH(3, 4-Cl_2–C_6H_3), CONH(4-NO_2–C_6H_4), CO–$NHCH_3$, $CONHCH{=}CHCH_3$, CONH–*cyclo*-C_6H_{11}, CHO

$(C_6H_5)_3PRhCl$ was only possible following the fundamental investigations of *Wilkinson et al.*[13].

At the beginning of this brilliant development, in 1961, came the first synthesis of optically active tertiary phosphanes by *Horner et al.*[14], which led, in 1968, to the production of chiral Wilkinson complexes with a high inductive activity by *Knowles et al.*[15]. The vigorous development in this area is reported on in a number of excellent review articles[3b,c, 16].

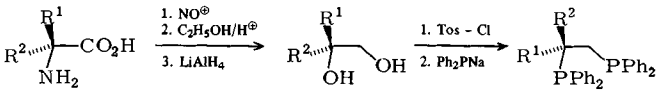
In 1976, *Achiwa*[17] synthesized the first functionalized chiral bisphosphanes based on an amino acid. Starting from 4-(*S*)-hydroxy-(*S*)-proline **5**, *Achiwa* obtained (2*S*,4*S*)-*N*-*tert*-butoxycarbonyl-4-diphenylphosphino-2-diphenylphosphinomethylpyrrolidine (BPPM) **6** and (2*S*,4*S*)-4-diphenylphosphino-2-diphenylphosphinomethylpyrrolidine (PPM) **7**. The bisphosphanes **8** were prepared by reaction of **7** with acid chlorides or isocyanates[18–22].

The α-amino acids (*S*)-alanine **9a** and (*S*)-valine **9b**, as well as their esters and sodium salts, can be converted into the *N*,*N*-bis(phosphinomethyl) derivatives **10** and **11**, respectively, in a modified Mannich reaction[23].



9a, R = CH_3 **10**, R = CH_3
9b, $CH(CH_3)_2$ **11**, R = $CH(CH_3)_2$

The chiral ligands (*R*)-Val-Phos (*R*)-**12** and (*R*)-Phe-Phos (*R*)-**13** have been synthesized from (*S*)-valine and (*S*)-phenylalanine, respectively[24].



(*R*)–**12**, $R^1 = CH(CH_3)_2$, $R^2 = H$
(*R*)–**13**, $R^1 = CH_2Ph$, $R^2 = H$
(*S*)–**12**, $R^1 = H$, $R^2 = CH(CH_3)_2$
(*S*)–**13**, $R^1 = H$, $R^2 = CH_2Ph$

The chiral ligand (*R*)-1,2-bis(diphenylphosphino)propane, (*R*)-Prophos[25], has been similarly synthesized from the (*S*)-alanine derivative (*S*)-lactic acid. Starting from (*S*)-mandelic acid, *King et al.*[26], as well as *Brown* and *Murrer*[27], obtained 1,2-bis(diphenylphosphino)-1-phenylethane. *Takeuchi* and *Ohgo* have reported a less stereoselective catalyst system based on (*S*)-*N*-methylproline[28].

2.1.2. Homogeneous Asymmetric Hydrogenation of CC Double Bonds

The most spectacular results in the hydrogenation of prochiral olefins have been observed in the presence of one or two polar functional groups such as —COOH or —NHCOR. *The homogeneous-catalytic hydrogenation of dehydroamino acids* **14** leads—frequently quantitatively—to the amino acid derivatives **15** with very good optical yields (Table 1).

Achiwa et al.[21] have reported a catalytic asymmetric hydrogenation of methyl β-acetylaminoacrylate **16** with Wil-

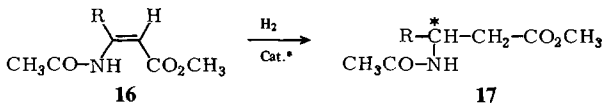
kinson complexes containing 4-(*S*)-hydroxy-(*S*)-proline derivatives as chiral ligands. The β-alanines **17** were obtained with optical yields of up to 55%.



16 17

R = CH_3 or C_6H_5

Cat.* = Rhodium complex of BPPM **6**

The *stereoselective synthesis of dipeptides*[30] by hydrogenation of dehydrodipeptides[29] with rhodium complexes as catalysts has recently been reported. Regarding the induction of asymmetry, the BPPM complexes were superior to the corresponding DIOP complexes (DIOP = *P,P'*-[2,2-dimethyl-1,3-dioxolane-4,5-bis(methylene)]bis(diphenylphosphane)) and to other bis(diphenylphosphane)rhodium complexes (a diastereomeric excess of 90—95% was generally obtained[30a]).

Kagan et al.[30c] have demonstrated that the species (*S*)-**18** are hydrogenated to the diastereomers (*S,S*)-**19** with an

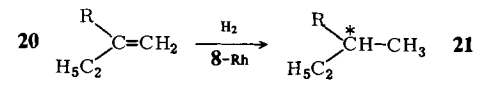
(*S,S*)-**19**

especially high optical yield when chiral Wilkinson complexes which show a pronounced (*S*)-stereoselectivity in the hydrogenation of (*Z*)-*N*-acetyldehydrophenylalanines are used; on the other hand, Wilkinson complexes that have an (*R*)-stereoselectivity in α-amino acid syntheses lead in the hydrogenation of **18** predominantly to (*R,S*)-**19**. However, the stereoselectivity is not very pronounced. This is explained by the fact that two asymmetry inducing centers—one in the catalyst, one in the educt—influence the course of the reaction; the effects can mutually augment or compensate each other. *Ojima* and *Suzuki*[30a] have also found that the (*S*)-chiral center in **18** has almost no influence on the stereoselectivity of chiral Wilkinson complexes in the synthesis of the dipeptide **19**. The stereoselective synthesis of dipeptides by asymmetric hydrogenation of dehydrodipeptides could attain preparative importance, since polypeptides with a "nonnatural" configuration at one center of asymmetry could also be synthesized by this method; these often have completely different biological activity from the natural peptides[65].

Stereoselective Hydrogenation of Other Prochiral Olefins: The hydrogenation of the olefinic double bond in the pure hydrocarbons **20** in the presence of **8**-Rh yielded only



a, R = $(CH_2)_3CH_3$, **b**, R = C_6H_5

small enantiomeric excesses[18]; the same applies for the asymmetric hydrogenation of the olefinic double bonds in **22**[32a], **23**[32b], and **24**[32c] using Wilkinson complexes containing BPPM as the chiral ligand.

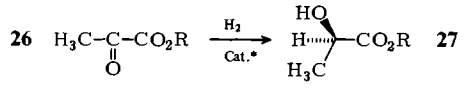
23 **24**

22, an intermediate in the synthesis of the natural compound salsolidine **25**, has also been hydrogenated[32a] in the presence of the rhodium complex of **8**; here too the optical yields were only moderate.

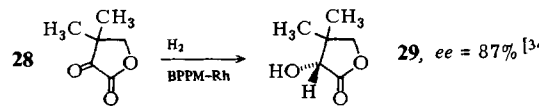
2.1.3. Homogeneous Asymmetric Hydrogenation of CO Double Bonds

Many chiral alcohols are important intermediates for the synthesis of complex molecules; unfortunately, however, there are few reports of the asymmetric reduction of carbonyl groups. Especially high optical inductions have been achieved with catalysts which contain BPPM (**6**), PPM (**7**), or **8** as chiral ligands. The pyruvic acid esters **26** were usually hydrogenated to the lactic acid esters **27** in quantitative chemical yields with an enantiomeric excess of 65 to 75%[18,33].



R = CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, i-C_4H_9

(*R*)-(−)-Pantolactone **29**, an important intermediate for the preparation of pantothenic acid, has been obtained with high stereoselectivity by the asymmetric hydrogenation of ketopantoyllactone **28** in the presence of a rhodium complex of BPPM[34a,b]. If **28** is hydrogenated in the presence of Rh-**8** (R = CO-*t*-C_4H_9), a smaller enantiomeric ex-



cess is obtained[34b]; with Rh-**7** the optical induction is even weaker[34b] and, moreover, the other enantiomer is obtained.

2.2. Heterogeneous Asymmetric Hydrogenation

A great advantage of heterogeneous catalysis, the ease of separating the catalyst from the product, is gained at the expense of the great disadvantage of its lower selectivity. All attempts to modify solid surfaces with optically active substances have so far given catalysts of only low stereoselectivity. This is due to the fact that too many active centers of different structures are present on the surfaces of solids. Consequently, in asymmetric hydrogenations homogeneous catalysis is superior to heterogeneous catalysis[35].

Enantioselective Raney nickel catalysts modified with chiral amino acids[36] or amino acid derivatives (α-hydroxycarboxylic acids[36d,37], dipeptides[38]) gave only very moderate enantiomeric excesses of between 0 and 10% in the hydrogenation of olefins, carbonyl compounds or oximes. Only on modification of the Raney nickel with (*S*)-tyrosine was a higher enantiomeric excess obtained[36a]. *Beamer et al.*[39] investigated enantioselective hydrogenations of α-methylcinnamic acid and of α-acetylaminocinnamic acid using palladium catalysts on chiral poly(amino acid) supports; however, the enantiomeric excesses did not exceed 6%.

An excellent review of the problems of the enantioselective heterocatalytic hydrogenation of prochiral double bonds has been compiled by *Izumi*[40].

2.3. Asymmetric Aldol Addition

According to *Weichert et al.*[41] and *Hajos et al.*[42], prochiral triketones **30** can be converted into optically active enediones **31** or **32**[41-47] with the aid of optically active catalysts having a primary or secondary amino group at the asymmetric center. More than 15 amino acids have so far been used as chiral auxiliaries[3a,47]. It is remarkable that in the cases described[41-46] catalysts of the (*S*)-series, to which most natural α-amino acids belong, cause the formation of an excess of **31**, *i.e.* they induce the (*S*)-configuration. Chiral auxiliaries of the (*R*)-series, on the other hand, lead predominantly to **32**, which has the (*R*)-configuration. The natural steroids have the same absolute configuration at C(13) as **31**.

The most thoroughly investigated reaction is the asymmetric cyclization of 2-methyl-2-(3-oxobutyl)-1,3-cyclopentanedione **30a**; the resulting enedione **31a** was used as the C,D-unit in the total syntheses of steroids having natural configuration[44,48-51]. With (*S*)-proline[3a], an enantiomeric excess of 95% was achieved in almost quantitative chemical yield[2a,52] (Table 2).

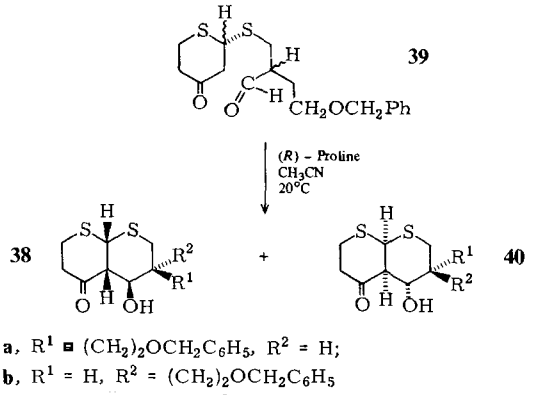
Hajos and *Parrish*[42] have shown that in the presence of only 3 mol-% of (*R*)- or (*S*)-proline in dimethylformamide (DMF) at room temperature **30a** is converted into the aldols **33a** and **34a**, respectively, which upon heating with *p*-toluenesulfonic acid in benzene readily eliminate water.

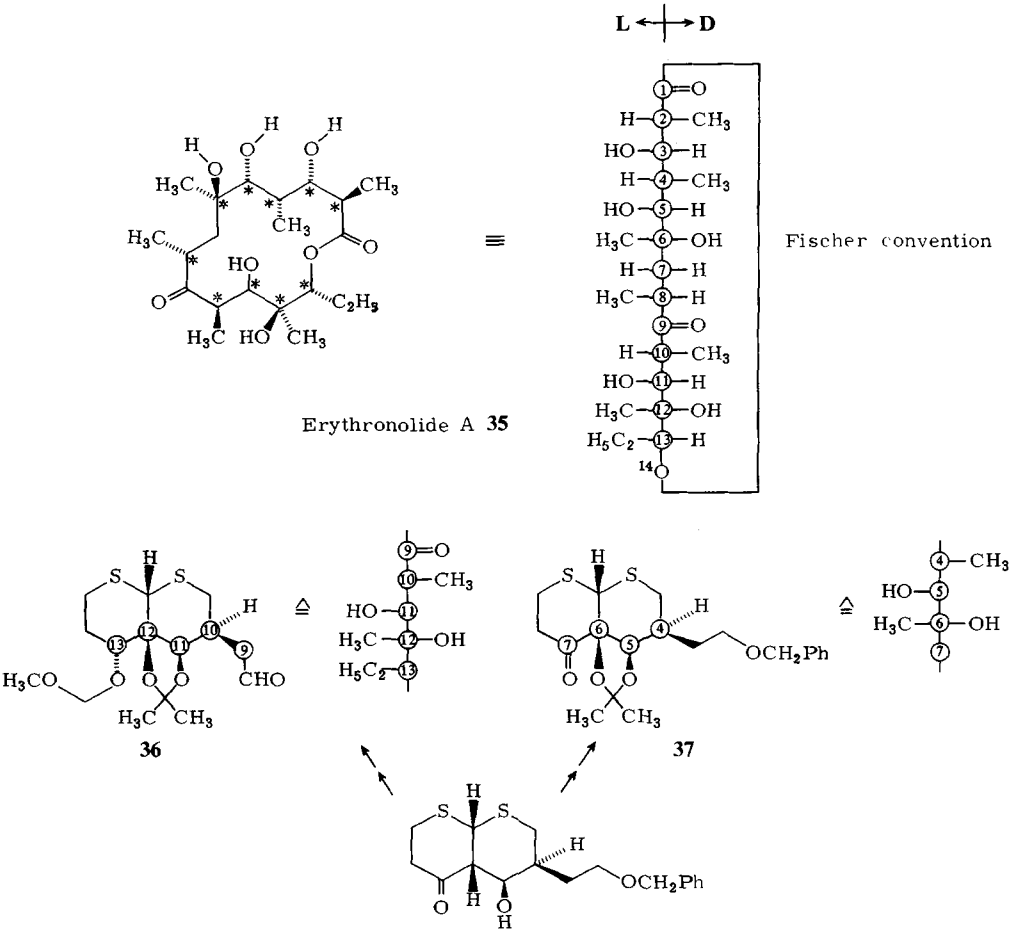
If **30a** is heated in acetonitrile in the presence of 40 mol-% of (*S*)-proline and a trace of anhydrous perchloric acid, **31a** is obtained directly[41] in 87% chemical and 84% optical yield. Table 2 summarizes the most important results of asymmetric aldol cyclizations induced by amino acids and amino acid derivatives. The best chemical and optical yields are obtained on using (*S*)- or (*R*)-proline. Numerous 19-norsteroids are prepared on a commercial scale from the products of the intramolecular aldol additions[3a]. The exact mechanism of the reaction is still unclear, but several proposals have been put forward for discussion[3a,8].

Recently, *Woodward*[58] reported advances in the synthesis of erythronolide A **35**. Careful analysis of the stereochemistry of **35** shows that the substitution patterns and configurations of the asymmetric centers at C-10, C-11, and C-12 on the one hand and at C-4, C-5, and C-6 on the other are identical. Therefore, both key substances, the aldehyde **36** and the ketone **37**, can be prepared from one and the same compound **38**.



The asymmetric synthesis of **38a** is achieved by intramolecular, (*R*)-proline-catalyzed aldol addition on the racemic dicarbonyl compound **39**[59].

38a and **40a** (7 : 3) as well as **38b** and **40b** are formed in equal chemical yields and can easily be separated from one another[59]. The CC bond formation observed in the intramolecular aldol addition leads with high selectivity to

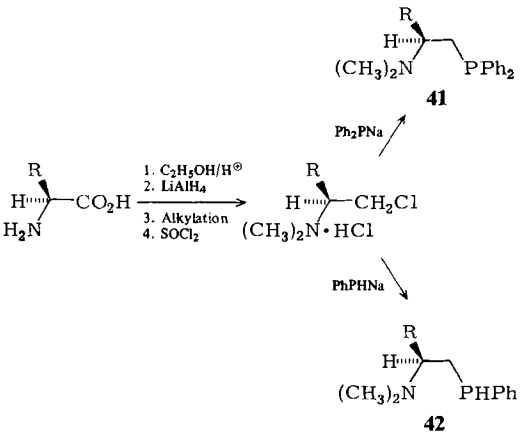


the *cis*-decalin system **38** and **40**; the (*S*)-proline-catalyzed intramolecular aldol addition of **30b**[41,60], which provides potential AB-ring synthons for steroid syntheses, proceeds analogously.

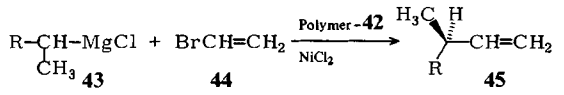
Especially striking in the asymmetric aldol additions described in this section is the particularly high stereoselectivity of the reactions catalyzed by proline and its derivatives.

2.4. Stereoselective CC Bond Formation with Grignard Reagents

Recently, *Kumada et al.*[61,62] reported on asymmetric CC coupling reactions with Grignard reagents, in which the chiral amino acid derivatives **41** or **42** — after immobilization — are used as catalysts. They can be prepared from (*S*)-valine (where R = *i*Pr) or (*S*)-phenylalanine (where R = $CH_2C_6H_5$)[61,62].



In the presence of **42**[61], which was immobilized with chloromethylated polystyrene, the nickel-catalyzed asymmetric coupling of the racemic Grignard compounds **43** with vinyl bromide **44** proceeds enantioselectively ($ee \leq 50\%$)[61].



R = C_6H_5, *p*-CH_3–C_6H_4, 2-Naphthyl

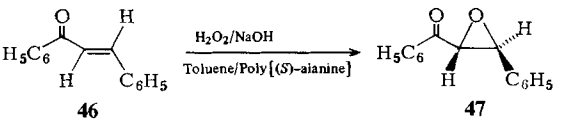
The enantiomeric excesses in similar reactions[62] with immobilized **41**[62] were smaller, and also the chemical yields were lower.

2.5. Asymmetric Cyanohydrin Syntheses

So far, optical yields of about 20% have been achieved for the addition of hydrocyanic acid to aldehydes using linear or cyclic dipeptides derived from histidine and alanine as catalysts[63a,b]. Recently, *Inoue et al.*[63c] reported *ee* values of up to 90% for the addition of HCN to benzaldehyde with *cyclo*-(*S*)-phenylalanyl-(*S*)-histidine as catalyst.

2.6. Stereoselective Epoxidation

Julia et al.[64] recently reported the first example of an almost stereospecific epoxidation catalyzed by a readily available synthetic chiral polypeptide. With poly[(*S*)-alanine] as catalyst, chalcone **46** is epoxidized, with a good chemical conversion, to the levorotatory epoxide **47** ($ee \geq 90\%$)[64]. If the poly[(*S*)-alanine] is replaced by poly[5-benzyl-(*S*)-glutamate] or poly[5-butyl-(*S*)-glutamate], both the optical and the chemical yields of **47** are markedly lower[64]. Without the addition of poly(amino acids) no epoxidation occurs under the reaction conditions, which indicates that the reaction takes place at the boundary of the chiral phase. Synthetic peptides prove to be interesting alternatives to enzymes as stereoselective catalysts[65].



3. Transfer of Asymmetry

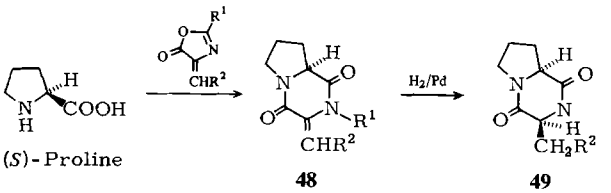
In the preceding section we considered the induction of asymmetry by *catalytic* amounts of "chiral information" (amino acids and their derivatives). The chiral information is transferred onto a prochiral substrate. In this section we turn to reactions in which at least *equimolar* amounts of chiral information are required for the induction of asymmetry. The newly formed asymmetric center can be induced by either intramolecular or by intermolecular interactions.

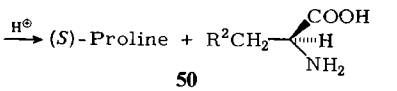
3.1. Hydrogenations

3.1.1. Asymmetric Hydrogenation of CC Double Bonds

If it is desired to hydrogenate C=C bonds asymmetrically in the presence of achiral catalysts, chiral information must be present in the substrate. In the catalytic hydrogenation of peptides and cyclopeptides containing dehydroamino acid units, the chiral center of the neighboring amino acid frequently brings about an intramolecular induction of asymmetry[30,66,67]. The optical yields have always been lower than 50% for the hydrogenation of open-chain dehydrodipeptides **18** in the presence of achiral catalysts in homogeneous or heterogeneous phase[30a,d,66c–e].

On the other hand, excellent optical yields have been obtained for the hydrogenation of bicyclic piperazinediones **48**; according to *Poisel* and *Schmidt*[66d], the best stereoselectivity is achieved in the case of (*S*)-proline de-

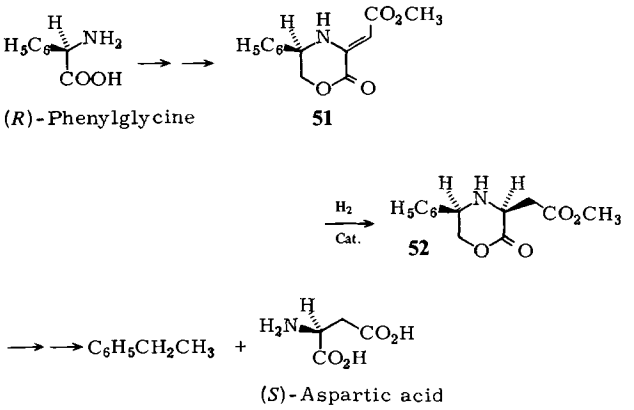




R^1 = H, CH_3; R^2 = Aryl[66d], Alkyl[66b]

rivatives. *Hydrolysis* of the resulting (*S,S*)-cyclodipeptides **49** (*ee* > 90%) affords the chiral amino acids **50** and (*S*)-proline.

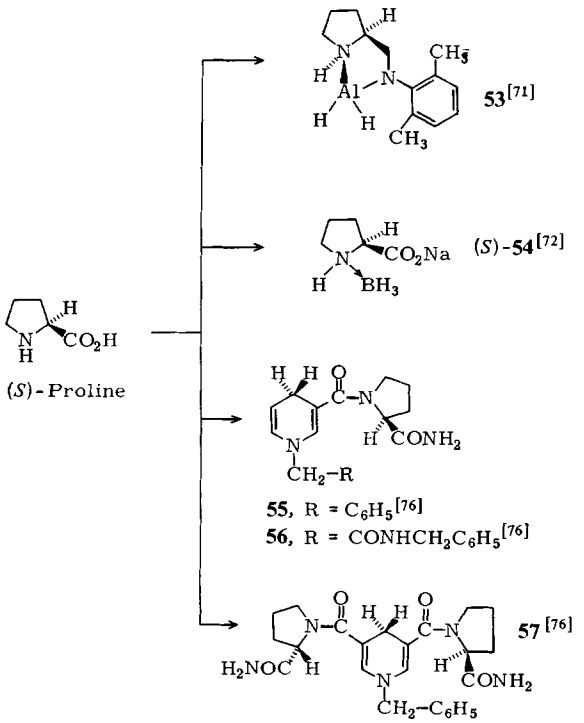
In the asymmetric hydrogenation of the olefinic double bond of (*R*)-phenylglycine derivative **51** in the presence of achiral catalysts the stereoselectivity was always low (*ee* ≤ 17%)[68]. The preferred formation of **52** can be attributed to the influence of the bulky phenyl residue in **51**. **52** could subsequently be converted into (*S*)-aspartic acid. This synthesis, carried out by *Tamura* and *Harada*[68], is an example of the transfer of chirality with subsequent disappearance of the original chiral center.



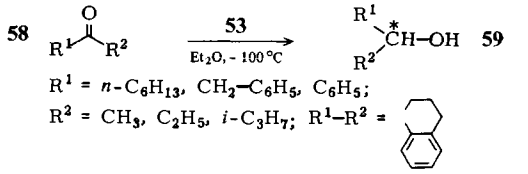
The asymmetric hydrogenation of a CC double bond in a total synthesis of gephrytoxin with diisobutylaluminum hydride has been described by *Kishi et al.*[69]. Optically active pyrrolizidine bases have been synthesized by *Robins* and *Sakdarat*[70] by hydrogenation of a chiral hydroxyproline derivative (*de* > 60%).

3.1.2. Asymmetric Hydrogenation of CO Double Bonds

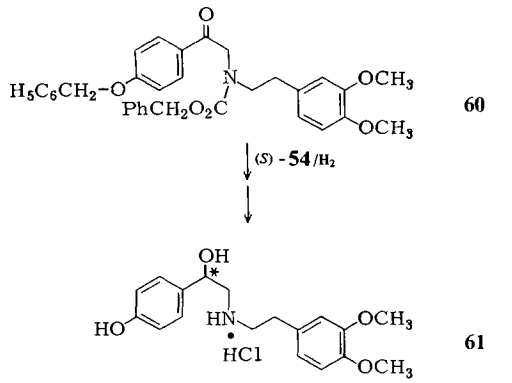
The reducing agents **53** to **57**, derived from (*S*)-proline, are eminently suitable for the hydrogenation of prochiral ketones.



The ketones **58** are reduced with **53** at −100 °C in high chemical (82—97%) and optical (31—96%) yields[71] to the (*S*)-alcohols **59**. The chiral precursor of **53** can be recovered.



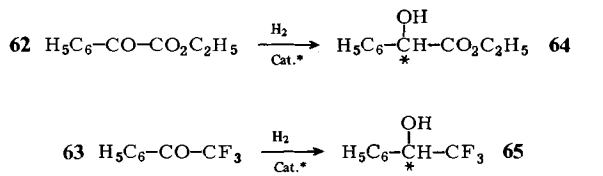
The BH_3-adduct (*S*)-**54** reduces prochiral aryl alkyl ketones and dialkyl ketones to the corresponding chiral alcohols in chemical yields of 66 to 92% and optical yields of up to 62%[72]. (*S*)-**54** has also been used as a stereoselective reducing agent for the hydrogenation of the ketone **60** with formation of the HCl-adduct **61**, which is used as a drug.



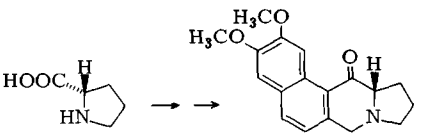
Reduction of the ketones **58** with the mirror image of (*S*)-**54**, *i.e.* (*R*)-**54** derived from the nonnatural (*R*)-proline, gave the expected alcohols with the inverted configuration[72].

The stereochemistry of NADH model reactions is of special interest to biochemists who wish to study the origin of the induction of asymmetry in such reactions. Thus, the influence of peptide derivatives[73] on the course of NADH model reactions, the incorporation of chiral 1,4-dihydronicotinamide in crown ethers[74], and electronic factors[75] which influence NADH model reactions have been investigated. *Inouye et al.*[76] obtained the chiral alcohols **64** and **65** in yields of up to 84% (*ee* ≤ 83%) from the asymmetric reduction of the corresponding prochiral carbonyl substrates **62** and **63** with (*S*)-prolinamide derivatives of 1,4-dihydronicotinamide such as **55** to **57** and ionic metal catalysts ($Mg(ClO_4)_2$, $ZnCl_2$ or $CoCl_2$).

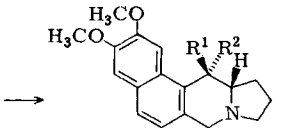
It is striking that the cyclic amino acid proline is the source of the chiral information in the particularly selective hydrogenation catalysts **53** to **57**, while the stereoselectivity of chiral catalysts derived from acyclic amino acids leads maximally to an optical yield of 23%.



Wiegrebe et al.[78] found that the (*S*)-proline derivative **66** is preferentially hydrogenated to **67a**.



(*S*)-Proline **66**

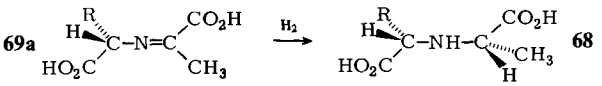


67a, R^1 = H, R^2 = OH
67b, R^1 = OH, R^2 = H

With $LiAlH_4$ or $NaBH_4$ (in 70% ethanol) the diastereomers **67a** and **67b** are formed in a ratio of 4:1 ($LiAlH_4$) or 2:1 ($NaBH_4$)[78]. The same diastereoselectivity was achieved by *Crooks* and *Rosenberg*[79] for the reduction of a keto function in a spiro compound derived from proline.

3.1.3. Asymmetric Hydrogenation of CN Double Bonds

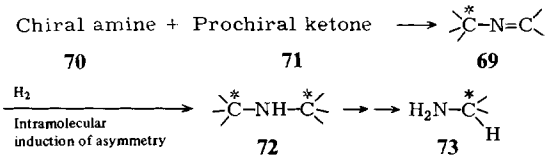
As early as 1939 *Knoop* and *Martius*[80] reported the synthesis of isooctopine **68**[81] by the hydrogenation of the Schiff base **69a** obtained from (*S*)-arginine and pyruvic acid.



69a **68**

R = $(CH_2)_3NHC(NH_2)=NH$

A whole series of such chemical transaminations from optically active amino acids[80] and amino acid derivatives



70 **71** **69** **72** **73**

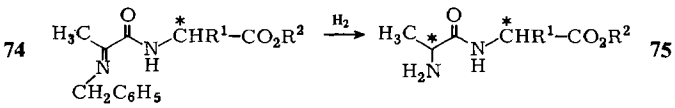
70 (esters[81], amino alcohols[82]) to carbonyl functions in **71** (α-keto acids[80], α-keto esters[81,82], ketones[81b]) are known today. In each case a Schiff base **69** is an intermediate.

It can be seen from a comparison of the asymmetric hydrogenations of CC and CN double bonds (see Tables 1 and 3) that considerably lower *ee* values were achieved in the latter.

In the reduction of the Schiff base **69** to the secondary amine **72**, an intramolecular transfer of asymmetry takes place. **72** can be converted by further reactions into a chiral primary amine **73**. The mechanism[80c] and the temperature dependence[80d] of such reactions have been investigated by *Harada et al.* Better optical yields are obtained in nonpolar solvents, such as benzene, than in polar solvents such as methanol[81c].

In the copper(II)-pyridoxal-catalyzed nonenzymatic transamination between (*S*)-alanine or (*S*)-phenylalanine and α-ketoglutaric acid formation of (*S*)-glutamic acid is preferred[83]. When (*R*)-alanine or (*R*)-phenylalanine is used, (*R*)-glutamic acid is formed preferentially[83].

The hydrogenation of the CN double bond in the Schiff bases **74** from achiral amides and chiral *N*-α-ketoacylamino acids[84] and their esters[85] takes place with intramolecular transfer of the chirality with concomitant cleavage of the benzyl group.



74 **75**

R^1 = CH_3, C_2H_5, i-C_3H_7, i-C_4H_9, $CH_2C_6H_5$, CH_2CO_2-i-C_4H_9
R^2 = H, CH_3, i-C_4H_9

The optical yield obtained in the hydrogenation **74**→**75** is between 17 and 64%[84,85]. On the other hand, *Iwakuma et al.*[71] and *Sunjic et al.*[86] obtained *ee* values of up to 98% in the reduction of cyclic imines.

3.2. CC Bond-Forming Reactions

In this section asymmetric CC bond-forming reactions are considered in which chiral amino acids and amino acid derivatives are used as auxiliary reagents:

Table 3. Asymmetric reduktion of Schiff bases **71**.

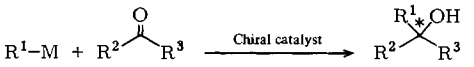
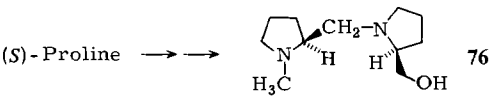
— reactions of the Pictet-Spengler type,
— electrocyclic reactions.

3.2.1. Reactions at the Carbonyl Group

1,2-Additions of Organometallic Compounds: Many efforts have already been made to prepare optically active alcohols by the asymmetric addition of organometallic compounds to carbonyl compounds. With few exceptions, the optical yields in the addition reactions of Grignard reagents[87], alkyllithium compounds[88], organocopper[89] and organocadmium[90] compounds in chiral solvents or in the presence of chiral auxiliary reagents (ligands) are quite low[91].



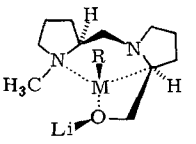
Since the prochiral substrate is only weakly bound to the chiral auxiliary reagent, the latter must be used in a considerable excess relative to the compound to be alkylated. In the addition of alkyllithium compounds to aldehydes, *Mukaiyama et al.*[92] used the (*S*)-proline derivative **76** as a new chiral ligand.



76

The reactions, which were carried out between 0 °C and −123 °C in various solvents[92], proceed in part with high optical yields (see Table 4).

Both nitrogen atoms as well as the free hydroxy group in **76** appear to be essential centers for coordination with the



77, M = Li, Mg

alkylmetal; the quasi-rigid complex **77** provides the right chiral environment for induction. Aside from alkyllithium compounds, only dialkylmagnesium compounds gave high optical yields of the alcohols[92b,93]. α-Ketoaldehydes can also be alkylated asymmetrically. For this purpose, these

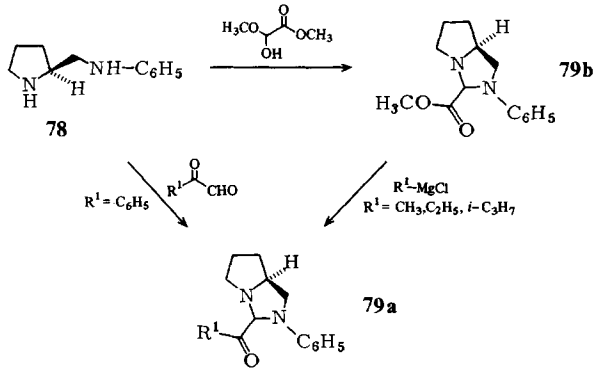


Table 4. Synthesis of optically active alkohols with the chiral ligands **76** [92]: R^1—Li + R^2—CHO → R^1R^2CHOH.

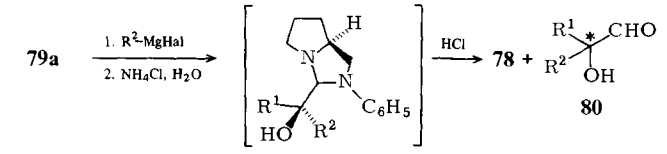
[a] R = H, trialkylsilyl or triarylsilyl groups. The highest chemical yield was obtained with the trimethylsilyl protecting group at −78 °C and the highest optical yield with the same group at −123 °C.

are converted with the (*S*)-proline derivative **78** into the aminals **79a**. A direct synthesis of these aminals is successful only with phenylglyoxal; aminals of alkylglyoxals must be prepared from the hemiacetal of the methyl glyoxylate and **78** *via* the intermediate **79b**[94].

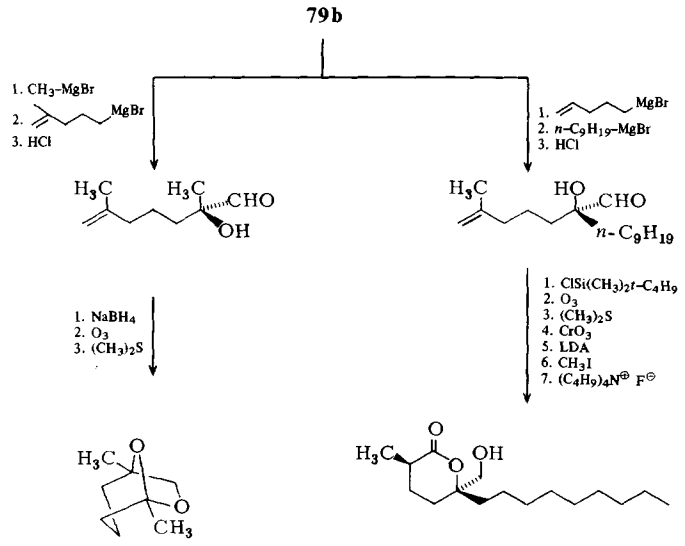
The subsequent Grignard reaction of **79a** furnishes the α-hydroxyaldehyde **80** in yields of 40 to 80% (*ee* = 75 to 100%)[94]. If, according to the CIP rules, R^1 has a higher



R^1 = CH_3, C_2H_5, i-C_3H_7, C_6H_5
R^2 = CH_3, C_2H_5, i-C_3H_7, $CH{=}CH_2$, C_6H_5

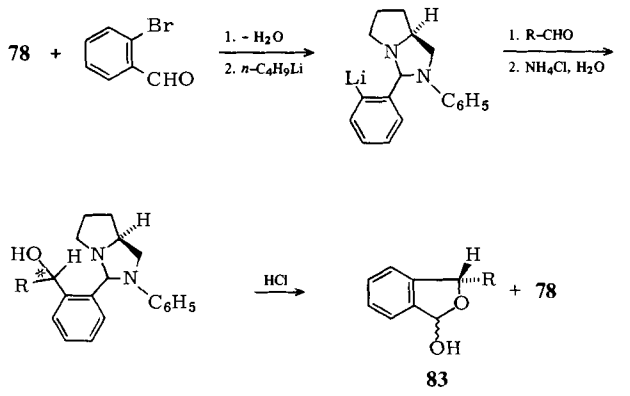
priority than R^2, then **80** has an (*S*)-configuration; otherwise it has an (*R*)-configuration.

This synthetic principle was used by *Mukaiyama et al.* in the asymmetric total synthesis of the pheromone (*R*)-frontalin **81**[95] and of the algal antibiotic (2*R*,5*S*)-malyngolid **82**[96]. In both cases the key reaction is the synthesis of an optically active α-hydroxyaldehyde. If the two Grignard reagents are added in the reverse sequence to **79b** in the synthesis of **81**, the (*S*)-frontalin is formed.

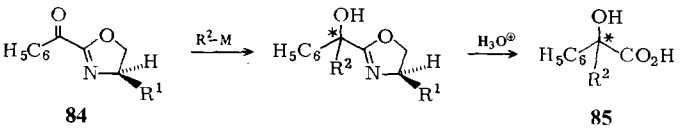


LDA = Lithium diisopropylamide

An asymmetric induction also takes place when achiral aldehydes are alkylated with chiral lithium compounds. *Mukaiyama et al.*[97] succeeded in realizing this type of reaction, again with the use of **78**. The optical yields of the lactols **83** lie between 20% (crotonaldehyde) and 90% (isobutyraldehyde). By oxidation of the lactol **83** ($R = n$-C_4H_9) with silver oxide it was possible to prepare (*S*)-3-butylphthalide, a constituent of the aroma of the celery plant, in 88% yield without racemization.

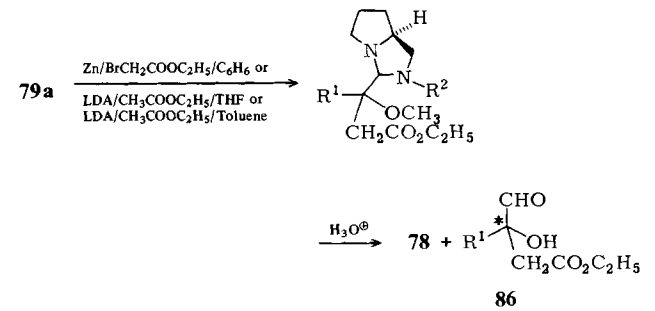


Meyers et al.[98] used the benzoyloxazolines **84**, which are derived from (*R*)-phenylglycine or (*R*)-phenylalanine, as chiral carbonyl compounds. Reaction with Grignard compounds and alkyllithium compounds yields, after hydrolysis, the optically active α-substituted mandelic acid derivatives **85** (*ee* ≤ 40%). The oxazolines **84** give substantially poorer optical induction than the proline compounds **76** and **78** used by *Mukaiyama et al.*



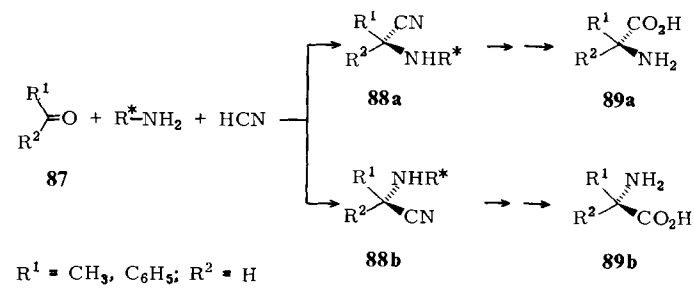
R^1 = C_6H_5, $CH_2C_6H_5$; R^2 = CH_3, C_2H_5, 4-CH_3-C_6H_4

Mukaiyama et al.[99] also carried out the alkylation of the chiral α-ketoaminals **79a** with various metal enolates of ethyl acetate. Astonishingly, even the alkylations with the zinc enolates, which were carried out in refluxing benzene, gave very high optical yields of substituted 3-formyl-3-hydroxypropionic esters **86**.



R^1 = CH_3, C_2H_5, i-C_3H_7, C_6H_5; R^2 = C_6H_5, 2-CH_3O-C_6H_5

Asymmetric Strecker Syntheses are characterized by the reaction of a carbonyl component **87** with an optically active amine and hydrocyanic acid to preferentially form one



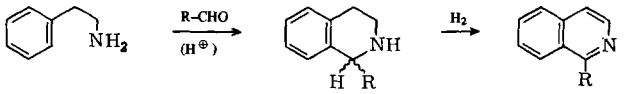
R^1 = CH_3, C_6H_5; R^2 = H

of the two diastereomeric aminonitriles **88a** or **88b**. To prepare the chiral amino acids **89a** or **89b**, **88a** or **88b** is hydrolyzed with mineral acids, whereupon R* is cleaved.

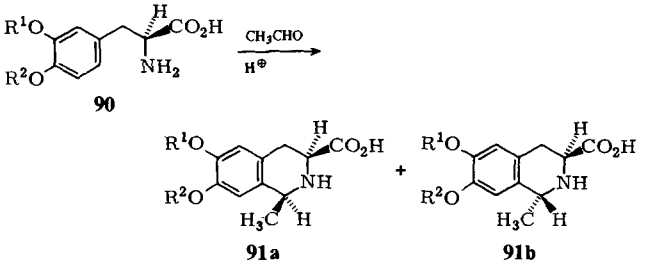
The most commonly used chiral amine in the asymmetric Strecker synthesis is α-phenylethylamine[100]. Amino acid derivatives have also been used quite successfully as chiral amines. (*S*)-*tert*-Butylglycine *tert*-butyl ester has proved to be an especially good source of chiral information, the optical yields obtained with it amounting to up to 96.5%. The best results are obtained in nonpolar solvents such as *n*-hexane[101].

The use of the asymmetric Strecker synthesis in the preparation of other chiral products has been dealt with by *Achiwa* and *Yamada*[103], and *Harada* and *Okawara*[102, 104], and reviewed by *Morrison* and *Mosher*[105]. In all of these cases an amino acid derivative is used as the chiral amine component which is responsible for the induction of asymmetry.

Reactions of the Pictet-Spengler Type: The "Pictet-Spengler reaction" has long been used in heterocyclic chemistry for the synthesis of the isoquinoline ring system; the tetrahydroisoquinoline intermediate here is a racemate.

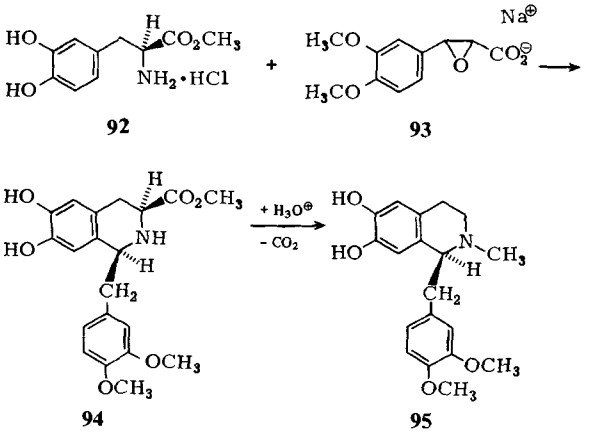


Phenylalanine and tryptophan derivatives possess a β-arylethylamine structure and can therefore take part in reactions of this type with aldehydes. The phenylalanines give rise primarily to tetrahydroisoquinolinecarboxylic acid derivatives and the tryptophans to tetrahydro-β-carbolines, which are of interest as starting compounds for alkaloid syntheses. Such carbolines were synthesized by *Snyder et al.*[106] as early as 1948, but from racemic tryptophan. In 1972, *Brossi et al.*[107] reported a Pictet-Spengler condensation of (*S*)-Dopa **90** and of its *O*-alkyl derivatives with acetaldehyde which occurred with asymmetric induction. This gave rise predominantly to the tetrahydroisoquinolinecarboxylic acids **91a** ($de \leq 80\%$) in which the carboxyl and methyl groups are in the *cis* position to one another. The absolute configuration of the products was established by X-ray structure analysis. The optically active center of the amino acid induces the configuration at C-1 with high stereoselectivity.



$R^1 = R^2 = H, CH_3$

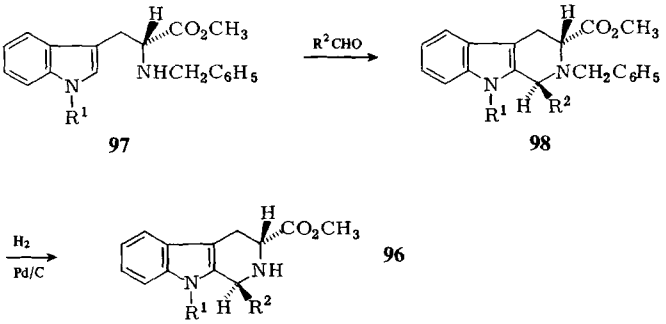
Condensation of (*S*)-dopa methyl ester hydrochloride **92** with the carboxylate **93** (precursor of 3,4-dimethoxybenzaldehyde) gives the tetrahydroisoquinoline **94** ($ee = 76\%$)[108], which, after decarboxylation (*i.e.* removal of the original asymmetric center), is converted into (*S*)-laudanosine **95**[109].



(*R*)-Laudanosine[110] and (*S*)-reticuline[111] have been prepared by the same method. Syntheses of 8- and 13-methylberberine alkaloids starting from **91a** ($R^1 = R^2 = H$) have been reported by *Rapoport et al.*[112].

The interest in β-carboline alkaloids became particularly acute after the discovery of their pharmacological activity in syndromes such as alcoholism and mental illness[113]. The pronounced sedative, analgesic, and antidepressant properties of 1,3-disubstituted 1,2,3,4-tetrahydro-β-carbolines stimulated further investigations in this sector[114].

Cook et al.[115] were the first to obtain the *trans*-1,3-disubstituted β-carbolines **96** practically stereospecifically by condensing *N*-benzyltryptophan methyl ester **97** with aldehydes. The benzyl group could subsequently be removed hydrogenolytically. This exclusive formation of the *trans* isomers can be ascribed to the steric effect of the *N*-benzyl group, for a *trans* arrangement of the substituents in the 1,3-position in **98** leads to a pronounced decrease in the steric hindrance.



R^1 = H, CH_3; R^2 = C_2H_5, *cyclo*-C_6H_{11}, 2-HO-C_6H_4

3.2.2. Reactions at the α-C Atom of Carbonyl Groups

Alkylation of Imino- and Enamino Compounds: Enantioselective CC bond formation in the α-position of prochiral carbonyl compounds is one of the oldest fields of application of asymmetric syntheses. As pointed out by *Stork et al.*[116], the alkylation of an imino anion is one of the best

methods for the α-alkylation of ketones. If a chiral amine is used for the synthesis of the imine, the alkylation process can be carried out enantioselectively.

Horeau et al.[117] first reported as long ago as 1968 an enantioselective methylation of cyclohexanone *via* an optically active isobornylimine to 2-methylcyclohexanone (*ee* = 72%). *Kitamoto et al.*[118] used (*S*)-α-phenylethylamine and (*S*)-2-aminobutane as chiral amines but obtained optical yields of only between 6 and 30%.

The following deals only with those chiral amino compounds that are derived directly from amino acids[119].

The alkylation of cyclohexanone has been thoroughly studied as a model reaction. Generally, enamino compounds **99** of ketones are allowed to react with alkyl halides or α,β-unsaturated carbonyl compounds; the enamine **100** is prepared directly from **99** with chiral secondary amines (Scheme 1, route A). A "metalloenamine" **101** can also be synthesized from chiral imines by metalation (Scheme 1, route B). The primary amines used for the formation of imines must possess an oxygen function on a carbon atom adjacent to the asymmetric center so that the rigid chelate complex **101** is capable of forming.

A series of amines has been used (see Table 5), the best optical yields having been obtained with phenylalanine derivatives and *tert*-leucine *tert*-butyl ester **105** (see Table 5)[120].

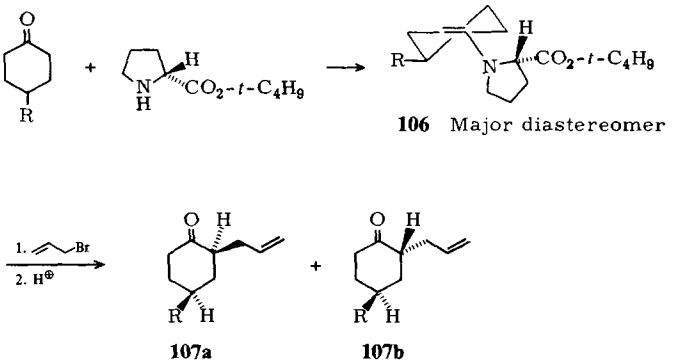
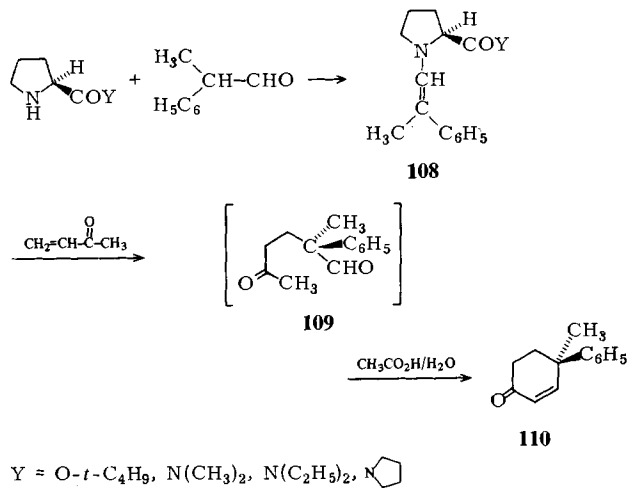
[a] M = Sn. [b] $R^3 = C_6H_5$.

The alkylation of the enamines **106**[121] with allyl bromide gives the 2-allylcyclohexanones **107** in poor yields. Compound **107b** is obtained in a diastereomeric excess of 74%.

The enamine **108** reacts with methyl vinyl ketone to give the 1,5-dicarbonyl compound **109** which, on treatment



with aqueous acetic acid, cyclizes to **110**. Optical yields of up to 49% have been achieved[122, 123].



108

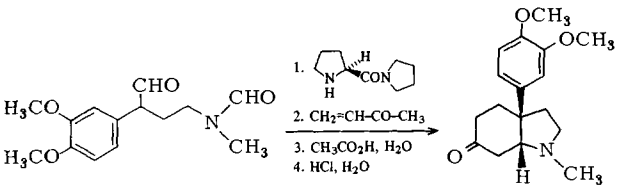
109

110

Y = O-*t*-C_4H_9, $N(CH_3)_2$, $N(C_2H_5)_2$, N⬡

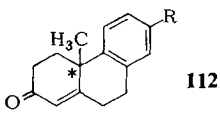
In 1969 *Yamada* reported for the first time the alkylation of enamines **100** (Y = OMe, OEt, O*t*Bu) derived from (*S*)-proline esters (Scheme 1, route A)[124a]. Activated olefins such as acrylonitrile and methyl acrylate, and halides such as allyl bromide and ethyl bromoacetate were used as electrophiles[124]. The enamines **100** react in polar solvents such as alcohols and acetonitrile with acceptable chemical, but poor optical yields. In nonpolar solvents, on the other hand, the reactivity is low, but the enantioselectivity good. Of the proline esters, (*S*)-proline *tert*-butyl ester gives the best optical yields.

This reaction principle has been used successfully for the synthesis of (+)-mesembrine **111**[125, 126].



111

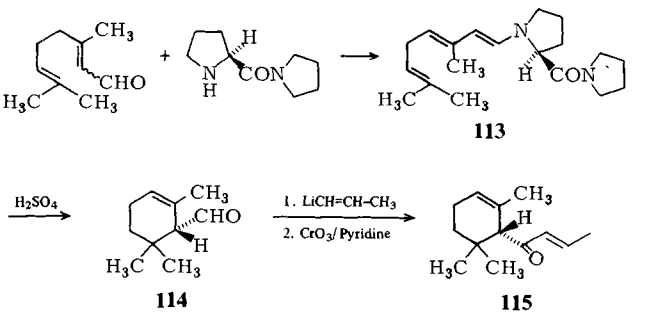
In more extensive investigations, in which the structures of the carbonyl compounds[122, 127] and of the proline derivatives[128] were widely varied, it was possible to raise the optical yields of 4,4-disubstituted cyclohexenones of the type **110** to a maximum of 54%. The reactivity-selectivity problem could not be overcome.



112

Phenanthrone derivatives **112** have been prepared from **110** and used as important intermediates for the synthesis of optically active diterpenes and steroids such as podocarpic acid[129], (*R*)- and (*S*)-$\Delta^{1,9}$-2-octalone[130], or vincamine[131].

By an acid-catalyzed cyclization of the optically active citralenamine **113** it was possible to obtain, in 33% optical



113

114

115

yield, (*R*)-α-cyclocitral **114**, from which (*R*)-(+)-*trans*-α-damascone **115** can be prepared[132].

[a] Total yield from the alkylation.

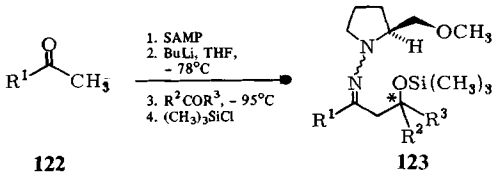
In 1976 *Enders et al.*[133] introduced a new chiral auxiliary, namely (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP) **116**, which can be easily prepared from (*S*)-proline. Aldehydes and ketones react with SAMP **116** to give the hydrazones **118**, which can be alkylated asymmetrically in the α-position[133,134].

Lithiation[135,138] of the SAMP hydrazones **118**, which are formed in high yields, leads to the chelate complexes **119**, which have (Z_{CN},E_{CC})-configurations, as has been demonstrated by ^{1}H- and ^{13}C-NMR studies[136,137].

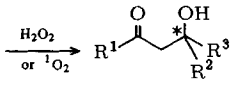
The liberation of the alkylated carbonyl compounds **121** from **120** with regeneration of **116** was carried out either with ozone at low temperatures or hydrolytically after methylation (Table 7).

(*S*)-(+)-4-Methyl-3-heptanone **121f**, the main alarm pheromone of the leaf-cutting ant *Atta texana*, could be synthesized almost enantiospecifically.

Regiospecific and enantioselective aldol reactions were also performed with SAMP **116**[139]. The lithiated hydrazones obtained from ketones **122** were alkylated with carbonyl compounds and the adducts then treated with chloro(trimethyl)silane; the resulting trimethylsilyl ethers **123** were finally oxidatively hydrolyzed to the chiral β-hydroxyketones **124** (*ee* = 31–62%).

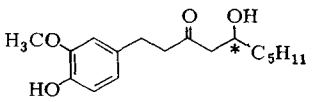


122 **123**



124

This method was used in the asymmetric synthesis of (−)-(*R*)- and (+)-(*S*)-gingerol **125**, the main flavor component of ginger, from acetone, vanillin, and hexanal in an optical yield of 36–39%[140].

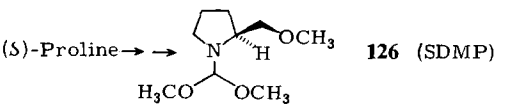


125

Enders and *Lotter*[141] recently reported a less stereoselective synthesis of α-hydroxyketones and vicinal diols using (*S*)-1-formyl-2-methoxymethylpyrrolidine. *Kolb* and *Barth*[142] employed the (*S*)-proline derivative (−)-(*S*)-1-dimethoxymethyl-2-methoxymethylpyrrolidine (SDMP) **126** as auxiliary chiral agent. The metalation of the amidines **127** leads to azaallyl anions homologous with **119** which, after alkylation, give α-substituted optically active amines or amino acids **128**.

Alkylation of Enolates: Chiral carboxylic acid esters or amides **129** can be converted by metalation into their enolates **130** which, after alkylation and hydrolysis, yield optically active α-alkylcarboxylic acids **131**.

Chiral α-alkylcarboxylic acids **131** have been synthesized by metalation and alkylation of chiral oxazolines[143] and ephedrinamides[144]. Optical induction is at its highest



126 (SDMP)

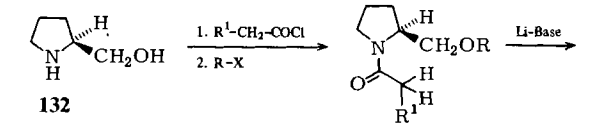
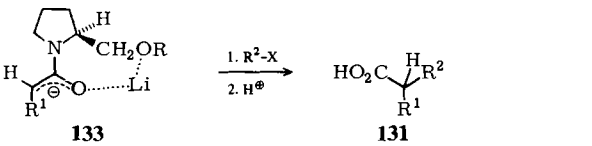
A* = Chiral moiety OR* or NHR*

active α-alkylcarboxylic acids by the asymmetric alkylation of chiral amide enolates **133** derived from (*S*)-prolinol **132**[145].



132

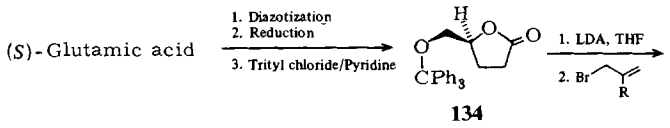


133 **131**

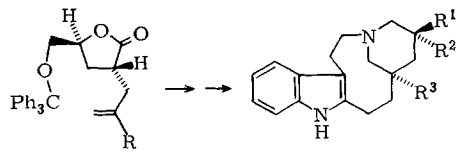
R^1 = CH_3, C_2H_5;
R^2 = CH_3, C_2H_5, *n*-C_4H_9, *i*-C_4H_9, $C_6H_5CH_2$, CH_2=$CHCH_2$

The carboxylic acids **131** were obtained in chemical yields of 78–96% and optical yields of 69–95%[145]. Methylation of the monoanion **133** (R = CH_3) gave the (*S*)-configuration of the α-alkylcarboxylic acids **131**, while the same reaction of the dianion **133** (R = Li) gave the (*R*)-configuration.

The chiral lactone alcohol derivative **134**[146], which can be readily prepared from (*S*)-glutamic acid, can be alkylated—with self-induction—to give the optically active 3-substituted lactone alcohols **135**, which are intermediates in the synthesis of the Pandaca alkaloids (+)-quebrachamine **136**, (−)-velbanamine **137**, and (+)-isovelbanamine **138**[147].

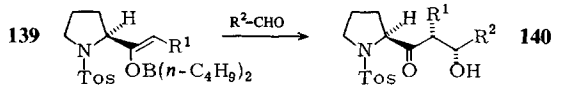


134



135 **136**, $R^1 = R^2 = H$; $R^3 = C_2H_5$
137, $R^1 = C_2H_5$; $R^2 = OH$; $R^3 = H$
138, $R^1 = OH$; $R^2 = C_2H_5$; $R^3 = H$

Evans et al.[148] achieved an enantioselective aldol condensation in optical yields of up to 97% on using the boryl enolates **139** prepared from (*S*)-proline. The corresponding reactions with lithium enolates gave lower optical yields.

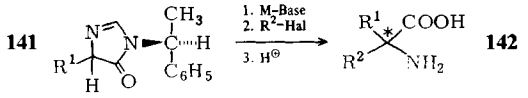


R^1 = H, CH_3; R^2 = C_6H_5, *i*-C_3H_7

Meyers and *Yamamoto*[149] recently reported enantioselective aldol reactions of high *threo*- or *erythro*-selectivity with the use of boryl azaenolates.

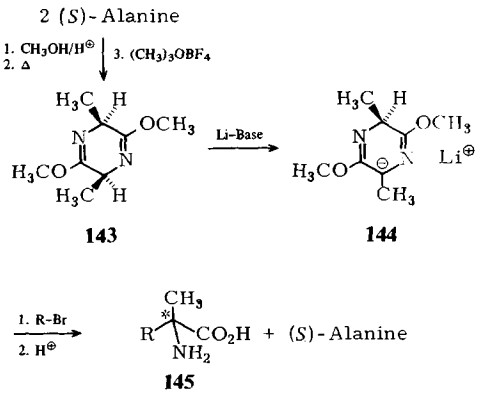
α-Alkylations of α-Amino Acid Derivatives: Because of the high biological activity of some representatives, α-alkyl-α-amino acids have recently attracted a great deal of interest.

Schöllkopf et al. synthesized α-alkyl-α-amino acids **142** by the alkylation of 1-chiral-substituted 2-imidazolin-5-ones **141**, which can be prepared from (*S*)-phenylethyl-



R^1 = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, $CH_2CH{=}CH_2$, CH_2–Aryl;
R^2 = CH_3, *i*-C_3H_7, *n*-C_4H_9, $CH_2CH{=}CH_2$, $CH_2CO_2C_2H_5$, CH_2–Aryl

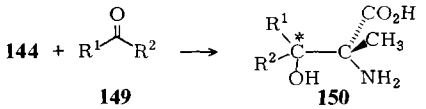
amides of α-amino acids and orthoformic esters. The optical yields of **142** are in many cases greater than 95%.



R = *i*-C_3H_7, $CH_2CH{=}CH_2$, CH_2–Aryl, $C(OH)(C_6H_5)_2$

A further development of this method is the base-induced alkylation of the lactim ether of cyclo-(*S*)-Ala-(*S*)-Ala **143**, which provides, after hydrolysis, the α-methyl-α-amino acids **145** (*ee* = 90—93%)[151].

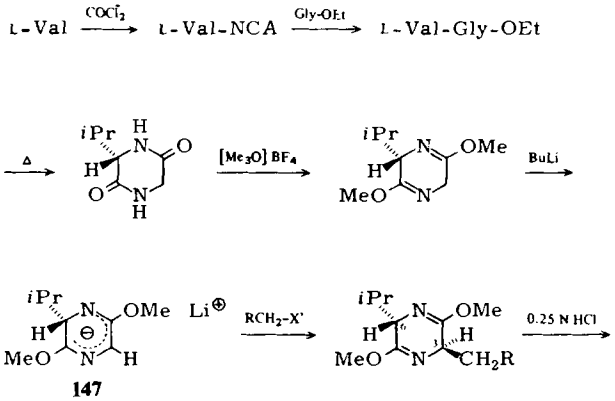
If the lithiated lactim ether **144** is reacted with carbonyl compounds **149** in an aldol condensation with subsequent hydrolysis, chiral α-methylserines **150** are formed with high optical yields. With aldehydes and unsymmetric ketones an additional chiral center appears in the β-position of the serines, albeit with lower induction[153].

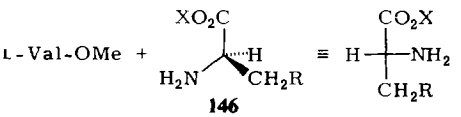


R^1 = H, CH_3, C_6H_5, 4-CH_3O–C_6H_4; R^2 = H, CH_3, C_6H_5

Starting from (*S*)-valine, *Schöllkopf et al.*[152] were able to synthesize a series of β-alkylated (*R*)-alanine derivatives **146** in high chemical and optical yields.

To explain the induction of asymmetry, the above mentioned authors[152] assumed that the lithium compound **147** contains a planar dihydropyrazine anion in which one diastereotopic side is quite effectively screened by the iso-





NCA = *N*-Carboxyanhydride, X = CH_3, H

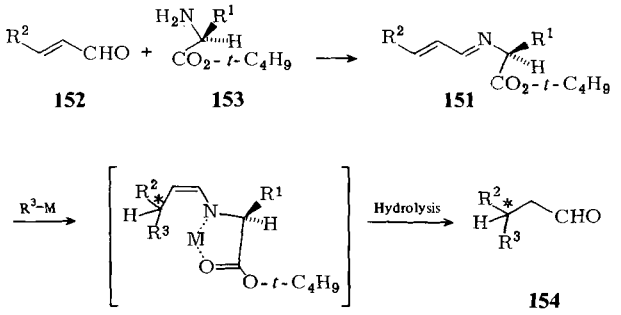
propyl group. The structure **148** is postulated for the more favorable of the two transition states.

3.2.3. Reactions at the β-Carbon Atom of Carbonyl Groups

Michael-Additions: The most important application of this type of reaction is CC bond formation β to a carbonyl function by the addition of carbanions to α,β-unsaturated carbonyl compounds, which are readily accessible *via* aldol or ester condensations. Asymmetric Michael additions have also been known for some time. Thus, as long ago as 1973 a synthesis of (*R*)-3-phenylbutyric acid was presented in which the decisive step is the asymmetric Michael addition of diethyl malonate to an optically active vinyl sulfoxide[154]. On addition of β-dicarbonyl compounds, α-nitrosulfones, and α-nitro esters to methyl vinyl ketone in the presence of catalytic amounts of the alkaloid (−)-quinine enantiomeric excesses of up to 68% were achieved[155]. *Meyers* and *Whitten* synthesized 3-substituted alkanecarboxylic acids, mostly in over 90% optical yield, by addition of organolithium reagents to chiral oxazolines[156]. *Mukaiyama et al.*[157] obtained 3-substituted alkanecarboxylic acids, in some cases with almost quantitative optical purity, by the addition of Grignard reagents or lithium dialkylcuprates to chiral 1,4-oxazepine-5,7-diones.

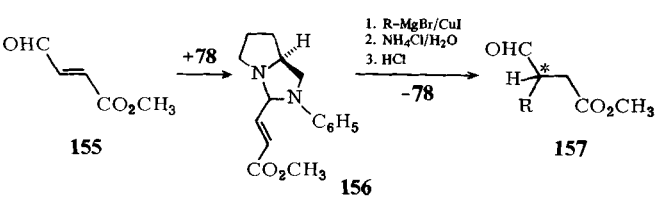
The first asymmetric Michael addition with amino acid derivatives was carried out by *Koga et al.*[158]. They obtained aldehydes **154** (*ee* ≤ 98%, yield *ca.* 50%) substituted in the 3-position by the 1,4-addition of carbanions to chiral, α-β-unsaturated aldimines **151** prepared from α,β-unsaturated aldehydes **152** and α-amino acid *tert*-butyl esters **153**. This method has also been used for the preparation of 2-substituted cycloalkane-[159a] and 1-methylcycloalkanecarbaldehydes[159b] (*ee* = 82–93%).



152 **153** **151** **154**

M = K, Mg
R^1 = *i*-C_3H_9, *i*-C_4H_9, *t*-C_4H_9; R^2 = CH_3, C_6H_5 ;
R^3 = C_2H_5, *n*-C_4H_9, *cyclo*-C_6H_{11}, $CH(CO_2C_2H_5)_2$, C_6H_5, $(CH_3)_2C{=}CH(CH_2)_2$

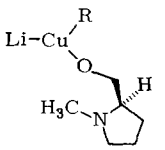
Mukaiyama et al.[160] were able to react (*S*)-2-anilinomethylpyrrolidine **78** with methyl 3-formylacrylate **155** to give the chiral aminals **156**. These react with Grignard compounds to give high optical yields of the methyl 3-alkyl-3-formylpropionates **157** (*ee* ≤ 93%).



155 **156** **157**

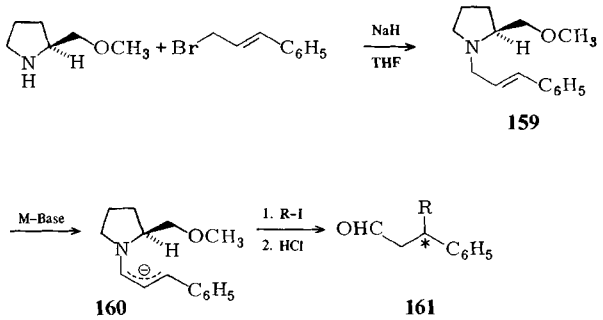
R = C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, *n*-C_5H_{11}, $C_6H_5CH_2$

In the reversed mode of operation, addition of chiral organocuprates of type **158** to achiral α,β-unsaturated carbonyl compounds, lower optical yields were obtained. Thus, in the reactions of 2-cyclohexenone and of 4-phenylbut-3-en-2-one with **158** (R = *n*-C_4H_9), optical yields of 5 and 15%, respectively, were obtained[161]. Methylation of 1,3-diphenyl-2-propen-1-one with **158** (R = CH_3) gave (*S*)-1,3-diphenyl-1-butanone (*ee* = 68%)[162].



158

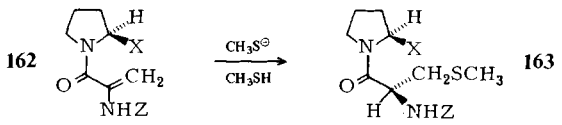
Ahlbrecht and *Enders et al.*[163] metalated the chiral allylamines **159**; the resulting chiral homoenolates **160** were then alkylated. Subsequent hydrolysis furnished the β-substituted aldehydes **161** (*ee* = 64–67%).



159 **160** **161**

R = CH_3, C_2H_5, *i*-C_3H_7

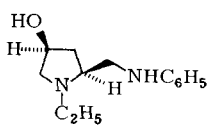
Aside from C-nucleophiles, other nucleophiles can also be added asymmetrically to α,β-unsaturated carbonyl compounds. While attempting the biomimetic formation of cysteine, *Schmidt et al.*[164] added thiolates to *N*-protected chiral α-aminoacrylic acid derivatives **162** (dehydropeptides). The optical yields of **163** were up to 90%.



162 **163**

X = $CONHCH_3$, $CONH_2$, $CON(CH_3)_2$; Z = $C_6H_5CH_2OCO$

An analogous asymmetric addition of thiolates to 2-cyclohexenone induced by catalytic amounts of the (*S*)-4-hydroxyproline derivative **164** has recently been described[165].

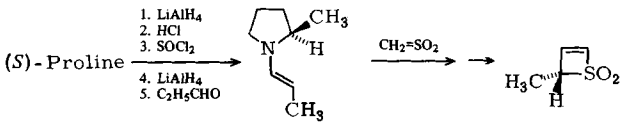


164

An asymmetric Michael addition has been described by *Kishi et al.* in the enantioselective total synthesis of the bacteriostatic gliotoxin[166].

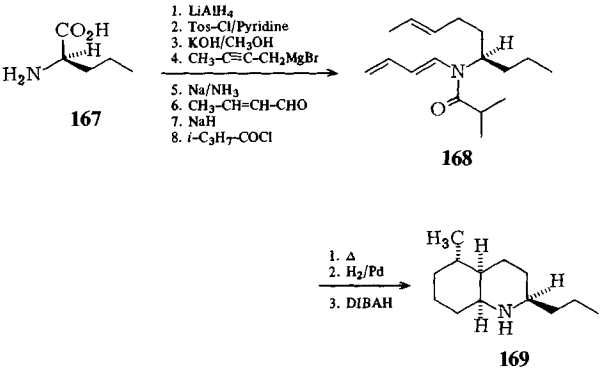
3.2.4. Cycloadditions

Synchronous cycloadditions, which show a high regioselectivity, are also enantio- or stereoselective if one of the reaction partners is chiral. *Paquette et al.*[167] obtained (*R*)-(−)-4-methylthiete *S,S*-dioxide **166** in 25% optical yield in the [2+2]-cycloaddition of thioformaldehyde *S,S*-dioxide to the enamine **165**.



165 **166**

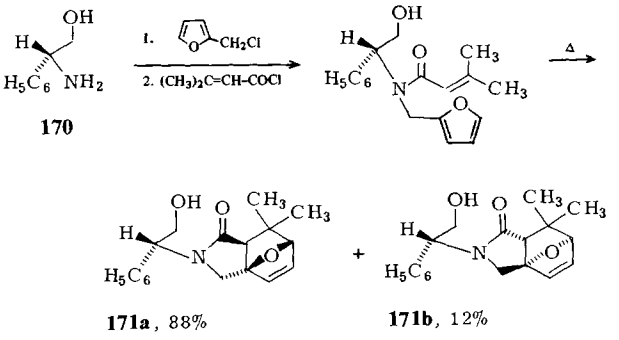
Asymmetric Diels-Alder reactions have been performed with variable success[168]. Especially high optical induction can be obtained in the intramolecular Diels-Alder reactions of chiral molecules. (2*R*)-Pumiliotoxin C **169** has been prepared from (*R*)-norvaline **167** (*ee* = 97%). Here the asymmetric center of the triene **168** controls the configuration at three carbon atoms[169].



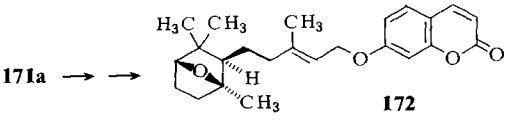
167 **168** **169**

Asymmetric Diels-Alder reactions also play a decisive role in the synthesis of cytochalasins. The primary chiral information is carried by (*S*)-alanine and (*S*)-phenylalanine in this case[170].

Mukaiyama et al.[171] have reported the total synthesis of the sesquiterpene (+)-farnesiferol C **172**, starting from (*R*)-phenylglycinol **170**. The key step of this synthesis is likewise an intramolecular Diels-Alder reaction with high asymmetric induction. In this case the two cycloadducts **171** are formed in a diastereomeric ratio of 88 : 12.



170 **171a**, 88% **171b**, 12%

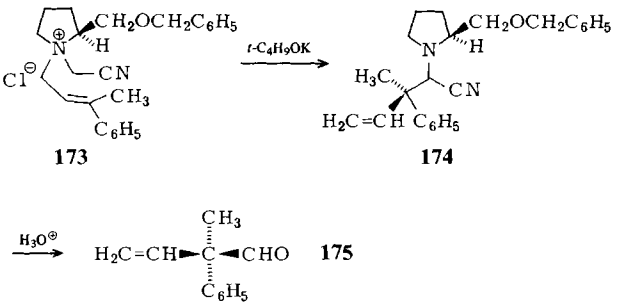


172

Danishefsky et al.[172] have succeeded in synthesizing pretyrosine, the biosynthetic precursor of (*S*)-tyrosine, by a [4+2]-cycloaddition using an (*S*)-pyroglutamic acid derivative. *Grigg* and *Kemp et al.*[173] have reported an asymmetric variation of a 1,3-dipolar cycloaddition in which phenylglycine was used as the source of the chiral information.

3.2.5. [2,3]-Sigmatropic Rearrangements *via* Chiral Ammonium Ylides

The asymmetric [2,3]-sigmatropic rearrangement of (*S*)-(*E*)-**173**, a derivative of (*S*)-proline, gave the (*E*)-aminonitrile **174**, which was saponified to (+)-2-methyl-2-phenyl-3-butenal **175** (*ee* = 90%)[174]. If the benzyloxymethyl moiety in **173** is replaced by a methyl group, the optical yield of the chiral aldehyde **175** falls drastically[174].



173 **174** **175**

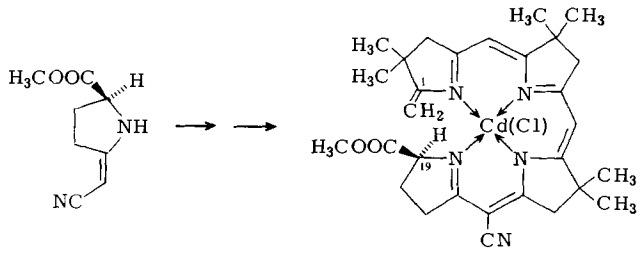
3.2.6. β-Lactam Syntheses

The stereoselective synthesis of β-lactams, particularly penicillins and cephalosporins, has been intensively investigated for many years because of the great pharmacological importance of these substances. A detailed discussion of the numerous β-lactam syntheses in which the induction of asymmetry by chiral amino acids plays a role would be beyond the scope of this contribution. Therefore, the reader is referred to reviews[175, 176] and the more recent original publications[177] specifically dealing with this topic.

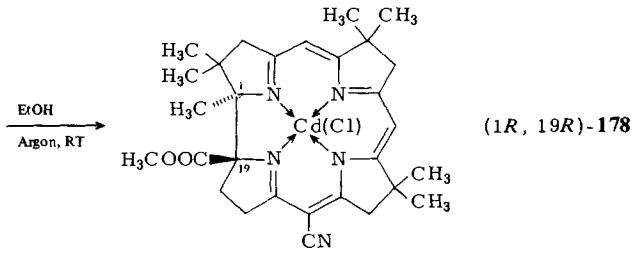
3.2.7. Photochemical Cyclization

In investigations on the biosynthesis of corrinoids the central theme is the nature of the ring-closure reaction by means of which the characteristic direct coupling of rings A and D in the corrin ligand takes place. *Eschenmoser et al.*[178] have shown that a transformation from the porphyrinogen structure type to that of the corrins can occur without the participation of an external reducing agent.

The synthesis of the corrinate **178** starts from the (*S*)-pyroglutamic acid derivative **176**; the key reaction is a photochemically induced A/D-secocorrin→corrin cycloisomerization of the secocorrinate **177**. No optical yield is reported. A comparison of the spectrum with the spectra of natural corrinoids leaves no doubt of the (*R*)-configuration at C-19.



176 (19S)-177

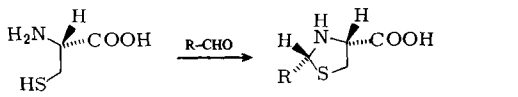


(1R, 19R)-178

3.3. Other Reactions Taking Place with the Transfer of Asymmetry

3.3.1. Stereoselective Addition of NH- and SH-Compounds to Carbonyl Groups

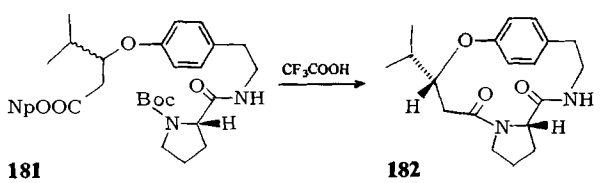
The vitamin (+)-biotin has been synthesized from naturally occurring hexoses[179] or pentoses[179] or from (*R*)-cysteine **179**. When **179** is used as starting material, it is first condensed with benzaldehyde to give the sterically pure product **180a** in almost quantitative yield. Reaction of **179** with 4-methylbenzaldehyde also occurs stereospecifically to yield **180b**[181]. These results are consistent with the configuration found previously for the thiazolidines formed from (*S*)-penicillamine and various aldehydes[182].



179

180a, R = C_6H_5
180b, R = 4-CH_3-C_6H_4

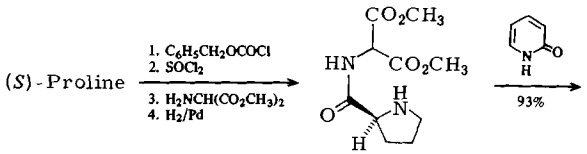
The particular suitability of proline as a carrier of chiral information to other centers of complex molecules will be outlined on the basis of three examples[183]. In the peptide cyclization of **181**, the peptide **182** is obtained with high stereoselectivity by the intramolecular optical induction of the (*S*)-proline moiety[183a].



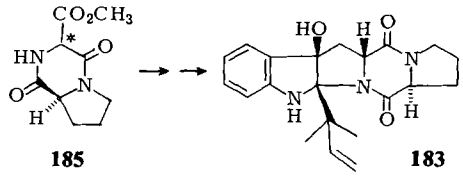
181 **182**

Np = *p*-NO_2-C_6H_4
Boc = *t*-C_4H_9O-CO

In the asymmetric total synthesis of brevianamide E **183** *Kametani et al.*[183] started from natural (*S*)-proline. An important step in this synthesis was the stereospecific cyclization of **184** with the formation of the diketopiperazine **185**.

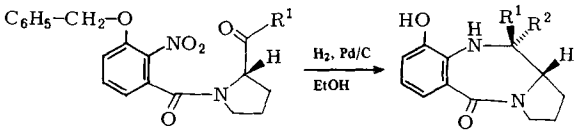


184



185 **183**

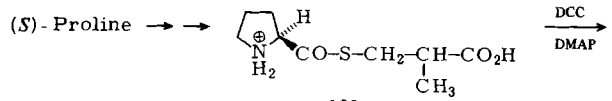
Excellent stereoselectivity was observed by *Mohr*[183c] for the cyclization of the (*S*)-proline derivative **186** to the benzodiazepine system **187**. The cyclization occurs after hydrogenation of the nitro-group to an amine.



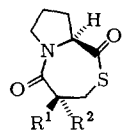
186, R^1 = 3-Indolyl

187a, R^1 = H; R^2 = 3-Indolyl(92%)
187b, R^1 = 3-Indolyl; R^2 = H(8%)

The thiol ester **188** cyclizes upon treatment with dicyclohexylcarbodiimide (DCC) and 4-dimethylaminopyridine (DMAP) in dichloromethane at room temperature to a mixture of the diastereomeric bicyclic compounds **189a** and **189b** (7:3)[184]. Compound **189a** could acquire pharmacological importance as an antihypertensive agent.



188



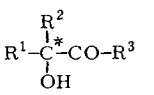
189a, R^1 = CH_3, R^2 = H
189b, R^1 = H, R^2 = CH_3

Shin et al. recently reported on the stereoselective addition of chiral α-amino acids to β,β-dibromo-α-imino acids[185].

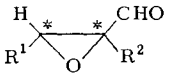
3.3.2. Asymmetric Halolactonization

An asymmetric variation of the well-known halolactonization reaction[187] has recently been reported by *Terashima et al.*[186]. This new, highly stereoselective synthesis permits the preparation of intermediates for chiral α,α-disubstituted α-hydroxycarboxylic acids **190**[186c], α-hydroxyketones **191**[186c], and functionalized epoxides **192**[186d].

The source of the chiral information is consistently amino acids. Particularly high stereoselectivity has been found with the use of chiral proline.

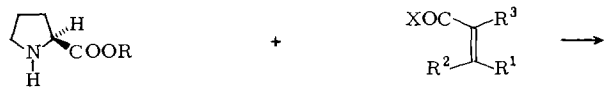


190, R^1, R^2 = Alkyl or Aryl
R^3 = OH
191, R^1, R^2 R^3 = Alkyl or Aryl



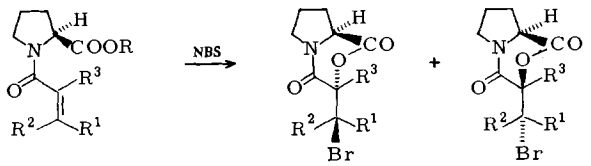
192, R^1, R^2 = Alkyl or Aryl

The reactions of (*S*)-proline or (*S*)-proline ethyl ester with appropriately substituted acrylic acids **193a** or acrylic acid chlorides **193b** yield α,β-unsaturated *N*-acyl-(*S*)-prolines **194**. The halolactonization of **194** with *N*-bromosuccinimide (NBS) leads to formation of a mixture of diastereomeric lactones **195** and **196**, **195** being formed preferentially (*de* > 90%)[186].



(*S*)-Proline, R = H
(*S*)-Prolineethyl ester, R = C_2H_5

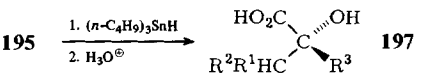
193a, X = OH
193b, X = Cl



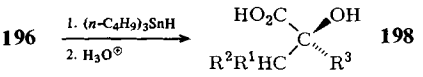
194 **195** **196**

R^1 = H, CH_3, n-C_6H_{13}, C_6H_5; R^2 = H, CH_3; R^3 = CH_3

The intramolecular transfer of the asymmetry of the chiral center of (*S*)-proline to the new asymmetric center in **195** or **196** proceeds *via* a bromonium ion[186c]. Debromination[188] of **195** and **196** with tri-*n*-butyltin hydride followed by hydrolysis leads to the chiral α-hydroxycarboxylic acids **197** and **198**, respectively, and (*S*)-proline.



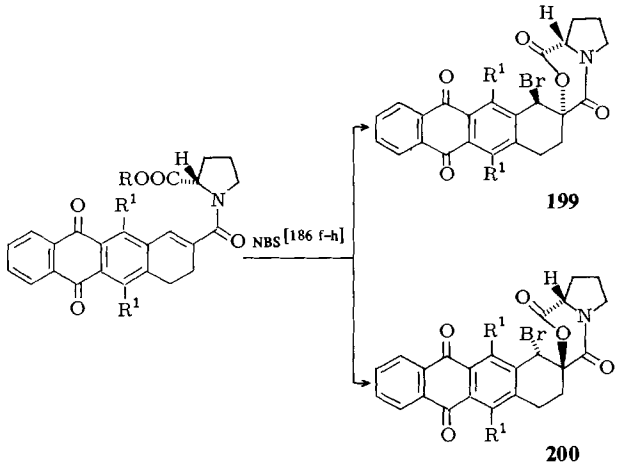
195 **197**



196 **198**

When a mixture of the diastereomers **195** and **196** was converted into the epoxide **192** with simultaneous reductive removal of the (*S*)-proline function, **192** was obtained in optically active form[186d].

One particularly interesting aspect is the application of the (*S*)-proline-induced asymmetric halolactonization to the stereoselective synthesis of some anthracycline antibiotics. The bromolactones **199** and **200** are formed in the ratio 96:4[186g]. If the (*S*)-proline in the α,β-unsaturated *N*-acyl-(*S*)-prolines **194** is replaced by other amino acids such as (*S*)-phenylalanine, *N*-benzyl-(*S*)-phenylalanine, or 1,2,3,4-tetrahydroisoquinoline-3-(*S*)-carboxylic acid, the induction of asymmetry in the halolactonization is smaller, or no lactone at all is produced[186c,e].



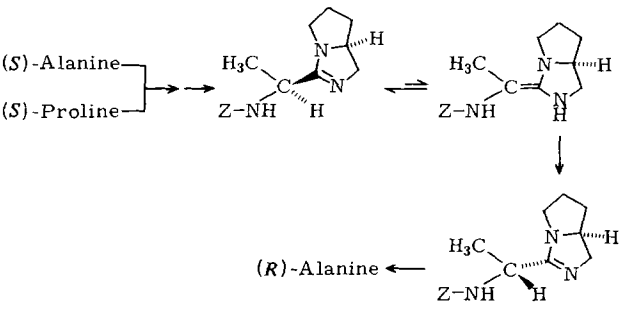
199

200

R = H, C_2H_5; R^1 = H, OH, OCH_3

3.3.3. Equilibration and Stereoselective Protonation

Imidazolines **201**, prepared from (*S*)-alanine and (*S*)-proline, gave (*R*)-alanine on hydrolysis. This can be best explained in terms of epimerization and stereoselective protonation with induction by the chiral center originating from (*S*)-proline[189].



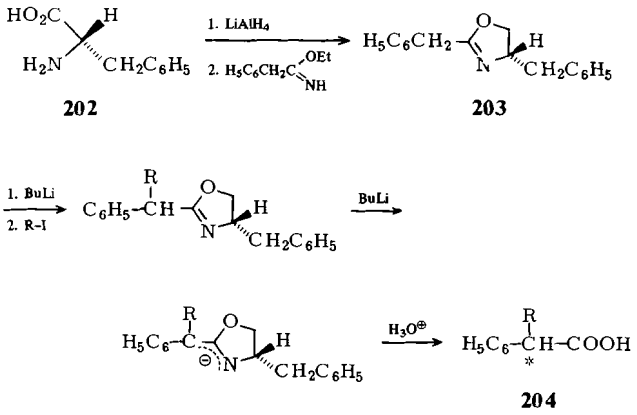
Z = $C_6H_5CH_2OCO$ **201**

The (*R*)-analine was obtained in an optical yield of up to 94%[189]. Nonnatural (*R*)-analine can, of course, also be obtained from racemic alanine in this way.

In the synthesis of chiral 2-phenylalkanecarboxylic acids **204** *via* chiral oxazolines **203**, (*S*)-phenylalanine **202** was used as the source of the chiral information[190].

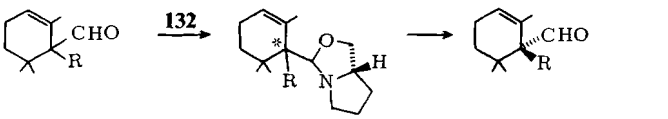
The carboxylic acids **204** were obtained in optical yields of up to 53%[190]. More effective than this is the asymmetric alkylation of chiral amide enolates based on (*S*)-prolinol **132**[145].

The chiral oxazolidine derivative **205a**, prepared from racemic cyclocitral **206a** and (*S*)-prolinol **132** in the presence of catalytic amounts of *p*-toluenesulfonic acid, gave, upon acid hydrolysis, (*R*)-cyclocitral (*S*)-**206a** in 19% optical purity[191].



R = CH_3, C_2H_5, *i*-C_3H_7, *n*-C_4H_9, *n*-C_5H_{11}

Analogously, (*S*)-6-hydroxycyclocitral (*R*)-**206c** has been obtained from racemic 6-benzoyloxycyclocitral **206b** (*ee* = 63%)[191].

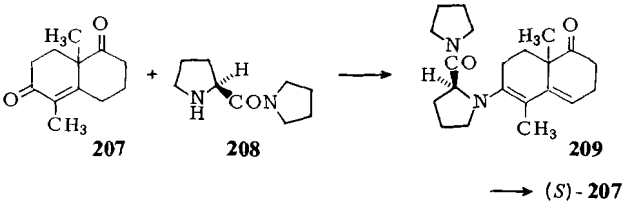


(*R*,*S*)-**206a**, R = H
(*R*,*S*)-**206b**, R = $OCOC_6H_5$

205a, R = H
205b, R = OH

(*R*)-**206a**, R = H
(*S*)-**206b**, R = OH

By heating the racemic dicarbonyl compound **207** with an equimolar amount of (*S*)-proline pyrrolidide **208**, the dienamine **209** was obtained, which, upon hydrolysis with hydrochloric acid, gave the diketone **207** in the (*S*)-configuration (*ee* ≤ 63%)[192].



207 **208** **209**

→ (*S*)-**207**

3.3.4. Stereoselective Acylation of Cyclic *meso*-Diols

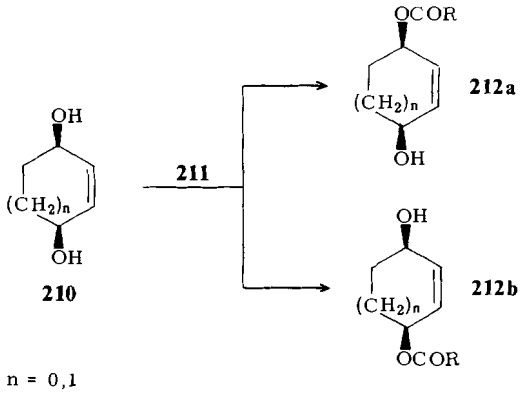
In the reaction of cyclic *meso*-1,3-diols **210** with *N*-protected phenylalanyl chlorides **211**, *Yamada et al.*[193] observed the preferential formation of one of the two possible diastereomeric monoesters **212**.

The stereoselectivity of the above acylation is not particularly good. The monoesters **212** partially ring-substituted by alkyl groups have been used for the synthesis of optically pure steroids[194] and prostaglandins[195].

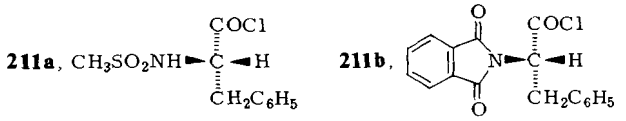
3.3.5. Stereoselective Epoxidation

A key reaction in the stereoselective total synthesis of dendrobatide toxin 251 D is the epoxidation of the (*S*)-proline derivative **213**, which is accomplished with a diastereomeric excess of more than 80%.

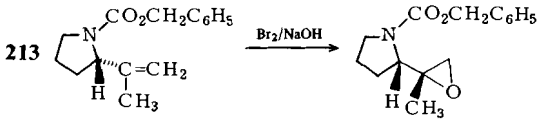
In the epoxidation of **213** with *m*-chloroperbenzoic acid no diastereoselectivity was observed[196b]. The stereoselective epoxidation of (*S*)-*N*-tosyl-3,4-dehydroproline with



n = 0,1



trifluoroperacetic acid has been investigated by *Kahl* and *Wieland*[197].



3.3.6. Synthesis of Chiral Phosphorus Compounds

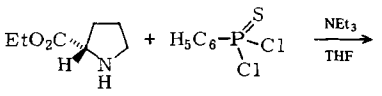
A series of chiral organophosphorus compounds **214** has been synthesized by *Koizumi et al.*[198], whereby amino acids were used as the source of the chiral information.

R^1 = CH_3, C_6H_5, OC_6H_5; R^2 = C_2H_5, *n*-C_4H_9, C_6H_5, OC_6H_5;
R^3 = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7

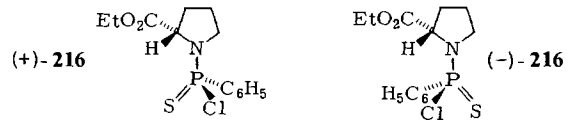
The authors do not give the absolute configurations for either the educts or **214**, but of the two chromatographically separable diastereomeric educts one is always formed preferentially because of the influence of the chiral center of the (*S*)-proline ethyl ester. The chiral, practically enantiomerically pure organophosphorus compounds **214** are obtained from the pure diastereomers by acid alcoholysis.

The reaction of phenylphosphonothioic dichloride **215a** with (*S*)-proline ethyl ester in THF/triethylamine at room temperature leads to a mixture of diastereomeric monochlorides **216** in 90% yield[198d]. After chromatographic separation, 48% of (+)-**216** and only 5% of (−)-**216** is isolated[198d].

Starting from (+)-**216**[198d], a series of optically active phosphorus(v) compounds could be synthesized by substitution of the chlorine atom attached to the phosphorus with OC_6H_5, OCH_3, and NH_2 groups. Walden inversion takes place in every case. By treatment with *m*-chloroper-



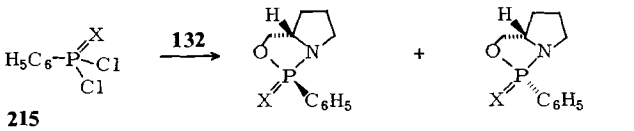
(*S*)-Proline ethyl ester **215a**



(+)-**216** (−)-**216**

benzoic acid the sulfur can be replaced by an oxygen atom with retention of optical activity. Finally, by acid alcoholysis the pyrrolidine moiety can be replaced by an alkoxy residue.

Koizumi et al.[198e] observed a remarkable diastereoselectivity in the reaction of (*S*)-prolinol **132** with **215a**. The absolute configuration of the resulting diastereomeric bicyclic compounds **217a** and **218a** was determined by NMR spectroscopy. The diastereoselectivity in the reaction of (*S*)-prolinol with **215a** was lower than that observed with the isoelectronic oxygen compound **215b**.



215

a, X = S; **b**, X = O

217a (35–45%) **218a** (40–45%)
217b (40–60%) **218b** (10–35%)

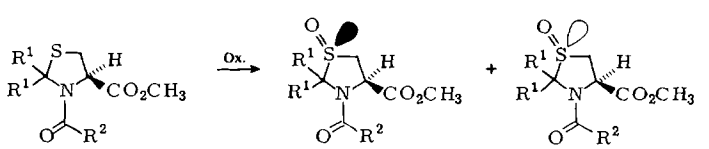
From the diastereomers **217** and **218**, which can be separated chromatographically[198g], numerous enantiomerically pure phosphorus(V) compounds were synthesized[198f,g]. In particular the base-catalyzed methanolysis as well as reactions with Grignard reagents were investigated.

3.3.7. Synthesis of Chiral Sulfur Compounds

In the reactions of optically active sulfides asymmetry is produced in the *S*-substituted diastereomeric compounds formed[199].

El = Electrophile

Optically active cysteine and methionine derivatives could be oxidized, with asymmetric induction, to the sulfoxides. Thus, (*S*)-methionine reacts stereospecifically with H_2O_2[200a] or gold(III) compounds[200b] to give the (*S,S*)-methionine *S*-oxide. In the oxidation of the chiral thiazolidine-4-carboxylic acid methyl esters **219** the diastereomeric sulfoxides **220a** and **220b** are formed (1 : 1.5)[201].



219 **220a** (60%) **220b** (40%)

R^1 = H, CH_3; R^2 = CH_3, C_6H_5

3.3.8. Miscellaneous

Recent literature describes a series of further investigations in which the chirality of amino acids or amino acid derivatives is used to prepare optically active natural products. Transfer of the chirality from the amino acids to a newly arising asymmetric center occurs one or more times in the course of these syntheses. Examples of such syntheses of natural products are the preparation of sugars from (*S*)-alanine[202], (*R*)-threonine[203], or (*S*)-glutamic acid[204], and syntheses of alkaloids[205], terpenes[206] and peptide derivatives[207].

Optically active micellar systems have been used to influence the stereochemical course of reactions through the formation of micelles. In particular, control of the hydrolysis reactions of racemic esters by chiral micellar structures based on histidine, phenylalanine, alanine and cysteine has been investigated[208].

4. Concluding Remarks

Nature provides us with a wide range of optically active natural compounds ("chiral pool"); these can be used as substrates in stereoselective syntheses. Particularly frequent use is made here of sugars and naturally occurring hydroxycarboxylic acids such as tartaric acid and malic acid. In recent years, however, increasing use has been made of amino acids as educts in asymmetric syntheses. The reasons for this lie in the great structural variety and ready availability of this class of compounds. Particularly attractive here is that—other than in the case of sugars and hydroxycarboxylic acids—usually both optical antipodes are industrially available.

Strikingly high selectivities have been achieved in asymmetric syntheses with proline or proline derivatives, probably because of the rigidity of the five-membered ring.

The amino acids hitherto used principally for peptide syntheses will in future become the subject of ever-increasing attention as the starting materials for chiral target molecules with widely variable structures. The processes in which achiral precursors are converted with the aid of catalytic amounts of an optically active amino acid into a stereoisomer of the target molecule seem particularly attractive.

Natural *versus* Indexing Language in Chemical Documentation

By Robert Fugmann*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

In any literature search one must be able to *predict* which modes of expression have been used to represent the concepts of interest in the search file. It is these lingual expressions which will be looked up or will constitute the search parameters in a mechanized search. In the case of *general* concepts and statements, uncontrolled natural language lacks the required representational predictability, as is demonstrated, for example, for classes of chemical compounds and for types of reactions. Hence, considerable loss of relevant information is bound to occur in searches for these concepts in free text files, regardless of how advanced a computer program may be. By restricting the modes of expression as is achieved by means of an indexing language and its reliable employment, predicability is increased and, consequently, information loss is drastically reduced.—In contrast, the modes of expression for *individual* concepts (*e.g.* individual chemical substances, authors, institutions) are, by their very nature, often sufficiently predictable in uncontrolled natural language. In these cases, the value of translating them into indexing-language expressions is often questionable. This holds true in particular if an indexing language does not (yet) provide adequate expressions to represent the concepts, and also in the case of ambiguous natural language expressions. Here, preserving the original, uncontrolled terms in the search file is advisable, at least in addition to an attempted translation into the indexing language.—The weaknesses of uncontrolled natural language files become apparent only at a rather late stage in the continual expansion of an information system. In its early stages the necessity of predictability is reduced through the effectiveness of human memory and the—initially—relatively high homogeneity of the experts' linguistic usage during that short period of time. Furthermore, loss of relevant information as a consequence of the lack of predictability will at first be minimal and will not yet be noticed as a steadily increasing source of search failure. Nor does the steady rise in costs for excogitating and phrasing queries with more and more alternatives become apparent at this stage. It is largely for these reasons that uncontrolled natural language systems have unjustifiably frequently been preferred. The typical weaknesses and strengths of both kinds of language suggest combining them so that their inherent strengths are retained and utilized as far as possible.

1. Introduction

When one sets out for searching the literature relevant to a topic of interest one must excogitate a keyword—or several of them—for this topic. It is hoped that under such a keyword relevant references are listed in an index, or one uses these keywords as search parameters in a mechanized file which comprises the literature of the subject field.

It will always be appreciated by an inquirer if these key-

[*] Dr. R. Fugmann
Wissenschaftliche Dokumentation, Hoechst AG
D-6230 Frankfurt am Main 80 (Germany)

words originate from his familiar expert language and when he need not subject himself to restrictions in his lingual usage. This is possible in printed indexes and also in many computerized search files. Any kind of artificial, "indexing-language" mode of expression is felt more cumbersome because it must be learnt beforehand and continually exercised. These expressions are well known in library classification and in certain computerized files as well. Obviously, however, simplicity and convenience are not the only factors to take into consideration when designing or acquiring an information system. Any system should be rejected which does not enable one to attain the goal of sufficiently accurate literature searches, however cheap and simple the system may be.

The necessity or dispensability of indexing or natural language in information systems has often been investigated, but the results and conclusions have been contradictory (cf. *e.g.* [1-23]). Some workers postulate that there is nothing easier and more effective than entering the original texts into the file without any modification. One should be able to answer any conceivable inquiry using such a file, it is argued, because nothing will be lost and nothing will be added, and, moreover, the expensive translation into an indexing language will be circumvented. Other workers hold against the ambiguity of the free lingual usage of the authors, the context-dependence of the meaning of words and the incessant change in their meaning with the course of time. All this impairs the accuracy of the searches in an author-lingual file. Most important, however, unrestricted modes of expression often lack that peculiar property which is crucial if the language is not used for conversation and the mere communication of ideas but instead for the purpose of directed searching through a file of documents: We are dealing here with the *predictability* of the modes of expression for the concepts in the search file[5,6,13,24,25]. It is inherent in indexing languages that they provide this predictability, particularly if they are employed sufficiently reliably. We shall investigate this topic in some detail in the following.

2. The Semantic Triangle

We shall base our considerations on a variant of the "semantic triangle" of *Ogden* and *Richards*[26] (cf. also [27-30]). The corners of the triangle are occupied by the "Referent", the "Concept" and the lingual "Expression" for the concept (Fig. 1).

By "referent" we mean everything about which one can make a meaningful statement[28]. A molecule, for example, is a concrete referent. One can say which atoms are contained in it and how they are connected with each other, and which biological and chemical properties it displays *etc.* An abstract referent is a chemical reaction or a property of matter.

"Concept" is taken as the imagined summarization of all meaningfull statements that can be made on a referent. In other words, the concept is the entirety of the essential features of a referent.

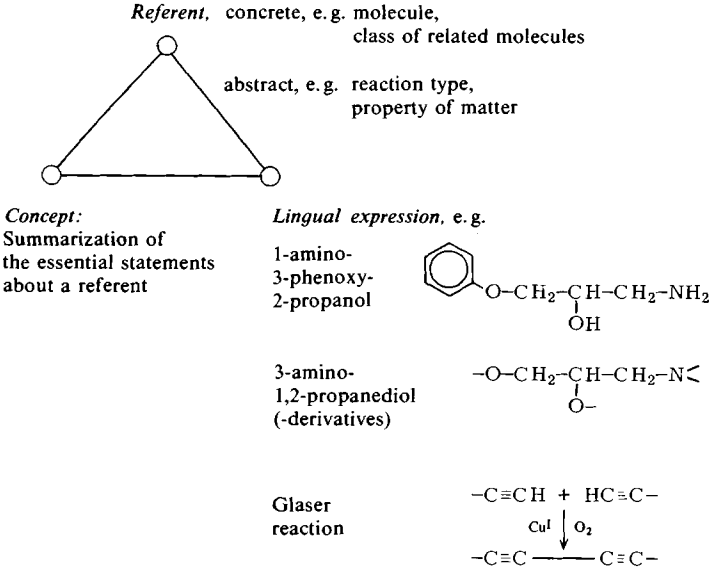

Fig. 1. The semantic triangle.

If we want to talk or write about something imagined we must somehow express the imagined. We must denote it with symbols or the words of our language. We have therefore agreed upon through which symbol, word, or group of words a certain concept is to be expressed. Thus, "Glaser reaction" means a particular way of connecting acetylenic carbon atoms with each other.

Using the semantic triangle we can easily attain certainty on which is the search goal if an inquirer requests information on, *e.g.*, aminopropylene glycol.

Certainly he does not search for the referent itself, *i.e.* for the substance aminopropylene glycol, for in this case he would order the desired amount from a supplier. Besides that, abstract referents, *e.g.* a property of matter or a type of chemical reaction, could not be provided physically to him.

Nor can the expression, which an inquirer happens to have used to describe the topic of his interest, be the real goal of his search. For example, an inquirer may be interested in the Glaser reaction. Then it would be a great misunderstanding on the part of the documentalist if he restricted the search to those documents in which precisely the expression "Glaser reaction" occurs. Much more, any text is relevant in which the *concept* of this reaction is expressed, and in fact independent of the kind of words, sentences, structural formulas *etc.* having been used.

For example, an author may have spoken of the Eglinton, Hay, or Cadiot-Chodkiewicz reaction, or may have avoided any of these names and chosen the reaction equation instead, as shown in Figure 2.

Not only can one and the same concept be expressed differently, but one and the same lingual expression can have different meanings. Thus, the term Cadiot-Chodkiewicz reaction is also used for the coupling of acetylenes with halogenated allenes to yield conjugated enynes (cf. Fig. 2). For many reactions one will encounter a great variety of definitions in the literature.

Hence, it is always the concept which is searched by an inquirer, and not the referent nor the expression of the in-

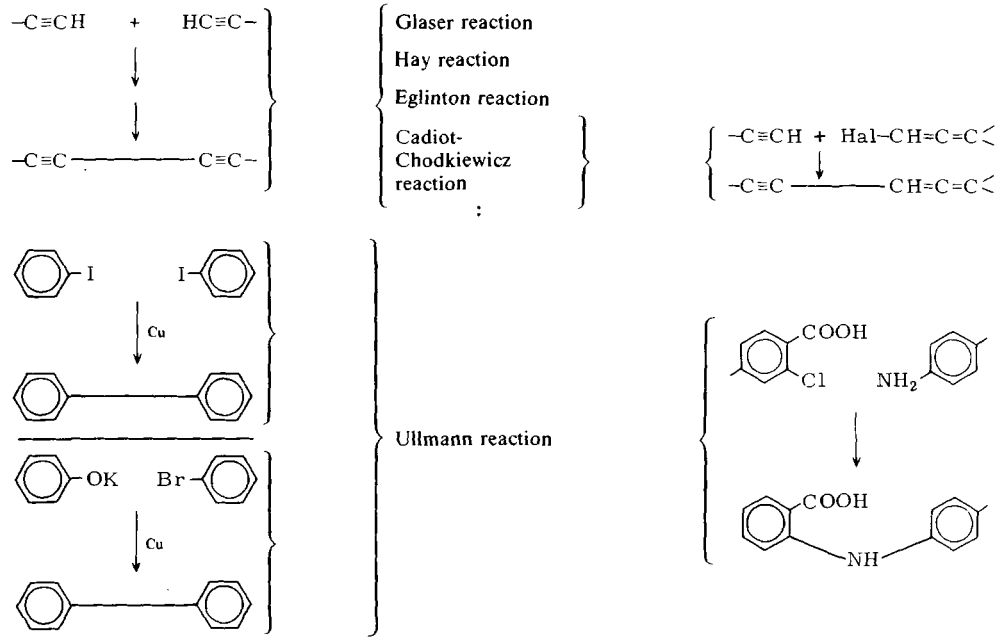

Fig. 2. Ambiguity and multiplicity of natural language expressions.

quirer. The expression only serves as an aid for reaching the search goal, but by no means does it constitute the goal itself. According to these considerations we complete our semantic triangle using the Glaser reaction as an example, and at the same time we introduce an important differentiation between two kinds of lingual expression (see Fig. 3).

3. Lexical *versus* Non-Lexical Mode of Expression

It is conducive to our later discussion to separate the "lexical" expressions from the "non-lexical" ones. A *lexical* expression is deemed one which can unambiguously be entered into and located in a dictionary or lexicon. This holds true for any firmly determined, agreed-upon, linear sequence of alphanumeric symbols with which a concept is expressed, *e.g.* a name for a reaction, a substance, or a person. If for a concept *non-lexical* expressions are in use, for example multi-word phrases of any kind, (such as, *e.g.* expressions of the type of definitions), then the variety of these expressions is very large, often even infinitely large. This is particularly apparent in the case of chemical reactions. This has far-reaching consequences for the retrieval of the concepts expressed in this non-lexical manner (see Sections 3.1 and 3.2).

3.1. Expressions for Reaction Types

For oxidative coupling reactions of acetylenes half a dozen reaction names may have to be taken into consideration, four of which have been entered in Figure 3. This concept may, however, have been expressed in the non-lexical manner as well, namely through typical educts and products in the Glaser reaction. This mode of expression for reactions even markedly dominates in the literature, and in fact for good reasons, which shall, however, not be discussed here in detail. It is essential for our considerations that the number of conceivable, non-lexical expressions for this concept is infinitely large. Their multiplicity corresponds to that of the conceivable individual educts and products in this reaction.

When commencing a literature search for a concept of interest, one must always know in advance how this concept is represented in the search file, for precisely these expressions will have to be adressed by corresponding, alternative search parameters. If one omits only one of the expressions through which the concept of interest is expressed in the search file, then this will inevitably lead to loss of relevant information. All those references in which the omitted expression was used will not be found.

If, now, all the various author-lingual expressions for a reaction were entered into the search file without any restriction, one would have to enumerate as search alternatives in the query all those educts and products through which, *e.g.*, a Glaser reaction might have been expressed in the literature. Since this is impossible, it is correspondingly impossible to perform a literature search anything like completely in a file which has been compiled in this manner.

If there is at least one single name for a reaction of interest, the incompleteness of a search with this name as a parameter is not so conspicuous. One will always find a few references, but which and how many had escaped the search remains hidden.—It is, however, only a very small fraction of reactions for which a name has ever been coined. Hence, the majority of reactions cannot be found at all by names.

It has occasionally been held against these considerations that one need not phrase *any conceivable* author-lingual expression, but only those few which have in fact *entered the file*. The expert could, it is argued, fairly reliably conjecture which specific examples might have been published, and he could therefore restrict his search parameters to just these "practically important" ones. This is how-

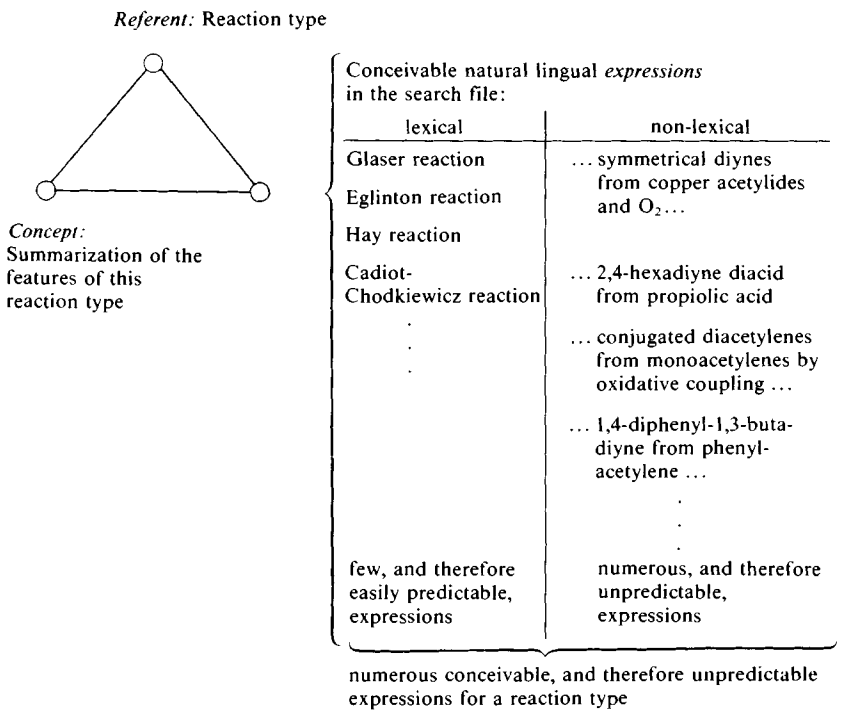

Fig. 3. Lack of predictability of unrestricted natural language expressions for a reaction type.

ever no way out, for in practice and in the case of large files one cannot possibly know through which specific examples a reaction of interest might have been represented. Knowledge about the expressions for these examples could only result from looking into the relevant texts. These are however just those still to be retrieved, and their wording cannot be anticipated. In other words, this argument requires just that to be known in advance which is still to be discovered.

3.2. Expressions for Classes of Compounds

Let us consider another example of lacking predictability of the natural, unrestricted mode of expression. A chemist may be searching a certain class of compounds. He may intend to synthesize one of its representatives, to use it as an educt, or he may be interested in the properties common to the members of this class of compounds. The corners of our semantic triangle are in this case occupied as is shown in Figure 4.

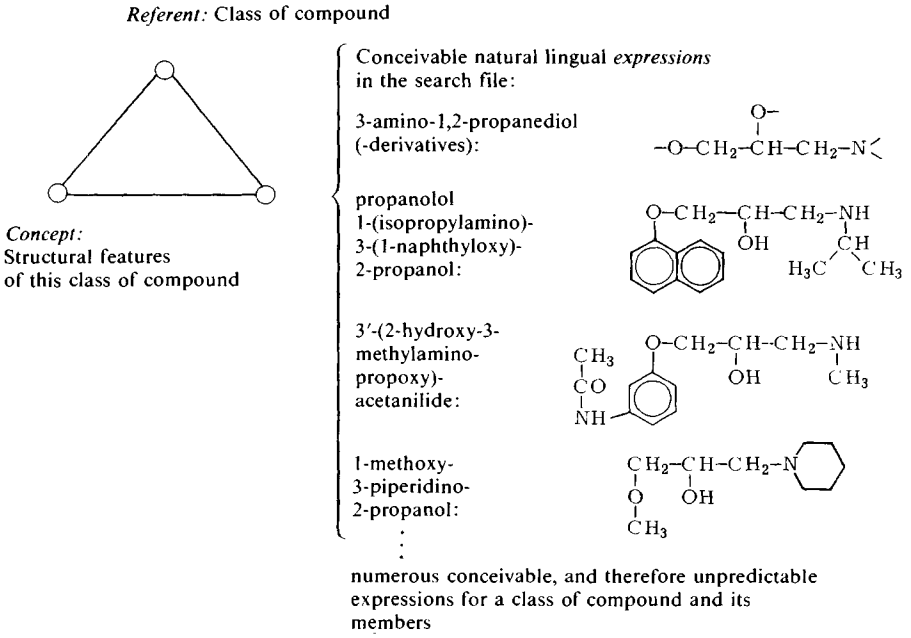

Fig. 4. Lack of predictability of unrestricted natural language expressions for a class of compounds.

Only in exceptional cases will this class of compounds be represented in the original texts through the name that the inquirer quoted, *e.g.* "3-amino-1,2-propanediol derivatives". Mostly, this class will be represented by the names of the individual compounds pertaining to this class of interest.

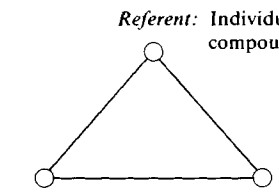
But again the number of all the conceivable individual compounds of this kind is infinitely large. Correspondingly large is therefore also the number of compound names which would have to be exhaustively enumerated as alternative search parameters in the query. An inquirer can only conjecture which of these names might in fact have entered the file. A search for a class of compounds will therefore necessarily be incomplete in a file in which compounds are represented merely by their names.

The weaknesses of search files containing unrestricted natural language texts have occasionally been attributed to the ambiguity of this mode of expression. But this cannot be the genuine reason for the seriously limited suitability of these texts for retrieval. Chemical nomenclature, for example, is extremely precise and makes possible the denotation of almost any individual molecular structure. In spite of that, it is unsuitable for the retrieval of compound classes, as we realized in the case of the aminopropanediols. Rather, the genuine source of this weakness is the impossibility of predicting at the time of commencing a search through which and how many compound names a class of chemical compounds may be represented in the search file.

It has often been argued in favor of unrestricted natural language input that it cannot lead to distortions or omissions. Although this is true it is obvious from the foregoing examples that this kind of input can lead to unsatisfactory retrieval and that a mode of expression *different* from that of the authors is indispensable.

3.3. Expressions for Individual Compounds

As another informative example, let us consider the case of individual compounds. They have always constituted an exception from the information-scientist's point of view in that they do not normally occur in the non-lexical mode of expression. One need not take into account that, *e.g.*, the individual compound in Figure 5 was represented in terms of a sentence or even several sentences. Either a name will be presented in the text or a structural formula, which however can be algorithmically transformed into a name or into a canonical connection table *i.e.*, into a variant of lexical expression (cf. [39]). Hence, only few natural-language expressions for an individual compound will be encountered, which is in sharp contrast with the expressions for reactions and compound classes. Furthermore, when compiling the names for an individual compound of interest, one need not rack one's brains for them. It is inherent in their lexical nature that they can be looked up in dictionaries, and that at these locations one will encounter additional, synonymous names or the unique Chemical Abstracts registry number. In cases of doubt any nomenclature expert will develop a name for the compound in question.—In other words, in the case of individual compounds it is well predictable through which expressions they are represented in an unrestricted natural-language file. It is correspondingly easy to phrase a query for an individual compound even for a file like this.



lexical	non-lexical
3-amino-1,2-propanediol	lacking
1,2-propanediol, 3-amino	
aminopropylene glycol	
only few expressions, which are therefore easily predictable	

Fig. 5. Good predictability of natural language expressions for an individual compound.

If in an information system one contents oneself with searching exclusively for individual compounds, then it is therefore quite adequate to accept the original, author-lingual expression for the search file. This approach suggests itself at least if the authors in the subject field are accustomed to naming their individual compounds.

4. Indexing Languages in Chemistry

We have realized in the foregoing that it is not sufficient for inquiries for reactions and classes of compounds merely to transcribe the author-lingual expressions into the search file. Rather, the essentials of any publication of potential interest must be translated into another language, and in fact into one which is more conducive to the later retrieval of these documents. We shall call this language, the task of which is to provide an enhanced representational predictability, an "indexing language" and the process of employing this language "indexing"[*].

The most obvious and natural way of representing a molecular structure is the topological method. Each atom of a structure is recorded, *e.g.* in a connection table, together with all its connections that it has in common with its neighboring atoms, and in fact at just that degree of precision which is inherent in the structural formula (cf. [36]). In contrast to the established nomenclature this representation of a substructure is independent of how it is embedded into the entire molecular structure. Hence, in the case of the aminopropylene glycols the chain of exactly three interconnected carbon atoms can be algorithmically identified in any molecule as a substructure, together with the nitrogen atom and the two oxygen atoms as substituents in exactly the correct positions.

[*] More precisely, "indexing" can be regarded as "representing the essentials of a document of potential interest with a sufficient degree of predictability and fidelity" [cf. 6, 40, 41].

The applicability of topological methods is restricted to those (sub-)structures which are defined atom by atom. The occurrence of an alkyl or alkylene residue of unspecified length and branching will defeat the topological representation of this structure. To represent general concepts like these is the domain of fragmentation codes (cf. [32-34]). In principle, fragmentation codes can represent any generalized substructure, but it is most important that they can cope with those generalizations which in fact occur in the documents of interest and in the inquiries. Purely formal generalizations will prove largely useless in practice, because they can only rarely—if at all—be employed in storage and retrieval. An example is a "fragment" for the number of rings contained in a class of molecules wanted, or the number of nitrogen and/or oxygen atoms in the members of such a class. Nor must fragmentation codes be so large and difficult to survey that they cannot be reliably employed in daily practice. This danger prevails for all those fragmentation codes which are restricted in their vocabulary and dispense with any grammar.

As far as reaction documentation is concerned, exclusively fragmentation codes are in operational use at present (*e.g.* [33-35, 37]). In principle, the reaction sites are identified and described in their state before and after the reaction. In a sequence of reaction steps several denotations pertain to one and the same reaction site (*e.g.* a carbon atom). The mutual correspondence of these denotations must also be expressed for a sufficiently precise retrieval[37].

As for the representation of non-structural concepts, it can be made sufficiently well predictable by the employment of classifications and thesauri. Chemical engineering terms and properties and uses of substances are examples of these concepts. A large variety of vocabularies is in operational use for this purpose.

5. Individual *versus* General Concept

All this raises the question to which extent our considerations on the necessity or dispensability of an indexing language can be generalized. If we could infer from a general principle, whether a concept should preferably be represented in indexing or natural language in the file, respectively, then this would be of great use.

In order to answer this question we must again undertake a short excursion into the philosophical field, and consider Figure 6.

We refer to our statement made in the foregoing that the concept is the entirety of the essential features of a referent. Through the word "essential" the marked subjectivity of concept formation is expressed and also how strongly it depends from the individual viewpoint of the human. The authoritative viewpoint in *our* considerations is that of the chemist, who, when looking at a bottle marked "aminopropylene glycol", is primarily interested in the contents of this bottle and, in fact, in the molecular structure of the contents.

Here, the primary amino group and the alcohol group will, *inter alia,* doubtlessly be considered as essential by a chemist. These two conceptual features suffice to form the meaningful general concept of the aliphatic amino alcohols. Another essential feature is the occurrence of the secondary alcohol group. If we add this feature to the general concept already discussed, we obtain the more specific

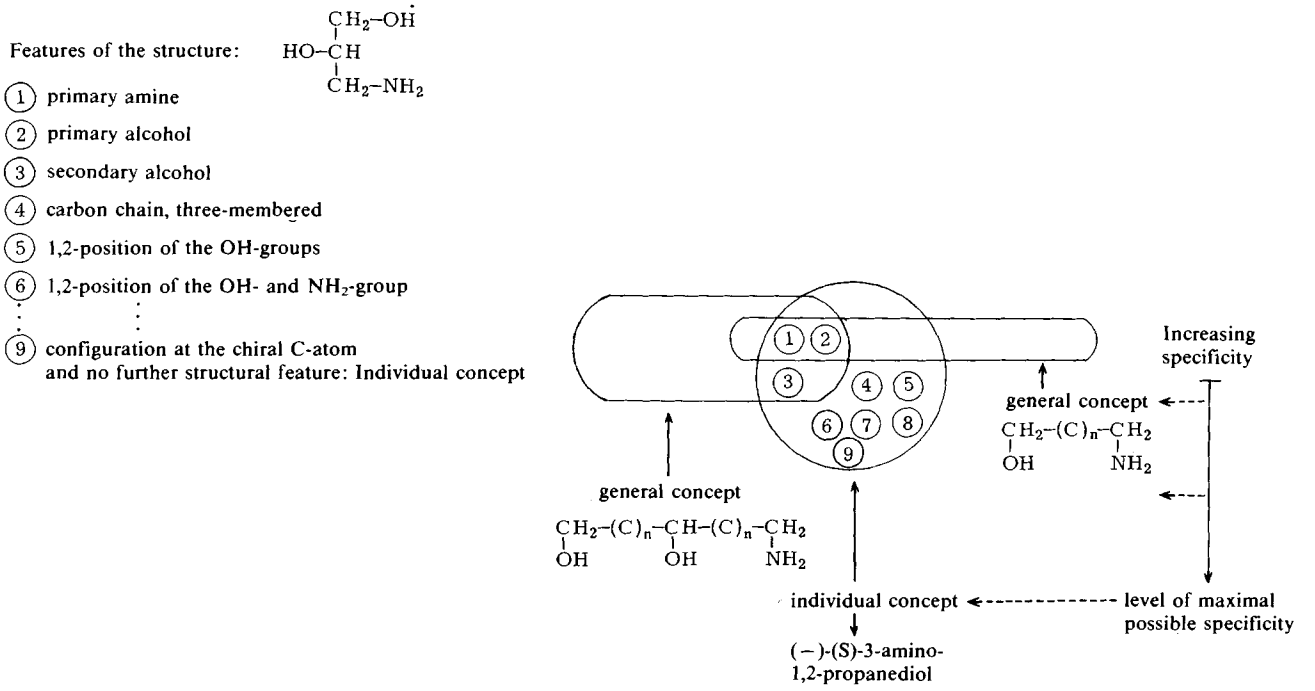


Fig. 6. Transition from general to individual concept by successive and finally complete accumulation of conceptual features.

concept of the aliphatic aminodiols. Thus, more and more features can be added to a general concept to yield more and more specific concepts. The last feature to be added may be the configuration encountered at the chiral carbon atom. Then, however, the process of making a concept more and more specific comes to an end. Admittedly, one could specify chemical, biological, and physical properties, in addition to the features already mentioned, but this would not contribute to an increased specificity of the definition of the molecule. In other words, in our process of successively making a general concept more and more specific, we have arrived at an "individual concept", *i.e.* at a concept for which no more specific concept exists which would still be meaningful to an expert of the subject field (after *von Freytag-Lörringhoff*[31]).

In what way are these considerations related with the question of indexing-lingual *vs.* author-lingual representation of concepts? Extended experience has revealed that it is markedly the general concepts for which one must take into account an almost unlimited number of (lexical or non-lexical) expressions in unrestricted natural language, *i.e.* in a mode of expression which is inherently unpredictable. Individual concepts, on the other hand, are almost exclusively expressed in the lexical manner in natural, unrestricted language, *i.e.* in a mode of expression which is fairly well predictable by nature.

If we remember an indexing language's task as one to attain representational predictability, then it is obvious that the necessity of employing an indexing language is drastically reduced in the case of *individual* concepts[5,6,13]. Seen from this angle, chemical reactions appear as *general* concepts, and it is by no means surprising that we encounter them predominantly in the non-lexical mode of expression which requires the employment of an indexing language for their improved representational predictability and retrieval. The "Glaser reaction", for example, reveals itself as a general concept in so far as it includes the—more specific—concepts of the Eglinton and Hay reactions. These reactions, too, could be subdivided further by specifying the reaction conditions, and it is immaterial whether names have hitherto been coined or not for these still more specific reactions.

Another type of generality is encountered in chemical engineering concepts, *e.g.* distillation, filtration, crystallization, *etc.* The pertinent property concepts, such as the capability of being subjected to these processes, *i.e.* of being distilled, crystallized, and many other properties and uses of matter must be counted among the general concepts as well.

A typical individual concept, on the other hand, is the author of a publication, a specific institution, a country, a patent specification, a specific book, *etc.* That all these concepts have received a proper name or a unique number, *i.e.* a lexical expression, has always considerably facilitated their handling in information systems. Thus, the indexes of authors and empirical formulas have always been faster and cheaper to compile and to search than those of general subjects.—It is true that structural formulas of individual substances and also the corresponding connection tables (cf. Section 3.3) are of the non-lexical kind, but they can easily be transformed through a machine algorithm into a canonical and, hence, lexical form, for example the one developed by *Morgan*[39]. This is due to the extraordinarily highly systematic syntax which is inherent in these connection tables, but we shall not discuss this phenomenon in more detail here.

6. The Rejection of Indexing Languages in Chemical Documentation

In many data banks, which are now accessible commercially and on-line, the employment of indexing languages has been dispensed with. The reasons given are that the high costs for reliable expert literature analyses and for sophisticated machine programs would be saved. Poor experience with certain indexing languages has also been quoted as an argument, as well as the equality or even superiority of unrestricted natural language which alledgedly could be inferred from several retrieval system evaluation experiments. Adherence to indexing languages was also said to be an obsolete attitude. These arguments have been put forward so frequently and one-sidedly that such a picture must be corrected to counteract the misdirection of development and the entering of blind alleys[42,43]. The speed and elegance of access, often over large distances, has often veiled the low retrieval accuracy, which regularly occurs when indexing is dispensed with.

As far as avoiding the expenses incurred for expert work is concerned, this is perfectly possible in the case of the individual concepts. They are easily perceived in the text and clearly delimited against other concepts through their proper names. This is in sharp contrast with general concepts. Expert knowledge is indispensable for their perception in their context, their selection, and proper designation. For example, in the literature analysis tens of thousands of individual names of peptides and fungi must be understood and identified as belonging to these general concepts. Otherwise an inquiry, *e.g.* for peptide-like bitter principles occurring in mushrooms, could not be answered, except by enumerating a very large and steadily increasing number of individual names as alternative search parameters in a query. Nobody could perform this work in advance, *i.e.* before the emergence of such a name, and include the relevant instructions in a program. It adds only to these difficulties that the meaning of words can often only be inferred from the context. This context may, however, be expressed in an unpredictable way and will thus escape any pre-programmed, mechanical analysis.

If in the renunciation of any indexing one confidently relies on future machine programs, then these would in some mysterious way have to solve a task for which the human (who would have to write these programs) does not know a solution, for, he cannot anticipate all the situations which would have to be managed by the program. How confidently would one rely on an automobile repair shop which frankly declares that only untrained people and robots are employed?

In reaction documentation the detection of the reaction site often requires expert indexers, as well as establishing the correspondence of these centers in the various educts and products. Here, the renunciation of any (mechanical

and intellectual) indexing is equivalent to the renunciation of any serviceable reaction documentation.

The possibilities and limitations of the algorithmical detection of reaction sites have been investigated by *Lynch* and *Willett et al.*[44-47]. In the REACCS system[48] of *Wipke* the algorithmical and the manual way of reaction indexing are combined.

As regards judgement of the accuracy of retrieval, it is commonly still characterized by fallacies (cf. also [38]). An inquirer who is highly satisfied with the results of a search today, may be very dissatisfied tomorrow when he realizes what and how much information has hitherto escaped him in his searches.—Often, one soothes oneself with conceding that some few "good" references are sufficient and that no search necessitates anything like a complete set of references. But is it really acceptable that the selection of these few good references is left to chance and contingency as is almost always the case in an inaccurate retrieval? In most cases an evaluation by the system user rests on a deceptive impression, for he only considers the cases of irrelevant references retrieved—because of their obviousness—and he disregards the relevant references *not* retrieved—because of their latency. A detailed investigation would reveal that any evaluative comparison of a retrieval system is surprisingly difficult, time consuming, and expensive in several respects, if conclusive results are to be attained. The literature abounds with extensive studies and everlasting controversies in this particular field.

It has also been concluded from several evaluative retrieval experiments that one could dispense with any special indexing language and that one unhesitatingly could store the texts of interest without any terminological control. But often these experiments have been conducted with unrealistically small documentation collections, in which, furthermore, one had been content with the literature over only a short period of time. Under these artificial circumstances the experimentalists have had an unnaturally good insight into the wording of the test documents, an insight which was persistently refreshed through the repetitive perusal of these documents during the experiments. Furthermore, the large heterogeneity of natural-language modes of expression, which always prevails in documentation collections that extend far into the past, cannot come into play. Under these artificial test conditions representational predictability was not seriously put to the test and largely replaced by effort of human memory. This holds particularly true when storage and retrieval have been the responsibility of one single person. Unrestricted natural language will necessarily show up deceptively well under these circumstances.

However, any translation of a text into another language encounters difficulties if the text is ambiguous and/or if in the target language there is not (yet) an appropriate expression. Translation into an indexing language does not constitute an exception to this rule. In these cases it is advisable to preserve the expressions of the original text in the search file, at least in addition to an attempted translation into indexing-lingual expressions. An indexing language vocabulary for polymer chemistry may, for example, provide only a term for the general concept of spinning. One should, however, be able additionally to enter the more specific concepts of melt spinning, dry spinning, wet spinning *etc.* into the file using these natural language terms, even if not with the degree of reliability which is inherent in the indexing language vocabulary terms. Such a combination of both kinds of language has proved extraordinarily effective in our practice and in that of the IDC[*].

7. Conclusion

In this article the question of the capabilities and limitations of natural *versus* indexing language has been raised. According to our investigations unrestricted natural language is advisable or even superior if in an information system only inquiries for individual concepts need be processed or if all the concepts of interest to an inquirer can be translated into an indexing language only with difficulties and serious distortions. An indexing language, on the other hand, cannot be dispensed with if inquiries for general concepts are also to be processed with an acceptable degree of accuracy. The reason is the inherent unpredictability of the unrestricted natural-language mode of expression for these concepts.

One should therefore refrain from generally stating that unrestricted natural language is the only reasonable choice for documentation purposes and that indexing languages are dispensable, or that precisely the contrary be valid. It should always be specified whether in the system under consideration the emphasis is on individual or on general concepts, what demands are made on the accuracy of the retrieval, and in particular, how large the document collections had been from which these conclusions have been inferred and how far these collections have extended into the past.

If high demands are made on the performance of an information system then they can be satisfied only by a well-planned combination of both kinds af language. Analysis of the problems encountered in chemical documentation suggests this conclusion most convincingly. The situation in the documentation of other fields gains much in clarity if it is seen from the same theoretical point of view. If this is kept in mind an old and highly controversial issue, on which many vehement discussions have arisen in the past, vanishes.

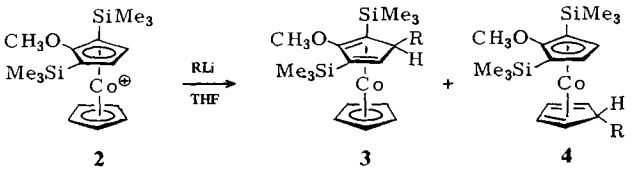
Cyclopentadienone Complexes as Synthons: Ring- and Regiospecific Nucleophilic Additions to Cobaltocenium Salts—Synthesis of Substituted Cyclopentadienes and Cyclopentenones**

By *Jeffrey P. Tane* and *K. Peter C. Vollhardt**

The recent emergence of a variety of novel cyclopentanoid natural products[1], particularly those exhibiting physiological activity, has led to a renaissance in synthetic approaches to five-membered ring compounds[2]. Few have relied on transition metal mediated or controlled CC bond formations[1,5]. We have reported on the photochemical [2+2+2] cycloaddition of two alkynes and carbon monoxide to cobalt-complexed cyclopentadienones[6] and now describe the exploitation of the metal as a stabilizing and directing group[7].



2 3 4

Table 2. Nucleophilic addition of RLi to **2**.

	R	3 :	4	Yield [%]
a	*t*-Bu	0	100	84
b	CH_3	29	71	98
c	*n*-C_6H_{13}—CH=CH (*trans*)	55	45	85
d	*n*-C_6H_{13}—CH=CH (*cis*)	19	81	80
e	*n*-C_6H_{13}—C≡C	73	27	95
f	Me_3Si—C≡C	80	20	83
g	CH_3O—C≡C	74	26	92
h	*t*-BuO—C≡C	69	31	94
i	C_6H_5S—C≡C	75	25	89
j	Cl—C≡C	74	26	79
k	H	75	25	100

The neutral η^4-2,5-bis(trimethylsilyl)cyclopentadienone-(η^5-cyclopentadiene)cobalt **1** gives **2** on treatment with dimethyl sulfate: **2** is converted by organolithium reagents in tetrahydrofuran (THF) into mixtures of **3** and **4** (Table 2). The observed ring selectivity is clearly suggestive of an electronic preference to attack the substituted five-membered ring, whereas steric factors force relatively bulky nucleophiles R to add to the unsubstituted ligand. The stereoretention observed in the preparation of **3c/4c** and **3d/4d** is strongly indicative of a true nucleophilic substitution mechanism.

The less substituted cobaltocenium salts **5** react with organolithium reagents to give **6**—**9** (Table 3). The results show that the additions are governed by a subtle interplay of steric, charge and orbital control; this is backed up by extended Hückel calculations.

Table 3. Nucleophilic addition of RLi to **5**.

	R	6 :	7 :	8 :	9	Yield [%]
a	*t*-Bu	59	4	0	37	75
b	CH_3	64	20	0	16	82
c	*n*-C_6H_{13}—CH=CH (*trans*)	66	21	0	13	89
d	Me_3Si—C≡C	68	14	10	8	77

The synthetic utility of the method for five-membered ring compounds is demonstrated by the oxidative demetallation of **3** to furnish the free ligand, or by the application of an oxidation-hydrolysis sequence (typically $CuCl_2 \cdot 2H_2O$ or $FeCl_3 \cdot 6H_2O$ and oxalic acid) to generate potentially valuable 4-substituted 2-trimethylsilyl-2-cyclopentenones **10**—**13**.

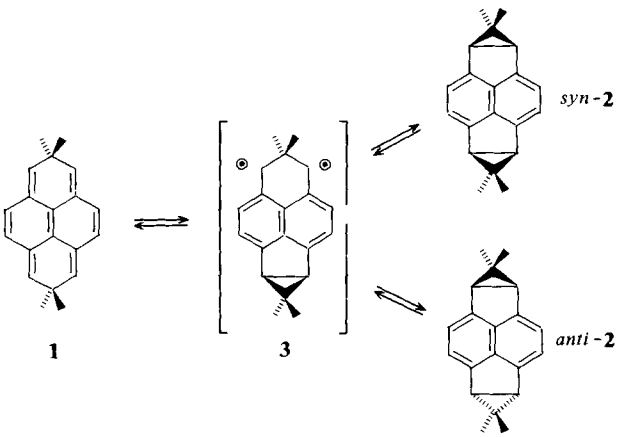
Synthesis and Valence Isomerization of 2,7-Dihydro-2,2,7,7-tetramethylpyrene**

By *Jean Ackermann, Herbert Angliker, Erich Hasler,* and *Jakob Wirz**

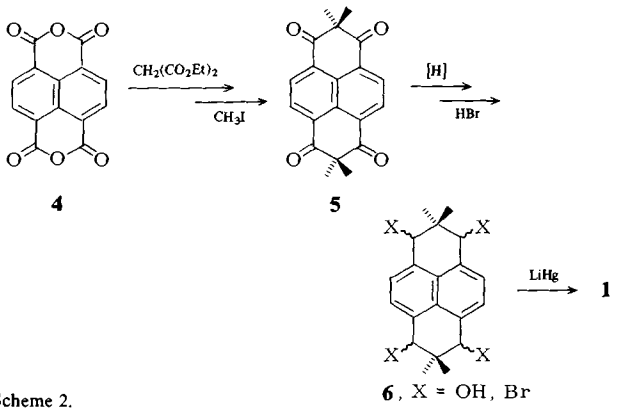
The potential to study the photochemical and thermal valence isomerization shown in Scheme 1 has been our prime incentive to synthesize the cross-conjugated polyene 2,7-dihydropyrene. We chose the blocked and sterically shielded 2,2,7,7-tetramethyl derivative **1** as a model compound to protect the system against polymerization, tautomerization, disproportionation, and oxidation. Due to geometrical constraints, ring opening of a cyclopropane fused to the *peri*-positions of naphthalene can proceed only in a disrotatory manner; the valence isomerizations **1** ⇌ *syn*-**2** and **1** ⇌ *anti*-**2** can therefore be classified as intramolecular $[_\pi 6_s + _\pi 6_s]$ and $[_\pi 6_a + _\pi 6_a]$ cycloadditions/cycloreversions, respectively. They are thus "forbidden" in the sense of the Woodward-Hoffmann rules and are likely to proceed *via* a reactive diradical intermediate **3**[3] (Scheme 1).



Scheme 1.

The preparation of **1** was achieved in a five-step synthesis starting from 1,8:4,5-naphthalenetetracarboxylic acid dianhydride **4** (Scheme 2). **1** is isolable as a yellow, crystalline solid (decomp. 180 °C) and is stable in solution in the presence of air if light is rigorously excluded. The NMR chemical shifts of the vinyl H atoms substantiate the expected polyene character of **1** and provide no evidence for the presence of an "aromatic" ring current in the central naphthalene moiety. 1,2,3,6,7,8-Hexahydro-2,2,7,7-tetramethylpyrene is obtained in quantitative yield upon hydrogenation of **1** in presence of PtO_2 in isooctane.

Solutions of **1** are rapidly bleached in diffuse daylight or upon irradiation at $\lambda = 405$ nm, whereby the valence



Scheme 2.

isomers *syn*-**2** and *anti*-**2** (≈1:1) are formed, which are readily separated by chromatography. The photoreaction is reversible upon short wavelength irradiation ($\lambda = 313$ nm), but the photostationary equilibrium is strongly temperature dependent, favoring **2** at room temperature and **1** at 77 K. The thermal equilibrium lies entirely on the side of **1** in agreement with the predictions of thermochemical additivity rules (calculated heats of formation: $\Delta_f H(\mathbf{1}) = 246$, $\Delta_f H(\mathbf{2}) = 295$ kJ/mol). However, the equilibrium between the two stereochemical isomers *syn*-**2** and *anti*-**2** proceeds at a rate which is at least two orders of magnitude faster than that of the rearrangement **2** → **1** (*ca.* 10^{-4} s^{-1} at 100 °C). We conclude that the recyclization of the diradical (**3** → **2**) requires a significantly lower activation energy than the cleavage of the second ring (**3** → **1**) although the second reaction leads to the more stable product. Clearly, the cycloreversion **2** → **1** is not a concerted process, since it requires a higher activation energy than the cleavage of only one bond to form **3**.

Fourfold Bridging of the Benzene Ring in One Step[1]**

By *Brigitte Klieser* and *Fritz Vögtle**

Until now, two benzene rings could be linked by more than three bridges only *via* multistage indirect routes[2, 3, 5]. We have now found that the fourfold intermolecular coupling of *ortho*-positions can be accomplished in a single step using the "cesium effect"[8].

3a

3b

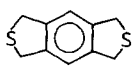
Reaction of the tetrathiol **1** with the tetrabromide **2** in dimethylformamide (DMF) in presence of Cs_2CO_3 yielded the novel tetrathia[3.3.3.3]cyclophane **3**. Previous attempts to synthesize **3** in this way—using other base-solvent combinations—resulted only in isolation of the dithia compound **4**.

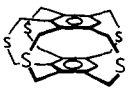
The new method led to two products (10% yield), which could be separated only with difficulty by chromatography ($R_F = 0.27$ and 0.31; TLC plates: silica gel 60 F_{254}, Merck, solvent: toluene), which we assigned as isomers **3a** and **3b** (*ca.* 1 : 1; both m.p. > 350 °C, decomp.). Their formation is expected from a consideration of molecular models. **3b** is the first (1,2,4,5)(1,5,4,2)cyclophane.

The structures of **3a** and **3b** are primarily supported by the ^{1}H-NMR spectra: Each of the isomers exhibits both a single AB system for the CH_2 protons and a singlet for the aromatic protons. This signifies that in both isomers the CH_2SCH_2 bridges are conformationally mobile, since otherwise both signals would have to be further split. Because the two benzene rings in **3b** can be mutually displaced to a lesser extent than those in **3a** due to ring strain effects, it can be assumed that the low-field shifted arene signals belong to this isomer: **3b**: $\delta_A(CH_2) = 3.75$, $\delta_B(CH_2) = 3.99$ ($J = 14$ Hz), δ(H-aromat.) = 7.73; **3a**: $\delta_A(CH_2) = 3.63$, $\delta_B(CH_2) = 4.50$ ($J = 15$ Hz), δ(H-aromat.) = 7.28.

When K_2CO_3 was used instead of Cs_2CO_3 only traces of **3** were formed. The efficacy of the carbonates corresponds to the sequence found by *Kellog et al.* in another connection[8a].

4





7

This method permits intramolecular reactions of **1** to afford five-membered rings like **4** to be suppressed in favor of dimerization; since from the first phane-sulfone pyrolysis[10] onwards sulfides have proved to be ideal intermediates for strained hydrocarbons and their oligoenes, this method signifies a considerable extension of the synthetic potential of cyclophane chemistry[3,5][***].

We were able to detect the formation of the pentathia[3.3.3.3.3]benzenophane **7**, generated using this new method, by mass spectroscopy.

H_2S as a Promotor for the Water Gas Shift Reaction**

By *Virgil I. Stenberg*, K. Raman, V. R. Srinivas, R. J. Baltisberger,* and *N. F. Woolsey*

We have found that H_2S is the first gaseous promotor of the water gas shift reaction. H_2S, a by-product from the cleaning of natural gas, crude oil or coal, is a source of hydrogen for some chemical processes; a mixture of CO and H_2S enhances coal liquefaction to an ethyl acetate-soluble material[1]. A mixture of synthesis gas and H_2S allows the best conversion of lignite into a tetrahydrofuran-soluble material[2]. Consequently, the effect of H_2S on the water gas shift reaction was examined at liquefaction temperatures (425 °C) to give a possible explanation of the liquefaction data.

Table 1. Water gas shift reaction in presence of H_2S. Reactions were performed in a 316 stainless steel batch autoclave (12 mL) using a charge of CO (48 bar, 23 mmol) and H_2O (0.42 g, 23 mmol) for 2 h at 425 °C [3].

Run No.	H_2S [mmol]	Products H_2 [mmol]	Products CO_2 [mmol]

[a] Metal sulfide layer. [b] G-3 high temperature catalyst supplied by United Catalysts Inc., Louisville, KY (USA), 10 wt.-% of CO.

The results of the H_2S-assisted shift reaction are presented in Table 1. In the absence of H_2S there is little H_2 and CO_2 formation in 2 h (run 1). However, addition of H_2S to the mixture of CO and H_2O enhances formation of H_2 and CO_2 approximately 13 fold under identical experimental conditions (cf. runs 1 and 2). No additional change in the extent of shift reaction is observed over the H_2S concentration range used (cf. runs 2–6). The reactions were carried out in stainless steel batch autoclave reactors, which became coated with a black metal sulfide layer during the reactions in presence of H_2S. This metal sulfide-coating of the stainless steel reactor is not as effective at promoting the reaction as H_2S, but is slightly better than that of the control (cf. runs 7 and 1). In run 7 there is an imbalance between the amounts of H_2 and CO_2 produced.

Grand Forks, ND 58202 (USA)

[**] This work was supported by the U. S. Department of Energy (Contract No. DE-AB18-78FCO2101).

This can be explained by the direct reaction of H_2 with the metal sulfide surface according to eq. (1).

$$MS + H_2 \rightarrow H_2S + M \quad (1)$$

Since CO is known to react with H_2S to give COS, which is readily hydrolyzed by H_2O [eq. (2) and (3)][4], the action of H_2S can be explained by the summation of these two equations.

$$CO + H_2S \rightarrow COS + H_2 \quad (2)$$
$$COS + H_2O \rightarrow CO_2 + H_2S \quad (3)$$

The thermal decomposition of COS into CO and S is known[5]. The slight excess of H_2 over CO_2 produced in H_2S-assisted reactions is presumably due to some decomposition of COS in competition with its hydrolysis (runs 2–6, deviation from 1 : 1 molar ratio). Run 8 shows the effect of a commercial, heterogeneous, high temperature, shift reaction catalyst on the reaction. Although H_2S is not as efficient as the solid catalyst, it holds promise by being a low cost, pumpable, recyclable gaseous catalyst.

Intramolecular Diels-Alder Reaction of Allenecarboxanilides**

By *Gerhard Himbert** and *Lothar Henn*

Diels-Alder reactions have been thoroughly studied theoretically and mechanistically[1], and both the *inter*molecular[2] and *intra*molecular variants[4] are of considerable preparative importance. Here we report the first case in which a monosubstituted benzene ring assumes the diene function in an intramolecular [4+2]cycloaddition: when heated to a little over 100 °C, in the presence or not of solvent, the allenecarboxanilides **1**[11] isomerize to the tricycles **2**.

The existence of the substituent-dependent equilibrium **1** ⇌ **2** is suggested by the fact that upon heating **2f** in xylene it is partially reconverted into the allene **1f**. Tricycles **2** could even be isolated from equilibrium mixtures, since they have higher melting points (Table 1) and crystallize more readily than the allenes **1**. We explain the astonishingly high tendency of **2** to be formed as a concurrence of several factors: The relative ease of formation of five-membered lactams, the partial activation of the benzene ring in **1** by the amino group, the increased energy-content of allenic π-systems relative to olefins, and the comparatively high rigidity in the allene and carboxamide moieties.

Table 1 (Part). Experimental and spectroscopic data of some of the tricycles **2**.

5-Pivaloyl-2*H*-isoindole—An Isolable and Crystallizable *o*-Quinonoid Heteroarene**

By *Richard Kreher**, *Norbert Kohl*, and *Götz Use*

Dedicated to Professor Georg Wittig on the occasion of his 85th birthday

Whereas 2*H*-isoindole **2a** is capable of existence in solution[1], it polymerizes in the solid state[2] at room temperature. Our results indicate that the pivaloyl group in the 5-position exerts an enormous stabilization effect: 5-pivaloyl 2*H*-isoindole **2b** is isolable in crystalline form and can be stored under nitrogen.

It can be prepared by allowing 2-mesyl-5-pivaloylisoindoline[3] to react with potassium *tert*-butylalcoholate in dimethyl sulfoxide (2 h/RT). Base-induced 1,2-elimination of methanesulfinic acid to afford 1*H*-isoindole **1b** is followed by a tautomeric rearrangement to 2*H*-isoindole **2b** (yield 94%). From the ^{1}H-NMR spectra (Table 1), the *o*-quinonoid form **2b** is present almost exclusively in organic solvents ($DCCl_3$, [D_6]dimethyl sulfoxide, [D_6]acetone), whereas even in [D_5]pyridine the benzenoid form **1b** is not detectable; the ^{13}C-NMR spectra ($DCCl_3$ and [D_5]pyridine) lead to the same result. The NH/ND exchange occurs extremely rapidly according to NMR spectroscopy; the CH/CD exchange at the 1,3-position is slower.

a, R = H; **b**, R = $(CH_3)_3C$–CO; **c**, R = $(CH_3)_3C$

Table 1. (Part) Selected physical data of **2b**.

M.p. = 115 °C; ^{1}H-NMR ($DCCl_3$/300 MHz): δ = 1.43 (s; $C(CH_3)_3$), 7.20 (ddd, J = 2.0 Hz, 0.9 Hz, 3.0 Hz; H-1), 7.35 (ddd, J = 2.0 Hz, 1.0 Hz, 3.0 Hz; H-3), 7.39 (dd, J = 9.1 Hz, 1.4 Hz; H-6), 7.57 (ddd, J = 9.1 Hz, 1.0 Hz, 1.0 Hz; H-7), 8.21 (ddd, J = 1.4 Hz, 1.0 Hz, 0.9 Hz; H-4), 9.8–10.7 (b, NH); MS (70 eV, 150 °C): *m/z* (selection) 201 (81%, M^+), 144 (100%, $M^+ - C(CH_3)_3$)

Despite its considerable kinetic stability, **2b** forms Diels-Alder adducts with *N*-alkyl- and *N*-arylmaleimides—just as does **2a**[1,2]—in solution; yields of 95% were obtained by fractionating work-up. Because of the reversible course of the cycloaddition, the *endo*-form of the 1:1 adducts is thermolabile: the *exo*-form is thermally stable. Reactions with *N,N*-dienophiles (*e.g.* dimethyl azodicarboxylate), just as those with activated alkynes (*e.g.* dimethyl acetylenedicarboxylate), proceed less readily. An umpolung of the regioselectivity of addition reactions does not occur; despite the unsymmetric substitution of the *o*-quinonoid 10π system, a substituting ene-reaction does not take place.

The enormous stabilization of the 2*H*-isoindole form **2** may be caused by the electronic interaction between the carbonyl group at the six-membered ring and the NH-group on the five-membered ring. In contrast, a *tert*-butyl group in the 5-position is not sufficient to make a 2*H*-isoindole **2c** isolable; **2c** could, however, be detected in solution by spectroscopy and *via* Diels-Alder reactions. Hence, the *tert*-butyl group in the 5-position does not have the same stabilizing effect as that in the 2-position at the heteroatom[10].

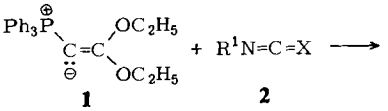
Regioselective 5-*exo-trig* Cyclization in the Reaction of [Bis(ethylthio)vinylidene]triphenylphosphorane with Heteroallenes

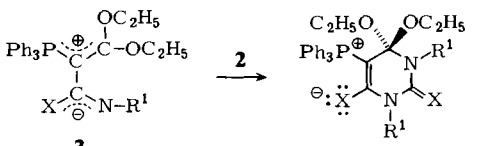
By *Hans Jürgen Bestmann** and *Kurt Roth*

Dedicated to Professor Georg Wittig on the occasion of his 85th birthday

(Diethoxyvinylidene)triphenylphosphorane **1** reacts with heteroallenes **2** (X = O, S, molar ratio 1:2) *via* intermediate **3** to give the pyrimidine derivatives **4**[1]. By analogy with **2** (**2** = **7**), [bis(ethylthio)vinylidene]triphenylphosphorane **5**[2] should form betaines **8** *via* intermediate **6**. On the basis of our earlier results[2], it was expected that in contrast to the ethoxy compounds **1**, *two* cyclization



1 **2**

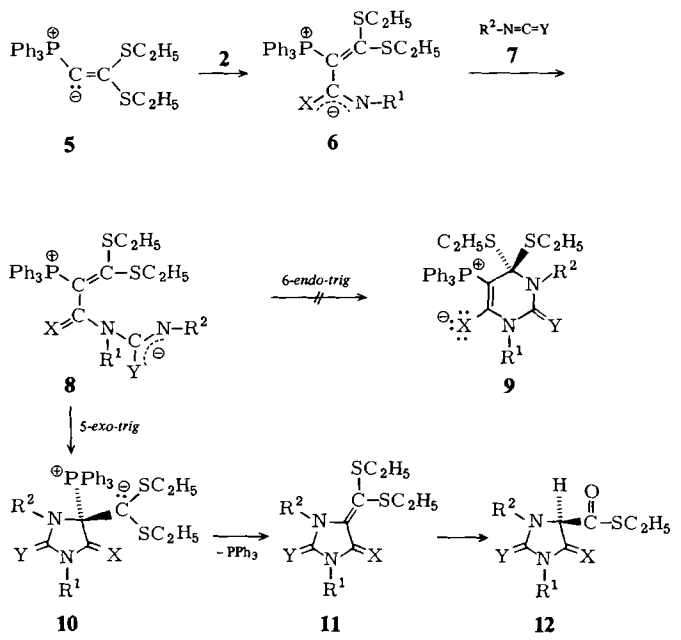


3 **4**

pathways could be followed by **8**: a) 6-*endo-trig* ring-closure to **9** and b) 5-*exo-trig* ring-closure to **10**[3]. The route to **10** thus arises because the sulfur atoms are able to stabilize the negative charge on the β-C atom (relative to phosphorus)[2]. As an E1cB intermediate, **10** loses triphenylphosphane to form **11**. From studies of models, the Bürgi-Dunitz-Lehn pathway[4] for the approach of the nucleophilic N atom in **8** to the trigonal C atoms of the double bond should be considerably more energetically favorable for 5-*exo*- than for 6-*endo*-cyclization[5]. Our results confirm this. Reaction of **5** and isothiocyanates **2** (X = S) results in formation of the crystalline betaines **6**, whose

[*] Prof. Dr. H. J. Bestmann, Dr. K. Roth
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (Germany)

reaction with aliphatic isocyanates **7** (R^2 = alkyl; Y = O) leads regioselectively, *via* 5-*exo*-*trig* cyclization of **8** (X = S, Y = O) and subsequent displacement of triphenylphosphane, to the hydantoin derivatives **11** (X = S, Y = O). In the reaction of **5** with isocyanates **2** (X = O), the betaines **6** cannot be isolated, because they immediately react with more heteroallene **2** (**2** = **7**, X = Y = O) to afford **11** (X = Y = O) (Table 1). Pyrimidine derivatives **9** formed by 6-*endo*-*trig* cyclization could not be detected by ^{31}P-NMR or mass spectroscopy.



5 **6** **8** **9** **10** **11** **12**

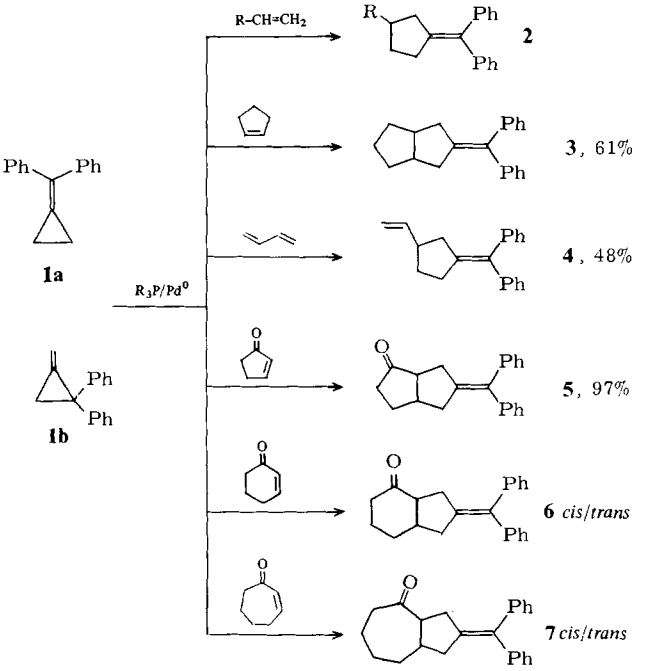
Palladium(0)-Catalyzed [3 + 2]-Cycloadditions of Diphenylmethylenecyclopropanes to Alkenes**

By *Paul Binger** and *Peter Bentz*

[3 + 2]-Cycloadditions are the simplest route to cyclopentane derivatives, which also play an important role in the synthesis of natural products. The palladium(0)-catalyzed [3 + 2]-cycloaddition of methylenecyclopropane to alkenes developed by us did not previously correspond to the requirements of a generally applicable synthesis, since it could only be carried out with a limited number of alkenes (alkyl acrylates, dialkyl fumarates or maleates, and alkenes with strained double bonds)[1]. We have now found that with 1-(diphenylmethylene)cyclopropane **1a** or 2-methylene-1,1-diphenylcyclopropane **1b** these difficulties can be overcome.

1a and **1b** react faster and more selectively than methylenecyclopropane with the above mentioned alkenes. Furthermore, 1-alkenes, cyclopentene, 1,3-butadiene, or 2-cycloalken-1-ones also undergo this Pd(0)-catalyzed reaction.



2a, R = H, 83% yield; **2b**, R = CH_3, 83%, **2c**, R = C_2H_5, 86%; **2d**, R = Ph, 88%; **6**, 76% (*cis* : *trans* = 74 : 26); **7**, 80% (*cis* : *trans* = 16 : 84); the values given are crude yields for the reaction with **1a** (determined by GC). All compounds were characterized by elemental analysis and spectroscopic methods.—Example: **2c**, synthesized from **1a**, iPr$_3$P, (η^5-C_5H_5)(η^3-C_3H_5)Pd (25 : 1 : 1) in toluene, 0 °C, 1.5 bar, 1-butene.

[*] Dr. P. Binger, P. Bentz
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim an der Ruhr (Germany)

[**] This work contains parts of the dissertation planned to be presented by P. Bentz, Universität Kaiserslautern in 1982.

Irrespective of the substitution pattern of educt **1** (**1a** or **1b**), 3- or 3,4-substituted, 1-(diphenylmethylene)cyclopentanes are obtained, mainly in high yields, after 1–8 h at 80–130 °C.

1-(Dialkylmethylene)cyclopropanes are less suitable as educts, since their isomerization to 1,3- and/or 1,4-alkadiene derivatives, which is also catalyzed by Pd(0), on the whole proceeds faster than the desired cycloadditions.

The methylenecyclopentane derivatives **2**–**7** are, in part, interesting educts for the synthesis of natural products containing cyclopentane, since **2**–**7** can be converted readily *via* ozonolysis into cyclopentanone derivatives and, *e.g.*, instead of pure 1-alkenes, heteroatom-containing 1-alkenes, 1,x-dienes, or enynes, whose middle double or triple bonds do not react in these [3+2]cycloadditions, can also be used.

In **1** the reactivity of the double bond is markedly less than in methylenecyclopropane. Consequently, Pd(0)-catalyzed cyclodimerization of **1** largely does not occur, and hence cycloadditions to less reactive olefins also become possible. The formation of the same final products **2**–**7** irrespective of whether **1a** or **1b** is used requires an isomerization during the reaction. This should occur in an organopalladium intermediate that can be written in several valence isomeric forms[1,3,4].

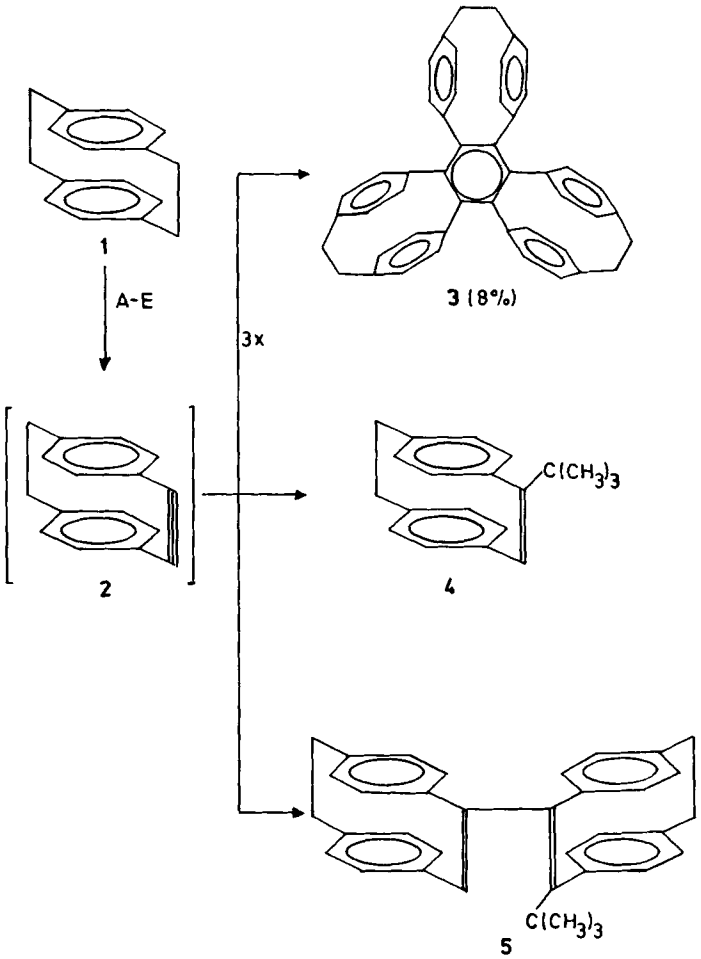
Trifoliaphane—The Trimer of a [2.2]Paracyclophane with an Ethyno-Bridge**

By *Manfred Psiorz* and *Henning Hopf**

The tendency of strained cycloalkynes to participate in addition reactions has been especially valuable for the synthesis of polycyclic hydrocarbons[1]. We were interested whether the 1-alkyne **2** may be generated from [2.2]paracyclophane **1**, and whether the former, presumably very reactive "cyclophyne" trimerizes to the hexaphenylbenzene derivative **3**. In contrast to hexaphenylbenzene itself, which in its crystalline state possesses a propeller-type structure with a pitch of 65°[2], in **3** the benzene rings, because of the bridging, should be aligned in a parallel fashion and perpendicular to the central ring; this structural feature could give rise to an electronic interaction between the peripheral rings extending like a torus around the inner, orthogonal π-system.



Scheme 1. A: anhydrous CCl_4, 2000 W-daylight lamp, Br_2; B: KO*t*Bu, dimethyl sulfoxide, 1 h, 20 °C (A and B 44% yield); C: toluene, PCl_5, 1 h, reflux (63%); D: *t*BuOH, 1 M KO*t*Bu, 1 h, reflux (95%); E (lithiation/elimination): a) *t*BuLi, 2 h at −60 °C in tetrahydrofuran (THF); b) add solution in boiling THF dropwise, 2 h reflux.

Hydrocarbon **3** (dec. >360 °C) may indeed be obtained from **1** by the five-step reaction sequence shown in Scheme 1. The proof of structure for **3** rests on the mass spectrum [(*m/z* 612 ($M^{\oplus}$, 61%), 306 ($M^{2\oplus}$, 100%) and predominantly on the NMR-spectra [^{1}H-NMR ($CDCl_3$, int. TMS): $\delta = 3.02$ (s, 12H, ethano-bridges), 6.65 (q, pseudo-AB-system $J_{AB} = 4.5$ Hz, 24H, aromatic protons); ^{13}C-NMR ($CDCl_3$, int. TMS): $\delta = 141.15$ (s), 140.04 (s), 138.87 (s), 133.03 (d), 132.49 (d) and 34.93 (t)]. The vibrational spectrum [(KBr): $\nu = 3000$ (m), 2920 (s), 2845 (m), 1587 (s-m), 1490 (m), 1392 (m), 1088 (m), 925 (m), 760 (m), and 719 cm^{-1} (vs)] and electronic spectrum [(CH_3CN): $\lambda_{max} = 307$ ($\varepsilon = 1400$), 230 (51000), 210 nm (3900)] are comparatively simple and unstructured, respectively, and resemble the corresponding spectra of **1** and [2](4,4'')orthoterphenylophane[3]. The last elimination step provides, besides **3**, varying amounts of the etheno-bridged paracyclophanes **4** and **5**[4], supporting the intermediate formation of **2**, since analogous alkylation and coupling products arise from other strained cycloalkynes as well[5].

We suggest the trivial name trifoliaphane for the novel hydrocarbon **3**, since its structure reminds one of a three-

Ferromagnetic Interaction between Orthogonal "Magnetic" Orbitals in Dinuclear $Cu^{II}Cr^{III}$ Complexes

By *Yves Journaux, Olivier Kahn**, and *Hubert Coudanne*

One of the goals of our work on heterodinuclear complexes is to design a synthetic strategy to compounds exhibiting intramolecular ferromagnetic coupling. We have previously obtained the $CuVO(fsa)_2en \cdot CH_3OH$[1] and $CoCu(fsa)_2en \cdot 3H_2O$[2] complexes [$(fsa)_2en^{4-}$ is a bichelate ligand derived from the Schiff base 3,3'-ethylenebis(nitrilomethylidyne)disalicylic acid]. In both cases, the "magnetic" orbitals[3]—singly occupied orbitals of transition metal ions, which are partly delocalized in the direction of the surrounding ligands—of both metal ions are strictly orthogonal. We now describe a heterodinuclear complex in which one of the two metal ions possesses more than one unpaired electron.

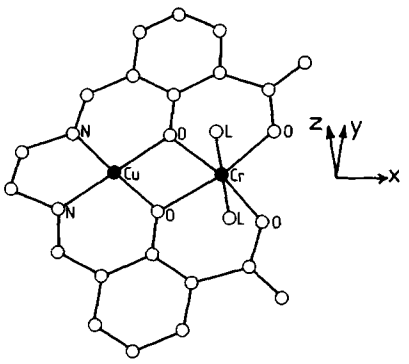

Fig. 1. Schematic representation of the structure of $[Cu^{II}Cr^{III}(fsa)_2enL_2]^+$.

$[Cu^{II}Cr^{III}(fsa)_2en(H_2O)_2]Cl \cdot 3H_2O$ **1**, the first $Cu^{II}Cr^{III}$ complex, also has strictly orthogonal magnetic orbitals. Indeed, if the Cu^{II} ion is in a planar N_2O_2 environment and the Cr^{III} ion in a pseudo-octahedra $O_2O_2L_2$ environment (see Fig. 1), the symmetry of each metallic site is very close to C_{2v}. It turns out that the unpaired electron on the Cu^{II} occupies a xy-type orbital (B_1) and that the three unpaired electrons around Cr^{III} occupy x^2-y^2, xz, and yz-type orbitals (A_1, B_2, and A_2, respectively). There is no overlap between the B_1 magnetic orbital around Cu^{II} and the A_1, B_2, and A_2 magnetic orbitals around Cr^{III}, and this makes pairing of electrons in MO's of low energy unfavorable. Consequently, it might be predicted that the $Cu^{II}Cr^{III}$ complex would exhibit strong ferromagnetic interaction.

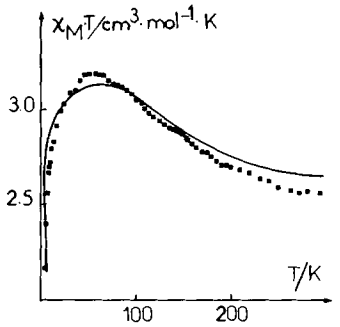

Fig. 2. Temperature dependence of $\chi_M T$ for **1**. ■: experimental points; — calculated curve.

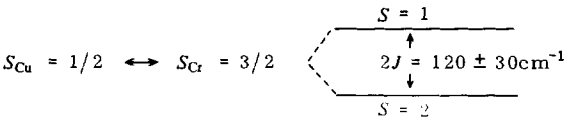
Figure 2 shows the temperature dependence of the product of the molar magnetic susceptibility χ_M temperature T between 4 and 300 K. $\chi_M T$ increases as **1** is cooled from 300 K to about 45 K, reaches a maximum (3.19 cm^3 mol^{-1} K), and then decreases below this temperature. Qualitatively, the interpretation of the curve is straightforward. The interaction between the Cu^{II} doublet and the Cr^{III} quartet states gives rise to two spin states characterized by $S=1$ and $S=2$, the latter being the lower in energy. The maximum value of $\chi_M T$ corresponds to what it is expected for a totally populated quintet ground state without first order angular momentum. The decrease of $\chi_M T$ below 45 K could be due to the combined effect of intermolecular interaction and zero field splitting of the ground state quintet. Quantitatively, an agreement between calculated[4] and observed $\chi_M T$ values is obtained for a triplet-quintet energy gap $2J$ between triplet and quintet states of 120 ± 30 cm^{-1} (Scheme 1).



Scheme 1.

The intramolecular ferromagnetic coupling observed in this $Cu^{II}Cr^{III}$ pair confirms the concept of orthogonality of the magnetic orbitals.

[6] The theoretical magnetic susceptibility was derived from the spin Hamiltonian $[\mathcal{H}=(g_{Cu}\hat{S}_{Cu}+g_{Cr}\hat{S}_{Cr})\beta H-J\hat{S}_{Cu}\cdot\hat{S}_{Cr}-ZJ'\hat{S}_z\langle\hat{S}_z\rangle]$ where the symbols have their usual meaning. The last term accounts for the intermolecular interaction.

Functionalization at Proanomeric Centres by Photobromination: A Novel Access to Oxo- and Acyloxyimino-glycosyl Bromides**

By *Frieder W. Lichtenthaler** and *Pan Jarglis*

Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday

The range of reactions undergone by sugars at the anomeric centre form the backbone of carbohydrate chemistry[2]. In contrast, reactions of monosaccharides at their proanomeric centres, *i.e.* those which become anomeric by introduction of a functional group at C-4 in furanoid or at C-5 in pyranoid systems, are rare; they usually involve elaboration of a double bond in the proanomeric position and subsequent addition reactions[3] or free-radical bromination[4] which, however, mostly give low to moderate yields.

By placing an electron acceptor group, *i.e.* oxo- or acyloxyimino functionalities next to the proanomeric centre, its C—H bond becomes push-pull—or capto-datively[7]—substituted, and, hence, highly radicophilic. Thus, radical reactions proceed with considerably greater ease with higher regio- and stereoselectivity, as is amply demonstrated by the smooth, high yield photobrominations of **1**—**6** (cf. Scheme 1).

With **1** and **2**, photobromination is essentially stereospecific, and no products other than α-glycosyl bromides **7** and **8** are obtained which have high potential for the preparation of α- and β-linked glycosyl glycosides. Enolones are also readily accessible, since alcoholysis under slightly basic conditions is accompanied by β-elimination. Accordingly, upon *in situ* anomerization with tetraethylammonium bromide followed by methanolysis **7** preferentially affords (isolated yield: 66%) the α-D-enolone (**3**, OMe instead of α-OBz), whereas exposure to methanol in the presence of $NaHCO_3$ yields the respective β-D-anomer (80%).

In the tribenzoyl enolone **3** the proanomeric centre is vinylogously push-pull activated, yet due to the presence of only one conformationally determining substituent in the radical intermediate, a 3:1 mixture of anomers result, of which the major, α,α-isomer **9**, is isolable in 51% yield.

Utilization of hydroxyimino functions as the captive ("pull") element of a capto-dative system also requires protection of this OH group, which is most suitably effected by benzoylation. Thus, the peracylated 1,5-anhydro-D-fructose derivatives **4** and **5** readily give the oximinoglycosyl α-bromides **10** and **11** in high yield. The availability of such α-bromides in stable, storable form is capable of providing an efficient access to amino sugar-containing oligosaccharides by simple displacement of the bromine *via* a Königs-Knorr glycosylation reaction, reduction, and deblocking. This approach has close analogies to *Lemieux*'s nitroso-halogenide procedure[21], yet holds the additional advantage that disaccharide-derived analogs of **10** and **11**, which constitute versatile building blocks for the construction of lactosamine-, maltosamine-, and cellobiosamine-containing oligosaccharides, may easily be prepared. The

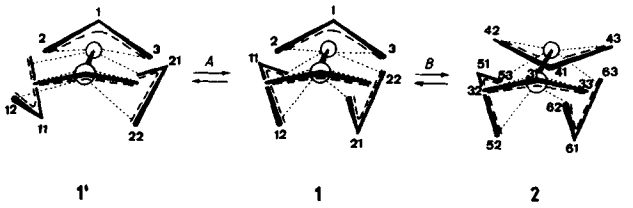
Two-Dimensional Dynamic ^{13}C-NMR Spectroscopy—An Investigation of $(\eta^3\text{-}C_3H_5)_4Cr_2$

By *Reinhard Benn**

Chemical exchange processes were hitherto investigated NMR spectroscopically almost solely by line-shape analysis[1] and magnetization-transfer methods[2]. It has already been shown[3] that exchange networks can be obtained directly with the aid of two-dimensional NMR spectroscopy (2D-NMR). In the following it is demonstrated with tetraallyldichromium $(\eta^3\text{-}C_3H_5)_4Cr_2$ as example, that two-dimensional ^{13}C-^{13}C-shift correlation diagrams are especially suitable for the qualitative investigation of exchange processes.



In [D$_6$]benzene at 30 °C $(\eta^3\text{-}C_3H_5)_4Cr_2$ is present as a 60:40 mixture of the isomers **1** and **2**. Each isomer has two *trans* η^3-allyl groups bridging the metal atoms. The other two η^3-allyl ligands are *cis*-oriented in **1** and *trans*-oriented in **2**[4]. Accordingly, the noise-decoupled ^{13}C-NMR spectrum of **1** shows seven signals, that of **2** twelve signals (Table 1); these were assigned on the basis of a two-dimensional ^{13}C-^{1}H-shift correlation diagram[5] using the ^{1}H chemical shifts[4].

The structural dynamic behavior of **1** and **2** can be deduced from the two-dimensional ^{13}C-^{13}C-shift correlation diagram without a detailed knowledge of the assignment. A section from the contour plot of the ^{13}C-^{13}C-shift correlation diagram is shown in Figure 1. The positions of the ^{13}C-NMR signals are given as contour lines on the middle line; for clarification the conventional one-dimensional ^{13}C-NMR spectrum is reproduced at the top of Figure 1. In the two-dimensional spectrum further contour lines, so-called cross peaks, appear above and below the middle line. Differences in the ^{13}C chemical shifts are indicated on the vertical axis; related cross peaks have the coordinates $[\delta_a; \frac{1}{2}(\delta_a-\delta_b)]$ and $[\delta_b; \frac{1}{2}(\delta_b-\delta_a)]$[3]; *e.g.* the cross peaks of C21 and C11 connected by an extrapolated line have the coordinates (106.90; 2.35) and (102.20; −2.35). These cross peaks provide direct evidence of an exchange of C21 with C11, which is caused by a 180° rotation of the

bridging η^3-allyl groups (in phase with respect to the NMR time scale) (Process *A*; **1** and **1'** are mirror images). In addition, two further cross peaks each are observed on the vertical axis of the signals of C21 and C11: the peaks belonging to them, with which they are connected by dotted lines, lie on the vertical axis of δ(C61) and δ(C51). These cross peaks indicate a second exchange process (*B*), namely the exchange of **1** with **2**, most likely by rotation of a non-bridging η^3-allyl group about the metal-metal axis. As a result of both processes C21 is exchanged with C61 and C51, and C11 with C61 and C51, respectively; a further consequence is the exchange of C51 with C61. The relevant cross peaks are likewise connected by a dotted line.

^{13}C-^{13}C-exchange networks, in contrast to those of protons, have the advantage that cross peaks do not occur as a result of homonuclear scalar couplings or nuclear-Overhauser interactions[3]. It would therefore appear that a ^{13}C-^{13}C-shift correlation diagram is the best method for the qualitative investigation of exchange processes in the case of readily soluble samples.

Double Layer Formation with a Surfactant-Type Crown Ether Complex: Crystal Structure of 15,15-Bis(dodecyloxymethyl)[16]crown-5 · NaSCN**

By *Mátyás Czugler, Edwin Weber*, Alajos Kálmán, Birgitta Stensland,* and *László Párkányi*

Crown ethers containing structural units which are typical for surfactants[1a] are of interest for problems of energy transport and storage and in organic semiconductor and liquid-crystal technology[1b]. We report here for the first time on the molecular structure of a surfactant-type crown ether alkali metal ion complex and on the state of order in the crystal lattice.

Dr. B. Stensland
Arrhenius Laborium der Universität
S-10691 Stockholm (Sweden)

[**] We thank Prof. Dr. P. Kierkegaard (Stockholm) for helpful discussions; this work was supported by the Hungarian Academy of Sciences and the Royal Swedish Academy.

The crown ether **1**[2] forms a 1:1 complex with NaSCN in acetone/ether (yield 75%, colorless platelets, m.p. 75–77 °C). According to an X-ray structure analysis of this amphiphilic complex (Fig. 1) the conditions within the crown ether moiety closely resemble those in the Na^+-complex of the unsubstituted [15]crown-5[4].

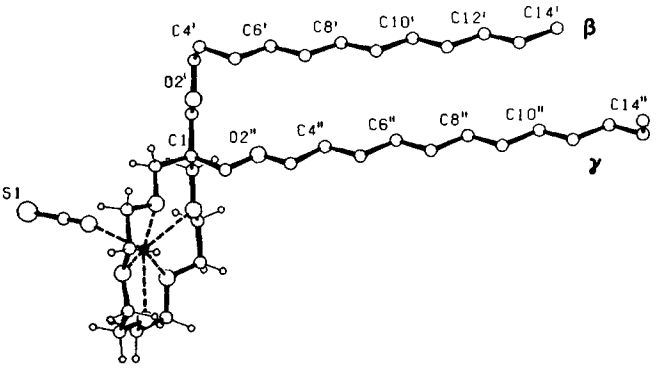

Fig. 1. Structure of **1** · NaSCN in the crystal (average distances: NaO = 243 pm, NaN = 233.4 pm).

Surprisingly, the tail groups differ from each other considerably in their conformation: The chain pseudoaxial to the crown ether ring plane ("γ-chain") is, with exception of the C13"C14" bond (*gauche* arrangement), *all-trans* configurated, whereas in the pseudoequatorial chain ("β-chain") a characteristic *helical kink* arises from the presence of two immediately consecutive *gauche* arrangements at the C4' atom.

Thus, the structure of the crystalline **1** · NaSCN complex shows interesting parallels to membrane-forming lipids such as 3-lauroylpropanediol-1-phosphorylcholine monohydrate (LPPC)[6] or egg phosphatidylcholine (EPC)[7]: the expanse of the crown ether head group (70 $Å^2$) closely approaches that found at the surface of EPC vesicles (74 $Å^2$[7]); crystalline LPPC shows an analogous helical kink, which lies merely one C-atom nearer to the chain terminal[6].

The *double layer structure* of type "M//"[6] characteristic for LPPC crystals is also found in the crystals of **1** · NaSCN, the head and tail groups of the ligand each being aggregated (Fig. 2). Interlamellar contacts protruding out from the "anionic" sides of the crown ether rings (external surface of the double layer) do not exist. In the crystal of **1** · NaSCN the double layer has a diameter of 2270 pm, in LPPC crystals it is only slightly thicker (2350 pm)[6].

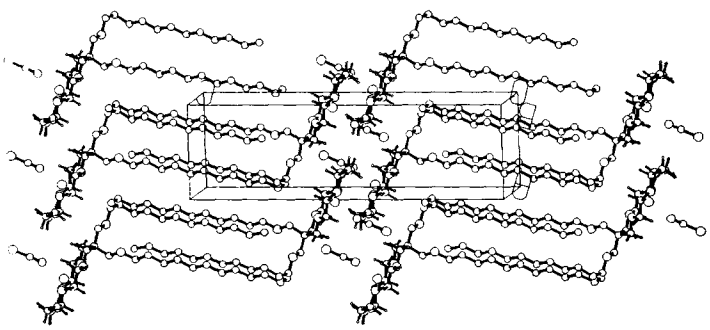

Fig. 2. Molecular packing in the crystal of the **1** · NaSCN complex showing the unit cell (as in Fig. 1, the H-atoms have been omitted for clarity).

These results demonstrate that such surfactant crown ethers and their complexes are suitable as model compounds for biogenic lipid molecules; this is important in as much as the fine structure of natural membrane-forming compounds could so far be determined only in very few cases and with limited accuracy. It is suggested that the free ligand **1** could be used as an ion-selective membrane carrier.

cis-$[Ru(bpy)_2(CO)H]^+$ — A Possible Intermediate in the Photochemical Production of H_2 from Water Catalyzed by $[Ru(bpy)_3]^{2+}$?**

By *John M. Kelly** and *Johannes G. Vos*

The intensity of interest in the chemistry of bipyridyl complexes of ruthenium has been largely generated by the use of these complexes as intermediaries in the photodissociation of water by visible light[1]. Another possible approach would be to use hydride complexes as the hydrogen-evolving centers with the same complex possibly also acting as primary electron acceptor. We now report the ready preparation of the PF_6 salt of $[Ru(bpy)_2(CO)H]^+$, a complex cation which in aqueous solution below pH 7 is converted into $[Ru(bpy)_2(CO)(H_2O)]^{2+}$ and H_2.

cis-$[Ru(bpy)_2(CO)Cl]^+$ and $NaBH_4$ react in aqueous ethanol to give *cis*-$[Ru(bpy)_2(CO)H]^+$ **1**, the complex being isolated as its hexafluorophosphate derivative in greater than 70% yield. The corresponding 4,4′-dimethylbipyridyl derivative *cis*-$[Ru(C_{12}H_{12}N_2)_2(CO)H]^+$ **2** was prepared analogously. Both products gave satisfactory elemental analysis and were identified by IR and NMR spectroscopy. A singlet in the ^{1}H-NMR of **1** at $\delta = -11.47$ is direct evidence for the presence of the hydride ligand[2], whereas the resonances in the region $\delta = 7.2-9.3$ are those expected for the 16 magnetically nonequivalent bpy protons (the two different *cis*-bpy ligands have different environments). The carbonyl stretch ν_{CO} for **1** at 1930 cm^{-1} is at a lower wavenumber than that in $[Ru(bpy)_2CO(Cl)]^+$ and other $[Ru^{II}(bpy)_2(CO)X]^{n+}$ complexes[3], consistent with the electron donating ability of the hydride ion. The absorption spectrum of the PF_6 salt of **1** (over the range 300 nm to 600 nm) is given in Figure 1 together with those of $[Ru(bpy)_2(CO)Cl]^+$ **3** and $[Ru(bpy)_2(CO)_2]^{2+}$ **4**. In **3** or **4** the metal-ligand charge transfer (MLCT) band, which is found in the visible region in many other $Ru(bpy)_2$ complexes[3], is shifted to shorter wavelengths. The spectrum of **1** is distinguished by a band at 448 nm, which may possibly be due to an MLCT transition. It is probable that the lowest excited state of **1** is different from that of **3** and **4**, since irradiation of methanolic solutions of **1** ($\lambda > 330$ nm) leads only to very slow decomposition, whereas decarbonylation of other $[Ru^{II}(bpy)_2(CO)X]^{n+}$ complexes takes place rapidly under identical irradiation conditions.

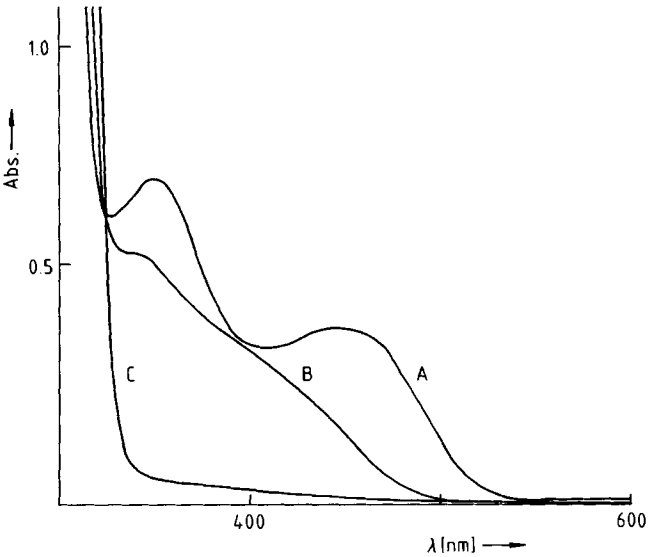

Fig. 1. Absorption spectra of 1.0×10^{-4} M CH_3CN solutions of the PF_6 salts of $[Ru(bpy)_2(CO)H]^+$ **1** (A), $[Ru(bpy)_2COCl]^+$ **3** (B), and $[Ru(bpy)_2(CO)_2]^+$ (C).

The hydride complex cations **1** and **2** are stable in organic solvents or in weakly alkaline aqueous buffer solution (*e.g.* at pH 9.1). In the presence of acid, however, **1** decomposes rapidly giving $[Ru(bpy)_2(CO)(H_2O)]^{2+}$ **5** and H_2 [eq. (a)]. The aquocomplex **5** was identified from its NMR and UV/VIS spectra by comparison with an independently prepared sample[5a], and the H_2 detected by mass spectrometry[5b]. The decomposition of **1** proceeds slowly even in neutral aqueous solutions and more rapidly in weakly acidic solution. At pH 5.1 (0.1 M potassium hydrogen phthalate buffer) the half-life of **1** at 18 ± 1 °C is *ca.* 10 min.

$$\underset{\mathbf{1}}{[Ru(bpy)_2(CO)(H)]^+} + H_3O^+ \rightarrow \underset{\mathbf{5}}{[Ru(bpy)_2(CO)H_2O]^{2+}} + H_2 \quad (a)$$

The observation that this relatively photostable hydride complex may be readily prepared and that it rapidly decomposes in weakly acid solution to give H_2 suggests that it may well be able to act as a hydrogen producing center in photocatalytic reactions. It is interesting to note that **1** is prepared from $[Ru(bpy)_2(CO)Cl]^+$, which we previously[3] showed to be a substantial byproduct of the reaction used to prepare $[Ru(bpy)_2Cl_2]$ for the synthesis of surfactant derivatives of $[Ru(bpy)_3]^{2+}$[6a]. Although monolayers of these surfactant derivatives were initially reported to sensitize photoproduction of H_2 from water, this was not the case for carefully purified samples, and it was assumed that some unidentified impurity was responsible for the observed activity[6a,b]. It is intriguing to speculate whether hydride complexes such as **1** might have played a role in the original photoreaction. Complexes such as **1** and **2** may also have potential as water gas shift or hydroformylation catalysts, particularly in view of the recent report that $[Ru(bpy)_2COCl]^+$ acts as a catalyst for the photo-induced water gas shift reaction[6c].

Procedure

$[Ru(bpy)_2(CO)Cl]ClO_4$ (0.5 g) in refluxing ethanol/water (2 : 1 v/v) was treated with $NaBH_4$ (0.5 g) dissolved in the minimum of water. After being refluxed for 20 min, excess of an aqueous solution of NH_4PF_6 was added. Upon standing (12 h) crystals formed in the solution (yield 0.42 g; 80%). The crude material was further purified by chromatography on neutral alumina using acetone as eluent, and then recrystallized from acetone/water mixtures. The orange crystals obtained were dried *in vacuo* at room temperature. $1 \cdot PF_6 \cdot 0.5(CH_3)_2CO$: ^{1}H-NMR (80 MHz, CD_3CN); $\delta = 9.1-9.3$ (m, 2H), 7.2—8.6 (m, 14H), 2.09 (s, 3H), −11.47 (s, 1H). UV/VIS (CH_3CN) $\lambda_{max} = 275$ ($\lg\varepsilon = 4.48$), 353 (3.70), 448 (3.49). IR (KBr): $\nu_{CO} = 1930$ cm^{-1}.

Designed Synthesis of an Alkylidyne-Capped Trinuclear (Mo, Mo, W) Metal Cluster**

By *F. Albert Cotton** and *Willi Schwotzer*

Methods for the intentional assembly of preselected metal atom clusters (designed syntheses) are still scarce. This is particularly true for the so-called "electron-poor trinuclear clusters" recently reviewed[1] and currently under active study here and elsewhere[2, 3]. We report here on a successful designed synthesis that has led to a mixed-metal cluster compound with the metal atoms (namely Mo and W) in relatively high oxidation states (average = 10/3) and a capping alkylidyne ($\equiv C-C_6H_5$) group. The new compound **1** has been conclusively identified (NMR, IR) and structurally characterized by X-ray crystallography. Not only is the cluster compound of interest, but the reaction used to prepare it is a paradigm for other such syntheses.

The preparative method used was the following:

$$(\eta^5\text{-Cp})(OC)_2Mo{\equiv}Mo(CO)_2(\eta^5\text{-Cp}) + \textit{trans}\text{-}Br(OC)_5W{\equiv}CC_6H_5 \rightarrow$$

$$Mo_2WBr_3(CO)_3(\eta^5\text{-Cp})_2(CC_6H_5)$$

1

The principle involved[4] is the addition of an M≡M bond to an M′≡CR bond to generate a tetrahedral cluster of the type $M_2M'C$[5]. There are some additional complications involved in this particular reaction since the Br/W ratio in the product (3 : 1) is greater than that in the reactant (1 : 1) and some CO is eliminated. These features of the reaction are still under study.

The product **1**, after chromatographic purification, is obtained as a brownish-black crystalline solid (yield 20%) that slowly decomposes in moist air. The crystal contains molecules (Fig. 1) in which an isosceles triangle of two Mo atoms and one W atom, bonded to each other, is capped by a C_6H_5C group that forms a C—M bond to each metal atom. On the opposite side of the Mo_2W plane there is a bridging CO group across the Mo—Mo bond and bridging Br atoms across each Mo—W bond. Three ligands (Br, 2CO) complete a distorted octahedron around the W atom, and the η^5-C_5H_5 ligand on each Mo atom can be considered, formally, to occupy three mutually *cis* octahedral coordination sites on those atoms. The structure is thus of the same type already well known[1] for $[Mo_3O_4F_9]^{5-}$, $[W_3O_4F_9]^{5-}$, and many complexes of the trinuclear aquomolybdenum(IV) ion.

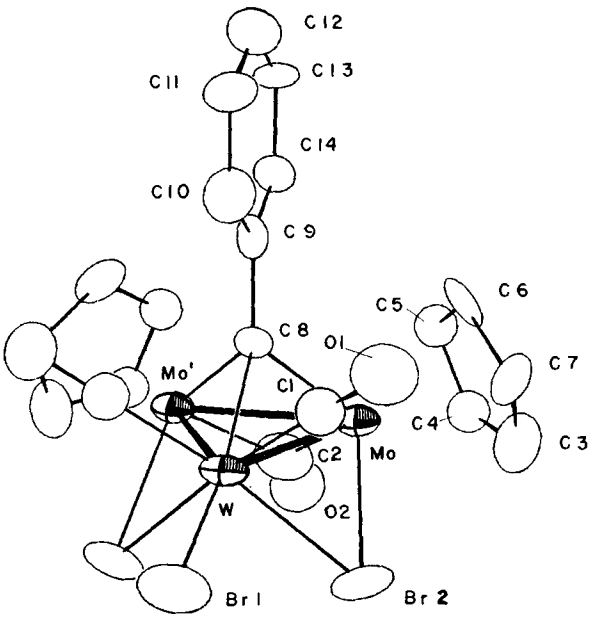

Fig. 1. ORTEP drawing of the molecular structure of **1**. The metal atom cluster, Mo_2W, and the metal-metal bonds are shown with heavier lines at the center.

Some important bond lengths [pm] are: Mo—Mo, 276.6(3); Mo—W, 264.7(2); Mo—CPh, 198(1); W—CPh, 215(2). Compound **1** crystallizes in the space group Pnma with $Z = 4$; each molecule has a crystallographic plane of symmetry containing the W, μ-CO, the entire capping group, and the terminal Br atom. Assigning valences of −1 to the Br and C_5H_5 groups, −3 to PhC and −2 to μ-CO, the Mo_2W cluster is found to have 8 electrons. According to previous analyses of bonding in cluster compounds with this type of structure[3] this gives rise to a set of three single bonds with two additional electrons occupying a delocalized, symmetrical molecular orbital that is slightly antibonding with respect to the Mo_2W ring.

Coupling of Sterically Hindered Peptide Bonds—A Renaissance of the Acid Chloride Method**

By *Hans-Heinrich Bechtolsheimer* and *Horst Kunz**

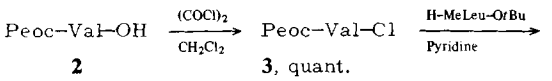
Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

Because of the high incidence of side reactions, high susceptibility to racemization, and contamination by phosphorus compounds, activation of the carboxy group *via* the acid chloride has largely lost significance in peptide synthesis[1]. The advantages of the high reactivity of the acid chloride are thus no longer exploited.

However, in the coupling of sterically demanding amide bonds, as they frequently occur *e.g.* in natural depsipeptides, a strong activation of the carboxylic acid cannot be circumvented. Hence, for the formation of the strongly hindred amide bonds of sporidesmolic acid B **1** *Ovchinnokov et al.*[2] resorted to the acid chlorides of *N*-and *O*-benzyloxycarbonyl-protected synthons, despite the danger of benzyl chloride cleavage and the side reactions of the Leuchs-anhydrides.

H-Hyiv-Val-MeLeu-OH **1**

The extremely acid-stable 2-(triphenylphosphonio)-ethoxycarbonyl (Peoc) protecting group developed by us[3] now enables synthesis of the stable acid chlorides of the amino and hydroxy acids, even at room temperature. In contrast to amino acids with other N-protecting groups even oxalyl chloride can be used as reagent. For example, after addition of reagent at 0 °C in dichloromethane, the acid chloride **3** is smoothly generated from Peoc-valine **2**



2 **3**, quant.

Peoc–Val–MeLeu–O*t*Bu

4, 81%

on warming to room temperature. Since only volatile by-products are formed there is no fear of contamination of the resulting peptides. Solvent and excess oxalyl chloride are removed *in vacuo*. Because of its high reactivity we could couple **3** with *N*-methylleucine *tert*-butyl ester to give the Peoc-dipeptide ester **4**, for the synthesis of **1**. This process, which requires 1 h at −20 °C, followed by 12 h at room temperature, is of general utility for the synthesis of sterically hindered peptide bonds.

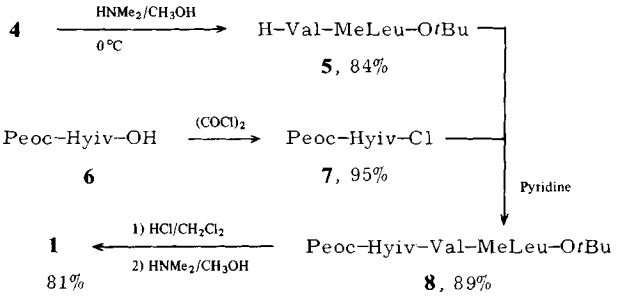
Institut für Organische Chemie der Universität
Johann-Joachim-Becher-Weg 18–20, D-6500 Mainz (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

After removal[3] of the Peoc group from **4**, **5** is coupled with the free amino function on the *O*-Peoc-hydroxyisovaleroyl chloride **7** obtained from **6**[4] to give the completely protected sporidesmolic acid B derivative **8**. The structure of **8** was confirmed by the 200-MHz ^{1}H-NMR spectrum.—



Successive cleavage of the *tert*-butyl group and the Peoc group at 0 °C affords the free sporidesmolic acid B **1**. Its melting point and IR spectrum were identical with those of an authentic sample obtained from natural sporidesmolide I[5]. The rotation ($[\alpha]_D^{21} = -106.7$ ($c = 0.47$, glacial acetic acid)) also almost reached that of the natural product ($[\alpha]_D^{19} = -108$, glacial acetic acid), thus indicating that no racemization has taken place on using this acid chloride method despite the twofold activation and condensation involved.

New Method for the Synthesis of *N*-Vinylamides**

By *Günter Schmitt** and *Wolfgang Ebertz*

Dedicated to Professor Friedrich Asinger on the occasion of his 75th birthday

Attempted basic hydrolysis of 2-ferrocenyl-2-oxazolines, interesting intermediates for the preparation of 1,2-disubstituted ferrocenes[2], led to the discovery of novel, general reaction patterns for 2-oxazolines. It was found that 2-oxazolines **1** having at least one H-atom in the 4-position always isomerize to *N*-vinylamides **2** on reaction with potassium *tert*-butoxide (KO*t*Bu) in solvents such as hexamethylphosphoric triamide (HMPT), dimethyl sulfoxide or dimethoxyethane if C-5 is substituted by at least one alkyl

[*] Priv.-Doz. Dr. G. Schmitt, Dr. W. Ebertz

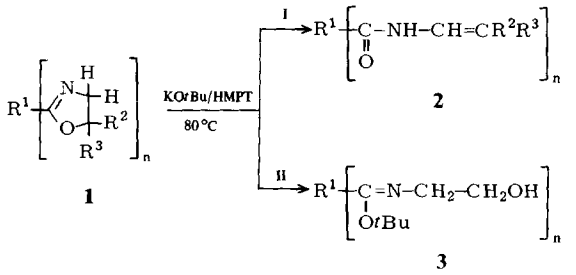
[**] This work was supported by the Fonds der Chemischen Industrie.

or aryl group (Route I). If the 5-position bears only hydrogen atoms then *tert*-butyl *N*-(2-hydroxyethyl)imidates **3** are formed (Route II). The reactions always proceed selectively in only one direction, irrespective of the type of substituents at the 2-position. Table 1 lists some examples.

Table 1. Reaction of 2-oxazolines **1** in the system KO*t*Bu/HMPT [a]. n = 1; in the case of **1i**, n = 2. Ferr = ferrocenyl.



Cpd.	R^1	R^2	R^3	*t* [h]	Product	Yield [%] [b]

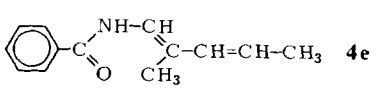
1o	Ferr.	H	H	196	**3d**	28

[a] Molar ratio KO*t*Bu : **1** = 5 : 1; 80 °C. [b] The isolated products gave correct elemental analyses and spectroscopic data. [c] Not isolated; same boiling point as HMPT, soluble in water. Characterization by ^{1}H-NMR in HMPT. [d] Mixture of the *Z*- and *E*-form; *Z*-fraction 70–75%. [e] 110 °C. [f] 100 °C.

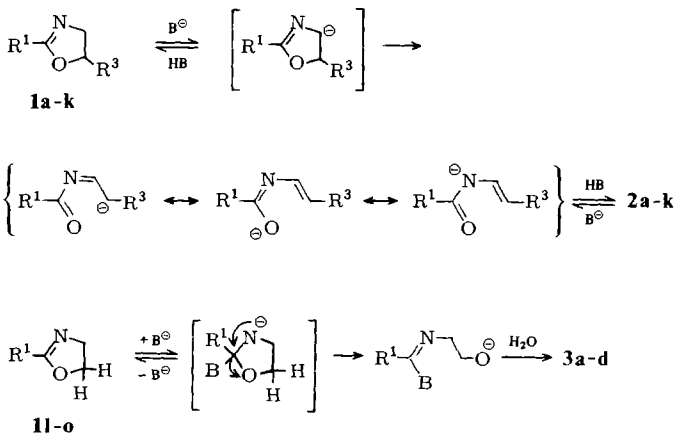
The rate of reaction strongly depends on the temperature and on the molar ratio KO*t*Bu : **1**. Thus, *e.g.*, reaction of **1e** in the system KO*t*Bu/HMPT at 100 °C with a molar ratio KO*t*Bu : **1e** of 5 : 1 proceeds quantitatively only after about 2 h, at 140 °C even after 2 min. A molar ratio of KO*t*Bu : **1** = 5 : 1 is recommended for syntheses on a preparative scale. A sudden drop in the rate of reaction is observed at molar ratios of less than 2 : 1. At a molar ratio of 1.5 : 1 quantitative conversion requires 5 h. With equimolar amounts of KO*t*Bu and **1** the reaction is even slower, and the vinylamide **2** formed as intermediate reacts further to give a byproduct; *e.g.* **1e** reacts at 110 °C to give **4e** (22% yield).



4e

According to current interpretations of the reaction mechanism the products **2** and **3** are formed as shown (B = *t*Bu).

This novel method can be exploited for the preparation of variously substituted *N*-vinylamides in satisfactory to good yields from 2-oxazolines, which in turn are readily accessible *via* numerous routes[4]. Because of its broad spectrum of use this new method is, from a preparative



point of view, far superior than any of the previously reported methods.

Controlled Modification of Crystal Habit by "Tailor-Made" Impurities: Application to Benzamide**

By *Ziva Berkovitch-Yellin, Lia Addadi, Marian Idelson, Mein Lahav,* and *Leslie Leiserowitz*

Minute amounts of impurities (or additives) present in solution during crystallization may have a pronounced effect on the crystallization process, in particular on the morphology of the deposited crystals[2]. We previously reported changes in habit of amino acids and derivatives induced during crystallization by the presence of minute amounts of chiral impurities of similar structure to the substrate[4–7]. Through these changes a stereochemical correla-

Rehovot, 76100 (Israel)

[**] This work was supported by the Stiftung Volkswagenwerk. We thank Prof. M. D. Cohen for discussions.

tion was established between the molecular structure of the impurity, the crystal structure of the substrate, and the effected growth directions, leading to a proposal of a two-step mechanism for the binding of the impurity at the growing crystal faces and retardation of growth. We have found that slightly modified substrate molecules yield impurities which are particularly effective in inducing such morphological changes.

By application of these principles it becomes possible to grow crystals with desired morphologies by "tailoring" impurities which bind at a preselected face and thus inhibit growth in a predictable manner. An advantage of this method is that the effect of factors such as temperature, solvent, and supersaturation may be kept constant by performing all crystallization experiments under identical conditions, except for the nature and concentration of the impurity. This approach is illustrated here for benzamide.

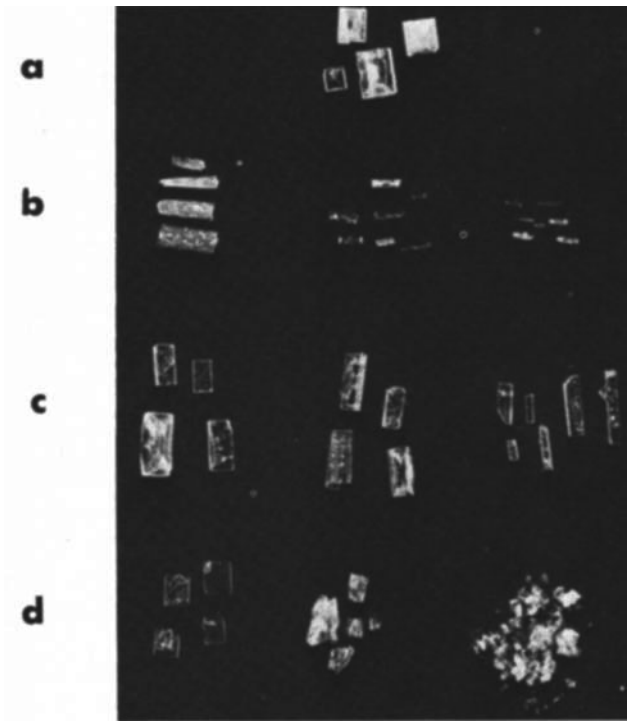

Fig. 1. Crystals of benzamide grown in absence and in presence of increasing amounts of impurities: a) pure benzamide, b) with benzoic acid (3%, 5%, 10%), c) with *o*-toluamide (1%, 5%, 10%), d) with *p*-toluamide (3%, 5%, 10%).

Benzamide crystallizes from ethanol in plate-like crystals elongated along the *b*-direction (Fig. 1a). The general features of this morphology may be rationalized in terms of the packing characteristics.

In the light of the correlation between the crystal structure and morphology of benzamide, it was possible to choose impurities to specifically modify the relative rates of growth along the three principal directions: Retardation of growth primarily along the *b*-axis was achieved by adding benzoic acid. This induces the crystals to grow in rod-form extending along the *a*-direction (Fig. 1b). Retardation of growth along the *a* axis was achieved by adding 1—10% of *o*-toluamide to the mother solution. This induces the crystals to grow in the form of rods extending along the *b*-direction (Fig. 1c). Finally, as expected, thinner and thinner platelets (Fig. 1d) were obtained by adding increasing amounts of *p*-toluamide.

In all cases the habit was modified gradually with the concentration of impurity in solution (Fig. 1). HPLC analysis indicates that only 0.2—0.5% impurities are found in the bulk of the crystal, even when the amount in solution was as high as 10%.

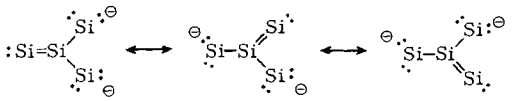
$Li_{12}Si_7$: Theoretical Interest Aroused

By *Joel F. Liebman** and *James S. Vincent**

Von Schnering et al. recently reported[1] the remarkable crystal structure of $Li_{12}Si_7$, a compound containing planar Si_4 star clusters and planar Si_5 rings. For our description of these two inherent structures we present here alternatives and precedents based on qualitative and quantitative MO considerations or on comparisons with isoelectronic species.

We start with the Si_4 stars, which contain singly coordinated terminal silicon atoms, as found in HNSi and H_2CSi[3]; they can be formulated as Si_4^{-2} (**A**).

This anion is "π-isoelectronic" with the Y-aromatic[6] carbonate ion CO_3^{2-}, *i.e.* both ions have the same number of π-electrons and atoms. Because of the smaller charge, Si_4^{2-} should be more stable than the Si_4^{8-} species postulated by *von Schnering et al.*[1].



A

Also, because of the high charge, the existence of the postulated Si_5^{8-} and Si_5^{10-} anions[1] is not very likely. In our opinion the Si_5 rings should be formulated as Si_5^{6-} ions; such species are π-isoelectronic with the well-known cyclopentadienide ion. The possible presence of the 2π Si_5^{-2} species has also been considered. From symmetry considerations and mathematical operations, as well as consideration of the crystal structure, we deduced that lithium is present as Li^+ and Li_3^+ in $Li_{12}Si_7$[10]. We therefore suggest that $Li_{12}Si_7$ be formulated as $Li_{24}Si_{14} \equiv (Li^+)_9(Li_3^+)_5(Si_4^{2-})(Si_5^{6-})_2$.

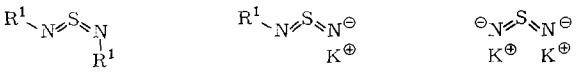
Dipotassium Sulfur Diimide, K_2SN_2**

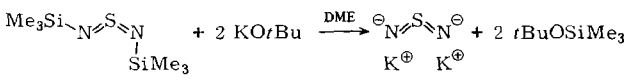
By *Max Herberhold** and *Wolfgang Ehrenreich*

Organosulfur diimides, $S(NR^1)_2$ **1**, are attacked at the sulfur by nucleophiles such as carbanions, alkoxide ions, or amide ions[1-3]. Reaction of $S(NR^1)_2$ [R^1 = $SiMe_3$ (**1a**) or *t*Bu (**1b**)] with potassium amide in liquid ammonia leads to displacement of one of the two R^1 groups with formation of salts of the type $K[NSNR^1]$ **5**[4]. More drastic reaction conditions lead to the loss of both R^1 substituents.

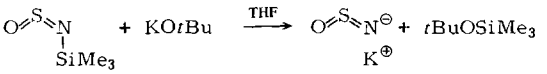


1a, R^1 = $SiMe_3$ **5a**, R^1 = $SiMe_3$ **6**
1b, R^1 = *t*Bu **5b**, R^1 = *t*Bu

We have found that the reaction of **1a** with potassium *tert*-butoxide in boiling dimethoxyethane (DME) opens up a route for preparing the pale yellow salt K_2SN_2 **6** in high yield (85–96%), thus making it a useful reagent for further syntheses. Potassium sulfinylamide, KNSO **7**, can be prepared in an analogous way[5].



1a **6**



7

The salt **6** is stable up to 180 °C and above. It reacts explosively with water, methanol, or halomethanes (CH_2Cl_2, $CHCl_3$, CCl_4) thereby bursting into flames. It is insoluble in hydrocarbons, ethers, and liquid ammonia.

Table 1. Comparison of the fundamental vibrations [cm^{-1}] of the three isoelectronic 18e-systems SO_2, $NSO^{\ominus}$, and $SN_2^{2\ominus}$.

Compound	OSO [a]	**7** [b]	**6** [c]
Assignment			
ν_{as}	1360 vs	1270 vs	1198 vs
ν_s	1151 m	990 vs	1001 m
δ	518 m	515 vs	528 m

Universitätsstrasse 30, D-8580 Bayreuth (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We assume, on the basis of its very simple IR spectrum with only three absorptions (cf. Table 1), that **6** is best represented as the salt of the anion $SN_2^{2\ominus}$ (point group C_{2v}) which is isoelectronic with SO_2.

Reaction of K_2SN_2 (**6**) with chloro(trimethyl)-silane or -stannane affords the sulfur diimides $S(NSiMe_3)_2$ (**1a**) and $S(NSnMe_3)_2$ in 75 and 87% yield, respectively. The reaction of **6** with hexacarbonyltungsten leads to formation of the isocyanato complex $K[W(CO)_5(NCO)]$ **8**.

Procedure:

All operations were carried out in oven-dried apparatus under an atmosphere of dry argon; the solvents were anhydrous and saturated with argon. To 100 mL of a clear 0.79 M solution of KO*t*Bu in DME (content determined by titration with 0.1 N HCl), heated under reflux (oil bath *ca.* 95 °C), was added a solution of **1a** (8.0 g, 38.8 mmol) in DME (30 mL), dropwise within 3 h. About 15 min after starting the addition a yellow precipitate formed, the amount of which steadily increased. After completion of the addition the reaction mixture was kept at the boiling point for an additional hour. The solution was then decanted, the precipitate **6** washed with THF and ether, and dried for 3 h in a high vacuum: yield 4.6 g (85%).

$K_2[Ni_2(N_2S_2)_2(CN)_2]$—A Dinuclear Complex with the $S_2N_2^{2\ominus}$ Chelate Ligand**

By *Karlheinz Hornemann* and *Johannes Weiss**

Dedicated to Professor Georg Wittig on the occasion of his 85th birthday

Mononuclear complexes of Co^{II}, Ni^{II}, Pd^{II}, and Pt^{II} with the chelate ligand $[S{=}N{-}S{-}NH]^{\ominus}$ have been known for some time. These planar complexes **1** are stable, intensely colored, and have a *cis*-configuration. They are formed as the major products in the reaction of S_4N_4 with $CoCl_2$, $NiCl_2$, $PdCl_2$, and H_2PtCl_6[1].

We have now prepared the first dinuclear complex with the dianionic chelate ligand. It is formed from **1**, M = Ni, and KCN in methanolic solution in presence of $KHCO_3$[2]; in contrast, in more alkaline media, *i.e.* in the absence of $KHCO_3$, the previously known mononuclear complex **2** is

3

produced[3]. The potassium salt of the novel dinuclear complex **3**, which was characterized by elemental analysis and IR spectroscopy, is insoluble in nonpolar but soluble in polar organic solvents; aqueous solutions decompose slowly.

An X-ray crystal structure analysis was carried out on the tetraphenylarsonium salt $[Ph_4As]_2[Ni_2(N_2S_2)_2(CN)_2]$ **3a**[2] which crystallizes more readily[4].

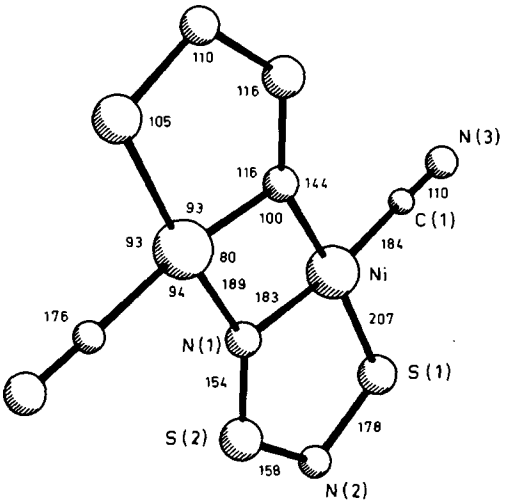

Fig. 1. Structure of the anion of **3a**. Distances in pm. The ion has a center of symmetry. All atoms, which the exception of C and N of the cyanide groups are almost coplanar; deviations of the atoms of the cyanide group from this plane: C 17 pm, N(3) 22 pm. NiNi distance 286.2(7) pm.

Chem. Soc. Dalton Trans. 1980*, 1910; S. Millefiori, A. Millefiori, G. Granozzi, *Inorg. Chim. Acta 48* (1981) 233.

[2] Procedure: **1** (490 mg, 2 mmol), KCN (260 mg, 4 mmol), and $KHCO_3$ (200 mg, 2 mmol) are refluxed for 2 h in 100 mL of methanol. The red-violet solution is filtered, concentrated, the residue dissolved in 50 mL of acetone and added slowly with stirring to 450 mL of benzene. The precipitate is filtered off and washed with benzene. Further purification was carried out by taking up the precipitate on the filter in a little methanol (≈20 mL) and treating the solution with *ca.* 200 mL of ether. The intensely violet precipitate is filtered off, washed with ether, and dried *in vacuo*. Yield 30 mg **3**. No definite melting point is observed, and the compound explodes at 239 °C. – A solution of $[(C_6H_5)_4As]Cl \cdot H_2O$ (150 mg) in 4 mL of ethanol is added to a solution of **3** (75 mg) in 40 mL of acetone. After 2 h, KCl is filtered off and the solution slowly evaporated. Violet-black, strongly intergrown crystals of **3a**, m.p. = 276 °C, are formed.

Cleavage of S_4N_4 to S_2N_2 at Room Temperature: Formation and Structure of $(AlCl_3)_2S_2N_2$**

By *Ulf Thewalt** and *Maria Burger*

The smallest cyclic $(SN)_n$ compound, which is readily accessible by thermolysis of S_4N_4 vapor over a catalyst, is S_2N_2, whose solid-state polymerization leads to metal-like $(SN)_x$[1]. It is well known that reaction of S_2N_2 with Lewis acids such as $SbCl_5$[2a, b] or BCl_3[2c] affords isolable S_2N_2-adducts. Surprisingly, we have now been able to obtain an $S_2N_2/AlCl_3$ adduct by reaction of S_4N_4 with $AlCl_3$ at room temperature.

When a mixture of solid $AlCl_3$ and S_4N_4 is covered by a layer of CH_2Cl_2 and allowed to stand for a few days, $(AlCl_3)_2S_2N_2$ **1** is formed, along with other products, as colorless crystalline needles[3]. On contact with water or even on exposure to air the compound **1** decomposes with separation of black insoluble products. On reaction of $AlCl_3$ and S_4N_4 under conditions other than those given here, *Chan* and *Olsen*[4] obtained the S_4N_4-complex $(AlCl_3)S_4N_4$ as sole product.

The result of an X-ray structure analysis carried out for the unequivocal characterization of **1** is presented in Figure 1[5]. As in $(SbCl_5)_2S_2N_2$[2b] and in free S_2N_2[6a], the central S_2N_2-ring in **1** is completely planar. (At its center there is a crystallographic center of symmetry.) The S—N distances hardly differ from those in free S_2N_2 (1.657(1) and 1.651(1) Å[6a]). Noteworthy are the relatively short S...Cl contacts.

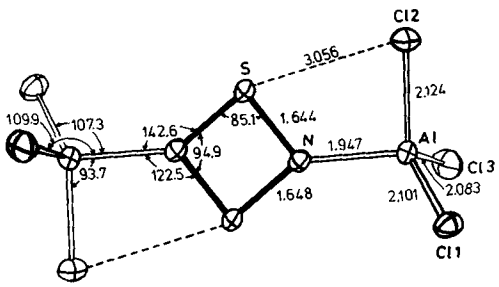

Fig. 1. Structure of the $(AlCl_3)_2S_2N_2$ complex in the crystal, with bond lengths [Å] and angles [°]. Errors in the S—N, Al—N, and Al—Cl bond lengths: 0.003, 0.003, and 0.002 Å, respectively; errors in the bond angles at S, N, and Al: 0.2, 0.2, and 0.1°, respectively. Deviations from the S_2N_2 plane: Al 0.004 Å, Cl2 −0.087 Å.

Symmetrical cleavage of the S_4N_4 cage with formation of neutral S_2N_2 rings evidently proceeds quite readily and can be preparatively exploited if—firstly—a Lewis acid which has the ability to combine with both S_4N_4 as well as S_2N_2 is present and—secondly—if the solubilities of the individual compounds are such that the S_2N_2-adduct crystallizes out. These prerequisites are fulfilled in the case of $AlCl_3$ in CH_2Cl_2. The same applies for the system $CuCl_2/S_4N_4$ in acetonitrile; in this case the polymeric complex

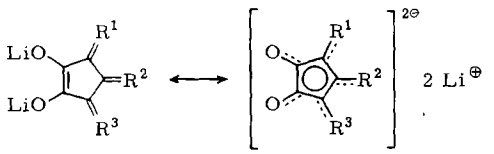
Electrochemical Oxidation of Croconate Salts; Evidence of the Chemical Equivalence of the Carbonyl Oxygen Atom and the Dicyanomethylene Group**

By *Lawrence M. Doane* and *Alexander J. Fatiadi**

We have found that dicyanomethylene derivatives of croconates [pseudooxocarbon compounds of general formula $C_nO_m[C(CN)_2]_{n-m}^{r-}$][1] are excellent models for testing the concept of *Wallenfels*[2] on the chemical equivalence of carbonyl oxygen and the dicyanomethylene group. Several electrochemical studies have been carried out on aromatic oxocarbon[3a] and pseudooxocarbon compounds[3b], but, as yet, no reversible electron transfer reactions have been reported for croconates. We report here: (i) on some cyclovoltammetric and ESR investigations of salts of the oxocarbon dianion, croconate **1**, and the pseudooxocarbon dianions[4], 3-(dicyanomethylene)croconate **2**, 3,5-bis(dicyanomethylene)croconate [croconate violet] **3**, and 3,4,5-tris(dicyanomethylene)croconate [croconate blue] **4**; (ii) on the first supporting electrochemical evidence for the postulated chemical equivalence of $=O$ and $=C(CN)_2$.



1, $R^1=R^2=R^3=O$
2, $R^1=R^3=O$, $R^2=C(CN)_2$
3, $R^2=O$, $R^1=R^3=C(CN)_2$
4, $R^1=R^2=R^3=C(CN)_2$

Figure 1 shows cyclic voltammograms of the salts of **1**–**4** in *N,N*-dimethylformamide (DMF) containing 0.5 mol/L tetraethylammonium perchlorate (TEAP); the peak potentials are given in Table 1. The general behavior of dianions of **1**–**4** is similar and is characterized by essentially equal anodic and reversal cathodic peak currents and a peak potential separation ($E_{pa}-E_{pc}$) of 0.06–0.07 V. These results suggest a reversible one-electron oxidation of the dianion to a stable radical anion followed by a reversible one-electron oxidation of the radical anion to the neutral molecule. At scan rates less than 20 mV/s, the more positive cathodic wave of the dianion of **4** is very small, indicating a fast chemical reaction following the electron transfer.

Thin-layer cyclic voltammetry provides further evidence of the electrochemical reversibility and the stability of the components of the redox couple[5]. If scan reversal occurs immediately after the first oxidation wave, essentially equal anodic peak and reversal cathodic peak currents are obtained for all dianions. The stability of the radical anion is therefore no less than several minutes. Equal anodic and cathodic peak currents are obtained at the second redox couple of the dianion of **1**. However, for dianions of **3** and **4**, scan reversal after the second oxidation wave gives no cathodic wave where reversible reduction of the neutral species and the radical anion should each occur. For the dianion of **2**, three cathodic waves appear on reversal after the second oxidation wave. Despite the results of cyclic voltammetry this indicates that the neutral species [except in the case of **1**] undergo chemical transformations that alter their cathodic waves.

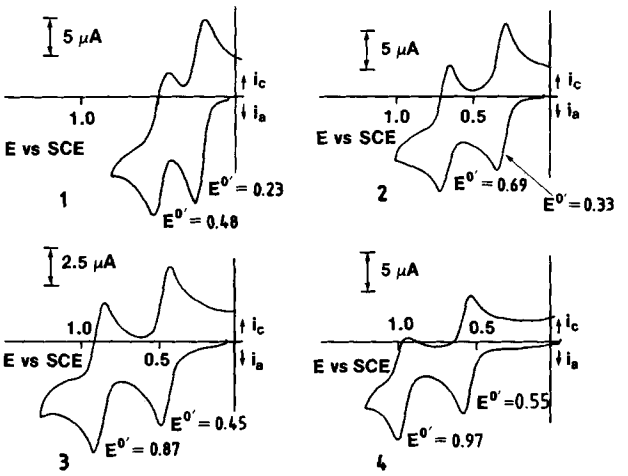


Fig. 1. Cyclovoltammograms of the dianions **1**–**4**. For conditions see Table 1.

Table 1. Cyclovoltammometric data for the oxidation of croconates in DMF [a]. E [V] *vs.* SCE.—In the case of **1**–**4** two reduction steps were observed in each case (E_{pc1}, E_{pc2} [V] *vs.* SCE): **1**: −0.78, −1.21; **2**: −0.68, −0.88; **3**: −1.48, −1.73; **4**: −1.05, −1.40. Except in the case of **4**, the reductions were reversible.

Dianion of	1. Peak [b] E_{pa}	E_{pc}	ΔE_p	2. Peak [b] E_{pa}	E_{pc}	ΔE_p

2	0.36	0.30	0.06	0.72	0.66	0.06
3	0.48	0.41	0.07	0.90	0.83	0.07
4	0.58	0.51	0.07	1.00	0.94 [c]	0.06

[a] Concentration of TEAP 0.5 mol/L. Working electrode: gold disk with surface area of 0.079 cm^2 (in the case of **3**: 0.051 cm^2), sweep rate 0.05 V/s. [b] E_{pa} and E_{pc} are the anodic and cathodic peak potentials, respectively. [c] Weak current on scan reversal.

Evidence of radical anion formation was obtained from ESR spectra of dianion solutions electrooxidized in DMSO at a potential approximately 100 mV more positive than the peak potential of the first oxidation wave. The ESR spectrum of the electrooxidized solution of the salt **3** shows a 9-line pattern, which possibly indicates interac-

[*] Dr. A. J. Fatiadi, Dr. L. M. Doane

[**] We thank Dr. Ts-Tse Chang for assistance with the ESR experiments.

tion of the unpaired electron with four magnetically equivalent nitrogen atoms ($a^N = 5.2$ G). The half-life of the radical anion is *ca.* 100 minutes. *Russell* and *Osuch*[6] have shown that the ESR spectrum of the 1,2-cyclopentanesemidione radical is a symmetrical pentet; the unpaired electron is delocalized over the semidione group. The 9-line pattern of the radical anion of **3** indicates that the unpaired electron is delocalized over the dicyanomethylene group and the oxygen atoms.

Wallenfels[2] has proposed that the dicyanomethylene group and the oxygen atom are chemically analogous and that substitution of one group for the other merely reflects a change in electronegativity. The potential of the first oxidation wave increases linearly by *ca.* 100 mV on addition of each dicyanomethylene group [see **1**—**4** in Table 1 and Fig. 1]; *i.e.* the electrochemical oxidation becomes increasingly difficult in the series **1**—**4**. This linearity and the delocalization in the radical anions indicate that the inductive effect of each dicyanomethylene group is independent of the other and independent of the position in the ring. Clearly a linear change in electronegativity of the substituting dicyanomethylene group supports *Wallenfels*' concept of chemical equivalency of =O and $=C(CN)_2$.

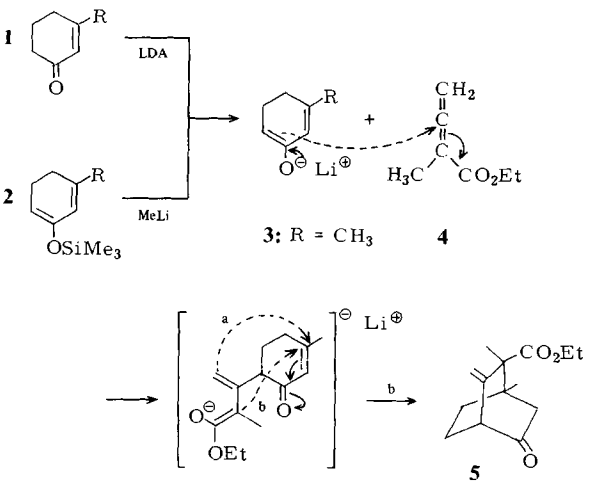
Bicyclo[2.2.2]octanes from Allenecarboxylic Acid Esters and Cyclohexadienolates

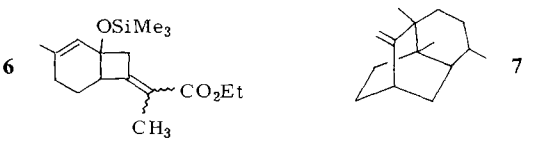
By *Dietrich Spitzner**

Cyclohexenones such as **1** can be selectively deprotonated in a kinetically controlled reaction with lithiated bases such as lithium diisopropylamide (LDA) to give lithium cyclohexadienolates of type **3**. Compounds **3** react with acrylic acid esters in what may be formulated as a Diels-Alder cycloaddition or Michael cascade reaction to give 5-oxobicyclo[2.2.2]octane-2-carboxylic acid esters, exclusively in the *endo*-form[1a].

Allenecarboxylic acid esters are capable of undergoing [2+2]- as well as [4+2]-cycloadditions; Lewis acids accelerate both reactions, but decisively improve the *endo* selectivity only in the case of the [2+2]-cycloaddition[1b]. We have now reacted the allenecarboxylic acid ester ethyl 2-methyl-2,3-butadienoate **4**[2] with **3** in amine-free medium and obtained isomer-free (capillary-GC/MS) ethyl 1,2-dimethyl-3-methylene-5-oxobicyclo[2.2.2]octane-2-carboxylate **5**[3] (Route b).



The high *endo*-selectivity of the addition is noteworthy also in this example. However, although acrylic acid esters react with both cyclohexadienolates of type **3** as well as with the corresponding trimethylsiloxycyclohexadienes **2** to give 5-oxobicyclo[2.2.2]octane-2-carboxylic acid esters, allenecarboxylic acid esters such as **4** form the bicycles **5** only on reaction with **3**; with trimethylsiloxy-activated



dienes such as **2** they undergo polar [2+2]-cycloaddition to give mainly cyclobutylideneacetic acid esters (*e.g.* **6**)[4]. Both **5** as well as analogous bicyclo[2.2.2]octanes are suitable educts[5] for the synthesis of tricyclic sesquiterpenes such as seychellene **7**.

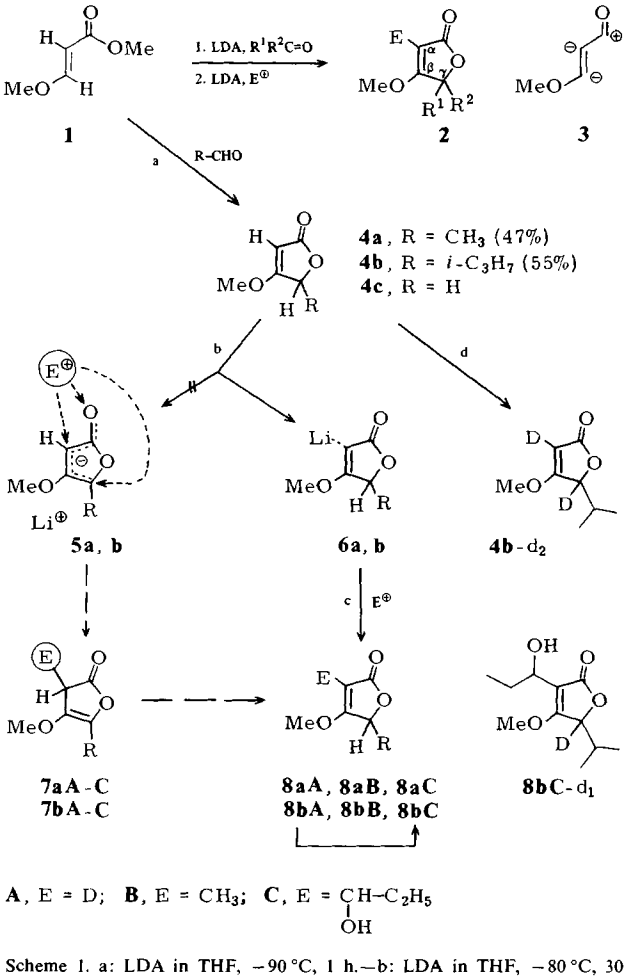
Kinetic Acidity of Methine Protons and Carbonyl-Activated Methylene Protons**

By *Okiko Miyata* and *Richard R. Schmidt**

We have introduced the substituted acrylic ester **1** as a versatile synthon **3**[1]. Hence, the α,γ,γ-trisubstituted γ-lactones (tetronates) **2** could be synthesized from **1** in two steps[2,3]; by means of acetaldehyde and isobutyraldehyde the γ-substituted lactones **4a** and **4b** were synthesized in a one-step reaction (Scheme 1).



Scheme 1. a: LDA in THF, −90 °C, 1 h.—b: LDA in THF, −80 °C, 30 min.—c: 40 min at −80 °C, 30 min at −50 °C; yield: quant. **8aA**, 61% **8aB**, 48% **8aC**, quant. **8bA**, 68% **8bB**, 56% **8bC**.—d: 1 M NaOMe in MeOD, R. T., 20 h; yield: quant. **4b**-d_2.

After deprotonation, the parent compound **4c**—as found by *Pelter et al.*[4]—reacts with electrophiles in aprotic media at the γ-carbon atom or at the carbonyl oxygen atom. Surprisingly, the α-substituted products **8aA**—**8aC** and **8bA**—**8bC** were obtained from **4a** and **4b** after deprotonation with lithium diisopropylamide (LDA) in tetrahydrofuran (THF) and reaction with CH_3OD, CH_3I, or C_2H_5CHO. These products could also have arisen from the γ-deprotonated species **5a** and **5b** *via* **7aA**—**7aC** and **7bA**—**7bC**; to exclude this route **8bA** was deprotonated and treated with propionaldehyde; following work-up with D_2O, however, no **8bC**-d_1 was formed.

In consequence, direct lithiation of **4a** and **4b** to afford **6a** and **6b**, respectively, must be assumed. Rapid H/D exchange in basic protic media was established through formation of **4b**-d_2 from **4b** in NaOMe/MeOD.

These investigations show that in the LDA/THF system the kinetic acidity of the α-vinyl protons of **4a** and **4b** is greater than that of the carbonyl-activated γ-methylene protons, although abstraction of the latter would lead to the resonance-stabilized oxapentadienyl anions **5a** and **5b**, respectively. This result emphasizes the importance of the direct deprotonation of inductively activated vinylic methine groups; of course, it is also important that the metalated species can be intramolecularly complexed[1].

A 2,6-Diazasemibullvalene**

By *Christoph Schnieders, Hans-Josef Altenbach* and *Klaus Müllen**

In the extreme case, lowering the energy barrier for the degenerate Cope rearrangement in bullvalene, barbaralane, and semibullvalene systems leads to a "bishomoconjugated" ground state[1]. According to theoretical considerations[2], a ground state of this type occurs in semibullvalenes in which the CH groups in the 2- and 6-, or 3- and 7-, positions have been replaced by N atoms[3]. We have now succeeded in synthesizing the first diazasemibullvalene with which we have been able to test the predictions experimentally.

Our studies of the bisallyl system **3**, which we obtained from the semibullvalene **1**[4] by reductive cleavage of the σ-bond[5], indicated that the readily accessible diaza analogue **4** and the dihydro derivative **5**[6] were suitable precursors for **2**. **5** reacts with *N*-bromosuccinimide to afford a mixture of the mono-, di-, and tribromides **6**—**8**; according to the spectral data **7** is configurationally uniform.

$R^1 = CH_3$, $R^2 = Ph$

The reductive elimination of **7** (lithium, [D_8]tetrahydrofuran (THF), −78 °C), which was monitored by NMR spectroscopy, led within a few seconds to **2**: elemental composition (FD-MS) confirmed that both bromine atoms had been cleaved off.

Just as in **7**, the number of ^{1}H- and ^{13}C-NMR signals [^{1}H-NMR ([D_8]THF, 300 MHz, −30 °C): $\delta = 1.43$ (1-CH_3, 5-CH_3); 5.50 (H-4, H-8); 7.67 (H-*o*-phenyl); 7.22 (H-*m*,*p*-phenyl); ^{13}C-NMR ([D_8]THF, 75.5 MHz, −30 °C): $\delta = 80.2$ (C-1, C-5); 15.6 (1-CH_3, 5-CH_3); 152.7 (C-3, C-7); 99.4 (C-4, C-8); 135.6 (quart. C-phenyl), 129.7, 129.0, 127.5 (C-phenyl)] confirm the existence of an effective C_2 axis which arises on the NMR time scale because of the rapid degenerate Cope rearrangement **2** ⇌ **2′**. The position of the signals from C-4 and C-8 ($\delta = 99.4$), as well as that from H-4 and H-8 ($\delta = 5.50$) is in accord with an averaged olefin and aziridine "environment".

As expected for a degenerate Cope rearrangement **1** ⇌ **1′**, the ^{13}C-NMR signal (75.5 MHz) for C-4 and C-8 at −90 °C in the semibullvalene **1** experiences a pronounced line broadening (width at half-height $\Delta_{1/2} \approx 570$ Hz). Under the same conditions, the corresponding signal of the diaza analogue **2** exhibits no broadening ($\Delta_{1/2}(-90\,°C) = 5$ Hz). We attribute this to a drastic increase in the rate of the Cope rearrangement and not to the existence of a bishomoconjugated ground state, since the signal becomes broader upon lowering the temperature further ($\Delta_{1/2}(-120\,°C) = 19$ Hz).

Debromination of the tribromide **8** leads to formation of the monobromosemibullvalene **9** ⇌ **10** [^{1}H-NMR ([D_8]THF, 300 MHz, −30 °C): $\delta = 1.52$, 1.45 (1-CH_3 and 5-CH_3, respectively); 5.12 (H-8); 7.30–7.90 (H-phenyl); ^{13}C-NMR ([D_8]THF, 75.5 MHz, −30 °C): $\delta = 76.1$, 84.3 (1-CH_3 and 5-CH_3, respectively); 14.5, 15.7 (1-CH_3 and 5-CH_3, respectively); 144.6, 158.8 (C-3 and C-7, respectively); 112.8 (C-4); 79.1 (C-8); 135.0 (quart. C-phenyl); 134.6 (quart. C-phenyl), 128.3–130.9 (C-phenyl)]. The ^{13}C chemical shifts suggest a valence isomerism[3,4] **9** ⇌ **10** with **9** as the predominant form.

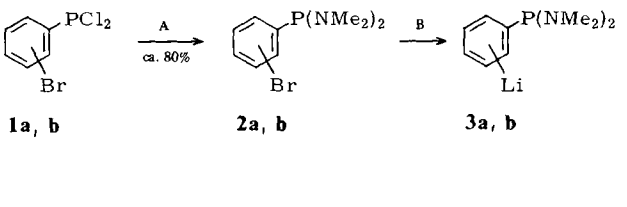
o- and *m*-Phenylenebis(dichlorophosphane)—Versatile, Useful Synthetic Building Blocks

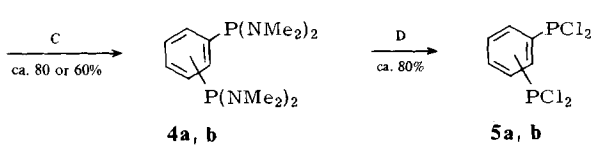
By *Kurt Drewelies* and *Hans Peter Latscha**

Dedicated to Professor Georg Wittig on the occasion of his 85th birthday

Of the possible phenylenebis(dihalophosphanes) only the *p*-phenylene compounds have been described so far[1]. We have now been able to synthesize and purify *o*- and *m*-phenylenebis(dichlorophosphane) **5a** and **5b**, respectively. The syntheses (Scheme 1) *via* the novel intermediates **2**, **3**, and **4** proceed in good yields at each stage.



1a, b **2a, b** **3a, b**



4a, b **5a, b**

Scheme 1. **a**: *ortho*, **b**: *meta*. A: Et_2O, Me_2NH until saturated; B: Et_2O, BuLi in *n*-hexane; C: Et_2O, $ClP(NMe_2)_2$ in Et_2O (isolation of **3** not necessary); D: Et_2O, HCl gas. All operations were performed with rigorous exclusion of moisture under argon.

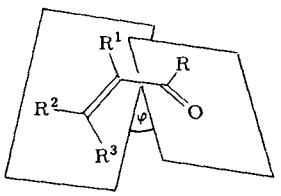
Determination of the Conformation of Acyclic α,β-Unsaturated Aldehydes and Ketones from Their Infrared and Raman Spectra—Results and Limitations of Model Calculations**

By *Hans-Joachim Oelichmann, Daniel Bougeard,* and *Bernhard Schrader**

The α,β-unsaturated aldehydes (R = H) and ketones (R = alkyl) **1** may exist in two planar conformations, the *s-cis* ($\varphi = 0°$) and the *s-trans* conformation ($\varphi = 180°$), as well as in non-planar conformations.



1

Of the spectroscopic methods available, for the determination of the dihedral angle φ IR and Raman spectroscopy would appear to be especially suitable. Known empirical observations[3,8] were extended by model calculations[11] of the frequencies and IR and Raman intensities of *s-cis-* and *s-trans*-acrolein, *trans-* and *cis*-crotonaldehyde, methacrolein, and *s-cis-* and *s-trans*-methyl vinyl ketone[12,13]. The transferable sets of force constants determined thereby enabled calculation of the frequencies of a model molecule **1**, R, R^1, R^2, R^3 with point masses, m = 15, for $\varphi = 0, 30, \ldots 180°$. Furthermore, we have calculated the IR and Raman intensities of methyl vinyl ketone for $\varphi = 0, 30, \ldots 180°$. These model calculations together with old and new experimental data allow the following general conclusions to be drawn from the IR and Raman spectra of **1**:

In the IR and the Raman spectrum the frequency of the C=O stretching vibration is greater than 1670 cm^{-1} and that of the C=C stretching vibration lower than 1670 cm^{-1}; the vibrational energy is located to 65–85% on the bond in question. Despite conjugation the coupling of the C=O and C=C vibrations is smaller than 10%; as is the case for conjugated dienes[15], in the *s-trans* conformers the vibration with the higher frequency has in-phase character, whereas the reverse is true for the *s-cis* conformers.

It emerges that the relative values of the C=O and C=C frequencies and the integral intensities, which are readily accessible from the spectra, provide more information than the absolute values about the dihedral angle φ. Table 2 contains limiting and mean values.

Table 2. General IR and Raman characteristics for the determination of the conformation of α,β-unsaturated ketones and aldehydes [3, 7, 8, 12, 13].

	s-cis	*s-trans*
$\Delta\tilde{\nu} = \nu(C{=}O) - \nu(C{=}C)$	> 60 (≈ 68)	< 60 (≈ 40)
IR intensity $A_{C-O}/A_{C=C}$	< 2.6 (≈ 1.4)	> 2.6 (≈ 5.2)
Raman intensity $I_{C-O}/I_{C=C}$	< 0.5 (≈ 0.25)	> 0.5 (≈ 0.7)
Depolarization ratio ρ(C=O) (Raman)	> 0.3 (≈ 0.4)	< 0.3 (≈ 0.2)

Model calculations of the frequencies and IR and Raman intensities for particular molecules can provide more definite information about the conformation. An accurate determination of the dihedral angle φ is, however, not yet possible; on the one hand because of the inadequacy of the semiempirical quantum chemical methods required for the intensity calculation and, on the other, because of the unbearable expense of *ab initio* methods.

Chemistry of Coal Utilization, Second Supplementary Volume. Edited by M. A. Elliot, Wiley-Interscience, New York 1981. 2374 pages, bound, $ 165.00.

The American "Chemistry of Coal Utilization", a handbook that has already become a classic and that is certainly unique in its scope and treatment of the material, has now been updated by the appearance of the second supplementary volume, after the original two-volume work of 1945, edited by *H. H. Lowry*, was first supplemented in 1963. As in the case of the previous volumes, a committee of the National Research Council of the U.S. National Academy of Sciences assumed the sponsorship of the new supplementary volume which, under the new editor *Elliot—Lowry* died ten years ago—includes contributions from 60 well-known authors. In continuation of the earlier work, detailed information is given not only on coal chemistry in the narrower sense but also, with the exception of mining technology, on all technologies for the utilization and upgrading of coal and on the conversion of coal into energy, fuels, and chemical raw materials. In spite of the primary aim to take up the story at the point at which the review of the first supplementary volume ended, *i.e.* essentially to give a critical review of the literature between about 1958 and the second half of the seventies and to describe further developments in this period, to a large extent the result has been an almost textbook-like account rather more suitable for advanced readers. Specifically, the 31 chapters deal with the coal industry, coal research and development (an overview written by the editor himself); coal resources (only the deposits of the United States are treated in detail); origin, petrography, and classification of coal; physical properties of coal and coal products; mechanical properties; plastic properties; analysis of coal, trace elements, and mineral constituents; chemical reactions and chemical constitution of coal; transport, storage, and handling; preparation; briquetting; pyrolysis and hydropyrolysis (3 chapters); solid pyrolysis products; coar tar (2 chapters); coke-oven gas; combustion of coal (2 chapters); coal ash—its effect on combustion; control of pollution from combustion processes; gasification of coal (3 chapters); underground gasification of coal; liquefaction of coal (3 chapters); conversion of coal and coal gases into fuels, chemicals, and other products; and environmental, health, and safety implications of increased coal utilization.

On the whole, it must be said that the compilation and organization of the enormous volume of material has been highly successful. Overlapping between individual chapters, unavoidable because closely related subjects are treated by different authors, is kept to reasonable limits. The reviewer is not in a position to judge to what extent it has been possible to take into account the literature and all the developments of the various technologies. After all, the quality of the contribution depends in the final account on the knowledge, experience, and carefulness of the particular author (information about the professional career and the present position of each author is given by brief biographies at the beginning of the chapters). Apart from some contributions from the United Kingdom, Australia, and the German Federal Republic, the majority of the chapters have been written by American authors. In reading some chapters one cannot quite escape the (subjective) impression that the account, particularly of the economic and technical developments, is frequently limited substantially to the situation in the United States. For example, in Chapter 28 (Liquefaction Processes) all the American processes for direct liquefaction of coal are described in detail, whereas there is nothing about the corresponding developments of the National Coal Board in the United Kingdom and there are only a few lines on the IG-"Neu" Process in Germany, by which is meant the new activities in connection with the hydrogenation of coal, based on the old IG process. A partial explanation for this shortcoming may be that these European developments really started up only in the mid-seventies, not long before the early editorial deadline (depending on the chapter, between August 1976 and the end of 1978). Other examples could be quoted. Another point of criticism relates to the use of units: it must be just as annoying for the English or American reader when, for example as on page 1782, temperatures are given in degrees Fahrenheit and enthalpies in Btu/lb-mole in one place and four pages later the same author uses the units Kelvin and kcal/g-mole!

The extensive subdivision of the text by headings makes for clarity, the graphic presentation including the figures and tables is excellent, and the citation of references in footnotes on the same page is exemplary. Small mistakes and printing errors do not appear to exceed the usual quota. The subject index, however, leaves something to be desired.

All in all, this second supplementary volume in combination with the earlier work offers a unique compilation, of inestimable value, of the scientific and technical literature on coal. No library should therefore delay in getting this supplement to their "Lowry". But even without the earlier volumes, which, by the way, can still be obtained as reprints, the book will be highly valuable for the interested specialists, if not indeed indispensable.

Matthias W. Haenel [NB 562 IE]

Protective Groups in Organic Synthesis. By *T. H. Green*. John Wiley & Sons, Chichester 1981. xiii, 349 pp., bound, £ 26.25.

Although the use of protective groups for the blockage (deactivation and differentiation) of functional groups is indispensable in many organic reactions, particularly in special classes of substances such as the carbohydrates and the amino acids, in the planning of a particular synthesis one should always bear in mind that this advantage is accompanied by a drawback: Two additional reaction steps

are usually necessary, for the protective groups must first be introduced and then removed. A large number of protective groups have been proposed for a variety of purposes, differing in the nature of their introduction, their differentiated removal, their stability to special reagents, *etc.*, and frequently capable of being used for only one reaction step. Thus, recently, protective groups that can be removed photochemically or electrochemically have been called upon. The fact that, after the widely used book by *McOmie* (1973), another book on protective groups has now appeared, in which the modern developments in this field have been particularly taken into account, is highly welcome.

A short introduction on the importance of protective groups in organic chemical synthesis is followed by a description, in six chapters, of about 400 protective groups for the important functional groups. The following protective groups are discussed in detail: monohydroxy compounds: substituted alkyl ethers (42), silyl ethers (12), and esters (52); 1,2- and 1,3-diols: acetals and orthoesters (31); phenols: ethers, esters, carbonates, carbamates, and sulfonates (32); carbonyl compounds: full acetals, thioacetals, hemithioacetals, *O*-substituted cyanohydrins, substituted hydrazones, imines, oxazolidines, imidazolidines, and thiazolidines (37). (The monoblockage of dicarbonyl compounds is also described here (7).) Carboxy compounds: esters, amides, and hydrazides (63); thiols: thioethers (28), thioesters (9), disulfides (2) and sulfenyl derivatives (2); amines: carbamates, amides, imides, *N*-alkyl compounds, aminoacetals, imines, enamines, *N*-metal compounds, and *N*-heteroatom derivatives (91). There is no information on the protective groups for olefinic double bonds.

For the individual protective groups the processes of their formation and removal are described, always with references to the literature and, wherever possible, with special observations (range of application, stability, *etc.*). No information is given on the availability or synthetic accessibility of the reagents used.

A particularly valuable feature of the book is Chapter 8, "Reactivities, Reagents, and Reactivity Charts," in which the stability of many of the protective groups described in the book with respect to 108 prototype reagents from 16 reaction areas (*e.g.* oxidation, reduction, and organometallic reactions) is summarized in tabular form. For example, it can be deduced from the tables that *tert*-butyl diphenylsilyl ethers are still stable at pH 2–4, while the *tert*-butyl dimethylsilyl ethers are already cleaved in this pH range.

The book is arranged systematically; however, because of the wealth of information, the reader will need some time to become familiar with its use.

This could have been avoided by selecting three to five "standard protective groups" supplementing one another for each of the individual functionalities, that would ensure success in 80–90% of the cases. It would then have been possible to include experimental instructions for the formation and the removal of these standard groups. Some description of the elegant methods for the blocking and activation of functionalities, *e.g. via S-* or *O*-acetals, would also have been desirable.

In conclusion, the book will undoubtedly prove very useful for the synthetic chemist both in industry and academic circles, and it can be expected to find wide use.

Signal Substances and their Reception in the Sexual Cycle of Marine Brown Algae

By Lothar Jaenicke* and Wilhelm Boland

Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday

Attraction and repulsion are responses to chemical stimuli which can be received and processed even by unicellular organisms without a morphologically defined nervous system. Chemical substances trigger off a chain of events which starts with a membrane-bound signal receptor and, after a sequence of regulatory and modulatory steps, ends in the modulation of a motor effector organ. Binding of the signal substances to the receptor produces conformational changes in which the receptor subunits are mutually dependent on one another, and also leads to chemical modification of the subunits and affects their molecular activity. These interactions, together with the characteristic type of movement, result in a physiological pattern of behavior which enables the flagellated sex cells (gametes) of marine brown algae to finally locate their partners. The simple but highly specific brown algae gamete systems have been investigated structurally and their biological activity analyzed. The signal substances are mainly highly unsaturated aliphatic or cyclic hydrocarbons with unsaturated side chains (general formula *e.g.* $C_{11}H_{14}$, $C_{11}H_{16}$, $C_{11}H_{18}$). These systems also serve as a simplifying model which helps in the understanding of complex ganglionic pathways in higher living organisms where the sense organs convey information from the surroundings to the central nervous system through nerve pathways. The information is then processed and answered, *via* efferent pathways, as movement.

1. Introduction

Communication by means of chemical signals made an early appearance in the history of evolution. Even bacteria are equipped for the reception and processing of signals to enable them to find a suitable environment; these systems have been studied biochemically in great detail[1]. Ciliates prepare for copulation by means of a chemical information system whose components are known, but whose mode of action remains to be elucidated[2]. The pheromone system of insects is extremely sensitive; it was first investigated in the classical studies of *Butenandt et al.* on the silkmoth and has since been studied extensively by chemists and sensory physiologists[3]. These systems have given considerable insight into the way in which signals are transmitted from the nerve cells to the central nervous system. Vertebrates are not inferior to insects in this respect. One only needs to think of the remarkably sensitive olfactory organs of fish, the tracking capabilities of dogs, and other similar phenomena known to nature watchers and hunters. Such signal sequences came to be expected in mobile organisms which require specific instructions when searching for food or sexual partners, for brood care or defence.

[*] Prof. Dr. L. Jaenicke, Dr. W. Boland

It also seems logical that signals within an organism are responsible for the regulation of metabolism or organ function, as is the case with hormones. This is one of the branches of chemical life sciences which has been investigated most intensively and which holds the most promise for the future.

2. Chemotaxis in Plants

It was not necessarily expected that such communication sequences of stimuli and information would be found in plants which were rooted to one spot. However, observations made over a century ago show that, at least as far as lower plants are concerned, communication between individuals occurs by means of chemical compounds[4]. This is not surprising since chemotactic processes and even motile gametes are found in the generation cycle of these thallophytes. The broad spectrum of such signal substances is illustrated by some examples taken from fungi: mucorales with their trisporic acid system, *Achlya* with their antheridol/oogoniol cycle and *Allomyces* with sirenin have all developed chains of communication which aid in the formation and location of a sexual partner. These substances are all terpenoids, the *Achlya* compounds are even steroids; there is thus an interesting similarity between them and mammalian sex hormones[5].

Brown algae or seaweeds (Fig. 1) are widely distributed throughout the oceans and continental shelf regions of the world. They are technically important firstly as sources of polysaccharides (alginic acid, agar-agar *etc.*), and secondly as food for human consumption, as anyone who has travelled to Japan will know. The oily contents of the Pacific seaweed (*Dictyopteris*, see Table 1) was used in ancient times as a substitute for mustard in Hawaii[6]. Their most interesting features from the biologist's point of view are the diverse forms and different ways which nature has adopted to maintain and distribute this type of marine flora. In addition to simple vegetative cycles where sporophytes form zoospores, there are also several types of sexual reproduction, although the importance of this varies as far as the survival cycle is concerned. As is the case in higher animals some forms must regularly undergo an alternation of haploid and diploid phases; in the case of other species generative reproduction merely increases their chance of surviving and adapting under stress conditions. In all cases, however, sexual plants or gametophytes are formed which produce the (motile) sex cells. These sex cells are of opposite polarity. If they cannot be distinguished from one another morphologically they are called plus and minus gametes—isogamy; if the two types of sex cells are motile but of different sizes they are referred to as gyno- and androgametes—anisogamy (the larger ones are generously designated as the gynogametes and the smaller ones as the androgametes); finally there is oogamy in which large immotile egg cells and many small spermatozoids are formed. The latter situation is regarded as being the most highly developed and it is here, namely in *Fucus serratus* and in the closely related *Fucus vesiculosus*, that it was first suspected that the male sex cells were directed to the female

Fig. 1. "Portraits" of some brown algae. a) *Desmaresta aculeata*, b) *Cutleria multifida* (both ca. 30% natural size), c) *Fucus serratus*, d) *Laminaria digitata* (both ca. 15% natural size) (Photograph: Prof. D. G. Müller, Universität Konstanz).

eggs by a diffusible signal[7]. This was confirmed approximately a century later[8].

2.1. Laboratory Culture and Pheromone Isolation

It is difficult to work with the often very large species of algae which are found in the ocean. Species such as the giant kelp (*Macrocystis pyrifera*), which may reach a length of 60 m, or the *Laminaria* species found in our coastal waters which measure up to 5 m, or even the meter long *Fucus* are only suitable for field studies and marine stations. It is easier for "landlubbers" to work with Mediterranean spe-

cies which are more suitable for the laboratory scale: examples are *Ectocarpus siliculosus* or *Cutleria multifida*, which is distinguished by a remarkable alternation of generations; fusion of one of its gynogametes with an androgamete produces a zygote which develops into a small motile crust-like precursor *(Aglaozonia);* this later forms spores which grow into the seaweed which is about as long as an outstretched hand. It is here that the gametangia are formed.

The alga *Ectocarpus siliculosus* has become a popular, easy-to-handle research tool in connection with (unconfirmed) hypotheses on "relative sexuality"[9]. This alga has been employed for the detailed study of the seasonal rhythm of sexual events and their dependence on external parameters[10]. Gametangia are produced mainly when environmental conditions deteriorate; gamete release depends on the time of day but can also be induced by changes in temperature. *Ectocarpus* is a dioecious isogamic form with physiological anisogamy. Petri dishes containing mature (+)-(gyno)gametes release a fine, aromatic scent when opened; this is not observed with male (−)-cultures. The scented compound is lipophilic, soluble in organic solvents, condenses at low temperatures, can be adsorbed on charcoal, and desorbed by heating, *i.e.* it is stable and of low molecular weight. If vaseline or oil droplets are allowed to absorb some of the scented compound from the atmosphere above ripe gynogamete suspensions and are then presented to androgametes in suspension, the latter will accumulate around this lure. This phenomenon provides the basis for a biological test which is used for monitoring purposes when isolating the attractant. The properties of the scented substance are such that simple or refined gas chromatography is the ideal method for its purification, whereas nuclear magnetic resonance and mass spectrometry are used to determine the structure of the isolated compounds and their hydrogenation products. The methods for collecting and processing volatile active substances released into the surrounding sea water by brown algae gametes have been continually refined and improved during the course of the investigations which have now been going on for approximately ten years. The original methods of distilling off and freezing out[11] have been replaced by adsorption onto activated charcoal in a closed loop, as described by *Grob* and *Zürcher*[12], and modified to near perfection by *Gassmann*[13] for the problems in question. The procedure had to be scaled down because of the very small quantities of volatile substance involved[*]. Air bubbled through a gamete suspension is circulated through a charcoal filter which is extracted occasionally with dichloromethane. The substances collected are then analyzed by combined GC/MS.

The processing of the active substance from *Desmarestia* will be described as an example[15]. This brown alga forms large vegetative plants and small gametophytes which only consist of a few cells; the female gametes found in their gametangia liberate a bouquet of three substances (**1**—**3**). Desmarestene **1** serves not only as an attractant but also instantaneously releases the spermatazoid from the gametangium by an as yet unknown mechanism, but probably by activating an enzyme which lyses the gametangium's capsule. The substances released by the *Laminaria*[14] and *Chorda tomentosa* gynogametes[16] have an analogous action. The two other substances viridiene **3** and ectocarpene **2** are species and genus specific, respectively, but do not display any known biological activity here. If the isolation is to be successful, the gametes should be used exactly when pheromone is produced. Mature female gametes of *Desmarestia* give a chromatographic profile (B) showing the significant peaks of the three C_{11}-hydrocarbons, which, however, do not appear in the profile of immature gametes (A)[15] (Fig. 2).

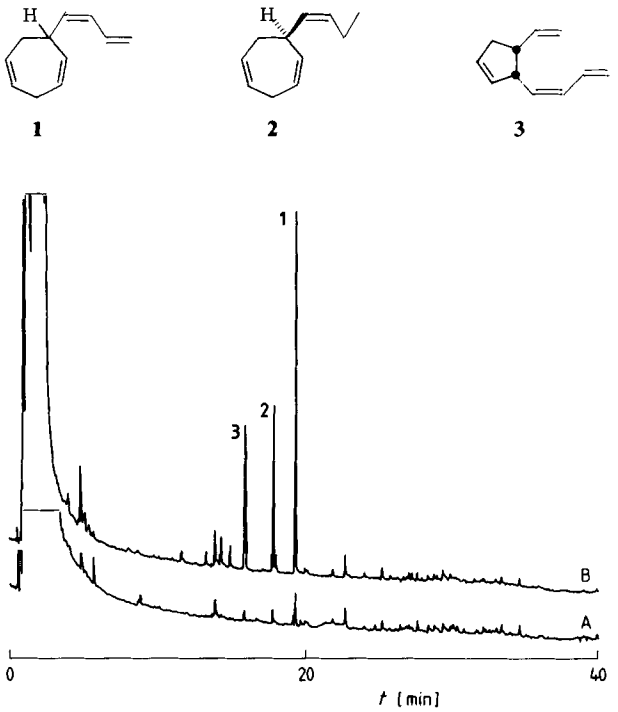

Fig. 2. Capillary gas chromatography of *Desmarestia viridis* gametophytes. Significant pheromone production is only detected after liberation of the gynogametes (B). Prior to this, blank runs (A) show an indifferent pattern with no recognizable major products. All structures were confirmed by synthesis [32], co-chromatography with the authentic substances, and quantitative bioassay [15].

"Sirenins" have been isolated with the help of these methods from eight species of brown algae which all exhibit different stages of evolutionary development; the constitution of these compounds has also been elucidated. The structures were mainly deduced from only a few parameters but were all confirmed by synthesis. When possible the syntheses were designed so that homologs and analogs could be prepared.

2.2. Algae Species and their Signal Substances

Mature gynogametes of *Ectocarpus* from more than 1000 culture dishes were collected by means of their phototaxis; 7 mg of the pheromone was obtained from this suspension by the evaporation procedure. On the basis of mass and NMR spectroscopic data the structure of ectocarpene **2** was established to be 6-(1*Z*-butenyl)-1,4-cycloheptadiene,

[*] Some idea of the scale involved is given by the following figures: In one minute a gynogamete of *Laminaria* produces 10000 molecules of the specific hormone, 15000 molecules of ectocarpene, and 30000 molecules of *n*-pentadecane [14].

$C_{11}H_{16}$[17]. This natural product is dextrarotatory ($[\alpha]_{578}^{22.5°}$ 82°); diimide reduction of the side chain and ozonolysis of the resulting 6-butyl-1,4-cycloheptadiene give (*R*)-2-butylsuccinic acid which shows that ectocarpene is (*S*)-(+)-6-(1*Z*-butenyl)-1,4-cycloheptadiene.

Ectocarpene is also the major product of the dioecious marine alga *Sphacelaria furcigera*[16], whereas in other iso- and anisogamic forms of the Phaeophycidae[*] it occurs as a secondary component of the total bouquet. It may in this case be an evolutionary relict, serve as a chemotaxonomic leitmotiv or, in individual cases where the same habitat is shared, may be used for chemical defence of the surroundings and to ward off competing neighbors. This theory would seem to be justified if anisogamic forms are present which naturally produce mature fertilizable females only in small numbers. Although in this case the zygotes will possibly be better equipped for survival, their gynogametes have a poorer chance of being encountered by males. If the chances of the isogamic forms—approximately equal numbers of plus and minus gametes—are reduced by luring some of the minus gametes away, the chances of the higher form will be accordingly greater. This mimicry is only advantageous for forms which live in the same surroundings; however, it stands on somewhat shaky ground in so far as primitive species are by no means dependent on sexual reproduction with zygote formation; they only resort to this mechanism if the environmental conditions deteriorate.

Ectocarpus is one of the less evolved isogamic forms. *Cutleria multifida* is anisogamic, whereas the closely related *Laminariales* are oogamic. *Dictyota* is characterized by unicellular oogonia but the antheridia are still multicellular; the oogonia and antheridia of *Laminaria* each only contain one gamete. Pheromone mixtures derived from C_{11}-hydrocarbons have been detected in all these Phaeophycidae (cf. Table 1). In *Cutleria* the mixture consists of ectocarpene **2** (5%), aucantene **6** (27%), which does not attract gametes, and the biologically active compound multifidene **7** (68%)[19]. Multifidene (85%) is also found in *Chorda tomentosa* extracts along with ectocarpene (8%), 6-butyl-1,4-cycloheptadiene **4**, and two other products (5%); the combination of all these compounds is responsible for the final bouquet[16]. **4** is also the major product of *Dictyota* eggs and at higher concentrations causes massive attraction of the corresponding androgametes[20]. More highly unsaturated derivatives of the C_{11}-polyenes mentioned are found in the gynogametes of the genus *Desmarestia aculeata* and *Desmarestia viridis* (cf. Fig. 2): the biologically active substance desmarestene **1** (60%) and the hydrocarbon viridiene **3** (20%); ectocarpene **2** (20%) is also present as is usually the case in this subclass[15].

In *Laminaria digitata* and *L. hyperborea* an ectocarpene derivative with an oxygen group in its side chain has been identified; this compound is presumably derived from desmarestene and serves both for release and attraction of the androgametes[14]. Its structure is still unknown, however, as only minute quantities can be produced and isolated in the laboratory. The suggested formula **5** is plausible and is based on synthetic evidence[16].

Moore[21] has isolated several "dictyopterenes" not as sexual pheromones but from vegetative parts of the Pacific seaweeds *Dictyopteris australis* and *Dictyopteris plagiogramma*; these compounds were shown to be C_{11}-hydrocarbons. Dictyopterene B **8** was found and can readily be thermally or photochemically converted into ectocarpene **2** (chair form, diradical transition state)[22]. Dictyopterene A **9**, which is isomeric with **4**, was also identified (cf. Section 4). In addition, *Dictyopteris* contains 1,3*E*,5*Z*,8*Z*-undecatetraene **10**, an open chain isomer of dictyopterene B **8**, aucantene **6**, multifidene **7** and ectocarpene **2**. The hydrocarbon **10** is also the sex-specific substance of the marine alga *Spermatochnus paradoxus*[23]. Lower molecular

Table 1. Signal substances and other compounds found in brown algae. An asterisk indicates that the substance acts as an effective attractant for the species in question.

Formula		Name	Species
	**2**	Ectocarpene $C_{11}H_{16}$	*Ectocarpus siliculosus** [1], *Sphacelaria furcigera* [16], all *Phaeophycidae* with the exception of *Dictyota dichotoma* [20], *Spermatochnus paradoxus* [23]
	**4**	Dictyopterene C′ $C_{11}H_{18}$	*Dictyota dichotoma** [20], *Dictyopteris australis* and *Dictyopteris plagiogramma* [21]
	**1**	Desmarestene $C_{11}H_{14}$	*Desmarestia aculeata** and *Desmarestia viridis** [15]
	**5**	$C_{11}H_{14}O$	*Laminaria digitata** and *Laminaria hyperborea** [14]
	**6**	Aucantene $C_{11}H_{16}$	*Cutleria multifida* [19]
	**7**	Multifidene $C_{11}H_{16}$	*Cutleria multifida** [19] *Chorda tomentosa* [16]
	**3**	Viridiene $C_{11}H_{14}$	*Desmarestia aculeata* and *Desmarestia viridis** [15]
	**8**	Dictyopterene B $C_{11}H_{16}$	*Dictyopteris australis* and *Dictyopteris plagiogramma* [21]
	**9**	Dictyopterene A $C_{11}H_{18}$ 1,3*E*,5*Z*,8*Z*-	*Dictyopteris australis* and *Dictyopteris plagiogramma* [21] *Spermatochnus paradoxus* [23],
	**10**	Undecatetraene $C_{11}H_{16}$	*Dictyopteris australis* and *Dictyopteris plagiogramma* [21]
	**11**	Fucoserratene C_8H_{12}	*Fucus serratus** [24] and *Fucus vesiculosus** [25]

[*] The class of the brown algae (Phaeophyceae) is divided into two subclasses: (1) The more primitive Phaeophycidae with typical alteration of generations between diploid sporophytes and haploid gemetophytes; it comprises several orders with many species. (2) The more highly evolved Cyclosporidae, pure diplonts, without heterogenesis; it consists only of the orders Fucales and Durvillaeales [18].

weight homologs of **10** serve as attractants which are released from the eggs of the obligatory oogamic *Fucus* species as signal compounds for the 20000 fold smaller spermatozoids. Both *Fucus serratus*[24] and *Fucus vesiculosus*[25] from the North Atlantic give off fucoserratene **11** as their sole active compound. The structure of this substance was established by means of UV, mass, and NMR spectroscopic studies on the signal substance and its hexahydrogenated product (*n*-octane). Synthesis and comparative gas chromatography (Kovàts indices) of all isomeric 1,3,5- and 2,4,6-conjugated octatrienes showed that the natural product **11** was identical with 1,3*E*,5*Z*-octatriene[26].

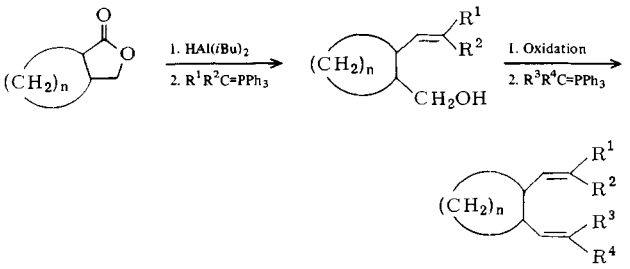
Although the two types of spermatozoid can be attracted to both of the *Fucus* species, these two stable species cannot be cross-fertilized. According to the work of *Bolwell et al.*[27] there must be an immune-type barrier within the surface glycoproteins which ensures species-specific recognition of the egg and spermatozoid.

It should also be mentioned that the analytical patterns of the volatile hydrocarbons of marine algae are generally complex and contain, in addition to the bioactive substances, numerous saturated and unsaturated linear and terpenoid hydrocarbons[28].

3. Pheromone Synthesis

Many pheromones are enantiomerically uniform vicinal dialkylated C_{11}-carbocycles. For their synthesis it is advisable to start with easily accessible, sterically pure *cis*- or *trans*-disubstituted compounds. Bicyclic lactones are most suitable, since they satisfy these requirements and also have two side chain synthons with different oxidation states. Conversion of the synthons into olefinic structures with a defined geometry is a subsequent step of such synthetic sequences.

"Reductive olefination"[29] constitutes a very useful lactone→olefin transformation. The lactones are allowed to react with diisobutylaluminum hydride to give low-temperature stable (−70 °C) organoaluminum substituted hemiacetals (esters react analogously), which then react with phosphoranes at 0 °C to form olefinic alcohols. The second side chain can then be completed with the customary repertoire of reactions (oxidation, Wittig reaction) (Scheme 1). However, if the side chain is first derivatized



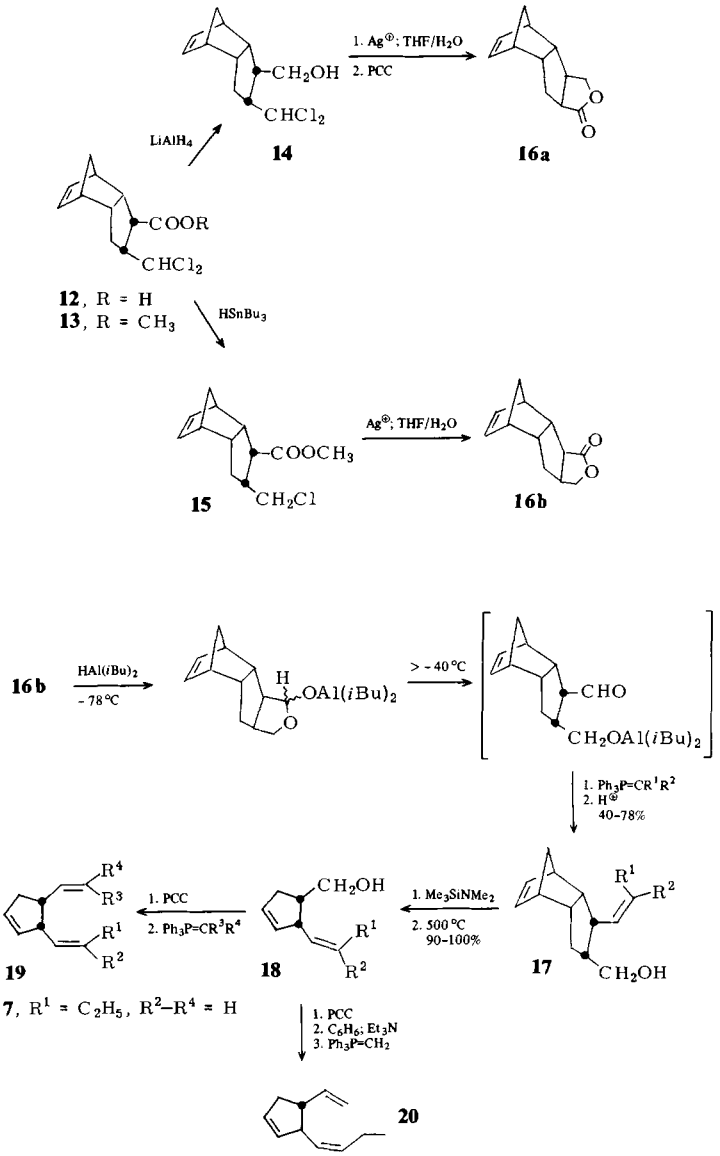
Scheme 1. Principle of the synthesis of brown algae pheromones of types **3** and **6**–**9**.

with optically active reagents, chromatographic resolution can be introduced under favorable conditions; *both* enantiomeric attractant molecules are then accessible. This principle can be applied to all carbocyclic pheromones isolated so far, and will be illustrated using the synthesis of multifidene **7** (Section 3.1).

3.1. Synthesis of Multifidene[31]

Bearing in mind the ultimate aim of performing a wide range of receptor studies, the synthesis of multifidene **7** (Scheme 2) makes special demands as regards stereospecificity and stereoselectivity and the range of possible variations. The synthesis has to take into account the need to alter chain length and chain branching, and ensure uniform geometry and chirality. Heteroatoms also should be introduced without fundamentally changing the basic concept of the synthesis[30–33].

The α-(dichloromethyl)carboxylic acid **12** proved to be a highly suitable starting compound, which can be synthesized in a few steps in high yield from dicyclopentadiene and dichloroketene[34]. After esterification of **12** with $BF_3 \cdot MeOH$ to **13**, reduction of one of the two side chains determines the stereochemistry of the lactone **16a** or **16b**. Selective dehalogenation of **13** with tri-*n*-butyltin hydride

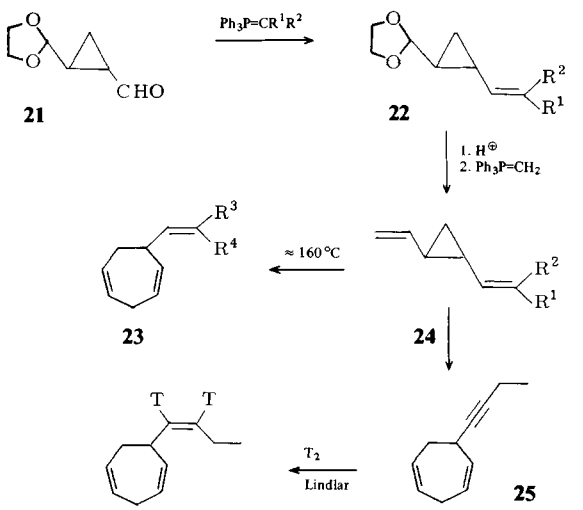


Scheme 2. Synthesis of multifidene **7**. THF = tetrahydrofuran, PCC = pyridinium chlorochromate.

produces the monochloro ester **15** and subsequent cyclization yields the key compound **16b**. Side chains with various residues (R^1; R^2) can be introduced smoothly into **16a** or **16b** with uniform stereochemistry by "reductive olefination"[29], to yield olefinic alcohols of type **17**. The cyclopentadienyl protecting group is readily removed by flash pyrolysis without altering the existing geometry; the monomeric alcohols **18** are then formed as versatile intermediates, which can be modified in a number of ways. After oxidation to an aldehyde, the second side chain (R^3; R^4) in **19** can be modified by employing the entire range of Wittig reactions. Reaction of **18** with optically active phenylethyl isocyanate yields diastereomeric carbamates which can be resolved into their enantiomers by simple chromatography on silica gel[35] (>97% e.e.). The chiral attractants can be obtained from these compounds in a high degree of optical purity in a few steps. *trans*-Disubstituted "multifidenes" **20** can be prepared after base-induced rearrangement of the intermediary aldehyde, thus completing the synthesis in this direction. Heteroatoms (*e.g.* a homologous series of halogens) can also be easily introduced into the alcohols **18** giving an array of molecular "probes", all with the same shape and volume[36].

3.2. Synthesis of Ectocarpenes and Dictyopterenes[37]

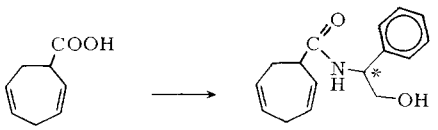
The synthesis of ectocarpenes and dictyopterenes begins with the versatile compound, **21**, the monoacetal of *trans*-cyclopropanedicarbaldehyde, which is allowed to react with various Wittig reagents (R^1; R^2) to give the desired alkenylcyclopropylcarbaldehyde acetal **22** (Scheme 3).



Scheme 3. Synthesis of ectocarpenes (**23**, R^3 = H, R^4 = C_2H_5, = ectocarpene **2**) and dictyopterenes (**24**, R^1 = H, R^2 = Z-$C_2H_5CH{=}CH$, = dictyopterene B **8**; **24**, R^1 = H, R^2 = C_4H_9, = dictyopterene A **9**), schematic.

The basic C_{11}-skeleton is completed by performing a second Wittig reaction—in principle any Wittig reagent may be chosen, but for this present class of natural products methylenephosphoranes are the obvious reactants—only a few steps are then required to synthesize the dictyopterenes (type **24**). Subsequent Cope rearrangement at approximately 160 °C (chair form, diradical transition state) yields ectocarpenes (type **23**), which can also be obtained with various side chains (R^3; R^4) by the same method. Acetylenic cyclopropane derivatives can also withstand the conditions of the Cope rearrangement intact; radiolabeled ectocarpene can thus easily be obtained by tritiation of butynylcycloheptadiene **25**[38].

The brucine or strychnine salts of 2,5-cycloheptadiene-1-carboxylic acid **26** are not very suitable for the synthesis of optically active ectocarpenes (<30% e.e.)[39]; a method was therefore chosen which is analogous to the liquid chromatographic separation of diastereomeric γ-hydroxycarboxylic acid amides[40] (Scheme 4).



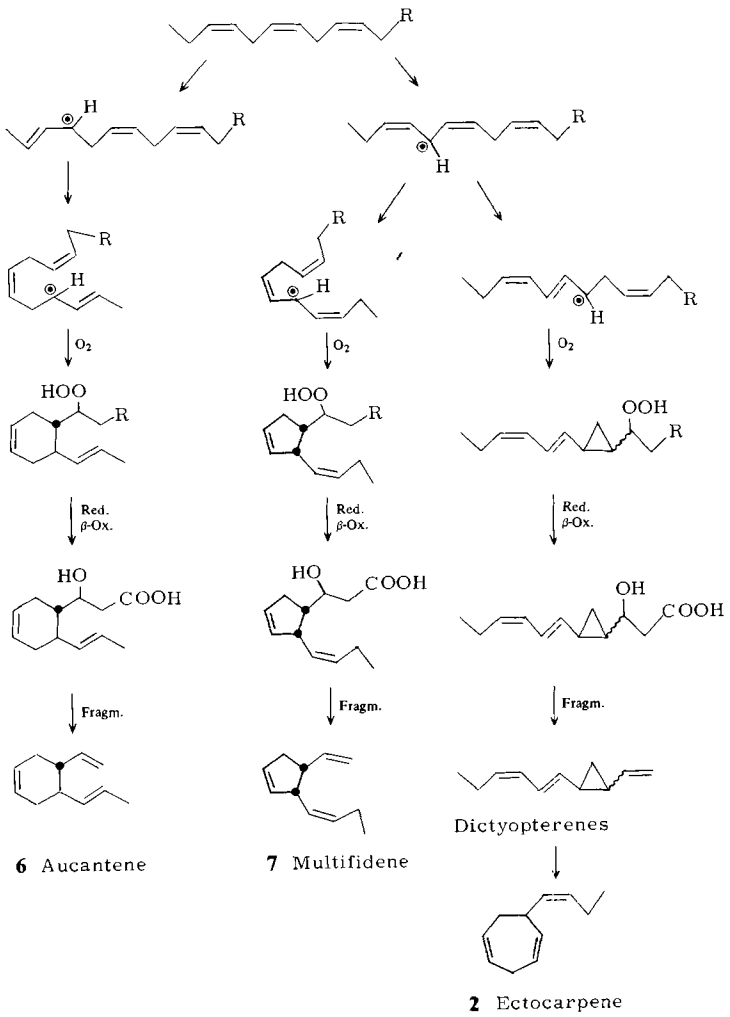
26 **27**

Scheme 4. Preparation of the diastereomic amides **27** from the acid **26** with 1) *N,N'*-carbonyldiimidazole and 2) 2-amino-2-phenylethanol.

26[37] is converted by reaction with *N,N'*-carbonyldiimidazole into the reactive imidazolide, which is allowed to react with optically pure 2-amino-2-phenylethanol ("phenylglycinol") to give the diastereomeric pair **27**: this can be resolved into its two enantiomers on silica gel columns (Nucleosil 50-5) with a factor $\alpha = 1.2$[41]. *Kajiwara et al.*[42] used a biochemical method; they diastereoselectively saponified ethyl 2,5-cycloheptadiene-1-carboxylate with *Rhodotorula* species. The resulting optical yields were 78 and 95% e.e.; these authors were also able to resolve the diastereomeric quinine salts (95% e.e.).

4. Biogenetic Relationship of C_{11}-Hydrocarbons

It is obvious that there is a structural similarity between the sex-specific pheromones of brown algae species so far isolated (compiled in Table 1). They all contain a vinyl or cycloheptadienyl group and, depending on their origin, a *Z*-butenyl, *E*-propenyl or *E*-hexenyl group (in some cases these groups are hydrogenated or dehydrogenated). Some also exhibit a homoconjugated 1,4-rhythm, which is characteristic of polyunsaturated fatty acids. We have further seen that the C_{11}-polyenes may also have rings of varying sizes; cyclopropane, cyclopentene, cyclohexene, and 1,4-cycloheptadiene are found. In the C_8-compounds the ring structure is absent, but vinyl and *Z*-butenyl terminal groups are present. Fatty acids are more obviously the biogenetic source of 1,3*E*,5*Z*,8*Z*-undecatetraene, in which the aliphatic fatty acid terminus is almost unchanged. This comparison suggests that the pheromones are biogenetically related to one another, whereby linolenic acid may be a common precursor. This compound occurs not only in marine algae (from where it reaches the liver oil of fish) but also has a terminal *Z*-butenyl group. Lower molecular weight homologs may also be suitable starting compounds *e.g.* dodecatrienoic acid, which can be produced from linolenic acid by three consecutive β-oxidations. It seems plausible that these natural products may be formed in the membrane fractions of gynogametes from (β-oxidized) polyenic fatty acids by a combination of radical cyclization and subsequent heterolytic fragmentation.



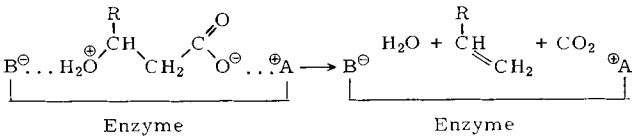
Scheme 5. Model for the biogenesis of C_{11}-polyenes from unsaturated fatty acids. Red. = reduction of hydroperoxides, β-Ox. = β-oxidation, Fr. = heterolytic fragmentation.

The reaction sequence postulated in Scheme 5 is based on the following considerations:

- One of the olefin-flanked CH_2 groups is activated as a radical by analogy to the primary step of lipoxygenase-catalyzed reactions. In radicals the entire flexibility of the lipid chain is retained, which is not the case in cationic structures.
- The reactive species can undergo cyclization either directly (multifidene) or after rearrangement (dictyopterenes) to give a conjugated pentadienyl radical. Positioning at the active center of the enzyme concerned largely determines the ring size and substitution pattern (note the analogy between conjugated C_{11}-hydrocarbons—*E,Z* geometry— and the products of lipoxygenase reactions).
- After ring closure or rearrangement, reaction with oxygen (ground state) terminates the radical process yielding hydroperoxy acids (Δ^9) if the starting molecule is linolenic acid, Δ^3 if it is dodecatrienoic acid).

Reduction of the hydroperoxides and triple β-oxidation (only in the case of linolenic acid) leads to the formation of 3-hydroxy acids. These compounds act as substrates for heterolytic fragmentation in which the functional groups present are removed in the form of CO_2 or H_2O.

The mechanism of this fragmentation involves general acid/base catalysis (Scheme 6).



Scheme 6. Fragmentation by general acid/base catalysis.

Longer chain or more highly unsaturated fatty acids are also possible educts for this reaction, for example arachidonic acid which could be liberated from membrane phospholipids by a phospholipase.

Similar lipid-activating, oxygen-dependent enzymes may be involved in the genesis of C_8-compounds (*e.g.* fucoserratene **8**). A diol intermediate could thus be obtained from 1,5*Z*,8*Z*-undecatrien-3-ol, and *Yamada et al.* established that this compound is present in *Dictyopteris* species[43]. Fragmentation of the diol intermediate with retention of the 5*Z*-geometry would then produce fucoserratene **8**. Retention of the 5*Z*-geometry has been confirmed experimentally by means of biomimetic model reactions[44].

A South African composite *(Senecio isatideus)* has proved to be of value for such biogenetic experiments; when in flower this species contains considerable quantities of ectocarpene in its aerial parts[45], whereas sesquiterpenes and a range of open chain C_{15}—C_{17}-hydrocarbons are to be found in the roots[46]. The latter compounds all possess a characteristic vinyl group and double bonds at the positions expected if they are derived from polyunsaturated fatty acids. Biogenetic experiments with labeled precursors have been performed with both *Senecio* and dyer's thistle *Carthamus tinctorius*, whose seedlings also contain significant quantities of vinyl hydrocarbons in their lipids shortly after germination[47]. 1-Pentadecene, 1,8*Z*,11*Z*-heptadecatriene, and 1,8*Z*,11*Z*,14*Z*-heptadecatetraene (major product) have been identified in the very early developmental stages (this profile is comparable with that of *Senecio*). Labeling experiments with ^{3}H-linolenic acid were therefore first carried out on this easily accessible plant. Incorporation ratios of up to 4‰ were found, which support the hypothesis that these fatty acids act as precursors[48]; it is open to discussion whether activated derivatives of the fatty acids take part in these reactions.

5. Reception of Signal Substances

It is still not known exactly where the attractant is bound to the androgametes, how its stimulus is processed and transmitted to the motile flagella and, finally, how the signal is terminated and inactivated. Preliminary experiments with labeled ectocarpene **2** suggest that the receptors are grouped around the attachment sites of the flagella. By analogy with observations on chemotactic microorganisms it can be concluded that the transmission and processing of the stimulus involve the chemical or conformational modification of binding, carrier, adaptation, and

transformation proteins resulting in a modulation of flagella movement—whether it be by ion or energy flux[49]. Cinematographic studies on the movement patterns of *Ectocarpus*' androgametes indicate that the attractant-sensory system acts on the steering movements of the small flagellum[50]. The dorsiventral gametes react strongly thigmotactically and are pulled along the underlying surface by the large, motile flagellum which is equipped with passively moving side hairs (mastigonemata). The gametes do not, therefore, swim freely but rather crawl in the limited space between seaweed filaments or along the surface of a brown alga thallus or some other surface. The gametes initially move in a straight line or wide circle but this is changed in presence of a lure to a right-handed spiral by an increase in the beating frequency of the short flagella. The males thus first encircle and finally reach the source of the attractant, the gynogamete, if positioned to the right (Fig. 3). An emitter to the left is missed and the gamete, after passing through the signal gradient, resumes its straight movement without hitting the goal. Thus, net mating probability is 0.5.

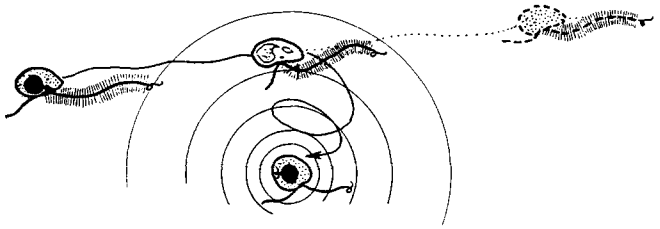


Fig. 3. Changes in the movement patterns of algae gametes in an attractant gradient. An increase in the pheromone concentration increases the beating frequency of the asymmetrically arranged short flagella, this causes the gametes to move in a right-handed spiral and reach the gynogametes.

The sender (emitter) can be located due to the fact that one or all of the conformatively altered proteins have a memory (which must be short-lived so that a gradient can be detected and followed). The spatial data can be transformed into time-based information by inactivation of the stimulant, so that the system only requires one type of receptor and can dispense with a gradient control along the gamete (dc/dx). The still largely hypothetical model of stimulus response in unicellular eukaryotic organisms requires specific receptors; we have, however, shown the existence and action of these receptors by chemical and sensory physiological experiments.

5.1. Biological Activity Assay

We have utilized a modification of the method mentioned in Section 2.1 to obtain quantitative data about the informational value of an attractant[51]. Microdroplets (0.1 μL) of serial dilutions of the attractant in a biologically inert perfluoro ether (FC 78)[*] are brought into contact with gamete suspensions for a defined length of time in the dark (to eliminate phototactic interference). A solvent blank is also determined. A flash-light dark-field exposure is made and the number of gametes found in a given area is compared with a corresponding blank[**]. The value obtained is reproducibly proportional to the concentration of the attractant, so that a dose-response curve can be drawn. If the results are plotted logarithmically, the curve almost becomes a straight line, indicating that the Weber-Fechner law also applies to these primitive sensory cells (logarithmic dependence of stimulus strength and stimulus response). The stimulus threshold is the limiting concentration at which the sample value just exceeds the blank. The actual concentration of the active substance (C_L') is obtained by employing the appropriate distribution coefficients (K_{fcw}) of a substance between the organic phase (FC 78) and seawater. The distribution coefficients are determined by gas chromatography or UV measurements (in the case of conjugated compounds). The product of the threshold concentration in the organic phase (C_L) and K_{fcw} corresponds to the actual concentration of the active substance in the aqueous phase (C_L')[52].

Under the stringent conditions assumed, experimentally reproducible results are obtained, which can be rationalized and open up systematic investigation of the signal substance/binding site system. Quantitative evaluation gives impressively low values for the threshold concentrations of pheromone in the aqueous phase which are necessary to trigger off a stimulus. In the (*S*)-(+)-ectocarpene/*Ectocarpus* and (+)-multifidene/*Cutleria* androgamete systems the values were determined to be 8.9×10^{-10} mol/L[54] and 6.5×10^{-12} mol/L[52], respectively. After consideration of the swimming behavior, reaction time, and the action volume of the gametes it has been calculated that 1 to 10 attractant molecules are required per gamete to effectively trigger the luring reaction. Comparison of the steepness of the stimulus/response curves and the thresholds for stimulation in the systems is of illustrative value. The gametes of the primitive, isogamic *Ectocarpus* have low sensitivity and do not need to travel long distances within the closely woven environment of filamentous gametophytes. A strongly attracting sign language is not called for as there are equal numbers of andro- and gynogametes, whereas in anisogamic and oogamic forms more effective systems of communication had to be developed. The steepness of the response curves of the multifidene/*Cutleria* androgamete and fucoserratene/*Fucus* spermatozoid receptor systems are accordingly much greater[51]. As is the case in all the other systems a range of approximately 1 mm is sufficient for the biotope (Fig. 4).

The specificity of the attractant systems is also quite remarkable. In the natural system only the attractant of the species in question is highly effective; however, it can pro-

[*] FC 78 is a trade name of the 3M Company for a low molecular weight perfluoro ether with the empirical formula $C_8F_{16}O$.

[**] The result is expressed as an attraction ratio Q = number of gametes per standard area of the sample divided by the number of gametes per standard area without attractant, and is then treated statistically. By definition, the uncorrected threshold concentration of a substance is attained when Q tends to a value of 1.00. This activity test is based on a knowledge of the limiting concentration in the aqueous phase surrounding the gametes directly above the FC 78 limiting surface. The diffusion rates of the signal substances must therefore be taken into consideration. According to Fick's first law the number of molecules transported in a given time is given by $dn/dt = -AD \cdot dc/dt$ and is thus related to the concentration in the FC 78 phase. The population above the sample droplet is therefore time and concentration dependent. The influence of these effects was determined by counting the number of gametes above the droplet at 1 min intervals with different concentrations of attractant; the optimal time was found to be 4 min [53]. Furthermore, the prerequisites are that the lipophilic substances must undergo *molecular* dissolution (no micelle formation) and must be chemically stable throughout the measurement.

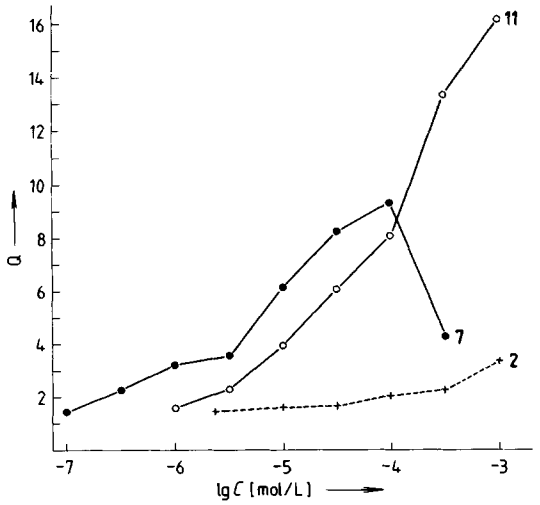

Fig. 4. Dose/response diagram for brown algae attractants (illustration of the Weber-Fechner law). 2 = ectocarpene in *Ectocarpus*; 7 = (+)-multifidene in *Cutleria*; 11 = fucoserratene in *Fucus*. The "luring quotients" Q are plotted against the logarithm of the pheromone concentration C in the organic phase ($Q = K \lg C$).

duce an effect in related forms, although the threshold for attraction is often higher (by several orders of magnitude). *Cutleria* androgametes thus respond not only to multifidene **7** but also to ectocarpene **2**[54]. Scheme 7 offers an explanation for this phenomenon: certain conformations of the two substances resemble each other, hence each substance can bind not only to its "own" receptor but also to the surface of the receptor whose configuration is primarily adapted to fit the other attractant.

Scheme 7.

If the ectocarpene is modified, however, only the *Ectocarpus* system reacts in a sensitive manner; the *Cutleria* system does not exhibit such a behavior. If, for example, the *Z*-butenyl side chain of **2** is substituted by an *E*-propenyl side chain, the informational content for *Ectocarpus* androgametes decreases by a factor of 10^3, but for *Cutleria* spermatozoids only by a factor of ten[54].

5.2. Receptor Scan with Synthetic "Multifidenes"

The multifidene molecule **7** has two side chains and its cyclopentene ring has specific stereochemistry and double bond positions; it is therefore more variable than ectocarpene **2**, and is thus better suited for the investigation of the appropriate receptor. The synthesis described in Scheme 2 was used to prepare more than 40 isomers, homologs, and analogs of multifidene in which the position of the ring double-bond is altered and heteroatoms are introduced into the side chains. The compounds were obtained with a purity of more than 99% by means of preparative gas chromatography[31]. The two enantiomers (+)- and (−)-multifidene were also synthesized in a high degree of purity[35]. The ways in which this molecule may be modified can be classified as follows: 1) The double bonds are reduced or transferred to a different position; 2) One or other of the side chains is shortened or lengthened, with *cis*- or *trans*-orientation; 3) A double bond is substituted by a C-heteroatom group[53].

In the first group the biological activity is generally diminished by a factor of 10^2 if one double bond is absent; loss of further double bonds is less critical (cooperative binding). The activity is also drastically reduced (in extreme cases by a factor of 10^3) in the second group. Only molecules with a *cis* geometry are effective, and this geometry is found in the naturally occurring molecule. Figure 5 demonstrates the differing activities of the enantiomers. The natural (+)-enantiomer is approximately 100 times more effective than its (−)-enantiomer (>98% e.e.). This means that the unnatural enantiomer is almost inactive but, at least, does not have any antagonistic effects.

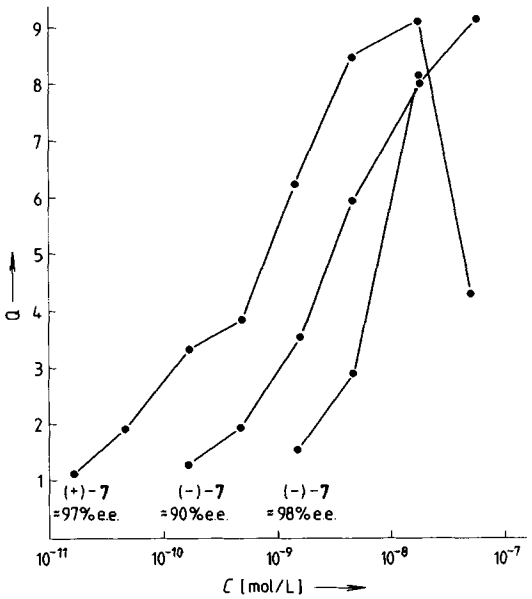

Fig. 5. Dose/response diagram for (+)- and (−)-multifidene **7** (in seawater).

The most important factors controlling binding are, in addition to shape and size, the double bonds in the multiunsaturated hydrocarbon multifidene. Binding to the receptor is thus brought about by π electrons, *i.e.* by induced dispersion interactions. We have proposed a model for the receptor cavity in which dipole/dipole interactions cause the binding of the signal molecule, and where hydrophobic forces play a considerable role in the formation of the ligand/receptor complex at the boundary surface between the water and the gamete surface[52] (Fig. 6).

The specifically constructed receptor surface contains electrophilic groups which are complementary to the double bond positions of the pheromone and therefore cause mutual polarization of the partner. The binding process or a subsequent reaction produces a conformational change in the complex and thus brings about a biological effect. In order to investigate the binding of multifidene to its receptor without disturbing steric, conformational or solvation effects, almost equivalent parapheromones (artificial signal molecules) with systematically modified electronic properties were synthesized[36]. The results of the binding

studies largely confirmed the proposed receptor model and thus gave a clear insight into the primary steps of molecular recognition in the gamete cycle of the Phaeophyceae[53].

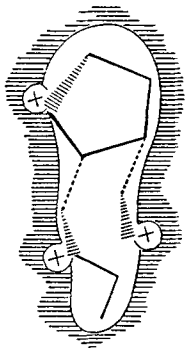

Fig. 6. The "ear" of the gametes for the language of the attraction signals. Schematic representation of the mutual polarization of the ligand (multifidene 7) and receptor. Electrophilic groups whose arrangement is complementary to the π electrons of the signal molecule can contribute to binding and accompanying conformational changes in the receptor/ligand system by induction of dipole moments.

Side chains with strongly polarizable groups play a more important role in determining the activity of the parapheromone than those with more weakly polarizable groups. The biological activity of analogs in which the original vinyl group is replaced by a halomethyl group is greater the stronger the polarizability of the halogen unit. The iodine derivative is, as is to be expected, a perfect imitator of the natural product and even slightly surpasses it (Fig. 7, cf. Scheme 8). The molecules resemble each other both sterically and with respect to their permanent dipole moments (in the case of the latter, resemblance is only approximate) so that the results can be directly related to the electronic properties of the substituent in question. The differences between the dose-response curves of the CH_2Cl and CH_2I derivatives (approximately 1 : 4) is thus a reflection of the higher polarizability of iodine compared with chlorine and the related electron donor properties.

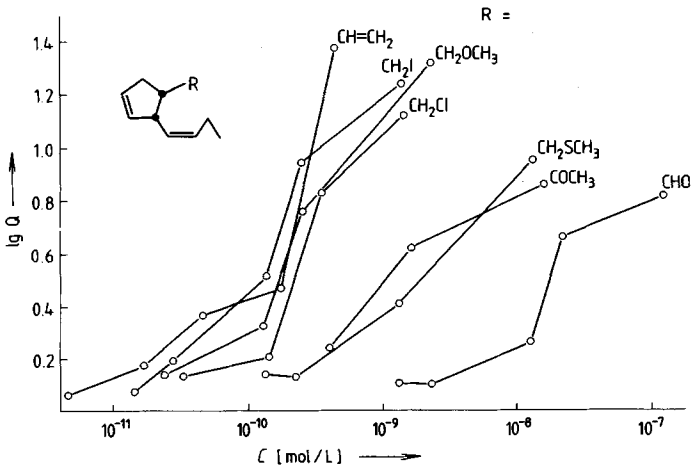

Fig. 7. Dose/response diagram for selected derivatives of multifidene 7 (R = CH=CH_2). All of the curves begin at the actual calculated limiting concentration in the aqueous (seawater) phase (C_L^*).

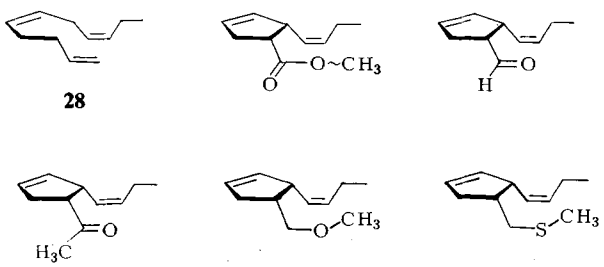
The oxa- and thiamultifidenes represent another group of parapheromones which are of interest in this context[36,53]. The aldehyde derivative (cf. Fig. 7) exhibits unexpectedly low activity. This can be interpreted as follows: only the bonding electron pair of the C=O double bond is accessible to mutual polarization and formation of a π complex, since it is the only one which is located in the same plane as the electron cloud of the original vinylic double bond. The orbitals of the two lone electron pairs are, however, mutually perpendicular in such a way that they cannot participate in the donor and polarization processes. This accounts not only for the low activity of the aldehyde and the acetyl compound but also for the high activity of the ether. In the ether the polarizable lone electron pair of the oxygen can easily be accomodated in the plane of maximal interaction, since an sp^3-hybridized side chain possesses all the rotational degrees of freedom. This hypothesis is further substantiated by the behavior of the corresponding thioether, which should exhibit typical acceptor properties on account of the vacant 3d orbitals of its sulphur atom. Its biological activity is indeed only approximately 30% of that of the ether, although the two compounds can be regarded as being sterically equivalent (Scheme 8).



Scheme 8. Representation of several mock-pheromones in perspective (cf. Fig. 7).

The ester is of interest, since its activity lies remarkably close to that of the natural substance. The concept of molecular interaction can also be applied successfully here. The electron distribution of the ester can resemble that of the ether, whereby resonance effectively backs-up the polarization effects. Appropriate three dimensional structure and stereochemistry are other important conditions for effective binding of nonpolar molecules. Induced fit does not seem to be solely responsible, since 1,5*Z*,8*Z*-undecatriene **28** can adopt the conformation of multifidene **7**, but is practically inactive. We are, however, aware of the fact that in such a linear molecule the bond lengths do not fully correspond to those of the alicyclic pheromone. The rigid nature of multifidene seems to be necessary to induce the appropriate forces in the receptor.

6. Conclusions and Outlook

The macroscopically observable radius of action of brown algae pheromones barely exceeds 1 mm (depending on the species in question this corresponds to the diameter of 10 to 70 gynogametes), nevertheless these compounds are comparable to the extremely sensitive olfactory systems of insects[55,53]. In the absence of pheromones the androgametes, because of their high speed (up to 350 μm/s), would shoot past their target before their course could be corrected. The pheromones increase the beating frequency

of the small posterior flagellum so that as more pheromone molecules hit their target, and as a result of the pull of the anterior flagellum the androgametes move in a spiral, this spiral movement becomes increasingly narrower and slower. An androgamete which lies outside the "transmitting area" of a gynogamete cannot locate the source of the attractant and will only reach it coincidentally. If this movement can indeed be induced by just a few hormone molecules, we must postulate that there is an effective trigger mechanism in which existing membrane potentials at the surface of the receptor suddenly collapse upon arrival of the chemical signal; this mechanism has also been proposed for the recognition of insect pheromones[56]. This unique sensitivity requires, however, a high signal-to-noise ratio. In the case of the brown algae pheromones this is brought about in the simplest possible way by the largely nonpolar nature of the signal substance in its highly polar aqueous carrier medium. Other mechanisms must dispose of excess pheromone or inactivate it. This is accomplished firstly by the very high volatility of the spherical molecules and secondly by chemical attack at the reactive double bonds *e.g.* the divinyl-methane system in ectocarpene **2**. As has been shown, polar substituents in the attractant molecule result in an almost total loss of activity[52]. This "self cleaning" of the environment can be due to light-induced oxygenation in shallow continental shelf areas, but heavy metal-catalyzed hydration or active enzymatic processes at the surface or inside the gametes may also be responsible.

It can be concluded from our studies, especially those on the multifidene/*Cutleria* system, that the "ear of the gametes" for the language of the attraction signals is located on protein molecules at the cell surface or within the cell. The shape of the "ear" is such that the signal compound fits it exactly and is held tightly at clearly defined positions by maximal interactions resulting from dispersion forces and electrophilic groups. Only the natural (+)-form of multifidene satisfies these requirements and is thus the only substance which can exercise the physiological function of conveying information to the processing units of the gametes. Dipole/dipole interactions with strengths of approximately 13 to 17 kJ/mol are responsible for orientation. Using the threshold concentration of the native multifidene, the total binding energy can be roughly estimated to be 70 kJ/mol. This means that approximately half of the energy is accounted for by forces other than those discussed and measured here. These may well be the entropy terms of the entire attractant/receptor/environment system. We are well aware that the multifidene/*Cutleria* androgamete system only provides a model for the sensory mechanisms involved in smell and taste of higher organisms. The impressive results obtained, however, certainly encourage such extrapolations.

The Unambiguous Specification of the Steric Course of Asymmetric Syntheses

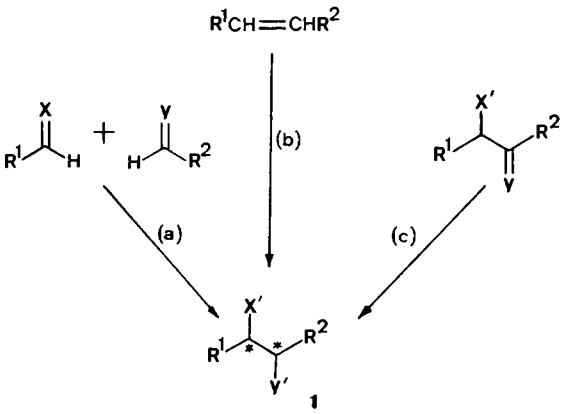
By Dieter Seebach* and Vladimir Prelog

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The nomenclature of organic chemistry has not kept pace with the staggering advances made in asymmetric syntheses over the last 15 years. Efforts to specify the steric course of stereoselective reactions by use of the terms *erythro* and *threo*, and by other descriptors have led to ambiguous notation and consequently to an almost Babylonic confusion. We propose here a method, based on the CIP-(Cahn-Ingold-Prelog) system, for the unambiguous specification of the steric course and the product configuration of diastereoselective reactions. The reflection-invariant *relative topicity* of approach of reactants is defined as like *(lk)* and unlike *(ul)* if the corresponding descriptor pairs are *Re*,Re** or *R*,Re**, and *Re*,Si** or *R*,Si**, respectively. The descriptor pair notations (*lk* and *ul*) of reactants disclose related steric courses of reactions more often than do the relative configurations of their products, for which the configurational notation $l = R^*,R^*$ and $u = R^*,S^*$ is proposed. The advantage of specifying the relative topicity is demonstrated by means of a series of recent examples of importance to the synthetic organic chemist taken from the literature and from our own work.

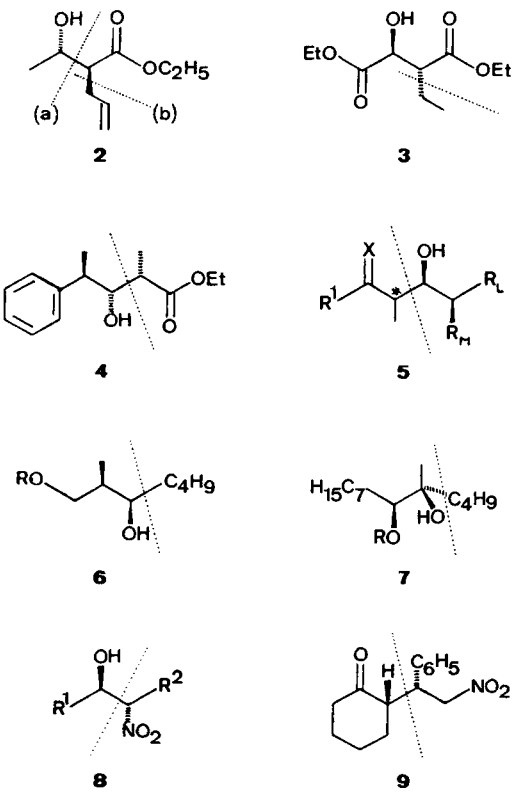
1. Introduction—The Problem

Complex natural products such as macrolides, ionophores, and related compounds have recently become target molecules for synthetic organic chemists[1]. The often formidable array of asymmetric carbon atoms in the structures of these compounds[2] has stimulated the development of highly stereoselective asymmetric syntheses. Foremost amongst these are the aldol[3-5], nitroaldol[6,7], and Michael additions[8]. In all these reactions two planar trigonal carbon atoms are linked together to create a pair of asymmetric tetrahedral carbon atoms [route (a) in Scheme 1]. Stereoselective additions to olefins[9] and to trigonal carbon atoms α to an asymmetric carbon [routes (b) and (c), respectively, in Scheme 1], give the same type of products **1**[7,9-12].



Scheme 1. Three independent routes to structure **1**.

Although these developments represent formidable progress in the art of organic synthesis, attempts to specify the steric course of these reactions have unfortunately led to bizarre nomenclatures, of which the following examples are representative (see Scheme 2): Compound **2** has been termed a "*threo*" aldol product[3,5,17]; **3** an "*erythro*"



Scheme 2. **2a**: *l* by *lk*-aldol addition; **2b**: *l* by *lk*-allylation of an enolate; **3**: *u* by *ul*-ethylation; **4**: *u*, *l* by *ul*-aldol addition with *ul*-1,2-induction; **5**: *lk*-1,2-induction; **6**: *l* by *lk*-addition; **7**: *l* by *lk*-addition; **8**: *u* by *ul*-nitroaldol addition; **9**: *u* by *lk*-Michael addition.

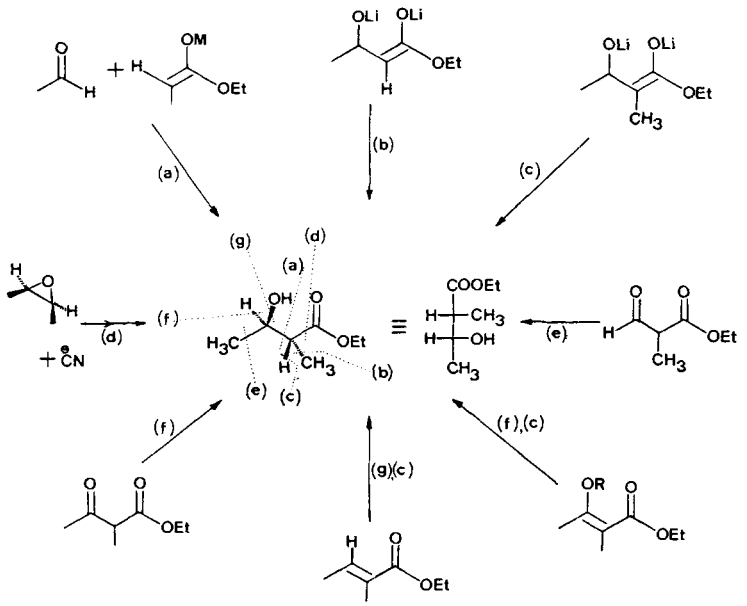
branched malic ester[11]; **4** an "*erythro-anti*-Cram"[3] or "*syn-anti*-Cram" product[4]; **5** a "cram[α- or β-Me]" product, formed in a "CT- (for Cram-*Trans*-enolate) or in a CC (for Cram-*Cis*-enolate)" process[5], respectively; **6** an "*erythro* (Cram steric)" adduct[10a] **7** a "*threo*" glycol derivative[10], **8** an "*erythro*" nitroaldol[7], and **9** an "*erythro*" Michael adduct of an enamine with ω-nitrostyrene[18].

Clearly, there is no agreement about the use of these configurational notations and especially about the meaning of the prefixes *threo* and *erythro*[19]. The attempted redefinition[23] for the purpose of specifying the diastereoselective formation of certain stereoisomers by a particular reaction is certainly not a good basis for configurational notation, because many compounds, such as the β-hydroxyester shown in the center of Scheme 3, can be obtained by



Scheme 3. Formation of *l*-ethyl-3-hydroxy-2-methyl-butanoate with creation of the bonds (a)—(g). (a): *lk*-aldol addition [3–5]; (b): *lk*-methylation of enolate [11, 16]; (c) *ul*-protonation of enolate; (d): opening of *u*-epoxide with inversion (S_N2); (e): *lk*-addition of CH_3-metal derivative [10]; (f) *ul*-hydrogenation of C=O [10b]; (g), (c): *ul*-Michael addition of water to *ul*-olefin; (f), (c): *lk*-hydrogenation of *ul*-enol ether.

several routes [(a—g)], which could well lead to different configurational notations. According to the "aldol-notation"[3,5,17], the (2*R*,3*R*)-3-hydroxy-2-methylbutanoic acid ester in Scheme 3 is specified as "*threo*"; however, according to textbooks of stereochemistry[20] the same compound is specified *erythro*[11].

The present situation in this area is reminiscent of the days when such a simple molecule as dextrorotatory tartaric acid was specified D by European chemists (following *Fischer* and *Freudenberg*) and L by Americans (following *Rosanoff*), because it can be chemically correlated by different reactions with either D- or L-glyceraldehyde[27].

It was in order to avoid such ambiguities that the CIP-system was introduced[28,29]. This specifies the chirality sense of individual two- or three-dimensionally chiral stereogenic atoms (or more generally, stereogenic units, such as centers, axes, planes) by descriptors *Re,Si* or *R,S*, respectively. This system thus specifies not only absolute but also *relative topicities* and configurations by relationships among the descriptors. The duality of diastereomorphic relationships based on combination of two stereogenic atoms and their descriptors leads to two classes which are conventionally specified in the CIP-system (Rule 4[28]) by calling the descriptor pairs with the same first letters (such as *Re,Re*; *R,R etc.*) like (abbreviations *lk* or *l*, respectively) and those with different first letters (such as *Re,Si*; *R,S* etc.) unlike (abbreviations *ul* or *u*, respectively)[28b,30,31].

We now propose an analogous procedure for the unambiguous specification of the steric course of a single diastereoselective asymmetric reaction or of a class of closely related reactions by specifying diastereomorphic relationships between the two-dimensionally stereogenic trigonal atoms and/or three-dimensionally stereogenic tetrahedral atoms in reactants and in products. This will be explained and illustrated by examples.

2. The *Relative Topicity lk* or *ul* of Reactants and the *Relative Configuration l* or *u* of the Products

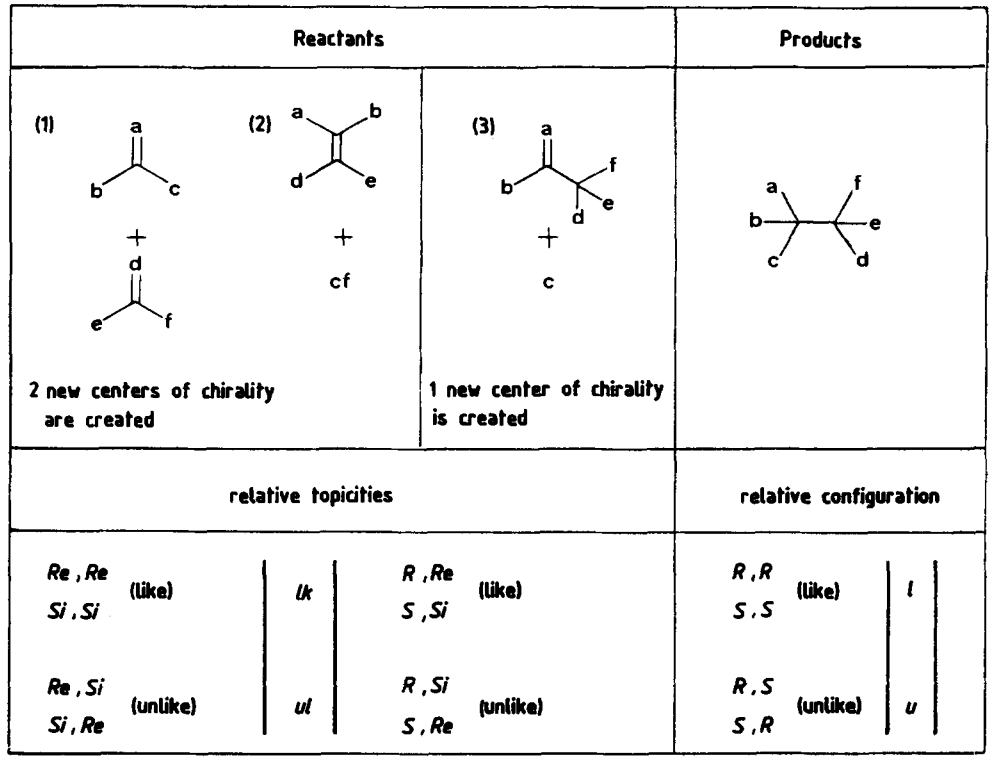
Only one enantiomeric set is shown in all *formulae* representing diastereotopic or diastereomeric relationships. The steric course of reactions leading from reactants with one or two two-dimensionally stereogenic centers to products with two three-dimensionally stereogenic centers is defined by a descriptor pair, and so is the configuration of the product, as shown in Scheme 4. The descriptor pair may be like or unlike. The steric-approach descriptor pairs define *relative topicities*, for instance (*Re,Re*)-approach or addition from the (*Si*)-face of the (*R*)-enantiomer, and are abbreviated as *lk* (like) and as *ul* (unlike), respectively. Similarly, the configurations of the products formed are designated *l* for (*R,R/S,S*) or (*R*,R**) and *u* for (*R,S/S,R*) or (*R*,S**)[30,32]. Procedures for applications to more complex processes or to more complex reactants are given in the legend to Scheme 4.

3. Examples of the Application of the like/unlike Descriptor Pair Notation

As first examples, the abbreviations *l* and *lk* for like and *u* and *ul* for unlike have been appended for specification of reactions shown in Schemes 2 and 3 (Section 1).

The examples in Scheme 5 show that the *u,l* configurational notation is concise and unambiguous, even in complex cases such as **10**–**12**; in addition, *cis/trans*-diastereomeric olefins, for instance **13** and **14**, can be specified by the same notation[28b].

In Schemes 6–12 a variety of different reactions are specified. Thus, the favored course of aldol and related additions[3–5,8] in nonpolar media turns out to be *ul* with *syn*-enolates and *lk* with *anti*-enolates (see Scheme 6). In Scheme 7 an iodolactonization-type reaction[9], an epoxidation of a homoallylic alcohol[13b], and the conversion of specifically labeled linalol, (*ul,lk*)-1,2,8-trideuterio-3,7-dimethyl-1,6-octadien-3-ol, into terpineol[33] are described with the like, unlike descriptors: the 1,2-induction of the epoxidation in the middle of Scheme 7 is *lk* for all known examples, regardless of the configuration of the atom carrying the hydroxy group[13b]; with the terpineol-forming



Scheme 4. In complex processes, the relative topicities (1), (2), and (3) are given in this order. The distance between the inducing center of chirality and the reacting atom is specified by 1,2; 1,3; 1,4 ... *etc.* If several centers in the inducing part of the reactant are present, the one which has priority according to the revised CIP system [28] takes precedence.

14
lk-diastereomer

Scheme 5. **12**: (*u,l,u,l,lk*)-4,6,10-trihydroxy-3,5,7-trimethyl-8-decen-2-one; (order of descriptor pairs according to increasing numbering in IUPAC name).

process, the information content of the relative topicity signs is impressive: the *lk*, *ul*, *ul*-1,3 description specifies (a) that the new CC bond is formed with relative topicity *Re,Re/Si,Si*, (b) that the addition of C and O to the C=C bond occurs with *Re,Si/Si,Re* steric approach, and (c) that the (*R*)- or (*S*)-enantiomeric starting material undergoes CC bond formation with *Si,Si* or *Re,Re* relative topicity, respectively.

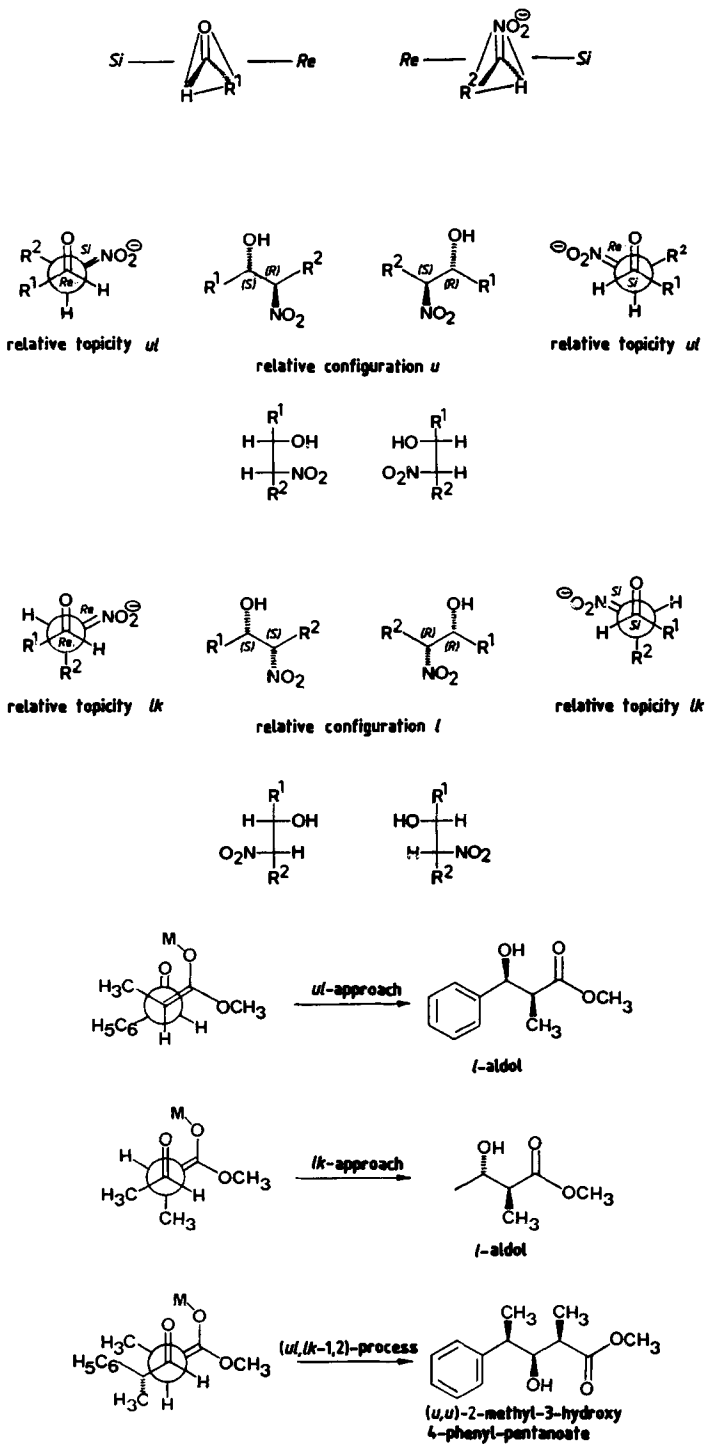
Scheme 8 contains examples of the application of the *lk/ul* descriptor pair abbreviations to reactions following the classical Cram[34], Cornforth[35], and Prelog[36] rules; it is evident, that the acyclic and the cyclic models of the Cram rule are both specified by *lk*. Additions to α-ketoesters of chiral alcohols proceed with *ul*-1,4 induction, irrespective of the priority sequence of the substituents.

In Scheme 9 three examples are shown of reactions which follow a newly established rule for diastereoselective approach of electrophiles to donor double bonds[7, 11, 17].

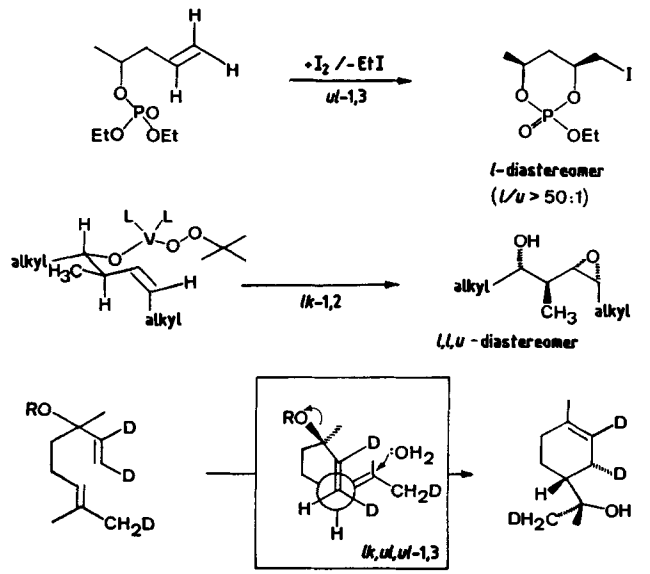
Examples of recently described 1,4- and 1,5-inductions are the reaction sequences (1), (2), and (3) in Scheme 10. The alkylation of the enamine from cyclohexanone and prolinol ether by ω-nitrostyrenes furnishes one of the four possible stereoisomeric 4-nitroketones with >90% selectivity; the first *lk* in the relative topicity specification indicates that the new CC-bond results from a *Re*,Re**-combination of the trigonal centers with formation of the *u*-diastereomer, while the *ul*-1,4 signals that the (*S*)-prolinol ether leads to the (2*S*,1′*R*)-enantiomer of 2-(1′-aryl-2′-nitroethyl)-cyclohexanone[8]. Methylation of the (*S*)-prolinol derivative [see (2) in Scheme 10] occurs from the *Re*-face; a *ul*-1,5 induction[15]. The Michael addition (3) in Scheme 10 can produce[37] (*R*)- or (*S*)-β-branched carboxylic acids, depending upon the sequence in which R^1 and R^2 are attached to the heterocyclic system, with *lk*-1,5 induction.

In Scheme 11, the steric approach in a [2+2]-cycloaddition and in two Diels-Alder reactions is described with the relative topicity notation. Other conversions following the Woodward-Hoffmann rules[38] are of course also amenable to specification by this notation; the intramolecular cycloaddition described in the third equation of Scheme 11 demonstrates the simplicity of the proposed procedure as compared to conventional ways of specification[39].

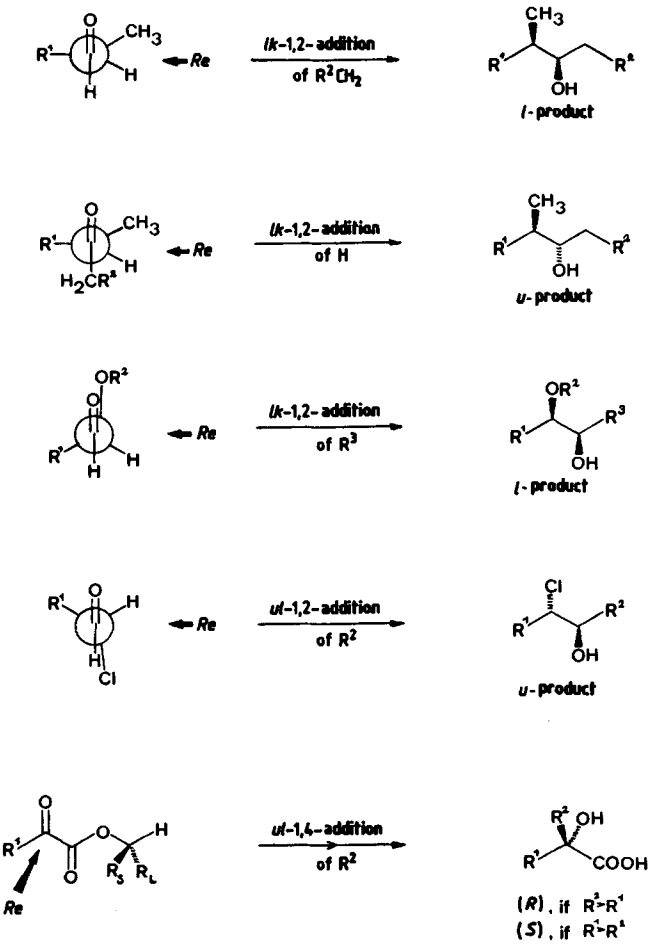
Although not covered by (1), (2), and (3) in Scheme 4, the relative topicities can also be defined in other asym-



Scheme 6. Aldol and nitroaldol additions. Top: Procedure for the specification of the relative topicities of the two possible reactant approaches in the nitroaldol addition and specification of the relative configuration of the products.—Below: Aldol additions of *cis*/*trans*-isomeric enolates to aldehydes. Specification of relative topicities of the first two reactions discloses their different steric course, while specification of the product configurations does not.—The third reaction follows the Cram rule: it exhibits the typical *lk*-relative topicity of the 1,2-induction (see Scheme 8, first three equations).

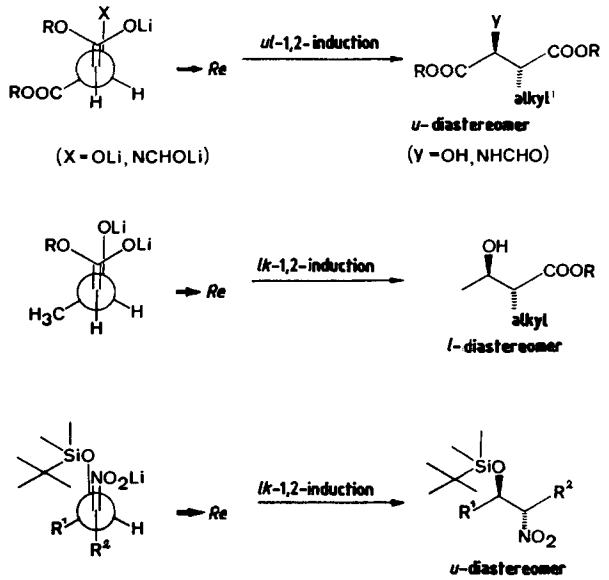


Scheme 7. 1,2- and 1,3-inductions in reactions of substrates with allylic and homoallylic structures.—In the last reaction all three types of processes specified in Scheme 4 occur: (1) formation of a new CC bond between two trigonal centers; (2) addition to a double bond; (3) a 1,3-induction. Notice that the cyclization follows the rule of "antiperiplanar hydrogen atoms" with respect to both double bonds (see 15 in Scheme 11)[8].

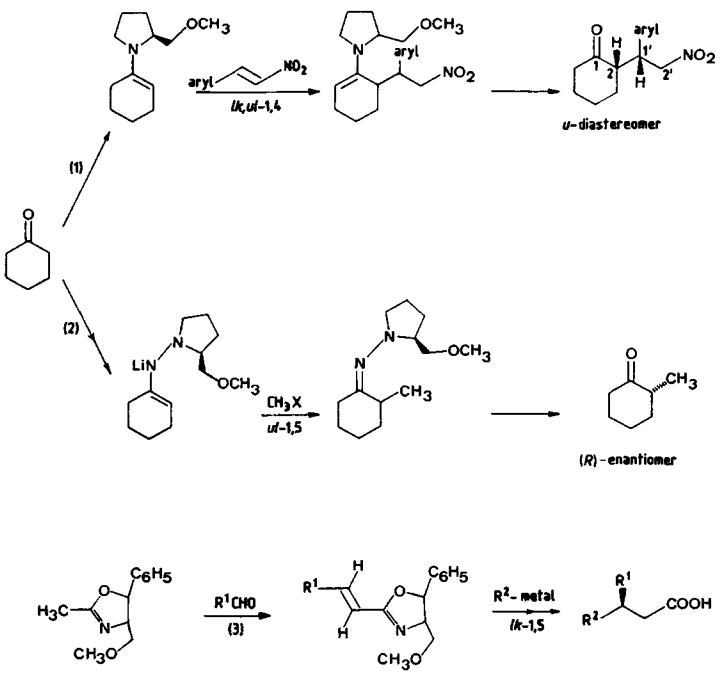


Scheme 8. Specification of reactions following the Cram or Prelog rule. With the normal priority order of substituents at the inducing and at the trigonal centers, both the open-chain [$CO > R^1$, $CH(CH_3)R^1 > CH_2R^2$] and the cyclic [$OR^2 > CO > R^1$] models of the Cram rule have the relative topicity *l* [approach from the *Re*-face of the (*R*)-enantiomer or from the *Si*-face of the (*S*)-enantiomer (see first three equations of the scheme)]. Similarly, the Prelog rule always describes processes with relative topicity *ul* [priority order $R_L > R_S$ (fourth equation)].

metric syntheses. Three such reactions are described by the equations in Scheme 12. In the Horeau method of kinetic resolution[40] an (*R*)-alcohol reacts preferentially with the (*R*)-acylating reagent, a like-selectivity. In the so-called "immolative" asymmetric synthesis[20] of an alcohol by re-

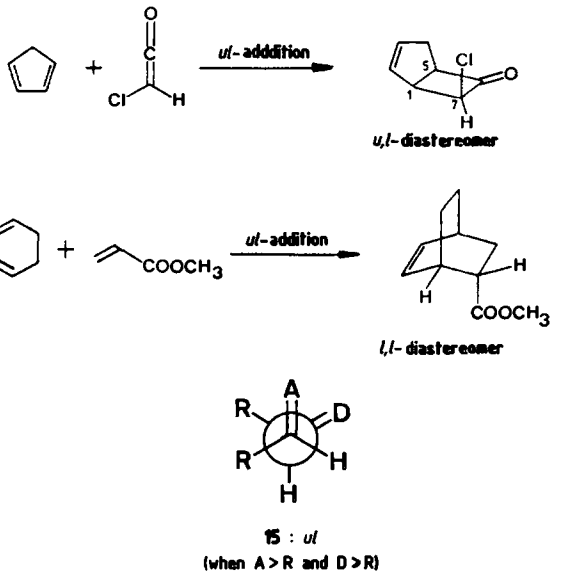


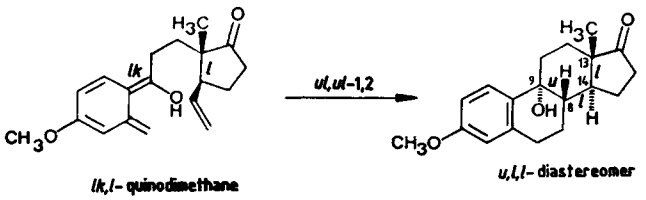
Scheme 9. Specification of three reactions following a rule for electrophilic addition to donor double bonds (cyclic model). On comparison of the second with the third reaction, common features are revealed by the relative topicities rather than by the relative configurations of the products (OLi > C=C > CH_3 and OSi > C=N > R^1); cf. text for a comparison of the first two reactions.



Scheme 10. 1,4- and 1,5-Inductions in the side chain of heterocycles.—The "natural" enantiomers of the prolinol derivatives in reaction (1) and (2) are shown.—The intermediates given do not have to be isolable for specification of relative topicities: formation of (*R*)-methylcyclohexanone under the influence of the (*S*)-center of the heterocycle is a *ul*-process (cf. Scheme 12).—The substrate of reaction (3) contains two 1,5-inducing centers; the route of highest priority leads to the phenyl-substituted center which serves for the purpose of specification (cf. Scheme 4).

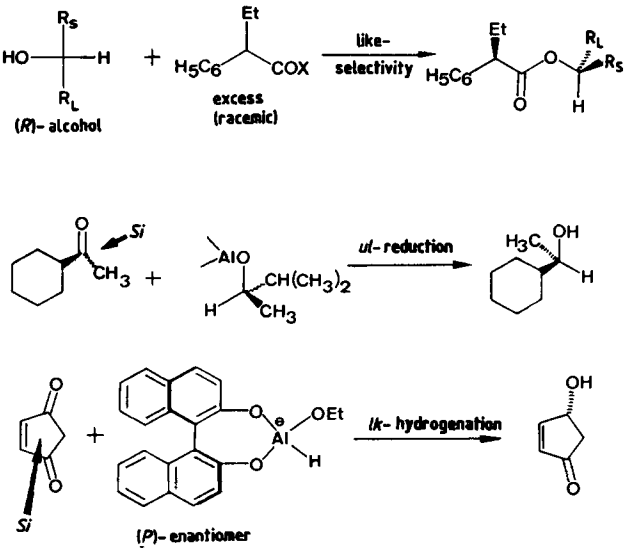
duction of a ketone with an enantiomerically pure aluminum alkoxide, the reducing reagent with (*R*)-configuration approaches the ketone from the *Si*-face[41], *i.e.* with unlike selectivity. If axes or planes of chirality, or helical structures[28] are formed during a reaction or are present in one of the reactants, the convention proposed here can be ap-





Scheme 11. Specification of relative topicities of cycloadditions.—Notice that the *endo*-additions of chloroketene and of acrylic ester turn out to have *ul* relative topicities—just like the preferred mode of nitroaldol and aldol additions (see Scheme 6). All of these reactions are in agreement with the "H-antiperiplanarity rule" [8], see **15** (cf. also third equation in Scheme 7).

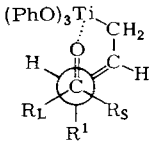
plied by extending the meaning of "like" to the combinations (*R,M*), (*S,P*), (*M,Re*), and (*P,Si*), and of "unlike" to (*R,P*), (*S,M*), (*P,Re*), and (*M,Si*). By means of this extension, the "enantioface differentiation"[42] by an axially chiral aluminate reducing reagent, shown in Scheme 12[43], is *lk*.

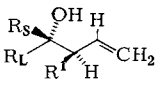


Scheme 12. Application of the like/unlike-specification to asymmetric syntheses, which are not included in the general types (1)—(3) of Scheme 4.

4. Conclusion

Current procedures for specification of the steric course of diastereoselective reactions are often arbitrary and ambiguous. In this paper we propose a slight extension of the CIP-system for specifying the steric course in terms of *relative topicities* and configurations of reactants and for the specification of relative configuration of the product. The advantage of specifying *relative topicity* rather than product configuration is that the former more often discloses similarities and differences in the steric course of reactions (see Scheme 13). The reason is not hard to find: the number of ligands at the stereogenic centers is smaller.





R_L	R_S	R^1	% *ds* [14]	Relative Topicity	Relative Configuration

Scheme 13. Illustration of the usefulness of specifying the relative topicity by means of a further example of practical importance: the addition of 2-alkenyl(triphenoxy)titanium compounds to aldehydes and unsymmetrical ketones proceeds in such a way that the more bulky substituent R_L on the carbonyl C atom is orientated antiperiplanar to the allyltitanium part of the nucleophile which is anchored to the carbonyl O atom. With one exception, in all the cases shown the relative topicity is *lk*, whereas in 19 cases the product configuration is specified as *l*, and in 9 cases as *u* [44].

Different CIP-sequences of ligands will sometimes lead to different descriptors for reactions with analogous diastereoselectivity, but chemists familiar with the CIP-system will easily recognize them.

[19] According to textbooks on stereochemistry [20], a carbon chain R^1—Cab—Cac—R^2 with at least one pair of identical substituents a on the asymmetric carbon atoms must be defined, a view which is not shared by some authors [3, 4, 21] who require two pairs of identical substituents as in R^1—Cab—Cab—R^2. The "aldol-notation" [3–5], applied to other reactions as well (see the collection in [22]), defines *threo* and *erythro* as the zigzag arrangement of an α-substituted aldol R^3—CH(OH)—CHR^2—COR^1 in which OH and R^2 are on opposite sides and on the same side, respectively.

[23] The configuration of a molecule formed actually or conceptually by joining two two-dimensionally chiral centers [24, 25] has been proposed to be *threo* (or homofacial) and *erythro* (or heterofacial) if *Re,Re/Si,Si* and *Re,Si/Si,Re* half-spaces, respectively, face each other in the bond under consideration. If the first proposal [24] were followed, two different uses of *erythro* and *threo* would exist, the old one and the new one, a situation which has prevented adoption of previous redefinitions of these terms [26]. Homo- and heterofacial [25], on the other hand, were chosen by analogy with supra- and antarafacial of the Woodward-Hoffmann rules; whereas supra- and antarafacial are independent of priority sequence rules and thus of the substitution pattern, homo- and heterofacial are not, and therefore they promise a "recognition quality" that they lack.

[30] I. Ugi proposed some time ago [*Z. Naturforsch. B 20* (1965) 405] to label (*R,R*) = (plus × plus) or (*S,S*) = (minus × minus) relative configurations *p* (positive) and (*R,S*) = (plus × minus) or (*S,R*) = (minus × plus) configura-

tions *n* (negative). We prefer the abbreviations *l* and *u*, because *P* and *p* are reserved for specification of axial, planar, and helical elements of chirality [28].
[31] The descriptors *re* and *si* introduced by K. R. Hanson [*J. Am. Chem. Soc. 88* (1966) 2731] for the specification of the faces of planar trigonal centers of chirality are differentiated by using *Re* and *Si* (beginning with capital letters) for specification of reflection-variant 2-dimensionally stereogenic centers and *re* and *si* for reflection-invariant stereogenic centers or heterotopic half-spaces, respectively; this is in analogy with *R,S* and *r,s* for three-dimensionally stereogenic centers [28, 29].
[32] For molecules containing pairs of constitutionally identical elements of chirality, the terms *meso*- and (*d,l*)- or racemic form do not lead to ambiguity.

Synthetic Membranes—Preparation, Structure, and Application

By Wolfgang Pusch* and Axel Walch*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

After a long period of dormancy, membrane separation processes have begun to emerge as technically significant and commercially relevant unit operations. Prior to the mid-sixties, synthetic membranes were employed for those few specialized laboratory applications which could tolerate low permeability and poor selectivity or in electrochemical applications excluding, *e.g.*, batteries, fuel cells, chloride-alkali electrolysis, where marginal chemical stability remained a severe limitation. Within the framework of a broad R & D program started in the US in the mid-fifties and devoted to the production of fresh water from brackish and seawater, developments of more suitable membranes arose out of the application of the principles of physical chemistry, modern polymer chemistry (especially surface or interfacial polymerization and polycondensation technology), and electron microscopy. In particular, it was learned that asymmetric membrane structures comprise a very thin consolidated barrier layer (5000 Å or less for membranes with economically practical filtration rates) supported by an integral but less dense substrate which does not participate in the transport process. Later and after much effort, composite membranes were developed in which the salt-rejecting skin (still only 5000 Å thick) was placed atop a supporting matrix formed from a more chemically and mechanically stable polymer.—The main desalination research effort led to several spin-off developments in related membrane fields, *e.g.* the successful preparation and commercialization of ultrafiltration technology in the automobile, food, and chemical industries. Also, ion-exchange membranes prepared from perfluorinated polymers offered the electrochemical industry much better chemical stability than the earlier phenolic-resin-based ion-exchange membranes.—Current efforts are aimed at the improved selectivity and stability required for very specific separation processes (*e.g.* separation of heavy metal salts from waste water or selective enrichment of gases). In the future, the mechanisms of biological processes will have to be exploited for successful development of synthetic membranes suitable for more sophisticated separations.

1. Introduction

Membranes continue to be the object of intensive research in the fields of physical and polymer chemistry, biology, medicine, and physiology[1-10]. Moreover, synthetic

membranes are being applied to the solution of process engineering separation problems in the pharmaceutical industry[13, 14], and in medicine for therapeutic (artificial kidney[11]) and diagnostic purposes (multilayer, thin-film colorimetric assay for clinical analysis[12]). Further impetus for the application of membranes comes from biotechnology where the substrates and/or products are concentrated and purified by means of synthetic membranes[15, 16]. In the food industry, and especially in the milk and whey processing segments, processes were modified early on to take advantage of membrane separation technology[17–20]. The success of such installations encouraged the textile and metal finishing industries to exploit similar technology for improved production efficiencies and for the solution of waste water problems. Membrane separation processes for recycling of electroplating effluents and for recovery of rinse waters containing water-soluble and lubricating oils are now fully established[21, 22]. Additional possibilities for process improvement were offered to the chemical industry by the cleaning of polymer latices, by the electrowinning of Cl_2 and NaOH by means of the chloride-alkali electrolysis process, and by concentration of specified components from the gas phase (gas separation[23–26]) and from solution *via* the vapor phase (pervaporation[27–29]). Additional fields for the application of synthetic membranes include the preparation of ultrapure water for the electronics industry[30], deacidification of natural gas[31], enrichment of O_2 for combustion processes[32], and last but not least brackish and seawater desalination[33–37] which has initially and decisively contributed to the progress of membrane technology during the past twenty years.

Table 1. Membrane separation processes, Δc = concentration difference; $\Delta\Pi$ = osmotic pressure difference; ΔE = electrical potential difference; ΔP = pressure difference.

Driving force	Process	Field of Application
$\Delta c(\Delta\Pi)$	Dialysis	Purification of polymer solutions (separation of electrolytes and low molecular weight non-electrolytes) Artificial kidney, controlled release
ΔE	Electrodialysis	Production of salt and of fresh water from brackish and seawater; reduction of acidity of citrus juices; processing of special galvanic waste waters (Cr-salt containing solutions); aqueous metallurgy of uranium
ΔP	Ultrafiltration	Purification and concentration of juices and polymer solutions; protein recovery from waste waters of dairy industry; waste water purification
	Hyperfiltration	Preparation of fresh water from brackish and sea water; purification of waste waters; recovery of valuable metal salts from galvanic industry waste waters
	Piezodialysis	Separation of electrolytes

The combination of applied research and practical experience from existing installations has led to the development of ecologically beneficial membrane processes which, for example, conserve energy and protect raw materials. Table 1 summarizes typical membrane processes along with their fields of application and the corresponding driving forces. Tables 2 and 3 contain a compilation of membrane processes used for the protection and recovery of raw materials, while Table 4 gives an overview of the medical applications of membrane processes.

Table 2. Membrane processes for raw material production.

Market segment	Raw material	Membrane process (Requirements on the membrane)
Chemical industry	Plastics	Micro-, ultra- and hyperfiltration
	Organic chemicals (Perfluoropropylene oxide)	Membrane electrolysis (current efficiency)
	Inorganic chemicals (chlorine, caustic soda)	Membrane Electrolysis (current efficiency)
	Boiler Water	Hyperfiltration
Pharmaceutical industry	Products of fermentation broth (antibiotics, proteins)	Microfiltration (reduced absorption capability)
	Plasma proteins	Ultrafiltration
	Vaccines	Ultrafiltration
	Enzyme products (saccharides, antibiotics)	UF and enzyme reactor (reduced absorption capability)
Milk and whey industry	Proteins	Electrodialysis (reduced absorption capability) Ultrafiltration
	Lactose (→ethanol)	Hyperfiltration (resistant to acids, bases, and oxidizing agents)
Food industry (sea water)	Fresh water	Ultrafiltration Hyperfiltration (temperature resistant, resistant to oxidizing agents)
	Salt	Electrodialysis (critical current density)
Fuels	Ethanol (separation of azeotropes)	Pervaporation (permselectivity [a])
Industrial gas	Hydrogen Helium Propylene	Gas separation (permselectivity [a])
Natural gas	Methane (marsh gas) (deacidification: CO_2, H_2O)	Gas separation (permselectivity)
O_2 Enrichment	Oxygen	Gas separation (permeability)

[a] Permselectivity is a preferred permeability of the membrane to one or more components of a mixture.

The wide variety of applications for membrane processes calls for synthetic membranes with widely differing properties and performance characteristics. The following are the principal considerations guiding the selection of an appropriate membrane for a particular separation process:

1. The mechanism of separation (*e.g.* sieve effects, electrochemical effects, and solubility).

Table 3. Membrane processes for raw material production—recovery of raw materials.

Market segment	Raw material	Membrane process (Requirements on the membrane)
Cellulose processing industry	Process water Chemicals Rinse water	Ultrafiltration Hyperfiltration (resistant to higher and lower pH and to chemicals)
Textile industry	Auxiliary substances Wash waters	Ultrafiltration
Automobile industry	Electroplating paints Rinse water	Ultrafiltration (reduced absorption capability) Hyperfiltration
Metal finishing industry (cutting and lubricating oils)	Ground and surface water	Ultrafiltration (resistant to solvents)
Membrane fabrication	Process water Solvents	Hyperfiltration (permselectivity)

3. Mechanical and chemical stability of the membrane.
4. Compatibility of the membrane with materials being processed [biocompatibility, absorption, and predisposition to the formation of deposits (*e.g.* membrane fouling and scaling)].

There are essentially three mechanisms of separation:

1. Separation based on large differences in the molecular sizes of the permeants (sieve effect).
2. Separation based on differences in the charges of the substances to be separated (salts or ions of different valencies, mixtures of electrolytes and non-electrolytes) (electrochemical effect).
3. Separation depending on the differences in solubility of materials in the membrane phase because of the physico-chemical features of the substances to be separated (*e.g.* polarity) (solubility effect).

Existing membranes are generally regarded as belonging to one of the three classes illustrated in Figure 1: coarsely porous, finely porous, or non-porous. When employed for

Table 4. Medical application of membrane devices. m = membrane.

Application	Process		Membranes	"State of the art"
Lung (oxygenation)	Blood	m: Air, CO_2, O_2	Silicone/polycarbonate Porous polypropylene (perfluoroacyl ethyl cellulose)	Clinical application
Kidney; blood (hemodialysis, hemofiltration, plasmapheresis)	Blood	m: Dialysate (filtrate) toxic metabolites (water)	Regenerated cellulose Cellulose acetate	Clinical application (clinical introduction)
Liver (hemoperfusion, cell perfusion)	Blood amino acids (con. bilirubin)	m: Adsorbent (hepatoma cells)	Poly-HEMA [a] Cellulose acetate Co-polyacrylonitrile	Clinical introduction (animal test)
Pancreas (cell implantation)	Blood glucose insulin	m: Langerhans islets	Modacrylic polymer [b]	Animal test
Skin (wound therapy)	Air H_2O O_2	m: Foam (gel)	Polytetrafluoroethylene Polyurethane (cellulose ether)	Clinical application
Eye (soft lenses)	O_2	m: Transcellular liquid H_2O	Poly-HEMA Silicone Cellulose acetobutyrate	Therapeutic application
Pharmaceutics (drug release systems)	drug	m: Extra-/transcellular liquid H_2O	Ethylene/vinylacetate-copolymer Cellulose ester	Therapeutic introduction
Metabolites (diagnostic systems)		m: Blood, transcellular liquid metabolites	Regenerated cellulose Cellulose ester	Diagnostic application

[a] Poly-HEMA = poly(hydroxyethylmethacrylate). [b] Modacryl = copolymer of *e.g.* 40% acrylonitrile and 60% vinyl chloride.

2. The permeation properties of the membrane towards the substances to be separated (volume flux and rejection of gaseous, dispersed or dissolved substances).

the separation of substances differing markedly in molecular size (salt from polymer for instance), such membranes should not interact strongly with either solvent or solute.

Such interactions may interfere with the sieve effect separation which depends upon geometric considerations alone[38]. Membranes possessing pore diameters larger than about 50 Å are usually considered as coarsely porous membranes. Therefore, a porous plug or glass frit might serve as prototype of a coarsely porous membrane. As long as electrokinetic effects are negligible, the volume flux

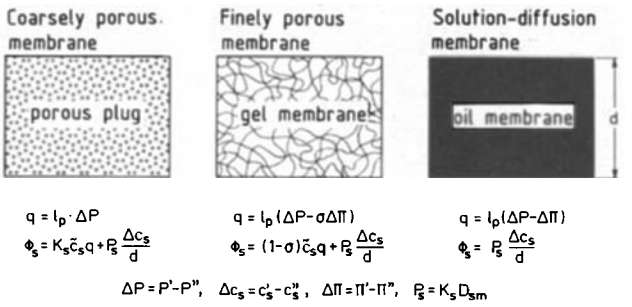

Fig. 1. Diagrammatic presentation of the prototypes of homogeneous synthetic membranes. $K_s = C_s/c_s$ is the solute partition coefficient, C_s the solute concentration within the membrane at the surface in contact with the external solution, c_s the solute concentration of the external solution, $\bar{c}_s$ an average solute concentration which can be calculated from the external concentrations c'_s and c''_s at both sides of the membrane, $P_s = K_s D_{sm}$ the solute permeability, D_{sm} the concentration-independent solute diffusion coefficient within the membrane, d the effective thickness of the membrane, $\Delta c_s = c'_s - c''_s$ the solute concentration difference across the membrane (driving force of the diffusive part of the solute flux), and q the volume flux, l_p = hydrodynamic permeability, σ = Staverman reflection coefficient [86].

across a coarsely porous membrane depends only on the hydrostatic pressure difference (ΔP) and is not affected by the osmotic difference ($\Delta\Pi$) since, *inter alia*, there is no interaction between the membrane matrix and the solvent. The solute flux Φ_s is composed of a convective part ($K_s \bar{c}_s q$) and a diffusive part ($(P_s/d)\cdot\Delta c_s$).

Substances differing in their valences and/or other physicochemical features can be separated by either a finely porous or a solution-diffusion (SD) membrane. Finely porous membranes possess pore diameters from about 10 Å up to about 50 Å. SD membranes either have no pores (liquid membrane) or behave as a homogeneous phase; for polymer films this means that the interstices between polymer chains of the membrane matrix are smaller than 10 Å. Hydrogels of lower water content (<30 wt.-%) are a good example of finely porous membranes. Most of the finely porous membranes (*e.g.* ion-exchange, cellulose, and cellulose acetate membranes) show a moderate to strong interaction between solvent (typically water) and the membrane matrix, which is observable, *e.g.*, by swelling of the membrane. As a consequence of this interaction, an effective osmotic pressure difference ($\sigma\cdot\Delta\Pi$) develops when such membranes are interposed between solutions with different solute concentrations; σ is the so-called reflection coefficient of the membrane to the solute as introduced by *Staverman*[39]. It commonly ranges from 0 to 1, but may also be negative[40–43]. In presence of a concentration difference across a membrane, the effective osmotic pressure difference causes a volume flux through the membrane (osmosis). The solute can be transported convectively ($(1-\sigma)\cdot\bar{c}_s q$) and diffusively ($(P_s/d)\cdot\Delta c_s$).

A film of oil, typically surrounding a droplet, is a good illustration of a SD membrane[44]. In the absence of pores there can be no convective transport. All components of a solution which are soluble in the membrane phase are transported across the membrane solely by diffusion (Fickian-, pressure-, and electro-diffusion)[45,46]. The SD model assumes that transport of each component follows only its own chemical (grad μ_i) or electrochemical potential gradient (grad η_i) in the membrane, *i.e.* it is assumed that the fluxes of the different neutral components (salts, non-electrolytes) are not coupled. Additionally, the classical SD model assumes that the pressure dependent portion of the chemical potential of the solute ($\bar{V}_i\cdot\mathrm{grad}\,P$; $\bar{V}_i$ = partial molar volume of solute within the membrane) is negligible in comparison to its concentration dependent part: $(\mathrm{grad}_c\,\mu_i = (\partial\mu_i/\partial c_i)_{T,P}\cdot(\mathrm{d}c_i/\mathrm{d}x))$. Given these assumptions, the solute is transported simply by Fickian and ultimately electrodiffusion. Figure 2 illustrates the application of these models to ultra- and hyperfiltration.

In addition to the pore structure, the ion-exchange capacity of a synthetic membrane affects its separative utili-

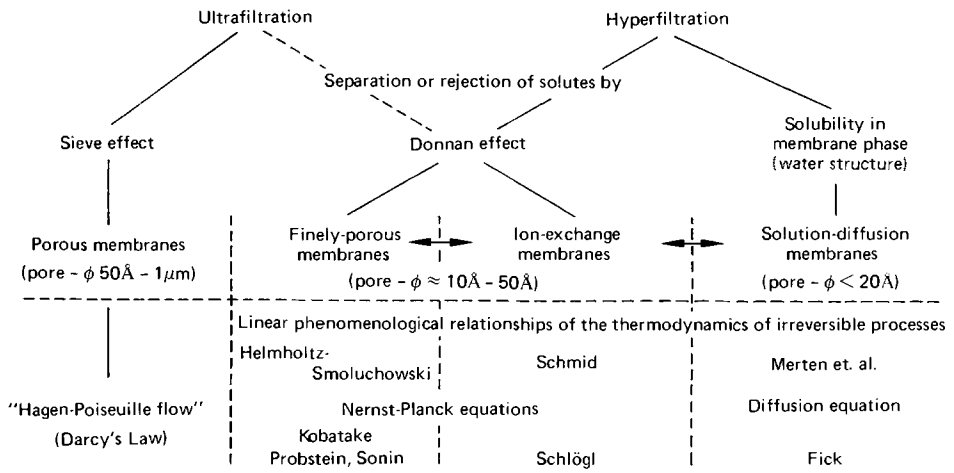

Fig. 2. Diagrammatic presentation of the basic transport mechanisms for synthetic membranes using ultra- and hyperfiltration as an example (pressure gradient; the pore diameter serves only as a guiding value) [86].

ty. By definition, ion-exchange membranes possess ionic groups (fixed charges), mostly covalently bound to the membrane matrix, whereas completely neutral membranes do not have ionic groups. The ionic groups of an ion-exchange membrane are subject to a dissociation equilibrium. Membranes whose substituted groups have a pK_a value between 3 and 9 are generally considered weak ion exchange membranes, those with larger or lower values are strong ion-exchange membranes. The fixed charge concentration of a strong ion-exchange membrane is rarely if at all affected by the pH value and the electrolyte concentration of the external solution, whereas the fixed charge concentration of a weak ion-exchange membrane strongly varies within certain ranges of external pH and electrolyte concentration[47-49]. At electrolyte concentrations smaller than the fixed charge concentration of the membrane, co-ions (ions with the same charge as the fixed charges) are excluded from the membrane phase on account of the Donnan equilibria at the phase boundaries between the membrane and the external solutions (Donnan exclusion). In the absence of electrical current through the membrane, counterions (ions possessing a charge opposite to that of the fixed charges) are also excluded from the membrane on account of the local electroneutrality condition within the membrane. Therefore, ion-exchange membranes reject salts and, in principle, can be employed for the separation of electrolytes from non-electrolytes. Ions may preferentially permeate an ion-exchange membrane when an electric current is applied as in the case of electrodialysis or when the membrane is composed of cationic and anionic regions (mosaic membrane) and thus exhibits electroneutrality *per se* (piezodialysis).

Very specific membranes (*e.g.* liquid membranes[53], microcapsules[54,55], and enzyme-loaded membranes) are used for special separation processes (*e.g.* extraction of heavy metal ions from very dilute solutions, enrichment of uranium, purification of waste gases by facilitated transport, control of enzyme reactions, and for diagnostic purposes in the public health service[50-52]). Liquid membranes are emulsions containing many microvacuoles suspended in an external solution. The ≈ 10 μm vacuole wall (liquid membrane) is an immiscible phase separating an internal solution (extraction or stripping solution) from an external solution (*e.g.* heavy metal ions to be separated or extracted). For example, when the internal phase of the vacuoles contains appropriate chelating agents, heavy metal ions will migrate from the external to the internal phase with enrichment factors reaching as high as 10^4. Instead of chelating agents, the internal phase may also contain enzymes or specific catalysts. Practical use of these liquid membrane suspensions firstly requires separation of the droplets from the waste solution and then the splitting of the emulsion into the droplet and the extraction phase, the latter containing the heavy metal ions. In order to circumvent this tedious procedure, supported liquid membranes are also available; they are prepared by soaking a porous membrane with the liquid membrane solvent loaded with a specific catalyst. Just as with liquid membranes, microcapsules possess an enormous surface area for mass transfer (10 mL of a suspension of microcapsules with diameters of about 20 μm possess a membrane surface of more than 2 m^2). They are made, *inter alia*, by encasing either an emulsion (*e.g.* enzyme containing solution) or a solid phase (*e.g.* active carbon) within a thin polymer film (*e.g.* cellulose ester). The solid phase is typically sprayed with the casting solution of the thin film. Enzyme membranes are prepared by physically or chemically fixing enzymes to an appropriate membrane matrix. Hydrophilic membranes, for instance those cast from cellulose and cellulose derivatives[56,57], exhibit minimal non-specific interaction with the enzyme, the substrate, and the product, and are thus preferred for the preparation of enzyme membranes. The enzymes can be attached to the membrane matrix by a variety of covalent and secondary bonds. Since this article is concerned only with commercial synthetic membranes such special, non-commercial membranes will not be dealt with any further.

2. Structure of Synthetic Membranes

During the early stages of membrane research, synthetic membranes were considered to be on the same level as sieves and sponges and essentially characterized by an average pore diameter or a pore size distribution[58-61]. Average pore diameters or pore size distribution curves can be established by means of mercury-intrusion, although only by assuming that the pores are cylindrical and at right angles to the membrane surface. However, prediction of the permeability behavior of synthetic membranes on the basis of average pore diameters or pore size distribution curves was not always successful. It was thus a great step forward when in 1949 *Hansmann* and *Pietsch*[62] succeeded in obtaining the first electron microscopic pictures of membrane filters. Subsequently, extensive electron microscopic investigations by *Helmcke*[63,64] led to a first classification of synthetic membranes according to their scale of porosity as either very finely, finely, or coarsely porous. *Maier et al.*[65,66], *Spandau et al.*[67] and more recently *Frommer et al.*[68] have partially elucidated the mechanism of membrane formation using information on the pore structure obtained from electron microscopic investigations.

However, it was not until the fifties that membrane research and development received major emphasis and funding from an extensive research program in the USA (Office of Saline Water, OSW) directed to the production of fresh water from brackish water and seawater. *Reid* and *Breton*[69] were among those who, extrapolating from past experience with osmosis and dialysis, tried to "press" salt water through membranes possessing an effective salt rejection and an adequate water permeability. They first demonstrated that cellulose acetate (CA) membranes are effective barriers for common salts. However, the water permeabilities of the approximately 5 μm thick CA membranes were too low for economic utilization in the production of fresh water.

Loeb and *Sourirajan*[70], who at almost the same time were studying the permeation behavior of commercially available CA membranes supplied by the Schleicher & Schüll Company, were the first to discover the possibility of an economic production of fresh water by means of synthetic membranes. The CA membranes used for their in-

vestigations possessed such a high water and salt permeability that they were originally considered useless for desalination of brackish water and seawater. However, when these membranes were annealed in a water bath at 75 to 95 °C, their salt permeability decreased considerably. Highly-annealed membranes acquired a high salt rejection, yet maintained a water permeability about one hundered times larger than that reported by *Reid* and *Breton*. It remained for *Merten et al.*[71,72] to clarify the structure of Loeb-Sourirajan membranes by electron microscopic investigations and thus to elucidate the mechanism by which the comparatively high water permeability and the low salt permeability coexisted. In contrast to the homogeneous membrane of *Reid* and *Breton* the modified membranes of *Loeb* and *Sourirajan* consisted of a very thin, dense layer of CA (active layer) resting on top of a porous supporting matrix. The active layer is comparable with a very thin homogeneous CA membrane. The supporting layer possesses negligible hydraulic resistance and is present for mechanical support only. The thickness of the active layer is about 2000 to 5000 Å out of an entire membrane thickness of about 100 μm. However, the water permeability of modified CA membranes when used for hyperfiltration at pressures of 50 bar up to 100 bar decreased continually with time. This phenomenon was principally a consequence of compaction of the porous matrix and the transition layer between the active layer and the porous matrix. Once the structure of asymmetric CA membranes had been clarified, a logical next step was preparation of membranes in which the very thin active layer was cast on top of a porous support made from a different and more pressure-resistant material. *Cadotte et al.*[73] and *Merten et al.* (see [74]) were the first to produce such composite membranes using originally membrane filters cast from cellulose nitrate and later very finely porous polysulfone membranes as supporting matrices. The supporting matrix was coated with a thin homogeneous film (*ca.* 1000 Å) of cellulose acetate. During manufacture the surface of the porous support was masked by a gel layer in order to prevent penetration of the casting solution for the thin-film into the pores of the porous support. Figure 3 illustrates the cross-section of a composite membrane. Several materials (*e.g.* polyamides,

poly(ether/amides), poly(ether/ureas), polybenzimidazolones; cf. Section 4.3.2) have been employed to form the active layer. It proved much easier to deposit permselective homogeneous thin-films, produced from appropriate polymers, on top of a tailor-made finely porous support than to cast a single polymer directly into a permselective asymmetric membrane. The development of membranes during the years 1953–1979 is summarized in Scheme 1 using hyperfiltration membranes as an example.

2.1. Electron Microscopic Investigations of the Pore Structure of Synthetic Membranes

Electron microscopy provides the only reliable tool for examining the microstructure and morphology of synthetic membranes. With the aid of electron microscopic pictures, it is possible to differentiate coarsely porous membranes from finely porous and dense (non-porous) membranes. In addition, membranes can be classified as homogeneous, asymmetric, or composite according to their structure. No pores are visible in electron microscopic pictures of finely porous and dense membranes; such materials nevertheless might possess pores with diameters ranging from a few Angstroms up to about 50 Å since these dimensions are not resolved by common electron and scanning electron microscopes. Figures 4–20 reproduce electron (EM) and scanning electron micrographs (SEM) of membrane surfaces and cross-sections. Figure 4 shows SEMs of the cross-sections of commercial cellulose membranes (®Cuprophan (4a, b) and ®Nadir membranes (4c, d)) principally used for artificial kidneys. ®Cuprophan films are cast from solutions of cellulose tetraamminecopper complexes, whereas

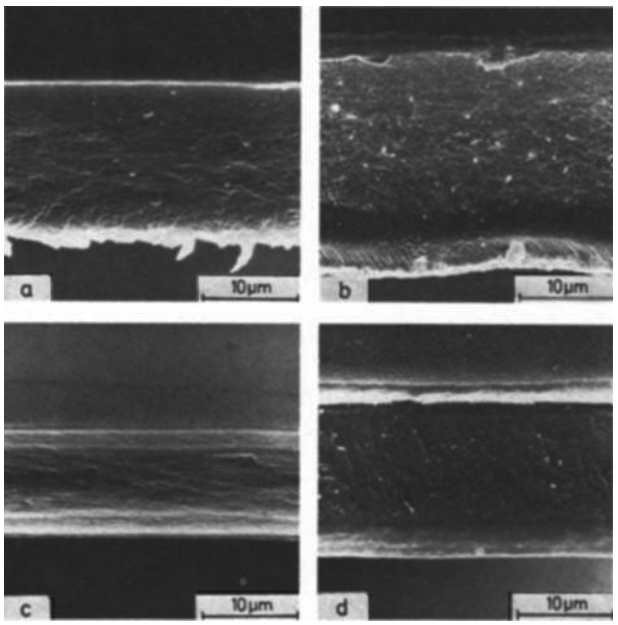

Fig. 4. SEMs of cross-sectional view (with a partial top view of one surface) of a ®Cuprophan (a, b) and a ®Nadir (c, d) membrane. The membrane samples used for the cross-section were directly immersed in liquid N_2 and then fractured (a, c), or the water of the samples was previously removed by the critical point method (b, d) [86].

®Nadir membranes are spun from viscose (cellulose xanthogenate solutions). The membranes are not completely homogeneous but rather possess surface layers clearly differing in structure from the internal homogeneous membrane matrix. Electron micrographs of cellulose membranes taken at large magnifications ($> \times 50000$) indicate pores with diameters of 40 to 60 Å in the inner membrane although the surface layers do not show any pores even at very large magnification. Cellulose membranes apparently consist of a fine porous matrix located between two dense (non-porous) surfaces (*ca.* 1000 to 3000 Å thick). Figure 5 shows similar SEMs of cross-sections of membranes cast from a polyacrylonitrile copolymer (5a) and a polycarbonate block copolymer (5b). These membranes, of which only the polyacrylonitrile membrane exhibits a fully homogeneous structure, are also used in artificial kidneys.

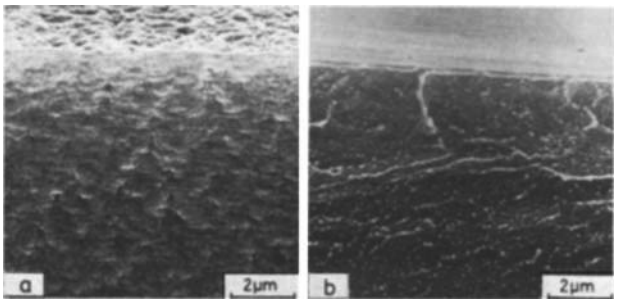

Fig. 5. SEMs of cross-sectional view (with a partial top view of one surface) of a symmetric hydrophilic gel-membrane made from an acrylonitrile copolymer (a) and an asymmetric, hydrophilic gel-membrane made from a polycarbonate block polymer (b), which are principally used as dialysis membranes [86].

Figures 6 to 8 show EMs and SEMs of the cross-sections and surfaces of the coarsely porous membranes typically employed for the concentration of polymer solutions and the separation of salts from polymer-salt solutions by ultrafiltration. There are two kinds of coarsely porous membranes: one group has a rather broad pore size distribution (Figures 6 and 7, "sponge structure"), whereas the other group has pores of nearly uniform diameter (narrow pore size distribution; Figure 8, "sieve structure").

The production of membranes with pores of uniform diameters originated from the belief that ultrafilters act like sieves and thus separate molecules according to their size. This one-sided view of the filter action of porous membranes continues to exist, even though it could be learned from the rudiments of membrane science that the permeation of molecules across porous membranes is mainly governed by interactions of the molecules with the pore walls of the membrane. For example, many attempts were made to fractionate polymers according to their molecular sizes using porous membranes with uniform pore diameters, even though *Ferry*[38] had pointed out in 1936 in his review article on ultrafiltration that factors completely different from the molecular size must govern the permeation of a molecule through a membrane. This is illustrated by SEMs of ®Nuclepore filters (Fig. 9) which were used for the fil-

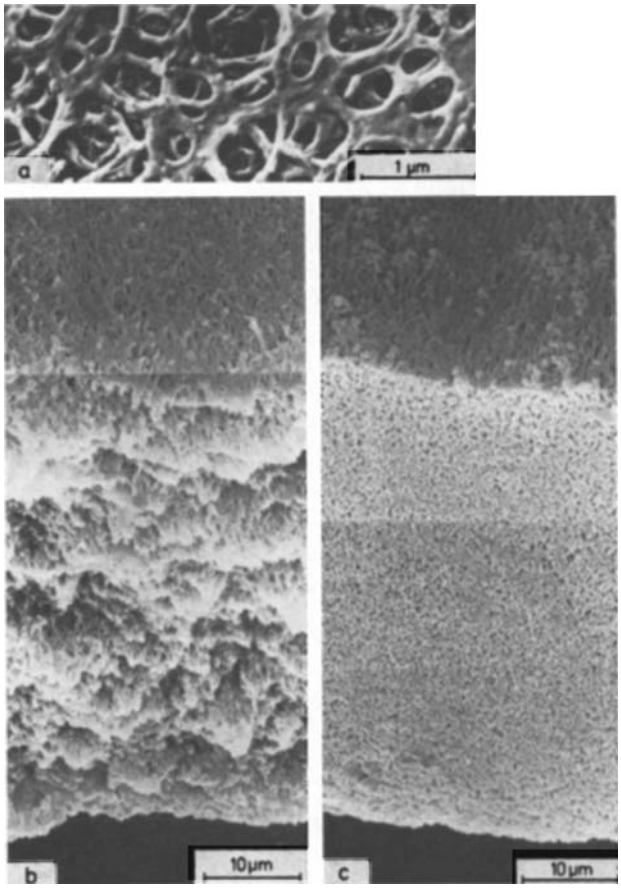

Fig. 6. EM of top view of a membrane filter made from cellulose nitrate (a) and SEMs of cross-sections (with partial top view of internal surface) of a porous cellulose diacetate capillary membrane (Asahi), unused (b) and after use for plasmapheresis (c) [86].

tration of polystyrene dispersions. The diameters of the polystyrene particles are clearly much smaller than the pore diameter of the membrane used (*ca.* 1 : 10). Neverthe-

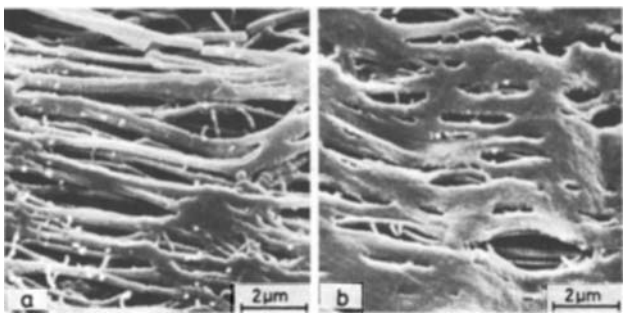

Fig. 7. SEMs of top (a) and bottom (b) surface of a Celgard 2400 membrane.

less, the polystyrene particles are nearly completely rejected as they adhere to the pore walls and thus the pores become progressively blocked.

This interpretation is supported by further SEMs (Fig. 10) showing surfaces of ®Nuclepore filters after their use for filtering erythrocytes. Although the dimensions of the erythrocytes are somewhat larger than the pore diameter of

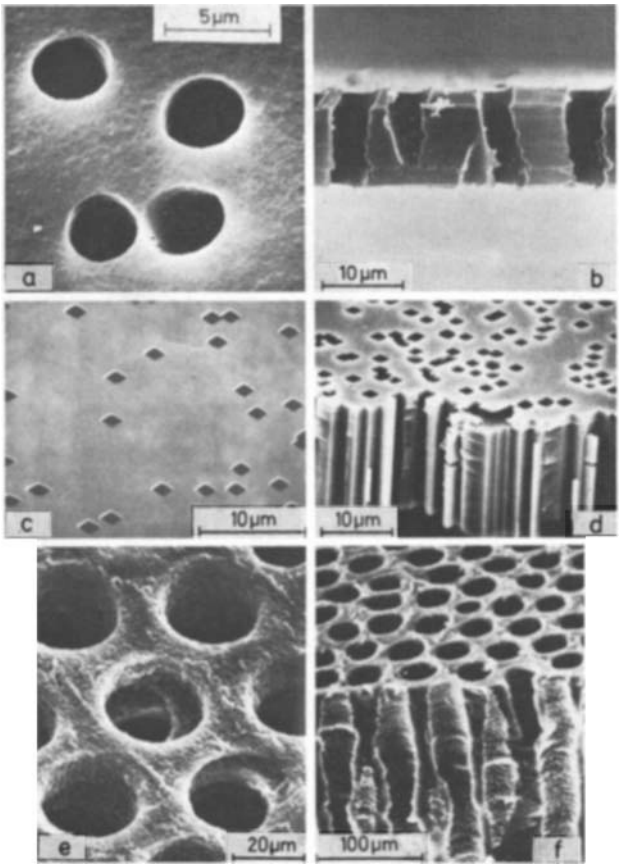

Fig. 8. SEMs of top (a, c, e) and cross-sectional (b, d, f) view of ®Nuclepore (a, b), mica (c, d), and Thiele membrane (e, f) [86] (cf. Section 3).

the membrane filter used, they pass the pores as they are flexible and scarcely interact with the pore walls. Both examples demonstrate that interactions between permeating

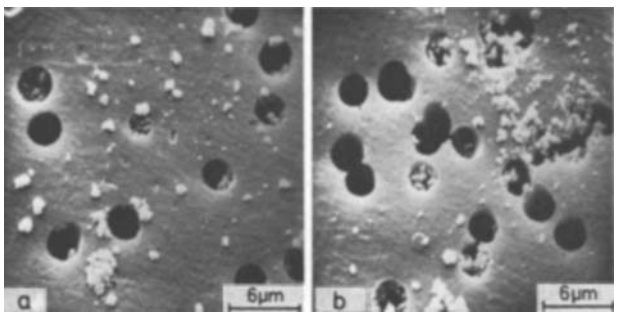

Fig. 9. SEMs of top view of ®Nuclepore filters used for the filtration of polystyrene particles [86].

molecules and the membrane matrix are more important in determining ultrafiltration behavior than the "theoretical" dimensions of molecules or particles.

Figures 12 and 14—20 show SEMs of cross-sections of asymmetric and composite membranes. All these membranes consist of an extremely thin film (active layer) on top of a more or less porous supporting framework (matrix). In the case of asymmetric membranes, the porosity of the supporting matrix increases across the membrane from top to bottom. The pore diameters, the shape of the pores, and

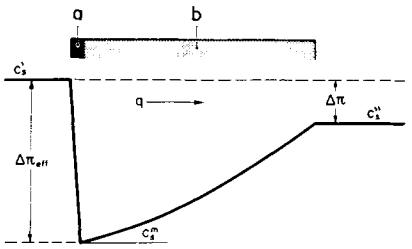

Fig. 11. Schematic presentation of the concentration profile across an asymmetric membrane when a concentration ($\Delta c_s = c_s' - c_s''$; $c_s' \leqslant c_s''$) and a pressure difference (ΔP) are applied causing a volume flux $Q = A \cdot q$ from the (')-phase to the (")-phase (A = effective membrane area) [147].

the porosity of the supporting framework can be varied within certain limits by adjusting the composition of the casting solution and conditions of membrane fabrication.

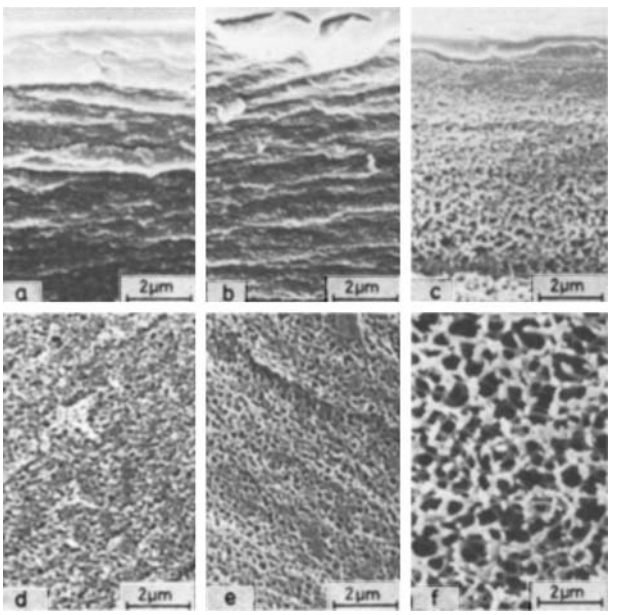

Fig. 12. SEMs of cross-sectional view of asymmetric cellulose acetate (CA) membranes. The upper row (a, b, c) exhibits a partial top view of the active layer and the junction between the surface and substructure. The lower row (d, e, f) displays the bottom part of each membrane. Figures a and d show the top and bottom part of an asymmetric CA membrane annealed at 85 °C; Figures b and e exhibit the top and bottom parts of the corresponding unannealed membrane; Figures c and f are an unannealed asymmetric CA membrane prepared from a casting solution formulated to yield highly porous membranes. The nominal molecular weight cutoffs are MW = 10000 (b, e) and MW = 100000 (c, f) [86].

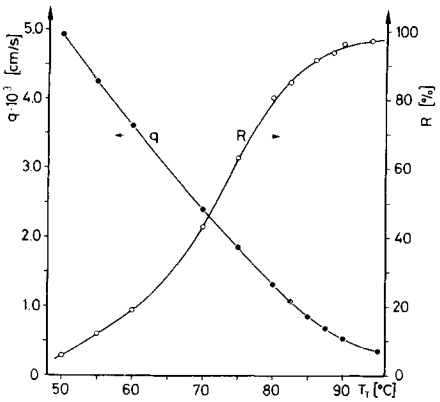

Fig. 13. Salt rejection R and volume flux q of an asymmetric CA membrane (manufactured by Kalle Niederlassung der Hoechst AG) at 25 °C as functions of the annealing temperature T_t; $R = r$ (salt rejection) × 100 [%]; $r = (c_s' - c_s'')/c_s'$; c_s' = brine concentration (= 0.1 M NaCl) and c_s'' = product concentration of the salt [75].

The transport properties of asymmetric and composite membranes in hyperfiltration experiments are exclusively

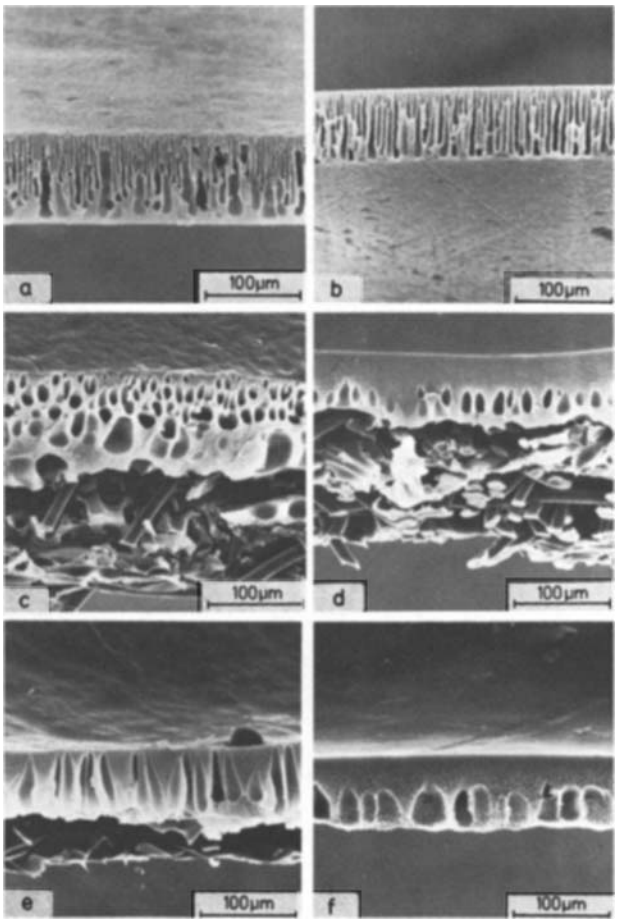

Fig. 14. SEMs of cross-sections (including partial top view of active layer) of typical PS membranes. Figures a and b show membranes with irregular (a) and regular (b) finger structures of the supporting framework where the interfacial tension at the surfaces of the corresponding casting solutions was different and the compatibility of the casting solutions with the precipitation baths was poor. Figures c–f display cross-sectional views of membranes with foam-like and finger structure (c, d, e) of the supporting matrix at low (c, e) and high (d) polymer concentration of the casting solution as well as medium (c, d) and good (e) compatability with the precipitation bath, and with foam-like structure and cavity formation (f) at low polymer concentration of the casting solution and a good compatability with the precipitation bath.

governed by the transport characteristics of the active layer. On the other hand, the support layer might strongly affect the transport properties of these membranes in dialysis-osmosis experiments because of so-called concentration polarization effects within the porous support[75,76]. In this connection, concentration polarization means the formation of a concentration gradient across the porous support (Fig. 11) affecting the solute concentration just at the junction between the active layer and porous support. Under the assumption that the reflection coefficient σ of the porous support is nearly zero (see Fig. 1), this concentration gradient affects the osmotic pressure difference across the active layer and thus the volume flux across the entire membrane.

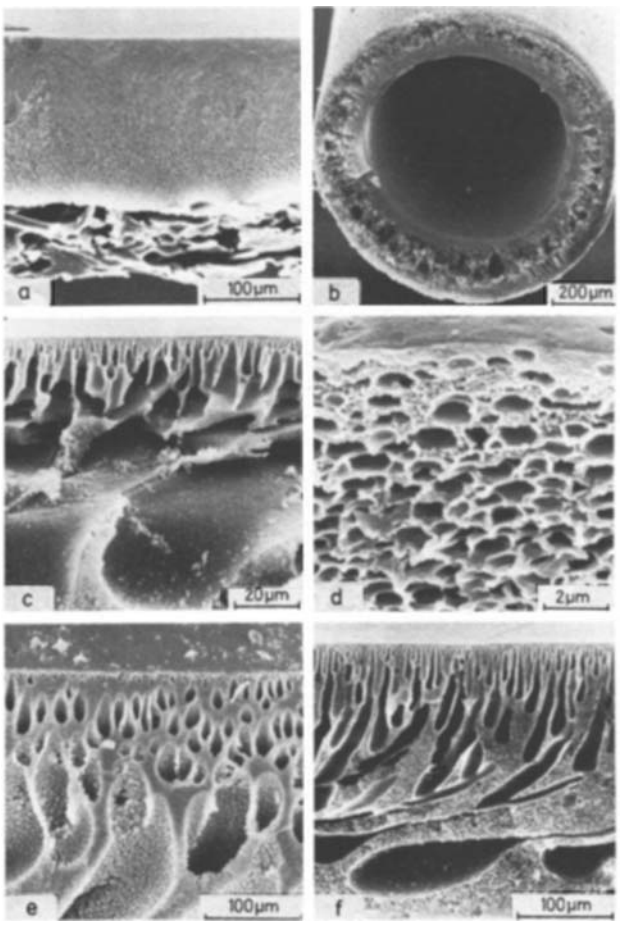

Fig. 15. SEMs of cross-sectional views (with partial top view of active layer) of asymmetric flat sheet (a, c, d, f), capillary (b) and tube membranes (e) fabricated from PS (a—d), modified PVDF (e), and PA (f) possessing only foam-like (a), foam-like and finger (b, c, e, f), and honeycomb (d) structure of the supporting framework. The fingers in the PA membrane (f) are strongly bent. The compatibility of the casting solution with the precipitation bath was good (a, b) and poor (c), Therefore, the asymmetric PS membrane shown in c exhibits large cavities.

Figure 12 shows SEMs of cross-sections of three different asymmetric CA membranes. The upper row exhibits a partial top view of the membrane surface (active layer) and the junction between the surface and substructure. The lower row displays the bottom part of each membrane. Figure 12a shows the cross-section of an asymmetric CA membrane, annealed at 85 °C; Figure 12b exhibits the cross-section of the corresponding unannealed membrane; Figure 12c shows an unannealed asymmetric CA membrane prepared from a casting solution formulated to yield highly porous membranes. Annealing of asymmetric CA membranes in a water bath at temperatures of 75 to 95 °C leads to a compaction of the membrane matrix (reorientation of the polymer chains) and thus to a decrease in its water and solute (salt) permeability (Figure 13). The decrease in the salt permeability corresponds to an increase in the salt rejection r ($R = r \cdot 100$). Figures 12 a–f illustrate the possibilities for varying porosity, its gradient across the membrane, and the pore structure over a wide range by proper selection of the composition of the casting solution and the casting conditions as well as of the annealing temperature. The properties of the active layer will also change when the casting solution and conditions are varied. In principle, it is even possible to change the relative positions of the active and porous layers by systematically varying the composition of the casting solution[77,78].

Figures 14—18 contain a number of SEMs illustrating cross-sections of typical asymmetric polyamide (PA), polysulfone (PS), polyvinylidene fluoride (PVDF) and polyacrylonitrile copolymer (PAN) membranes. In contrast to normal asymmetric CA membranes, the supporting matrices of these membranes possess, in addition to a foam-like pore structure, characteristic finger-like structures. The internal surface of the cylindrical, drop-, cone-, or

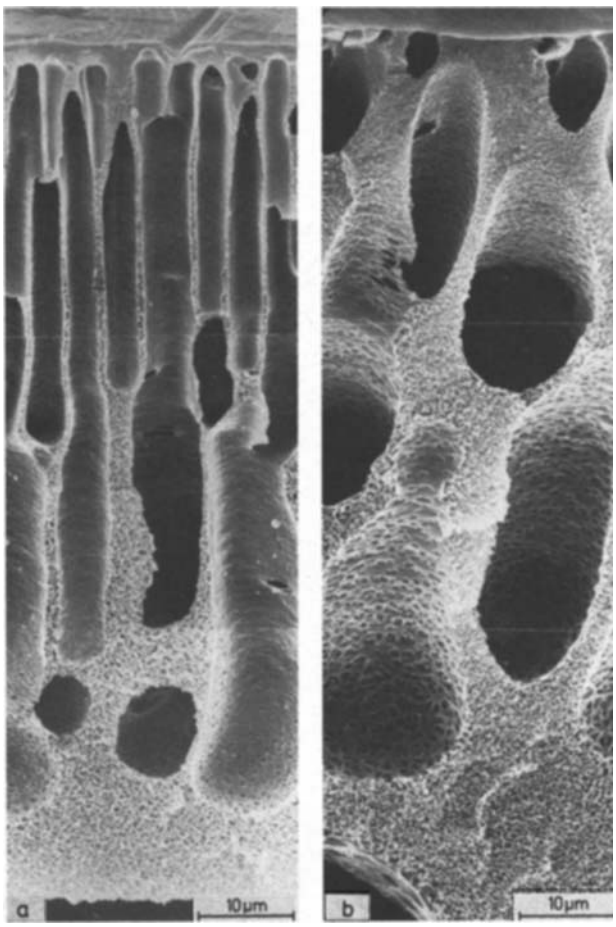

Fig. 16. SEMs of cross-sectional view of a PA (a) and a PS (b) membrane including partial top view of active layer.

needle-shaped[79] cavities may be porous or non-porous. The production of asymmetric PA, PS, and PAN membranes is complicated by the finger formation in the porous matrix since these fingers can extend into the active layer and create defects (Figs. 14c and 15e). It is possible but not usual, to cast asymmetric cellulose acetate[68, 80] and cellulose nitrate membranes[81] possessing similar finger-like structures. In contrast to CA membranes, PA and especially PS membranes are much more resistant to acids and bases, to microbes, and higher temperatures; PA membranes, however, are quite sensitive to chlorine, tolerating less than 1 ppm of Cl_2. The maximum working temperature for the membranes is, of course, not the same as that of the pure polymer but is determined by the gel structure of the membrane; the glass transition temperature of the solvated polymer is less than that of the polymer alone.

The transport of the components of a solution takes place within pores of the membrane scaffolding as well as across the finger-like cavities whereever the internal lining membrane of the cavities is porous (cf. Fig. 16). Therefore, the hydrodynamic resistance of these membranes is lower than that of asymmetric CA membranes possessing a comparable porosity. On the other hand, when the internal lining membrane of the cavities is dense and impermeable, the solute and solvent are transported through the extrastitial phase only. The permeation rate also decreases when the fingers are bent due to membrane formation or aftertreatment (Fig. 15e).

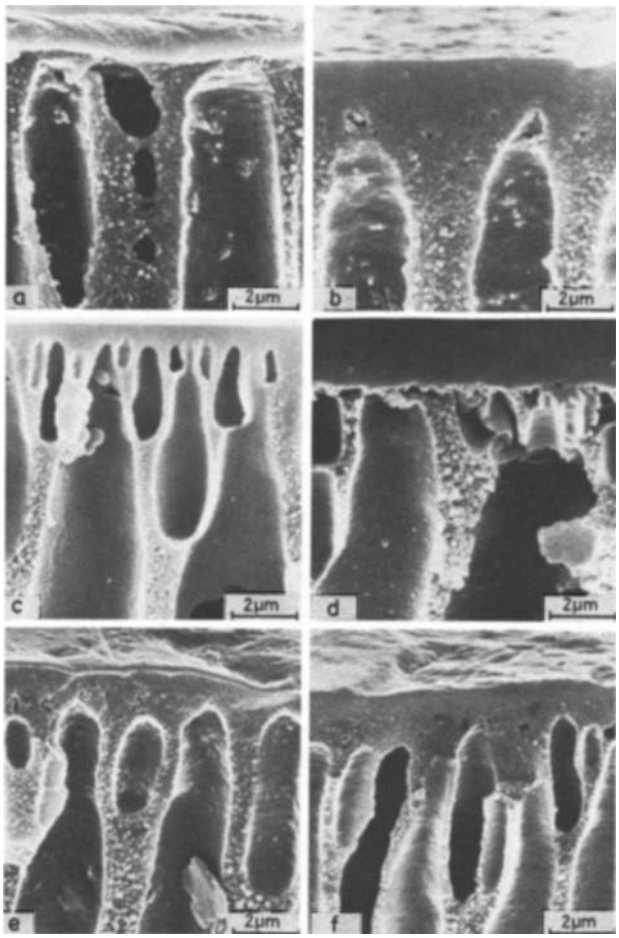

Fig. 17. SEMs of cross-sectional views showing the junction active layer/supporting framework of some PS (a–d) and PA (e, f) membranes. The membranes were cast from solutions of lower (a) and higher (b) polymer concentration and possess high (a) and low (b) porosity with large (a) and small (b) cavities. The PS membranes (c, d) were dried with (c) and without (d) glycerine added, yielding open porous (c) and closed porous (d) dispersed phases. The PA membranes exhibit a discontinuous (e) and continuous (f) transition of the active layer into the supporting framework. After precipitation, these membranes were stored wet (e) or dry (f) with glycerine added.

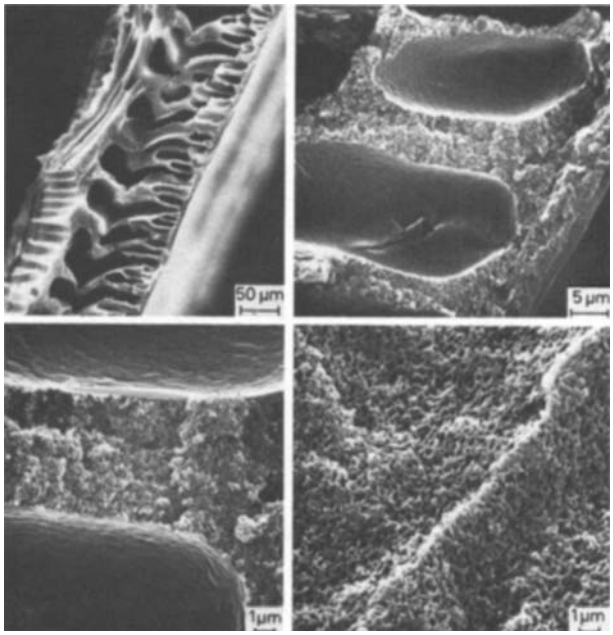

Fig. 18. SEMs of cross-sectional view of an asymmetric polyacrylonitrile membrane (Solrox-200 manufactured by Sumitomo Electric Industries, Tokyo, Japan) with foam and finger structure using graded magnification. (Stereoscan photographs by *Ch. Brücher*, Ciba-Geigy AG, Basel.)

Closing this chapter, SEMs of cross-sections of typical composite membranes are shown in Figures 19 and 20. Figure 19 shows cross-sections of two RC-100 membranes manufactured by UOP (Universal Oil Products, Fluid Systems Division, San Diego, Calif.) where the active layer is made from poly(ether/urea). The figures illustrate the different possible formations of the thin-film (active layer) on top of a porous matrix. In Figure 19a the transition layer of about 0.5 µm thickness becomes clearly visible whereas the active layer of about 250 to 500 Å thickness is not resolved. The active layer of this membrane was formed by coating, dipping, or interfacial polycondensation. In contrast, the just barely visible transition layer of the membrane shown in Figure 19b was formed by interfacial cross-linking. In this procedure, the porous support is soaked with the appropriate polymer solution and subsequently the polymer is subjected to a covalent cross-linking reaction at the membrane surface (see Section 4).

Finally, Figures 20 exhibit further SEMs of cross-sections of composite membranes. The porous support, usually PS, and the *ca.* 0.5 µm transition layer (gel layer) are visible, whereas the 250 to 500 Å thick active layer can only be seen in the top view.

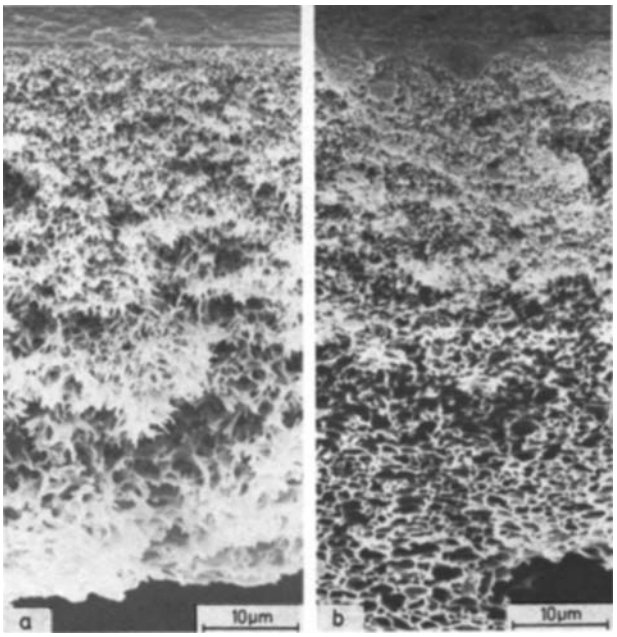

Fig. 19. SEMs of cross-sectional view (with partial top view of active layer) of two composite RC-100 membranes manufactured by UOP, San Diego, California, where the active layer is prepared from poly(ether/urea). The active layer in (a) was generated by coating, dipping or interfacial polycondensation, in (b) by interfacial cross-linking [86].

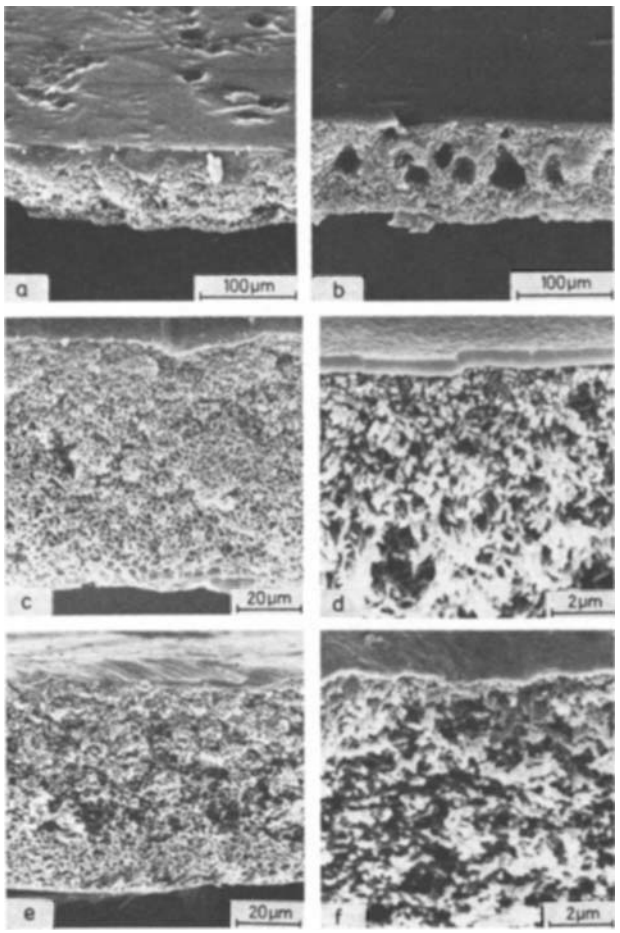

Fig. 20. SEMs of cross-sectional view (with partial top view of active layer) of composite PA-300 (a), Desal-LP (b–d; LP = low pressure, and RC-100 (e, f) membrane where the active layer is formed from poly(ether/amide) (a), a modified PA (b–d), and poly(ether/urea) (e, f). Using a 0.1 M NaCl brine solution at 25 °C, the Desal-LP membrane exhibits permeation rates of about 1500 to 2000 L m^{-2} d^{-1} and salt rejections of 92% to 96% at pressures of 15 to 25 bar [86].

2.2. Structure of Finely Porous and Dense Membranes

The pore structure of finely porous and dense (solution diffusion, SD) membranes can only be characterized by indirect methods such as gas and liquid permeation or gas sorption (sorption isotherms)[82–85] since the dimensions of interest are not resolved under the electron microscope. Thus, only model parameters are determined and these do not necessarily reflect the true physical and physicochemical membrane properties. This subject was discussed in detail in a recently published review[86] and need not be considered in more detail at this time. In addition to pore structure, the micellar organization and arrangement of polymer chains and chain segments (Fig. 21), for instance, as well as the physicochemical state of the polymer (crystalline, glassy, amorphous, *etc.*) play a decisive role in transport through finely-porous and dense membranes. Different mechanisms of gas permeation are found, for instance, below and above the glass transition temperature

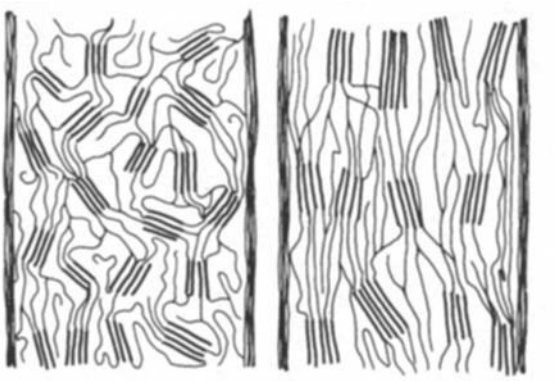

Fig. 21. Two figures illustrating the arrangement of amorphous and crystalline regions of polymer segments in semi-crystalline polymers [148].

of the constituent membrane polymer[87]. A summary of potential methods for the investigation of the molecular structure of synthetic membranes is given in Table 5.

2.3. Water Structure in Synthetic Membranes

In addition to the membrane characteristics, the water structure within a synthetic membrane also governs transport mechanisms for both solutes and solvents[88-90]. For example, as long as free water exists along with so-called "bound water" within finely porous membranes, matter is transported primarily by convection and Fickian diffusion. On the other hand, if finely porous membranes and SD membranes contain only bound water, convective transport can be almost entirely excluded and the components of a solution will pass the membrane exclusively by diffusive processes (Fickian-, pressure-, and electro-diffusion). The water structure within a synthetic membrane may be characterized by NMR and IR spectroscopic investigations[91-94], by determination of thermodynamic data such as enthalpy, entropy, Gibbs free energy[95] of water sorption, and partial specific heat of water within the membrane[96-99], or by the water vapor sorption of the membrane. For example, it has been demonstrated that the partial specific heat of water within homogeneous CA membranes is always larger than that of free water (Fig. 22), indicating an interaction between water molecules and the polymer chains of the membrane matrix (hydrophobic interaction, H-bonds, dipole-charge interactions). This interaction of water with the membrane matrix decreases the

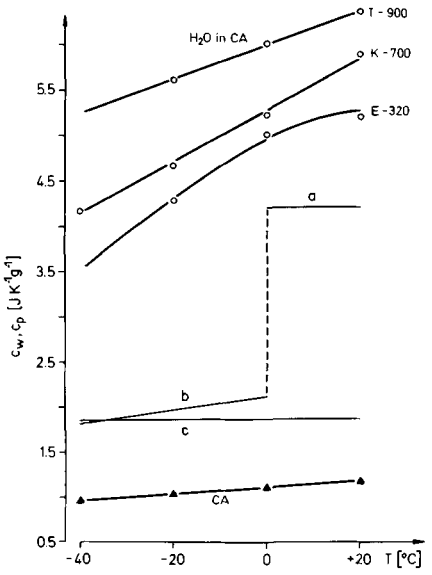

Fig. 22. Partial specific heat capacity of water c_w in homogeneous CA membranes of various acetyl contents as a function of temperature T. The specific heat capacities of water (a), ice (b), and water vapor (c) are shown for comparison. The acetyl contents of the CA membranes are: 32 wt.-% (E-320), 39.1 wt.-% (K-700), and 43.7 wt.-% (T-900) [96, 97].

available energy of hydration per water molecule, *i.e.* reduces the capacity of water to hydrate ions. Electrolytes and non-electrolytes are thus poorly dissolved and their sorption and transport is correspondingly inhibited. However, the water-polymer interaction is not so strong as to completely immobilize the water molecules. Thus, water transport can still occur by so-called activated diffusion.

3. Formation of Synthetic Membranes

The formation of synthetic membranes can, somewhat arbitrarily, be characterized by the following three mechanisms:

1. Formation of a polymer film by extrusion of the polymer material, by desiccation of a corresponding polymer solution (dry spinning process), or by *in-situ* polymerization and polycondensation.
2. Formation of a gel layer by a sol-gel transition.
3. Production of surface modified porous inorganic membranes (glass and ZrO_2/carbon capillaries) or of thin porous sheets of inorganic materials such as mica laminates creating pores by bombardment with heavy ions and subsequent etching of the nuclear tracks (cf. Fig. 8c, d[100]).

The formation of films from binary polymer solutions according to Method 1 yields homogeneous dense membranes without pores. Porous membranes can be produced by this method only by use of heterogeneous systems (*e.g.* addition of extractable fillers; ®Accurel). Moreover, it is possible to create pores in an as-cast polymer film by aftertreatment, *i.e.* mono- or biaxially stretching the film (®Celgard, ®Goretex, ®Poreflon) or bombarding the film with neutron-induced nuclear fragments or heavy ions, and subsequently etching the nuclear tracks (®Nuclepore filter).

Gel formation (Method 2), on the other hand, generally yields an asymmetric membrane where the porosity and its gradient across the membrane can be varied from very finely to coarsely porous by adjusting the composition of the casting solution and by selection of the conditions for gel formation. *Maier* and *Scheuermann et al.*[65,66] investigated the mechanism of membrane formation and discovered that the formation of pores within gel-membranes is closely related to the formation of coacervates in colloid solutions which was extensively researched and reported, *inter alia*, by *Bungenberg de Jong* and *Kruyt*[101]. Coacervate formation is a kind of segregation in colloidal solutions which does not yield two macroscopic phases (as could be observed in phenol-water mixtures) but rather a dispersion where one phase is colloidally dispersed in a second phase (coarse emulsion)[101]. Accordingly, a coacervate-like separation must occur during the production of porous gel-membranes. It can be induced by temperature variation, or by bringing the polymer-solvent film into contact with a non-solvent or poor solvent for the polymer. The non-solvent may be introduced to the polymer solution in the following four ways:

a) the non-solvent or poor solvent, which acts as a swelling or precipitation agent, is added to the polymer solution *via* a saturated vapor phase. Coarsely porous membranes are prepared by this procedure with a slight gradient of porosity across the membrane. Various membrane filters are prepared by this method[102].

b) The casting solution is formulated to contain both strong solvent(s) and poor or non-solvent(s) for the polymer (ternary and quaternary systems are preferred). The strong solvents are selected to be most volatile and are preferentially evaporated from the casting solution during membrane formation. When a critical polymer concentration is reached during the evaporation period, phase sepa-

ration will occur leading to the formation and agglomeration of solvent rich polyhedrally-shaped droplets. In a further step, an enrichment of the polymer occurs at the points of contact of the polyhedrally arranged droplets. Because of the concurrent dilution of the remaining droplet wall and the contraction pressure of the droplet, the vacuole system (pores) will open and the enclosed liquid will be "discharged". Alternatively, the droplets may be stable enough not to burst under these forces. This latter kind of membrane, which still contains packed spheres (nodules) in the final state, was first reported by *Cabasso et al.*[103]. Such membranes have good pressure stability since spheres, in contrast to droplets, do not collapse under pressure.

c) The polymer solution is cast into a film and directly or after a short evaporation period (period of contact with air or another gas phase) immersed into a "precipitation" bath containing a liquid (usually water) which is a non-solvent for the polymer but is miscible with the other components in the casting solution. The phase separation described above does not take place before the as-cast film enters the precipitation bath.

d) Production of ionotropic gels from polyelectrolyte solutions by diffusion of appropriate counterions into the polyelectrolyte sol (Thiele membranes[104]; Fig. 8e, f).

Asymmetric membranes with an active layer are frequently prepared by method c, or by a combination of methods b and c where the interfacial tension is one factor determining the relative thickness of the active layer. The thickness of the active layer as well as the pore structure of the supporting membrane can be controlled by the composition of the casting solution, its viscosity and polymer concentration, the duration of the period of contact with the gas phase, and the conditions of precipitation (phase separation) (for typical examples see Section 4).

Firstly, the pore structure of synthetic gel membranes will depend on solubility effects such as the "quality" of the solvents and the "power" of the precipitation agent[105–107]. The "quality" of a solvent can be graduated, for instance, by mixing (blending) a good solvent (for the polymer) with a weak or non-solvent. Ultimately however, the pore structure is determined by the kinetics of phase separation (similarly to crystallization processes from solutions). This may, in turn, be manipulated by adding salts (preferentially Li-salts) or polyelectrolytes to the casting solution to vary its viscosity and to control the kinetics of phase separation (*e.g.* by associate formation). Moreover, the action of the precipitation bath can be varied by presence of additives and by temperature changes. According to *Grethlein*[108], membrane formation thus depends on so many parameters in such ways that no quantitative statements can be made regarding the effect of the individual parameters and even qualitative statements possess limited validity for a specified system. Experience gathered from casting flat sheet, tubular, or hollow-fiber membranes, with a given polymer cannot be readily applied to other casting solutions. Nevertheless, a few general qualitative statements are possible:

Formulation of a casting solution with a strong solvent for the polymer promotes the formation of more dense membranes.

Rapid phase separation, which will result from "powerful" (highly immiscible) precipitation agents, contributes to formation of a thinner and more compact active layer and might also lead to finger-structures in the substrate.

The quicker the phase separation occurs the more likely it is that the internal surface of the fingers (if any) will be porous.

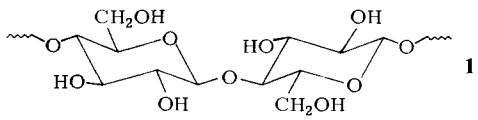
Higher polymer concentration or casting solution viscosity reduces the formation of fingers and cavities.

Employment of a weak solvent for the polymer and/or a weak precipitation agent leads to membranes with a limited asymmetry in their porosity *i.e.* small gradient of the porosity across the membrane.

The formation of the dense, homogeneous active layer of asymmetric membranes requires considerable enrichment of the polymer concentration relative to its level in the casting solution. This is accomplished by selection of an appropriate interfacial tension and partially by evaporation of the solvent from the surface of the as-cast film prior to precipitation. During preparation of hollow fibers with an active layer at the external surface of the fibers, the residence time is controlled by the length of the air segment through which the fiber leaving the spinneret has to pass before entering the precipitation bath. As no sol-gel transition occurs during the formation of the active layer, the resulting membrane consists of a thin-film (active layer) continuously merging into a gel-membrane (porous supporting framework).

4. Preparation of Typical Synthetic Membranes

Initially, virtually all synthetic membranes were cast from cellulose **1** (Fig. 23) and cellulose derivatives since these polymer materials were readily available and were



1

Fig. 23. Cross-section from the structural formula of cellulose **1**.

known to be good film-forming substances[109]. After dissolving cellulose or its derivatives in appropriate solvents, a variety of techniques can be employed to cast thin-films or gel-membranes of *ca.* 1 to 1000 μm in thickness from the viscous solutions on appropriate supports.

®Cuprophan membranes are obtained when cellulose is dissolved as tetraamminecopper complex[110], then precipitated again from this solution by use of NaOH, and subsequently regenerated by means of H_2SO_4. In contrast, ®Nadir is spun from viscose solution (cellulose xanthogenate) which is precipitated in an acidic precipitation bath and subsequently regenerated into cellulose. The permeability of the as-cast membrane may be adjusted by mechanical or chemical aftertreatment[111]. Nowadays, membranes made from regenerated cellulose are used primarily for hemodialysis (artificial kidney) and also in "technical" dialysis

processes such as concentration and purification of protein solutions. Some typical physicochemical properties of cellulose membranes are listed in Tables 6 and 7.

night. (Unannealed homogeneous CA membranes exhibit a larger flux decline in hyperfiltration experiments at 50 to 100 bar during the first two weeks of operation.)

Table 6. Solute permeabilities P_s of some typical membranes of thickness d (concentration 0.1 wt.-%) at $T = 25\,^{\circ}C$. Membranes of this kind are used for artificial kidneys. Dextran T-20 (M.W. ≈ 20000) cannot permeate any of the membranes.

[a] For example glycerine.

Cellulose acetate (CA), another cellulose ester widely used in membranes, is obtained by reaction of cellulose with acetic acid in the presence of acetic anhydride (H_2SO_4 catalysis). This reaction proceeds almost to completion giving almost fully esterified cellulose (triacetate[112]). Cellulose acetates of improved solubility are obtained by hydrolyzing some (10%—30%) of the acetate groups (secondary acetates; *e.g.* cellulose 2.5-acetate, in which on average 2.5 of the 3 OH-groups are acetylated). Such CA materials are dissolved in acetone, chloroform, or dimethylformamide, or similar solvents, to form viscous solutions from which homogeneous membranes can be cast. A typical recipe is as follows: *ca.* 10 wt.-% CA (*e.g.* Bayer Cellit K-700) is dissolved in acetone with continuous stirring of the solution. This casting solution is filtered to remove undissolved components such as gel particles. Homogeneous CA membranes are then cast by pouring this solution onto a glass plate at 30 °C and relative humidity ≤30% using a doctor blade (slit width 100 to 200 μm). The drawdowns are maintained at 30 °C overnight to yield membranes with a thickness of 10 to 20 μm. The membranes are subsequently annealed in an oven at 110 to 130 °C, also over-

4.1. Preparation of Micro-Filters (Membrane Filters)

Microfilters (microporous filters) can be produced from cellulose nitrate (CN), CA, and CN/CA blends. A typical casting solution for porous CN membrane filters is prepared by dissolving CN (5 wt.-%) in a mixture of methyl acetate (54.2 wt.-%), ethanol (23.7 wt.-%), butanol (12.3 wt.-%), H_2O (3.3 wt.-%), and glycerine (1.5 wt.-%). The resulting solution is then cast into a film and the solvent allowed to evaporate. In a common formulation for the preparation of CA microfilters Bayer Cellit F-1000 (3.3 g) and L-1000 (2.2 g) are dissolved in a mixture of dichloromethane (50 mL), ethanol (50 mL), and H_2O (4 mL). The film is then formed by volatilizing the solvents (no contact with saturated vapor phase). Porous membranes can be similarly prepared from CA/CN blends dissolved in mixtures of acetone, 1-propanol, ethanol, glycerine, ®triton X, and H_2O[113]. Figure 24 shows EMs of carbon replicas of the top and bottom surfaces of typical microfilters cast from CN/CA blends[113]. Such microfilters characteristically exhibit only a weak asymmetry in their porosity across the membrane. Any skin which may have (inadverdently) been

formed on the membrane surface will disintegrate when the pores are opened. Definite and graduated conditions of temperature, humidity, and air circulation must be carefully observed since phase separation is initiated by evaporation of the solvent(s). For many years, only microfilters based on cellulose esters were commercially available. Microfilters from additional polymers (*e.g.* polyvinyl chloride, polyamide, polytetrafluoroethylene, polyvinylidene fluoride) have just recently been commercialized.

filtration is used not only for the purification or separation of suspended or dispersed substances in mixtures but also for the removal of oligomeric or macromolecular substances from solutions. Virtually all current ultrafilters are asymmetric porous membranes. For instance, a typical ultrafiltration membrane is manufactured from cellulose acetate by using a casting solution prepared from cellulose 2.5-acetate (25 wt.-% Eastman CA-398) dissolved in acetone (45 wt.-%) and formamide (30 wt.-%)[115]. The viscous

Composition of casting solutions: CN : CA : acetone : 1-propanol : ethanol : glycerine : triton : water (wt.-%) = 8.5 : 1.5 : 60 : 23 : 4.5 : 1 : 0.5 : 1 (G-1); as G-1 but with a different CA material (G-2); 11.9 : 2.1 : 57.6 : 19.8 : 6.25 : 1 : 0.5 : 1 (G-3); 11.9 : 2.1 : 56 : 21.4 : 6.25 : 1 : 0.5 : 1 (G-4). Materials: CN HP-800 and Bayer-Cellit F-700 except for G-2 where Bayer-Cellit L-700 was used [86, 113].

Polysulfone (PS) is one additional polymer extensively studied for membrane application because of its chemical resistivity. Porous PS membranes were initially utilized as supporting matrices for composite membranes[114] since they are insoluble in several solvents commonly used to prepare the casting solutions of active layers. In addition to exhibiting chemical compatability, the supporting layer of composite membranes must combine high surface porosity with minimal pore diameters. This requirement is self-contradictory since the pore diameter of a gel-membrane generally increases with increasing porosity. However, satisfactory films were eventually achieved by very exact control of air temperature, humidity, and air flow velocity during the evaporation period and, also, by addition of surface active materials to the casting solution.

4.2. Preparation of Ultrafiltration Membranes

The production of ultrafilters (UF membranes) requiring a finely porous separative layer on top of the membrane was also initially based on cellulose esters, and these still play an important role because of their comparatively low material price and their good compatibility with biological materials, especially proteins. Unlike microfiltration, ultra-

solution is degassed under vacuum and then cast onto a glass plate using a doctor blade with a slit width of 100 to 200 µm. After a short evaporation period of only a few seconds, the polymer sheet is precipitated in a water bath (sol-gel transition). The membrane is then washed with water for at least 10 min to extract solvents and swelling agents. Asymmetric UF CA membranes with molecular weight cutoffs ranging from 5000 up to 20000 Daltons are formed using this recipe, the molecular weight cutoff primarily depending on the duration of exposure to air (evaporation period) and the temperature of the precipitation bath. A higher content of swelling agent in the casting solution affords more open (coarsely porous) membranes (higher molecular weight cutoff), whereas a larger proportion of solvent leads to more consolidated membranes (lower molecular weight cutoff). The phase separation, which takes place at the time of the immersion of the membrane into the precipitation bath, is essentially controlled by the ratio of solvent to swelling agent. The lower the content of solvent the faster phase separation occurs and this yields more open (coarsely porous) membranes.

UF membranes with a comparatively low molecular weight cutoff ($\leq$ 2000 Dalton) may also be prepared in this way, for example by annealing low porosity, as-cast films at 80 °C to consolidate the active layer. Cellulose acetate

membranes of graduated porosity, ranging from coarsely porous to finely porous and even to dense, can be cast by varying the casting solution, bath conditions, and aftertreatment. Membranes with low molecular weight cutoffs, bridging ultra- and hyperfiltration membranes, are of special interest for concentration and purification of peptides, hormones, and nucleotides.

Increasing attention is also being paid to other, more chemically and thermally stable polymers required for applications employing higher temperatures and more aggressive agents, *e.g.* in the food industry where membrane plants must be periodically sterilized and sanitized. The first generation of non-cellulosic UF membranes were made from polyelectrolyte complexes, modacrylic polymers, acrylonitrile copolymers, and polyamides; they are still being used for special purpose applications, *i.e.* certain molecular weight cutoffs or where non-specific absorption is a problem. Today, however, polysulfone and polyvinylidene fluoride (PVDF) membranes are preferentially used for ultrafiltration since they offer bettter temperature resistivity ($\leqslant 90$ °C), acid and base stability, and higher resistivity towards oxidizing agents (*e.g.* $\leqslant 2\%$ NaOCl).

Polysulfone, *e.g.* Udel 1700 manufactured by Union Carbide, is used for the production of porous PS membranes from casting solutions prepared from strongly polar, aprotic solvents[116] such as dimethyl formamide (DMF), dimethyl acetamide (DMA), *N*-methylpyrrolidone (NMP), or cyclohexanone, and occasionally swelling agents such as methanol. The casting process is the same as for CA membranes. The formation of the active layer (skin) as well as of the pore structure again depends on the viscosity of the polymer solution and on the interaction with the precipitation bath (hydrophilic-hydrophobic balance). Polymers such as polyethylene glycol (MW = 600) or polyvinylpyrrolidone (MW = 10000) are frequently added to the casting solution to yield a more dense and more foam-like pore structure by influencing the kinetics of precipitation (delaying phase separation). These rather lower molecular weight additives are extracted from the membrane in the precipitation bath[105].

The development of UF membranes thus began with the more hydrophylic polymers (*e.g.* CA, polyelectrolyte complexes) and progressively led to the use of more hydrophobic polymers (*e.g.* PS, PVDF). Application of these membranes in technical equipment to process increasingly diversified macromolecular or dispersed solution components (*e.g.* anaphoretic or cataphoretic electropaints, sweet or sour whey) requires UF membranes which will not absorb the dissolved or dispersed substances from the process system.

The hydrophilic/hydrophobic character of a polymer is also important when the membrane or complete system must be sterilized[117]. Attempts have been made during the

[a] The letters and/or numbers after some names signify tradenames or type designations. [b] Abbreviations: F = flat sheet, C = capillary membrane, P = plate, T = tube, and S = spiral-wound module.

entire course of membrane development to upgrade the hydrophobic character of membranes by introducing appropriate hydrophilic groups[118-120], the most successful example of which is the sulfonation of polysulfone[121,122]. Attempts were also made to blend appropriate hydrophobic polymers with hydrophilic ones. As different polymers are very often immiscible because of their positive enthalpy of mixing ($\Delta H > 0$) and their essentially small entropy of mixing ($\Delta S \approx 0$), considerable effort was required to develop miscible hydrophilic/hydrophobic polymer systems. For example, cellulose acetate is miscible with poly(phenylene oxyphosphate) esters[119,123] as well as with poly(4-vinylpyridine)[120]. In addition, PVDF and poly(vinyl alcohol) (PVA) can be blended if their poor miscibility is circumvented by use of poly(vinyl acetate) and its subsequent hydrolysis[124].

The interrelated aspects of boundary layer formation, interfacial tension, and non-specific adsorption are of particular importance in connection with ultrafiltration of complex physiological solutions such as blood (hemofiltration, hemodialysis, plasmapheresis, *etc.*). The volume flux of water *in vitro* is much larger than *in vivo*; this is not only due to the influence of special factors such as concentration polarization and the formation of secondary membranes (*e.g.* deposits of protein upon the original membrane), but also to the influence of the individual membrane polymer on the permeation behavior of the membrane in presence of more physiological solutions like blood.

Improved chemical resistivity towards a wide spectrum of organic solvents represents the most important potential improvement in UF membranes. This requirement is not readily achieved since the membrane formation process requires the polymer to be soluble in organic solvents. This problem might be resolved by cross-linking, after casting, polymer components of membranes composed from different soluble prepolymers (*e.g.* intermolecular cross-linked polyimide membranes). Porous inorganic membranes represent another possibility for improved solvent resistance. Such membranes are fabricated from porous carbon (by modification of its surface with ZrO_2[125]) and from porous glass (by phase separation of incompatible glasses[126,127]) and are preferentially shaped into tubular or capillary form. However, the comparatively high price of these products and the poor variability of their molecular weight cutoff limit their use. A complete list of commercial UF membranes and modules together with manufacturers is compiled in Table 8.

4.3. Preparation of Hyperfiltration Membranes

The principal uses of hyperfiltration are for the production of fresh water from brackish water and seawater, the preparation of ultrapure water, and the processing of service waters. Two requirements are paramount for fresh water production: the product water should contain a low concentration of salt (possibly WHO standards, *i.e.* ≤ 500 ppm salt) and the fresh water output should be as high as possible (*e.g.* 1000 up to 400000 m^3/d; see Table 9). The product water purity specifications will determine the properties of the membranes to be used, whereas the requirement

Table 9. Hyperfiltration plants (* 1980 under construction).

for high daily output can only be met by a combination of highly water-permeable membranes with a comparatively large membrane area. This in turn requires high packing density (membrane surface area/module volume), which is obtained by appropriate membrane configurations in compact module constructions (plate and frame, spiral-wound, tube, and hollow-fiber modules). Plate and frame as well as spiral-wound modules require flat sheet membranes; tube modules require tubular membranes. The latter are prepared by either directly casting tubular membranes or shaping flat sheet membranes into tubular form. For the economic production of fresh water, plate and frame, spiral-wound, and tubular modules must be equipped with asymmetric or composite membranes (high water permeability). In contrast, in the case of hollow-fiber modules, which have more efficient packing density, one may employ either homogeneous or asymmetric hollow-fibers. The techniques given above for the preparation of homogeneous membranes from polymer solutions apply to hyperfiltration membranes as well and will not be repeated here. Only the preparation of typical asymmetric and composite membranes will be dealt with here.

Membranes for ultra- and hyperfiltration are prepared as flat sheet, tubular, and hollow-fiber membranes. Asymmetric hollow-fibers can be prepared with the active layer on either the inside or the outside of the fiber or both. Hollow-fibers employed for hyperfiltration have to withstand high pressures (*ca.* 30 to 70 bar) and generally have a relatively small inner fiber diameter so as to prevent collapsing. The bore diameter of the hollow-fine fibers used by the Du Pont Company in their B-9 and B-10 modules (for

brackish water and seawater desalination, respectively) is about 40 μm (Fig. 25d). To date, no hollow fibers are available for hyperfiltration where the brine is fed to the inside of the fibers. This would require an internal fiber diameter of 1 to 5 mm in order to approach economical flow conditions of the feed solution within the fibers. Moreover, when pressure is applied from the inside, a "self sealing" of the fibers in case of damage is impossible. Hollow fiber membranes, which cannot be supported as can flat sheet and tubular membranes, have limited mechanical stability and commonly function up to a few bar only, depending on their internal diameters; hence, their utility is limited to ultrafiltration. Figure 25 shows SEMs of the cross-sections of different capillaries and hollow fibers. In contrast to other viscose capillaries[128], also cellulose capillaries cast from viscose are completely free of imperfections and voids (for the status of hollow fiber preparation see [129]). As noted earlier, the selection of geometry for these membranes is chiefly dependent upon the feed solution to be processed.

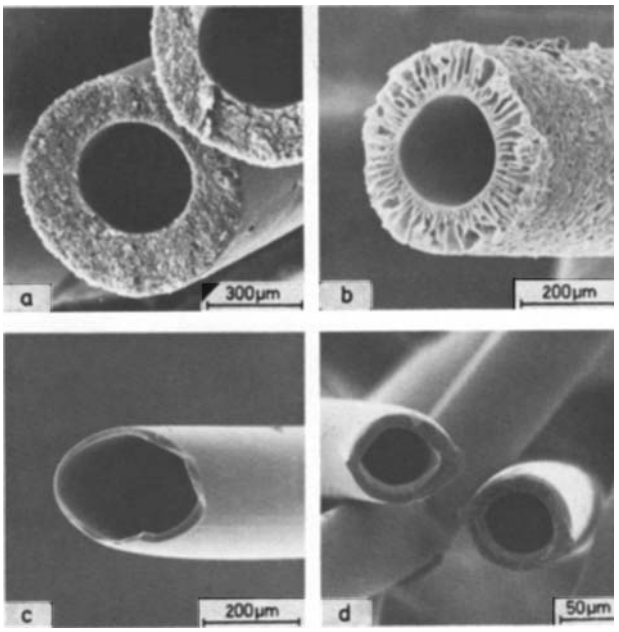

Fig. 25. SEMs of cross-sectional views of various capillary and hollow fiber membranes: symmetric, heteroporous microfilter from polypropylene (a; Membrana PP-105), asymmetric, heteroporous ultra/hemofilter from polysulfone (b; Amicon), symmetric and finely porous to dense hydrophilic gel-membrane from regenerated cellulose *e.g.* applied for hemodialysis (c; Kalle Niederlassung der Hoechst AG), and asymmetric, finely porous to dense polyamide hollow fiber (used for hyperfiltration) with the active layer on the outside surface (d; Du Pont B-9).

4.3.1. Preparation of Asymmetric Membranes

Most membranes are quite efficient substrates for the growth of bacteria and during use must be periodically sterilized. Cl_2 is the cheapest and most effective disinfectant, and desalination membranes should be able to resist Cl_2 concentrations of up to 20 ppm for short periods of time. CA membranes are the only practical material meeting this requirement. Therefore, cellulose acetates of varying acetyl content again have been the basic materials for the preparation of asymmetric desalination membranes. Asymmetric CA membranes are primarily cast from ternary or quaternary casting solutions. *Loeb, McCutchan,* and *Manjikian*[130] have prepared various casting solutions of CA in acetone and formamide, a typical example of which is CA (22 wt.-%), acetone (42 wt.-%), and formamide (36 wt.-%). After being filtered, the viscous solutions are subsequently cast onto a glass plate. During the evaporation period (30 to 60 s, which may be longer than for the preparation of UF membranes), the active layer is formed. Phase separation occurs when the film is immersed into the precipitation bath (water). The membranes remain in the water bath for 1 to 2 hours for solvent removal, and the water is repeatedly exchanged. The salt rejection of asym-

[a] The number preceding "acetate" signifies the average number of acetylated OH-groups per glucose unit. [b] Abbreviations, see Table 8. H = hollow fiber. [c] Tangential flow.

metric CA membranes can be adjusted by annealing the membranes in a water bath at temperatures between 75 and 95 °C, depending on the material; Eastman CA is annealed at temperatures of 75 to 85 °C and Bayer Cellit K-700 from 80 to 95 °C (see Fig. 13). Asymmetric CA membranes are cast into flat sheet and tubular membranes as well as into hollow fibers (Table 10a). The active layer can be produced at the inner or outer fiber wall. The poor chemical resistivity of asymmetric CA membranes and their susceptibility to hydrolysis, decreasing as the degree of acetylation increases, limit their application. Susceptibility to hydrolysis requires maintaining of a very narrow pH range ($5 \leqslant pH \leqslant 7$). In addition, common asymmetric CA membranes must either be treated with softeners before being dried or be stored wet.

Besides cellulose acetate, mixed esters such as cellulose acetate-butyrate, -palmitate, -acetoacetate, -methoxycarbonylpropionate, -dimethyl sulfamate, -hydrogen phthalate *etc.* have also been investigated regarding their suitability for the preparation of hyperfiltration membranes. *Cadotte et al.*[131] measured the transport properties of homogeneous membranes prepared from about 15 mixed esters of CA. Compared to CA, membranes prepared from the blends yielded either a lower salt rejection at better fluxes or a substantially lower flux at equivalent salt rejections.

CA membranes are precluded from many applications because of their susceptability to hydrolysis and biological degradation. After several false starts[132], development of membranes from completely synthetic polymers was finally successful. The Du Pont Company (Wilmington, Delaware)[133] and Monsanto-Chemstrand (Durham, North Carolina)[134] successfully prepared asymmetric membranes based on aromatic polyamides. The structural formulas of the basic units of polyamides and polar heterocyclic polycondensates used for the preparation of asymmetric membranes are compiled in Figure 26. Most polyamides are prepared by polycondensation (preferably low-temperature solution polycondensation) of complementary bifunctional compounds and cyclic or blocked monomeric intermediates (with two functional groups). The preparation of asymmetric membranes from the corresponding polyamides is fundamentally the same as that for asymmetric CA membranes. However, the evaporation periods for the solvents are longer since those used (*e.g.* dimethylacetamide (DMA), *N*-methylpyrrolidone (NMP), dimethyl sulfoxide (DMSO)) exhibit higher boiling points than, for example, acetone-formamide. Therefore, membranes drawn from viscous polyamide (PA) solutions, for example, are "dried" from about 5 min up to several hours in ovens with sufficient air circulation at temperatures ranging from 60 to 120 °C (PA solutions in DMA or NMP) or 80 to 160 °C (PA solutions in DMSO). Here also the active layer forms during the evaporation period. The "dried" membranes, still containing 15% to 75% of solvent, are then precipitated in a water bath at temperatures below 25 °C (phase separation). The membranes are then washed for several hours with water to remove all the solvents. The salt rejection and the water permeability of the membranes can be adjusted by varying the length of the evaporation period or by adding swelling agents (*e.g.* $CaCl_2 + H_2O$, butanol, cresol, glycerine, ethylene glycol, aromatic amides, *etc.*) to the casting solution. In contrast to asymmetric CA membranes, the permeation properties of asymmetric polyamide membranes are generally not improved by annealing.

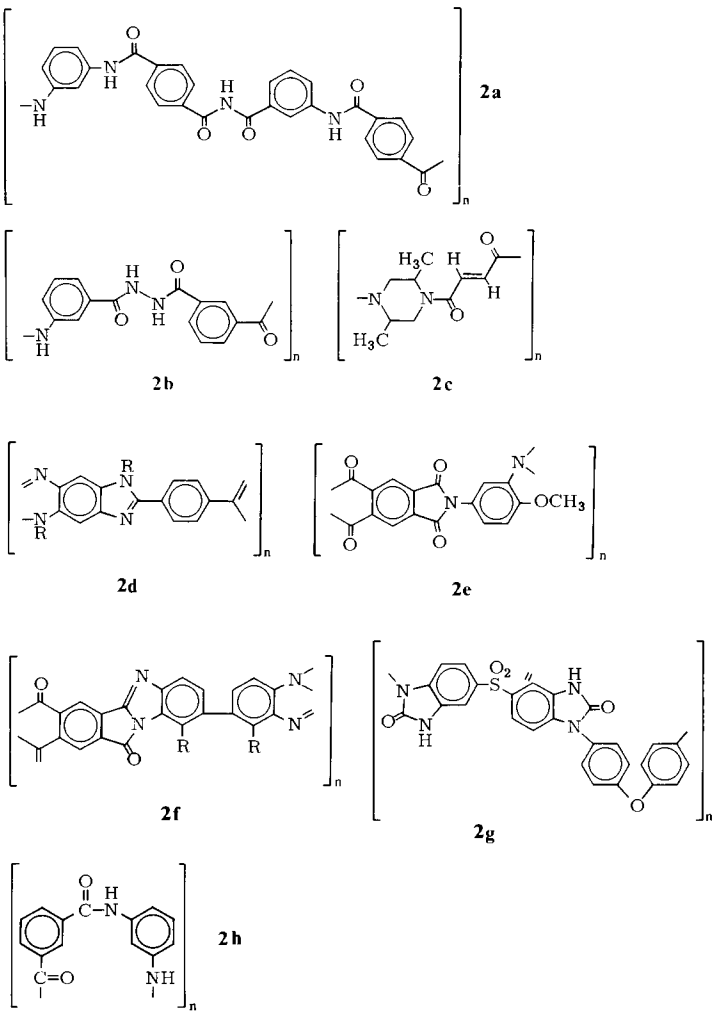

Fig. 26. Structural formulas for basic units of polyamides and polar heterocyclic polycondensates suitable for the fabrication of asymmetric membranes for hyperfiltration. Copolyamides **2a** (*e.g.* from terephthalic acid, *m*-aminobenzamide, *m*-phenylenediamine [149]), polyamide hydrazides **2b** (*e.g.* from isophthalic acid, *m*-aminobenzhydrazide [150]), polypiperazine amides **2c** (*e.g.* from fumaric acid, dimethylpiperazine [151, 152]), polybenzimidazoles **2d** (*e.g.* from terephthalic acid, tetraaminobenzene (substituted) [153], polyimides **2e** (*e.g.* from pyromellitic dianhydride, methoxy-*m*-phenylenediamine [154]), pyrrones **2f** (*e.g.* from pyromellitic dianhydride, diaminobenzidine (substituted) [155]), polybenzimidazolones **2g** (*e.g.* from diaminodiphenyl ether, dichlorodiphenylsulfone (substituted, cyclized) [156]), and *m*-phenyleneisophthalamide/terephthalamide copolymer (70:30) **2h** [133].

Polyacrylonitrile (PAN) copolymers have also been considered for the preparation of asymmetric membranes. However, the active layer in PAN membranes is generally too porous for use in desalination and only suited for ultrafiltration purposes. Recently, however, Sumitomo Electric Industries (Tokyo, Japan)[135] succeeded in obtaining a dense surface layer by plasma treatment of the porous surface. The asymmetric membranes prepared in this way exhibit volume fluxes of the order of 2000 to 3000 L m^{-2} d^{-1} at pressures of 80 to 100 bars and salt rejections for 0.1 M NaCl brine solutions ranging from 94 to 98% (see Table 10b).

4.3.2. Preparation of Composite Membranes

As already mentioned, not every polymer can be cast into an asymmetric membrane. Moreover, the thickness of the active layer and the resultant water permeability of the membrane cannot always be optimally controlled. Hence, it was a logical next step to attempt to prepare membranes similar to asymmetric ones by coating an appropriate supporting matrix with a thin homogeneous film. The thin homogeneous film (active layer) could be cast by dipping the support into the corresponding casting solution, by spraying the casting solution onto the porous support, by a cross-linking surface polymerization, or by interfacial cross-linking reactions. The supporting framework must be either refractory to the solvents in the casting solution for the thin-film or must be protected against these solvents by a water soluble intermediate layer. Because of its chemical stability, PS is generally employed to fabricate the fine-porous supporting membrane. When the active layer is prepared by dipping or spraying, penetration of the thin-film casting solution into the pores of the supporting framework is prevented by coating the surface of the porous support with a thin gel-layer (intermediate layer) usually formed by a water-soluble polymer. This gel-layer concomitantly protects the porous support from the solvents of the casting solution. If the polymer molecules of the gel-layer can pass the porous support, the intermediate layer is progressively extracted during operation of the composite membrane. Thus the active layer will finally lie only on the porous support and will have poor mechanical stability. It can be easily delaminated by a sudden drop in the pressure within the membrane module. The mechanical stability of the intermediate layer can be improved by cross-linking the gel. The water content of the cross-linked

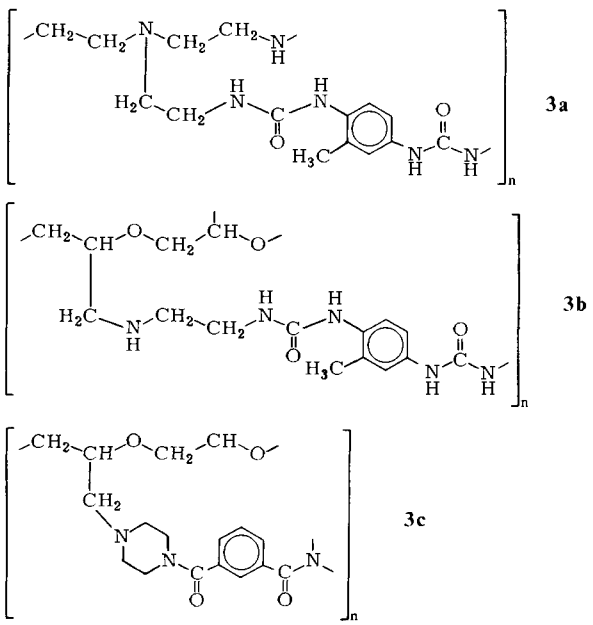

Fig. 27. Structural formulas of basic units of several polymers suitable for the formation of the thin-film of composite membranes. Polyureas **3a** (*e.g.* from polyethylenimine, toluylene diisocyanate [157]), poly(ether/ureas) **3b** (*e.g.* from polyepichlorohydrin (substituted with ethylenediamine), toluylene diisocyanate [158]), and poly(ether/amides) **3c** (*e.g.* from polyepiiodohydrin (substituted with piperazine), isophthalic acid [159]).

intermediate layer should be as high as possible to minimize its hydrodynamic resistance. The active layer can also be attached by covalently cross-linking a gel-layer (*e.g.* amine-modified polyepichlorohydrin) at its surface (interfacial cross-linking). During fabrication the porous support is soaked with the casting solution containing the multifunctional polymer and subsequently brought into contact with a solution of the cross-linking agent (*e.g.* toluylene diisocyanate, isophthaloyl dichloride) in an appropriate organic solvent. In this way an improvement in the adhesion between active layer and supporting framework is obtained. Finally the active layer might be formed from multifunctional amines or acids by direct interfacial polycondensation.

In addition to CA, several other polymers including polyamides, poly(ether/amides), poly(ether/urea), and polybenzimidazolone (PBIL) form suitable barrier films. Figure 27 lists the structural formulas of the monomer units of typical polymers employed in the preparation of thin-films of composite membranes. Table 10b gives an overview of asymmetric and composite membranes.

Improved chemical resistance towards more aggressive process streams and cleaning agents has accelerated the application of synthetic membranes for purposes other than brackish water and seawater desalination. For example, in whey processing, hyperfiltration is gradually supplanting ultrafiltration. In fact, in the USA more hyperfiltration plants were installed for this purpose during 1978—81 than were ultrafiltration plants from 1972—1981. Often, final products may be refined and waste streams purified by using hyperfiltration to concentrate the permeate of ultrafiltration plants. The chemical resistivity necessary for such applications is increasingly being realized with composite membranes containing covalently cross-linked separation layers.

The technical achievements attending hyperfiltration with modules (high packing density) and membranes (high water permeability) have been promptly exploited in gas phase separation processes. Accordingly, homogeneous SD membranes are designed to be preferentially selective towards O_2, CO_2, or He. The properties of synthetic membranes which are predominantly used for gas separation are listed in Table 11 together with permeabilities for selected gases.

Finally, mention should be made of two special composite membranes which have recently been developed for gas separation. The Monsanto Company[136] has successfully developed a composite hollow fiber for gas separation by laminating a void-free non-porous membrane (silicone) onto an asymmetric heteroporous supporting framework. The supporting material was composed of a poylmer (polysulfone) with high selectivity for certain permeant gases (*e.g.* H_2/CO_2) but incapable of being formed into an asymmetric membrane with a pore-free (pin-hole free) skin. The thin-layer (coating) consists of a comparatively permeable but poorly selective polymer. During fabrication, it penetrates into the pin-holes/pores of the active layer of the supporting framework and blocks (*i.e.* prevents convective flow through) these pores. The thickness of this coating varies with depth of penetration. Using such a composite membrane, the theoretically possible separation factor is approached more closely at small ratios of effective surface area of imperfections A_i to effective surface of intact active layer A_a. Monsanto fibers possess a ratio $(A_i/A_a) \simeq 2 \times 10^{-6}$, so that a separation factor of about 33 is calculated for the separation of H_2 from a H_2/CO mixture; this is less than the maximum possible value of 40 for a PS hollow-fiber membrane possessing a completely intact active layer, but is still high enough to make the separation of H_2 from corresponding gas mixtures (*e.g.* H_2/CO) economically feasible.

The second composite membrane concerns SiO_2, which is selectively permeable to O_2; the enrichment of O_2 from air can be achieved by the permeation of air through membranes prepared by sputtering thin films of SiO_2 onto supporting frameworks.

Table 11. Permeabilities $P_s = \Phi_v d/\Delta p$ and separation factors of membranes for gas separation. d = effective membrane thickness, Φ_v = gas flux density, Δp = partial pressure difference across the membrane. P_s is given in [cm³ (STP) cm/(cm² s torr × 10)].

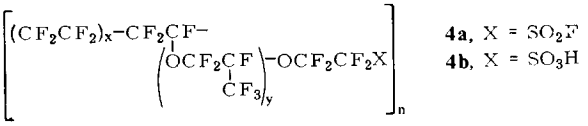
4.4. Preparation of Ion-Exchange Membranes

Ion-exchange membranes should contain an as high as possible fixed charge concentration (concentration of ionic groups). Therefore, they have traditionally been prepared from polyelectrolytes rendered water insoluble by cross-linking[137]. Since numerous monographs on ion-exchange membranes are available[138-140], the technique and chemistry of ion-exchange membrane preparation will not be discussed in further detail. Ion-exchange membranes are used for the recovery of salt from seawater as well as for the production of fresh water from brackish water. Original ion-exchange membranes were inadequately chemically resistive for such important applications as in chloride-alkali electrolysis (preparation of NaOH and Cl_2 by electrolysis), or as battery separators, and for separating the cathode and/or anode region from the reaction space in organic electrosyntheses and in fuel cells. The demand for more resistant membranes may be met by polymer materials of higher chemical resistivity such as polystyrene, polyisoprene, polybutadiene, and polytetrafluoroethylene (PTFE). The requisite ionic groups may be attached either to the polymer itself or to the finished film. For example, block copolymers[141] (*e.g.* polystyrene/polyisoprene/polystyrene (SIS-blocks)) to which SO_3H-groups were bound have been successfully prepared. In addition, grafted polymers may be employed[142, 143]. Also *Munari et al.* produced ion-exchange membranes of high thermal and chemical stability by grafting 4-vinylpyridine onto PTFE-films[144]. The Du Pont Company produces a prepolymer for a chemically resistant asymmetric ion-exchange membrane (®Nafion) directly from a perfluorinated monomer. The membrane is formed by extrusion of a perfluorinated polymer containing SO_2F-groups (Fig. 28) and subsequently hydrolyzing the functional groups to SO_3H[145, 146]. There is still a demand for an analogous anion exchange membrane (*e.g.* for electrosyntheses) to complement this chemically stable cation exchange membrane. However, the development of such membranes is rendered difficult owing to the demand for extremely high resistivity towards strong oxidizing agents. Some typical chemically stable ion-exchange membranes are listed in Table 12 together with their most important fields of application.



4a, X = SO_2F
4b, X = SO_3H

Fig. 28. Structural formulas for the basic units of the extrudable perfluoropolymer **4a** used for the preparation of ®Nafion membranes and of the hydrolyzed polymer **4b** with ionic group [145].

5. Future Prospects of Membrane Development

The following separation problems can be elegantly solved with presently available synthetic membranes: Concentration and purification of macromolecular solutions, separation of electrolytes and lower molecular weight non-electrolytes from aqueous solutions, economical fractionation of gas mixtures, and separation of electrode spaces, *e.g.* in electrosyntheses. For these and similar applications a healthy commercial activity has emerged, and its volume will undoubtedly increase in the future (Table 13).

Successful application of membrane technology has generally involved broad-based or categorial separations such as the removal of all polymers or nearly all electrolytes and non-electrolytes from aqueous solutions. Other desirable separations require membranes more selective or more chemically stable than presently available, *e.g.* the fractionation of organic mixtures or separation of selected components from mixtures of electrolytes or non-electrolytes, as in the removal of heavy metal salts from waste

waters encountered in the electroplating industry. The chemically stable synthetic membranes presently available (essentially for hyperfiltration) which might be considered for the separation of organic substances all contain water of hydration (and perhaps capillary water). The water of hydration in these membranes is displaced by the organic reagents and the permeability of the membranes decreases continuously with increasing concentration of the organic solvent until $q \simeq 0$[45].

The selectivity of the currently available membranes is insufficient for the solution of specified separation problems since no discrimination occurs between substances of similar size with similar properties (*e.g.* closely related electrolytes or non-electrolytes, different oligomers). Certainly, efforts at developing more discriminating membranes must be mindful of the separative mechanisms in naturally occurring biological membranes, even though these are not yet fully elucidated. In particular, future generations of synthetic membranes might incorporate the hierarchic structure characteristic of living systems, instead of the present format which is unstructured on the molecular level and thus exhibits an irregular (statistical) arrangement of polymer segments.

The authors are indebted to Mr. K. Muth, Physiklabor of Kalle Niederlassung der Hoechst AG, Wiesbaden, for supplying most of the SEMs, to Dr. R. Spohr, Gesellschaft für Schwerionenforschung (GSI), Darmstadt, and to Mrs. W. Schaefer and Dr. D. Dietrich, Enka AG, Research Institute Obernburg, for kindly supplying the SEMs of the mica filters and the Nuclepore filters (used for the filtration of polystyrene particles), respectively. In addition, the authors are grateful to Mrs. I. Hase and Mrs. R. Petzold, MPI für Biophysik, for preparing the figures and tables. Mr. J. Wildhardt (Ing. Grad.) and Mr. D. Beissel, Kalle Niederlassung der Hoechst AG, are thanked for their valuable cooperation and Mr. R. Gröpl, MPI für Biophysik, for his preparation of the CA/CN membrane filters and for valuable discussions on the fabrication of synthetic membranes. Thanks are also due to Mr. Michael Lysaght, presently at the "Nephrologische Abteilung der Medizinischen Klinik I, Klinikum Grosshadern, München", for his excellent proofreading of the English manuscript and helpful discussion regarding the text.

The Thermal Conversion of 1,5,9-Triynes into Arenes: [2+2+2]-Cycloadditions or Sigmatropic Rearrangements?**

By *William V. Dower* and *K. Peter C. Vollhardt**

We have shown that 1,5,9-cyclododecatriyne rearranges to hexaradialene under flash pyrolytic conditions[1] through the likely intermediacy of [1,2:3,4:5,6]-tricyclobutenobenzene. However, theoretical work indicates that the thermal [2+2+2]-cycloaddition of three ethynes to benzene is associated, despite being allowed by the Woodward-Hoffmann rules, with a high activation barrier[4] suggesting an alternative: namely, a series of [3.3]-sigmatropic rearrangements involving the 1,5-diyne moieties[5]. We therefore turned to 1,5,9-decatriyne **1**[6], the pyrolysis of which, if it follows the cycloaddition path, should lead to [1,2:3,4]-dicyclobutenobenzene.

Surprisingly, flash or flow pyrolysis of **1** furnishes the linear [1,2:4,5] dicyclobutenobenzene **4**[11] in addition to naphthalene (flash) or the dimethylenecyclobutene **5** (flow). Independent flash pyrolysis of **5** gave **4** and **6** in the same ratio as that obtained from **1**. Compound **4** is stable to the conditions under which it is formed. Pyrolysis of [1,10-D_2]-**1** gave [3,6-D_2]-**4** and [2,10-D_2]-**5**, cleanly.

Schemes 1 and 2 suggest two mechanisms consistent with the observed results, and are distinguishable by a ^{13}C-labeling experiment. The requisite [($^{13}C)_2$]-**1** was prepared from $^{13}C_2H_2$ (90% ^{13}C) by deprotonation, iodination to $^{13}C_2I_2$, coupling with 4-trimethylsilyl-3-butyn-1-ylcopper and protodesilylation. Pyrolysis gave only unscrambled products: [1,2-($^{13}C)_2$]-**4**, [1,4-($^{13}C)_2$]-**5** (Scheme 1), and [9,10-($^{13}C)_2$]-**6** (Scheme 2) as ascertained by high field ^1H- and ^{13}C-NMR experiments, including homo- and heteronuclear decoupling and spectral simulations. In particular, the ^{13}C-NMR absorption for [($^{13}C)_2$]-**4** after ^1H ($\delta = 3.03$) decoupling appears as a triplet at $\delta = 143.3$ ($J = 3.9$ Hz) with the same line-shape as that simulated for the AA'XX' spin system of [1,2-($^{13}C)_2$]-**4** and inconsistent with that calculated for [1,4-($^{13}C)_2$]-**4**. The [1,4-($^{13}C)_2$]-pattern observed for **5** shows that the degenerate rearrangement (**5** ⇌ **9** ⇌ **5**)

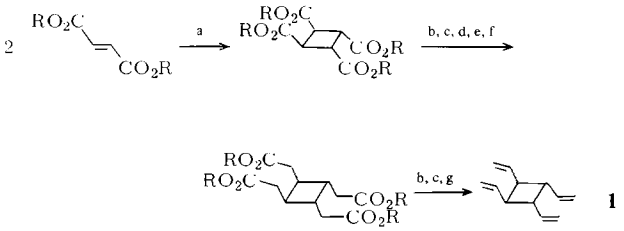
From *cis,trans,cis*-1,2,3,4-Tetravinylcyclobutane to Cyclododecatetraene—Two Consecutive Cope Rearrangements**

By *Klaus Gubernator* and *Rolf Gleiter**

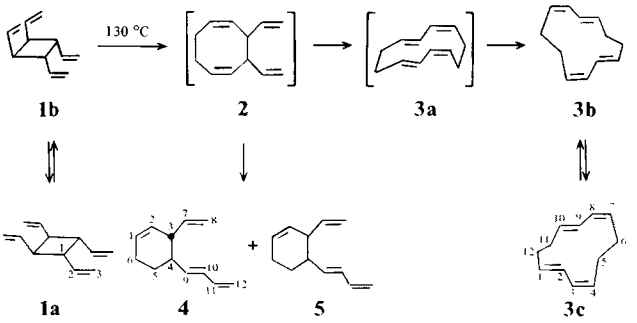
Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday

cis,trans,cis-1,2,3,4-Tetravinylcyclobutane **1** [^{1}H-NMR (300 MHz, $CDCl_3$/TMS): $\delta = 5.93$ (dddd, 4H), 5.06 (dd, 4H), 5.04 (dd, 4H), 3.00 (br. d, 4H); ^{13}C-NMR (72.46 MHz, $CDCl_3$/TMS): $\delta = 138.3$, 115.0, 45.3] has been synthesized according to the sequence indicated in Scheme 1.



Scheme 1. *a:* hv, suspension in H_2O, 20 °C; *b:* $LiAlH_4$, tetrahydrofuran (THF), 66 °C; *c:* PBr_3, 120 °C; *d:* KCN, H_2O/C_2H_5OH, 78 °C; *e:* HCl conc. 100 °C; *f:* $CH_3OH/H^{\oplus}$, 60 °C; *g:* KO*t*Bu, THF, 66 °C. R = CH_3.

At temperatures above 120 °C, **1** isomerizes readily and almost quantitatively to a mixture of cyclododeca-1,3,7,9-tetraene **3** and *anti-* and *syn*-4-butadienyl-3-vinyl-1-cyclohexene, **4** and **5**[2], respectively (Scheme 2).



Scheme 2.

The product ratio (63 : 23 : 14) for **3**, **4**, and **5** is essentially independent of reaction temperature and medium (**1** was thermolyzed in the gas phase, as pure liquid or in dimethyl sulfoxide (DMSO) solution). The mixture was separated by preparative gas-chromatography. The isolated pure compounds were stable towards further thermal isomerization at least up to 200 °C.

[*] Prof. Dr. R. Gleiter, K. Gubernator
Organisch-chemisches Institut der Universität

[**] We are grateful to Dr. P. Kunzelmann, Dr. H. Hiller, and Frau G. Rissmann for some spectroscopic measurements as well as to J. Schwab for preparative work. We appreciate financial support from the Deutsche Forschungsgemeinschaft, Fonds der Chemischen Industrie, and BASF Aktiengesellschaft, Ludwigshafen.

We interprete the low temperature of isomerization in terms of a concerted mechanism. It is postulated that **1a** first undergoes a Cope rearrangement[5,6] to 3,4-divinyl-1,5-cyclooctadiene **2** *via* **1b** (see Scheme 2). The intermediate **2** is presumably unstable at the reaction temperature, and undergoes either a second Cope rearrangement to yield **3** or a 1,3-shift[7] to afford the cyclohexene derivatives **4** and **5**[8].

Mechanistic Aspects of the Carbonylation of Nitrobenzene with Rhodium Catalysts

By *B. Elleuch, Y. Ben Taarit, J. M. Basset**, and *J. Kervennal***

Nitro- or dinitroarene compounds in the liquid phase can be carbonylated by rhodium chlorides or rhodium oxides at 120 to 190 °C under CO pressure[1]. Interestingly, the same catalysts as well as the Rh^0 cluster $Rh_6(CO)_{16}$ reduce nitroarenes with CO/H_2O to the corresponding amines[2]. We report here that the carbonylation of nitrobenzene **1** to form phenyl isocyanate **7** can also be performed with metallic rhodium supported on Al_2O_3, and propose a general redox mechanism based on IR studies. This mechanism involves the three common oxidation states of rhodium and the intermediacy of a nitrenerhodium surface complex based on analogues in the coordination chemistry of clusters[3].

Using 461 mg of the Rh^0/Al_2O_3[4] catalyst, nitrobenzene (10 g) in 100 mL of *ortho*-dichlorobenzene in presence of 1 g pyridine is converted into phenyl isocyanate at 240 °C and a CO pressure of 200 bar in 70% yield with 100% conversion after 405 min (1 h initiation time). Among the by-products only azobenzene (0.25%) was identified.

Room temperature adsorption of carefully dried nitrobenzene **1** (1 torr) on the catalyst gives IR bands (Fig. 1) at 1350 (s) and 1520 (s) cm^{-1}, corresponding to the asymmetric and symmetric NO vibrations of adsorbed $Ph-NO_2$, **1**. In addition, a multiplet of weak intensity (1585, 1605, 1620 and 1640 cm^{-1}) corresponding to the CC stretching bands of the phenyl ring occurs. Upon heating the sample to 50 °C or above, the intensity of the ν(NO) bands decreases significantly. Subsequent adsorption of CO (20 torr) gives IR bands at 2125, 2100, and 2029 cm^{-1} corresponding to a $(CO)Rh^{I}$[5] (band at 2125 cm^{-1}) and to a $(CO)_2Rh^{I}$ species. Simultaneously bands which appear at 1650, 1454 and 1230 cm^{-1} indicate the formation of CO_2/carbonates.

Upon increasing the temperature to 120 °C, a band of low intensity is observed at 2262 cm^{-1}, which is typical of adsorbed phenyl isocyanate: the intensity of the bands at 2100 and 2029 cm^{-1} (Rh^{I} species) increases, whereas two bands appear at 2059 and 1860 cm^{-1} corresponding to CO coordinated to metallic rhodium[5]. At 170 °C the ν(CO) bands corresponding to $(CO)Rh^{III}$ and $(CO)_2Rh^{I}$ disap-

pear; only CO coordinated to Rh^0 and gaseous CO_2 can be detected.

Similar behavior is observed if CO is adsorbed on the catalyst prior to the addition of nitrobenzene. Bands corresponding to CO chemisorbed on Rh (2075 (s) and 1870 (br) cm^{-1}) occur. The subsequent adsorption of $PhNO_2$ (1 torr) at room temperature results in a drastic reduction of the intensity of these bands, which are partially replaced by the doublet characteristic of the $(CO)_2Rh^I$ species. Introduction of CO (380 torr) at 100 °C results in the simultaneous formation of Rh^0 coordinated to CO (bands at 2075 and 1870 cm^{-1}) and of phenyl isocyanate (band at 2260 cm^{-1}).

The results can be explained on the basis of the redox mechanism shown in Scheme 1. Nitrobenzene **1** can oxidize Rh^0 **2** to Rh^{III}/Rh^I surface complexes **4**. Simultaneously a phenyl nitrene complex **3** is formed with a structure similar to that already observed in Fe or Ru clusters[3]. The Rh^I/Rh^{III} surface complex **4** can be reduced at 25 °C by CO to $(CO)_2Rh^I$ **5** with simultaneous formation of CO_2. Formation of phenyl isocyanate **7** is observed when **5** is reduced to Rh^0 surface complexes **8**, which would favor CO insertion into the RhN bond. Such insertion is probably the rate-determining step, and at low CO pressure, *i.e.* under non-catalytic conditions, it does not occur.

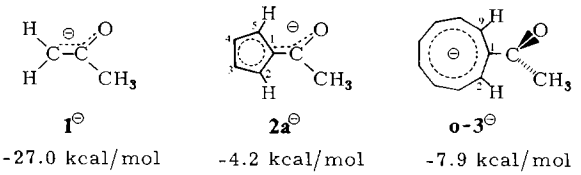
Easy Rotation about the Carbon-Carbon Bond in Lithium Cyclopentadienyl (Ester-)Enolates**

By *Gernot Boche**, *Robert Eiben*, and *Walter Thiel*

The CC "double bond" in (ester-)enolates is conformationally stable referred to the NMR time scale[3d,j]; its double bond character has recently been confirmed by crystal structure data[4]. MNDO calculations are in agreement with both findings[5]: The planar acetone anion $\mathbf{1}^{\ominus}$, *e.g.*, is about 27 kcal/mol more stable than the orthogonal anion $\mathbf{o\text{-}1}^{\ominus}$, rotated through 90° at the CC bond.

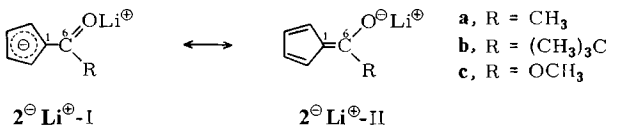
Interestingly, the situation is exactly the reverse in the case of the acetyl-[9]annulene anion $\mathbf{3}^{\ominus}$. The NMR signal of C^{10} ($K^{\oplus}$-salt in [D_8]THF) appears at $\delta = 206.7$[5]. This finding is in no way compatible with a planar enolate structure[3d], but with a non-conjugated methyl ketone.



$\mathbf{1}^{\ominus}$ -27.0 kcal/mol | $\mathbf{2a}^{\ominus}$ -4.2 kcal/mol | $\mathbf{o\text{-}3}^{\ominus}$ -7.9 kcal/mol

Once again, experiment is confirmed by MNDO calculations: the orthogonal anion $\mathbf{o\text{-}3}^{\ominus}$ is about 7.9 kcal/mol more stable than the planar anion $\mathbf{3}^{\ominus}$.

According to MNDO calculations, in the case of the anion of the cyclopentadienyl methyl ketone $\mathbf{2a}^{\ominus}$ the planar conformation is slightly (4.2 kcal/mol) more stable than the orthogonal one, so that (ester-)enolates of this type should be conformationally labile. The ^{1}H- and ^{13}C-NMR spectra (Table 1) of $\mathbf{2a\text{–}c}^{\ominus}\mathbf{Li}^{\oplus}$ confirm this prediction.



$\mathbf{2}^{\ominus}\mathbf{Li}^{\oplus}$-I ⟷ $\mathbf{2}^{\ominus}\mathbf{Li}^{\oplus}$-II

a, R = CH_3
b, R = $(CH_3)_3C$
c, R = OCH_3

Table 1. ^{13}C-NMR spectra (δ values, referred to the solvent [D_8]-tetrahydrofuran (THF)) of $\mathbf{2a\text{–}c}^{\ominus}\mathbf{Li}^{\oplus}$ with 2 equivalents of hexamethylphosphoric triamide (HMPT). Signal indices: without index = sharp; sb = slightly broadened; b = broadened; hb = highly broadened.

	−34	120.7	115.6 (b)	114.0 (b)	111.4 (b)	110.4 (b)	193.6
	−62	120.6	115.4 (sb)	113.8 (sb)	111.1 (sb)	110.3 (sb)	193.5
$\mathbf{2c}^{\ominus}\mathbf{Li}^{\oplus}$	27	107.8	113.4		110.0		168.7
	−20	107.7	113.7 (hb)	113.2 (hb)	111.1 (hb)		168.7
	−40	107.8	113.9 (sb)	113.0 (sb)	111.5 (sb)	111.0 (sb)	168.5

Methyl enolate $\mathbf{2a}^{\ominus}\mathbf{Li}^{\oplus}$: From −60 to 55 °C the same spectra are obtained as at 27 °C. The constantly sharp and different signals of C^2 and C^5 allow only one interpretation: The rotation about the C^1C^5 bond is slow referred to the NMR time scale.

tert-Butyl enolate $\mathbf{2b}^{\ominus}\mathbf{Li}^{\oplus}$: At 27 °C, the atom pairs C^2 and C^5 as well as C^3 and C^4 each give *one* sharp signal; at −21 °C these signals are broadened, and at −34 °C each are split into two lines, which, at −62 °C, are only slightly broadened: C^1 and C^6, on the other hand, always show sharp signals. This spectral behavior is compatible only with a dynamic process due to rotation about the C^1C^6 bond. Other likely causes for such a behavior, namely protonation-deprotonation or aldol-like reactions with any *tert*-butylcyclopentadienyl ketone that may be present, would involve all C atoms participating in the dynamic process and, moreover, should also occur in the case of $\mathbf{2a}^{\ominus}\mathbf{Li}^{\oplus}$. From the coalescence temperature of the signals of C^2 and C^5 the values $k = 96.5\ s^{-1}$ and $\Delta G^{\neq} = 12.4 \pm 0.2$ kcal/mol are obtained for the rotation at 21 ± 4 °C. Since the spectra of $\mathbf{2b}^{\ominus}\mathbf{Li}^{\oplus}$ in [D_8]THF *without* HMPT are almost the same, aggregation and ion-pair effects are, remarkably, of no decisive importance in the rotation about the C^1C^6 bond in $\mathbf{2b}^{\ominus}\mathbf{Li}^{\oplus}$[14c]. The difference in behavior of $\mathbf{2a}^{\ominus}\mathbf{Li}^{\oplus}$ and $\mathbf{2b}^{\ominus}\mathbf{Li}^{\oplus}$ stems from the steric hindrance in the ground state of $\mathbf{2b}^{\ominus}\mathbf{Li}^{\oplus}$. The "transition states" **o-**

[**] This work was supported by the Fonds der Chemischen Industrie.

2a$^{\ominus}$**Li**$^{\oplus}$ and **o-2b**$^{\ominus}$**Li**$^{\oplus}$ should have comparable energies[14c].

Ester enolate **2c**$^{\ominus}$**Li**$^{\oplus}$: The same applies for **2c**$^{\ominus}$**Li**$^{\oplus}$ as for **2b**$^{\ominus}$**Li**$^{\oplus}$ (Table 1); the influence of HMPT is likewise minimal. At -14 ± 4 °C $k=51.4$ s^{-1}, $\Delta G^{\neq}=13.0\pm0.2$ kcal/mol. What distinguishes **2c**$^{\ominus}$**Li**$^{\oplus}$ from **2a**$^{\ominus}$**Li**$^{\oplus}$? Since the steric relations ought to be similar, it must be the weaker acceptor properties of the methoxycarbonyl group, which, in the case of the ester enolate, gives relatively greater importance to the resonance structure **2c**$^{\ominus}$**Li**$^{\oplus}$-I, corresponding to easier rotation.

The signals of the "carbonyl" C-atoms (C^6) of **2a,b**$^{\ominus}$**Li**$^{\oplus}$ lie close to those in the corresponding ketones ($\Delta\delta=13.0$ and 7.2 ppm, respectively; silyl enol ether: $\Delta\delta=21.2$ and 22.4 ppm, respectively). In contrast, in the case of "normal" enolates[3d] the values resemble rather those of the silyl enol ether. This confirms the stability of the planar conformation of "normal" enolates and is thus in accord with the ease of rotation about the CC "double bond" observed in **2b,c**$^{\ominus}$**Li**$^{\oplus}$ and predicted by MNDO calculations[19]. This effect was hitherto not known in the case of (ester-) enolates.

Solid-State ^{13}C-NMR Spectra of Cyclotriprolines**

By *Horst Kessler**, *Wolfgang Bermel*, and *Hans Förster*

Although thanks to the cross polarization magic angle spinning technique (CP-MAS) high resolution ^{13}C-NMR spectra of compounds in the solid-state can almost be obtained on a routine basis today, there are only a few compounds for which X-ray structural analyses *and* solid-state NMR spectra have been obtained[1]. Studies of this type, however, must be carried out in order to understand the influence of intermolecular interactions on chemical shifts in ^{13}C-NMR spectra in the solid-state.

Both X-ray structural analysis[2], and ^{1}H- and ^{13}C-NMR studies in solution[3] have been carried out on the two cyclotriprolines *cyclo*[L-Pro_3] **1** and *cyclo*[L-Pro_2-D-Pro] **2**. In the crystal each compound exists in two independent molecular forms, which also differ from each other in the conformations of the proline ring. In consequence, six signals for each type of carbon atom (CO, C_α, C_β, C_γ, C_δ) are expected for the solid-state ^{13}C-NMR spectrum of **1**, which has C_3 symmetry in solution. However, this is not observed. Only the signals for CO exhibit two additional signals. The carbon atoms of the ring show only relatively broad singlets with a hint of splittings (Fig. 1, top). Even in solution the unsymmetric cyclotriproline **2** exhibits $3\times5=15$ signals[4]. Every signal should be doubled-up in the crystal. The ^{13}C-CP-MAS spectrum (Fig. 1, bottom)

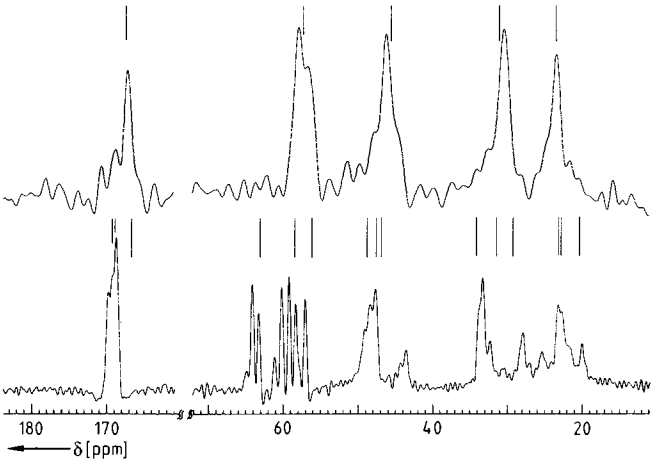

Fig. 1. Solid-state ^{13}C-NMR-CP-MAS spectra (300 MHz, RT) of *cyclo*[L-Pro_3] **1** (top) and *cyclo*[L-Pro_2-D-Pro] **2** (bottom). For purposes of comparison the position of the signals in the solution spectrum ($CDCl_3$) is shown in the middle. The signals are assigned for left to right in the sequence CO, C_α, C_δ, C_β, and C_γ.

clearly shows this effect for the C_α atoms; we do not interpret the splittings for these atoms as arising from ^{14}N quadrupolar coupling[5], since at the field strength used (300 MHz (^1H) = 7.05 T) the splittings should be smaller. Moreover, more asymmetric bands of greater line width would be expected. In the C_δ ($\delta=40-50$), and C_β and C_γ ($\delta=20-35$) regions also, an increased number of lines is indicated because of splittings and anomalous signal intensities. Conspicuous is the difference between the solid-state and solution spectra in the carbonyl region. In solution, the three CO signals (in $CDCl_3$: $\delta=166.8$, 168.9, 169.3) can be readily resolved, whereas in the solid-state, instead of the expected six signals, the splitting of the signals between $\delta=168$ and 170 is only hinted at. In the solid-state spectrum the lines, which compared to those of the solution spectrum are broader, nearly coalesce. A similar effect is found for the C_β signals (in $CDCl_3$: $\delta=29.1$, 31.3, 34.0).

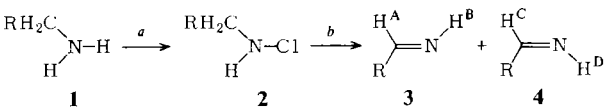
Vacuum Dynamic Gas Phase/Solid-Phase Reactions: *N*-Chlorination of Primary Amines and α-Elimination of the Resulting Chloramines; Synthesis of Reactive (*E*)- and (*Z*)-Aldimines

By *Jean-Claude Guillemin* and *Jean-Marc Denis**

The (*E*)- and (*Z*)-aldimines **3** and **4** are intermediates in chemical and enzymatic oxidations of primary amines, as well as in the dehydration of aldehyde-ammonia adducts. Several of them have been detected in the pyrolysis decomposition products of alkylamines, cyclic aldimine trimers, and alkylazides, but information concerning their stereochemistry is scarce and conflicting. Attempts to isolate and characterize both the (*E*)- and (*Z*)-isomers of this class of compounds as stable free bases have so far failed.

Reactive species have been recently synthesized by vacuum dynamic gas/solid phase reactions[1]. We report here the direct synthesis of the reactive aldimines **3a—3f** and **4a—4f** by a "one-pot" multistep sequence carried out in a single vacuum line: *N*-chlorination of the primary amines **1** on solid *N*-chlorosuccinimide (NCS) is followed by an α-elimination reaction of the resulting N-chloramines **2**[7] over solid potassium *tert*-butoxide[13] (Scheme 1).



1 **2** **3** **4**

a, R = CH_3; **b**, R = C_2H_5; **c**, R = C_3H_7; **d**, R = $CH{=}CH_2$;
e, R = $CH_2{-}CH{=}CH_2$; **f**, R = $=(CH_2)_2{-}CH{=}CH_2$

Scheme 1. Synthesis of **3a—3f** and **4a—4f**. *a:* solid NCS, RT, 10^{-1} torr; *b:* solid KO*t*Bu, 55 °C, 10^{-1} torr. In **3e** and **4e** R = CH=CH—CH_3, the CC double bond is (*E*)-configurated.

Unsaturated *N*-chloramines **2d—2f** are unstable and cannot be revaporized. For this reason, vacuum chlorination of amines **1** on solid NCS and elimination of the resulting chloramines **2** on solid potassium *tert*-butoxide[13] were carried out successively in a single vacuum line, leading in good yields to a mixture of the reactive (*E*)- and (*Z*)-aldimines **3** and **4**, which were characterized by their low temperature IR (−196 °C), ^{1}H-, and ^{13}C-NMR spectra (−100 °C) (Table 2). No (*E*)/(*Z*)-isomerization occurs in solution at low temperature. Stereoselectivity was observed, the main product in all cases being the (*E*)-isomer (72%), even though—as was found in the case of **3a**[14]—it is the less thermodynamically stable isomer. Proof of the constitution of the imines is provided by the low-temperature formation of *s*-triazines. In absence of solvent, the imines polymerize at *ca.* −120 °C.

Table 2. (*E*)- and (*Z*)-aldimines **3** and **4** from **1** [a].

	Yield		^{1}H-NMR [c]		IR [d]
	3+4 [%] [b]	**3/4**	$^3J_{H^AH^B}$ [Hz]	$^3J_{H^CH^D}$ [Hz]	$\tilde{\nu}$(C=N) [cm^{-1}]

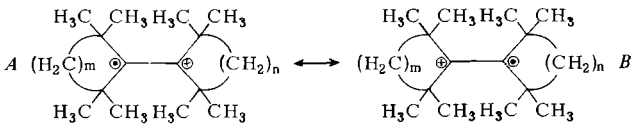
Is the Unpaired Electron in Radical Cations of Sterically Hindered Alkenes Localized or Delocalized?**

By *Horst Eierdanz* and *Armin Berndt**

An electron exchange between the *localized* structures *A* and *B* was recently postulated[1] for the sterically hindered radical cations **1—3**; it was suggested that the frequency of this process strongly decreases with increasing steric hindrance, and that **3** behaves like an alkyl radical ESR spectroscopically.

By labeling an sp^2 C atom of **3** with ^{13}C we have now been able to demonstrate that the unpaired electron in **3**— and, hence, also in the less hindered radical cations **1** and **2**—is *delocalized*.



1, m = n = 1;
2, m = 1, n = 2;
3, m = n = 2

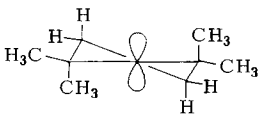
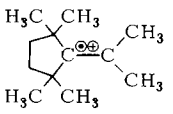
[**] This work was supported by the Fonds der Chemischen Industrie.

The *localized* structure *A* or *B* for **3** was derived from the result that only 12 of the total 24 methyl protons and only four of the total eight methylene protons lead to a splitting of the ESR spectrum. From this is was concluded that the unpaired electron couples with the protons "in *only one* cyclopentylidene-half"[1]. The result is, however, also consistent with a *delocalized* structure $A \leftrightarrow B$, if one assumes that the cyclopentylidene rings occur in conformation *C*[2], which is fixed on the ESR time scale, with a total of four axial and four equatorial methyl groups and methylene protons, of which only one of each type couple with the unpaired electron.

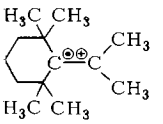
This alternative appears at first to be less attractive, since it must be combined with a high inversion barrier[6b] and infinitesimally small coupling constants for half of the protons[6c]. We obtained evidence, however, that this could be the case by studying the radical cations **4** and **5** ($a^{H}_{\beta\text{-}CH_3} = 1.43$ and 1.38 mT, respectively), which at −90 °C exhibit ESR coupling constants of 0.23 and 0.25 mT, respectively (**3**: 0.203 mT[1]) for *only six* of the twelve γ-methyl protons.



C

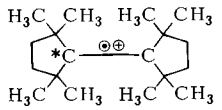


4

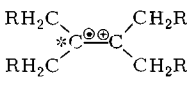


5

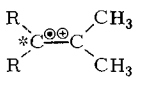
The alternatives should be clearly distinguishable from one another in the ^{13}C labeled radical **3***: *two* coupling constants having values similar to those of a tertiary alkyl radical (*ca.* 4.5 mT for the radical center and *ca.* 1.2 mT for the neighboring sp^2-C atom with the positive charge) are cted for the localized structure. In contrast, for the delocalized structure only *one* coupling constant is expected which—as in the delocalized radical cations **6***[3] ($a^{C} = 0.85$ mT) and **7*** (at −40 °C: $a^{H} = 1.48$ mT (6H), $a^{H} = 0.065$ mT (18H), $a^{C} = 0.86$ mT, $g = 2.0027$)—should be *ca.* 0.9 mT.



3*



6*



7*

* = ^{13}C-labeled; R = $C(CH_3)_3$

We obtained cyclopentanone with a ^{13}C labeled carbonyl group in 38% yield by allowing the dimagnesium compound of 1,4-dibromobutane[4] to react with $^{13}CO_2$ (24% ^{13}C) in tetrahydrofuran; **3*** was then prepared as described[5].

The ESR spectrum of **3*** can be simulated using the proton coupling constants mentioned in [1] and *one* ^{13}C coupling constant of 0.88 mT [6]; this proves the delocalized electronic structure $A \leftrightarrow B$ for **3**. The less hindered radicals **1** and **2** should have the same electronic structure. The temperature-dependent line-width effects observed for **2**[1] may not arise from electron exchange but from ring inversion of the cyclopentyl ring, which because of the smaller steric hindrance takes place with a higher frequency than in **3**.

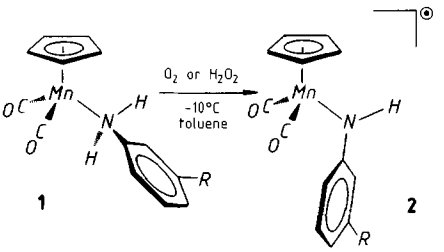
[6] Furthermore, in **3** and **3*** we observed a ^{13}C coupling constant for four C atoms in natural abundance with $a^{C} = 0.98$ mT, which we assign to the C atoms of the four axial methyl groups. b) The barrier must be higher than *ca.* 8 kcal/mol, since even at +30 °C the width of the hyperfine lines is only 0.007 mT, and hence no indication of an inversion process is obvious (F. Gerson, personal communication). c) This is apparent both from the narrow ESR line width and from the fact that no signals near the frequency of the free proton are observed in the ENDOR spectrum (F. Gerson, personal communication).

$C_5H_5(CO)_2Mn$(*m*-Toluidinyl), An Isolable Aminyl Complex**

By *Dieter Sellmann**, *Jürgen Müller*, and *Peter Hofmann*

Aminyl radicals, $^{\odot}NHR$, usually cannot be isolated because of their high reactivity; they are assumed to be intermediates in oxidation reactions catalyzed by metal enzymes (*e.g.* peroxidase) and in the photolysis or radiolysis of amines[1]. During our investigation of redox reactions of metal complexes with nitrogen ligands we succeeded in trapping and stabilizing the toluidinyl radical, which is not isolable as such, in the paramagnetic manganese complex **2**, R = CH_3; to our knowledge this compound represents the first aminyl complex.



1 **2**

If the *m*-toluidine complex **1** (ν_{CO}: 1922, 1847 cm^{-1}, obtained from $C_5H_5(CO)_2Mn(THF)$ and *m*-$CH_3C_6H_4NH_2$ by standard procedures[2a]) is oxidized with air or H_2O_2, the red-brown toluene solution immediately turns deep blue and two new ν_{CO}-bands can be observed IR-spectroscopically at 1968 and 1920 cm^{-1}. After concentration of the solution and addition of hexane the blue-black *m*-toluidinyl complex **2** crystallizes at −78 °C as analytically pure microcrystals[2b].

In the solid state **2** is stable at room temperature for several hours; it is characterized by one ν_{NH}- and two ν_{CO}-bands at 3340 and 1959/1902 cm^{-1} (KBr), by its mass-

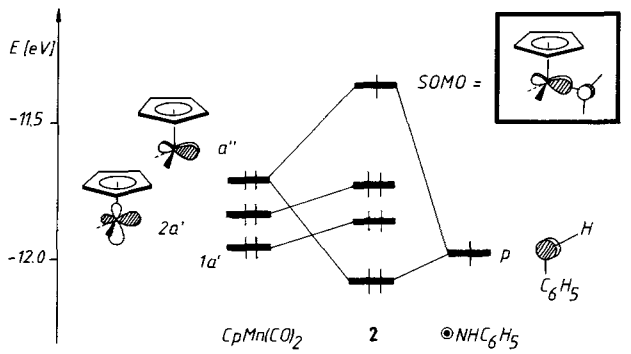
[**] Reactions of Complexed Ligands, Part 34. This work was supported by the Fonds der Chemischen Industrie and the Dr. Otto Röhm-Gedächtnisstiftung. We are indebted to Dr. G. Grampp for recording the ESR spectra.—Part 33: D. Sellmann, H. E. Jonk, H. R. Pfeil, G. Huttner, J. von Seyerl, *J. Organomet. Chem.* 191 (1980) 171.

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/0909-0691 $ 02.50/0

spectrum (FD and EI; M^+ at $m/z = 282$, 70% rel. int.), and by an absorption at $\lambda = 660$ nm ($\varepsilon_{max} = 4060$ L/cm mol). The paramagnetism expected from the empirical formula is confirmed by a magnetic moment of 2.2 μ_B (Gouy-balance). From the observed sextet in the ESR-spectrum (acetone solution, -30 °C) with $a^{55}_{Mn} = 5.0$ mT one can conclude, that the unpaired electron is localized in a molecular orbital with predominant metal character; no coupling to N or H nuclei is observed.

Aminyl complexes like **2** are isoelectronic to radical anions of carbene complexes; according to ESR measurements the unpaired electron of the latter is localized mainly at the carbene ligand[3]. The different electronic structure of both species is revealed by MO calculations[4] on $C_5H_5(CO)_2MnNHC_6H_5$ (**2**, R = H). The geometry of **2** in the structural formula with planar coordination of the N atom is found to be the conformation of lowest energy. The rotational barriers around the N-phenyl and especially the Mn—N bond, however, are very low. The unpaired electron is located in an energetically stable molecular orbital (energy difference to the LUMO *ca.* 3 eV) independent of the conformation; this MO is localized 70—80% in the $C_5H_5(CO)_2Mn$-part of the molecule. As shown in Scheme 1, the SOMO is to be regarded as the antibonding linear combination of the $C_5H_5(CO)_2Mn$-HOMO (a″) with the nitrogen p-orbital. At an orthogonal position of the $^{\odot}$NHR ligand the $C_5H_5(CO)_2Mn$ fragment orbital 2a′, nearly degenerate with a″, takes over the role of the latter; for positions in between an appropriate linear combination of both MO's is utilized.



Scheme 1. Simplified interaction diagram for metal complex fragment [5] and aminyl radical.

Thus, for aminyl complexes like **2** the higher electronegativity of the nitrogen-center compared to carbon causes localization of two electrons as a lone pair at N (lowest level in Scheme 1) and of the unpaired electron in the d-shell of the metal, in accordance with the rules of the perturbation theory. On the other hand, the d-shell of carbene complex radical anions (p in Scheme 1 lies at substantially higher orbital energy) remains fully occupied and the radical electron resides on the ligand-system in the original LUMO of the neutral carbene complex. In a one-electron scheme the lowest absorption in the electronic spectrum of **2** corresponds to a transition from the d-shell to the SOMO with π^*_{dp}-character, analogous to the $d \rightarrow \pi^*_{NN}$-transition in $[C_5H_5(CO)_2Mn]_2N_2H_2$.

Cluster Synthesis by Exchange of Bridge-Forming Carboxylate Ligands**

By *Helmut Werner** and *Peter Thometzek*

Procedures for the directed synthesis of metal clusters from smaller mono- and binuclear synthons are still sparsely documented[1]. We have recently shown that dipalladium complexes $(\mu\text{-X})(\mu\text{-Y})Pd_2(PR_3)_2$ are obtainable by "[1 + 1]-addition" of a Pd^0- and a Pd^{II}-compound, and that a large variety of bridge ligands, such as C_5H_5, 2-RC_3H_4, Cl, SR, RCO_2 *etc.*, have proven suitable in such additions[2].

According to MO calculations by *Hofmann*[3] metal complex anions $[L_nM]^-$ should also be capable of bridge formation with the fragment $(\mu\text{-Y})Pd_2(PH_3)_2^+$ if they contain two donor orbitals of symmetry a_1 and b_2 which can overlap with the corresponding acceptor orbitals of the Pd_2-moiety. This prerequisite is fulfilled, *e.g.*, in the case of the carbonyl(cyclopentadienyl)metalates $[C_5H_5(CO)_nM]^-$ (M = Ni, Fe, Cr; $n = 1, 2, 3$)[3]. In preliminary experiments we were able to demonstrate that, as predicted, the complex $(C_5H_5)(t\text{BuCO}_2)Pd_2(P\text{i}Pr_3)_2$ **1** does in fact react with $[C_5H_5(CO)_3Cr]Na$ and $[C_5H_5(CO)_3Mo]Na$, and that replacement of the carboxylate by the metalate takes place[2d].

This exchange process is, however, not restricted to the anions $[C_5H_5(CO)_3M]^-$. Reaction of **1** and $[(CO)_4Co]Na$ (toluene, 25 °C, 24 h) affords the Pd_2Co-cluster **2** which forms dark violet, permanganate-like crystals (yield 78%). We assume that in **2** the cyclopentadienyl ring and the $(CO)_4Co$-moiety are symmetrically coordinated to the Pd—Pd bond. The ^{1}H-NMR spectrum (C_6D_6) shows, aside from the signals of the $i\text{Pr}_3$P-ligand, a 1 : 2 : 1 triplet for the C_5H_5 protons [$\delta = 5.74$ (t, $J_{PH} = 1.9$ Hz)], whereas the ^{31}P-NMR spectrum (C_6D_6) shows a singlet for the two equivalent phosphorus atoms [$\delta = 37.78$ (s)]. The IR spectrum (KBr) shows bands for both terminal [2029, 2011, 1990, 1961 cm^{-1}] as well as bridging CO groups [1858 cm^{-1}].

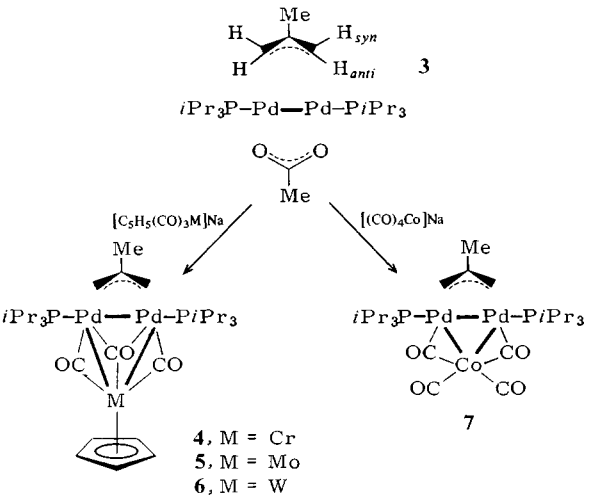
1 2

Reaction of **1** with $[(CO)_5Mn]Na$ does not lead to the expected Pd_2Mn-cluster; instead, $C_5H_5Mn(CO)_3$ is formed, so presumably attack of the metalate at the bridging cyclopentadienyl ring takes place.

The carboxylate bridge in compound **3** is also replacable by one of the complex anions $[C_5H_5(CO)_3M]^-$ (M = Cr, Mo, W) and $[(CO)_4Co]^-$. In toluene (25 °C, 24 h) the Pd_2Cr- and Pd_2Co-clusters **4** and **7** are formed almost quantitatively. With a molar ratio of **3** : $[C_5H_5(CO)_3M]^-$ of *ca.* 1 : 1 the yields of **5** and **6** are considerably lower because the hydrido compounds $C_5H_5(CO)_3MH$ (M = Mo, W) are formed as well as the trinuclear complex. These can be separated by column chromatography on silica gel with pentane and toluene as eluent. In each case, the ^1H-NMR spectra (C_6D_6) show, in addition to the signals for the cyclopentadienyl and phosphane ligands, a virtual triplet for the H_{syn}-, a broadened singlet for the H_{anti}-, and a virtual triplet for the 2-CH_3-allyl protons. After ^{31}P-decoupling the virtual triplets transform into a singlets. The IR spectra (KBr) of **4**—**6** each show three ν(CO) bands at *ca.* 1840, 1770, and 1725 cm^{-1} which are assigned to the doubly and triply bridging CO ligands. The IR spectra of **2** and **7** are very similar. The empirical formulas of the compounds **4**—**7** are confirmed by elemental analyses and field desorption mass spectra.



4, M = Cr
5, M = Mo
6, M = W

The bridge-forming property of the $[(C_5H_5(CO)_3M]$- and $(CO)_4Co$-moieties in Pd^{II} complexes has recently been described in the literature[4]; in these cases, however, owing to the oxidation number II of the palladium no Pd—Pd bonds, and thus no clusters, are strictly present[5].

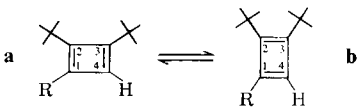
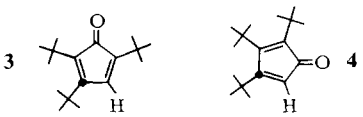
Cyclobutadiene: Mesomerism or Valence Isomerism?**

By *Günther Maier**, *Hans-Otto Kalinowski*, and *Klaus Euler*

Benzene and cyclobutadiene are worlds apart: in benzene the π electrons are completely delocalized and the two Kekulé structures merely serve to describe the mesomerically stabilized molecule. In contrast, in cyclobutadiene[1] both forms **a** and **b**—on condition of a rectangular singlet ground state—are capable of existing in a dynamic equilibrium of valence isomers. We report here the first direct spectroscopic evidence[2] for this postulate. Since the



1, R = t-C_4H_9; **2**, R = t-C_4D_9



equilibrium **1a** ⇌ **1b** could not be frozen (even at −185 °C the olefinic C atoms C-1 and C-3 exhibit a single sharp signal)[3a], we used the isotopic perturbation method of *Saunders*[4], *i.e.* we studied the degenerate equilibrium **2a** ⇌ **2b**.

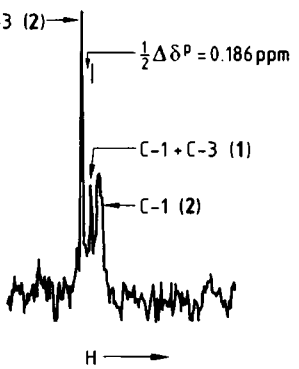


Fig. 1. Part (C-1 + C-3) of the 25.2 MHz ^{13}C-NMR spectrum of a mixture of **1** and **2** (1 : 9) in deuterated diethyl ether at −82 °C.

[**] Small Rings, Part 45. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 44: G. Maier, K.-A. Schneider, K.-D. Malsch, H. Irngartinger, A. Lenz, *Angew. Chem. 94* (1982) 446; *Angew. Chem. Int. Ed. Engl. 21* (1982) 437; *Angew. Chem. Suppl. 1982*, 1072.

2 can be prepared from di-*tert*-butylacetylene and (nonadeuterio-*tert*-butyl)maleic acid anhydride[3]. The ^{13}C-NMR spectrum of a mixture of **1** and **2** differs from that of **1** in that in **2** the signal for C-1/C-3 (**1**: $\delta = 151$) is split. Apparently the deuterium substitution perturbs the equilibrium **2a** $\rightleftharpoons$ **2b** and, in consequence, C-1 and C-3 can be observed separately. Not only C-3, but also C-1 shows practically no intrinsic isotope effect. The high-field signal is broadened by vicinal ^{13}C-D coupling, whereas the low-field signal exhibits no fine structure. We have, therefore, ascribed the splitting to a doubling of the separation between the signal for C-1/C-3 in **1** and the low-field signal for C-3 in **2**. The splitting $\Delta\delta^p$ (p $\triangleq$ perturbation) thus obtained is temperature dependent and increases from 0.30 ppm at $-62\,^\circ C$ to 0.45 ppm at $-96\,^\circ C$ and is 0.37 ppm at $-82\,^\circ C$ (Fig. 1). The temperature dependence of $\Delta\delta^p$ clearly suggests a dynamic equilibrium **2a** $\rightleftharpoons$ **2b** and not a delocalized π system[4b].

Since the chemical shifts for C-1 and C-3 in **2** cannot be determined in the "frozen" state, suitable models must be used to determine the splitting to be expected in the static molecule ($\Delta\delta^{st}$). Neighboring effects as in **2a** and **2b** (coupling of C-1 with C-2 and C-4 *via* a single and double bond; additional *tert*-butyl group at C-3) also occur in the cyclopentadienones[5] **3** and **4**. In this way a value of 8.5 ppm is estimated for $\Delta\delta^{st}$.

$$K = \frac{\Delta\delta^{st} + \Delta\delta^{p}}{\Delta\delta^{st} - \Delta\delta^{p}} \qquad \text{(a)}$$

Using eq. (a)[4] the equilibrium constant $K = 1.0915$ is obtained; this corresponds to a ratio of 52 : 48 for the valence isomers; the temperature dependence of K gives the ground state values $\Delta H^0 = -354$ (± 46) J mol^{-1} and $\Delta S^0 = -1.1$ (± 0.3) J mol^{-1} K^{-1}.

Since the high-field signal in **2**, on the basis of the ^{13}C-D coupling, is assigned to C-1, the equilibrium must be displaced in favor of **2a**. The high-field shift of C-1 is reasonable, since comparison with the cyclopentadienones indicates that in the isomer **3** with substitution pattern analogous to **2a** (double bond to the *tert*-butylated neighbor) the labeled C atom appears at higher field than the corresponding atom in **4**. The preference for **2a** depends on the "steric isotope effect"[4c]: the t-C_4D_9 is smaller than the t-C_4H_9 group and results in a greater reduction in energy in **2a** than in **2b**.

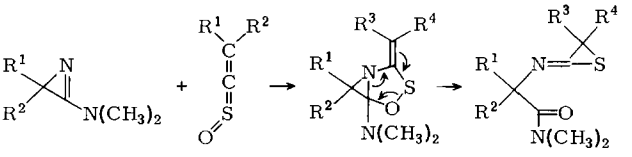
A Novel Method for the Synthesis of Thiiranimines**

By *Ernst Schaumann**, *Hildegard Nimmesgern*, and *Gunadi Adiwidjaja*

Thiiranimines—heterocyclic analogs of methylenecyclopropanes—have hitherto been the subject of very few investigations[1]. We have now found that reaction of 3-dimethylamino-2*H*-azirines **1** with thioketene *S*-oxides **2** provides a surprisingly simple entry to the thiiranimine system **4**. Probably a 1,3-dipolar cycloaddition first takes place with formation of the (not isolated) highly strained bicycle **3**, which then rearranges to **4**. The yields of **4** are generally very good (Table 1); side reactions occur only in the case of 2-methyl-2-phenylazirine **1c**. That the 2-monosubstituted azirine **1b** also reacts smoothly is remarkable, for reactions of this compound normally include hydrogen shifts[4].



1 **2** **3** **4**

Scheme 1. **1a**, $R^1 = R^2 = CH_3$; **1b**, $R^1 = CON(CH_3)_2$, $R^2 = H$; **1c**, $R^1 = CH_3$, $R^2 = C_6H_5$; **2a**, $R^1 = CH(CH_3)_2$, $R^2 = C(CH_3)_3$; **2b**, $R^1 + R^2 = -C(CH_3)_2-(CH_2)_3-C(CH_3)_2-$; **2c**, $R^1 = R^2 = C(CH_3)_3$.

[**] This work was supported by the Fonds der Chemischen Industrie.

As is to be expected for the case of an exocyclic double bond on the three-membered ring[5], the C=N stretching vibration of the products **4** appears at relatively high wave-number (Table 1). An X-ray structure analysis has been carried out on **4f** (Fig. 1). Most striking, though also observed with other hetero-analogous methylenethiiranes[1], are the S—C2 bond length, which markedly exceeds the sum of the covalent radii, and the particularly small bond angle at the sulfur. The exocyclic C=N bond is somewhat shorter than in cyclic thioimidic esters[7].

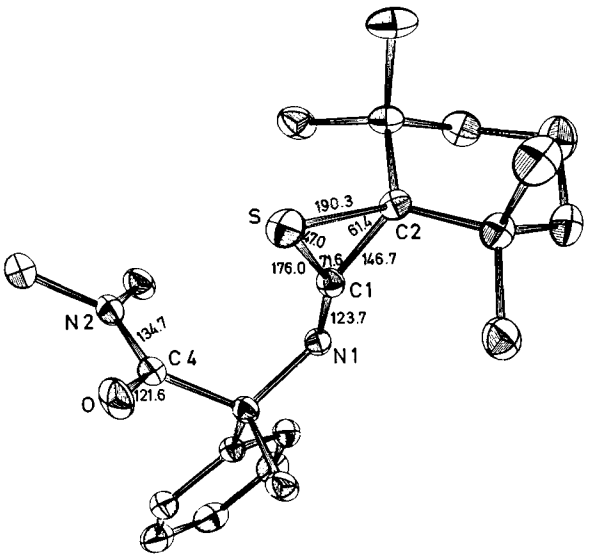

Fig. 1. Molecular structure of **4f** in the crystal, with most important bond lengths [pm] and angles [°] (ORTEP diagram).

The thiiranimines **4** are thermally relatively stable. **4a** cannot be desulfurized, even by heating (diethyl ether, 35 °C, 48 h) with tributylphosphane.

Simple Transformation of the Azulene System into the Pentalene System**

By *Klaus Hafner** and *Michael Goltz*

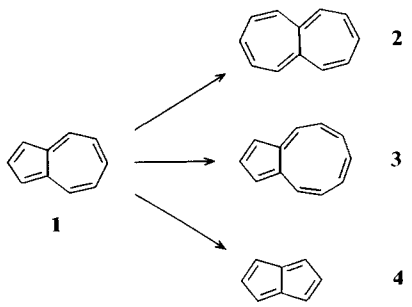
Dedicated to Professor Hermann Stetter on the occasion of his 65th birthday

Cycloaddition reactions of the azulene system **1** with electron-poor and electron-rich alkynes provide a simple entry to derivatives of heptalene **2**[1] and cyclopentacyclononene **3**[2]. We have recently also been able to accomplish the transformation of **1** into the pentalene system **4**.

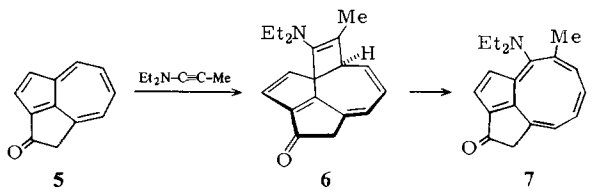
[*] Prof. Dr. K. Hafner, M. Goltz
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

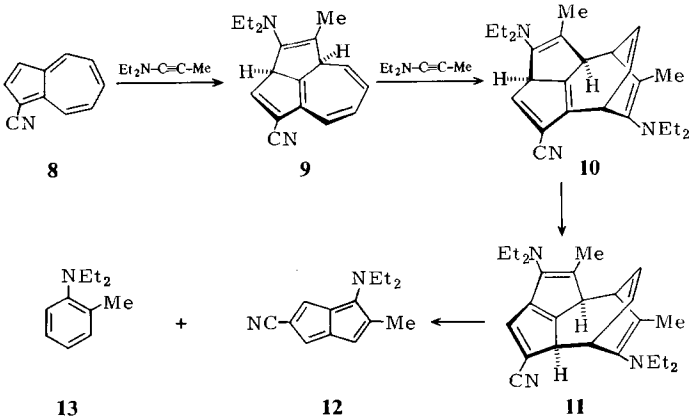
In the homologization of azulene with 1-diethylaminopropyne (**1**→**3**) electron-acceptors in the 1-position strongly influence both the rate as well as the course of the cycloaddition. 2-Oxo-1,2-dihydrocyclopenta[*cd*]azulene



5[3] reacts with 1-diethylaminopropyne even at 25 °C in dichloromethane (14 h) or in benzene (4 d), presumably in a dipolar [2+2]-cycloaddition, to give the non-isolable adduct **6**; valence isomerization of **6** then affords 5-*N*,*N*-diethylamino-6-methyl-2-oxo-1,2-dihydrocyclonona[*cd*]-pentalene **7** (golden yellow crystals, m.p. 167—169 °C (dec)) in 60 or 80% yield, respectively[4,5a]. The analogous reaction of the 1,2-dihydrocyclopenta[*cd*]azulene yields only 43% of the corresponding ring-expansion product after about 20 d[2].



In contrast, 1-azulenecarbonitrile **8** reacts with the same ynamine at 25 °C in dichloromethane (15 min) to give the 4-(*N*,*N*-diethylamino)-5-methyl-2-pentalenecarbonitrile **12** (30%, olive-green crystals, m.p. >110 °C (dec))[5b], which is stable at room temperature and on exposure to air, together with 38% *N*,*N*-diethyl-*o*-toluidine **13**[5c]. In contrast to **5**, the azulene **8** apparently adds the ynamine in the 3,4-position to give the dihydrocyclopenta[*cd*]azulene derivative **9**, whereby the cycloaddition, as in the formation of **6**, may be initiated by a nucleophilic attack of the electron-rich alkyne in the 4-position of the azulene system. This presumably reacts in a subsequent Diels-Alder reaction with inverse electron-demand to give the 1:2 adduct **10**. Isomerization to **11** followed by cycloreversion finally



yields the pentalene **12**, stabilized by donor and acceptor groups, as well as **13**.

Synthesis of Spirorenone—A Novel Highly Active Aldosterone Antagonist

By *Dieter Bittler, Helmut Hofmeister, Henry Laurent, Klaus Nickisch, Robert Nickolson, Karl Petzoldt,* and *Rudolf Wiechert**

Spironolactone (7α-acetylthio-3-oxo-17α-pregn-4-ene-21,17-carbolactone)[1] is a competitive antagonist of aldosterone, the most active natural mineralocorticoid. It has been used therapeutically for approximately twenty years to treat edamatous diseases and essential hypertonia. As a side effect—particularly when used over longer periods of time and at higher doses—endocrinological disorders have been observed, which can be attributed to antiandrogenic and to progestational properties of the compound. In the search for an aldosterone antagonist having increased main activity without relevant side effects, we synthesized 6β,7β:15β,16β-dimethylene-3-oxo-17α-pregna-1,4-diene-21,17-carbolactone, **10**, spirorenone.

The starting material **1**[2], which was hydroxylated microbiologically in the 7β-position using the fungal strain *Botryodiplodia malorum*, was obtained from 3β-hydroxy-5,15-androstadien-17-one by Corey cyclopropanation. Selective esterification of the 3β-hydroxy group of **2a** was performed using pivalic anhydride. According to *Hanson et al.*[3], 7β-hydroxy-Δ^5-steroids react stereospecifically with *tert*-butyl hydroperoxide under vanadium(IV) oxide-acetylacetonate catalysis to afford 5β,6β-epoxides, which can be converted by treatment with Ph_3P/CCl_4 in pyridine into 7β-chloro derivatives. Applying this reaction sequence to **2b** gave the chloro epoxide **4**, which yielded the 5β-hydroxy-Δ^6-derivative **5a** upon reductive elimination of the chlorine atom (Zn/CH_3CO_2H). Saponification with KOH/$NaClO_4$ in methanol results in formation of the 3β,5β-diol **5b**, the key compound for stereospecific cyclopropanation using the Simmons-Smith method (**5b**→**6**)[4]. To form the spirolactone ring, propargyl alcohol was added to the ketone **6**. Hydrogenation of the triple bond followed by oxidation of the tetrol **8** with pyridinium dichromate in dimethylformamide (DMF) led, *via* formation of the α,β-unsaturated ketone and the lactone ring, to compound **9** [UV

[*] Prof. Dr. R. Wiechert, D. Bittler, Dr. H. Hofmeister, Dr. H. Laurent, Dr. K. Nickisch, Dr. R. Nickolson, Dr. K. Petzoldt
Forschungslaboratorium der Schering AG Berlin/Bergkamen
Müllerstrasse 170–178, D-1000 Berlin 65 (Germany)

(MeOH): $\varepsilon_{265} = 19000$; characteristic ^{1}H-NMR data ($CDCl_3$): $\delta = 0.40-0.67$ (m, 1H, cyclopropyl H), 1.01 (s, 3H, 18-H), 1.11 (s, 3H, 19-H), 6.04 (s, 1H, 4-H)]. The lactone **9** was dehydrogenated using 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to afford **10** [UV (MeOH): $\varepsilon_{245} = 12100$, $\varepsilon_{286} = 9950$; characteristic ^{1}H-NMR data ($CDCl_3$): $\delta = 0.42-0.69$ (m, 1H, cyclopropyl H), 1.04 (s, 3H, 18-H), 1.15 (s, 3H, 19-H), 6.18 (dd, $J = 10$ and 2 Hz, 1H, 2-H), 6.34 (d, $J = 2$ Hz, 1H, 4-H), 6.88 (d, $J = 10$ Hz, 1H, 1-H].

The spirolactone derivatives **9** and **10** exhibit in humans an activity equal to *ca.* 5 times that of spironolactone, which corresponds to the activity of these substances found in the rat. Whereas tests with animals indicate that **9** exhibits both progestational and antiandrogenic effects, comparable doses of spirorenone **10** exhibit no antiandrogenic and considerably weaker progestational activity[5].

$[Ag_5I_6]^-$, A One-Dimensional Infinite Anion with 10_5 mc Symmetry

By *Karl Peters, Walter Ott,* and *Hans Georg von Schnering**

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

We have been able to detect polymeric anions $[Ag_nI_{n+1}]^-$ formed during the synthesis of complex silver iodides with large organic cations in organic bases. Structural studies revealed that in these anions AgI_4 tetrahedra are condensed to give one-dimensional infinite polyanions[1,2]. These compounds contain, in part, the anion $^1_\infty[Ag_2I_3]^-$, which was previously obtained as the cesium salt in aqueous solution[3,4].

In the light of the previous reports, the existence of the novel polyanion $^1_\infty[Ag_5I_6]^-$ is surprising. This anion, which has been detected in two compounds for the first time, has a fascinating topology (Fig. 1). $^1_\infty[Ag_5I_6]^-$ has a 10_5 mc rod group symmetry, formed by the cyclocondensation of two groups of 5 AgI_4 tetrahedra. Every group of 5 AgI_4 tetrahedra has an iodine atom in common which occupies the center of the decagonal channel. This atom can be viewed as the additional $I^- : {}^1_\infty[(AgI_{3/3}I_{1/5})_5]^-$. The intensity distribution of the X-ray reflections in the projections parallel to the one-dimensional channel exhibits the Fourier transform of a tenfold structural unit.

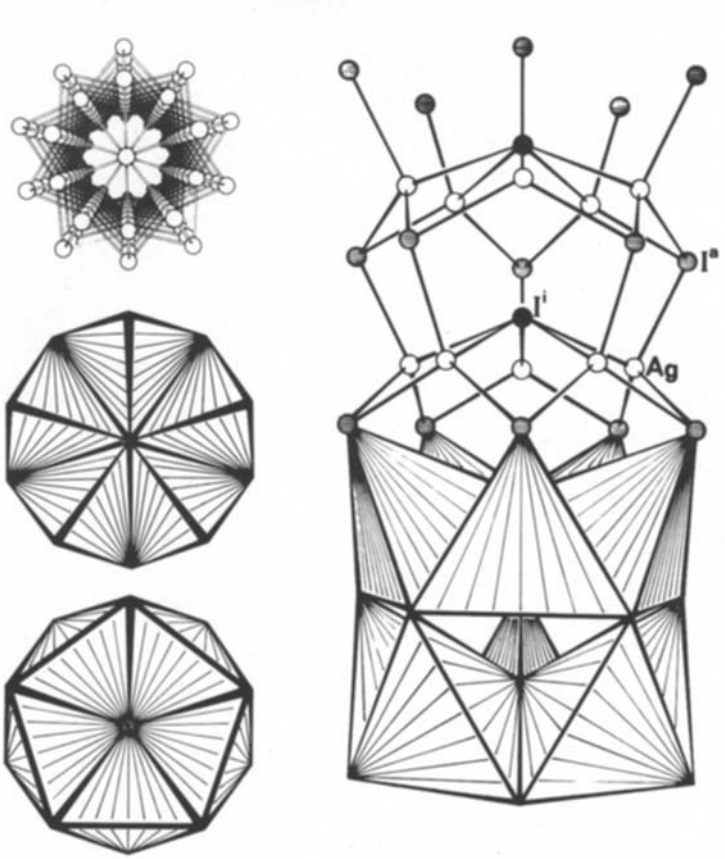

Fig. 1. The polymeric anion $^1_\infty[Ag_5I_6]^-$. Left (top): view along the 10_5 screw axis, sequence of atoms from inside to outside is I^i-Ag-I^a; (middle, bottom): under- and topside of the five condensed AgI_4 tetrahedra. Right: view perpendicular to the decagonal channel.

Both compounds with $[Ag_5I_6]^-$ are formed from a suspension of AgI in the basic solvents L (L = *N,N*-diethylacetamide or *N*-methyl-2-pyrrolidinone) following addition of hydriodic acid, and precipitate as colorless needles upon subsequent addition of acetone. The crystals contain $HAg_5I_6 \cdot 2L$; X-ray structural analysis does not permit determination of the location of the proton. The decagonal columns of anions are arranged parallel to the needle axis and in both crystals form the framework of a primitive-square rod packing, in whose gaps the (in part, protonated) organic bases are located.

In both compounds the Ag—I bond lengths in the polymeric anion differ only slightly and are 297.3 pm, on average, to the central I atom, and 284.2 pm, on average, to the peripheral I atoms.

The structure of this channel-like polymeric anion is a good example for the formation of a symmetry, which is disallowed in 3 D space groups, by reduction of the dimensionality. The assignment of the I^- to the center of the channel is reminiscent of the linear chains of iodine in other compounds[5,6]. They offer an opportunity for modifications—for example by redox reactions.

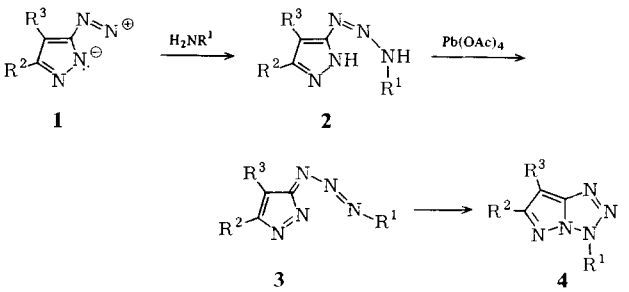
A Ring Building-Up Synthesis of *N*-Glycosides: Dehydrogenation of Glycosyltriazeno-1*H*-pyrazoles**

By *Günter Ege**, *Karlheinz Gilbert*, and *Reinhard Heck*

Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday

In the ring building-up synthesis of *N*-glycosides[2c] the heterocycle is synthesized after the glycosidation step. We report here on a synthetic route which leads to 3*H*-pyrazolo[1,5-*d*]tetrazoles **4**, and which makes *N*-glycosides of this heterobicyclic system as well as related substitution products accessible. 3-Diazo-3*H*-pyrazoles **1** react with primary amines to give 3-mono-substituted 1-pyrazolyltriazenes **2**, which in some cases crystallize out from the reaction solution (CH_2Cl_2) (*e.g.* with $R^2=CH_3$, $R^3=C_6H_5$ when $R^1=4$-$O_2NC_6H_4$ and $R^1=CH_2CO_2CH_3$). Dehydrogenation of the triazenes **2**[3] in solution or in suspension with lead(IV) acetate furnishes the colorless to orange-yellow pyrazolotetrazoles **4**.



1 **2** **3** **4**

This new method for the synthesis of the bicyclic ring system **4** is especially attractive owing to the wide variability that is possible with respect to R^1, R^2, and R^3 (Table 1). Reactions of tetra-*O*-acetyl-2-deoxy-2-glucosamine and of *O*-acetylated pento- and hexo-1-pyranosylamines afford the glycosides **4j—4n**. In the case of **4k—4n** the ^{1}H-NMR spectra ($J_{1,2}=8.5$—9.5 Hz) reveal that the heterocycles are β-glycosidically linked with the sugar moieties. The *N*-glycosides **4k—4n** are stable in the crystalline state, but in protic solvents ring-opening with splitting off of the sugar moiety slowly takes place, giving the corresponding 3-azido-1*H*-pyrazole.

In the course of the novel ring synthesis **1**→**4** the nitrogen atom of a primary amine is incorporated into the heterobicycle in a [7+1]-cycloreaction[5]; a coupling reaction (**1**→**2**) and dehydrogenation (**2**→**3**) are followed by a 1,8-electrocyclization[7] to the 1,2,3,3a,4-pentaazapentalene system **4**.

Table 1. Yields and melting points of **4a—4n**; $R^2=CH_3$ [a].

Alkyl-Substituted 3,4-Dihydro-2*H*-pyrans: Mass Spectroscopy, Synthesis, and Identification as Insect Constituents**

By *Wittko Francke** and *Wolfgang Mackenroth*

Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday

Many of the known insect constituents with nitrogen heterocycles having five- and six-membered ring structures are apparently formed from oxygen-containing precursors. Hence, cyclic azomethines[1,2] may be formed from hydroxy ketones. Direct cyclization of these precursors should lead to cyclic enol ethers not previously isolated from insects. In order to facilitate the identification of sub-

stances of this type in biological material we studied the mass spectroscopic fragmentation of alkyl-substituted 3,4-dihydro-2*H*-pyrans **1**.

	R^1	R^2	R^3	R^4	R^5
1a	Me	H	H	H	Me
1r	Et	Me	H	Me	Et

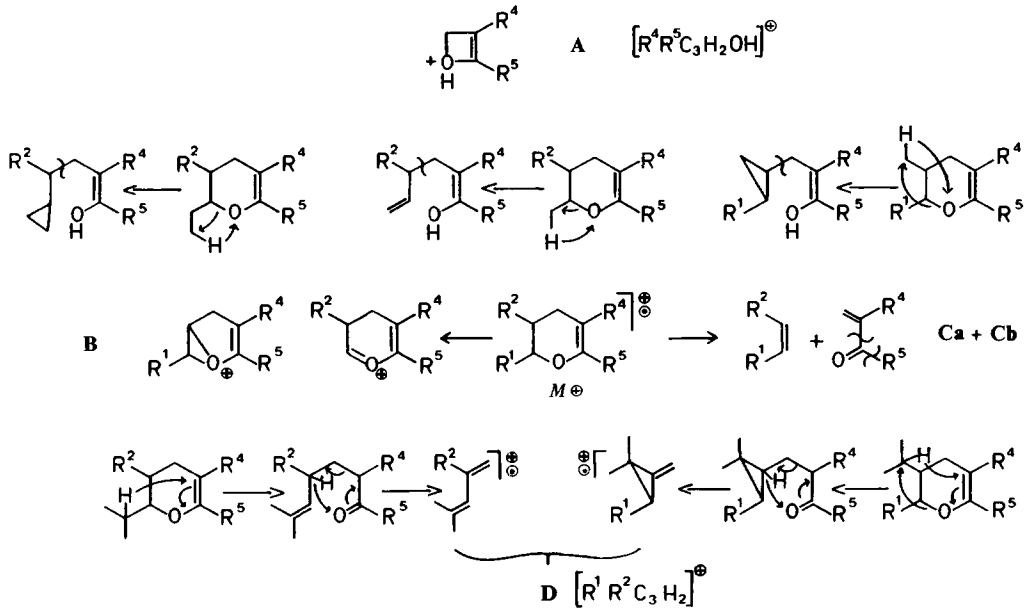
Scheme 1 shows the key ions of these compounds. Additional fragments are less significant. The exact composition of all the ions was determined by high resolution techniques. All of the hydrogen shifts exhibited in Scheme 1 were corroborated by deuterium labeling. Although the structures of the ions are unknown, proposals were made, which reflect elements of the starting structures, in order to give a clear indication of the original substitution pattern.

fragments, occur relatively frequently; occasionally, intense daughter ions from **C** occur.

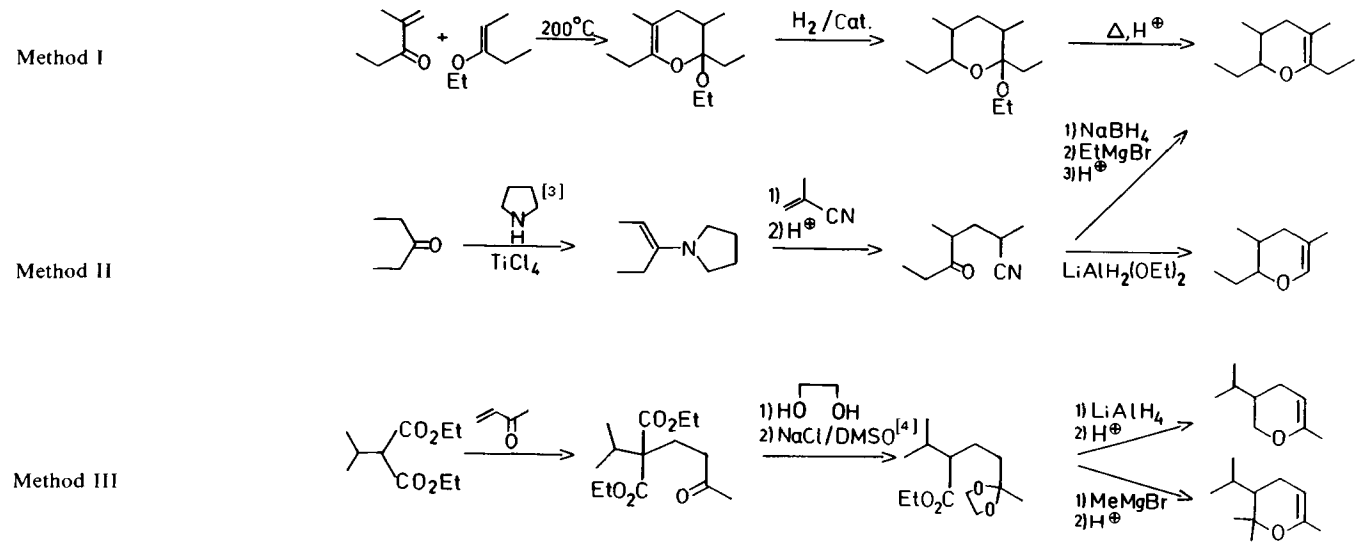
The ions **A** and **D** are formed after hydrogen shift, particularly from substituents R^1 and R^2; their intensity is therefore strongly dependent upon the substitution pattern. If R^1 is ethyl or a higher alkyl moiety, **A** often becomes the base peak of the spectrum.

The alkyl substituted 3,4-dihydro-2*H*-pyrans **1** were synthesized as outlined in Scheme 2.

We were also able for the first time to identify the 3,4-dihydro-2*H*-pyrans **1a** and **1r** as insect constituents. The extremely volatile **1a** occurs in the heads of female honeybee workers *Apis mellifica*, whereas **1r** is a sex pheromone of the female cigarette beetle *Lasioderma serricorne*. In behavioral studies[8], racemic **1r** exhibited a 10^3fold biological activity relative to the open-chain hydroxy ketone[9], which also occurs in the cigarette beetle.



Scheme 1. Schematic representation of the fragmentation pattern of the alkyl-substituted 3,4-dihydro-2*H*-pyrans **1**.



Scheme 2.

All the spectra display pronounced molecular ion peaks and, as expected, intense ions **B**. The products **C** of the retro Diels-Alder cleavage, in particular the hydrocarbon

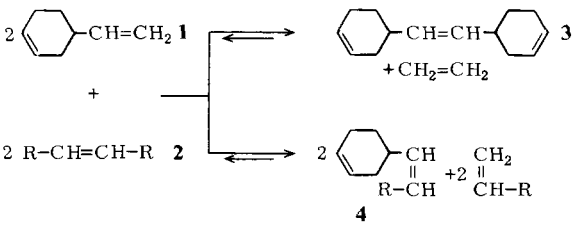
Synthesis of Primary Alkylarenes without Benzene *via* Olefin Metathesis**

By *Siegfried Warwel**, *Heinz Ridder*, and *Wolfgang Winkelmüller*

Dedicated to Professor Friedrich Asinger on the occasion of his 75th birthday

Higher alkylarenes, as important precursors of surfactants, are synthesized on an industrial scale by alkylation of benzene with higher olefins or alkyl chlorides (C_{10}—C_{13}), which always results in structural isomers being formed[3]. We have developed a new synthetic method, which does not require the use of benzene and yields exclusively primary alkylarenes (1-phenylalkanes).

The starting compound in our two-step synthesis is 4-vinylcyclohexene **1**, which is also readily accessible on an industrial scale from butadiene[5]. The carbon skeleton of the primary alkylarenes was obtained by metathesis of **1** with symmetric monoolefins **2** (catalyst: $WCl_6/Et_2O/Sn(n\text{-}C_4H_9)_4$ or Re_2O_7/Al_2O_3).



Of the two possible parallel reactions—homometathesis of **1** to give 1,2-dicyclohexenylethylene **3** and co-metathesis of **1** with **2** to give 1-(3-cyclohexenyl)-1-alkenes **4**—the latter with excess **2** proved to be markedly preferred (see Table 1).

Table 1. Metathesis of 4-vinylcyclohexene **1** with symmetric olefins **2** to give **4** [a].

R	**2**	Conversion of **1** [%]	Selectivity **1**→**4** [%]
CH_3	2-Butene	84	92
$n\text{-}C_4H_9$	5-Decene	84	84
$n\text{-}C_6H_{13}$	7-Tetradecene	82	91
$n\text{-}C_8H_{17}$	9-Octadecene	80	86

[a] Catalyst: $WCl_6 : Et_2O : Sn(n\text{-}C_4H_9)_4 = 1:1:2$; $WCl_6 : \mathbf{1} : \mathbf{2} = 1:165:330$; $CHCl_3$ as solvent: 50 °C; 1 h.

[**] Olefin Metathesis, Part 9. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein Westfalen and the Fonds der Chemischen Industrie. Part 8: S. Warwel, E. Janssen, *Chem.-Ztg. 106* (1982) 266.

With exception of 2-butene, the symmetric olefins **2** employed were prepared by metathesis of α-olefins according to [7]:

$$2\,R\text{—}CH{=}CH_2 \rightleftharpoons \mathbf{2} + CH_2{=}CH_2$$

For the synthesis **4**, however, the α-olefins also could be used directly.

The conversion of **4** into primary alkylarenes was achieved by isomerizing dehydrogenation on K/Al_2O_3 ($K:\mathbf{4} = 1:10$; 120 °C; 2 h; conversion: 100%; selectivity 88—95%).

The isomerization catalyst Na/Al_2O_3 employed by *Ruckelshauss* and *Kosswig*[10] for the synthesis of ethylbenzene from **1** was not active enough. A substantial improvement of this synthetic step was possible with typical hydrogenation-dehydrogenation catalysts. Independent of the chain length of the alkenyl group, **4** could be converted in the gas phase at 350 °C on Pd/Al_2O_3 or Pt/Al_2O_3 in a continuous flow reactor into primary alkylarenes with conversions of >99% and selectivities of 95–98%.

Heterocyclic Radical Anions as Ligands: An Unexpected Change of Coordination in Pentacarbonylmetal Complexes

By *Wolfgang Kaim** and *Volker Kasack*

Heterocyclic π radical anions may act as substituents in carbonylmetal complexes: The σ-coordination *via* the lone pairs of the heteroatom is complemented by the π backbonding from the metal to the half-filled ligand molecular orbital. In the course of studies[1] using hexacarbonylchromium, -molybdenum, and -tungsten we have reacted these complexes in tetrahydrofuran (THF) with reduced 2,1,3-benzochalcogenadiazoles **1**[2]. Formally, these ligands consist of a radical-stabilizing organic part and of an inorganic coordinating component.

The ESR spectroscopic investigation of the substitution behavior has now revealed a remarkable change in the coordination mode. *N,N'*-dicoordinated 1:2 complexes **3** were observed for eight of the nine possible combinations, in some cases the 1:1 intermediate complexes **2** could be identified, too. Spectroscopic effects expected for the $(OC)_5M$ coordination[1] have been observed, such as the occurrence of metal isotope coupling, the increase of the ^{14}N splitting, or the characteristic dependence of g on the nature of the metal (Table 1).

[*] Dr. W. Kaim, V. Kasack
Institut für Anorganische Chemie der Universität
Niederurseler Hang, D-6000 Frankfurt/Main 50 (Germany)

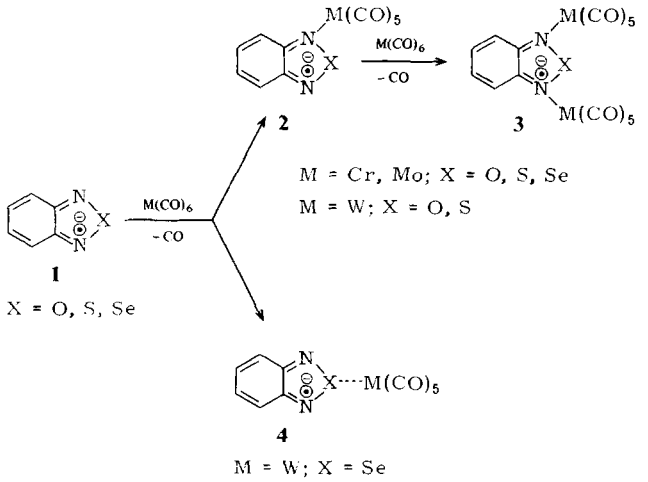

Table 1. ESR data of radical complexes **1**, **3**, and **4**; coupling constants a_x in mT.

Radical	X	M	$a_{H(4)}$	$a_{H(5)}$	a_N	a_M [a]	g
1 [2]	O	—	0.351	0.218	0.561	—	[b]
3	O	Cr	0.243	0.206	0.710	0.056	2.0042
3	O	Mo	0.245	0.206	0.713	0.124	2.0045
3	O	W	0.215	0.202	0.703	0.200	2.0062
1 [2]	S	—	0.259	0.159	0.518	—	[b]
3	S	Cr	0.186	0.160	0.650	0.040	2.0043
3	S	Mo	0.176	0.155	0.633	0.087	2.0046
3	S	W	0.16	0.16	0.640	0.150	2.0065
1 [2]	Se	—	0.248	0.165	0.579	—	[b]
3	Se	Cr	0.17	0.17	0.720	[b]	2.0042
3	Se	Mo	0.16	0.16	0.700	0.098	2.0045
⇒ **4**	Se	W	0.225	0.112	0.641	[b]	2.0056

[a] ^{53}Cr: 9.5%, $I = 3/2$; ^{95,97}Mo: 25.4%, $I = 5/2$; ^{183}W: 14.3%, $I = 1/2$. [b] Not observed or reported.

In contrast, the paramagnetic complex **4** formed on reaction of $W(CO)_6$ with **1**, X = Se, displays a rather different spectroscopic behavior: The ESR splitting pattern (Fig. 1) indicates an at least C_s- or C_2-symmetric species, and the large line width suggests the presence of Se[3]; however, the ^{14}N splitting is significantly smaller than that expected for an *N*-coordination (Tab. 1). The relatively small g value suggests coordination of only *one* $(OC)_5W$ fragment, and finally, the ^{1}H coupling constants are very different from each other (cf. however complexes **3**).

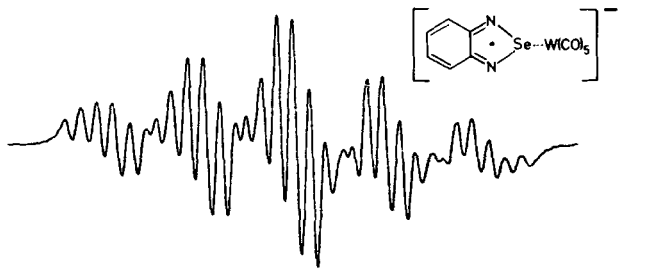

Fig. 1. ESR spectrum of the radical complex **4** at 300 K in THF, counter ion K^+.

The similarity of spin distributions in **4** and in the ligand radical **1**, X = Se, indicates also that the spin bearing π system does not essentially participate in the metal carbonyl coordination. Considering these arguments, we infer a σ coordination of $(OC)_5W$ at the selenium atom[4]; it is especially noteworthy that this differing coordination occurs only with the combination of the heaviest atoms.

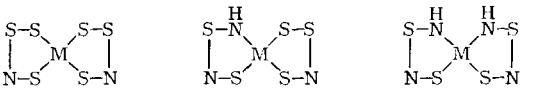
$[(S_3NNi)_3S_2]^{\ominus}$—A Ni_3S_2 Cluster with $S_3N^{\ominus}$ Chelate Ligands**

By *Johannes Weiss**

Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday

Mononuclear complexes such as **1** and **2** with the chelate ligand $[S=N—S—S]^{\ominus}$ have been known for some time as by-products in the synthesis of the M^{II} complexes **3**[1].



Compounds with $S_3N^{\ominus}$ are accessible, however, in other ways[2]. Thus, *Bojes* and *Chivers*[2b] prepared $S_3N^{\ominus}$ from $S_4N^{\ominus}$, which in turn can be obtained from S_7NH[3].

We have now found that metal complexes with the chelate ligand $S_3N^{\ominus}$ can be prepared in alkaline media, without isolation of intermediates, starting from S_7NH. Surprisingly, a trinuclear complex $[(S_3NNi)_3S_2]^{\ominus}$, in which the three $>NiS_3N$ moieties are bridged by two sulfur atoms, is formed in this way with $NiCl_2$. This anion can be isolated as a stable, readily crystallizing tetra-*n*-butylammonium salt[4], whose structure was obtained by X-ray crystallography[5].

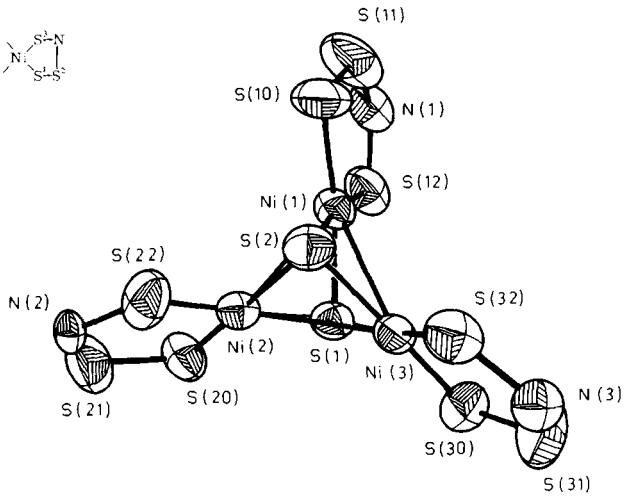


Fig. 1. Structure of the complex anion $[(S_3NNi)_3S_2]^{\ominus}$ in the tetrabutylammonium salt. Average distances [pm]: Ni—Ni 290.4(44), Ni—μ_3-S 220.1(3), Ni—S^1 212.3(2), S^1—S^2 201.4(15), Ni—S^3 212.0(3), S^2—N 145.2(47), S^3—N 175.3(13).

A Novel Three-Dimensional Tellurium Array: High-Pressure Synthesis and Crystal Structure of $AgTe_3$**

By *Klaus-Jürgen Range**, *Manfred Zabel, Franz Rau, Freia von Krziwanek, Rupert Marx*, and *Beate Panzer*

It has long been known that the chain structure of the trigonal, semiconducting tellurium modification[1a] can be derived[1c,d] from the cubic structure of metallic α-polonium[1b] by a relatively slight atom shift. A metallic tellurium modification with α-Po structure[1c] was first discussed almost 35 years ago, but so far it has never been realized[2]. The previously unknown compound $AgTe_3$ of the Ag—Te system, which we have now synthesized under high pressures, contains a three-dimensional array of tellurium atoms that is very closely related to the α-Po structure.

We first detected $AgTe_3$ during the high-pressure decomposition of $AgGaTe_2$ in an NH_4Cl-melt (20 kbar, 900 °C, 60 min). This brittle, golden-colored substance having a metallic luster is formed in the pure state when the respective elements are allowed to react under high pressure ($P > 12$ kbar) in a modified Belt apparatus[3] at $T = 100-1200$ °C (sintered BN high-pressure capsule, 30 min) and subsequently chilled to normal conditions. $AgTe_3$ is only metastable at normal pressure; conversion into the thermodynamically stable mixture of $Ag_{5-x}Te_3$ and Te[4] proceeds quantitatively within a few minutes at 1 bar and 300 °C. This is easily recognizable—especially with larger specimens—by the abrupt transition from golden luster to silver luster.

The crystal structure of $AgTe_3$ is best interpreted in terms of an inner-centered, pseudocubic ($\alpha = 90.15°$) arrangement of the rhombohedral unit cell (Fig. 1). In this arrangement the Ag atoms occupy the center and corners, the Te atoms the face- and edge-centers of a cube. Thus the crystal structure of $AgTe_3$ is the first example of a combination of the (slightly distorted) cubic lattice complexes I and J*[5a] and it should be regarded as an ordered (1:3; Ag:Te) analogue of the α-polonium structure.

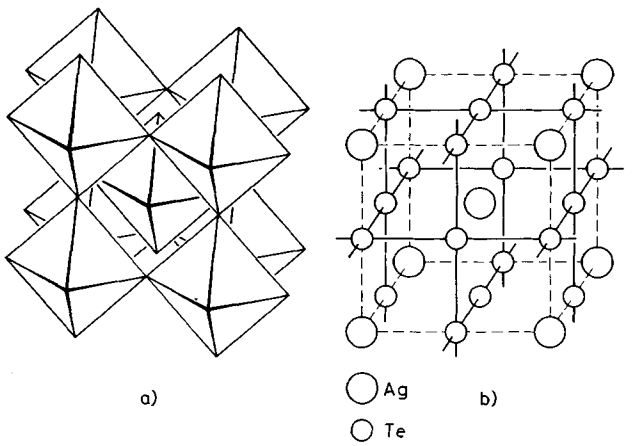

Fig. 1. Section from the crystal structure of $AgTe_3$: a) arrangement of the $AgTe_3$ octahedron, b) three-dimensional array of the tellurium atoms.—Crystallographic data ($T = 293$ K): R3m, $a = 8.645$, $c = 5.272$ Å, $\gamma = 120°$, $Z = 3$; 3 Ag in 3 *a* with $z = 0.0$, 9 Te in 9 *b* with $x = 0.1672$, $z = 0.3413$; $R = 5.53\%$ (207 reflections with $I > 2\sigma(I)$).

Ag is octahedrally coordinated by Te (Ag—Te: 3 × 302.2(5), 3 × 308.3(5) pm), each Te in turn being surrounded by a square arrangement of four further Te atoms together with two Ag atoms to give a $Te(Te_4Ag_2)$ octahedron (distances: 4 × Te—Te 305.2(5), 1 × Ag—Te 302.2(5), 1 × Ag—Te 308.3(5) pm). The Te—Te distances in the three-dimensional array of tellurium atoms are close to the value of 302 pm postulated for metallic tellurium with α-Po structure[1c]; the valence angles at Te are almost 90° (89.79, 89.84, 90.52°). The metallic luster and metallic conductivity ($\rho(20\,K) = 1.5 \times 10^{-6}$, $\rho(300\,K) = 100 \times 10^{-6}\ \Omega$ cm) show that its description as Ag-stabilized cubic tellurium is possible and has more than formal significance.

$AgTe_3$ has a phase width which strongly depends on the pressure used in its preparation. Samples prepared at 25 kbar and 1200 °C exhibit a region of homogeneity from 75.6 to 60.8 atom-% Te. At 10 kbar/1200 °C this region only extends from 75.0 to 73.0 atom-% Te. It follows from density measurements and the intensities of the X-ray reflections that no vacant Te-lattice sites occur in the phases of composition deviating from that of $AgTe_3$, but that a replacement of tellurium by silver corresponding to the formulation $Ag_{1+x}Te_{3-x}$ takes place. About one third of the tellurium in $AgTe_3$ can be replaced by selenium without the structure being changed. Attempts to prepare $CuTe_3$ and $AuTe_3$ have so far not met with success. A phase obtained as a thin film by *Luo* and *Klement*[5b] on rapidly chilling Ag—Te melts is presumably related with $AgTe_3$, but it could not be satisfactorily characterized by X-ray crystallography.

Cleavage of the Metal-Metal Triple Bond by Chelate-Forming Diazoalkane Bridges[1]

By *Wolfgang A. Herrmann**, *Gangolf W. Kriechbaum*, *Manfred Ziegler*, and *Heike Pfisterer*

Dedicated to Professor Klaus Weissermel on the occasion of his 60th birthday

The availability of diazoalkanes to readily undergo addition of their carbene moieties to metal-metal double bonds has recently led to a convenient and high-yield standard method for the synthesis of μ-methylene complexes[2]. This type of reaction has occasionally been observed with metal-metal triple bonds too, but in this case the structure and reactivity of the resulting alkylidene complex is strongly influenced by the nature of the bridging ligands and by the peripheral ligands[3]. We now demonstrate by means of a typical example that α-diazoketones bring about cleavage of the metal-metal bond in the organometal substrate before the elimination of nitrogen and thus are suitable for the synthesis of novel *O,N*-chelate complexes having diazoalkane bridges.

Like diphenyldiazomethane[3a] and other diazoalkanes[3b,4], the α-diazoketone **2** reacts with the molybdenum complex **1** at room temperature with formation of a 1:1 adduct. From the composition and the IR and ^{1}H-NMR data the structure of a μ-diazoalkane complex containing a three-membered M_2N-ring was to be expected for

[**] *Note added in proof* (August 12, 1982): A conventional methylene bridge is present in the complex of composition $(\eta^5\text{-}C_5Me_5)_2Mo_2(CO)_4(\mu\text{-}CH_2)(\mu\text{-}CH_2N_2)$ synthesized from **4** and CH_2N_2 (L. K. Bell, W. A. Herrmann, unpublished results 1982).

the crystalline product **3**, which can be isolated in almost quantitative yield. Surprisingly, however, the X-ray structure analysis showed that **3** fundamentally differs from all previously known organometallic diazo compounds (Fig. 1):

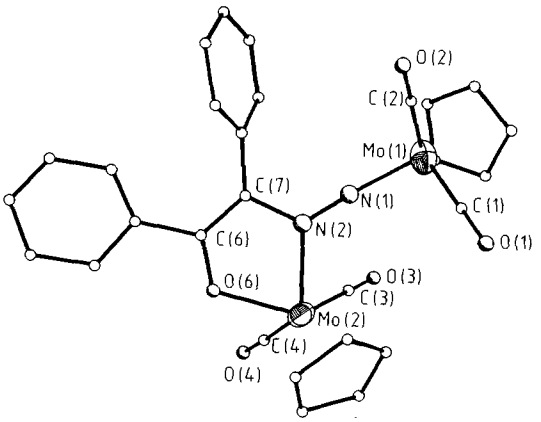

Fig. 1. Structure of the α-diazoketone complex **3** in the crystal. Selected bond lengths [pm] and angles [°]: Mo(1)—N(1) 185.8(4), Mo(2)—N(2) 218.9(4), N(1)—N(2) 125.5(6), N(2)—C(7) 143.8(6), C(6)—C(7) 137.2(7), C(6)—O(6) 131.9(6), Mo(2)—O(6) 211.5(3); Mo(1)—N(1)—N(2) 174.1(3), Mo(2)—N(2)—C(7) 116.6(3), N(2)—C(7)—C(6) 110.7(4), C(6)—O(6)—Mo(2) 118.6(3), O(6)—Mo(2)—N(2) 73.1(1), C(7)—C(6)—O(6) 120.9(4), C(1)—Mo(1)—C(2) 81.6(3), C(3)—Mo(2)—C(4) 75.1(2). — $R = 0.081$, $R_{aniso} = 0.036$.

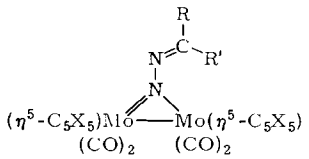
1) Coordination of the diazo ligand **2** causes irreversible cleavage of the MoMo triple bond in **1** [Mo—Mo > 380 pm]; by way of contrast, the addition of π-acidic ligands (*e.g.* diphenyldiazomethane, CO, alkynes, allene) usually proceeds with preservation of the metal-metal bond.

2) The diazo function flanking the carbonyl moiety links the two $Cp(CO)_2Mo$ fragments as a 6-electron bridging ligand which simultaneously accomplishes two very different possible modes of complexation: the terminal nitrogen atom N(1) occupies the coordination gap of the metal atom Mo(1) [Mo(1)—N(1) 185.8(4) pm], which is situated at the center of a tetrahedral coordination polyhedra. While terminal diazoalkanes are known to behave as CO-analogous ligands[12], the present mode of coordination is reminiscent of diazonium complexes of type $Cp(CO)_2M\text{—}N_2CH_3$ (M = Mo, W)[13], with the terminal nitrogen atom N(1) acting as a 3-electron donor. The same electron balance results for the chelating backbone O(6)—C(6)—C(7)—N(2) coordinated to the metal center Mo(2); however, the planar metallacycle thus formed completes a square pyramidal coordination polyhedra characteristic of compounds of type $Cp(CO)_2MLL'$. Additional coordination of the second nitrogen atom N(2) bound to the diazo-carbon might be due to a chelating effect with cooperation of the α-keto group.

Considering the results obtained with the sterically demanding methyl derivative $[(\eta^5\text{-}C_5Me_5)Mo(CO)_2]_2$ **4** as a substrate[4], the versatility of the diazoalkane reactions now manifests itself: In the initial step, the intact diazo compound coordinates *via* one or both nitrogen atoms as bridging ligand; this holds also for the reaction of **4** with **2** or diazocyclopentadiene **5**, when the complexes **6**[4] which are stable at room temperature are formed.

Depending upon the substituents R and R′, the type of structure **6** undergoes the following secondary reactions: a) N_2-elimination with formation of μ-alkylidene deriva-

tives, which as a rule are stabilized by the participation of the substituents (*e.g.* R, R′ = phenyl) in the complexation[**]; b) simultaneous CO/N_2-elimination in the case of



6, X = H, CH_3

diazoalkanes whose carbene moieties have a strong tendency to aromatize (*e.g.* diazocyclopentadiene); c) rearrangement of the diazoalkane bridges with rupture of the metal-metal bond.

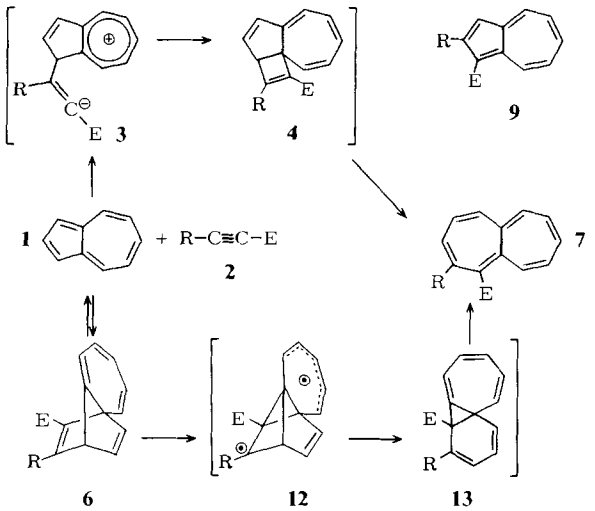
Cycloadditions of Azulene at High Pressure**

By *Frank-Gerrit Klärner**, *Barbara Dogan*, *Wolfgang R. Roth*, and *Klaus Hafner*

Dedicated to Professor William von E. Doering on the occasion of his 65th birthday

Reaction of dimethyl acetylenedicarboxylate **2a** with azulene **1** (boiling tetralin, 207.6 °C) leads to the heptalene-dicarboxylic acid dimethyl ester **7a**[1]. It was presumed that the intermediates **3a** and **4a** are involved. We have now established that high pressure (7 kbar) has an accelerating effect on this reaction and have also been able to isolate an intermediate from which the heptalene derivative **7a** is formed. This result makes it necessary to postulate a new mechanism. The addition of **2a** to **1** at 7 kbar occurs at 50 °C, at which temperature no reaction is observed at atmospheric pressure. After 67 h, apart from **7a** (11.7%) and **9a** (*ca.* 1%), the novel adduct **6a** (39.4%) was isolated (yields relative to reacted **1**; conversion: 19%).

Thermolysis of **6a** (0.09 M in [D_8]toluene, 60 °C, 1 bar, 30 h, conversion: *ca.* 55%) leads, *via* retro-cleavage, to **1** and **2a**, as well as to the heptalene diester **7a** (**1**:**7a** = 4.5). By means of control experiments it was established that under these conditions addition of **2a** to **1** does not occur (each 0.09 M in [D_8]toluene, 60 °C, 30 h). If **6a** is thermolyzed under pressure (0.09 M in toluene, 60 °C, 7 kbar, 30 h, conversion: *ca.* 51%), a greater amount of heptalene diester **7a** is formed (**1**:**7a** = 1.0); however, under these conditions addition of **2a** to **1** is observed (each 0.09 M in toluene, 60 °C, 7 kbar, 30 h, yield: **6a** (13%), **7a** (4%)).



a, R = CO_2CH_3; **b**, R = H
E = CO_2CH_3

1 also reacts with **2b** at 7 kbar and 70 °C to afford the adduct **6b**, although the reaction is very slow and the yield only moderate (*ca.* 1% after 66 h); neither yield nor conversion can be improved by increasing the temperature because at 150 °C the 1-azulene ester **9b** is now formed through cleavage of acetylene from **6b**. Thermolysis of **6b** at 80 °C, both at 7 kbar and at 1 bar (126 h, 70–80% conversion in each case) leads only to **1** and **2b**. In no case is the 1-heptalene ester **7b** formed.

These results cannot be accounted for by the reaction mechanism originally postulated. The intermediate **4a** is also not observed at 60 °C[7]. Apparently, **6a** is an intermediate on the route to the heptalene derivative **7a**. The question of whether the reversible reaction **1** + **2** ⇄ **6** proceeds *via* the dipolar intermediate **3** or by concerted [4+2]-cycloaddition[8] remains open. Here, the effect of pressure is less revealing. In both cases a strongly negative volume of activation is expected[9]. Since **6a** reacts 22 times faster than **6b** at 80 °C, we presume that a concerted Diels-Alder reaction occurs.

The different thermal behavior of **6a** and **6b** suggests the diradical intermediate **12a** is involved in the rearrangement **6a** → **7a**; **12a** is transformed into the norcaradiene **13a**, which can readily react further to **7a** *via* valence bond isomerization[10]. Formation of the diradical interme-

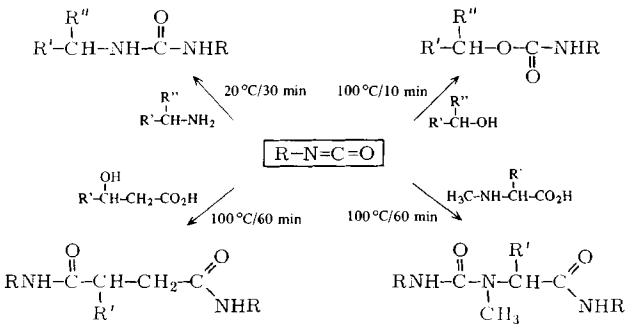
Isocyanates as Universal Reagents for the Formation of Derivatives for Gas Chromatographic Enantiomer Separation**

By *Ingrid Benecke* and *Wilfried A. König**

Hitherto, the formation of volatile derivatives for the gas chromatographic separation of enantiomers on chiral stationary phases required several different reaction steps, depending on the class of substance in question. We have now achieved this aim in only *one* step for some important classes of compounds by using isocyanates as reagents (Scheme 1). The separation effects, as obtained by the formation of diastereomeric association complexes between the chiral sample molecules and the chiral stationary phase, are considerably increased by the carbamate-, ureido- or amide-derivatives, which are obtained on reaction with isocyanates.

In this way the eight stereoisomers of menthol could be separated as *N*-isopropylcarbamates[8]. Chiral alcohols are



Scheme 1. (Selection) Reaction of isocyanates (R = CH_3, $CH(CH_3)_2$, $C(CH_3)_3$, C_6H_5) with amines, secondary alcohols, β-hydroxycarboxylic acids and *N*-methylamino acids (R′ ≠ R″ = alkyl, aryl).

[*] Prof. Dr. W. A. König, I. Benecke
Institut für Organische Chemie und Biochemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

of considerable importance in flavor and pheromone chemistry. For the first time β-hydroxy acids can now be separated as well as α-hydroxy acids[9]. Such acids frequently occur as natural metabolites or as chiral constituents of natural products. The formation of derivatives is simple: On heating *ca.* 0.1 mg of the sample for 1 h in isopropyl isocyanate and dichloromethane (1 : 2 v/v) the *N*-isopropyl-β-(*N*-isopropylcarbamoyloxy)alkane amides are readily obtained. The preparation of amides by heating carboxylic acids and isocyanates[11] has been known for some time but has never been used in microanalysis.

By analogy, the procedure mentioned here allows for the first time the preparation of derivatives of *N*-methylamino acids which are suitable for direct enantiomer separation. *N*-Methylamino acids frequently occur as constituents of peptide antibiotics and have gained increasing importance in peptide synthesis. Under the conditions described here the ureido derivatives are obtained in only *one* step. A racemization test for *N*-methylamino acids is of particular interest because of the strong tendency of such acids to undergo racemization during peptide coupling[14].

Chiral amines, which could be separated as *N*-trifluoroacetyl derivatives only on special stationary phases, readily form *N*-isopropylureido derivatives even at room temperature. They are separated with unusually high separation factors[9]. The same is true for α-branched amino acid derivatives and carboxylic acids.

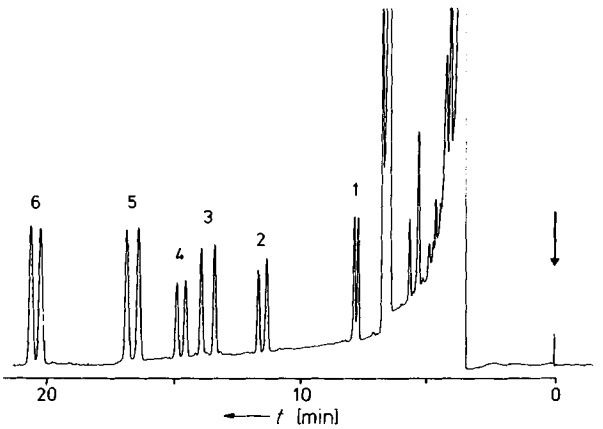


Fig. 2. Separation of racemic mixtures of 2-phenylbutanoic acid **1**, *S*-enantiomer = 2nd peak; lactic acid **2**, L-enantiomer = 2nd peak; 2-hydroxybutanoic acid **3**, L-enantiomer = 2nd peak; *N*-methylvaline **4**, D-enantiomer = 2nd peak; 2-amino-6-methylheptane **5**, no peak assignment; 3-hydroxybutanoic acid **6**, no peak assignment. Derivatives were obtained as shown in Scheme 1 by reaction with isopropyl isocyanate. Glass capillary (borosilicate glass, 40 m, 0.2 mm i.d.) coated with XE-60-L-valine-(*S*)-α-phenylethylamide [7], $T = 190\,^{\circ}C$ (Carlo Erba Model 2101 A gas chromatograph, carrier gas: 0.7 bar H_2).

The carbamate-, ureido-, and amide-derivatives, prepared with isopropyl isocyanate as universal reagent, are stable over months in solution; no racemization during formation of derivatives has been observed so far.

Chemistry of Coal Utilization, Second Supplementary Volume. Edited by M. A. Elliot, Wiley-Interscience, New York 1981. 2374 pages, bound, $ 165.00.

The American "Chemistry of Coal Utilization", a handbook that has already become a classic and that is certainly unique in its scope and treatment of the material, has now been updated by the appearance of the second supplementary volume, after the original two-volume work of 1945, edited by *H. H. Lowry*, was first supplemented in 1963. As in the case of the previous volumes, a committee of the National Research Council of the U.S. National Academy of Sciences assumed the sponsorship of the new supplementary volume which, under the new editor *Elliot—Lowry* died ten years ago—includes contributions from 60 well-known authors. In continuation of the earlier work, detailed information is given not only on coal chemistry in the narrower sense but also, with the exception of mining technology, on all technologies for the utilization and upgrading of coal and on the conversion of coal into energy, fuels, and chemical raw materials. In spite of the primary aim to take up the story at the point at which the review of the first supplementary volume ended, *i.e.* essentially to give a critical review of the literature between about 1958 and the second half of the seventies and to describe further developments in this period, to a large extent the result has been an almost textbook-like account rather more suitable for advanced readers. Specifically, the 31 chapters deal with the coal industry, coal research and development (an overview written by the editor himself); coal resources (only the deposits of the United States are treated in detail); origin, petrography, and classification of coal; physical properties of coal and coal products; mechanical properties; plastic properties; analysis of coal, trace elements, and mineral constituents; chemical reactions and chemical constitution of coal; transport, storage, and handling; preparation; briquetting; pyrolysis and hydropyrolysis (3 chapters); solid pyrolysis products; coal tar (2 chapters); coke-oven gas; combustion of coal (2 chapters); coal ash—its effect on combustion; control of pollution from combustion processes; gasification of coal (3 Chapters); underground gasification of coal; liquefaction of coal (3 chapters); conversion of coal and coal gases into fuels, chemicals, and other products; and environmental health and safety implications of increased coal utilization.

On the whole, it must be said that the compilation and organization of the enormous volume of material has been highly successful. Overlapping between individual chapters, unavoidable because closely related subjects are treated by different authors, is kept to reasonable limits. The reviewer is not in a position to judge to what extent is has been possible to take into account the literature and all the developments of the various technologies. After all, the quality of the contribution depends in the final account on the knowledge, experience, and carefulness of the particular author (information about the professional career and the present position of each author is given by brief biographies at the beginning of the chapters). Apart from some contributions from the United Kingdom, Australia, and the German Federal Republic, the majority of the chapters have been written by American authors. In reading some chapters one cannot quite escape the (subjective) impression that the account, particularly of the economic and technical developments, is frequently limited substantially to the situation in the United States. For example, in Chapter 28 (Liquefaction Processes) all the American processes for direct liquefaction of coal are described in detail, whereas there is nothing about the corresponding developments of the National Coal Board in the United Kingdom and there are only a few lines on the "IG Nue Process" [*sic*] in Germany, by which is meant the new activities in connection with the hydrogenation of coal, based on the old IG process. A partial explanation for this shortcoming may be that these European developments really started up only in the mid-seventies, not long before the early editorial deadline (depending on the chapter, between August 1976 and the end of 1978). Other examples could be quoted. Another point of criticism relates to the use of units: it must be just as annoying for the English or American reader when, for example as on page 1782, temperatures are given in degrees Fahrenheit and enthalpies in Btu/lb-mole in one place and four pages later the same author uses Kelvin and kcal/g-mole!

The extensive subdivision of the text by heading makes for clarity, the graphic presentation including the figures and tables is excellent, and the citation of references in footnotes on the same page is exemplary. Small mistakes and printing errors do not appear to exceed the usual quota. The subject index, however, leaves something to be desired.

All in all, this second supplementary volume in combination with the earlier work offers a unique compilation, of inestimable value, of the scientific and technical literature on coal. No library should therefore delay in getting this supplement to their "Lowry". But even without the earlier volumes, which, by the way, can still be obtained as reprints, the book will be highly valuable for the interested specialists, if not indeed indispensable.

Building Bridges Between Inorganic and Organic Chemistry (Nobel Lecture)**

By Roald Hoffmann*

Robert B. Woodward, a supreme patterner of chaos, was one of my teachers. I dedicate this lecture to him, for it is our collaboration on orbital symmetry conservation, the electronic factors which govern the course of chemical reactions, which is recognized by half of the 1981 Nobel Prize in Chemistry. From Woodward I learned much: the significance of the experimental stimulus to theory, the craft of constructing explanations, and the importance of aesthetics in science. I will try to show you how these characteristics of chemical theory may be applied to the construction of conceptual bridges between inorganic and organic chemistry.

Fragments

Chains, rings, substituents—those are the building blocks of the marvelous edifice of modern organic chemistry. Any hydrocarbon may be constructed on paper from methyl groups (CH_3), methylenes (CH_2), methynes (CH), and carbon atoms (C). By substitution and the introduction of heteroatoms all of the skeletons and functional groupings imaginable, from ethane to tetrodotoxin, may be obtained.

The last thirty years have witnessed a remarkable renaissance of inorganic chemistry, and the particular flowering of the field of transition-metal organometallic chemistry. The complexes **1**—**9** are a selection of some of the simpler creations of the laboratory in this rich and ever-growing field.

Structures **1**—**3** illustrate at a glance one remarkable feature of transition-metal fragments. Here are three tricarbonyliron complexes of organic moieties—cyclobutadiene, trimethylenemethane, and 1-hydroxy-1,3-butadiene—which on their own would have little kinetic or thermodynamic stability. Yet complexed to $Fe(CO)_3$ these molecules are relatively stable: they exist in a bottle. The inorganic fragment is not merely a weakly attached innocent bystander: it transforms essentially and strongly the bonding relationships in the molecule.

Structures **4**—**6** contain the ubiquitous cyclopentadienyl ligand (Cp), two of them in the archetypical ferrocene, one in $CpMn(CO)_3$, two bent back in $Cp_2Ti(CO)_2$. Structures **7**—**9** introduce us to the simplest representatives of the

burgeoning class of clusters—assemblages of two or more metal atoms embellished with external ligands.

If we seek order, unity, a way of thinking about these complexes, it is not difficult to perceive that the molecules contain as building blocks transition metal-ligand fragments, ML_n, such as $M(CO)_5$, $M(CO)_4$, $M(CO)_3$, or MCp. It must be said immediately that there is nothing special about the carbonyl ligand. It is merely a representative and common component of organometallic complexes. Phosphanes, olefins, alkyls will do as well.

To reconstruct the complexes **1**—**9**, we need to know the electronic structure of the fragments. For the simple qualitative picture of the bonding in these molecules that we seek, we do not need to know every last detail of the electronic structure of each molecule. It will suffice that we know the frontier orbitals of the fragments—the higher occupied and the lower unoccupied levels—in other words the valence active orbitals of each fragment. It is *Kenichi Fukui* who taught us the importance of the frontier orbitals. We shall soon see that it is the resemblance of the frontier orbitals of inorganic and organic moieties that will provide the bridge that we seek between the subfields of our science.

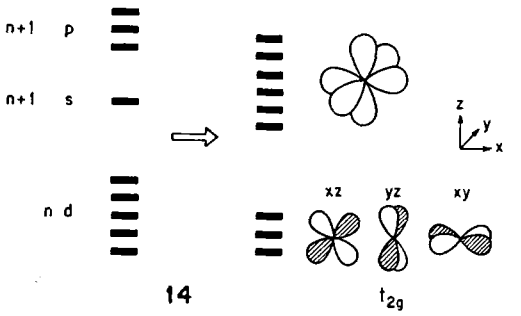
Over the last eight years my coworkers and I have built up a library of the orbitals of ML_n fragments[1-3]. We have done so using entirely qualitative, approximate molecular orbital calculations of the extended Hückel type (a procedure for its time, developed with another of my teachers, *William N. Lipscomb*) and symmetry arguments (the value of which I first learned from still another of my teachers, *Martin P. Gouterman*). Molecular orbital theory, *Robert S. Mulliken*'s great contribution to chemistry, is fundamental to our approach, be it in the construction of the very orbitals of the fragments, their changes on molecular deformation, or the interaction of several such fragments to restore the composite molecule. Yet when I seek the simplest of all possible ways to tell you of the orbitals of these fragments, I am led back to the valence bond picture introduced into chemistry by *Linus Pauling*[4].

Let us go back to the building blocks. The general fragments ML_n, **10**—**13**, may be viewed in many ways. One convenient approach is to consider them as pieces of an octahedron.

10 **11** **12** **13**

This is quite analogous to perceiving CH_3, CH_2, and CH in a tetrahedron. If not a unique viewpoint, it is a useful one. Given that we have an octahedron, or pieces thereof, let us prepare the metal atom for octahedral bonding, and then introduce the appropriate number of ligands.

The valence orbitals of the transition metals are nd, (n+1)s and (n+1)p, with n=3, 4, 5. To prepare the metal atom for bonding we must form six equivalent octahedral hybrids. This is accomplished (cf. **14**), by using all of the s and p functions and two of the d's. Three d functions, d_{xz}, d_{xy}, and d_{yz}, are left unhybridized. They may be described as the t_{2g} set of the crystal field, ligand field, or molecular orbital theories of an octahedral complex[5].



14 t_{2g}

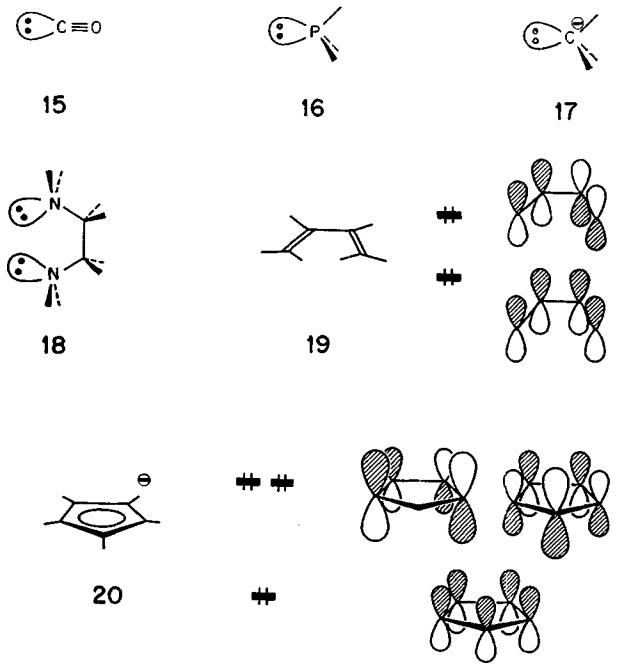
To form an octahedral complex we would introduce six ligands to make use of the six octahedral hybrids. Perhaps it is appropriate to digress here and make clear our ligand convention, which is to consider the ligand always as an even-electron Lewis base. While acceptor character or Lewis acidity is a desirable feature in a ligand, Lewis basicity or donation is essential. We see the basicity in the form of the lone pairs of CO, PH_3, and CH_3^- (**15**—**17**), in bidentate four-electron ligands, be they ethylenediamine (**18**) or butadiene (**19**), or in the electronically tridentate $C_5H_5^-$ (Cp^-, **20**), the equivalent of three two-electron bases[6].

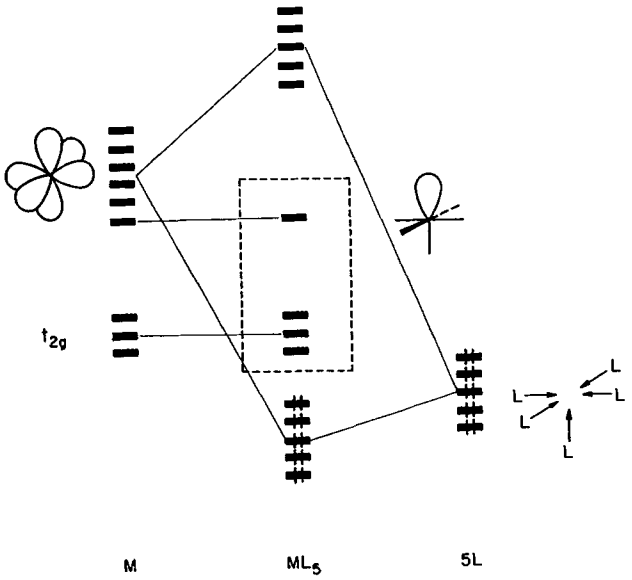
Let six two-electron ligands approach the metal atom prepared for octahedral bonding (cf. **21**). Sizable σ overlaps lead to formation of strongly metal-ligand σ bonding combinations, and their strongly metal-ligand σ* antibonding counterparts. The six electron pairs of the ligands enter the six bonding combinations. Any electrons the metal contributes enter the t_{2g} orbital left behind. Indeed, for $Cr(CO)_6$ with its 6 metal electrons we attain a nice closed shell configuration, a situation we have learned to associate with relative kinetic and thermodynamic stability in organic chemistry.

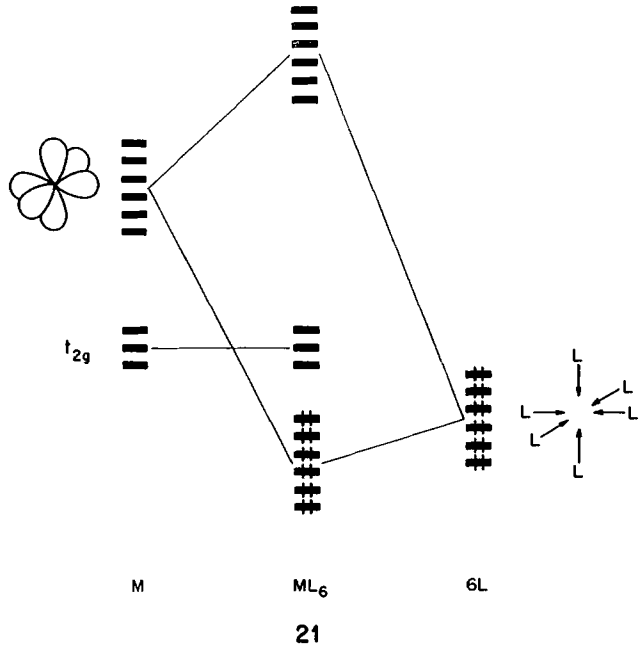
What if we have not six ligands coming in, but only five? This situation is depicted in **22**. Five hybrids interact strongly, are removed from the frontier orbital region, just as all six were in **21**. One hybrid, the one pointing toward where no ligand is, remains roughly untouched, relatively low-lying in energy. The frontier orbitals, enclosed in a dashed box in **22**, now contain the t_{2g} set plus one hybrid.

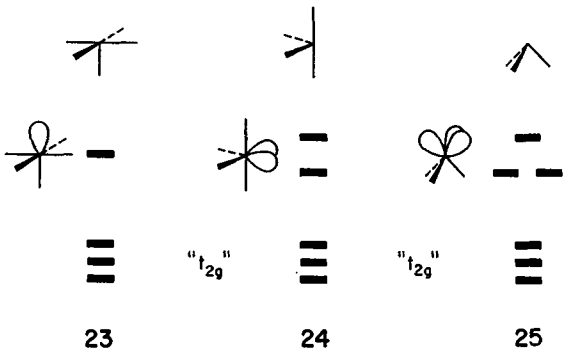
What if we have four ligands (ML_4) or three (ML_3)? Much the same thing happens. In ML_4 two hybrids are left behind, in ML_3 three. We have thus reached the simplest of all possible pictures of the electronic structure of the ML_n fragments with n=5, 4, 3, namely that given in **23**—**25**. The ML_n fragment's frontier orbitals consist of the descendants of an octahedral t_{2g} set at relatively low energy, and above them 6−n (one for n=5, two for n=4, three for n=3) hybrids pointing toward the missing octahedral vertices.

What remains is to decide how many electrons to place into these frontier orbitals, and here the ever-useful Mendeleev Table, modified in **26** for electron counting purposes, tells us that Fe in oxidation state zero will have eight electrons in $Fe(CO)_4$ or $Fe(CO)_3$, and so will Co^I or Ni^{II}.









4	5	6	7	8	9	10

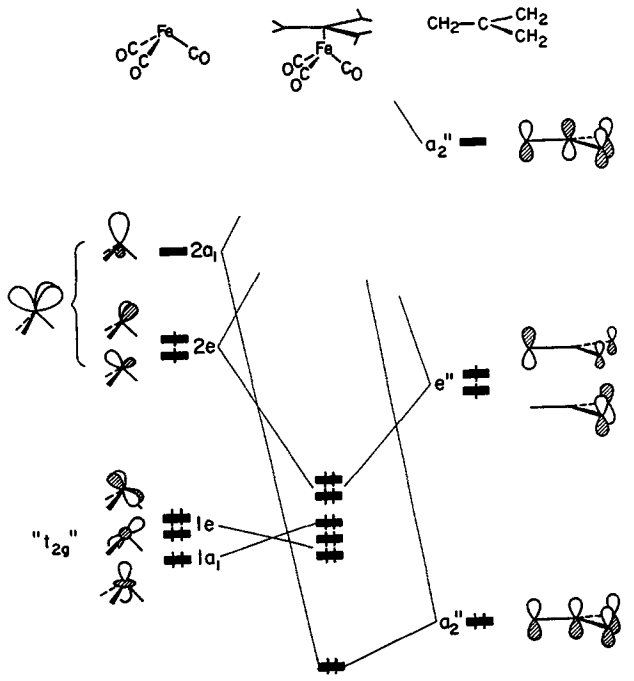
Zr	Nb	Mo	Tc	Ru	Rh	Pd
Hf	Ta	W	Re	Os	Ir	Pt

26

The reader had best beware. The account given here is simplified, as much as I dare simplify it. In that process, perforce, is lost the beautiful detail and complexity that makes $Fe(CO)_3$ different from $FeCl_3^{3-}$. There is a time for detail and there is a time for generality. The reader of my papers will know that my coworkers and I do not stint on detail, whether it is in explication or in perusal of the literature. But the time now, here, is for building conceptual frameworks and so similarity and unity take temporary precedence over difference and diversity.

Recall that the reason for building up the frontier orbitals of inorganic fragments is that we wish to use these orbitals in the construction of organometallic and inorganic complexes. We are now ready for that task. For instance, if we want tricarbonyl(trimethylenemethane)iron we construct a molecular orbital interaction diagram (cf. 27). On one side are the orbitals of $Fe(CO)_3$ just discussed, on the other side the older, better known frontier orbitals of $C(CH_2)_3$. We interact the two, using the full armament of group theory and perturbation theory[7] to follow what happens.

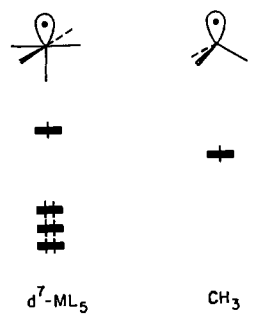
I will not trace this argument any further, for the primary purpose of this lecture is not the description of the electronic structure of organometallic complexes. My coworkers and I have done this comprehensively elsewhere[1,8]. Instead, I wish to describe a bridge between organic and inorganic chemistry that becomes possible the moment we gain knowledge of the orbitals of the ML_n fragments.



27

The Isolobal Analogy

Consider the d^7-fragment, $Mn(CO)_5$ (or $Co(CN)_5^{3-}$). Above the three lone pairs in the t_{2g} set this doublet molecule has a single electron in a hybrid pointing away from the ML_5. The similarity to CH_3, the methyl radical, is obvious (cf. **28**).



28

The representation **28** is, of course, schematic. Figure 1 shows the a_1 orbitals of MnH_5^{5-} and CH_3, so as to provide a more realistic comparison.

If d^7-ML_5 is like CH_3 then they should both behave similarly. Let us think about what a methyl radical does. It dimerizes to ethane and starts radical chains. $Mn(CO)_5$ or $Co(CN)_5^{3-}$ do similar things. They dimerize to $Mn_2(CO)_{10}$ or $Co_2(CN)_{10}^{6-}$ (cf. **29**), and each has a rich radical-type chemistry[9]. One can even codimerize the organic and inorganic fragments to give $(CO)_5MnCH_3$. That may not be the preferred way to make this quite normal organometallic alkyl complex in the laboratory, but the construction on paper is quite permissible.

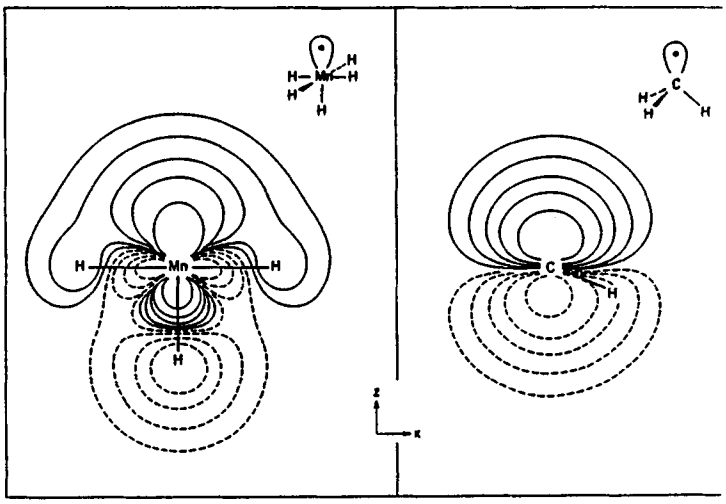


Fig. 1. Contour diagram of the isolobal a_1 orbitals of MnH_5^{5-} (left) and CH_3 (right), as computed by the extended Hückel method. The contours of Ψ, plotted in a plane passing through Mn and three H's (left) and C and one H (right), are ± 0.2, ± 0.1, ± 0.055, ± 0.025, ± 0.01.

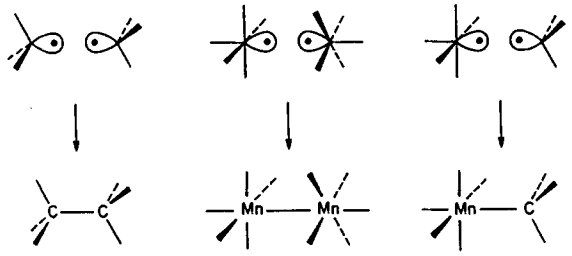

29

CH_3 and d^7-ML_5 resemble each other. Another way we can see that resemblance, traceable to their singly occupied a_1 orbitals, is to compare the overlap of both orbitals with a probe ligand, let us say a hydrogen atom. This is done in Figure 2. Note the remarkable parallelism of the two overlaps. The H—CH_3 overlap is everywhere smaller than the H—MnL_5 overlap, but the dependence of both on the distance is quite similar.

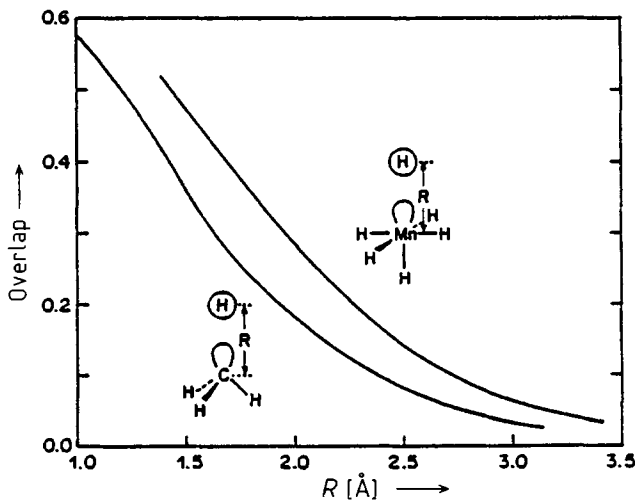

Fig. 2. Overlap integrals between the a_1 frontier orbital of MnH_5^{5-} and CH_3 and a H 1s orbital at a distance R from the Mn or c atom.

A word is needed to describe the resemblance of the two fragments, CH_3 and d^7-ML_5. They are certainly not isostructural, nor are they isoelectronic. However, both possess a frontier orbital which looks approximately the same for the two fragments. We will call two fragments *isolobal* if the number, symmetry properties, approximate energy and shape of the frontier orbitals and the number of electrons in them are similar—not identical, but similar[10]. Thus CH_3 is isolobal with $Mn(CO)_5$. We will introduce a symbol for the isolobal relationship: a "two-headed" arrow with half an orbital below. Thus,

$CH_3 \leftrightarrow Mn(CO)_5$

Let's extend the definition a little:

1) If $Mn(CO)_5$ is isolobal with CH_3, so are $Tc(CO)_5$ and $Re(CO)_5$, as well as $Fe(CO)_5^+$. The shape of the a_1 hybrid will vary slightly with different principal quantum numbers, but essentially it is only the d-electron count that matters.

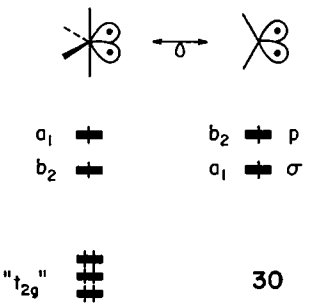
2) If $Mn(CO)_5$ is isolobal with CH_3, then $Cr(CO)_5$, $Mo(CO)_5$ or $W(CO)_5$ are isolobal with CH_3^+, and $Fe(CO)_5$ (square pyramidal!) is isolobal with CH_3^-.

3) If $Mn(CO)_5$ is isolobal with CH_3, so are $Mn(PR_3)_5$ or $MnCl_5^{2-}$ or any d^7-ML_5 species. And so is $CpFe(CO)_2$, a ubiquitous fragment. The procedure here is to write $CpFe(CO)_2$ as $Cp^-Fe^+(CO)_2$, and to replace the Cp^- by its isolobal equivalent of three carbonyls, reaching $Fe(CO)_5^+$, which is isoelectronic with $Mn(CO)_5$.

Let us go on to the ML_4 fragment. It is clear that a d^8-ML_4 species, *e.g.* $Fe(CO)_4$, is isolobal with a methylene or (carbene, CH_2).

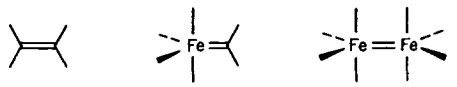
$Fe(CO)_4 \leftrightarrow CH_2$

As **30** reveals, both fragments have two electrons in delocalized a_1 and b_2 orbitals which are the equivalent of two localized hybrids. There are explicable differences in the ordering of the two combinations[11]. The different ordering has, however, no grave consequences—recall that we are not so much interested in the fragments themselves as in their bonding capabilities. The moment we interact $Fe(CO)_4$ or CH_2 with another ligand, the initial ordering of a_1 and b_2 becomes relatively unimportant since both are typically strongly involved in the bonding.



30

Dimerize, conceptually, the isolobal fragments $Fe(CO)_4$ and CH_2. One gets the known ethylene, **31**, the tetracarbonyliron carbene complex, **32**, derivatives of which are known[12], and $Fe_2(CO)_8$, **33**. The last molecule is unstable, and so far has been observed only in a matrix[13]. We come here to a cautionary note on the isolobal analogy. The isolobal analogy carries one between organic and inorganic molecules of similar electronic structure. But there is no guarantee that the result of such an isolobal mapping (**31** $\leftrightarrow$ **33**) leads one to a molecule of great kinetic stability. It might, or it might not.

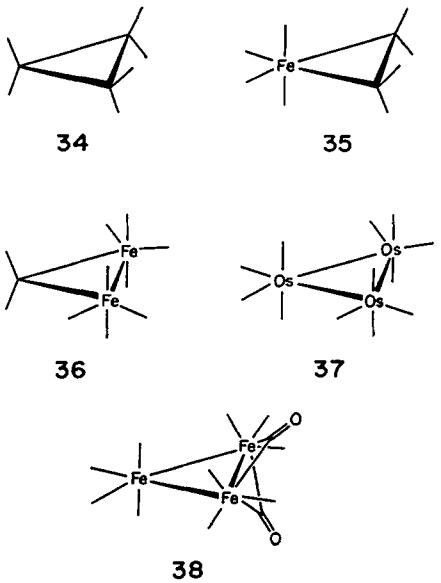


31 **32** **33**

Lest the reader be concerned about this limitation of the analogy let me remind him or her of what happens as one proceeds from ethylene down Group IV. Si, Ge, Sn, Pb substitution leads to olefin analogues, but they are kinetically and thermodynamically so unstable that it has taken great effort to provide evidence for their fleeting existence.

$Fe_2(CO)_8$, **33**, has π and π^* levels similar to those of ethylene. But the low energy of its π^* makes this molecule coordinatively unsaturated. It can, for instance, add another CO to reach the stable enneacarbonyldiiron. More interesting, as we will soon see, is the strategy of stabilizing the unstable $Fe_2(CO)_8$ by making a complex of it, just as is routinely done for unstable organic molecules (**1**—**3**).

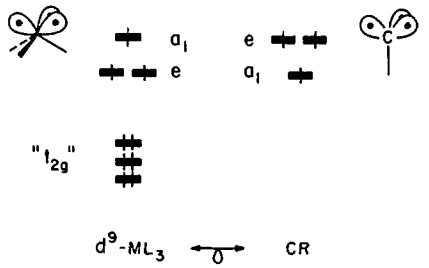
$Fe(CO)_4$, $Ru(CO)_4$, or $Os(CO)_4$ may be trimerized in various combinations with methylene, as in **34**—**37**. These cyclopropanes, ranging from all-organic to all-inorganic, are known. But note that when I show the "all-metallic" three-membered ring I have to go to Os. It is well known that the ground state structure of $Fe_3(CO)_{12}$ is **38**, with two bridging carbonyls[14]. Another limitation of the isolobal analogy is exposed here: the unbridged Fe structure analogous to **37** is certainly not much higher in energy than **38**, but nevertheless the lowest energy structure is bridged. Movement of some ligands (*e.g.* carbonyls, but not phosphanes) in and out of bridging sites is an experimental reality, a facile process, for transition metal complexes, especially of



34 **35** **36** **37** **38**

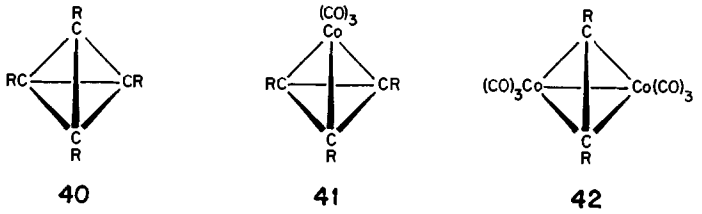
the first transition series. Such easy terminal to bridging interconversions are rare in organic chemistry, with the exception of carbonium ions. Bridging in inorganic structures, when it does occur, does not cause a major perturbation in the nature of the frontier orbitals.

Consider next the d^9-ML_3 fragment, *e.g.* $Co(CO)_3$. This is isolobal with a methylidyne (or carbyne) CH, as shown in **39**. Once again there are differences, though of no great

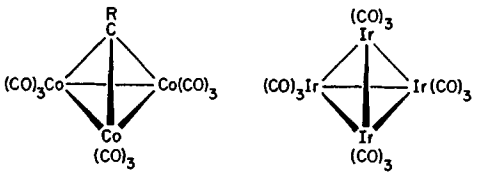


39

significance, in the a_1 versus e energy ordering between the two fragments. Their similarity is revealed most strikingly by the existence of the entire series of mixed organic and inorganic tetrahedranes, **40**—**44**. To be sure, **41** can be



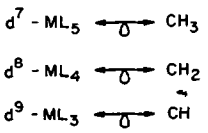
40 **41** **42**



43 **44**

called a cyclopropenyl complex and **42** a binuclear acetylene complex, but I believe something is gained in seeing the entire series as a progression of isolobal substitution.

The fundamentals of the isolobal analogy have now been exposed. Just how far-reaching the relationships written here



are, will become clearer shortly. For the moment it is important to note that the isolobal analogy is not solely the creation of my research group. In his fruitful explorations of the reactivity of d^8-square planar complexes *Halpern* often made use of the similarity of such an ML_4 entity to a carbene[9a]. He did the same for d^7-ML_5 and organic free radicals[9a]. *Dahl*, in a beautiful series of structural studies of transition metal clusters, saw clearly the relationship of the orbitals of an ML_n fragment to a chalcogen or pnicogen atom, which of course are easily related to CR[15,16]. And most importantly, *Wade*[17] and *Mingos*[18] independently developed a comprehensive and elegant picture of the electronic structure of transition- metal clusters by relating them to the polyhedral boron hydrides (which *Lipscomb* and I studied—the circle closes!). It is a trivial step from BH to CH^+. All of these workers saw the essence of the isolobal analogy.

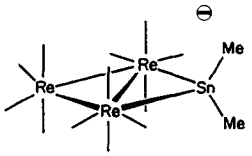
Structural Implications of the Isolobal Analogy

How quickly the hands and mind of man provide us with the problem of choice! The molecules I would need to illustrate the isolobal analogy at work did not exist thirty years ago. Now they are around us, in superabundance. I have made a selection, based in part on the ease with which these lovely molecules illustrate the principles, in part on the ambiguous and ephemeral basis of recent (1981) appearance in the literature.

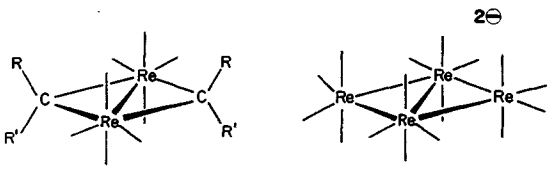
One obvious use of the isolobal analogy is in the structural sense. The analogy allows us to see the simple essence of seemingly complex structures. I should like to show you some examples centering on the ML_4 fragment.

Last year there appeared a structure of the cluster $HRe_3(CO)_{12}Sn(CH_3)_2$ from the work of *Kaesz et al.*[19]. The unique hydrogen was not located; presumably it bridges one Re—Re bond. If we remove the hydrogen as a proton, a convention we have found useful[8n], we reach $Re_3(CO)_{12}Sn(CH_3)_2^-$, **45**. Not a usual molecule, but the isolobal chain

allows us immediately to see the very close similarity of this structure to the previously known **46**[20] and **47**[21].



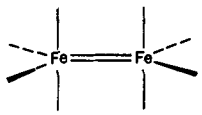
45



46 **47**

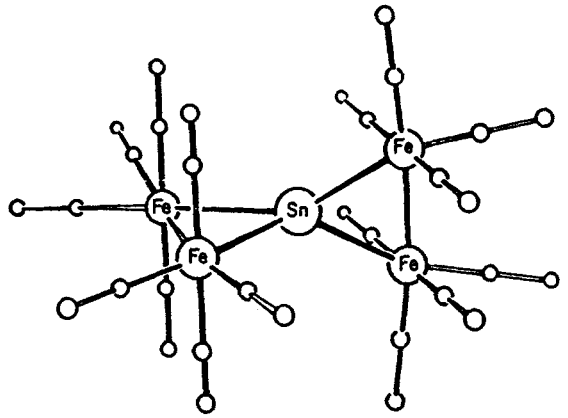
It is interesting to speculate when we might see the missing members of the series on the organic side, $(CO)_4Re(CH_2)_3^+$ and $(CH_2)_4^{2+}$.

Two ML_4 fragments united yield the aforementioned unstable $Fe_2(CO)_8$ system, **48**. It was hinted before that one should think of stabilizing this species by complexation. A pretty example is at hand, **49**[22]. Two $Fe_2(CO)_8$ units are complexed by a tin atom! Note the pinning back of the



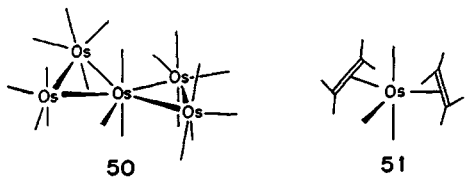
48

equatorial carbonyls, analogous to the bending back of hydrogens in a transition metal complexed olefin. Alternatively, and interestingly, this can be considered as a spiropentane.



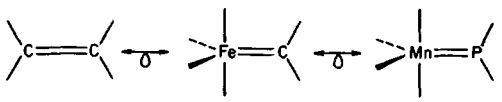
49

Earlier last year, *Lewis, Johnson et al.* published a synthesis and structure of $Os_5(CO)_{19}$[23]. The structure, **50**, appears terribly complicated until one realizes it is really **51**, a typical trigonal bipyramidal $Os(CO)_5$ derivative, with two of the equatorial carbonyls substituted by olefins, or rather by the $Os_2(CO)_8$ olefin analogues. The "olefin" orientation is just as it should be[1k,o].



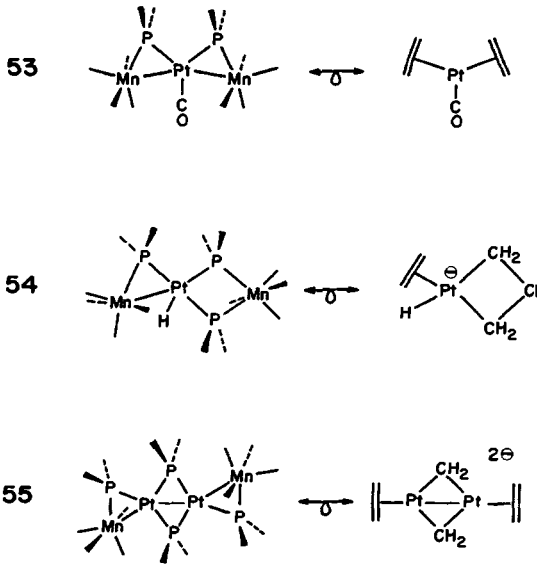
50 51

Another system isolobal to ethylene and $Fe_2(CO)_8$ is the "mixed dimer" $(CO)_4FeCH_2$. Upon formally shifting an electron from the metal to the carbon, a bit of alchemy, one gets to a phosphido complex **52**:



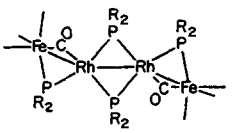
52

The reason for this transformation sequence is that complexes of $Mn(CO)_4PR_2$ have been made. *Braunstein, Grandjean et al.* have reported a remarkable set of structures, among them the three shown with their isolobal analogues in **53**—**55**[24]. In each structure we can see the obvious ethylene-like $(CO)_4MnPR_2$ entity.



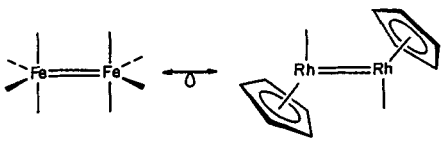
53 54 55

At the same time that these structures were published there appeared a structure of **56**, synthesized in an entirely different way by *Haines, Steen,* and *English*[25]. Unbridge the two semibridged carbonyls, do a bit more electronic alchemy relating Mn—Pt to Fe—Rh, and the relationship to **55** becomes crystal clear.



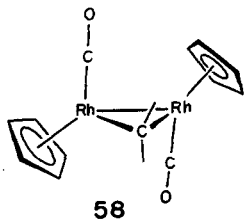
56

Realizing that $Fe(CO)_4 \leftrightarrow CpFe(CO)^- \leftrightarrow CpRhCO$, we see immediately that **57** is yet another $Fe_2(CO)_8$ analogue.



57

Thus, the methylene complex, **58**, synthesized by *Herrmann* is a two-thirds inorganic cyclopropane[26].

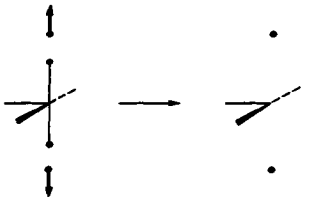


58

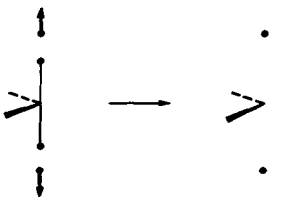
There are a few more fascinating $Cp_2Rh_2(CO)_2$ structures to be shown, but first we need to examine one extension of the isolobal concept.

The Relationship between ML_n and ML_{n-2} Fragments

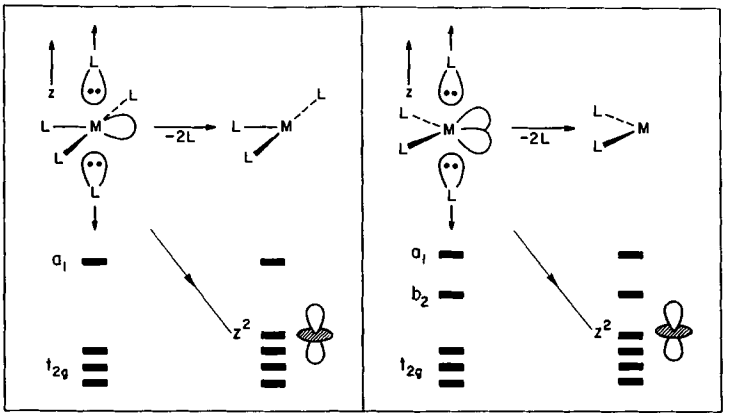
Earlier in the discussion we looked at two octahedral fragments, ML_5 and ML_4, in which a pair of axial ligands remained. If we remove these ligands (cf. **59**) an interesting extension of the isolobal analogy emerges.



59

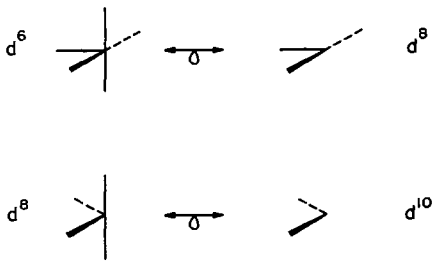


If the z-axis is oriented along the direction of the vanishing ligands, then it is clear that the main result of this perturbation is that the metal d_{z^2} atomic orbital is lowered in energy. It returns from the metal-ligand σ-antibonding manifold to become a non-bonding orbital (cf. **60**, **61**)[10a, 3c].



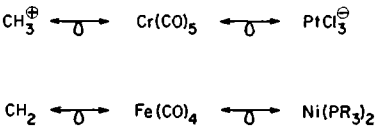
60 **61**

The high-lying orbitals (one in ML_5, two in ML_4) remain[27]. The obvious relationships that emerge then are those between a d^n-ML_5 and a d^{n+2}(C_{2v})- or T-shaped ML_3; and between d^n(C_{2v})-ML_4 and d^{n+2}-ML_2. Or to put it explicitly in terms of the most common fragments, **62**.



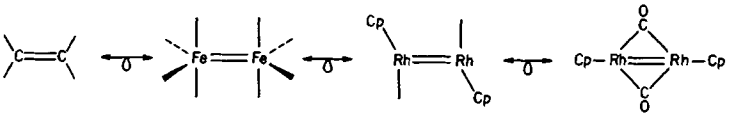
62

So we now add some further diversity to the non-isolobal mapping which is the isolobal relationship:



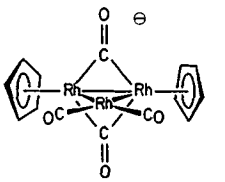
An obvious application is to olefin complexes; the similarity of $(CO)_4Fe(C_2H_4)$ to $(PR_3)_2Ni(C_2H_4)$, and that of $(CO)_5Cr(C_2H_4)$ to Zeise's salt emerges directly[10a, x].

Returning to the $[CpRh(CO)]_2$ analogue of ethylene, we can now think about some other structures. First, it turns out that moving the carbonyl groups into the bridge does little to change the ethylene-like nature of the dirhodium fragment, **63**[11a].



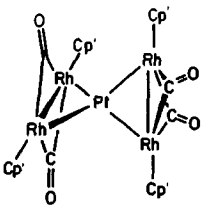
63

Since $CH_2 \leftarrow\!\!\rightarrow Fe(CO)_4 \leftarrow\!\!\rightarrow Pt(CO)_2 \leftarrow\!\!\rightarrow Rh(CO)_2^-$, it is possible to see in the compound of *Bergman et al.*, **64**[28], an analogue of *Herrmann*'s compound **58**.

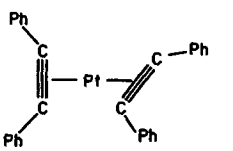


64

Essentially the same fragment, **63**, reappears in the fantastic $[CpRh(CO)]_4Pt$ structure, **65**, of *Stone et al.*[29] ($Cp = \eta^5$-C_5Me_5) and can be related to the $(RC{\equiv}CR)_2Pt$ structure, **66**, earlier synthesized by the same group[30].



65



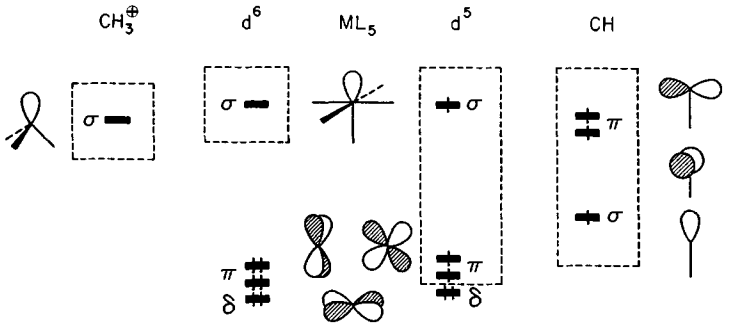
66

Into the t_{2g} Shell

It turns out that not only is d^9-$Co(CO)_3$ isolobal with CH, but so is d^5-$CpW(CO)_2$. To see how this comes about let us first relate the Cp complex to a simple ML_n.

As was shown earlier, $Cr(CO)_5^+$ is isolobal with CH_3^{2+}. That is not a very productive analogy. So let us examine

$Cr(CO)_5^+$ in more detail. The electronic structure of an ML_5 fragment was given earlier. It is repeated in more detail on the left of **67**. The ML_5–CH_3 analogy concentrates on the hybrid of $\sigma(a_1)$ symmetry. But the t_{2g} set, even if it is less "directional" than the hybrids, has extent in space and well-defined symmetry properties. In particular, two of the t_{2g} orbitals are of π pseudosymmetry, one of δ-type. If, as we are forced to by the electron deficiency, we extend our view at least to the π component of the t_{2g} set (dotted lines at right in **67**), we see a clear relationship between d^5-ML_5 and CH, just as there is between d^7-ML_5 and CH_3.



67

A little further reflection will show that by using one half of the π set of the t_{2g} we can get a relationship between d^6-ML_5 and CH_2.

To summarize:

d^7-ML_5 ⟷ CH_3

d^6-ML_5 ⟷ CH_2

d^5-ML_5 ⟷ CH

or to put it another way

d^6-ML_5 ⟷ $CH_3^\oplus$

d^6-ML_5 ⟷ CH_2

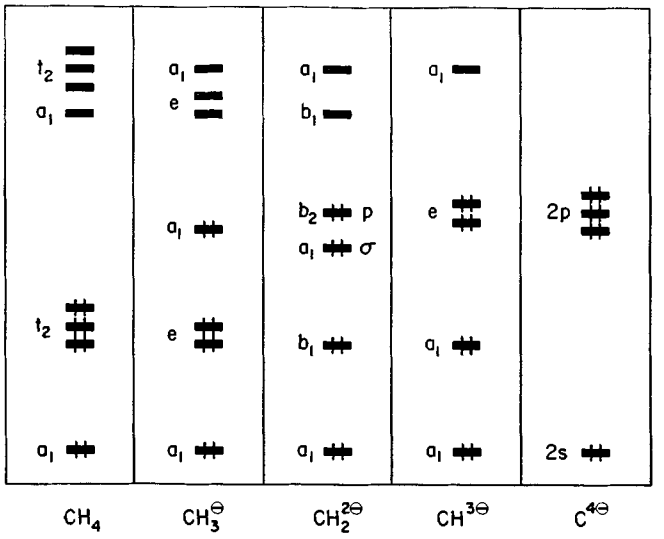
d^6-ML_5 ⟷ $CH^\ominus$

This gives us another way of looking at things, a *deprotonation analogy*. In what way is CH_3^+ like CH_2 or CH^-? Let us draw out their orbitals schematically, including CH_4 for good measure, in **68**.

Taking away a proton from each molecular fragment does not change its ability to function as a donor (though its quality or donor strength will be *very* different). Each fragment, from CH_4 to C^{4-}, is in principle an eight-electron donor.

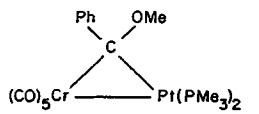
To recapitulate: the isolobal analogy is not a one-to-one mapping. A d^6-ML_5 fragment is isolobal with CH_3^+, CH_2, and CH^-. This is why the d^5-$CpW(CO)_2$ is isolobal with CH.

The isolobal analogy for low d-electron count metals has been exploited most notably in the work of *Stone*'s group at Bristol. Just four compounds from their many beautiful examples are shown in **69**–**72**[31].

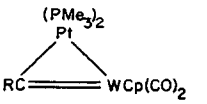


68

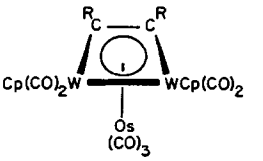
Since d^6-$Cr(CO)_5$ ⟷ CH_2 ⟷ d^{10}-$Pt(PR_3)_2$, **69** corresponds to cyclopropane. Since $CpW(CO)_2$ is isolobal with CR, **70** corresponds to cyclopropene. Both isomers **71** and **72** are related to $(CO)_3Fe$(cyclobutadiene), **1**, or for that matter to the organic square-pyramidal $C_5H_5^+$[32].



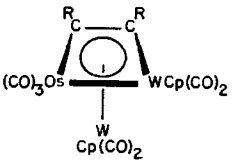
69



70



71

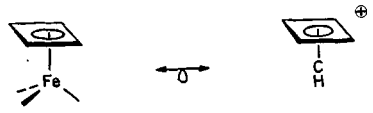


72

From Inorganic to Organic Chemistry

The psychological direction of the isolobal analogy in general has been to make one feel more comfortable about the structures of complex inorganic molecules by relating them to known, presumably simpler, organic molecules. It is interesting to reverse this process and think about as yet unsynthesized organic structures related to known inorganic ones. The mapping from one realm of chemistry to the other must be accompanied by the warning already given: there is no guarantee that the "product" of an isolobal transformation is as stable, kinetically or thermodynamically, as the "reactant"[33].

$Fe(CO)_3$ is isolobal with CH^+. Thus, **1** is related to $C_5H_5^+$, **73**[32], and the ubiquitous ferroles, **74**[34], are related to $C_6R_6^{2+}$, **75**[35]. Another product of the interaction of acetylenes with carbonyliron species is the "flyover bridge" molecule, **76**, a binuclear ring-opened fulvene complex[34]. The isolobal replacement carries over to **77**.



1 73

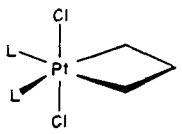
74 75

This is an unusual hydrocarbon $C_8H_8^{2+}$ of C_2 symmetry, a hypothetical doubly homoallylic cation. It is not a geometry one would normally have thought of for a heptafulvene dication, yet once reached by the isolobal mapping it appears to be geometrically reasonable[36]. More mappings of this type await exploitation.

76 77

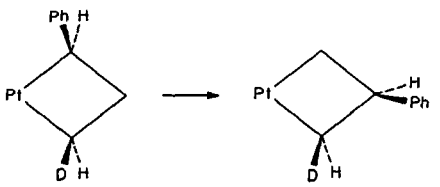
From Organic to Inorganic Reaction Mechanisms

Puddephatt, Tipper et al.[37] have discovered a remarkable rearrangement of a platinacyclobutane, **78**, in which a carbon atom adjacent to the metal, with its substituents,



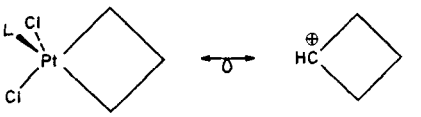
78

exchanges in a very specific way with the carbon atom opposite the metal[37]. The labeling experiment of *Casey et al.* showing this phenomenon most directly is given in **79**[38]. How does this happen?



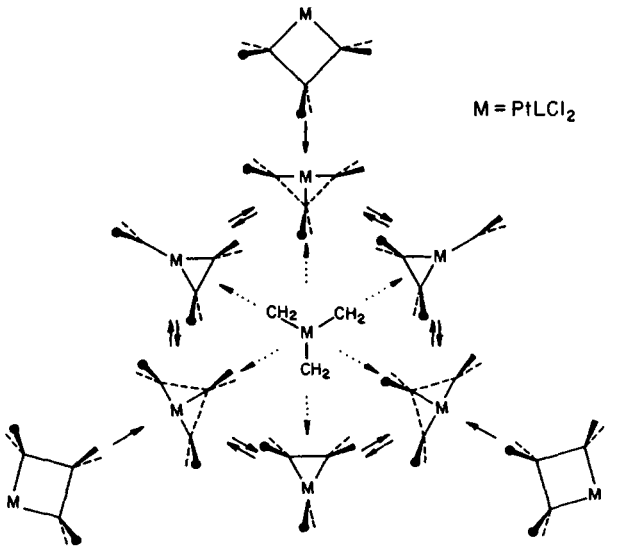
79

Kinetic evidence for a primary dissociative step to $Cl_2(py)Pt(CH_2)_3$ exists[37]. Suppose the ML_3 fragment can distort from its original T-shape to a C_{3v} geometry. Since d^8-$PtCl_2(py)$ is isolobal with CH^+, we can see a relationship to the cyclobutyl cation, **80**.



80

This association immediately brings to mind the entire complex of speculations and facts surrounding the facile rearrangement of cyclobutyl cations through "bicyclobutonium" waypoints[39]. The motions likely to occur are shown in **81**. Ligand loss is followed by geometric reorganization at the metal, approach to a "bicyclobutonium structure", an itinerary around the periphery of a Jahn-Teller wheel through "cyclopropyl carbinyl" waypoints, and exit through an isomeric "bicyclobutonium" structure.



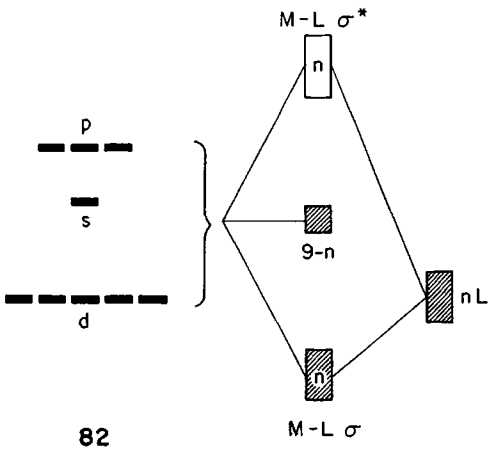
81

This is but one instance among many where the isolobal analogy is useful in moving between organic and inorganic reaction mechanisms.

Beyond the Octahedron

The octahedron was a most useful starting point for generating fragment frontier orbitals, thereby engendering the isolobal analogy. But the octahedral polytype is not unique for six-coordinate complexes, and higher coordination numbers are feasible. We seek another more far-ranging derivation and find one based on the 18-electron rule.

An (unoriginal) justification of this rule goes as follows: Consider n ligands, $n \leq 9$, approaching a metal with its 9 valence orbitals (cf. **82**). A little group theory shows that for the octahedron and most, but not quite all, coordination geometries the n ligand orbitals will find a match in number, symmetry properties, and extent in space among the hybrid sets that can be formed from the nine metal orbitals. The exceptions are very well understood[40]. Given this match, n M—L σ bonding combinations will go down in energy, n M—L σ^* antibonding combinations will go up, and $9-n$ metal orbitals will remain relatively un-

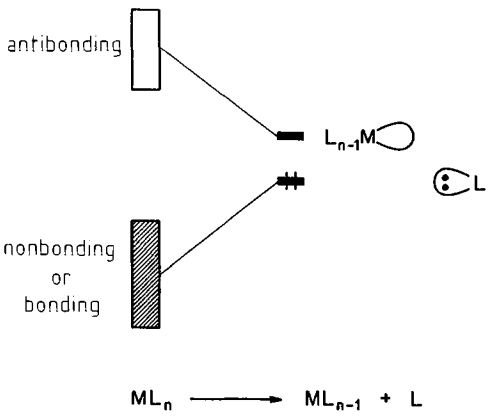


82

touched, approximately non-bonding. The 18-electron rule then is the statement: "Thou shalt not fill antibonding orbitals". Filling bonding (n)+nonbonding (9−n) orbitals leads to 9 electron pairs or 18 electrons.

This "proof" is trivial but not silly. Upon a little reflection it will lay bare the limitations of the 18-electron rule on the left and right side of the transition series, for special symmetry cases, and for weak field ligands.

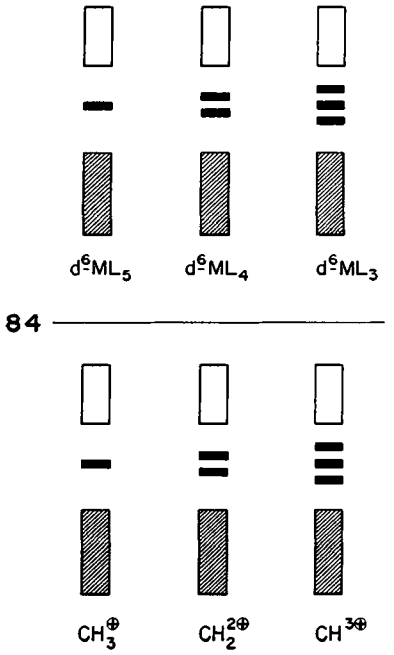
We next remove a ligand, a base, from the 18-electron complex. A localized hole on the metal, a directional hybrid, is created. The electron pair leaves with the ligand (cf. **83**). To put it in another way, in some localized description of the bonding, one M—L σ bond was formed by interaction of a ligand pair of electrons with a metal-based hybrid. Reversing the process, breaking the bond, frees that hybrid.



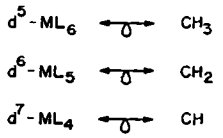
83

A parallel analysis for main group elements leads to the octet rule, since only s and p are considered as valence orbitals. Hybrids are freed by removing ligands, so that CH_3^+ has one vacant directional orbital, CH_2^{2+} has two such.

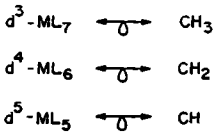
The parallel between ML_n and EL_n fragments (M = transition metal, E = main group element) is derived from the generation of similar hybrid patterns on removal of ligands from 18- or 8-electron configurations. For instance, if the octahedral polytype is used as a starting point, the 18-electron rule is satisfied for a d^6-ML_6. Then d^6-ML_5 will have one hybrid and no electrons in the gap between antibonding and bonding or nonbonding levels, just like CH_3^+, **84**: d^6-ML_4 will have two empty hybrids, so will CH_2^{2+}. The common form of the isolobal analogy follows from this.



The advantage of this alternative derivation is that it is easily extended to higher coordination numbers. For instance in any of the multitude of seven-coordinate geometries[8g] the 18-electron configuration is d^4. It follows immediately for fragments derived from these seven-coordinate structures that



From an eight-coordinate starting point[8p], where the 18-electron configuration is d^2:



The conclusions may be summarized in Table 1. Note once again the nonisomorphic, "many-to-one" nature of the isolobal analogy. Also, the results of the previous section on "Into the t_{2g} Shell" are contained in the present discussion.

Table 1. Isolobal Analogies.

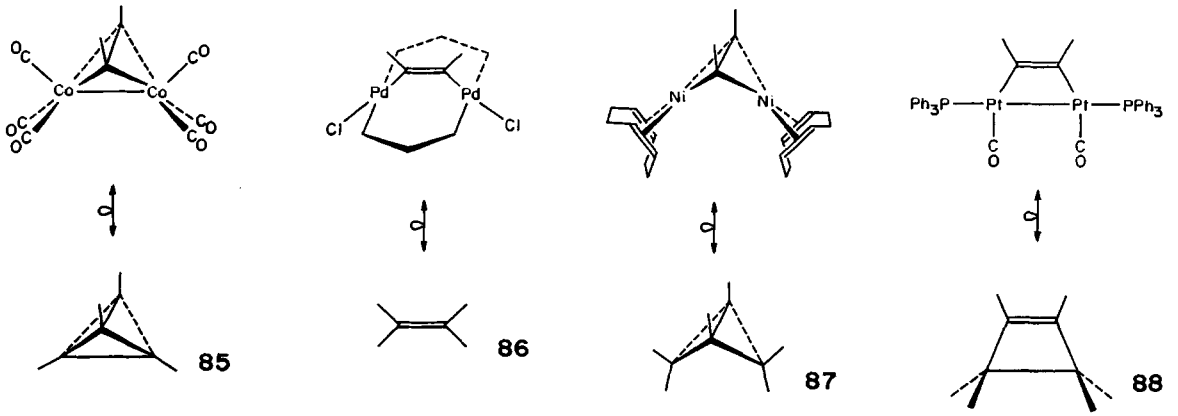
Organic Fragment	Transition Metal Coordination Number on which Analogy is Based				
	9	8	7	6	5
CH_3	d^1-ML_8	d^3-ML_7	d^5-ML_6	d^7-ML_5	d^9-ML_4
CH_2	d^2-ML_7	d^4-ML_6	d^6-ML_5	d^8-ML_4	d^{10}-ML_3
CH	d^3-ML_6	d^5-ML_5	d^7-ML_4	d^9-ML_3	

L = neutral two electron ligand.

Miscellanea

The general rules in hand, the cautions understood, one can proceed to apply the isolobal analogy. Indeed my strategy has been to show the applications as I introduced extensions of the model. Here are some additional examples:

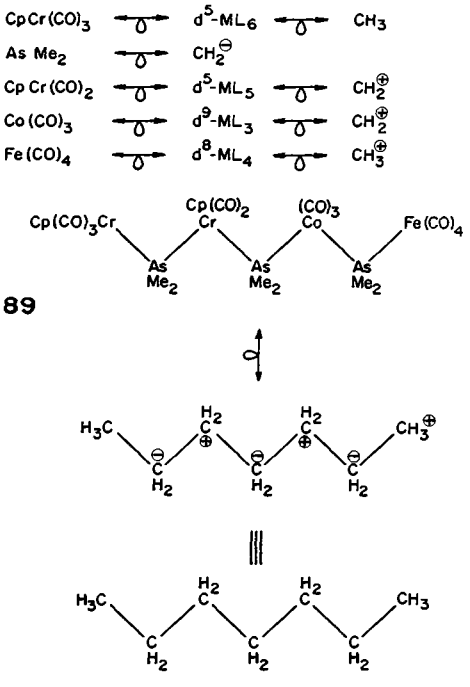
In a recent study of binuclear acetylene complexes the discussion focused on four structural types, **85**—**88**[41].



85 **86** **87** **88**

That these were isolobal with tetrahedrane, an olefin, bicyclobutane and cyclobutene was not only a curiosity, but actually made easier for us the complicated analysis of the interconversions of these molecules. And the isolobal analogy points to the synthesis of the as yet unknown "isomers" in the series, dimetallacyclobutadienes and butadienes, already known in complexed form.

Finally for amusement, consider the chain, **89**, assembled by *Vahrenkamp et al.*[42] (no implication is made in the simplified drawing of the chain stereochemistry.) There had better be a relationship to *n*-heptane! And so there is. We proceed using Table 1 as needed. $CpCr(CO)_3$ appears in a seven-coordinate guise here, so does $CpCr(CO)_2$; while $Co(CO)_3$ and $Fe(CO)_4$ are in a five-coordinate environment. It follows that:



89

Now it is simple—the inorganic chain **89** *is* really *n*-heptane!

One of Many Bridges

The isolobal analogy is a model. It is the duty of our scientific craft to push it to its extremes, and being only a model it is certain to fail somewhere, for any model, as ingenious a construction as it might be, is bound to abstract only a piece of reality. The reader has seen just how far the model can be pushed and where it breaks down.

The pleasing aspect of this particular model is that it brings together different subfields of our central science. We are separated, split asunder—organic, inorganic, physical, biological, analytical chemists—by the very largesse of our creation. The variety of molecules we create, and the methods we use to study them breed jargon and specialization. Yet underneath the seeming complexity there must be a deep unity. I think this approach would have pleased *R. B. W.*

It should be obvious to the reader that the spirit of this new line of work of my group owes much to what went on before. In particular I owe a direct debt of gratitude to my teachers M. P. Gouterman, W. N. Lipscomb, Jr., E. J. Corey, R. B. Woodward and my younger collaborators in the "organic days". E. L. Muetterties helped me learn inorganic chemistry. But it is my coworkers—graduate students, postdoctoral fellows, senior visitors—who in long group meetings, patiently yet with inspiration helped me shape this view of a piece of chemical experience. In rough chronological order of passing through Baker Lab in the "inorganic days" they are: M. Elian, N. Rösch, A. R. Rossi, J. M. Howell, M. M.-L. Chen, D. M. P. Mingos, A. B. Anderson, P. D. Mollère, P. J. Hay, J. C. Thibeault, P. Hofmann, J. W. Lauher, R. H. Summerville, T. A. Albright, D. L. Thorn, D. L. DuBois, Nguyen Trong Anh, A. Dedieu, E. M. Shustrovich, P. K. Mehrotra, M.-H. Whangbo, B. E. R. Schilling, K. Tatsumi, J. K. Burdett, H. Berke, A. R. Pinhas, S. Shaik, E. D. Jemmis, D. Cox, A. Stockis, R. D. Harcourt, R. D. Bach, O. Eisenstein, R. J. Goddard, H. H. Dunken, P. Kubáček, D. M. Hoffman, C. Mealli, Z. Havlas, C. N. Wilker, T. Hughbanks, S.-Y. Chu, S. Wijeyesekera, C. Minot, S. Cain, S. Sung, M. Kertész, C. Zheng. Kaz Tatsumi was especially helpful in the preparation of this paper.

I am in the business of communicating ideas to people. The graphical aspect of this enterprise, be it lecture slides or published articles, is critical. Throughout these years nearly

all of my drawings, containing countless "lined orbitals", have been expertly and beautifully executed by Jane S. Jorgensen and Elisabeth Fields, to whom I'm most grateful. The typing of my manuscripts and the associated details of production are the outcome of hard work by Eleanor R. Stolz and Eda J. Kronman, and I thank them for their help.

Throughout this period my research has been generously supported almost entirely by a research grant from the National Science Foundations' Quantum Chemistry Program. Other support has come from the Materials Science Center at Cornell, and smaller unrestricted research grants from Eli Lilly, Allied and Exxon Foundation.

[10] The term "isolobal" was introduced in [1e], but the concept, as we will see below, is older.

[11] In methylene a_1 is below b_2, because the latter is a pure p orbital, while the former has some s character. In $Fe(CO)_4$ the a_1 and b_2 can be thought of as being derived from the e_g orbital (z^2, x^2-y^2) of the octahedron. Removal of two *cis*-ligands stabilizes x^2-y^2 (b_2) more than it does z^2 (a_1). Were the ligands removed *trans*, to reach the square-planar ML_4 fragment, the situation would be reversed. Cf. also [3].

[27] There are some further details, not discussed here but treated elsewhere [1o, 1x, 3c]. In particular, the ML_2 will have another relatively low-lying orbital when L is a π acceptor.

Polarity of Binary Liquid Mixtures

By Heinz Langhals*

In contrast to the thoroughly studied polarity properties of pure liquids, only little is known about the polarity of mixtures of liquids, although the majority of mechanistic and preparative work is not carried out in pure phases. Using a widely applicable two-parameter equation, polar behavior of binary liquid mixtures can be described quantitatively as a function of their composition. Based on this equation, satisfactory explanations are found for deviations observed for binary solvent mixtures from the linear correlation of polarity scales, as well as for the unusual activation parameters estimated by *Winstein* for solvolysis of *tert*-butyl chloride. Applications of the equation range from a rapid test for determining water contents of solvents, the study of reaction mechanisms, to polymer chemistry.

1. Introduction

Solvent polarity has been interesting to chemists for some considerable time[1–4]. Macroscopic physical quantities, such as dielectric constant or refractive index are of only limited use for studying chemical reaction behavior and the associated molecular processes[1,5–8]: the development of the empirical polarity scales, however, was a substantial advance. The oldest, the *Y*-scale of *Winstein* and *Grunwald*[9–11], shown in equation (1), is based on the solvolysis of *tert*-butyl chloride and often correctly describes the influence of solvents on the rate of chemical reactions.

$$\lg \frac{k}{k_0} = Y \qquad (1)$$

k = rate constant of the solvolysis of $(CH_3)_3CCl$ in the medium to be studied

k_0 = rate constant of the solvolysis of $(CH_3)_3CCl$ in 80% ethanol-water.

2. Empirical Polarity Scales

Today, the Winstein *Y*-values are widely used as a primary polarity scale. Being derived from a solvolysis reaction, the *Y*-scale is, however, confined to polar media. Therefore, a number of other polarity scales[1] of wider applicability were developed, based on reaction kinetics or spectroscopic data. Scales derived from solvatochromism of dyes are noted for their straightforward and precise measurement[12,13]. Most remarkable is the $E_T(30)$-scale of *Dimroth* and *Reichardt*[14,15], which has become the most widely used scale: the solvatochromic dye pentaphenyl pyridiniumphenolate **1**, which serves as reference substance,

exhibits a peak shift of its longest wavelength UV/VIS-absorption maximum—one of the largest known—when the solvent polarity is changed; moreover, it is soluble in almost all known solvents. The $E_T(30)$-values are the excitation energies [kcal·mol^{-1}] of **1** and are calculated from λ_{max} of the solvatochromic peak of **1** according to formula (2).

$$E_T(30) = 28\,590\ [\text{kcal}\cdot\text{nm}\cdot\text{mol}^{-1}]/\lambda_{max} \quad (2)$$

$E_T(30)$-values show good linear correlation with the *Y*-values of various solvents[1]. It is remarkable that such linear correlation of polarity scales is observed not only between $E_T(30)$ and *Y*, but also applies to most empirical scales[*].

The fact that a polarity concept applicable on the molecular scale exists, even if it is only comprehensible on an empirical basis, had important consequences for both mechanistic and preparative organic chemistry.

A few polarity scales do not correlate with the $E_T(30)$-scale (see Section 3.2). One, for example, is the donor number *DN* of *Gutmann*[16], which describes Lewis basicity rather than polarity of a solvent. The *DN*-scale has proved useful for describing processes involving the nucleophilicity of the solvent. It was recently attempted to include other such solvent properties together with polarity in a multi-parameter equation[17,18]. This evaluation corresponds to the principle of polylinearity (PPL) of *Palm*[19], and is similar to the multi-parameter evaluation of *Cramer*[20,21].

3. Binary Mixtures

For practical applications empirical polarity scales characterize polar behavior of liquids reasonably well. Surprisingly, however, the linear correlation which applies to pure solvents deteriorates when solvent mixtures are included[1,15,22]. However, such mixtures are rather useful for studying solvent effects, since the properties of various solvents can be adjusted continuously by changing the mixture ratio.

3.1. Polarity as a Function of Composition

A widely applicable equation containing only a few parameters for the quantitative description of the polarity of binary solvent mixtures as a function of their composition was long a key problem.

Dimroth and *Reichardt et al.*[14,15] used the $E_T(30)$-scale, for example, to study the polarity of the binary mixtures ethanol-water, isopropanol-water, methanol-water, acetone-water, 1,4-dioxane-water, pyridine-water, 2,6-lutidine-water, and piperidine-water as a function of their composition. Plotting the $E_T(30)$-values *versus* composition, expressed as vol.-% of one component, however, does not afford a linear relationship, as one might expect but strongly curved lines which could not, as previously found in other cases[1,20,23], be readily interpreted. Approximation of the complex functional curve has been attempted by Taylor series expansion[24] as well as by using several hyperbolic functions[25].

It was shown recently[26] that plotting $E_T(30)$-values against the logarithm of the molar concentration of the more polar component ($\ln c_p$) produces curves with a linear section. This is shown in Figure 1a for the typical mixture *N-tert*-butylformamide-benzene.

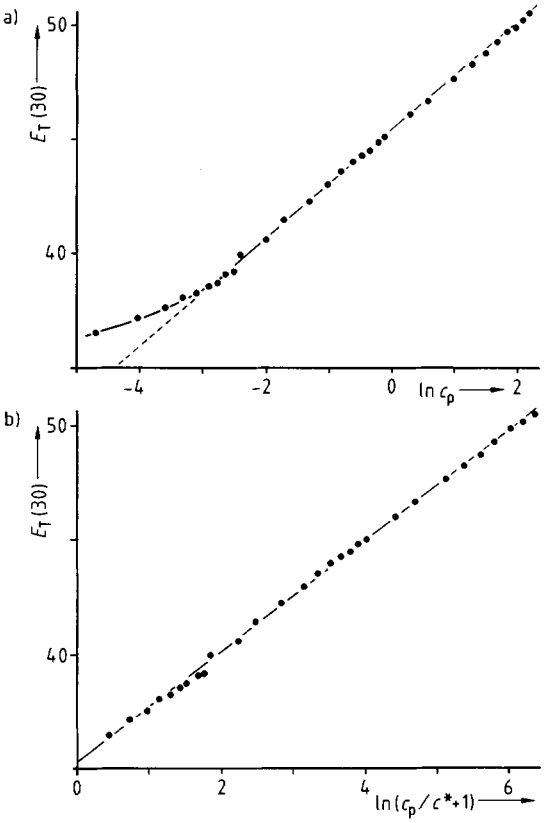

Fig. 1. $E_T(30)$-values for the mixture *N-tert*-butylformamide-benzene, a) as a function of $\ln c_p$, b) as a function of $\ln(c_p/c^* + 1)$ from equation (3).

In the study of solvolysis reactions, *Tommila*[27] also found curves with linear sections by plotting $\lg c_p$ of binary mixtures against the free activation enthalpy of solvolysis. The linear section was interpreted as arising from nucleophilic solvent participation in the reaction. Nucleophilic solvent participation of this type, however, is not possible in the case of the $E_T(30)$-scale.

Using the $E_T(30)$-scale with dye **1** as reference substance the course of the curve can be examined even at low concentrations c_p. In this region the curve deviates from linearity and as $c_p \rightarrow 0$ it tends to $E_T^0(30)$, the $E_T(30)$-value of the pure, less polar component (cf. Fig. 1a). Using the dual-parameter equation (3) the entire course of the curve can be described in closed form, including the curved section[26].

$$E_T(30) = E_D \cdot \ln\left(\frac{c_p}{c^*} + 1\right) + E_T^0(30) \quad (3)$$

$E_T(30)$ in equation (3) is the polarity of the binary mixture: $E_T^0(30)$ and c_p were explained above, and E_D and c^* are the parameters of the equation. They can be determined graphically[26,28] or using the POLAR computer program[26]. The validity of equation (3) can be demonstrated

[*] If a relationship between two scales is not only monotonic, but also linear, it can be concluded that both scales conform to the same law.

by plotting $E_T(30)$ against $\ln(c_p/c^* + 1)$ using, for example, the mixture *N-tert*-butylformamide-benzene (Fig. 1b). This produces a straight line which is shown covering a region of three orders of magnitude of c_p. Deviations from this linear section are statistical in nature and correspond to experimental error.

3.1.1. The Parameters of Equation (3)

The parameter E_D has the dimension of energy and is a measure of the sensitivity of the $E_T(30)$-scale towards relative changes of c_p. The parameter c^*, with the dimension of concentration, divides the curve in Figure 1a into two parts—this can be demonstrated by considering the limiting value of c_p[26]. If $c_p \ll c^*$, a linear relationship between $E_T(30)$ and c_p results, as can be shown by applying a series expansion to equation (3). Thus, in this concentration range, the contributions of both components to polarity are cumulative[*].

If, however, $c_p \gg c^*$ a linear relationship between $E_T(30)$ and $\ln c_p$ results. This case corresponds to the linear part of the curve in Figure 1a; thus, c^* divides this curve into a linear and a logarithmic part, and specifies the threshold value at which the two liquids start to interact according to equation (3).

The experimentally accessible range of c_p extends from the pure, less polar component, $c_p = 0$, to the pure, more polar component, $c_p = c_p^{max}$. As mentioned previously, the polar contributions of both components are approximately cumulative over the entire range, if $c^* \gg c_p^{max}$, and the frequently postulated linear relationship between polarity and composition of the mixture is satisfied (review: [1,2]). If, however, c^* is very small, say < 0.06 mol·L^{-1}, the correlation between polarity and c_p is non-linear over the experimentally relevant concentration range.

3.1.2. Further Polarity Scales

The conformity to a natural law indicated by equation (3) for the $E_T(30)$-scale has also been found with other polarity scales[29-31], and can be expressed in general form by equation (4).

$$P_G = E_D \cdot \ln\left(\frac{c_p}{c^*} + 1\right) + P_G^0 \qquad (4)$$

In equation (4) P_G is the polarity of the binary liquid mixture according to an empirical polarity scale and P_G^0 is the P_G value of the pure, less polar component. The parameters c_p, c^*, and E_D are as described in equation (3). Essentially, both equations show similar behavior when considering limiting values (see Section 3.1.1).

Empirical polarity scales, a selection of which is shown in Table 1, are based on various effects, such as $\pi \rightarrow \pi^*$ absorption (Nos. 1, 4–7), charge-transfer absorption (No. 3), fluorescence (Nos. 8, 9), and solvolysis (No. 2). The $E_T(1)$-scale (No. 5) responds not only to the polarity of the medium, but also shows sensitive response to its hydrogen bonding/donor character.

[*] Plotting $E_T(30)$ values against $\ln c_p$ produces a curved line: the left branch in Figure 1a.

In terms of the criteria used in all the polarity scales studied to date, equation (4) is a valid description of polar behavior of binary liquid mixtures as a function of their composition[29]. The linear relationship between P_G or $P_G - P_G^0$, respectively, and $\ln(c_p/c^* + 1)$, for some polarity scales mentioned in Table 1 is illustrated in Figure 2.

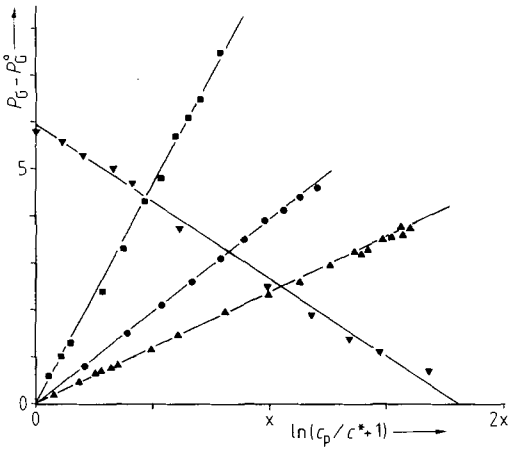

Fig. 2. Linear relationship between P_G and $\ln(c_p/c^* + 1)$ for various polarity scales (equation 4): ▲ $E_T(30)$ ethanol-1-decanol, x = 1; ● Y water-methanol, x = 1; ■ Z methanol-acetone, x = 2; ▼ π_1^* ethanol-*n*-heptane, x = 1, ordinate $P_G - P_G^0 + 5.8$.

Table 2 gives an impression of the range of validity of equation (4), and shows the results of applying it to the nine polarity scales in Table 1. The number and variety of the components used—polar protic, dipolar aprotic, and non-polar solvents, including aromatic solvents, were combined—lead to the conclusion that equation (4) provides a general description of the polarity of binary mixtures and is not confined to certain types of solvent[38]. Its validity for scale 5 and the mixture ethanol-water[29], which has a strong tendency to form H-bonds, is particularly notable. Thus, polarity effects caused by hydrogen bonding are also described by equation (4).

3.1.3. Special Cases

Special features are observed with the solvent mixture water-1,4-dioxane: up to a water content of *ca.* 50%, normal behavior according to equation (3) is observed with the $E_T(30)$-scale. At a certain critical concentration c_k, however, the linear relationship abruptly gives way to a second, steeper relationship with other E_D- and c^*-values[29].

In the following discussion, the concentration ranges $c_p < c_k$ and $c_p > c_k$ are designated region I and region II. For the mixture water-1,4-dioxane, the sudden change at c_k (discontinuity in the 1st derivative) can even be detected if $E_T(30)$ is plotted against $\ln c_p$, *i.e.* without introducing further parameters.

The existence of two regions of validity for equation (3) with a critical change at c_k could be interpreted by considering that largely isolated water molecules occur at low water concentrations in region I, and that formation of hydrogen bonded structures of water occur in region II. In another context it was postulated that 1,4-dioxane acts as a "solvent-structure-breaker"[39]. This model is consistent with the results of the polarity measurements.

Table 1. Empirical solvent polarity scales.

No.	Scala [a]	Reference Substance	Solvent dependent process	Definition [b]	Ref.
1	$E_T(30)$	**1**	$\pi\rightarrow\pi^*$-absorption	$E_T(30)=28590/\lambda_{max}$ [c]	[14, 15]

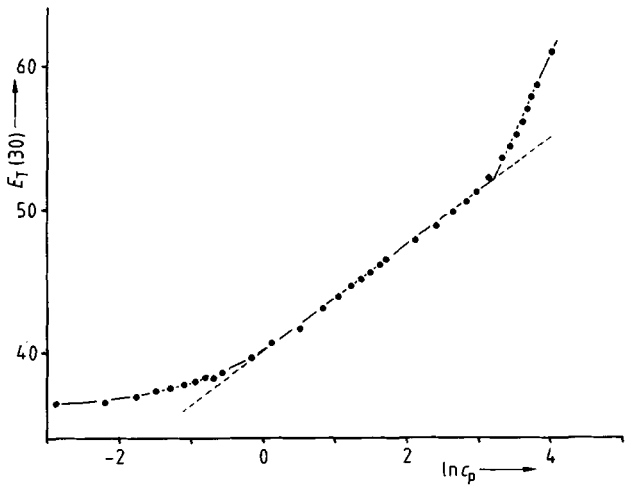

Fig. 3. Double line for the mixture water-1,4-dioxane (No. 28).

In Figure 3, the linear part of region I can be extrapolated into region II (broken line; an even more exact result is achieved by plotting against $\ln(c_p/c^* + 1)$ instead of $\ln c_p$). Thus, for $c_p = c_p^{max}$, a virtual polarity value is obtained for water, $P_V = 56$, which is smaller than the actual polarity value of 63.1[2]. P_V is the polarity with which water, as the more polar component, affects dioxane within region I. Since the effective polarity of water is substantially lower at high dilution than in concentrated solutions, one might venture to conclude that specific interaction of water molecules in molecular associates is responsible for the high polarity of pure water, rather than the characteristics of the isolated water molecule.

The occurrence of a second, steeper line according to equation (3) is not confined to the mixture water-1,4-dioxane, but can also be observed with other mixtures, especially with those including water, *e.g.* water-acetone[40]. The mixture water-ethanol has been studied extensively using several polarity scales[29]. All the scales studied produced double lines (three examples are shown in Figure 4).

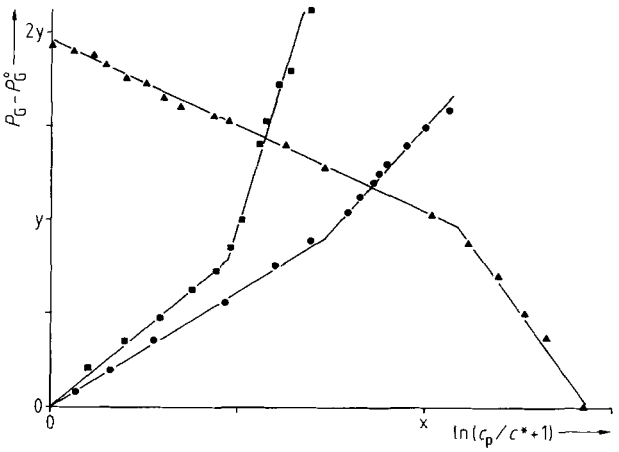

Fig. 4. Double lines according to equation (4) for the mixture water-ethanol (No. 29): ● Y, x = 2, y = 1; ■ $E_T(1)$, x = 1, y = 4; ▲ π_1^*, x = 1, y = 4, ordinate: $P_G - P_G^0 + 7.7$.

It is remarkable that the various polarity scales produce c_k-values which coincide within the limits of experimental error[*]. Thus, the double-line phenomenon is not peculiar to the $E_T(30)$-scale, but must be taken as a characteristic of the binary mixture water-ethanol. This problem will be discussed in more detail in Section 4.1.

Even more interesting than the examples mentioned above are mixtures of 1-butanol and acetonitrile or nitromethane, and of ethanol and nitromethane, which repre-

[*] In Figure 4 the break points appear at different abscissae since the c^* values vary for each polarity scale.

sent a further type of binary mixture[31]. Here, also, two straight lines are observed. The second line, however, has a negative slope, contrary to the previous cases. This is shown in Figure 5 for the mixture 1-butanol-nitromethane.

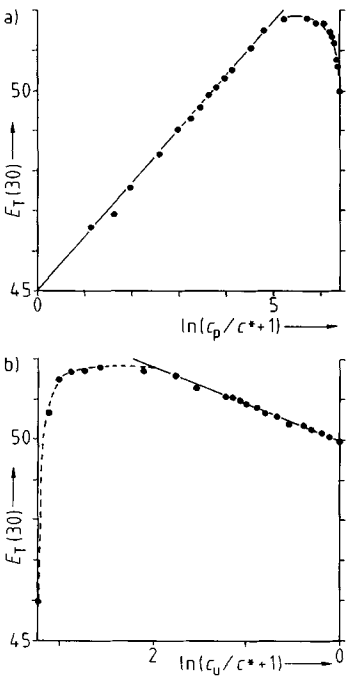

Fig. 5. Relationship between $E_T(30)$ and a) $\ln(c_p/c^*+1)$ and b) $\ln(c_u/c^*+1)$ for the mixture 1-butanol-nitromethane.

The polarity of the mixture increases as c_p increases and reaches its maximum at c_k. As c_p increases further, however, the polarity again decreases and attains the polarity value of the pure, more polar component at c_p^{max}. Within region I, $c_p < c_k$, normal behavior according to equation (3) is observed (see Fig. 5a). Within region II, however, nitromethane, which as a pure substance is less polar, interacts with 1-butanol like a more polar additive. Accordingly, in this region there is a linear relationship between $E_T(30)$ and $\ln(c_u/c^*+1)$, where c_u is the molar concentration of the less polar component (Fig. 5b). By analogy to the previous examples, a virtual polarity can be defined for the polar component 1-butanol. Contrary to these previous cases, however, it is greater than the actual polarity of the alcohol.

Mixtures with $c_p = c_k$ are substantially more polar than their components. This phenomenon, known as "elevated polarity"[31] or the "synergetic polarity effect"[41], can be explained by a hydrogen-bond/donor-acceptor model: the additive, which itself has low polarity, promotes the formation of a polar solvent structure. This behavior is remarkable insofar as it contradicts the usual view that the polarity of a solvent mixture lies within the limits of the polarity of its components; furthermore, the polarity of solvents can be enhanced by adding less polar components.

3.2. Slow and Fast Processes

The majority of polarity scales show mutual linear correlation and with the *Y*- and $E_T(30)$-scales, as far as pure solvents are concerned. A few scales form an exception, but these also mutually correlate. This behavior typically occurs with weakly polar merocyanines with positive solvatochromism[6,42]. One of the first cases to be studied is *Brooker*'s[13] χ_R-scale (Table 1, No. 7), which is based on the solvatochromism of dye **7**. Polarity scales such as χ_R will be discussed extensively here, particularly their application to binary solvent mixtures.

Studies of the solvatochromism of phthalimide derivatives **8** indicate that these exhibit strongly positive solvatochromism in fluorescence phenomena, and this was proposed as the basis for the *S* polarity scale by *Zelinski et al.*[35,36] (for the influence of oxygen, cf. [37]). Absorption by these dyes is also solvatochromic[30]. A linear relationship with the $E_T(30)$-scale exists for fluorescence, but for absorption a linear relationship with the χ_R-scale is observed. Thus, dye **8** is especially suitable for clarifying the previously mentioned exceptions, since it supplies a common basis for both groups of polarity scales.

It is known that the ground state (S_0) of **8** has only a small dipole moment; however, the first electronically excited state (S_1), has a large dipole moment[7]. The different behavior of **8** in absorption and emission can be explained by assuming that states with large dipole moments are strongly solvated by polar solvents, whereas states with small dipole moments are solvated weakly: the Franck-Condon principle for electronic transitions applies to the solvating shell of a dye[43]. The electronic transition takes place in such a short period of time that solvation is unable to follow by reorienting the solvent molecules. Consequently, orientation will only influence solvation in the initial state of an electronic transition, but not the final state. The latter will still bear the solvating shell of the initial state, and can only be stabilized by polarization effects. Absorption and fluorescence of **8** proceed as given in the scheme in Figure 6. The initial state, S_0, is little influenced by polar solvents.

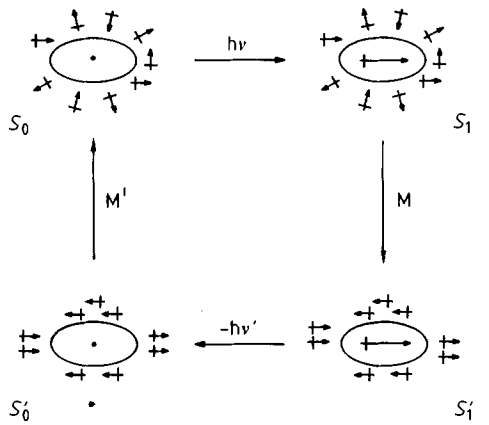

Fig. 6. Schematic representation of absorption and emission processes of dye **8** in polar solvents.

The excited state, S_1, has a large dipole moment, but is surrounded by the solvating shell of the S_0 state. Thus, solvent polarization effects are crucial for absorption—by analogy to the χ_R scale.

Excitation is followed by relaxation of the solvating shell; the lifetime of the excited state (S_1) of *ca.* 10^{-8} to

10^{-9} s is long enough to permit a more favorable orientation of the solvent molecules surrounding the dye molecule. The transition from S_1 to S_1' corresponds to the modification (M) as described for reactions of the excited state in which the excitation energy is conserved[44]. Finally, the transition from S_1' to S_0' occurs by fluorescence, the energy of which is fully influenced by solvent orientation phenomena (besides polarization effects) because the dipole moment of the initial state of this electronic transition is large. It is therefore reasonable that the fluorescence of **8** correlates with the $E_T(30)$-scale. The absorption of dye **1** is subject to an analogous situation. However, in most cases, the behavior of other dyes is by no means as extreme as the absorption of **7** or **8**, and a combination of polarization and orientation effects are observed. Frequently, however, the orientation phenomena prevail, and this results in correlation with the $E_T(30)$-scale. These considerations allow the conclusion to be made that dye **7** (χ_R scale) is a polarity indicator for short measuring times, whereas dye **1** ($E_T(30)$ scale) is suitable for long measuring times (cf. the concept proposed by *Bakhshiev*[45]). In organic chemistry the orientation of the solvent, a relatively slow process, is of crucial influence. Thus, it is reasonable that such processes are correctly described by the $E_T(30)$-scale.

Equation (4) characterizes the polar behavior of binary liquid mixtures according to the χ_R-scale or to an absorption scale using dye **8** as reference. Thus, it can be concluded, that equation (4) will also describe the polar behavior of binary solvent mixtures in fast processes. Equation (4) cannot, therefore, be solely attributed to the concentration of the polar solvent on the surface of the dye[46,47]. Further information on solvent structure is provided by comparing the c^* values of dye **8** in solvent mixtures for absorption and emission[30].

4. Applications of Equation (4)

Equation (4) characterizes, quantitatively, the polar behavior of binary liquid mixtures, and there are no shortage of examples of its use as a "tool" in many areas of chemistry. Applications to mechanistic problems are discussed first.

4.1. Solvolysis of *tert*-Butyl Chloride in Ethanol-Water

The discovery of the Winstein relationship[9], which is based on the solvolysis of *tert*-butyl chloride, played a key role in the development of the empirical polarity concept. Subsequently, *Winstein* studied the influence of temperature on the solvolysis of *tert*-butyl chloride in ethanol-water mixtures[11]. The free energy of activation, $\Delta G^{\neq}$, of this reaction decreases as a monotonic function without strong curves as the water content of the mixture is decreased: the course of $\Delta H^{\neq}$ and $\Delta S^{\neq}$, however, is more complex and maxima and minima occur (see Fig. 7).

This unusual and surprising behavior led to numerous speculations[6,39,48-54]. A satisfying explanation of the experimental data published 25 years ago has yet to be found. It seems to contradict experience that the $\Delta G^{\neq}$ value, which is composed of enthalpy and entropy terms has a

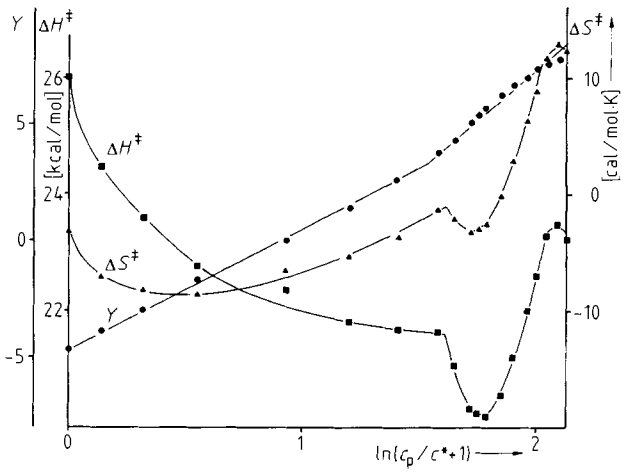

Fig. 7. Thermodynamic data for the solvolysis of *tert*-butyl chloride in ethanol-water [11].

simple functional course, and that the apparently simpler quantities $\Delta H^{\neq}$ and $\Delta S^{\neq}$, however, appear so complicated. Since the solvolysis of *tert*-butyl chloride is sensitive to polarity changes in the medium, an analysis of *Winstein*'s and *Fainberg*'s measurements using equation (4) appears appropriate. As shown in Figure 8, the free energy of activation $\Delta G^{\neq}_{298}$ of the solvolysis of *tert*-butyl chloride in ethanol-water mixtures and the correspondingly proportional quantities $\ln k_{298}$ or Y can be described quantitatively by equation (4) as a function of composition.

An interesting point is—as with other polarity scales (see Section 3.1.3)—that two regions of validity of equation (4) with a critical transition point at $c_k \approx 25$ mol·L^{-1} (double lines) are observed. Thus, the free entropy of activation shows nothing anomalous. The high precision of *Winstein*'s kinetic measurements must be stressed; this is clearly expressed by the lines in Figure 8 and Figure 2.

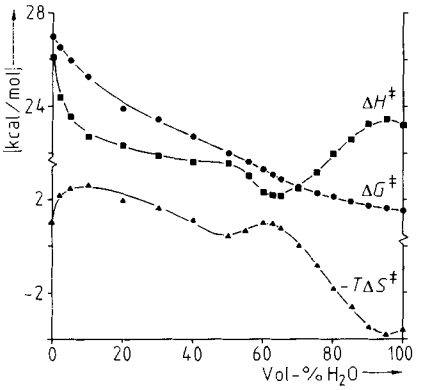

Fig. 8. Analysis of solvolysis data of *tert*-butyl chloride in ethanol-water according to equation (4).

The activation enthalpy $\Delta H^{\neq}$ and the activation entropy $\Delta S^{\neq}$ of the reaction were calculated from the rate constants at only two temperatures, respectively[11], in the range 0 to 45 vol.% water at 25° and 50 °C and in the range of 50 to 100 vol.% water at 0° and 25 °C. It can be shown that for the series of measurements at 0 °C and 50 °C equation (4) also holds (see Table 3); their E_D and c^* values are only slightly different from the measurements at 25 °C.

Table 3. Application of equation (4) to the Winstein scale.

T [a]	Range [b]	E_D [c]	c^* [d]	Y^0 [e]	r [f]	n [g]
25	I	2.9	11.6	− 1.97	0.9991	9
50	I	2.4	9.7	− 0.52	0.9998	7
0	II	2.6	0.001	(−26.9)	0.9845	12
25	II	2.7	0.001	(−26.1)	0.9935	10
(ΔH^+) [b]	I	−0.944 [i]	0.26	(26.1) [h, i]	0.9996	6

[a] Temperature in °C. [b] See text. [c] In Y units. [d] mol·L^{-1}. [e] Extrapolated Y value for ethanol. [f] Correlation coefficient. [g] Number of points. [h] Activation energy. [i] In kcal·mol^{-1}.

The change of temperature from 0° to 50 °C for the calculation of the activation data was conducted at a water concentration of *ca.* 25 mol·L^{-1} (the second temperature was 25 °C in all cases). By chance, this value coincides approximately with the value of c_k corresponding to the intersection point of the two lines in Figure 8. Based on this, the course of the functional curve of ΔH^+ in Figure 7 can be characterized.

For $c_p < c_k$ (region I, $\Delta H^+ \sim \ln k_{298} - \ln k_{323}$), ΔH^+ is a monotonic function of the water content. The E_D and c^* values of $\ln k$ are only slightly different at 25 and 50 °C. Thus, even the solvent dependence of ΔH^+ is approximately described by equation (4) (Table 3). In this correlation the expansion of the liquid must be taken into account, since at a given content in vol.% the molar water content is temperature dependent.

In the region $c_p \approx c_k$ a number of factors cause ΔH^+ to have a rather complex dependence on concentration. Going beyond c_k, its temperature dependence and the temperature change have the effect that the individual measurements for determining ΔH^+ are made partly in region I and in region II. This results in the unusual functional course of ΔH^+.

Finally, in the region $c_p > c_k$ (region II) a monotonic dependence of the ΔH^+ values on the solvent composition is observed, as in region I. The additional maximum at very high water contents may be a result of mixing problems and will not be discussed here (this is dealt with in [48, 55]). The concentration dependence of ΔS^+ (Figs. 7 and 8), can be explained in an analogous manner to the difference between ΔH^+ and ΔG^+.

The solvolysis of *tert*-butyl chloride in ethanol-water, discussed here at length, is characteristic of other solvolysis reactions in solvent mixtures[39, 52, 53, 56, 57], which can be treated in an analogous way, and is also generally typical of mechanistic studies in them. Furthermore, the reference point of the Y-scale, 80 vol.% ethanol/water, may present problems if the temperature differs substantially from 25 °C.
