ETC: A Mechanistic Concept for Inorganic and Organic Chemistry**

By Michel Chanon* and Martin L. Tobe*

Dedicated to Professor Jacques Metzger on the occasion of his 60th birthday

The concept of electron transfer catalysis (ETC), or more specifically "Double Activation Induced by Single Electron Transfer" (DAISET) gives an opportunity to connect experimental facts never previously correlated. The first activation results from the transfer of an electron to (or from) a molecular species; the second activation results from the build-up of a reaction chain able to reproduce the species formed in the first step. The starting point of this review is the $S_{RN}1$ mechanism where principle and experimental diagnostic criteria are critically discussed. The thermal and photochemical exchange and substitution reactions of Pt^{IV} complexes are then reviewed together with the exchange reaction $[AuCl_4]^-/Cl^-$, reactions with Grignard reagents and other organometallic reagents, as well as the redox behavior of electronically excited organic compounds. Photochemical applications, including solar energy conversion are discussed. New aspects are also presented for the mechanistic problem "S_N2 reaction or SET process?" Moreover, the concept has significance for S_H2 reactions at metal centers, molecule-induced homolyses, reactions of complexes, as well as electrochemical processes.—Unless otherwise specified, only double activation (DAISET) processes will be discussed in this article.

1. Introduction

The subject of chain reactions is usually not considered as a whole but rather in relation to organic radical reactions and oxidations, polymerizations, gas phase chemistry, photochemistry, catalysis, *etc.* (cf. *e.g.* [1]). This dispersion presents serious drawbacks. In the present article we shall compare the mechanistic features of a special type of chain reaction whose study has, until now, developed completely independently in two apparently unrelated parts of chemistry; reactions at carbon, and reactions of transition metal complexes. All these reactions have been explained by single electron transfer (SET). Analysis of these reactions leads to the formulation of a concept which applies specifically to organic and inorganic exchange reactions but, in a wider sense, to some aspects of halogenations, isomerizations, eliminations, reductions, oxidations, polymerizations, transition-metal catalyzed reactions, sigmatropic rearrangements, and oxidative additions. The common feature of this class of reaction is the "DAISET" behavior: electron transfer to or from the substrate activates this toward association, dissociation or isomerization (first activation); the species thus created then enter into a catalytic cycle (second activation). An equivalent and simpler descriptor is therefore "Electron Transfer Catalysis" (ETC). The pervasiveness of this class of reaction leads one to expect a variety of applications, *e.g.* in photochemistry, in polymerizations, and in the conception of new chemical processes.

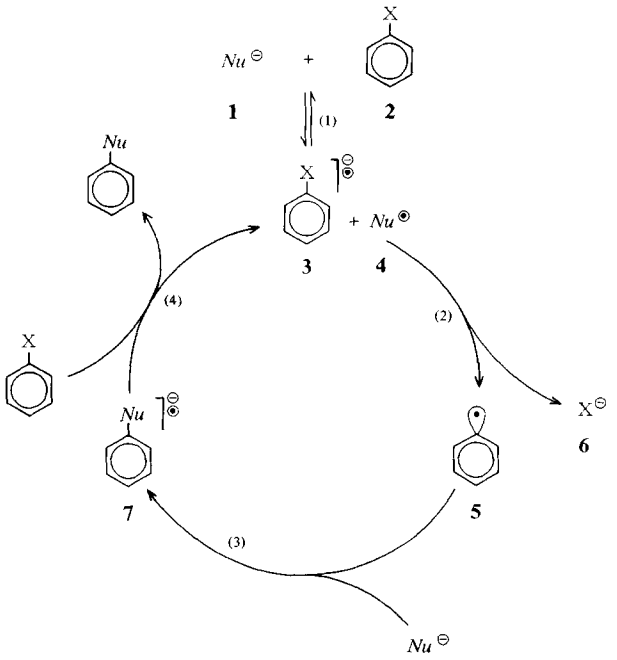
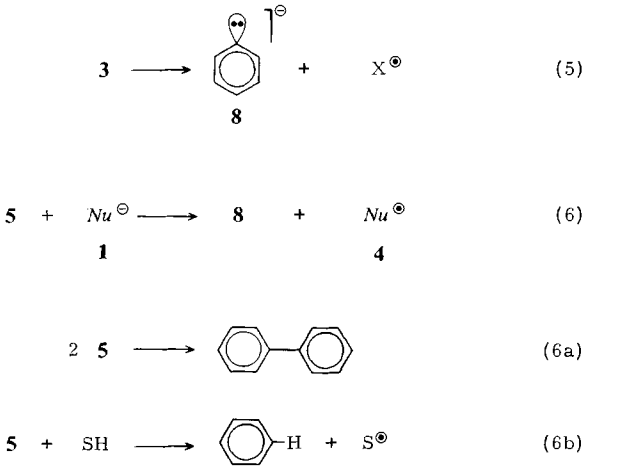
2. Principles of the ETC Concept for Substitution Reactions at Carbon

The mechanism we shall focus on now was proposed in 1966[2a–c]. It explained some very unexpected results of ambident alkylations and permitted the development of novel mild synthetic processes[2d]. *Bunnett* later extended it to substitution reactions of aromatic compounds, termed it $S_{RN}1$, and clearly showed its great potential in synthetic chemistry[3].

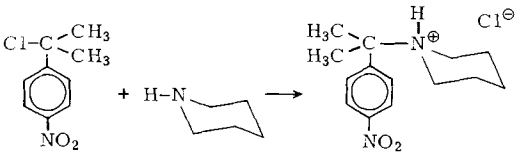


Termination



Scheme 1.

The ETC concept is illustrated in Scheme 1. The first activation occurs in step (1) with the transfer of an electron to the arene; thereby the quite unreactive C_{sp^2}—X bond is activated. The second activation results from the creation of a chain reaction whose active carrier is the radical anion **3**. The overall macroscopic result of this double activation is that reactions such as (7), usually thought to be highly improbable, become feasible under mild conditions[4]. Scheme 1 provides additional information.



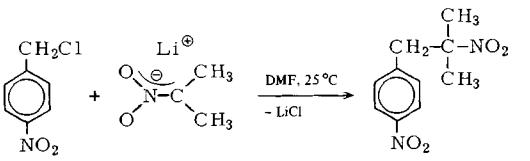
Waters was the first to propose a reaction such as the addition of the radical **5** to an anion **1** as long ago as 1942[5]; however, the first concrete evidence was provided much later by the ESR studies of *Russell*[6a]. This type of reaction is now widely accepted[6b]. The radical anion **7** must be more stable towards dissociation than **3**, otherwise it will decompose faster than electron transfer to the substrate **2**. Finally, the generation of any of the species **3**, **5**, or **7** in the medium by an appropriate reagent will provide entry to the chain propagation cycle.

3. Experimental Criteria Relating to the Assignment of the $S_{RN}1$ Mechanism

Since in the following sections we intend to compare apparently unconnected topics, it is important to enumerate the major pieces of experimental evidence for the involvement of an $S_{RN}1$ mechanism. This is particularly critical if it is noted that the overall stoichiometry of $S_{RN}1$ and S_N2 reactions are almost identical (products of termination reactions generally being present in trace amounts).

3.1. Failure to Follow a Simple Linear Free Energy Relationship

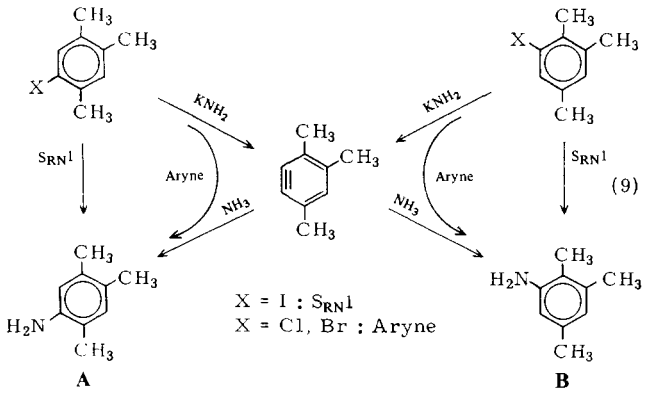
The starting point of the discovery of the $S_{RN}1$ mechanism was the unusual behavior of *p*-nitrobenzyl chloride which reacted with the ambident anion of 2-nitropropane to give a *C*-alkylated product in 92% yield[7].



Other *p*-substituted benzylic chlorides (CN, CF_3, $\overset{+}{N}(CH_3)_3Cl^-$, CH_3, Br) react with the anion mentioned to give exclusively the *O*-alkylated product. This result cannot be explained by σ parameters.

When *Bunnett et al.* discovered the $S_{RN}1$ mechanism his attention was drawn to analogous experimental evidence[8a]. On reacting 1,2,4-trimethylbenzenes with KNH_2 in ammonia, *i.e.* under conditions where the production of an aryne intermediate was expected, he observed an unexpected selectivity ratio **A/B** for the iodo compound.

Bunnett explained this result on the ground that iodated 1,2,4-trimethylbenzenes are able to react *via* an $S_{RN}1$ mechanism, whereas bromo and chloro derivatives do not.

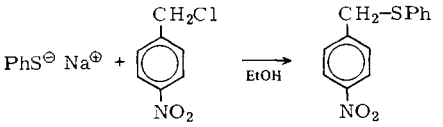


(9)

Many reactions which do not proceed according to this mechanism do not obey simple linear free energy relationships[8b]. Hence, this criterion may be a valuable preliminary indication, but is seldom a definite proof.

3.2. Detection of Radicals by ESR Studies

The proof that paramagnetic intermediates are involved in the $S_{RN}1$ mechanism was demonstrated by ESR studies[9a]. Reaction (8) carried out in dimethylformamide at $-50\,^{\circ}C$ reveals an unambiguous, albeit unresolved ESR signal of *ca.* 30 Gauss line width. Recently *Russell et al.*[10] were able to obtain fairly well resolved ESR spectra in reaction (10).



(10)

As a physical method very sensitive to trace amounts of material, ESR spectroscopy may strongly suggest the participation of an $S_{RN}1$ mechanism but cannot prove that this is the only one involved.

3.3. Abnormal Order of Leaving Groups

In the reaction of benzyl halides with the lithium salt of 2-nitropropane[9a], originally studied by *Kornblum et al.*, the rate of *O*-alkylation (normal S_N2 reaction) increases by a factor of 900 on proceeding from the chloride *via* the bromide to the iodide; in sharp contrast, the rate of *C*-alkylation only increases by a factor of 6[9a]. With aromatic substrates the usual order of reactivity for nucleophilic substitution is

$$ArylF \gg ArylCl \approx ArylBr \approx ArylI$$

which for the $S_{NR}1$ reaction becomes:

$$ArylI > ArylBr > ArylCl > ArylF$$

However, as already mentioned (Section 3.1) this criterion may be ambiguous: for example the aryne mechanism may also cause the "abnormal" order of leaving group abilities.

3.4. Chain-Interruption by Scavengers

If a scavenger able to trap one of the intermediates involved in the chain propagation step is added to the reaction mixture, the reaction is suppressed. This has been the most commonly used criterion to demonstrate that the $S_{RN}1$ mechanism actually operates. *Kornblum et al.* used *p*-dinitrobenzene as inhibitor of the *C*-alkylation[2a], and *Bunnett et al.* used tetraphenylhydrazine to scavenge the intermediates of the $S_{RN}1$ reaction[8a]. However, it must be kept in mind that a scavenger can compete with the other species present in the chain and may give negative results simply because it is not reactive enough. A chain mechanism for the reaction of oxygen with diborane was only proved when the highly reactive scavenger, galvinoxyl, became available[11] (cf. Section 6.4).

3.5. Photostimulation

$S_{RN}1$ reactions are usually greatly accelerated by irradiation. For example, the photochemically accelerated reaction between diethylphosphite and iodobenzene[12] in dimethyl sulfoxide was shown to occur with quantum yields of 50[14], and *Wade*[13] found even greater quantum yields for the photochemically induced substitution of *p*-nitrobenzyl halides. The catalytic function of the near UV is probably due to single electron transfer (SET) from the nucleophile to the substrate *via* an intermediate CT-complex[14]. This criterion is often used without precise measurement of quantum yields, and can provide misleading information; many reactions are photostimulated, and *inter alia Cornelisse* and *Havinga*[15] have reviewed arene substitutions. A feature of the photostimulated $S_{RN}1$ reaction is the high quantum yield. However, since the rate of a chain reaction is equal to the product of the chain length (chain length = chain propagation rate/chain termination rate) and the rate of formation of active species, one can readily imagine $S_{RN}1$ reactions that lead to quantum yields < 1. The necessary conditions are the association of a rather short chain with a very low primary quantum yield.

3.6. Racemization

Because of experimental problems, this criterion has seldom been used. It nevertheless played an important role in the development of the $S_{RN}1$ concept since it provided the first experimental evidence that the same nucleophile may react simultaneously *via* an SET process and an S_N2 reaction[16]. Whereas the SET process is characterized by racemization, the S_N2 mechanism leads to an inversion of configuration at the electrophilic center[17].

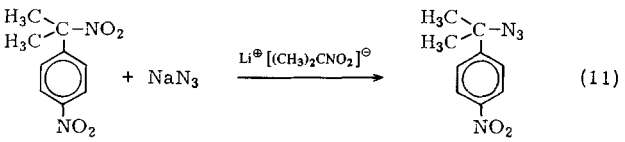
3.7. Formation of Typical Secondary Products

Since radicals play an important role in the $S_{RN}1$ mechanism, secondary products resulting from their dimerization or disproportionation should be observed. However, if the chain process is efficient the final products will be almost free of by-products. Dimerization products have neverthe-

less been reported[18] and, when present, give a valuable indication of the possible occurrence of an $S_{RN}1$ mechanism.

3.8. Activation by Catalytic Chain Initiation

The chain mechanism (Scheme 1) suggests that a catalytic amount of a reactive nucleophile might induce the reaction of a less reactive or even non-reactive nucleophile with an electrophilic center susceptible to $S_{RN}1$ reactivity. The role of the activator is to initiate the propagation cycle which continues by consuming the non-reactive nucleophile. The reaction of α-*p*-dinitrocumene and sodium azide provides a striking example of this phenomenon. These two compounds do not react at all within 48 h in the dark, but when the mixture is treated with the lithium salt of 2-nitropropane (1 : 2 : 0.1 molar ratio) a 97% yield of pure *p*-nitrocumyl azide is obtained in 3 h[19].



(11)

This criterion of catalytic chain initiation has been widely used in aromatic $S_{RN}1$ reactions where the added species ("solvated electron") may either be generated by an excess of alkali metals[20] or at the cathode[21,22].

3.9. Typical Electrochemical Processes

When the electron is generated electrochemically, deeper insight into the detailed mechanism is gained by use of cyclic voltammetry and polarography. By means of these methods considerable information about the fundamentals of the $S_{RN}1$ mechanism has been gained[21,22,300].

3.10. Kinetic Data

It is worth noting that kinetic rate laws have seldom if at all been used as a definite proof for the $S_{RN}1$ mechanism. The first reports by *Kornblum* interpreted the rate of *C*-alkylation by the approximation:

$$v = k[RX][Nu]$$

which does not, obviously, suggest a chain mechanism. According to *Shein*[23], the presently accepted classification of the reaction mechanisms of nucleophilic substitutions of arenes based on the reaction order, is inadequate. This lack of data may be partly understood since there are more elementary reactions than products[24]. However, some indications may be gained by kinetic measurements[25]. In any case, the application of kinetic simulations[26] to chain mechanisms in solution should help to clarify the effect of changes in the elementary steps on the overall kinetics.

3.11. Induced Polymerization of Styrene

An original and efficient way of showing that radical species are present in a solution is to use them to initiate a chain reaction. In this way, even if the amounts of radical are very small, a "chemical amplification" arises[27]. Using this principle, *Surzur et al.*[28] were able to demonstrate the presence of free radicals in the reaction (12).

(12)

This experiment, however, does not guarantee that a chain develops from the radical when styrene is no longer present.

3.12. Magnitude of Isotope Effects

In investigations of radical production from the interaction of closed-shell molecules, *Pryor et al.*[29] discovered an interesting test for distinguishing S_N2 reactions from SET mechanisms. Reactions of nucleophiles with peroxides can be divided, according to isotope effect, into two classes. If the rate constant for β-deuteration displays an inverse isotope effect (*i.e.* $k_H/k_D < 1$) then the mechanism is probably S_N2. In contrast, if $k_H/k_D > 1$, then the SET mechanism is preferred. Besides its practical importance, this test could provide deeper insights (Section 6.3) into the actual mechanistic competition between the S_N2 and SET within a given solvent cage ("magnetic isotope effect"[30]).

3.13. Replacement of Two Substituents without the Intermediate Formation of Monosubstitution Products

Several dihalobenzenes react photochemically with phenoxide ion to form disubstituted products without substantial formation of monosubstitution products as intermediates[31]. This result is consistent with the $S_{RN}1$ mechanism and constitutes powerful evidence for this reaction path.

3.14. Synergic Criteria

A chemist interested in the $S_{RN}1$ mechanism might well ask whether all thirteen criteria should be satisfied to prove the mechanism. Table 1 contains some information concerning the answer to this question: typical reactions have been collected, together with the experimental evidence required to prove an $S_{RN}1$ mechanism. No attempt has been made to be comprehensive. Table 1 shows that a single observation of photostimulation may be misleading (Section 3.5); observation of photostimulation and scavenging effects seems acceptable as a definite proof of an $S_{RN}1$ mechanism in exchange reactions[45,46] (cf. however, Section 6.1.2).

Table 1. Experimental evidence indicating an $S_{RN}1$ mechanism.

Reaction	Solvent [a]	Criterion No. [b]												
		1	2	3	4	5A 5B	6	7	8	9	10	11	12	13
	DMF	[32] [35]	[9a]	[9a]	[33a]	[34][13]	[13,17]		[36]			[28]		
PhX + $Nu^{\ominus}$ → PhNu + $X^{\ominus}$	NH_3 [8] DMSO [39]	[37]		[38]	[8]	[12][14]	[c]		[40,41]	[21] [22]				[31]
	[e] [25]				[25]			[25]			[25]			
	MeOH [14]		[42]		[18]	[18][d]		[18]						
	NH_3 [43]	[43]				[43]			[43]					
	NH_3 [45]					[44]		[44]	[44]					
	DMSO DMF [45]				[45]	[45]								
	THF [46]				[46]	[46]								

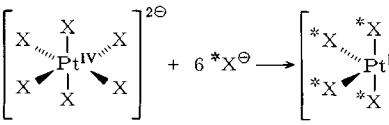
[a] Representative solvent. [b] The criteria are numbered as in the text; *e.g.* "4" corresponds to Section 3.4. 5A signifies: qualitative photostimulation; 5B signifies: determination of the quantum yield. [c] In this instance the stereochemistry is unimportant. [d] Weak effect. [e] Aqueous buffer solution.

4. ETC S in Octahedral Complexes[*]

4.1. Experimental Observation and Reexamination of the Mechanisms

To find the inorganic counterpart of the $S_{RN}1$ mechanism we must look for a reaction which fulfills most of the criteria given in Table 1. Table 2 summarizes the observations relating to reaction (13), X = Cl.

From a comparison of Tables 1 and 2 it follows that reaction (13) proceeds *via* an ETC mechanism (Scheme 2; the species and reaction steps are numbered as in Scheme 1).



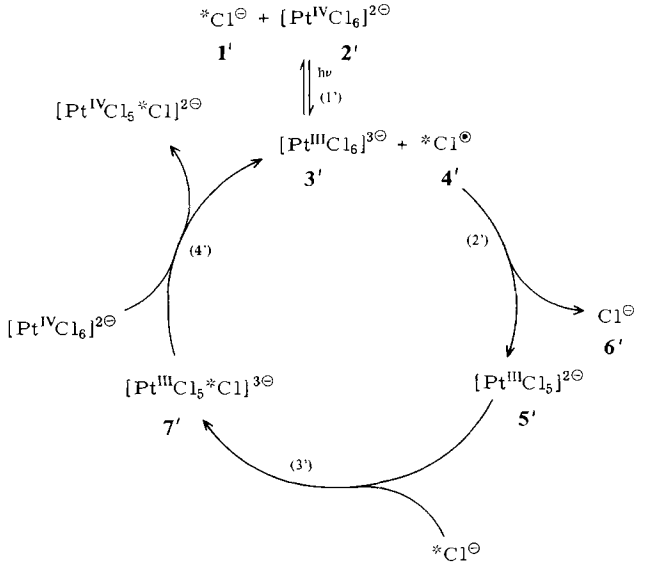
(13)

Table 2. Observations on reaction (13), X = Cl, a typical inorganic $S_{RN}1$ reaction (criteria no. 5A, 5B, see Table 1; cf. also Scheme 2).

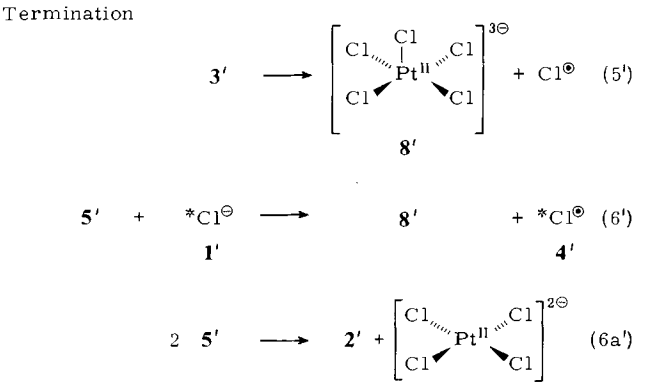
Observation	Method Criteria No.	Ref.
Aqueous solutions of K_2PtCl_6 (0.039 mol/L) in the dark in presence of $Cl^{\ominus}$ ions (0.0087 mol/L) at 25° exchanges 20% in 20 min in the dark. The same solution in diffuse day light exchanges 100% in the same time.	Kinetics with ^{36}Cl (5A)	[47a]
In the presence of hydroquinone or $K_3Fe(CN)_6$ the exchange no longer takes place.	Kinetics with ^{36}Cl (4)	[47a]
The rate of exchange in Pt^{IV} complexes depends upon the concentration of the substituting agent. These data have been interpreted as a redox process which sets up a chain mechanism. The equation $k_{obs} = k_1 \left[\frac{k_1}{k_2}\right]^{1/2} \left[\frac{Pt^{II}}{Pt^{IV}}\right]^{1/2} [Y]$ derived from the above mechanism is found to agree with the observed results.	Kinetics (10)	[48]
The $[PtCl_6]^{2-}$ /I exchange reaction is greatly accelerated by small amounts of thiosulfate or Fe^{II}.	Kinetics (8)	[49, 50]
The quantum yields of the exchange reaction $[(PtCl_6]^{2-}$ /Cl have been measured at various temperatures, pH values, and wavelengths and vary between 15 and 1000 [51]. The values depend on the square root of the light intensity and on the halide concentration [52].	Photochemistry (5B)	[51, 52]
The spectrum of the transient obtained during a flash photolysis study of $[PtCl_6]^{2-}$ [53] is virtually identical to that of the Pt^{III} species obtained by pulse radiolysis of $[PtCl_6]^{2-}$ [54].	Flash photolysis Pulse radiolysis (2)	[53–56]
The UV spectrum of *trans*-$[Pt(en)_2Cl_2]^{2+}$ changes considerably [57] on addition of excess Br or I . This was explained by the formation of a CT-complex. CT-complexes have been observed in typical $S_{RN}1$ reactions [14].		[57, 58]

[*] S signifies substitution.

This mechanism has never been considered before for this reaction. For sake of brevity we only represent the case where a radioactive chloride at the labile Pt^{II} complex is exchanged. It is clear however, that, depending on the relative rates of SET and substitution, several successive substitutions may occur before the last electron transfer occurs. This situation would exactly correspond to the reactivity of polyhaloarenes[31]. In 1954, *Taube et al.*[47a] proposed the mechanism in Scheme 3 for this kind of reaction,



Termination



Scheme 2. *Cl = ^{36}Cl.

Initiation

$$[Pt^{IV}Cl_6]^{2\ominus} \xrightarrow[\text{Photo-dissociation}]{h\nu} [Pt^{III}Cl_5]^{2\ominus} + Cl^{\odot} \quad (14)$$

Propagation

$$[Pt^{III}Cl_5]^{2\ominus} + {}^*Cl^{\ominus} \xrightarrow{\text{Exchange}} [Pt^{III}Cl_4{}^*Cl]^{2\ominus} + Cl^{\ominus} \quad (15)$$

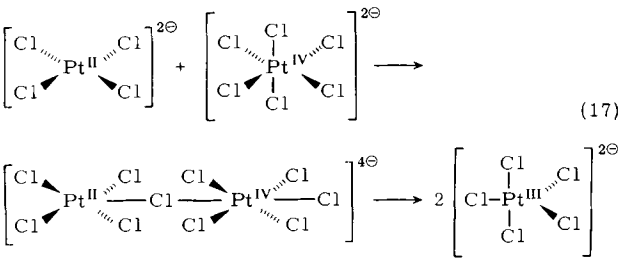
$$[Pt^{III}Cl_4{}^*Cl]^{2\ominus} + [Pt^{IV}Cl_6]^{2\ominus} \xrightarrow[\text{Inner Sphere}]{\text{SET}} [Pt^{IV}Cl_5{}^*Cl]^{2\ominus} + [Pt^{III}Cl_5]^{2\ominus} \quad (16)$$

Termination

$$2\,[Pt^{III}Cl_5]^{2\ominus} \xrightarrow[\text{tionation}]{\text{Dispropor-}} [Pt^{IV}Cl_6]^{2\ominus} + [Pt^{II}Cl_4]^{2\ominus}$$

Scheme 3. *Cl = ^{36}Cl.

discovered experimentally as early as 1832[59] and sporadically studied before 1954[60,61]: in the absence of experimental evidence the termination step was only tentatively suggested. Clearly, the mechanism (14)—(16) explained the catalytic action of reducing agents (including $[Pt^{II}Cl_4]^{2-}$) *via* an inner sphere redox mechanism (17).



Taube's mechanism departs from the $S_{RN}1$ type in one major point. At least in the Pt^{IV} complex, the presence of two chloride ions, one for the initiation step and the other for the substitution step, are required. As a consequence, *Taube*'s mechanism cannot be extended to organic substrates where an $S_{RN}1$ mechanism was discovered; on the other hand the $S_{RN}1$ mechanism perfectly (but see [47b]) explains the experimental data reported for inorganic substrates including the fact that $[Pt^{IV}(NH_3)_5I]^{3+}$ undergoes ligand exchange I^-/Br^-, catalyzed by $[Pt(NH_3)_4]^{2+}$[62]. In addition, the $S_{RN}1$ mechanism explains why a) conflicting rate laws were reported for this type of reaction[48,51], b) the addition of Ce^{IV} as quencher[64] may lead to equivocal results, and c) hydration products may be formed during the exchange[63c,65,66].

The $S_{RN}1$ mechanism is consistent with physical data obtained by flash photolysis[66–69] and pulse radiolysis[55,56,70,71] studies, and until now unconnected with the results of "classical" evidence. The isotopic exchange reaction of $[Pt^{IV}Br_6]^{2-}$[72,73] and the ligand exchange reactions $[Pt^{IV}Cl_6]^{2-}/Br^-$[63d] and $[Pt^{IV}Br_6]^{2-}/Cl^-$[63e], may be reinterpreted in the light of the $S_{RN}1$ mechanism.

Table 3 tentatively summarizes the insights that the present unification brings to organic and inorganic chemists.

4.2. Inspection of the Double Electron Transfer Mechanism

One point related to isotopic exchange catalyzed by Pt^{II} complexes deserves further comment.

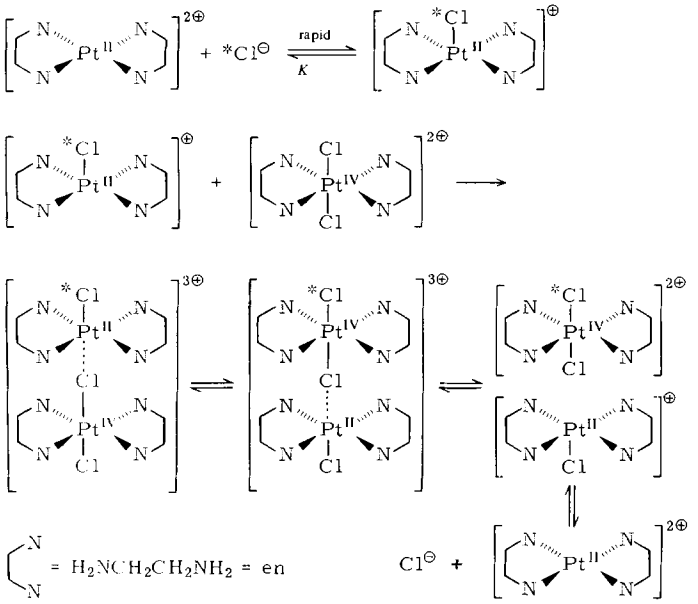
In 1958 *Basolo, Pearson et al.*[64a,83,84] proposed a mechanism to explain the catalytic activity of $[Pt^{II}(en)_2]^{2+}$ in chloride exchange in $[Pt^{IV}Cl_2(en)_2]^{2+}$ (Scheme 4). This, in the meantime, classic mechanism involves a "double electron transfer".

In a typical run, an aqueous solution of *trans*-$[Pt^{IV}(en)_2Cl_2]^{2+}$ (0.001 mol/L) in the presence of excess HCl (0.01 mol/L) and catalytic amounts of $[Pt^{II}(en)_2]^{2+}$ (0.0002 mol/L) kept at 25 °C in the dark exchanged chloride at a rate of 9.2×10^2 mol L^{-1} min^{-1}. Addition of 0.002 mol/L hydroquinone after one half-life did not measurably alter the exchange rate. (In [64a] it is not specified why

Table 3. New Insights provided by the unification of experimental results from inorganic and organic chemistry within the ETC concept.

Inorganic Chemistry	Organic Chemistry
The mechanism of isotopic exchange proposed for platinum complexes [47a] should be modified.	Flash photolysis and pulse radiolysis could provide more information on the ETC concept of organic substrates.
The chain mechanism $S_{RN}1$ may coexist with the double electron transfer mechanism [83] for some Pt^{IV} complexes. This proposition should also be checked for the other complexes displaying ETC behavior (Table 6).	Precise quantum yield determinations should be reexamined after the publication by *Stranks et al.* [80].
The electrochemistry of some inorganic complexes [74] should be reinvestigated taking into account the results obtained by *Savéant et al.* [21] and *Simonet-Lund et al.* [22].	Some exchange reactions could proceed *via* an $S_{RN}1$ mechanism.
Some aspects of reactivity linked to square planar complexes [75-77] should be considered keeping in mind the parallel between the activity of arenes and square planar complexes.	Some ETC reactions could start *via* an inner sphere SET. More generally the inner sphere outer sphere distinction [82] could profitably be introduced in the organic chemistry nomenclature.
The ETC concept could find other applications in the reactions of Pt^{IV} and Pt^{II} [78].	Oxidative ETC reactions should be more often considered as a possible mechanism (Section 5.2) and the experiments necessary to reject it conceived.
Reactions between paramagnetic inorganic complexes and generalized nucleophiles, according to step (3) should be carried out.	More attention should be paid to the experimental determination [143] of redox properties of excited states.
The ambident reactivity of some nucleophiles towards inorganic complexes [79] could sometimes parallel the behavior described by *Kornblum et al.* [2a, c, d].	The relation between standard potential proposed in 1978 [21b, c] is not an absolute necessity for the observation of ETC.
Inorganic photochemical reactions should be carefully considered in relation to the ETC mechanism.	Exploration of the reactivity of polyhalogeno alkanes and alkenes could be interesting within ETC. ETC reactions may occur in water.
	The treatment of general acid/base catalysis should, under certain conditions, include a SET term.
	ETC S, E, A, Re, Ra, Ox mechanisms should systematically be investigated as an efficient way to activate inert substrates.
	The photochemical reactivity of organic species in the presence of oxidizing and reducing agents should be systematically investigated.
	Molecular assisted homolysis (MAH) should be reexamined [252d] in relation to ETC (see Section 6.5.4).

the addition was carried out after one half-life rather than at the start.)

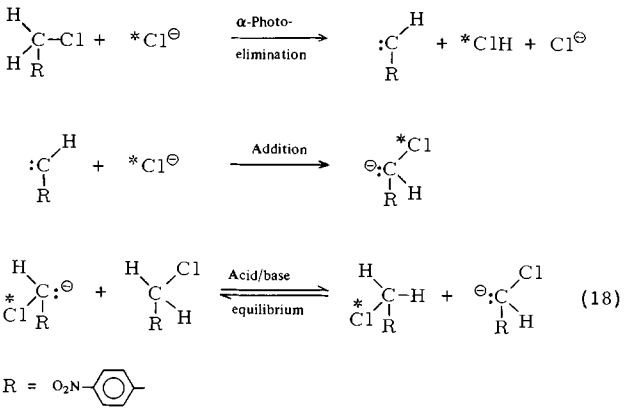


Scheme 4. *Cl = ^{36}Cl.

The two electron transfer mechanism has been the starting point for a large number of quantitative studies (cf. *e.g.* [86]).

Application of the mechanism (Scheme 4) to a supposed radioactive chloride exchange on a benzylic substrate is shown in Scheme 5.

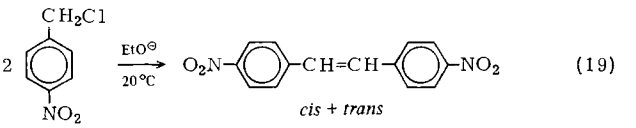
In this analogy, the carbene corresponds to a square planar Pt^{II} complex: to pass from an octahedral $[Pt^{IV}X_6]^{2-}$ to the planar $[Pt^{II}Cl_4]^{2-}$, a reductive elimination is required which is exactly equivalent to the α-elimination in the language of the organic chemist. In reaction (18) the "bridge" is formed by the H atom.



(18)

Scheme 5. *Cl = ^{36}Cl.

Some organic reactions originally thought to involve carbenes[87-89] have recently been reinterpreted by *Russell et al.*[10] in terms of an $S_{RN}1$ mechanism, *e.g.* reaction (19)[87].



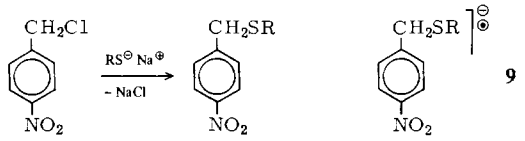
(19)

Before *Kornblum* proposed the chain mechanism he performed several experiments to reject the carbenoid hypothesis[90].

Recently, *Elding* and *Gustafson*[91,92] noticed that during chloride addition to *trans*-$[Pt^{IV}Cl_4(H_2O)_2]$ and to *trans*-$[Pt^{IV}(CN)_4Cl(H_2O)]^-$ in the presence of $[Pt^{II}Cl_4]^{2-}$ the primary reaction product was $[Pt^{IV}Cl_5(H_2O)]^-$. Furthermore, a discrepancy between the value of the equilibrium constant for the process

$$[Pt^{II}L_4]^{2\oplus} + X^{\ominus} \overset{K}{\rightleftharpoons} [PtL_4X]^{\oplus}$$

obtained from a kinetic analysis using the expression derived from the bridged mechanism and that estimated directly by spectrophotometry was found. To rationalize these findings the authors proposed that the thermal reaction begins with the formation of a dinuclear complex from the Pt^{IV} substrate complex and the simple Pt^{II} complex hydrated in the axial position is formed. In this mechanism, the implicit assumption is made that the bridged intermediate is sufficiently long-lived to undergo substitution and two electron transfer. The experimental results could, however, be interpretated completely differently according to the recent report of *Russell* on organic derivatives[45]. This author showed that a given nucleophile and electrophile may simultaneously undergo $S_{RN}1$- and S_N2-substitutions. The reaction of thiophenoxide or methanethiolate ion with *p*-nitrobenzyl chloride in ethanol yields the corresponding *p*-nitrobenzyl sulfides in 97 and 68% yields, respectively (cf. also reaction (10)).



9

In both cases *Russell* obtained evidence for the radical anion **9** which establishes the involvement of the $S_{RN}1$ mechanism in the overall substitution. However, when R = Ph, the reaction is not retarded by addition of 10 mol% of *p*-dinitrobenzene or accelerated by illumination with visible light. When R = Me the effects also occur but are relatively small.

These results enable the mechanisms for substitution at Pt^{IV} to be viewed in a new light. It appears[93a] that only the base hydrolysis of $[Pt(NH_3)_5Cl]^{3+}$, *cis*-$[Pt(NH_3)_4Cl_2]^{2+}$, and *mer*-$[Pt(NH_3)_3Cl_3]^+$ are nucleophilic substitutions[94] at Pt^{IV} complexes. Most other examples should rather be considered as substitutions at the reaction center X^+ (X = halogen). — Nomenclature: reaction (20) is termed an

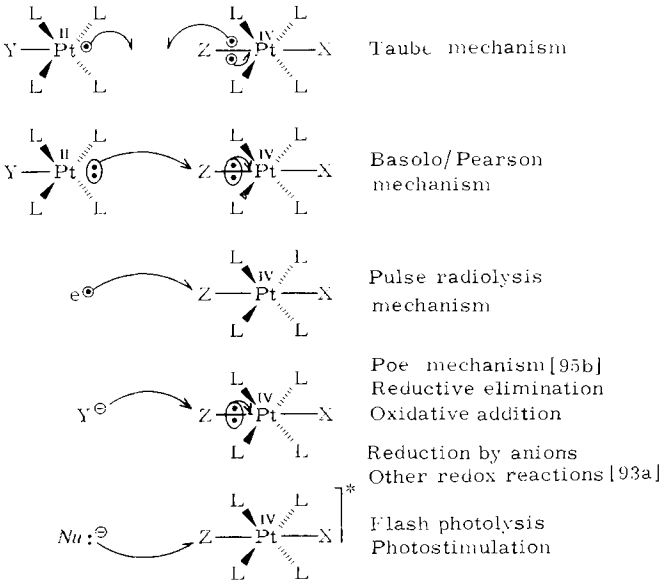
(20)

inner sphere atom transfer redox process or a two electron transfer process by inorganic chemists and a nucleophilic substitution on the electrophilic center X^+ by organic chemists.

The primary steps in substitutions at the center may be represented symbolically as shown in Scheme 6.

These simple schemes represent the perfect analogy[93b] that exists between the *Russell* experiment and the reactions of the platinum complexes. The main difference between *Russell*'s interpretation and the first step of the *Taube* catalysis is that *Taube*'s reducing agent $[Pt^{II}L_4Y]$ acts as an inner sphere reductant (reaction (17)). The consequence of this analogy is that, in our opinion, many reactions which have been described as involving a bridged mechanism are in *fact a combination of two mechanisms*. This obviously covers both substitutions[86] and reductions by anions[93a].

Since this hypothesis can be applied to several inorganic reactions we give some criteria which could be indicative



Scheme 6.

of such a combination. The first is the existence of photostimulation; this means that at least part of the mechanism involves a *Taube* initiation. The second is the demonstration that one electron reducing agents increase the rate of the reaction. The third is the unexpected hydrolysis products; H_2O can trap unstable Pt^{III} intermediates[55,56]. It is well known that the $S_{RN}1$ mechanism permits ready exchange of one or two ligands by water (see Section 3.13).

Application of these simple criteria could allow rapid reexamination of many results on substitution and reduction of Pt^{IV} compounds[62,78,86,93a]. Reaction (21), which

$$trans\text{-}[Pt^{IV}(en)_2Cl_2]^{2\oplus} + 2\,Br^{\ominus} \rightarrow trans\text{-}[Pt^{IV}(en)_2Br_2]^{2\oplus} + 2\,Cl^{\ominus} \quad (21)$$

undergoes photostimulation, has already been tested[48]. To obtain a reaction rate in the dark comparable to that obtained in light at 25 °C the solution temperature had to be raised to approx. 50 °C. For the reaction between $[Pt^{IV}(NH_3)_2(NO_2)_2Cl_2]$ and pyridine, photostimulation and Pt^{II} catalysis have been simultaneously observed[48].

5. ETC S in Square Planar Complexes

Does the parallel between organic and inorganic compounds, already established for "saturated" electrophilic centers, continue with unsaturated species?

5.1. Reductive ETC S

In 1954, *Taube et al.*[96] reported that the exchange between $[Au^{III}Cl_4]^-$ (d^8), and $^{36}Cl^-$ was greatly accelerated by addition of catalytic amounts of $[Fe^{II}(CN)_6]^{4-}$. A turnover of 10^4 $^{36}Cl^-$ per Fe^{2+} was observed. Other reducing agents (Sn^{II}, Sb^{III}, Au^I, V^{IV}) proved to be efficient catalysts but to a lesser extent than Fe^{II}. *Taube* proposed the mechanism shown in Scheme 7.

Initiation

$$[AuCl_4]^{\ominus} + [Fe(CN)_6]^{4\ominus} \xrightarrow[k_1]{SET} [AuCl_4]^{2\ominus} + [Fe(CN)_6]^{3\ominus}$$

Propagation

$$[AuCl_4]^{2\ominus} + {}^*Cl^{\ominus} \xrightarrow[\text{exchange}]{\text{rapid}} [AuCl_3{}^*Cl]^{2\ominus} + Cl^{\ominus} \qquad (22)$$

$$[AuCl_3{}^*Cl]^{2\ominus} + [AuCl_4]^{\ominus} \xrightarrow{SET} [AuCl_3{}^*Cl]^{\ominus} + [AuCl_4]^{2\ominus}$$

Termination

$$2\,Au^{II} \longrightarrow Au^{I} + Au^{III}$$

Scheme 7. *Cl = ^{36}Cl.

The kinetic law expected for such a mechanism with long chains was strictly followed. This mechanism differs from the $S_{RN}1$ mechanism: the direct exchange (step 22) would have to be replaced by a dissociative step followed by recombination with $^{36}Cl^-$ to parallel the $S_{RN}1$ mechanism. Tests recently proposed by *Bunnett* to distinguish between $S_{RN}1$ and $S_{RN}2$ should be applied to this reaction[97].

Transient Au^{II} species have been obtained by pulse radiolysis of $[Au^{III}Cl_4]^-$; it appears that the number of coordinating ligands is dependent on the concentration of free ligand in solution[98,99]. Very little is known about the dissociative ability of square planar d^9 complexes[100]. Quantitative data on the photostimulated chloride exchange have not been published, but the use of $[Au^{III}Cl_4]^-$ as a sensitizer in the photopolymerization of *N*-vinylcarbazole[101] suggests that $[Au^{III}Cl_4]^-$ could possibly be a better oxidant in the excited state.

5.2. Oxidative ETC S: Consequences for the Reactivity of Organic Substrates

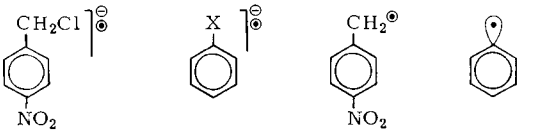
Until now we have only considered double activation reactions induced by reduction of the substrate: in the following we will show that ETC S can also occur by a mechanism that involves oxidation of the substrate as the first step.

A solution of $[Pt^{II}Cl_4]^{2-}$ (0.0125 mol/L) in presence of NaCl (0.0342 mol/L) and HNO_3 (0.062 mol/L) undergoes 1% exchange with radioactive chloride in 30 min at 0 °C. Addition of catalytic amounts of Ce^{IV} (5.5×10^{-4} mol/L), results in 87% exchange in 4 min. The proposed mechanism (Scheme 8) involves the generation of Pt^{III} intermediates[47].

Depending on the relative rates of SET and substitution, $[Pt^{II}Cl_3OH]^{2-}$ may or may not be observed as a secondary product in the exchange reaction.

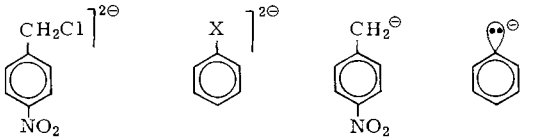
The really important conclusion is that an *oxidatively induced ETC mechanism* is possible. Furthermore, photostimulation operates in this system. The light catalyzed reaction of I^- and $[Pt^{II}Cl_4]^{2-}$ has been observed to be inhibited by thiosulfate ions, which probably indicates catalysis by Pt^{III}[102]. A closer look at anomalies in ligand exchange reactions[76,77] in Pt^{II} complexes could provide other examples of the oxidative ETC mechanism.

In organic systems active species can also either be generated by addition or by loss of an electron. In the $S_{RN}1$ mechanism the active species are either of type **10** or **11**, or of type **12** or **13**.



10 **11** **12** **13**

To obtain these species by oxidation the dianions **10a** and **11a**, or the sp^3 carbanion **12a** and the sp^2 carbanion **13a** must be used as starting agents.

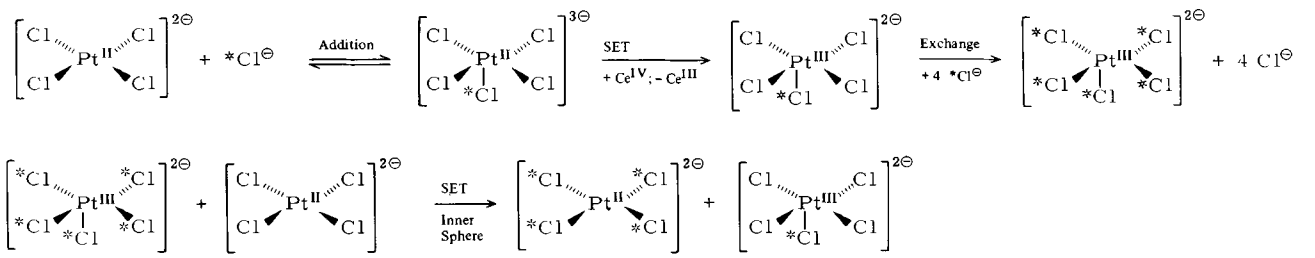


10a **11a** **12a** **13a**

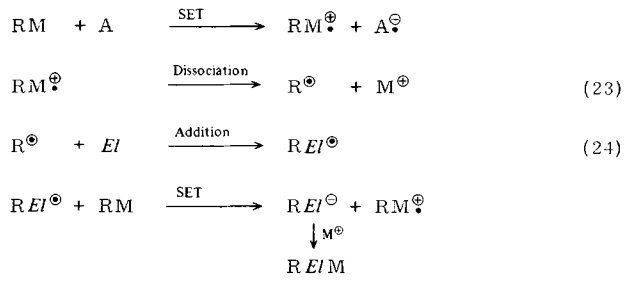
The generation of organic dianions in solution is usually difficult[103]. They can, however, be obtained fairly easily in aprotic solvents by electrochemical means[22a]. In presence of appropriate oxidizing agents (light may be the oxidizing agent, cf. Section 6.1.2) an oxidatively induced ETC reaction could be produced.

Carbanion intermediates pervade the whole of organic chemistry[104]. They usually do not exist (except in special cases[105]) as free species in solution but rather as ion pairs[106] or solvated ions[107]. Discussion will be limited to the example of the ETC mechanism in Scheme 9 which until now has not been applied to this field.

In this mechanism a catalytic oxidant (chemical or light) induces a chain reaction.

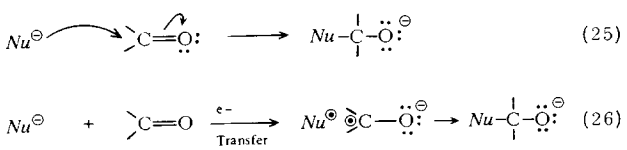


Scheme 8. *Cl = ^{36}Cl.



Scheme 9. *El* = electrophilic center; A = electron acceptor (possibly identical with *El*); M = metal or MgX; R = carbanion precursor.

A clear distinction should be made between the ETC variant of DAISET, *i.e.* the double activation induced by single electron transfer and the "SAISET"[*] mechanism[109]. For example, it has been shown that small amounts of impurities in the magnesium seem to have a great effect on the kinetics of the reaction involving addition of Grignard reagents to aldehydes and ketones[110]. *House*[111] proposed the following scheme to rationalize the observed facts: One-step nucleophilic addition (reaction 25) and two-step electron transfer (reaction 26).



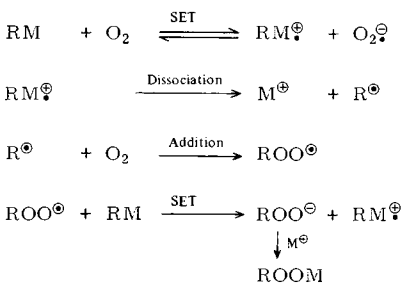
This reaction scheme (cf. [112]) corresponds to a competition between nucleophilic addition and a reductive SAISET mechanism: *i.e.* a special reactivity is induced in the carbonyl group by a single electron transfer. Most electrochemically induced reactions[109] are of this type. *House*'s results could also be interpreted as resulting from an oxidative DAISET S; set *El* = >C=O in reaction (24)[112]. Similarly, the formation of the Grignard reagent from magnesium and an alkyl halide, which is known to be catalyzed by oxidizing agents[113, 114] and sensitive to irradiation[114a], could be regarded as an oxidative DAISET reaction. In this case, it could give some interesting clues for the heterogeneous catalysis in solution[115].

The oxidative ETC mechanism has also never been considered for the autoxidation of boranes, which has been viewed as a chain mechanism[108b, 116] similar to that involved in the autoxidation of other organoelement compounds[117].

Furthermore "Bimolecular Homolytic Substitution at a Metal Center" (S_H2) mechanism, depends on this reaction type:

The chain mechanism for the autoxidation is probably correct; in the ETC alternative (Scheme 10), which has not previously been considered, the S_H2 step can be circumvented.

The discussions on this point are misleading since they suggest that the S_H2 and electron transfer mechanisms



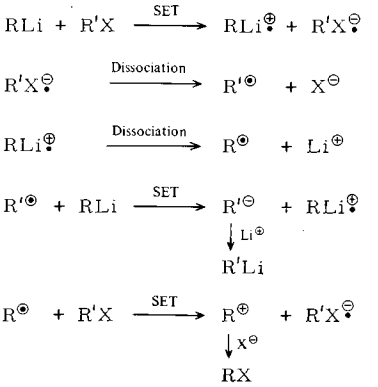
Scheme 10.

only differ in the degree of charge separation in the transition state[118]. In the ETC process, $ROO^{\ominus}$ attacks another metal center.

The possibility of a ETC mechanism has also been neglected in the interpretation of CIDNP results. In a review on CIDNP[119] theory it is stated that no CIDNP effect was found in the reaction of *tert*-butyllithium with *n*-butyl iodide at −70 °C under conditions where rapid halogen-metal exchange, but no C—C coupling occurs[120]. This indicates that no electron transfer occurs in the exchange

RLi + R'Hal → RHal + R'Li

in spite of earlier reports[121]. The ETC alternative where electron transfer is followed by a chain reaction, so that there is the possibility that the initial polarization can relax, is not discussed (Scheme 11).



Scheme 11. Other possibility: S_H2 reaction of R with R'X (see [47b, 304]).

6. More about the ETC Concept

6.1. The First Activation

6.1.1. Quantitative Estimation

We have defined the first activation in the ETC mechanism as *the transfer of a single electron* to/or from the substrate to be activated.

Reductive activation can spectacularly enhance molecular reactivity. Some results are gathered together in Table 4. There are also a number of systems that do not change their reaction behavior upon oxidation or reduction. For example, V^{III} and V^{II} exhibit almost identical rates of exchange of water between the coordination sphere and sol-

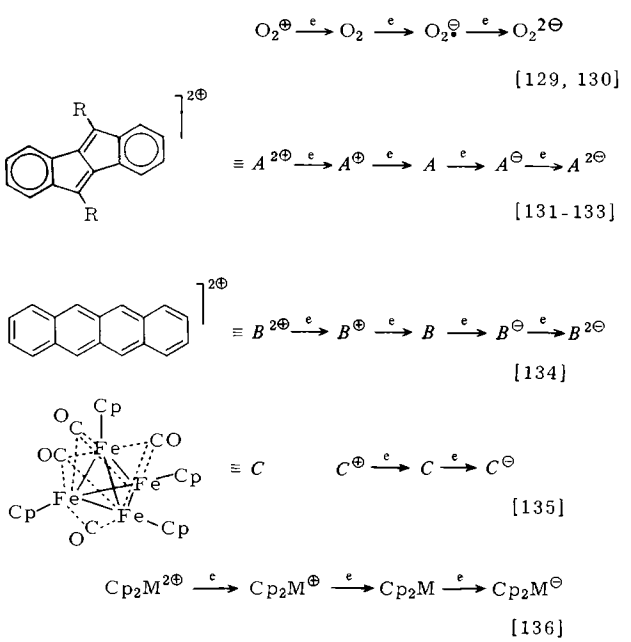
[*] SAISET = "*S*ingle *A*ctivation *I*nduced by *S*ingle *E*lectron *T*ransfer".

Table 4. The first activation in the ETC mechanism.

Reaction type	k (M^0)	k ($M^{\ominus}$) [a]	Ratio [b]	Ref.
$[Cr^{III}(H_2O)_6]^{3\oplus} + H_2O^* \rightarrow [Cr^{III}(H_2O)_5H_2O^*]^{3\oplus} + H_2O$	3×10^{-6}			[122]
$[Cr^{II}(H_2O)_6]^{2\oplus} + H_2O^* \rightarrow [Cr^{II}(H_2O)_5H_2O^*]^{2\oplus} + H_2O$		10^{9}	10^{-15}	[122]
$[Ru^{III}(H_2O)_6]^{3\oplus} + H_2O^* \rightarrow [Ru^{III}(H_2O)_5H_2O^*]^{3\oplus} + H_2O$	$< 10^{-6}$			[122]
$[Ru^{II}(H_2O)_6]^{3\oplus} + H_2O^* \rightarrow [Ru^{II}(H_2O)_5H_2O^*]^{2\oplus} + H_2O$		10	10^{-7}	[122]
$PhCO_2^{\bullet\oplus} \rightarrow CO_2 + Ph^{\bullet\oplus}$	$\approx 10^{5}$			[124]
$PhCO_2^{\ominus} \rightarrow CO_2 + Ph^{\ominus}$		10^{-6}	10^{11}	[125]
 $\rightarrow$ PhC≡CPh + CO	[c]			[126]
 $\rightarrow$ PhC≡CPh + CO		[d]		[127]
	$\approx 10^{-12}$			[127]
		10^{3}	10^{-15}	[127]

[a] Reduced form. [b] $k(M^{II})/k(M^{\circ}) < 1$: reductive activation; $k(M^{II})/k(M^{\circ}) > 1$: oxidative activation. For further examples of reductive activation, see [128]. [c] Thermal CO cleavage at 150 °C. [d] Lifetime of the initial radical at −90 °C; 20 min.

vent[122]. The study of electrochemical reduction of halogenosilanes and halogenogermanes demonstrated that their radical anions tend to dissociate less than their haloalkane counterparts[123]. Some molecular species are dissociatively inert over a range of oxidation states (Scheme 12).



Scheme 12. Cp = cyclopentadienyl, M = Ni or V.

It is of note that until now, little theoretical work has been carried out to investigate the dependence of the reactivity on the oxidation state. A simple approach would be to examine the LUMO since if this is strongly antibonding, the molecular species would be strongly dissociatively activated by reductive initiation; in contrast, if the HOMO is strongly bonding the species could be easily oxidatively activated[137-139]. These statements are probably not sufficient. SCF-X_α molecular orbital calculations could be a starting point for more detailed investigations (cf. [140]).

6.1.2. The Photon as a Chemical Reagent

Kochi recently stressed the equivalence of the terms "charge transfer" (organic vocabulary) and electron transfer (inorganic vocabulary)[108c]. An examination of the literature of organic chemistry shows that while the acid/base properties of excited states[141] have frequently been investigated, their redox properties have, with some exceptions[142], been neglected. *Balzani et al.* in their review articles[143] clearly emphasized several very important points for inorganic systems: species that are in excited states may be quenched in bimolecular processes involving electron transfer reactions, and that an excited state may be *both* a better oxidant and a better reductant than the ground state. For example the excited complex $[Ru^{II}(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridyl) can both reduce and oxidize water[144]. This explains in part the enormous increase in interest in the photochemistry of such complexes and their possible role as catalysts in the conversion of light into chemical energy[145].

To transfer or accept an electron, an excited state must have a lifetime longer than 10^{-9}–10^{-10} s[143c]. This is quite normal for organic molecules, but transition metal complexes usually have shorter lifetimes. However, here again the ETC concept can add a new dimension. If the primary electron transfer is of very low efficiency (low primary quantum yield) due to the short lifetime of the excited state, but induces a fairly long chain, then neglected chemical reactions assume significance. For example, much of

the photochemical reactivity of $[Pt^{IV}X_6]^{2-}$ complexes has been rationalized (see [146d], p. 227) on the basis that the primary step in the photoexchange reaction is reaction (14).

$$[Pt^{IV}Cl_6]^{2\ominus} \xrightarrow{h\nu} [Pt^{III}Cl_5]^{2\ominus} + Cl^{\odot} \qquad (14)$$

The hypothesis

$$[Pt^{IV}Cl_6]^{2\ominus} + Cl^{\odot} \rightarrow [Pt^{III}Cl_6]^{3\ominus} + Cl^{\oplus} \qquad (1')$$

good oxidant in the excited state

$$[Pt^{III}Cl_6]^{3\ominus} \rightarrow [Pt^{III}Cl_5]^{2\ominus} + Cl^{\odot} \qquad (2')$$

has never been formulated[146], probably because it is assumed that the lifetime of the excited state is too short. When it is considered that in flash photolysis experiments addition of X^- accelerates the appearance of the transient[68], reexamination of this rationalization in Pt^{IV} photochemistry could be worthwhile. This also applies to many other photochemical reactions where a step currently interpreted as an induced homolysis could just as well be rationalized by SET in the excited state, inducing bond dissociation followed by a chain reaction[147, 148].

An interesting property of the photon is that, due to the short lifetime of excited states, it probably mainly induces one electron exchanges between the redox couple. This may be useful in mechanistic studies. Another favorable property of the photon is that it disappears after the induction reaction, in contrast to "normal" chemical reagents that may shorten the chain. On the other hand it could be expected that the synergic criteria (Section 3.14) involving the double experiment "scavenging of radicals + photostimulation" can sometimes break down. It is possible to imagine some species whose excited-state lifetime is not long enough to allow an electron transfer, or whose range of photoexcitation is beyond the usually accessible wavelengths.

Interesting applications resulting from combinations of photochemistry and electrochemistry have been recently reported and these extend the scope of the photon as a reagent to an even greater extent[149].

6.2. The Second Activation

It is very difficult *a priori* to answer the question of whether a reaction chain is formed or not. *Savéant et al.*[21b] proposed the relation $E_2^0 < E_1^0$: E_2^0 and E_1^0 are the standard potentials for the reactions

$$ArylNu^{\ominus} - e \rightleftharpoons ArylNu \quad \text{and}$$
$$ArylX + e \rightleftharpoons ArylX^{\ominus}$$

(see Scheme 1). This does not, however fully resolve the problem because:

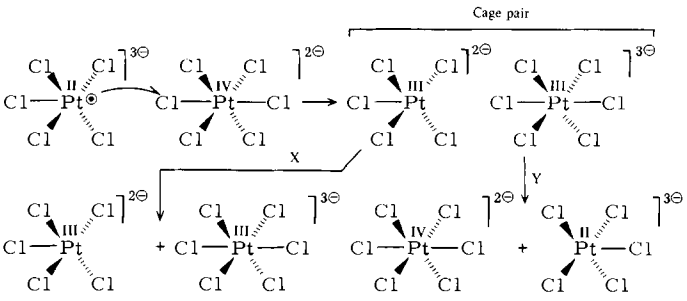
Savéant et al. later demonstrated that for halobenzene and halopyridine substrates this criterion need not be fullfilled for the $S_{RN}1$ mechanism to be observed[21d].

For isotopic exchange reactions (Section 4.1) $E_2^0 = E_1^0$.

Most of the tabulated data[150] concern the half-wave potentials ($E_{1/2}$) rather than actual standard potentials. The use of these $E_{1/2}$ values instead of standard potentials is problematic: the $E_{1/2}$ values of *p*-substituted benzyl chlorides are apparently not correlated with the ease of benzyl radical production. The discrepancies can be quite large; for example, *Flesia*[151] recently evaluated, from $E_{1/2(red)}$ of *p*-nitrobenzyl chloride and $E_{1/2(ox)}$ of thiophenoxide that only 10^{-18} mol/L of the *p*-nitrobenzyl chloride radical anion is present in solution. This value is probably too low. There is clearly a lack of semiempirical methods[152] for estimating standard potentials from half-wave potential values, and more generally an uncertainty about factors which stabilize radical species[153, 154]. All this shows that at present the best way to answer the proposed question is experimentally.

6.3. SET Mechanism or S_N2 Reaction? The "Retro-CIDNP" Alternative

Flesia[151] has proposed a provocative model for the unification of SET- and S_N2-pathways. In this model, $S_{RN}1$- and S_N2-reactions proceed by almost identical routes. In both cases the nucleophile first gives up an electron to the electrophilic center and the selection between $S_{RN}1$ and S_N2 paths occurs within the radical pair. If the two radicals recombine in the cage (Y), the normal S_N2 process occurs, whereas if they can escape from the radical pair and initiate a chain, the $S_{NR}1$ mechanism takes place. For the exchange at $[Pt^{IV}Cl_6]^{2-}$, catalyzed by $[Pt^{II}Cl_4]^{2-}$ this process can be formulated as in Scheme 13.



Scheme 13. The steps (2'), (3')... follow (X, Y, see text).

Flesia's model has been subjected to strong criticism from organic chemists[155d], but it can be taken as a working hypothesis. The different mixtures of products in a chemical reaction are normally related to a Boltzmann distribution of the transition states: twice as much of product A as product B is obtained if the difference $\Delta\Delta G^{+}$ between the processes leading to A and B is *ca.* 400 cal/mol. The results of *Surzur et al.*[28] and *Russell et al.*[45] must answer the question: what factors determine the competition between a chain and a non-chain process and at what precise step is the Boltzmann distribution to be considered?

We propose that the Boltzmann distribution becomes important in the common cage pair—in accord with *Flesia*'s hypothesis—but we extend the reasoning further. One can imagine that the ETC process allows the revelation of phenomena always present in exchange reactions, but seldom seen because they are unfavored in the Boltzmann distribution by a $\Delta\Delta G^{+} \geq 3$ kcal. This follows from the fact

that the "impurity" created can enter a chain with a rate far greater than that of the normal exchange reaction. This "impurity" may be formed either when the solvent cage is loose enough to allow the primary radical pair to escape (SET may occur at distances greater than 10 Å) or when a singlet-triplet transition promotes formation of this species. The phenomenon, always present in exchange reactions, is a type of "retro-CIDNP effect". *Kaptein et al.*[157a,b] and *Closs et al.*[157c,d] proposed that in any homolytic cleavage of a bond there is a favorable separation where the crossing of singlet and triplet states can occur. These two states, always present in pairs of radicals usually do not mix and even the mixing occurring at the most favorable separation is very weak. The CIDNP phenomenon enhances this effect through magnetic resonance[158]. The phenomenon can, in our opinion, also be enhanced by building a chain long enough to balance the $\Delta\Delta G^{+}$ difference: we term this the "retro-CIDNP effect" because now the *S-T* crossing takes place in the formation of the bond. Because of the chain nature of the process, it is difficult to detect it by NMR measurements. However, the action of appropriate magnetic fields[159] on chemical reactivity[7,8a] should make it possible to confirm or reject this hypothesis. *Sagdeev*[30] has recently published an authoritative review which should allow the best experimental conditions to be chosen (temperature, viscosity of the solvent) for the demonstration of magnetic effects on $S_{RN}1$ reactions. An alternative could be to show that one of the two main reactions studied by *Sagdeev*

$$RCl + n\text{BuLi} \xrightarrow[t=40\,^{\circ}C]{\text{hexane}} RBu + RR + LiCl + C_8H_{18} \quad [160a]$$

$$ArylN_2^{\oplus} + RO^{\ominus} + ROH \longrightarrow ArylH + N_2 + \ldots \quad [160b]$$

actually involves an ETC mechanistic pathway.

Despite the fact that carbanions[161], trimethylsilyl-[162], trialkylstannyl-[163a,b] and trialkylgermyl-anions[163c] are excellent electron transfer reagents it is only for the two last anions that an $S_{RN}1$ mechanism has been proposed. *Quintard* and *Pereyre et al.*[46,163] demonstrated that for

$$PhX + Bu_3SnLi \rightarrow PhSnBu_3 + LiX$$

an $S_{RN}1$ mechanism (short chain type) and a classic halogen metal exchange mechanism (and possibly others) compete. This kind of competition was also found in the reaction between bromo- or iodobenzene and R_3GeLi[163c].

An experiment which could transfer the problem of SET *versus* S_N2 from the field of semantics to an experimentally answerable question[156] would be significant. Investigations of the role of spin-orbit coupling[164] in bimolecular reactions could provide information on molecular motions in and out of the solvent cage[165], and their behavior in collisions[166].

6.4. Experimental Difficulties in the Study of ETC Processes

How can we measure the proportion of each process in the overall reaction? Two problems of very different difficulty must be distinguished there. The first is dealt with qualitatively and answers whether the reaction proceeds *via* two simultaneous processes (cf. [108f,167]). The second is the quantitative estimation of each mechanism under various conditions; consideration of the fundamentals of the ETC concept (Section 6.1) immediately indicates how laborious this task is.

Two examples of the obstacles encountered in using the concepts of scavengers and catalysts are given: Studies of the exchange reactions at Pt^{IV} involving inhibition of light induced substitution reactions of $[Pt^{IV}Br_6]^{2-}$ and $[Pt^{IV}I_6]^{2-}$ by $[Ir^{IV}Cl_6]^{2-}$ indicated that the spectrum of $[Ir^{IV}Cl_6]^{2-}$ rapidly disappeared in the presence of iodide, although the inhibitory properties appeared to be retained[168]. $[Ir^{IV}Cl_6]^{2-}$ is extensively used to suppress the participation of the ETC mechanism in reductive elimination/oxidative addition reactions[95,196] and it may be asked if the ETC reaction is completely suppressed[108f]. The exchanging nucleophile *often functions as a reducing agent.* In the original work by *Taube et al.*[47] the concentration of nucleophile was far less than that of the complex (*e.g.*: $[Pt^{IV}Cl_6]^{2-}$ 0.039 mol/L; Cl^{-} 0.0087 mol/L), in which case the effect of quenchers was meaningful. In most of the later studies, however, the concentration of nucleophile was considerably higher: in a typical run *Poë et al.* studied a solution 9×10^{-5} mol/L in $[Pt^{IV}Br_6]^{2-}$, 5×10^{-2} mol/L in I^{-} and 8×10^{-6} mol/L in $[Pt^{IV}Cl_6]^{2-}$[95b]. A further example is provided by the report by *Elding et al.*[91], who found that the rate of the reaction in the dark was unaffected by addition of small concentrations of Fe^{III}. When it is realized that a large excess of the reducing species Pt^{II} is also present in these experiments in the dark it can be asked whether the mechanism for the dark reaction does not probably involve Pt^{III} catalysis[91]. The problem is increased by the fact that scavengers may be an unrecognized part of the reaction mixture: *Dreyer*[51] has shown the presence of Br_2 in commercial HBr and *Grinberg et al.*[170] has shown that under certain pH conditions $[Pt^{IV}X_6]^{2-}$ releases X_2 into solution.

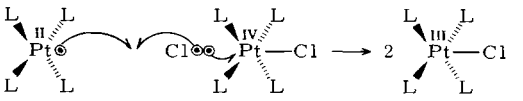
The precise determination of quantum yields for photostimulated ETC reactions is also very troublesome. *Stranks* and *Yandell*[80] have proved that the light intensity exponent can easily rise from 0.5 to 0.7 in solutions containing micromolar concentration of impurities.

6.5. Scope of the ETC Concept

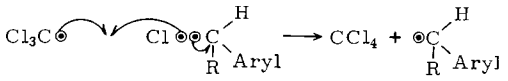
6.5.1. More about Chain Reactions

According to *Cotton* and *Wilkinson*'s[171] generalized definition, complexes are species, charged or uncharged, in which a central atom is surrounded by a set of atoms or ligands (CH_4 is a complex within this definition). This definition is convenient to use in investigating the scope of ETC S.

However, as we intend to cover most molecular species within this approach, we must first clarify a particular point of nomenclature. In the inorganic nomenclature an inner sphere redox process may be represented as



and in organic nomenclature the S_H2 process is written[108d, 172]



A major difficulty in the extension of the inner sphere definition to S_H2 reaction arises from ambiguities in the determination of the oxidation number of carbon[173]. For this reason S_H2-induced chain reactions will not be discussed.

A representation of complexes describing both inorganic and organic species must specify:
The coordination number m, the total charge q, and the number of unpaired electrons s.

The same representation covers both electron acceptor and electron donor complexes:

$$[ML_m]^q_s \quad \text{and} \quad [M'L'_{m'}]^{q'}_{s'}$$

For example in CH_3S^-: M' = C, L' = H, S, q = −1, s = 0.

Within these conventions, a typical $S_{RN}1$ mechanism is shown in Scheme 14:

Initiation

$$[ML_m]^q + [M'L'_{m'}]^{q'} \underset{\text{outer sphere}}{\overset{\text{SET}}{\rightleftharpoons}} [ML_m]^{q+(-1)} + [M'L'_{m'}]^{q'-(-1)}$$

acceptor donor

Propagation

$$[ML_m]^{q+(-1)} \xrightarrow{\text{dissociation}} [ML_{m-1}]^{q+(-1)} + L$$

$$[ML_{m-1}]^{q+(-1)} + [M'L'_{m'}]^{q'} \xrightarrow{\text{association}} \underbrace{[ML_{m-1}]^{q+(-1)}[M'L'_{m'}]^{q'}}_{\text{pair}}$$

$$\text{pair} + [ML_m]^q \xrightarrow{\text{SET}} [[ML_{m-1}]^q[M'L'_{m'}]^{q'}] + [ML_m]^{q+(-1)}$$

Scheme 14.

The value of s must be examined for every particular case because of the filling of d orbitals in transition metal complexes. The extention to charged ligands is easy. The general Scheme 14 may be modified to represent an ETC reaction where the initiation step is an inner sphere single electron transfer.

$$[ML_m]^q + [M'L'_{m'}]^{q'} \xrightarrow[\text{inner sphere}]{\text{SET}} [ML_{m-1}]^{q+(-1)} + [M'L'_{m'}L]^{q'-(-1)}$$

$$[ML_{m-1}]^{q+(-1)} + [M'L'_{m'}]^{q'} \rightarrow \underbrace{[ML_{m-1}]^{q+(-1)}[M'L'_{m'}]^{q'}}_{\text{pair}}$$

$$\text{pair} + [ML_m]^q \xrightarrow{\text{SET}} [ML_m]^{q+(-1)} + \underline{[ML_{m-1}]^q[M'L'_{m'}]^q}$$

$$[ML_m]^{q+(-1)} \rightarrow [ML_{m-1}]^{q+(-1)} + L$$

etc....

Scheme 15.

Scheme 15 corresponds to the case where a strong primary activation is needed: the reducing agent initiates the chain, which then propagates without further assistance. The general oxidative ETC S mechanism could be written according to the same principles (Section 5.2).

These general mechanisms can be modified according to need; an exhaustive study of the ETC concept could reveal new chain reactions or combinations of chains[174]. Enzymatic catalytic chains[175] indicate that even apparently simple reactions must be explained by fairly elaborate combinations of ETC mechanisms.

6.5.2. The SET Matrix

In a publication dealing with the unification of the S_N2 and SET mechanisms (cf. Section 6.3), *Flesia*[151] proposed an ingenious matrix to represent the possibilities of single electron transfer between organic species. Figure 1 illustrates how the matrix can be extended from organic chemistry to all molecular species. In principle, any of the single electron transfers described in this matrix could be the starting point for a chain reaction with the possibility of an ETC process.

For organic molecular reactions, however, only the two cases

$$Nu^{\ominus} + RX \quad \text{and} \quad Nu + RX$$

have been proven to react according to an ETC mechanism.

6.5.3. The Relationship between Electronic Configuration and Reactivity in Transition Metal Complexes

If one wishes to predict which types of transition metal complexes might be expected to undergo exchange reactions of the ETC-type it is necessary to take a number of factors into consideration. In the first place the substrate should be substitutionally inert, *i.e.*, the simple substitution reaction should be slow enough to allow the alternative mechanism to make a major contribution to the overall process. The intermediate of lower or higher oxidation state must be substitutionally more labile than the substrate, and the redox reaction between the intermediate and the substrate should also be fast[82], thereby allowing a chain reaction to occur. Finally, the relative stabilities of the oxidation states[208] should be considered since these will be of importance to initiation and termination processes. The electronic configuration and formal charge of the reaction center serve as a basis for classification. Redox potentials and the rates of redox processes are also very sensitive to the nature of the ligands attached to the reaction center[82].

The simplest and shortest way of discovering transition metals where ETC S can occur is to use the "angular overlap" model[210]. It is, however necessary to reiterate that the lability of a particular leaving group will be very dependent upon its properties: the published rate constants for the exchange of X by H_2O in the complex $[Co(NH_3)_5X]^{n+}$ cover a range of at least 5 orders of magnitude[209]. The following treatment is therefore only an approximate guideline.

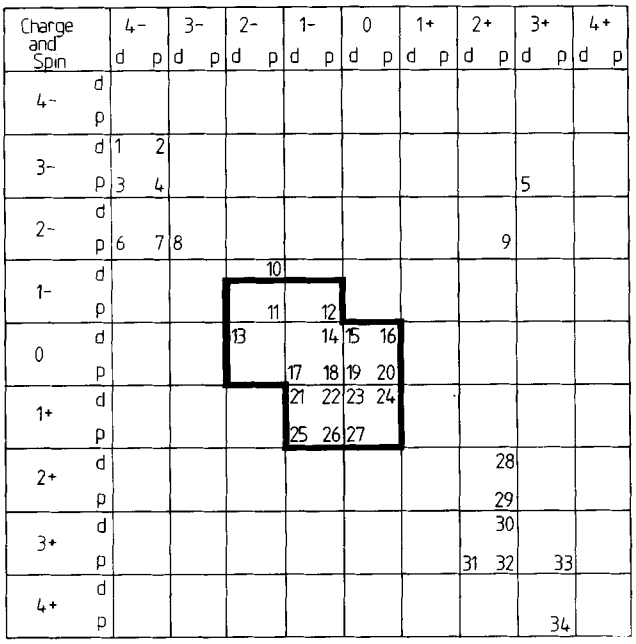


Fig. 1. Matrix showing some possible reactions between molecules and complexes. No attempt has been made to be comprehensive. d signifies a diamagnetic, p a paramagnetic species. For inorganic species this data comes from [176]. The numbers given in the squares refer to the examples below (number, donor + acceptor, reference). Examples from organic chemistry are located in the enclosed area.

1: $[W(CN)_8]^{4-}$ + $[Mo(CN)_8]^{3-}$ [177]
2: $[Fe(CN)_6]^{4-}$ + $[Mo(CN)_8]^{3-}$ [177]
3: $[W(CN)_8]^{4-}$ + $[Fe(CN)_6]^{3-}$ [177]
4: $[Fe(CN)_6]^{4-}$ + $[Fe(CN)_6]^{3-}$ [178]
5: $[Co(NH_3)_5(4,4'\text{-bpy})]^{3+}$ + $[Fe(CN)_5(H_2O)]^{3-}$ [179]
6: $[W(CN)_8]^{4-}$ + $[IrCl_6]^{2-}$ [177]
7: $[Fe(CN)_6]^{4-}$ + $[IrCl_6]^{2-}$ [180]
8: $[IrCl_6]^{3-}$ + $[IrCl_6]^{2-}$ [181]
9: $[Cr(H_2O)_6]^{2+}$ + $[IrCl_6]^{2-}$ [182]
10: $[MnO_4]^{2-}$ + $[MnO_4]^{1-}$ [183]
11: aromatic dianion + associated radical anion [184]
12: perylene radical anion + perylene radical anion [185]
13: perylene dianion + *p*-dichlorobenzene [186]
14: radical anion + neutral paramagnetic molecule [187, 188]
15: R_3N + trinitrobenzene [189]
16: 1-ethyl-4-methoxycarbonylpyridyl radical + 4-nitrobenzyl chloride [190]
17: phenoxide ions + phenoxyl radicals [191a]
coupling of radicals with nucleophiles [191b]
18: naphthalene radical anion + alkyl radicals [192]
19: principle reported in [193]; no precise examples given
20: $(CH_3)_3CH_2^-$ + *m*-$ClC_6H_4CO_2^-$ [194]
21: carbanion + $[Aryl_2I]^+$ [195]
22: naphthalene radical anion + 4-substituted 1-methylpyridinium halides [196]
23: *N*-methylcarbazole + tropylium tetrafluoroborate [197]
24: $Ph_2C(OH)^-$ + 4-cyano-1-methylpyridinium iodide [196]
25: halide ions + perylene radical cation [198]
26: aromatic radical anion + benzoyl peroxide [199]
27: ArylH + $(Aryl'H)^+$ [200]
28: $[Cr(H_2O)_6]^{2+}$ + $[Co(NH_3)_6]^{3+}$ [201]
29: $[Cr(H_2O)_6]^{2+}$ + $[Cr(H_2O)_5OH]^{2+}$ [202]
30: $[Co(H_2O)_6]^{2+}$ + $[Co(H_2O)_6]^{3+}$ [203]
31: $[Ru(NH_3)_6]^{2+}$ + $[Ru(ND_3)_6]^{3+}$ [204]
32: $[Fe(H_2O)_6]^{2+}$ + $[Fe(H_2O)_6]^{3+}$ [205]
33: $[V(H_2O)_6]^{3+}$ + $[Fe(H_2O)_6]^{3+}$ [206]
34: $[Pu(H_2O)_n]^{3+}$ + $[Pu(H_2O)_n]^{4+}$ [207]

The angular overlap model[210] tentatively estimates the energies of the d orbitals in both the ground (O_h) and transition state (D_{3h} or D_{4h}) of a dissociative substitution. If the difference between these two energies is less than a given value, the complex is predicted to be "labile". *Purcell et al.*[210a] applied this principle to the dissociation substitution of O_h complexes and found the results given in Table 5. For our purposes the use of Table 5 is quite simple: if when adding an electron to the configuration one passes from an inert complex to a labile one, then a reductive ETC S process is possible. The reverse reasoning applies to oxidative ETC S processes.

Table 5. Electron Configurations and lability of octahedral transition metal complexes (see [85a], p. 720). l.s. = "low spin", h.s. = "high spin".

Configuration		Transition state or intermediate	
		C_{4v} Tetragonal pyramidal	D_{3h} Trigonal pyramidal
d^0, d^1, d^2, d^3		inert	inert
d^4, d^5, d^6	l.s.	inert	inert
	h.s.	labile	labile
d^7	l.s.	labile	inert
	h.s.	labile	labile
d^8		labile	inert
d^9, d^{10}		labile	labile

d^3-Systems V^{II}, *Nb^{II}*, *Ta^{II}*, Cr^{III}, *Mo^{III}*, *W^{III}*, Mn^{IV}, *Re^{IV}* are possible candidates for reductive ETC S reactions. Ligands favoring high spin states in the d^4-configuration should be preferred (Table 5). The quintet state of the first row d^4-elements leads to extremely labile complexes especially for Cr^{II}. There are many cases of exchange reactions at Cr^{III} that are catalyzed by Cr^{II}[211], among which is the method of dissolving the insoluble anhydrous $CrCl_3$ in water by addition of a small amount of a reducing agent ($SnCl_2$, Zn or Cr^{II})[171b]. Since Δ_0 increases with the heavier homologues within a given group, d^3-octahedral complexes (printed in italics for the above elements) should not be suitable for ETC S reactions. Moreover, V^{II} and V^{III} ions exchange water at similar rates[122].

The d^6-low spin configuration in Mn^{I}, Re^{I}, Fe^{II}, Ru^{II}, Os^{II}, Co^{III}, Rh^{III}, Ir^{III}, Ni^{IV}, Pd^{IV}, and Pt^{IV} is also suitable for reductive ETC S processes (Table 5). Because of their low spin states, organometallic compounds of first row elements and complexes of heavier elements surrounded by "weaker" field ligands should be preferred as possible candidates. It is encouraging to find that according to the very crude angular overlap model, Pt^{IV} and Rh^{III} are among the possible ETC S candidates. Reductive ETC behavior, although differently interpreted, has effectively been found in Co^{III}[212–215], Ir^{III}[216], Rh^{III}[86, 217–220], and Pt^{IV} (cf. Section 4).

An octahedral complex with more than six d-electrons would exceed the 18-electron rule which, though possible, is not usual[221].

For oxidative ETC reactions, Table 5 predicts only d^8-octahedral complexes as possible candidates (*e.g.* Ni^{II}).

When square planar complexes are considered, the angular overlap model is less useful, because the dissociative mechanism rarely operates. The only guideline is to assume reductive ETC S reactions are possible for the d^8-configuration (Rh^{I}, Ir^{I}, Ni^{II}, Pd^{II}, Pt^{II}, Au^{III}); such a mechanism has been discovered for Au^{III} (Section 5.1). The process described for Pt^{II} complexes in Section 5.2 also serves as a reference point.

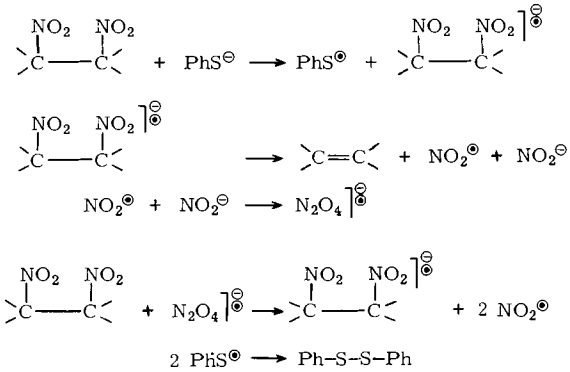
Data for complexes with higher coordination numbers would be interesting; it is known that $[Mo^{V}(CN)_8]^{3-}$ reacts photochemically with quantum yields > 1[222].

In the foregoing discussion we purposely omitted discussion of organotransition-metal reactions. Some recent examples suggest that the ETC mechanism also operates in this field[45, 223, 224]. The often polarizable organometallic compounds[225] could behave as good electron donors[226] in the first ETC step (*e.g.* in oxidative additions[227]).

6.5.4. ETC E, A, Ra, Re, Ox

There have been several attempts to underline the importance of chain homolytic processes, and of redox catalysis[224]. However, even if these approaches were important steps towards understanding the reaction mechanisms, they were perhaps still insufficient to bring about satisfactory overall coherence. For example in none of the best recent reviews on the topic of redox activation[224, 228] is *Kornblum*'s work on the $S_{RN}1$ mechanism cited. The examples already discussed in the present article illustrate how informative the application of the ETC concept may be in apparently unrelated fields. Until now we have focussed on the ETC S mechanism, but to show the generality of the approach, examples of ETC E should be presented (elimination), A (addition), Ra (Ra rearrangement) (classification, see [1a]).

Scheme 16 shows a typical example of ETC E[17, 229]:

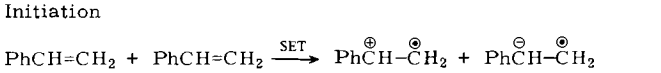


Scheme 16.

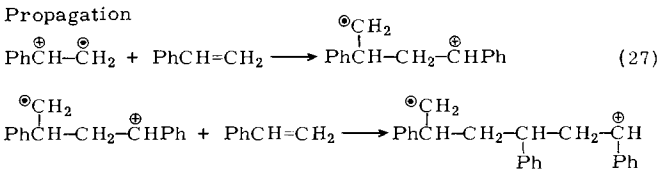
Highly hindered alkenes may be obtained using this process. It corresponds to a reductive ETC process of the educt. Examples of oxidative ETC E are found in organometallic compounds.

The polymerization of styrene[230] could tentatively be given as an example of ETC A (Scheme 17).

Initiation



Propagation

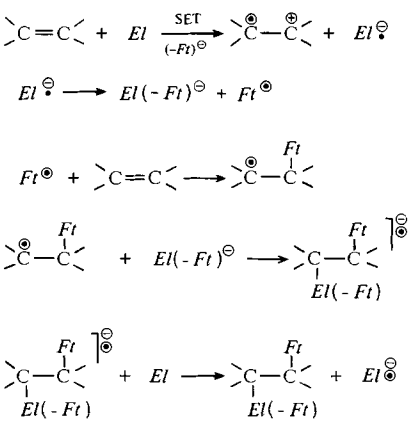


(27)

Scheme 17. The process is promoted by traces of oxidizing or reducing agents.

Here we present only the radical cation chain; the rapid formation[139, 231] of tetracyclic systems from *anti*-[2.2]metacyclophane when treated with an alkali metal, and the behavior of "living polymers"[232] show that a radical-anion chain can equally develop. The ETC A mechanism explains why small amounts of O_2 favor "spontaneous" styrene polymerization and are in accord with a photochemical initiation reaction[233] which provides polymers whose molecular weight distribution is the same as that obtained by thermal polymerization. It is very difficult to know if the "spontaneous" polymerization proceeds analogously to reaction (27); the reaction order[234] for the "spontaneous" chain reaction is not entirely in accord with this.

The ETC A scheme is not limited to polymerizations. The activation of unsaturated reaction centers (C=C, C≡C, C=N, C=M, M=N, ...) could be conceived as shown in Scheme 18.



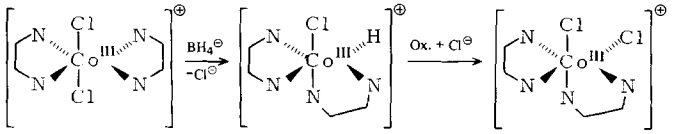
Scheme 18. *El:* electrophilic species; *Ft:* molecular fragment.

At this point it must be mentioned that the usual description of reaction mechanisms clearly stresses the stoichiometric result. If one adopts another nomenclature based on "the direction of travel of electron densities", then *e.g.* olefins become generalized nucleophiles and can donate one electron to a chosen electrophilic substrate. Following this idea, the one-track minded ETC chemist is led unavoidably to the conclusion that competition between ionic and radical addition of HBr to olefins[235] is an example of the ETC concept. It is easy to write down a ETC scheme in which the chain carrier species is $HBr^{\bullet}$ formed by a SET process between the olefin (donor) and HBr (acceptor). However, here we meet a difficulty already stressed by *Hoz* and *Bunnett*[14] (cf. Section 6.1.2): plausible initiation mechanisms can be formulated to account for initiation either by iodobenzene-absorbed photons or by CT-absorbed photons. When does the photon act as a direct homolytic breaker of bonds and when does it create a highly reducing or oxidizing species able to induce the same fracture of the bond?[236] A clear answer to this question would avoid excessive extension of the ETC concept to reaction mechanisms. A straightforward look at the difference in electron affinity of the acceptor and ionization potential of the donor should indicate if the initial single electron transfer SET is feasible[237]. A threshold problem nevertheless remains: consideration of half-

wave redox potentials leads to the conclusion[151] that the first step may be such that not more than 10^{-18} mol/L of the initiator species is present in the reaction between *p*-nitrobenzyl chloride and thiophenoxide (cf. however Section 6.2). The threshold problem is important because there is no reason not to consider the very weak bases C—H and C—C as electron donors[238] to the appropriate oxidizing agents. A final point raised by the "electron density flux" concept is that of oxidative or reductive ETC mechanism. Within this concept, the example of oxidative ETC reactions that (Section 5.2) becomes a special kind of reductive ETC reaction: RMgX is a generalized reducing species which donates an electron. The new fact then is that in this case the "nucleophile" is activated by a SET and the question arises: which mechanism prevails when both the nucleophile and the electrophile could be dissociatively activated (RMgX + RX)? Appropriate addition of reducing or oxidizing agents could perhaps selectively favor one of the two possible chains when both develop. Puzzling organometallic reactions[239] could possibly be explained by *Emmanuel*'s masterful review on selectivity of chemical reactions dealing with competition between chain reactions[240].

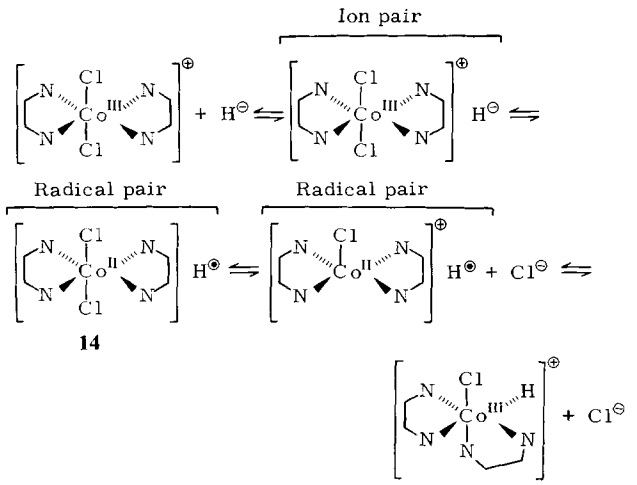
The rearrangement of *trans*-$[Co^{III}(en)_2Cl_2]^+Cl^-$ to *cis*-$[Co^{III}(en)_2Cl_2]^+Cl^-$ is catalyzed by BH_4^- and similar reagents.

Even in ice-cold aqueous solutions, no evidence for a hydride was obtained[241]. Exchange experiments with ^{36}Cl showed that only one of the chloride ligands is involved in the reaction (Scheme 19).



Scheme 19. Ox = oxidizing agent.

In 1967 *Gillard*[242] suggested a general mechanism for base hydrolysis and similar reactions of Co^{III} complexes. Application to the *trans-cis*-isomerization leads to Scheme 20.



14

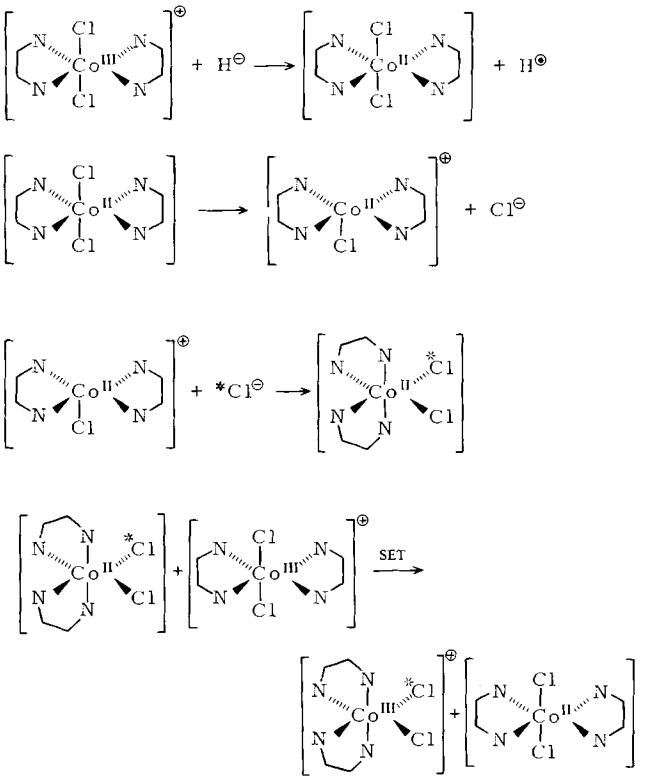
14 $\rightleftharpoons Co^{2\oplus} + 2\ en_2 + 2\ Cl^{\ominus}$

$2\ H^{\circledcirc} \rightleftharpoons H_2$

Scheme 20.

In the case of non-chelating ligands the radical pair **14** could dissociatively exchange the ligand L for X in $[Co^{III}XL_5]^{n+}$. This general mechanism was in a certain sense a precursor of the ETC S concept. However, the problem of the very rapid solvolysis of the Co^{III} ligand-bond is difficult to explain. The base may give up an electron to transform the Co^{III} complex into a highly labile Co^{II} species but it may also transform the Co^{III} complex into its conjugate base which is highly activated towards substitution[209b]. This is a very interesting aspect of the ETC concept which could find applications in the important field of acid/base catalyzed processes[243]. In any case, it was shown that the rate of hydrolysis of $[Co^{III}(NH_3)_5(NO_3)]^{2+}$ is unaffected by large amounts[244] of Cl^-, I^-, or HO_2^-, all of which are better reducing agents than OH^-; therefore, the *Gillard* mechanism (Scheme 20) was either neglected[245] or considered with some scepticism in subsequent reviews[246]. This hypothesis merits however more attention, *e.g.* by pulse radiolysis, which has already been used to measure the substitutional lability of $[Co^{II}(NH_3)_5]^{2+}$[247]. In any case, the highly polarizable hydride nucleophile seems less prone than OH^- to attack an acidic proton on nitrogen.

For these reasons we suggest as a tentative model the ETC Ra mechanism for the Co^{III} complex (Scheme 21).



Scheme 21. *Cl = ^{36}Cl.

(There is evidence that some reductions with $NaBH_4$ take place by a free radical mechanism[248]).

The observation that only one Cl ligand is exchanged requires that final single electron transfer is fast enough to prevent a second substitution of the labile Co^{II} intermediate. Other examples of ETC Ra reactions have been observed in the anodic reactions of enamines[249a], and in the cathodic reactions of azobenzenes[249b], diethyl malates or

fumarates[249c], and the diphenyl esters of thiophthalic acid[249d].

Re and Ox relate to chain reactions induced by a single electron transfer, whose overall stoichiometry correspond to a reduction[250] or an oxidation[251] of starting material. They have been repeatedly treated in reviews[252] to which the reader is referred.

The last point which should be mentioned is that intramolecular $S_{RN}1$ reactions have been described[253].

6.5.5. Principle of Redox Activation of Reactive Intermediates

The examples in this article show how a redox reagent transforms a compound into an intermediate which is able to participate in a chain reaction. We have mainly discussed reactive radical species, but there are other active intermediates[254]: carbocations[255], carbanions[104], carbenoid species[256], nitrenes[257], sulfenes[258], species with unstable oxidation states[70], highly active 1,3-dipoles[259], and substrates appropriately substituted for rapid cycloaddition[260]. These intermediates may be generated by redox reactions[261] and participate in an ETC reaction chain. The principle is not totally new[262] and has already been applied to molecular processes[263]. The ETC concept[264] should lead to a more systematic investigation of reactivity of activation processes. The variety of selective reducing[265] and oxidizing agents[266] and their combinations[267] leaves open many possibilities in this field.

7. Outlook

We close this article by apologizing to those authors whose work is relevant to the ETC concept but which we did not cite. The main reason for this is contained in Table 6 which shows the scope of this concept to date. Table 6 could also be considered as a step in improving communications between organic and inorganic chemists. In organic chemistry at present there are intensive discussions[155] to determine the relative importance of one and two electron transfers in substitutions; none of these publications cite or consider the related inorganic species[268]. The same situation prevails with the problem of associative and dissociative substitutions; the time is ripe for a more unified approach.

Between writing the first draft of this essay and publication of its final version several new papers appeared. The most relevant reviews are those on the $S_{RN}1$ mechanism[298], free-radical clocks[299], and on catalysis by electrodes[300]. The last mentioned review converges with the present essay and a more recent communication[301] to convey the message that there is indeed a class of reactions whose generality had been largely underestimated. It would seem, considering the progress in catalysis[302, 303], that the most pregnant name could be Electron Transfer Catalysis (ETC). In further reviews[303-305] we will extend the study of this new catalytic type to organometallic chemistry[304] and photochemistry[305]. $S_{RN}2$ chain mechanisms have been proposed[306] and the role of reversibility of some step on the overall selectivity[307] examined. The recently published book "Electron Transfer Reactions"[308] ignores electron transfer catalysis. A symposium on electron transfer reactions[309] is in press, and a review[310] dealing with chain substitution reaction at a C_{sp^3} atom should appear in 1982. A very important (and controversial) series of papers is expected soon: they expand the field of electron transfer mechanisms to classical electrophilic and Diels-Alder reactions[311]. The increasing number of publications in this field is reminiscent of the growth of a chain reaction.

Table 6. Application of the ETC concept. No attempt at completeness has been made; reactions of organometallic compounds of the situation of DAISET in chemical reactivity have not been considered. Some references relate to experimental results not yet interpreted within the ETC mechanism, and in some cases, the originally proposed mechanism may be the only one involved.

Compounds of	Function: Acceptor (A) Donor (D)	Oxidation State	Ref. [a]

[47] a) R. L. Rich, H. Taube, *J. Am. Chem. Soc. 76* (1954) 2608; b) *R. Klinger* has pointed out to us that the second electron transfer (step 4) in the inner sphere version (Taube Scheme) permits a more effective chain propagation than the outer sphere process ($S_{RN}1$). In both cases an ETC process is involed. This illustrates the different degrees of general validity of ETC and $S_{RN}1$. Including the reactions of organometallic compounds, formally nine different sorts of ETC are expected: see [304].

[264] We may be not totally objective when we feel that "ETC" and "DAISET" are more precise than the general term "redox catalysis" whose chemical and electrochemical meanings differ [21c]). In any case we advocate the use of the symbols $S_{RN}1$ ($S_{RN}1'$), $E_{RN}1$ ($E_{RN}1'$), $A_{RN}1$ ($A_{RN}1'$), $Ra_{RN}1$ ($Ra_{RN}1'$), $Ox_{RN}1$ und $Re_{RN}1$, where S = substitution, E = elimination, A = addition, Ra = rearrangement, Ox = oxidation, and Re = reduction. Furthermore, reductively and oxidatively initiated processes (the latter displayed in brackets) are distinguished from one another. $S_{RN}2$, $E_{RN}2$, ... can also be incorporated if the first activation is associative (for nomenclature cf. [47b, 303]).

The Bacterial Ribosome: A Programmed Enzyme

By Hans Günter Gassen*

Ribosome-dependent protein synthesis in bacteria represents a complex sequence of reactions involving more than 150 compounds. The ribosome, constructed from 53 individual proteins and 3 nucleic acids, functions as the enzyme which catalyzes peptide bond formation. In contrast to most known enzymes the ribosome is "programmed" by the mRNA—the short-lived transcript of DNA. The ribosome reads the nucleotide message of the mRNA and transforms its information into the amino acid sequence of a protein. In the course of this process, chemical bond energy is converted into directed mechanical motion. The model of protein biosynthesis on the programmable ribosome provides answers to the following questions: how is the mRNA framed into information units, how is the substrate specificity of the ribosome modulated by the codon of the mRNA, and how does the mRNA move with respect to the ribosome by one trinucleotide per peptide bond formed?

1. Introduction**

Proteins, whose amino acid sequence corresponds in a linear fashion to the nucleotide sequence in deoxyribonucleic acid (DNA), are synthesized in all living cells on cytoplasmic particles called ribosomes. As the first step in this pathway the information of the DNA is copied onto the single stranded ribonucleic acid (RNA), mRNA. Thus, the mRNA is the short-lived programme which can be read by the ribosomes and used as information for gene encoded protein synthesis. Three nucleotides represent a codon, which is the information unit corresponding to one amino acid. The correlation between codon and amino acid is called the genetic code, which is, with a few exceptions, universal to all living beings[1].

Bacterial ribosomes are complicated particles with molecular weights (MW) of *ca.* 2.8×10^6 and are composed of 53 defined proteins and three ribonucleic acids (rRNAs). Viewed as an enzyme the ribosome catalyzes a simple chemical reaction; the conversion of an ester bond into a peptide bond. Other cellular peptide synthetases, such as the alanine-adding enzyme involved in murein synthesis, are small proteins with a MW of *ca.* 50000, but nevertheless catalyze similar reactions to the ribosome. However, the synthesis of a non mRNA-encoded polypeptide requires a multienzyme complex, in which each of the subunits is specialized in the attachment of one amino acid to the growing peptide chain[2].

In the mRNA-programmed ribosomal biosynthesis a distinctly different mechanistic principle occurs. The active center of the ribosome is modulated with respect to its substrate specificity by a defined codon, such that it can differentiate between at least 20 aminoacyl-tRNAs with high selectivity (Fig. 1). If the ribosome is viewed as a programmed enzyme the following mechanistic problems must be considered:

1) How is the start signal within the mRNA recognized and the nucleotide text framed into coding units.
2) How does the codon modulate the substrate specifity of the aminoacyl-tRNA binding site of the ribosome.
3) How is the mRNA as an "information tape" shifted by one trinucleotide per peptide bond formed.

After a basic introduction into the consecutive steps of ribosome-dependent protein synthesis and the structure of the compounds involved, an attempt is made to elucidate the mechanistic principles of the ribosome as a programmed enzyme.

[**] *Abbreviations:* GMPPCP = Guanosine 5′-(β,γ-methylene)-triphosphate (the "triphosphate unit" bridges between P^{β} and P^{γ} *via* a CH_2 group), AcPhe-tRNA = N^{α}-acetyl-phenylalanyl-tRNA, GTPase = a phosphatase, associated with the 50S ribosomal subunit, which catalyzes the hydrolysis of GTP to GDP + P_i, N = unspecified nucleoside.

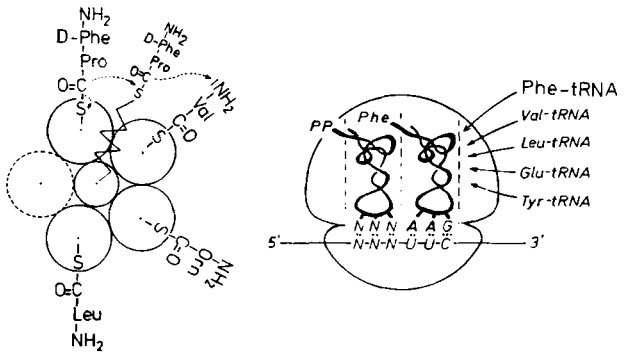

Fig. 1. Comparison of multienzyme complex displaying substrate specificity and the ribosome as a programmed enzyme.—Left: a multienzyme complex which catalyzes the synthesis of peptide antibiotics [2]. In order to explain the role of the pantetheine carrier the peptide synthetase is drawn to emphasize the similarities with the fatty acid synthetase. Right: the substrate specificity of the ribosomal aminoacyl-tRNA binding site is governed by the codon of the mRNA.

2. Bird's-Eye View of Ribosome-Dependent Protein Biosynthesis

Comparable to any other chemical or biological polymerization reaction, the biosyntheses of polypeptides can be subdivided into initiation, elongation, and termination. Each of the part-reactions is specific with respect to the compounds participating in the individual steps and the precise reaction pathway.

In the course of the initiation reaction the mRNA is framed into coding units by finding the initiator codon AUG or GUG. The initiator tRNA (fMet-tRNA$_f^{Met}$), the three initiation factors (IF-1, IF-2, and IF-3), and the small ribosomal subunit, termed the 30S subunit after its Svedberg constant, cooperate in the search for the correct start signal within the mRNA. The so-called 30S initiation complex is formed *via* a number of intermediates as depicted in Figure 2. The formation of the 30S initiation complex (30S·mRNA·(fMet-tRNA$_f^{Met}$·IF-2·GTP)·IF-1·IF-3) defines the start of a gene or a cistron. The α-amino group of the initiator tRNA has already been formylated in a non-ribosome dependent reaction: fMet-tRNA$_f^{Met}$, therefore, already carries a peptide residue that determines the direction of protein synthesis from the α-amino group to the terminal carboxyl group. Comparable to peptide synthesis by chemical means, the formylmethionine only acts as a blocking group, since the formyl group as well as the methionine residue are cleaved off in the final protein.

In the next step, the 50S subunit associates with the 30S initiation complex. In an energy-requiring reaction (hydrolysis of GTP to yield GDP + P_i), and with the concomitant release of the initiation factors IF-2·GDP, IF-1, IF3, and the so-called 70S initiation complex, 70S·mRNA·fMet·tRNA is formed: association of the two ribosomal subunits leads to formation of the aminoacyl-tRNA binding site (A site). The fMet-tRNA$_f^{Met}$ now occupies the peptidyl-tRNA binding site (P site) and an aminoacyl-tRNA may attach itself to the A site. Only the adjacent binding of two tRNA molecules to the 70S initiation complex frames the mRNA into coding units[3-5].

In the elongation cycle the aminoacyl-tRNA (AA-tRNA) in combination with its carrier protein the elongation factor EF-Tu·GTP, *i.e.* the ternary complex AA-tRNA·EF-Tu·GTP, binds to the A site of the 70S ribosome. The specificity of the A site for one defined aminoacyl-tRNA is determined by the mRNA-codon already present in the same center. The carrier protein discriminates between free tRNA and AA-tRNA, and thus prevents tRNA from binding to the A site. Both tRNAs (PP-tRNA and AA-tRNA) are now so positioned on the ribo-

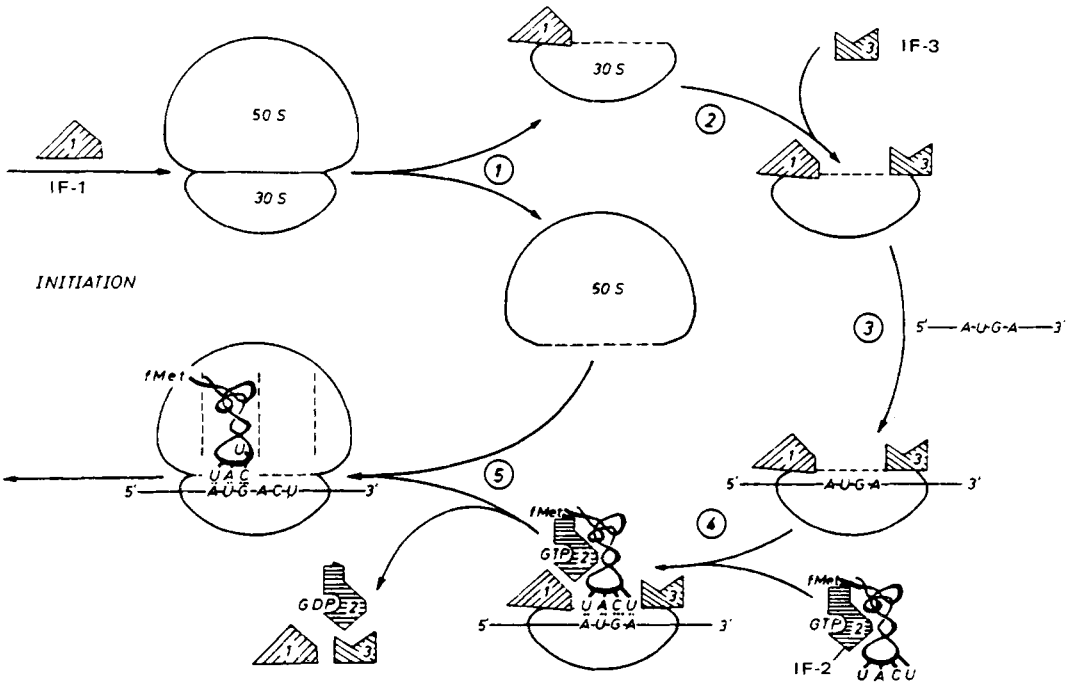

Fig. 2. Intermediate reactions in the formation of the initiation complex. ① Dissociation of the 70S ribosome into the 30S and 50S subunits; ② stabilization of the 30S subunit by the initiation factors; ③ binding of the mRNA to the small subunit; ④ formation of the 30S initiation complex; ⑤ dissociation of the factors and formation of the 70S complex. Sections 4.1 and 4.2 deal with the switch from the 30S to the 70S initiation complex in greater detail.

some that the free α-amino group of the aminoacyl-tRNA can act as a nucleophile and react with the ester bond of the neighboring fMet-tRNA$_f^{Met}$ (Fig. 3).

Prior to formation of the peptide bond *i.e.* transfer of the formylmethionine group to the aminoacyl moiety of the AA-tRNA, the elongation factor EF-Tu·GDP has to leave the ribosome. Transfer of the peptidyl moiety is catalyzed by the so-called peptidyl transferase, which is an integral part of the 50S ribosomal subunit.

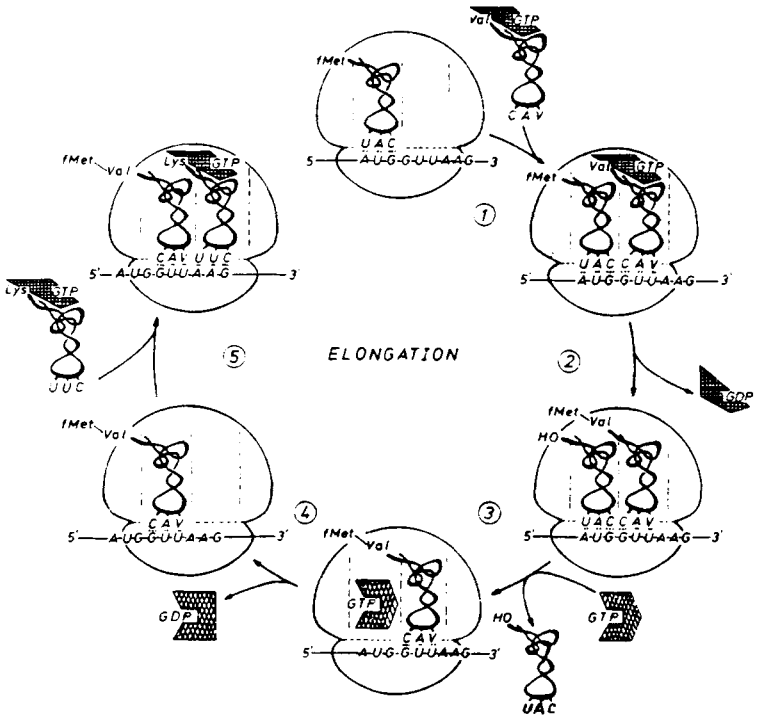

Fig. 3. The elongation cycle within the translation process. ① Binding of the ternary complex AA-tRNA·EF-Tu·GTP to the A site of a ribosome·mRNA·PP-tRNA complex; ② removal of the elongation factor EF-Tu·GDP and the simultaneous transfer of the peptidyl residue (fMet-) onto the aminoacyl-tRNA; ③ exchange of the deacylated tRNA from the P site for the elongation factor EF-G·GTP; ④ release of EF-G·GDP and the synchronous translocation of the mRNA·PP-tRNA complex; ⑤ binding of a new aminoacyl-tRNA to the now vacant A site to complete the cycle (V = modified uridine).

After transfer of the peptidyl group, a deacylated tRNA remains in the P site and the resulting peptidyl-tRNA (PP-tRNA) occupies the A site. The next step is the translocation: Catalyzed by the second elongation factor EF-G·GTP, the deacylated tRNA is removed from the P site. The peptidyl-tRNA now diffuses from the A site to the P site and a further ternary complex AA-tRNA·EF-Tu·GTP binds to the vacant A site. This series of reactions occurs once per peptide bond formed. It is terminated, when a termination codon reaches the A site of the ribosome[6–8].

In contrast to the initiation phase of translation, no termination tRNA exists for the recognition of the three termination codons UAA, UGA, and UAG. One or two termination signals in tandem are recognized by a class of proteins called termination or release factors (RF-1, RF-2, and RF-3). In cooperation with the peptidyl transferase the release factors activate a water molecule which then hydrolyzes the peptide from the tRNA (Fig. 4). After removal of the tRNA from the P site, the initiation factors IF-1 and

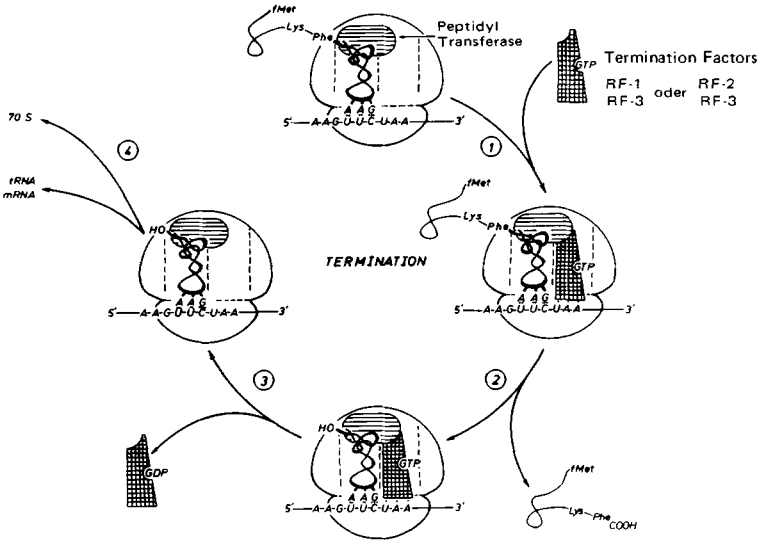

Fig. 4. Termination of peptide synthesis. ① Binding of the termination ("release") factors to the ribosome. Association of the RF-3 with the ribosome is mediated by GTP. The role of the release factors is not specified, since their molecular function is still far from being understood; ② hydrolytic release of the peptide from the tRNA. The water molecule is activated by the cooperative action of the release factors and the peptidyl transferase; ③ dissociation of the release factors accompanied by GTP hydrolysis; ④ dissociation of all components involved in peptide bond formation.

IF-3 dissociate the 70S ribosome into its subunits[9, 10]. The 30S subunit made available can then translate a new mRNA molecule into a protein.

3. Structure and Function of the Ribosomal Machinery

3.1. Ribosomes

Ribosomes have many functions. As described in Section 2 they supply the binding centers for the mRNA, the different protein factors, and the tRNA. They also create a non-aqueous microspace, enhance the catalytic activities of the factors, and display enzymic activity themselves (Fig. 5)[11].

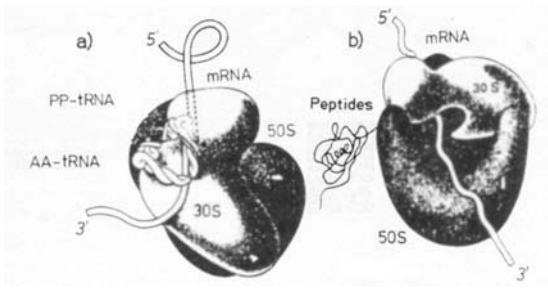

Fig. 5. Schematic representation of the binding of the tRNA and the mRNA to the ribosome.—Part a) illustrates the dimensions of both the ribosome and the tRNA. The binding domain for the AA-tRNA should be easily accessible in order to facilitate the selection of the correct AA-tRNA. The P site, however, could by buried inside the ribosome. In part b) a model for the channeling of the mRNA through the interface formed by both subunits is given. This arrangements reduces mRNA movement to an one dimensional motion. The differences in the shape of the ribosomes are explained in the legend to Fig. 6.

Bacterial 70S ribosomes are nucleic acid-protein complexes with a molecular weight of *ca.* 2.8×10^6. Following translation of the mRNA, the ribosome dissociate into two, non-identical subunits which are referred to as 30S and 50S. This dissociation occurs *in vitro* at $[Mg^{2+}] < 5$ mM. The 50S subunit (MW 1.8×10^6) contains 32 different proteins, whose molecular weights range from 8000 to 34000. They are designated L1 to L32 (L stands for large subunit). With the exception of the proteins L7 and L12, which differ only by the acetylation of their *N*-terminal amino acid, all other 50S proteins show no extended stretches of sequence homologies[12]. The 50S subunit contains two nucleic acids, 23S RNA with 2904 nucleotides and 5S RNA with 120 nucleotides[13]. The 30S subunit is constructed from 21 discrete proteins (S1—S21, S stands for small, MW 8000—64000). Protein S6 occurs in two copies within the 30S subunits, and S20, an interface protein, is identical to L26. The nucleic acid constituent—16S RNA—contains 1541 nucleotides[14, 15].

Ribosomes are spherical particles with a diameter of *ca.* 20 nm. The interpretation of pictures obtained by electron microscopy has produced different models for ribosomal shape. Three of the current models are shown in Figure 6[16–18]. The position of individual ribosomal proteins on the surface of both subparticles has been determined by immune electron microscopy[19, 20]. With the exception of protein S4, all ribosomal proteins contain an antigenic determinant, which means that parts of their structures are exposed to the surface[21]. As shown by small angle X-ray diffraction the nucleic acids form the core of each subparticle. The proteins, which are partly globular and partly elongated, form the outer layer of the nucleic acid-protein complex[22].

Fig. 6. Three-dimensional structure of 70S ribosomes and their subunits: shaded particle shows the 30S subunit. The three different models serve to illustrate the breadth of interpretations which are possible with electron microscopic images [16—18].

Using chemical methods, such as nucleic acid-specific reagents, or affinity labeling, it has been demonstrated that besides the proteins, segments of the nucleic acids are located on the surface of the ribosome. These parts of the ribosomal RNAs participate in the binding of the different substrates to the ribosome[23]. Furthermore, they are responsible for the polyanionic behavior of ribosomal particles.

The ribosomal proteins and nucleic acids are held together by electrostatic forces, hydrogen bonds, and hydrophobic interactions; covalent bonds have not been detected. Increasing the ionic strength and lowering the Mg^{2+} concentration in the medium causes a number of proteins to dissociate from the subparticles. Complete dissociation of the ribosome is achieved in 7 M urea and 4 M LiCl. From the highly purified proteins and nucleic acids isolated, active ribosomal particles can be reconstituted[24, 25].

Immune electron microscopy, affinity labeling and cross-linking were used to localize functional domains on the ribosome. With the aid of these techniques the approximate positions of the A and the P site, the peptidyl transferase center, and the binding sites of many antibiotics have been mapped (Table 1)[26].

Table 1. Localization of functional domains of the ribosome by affinity labeling. The substrates, - tRNA, antibiotics etc. - are functionalized by either chemical alkylation or by photosensitive (aromatic azides) groups[23]. The modified proteins are identified by two-dimensional gel electrophoresis or by immune precipitation. With one or two exceptions it was not possible to locate the exact nucleotide within the rRNA sequence which was modified by the affinity reagent.

Component	modified Protein or rRNA
Puromycin [a]	L23
Chloramphenicol [a]	L2, L16, L27
$tRNA_f^{Met}$	L2, L27, 23S RNA
Phe-$tRNA^{Phe}$	L2, L18, L27, S18, 23S RNA
mRNA and analogues	S1, S3, S4, S12, S18, 16S RNA
GTPase center	L2, L16, L27

[a] Both antibiotics bind to the peptidyl transferase center.

The small ribosomal (30S) subunit can bind one tRNA in the presence of mRNA, whereas the 50S subunit associates with one tRNA molecule regardless of the presence of mRNA. Programmed 70S ribosomes, however, can bind two tRNAs. At Mg^{2+} concentrations > 20 mM the binding of the tRNAs becomes independent of the mRNA. Two factors determine the substrate specificity of the tRNA binding sites. The peptidyl group directs the peptidyl-tRNA preferentially to the P site, whereas the ternary complex AA-tRNA·EF-Tu·GTP binds exclusively to the A site. The initiator tRNA·fMet-$tRNA_f^{Met}$ can only occupy the P site, and the $tRNA_f^{Met}$ by virtue of its conformation can discriminate between A and P sites (Fig. 7)[27].

A lengthy and intensive discussion has dealt with the question of whether the ribosome represents a multienzyme complex or whether the peptidyl transferase provides the sole enzymic activity of the particle. With the peptidyl transferase the term enzyme is put on trial. Peptide bond formation is not catalyzed by an individual protein, but by an as yet undetermined number of 50S proteins and segments of the nucleic acids which constitute the peptidyl transferase center[28]. It is not known at present whether the 5S RNA and 23S RNA only determine the active conformation of the proteins or if they participate in catalysis.

The GTPases represent further candidates for ribosomal enzymes. They hydrolyze the GTP within IF-2·GTP, EF-Tu·GTP, and EF-G·GTP to the respective factor·GDP complex and inorganic phosphate. Two concepts of GTP-hydrolysis are under discussion at present. On the one hand it is believed that the GTPases are integrated functions of the ribosome. Other experiments, however, can be so interpreted that the factors themselves have a latent activity which becomes apparent when these proteins associate with the ribosomes. In the presence of the antibiotic kirromycin the elongation factor Tu shows a GTPase activity which is otherwise only apparent when the factor is associated with the ribosome[29, 30].

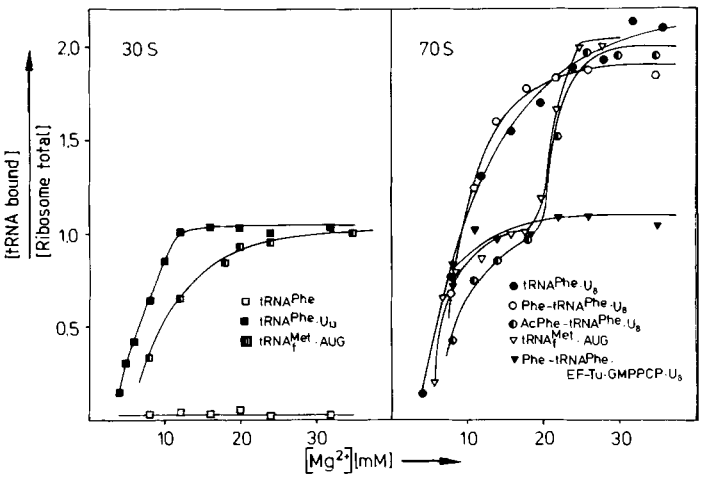

Fig. 7. Binding of different tRNAs to the ribosome.—The binding of aminoacyl-tRNA, peptidyl-tRNA, and tRNA to either 70S or 30S ribosomes was investigated by velocity sedimentation in the analytical ultracentrifuge [88]. The free tRNA boundaries were compared in the absence and presence of ribosomes. Programmed 30S subunits bind one tRNA molecule, whereas tRNA is not associated with the small subunit in the absence of the mRNA. At $[Mg^{2+}] > 20$ mM two $tRNA^{Phe}$ or Phe-$tRNA^{Phe}$ molecules bind to the 70S ribosome. Peptidyl-tRNA (AcPhe-tRNA) and $tRNA_f^{Met}$ preferentially bind to one ribosomal site at $[Mg^{2+}] \approx 15$ mM (P site). Regardless of the $[Mg^{2+}]$ only one molecule of Phe-tRNA·EF-Tu·GMPPCP can be attached to the ribosome. GTP has to be replaced by GMPPCP in this experiment to avoid hydrolysis of GTP by a ribosome-owned GTPase which would result in subsequent removal of the EF-Tu·GDP. U_8 is an octanucleotide consisting of only uridylic acid.

Comparable to other multienzyme complexes, two structural concepts have been discussed for the ribosome. In one of them the ribosome is viewed as a rigid particle which acts as a solid phase for peptide synthesis. The other model postulates a dynamic ribosome which underlies ligand-induced structural changes. These modulations of the ribosome's conformation should positively influence the rate of individual reactions within protein synthesis. Recent experimental results, such as the Mg^{2+}-dependent activation of the 30S subunit, or differences in the ^{125}iodine labeling of proteins in different functional states of the ribosome point towards a structural flexibility of the ribosome[31,32].

3.2. Transfer Ribonucleic Acids

Transfer ribonucleic acids (tRNAs) are the connecting link between the mRNA involved in the transportation of information and the proteins, multifunctional entities in living beings. Their structures also represent hybrids of nucleic acids and proteins. They contain up to 20 modified nucleosides and possess a highly complicated tertiary structure[33–35]. Within the translation process we can differentiate between four types of tRNA: initiator tRNA, aminoacyl(AA)-tRNA, peptidyl(PP)-tRNA, and deacylated tRNA. The first two only exist in their carrier-bound form, whereas PP-tRNA is always associated with ribosomes. Apart from $fMet\text{-}tRNA_f^{Met}$, peptidyl-tRNA is formed on the ribosome by the peptidyl transferase and is the substrate for the translocation process. Deacylated tRNA represents the product of the P site of the ribosome, and is removed from the ribosome by the elongation factor G under GTP hydrolysis.

The primary sequences of 120—130 tRNAs are known. With the exception of some tRNAs isolated from mitochondria, their secondary structures can be arranged in the so-called "clover leaf secondary structure"[36]. The tertiary structures of phenylalanine tRNA from yeast and of the initiator tRNA from *E. coli* have been determined by X-ray analysis in the solid state[37–39]. tRNA forms an L-shaped molecule composed of two helices positioned at right angles to one another (Fig. 8). The longer helix terminates in the single stranded anticodon loop, the shorter one in the unpaired CCA 3′-terminus. The remaining parts of both helices, designated as the dehydrouridine loop and the TΨCG-loop (Ψ signifies pseudouridine), form a functional domain which is stabilized by tertiary hydrogen bonds. It is possible that this part of the tRNA is involved in binding to the 50S ribosomal subunit [40].

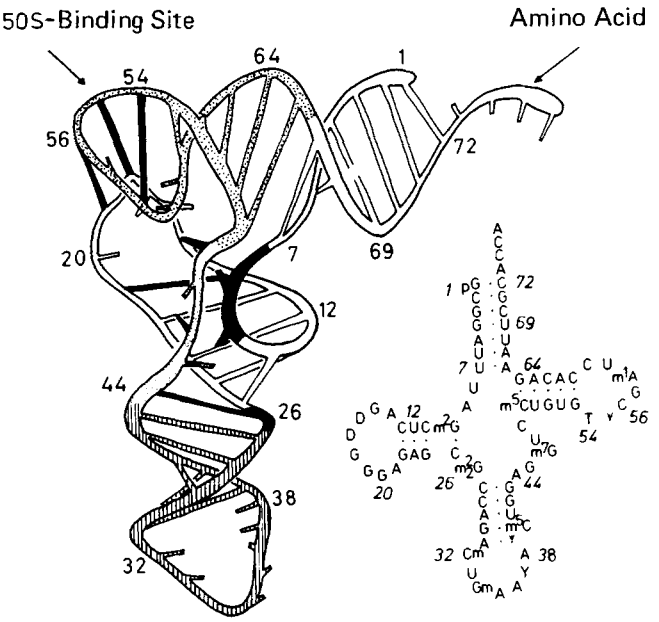

Fig. 8. Clover leaf model and tertiary structure of $tRNA^{Phe}$ from yeast. Right: the sequence of $tRNA^{Phe}$ arranged in the clover leaf form. Left: the three-dimensional structure determined by *Quigley et al.* [38]. The numerical order of the nucleotides is given to facilitate comparison between the secondary and tertiary structures.

When a tRNA binds to a mRNA programmed ribosome, the resulting codon-anticodon complex may be visualized as a continuation of the anticodon helix. The carrier protein EF-Tu·GTP should stabilize the single stranded CCA-end[41,42]. The solid state structure of $tRNA^{Phe}$ represents only one of the possible tRNA conformations. The solution structure of tRNA was therefore investigated with a battery of different techniques, such as tritium exchange, sedimentation velocity measurements, differential melting studies, ^{1}H- and ^{31}P-NMR spectroscopy, ESR spectroscopy, Raman spectroscopy, fluorescence spectroscopy, circular dichroism, laser light scattering, and low angle X-ray scattering[43]. Up until now most measurements have confirmed that the structure of tRNA in the crystal and in solution are the same. However, there is increasing evidence

that the structure of tRNA functioning in biochemical processes is not static, but may exist in different conformations optimized towards its specific function[44]. Conformational changes in tRNA may be induced by the aminoacyl and peptidyl moieties, the elongation factor Tu·GTP, the codon of the mRNA, and assorted mono- and divalent cations[45].

Structural transitions are not restricted to the ligand's binding domain, but the ligand may induce long-range effects similar to allosteric conformational changes found in proteins. It has been shown that complex formation between the codon and the mRNA not only influences the conformation of the anticodon region, but in addition influences the structure of the TΨC-loop 5 nm away[46,47]. CGAA, a tetranucleotide which is complementary to the TΨCG sequence in $tRNA^{Phe}$ and $tRNA^{Lys}$ associates only with the codon·tRNA complex, but not with free tRNA. In similar experiments evidence has been given that the reactivity of guanine bases towards kethoxal* is different with lysine tRNA and codon·lysine tRNA complexes[48]. We will deal with the codon as an allosteric effector of the tRNA conformation in more detail in Section 5.1.

The aminoacylation of the tRNA occurs in two steps. In the first reaction the aminoacyl adenylate is formed from the amino acid and ATP. Then the aminoacyl residue is transferred to either the 2′- or 3′-hydroxyl group of the terminal adenosine in tRNA. Both reactions are catalyzed by one enzyme, aminoacyl synthetase[49]. One enzyme is specific for one amino acid and the cognate tRNA. Within the cytoplasm, the AA-tRNA is immediately complexed with its carrier protein EF-Tu·GTP to avoid deacylation of the aminoacyl residue from the tRNA. The ternary complex AA-tRNA·EF-Tu·GTP represents the substrate for the aminoacyl site of the ribosome. Only AA-tRNA can form a complex with the elongation factor Tu, which prevents tRNA from blocking the A site of the ribosome[50]. In this sense tRNA can be visualized as a coenzyme which transports the aminoacyl residue and can function only when coexisting with its apoenzyme, namely elongation factor Tu·GTP.

3.3. mRNA — the Programme for the Biosynthesis of Proteins

The transcription of the mRNA from the DNA template and the translation of the template occur in bacteria in a concerted process. As soon as the 5′-end of the mRNA comes off the RNA polymerase it is occupied by ribosomes and the protein synthesis starts. Many ribosomes translate one mRNA strand simultaneously. The polysomes thus formed increase the efficiency of translation and furthermore protect the mRNA against degradation by cytoplasmatic nucleases. Prokaryotic mRNAs are mostly polycistronic, *i.e.* the information for a number of proteins is stored within one mRNA strand. Functionally, the mRNA may be subdivided into the precistronic sequence, the structural gene, the intercistronic sequence, the second and further structural genes, and the 3′-terminal sequence. The structural gene itself may be further subdivided into the initiator codons AUG or GUG, the elongation codons, and the termination codons UAA, UGA, and UAG (Fig. 9). The correlation between the mRNA codons and the individual amino acids is called the genetic code.

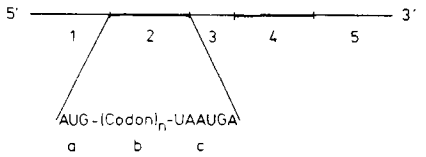

Fig. 9. Schematic representation of a polycistronic mRNA containing two cistrons. The cistronic regions containing the structural genes are indicated by a heavy line. The first cistron (gene) is subdivided into a) the initiator codon, b) the elongation codons and c) two termination codons. 1) Precistronic sequence; 2) first cistron (gene); 3) intercistronic sequence; 4) second cistron; 5) 3′-terminal sequence.

The stable interaction between the mRNA and both the 30S subunits and the 70S ribosomes depends on the Mg^{2+} concentration[51]. The nucleotide sequence in the precistronic region of mRNA is important for its association to the 30S ribosomal subunit. However, in the 70S ribosome the tRNAs regulate the stability of the mRNA·ribosome complex. At present very little is known about the molecular details of the mRNA·ribosome interaction. Since both partners are of polyanionic nature, Mg^{2+} may act as a chelating agent to bridge the negative charges of the phosphodiester bonds from both the rRNA and the mRNA. In addition, the carboxylate group from the ribosomal proteins may participate in this reaction[52].

3.4. The Factors: Proteins which Function as Enzymes, as Carriers, and as Modulators of tRNA Conformation

A number of proteins that catalyze individual steps in the translation cycle associate only temporarily with the ribosome. According to their function they are subdivided into initiation, elongation, and termination factors. The use of the term "factor" is evidence of our limited knowledge of the precise function of these proteins. The elongation factor Tu for example may act as a GTPase, represents the carrier protein for AA-tRNA, and possibly modulates the conformation of the tRNA.

The physical and biochemical properties of these factors are summarized in Table 2. In the following we deal particularly with the initiation factor 2 and both elongation factors Tu and G. IF-2·GTP and EF-Tu·GTP serve as carrier proteins for the initiator and the elongator tRNA, whereas EF-G·GTP functions as "tRNA release protein." As a common feature the three factors use GTP as an energy source to increase the speed and fidelity of protein synthesis. GTP binds to the factor and transforms it into an entity with a high affinity for either the tRNA or the ribosome. The complexes $fMet\text{-}tRNA_f^{Met}$ · IF- GTP, AA-tRNA·EF-Tu·GTP, and EF-G·GTP bind to the ribosome and fulfill their defined function. GTP is hydrolyzed to GDP by either a ribosome-owned GTPase or by the factor itself (EF-Tu), and the factor·GDP complex or the free protein

[*] 3-ethoxy-1,1-dihydroxy-2-butanone.

Table 2. Survey of the "factors" active in protein biosynthesis

Factor	MW and Cofactor	Main Function
Initiation		
IF-1	9000	Catalyzes 70S dissociation, stimulates the IF-2-and IF-3-functions
IF-2	115000, GTP	Carrier protein for fMet-tRNA$_f^{Met}$
IF-3	21000	mRNA-binding, dissociation of 70S ribosomes in 30S and 50S subunits
Elongation		
EF-Tu [a]	44000, GTP	Carrier protein for AA-tRNA
EF-Ts [a]	30000	Regenerates EF-Tu·GTP
EF-G [a]	80000, GTP (not tightly associated)	Translocation factor, release protein for the tRNA from the P site
Termination		
RF-1	44000	Terminates with UAA and UAG
RF-2	47000	Terminates with UAA and UGA
RF-3	46000, GTP	Activates RF-1 and RF-2, codon-independent

[a] The abbreviations Tu, Ts and G signify "temperature unstable", "temperature stable", and "GTP-cleavage", respectively.

leaves the ribosome. Reloading the factor with GTP occurs either through a high excess of GTP or by catalysis through a second protein. As an aid in understanding these complicated processes, the role of the elongation factor Tu is outlined in Figure 10[53]. IF-2·GTP and EF-Tu·GTP both modulatate the tRNA conformation. The function of the initiator factor 2 in the adjustment of the anticodon of fMet-tRNA$_f^{Met}$ is detailed in Section 4.1.

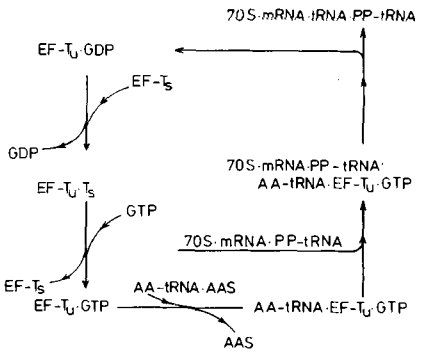

Fig. 10. Regeneration of the elongation factor EF-Tu·GTP. The scheme is to be read in a counterclockwise sense. The elongation factor Tu when activated by GTP can accept the AA-tRNA from the aminoacyl synthetase (AAS). The factor positions the aminoacyl-tRNA into the A site of the ribosome. Upon hydrolysis of GTP to GDP the factor leaves the ribosome as the EF-Tu·GDP complex. GDP is removed by the elongation factor Ts, since it has a 10-fold higher affinity compared to GTP towards EF-Tu ($K_{A_{ss}} = 2 \times 10^8\ M^{-1}$). The EF-Tu·GTP complex can be regenerated from the EF-Tu·EF-Ts dimer.

3.5. Function of Mg^{2+} Ions in Protein Biosynthesis

mRNA-dependent protein synthesis shows a distinct optimum at a Mg^{2+} concentration of 12—14 mM in cell-free systems (Fig. 11), whereas it is estimated that the Mg^{2+} concentration is 5 mM *in vivo*[54,55]. The bell-shaped curve can be subdivided into the Mg^{2+}-dependent association of the ternary complex AA-tRNA·EF-Tu·GTP and the inhibition of tRNA release from the P site by increased Mg^{2+} contrations. At $[Mg^{2+}] > 20$ mM the binding of the AA-tRNA reaches its plateau level, whilst becoming independent of mRNA. This indicates, that at high $[Mg^{2+}]$ the selectivity of the A site for a specific tRNA is lost. Likewise,

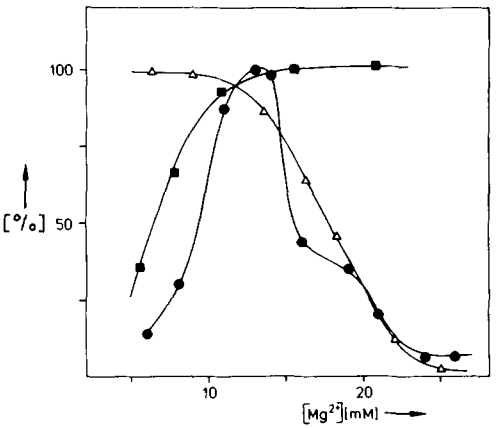

Fig. 11. Mg^{2+} dependance of the *in vitro* protein synthesis. ● Poly(Phe) synthesized; ■ Phe-tRNA·EF-Tu·GTP bound; △ $tRNA^{Phe}$ released. Poly(U) dependent ribosomal synthesis of poly(Phe) proceeds optimally at Mg^{2+} concentrations of 12—14 mM. The ascending slope of the bell shaped curve represents the Mg^{2+} dependent binding of the ternary complex AA-tRNA·EF-Tu·GTP to the ribosome. The descending slope can be explained by the effect of Mg^{2+} ions on the EF-G·GTP catalyzed release of deacylated tRNA from the P site. At $[Mg^{2+}] = 10$ mM the tRNA can be completely discharged from the ribosome by EF-G·GTP. At $[Mg^{2+}] > 25$ mM, tRNA release is blocked.

nearly all the individual steps in protein synthesis, such as the association of the mRNA to the ribosome, are Mg^{2+}-dependent. Furthermore, Mg^{2+} influences the conformation of the ribosome, the mRNA, and the tRNA. Factors and Mg^{2+} ions always act cooperatively.

Besides Mg^{2+}, the cytoplasm of bacteria contains high concentrations of polyamines such as putrescine, spermine, and spermidine. Recently it was shown by *Kurland et al.*[56] that these polyamines, as well as Ca^{2+}, increase the effectivity and fidelity of protein synthesis.

4. Selection of the Beginning of a Gene and Framing the mRNA by Formation of the Initiation Complex

During the replication and transcription processes, information is transmitted by complementary bases. Adenine pairs with thymine (uracil), and guanine recognizes cytosine and *vice versa*. However, to transform the information stored within the mRNA into the amino acid sequence of a protein three nucleotides have to be framed into a coding unit, a trinucleotide, or a codon. A framing incorrect by only one nucleotide results in a completely different amino acid sequence and such "frame shifts" are usually lethal to the cell. Therefore, cells have to be very careful in the formation of the 30S and 70S initiation complex. In a two-step procedure the 30S initiation complex selects the initiation signal AUG or GUG on the mRNA and the framing of the mRNA into coding units is achieved by formation of the 70S initiation complex.

4.1. Recognition of the Start Signal by Formation of the 30S Initiation Complex

The initiation codon AUG is selected *via* formation of the 30S initiation complex, and simultaneously the setting of the reading frame is started. One major element in the selection of the initiator codon AUG is brought about by the double strand formation between the codon of the mRNA and the anticodon of the tRNA. However, AUG is not only the initiator codon since when it occurs in the middle of a mRNA chain it also decodes methionine. Therefore, complex formation between AUG and fMet-$tRNA_f^{Met}$ cannot sufficiently explain the precision in the recognition of the beginning of a gene[57]. With bacteria the situation is even more complex. Procaryotic mRNA is polycistronic and the proteins encoded on one mRNA strand are made in varying amounts. The mRNA of the phage MS2 contains the information for the synthesis of four proteins namely maturation protein, coat protein, lysis protein, and replicase[58]. The coat protein is made in copy numbers far exceeding the remaining three proteins, in spite of the fact that its gene is located in the middle of the genome. There is only one feasible explanation for this phenomenon: the ribosome can differentiate between the initiator codons of a polycistronic mRNA. It must, therefore, be explained how the initiation system differentiates between initiator AUG and elongator AUG, and between multiple start codons within a mRNA (Fig. 12).

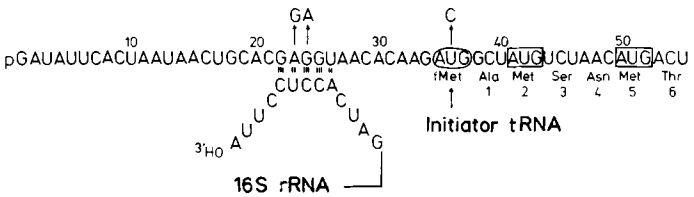

Fig. 12. Initiator sequence of the mRNA coding for a protein of the T7 phage. The sequence contains three AUG codons in the starting region of the mRNA. The initiator AUG (encircled) is followed by two elongator AUGs (boxed), which decode methionine. This demonstrates the problems in the selection of the initiator codon. The double strand formation between the 3'-end of 16S RNA and the precistronic region 7–10 nucleotides upstream of the AUG guarantees the selection of the proper AUG. Point mutations in this region or in the initiator codon reduce the efficiency of initiation complex formation [57].

At present, three explanations exist for the preferential recognition of one start codon: 1) mRNAs have a defined tertiary structure, which exposes only the initiator codon[59]. 2) mRNAs contain in their precistronic region a nucleotide sequence which is complementary to the 16S RNA of the 30S subunit. 3) The initiator tRNA may bind to more than three nucleotides of the mRNA.

In the following we will deal with theories mentioned under 2 and 3 above, since they shed some light on the mechanism of the initiation reaction.

When *Shine* and *Dalgarno* sequenced the 3'-end of the 16S RNA, they pointed out that this part of the rRNA was complementary to the precistronic region of some mRNAs. They postulated that the double strand formed between mRNA and rRNA should stabilize the ribosome·mRNA complex[60]. We now know the partial sequences (ribosomal binding sites) of *ca.* 100 mRNAs and analysis of their precistronic regions confirms the theory outlined by *Shine* and *Dalgarno*[61]. Three to nine nucleotides, which are seven to ten nucleotides upstream of the initiator codon, may form a double stranded RNA. The stability of an mRNA·30S complex is proportional to the number of complementary bases[62]. Oligonucleotides that may form a double strand with the 3'-end of the 16S RNA inhibit the formation of an initiation complex by up to 80%[63]. From these data it can be concluded that the 30S initiation complex is stabilized by the mRNA·rRNA complex. The number of complementary bases may have a regulatory function.

The trinucleotide code results in effective use of the information stored in the mRNA. On the other hand, the short RNA·RNA double strand only guarantees low stability for the mRNA·tRNA complexes. Since a tight interaction between the initiator tRNA and the mRNA is crucial for the correct reading of a gene, it has been discussed whether the fMet-$tRNA_f^{Met}$ can bind to more than three nucleotides within the 30S initiation complex. *Tanaguchi* and *Weissmann* were the first to present experimental evidence for this theory[64]. A mutant of the Qβ phage contains an mRNA in which one initiation sequence has been changed from *AUG*G to *AUG*A. The new start signal is more efficient in initiation compared to the wild type. A double mutation leading to AUAA can still recognize the initiator tRNA, whereas AUAG no longer functions as an initiation signal. It was postulated that the interaction between the 3'-terminal adenosine in AUGA and uridine 33 next to the anticodon in $tRNA_f^{Met}$ may further stabilize the codon-anticodon complex.

Table 3. Binding of fMet-tRNA or AcPhe-$tRNA^{Phe}$ to 30S- or 70S-ribosomes related to the codon. The percentage of ribosomes which exist as ribosome·tRNA complexes is listed. The amount of tRNA is kept constant, and the concentration of oligonucleotide is adjusted to optimal complex formation. With the two exceptions indicated, all experiments were performed in the presence of the initiation factor IF-2 and GTP. Tetranucleotides containing a 3'-terminal purine nucleoside (A, G, h^6A) are more efficient in forming a 30S initiation complex than AUG. However, AUG represents the best codon for formation of the 70S initiation complex. The lower part of the table shows that in the presence of initiation factor 2 UUCA can stimulate the binding of the "pseudo" initiator-tRNA AcPhe-tRNA. The amount of AcPhe-tRNA bound to the ribosome in the absence of IF-2·GTP is considerably lower.

Oligonucleotide	Percentage of tRNA-binding ribosomes	
	30S [%]	70S [%]
		fMet-tRNA
AUG	44	71
AUGA	72	44
AUGG	68	43
AUGU	52	63
AUGC	56	57
AUGh^6A [a]	61	47
AUUA	9	11
AUUU	0	0
AUG(−GTP)	22	—
AUG(+GMPPCP)	—	46
AUGA(−GTP)	35	—
AUGA(+GMPPCP)	—	65
		AcPhe-tRNA
UC(−IF-2, −GTP)	28	—
UUC	36	—
UUCA (−IF-2, GTP)	9	—
UUCA	47	—

[a] h^6A is deaminated in position 6 of the adenosine.

This hypothesis is supported by the known tertiary structure of the initiator tRNA. In contrast to $tRNA^{Phe}$, uridine 33 occupies an exposed position in $tRNA_f^{Met}$. There is the possibility that an additional Watson-Crick type base pair between adenosine and uridine is formed[39]. Tetranucleotides such as U*AUG* and *AUG*A, which may form a four base-paired complex with the $tRNA_f^{Met}$, are more efficient as initiation codons compared to AUG. Here, efficient means that a higher percentage of 30S ribosomal subunits can be saturated with fMet-$tRNA_f^{Met}$·IF-2·GTP in the presence of either U*AUG* or *AUG*A[65–68]. Since both neighboring nucleotides show this stimulatory effect, the pentanucleotide U*AUG*A may represent the ideal initiation sequence.

The initiation factor IF-2 plays an important role in recognition of the start signal by the initiator tRNA. Unlike the free fMet-$tRNA_f^{Met}$, the ternary complex fMet-$tRNA_f^{Met}$·IF-2·GTP prefers the tetranucleotide. If the initiator tRNA is replaced by AcPhe-tRNA—a pseudo-initiator tRNA—then the free AcPhe-tRNA prefers the codon UUC. The ternary complex AcPhe-tRNA·IF-2·GTP, however, reacts preferentially with the tetranucleotide UUCA (Table 3)[66]. IF-2·GTP alters the tertiary structure of the fMet-$tRNA_f^{Met}$ in such a way that four or five anticodon bases may interact with the start signal on the mRNA (Fig. 13).

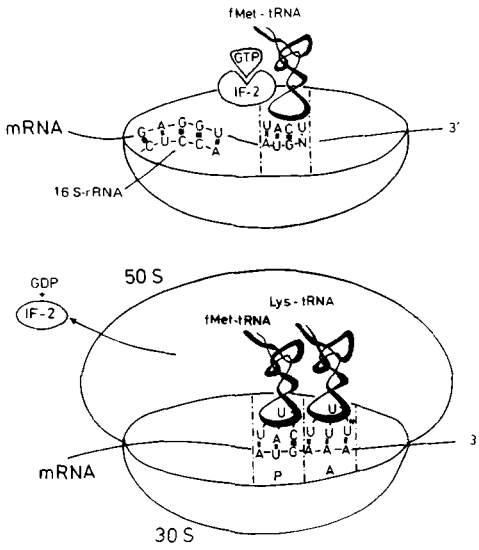

Fig. 13. Model of the 30S and 70S initiation complex. The 30S initiation complex is stabilized by the formation of two RNA·RNA double strands. The ternary complex fMet-$tRNA_f^{Met}$·IF-2·GTP can bind to more than three nucleotides of the mRNA. In the 70S initiation complex, the two tRNAs and the mRNA may form a continous hexanucleotide double strand (see Fig. 1 step 4 and 5).

In summarizing points two and three mentioned above, the high specificity in the recognition of the gene start may be explained as follows: The 30S ribosomal complex is stabilized by two RNA·double strands that are at a defined distance of about 2.5 nm from one another. The 16S RNA binds the intercistronic sequence of the mRNA and the fMet-tRNA·IF-2·GTP holds the start codon[69]. Initially, 30S ribosomal subunits and mRNA form a loose association which is stabilized by electrostatic interactions using Mg^{2+} as a chelating agent. By a "slide and search mechanism" the correct binding of the mRNA is achieved by formation of a three to nine nucleotides-long hybrid between the 16S RNA and the mRNA. However, only the second interaction between the initiator tRNA and the initiator codon results in the formation of a stable initiation complex (Fig. 13).

From an analysis of the ribosomal binding sites of more than 100 mRNAs it becomes evident that AUGA/G is always used as a start codon when the number of complementary bases in the precistronic region of the mRNA is low[61]. This could indicate, that the efficiency of initiation complex formation, *i.e.* the number of protein copies from a given mRNA, is regulated by the degree of base complementary in both the precistronic region and the initiator codon.

4.2. Final Framing of the mRNA within the 70S Initiation Complex

The addition of the 50S subunit to the 30S initiation complex results in the formation of the 70S initiation complex. GTP is hydrolyzed to GDP and inorganic phosphate, and IF-2·GDP leaves the ribosome. The free fMet-$tRNA_f^{Met}$ occupies the P site and now represents a peptidyl-tRNA.

The second tRNA binding site, specific for the aminoacyl-tRNA is now formed. However, before a second tRNA can be bound next to the fMet-$tRNA_f^{Met}$, the postulated tetranucleotide complex between the fMet-$tRNA_f^{Met}$ and the mRNA has to be reduced to the normal trinucleotide code. Only by formation of 70S·mRNA·PP-tRNA·AA-tRNA is the framing of the mRNA to trinucleotide coding units achieved.

In order to understand the switch from the tetranucleotide code in initiation to the trinucleotide code in elongation at a molecular level we investigated the function of the initiation factor IF-2 (Table 3). The ternary complex fMet-$tRNA_f^{Met}$·IF-2·GTP binds with preference to *AUGA* or *AUGG* programmed 30S subunits. However, with 70S ribosomes AUG is more effective in the binding of the fMet-$tRNA_f^{Met}$ compared to *AUGA* or *AUGG*. The dissociation of the initiation factor IF-2 from the 70S ribosome can be prevented by replacing GTP with the non-cleavable analogue GMPPCP. Under these experimental conditions, *i.e.* the existence of a fMet-$tRNA_f^{Met}$·IF-2·GMPPCP complex on the 70S ribosome, the tetranucleotide *AUGA* is again the better codon compared to AUG. Furthermore, the presence of IF-2·GMPPCP on the 70S ribosome blocks the binding of aminoacyl-tRNA to the A site.

The carrier protein IF-2·GTP of the fMet-$tRNA_f^{Met}$ adjusts its conformation such that the initiator tRNA may bind to more than three nucleotides on the mRNA (Fig. 13). In the 70S ribosome, however, by necessity of the elongation process interaction between the tRNA and the mRNA has to be reduced to the trinucleotide code. A ribosomal GTPase hydrolyzes GTP and the resulting binary complex IF-2·GDP leaves the ribosome. The binding of fMet-$tRNA_f^{Met}$ to the 70S ribosome should now be additionally stabilized by interaction between the "peptidyl" group and components of the 50S subunit[70]. As soon as the first complex, AA-tRNA·EF-Tu·GTP, binds to the A site of the ribosome the framing of the mRNA is guaranteed.

5. Peptide Chain Elongation in Protein Biosynthesis: Modulation of Substrate Specificity and the Transport of the Programme

Two aspects of the elongation cycle in ribosomal protein biosynthesis deserve special attention with regard to their mechanism: Modulation of the substrate specifity of the A site for the different aminoacyl-tRNAs by the mRNA codon, and the GTP-dependent translocation of the mRNA by one codon per peptide bond formed.

5.1. The Selection of a Cognate Aminoacyl-tRNA by a Programmed 70S Ribosome

The ternary complex AA-tRNA·EF-Tu·GTP binds to a 70S ribosome which contains a peptidyl-tRNA in the P site and a free mRNA codon in the A site. The "A site" binding domain, by virtue of its protein and nucleic acid composition, guarantees stable binding of the aminoacyl-tRNA ($K_{Ass} \approx 10^8$ M^{-1} at [Mg^{2+}] > 20 mM). On the other hand, the codon determines the selective capacity of the A site, *i.e.* which of the 50—100 different AA-tRNAs becomes associated with the A site[71]. The selection of the cognate tRNA depends not only on the three anticodon bases, but also on the neighboring nucleotides of the anticodon. In addition, the 16S RNA and proteins located in the decoding domain also contribute to the selectivity[72].

Initially, the selection of the correct AA-tRNA was explained by formation of a trinucleotide double strand between the codon of the mRNA and the anticodon of the tRNA. This assumption, however, is not sufficient to explain the low error frequency of 10^{-4}. Trinucleotides with complementary bases do not form dimers in aqueous solution, and complex formation between a tRNA and a cognate trinucleotide is only of low stability ($K_{Ass} \approx 10^3 - 10^4$ M^{-1})[73,74]. If the trinucleotide is replaced by a second tRNA whose anticodon is complementary to the first tRNA, *i.e.* $tRNA^{Phe}$ (UUC) and $tRNA^{Glu}$ (GAA), then stable tRNA dimers are formed with association constants in the range of 10^6 M^{-1}[75]. The association rate constants of oligonucleotide·tRNA complexes are comparable with those of tRNA dimers, whereas the dissociation rate constants of the dimeric tRNA are slower by a factor of 10^6 ($k_{Diss} \approx 5$ s^{-1})[76].

Recently, a number of experiments have contributed to the understanding of correct aminoacyl-tRNA selection by the programmed A site. Using the above mentioned tRNA dimers as a model system, evidence was given that differences in the association constants between cognate (three base pairs) and non-cognate (only two base pairs) tRNA dimers result from differences in the dissociation rate constants. The association rate constants are, within small limits, the same for cognate and non-cognate dimers[77,78]. We were able to show that a codon allosterically affects the conformation of the tRNA[46]. The sequence TΨC(G,A), common to nearly all tRNAs active in ribosomal protein synthesis, is buried within the tertiary structure of tRNA. This sequence is neither accessible for chemical modification nor for the binding of complementary oligonucleotides such as CGAA (see Fig. 8). However, in the codon·tRNA complex this region of the tRNA molecule becomes accessible to both chemical reagents and for oligonucleotide binding. CGAA binds to a U_8·$tRNA^{Phe}$ complex with an association constant of 5×10^4 M^{-1}[46]. The presence of CGA increases the stability of the codon·anticodon complex by a factor of 10 (Fig. 14). Kinetic experiments performed by *Pörschke et al.* confirmed the codon-induced conformational change of the tRNA[79].

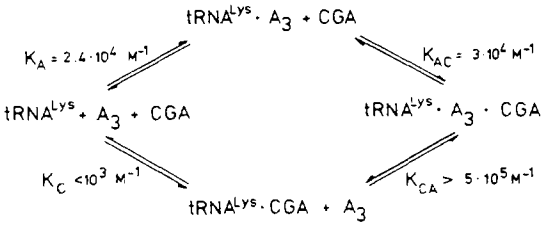

Fig. 14. Codon-induced structural transition in tRNA. Reaction scheme for the binding of A_3 and CGA to $tRNA^{Lys}$. The trinucleotide CGA binds to an $tRNA^{Lys} \cdot A_3$ complex ($K_{AC} = 3 \times 10^6$ M^{-1}) but not to free tRNA. In the presence of CGA the stability of the codon-anticodon complex is increased by a factor of 10 ($K_{CA} = 5 \times 10^5$ M^{-1}).

The TΨC(G,A) sequence, as exposed in the codon·tRNA complex, may bind to a complementary sequence within the 5S RNA (C43GAA46) or similar sequences in 16S RNA[80]. The mRNA codon acts as an allosteric effector which induces the binding type conformation of the tRNA. As a consequence of the codon-anticodon complex the conformation of the tRNA is altered such that a RNA-RNA double strand is formed between the tRNA (TΨC(G,A)), and the ribosomal RNA. This type of interaction is identical for all tRNAs, whereas the formation of the codon·anticodon complex is a selective type of reaction. Each AA-tRNA associates with the codon-programmed A site in the form of its ternary complex AA-tRNA·EF-Tu·GTP. When the codon and the anticodon of tRNA do not match, the tRNA dissociates from the A site again ($k = 10^{-5}$ s^{-1}). A matching codon-anticodon complex induces a conformational change in the tRNA that results in stable binding of the AA-tRNA to the A site. The double strand formation between the now exposed TΨC(G,A) sequence and the ribosomal RNA is part of the stable interaction. In the *in vivo* situation the AA-tRNA does not dissociate from the ribosome, but following the removal of the elongation factor EF-Tu·GDP and transfer of the peptidyl moiety as peptidyl-tRNA is translocated to the P site.

5.2. Translocation, the Energy-Dependent Movement of the mRNA with Respect to the Ribosome

Elongation is a cyclic process within protein synthesis which occurs once per peptide bond formed. A peptidyl-tRNA occupies the P site and an aminoacyl-tRNA is located in the A site. Following the dissociation of the elongation factor as EF-Tu·GDP, the peptidyl moiety is transferred to the aminoacyl group of the AA-tRNA. This reaction is thought to be catalyzed by peptidyl transferase. This state of the ribosome represents the pre-translocational state, which means that a tRNA is now in the P site and the peptidyl-tRNA occupies the A site. The consecutive trans-

location process can be subdivided into two individual steps: removal of the deacylated tRNA from the P site, and movement of the mRNA and PP-tRNA by a codon's length from the A to the P site. A peptidyl-tRNA, containing a peptidyl moiety elongated by one amino acid, is located in the P site and the neighboring A site is again free for the acceptance of a new AA-tRNA. However, the deacylated tRNA has to be removed from the P site before translocation can occur. This process requires chemical bond energy in the form of GTP, and the elongation factor EF-G·GTP replaces the tRNA in a stoichiometric exchange reaction. The data shown in Figure 15 demonstrate that the stoichiometry and the rates of the EF-G·GTP-dependent release of tRNA may be correlated with the binding of a new AA-tRNA and thus with the translocation reaction[81]. Following this, it could be said that the second elongation factor functions as the counterpart of the elongation factor Tu. The EF-G·GTP complex has a high affinity for the ribosome and acts as a tRNA release protein. At present it is not known whether factor and tRNA compete for the same binding site, or whether the elongation factor reduces the affinity of the ribosome for the tRNA in an allosteric fashion. Prior to translocation of mRNA and

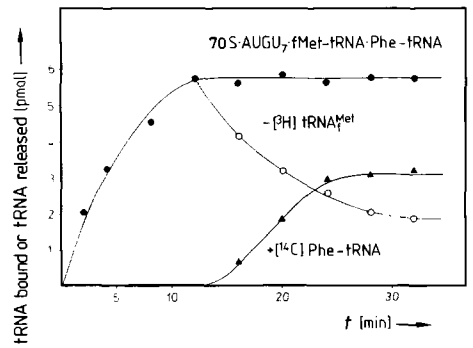

Fig. 15. Binding of an additional Phe-tRNA to the complex 70S·AUGU$_7$·fMet-tRNA·Phe-tRNA after addition of EF-G·GTP. The translocation of the PP-tRNA·mRNA complex occurs simultaneously with the EF-G·GTP-catalyzed release of tRNA. In the initial complex, an fMet[^{3}H]-tRNA$_f^{Met}$ (tritium labeled at the CCA end) occupies the P site, whereas a Phe-tRNA binds to the A site. The curve marked (●) shows the kinetics of formation of the complex 70S·AUGU$_7$·fMet-[^{3}H]tRNA·Phe-tRNA. 10 pmol 70S ribosomes were used. After 12 min, the addition of EF-G·GTP and [^{14}C]Phe-tRNA^{Phe} (labeled in the amino acid) induced the release of deacylated tRNA ([^{3}H]tRNA$_f^{Met}$ (○)) and the simultaneous formation of a new Phe-tRNA (△). This indicates that the 70S·AUGU$_7$·fMet-Phe-tRNA·Phe-tRNA complex was formed.

PP-tRNA, the factor G has to be removed from the ribosome. GTP is hydrolyzed to GDP and inorganic phosphate by a 50S subunit-owned GTPase[82]. This GTPase activity may be one of the functions of the protein pair L7/L12 which exists in duplicate on the large subunit. If GTP is replaced by the analogous GMPPCP, tRNA is still removed from the ribosome, but the factor remains associated with the ribosome, and peptide synthesis stops[34,83]. Furthermore, tRNA can be displaced from the P site by lowering the Mg^{2+} concentration from about 15 to 7 mM. Under these conditions (factor-free system), all partial reactions of the elongation cycle occur, albeit at a very low rate. The energy of the ester bond stored in AA-tRNA is sufficient to form a peptide bond. Chemical bond energy in the form of GTP is used to regulate the affinity of a tRNA release protein towards the ribosome and to increase the rate of tRNA-dissociation. With both factors, EF-Tu and EF-G·GTP, hydrolysis has to occur before the factor can be removed from the ribosome.

The movement of the peptidyl-tRNA from the A to the P site may be explained if one accepts a concept originally proposed by *Leder*[84]. The binding domain of an enzyme has a high affinity for its substrate and a reduced affinity for the resulting product. Applied to the translocation process this should mean the following. The transfer of the peptidyl moiety converts the AA-tRNA in the A site to a peptidyl-tRNA and thus to the product of the A site. The same conversion occurs at the P site, the deacylated tRNA representing the product of the P site, which is released by EF-G·GTP action. Now the neighboring P site is free and represents the high affinity site for the peptidyl-tRNA (substrate). Thus, peptidyl-tRNA should diffuse from A to P as soon as the P site is empty. Up until now it has been difficult to prove this elegant theory from quantitative experimental data. The purity of the individual components, as well as the techniques applied, *i.e.* adsorption of the complexes on nitrocellulose filters, have not allowed the exact determination of the association constants under equilibrium conditions. Previously we have shown that one can prepare 70S ribosomes that under appropriate experimental conditions will bind exactly two RNA molecules. Working in collaboration with *Riesner*, we used velocity sedimentation in the analytical ultracentrifuge to make separate determinations of the affinity constants of PP-tRNA to the A and P sites of the ribosome[27]. The respective data listed in Table 4 confirm the theory proposed by *Leder*. AcPhe-tRNA, an analogue of peptidyl-tRNA, or $(Phe)_2$-tRNA has a 20-fold higher affinity for the P compared to the A site. Thus, translocation of the peptidyl-tRNA has to be visualized as a directed diffusion reaction which occurs spontaneously as soon as the P site is free. The 20-fold difference in the association constants indicates that under equilibrium conditions both domains are occupied to an extent 95% P and 5% A. However, the reaction becomes irreversible when the ternary complex AA-tRNA·EF-Tu·GTP binds to the A site. Only this reaction guarantees the directed diffusion of the PP-tRNA from the A to the P site.

Table 4. Apparent binding constants of AA-tRNA, peptidyl-tRNA, and tRNA to programmed 70S ribosomes; number per ribosome bound.

tRNA	Number of bound tRNAs	Binding site [a]	K_{ass} [M^{-1}] [b]
Phe-tRNA·EF-Tu·GMPPCP [c]	1	A	$6.6 \cdot 10^6$
AcPhe-tRNA	1	P	$3.5 \cdot 10^6$
AcPhe-tRNA	1	A	$1.8 \cdot 10^5$
Phe-tRNA	2	A, P	—
tRNA$_f^{Met}$	1	P	$2.1 \cdot 10^5$
tRNA^{Phe}	2	A, P	—

[a] The specifity of the peptidyl-tRNA for either A or P site can be deduced from the accepted mechanism of translocation. No direct experimental evidence exists, as yet, for the site-specificity. [b] The association constants K_{ass} were calculated from the sedimentation of the complexes in the analytical ultracentrifuge at a Mg^{2+} concentration of 8 mM (see also Fig. 7). [c] Within the ternary complex Phe-tRNA·EF-Tu·GTP, GTP was replaced by the non-cleavable GMPPCP to prevent hydrolysis by 70S-GTPase.

One of the crucial questions in the translocation process left to be solved was whether the peptidyl-tRNA and the mRNA are translocated as a codon-anticodon associated unity, or whether the individual components are transported separately. This problem was answered by an elegant experiment performed by *Küchler*[85]. In the 70S·poly(U)·AcPhe-tRNA complex he crosslinked (by UV irradiation) the tRNA covalently to the polyuridylate *via* the codon and anticodon bases. The crosslinked poly(U)·AcPhe-tRNA entity translocates normally from the A to the P site, and the peptidyl group can then be transferred to puromycin. Further evidence for the translocation of a PP-tRNA·mRNA complex comes from a frame shift suppressor tRNA, which occupies four mRNA bases and moves the mRNA by four nucleotides[86a].

In order to investigate the molecular details of the translocation process we devised our experiments according to the following assumptions: Release of the deacylated tRNA from the P site, should destabilize the mRNA ribosome interaction. On the other hand, the peptidyl-tRNA should have an increased affinity for the mRNA, brought about by the tightening of the codon·anticodon complex. Therefore, we measured the binding of oligonucleotides to the ribosome as related to the presence of cognate tRNAs (Table 5). A stable interaction ($K_{Ass}=2.2\times10^{8}$ M^{-1}) between the mRNA analogues and the 70S ribosome occurs either in the presence of two cognate tRNAs or a peptidyl-tRNA[87]. With only one tRNA present the ribosome·oligonucleotide complex is of intermediate stability, a state of the ribosome which may be correlated to the pretranslocational state. From the data listed in Table 5 it is evident that the affinity of an mRNA for the ribosome is not determined by its chain length, but by the number of cognate tRNAs.

Table 5. Effect of the chain length of polyuridylic acid and cognate tRNAs on the formation of the formation of the 70S AUGU$_n$ complex [88]. The association constants were measured by equilibrium dialysis and were derived from a Scatchard plot for ten different oligonucleotide concentrations.

Complex	tRNA	K_{Ass} [M^{-1}]	Number of binding stites
70S·AUGU$_3$	–	$6.8\cdot10^{5}$	1.3
70S·AUGU$_6$	–	$8.7\cdot10^{5}$	1.3
70S·AUGU$_{13}$	–	$9.3\cdot10^{5}$	1.4
70S·AUGU$_3$	tRNA$_f^{Met}$	$4.6\cdot10^{7}$	1.0
70S·AUGU$_3$	tRNA$_m^{Met}$	$3.9\cdot10^{6}$	1.0
70S·AUGU$_3$	tRNA^{Phe}	$4.1\cdot10^{6}$	1.2
70S·AUGU$_3$	tRNA$_f^{Met}$, tRNA^{Phe}	$2.2\cdot10^{8}$	1.1
70S·AUGU$_6$	tRNA$_f^{Met}$, tRNA^{Phe}	$2.1\cdot10^{8}$	1.0
70S·AUGU$_{13}$	tRNA$_f^{Met}$, tRNA^{Phe}	$2.2\cdot10^{8}$	1.1
70S·AUGU$_3$	fMet-tRNA$_f^{Met}$	$1.1\cdot10^{8}$	1.1
70S·AUGU$_3$	AcMet-tRNA$_m^{Met}$	$5.3\cdot10^{7}$	1.1

In order to prove our second assumption we compared the association constants of a peptidyl-tRNA·oligonucleotide complex with either tRNA or aminoacyl-tRNA (Table 6). The peptidyl-tRNA, with or without ribosomes, binds a cognate oligonucleotide 3–20 times tighter than deacylated tRNA[86b]. These data further support the idea of translocation of a peptidyl-tRNA·mRNA complex.

Table 6. Effect of the peptidyl moiety on the stability of the oligonucleotide·tRNA-or ribosome·oligonucleotide-tRNA complex.

Oligonucleotide	tRNA	Ribosome	K_{Ass} [M^{-1}] [a]
AUG	tRNA$_f^{Met}$	–	$4.4\cdot10^{3}$
	fMet-tRNA	–	$1.2\cdot10^{4}$
AUGA	tRNA$_f^{Met}$	–	$4.0\cdot10^{4}$
	fMet-tRNA$_f^{Met}$	–	$1.2\cdot10^{5}$
UUC	tRNA^{Phe}	–	$1.7\cdot10^{3}$
	AcPhe-tRNA^{Phe}	–	$1.1\cdot10^{4}$
	tRNA^{Phe}	+	$6.3\cdot10^{5}$
	AcPhe-tRNA^{Phe}	+	$9.5\cdot10^{6}$
UUCA	tRNA^{Phe}	–	$3.2\cdot10^{4}$
	AcPhe-tRNA^{Phe}	–	$1.9\cdot10^{5}$
	tRNA^{Phe}	+	$2.3\cdot10^{6}$
	AcPhe-tRNA^{Phe}	+	$1.8\cdot10^{7}$

[a] Association constants were determined by equilibrium dialysis.

Translocation has to be viewed as a concerted reaction. Transfer of the peptidyl moiety from the tRNA in the P site to the AA-tRNA placed in the A site and consequent removal of the deacylated tRNA from the P site result in PP-tRNA in the A site, and an empty P site. The PP-tRNA, however, has a higher affinity for the P site and the peptidyl moiety induces a structural change within the tRNA which increases the stability of codon-anticodon interaction 5–20fold. The mRNA is primarily held in the ribosomal complex by binding to the tRNA, and hence translocation may be regarded as a shift of the PP-tRNA·mRNA from its site of low affinity to that of high affinity. Given the relevant binding constants, the shift of the PP-tRNA to the P site should only occur to an extent of 95%; however, it is driven to irreversibility by the binding of the ternary complex AA-tRNA EF-Tu·GTP to the vacant A site.

The main function of the ribosome could be to provide the specific binding sites for the components necessary for peptide bond formation and to form a cavity which prevents dilution of the PP-tRNA and the mRNA during translocation. Mechanical movement is explained as a diffusion from a low- to a high-affinity binding site. The continuous shift in one direction is guaranteed by the consecutive irreversible GTP hydrolysis. Conformational transitions of the ribosome do not seem to be necessary for this mechanism.

6. Prospects

Many details of the initiation and elongation steps in bacterial protein biosynthesis are known and it is only the mechanism of the termination reaction that remains in the dark. However, kinetic data on these processes, which should shed some light on the speed and accuracy of peptide synthesis, are still missing. This type of experiment has failed up to now, since the complexity of the systems involved does not allow the unambiguous interpretation of the experimental data. An area which shows great promise for the future is the X-ray structural analysis of ribosomal components and of the ribosome itself. Comparable to the scientific impact of the three-dimensional structure of the tRNA^{Phe}, the determination of the three-dimensional structure of the ribosome now in progress, should deepen our understanding of the molecular principles of protein-nucleic acid interaction.

It is interesting to compare facts known about bacterial synthesis with those valid for eukaryotic systems. The eukaryotic 80S ribosome consists of about 80 proteins and four nucleic acids, and thus shows a far greater complexity compared to the bacterial ribosome. The mRNA is monocistronic, starting with the cap sequence and containing a 200 nucleotide poly(A) segment at the 3'-end. The initiator tRNA is not formylated, and the seven initiator factors have a molecular weight of more than one million in total[88]. Whereas the elongation cycle and the termination reaction are similar in prokaryotes and eukaryotes, with respect to their mechanisms, the initiation process is very different in this respect. All known regulatory mechanisms work at the level of the initiation process. The initiation factor IF-2 (eIF-2), which functions as a carrier protein for Met-tRNA$_{i}^{Met}$, can be inactivated by a protein kinase catalyzed phosphorylation. The inactivation of the initiation factor is further coregulated by some interferons, 2',5'-oligo(A) synthetase, and cAMP protein kinases[89]. The mechanism of eukaryotic initiation may provide some clues on the molecular principles of cell differentiation and growth of malignant cells.

The Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie are thanked for financial support. I am grateful to Mrs. E. Rönnfeldt for her help in preparing the manuscript.

The Chemistry of Acyl Cyanides

By Siegfried Hünig* and Rainer Schaller

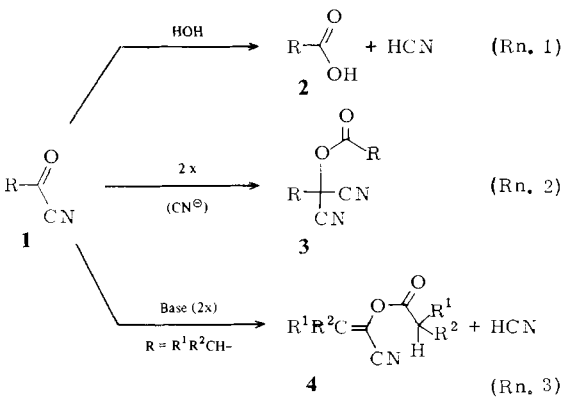
Through improved and novel syntheses, acyl cyanides—especially aliphatic acyl cyanides—have become so readily accessible that numerous synthetic applications present themselves. The present review surveys the development of the chemistry of the acyl cyanides during the last 25 years. The syntheses and most important reaction possibilities of R—CO—CN are outlined in four large schemes: reactions of the CO- and CN-groups—in each case with preservation of the carbon skeletal framework—as well as acylations with cleavage of cyanide ions.

1. Introduction

Although the first acyl cyanide had already been reported[2] as long ago as 1832, it was not until 1956 before a comprehensive review of the acyl cyanides and their chemistry appeared in the literature, by *Thesing et al.*[1]. During recent years this class of compounds has substantially gained in importance, especially as a result of new synthetic methods and their use as building blocks for heterocycles (herbicides), so that a fresh survey may be rewarding. We start deliberately from *Thesing*'s presentation, the contents of which are largely taken for granted.—A later survey of synthetic methods covers the literature up to 1974[3].

2. General Properties of Acyl Cyanides

Acyl cyanides **1** are usually colorless solids or liquids. Their infrared spectrum shows an intense and sharp CN-band at 2210—2250 cm^{-1} and a strong CO-band at 1645—1720 cm^{-1}[4], which can be used as good indicators to follow the course of a reaction. Because of their strong carbonyl activity, which can be utilized for mild acylations (Section 4.4), they are sensitive to hydrolysis **(1→2)** (Section 4.4.1). In presence of cyanide ions (hydrolysis!) "dimeric acyl cyanides" **3** are formed (Section 5). Finally, bases can convert enolizable acyl cyanides into their acylated enols **4** (Section 4.2.3).



In the synthesis of acyl cyanides, as well as in any application, their reactivity according to reactions 1—3 has to be taken into account. It is especially due to the formation of **3** and **4** that no satisfactory syntheses of aliphatic acyl cyanides have existed until recently. For the same reason it was only lately that a series of consecutive reactions could be developed for syntheses of preparative value.

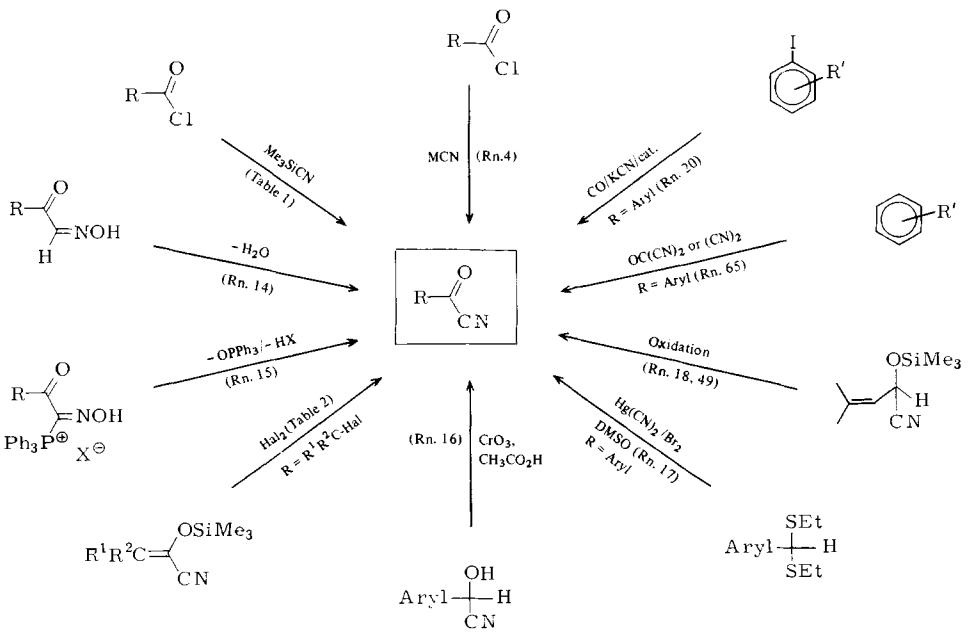
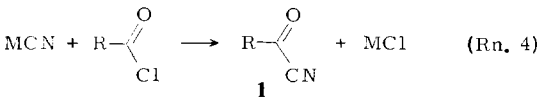
3. Synthesis of Acyl Cyanides



Scheme 1.

The most important synthetic routes to acyl cyanides **1** are shown in Scheme 1.

3.1. Acyl Cyanides from Carboxylic Acid Halides



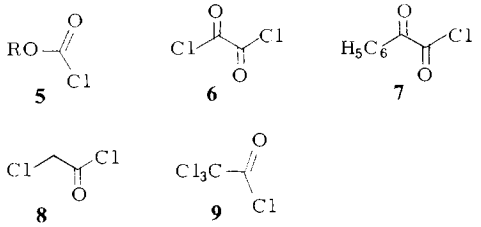
MCN + R–C(=O)–Cl ⟶ R–C(=O)–CN + MCl (Rn. 4)

1

Rn.	MCN	Conditions	R	Yield [%]
4a	CuCN	Acetonitrile, 80°C, 15 min	Aryl, alkyl	50-75 [5]
4b	CuCN	LiI, ether, 30°C, 2h	C_6H_5	62 [6]
4c	TlCN	Ether, ethyl acetate 20°C, 1-3 h	Aryl	45-89 [4]
4d	NaCN (CuCN)	Org. solvent 50 to 300°C	Aryl, alkyl	50-95 [17]
4e	KCN	[18]Crown-6, CH_2Cl_2-H_2O	RO	62-94 [7]
4f	Et_4NCN	CH_2Cl_2, −40 to +20°C	R_2N, C_6H_5O	≈90 [8]
4g	NaCN	TBABr [a], CH_2Cl_2-H_2O	Aryl	50-75 [9]
4h	Me_3SiCN	Cf. Tables 1 and 2	RO, (Aryl?) Alkyl	50-100 [10, 11]
4i	nBu_3SnCN	Without solvent, 75°C, 5 min	Aryl	80-95 [12]

[a] TBABr = tetra-*n*-butylammonium bromide.

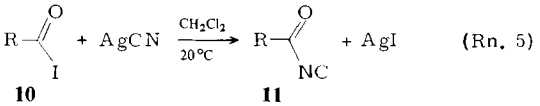
The classical reaction of carboxylic acid halides with heavy metal cyanides (Cu^I, Hg^I, Ag^I, low cyanide concentration!) demands heating for hours at 120—160°C and for aliphatic derivatives the use of acid bromides[1]. In the latter case the addition of phosphorus pentoxide increases the yield[5]. CuCN, complexed with acetonitrile as solvent yields acyl cyanides in 50—75% yield (Rn. 4a) already after 15 minutes at 80°C—even from aliphatic acid chlorides. This method does not succeed with the acid chlorides **5** (too unreactive) and **6** (exothermic reaction). Compound **7** reacts—probably *via* radical decarbonylation[13]—to give benzoyl cyanide. From **8** and **9** only products of cyanation are obtained[6].



5 **6** **7** **8** **9**

The activation of copper cyanide by lithium iodide is noteworthy, but is not suitable for the synthesis of aliphatic acyl cyanides[6] (Rn. 4b). Thallium(I) cyanide reacts particularly smoothly with aromatic acid chlorides, even if they are activated by electron acceptors[4] (Rn. 4c). However, it is questionable whether the high yield of 85% of *p*-nitrobenzoyl cyanide (Rn. 4a 64%) justifies preparation of the reagent from anhydrous thallium(I) phenolate and hydrocyanic acid. After all, this cyanide is sufficiently reactive to convert even **5** into cyanoformic ester in 90% yield, while aliphatic acid chlorides furnish mostly only dimeric acyl cyanides **3**[4].

In contrast to the well known alkyl isocyanides, the formation of acyl isocyanides **11** from heavy metal cyanides could only recently be demonstrated[14] through the use of acyl *iodides* **10**. Compounds **11** easily rearrange into acyl cyanides (especially by catalysis of 4-pyrrolidinopyridine[15]), for which reason they were presumably overlooked.

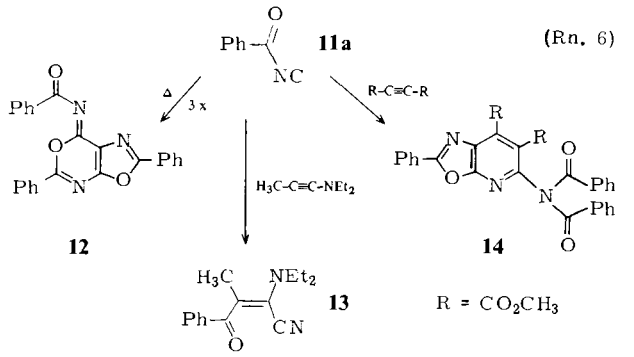


R–C(=O)–I + AgCN $\xrightarrow[20°C]{CH_2Cl_2}$ R–C(=O)–NC + AgI (Rn. 5)

10 **11**

R = Aryl, Alkyl

When heated above its melting point, the isolable benzoyl isocyanide **11a** trimerizes to a compound which *Nef*[16] had already obtained as a "trimeric benzoyl cyanide" and whose hitherto accepted structure[1] was rejected[14] in favor of **12**. The reaction **11a**→**13** proves the acylation potential of **11a**, while its reaction to give **14** demonstrates its ability to undergo cycloadditions.



High yields of **1** are also obtained from the heterogeneous reaction of sodium (potassium) cyanide with acyl chlorides[17a] or anhydrides[17b], especially in the presence of Cu^{I} salts[17c] (Rn. 4d). From an industrial point of view syntheses of **1** from anhydrous hydrocyanic acid have been developed[17c]. By means of solid-liquid phase-transfer catalysis the unreactive chloroformic acid esters **5** react smoothly with potassium cyanide to yield cyanoformic esters (Rn. 4e)[7]. Tetraethylammonium cyanide, which is used for a general nitrile synthesis[8a], does not require a phase-transfer catalyst because of its high solubility in dichloromethane. Due to its high reactivity, however, chloroformic alkyl esters will be decarboxylated, so that only chloroformic aryl esters and -dialkylamides are suitable educts (Rn. 4f)[8a]. While the formation of dimers according to Rn. 4e and 4f does not occur, it cannot be avoided in the solid-liquid phase-transfer catalyzed reaction between aromatic acid chlorides and sodium cyanide (Rn. 4g) because of the high cyanide ion concentration (cf. Rn. 2). With strongly electron accepting substituents dimerization becomes the main reaction[9] (cf. Rn. 67). Without phase-transfer catalyst, however, on addition of hydrocyanic acid and a tertiary amine, the reaction stops at **1** (≈90%) in the case of benzoyl chloride[9b].

(For the Friedel-Crafts synthesis of aromatic acyl cyanides cf. Section 4.4.2, Rn. 65.)

A general synthesis, according to which the preparatively more important aliphatic acyl cyanides are readily accessible in high yield, was recently achieved independently by two groups[10, 11] using cyano(trimethyl)silane **15**[18] (Rn. 4h). This reagent, which adds in high yield to various carbonyl groups[18a, d, 19, 20] was already known to react smoothly with chloroformic ester (70%)[18d]. Table 1 contains the aliphatic and benzylic acyl cyanides **1a**—**1v** which are formed in a reaction of equimolar components in the absence of solvent. The autocatalyzed reaction[10] is easily monitored by IR spectroscopy and is strongly accelerated by bromo(trimethyl)silane[10], zinc iodide[11] or aluminum chloride[11].

Table 1: Synthesis of aliphatic α,β-unsaturated acyl cyanides (**1a-1v**). *Experimental Procedure* [11]: Under the reaction conditions given in Table 1 equimolar quantities of carboxylic acid chloride and **15** are stirred without solvent and with exclusion of moisture (if necessary addition of ≈0.5% ZnI_2). The course of the reaction is followed by IR-spectroscopy by means of the nitrile bands. After **15** is completely consumed the solution is distilled or allowed to react directly.

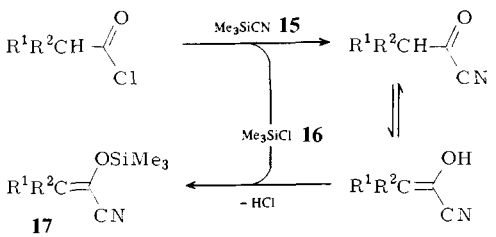
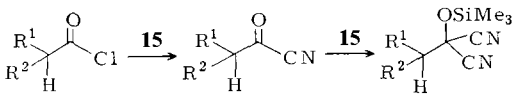
[a] Addition of catalytic amounts of Lewis acid. [b] Conversion and purity determined by IR-spectroscopy. [c] Secondary reaction to give a 2-(trimethylsiloxy)-2-propenonitrile derivative (Rn. 7).

Even α-halogenated acyl cyanides are accessible by this convenient route (cf. also Table 2). In some cases with acyl cyanides carrying α-hydrogen a consecutive reaction is observed, particularly on addition of a catalyst, yielding 2-(trimethylsiloxy)-2-propenonitriles **17**. The formation of **17** is probably due to the ready enolization of these acyl cyanides which are then *O*-silylated to **17** by the generated chloro(trimethyl)silane **16**. Accordingly, only **17** ($R^1 = C_6H_5$, $R^2 = H$) is isolated from phenylacetyl chloride instead of the acyl cyanide. This reaction can be extended into a general synthesis[11c] of **17** by addition of triethylamine.



A further difficulty arises with acyl cyanides which add another molecule of **15** to the carbonyl group. With the less enolizable acyl cyanides of type **18** (*e.g.* **1d** or **1j**, cf.

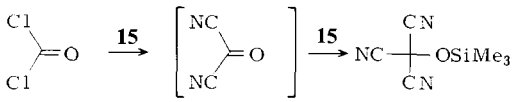
Table 1) adducts **19** are formed in a slower subsequent reaction[11b]. When exactly one equivalent of **15** is used with ZnI_2 catalysis this undesirable consecutive reaction can be completely suppressed[11d]. If under these conditions ZnI_2 is replaced by $(n\text{-}C_4H_9)_4N^{\oplus}I^{\ominus}$, compound **19** ($R^1$, $R^2 = CH_3$, 50%) is exclusively formed although acid chloride (50%) is still present. Thus, in this case the second step of the reaction proceeds much faster than the first[11d].



(Rn. 8)

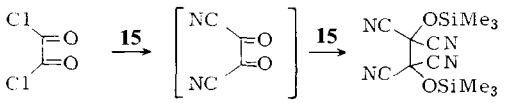
18 **19**

Even without catalysis this mode of reaction can be observed, if as in the examples **20, 22,** and **24** the intermediate acyl cyanides possess a high carbonyl activity, so that the adducts **21, 23** and **25** are formed immediately[18a].



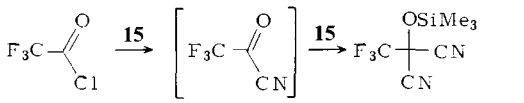
(Rn. 9)

20 **21**



(Rn. 10)

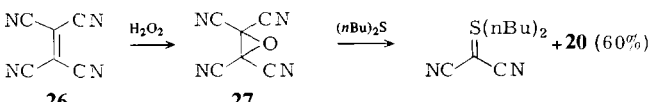
22 **23**



(Rn. 11)

24 **25**

Carbonyl cyanide **20** is, however, accessible by pyrolysis of acetylated bis(isonitroso)acetone, whereby the yield has been improved from 25%[1] to 40%[24]. The route *via* tetracyanoethylene **26** and its oxide **27**[25] appears even more practical, the latter furnishing[26] 60% of **20** on reaction with dibutyl sulfide (Rn. 12).



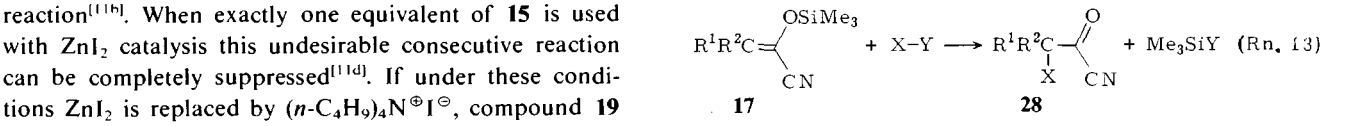
(Rn. 12)

26 **27**

Cyano(trimethyl)silane **15** should also smoothly convert aromatic acid chlorides into acyl cyanides—a reaction for which tri-*n*-butyl(cyano)tin was recently described as particularly suitable (Rn. 4i). With aliphatic acyl chlorides whose alkyl groups are primary or secondary this reagent furnishes only dimeric acyl cyanides[12].

The above preparation of the 2-(trimethylsiloxy)-2-propenonitrile derivative **17** can be utilized for a very efficient synthesis of α-halogenoacyl cyanides **28**. Reaction of **17** with halogens proceeds fast and practically quantitatively[11a]; therefore, the sensitive acyl cyanides **28** (Table 2) need not be distilled for further reactions.

Tabelle 2. α-Haloacyl cyanides **28** *via* desilylating halogenation of **17** [11].



(Rn. 13)

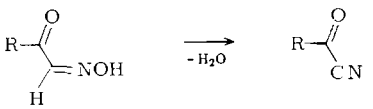
[a] Acyl cyanide was not isolated, conversion and purity determined by IR-spectroscopy.

3.2. Acyl Cyanides from Aldehydic and Ketonic Derivatives

The dehydration of aldoximes with acetyl chloride, thionyl chloride, and similar reagents to give nitriles has also been applied[1,24a] to α-oxo-aldoximes **29.** Instead of **29** the corresponding derivatives from α-oxo-aldehydes and 1-amino-4,6-diphenyl-2-pyridone are suitable for the formation of aromatic acyl cyanides by thermolysis in 85–95% yield[24b].

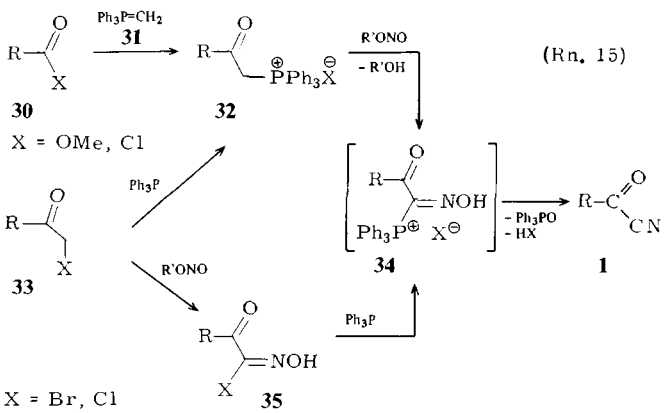


(Rn. 14)

29 **1**

R = Aryl, Alkyl (40-75%) [1]

The spontaneous decomposition of the intermediary oximes **34** into the acyl cyanides **1** represents a related reaction. Compound **34** is formed by nitrosation of **32**[22,29] as well as by the reaction of **35** with triphenylphosphane[30]. The phosphonium salts **32** are accessible from the carbonic acid derivatives **30** and the Wittig reagent **31**[31], or from halomethyl ketones **33** and triphenylphosphane[32];

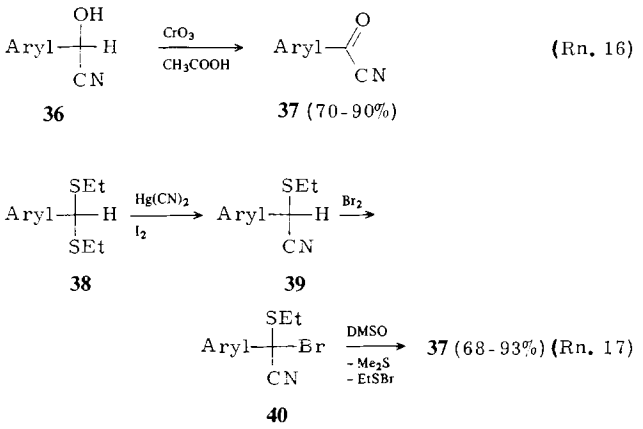


(Rn. 15)

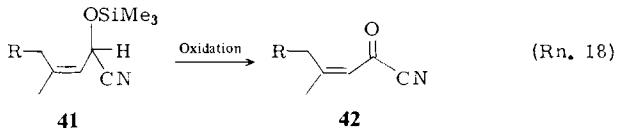
30 **32** **33** **34** **1** **35**

the oximes **35** are obtained from **33** by nitrosation[30]. The alcohol which is generated by nitrosation of **32** instantaneously converts the aliphatic acyl cyanides produced into esters (cf. Section 4.4.1).

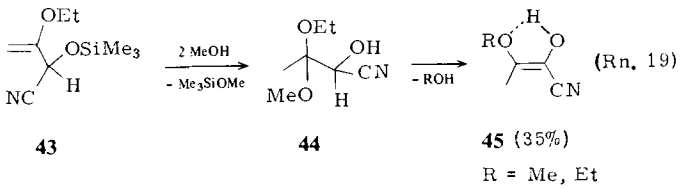
The known oxidation of aromatic cyanohydrins **36** with chromic acid/glacial acetic acid has been varied in several ways[1]. Thus, the aromatic acyl cyanides **37** are produced in a type of Kornblum-oxidation[33] from the unstable α-bromo-α-(ethylthio) derivatives **40** which in turn are formed[34] *via* **38** and **39** (DMSO = dimethyl sulfoxide).



Supposedly, the oxidation of the adducts of cyanotrimethylsilane to α,β-unsaturated aldehydes **41**[35] is, much more important. Although **42** may be isolated, its significance depends on the subsequent products (see Rn. 18 and 49)[36].

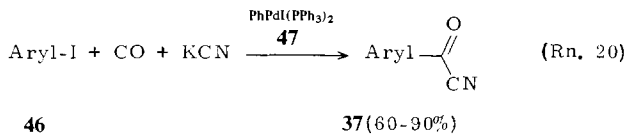


The methanolysis of the cyano(trimethyl)silane adduct **43** according to Rn. 19 can be construed as an intramolecular disproportionation in which the α-alkoxyacyl cyanides formed *via* **44** can be described as enols **45**[37a].



3.3. Acyl Cyanides Through Cyanocarbonylation

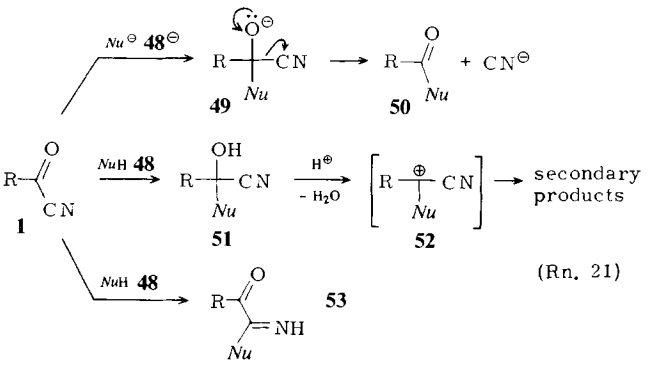
A novel approach to aromatic acyl cyanides has been opened up by the cyanocarbonylation of aryl iodides **46** by means of the palladium complex **47**[37b].



4. Reactions of Acyl Cyanides

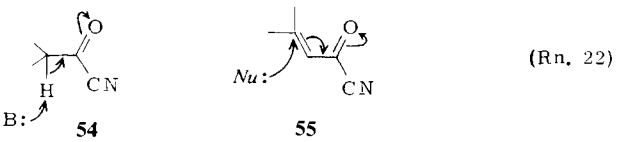
4.1. General Rules

The electrophilicity of both functions in acyl cyanides is enhanced by the proximity of the CO and CN groups (see Rn. 21). As a rule, nucleophiles **48** preferentially attack the CO group. The cyano group as a pseudohalogen is thereby displaced with formation of **50** if its nucleophilic fugacity is increased by protic solvents and the anionic intermediate **49** is present in sufficient concentration.



The cyanide **1** acts as a mild acylating agent (Section 4.4) leading to CC fission with water (Rn. 1!), alcohols, amines, CH-acidic compounds *etc.* Under aprotic conditions or in strongly acid media the lifetime of the adduct **51** is apparently sufficient to produce without C—C fission, via **52**, the typical reaction products of carbonyl compounds with nucleophiles which result from loss of water (section 4.2).

Finally, one must bear in mind the effect of the CO group in **1** on the neighboring C-skeleton: deprotonation as in **54** or Michael-additions as in **55** may occur (*cf.* Sections 4.2.3 and 4.2.4).



Additions to the CN-group to give **53**, *i.e.* with preservation of the CO-function, are only achieved with soft nucleophiles (H_2S) or under strongly acidic conditions which substantially increase (*cf.* Eq. 44) the electrophilicity of the nitrile group through protonation (*cf.* reactions of nitrilium salts). This is exemplified by the saponification of **1** to α-oxoamides or α-oxoacids[1].

4.2. Reactions of the CO-Group with Preservation of the C-Skeleton

Typical reactions of the CO-group **1** with preservation of the carbon skeleton are collected in Scheme 2.

4.2.1. Reactions of the CO-Group with C-Nucleophiles

Reactions of **1** with anionic C-nucleophiles terminate with cleavage of cyanide (for older reactions, see[1]); in contrast, as already mentioned, this does not take place in the smooth addition of cyanotrimethylsilane to activated acyl cyanides (Rn. 8—11). While acyl cyanides cause C-acylation of enolate ions (Rn. 60, 61), the reaction of silyl enol ethers **56** in presence of $TiCl_4$ terminates at the stage of the aldol adducts **57**. Allyltrimethylsilane is added simi-

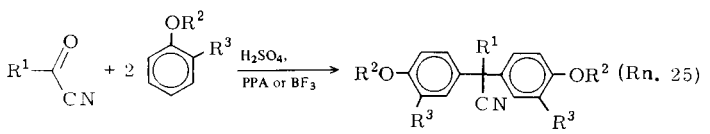
(Rn. 24)

1 **58**, X = Cl, Br **59**, R = C_6H_5, X = Cl (75%)
60, R = Cl_2C=CH, X = Br (77%)

The condensation with phenols in strong acid[41], which so far has only been possible for aromatic acyl cyanides, has been extended to acetyl cyanide and carbonyl cyanide (reaction with dimethylaniline is known[1]) and even applied to phenolic ethers **61** resulting in bisphenol derivatives **62**[42] (PPA = polyphosphoric acid) (cf. also the synthesis of aromatic acyl cyanides from carbonyl cyanide, Section 4.4.2, Rn. 65).

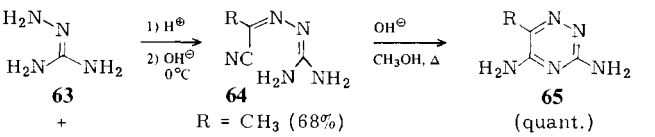


(Rn. 25)

61 **62**

4.2.2. Reactions of the CO Group with N-Nucleophiles

The condensation of acyl cyanides with phenylhydrazine or thiosemicarbazide in strongly acid medium with elimination of water[1] can also be extended to aminoguanidine **63**[43,44]. On warming with methanolic sodium hydroxide, the products **64** quantitatively undergo ring-closure to yield **65**[44].



63 + **64** **65**

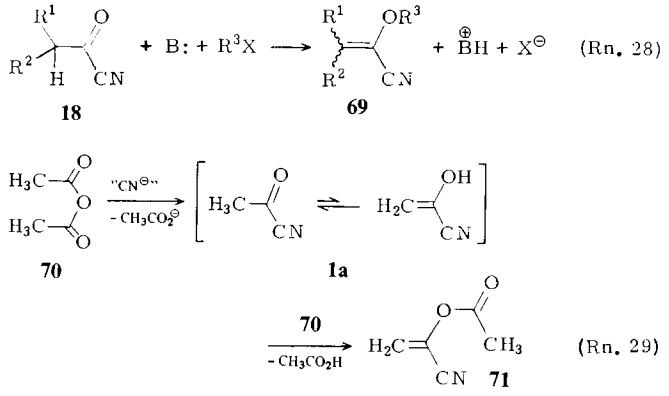
R = Ph (quant.)

The dinitrile of diaminomaleic acid **66** converts **1**, even with catalytic amounts of acid, into the Schiff's bases **67**, which can be cyclized to pyrazines **68**[45].

4.2.3. Preparation of Enol Derivatives

Since acyl cyanides of type **18** can, in principle, be deprotonated, enol derivatives **69** should be accessible according to Rn. 28. Thus, for instance, the enol ester **71**[46] and not acetyl cyanide **1a** is formed by interaction of acetic anhydride **70** and potassium cyanide in the presence of [18]crown-6.

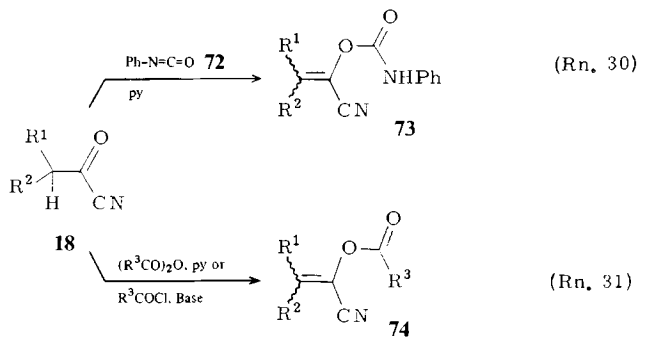
The fact that excess of acetic anhydride acylates the enolic form of the intermediate acyl cyanide **1a** can be demonstrated by using mixed anhydrides, as well as by acylation of **18** with phenyl isocyanate **(72)** yielding **73**[46].



(Rn. 28)

(Rn. 29)

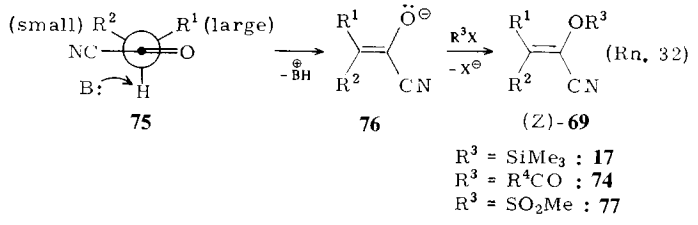
Compound **74** is produced even more conveniently by acylation with acid chlorides or anhydrides in the presence of pyridine or [2,2,2]-diazobicyclooctane (yield 35–75%)[46]. The rate of this acylation depends on the concentration of acyl cyanide and base, but scarcely, if at all, on that of the acid chloride. Thus the deprotonation of **18** may represent the rate determining step[46].



(Rn. 30)

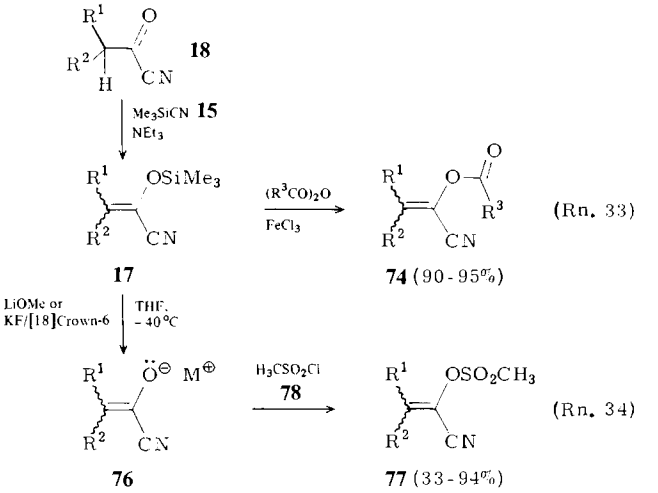
(Rn. 31)

In order to gain maximum π-conjugation the transition state should develop mainly from the conformation **75**. Here, the large group R^1 is located *syn* to the oxygen atom, which in comparison to the CN group is substantially smaller. Thus, according to Rn. 32 the products **(17, 74, 77)** should be produced in their *Z*-form *via* the *Z*-form of the enolate **76.** In fact **74** ($R^1=CH_3$, $R^2=H$, $R^3=COC_2H_5$) is present as a *Z/E* mixture (80/20)[47]. A corresponding situation applies to **17** for the same reasons. For instance, the derivatives $R^2=H$, R^1=t-butyl, phenyl, Br, I contain the large substituents R^1 and $(CH_3)_3SiO$ exclusively in the *cis*-arrangement (*Z*-form)[11c]. Whether formation of (*Z*)-**69** profits additionally from the energetically favorable *trans*-arrangement[48] of R^1 as σ_R-donor[49] with the cyano-group as acceptor is still unclear.



(Rn. 32)

The previously mentioned silylation of **18** to **17** belongs here[11c]. By analogy to silyl ethers[50], **17** is easily transformed with acid anhydrides and $FeCl_3$ catalysis into the enol esters **74**[11c]. But above all, **17** makes it possible for the first time to prepare the configurationally stable enolates **76** by desilylation with lithium methoxide, or better with potassium fluoride/[18]crown-6 [11c]. The most important reaction of **76** with electrophiles so far is the successfully tested[11c] mesylation with **78** to give the esters **77**, whose synthetic potential exceeds to some extent the frequently used α-chloroacrylonitrile[11b] (THF = tetrahydrofuran).



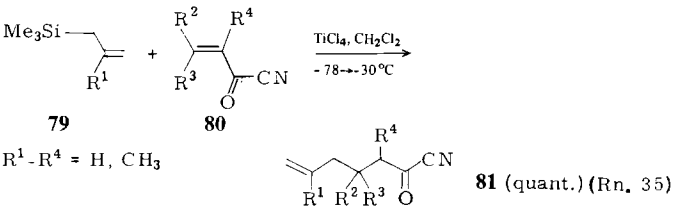
(Rn. 33)

(Rn. 34)

As members of synthetic sequences, importance also attaches to the acyl cyanide-enol derivatives **102** and **115,** in which the C=C bond is the newly formed one (Rn. 44 and 53).

4.2.4. Michael-Additions to α,β-Unsaturated Acyl Cyanides

As recently shown, the $TiCl_4$-catalyzed reaction of allyl silanes **79** with α,β-enones[51] may be extended to α,β-unsaturated acyl cyanides **80,** which react under milder conditions apparently quantitatively[52] (Rn. 35). By rapid work-up, the acyl cyanides **81** can be isolated if carbonic acids (+H_2O) or their methyl esters (+CH_3OH) are not wanted.

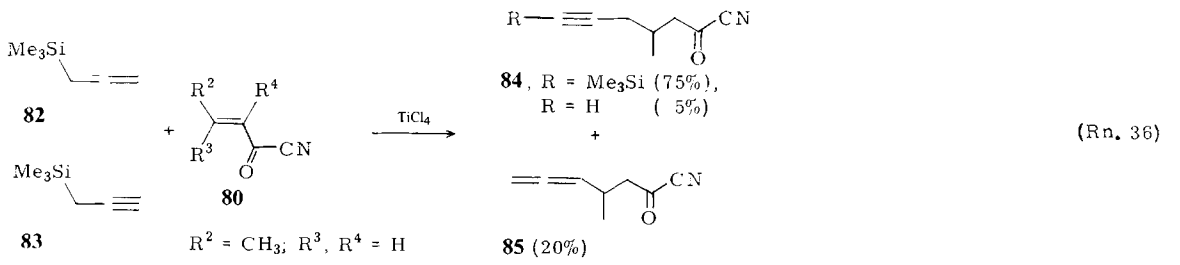


(Rn. 35)

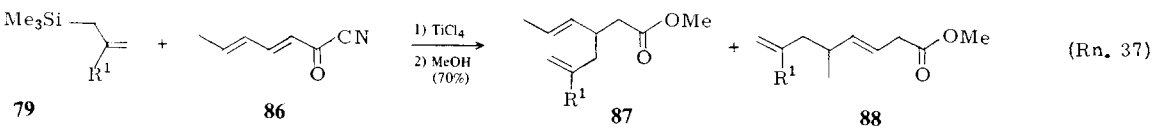
The propadienylsilane **82** behaves, correspondingly, in the same fashion. It contains 20% **83** and furnishes the mixture **84/85.**

Compound **79** adds to **86** in the β- as well as in the δ-position to give a mixture of **87** and **88** (*ca.* 1:1).

Because α,β-unsaturated esters do not react with allyl silanes, and since in the corresponding acid chlorides the halogen is substituted, the reactions according to Rn. 35–37 may acquire greater preparative importance.



(Rn. 36)



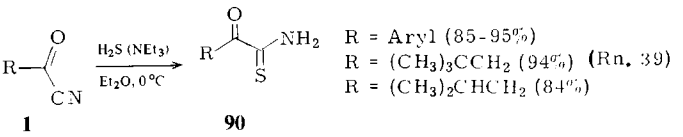
(Rn. 37)

4.3. Reactions of the CN-Group with Preservation of the C-Skeleton

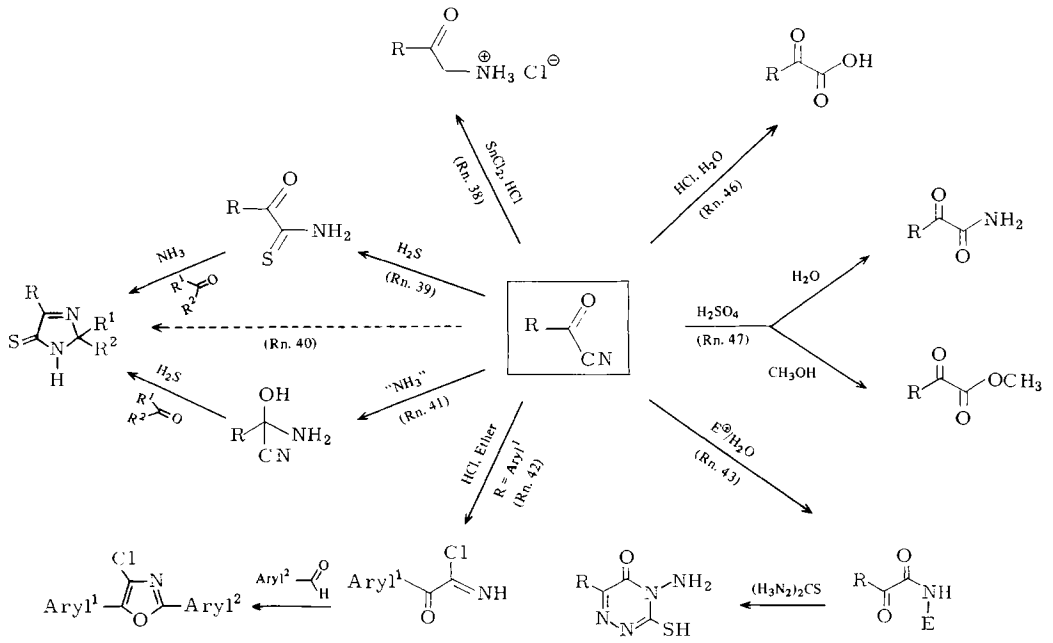
Scheme 3 shows typical reactions of the CN-group in **1** with preservation of the carbon skeleton.

While aromatic acyl cyanides **1** (R = Ar) are reduced by excess of lithium aluminum hydride or hydrogen/palladium in glacial acetic acid to give the pharmacologically interesting 2-amino-1-aryl-ethanols[1], Stephens' reagent

The known base-catalyzed addition of H_2S to nitriles resulting in thioamides cannot only be accomplished[1] with deactivated acyl cyanides **1** (R = RO, RNH, R_2N), but α-oxothioamides **90**[5,55] are generally produced under mild conditions.



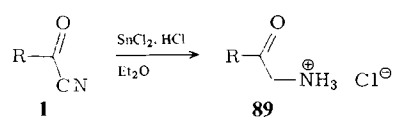
(Rn. 39)



Scheme 3.

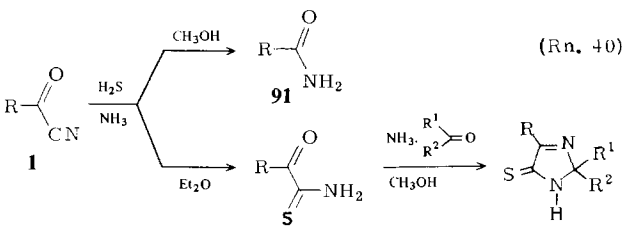
$SnCl_2$/HCl/ether attacks only the nitrile group. The sensitive aminoketones **89** are formed relatively smoothly[53a] (see, however, reduction with $TiCl_3$[53b]).

A selective, catalyzed hydrogenation is reported also to be possible[54].

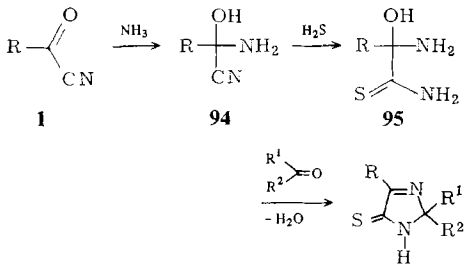


(Rn. 38)

Reaction 40 demonstrates how decisively the solvent influences the course of the reaction: While the mixture



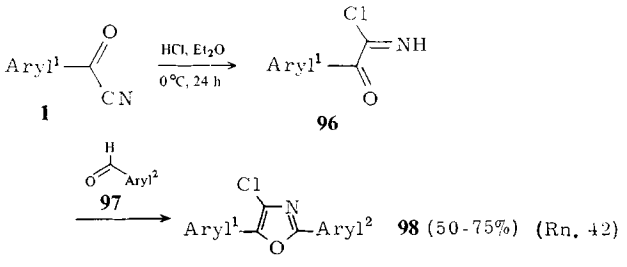
(Rn. 40)



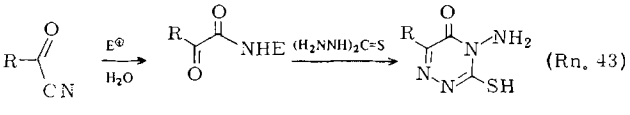
1 **94** **95** **93** (Rn. 41)

H_2S/NH_3 with benzoyl cyanide in methanol reacts with acylating cleavage to give benzamide, H_2S adds in ether to the nitrile group forming thioamide **92,** in spite of the presence of the same base[56]. In methanol, **92** reacts with ammonia and aldehydes or ketones very rapidly and almost quantitatively to give 3-imidazoline-5-thiones **93**[5]. Compound **93** is also formed stepwise from acyl cyanides *via* the semiaminal **94**[57].

The fact that the nitrile group in aromatic acyl cyanides can be converted into the imidochlorides **96** has already been known for the Houben-Hoesch reaction of phenols to give α-diketones[1]. The cyclization of **96** with aromatic aldehydes **97** to give the oxazoles **98** has now also been successfully carried out[58].



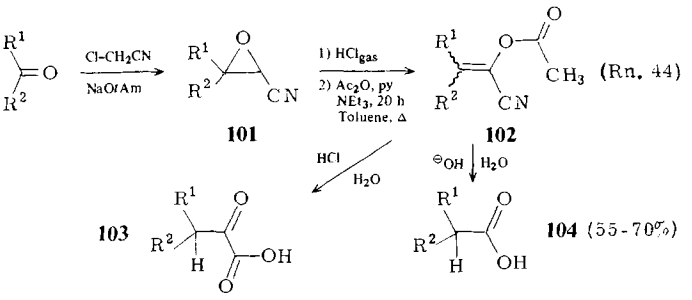
1 **96** **97** **98** (50-75%) (Rn. 42)



E = H: **99a** **100**
E = R'_3C: **99b**

Aliphatic acyl cyanides are also transformed by gaseous hydrogen chloride into imide chlorides, which are smoothly hydrolyzed to the ketoamides **99a**[59] (see Rn. 47). In a similar fashion with tertiary alcohols and the corresponding alkenes[60a] or ethers[60b] in the presence of acid the alkylated ketoamides **99b** are obtained in a Ritter reaction. Both derivatives serve as important building blocks for heterocycles, *e.g.* for triazinones **100** (herbicides)[59b,60b,60c].

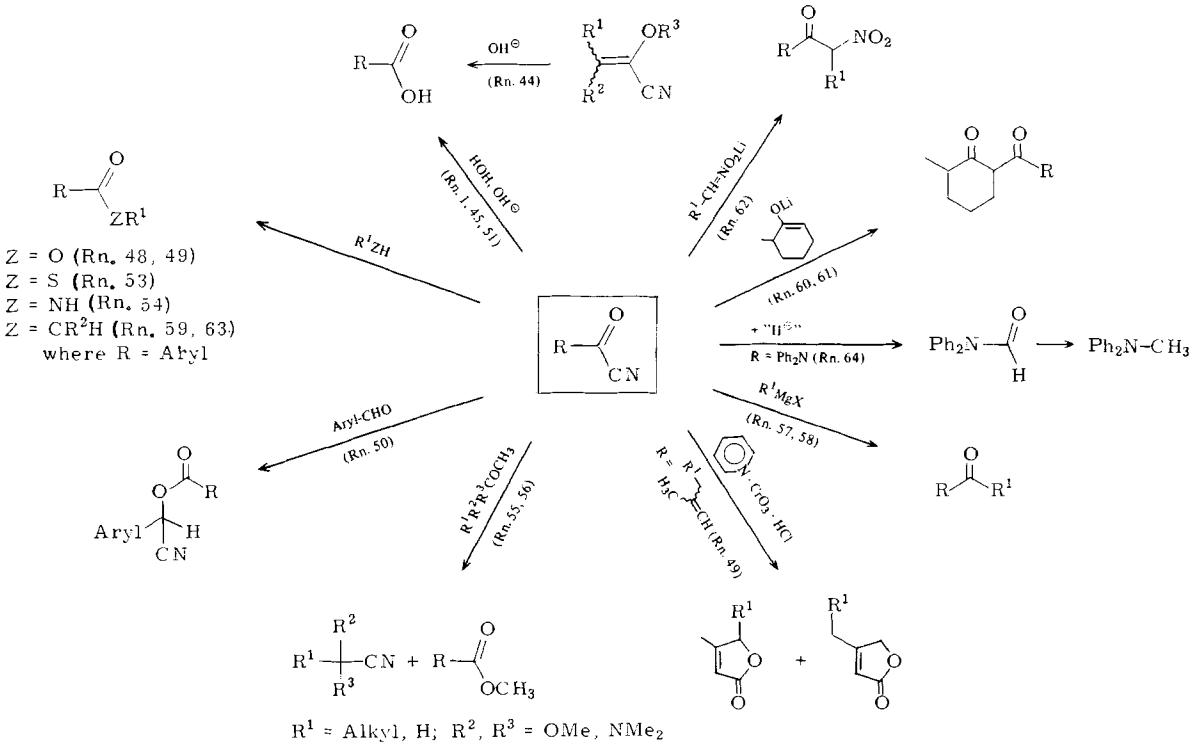
Acyl cyanides appear as intermediates in a synthetic sequence in which ketones are converted into homologous α-ketocarboxylic acids **103** or, with loss of the cyano-group, into carboxylic acids **104.** The intermediates **101** and **102**[61] are isolable (Rn. 44).



101 **102** **103** **104** (55-70%)

4.4. Reaction of the CO-Group with Separation of Cyanide Ions

As already shown, in reaction 21, acyl cyanides act in this important cleavage reaction as mild acylating agents



Z = O (Rn. 48, 49)
Z = S (Rn. 53)
Z = NH (Rn. 54)
Z = CR^2H (Rn. 59, 63)
where R = Aryl

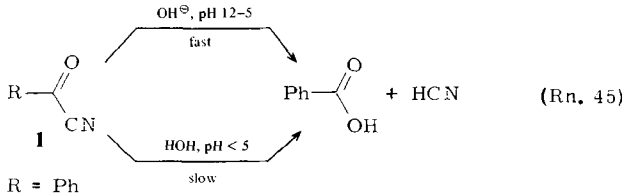
R^1 = Alkyl, H; R^2, R^3 = OMe, NMe_2

Scheme 4.

for hetero- and C-nucleophiles (see Scheme 4). Compared with acid chlorides their advantage rests on the low acidity of the hydrocyanic acid formed. Therefore, no auxiliary base is needed, even with amines as nucleophiles. Similarly favorable properties are shown only by the *N*-acylimidazoles[62].

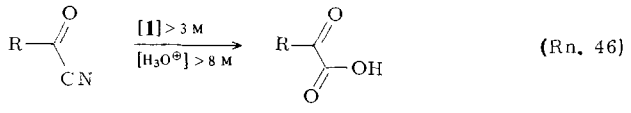
4.4.1. Reactions with HOH, ROH, RNH_2, and RSH

The reaction of benzoyl cyanide (**1**, R = Ph) with *water*, resulting in the displacement of the cyano-group, shows a pronounced pH-dependence. In the region of pH 12–5 a fast bimolecular reaction with hydroxyl ions takes place. At lower pH values water attacks appreciably slower, whereby this cleavage is subject to a general base catalysis, so that acids inhibit the cleavage of acyl cyanide (Rn. 45: important observation for the work-up of reaction mixtures, *e.g.* according to reaction 38, and also for the electrophilic substition of aromatics by acyl cyanides as in Rn. 25 and 65!)



(Rn. 45)

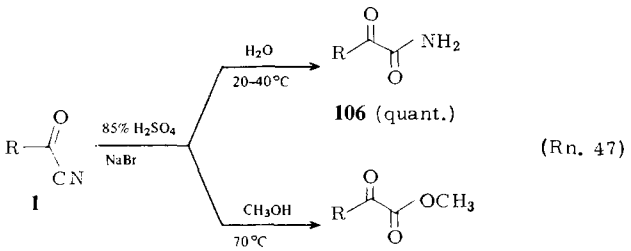
1 R = Ph



(Rn. 46)

1 R = CH_3, C_2H_5 **105**

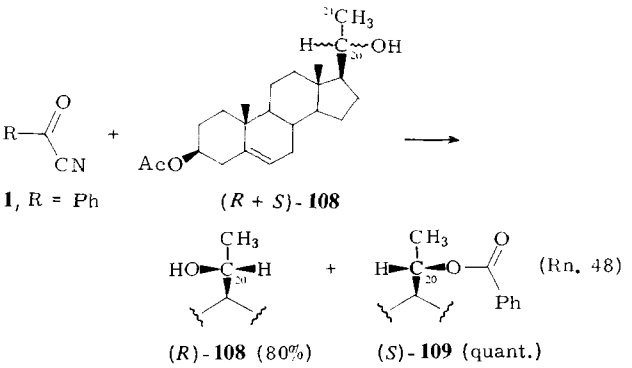
With aliphatic acyl cyanides the hydrolytic fission slows down with increasing concentration of strong acid (up to *ca.* 8 M). Only then does acid-catalysis start, which, however, now leads to the α-oxoacid **105** as in reaction 46, if at the same time the concentraion of **1** is >3 M[63]. Saponification of the nitrile group is strongly catalyzed by bromide ions. Thus, the addition of sodium bromide to benzoyl cyanide in 85% sulfuric acid causes a strongly exothermic reaction. After addition of water, benzoyl formamide **106** can be quantitatively isolated, while with methanol 85% methyl benzoylformate **107** is formed[64].



(Rn. 47)

1 R = Ph **106** (quant.) **107** (85%)

The well known fission of **1** by *alcohols* has proved to be a highly selective reaction for derivatizing hydroxysteroids in presence of benzoyl cyanide (**1**, R = Ph). By this procedure, epimers are separable because of their different rates of benzoylation. As demonstrated by reaction 48, this separation is even successful if the hydroxyl group is not bound to the rigid steroid framework, as in the case of the



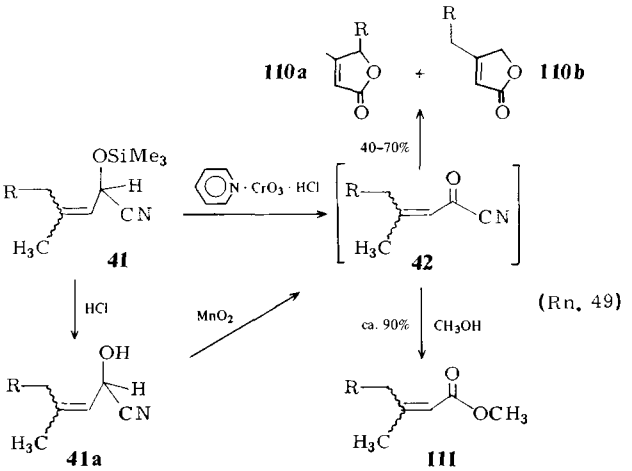
1, R = Ph (*R* + *S*)-**108**

(Rn. 48)

(*R*)-**108** (80%) (*S*)-**109** (quant.)

mixture of (20*R*)- and (20*S*)-3β-acetoxy-20-hydroxy-5-pregnene (*R*+*S*)-**108**, from which only the *S*-form is benzoylated to (*S*)-**109**. The reactivity of **1**, R = Ph, towards hydroxy-steroids follows the sequence: 21 > 17β > 3β > 6α,3α ≫ 20α > 20β ≫ 7β ≫ 7α > 6β > 2β > 22α[65a].

The smooth formation of esters from acyl cyanides is particularly advantageous for the conversion of sensitive, unsaturated aldehydes into carboxylic acid methyl esters **111**. The appropriate cyanohydrins **41a** or their trimethyl silylethers **41** (+ $H^{\oplus}$) are dehydrated with active manganese dioxide in methanol (yields ≈90%[36a]). On the other hand, the importance of the oxidation of the allyl ethers **41** with pyridinium chlorochromate in absence of alcohol lies in the unusual oxidative intramolecular acylation to butenolides (*e.g.* **110a** and **110b**)[36b].

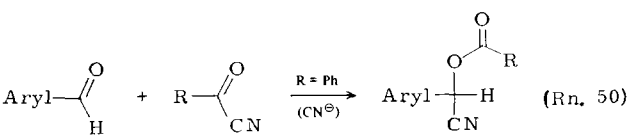


(Rn. 49)

41 **42** **41a** **111**

In the addition the already mentioned 'dimerization' of the acyl cyanides (Rn. 2), as well as the formation of enol esters (Rn. 3) rest upon the acylation potential of the acyl cyanides (cf. Section 5.1, Rn. 66). This is true also for the so-called cyanoacylations of aldehydes, whereby the cyano-group is finally incorporated into **112** as is shown in Rn. 50[1].

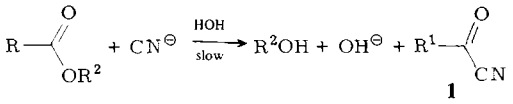
The reduction of **1** with BH_4 leads to the same type of product **112**, but with R = Ar. Here too intermediate cyanohydrin anion becomes acylated.

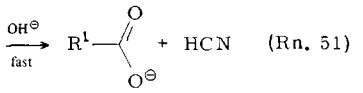


(Rn. 50)

1 **112**

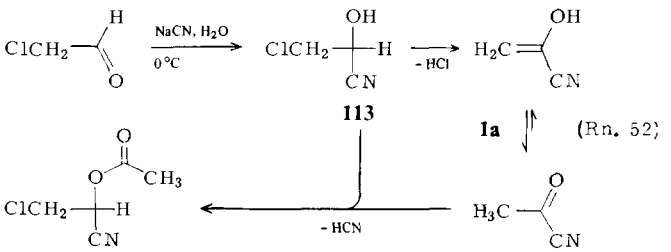
The cyanide-catalyzed ester hydrolysis examined in buffer solutions also proceeds *via* an acyl cyanide intermediate **1** which is quickly hydrolyzed[66b] (Rn. 51).





(Rn. 51)

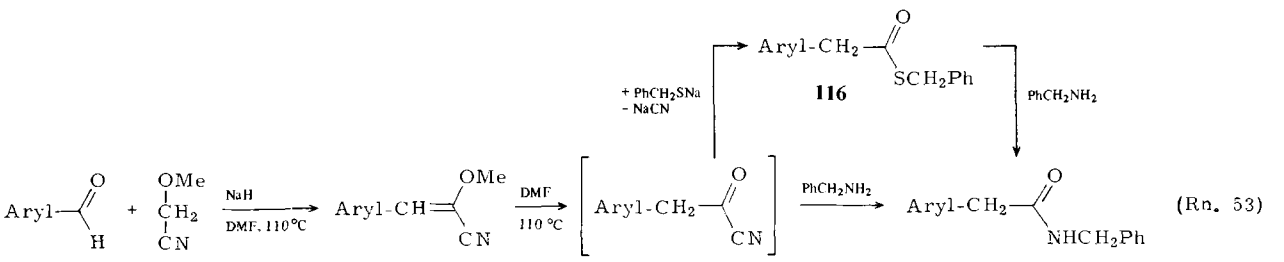
The hydrolysis of ethyl thiolacetate is also catalyzed by HCN[66b]. In the cyanide catalysis of the enzymatic acylation by means of acetyl coenzyme-A, acetyl cyanide was already assumed to be the effective intermediate[68]. Its powerful acylation potential is demonstrated by the reaction of chloroacetaldehyde with sodium cyanide in water. Here, formation of the intermediary cyanohydrin **113**, followed by HCl elimination (see Rn. 20) affords first **1a** ($R=CH_3$), which then acylates excess of **113**, so that finally 90% **114** can be isolated[69].



(Rn. 52)

114 (90%)

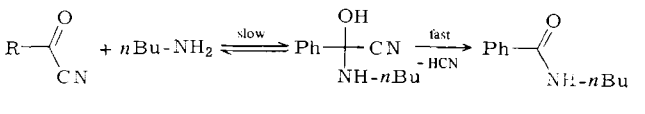
An intermediate acyl cyanide is also liberated from the enol ether **115**, with benzyl thioalcoholate. Since benzylamine is present at the same time it reacts either directly and/or *via* the thiolester **116** to form the end product, the amide **117**[70] (DMF = dimethylformamide).



(Rn. 53)

115 (81%) **117** (95%)

Amines such as *n*-butylamine cleave **1** ($R=Ph$) in ether according to a complex kinetic law. The main part of the reaction may proceed *via* the intermediate **118**[66c].

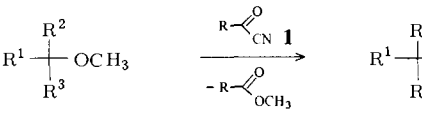


(Rn. 54)

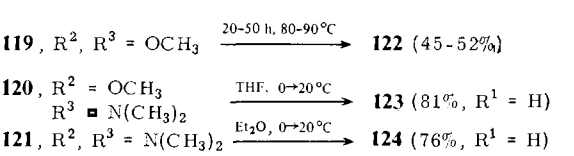
1, R = Ph **118**

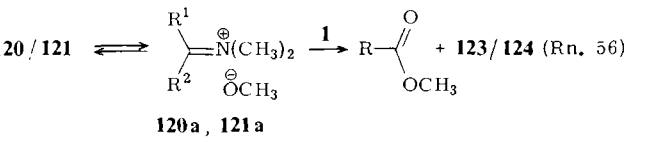
Since acyl cyanides are now readily accessible, their proposed use as mild acylating agents in peptide synthesis[67] should gain in importance.

The cleavage reactions of the acyl cyanides so far discussed utilize, almost without exception, the acylation products formed. Reaction 55 shows examples in which orthoesters **119**[71], amidoacetals **120**[72], and aminal esters **121**[72] exchange a methoxy-group for cyanide; the products **122—124** are also to be regarded as derivatives of acyl cyanides. In this way **1** acts as a convenient substitute for the otherwise necessary anhydrous hydrocyanic acid. The strongly exothermic reaction with **120** and **121** may proceed better *via* the equilibrated ion pair **120a** and **121a** according to reaction 56 than *via* intermediate *N*-acylation[72].



(Rn. 55)



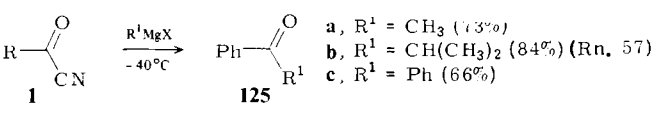


(Rn. 56)

120a, **121a**

4.4.2. Reactions with Organometallics, CH-Acidic Compounds, and Hydride Reagents

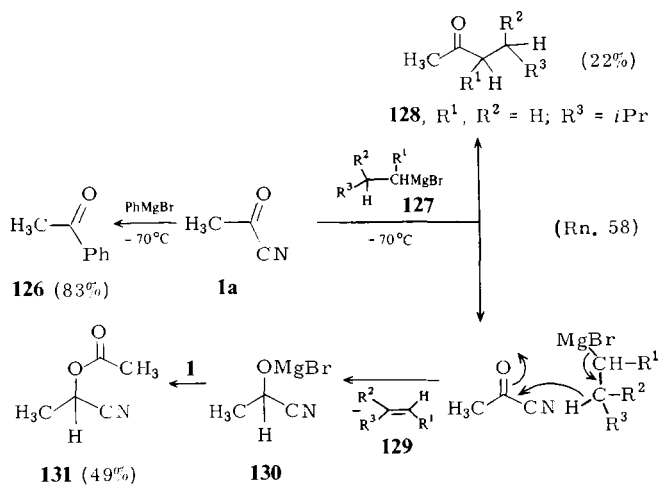
The well known reaction of benzoyl cyanide with phenyl magnesium bromide to give triphenyl acetonitrile or triphenylcarbinol[1] can generally be interrupted at low temperatures if carried out in a 1:1 stoichiometry with formation of the ketones **125**[73]. In the case of **125a** the substituents of the reactants can even be exchanged and thereby acetyl cyanide (**1**, ($R=CH_3$)) transformed into acetophenone **126**. Grignard compounds that are easily

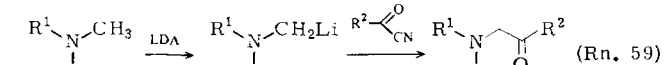


(Rn. 57)

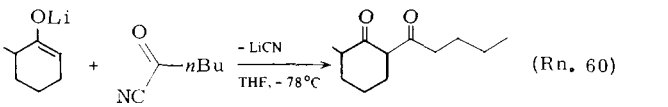
R = Ph

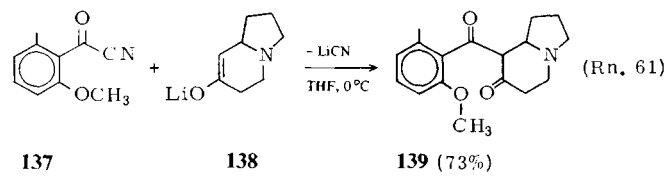
dehydrogenated[74] (*e.g.* **127**) yield with **1** (R = CH_3), α-acetoxypropionitrile **131** together with small amounts of ketone **128**. Obviously cyanohydrin salt **130** formed in addition to the olefin **129** is extremely rapidly acylated by the still available **1** to yield **131**[73]. The acylation of the lithium compounds **133** prepared from the nitrosamines **132** can be better stopped at the ketonic stage **134** by means of acyl cyanides, than by using acid chlorides or esters[75] (LDA = Lithium diisopropylamide).





The high reactivity of acyl cyanides at −78 °C also permits the clean *C*-acylation of kinetically generated enolates without causing *O*- or di-acylation, as the example **135** → **136** demonstrates[76].

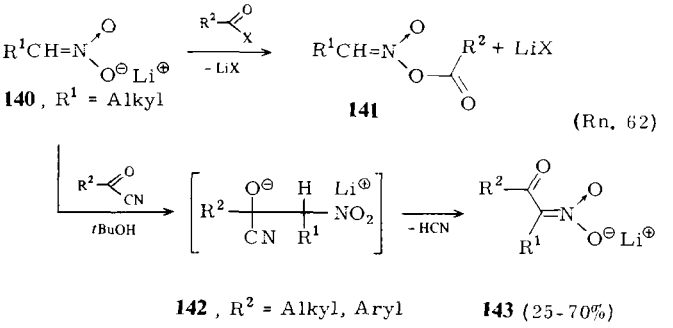




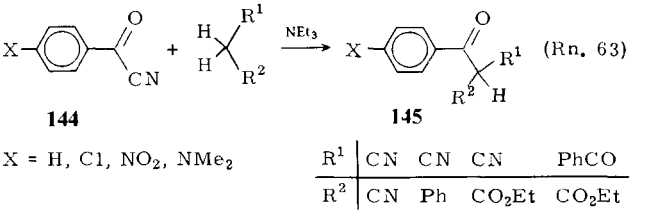
Even the aminoenolate **138**, which does not react in the desired way with other acylating agents, reacts smoothly with acyl cyanide **137** to give **139**[76].

Acyl cyanides prove also to be *C*-acylating agents for lithium salts of nitrocompounds **140**, while various other acylating agents produce only nitronic esters **141**.

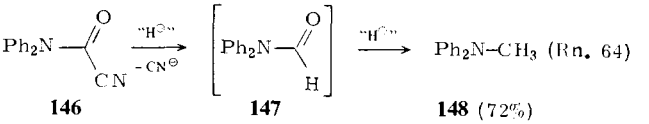
One would expect that the addition of acyl cyanide to the nitronic group is kinetically controlled, but that the adduct is in equilibrium with the reactants. These react finally *via* **142** with loss of HCN to give **143**. Such a reaction path rationalizes the fact that only primary nitroalkanes can be *C*-acylated[77] (Rn. 63). In contrast to benzoyl



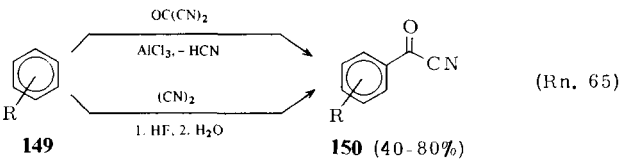
chloride, aromatic acyl cyanides **144** smoothly convert relatively acidic methylene compounds by *C*-acylation into the ketones **145**[78] (Rn. 63).



Acyl cyanides are reduced[1] by lithium aluminum hydride at both functional groups with preservation of their carbon skeleton. The carbamoyl cyanide **146**, however, suffers reductive cleavage to give **148**, presumably *via* the step **147**[79]—with formal acylation of the hydride ion (cf. the formation of **112** by BH_4^-[65b]).



As a special case the acylation of arenes **149** with carbonyl cyanide or dicyanogen under Friedel-Crafts conditions should be mentioned. In this case the reaction stops at the stage of the aromatic acyl cyanides **150** (cf., however, Section 4.2.1 Rn. 25!) which are thus also accessible by another pathway.

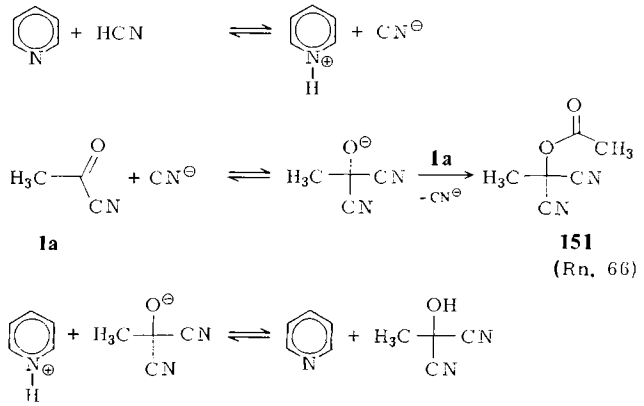


5. Dimeric Acyl Cyanides

5.1. Formation of Dimeric Acyl Cyanides

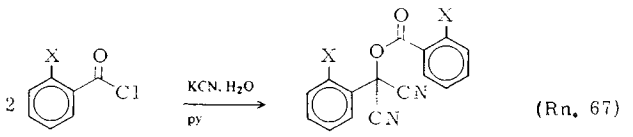
As mentioned in Section 2 acyl cyanides "dimerize" extremely easily[1]. A kinetic study of the particularly sensi-

tive acetyl cyanide **1a** in presence of HCN/pyridine has led to the following picture for the formation of **151**[81].



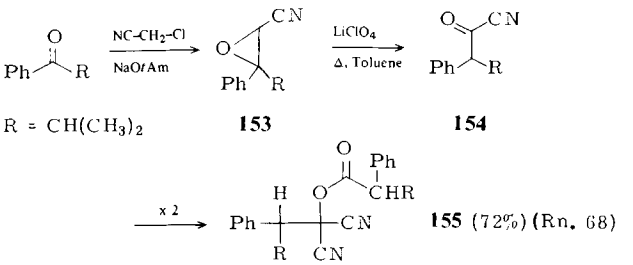
1a **151** (Rn. 66)

As a result of the strong cyanide ion catalysis, it is obvious that "dimers" from aromatic acyl chlorides and potassium cyanide do not only occur under phase-transfer catalysis (cf. Rn. 4g), but can also be isolated in presence of water/pyridine as the sole products **152**[82].



X = Cl, Br, OMe, NO_2 **152** (20–50%) (Rn. 67)

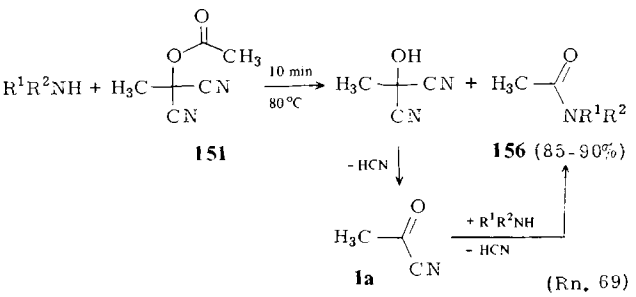
Evidently the hydrocyanic acid produced in a side reaction during the isomerization of **153** is sufficient to convert the acyl cyanide **154** largely into the dimer **155**[61] (cf. also Rn. 44).



R = $CH(CH_3)_2$ **153** **154** **155** (72%) (Rn. 68)

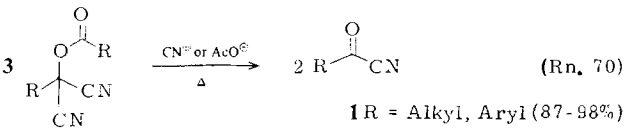
5.2. Reactions of Dimeric Acyl Cyanides

As has been known for a considerable time both acyl moieties of the "dimer" can be utilized[1] in the hydrolysis with dilute acids or bases as well as in the reaction with ammonia or phenylhydrazine. For instance, the reaction sequence 68 followed by hydrolysis is, therefore, suitable for transforming ketones into homologous carboxylic acids. While no ester interchange is observed with alcohols, aliphatic (not aromatic) amines react specifically to yield the amides **156**[83].



151 **156** (85–90%) **1a** (Rn. 69)

As was found recently, the dimeric acyl cyanides **3**, upon heating, can be smoothly converted by base into monomers[84] by reversing their formation as in reaction 66. Thus **3** is likely to gain in importance as a stable form for storing sensitive acyl cyanides.



1 R = Alkyl, Aryl (87–98%)

6. Summary and Prospects

The present review demonstrates that the reaction potential of acyl cyanides has been considerably extended during the past 25 years. This, however, can only now be fully utilized, as even sensitive (aliphatic) acyl cyanides have become easily accessible under very mild conditions (Scheme in Section 3). Acyl cyanides can be recommended as (selective) O-, S- and N-acylating agents under almost neutral conditions, as they require no auxiliary bases. Ambidentate enolate ions are obviously *C*-acylated in a largely specific way (Scheme 4 in Section 4.4).

All reactions with preservation of the C-framework lead at the same time to a C_1-extension of the respective carboxylic acids. In this manner nucleophiles can be made to attack one of the two functional groups, so that in the reaction with the CO-function substituted nitriles are produced (Scheme 2 in Section 4.2), while attack on the CN-group furnishes α-oxocarboxylic acid derivatives (Scheme 3 in Section 4.3). The directed, stepwise ring-closure with bifunctional nucleophiles transforms acyl cyanides into 5- and 6-membered heterocycles (Schemes 2 and 3).

The synthetic potential of the cyanotrimethysilane adducts as in reactions 8—11 has so far not been exploited, nor has that of the acyl cyanide enolic derivatives according to reactions 28—34 which are at present being studied in our laboratory.

The results of the Würzburg group presented in this review originate from the extensive and critical investigations of U. Hertenstein, H. Reichelt and R. Schaller[11]*. For the generous sponsorship of these studies we thank the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and BASF, Ludwigshafen/Rhein (Germany).*

Optimal Parameters in High Speed Liquid Chromatography (HPLC)

By István Halász* and Gerhard Görlitz

Dedicated to Professor Géza Schay on the occasion of his 81st birthday

After a decade, the first storm of development in high performance liquid chromatography seems to be abating. Providing the stationary phase and eluent are optimized, most routine analytical and semi-preparative separation problems require columns having between 1000 and 10000 theoretical plates. Commercial apparatus and columns completely satisfy these requirements. For many separation problems the efficiency of the columns on offer is greater than required. Since optimal (not maximal) separation is required with shorter analysis times, the column inlet pressure is increased in order to increase the eluent velocity, while at the same time reducing the column efficiency. The same result can be obtained by using shorter columns and lower pressures. Since inlet pressures of more than 100 bar are seldom required in routine analysis, the term "*high pressure* liquid chromatography" is a misnomer.—It is probable that difficult separation problems, where several 100000 theoretical plates are required, will be studied in the next phase of development. It can be shown using nomograms that such problems can be solved within acceptable time limits using inlet pressures of less than 500 bar. Further possible directions of development are indicated.

1. Introduction—The State of the Art

The theoretical and experimental foundations of high speed liquid chromatography (high performance liquid chromatography HPLC) were laid down in late 1960's[1-18]. The pioneers of this renaissance of classical column chromatography were almost all originally gas chromatographers and sought to apply to liquid chromatography (LC) the experience they had gained in gas chromatography (GC). The aim was to increase the efficiency, sensitivity and speed of analysis by a factor of about 100. Since the theory of band-broadening in chromatography does not depend upon whether the eluent is a gas or a liquid, the main difference between GC and LC was seen in the diffusion coefficients and viscosities. The solubility of the sample was another difficulty in LC. The eluent in GC is almost inert and there is practically no interaction between eluent and stationary phase. Eluent and samples in LC must—because of the solubility problem—be similar to each other, so that the heats of adsorption of the eluent and of the sample are of the same order of magnitude. The problems of instrumentation in LC were also overestimated at first. The breakthrough for the routine use of HPLC took place at the 5th International Symposium, Las Vegas, 1969[19]. The first commercial instruments were exhibited there, and significant advances in practical applications were described. The development thereafter was explosive. It became more and more obvious that the additional parameter, the eluent, represented not only a limitation, but also a new degree of freedom. The separation conditions, *i.e.* the relative retentions, for a single stationary phase (column) can be accordingly varied within wide limits. Relatively reproducible methods have been developed for the production of chemically modified phases and especially for reversed phases. The "balanced density"[20-22] and viscosity[23] methods have proved suitable for packing columns. Particles of sieve fractions 5μ—10μ have been shown to be optimal and are to be recommended in practice. The introduction of easily manipulated sample ports of variable volume was an important instrumental development, while the introduction of stepping-motor driven piston pumps which could deliver liquids at 0.1 to 10 mL/min at pressures of up to 400 bar made it possible to produce programmes for gradient elution accurately and reproducibly by mixing the eluent components on the high-pressure side. In the last few years noteworthy innovations in apparatus design have not occurred. Detectors which operate on novel principles would be desirable. All the detectors used until now in routine LC are concentration- and not mass/velocity-sensitive[24]. The constancy of the eluent rate of flow thus determines the accuracy and reproducibility of quantitative analysis.

Modern commercial instruments almost invariably utilize piston pumps driven by stepping or rotating disc motors so that the liquid flow rate is reproducible within ±0.5% to ±1.5%. Delivery is almost pulse-free and the pumps are easily controlled. The constancy of the flow-rate at low delivery rates, however, is significantly worse than the values quoted, which can cause difficulties when gradient elution is practised. Pulse-free elution delivery increases the working life of the column, on the one hand, and the sensitivity of the detector on the other, especially when a refractive index detector is used. Piston pumps suffer from the disadvantage that non-polar solvents, such as heptane, do not wet the pistons and that maintenance is not entirely free from difficulties. Membrane pumps are significantly more reliable and require less maintenance than piston pumps. The flow, however, is constant to only

$\pm 1.5\%$ to $\pm 5\%$: pulsating delivery is also a disadvantage and it is necessary to smooth this out using a damper, whose dead-volume makes gradient elution difficult. These economically priced pumps are hardly suitable for gradient elution, because they are not driven by stepping motors, and are hence difficult to control. The optimal pump for modern HPLC has yet to be developed.

The introduction of the flame ionization detector (FID) enormously increased the effectivity and applicability of GC. This detector is sensitive to mass velocity and its noise level is extraordinarily low (about 10^{-12} A or 10^{-10} g carbon/s). Its response factor for hydrocarbons is roughly independent of chemical constitution and structure. A detection principle of similar quality has not yet been discovered for HPLC.

Differential refractometers or spectrometers (IR, UV, fluorescence) are the predominantly used detectors in modern HPLC. All are sensitive to concentration and their response factors are very dependant upon the substance. Apart from a few exceptions the noise level of such detectors lies in the range 10^{-6}—10^{-7} g/g eluent. The concentration of sample in the eluent, however, is seldom greater than 100 ppm at peak maximum.

The absolute and relative retentions of samples are a function of the column temperature. Experience has shown that around room temperature it is sufficient to hold the column temperature constant to within $\pm 1\,^{\circ}C$. This may not be sufficient for samples having excessively long retention times (large heats of sorption). Chromatographic columns are packed with heat insulating materials, and hence the conduction of heat radially is very limited. It is not sufficient, therefore, simply to "thermostat" columns externally, but is also necessary to pre-thermostat the eluent. Experience has shown that about 30 cm of coiled steel capillary tubing (internal diameter 0.25 mm, external diameter 1.6 mm) is sufficient to achieve the necessary constancy. The band-broadening caused by such a capillary is usually negligible in analytical work with columns >15 cm long and >4 mm internal diameter with particle sizes >5 μm. The heat exchanger can, in such cases, be placed between the sample port and the separating column. If optimal separation is of importance then the heat exchanger should be placed before the sample port. In this case, however, the whole path of the eluent (including the sample port) up to the column must be thermostatted.

2. The Separating Column

In the age of the microprocessor it is particularly necessary to emphasize the triviality that components of a mixture which are not separated in the column cannot thereafter be electronically "resolved". The separating column remains the principal item of the chromatographic apparatus. The chromatographic separation depends upon the varying migration velocities of the various components of the sample mixture through the sample column. These differences in migration velocity, *i.e.* in the relative retentions (α) result from the different distribution coefficients of the various components of the sample, between the eluent and the stationary phase. With the exception of exclusion chromatography, these distribution coefficients are thermodynamic quantities that depend upon the nature of the sample, of the stationary and of the mobile phase, as well as upon the temperature. Pressure is also a significant parameter in chromatography under supercritical conditions. The cardinal problem in chromatography is the selection of a suitable separation system. Here, the experience of the chemist is decisive.

Elution chromatography, strictly speaking, is not a separation process in the usual thermodynamic sense[25]. The components of a mixture are certainly separated from each other, but they are at the same time diluted by the eluent. This dilution effect (increase in entropy) is described in the kinetic theory of chromatography in terms of the relative band-broadening h, or the number of theoretical plates n[*].

To a good approximation, the separation (R) of two neighboring peaks[26] is:

$$R = \frac{\alpha - 1}{4\alpha} \cdot \frac{k'_2}{1 + k'_2} \cdot \sqrt{n_2} \qquad (1)$$

Since for two closely neighboring peaks α is approximately 1, and since R is proportional to $(\alpha - 1)$ on the one hand, and only to $\sqrt{n}$ on the other, α must first be optimized. In what follows it will be assumed that the relative retentions, α, have already been optimized. This is usually achieved in HPLC by adjusting the composition of the eluent. Experience has shown that five (or less) different stationary phases are sufficient for solving many of the separation problems.

Because of the favorable relative retentions it is usual to work routinely with columns that are at most 30 cm long. Difficult separation problems—*e.g.* in fields such as biology, biochemistry, pharmaceuticals, and petrochemistry—where plate numbers of more than 50000 are required and where capillary GC is not applicable, have hardly been tackled until now. Hereby, either the α values are small or the number of components to be separated, and hence the peak capacity required, is large. For this reason the evaluation of the optimal kinetic parameters will be discussed in this article. It will be assumed that the h-values are independent of the length of the column.

2.1. Column Packing

Without going into the details of this problem it need only be mentioned that sufficiently narrow sieve fractions for the production of columns are commercially available having stationary phase average particle sizes of between 5 and 30 μm. Such solid particles have a large surface area and are almost colloidal in size: packing methods described in the literature are thus empirical and not always properly reproducible. It is for this reason that the efficien-

[*] The commonly used symbols are tabulated in the list on p. 57. The most important parameters for HPLC (*e.g.* viscosity and diffusion coefficients) are still tabulated in CGS units. Consequently these units are overwhelmingly used in practice and in the literature.

cies of commercial columns vary so greatly. The efficiencies of such columns are often quoted in terms of plates per metre, which can be misleading. For example, when 25 cm columns are coupled together into longer columns, it often transpires that the plate number does not increase proportionally.

A simple quantitative method for the evaluation of packed columns will be described in this article.

2.2. Asymmetry Factor

The theory of chromatography assumes that eluted peaks possess a Gaussian distribution. Such peaks have, unfortunately, not yet been observed experimentally. The plate number is often calculated from the "mother"[23] peak, neglecting its leading and tailing edges. When a separation as far as the base line ($R = 1.5$) is required, which is a necessary condition for quantitative analysis, such methods are invalid. Asymmetrical peaks can be caused by strong interactions between the sample and the stationary phase and/or by instrumental or packing defects. If the asymmetry is attributable to the latter causes then the asymmetry factor (As)[23] decreases with increasing retention time. In this article asymmetry factors of between $As = 0.9$ and 1.2 will be assumed for capacity factors k' of between 1 and 2. This condition is fulfilled by good commercial columns.

2.3. The Particle Size of the Packing Material

The average particle size of a sieve fraction suitable for HPLC is a function of: 1. The method of measurement (optical, sedimentation, conductivity, Coulter counter, *etc*), and 2. The form in which it is reported (*i.e.* as number or as weight average). These methods require complicated equipment and a great deal of time, and can only measure the size of particles outside the column. They are unable to furnish information about the well-known problem of agglomeration during the packing of the column, which can lead to appreciable reduction in column efficiency.

We prefer to define the average particle size (δ) in the packed column using a chromatographic method[27]:

$$\delta = \sqrt{10^3 K_r} \equiv \sqrt{\frac{10^3 F \eta L}{r^2 \pi \Delta P}} \qquad (2)$$

For irregular particles the empirical factor of 1000 makes the value of δ agree well with the optically measured number-average particle size[27]. In our experience, a factor of 700 (instead of 1000) would be required in eq. (2) if the particles were spherical. We prefer, however, irrespective of the particle geometry, to define the particle size in terms of eq. (2) since δ is then defined in terms of the "price" (pressure drop) that has to be paid for a particular particle size. Values of δ approximately 15–20% larger are then computed for spherical particles than for irregular ones. Experience has shown that, independent of particle shape, the agreement between δ-values and the average particle diameters, d_p, quoted by manufacturers of commercial columns is acceptable[28].

The quality of a column is often described in terms of the dimensionless reduced plate height, h/δ. According to the definition of δ in eq. (2), smaller (better) reduced plate heights should be obtained using spherical particles. Surprisingly, however, experience has shown that the reduced plate heights obtained using spherical and irregular particles are not different[28,29].

The question of the advantages and disadvantages of spherical or irregular particles is often and exhaustively discussed. Some workers maintain that the quality and reproducibility of columns packed with spherical particles should be better. Others, hold the contrasting viewpoint that spherical particles are more easily displaced during packing. Possibly these effects depend more upon the dispersion of the sieve fraction than upon the geometry of the particles. At the present time, fractions are commercially available for HPLC that ought to be completely satisfactory. This applies not only to the dispersion of the sieve fraction but also to the reproducibility of the specific surface area and to the pore size distribution. Returning to the discussion concerning the geometry of the particles, only one thing seems certain: spherical particles are significantly more expensive.

The reproducible production of columns packed with particles larger than 4 μm (mostly smaller than 15 μm) has been mastered. This applies to columns packed with silica and alumina, as well as to those packed with chemically bonded phases. When operating short columns ($L = 10$ cm) with 5 μm particles the band-broadening resulting outside the column is, in many commercial instruments, comparable with that occuring within the column. Such columns are popular because of the high rates of analysis that can be obtained using them. As a result, the reduced plate heights obtained with these columns (5 μm) are significantly worse (larger) than columns packed with 10 μm particles. In other words, 5 μm ($L = 10$ cm) columns produce, under these conditions, fewer theoretical plates than 10 μm ($L = 20$ cm) columns. The pressure drop and rate of analysis are, however, larger for the former columns.

Columns packed with 3 μm particles were described five years ago[30] and are now commercially available. However, not only the analysis rate, but also the instrumental difficulties, the pressure drop, and the reduced plate height are large for such columns.

2.4. Simple Separation Problems

It will be assumed in what follows that the particle sizes, as is usual today, lie between 5 μm and 10 μm and that the HPLC separation is performed isocratically. About 10000 plates can be produced by a normal 30 cm column at the minimum in its h, u curve (*i.e.* at u_{min}). It can be calculated using eq. (1) that in the $k' = 1$ region, substances with relative retentions greater than 1.14 can be separated to the base line. In fact the α values are significantly larger than 1.14 for most routine separations in simple systems and, hence, the separations achieved are better than base line separations ($R > 1.5$). If a shorter column whose separating ability was sufficient for quantitative analysis ($R = 1.5$) were used then, if the other parameters were kept constant,

the analysis time would decrease and the detection sensitivity increase.

Instrumentally, it is easier to decrease the analysis time by increasing the linear velocity of the eluent, whereby the h-value increases. Then, not only the rate of separation but also the pressure drop increases, while the detection sensitivity decreases. The routine application of this method of decreasing the analysis time is certainly a significant reason for the frequent use of expensive high pressure pumps. Pumps which deliver 400 bar or more are unnecessary for most routine applications.

Experience shows that most everyday problems in HPLC can be solved using two lengths of column (*e.g.* 10 and 30 cm). The shorter column should, however, have a larger internal diameter (*e.g.* 6 mm) than the longer (*e.g.* 4 mm) in order to be able to neglect band-broadening outside the column.

Longer column working life and less wear and tear on the apparatus are further significant advantages of working with short columns and small pressure drops.

The quantitative computation of the optimal parameters for such short columns ($L \leq 30$ cm, $\delta \geq 5$ μm) is unnecessary since, as described above, commercial pumps have a sufficient pressure reserve.

2.5. Difficult Separation Problems

When the relative retentions of the substances to be separated are about 1.06 then approximately 50000 plates are required when $k' = 1$. Such plate numbers can be achieved either using longer columns or much smaller particles for the stationary phase. This also applies to the separation of multiple component mixtures that require a large peak capacity[31]. Finding the optimal conditions for the operation of such columns is an urgent task.

Whereas pressure drop and analysis times (or speed of analysis) were of subordinate importance with short columns, they become parameters of extraordinary importance for complicated separations. For such problems pressure drops are in the kilobar range and analysis times are measured in hours. Both are *reciprocal* functions of the linear velocity u of the eluent. How is the optimal velocity u established? The problems involved can be underlined by reference to gas chromatography and by comparing GC with HPLC.

2.6. Speed of Analysis and Pressure Drop in GC and in LC

Independent of the phase of the eluent, the speed of analysis in chromatography is characterized[32] by the number of theoretical plates generated per unit time ($n/t \sim u/h$). The necessary pressure drop, on the other hand, is proportional to the product $h \cdot u$, when a constant separating ability (number of plates) is required. It is meaningful, therefore, to plot the analysis time as a function of the pressure drop ($\sim h \cdot u$). Such a plot for peaks of similar capacity factors in typical GC and typical HPLC columns are illustrated in Figure 1. In order to allow direct comparison, both sets of axes are normalized with respect to the minimum in the h,u curve. It can be seen that for GC the speed of analysis reaches an upper limit at relatively low pressure drops. Speeds of analysis, which are barely affected by further increases in pressure drop, are achieved at relatively low pressures ($\sim h \cdot u$). It can, therefore, be taken as a rule of thumb that the optimal linear velocity u_{opt} is:

$$u_{opt} \simeq 2u_{min} \tag{3}$$

It can be seen, among others, from Figure 1 that the LC curve has not reached a limiting value even at 20 times u_{min}. For this reason there is no optimal velocity in the range of practical HPLC ($\Delta P < 600$ bar). With increasing pressure the speed of analysis is greatly increased.

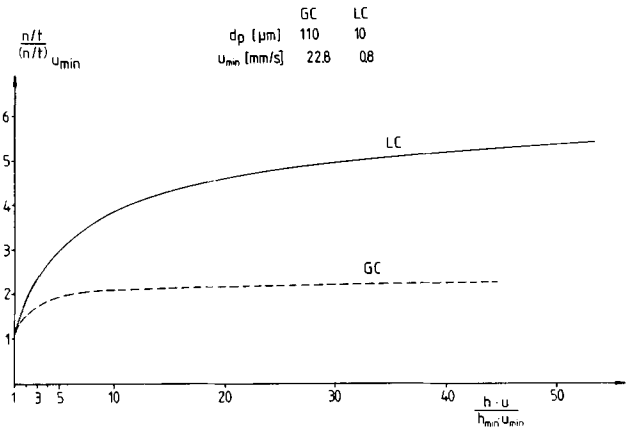

Fig. 1. Normalized velocity of analysis as a function of expense of analysis ($\sim \Delta P$). Normalization: N/t and $h \cdot u$ are normalized with respect to the values at the minimum of the h,u-curve. Column data for GC [33]: Conventionally packed column, $L = 200$ cm, internal diameter = 4 mm, 5% squalane on Chromosorb W, sieve fraction = 100–120 μm, carrier gas = N_2, 75 °C, sample = *n*-hexane; $k' = 1.51$, $h = 1.26 \times 10^{-2} + 8.3 \times 10^{-2}/u + 1.6 \times 10^{-2} u$ [h in cm and u in cm/s]. Column data for LC: $L = 10$ cm, internal diameter = 4.6 mm, Lichrosorb SI 100 (Merck), $\delta = 10$ μm, *n*-heptane, 25 °C, sample chrysene, $k' = 1.5$, $h = 23 + 4/u + 6.3u$ [h in μm, u in mm/s].

Whereas in GC it is usual to work with sieve fractions of 100 to 200 μm, experience has shown that in HPLC it is better to increase the speed of analysis by using much smaller particle sizes, than by increasing the speed of flow with longer columns.

Several investigations concern themselves with evaluating the optimal experimental conditions for LC[34-40]. The techniques suggested are mathematically complicated and not easy for experimentalists to manipulate.

A simple method which allows the graphical determination of optimal parameters had been developed and reported in 1977[41]. Its further development is reported here.

2.7. A Semiempirical Description of the Plate Height in HPLC as a Function of the Particle Size and the Eluent Velocity

The relative band-broadening h is a complicated function of many parameters. The most important, which will be discussed here, are: the velocity of the mobile phase (u), the particle size of the stationary phase (δ), the diffusion coefficient of the sample in the eluent (D_m), and the capac-

ity factor of the sample (k'). The last two parameters are themselves dependent upon the temperature. If the relative molecular weights of the samples lie between 75 and 300 (which is typical in separations of organic substances) then, to a first approximation, standard values of D_m can be adopted for particular values of the viscosity of the eluent (*e.g.* for $\eta = 0.4$ cP, $D_m = 3 \times 10^{-5}$ cm^2/s). For this reason we have taken the viscosity as a parameter, instead of the sample's diffusion coefficient whose exact value is usually unknown.

The h-value usually increases with increasing k'. For the sake of simplicity a value of $k' = 2$, which lies in the middle of the practical range, is assumed.

Using these boundary conditions, the value of h in HPLC can be described using the following semiempirical function of u and δ[42]:

$$h = a\delta + \frac{b}{u} + c\delta^2 u \tag{4}$$

where the constants a, b, and c depend upon the quality of the packing and the viscosity of the eluent η (*i.e.* upon D_m). As packing methods are improved, the values of the empirical constants in eq. (4) will decrease. It appears that the values of these parameters are independent of whether silica gel, aluminum oxide, or chemically bonded reversed phases are used as packing materials.

Two standard systems which correspond to columns packed by state of the art methods are mathematically described in what follows. For eluents of low viscosity, such as *n*-heptane, dichloromethane, acetonitrile, methanol *etc.* (η between 0.4 and 0.6 cP), the following equation applies:

$$h = 1.5\delta + \frac{6}{u} + \frac{\delta^2}{16}u \qquad \text{"formula I"} \tag{5}$$

where the usual HPLC units of measurement are used, *i.e.* h and δ are expressed in μm and u in mm/s. The constants 1.5, 6 and 1/16 of course have the corresponding dimensions.

For a more viscous eluent, such as a mixture of water and acetonitrile, or water and methanol (η between 0.7 and 1.5 cP), the following equation applies:

$$h = 2\delta + \frac{3}{u} + \frac{\delta^2}{8}u \qquad \text{"formula II"} \tag{6}$$

Equations (5) and (6) correspond to the experimental results if

1) the particle size δ of the stationary phase lies between 3 and 30 μm;
2) the linear velocity of the mobile phase is less than $20u_{min}$;
3) the relative molecular weight of the sample is less than 300 and its capacity factor k' is approximately 2.

Both these formulae are approximations. They are, however, easy to manipulate and require only easily measured quantities. They can be used, for example, to judge the quality of columns that have been packed with different materials. Use of eq. (2) to determine the particle size in eqs. (5) and (6) enables one to be independent of manufacturers' data. It should be mentioned that calculated and measured values will only agree if extra-column band-broadening is negligible.

3. HPLC Optimization

The most important parameters in the optimization of an HPLC analysis are: α, D_m, k', η, L, n, t_0, ΔP, and δ; other parameters (*e.g.* u, R, h, n/t_0 *etc.*) can be derived from them. Optimal relative retentions α are assumed. The diffusion coefficient D_m, the viscosity of the eluent η, and the capacity factor k' are given standard values in eqs. (5) and (6). The remaining five parameters are not independent of each other. The column length L can be eliminated, between eq. (2) and:

$$u = \frac{L}{t_0} = \frac{F}{r^2 \pi \varepsilon_T} \tag{7}$$

where ε_T is the total porosity, it follows that

$$L = \delta \sqrt{\frac{t_0 \Delta P}{10^3 \eta \varepsilon_T}} \tag{8}$$

so that eq. (4) with $h = L/n$ can be rearranged using the remaining four parameters to give:

$$n = \left[a \sqrt{\frac{10^3 \eta \varepsilon_T}{t_0 \Delta P}} + \frac{10^3 b \eta \varepsilon_T}{\delta^2 \Delta P} + \frac{c\delta^2}{t_0} \right]^{-1} \tag{9}$$

Figures 2 and 3 show the plate number as a function of particle size for various values of t_0 and ΔP using formula I [eq. (5)] and formula II [eq. (6)]. This is of significance because, as already discussed, analysis time and pressure drop are limiting parameters in difficult separations.

In Figure 2, where a "low viscosity" eluent ($\eta = 0.44$ cP), a porosity which is typical for silica gel ($\varepsilon_T = 0.82$), and the validity of formula I [eq. (5)] are assumed, the breakthrough time remains constant, 5 min, in all three cases.

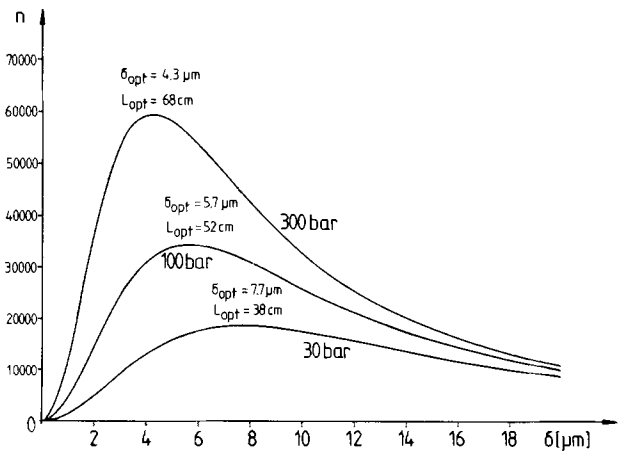

Fig. 2. Number of plates as a function of the particle size for "low viscosity" eluents at $t_0 = 300$ s and constant ΔP.
$h = 1.5\delta + 6/u + \delta^2 u/16$, $\eta = 0.44$ cP, $\varepsilon_T = 0.82$.

Figure 3 is valid for a "high viscosity" eluent ($\eta = 1.2$ cP), and for a porosity ($\varepsilon_T = 0.70$) which is typical for a chemically modified phase. Formula II [eq. (6)] was used and a pressure drop of $\Delta P = 100$ bar assumed in all cases. All the curves in both figures pass through a maximum, *i.e.* under these conditions the maximum number of plates can only be achieved with a particular particle size. The column length which corresponds to the optimum can be calculated from eq. (8).

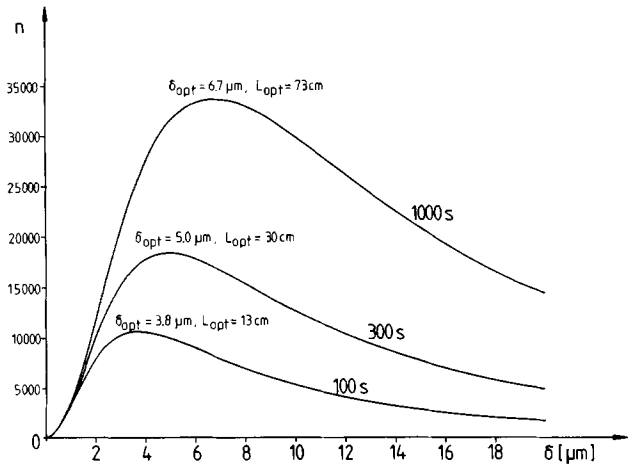

Fig. 3. Number of plates as a function of the particle size for "high viscosity" eluents when $\Delta P = 100$ bar and t_0 is constant.
$h = 2\delta + 3/u + \delta^2 u/8$, $\eta = 1.2$ cP, $\varepsilon_t = 0.70$.

As can be seen from Figure 3 it is possible to generate *ca.* 35000 plates within 1000s for t_0, with a pressure drop of only 100 bar, using a system which is typical for reversed phases. The optimal particle size is about 7 µm and the column is 73 cm long. Separating ability, which is the factor of interest to the chromatographer, only increases as the square root of the number of plates [eq. (1)] and for this reason a loss in n of 10—20% is acceptable in practice. If such a reduction is accepted then δ can be varied over the range 4—10 µm. When δ is changed, the corresponding column length must also be, according to eq. (8). As is evident from this example (cf. Section 2.7), this form of optimization requires only a rough gradation of particle size and column length. For the user this means that he can work optimally under many different sets of conditions by choosing from a very few types of column.

In the appendix it is shown that the maximum in the n,δ-curve (ΔP and t_0 constant) can also be derived mathematically. All parameters which apply to the maximum will be designated with the subscript "opt". The equations for calculating δ_{opt}, L_{opt}, and n_{opt} can be found in the appendix [eqs. (A6) to (A8)]. If L_{opt} in eq. (7) is divided by t_0, and t_0 and ΔP are eliminated using the equation for δ_{opt} (A6), a value is obtained for the linear velocity which corresponds to the maximum of the n,δ-curve.

$$u_{opt} = \frac{1}{\delta}\sqrt{\frac{b}{c}} \qquad (10)$$

This velocity is identical to the minimum in the h,u-curve calculated from eq. (4). The velocity $u_{opt} = u_{min}$ can be calculated for "low viscosity" eluents using formula I:

$$\delta u_{min} \approx 10\ [\mu m\ mm/s] \qquad (11)$$

and for "high viscosity" eluents using formula II:

$$\delta u_{min} \approx 5\ [\mu m\ mm/s] \qquad (12)$$

From our arguments we can establish:

1) For a given pressure and analysis time, maximal efficiency can only be achieved when L and δ are chosen such that one is working at $u_{min} = u_{opt}$.

2) The maximal number of plates n_{opt} is proportional to the square root of the pressure and the analysis time.

3) The optimal particle size decreases with increasing pressure [$\delta \sim (\Delta P)^{-0.25}$], and increases with increasing analysis time [$\delta \sim t_0^{+0.25}$].

Working at u_{min} has the additional advantages:

a) The relative band-broadening h hardly varies as k' changes. In contrast, at eluent velocities significantly greater than u_{min} (*e.g.* $u > 5u_{min}$) the h value increases rapidly with increasing k'.

b) Since the relative band-broadening is minimal at u_{min}, it follows that peak height is maximal. This is of particular importance for trace analysis.

c) The working life of the column is extended because of the lower pressures required.

d) At fixed particle size the speed of analysis increases with increasing linear velocity of the eluent (cf. Fig. 1). When L and δ can be freely chosen, the maximum speed of analysis can, quite unexpectedly, be achieved at $u_{min} = u_{opt}$. This would seem, at first sight, to require an unacceptably large stock of different columns. That in practice just a few columns are sufficient will be shown using a nomogram (see Section 4).

Optimal Speed of Analysis

The speed of analysis decreases with increasing retention. The inert sample n/t_0 is always referred to here. Furthermore, ΔP and n are taken as required boundary conditions. If eq. (9) is solved for t_0 [eqs. (A10)—(A13)], then n/t_0 can be calculated as a function of δ [eq. (A15)]. Examples of such curves are shown in Figures 4 and 5.

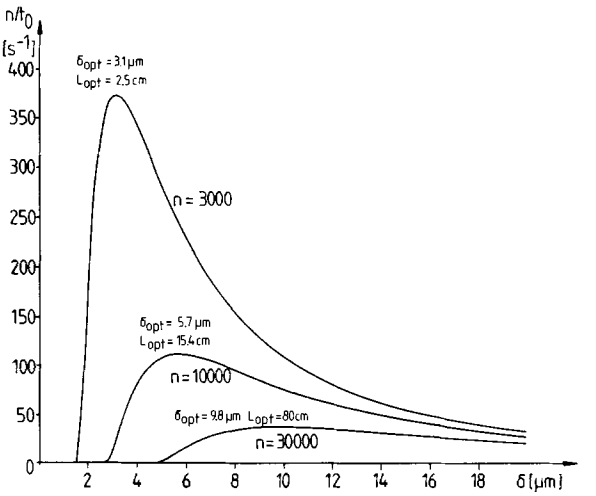

Fig. 4. Speed of analysis as a function of particle size for "low viscosity" eluents at $\Delta P = 30$ bar.
$h = 1.5\delta + 6/u + \delta^2 u/16$, $\eta = 0.44$ cP, $\varepsilon_t = 0.82$.

Once again it is evident that optimal working conditions—*i.e.* here the maximal speed of analysis—can only be achieved using a particular particle size and column length, which are determined by the chosen plate number and pressure drop.

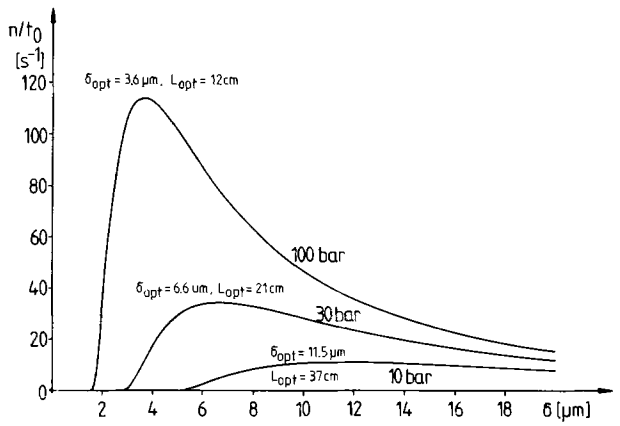

Fig. 5. Speed of analysis as a function of particle size for "high viscosity" eluents at $n = 10000$.
$h = 2\delta + 3/u + \delta^2 u/8$, $\eta = 1.2$ cP, $\varepsilon_t = 0.70$.

It can be seen from Figures 4 and 5 that for a given ΔP there is a minimum particle size below which it is impossible to obtain the required plate number, no matter what the speed of analysis. The sharp increase in n/t_0 at small values of δ can be explained as follows. On the one hand, according to eq. (11) u_{min} increases as δ decreases and, on the other, it follows from eq. (4) that:

$$h_{min} = \delta(a + 1.22) \approx \delta(a + 1) \qquad (13)$$

h_{min} is thus a linear function of δ. At the same time, the permeability K decreases as the square of δ. Taken together these phenomena have the effect that for a given ΔP there is a particular number of theoretical plates which it is no longer possible to generate below a certain minimum particle size.

It can be seen from Figure 5 that the number of theoretical plates required for routine analysis can be generated speedily and at a relatively low pressure drop. Take, for example, a C_{18} reversed phase and an H_2O/CH_3OH mixture with a high viscosity of 1.2 cP, if 10000 theoretical plates are required: for $\Delta P = 30$ bar the inert peak is eluted after 5 min. The column is, in this case, *ca.* 21 cm long and packed with 6.6 µm particles. It can also be seen that such an optimal separation can be approached using particles varying in size from 5—10 µm. The column length must then be increased with increasing δ. This example also illustrates the fact that the delivery pressure demanded of the pump is often far too high. Working at high pressures increases the cost of the apparatus, while the working-life of the column is decreased.

Eq. (A15), which describes the $n/t_0,\delta$-curve, is difficult to handle explicitly. It is possible, however, to show numerically that, for given values of n and ΔP, the maximum of n/t_0 is produced at u_{min}. When the shape of the $n/t,h\cdot u(\sim\Delta P)$ curves (Fig. 1) are considered, in view of the steep increase in h_{min} and u_{min} this result seems very improbable. This apparent contradiction can be resolved using a simple model.

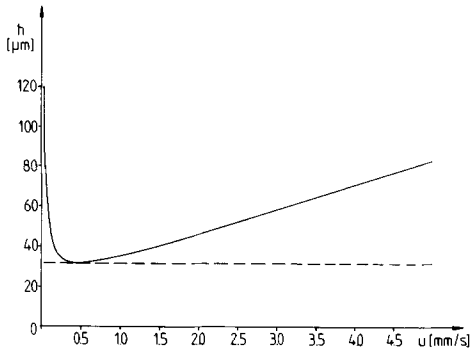

Fig. 6. h,u-Curves for a real and for a hypothetical (broken line) HPLC column.
Real Column: $\delta = 10$ µm, $\eta = 1.2$ cP. The solid curve was calculated using formula II [eq. (6)].

Consider a hypothetical HPLC column where the value of h is independent of the velocity and is always equal to h_{min} as described in eq. (13), and shown by the broken line in Figure 6. The relationship between the speed of analysis and the particle size can be deduced as follows:

1) Since the number of plates n remains constant and $h = h_{min}$ is proportional to δ [eq. (13)], the column length must also remain proportional to $\delta (L \sim \delta)$.

2) If ΔP is constant then u is proportional to δ^2 and inversely proportional to $L (u \sim \delta^2/L)$. Because $L \sim \delta$ it follows that $u \sim \delta$.

3) The breakthrough time of the inert peak ($t_0 = L/u$) is thus independent of the particle size.

Since n was taken as a constant, the speed of analysis n/t_0 must also be independent of δ and remain constant.

Thus the speed of analysis in this hypothetical column is independent of particle size of the stationary phase and linear velocity of the mobile phase (n and ΔP are constant).

The value of h in a real column is, except at u_{min}, always larger than h_{min}. Since $n/t_0 \sim u/h$, larger values of h imply lower speeds of analysis.

If the plate number and pressure drop in the column are taken as boundary conditions then the maximum speed of analysis will be achieved at u_{min}. Column length and particle size must, of course, be open to choice.

4. Graphical Determination of the Optimal Parameters

The equations for δ_{opt}, L_{opt}, and n_{opt} [eqs. (A6)—(A8)] can be transformed so that n_{opt} appears as a function of δ_{opt} and another parameter (either ΔP_{opt}, or L_{opt} or $t_{0,opt}$). These relationships [eqs. (A16)—(A18)], can be used to construct nomograms having the axes δ, n, ΔP, t_0, and L. Other parameters which can be deduced from these values are u_{opt}, h_{min}, and n/t_0. These are simply a function of δ and can accordingly be represented along an axis parallel to the δ axis and are added below the nomogram. It must be taken that 1) the particle size is that defined in eq. (2), 2)

the h,u-curve follows eq. (4) and can be explicitly described using either eq. (5) or eq. (6), 3) standard values are assumed for the viscosity of the eluent η and for the total porosity ε_T.

Good packing technique is assumed in eqs. (5) and (6): a good reproducible packing technique is available for columns having internal diameters of *ca.* 2 to 8 mm, lengths of 10 to 50 cm, and particle sizes ranging from 3 to 30 μm. Such columns should, furthermore, be capable of being coupled in series without loss in h-values.

The nomogram for "low viscosity" eluents is reproduced in Figure 7 and that for "high viscosity" eluents in Figure 8. These nomograms cover a wide range, *e.g.* particle sizes up to 100 μm and plate numbers up to 10^6. The portions of these diagrams which apply and are of interest in present day HPLC are reproduced in Figures 9 and 10. The values of the parameters held constant in construction of each nomogram are included in the figures.

Two of the five parameters (coordinate axes) may be chosen arbitrarily. An optimal combination of those remaining can then be read off the nomogram.

The silica gel/dichloromethane system—with a separating capacity of 100000 plates—is required for the relative retentions involved in a particular separation problem.

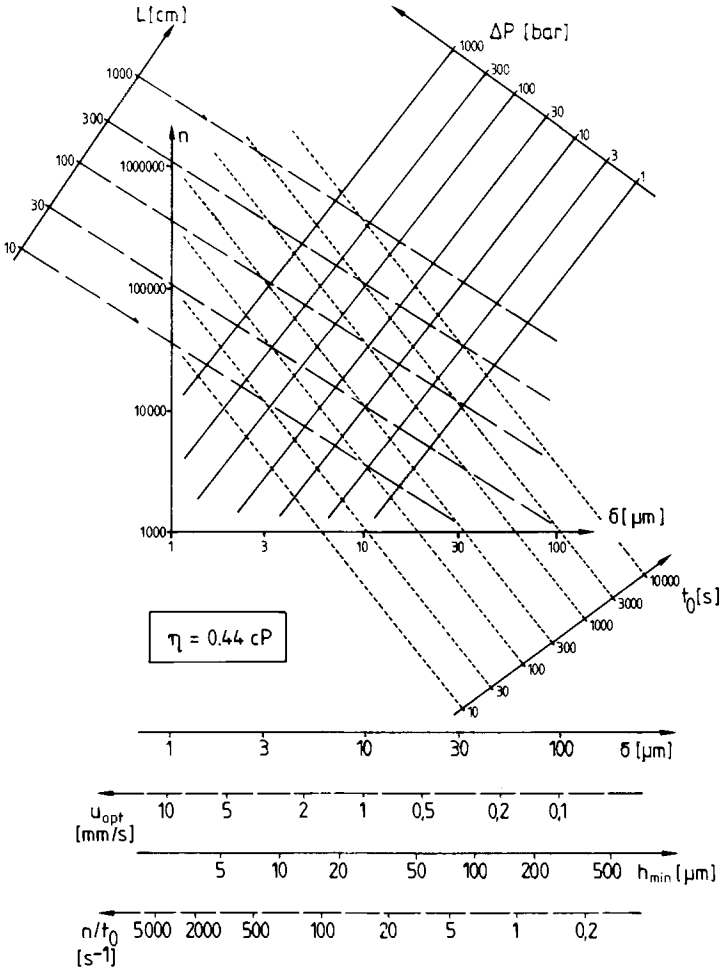

Fig. 7. Nomogram: Optimal parameters for "low viscosity" eluents, *e.g.* for the system silica gel/dichloromethane.
$h = 1.5\delta + 6/u + \delta^2 u/16$ [eq. (5)], $\eta = 0.44$ cP, $D_m \approx 3 \times 10^{-5}$ cm²/s, $\varepsilon_t = 0.82$.

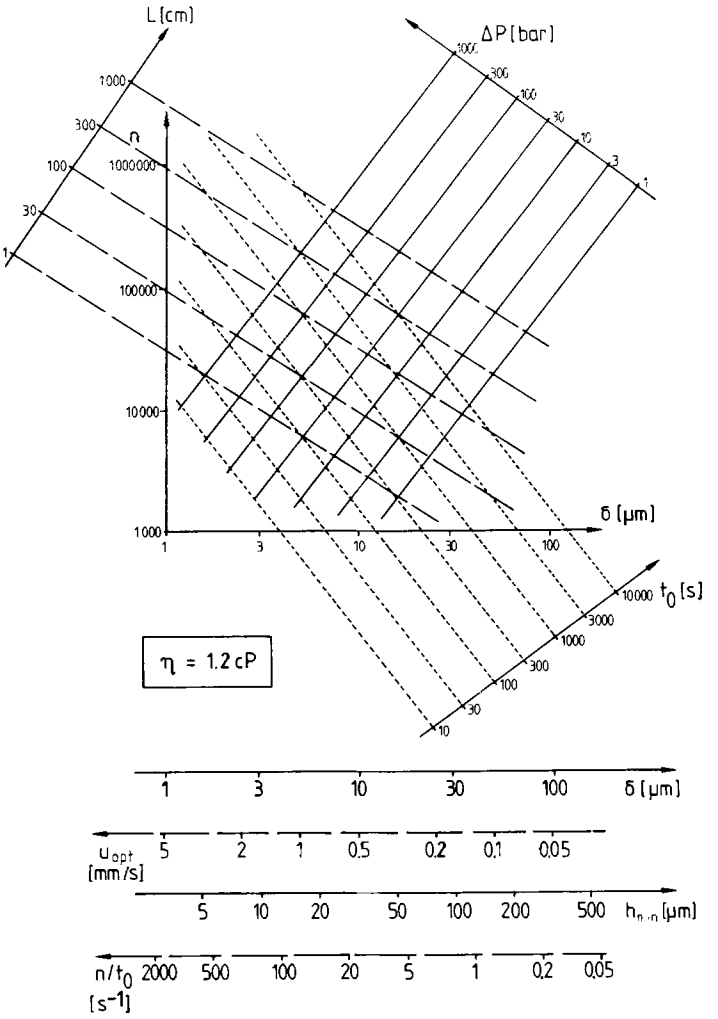

Fig. 8. Nomogram: Optimal parameters for "high viscosity" eluents, *e.g.* for the C_{18}-reversed phase/methanol-water system.
$h = 2\delta + 3/u + \delta^2 u/8$ [eq. (6)], $\eta = 1.2$ cP, $D_m \approx 1.5 \times 10^{-5}$ cm/s, $\varepsilon_t = 0.70$.

This is accomplished, in the first instance, by using a 50 cm long column (or two 25 cm columns in series). From the nomogram in Figure 7 it can be seen that a packing of *ca.* 2 μm (1.84 μm) particles and a pressure drop of almost 3000 bar (2850 bar) are required. The values in brackets were calculated using the relevant equations [(A 17) and (A 16)]. Such conditions are not realizable with present day techniques, nor are they to be recommended in principle[42]. The otherwise excellent values for $t_0 \approx 1.5$ min [93.8 s from eq. (18)] and hence $n/t_0 = 1070$/s are thus of theoretical interest only.

Since the plate value required in the above separation problem is $n = 100000$, it is necessary to insert the maximum available pressure as the second selected parameter. A maximum pressure of 300 bar can be reached, without problems, using modern commercial instruments. When $n = 10^5$ and $\Delta P = 300$ bar, the following values can be read off the nomogram: $\delta \approx 5.7$ μm, $L \approx 150$ cm, $t_0 \approx 900$/s, and $n/t_0 = 110$/s. These parameters seem acceptable. Whether the detection limits for the separated peaks are adequate remains a matter which can be most rapidly checked by experiment. As t_0 and k' increase, the peak height and the sensitivity of the analysis decrease. It can follow from this

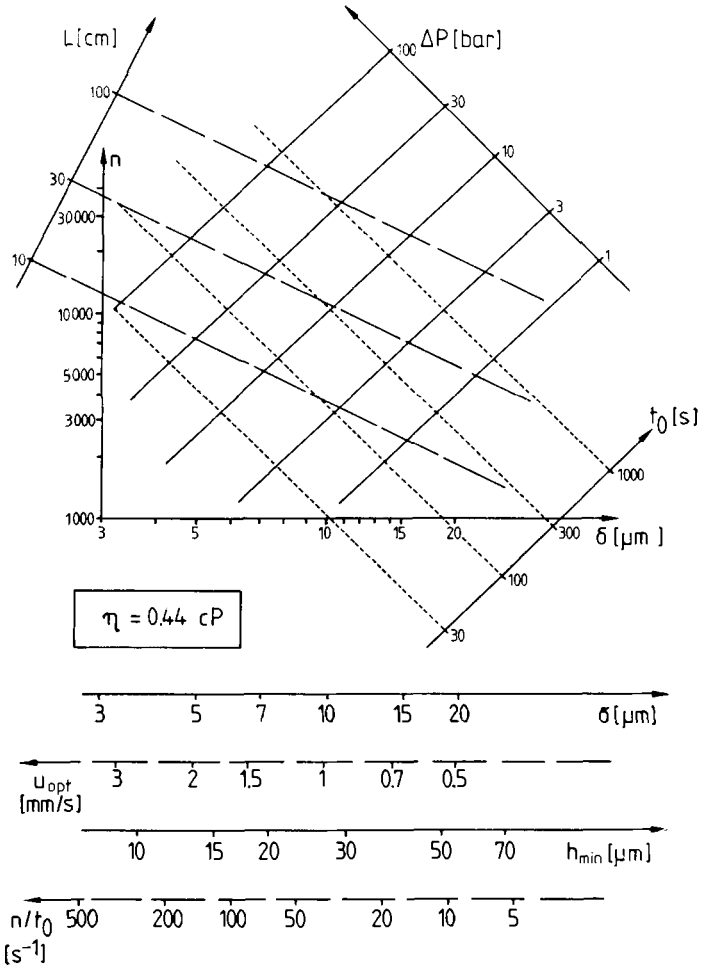

Fig. 9. Detail from nomogram in Fig. 7 ("low viscosity" eluent).

that a smaller value of t_0 together with n = constant must be taken as the selected parameter to be inserted into the nomogram.

The big advantage of the graphical representation is that it can be quickly ascertained whether a problem is soluble with present day techniques, what are the critical parameters, and what compromises must be made.

Several everyday analysis problems will now be discussed in terms of Figure 10. Here, a chemically modified phase, such as a C_{18} reversed phase, will be taken as the stationary phase, and a relatively viscous eluent ($\eta = 1.2$ cP), *e.g.* H_2O/CH_3OH. It can be shown once again that, in general, significantly lower pressures are necessary than are normally presumed and used.

With a required plate number of 10000 and a column length of 15 cm as the chosen parameters it can be read off the nomogram in Figure 10 that $\delta \approx 5$ μm and $\Delta P \approx 60$ bar are required. For an analysis time $n/t_0 = 70$ s an inert peak requires 2.5 min to breakthrough.

If the separation problem is simpler, so that $n = 5000$ is sufficient, then taking $\delta = 10$ μm, the following values can be read off from Figure 10: the column length remains almost constant ($L \approx 16$ cm), the analysis-time is approximately doubled ($t_0 \approx 5.5$ min and $n/t_0 \approx 15$/sec), while the pressure drop sinks to 7 bar.

These problems show that our nomograms (Figs. 7–10) provide a rough guide for the determination of optimal parameters. Two column lengths of 10 and 25 cm and two sieve fractions of $\delta = 5$ and 10 μm, respectively, suffice for the majority of problems. It is necessary to be able to connect the columns in series without raising the h-value.

If our suggestions are followed then perhaps twice as many columns should be stocked as has been usual up to now. This small increase in expenditure, however, produces the advantages of optimization. When working with the optimal parameters, pressures of more than 150 bar are seldom required. Cheaper, simpler and more reliable instruments can, therefore, be used for routine analysis. This applies not only to the pumps but also, to the same extent, to the injection ports *etc.* Although the manufacturers of chromatographic apparatus are perfectly willing and able to offer such components, there seems to be no demand for them at the moment.

Can it be a question of prestige? This must be considered since it is known that the working life of columns and, therewith, the reproducibility of analysis is significantly increased by careful use.

In order to avoid misunderstanding it should be mentioned that the large instruments, indispensable for the development of new methods, research, and the solution of complex problems, are not to be included in this stricture. When such problems are to be solved then the limits can be estimated quickly from the nomograms in Figures 7 and 8.

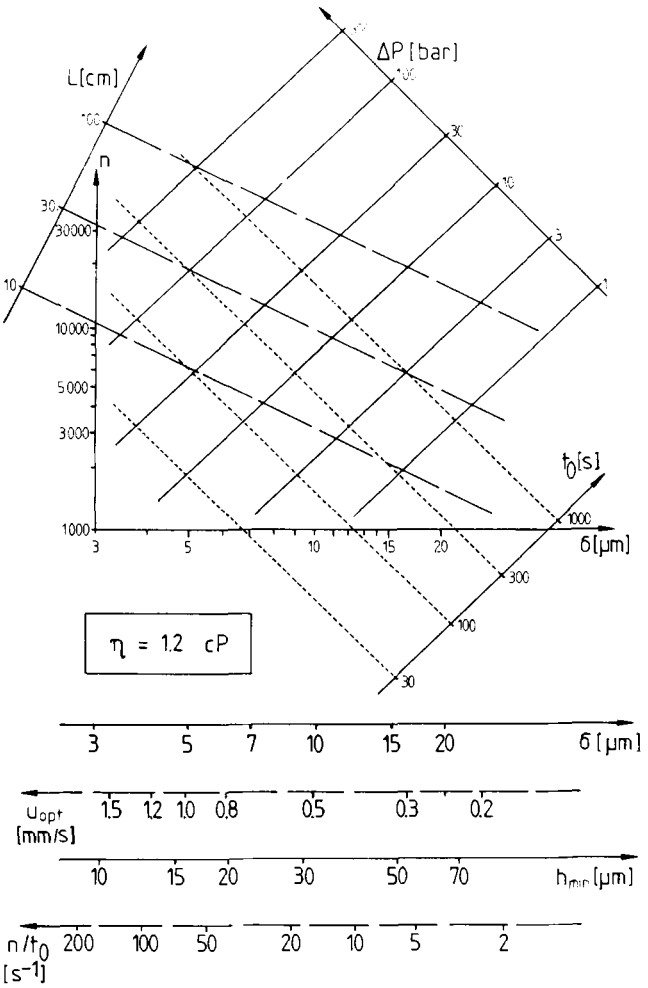

Fig. 10. Detail from nomogram in Fig. 8 ("high viscosity" eluent).

The necessary condition for the construction of the nomogram was isocratic elution (constant temperature, constant pressure and eluent composition). It should be mentioned that some of the problems which are at present solved using gradient elution can also be tackled isocratically. When computing the analysis time for a gradient elution the time required for column-regeneration should not be omitted.

5. Conclusions and Outlook

A short review of present day techniques with respect to instrumental difficulties in high speed liquid chromatography was followed by a comparison of the establishment of optimal separation conditions in gas and in liquid chromatography. Here it was shown that the optimal linear velocity is obtained at the minimum in the h,u-curve and that this occurs when a maximal plate count with limited ΔP and t_0 is aimed at, as well as when the maximal speed of analysis for a particular plate number and a limited pressure is the aim. Other advantages of working at u_{min} were discussed. We have developed nomograms which relate the parameters: plate number (n), particle size (δ), pressure drop in the column (ΔP), breakthrough time of the inert peak (t_0), and column length (L). Two of these parameters can be arbitrarily chosen and an optimal combination of the remainder read off. Since the values of u_{opt}, h_{min}, and n/t_0 are determined by the value of δ, these values can be determined using subsidiary axes below the nomogram. The viscosity of the eluent (diffusion coefficient of the sample) has a significant effect on the optimal parameters; in contrast, the particular kind of stationary phase has a much smaller effect. Nomograms were constructed for two typical systems and their possible uses were illustrated by using examples of simple and complicated separation problems. It turns out that significantly lower pressures can be used to solve routine problems than is often accepted. In conclusion we would like to survey some interesting possible directions of development.

When optimal conditions ($u = u_{min}$) are employed, the speed of analysis (*i.e.* the number of plates generated per unit time) increases approximately quadratically with decreasing particle size. Currently, columns packed with 10 μm or 5 μm particles are generally used. Recently, however, columns packed with 3 μm particles have become available. Here, the increase in speed of analysis must be paid for with the solution of new problems which arise. As the particle size is decreased the colloidal region is approached. The probability of coagulation will, consequently, be greater, the packing of the columns more difficult, their reproducibility less and their working-life shorter. With decreasing particle size, column length is decreased when constant plate numbers are required. If the column diameter remains unchanged then the peak volumes will be smaller and the cell volume of the detector must be decreased (to about 1 μL). The construction of such cells without decreasing sensitivity presents difficulties. It is worth mentioning that with 5 μm particles (column $L = 10$ cm internal diameter = 4 mm) most commercial instruments can only realize a fraction of the possible efficiency because of extra-column band-broadening.

Packing 1 mm internal diameter columns is difficult, but not impossible. The instrumental problems mentioned previously (sample application, cell volume) also occur here. Use of such columns can only be recommended when the amount of sample available is extraordinarily small or the optimal eluent very expensive.

Packed capillary columns show advantages for gas chromatography in that, compared to "classically" packed columns of the same particle size, they have a similar efficiency with a *ca.* 10 times greater specific permeability. Since significantly higher sheer forces are found in liquid chromatography, the reproducible production of such columns is more difficult and their working-life shorter. In our experience, the increased permeability, if it occurs at all, is significantly less than that found in gas chromatography. The low peak volumes produced here also occasion the previously mentioned instrumental problems.

It can be deduced theoretically (and demonstrated experimentally) that open tubular columns—also known as capillary columns—are only competitive with conventionally packed columns when their internal diameter is about 10 μm. In the literature the band-broadening of the inert peak is chiefly discussed. It is well known, however, that, on the one hand, because of sheer forces an even coating of stationary phase is extraordinarily difficult to achieve and, on the other, that the band-broadening of a retarded substance compared to that of an inert peak increases more rapidly than is the case with packed columns. Because of the very small sample volumes, cell volumes in the nanolitre range are required, and reliable pumps with low delivery rates are necessary. Capillary columns have advantages when the amount of sample is limited and the eluent is expensive. The technical difficulties, however, make it unlikely that this type of column could be made available in the near future for routine work.

Conventional columns up to 50 cm long can be packed satisfactorily using present techniques. When higher plate numbers ($n > 100000$) are required for difficult separations, then the minima of the h,u-curves are displaced to lower velocities and the ascending branch of the curve becomes steeper. Since these minima decrease with decreasing capacity factor, the speed of analysis also decreases rapidly. In such cases the analysis time soon becomes intolerably long. If columns coupled together in series to give an effective length of several meters are used, a new packing technology must be developed.

The separation of crude oil fractions, natural product extracts *etc.* is often difficult, because the polarity range of the individual components is large. Such complicated mixtures can be pre-separated by use of the extrographic method of separation (for extrography see [46]) (Samples of from about 30—250 g can be pre-separated within about 3 h). The fractions thus obtained can then be further separated by retentive- or by exclusion-chromatography.

If only a fraction of the components in the mixture is required then the technique column switching can be used, employing several stationary phases and diverse eluents; this can be viewed as an *in situ* sample preparation. In the case of multiple analyses, such as are undertaken in the fields of biochemistry and pharmacy, the time of analysis can be significantly shortened.

In liquid chromatography the internal diameter of a packed column can be increased to 50 mm or more, without significantly decreasing efficiency. In preparative separations, the amount of sample per unit amount of stationary phase is very often increased and the separation occurs according to the principles of displacement chromatography and not to those of elution chromatography. By proper choice of conditions remarkable purities and yields can be attained.

In the last few years it has become possible to record the UV/VIS spectrum as a function of time using diode array detectors. The absorption at more than 500 wavelengths can be simultaneously and repeatedly recorded at a frequency of 5 sec^{-1} or more, and stored. The necessary data processing makes such instruments expensive and the software on offer is not optimal. The optimal wavelength for routine analysis can be quickly established. If several components of differing and known spectra are hidden under a peak they can be estimated quantitatively. Very rapid identification of separated peaks is possible since a particular spectrum can be recalled at any time. If the analysis time of an abnormally complicated mixture is several hours and if the absorption maxima of the components have different wavelengths, such a detector is almost irreplaceable.

Most of the substances separated by exclusion chromatography have high molecular weight. Because of the small interdiffusional coefficients, band-broadening is significantly greater than is usual in retentive chromatography. Significantly better separations can be obtained here, without instrumental difficulties, by using particle sizes which are significantly less than the 10 μm usual today.

The separation and/or identification of single components (or groups) often requires multidimensional analysis. High speed liquid chromatography is being increasingly coupled with mass-, infrared- or nuclear resonance-spectroscopy. "On-line" coupling is, without question, quicker and more elegant. It is also instrumentally more taxing. Since the collection of HPLC fractions is simple, it is necessary to establish for each case whether "off-line" or "on-line" coupling is more suitable.

The ever recurring dream of users of modern liquid chromatography—that someone will invent a relatively simple, reliable detector that is *not substance specific*—will not be discussed here.

We thank the Deutschen Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

Appendix

As shown previously, the basic empirical equations are:

$$\delta = \sqrt{10^3 K_1} = \sqrt{\frac{10^3 \varepsilon_1 \eta u L}{\Delta P}} \tag{2}$$

$$h = a\delta + \frac{b}{u} + c\delta^2 u \tag{4}$$

Where a, b, c, ε_1, and η must be treated as system-dependent constants. The intensive quantities h and u are substituted by the extensive quantities (L/n and L/t_0) so that five variables appear: n, L, t_0, ΔP, and δ. With the definitions

$$n = L/h \tag{A1}$$

$$u = L/t_0 \tag{7}$$

the two following equations result

$$L = \delta \sqrt{\frac{t_0 \Delta P}{10^3 \eta \varepsilon_1}} \tag{8}$$

$$n = \frac{L}{a\delta + \frac{b t_0}{L} + \frac{c\delta^2 L}{t_0}} \tag{A2}$$

The independent variable L can be eliminated:

$$n = \left[\frac{a\sqrt{10^3 \eta \varepsilon_1}}{\sqrt{t_0 \Delta P}} + \frac{10^3 b \eta \varepsilon_1}{\delta^2 \Delta P} + \frac{c\delta^2}{t_0}\right]^{-1} \tag{9}$$

The maximum in the n,δ-curve follows by differentiation:

$$\left(\frac{\partial n}{\partial \delta}\right)_{t_0, \Delta P} = 0 \tag{A3}$$

$$\left(\frac{\partial n}{\partial \delta}\right)_{t_0, \Delta P} = \frac{\frac{2c\delta}{t_0} - \frac{2 \times 10^3 b \eta \varepsilon_1}{\delta^3 \Delta P}}{([\text{eq. } 9])^2} \tag{A4}$$

As long as eq. (9) $\neq 0$, which always applies in chromatographic systems, then for the maximum

$$\frac{2c\delta}{t_0} - \frac{2 \times 10^3 b \eta \varepsilon_1}{\delta^3 \Delta P} = 0 \tag{A5}$$

with the physically meaningful solution:

$$\delta_{opt} = \left[\frac{10^3 b \eta \varepsilon_1}{c} \cdot \frac{t_0}{\Delta P}\right]^{1/4} \tag{A6}$$

Since a further degree of freedom is lost at the maximum the following equations with two variables result:

$$L_{opt} = \left(\frac{b}{10^3 c \eta \varepsilon_1} \Delta P t_0^3\right)^{1/4} \tag{A7}$$

$$\eta_{opt} = \frac{1}{a + 2\sqrt{bc}} \sqrt{\frac{\Delta P t_0}{10^3 \eta \varepsilon_1}} \tag{A8}$$

From eq. (A7) and eq. (7) it follows that the linear velocity at the maximum of the n,δ-curve is

$$u_{opt} = \left(\frac{b}{10^3 c \eta \varepsilon_1} \cdot \frac{\Delta P}{t_0}\right)^{1/4} \tag{A9}$$

If eq. (A6) is solved for $\Delta P/t_0$ and substituted into eq. (A9) it follows that:

$$u_{opt} = \frac{1}{\delta} \cdot \sqrt{\frac{b}{c}} = u_{min} \tag{10}$$

as discussed in Section 3.

The equation for the $n/t_0,\delta$-curve in Figures 4 and 5 results when eq. (9) is solved with respect to t_0:

$$\sqrt{t_0} = -\frac{e}{2f} \pm \sqrt{\left(\frac{e}{2f}\right)^2 - \frac{g}{f}} \tag{A10}$$

with

$$e = an\sqrt{\frac{10^3 \eta \varepsilon_1}{\Delta P}} \tag{A11}$$

$$f = \frac{10^3 bn \eta \varepsilon_1}{\delta^2 \Delta P} - 1 \tag{A12}$$

$$g = cn\delta^2 \tag{A13}$$

Of the two solutions to eq. (A 10) only the positive one is physically meaningful. This solution possesses two branches with a discontinuity at

$$\delta_{disc} = \sqrt{\frac{10^3 b n \eta \varepsilon_t}{\Delta P}} \tag{A 14}$$

The branch where $\delta \leq \delta_{disc}$ has no physical meaning.

Instead of representing t_0 as a function of n, ΔP, and δ using eq. (10), the reciprocal of this equation can be calculated and multiplied by n, so that the speed of analysis n/t_0 is obtained as a function of n, ΔP, and δ:

$$\frac{n}{t_0} = n\left[\frac{1}{2}\left(\frac{e}{f}\right) - \frac{e}{f}\sqrt{\left(\frac{e}{2f}\right)^2 - \frac{g}{f}} - \frac{g}{f}\right] \tag{A 15}$$

In order to calculate the nomogram, eqs. (A 6), (A 7), and (A 8) successively, were transformed so that n_{opt} was a function of δ_{opt} and one other parameter (either ΔP_{opt}, L_{opt} or $t_{0,opt}$):

$$n_{opt} = \frac{\sqrt{c/b}}{10^3 \eta \varepsilon_t (a + 2\sqrt{bc})} \cdot \delta_{opt}^2 \Delta P_{opt} \tag{A 16}$$

$$n_{opt} = \frac{1}{a + 2\sqrt{bc}} \cdot \frac{L_{opt}}{\delta_{opt}} \tag{A 17}$$

$$n_{opt} = \frac{\sqrt{b/c}}{a + 2\sqrt{bc}} \cdot \frac{t_{0,opt}}{\delta_{opt}^2} \tag{A 18}$$

List of Symbols:

a, b, c	Constants in eq. (4)
As	Asymmetry factor (23)
D_m	Diffusion coefficient of the sample in the eluent
F	Flow velocity
$h = L/n$	Height equivalent to a theoretical plate
h_{min}	h at the minimum in the h,u curve
K_t	Permeability defined in terms of the empty column velocity [eq. (2)]
$k' = (t_R - t_0)/t_0 = t'_R/t_0$	Capacity factor
L	Column length
n	Number of theoretical plates
n/t	Speed of analysis (plates per unit time)
ΔP	Pressure drop in a column
$R = (t_{R2} - t_{R1})/w$	Resolution
r	Internal radius of a column
t_0	Elution time of an inert sample
t_R	Elution time of a retarded sample
u	Linear velocity of the eluent
u_{min}	u at the minimum of the h,u curve
V_t	Column empty volume
V_m	Volume of eluent in the column
w	Intercept on the time axis of the tangent of the inflexion
$\alpha = k'_2/k'_1$	Relative retention
δ	Chromatographically defined particle size [eq. (2)]
ε_t	Total porosity
η	Viscosity of the eluent

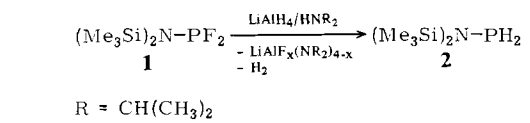
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Bis(trimethylsilyl)aminophosphane**

By *Edgar Niecke** and *Reinhold Rüger*

The stability[1] and synthetic potential[2] of the secondary aminophosphane *N,N,N'*-tris(trimethylsilyl)diaminophosphane stimulated our investigations into the synthesis of a primary aminophosphane.

We have now obtained bis(trimethylsilyl)aminophosphane **2** as the first representative of this class of compounds by selective F/H exchange in bis(trimethylsilyl)aminodifluorophosphane **1**[3] with $LiAlH_4/HN(iPr)_2$.



2 is a water-clear, highly pyrophoric liquid, which is stable up to at least 100 °C. Its composition is confirmed by elemental analysis and by its mass spectrum [70 eV: *m/z* 193 (M^+, 30%), 192 ($M^+ - H$, 2.3), 191 ($M^+ - H_2$, 1.5), 178 ($M^+ - Me$, 100) *etc.* The $H_2P—NSi_2$ skeletal framework can be deduced from the following characteristic IR absorptions of gaseous **2**: 2260 m, 2255 sh $\nu_{as,s}(PH_2)$, 1070 m $\delta(PH_2)$, 981 m $\nu(PN)$, 903 s $\nu_{as}(NSi_2)$, and 479 cm^{-1} m $\nu_s(NSi_2)$.

The triplet structure of the signal at $\delta = -59.3$ ($^1J_{HP} = 189.4$ Hz) in the ^{31}P-NMR (30% in CD_2Cl_2, H_3PO_4 ext.) proves the presence of a PH_2-group; the amine ligand leads to a stronger deshielding of the phosphorus nucleus than in primary phosphanes[4]. The ^1H-, $^{13}C\{^1H\}$- and $^{29}Si\{^1H\}$-NMR spectra (30% in CD_2Cl_2, TMS int.) show the signal to be expected for free rotation about the P—N bond: ^1H: $\delta = 0.29$ ($^4J_{HP} = 1.1$ Hz), 4.75 ($^1J_{HP} = 189.5$ Hz); ^{13}C: $\delta = 1.14$ ($^3J_{CP} = 5.3$ Hz), and ^{29}Si: $\delta = 10.41$ ($^2J_{SiP} = 10.8$ Hz).

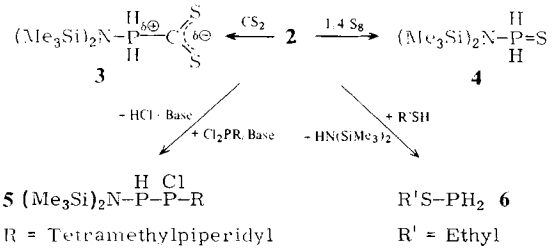
Postfach 8460, D-4800 Bielefeld (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The high reactivity towards oxidative attack, *e.g.* nucleophilic substitution at the phosphorus atom makes **2** an extremely interesting synthon. For example, **2** smoothly reacts with carbon disulfide or sulfur with increase in coordination number of the phosphorus to give **3**[5] and **4**[5], respectively, while reaction with dichlorophosphanes affords access to β-functional diphosphanes such as **5**[5] and with thiols yields mercaptophosphanes such as **6**[5].



Experimental

All experiments were carried out under an inert gas with rigorous exclusion of air and moisture. The solvents were re-purified and dried by column chromatography on Al_2O_3 (super I, basic).—**2**: $LiAlH_4$ (1.14 g, 30 mmol) and $HN(iPr)_2$ (2.2 g, 20 mmol) are added to a solution of **1** (6.97 g, 30 mmol) in pentane (60 mL) at −20 °C. The mixture is stirred and treated with 10 mL of THF, which initiates reaction (evolution of gas). Stirring is continued for a further 24 h, during which time the mixture is allowed to warm to room temperature. Solvent and product are collected under oil-pump vacuum in three cold traps (−10, −50, −196 °C), whereby the residue is heated to 50 °C. **2** condenses at −10 and −50 °C together with solvent residues. Fractional distillation under vacuum furnishes 3.15 g (16 mmol ≙ 53%) of pure **2**.

Palladacycloalkanes by Oxidative Coupling of 3,3-Dimethylcyclopropene with Palladium(0) Compounds**

By *Paul Binger**, *Holger Michael Büch*, *Reinhard Benn*, and *Richard Mynott*

Transition metal-catalyzed cyclooligomerization of alkenes proceeds smoothly and in high yields if the double

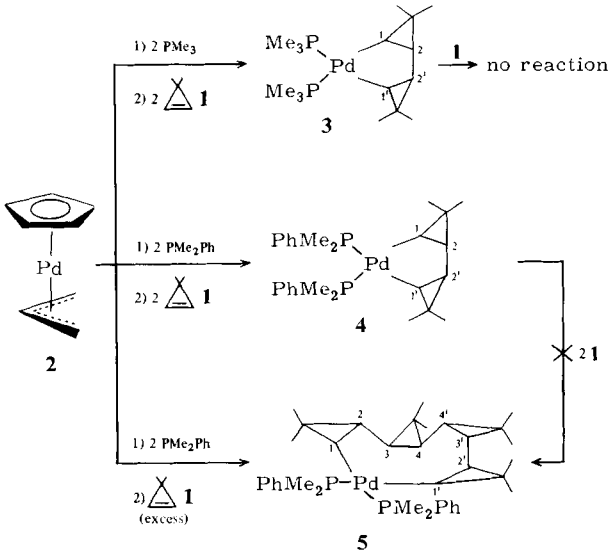
bond of the substrate is activated by ring strain. Thus, *e.g.*, 3,3-dimethylcyclopropene **1** is cyclooligomerized, sometimes highly chemoselectively, on palladium(0) catalysts[2]. Palladacycloalkanes of various ring size have been discussed as intermediates.

We have now succeeded in preparing five- and nine-membered palladacycloalkanes in stoichiometric reactions, and have simulated a catalytic cycle by their thermal decomposition. We synthesized the colorless palladacycloalkanes **3** to **5** by reaction of the dark-red complex (η^3-allyl)(η^5-cyclopentadienyl)palladium **2** with the relevant phosphane and **1** at -30 to $+20$ °C in hexane. To our knowledge **3** to **5** are the first palladacycloalkanes to have been obtained by oxidative coupling of alkenes. In contrast, diligand palladacyclopentanes are readily accessible by elimination of LiCl[3].



With trimethylphosphane as ligand, only the metallacyclopentane derivative **3** is obtained. With dimethylphenylphosphane, the five-membered ring **4**, the nine-membered ring **5**, or (with **2**:**1** = 1:3) a mixture of equal parts of **4** and **5** are formed depending on the ratio **2**:**1**. A palladacycloheptane derivative could not be isolated. Neither **3** nor **4** undergo further reaction with **1**. **4** and **5** are apparently formed from the same precursor—possibly a dinuclear complex.

Under inert gas, **3** and **4** first start to decompose at *ca.* 170–175 °C; **5** already decomposes at *ca.* 85 °C. In solution (decalin), the hydrocarbon residue is completely cleaved from **3** within 4 h on heating to 200 °C; in the case of **5**, reductive elimination can be achieved even in boiling diethyl ether. The products of thermolysis are the cyclohexadiene derivative **7** and the cyclotetramer **8**, respectively[2, 7]. The precursor for formation of **7** must be the tricyclohexane **6**, which rearranges quantitatively to **7** under the reaction conditions.

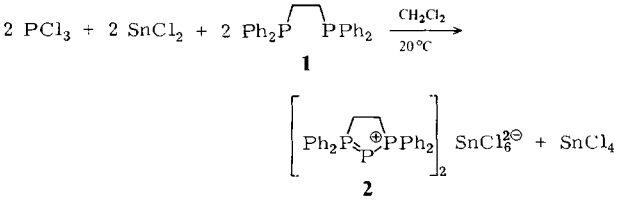
A diphos-Complex of $P^{\oplus}$: The 1,1,3,3-Tetraphenyl-1λ^5,2λ^3,3λ^5-triphospholenyl Cation**

By *Alfred Schmidpeter**, *Siegfried Lochschmidt*, and *William S. Sheldrick**

Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday

In reactions which should lead to phosphorus(I) halides PX (X = Cl, Br, I), such as the reduction of phosphorus(III) halides PX_3[1a], the disproportionation of diphosphorus tetrahalides P_2X_4[1b], or the decomposition of dihalophosphanylmetal compounds L_nMPX_2[1c], orange-red, X-ray-amorphous solids, some with X/P ratios widely differing from 1, are formed.

The product obtained on reaction of PCl_3 with $SnCl_2$ in the presence of [18]crown-6/KCl in dichloromethane also separates, quantitatively, as an orange-red precipitate. However, if the reaction is carried out in the presence of ethylenebis(diphenylphosphane) **1** (diphos) a clear solution is formed, from which the hexachlorostannate of the title cation **2** can be isolated as well-formed, colorless crystals (m.p. 230 °C).



The "complex cation" in **2** is the first phosphorus(I) compound in which the formal charge of $P^{\oplus}$ is also preserved as a net charge. It thus completes the series L_2P^n, $n = -1$ (two anionic ligands L, *e.g.* NC—P—CN[2a], $(RO)_2OP$—P—$PO(OR)_2$[2c]), $n = 0$ (one anionic, one neutral ligand, *e.g.* R_3P—P—CN[2b], R_3P—P—$PO(OR)_2$[2d] with $n = +1$ (two neutral ligands). On the other hand, **2** can be regarded as an unusual 1,2,3-triphospholane derivative[3].

The structure of the cation follows from its ^{31}P-NMR spectrum: AB_2 type, $\delta_{P(A)} = -231.6$, $\delta_{P(B)} = +63.8$,

[**] Four- and Five-Membered Phosphorus Heterocycles, Part 54. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 53: A. Schmidpeter, K. Karaghiosoff, *Z. Naturforsch. B* **36** (1981) 1273.

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/0101-0063 $ 02.50/0

J_{PP} = 448.9 Hz. The chemical shift of the central phosphorus $\delta_{P(A)}$ continues the trend found for the other L_2P'' compounds mentioned above (δ_P = −188 to −218), as $^1J_{PP}$ corresponds to the coupling constants found in those compounds.

According to an X-ray structure analysis, **2** crystallizes with two molecules of CH_2Cl_2. The five-membered ring of the cation (Fig. 1) has an envelope conformation. While in most other cases the PP bond length is "remarkably constant at 220–225 pm and seems insensitive to the bonding situation at the phosphorus"[4], here it is considerably shorter. The angle at the central phosphorus is very small, but is also just as small at the doubly coordinated phosphorus in diazaphospholene[5].

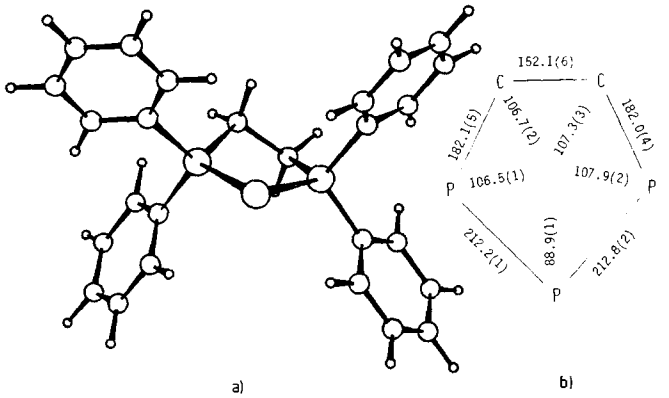

Fig. 1. a) Structure of the cation in $2 \cdot 2CH_2Cl_2$; monoclinic, space group $P\bar{1}$, a = 1165.5(2), b = 1317.4(3), c = 1098.2(6) pm, α = 100.38(2), β = 98.55(3), γ = 68.20(20)°, Z = 2, ρ_{calc} = 1.47 g/cm^{-3}, 4091 independent reflections ($Mo_{K\alpha}$, $F^2 \geq 2.0\sigma(F^2)$, $2\theta \leq 50°$), R = 0.042, R_w = 0.040.—b) Bond lengths [ppm] and angles [°] in the triphospholane ring.

Further experiments show that the "complexes" $L_2P^{\oplus}$ are variable, both with respect to the phosphane ligands L, and as regards the generation of $P^{\oplus}$; in particular, acyclic species can also be prepared.

Is Hexazine Stable?

By *Hanspeter Huber**

Dedicated to Professor Edgar Heilbronner on the occasion of his 60th birthday

Vogler et al.[1], on the basis of experimental evidence, have recently postulated that N_6 (hexazine, hexaazobenzene, cyclohexaazatriene) exists at low temperatures. In the discussion of evidence, three theoretical papers were cited, one of which[2b] was effectively interpreted as indicating that N_6 "is slightly stabilized". A considerably more accurate calculation is presented in the following; earlier work is shown in a critical light.

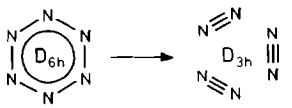
The semiempirical studies of *Dewar*[2c] involve two calculations: A MINDO/3 calculation predicts that hexaazine is more stable than dinitrogen; this result is considered to be unreliable by *Dewar*, because repulsion between the lone pairs of electrons is not considered. A MNDDO/1 calculation indicates that N_6 is approximately 1351 kJ/mol higher in energy than $3N_2$, and decomposes without an activation barrier.

In their *ab initio* SCF calculation, without geometrical optimization, *Palmer et al.*[2a] used a minimal basis. The energies thus obtained are shown in Table 1. No statement was made about the stability of hexazine.

Table 1. Theoretical comparison of stabilities of hexazine/dinitrogen.

Method	N_6, E/E_h	N_2, E/E_h	$(N_6 - 3N_2)$, E/kJ mol
Ref. [2a]	−325.290	−108.526	756
Ref. [2b]	−325.468	−108.569	631
FOGO	−325.988	−108.801	1089

Wright[2b] also used a minimal basis in his *ab initio* SCF calculations with geometrical optimization under D_{6h} symmetry. The energies for the optimal bond lengths of 137.9 pm are also included in Table 1. By comparison with standard bond energies, and the corresponding calculation for N_4, he comes to the conclusion that hexazine exhibits "a genuine stabilizing effect". However, whether the decomposition $N_6 \rightarrow 3N_2$ is hindered by an activation barrier was not investigated. Such a decomposition would only be possible if the symmetry were lowered from D_{6h} to D_{3h}.



Starting from *Wright*'s geometry[2b] we optimized the structure of N_6 with D_{6h} symmetry. We used the FOGO method[3] with sliding orbitals; this corresponds to a (DZ + P) basis and is, hence, a considerable improvement on the earlier calculations with minimal bases (the total energy lies approximately 1360 kJ/mol lower than that of the previous best calculation[2b]). The energy for an NN separation of 131.1 pm, which is found for the stationary point, is also reproduced in Table 1.

In order to decide whether this stationary point is a genuine minimum, the force constant matrix was calculated using *Pulay*'s "force" method[4]. Normal coordinate analysis indicated that this is *not a minimum, but, rather, a saddle point*. From the results of our calculations, N_6 with D_{6h} symmetry is not stable, but decomposes without an activation barrier in accord with *Dewar*'s MNDDO/1 calculation. Based on experience with calculations of this level, the result should not differ substantially by extending the basis. A geometrical optimization including electron correlation (and a sufficiently large basis) is too involved at present. The influence of the electron correlation on the stability is difficult to estimate. Also, stabilization by solvation cannot be completely excluded.

[*] Dr. H. Huber
Physikalisch-chemisches Institut der Universität

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/0101-0064 $ 02.50/0

In summary, none of the calculations yield an activation energy and (with the exception of the MINDO/3 calculation) all predict that in the gas phase N_6 is *ca.* 10^3 kJ/mol less stable than $3N_2$. For as long as no direct experimental proof for the existence of N_6 exists we must assume that hexazine is neither thermodynamically nor kinetically stable.

[**] Syntheses with Aliphatic Dialdehydes, Part 30. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. — Part 29: [1].

We report here on the preparation of the title compound **7**, which belongs to the hitherto rarely investigated cycloalkylidenemalondialdehydes. Starting from the sodium salt **1** of malondialdehyde, **7**[10] is obtainable as orange-red crystals (m.p. 132—133 °C, dec.) *via* the isolable intermediates **2** to **6** (Scheme 1).

According to NMR spectra, **7** is in equilibrium with the valence isomer 3-formyl-8a*H*-cyclohepta[b]furan **8** in solution (D_2O: 100% **7**; CCl_4: 37% **7**).

The X-ray structure analysis shows that exclusively the valence isomer **7** exists in the crystal. As a result of steric interactions, between 2-H/7-H on the one hand, and the two aldehyde oxygen atoms on the other, the seven-membered ring and the malondialdehyde group are rotated through 18.1° with respect to each other. This and the participation of the dipolar mesomeric resonance structure **7b** lead to a relatively long C-1/C-8 bond (143 pm; C_{sp^2}—C_{sp^2} single bond: 148 pm; double bond: 134 pm).

MNDO calculations[16] give a dipole moment of 3.0 D for a partially optimized completely planar conformation of **7**. An experimental determination of the dipole moment of **7** was not possible owing to the concomitant presence of the valence isomer **8** in solution.

Convenient General Synthesis of Alkynylcyclopropanes**

By *Thomas Liese* and *Armin de Meijere**

Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday

Although donor-, acceptor-, as well as vinyl-substituted cyclopropanes have become established synthetic tools, alkynylcyclopropanes[4], which because of the junction of a cyclopropyl and an alkynyl group offer an interesting and powerful synthetic potential, have not been widely recognized.

We recently found that the easily accessible 1-chloro-1-(trichlorovinyl)cyclopropanes **1**[5] react cleanly with 2 moles of *n*-butyllithium to give (1-chlorocyclopropyl)-substituted lithium acetylides **6** (Scheme 1), which can be solvolyzed by methanol or water to yield (1-chlorocyclopropyl)acetylenes **7** (Table 1) or trapped by a wide variety of electrophiles EX to give acetylene derivatives **5a** (Table 2).

The 1-chloro-1-alkynylcyclopropanes **5** and **7** are polyfunctional molecules, and as such valuable building blocks for organic synthesis. Among the reactions which can be

Thermal Conversion of 1,3-Cyclooctadien-5-yne into Benzocyclobutene—A Novel Isomerization on the C_8H_8 Hypersurface**

By *Herbert Meier**, *Norbert Hanold*, and *Heinz Kolshorn*

Synthesis of the first highly-strained cyclic enyne was accomplished some time ago[3]. Incorporation of a double bond into the cyclooctyne ring system considerably increases the geometric strain; insertion of two double bonds is expected to lead to a still greater increase in strain. Figure 1 shows the enthalpies of formation of 1,3,5-cyclooctatriene and 1,3-cyclooctadien-5-yne calculated on the basis of complete optimization of geometry according to the MNDO method[4]. Both molecules have a C_1 conformation in the lowest energy state. *cis*-2-Butene (with C_{2v} symmetry) and 2-butyne (with D_{3d} symmetry) are listed as reference systems. A characteristic feature is the large difference in the heat of hydrogenation in the *cyclo*-C_8- and C_4-systems (236 and 120 kJ/mol, respectively). The high value for the hydrogenation of cyclooctadienyne to cyclooctatriene is ascribed to release of ring strain. The difference in the heat of hydrogenation of the two systems (116 kJ/mol) can be regarded as a direct measure of the geometrical ring strain[3].

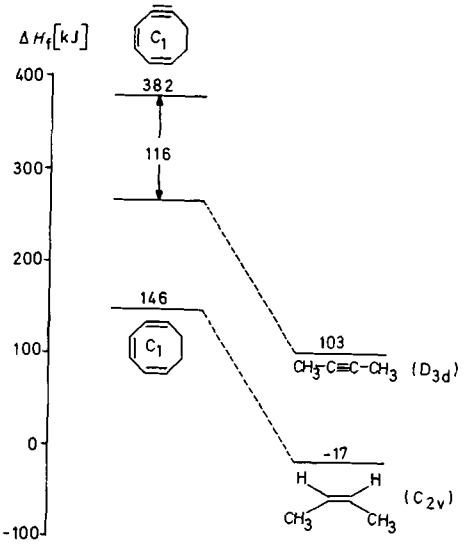

Fig. 1. Comparison of the heats of hydrogenation of 1,3-cyclooctadien-5-yne and 2-butyne on the basis of calculated[4] enthalpies of formation ΔH_f.

1,3-Cyclooctadien-5-yne **7** was obtained by thermal fragmentation of the selenadiazole compound **6**. **7** can be converted into **8**, *e.g.*, by reaction with tetracyclone. On attempting to condense **7** directly into a cold trap, only traces of the compound remained unchanged; to our surprise we isolated almost exclusively benzocyclobutene **10**. Apparently **7** is far much less stable than the isomeric 1,5-cyclooctadien-3-yne[11].

The conversion must take place on the S_0 energy hypersurface of the C_8H_8 hydrocarbon with a relatively low activation barrier. This behavior is reminiscent of the valence

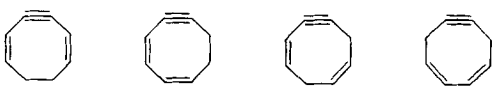
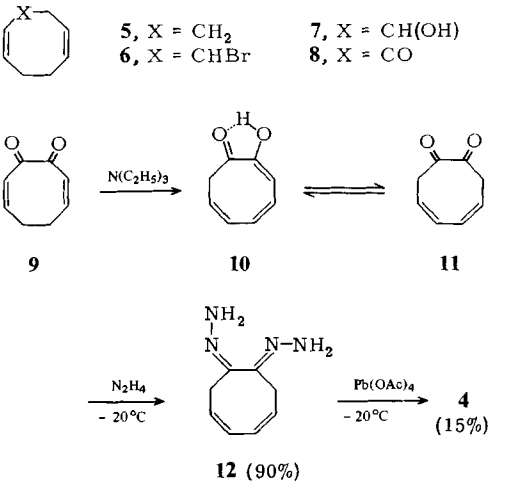
1,3-Cyclooctadien-6-yne—An Isolable Bishomodehydrobenzene**

By *Herbert Meier** and *Toni Echter*

The highly strained and highly reactive cyclooctadienynes belong to the C_8H_8-series of hydrocarbons. Of the four constitutional isomers **1**—**4**, only the 1,5-cyclooctadien-3-yne **1** has so far been isolated[1] (half-life of a 0.3 M solution in chloroform *ca.* 2 h). According to a MNDO calculation there is very little difference in the standard enthalpies of formation of **1**—**4** ($\Delta\Delta H_f < 2$ kcal/mol)[2]. Aside from oligomerizations, isomerizations on the C_8H_8 S_0-energy hypersurface are particularly decisive regarding kinetic stability. Thus, on attempted isolation **2** and **3** are converted into benzylcyclobutene and styrene.

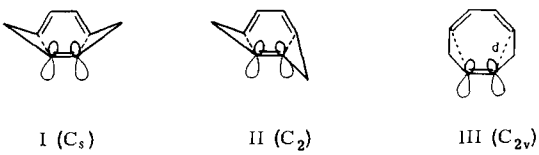


We have now synthesized 1,3-cyclooctadien-6-yne **4** from 1,5-cyclooctadiene **5** *via* the intermediates **6**—**8**[1], **9**[3], **10**[3], **11**, and **12**. Compound **4**, a colorless oil which solidifies at *ca.* −20 °C, can function as diene as well as dienophile in Diels-Alder reactions.



4 (as oil) has a half-life of *ca.* 5 h at room temperature; when dissolved in chloroform it is stable for a number of days.

Is **4** a bishomodehydrobenzene with a stabilizing π-electron sextet? Such a species could have the conformations I—III, in each of which the diene moiety and the triple bond are coplanar. The MNDO calculation gives a lowest energy C_2 conformation, which deviates only minimally



from the planar C_{2v} conformation[2]. The four methylene protons are chemically equivalent. This would imply conformation III or that of I/II with rapid ring inversion (on the NMR time-scale). The ^{1}H-NMR spectrum also remains practically unchanged on cooling. An almost planar C_2-form should in fact have a very low inversion barrier. The distances *d* (dotted) between the diene moiety and the triple bond are of decisive importance for the π-electron sextet theory. According to the MNDO calculation and the spectroscopic characterization, all data indicate that **4** is planar or almost planar and that *d* has a relatively large value. Hence, the homoaromaticity is, any case, subordinate to the geometric strain[5], *i.e.* a higher deformation energy cannot be compensated or even over-compensated by better overlapping in the π-electron sextet. Thus, there are no thermodynamic reasons for the greater stability of **4** compared to that of **1**—**3**; rather it is of a kinetic nature.

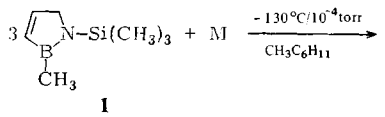
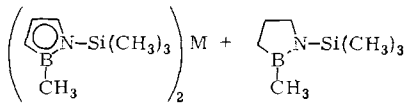
Azaborolinyl-Iron and -Cobalt Sandwich Complexes by Metal Atom Synthesis**

By *Saeid Amirkhalili, Uwe Höhner,* and *Günter Schmid**

Anions of 1,2-azaborolines, which are isoelectronic with cyclopentadiene, could be used as 6 π electron donors in numerous carbonyliron complexes[1-4]; until now, sandwich compounds have been inaccessible. We have now prepared, for the first time, the ferrocene and cobaltocene analogues **2** and **3**, respectively, by metal atom synthesis from **1**[3].



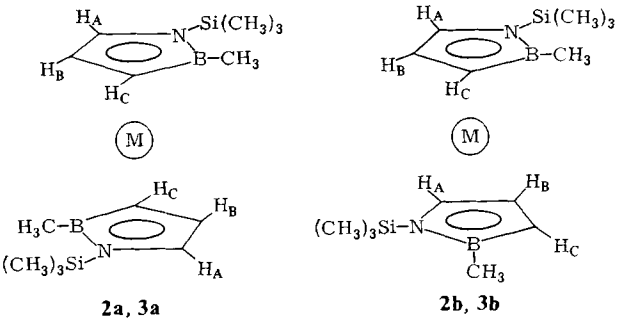
1



2, M = Fe
3, M = Co

4

The red-brown, diamagnetic **2** and the green, paramagnetic **3** can each be separated by fractional sublimation *in vacuo* into isomers, which can be characterized as the staggered form **a** and eclipsed form **b** by X-ray structural analysis.



2a, 3a **2b, 3b**

In the mass spectra of **2** and **3**, the molecular ions appear at $m/z = 360$ (100%) and 363 (100%), respectively. The ring protons H_A, H_B, and H_C of **2a** and **2b** show separate signals in the ^{1}H-NMR. The ^{11}B-NMR signals of **2** ($\delta = 24 \pm 1$) and **3** ($\delta = 22 \pm 1$) are, as expected, shifted upfield relative to the signal of **1** ($\delta = 38$). From the crystal structure analysis, the *pentahapto*-bound heterorings are planar; this result, and the ^{11}B-NMR spectra document the involvement of the boron atoms in the interaction of the rings with the metal atoms.

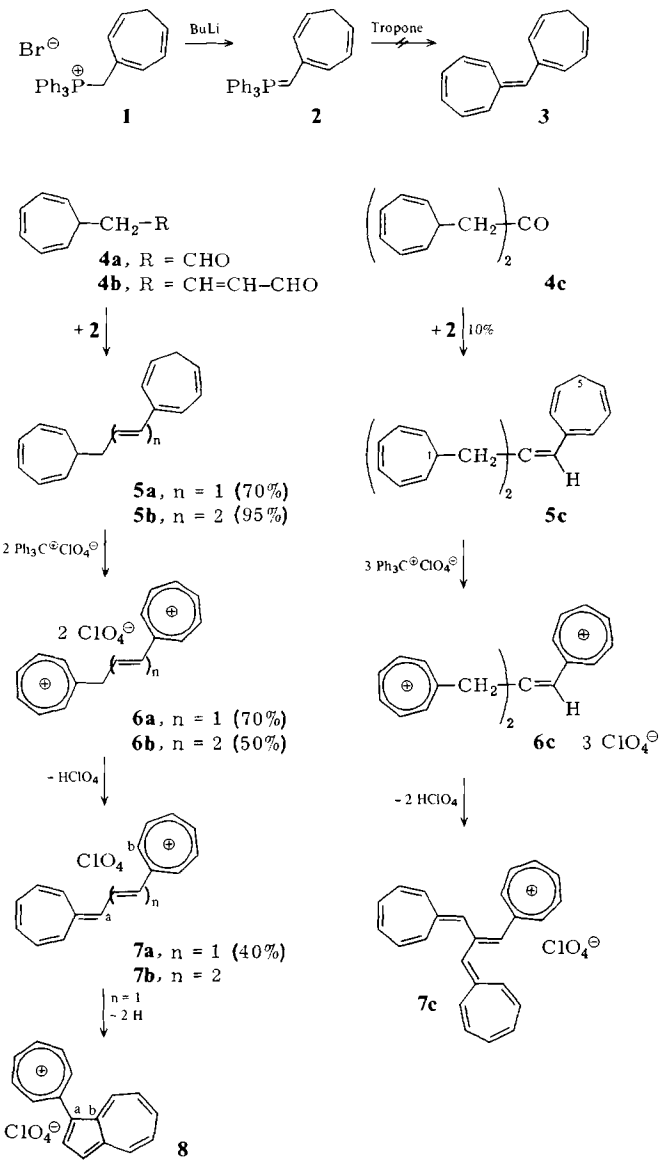
Polymethines with Heptafulvenyl Terminal Groups**

By *Norbert Ott* and *Dieter Rewicki**

Dedicated to Professor Georg Manecke on the occasion of his 65th birthday

Numerous carbanionomethines with anion-stabilizing carbocyclic terminal groups have been described as conjugated bases of "highly acidic" hydrocarbons[1]. The corresponding cationic polymethines on the other hand, are hardly known[2].

The key compound of our synthesis is deep-red **2** (generated from **1**[3] by reaction with *n*-butyllithium in tetrahydrofuran[4]), which reacts smoothly with aldehydes and ketones to give 1,3,6-cycloheptatrienylalkenes. **2** reacts quantitatively with tropone even at −50 to 25 °C; however, we could not isolate either the thermolabile **3** or **7**, $n = 0$[2b]. It should be possible, on the other hand, to synthesize the cationic polymethines **7a**–**7c** from the carbonyl compounds



[*] Prof. Dr. D. Rewicki, Dr. N. Ott
Institut für Organische Chemie der Freien Universität
Takustrasse 3, D-1000 Berlin 33 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

4a—**4c** without formation of neutral heptafulvene intermediates.

In CH_3CN/H_2O (95:5), the crystalline dication salt **6a** [$\lambda_{max}=348$ nm ($\log\varepsilon=4.20$), in CF_3CO_2H/H_2SO_4] obtained from **4a** furnishes the deep blue trimethine **7a** in quantitative yield. Chromatography (CH_3CN/CH_2Cl_2 1:1) on deactivated silica gel affords **7a** [dark blue crystals, decomp. >250 °C; $\lambda_{max}=713$ nm ($\lg\varepsilon=4.88$), in CH_3CN; ^{1}H-NMR (CD_3CN): $\delta=6.48$ (2H, d, $J=13.2$ Hz), 7.2—7.8 (m, 12H), 8.26 (1H, t, $J=13.2$ Hz); pK_{R^+} (in CH_3CN/H_2O (1:1))=6.90; for comparison: tropylium perchlorate: $pK_{R^+}=4.01$]. **7a** cyclizes in solution to give a violet carbocation [λ_{max} ($\lg\varepsilon$)=554 nm (4.38), in CH_3CN], which was isolated as the crystalline perchlorate **8**[5]. The previously[6] described synthesis of **7a** leads to other products.

6b was obtained analogously to **6a**; in CH_3CN/H_2O it forms olive-green non-isolable **7b** [$\lambda_{max}=817$ nm ($\lg\varepsilon>4.5$), $pK_{R^+}=4.9$]. In trifluoroacetic acid, **7a** and **7b** are quantitatively converted into **6a** and **6b**, respectively.

Attempted synthesis of **7c** failed at the step **5c** (from **4c**)→**6c** [**5c**: oil, MS: m/z 326 (M^+), ^{1}H-NMR: $\delta=1.77$ (m, 2H-1) and 2.26 (t, 2H-5)]. Since hydride abstraction from C7-substituted cycloheptatrienes is difficult, **5c** was heated for 30 min at 200 °C; an isomeric mixture with almost double the amount of C3-substituted seven-membered rings (*i.e.* 1,3,6-cycloheptatrienyl groups) was formed. After hydride transfer with trityl perchlorate in dichloromethane, treatment with ether leads to precipitation of a mixture of perchlorates, which dissolve in CH_3CN/H_2O to give a blue solution ($\lambda_{max}=690$ nm); we interpret this finding as the first indication of partical formation of **7c**.

Reversible Electrochemical Formation of Graphite Fluoride from Aqueous Hydrofluoric Acid**

By *Fritz Beck**, *Werner Kaiser*, and *Holger Krohn*

From the work of *Ruff* and *Rüdorff* it is known that graphite can form intercalation compounds of composition $(CF)_x$, $(C_4F)_x$, and $(C_n^+HF_2^-\cdot 2H_2F_2)_x$ with fluorine, where $n\geq 24$[1a,4]. They contain weakly bound fluorine and their high electrical conductivity changes little with the composition, up to saturation. The components are cheap and readily available. Compounds of this type are therefore interesting as positive active substances in galvanic cells. In terms of practical applications, graphite fluoride has been held to be sensitive to hydrolysis.

We have found that reversible electrochemical formation of graphite-fluorine intercalation compounds of the "salt type" $(C_n^+HF_2^-\cdot 2H_2F_2)_x$ from aqueous hydrofluoric acid over the concentration range 5—50 mol/L (10—100% wt) is possible. To date, it appears that this graphite salt can only be prepared in the absence of water[4].

In the overall equation (1), C and D signify "charge" and "discharge" (relative to the potential application as positive electrodes in accumulators):

$$(C_n)_x + 3x\,H_2F_2 \underset{D}{\overset{C}{\rightleftharpoons}} (C_n^+HF_2^-\cdot 2H_2F_2)_x + x\,H^+ + x\,e^- \qquad (1)$$

We have performed slow cyclovoltammetric measurements (voltage scan 1 mV/s) using CPP electrodes composed of 80% natural graphite flakes (94% "Kropfmühl Normalflocke") and 20% polypropylene. Measurements in 10 M and 25 M HF yielded the following:

Sharp increase in current after reaching a critical anode potential ("intercalation potential" E_I) whereby anodic intercalation occurs.

Limitation of the current density to *ca.* 5 mA/cm² arising from transport limitation in the CPP.

No overpotential in cathodic deintercalation in those cases where anodic intercalation occurs below 200 mV.

Reversible cyclizability at charge densities of 0.03—0.3 Ah/dm² at a 3 mm thick CPP electrode, whereby a formation effect is observed in the first cycle.

Ah yields of 90—100%.

We have already observed similar behavior with aqueous solutions of the acids H_2SO_4, $HClO_4$, and HBF_4[6]. Novel in the HF system is that the intercalation potential *linearly* decreases to a lesser extent than with other acids. Particularly positive intercalation potentials are therefore obtained with HF; with $c=10$ mol/L, E_I is 1.82 V (*vs.* SHE), whereas with the other acids the potential has fallen off to 1.24—1.43 V at the same concentration. Furthermore, in 70—90% HF, even at high overpotentials, reversible processes, which are absent in the other acids, were surprisingly found. This could signify a loading beyond $C_{24}F$.

Our results have considerable practical implications for the development of novel secondary cells with HF electrolytes. The battery metals M = Cu, Pb, Cd, Zn, and Mn in these electrolytes act as negative electrodes of the second kind. The overall reaction in the cycle is thus.

$$0.5x\,MF_2 + x\,H^+ + x\,e^- \underset{D}{\overset{C}{\rightleftharpoons}} 0.5x\,M + 0.5x\,H_2F_2 \qquad (2)$$

The sum of equations **1** and **2** indicates that on charging the cell 2.5 mol of H_2F_2 (as solvate acid) are consumed per Faraday. Because of the reversible behavior of the electrodes over a wide concentration range, this consumption is, however, not a limiting factor. To date, cyclic investigations with battery cells (Cu, Pb) have yielded over 1000 cycles (1 h charging at 3 mA/cm²) at small to intermediate conversions[8]. Stationary discharge potentials of 2.2 V, without a passivation tendency were observed with zinc as the negative electrode.

$[(CH_3)_5C_5Sn(C_5H_5N)]^+$: Synthesis, Structure and Bonding**

By *Peter Jutzi**, *Franz Kohl*, *Carl Krüger*, *Gotthelf Wolmershäuser*, *Peter Hofmann*, and *Peter Stauffert*

We recently reported on the synthesis, structure, and bonding of the *nido*-cluster $(CH_3)_5C_5Sn^+$[1,2]. The observed tendency of $(CH_3)_5C_5Sn^+CF_3SO_3^-$ to undergo covalent cation-anion interactions, and the existence of the covalent species $(CH_3)_5C_5Sn$—X (X = CF_3CO_2, CCl_3CO_2)[3] indicate the electrophilic character of the tin atom in the cluster cation. We have now succeeded in synthesizing an adduct of this species containing a nucleophilic neutral ligand.

On reaction of pentamethylcyclopentadienyltin trifluoromethanesulfonate **1**[3] with pyridine, the 1:1-adduct **2** is obtained as large, colorless crystals.

$$(CH_3)_5C_5Sn^+CF_3SO_3^- \xrightarrow[CH_2Cl_2]{C_5H_5N} [(CH_3)_5C_5Sn \leftarrow NC_5H_5]^+CF_3SO_3^-$$

1 → **2**

In the ^{1}H-NMR spectrum of **2** (in CH_2Cl_2, ext. TMS) the signals of the pyridine protons in the 2- and 4-positions are shifted downfield (relative to free pyridine); the singlet of the $(CH_3)_5C_5$-group of **2** ($\delta = 2.03$) appears at higher field than that of **1** ($\delta = 2.13$). Cryoscopic molecular weight determinations indicate the ionogenic character of **1** and **2** in solution (nitrobenzene). An X-ray structure analysis has been carried out on **2**[4] (Fig. 1).

The additional pyridine coordination compared to that in the free cluster cation[1,2] leads to a distortion towards a dihapto-structure within the $(CH_3)_5C_5Sn$ moiety. The Sn—C_{ring} bond lengths for C1 and C5 (adjacent to the pyridine) are shortest; as in η^5-$(CH_3)_5C_5Sn^+$, the methyl groups are tilted away from the ring plane of the central atom[1,2], the degree of tilting being greater, the shorter the length of the respective SnC bond. According to model calculations the observed weak coordination of the Sn-atom to one O-atom from each of the two anions (indicated by X in Fig. 1) is necessary in order to stabilize unsymmetric coordination of the five-membered ring and to prevent base-promoted loss of the pentamethylcyclopentadienyl ligand.

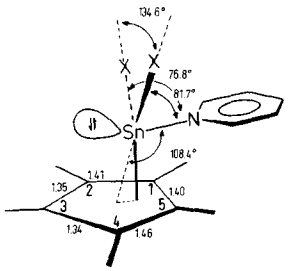

Fig. 1. Structure of **2** in the crystal (X = $CF_3SO_3^-$). The following SnC bond lengths were determined: Sn—C1 = 2.426 Å, Sn—C2 = 2.545 Å, Sn—C3 = 2.651 Å, Sn—C4 = 2.578 Å, Sn—C5 = 2.447 Å.

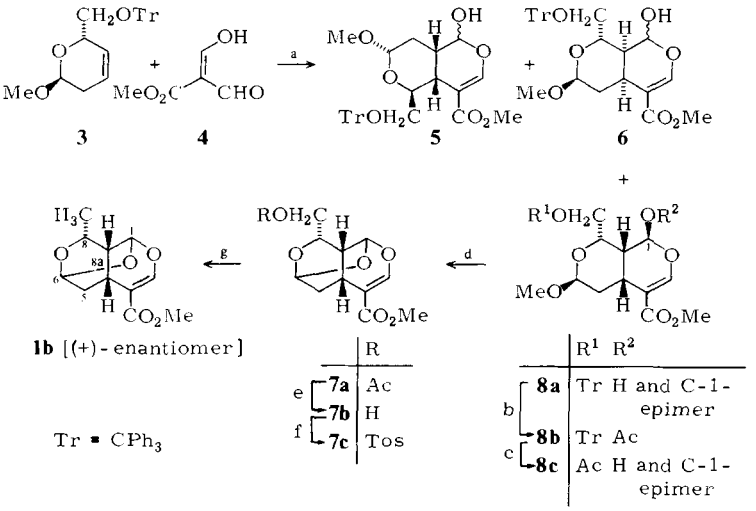
to the secoiridoid glycoside secologanin **2** and contains a dihydropyranyl ether group as characteristic structural element. We describe the synthesis of the enantiomerically pure (unnatural) (+)-sarracenin **1b**[4]. The key-step is the photochemical cycloaddition of the chiral olefin **3**[6], obtained in four steps from galactose in 31% yield, to methyl diformylacetate **4**[7].

Irradiation of **3** and **4** yielded the isomers **5** and **8a** as main products, together with **6**. Presumably $[_\pi 2 + _\pi 2]$-cycloadducts, which open *via* a retroaldol cleavage step to give the 1,5-dialdehydes and finally recyclize to give **5** (25%), **6** (5%), and **8a** (32%)[9], are involved as intermediates.

Further steps in the synthesis of (+)-sarracenin **1b**[11] starting from **8a** are illustrated in Scheme 1.



Scheme 1. a: 500 Watt Hg high pressure lamp, pyrex, **3**:**4** = 20:1 in cyclohexane, 9 h, 20°C; SC (silica gel; diisopropyl ether/cyclohexane = 3:1); **8a**: $R_f = 0.21$ (32%), $[\alpha]_D^{20} = +42$ ($c = 1$ in MeOH); **6**: $R_f = 0.17$ (5%); **5**: $R_f = 0.15$ (25%), m.p. = 215°C.—b: AcCl/pyridine/toluene 5 h, 20°C, 86% **8b**, m.p. = 209°C.—c: IR 120 ($H^{\oplus}$)/CH_2Cl_2, 35 h, 20°C, 84% **8c**.—d: HOAc/$HClO_4$, 8 min, 50°C, 77% **7a**, m.p. = 89°C.—e: MeOH/NaOMe, 30 min, 20°C, 94% **7b**, m.p. = 98°C.—f: TosCl/pyridine, 1 h, 20°C, 80% **7c**, m.p. = 143°C.—g: $NaBH_4$/DMSO, 90 min, 90°C, 61% **1b**, m.p. = 125°C.

The reaction sequence described is also suitable for the synthesis of secoiridoids which are functionalized at C-12.

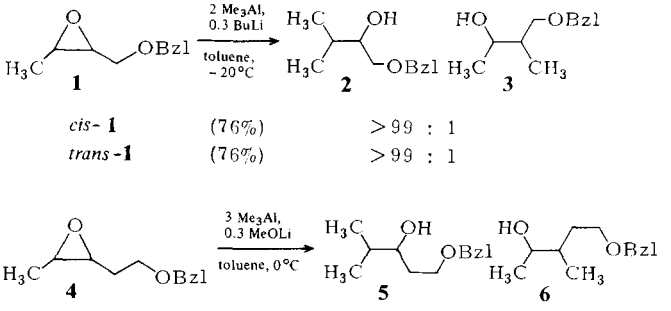
Regioselective Opening of α- and β-Alkoxyepoxides with Trimethylaluminum**

By *Andreas Pfaltz** and *Anton Mattenberger*

The development of efficient methods for the diastereo- and enantioselective epoxidation of allylic and homoallylic alcohols[1] has encouraged the use of α- and β-hydroxyepoxides as intermediates in the synthesis of acyclic systems[2]. Nucleophilic ring opening of these epoxides can lead to a wide variety of substituted alcohols. Such transformations are of particular interest when only one of the epoxide carbon atoms is attacked by the nucleophile[1d, 3].

We have investigated the reactions of various organometallic compounds with the α- and β-benzyloxyepoxides **1** and **4**. We have found that trimethylaluminum in the presence of catalytic amounts of butyllithium or lithium methoxide gives, respectively, the 1,2- and 1,3-dioxy compounds **2** and **5**. The regioisomeric alcohols **3** and **6** are only produced in trace amounts. Methylmagnesium bromide, methyllithium, lithium dimethylcuprate, or dimethylmagnesium react considerably less selectively. Pure trimethylaluminum reacts very slowly under the conditions given in Scheme 1[6]. Addition of catalytic amounts of butyllithium or lithium methoxide leads to a marked acceleration of the reaction. Hydrocarbons are particularly suitable solvents; ether or THF almost completely stop the reaction by forming complexes with the aluminum reagent.



Bzl = $CH_2C_6H_5$

Synthesis of Linear and Branched Cellotetraoses**

By *Richard R. Schmidt** and *Josef Michel*

Versatile and efficient syntheses of 1,2-*trans*-β-glycopyranosides are a prerequisite for the synthesis of oligosaccharides[1]. Exclusively β-D-glucopyranosides are obtained when the α-trichloroacetimidate of 2,3,4,6-tetra-*O*-acetylglucopyranose is used as starting material[2]. We have now found that the conveniently accessible and isolable, but very reactive α-trichloroacetimidates **1α, 6α,** and **11α,** with benzyl protecting groups not capable of neighboring group participation, likewise react with high β-selectivity[3]. The ease with which the individual reaction steps can be carried out on a preparative scale enables, *e.g.*, the stepwise synthesis of the branched and linear cellotetraose derivatives **12β** and **13β,** and **14β, 15β** and **16β,** respectively (Scheme 1)[4]. The intermediates thus formed are extremely useful synthons for block syntheses[5].

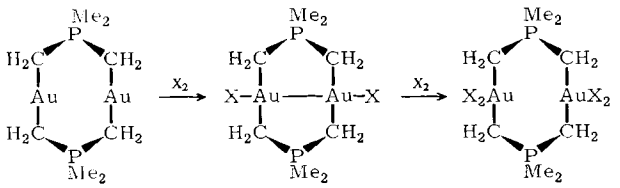
Methylene Bridging of two Gold Atoms through Double Oxidative Addition of Methylene Dihalides to a Cyclic Ylide Complex**

By *Petr Jandik, Ulrich Schubert,* and *Hubert Schmidbaur**

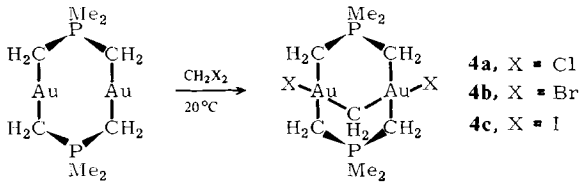
Gold(I) compounds easily undergo oxidative addition.

In the first step of the addition of halogen to binuclear cyclic ylide complexes[2,3] **1**, a transannular gold(II)—gold(II) bond, which subsequently may be cleaved again by excess halogen to give classical gold(III) compounds[2-4] **3**, is observed in the intermediate **2** (Me = methyl).



1 **2** **3**

We now report on the addition of methylene dihalides to the heterocycle **1**, leading to formation of bridged bicyclic compounds.



4a, X = Cl
4b, X = Br
4c, X = I

1

The reaction proceeds even at room temperature in 60—65% yield, and the resulting crystalline, air-stable compounds **4** are virtually free of by-products.

The structures of the new compounds **4a—c** have been confirmed by an X-ray diffraction analysis of **4a** (Fig. 1), as well as by elemental analyses, mass spectra, ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra. The non-equivalence of the methyl groups at each phosphorus atom and of the hydrogen atoms in each PCH_2Au bridge is diagnostic, as is the magnetic equivalence of the P atoms and of the two H atoms of the $AuCH_2Au$ bridge (C_{2v} symmetry).

Molecular ions appear in the EI mass spectra, along with fragments stemming from loss of halogen, and the heterocycle **1**. In the IR spectrum of **4a**, ν(AuCl) is located at 262 cm^{-1}. A band at 360 cm^{-1} is characteristic of the $AuCH_2Au$ bridge in all three homologues.

The thermal stability of the compounds **4a—c** is surprisingly high (decomp. at *ca.* 200 °C). They are also chemically relatively recalcitrant, and complex **4a**, which is insoluble in most other solvents, is soluble in trifluoroacetic acid and can be stored in this solution at room temperature for several days without decomposition (NMR solvent).

The oxidative addition of CH_2X_2 to binuclear complexes described here (cf. Supplement) is of particular interest, since to the best of our knowledge it is the first reported example in which *both* C—X bonds are involved; previously only the formation of halomethyl derivatives could be achieved[7].

$$M + CH_2X_2 \rightarrow X—M—CH_2X$$

This type of reaction is currently of great interest[8].

Activation of Silanes on a Ruthenium Cluster: Synthesis, Characterization, and Catalytic Action of the Cluster Anion $[HRu_3(CO)_{10}(SiEt_3)_2]^-$

By *Georg Süss-Fink**

In the course of the rapid development in homogeneous catalysis, considerable interest has been focused on syntheses involving silanes[1]. In order to understand the basic catalytic processes of these reactions, the activation of the

[*] Dr. G. Süss-Fink
Laboratorium für Anorganische Chemie der Universität
Universitätsstrasse 30, D-8580 Bayreuth (Germany)

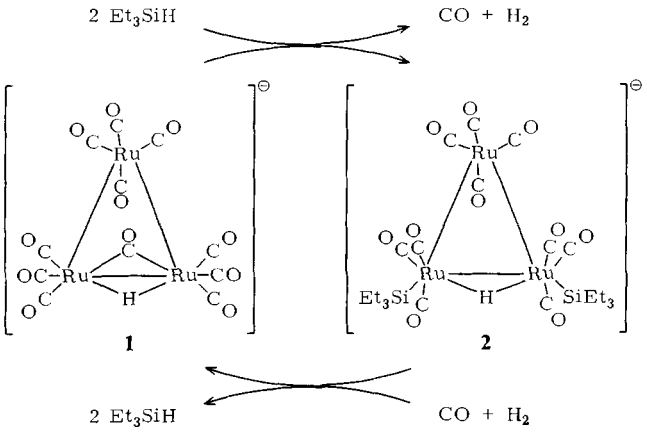
silane molecule on transition metal complexes is of significance.

The novel cluster anion **2** is formed by reacting the cluster anion **1** with triethylsilane in tetrahydrofuran (THF) solution; gas chromatographic analysis of the reaction gas shows that CO and H_2 are liberated.

$$\underset{\mathbf{1}}{[HRu_3(CO)_{11}]^-} + 2\,Et_3SiH \xrightarrow{THF} \underset{\mathbf{2}}{[HRu_3(CO)_{10}(SiEt_3)_2]^-} + CO + H_2$$

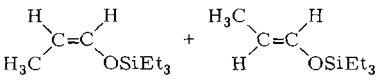
The reaction proceeds almost quantitatively at room temperature. The anion **2** can be isolated as the bis(triphenylphosphoranediyl) ammonium salt $[N(PPh_3)_2][HRu_3(CO)_{10}(SiEt_3)_2]$ (slightly air-sensitive red crystals). This formula is consistent with the results of elemental analysis, molecular weight determination, and conductivity measurements. IR- and NMR-data [$^1H(CD_3COCD_3$, $-75\,^\circ C$): $\delta = 7.64$ (m, 30H), 0.98 (m, 30H), -18.46 (s, 1H); ^{13}C, ^{29}Si] suggest that **2** consists of an isosceles Ru_3-triangle with a hydride bridge and a silyl group at each bridgehead atom.

In the presence of CO and H_2 under pressure, **2** is converted back into **1**, which upon reduction of pressure reacts again with the liberated Et_3SiH to give **2**.



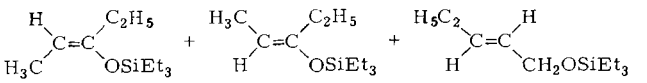
This equilibrium apparently is decisive for the catalytic action of **1** and **2**: In THF under mild conditions **1** or **2** catalyzes the reaction of ethylene, CO, and triethylsilane to the unsaturated silyl ethers **3**—**7**.

$$H_2C{=}CH_2 + CO + Et_3SiH \longrightarrow$$



3, 29% **4**, 21%

$$2\,H_2C{=}CH_2 + CO + Et_3SiH \longrightarrow$$



5, 7% **6**, 6% **7**, 12%

After reaction, the solution contains—irrespective of whether **1** or **2** were employed—a mixture of **1** and **2**, which remains catalytically active in subsequent reactions.

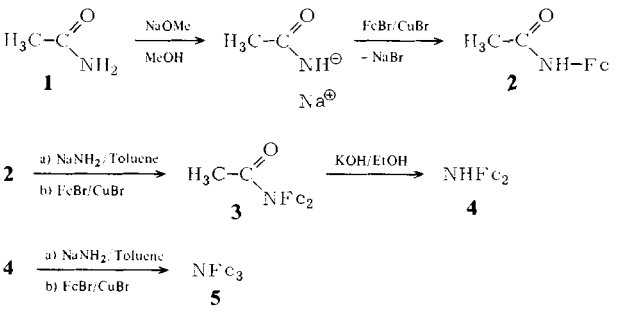
Triferrocenylamine, NFc_3

By *Max Herberhold**, *Max Ellinger*, *Ulf Thewalt*, and *Friederike Stollmaier*

We report here on the preparation, characterization, and X-ray structural analysis of the tertiary amine triferrocenylamine, NFc_3 **5** (Fc = ferrocenyl = $-C_5H_4FeC_5H_5$).

Using acetamide **1** as starting material, three ferrocenyl substituents were stepwise attached to the nitrogen atom as shown below.



The intermediates **3** and **4** were first obtained by *Nesmeyanov et al.*[2]. Further ferrocenylation of **4** with ferrocenyl bromide/copper(I) bromide gave **5** in the form of reddish brown, air-stable crystals. **5** was identified on the basis of elemental analysis and its ^1H-NMR, ^{13}C-NMR, and mass spectra.

According to an X-ray structural analysis the arrangement around the central N-atom in **5** is almost planar; the N-atom is only about 6 pm out of the plane of the directly bonded C-atoms (C1, C11, and C21) (Fig. 1). The three ferrocenyl groups are oriented differently with respect to this plane—but not in a propeller-like fashion. The amine **5** no longer reacts basically.

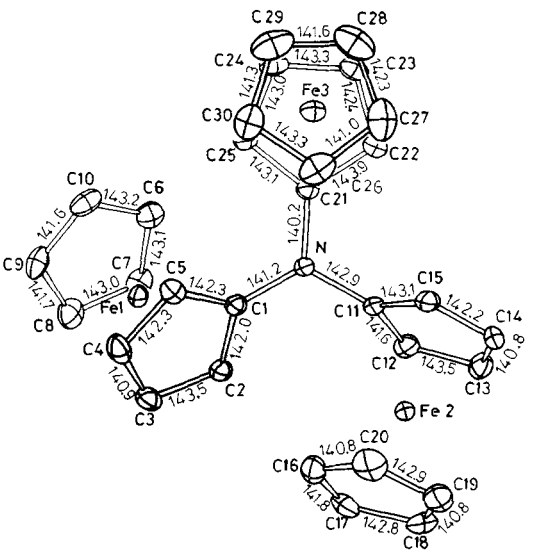


Fig. 1. Molecular structure of NFc_3 **5** in the crystal, projected on the C1, C11, C21 plane. The errors in the distances amount to 0.6 pm.

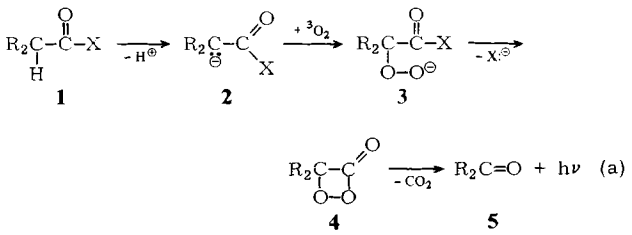
Formation of $^1O_2$ in the Reversible Autoxidation of Enolates Derived from Carboxylic Acids**

By *Waldemar Adam**, *Omar Cueto*, and *Hector Rebollo*

Oxidative decarboxylation of carboxylic acids is one of the important metabolic processes that leads to the next lower homolog[1]. The general mechanism is given in [eq. (a)][2]. Previously we have been concerned with the mechanistic details of step **4**→**5**, and through model studies we showed that α-peroxylactones **4** are the "high energy"



intermediates responsible for light emission[3]. Presently we have turned our attention to step **2**→**3**, in the hope of elucidating its mechanism. Our model experiments on diphenylacetic acid **1a** (R = C_6H_5, X = OH) and isobutyric acid **1b** (R = CH_3, X = OH) show that

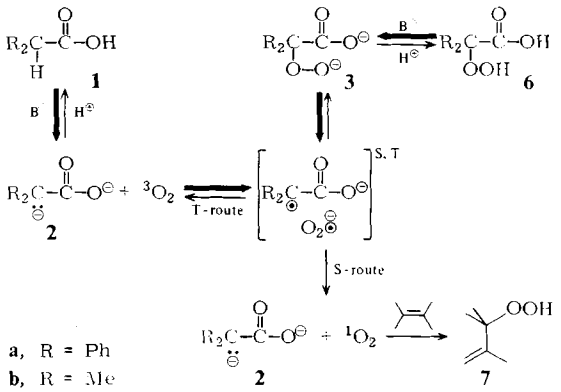
1) the oxygenation of the carboxylate dianion **2** (X = $O^\ominus$) is reversible and
2) $^1O_2$ is formed in the reverse process **3**→**2**.

Treatment of a 0.1 M solution of **1a** in tetrahydrofuran (THF) with 2 equivalents of *n*BuLi at −78 °C produced **2a** quantitatively (100% α-deuteration with D_2O). After oxygenation with $^3O_2$ and protonation with HCl at −78 °C, pure **6** was isolated in 80% yield[4]. Only *ca.* 5% of **1a** could be detected by ^{1}H-NMR. When a solution of **3a** in THF was warmed up over 2h to 25°, held there for 60 min and protonated with HCl, the yield of **1a** was *ca.* 12%, along with *ca.* 24% decomposition products of **3a** (benzophenone, benzilic acid).

Deprotonation of a 0.1 M solution of **6a** in THF with *n*BuLi or lithium diisopropylamide at −78 °C, followed by warming (see above), maintainance of this temperature for 60 min, and protonation with HCl gave *ca.* 13% **1a** along with *ca.* 30% benzophenone and benzilic acid. If a solution of 0.5 M tetramethylethylene (TME) in THF was added to the reaction mixtures from **1a** or **6a** before they were warmed up to 25 °C, after protonation with HCl, 6—8% **7** was obtained, and was identified by comparison with authentic material. Similarly under these conditions **6b** gave *ca.* 1.5% **1b** and 2.5% **7**.

7 is in fact a product of $^1O_2$ oxygenation since at 25 °C $^3O_2$, either alone or with *n*BuLi does not convert TME into **7**, but addition of **2a** to a solution of TME in THF at −60 °C through which $^3O_2$ was bubbled did. TME did not produce **7** on treatment with KO_2 at 25 °C.

Double deprotonation of **6b** under the above conditions produces 1.5% **1b** and 2.5% **7**. Since the direct reaction of **2** with $^3O_2$ to give the α-peroxy dianion **3** is spin forbidden, the oxygenation **2**→**3** must proceed stepwise *via* one-electron transfer to give the superoxide ion-enolate radical anion cage. Cage recombination and subsequent protonation lead to the α-hydroperoxy carboxylic acid **6** (Scheme 1). In competition with the formation of **3**, the radical cage can release $^3O_2$ (T route) or form $^1O_2$ (S route). Alternatively, the radical cage can be generated by double deprotonation of **6**.



Scheme 1.

In conclusion, the α-oxygenation of enolates provides a hitherto unprecedented potential source of $^1O_2$. In view of the serious pathological effects of $^1O_2$, it seems relevant to demonstrate its involvement in enzymatic autoxidations.

How Similar are Tropoquinones and Benzoquinones?**

By *Rolf Gleiter**, *Walter Dobler*, and *Mirjana Eckert-Maksić*

4,6-Cycloheptadiene-1,2,3-trione **1**[1] and 3,6-cycloheptadiene-1,2,5-trione **2**[2] are structural isomers which have been designated *o*-tropoquinone and *p*-tropoquinone due to their analogy with *o*-benzoquinone **3** and *p*-benzoquinone **4**. In order to determine *de facto* how far the similarity applies, we recorded the He(I) photoelectron (PE) spectra of **1** and **2** and compared those with the PE spectra of **3**[3] and **4**[4] (cf. Fig. 1).

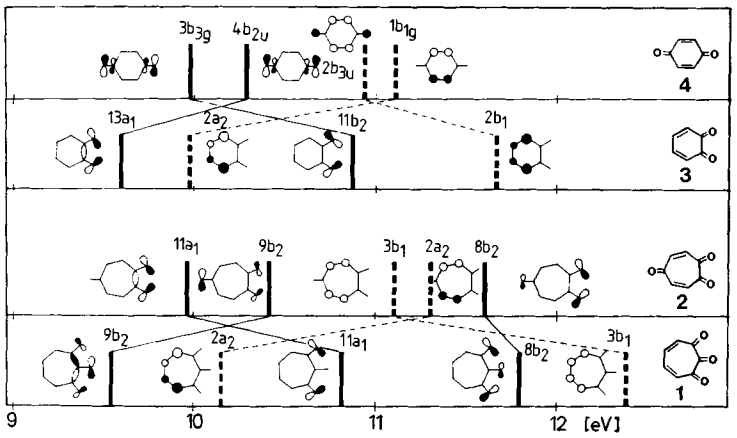

Fig. 1. Comparison of the first PE bands of **1**–**4**.

The PE spectra of the *p*-quinones **4** and **2** (cf. Fig. 1) contain closely spaced bands which correspond to ionizations from the n orbitals ($3b_{3g}$, $4b_{2u}$ for **4**, and $11a_1$, $9b_2$ for **2**) and the π orbitals ($2b_{3u}$, $1b_{1g}$ for **4**, and $3b_1$, $2a_2$ for **2**). In contrast, in the *o*-quinones **3** and **1** the bands corresponding to ionization from n orbitals ($13a_1$, $11b_2$ for **3**, and $9b_2$, $11a_1$ for **1**) and π orbitals ($2a_2$, $2b_1$ for **3** and $2a_2$, $3b_1$ for **1**) are widely separated from each other. The great similarity between benzoquinones and tropoquinones with respect to the position of the cationic states (Fig. 1) depends upon the fact that the relative energies and the wave functions of the n and π orbitals are comparable in both systems.

A similar conclusion can also be drawn from a comparison of the first excited states: a similar hypsochromic shift is observed between the 1st bands of the absorption spectra of **3** (16400 cm^{-1})[8] and **4** (21800 cm^{-1})[8] and the corresponding bands of **1** (17800 cm^{-1})[1] and **2** (22700 cm^{-1})[2].

Oxanickelacyclopentene Derivatives from Nickel(0), Carbon Dioxide, and Alkynes

By *Georg Burkhart* and *Heinz Hoberg**

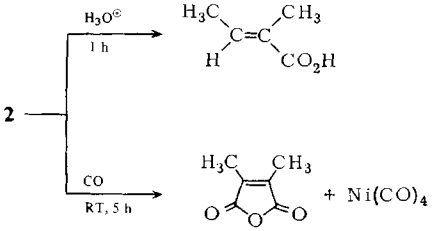
We have extended our investigations of the nickel(0) hetero-1,2-diene system[1–4] to carbon dioxide. We have found that nickel(0) in combination with the strongly basic chelating ligand *N,N,N',N'*-tetramethylethylenediamine (Me_4en) causes disproportion of CO_2 to $(Me_4en)Ni(CO_3)$ **1** and tetracarbonylnickel (cdt = 1,5,9-cyclododecatriene).

$$5\ (cdt)Ni + 8\ CO_2 \xrightarrow[RT,\ 72\ h]{+\ Me_4en} 4\ (Me_4en)Ni(CO_3) + Ni(CO)_4$$
1

In the presence of 2-butyne, disproportionation does not occur and the oxanickelacyclopentene derivative **2** is formed. [Yield 65%; m.p. = 170 °C (decomp.); IR(KBr): 1620 (νCO), 500 cm^{-1} (νNiO)].

$$(cdt)Ni + H_3CC{\equiv}CCH_3 + CO_2 \xrightarrow[RT,\ 48\ h]{+\ Me_4en} (Me_4en)Ni$$
2

Protonolysis of **2** led to 2-methylcrotonic acid, and reaction of **2** with carbon monoxide gave dimethylmaleic anhydride and tetracarbonylnickel.



Compounds of type **2** are potential intermediates in the nickel-catalyzed synthesis of 2-pyrone from alkynes and carbon dioxide[6].

A 1,2-Dithiolenenickel Complex with Different Substituents—a Novel Type of Mixed-Valence Compounds**

By *Arnd Vogler** and *Horst Kunkely*

Mixed-valence (intervalence (IT)) compounds[1] are distinguished, among other characteristics, by unusual bands in their absorption spectra. If the metal-metal interaction is weak, definite oxidation states can be assigned to the metals, and charge transfer (CT) electronic transitions from reduced to oxidized metal occur at relatively low energies. The associated IT absorption bands lie in the long wavelength spectral region, frequently in the near IR, and their position is solvent dependent.

Mononuclear metal complexes, in which a ligand occurs in different oxidation states ($L_{red}ML_{ox}$), can also be viewed as IT compounds. In this case too, CT electronic transitions from the reduced to the oxidized ligands should be possible. No IT absorption bands can be detected in complexes having catecholate and *o*-semiquinone as IT-ligands[2]. Mixed valence ligands are also present in the 1,2-dithiolene complexes of Ni^{II}, Pd^{II}, and Pt^{II}.

When R = R′ the ground state is described by the two resonance forms **A** and **B**[3]; both the highest occupied ($2b_{1u}$) and the lowest unoccupied ($3b_{2g}$) ligand orbitals—both are not degenerate—are delocalized over both ligands[3]. In consequence, the $3b_{2g} \leftarrow 2b_{1u}$ electronic transition has no CT contribution and the position of the associated absorption band is not dependent on the solvent. The complexes are not mixed-valence compounds.

The resonance form **B** (R = CN, R′ = C_6H_5) contributes strongly to the ground state of the complex

$[Ni\{S_2C_2(CN)_2\}\{S_2C_2(C_6H_5)_2\}]$ **1**

This assumption is consistent with the observation that homogeneous complexes with R = R′ = CN are considerably more difficult to oxidize than those with R = R′ = C_6H_5[4]. The donor orbital $2b_{1u}$ is more strongly localized on the ligand with R = CN, and the acceptor orbital $3b_{2g}$ more strongly localized on the ligand with R′ = C_6H_5. The electronic transition between both orbitals, therefore, possesses more CT character and the position of the associated absorption band should depend on the solvent.

1 is not stable, however, the anion $\mathbf{1}^{\ominus}$[4] is; in the latter compound the acceptor orbital $3b_{2g}$ is singly occupied, but the electronic transition $3b_{2g} \leftarrow 2b_{1u}$ is still possible. The typical, intense longwave absorption band (Fig. 1) is dependent upon the solvent. For the solvents chlorobenzene, chloroform, pyridine, dimethyl sulfoxide, and acetonitrile a linear plot of the wavenumber of the maximum *vs.* $1/n^2 - 1/D$[1] (n^2 and D are, respectively, the optical and static dielectric constants of the solvent) is obtained with a slope of 440 cm^{-1}. The solvent dependence is certainly much smaller than that of the "mixed" 1,2-dithiolatediimine complexes of Ni^{II}[5] and Pt^{II}[6], in whose ground state the resonance form with dithiolate and diimine as ligands almost exclusively occurs.

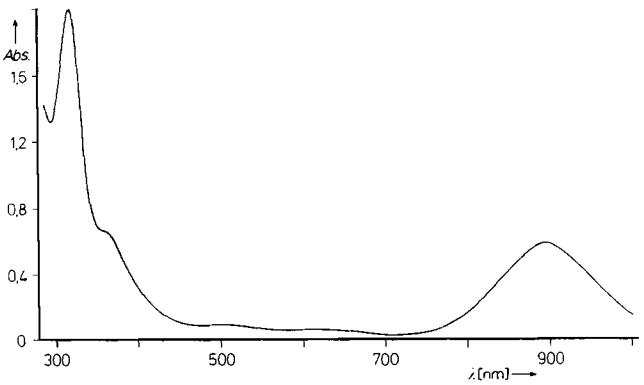

Fig. 1. Absorption spectrum of $\mathbf{1}^{\ominus}$ ($c = 6.75 \cdot 10^{-5}$ mol/L, CH_3CN, 1 cm cuvette).

Intervalence Transfer between Hexaaminecobalt(III) and Hexacyanoruthenate(II)**

By *Arnd Vogler** and *Josef Kisslinger*

A distinction is made between outer-sphere and inner-sphere redox reactions in thermal electron transfer between transition-metal complexes[1]; optical charge-transfer transitions (CT) between a reducing and an oxidizing metal center can be observed (intervalence transfer, IT)[2], either if both metals are bonded *via* bridging ligands in a dinuclear complex (inner-sphere) or are in close contact in separated metal complexes (outer-sphere), *e.g.* as ion-pairs[3]. Until now, inner- *and* outer-sphere IT-transitions in *one* system have never been observed. We have previously investigated the dinuclear complex $[(NH_3)_5Co^{III}(\mu\text{-}NC)Ru^{II}(CN)_5]^-$ **1**[4] and now describe the ion-pair $[Co(NH_3)_6]^{3+}/[Ru(CN)_6]^{4-}$, the mononuclear components of **1**.

Earlier attempts to study $[Co(NH_3)_6]^{3+}/[Ru(CN)_6]^{4-}$ in solution were thwarted by the fact that $[Co(NH_3)_6]_4[Ru(CN)_6]_3$, which is insoluble in all the usual solvents, immediately precipitates out. We have now found that supersaturated solutions, from which the difficultly soluble precipitate is first formed after several hours, are formed from mixtures of not too concentrated solutions ($c < 5 \times 10^{-3}$ mol/L) of $[N(C_2H_5)_4]_4[Ru(CN)_6]$ and $[Co(NH_3)_6]^{3+}(CH_3CO_2^-)_3$ in dimethyl sulfoxide (DMSO).

[*] Prof. Dr. A. Vogler, J. Kisslinger
Institut für Anorganische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Whereas the absorption spectra of both separated mononuclear complexes only contain both the ligand-field bands of $[Co(NH_3)_6]^{3+}$ above 300 nm ($[Ru(CN)_6]^{4-}$ first absorbs below 300 nm), the supersaturated solution of the ion-pair $[Co(NH_3)_6]^{3+}/[Ru(CN)_6]^{4-}$ in DMSO exhibits, apart from the ligand field band, (shoulder at 475 nm), a novel band with $\lambda_{max} = 360$ nm, which we assign to the IT transition from reducing Ru^{II} to oxidizing Co^{III} (Fig. 1). Since at concentrations between 5×10^{-3} and 1×10^{-3}

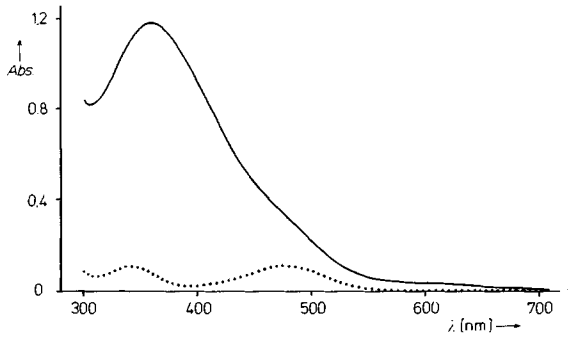

Fig. 1. Absorption spectrum of $[Co(NH_3)_6](CH_3CO_2^-)_3$ ($c = 2 \times 10^{-3}$ mol/L) alone (.....) and together with $[N(C_2H_5)_4]_4[Ru(CN)_6]$ (2×10^{-3} mol/L) (——) in DMSO.

mol/L the Beer/Lambert law applies, we presume that complete ion-pairing occurs; the maximum of the IT absorption has an extinction coefficient $\varepsilon = 580$. The width at half-height $\Delta\tilde{\nu}_{1/2} = 10870$ cm^{-1} is approximately a factor of 1.5 larger than the theoretical value calculated according to *Hush*[2]:

$$\Delta\tilde{\nu}_{1/2}(\text{theor.}) = (2310\,\tilde{\nu}_{max} - \Delta E)^{1/2} = 7085 \text{ cm}^{-1}$$

Thereby, $\tilde{\nu}_{max}$ is the wavenumber of the IT band at the maximum, and ΔE the energy difference of the system in thermal equilibrium, before and after the electronic transition:

$$[Co(NH_3)_6]^{3+}/[Ru(CN)_6]^{4-} \xrightarrow{\Delta E} [Co(NH_3)_6]^{2+}/[Ru(CN)_6]^{3-}$$

ΔE was calculated from the standard potentials of $[Co(NH_3)_6]^{3+/2+}$ ($E_0 = +0.11$ V)[5] and $[Ru(CN)_6]^{3-/4-}$ ($E_0 = +0.86$ V)[5]. A similar difference between theoretical and experimental widths at half-height has been observed for the IT bands of other systems[2].

It is astonishing that the absorption spectrum of the ion-pair is very similar to that of the dinuclear complex **1** (IT band: $\lambda_{max} = 375$ nm, $\varepsilon = 690$, $\Delta\tilde{\nu}_{1/2} = 7980$ cm^{-1})[4]. It therefore follows that the inner-sphere- and outer-sphere-IT interactions are of similar magnitude. The small long-wavelength shift of the IT band in **1** may be traced back to the short distance between both metal ions[2]. In the ion-pair, Co^{III} and Ru^{II} are separated by a cyanide and an ammonia ligand, and in **1** only by a cyanide ligand.

Irradiation ($\lambda = 366$ nm) of the ion-pair results, as with the bridged complex, in a photoredox reaction (quantum yield: $\phi = 0.034$):

$$[Co(NH_3)_6]^{3+} + [Ru(CN)_6]^{4-} \rightarrow Co^{2+} + 6\,NH_3 + [Ru(CN)_6]^{3-}$$

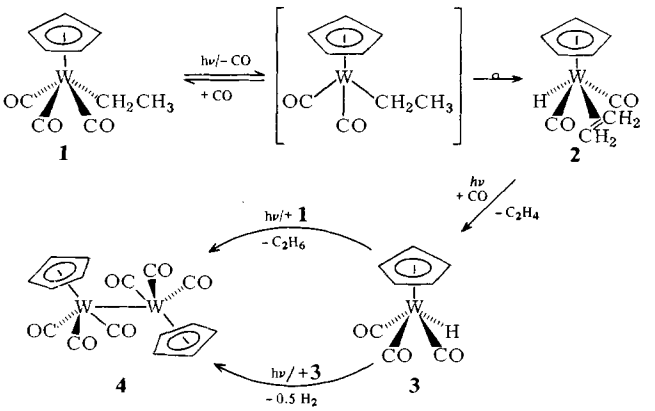
Preparation of an Ethylene(hydrido)tungsten Complex by Photo-Induced β-Elimination**

By *Helmut Guido Alt** and *Manfred Erwin Eichner*

The β-elimination reaction is considered to be a typical "decomposition" pathway for alkyl transition-metal complexes having alkyl ligands with more than one C atom. In many instances, dealkylations of this type are plausible thermal decompositions[1] and are presumed to occur in some photo-induced reactions[2]. Reversible dealkylation of some transition-metal complexes is involved in many important industrial processes with olefins, *e.g.* homogeneously catalyzed hydroformylation, hydrogenation, or isomerization. We have now succeeded in isolating the intermediates **2** and **3**, which are characteristic of β-elimination, by photolyzing the thermally stable ethyl complex **1** in solution.



The rate determining step is the reversible CO cleavage from **1**. In the presence of CO, a drastic retardation of the photolysis is observed; phosphanes and phosphites (L) form the substitution products $C_5H_5W(CO)_2(L)Et$[3]. Continuous removal of the cleaved CO by gaseous means (Ar, N_2, H_2) increases the fraction of **2**; the highest yield (6%) was obtained by passing ethylene through the solution. The ethylene(hydrido) complex **2** (decomp. 70 °C) was characterized spectroscopically [IR (pentane): ν(CO) = 1978 s, 1903 vs cm^{-1}; ^{1}H-NMR ([D$_6$] acetone, room temperature): $\delta = 5.43$ (C_5H_5, s, 5), 2.00 (C_2H_4, s, br, 4), −5.71 (*H*, s, br, 1); ^{13}C-NMR ([D$_6$]acetone): $\delta = 90.6$ (C_5H_5), 218.8 (*C*O), 21.1 (C_2H_4); MS: *m/z* 334 (M^+) relative to ^{184}W. The ethylene ligand—similar to that in $C_5H_5W(CO)_2(C_2H_4)CH_3$ and its indenyl analog[4]—exhibits intramolecular motion.

Proof that exclusive H_β migration is responsible for the reaction of **1**→**2** is provided by the photolysis of

[*] Priv.-Doz. Dr. H. G. Alt, M. E. Eichner

$C_5H_5W(CO)_3CD_2CH_3$. The work-up of this reaction gives only **3** and no $C_5H_5W(CO)_3D$. The formation of ethane is interpreted by the photo-induced reaction of **3** with **1**. The molybdenum analogue of **2** was observed by IR spectroscopy [ν(CO) = 1985 s, 1901 vs] in the photolytic degradation of $C_5H_5Mo(CO)_3Et$ in solution; however, no olefin(hydrido) complex could be isolated.

Procedure

2 (All operations were performed under Ar using anhydrous solvents): A solution of **1** (1300 mg, 3.6 mmol) in 250 mL of pentane was irradiated with an Hg high-pressure lamp (Hanovia L 450 W) for 10 min at −20 °C while ethylene was passed in. The filtrate of the suspension was placed on a frit covered with a 5 cm thick layer of silica gel. **1** and **2** were eluted at −10 °C using pentane. Fractional crystallization at −78 °C yielded **2** as brown crystals (75 mg ≙ 6%).

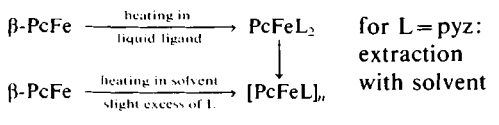
A Novel Type of Organic Conductor: One-Dimensionally Polymerized Phthalocyaninatoiron(II)**

By *Otto Schneider* and *Michael Hanack**

Phthalocyaninato(μ-pyrazine)iron(II), $[PcFe(pyz)]_n$, **1a**, the first phthalocyaninatoiron(II) polymerized *via* a bidentate bridging ligand, has an electric conductivity of up to 10^7 times higher than that of the monomer $PcFe(pyz)_2$[2]. Consistent with our new concept[3], increases in conductivity should also be achieved with other linear, π electron-rich bridging-ligands L by polymerization.

We obtained the polymers **1a-c** and the monomers $PcFe(bpy)_2$ **2** and bis(benzylisocyanide)phthalocyaninatoiron(II), $PcFe(bzNC)_2$, as follows:

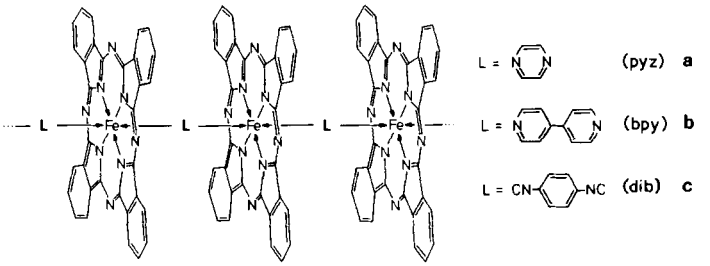


The products were characterized by thermogravimetry (TG)/differential thermal analysis (DTA) and by IR/FIR and UV/VIS/NIR measurements.

$$PcFeL_x \xrightarrow{\Delta} PcFe + xL \qquad (x = 1, 2)$$

According to TG/DTA measurements the thermal stability of these compounds increases along the series:

$PcFe(pyz)_2$ < $PcFe(bzNC)_2$ < $PcFe(bpy)_2$ **2** ≈ $[PcFe(bpy)]_n$ **1b** < $[PcFe(dib)]_n$ **1c** ≈ $[PcFe(pyz)]_n$ **1a**
(bz = $C_6H_5CH_2$)



1a-1c

The effect of the increase in conductivity is achieved without additional doping[19] and, in these new compounds, does not appear to be dependent, or if so only slightly, on the length of the linear, bidentate bridging ligands (Table 1).

Table 1. (Selected data). Electrical direct current dark conductivities measured on compressed pellets by the 2-probe technique (2 kbar) or (**1a** and **1c**) by the 4-probe technique (1 kbar).

	σ_{RT} [$\Omega^{-1}\cdot cm^{-1}$]		σ_{RT} [$\Omega^{-1}\cdot cm^{-1}$]
β-PcFe	$4\cdot10^{-11}$	**2** $PcFe(bpy)_2$	$5\cdot10^{-13}$
$PcFe(pyz)_2$	$2\cdot10^{-12}$	**1b** $[PcFe(bpy)]_n$	$2\cdot10^{-8}$
1a $[PcFe(pyz)]_n$	$2\cdot10^{-5}$	$PcFe(bzNC)_2$	$2\cdot10^{-12}$
$PcFe(bpy)_2\cdot1bpy$	$3\cdot10^{-12}$	**1c** $[PcFe(dib)]_n$	$2\cdot10^{-5}$

Doping **1a** with iodine leads to $[PcFe(pyz)I_2]_n$, whose conductivity is $1\times10^{-2}\ \Omega^{-1}\ cm^{-1}$.

α,β-Unsaturated Ketones by Cathodic Addition of Benzotrichloride to Ketones**

By *Michael Steiniger* and *Hans J. Schäfer**

Organic halides can be reductively added to activated double bonds to give cyclopropanes[1] or to carbonyl compounds to give alcohols[2] or olefins[3]. We have now found that α,β-unsaturated phenylketones (eq. 1) can be prepared in good yields in one step by cathodic reduction of benzotrichloride in the presence of ketones (Table 1). The main by-product of the reaction is benzylidene dichloride, the amount of which can, however, be reduced by addition of sodium hydride.

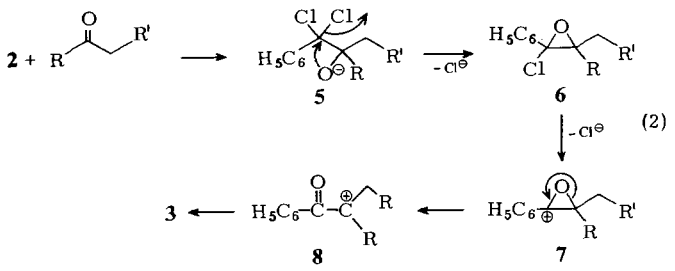
(1)

Table 1. (Selected data). Cathodic addition of benzotrichloride to ketones.

Ketone [a]	Products [b]	Yield [%] [c] 3	4
2-Butanone	2-Ethyl-1-phenyl-2-propen-1-one (40) (*E,Z*)-2-Methyl-1-phenyl-2-buten-1-one (60)	(48)	(40)
3-Methyl-2-butanone	2-Isopropyl-1-phenyl-2-propen-1-one (70) 2,3-Dimethyl-1-phenyl-2-buten-1-one (30)	59	16
3-Pentanone	(*E,Z*)-2-Ethyl-1-phenyl-2-buten-1-one	65 (34)	23 (59)
Acetophenone	1,2-Diphenyl-2-propen-1-one	58 (28)	29 (56)
Cyclopentanone	1-Cyclopentenyl phenyl ketone	64 (38)	22 (58)

[a] A solution of **1** (5–10 mmol) and ketone (10–20 mmol) in 50–70 mL of catholyte (0.5 M $LiClO_4$/tetrahydrofuran) is electrolyzed at 0 °C and −0.8 V (against Marple electrode) in a divided cell (cathode: Hg; anode Pt; diaphragm: G4 frit; anolyte: 0.2 M $LiClO_4$/dimethylformamide) until 100% conversion. [b] Characterized by elemental analysis and spectroscopic data; relative yields in brackets. [c] Current yield of isolated product with sodium hydride in the electrolyte (numbers in brackets without sodium hydride); **3** and **4** constitute 70–93% of the products.

The following reaction path seems plausible (eq. 2):



(2)

Reductive cleavage of **1** affords the anion **2**, which adds to the ketone to give **5**. The adduct cyclizes to the oxirane **6**, whose heterolysis leads to the intermediate cation **7**, which rearranges to **8**[5]. Subsequent deprotonation of **8** furnishes **3**. Benzylidene dichloride **4** may be formed by protonation of **2**, partly by H^+ ions from the anode compartment. An indication of **8** being formed as intermediate is afforded by the adducts obtained with norcamphor.

Table 3 (Selected data). Cathodic addition of benzotrichloride to methyl vinyl ketone and aldehydes.

Carbonyl compound [a]	Products (yield [%] [b])	Current yield of **4** [%]
Methyl vinyl-ketone	1,1-Dichlor-2-methyl-1-phenyl-3-buten-2-ol (12), *cis,trans*-2-Acetyl-1-chlor-1-phenylcyclopropane (24)	8
Pentanal	1,1-Dichlor-1-phenyl-2-hexanol (24), 1-Benzoyl-1-chlorpentane (23)	9
Isobutyr-aldehyde	1-Chlor-2-isopropyl-1-phenyloxirane (48) [e]	8

[a] Analogous to [a] in Table 1. [b] Current yield of isolated product. [e] Conversion into 1-benzoyl-1-chloro-2-methylpropane (15%) and 1-benzoyl-2-methyl-1-propanol (33%) on column filtration.

With methyl vinyl ketone and aldehydes, the reaction already terminates at **5** or **6** (Table 3).

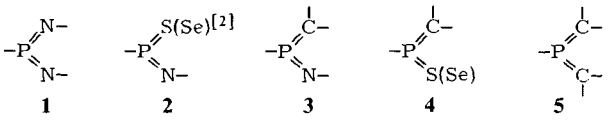
The First Bis(methylene)phosphoranes of Type R—P[=C(SiMe$_3$)$_2$]$_2$ with Tricoordinated Pentavalent Phosphorus**

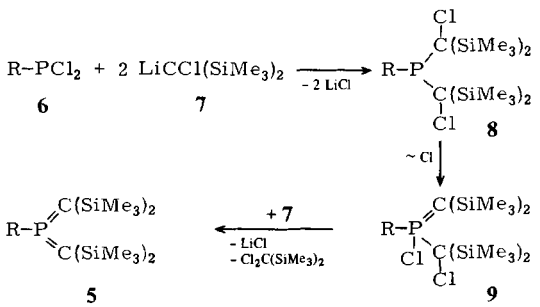
By *Rolf Appel**, *Johannes Peters*, and *Axel Westerhaus*

Dedicated to Professor Heinrich Puff on the occasion of his 60th birthday

In the search for unusual coordination numbers and novel bonding states of the phosphorus atom, stable phospha-alkenes, -alkynes[1] and three-coordinated phosphoranes of type **1–4**[2] have been found. Until now, attempts to synthesize the missing structural type **5** by oxidative addition of diazoalkenes to methylenephosphanes led only to the isomeric (PC_2)-phosphirane three-membered ring[3].



We have now been able to synthesize the compounds **5a–5c** for the first time by reaction of the lithiated chlorobis(silyl)methane **7** with the dichlorophosphanes **6a–6c**. Presumably the reaction proceeds according to Scheme 1.



Scheme 1.

The surprising 1,2 (C→P) chlorine migration **8**→**9** could be confirmed[4a] with model compound **10**, prepared from $(Me_2N)_2PCl$ and **7**.

[**] Low-Coordinated Phosphorus Compounds, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen. — Part 6: R. Appel, U. Kündgen, *Angew. Chem.*, in press.

The bisylides **5a–5c** can be purified by vacuum distillation. They distill as red oils, which crystallize as yellow crystals. Their constitutions are confirmed by correct elemental analyses, molecular weight determinations, NMR spectra[5], and for **5c**, which is chiral in the crystal, by X-ray structure analysis[4b].

The formation and surprising stability of the novel bisylides **5** can be explained by the combination of kinetically controlled chlorotropy with 1,2-dechlorination and stabilisation by tetrasilylation of both carbanoid centers.

Procedure

56.6 mL of a commercial 1.6 M solution of *n*BuLi in hexane (87 mmol) is slowly dropped at −110 °C into a mixture of 200 mL of tetrahydrofuran (THF), 20 mL of diethylether, 20 mL of *n*-pentane, and dichlorobis(trimethylsilyl)methane (20 g, 87 mmol). The mixture is stirred for 3 h and a solution of **6** (29 mmol) in 20 mL of THF is slowly added. After warming up to room temperature overnight, the volatile fraction is removed *in vacuo*. The residue is taken up in 20 mL of *n*-pentane, filtered, and fractionated by distillation at 0.001 torr [**5a**: 131 °C, **5b**: 136 °C, **5c**: 118 °C]; yield 65–70%.

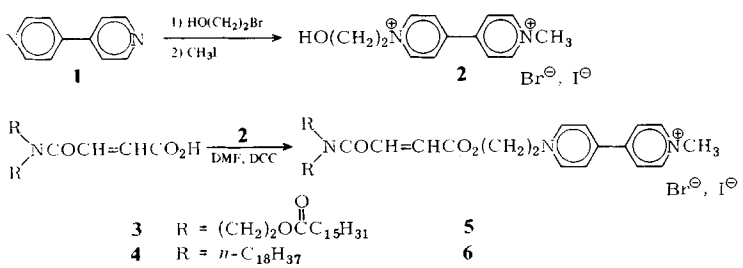
Chemically Dissymmetrical, Polymerized Surfactant Vesicles: Synthesis and Possible Utilization in Artificial Photosynthesis**

By *Pietro Tundo, Kazue Kurihara, Donald J. Kippenberger, Mario Politi,* and *Janos H. Fendler**

The present communication reports the synthesis of the first chemically dissymmetrical[1a], redox-active[1b], polymeric[2] surfactant vesicles.



3 R = $(CH_2)_2OCC_{15}H_{31}$ (O) **5**

4 R = n-$C_{18}H_{37}$ **6**

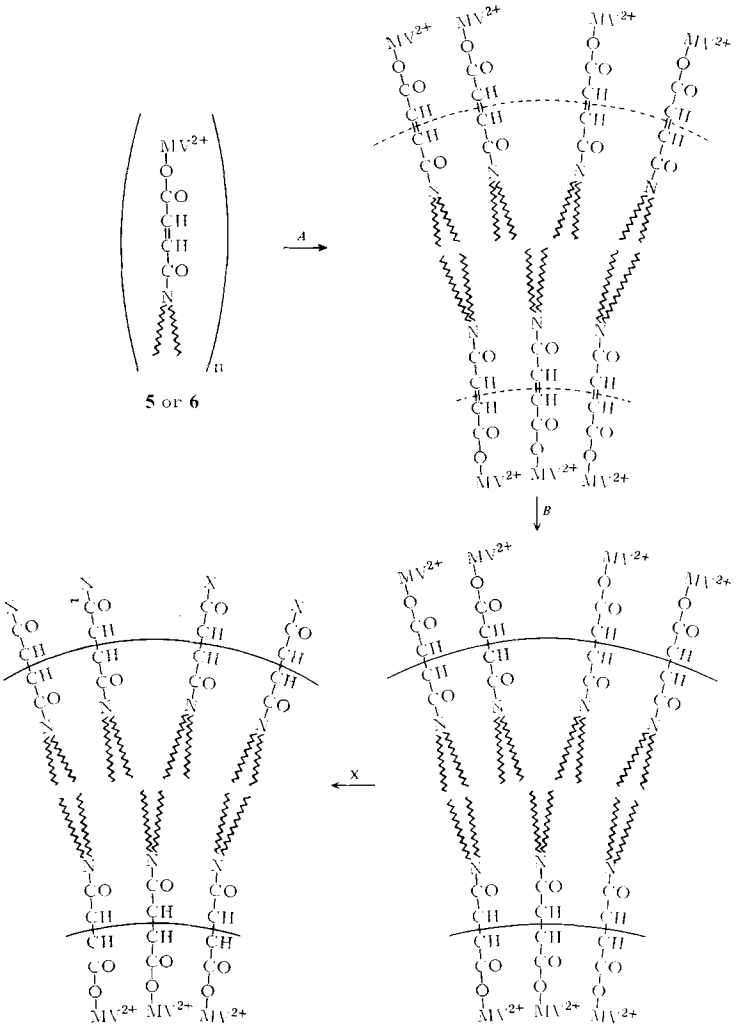
[**] Support of this work by the Department of Energy is gratefully acknowledged.

The vesicles, formed by sonication of **5** and **6**, have been characterized by electron microscopy, ^{1}H-NMR spectroscopy, and substrate entrapment[3]. Polymerization of the vesicles by azoisobutyronitrile (AIBN) or by irradiation occured slowly. Efficient copolymerization could be carried out, however, by adding acrylonitrile. Polymerization was followed by studying the disappearance of vinyl protons in the surfactants and in acrylonitrile by ^{1}H-NMR spectroscopy (200 MHz). Copolymerized vesicles remain stable in 25% EtOH.

Chemically dissymmetrical vesicles were prepared by reacting copolymerized vesicles with iminodiethanol (X in Scheme 1):



Scheme 1. X = iminoethanol; A = sonication; B = polymerization or copolymerization.

Photoexcitation of tris(2,2′-bipyridine)ruthenium perchlorate placed on the outside of the dissymmetrical vesicles **5** resulted in electron transfer from $Ru(bpy)_3^{2+}$ across the bilayers to give the long-lived reduced form of methyl viologen ($MV^{\oplus}$)[4]. This result is of interest in relation to the photosynthetic-analogous conversion of energy[5].

Procedure

2: **1** (25 mmol) was reacted with 2-bromoethanol (10 mmol) in 60 mL dimethylformamide (DMF) at 85 °C for 12 h. The insoluble disubstituted derivative was filtered off and the filtrate treated with diethyl ether, leading to the monoalkylated bipyridinium bromide in 77% yield

(m.p. = 195–197 °C, EtOH/Et_2O); 10 mmol in 50 mL DMF was added to a large excess of CH_3I; after 12 h at room temperature diethyl ether was added and the orange solid **2** filtered off; yield 92% (m.p. > 200 °C, MeOH).

5 and **6**: **3** (or **4**) (4 mmol) and **2** (3 mmol) in 10 mL of DMF and 5 mL of $CHCl_3$ were stirred for 12 h at 40 °C in the presence of 4.5 mmol of *N,N'*-dicyclohexylcarbodiimide (DCC). After cooling, the reaction mixture was filtered and **5** (or **6**) recovered by crystallization from MeOH. Yield: 40% **5**, 45% **6**; m.p. = 190 °C (decomp.) **5**; 180 °C (decomp.) **6**. All compounds gave correct ^{1}H-NMR spectra.

Vesicles: Chemically dissymmetrical vesicles were prepared as follows. 25 mg of **5** (or **6**), 3.6 mg of acrylonitrile, and 0.4 mg of AIBN (1 : 3 : 0.1) in 3 mL of water are sonicated for 9 min, and heated at 80 °C for 20 h. 68 mL of a 0.5 N aqueous solution of iminodiethanol (1.5 equiv.) was added. After 2.5 h at room temperature the solution was gel filtered on Sephadex (20–80 μ). Removal of viologen groups from the outer vesicle surface was demonstrated by the dithionite test[1b].

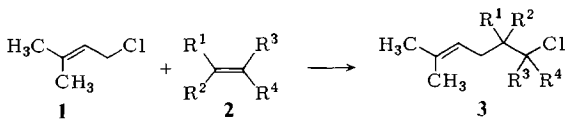
Cationic Prenylation of Olefins**

By *Herbert Klein, Anne Erbe,* and *Herbert Mayr**

Incorporation of the prenyl (3-methyl-2-butenyl) group into monoterpenes should provide an attractive synthetic route to sesquiterpenes. Previously, we have demonstrated[3] that Lewis acid catalyzed additions of alkyl halides to olefins may yield 1 : 1 addition products if the products solvolyze more slowly than the starting alkyl halides; otherwise, the alkyl halides are only converted to a small extent and polymerization of the alkenes takes place.

In this communication we report some consequences of this rule for the cationic prenylation of alkenes **2**, which are considered models for monoterpenes.



When prenyl chloride **1** is added dropwise to solutions of **2a–2j** and $ZnCl_2/Et_2O$ in CH_2Cl_2[4] at −78 °C, the 1 : 1 products **3a–3j** are obtained in moderate to good yields (Table 1). Both **2k** and ethyl vinyl ether **2l** polymerize under these reaction conditions, even if their concentration is kept small by simultaneous dropwise addition of the reactants to the catalyst solution. The ^{13}C-NMR spectra of the 1 : 1 products show that the addition reactions generally take place in a Markovnikov sense and that the prenyl cation is attacked almost exclusively at the CH_2 group.

Table 1. $ZnCl_2/Et_2O$ catalyzed additions of prenyl chloride to olefins **2**.

	Olefins **2**	Yield of **3** [%]
a	$H_2C{=}CHCH_3$	32 [a]

l	$H_2C{=}CHOC_2H_5$	—

[a] $C_xH_{15}Cl$-isomeric mixture. [b] Apart from *ca.* 10% hydride shift product. [c] *cis-trans*-Mixture.

The different behavior of **2a–2j** and of **2k** and **2l** can be rationalized by considering the relative solvolysis rates[7] of educts and products. Olefins **2a–2j** yield secondary and tertiary alkyl chlorides, respectively, which dissociate more slowly than **1**: the addition reactions, therefore, terminate at the 1 : 1 stage. On the other hand, **2l** and **2k** give dialkylphenylcarbinyl chlorides and α-chloro ethers, respectively. Because of their high dissociation rates, these intermediate products react faster with olefins than with **1**, thus leading to polymers.

In the reaction of **1** with propene **2a** only a relatively small yield of 1 : 1 products is isolated, although here the biggest difference in solvolysis rates between educt and product exists. Adducts **3** are not only potential alkylating agents, but can also be electrophilically attacked at the trisubstituted double bond by prenyl cations. This side reaction can usually be suppressed by using a three-to five-fold molar excess of olefin. For example, the yield of **3g** increases from 47 to 78% when **1** is added to **2g** in the molar ratio 1 : 4 instead of 1 : 1; the difference between the dissociation rates of **1** and **3g** is obviously sufficient to prevent reaction of **3g** with the excess olefin **2g**. Since the double bond of **3a** is considerably more nucleophilic than the double bond of propene **2a**, we only obtained a moderate yield of 1 : 1-product even when a ten-fold excess of propene was used.

These results demonstrate that problems arise with Lewis acid catalyzed additions of prenyl chloride to olefins of high and of low nucleophilicity; in one case electrophilic, and in the other case nucleophilic sequence reactions take place. 1,1-Dialkyl-, trialkyl-, and tetraalkylethylenes, simple analogues of many terpenes, however, possess intermediate nucleophilicity and can be monoprenylated in good yields.

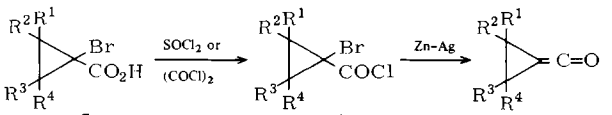
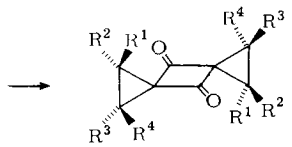
Carbonylcyclopropanes (Cyclopropylidenemethanones): Preparation and Steric Course of Cyclodimerization to Dispiro[2.1.2.1]octane-4,8-diones**

By *H. M. R. Hoffmann*, Jan Michael Wulff, Angela Kütz,* and *Rudolf Wartchow*

Substituted carbonylcyclopropane derivatives (cyclopropylidenemethanones) and their dimers have hitherto not been described, although the parent compounds **7a** and **8a** are known[1]. However, **7a** cannot be obtained on a preparative scale and derivatives of **7a** are not accessible[1,2]. Furthermore, dehydrochlorination of cyclopropanecarboxylic acid chloride with tertiary amines was not successful. Since a well-known approach to ketenes involves metal-induced dehalogenation of 2-halogenocarboxylic acid halides[5], we synthesized the 1-bromocyclopropanecarboxylic acids **5b—5d** as described by *Köbrich*[6]. Conversion of **5b—5d** into 1-bromocyclopropanecarboxylic acid chlorides **6b—6d** followed by dehalogenation with Zn/Ag[7] gave, after aqueous work-up, alkylated dispiro[2.1.2.1]octane-4,8-diones **8b—8d** as major products and, interestingly, some cyclic trimers.

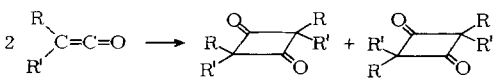


5 6 7



8a, $R^1 = R^2 = R^3 = R^4 = H$
8b, $R^1 = R^2 = H$; $R^3 = R^4 = Me$
8c, $R^1 = R^2 = R^3 = R^4 = Me$
8d, $R^1 = R^4 = H$; $R^2 R^3 = (CH_2)_4$

The structures of the colorless, crystalline cyclodimers **8b—8d** were secured spectroscopically; **8c** shows only one signal in the ^{1}H-NMR. spectrum ($\delta = 1.39$), and three singlets and one quartet in the ^{13}C-NMR spectrum. Hitherto, there have been no attempts to study the steric course of cyclodimerization of ketenes[5]. *A priori*, two isomeric cyclobutane-1,3-diones, the *syn*-dimer **10** and the *anti*-dimer **11** can be formed.



9 10 11

X-Ray crystal structure analysis (Fig. 1) shows that **7d** cyclodimerizes to the less encumbered *anti*-dimer **8d**, in which the two cyclohexane moieties are *trans* to each other. It is worthy of note that the cyclodimerization of **7b** to **8b** is again stereoselective (≥95%), and we assume that the *anti*-dimer **8b** is also formed preferentially in this reaction.

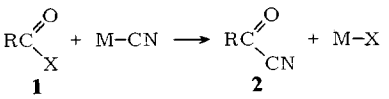
Synthesis of Acyl Cyanides from Acyl Iodides**

By *Klaus Haase* and *H. M. R. Hoffmann**

Acyl cyanides (α-ketonitriles) **2** are versatile synthetic intermediates[1], and are generally prepared by the reaction of carboxylic acid chlorides, carboxylic acid bromides, and occasionally carboxylic acid anhydrides with a variety of metal cyanides[1].



1 **2**

R = Alkyl, Aryl; X = Cl, Br, I, OCOR;
M = Na, Cu, Tl, Me_3Si, Bu_3Sn, H

We now report that acyl cyanides **2** can be prepared conveniently using the very reactive acyl iodides **1** (X = I)[2] and CuCN (Table 1). Two solvents, *i.e.* dichloromethane (method A) and acetonitrile (method B), were employed. While CuCN is partially soluble in CH_3CN, CH_2Cl_2 can be removed more easily on work-up of the reaction mixture. *Inter alia* we have successfully synthesized 2-oxo-3-phenylpropanenitrile **2e**, which cannot be

[a] Yields were not optimized. [b] 2,7-Dioxo-octanedinitrile. [c] Crude yield; F. Asinger, A. Saus, H. Offermanns, H. D. Hahn, *Justus Liebigs Ann. Chem. 691* (1966) 92.

prepared by the convential procedure[1c]. Similarly, α,β-unsaturated acyl cyanides such as 3,4-dimethyl-2-oxo-3-pentenenitrile have been obtained[3]; hereby, the olefinic double bond tends to shift out of conjugation under more forcing conditions.

Acyl cyanides **2** can also be rapidly prepared under mild conditions in a one-pot procedure starting from acyl chlorides, CuCN, and iodide ion[3].

Experimental Procedure

All reactions are carried out under an atmosphere of N_2, because acyl iodides **1** (X = I) are easily oxidized.

Method A: **2d:** CuCN (1.2 g, 13 mmol) was gently refluxed in CH_2Cl_2 (15 mL) and **1d** (1.4 g, 7.1 mmol) added in one batch. After being refluxed for 1–2 h, the mixture was filtered from CuI, and CH_2Cl_2 was removed at 0–5 °C. Kugelrohr distillation gave **2d** (420 mg, 62%)[4].

Method B: **2e:** A suspension of CuCN (1.2 g, 13 mmol) in anhydrous acetonitrile (100 mL) was warmed to 40–60 °C and **1e**[2] (2.5 g, 10 mmol) was added in one batch: after 2–3 min a yellow, almost clear solution resulted. The solution was stirred for 1 h, and the acetonitrile was removed using a rotary evaporator. The product was dissolved in CH_2Cl_2 and CuI filtered off. After evaporation of CH_2Cl_2 the residue was distilled twice (Kugelrohr, b.p. 100–120 °C/3 torr) giving pure **2e** (730 mg, 50%)[5].

BOOK REVIEWS

Nucleotide Analogs. Synthesis and Biological Function. By *K. H. Scheit.* John Wiley & Sons, New York 1980. xi, 288 pp., price £ 16.00.

The importance of nucleotides in biological processes has led to intense preoccupation with this class of natural substances. The base, sugar and phosphate portions are modified for a variety of purposes. One reason for the synthesis of nucleotide analogs is doubtless to use them in obtaining information about nucleotide metabolism and about the expression and replication of genetic information. Another driving force is the hope that once the mechanisms of expression and replication are known, nucleotide analogs may be designed for general use as chemotherapeutics, for example as interferon inducers or antiviral agents. A wealth of literature difficult to grasp other than by a specialist has been devoted to this theme, which has been studied for many years and is still growing today. This book fills a gap in this respect, since apart from an introduction to the subject, it presents an up-to-date review of the synthesis and properties of nucleotide analogs, taking into account the structure-function relationships. Nucleotides are described that are modified on or in the heterocycle, together with others with unusual *N*-glycosyl bonds and altered sugar radicals. Moreover, the book gives an account of the newer methods of synthesizing phosphate esters, nucleotide polyphosphates and nucleotides with modified phosphate radicals. The final chapter deals with the synthesis of chemically reactive and photoreactive derivatives, *e.g.* for use in affinity labeling and affinity chromatography. Ample references at the end of each chapter constitute an introduction to the primary literature. The many summary formula illustrations facilitate the reading of the text. Thus, a study of this book should be profitable both for those new to the field and for those who have been involved in it for years. For the first of these, it is a modern introduction, and for the latter, an up-to-date summary from which they should certainly derive stimulus for their own research.

Ullmanns Encyklopädie der technischen Chemie. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (deceased), *W. M. Wiegert* (deceased), *and E. Weise.* Vol. 19: Polyacryl-Verbindungen bis Quecksilber. Verlag Chemie, Weinheim 1980. 4th Edition, xvi, 672 pp., bound, DM 525.00.

This 19th volume of Ullmann's Encyclopedia[*] deals mostly with the polymers, which occupy over half of the volume; if the biopolymers are included (proteins with 67 pp., and polysaccharides, with 31 pp.), this rises to two-

[*] See *Angew. Chem. 92* (1980) 866; *Angew. Chem. Int. Ed. Engl. 19* (1980) 838.

thirds. There are two other classes of biopolymers, namely cellulose and starches, that are not only dealt with in this volume, but appear as cross-references to other volumes. Further articles in this volume relate to organic intermediate products (*e.g.* Propanediol, 8 pp.; Propionic acid and its derivatives, 9 pp.; Propylene, 8 pp.; Propylene oxide, 11 pp.; Propanol, 9 pp.; Propanolamine, 11 pp.; Pyridine and its derivatives, 27 pp.), to pharmaceuticals and their pre-products (Prostaglandins, 8 pp.; Purine and its derivatives, 5 pp.; Pyrazolone, 8 pp.; Pyrimidine and its derivatives, 3 pp.), to inorganic chemistry (Mercury, 29 pp.; Porcelain, 20 pp.), and to applied technologies (Pelleting compounds, 14 pp.; Powder metallurgy, 14 pp.; Pyrotechnics, 16 pp.). Of the polymers themselves, the polyolefins take up the most space with 60 pp., corresponding to their importance, followed by the polyurethanes with 41 pp., polystyrene including its copolymers with 31 pp., polyacrylates and polymethacrylates with 30 pp., and finally the polyesters with 28 pp. Under these entries for the individual classes of polymers, essentially only the manufacture and the chemical properties are dealt with, while anything to do with the application of the polymers is to be found under other entries, mainly in Volume 15 under Plastics or under special entries, for example Fibers, in which, *inter alia*, the application of polyesters as chemical fibers is dealt with. Special mention should also be made of the entry on Polymerization techniques (59 pp.), which gives a summary treatment of polymerization processes such as solution, suspension and emulsion polymerization. This review of an aspect of the technical production of polymers that is becoming increasingly important, fills a long-standing gap in this area, and raises the question whether it might not be worthwhile to expand this entry, in due course, into a monograph. It should also be mentioned that the entry on Proteins also gives an account of modern methods for the biotechnological preparation of individual proteins on the basis of unconventional carbon sources (ethanol, alkanes). Finally, it only remains to be said that this volume maintains the familiar high quality of Ullmann's Encyclopedia, which should be available in any chemical library on account of its information content.

The Norbornyl Cation: Prototype of a 1,3-Bridged Carbocation

By Cyril A. Grob*

The protracted discussion of whether 2-norbornyl cations are bridged or unbridged, *i.e.* nonclassical or classical, has lost most of its meaning, because these terms apply to the extremes of a graded series of structures. This is shown by a study of the solvolysis of stereoisomeric 6-substituted 2-norbornyl toluenesulfonates. Norbornyl and other bicyclic cations, to which nucleophiles have limited access, are stabilized by bridging between the cationic center and a saturated carbon atom in the β-position. Bridging is reduced by electron-attracting substituents and by bridging.

1. Introduction

During the past three decades numerous chemists have been engaged in attempts to elucidate the structure of the 2-norbornyl cation. Despite these efforts a stalemate rather than an agreement has been reached[**], the reiteration of the same positions having largely replaced the quest for new solutions. This development is deplorable, in that the issue is not relevant to norbornyl cations alone, but applies to the structure of carbocations in general, *i.e.* to important intermediates in organic and bioorganic processes. The experimental results described in the following article, although they partly confirm present hypotheses, open up fresh perspectives. The following summary of current views should help in understanding the nature of the problem.

2. The Problem

Thirty years ago *Winstein* and *Trifan*[3] reported the surprising results of their investigation of the reactions of optically active 2-*exo*- and 2-*endo*-norbornyl *p*-bromobenzenesulfonates, *i.e.* the "brosylates" **1** and **2**, in acetic acid. In these "acetolyses" the *exo*-brosylate **1** reacted 350 times faster than the *endo*-epimer **2**. Since the 2-*exo*-acetate **3** was obtained almost exclusively in both cases the *exo*-brosylate had evidently undergone substitution at C2 with retention, the *endo*-brosylate with inversion of configuration at C2. Furthermore, while the acetate derived from **1** was completely racemized, and hence consisted of equal amounts of the enantiomers **3a** and **3b**, the acetate from **2** retained some optical activity.

Winstein postulated a common cause for the higher rate of the 2-*exo*-brosylate **1** and for its conversion to racemic *exo*-acetate **3**, namely anchimeric assistance to ionization

of the OBs group by the antiperiplanar C1—C6 bond[*] with formation of the symmetrically bridged cation **4**. It was reasoned that attack by acetic acid, or by other nucleophiles, should take place on the *exo*-side of the cation **4** only, because of shielding by the partial bonds between C6—C1 and C6—C2.

Furthermore, since the atoms C1, C2 and C3 are held together by two electrons only and since C6 is (untypically) pentacoordinate, the cation **4** was called "nonclassical", following a suggestion by *Roberts*[4]. In contrast to **4**, "classical" carbenium ions, such as **6**, are well represented by the usual two-electron (Lewis) bonds. *Winstein*'s formula for the cation **4** was not novel; indeed a similar "nonclassical" structure **5** had been proposed ten years earlier by *Wilson et al.*[5] to describe the intermediate in the camphene hydrochloride/isobornyl chloride rearrangement.

The 2-*endo*-brosylate **2** does not fulfill the stereoelectronic requirement for effective participation of the C1—C6 bond because the latter and the C2—OBs bond are not antiperiplanar. According to *Winstein* the brosylate **2** therefore reacts at a normal rate to form the "classical" carbenium ion **6a**. He assumed, however, that it was subsequently converted into the bridged cation **4** because the derived *exo*-acetate **3** was extensively racemized.

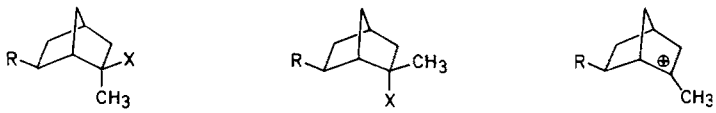
6a **6b** **6b**

Brown and others have shown since then that the norbornane molecule is preferentially attacked on the *exo*-side by numerous reagents[1]. Consequently, there no longer was a compelling reason to postulate a bridged cation **4** in order to rationalize the formation of the *exo*-acetate **3** from **1** and **2**. Indeed, if the unbridged cation **6a** underwent a rapid "degenerate" Wagner-Meerwein rearrangement[**] before being captured by solvent, racemic acetate **3** should also be produced. *Brown* attributed the 350-fold lower rate of the *endo*-brosylate **2** to sterically hindered departure of the OBs group due to the *endo*-H atom at C6 in the U-shaped structure. Furthermore, he assumed that the carbenium ions **6a** and **6b** were stabilized by inductive and hyperconjugative effects, which do not involve a significant change of molecular structure[1]. Since this time, the question "classical" or "nonclassical" has dominated the dispute about the norbornyl cation.

More recently *Jensen et al.*[6a] and *Traylor et al.*[6b] suggested an alternative explanation for the high k_t/k_2 ratio

7 **8**

based on hyperconjugation of the C1—C6 bond, which, in the 2-*exo*-brosylate **1**, is antiperiplanar with respect to the C2—OBs bond. In this way, part of the positive charge generated in the transition state **7** can be transferred to C6 without causing additional strain. But since the cation **8** derived from **1** possesses the same geometry as the unbridged cation **6**, the formation of racemic acetate **3** still requires a rapid and reversible rearrangement of **8** to its enantiomer. The rate of reaction of the *endo*-brosylate, however, was thought to be considerably reduced because the C1—C7 and the C2—OBs bonds are only approximately antiperiplanar and the delocalization of positive charge therefore less favorable.



9 **10** **11**

Many arguments have been advanced for and against these hypotheses[1]; however, there appears to be agreement that tertiary 2-norbornyl derivatives, such as **9** and **10** (R = H, X = *p*-$NO_2C_6H_4COO$) react *via* "classical" carbenium ions **11** and that the high *exo*/*endo* rate ratios, which are also observed in this series, are due to sterically hindered ionization of the 2-*endo*-nucleofuge X in **10**[1]. However, caution is also indicated here, as will be shown later.

The main problem, therefore, is how to explain high *exo*/*endo* rate ratios and how to describe the intermediate cations; *i.e.* are the unsymmetrical cations **6a** and **6b** energy minima on the energy hypersurface, and is the symmetrically bridged cation **4** the transition state for rearrangement, or does the cation **4** correspond to a single minimum of lower energy (cf. the unbroken curves in Fig. 1), as supporters of "nonclassical" carbocations assume.

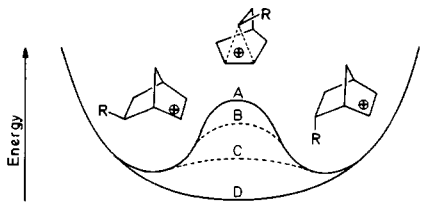


Fig. 1. Solvolysis of 6-substituted 2-norbornyl sulfonates Section from a plot of the potential energy *versus* the reaction coordinate. Full curves, A: double minima for two "classical" norbornyl cations **6**; D: Energy minimum for the hypothetical "nonclassical" cation **4**. Dotted curves B and C: Energy barriers (lowered due to 1,3-bridging) between the two energy minima corresponding to the classical norbornyl cations **6**.

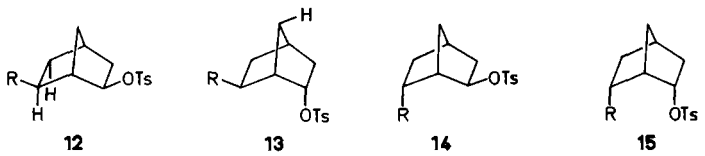
Possibly, carbocations conform to a continuous range of intermediate, partially bridged structures, as recently proposed by *Olah* and *Schleyer et al.*[7]. It is also conceivable that the height of the energy barriers in Figure 1 is influenced by substituents. In fact, studies of this kind have been carried out with 1-substituted[8] and with some 5-substituted norbornyl derivatives[9]. For various reasons it appeared more promising to study the effect of substituents at C6 on the rates and products of 2-norbornyl *p*-toluene-

[*] The term "anchimeric" normally describes the participation of a neighboring nucleophilic substituent, such as R_2N, HO, $COO^{\ominus}$, RS or a π-bond, in the ionization step. In this case the use of the term is extended to include the participation of a C—C single bond, *i.e.* so-called σ-participation.

[**] That is, a rearrangement leading to the same structure and therefore not detectable by the usual means.

sulfonates (tosylates) in all their stereoisomeric variations, namely **12**, **13**, **14**, and **15**, including the tertiary 2,4-dinitrophenyl ethers **9** and **10** (X = 2,4-$(NO_2)_2C_6H_3O$)[*]. These



12 **13** **14** **15**

studies should reveal whether substituents at C6, including hydrogen, exert a polar, a steric or a stereoelectronic effect or, possibly, a combination of these.

3. Special Features of Norbornane Derivatives

In order to understand the unique reactivity of 2-norbornyl sulfonates some features peculiar to their bicyclic structure should be recognized. Thus, the latter has a strain energy of *ca.* 17 kcal/mol[13] due to the fixed boat conformation and the C1—C7—C4 bond angle of 94°[12]. Furthermore, rearside *exo*- and *endo*-attack at C2 is sterically hindered by the *endo* hydrogen atoms at C5 and C6 and by the *syn* hydrogen atom at C7, respectively, as shown in **12** and **13**, R = H. Therefore, these compounds do not react with strong nucleophiles such as KOH and C_6H_5SNa[14] by the bimolecular substitution mechanism (S_N2), nor with less nucleophilic solvents[15] in a k_s process[**]. In fact they react by the unimolecular (S_N1) substitution mechanism, *i.e.* by a k_c process[***]. Since the positive charge generated in the transition state cannot be directly transferred to the solvent, it must be delocalized internally by induction, hyperconjugation or fragmentation[***]. Degenerate rearrangements and hydride shifts[17], commonly observed with secondary norbornyl derivatives, are a further consequence of sterically hindered nucleophilic solvation.

4. Polar or Steric Substituent Effects in Secondary Norbornyl Tosylates

Our previous studies of the influence of substituents upon the solvolysis rates of saturated compounds have shown their inductive (I) effect to be dominant[18]. In these studies the difference between the pK_a values of quinuclidinium perchlorate **16** (R = H) and its 4-substituted derivatives served as a measure of the I-effect; additional factors, such as steric, mesomeric and hyperconjugative effects cannot be significant in these saturated salts. Inductive substituent constants σ_I^q were thus derived using the equation

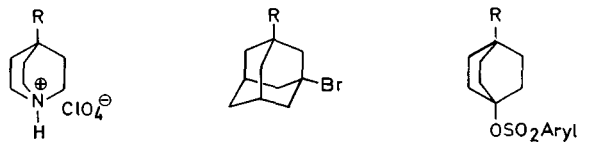
$$pK_a^H - pK_a^R = \rho\sigma_I^q \qquad [****]$$

in which the reaction constant ρ is unity by definition[19].

As follows from the Hammett-Taft relationship

$$\lg(k/k_0) = \rho\sigma_I^q$$

the logarithms of the rate constants ($\lg k$) for a series of substituted norbornyl tosylates should correlate linearly with the respective σ_I^q values if the rates are controlled by the I effect of the substituent only, as in the case of the pK_a values for the corresponding quinuclidines **16**. In addition, the reaction constant ρ measures the sensitivity of the rate to the polarity of the substituent. Thus, $\lg k$ for the unstrained 1-substituted 3-bromoadamantantes **17**[18b] and for the 4-substituted bicyclo[2.2.2]octyl sulfonates **18**[18d] correlate well with σ_I^q values, when R represents a neutral or a −I substituent, such as hydrogen, alkyl, halogen, $COOCH_3$ or NO_2. Clearly, these substituents control ionization rates by exerting their I effect.



16 **17** **18**

This applies also to the norbornyl tosylates **12** and **13** as shown by the plots in Figure 2. However, the reaction constant ρ of −2.0 for the *exo*-tosylates **12** is more than twice

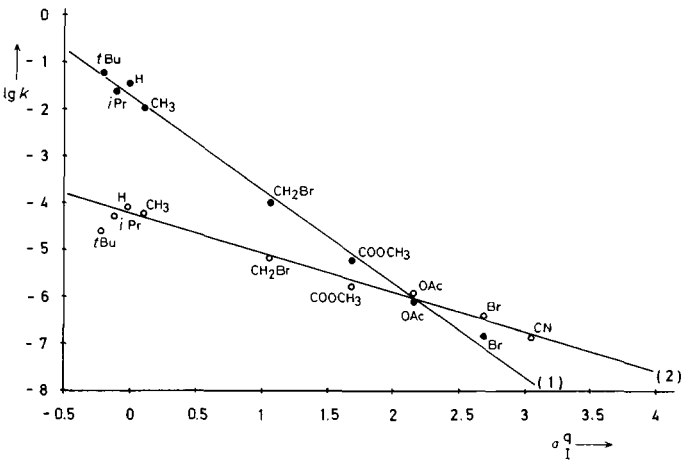


Fig. 2. Plots of lg *k* of the solvolysis of 6-*exo*-substituted 2-*exo*- (curve 1) and 2-*endo*-norbornyl tosylate (curve 2) **12** and **13**, respectively, against inductive substituent constants σ_I^q (80% ethanol, 70 °C).

as large as that of −0.86 for the *endo*-tosylates **13**. It follows that the I effect is transmitted far more strongly in the W-like conformation **12** than in the sickle-like conformation **13**[*]. Moreover, the correlation of $\lg k$ for **12** and **13** with the respective σ_I^q values eliminates the need to postulate an additional effect, such as CC-hyperconjugation (see Section 2). On the other hand, induction depends not only on the conformation of the transmitting chain of atoms,

[*] The more important results have been reported in communications [10]; for the preparation of some of the model compounds cf. [11].

[**] By definition [11] the solvent is involved as a nucleophile in a k_s process, not however, in a k_c process [16].

[***] As recently noted [14], k_c processes are anticipated for bicyclic and tricyclic compounds, in which the nucleofuge is adjacent to one of two bridgehead atoms.

[****] The superscript in the symbol σ_I^q indicates that *q*uinuclidines serve as the model.

[*] It was recently reported that the rates of 2-*exo*-norbornyl sulfonates are also more strongly affected by substituents at C1 [8] and at C5 [9] than the rates of the 2-*endo* epimers.

because the bromoadamantanes **17**, which have the same W-like arrangement as the norbornyl tosylates **12**, correlate with a reaction constant ρ of only -1.14. As will be shown in Section 6, the polarizability of the carbon chain also plays an important role.

The different sensitivity of rates to substituents at C6 in the series **12** and **13** causes the rate ratios k_{12}/k_{13} to decrease from 2388 for R = *t*-butyl to 0.37 for R = Br (Table 1). But since 6-*exo*-substituents do not substantially change the steric environment of the 2-*endo*-OTs groups in **13**, steric hindrance to ionization, as postulated by *Brown*[1], cannot be the cause of the high k_{12}/k_{13} rate ratio of 425 (Table 1) for the unsubstituted tosylates **12** and **13** (R = H).

Table 1. Rate constants for the solvolysis of some 6-*exo*-substituted 2-*exo*- and 2-*endo*-norbornyl *p*-toluenesulfonates **12** and **13**, respectively, in 80 vol.-% ethanol at 70.0 °C and k_{12}/k_{13} rate ratios [10b].

R	k_{12} [s^{-1}]	k_{13} [s^{-1}]	k_{12}/k_{13}
$(CH_3)_3C$	6.09×10^{-2}	2.55×10^{-5}	2388
$COO^{\ominus}$	7.04×10^{-2}	1.16×10^{-4}	607

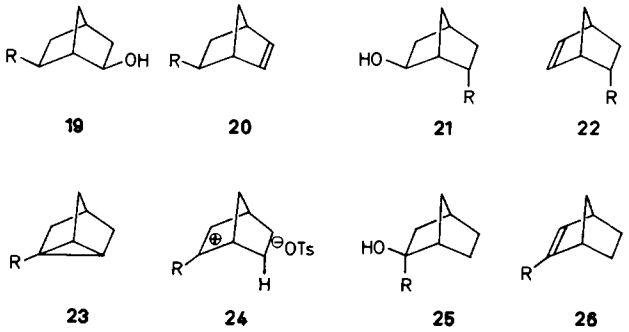
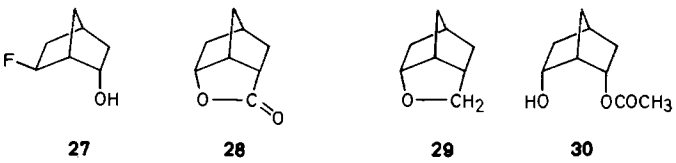
H	3.58×10^{-2}	8.42×10^{-5}	425
CH_2NH_2	8.84×10^{-3}	3.75×10^{-5}	236
CH_3	1.09×10^{-2}	6.02×10^{-5}	181
CH_2OH	5.97×10^{-3}	4.39×10^{-5}	136
CH_2Br	1.06×10^{-4}	6.75×10^{-6}	16
$CONH_2$	7.56×10^{-5}	7.12×10^{-6}	11
OH	6.05×10^{-4}	1.00×10^{-4}	6.0
$COOCH_3$	6.33×10^{-6}	1.73×10^{-6}	3.7
CN	1.23×10^{-7}	1.40×10^{-7}	0.88
$OCOCH_3$	8.14×10^{-7}	1.21×10^{-6}	0.67
F	7.21×10^{-7}	1.53×10^{-6}	0.47
Br	1.51×10^{-7}	4.06×10^{-7}	0.37

This conclusion is supported by comparison of the tosylates **12** and **13** (R = H) with their 6-*endo*-alkyl derivatives **14** and **15** ($R = CH_3$ or *t*-butyl). Thus, the methyl group in **14** ($R = CH_3$) reduces the rate by a factor of 6.4 due, probably, to steric hindrance to solvation. The 6-*endo* methyl group in **15** reduces the rate by almost the same factor, namely 7, although ionization should be more strongly hindered according to *Brown*'s hypothesis[1]. Introduction of the even bulkier 6-*endo*-*tert*-butyl substituent in **14** and **15** has a similar effect, *i.e.* a rate reduction of 1.1 and 4, respectively, compared to that of the unsubstituted tosylate. High $k_{2\text{-}exo}/k_{2\text{-}endo}$ ratios must, therefore, have another cause and will be discussed, following an account of the hydrolysis products of the tosylates **12** and **13** in 70% aqueous dioxane.

As a rule, epimeric tosylates **12** and **13** yield different amounts of the same products[20], as is frequently observed in solvolysis reactions involving stereoisomeric ion pairs as intermediates[*]. The products include unrearranged *exo*-alcohols **19** *and* olefins **20**, *and* smaller amounts of their rearranged isomers **21** *and* **22**, *and* the nortricyclene derivatives **23.** As is well known, solvolysis of the unsubstituted 2-*exo*-tosylate **12** (R = H) leads to extensive C6→C2 and C3→C2 hydride shifts, which are only detectable by isotopic labeling[17]. The 6-alkyl derivatives **12** ($R = CH_3$, *i*-C_3H_7, and *t*-C_4H_9) undergo C6→C2 hydride shifts leading to the more stable tertiary carbenium ions **24**, as evidenced by the formation of 50 to 80% of the tertiary alcohols **25** and the olefins **26.**



As mentioned in Section 2, it has hitherto been assumed that 2-norbornyl cations, whether "classical" **6** or "nonclassical" **4**, react almost exclusively on their *exo*-side with nucleophiles[1]. It was therefore surprising to find that several tosylates **12** and **13** led to large amounts of 2-*endo*-substitution products. Thus, the 6-*exo*-fluoride **12** (R = F) yielded 57% of the 2-*endo*-alcohol **27** and only 9% of the 2-*exo*-alcohol **19** (R = F), besides olefins. Furthermore, considerable amounts of *endo*-cyclized products, *i.e.* the lactone **28**, the ether **29**, and the *endo*-diol monoacetate **30** were obtained from both tosylates **12** and **13**, which contained the nucleophilic substituents $COO^{\ominus}$, COOH, $COOCH_3$, $CONH_2$, CH_2OH, and CH_3COO at C6[20]. The hypotheses outlined in Section 2 do not convincingly explain these results, especially in view of the fact that these tosylates have k_{12}/k_{13} ratios between 607 (for $COO^{\ominus}$) and 0.47 (for R = F) (Table 1).



The behavior of the tosylates **12** and **13**, in which R represents an electrofugal group, *i.e.* CH_2NH_2, CH_2OH, $CONH_2$, and $COO^{\ominus}$ is also noteworthy. During heterolytic fragmentation of the type

$$a—b—c—d—X \rightarrow a—b + c=d + X:$$

such groups are eliminated as electrofugal fragments $CH_2=\overset{\oplus}{N}H_2$, $CH_2=O$, $HN=C=O$, and CO_2, respectively[22]; hence they act as σ-electron donors. When present in 2-*exo*-tosylates **12**, these substituents cause a fourfold (CH_2NH_2) to hundredfold ($COO^{\ominus}$) increase in rate based on the inductive regression line in Figure 2[*]. Again, these accelerations are more pronounced in the *exo*-compounds **12** than in the *endo*-compounds **13**[10b]. The reason for the exalted polar effects of electrofugal substituents, which are also observed in the 3-bromoadamantane derivatives **17**[18b], is not yet clear. However, they appear to be connected with the increased polarizability of molecules un-

[*] Cf. [21] and references cited therein.

[*] These points have been omitted in Figure 2 for the sake of clarity.

dergoing reaction in a k_c process. It is also striking that substantial amounts of nortricyclene **23** (R = H) and of the corresponding acid **23** (R = COOH) are obtained from the sodium salts **12** and **13** (R = COONa) by 1,3-elimination of CO_2 (homofragmentation) and of a proton at C6, respectively, in addition to the expected hydroxy acids **19** and **25** (R = COOH).

31   **32**

Large accelerations by factors of 40 to 100 are also observed in the reactions of 2-*exo*-tosylates **12** in which R represents an n-electron donor such as CH_3S, CH_3O, HO, or $(CH_3)_2N$[20]. These compounds, however, undergo concerted and therefore accelerated fragmentation[22] to the salts **31**, which are immediately hydrolyzed to (3-cyclopentenyl)acetaldehyde **32**.

5. Tertiary 2-Norbornyl Derivatives

As mentioned in Section 2, it has hitherto been accepted that tertiary 2-norbornyl derivatives **9** and **10** (R = H) react *via* "classical" carbenium ions **11**[*], which do not require intramolecular bridging because of their enhanced stability. Likewise, it seems to be agreed that high k_9/k_{10} rate ratios, also observed in the tertiary series (Table 2), are due to hindered ionization of the *endo*-epimer **10**[1]. However, studies of 6-substituted 2,4-dinitrophenyl ethers **9** and **10**

 **33**

 **34**

 **35**

(X = 2,4-$(NO_2)_2C_6H_3O$) provide reasons to doubt these assumptions [10c]. Thus, not only are *exo*-alcohols **33** obtained exclusively, besides the olefins **34** and **35**, upon hydrolysis

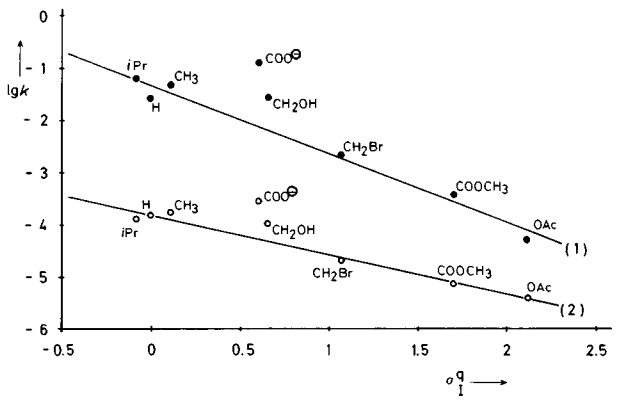


Fig. 3. Plots of lg *k* for the solvolysis of 2-*exo*- (curve 1) and 2-*endo*-2,4-dinitrophenyl ethers (curve 2) of 6-*exo*-substituted 2-methylnorbornanols, **9** and **10**, respectively, against σ_I (80% ethanol, 100°). Points for $COO^{\ominus}$ and CH_2OH are not included in the regression.

[*] The tertiary 2-methyl-2-norbornyl cation **11** (R = H) is an exception, in that *Paasivirta* [30] proposed a "semiclassical" structure analogous to **40** in order to explain the exclusive *exo*-addition of formic acid.

of **9** and **10**, indicating exclusive *exo*-attack of solvent on the intermediate tertiary cations **11**, but it is also significant that lg*k* for the *exo*- and *endo*-ethers, **9** and **10**, respectively, again correlate linearly with the corresponding inductive substituent constants σ_I (Fig. 3). Hence, ionization is also controlled by the I effect of R, and again more strongly in the *exo*-series **9** than in the *endo*-series **10**. This is reflected in the ρ values of -1.30 and -0.75, respectively, which are, as expected, lower than those for the secondary tosylates **12** and **13**.

The different degrees to which rates are controlled by 6-*exo*-substituents in the series **9** and **10** again lead to varying k_9/k_{10} ratios. These approach unity as the $-$I effect of R increases (Table 2). Thus, once again steric hindrance to ionization of the *endo*-2,4-dinitrophenyl ethers **10** cannot be the reason for high k_9/k_{10} ratios. Furthermore in these

Table 2. Rate ratios for 2-*exo*- and 2-*endo*-dinitrophenyl ethers **9** and **10** (X = 2,4-$(NO_2)_2C_6H_3$) in 80 vol.-% ethanol at 100 °C [10c].

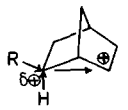
series the electrofugal groups $COO^{\ominus}$ and CH_2OH also exert exalted polar effects, as shown by the deviations of the respective points from the inductive regression line in Figure 3.

6. Inductive Effects and 1,3-Bridging

An interpretation of *exo*/*endo* rate ratios is essential for an understanding of the nature of norbornyl cations. As shown above, these ratios are controlled by the I effect of substituents at C6, and this effect is transmitted more strongly in the secondary series and in the *exo*-tosylates than in the tertiary series and in the *endo*-tosylates. It is particularly important that a linear correlation is observed not only between the lg*k* values for the secondary *exo*- and *endo*-tosylates **12** and **13** and for the tertiary *exo*- and *endo*-ethers **9** and **10**, respectively, but also between the lg*k* values for the secondary and tertiary series[10c]. This fact indicates that the transition states for these reactions differ quantitatively rather than qualitatively. In view of *Winstein*'s hypothesis, as presented in Section 2, the question must therefore be raised whether induction and bridging, hitherto regarded as unrelated, are in fact interrelated phenomena.

As is well known, conventional valence bond symbols, such as in **12** and **13**, are inaccurate and frequently misleading representations of the actual electron distribution in a molecule. Thus, in norbornane the electrons which form the C6—C1—C2 bonds are not confined to the regions between consecutive atoms; they also occupy much of the space between alternate atoms, *i.e.* C6 and C2. This is made clear by space-filling models which take account

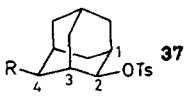
of covalent radii. Provided that the substituents are electron donors, the electrons around C6 will tend to move towards a cationic center at C2, as illustrated by the arrows in **36**. A bonding interaction between C6 and C2, *i.e.* 1,3-bridging, as shown in **40** (Scheme 1) will result, the



36

strength of which should vary according to the relative electronegativities of R and of the cationic C2. 1,3-Bridging should be stronger in a free carbocation than in a contact ion pair, such as **40**, because the anion stabilizes the cation. Strong bridging should also occur in free carbocations generated in non-nucleophilic solvents, as shown by the work of *Olah*[2b]. But it should also occur in k_c processes, where a neighboring carbon atom assumes the function of a nucleophilic solvent and thereby becomes pentacoordinate, while the cationic center becomes tetracoordinate, as in **40**.

A strong indication that donor induction and bridging are related is the increase in *endo*-substitution which is observed in the solvolysis of **12** in the sequence CH_2OH (0%), $COOCH_3$ (28%), CH_3COO (41%), F (57%), *i.e.* with the −I effect of R[19][*]. Electron-attracting (−I) substituents thus hinder bridging and thereby facilitate *endo*-attack at the ion pair **38** (Scheme 1).



37

A further indication for the connection between induction and bridging is provided by a comparison between the tosylates **12** and 4-substituted 2-adamantyl tosylates **37**, which possess the same W-like conformation of the R—C—C—C—OTs chain and which likewise react in a k_c process[23]. In contrast, however, to the norbornyl tosylates **12**, which are already strained, the adamantyl tosylates **37** are unstrained until bridging between C2 and C4 deforms the derived cations. This appears to be one of the reasons why **37** (R = H) reacts almost 7000 times more slowly than **12** (R = H) (Table 4), and why, unlike the latter, it shows little tendency to rearrange[24]. More important is the fact that the reaction constant ρ for the solvolysis of the tosylates **37** in 80% ethanol is only −0.82, *i.e.* much smaller than for the tosylates **12** (−2.0). Hence, the less bridging and rearrangement, the less the rate depends on the inductive effect of the substituent. Induction and bridging do indeed appear to be related.

7. Epimeric or Enantiomeric Norbornyl Cations

The reaction rates of 6-*endo*-substituted 2-*exo*-tosylates **14** are almost as dependent upon the I effect of R as the rates of their epimers **12**. This follows from the somewhat smaller ρ value of −1.76 and the k_{12}/k_{14} ratios which are close to one (Table 3). The directional effect of the substituent at C6 is therefore small. However, hydrolysis of C6-epimeric tosylates **12** and **14**, where R = H or alkyl, leads

Table 3. Rate ratios for 6-*exo*- and 6-*endo*-substituted 2-*exo*-norbornyl *p*-toluenesulfonates **12** and **14**, respectively, in 80 vol.-% ethanol at 70 °C [20b].

R	k_{12}/k_{14}

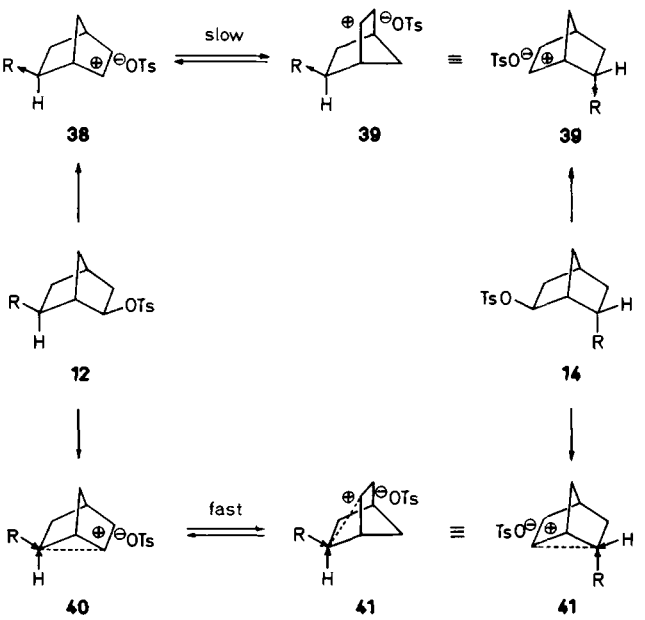
F	1.54
Br	0.77
CN	2.84

to *identical* mixtures of products, whereas *different* mixtures of products are obtained when R = CH_2Br, F, Br, and CN[20b]. This proves that the products have a common origin in the first case, but are formed from different intermediates in the second. The latter must be the C6-epimeric ion pairs **38** and **39**[*] which react faster with water than they equilibrate (Scheme 1). Therefore, −I substituents not only hinder bridging, they also reduce the rate of the Wagner-Meerwein rearrangement. It is, therefore, appropriate to call these norbornyl cations "classical".



Scheme 1.

It is conceivable that the epimeric 6-alkyl 2-*exo*-tosylates **12** and **14**, which yield identical product mixtures, ionize directly to the doubly bridged "nonclassical" cations **42a** and **42b**, for these are enantiomers. On the other hand, it seems improbable that an overall asymmetric cation, such as the 6-*tert*-butyl derivative, would be symmetrically bridged, as in **42** (R = *t*Bu). This is more likely to be the

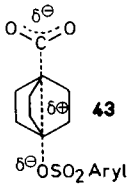
[*] In a strict sense *endo* attack of water at C2 should not be compared to *endo*-cyclization by nucleophilic substituents at C6, because the latter is a favored intramolecular process.

[*] Only one possible enantiomer is shown.

case when R = H. But the fact that the k_{12}/k_{13} ratio is 425 when R = H and 2388 when R = *t*Bu (Table 1) militates against this possibility; because if symmetry were to confer special stability to carbocations, the k_{12}/k_{13} ratio should be larger for R = H. But there are further reasons to reject symmetrical bridging even for the unsubstituted norbornyl cation, such as the fact that **12** (R = H) correlates equally well with σ_1^+ as do its 6-substituted derivatives (Fig. 2) and the fact that nortricyclene **23** (R = H) is approximately twice as strained as norbornane[25]. A considerable part of this strain would be conserved in the cation **42**, even though the partial bonds are longer than in **23**. The results for the tosylates **12**, **13**, **14** and **15**, therefore, do not make it necessary to postulate a different kind of bonding for the unsubstituted norbornyl cation.

The alternative to symmetrical bridging is asymmetrical or 1,3-bridging, as exemplified by the cations **40** and **41** which, by graded bonding between C6 and C2, merge with the unbridged cations **38** and **39**[10e]. The formulations **40** or **36** are preferred to *Winstein*'s "nonclassical" formula **42**[3] because they convey that the C2—C6 bond is longer and therefore weaker than the C1—C6 bond and that donor substituents at C6 enhance 1,3-bridging and hence ionization rates. A large part of the positive charge generated in the transition state is transferred to these substituents, as evidenced by the enormous increase in reaction rate by a factor of 10^5 to 10^6 when a halogen atom at C6 in **12** is replaced by *tert*-butyl (Table 1). The positive charge is also delocalized to other adjacent atoms. However, as shown by *Brown et al.*[26], less charge is transferred to C1 than is implied by formula **42**.

C atom participation should not be restricted to 1,3-bridging, as in **40**, as long as it can take place at the rear of an incipient cationic center in a k_c process. This is exemplified by the abnormally large rate increase which results when hydrogen at C4 of the bicyclo[2.2.2]octyl sulfonate **18** is substituted by COONa and which can be attributed to weak 1,4-bridging, as expressed in **43**[18d][*].



1,3-Bridging is very strongly in evidence in the solvolysis of the sodium salt of the 2-*exo*-tosyloxycarboxylic acid **12** (R = COONa), which reacts 100 times faster than the rate calculated on the basis of the σ_1^+ value for $COO^{\ominus}$[20a]. The k_{12}/k_{13} ratio of 607 (Table 1) indicates that ionization is strongly assisted by electron donation from the electrofugal $COO^{\ominus}$ group. As foreshadowed by the bridged structure of the intermediate **40** (R = COONa), more than 20% of the nortricyclenes **23** (R = H and COOH) are formed by elimination of CO_2 and a proton, respectively.

When the solvolysis of 2-*exo*-norbornyl tosylate **12** (R = H) is carried out in the presence of KOH the yield of nortricyclene **23** (R = H) is 40%, while the 6-*endo*-cyano derivative **14** (R = CN) yields 80% of **23** (R = CN) even in the absence of base. However, the orientation of the C6—H bond has little effect on the ionization rate, as the nearly equal rates of 6-*exo*- and 6-*endo*-substituted norbornyl tosylates **12** and **14**, respectively, show.

1,3-Bridging can reduce the energy barrier to interconversion of the cations **40** ⇄ **41** (Fig. 1) to the point where their equilibration becomes faster than their capture by solvent. An energy barrier of *ca.* 2.5 kcal/mol corresponds to a skeletal vibration of frequency 1000 cm^{-1}[*] in which case the cations should behave like enantiomers.

8. *exo*/*endo* Rate Ratios and 1,3-Bridging in Bicyclic Compounds

The results described so far indicate that induction by donor substituents at C6 leads to 1,3-bridging. They do not, however, explain why the k_{12}/k_{13} ratio for the unsubstituted tosylates **12** and **13** (R = H) is so high, namely 425 (Table 1), for both epimers contain a methylene group in the β-position to the incipient cationic center. A steric effect was ruled out in Section 4. The question therefore arises whether a stereoelectronic effect is responsible for the different reactivity of these epimers.

Winstein assumed that in the antiperiplanar arrangement of the *exo*-brosylate **1** the electrons forming the C1—C6 bond are far more effective in assisting ionization than in the *gauche* arrangement which is present in the *endo*-brosylate **2**[3]. Apparently, he did not envisage the participation of the C1—C7 bonding electrons in the ionization of **2**, presumably because they deviate from the plane comprising C1, C2, and OBs by *ca.* 30°. It was therefore essential to test whether this deviation, *i.e.* a stereoelectronic factor, provides a satisfactory explanation for the k_{12}/k_{13} ratio of 425. This could only be accomplished by studying other bicyclic tosylates.

Molecular models of the epimeric bicyclo[3.2.1]oct-8-yl tosylates **44** (Table 4) show that neither the *exo*-C—OTs nor the *endo*-C—OTs bond[**] deviates significantly from the planes comprising the C1—C2 and C4—C5 bonds in the *exo*-tosylate, the C1—C7 and C5—C6 bonds in the *endo*-tosylate. Despite their stereoelectronic equivalence the epimeric tosylates **44** react at widely different rates, the k_{exo}/k_{endo} ratio being 1125 at 130 °C[10f][***], *i.e.* 562 per antiperiplanar CC-bond. Since the k_{exo}/k_{endo} ratio for the epimeric 2-norbornyl tosylates **45** is 425 at 70 °C (and 550 at 40 °C) the conclusion must be that a stereoelectronic

[*] A less satisfying explanation is offered in [18d].

[*] From his study of the deuterium isotope effect on the ^{13}C-NMR spectrum of the norbornyl cation under stable ion conditions, *Saunders* has concluded that the energy barrier is less than 3 kcal/mol and that a static, symmetrical structure is consistent with this result [27].

[**] In formulas **44**—**47** (Table 4), *exo* and *endo* denote the corresponding OTs and OH groups.

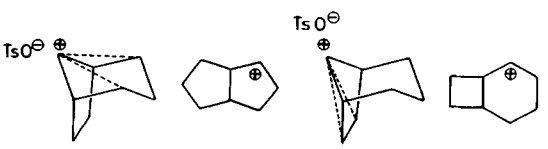
[***] According to *Foote* and *Woodward* [28] k_{exo}/k_{endo} for acetolysis of the tosylates **44** is 1500 at 100 °C.

Table 4. Strain energies of some bicyclic *p*-toluenesulfonates and the k_{rel} values, k_{exo}/k_{endo}, rate ratios of their solvolysis in 80 vol.-% ethanol at 40 °C (**44** at 130 °C).

Compound		k_{rel}	$\frac{k_{exo}}{k_{endo}}$	Strain energy [13] [kcal/mol]	
	44	*exo* 5.1 *endo* $4 \cdot 10^{-3}$	1275	12.1	
	45	*exo* 6790 *endo* 12.4	548	17	
	46	*exo* 400 *endo* 31	13	12.1	
	47	*exo* 523 *endo* 361	1.45	15	
	48	1046	1	13	
	49	1		7	

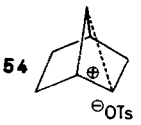
factor alone does not account for a high *exo/endo* rate ratio.

The additional factor, however, could be differential angle strain attending 1,3-bridging in the ionization of an epimeric pair of tosylates, such as *exo*- and *endo*-**44** or **45**[10f]. Thus, the bridged cation **52** from the *endo*-tosylate **44** is much more strained than the bridged cation **50** from the *exo*-tosylate **44.** The former will therefore be only weakly bridged. Rearrangement of these cations should yield the cations **51** and **53,** respectively, the latter being again more strained due to the cyclobutane ring. The *exo*-tosylate **44** actually leads to 86% of alcohols and olefins derived from the bicyclo[3.3.0]oct-2-yl cation **51,** beside 14% of *exo*-alcohol **44** from the unrearranged cation **50.** On the other hand, the *endo*-tosylate **44** does not yield products derived from the rearranged and far more strained bicyclo[4.2.0]oct-2-yl cation **53.** In fact, they are also derived from **50** (38%) and **51** (62%). The fact that the more reactive *exo*-tosylate **44** cannot form a symmetrically bridged "nonclassical" ion of the *Wilson-Winstein* type **42** deserves special attention.



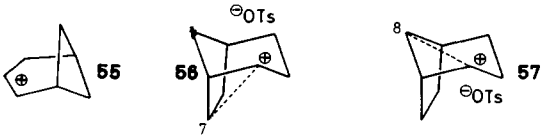
50 **51** **52** **53**

Large differential bridging strains are apparent in the ionization of 2-*exo*- and 2-*endo*-norbornyl tosylate **45.** Thus, bridging of C6 in the *exo*-ion pair **40** (R = H, Scheme 1) causes only slight additional strain, which remains constant in the subsequent degenerate rearrangement to **41.** On the other hand, bridging of C7 in the *endo*-ion pair **54,** and especially its rearrangement to the bicyclo[3.1.1]oct-2-yl cation **55,** would entail a considerable increase of angle strain due to formation of the cyclobutane ring. It is therefore not surprising that none of the products (mostly 2-*exo*-norbornanol[20a]) derive from **55**[10f].

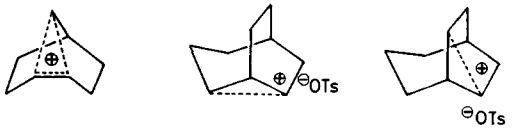


54

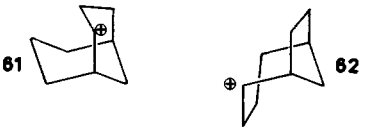
In this view the rates of epimeric and stereoelectronically equivalent compounds should be similar in cases where bridging strains are comparable. This is exemplified by the 2-*exo*- and 2-*endo*-bicyclo[3.2.1]octyl tosylates **46,** the *exo/endo* rate ratio of which is only 13 (Table 4). Bridging of C7 in the *exo*-tosylate leads to the cation **56,** in which the seven-membered ring is contracted to a *quasi* six-membered ring. On the other hand, bridging of C8 in the *endo*-tosylate leads to the cation **57,** in which the six-membered ring is contracted to a slightly more strained five-membered ring. The latter example is of special significance because symmetrical bridging would lead to the totally symmetric cation **58.** Being "nonclassical" in the *Wilson-Winstein* sense, it should be exceptionally stable and therefore be formed more rapidly. In fact the *endo*-tosylate **46** reacts 13 times more slowly than the *exo*-epimer, which cannot form **58** directly. Hydrolysis of the *exo*-tosylate **46** to the *exo*-alcohol **46** occurs with retention and is accompanied by rearrangement to bicyclo[2.2.2]oct-2-yl tosylate **48** and the formation of the corresponding alcohol **48.** The *endo*-tosylate **46,** however, yields 92% of the *endo*-alcohol with retention, besides 8% of the *exo*-alcohol with inversion[10f][*].



55 **56** **57**



58 **59** **60**



61 **62**

The epimeric 6-*exo*- and 6-*endo*-bicyclo[3.2.2]nonyl tosylates **47** (Table 4) are again stereoelectronically equivalent. Moreover, models do not indicate different bridging strains in the cations **59** and **60.** It is therefore not surprising that the *exo/endo* rate ratio is only 1.45. Again, it is the larger *exo*-bridge which provides stronger assistance to ionization. The products of both tosylates **47,** *i.e.* alcohols

[*] The acetolysis of the epimeric tosylates **46** was previously studied in detail by *Goering et al.* [29].

and olefins, derive from the rearranged cations **61** and **62**. Finally, the stereoisomers of bicyclo[2.2.2]oct-2-yl tosylate **48** are enantiomers and therefore chemically equivalent.

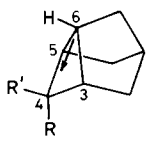
Table 4 also lists some relative reaction rates (k_{rel}) and calculated strain energies[13]. The former are based on 2-adamantyl tosylate **49**, because it shows the least tendency to bridge and to rearrange. The absence of a relationship between *exo/endo* rate ratios and strain energies is striking and particularly noticeable when comparing the tosylates **44** and **45**. On the other hand, the most strained tosylates, namely *exo*-**45**, *exo*-**47** and **48**, which should therefore be most inclined to bridge, react the fastest. But the strikingly low rates of the tosylates **44** clearly indicate that further factors contribute to the reactivity of bicyclic compounds, such as hyperconjugation of β-CH bonds which, for stereoelectronic reasons, is hindered in the bicyclo[3.2.1]oct-8-yl cations **50** and **52**, and by steric resistance towards an increase of the bond angle C1C8C5.

9. Conclusions and Outlook

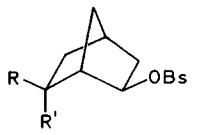
After many years of discussion whether solvolytically generated 2-norbornyl cations are unbridged or bridged, *i.e.* classical or nonclassical, it is now evident that the question is faulty, in that these terms denote only the structural extremes of a graded series. Thus, the high k_{12}/k_{13} rate ratio of 425 and the formation of racemic 2-*exo*-norbornanol from optically active 2-*exo*-norbornyl tosylate **12** (R = H) point to a strongly bridged intermediate. However, the latter is not necessarily a static, symmetrically bridged cation, such as **42** (R = H), for high *exo/endo* rate ratios and retention of configuration are also observed when symmetrical bridging must be excluded for structural reasons (see the *exo*-tosylate **44**). Therefore, very rapidly equilibrating 1,3-bridged cations **40** ⇄ **41** are preferred to **42** (R = H). On the other hand, electron-attracting substituents at C6 reduce bridging and the rate of rearrangement to the point where the *exo/endo* rate ratio falls below one (Table 1) and 2-*endo*-substitution products are also formed.

Intramolecular 1,3-bridging, as postulated here, is due to the absence of nucleophilic solvation during the formation of bicyclic cations. It is especially pronounced in the strained and hence easily polarized 2-norbornyl cation. When 1,3-bridging in the transition state of epimers differs widely due to differential bridging strain, as for **12** and **13** (R = H), the rates will also differ considerably, and this leads to high *exo/endo* rate ratios.

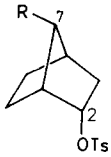
An extremely large difference in rate of more than 500000 was observed for the epimers **63a** and **63b** of tricyclo[3.2.1.$0^{3,6}$]oct-4-yl methanesulfonate[31]. The higher reactivity of **63a** was ascribed to stronger bridging between C4 and C6 in the transition state for this epimer; for only here is C6 approximately coaxial with respect to the C4—OSO_2CH_3 bond. Furthermore, the C4—C6 distance is reduced due to puckering of the cyclobutane ring, which leads to stronger 1,3-bonding in the incipient cation[*]. *Bauld* has provided a quantum mechanical explanation for the stabilization of cyclobutyl and 2-norbornyl cations[32], which closely resembles the concept of 1,3-bridging as developed here.



63a, R = CH_3SO_2O, R' = H
63b, R = H, R' = CH_3SO_2O



64a, R = D, R' = H
64b, R = H, R' = D



65

It should also be mentioned that the unusually large kinetic isotope effects (for γ-deuterium) observed in the solvolysis of 6-deuterated 2-*exo*-norbornyl brosylates **64a** and **64b**[33] likewise point to a strong interaction between C2 and C6 in the transition state.

The fact that differential bridging strain explains, at least qualitatively, the different reactivity of the epimeric sulfonates mentioned above should stimulate the study of other pairs of epimers. Thus, it is to be expected that 1,3-bridging will be unfavorable for 7-*anti*-substituted 2-*endo*-norbornyl tosylates **65** because it entails the formation of a *quasi* four-membered ring. A considerably less negative reaction constant is therefore anticipated as compared to the more easily bridged tosylates **12** ($\rho = -2.0$).

In view of the postulated connection between inductive charge transfer and bridging (Section 6) it would also seem desirable to investigate the effects of substituents in other bicyclic systems. The object is to determine their influence on reactivity (expressed as ρ values) as a function of the charge at the reaction center, the distance and orientation of the bridging atom, and the conformation of the intervening chain. Such studies should eventually lead to a better understanding of the mechanism of transmission of polar effects in saturated molecules.

Lewis Acid Induced α-Alkylation of Carbonyl Compounds

New synthetic methods (35)

By Manfred T. Reetz*

Carbonyl compounds undergo α-alkylation *via* the corresponding silyl enol ethers using S_N1 active alkyl halides or acetates in the presence of Lewis acids. This methodology extends the scope of carbonyl chemistry considerably, since S_N1 active alkylating agents are generally base sensitive and therefore unsuitable for reactions with enolate anions or nitrogen analogs. A prime example is the α-*tert*-alkylation of aldehydes, ketones and esters.

1. Introduction

The α-alkylation of carbonyl compounds is an important C—C bond forming reaction[1]. With the aid of a strong base the carbonyl compound is converted into the enolate anion, which in turn undergoes S_N2 reactions with proper alkyl halides or tosylates (Scheme 1). The same applies to nitrogen analogs such as deprotonated Schiff bases, oximes or hydrazones. Unfortunately, the pronounced basicity of these nucleophiles imposes limits on the variation of the alkylating agents. Only S_N2 active compounds such as methyl, allyl, benzyl, and some primary alkyl halides consistently afford good to excellent yields[1]. In these cases such problems as polyalkylation[2], lack of regiospecificity in the case of unsymmetrical ketones[1,2] or low stereoselectivity[3] have been solved to some extent. In contrast, many secondary alkyl halides undergo competing base-induced HX-elimination, the extent of which depends upon the pK_a value of the ketone[4]. The amount of undesired olefin formation can vary up to 100% even in the case of isopropyl iodide. Furthermore, secondary alkyl halides react slowly, so that regiospecificity is not always ensured[1]. The detour *via* metalated hydrazones is often recommended, but has the disadvantage that in case of unsymmetrical ketones only the less substituted α-position can be alkylated[1]. Tertiary alkyl halides are completely unsuitable because the basic enolate anions cause rapid HX-elimination[1]. Even the less basic enamines fail to undergo C—C bond formation[5]. Thus, until recent times α-

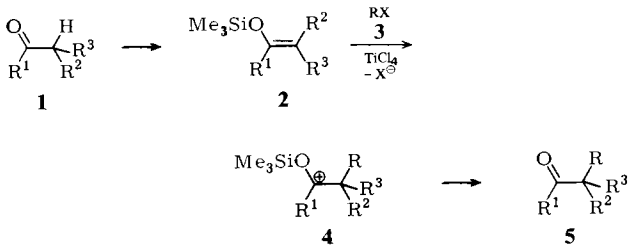
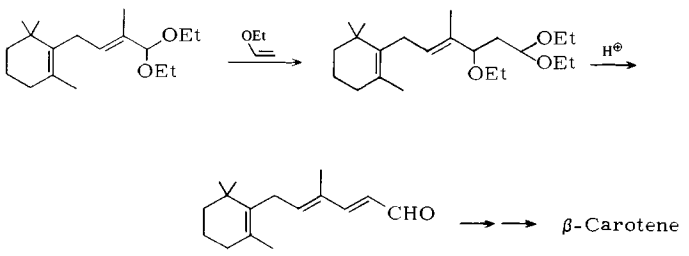
tert-alkylated carbonyl compounds were accessible only indirectly *via* several steps[6].

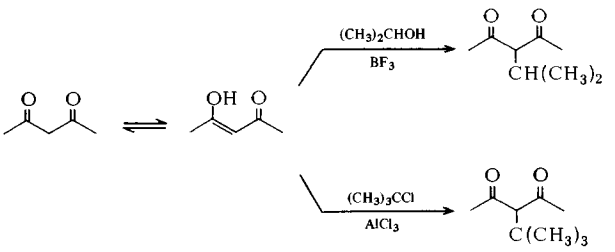
We recently found a simple solution to the above problems and have been able to considerably extend the area of carbonyl chemistry. The carbonyl component **1** is first converted into the electron-rich but non-basic silyl enol ether **2**. A variety of excellent silylation procedures is known[7], including the very mild reaction of carbonyl compounds with ethyl trimethylsilylacetate in the presence of tetra-*n*-butylammonium fluoride[7c] or with trimethylchlorosilane/triethylamine in the presence of sodium iodide[7d] at *room temperature*. The actual C—C bond formation **2**→**5** is accomplished by using suitable alkyl halides **3** in the presence of such Lewis acids as $TiCl_4$, $SnCl_4$ or ZnX_2[8]. Lewis acid promoted ionization of **3** to form the corresponding carbocation R^+ is plausible, which is trapped by the silyl enol ether **2**. The initial addition product **4** is rapidly desilylated, making oligomerization impossible. *This means that not only tertiary alkyl halides, but all* S_N1 *active species should be excellent alkylating agents*[9, 10]. It is important to stress that it is precisely this class of alkylating agents which fails or seldom works in classical enolate chemistry. S_N2 reactions of basic enolates on the one hand, and Lewis acid induced C—C bond formation using silyl enol ethers are thus complementary methodologies.



The predecessor of the above concept is the BF_3 mediated "aldol addition" of acetals to vinyl ethers, discovered in 1939[11a]. This process[11b] was used in the key-step of the Roche synthesis of β-carotene and similar compounds[11c].

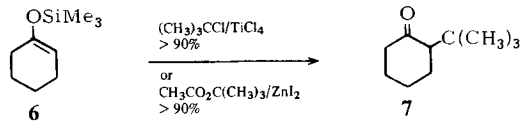


Later, *Mukaiyama* replaced alkyl enol ethers by silyl analogs and carried out an impressive series of aldol additions with acetals, aldehydes and ketones[12]. Mechanistically related are also the isopropylation and *tert*-butylation of certain 1,3-dicarbonyl compounds (14—68% yields) under Friedel-Crafts conditions as reported by *Hauser et al.*[13a] and *Boldt et al.*[13b]. Finally, the synthetically useful "Friedel-Crafts" reactions of carbocations with chlorinated olefins according to *Schmerling*[14] and *Bott* and *Hellmann*[15] are worthy of mention.

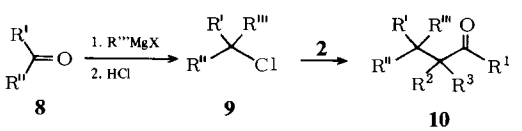


2. α-*tert*-Alkylation of Carbonyl Compounds

As a result of careful optimization, we discovered that the α-*tert*-butylation of the silyl enol ether **6** derived from cyclohexanone occurs rapidly and with high conversion (90%) if $TiCl_4$ is used as the Lewis acid at −30 °C to −60 °C in dichloromethane[8, 16a]. When carrying out the reaction, an equivalent amount of $TiCl_4$ is added rapidly to a mixture of **6** and *tert*-butyl chloride, followed by aqueous work-up after about two hours. If the silyl enol ether is added to a mixture of $TiCl_4$ and *tert*-butyl chloride, conversion is only 50—60%[16a], a variation which was independently described by *Chan et al.*[17]. Other ways of carrying out the reaction are also inferior, *e.g.*, addition of *tert*-butyl chloride to a mixture of **6** and $TiCl_4$[16b]. Besides $TiCl_4$, milder Lewis acids such as $SnCl_4$ (equivalent amounts at 0 °C) or $ZnCl_2$ (catalytic amounts at room temperature) are effective (≈90% and >70% conversion, respectively[6]). *Tert*-butyl acetate and *tert*-butyl methyl ether also behave as alkylating agents in $TiCl_4$-induced reactions, but the yields are lower (30—55%)[6]. In contrast, C—C bond formation is particularly smooth with *tert*-butyl acetate if ZnI_2 is used as the Lewis acid, *e.g.*, **6**→**7** to the extent of >90%[18]. Unfortunately, more complex acetates often show significant amounts of undesired elimination[*].



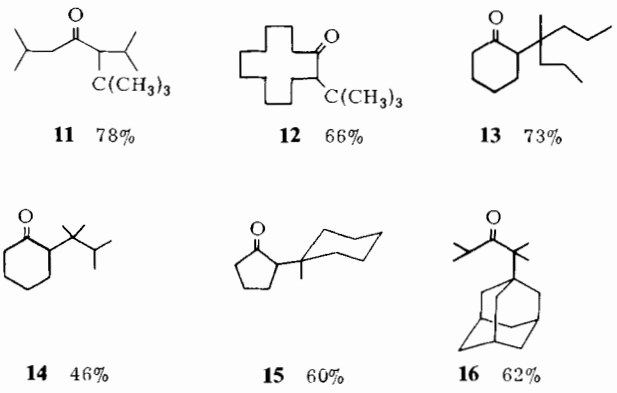
Not only *tert*-butyl chloride, but practically all *tert*-alkyl halides **9** are effective[19], thereby providing a new and simple method for the geminal dialkylation of ketones **8**→**10**. Quaternary carbon atoms not only occur frequently in natural products[20], but also in synthetic fragrances (*e.g.*, **7**)[21], pharmacologically active substances[22], and theoretically[23] and spectroscopically interesting compounds[24]. So far not many α-*tert*-alkylations of aldehydes have been carried out[6, 8, 17].



[*] Examples are methylcyclopentyl and methylcyclohexyl acetate.

2.1. Variation of the *tert*-Alkyl Halide and the Ketone

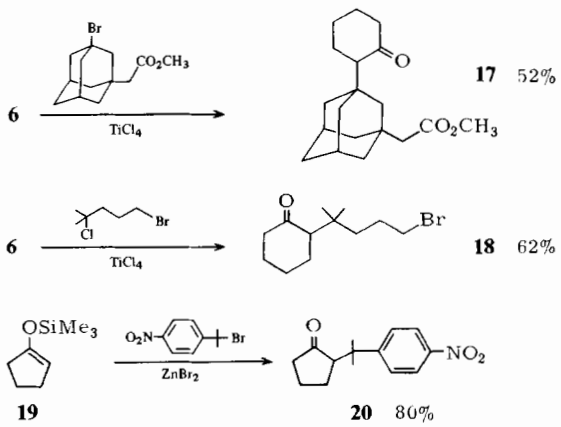
We have successfully alkylated a large number of ketones with structurally different *tert*-alkyl halides[19,25]. (The figures next to the numbers of the compounds refer to yields of isolated products in the alkylation of the corresponding silyl enol ethers.) It is important to note that branched alkyl halides do *not* undergo undesired *Wagner-Meerwein* rearrangements which would lead to a loss of positional specificity (see **13**, **14**, and **15**)[19,25]. Reactive bridgehead alkyl halides also participate (see for example **16**)[19,26], but not such strained compounds as 1-bromobicyclo[2.2.2]octane[27]. Undesired di- or polyalkylation does not occur. However, a second *tert*-alkyl group can be introduced by a stepwise procedure if so desired. In this case, α,α'-, but not α,α-dialkylation is possible[19].

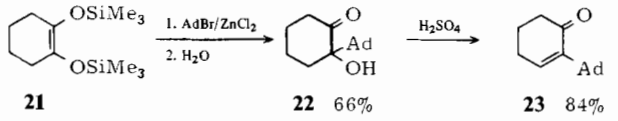


2.2. Chemoselectivity

The process of alkylation is not disrupted if the *tert*-alkyl halide contains such additional functional groups as aryl (*cf.* **19**→**20**)[28], alkoxycarbonyl (cf. **6**→**17**)[19], alkenyl[27], ω-bromoalkyl[19] (cf. **6**→**18**) or nitro groups[28] (cf. **19**→**20**). In some cases $TiCl_4$ should be replaced by milder Lewis acids such as ZnX_2. The reaction of *p*-nitrocumyl chloride leading to **20** is complementary to the reactions described by *Kornblum*, in which soft, resonance stabilized carbanions are required[29]. The latter reactions are radical processes.

Certain additional functional groups in the ketone component likewise pose no problems, *e.g.*, aryl[19], alkenyl[27], and hydroxy groups[27], the latter being protected in the silylated form. For example, α-hydroxy ketones (acyloins) can be α-*tert*-alkylated using the bis-silylated form **(21**→**22)**. Dehydration affording the α,β-unsaturated ketone (here **23**) is possible[27].

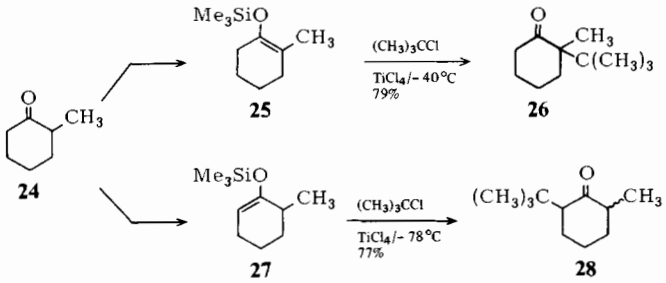




Ad = 1-Adamantyl

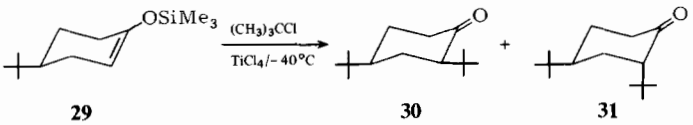
2.3. Regiospecificity in Unsymmetrical Ketones

Since unsymmetrical ketones can be converted selectively into the "kinetic" or "thermodynamic" silyl enol ether[7], the possibility of regiospecific α-*tert*-alkylation arises. The first system to be studied was 2-methylcyclohexanone **24**[8,17,19]. The reactions **25**→**26** and **27**→**28** are 100% and 89% regiospecific, respectively. Acyclic ketones behave similarly[19]. However, if the reactive centers of the components are extremely sterically hindered, complete loss of regiospecificity may ensue[27,30]. The high yield of isolated product **26** is rather astounding, since the compound is a hexasubstituted ethane with two neighboring quaternary carbon atoms. The method was also found to lead to products having this structural characteristic in a number of other cases[8,17,19].

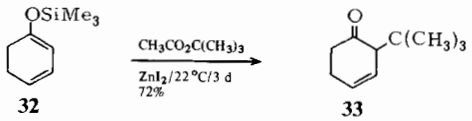


2.4. Diastereo- and Regioselectivity

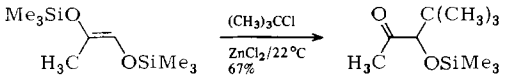
The *tert*-butylation of **29** yielding 85% of **30** and 15% of **31** shows that equatorial attack is preferred[31]. This is in complete contrast to methylation or ethylation of the corresponding lithium enolate, which show no diastereoselectivity (1:1 mixtures)[32]. Although different reaction types (S_N1 and S_N2 reactions) are involved, steric factors are likely to be responsible.



Concerning α,γ-selectivity in α,β-unsaturated ketones, we found exclusive α-alkylation, *e.g.*, **32**→**33**[27].



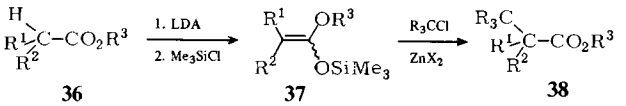
In the case of unsymmetrical bis-silylated acyloins, complete regioselectivity results, since only the "Markovnikov products" are observed[27], *e.g.*, **34**→**35**. Homologous compounds of the type **35** have been used by *Heathcock* in stereoselective aldol additions[33].



34 **35**

2.5. α-*tert*-Alkylation of Carboxylic Acid Esters

Whereas little is known about the α-*tert*-alkylation of aldehydes[6,8,17], that of carboxylic acid esters **36** has been studied in greater detail[26,35]. In these cases the corresponding *O*-silylated ketene ketals **37** are reacted with *tert*-alkyl halides or acetates in the presence of catalytic amounts of ZnX_2 (X = C, Br, I) in dichloromethane or nitromethane. $TiCl_4$ or $SnCl_4$ are unsuitable, since they are reduced by the electron-rich double bond of the silyl enol ether[35].



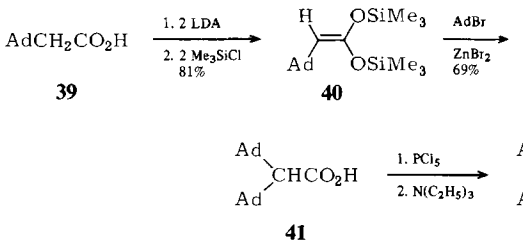
36 **37** **38**

In the case of *tert*-butyl chloride and 1-adamantyl bromide the yields of **38** are good (60—85%)[26,34]; however, with branched alkylating agents they are only 20—60%[35,36]. In nitromethane the reactions are faster and the yields higher than in dichloromethane. If *both* reaction partners are sterically demanding, the reaction may not occur at all[35,36].

In contrast, ZnX_2-mediated α-alkylation of **37** with aryl-activated acetates of the type $ArylR_2COAc$ is unexpectantly smooth[35]. Since the analogous reactions with silyl enol ethers often fail, a radical process may be involved[35]. Generally, the ester component can be varied over a wide range. An exception pertains to the parent compound (ethyl acetate), the silyl ketene ketal of which undergoes rapid ZnX_2-induced rearrangement to the *C*-silyl derivative which is not capable of alkylation[34].

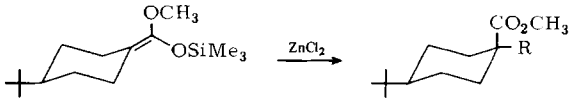
It is also possible to employ carboxylic acids themselves. They are first bis-silylated *via* the corresponding dianions before the actual *tert*-alkylation is performed[35]. The adamantylation of adamantylacetic acid **39**[37] is an example which also shows that compounds having *two* quaternary carbon atoms at *one* center are accessible[35]. This unusual property of the method is restricted mainly to the adamantyl group[26]. The yields in the case of *tert*-butyl chloride is in the order of 20—30%, since HCl-elimination predominates. Noteworthy is the smooth conversion into diadamantylacetic acid **41** and the theoretically interesting diadamantyl ketene **42**[35], both of which are new compounds.

In the α-*tert*-alkylation of **43** the axial ester **44** is the sole product, the stereochemistry of which was proven by X-ray analysis[38]. In contrast, diastereoselectivity in the



39 **40** **41** **42** 80%

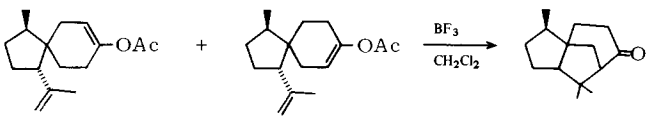
methylation of the corresponding lithium enolate (84 : 16) or the dilithium salt (1 : 1) is lower[39].



43 **44a**, R = 1-Adamantyl
44b, R = $C(CH_3)_3$

2.6. Intramolecular α-*tert*-Alkylation of Carbonyl Compounds

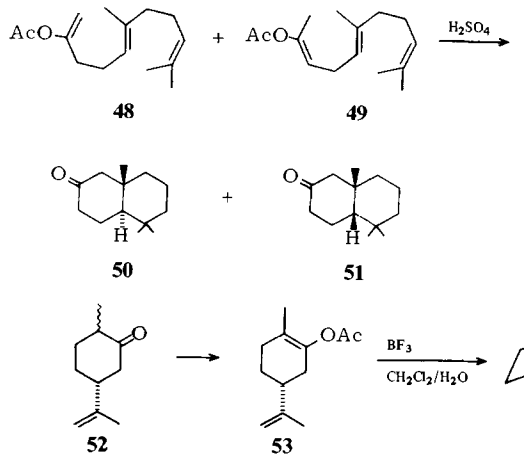
The literature contains only isolated cases of reactions which may be viewed as intramolecular α-*tert*-alkylations. *Corey*'s BF_3-induced cyclization of the acetate mixture **45** and **46** leading to **47** is a prominent example[40a]. Presumably the solvent (methylene chloride) contained water which provided the necessary protons. Addition of methyllithium to **47** completes the synthesis of (±)-cedrol. *Stork* and *Grieco* described several related reactions in which ketones containing olefinic functions undergo BF_3-mediated cyclizations[40b]. They also exploited $SnCl_4$-induced ring opening of cyclopropyl ketones, a process which generates tertiary carbonium ions and tin enolates within one molecule, thereby triggering intramolecular α-*tert*-alkylation[40b].



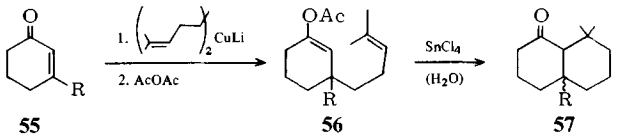
45 **46** **47**

As part of their studies concerning the synthesis of fragrances, *Ohloff et al.* used H_2SO_4 to cyclize the enol acetates **48** and **49** with the formation of decalones **50** and **51**[41]. The total yield was 30% and the diastereomeric ratio 84 : 16. An interesting biomimetic cyclization involving the acetate **53** derived from dihydrocarvone **52** has been reported by *Money et al.*[42]. At high dilution conversion to camphor **54** is ≈90%, but the product was found to be racemic. The isopropenyl group in **53** is probably protonated, generating carbocations which undergo racemizing, reversible 1,2 hydride shifts prior to intramolecular capture by the enol acetate.

Systematic studies of intramolecular α-*tert*-alkylations have only recently been initiated[43]. The starting point was the cyclization of the enol acetate **56a** obtained from cyclohexenone **55a**[43b]. Various Lewis acids such as BF_3, $SnCl_4$ and $TiCl_4$ were tested in moist dichloromethane at room temperature. $SnCl_4$ turned out to be the Lewis acid of choice. Conversion to **57a** was about 60%, from which

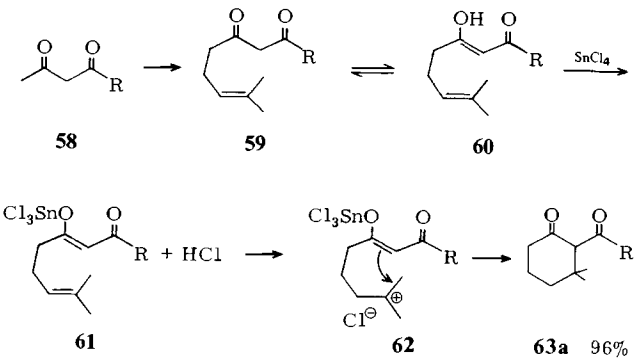


50% was isolated in analytically pure form. If the enol acetate bears an additional methyl group (*e.g.*, **56b**), intramolecular α-*tert*-alkylation to form **57b** is particularly smooth (>90% conversion; 80% isolated). With the assumption of a chair conformation, preliminary studies using NMR shift reagents seem to point to the *cis* form[43b]. However, a definite assignment has not been made.



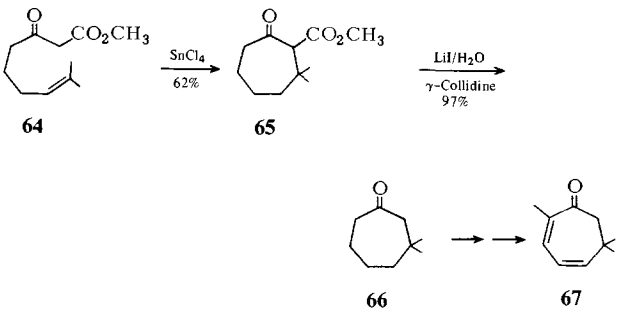
a, R = H; **b**, R = CH_3

A second strategy makes use of simple starting materials such as acetoacetic ester **58a** or acetylacetone **58b**[35,43a,c]. It is known that the dianions of these compounds are readily alkylated at the less resonance stabilized carbon atom[44]. Prenylation affording **59** is thus possible. The ac-

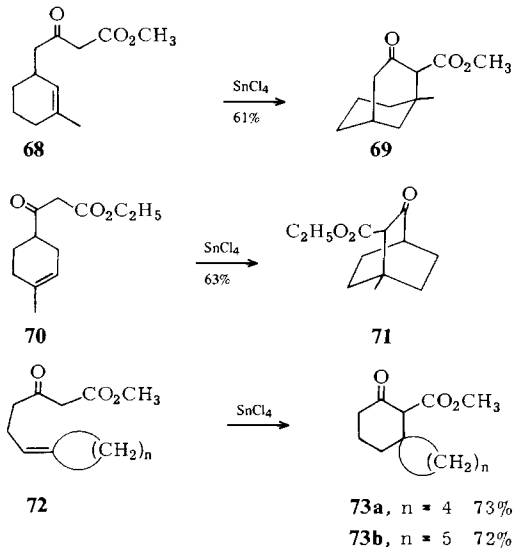


a, R = OCH_3; **b**, R = CH_3

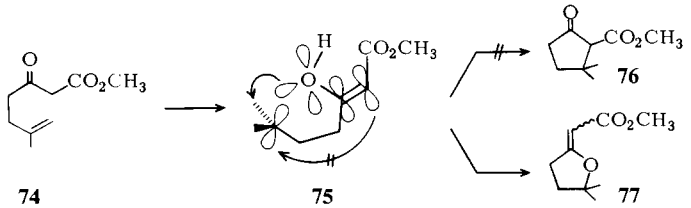
tual intramolecular α-*tert*-alkylation is mediated by catalytic amounts of $SnCl_4$. *O*-Stannylation of the enolized form **60** generating **61** and HCl followed by protonation of the double bond seems reasonable[43a]. Species **62** contains an electron-rich enol function and a tertiary carbocation, so that cyclization to **63** should result. Indeed, this reaction is almost quantitative after about 12 hours. Other catalysts such as $TiCl_4$, HCl or acidic ion-exchange resins are also effective, but result in lower yields[43c]. Although it is not clear whether the Baldwin rules are theoretically well founded in the case of cations, the cyclizations discussed here may formally be regarded as 6-*endo*-trigonal processes[45]. *Weiler* et al. have recently described the cyclization of **59a** independently of us[46]. They made elegant use of **63a** in a synthesis of mokupalide[46]. **63b** is a key compound in the Näf-synthesis of γ-damascone[47] and was synthesized by copper-catalyzed 1,4-Grignard addition to **55b** followed by acylation (30% overall yield)[47]. Thus, the present synthesis utilizing **59b** is an attractive alternative. The $SnCl_4$-mediated cyclization is also useful in other cases, *e.g.*, in the "allowed" 7-*endo*-trigonal reaction of **64** to **65**[43a]. Decarboxylation of **65** affords **66**, which is a precursor of the terpene eucarvone **67**[43a].



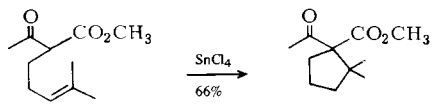
More complex systems undergo analogous intramolecular α-*tert*-alkylations. Thus, bicyclic compounds **69** and **71** as well as spiro derivatives **73** are easily accessible[43a,c]. Decarboxylation to the corresponding ketones poses no problems.



In contrast, the 5-*endo*-trigonal cyclization **74**→**76** failed[43]; this is consistent with the Baldwin rules. The *O*-alkylated isomer **77** is the sole product. Perhaps the cationic center can interact stereoelectronically better with the lone electron pair at oxygen than with the π-system which is perpendicular to it (see **75**)[48]. Noteworthy is the observation that **78** gives smooth *C*-alkylation to form **79**. This case is different, since favored 5-*exo*-trigonal cyclization affording a product with the ketone function outside of the ring is involved[43a].

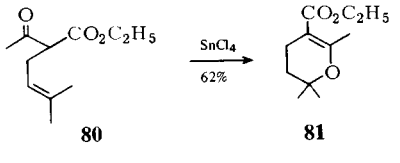


74 75 76 77

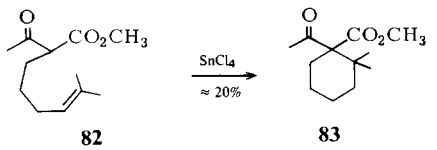


78 79

The limits of the method became clear during attempts to induce favored 4- and 6-*exo*-trigonal cyclizations of **80** and **82**, respectively[43]. In the former case only the *O*-alkylated product **81** was rapidly formed. On the other hand, the homolog **82** reacted very slowly, affording less than 20% of **83** after four days. Since large amounts of the starting material **82** remained unchanged, reversibility may be responsible.

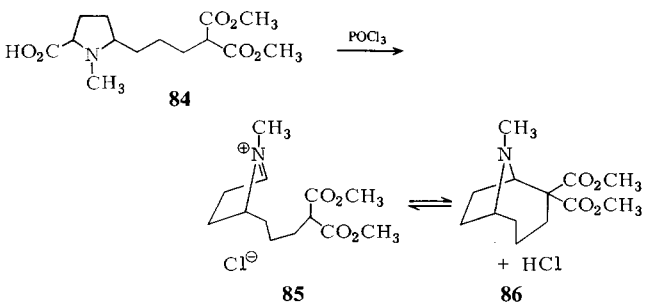


80 81



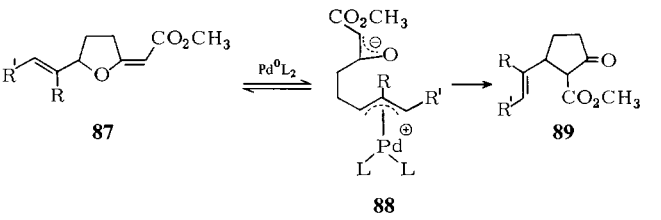
82 83

In this connection the observation made by *Rapoport et al.* is relevant, according to which the unfavorable position of the equilibrium **85** ⇌ **86** prevents useful yields of cyclization products[49a]. In other cases the regioselective cyclizations of alkylideneammonium salts discovered by these authors are essentially irreversible[49a]. Selenium-induced cyclizations of alkenyl-β-dicarbonyl compounds according to *Ley et al.* are also synthetically useful[49b]. Hg^{II}-salts generally effect intramolecular *O*-alkylation, although C—C bond formation predominates in certain cases[49c]. *Corey et al.* made use of the latter in their synthesis of (±)-aphidicolin[49c].



84 85 86

Although one must count with reversibility in $SnCl_4$ promoted cyclizations, it has not yet been possible to isomerize such *O*-alkylated products as **77** or **81** to the *C*-derivatives[43c]. Related and synthetically important processes are based on Pd^0-catalysis as reported recently by *Trost et al.*[50]. These processes are restricted to allyl systems, *e.g.*, **87**→**88**→**89**.

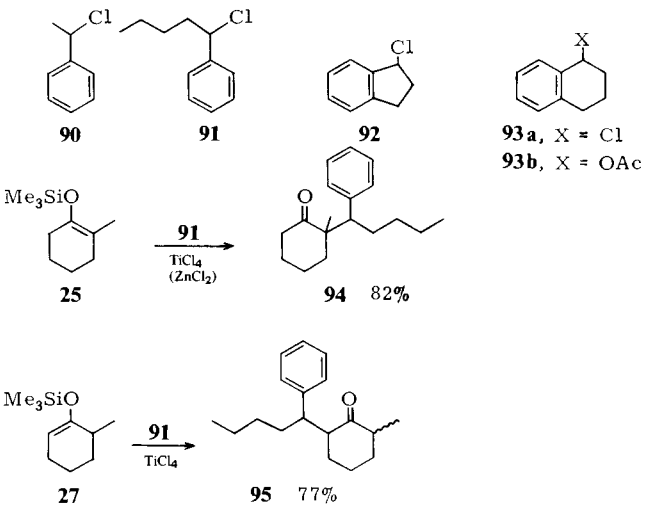


87 88 89

3. α-*sec*-Alkylation of Ketones and Carboxylic Acid Esters

As already stressed, conventional enolate chemistry is often of little use in the case of secondary alkyl halides, since elimination and loss of regiospecificity dominate. We therefore attempted to extend the concept of α-*tert*-alkylation to secondary alkyl halides. It turned out that the parent compound, isopropyl bromide, *fails* to alkylate silyl enol ethers of ketones in the presence of $TiCl_4$, since it is not S_N1 active enough[51]. The same applies to isopropyl iodide in the presence of silylated ketene ketals and ZnX_2[51].

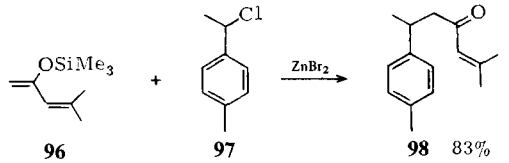
In sharp contrast, aryl-activated secondary alkyl halides such as **90**—**93** undergo smooth $TiCl_4$- or ZnX_2-induced α-alkylations[9,10,52]. We have demonstrated regiospecificity, *e.g.*, **25**→**94** and **27**→**95**. This, as well as the lack of polyalkylation underline the value of the method. In stereochemically relevant cases mixtures of diastereomers result. An application in the field of terpene chemistry is *Paterson*'s simple synthesis of tumerone **98**[52]. Surprisingly, activated secondary alkyl *acetates* can also be made to react at room temperature using ZnI_2 or $ZnBr_2$, *e.g.*, **99**+**93b**→**100**[18]. Also, carboxylic acid esters as well as acyloins are easily *sec*-alkylated as shown by the conversion of **21** into **101**[27]. Working with acetates is sometimes advantageous, since they are readily available and can be stored essentially indefinitely. Of course, they *cannot* be used in classical enolate chemistry, since they undergo *Claisen* condensation under the basic conditions.

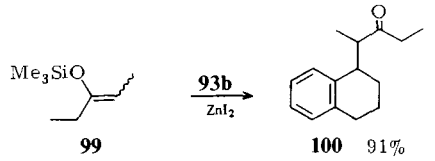


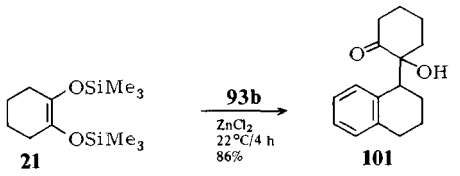
90 91 92 93a, X = Cl 93b, X = OAc

25 94 82%

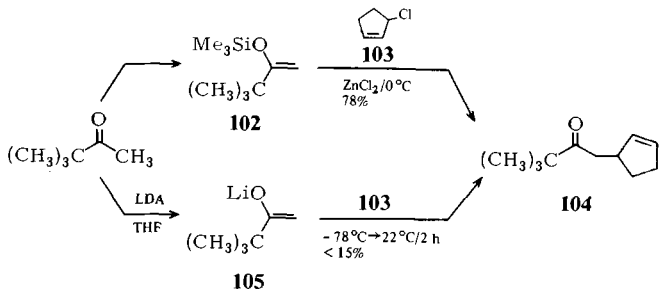
27 95 77%



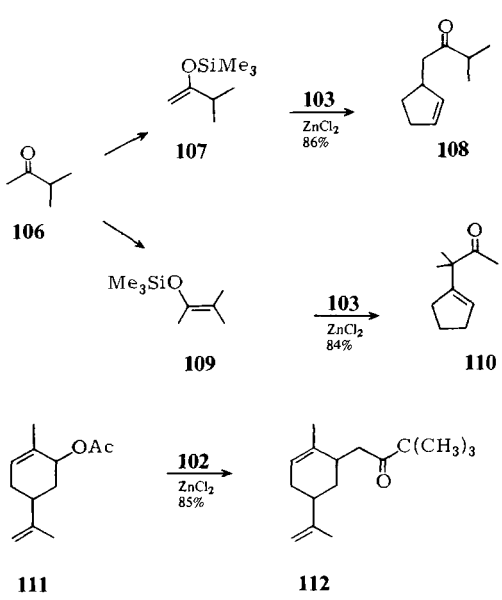




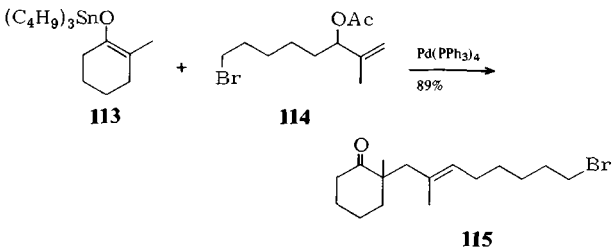
Secondary allyl halides and acetates are excellent reaction partners. The ZnX_2 induced reaction of **103** with a number of silyl enol ethers such as **102** occurs rapidly and essentially quantitatively under mild conditions without competing HCl-elimination[53]. The corresponding acetate



behaves analogously. In contrast, the very basic lithium enolate **105** derived from pinacolone affords less than 15% of the desired product **104**[53]! Complete regiospecificity in the reactions **107**→**108** and **109**→**110** is also impressive. The olefinic double bonds in **108** and **110** are easily hydrogenated, so that regiospecific cyclopentylation is possible for the first time. Cyclohexenyl acetates (*e.g.*, carvyl acetate **111**) react analogously at 22°C. Racemization points to a carbonium ion mechanism[53]. Open-chain secondary allyl acetates such as 1-methylallyl acetate react in the presence of $ZnCl_2$ considerably slower. The latter attacks the silyl enol ether derived from cyclopentanone at 70°C (1 h) to form 2-(1-methylallyl)cyclopentanone to the extent of 60%[53b]. The difference in reactivity has to do with the fact that the corresponding allyl cation is stabilized by only *one* alkyl group.

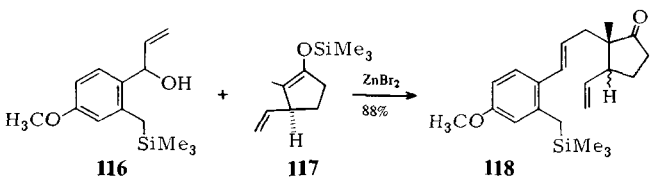


Excellent control of stereoselectivity in the use of allyl acetates as alkylating agents is possible *via* the corresponding π-Pd-complexes according to *Trost*'s general method[54a]. Although soft nucleophiles such as the anions of malonic acid esters are usually employed, stannyl enol ethers derived from ketones are also reactive **(113+114→115)**[54b]. The latter methodology is beset with problems, since stannyl enol ethers are not always easily



accessible, and the actual alkylation is not regiospecific in all cases[54b]. It has recently been reported that under certain conditions hard enolate anions participate in Pd-induced allylations[54c].

Secondary benzyl or allyl *alcohols* generally lead to poor results in Lewis acid mediated alkylations of silyl enol ethers[53]. An interesting exception is exemplified by the unusually reactive alcohol **116**, which reacts with **117** regiospecifically to afford **118**[55]. The product consists of a 4:1 diastereomeric mixture in which hydrogen is *trans* to the methyl group. It was easily converted into 11-α-hydroxy-

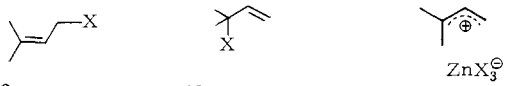


estrone methyl ether. The acetate of **116** is likely to behave similarly.

4. α-Prenylation of Ketones, Acyloins, Carboxylic Acid Esters and Lactones

Although prenyl halides **119a, b** are S_N2 reactive in enolate chemistry, they have not been used extensively[56]. Such possible problems as lack of regiospecifity or polyalkylation have not been investigated thoroughly[56]. In contrast, systematic studies relating to ZnX_2-induced prenylations have been performed[10,18,52,53]. All results using halides and acetates of the type **119a—c** and **120a, b** have

been positive to date. Since the assumption of intermediate ambident prenyl cations **121** is rather plausible, α-tertiary or α-primary alkylations can be expected.

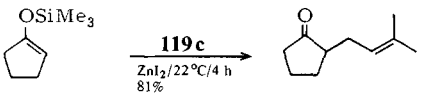


119a, X = Cl
119b, X = Br
119c, X = OAc

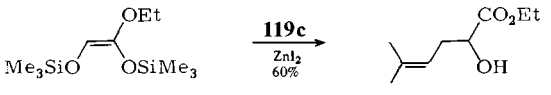
120a, X = Cl
120b, X = OAc

121

We have found that silyl enol ethers having tetrasubstituted double bonds undergo exclusive primary alkylation (prenylation)[10], as also reported by *Paterson*[52]. In all other cases up to 30–40% of isolable *tert*-alkylated compounds are formed[10]. The ratio of primary to tertiary attack is usually independent of the structure of the alkylating agent, since ZnX_2 induces rapid isomerization **120a**→**119a**. Thus, the discovery that the nature of the halogen attached to zinc affects the product ratio is synthetically important[10]. Whereas $ZnCl_2$ leads to appreciable amounts of *tert*-alkylated products, only traces are formed in case of ZnI_2; they are easily separated from the prenylated products during work-up. The same effect is observed if the less reactive CuI is used[10]. An even simpler prenylation procedure is the reaction of the easily accessible prenyl acetate **119c** or the isomer **120b** with silyl enol ethers in the presence of ZnI_2 at room temperature, *e.g.*, **122**→**123**[18]. The method is very mild, regiospecific, and does not yield undesired polyalkylation products. Other Lewis acids such as $TiCl_4$ or $SnCl_4$ lead to lower yields. Carboxylic acid esters[52,53], lactones[52] and acyloins[53] can also be prenylated *via* the silylated form, *e.g.*, **124**→**125**[53]. Application in terpene chemistry is likely to be successful. However, the yields in the case of geranyl acetate are disappointingly low (>30%)[53].

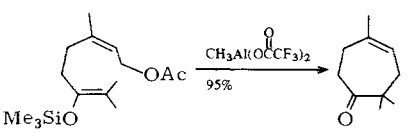


122 **123**



124 **125**

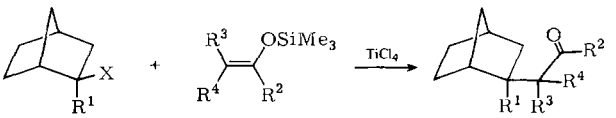
Intramolecular "prenylations" have also been carried out; *e.g.*, the methylaluminum bis(trifluoroacetate)-induced cyclization of the acetate **126** leading to karahanaenone **127** as described by *Nozaki et al.*[57]. This Lewis acid is made by treating trimethylaluminum with trifluoroacetic acid, and seems to be exceptionally mild. It results in higher yields than $AlCl_3$, Et_2AlCl, $TiCl_4$ or $SnCl_4$ (ZnX_2 was not tested in this case). The above process was also applied in other biomimetic cyclizations[57]. Pd(0)-induced intramolecular allylations involving anionized active methylene groups as acceptors are also known[58].



126 **127**

5. Anchimerically Accelerated Alkylations

Anchimeric assistance is another phenomenon which is known to increase S_N1 activity during solvolysis[59]. Since the solvent often displaces the neighboring group in the step which follows, retention of configuration results. We therefore posed the question whether "solvolytic" reactions with silyl enol ethers are possible in which the new C—C bond is formed stereoselectively with retention of configuration[60]. Indeed, *exo*-2-norbornyl bromide **128a** reacts with equivalent amounts of various silyl enol ethers **129** to form *exo* products **130** exclusively (Table 1). The tertiary alkyl chloride **128b** also gives only *exo* compounds[60]. Since the corresponding tertiary carbocation is classical, steric factors are responsible.



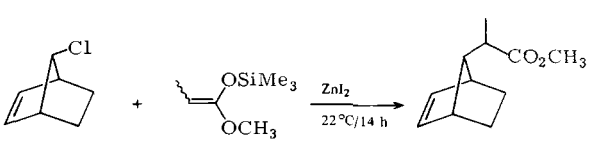
128a, R^1 = H, X = Br
128b, R^1 = CH_3, X = Cl

129 **130**

Table 1. α-Norbornylation of ketones to **130** [60].

Alkylating Agent	R^1	R^2	R^3	R^4	Yield of **130** [%]
128a	H	C_2H_5	CH_3	H	40
128a	H	$C(CH_3)_3$	H	H	73
128a	H	$CH_2C(CH_3)_3$	H	H	48
128a	H	$CH(CH_3)_2$	CH_3	CH_3	61
128b	CH_3	C_2H_5	CH_3	H	90
128b	CH_3	$C(CH_3)_3$	H	H	66
128b	CH_3	—$(CH_2)_3$—		H	65
128b	CH_3	—$(CH_2)_4$—		H	78

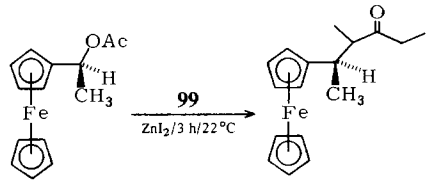
A widely quoted example for the drastic increase in solvolytic rate based on anchimeric assistance by a double bond pertains to *anti*-7-chloro-norbornene **131**[59]. A nonclassical carbocation as the reactive intermediate is generally postulated, which is attacked stereoselectively from the *anti* side by the solvent. The expectation that **131** reacts with silyl enol ethers with retention of configuration was fulfilled[60]. The best results were obtained using ZnI_2 at room temperature. Acyclic ketones as well as carboxylic acid esters are easily α-norbornenylated (*e.g.*, **132**→**133**), but not cyclic ketones[61]. The method is potentially useful, because oxidative cleavage of the double bond in the products (*e.g.*, **133**) yields trisubstituted cyclopentane derivatives with complete control of relative stereochemistry[60].



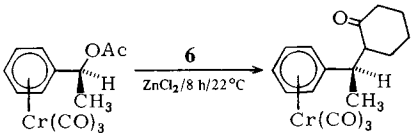
131 **132** **133** 95%

Obviously the above α-alkylations cannot be performed using classical enolate anions or nitrogen analogs. Therefore, the methods are complementary, as in most of the previously discussed cases. The broad spectrum of traditional carbonium ion chemistry contains many cases of neighboring group participation, so that the discovery of additional examples of anchimerically assisted alkylations is likely.

In more recent times unusually high solvolytic rates of certain transition metal complexes of the type **134** and **136** have been found[62]. This has to do with the fact that the



134 **135** 89%



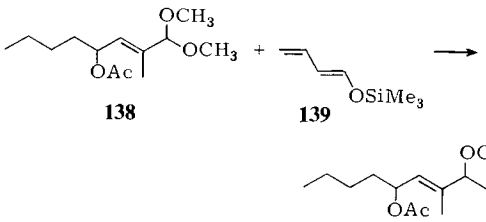
136 **137** 68%

carbocations being generated are significantly stabilized by the presence of the metal[62]. We have therefore initiated systematic studies concerning the use of **134** and **136** as alkylating agents. Indeed, the concept of S_N1 activity in Lewis acid promoted alkylations again proved to be useful as shown by the smooth reactions with **99** and **6**, respectively[63]. Whereas in the ferrocene derivative **134** both $ZnCl_2$ and ZnI_2 can be used as the catalyst, ZnI_2 fails in the case of **136** because it induces cleavage of chromium[63]. These α-alkylations are not possible using enolate anions, since the corresponding chlorides are extremely base sensitive. Although stereochemical studies of these unusual C—C bond forming reactions have not been completed, retention of configuration is likely to prevail. In the case of the chromium compounds, the metal is particularly easily introduced and then cleaved at a later stage, so that interesting synthetic perspectives arise. The metal functions as a vehicle for stereoselective C—C bond formation. Relevant are reactions of cationic tricarbonyl(dienyl)iron complexes with such nucleophiles as soft enolate anions[64a] and silyl enol ethers[64b] as reported by *Pearson* and *Birch*. The synthetically rewarding reactions of silyl enol ethers with hexacarbonyl(propargyl)dicobalt cations are also related[64c].

6. α-Alkoxyalkylation

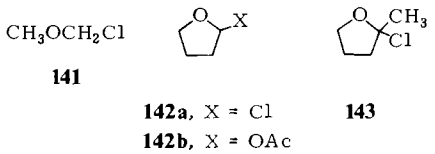
As already mentioned in the introduction, silyl enol ethers react with acetals in the presence of $TiCl_4$ to form β-alkoxyketones in a type of aldol addition[12]. If the system is particularly sensitive, a 1:1 mixture of $TiCl_4$ and $Ti[OCH(CH_3)_2]_4$ is recommended[12], which rapidly forms the milder Lewis acid $Cl_2Ti[OCH(CH_3)_2]_2$[65].

Thus, the reaction of **138** with **139** to form **140** is possible, which is a key intermediate in *Mukaiyama*'s total synthesis of variotin[66a]. Noteworthy is the γ-selectivity as well as the fact that the acetoxy group in the product **140** is not cleaved under the reaction conditions! The same principle was used in the synthesis of vitamin A[66b]. Similar reactions are catalyzed by trimethylsilyl trifluoromethanesulfonate as described by *Noyori et al.*[67]. Of prime importance is the observation that in this system C—C bond formation occurs diastereoselectively[67]. The reaction of 1,2-bis(trimethylsiloxy)cyclobutene with ketals in the presence of $TiCl_4$ or BF_3-ether is also useful, since the primary products are easily transformed into 2,2-dialkyl-1,3-cyclopentadiones[68]. Benzyloxymethylation of silyl enol ethers are of synthetic interest because hydrogenolysis of the products yields α-hydroxymethylketones[69a]. Finally, alkyl orthoformates likewise undergo Lewis acid promoted C—C bond formation with silyl enol ethers[12,69b].



138 **139** **140**

α-Alkoxyalkylation of enolate anions using α-chloroethers is possible in certain cases, *e.g.*, in the case of soft anions as are present in sodium-malonic acid diester[70]. Not much is known concerning analogous reactions of the more basic enolate anions of non-activated ketones or al-



141 **142a**, X = Cl **143**

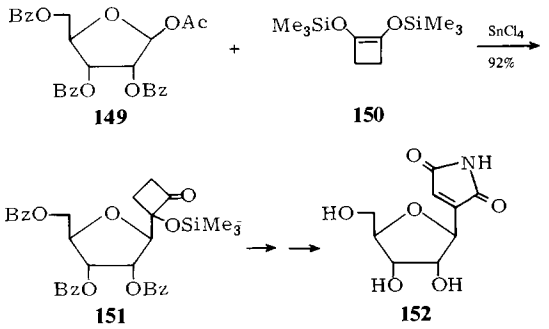
148 83%

dehydes. In these cases Lewis acid catalyzed α-alkylation seems to be the method of choice, since the α-chloroethers are extremely S_N1 active. Besides the parent compound **141**[52,71], cyclic α-chloroethers **142—145** also undergo smooth $ZnCl_2$-catalyzed α-alkoxyalkylations[72]. We were able to prove that the reactions are regiospecific. Worthy of note is the observation that the corresponding acetates **142b, 144b** and **145b** behave analogously[72]. Whereas the chlorides react rapidly at −20 °C (1—2 h) using catalytic amounts of ZnX_2, the acetates require room temperature (4—6 h). Interestingly, the usual dichloromethane can be replaced by ether. The latter dissolves zinc halides and ensures homogeneous catalysis. The reactions leading to **146—148** are typical for this mild alkylation procedure[72].

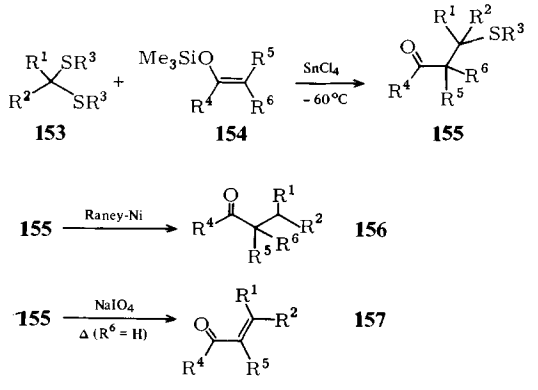
The above reaction type should have application in carbohydrate chemistry, particularly in the synthesis of *C*-substituted compounds. Indeed, a related $SnCl_4$-induced reaction between the protected β-D-ribose derivative **149** and the bis-silylated acyloin **150** was successful[73a]. The product **151** was converted in four additional steps into the antibiotic showdomycin **152.** Inspite of the fact that *Hanessian et al.* had already reported similar reactions[73b],



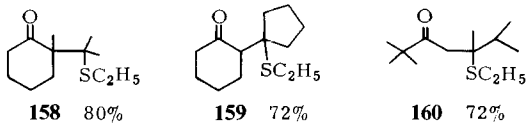
it is not clear whether the process can be carried out with other sugars in a general way (Bz = benzoyl).

7. α-Thioalkylation

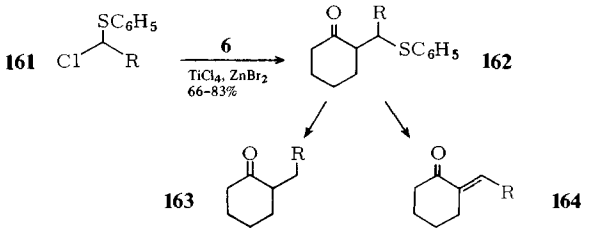
A synthetically interesting reaction is the Lewis acid induced α-thioalkylation of silyl enol ethers **154** with thioketals **153** to form **155.** Even upon varying the R groups considerably, we were able to obtain yields of 65—80%[10,74]. Furthermore, this thioalkylation is regiospecific. Whereas $FeCl_3$ was originally used as a thiophilic Lewis acid[10], $SnCl_4$ later turned out to be most effective[74].



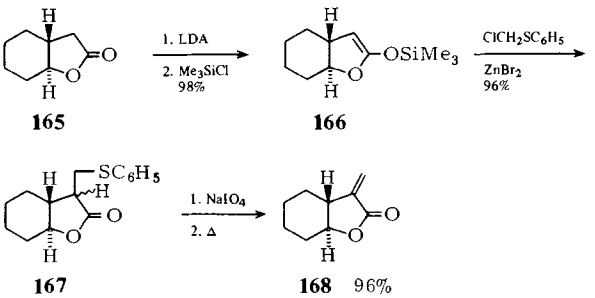
The value of the method lies in the fact that the products **155** can be treated with Raney Nickel to form **156,** or, in the case of $R^6 = H$, oxidatively converted into α,β-unsaturated carbonyl compounds **157.** In the former case the two-step sequence is equivalent to regiospecific α-*sec*-alkylation. The directed introduction of secondary alkyl groups in the α- *and* α′-position of unsymmetrical thioketals was previously not possible using conventional methods[1]. It is worthwhile to note that cyclic as well as branched groups can be introduced. In case of oxidative work-up, the sequence is equivalent to crossed aldol condensation, since both components **153** and **154** are derived from ketones. **158—160** serve as typical examples.



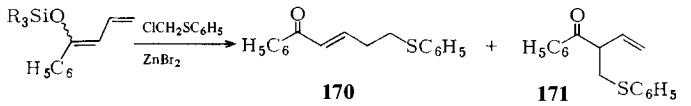
Thioalkylations using α-chlorothioethers **161** have been reported by *Paterson* and *Fleming*[75]. The products can be worked up reductively or oxidatively as described above, *e.g.*, **162→163** or **162→164**[75c]. In contrast to the previous reactions with thioketals, this sequence enables the intro-



duction of *primary* alkyl groups. Regiospecific methylation is thus possible[75b]. Based on the same principle, methenylation has been realized, *e.g.*, **165→168**[75a]. Parenthetically, lithium enolates derived from lactones give poor yields of thioalkylated products using $C_6H_5SCH_2I$, CH_3SCH_2Cl, CH_3SCH_2I or $C_6H_5CH_2SCH_2Br$[75a]. The $ZnBr_2$-induced thiomethylation is likely to be of use in the synthesis of certain cytotoxic sesquiterpene lactones such as vernolepin, helenalin or elephantin[76].



An interesting way to influence the α,γ-ratio in the alkylation of silyl dienol ethers is to vary the groups at silicon[77]. Upon substituting methyl by phenyl groups, the percentage of γ-alkylation increases. For example, thiomethylation of **169a** and **169b** gives rise to **170** and **171** in the ratios of 45 : 55 and 85 : 15, respectively. However, the

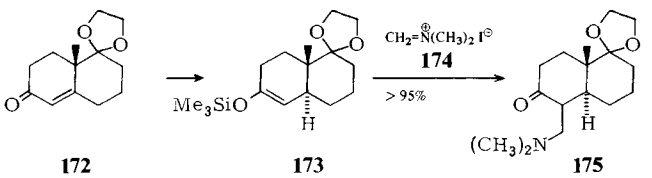


169a, R = CH_3
169b, R = C_6H_5

yields in the synthesis of silyl enol ethers are not always good[77].

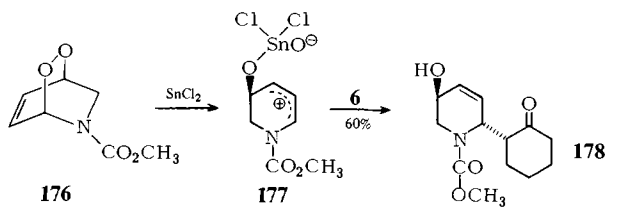
8. α-Aminoalkylation

According to *Danishefsky et al.*, silyl enol ethers, *e.g.* **173**, react with methyleneammonium salt **174** in the absence of Lewis acids[78a]. This reaction has also been observed with lithium[78b] or boron enolates[78c]. At higher temperatures even ketones and aldehydes themselves react[78d]. The Mannich bases can be transformed into α-methylenecarbonyl compounds in two steps, as in the synthesis of vernolepin[78a].



172 **173** **175**

Besides older α-aminoalkylation methods[70,79], more recent procedures[80a], in particular intramolecular cationic processes have been described which are exceedingly useful in the synthesis of alkaloids[49,80b]. An unusual α-aminoalkylation is based upon reductive cleavage of the peroxide bridge in **176** with the aid of $SnCl_2$[81]. The intermediate amino-stabilized allyl cation **177** reacts regio- and stereoselectively with **6** at the α-position to form **178.** This method has application in the field of alkaloid chemistry[81].

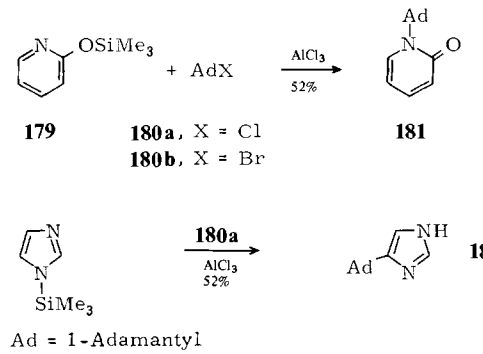


176 **177** **178**

9. Alkylation of Heterocycles

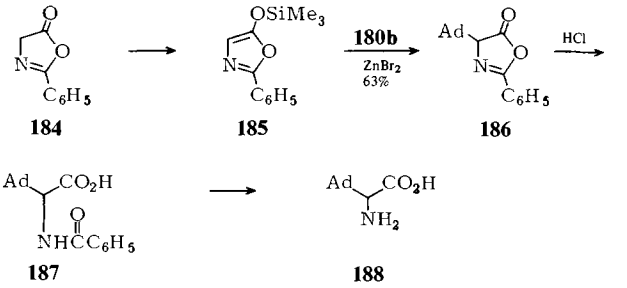
Not much is known concerning Lewis acid induced *C*-alkylation of *O*- or *N*-silylated heterocycles. For example, **179** reacts with **180a** not at carbon, but at nitrogen to form **181**[82]. *N*-Trimethylsilylimidazole **182** is selectively alkylated at carbon, since **183** is the only product isolated[82].

$ZnBr_2$-induced *C*-alkylations of the *O*-silyl derivative **185**[83] of the oxazolinone **184** are promising[84]. For example, **185** reacts smoothly with adamantyl bromide **180b** to form **186**[84]. Under acidic conditions the latter can be cleaved to **187** which is a precursor of **188.** In a formal sense glycine has been α-adamantylated. Other amino acids as well as acylamino ketones are also accessible *via* this route. It should be mentioned that under weakly basic conditions **184** reacts readily with S_N2 active alkylating agents, thereby providing the basis for some interesting chemistry as reported by *Steglich et al.*[85a]. These authors have also described a general sequence for the synthesis of amino acids having bulky groups at the α-position[85b]. However, it cannot be used for the introduction of polycyclic residues such as the adamantyl group.



179 **180a**, X = Cl; **180b**, X = Br **181**

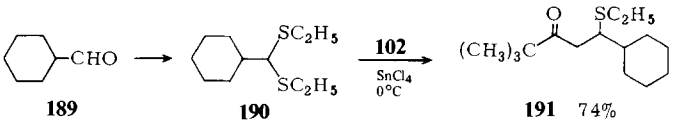
Ad = 1-Adamantyl



184 **185** **186** **187** **188**

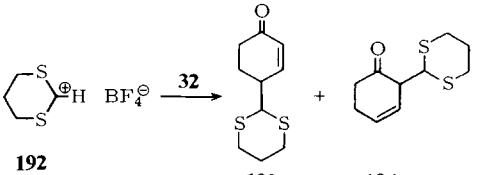
10. Summary and Future Work

During the short time between submission and correction of this review, several new aspects have appeared in the literature. The regiospecific thioalkylation using thioketals can be easily extended to thioacetals. Yields of 65—85% are common; an example is the synthesis of **191**[72]. This type of C—C bond formation is equivalent to that observed using primary α-chlorothioethers (*e.g.*, **161→162**)[75,86]. The only difference lies in the fact that in the new procedure stable thioacetals, easily obtained from aldehydes, are used as alkylating agents.



189 **190** **191** 74%

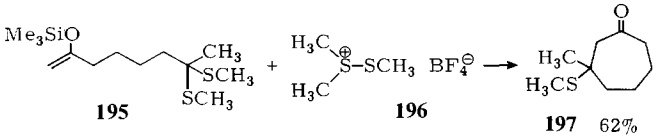
Thioalkylation of silyl enol ethers is also possible using 1,3-dithienium tetrafluoroborate **192**[87a]. Remarkably, silyl dienol ethers are alkylated regioselectively at the γ-position[87b], *e.g.*, **192+32→193.** Similar reactions have been carried out with 2-ethoxy-1,3-dithiolane[88].



192 **193** **194**

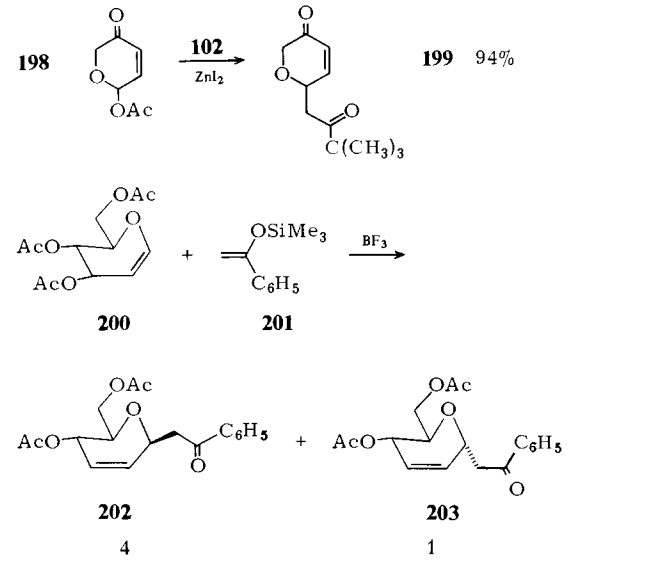
95 : 5

Intramolecular thioalkylations involving silyl enol ethers to form five-, six- and seven-membered rings are possible with dimethyl(methylthio)sulfonium tetrafluoroborate **196**, but not with such common Lewis acids as $SnCl_4$ or BF_3, *e.g.*, **195**→**197**[89].



195 **196** **197** 62%

Advances have also been made in the field of carbohydrate chemistry. Deoxyenonepyranosides of the type **198** react regioselectively with silyl enol ethers (*e.g.*, **102**→**199**)[72]. Closely related is the elegant reaction **200**→**202**[90].



198 **199** 94%

200 **201**

202 **203**

4 1

During the last four years the concept of Lewis acid-induced α-alkylations of *O*-silylated carbonyl compounds with S_N1 active alkylating agents has emerged as a powerful tool in synthetic organic chemistry. It was developed systematically in order to make that type of C—C bond formation amenable, which is not possible using classical enolate chemistry. Among others the long pending problem of α-*tert*-alkylation of carbonyl compounds was solved. Despite the fact that most of the reactions described in this review occur under mild conditions, generally show regiospecificity, and do not afford undesired polyalkylated products, some problems remain unexplored. Mechanistic aspects are currently unclear, in particular with respect to the Lewis acid. Radical processes appear likely in certain cases[16,35]. Also, the possible influence of the nature of the Lewis acid on diastereoselectivity during C—C bond formation has not been studied systematically. Finally, potential enantioselectivity in reactions of silyl enol ethers having chirally modified silyl groups ought to be considered. The same applies to the use of chiral Lewis acids.

I would like to thank my coworkers who have skillfully explored a number of reactions described in this review. Support by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

Problems of Economic Exploitation of Basic Research Findings (Discoveries, Inventions, Patents, Licenses)**

By Friedrich-Karl Beier*

In spite of high expenditures for basic research and its indisputable significance for technological development, the knowledge so gained seldom finds its way into industrial practice without difficulty and undue delay. Even without changing the aims of basic research, more commercially exploitable research results will be obtained in the future. It is in the interests of the public and the scientists themselves that such results, not only broaden scientific knowledge, but also be transferred in the best possible way into innovative practice. An intensified patent and license policy for scientists' inventions is a more appropriate solution to this effect than any independent legal protection for scientific discoveries.

1. Introduction

The evolution of genetic engineering during the last few years is perhaps the most impressive example of the extraordinary significance which the results of basic research hold, not just for scientific, but for the technical, economic and social progress in our society. Emanating from the basic findings of molecular biology of the 1950's and 1960's, genetic science and engineering have today already reached a position where multifarious and important applications in medicine, agriculture, and engineering can be expected in the immediate and longer-range future. Human insulin, interferon, new vaccines against viruses and pathogens, genetically manipulated microorganisms for the manufacture of hormones and antibiotics, simplified and improved methods for cultivating plants and breeding animals, ethylene conversion, and manufacture of ethyl alcohol with the help of genetically altered bacteria; these are only some key words for applications, more or less near-at-hand - a list which could easily be extended.

Reports in newspapers and scientific publications give evidence of initiatives in the area of genetic engineering which leading scientists in the USA, Switzerland, and France have taken in order to convert their findings into industrial practice. To this end, they have not only succeeded in getting patents and offering them for licensed commercialization to the largest firms in the pharmaceutical and chemical industries, but have taken matters into their own hands by establishing their own development and production companies[1]. That these initiatives, uncustomary for scientists, might have good chances of economic success is perhaps best illustrated by the fact that the stock market value of the first four companies established with relatively modest means, namely, Citus, Genentech, Genex, and Biogen was already around 225 million dollars at the end of 1979[2].

2. The Problem

This development gives us occasion to reflect, more generally, upon what should be done in the future with the results of basic research, the discoveries and new findings brought forth in research institutes of universities and other research establishments, and indeed, not only in the area of biochemical research.

Should science be concerned only about *scientific* progress or also about *technical* progress, *i.e.*, about the transfer of scientific knowledge into technology, and then also, about the reduction of such technology to practice, through the acquisition of patent protection and licensing? Putting it somewhat provocatively, should scientists confine themselves to their primary role as researchers, publishing their research results and being content with scientific recognition and their salary, or should they—not only occasionally but in all promising cases which come along—also become *inventors*, develop their findings into useful industrial inventions, apply for patents and exploit these by granting licenses?

The question is multi-faceted and does not allow for a general answer. It holds not only many, still unresolved problems of a legal and organizational kind, but at the same time, touches on basic questions of science and research policy, *i.e.* the way in which a scientist sees his role, basic *versus* applied research, the relationship of science to the state, economy and business, and finally, questions of financing and organizing research. These questions cannot be discussed at length in this article, which will concentrate on the following general question: should scientists involved with basic research pay more attention to the economic exploitation of their own research results, and should their research organizations pursue a stronger patent and license policy?

[*] Prof. Dr. F. K. Beier
Max-Planck-Institut für ausländisches und internationales Patent-, Urheber- und Wettbewerbsrecht
Siebertstrasse 3, D-8000 München 80 (Germany)

[**] This paper is based on a lecture delivered by the author on January 22, 1981 in Heidelberg before the Wissenschaftlicher Rat der Max-Planck-Gesellschaft (Scientific Council of the Max-Planck-Gesellschaft), in connection with a report by Prof. Dr. *Charles Weissman*, Universität Zürich, on the "Theorie und Praxis der Gentechnology" ("Theory and Practice of Genetic Engineering"). The paper deals with only some of the aspects of the complex problems associated with transferring technology from research into practice, and along with the following references, provides only a general outline of information. This subject will be treated in more detail in two forthcoming publications: F. K. Beier/J. Straus: *Der Schutz wissenschaftlicher Forschungsergebnisse (The Protection of Scientific Research Results)*, Verlag Chemie, Weinheim 1982; F. K. Beier/H. Ullrich: Öffentlich geförderte Forschung und Patentschutz (Publicly-supported Research and Patent Protection), 3 Volumes, Verlag Chemie, Weinheim 1982.

3. The Role of Basic Research[3]

To answer the question affirmatively does not mean changing the aims and functions of basic research, which must continue to be directed primarily to the acquisition of new scientific knowledge. Reducing results of basic research to practice does not mean that the emphasis should be shifted to applied research, which aims directly at the practical, industrial application of its results. That would be a fatal mistake. This emphasis on basic research is based neither on an elitist view of science nor on a lack of understanding by scientists of the so-called "social relevance" of their work. On the contrary, even if one assesses the value of research only by its economic and social returns, basic research as carried out in universities and other research institutions such as the Max-Planck-Gesellschaft (MPG) or the Centre National de la Recherche Scientifique (CNRS) has become more important than ever[4]. Today, basic innovations clearly promoting technical, economic and social progress cannot be realized without a basis in new scientific findings. In most cases, these findings can be brought forth only through systematic, long-term basic research, which is normally very expensive and full of risks. It may well be said that the more open the formulation of the problem, the more numerous the alternatives explored, the less one has of a specific practical result in sight from the beginning, and the greater the consequent risk for success, then the greater is the likelihood that something really basic emerges[5].

Total %	46.7	—	28.1	18.6	50.4	—	2.9	100	—

[a] Divided according to Federal government and States (including municipalities); in part, estimated figures. [b] Including private domestic institutions (PNP) and foreign countries. [c] Including municipalities. [d] Non-university research organizations include state organizations (Federal- and State-owned scientific organizations), private non-profit institutions (*e.g.*, major research organizations, Max-Planck-Gesellschaft) and foreign countries (*e.g.*, international research organizations). [e] Inclusive of estimated R & D portions in the financing of university construction, of 285 Million DM.

In industry, without governmental support, only large firms are in a position to carry out such research, and even they must concentrate primarily on areas of R & D which offer at least some prospects for commercial exploitation. The remaining industry, if it is carrying out not only development but also research, necessarily orients its research objectives to the immediate and short-term demands of the market for new products and processes. It must recover its R & D outlays within a foreseeable time, and therefore cannot, as a rule, even if it has great financial strength, conduct longer-term, high-risk projects. Basic research in universities and non-university research organizations must fill this gap.

Table 1 and Figure 1 present information about the distribution of total R & D expenditures for industrial and non-industrial research in university and other research organizations, which also provides an approximate indication of expenditures for basic research.

This division of functions is perfectly sensible, and it is therefore necessary[6] for the universities and research organizations to continue to concentrate on what others cannot do; namely, to carry out the laborious work of basic research, to which also belongs such long-term research projects as are carried out in the field of nuclear and plasma physics in the Garching, Karlsruhe, and Jülich research centers. It is also essential that the government (*i.e.*, the general public as taxpayers) finance this type of research.

4. Reasons for an Intensified Patent- und License Policy for Science

If this division of functions is in principle sensible, why then should scientists concern themselves with the exploitation of their research results, and to this end, engage in activities essentially alien to scientific research, such as the acquisition of patent protection and the granting of licenses? For this there is a series of reasons. These were

thoroughly discussed some time ago by a group of experts in the German Federal Ministry for Research and Technology (Bundesministerium für Forschung und Technologie—BMFT), and made the object of recommendations[7]. Shortly thereafter, this discussion was continued with scientists in a colloquium of the Max-Planck-Gesellschaft in Munich[8].

The results of these deliberations clearly run in the direction of an intensified patent and license policy in the area of publicly supported research, including basic research[9]. The main reasons for this may be summarized as follows:

4.1. Public Interest

1. The public not only has an interest that basic research be carried out, but also that its results, the new scientific findings, be put into technical, medical, and economic practice to thereby directly benefit the general public. In other words, the public is interested not only in scientific progress but, at the same time, in technical, economic, and social progress.

2. Scientific findings which have an economic use, or at least form the basis for it, are accruing today not only in industrial and applied research, but also in basic research. The most prominent example in Germany is the Max-Planck-Institut für Kohlenforschung in Mühlheim, which is today still fully self-financing from license revenues which are based on the fundamental discoveries of *Karl Ziegler* in the 1950's. But in many other areas also, in metal and semiconductor research, cultivation and breeding research, plasma physics, biochemical and biophysical research, many new and exploitable findings are constantly being made. The range of possible inventions from basic research institutes is large: from new chemical compounds, amalgams, pharmaceuticals, vaccines, plant cultivation and animal breeding, physical-technical manufacturing methods and analysis and measurement methods, to scientific devices and instruments.

3. The conversion of basic research results into new, economically usable products and procedures does not take place by itself, but *requires active participation from all who are involved in this innovative process* from the basic researcher to the development engineer, to the patent attorney, to the entrepreneur and the marketing specialist. A look at Figure 2 indicates that this process is lengthy, tiresome, and susceptible to problems.

The innovation process comprises the three main stages of *research, development* and *application,* and is only completed when, from the scientific findings gained in the research stage, an economically usable invention is developed in the invention and development stages, and when the object of this invention, the new product, is not only manufactured in the application stage, but also made available to a sufficient number of consumers in the market place. Only then, has scientific progress achieved, *via* the way of technical progress, finally economic and social progress.

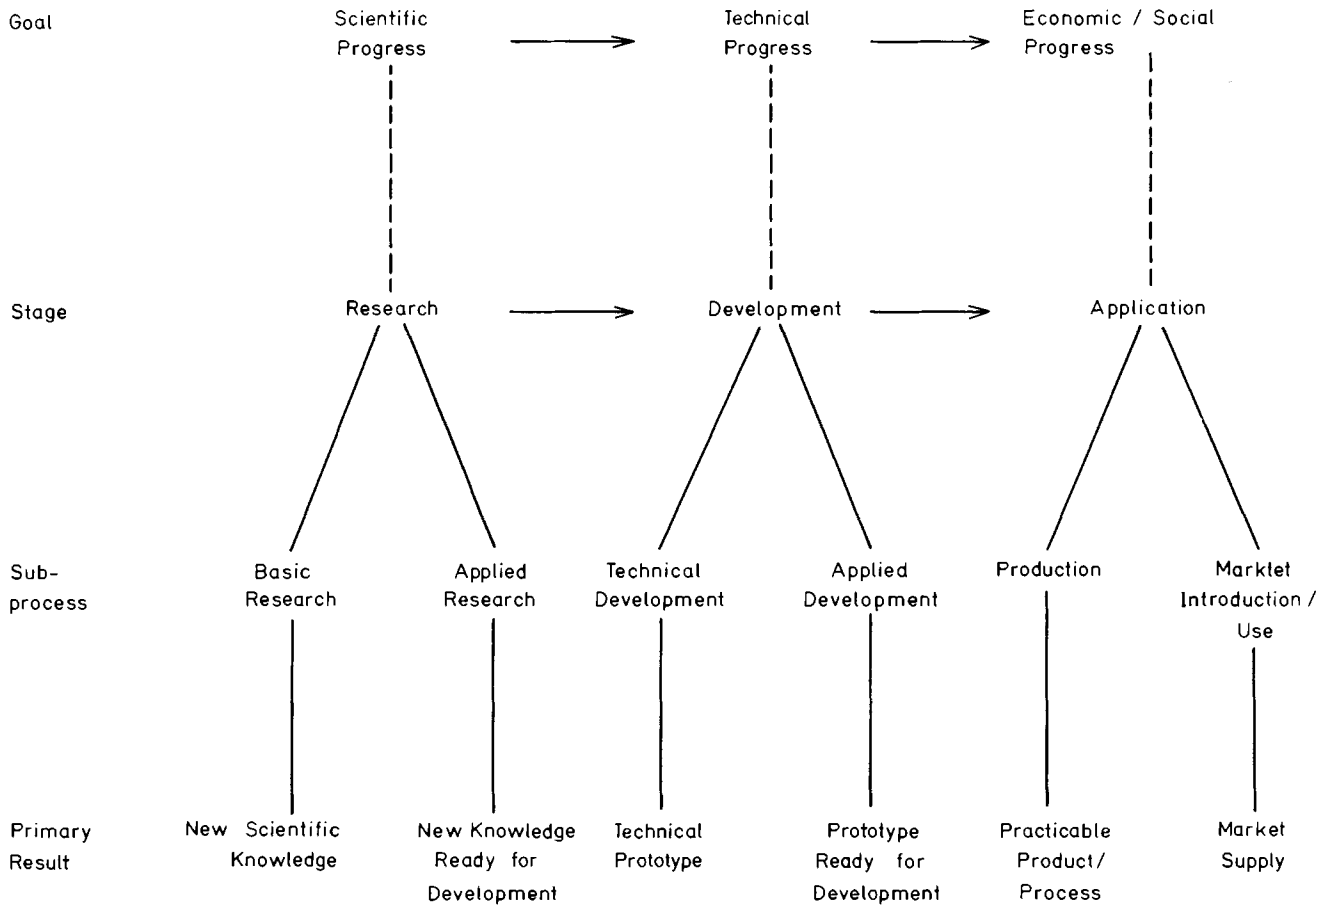

Fig. 2. Subdivision of the innovation process.

4. In fact, this process of reducing research results to practice functions either not at all or only imperfectly, if scientists, especially the basic researchers standing at the beginning of the chain of innovation, confine themselves to producing new scientific knowledge and making it available through reports and publications to the scientific community. This might promote scientific progress, but technical and economic progress are advanced only indirectly and with long time delays.

One would think that the best way of transferring knowledge into practical use is to publish new findings for everyone's free use, and that this method is even the most adequate in the field of publically financed research. But, the experience gained not only in the Federal Republic of Germany, but also in other countries, with such methods of imparting knowledge is definitely negative[10].

5. There are, above all, three reasons for this: a) scientific literature has only minimal value as a basis for investment decisions by industry; b) the published research results are as a rule still too far from industrial application, and hence, the development and market introduction risks too great; c) even in cases of research findings promising a successful technical and economic use, industry is not easily prepared to incorporate into its development and production programs such research results which have been made freely available through publication. No one is seriously interested in gratis technology, available equally to everyone, not only because man is inclined to doubt the value of a gift, but above all, because the recipient of this dubious gift, in which much more money must still be invested, is not alone in receiving it, but must participate with everyone else.

6. For this simple reason, it is essential, even in the area of publicly financed research, to combine the traditional publication policy with an intensified *patent and license policy*. Only this can ensure a satisfactory transfer of knowledge into practice. Industry is interested in research results only if they are patented or, at least, patentable, for patent protection assures the company a preferential position against its competitors which allows it to invest in the further development and market introduction[11]. The experience, including that of the Garching Instrumente GmbH, founded by the Max-Planck-Gesellschaft to exploit inventions made in research institutes, shows that inventions from government supported research can only be commerialized if patent protection is acquired and—in most cases—exclusive licenses are granted[12]. This was also the undisputed outcome of the debates within the BMFT (Federal Ministry for Research and Technology in the Federal Republic of Germany) group of experts and the Munich colloquium mentioned previously[13].

What can be done?

What then, does this call for a strengthened patent and license policy mean *for those scientists involved in basic research?*

1. Scientists should not be shy about developing their *"invent and patent" consciousness* somewhat more than they have hitherto. This requires above all, that they examine their findings for possible industrial applications, and indeed before results are published, as otherwise, later patent-protected exploitation is lost[14].

2. As to the *further development* of scientific knowledge to a patentable invention, two cases may be distinguished: a) If the development is drawn-out, expensive, or too far removed from the research objectives of the institute, it cannot in principle be the function of the individual scientists or their institutes to undertake by themselves such unfamiliar development activity. In cases having good prospects of commercial success, a development or cooperation contract should, be entered into with industry or appropriate institutes, with the help of state or private funds[15].—b) There is, however, an increasingly larger and more important area in which a scientific discovery is at the same time a patentable ivention, or may readily be developed into one without great expense (cf. Table 2). Gene research and technology on the one hand, plasma physics and nuclear engineering on the other, are examples of the fact that especially in promising areas, the traditional boundaries between basic and applied research, between discovery and invention, between pure science and engineering become more and more blurred, and progress in basic research cannot be achieved without advanced technology, and *vice versa*. A new microorganism with defined technical, pharmacological, or serological characteristics produced by a gene researcher with the help of gene technology, is at the same time a discovery and an invention, industrially applicable, and hence patentable[16]. Conversely, in plasma physics and other fields of basic research no progress can be achieved without self-developed technology—extensive, costly technology.

In my opinion, the patent and license policy of universities and other research organizations such as the Max-Planck-Gesellschaft should be aimed, above all, at such technical inventions which necessarily result from, or are needed for, basic research without additional development expenditures[17].

Table 2. Basic terms.

Discoveries	Inventions
Definition	Definition
Pure knowledge/finding of - laws of nature - pure theories - characteristics of nature - natural phenomenon	- solution directed to a specific problem - influence of natural forces
Protection	Protection
- patent law, no protection possibility - copyright law, protection of the form of presentation, not contents - trade secrets protection	- patent law - protection of plant varieties - trade secrets protection

3. In the case of a patentable invention with realistic prospects for exploitation, and where the scientist has the impression from his own knowledge of the state of technology or from a self-conducted search, that it relates to a new and not obvious invention, a *patent or utility model application* should be filed in every appropriate case, in order to secure priority and a basis for later commercialization.

In view of the increasing complexity of the filing and examination procedures, and the numerous possibilities for patent protection at the national, European and international levels[18], today less than ever, can one do without the expert advice of a patent attorney or patent agent experienced in patent and licensing matters, not the least, to save oneself needless clerical work and expenditures of time[19].

An important distinction is to be observed in the Federal Republic of Germany with respect to acquiring patent protection: professors, assistant professors, and academic assistants in universities are not governed by the provisions of the law on employee inventions of 1957; their research results are *independent inventions*, which they themselves can apply to protect and independently exploit. However, this so-called "academic's privilege" does not apply to the scientists working in the institutes of the Max-Planck-Gesellschaft, or Federal or state-owned research organizations. Their inventions, made in this capacity, are *employee inventions* which, according to the provisions of the employee invention law, the employer may claim as his property and apply to protect and exploit it. This right of the employer is, however, combined with the legal obligation to file a patent application for the employee's invention, and in cases where protectable, to pay the salaried inventor a reasonable compensation[20], which according to the rules for inventors in the Max-Planck-Gesellschaft, for example, amounts to 30% of the gross license receipts.

Which of these two routes is more advantagous for the scientist, and, which one ensures that research results are better reduced to practice, is still an unresolved question, and difficult to clarify because of the lack of safe data. The university researcher has more freedom to exploit his invention, and hence in theory, can obtain higher license revenues, but he bears the total and not insignificant costs of patenting, further development, and commercialization, and with that, the entire risk. All of this will normally be too much for him. In the face of these difficulties many professors completely refrain from economically exploiting their inventions. Others relinquish both the legal protection and the later commercialization completely to an industrial enterprise, provided they are successful in enjoying an actual interest in a given enterprise. Frequently, this presupposes that the academic inventor upholds close cooperation with certain enterprises, and is satisfied with a quite modest compensation, for his inventive efforts. Unlike in the USA, for instance, the German universities offer little assistance to their academic inventors in patenting and exploiting their inventions. On the contrary, the university administrations, and above all the Ministries of Education and Cultural Affairs in charge, view invention and the industrial activity of professors with suspicion, as an undesirable "activity on the side". Although of great economic value, the inventing and patenting activity of a teacher is viewed as an interference with his primary teaching obligations, which also endangers the standard salary structure. This is a most unsatisfactory situation[21].

The situation is different with inventions made by research done outside the universities. They are normally claimed by the employing research organization, *e.g.*, the Max-Planck-Gesellschaft, in accordance with the rules of the employee invention law. This not only increases the interest of the research organization in economic exploitation but also obliges the employer at the same time to apply for patent protection, to assume the entire costs, and to pay a reasonable compensation to the scientist in case of successful commercialization of the invention. The commercialization risk and the basically atypical legal-business activity of exploiting the invention are both taken away from the scientist.

To fulfil these tasks, the large state-owned research centers and the research organizations have set up their own patent departments. The Max-Planck-Gesellschaft has, in addition, created its own exploitation company, the Garching Instrumente GmbH, whose assisting functions are not restricted to inventions from the Max-Planck-Gesellschaft. In the first ten years of its existence, it was able to achieve not overwhelming, but certainly considerable, success in commercializing scientists' inventions[22].

4. Yet, even with the involvement of exploitation companies of this kind, the problem of putting research results into practice is only partially resolved. The road from a patentable invention to a successful product or process, from the inventing stage to the application stage, is often still long, and in most cases requires high investments for the necessary *further development and market introduction.* Prospective licensees from small and medium sized industrial organizations which for lack of their own research capacity, are especially interested in inventions from state supported research, need risk capital which should be made available to a considerably increased extent and in an unbureaucratic manner. The government bodies responsible for promoting research and economic affairs should devote stronger attention to this, as yet unresolved, question. For it goes without saying, that today it is more important than ever to make full use of the innovative potential available in our research institutions. The public has a vital interest in this.

4.2. The Interests of Science

Where, however, do the interests of the research organizations, research institutes and the individual scientist lie in an improved transfer of their research results into practice?

General Aspects

1. Probably every scientist should be interested, not only in having his research results noticed and discussed by his colleagues, but in having them find their way into technical, medical and industrial practice, and thereby to gain wider public recognition as a substantial creative contribution to technical and economic progress. The reputations of *Otto Hahn*, of *Adolf Butenandt*, and of *Karl Ziegler* have not been damaged as a result of these scholars having paid attention to the transfer of their discoveries into industrial practice, having worked together with industry, having made inventions, and having taken out patents[23].

2. Increased contacts between scientists and industry give both sides valuable encouragement and assistance in

their research and development activities. A welcome side-effect of these contacts is to improve the *mobility* of scientists, namely to facilitate the often difficult movement from positions in research to positions in industry, and *vice versa*. On the one hand industry offers scientists with a practical, inventive mind better career prospects than pure theorists. Because of the limited positions available in institutes, the institute should welcome every transfer to industry promoted by contact therewith, even if the loss of good assistants is sometimes painful. On the other hand a research scientist in industry will more readily accept a job in a university, if through prior contacts, he knows his future place of operation and can continue his inventive activity there.

3. Furthermore, a scientist can really have nothing against being named as inventor or co-inventor in a patent, and entering, with his technology-enriching accomplishment, the world-wide patent documentation system[24]. In this way, his discovery is not only extensively disseminated within industry and science, but the being named as inventor will also be regarded as a proof of quality and efficiency of his research endeavor.

4. Finally, one more important aspect: through an intensive invention, patent and license policy, science can, in a simple, understandable and effective way, demonstrate to the government, whose members are continuously asking what comes out of the research billions, just what service it renders the public. The talk about "ivory towers" in the scientific community could be dispelled more effectively than through verbal denials, if the public could more often be presented with a scientist's important invention, with all of its useful consequences for economic growth and social progress.

Financial Aspects

What financial benefit could be brought about for research institutes and the individual scientists by an intensified invention, patent and license activity?

1. First of all, a warning should be given against exaggerated expectations. It would be absolutely unrealistic to think that *e.g.*, the Max-Planck-Gesellschaft, could possibly ever finance its total expenses (annual budget 860 million DM), or even a considerable portion thereof, from its own license revenues. This much is not brought in, even by important inventions. Even if all research results which are industrially applicable could in future be recognized, patented and optimally commercialized as such, the income obtainable therefrom could at best make up only a small fraction of the total research budget. The Institut für Kohlenforschung in Mühlheim (Germany), which has been able to finance itself for decades from the *Ziegler* inventions, is a special and exceptional case that cannot be generalized[25]. Nevertheless, the Mühlheim example shows that economic exploitation of research results, if carried out in an expert way through licensing, can definitely be a rewarding business. Experience in the USA with the commercialization of university inventions, as well as the success to date of Garching Instrumente GmbH, also point in the same direction.

2. Even if no spectacular revenues can be expected, it is still worth taking the trouble in every appropriate case. We see that public funds for research are becoming ever tighter, and sufficient financing for research purposes can only be achieved through tough negotiations and through ever new concessions to the government. In such times, every single *additional* million of hard currency flowing into research must be highly welcomed, and must not be viewed as a negligible quantity.

3. The accent is on the word *additional*, and that means: license revenues from inventions are only of interest for the scientist if they do not lead to a corresponding reduction in the supporting funds from the government, but are freely available for additional research and development activities. Research could thereby win back some freedom and flexibility which it had at one time, which it needs, and which has been limited as a result of its ever stronger commitment to governmental budgetary rules. This greater *freedom of research* obtained through one's own initiative is in my opinion the most important reason, from the point of view of science, for a strengthened patent and license policy.

Legal Aspects

Finally, what is the situation regarding legal protection for scientific research results?

No Legal Protection for Discoveries

1. It undoubtedly contradicts the natural *sense of justice* that the inventor of a toothbrush or the composer of a pop song can obtain from their "creative" output by patent or copyright protection considerable incomes (the composer even until 50 or 70 years following his death), while the scientist who has made a basic discovery receives no legal protection for it and is consequently left empty-handed. He must continue to fight for the necessary research money from public or private donations, looking on as industry proceeds to make profitable inventions and a good business from his discovery.

2. This situation has frequently been deplored and has given rise to numerous suggestions to also give scientists and basic researchers an *exclusive right* to their discoveries, a "droit des savants" (scholars' right), or at any rate, to give them a share in the economic exploitation of their discoveries by way of an industry-fed pool of funds[26]. All of these demands and suggestions, which were thoroughly discussed in the League of Nations during the 1920's, and in UNESCO during the 1950's, never got off the ground, admittedly with good reason. They ignored the fact that scientific findings as such, which are still too far removed from economic utilization, cannot be made the subject of exclusive rights or claims for compensation, without unreasably hindering scientific and technical development.

3. We can therefore shelve all of these suggestions for independent legal protection for scientific discoveries, even if some socialist countries have introduced them, and recently, at the initiative of the Soviet Union, an international agreement for the registration of scientific discoveries was concluded in Geneva. This agreement provides no legal protection of any kind, only international registration for those scientific discoveries which are recognized as such in their country of origin. Accordingly, it is really ac-

ceptable only to countries such as the Soviet Union, where a state authority can decide what is a scientific discovery and who is its discoverer[27].

Inclusion of Discoveries in the System of Patent Protection

1. A better approach to the problem is to include the growing number of basic research findings, which are at the same time useful inventions or can be made such without significant development expenditures, into the traditional patent system. This is, even under the present state of the law, a possible and sensible solution. In the area of biochemical, biological, and largely also in the area of chemical-pharmaceutical research, patent protection is already available for new findings which are discoveries as well as inventions. A new microorganism or a new inorganic or organic compound, whose structure and characteristics have been clarified, is an invention for which patents will be granted (cf. Tables 2 and 3).

Table 3. Patent protection.

Patentable inventions
Definition
- Instruction of systematic technical action
- Application of controllable forces of nature
- Achievement of a result through foreseeable causal development
Criteria
- Novelty
• solution not known
• standard: state of the art at filing date
• novelty-defeating: other and own publications, oral disclosures, non-secret use
- Inventive step
• solution not obvious
• standard: entire state of the art, average skilled man in the art
- Industrial applicability
• suitability for industrial manufacture
• suitability for industrial utilization
Exceptions
- Discoveries
- Scientific theories
- Mathematical methods
- Computer programs
- Pure ideas and business rules
- Plant varieties (→plant variety protection) animal breeds (microorganism Patentable)
- Medical treatment methods
- Unlawful and immoral inventions

2. Although the patent laws of all countries, as well as the new European patent law, adhere to the traditional principle whereby discoveries and other scientific findings (Table 2) are excluded, as such, from patent protection, *more recent jurisprudential developments*, and indeed, precisely in the above-mentioned research fields, indicate a distinct trend towards advancing the threshold of patentability into the area of scientific discoveries, and therewith, basic research[28]. Judicial recognition of the protection of microorganisms, new plant varieties, the adoption of absolute product protection for chemical compounds, including natural substances, the patentability of intermediate chemical products, the possibility to file additional, or modify existing, descriptions of the technical, medical, or other fields of application of a chemical compound during the examination of a patent application (which means up to 10 years after the filing date)—all of these indicate the *on-going trend towards patent protection for basic research results.*

Protection Against One's Own Prior Publications

1. For attaining effective patent protection, one more step should be taken, namely, the re-introduction of a suitably long grace period for disclosures made by the scientist-inventor himself into the national and European patent laws, and if possible, on a world-wide basis[29]. According to the so-called absolute novelty concept, quite recently introduced and now in effect throughout the whole of Europe, patentability is excluded for any material disclosed by written or oral description, or by use, prior to the filing of the patent application, and it does not matter whether the disclosure comes from the inventor himself or a third party.

2. This severe rule is unbearable, not only for independent inventors and small and medium sized industry, but above all, for the scientist working in a research laboratory. It necessarily leads to a conflict between his legitimate and recognized interest in publishing his research results as soon as possible, and the interest in subsequent patent protection as a basic requirement for economic exploitation. This forces him to adopt a "wait and see" attitude with respect to publication, until he, or his institute's management, has investigated the economic relevance of the research results, and if warranted, a patent application has been filed. In some institutes with a developed patent consciousness, such an investigation is indeed undertaken as a matter of routine, just as in industry, without the publication being appreciably delayed. This is certainly possible and *de lege lata* important. But something important can so easily be overlooked, and then patent protection is lost once and for all[30]. The fact alone that important findings recognized as economically relevant must anxiously be kept secret from colleagues and visitors until a subsequent patent application, is embarrassing enough.

3. Only a six-month or even one year grace period for disclosures by the inventor himself, or his legal successor, such as for example, the USA and Japan recognize, and such as we had until recently in Germany, can bring relief to this situation. The scientist can then safely publish, and, after that, still has a half or a whole year's time to investigate the economic relevance of his new finding, and if worthy, to reflect on it and test it further in order to prepare and file, with expert help, a patent application. The publication or public use during the grace period defeats neither the novelty nor the inventive step required for the patent application subsequently filed by him or his legal successor.

At the present time, this topic is being debated with some prospects of success by national and international bodies concerned with legal protection of industrial property. But, a fairly long time will certainly pass until an appropriate change in the present German and European patent laws, which have only just come into effect, may be expected. Until then, if the scientist does not want to cut himself off from the possibility of economic exploitation of his research results, he has to live up to the unfortunate

maxim that he must not speak or write about his research results until the moment he has applied for patent protection.

Bossung: "Stand der Technik und eigene Vorverlautbarung im internationalen, europäischen und nationalen Patentrecht" ("State of the Art and One's Own Prior Disclosure in International, European and National Patent Laws"), *GRUR Int. 1978*, p. 381; E. von Pechmann: "Ist der Fortfall der Neuheitsschonfrist des §2 Satz 2 PatG noch zeitgemäß?" ("Is the Abolition of the Grace Period in §2 (2) of the Patent Act Still Opportune?"), *GRUR 1980*, 436; also [26b], No. 95.

[30] N. Wade notes (cf. [16]) that the patent application for the basic invention by *Boyer* in the field of genetic engineering, was only made after a Stanford University official responsible for patents had read about *Boyer*'s work in the New York Times. The application could still just be effected within the one-year grace period which exists in the USA.

Organometallic Aspects of the Fischer-Tropsch Synthesis

By Wolfgang A. Herrmann*

In memoriam Rowland Pettit

The Fischer-Tropsch Synthesis counts among the industrial-scale processes having a versatile and broad product range, and has for decades offered the most attractive possibility for the use of coal as a source of heating oil and fuels. This conceivably simple reaction, the catalytic hydrogenation of carbon monoxide, generally leads to simple hydrocarbons as well (*i.e.* short chain olefins) that have been sought as chemical feedstocks since the oil crisis of the seventies, but fails to provide the large-scale, economic process required, due in large part to the minimal selectivity of traditional Fischer-Tropsch processes. In an effort to solve this problem current research in this sector is concerned not only with the optimization of old and the development of new catalytic systems, but also increasingly with the elucidation of numerous relevant reaction mechanisms. This article will discuss, from the viewpoint of an organometallic chemist, the significance of typical model reactions, both with regard to some fundamental aspects of synthesis gas chemistry, and in comparison with previous views concerning the mechanism of the Fischer-Tropsch Synthesis. The importance of various unique classes of complexes that have been studied in the context of Fischer-Tropsch chemistry is also evaluated with regard to their importance in the synthesis of hydrocarbons from carbon monoxide and hydrogen. It emerges that the primary steps of the reductive oligomerization of carbon monoxide are best described by the carbide/methylene mechanism, as originally proposed by *Hans Fischer* and *Franz Tropsch*.

1. Introduction

The versatile and technically well-established Fischer-Tropsch Synthesis[1-3] has recently joined olefin metathesis[4] as one of the most attractive and productive areas of organometallic research. The mechanistic features of the Oxo-synthesis have long since been explained[5], and the elegant model studies of *Casey, Katz, Grubbs,* and *Schrock* into the mechanism of olefin metathesis have reached their culmination point. Nevertheless, the mechanistic steps of the catalytic hydrogenation of carbon monoxide continue to be strongly debated.

At first glance the Fischer-Tropsch synthesis obeys the trivial-looking, idealized equation (a)

$$n\,CO + 2n\,H_2 \rightarrow -(CH_2)_n- + n\,H_2O \qquad (a)$$
$$(\Delta H_{500\,K} = -39.4\ \text{kcal/mol})$$

giving in an exothermic reaction a plethora of products including straight chain alkanes, alkenes, alcohols, aldehydes, carboxylic acids, esters, as well as arenes. The highly selective Union Carbide process, a rhodium- and ruthenium-catalyzed ethylene glycol synthesis[6], as well as the predominantly nickel-catalyzed production of methane from synthesis gas ("CO methanation")[7], are notable special cases of CO hydrogenation. It is still not known, however, whether these processes involve uniform reaction sequences. The comprehensive mechanisms proposed for the catalytic formation of Fischer-Tropsch products are particularly speculative, since the classical, low-selectivity synthesis normally employs heterogeneous alkaline iron and cobalt melt- or precipitation catalysts, under which conditions a confusing array of parallel and subsequent reactions appears to occur. The spectrum of products is virtually always dominated by aliphatic and α-olefinic hydrocarbons, but is strongly affected by rather small changes in pressure and temperature, the catalyst and its preparation and promoter content, as well as some parameters of the process-technology. For example, *Pichler* has shown that the use of specific ruthenium catalysts at high pressure (up to 2000 bar) and relatively low temperature leads to high-melting, straight chain paraffins ("polymethylenes") largely identical with Ziegler polyethylene, and with an average molecular weight of up to 240000. By way of contrast, rhodium catalysts yield low molecular weight oxygenated products[2a,b]. In the Mobil process, the synthesis gas reaction induced by ZnO/Cr_2O_3 catalysts (high pressure) or copper-containing catalysts (medium pressure) is utilized for the synthesis of methanol, which, in turn, is subsequently converted into gasoline type hydrocarbons by means of zeolite supported catalysts. The activity and selectivity of the catalyst is particularly sensitive to the degree of alkalization, which is thought to increase the ability of the catalyst to chemisorb the reactants, as well as increase the rate of all carbon monoxide consuming reactions (CO reduction, water gas shift reaction, carbide formation, *etc.*). Finally the *water gas shift equilibrium*[3b]

$$CO + H_2O \rightleftarrows H_2 + CO_2$$
$$(\Delta H_{500\,K} = -9.5\ \text{kcal/mol})$$

affects not only the composition of the coal-derived synthesis gas (CO/H_2) but also the nature and molecular weight distribution of the Fischer-Tropsch products.

2. Present-Day Objectives of the Fischer-Tropsch Synthesis

The necessity of developing economically profitable alternative sources of chemical raw materials as a result of the oil crisis of the seventies has completely reversed the selectivity goal of the Fischer-Tropsch synthesis. The efficiency of a catalyst was previously measured in terms of the "degree of liquefaction", resulting from the production of liquid fuels from synthesis gas, whereas nowadays the achievement of as narrow as possible a product distribution is of particular interest (for example, short chain olefins as chemical feedstocks, $C_5 \ldots C_{11}$ olefins for conversion into softener alcohols, $C_9 \ldots C_{10}$ aliphatics as detergent raw materials). Economic estimates lead to the conclusion that a complete replacement of petroleum products by hydrocarbons derived from synthesis gas is not possible, at least at present, in the Federal Republic of Germany. Although short-, medium length, and long-chain alkenes bring far higher returns as chemical feedstocks than as fuels and heating oils, this reversion would result in a 6—7-fold increase in the demand for hard coal (4 t per 1 t primary product, *i.e.* 600 million tons per year). Hence, the Fischer-Tropsch synthesis could compete with petroleum only if the process selectivity could be considerably improved, and if crude oil were to be scarce and coal comparatively cheap. The last two of these conditions are already met with in some countries, *e.g.*, South Africa and Australia. Therefore, allowing for a certain amount of flexibility in the demand for basic chemicals, a new generation Fischer-Tropsch synthesis must be marked by high selectivity in order to compete effectively. It is generally agreed, that the development of new types of catalysts deserves primary attention. In view of the advanced state of our technical knowledge of the classical Fischer-Tropsch synthesis the emphasis will be on the use of alkalized heterogeneous catalysts, but a great deal of effort will be directed towards the development of homogeneous catalysts[8] with their potential for selective product control. This goal seems to be within reach now that the metal-induced model reactions discussed in this article have not only characterized numerous previously unknown classes of compounds, but also decidedly increased our understanding of the elementary steps of carbon monoxide hydrogenation.

3. Limiting Conditions for Reaction Mechanisms

Every possible reaction mechanism for the Fischer-Tropsch synthesis must fulfil the following limiting conditions: 1) The reaction formally obeys polymerization kinetics giving a Schultz-Flory product molecular weight distribution. 2) α-Olefins and alcohols are primary products. ^{14}C-Tracer studies[1b,9] have established that saturated hydrocarbons arise independently by olefin hydrogenation subsequent to the actual chain growth process. Beyond that, there is no doubt α-olefins as well as alcohols and aldehydes are incorporated into growing chains. 3) The chain termination steps do not deactivate the catalytic center, for the rate of chain growth normally remains unchanged for weeks. 4) The formation of hydrocarbons from synthesis gas according to eq. (a) results in the reduction of carbon monoxide to CH_2 building blocks with concomitant formation of water (!).

4. The Carbide/Methylene Mechanism

In one of their first publications, *Fischer* and *Tropsch* considered CO hydrogenation as a "Polymerisation von Methylen-Gruppen" wherein surface carbide species were formulated as the pivotal precursors of the methylene groups[10a]. Since the discovery and complete characterization of stable transition metal-methylene complexes with terminal **1**[11,12] and with bridging CH_2-functions **2**[13,14] (Fig. 1), this viewpoint has been revived through results of elegant experiments. Thus, nickel, cobalt, and ruthenium-based catalysts were doped with labeled carbon using the Boudouard disproportionation of ^{13}CO and were then treated with $^{12}CO/H_2$ mixtures under Fischer-Tropsch (F-T) conditions. The resulting product mixture consists mainly of $^{13}CH_4$ and hydrocarbons containing *several* (!) ^{13}C-atoms in one and the same molecule[10b].

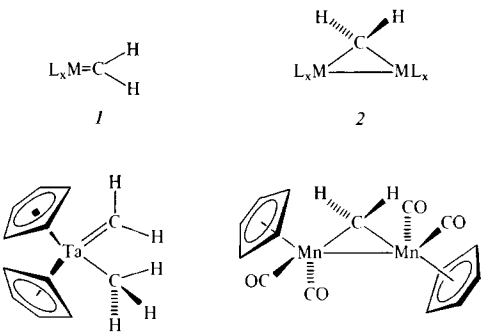

Fig. 1. Typical methylene complexes of type **1** with terminal ligands and of type **2** with bridge-bound ligands. The mononuclear tantalum complex is accessible by selective deprotonation of the cationic precursor $[(\eta^5\text{-}C_5H_5)_2Ta(CH_3)_2]^+$ [11, 12], while the methylene bridge of the dinuclear manganese complex is achievable with diazomethane [13, 14].

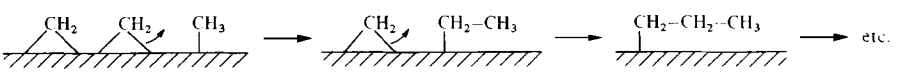
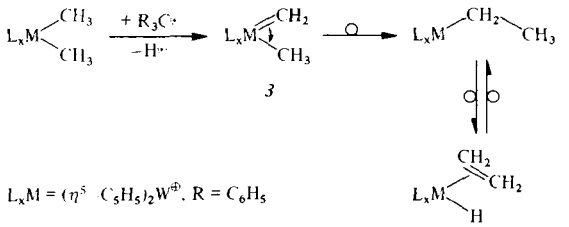
Other results support the conclusion that carbon monoxide rapidly dissociatively chemisorbs on F-T catalysts to give carbide species, which then react with hydrogen to give oxygen-free CH_x intermediates ($x = 1-3$) and in this way result in chain growth (Scheme 1)[10b]. Mention should be made in this context that surface-bound CH_2 groups can also become involved in competitive olefin metathesis[4,10b]. Furthermore, carbidization of the catalyst under



Scheme 1.

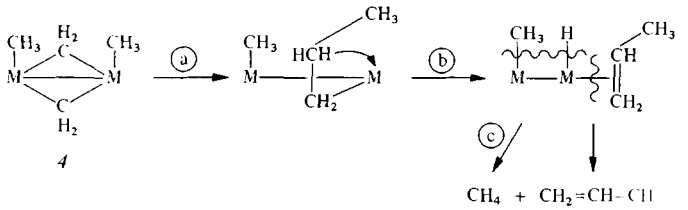
real F-T conditions is well known[1a]. The mechanistic viability of the insertion of a methylene group into a metal-methyl bond finally leading to polymerization as outlined in Scheme 1, could recently be verified in a stoichiometric model reaction of an electrophilic CH_2-complex **3** with the help of labeling studies[15a]. Beyond that, the products of



3

$L_xM = (\eta^5\text{-}C_5H_5)_2W^{\oplus}$, $R = C_6H_5$

the thermolysis of dinuclear μ-methylene-methyl complex **4** impressively confirm the methylene insertion step[15b]: At 350 °C the *cis*-isomer yields primarily methane (48%), ethylene (20%), ethane (2%), and propene (30%); only traces of propane and C_{4+} hydrocarbons are formed, while cyclopropane is not formed at all. Control experiments rule out the participation of π-bonded $C_5(CH_3)_5$ ligands in the synthesis of the observed hydrocarbons. Of particular importance is the predominance of propene over propane—α-olefins are among the primary products of the Fischer-



4

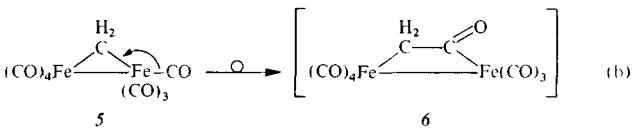
$M = (\eta^5\text{-}C_5Me_5)Rh$

Scheme 2. ⓐ—ⓒ, see text.

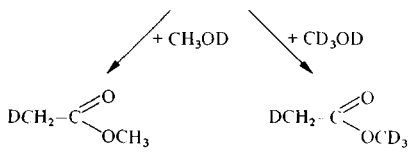
Tropsch synthesis! The most pertinent aspects of the thermal decomposition of the dinuclear system **4** are summarized in Scheme 2; they include the initial double CH_2-insertion ⓐ (C—C coupling), and the two conceivably most important termination steps under real Fischer-Tropsch conditions, *e.g.*, the kinetically highly favored β-hydrogen elimination ⓑ and the dinuclear alkyl/hydrogen reductive elimination ⓒ (giving alkanes; in this case, methane). The latter process liberates the olefin, in this case propene. Bis(μ-alkylidene) complexes *without* additional alkyl ligands generally decompose to give only olefins, resulting from carbene dimerization[15c]. The mode of coordination of CH_2-species attached to surfaces (**1** or **2**) remains uncertain, especially considering the fact that specific dinuclear metal complexes can contain both terminal as well as bridging methylene ligands[16]. Recent HMO calculations indicate that the C-atoms of the surface-bound bridging methylenes are not tetrahedrally coordinated, as in **2**, but are planar coordinated[23a], whereas in all isolable dinuclear complexes reported in the literature a distorted tetrahedral structure is found, irrespective of whether a metal-metal bond is present at the same time or not[14].

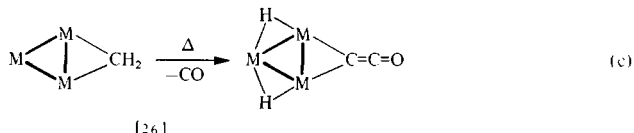
4.1. Dimetallacyclopropanes

Dimetallacyclopropanes **2** comprise a structurally and spectroscopically well established class of compounds and represent the most simple available model systems for the simulation of the chemistry of surface-bound methylene or alkylidene species. They are marked by an especially high tendency toward incorporation of olefins (→olefin homologation) and acetylene derivatives[14b], as well as a high reactivity *vis-à-vis* hydrogen (→methane)[14b] and protic acids (→μ-methylidyne complexes)[14b]. A μ,η^2-ketene intermediate **6** (CO-insertion) is proposed to account for the interesting formation of methyl acetate (80%) in the decomposition of the μ-methylene iron complex **5** with methanol according to eq. (b); nothing is known, however, about the fate of the complex fragment[17a]. This reaction may provide a starting point for a better understanding of catalytic *alcohol homologation* processes. Also worth mentioning in this respect is the observed carbonylation of a bridging methylene group to give the corresponding ketenylidene function [eq. (c)][17b]. Should recent reports of an as yet mechanistically poorly understood isomerization of an alkylidene chain along a metal-metal unit turn out to be a general pathway [eq. (d)][17c], then this process offers yet another model for the isomerization of mobile alkylidene species on metal surfaces[18]. The equilibrium (d) allows the bridging methylene with the lowest degree of substitution [$R(CH_2)_{x+1}CH$] to be achieved[17c]. Model studies have established that elimination of an alkylidene species from the metal centers is strongly favored by β-hydrogen migration (→olefins), but is much less favorable than decarbonylation if it should happen that the complex displays CO ligands at the same time[14b].



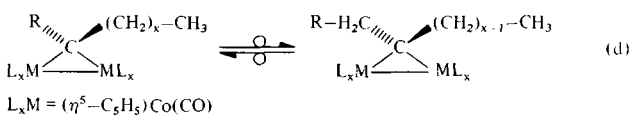
5 *6* (b)





(c)

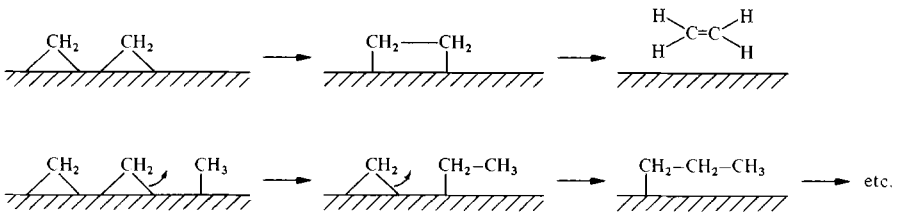
$M_3 = Os_3(CO)_{11}$ [26] $M_3 = Os_3(CO)_9$



(d)

$L_xM = (\eta^5\text{-}C_5H_5)Co(CO)$

The most convincing support of the carbide/methylene mechanism was provided by a detailed investigation, *inter alia*, of the Fischer-Tropsch catalyst-induced decomposi-



Scheme 3.

tion of gaseous diazomethane[10c]. *Exclusively* ethylene and dinitrogen are formed on Ni-, Pd-, Fe-, Co-, Ru-, and Cu-surfaces in the temperature range 25–250 °C at atmospheric pressure. Therefore, in the absence of other reactants, only dimerization and no polymerization of the surface absorbed CH_2-fragments occurs (Scheme 3, top). On the other hand, reaction of a mixture of H_2/CH_2N_2 over Co-, Fe-, and Ru-catalysts leads to a wide variety of hydrocarbons (primarily linear alkanes and olefins) with the isomer and molecular weight distribution of typical Fischer-Tropsch reactions! The results for H_2/CH_2N_2 and H_2/CO reactions under comparable conditions, illustrated in Figure 2, suggest the same polymerization mechanism as in Scheme 3 (bottom). Besides CO-activation (→carbide→methylene) the dissociative chemisorption of H_2 is also a prerequisite for this mechanism: If the catalyst surface (*e.g.* copper) is not capable of this latter process then no Fischer-Tropsch reactivity is observed, and, as expected, CH_2N_2 decomposition gives only ethylene, even in the presence of H_2[10c]. The production of CH_4[19a] in the reaction of H_2 (*ca.* 12 bar, benzene, 60 °C) with the isolable model complex $(\mu\text{-}CH_2)Fe_2(CO)_8$ does not contradict this mechanism, since multiple CH_2-insertions are not possible in this *mono*methylene system. Furthermore, the selective formation of ethylene in the reduction of coordinated carbon monoxide with AlH_3[19b] is probably attributable to the methylene complex as formulated in eq. (e): Thus, $Cr(CO)_6$ gives exclusively ethylene, in a rapid reaction (15 min, 22 °C), even with a large excess of AlH_3; only after acidification of the reaction mixture with H_2SO_4 are methane and ethane formed.

Finally, in accord with the chain growth formalism of Scheme 3 (bottom) it is found that the composition of the product gases of the F-T synthesis over different catalysts is identical with that of the hydrocarbon mixture obtained upon treatment of the expended catalyst with acid[19c].

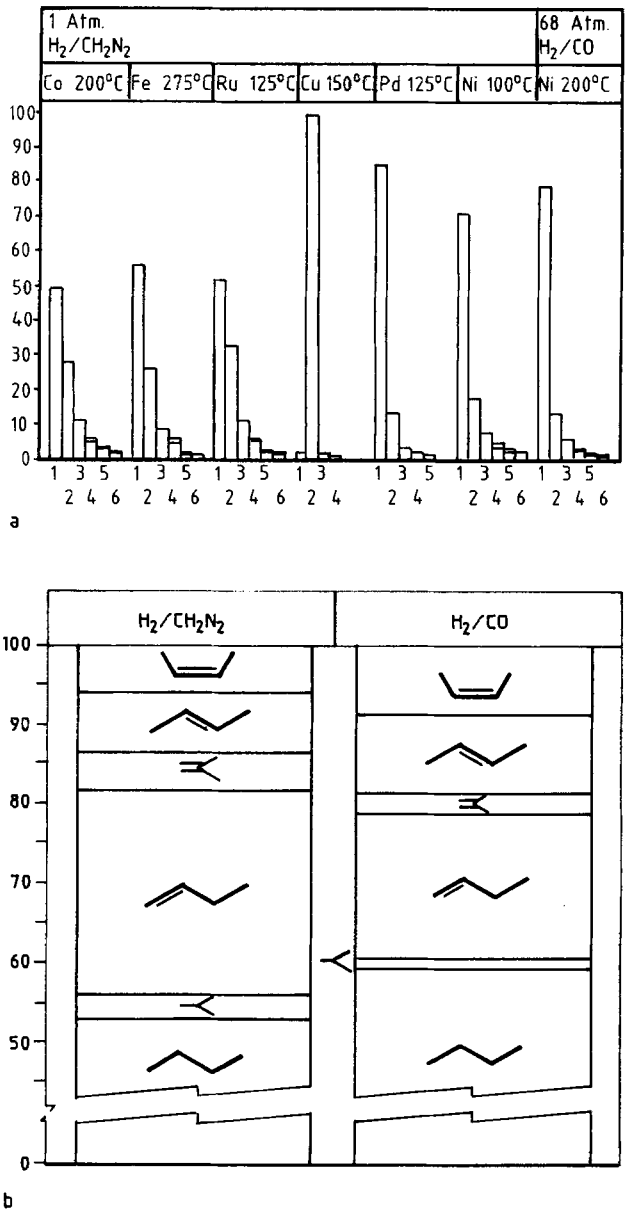


Fig. 2. a) Molecular weight distribution of hydrocarbon fractions formed from H_2/CH_2N_2 and H_2/CO on F-T catalysts. Alkanes and olefins are presented together corresponding to their chain lengths (abscissa). The block starting from the zero line represents the proportion of linear hydrocarbons, while the proportion of branched isomers are represented by the upper sections. Ordinate: Wt.-%. b) Comparison of the C_4-hydrocarbon fractions obtained from H_2/CH_2N_2 and H_2/CO, resp. (39% cobalt/silica catalyst, 210 °C, 1 bar). Ordinate: Wt.-%. (After [10c].)

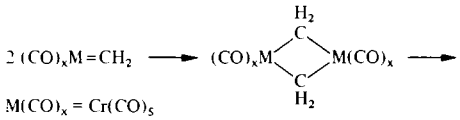
4.2. Carbide Clusters

The metal-induced decomposition of carbon monoxide leading to formation of cluster complexes with "naked" C-



atoms as ligands is no longer a curiosity in organometallic chemistry. The rupture of the C—O bond, especially on metal surfaces, may be facilitated by the coordination of

both atoms[20], as has been demonstrated in a series of structurally well-characterized multinuclear complexes (*e.g.* **7** and **8**; THF = tetrahydrofuran)[21]. The η^2,μ_3-complexation in the niobium cluster **8d** leads to an extreme lengthening of the C—O distance (*ca.* 130 pm)[21e]. The ytterbium(III) complex **8e** is an illustrative example, revealing the oxophilic character of lanthanoid elements. Here too, the C—O bond of the carbonyl bridge is significantly weakened as compared with the usual type of complexation[21f].

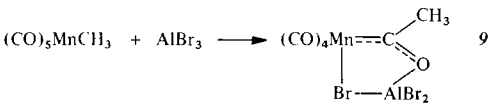
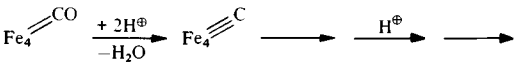
8e[21f]

Besides *O*-complexation, the activating effect of Lewis acids has also been well investigated since the time that *Shriver et al.* carried out their formative studies in this sector[22a,b]. Thus, the addition of aluminum tribromide increases the rate of the intramolecular methyl migration by orders of magnitude. In the resulting X-ray structurally



9

characterized product **9** the "ambiphilic" Lewis acid stabilizes not only the free coordination site on the transition metal formed as a result of methyl migration, but also complexes the basic acetyl function through the electron-deficient aluminum atom. Alumina surfaces show a comparable effect on the rate of methyl-to-carbonyl transfer to that observed for $AlBr_3$ in solution[28].

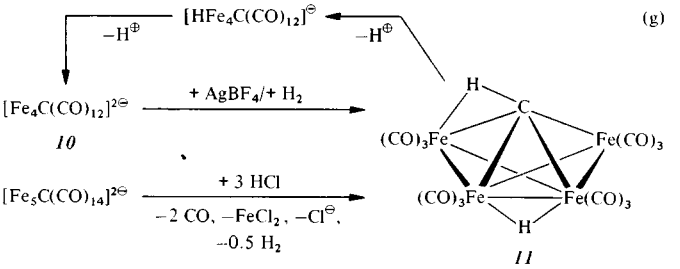


(f)

$CH_4 + Fe^{2\oplus} + CO$–Fe–Compounds

Treatment with Brønsted acids allowed an anionic carbonyl complex to be smoothly decomposed with formation of CH_4 and H_2 [eq. (f)]. It was proven by deuterium labeling experiments, that the hydrocarbon hydrogens came from the added acid[22c]. Accordingly, the mononuclear and dinuclear complexes $(\eta^5$-$C_5H_5)$Fe(CO)$_2$Li and Mg[$(\eta^5$-$C_5H_5)$Fe(CO)$_2$]$_2\cdot x$THF produce methane, ethylene, and ethane as a result of η^2, $\mu(C,O)$-coordination, even at low temperatures. The formation of cationic Fe=CH_2 species in this reaction has been postulated[22d]. The plausibility of these proposed mechanisms, however, is diminished by the normally low yields of hydrocarbons produced in the course of such reactions. In the light of this, strongly oxophilic centers should favor carbide formation. However, it is exactly such transition metals, from groups IV and V, which strangely enough hinder Fischer-Tropsch reactivity.

Muetterties has recently developed rational synthetic methods for the generation of carbide complexes[23], and, moreover, has shown[24a] that structurally characterized compounds with four-fold coordinated anionic carbide C-atoms react with H_2 under oxidative conditions to give CH-functionalities [eq. (g)], and are thus to be seriously considered as key species in the formation of CH_2-moieties from CO. Alternatively, it proved possible to form C—H bonds by protonation [eq. (f) and (g)]. Rapid hydrogen exchange between the C*H* and the Fe—*H* groups would indicate the importance of such processes on metal surfaces. The fully-characterized μ_4,η^2-CH-three-center bond[24a,b] in



(g)

the "butterfly" molecule **11** (see Fig. 3) appears to approach the energetically most favorable form of methylidyne complexation on top of specific metal surfaces[24c], and emphasizes the importance of M—H interactions in

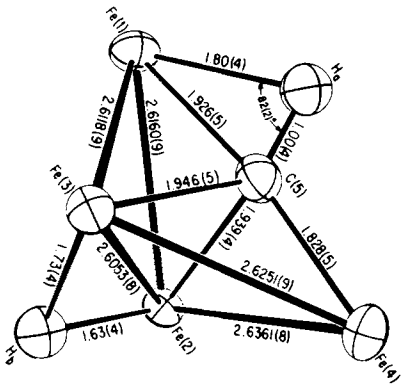


Fig. 3. Structural section from the μ_4,η^2-methylidyne cluster **11**. For sake of clarity the carbonyl ligands have been omitted; bond lengths in pm (after [24b]; reproduced by permission of the American Chemical Society).

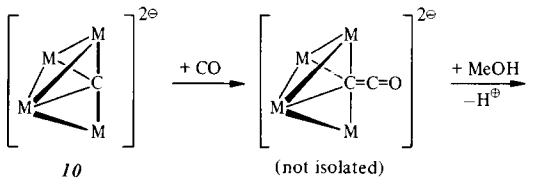
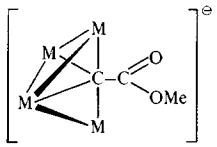
catalytic processes. Besides oxidative addition of H_2, carbide clusters (such as **10**) are also capable of carbonylation[24d].



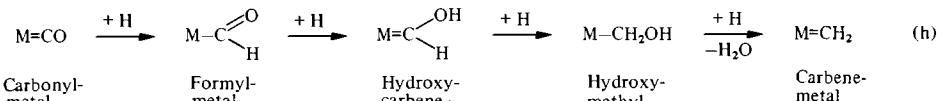
10 (not isolated)



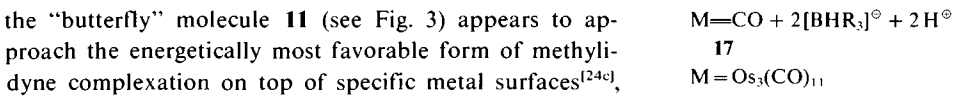
M = $Fe(CO)_3$

4.3. Stepwise CO-Hydrogenation

A much discussed alternative approach to methylene species is the *stepwise* hydrogenation of (in **12** metal-coordinated) carbon monoxide, a reaction sequence [(h)] which should involve the structural types **13**—**15**[12,14,25], that are now preparatively available as more or less stable mono- and



dinuclear complexes. Starting from the trinuclear osmium complex **17**, and using spectroscopy and [^{2}H]-labeling experiments, the entire sequence **12**—**16** has been established by consecutive reaction with H^- and H^+ as shown in the following equation[26]:



Of particular significance here is the observation, that the *hydride* hydrogen from the reductant K[BH(O—*i*-$C_3H_7)_3$] appears in the methylene group of **18**, whereas the subsequently added phosphoric acid (H^+) is required for the detachment of the carbonyl oxygen. Consistent with this finding, formation of the methylene cluster **18** does not occur when these reagents are added to the carbonyl complex **17** in the opposite order. The intermediate anionic formyl complex $Os_3(CO)_{11}[C(=O)H]^-$ produced by H^--addition is characterized by a ^{1}H-NMR signal observed at $\delta = 16.0$ as well as by an intense νCO band at 1577 cm^{-1} [26].

4.4. Formyl Complexes

Since the extensive studies of *Casey*[25a] and *Gladysz*[25b], structurally well-characterized mono- and multinuclear complexes with up to two η^1-bound formyl functionalities per metal are readily accessible in large quantities by reduction of the appropriate cationic or neutral metal carbonyl precursor with commercially available hydride reagents. Formyl ligands can easily be detected ^{1}H-NMR spectroscopically by means of low field signals in the region $\delta > 10$ ppm. Complex *anions* of this kind are chemically characterized by a pronounced hydride reactivity: Thus the extensively investigated iron complex $[L(CO)_3Fe\{C(=O)H\}]^-$ ($L = P(OC_6H_5)_3$) is suitable not only for the smooth reduction of 2-butanone to 2-butanol (92%), but also for hydride transfer to neutral Fischer carbenes or carbonylmetal compounds, for example $(CO)_5W{=}C(OCH_3)C_6H_5$ or $Re_2(CO)_{10}$[25a]. Moreover, reactivity studies suggest participation of the oxo-carbene structure $M{=}C(O^-)H$ in the ground state of anionic formylmetal systems. In the absence of appropriate reactants the irreversible decarbonylation typical of neutral formyl complexes normally dominates, whereby generally good yields of metal hydride derivatives result according to the scheme M—C(=O)H → M—H + CO[25a,b]. Occasionally, metalformyls also undergo intermolecular Claisen-Tischtschenko-type dismutation reactions. Thus, the neutral formylmanganese complex of composition *mer*-$(CO)_3[P(OCH_3)_3]_2Mn[C(=O)H]$ decomposes above 0° C with CO_2- and CO-elimination and concomitant formation of both the known mononuclear methyl derivative *mer*-$(CO)_3[P(OCH_3)_3]_2MnCH_3$ (40%) and the novel dinuclear complex $Mn_2(CO)_6[P(OCH_3)_3]_4$ (8%). This observation nicely points to a general, metal-centered pathway starting from formyl and leading to methyl functionalities[25d].

4.5. The Formyl/Hydrido(carbonyl) Equilibrium

The formation of the first C—H bond is of crucial importance to the stepwise, that is non-dissociative, CO reduction. Although the formyl/hydrido(carbonyl) equilibrium (i) has been cited for years as an analogous case to the well-established, completely reversible acetyl/methyl(carbonyl) system[35] in the explanation of kinetic data for CO substitution in carbonyl(hydrido)metal compounds, recent observations have strengthened the suspicion that the isomerization **19**→**13** does not occur to any appreciable extent for thermodynamic reasons. From model reactions [eq. (j)], carried out with isolable formyl and acetyl complexes, an equilibrium ratio of $K_1/K_2 > 10^5$ was ascertained, from which it follows that the kinetically moderately stable formyl species are thermodynamically less stable by a few orders of magnitude than the analogous acetyl complexes[25a]. Consequently, whereas decarbonylation (see *e.g.* Section 4.4) as well as the formyl→hydrido(carbonyl) reaction **13**→**19** can practically always be achieved preparatively, the reverse "CO-insertion" (**19**→**13**), as formulated in eq. (i), has not yet been observed. It can be supposed that the 20—30 kcal/mol greater stability of the M—H bond compared with a M—CH_3 bond is responsible for the strongly divergent equilibrium relationship in eq. (j).

19 $\quad H-M-CO \rightleftharpoons M-C(H)=O \quad$ *13* (i)

$(R_3P)(CO)(OC)(CO)Fe^{\ominus}-C(H)=O \rightleftharpoons R_3P + (CO)_4Fe^{\ominus}-H \quad (K_1)$

(j)

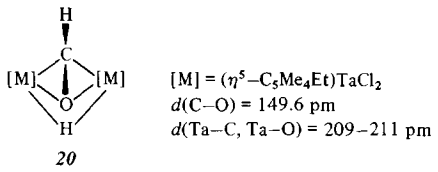
$(R_3P)(CO)(OC)(CO)Fe^{\ominus}-C(CH_3)=O \rightleftharpoons R_3P + (CO)_4Fe^{\ominus}-CH_3 \quad (K_2)$

$R = OC_2H_5$

$$K_1 = \frac{[R_3P]\,[(CO)_4Fe^{\ominus}-H]}{[(R_3P)(CO)_3Fe^{\ominus}-C(=O)H]}\,;\quad K_2 = \frac{[R_3P]\,[(CO)_4Fe^{\ominus}-CH_3]}{[(R_3P)(CO)_3Fe^{\ominus}-C(=O)CH_3]}$$

Nevertheless, it cannot be ruled out that formyl formation [eq. (i)] is favored on *heterogeneous* catalysts by an additional coordination of the formyl oxygen atom [cf. **20**—**22**, eq. (k)][27a,b], because Lewis acid effects of this kind also accelerate the formally analogous methyl group migration (CH_3—M—CO → M—C(=O)CH_3) by several orders of magnitude in homogeneous as well as heterogeneous systems (see Section 4.2).

Thus, the X-ray structurally characterized μ,η^2-formyl complex **20** originates from addition of CO to the hydrido-precursor $[(\eta^5\text{-}C_5Me_4Et)TaCl_2]_2H_2$[27a]; the equilibrium (l) has been demonstrated IR- and NMR-spectroscopically[27c]. Moreover, destabilization of M—CO bonds by d^0-metals should contribute to the preference for **13** [eq. (i)].



20

$[M] = (\eta^5\text{-}C_5Me_4Et)TaCl_2$
$d(C-O) = 149.6$ pm
$d(Ta-C, Ta-O) = 209-211$ pm

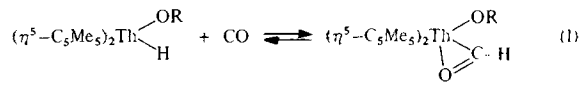
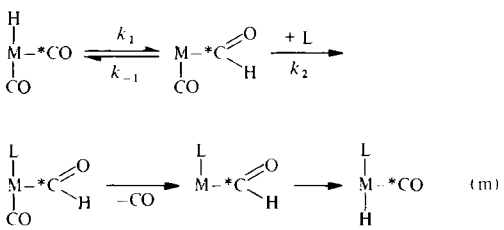
[M] = $Os(CO)_2[P(C_6H_5)_3]_2$



(l)

R = 1-*tert*-butyl-2,2-dimethylpropyl or 2,6-di-*tert*-butylphenyl

Several authors have recently commented[27d] on the well-known, abnormally fast CO-substitution in anionic, neutral as well as cationic carbonyl(hydrido)metal complexes (*e.g.* $HMn(CO)_5$), and have suggested that precisely the kinetic character of such reactions is attributable to only *small* concentrations of formylmetal intermediates [eq. (m)]. Earlier observations of *Basolo*, *Heck*, and *Brown*, concerning the reactivity of $H_2Fe(CO)_4$, $H_2Ru(CO)_4$ and their derivatives, would suggest that the thermodynamic



(m)

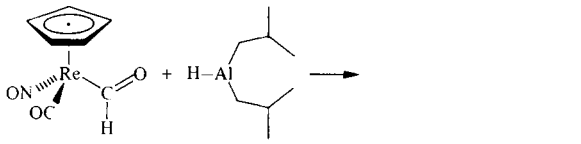
L = phosphane or phosphite, M = *e.g.* $Mn(CO)_3$ or $HFe(CO)_2$

instability of the formyl intermediate is a necessary prerequisite for the irreversible reaction of type **13**→**19** subsequent to substitution[27d]. The question as to the realizability of the equilibrium (i) on catalyst surfaces remains unanswered.

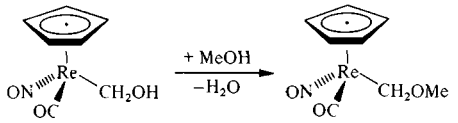
4.6. Hydroxymethyl, Methoxymethyl, Methoxy and Hydroxycarbene Complexes

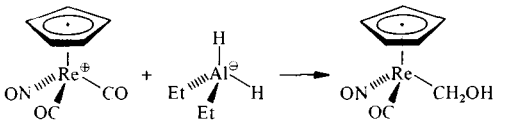
In principle, starting from formyl complexes, further reduction can lead to hydroxymethyl derivatives. Thus *Casey*

et al. described the clean reaction (n), achieved on using the potent hydride transfer reagent diisobutylaluminum hydride ("DIBAL-H"). It is to be noted, however, that hydroxymethyl ligands are often preparatively more easily accessible [eq. (o)] *via* direct reaction of the corresponding carbonyl compound with hydride derivatives of boron and aluminum (*i.e.*, BH_3, $[H_2AlEt_2]^-$, *etc.*)[25a,b]. The most striking property of hydroxymethyl complexes is their behavior towards methanol, with which they react to give methoxymethyl derivatives [eq. (n)][25a].



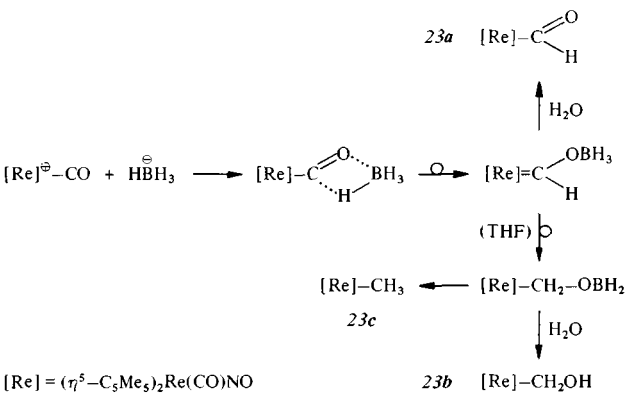
(n)



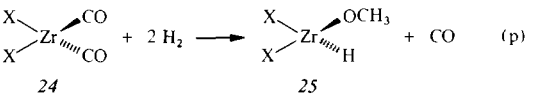


(o)

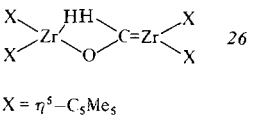
As model example for the stepwise reduction of coordinated carbon monoxide to isolable formyl, hydroxymethyl, and methyl ligands **23a—c**, *Sweet* and *Graham* have underscored the mechanism of the reaction of the complex cation $[(\eta^5\text{-}C_5Me_5)_2Re(CO)_2NO]^+$ with $NaBH_4$ in THF/H_2O[29a]. Under similar conditions, but dependent upon the water content of the solvent, the reaction time and temperature, the analogues of **23a—c** had already been prepared in surprisingly high yields (up to 95%) from the corresponding cyclopentadienyl complex[29b].



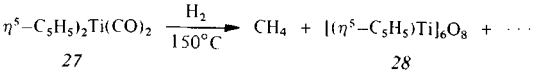
The first stoichiometric hydrogenation of complexed carbon monoxide in the homogeneous phase [eq. (p)] was achieved by altering the coordination atom in the ligand[30a,b]. This reaction is not entirely resolved mechanistically; however, it does provide a convincing example of the pronounced oxophilicity of electron-deficient transition metals [here: Zr^{II}] and for the strongly *hydridic* character ($M^{\delta+}$—$H^{\delta-}$) of their hydrido derivatives [here: $(\eta^5\text{-}C_5Me_5)_2ZrH_2$ or $(\eta^5\text{-}C_5Me_5)_2Zr(CO)H_2$]. If the conversion



(p)



24→25 really proceeds intermolecularly, then formation of zirconoxycarbene intermediates **26** is likely, as have been isolated from the reaction of $(\eta^5\text{-}C_5Me_5)_2ZrH_2$ with $W(CO)_6$[30a]. Reduction of the carbonyltitanium compound **27** with H_2 gives *methane* with concomitant formation of the structurally characterized hexanuclear oxo complex **28**[30b,c].



On using nucleophilic, H_2O-resistant hydridoniobium complexes [*e.g.*, $(\eta^5\text{-}C_5H_5)_2NbH_3$] for the reduction of electrophilic carbonylmetal compounds $M(CO)_x$, *Labinger et al.*[31a,b] observed selective alkane formation in specific cases [*e.g.* $Cr(CO)_6$, 2 h, 45 °C]; labeling experiments indicated that ethylene is the initial product, which is subsequently catalytically hydrogenated to ethane[31a]. The spec-

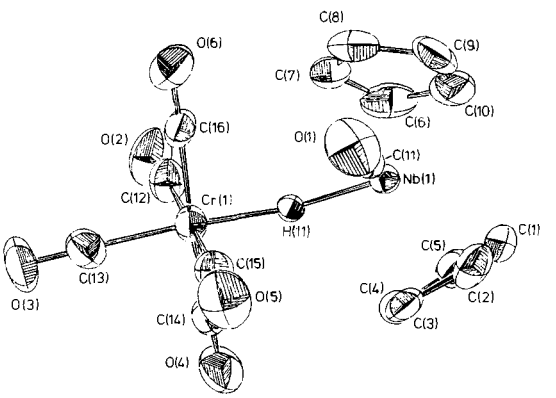


Fig. 4. Molecular structure of the μ-hydrido complex $(\eta^5\text{-}C_5H_5)_2Nb(CO)$—H—$Cr(CO)_5$ (type **30**), which is accessible as stable product by photolysis of $(\eta^5\text{-}C_5H_5)_2NbH_3$ and $Cr(CO)_6$. The formation of such compounds can be explained in terms of an oxycarbene intermediate (type **29**) through hydrogen transfer. Selected molecular data: Nb(1)—Cr(1) 345.3(2), Cr(1)—H(11) 118.2(102), Nb(1)—H(11) 182.4(99) pm; Cr(1), H(11), Nb(1) 137.4(54)°; $R_{iso}=0.045$, $R_{aniso}=0.077$. *(W. A. Hermann, M. L. Ziegler et al.*, unpublished results 1980/81).

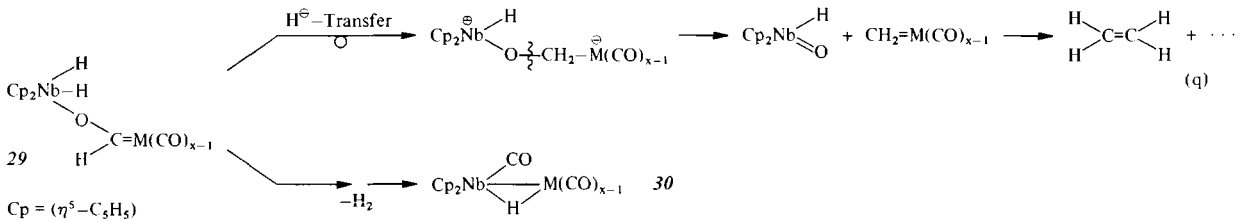
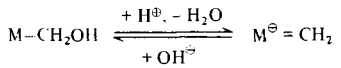
troscopically identified initial dinuclear products of type **29**, however, open the possibility for side reactions [eq. (q)], which often lead to stable μ-hydrido complexes **30**

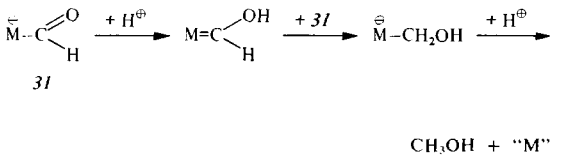


(Fig. 4)[31b–d]. Naturally, CO-reductions with hydridotransition metal complexes have proven to be much more complex than those with hydrides of the main group elements of comparable reducing strength (*e.g.*, Red-Al®, K-Selectride, *etc.*). Nevertheless, owing to their extreme tendency to hydrolyze, the latter are only suitable for stoichiometric reactions.

Methylene complexes $M^+{=}CH_2$ are related to their hydroxymethyl precursors by the acid/base equilibrium

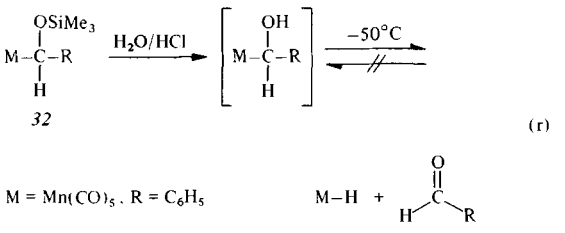


The protonation of anionic formyl derivatives such as **31** possibly involves hydroxycarbene complexes according to the overall sequence



M = Fe(CO)$_3$[P(OC$_6$H$_5$)$_3$]

Nevertheless, the primary formation of formaldehyde and its subsequent reduction by the hydride donor **31** cannot be ruled out[32]. Although the occurrence of free formaldehyde under real Fischer-Tropsch conditions is often not explicitly taken into consideration[2a], there is mass spectroscopic evidence for its presence among the initial products[33a]. According to a recent report concerning the protodesilylation of **32**, α-hydroxyalkyl complexes can be expected to irreversibly decompose to free aldehyde and the corresponding metal hydride [eq. (r)][34].

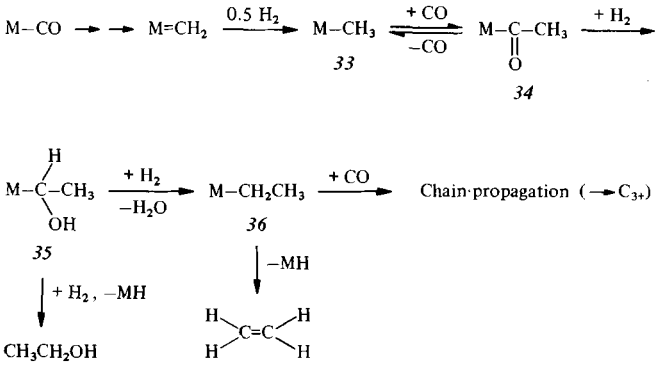


M = Mn(CO)$_5$, R = C$_6$H$_5$

It was very recently reported that free formaldehyde is capable of acting as a hydride donor toward ketones or higher aldehydes in the sense of metal-catalyzed Cannizzaro reactions with formation of the corresponding alcohols[33b]. Zirconocene dichloride-catalyzed reductive CO-oligomerization with diisobutylaluminum hydride gives a mixture of methanol, ethanol, 1-propanol, and 1-butanol (1.0 : 0.10 : 0.15 : 0.03)[33c]. Even octacarbonyldicobalt behaves as a weak catalyst for methanol formation from synthesis gas, but in this case rather drastic reaction conditions (300 bar, 200 °C) are required to achieve acceptable yields[33d].

5. The Carbon Monoxide Insertion Mechanism

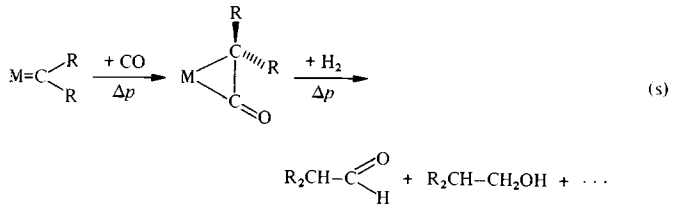
The most popular mechanism, but which according to the current state of our knowledge is presumably at best dominant in the synthesis of oxygen-containing F-T products, is based upon "CO-insertion"[35] into a metal-carbon bond as the fundamental chain growth step (alkyl migration)[2a]. According to this mechanism, the first M—CH_3 group **33** is formed by reduction of a metal-bound formyl intermediate, as outlined in principle in eq. (h). Subsequent reduction of the resulting acetyl moiety to an ethyl moiety is viewed as the key reaction along the path to consecutive incorporation of CO. If decarbonylation **34**→**33** is faster than alkyl transfer, then the formation of higher products will not result. A most important aspect of this



sequence is the reduction of α-hydroxyalkyl intermediates (*e.g.*, **35**) with cleavage of the metal-to-carbon bond to give alcohols, as well as β-hydrogen abstraction in the alkyl state (*e.g.*, **36**) to give α-olefins in competition with chain growth. On the other hand, alcohol formation could also arise from metal carbene species: mononuclear model systems for both hydrogenolytic cleavage of the carbene intermediate[36] and CO-addition have hitherto been established [eqs. (s)—(u)][37a,b,f].

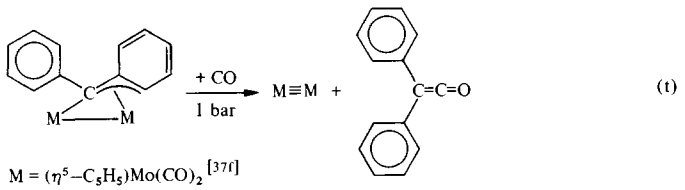
The latter reaction gives primarily the corresponding, in some cases isolable, structurally well-characterized ketene complexes (cf. Fig. 5)[14a,37a]. Decisive for the course of the reaction (u), is the metallocyclobutane/metal-olefin-me-

thylene equilibrium, that is also established for metallacycles of platinum[37b]. The observation of intramolecular CO-exchange in multiply metal-bonded ketenes suggests



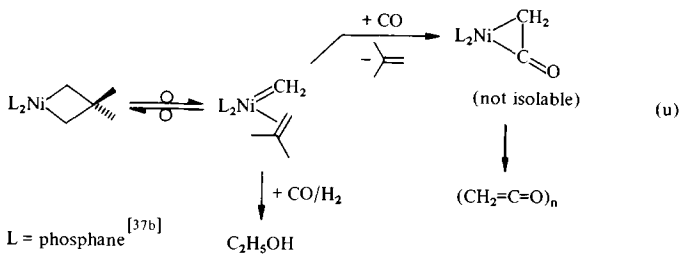
(s)

M = $(\eta^5-C_5H_5)Mn(CO)_2$, R = C_6H_5 [37a]



(t)

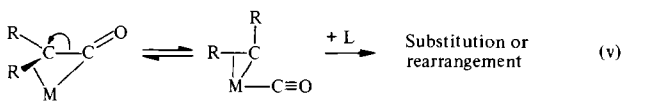
M = $(\eta^5-C_5H_5)Mo(CO)_2$ [37f]



(u)

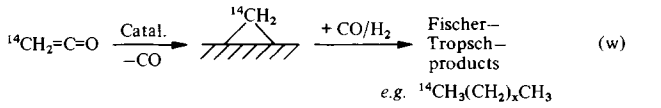
L = phosphane [37b]

reversible cleavage of a ketene C—C bond within the coordination sphere of the metal as in eq. (v) (Fig. 6)[37c]. Thus surface-bound ketenes could also take part in chain growth. In this connection, it should be remembered that incorporation of the methylene fragment from ketene into F-T products has been known for some time [eq. (w)][5a].



(v)

M = $Fe(CO)_3$, R = C_6H_5



(w)

Alternatively, it is possible to form ketene functionalities by carbene transfer to carbonyl-metal compounds[37e]. The synthetic step **34**→**36** has been established in the reduction of mononuclear acetyliron and acetylruthenium complexes with borane, and thus, in principle, could take place in catalytic cycles as well[37d]. The possibility of *selective* formation of oxygen-containing products by CO insertion

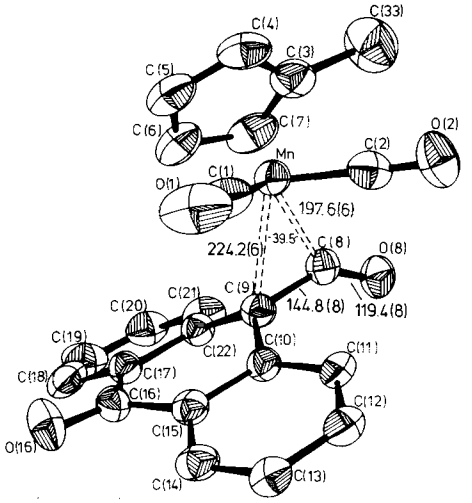


Fig. 5. Molecular structure of the ketene derivative dicarbonyl (η^2-10-carbonyl-9-anthrone)(η^5-methylcyclopentadienyl)manganese obtained by metal-induced carbene transfer to a manganese-CO function (bond lengths in pm, angles in degrees) [37e].

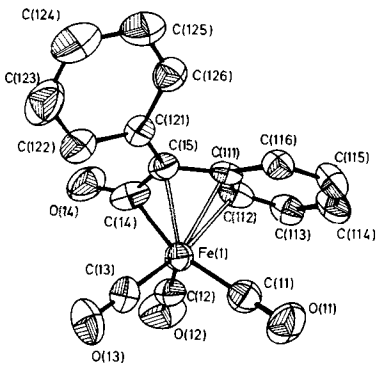

Fig. 6. Molecular structure of the η^1-η^3-diphenylketene complex $[(C_6H_5)_2C—C—O]Fe(CO)_3$. The intramolecular rupture of the C(14)—C(15) bond activated by complexation of the heterocumulene was established by labeling and crossover experiments [37c].

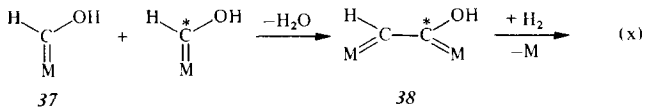
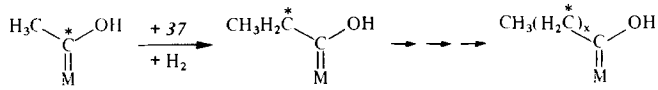
into surface-bound bridging alkylidenes was mentioned earlier (Section 4.1).

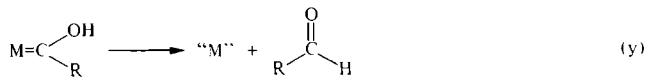
6. The Hydroxycarbene Mechanism

A proposal originally put forward by *Storch et al.*[1c,38] and later reiterated by *Kölbel et al.*[39] attributes chain growth to intermolecular ("multi-site") condensation reactions of hydroxycarbene species (*ex* formyl). Unfortunately, from the organometallic chemistry viewpoint, too little is known about the reactivity of the generally very unstable hydroxycarbene complexes, so it cannot be ascertained whether the proposed chain growth sequence [eq. (x)] should be considered seriously. A strong argument in favor of the formation of "enolic" primary complexes has been cited, *inter alia*, on the basis of investigations into the incorporation of alcohols and aldehydes into F-T products[1a]. But, at least in the case of homogeneous model systems, the selective hydrogenation of only *one* M=C bond in the dicarbene bridge **38** should be looked upon with scepticism. Moreover, the well-documented decomposition of isolable hydroxycarbene complexes *via* 1,2-hydrogen

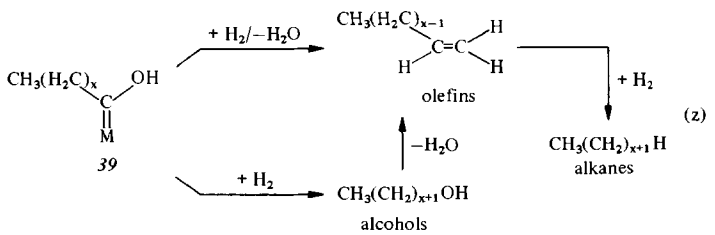
shift with concomitant formation of free aldehyde [eq. (y)] is also to be expected for surface-bound hydroxycarbenes[25c,40]. It is not certain whether this reaction, in the sense of a $d^n \rightarrow d^{n-2} \rightarrow d^n$ process, involves a hydrido(acyl) intermediate (d^{n-2}).







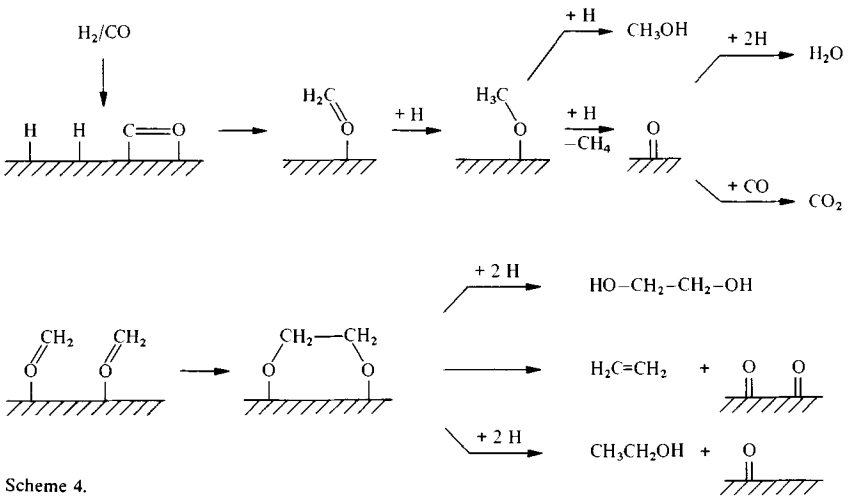
Model reactions for the reverse of eq. (y) are as yet unknown; this is unfortunate since their feasibility would not only give strong support to the mechanistic involvement of aldehydes in the Fischer-Tropsch synthesis but also would furnish an elegant synthetic route to hydroxycarbene complexes of which only scattered examples have so far been reported. Both these aspects represent a true challenge to the organometallic chemist.



A crucial test for the usefulness of the hydroxycarbene or hydroxymethylene model [eq. (x)] are the terminating steps outlined in eq. (z): None of the most conceivable degradation reactions considered here have been verified starting from isolable hydroxycarbene complexes of type **39**. It must be conceded, however, that the failure of these reactions to occur may possibly be due to coordinative saturation of the available substrates. Polynuclear systems bridged by hydroxyalkylidene functionalities and bearing supporting ligands that are prone to easy elimination could in fact basically change this pattern.

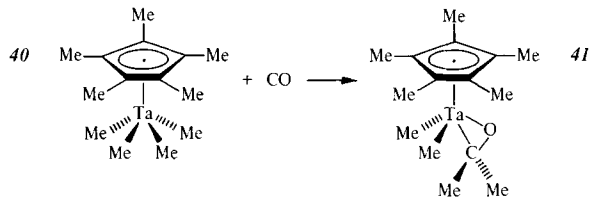
7. The Oxide Mechanism

The most recent mechanism put forward for the Fischer-Tropsch process, namely the "Oxide Mechanism" proposed by *R. S. Sapienza*[42] (Brookhaven National Laboratory) at an ACS meeting in August 1981, suffers from the grave disadvantage that it is quite speculative and, as yet, there is no suitable model system warranting its support. The general concept of this mechanism is that chain growth is accomplished on metal oxide surfaces and that the carbon atoms to be connected with each other do not touch the metal centers of the catalyst. In this context, formaldehyde is believed to be formed as the initial product and is anchored to the catalyst surface by means of the oxygen atom only. According to this view, the stability of the metal-to-oxygen linkage decidedly governs the product pattern (Scheme 4): After reductive coupling of the formaldehyde groups, hydrocarbons (in the case of strong M—O bonds) or oxygenates (in the case of weak M—O bonds) are formed. There is little doubt that the formation of oxidic surface layers has an effective influence upon the product pattern, but to overlook any possible metal-centered reaction steps would seem far too much of an oversimplification. Both the "Oxide Mechanism" as well as a related mechanism emphasizing the importance of hydroxy groups anchored to the catalyst surface[43] are inconsistent with the basic observation that even pronounced oxophilic metals (Ta^I) and metals in higher oxidation states (W^{IV}) do not bind simple *O,C*-ligands exclusively *via* the oxygen atom, and, conversely, that oxo(methylene)

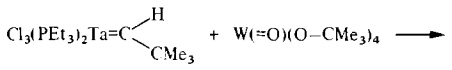


Scheme 4.

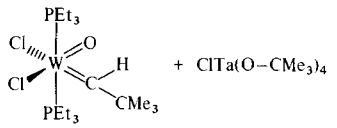
complexes obviously do not display any tendency to rearrange to aldehyde or keto derivatives. A typical example in support of this assessment is the well-characterized η^2-acetone complex **41,** which is formed by means of CO-insertion into the metal-methyl bond of the precursor molecule **40**[44]. In addition, the *Floriani* group has shown that *C*-coordination survives in the course of cycloaddition reactions between diphenylketene and certain titanium complexes[45]. Finally, the neopentylidene group of **42** is not transferred from tantalum to the oxo ligand of the carbene acceptor molecule **43,** but rather to its metal center. The



40 + CO → *41*



42 + W(=O)(O–CMe$_3$)$_4$ → *43*



44 + ClTa(O–CMe$_3$)$_4$

catalytic activity of the "tetravalent" tungsten compound **44** (olefin metathesis) is exclusively due to a phosphane dissociation pre-equilibrium and, thus, proceeds immediately in the center of the molecule but does not involve peripheral ligands[46].

8. Closing Remarks—Future Trends

What have we learned in the foregoing discussion? Organometallic model reactions have uncovered numerous, in part entirely new fundamental pathways in synthesis gas chemistry. Moreover, they have provided detailed knowledge of simple organometallic species, *e.g.* formyl and μ-methylene compounds. The mechanistic concept of the Fischer-Tropsch synthesis becomes clearer now in that the reaction principles regarding carbide, methylene, hydroxymethyl, formyl and hydroxycarbene complexes are far better understood than a few years ago. Therefore, unrealistic pathways for synthesis gas reactions can be excluded on the basis of such knowledge. There is increasing evidence that the carbide/methylene mechanism should be considered as offering the best description of reductive oligomerization of carbon monoxide giving oxygen-free products. Since there is no unambiguous proof for the hydrido(carbonyl)→η^1-formyl interconversion, caution has to be exercised in focusing on the participation of formyl intermediates in the chain-growth process, at least from the viewpoint of a critical organometallic chemist, because this important question is lacking a comprehensive, clear answer.

We should not forget that several striking experimental results still await elucidation. For example, all mechanisms that have hitherto been considered by various researchers do not sufficiently explain the fact that increasing H_2/CO pressure ratios favor the formation of alcohols under the conditions of heterogeneous F-T catalysis. In addition, both the participation of the side product water in the initial steps of the Fischer-Tropsch synthesis [eq. (a)] and the possibility of consecutive CO insertion reactions into methylene- and alkyl-metal bonds remain unclear. A comprehensive mechanism for carbon monoxide hydrogenation yielding oxygenates as well as the mechanistic explanation of alcohol homologation processes offer serious problems. Here, model studies involving carbonylation of metallacycles should provide a means of throwing some light on these questions.

Dinuclear μ-methylene complexes will undoubtedly play a pivotal role in further model studies. In this context it should be investigated whether combination of typical Fischer-Tropsch metals (*e.g.* transition metals of group VIII) with the pronounced oxophilic, electron-deficient early transition metals (*e.g.*, group IV and V-metals such as Ti, Nb, and Ta) renders catalytic CO/H_2 reactions possible. Finally, carbide cluster compounds that are nowadays easily accessible require further investigations into their capability for initiating Fischer-Tropsch-type reactions. Immobilized, polymer-supported catalytic centers[41] are expected to demonstrate the borderline between heterogeneously and homogeneously catalyzed synthesis gas reactions and to reveal the importance of multi-site activation in the course of the F-T process. It should prove possible to recognize the interrelationship with other kinds of catalytic reactions such as the olefin metathesis.

At present, considerable interest is attached to the stepwise improvement of heterogeneous catalysts in order to gradually approach the new selectivity goal mentioned in the Introduction. These developments should not have been neglected here; therefore, we conclude our review by pointing out the quintessence of two outstanding papers which nicely demonstrate future trends. Thus, the selectivity for C_2- to C_5-olefins is enhanced from 40 to 55% ($H_2:CO=2:1$; 200 °C) if ruthenium carbonyl, $Ru_3(CO)_{12}$, is used in place of the usual precursors $RuCl_3$ or $Ru(NO)(NO_3)_3$ for the preparation of $Ru/\gamma\text{-}Al_2O_3$ catalysts. Even more informative is the result that addition of the standard promoter potassium to the "$Ru_3(CO)_{12}$"/γ-Al_2O_3 catalyst once again enhances the process selectivity for low molecular weight olefins (80% at 1% K-content); at the same time, the overall activity of the catalyst for CO hydrogenation is found to decrease to a very large extent (*ca.* 50%)[47]. This striking contradictory effect —selectivity *versus* activity— is less pronounced in the case of the conventional "$RuCl_3$"/γ-Al_2O_3 catalyst. From these results, it is suggested that addition of potassium suppresses surface-induced hydrogen dissociation and, at the same time, stabilizes the adsorbed carbon monoxide, thus decreasing the activity for hydrogenation of CO. The enhancement of the olefin selectivity indicates that the surface-anchored alkyl intermediates experience an acceleration in β-hydrogen ab-

straction[47]. Another study has shown that ruthenium/zeolite catalysts (*e.g.*, Ru/zeolon; 3% Ru; Si/Al = 5 : 1) suffer from decreasing activity for syn-gas methanation with increasing acidity of the catalyst support—an observation which directly corresponds to increasing electron-deficiency of the catalytically active metal[48]. These and related findings are certainly interesting for the tailoring of new Fischer-Tropsch catalysts.

The results of my group that have been mentioned in this review arise from the enthusiasm of my coworkers, whose work I greatly appreciate. Generous support by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the BASF Aktiengesellschaft, the Hoechst Aktiengesellschaft, the Chemische Werke Hüls, the Degussa Hanau, the Humboldt Foundation, and the Karl-Winnacker Foundation is also gratefully acknowledged.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Umpolung of Carbonyl Reactivity *via* Acetoxyalkyl Radicals**

By *Bernd Giese** and *Ulrich Erfort*

The nucleophilic acetoxy radicals **7** can be generated from ketones **6** *via* the hydrazones **8** by mercuration (**8**→**9**) and reduction (**9**→**7**). The carbonyl carbon atom thus undergoes an umpolung from an acceptor to a donor[5]. Generation of the radicals **7** in the presence of acrylonitrile leads to formation of the product **10** *via* a radical chain mechanism (see Table 1) in a reaction analogous to that of the unsubstituted alkylmercury salts[2].

[*] Prof. Dr. B. Giese, U. Erfort
Institut für Organische Chemie und Biochemie
der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

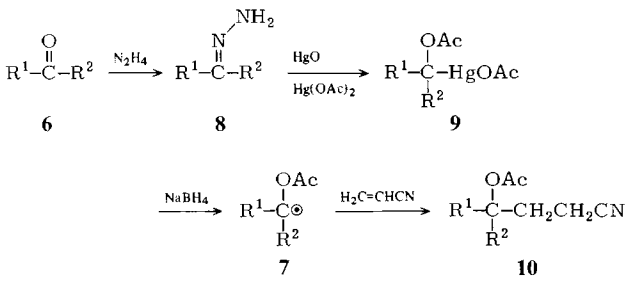

Table 1. Synthesis of **10** by mercuration of hydrazones (**8**→**9**) and reduction in the presence of acrylonitrile (**9**→**10**).

R^1	R^2	Yield **8**→**9** [%]	Yield **9**→**10** [%]
CH_3	CH_3	71	70
CH_3	C_2H_5	61	65
CH_3	i-C_3H_7	35	62
C_2H_5	C_2H_5	45	71
i-C_3H_7	i-C_3H_7	14	33
—$(CH_2)_4$—		54	72
—$(CH_2)_5$—		52	72

In the mercuration step (**8**→**9**) and the radical chain reaction (**9**→**10**) up to 72% yields are obtained. Only upon incorporation of two bulky isopropyl groups are the yields lowered to 14% and 33%, respectively (Table 1). These CC coupling reactions are not limited to acrylonitrile, but can also be performed with ester-, ketone-, anhydride-, phenyl-, or chloro-substituents. In this connection the yields are higher the more rapidly the alkenes react with nucleophilic radicals[7].

Evolution of Hydrogen from Photochemically Reduced Water-Soluble Tin(IV)-Porphyrins

By *Wolfgang Krüger* and *Jürgen-Hinrich Fuhrhop**

The tin(IV) complex **1** of a water-soluble porphyrin[3] was reduced to the green chlorin **3** ($\lambda_{max}=620$ nm) on irradiation with visible light in the presence of ethylenediaminetetraacetic acid (EDTA). The phlorin monocation **2**, which has been detected previously in similar photoreductions[4], is most likely formed as intermediate. On further irradiation the chlorin **3** is converted into the isobacteriochlorin containing two reduced pyrrole rings ($\lambda_{max}=604$ nm).

We have carried out the same photoreduction with a 5×10^{-5} M solution of **1** in presence of colloidal platinum[5] (2×10^{-5} mol/L). **1** was likewise reduced to **3**, but not to the isobacteriochlorin. Moreover, within one hour 10—20 mL of H_2 was formed per liter of solution at pH 4, and 20—30 mL per liter of solution at pH 5. The amount of hydrogen was independent of the conversion **1**→**3**. We assume that the phlorins **2** and **4** act in like manner as hydride-generating molecules. In presence of *N,N'*-dimethyl-4,4'-bi(pyridinium) dichloride (10^{-3} mol/L) the amount of hydrogen remains essentially unchanged (20—40 mL).

At higher or lower pH values, or on replacement of **1** by the analogous zinc porphyrinate, no hydrogen is evolved. After several hours, increasing aggregation of the porphyrin **1** and of the chlorin **3** was observed. No hydrogen was generated in such aged solutions.

The reaction sequence is outlined in the scheme below, where it is seen that a reaction of chlorophyll biogenesis (porphyrin reduction) is coupled with a partial step of photosynthesis (hydrogen formation).

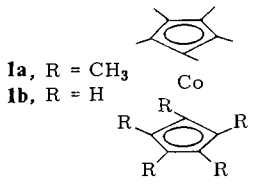
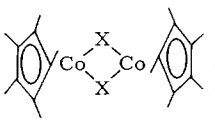
[**] Pentamethylcyclopentadienylmetal complexes, Part 4.—Part 3: U. Kölle, F. Khouzami, *Chem. Ber.*, in press.

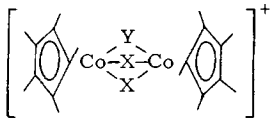
C_5Me_5Li, following *in situ* oxidation with $FeCl_3$, is not the expected pale yellow cation **1a**$^+$, but a violet salt whose properties are consistent with a complex cation of type **3**$^+$ (X = NH_2, Cl).



1a, R = CH_3
1b, R = H



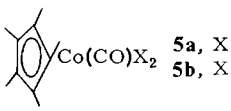
2a, X = Cl
2b, X = Br
2c, X = I
2d, X = NH_2



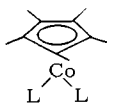
3a, X = Y = Cl[13]
3b, X = Y = Br
3c, X = Y = I
3d, X = NH_2, Y = Cl

To elucidate the course of the reaction, the Co(II) salts $[Co(NH_3)_6](BF_4)_2$, $CoCl_2$, $CoBr_2 \cdot$ 1,2-dimethoxyethane, and CoI_2 were reacted with C_5Me_5Li (in the molar ratio 1 : 1) as a suspension in tetrahydrofuran at 0—35 °C; thereby, the neutral complexes **2a—2d**, which are soluble in pentane, were obtained. The compositions of **2a** and **2b** were established by elemental analysis; their formulation as dimers stems from the mass spectra of **2a, 2b,** and **2d.** The stability of the complexes decreases along the series X = Cl > Br > $NH_2 \gg$ I, and hence the existence of **2c** can only be deduced from its subsequent reactions with *e.g.* CO to give **4** and **5b.** The complexes **2** are extremely air-sensitive and paramagnetic; ESR data of **2a, 2b,** and **2d** suggest rhombic d^7-systems.

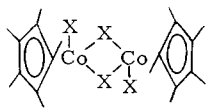
4



5a, X = Br
5b, X = I



6a, L = C_2H_4
6b, L = 1/2 1,5-Cyclooctadiene
6c, L = 1/2 1,3-Butadiene
6d, L = 1/2 1,2,3,4-Tetraphenylcyclobutadiene



7a, X = Cl
7b, X = Br

The labile compounds **2** can be oxidized by FeY_3 (Y = Cl, Br) or I_2 to give **3** and can be reduced by CO or Na/Hg in the presence of ethylene to give **4** or **6a,** respectively; disproportionation of **2b** and **2c** with CO led to **4** and **5,** while reaction of **2a** and **2b** with 1,5-cyclooctadiene, 1,3-butadiene or tolan yields **6b, 6c,** and **6d,** in addition to **7a** and **7b,** respectively. The reactions proceed spontaneously, at or below room temperature, to give the products in 60 to 90% yield; since the intermediates **2** need not be isolated, these complexes can *de facto* be prepared in a one-pot system from a Co(II) salt, C_5Me_5Li, and another anionic or neutral ligand. The significance of this novel synthetic principle lies in the fact that Co(I) compounds **4**[10] and **6a,** as well as the Co(III) complexes **3**$^+$, **5,** and **7** can be converted into a multiplicity of new Co sandwich and semi-sandwich complexes *via* addition or exchange reactions.

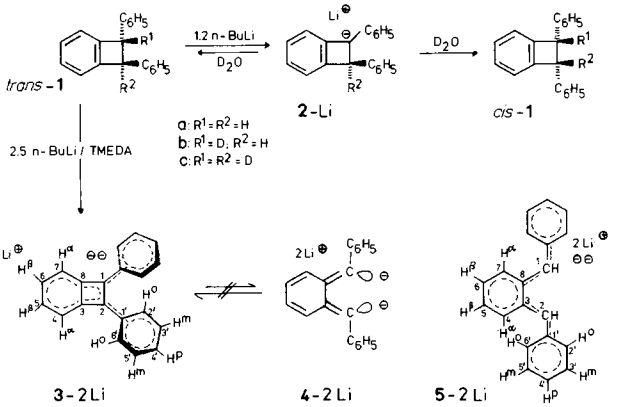
The Dianion 1,2-Diphenylbenzocyclobutadienediide**

By *Gernot Boche*, Heinz Etzrodt, Michael Marsch,* and *Walter Thiel*

Although the series of compounds which should be aromatic according to the Hückel rule have been the subject of numerous intensive studies[2], no convincing proof of the existence of the cyclobutadienediide dianion has so far been reported[2, 7]. What is the reason for this? The two and four additional π-electrons which the dianion has in comparison to the neutral molecule and the dication, respectively, leads to a closed $(4n+2)$ π-electron configuration, but, within the framework of the Hückel approximation, *not to an increase in the π-bonding energy.* Thus, the strong electron repulsion in a planar $C_4H_4^{2\ominus}$ could become the domineering destabilizing factor, similarly as the ring strain in cyclodecapentaene[2].

Further information in this respect is afforded by the dilithium salt of the 1,2-diphenylbenzocyclobutadienediide **3**-2Li, which we prepared by reaction of *trans*-**1a** with 2.5 equiv. of *n*-BuLi/tetramethylethylenediamine (TMEDA) (1 : 1) in tetrahydrofuran. With *n*-BuLi alone only the monoanion **2**-Li is formed, which on reaction with D_2O yielded *cis*- and *trans*-**1b**; **3**-2Li was deuteriated with D_2O to *cis*- and *trans*-**1c.** That the latter was not formed from **4**-2Li and D_2O followed from the ^{13}C-NMR spectrum of the dianion solution: The signals of C^1 and C^2 appear at $\delta = 83.8$; in the case of **4**-2Li the signals would have appeared much further downfield. Moreover, according to MNDO calculations, $\mathbf{4}^{2\ominus}$ is about 20.7 kcal/mol less stable than $\mathbf{3}^{2\ominus}$.



The bonding situation in **3**-2Li was investigated NMR spectroscopically, the open-ring dianion **5**-2Li serving as suitable reference substance.

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. *H. Günther,* Siegen, and Prof. *G. Maier,* Giessen, for helpful discussions.

From the ^{13}C-NMR spectrum of **3**-2Li empirically derivable charges ρ_{emp}[19d] are obtained which are in good agreement with the calculated MNDO charges of $3^{2\ominus}$. A comparison of the $\delta(^{13}C)$- and ρ_{emp}-values of the two dianions shows that the electron density distributions in the cyclic **3**-2Li and in the acyclic **5**-2Li are almost the same. Furthermore, in **3**-2Li only about 48% of both charges appear in the benzocyclobutene moiety. Thus, a preferred cyclic delocalization with formation of an aromatic $(4n+2)$ π-electron system is not observed in the case of **3**-2Li.

Analysis of the ^{1}H-NMR spectrum using a method described by *Günther et al.*[20d], in which the benzene ring in **3**-2Li serves as a probe for the properties of the attached annulene, led to the same result. Thus, the "Alternanzparameter" Q for **3**-2Li (1.05) is reconcilable only with an "olefinic" and not with an "aromatic" π-system in the four-membered ring.

The low acidity of **2**-Li, the electron distribution in **3**-2Li, and the Q-value of **3**-2Li preclude the latter dianion being designated as an aromatic compound. **3**-2Li is preparable because the negative charges are largely taken over by the substituents. This reduces unfavorable electron repulsion in the four-membered ring.

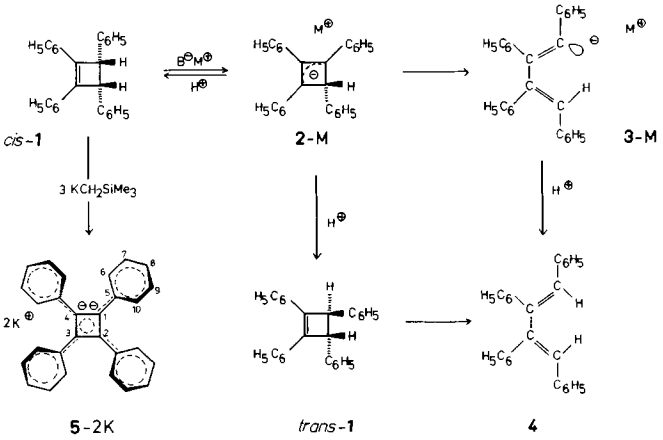
The Dianion 1,2,3,4-Tetraphenylcyclobutadienediide**

By *Gernot Boche**, *Heinz Etzrodt*, *Michael Marsch*, and *Walter Thiel*

Lack of information on the cyclobutadienediide dianion (cf. [1]) induced us to re-attempt the synthesis of the tetraphenylcyclobutadienediide dianion $5^{2\ominus}$[2]. In the following communication we report on the access to and the properties of **5**-2K.

Previous attempts[2] to prepare **5**-2M from *cis*-**1** and bases ($B^{\ominus}M^{\oplus}$) had led with *n*-BuLi in tetrahydrofuran (THF) to the stable lithium salt of the monoanion **2**-Li, and with KO*t*Bu in dimethyl sulfoxide *via* **3**-K to **4**. Reaction of *cis*-**1** with KO*t*Bu or lithium dicyclohexylamide in THF had afforded **4** *via trans*-**1**. The same was observed with lithium diisopropylamide, lithium *tert*-butylcyclohexylamide and lithium tetramethylpiperidide in THF; *n*-BuLi/tetramethylethylenediamine and *t*BuLi in THF, on the other hand, led to **2**-Li and to addition of base at the stilbene double bond.

Only the strongest base known at present, namely $(CH_3)_3SiCH_2K$[5], in THF led to **5**-2K. Reaction with D_2O, giving dideuterio-*cis*- and dideuterio-*trans*-**1** proved the presence of the dianionic four-membered ring. This ruled



out the presence of the valence isomer of **5**-2K corresponding to **3**-M and **4**, the 1,4-dipotassio-1,2,3,4-tetraphenylbutadiene **6**-2K, as an alternative. Nevertheless, according to MNDO calculations $6^{2\ominus}$ is only 11.2 kcal/mol less stable than $5^{2\ominus}$.

The NMR spectra of the dianion confirm the presence of **5**-2K: ^{13}C-NMR: $\delta = 108.8$ (C^{1-4}), 141.9 (C^5), 122.9 ($C^{6,10}$), 127.7 ($C^{7,9}$), 112.8 (C^8); ^{1}H-NMR: $\delta = 6.93$ (d, $H^{6,10}$), 6.61 (t, $H^{7,9}$), 5.97 (t, H^8).

Furthermore, it follows from the NMR spectra that the phenyl groups take over a considerable part of the negative charges. Thus, the charges ρ_{emp}[1], which can be determined from the ^{13}C-NMR spectrum, and which correlate with the calculated ρ_{MNDO} charges, indicate that only about 36% of the two negative charges are found on the four-membered ring C-atoms. Also consistent with this conclusion is the calculated MNDO π-bond order of 0.470 for the exocyclic bonds (*e.g.* C^1—C^5), whereas a bond order of only 0.450 is obtained for the bonds in the four-membered ring.

The exceptionally low acidity of **2**-M, the calculated enthalpies of formation ΔH_f, and the charge distribution obtained from the NMR data do not characterize **5**-2K as "aromatic"[1, 12b]. It can be concluded from these results that the unsubstituted cyclobutadienediide dianion must be still more energy-rich and more basic than **5**-2K, because stabilization by delocalization of charge(s) in the phenyl groups is missing there.

Rotation of Polymerized Vesicles in an Alternating Electric Field**

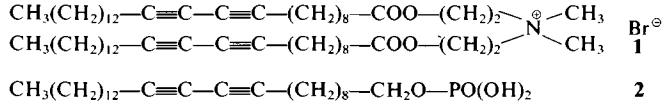
By *Hans-Henning Hub, Helmut Ringsdorf,* and *Ulrich Zimmermann**

Suspended cells rotate at certain frequencies in alternating electric fields[1a]. The frequency ranges in which suspended cells rotate are species-specific and/or membrane-specific (*e.g.* 20—40 kHz for mesophyll protoplasts of *Avena sativa,* 100—200 kHz for erythrocytes, 140—180 kHz for yeast cells, 30—40 kHz for permanent cell lines, and 1 MHz for plant protoplasts and erythrocytes treated with pronase). The rotation (about 1 rotation/s) is a function of the square of the field intensity[1]. Theoretically, it can be attributed to an interaction between induced dipoles in neighboring cells. Maximum coupling between the neighboring dipoles occurs when the cells are oriented at an angle of 45° to each other[1b]. Rotation of a free cell is, therefore, not possible if the cell is far enough away from the electrodes and other cells (however, see[2]). Dipole-dipole interaction between two neighboring cells leads to a mean torque different from zero.

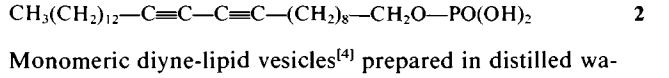
Maximum torque occurs when $\omega\tau = 1$ (τ is the relaxation time of the dipole build-up and ω is the angular frequency). According to theory[1b], the number of rotating cells should, therefore, progressively decrease towards higher and lower frequencies.

On the other hand, our studies of erythrocytes, plant protoplasts, and permanent cell lines have revealed that cell rotation can be induced in the frequency range 70—140 MHz. The discrepancy between theory and experiment can be explained if it is assumed that various relaxation mechanisms underlie the build-up of a dipole in cells. Dipoles may be, induced, *inter alia*, by the orientation of the phospholipids and/or proteins in the membrane or by charge separation at the membrane. The relaxation time, τ, can be calculated for the latter mechanism[3].

Systems such as polymeric diyne-lipid vesicles (from lipid **1** or **2**), which are homogeneous and have fixed components, should therefore exhibit only one frequency range for maximum rotation, since dipoles can only be built up by charge separation.



1



2

Monomeric diyne-lipid vesicles[4] prepared in distilled water at 70 °C and polymerized afterwards, were exposed to an alternating field of 100 kHz between two parallel cylindrical electrodes glued to a microscope slide. Because of the inhomogeneity of the field the vesicles migrate towards the region of higher field intensity (*i.e.* towards the electrodes) and form "pearl chains" as a result of the forces of attraction between the dipoles induced in the vesicles by the field[1]. If several parallel pearl chains are formed, many vesicles are oriented at an angle of 45° to each other. Rotation of the vesicles is observed in the frequency range 1—4 MHz. As predicted by theory, no rotation was observed outside this frequency range up to 170 MHz or down to 10 kHz (minimum output voltage of the high frequency generator 3-5 V, electrode distance 100 μm). No experiments could be carried out in the frequency range 40—70 MHz because of resonance in the experimental system.

According to theory[3], the frequency at which all vesicles rotate is displaced to higher values when the intra- and/or extravesicular conductivity of the vesicles is increased. Polymeric vesicles prepared and incubated in a 10^{-3} M KCl solution exhibited the predicted shift towards higher frequency (7—15 MHz). No rotation was observed in the remaining, experimentally accessible frequency range. If the intravesicular KCl concentration was raised to 10^{-2} M KCl no rotation was observed in the entire frequency range. The reason for this observation may be that the membranes become permeable so that charge separation can no longer take place.

These results demonstrate that the rotation observed in the range 20 kHz—3 MHz in different cell types is very probably attributable to charge separation. Rotation of cells in the 100 MHz range must thus be attributable to an orientation of dipoles within the membrane or to the occurrence of rotating fields in this frequency range. If it were possible to determine and assign the respective specific frequencies for the orientation of these components in the high frequency range using artificial lipid vesicles of various compositions and fluidities, *the determination of*

the rotational spectrum could become an important tool in cell and membrane research. The experimental result that rotation ceases when the membrane permeability is increased may explain why electrically induced fusion of monomeric vesicles is observed only occasionally and not reproducibly. In permeable membranes the breakdown voltage can no longer be reached so that fusion cannot be initiated. For the purpose of electric field induced fusion, the occurrence of rotation in an alternating field thus represents an accessible criterion for the integrity of biological and artificial membranes.

Stereoselectivity and Relative Reactivity in the Reaction of Organotitanium and -zirconium Reagents with Carbonyl Compounds**

By *Manfred T. Reetz*, Rainer Steinbach, Jürgen Westermann, Ralf Urz, Bernd Wenderoth,* and *Roland Peter*

Organotitanium and -zirconium compounds[1a,b,2a,c] such as **1**—**6** react far more selectively than their lithium-, magnesium- and zinc analogues.

$RTi(O\text{-}i\text{-}C_3H_7)_3$
1a, R = CH_3
1b, R = CD_3
1c, R = n-C_4H_9
1d, R = CH_2=$CHCH_2$

$CH_3Ti(OC_2H_5)_3$ **2**

$R_2Ti(O\text{-}i\text{-}C_3H_7)_2$
3a, R = CH_3
3b, R = CD_3

$Ti(CH_3)_4$ **4**

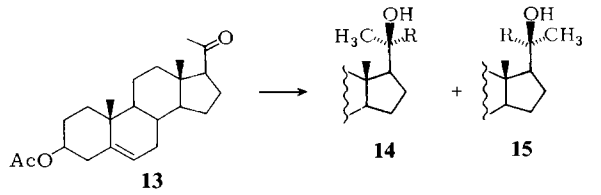
$CH_3Zr(O\text{-}n\text{-}C_3H_7)_3$ **5**

$Zr(CH_3)_4$ **6**

Addition of **1a, 1c, 2, 4,** and **5** to 2-phenylpropanal leads preferentially to the "Cram products" (*erythro* : *threo* up to 93 : 7). Other zirconium reagents react similarly, whereas the analogous lithium and magnesium reagents display far less diastereodifferentiation ($\approx$2 : 1).

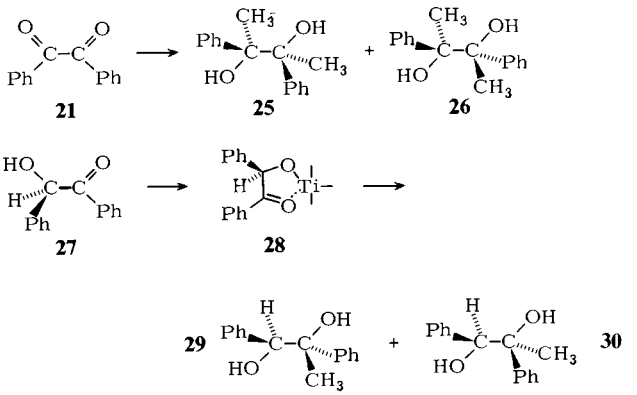
Asymmetric induction in the construction of steroid side chains can be realized particularly easily with titanium reagents, but not with zirconium reagents. Reaction of **13** with **1d** or **1b** leads to formation of the diastereomers **14a** and **15a** or **14b** and **15b** in the ratio >90 : 10 and 96 : 4, respectively. Furthermore, a titanium enolate derived from *O*-methylestrone undergoes an *erythro*-selective aldol addition, whereby practically only one of the four possible diastereomers is formed.

In order to test whether *Cram*'s "cyclic model" is applicable in the case of titanium and zirconium reagents, benzil **21** was allowed to react with **1a, 2, 3** or **4** to give **25** (*d,l*~*threo*) + **26** (*meso*~*erythro*) (>98 : 2, 60 : 40, 93 : 7 and 98 : 2, respectively). This is a *reversal* of the 1,2-asymmetric induction observed on reaction with **5**, methyllithium or methylmagnesium bromide (**25** : **26** in the ratios of 19 : 81, 15 : 85, and 28 : 72 respectively) and thus supports *Anh*'s open-chain model[5]. Reaction of **27** with **1a** or **4** yields exclusively the *erythro* isomer (**29** : **30** in the ratio >99 : 1), indicating intermediary formation of the sterically less strained chelate **28.**



13 **14** **15**

a, R = CH_2=$CHCH_2$; **b**, R = CD_3



21 **25** **26**

27 **28**

29 **30**

Noticeable 1,3- and 1,4-asymmetric induction is observed on addition of **1a** and **4** to 3-hydroxybutyraldehyde or phthalaldehyde (diastereomeric ratios up to 70 : 30 and 83 : 17, respectively).

The rate of addition of the reagents to ketones decreases along the series **4**$\approx$**6**>**3**>**1a**$\approx$**5**. In the titanium series itself: allyl > methyl > *n*-butyl. The *highly reactive but not very basic tetramethylzirconium* **6** adds to sterically highly hindered compounds, particularly in cases in which methyllithium, **1a** or **5** fail. Titanium or zirconium reagents react selectively with ketones in the presence of ester groups, but lactonization can occur.

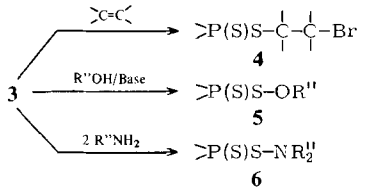
class of compounds, the sulphenyl bromides **3**, in quantitative yield. The reaction proceeds *via* the disulphides **2**, which can be used advantageously as educts. The bromides **3** are also formed in quantitative yield by the action of Br_2 on trimethylsilyl esters **1** ($X = SiMe_3$).

$$\underset{\mathbf{1}}{2\,RR'P(S)SX} \xrightarrow[-2XBr]{Br_2} \underset{\mathbf{2}}{RR'P(S)SS(S)PRR'} \xrightarrow{Br_2} \underset{\mathbf{3}}{2\,RR'P(S)SBr}$$

a, $R = R' = tBuCH_2O$; **b**, $R = R' = iPrO$; **c**, $R = R' = MeO$; **d**, $R = R' = PhO$; **e**, $R = tBu$, $R' = MeO$

By analogy, *O*-methyl butyldithiophosphonate **1e** ($X = H$) reacts to give **3e**. The sulfenyl bromides **3** can be isolated in a pure state[1], but decompose at room temperature (within a few days) to the bromides RR'P(S)Br and sulfur.

The bromides **3** react readily at room temperature or below with various nucleophiles giving a variety of novel or difficultly accessible organophosphorus compounds.



Compounds of type **5** react with trimethylsilyl chloride to give in high yield sulfenyl chlorides **7** which, due to their reactivity, are suitable educts for the synthesis of other organophosphorus compounds[2].

$$\underset{\mathbf{5}}{RR'P(S)S{-}OR''} + ClSiMe_3 \rightarrow \underset{\mathbf{7}}{RR'P(S)SCl} + R''OSiMe_3$$

Experimental[1]

3c: A solution of Br_2 (1.6 g, 10 mmol) in 5 mL of CCl_4 was added to a stirred solution of **2c** (3.14 g, 10 mmol) in 10 mL of CCl_4 at $-25\,^\circ C$. Solvent was removed at 0—5 °C/5 torr, yielding **3c** (4.7 g) as a yellow oil. **3c** could be added to cyclohexene in CH_2Cl_2 at 0 °C to give the 2-bromocyclohexyl compound $(MeO)_2P(S)SC_6H_{10}Br$ (type **4**) in 88% yield; b.p. = 105—108 °C/0.01 torr, ^{31}P-NMR (C_6H_6): $\delta = +97$.

7a: Me_3SiCl (1.3 g, 12 mmol) was added to a stirred solution of **5a** (3.5 g, 10 mmol) ($R = R' = R'' = tBuCH_2O$) in 20 mL of CH_2Cl_2 at $-10\,^\circ C$, and the mixture stirred for 20 min at $-5\,^\circ C$. After removal of the solvent and trimethylsilyl ether at 0 °C under reduced pressure, **7a** (3.0 g) was obtained; ^{31}P-NMR (CH_2Cl_2): $\delta = +79.5$. **7a** reacts with piperidine to give the piperidide (m.p. = 67 °C) in 86% yield.

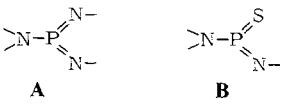
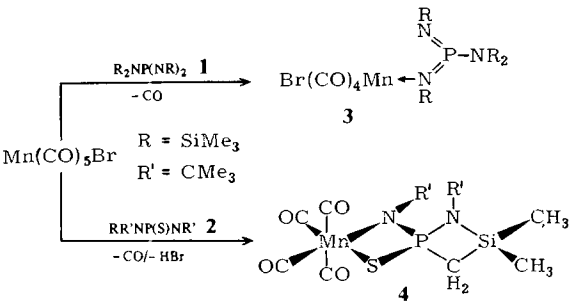
Manganese Complexes with "End-On" and Spirocyclic Bonded σ^3,λ^5-Phosphazene Ligands**

By *Otto J. Scherer**, *Jürgen Kerth*, *Barbara K. Balbach* and *Manfred L. Ziegler*

Until now the complex chemistry of σ^3,λ^5-phosphazenes **A** [aminobis(imino)phosphoranes] and **B** [amino(imino)thiophosphoranes] has been limited to two reaction types.



Whereas the double ylide **A** reacts with, *e.g.*, $TiCl_4$[1] or $(C_3H_5)_2Pd$[2] to give the transition metal chelate complexes $L_xM(NR)_2PR'R''$ with a four-membered ring framework, obtainable with platinum by other means[3], reaction of **B** with $(Ph_3P)_2Pt(C_2H_4)$ led to "side-on" coordination of the P=S group[4]. We have now found that with $R_2N{-}P(=NR)_2$ **1**, $Mn(CO)_5Br$ forms the complex **3** which contains an "end-on" bonded σ^3,λ^5-phosphazene ligand, while with $RR'N{-}P(S){=}NR'$ **2**, it forms the phosphorus spiro compound **4** whose ring framework consists of two four-membered rings each of which contains four different elements.



3 can be isolated from hexane as permanganate-colored, extremely air-sensitive crystals which are readily soluble in ether, benzene, *n*-hexane, and dichloromethane. In solution, **3** exhibits dynamic behavior: the intramolecular exchange of the $Br(CO)_4Mn$ moiety from one to the other imino group, which at room temperature occurs rapidly on the NMR time scale, is measurably slowed down at low temperatures ($\Delta G_c^{\neq} = 51\ kJ \cdot mol^{-1}$)[6]. When **3** and Ph_3P (molar ratio 1:2) are warmed for 2.5 h at 40 °C in hexane, uncoordinated double ylide **1** is formed in high yield together with a mixture of *fac*-$Mn(CO)_3(PPh_3)_2Br$ [*ca.* 80%: ^{31}P-NMR (CD_2Cl_2, $-50\,^\circ C$): $\delta = 35.2$(s)] and *mer*-$Mn(CO)_3$-*ce*-$(PPh_3)_2Br$ [*ca.* 20%; ^{31}P-NMR: $\delta = 54.5$ (s)].

4 forms yellow-brown, slightly air-sensitive crystals from ether which are readily soluble in CH_2Cl_2 and CH_3CN, moderately soluble in ether and benzene, and sparingly soluble in *n*-hexane. The NMR data (*e.g.* the four expected singlets from the CO groups are found in the $^{13}C\{^1H\}$ spectrum) of **4**, as well as the X-ray structure analysis confirm the tetrahedral environment of the P atom.

Efficient Synthesis of 8-Oxabicyclo[3.2.1]oct-6-en-3-ones, Preparatively Useful [4+3]-Cycloadducts**

By *Baldur Föhlisch**, *Eberhard Gehrlach*, and *Rolf Herter*

The title compounds **2**, accessible by cycloaddition of allylium-2-olates to furans have proven to be valuable educts for the synthesis of natural products and biologically active analogues. Previously, however, the cycloadducts could only be synthesized using tedious and expensive methods[2a,3a,4,5,7]. We have now found a method in which not only α-bromoketones but also the less expensive and more stable α-chloroketones can be reacted with readily available bases.

The α-haloketones **1a–h** react with furan in 2,2,2-trifluoroethanol (TFE), a very weakly nucleophilic and powerful ionizing solvent, in the presence of triethylamine or sodium 2,2,2-trifluoroethoxide generated *in situ* to give 8-oxabicyclo[3.2.1]oct-6-en-3-ones **2** (Table 1). The yields are good, and work-up is simple. The bicyclic compounds **2b—f** are formed stereoselectively. By reduction of **2f** or **2g** with the Zn/Cu couple, the unsubstituted ketone **2**, $R^1 - R^4 = H$, is also accessible in good yields. α-Chloroketones can not only be prepared by chlorination of ketones, but also *via* several other routes, by C—C coupling reactions. Thus, the [4+3]-cycloaddition of allylium-2-olates opens up promising applications in synthetic chemistry.

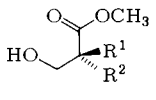
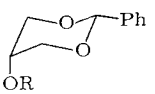
an even better starting material. Certain types of optically active glycerol derivatives can be prepared from **3** with a minimum of protecting group chemistry. Starting from **3** we have synthesized **6** and **7**, as well as **15**, a structural analogue of the antibiotic moenomycin A[6].

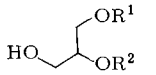
Alkylation of **3**[8] with 1-bromooctadecane or with 2,3-dihydrophytyl bromide in dimethylformamide afforded **4** (81%) and **5** (70%), respectively. Hydrolytic cleavage of the benzylidene protecting groups, followed by diol cleavage with sodium metaperiodate, subsequent oxidation of the aldehyde with silver(II) oxide and esterification of the resulting acid then furnished the *R*-glyceric acid derivatives **6** (36%) and **7** (56%), respectively.



6, R^1 = H, R^2 = $OC_{18}H_{37}$
7, R^1 = H, R^2 = $OC_{20}H_{41}$
8, R^1, R^2 = H, $OC_{18}H_{37}$



9, R = H
10, R = $C_{18}H_{37}$

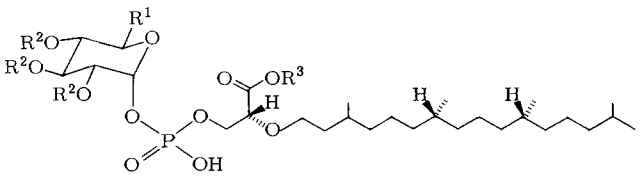


11, R^1 = COC_6H_5, R^2 = $C_{18}H_{37}$
12, R^1 = $COCH_3$, R^2 = $C_{18}H_{37}$

The racemic ester **8** was synthesized from *cis*-5-hydroxy-2-phenyl-1,3-dioxane **9**. *O*-Alkylation with 1-chlorooctadecane (phase-transfer catalysis) furnished **10** in 67% yield. Deslongchamps opening[14] of **10** to the hydroxybenzoate **11**, Jones oxidation, and esterification of the acid afforded the racemic ester **8** (51%, referred to **10**). **8** is also accessible in a total yield of 61% from **10** by hydrolytic cleavage of the benzylidene group, monoacetylation to **12**, Jones oxidation, and subsequent esterification.

In presence of the optically active shift reagent Eu(tfc)$_3$ the ^{1}H-NMR spectrum of **8** shows two OCH_3 signals (ratio: 1 : 1), while the spectrum of **6** recorded under the same conditions shows only one: hence, within the limits of NMR detection, **6** is formed in optically pure form.

For the preparation of **15**, **7** was allowed to react with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl 1-phosphate according to the phosphoric acid diester method using 2,4,6-triisopropylbenzenesulfonyl chloride to give the diester **13**. Cleavage of the protecting groups with lithium hydroxide yielded the dilithium salt of **14**, which was converted by catalytic oxidation into the glucuronic acid derivative **15** (after ion-exchange).



13, R^1 = CH_2OAc, R^2 = Ac, R^3 = CH_3
14, R^1 = CH_2OH, R^2 = H, R^3 = H
15, R^1 = COOH, R^2 = H, R^3 = H

The antibiotic moenomycin A is one of the most active inhibitors of bacterial cell-wall biosynthesis[6]. However, a correlation between its very complex structure and biological activity has thus far been lacking. The synthetic access to model substances such as **15** now opens up the possibility of investigating this problem experimentally.

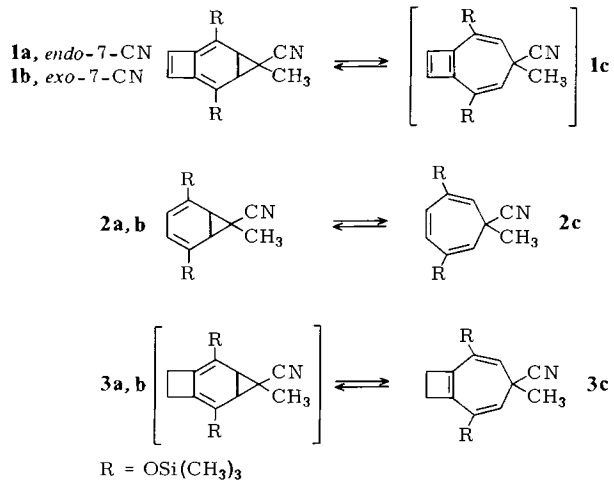
The Effect of an Annelated Cyclobutene or Cyclobutadiene Ring on the Norcaradiene—Cycloheptatriene Equilibrium**

By *Frank-Gerrit Klärner**, *Eckhart K. G. Schmidt*, and *Mahmoud Abdel Rahman*

The question of the antiaromaticity of 1,3-cyclobutadiene has been the subject of repeated theoretical and experimental investigations[1]. In the valence tautomeric equilibrium **1a, b** ⇌ **1c**, the cycloheptatriene derivative **1c** contains a cyclobutadiene ring as a subunit. Provided that cyclobutadiene is antiaromatic, the equilibrium is expected to be shifted in favor of the norcaradienes **1a** and **1b**. We report here on the syntheses and properties of the systems **1, 2,** and **3.**



The syntheses of **1, 2,** and **3** start from 7-methyl-1,3,5-cycloheptatrien-7-carbonitrile[3]. Addition of $^1O_2$ leads to **4** (yield 96%), which on subsequent reduction ($(NH_2)_2CS$ or Pt/H_2) and oxidation (MnO_2 or CrO_3) is converted into **5** (64%) or **6** (54%), respectively. Photochemical addition of

[**] This work was supported by the Fonds der Chemischen Industrie.

ethyne or ethene to **5** affords **8** (97%) or **9** (93%), respectively. On reaction of compounds **6**, **8**, and **9** with CF_3SO_3—$Si(CH_3)_3$[5], the enol ethers **2**, **1**, and **3**, respectively, are obtained in yields of 80, 75, and 80%.

According to the ^{1}H-NMR spectra measured between +50 °C and −100 °C, **1** has the structure of the norcaradiene derivative **1a**, and **3** of the cycloheptatriene derivative **3c**. **2** consists of a mixture of **2a**, **2b**, and **2c** (equilibrium ratio, at −90 °C, 52 : 41 : 7); at room temperature the equilibration **2a** ⇌ **2c** ⇌ **2b** is rapid on the NMR time scale ($\Delta G^{\neq}$ values between 10 and 14 kcal/mol). Spectroscopic assignment is confirmed by the secondary reactions of **1**, **2**, and **3**. Hydrolysis of the enol ether functions of **1** leads only to regeneration of **8**. In the case of **2** and **3**, on the other hand, only the respective diketones **7** and **10** formed from **2c** and **3c** are obtained. Consequently, the rapid valence isomerization observed in the other systems **2a** and **3a** does not take place in the norcaradiene **1a**, either under conditions of formation or hydrolysis. This is due to the destabilizing effect of the annelated cyclobutadiene ring in the cycloheptatriene derivative **1c**.

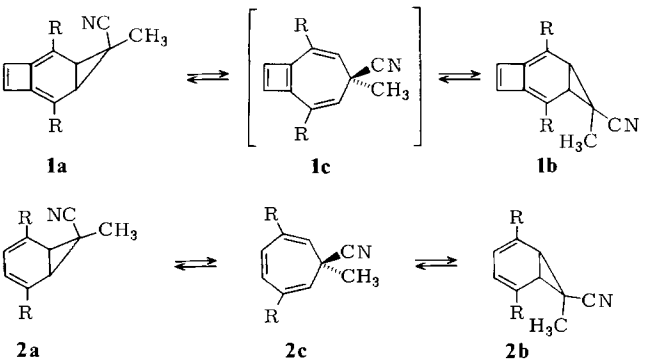
The Question of the Antiaromaticity of 1,3-Cyclobutadiene: Thermal Valence Isomerization of the Tricyclo[5.2.0.0^{3,5}]nona-1,6,8-triene System**

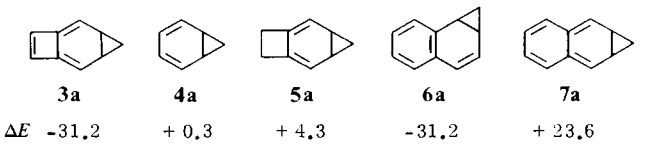
By *Frank-Gerrit Klärner**, *Eckhart K. G. Schmidt*, *Mahmoud A. Abdel Rahman*, and *Herbert Kollmar*

Negative resonance energy is frequently cited as a criterion of antiaromaticity. Values between 0 and −33 kcal/mol have been calculated for cyclobutadiene[2c]; the data derived from experiments vary between −11 and −16 kcal/mol[2c]. We report here on the negative resonance energy of cyclobutadiene, which follows from a study of the equilibria **1a** ⇌ **1c** ⇌ **1b** and **2a** ⇌ **2b** ⇌ **2c**. Unlike **2a**[4], the norcaradiene **1a** rearranges to the diastereoisomer **1b** up to the equilibrium ratio (70 : 30) only on heating (60 °C). The ^{1}H-NMR spectroscopically determined activation parameters for the isomerization **1a** ⇌ **1b** still do not give any direct information about the position of the equilibria **1a** ⇌ **1c** and **1b** ⇌ **1c**. For the valence isomerizations **1c** → **1a**, **1c** — **1b**, and **2c** → **2a**, **2c** — **2b** which are of the same type similar activation barriers can be assumed to a first approximation. From the kinetic data given in Scheme 1 the norcaradienes **1a** and **1b** can be estimated to be each *ca.* 14 kcal/mol more stable than the cycloheptatriene derivative **1c**.

In order to determine the antiaromaticity of the unsubstituted cyclobutadiene, the additional effects of the conjugated systems (3,4-dimethylenecyclobutene and 1,2-divinylcyclobutadiene) occurring in **1a** or **1b** and **1c** must be considered. According to an *ab initio* SCF calculation (5.2/2, minimal base)[2a, 2b] 3,4-dimethylenecyclobutene has a small negative resonance energy (−2.7 kcal/mol), while 1,2-divinylcyclobutadiene is favored by resonance by about 4 kcal/mol in comparison to the components cyclobutadiene and 1,3,5-hexatriene. Adding these corrections to the experimentally derived value a negative resonance energy of *ca.* −21 kcal/mol is obtained for cyclobutadiene, which is of the same order of magnitude as the positive resonance energy of benzene.



Scheme 1. Thermal valence isomerizations of the norcaradiene derivatives **1a** and **2a**. $k_{1a,1b}$ (60 °C) = (3.6 ± 0.1) × 10^{-5} s^{-1}, $\Delta G^{\neq}$ = 26.3 kcal/mol; $k_{1b,1a}$ (60 °C) = (8.3 ± 0.5) × 10^{-5} s^{-1}, $\Delta G^{\neq}$ = 25.8 kcal/mol. **2a** → **2c** (−54 °C): $\Delta G^{\neq}$ = 11.5; **2c** → **2a** (−54 °C): $\Delta G^{\neq}$ = 10.7; **2b** → **2c** (−15 °C): $\Delta G^{\neq}$ = 13.3; **2c** → **2b** (−15 °C): $\Delta G^{\neq}$ = 12.4.



Scheme 2. *Ab initio* SCF energy values (ΔE in kcal/mol) of the norcaradienes **3a** to **7a** (relative to the corresponding (not shown) cycloheptatrienes **3c** to **7c**) [2a, b].

A comparison of the experimental and calculated energy values for **1a** and **3a** and for **6a**[7b] shows that the influence of antiaromaticity, like that of aromaticity, is overestimated from the calculation.

C-Carboxylation of Nitroalkanes with 1-Ethoxycarbonylbenzotriazole

By *Mladen V. Proštenik** and *Ivan Butula*

The synthetic utility of *C*-carboxylation of simple nitroalkanes for the preparation of 2-nitrocarboxylic acid es-

[*] Dr. M. V. Proštenik
INA Research and Development

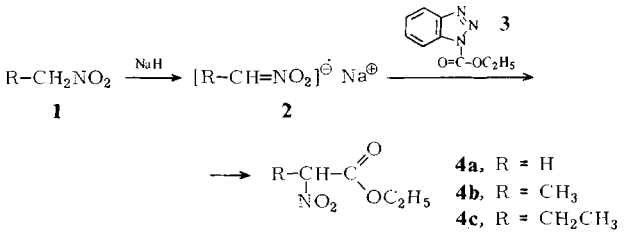
A. Kovačića 1, 41000 Zagreb (Yugoslavia)

ters **4** is low because of the low nucleophilicity of the anionic species, which has a strong tendency to *O*-carboxylation. An exception is the dilithium salts $[R{-}C{=}NO_2]^{2\ominus}2Li^{\oplus}$ which are carboxylated by various reagents[6].



$$R{-}CH_2NO_2 \xrightarrow{NaH} [R{-}CH{=}NO_2]^{\ominus}\,Na^{\oplus} \xrightarrow{O{=}C{-}OC_2H_5}$$

1 **2**

$$\longrightarrow R{-}\underset{NO_2}{\underset{|}{CH}}{-}\overset{O}{\overset{\|}{C}}{-}OC_2H_5$$

4a, R = H
4b, R = CH_3
4c, R = CH_2CH_3

We now report the *C*-carboxylation of the sodium salts **2** of nitroalkanes **1** with 1-ethoxycarbonylbenzotriazole **3**, in which the electrophilicity of the carbonyl C atom is increased by the presence of the benzotriazole moiety. In this reaction, the nitroesters **4a—4c** were obtained at 30 °C from **1** (R = H, CH_3, C_2H_5) in 55—80% yield in dimethyl sulfoxide (DMSO) or dimethylformamide (DMF) as solvent using sodium hydride as base. In tetrahydrofuran or dioxane the reaction proceeds with lower conversions, even at higher temperatures. Nitro(phenyl)methane cannot be carboxylated in this way.

The present method for preparation of nitroesters **4** offers advantages over existing procedures in terms of simplicity, ease of work-up, and yields[3–5]. The reagent **3** is easy to prepare[7] and can be regenerated from the liberated benzotriazole.

Electron Transfer by Grignard Reagents: Direct Evidence for Organomagnesium Radical Complexes

By *Wolfgang Kaim**

Electron transfer mechanisms are increasingly being invoked to describe the reactions of alkylmetal compounds with organic substrates[1]. The formation of radical ions in the reaction of electron deficient compounds with Grignard reagents has frequently been reported[5]; however, the nature of these paramagnetic species has remained uncertain[5].

Investigations of the reducibility of pyrazines[6] have now shown that these compounds react with RMgX or R_2Mg in ethers to give persistent radicals whose ESR parameters deviate significantly from those of the "free" radical anions (Table 1).

[*] Dr. W. Kaim
Institut für Anorganische Chemie der Universität
Niederurseler Hang, D-6000 Frankfurt am Main 50 (Germany)

Reaction of pyrazine with Grignard reagents produces radicals having complex ESR spectra with nonequivalent nuclei. Addition of an alkali metal to this solution results in the observation of the spectrum (Fig. 1 B) of a symmetrical species. At high resolution, apart from the ^{13}C satellite coupling (4C), the interaction of the unpaired electron with two magnesium nuclei in natural abundance can be detected.

Table 1. ESR coupling constants a_i [mT] of organomagnesium radical complexes [a].

Radical	a_N	a_H^{CH}	a^{25}_{Mg}	a^{13}_{C}
$Pz^{\cdot-}$	0.718	0.264	–	0.288
$[Pz(MgC_2H_5)]\cdot$	0.684	0.272 0.304 [b]	[c]	[c]
$[Pz(MgC_2H_5)_2]^{\cdot+}$	0.685	0.284	0.029	0.31
$[Pz(MgC_6H_5)]\cdot$	0.680	0.260 0.310 [b]	[c]	[c]
$[Pz(MgC_6H_5)_2]^{\cdot+}$	0.677	0.285	0.036	0.33
$[(Me_4Pz)(K)]\cdot$	0.618	0.173 [d]	–	[c]
$[(Me_4Pz)(MgC_6H_5)_2]^{\cdot+}$	0.595	0.192 [d]	0.024	[c]

[a] Pz = pyrazine; Me_4Pz = tetramethylpyrazine. [b] Coupling constants of nonequivalent nuclei. [c] Not observed. [d] Methyl proton coupling constants.

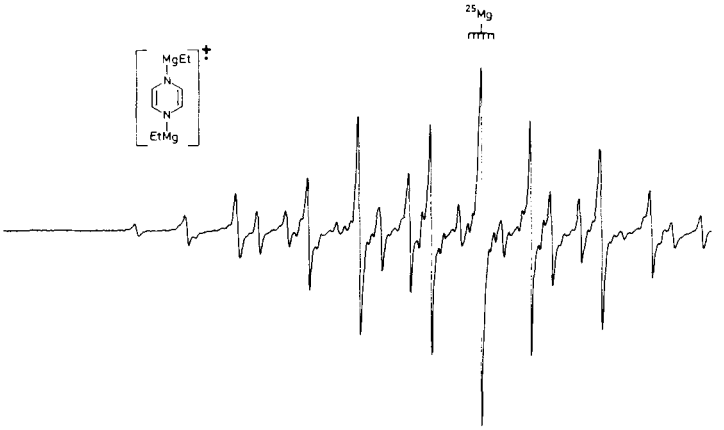

Fig. 1 B). Part of the ESR spectrum of the radical complex formed in the reaction of pyrazine with diethylmagnesium and potassium in tetrahydrofuran (THF). The ^{25}Mg satellites of the most intense line are indicated (^{25}Mg: $I = 5/2$, 10%).

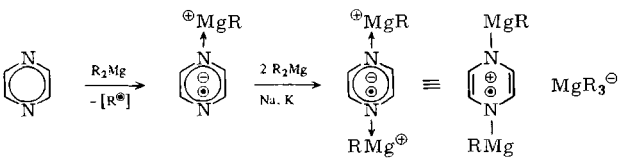
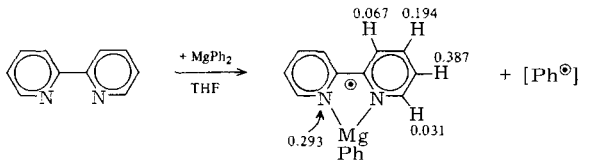
The description of the radical complexes is supported by the interpretation of analogous organoaluminum[6a] and organosilicon coordination compounds[6b]. Favored by the dissociation of organomagnesium compounds in ether[10],

$$2\,R_2Mg \rightleftharpoons RMg^{\oplus} + R_3Mg^{\ominus}$$

an acceptor RMg^+ initially coordinates to the reduced form of pyrazine resulting from electron transfer; reduction by alkali metal leads to coordination of RMg^+ to *both* N atoms.



A highly persistent radical can also be obtained from Grignard reagents and the chelate-forming 2,2′-bipyridyl (ESR coupling constants in mT).



The reaction of Grignard reagents with readily reducible oxygen compounds, *e.g.* ketones, should be interpreted analogously: The observed radical "intermediates"[5] would then be formulated as radical anion-organometallic cation complexes.

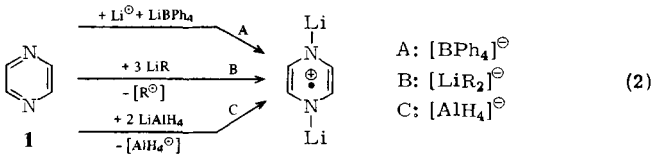
Ambivalent Coordination Behavior of Lithium Aluminum Hydride in Electron Transfer Reactions

By *Wolfgang Kaim**

Recent studies[1] have demonstrated the important role of electron transfer mechanisms in the reactions of organometal and hydridometal compounds with reducible organic substrates. N-Heterocycles such as pyrazine **1** can be advantageously used as "electron transfer traps"[11], because complete reduction would lead to an unfavorable electron configuration[8]; the radical ion intermediates are thus detected by stationary methods (ESR, UV). With the heterocycles pyrazine **1**, quinoxaline **2** and 4,4'-bipyridine **3** as substrates in the electron transfer reaction with the complex hydride $LiAlH_4$ we have now found that the metal coordination exhibits remarkable ambivalence. **1** reacts with $LiAlH_4$ as well as with LiR *via* electron transfer to yield radical "triple ions"[12] with two coordinated lithium ions.

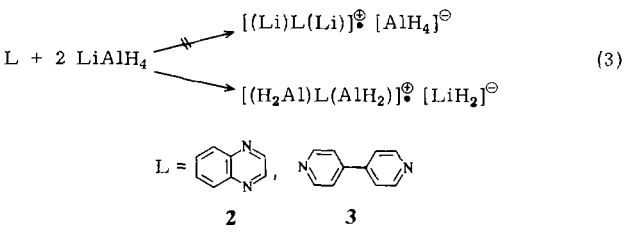


(2)

R = CH_3, n-C_4H_9, C_6H_5

In contrast, the radical anions $2^{\ominus}$ and $3^{\ominus}$ do not employ the Li^+ but the H_2Al^+ cations as coordinated metal species. The ESR parameters of these radical complexes agree well with the data of corresponding dimethylaluminum complexes (Table 1).

[*] Dr. W. Kaim
Institut für Anorganische Chemie der Universität
Niederurseler Hang, D-6000 Frankfurt/Main 50 (Germany)

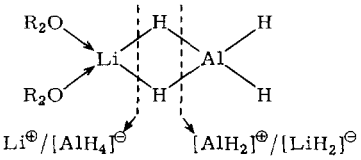


(3)

Table 1. ESR coupling constants a [mT] of organoaluminum radical complexes.

	$[2(AlX_2)_2]^{\ominus\bullet}$ X = H	X = CH_3 [10]		$[3(AlX_2)_2]^{\ominus\bullet}$ X = H	X = CH_3 [10]
a_N	0.618	0.611	a_N	0.347	0.352
$a_{H_{2,3}}$	0.380	0.368	a_{H_2}	0.099	0.096
$a_{H_{5,8}}$	0.120	0.120	a_{H_3}	0.198	0.192
$a_{H_{6,7}}$	0.120	0.120	a^{27Al}	0.149	0.128
a^{27Al}	0.238	0.203	a_H^{AlH}	≤0.020	—
a_H^{AlH}	0.028	—			

The ambivalent coordination behavior of $LiAlH_4$ is a result of its structure in solution; an arrangement such as (4) allows two reasonable polar dissociation mechanisms.



(4)

Whereas reduced pyrazines show a distinct propensity to form ion pairs or triple ions with alkali metal cations[12], corresponding complexes have not been reported for the less basic radical anions $2^{\ominus}$ and $3^{\ominus}$. Therefore, in the electron transfer reaction with $LiAlH_4$ their preference is for the stronger coordinating[10] H_2Al^+ ions.

Stereospecific Synthesis of (*S,S*)-Palythazine from D-Glucose**

By *Pan Jarglis* and *Frieder W. Lichtenthaler**

Apart from the exceedingly poisonous palytoxin[2] and a number of cyclohexanoid iminium salts such as palythene and palythinol, the invertebrate salt water animal *Palythoa tuberculosa* produces two heterocycles with the novel dipy-

[*] Prof. Dr. F. W. Lichtenthaler, Dr. P. Jarglis

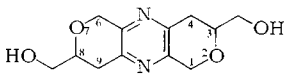
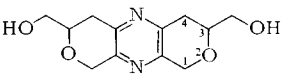
[**] Sugar Enolones, Part 15.—Part 14: [8].

ranopyrazine skeleton, for which structures **1** ("palythazine") and **2** ("isopalythazine") have been delineated on the basis of analytical, UV, and NMR evidence[4]. Their absolute configurations, however, have not yet been established.



1



2

For each of these hexahydrodipyranopyrazines three configurational isomers are possible, *i.e.* an (*R,R*)- an (*S,S*)-, and a *meso*-form of which the latter can be ruled out, since **1** as well as **2** are optically active[4]. We chose to answer the question of whether the *Polythoa* containing **1** has an (*R,R*)- or (*S,S*)-configuration by synthesizing (*S,S*)-**1** stereospecifically *via* sugar enolones[6] by unambiguous derivation of both chiral centers from the configuration at C-5 of D-glucose.

The tetra-*O*-benzoyl derivative **3**, readily accessible from D-glucose, undergoes selective hydroxylaminolysis[8] resulting in cleavage of the enol ester function to give, in essentially quantitative yield, the ketoxime **4**, which with acetaldehyde is readily converted into the parent ketose **5** (Scheme 1).

Due to the high propensity of peracylated pyranosuloses to eliminate acyloxy functions β to the carbonyl group[6], the conversion **5**→**6** is effected cleanly under mild conditions. When subjected to standard deacylation conditions (Scheme 1), enolone **6** yields a complex product mixture due to concomitant aldol type condensations and/or benzilic acid rearrangements of the liberated diketone; in contrast, the benzoyl protecting groups in oxime **7** are readily cleaved off on of the hydroxyimino group providing the nitrogen functionality required in consecutive steps, as well as protection of the carbonyl group against condensation reactions[9].

8 can be converted by controlled catalytic reduction into the aminoketone **9**, which undergoes self-condensation under Gutknecht conditions; oxidation of the tricyclic dihydropyrazine formed gives **1**. The resulting (57% overall yield for 3 steps) (*S,S*)-palythazine **1** is highly crystalline, has a high melting point (223—225 °C after sublimation at *ca.* 190 °C), exhibits a high negative rotation ($[\alpha]_D^{25}$ −199°, methanol), and gives ^{1}H- and ^{13}C-NMR data in accord with the hexahydrodipyranopyrazine structure.

Comparison of synthetic (*S,S*)-**1** with the *Palythoa tuberculosa*-derived product[4] has mainly been confined to the melting points, since rotational data were not disclosed[4]. Surprisingly, the melting point of synthetic **1** closely corresponds to that reported for the natural isopalythazine **2** (216—219 °C[4]), and differs markedly from that given for palythazine **1** (169—170 °C[4]). This indicates that the structures of the *Palythoa* pyrazines have been incorrectly assigned, *i.e.* that the high melting isomer has the structure of palythazine **1** while the low melting isomer has that of **2**. Support for this interpretation is derived from the fact that the ^{13}C-NMR data reported for **1** and **2**[4] are so similar as to preclude unambiguous differentiation.

In relation to biogenesis of **1** and **2**, it appears not unlikely that *Palythoa tuberculosa* synthesizes these products from D-glucose through a series of oxidation and transamination reactions, conceivably involving **9** as intermediate.

If so, the (*S,S*)-**1** synthesized not only constitutes the natural polythazine but the strategy followed for its synthesis parallels its biosynthesis to a significant extent.

Metal Hexamethoxides**

By *Eberhard Jacob**

$U(OCH_3)_6$ **1** is interesting as a substrate for the enrichment of uranium 235 by multiphoton dissociation with a CO_2 laser[2]. Since the compound is accessible only with difficulty, we attempted a direct synthesis from UF_6 *via* ligand exchange. By analogy, as yet unknown metal hexa-

Postfach 500620, D-8000 München 50 (Germany)

[**] Low temperature Co-Condensation of Fluorine Compounds, Part 5. Dr. *W. Storch*, Universität München is thanked for valuable discussions.—Part 4 [1].

methoxides should also be able of being synthesized in this way.

The volatile $Si(OCH_3)_4$ **2** was selected as ligand carrier. UF_6 reacts with excess **2** as a solid co-condensate at $-196\,^{\circ}C$ with partial, and after warming with complete ligand exchange (IR thin film spectrum!) The method is also suitable for conversions on the preparative scale (molar ratio of the educts 1 : 10)

$$\underset{\mathbf{2}}{UF_6} + 6\,Si(OCH_3)_4 \xrightarrow[100\%]{\mathbf{2}} \underset{\mathbf{1}}{U(OCH_3)_6} + 6\,\underset{\mathbf{3}}{SiF(OCH_3)_3}$$

and after pumping off the methoxysilanes **2** and **3**, pure **1** is obtained.

Under similar conditions ReF_6 reacts with **2** to give a crimson solution from which the previously unknown $Re(OCH_3)_6$ **4** was isolated (yield 80%); since **4** is volatile in high vacuum at room temperature, it can be separated from by-products by sublimation. The analogous reaction of MoF_6 yielded for the first time $Mo(OCH_3)_6$ **5** and because of the equilibrium

$$MoF(OCH_3)_5 + \mathbf{2} \rightleftharpoons \mathbf{5} + \mathbf{3}$$

only proceeds to completion if **3** is removed during the reaction by pumping. WF_6 reacts with **2** in the absence of marked heat of reaction (co-condensation not required), accordingly

$$WF_6 + 5\,\mathbf{2} \rightarrow \underset{\mathbf{6}}{WF(OCH_3)_5} + 5\,\mathbf{3}$$

The tungsten compound **6** is liquid (m.p. $< -10\,^{\circ}C$) and reacts only partially with **2** to give $W(OCH_3)_6$ **7**[11], *i.e.* the position of the equilibrium is more unfavorable for exchange of the last fluorine ligand than in the case of the molybdenum compound. Complete methoxylation of **6** can be achieved with a methanolic $NaOCH_3$ solution; **7** can be isolated by vacuum sublimation. In general, metal hexamethoxides are volatile solids which are readily soluble in non-polar solvents. Under reduced pressure **6** can be distilled at 60—80 °C, whereas, hereby, the corresponding molybdenum compound[9] decomposes. The ^1H- and ^{13}C-NMR spectra in solution suggest equivalent methoxy groups. The vibrational spectra are dominated below 600 cm^{-1} by the skeletal vibrations of the MO_6 octahedra. The Raman spectra of solid **5** and **7** differ little from those of their solutions. Thermal stability decreases along the series $\mathbf{7} \gg \mathbf{1} > \mathbf{5} > \mathbf{4}$. Thermolysis of **1**, **4**, and **5** at 85 °C led to slow formation of $CH_2(OCH_3)_2$, a little $(CH_3)_2O$, and CH_3OH as cleavage products. In moist-air rapid hydrolysis ensues (particularly with **1** and **4**). The colored compounds **1**, **4**, and **5** are light sensitive. **5** and **7** act as methoxide acceptors. In the reaction with F_2, metal oxide fluorides, COF_2, and HF are formed.

By means of the low temperature co-condensation technique[6], the dominant oxidative fluorinating activity of UF_6, ReF_6, and MoF_6 can be suppressed in favor of an exchange reaction. Methoxy groups are sufficiently electronegative and sterically undemanding to be able to stabilize high oxidation states—for example Re^{VI}. The route presented here has general applications.

Peptide Formation by Activation with Phenyltetrazolinethione/Isocyanide**

By *Ulrich Schmidt** and *Manfred Dietsche*

Dedicated to Professor Werner Reif on the occasion of his 60th birthday

ω-Hydroxyacids react with phenyltetrazolinethione and isocyanide to give a mixture of *N*- and *S*-acyltetrazoles, which can be used for the formation of macrocyclic lactones[1]. This activation is also particularly suitable for peptide formation. Z- or Boc-amino acids[2] are allowed to react with the adduct **1** of phenyltetrazolinethione and an isocyanide in concentrated solution at −40 °C. The mixture of *N*- and *S*-acyl compounds of type **2** thus formed already reacts very rapidly at −40 °C on addition of an amino acid ester to give the dipeptide ester in good yields (see Table 1).

In the dipeptide formation corresponding to the first Weygand test[3a] (formation of TFA-Val-Val-OMe[2] as well as formation of Z-Val-Val-OMe and conversion into TFA-Val-Val-OMe) and the third Weygand test[3b] (formation of TFA-Pro-Val-Pro-OMe), in each case at −40 °C, no trace of a racemization could be detected, even by capillary gas-chromatography. No allo-isoleucine compounds are

[4] We thank Dr. *K.-D. Jany* for the allo-isoleucine determinations.

[5] *Procedure:* A solution of phenyltetrazolinethione (980 mg, 5.5 mmol) is treated with cyclohexyl isocyanide (600 mg, 5.5 mmol) at room temperature and the mixture stirred until all is in solution (*ca.* 10 min). After cooling to −40 °C the solution is treated with a cold solution of Z-Leu-OH (1325 mg, 5 mmol) in CH_2Cl_2 (5 mL) and after 2 min with a cold solution of H-Phe-OMe (896 mg, 5 mmol) in CH_2Cl_2 (5 ml). The mixture is warmed to room temperature, diluted with CH_2Cl_2 and extracted several times with 0.5 N NaOH, then with water, 0.5 N $KHSO_4$ and water. The washed solution is evaporated to dryness and the residue taken up in ethyl acetate, filtered through a silica gel column and the solvent removed; yield: 1786 mg Z-Leu-Phe-OMe (84%).—For the synthesis of peptides which are also very sensitive to sodium hydroxide (extraction of phenyltetrazolinethione) in organic solvents, 1-(*m*-dimethylaminophenyl)tetrazolinethione is used for the activation, and can be extracted with dilute acids (preparation from *m*-dimethylaminophenyl isocyanate (R. Zahradník *et al., Collect. Czech. Chem. Commun. 28* (1963) 1651) and sodium azide).

Alkylchromium(III) Dichlorides, Highly Selective Reagents for the Addition of Nucleophiles to Aldehydes**

By *Thomas Kauffmann**, *Angelika Hamsen*, and *Christoph Beirich*

Owing to the preparative significance of CC-coupling by reaction of carbanionic or carbanionoid compounds with electrophiles the finding that the carbanionoids $Cl_3Ti—CH_3$ and $(i\text{-}C_3H_7O)_3Ti—Alk$ (Alk = CH_3, $n\text{-}C_4H_9$) as alkylating reagents distinguish very selectively between aldehydes and ketones[1] is of great importance to the synthetic organic chemist.

We have found that the alkyldichlorotris(tetrahydrofuran)chromium(III) compounds **1** are likewise alkylating reagents which show high aldehyde selectivity. The reagents, which are readily accessible according to the scheme below (or from organolithium compounds)[2] were treated—partly in competition experiments—in tetrahydrofuran (THF) at −60 °C with carbonyl compounds **2**. The reaction mixture was then allowed to warm to room temperature within 18 h, and hydrolyzed with water. As shown in Table 1 the chromium compounds react with aldehydes, but not with ketones, and undergo *C*-alkylation to give the alcohols **3**[3]. Unconsumed aldehydes could not be recovered, and the ketones only to 40—71%[4].

Table 1. Aldehyde-selective alkylations with **1**.

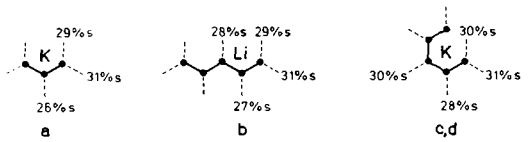
Non-Planar Structures of Allyl- and Pentadienylmetal Compounds: Pleating to Achieve a Better Charge Distribution?**

By *Manfred Schlosser** and *Manfred Stähle*

$^2J_{C,H}$ coupling constants serve as a measure of bond angles, $^3J_{H,H}$ coupling constants as a measure of dihedral angles. Taken together, both values should provide profound structural information. By this means we have reached surprising, novel conclusions on allyl- and pentadienyl-(earth) alkali metal compounds.

The C,H coupling constants at the terminal methylene groups increase uniformly along the series allylmagnesium bromide, -lithium, -sodium, and -potassium[6] and at the same time decrease at the intermediate methine groups (Table 1). Not only does the potassium compound exhibit the most striking values but also—because of frozen-in torsional movement—the *cis*- and *trans*-orientated hydrogen atoms at the allyl ends can be distinguished. All C,H bonds appear to deviate from the carbon atom plane, however, those in the *cis*- more than those in the *trans*-position. The methine group in the allyl middle even approximates a tetrahedral angle, as indicated by the "s-character" of 26% (rule of thumb[2]: $\%s = 1/5 \cdot J_{C,H}$).



In proceeding from allylpotassium **(a)** to the W-shaped[10,11] pentadienyllithium **(b)** and to the U-shaped[8,10] pentadienylpotassium **(c)**, as well as to (*E*)-hexadienylpotassium **(d)**, the s-fraction indeed increases slightly (Table 2). Despite this, the coupling constants of the *cis*-CH bonds to the electron-rich odd-numbered sites and, in particular, of the CH bonds to the even-numbered sites ("nodes") are extraordinarily small. They are hardly compatible with the assumption of completely planar structures.

The *cis*-orientated hydrogen atom at the terminus and its vicinal neighbor apparently point in opposite directions with respect to the carbon atom plane. The large H,H-coupling constants are inconsistent with any other interpretation. This gives the clue for a plausible explanation of the peculiar pleating of allyl and pentadienyl alkali metal structures. The metal atom essentially establishes a binding interaction with the electron-rich odd number sites of the ligands. In order to improve this binding, π-electron density accumulates at these positions on the metal carrying face. To compensate, the "nonbonding", even numbered sites are polarized in the opposite sense: here the higher electron density is accumulated on the metal-remote face. Because of electrostatic repulsion the CH bonds move towards the electron deficient side. The planar ideal structures **(a–d)** are deformed to give pleated structures.

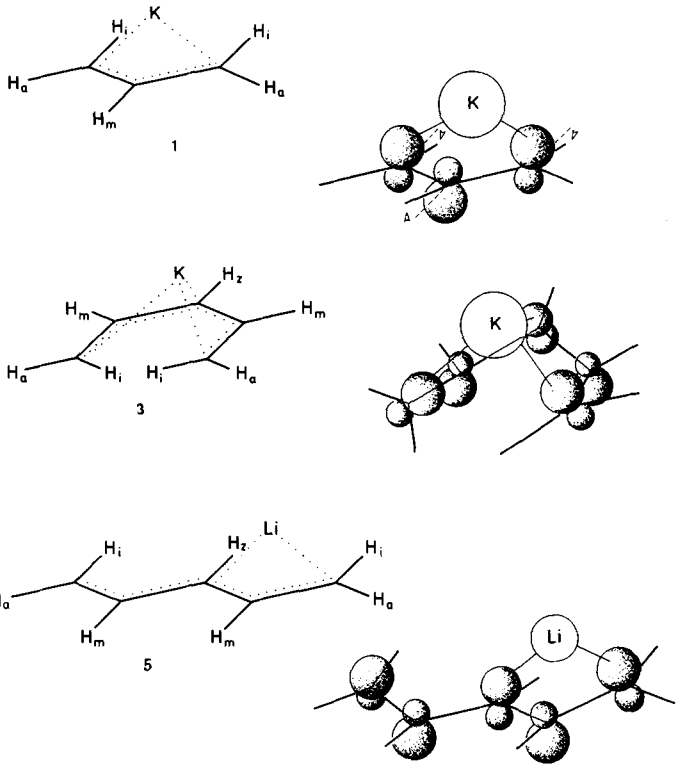


Table 1. $^{13}C,^1H$-coupling constants [Hz] of some allylmetal compounds in tetrahydrofuran (the s-character of the CH bonds is shown in parentheses). Cf. also formula **2** and details in the Supplement.

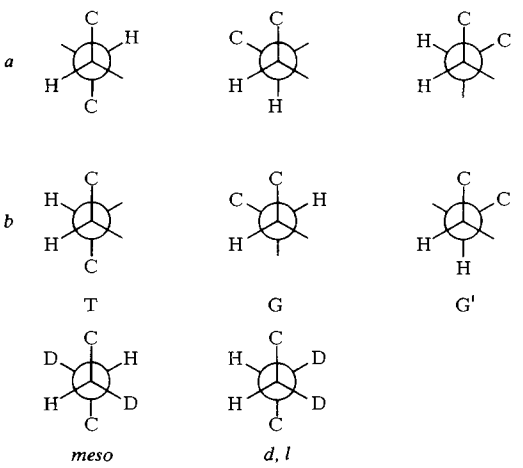
The Conformational Equilibrium of the Lower Alkanes**

By *Gerd Schrumpf**

Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday

That the *trans* conformer of butane is more stable than the two *gauche* conformers has so far only been demonstrated in the gas-phase—by electron diffraction measurements[1]. We have now been able to show by NMR spectroscopy that this is also the case in solution.

The ^{1}H-NMR spectra of 1,2-disubstituted ethanes at room temperature give two coupling constants for the vicinal protons on the central C—C bond (type AA'BB' spin system[2a]) which (despite the $J_t > J_g$ rule[2b]) cannot be assigned without additional assumptions.



Scheme 1.

In the *meso*-[2,3-D_2]butane **1a**[3a] the vicinal coupling constant is clearly assigned to the proton pair *a* (Scheme 1).

CH_3–$\overset{2}{C}$HD–$\overset{3}{C}$HD–CH_3 CHD_2–$\overset{2}{C}$HD–$\overset{3}{C}$HD–CD_2–R **2**, R = CD_3
1a: *meso* **3a**, R = C_2D_5
1b: *d, l* C2–C3: *erythro* **4**, R = C_3D_7

CD_3–$\overset{2}{C}$HD–$\overset{3}{C}$HD–$\overset{4}{C}$HD–C_2H_5 **3b**, C2–C3: *threo*
C3–C4: *erythro* **3c**, C2–C3: *erythro*

The spin system of **1a** is of the $[A_3B]_2$-type[4] with numerous transitions. A precise analysis is possible only by means of the signals in the methylene region, since only here is the line density small enough to enable identification of the individual transitions. The numerical analysis of the spectrum was carried out both with lines of all subspectra as well as with those of the readily identifiable subspectrum $[D_AD_B]_2$. The results are in good agreement in both cases. A value of 8.76 Hz is obtained for the vicinal coupling constant J(2H,3H) in tetramethylsilane (TMS), *i.e.* the larger of two previously measured values[5]. This means that a larger proportion of the conformer with antiperiplanar orientation of 2-H and 3-H occurs, as observed in **1a** in the *trans*-conformation. The NMR spectrum of *d,l*-[2,3-D_2]butane **1b**[3a] in TMS was also analyzed. The vicinal coupling constant is found to be 6.11 Hz. This also is consistent with a predominance of the *trans*-conformation.

Furthermore, we have synthesized the following stereospecifically deuteriated compounds: the pentane **2**, the hexanes **3a**, **3b** and **3c**, as well as the heptane **4**. For **2**, **3a**, and **4** we obtained coupling constants J(2H,3H) of 9.13, 9.15, and 9.13 Hz, respectively. Similarly as in the case of **1a**, it can be concluded that the *trans*-conformer (C2—C3 bond) is dominant.

In the **3b/3c** mixture, the *erythro*-relationship of 3-H and 4-H is fixed by synthesis; 2-H and 3-H are oriented in the *threo*- and the *erythro*-arrangement, respectively. From the overlapping spectra we determined J(3H,4H) = 9.08 Hz and J(2H,3H) = 9.11 and 5.97 Hz, respectively. The latter finding shows that the vicinal coupling constant for the *erythro* form is here again larger than for the *threo*-form. From J(3H,4H) = 9.08 Hz it can be concluded that the conformational equilibrium is also on the side of the *trans*-conformer (C3—C4 bond)[3b] in the case of hexane in TMS.

Selective Hydroxylations of Chiral and Substituted Paraffins**

By *Hans-Jörg Schneider* and *Walter Müller**

The selective oxidation of alkanes belongs to those accomplishments of nature, for which, so far, only very few analogous reactions can be performed in the laboratory. We wish to report that activated peroxycarboxylic acids in hydrophobic solvents convert not only cyclic[1], but also open chain hydrocarbons, such as **1**—**5**, into tertiary alcohols with high regioselectivity. With tetrahydrocitronellene **4** the configuration is retained also in the direct attack at

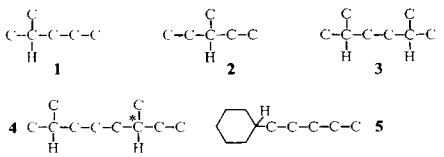
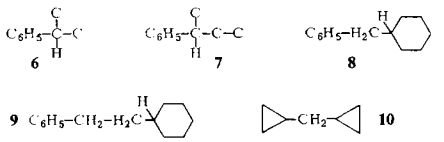
the chiral center (Table 1). Open chain hydrocarbons are generally oxidized somewhat slower than alicyclies by peroxycarboxylic acids so that radical side reactions can take place in certain circumstances.

Table 1. Hydroxylation of alkanes RH and aryl- or cyclopropyl-substituted alkanes [a].



RH	Conversion [%]	*tert*-ROH [%]	k_t/k_s [b]
1	43	77	13
2	49	84	20
3	57	93 [c]	23
4	33.5	85 [d]	23
5	15.5	77	53

After 24—48 h <4% conversion

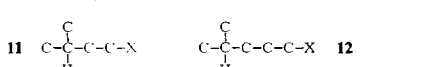


[a] In $CHCl_3$ (reflux) or at 60±5°C (**1**, **2**), RH: *p*-nitroperoxybenzoic acid 1:1 or 1:2 (**3**), 30—36 h or (**5**) [RH]=0.7—1.4 mol/L. [b] Ratio of the hydroxylation rates of *tert*- and *sec*-C—H bonds (prerequisite: attack at CH_3 < 1%). [c] 91% Mono-, 9% dihydroxy-product. [d] 38% 2-, 62% 6-hydroxy compound ($[\alpha]_D^{20} = -0.909$, ref. [4]: $[\alpha]_D^{20} = -0.78$ (neat)).

In contrast to their reactions with peroxytrifluoroacetic acid[2] substituted arenes (cf. **6**—**9**) are remarkably inert towards *p*-nitroperbenzoic acid; exeptions are only very reactive compounds such as mesitylene. Moreover, aromatic substituents even prevent attack at tertiary C—H bonds which are separated by several bonds from the π system (see compounds **8**, **9**). This is explained by the H-bond acceptor properties of arenes, which is known to reduce the reactivity of peracids in the Prileschajev reaction[3].

Similarly, oxygen substituents, which act has H-bond acceptors, lead to diminished reactivity of the substrate. This is visible in the small yields of diols obtained from alkanes where the tertiary C—H bonds are far removed from the oxygen (**3**, **4**), or with acetoxyalkanes (Table 2). With primary hydroxy or methoxy derivatives only products from the oxidation of C—H bonds in α-position to the oxygen substituent are obtained.

Table 2. Hydroxylation of heterosubstituted alkanes [a].



11, X=	H	Cl	$OOCCH_3$	OH [b]
k_X/k_H	1.00	0.06±0.01	0.06±0.02	<0.05

12, X=	H	Cl	OCH_3 [c]
k_X/k_H	1.00	0.77±0.05	<0.05

[a] Rate constants relative to **11** and **12** (X=H), from competition reactions followed by NMR analysis of the product. [b] Main products: 3-methylbutanoic acid (50%) and its ester (5%); *tert*-hydroxylation product <5%. [c] Main products: 4-methylpentanoic acid (43%), 4-methyl-1-pentanol (14%).

Polar substituents such as chlorine in **11** and **12**, which only exert inductive effects within the substrate and cannot deactivate the peroxy acids, again yield normal hydroxylation products. The reduced rate observed with γ-halogen substituents (**11**), and to a much lesser degree with δ-halogen substituents (**12**) is in accord with the electrophilic character of the reaction[1]. The observed stereospecificity, however, is at variance with carbocationic intermediates of longer lifetime.

Selective Inclusion of Uncharged Guest Molecules by Neutral Hosts with Fence-Shaped Side Arms**

By *Fritz Vögtle** and *Walter M. Müller*

Dedicated to Professor Heinrich Puff on the occasion of his 60th birthday

As already observed more than 25 years ago[1], benzene and other lipophilic guest molecules appear to be intercalated in the cavities of synthetic guest molecules; however, a generalization of this type of host-guest combination[2-4] has not yet been achieved.

We have furnished multimembered monocycles with side arms, in such a way that a versatile enclosed molecular cavity for the up-take of organic guest molecules can be formed. The substituents fulfill the function of a molecular fence[6]; their number and size are determined by the number of ring members. Space filling models of compounds of this type such as **1b** show that according to this general concept, large spherically shaped molecules should be accommodated. The advantages over polycyclic large-ring cage compounds[4] are the straightforward synthesis of the monocycles and the easier adaptability to potential guest molecules caused by the conformational mobility of the framework and its arms.

For the synthesis of **1** and analogous cavity molecules **2** and **3**, *N,N'*-dibenzyl- or *N,N'*-dimethylethylenediamine were allowed to react under conditions of high dilution with the corresponding dicarboxylic acid dichlorides (terephthalic-, 4,4'-biphenyl, *o*-terphenyl-4,4''-) to give, respectively, the hexa- or tetracarboxylic acid amides, which can

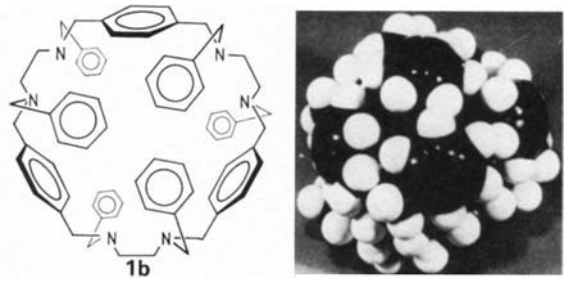
be reduced to the polyamines with B_2H_6. Apart from the trimer **1b** (20% yield, m.p. 176–178 °C), the dimers **2b** (12%, 163–165 °C), **2c** (18%, 158–162 °C), or **3** [30%, glassy, δ(benzyl-*H*) = 3.55, δ(ethano-*H*) = 2.61, in $CDCl_3$], lower and higher oligomers, which were separated chromatographically, are formed.



Whereas previous attempts to include uncharged organic guest molecules into **1b** have been unsuccessful, recrystallization of the 32-membered ring compound **2b** from *cyclohexane* produced crystals, which after drying for 24 h at 50 °C/12 torr occur as a 1 : 1 complex (93% yield, m.p. = 84–90 °C and 163–165 °C (recrystallized twice) ^{1}H-NMR, elemental analysis). Cyclohexane was tenaciously retained, as were also *dioxane*, *tetrahydropyran*, and *morpholine* even after extended drying (15 h) at 50 °C/12 torr.

In contrast, the molecules methylcyclohexane, cycloheptane, cyclooctane, decalin, and tetralin, as well as benzene and toluene, which only differ slightly in spacial requirement are not retained in a similar manner, Recrystallization of **2b** from a 1 : 1 *benzene/cyclohexane* mixture yields only the cyclohexane complex, thus opening up a separation mode for benzene and cyclohexane. Likewise, *mesitylene* adheres to a lesser extent than cyclohexane: for a few hours at 20 °C *in vacuo*; after a longer time it is removed without residue.

Although only X-ray structural analyses finally will indicate an "intramolecular" guest inclusion, or the not less interesting inclusion in the host lattice, the precise stoichiometry and selectivity of the guest up-take might indicate the first reported host-guest complexation.

Attempts at complexing with **2c**, in which the benzyl- are replaced by methyl-groups, did not lead to formation of inclusion compounds. This indicates the influence of the appropriate side arm on the host-guest interaction.

In order to investigate whether the Stetter complex[1] could be the first representative of a systematic host-guest chemistry, we studied the likewise 28-membered ring compound **3**, which also contains two biphenyl units, but in which CH_2 and N have changed places and—in the sense of our concept—substituents on nitrogen are present. This host molecule is able to stoichiometrically bind *penta-* and *hexafluorobenzene*, but not, however, benzene, cyclohexane, dioxane, and fluorobenzene.

We conclude that novel inclusion compounds between uncharged organic molecules can be tailor-made according to this principle.

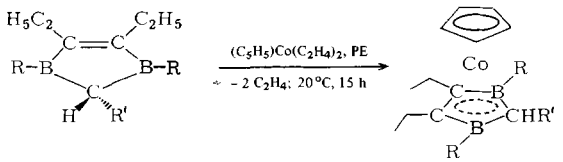
η^5-Cyclopentadienyl(η^5-1,3-diborolene)cobalt — A Novel Type of Sandwich Complexes with a Pentacoordinated Carbon Atom**

By *Walter Siebert**, *Joseph Edwin*, and *Hans Pritzkow*

During the synthesis of the paramagnetic triple-decker sandwich complex **3a**[1] from the Δ^4-1,3-diborolene **1a** and dicarbonyl(η^5-cyclopentadienyl)cobalt we found traces of the red mononuclear complex **2a**. Our hypothesis that the dinuclear complex **3** is formed by "stacking", from the sandwich **2** and a $(C_5H_5)Co$ fragment, has now been confirmed by the reaction of η^5-cyclopentadienylbis(ethene)cobalt[2] with **1b** *via* **2b** (65% yield, b.p. 70 °C/0.01 torr, m.p. 62 °C) to give the triple-decker **3b** (54% yield). **2a** can be prepared in an analogous way from **1a**[3] in petroleum ether (PE) (48% yield, m.p. 92 °C).



1a: R = C_2H_5, R' = CH_3 **2a**
1b: R = CH_3, R' = H **2b**

The constitution of these novel sandwich complexes follows from analytical and spectroscopic data: In the mass

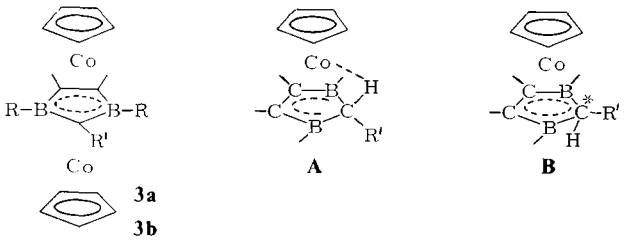
[**] Diborylethylene Compounds as Ligands in Metal Complexes, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 10: W. Siebert, H. Schmidt, R. Full, *Z. Naturforsch. B 35* (1980) 873.

spectrum the molecular ion for **2a** appears at $m/z = 314$ (46%) and that for **2b** at $m/z = 272$ (100% rel. int.). The NMR spectra [δ¹H(C_6D_6) **2a**: 4.09 (s, 5), 2.3 (m, 2), 1.7 (m, 6), 1.35 (t, 6), 1.17 (t, 6), 0.94 (d, 3), −8.37 (q, 1); **2b**: 4.11 (s, 5), 2.3 (m, 2), 1.7 (m, 2), 1.17 (t, 6), 1.09 (s, 6), 0.11 (d, 1), −8.62 (d, 1)], with the unusual upfield shift for the proton of the CHR'-group (quartet at −8.37 and doublet at −8.62) indicate a special bonding relationship to the cobalt atom. The δ¹¹B values (27.5 and 27.3, respectively) measured for the complexes **2a** and **2b** show an upfield shift of about 41 ppm compared to the free ligands **1a** and **1b**.

On the basis of the 18-electron rule, two structures would appear possible: Structure **A** with a 3c/2e bond C—H · · · Co is consistent with the ¹H-NMR upfield shifts, as has been observed in complexes displaying C—H · · · M interaction[4]. The large $\Delta\delta$¹¹B values indicate strong metal-boron interaction, which supports a *tetra-* or *pentahapto*-structure **B** rather than that of **A**.



The X-ray structure analysis of **2a** confirms the structure **B**. Crystallographic data: orthorhombic, Pnma, $a = 9.258(3)$, $b = 15.253(4)$, $c = 12.478(3)$ Å, $V = 1762.02$ Å³, $Z = 4$; 2698 reflections, 2190 observed, $R = 0.044$, $R_w = 0.040$. The two ring ligands are coplanar, the distances of the ring planes from the cobalt atom are 1.66 [Co—(C_5H_5)] and 1.56 Å [Co—(C_2B_2C)]. In comparison to other sandwich and triple-decker complexes the diborolene ring exhibits differences at the methylene carbon atom (C*): The B—C* bonds (1.63 Å) are considerably longer, the C-atom of the methyl group ($R' = CH_3$) is shifted 0.15 Å from the best plane through the C_2B_2C-ring in the direction of the Co atom; the H atom on C* is situated on the other side of the ring, and comes into contact with the B atoms (B ····· H 1.70 Å). Despite the uncertainty regarding the position of the axial hydrogen, we interpret the spectroscopic and structural data as follows: In the sandwich complexes **2** the C atom of a methylene bridge is bound to an electron-deficient metal center (Co—C* 2.03 Å), a bonding not observed previously. The 3c/2e interaction H ····· C* ····· Co is presumably *via* an orbital with strong p-character, since $^1J_{^{13}C,H}$ is only ≈70 Hz.

Stacking onto the sandwich **2** can also be achieved with the one-electron donors (C_5H_5)Fe and $(CO)_3$Mn, whereby the corresponding 30 valence-electron triple-decker complexes are obtained from **2a** and $[(C_5H_5)Fe(CO)_2]_2$ or $Mn(CO)_{10}$ in 24 and 80% yield, respectively, *via* elimination of a hydrogen atom.

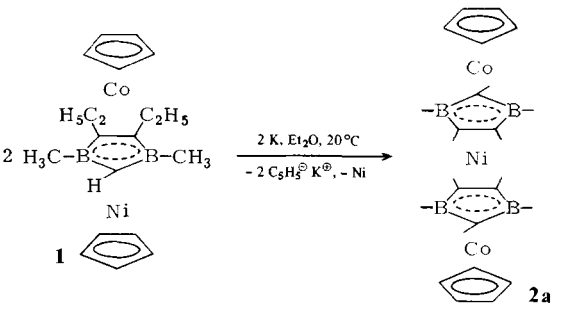
μ,η⁵-1,3-Diborolenyl Tetradecker Sandwich Complexes**

By *Walter Siebert**, *Joseph Edwin*, *Hubert Wadepohl*, and *Hans Pritzkow*

Ferrocene and cobaltocene react with alkali metal/alkene to give η⁵-cyclopentadienyl(alkene)metal complexes and cyclopentadienide[2]. Extension of this reaction to triple-decker sandwich complexes led, on reaction of paramagnetic **1** (32 valence electrons[3]) with potassium, unexpectedly to the green μ,η⁵-1,3-diborolenyl tetradecker sandwich complex **2a** (81% yield, m.p. 180 °C). From NMR and mass spectroscopic data [δ¹H(C_6D_6): −22.8, −7.0, 14.9, 18.8, 21.7; $m/z = 600$ (M^+, 100% rel. int.)] as well as chemical findings it follows that paramagnetic **2a** (44e) has a tetradecker constitution, which is confirmed by X-ray structure analysis[4]. As in the bis(μ,η⁵-1,2,5-thiadiborolene) tetradecker complexes[1] the bridging ligands in **2a** are coplanar and oriented in a *trans*-arrangement with the Ni atom as inversion center. The distances of the best ring planes to the metal atoms are 1.66 [(C_5H_5)—Co] 1.59 [Co(C_2B_2C)], and 1.75 Å [(C_2B_2C)—Ni].



The neutral complex **2a** can be reduced with potassium in tetrahydrofuran (THF) to the diamagnetic dianion $\mathbf{2a}^{2-}$ (46e) [δ¹H (D_8-THF): 0.30 (s, 6), 0.49 (s, 1), 1.33 (t, 6), 1.7 and 1.8 (m, 4), 4.03 (s, 5)], which in the presence of excess potassium slowly decomposes with elimination of Ni into two sandwich anions **3** (18e) [δ¹H(D_8-THF): 1.51 (s), 2.04 (s), 0.94 (t), 1.9 and 2.4 (m), 3.97 (s)]. On reaction with $ZnCl_2$, **3** is converted into golden-yellow **2b** [46e, isoelectronic with $\mathbf{2a}^{2-}$; 34% yield, m.p. 230 °C; δ¹H(C_6D_6): 0.91 (s, 6), 1.22 (t, 6), 2.12 (s, 1), 2.4 and 1.8 (m, 4), 4.10 (s, 5); δ¹¹B (C_6D_6): 14.0; $m/z = 606$ (M^+, 51% rel. int.)], while on reaction with $FeCl_2 \cdot 2THF$ the *paramagnetic* 42e-tetradecker **2c** [60% yield, m.p. 196 °C; $m/z = 598$ (M^+, 100% rel. int.)] is formed.

[**] Tetradecker Complexes, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. — Part 3: [1].

The red-brown tricobalt compound **2d** (43e) can be conveniently prepared by reaction of protonated **3** — η^5-cyclopentadienyl(η^5-1,3-diborolene)cobalt[5] — with $(C_5H_5)Co(CO)_2$ in mesitylene at 170 °C [74% yield, m.p. 209 °C; $\delta^1H(C_6D_6)$: 14.6, 9.3, −10.0, −12.9, −38.1; $m/z = 601$ (M^+, 100% rel. int.)]. Silver ions oxidize **2d** to the dark-red, diamagnetic 42e cation **2d**$^+$ [78% yield; $\delta^1H(CD_2Cl_2)$: 1.32 (s, 6), 1.27 (t, 6), 2.19 (s, 1), 2.8 and 2.1 (m, 4), 4.65 (s, 5); $\delta^{11}B$: 18.3].

These results reveal the unusual ligand properties of 1,3-diborolene for the construction of tetradecker complexes containing 42 to 46 valence electrons. With exception of the paramagnetic **2c**, with "high-spin" d^6 Fe, the new trinuclear complexes are electronically closely related to the corresponding mono- and dinuclear complexes: Formal insertion of the 12e-fragment 1,3-diborolenylcobalt [$(C_2B_2C)Co$] between C_5H_5 and Ni in nickelocene affords **1**, and then **2a**. Since the 17e-sandwich radical $[(C_5H_5)Co(C_2B_2C)]^{\odot}$ corresponds to the 5e-ligand $C_5H_5^{\odot}$, a nickelocene-like chemistry is to be expected, at least in the case of the triple-decker **1**.

Isolation of Crystalline Acylsulfenyl Iodides—Intermediates in the I_2-Oxidation of Thiocarboxylic Acids

By *Shinzi Kato**, *Eiji Hattori*, *Masateru Mizuta*, and *Masaru Ishida*

Sulfenyl iodides (RSI) probably play a decisive role as reactive intermediates, both in the iodation reaction in the thyroid gland[1] and in the I_2-oxidation of thiols[2]. However, because of their instability, such compounds have rarely been investigated[3] since the first attempts were made by *Rheinboldt* and *Motzkus*[4] to isolate *tert*-butylsulfenyl iodide.

$$\underset{\mathbf{1}}{RCSHgPh} \xrightarrow{I_2} \underset{\mathbf{2}}{RCSI} + PhHgI$$

Table 1. Acylsulfenyl iodides **2** by reaction of the phenylmercury derivative **1** with iodine.

Cpd.	R	Yield [%]	M.p. [°C] [a]	IR [cm^{-1}] ν(C=O) [b]
2a	C_6H_5	72	45–46	1667
2b	4-$CH_3C_6H_4$	79	40 (dec)	1650
2c	4-$CH_3OC_6H_4$	73	32 (dec)	1648
2d	4-ClC_6H_4	64	48 (dec)	1678

[a] Decomposition. [b] KBr.

Gifu University
Yanagido, Gifu 50111 (Japan)

We now report the first successful isolation of the crystalline acylsulfenyl iodides **2** (Table 1), which were obtained by reaction of phenylmercury thiocarboxylates **1** with iodine. The PhHgI, which is also formed, is readily reconverted into the educt by reaction with piperidinium- or potassium-thiocarboxylates.

The acylsulfenyl iodides **2** were characterized by spectral data and by elemental analyses. For example, in the mass spectrum, **2b** shows a molecular ion at m/z 278. The IR spectrum shows a characteristic absorption band at 1650 cm^{-1} due to the ν(C=O) vibration; its position differs distinctly from that of the corresponding band of the educt **1** (1625 cm^{-1}) and from that of bis(4-methylbenzoyl) disulfide (1692 cm^{-1}), the possible decomposition product. **2b** reacts with dithiobenzoic acid to give the unsymmetrical 4-methylbenzoyl(thiobenzoyl) disulfide[5a] in almost quantitative yield.

The acylsulfenyl iodides **2** obtained are stable for several hours at room temperature, both in the solid state and in solution (methanol or *n*-hexane); however, they decompose below 50 °C, or on irradiation with sunlight, liberating free iodine.

Experimental

2b: To a suspension of **1b**[5b] (0.21 g, 0.5 mmol) in methanol (30 ml) was added 5 mL of 0.1 N $I_2/CHCl_3$ solution. The purple colored solution immediately turned yellow. The mixture was stirred at room temperature for 1 h and then allowed to stand at *ca.* −60 °C for 1 h. After removal of the white precipitate (PhHgI) by filtration, the solvent was evaporated off *in vacuo*. Recrystallization of the solid residue from *n*-hexane (*ca.* 40 mL) at −60 °C gave 0.11 g (79%) of **2b** as a yellow microcrystalline solid.

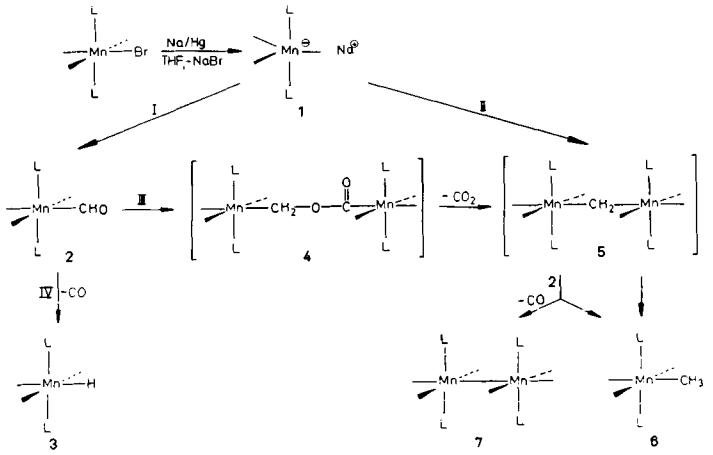
From a Formyl to a Methyl Complex

By *Heinz Berke** and *Gertrud Weiler*

Neutral formyl complexes are assumed to be important intermediates in homogeneous carbon monoxide hydrogenation processes[1]. However, their thermodynamic instability relative to the products, metal-hydride complex and carbon monoxide, has, with few exceptions[5,6], so far hindered isolation or investigation of secondary reactions. According to theoretical considerations a formyl moiety in pseudooctahedral environment should be additionally stabilized by a meridional arrangement of phosphite ligands.

[*] Dr. H. Berke, G. Weiler
Fakultät für Chemie der Universität
Postfach 5560, D-7750 Konstanz (Germany)

When the tricarbonylbis(trimethylphosphite)manganate(1−) ion **1** (obtained from the bromotricarbonyl complex)[11] is allowed to react with acetic formic mixed anhydride at −30 °C, the expected formylmanganese (I) compound **2** is formed.



I: −30 °C, $HCOOC(O)CH_3$; II: RT, CH_2Br_2 or $CH_2(OTos)_2$; III: 0 °C, traces of H_2O; IV: RT. L = $P(OCH_3)_3$; CO groups not shown; all reactions in tetrahydrofuran (THF).

2 was identified ^{1}H-NMR spectroscopically on the basis of its characteristic formyl resonance [(in [D$_8$]THF, rel. TMS, −30 °C): $\delta = 14.04$]. It decomposes above 0 °C, with decarbonylation to the hydrido complex **3**[12].

In the presence of catalytic amounts of water, compound **2** gives the complexes **6**[13] [m.p. 62 °C; IR (*n*-hexane): 2020, 1940, 1905 cm^{-1}; ^{1}H-NMR ([D$_6$]acetone, rel. TMS, 35 °C): $\delta = 3.73$ (t, $J = 6$ Hz), −0.3 (t, $J = 8$ Hz)] and **7** [m.p. 78 °C; IR (*n*-hexane): 2055, 1973, 1953, 1942, 1927, 1906 cm^{-1}; ^{1}H-NMR ($CDCl_3$, rel. TMS, 35 °C): $\delta = 3.87$ (t, $J = 6$ Hz); ^{31}P-NMR (toluene, rel. H_3PO_4, −30 °C): $\delta = 169.4$].

The reaction leading to **6** and **7** presumably proceeds *via* a Claisen-Tischtschenko-like disproportionation[5,6], giving the μ-methyleneoxycarbonyl complex **4**, which in turn decomposes with decarboxylation (CO_2 was identified IR spectroscopically) to the μ-methylene compound **5** [^{1}H-NMR (CS_2, rel. TMS): $\delta = 1.76$ (q, CH_2)]. We explain the formation of **7** together with **6** in terms of a hydride transfer between **2** and **5**. Moreover, **7** could possibly also be formed by decomposition of **5**.

The other feasible generation of **5** from **1** and CH_2Br_2 or CH_2(OTosyl)$_2$ and the formation of **6** from **1** (in absence of **2**) would indicate that **5** also undergoes spontaneous hydrogen disproportion. Products with carbidic bridge ligands could, however, not be detected.

"Bichromocenylene": A Sandwich with Partly Decoupled Electrons

By *Frank Herwig Köhler*, Karl Heinz Doll, Wolfram Prössdorf*, and *Jörn Müller*

In bimetallocenylenes—alternatively: bis(fulvalene)dimetal compounds—$(C_{10}H_8)_2M_2$ (cf. Fig. 1) the ligand forces two metal atoms to a distance of >390 pm[2a]; this value raises the question of metal-metal interactions. Initial studies surprisingly indicated that $[(C_{10}H_8)_2Fe_2]^{2+}$ is diamagnetic[3], although two unpaired electrons are to be expected for a ferrocenium analogue. Later, magnetic measurements indicated that $(C_{10}H_8)_2Ni_2$ and $(C_{10}H_8)_2V_2$ are diamagnetic as well[4a]. Considering however that the MOs lie close together energetically[5], diamagnetism is not necessarily to be expected; moreover, it is still unclear by which interaction it is produced. We have synthesized the previously missing chromium compound of the $(C_{10}H_8)_2M_2$-series and found it to exhibit completely different properties. We report here on the use of NMR spectroscopy for the detection of electron interactions indicated by slight paramagnetism in coupled sandwich complexes.

We obtained bichromocenylene, $(C_{10}H_8)_2Cr_2$, **1**, as a dark powder from sodium cyclopentadienide *via* the fulvalene dianion. No contamination with possible oligomers could be detected by mass spectroscopy up to 195 °C. Referred to ^{52}Cr the most important masses at 70 eV are: $[M+2]^+$ (15), $[M+1]^+$ (44), M^+ (100), $[M-Cr-2]^+$ (15), M^{2+} (24), $C_{10}H_8^+$ (10), Cr^+ (32); the molecular ion appears with the calculated isotopic distribution. **1** is moderately soluble in toluene at 100 °C, giving a yellow solution;

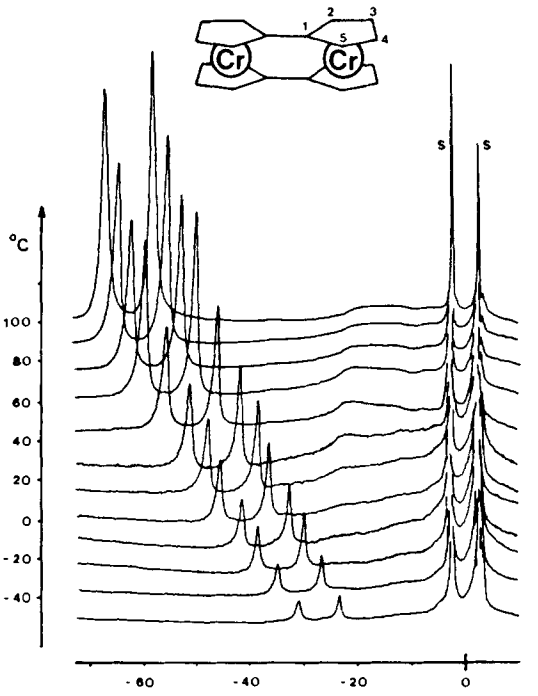

Fig. 1. 200 MHz ^{1}H-NMR spectra of $(C_{10}H_8)_2Cr_2$ **1** in [D$_8$]toluene in dependence of temperature. S = solvent. δ-Values rel. ferrocene; paramagnetic low-field shifts are negative.

all previously reported chromocene derivatives are red. We have recorded the ^{1}H-NMR spectra (Bruker CXP 200) of a saturated solution of **1** in [D$_8$]toluene between -52 and 103 °C; besides the signals for the solvent they show only two additional signals for H2/5 and H3/4 (cf. Fig. 1).

The shifts clearly indicate that **1** is paramagnetic. However, whereas chromocene with two unpaired electrons gives δ^{para} (^{1}H) = -324 at 298K, the comparable signals of **1** are 7 times less shifted. Our findings are understandable if **1** has a diamagnetic ground state, and if paramagnetic excited states may be populated thermally. A corresponding coupling of the spins of both chromocene halves is demonstrated by the temperature dependence in Figure 1. With phenylated chromocene we could show that spin transfer to aromatic substituents is not important. Consequently, metal-metal interaction rather than superexchange dominates in the spin coupling in **1**.

Similarly as in the case of chromocene, dipolar shifts should not play a role in **1**. Thus, the temperature-dependence of the δ^{para} values may be predicted[11b]. Taking into account two excited states the fitting of the experimental data yields a singlet-triplet excitation energy which lies in the range of 300–380 cm^{-1}; the hyperfine interaction constants are 1.1 to 1.3 times greater in the second than in the first excited state. We have also observed a similar temperature behavior of paramagnetic ^{1}H-NMR signals in the case of $(C_{10}H_8)_2V_2$ and $(C_{10}H_8)_2Ni$.

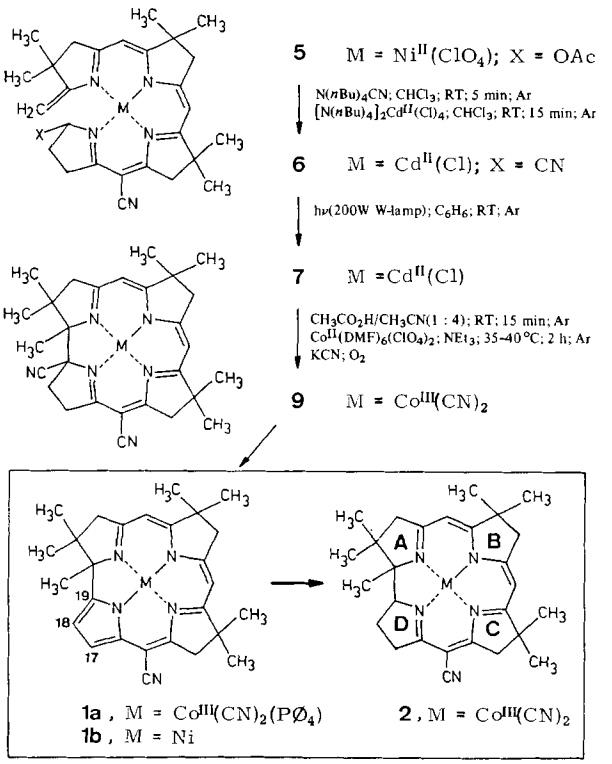
Synthesis of a Dicyanocobalt(III) D-Didehydrocorrinate and Its Reduction to the Dicyanocobalt(III) Corrinate**

By *Bernhard Kräutler* and *Kurt Hilpert**

Experimental experience regarding access to the corrin system *via* reduction of D-didehydrocorrins is still lacking, though aquisition of such knowledge is of great interest in view of the questions concerning the natural formation of corrins such as vitamin B_{12} (cf. [1]). The D-didehydrocorrin structural type became accessible for the first time in the form of the nickel(II) complex **1b** several years ago[2b, 11a,d]. For preparation of the analogous dicyanocobalt(III) D-didehydrocorrinate **1a** we made use of the electrochemically readily obtainable nickel(II) 19-acetoxysecocorrinate **5**. Outlined below is the synthetic route to the corrinoid cobalt complex **9**, the precursor of **1a**, which we obtained in *ca.* 70% overall yield. The liberation of the pyrroloid D ring of **1a** was achieved by heating a carefully degassed mixture of **9**, dimethylsulfone, and an excess of 1,8-diazabicyclo[5.4.0]undec-7-ene. The light-sensitive pyrroloid cobalt(III) D-didehydrocorrinate **1a** could be isolated in high crude yields as a green powder. The constitution of **1a** is assigned, in particular, on the basis of the ^{1}H-NMR spectrum (300 MHz, CD_2Cl_2, -40 °C). **1a** shows strongly bathochromically shifted, broad absorption bands in the UV/VIS spectrum (α-bands at *ca.* 710 nm). On shaking a benzene solution of **1a** with a 1 M aqueous HCN solution (phosphate buffer pH 3.5), **1a** can be reversibly converted into a deep-violet complex, which according to the UV/VIS spectrum (α-band at 598 nm) and ^{1}H-NMR spectrum should be the dicyanocobalt(III) Δ^{18}-didehydrocorrinate **3** formed by C-17 protonation (analogous behavior of **1b**[11d]). Treatment of **1a** with acid, without addition of HCN rapidly leads *via* **3** to a further change of color to red (loss of an axial cyano ligand (?), **3**→**4**, UV/VIS: α-band at 540 nm).



The reduction **1a**→**2** was accomplished (after treatment of **1a** with trifluoroacetic acid (→**4**)) by addition of an excess of zinc dust to an N_2-saturated acetic acid solution (RT, 1 h). Bright-red compound **2** was isolated in 22% yield by neutralization, addition of cyanide and air oxidation, and was identified after crystallization by comparison with authentic **2**[16a]. Thus, the corrin system has been shown to be accessible for the first time *via* reduction of a D-didehydrocorrin.

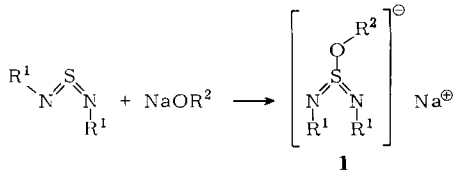
Synthesis and Structure of Triply Coordinated Sulfur Anions**

By *Herbert W. Roesky, Wilfried Schmieder, Wilhelm Isenberg, Dieter Böhler,* and *George M. Sheldrick**

No products containing triply coordinated sulfur are detected on degradation of elemental sulfur with nucleophiles in solution. In contrast, the eight-membered heterocycle $S_4N_4O_2$ reacts with sodium alkoxides to give one of the few known anions with triply coordinated sulfur[1]. We have now extended this reaction to acyclic sulfur diimides[4].



1

1a, $R^1 = CF_3SO_2$, $R^2 = CH_3$ } in R^2OH
1b, $R^1 = CF_3SO_2$, $R^2 = C_2H_5$ }
1c, $R^1 = C_6H_5SO_2$, $R^2 = CH_3$ } in CH_3CN
1d, $R^1 = C_6H_5SO_2$, $R^2 = C_2H_5$ }
1e, $R^1 = CH_3C_6H_4SO_2$, $R^2 = (CH_3)_2CH$ }

The very stable anions **1** thus obtained in 74—99% yield form colorless salts which are slightly sensitive to moisture and decompose at *ca.* 200 °C.

For a single crystal structure analysis, **1b** was converted into the tetraphenylphosphonium salt **1f**. The X-ray structure analysis (Fig. 1) shows that the introduction of the ethoxy group enlarges the S—N distance from *ca.* 1.53 Å to 1.609 Å (mean value).

The stability of the anions is essentially due to delocalization of the negative charge over the $—SO_2—NS(OR^2)NSO_2$-system, whereby the SO_2 groups play a cardinal role. Corresponding reactions with other sulfur diimides in which, for example, $R^1 = C_6F_5$ or $(CH_3)_3C$ proceeded in a complex manner and did not yield stable, isolable anions.

If, on the other hand, bis(trimethylsilyl)sulfur diimide **2** is allowed to react in CH_2Cl_2 with CsF, which contains about 7% water, the monomeric cesium salt **3** of the sulfonyl imide is formed:

2 **3**

Salts of the sulfonyl imide have previously only been isolated as trimers.

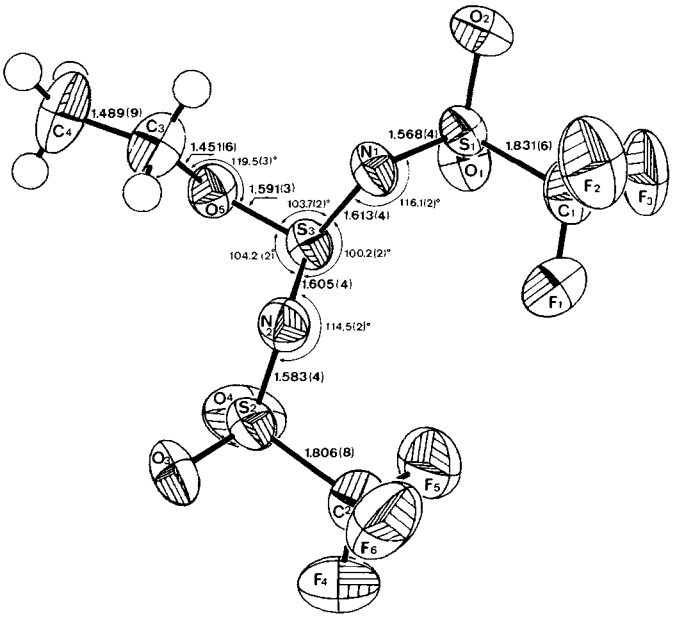


Fig. 1. Molecular structure of **1f** in the crystal; atomic distances in Å; standard deviations in brackets. S(1,2)—O(1,2,3,4) 1.423; C—F 1.313 Å; NS(1,2)O 113.1; CS(1,2)O 103.8; CS(1,2)N 102.6; OSO 118.1° (all mean values).

3, an amorphous powder that is sensitive to hydrolysis, is practically insoluble in all the usual organic solvents. For characterization of **3**, the salts $Ph_4P^+NSO_2^-$ **3a** and $Ph_3PNPPh_3^+NSO_2^-$ **3b** were prepared; in the field-desorption mass spectrum[9] they show the molecular ion. — All the new compounds have been characterized by elemental analysis and by IR, ^{1}H-NMR, and ^{19}F-NMR measurements.

BOOK REVIEWS

The Heterocyclic Chemistry of Phosphorus. Systems Based on the Phosphorus-Carbon Bond. By *L. D. Quin.* J. Wiley & Sons, Chichester 1981.

Considering the description of the then known heterocyclic phosphorus compounds given by *F. G. Mann* in the 2nd edition of his book "The Heterocyclic Derivatives of Phosphorus, Arsenic, Antimony and Bismuth" (1970), it would have been impossible for anyone to anticipate the almost explosive development of this field in hardly more than a decade since that time. This book by *Quin*, one of the most experienced and imaginative experts in the field of phospholes and their hydrogen derivatives, will become an indispensable aid to any who have to do with these compounds, though—or rather, directly because—with typical order and skill, it briefly outlines the general fundamentals required for the understanding of reactions in the

broad field of organophosphorus chemistry, for the benefit of chemists not particularly specialized in this area. The main preoccupation of the book lies in describing the syntheses and reactions of the five-ring compounds; other heterocyclic phosphorus compounds are also dealt with, though in less detail. Outstanding features of the work are an introductory chapter, in which the author has successfully tackled the task of relieving the aversion felt by many chemists for the often quite unpleasant phosphorus compounds, and three further chapters in which the spectroscopic aspects are dealt with. These latter give the most important results of ^{31}P, ^{13}C and ^{1}H-NMR spectroscopy, without which no chemist can work successfully in this field. The book concludes with a chapter on the problem of "aromaticity" in phospholes and phosphorins, and on their transition metal complexes—though the latter are treated somewhat briefly. Thanks to the many references given, the book is also an indispensable aid to the specialist. The present high rate of development will no doubt very soon necessitate a second edition, in which the few and mostly quite trivial printing errors in the text and formulas can be corrected. All in all, this is a long-awaited book, of appeal not only to the "phosphorus chemist" but also to any who desire a brief review of the state of knowledge in organophosphorus chemistry, and not just the heterocyclic compounds.

Advances in Selective Chemical Syntheses of Complex Oligosaccharides

By Hans Paulsen*

A wide variety of complex oligosaccharides has now been made accessible as a result of methodological improvements in the sphere of chemical synthesis, which can be used for the study of conformations and interactions with protein-receptor molecules. Such work is of particular importance because the oligosaccharide chains of glycoproteins and glycolipids anchored to the plasma membrane are important in cell-cell interactions and are receptors for enzymes, hormones, proteins, and viruses; furthermore, they determine the antigen properties of cells. The methods of synthesis available for the production of selective linkages in oligosaccharides are dealt with, particular attention being paid to conversion of saccharides into oligosaccharides, which are important from the biological point of view.

1. Introduction

Carbohydrate chemistry, and especially the sector of monosaccharides, is currently undergoing a major upsurge that started in the mid-1950's following the introduction of new synthetic methods, analytical methods of separation, and the appearance of new possibilities of elucidating structures by physicochemical methods. Many new natural sugars were discovered as a result, and a particularly stimulating factor was the discovery of some unusual amino sugars in aminoglycoside antibiotics and bacterial polysaccharides[1]. The development of stereo- and enantioselective syntheses made it possible to synthesize virtually any desired sugar and amino sugar starting from various readily accessible saccharides. Interest in asymmetric syntheses was already growing in organic chemistry at that time, and it also became possible to extend the modification techniques to complex aminoglycoside antibiotics to obtain modified products[2].

Some decisive developments occurred at the beginning of the 1970's. By his discovery of sugar-nucleotide compounds, which led to the clarification of the biosynthesis of polysaccharides, *Leloir*[3] pushed carbohydrates once again into the center of the biochemical arena. Whereas hitherto polysaccharides had been regarded only as a supporting material and a source of energy, the importance of the complex glycoconjugates was now recognized[4–6]. These compounds, difficult to investigate, contain a protein, lipid, or phospholipid component in addition to an oligosaccharide chain. It was found that it was the oligosaccharide residue of the glycoconjugates that is of importance for the biological functions of this class of substances. There therefore followed a tumultuous development in glycoconjugate biochemistry.

The glycoconjugates include, for example, glycolipids, whose lipid part serves as a means of anchorage in the double layer of the cell membrane[7]: the oligosaccharide component protrudes from the cell membrane and is the determinant whose structure is decisive for the specificity of the immune reaction[8]. The glycoproteins found on the cell-surface membranes, in which the oligosaccharide residue is likewise exposed, play a role in intercellular recog-

nition[9, 10], acting as receptors for enzymes, hormones, proteins, and viruses. They are able to regulate the transportation of proteins between cells, and should thus be regarded as signal substances in cell metabolism[4, 10]. Glycoproteins are also important in governing the water-molecule concentration at the membrane and the permeation of inorganic ions. In addition, they protect the peptide chain against proteolytic attack. Intensive studies are in progress for the purpose of a more detailed clarification of these many functions. The prophetic words of *Nathan Sharon* indeed seem to have come true—"We know now that the specificity of many natural polymers is written in terms of sugar residues, not of amino acids or nucleotides"[4a].

The advances made in this sphere have been due to the improvements made in recent years in the chemical, physical, and enzymic methods of structure analysis[10]. High-field NMR spectroscopy, in particular, has contributed to rapid clarification of the structure of the oligosaccharide chains in glycoproteins. The sequence in the oligosaccharide residue is now known in an appreciable number of glycoproteins and glycolipids, and it is also known that it is largely the terminal sequences of the oligosaccharide, the determinants or antennae, that are responsible for the specific biological action. Preparative organic chemists are now called upon to synthesize such sequences of oligosaccharide determinants since biogenic material is frequently difficult to obtain. Modified determinants could provide information on the nature of the sites of attachment and thus on the mechanism of the biological interaction between the oligosaccharide hapten and the antibody or protein with which it reacts. The aim of this review is to report the advances made in the field of selective chemical synthesis of oligosaccharides.

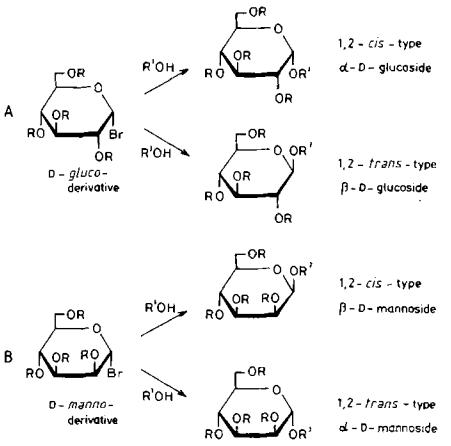
2. Selective Oligosaccharide Synthesis

2.1. General Points

Until a few years ago the synthesis of a disaccharide was still an outstanding achievement, and syntheses of trisaccharides with various structural units and types of linkages were successful only in isolated cases[11, 12]. Although we have now learned to synthesize oligosaccharides, it should be emphasized that each oligosaccharide synthesis remains an independent problem, whose resolution requires considerable systematic research and a good deal of know-how. There are no universal reaction conditions for oligosaccharide syntheses.

In an oligosaccharide synthesis two polyfunctional reaction partners must be coupled. Both must be able to be selectively blocked and deblocked. In the glycosyl component it must be possible to expose and functionalize the anomeric center: in the hydroxyl component only the hydroxyl group intended for the coupling step must be selectively deblocked. The reactivities at the anomeric center of the glycosyl component and of the OH group of the reaction partner depend very strongly on the type of blocking pattern of the two compounds. A variation of the blocking pattern can exert a decisive influence on the coupling step. Conformational and steric influences, and the molecular sizes of the two partners are also significant. The coupling step should proceed as stereoselectively as possible and result in only one of the two possible anomers if expensive anomer separation is to be avoided, a procedure that is extremely difficult in the case of the larger oligosaccharides. All these relationships mean that the reaction conditions must be carefully tried out for each coupling step, and solid-state oligosaccharide syntheses, such as are used successfully for peptides and nucleotides, therefore do not seem very promising. Experiments performed in this direction have not yielded any useful procedures[13].

In the syntheses of the larger oligosaccharides, glycosyl halides are still the most important educts, whose reactivity can be modified over wide limits *via* blocking groups; many suitable catalysts can be selected according to each purpose. A number of different glycoside-linking methods have also been investigated, but so far these have been used only occasionally for the synthesis of large molecules.



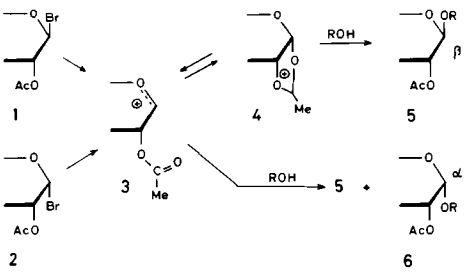
Since the methods for coupling two sugar residues with formation of a 1,2-*cis*- or 1,2-*trans*-glycopyranoside bond are completely different, the two types of reaction will be treated separately. In the case of the 1,2-*cis* type **A** the establishment of an α-glycoside link in the *gluco*- and *galacto*-series is involved, and the production of a β-glycoside bond in the *manno* series. Correspondingly, formation of a 1,2-*trans*-type **B** involves the production of a β-glycoside bond in the *gluco*- and *galacto*-series and of an α-glycoside bond in the *manno*-series. Thereby the essential structures occurring in biologically important oligosaccharides are covered.

2.2. Preparation of 1,2-*cis*-Glycopyranoside Bonds

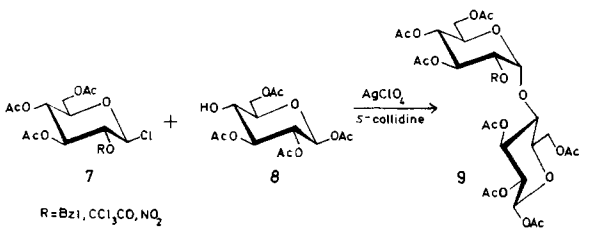
2.2.1. α-Glycopyranosides of the *gluco*- and *galacto*-Series

After the halide has been split off, pyranosyl halides in which the H atom on 2-OH is replaced by a neighboring-group-active substituent, irrespective of whether the β-form **1** or the α-form **2** is used, react *via* the oxocarbenium ion **3** to give the dioxocarbenium ion (acetoxonium ion) **4**, which is stabilized with respect to the more reactive **3**[14]. Nucleophilic ring opening of **4** with an alcohol component at C-1 leads, for steric reasons, only to the β-glycoside **5**.

This reaction sequence is utilized to bring about stereoselective β-glycoside synthesis (Section 2.3). In reactions with only moderately reactive alcohols, **3** is also sometimes capable of reacting, so that an anomeric mixture of **5** and **6** forms.



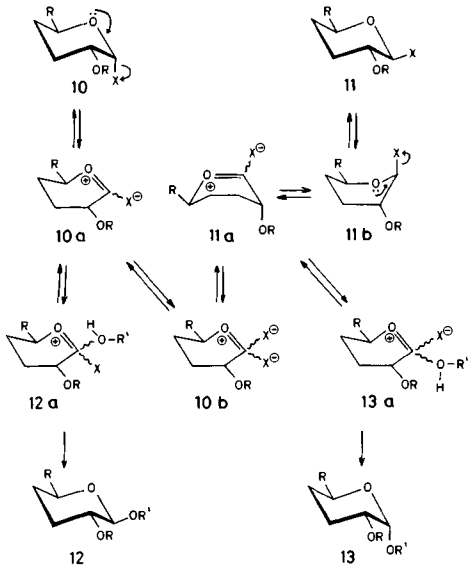
The first prerequisite for an α-glycoside synthesis is thus that the H atom of 2-OH of the pyranosyl halide must have been replaced by a nonneighboring-group-active substituent. As shown in reactions **7**→**9**, a number of substituents have been tried out for this purpose[*]. The benzyl group has proved the most favorable, since good reactivity of the halide is observed. In the case of the likewise well tried trichloroacetyl group the halide is more stable but its reactivity is lower.



To achieve an α-glycoside synthesis the less stable β-halide **7** must be taken as the starting substance and the nucleophilic substitution with the alcohol component be conducted in such a way that it proceeds as completely as possible with inversion in the sense of an S_N2 reaction. This can be done in a solvent of low polarity such as dichloromethane or ether in the presence of an active catalyst such as $AgClO_4$ or $AgClO_4/Ag_2CO_3$. Thus, **7** (R = Bzl) reacts with the extremely weakly reactive 4-OH group of **8** to give the maltose derivative **9** (43%)[15]. Corresponding reactions can be carried out with **7** ($R = CCl_3CO$)[16].

However, this process is possible only with relatively stable isolable β-halides. In the majority of cases the labile β-halide can be used only with difficulty, or indeed not at all. This applies in particular to the disaccharide halides, intended for the construction of larger units. In this respect the process has only limited applicability.

Synthesis of α-glycosides by in situ anomerization of α-glycosyl halides: To avoid these difficulties, the α-glycoside synthesis must proceed directly from the more easily accessible and more stable α-glycosyl halide **10.** According to *Lemieux et al.*[17], the α-halogenide **10** exists in equilibrium with the more unstable β-halide **11**; the equilibration reaction is catalyzed by halide ions. Especially when a solvent of low polarity is used, such as dichloromethane, one ion pair **10a** can be produced from the α-halide **10,** and a different ion pair **11a** from the β-halide **11** *via* conformation **11b.** The two ion pairs **10a** and **11a** are in equilibrium *via* the ion triplet **10b**[18]. At equilibrium the proportion of more stable **10** is high. Destabilization of the β-halide **11** takes place as a result of an anomeric effect, which is particularly powerful in halide substituents.



The energy barrier for a nucleophilic reaction of glycosyl halides such as **10** and **11** with alcohols R'OH with inversion *via* **11**→**11a**→**13a**→**13** is lower than that for the corresponding reaction **10**→**10a**→**12a**→**12,** so that formation of α-glycoside **13** is faster than that of β-glycoside **12**[18]. Control of the whole reaction, exploiting this difference in reaction rates, permits the selective synthesis of α-glycosides from the α-halide **10.** If this difference is large enough, it is possible to steer the whole reaction so that virtually no β-glycoside is produced, and the only product is the α-glycoside **13,** even if the concentration of **11** or **11a** is low. However, the establishment of the equilibrium **10** ⇌ **11** must be fast enough so that new **11** or **11a** can be constantly produced from **10.**

In this reaction, termed a halide-catalyzed glycosidation by *Lemieux et al.*[18] tetraalkylammonium halides were used as catalysts. The reaction has proved itself in many instances, but requires very reactive pyranosyl halides and relatively long reaction times. The high selectivity indicates a reaction sequence proceeding *via* the extremely reactive β-halide-like ion pair **11a.** The preferential formation of α-glycoside cannot be attributed to an anomeric effect. If a polar solvent is used for the reaction, separated ion pairs with carboxonium-like intermediate cations occur, and the selectivity is considerably reduced. Anomeric mixtures are also obtained in the subsequent isomerization of the glycosides.

Reaction of the α-halide **10** to the α-glycoside **13** in dichloromethane can also be carried out in presence of the

[*] In accordance with the rules of the International Union of Biochemistry the following abbreviations have been used: Ac = acetyl, Bz = benzoyl, Bzl = benzyl, Cbz = benzoyloxycarbonyl, Trt = trityl. Other abbreviations are explained in the text.

soluble catalysts mercuric cyanide, mercuric bromide, silver perchlorate, and silver triflate likewise with high selectivity[19]. These catalysts are actually much more active than tetraethylammonium halides, and, even less reactive halides react under very much milder conditions[19-21]. We presume that the α-halide complexes with the mercury salts, and probably also with the silver salts, to form ion pairs **10a, 10b,** and **11a** whose precise structures are, however, unknown (X would then be $BrHgBr_2$, $BrHg(CN)_2$, or ClO_4 or CF_3SO_3).

The energy barrier for the reaction sequence **11a**→**13a**→**13,** as well as that for **10a**→**12a**→**12** may be lowered, so that over-all both reactions are accelerated. It should be borne in mind that if the catalysis is too strong, the difference between the rates of formation of **13** and **12** can decrease, with an adverse effect on selectivity. Even if it is assumed that in the reaction of the α-halide **10** with $AgClO_4$ or $AgCF_3SO_3$ only glycosyl perchlorates[14] or glycosyl triflates are formed, the preferred formation of **13** (X = ClO_4 or CF_3SO_3) can be analogously explained[20,21].

The course of an oligosaccharide synthesis can be essentially influenced by the reactivities of the halide, the catalyst, and the alcohol[21]. The reactions are conducted in solvents of low polarity, such as dichloromethane, possibly mixed with toluene.

The reactivity of the halide is influenced primarily by varying the substituents on the hydroxyl groups (see Table 1). Benzyl compounds are always more reactive than the acetylated or benzoylated derivatives, the position of the benzyl ether groups being less important than their number. This is apparent in the rates of anomerization of α-glycosyl halides carrying mixed substituents and in comparable reactions[22]. Trichloroacetyl groups decrease, and deoxy groups increase the reactivity of the halide, the effect being large in both cases. Bromides are always more reactive than chlorides, but they are also less stable.

Table 1. Reactivity of halides, catalysts, and alcohols in oligosaccharide synthesis.

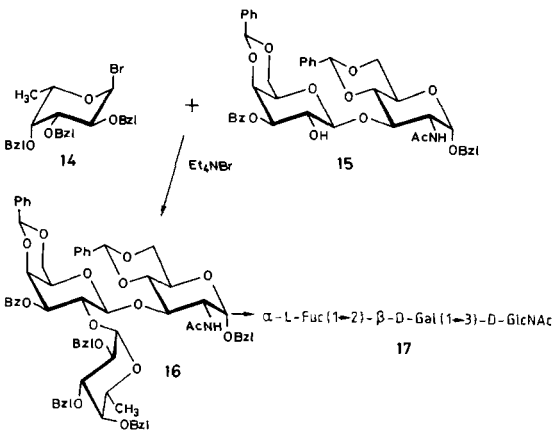
Halide	Catalyst	Alcohol
 R ~ Bzl > Bz ≳ Ac; X ~ I > Br > Cl	Et_4NBr / molecular sieve 4 Å $Hg(CN)_2$ $Hg(CN)_2$ / $HgBr_2$ $HgBr_2$ / molecular sieve 4 Å $AgClO_4$, Ag_2CO_3 Ag triflate, Ag_2CO_3	HO-CH_3 >> HO-CH_2R > 6-OH  6-OH >> 3-OH > 2-OH > 4-OH

The catalyst must be regarded as the most important factor influencing the reaction. A tetraethylammonium halide is the mildest catalyst and demands very high reactivity on the part of the two reactants. If the reaction is carried out with the very mild catalyst tetraethylammonium chloride, in accordance with the original procedure[18], the solvent is dichloromethane with a small amount of dimethylformamide. Mercury compounds are more catalytically active and can also be used as mixtures in various proportions (see Table 1). Most active of all are silver perchlorate and silver triflate. In the case of the triflate it should be borne in mind that the reaction of α-halide to β-glycoside is also catalyzed, so that the stereoselectivity can decrease; this can be countered by conducting the reaction at a lower temperature.

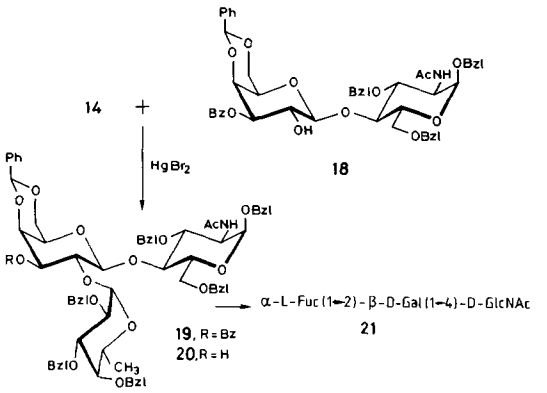
As a rule the reactivity of the alcohol cannot really be influenced, since as a reaction partner it is determined in advance. On the whole, it can also be said that alkyl substituted derivatives are more reactive than those bearing acyl substituents[23]. Secondary hydroxyl groups in pyranoses, which are important for saccharide linkages, have a moderate reactivity and are particularly suitable for reactions with reactive halides under the above conditions, whereby a high selectivity is achieved. Primary hydroxyl groups such as the 6-OH of sugars or that in serine are considerably more reactive. In this case the differences in the rates of reactions to α- and β-glycoside are smaller, and the stereoselectivity decreases. In such instances a milder catalyst must be selected or, as described above, the pure β-halide must be used directly. The β-halide can also be obtained by controlled inversion techniques[24-26], whereby it must be used directly for the reaction. The most reactive hydroxyl group is found in methanol whose reactions are therefore least comparable with those of saccharides.

In all glycoside syntheses it is extremely important to make absolutely certain that moisture is excluded, and all operations should be carried out under argon or nitrogen using the same techniques employed for sensitive organometallic compounds. Traces of moisture frequently result in considerable losses in yield and are the usual cause of failure to achieve the desired result; it is also recommended that reactions be performed in brown glass vessels.

Influence of the catalyst reactivity: The *in situ* anomerization method can be applied very advantageously to the halide of L-fucose **14.** In the presence of the mild catalyst tetraethylammonium bromide, **14** reacts with the disaccharide **15** to give the trisaccharide **16,** this reaction being stereoselective with a yield of 80% relative to the α-glycoside **16**[27]. Deblocking of **16** yields **17,** the trisaccharide determinant of blood-group substance H (type 1). α-L-Fuc(1→2)-[α-D-Gal(1→3)]-D-Gal, the trisaccharide determinant of blood-group substance B (type 1)[28], and β-D-Gal(1→3)-[α-L-Fuc(1→4)]-D-GlcNAc, the trisaccharide determinant of the Lewis a blood-group substance[29,30] have been analogously produced.

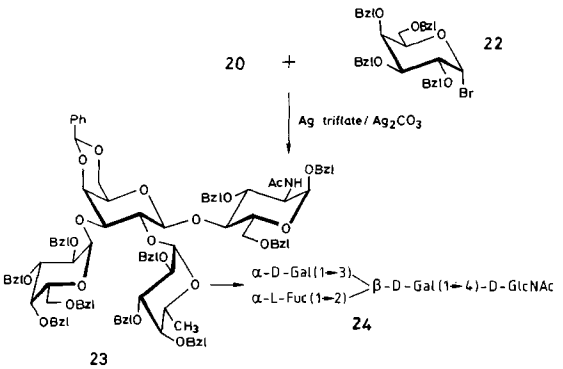


In the very similar disaccharide **18,** surprisingly enough, the 2-OH group of the non-reducing unit is considerably less reactive than that of disaccharide **15.** Disaccharides **15** and **18** are identical in the non-reducing unit and differ only in the type of linkage: in **15** a 1→3-, while in **18** a 1→4-link is present. In the presence of tetraethylammonium chloride catalyst **18** reacts with fucosyl bromide **14** to give the trisaccharide **19** in only 30% yield. The reaction can now be improved by increasing the reactivity of the catalyst. Thus, 40, 50, and 80% yields of **19** can be obtained with $Hg(CN)_2$, $Hg(CN)_2/HgBr_2$, $HgBr_2$ catalysts, respectively, the reaction proceeding stereoselectively so that only the α-glycoside is produced[21]. The determinant of blood-group substance H (type 2) **21** can be obtained from **19**[21,31].



With L-fucose derivatives the situation is so favorable that the selectivity hardly decreases in the *in situ* anomerization reaction, even in the polar medium nitromethane/toluene—in contrast to D-galactose and D-glucose derivatives. In the presence of $Hg(CN)_2$ in nitromethane/toluene, the disaccharides α-L-Fuc(1→3)-L-Fuc[32], α-L-Fuc(1→4)-L-Fuc[33], and α-L-Fuc(1→2)-L-Fuc[34] can be obtained with good selectivity. The determinants of the Lewis d blood-group substance, in which two L-fucose residues are connected in a stepwise manner to β-D-Gal(1→4)-D-GlcNAc, were synthesized by tetraethylammonium halide catalysis in 1,2-dichloroethane[35].

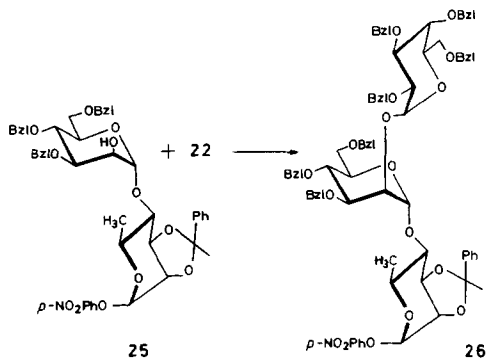
Likewise, α-glycoside linkages can be produced stereoselectively with the pyranosyl halide of D-galactose **22** and the corresponding D-glucose compound by *in situ* anomerization in the presence of tetraethylammonium halide. This is demonstrated in the above-mentioned synthesis of the trisaccharide determinant of blood-group substance B[28]



and in the synthesis of the unit α-D-Glu(1→2)-D-Gal[36,37].

In the more difficult oligosaccharide syntheses the hydroxyl groups are often less reactive, and a far more reactive catalyst is needed than tetraethylammonium chloride. When the trisaccharide **20** reacts with the galactopyranosyl bromide **22** in the presence of tetraethylammonium chloride, practically no coupled product **23** is formed; an 80% yield of pure α-linked tetrasaccharide **23** is, however, produced with $HgBr_2$, and a molecular sieve of 4 Å, and a 77% yield of **23** is obtained with silver triflate/silver carbonate[27]. It should be noted that the reaction with triflate must be performed at −25 °C to preserve the stereoselectivity. In selecting the catalyst a compromise must be reached between yield and selectivity. The tetrasaccharide **23** can be deblocked to **24,** the tetrasaccharide determinant of blood-group substance B (type 2)[27].

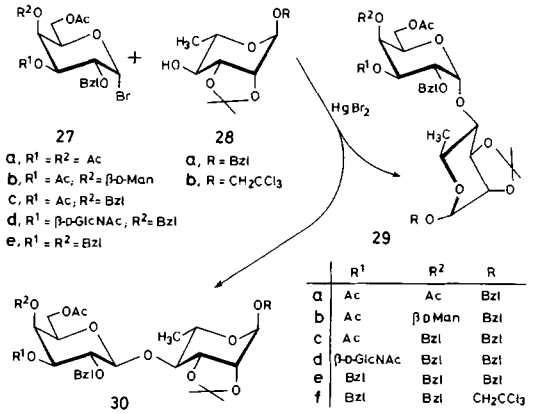
The trisaccharide **26** is obtained with good stereoselectivity from the galactose derivative **22** and the disaccharide **25**[38]. Deblocking **26** gives α-D-Gal(1→2)-α-D-Man(1→4)-α-L-Rha, which represents the repeating unit of a *Salmonella* lipopolysaccharide. Silver triflate/s-collidine in toluene at −70 to 20 °C is used as the catalyst.



It may be emphasized that in the reaction with galactopyranosyl bromide **22** the selectivity decreases if a polar solvent such as nitromethane/benzene is used in place of dichloromethane or toluene. As has been demonstrated[39,40], although the α-glycoside-linked compound is obtained as the main product, the proportion of a β-glycoside product is still considerable.

The influence exerted by the reactivity of the halide and the hydroxyl component was studied using a model reaction between variously substituted galactosyl bromides **27** and the rhamnosides **28a** and **28b**[41]. The reactions were carried out under standardized conditions ($HgBr_2/CH_2Cl_2$) and the selectivity determined. The 4-OH group of the rhamnose derivative **28** is almost as reactive as that of a primary 6-OH group. In components with reactive hydroxyl groups the selectivity can be considerably impaired during glycoside synthesis, since reactions **10**→**13** are partially replaced by reactions **10**→**12.** It is then necessary to improve the selectivity either by reducing the reactivity of the halide or through a milder catalyst.

The bromides **27a** to **27e** vary considerably in reactivity (see Table 1); benzyl groups increase, and acetyl groups decrease reactivity. An additional glycosyl residue has only a slightly weaker activating effect than a benzyl group.



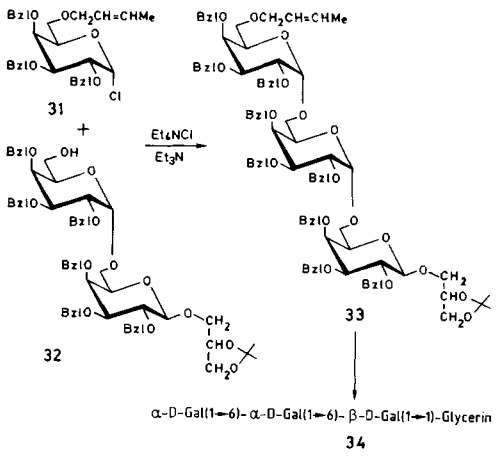
The least reactive bromide **27a** reacted with **28a** to always give the α-linked disaccharide **29a.** The most reactive bromide **27e,** on the other hand, gives a mixture of anomers **29e** and **30e** (19:81) with **28a** *i.e.* the β-form is therefore now the main product. The compounds with mixed substitution **27b** to **27d** have intermediate reactivity. Thus reaction of the disaccharide halide **27b** with **28a** yields virtually only the α-linked trisaccharide **29b.** The corresponding reaction of the mixed-substituted compound **27c,** on the other hand, yields an α:β product ratio [**29c** : **30c**] of (88:12), and **27d** gives a product mixture with an α:β ratio [**29d** : **30d**] of 16:84. These examples clearly show how the selectivity can be influenced by the reactivity of the halide used[41].

The reactivity of the hydroxyl group in the rhamnoside **28a** was reduced by exchange of the benzyl for a trichloroethyl group, and reacted with the most reactive halide **27e** under standard conditions to give the anomeric mixture **29f/30f** (81:19). The product ratio has therefore now been shifted in favor of the α-form, in contrast to the reaction of **27e** with **28a.** A similar effect can be observed in other glycosidation reactions with **28b.** It is therefore possible to modify the reactivity of the hydroxyl component by varying its substituents, and thus to influence the selectivity of the reaction[41].

Of course the catalyst can be varied to improve the poor selectivity of the reaction of **27e** with **28a.** If instead of $HgBr_2$ the milder catalyst tetraethylammonium bromide is used, the reaction of **27e** with **28a** yields almost exclusively the α-glycoside **29e,** although reduction in yield can occur[20]. With sensitive disaccharide and trisaccharide halides the halide-catalyzed reaction cannot be carried out with tetraethylammonium halide, since too much time and an elevated temperatures are required. Disaccharide and trisaccharide halides must be treated as quickly as possible with the most reactive catalysts.

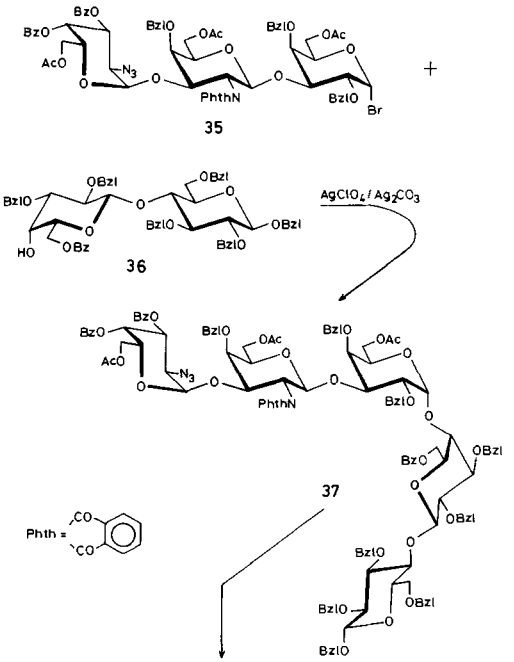
The fact that very reactive 6-OH groups can be converted into α-glycosides with satisfactory selectivity is demonstrated by the synthesis of α-D-Glc(1→6)-D-Gal and α-D-Gal(1→6)-D-Gal[42,43]. In these instances a mild tetraethylammonium halide catalyst was used to afford good selectivity. Under these reaction conditions the halide **31** reacts with the disaccharide **32** to give a trisaccharide glyceride **33,** which could be deblocked to give **34.**

Summarizing, it can be said[21,41] that reactive halides can react with hydroxyl groups of moderate reactivity to give α-glycosides in very high selectivity. The catalyst should be selected to suit the reactivity of the hydroxyl group. In the case of very reactive hydroxyl groups the reactivity of the halide or the catalyst must be reduced to



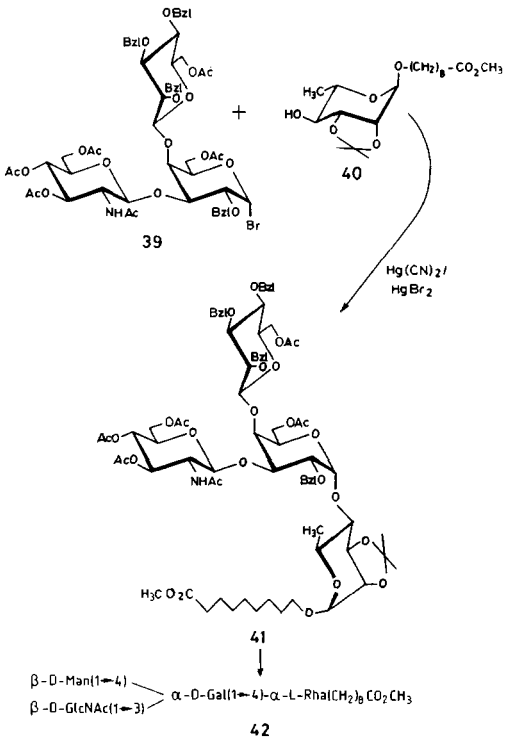
maintain satisfactory selectivity as regards the anomeric ratio, or the pure β-halide must be used as the starting material.

Block Syntheses: Since as a result of *in situ* anomerization a very reactive β-halide-like intermediate reacts to give an α-glycoside stabilized by the anomeric effect, this coupling method can be regarded as extremely effective. It is also suitable for coupling previously prepared oligosaccharide units to larger molecules, potentially a very useful way of making larger complex oligosaccharides. In the synthesis of longer saccharide chains it is therefore advantageous to select an α-glycosidic linkage for the block cou-



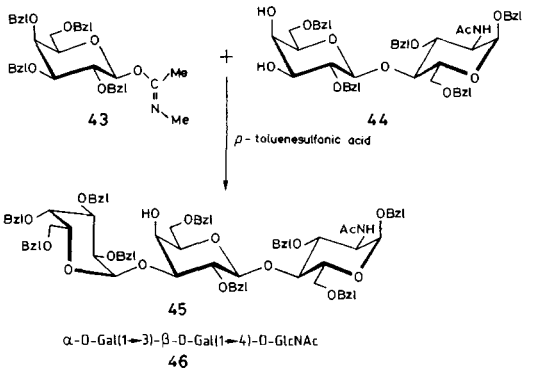
pling step. This strategy may be seen in the synthesis of the pentasaccharide chain **38** of the Forssman antigen[45,46].

Since both galactose units are linked *via* an α-glycosidic link, it is therefore best to couple a trisaccharide halide **35** with a disaccharide hydroxyl component **36,** a lactose derivative. However, special methods are necessary for the preparation and handling of sensitive halides like **35.** The latter is produced from the acetyl derivative and $TiBr_4$ under anhydrous conditions[45,46]. It is thus possible to couple the trisaccharide halide **35** with **36** in the presence of $AgClO_4/Ag_2CO_3$ to give the pentasaccharide **37** in 28% yield[45,46]. Considering the well-known poor reactivity of the 4-OH group of the lactose derivative **36** in reactions with monosaccharides, this is a remarkably good result. Deblocking yields the pentasaccharide hapten **38** of Forssman's antigen. The tetrasaccharide chain of globoside (P-antigen) is synthesized in a similar manner[47].



A further example of a block synthesis is the coupling of the branched trisaccharide halide **39** with the rhamnose derivative **40**[48]. The 4-OH group in **40** is, as already stated, extremely reactive. Since, however, with two specific glycosyl residues the reactivity of the halide **39** can no longer be varied, even use of the mildest possible catalyst, $Hg(CN)_2/HgBr_2$, yields an anomeric mixture of the tetrasaccharides in the ratio of *ca.* 1 : 1, which can, however, be separated[48]. Deblocking the α-glycosidically linked product **41** results in a tetrasaccharide **42,** which represents the repeating unit of the lipopolysaccharide of *Escherichia coli* O75. A spacer is attached to the reducing end, permitting direct coupling with a protein, and in this way a synthetic antigen can be obtained containing the synthetic tetrasaccharide of **42** as determinant.

Imidate method and methods with other leaving groups: Sinay et al.[23,49] discovered that the *N*-methylacetimidoyloxy moiety is a good leaving group for glycoside syntheses. β-Imidates of this type, *e.g.* **43,** can be made by reacting pyranosyl halides with *N*-methylacetamide and freshly prepared silver oxide in the presence of diisopropylamine, and are stable enough to be isolated and stored. They react with hydroxyl components in nitromethane in the presence of *p*-toluenesulfonic acid and a molecular sieve of 4 Å with inversion to give α-glycosides.

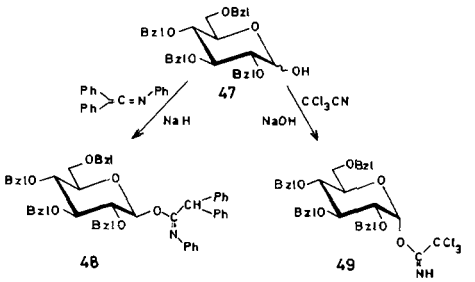


The synthesis of the trisaccharide **46,** which represents a building block of the determinant of the B blood-group substance serves as an example[50]. Under the above conditions, the imidate **43** reacts with the disaccharide **44,** to give, in high selectivity and good yield, the α-glycosidically linked trisaccharide **45,** which can then be deblocked to give **46.** Only the more reactive 3'-OH group takes part in the reaction.

A wide range of oligosaccharides has been prepared in this way[23,49]. Glucose, galactose, and fucose derivatives are suitable for the glycosidation step. The trisaccharide **21**[51] and the tetrasaccharide **24**[52] can also be prepared by the imidate method, when in place of the halides **14** and **22** the corresponding imidate is used for the coupling step.

The disadvantage of the method is that the imidates must first be prepared from pyranosyl halides, from which the desired end product can also be obtained by *in situ* anomerization. The overall yields in both cases are of the same order of magnitude. Furthermore, it should be noted that imidates such as **43** only react well when the sugar moiety contains exclusively benzyl groups *i.e.* the substitution must be such as to produce the highest reactivity at the anomeric center. The presence of even one acyl group in the molecule is sufficient to depress the reactivity to a considerable extent. Attempts to make disaccharide imidates react have so far been unsuccessful[41].

Another suggestion, to prepare an imidate directly from a component such as **47** not substituted at 1-OH, has been made[53a]. With ketenimine a β-imidate **48** is obtained from **47,** whereas with trichloroacetonitrile the product is the α-imidate **49.** Both compounds should be suitable for disac-



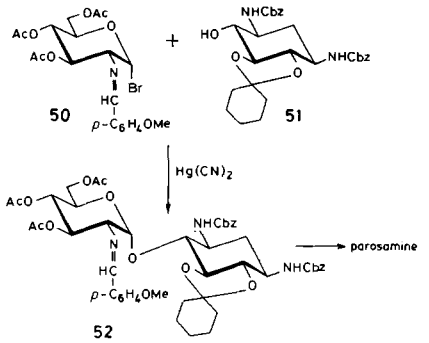
charide syntheses, α-glycosides being produced preferentially from **48**, and β-glycosidic linkages from **49**. It remains to be seen whether the procedure will prove successful and exhibit sufficient selectivity.

Delicate β-glycoside linkages, *e.g.* those of D-mannose[53b] and L-rhamnose[53c] derivatives cannot be produced from α-imidates. In this case α-glycosides are obtained with retention (cf. Section 2.3.3).

Sulfur-containing leaving groups, such as in 1-thio-β-glycosides with (2-pyridyl)-[54], (2-pyrimidyl)-[55], and (2-benzothiazolyl)-1-thio-β-glycosides[56] have been suggested for use in glycoside syntheses. Positively charged leaving groups, such as ammonium groups[57] and 1-*O*-sulfonates[58], have also been investigated. In addition, it has been postulated for reactions in acetonitrile that a nitrilium ion appears as an intermediate which, when reacted further, could be used to steer the glycoside synthesis[55,59]. According to another method, alkali-stable saccharides with a free 1-OH group are converted into their sodium alcoholates, which can then be alkylated to the glycoside with the triflate of the alcohol component[60]. None of these methods has yet found wider acceptance in oligosaccharide syntheses.

2.2.2. 2-Amino-2-deoxy-α-D-glycopyranosides of the *gluco*- and *galacto*-Series

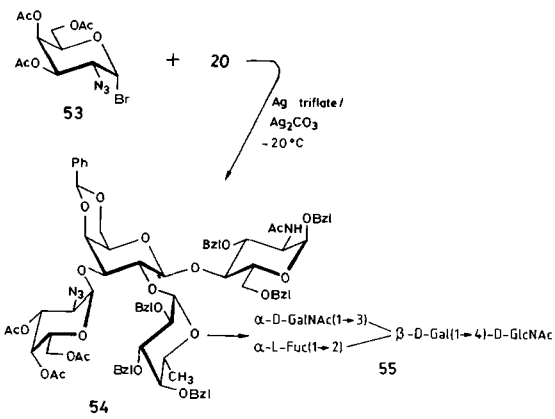
As already discussed in Section 2.2.1, for the synthesis of α-glycosides from 2-amino sugars it is necessary that a non-neighboring-group-active substituent be present at C-2. 2-Acylamino sugars are therefore unsuitable for α-glycoside syntheses. Thus, 3,4,6-tri-*O*-acetyl-2-acetamino-2-deoxy-D-glucosyl halides yield either oxazolines, with involvement of the neighboring group, or preferentially form β-glycosides. The diphenylphosphono group[61] and the 2,4-dinitrophenyl group[62] have proved suitable non-neighboring-group-active substituents on the nitrogen. *p*-Methoxybenzylidene compounds such as **50** have also been used[63].



50 can be converted with the deoxystreptamine derivative **51** in the presence of $Hg(CN)_2$ into **52**, with preferential formation of the α-glycoside; parosamine can be obtained from **52** by deblocking. Dihydrostreptamine[65] and neamine[66] can be synthesized in a similar fashion. It should further be mentioned that many other amino sugars in which the amino group is not bound at C-2 have been used for glycoside syntheses of glycoside antibiotics[63]. For this purpose amino sugars of this kind can be regarded as normal sugars (Section 2.2.1).

The Azide Method: The best method, and one that can be applied to a very wide range of α-glycoside syntheses of 2-amino sugars is, however, the azide method[24-27], in which use is made of 2-azido sugars, which can now be obtained by various methods[24,26,67]. The azido group is a non-neighboring-group-active substituent which is subsequently readily converted into an amino group. In addition, azido sugars have some particularly advantageous solubility properties for glycoside syntheses. The yields and the selectivities are high. The advantage of the method is that 2-azido-2-deoxy-D-glycopyranosyl halides can be converted selectively into α-glycosides both directly as β-halides, or by *in situ* anomerization as α-halides[19]. In the direct process the 2-azido-2-deoxy-α-D-glycopyranosyl halide obtained on halogenation must first be reacted to give the desired 2-azido-2-deoxy-β-D-glycopyranosyl halide in a controlled anomerization reaction using tetraethylammonium halide with acetonitrile as solvent[24]. This reaction can easily be followed polarimetrically and must be terminated by addition of toluene when the maximum proportion of β-halide (highest negative rotation value) has been reached, since otherwise further re-anomerization takes place. The resulting β-chloride then reacts rapidly with the alcohol component in the presence of $AgClO_4/Ag_2CO_3$ under very mild conditions in CH_2Cl_2. The α-glycosides are obtained with good selectivity and in high yields[24]. This method has proved to be of value with reactive hydroxyl components, since with these the selectivity decreases when the *in situ* anomerization method is used.

In situ anomerization is, however, the best method for moderately reactive hydroxyl groups, such as secondary hydroxyls, the same parameters applying as have already

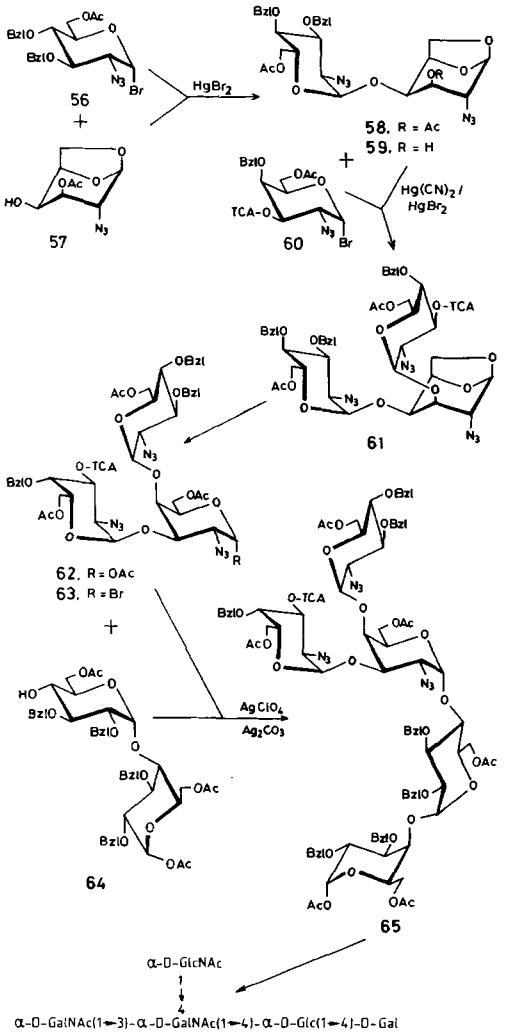


been given for normal sugars in Section 2.2.1. In this instance the reactivity is obviously governed by the nature of the substituents in the pyranosyl halide. As a rule, in comparable reactions somewhat more active catalysts are necessary with the azido sugars compared to normal sugars[21].

The synthesis of the tetrasaccharide determinant of blood-group substance A may be given as an example[21]. The 2-azidogalacto sugar **53** can react with the trisaccharide **20** in the presence of silver triflate/silver carbonate at −25 °C to give a 75% yield of the tetrasaccharide **54**. Deblocking then yields the tetrasaccharide determinant **55** of blood-group substance A. The reaction with silver triflate proceeds stereoselectively at −20 °C, but in contrast, non-

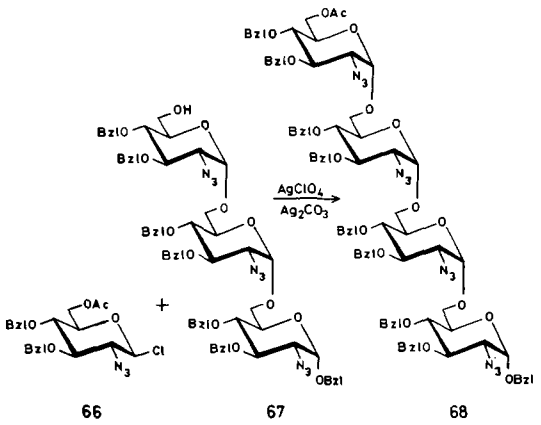
stereoselectively at room temperature, both α- and β-forms being produced. In such cases the catalyst is too active, promoting direct reaction of the α-halide, and hence the catalyst activity must be adjusted exactly.

When the azide method is used with *in situ* anomerization, block syntheses yielding larger oligosaccharide units are also possible. A very good example demonstrating the potential of the method is the synthesis of a branched pentasaccharide[68], which is the repeating unit of the O-specific chain of the lipopolysaccharide of *Shigella dysenteriae* (serotype 2).

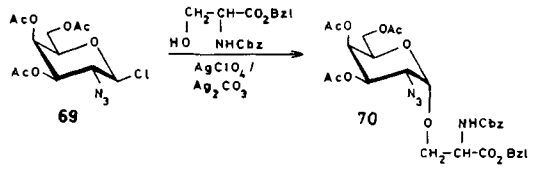


The 2-azidoglucopyranosyl bromide **56** is first coupled with the 1,6-anhydro sugar **57** in the presence of $HgBr_2$ to give the α-glycosidically linked disaccharide **58.** After conversion of **58** into **59** the 3-OH group of the latter can be α-linked with the halide of the galactose derivative **60** (TCA = trichloroacetyl); the branched trisaccharide **61** obtained is acetolyzed to **62,** which can be converted into the corresponding α-bromide **63** with $TiBr_4$[45]. A coupling reaction with the disaccharide **64** with $AgClO_4/Ag_2CO_3$ results stereoselectively in the pentasaccharide **65,** although the 4'-OH group in the disaccharide **64** has extremely low reactivity. Deblocking of **65** then yields the desired pentasaccharide.

In the case of compounds with reactive hydroxyl groups such as the 6-OH group, the OH groups of serine and threonine, and simple alcohols the selectivity decreases in the *in situ* process. The effect cannot be countered by selecting a milder catalyst, because the process of halide ion catalysis with tetraethylammonium halides cannot be used with 2-azido halides. The imidate method is also unsuitable, since the imidates of 2-azido sugars react very poorly. For this reason the β-halides obtained from the α-halides by controlled anomerization must now be used directly. In this way the α-linked tetrasaccharide **68** can be obtained from the trisaccharide **67** — obtained by successive synthesis — using the β-halide **66** and an $AgClO_4/Ag_2CO_3$ catalyst[24].



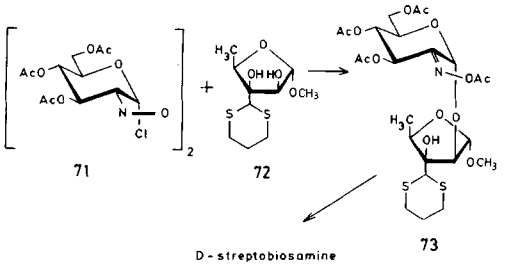
The reaction is particularly difficult with serine and threonine, and a mixture of dichloromethane and toluene must be used together with a β-halide to keep the reaction under control; toluene slows down re-anomerization of the β-chloride to the α-chloride. When a dichloromethane/toluene mixture is used with $AgClO_4/Ag_2CO_3$, the crystalline galactose derivative **69** can be converted into the α-glycoside **70** with high selectivity and in good yield[69]. A corresponding reaction can be performed with a threonine derivative. Both compounds can be converted into disaccharide amino acids by coupling to a galactose residue, these compounds representing the determinants of T-antigen[69].



The Nitroso Halide Method: A completely different method of α-glycoside synthesis has been developed by *Lemieux et al.*[70,71]. Addition of nitrosyl chloride to tri-*O*-acetylglucal produces a nitroso chloride **71** in dimeric form. This can be reacted with hydroxyl components, even those having reduced reactivity, to give α-glycosides. The resultant product is, however, a 2-oxime that, after acylation, must be reduced to an amino compound. In the *gluco*-series this reduction can be performed stereoselectively with diborane, resulting in formation of α-glycosidically linked disaccharides of the glucosamine.

The method may be illustrated using the example of the synthesis of D-streptobiosamine[72]. The nitroso component **71** reacts with the streptose derivative **72** to give, after acylation, 2-oximo-α-glycoside **73.** Reduction of the oxime

with diborane then yields the D-streptobiosamine derivative, from which the free disaccharide can be obtained by deblocking. The synthesis has been used in the same way to obtain natural L-streptobiosamine[72].



A number of modified gentamicin derivatives have also been obtained in this way[73,74]. However, at times a loss of stereoselectivity has also been observed[74,75]. α-Glycosides of galactosamine cannot be produced in this way, since 2-oximoglycosides thus obtained are preferentially reduced to talosamine glycosides.

2.2.3. β-D-Mannopyranosides and β-L-Rhamnopyranosides

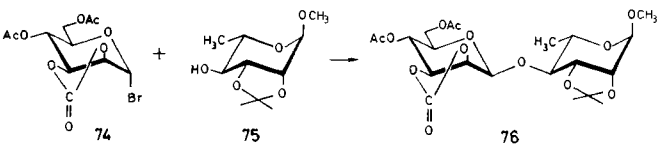
In mannose derivatives the hydroxyl group on C-2, important for guiding the glycoside synthesis, is positioned axially in contrast to the situation in glucose and galactose derivatives. The same applies to L-rhamnose. If a neighboring-group-active substituent is present at 2-OH, an acetoxonium intermediate can form from a mannopyranosyl halide as in reactions **1**→**4**, in which the configuration at C-1 and C-2 is the opposite to that in **4**. Opening this acetoxonium ring by a nucleophile at C-1 then leads to formation of α-D-mannopyranosides. This reaction proceeds well, and it is therefore relatively simple to prepare α-glycosidic linkages with D-mannose. A number of higher mannose oligosaccharides have already been synthesized in this way (Section 2.3.3).

The formation of a β-D-mannopyranosidic link, on the other hand, is the most difficult type of linkage to realize. In the presence of a neighboring-group-active substituent at C-2 only α-glycosides are obtained, but even with other substituents at C-2 formation of α-glycosides is still often the preferred reaction. The difficult problem is the conversion of a relatively stable α-halide, with inversion, into a non-stabilized β-glycoside. An *in situ* anomerization process, such as can be used very successfully in α-glycoside synthesis, is therefore impossible in this case. All the catalysts listed in Table 1 are therefore unsuitable for this glycosidation, since they would promote anomerization to the reactive β-halide, resulting in formation of the undesired α-glycoside as the main product. Therefore, under these conditions α-D-mannosides are obtained from α-D-mannopyranosyl halides without neighboring-group participation.

To avoid these difficulties, elaborate synthetic routes have been traversed[76–79]. A glycoside synthesis was performed using D-glucose with neighboring-group participation which leads relatively easily and stereoselectively to the β-glucopyranoside. The 2-OH of the *gluco*-unit was selectively deblocked, oxidized to the keto group, and then selectively reduced, whereby a β-mannopyranoside was produced. Until very recently[80] this complex route was the only way to solve such problems, particularly that of formation of the β-D-Man(1→4)-β-D-GlcNAc linkage, which occurs in many glycoproteins[78,79].

Only an insoluble silver catalyst should promote the reaction of the α-halide to the β-glycoside, since when the reaction is carried out heterogeneously, anomerization to the reactive β-halide is severely restricted and reaction of the α-halide with inversion takes precedence. However, a halide with the greatest possible reactivity and a hydroxyl group of sufficient reactivity should be chosen, so that selectivity can be retained. With unreactive hydroxyl groups the proportion of α-glycoside increases, and can even become the main product. This constitutes a fundamental limitation of the method and block syntheses would hardly be possible. Silver oxide and the more reactive silver silicate, which is precipitated onto a carrier such as alumina, are considered to be the best catalysts[81].

Reactions with insoluble silver catalysts: The D-mannose derivative **74**[82], reacts with the rhamnose derivative **75** in the presence of silver oxide and a molecular sieve of 4 Å to the β-linked disaccharide **76** in good yield (up to 91%)[82–84]. However, it should be borne in mind that the reactivity of the 4-OH group of the rhamnose derivative **75** is comparable to that of a primary hydroxyl group. When other secondary hydroxyl groups of moderate reactivity are used, the yield on reaction with **74** is considerably smaller[85,86]. As shown in Table 1, the bromide **74** with its numerous acyl substituents is stable and not very reactive, and is thus not universally useful.

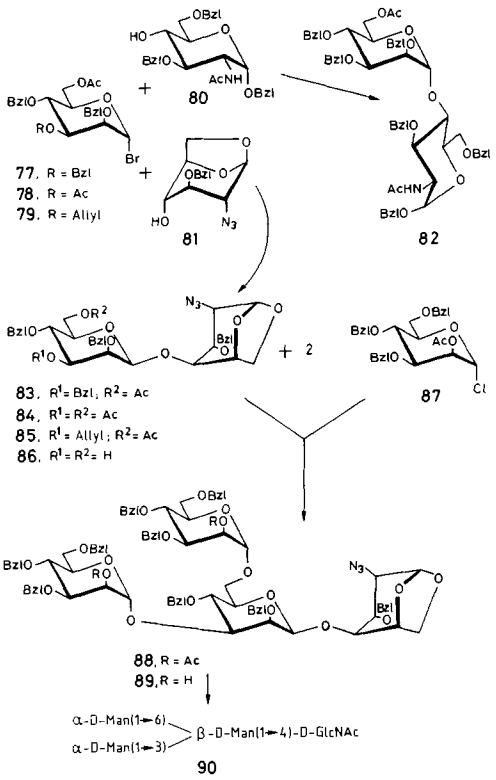


The benzylated compound **77** is much more reactive and reacts with 3-*O*-acetyl-1,6-anhydro-2-*O*-benzyl-D-galactopyranose in dichloromethane, using a reactive silver silicate catalyst, to give the corresponding β-glycosidically linked disaccharide in 70% yield[80].

Reaction of the reactive halide **77** with the glucosamine derivative **80**, present in the $^4C_1$ conformation[*], in the presence of a silver silicate catalyst results in formation of the undesired α-glycosidically linked product **82** in 75% yield. The 4-OH group in **80** is known to have low reactivity, and this has the effect of severely reducing selectivity in the direction of the β-product.

On the other hand, reaction of **77** with the glucosamine derivative **81**, present in the $^1C_4$ conformation, under the same conditions produces the desired β-glycosidically linked disaccharide **83** in up to 60% yield[80]. The α:β ratio is 1:6. If the less reactive halide **78**, which contains two acetyl groups, is allowed to react with the same hydroxyl

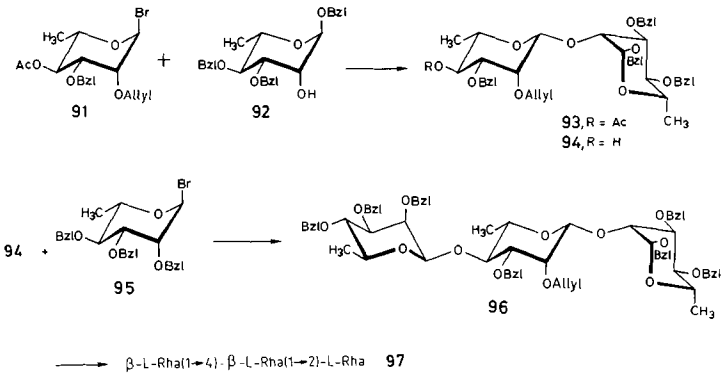
[*] In the $^4C_1$ conformation C-1 is directed below, and C-4 above a plane through atoms C-2, C-3, C-5, O-5 of the chair conformation. In the inverse $^1C_4$ conformation, C-1 is above and C-4 below the same plane. Cf. R. E. Reeves, *Adv. Carbohydr. Chem.* 6 (1951) 107.



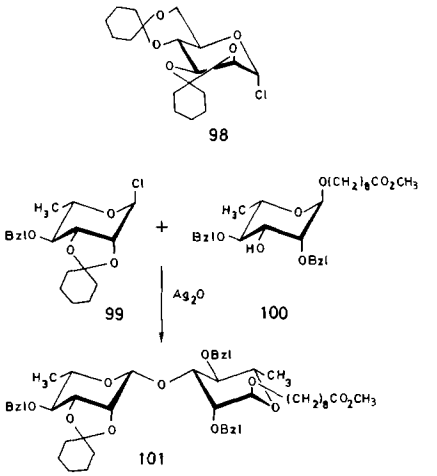
component **81**, only 40% of β-glycoside **84** can be isolated, since the α:β ratio is now only 1:1. This lower reactivity of the halide component is already manifested in a reduction of the selectivity. This demonstrates the importance of the halide reactivity.

Allyl substituents behave similarly to benzyl substituents, since **79** likewise reacts with **81** to give the β-glycoside **85** in 60% yield, corresponding to an α:β ratio of 1:6. Partial deblocking of **85** gives the disaccharide **86**, which under the conditions of α-glycoside synthesis can be coupled in the presence of silver triflate with two mannose residues **87** to give tetrasaccharide **88** in 80% yield[80]. The tetrasaccharide **90**, obtained after deblocking, is the most important key structural element of the carbohydrate chains of glycoproteins and occurs in virtually all glycoproteins with a saccharide-asparagine linkage as branching element; the above method was the first to make it directly accessible synthetically[80].

The behavior of L-rhamnose derivatives is similar to that of D-mannose derivatives. Because of the 6-deoxy group the halides are slightly more reactive, hence further promoting the selectivity of the reaction, but they are more difficult to handle. Many β-glycosidically coupled disaccharides have been produced with the benzylated α-L-rhamnopyranosyl bromides[87,88]. The synthesis of a trisaccharide with two β-glycoside linkages may be given as an example[88]. The bromide **91** is sufficiently reactive to react selectively with the rhamnose derivative **92** unsubstituted at the 2-OH group. In the presence of silver silicate only the β-glycosidically linked disaccharide **93** is obtained, in 70% yield. After conversion of **93** into **94** this reacts further with the bromide **95** at 4'-OH, to give the trisaccharide **96**, with exclusive formation of the β-glycoside in 70% yield. The deblocked trisaccharide **97** is a component of the repeating unit of the lipopolysaccharide of *Shigella flexneri* serotype 6[88].



The D-mannose and L-rhamnose derivatives **98** and **99** have also been proposed for β-glycoside synthesis[89,90]. The spiroketal grouping likewise endows the compounds with good reactivity, so that in this respect they are comparable with the benzyl compounds. The mannose derivative **98** reacts with sugars having primary 6-OH groups and a 4-OH group, known to be equally reactive, to give a good yield (*ca.* 80%) of β-glycosidically linked compounds[89]. However, with less reactive secondary hydroxyls the selectivity decreases, with the result that equal proportions of the α- and β-forms are usually produced. The rhamnose derivative **99**, like the bromide **91**, is somewhat better in relation to its reactivity. Approximately equal proportions of β-glycoside are obtained with both compounds. Coupling **99** with the spacer-containing *rhamno*-derivative **100** gives, *e.g.* in the presence of silver oxide, the β-linked disaccharide **101** in 62% yield[90]. A β-glycoside synthesis with 1-*O*-tosylates of D-mannose has so far only been possible with compounds having the primary 6-OH group[91].



2.3. Formation of 1,2-*trans*-Glycopyranoside Bonds

2.3.1. β-Glycopyranosides of the *gluco*- and *galacto*-Series

This type of reaction represents the oldest type of Koenig-Knorr synthesis[92]. Here, use is made of an α-D-glycopyranosyl halide with a neighboring-group-active substituent, such as acetyl or benzoyl, at 2-OH. In the presence of an insoluble silver catalyst the reaction should assume a

stronger S_N2 character and thus proceed largely with inversion.

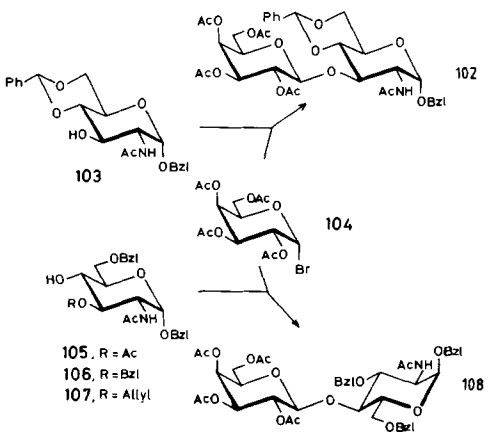
Presumably with soluble silver and mercury catalysts the oxocarbenium ion **3** is formed first, and this then reverts to the more stable cyclic acetoxonium ion **4.** Nucleophilic opening of the ring at C-1 can then only take place as a *trans*-cleavage, the acetoxonium intermediate guiding the reaction in the direction of β-glycoside **5.** Express reference should be made to the fact that the cation **4** is not present in the free form but presumably as an intimate ion-pair. The solvate-separated cation **4** undergoes a sequence of acetoxonium rearrangements with inversion at three C atoms, resulting in the *ido*-configuration[93,94]. Rearrangement products of this type have never been observed in glycoside syntheses proceeding *via* cation **4.**

The starting materials for the β-glycoside synthesis, the α-glycosyl halide or the stabilized acetoxonium ion **4,** are less reactive than the highly reactive β-glycosyl halide, the starting product for α-glycoside synthesis (Section 2.2.1). This can lead to certain difficulties in applying the method to block syntheses.

In principle, it is also possible to form a β-glycosidic link without neighboring-group participation of the substituent at C-2. Surface-active, insoluble catalysts such as silver silicate would have to be used, so that the reaction would proceed cargely by an S_N2 mechanism. The conditions would be similar to those described for the preparation of β-D-mannopyranosides. Because of the difficulties and limitations mentioned in Section 2.2.3, reactions of this kind have not been so thoroughly investigated.

Reactions with Silver or Mercury Catalysts: Insoluble silver catalysts such as Ag_2O and Ag_2CO_3, with which an S_N2-like mechanism is followed, have the disadvantage that water is formed in the course of the reaction, making it necessary to add drying agents such as Drierite. In oligosaccharide syntheses the yields are relatively low, a fact that renders this method rather less suitable.

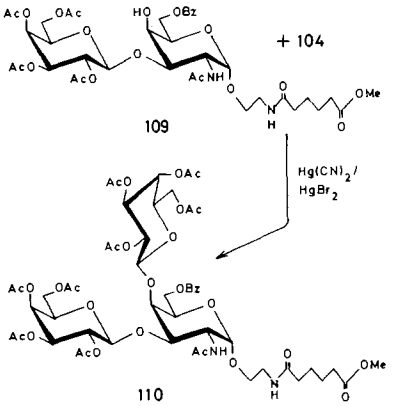
The Helferich catalyst $Hg(CN)_2$ has proved to be very effective[95]. The hydrogen cyanide produced during the reaction is able to escape or does not interfere with the main process, the formation of 1-cyano compounds as by-products being observed only in isolated cases. Since the reaction may proceed *via* an acetoxonium ion **4,** it is best to use a solvent of moderate polarity, such as a mixture of benzene and nitromethane, to facilitate ionization to **4.** It is also recommended that benzene be replaced by the less



toxic toluene. Reactions carried out in toluene/nitromethane mixtures proceed in exactly the same way. If excessively polar solvents are used, the halide easily decomposes. Solvents of low polarity such as dichloromethane are also highly suitable. The solvent ratio is a critical factor that can, in particular, influence selectivity and yield, and must be carefully optimized in each case. With slightly reactive OH groups, considerable proportions of α-glycoside can be formed, presumably because the ion **3** undergoes further, nonspecific reactions. $Hg(CN)_2$ can be activated by addition of $HgBr_2$. In this instance too the ratio of the two catalysts should be carefully adjusted.

A good example of an $Hg(CN)_2$-catalyzed process is the reaction of galactosyl bromide **104** with the glucosamine derivative **103** to give the disaccharide **102,** which in benzene/nitromethane (1 : 1) at 60 °C is obtained in 80% yield[96,97].

The 4-OH group in the glucosamine derivatives **105–107** is substantially less reactive than the 3-OH group in **103.** The importance of the type of substitution in the hydroxyl component is well demonstrated in compounds **105–107**[23]. On the whole, alkyl-substituted compounds (cf. Table 1) should be reactive. Compound **105,** substituted at 3-OH with an acetyl residue, can be converted into a disaccharide with the halide **104** but the yield is very low. The derivatives with *O*-benzyl or *O*-allyl substituents, **106** or **107,** on the other hand, give good results when used in the disaccharide synthesis with **104**[23]. The disaccharide **108** can be obtained from **104** and **106** in the presence of $Hg(CN)_2$ in benzene/nitromethane, although the reaction takes longer than that leading to **102**[21,98]. Using a different technique, the reaction is also possible in dichloromethane in the presence of $HgBr_2$ and powdered molecular sieve 4 Å, the yield then exceeding 70%[50]; the quality of the molecular sieve plays an important part. The disaccharides **102** and **108** are constituents of determinants of blood-group substances.



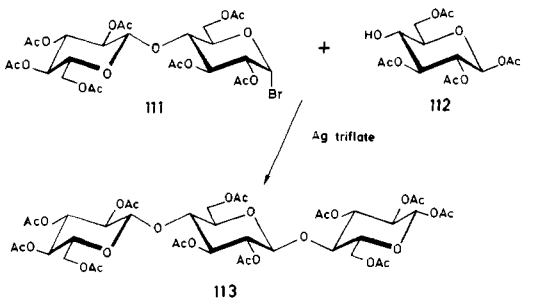
The disaccharide **109** which contains a galactosamine moiety with a spacer unit can be obtained in good yield by appropriate coupling with $Hg(CN)_2$ and addition of $HgBr_2$[99]. A further galactose residue can be coupled to **109** at the less reactive 4-OH group under the same conditions to give the branched trisaccharide **110**[99,100]. The order in which the two galactose residues are added to the galactosamine derivative is important. The disubstituted product **110** is obtained in high yield if the first galacto re-

sidue is coupled at 3-OH and the second at 4-OH. The saccharides **109** and **110** are components of the T-antigen. They can be coupled to proteins *via* the spacer, which allows the preparation of synthetic antigens[100].

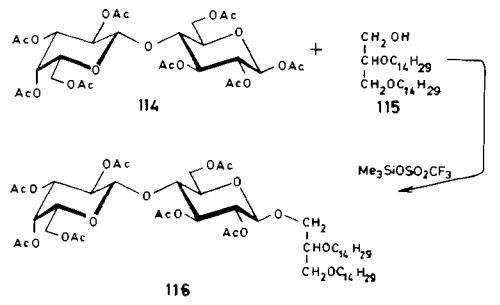
A block synthesis (CH_2Cl_2, $Hg(CN)_2$) has been reported in which the halide of β-D-Gal(1→4)-D-Gal reacts with 3-*O*-acetyl-1,6-anhydro-2-*O*-benzyl-D-glucopyranose[101]. However, during this reaction acyl migration of 3-OAc to 4-OH sometimes occurs, so that a mixture of the desired β(1→4)-coupled product and the undesired β(1→3) product is obtained.

Another reagent highly suitable for use as a promoter in β-glycoside synthesis is silver triflate[102]. The reaction is carried out in dichloromethane at low temperatures (−30 to 0 °C) using equimolar quantities. It is advantageous to add tetramethyl urea or, less advantageously, s-collidine, as acid scavenger. A disaccharide corresponding to **102**[102], or a disaccharide which contains the β(1→4) link as in **110**[103] can be similarly successfully prepared in this way.

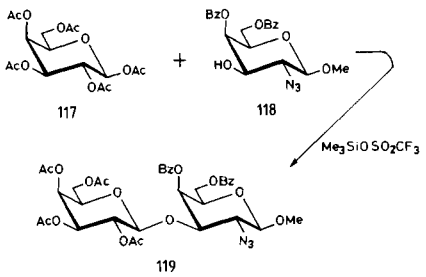
The effectiveness of the silver triflate method is evident in the syntheses of cellotriose derivatives. The very weakly reactive 4'-OH group in an acetylated cellobiose derivative reacts with acetobromoglucose in the presence of silver triflate to form the cellotriose derivative in 53% yield[104]. A block synthesis has also been successfully carried out. The cellobiose bromide **111** could be made to react with the difficultly reactive 4-OH group of the glucose derivative **112.** In the presence of silver triflate 39% of the cellotriose **113** was obtained in 1 h at −30 °C.



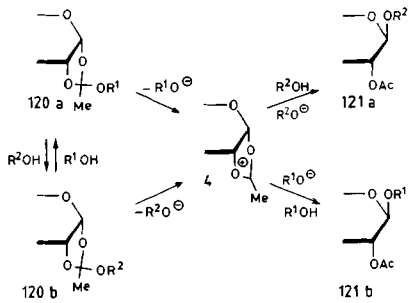
Trimethylsilyl triflate has recently been proposed as a coupling agent for β-glycoside synthesis. In this reaction it is unnecessary to use the halide, and instead the β-1-*O*-acetate itself can be used. Thus, the lactose derivative **114**



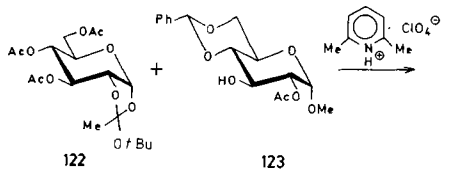
reacted with the glycerol derivative **115** in the presence of trimethylsilyl triflate and molecular sieve 4 Å (20°, 2 h) to give the glycoside **116** in 70% yield[105a]. In the meantime we have extended this technique to reactions with secondary hydroxyl groups[105b]. Penta-*O*-acetyl-β-D-galactopyranose **117** reacts with **118** in the presence of trimethylsilyl triflate to give a 70% yield of the disaccharide **118.** The 3-OH group in **119** has an extremely low reactivity, and a coupling reaction in the presence of $Hg(CN)_2$ or $Hg(CN)_2$/HgBr could only be performed in moderate yield with inadequate selectivity. It is possible that earlier described galactosylation reactions may also be satisfactorily performed by this new procedure.



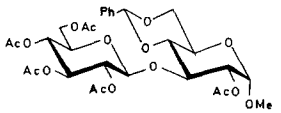
The Ortho-Ester Method: The cyclic acetoxonium ion **4** occurring as an intermediate during β-glycoside synthesis need not necessarily be derived from pyranosyl halides: it can be produced from ortho-esters by abstraction of an alkoxide anion, *e.g.* with $HgBr_2$. **4** reacts with the hydroxyl component *via trans*-opening to give the β-glycoside.



According to *Kochetkov et al.*[12, 106], two complications arise with the ortho-ester method. The alcohol R^1OH, formed in the cleavage reaction of ortho-ester **120a** to give the ion **4,** competes with the reacting alcohol component R^2OH, and two glycosides **121a** and **121b** can therefore be produced if the R^1OH is not removed from the equilibrium, *e.g.* by distillation. In addition, a transesterification of the ortho-ester **120a** with the alcohol component R^2OH can occur to give the ortho-ester **120b.** However, this can also be converted into the glycoside **121b** *via* the cation **4.** To avoid these difficulties, a *tert*-butyl ortho-ester has proved to be the best starting material, and 2,6-dimethylpyridinium perchlorate the best catalyst. Possible solvents are dichloromethane or, at higher temperatures, chlorobenzene. In this way **122** and **123** can be converted into the disaccharide **124** in about 50% yield[107]. A large number of ortho-esters have been prepared and reacted[106]. Polysaccharides with about 10—30 saccharide units can also be made in this way using compounds containing an ortho-ester and a hydroxyl group in the same molecule[12, 106].

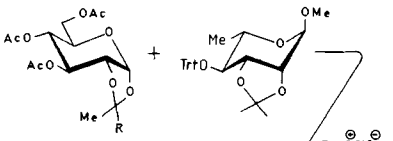


122 123



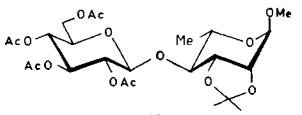
124

Nevertheless, the ortho-ester method is critical with weakly reactive hydroxyl groups. This is shown by the preparation of the lactosamine derivative **108**[108]. The ortho-ester method, in which a *tert*-butyl ortho-ester activated by benzyl-group substitution is actually used, yields 52% of β-glycoside **108**, 12% of the α-glycoside is also formed. With $Hg(CN)_2$ or $HgBr_2$ a 70—80% yield of β-glycoside **108** is obtained[21, 50].



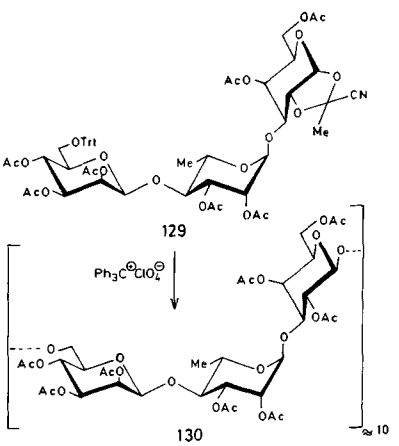
125, R = CN
126, R = p-MeC$_6$H$_4$S

127



128

The ortho-ester method can be modified using the 1,2-cyano compound **125**[109, 110] or the thio-ortho-ester **126**[111]. The alcohol component must, however, be used as a trityl ether. The Meerwein reagent triphenylcarbenium perchlorate serves as a catalyst. The triphenylcarbenium ion cleaves off the nitrile group from **125** and the thiol group from **126**, in both cases with formation of the cyclic acetoxonium ion **4**. The latter then reacts irreversibly with the trityl ether **127** to form the β-glycoside **128** and a tritylcarbenium ion, which is subsequently regenerated. In this way only catalytic quantities of triphenylcarbenium ion are necessary, and no perchloric acid is formed[110, 111]. By means of this method **125** can be converted into the disaccharide **128**, however, the 4-OH group of the rhamnose is so reactive that **128** can also be obtained by many simpler methods. By using the modified orthoester process, the rhamnose and galactose derivatives can also be coupled *via* the 2-OH and 3-OH groups, respectively[110]. On the other hand, the reaction with weakly active 4-OH groups does not proceed to completion. Compared to other direct methods, it should be noted that the derivatives **125** and **126** must be made from pyranosyl halides and the production of the trityl ether—often a difficult process—requires an additional step.



129

130

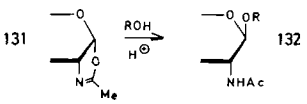
The modified ortho-ester method is primarily of interest for polysaccharide synthesis[112]. Trisaccharide **129** reacts with triphenylcarbenium perchlorate to give polymer **130** containing about ten trisaccharide units per molecule. The trisaccharide β-D-Man(1→4)-α-D-Rham(1→3)-β-D-Gal contained in **130** is the repeating unit of the O-antigenic lipopolysaccharide of *Salmonella newington*.

2.3.2. 2-Amino-2-deoxy-β-D-glycopyranosides of the D-*gluco*- and D-*galacto*-Series

In the case of the 2-amino sugars the substituent at C-2 is likewise of decisive importance for the course of the glycoside synthesis. The acetylated pyranosyl bromide of a 2-acetamido sugar is extremely labile and *via* neighboring-group participation can be converted into a 1,3-oxazoline **131**[113]. In contrast to the acetoxonium intermediate produced with normal sugars, the more stable oxazolines can be isolated. The acetylated pyranosyl chloride of a 2-acetamido sugar is considerably more stable, and with it β-glycoside syntheses can be carried out on reactive 6-OH groups in the presence of $Hg(CN)_2$[114].

If a non-neighboring-group active substituent is present at C-2, as in the acetylated pyranosyl halides of dichloroacetamido- and 2,4-dinitrophenylamino sugars, β-glycoside links can also be formed with compounds having 6-OH groups[115, 116]. However, the yield and the selectivity fall off drastically if derivatives with secondary hydroxyl groups are used for the glycoside synthesis[117]. It is therefore recommended to use the tried and tested methods described in the next section.

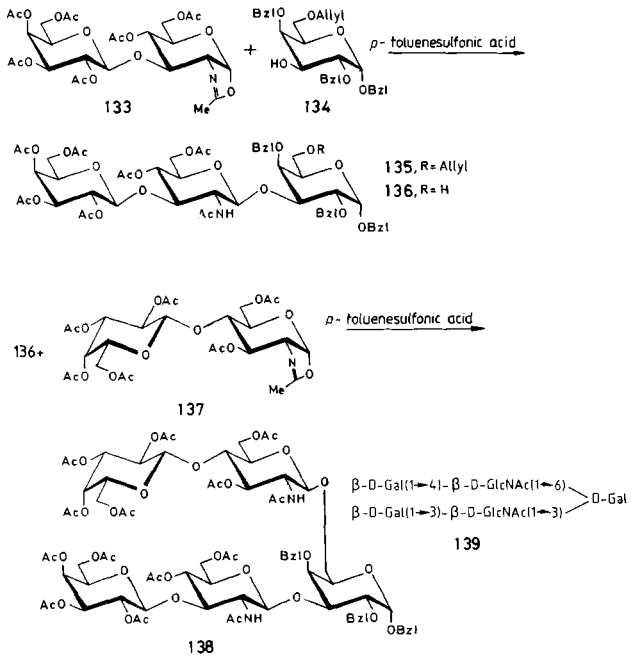
The Oxazoline Method: The oxazolines **131**, accessible from the pyranosyl halides, can be attacked by hydroxyl components at C-1, similarly to the acetoxonium intermediate **4**, whereby β-glycosides **132** are formed stereoselectively. The reaction is carried out in nitromethane/benzene and sometimes in dichloromethane using *p*-toluenesulfonic acid as catalyst[118].



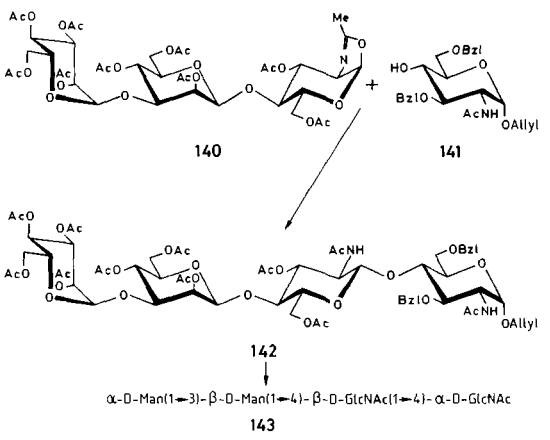
131 132

Newer methods have since been described for the production of oxazolines. Thus, β-1-*O*-acetates can be converted into oxazolines with $FeCl_3$[119], and propenyl glycosides, obtainable by rearrangement from allyl glycosides, are similarly converted using $HgCl_2$[120, 121]; oxazolines are, therefore, readily accessible. A large number of disaccharides has been prepared by the oxazoline method[118]. Very good yields are obtained with 6-OH groups[122, 123], and

even with secondary hydroxyls the yields are still satisfactory[123, 124]. Weakly reactive 4-OH groups can also be reacted. Thus, a chitobiose derivative has been synthesized in 43% yield[125].



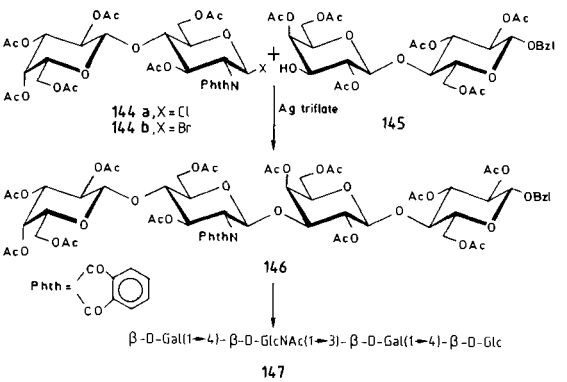
Block syntheses are advantageously carried out by the oxazoline method, *e.g.* with the oxazoline of the lactosamine **137** and the corresponding β(1→3)-linked disaccharide **133**[126]. The oxazoline **133** can be linked to the 3-OH of the galactose derivative **134** by heating in nitromethane/benzene in the presence of catalytic quantities of *p*-toluenesulfonic acid to give the trisaccharide **135.** After deblocking to give **136,** the oxazoline **137** can be linked to the trisaccharide **136,** resulting in the branched pentasaccharide **138**[126]. The yields lie between 50 and 70%. The oligosaccharide **139** obtained from **138** includes structures that occur in the blood-group substances Ii. Coupling with the oxazoline **133** is not without its problems; for example, the 3-OH group in mannose reacts only with difficulty[127].



In the meantime a trisaccharide-oxazoline **140** has been synthesized. Coupling **140** with the 4-OH group of **141** in dichloromethane gave the tetrasaccharide **142** in 22% yield[128]. This is a remarkable result, since the 4-OH group of glucosamine is known to be extremely weakly reactive. The tetrasaccharide **143** constitutes the saccharide chain by which asparagine-linked glycoproteins are connected to the peptide residue.

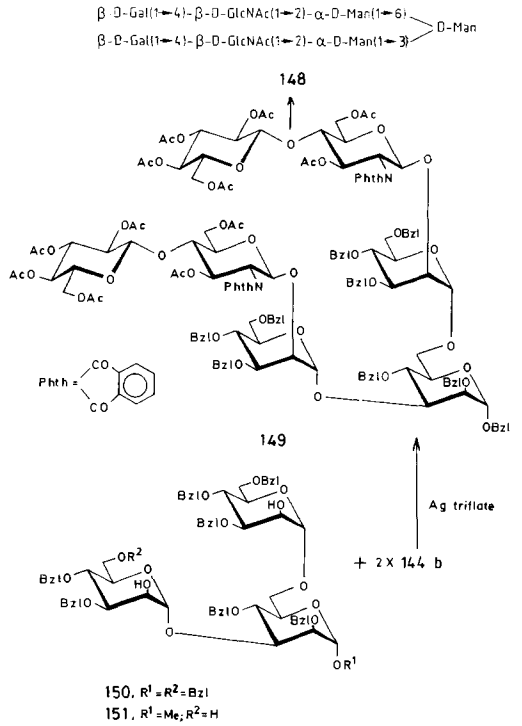
The Phthalimide Method: In addition to the oxazoline method, the phthalimide method has proved to be an effective method for β-glycoside synthesis from 2-amino sugars. A phthalimido group at C-2 is sterically demanding and favors the β-form. It is attributed neighboring-group activity in glycoside synthesis, which causes the reaction to be guided in the direction of the β-glycoside[129]. The reaction is performed at −50 to −20 °C in dichloromethane using silver triflate in the presence of s-collidine as catalyst. The phthalimido residue is cleaved off by hydrazine at higher temperatures during deblocking of the resultant oligosaccharide, a treatment not entirely free from problems if the oligosaccharide is sensitive to alkali.

A number of disaccharides have been synthesized by this method[129]. 3,4,6-Tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide can be linked to the 2-OH group of rhamnose or rhamnose trisaccharides in 70% yield[130, 131]. The phthalimide of the glucosaminyl chloride has been coupled to the extremely weakly reactive 4-OH of muramic acid to give muramic acid disaccharides in 38% yield[132].



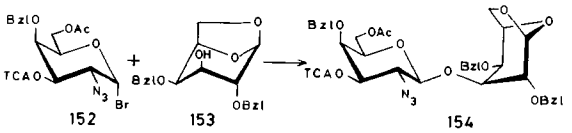
The phthalimide method is evidently also well suited for block syntheses[133]. The phthalimide of the lactosamine **144a** can be linked to the 3-OH group of the lactose derivative **145,** to give the tetrasaccharide **146** in 83% yield. This tetrasaccharide is the carbohydrate chain **147** of the paragloboside of a glycolipid. A similar reaction has also been performed using the oxazoline method[134] giving **146** in 79% yield, so that the phthalimide process can be regarded as somewhat more effective. Coupling to the weakly reactive 4-OH group in lactose has not yet been reported; this is an unsolved problem which is of importance with respect to the formation of biologically relevant oligosaccharides.

A block synthesis with the lactosamine derivative pyranosyl bromide **144b** could be used to synthesize larger oligosaccharide units. The mannose trisaccharide **150** reacts with **144b** (molar ratio 1:2) in the presence of silver triflate, whereby the branched heptasaccharide **149,** a key structure in the carbohydrate part of glycoproteins, is obtained. It contains a branched mannose trisaccharide unit carrying two lactosamine "antennas". This is a remarkable



result. Further syntheses of biologically interesting oligosaccharides can undoubtedly be expected in this sector.

Other Methods: 2-Azidopyranosyl halides, if they are sufficiently reactive, can also be converted into β-glycosides. The active silver silicate catalyst must be used so that the reaction proceeds in the heterogeneous phase. The conditions correspond to those in the β-glycoside synthesis of mannose derivatives (cf. Section 2.2.3). The azido sugar **152** has been coupled with the galactose derivative **153** in dichloromethane at $-20\,^{\circ}C$ to give the disaccharide **154** in 73% yield[46,47]. The disaccharide **154** is an important constituent in the synthesis of the tetrasaccharide chain of globoside (P-antigen)[47].

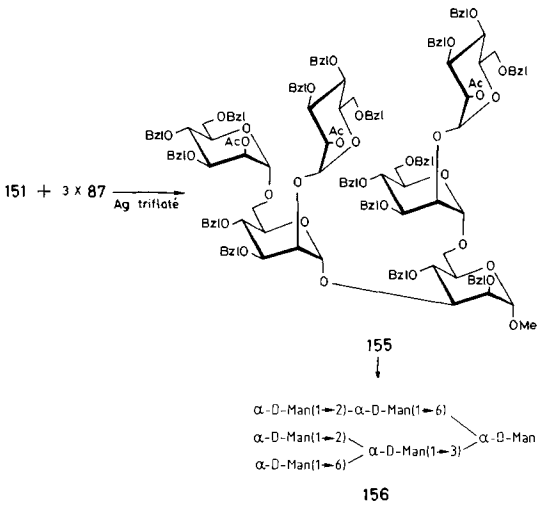


A new disaccharide synthesis, starting from β-1-*O*-acetyl derivatives of 2-acetamido sugars, has recently been reported[136]. 2-Acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-β-D-glucopyranose and 1.5 moles of $FeCl_3$ in dichloromethane, in the presence of tetramethylurea react with various saccharides containing free hydroxyl groups to give disaccharides. In the reaction with 6-OH the yield of β-linked disaccharide is about 80%; with 3-OH and 4-OH the yields are, respectively, *ca.* 60 and 40%. The reaction may proceed *via* an oxazoline-like intermediate. It is certainly worth looking into the possibilities of extending this method.

2.3.3. α-D-Mannopyranosides and α-L-Rhamnopyranosides

Similar prerequisites apply to α-glycoside synthesis in the D-*manno*- and the L-*rhamno*-series as to the β-glycoside synthesis in the *gluco*- and *galacto*-series; only the configuration at C-2 is inverted. In glycoside synthesis supported by neighboring-group participation, an inverted acetoxonium ion similar to **4** is formed, which in this case leads selectively to the α-glycoside as a result of *trans*-opening of the ring. Accordingly, the methods are similar to those used for the β-glycoside synthesis of D-glucose and D-galactose. The D-mannose and L-rhamnose halides are highly reactive, and α-glycosidic saccharide links can therefore be readily prepared. Considerable advances have been made in this field in the synthesis of larger oligosaccharide units.

Reactions with Mercury and Silver Catalysts: In addition to $Hg(CN)_2$[137], mixtures of $Hg(CN)_2/HgBr_2$ in the ratio of 1 : 1 have proved to be suitable catalysts favoring coupling reactions[138]. Using these mixtures the trisaccharide **150,** consisting of three mannose residues, can be prepared in *ca.* 50% yield by reacting a D-mannose derivative unsubstituted at 6-OH and 3-OH with 2-*O*-acetyl-3,4,6-tri-*O*-benzyl-D-mannopyranosyl chloride in toluene/nitromethane[138]. A similar reaction proceeds more advantageously with silver triflate in the presence of tetramethylurea in dichloromethane and an excess of the mannopyranosyl halide. In this reaction the tetrasaccharide **88** is obtained in 80% yield from the disaccharide **86** by attaching two mannose residues[80]. This is the branched key unit of a large number of glycoproteins.

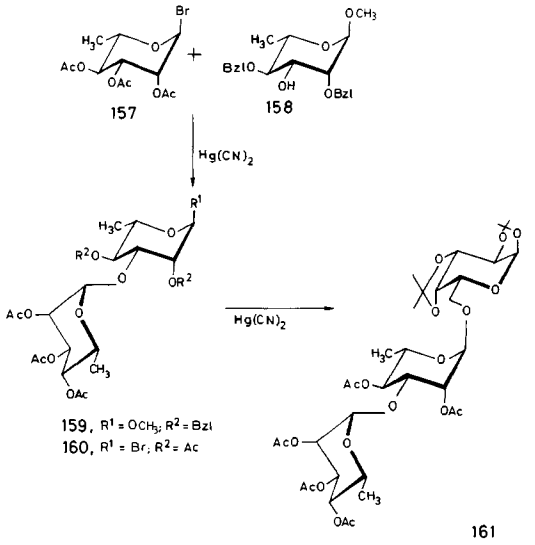


The silver triflate method has proved very effective in connecting several mannose residues. Three further mannose residues can be connected to the mannose trisaccharide **151** *via* three free hydroxyl groups in a single step to give the hexasaccharide **155** in 60% yield[139]. The free hexasaccharide **156** is an important constituent unit of glycoproteins containing mannose chains.

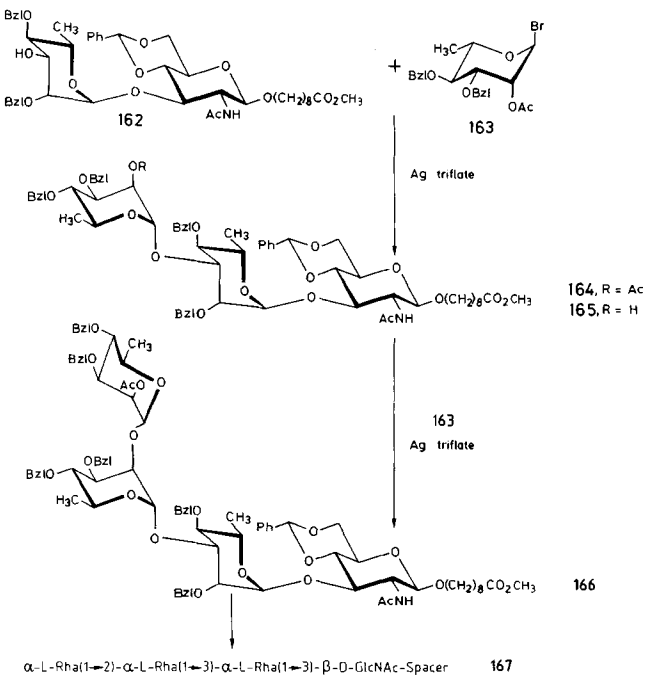
This procedure of simultaneously attaching several mannose residues has also been applied, with astonishing success, to the synthesis of further mannose-containing oligosaccharides. A hexasaccharide slightly modified relative to **155,** consisting of six mannose residues[140], and a number of related pentasaccharides[141,142] have already been synthesized.

The α-glycosidically linked oligosaccharides of L-rhamnose are of considerable interest because they occur rela-

tively widely in the repeating units of a very wide range of lipopolysaccharides. Reactions of the halides with hydroxyl components give the corresponding disaccharides in very good yields using $Hg(CN)_2$ in benzene/nitromethane. In this way the L-rhamnose disaccharides with a 1,2-linkage can be obtained in 95% yield, those with a 1,3-linkage in 78% yield, and those with a 1,4-linkage in 67% yield[143-145]. Block syntheses with rhamnose disaccharides have also been carried out. The 1,3-linked rhamnose disaccharide **159**, obtained by reaction of the halide **157** with **158**, has been converted into the halide **160** and then coupled with the 6-OH of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose to give the trisaccharide **161**[146]. Other examples are also known[147].



Among the oligosaccharide units in lipopolysaccharides those of *Shigella flexneri* have, in particular, been synthesized. The silver triflate method proved highly successful in this instance. The disaccharide **162** from D-glucosamine and L-rhamnose can be coupled at 3'-OH by reaction with the halide **163**, resulting in the trisaccharide **164** in 61% yield. After conversion of **164** into **165** a further L-rhamnose unit can be coupled to give the tetrasaccharide **166** in 70% yield. Other oligosaccharides, containing sequences from the chain **167** or shifted sequences, have likewise been synthesized[149-151].



The glucosamine unit of the tetrasaccharide **167** carries a spacer, which permits coupling to a protein. In this way a synthetic antigen, which contains the tetrasaccharide unit **167** as an immunological determinant, is obtained. Using this antigen, antibodies can be produced in experimental animals. These antibodies produced are directed against bacteria containing the tetrasaccharide unit **167** as a repeating unit in the immunodominant O-specific side chains of their lipopolysaccharides. They would be suitable for therapeutic or diagnostic purposes.

3. Future Prospects

The examples selected were intended to demonstrate the progress that has been made in the field of oligosaccharide synthesis, and to show how important it is to synthesize biochemically interesting, selectively linked oligosaccharide sequences.

There is no doubt that this area of carbohydrate chemistry will increase in significance in the coming years, and in so doing will expand further. Henceforth, the novel synthetic methods should be used to prepare larger oligosaccharide units; thereby, prefabricated synthetic blocks, *e.g.* disaccharide units, will presumably be used in future to a greater extent. Investigations may help to provide further information on the many functions of glycoconjugates, in particular the glycolipids and glycoproteins.

The interactions of the oligosaccharide determinants, *e.g.* in antigen-antibody reactions and receptor effects, may prove to be of particular interest. Empirical and semiempirical calculations have already given some very good indications of the preferred oligosaccharide conformations, and using high-field NMR spectroscopy it has been possible to make statements on conformations of oligosaccharides in solution. Both methods indicate that oligosaccharides do not exhibit great flexibility, and that to a large extent specific conformations are preferred by molecular interactions[152]. Information thus obtained on the topology of determinants, makes it possible to investigate which regions are bound to protein molecules. According to present findings and considerations, the bond may arise not so much from hydrogen bonds as from hydrophobic interactions[152, 153]. Hydrophobic parts of the protein are thus thought to be bound by hydrophobized parts of oligosaccharides. In the complex it is thought that after water has been removed the hydroxyl groups of the oligosaccharide are bound by intramolecular hydrogen bonds in such a way that a hydrophobic face of the oligosaccharide capable of forming a bond is formed. These problems will obviously be the subject of further stimulating work.

A considerable portion of this review is based on results obtained by my colleagues. I should like to thank the team who

worked jointly on the "Oligosaccharide Synthesis" project with Elan for their unremitting efforts and their determination and staying power in the solution of this very difficult problem. Thanks are due particularly to M. Armbrust, A. Bünsch, H. Bünsch, J. P. Hölck, Č. Kolář, W. Kutschker, R. Lebuhn, O. Lockhoff, H. Nürnberger, M. Paal, D. Schnell, and W. Stenzel.

Single-Phase Polymer Alloys of Polyvinyl Chloride and New Polymers

By Dietrich Hardt (deceased), Carlhans Süling*, Christian Lindner, and Leo Morbitzer

Dedicated to Prof. Herbert Grünewald on the occasion of his 60th birthday

Polymer alloying is acquiring ever increasing significance for the modification of polymeric materials. Polymer alloys are defined by their phase character, which in turn is determined by the mutual compatibility or incompatibility of the components. Suitable techniques for the analysis of the phase character include, *inter alia*, dynamic-mechanical methods, according to which a polymer alloy may be considered in a simplified manner as single-phase when only *one* glass transition is observed, even if it extends over a broader temperature range than in the case of the pure components. Aliphatic (polyester)-polycarbonates and tetramethylbisphenol-A polycarbonate are new, PVC-compatible, polymer modifiers. The (polyester)-polycarbonates (from adipic acid, hexane-1,6-diol, neopentanediol, and diphenyl carbonate) yield with PVC single-phase alloys that at temperatures above the glass transitions of the mixture display the characteristics of soft PVC and that are tough far below this temperature. The special high-temperature properties of the resin-like tetramethylbisphenol-A polycarbonate permits the preparation of alloys with increased dimensional stability under heat (higher deflection temperatures under load).

1. Introduction

Single-phase polymer alloys are mixtures of structurally different but mutually compatible polymers. In ideal mixtures of this kind there should be no abrupt change in any physical characteristic along any one spatial coordinate. No structural parameter (*e.g.* density, average molecular weights, impurities, chemical composition) is appreciably dependent upon local variation; however, the usual fluctuations in the structural parameters of the components are also present in the mixture.

The forerunners of the single-phase polymer alloys of today were single-phase mixtures made from a polymer and a low-molecular compound. The first examples of technical significance contained cellulose esters as the polymer component. The plasticization of nitrocellulose[1] with camphor (1870) initiated much extensive research and development work on the synthesis, structure, and application of single-phase polymer mixtures.

Plasticization with low-molecular compounds constituted an important stage in the development of thermoplastic processing of polyvinyl chloride (PVC) on an industrial scale. However, the many advantageous properties of PVC as a material can only be utilized when its limited thermal stability is increased by polymer-specific stabilizer systems[2] and when the difficulties of processing ensuing from its rheological properties[4,5,33] are overcome by the use of processing aids[6].

2. Scientific and Technical State of the Art of PVC Modification

It has been known since 1933[3] that PVC can be mixed with compounds such as di(*o*-nitrophenyl) ether, dibutyl phthalate, or tricresyl phosphate to give single-phase products (soft PVC types). Many other suitable low-molecular and high-molecular compounds have since been found. The addition of a plasticizer, *i.e.* a plasticizing modifier, generally causes a reduction in the elasticity modulus of amorphous polymers. Since the glass transition temperature of the polymer is lowered by the added component, thermoplastic processing of the mixtures becomes possible at lower temperatures.

While major efforts have primarily been aimed at practicable plasticizing modifiers, in recent years modifiers capable of extending the range of application of PVC to temperatures greater than 70 °C have aroused considerable interest in the industrial sector.

Unmodified PVC has a heat deflection temperature of up to 75—80 °C (Vicat B), a notch impact strength of 2 kJ/m^2 (at room temperature), and a Shore-D-hardness of over 80. By using impact-strength modifiers[7-9,15], multiphase polyblends (see Section 2.1) can be produced that have a notch impact strength varying between 2 and more than 40 kJ/m^2. We shall not go into closer details of the research that has resulted in this state of the art[11].

PVC alloys with an elevated heat deflection temperature under load and soft, flexible plastic alloys with improved low-temperature properties are likewise of potential industrial interest. The range of applications of PVC could be extended by these alloys if it were possible to transcend the present state of the art.

2.1. Physicochemical Principles

Polymer alloys are mixed systems made by intimate mixing of at least two structurally different polymers. *Plastic alloys* or polyblends contain, in addition, the aids necessary for technical applications, such as stabilizers, antioxidants, and light-protection agents[10]. An essential feature for the manufacture of single-phase polymer alloys is a mutual compatibility of the components.

Polymers of different composition or structure are in most cases not miscible homogeneously—*i.e.* cannot be molecularly dispersed in each other—in any given ratio, but exhibit regions of miscibility gaps. This means that polymers are normally mutually incompatible in mixtures and that single-phase polymer mixtures constitute an exception. The extent of miscibility (or incompatibility) depends on the composition of the polymer mixture, on temperature, and on the molecular weights of the polymer components.

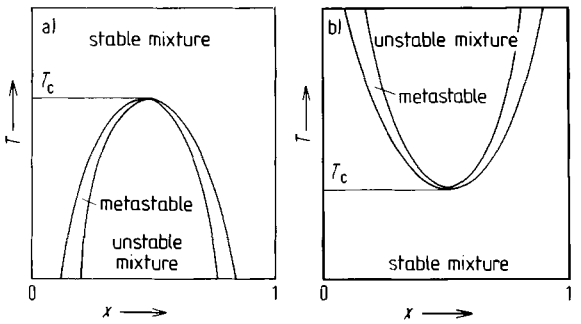

Fig. 1. Idealized phase diagrams for two-component polymer mixtures with a) upper, and b) lower critical solution temperature T_c (after [58]). x = mole fraction.

Figure 1 shows idealized phase diagrams characterizing the typical mixing behavior of two polymers. Above (Fig. 1a) and below (Fig. 1b) a critical temperature T_c the polymers are miscible in all proportions and form stable, single-phase mixtures. If the temperature falls below T_c or rises above T_c (upper and lower critical solution temperature), the two-component system may exist as a stable, as an unstable, or as a metastable mixture, depending on its composition[43].

The thermodynamic explanation for the normally incomplete miscibility of polymers is that mixed polymer systems almost invariably have a strongly positive free energy of mixing ΔG_m. It can be deduced from the basic equation:

$$\Delta G_m = \Delta H_m - T\Delta S_m$$

that ΔG_m only becomes negative or assumes small values when the entropy term $T\Delta S_m \geqq \Delta H_m$. In the case of the mixing of high-molecular compounds, however, the possible increase in entropy is small because only a small number of molecules are being mixed, whereas the mixing enthalpy ΔH_m is much the same as that for structurally similar low-molecular compounds[12-14]. The result is a high positive free energy of mixing in nearly all cases. Only when enthalpic effects are effectively absent, owing to minimal interaction between chain segments of the components, does the relatively small entropy increase suffice for $\Delta G_m \leq 0$. In these special cases molecular dispersion of the two polymers in each other is the energetically most favored state, and only then can mixtures of this type be thermodynamically stable.

The aim of these considerations was to answer, without resorting to experimental evidence, the question whether two or more given polymers would be miscible under specific conditions, and if so, under which? A quantitative equation must thus be given for the change in free energy ΔG_m. Starting out from the criteria for liquid polymer mixtures[12,39-41], it is usual to consider for ΔG_m an equation that essentially contains the polymer-specific Huggins interaction parameter, which is difficult to determine in solvent-free systems. A comparatively precise estimation is possible with the aid of the solubility parameters introduced by *Hildebrand et al.*[42] (summaries in [43-45]). ΔG_m has a mean value when the interaction parameter is at a minimum, and this occurs when the solubility parameters of the two polymers to be mixed are the same. These thermodynamic theories are still rarely used in the solution of practical problems, among other reasons because the requisite thermodynamic data are only adequately known in a few cases, the mathematical work is considerable, and the agreement between theory and practice is only semiquantitative. The solubility parameters or their components assigned to individual interaction forces are often used only for an approximation to the mixing behavior of two polymers. Detailed experimental investigation of the mixing behavior of the alloy components is indispensable; in particular, investigation of the mixture's stability as a function of various parameters, *e.g.* the thermomechanical history of the polymer mixture in question, is of major importance.

Many methods are known to give information on the mutual compatibility of polymers in a mixture, and thus to decide whether one is dealing with a single-phase or a multiphase system. For this purpose practically all the methods of polymer physics normally applied to the study of solid polymers can be used[46,47], the most important being an evaluation of a mixture for transparency, morphological investigations with the aid of optical and electron microscopy, techniques for the investigation of softening behavior (including all methods for studying glass and melt transitions), scattering methods (light scattering, X-ray scattering, neutron scattering), and the determination of surface tensions. For characterization and quantitative testing of the polymer mixtures under investigation we chose to use dynamic mechanical measurements for the determination of the glass-transition temperatures T_g. In these experiments the precondition was that single-phase mixed systems exhibit only *one* glass-transition temperature, which depends only on the proportions of the components present in the mixture. The axiom that *one* glass transition temperature T_g means a *single*-phase system holds true when the glass transitions of the mixture's components are sufficiently far apart. The glass transition is also frequently used as a characteristic parameter of a single-

phase system because it provides particularly valuable information about the potential range of application. Whereas by special phase construction multiphase systems can assume properties not exhibited by any of the starting components, this is obviously by definition impossible with single-phase systems. In general, single-phase polymer alloys can be characterized in respect of their material properties by the relative position of T_g (Table 1).

Table 1. Glass transition temperatures T_g and material properties of polymer alloys (M) made from the components A (main component) and B (modifier).

Material	Relative position of T_g	
Flexible polymer alloys, *i.e.* plasticized materials	$T_gA > T_gB$	$T_gM < \begin{matrix}\text{working}\\ \text{temperature}\end{matrix}$
Polymer alloys with improved heat deflection temperatures useful at elevated use temperatures	$T_gA < T_gB$	$T_gM > \begin{matrix}\text{working}\\ \text{temperature}\end{matrix}$

A PVC modifier must contain polar groups in order to be capable of solvating polyvinyl chloride chains. The modifier as an alloy component is the more effective, the more strongly it increases or decreases T_g when it is present in a specified quantity.

The above-mentioned dynamic mechanical methods of investigation use free or forced oscillations in the linear viscoelastic deformation range to determine the components of the complex modulus, usually as a function of temperature. Starting from low temperatures, the storage modulus (real part) decreases by several orders of magnitude when the temperature exceeds the glass transition region, while the loss modulus (imaginary part) passes through a maximum. Below the glass transition there are further maxima in the loss modulus, which generally are not as high as at the glass transition and which are assigned to secondary relaxations caused by migration of parts of the main chain or of side groups of the polymer molecule (see *e.g.* [48]).

According to this technique, polymer alloys made from mutually incompatible components have several glass transition regions corresponding to those of the pure components. Small temperature differences, frequently observed in such cases, indicate the occurrence of slight phase interactions[49] in the mixed system or partial compatibility of the components.

In compatible mixtures ideally there is only one glass transition, which, in the case of a molecular-dispersive mixing of the components, should be as sharp as in the individual components. However, a broadening of the glass transition range is often observed; this can be explained by the fact that several mixed phases are present, differing slightly in composition only. There is indeed compatibility, but in this case the polymer mixture cannot be regarded as a single-phase system in the strictest sense, as can also be demonstrated *e.g.* by scattering measurements[34]. In this sense the term "single-phase character" used here should be modified. We will use the expression "single-phase systems" for those mixtures that exhibit only *one* transition in the modulus in dynamic mechanical measurements, even if this transition extends over a broader temperature range than in the case of the pure components.

2.2. Single-Phase PVC Alloys

Beginning with the discovery of the first plasticizer for PVC in 1933[3] research and practical experience have yielded a very extensive volume of data on single-phase PVC mixtures[16]. Whereas at first purely empirically usable modifiers were sought and found, increased attention was subsequently paid to the extended theoretical knowledge of the morphology of polymers and of polymer structures. It was found that the PVC-manufacturing process and the polymerization conditions can influence both the fabrication of the PVC alloys and their final properties. A decisive factor in the selection of the most advantageous conditions for the processing of PVC to valuable polymer alloy is, for example, the morphology of the polymer particles, which varies considerably depending on the polymerization process used. In other words, the particle-size distributions of the PVC powder or emulsion and the fine structure of the powder[17-20,31,36,37] are of major importance in the selection of suitable types of PVC. Some important alloy properties also depend on the molecular weight of the PVC[21]. Intensive efforts have been made to correlate the constitution of plasticizers or plasticizing modifiers and their physical properties with the "plasticizer efficiency" or with their technical usefulness as an alloy component for PVC[28-30].

To gain a better understanding of the final properties of single-phase PVC alloys and of the dependence of these properties on the structure of modifiers, it is useful to begin by looking at the structure of polyvinyl chloride and of single-phase PVC alloys. In contrast to the completely amorphous polymers, such as the commercial polystyrenes or polymethyl methacrylates, polyvinyl chloride contains relatively low concentrations of ordered structures[22-27], which some authors even regard as crystalline fractions. However, these ordered structures are present in such small quantities, or have such small dimensions, that their exact and convincing description has so far proved impossible. What seems certain is that as a consequence of the existence of pronounced physical interactions in PVC there are stronger interactions with low-molecular and high-molecular foreign molecules than is the case in mixtures of other amorphous polymers and comparable components. The mode of action of the plasticizers in PVC mixtures has been described in detail on the basis of this special structure of polyvinyl chloride[30-33].

Summarizing, the situation is as follows: along the PVC chain there is a regular sequence of dipoles which in the normal amorphous state do not enter into any stabilizing interactions. Around these more or less free dipoles, local motions can take place, which, *e.g.* in dynamic mechanical experiments, are responsible for the well-known broad secondary relaxation region at temperatures around $-60\,^{\circ}C$ (at 1 Hz), which is typical for PVC. A vinyl chloride homopolymer should not, therefore, strictly speaking be regarded as a single-phase system: there is a physical net-

work with strongly variable network site densities[*]. If a further mixing component of polar character is added to a system of this kind, *e.g.* a modifier, modifier/PVC interactions arise at the expense of the PVC/PVC interactions. This can result in an enhancement or a reduction of the molecular or segment mobility in the PVC chains, and one can observe a decrease or increase in the glass transition temperature. As already mentioned, such PVC systems have been shown by some X-ray studies not to be strictly single-phase[33,35].

If a compatible modifier or plasticizer is added in a *small* quantity to polyvinyl chloride, it will first combine *predominantly with the dipoles not engaged in interactions*. The region around these dipoles before mixing had been preferentially available for local motions and thus constituted an essential prerequisite for the mobility of PVC chains or chain segments. As a result of the development of the first PVC/plasticizer dipole interactions the mobility of the polymer chains is locally restricted; in the dynamic mechanical measurement this leads to the leveling out or to a complete disappearance of the secondary relaxation region. Macroscopically observable consequences of the dipole/dipole relationships when small quantities of plasticizers have been added are an increase of the elasticity modulus and of the tensile strength and a reduction of the elongation at break, *i.e.* there is a decrease in toughness. Although the glass transition is lowered, the hardness and brittleness increase ("antiplasticization"); at plasticizer contents exceeding about 10% the modulus decreases again and the elongation at break increases[38,69].

A characteristic feature of high-molecular modifiers suitable for use as components of soft PVC mixtures with improved low-temperature properties is that the segment mobilities in the polymer chains are very much more pronounced than they are in chains of unmodified polyvinyl chloride. High-molecular modifiers for single-phase PVC alloys with improved heat deflection temperature, on the other hand, exhibit a lower segment mobility at higher temperatures than does polyvinyl chloride. With rising temperature the segment mobility increases less quickly than in polyvinyl chloride. In alloys of this kind polyvinyl chloride can be regarded formally as a "plasticizing modifier" for a mixing component with a higher glass transition temperature[7,66].

3. Synthesis of New Polymer Modifiers

3.1. High-Molecular Aliphatic Polyesters

Already in the 1940's *Biggs et al.*[50,51] were trying to obtain high-molecular aliphatic polyesters with a narrow molecular-weight distribution by fractional precipitation. However, fractional precipitation is unsuitable for the large-scale production of the desired product. Direct synthesis of high-molecular aliphatic polyesters by simple esterifications or transesterifications invariably yields polyesters with a broad distribution of the molecular weight. Azeotrope esterification, as recommended by *Batzer*[52], has so far also proved to be economically inviable for the synthesis of aliphatic polyesters of high molecular weight and narrow molecular weight distribution.

One example of high-molecular aliphatic polyesters with relatively narrow molecular-weight distributions are the polycaprolactones, which are compatible with PVC[53-55]. According to our measurements, however, the desired low-temperature properties cannot be achieved by modifying PVC with polycaprolactones, perhaps because of the latter's pronounced tendency to crystallize.

It should be possible to synthesize other high-molecular polyesters without low-molecular fractions, *i.e.* without fractions with molecular weights below 10^4 to 10^5, by multistage buildup of the chain (Fig. 2).

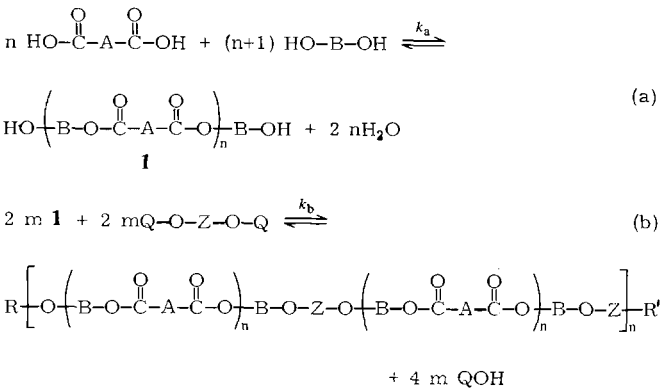

Fig. 2. Scheme of the synthesis for the preparation of aliphatic, high-molecular (polyester)-polycarbonates. (a) Chain buildup by esterification, (b) chain prolongation by transesterification. Q = active group; R, R' = end groups (H or Q); Z = difunctional acyl residue, preferably >C=O.

The most important criterion for useful, difunctional chain extenders suitable for a synthesis of this kind is that the ester groups of the chain extender react with hydroxy groups—*e.g.* by transesterification—whereas the ester linkages of the polymer chain are not allowed to react.

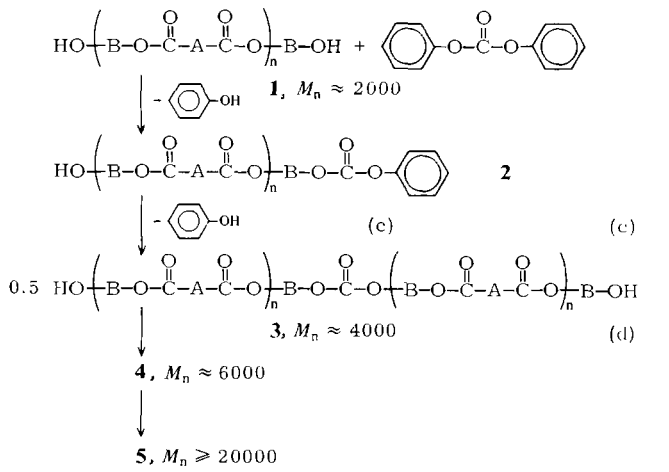

Fig. 3. Scheme of the synthesis for the preparation of (polyester)-polycarbonates. The second prolongation [step (d)] and the further reaction to high-molecular **4** and **5**, in accordance with the first prolongation [step (c)], proceed *via* phenoxycarbonyl-terminated macromolecules. A, B = alkene groups; $n \geq 4$. **1**, **3**, and **4** contain, respectively, about 16, 33, and, 50 ester bonds per macromolecule.

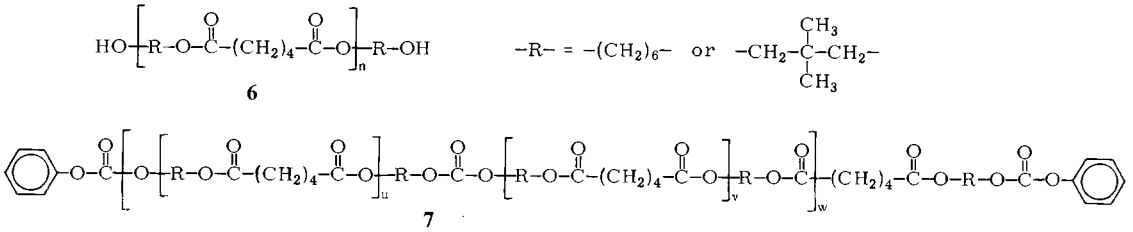
[*] The term network site density denotes the number of physical and chemical cross-linking sites per unit volume of polymer.

Very high-molecular aliphatic (polyester)-polycarbonates[*] can be made by using diaryl carbonates[**] as chain extenders in the presence of basic catalyst and within specific temperature ranges (Fig. 3).

High-molecular, aliphatic (polyester)-polycarbonates can be synthesized in this way without any broadening of the molecular-weight distribution towards low molecular weights. Reaction of aryl esters of aliphatic dicarboxylic acids as chain extenders under these conditions does not lead to corresponding high molecular products. Figure 4 shows the results of some model experiments performed to elucidate the course of the reaction, in which a polyester **6** having a terminal hydroxy group was prepared from adipic acid, hexane-1,6-diol, and neopentanediol ($\overline{M}_n \approx 1700$) and converted into **7** [see also Table 2; formulas **6** and **7** are idealized and presented in schematic form].



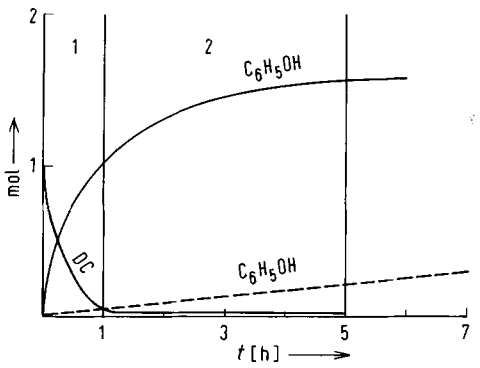


Fig. 4. Course of the polycondensation of diphenyldicarboxylic esters and an OH-terminated polyester **6** from adipic acid, hexane-1,6-diol, and neopentanediol to give (polyester)-polycarbonates **7** at 175 °C; catalyst: 0.0748 g of $NaOC_6H_5$/1000 g of the mixture:

Diphenyl ester + polyester → $2C_6H_5OH$ + (polyester)-polycarbonate
6 **7**

(——) reaction with diphenyl carbonate (DC), (----) reaction with diphenyl sebacate. Step 1: Rapid reaction of diphenyl carbonate to give polyester monoalcohols (cf. **2**); Step 2: condensation to oligomeric (polyester)-polycarbonates (cf. **3**). To achieve quantitative splitting off of the phenol and thus high-molecular (polyester)-polycarbonates, the phenol is distilled off as it forms. Under the same conditions diphenyl sebacate does not form high-molecular (polyester)-polysebacates.

[*] The nomenclature of (polyester)-polycarbonates, *e.g.* from an OH-group-terminated polyester (see **6**, weight-average molecular weight $\overline{M}_w = 2000$), obtained by the esterification of adipic acid with a mixture of hexane-1,6-diol and neopentanediol ["poly(oxycarbonyloxy-hexamethylenoxy-adipoyloxy neopentylene)" see 7], is still unsatisfactory. Some essential structural features, such as the length of the polyester blocks between the carboxylic ester groups, cannot be reproduced in the names.

[**] The particular suitability of diaryl carbonates for the synthesis of polycondensates has long been known (cf. [56, 57]).

As the reaction proceeds the molecular weight increases. Without any further measures being taken, however, only a state of quasiequilibrium is achieved; the average molecular weights $\overline{M}_w$ remain below 15000. For the polycondensation to continue further, it is necessary to remove the phenol formed during the chain-growth process. For example, by distilling off the phenol under vacuum, very high-molecular products ($\overline{M}_w \approx 400000$) can be obtained in relatively short time (4 and 5 h); however, a considerable broadening of the molecular-weight distribution towards higher molecular weights occurs at the same time. The preferred reaction temperatures are in the range 140 to 200 °C. Below about 140 °C the polycondensation slows down sharply with decreasing temperature. Degradation reactions predominate above 200 °C (*e.g.* decarboxylation). On acid catalysis no chain growth was observed.

We found that conversion of aliphatic diols with diphenyl carbonate into high-molecular compounds proceeds largely independently of the diol structure. Besides polyesters with terminal hydroxy groups, appropriate polyethers can also be used. Block copolymers containing both po-

Table 2. Structural parameters of samples of (polyester)-polycarbonate **7**. Reaction: Polycondensation (1 : 1) of diphenyl carbonate and **6** ($\overline{M}_n \approx 2000$) without continuous removal of the phenol by distillation; for the other conditions see Figure 4. Method: combination of gel permeation chromatography (GPC) and viscometry; column combination: Styragels 10^7, 10^6, 10^6, 5×10^5, 10^5, 10^4, 10^3 Å; eluent: $CHCl_3$ at room temperature; detector: refractometer, capillary viscometer. $V_{E,max}$ = elution volume at maximum in gel chromatogram; $U_n = (\overline{M}_w/\overline{M}_n)^{-1}$.

t [h]	$V_{E,max}$ [ct]	$[\eta]_{CHCl_3}$ [dL/g]	$\overline{M}_n$	$\overline{M}_w$	U_n
1	76.6	0.12	1400	2100	0.50
2	75.5	0.15	2200	3000	0.36
3	74.0	0.22	2800	5600	1.00
5	72.9	0.30	4100	9100	1.22
6	72.3	0.33	6700	12400	0.85

Table 3. Some polycarbonates synthesized on a laboratory scale. Molecular weight of the educts: *ca.* 2000. The $[\eta]$-values of the polycarbonates were measured in the specified solvent at 25 °C. THF = tetrahydrofuran. The educts contain two terminal hydroxy groups.

Educts	$[\eta]$-Values of the polycarbonates [dL/g]
Polytetrahydrofuran	≈ 1.1 ($CHCl_3$)
Polyethylene oxide	≈ 0.9 ($CHCl_3$)
Mixtures of polytetrahydrofuran and polybutadiene	≈ 1.0 ($CHCl_3$)
Polyester from adipic acid and diethylene glycol	≈ 1.1 (THF)
Polyester from adipic acid and hexane-1,6-diol	≈ 1.1 (THF)
Mixtures of polybutadiene and polyester **6**	1-2.0 (THF)

lyether and polyester blocks can be produced from mixtures of the two[59].

(Polyester)-polycarbonates **7** (prepared from **6** with $\overline{M}_n \approx 2000$, $[\eta]_{THF} = 1.15$ dL/g), which are particularly suitable for the production of alloys with PVC, have good rubber properties. Their strength (unfilled, green-strength values) is 0.15 MPa; their elongation at break is over 1200% (the corresponding figures for natural rubber are 0.16 MPa and 425%).

Table 3 gives a summary of some (polyester)- and (polyether)-polycarbonates and their block copolycarbonates that have been synthesized on a laboratory scale.

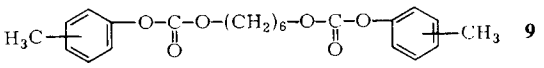
3.2. Tetramethylbisphenol-A Polycarbonate

Tetramethylbisphenol-A polycarbonate (MPC) consists of structural units **8** and can be synthesized from tetramethylbisphenol A and phosgene by interfacial polycondensation[65]. A polycondensation of this kind requires the most quantitative possible acylation of the phenolic hydroxy groups by phosgene or by the chlorocarbonate ester occurring as intermediate during the interfacial polycondensation. Large-scale preparation of MPC proceeds without any problems when the interfacial polycondensation is carried out with high concentrations of the catalyst, at very high pH, and with an excess of phosgene. The four aromatic methyl groups lower the reactivity of the bisphenol component during the polycondensation with acid chlorides, but on the other hand they also endow the tetramethylbisphenol-A polycarbonate with special technical properties, *e.g.* its high resistance to hydrolytic attack and its glass transition temperature of 200—205 °C, about 50 °C higher than that of bisphenol-A polycarbonate (see Table 5, Section 5).

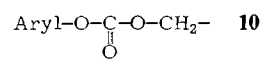
4. Properties of Polymer Alloys of (Polyester)-Polycarbonates and PVC

Adipic diesters with aliphatic monohydric alcohols have long been known as PVC plasticizers[60,64] and, depending on the alcohol, they are reasonably compatible with PVC. Aliphatic polyesters with terminal hydroxy groups and average molecular weights of up to 10000, obtained from diols, *e.g.* hexane-1,6-diol, and adipic or sebacic acid, have likewise been described as usable PVC plasticizers or plasticizing modifiers[61]; the (polyester)-polycarbonates **7** discussed above contain such polyester groups as structural elements.

Aliphatic-aromatic carboxylic esters such as hexamethylenebis(cresyl carbonate) **9** can also be used as plasticizers for PVC[62,63]. Thus, group **10**, the terminal group of the (polyester)-polycarbonates, can solvate the chains of the polyvinyl chloride. On the basis of these structure comparisons extensive solvation of the PVC chains by many



9



10

(polyester)-polycarbonates should be expected. The PVC compatibility of the (polyester)-polycarbonates **7** and of their precursors **6** is shown in Figure 5 by comparing modulus/temperature curves.

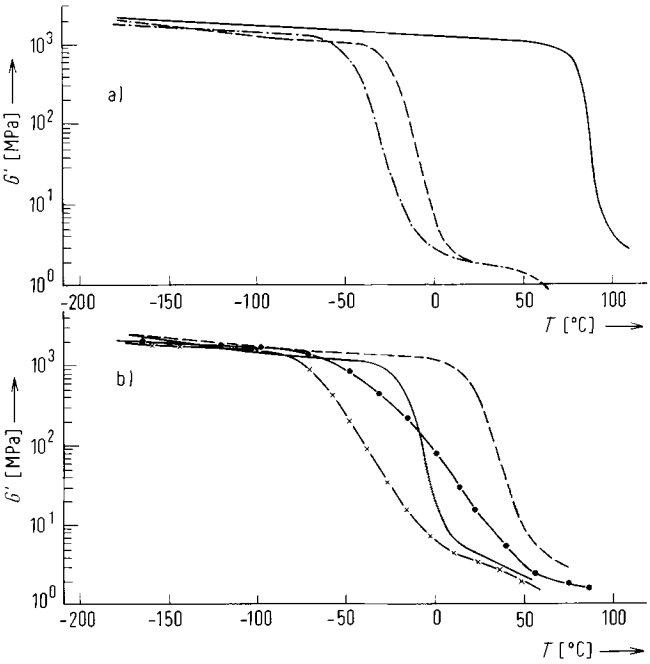


Fig. 5. Modulus/temperature curves of PVC and single-phase PVC alloys or mixtures (figures in wt-%). a) (——) PVC (suspension PVC with a K-value of 70), (----) 50% PVC + 50% polyester **6** ($\overline{M}_n \approx 2000$), (-·-·-) 50% PVC + 50% dioctyl phthalate. b) (——) 50% PVC + 50% (polyester)-polycarbonate **7** (obtained from **6** with $\overline{M}_n \approx 2000$), (----) 75% PVC + 25% **7**, (-•-•-•-) 70% PVC + 30% dioctyl adipate, (-×-×-) 60% PVC + 40% dioctyl adipate.

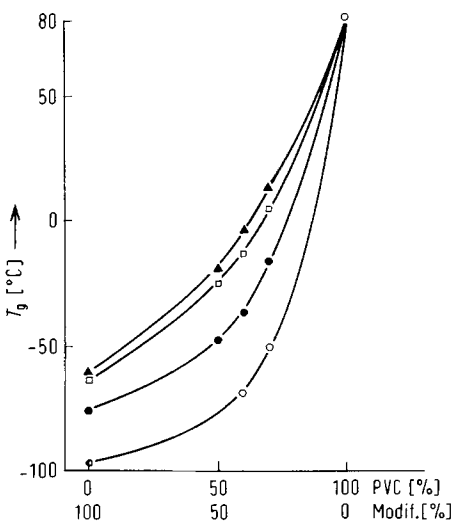

Fig. 6. Comparison of the glass transition temperatures T_g of flexible PVC alloys and mixtures as a function of the PVC content (wt-%), with various plasticizing modifiers (Modif.). (-▲-) PVC + (polyester)-polycarbonate **7** (obtained from **6** with $\overline{M}_n \approx 2000$), (-○-) PVC + dioctyl adipate, (-•-) PVC + dioctyl phthalate, (-□-) PVC + polyester **6** ($\overline{M}_n \approx 2000$).

Figure 6 illustrates the quantitative relationship between the glass point and the composition of several flexible PVC alloys.

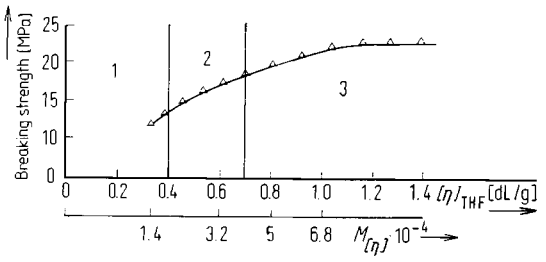

Fig. 7. Relationships between the processability, breaking strength (determined after DIN 53455), and molecular weight or Staudinger index in PVC/(polyester)-polycarbonate alloys; properties of the alloys as a function of the Staudinger index of the (polyester)-polycarbonates **7** (obtained from **6** with $\overline{M}_n \approx 2000$). Regions 1, 2, 3: not processable thermoplastically, moderately processable, and readily processable.

In manufacturing the alloys and by evaluation of samples it was found that the compatible (polyester)-polycarbonates can be particularly well processed with PVC under industrially practicable conditions when the molecular weight $M_{[\eta]}$ of the modifiers is more than 3.5×10^4 (Fig. 7). The characteristic data such as the breaking strength and the elongation at break of these PVC alloys attain a level expected of high-grade flexible PVC alloys only when (polyester)-polycarbonates with high molecular weights are used.

In spite of their high molecular weight, smaller quantities of the (polyester)-polycarbonates **7** are necessary than of other high-molecular modifiers for the production of flexible PVC alloys having a definite Shore hardness (Fig. 8). The migration stability of the (polyester)-polycarbonates **7** in a PVC alloy is illustrated in Table 4.

Table 4. Migration properties of PVC alloys. Migration of plasticizer from PVC alloys made from 60 wt-% PVC (K-value 70) and 40 wt-% modifier into hard PVC and bisphenol-A-polycarbonate (according to DIN 53405).

Modifier	Loss in weight [mg] of soft PVC foils in contact with			
	hard PVC		bisphenol-A-polycarbonate	
	after 24 h	after 12 d	after 24 h	after 12 d
6 ($\overline{M}_n \approx 2000$)	7.1	28.3	2.8	19.3
7 [a]	1.4	6.5	0.5	4.2

[a] **7** (obtained from **6** with $\overline{M}_n \approx 2000$), $[\eta]_{THF} = 1.0$ dL/g

Study of the low-temperature properties of alloys made from PVC and selected (polyester)-polycarbonates yielded the remarkable finding that there are no significant differences between the glass transition temperatures of PVC alloys with polyesters **6** ($\overline{M}_n \approx 2000$) and those with the high-molecular (polyester)-polycarbonates **7**. (Polyester)-polycarbonates of different structures that are compatible with PVC behave in similar fashion.

On the other hand, investigations on the low-temperature fracture behavior of PVC alloys have shown that among the high-molecular, *i.e.* migration-resistant, modifiers tested the (polyester)-polycarbonates **7** occupy a special position (Fig. 9). By using these it is possible to achieve a low-temperature fracture behavior, which is otherwise only obtainable using low-molecular plasticizers of the dioctyl adipate type.

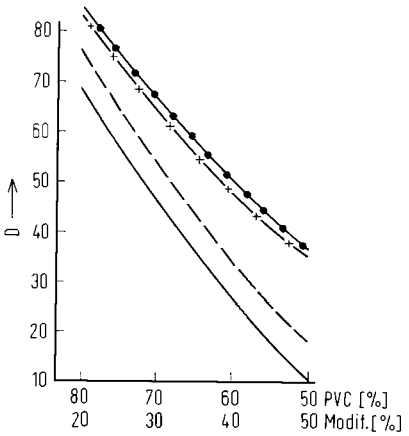

Fig. 8. Shore-D hardness (after DIN 53505) of PVC/(polyester)-polycarbonate alloys and PVC alloys with other modifiers (Modif.). Alloys based on suspension PVC with a K-value of 70; figures in wt-%. (-●-●-●-) (Polyester)-polyurethane (obtained from **6** with $\overline{M}_n \approx 1700$), (-×-×-×-) butadiene/acrylonitrile copolymer with about 30% of acrylonitrile, (----) (polyester-)-polycarbonate **7** (obtained from **6** with $\overline{M}_n \approx 2000$), (——) polyester **6** ($\overline{M}_n \approx 2000$).

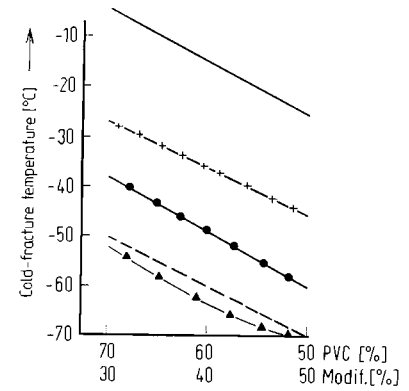

Fig. 9. Cold-fracture temperatures (after DIN 53372) of flexible PVC alloys and mixtures. (-●-●-●-) (Polyester)-polyurethane (obtained from **6** with $\overline{M}_n \approx 1700$), (-×-×-×-) butadiene/acrylonitrile copolymer with about 30 wt-% of acrylonitrile, (----) (polyester)-polycarbonate **7** (obtained from **6** with $\overline{M}_n \approx 2000$), (——) polyester **6** ($\overline{M}_n \approx 2000$), (-►-►-) dioctyl adipate.

The low-temperature behavior is characterized by the temperature range in which, with falling temperature, the failure mechanism changes from ductile to brittle fracture. PVC alloys based on selected (polyester)-polycarbonates accordingly also have a high impact strength below the region of the glass-transition temperature. This was in fact confirmed by plate penetration experiments.

The modulus/temperature variation and the low-temperature behavior provide special information on the mechanical properties of materials as a function of temperature. The shear moduli are measured using relatively low amplitudes, and the low-temperature fracture temperatures using relatively high amplitudes and high loading rates. If we are interested in the rigidity of materials as a function of temperature, the modulus and its abrupt change at the glass transition are the characteristic features; if, on the other hand, we consider the breaking strength as a func-

tion of temperature, then what is decisive is whether the fracture will be brittle or ductile at the temperature in question. The fracture mechanism does not correlate directly with the glass transition of a system; whether a fracture occurs depends on how much force or deformation a system can withstand. In the case of ductile fracture the force or energy necessary to induce failure is very much greater than in the case of a brittle fracture. The force during the breaking process can be measured in a plate-penetrating apparatus (drop weight impact). Information can thus be obtained on the fracture mechanism[70]. Figure 10 shows force/time diagrams from plate-penetrating tests on plates made from various PVC/modifier mixtures and alloys as a function of temperature. For each system there is

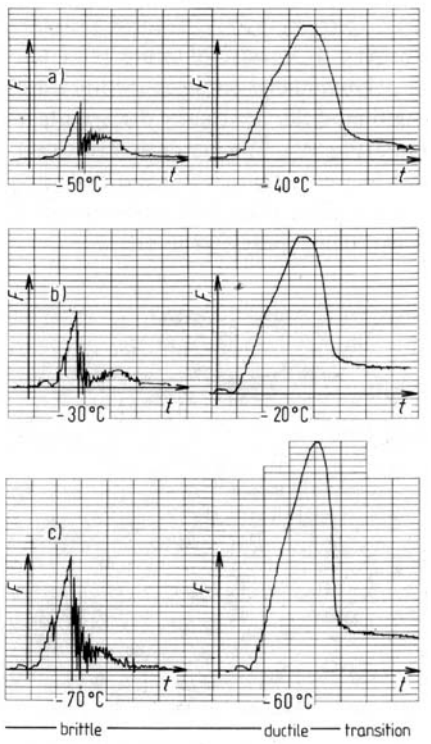

Fig. 10. Results of plate penetrating tests on PVC alloys with a recording dropping-weight apparatus as per DIN 53443: brittle/ductile transition of an alloy from a) 50% PVC + 50% dioctyl phthalate, b) 50% PVC + 50% polyester **6** ($\overline{M}_n \approx 2000$), c) 50% PVC + 50% (polyester)-polycarbonate **7** (obtained from **6** with $\overline{M}_n \approx 2000$).

a temperature range in which a brittle-ductile transition of the fracture behavior occurs under the given conditions. This temperature range can be considered in relation to the glass transition T_g. For the systems in Figures 10a—c the brittle/ductile transition occurs at -50 to $-40\,^{\circ}C$, -30 to $-20\,^{\circ}C$, and -70 to $-60\,^{\circ}C$, respectively; the corresponding T_g values are about -45, -23, and $-20\,^{\circ}C$.

The (polyester)-polycarbonates **7** (Fig. 10c) occupy a special position. The temperature at which the brittle/ductile transition occurs is the most strongly shifted in relation to T_g in the direction of lower temperatures. It remains to be clarified what special structural or morphological features are responsible for this effect.

We favor the following explanation: The PVC mixtures under discussion consist of microphases differing only slightly in composition. The microphases correlate with the fact that wider T_g ranges are found than, for example, in the single-phase "intimately plasticized polyvinyl chlorides"[67,68]. A direct confirmation of a "microphase" morphology of this kind with the aid of dynamic mechanical measurements has so far proved impossible, nor have X-ray small-angle scattering and electron-optical methods yielded any definite evidence.

Any suggestions about the structure and morphology of these systems must be able to account for both the temperature and the molecular-weight variations of the mechanical and elastic properties, *i.e.* for the effect that the temperature difference between the brittle/ductile transition and T_g becomes greater with increasing molecular weight of the (polyester)-polycarbonates **7**.

The following considerations may clarify the findings: the formation of microphases is favored by modifiers of high molecular weight. Even below T_g there are transition ranges of compatibility between the microphases. The effectiveness or stability of physical cross-linking within the microphases and also within the phase boundaries, which determines the mechanical properties of the entire system, depends upon the system's molecular weight and on the temperature.

The average molecular weight of the system (PVC + modifier) is at its lowest when dioctyl adipate is used as the other component, and the resulting poorer properties of the mixtures do not matter because the system has a very low glass-transition temperature.

In the case of the mixtures of PVC and the polyester **6** of $\overline{M}_n \approx 2000$ the average molecular weight of the mixture is higher than when dioctyl adipate is used, high enough to produce microphases. This increase of the molecular weight is, however, insufficient for the generation of a rubbery-elastic state.

In mixtures of PVC and (polyester)-polycarbonates the average molecular weight of the system is so high that a rubber-elastic state can be achieved; in spite of the higher T_g of the system, the physical cross-linking remains active at low temperatures.

Finally, the temperature/toughness characteristics of the mixtures and alloys under discussion here can be determined from these qualitative considerations. It is thus no longer surprising that the aim of improving the low-temperature fracture behavior has been achieved by increasing the molecular weight; it remains worth noting, however, that other properties of practical interest are not impaired by the use of the particularly high-molecular (polyester)-polycarbonates **7** as modifiers.

5. PVC Alloys with Higher Heat Distortion Temperatures

Although the wide range of applications of hard PVC shows that for many purposes the heat deflection temperature of these thermoplastic materials is sufficient, there has been no lack of successful attempts at opening up new fields of application by increasing the deflection stability[7]. The problem is that when the modifier content of PVC mixtures is increased the heat deflection temperature is indeed improved, but there is also an effect on other properties of the system; in many cases the desired aim

can only be achieved by a multicomponent mixture in which the single-phase PVC alloy is but one component. Some thermal and mechanical data for PVC, tetramethylbisphenol-A polycarbonate (MPC), and technical bisphenol-A polycarbonate (PC) are listed in Table 5[65]. What is

Table 5. Characteristics of bisphenol-A polycarbonate (PC), tetramethylbisphenol-A polycarbonate (MPC), and polyvinyl chloride (PVC).

		PVC	MPC	PC
Glass transition temperature (T_g)	[°C]	81	200–205	150
Processing temperature	[°C]	160–220	>260	>260
Refractive index		1.54–1.55	1.546	1.586
E modulus	[MPa]	3000	2400	2200
Tensile strength	[MPa]	65	80	65
Impact strength [a]	[kJ/m²]	[b]	45	[b]
Notch impact strength [a]	[kJ/m²]	2–4	4	>30

[a] At room temperature. [b] Not fractured.

particularly worth noting is the gradation of the glass transition temperatures; given compatibility, the new polycarbonate MPC should prove to be an outstanding modifier. Although the processing temperature of MPC is above 250 °C, this polycarbonate with its glass temperature of 205 °C can be alloyed with PVC. The prerequisite for this is a very good compatibility with PVC at higher temperatures and highly effective thermal stabilization of the system with tin compounds. The transparent alloys[71] (whose production conditions were discovered by *Serini*), exhibit the expected rise of the Vicat softening point (Fig. 11). However, the mixtures are brittle and hence not very useful, despite their very high Vicat grading.

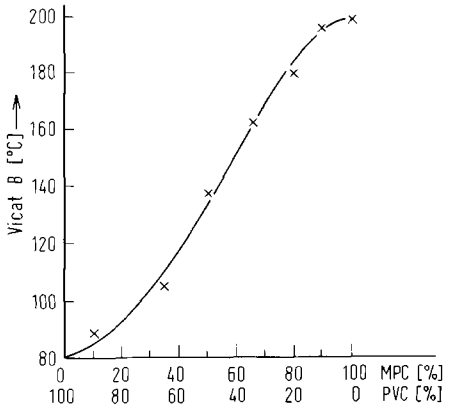

Fig. 11. Vicat B points (after DIN 53460) of alloys made from PVC and tetramethylbisphenol-A polycarbonate (MPC) (data in wt-%).

The method of using an impact-strength modifier active in PVC as an additional alloy component is used successfully in the combination of PVC and tetramethylbisphenol-A polycarbonate. Acrylonitrile-butadiene-styrene (ABS) copolymers, methyl acrylate-butadiene-styrene (MBS) copolymers, and high impact-strength polystyrene (HIPS), *i.e.* polystyrene modified with polybutadiene, are particularly advantageous. Figure 12 shows the relationships of the notch impact strength and the Vicat value as a function of the MPC/HIPS ratio in alloys containing 50% of PVC. In this system increasing quantities of HIPS lead to increasing loss of dimensional stability under heat, but with sufficient notch impact strength Vicat points of over 105 °C can still be achieved; this elevated thermal dimen-

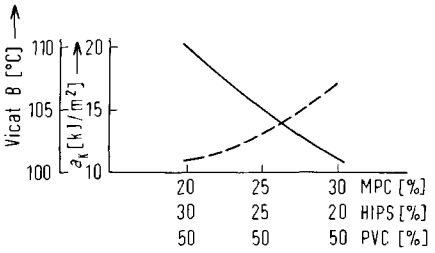

Fig. 12. Relationships between (---) heat deflection according to Vicat B and (——) notch impact strength (a_K, measured as per DIN 53453) in multiphase alloys of polyvinyl chloride (PVC) (suspension PVC with a K-value of 70), tetramethylbisphenol-A polycarbonate (MPC), and rubber-modified polystyrene (HIPS) (figures in wt-%).

sional stability combined with toughness represents a valuable additional advance in the PVC sector.

This alloy from PVC, tetramethylbisphenol-A polycarbonate, and HIPS proves to consist of more than one phase. The spherical polybutadiene particles incorporated with the impact strength modifier are clearly discernible in an electron micrograph (Fig. 13). The matrix is structured. The dark regions are characteristic of PVC and PVC-rich mixed phases. The light regions consist of mixed tetramethylbisphenol-A polycarbonate/polystyrene phases.

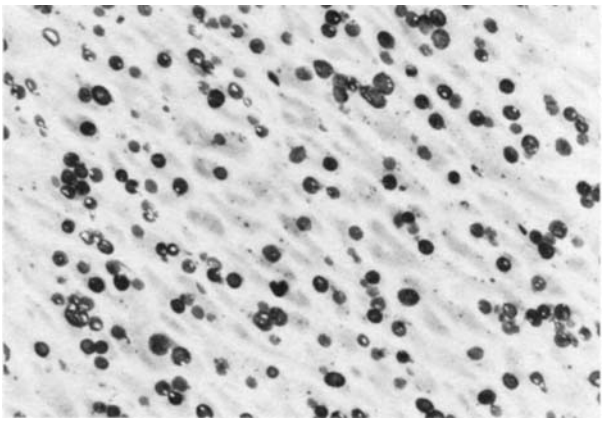

Fig. 13. Transmission electron micrographs (contrasted with OsO_4) of a polymer alloy from 50 wt-% PVC, 25 wt-% tetramethylbisphenol-A polycarbonate (MPC), and 25 wt-% rubber-modified polystyrene (HIPS) (magnification 12500×).

The shear modulus and the loss factor also determine interactions between the components, governed by their mutual solubility (Fig. 14).

The tgδ maximum due to polybutadiene is in the low-temperature region. The PVC peak is somewhat displaced

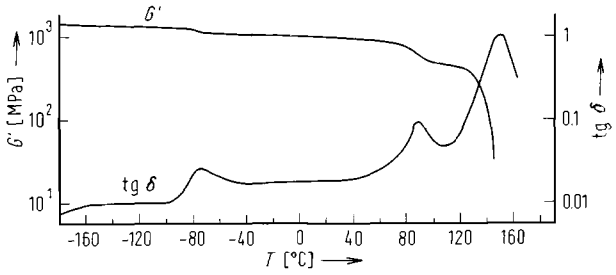

Fig. 14. Modulus/temperature curve of a multiphase polymer alloy from 30 wt-% PVC (suspension PVC with a K-value of 70), 35 wt-% tetramethylbisphenol-A polycarbonate (MPC), and 35 wt-% rubber-modified polystyrene (HIPS). G' = shear modulus, tgδ = loss factor.

in the direction of higher temperatures compared to the peak for pure PVC. No maxima are present for tetramethylbisphenol-A polycarbonate and for polystyrene; evidently these components of the multiphase alloy form a mixed phase, which can be recognized by a glass point of about 140 °C. The electron-optical findings and modulus measurements thus yield the same information about the structure of the alloy.

6. Outlook

In polymer research there is a general increase in interest being taken in single-phase and multiphase polymer alloys and in the development of synthetic plastics in which both these types of polymer alloys are combined with each other.

In the case of single-phase alloys the combination of several polymers frequently leads to new, technically interesting properties, *e.g.* increased or decreased softening points, better workability of thermoplastics, flexibility, or solvent resistance.

In multiphase alloys the generation of disperse polymer phases in a coherent polymer matrix leads to an improvement or removal of the desirable or undesirable properties, respectively, of the matrix (*e.g.* reduction of brittleness and hence increased breaking strength). Advantageous, technically important characteristic properties of the matrix, on the other hand, should not be altered, *e.g.* the softening behavior or workability.

Single-phase or multiphase alloying thus affords various possibilities for varying or adapting the properties of a synthetic plastic to meet more exacting or unusual technical requirements. It is already anticipated that many plastics of the future will be characterized by a combination of disperse phases with single phase multicomponent matrices.

In this review article we have reported on two promising polymers. Tetramethylbisphenol-A polycarbonate (MPC)—a polymer with particular affinities to polymers of other chemical structure—opens up an entry to novel single-phase polyvinyl chloride and polystyrene alloys[65] that display a particularly interesting property profile on additional combination with disperse rubber components.

(Polyester)-polycarbonate—a polymer whose modifying properties are opposite to those of MPC—is an example of a component for the preparation of highly flexible soft PVC alloys that have all the technically useful characteristics of rubber-elasticized multiphase systems at low temperatures.

In our opinion, the historical development of metallic materials and plastic materials shows remarkable parallels: Thus, today, not the pure metals but metal alloys are of major technical interest, so it can be assumed that also in the case of plastics the economic importance of the alloys will surpass that of the chemically individual polymers.

We should like to thank Dr. D. Freitag and Dr. V. Serini for stimulating contributions to our discussions. Thanks are also due to Frau K. Brudermanns for her involvement in the evaluation of measurements and test results.

Liquid Structure and Thermodynamics of Alkane Mixtures

By Andreas Heintz and Rüdiger N. Lichtenthaler*

Spectroscopic investigations and light scattering experiments with saturated, liquid hydrocarbons and their mixtures indicate a specific and distinct influence of the constitution, conformation, and flexibility of the molecule on the structure and macroscopic behavior of such liquids. Orientational order present in pure liquid *n*-alkanes, for example, characteristically affects the thermodynamic mixing properties, such as the enthalpy of mixing ΔH_M and the entropy of mixing ΔS_M, when these liquids are mixed with each other, or with other liquids. Nowadays it is possible to determine thermodynamic mixing properties experimentally with such precision that systematic investigations of these properties allow the behavior of liquids to be studied qualitatively and—with molecular theories of liquids—to some extent also quantitatively. The latest results in this respect, exemplified by mixtures of alkanes, are discussed. These results not only demonstrate the progress made in understanding the relations between molecular (microscopic) and macroscopic properties, but are also of importance for industrial applications (*e.g.* separation processes) in which mixtures of hydrocarbons are involved.

1. Introduction

Saturated hydrocarbons are molecular substances which, in general, are well known. The constitution of an alkane chain is one of the basic fundamentals in teaching structural organic chemistry. As solvents in the laboratory, as widely used raw material for chemical products, and as fuels for the generation of energy, hydrocarbons are of extraordinary importance. The chemical, and above all, the physical properties of these substances in their gaseous and liquid states play a major role in the recovery and refining of crude oil.

Accordingly, to a large extent hydrocarbons and their mixtures are involved in many chemical processes and physical methods in industry (*e.g.* separations). Proper development and economic design of appropriate equipment for these processes is only possible if the chemical and physical properties of the substances to be processed are known. It is, therefore, not surprising that the properties of hydrocarbons have been, and still are collected in comprehensive tabular compilations. Furthermore, many attempts have been made to correlate these data using semiempirical or theoretical approaches. In order to find out, for example, whether a liquid mixture with known composition can be separated into its components by distillation, it is necessary to know the composition of the gaseous phase with which it is in equilibrium. Of course an experiment will reveal the data, but it might be quite expensive and very time consuming. Thermodynamics does not give an answer to this question directly, but defines the conditions of equilibrium. To calculate the compositions of the different phases in equilibrium with one another, however, the chemical constitution of the molecules forming the mixture and the intermolecular interactions between them must be known. Only then does statistical thermodynamics, which connects molecular and macroscopic properties, in principle allow physical properties such as *e.g.* densities, vapor pressures, and phase compositions to be calculated.

However, at present, the calculation of physical properties is limited to simple, mostly atomic liquids and their mixtures (*e.g.* rare gases and methane). Even for simple, molecular fluids such as, N_2, CO, CO_2, C_2H_2, and H_2O it is still impossible to make quantitatively reliable, theoretical predictions. This is due to the anisotropic shape of these molecules, and intermolecular interactions which, accordingly, are not radially symmetrical, and to additional interactions between multipoles (*e.g.* the dipole of CO, the quadrupole of CO_2) or to hydrogen bonding (*e.g.* H_2O). Recently, however, computer-simulated calculations[1-3] and neutron-scattering experiments[4] have given insight into the relations between molecular structure and macroscopic behavior. Remarkable progress has also been made in the development of statistical theories[5-7]. But the calculation of physical properties using a complete, statistical theory is still not yet possible for "complicated" molecules such as long-chain alkanes, which have many different conformations and have various contributions to their intermolecular interactions. Nevertheless, many helpful methods have been developed, some of which are completely empirical while others are based on statistical models which allow the prediction of important properties such as *P,V,T*-data and phase equilibria.

In this article the latest results of experimental and theoretical investigations which deal with the properties of saturated hydrocarbons are dealt with. In particular, it is shown how new results on the structure of liquids obtained spectroscopically can be incorporated into thermodynamic model theories. In this way it is possible to make consistent predictions of the thermodynamic behavior of alkane mixtures which are important in technical applications. Firstly the behavior of a single molecule will be discussed, *i.e.* of a molecule in the gaseous state at low pressure; the changes which occur in the transition to the liquid state will then be described. Finally, thermodynamic investigations and a molecular theory of alkane mixtures, permitting conclusions with respect to the structure of the liquids will be discussed.

2. The Gaseous State

This section gives a short review of the conformations which a single alkane molecule may adopt. In the final analysis these conformations also determine the intermolecular interactions, and therewith the macroscopic and thermodynamic behavior in the liquid state.

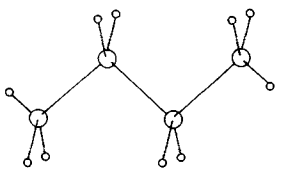

Fig. 1. A possible conformation of *n*-butane.

Figure 1 shows one possible conformation of *n*-butane. It has been established that, on the whole, only "staggered" conformations with a constant C—C—C angle along the chain exist, but that the angle of rotation around the C—C axis may vary. Because of energy restraints, three different angles of rotation are possible, in principle, for each structural unit; one *trans*- (*t*) and two *gauche*-conformations (g^+, g^-). In Figure 2 this is shown schematically for *n*-butane. Because of the strongly repulsive forces between the two methyl groups, the *t*-conformation is energetically more stable than the two *g*-conformations. All intermediate positions are of the *cis*-type, *i.e.* they are not favored energetically because of the repulsion between the CH_3 groups and the H atoms.

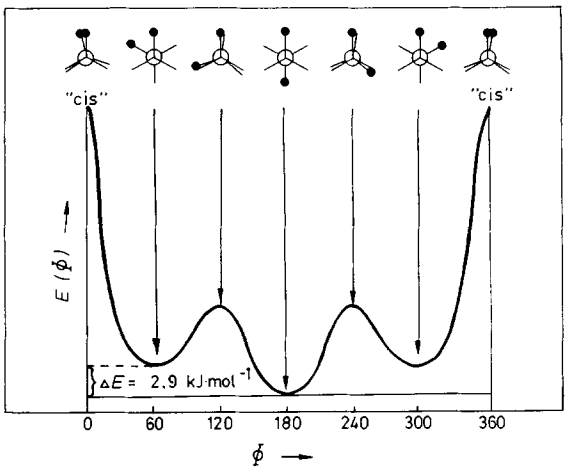

Fig. 2. Potential energy *E* as a function of the angle of rotation Φ of the hindered rotation around the central C—C bond of *n*-butane. 180°: *t*, 60°, 300°: g^+ or g^-; maxima: "*cis*"-conformation.

Put simply, it can be concluded that for an alkane chain different rotational isomers exist having distinct energies differing by $\Delta E(t \rightarrow g^{\pm})$. In case of *n*-butane only three rotational isomers are possible—the *t*-, g^+-, and g^--conformations. Longer chains with n C atoms have n-3 distinguishable structural units which are arranged either in the *t*- or $g^{\pm}$-formation.

If i units are in the g^+- or g^--form, the remaining (n−3−i) units must be in the *t*-form, and the fraction x_i with i $g^{\pm}$-units in the chain is given by [8]:

$$x_i \triangleq m_i \cdot \exp[-i \cdot \Delta E/kT] \qquad (1)$$

In this equation m_i is a weighting factor which accounts for the number of distinguishable distributions of the $g^{\pm}$- and *t*-units within the chain for a given number of *gauche*-units i; *k* is the Boltzmann factor and *T* the absolute temperature. According to *Pitzer*[9] adjacent g^-g^+- or g^+g^--sequences are not possible (steric hindrance) and are hence not included in determining the number m_i in eq. (1). At thermal equilibrium, individual alkane chains are arranged in different conformations, distinguished from one another by internal energies of conformation and molecular shape. The longer the chain, the greater the number of rotational isomers. In general, conformations with many *t*-units bestow a more extended shape to a molecule. In the extreme case when only *t*-units are present, a molecule is a long "zig-zag" rod. Many $g^{\pm}$-units, however, result in a more globular shape. In the gaseous state all these structural isomers exist in equilibrium with one another; their fraction x_i can be calculated from eq. (1) if ΔE is known.

Electron diffraction measurements performed with gaseous alkanes ranging from butane to heptane yield a value of 2.9 ± 0.4 kJ/mol for ΔE[10]. It is important, however, to recognize that for longer chains the energy difference $\Delta E(t \rightarrow g)$ for a structural unit is not completely independent of the arrangement of the other units (t, g^-, g^+). Using the approximation that there is only an effect between structural units located next to one another, *Flory*[11] has developed a matrix method, which is similar to the Ising-model, to calculate conformational equilibria. Up to heptane, exact calculations have been performed[12] for all possible conformations and clearly show a more complicated behavior than that corresponding to Figure 2 and eq. (1), which uses only one parameter ΔE and assumes independent structural units. Nevertheless eq. (1) represents an acceptable approximation for calculating the distribution of rotational isomers.

3. The Liquid State

In practical applications, alkanes are mostly used in the liquid state, and this also, in general, is of greater interest. Usually two cases of the liquid state are distinguished. In one case the alkanes are dissolved in a homogeneous isotropic solvent which consists of simple, approximately spherical molecules (*e.g.* CCl_4 or cyclohexane). The alkane concentration is so small that the molecules do not influence one another, *i.e.* the alkanes are infinitely diluted. In other words the "vacuum" present around an alkane molecule in the gaseous state is replaced by simple solvent molecules. The alkane molecules are kept in solution because of the largely nonspecific, intermolecular interactions with solvent molecules. It is therefore likely that the structural behavior, *i.e.* the equilibrium distribution of the rotational isomers, is essentially the same as in the diluted gaseous state. The other case is the liquid state of pure alkanes or concentrated solutions. Now it is likely that to some extent correlations exist between the alkane molecules because of their asymmetric, chain-like shape and because of the anisotropic intermolecular interactions. Consequently characteristic effects on the structure of the liquids and their thermodynamic properties have to be expected. In particular, it has to be considered to what extend the equilibrium distribution of rotational isomers has been changed compared to that in the gaseous state or in the infinitely diluted solution.

Therefore, those methods which allow the determination of the structure of a single alkane chain at infinite dilution in a simple solvent are firstly described. The extent to which the structure of the chain changes on proceeding to concentrated solutions or pure alkanes is then discussed.

A method widely used to study diluted solutions is the Rayleigh scattering of polarized light. This method is explained in some detail in Figure 3 which shows schematically a single alkane molecule in a momentary, fixed conformation. The incident light has intensity I_0 and wavelength λ, and is polarized in the XY-plane. The scattered light of total intensity I_T is more or less depolarized, *i.e.* the electric vector has amplitudes in the XY- and the XZ-plane. Suitable polarization filters allow the component I_{XZ} of the intensity I_T to be studied separately, *i.e.* the amplitudes of the electric vector of the scattered light in the XZ-plane. I_{XZ} only depends on the differences of the main polarizabilities α_1, α_2, α_3 of the molecule.

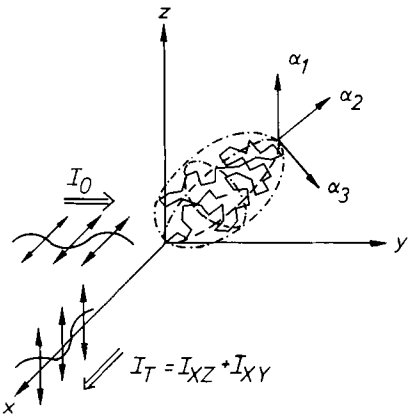

Fig. 3. Scattering of polarized light by a single chain molecule fixed in a momentary conformation (I_0 = incident intensity; I_T = scattered intensity; α_1, α_2, α_3 = main polarizabilities).

The polarizability is defined by the equation $p_i = \alpha_i \cdot E_e$, where p_i is the induced dipole moment in an electromagnetic field of intensity E_e. Optically isotropic molecules with radial symmetry have the same polarizability in all spatial orientations. Optically anisotropic molecules, however, have different polarizabilities α_i in the directions of the three main axis. I_{XZ}, therefore, is a measure of the optical anisotropy and, hence, in general of the anisotropy of the molecular structure. The ellipsoid of polarization enveloping the molecule, as shown in Figure 3, has three main polarizabilities α_1, α_2, α_3 and corresponds to the optical anisotropy of the distinct conformation.

Eq. (2), gives the scattered intensity, and is obtained by averaging all possible orientations of the molecule in space and all possible structures of the rotational isomers[13, 14]:

$$I_{XZ} = \frac{16\pi^4}{\lambda^4} \cdot \rho \cdot I_0 \cdot \frac{1}{15} \gamma^2 \left[\frac{n^2+2}{3}\right]^2 \tag{2}$$

where the molecular optical anisotropy γ^2 is defined by:

$$\gamma^2 = \tfrac{1}{2}[(\alpha_1-\alpha_2)^2 + (\alpha_2-\alpha_3)^2 + (\alpha_3-\alpha_1)^2] \tag{3}$$

In eq. (2), λ is again the wavelength and I_0 the intensity of the incident light *(in vacuo)*, ρ is the particle density of the dissolved molecules which scatter the light, and n is the refractive index of the surrounding medium; n accounts for the effect of the isotropic solvent on the scattered intensity. In order to exclude any effect due to anisotropic contributions from of the solvent, the expression

$$I^*_{XZ}\{(n^2+2)/(n^{*2}+2)\}\{\rho/\rho^*\}$$

has to be subtracted from eq. (2). I^*_{XZ} is the intensity of the corresponding polarized scattered light of the pure solvent, and n^* and ρ^* are its refractive index and density, respectively[15].

The quantitative measure of the anisotropy of a molecule is the molecular optical anisotropy γ^2, which accord-

ing to eq. (3) is the larger the greater the difference between the main polarizabilities of the molecule. Measurements of I_{XZ} yield γ^2 if the other parameters in eq. (2) are known. For a simple molecule like N_2, for example, the two polarizabilities α_1 and α_2 perpendicular to the chemical bond are equal, and the third one, α_3, along the chemical bond is larger ($\alpha_3 > \alpha_1 = \alpha_2$). For a chain molecule like an alkane, however, the α_i-values of each isomeric structure have first to be determined by summation of all the incremental polarizabilities of the C—C and the C—H bonds. The proper average has then to be taken with respect to the equilibrium distribution of all rotational isomers. *Flory*[11] terms this method the "optical valence scheme", which means a theoretical determination of γ^2 is possible, if the following parameters of an alkane chain molecule are known: the angle θ of the C—C—C linkage in the chain, the angle 2ψ of an H—C—H arrangement, the difference ΔE in the energy of the $g^{\pm}$-conformations with respect to the t-conformation, together with the corresponding angle Φ of rotation (compare Fig. 2). Furthermore the differences $\Delta\alpha_{CC}$ and $\Delta\alpha_{CH}$ of the polarizabilities parallel and perpendicular to a C—C and a C—H bond, respectively, must be known. For an alkane chain the following values have been determined: $\theta = 68°$, $\psi = 54.5°$, $\Phi = 120°$, and ΔE 2.9 kJ/mol[14].

The angle θ has been evaluated fairly accurately from electron diffraction measurements on butane to heptane[10]. The values of ψ and Φ are not known with the same accuracy, but it can be shown that small variations in ψ and Φ only influence the theoretical value of γ^2 slightly. On the other hand, the value of γ^2 depends markedly on the values of $\Gamma = (\Delta\alpha_{CC} - 2\Delta\alpha_{CH})$ and of ΔE. Since $\Gamma = 0.54$ Å^3 is a well established value, a fit of the theoretical expression of γ^2 to the experimental values of γ^2 allows ΔE to be determined. It is interesting to note that *Bothorel et al.*[15] obtained best agreement between theoretical and experimental values of γ^2 with $\Delta E = 2.9$ kJ/mol. This is the same result as that obtained from electron diffraction measurements in the gaseous state. This fact confirms the assumption that the conformations of alkanes are essentially the same at infinite dilution in an isotropic solvent like CCl_4 as in the ideal diluted gaseous state.

Now let us turn to the question to what extent the molecular optical anisotropy changes on going from diluted to concentrated solutions or to the pure, liquid alkanes. This problem has been studied extensively by *Bothorel et al.*[15] who performed light scattering experiments with n-alkane/CCl_4 mixtures of various compositions, and used eq. (2) to determine γ^2 in the composition range investigated. Their results are shown in Figure 4. It is obvious that γ^2 increases with increasing alkane concentration. This increase is greater the longer the alkane chain. In principle this behavior could be described by an increase of $\Delta E(t \rightarrow g)$. This would imply that t-conformations are favored energetically because of intermolecular interactions between alkane molecules. The number of t-conformations would have increased relative to the number of the g-conformations, and consequently the molecule should be more extended. Small angle neutron-scattering experiments, however, performed with mixtures of deuterated and protonated alkanes show clearly that the total conformation of an alkane molecule (*e.g. n*-hexadecane) does not change on going from dilute solutions of alkanes in cyclohexane to pure liquid alkanes[16]. Hence the distribution of t- and $g^{\pm}$-sequences within a molecule does not change.

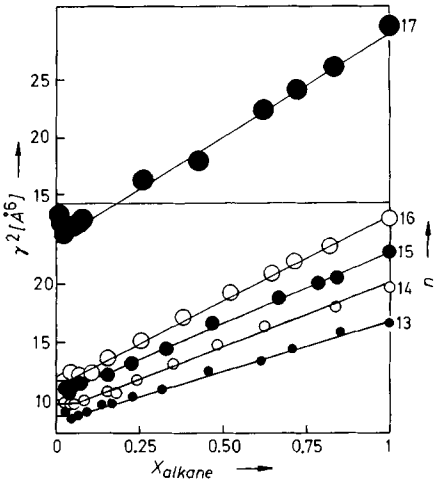

Fig. 4. Molecular optical anisotropy γ^2 of n-alkanes in CCl_4 as a function of mole fraction x [15] (n = number of C atoms).

Accordingly, only very small "ranges of correlation", possibly favoring a parallel orientation of the t-sequences of different molecules with one another, can be responsible for the observed increase in the molecular optical anisotropy. The total shape of a single molecule is not affected. *Kielich*[17] and *Tancrède et al.*[18] have developed a general expression for the average optical anisotropy γ^2_M of a binary mixture, which accounts for the effects of short-range intermolecular interactions:

$$\gamma^2_M = (x_1\gamma^2_{10} + x_2\gamma^2_{20}) + (x_1^2\gamma^2_{10}J_{11} + 2x_1x_2\gamma_{10}\gamma_{20}J_{12} + x_2^2\gamma^2_{20}J_{22}) \quad (4)$$

The contribution to γ^2_M given in the first bracket is due to the different anisotropies γ^2_{10} and γ^2_{20} of the molecules of the two components *1* and *2*, either in the gaseous state or when infinitely diluted in a simple solvent (subscript 0): x_1 and x_2 are the mole fractions of the two components. The term in the second bracket represents the contribution that originates from changes in anisotropy upon mixing because of intermolecular interactions and the correlation of different molecules with one another. J_{ij} is termed the correlation parameter of the molecular optical anisotropy of two molecules i and j. For mixtures of CCl_4 (1) and an n-alkane (2), $\gamma^2_{10} \approx 0$ and $J_{11} = 0$, so eq. (4) reduces to:

$$\gamma^2_M = x_2\gamma^2_{20} + x_2^2\gamma^2_{20}\cdot J_{22} = x_2\gamma^2_{20}(1 + x_2J_{22}) \quad (5)$$

γ^2_M/x_2 corresponds to the optical anisotropy γ^2 represented in Figure 4. The correlation parameter J_{22} of n-alkanes is *ca.* zero up to n-hexane and then increases with increasing chain length. This follows from the dependence of γ^2 on composition, which is linear and increases with $\gamma^2_{20}\cdot J_{22}$ as shown in Figure 4. This increase of optical anisotropy due to segmental, anisotropic interactions between the alkane molecules is called "*C*orrelation of *M*olecular *O*rder" (CMO)[19,20]. CMO occurs particularly with n-alkanes ($n > 6$) and is not observed for corresponding isom-

eric alkanes which are highly branched[21,22]. This is demonstrated in Figure 5 which shows the optical anisotropy γ_{ij} of different isomers of hexadecane, not only at infinite dilution in CCl_4 (γ_{20}^2), but also for the pure alkanes ($\gamma_{22}^2=\gamma_{20}^2(1+J_{22})$; cf. eq. (5) with $x_2=1$). The difference between γ_{20}^2 and γ_{22}^2 increases more and more with decreasing degree of branching on going from 2,2,4,4,6,8,8-heptamethylnonane (i-C_{16}) to n-hexadecane (n-C_{16}). In Figure 5, γ_{ij} is plotted against the ratio $\overline{R^2}/a^2$, where $\overline{R}$ is the average radius of gyration of a molecule and a is the distance between two C atoms.

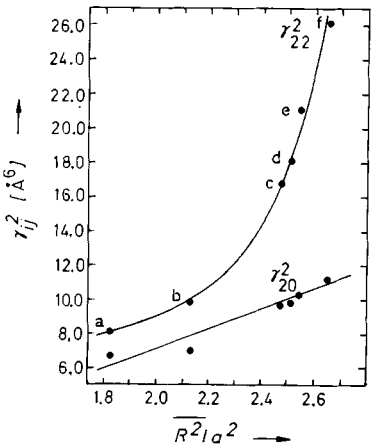

Fig. 5. Molecular optical anisotropy γ_{ij}^2 of isomeric hexadecanes as a function of the ratio $\overline{R^2}/a^2$ ($\overline{R^2}$ = radius of gyration, a = bond length C—C): γ_{20}^2 at infinite dilution in CCl_4; γ_{22}^2 pure hexadecanes. a) 2,2,4,4,6,8,8-heptamethylnonane, b) 6-pentylundecane, c) 6-methylpentadecane, d) 4-methylpentadecane, e) 2-methylpentadecane, f) n-hexadecane [22].

With increasing degree of branching, $\overline{R^2}$ decreases whereas a remains constant, *i.e.* $\overline{R^2}$ is a measure of the geometric anisotropy of the hexadecane molecules, having its largest value for the n-alkane. An increase in $\overline{R^2}$, therefore, is combined with an increase in the optical anisotropy. In fact, at infinite dilution in CCl_4 the corresponding increase of γ_{20}^2 is observed, which is not too marked and nearly linear. $\gamma_{22}^2=\gamma_{20}^2(1+J_{22})$ of the pure alkanes, however, increases considerably more with increasing $\overline{R^2}$, and hence the difference $(\gamma_{22}^2-\gamma_{20}^2)=\gamma_{20}^2\cdot J_{22}$ also increases. This is an immediate effect of the CMO found particularly between the molecules of the non-branched n-alkanes (large values of J_{22}) and only to a small extent between the molecules of highly branched isomers (small values of J_{22}). In the meantime, measurements of the magnetic birefringence performed on n-alkanes dissolved in CCl_4 have clearly confirmed the CMO[23].

IR spectroscopic investigations with liquid n-alkanes and polyethylene carried out by *Snyder*[24] point towards an increased amount of g-conformations at the ends of longer chains of alkanes. Consequently this would imply a change of the conformation of each individual molecule compared to that in the gaseous state or at infinite dilution. Raman spectroscopic investigations[25], however, show no change of the conformation of an alkane chain on going from the pure liquid to infinite dilution in CCl_4. The equilibrium distribution of t- and g-sequences within a molecule is essentially the same in both cases, since the Raman spectra are not altered (cf. also [23]). Only a variation in temperature results in a change in the Raman spectra, *i.e.* the characteristic frequencies and intensities are changed, because of conformational changes. At lower temperatures in the solid state, the alkanes are almost completely arranged parallel to one another, *i.e.* more or less only all-*trans* conformations are present. This has been established from the increased amount of longitudinal acoustic modes in the Raman spectra of all-*trans* n-alkane chains[26,27]. For the liquid state, discussed here, spectroscopic investigations confirm the conclusion already deduced from small angle neutron-scattering experiments: At a given temperature the CMO does not affect the total conformation of a chain, but represents short-range orientational order between a few neighboring chain segments of different molecules.

In general, it is not possible to predict *a priori*, how the CMO affects the macroscopic behavior of n-alkanes. In the following, the effects on the thermodynamic properties of these liquids are mainly discussed.

4. Thermodynamic Investigations

The importance of thermodynamic properties of alkane mixtures in technical applications has already been emphasized. Therefore, the thermodynamic properties of mixing alkane mixtures will now be discussed. A thermodynamic mixing property ΔZ_M of a binary mixture in general is given by:

$$\Delta Z_M = Z_M - x_1 Z_1 - x_2 Z_2 \qquad (6)$$

The property Z may be: the molar enthalpy H, the molar entropy S, the molar volume V, the molar internal energy U, the molar free energy F, or the molar free enthalpy G, *etc.* ΔZ_M is the difference between Z_M of the mixture (index M) and the contributions to Z of the pure components (indices 1 and 2); x_1 and x_2 are the mole fractions. ΔG_M, the free enthalpy of mixing, for example, can be used to determine the chemical potentials μ_1 and μ_2, which must be known for calculations of phase equilibria. As is well known, two phases are in thermodynamic equilibrium with each another, if the chemical potential of any component is the same in both phases.

Figure 6 shows experimental results for the molar enthalpy of mixing (ΔH_M) of some mixtures of n-alkanes and their branched isomers with cyclohexane. These results have been obtained using a new type of flow calorimeter[28,29]. In Figure 7, corresponding experimental data of the molar volume of mixing (ΔV_M) are shown[30], which have been determined from very precise density measurements[30]. It is noticeable on the one hand that ΔH_M and ΔV_M increase with increasing length of the n-alkane chain, and on the other that ΔH_M and ΔV_M are significantly smaller for those mixtures with branched isomers (*e.g.* i-C_{16}) compared to mixtures of the corresponding n-alkanes (*e.g.* n-C_{16}). A similar effect has been observed for the molar entropy of mixing, ΔS_M. The values ΔS_M of various isomeric alkanes mixed with cyclohexane (c-C_6) at equimolar composition are shown in Figure 8 as a function of the

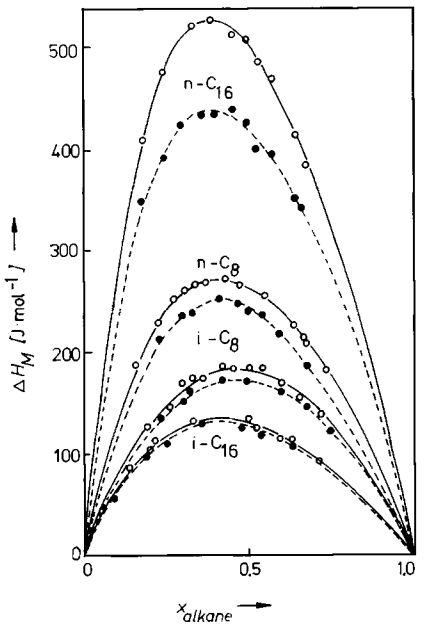

Fig. 6. Experimental molar enthalpy of mixing ΔH_M for mixtures of cyclohexane and isomeric alkanes as a function of the mole fraction x_{alkane} at 298.15 K (—, o) and at 313.15 K (---, •) at 1 bar [28] (i-C_8 = 2,2,4-trimethylpentane).

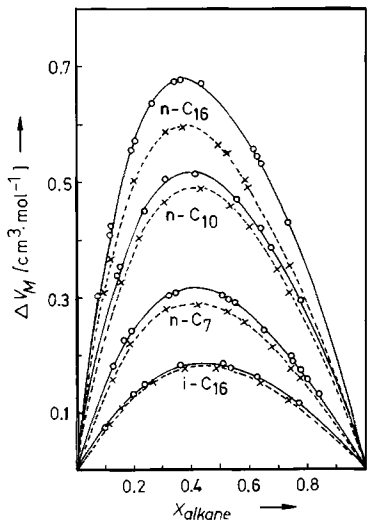

Fig. 7. Experimental molar volume of mixing ΔV_M for mixtures of cyclohexane and isomeric alkanes as a function of the mole fraction x_{alkane} at 298.15 K (—, o) and at 313.15 K (---, ×) [29].

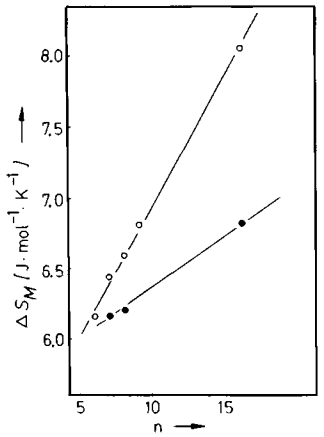

Fig. 8. Experimental molar entropy of mixing ΔS_M for equimolar mixtures of cyclohexane and isomeric alkanes as a function of the number n of C atoms: o n-alkanes, • isomeric alkanes (cf. text) [31].

number of carbon atoms n. It is clear that ΔS_M increases more markedly with n for n-alkanes than for the corresponding branched isomers. The ΔS_M data were obtained from measurements of the vapor pressure of the mixtures[31] from which the molar free energy of mixing (ΔG_M) was initially determined. The Helmholtz relationship $\Delta G_M = \Delta H_M - T\Delta S_M$ immediately yields ΔS_M, since ΔH_M is already known.

Investigations carried out by other groups have produced similar patterns[32-34], confirming a general conclusion, thus: For mixtures of globular molecules, like *e.g.* cyclohexane, CCl_4, or 2,2-dimethylbutane with higher n-alkanes (starting from n-hexane) ΔH_M and ΔS_M increase significantly with chain length, whereas for mixtures with higher branched isomers of these alkanes ΔH_M and ΔS_M are considerably smaller and increase only slightly with the number of C atoms. This effect increases with the degree of branching of the alkane. This is demonstrated in Figure 9[22], for example, with mixtures of 2,2-dimethylbutane and

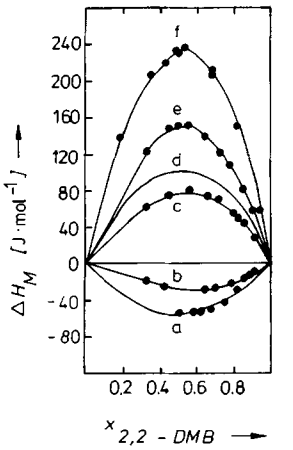

Fig. 9. Experimental molar enthalpy of mixing ΔH_M for mixtures of 2,2-dimethylbutane (2,2-DMB) and isomeric hexadecanes as a function of mole fraction x: a)-f) as in Fig. 5; no experimental data are shown for 4-methylpentadecane [22].

various isomeric hexadecanes: with decreasing degree of branching of the n-alkane, ΔH_M increased markedly extending even from negative to positive values.

It is surprising and important to known how significantly different the thermodynamic properties can be for mixtures of isomeric alkanes with the same solvent. Will it be possible to explain this phenomenon with a molecular, thermodynamic theory, which starts from the intermolecular interactions and structures of the molecules? Are there any correlations between the thermodynamic behavior and those structural changes of the n-alkanes in solution with concentration deduced from light-scattering data?

5. Molecular Theory of Alkane Mixtures

One of the most successful theories of the thermodynamic properties of mixtures of chain-like molecules or, more generally, of molecules differing significantly in shape and size is the one first developed by *Prigogine et*

al.[35], later improved by *Flory et al.*[36-38], and finally presented in a more general form by *Patterson et al.*[39]. It is commonly called the Flory theory and its essential physical principles will be briefly discussed.

The macroscopic volume of a liquid is envisaged to be divided up into single cells, each one occupied by one molecule. This conception is based upon the fact that the structure of a liquid is closely related to that of a solid. For chain-like molecules—linear or branched—each segment of a chain occupies a cell. It is not necessary to exactly define the absolute size of a segment (*e.g.* a —CH_2—CH_2- group). For mixtures of chain molecules (*e.g.* alkanes) with a simple molecule (*e.g.* CCl_4, cyclohexane) Figure 10 gives the corresponding representation of a possible molecular arrangement. The cell model of the liquid state is rather outdated for discussing the behavior of simple molecules and their mixtures. For chain molecules, however, and for flexible, complicated molecules and their mixtures, in general, the modern version of this model still represents the statistical fundamentals of the theoretical calculation of mixing properties[36-39].

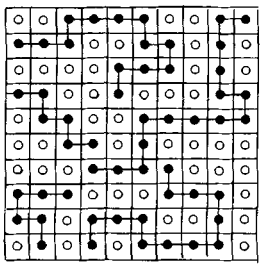

Fig. 10. A "lattice mixture" of chain molecules and simple molecules.

The calculation of thermodynamic behavior usually starts from the free energy F of the pure component or the mixture. For that purpose the following three assumptions are made:

1. Each molecule and each segment have a hard-core volume v^* per cell. The hard cores of the segments of different molecules i and j interact with one another with an attractive potential $-\eta_{ij}/v$, which only extends to the next nearest neighbors of a particular segment; v is the volume of the liquid and the constant of proportionality η_{ij} characterizes the interaction between i and j. In a binary mixture there are three types of such interactions, *i.e.* between segments of molecules of the same kind (η_{11}, η_{22}) and of different kind (η_{12}).
2. The segments of the chain molecules are randomly distributed within the cells, *i.e.* all possible arrangements of the molecules in the mixture are equally probable. It therefore follows that the probability of 1-1 contact with the interaction parameter η_{11} or of 2-2 contact with η_{22} is proportional to the probability of finding two segments of type 1 or 2 neighboring each another, *i.e.* proportional to φ_1^2 or φ_2^2 which are the squares of the probabilities φ_1 or φ_2 of finding a segment of type 1 or 2 in a particular cell. The values of φ_1 and φ_2 are identical with the segment fractions for the two types of molecules:

$$\varphi_1 = \frac{x_1 r_1 v^*}{x_1 r_1 v^* + x_2 r_2 v^*} = 1 - \varphi_2 \tag{7}$$

where x_i is the mole fraction and r_i is the number of segments of a molecule of type i (in the binary case considered here i = 1, 2); $r_i v^*$ is the hard-core volume of one molecule i; the abbreviation

$$V_i^* = r \cdot v^* \tag{8}$$

is used.

3. The third prerequisite concerns the flexibility of the segments within their cells. A single molecule consisting of one segment only ($r_i = 1$) has three degrees of freedom to move around within its cell (translational degrees of freedom). The volume available for unrestrained motion, the free volume v_f, is given by const. $(v^{1/3} - v^{*1/3})^3$. Since the diameter of a segment is proportional to $v^{*1/3}$, the distance between the centers of two neighboring segments is proportional to $v^{1/3}$, and hence the third power of the difference is proportional to v_f. A chain segment does not have three degrees of freedom, as it is chemically bonded to neighboring segments, and thereby is constrained in its motion within its cell. This effect is accounted for by $v_f = \text{const.}(v^{1/3} - v^{*1/3})^{3c}$, where $c < 1$. The smaller the value of c, the more rigid and inflexible is a chain molecule. The general expression for the free energy F_M of a mixture of chain molecules is then given by:

$$\begin{aligned} F_M = &-(A_{11}\eta_{11} + A_{22}\eta_{22} + A_{12}\eta_{12})/v_M \\ &+ T[3kN\bar{r}\bar{c}\ln(v_M^{1/3} - v^{*1/3}) + k\ln W_M] \\ &+ \text{const.} \end{aligned} \tag{9}$$

In the first term, A_{ij} signifies the number of contacts between segments of type i and j in the mixture. Multiplication of these values by η_{ij} and division of the whole term by v_M, the molar volume of the mixture, yield the internal energy U_M of the mixture. The contribution given in the term in square brackets is the entropy S_M of the mixture, corresponding to $F_M = U_M - TS_M$. S_M contains the free volume v_{fM} of the mixture and the number W_M of distinguishable distributions of all chain molecules within all cells: $\bar{r}$ and $\bar{c}$ are the average values of the number of segments per molecule in the mixture, and of the flexibility parameter c of the mixture, respectively. A_{ij}, W_M, $\bar{r}$, and $\bar{c}$ depend on the mole fraction x_i or the segment fraction φ_i of the mixture[37]. The constant "const." contains internal degrees of freedom such as molecular vibrations and depends on the temperature only. In order to calculate the volume v_M of the mixture the known relation $(\partial F/\partial V)_T = P$ (P = pressure) is applied to eq. (9) yielding the thermal equation of state which then can be used to calculate v_M at a given P and T.

For $x_1 = 1$ or $x_1 = 0$ the free energy F of the pure components is obtained from eq. (9) and insertion into eq. (6) gives the following expression[37]:

$$\Delta F_M = \Delta U_M - T\Delta S_M \tag{10}$$

$$\Delta U_M = (V_1^* x_1 + V_2^* x_2)\left\{(\tilde{v}_1^{-1} - \tilde{v}_M^{-1})\varphi_1 P_1^* + (\tilde{v}_2^{-1} - \tilde{v}_M^{-1})\varphi_2 P_2^* + \varphi_1\varphi_2\left(\frac{s_2/s_1}{\varphi_1 + s_2/s_1\varphi_2}\right)\frac{X_{12}}{\tilde{v}_M}\right\} \quad (11)$$

$$\Delta S_M = -k[N_1 \ln\varphi_1 + N_2 \ln\varphi_2] - 3\sum_{i=1}^{2}\frac{N_i V_i^*}{T_i^*}\ln\left(\frac{\tilde{v}_i^{1/3}-1}{\tilde{v}_M^{1/3}-1}\right) \quad (12)$$

$$\Delta V_M = (V_1^* \cdot x_1 + V_2^* x_2)(\tilde{v}_M - \varphi_1\tilde{v}_1 - \varphi_2\tilde{v}_2) \quad (13)$$

$$\Delta H_M = \Delta U_M - P\Delta V_M \quad (14)$$

$$\Delta G_M = \Delta H_M - T\Delta S_M \quad (15)$$

The abbreviation $\tilde{v}_i = v_i/V_i^*$ has been used in eq. (11)—(15). The parameters P_i^* have the dimensions of pressure and are proportional to η_{ii}; the quantities T_i^* have the dimensions of temperature and are defined as:

$$T_i^* = \frac{P_i^* v^*}{k c_i} \quad (16)$$

Another important definition is that of X_{12}:

$$X_{12} = \frac{s_1}{2v^{*2}}(\eta_{11} + \eta_{22} - 2\eta_{12}) \quad (17)$$

The parameters s_i are given as the ratio surface/volume of the hard cores. To some extent they are a measure of the compactness of a molecule.

Without discussing the derivation of these equations, the following general statements can be made: The energy of mixing, ΔU_M, given by eq. (11), is the sum of two contributions. The first term, the interaction-energy term with X_{12} contains the pair-interaction parameter η of the mixture multiplied by $\varphi_1\varphi_2$. This term causes ΔU_M to have the typical, parabolic composition dependence which is in fact observed experimentally. The second term is the equation of state term accounting for the difference of the free volumes of the pure components and the mixture. The second contribution usually is small compared to the first and takes into account the changes of volume upon mixing and the corresponding effects on ΔU_M.

The entropy of mixing also contains two contributions. The first term with $\ln\varphi_i$ is the combinatorial entropy, which takes into account the number of distinguishable distributions of all molecules of the mixture within all cells, reduced by the corresponding number of the pure components. This combinatorial entropy was first derived by *Flory* and *Huggins*[40,41].

The second contribution to ΔS_M is again the equation of state term which contains the logarithmic difference of the free volumes of the mixture and the pure components, and which is usually small compared to the combinatorial contribution.

The enthalpy of mixing ΔH_M differs from ΔU_M only by the additional term $P\Delta V_M$ which is negligible at ambient pressures, but plays a major role at high pressures.

For practical application of these theoretical expressions of the mixing properties it is important that all parameters of the pure components, like V_i^*, c_i, v_i, s_i, and P_i^*, be obtained by fitting the theoretical thermal equation of state to experimental data of the pure components. The thermal expansion coefficient and the compressibility, for example, are suitable for such a fitting procedure. Hence, the theoretical expressions of the mixing properties are already formed "in the trend of the problem" for any particular mixture. X_{12} is the only adjustable parameter. This is one of the reasons for the success of the Flory theory, *i.e.* using only one adjustable parameter (X_{12} to obtain a good representation of the mixing properties for a wide range of mixtures of chain molecules and polymer solutions. As a molecular property the parameter X_{12} must be independent of composition, temperature and pressure.

The significance of successful molecular theories, like the Flory theory just discussed, is given by the fact that thermodynamic mixing properties (*e.g.* ΔG_M), the chemical potentials of each component in a mixture and hence phase equilibria can be calculated knowing just the interaction parameter X_{12}. It is not necessary to have additional experimental data, whose determination usually is very time consuming and quite expensive.

6. Orientational Correlation (CMO) in Alkane Mixtures

To examine the applicability and consistency of the Flory theory values of X_{12} obtained by fitting the theoretical expression of ΔH_M to experimental ΔH_M data will be discussed. Values of X_{12} determined in this way for mixtures of cyclohexane and various alkanes of different chain length and different degree of branching are plotted against the number n of C atoms per molecule in Figure 11[29,32].

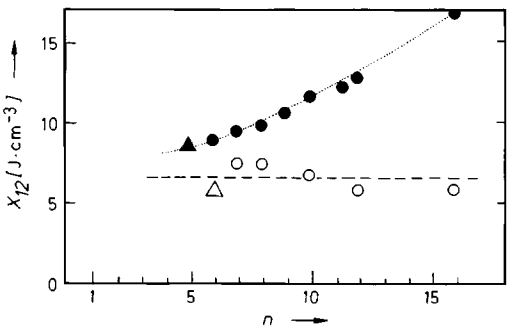

Fig. 11. Parameter X_{12}, determined from the compositional dependence of ΔH_M for mixtures of cyclohexane and isomeric alkanes as a function of the number n of C atoms at 298.15 K; ○, ● [29]; △, ▲ [32]; ●, ▲ *n*-alkanes; ○, △ branched alkanes (see text).

The following branched alkanes were investigated: *i*-C_6: 2,2-dimethylbutane, *i*-C_7: 2,2-dimethylpentane, *i*-C_8: 2,2,4-trimethylpentane, *i*-C_{10}: 2,6-dimethyloctane, *i*-C_{12}: 2,2,4,6,6-pentamethylheptane, *i*-C_{16}: 2,2,4,4,6,8,8-heptamethylnonane.

For mixtures containing *n*-alkanes X_{12} increases significantly with n, whereas it remains practically constant for those mixtures containing the branched alkanes. With short chains (small n) the difference in X_{12} between the two types of mixtures is small.

This result points towards the following discrepancy in the Flory theory: According to eq. (17), X_{12} represents the difference of the segmental interaction parameters η_{ii}.

Therefore, the values of X_{12} should vary only slightly in going from *n*- to branched alkanes. The intermolecular interactions between a methylene group and a CH_3 or $>CH$ group are expected to be fairly similar if the molecules are somewhat arbitrarily distributed in such segmental groups. A molecular interpretation of the results shown in Figure 11, however, would require a distinct difference in the interactions between the different segmental groups, which contradicts all plausible, physical arguments on the different interactions between chemically similar groups[32].

It is, therefore, reasonable to explain these discrepancies of the theory in terms of the molecular orientational correlations present between *n*-alkane molecules previously determined in light-scattering experiments, *i.e.* the parameter X_{12} has to be separated into two parts: one denoted X_{12}^{∞}, is independent of orientation and is the same for mixtures of *n*-alkanes or branched alkanes with cyclohexane, and the other which depends on orientation:

$$X_{12} = X_{12}^{\infty} + X_{12}(\mathrm{CMO}) \tag{18}$$

Comparison of Figure 11 and Figure 5 suggests a direct relationship between the behavior of γ^2 and X_{12}, and this has been formulated empirically[18]:

$$X_{12}(\mathrm{CMO}) = \mathrm{const.}\,\Delta J_{12} \tag{19}$$

where

$$\Delta J_{12} = \tfrac{1}{2}(J_{11} + J_{22}) - J_{12} \tag{20}$$

In case of alkane/cyclohexane (or CCl_4) mixtures $J_{11} = 0$ and hence $\Delta J_{12} = (J_{22}/2) - J_{12}$.

The introduction of CMO forces constitutes an extension of the Flory theory making it possible to rationalize the light-scattering results and the distinct differences in ΔH_M observed for isomeric alkane/cyclohexane mixtures: Upon mixing an *n*-alkane with a globular molecule, like cyclohexane, CCl_4 or 2,2-dimethylbutane, the partial parallel orientation of chain segments favored energetically in pure *n*-alkanes is destroyed. This results in a decrease in the optical anisotropy γ^2 and in an unusually large positive enthalpy of mixing ΔH_M. In comparison, γ^2 changes only slightly, and ΔH_M is much smaller for mixtures of isomeric branched alkanes with cyclohexane (or CCl_4), since there is practically no orientational order to be destroyed during the mixing process.

So far only a few examples of how CMO influences ΔH_M have been presented. This effect has been confirmed by further calorimetric investigations, *e.g.* for mixtures of *n*-alkanes and branched alkanes with tetrabutyltin, a molecule which is also of globular shape[42]. The equimolar ΔH_M is *ca.* 350 J/mol for tetrabutyltin + *n*-hexadecane, whereas for the mixture tetrabutyltin + 2,2,4,4,6,8,8-heptamethylnonane a value of -40 J/mol is observed. This is a significant indication that CMO exists in liquid *n*-hexadecane. Further investigations, confirming the CMO, have been performed with mixtures of squalane (2,6,10,15,19,23-hexamethyltetracosane) and other branched and nonbranched alkanes. Mixtures of branched alkanes with squalane exhibit small, sometimes negative values of ΔH_M, whereas mixtures of *n*-alkanes with squalane clearly exhibit positive, sometimes quite large values of ΔH_M[33]. CMO has been observed even for alkane chains separated by oxygen atoms, *i.e.* dialkyl ethers[43]. Ethylene-propylene copolymers show increasing CMO with increasing amounts of ethylene, *i.e.* with decreasing number of methyl side groups in the main polymer chain[44].

CMO, identified in the first instance by light-scattering experiments, also has a significant effect on the thermodynamic mixing properties. The effects caused by CMO cannot be studied using spectroscopic methods. This clearly shows that very careful investigations of thermodynamic properties are important for a more complete understanding of CMO. In particular, the question arises whether it is possible to give a quantitative description of CMO and consequently whether the influence of CMO on the thermodynamic mixing properties can be calculated.

7. Quantitative Formulation of CMO; Dependence of ΔH_M on Temperature and Pressure

The origin of those forces which are orientationally dependent and cause the CMO probably lie in sterically favored packing phenomena of the *n*-alkane chains which cause the an-isotropic segments to be brought closer to one another, thereby increasing the attractive interaction. In 1979 *Flory* published a semiquantitative theory of the parameter J_{22} characterizing the segmental orientational correlation within alkanes[45]. This theory shows that only steric packing phenomena with a correlation range of about seven segments determine the obtained values of J_{22}. *Vacatello et al.*[46] simulated the CMO using a computer model for liquid *n*-alkanes and found that the CMO has an effect only over short distances, *i.e.* it is limited, more or less, to next nearest neighbors.

With the existance of interactions depending on orientation, an effective dependence of the parameter X_{12} on temperature and pressure has to be expected, which contradicts the assumptions of the original Flory theory. The extension of the theory to take this into account is now discussed *via* the temperature dependence of the mixing properties of mixtures of alkanes and cyclohexane.

For mixtures of *n*-alkanes and cyclohexane, a significant decrease of ΔH_M with increasing temperature has to be expected. The CMO for pure *n*-alkanes is not large at higher temperatures because of thermal motion, and therefore less order is destroyed upon mixing with cyclohexane, *i.e.* less energy has to be supplied during the mixing process. The measure of the dependence of ΔH_M on temperature is the molar heat capacity of mixing:

$$\Delta C_{PM} = \left(\frac{\partial \Delta H_M}{\partial T}\right)_P \tag{21}$$

Negative values of ΔC_{PM} are expected experimentally for *n*-alkane/cyclohexane mixtures. In fact this conclusion is confirmed by the results shown in Figure 12: *n*-C_{16}/*c*-C_6 exhibits strongly negative values of ΔC_{PM}, whereas the values for *i*-C_{16}/*c*-C_6 are small and close to zero, since no CMO is present within the *i*-C_{16}. The data were measured with a Picker micro-flow calorimeter[47,48]. Mixtures con-

taining C_{16} isomers with an intermediate degree of branching fall between these two extreme cases. The curves calculated, using the Flory theory with X_{12} determined from ΔH_M at 25 °C, reproduce the experimental results of *i*-C_{16}/*c*-C_6 in sign and order of magnitude, whereas for *n*-C_{16}/*c*-C_6 values of ΔC_{PM} which are too small are predicted. If the CMO effect is present, the Flory theory fails.

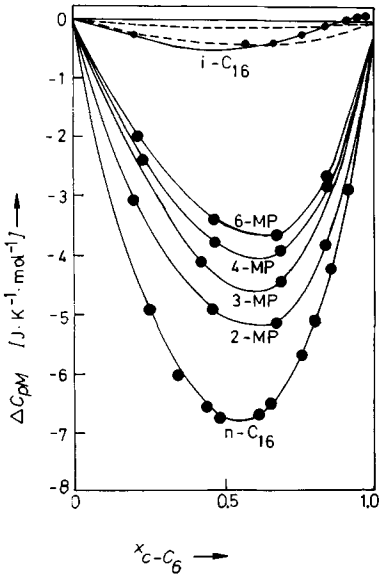

Fig. 12. Experimental molar heat capacity of mixing ΔC_{PM} for mixtures of cyclohexane and isomeric hexadecanes as a function of mole fraction x at 298.15 K; *i*-C_{16} (see text), MP = methylpentadecane; (----) *c*-C_6+*i*-C_{16} (top curve) and *c*-C_6+*n*-C_{16} (bottom curve) calculated with the Flory theory without taking CMO into account [48].

The values of X_{12} determined from ΔH_M data at 25 and 40 °C and given in Table 1 show why: the parameter X_{12} decreases with increasing temperature for the *c*-C_6/*n*-alkane mixtures, whereas it remains practically constant for the *c*-C_6/*c*-C_6 systems. This observation contradicts the Flory theory, which assumes the molecular parameter X_{12} to be independent of temperature.

Table 1. Parameters X_{12} and T_0 at 1 bar.

Mixture	X_{12} (25 °C) [J cm^{-3}]	X_{12} (40 °C) [J cm^{-3}]	T_0 [K]
c-C_6+*n*-C_6	8.8	8.2	180
c-C_6+*n*-C_{10}	11.3	9.8	226
c-C_6+*n*-C_{12}	12.5	10.6	235
c-C_6+*n*-C_{16}	16.5	14.1	232
c-C_6+*i*-C_{10}	6.4	6.2	—
c-C_6+*i*-C_{12}	5.3	5.1	—
c-C_6+*i*-C_{16}	5.2	5.0	—

A recently developed high-pressure flow calorimeter now makes it possible to measure the dependence of ΔH_M of liquid mixtures at pressure up to 600 bar[49–53]. Figure 13 shows results for the system *n*-C_{12}/*c*-C_6. The compositional dependence of the difference ΔH_M(high pressure) − ΔH_M(1 bar) = $\Delta(\Delta H_M)$ is given for several pressures. ΔH_M increases significantly with increasing pressure, namely ≈30 J/mol at the curve maximum for a change in pressure of 300 bar. This is *ca.* 8% of the absolute value of 361 J/mol measured for the equimolar mixture at 1 bar. The theoretical curves calculated with the Flory theory using a constant X_{12} obtained from the measurements at 1 bar predict a completely different dependence on pressure whose sign is wrong for both 180 and 291 bar. Agreement between theory and experiment is only possible when larger values of X_{12} at higher pressures are selected. Table 2 contains values of X_{12} for all systems investigated. The results also indicate that X_{12} is practically independent of pressure for mixtures of branched alkanes with cyclohexane.

Table 2. Parameters X_{12} and T_0 at 298.15 K.

Mixture	X_{12} (1 bar) [J cm^{-3}]	X_{12} (300 bar) [J cm^{-3}]	T_0 (300 bar) [K]
c-C_6+*n*-C_6	8.8	9.5	188
c-C_6+*n*-C_8	9.7	10.7	217
c-C_6+*n*-C_{12}	12.5	14.0	240
c-C_6+*n*-C_{16}	16.5	18.5 [a]	239 [a]
c-C_6+*i*-C_8	7.2	7.2	—
c-C_6+*i*-C_{16}	5.2	5.3 [b]	—
n-C_6+*n*-C_8	0.4	0.4	—
n-C_6+*n*-C_{10}	1.3	1.4	—

[a] Extrapolated from data at 180 bar. [b] Indirectly determined from ΔV_M data in [30].

To overcome these inconsistencies of the theory to predict the dependence on temperature and pressure of the thermodynamic properties of *n*-alkane/cyclohexane mixtures, the CMO has to be incorporated: the following considerations indicate how this can be achieved[52,53]: The motion of the $N \cdot r$ segments of the chain molecule in the liquid state corresponds to $3 \cdot N \cdot r \cdot c$ degrees of freedom ($c < 1$), *i.e.* the liquid is regarded as one containing $N \cdot r \cdot c$ quasi-free segments. Intermolecular forces, which not only depend on the intermolecular separation but also on the relative orientation causing structural order (CMO), act between these quasi-free segments of the *n*-alkanes. The molecular motion is hindered due to orientational correla-

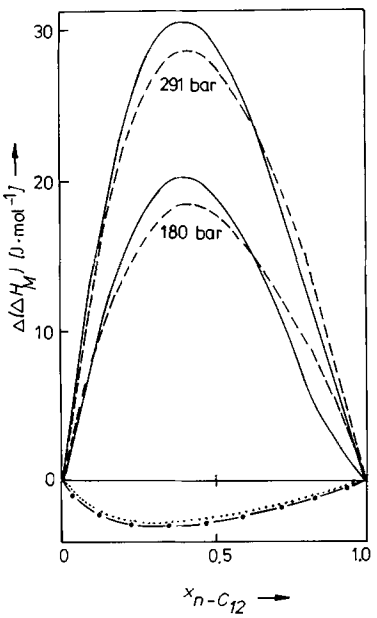

Fig. 13. Effect of pressure on the compositional dependence of ΔH_M for mixtures of cyclohexane and *n*-dodecane. $\Delta(\Delta H_M) = \Delta H_M(P) - \Delta H_M$(1 bar); (—) experimental (---) Flory theory with X_{12} dependent on pressure, (-·-·-) and (·····) Flory theory with X_{12} from 1 bar [52].

tion. The situation is completely analogous to the well-known phenomenon of orientational transitions of simple molecules in the solid state[54]. Figure 14 shows schematically how the particular orientation of an arbitrarily chosen particle (quasi-free segment or single molecule) has an orientational effect on neighboring particles. At larger

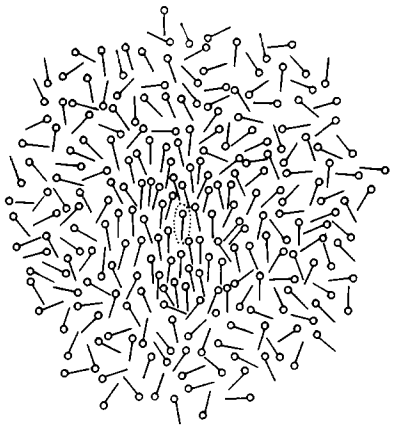

Fig. 14. Symbolic representation of an orientational correlation.

distances there is no correlation between central and remote particles. The range of orientational correlation is therefore limited to a distinct number N^* of neighboring particles which is much smaller than Avogadro's number. At low temperature the orientational order is pronounced; with increasing temperature this is destroyed more and more. Hence the typical character of a cooperative transition is observed where the transition between the more or less ordered state and the completely disordered state occurs within a relative narrow temperature range. Figure 15

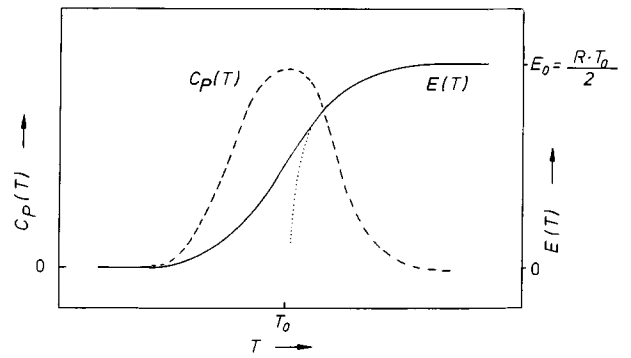

Fig. 15. Schematic representation of the transition energy $E(T)$ and the corresponding molar heat capacity $C_p(T)$ as a function of temperature [52].

shows schematically the temperature dependence of the energy E involved in this transition. E_0 is the total energy necessary to go from the completely ordered to the completely disordered state. The temperature dependence of the corresponding molar heat capacity C_p is also shown. C_p passes through a maximum at the pseudotransition temperature T_0. Above T_0 the dependence of E on temperature can be described as [52–54]:

$$E(T) = \frac{RT_0}{2}\left[1 - \frac{1}{N^*}\frac{T}{T-T_0}\right] \tag{22}$$

The curve from eq. (22) is shown in Figure 15 as the dotted line, and represents the temperature-dependence of the interactions with orientation.

For the chain segments of the *n*-alkanes this signifies that in addition to η_{ii}, an interaction parameter $b_{ii}(T)$—which depends on the orientation and thereby on the temperature must be included. For mixtures of *n*-alkanes with cyclohexane (2) $b_{22} = b_{12} = 0$ since pure liquid cyclohexane, being a globular small molecule, has no structural order. Hence, X_{12} can be formulated as [52,53]:

$$X_{12} = X_{12}^{\infty}\left(\frac{T}{T-T_0}\right) \tag{23}$$

X_{12}^{∞} contains, according to eq. (17), the difference of the η parameters and is independent of temperature and pressure. The second factor in eq. (23) describes the temperature dependence of the interactions containing the pseudotransition temperature T_0. A similar expression has been derived by *Bendler*[55] in a completely different way, by examining the applicability of a theory of structural transitions to the phases of liquid crystals[56].

According to eq. (23), X_{12} decreases with increasing temperature as is expected from the CMO effect and also observed experimentally (cf. Table 1). X_{12} data at different temperatures can be used to determine X_{12}^{∞} and T_0 in eq. (23). For all alkane/cyclohexane systems the values of X_{12}^{∞} are 3–4 J/cm^3, *i.e.* they are fairly constant. This is understandable physically, since X_{12}^{∞} is dependent only on the η-values which are not expected to vary for different alkanes. Values of T_0 are also given in Table 1 and lie in the region of, or slightly below, the melting points of the *n*-alkanes. It is of interest that transitions below the melting point have been observed for *n*-alkanes[57–60].

These considerations with respect to the CMO can be tested with the experimental temperature-dependence of the molecular optical anisotropy. γ_{22}^2 is the optical anisotropy of the pure, liquid alkanes, *i.e.* in this case CMO is present; γ_{20}^2 is the value at infinite dilution in an isotropic solvent, *i.e.* CMO is absent. Assuming X_{12} to be proportional to γ_{22}^2 and X_{12}^{∞} to be proportional to γ_{20}^2, with the same constant of proportionality in both cases, eq. (23) yields:

$$\gamma_{22}^2 = \gamma_{20}^2\left(\frac{T}{T-T_0}\right) \tag{24}$$

This relationship was used by *Dettenmaier et al.*[61] and *E. W. Fischer et al.*[23] to describe the temperature dependence of γ_{22}^2 determined experimentally by light scattering. For *c*-C_6/*n*-C_{12} and *c*-C_6/*n*-C_{16} values of T_0 which agree surprisingly well with the values given in Table 1 were found, thus confirming the temperature-dependent effect of the CMO.

The increase of X_{12} with pressure observed for *n*-alkane/cyclohexane mixtures (cf. Table 2) can be explained using eq. (23). As X_{12}^{∞} is constant, T_0 must increase with pressure if X_{12} increases ($T_0 < T$!). According to eq. (22) E_0, the energy necessary for complete destruction of order within the *n*-alkanes, also increases. This is exactly what is expected, since the higher the pressure, the closer the molecules are packed together, the stronger is the CMO, and the larger is

the transition energy. Table 1 and Table 2 indicate an increase in T_0 of about 8 K per 300 bar for *n*-alkane/cyclohexane mixtures. Orientational transitions observed in the solid state show similar behavior for the pressure-dependence of the transition temperature[59].

Recent Raman spectroscopic investigations at high pressures[62] show a decrease of the all-*trans* conformation and a general decrease of *t*- in favor of *g*-sequences for *n*-alkanes. Consequently, the chain assumes a more globular shape with increasing pressure. This result by no means contradicts the increase of CMO with increasing pressure, since Raman spectra are only affected by changes in the conformation of the total molecule. Changes of short-range intermolecular segmental correlations (*e.g.* the CMO) do not change the Raman spectra.

Eq. (23) is only valid for mixtures of chain molecules exhibiting CMO with small globular molecules without CMO. For mixtures of globular molecules with one another, X_{12} should remain constant. The examples *c*-C_6/CCl_4 and *c*-C_6/*i*-C_8 in Table 2 confirm this conclusion. Also if both components of a mixture exhibit approximately the same CMO, X_{12} should remain constant since the CMO remains constant in the mixture. The CMO effects of both components are mutually compensated (cf. eq. (20) with: $(J_{11}+J_{22})/2=J_{12}$). The values of X_{12} of the mixtures *n*-C_6/*n*-C_8 and *n*-C_6/*n*-C_{10} given in Table 2 reflect this behavior. For all mixtures lying between the extremes of complete destruction or retention of the CMO, it should be possible to derive a general relation for X_{12} by means of the theory developed.

So far the CMO theory has been applied exclusively to ΔH_M. The temperature dependence of X_{12} given by eq. (23) also significantly improves the description of ΔV_M of *n*-alkane/cyclohexane mixtures at various temperatures[30]. The same holds for the description of the entropy of mixing shown in Figure 8. The original Flory theory is only satisfactory for mixtures of branched alkanes with cyclohexane. The prediction of ΔS_M for *n*-alkane mixtures is much better with the CMO model.

The free enthalpy of mixing (ΔG_M) is the same for mixtures of linear or branched alkanes with cyclohexane. The CMO contributions to ΔH_M and $T\Delta S_M$ compensate one another in calculating ΔG_M[31,34]. This effect has also been found for activity coefficients of linear and branched alkanes at infinite dilution in a long-chain alkane with CMO [*e.g.* C_{18}, C_{36}] determined by gas chromatography. The activity coefficients of mixtures containing isomers are practically unchanged, because the CMO effects ΔH_M and ΔS_M producing mutual compensation.

To what extent the quantitative model of the CMO is applicable has not yet been proved. However, at high temperatures and low densities the theory developed is definitely limited, since even the basic assumptions of the Flory theory are only justified for liquid-like densities. Proper extension of the theory to larger temperature and pressure ranges has still to be undertaken.

8. The Effect of Steric Hindrance

For mixtures of long-chain *n*-alkanes with globular molecules like CCl_4, cyclohexane, or 2,2-dimethylbutane a significant contribution of the CMO to the thermodynamic mixing properties must always be expected. The contribution increases with chain length and with decreasing branching of the molecule. However, this order-breaking effect of globular molecules is not always the only additional contribution to ΔH_M and ΔS_M. This is shown by new results for mixtures of *n*-hexadecane with highly branched isomeric nonanes[18,65]. The globular isomers should destroy order in the *n*-C_{16}, and considerably positive ΔH_M and considerably negative ΔC_{pM} are, therefore, expected, by analogy to the mixture *n*-C_{16}/*c*-C_6. The results in Table 3, however, show that quite different, sometimes very low values of ΔH_M are obtained for mixtures of different, but similarly branched nonanes with *n*-hexadecane. For mixtures with *n*-octane the values are even lower, and may be significantly negative. Accordingly, the corresponding values of X_{12} are about zero or negative (*e.g.* $X_{12}=-2.4$ J/cm^3 for 3,3-diethylpentane/*n*-C_8[65]). Again at variance to expectations, ΔC_{pM} is found to be positive for some of these systems (*e.g.* $+0.15$ J·K^{-1}·mol^{-1} for 3,3-diethylpentane/*n*-C_8).

Table 3. Values of ΔH_M [J mol^{-1}] at 298.25 K for equimolar mixtures of *n*-octane or *n*-hexadecane and isomeric nonanes.

	n-C_8	*n*-C_{16}
2,2,4,4-tetramethylpentane	39	236
2,3,3,4-tetramethylpentane	−57	79
2,2,5-trimethylhexane	—	315
3,3-diethylpentane	−83	18

Since the destruction of CMO upon mixing the isomeric nonanes with *n*-alkanes has been detected by light-scattering experiments[18], the positive contribution of the CMO to the mixing properties must, therefore, be compensated by a new mixing effect in these systems. The following may be assumed: Globular molecules like 2,3,3,4-tetramethylpentane and 3,3-diethylpentane are fairly rigid and inflexible for stereochemical reasons. Hence, in the pure liquid a relatively large amount of space between the molecules, which cannot be occupied because of the restricted mobility of segments of these isomeric nonanes, is available. Upon mixing with *n*-C_{16}, the isomeric nonanes destroy the CMO, which consumes energy (positive contributions to ΔH_M and ΔS_M), but at the same time the flexible chains of *n*-C_{16} can occupy the space between the globular nonane molecules, thereby forming new intermolecular contacts, *i.e.* energy "production" (negative contribution to ΔH_M). In comparison to the separated pure components the mixture is closer packed, *i.e.* a higher degree of order is achieved (negative contribution to ΔS_M). For ΔV_M a negative contribution is also expected. The isomeric nonanes 2,2,4,4-tetramethylpentane and 2,2,5-trimethylhexane, however, have a higher flexibility; in the pure liquids less "free" space is available and hence the "steric effect" is not so large compared to the CMO effect upon mixing with *n*-C_{16}. For the corresponding mixtures with *n*-C_8, the CMO effect is not so important as with *n*-C_{16}. Therefore the steric effect, which is the same in both cases, is dominant and causes ΔH_M and X_{12} to be negative.

In general the steric effect will be of secondary importance for small globular molecules which in the liquid are packed so closely to one another that chain molecules cannot penetrate the free space (*e.g.* CCl_4, cyclohexane, 2,2-dimethylbutane). If the globular molecules are large (*e.g.* isomeric nonanes), but still flexible enough to leave no free space (*e.g.* tetrabutyltin), the steric effect is also small. The conclusion that $Sn(Bu)_4$ is rather a flexible, branched chain molecule than a rigid, globular molecule was deduced from the behavior of ΔV_M and ΔH_M of mixtures of this substance with *n*-C_{16} and *i*-C_{16}[30]. Only for large and inflexible globular molecules does the additional steric contribution become effective upon mixing with *n*-alkanes. The steric effect has also been discussed in the interpretation of the thermodynamic mixing properties of polymers (polyethylene, polyisobutylene) dissolved in liquids with large, inflexible molecules like isomeric nonanes and *e.g.* *trans*-decalin[66]. In mixtures of isomeric hexanes and heptanes with *n*-C_{16} and *i*-C_{16} this effect is also of importance[67].

So far, it is not yet clear how this steric effect, in addition to the CMO effect, may be taken into account quantitatively.

9. Conclusions

It has been shown how the large number of different molecular structures, and the macroscopic properties of saturated hydrocarbons and their mixtures can be determined systematically from comprehensive measurements, and how the results obtained can be interpreted. In particular, thermodynamic data of high precision, such as *e.g.* the dependence of the enthalpy of mixing on temperature and pressure, are of great help in developing theoretical concepts for the prediction of macroscopic properties. The Flory theory of mixtures of chain molecules was extended in order to take into account the CMO, a structural ordering effect existing within *n*-alkanes. In this way a more consistent description of the mixing properties of alkane mixtures is now possible. In addition to the CMO a "steric effect" has been observed for some particular types of mixtures which has not yet been incorporated quantitatively into the theory presented.

Recently, *le Noble* and *Kelm*[69] discussed quite extensively the effect of high pressure on chemical reactions in solution. When alkanes are used as solvents it is likely that the pressure dependence of the CMO influences the course of the reaction. Reactions at high pressure might proceed quite differently with an *n*-alkane as solvent (CMO present) than with a strongly branched, isomeric alkane (no CMO exists).

Of course alkanes are a specific group of substances having similar chemical and structural properties, and hence the intermolecular forces acting between the molecules do not vary greatly.

Within other groups of related substances, *e.g.* arenes, or molecules with polar groups, like —OH, —NH_2, and —COOH additional structural and intermolecular effects may occur (formation of hydrogen bonds, molecular complexes, *etc.*), making other theoretical concepts necessary. At present such theories are still not much more than models (see *e.g.* [68]), since the extremely complicated interactions of all molecular properties of large molecules can hardly be developed into a really precise theory which at the same time is easy to handle.

The topics discussed in detail here show, however, that model theories which take into account the essential features of the structure of liquids also give a good description of experimental results. What in particular has to be regarded as essential can only be determined by extensive and systematic investigations using as many methods as possible, *e.g.* spectroscopic and thermodynamic methods. In this respect experimental data for many pure liquid components and mixtures is not available, thus bringing forth a wide field of future research activities.

The authors are grateful to the Deutsche Forschungsgemeinschaft for financial support of their own research.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Synthesis and Reactivity of Metal Complexes with the Zwitterionic $Et_3P—CS_2$ Ligand. Structure of the Dithiocarbonato Complex [(triphos)Co(S_2CO)]

By *Claudio Bianchini, Andrea Meli,* and *Annabella Orlandini**

Reaction of triethylphosphane-carbon disulfide ($Et_3P \cdot CS_2$) with cobalt(II) or nickel(II) tetrafluoroborate in the presence of neopentanetriyltris(diphenylphosphane), triphos, and $NaBPh_4$, resulted in formation of the mononuclear complexes **2** and **3**, respectively. In these compounds the zwitterionic ligand $Et_3P—CS_2$ chelates the metal atom *via* both sulfur atoms.

The high reactivity of the ligand $Et_3P—CS_2$ enables the cobalt complex **2** to participate in a variety of reactions.

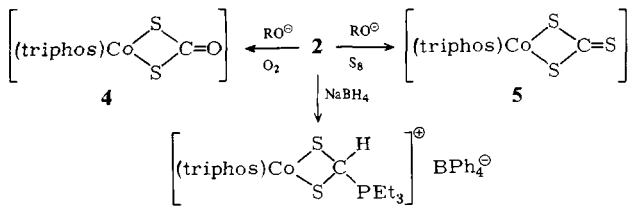
2, M = Co
3, M = Ni

The C^1—P bond can be cleaved by nucleophiles such as alkoxide ions; in the presence of O_2 or S_8, **4** or **5** are formed with the ligands S_2CO^{2-} and S_2CS^{2-}, respectively.



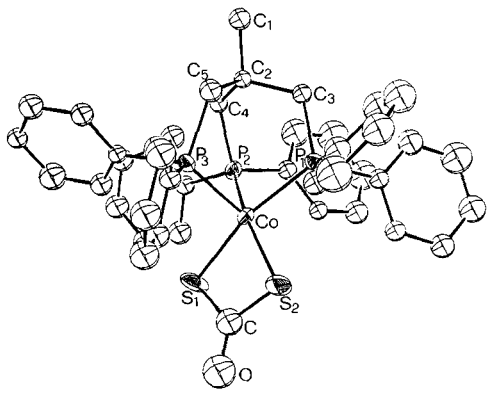


Fig. 1. ORTEP representation of the structure of **4** in the crystal; 50% probability ellipsoids. Important bond lengths [Å] and bond angles [°]: Co—P(1—3) = 2.246—2.271(7), Co—S1 = 2.260(7), Co—S2 = 2.250(6), C—S1 = 1.70(3), C—S2 = 1.69(3), C—O = 1.27(3) Å, S1—Co—P1 = 165.6(3), S2—Co—P2 = 155.5(4), S1—Co—S2 = 75.5(3), S1—C—S2 = 109.1(16), S1—C—O = 124.7(22), S2—C—O = 126.2(21)° [4].

In addition, nucleophiles add to the C^1—P bond; hence **2** and $NaBH_4$ react to give the hydride adduct **6.**

An X-ray structural investigation[4] of **4** (Fig. 1) indicates that the cobalt atom is five-coordinated by the three P atoms of the triphos ligand and by the two S atoms of the S_2CO^{2-} ligand in a distorted square pyramidal environment.

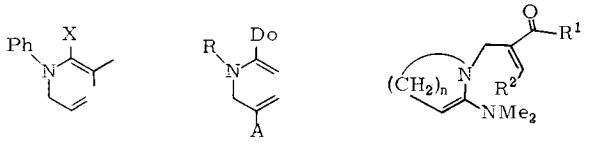
Competition between the Aza-Cope Rearrangement and Aldol Addition**

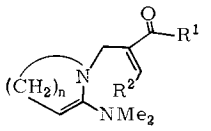
By *Rudolf Gompper** and *Bernhard Kohl*

Aza-Cope rearrangements[1] proceed, in general, at higher temperatures than oxa- and thia-Cope rearrangements. Lewis acids have an accelerating effect[2]. The dialkylamino group, which increases the rate of the oxa-Cope rearrangement[3] has a retarding effect in **1**: **1a** rearranges at 170 °C (cf. [2]), **1b** not until 280 °C[4]. On the basis of results with polar, two-step Cope, and thia-Cope rearrangements[5] it must be expected that the rearrangement will proceed very rapidly with donor-acceptor substituted compounds of type **2.** In fact the dienes **3,** prepared by reacting amidinium salts with sodium hydride, rearrange even at room temperature and *ca.* $10^6 - 10^8$ times as fast as **1b.**



1a, X = H
1b, X = NMe_2

2
Do = Donor
A = Acceptor



3, n = 2, 4

Starting from **4** and **5** we obtained the hygroscopic amidinium salts **6** (**6a**: yield 71%, m.p. = 93—94 °C; **6c**: yield 40%, m.p. = 103—104 °C). Reaction of **6a** with sodium hydride in tetrahydrofuran results in the very rapid formation of the pyrrolidinimine derivative **8** (yield 91%, b.p. = 150 °C/0.01 mbar). Treatment of **6b** with ethyldiisopropylamine in acetone, however, results in formation of the pyrrolopyridine derivative **9** in 79% yield

[m.p. = 164—166 °C; IR (KBr): 3165, 1668, 1513 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 1.46$ (t, $J = 7.3$ Hz; 3H), 1.66—2.65 (m; 2H, CH_2—CH_2—N), 3.47 (s; 3H), 3.63—4.15 (m; 5H), 4.53 (s; 2H, CH_2—NEt), 4.75 (s; 1H, =CH_2), 5.20 (s; 1H, =CH_2), 6.45 (s; 1H, OH), 7.20—7.78 (m; 5H)]. Instead of an aza-Cope rearrangement as in **7a,** intramolecular aldol addition occurs in **7b.** This indicates that because of their polarity, donor-acceptor substituents are able to participate directly in the reaction. Aldol reactions and [3,3]sigmatropic rearrangements have similar rates in systems such as **7**; here, orbital symmetry effects do not have an accelerating action.

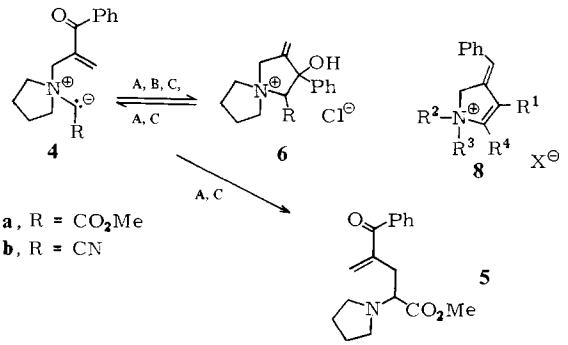
Dipolar Intermediates in the [2,3]Sigmatropic Rearrangement of Ammoniomethanides**

By *Rudolf Gompper** and *Bernhard Kohl*

On the whole, [2,3]sigmatropic rearrangements proceed rapidly even at room temperature (cf. [1]). Apart from the anionic oxa-Cope rearrangement, similarly high reaction rates are observed in [3,3]sigmatropic rearrangements, in general, only if donor-acceptor substituents are present; in such cases, dipolar intermediates are also found[2-4], *i.e.* the rearrangements are two-step. [2,3]Sigmatropic rearrangements of ylides, whereby S_N2' reactions with an anionic nucleophile and a cationic nucleofugic group are involved, can also be categorized in the donor-acceptor scheme. The question therefore arises of whether apart from orbital symmetry, charge effects play a greater role in [2,3]sigmatropic rearrangements than has been previously assumed. The detection of dipolar intermediates would assist in clarifying this matter.



A: NaH, CH_2Cl_2, Δ; B: i-Pr_2NEt, CH_2Cl_2, −10 °C, 1h; C: i-Pr_2NEt, CH_2Cl_2, 25 °C, 20h.

The reactions of the ammoniomethanides **4** indicate that at low temperatures, instead of a [2,3]sigmatropic rearrangement to **5,** an intramolecular aldol addition occurs to give **6** (**6a'**, ClO_4^- instead of Cl^-; m.p. = 214 °C). From differently substituted derivatives we obtained compounds of type **8** *via* **6.** Formation of **6** precedes that of **5**; only **5** (b.p. = 150 °C/0.01 mbar) is formed from **4a** and from **6a** at room temperature.

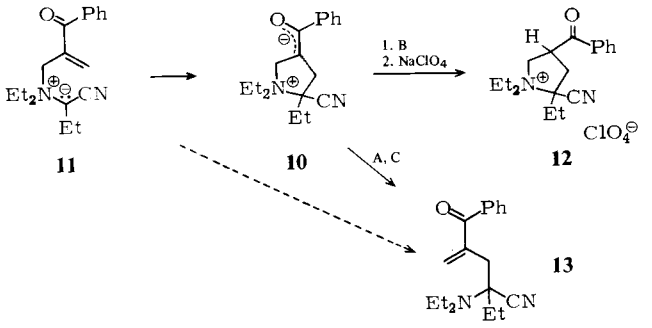
Karlstrasse 23, D-8000 München 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

Reaction of α-diethylaminobutyronitrile with α-chloromethylacrylophenone provides the evidence for dipolar intermediates in [2,3]sigmatropic rearrangements. Heating the components in acetonitrile in the presence of ethyldiisopropylamine leads to the rearrangement product **13**. The same reaction in the absence of base yields the pyrrolidinium salt **12**. Formation of **12** and **13** can, therefore, be



A: *i*Pr$_2$NEt, CH_3CN, Δ, 3d; B: CH_3CN, Δ, 5d; C: *i*Pr$_2$NEt, CH_2Cl_2, 25°C, 15h.

explained on the basis that the ylide **11** does not rearrange directly to **13** but forms the dipole **10**, which then, in the absence of ethyldiisopropylamine, is protonated to **12** by acid present in the reaction mixture. That **10** is also an intermediate in the [2,3]sigmatropic rearrangement of **11** to **13** is indicated by the fact that ethyldiisopropylamine completely converts **12** into **13** at room temperature.

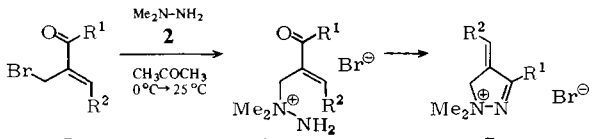
Two-Step Sigmatropic Rearrangement *versus* Aldol Addition of Ammonioimides**

By *Rudolf Gompper** and *Bernhard Kohl*

Ammonioimides liberated by the action of base on 1,1-dialkyl-1-allylhydrazinium salts rapidly rearrange to 1,1-dialkyl-2-allylhydrazines, even at room temperature[1,2]. In 1-acyl-2-allylhydrazinium salts, the [2,3]sigmatropic rearrangement is not observed until 130–150°C[1,3]. Two-step [2,3]sigmatropic rearrangement and intramolecular aldol reactions compete in acceptor substituted ammoniomethanides[4]. How do acceptor-substituted ammonioimides behave?



a, R^1, R^2 = Ph

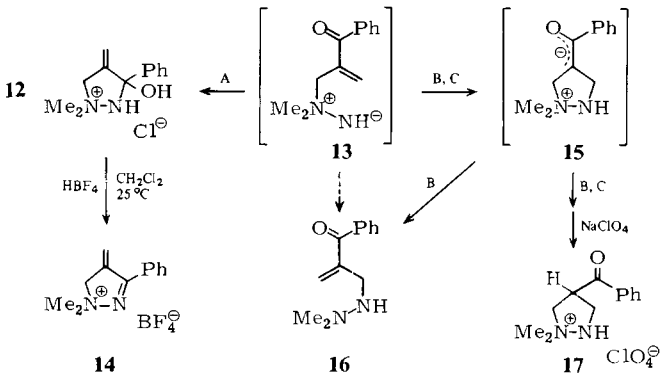
b, R^1 = Me, R^2 = Ph

[*] Prof. Dr. R. Gompper, Dr. B. Kohl
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

6, formed from **5** and *N,N*-dimethylhydrazine **2** does not react in a [2,3]sigmatropic rearrangement but rather *via* an intramolecular aldol addition to form the 4-benzylidenepyrazolinium salt **7**. When the reaction with **5a** is performed in ether, apart from **7a**, **6a** (decomp. 191–192°C) can be separated by fractional crystallization and be quantitatively converted into **7a** (m.p. = 202°C).

The intermediate appearance of dipolar intermediates **15** in the [2,3]sigmatropic rearrangement of ammonioimides **13** was established in the course of the reaction of α-chloromethylacrylophenone **10** with **2**. In acetone the hydroxypyrazolidinium salt **12** is formed, which gives the methylenepyrazolinium salt **14** (m.p. = 106°C) on reaction with tetrafluoroboric acid. When **10** is heated with **2** in ether, the pyrazolidinium salt **17** (m.p. = 164°C) is obtained after work-up. Its formation arises from protonation of the dipole **15** formed from the ammonioimide **13**. The



A: acetone, −10°C; B: *i*Pr$_2$NEt, Et$_2$O, 25°C; C: Et$_2$O, Δ.

action of **2** on **10** in ether in the presence of ethyldiisopropylamine leads to formation of a 2:3 mixture of **16** and **17**. This finding suggests that **15** is a common intermediate of the formation of **16** and **17**. Since **17** does not react with ethyldiisopropylamine, but is largely decomposed by sodium hydride (thereby only traces of **16** are formed), the mode of formation of **16** *via* **15** has not been completely established.

Dialkylmagnesium Compounds from Magnesium, Hydrogen, and 1-Alkenes

By *Borislav Bogdanović**, *Manfred Schwickardi*, and *Peter Sikorsky*

We report a two-step synthesis of dialkylmagnesium compounds from Mg, H_2, and 1-alkenes using the recently described method of preparing MgH_2[9].

[*] Prof. Dr. B. Bogdanović, M. Schwickardi, P. Sikorsky
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr 1 (Germany)

$$Mg + H_2 \xrightarrow{cat./THF} MgH_2 \quad (3)$$

$$MgH_2 + 2CH_2{=}CHR \xrightarrow{cat./THF} Mg(CH_2CH_2R)_2 \quad (4)$$

R = H, alkyl

The catalysts for the preparation of MgH_2 (Mg-anthracene-$CrCl_3$ or -$TiCl_4$)[9] are also suitable for the addition of MgH_2 to ethylene or propene to give, respectively, diethyl- or dipropylmagnesium.

Zirconium tetrahalides and magnesium hydride (MgH_2-ZrX_4; X = Cl, Br, I) are considerably more active catalysts for the addition step (4). By this means MgH_2 can also be added smoothly to higher 1-alkenes. The following modification to the procedure has proved useful: Mg is initially hydrogenated to the highly reactive MgH_2 in the presence of the chromium catalyst at room temperature; addition of 1 mol% zirconium tetrahalide at 70—90 °C in the presence of 1-alkenes leads to dialkylmagnesium compounds. The "hydromagnesation" of higher boiling 1-alkenes (b.p. > 70 °C) can be carried out at atmospheric pressure by refluxing (Fig. 1)[12]. The best results are obtained using catalysts containing ZrX_4, particularly ZrI_4 (80—85% conversion after 1—2 h).

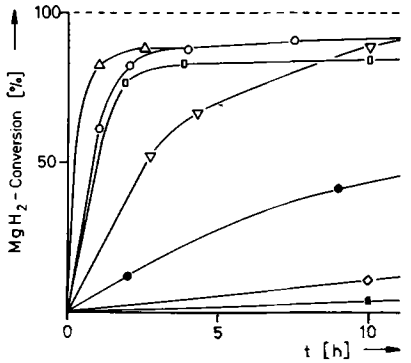

Fig. 1. Course of the MgH_2 addition to 1-octene with time using different catalysts in boiling media; MgH_2 prepared *in situ* at 25 °C in presence of the Cr catalyst. MgH_2 : 1-octene : cat. = 100 : 230 : 1; [cat.] = 0.012 mol/L; (— △ —), ZrI_4; (— ○ —), $ZrCl_4$; (— □ —), $ZrBr_4$; (— ▽ —), $TiCl_4$; (— ● —), $HfCl_4$; (— ◇ —), $(C_5H_5)_2TiCl_2$; (— ■ —), without catalyst.

Reaction of the dialkylmagnesium compounds with electrophiles indicates that the catalytic "hydromagnesation" of 1-alkenes proceeds practically regiospecifically (> 99.7%) in the sense of M→Cl addition. Addition of MgH_2 to 1,1- and 1,2-dialkylalkenes is, in comparison, very slow.

The dialkylmagnesium compounds can be isolated pure and catalyst-free. They can be used *in situ* in syntheses instead of Grignard reagents. For example, tetrabutyltin (83%) could be isolated from a solution containing catalyst, tin tetrachloride, and dibutylmagnesium, or nonanoic acid (78%) could be obtained from dioctylmagnesium with CO_2/H_2O. Trioctylphosphane (84%) and tetraoctyltin (95%) could be prepared, respectively, from pure isolated dioctylmagnesium and phosphorus trichloride and tin tetrachloride, respectively.

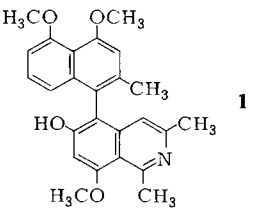
Isoquinolines and Naphthalenes from β-Polyketones: Model Reactions for an Extraordinary Alkaloid Biosynthesis**

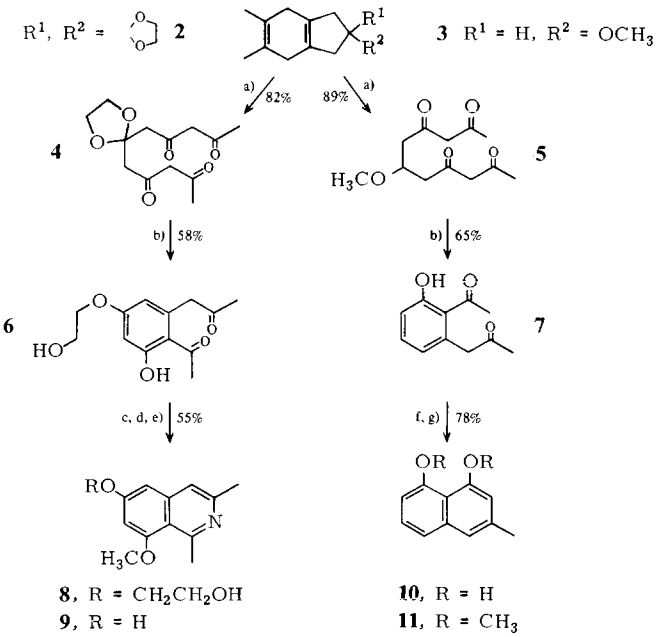
By *Gerhard Bringmann**

Until now it has been assumed that in nature isoquinoline alkaloids are formed, without exception, *via* the Mannich reaction of phenylethylamines with aldehydes or α-oxo acids. Because of its unusual substitution pattern, ancistrocladeine **1**, obtained from the spasmolytically active



1

tropical liana[1] *Ancistrocladus heyneanus*, appears to necessitate a different biosynthetic route. We report the synthetic approach to both molecular moieties (**9** and **11**) of **1** by successive cyclization of β-polyketones, which can be viewed as a model reaction for the formation of an isoquinoline alkaloid from acetate units.



Scheme 1. a) O_3, −78 °C (see *Procedure*). b) SiO_2, Et_2O, 25 °C. c) Me_2SO_4, K_2CO_3, acetone, 25 °C. d) Conc. NH_3, CH_3OH, 25 °C. e) KH, tetrahydrofuran, 25 °C. f) KOH, CH_3OH, 25 °C. g) Me_2SO_4, 10% aqueous KOH, CH_3OH, 12 h reflux.

The synthesis of **9** and **11** is shown in Scheme 1. The ketalized pentaketone **4** [^{1}H-NMR ($CDCl_3$): $\delta = 5.42$, s, olefin. CH of the enol form] is liberated as an oil from **2** by mild ozonolysis in the absence of oxygen. This method of obtaining **4** stems from *Birch et al.*[2], who did not succeed in cyclizing **4** to afford phenols. We found that the ring closure of **4** to **6** (m.p. = 139 °C) can, nevertheless, be realized smoothly by filtering the ozonolysis product through a

[*] Dr. G. Bringmann
Organisch-chemisches Institut der Universität
Orléans-Ring 23, D-4400 Münster (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

short silica gel column. After methylation of **6**, the second ring closure proceeds smoothly to give the isoquinoline **8** (m.p. = 187 °C), from which **9** (m.p. = 229–231 °C) can be obtained by selective cleavage of the hydroxyethyl group.

11, which also occurs in the free state in tropical ebonies[3], is synthesized from **3**, which like **2** can readily be prepared from 5,6-dimethyl-2-indanone. Mild ozonolysis affords **5**, which immediately cyclizes to **7** (m.p. = 125 °C) on silica gel. The latter compound condenses regiospecifically to the oxidation-sensitive **10**, which also occurs in the anthelmintically active berries of *Diospyros mollis*[4] (m.p. = 141 °C). Methylation leads to the naphthalene derivative **11** (m.p. = 87 °C).

This synthesis of both molecular moieties of **1**, which is orientated towards biogenetic considerations, also opens up an effective route to otherwise difficultly accessible 8-hydroxyisoquinolines.

Procedure

6: **2** (2.82 g, 13.7 mmol) in 1 L of ethanol at −78 °C was treated with oxygen-free ozone. After the apparatus had been flushed with argon, the mixture was hydrogenated immediately at room temperature and atmospheric pressure in the presence of Pd/C. The crude **4** was placed on a short column (silica gel Merck, particle size 0.05–0.2 mm). After 3 h this was eluted with Et_2O/MeOH (95:5). Crystallization from ether yielded **6** (1.65 g, 48%) as small colorless needles.

$[Fe_6S_9(SCH_2C_6H_5)_2]^{4-}$: A Hexanuclear Iron-Sulfur Cluster Anion Containing the Square-Pyramidal $[(\mu_4\text{-}S)Fe_4]$ Unit**

By *Gerald Henkel, Henry Strasdeit,* and *Bernt Krebs**

Low molecular weight iron-sulfur complexes with tetrahedral coordination of iron are important as model compounds for the active Fe—S centers of non-heme iron proteins[1].

We report the synthesis, properties, and structure of the novel hexanuclear cluster anion $[Fe_6S_9(SCH_2C_6H_5)_2]^{4-}$, obtained by reaction of $[Fe(SCH_2C_6H_5)_3]_n$ with Na_2S_2 and isolated as

$[(C_2H_5)_4N]_4[Fe_6S_9(SCH_2C_6H_5)_2]\cdot H_2O$ **4**

by precipitation with $[(C_2H_5)_4N]Cl$.

The Mössbauer spectrum of **4** at 77 K (source: Rh/Co, zero external magnetic field) exhibits two quadrupole doublets. Accordingly, **4** contains two types of non-equivalent Fe atoms (Fe^a: $\delta = 0.30$, $\Delta E_q = 0.69$ mm/s, Fe^b: $\delta = 0.11$, $\Delta E_q = 0.55$ mm/s, isomer shifts relative to metallic iron).

[*] Prof. Dr. B. Krebs, Dr. G. Henkel, Dipl.-Chem. H. Strasdeit
Anorganisch-chemisches Institut der Universität
Corrensstrasse 36, D-4400 Münster (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The X-ray structure determination of **4** (space group: $P2_1/c$, $a = 1633.9(3)$, $b = 1953.5(4)$, $c = 2172.9(4)$ pm, $\beta = 106.56(3)°$, $Z = 4$, four-circle diffractometer data, $R_1 = 0.060$) shows the presence of discrete $[Fe_6S_9(SCH_2C_6H_5)_2]^{4-}$ ions in the crystal (Fig. 1).

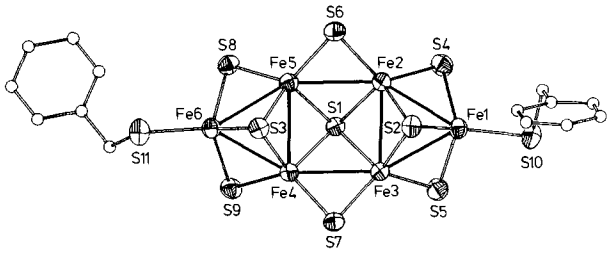

Fig. 1. Structure of $[Fe_6S_9(SCH_2C_6H_5)_2]^{4-}$ in crystals of **4**; vibration ellipsoids of the Fe and S atoms with 50% probability.

In the anion of **4** the six Fe atoms have an approximately planar arrangement (mean deviation from the best plane: 5.8 pm). The Fe_6 core consists of two nearly equilateral coplanar triangles of Fe atoms (∢Fe—Fe—Fe: 59.28(5) to 60.77(5)°, d(Fe—Fe): 269.4(2) to 273.5(2) pm) separated from each other by short Fe—Fe distances (280.4(2) and 274.8(2) pm) to form a square central Fe_4 unit.

A further novel structural principle is the quadruply bridging S1 atom which is located below the center of the Fe_4 square and defines the vertex of an approximately regular square-pyramidal $[(\mu_4\text{-}S)Fe_4]$ unit (mean Fe—S distance: 233.3 pm). In addition, the anion contains inorganic S atoms acting as triply- and doubly-bridging substituents.

The arrangement leads to a distorted tetrahedral coordination of the four central Fe atoms by inorganic S ligands (∢S—Fe—S: 100.32(9) to 124.95(9)°), whereas Fe1 and Fe6 are additionally bonded to one S atom of a benzylthiolate ligand (mean Fe—S distance: 228.4 pm, ∢S—Fe—S: 101.49(9) to 116.36(9)°).

The mean oxidation state of Fe is formally +2.67. Due to the short Fe—Fe distances, which indicate direct metal-metal interactions, assignment of discrete oxidation levels to the central and outer Fe atoms would result in an unsatisfactory description of the true electronic situation. According to the Mössbauer spectrum the two outer Fe atoms are presumably in a higher oxidation state.

The cyclic voltammogram of **4** (0.10 M tetraethylammonium perchlorate in acetonitrile) shows a reduction peak at −0.61 V and oxidation peaks at −0.36 and +0.40 V (relative to Ag/AgCl, scan rate 100 mV/s).

The electronic spectrum of a solution of **4** in acetonitrile shows two peaks at 296 and 329 nm of approximately equal intensities, as well as a shoulder at *ca.* 425 nm[11].

4 could serve as a starting point for the synthesis of a new class of tetrahedrally coordinated Fe—S cluster compounds. The closed parent compound of this class consists of a completely bonded metal cube defined by eight Fe atoms, having six μ_4-S ligands centered above each of its planes. The tetrahedral coordination of each Fe atom is achieved by organo-S ligands.

The central $[Fe_4S_9]$ unit of **4** can be regarded as a fragment of this $[Fe_8S_{14}]$ cage structure.

The $[Fe_7MoS_6]$ unit, which can formally be derived from the $[Fe_8S_{14}]$ cage by substituting one Fe atom of the $[Fe_8S_6]$ core is of particular interest as a model for the active site of the FeMo-protein of nitrogenase and of the isolated FeMo cofactor[6].

 © *Verlag Chemie GmbH, 6940 Weinheim, 1982* *0570-0833/82/0303-0201 $ 02.50/0*

Fe_7MoS_6 has a Fe : Mo : S* (S*: inorganic sulfur) ratio of 7 : 1 : 6, in good agreement with the composition of 7–8 : 1 : 6 determined analytically for the FeMo cofactor of *Azotobacter vinelandii*[6, 9].

EXAFS investigations[10] indicate that molybdenum in nitrogenase and in the FeMo cofactor has two to three iron neighbors ($d = 272$ pm) and three to four sulfur neighbors ($d = 236$ pm). These data are consistent with the coordination of molybdenum in a $[Fe_7MoS_6]$ cube structure.

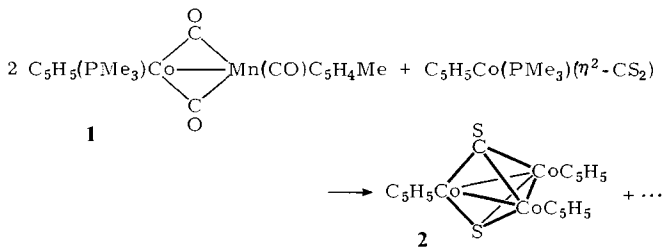
$(C_5H_5)_3CoMn_2(CO)_4(CS)PMe_3$ — A Hetero-Trinuclear Complex with a μ_2-*C*,η^1-*S* Bonded Thiocarbonyl Group**

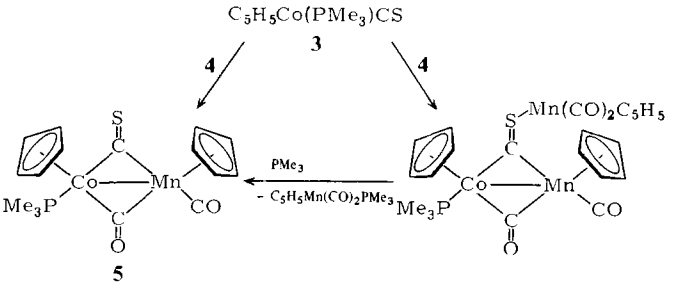
By *Oswald Kolb* and *Helmut Werner**

Recently we reported the synthesis of the first complex containing a μ_3-CS bridge which was obtained from **1** and $C_5H_5Co(PMe_3)(\eta^2\text{-}CS_2)$[1a], and characterized by crystal structure analysis[1b].



1

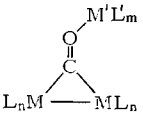
The (Co—Mn) compound **1**, which serves as the synthetic building block for **2**, is advantageously prepared from $C_5H_5Co(PMe_3)CO$ and $MeC_5H_4Mn(CO)_2(THF)$[2]. By means of the analogous reaction of the thiocarbonyl complex $C_5H_5Co(PMe_3)CS$ **3**[3] with $C_5H_5Mn(CO)_2(THF)$ **4** in tetrahydrofuran (25 °C, 24 h), the heterodinuclear complex **5**, in which both metal atoms are bridged by a CO- and a CS-group, [^{1}H-NMR in C_6D_6: $\delta = 4.60$ (C_5H_5Co; d; $J_{PH} = 0.8$ Hz), 4.56 (C_5H_5Mn; s), 0.80 (PMe_3; d, $J_{PH} = 10.0$ Hz); IR: $\nu(CO) = 1912$, 1777 cm^{-1} (in THF); $\nu(CS) = 1106$ cm^{-1} (in Nujol)], is formed. When the starting materials **3** and **4** are used in the molar ratio 1 : 1, in addition to **5** a small amount (*ca.* 5%) of the trinuclear complex **6** is formed, which according to the elemental analysis and mass spectrum [molecular ion m/z 596; additional fragments such as $\mathbf{5}^+$, $C_5H_5Mn(CO)_2CS^+$, and $C_5H_5CoPMe_3^+$] contains one cobalt and two manganese atoms; this product is obtained almost quantitatively by reacting **3** and **4** in the molar ratio 1 : 2.



5

The proposed structure for **6** is based on the NMR and IR spectra [^{1}H-NMR in C_6H_6: $\delta = 4.80$ (C_5H_5MnS; s), 4.55 (C_5H_5Mn; s), 4.40 (C_5H_5Co; d, $J_{PH} = 0.7$ Hz), 0.65 (PMe_3; d, $J_{PH} = 10.2$ Hz); IR: $\nu(CO) = 1950$, 1913, 1855, 1800 cm^{-1} (in CS_2); $\nu(CS) = 1050$ cm^{-1} (in Nujol)] as well as on the result of the reaction with PMe_3 (C_6H_6, 60 °C, 40 h) which produces **5** and $C_5H_5Mn(CO)_2PMe_3$, exclusively. Cleavage of the μ_2-CX bridges (X = O, S) in **5** does not occur under these conditions.

A triply bridging function (μ_2-*C*,η^1-*S*), as exhibited by the thiocarbonyl ligand in **6** towards three transition metal atoms, is not known for the CO group. *Shriver et al.*[4] found that strong Lewis acids such as BF_3 or $AlEt_3$ are able to add to the oxygen atom of the μ_2-CO bridges in $(C_5H_5)_2M_2(CO)_4$ (M = Fe, Ru); the electrophilicity of corresponding transition-metal species such as $C_5H_5Mn(CO)_2$ or $Cr(CO)_5$ does not appear to be sufficient for additional coordination to a μ_2-CO group of this type. Reaction of $(C_5H_5)_2Fe_2(CO)_3CS$, which is comparable with $(C_5H_5)_2Fe_2(CO)_4$, with $HgCl_2$ or $[C_5H_5Fe(CO)_2(THF)]^+$ led to isolation of the corresponding 1 : 1 adducts, which presumably have analogous structures to **6**[5].



The high nucleophilicity of the sulfur atom of the thiocarbonyl bridge in **5** is evident, not only in the addition of $C_5H_5Me(CO)_2$ but also in the very rapid and quantitative methylation with CF_3SO_3Me (C_6H_6, 25 °C, 5 min). The spectroscopic data of complex **7**, which contains a bridging methylthiocarbyne ligand, are consistent with the proposed structure [^{1}H-NMR in [D$_6$]acetone: $\delta = 5.52$ (C_5H_5Co; d, $J_{PH} = 0.8$ Hz), 5.43 (C_5H_5Mn; s), 3.50 (SMe; d, $J_{PH} = 0.5$ Hz), 1.37 (PMe_3; d, $J_{PH} = 11.1$ Hz); IR: $\nu(CO) = 1968$, 1833 cm^{-1} (in KBr)].

A Facile, Generally Applicable Synthesis of *N*-Acetyldehydro-α-amino Acids

By *Franz Effenberger** and *Thomas Beisswenger*

Dehydroamino acids are used as educts for the synthesis of α-amino acids. Thus, a series of amino acids could be prepared *e.g.* by addition of acidic compounds such as malonic acid derivatives, indole, imidazole, and thiols to dehydroamino acids[1]. Of particular synthetic significance is the enantioselective hydrogenation of *N*-acyldehydroamino acids or -amino acid esters in the presence of optically active metal complexes as catalysts which produce, respectively, amino acids or amino acid esters in very high optical yield[2].

Until now the known syntheses of dehydroamino acids are either involved, not generally applicable, or rely upon amino acids as starting materials[1].

The recently postulated intermediary 2-iminopropionic acid ester was trapped, by careful acylation, as the *N*-acetyldehydroalanine ester in the alkoxide-catalyzed preparation of pyruvic acid ester from 2-azidopropionic acid ester[3].

We have now obtained *N*-acetyl-**2** and/or *N,N*-diacetyldehydro-α-amino acid esters **3** by warming the 2-azidocarboxylic acid esters **1** in acetic anhydride or acetic anhydride/acetic acid in presence of catalytic amounts of rhenium heptasulfide (Table 1). The azidocarboxylic acid esters **1** are almost quantitatively accessible from the corresponding α-halogen derivatives *via* azide exchange by a phase-transfer reaction with Aliquat 336 as catalyst. Exclusive formation of **2** can be achieved using a smaller Ac_2O/AcOH ratio, advantageously in presence of HCl. Work-up

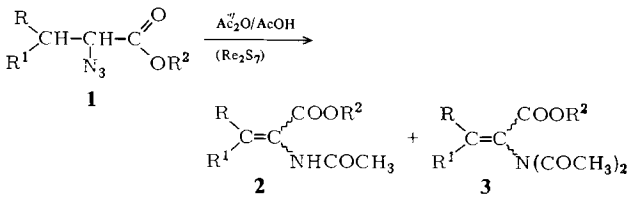

Table 1. *N*-Acetyl-**2** and *N,N*-diacetyldehydroamino acid esters **3** from 2-azidocarboxylic acid esters **1**. Solv. = solvent. A: in Ac_2O, B: in Ac_2O/AcOH (3/7), C: in Ac_2O/AcOH (2/3)/HCl, D: in Ac_2O/AcOH (1/1), E: in Ac_2O/AcOH (1/4)/HCl.

of the **2**+**3** mixture with water is even more favorable (practically no loss of yield).

Z/*E*-Isomeric mixtures of **2**, R^1 = H, R ≠ H, can be quantitatively converted with hydrogen chloride in ether[1] into the *Z*-isomers suitable for the enantioselective hydrogenation[2]. The alkaline saponification of **2** also proceeds smoothly and in high yield to give *N*-acetyldehydroamino acids[4].

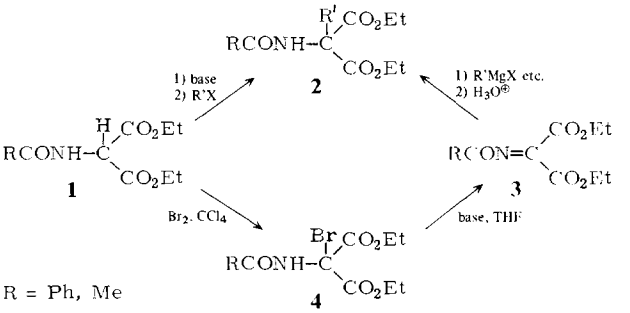
Reaction of Acyliminomalonic Esters with *C*-Nucleophiles, an Umpolung in the Acylaminomalonic Ester Synthesis of α-Amino Acids

By *Reiner Kober, Willi Hammes,* and *Wolfgang Steglich**

In the synthesis of α-amino acids after *Sörensen*[1], the alkylation of an acylaminomalonic ester (**1**→**2**) is the decisive step. We have now found that substitution products of this type can also be prepared by addition of organometallic compounds and other *C*-nucleophiles to acyliminomalonic esters **3**[2].



The bromoesters **4**, accessible in 80–88% yield by bromination of acylaminomalonic esters, have proved suitable precursors for **3**. The action of Hünig's base on *e.g.* **4** (R = Ph) in THF produced **3** (R = Ph) quantitatively, which was characterized by IR bands at 1696 and 1686 cm^{-1} ($CHCl_3$)[4]. Dropwise addition of the equimolar amount of a pre-cooled Grignard reagent in THF to this solution at −78 to −100 °C results in the *C*-addition product **2** in 50—85% yield (Table 1). **4** can also be transformed directly into **2** using two equivalents of R'MgX.

Use of the *N*-benzoyl group and working at low temperatures hinder side reactions such as addition of the organometallic components at nitrogen, attack at the ester groups, as well as radical reduction to **1**, and dimerization to **5**.

[a] All compounds gave satisfactory elemental analyses and spectroscopic data. [b] Ph′ = *p*-chlorophenyl.

The new method also permits the ready synthesis of *N*-alkyl-α-amino acids. For this purpose the crude product obtained after addition of the Grignard compound to the benzoyliminomalonic ester **3** (R = Ph) is methylated with excess dimethyl sulfate in the presence of a little NaH (60 h, 30 °C). After hydrolysis and decarboxylation with 48% HBr, *N*-methyl-2-(1-naphthyl)glycine **6**, for example, is obtained in good overall yield. CH acidic compounds such as nitroalkanes also add smoothly to **3** in the presence of bases. With enamines, adducts which yield 2-oxoalkyl derivatives (*e.g.* **2j**) upon acidic work-up are formed. Diethyl(1-propynyl)amine reacts with **3** (R = Ph) to give the isolable cycloadduct **7**, which is hydrolyzed by 1 N HCl to give the amide **2p**.

Using the new method aryl-, heteroaryl-, alkenyl-, and alkynyl moieties can be introduced into benzoylaminomalonic esters, whereby the range of application of the classic Sörensen synthesis, which is limited to electrophiles, is considerably extended.

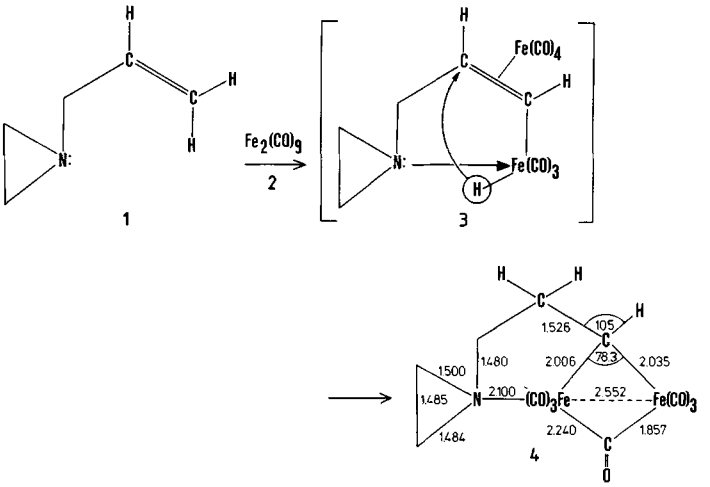
Doubly Metalated Carbon by Metal-Induced Vinyl-Ethylidene Rearrangement**

By *Rudolf Aumann**, *Gerald Henkel*, and *Bernt Krebs*

Metal complexes with multiply metalated carbon are of interest because of their structural relationship to intermediates reported to occur in methylene rearrangement reactions, the Fischer-Tropsch synthesis, and olefin metathesis[1]. We have previously reported on a twofold metalation by cleavage of two geminal C—C bonds[2] and now wish to describe a twofold metalation by metal-induced 1,2-migration of an olefinic C—H bond. Due to the "template effect", this reaction takes place at the γ-position to a donor atom: Thus, reaction of *N*-allylaziridine **1** with $Fe_2(CO)_9$ **2** in ether leads to formation of the μ-methylene complex **4** (red crystals, m.p. 86.5–87.5 °C; MS: $m/z = 391$; IR (hexane): ν(C≡O) 2067, 2016, 2000, 1989, 1965, 1932 cm^{-1}; ^{1}H-NMR ($C_6D_6/CS_2 = 1:2$): *H*CFe_2, $\delta = 8.05$ ($^3J = 4.5$, $^5J = 2.0$ Hz); ^{13}C-NMR ($CDCl_3$): *C*Fe_2, $\delta = 136.7$) as sole compound soluble in benzene in *ca.* 10–15% yield (Scheme 1).



Scheme 1. The bond lengths [Å] and bond angles [°] for **4** are given.

As precursor for **4** we postulate a dinuclear vinyl complex **3**, which isomerizes *via* π,σ rearrangement and migration of hydrogen from iron to the β-C atom to **4**. The methylene C-atom of **4** is bound symmetrically with almost equal bond lengths to the two Fe centers, which in turn are coupled by a strong bond (Fig. 1). The aziridine-N extends the coordination of Fe2, by the methylene-C, by three terminal CO- and one asymmetrically bound bridge CO-ligand, to a distorted octahedron. Fe1 is coordinated by the CH- and CO-bridges and by three terminal CO-ligands; there is also a weak bond to C7 (Fe—C 2.559(6) Å). The bonds in the aziridine ring of **4** are about the same length

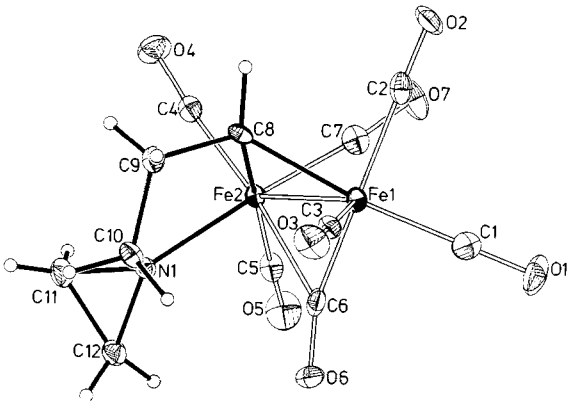


Fig. 1. Molecular structure of **4** in the crystal with vibration ellipsoids (30% probability). **4** crystallizes in the monoclinic system; space group $P2_1/c$ with $a = 13.307(2)$, $b = 9.225(2)$, $c = 13.329(2)$ Å, $\beta = 115.98(3)°$, $Z = 4$ (at −130 °C, $R = 0.044$).

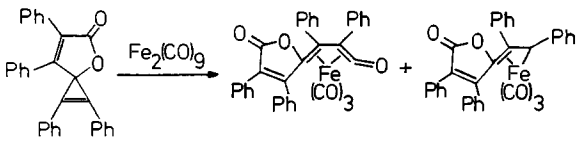
Cyclopropenes as Complex Ligands: $Fe_2(CO)_9$-Induced Ring-Opening of a Spirocyclopropene and Reversible CO-Addition to the Vinylcarbene Ligand

By *Jörg Klimes* and *Erwin Weiss**

Cyclopropenes react with $Fe_2(CO)_9$ even at room temperature, with ring opening, CO-insertion, and formation of (η^3:η^1-allylcarbonyl)- or (η^4-vinylketene)$Fe(CO)_3$ complexes[1,2].

The spirocyclic lactone **2** reacts with $Fe_2(CO)_9$ in toluene (20 °C, 16 h)—as expected—to give the η^4-vinylketene complex **3** (10%); in addition, a novel η^3-vinylcarbene complex **4** (30%) was formed, the structure of which was determined by X-ray analysis (Fig. 1).



2 **3** **4**

The complex **4** is one of the few carbene(carbonyl)iron compounds not having a stabilizing heteroatom (O, N, S) on the carbene carbon atom. It is astonishingly stable towards atmospheric oxygen, does not decompose in boiling benzene, and rapidly adds CO (toluene, room temperature, normal pressure) to form **3**, a reaction which at 60 °C is reversible.

The carbonylation of a manganese-coordinated carbene to give the corresponding ketene complex has already been observed previously[7]—albeit at high pressures—and has been proposed as a model system for a partial step of the Fischer-Tropsch synthesis (carbene complex → ketene complex → aldehyde/alkohol)[9].

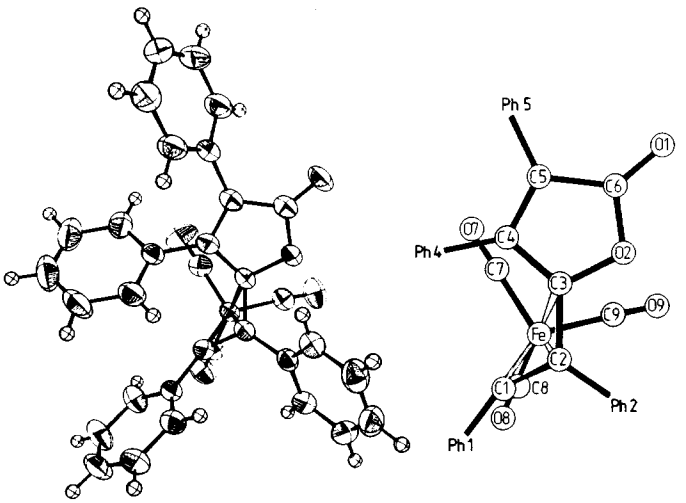


Fig. 1. Molecular structure of **4** in the crystal.

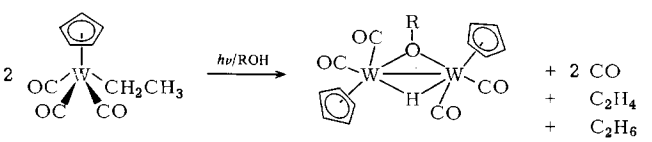
Photo-Induced Reaction of Alcohols with Tricarbonyl(η^5-cyclopentadienyl)ethyltungsten**

By *Helmut Guido Alt** and *Manfred Erwin Eichner*

The conversion of alcohols into μ-alkoxo-μ-hydrido transition metal complexes by activation of the OH bond at metal centers has previously succeeded only by thermal reaction of alcohols with multinuclear coordination compounds in solution[1].

In the photo-induced ($\lambda > 300$ nm, 2 h) reaction of the ethyl compound $C_5H_5W(CO)_3Et$ **1** with alcohols—*e.g.* methanol, ethanol and isopropyl alcohol—in pentane solution we have been able to isolate dinuclear species of the composition (μ-OR)(μ-H)$[C_5H_5W(CO)_2]_2$ **2** (**a**—**c**: R = Me, Et, *i*Pr) as main products (70—85%). The structure proposed for this type of compound is supported by elemental analysis and by mass, IR, ^{1}H-NMR and ^{13}C-NMR spectra.



1 **2**

The methoxo derivative **2a** shows the molecular ion ($m/z = 642$, referred to ^{184}W) in the mass spectrum. The four carbonyl bands in the IR spectrum (1932, 1903, 1830

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

and 1810 cm^{-1} in Nujol) can be assigned to two terminal and two "semi-bridging" CO ligands, similarly as in the case of complexes of the type (μ-alkyne)$[C_5H_5Mo(CO)_2]_2$[2]. A single cyclopentadienyl resonance signal ($\delta_{C,H_5}=5.86$) also appears in the ^{1}H-NMR spectrum at low temperatures (−80 °C, [D$_6$]acetone), indicating a symmetric arrangement of the methoxo- ($\delta_{OCH_3}=4.32$) and the hydrido-bridge ligands [$\delta_{WHW}=-10.56$; $J_{W,H}=57.4$ Hz]. This is supported by the ^{13}C-NMR spectrum of **2a** at −80 °C ($\delta_{C,H_5}=93.7$, $\delta_{OCH_3}=83.6$, $\delta_{CO}=248.1/246.0$). In addition, the proton-coupled ^{13}C-NMR spectrum shows a spin-spin interaction of the μ-H ligand with only one 'sort' of CO ligand [$\delta_{CO}=246.0$; $J_{C,H}=8$ Hz].

On reaction with bromine or iodine (X_2) the dinuclear complexes **2** are quantitatively converted into the known[3] $C_5H_5W(CO)_2X_3$ derivatives.

^{1}H-NMR spectroscopic investigations show that both the hydrido complex $C_5H_5W(CO)_3H$ as well as the ethylene(hydrido) complex $C_5H_5W(CO)_2(C_2H_4)H$, which are formed by β-elimination during the photolysis of **1**[4], play an important role in the photo-induced reaction of **1** with alcohols. The compounds are obviously reactive, monomeric alcohol complexes of the type $C_5H_5W(CO)_2(ROH)H$, which eliminate ethane on reaction with **1** to give the dinuclear species **2**. As expected, the methyl derivative $C_5H_5W(CO)_3Me$ does not furnish **2a** in the analogous photoreaction with methanol.

"Dodecasils"—A Novel Series of Polytypic Clathrate Compounds of SiO_2

By *Hermann Gies, Friedrich Liebau**, and *Horst Gerke*

The known structural analogy between H_2O and SiO_2, which is illustrated by the fact that several ice modifications are isotypic with those of SiO_2, also covers inclusion compounds (clathrates) of both oxides. Thus, the rare mineral melanophlogite is analogous to the clathrate hydrates of the type I *i.e.* it is a "clathrasil" of formula $46SiO_2 \cdot 8M$ ($M=CH_4$, N_2, CO_2 *etc.*)[1]. We report here the synthesis, crystal structure, and thermal properties of "dodecasil-3C", a clathrasil which is isotypic[3] with the clathrate hydrates of type II[2].

$Si(OCH_3)_4$ is hydrolyzed in aqueous solution with $[N(CH_3)_4]OH$, and the homogeneous solution fused in SiO_2 ampules with Ar, Kr, Xe, CH_4, N_2, CO_2, N_2O, $N(CH_3)_3$, $HN(CH_3)_2$, or mixtures of these components and heated to 200 °C for several days.

The general structural formula of the product dodecasil-3C is $136SiO_2 \cdot 16X \cdot 8Y$; $[SiO_4]$ tetrahedra are edge-linked to form pentagondodecahedra (Fig. 1), which are in turn linked *via* common faces to form layers of approximate sixfold symmetry (Fig. 2). Neighboring layers are mutually displaced by $(\vec{a}_0+\vec{b}_0+\vec{c}_0)/3$ and are connected to form a cubic 3-layer structure[4].

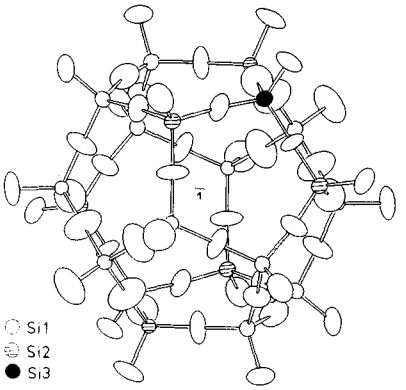

Fig. 1. Pentagondodecahedra in dodecasil-3C [X = CH_4, N_2; Y = $N(CH_3)_3$, $HN(CH_3)_2$]. Structure determination of a single crystal grown under (CH_4+N_2) using direct methods (SHELX-system): T_h^4-Fd3, $a_0=19.402(1)$ Å; 637 independent reflections, $R_w=0.064$, refined with anisotropic Si and O parameters; cages filled with guests, hydrogen atoms not considered.

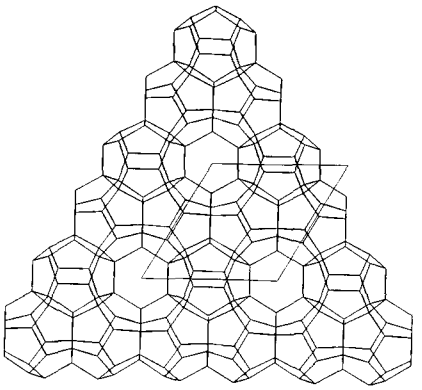

Fig. 2. Section of a layer of linked pentagondodecahedra of dodecasil-3C, parallel (111). The unit cell of the layer is indicated.

Every 16 pentagonododecahedra are linked to form a "super-tetrahedron". The nine upper pentagondodecahedra of Figure 2 represent a face of a super-tetrahedron of this type. This arrangement results in the formation of 8 further cavities, bounded by 16 faces (hexadecahedron). The incorporation of guest molecules into the SiO_2 framework was detected using room temperature mass spectroscopy. Electron density difference maps ($\rho_{obs}-\rho_{cal(Si,O)}$) of a dodecasil-3C crystallized under a (CH_4+N_2) atmosphere indicated that the small molecules CH_4 and N_2 could be assigned to the pentagondecahedral cages, and $N(CH_3)_3$ and $HN(CH_3)_2$ to the hexadecahedral cages. TGA studies of dodecasil-3C [X = Kr; Y = $N(CH_3)_3$, $HN(CH_3)_2$] and dodecasil-3C [X = N_2; Y = $N(CH_3)_3$, $HN(CH_3)_2$] at 950 °C indicated that these clathrasils are stable up to at least 950 °C, and after 3 h at this temperature do not release considerable amounts of guest molecules. N_2, Kr, $N(CH_3)_3$, and $HN(CH_3)_2$ were still detected in the mass spectrum after this type of thermal treatment. Analogous studies[5] on zeolite 5A indicated that incorporated guest molecules, such as Kr, were completely expelled after 30 min at 910 °C.

Apart from the cubic 3-layer structure of dodecasil-3C described here, the existence of further dodecasils with

[*] Prof. Dr. F. Liebau, H. Gies, Dr. H. Gerke
Mineralogisches Institut der Universität
Olshausenstrasse 40–60, D-2300 Kiel (Germany)

other layer sequences is to be expected. By analogy to the nomenclature of polytypes, the following symbols have been selected for dodecasil polytypes:

Symbol	Layer sequence	Symmetry	Lattice constants [Å] a_0	c_0
Dodecasil-1H	*A* A	hexagonal	13.8	11.2
Dodecasil-2H	*A B* A B	hexagonal	13.8	22.4
Dodecasil-3H	*A A B* A A B	hexagonal	13.8	33.6
Dodecasil-3C	*A B C* A B C	cubic	19.4	—
.	.	.	.	.
.	.	.	.	.
.	.	.	.	.
Dodecasil-D	disordered	"hexagonal"	13.8	non-periodic

Of these, we have obtained dodecasil-1H as single crystals. Clathrasils appear to be suitable as thermally stable, water- and acid-proof storage materials for radioactive noble gases produced in the generation of nuclear energy.

Novel BN Ligand with Six Competing π Electrons around the Transition Metal Coordination Center**

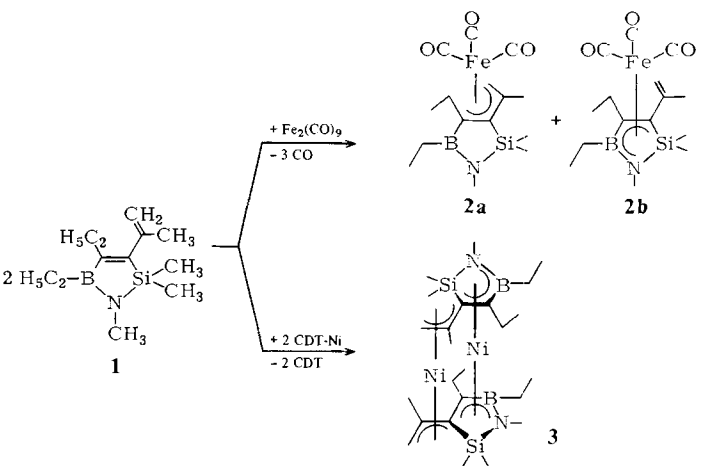
By *Roland Köster** and *Günter Seidel*

Hexaalkyl-Δ^3-1,2,5-azasilaborolines[1b] coordinate as 4π-ligands to transition metals[1a]. We have now synthesized in an analogous way[1b] the 3-vinyl-derivative **1** in order to investigate the complexation of the π bonds of the triene N=B—C=C—C=C which it contains.

Reaction of **1** ($\delta(^{11}B) = 46$)[2a] and nonacarbonyldiiron at 160 °C leads *via* cleavage of CO to formation of the mononuclear complexes **2a** (yellow, $\delta(^{11}B) = 50.3$[2a]) and **2b** (orange color, $\delta(^{11}B) = 18.2$[2a]) in 65% overall yield in the stable molar ratio 4 : 1. Composition and structure of these η^4-isomers are confirmed mass spectrometrically[2a] and by ^{1}H-NMR[2c] as well as ^{13}C-NMR spectroscopy[2a]. **2a** and **2b** can be separated from each other chromatographically (HPLC[2d]).

Reaction of *ttt*-1,5,9-cyclododecatrienenickel and **1** at *ca.* 80 °C affords the diamagnetic, red-black dinuclear sandwich complex **3** [m.p. 134—136 °C (dec.); mass spectrum[2b]: *m/z* 558 (Ni_2)], which is air-stable for a short time at room temperature. The ^{11}B-NMR signal of **3** [$\delta(^{11}B) = 26.4$[2a]] and the large shifts $\Delta\delta(^1H)$ and $\Delta\delta(^{13}C)$ of the two β-methylallyl groups of **3** compared to **1** clearly demonstrate that **3** contains two η^6-coordinated ligands. In the sandwich complex **3**, identified as isomerically pure on the basis of the MS[2b] and NMR data[2a,c], the two ligands **1** are held together by two central π-bonded nickel atoms.

As shown by the X-ray structure analysis[2e] of **3** [NiNi-distance 264.3(1) pm] the two ligands **1** are η^3/η^4-fixed to the Ni_2 dumbbell in a *syn*-arrangement to each other. The C^3 atoms of **1** each form a 2e/3c bond with both Ni atoms in **3**. The sequence of the ring atoms—reading clockwise—is different in each ligand **1**.



Apart from the transition metal π complexes with isolated bis(π-allyl)-structures[3] only a few compounds with linear[4] or crossed[5a] conjugated η^6-C_6 ligands are known. The bonding situation in **3** resembles that in bis(pentadienyl)dinickel[5b] with a cumulated electron system.

The competition of the π electrons of hetero- and homo-1,3,5-hexatrienes during complexation with transition metals—derivable from the structures of **2a**, **2b**, and **3**—opens up, *inter alia*, new prospects for catalysis and its control.

Procedure

2a and **2b**: A suspension of $Fe_2(CO)_9$ (2.07 g, 5.69 mmol) and **1** (2.89 g, 13 mmol) in mesitylene (10 mL) is heated under reflux (*ca.* 160 °C) for 3 h. 484 mL (21.6 mmol) of CO are liberated with concomitant formation of an Fe-mirror. After filtration (small amount of Fe) the solution is evaporated to dryness at ≤30 °C (bath)/10^{-3} torr and the residue sublimed at ≤60 °C/10^{-3} torr: 2.6 g (63%) of an orange-red, wax-like mixture (HPLC[2d]) of 78% **2a** and 22% **2b**, respectively.

3: The dark-red suspension of *ttt*-1,5,9-cyclododecatrienenickel (1.7 g, 7.7 mmol) and **1** (5.6 g, 25 mmol) is heated for 4 h at *ca.* 80 °C. After evaporation of the dark-brown suspension to dryness at ≤60 °C (bath)/10^{-3} torr the residue is crystallized from *ca.* 30 mL of pentane at −78 °C: 1.6 g (75%) of **3**, m.p. 134—135 °C (dec.).

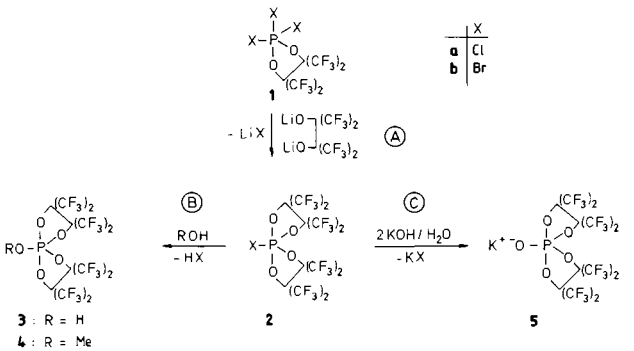
A Stable Tetraalkoxy(hydroxy)phosphorane and Phosphorane Oxide Anion by Hydrolysis of Tetraalkoxy(halogen)phosphoranes**

By *Gerd-Volker Röschenthaler** and *Werner Storzer*

Tetraalkoxy(hydroxy)phosphoranes were postulated as intermediates in the hydrolysis of alkyl(aryl)phosphates some time ago[1], but until now could only be synthesized in a few cases by oxidation of the corresponding hydrogen phosphoranes[2]. Hydrolysis of the halospirophosphoranes **2a** and **2b**, obtainable by treating the trihalophosphoranes[3a] **1a** and **1b** with dilithium perfluoropinacolate in neutral or alkaline aqueous ether solution, led to the hydroxyphosphorane **3** (m.p. = 72 °C, 78% yield) and potassium phosphorane oxide **5** (m.p. = 118 °C, 100% yield), respectively, without cleavage of the P—O ring bonds to form a P=O bond. A tautomeric monocyclic form[2] of **3** is not observed. The methoxy derivative **4** (m.p. = 68 °C, 92% yield) is obtained in the same way using methanol.



Scheme 1. Ⓐ 1 : 1; −196 to +160 °C (10 h) and +20 °C (24 h), respectively, petroleum ether extraction, Et_2O, sublimation: **2a** (62%, m.p. = 62 °C) and **2b** (43%, m.p. = 82 °C), respectively. Ⓑ 1 mL of water or methanol is added to a stirred solution of 0.003 mol **2a** or **2b** in 20 mL of Et_2O; after 30 min the organic phase is separated off and the aqueous phase extracted three times with ether. The mixture was then dried over Na_2SO_4, concentrated and the product recrystallized from Et_2O. Ⓒ 1.0 g of KOH in 5 mL of water is added to a stirred solution of 0.01 mol **2a** or **2b** in 30 mL of Et_2O; after 1 h the mixture is extracted three times with 20 mL of ether, dried over Na_2SO_4 and the solvent removed; yield 7.5 g **5**.

The ring-forming $OC(CF_3)_2C(CF_3)_2O$-substituents (electron withdrawing properties and spacial requirements of the CF_3 groups) produce the remarkable stability of **3**, **4**, and **5**. Hence, **3** can be sublimed out of concentrated sulfuric acid. The pK_a value was determined as 2.0[4].

The composition and constitution of all the novel compounds have been confirmed by elemental analysis, 70 eV mass spectra (apart from **5**), as well as by NMR spectra[5]. The highest mass ions are $M^+ - F$ for **2**, **3**, and **4**, and the most frequent fragment is CF_3^+ for **2** and **3**, and $M^+ - CF_3$ for **4**. The $\delta(^{31}P)$ values are typical of phosphoranes [−12.4 (**2a**), −37.9 (**2b**), −34.5 (**3**), −34.5 (**4**), −37.9 (**5**)]. From the $\delta(^{19}F)$ values it is clear that different sets of CF_3 groups are present in **2a**, **2b**, and **5** [−65.1, −65.6 (**2a**); −67.5, −68.0 (**2b**); −68.7, −69.4 (**5**)] since the first step of a ligand permutation process is slow on the time scale of the NMR experiment[3b]. The $\delta(^1H)$ values for **3** and **4** are 10.8 and 4.00, respectively ($^3J_{PH} = 15.1$ Hz).

Vehicle Mechanism, A New Model for the Interpretation of the Conductivity of Fast Proton Conductors

By *Klaus-Dieter Kreuer, Albrecht Rabenau**, and *Werner Weppner*

The conduction of protons in solids is generally explained, as in the case of liquid electrolytes, in terms of the Grotthuss Mechanism[1]: The protons move in an infinite network of hydrogen bonds. The process consists of two steps, the translation of a proton from an oxonium ion[2] to a water molecule by tunneling in a hydrogen bond and subsequent reorientation (rotation) of the water molecule thus formed in order to be able to take up the next proton (Fig. 1, top).

Our investigations lead to strong arguments in favor of another process, which we call the Vehicle Mechanism. According to this model the proton does not migrate as H^+ but as OH_3^+, NH_4^+, *etc.*, bonded to a "vehicle" such as H_2O, NH_3, *etc.* The "unladen" vehicles move in the opposite direction (Fig. 1, bottom). The vehicle shows a diffusion coefficient corresponding to the proton conduction and behaves like a Brønsted base (proton acceptor) towards its crystallographic environment.

Fig. 1. Model of proton conduction. Top: Grotthuss Mechanism; the protons are passed along the hydrogen bonds. Bottom: Vehicle Mechanism: the movement takes place with the aid of a moving "vehicle", *e.g.*, H_2O or NH_3 as complex ion (H_3O^+ or NH_4^+).

The Nernst-Einstein relation between the diffusion (translation) of the vehicle and the conductivity of protons is fulfilled, but no correlation between the rotation of the vehicle and the conductivity has been found (Table 1).

The Vehicle Mechanism makes the extremely large temperature factors which have been observed in X-ray and neutron diffraction studies understandable[1b] and is consistent with the observation that practically all good proton

	$-NH_3^+$ rotation	0.19 ± 0.01	—	^{1}H-NMR [5]
	$N_2H_5^+$ translation	0.7 ± 0.04	—	^{1}H-NMR [5]

[a] In collaboration with *R. Messer*, Max-Planck-Institut für Metallforschung, Stuttgart.

conductors are good ion-exchangers, in which oxonium ions are always exchanged, but individual protons never, *e.g.*,

$$HUO_2AsO_4 \cdot 4H_2O + Na^+ \rightleftharpoons NaUO_2AsO_4 \cdot 3H_2O + H_3O^+$$

Using the Vehicle Mechanism as a working principle a series of new proton conductors have been found[3a]. In particular proton conduction in zeolites has been optimized. Since the Vehicle Mechanism no longer requires an infinite hydrogen bond network, much stronger basic species, *e.g.* NH_3, which have a high self-diffusion coefficient, can be used. In the case of zeolites this is particularly important, since NH_3, in contrast to H_2O, is capable of binding a proton from the amphoteric host lattice with formation of NH_4^+.

The concept of the Vehicle Mechanism leads to new applications of solid proton conductors in electrochemical cells[3b]. Whereas the previously discussed mechanisms are based on pure proton transport between electrodes of different H-activity—as, *e.g.*, mixed conducting hydrides—electrodes of different oxygen activity can now also be taken into consideration. The transport of protons and water molecules in opposite direction give together an overall transport of O^{2-}. For example, proton conductors have already been used as electrolytes in metal-air and metal/metal oxide cells (Table 2).

Photochemical Oxidative Addition of Chlorine from Chloroform to 2,2′-Bipyridyldichloroplatinum(II)**

By *Arnd Vogler** and *Horst Kunkely*

The mechanism of light-induced multielectron transfer has been little studied. Increasing interest is being shown in reactions of this type in relation to photosynthesis, or to the photochemical splitting of water. Particularly important two-electron redox reactions of complexes are reductive elimination and oxidative addition. Some light-induced reductive eliminations have been studied in depth[1a]. In addition, a series of photolytic oxidative additions is known[1b]. However, in all cases the primary photochemical step consists of the release of a ligand. Consequently, oxidative addition is not strictly a photochemical reaction, but occurs more frequently as a thermal reaction at coordinatively unsaturated, reactive metal complexes. We report the first oxidative addition as the primary step in a photochemical reaction.

Irradiation of $[Pt^{II}(bpy)Cl_2]$[2] in acetonitrile led, in the absence of side-reactions, to substitution of chloride with formation of $[Pt(bpy)(CH_3CN)Cl]^{\oplus}$; irradiation at the long wavelength band of the complex ($\lambda \geq 320$ nm) was sufficient. The reaction did not proceed in $CHCl_3$ solutions. In contrast $[Pt^{II}(bpy)Cl_2]$ is smoothly oxidized to

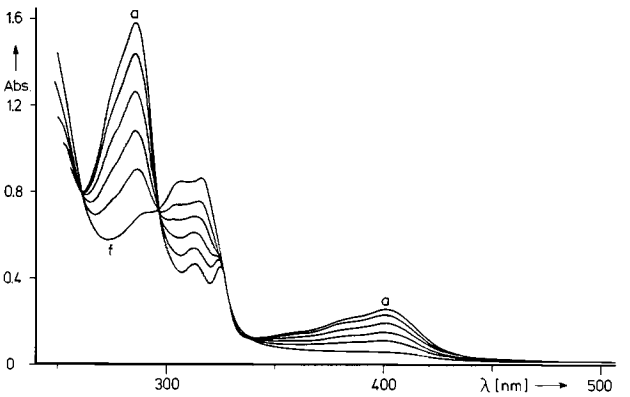

Fig. 1. Changes in the absorption spectrum during photolysis of $[Pt(bpy)Cl_2]$ (8.78×10^{-5} mol/L) in $CHCl_3$ in a 1 cm cuvette, excitation light: $\lambda > 280$ nm, irradiation time: a = 0, f = 10 min.

[*] Prof. Dr. A. Vogler, Dr. H. Kunkely

Universitätsstr. 31, D-8400 Regensburg 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

$[Pt^{IV}(bpy)Cl_4]$[2] when shorter wavelength light ($280 < \lambda < 300$ nm) is used for the irradiation. The spectral changes during photolysis (Fig. 1) can be simulated by oxidation of $[Pt(bpy)Cl_2]$ with Cl_2, or by reduction of $[Pt(bpy)Cl_4]$ with $NaBH_4$. The quantum yield of the photooxidation was $\phi = 0.06$ for irradiation with $\lambda = 280$ nm.

From these results it is improbable that a coordinatively unsaturated complex is formed in the primary photochemical step by release of a ligand. Summarizing, the following mechanism is proposed:

$$[Pt^{II}(bpy)Cl_2] + CHCl_3 \xrightarrow{h\nu} [Pt^{III}(bpy)Cl_3] + {}^{\circ}CHCl_2$$

$$[Pt^{III}(bpy)Cl_3] + {}^{\circ}CHCl_2 \longrightarrow [Pt^{IV}(bpy)Cl_3]^{\oplus} + CHCl_2^{\ominus}$$

$$[Pt^{IV}(bpy)Cl_3]^{\ominus} + CHCl_2^{\ominus} \longrightarrow [Pt^{IV}(bpy)Cl_4] + :CHCl$$

Two-electron reductions are well known for geminal dichlorides CR_2Cl_2[3]. In the initial step an electron is taken up *via* formation of ${}^{\circ}CR_2Cl$ and $Cl^{\ominus}$. The radicals ${}^{\circ}CR_2Cl$ are powerful oxidizing agents, which are able to rapidly add a further electron to form the $CR_2Cl^{\ominus}$ anion. This reaction mechanism is thus to be expected in all cases involving the reaction of geminal dichlorides with a two-electron reducing agent such as Pt^{II}. Presumably the intermediate products $[Pt^{III}(bpy)Cl_3]$ and ${}^{\circ}CHCl_2$ have a very short lifetime and rapidly exchange a further electron to form Pt^{IV}. In accord with this assumption radicals could not be detected during the photolysis. ESR signals could neither be registered during low temperature photolysis at 77 K nor by irradiation at room temperature in the presence of *N*-benzylidene-*tert*-butylamine *N*-oxide (*N*-*tert*-butylphenylnitron) as spin trap.

In the last step of the oxidative addition, the anion $CHCl_2^{\ominus}$ could add directly as a sixth ligand to the coordinatively unsaturated complex $[Pt^{IV}(bpy)Cl_3]^{\ominus}$ to form $[Pt^{IV}(bpy)Cl_3(CHCl_2)]$. This type of oxidative addition of chlorinated alkanes such as dichloromethane to Pt^{II} complexes is a well known thermal reaction[4]. In our example, however, the complex removes a chloride ion from the anion $CHCl_2^{\ominus}$. Thereby $[Pt^{IV}(bpy)Cl_4]$ is formed as a stable end product together with monochlorocarbene. Apparently, this carbene reacts with a further chloroform molecule by insertion into its C—Cl bond resulting in formation of 1,1,2,2-tetrachloroethane, which was detected by gas chromatography. This insertion reaction is a well known reaction type of carbenes[5]. Attempts to trap the monochlorocarbene with 2,3-dimethyl-2-butene did not lead to unambiguous results. At low concentrations of olefin (*ca.* 10^{-3} mol/L) the carbene reacts preferentially with solvent. With markedly higher concentrations of olefin the solubility of the complex is too low. In addition, complications from substitution reactions arise.

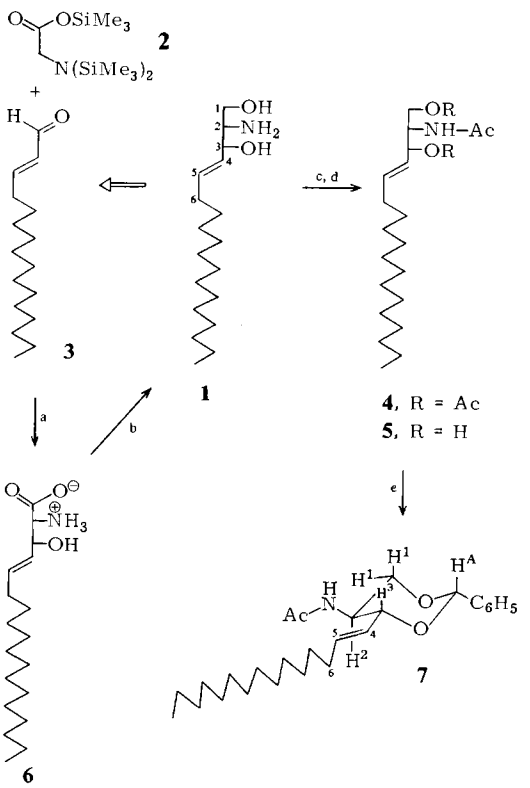
Diastereoselective Synthesis of D,L-Sphingosine**

By *Richard R. Schmidt** and *Rudolf Kläger*

Sphingosine **1**, an important membrane component, was previously accessible from achiral educts only *via* several steps involving formation of *threo*- and *erythro*-products[1, 2]. The natural product could be prepared—albeit in low yields—in more than ten steps from D-glucose[3]. According to the progress made in the diastereoselective synthesis of acyclic systems[4] it should be possible to prepare *erythro*-configurated D,L-sphingosine.



Scheme 1. a: LDA in THF, −80 °C, 1.5 h; yield 59—75% **6**, m.p. = 192—193 °C (dec.) from DMF.—b: 7 equiv. $LiAlH_4$ in THF, reflux, 36 h; yield 90% **1**; $R_F = 0.2$ (DC, silica gel, $CHCl_3$: methanol = 1 : 1).—c: pyridine/Ac_2O, RT, 15 h; yield 50% **4**; m.p. = 90—91 °C (Lit. [1]: 91—92 °C).—d: NaOMe in MeOH, RT, 1 h; yield 91% **5**; m.p. = 85—87 °C.—e: 3 equiv. C_6H_5—CHO and 1 equiv. $ZnCl_2$ in toluene, RT, 16 h; yield 89% **7**, m.p. = 114—115 °C from petroleum ether (40—60 °C)/ethyl acetate = 50 : 1.

We allowed the α,β-unsaturated C_{16}-aldehyde **3** to react with the α-carbanion of the protected glycine **2** (Scheme 1), since good results had already been achieved in this reaction with simple aldehydes[6]. The *erythro*-configurated, unsaturated β-hydroxy-α-amino acid **6** was formed exclusively.

The structure of **6** was confirmed by reduction with $LiAlH_4$ to the D,L-sphingosine **1** (90%) and conversion of the latter into the triacetyl derivative **4**[1]. Moreover, cleavage of the *O*-acetyl groups to give **5** and subsequent reaction with benzaldehyde afforded a 1,3-dioxane derivative **7**; the *trans* arrangement of H^2 and H^3, as is expected for the *erythro*-configuration, is demonstrated in the ^{1}H-NMR spectrum by the typical coupling constant of 8.9 Hz for

Selective C—H Bond Activation in Ethane Using Photoexcited Cu Atoms**

By *Geoffrey A. Ozin**, *Steven A. Mitchell*, and *Jamie García-Prieto*

In the general area of hydrocarbon conversions, reactions involving the selective cleavage of C—H and C—C bonds are of considerable industrial importance[1], but have been investigated only to a limited extent.

We report on the resonance excitation of the $^2P \leftarrow ^2S$ electronic transition of Cu atoms in the presence of ethane at 12 K, and on the subsequent reactions which promote the selective insertion of Cu atoms into the C—H bonds of ethane; in contrast, the C—C bond is not attacked.

Figure 1 (A and B) shows the UV-VIS spectra following deposition of a Cu/C_2H_6 mixture ($1:10^4$) at 12 K, and after annealing at 30 K. The splitting of the $^2P \leftarrow ^2S$ band of Cu atoms at *ca.* 320 nm in the 30 K spectrum (4315 cm^{-1}) is exceptionally large compared with the corresponding splittings for gaseous Cu atoms (284 cm^{-1}) and Cu atoms in rare gas (*e.g.* Ar, 760 cm^{-1}) and methane (2055 cm^{-1}) matrices. This is indicative of a rather strong interaction between the excited Cu atoms and the surrounding "ethane cage".

Irradiation (10 nm band-width at half height) of the Cu/C_2H_6 matrix at 12 K causes rapid first order decay of all Cu atom lines and simultaneous appearance of new bands at 330, 260, 230, and 220 nm (Fig. 1C). The overall picture bears a striking resemblance to the first order photokinetic decay and optical spectroscopic observations of excited Cu atoms in solid CH_4[6].

ESR studies indicated that irradiation at 320 nm causes rapid bleaching of all the Cu atom signals and concomitant growth of a strong multiplet signal around the free electron *g*-factor with the characteristic hyperfine pattern of C_2H_5 radicals[10]. Groups of much weaker lines to the low- and high-field side of the free electron *g*-factor appear in addition to the C_2H_5 radical; these disappear, however, in the course of the photolysis.

The evolution and spectral form of this intermediate species are reminiscent of the H_3CCuH primary photoinsertion product observed in the Cu/CH_4 system, implying that H_5C_2CuH probably occurs as an intermediate.

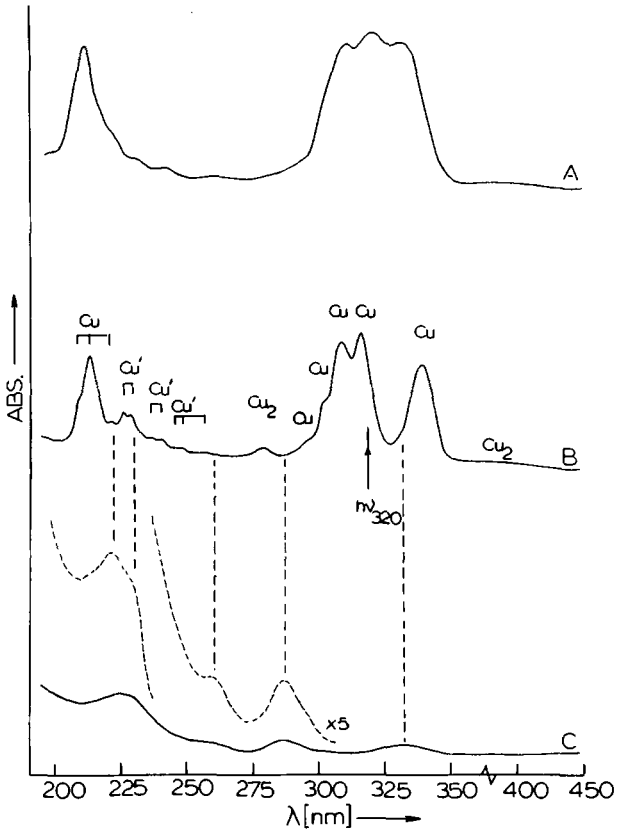

Fig. 1. UV-VIS spectra of Cu/C_2H_6 mixture ($1:10^4$) at 12 K (A), after annealing at 30 K (B), and (C) after photoexcitation (320 nm) at 12 K (*C*).

IR spectroscopic studies of UV-excited Cu/C_2H_6 matrices clearly identified CuH as a photoproduct (band at 1840 cm^{-1}). A weak stretching mode at 1690 cm^{-1} (νCuH) is tentatively ascribed to the proposed photoinsertion product H_5C_2CuH (H_3CCuH: $\nu CuH = 1697$ cm^{-1}[6]). In agreement with earlier studies, we found the IR absorbance of matrix isolated C_2H_5 radicals to be very weak[13]. All these results are, therefore, consistent with the following mechanism:

$$Cu(^2S)/C_2H_6 \xrightarrow[12\ K]{h\nu(300-340\,nm)} Cu(^2P)(C_2H_6) \xrightarrow{\text{photoinsertion}} H_5C_2CuH \xrightarrow{\text{secondary photolysis}} H_5C_2^{\odot} + CuH$$

Of particular significance in this study is that H_3CCuCH_3, H_3CCu, or $H_3C^{\odot}$ were not observed, which indicates that C—H bond insertion processes are highly favored over C—C bond insertion or cleavage reactions. The similar behavior of excited Cu atoms in CH_4 and C_2H_6 matrices supports the assumption that insertion into the C—H bond is the primary photochemical step.

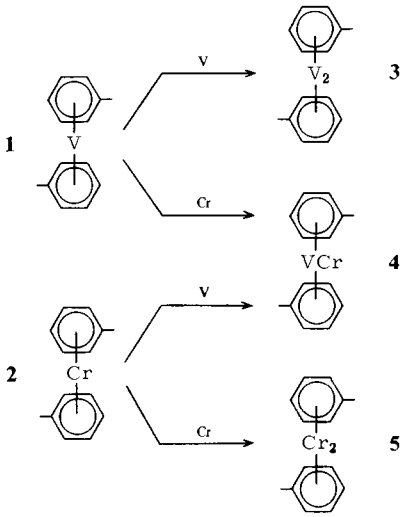
Arene-Metal Clusters: Metal Atom-Bis(arene)metal Solution Phase Chemistry**

By *Geoffrey A. Ozin** and *Mark P. Andrews*

Liquid organomono-[1], di-[2] and trimetallic polymers[3] have recently been synthesized at 250 K from transition metal atoms and poly(methylphenylsiloxane) (DC 510). Subsequent experiments led to the discovery of liquid polymer-stabilized parent members of series of homologous homo- and heterometallic clusters[2,4].

We have now investigated the initial stages of cluster formation in DC 510 and similar systems, whereby aggregates of composition $(arene)_nM_m$ are formed. The procedure employed in this study involved the reaction of pure samples of bis(toluene)vanadium **1** or bis(toluene)chromium **2** in methylcyclohexane solution at 140—160 K with vanadium or chromium atoms (metal atom microsolution method)[12]. Since the dimetal compounds **3—5** absorb at considerably longer wavelengths than the metal ligand charge transfer (MLCT) bands of complexes **1** and **2**, reactions can be followed by UV spectroscopy.

The absorption spectra of purified samples of **1** and **2** (synthesized both by Fisher-Hafner and metal atom methods) show very intense MLCT transitions at 324 and 318 nm, respectively. A solution of **1** in methylcyclohexane at 140 K reacts with V atoms to give the divanadium compound **3**, which absorbs at 453 nm (Scheme 1)[2-4]; **1** reacts with Cr atoms to give the heterodimetallic species **4**, which absorbs at 420 nm. The latter wavelength is the same as that attributed to CrV produced by co-condensation of atomic Cr and V into DC 510 (250 K)[2-4].

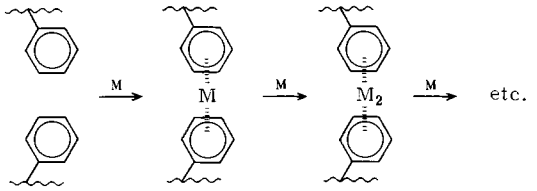


Scheme 1.

Similarly, Cr and V atoms react with the complex **2**; **2** reacts with Cr to give **5**, which absorbs at 405 nm, paralleling the observations made for the Cr/DC 510 system[2,4].

Since we found no evidence for free arene or metal displacement reactions, the dimetallic species **3—5** were probably formed by direct addition of a metal atom to the metal center of $(toluene)_2M$.

Based on our new results we propose that arene-stabilized dimetal complexes are produced *via* one-step addition of a metal atom to a bis(arene)metal target center, and that formation of dimetallic, trimetallic and higher clusters in DC 510 is a process proceeding from a parent bis(arene)transition-metal complex to higher nuclearity metal clusters as shown in Scheme 2.



Scheme 2.

The Cycloaddition of Carbonyl-Flanked Methylene Bridges— A Novel Method for the Synthesis of Metallacycles**

By *Christine Bauer, Ernst Guggolz, Wolfgang A. Herrmann*, Gangolf Kriechbaum*, and *Manfred L. Ziegler*

Carbene additions to metal-metal multiple bonds using diazoalkanes as starting compounds usually lead without difficulty to dimetallacyclopropanes. We now report on an exceptional case—the first cycloaddition of ketocarbenes to a coordinatively unsaturated carbonylmetal compound.

According to earlier findings[1,5,7,10b] it was expected that α-diazoketones **2a-d** would react with the dirhodium compound **1** to form the dimetallacyclopropanes **3a-d.** Indeed, **1** reacts rapidly with **2a-d** at −40 to +25 °C with quantitative elimination of N_2, but, instead of **3a-d,** their novel constitutional isomers **4a-d** are formed exclusively (isolated yields 80—95%). A single crystal X-ray structural analysis was carried out on **4a** (Fig. 2).

Figure 2 shows that the ketocarbene derived from **2a,** beyond conventional μ,η¹-fixation to the Rh=Rh bond of

1, adds *via* the oxygen atom to a carbon monoxide ligand. This bond [C(1)—O(2)] completes a five-membered, nonplanar metallacycle. In addition, the keto C-atom C(3) is coordinated to Rh(2), while the remaining CO group unsymmetrically bridges the RhRh single bond. Despite the practically equal Rh(1)—C(4) and Rh(2)—C(4) bond lengths (202.8(7) and 205.6(6) pm, respectively), as present in typical μ-methylenedirhodium complexes[5, 7, 10b], the angle θ (61.7°) between the Rh(1)—Rh(2) vector and the plane defined by C(3), C(4), C(41) does not fulfil the orthogonality criterion of this class of compounds. The methylene character of the ketocarbene derived from **2a** is thus essentially lost in favor of formation of a π-olefin-like coordination of C(3) and C(4) to Rh(2). It is confirmed by ^{13}CO labeling that the keto functions of **2a—d** preserve their identity during the synthesis of **4a—d.**

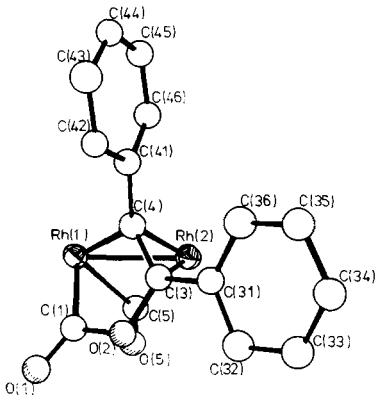

Fig. 2. ORTEP diagram of the structure of **4a** (without the centrally bound C_5Me_5 ligands) in the crystal.—**4a:** IR (ν(CO); cm^{-1}): 1813 vs, 1695 vs [THF]; 1815 vs, 1690 vs [KBr]. [^{13}CO]-**4a** has additional bands at 1773, 1655 [THF] and 1770, 1645 [KBr].—^1H-NMR (90 MHz, 25°C, [D_8]THF, int. TMS): δ(CH_3) 1.52 (s, 30H), δ(C_6H_5) 6.80—7.25 (m, 10H).—$^{13}C\{^1H\}$-NMR (22.63 MHz, 30°C, CD_2Cl_2, *ca.* 45% ^{13}CO-enrichment): δ(CH_3) 9.16, 8.51 (s); δ($C_5(CH_3)_5$) 103.73, 109.83 (d; $^1J_{Rh,C}$ = 4.9 Hz); δ(C_6H_5) 125.09, 126.41, 126.70, 127.85, 129.07, 137.5, 146.68; δ(C(4)) ≈ 169 (m); δ(C(1)) 190.82 (dt; $^1J_{Rh,C}$ = 52 Hz); δ(C(5)) 227.17 (ABXY-system with A = C(1), B = C(5), X, Y = Rh(1) and Rh(2); $^1J_{Rh,C}$ = 58 Hz).—FD-MS (from acetone): *m/z* 726 (molecular ion).—In the ^1H-NMR spectrum (CD_2Cl_2) of **4b** the $C_5(CH_3)_5$- and $C_6H_4OCH_3$-protons are also nonequivalent (δ 1.52, 1.53 and 3.69, 3.87, singlets).

In order to synthesize the metallacycles **4a—d** *via* the μ-methylene derivatives **3a—d** the following obstacles must be overcome: 1) The ketocarbene group of **2** or **3** may not be part of a rigid ring system that prevents twisting of the two ligand halves about the C(3)—C(4) bond. As a key example, compound **3** having a 1,3-dioxoindan-2-ylidene bridge that resists intramolecular cyclization even under drastic conditions may be cited[9].—2) The cyclization **3**→**4** calls for keto groups with strongly nucleophilic oxygen atoms, as has been demonstrated by internal competition experiments. Thus, if **1** is treated with **2e,** then *exclusively*

$C_2H_5OCO—C(=N_2)—C(=O)—COOC_2H_5$ **2e**

the keto O-atom, but not an ester O-atom adds to the CO ligand during the formation of **4e** (X-ray structure analysis). Consistent with this finding, subsequent intramolecular cycloaddition of the stable complexes [μ-$C(CO_2Alkyl)_2$][(η^5-C_5Me_5)Rh(CO)]$_2$ fails[5, 7, 10b]. According to IR spectroscopic investigations, reaction of **1** with **2e** rapidly forms **3e** at −78°C, which compound is subsequently converted at *ca.* −30°C into **4e.**—3) The ring-closure reactions analogously call for sufficiently electrophilic CO ligands. This explains why the cobalt analog of **1** does not yield cycloadducts of type **4** on reaction with **2a—e.**

A New Route to Pyridine Derivatives: Reaction of *N*-Methylene-*tert*-butylamine with Enamines**

By *Mitsuo Komatsu**, *Hideo Ohgishi, Shigeki Takamatsu, Yoshiki Ohshiro,* and *Toshio Agawa*

We report a new and mechanistically novel synthetic method for 3,5-disubstituted pyridines[2]. The present process is characterized by high conversions and ready availability of starting materials.

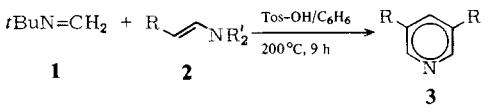

Table 1. Preparation of 3,5-disubstituted pyridines **3.**

	R	NR'_2	Catalyst	Yield [%] [a]
a	Me	piperidino	tos-OH	67
b	Et	piperidino	tos-OH	72
c	*i*-Pr	piperidino	tos-OH	78
d	*c*-C_6H_{11}	piperidino	—	85
e	Ph	morpholino	—	73
f	PhS	dimethylamino	tos-OH	87

[a] Yields determined by ^1H-NMR spectroscopy; yields of isolated products were 0-20% lower than these values.

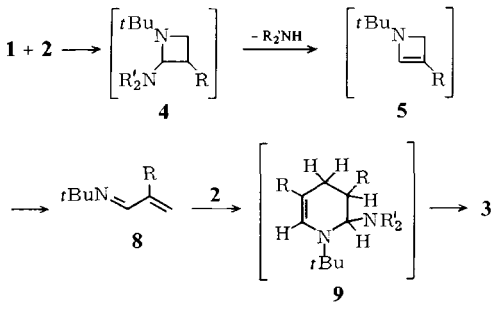
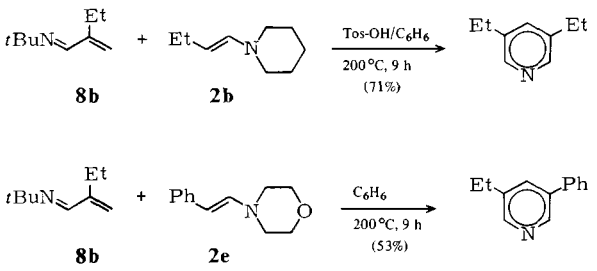
[**] This work was supported by grants from the Ministry of Education (No. 543025) and the Watanabe Foundation.

The pyridine derivatives **3** are easily obtained by heating *N*-methylene-*tert*-butylamine **1**[3] and enamines **2** (1:2 molar ratio) in the presence of *p*-toluenesulfonic acid (0.03 equiv.) (Table 1). The method can also be used for enamines having bulky substituents (Ph, *c*-C_6H_{11}).



We presume that the reaction proceeds *via* the intermediate azadiene **8**, which undergoes cycloaddition[4] with enamine **2** to give the tetrahydropyridine **9**. Subsequent thermal- or acid-catalyzed cleavage of R'_2NH, $CH_2{=}C(CH_3)_2$, and H_2 from **9** leads to the aromatic pyridine derivatives.



The intermediate **8** could be isolated in 13—53% yield under milder conditions when the substituent R is less bulky. Reaction of **8b** with 1-butenylpiperidine to give 3,5-diethylpyridine confirms the suggested mechanism. The reaction also offers a preparative route to unsymmetrical 3,5-disubstituted pyridines, as indicated by the reaction of **8b** with 1-styrylmorpholine to give 3-ethyl-5-phenylpyridine.

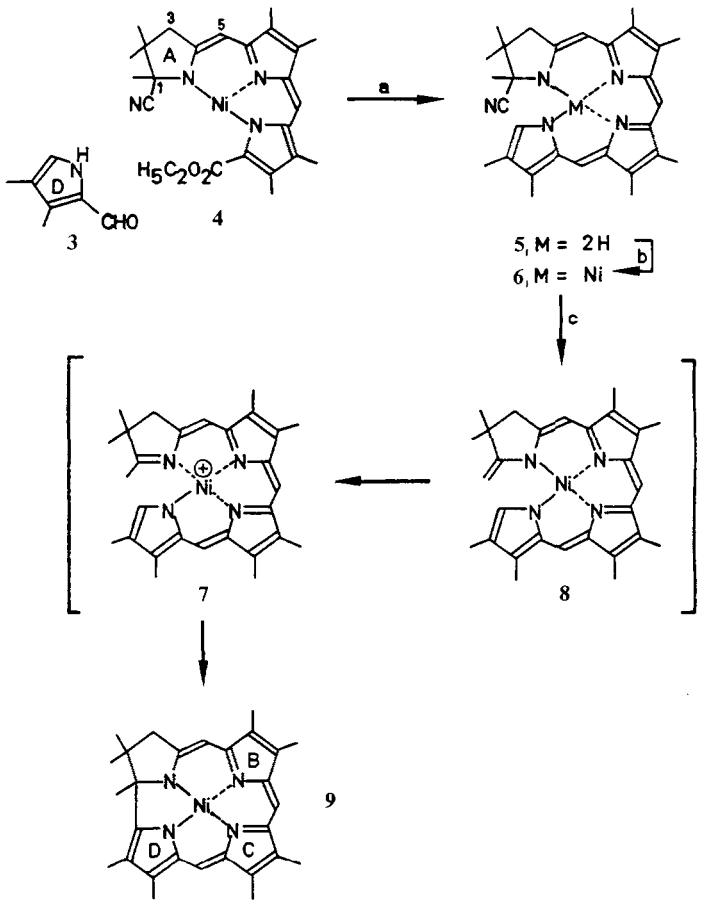
(A→D) Ring Closure to the Nickel(II)-B,C,D-Hexadehydrocorrinate**

By *Franz-Peter Montforts**

Direct coupling of rings A and D is an essential structural element of the corrins. The multiplicity of their modes of formation by cyclization is important regarding the question of the origin of the corrin structure[1]. The spectrum of ring closure reactions extends from the photochemical A→D cycloisomerization, a key step in the synthesis of vitamin B_{12}, to the acid-catalyzed dehydrobilin cyclizations, which yield the corroles and octadehydrocorrins. The B,C,D-hexadehydrocorrin-type **9**[6] has so far been a missing member of the corrin family. We report here on the synthesis of a correspondingly protected secocorrin **6** and its convenient cyclization to **9** (Scheme 1).



Scheme 1. Reaction conditions: a: 1) **4** in tetrahydrofuran (THF + 100 eq. KOH in CH_3OH-H_2O (9:1), reflux, under argon (hydrolysis of the ethyl ester), crude work-up; 2) +2.5 eq. **3** + 9 eq. *p*-toluenesulfonic acid in $CHCl_3$, reflux, under argon (50% crystalline), b: 4 eq. $Ni(CH_3CO_2)_2 \cdot 4H_2O$ + 28.5 eq. sodium acetate in CH_3OH-THF (2:1), room temperature (69% crystalline). c: 1) 100 eq. KO*t*Bu in *t*BuOH (degassed) 70°C, under argon; 2) KH_2PO_4, H_2O, CH_2Cl_2, extraction (73% crystalline). Selected UV/VIS data of **6** and **9**: **6** ($CHCl_3$): λ_{max} = 405 nm ($\log\varepsilon$ = 4.60), 726 (4.35). — **9** ($CHCl_3$): 405 (4.56), 765 (4.21).

Alkaline hydrolysis of the ester function of the nickel complex **4**[7], followed by acid-catalyzed condensation with decarboxylation and decomplexation with the pyrrolecarbaldehyde **3**[8] furnishes the tetracyclic ligand **5**, which is recomplexed with nickel acetate to give **6**. Base-induced elimination of the cyanide group to give **8** and, most likely, subsequent protonation[2d,9] of the 1-methylene group leads to **7**, which cyclizes, and after deprotonation yields **9**.

Heme Biosynthesis from Isomeric Uroporphyrinogens**

By *Burchard Franck**, *Wilfried Bock*, and *Udo Wolters*

Uroporphyrinogen III, **1a**, is precursor and key building block[1] in the biosynthesis of the blood pigment heme **4a**[2], as well as of related biologically active tetrapyrroles[3]. Of the three other **1a**-isomers, which differ from each other by "inversion" of the pyrrole rings (in dotted circles), only uroporphyrinogen I, **2a**, has been found in nature. Since uroporphyrinogen I, the red dehydration product of **2a**, is deposited in all organs with pathological disorders of heme biosynthesis (porphyrias) it has been assumed that **2a** is not a biosynthetic precursor of **4a**[4]. We have now found that uroporphyrinogen I, **2a**, and even II, **3a**, can be converted enzymically into heme **4a**.

[**] Tetrapyrrole Biosynthesis, Part 15.—Part 14: G. Bringmann, B. Franck, *Liebigs Ann. Chem.*, in press.

Hemolyzed duck blood served as the enzyme system for the incorporation experiments. In order to enable reliable statements to be made, the starting materials were dimensioned to correspond to amounts of product in the mmole region. ^{14}C- and ^{3}H-labeled uroporphyrinogens I, **2b**, II, **3b**, III, **1b**, and **1c** were obtained by total syntheses involving 15—22 steps. Selective ^{3}H-labeling of **1c** was performed using $[Mg(py)_6]I_2/^{3}H_2O$.

In order to be able to compare the incorporation of the isomeric uroporphyrinogens unimpaired from variations in enzyme activity, they were "fed" as pairs, one component of which was labeled with ^{14}C, the other with ^{3}H, to the enzyme system. Final ^{14}C- and ^{3}H-determination of the heme **4b**, which was isolated from these competition experiments and purified to constant radioactivity gave the incorporation values of the uroporphyrinogens (Table 1).

Table 1. Competitive incorporation of the isomeric uroporphyrinogens (Uro'gens) III, **1b**, **1c**, I, **2b**, and II, **3b** into heme **4b** over 48 h.

Experiment	Precursor	Radioactivity [nCi] Precursor	4b	Incorp. [%]
1	^{14}C-Uro'gen III **1b**	360	34.5	9.6
	^{3}H-Uro'gen III **1c**	750	23	3.1
2	^{14}C-Uro'gen I **2b**	1920	56.6	2.9
	^{3}H-Uro'gen III **1c**	910	32.8	11.2 [a]
3	^{14}C-Uro'gen II **3b**	610	10.2	1.7
	^{3}H-Uro'gen III **1c**	920	37.3	12.6 [a]

[a] Corrected with the tritium-loss factor from the experiment No. 1 (=3.10).

The uroporphyrinogens I, **2**, and II, **3**, which previously had not been considered as heme precursors, exhibit significant incorporation values of 2.9 and 1.7%, respectively, which are only smaller than those of uroporphyrinogen III, **1**, by a factor of 4 to 7. Presumably, inversion of the pyrrole nuclei D and B, respectively, occurs in the enzymic conversions of **2** and **3** into the blood pigment heme **4a**.

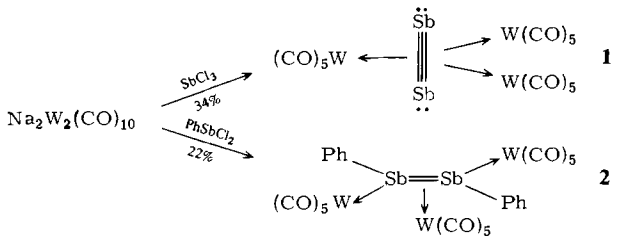
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

larly the homologue of azobenzene Ph—Sb=Sb—Ph is not stable as the monomeric molecule in the free state.

These reactive species have now been stabilized for the first time as complex ligands in the compounds **1** and **2**. The diantimony complex **1** is formed on reductive dehalogenation of $SbCl_3$ with $Na_2W_2(CO)_{10}$; under the same conditions (tetrahydrofuran, 20 °C; SiO_2, toluene/*n*-pentane as eluent), $PhSbCl_2$ furnishes the "stibobenzene" derivative **2**. Both complexes are obtained in the form of red



crystals (m.p. 140 and 110 °C (dec), respectively) which are stable at 20 °C, even on exposure to air. Their composition is secured by elemental analysis and spectroscopic data, their structure by X-ray structure analyses (Fig. 1).

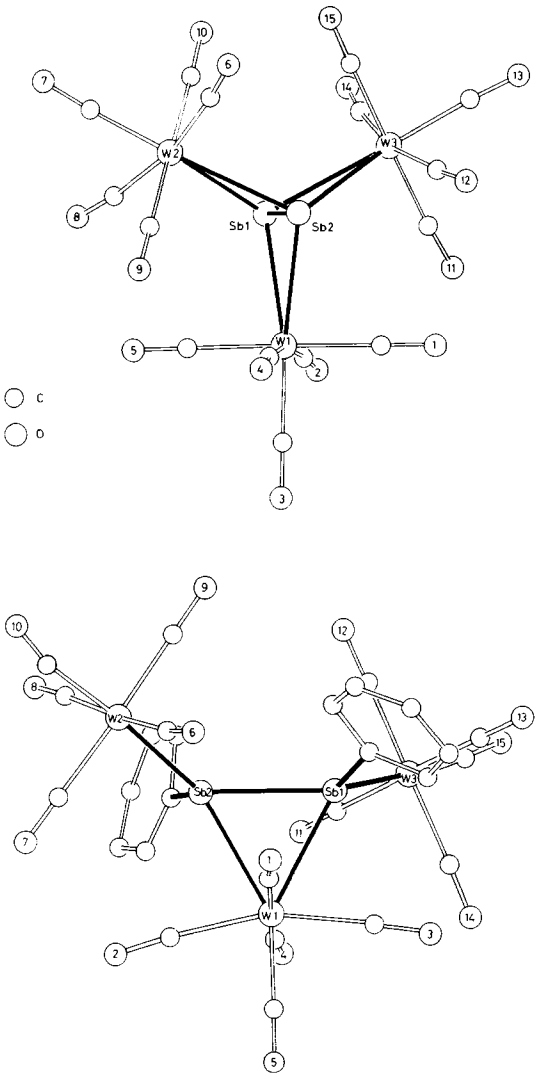


Fig. 1. Structures of the new complexes **1** (top) and **2** (bottom) in the crystal.

In the star-shaped diantimony complex **1** the Sb_2-dumbbell forms the axis of an Sb_2W_3 skeleton with idealized D_{3h} symmetry. All three bonding electron pairs of the Sb≡≡Sb ligand are coordinatively active and bind a total of three $W(CO)_5$ moieties. We recently observed and analyzed this novel bonding behavior, in which an N_2-homologous ligand is coordinated "side-on" as 6e donor to three 16e fragments, for the first time for the molecule $[As{\equiv}As\{W(CO)_5\}_3]$ homologous to **1**[6]. Despite lengthening by the coordinative interaction, the Sb—Sb distance in the diantimony ligand with a length of 266.3 pm is about 20 pm shorter than the Sb—Sb single bond[1b]. A similarly short Sb—Sb distance is found in **2**, in which the azobenzene-homologous PhSb=SbPh is coordinated *via* both free electron pairs as σ-ligand and *via* the double bond as π-ligand. While similar forms of coordination have already been observed previously for "arsenobenzene"[5b], **2** is the first example of a complex-stabilized "stibobenzene".

Novel Synthesis of Spiro[1,8a]dihydroindolizines; A New Photochemically Reversible System**

By *Hubert Gross* and *Heinz Dürr**

Photochromic systems are of interest, *inter alia*, in silver-free photography, in data storage[1a,c], and as potential solar energy conversion systems[2]. Photochromic systems based on spiro[1,8a]dihydroindolizines **7** are well known[3].

We report here on a novel synthesis of **7**, which does not require the use of spirocyclopropenes and which for the first time can also be carried out with thermally labile[4] as well as CN- or CF_3-substituted[3b] spiro-3H-pyrazoles **1**. The new systems **6a/7a** and **6b/7b** are photochemically reversible ("photochemically switchable").

Irradiation of a solution of **1** in **5**, or more advantageously of **1** dissolved in a 1% etheral solution of **5** (HPK/125 W lamp, Pyrex filter) affords **7** in moderate to very good yields (see Table 1). Intermediates formed in the pho-

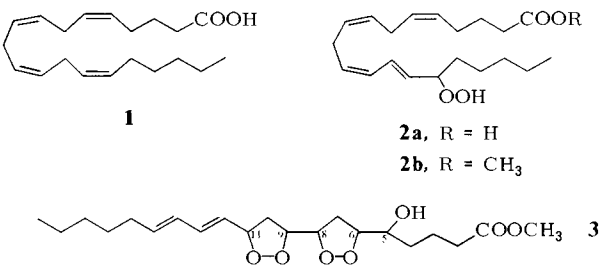
Serial Cyclizations of An Arachidonic Acid Hydroperoxide

By *Jamil A. Khan* and *Ned A. Porter**

The mechanistic pathways involved in the free radical autoxidation of polyunsaturated fatty acids and esters have not been fully elucidated. Autoxidation of 5,8,11,14-eicosatetraenoic acid (arachidonic acid) **1**, for example, leads not only to the biologically important[1] hydroperoxy eicosatetraenoic acids (HPETE) **2a**[1a], but also to cyclic peroxides (dioxolanes) that may have some biological significance.

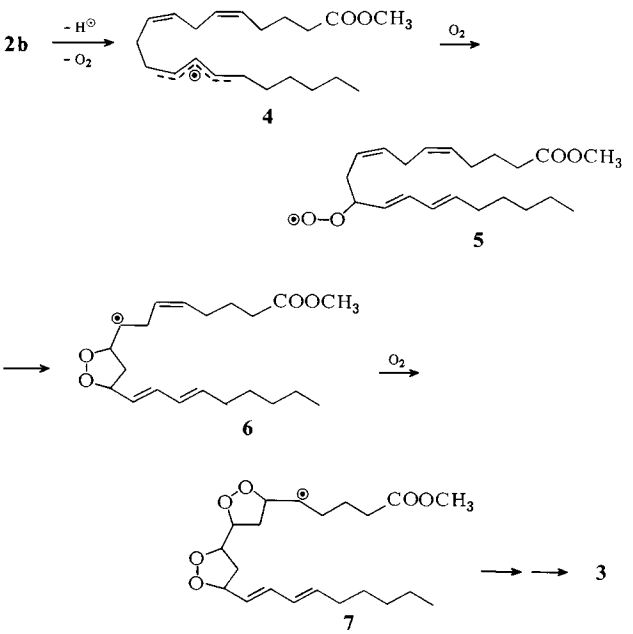
We have studied the free radical oxidation of methyl 15-hydroperoxy eicosatetraeonate (15-HPETE) **2b**, and report here on the isolation of the bisdioxolanes **3** formed in this reaction. Isolation of the polycyclic peroxides **3** from **2b** establishes the importance of β-scission of peroxyl radicals and serial cyclization in the oxidation of polyunsaturated fatty acids[1b, 15].

The autoxidation of **2b** was studied by leaving a solution of **2b** in the presence of di-*tert*-butyl hyponitrite for *ca.* 30 h under oxygen at room temperature.



The resulting product mixture was treated with polymer-bound triphenylphosphane to reduce any hydroperoxide functionality to hydroxide. The six most polar diastereomeric peroxides **3** were isolated by high-pressure liquid chromatography in 5—10% yield. The ^{1}H-NMR and UV spectra showed that these compounds are conjugated dienes and all had (*E,E*) configurations, suggesting the presence of two dioxolane rings and a secondary hydroxy group. The structural assignments followed from a mass spectroscopic analysis of the compounds formed after reduction to polyols by H_2/Pd and their subsequent silylation.

Since hydroperoxides are precursors of peroxyl radicals[15], and β-scission has been proposed to account for the product distribution in the autoxidation of linoleic and arachidonic acids[16], the mechanism shown in Scheme 1 could account for the formation of **3** from **2b**.



Scheme 1.

The formation of only six of the 16 possible diastereomers of **3** in the oxidation of **2b** suggests some stereoselectivity in the cyclization leading to **3**. In particular, the for-

mation of *cis*-3,5-disubstituted 1,2-dioxolanes is strongly favored[9, 15]. Only four diastereomers of **3**, however, could be *cis*-substituted on both dioxolane rings. While we cannot unambiguously assign structures to all diastereomers, comparison of ^{1}H-NMR spectroscopic data from **3** with that of other dioxolanes[17] suggests that four of the six products are *cis*-substituted on both dioxolane rings, while the remaining two isomers have one *cis*- and one *trans*-substituted dioxolane ring.

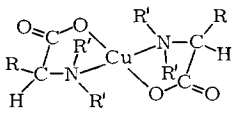
Resolution of D- and L-Amino Acids by HPLC using Copper Complexes of *N,N*-Dialkyl-α-amino Acids as Novel Chiral Additives

By *Shulamith Weinstein**

We report the separation of α-amino acid enantiomers by reversed phase high performance liquid chromatography (HPLC), using Cu^{II} complexes of *N,N*-dialkyl-α-amino acids **1** as chiral additives to the mobile phase. The



1

N,N-dialkyl groups were systematically varied to evaluate the influence of structural features on chiral differentiation, and hence contribute to the understanding of the technique and widen its scope. The work is based on the method of *Hare* and *Gil-Av*[1, 2], who resolved α-amino acids using the Cu^{II}-L-proline complex.

The stereoselectivity in the system stems from the difference in equilibrium constants for ligand exchange between the chiral additive CuL_2 (L is ligand of L-configuration) and the L′ and D′ molecules (L′ and D′ are L- and D-enantiomers, respectively) of the substrate undergoing resolution:

$$CuL_2 + L' \rightleftharpoons CuLL' + L \qquad CuL_2 + D' \rightleftharpoons CuLD' + L$$

Ligand exchange may occur in the aqueous mobile phase or on the stationary phase, which resembles an organic solvent by virtue of its long chain (C_{18}) molecules. The ligands L were constructed such that the number of *cis-trans* and conformational isomers of the square-planar complex be limited, and that its lipophilicity (for interaction with the stationary phase) could be gradually modified. *N,N*-dialkylamino acids fulfil these requirements. In addition, inspection of molecular models indicates that the ternary diastereomeric complexes of Cu^{II}, *N,N*-dialkylamino acid, and amino acid are also crowded molecules, reducing the number of possible isomers.

The following amino acid derivatives were prepared, converted into their copper(II) complexes **1**, and these added to the mobile phase for the HPLC separation:

$R'_2N—CHR—COOH$
$R = CH_3$ (alanine), $CH(CH_3)_2$ (valine)
$R' = CH_3$, C_2H_5, n-C_3H_7, n-C_4H_9, n-C_5H_{11}

Good resolutions were obtained e.g. the ratio of the elution times for the separation of L- and D-valine (62.1 and 11.0 min, respectively) using the Cu^{II} complex of *N,N*-dimethyl-L-valine is 5.65 and that of L- and D-glutamic acid using the Cu^{II} complex of *N,N*-di-*n*-propyl-L-alanine is 1.80. Relatively small variations in the length of the *N*-alkyl group strongly influence the stereoselectivity, whereas alanine and valine derivatives which had appreciably different α-carbon substituents but the same *N*-substituents were resolved to a similar extent. Using a given chiral eluent, the same order of elution for the enantiomers was observed for all the amino acids investigated (except for histidine). This indicates that for a given ligand L, the ternary complexes, CuLL′ and CuLD′ probably have a similar structure, and that the relative stabilities of CuLL′ to CuLD′ are the same for all the α-amino acid ternary complexes. The elution order of the enantiomers of all the amino acids is reversed when *N,N*-diethyl complexes are added to the eluent. This emphasizes the role played by the N atom coordinated to the metal. Because of the requirement for planarity in Cu^{II} complexes, and the high steric bulk around the alkylated nitrogen, small changes in structure and conformation in the coordination sphere produce a large effect on the selectivity in forming diastereomeric species.

The anomalous order of elution observed with the enantiomers of histidine in presence of the *N,N*-dimethyl- and *N,N*-diethyl-complexes of both alanine and valine is probably due to coordination of the imidazole nitrogen to Cu^{II}. With higher alkylated derivatives in the eluent, coordination of the imidazole nitrogen is sterically less favored, and "normal" elution occurs.

The fraction of complex **1** adsorbed on the stationary phase is greater than that in the aqueous phase. Furthermore, stability constants of copper(II)-amino acid complexes were found to be higher in organic solvents than in aqueous solution[8]. Thus, a higher percentage of diastereomeric species—upon which selectivity depends—is found in the stationary phase, supporting the view that chiral differentiation depends mainly on interactions with species adsorbed on the stationary phase.

The novel complexes **1** thus extend the scope of the method described by *Hare* and *Gil-Av*[1, 2]. The Cu^{II} complex of *N,N*-di-*n*-propyl-L-alanine, resolves *all the enantiomers of the protein amino acids* (with the exception of cysteine, resolved as cysteic acid)[14]. Problems of peak overlap of various amino acids can be solved by varying the *N,N*-dialkylamino acids, and/or by modifying the chromatographic conditions.

A Branched Chain of Seven Neutral Iodine Molecules in Crystalline Bis(dithizone)hepta(diiodine)**

By *Frank H. Herbstein** and *Willi Schwotzer*

Dedicated to Professor David Ginsburg on the occasion of his 60th birthday

Although oligomeric chains of iodine and iodide moieties (specifically I^-, I_2, I_3^-) are quite common among polyiodide anions[1] (the largest example known is the S-shaped ion I_{16}^{4-} ($I_3^- \cdot I_2 \cdot I_3^- \cdot I_3^- \cdot I_2 \cdot I_3^-$) found in crystalline (theobromine)$_2 \cdot H_2I_8$[2a]), only one oligomeric polyiodine cation is known (I_{15}^{3+} in $I_5^+SbF_6^-$[2b]), and only one compound containing a chain of neutral iodine molecules (bis(triphenylphosphane sulphide diiodine) diiodine[2c], in which an $(I_2)_3$-chain is anchored at its two ends by sulfur atoms).

We have now found that a mixture of dithizone and iodine (1 : 4) refluxed in $CHCl_3$ gives black needles of composition (dithizone)$_2(I_2)_7$ **1** on cooling. The known compound dithizone$\cdot I_2$[3] is obtained if a 1 : 1 molar ratio is used.

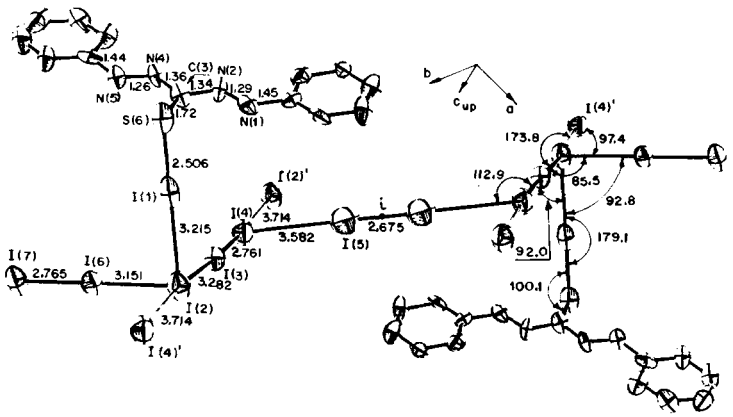

Fig. 1. Structure of **1** in the crystal. Standard deviations <0.005 Å (I—I), <0.04 Å (C—N, C—C), ≈0.1° (∢III).—**1** forms triclinic crystals, $a = 13.212(8)$, $b = 10.137(7)$, $c = 9.746(6)$ Å, $\alpha = 101.8(1)$, $\beta = 87.1(1)$, $\gamma = 109.4(1)°$, $Z = 1$, $P\bar{1}$; $Mo_{K\alpha}$ irradiation, solved using Patterson and direct methods (MULTAN 77), refined to $R = 8.6\%$ with 2916 reflections in the final refinement cycle. I(2)', I(4)', and the corresponding atoms in the other molecular half belong to neighboring molecules.

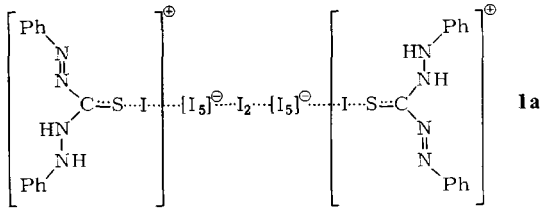
The centrosymmetric molecules **1** (Fig. 1) contain nonplanar $(I_2)_5$-chains anchored at both ends by sulfur atoms; furthermore the iodine chain is branched by bonding of two additional iodine molecules at I(2) and I(2'). The bond lengths and bond angles suggest that **1a** contributes significantly to the overall resonance hybrid.



1a

The I_5^- units have dimensions similar to those found in the discrete V-shaped pentaiodide ions of bis(potassium valinomycin)pentaiodide triiodide[4a] and the interacting V-shaped pentaiodide ions of tetramethylammonium pentaiodide[4b]. The CS distances in **1** (1.722(10) Å) are about the same as those in the CT-compound *N*-methylthiocaprolactam iodine[5a] (1.716(5) Å), and the SI distances in **1** (2.506(8) Å) are shorter than in the comparable compound (2.688(2) Å). Nevertheless the S-bound iodine moieties in **1** are not to be interpreted as true cations, for these would be expected to pack as separate units in the crystal structure (cf. [5b]). This description of the bonding in the iodine chain can only be a first approximation; the distances between the I atoms of neighboring molecules are only 3.714(3) Å.

The dithizone moieties have an *anti-s-trans* conformation as do other dithizone derivatives. Unfortunately, the bond lengths in the dithizone moiety are not accurate enough to allow conclusions to be drawn about the intramolecular bonding or tautomerism. H atoms bonded to nitrogen could not be detected in difference maps.

Ph(Me$_3$Si)C=PCl as Educt for Methylenephosphanes with Alkyl-, Amino-, Phosphino-, Alkoxy-, or Alkylthio-Groups on Phosphorus**

By *Rolf Appel** and *Ursula Kündgen*

Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday

Until now only compounds of two coordinated triply bonded phosphorus with doubly bonded nitrogen, phosphorus, and carbon were known[10]. In contrast to iminophosphanes[6, 7], as well as phosphandiyl-[8] and phosphorandiylphosphanes[9], methylenephosphane compounds with P—H, P—Si, and P—halogen bonds[5] have also been synthesized; acyclic *P*-phosphino, -alkoxy- and -alkylthio derivatives have, however, not been prepared.

We have now found that the *P*-chloro(methylene)phosphane **1**[5] is highly suitable for the preparation of the novel phosphanes **2**—**6** with X—P=C part structures (X = C, N, P, O, S).

Macrocycles of D- and L-Proline Residues**

By *Manfred Rothe** and *Werner Mästle*

Dedicated to Professor Leopold Horner on the occasion of his 70th birthday

Peptides containing consecutive proline residues are considerably restricted in their conformational flexibility because of the relatively rigid pyrrolidine rings and strong steric interactions with their neighboring proline residues. Linear oligoprolines with D- and L-structural units are therefore excellent examples for demonstrating the influence of conformation and configuration on the ring closure of a chain.

We have now synthesized for the first time macrocyclic peptides with up to 24 L- and D-proline residues by cyclooligomerization of activated triproline esters. A series of cyclic oligotripeptides *c*-(D-Pro-L-Pro-L-Pro)$_n$ with $n = 1$—8 was obtained, and their ring sizes were determined by MS and GPC (Table 1). *c*-(D-Pro-L-Pro-L-Pro) is the first cyclotripeptide which is present exclusively in the boat conformation, both in the crystal and in solution[4].

Table 1. Cyclopeptides *c*-(D-Pro-L-Pro-L-Pro)$_n$ [a].

5	250 (dec.)	−101.8	462	1455; $(M+Na)^+$

[a] Lyophilized products from water. [b] $c = 1$, H_2O. [c] Elution volumes (GPC, Sephadex LH 20).

Furthermore, we were also able to synthesize the alternating L,D-cyclohexapeptide *c*-(L-Pro-D-Pro)$_3$, for which a highly selective complexation of cations has been postulated[2] (26%, dec. >310 °C).

Tripeptides with CONH-groups in principle undergo cyclodimerization to give cyclohexapeptides; however, no larger rings than *c*-triprolyl are formed during ring closure of *all*-L-triproline even at higher concentrations. This can be attributed to the fact that, according to NMR findings, linear oligo-L-prolines already from $n = 3$ onwards have relatively rigid helical structures with spatially fixed terminal groups, and therefore cannot cyclize. The incorporation of D-proline alters the spatial orientation of the peptide chain. Due to the bridging of the N—C_α bond in the proline the configuration at C_α has a very much stronger influence on the backbone conformation of the peptide chain than in the "usual" amino acids of different chirality.

On ring closure of the diastereomeric L,D-triproline derivatives, each of which give identical cyclopeptides of definite ring size, drastically different cyclization tendencies

[**] Cyclic Peptides, Part 30. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. A. Sander for recording the mass spectra.—Part 29: M. Rothe, E. Frank, G. Schmidtberg in K. Brunfeldt: *Peptides 1980, Proc. 16th Eur. Peptide Symp.* Copenhagen 1980, p. 258.

were established depending on the configuration sequence and the reaction conditions (see Table 2).

Model considerations reveal that the terminal groups of the linear triproline derivatives containing *cis*-peptide bonds, which are required for ring closure to the cyclotripeptide, are present in a quasi-"cisoid" (L,L,L- and D,L,L-sequence) or quasi-"transoid" (L,D,L- and L,L,D-sequence) arrangement with respect to the less flexible peptide backbones. This leads to a greatly varying distance between the chain ends and thus to a very different tendency to undergo ring closure.

Thus, on using diastereomeric triprolines a very striking example has been discovered for demonstrating the dependence on sequence of the cyclization of linear peptides forming identical cyclopeptides[8]. This dependence on sequence is based on the different conformation of the educt chains due to changes in the α-carbon configuration.

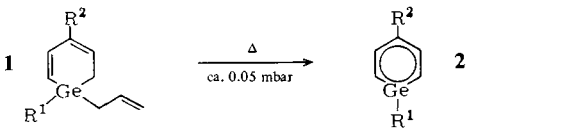
1,4-Dialkylgermabenzenes-Generation and Detection in the Gas Phase**

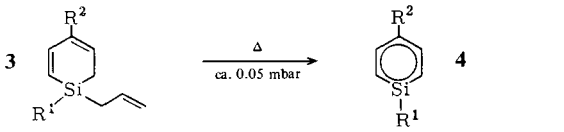
By *Gottfried Märkl, Dieter Rudnick, Reinhard Schulz,* and *Armin Schweig**

We report here on the first, direct spectroscopic detection of 1,4-dialkylated germabenzenes in the gas phase by VTPES (variable temperature photoelectron spectroscopy) experiments[3a, 4a].

The germabenzene and silabenzene derivatives, **2** and **4** respectively, were generated from the allylcyclohexadienes **1** and **3** by gas-phase pyrolysis (450–550 °C, *ca.* 0.05 mbar) according to the method of *Barton et al.*[6a, b]. Since only partial conversions (exception: **3b**→**4b**) can be achieved in these reactions the PE spectra of the compounds **2** and **4** in the region of their two ionization bands (7–9.5 eV) were obtained from the product and educt spectra by subtraction.



a, $R^1 = CH_3$, $R^2 = C(CH_3)_3$; **b**, $R^1 = CH_3$, $R^2 = C_2H_5$; **c**, $R^1 = CH_3$, $R^2 = CH(CH_3)_2$



a, $R^1 = CH_3$, $R^2 = C(CH_3)_3$; **b**, $R^1 = R^2 = CH_3$; **c**, $R^1 = H$, $R^2 = C(CH_3)_3$

That the germabenzene derivatives **2** are actually formed during thermolysis of **1** follows from the good agreement of the vertical ionization energies of germa- and the correspondingly substituted silabenzene derivatives (Fig. 4).

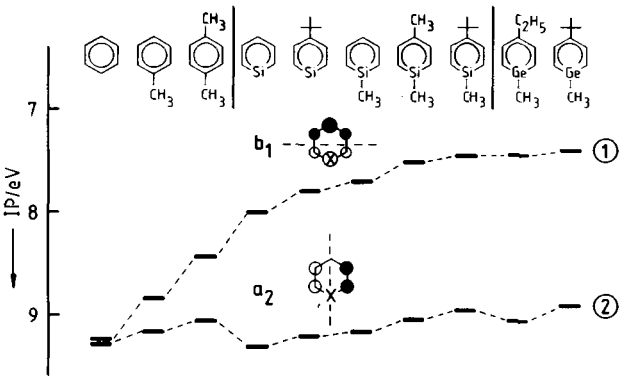


Fig. 4. Vertical ionization energies (IP) ($^2B_1(\pi)$ ① and $^2A_2(\pi)$ ②) of benzene-, silabenzene-, and germabenzene-derivatives. The data for unsubstituted silabenzene and for 1-methyl-1-silabenzene were taken from the literature ([7b] and [6c], respectively).

This agreement is not surprising, since the atomic ionization energies of silicon (8.15 eV) and germanium (7.88 eV) differ only slightly.

From these results we can expect the two first ionizations of the unsubstituted germabenzene to be at 7.95 [$^2B_1(\pi)$] and 9.25 eV [$^2A_2(\pi)$].

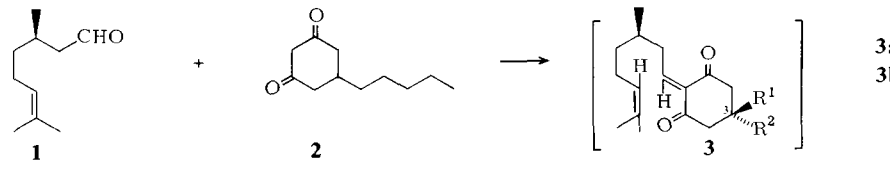
[**] Intramolecular Cycloadditions, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 3: L.-F. Tietze, G. von Kiedrowski, B. Berger, *Tetrahedron Lett. 1982*, 51.

epimer **4a** is almost as active as the natural Δ^8-tetrahydrocannabinol (Δ^8-THC) (**4**, $C^8{=}C^9$), whereas the (9*S*)-epimer **4b** is twenty times less active[1]. Until now, **4** has been synthesized by hydrogenation of Δ^8-THC or Δ^9-THC (**4**, $C^9{=}C^{10}$) resulting in formation of a mixture of both epimers **4a** and **4b**, which are, however, difficult to separate[1].

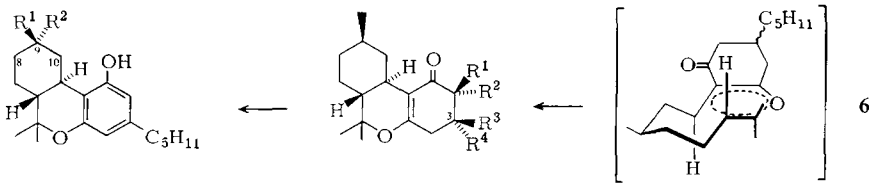
We describe a highly selective synthesis of **4a** and its enantiomer, the key step of which is a stereocontrolled intramolecular Diels-Alder reaction with inverse electron demand.

Condensation of (*R*)-citronellal **1** with 5-*n*-pentyl-1,3-cyclohexanedione[2] **2** at 100 °C in dimethylformamide (DMF) led *via* **3** to a *ca.* 1:2 mixture of both tricyclic pyran derivatives **5a** and **5b**[3] in 65% yield.

The cycloaddition, which presumably proceeds *via* the transition state **6**, is 100% stereocontrolled by the chiral center of citronellal **1**[4]. Formation of both epimeric C-3 compounds can be ascribed to the low stereoselectivity of the aldol condensation (**1**+**2**→**3a**+**3b**). This has, however, no significance for the synthesis of (−)-(9*R*)-HHC **4a**, since C-3 becomes achiral in the subsequent aromatization step.



3a, R^1 = H, R^2 = C_5H_{11}
3b, R^1 = C_5H_{11}, R^2 = H



4a, R^1 = CH_3, R^2 = H
4b, R^1 = H, R^2 = CH_3

5a {R^1 = R^2 = R^4 = H, R^3 = C_5H_{11}}
5b {R^1 = R^2 = R^3 = H, R^4 = C_5H_{11}}
5c {R^1 = SePh, R^2 = R^4 = H, R^3 = C_5H_{11}}
5d {R^1 = R^3 = H, R^2 = SePh, R^4 = C_5H_{11}}

For aromatization, the mixture **5a/5b** is deprotonated by lithium diisopropylamide and converted in 65% yield by phenylselenyl chloride into the selenides **5c** and **5d**, which can be separated by chromatography on silica gel. Oxidation of **5c** and **5d** with *m*-chloroperbenzoic acid at −40 °C to the selenium oxides and subsequent warming up to 25 °C gives, *via syn*-elimination and 1,5-hydrogen shift, the (−)-(3*R*)-HHC **4a**[5] in 70 and 56% yield, respectively. In the elimination step, 3,5-dimethoxyaniline is added to trap the phenylselenenic acid formed (see Part 3). Conversion of **5a/5b** into **4a** can also be carried out as a "one-pot" reaction without isolation of the selenides.

(+)-(9*S*)-HHC (enantiomer of **4a**) can be synthesized in this way using (*S*)-citronellal, which is also commercially available.

BOOK REVIEWS

Gas-Phase Reactions. By *V. N. Kondratiev* and *E. E. Nikitin*. Springer-Verlag, Berlin 1980. xiv, 241 pages, bound, DM 118.00.

V. N. Kondratiev, who died recently, and *E. E. Nikitin* are not just scientists who have made fundamental experimental and theoretical contributions to the knowledge of gas-phase reactions. They are also the authors of extensive books on this subject (*V. N. Kondratiev:* Chemical Kinetics of Gas Reactions, 1964; *E. E. Nikitin:* Theory of Elementary Atomic and Molecular Processes in Gases, 1974). The joint monograph presently in question is not an abridged version or a résumé of their previous books, although certain formal similarities and favorite examples are naturally present. It is an independent review of the subject of gas reactions.

Reaction order, rate lows of complex systems, detection of intermediates such as atoms and radicals, their reactions and macroscopic description are briefly summarized in

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/0303-0222 $ 02.50/0

two introductory chapters. The theory of elementary processes, Chapter 3, then provides the microscopic formulation of collision cross section/rate constants, the dynamics of adiabatic and diabatic transitions, several representative examples of energy hypersurfaces, and a summary of the transition state theory. A central theme of theoretical reaction kinetics—energy transfer in collisions—is treated thoroughly in 30 pages in Chapter 4. For translation (T), rotation (R), and vibration (V), the TR, RT, VT, and VRT processes are discussed, as well as the intermolecular and intramolecular VV processes and the energy transfer in electronically excited particles. A description of unimolecular reactions in theory and experiment follows in Chapter 5, with the keywords strong/weak collisions, high-pressure/low-pressure region, and activation energy. The treatment of recombination reactions follows logically in Chapter 6, where both the radiation and collision stabilization are considered. Chapter 7 gives a summary of bimolecular exchange reactions and the energy relationships observed in them. The fundamentals of photochemical reactions (excitation, fluorescence, sensitized photolysis) are discussed in Chapter 8 and reactions in electrical discharges with examples of the formation of C_2H_2, NH_3, and O_3 in Chapter 9. Chapter 10, written by *V. L. Talroze,* is an authoritative introduction to the field of radiation chemistry, with emphasis on negative ions, ion-molecule and ion-ion recombination reactions, and radiolysis of hydrocarbons, N_2+O_2, and NH_3. Chain reactions are presented in the splendid style of the Russian school *(Semenov)* in Chapter 11, with aspects on homogeneous/heterogeneous chain initiation, chain branching, induction period, influence of radiation and the examples of hydrocarbon $+O_2$, H_2+O_2, and H_2+halogens. The book ends with Chapter 12, a discussion of combustion processes (self-ignition, flames and flame-propagation velocity, detonation).

This presentation of the extensive subject of gas-phase reactions is limited to 225 pages of text, so that derivations, where given, could only be outlined; otherwise the formulas given are interpreted. Not an exceptional teaching book for students, it is nevertheless a compact, well-readable, and impressive presentation of a large subject with particular regard to elementary processes and could therefore win a good place for itself in competition with the many books on gas kinetics. Altogether it is a fine book, excellently made-up for a high price.

K. Hoyermann [NB 536 IE]

Photoacoustics and Photoacoustic Spectroscopy. By *A. Rosencwaig*. Wiley and Sons, Chichester 1980; xii, 309 pages, 139 figs., bound, £ 19.00.

The photoacoustic effect (*Bell* 1880), which until 1973 had been little considered, constitutes the basis of a new spectroscopic method, photoacoustic spectroscopy (PAS), a combination of optical spectroscopy and ultramicrocalorimetry. Its principle is that photons penetrating matter release thermal energy when absorbed and this energy produces pressure fluctuations in the atmosphere surrounding the sample, which can be picked up with a sensitive microphone. Photons that are not absorbed or scattered are photoacoustically inactive. With optically dense samples (*e.g.* powders, amorphous solids, gels, and colloids)—in contrast to conventional optical absorption spectrometry—specific signals from material components are obtained, and also an indication of the thermal and elastic properties of gaseous, liquid, or solid organic and inorganic substances. Among other things, photoacoustics can also be used to measure the thickness of thin layers and films.

The author of this first monograph on the relatively new field of photoacoustics and PAS participated in its pioneering development at Bell Laboratories, Murray Hill, New Jersey, and so this introduction into the theory and practice of the new method could hardly come from a more qualified source.

After a short historical presentation of the photoacoustic effect and PAS (8 pages), the PAS of gases, solids, and liquids is discussed in eleven chapters, in each case from theoretical and experimental aspects (121 pages). Sections then follow on the spectroscopic investigations of solids and liquids (28 pages) and of other matrices (26 pages), on the applications of PAS to the study of catalytic and chemical reactions (7 pages) and to the investigation of surfaces (9 pages), and on its uses in biology (11 pages) and medicine (32 pages). Some specific techniques and uses are dealt with in the last five chapters.

All things considered, the book presents the state of PAS and its various applications up to 1979 in a comprehensive and well arranged form and in easily understandable style.

As is so often observed with pioneers of a new method, the author is very euphoric about PAS. He says very little about the limitations already emerging clearly in practice, such as above all the poor signal resolution, the interference due to self-saturation, and the considerable difficulties with quantification. The reviewer should, therefore, like to warn against an overestimation of the present usefulness of PAS for the solution of problems in applied analysis when the substances to be investigated are more complex than the simple model samples, which are still used exclusively to illustrate the efficiency of the method. As the reviewer sees it, at the present stage of development very little can be said regarding the future of PAS. These critical observations, however, should by no means detract from the value of this introduction into a definitely promising field, which will certainly be gratefully received by people whose interests extend beyond analytical chemistry.

Corrigendum

The following correction should be made to the review article entitled "The Norbornyl Cation: Prototype of a 1,3-Bridged Carbocation" by Cyril A. Grob, *Angew. Chem. Int. Ed. Engl. 21* (1982) 87:

On p. 87, the last sentence of the summary should read: "Bridging is reduced by electron-attracting substituents and by *bridging strain*."

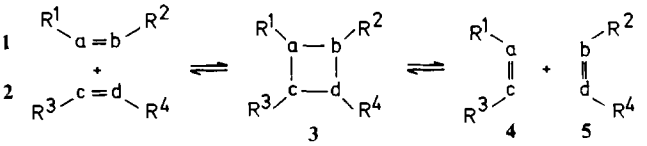
[2 + 2]-Cycloreversions

By Ernst Schaumann* and Roger Ketcham

Four-membered rings can be cleaved thermally, photochemically, or catalytically into two π bonded fragments. Theoretical calculations, kinetic studies, and investigations of stereo- and regioselectivity have been undertaken to clarify the question of whether the reaction involves one or two steps and to permit predictions on its course. [2 + 2]-Cycloreversions have been used to clarify the structure of four-membered rings, to prepare highly reactive π electron-systems and—in combination with a [2 + 2]-cycloaddition—to protect double bonds. The combination of a cycloaddition and -reversion can be used to convert a carbonyl group into an olefin. Starting with compounds containing annelated four-membered rings, compounds with two functional groups or large ring systems can be prepared. [2 + 2]-Cycloreversions have also been discussed in connection with storage of solar energy.

1. Introduction and Definitions

On the heels of the conservation of orbital symmetry rules formulated by *Woodward* and *Hoffmann*[1], cycloaddition chemistry experienced a boom. After significant work on the scope and mechanistic implications, increased interest is now being directed to the preparative uses of the cycloadducts. One aspect of this is the formal reverse of cycloaddition, that is cycloreversion. The synthetic potential of the retro-Diels-Alder reaction[2], 1,3-dipolar cycloreversions[3], and cleavage of three-membered rings[4] have been reviewed. [2 + 2]-Cycloreversions, however, have only been touched on in earlier reviews[5–9]. Here we attempt to review the relevant literature and to organize the material so as to encourage its synthetic application.



We will classify a reaction as a [2 + 2]-cycloreversion only when two opposing σ bonds of a carbo- or heterocyclic four-membered ring **3** are cleaved to give **1/2** or **4/5**. Other terms used in the literature, "retrograde [2 + 2]-cycloaddition", and "[4→2 + 2]-cycloelimination" are synonymous with [2 + 2]-cycloreversion. On the other hand, the concept "metathesis" has come to be used for the disproportionation of alkenes catalyzed by transition-metal compounds (cf. Section 4.1).

If in **1**—**5**, a/d and b/c are identical then the educts and products of the overall reaction of **1/2** to give **4/5** belong to the same chemical type, and only an exchange of substituents occurs. This specific type of cycloaddition and cycloreversion has been called an "exchange reaction" by *Ulrich*[10,11]. The complete reaction often takes place *in situ*

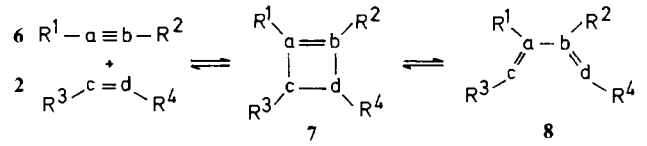
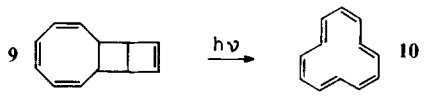
without isolation of the cycloadduct **3**, which is a plausible intermediate.



7 **8**

Starting from an unsaturated four-membered ring **7**, only formation of the fragments **2** and **6** is viewed as a cycloreversion. The electrocyclic ring opening **7**→**8** is not included in the above definition. Electrocyclic reactions will be considered only when they compete with cycloreversion to produce compounds of types **2** and **6**. Furthermore, ring-expansions of four-membered rings, which are annelated at opposite sides by 2n and 2m membered rings with n and m conjugated double bonds, are excluded. Thus, reactions such as conversion of the tricycle **9** into the annulene **10**[12] are better interpreted as a cyclic electron shift in the two outer rings than as a [2+2] cycloreversion of the central ring.

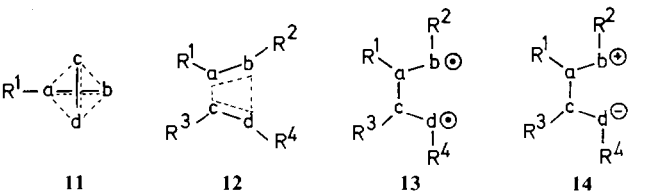


9 **10**

The [2+2]-cycloreversion of 1,2-oxaphosphetanes to give a phosphane oxide and an olefin constitute the last step in the Wittig reaction[13a]. Coverage of π-bond formation *via* phosphorus-containing four-membered rings would exceed the bounds of this review and the reader is therefore referred to the available monographs[13b].

2. Mechanism of [2+2]-Cycloreversions

According to the principle of microscopic reversibility the same considerations for the reaction mechanism must apply to the [2+2]-cycloreversion as to the [2+2]-cycloaddition. If the two σ-bonds are broken simultaneously, then according to the Woodward-Hoffmann rules[1] for a thermally induced cleavage this corresponds to a $[_\sigma 2_s + _\sigma 2_a]$-process having transition state **11** in which the fragments separate from each other in a "corkscrew"[5] motion. A geometrically more favorable $[_\sigma 2_s + _\sigma 2_s]$-reaction path *via* transition state **12**[14] is thermally "forbidden" *i.e.* would be associated with a much higher activation energy. In the case of photochemical [2+2]-cycloreversions the reverse relationships are expected, *i.e.* **12** would be favored over **11**[1].



11 **12** **13** **14**

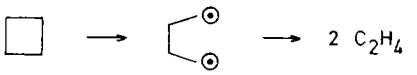
The burden of twisting as in **11** disappears if a two-step process involving successive cleavage of the bonds is assumed. As limiting cases for such an intermediate the 1,4-tetramethylene type diradical **13** and a 1,4-zwitterion **14** must be discussed. Viewed theoretically, **13** and **14** differ only in degree[15]. Heuristically it is useful to favor the diradical **13** for substituents which can stabilize unpaired electrons, and when R^2 is an electron-donor and R^4 an electron-acceptor to couch the discussion in terms of the zwitterion **14**.

Until the mid seventies the literature often reflected a tendency to interpret the experimental results in terms of the principle of conservation of orbital symmetry. This resulted from the fascination that the order and predictions of the Woodward-Hoffmann rules exerted on practicing synthetic organic chemists. The assumption of concerted cycloreversion also seemed to be supported by unproductive attempts to demonstrate the existence of an intermediate **13** or **14** by trapping experiments, and by theoretical calculations which indicated an energy hypersurface without an intermediate[16]. In the meantime, however, convincing evidence has accumulated that [2+2]-cycloreversions generally occur in two steps.

The clarification of the question of a one- or two-step course for [2+2]-cycloreversions is not an end in itself, but constitutes a basis for preparative use of the reaction. On the basis of mechanistic studies to be presented, rules which govern the cycloreversion of four-membered ring compounds can be worked out.

2.1. Theoretical Calculations

The fragmentation of cyclobutane **15** into two molecules of ethylene **17** is to be seen as the prototype of [2+2]-cycloreversions. An earlier attempt to describe the energy hypersurface by a Hückel calculation argued against tetramethylene **16** as a true intermediate. Rather it was shown that the potential surface is characterized by a broad plateau. Here the molecule should remain long enough so that rotation around the single bonds should be possible and that this so called "twixtyl" form might also be trapped[16]. Consequently a twixtyl and a species in a potential well cannot, in principle, be differentiated.



15 **16** **17**

The unsatisfactory twixtyl model has not been confirmed by more exact calculations. *Segal*, using an *ab initio* method, found that a tetramethylene **16** is best assumed as an intermediate in the cleavage of cyclobutane[17]. A MINDO/3 calculation by *Dewar* led to the same result[18]. Reservations on the reliability of *ab initio*- and MINDO-approaches which were expressed in a critical review of the mechanism of the Diels-Alder reaction[19] are also valid for [2+2]-cycloreversions and therefore do not permit incontestable conclusions about this mechanism.

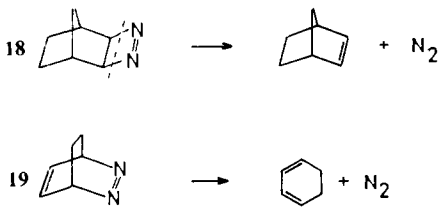
2.2. Kinetics

The thermal [2+2]-cycloreversion of many four-membered ring compounds in the gas phase or in solution exactly follows first-order kinetics. The fund of reliable acti-

vation parameters[20–23] is notably rich, and will be discussed in its relevance to the reaction mechanism.

The activation energy for cleavage of cyclobutane **15** into two molecules of ethylene **17** is, at 62.5 kcal/mol[24], fairly large. This may be taken as an indication that the geometrically favorable $[\sigma 2_s + \sigma 2_s]$ path is contrary to the conservation of orbital symmetry, and that the "allowed" $[\sigma 2_s + \sigma 2_a]$ path, because of the necessary twisting, leads to an energy-rich transition state. On the other hand, *Seebach* has pointed out that the measured value is approximately the difference between the C—C dissociation energy of an *n*-alkane (82 kcal/mol for the central bond of butane[25]) and the strain energy of cyclobutane (27.4 kcal/mol[26])[5] so that in the rate-determining step apparently only *one* CC bond is broken to give the 1,4-diradical **16**. *Benson*[22,27] has come to the same conclusion from a thermochemical estimate in which the measured activation energy for cleavage **15** → **17** is larger than the calculated energy difference between **15** and the diradical **16**. This approach has been criticized because the interaction between the unpaired electrons in **16** was not taken into consideration[18].

How much the transition from an "allowed" to a "forbidden" cycloreversion, which must therefore occur *via* the diradical path, costs in terms of activation energy becomes clear on comparison of the two heterocycles **18** and **19**. The elimination of N_2 from **18** at −78 °C proceeds by a factor of 10^{22} slower than in the presumably concerted retro-Diels-Alder reaction of **19**[28]. This corresponds to a difference in activation energy of about 18 kcal/mol.



If the cyclobutane ring is part of a bi- or polycycle then the strain energy is increased and cleavage becomes easier. There is, in fact, a qualitative inverse correlation between strain energy and activation energy of [2+2]-cycloreversions (Scheme 1).

	15	**20**	**21**	**22**	**23**
E_{SE}[26] =	27.4	30.5	41.2	50.7	80–90

Scheme 1. Relationship between strain energy E_{SE} [kcal/mol] and activation energy E_A [kcal/mol] of [2+2]-cycloreversions.

Alkyl substituents on cyclobutane should stabilize a diradical of type **13** relative to **16**, and thereby reduce the activation energy of [2+2]-cycloreversion. For increasing methyl substitution in **24**—**26** this appears to be confirmed (Scheme 2). The higher energy barrier in the tetramethyl derivative **27** is however unexpected. The same tendency is seen in the transition from cyclobutanone[38] to 2,2,4,4-tetramethylcyclobutanone[39].

	15	**24**	**25**

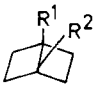
Scheme 2. Activation energies E_A (kcal/mol) of [2+2]-cycloreversions of methyl substituted cyclobutanes.

In bicyclo[2.2.0]hexanes **22** vicinal substitution actually retards cycloreversion[40].

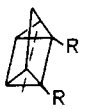
22b R = H; E_A = 34.5 kcal/mol
22c R = CH_3; E_A = 35.5 kcal/mol
22d R = C_2H_5; E_A = 36.2 kcal/mol
} in $Cl_2C{=}CCl_2$

As expected, functional groups which permit mesomeric stabilization of the radical intermediate **13** facilitate [2+2]-cycloreversion. Compared with the parent compound the energy barrier can be decreased by as much as 15 kcal/mol.

R =	$COOCH_3$	COC_2H_5	CHO	$CH{=}CH_2$
E_A =	57.3[41]	54.2[42]	53.3[43]	50.9 kcal/mol[44]

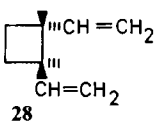


R^1 =	H	Cl	Cl	Cl	$COOCH_3$	CN
R^2 =	H	H	Cl	$COOCH_3$	$COOCH_3$	CN
E_A =	36.0[31]	34.5[40]	33.9[45]	30.2[46]	25.5[47]	21.7 kcal/mol[48]



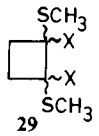
R = H; E_A = 38.3 kcal/mol[49] in toluene
R = $COOCH_3$; E_A = 34.9 kcal/mol in toluene

The possibility of both unpaired electrons in the diradical intermediate stabilizing themselves *via* allyl radicals makes **28** a particularly labile cyclobutane. The facile cycloreversion of compounds of type **29** which, at times, react even at room temperature[51] is apparently the result of capto-dative substitution which stabilizes the radical centers in a specific way[52].



28

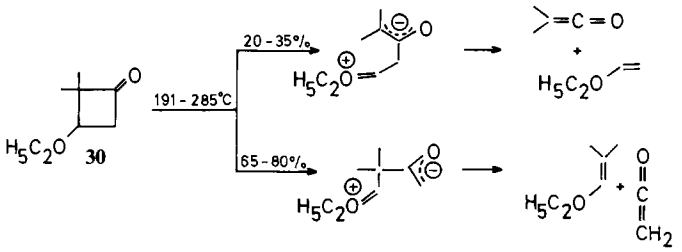
E_A = 32.2 kcal/mol[50]



29

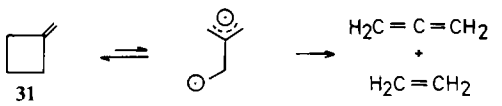
X = CN,CHO,$COOCH_3$, *etc.*

In four-membered rings with exocyclic double bonds the $[_\sigma 2_s + _\sigma 2_a]$-cycloreversion can be assisted by overlap of a σ orbital with the empty π^* orbital of the double bond[1]. In fact, the cycloreversion of cyclobutanone is more favorable by about 10 kcal/mol than that of cyclobutane **15**[38]. Alternatively, this effect is anticipated through the stabilization possibilities in the intermediate, which in the case of 3-alkoxy substitution as in **30** is particularly pronounced (E_A = 40.3 kcal/mol[53]).



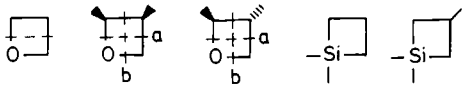
30

Methylenecyclobutane **31** represents a special case in which the intermediate recyclizes particularly easily so that the second step of the cycloreversion becomes rate-determining[54]. For complete ring cleavage, energies of 61.5 or 63.5 kcal/mol have been reported[55].



31

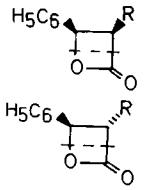
In oxetanes and siletanes (silacyclobutanes) exchange of a carbon atom in the cyclobutane by a heteroatom has only a slight influence on the energy barrier of the cycloreversion.



32 *cis*-**33** *trans*-**33** **34** **35**

E_A =	60.6[56]	a:62.5[57] b:63.2	a:63.7[57] b:64.7	62.3[35]	63.3 kcal/mol[58]

Comparison of **32** with **33**, and **34** with **35** demonstrates that these cycloreversions, as in the case of **27**, are retarded when more highly substituted. The same effect is encountered in 2-oxetanones[59].



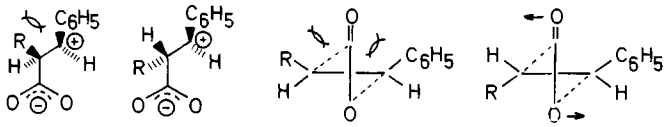
R =	CH_3	$CH(CH_3)_2$	$C(CH_3)_3$
k_{rel} =	1	0.31	0.028
k_{rel} =	11	4.3	2.1

A surprising difference appears in the influence of stereochemistry on the ease of bond breaking. In the 1,2-dimethylcyclobutanes **26** and the 2,3-dimethyloxetanes **33**, as well as the 2,3-dimethylcyclobutanones **60**[60] and tricyclo[4.2.0.$0^{2,5}$]octanes **99**[61] the *cis* compounds fragment faster in accord with their larger ground state steric interaction. With 2-oxetanones, however, the *trans* compound decarboxylates more easily. Three explanations for this and similar compounds have been considered:

1. Formation of the C=C bond during cycloreversion, starting from the *cis* compound results in stronger repulsion between the substituents. This effect was invoked by *Durst* to explain the fragmentation of stereoisomeric β-sultines[62,63] (cf. Section 3.5.1.), and could also explain the high thermal stability of highly fluorinated cyclobutanes[64].

2. In the dipole **36** resulting from a *cis*-oxetanone, the group R hinders the mesomeric stabilization of a positive charge by the phenyl group thus making **36** energy-rich relative to the *trans*-dipole **37**[65].

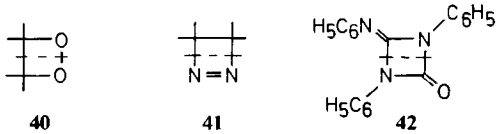
3. Assuming a concerted $[_\sigma 2_s + _\sigma 2_a]$-cycloreversion the substituents R or phenyl can avoid steric interactions with the oxygen atoms in a transition state analogous to **11** by slight deformation of the *trans*-orientation **39** whereas no such leeway is available in the *cis*-configuration **38**[59].



36 **37** **38** **39**

Based on what has been presented a clear distinction between these alternatives is not possible. It would be desirable to know the influences of methyl/phenyl substituents on the cycloreversion in cyclobutanes and oxetanes, as well as to test the behavior of 3,4-dialkyl-2-oxetanones of defined stereochemistry.

The lability of the oxygen-oxygen bond causes the [2+2]-cycloreversion of 1,2-dioxetanes such as **40** to occur much faster than for oxetanes **32**; the influence of alkyl substituents on the activation energy is poorly understood[66]. The facile elimination of nitrogen from **41** can be attributed to ring strain in the diazetine, while the relatively low activation energy in the decomposition of **42** may be explained by the charge stabilization of the zwitterion intermediate.



40 **41** **42**

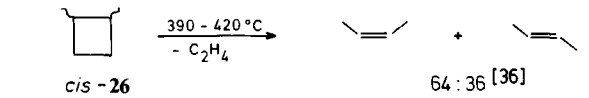
E_A =	27.6[66]	32.7[67]	28.2 kcal/mol[68]

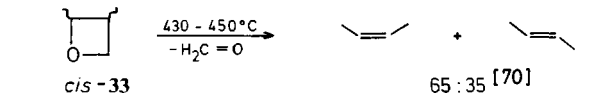
Besides the activation energies, the values of the *activation entropies* also support a two-step pathway for [2+2]-cycloreversion. In agreement with a conformationally flexible intermediate **13** or **14**, positive entropy values are usually observed, while for the concerted retro-Diels-Alder reaction the $\Delta S^{\neq}$ values lie near 0 cal $mol^{-1}K^{-1}$[19]. There have been reports of [2+2]-cycloreversions with negative activation entropies, which seem to be possible mainly in the fragmentation of polycyclic systems[69].

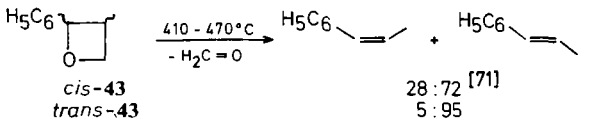
2.3. Stereochemistry

The most important consequence of the thermally allowed $[_\sigma 2_s + _\sigma 2_a]$ path of cycloreversion is inversion of configuration in the antarafacial component; in the photochemically induced four-membered ring cleavage the orientation of the substituents should remain unchanged according to the principle of conservation of orbital symmetry[1].

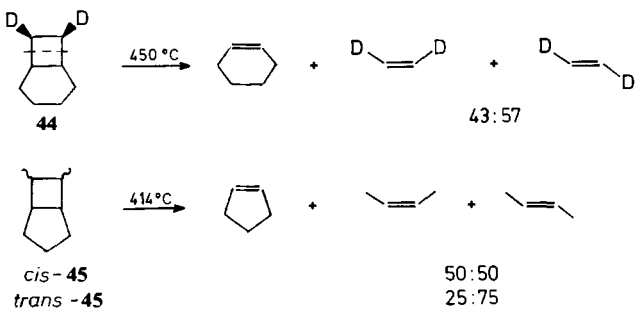
Experimentally, it has usually been found that partial retention of configuration occurs in the cycloreversion of 1,2-disubstituted four-membered rings. This tendency is more pronounced in *trans*- than *cis*-educts.



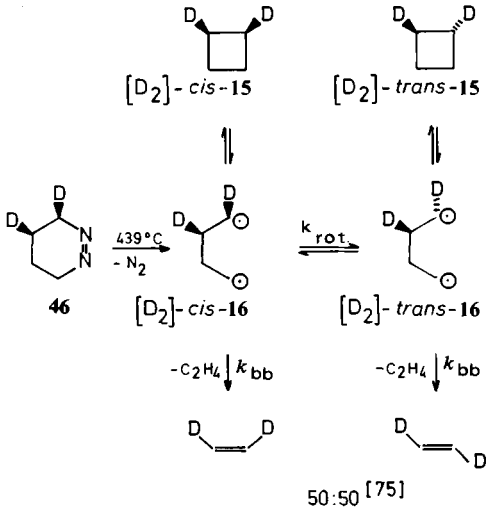




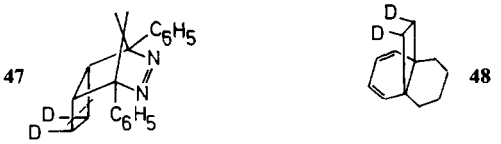
The lack of stereospecificity in **26**, **33**, and **43** does not in itself rule out a concerted cycloreversion since the *cis-trans* isomeric alkenes could represent either the supra- or the antarafacial fragment. Compelling evidence is seen in the cycloreversion of bicycles in which the four-membered ring is annelated onto a five- or six-membered ring. The resulting cycloalkene is now forced to be the suprafacial component while the other fragment—assuming a concerted reaction course—must by virtue of its antarafacial role suffer an inversion of configuration. The examples **44**[72] and **45**[73], however, show that this reorganization is only partially achieved.



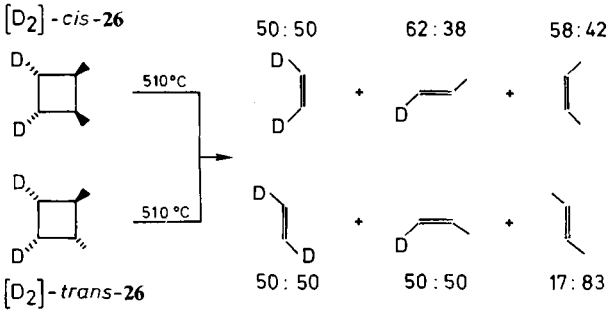
If the resulting *cis-trans* mixtures are described in terms of the diradical mechanism then the question of the relative rates of 2,3-bond breaking (k_{bb}) and rotation (k_{rot}) around the 1,2- and 3,4-bond in **13** arises. Numerous studies have shown that this ratio is strongly dependent upon the substituents, R^2 and R^4. Specifically, the ratio of k_{bb}/k_{rot} increases with the number of substituents, *i.e.* with changes from primary to secondary and finally tertiary groups, and the stereoselectivity also increases accordingly[74]. Thus, starting from $[D_2]$-*cis* and $[D_2]$-*trans*- **15**, diradicals **16**, in which rotation should be distinctly faster than cleavage, are formed. *Chickos* found essentially equal amounts of *cis*- and *trans*-1,2-dideuterioethylene[75] and a study of $[D_2]$-**16**, independently produced from tetrahydropyridazine **46** gave a value of 0.18 for k_{bb}/k_{rot}[76].



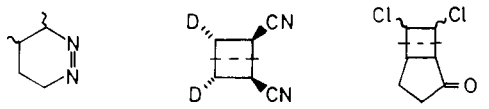
However, even with primary radical centers extensive or predominant retention is possible, as seen by formation of, respectively, 90 and 66% of *cis*-1,2-dideuterioethylene from the tricycles **47**[77] and **48**[78].



The dimethylcyclobutanes $[D_2]$-**26** permit complete stereochemical analysis of the cycloreversion products[79]. In the dideuterioethylene formed an equimolar mixture of *cis*- and *trans*-isomers is found, while for the 2-butene fraction, as in examples **26**, **33** and **43**, partial retention is observed. The k_{bb}/k_{rot} ratios were determined to be 1.24 from $[D_2]$-*cis*-**26** and 2.24 from $[D_2]$-*trans*-**26**, whereas the diradicals independently produced from **49** at 439 °C gave values of 1.13 and 3.0, respectively[80].

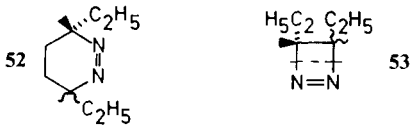


That rotation and cleavage occur at comparable rates with secondary radical centers is in agreement with the partial stereoretention observed in **50**[81] and **51**[82].



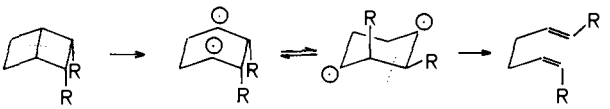
49 50 51

In triply substituted radical centers rotation is almost completely suppressed relative to cleavage. On the basis of fragmentation of heterocycle **52**, the ratio k_{bb}/k_{rot} in the diradical can be estimated to be *ca.* 50[83]. In agreement, the cycloreversion of the *cis-trans*-isomers of **53** occurs with >95% retention[84].



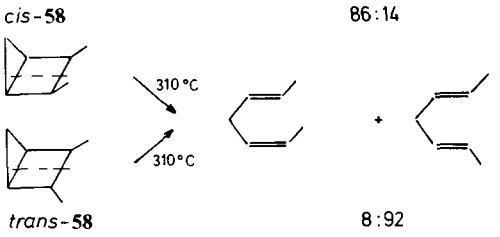
52 53

A special situation arises if the cyclobutane unit is annelated onto an additional small ring. In the thermolysis of bicyclo[2.2.0]hexanes **54** (R=D[85], CH_3[86], $COOCH_3$[87]) predominant inversion of configuration at one carbon atom occurs which otherwise was only observed for **44**. Although the stereochemistry corresponds to a $[\sigma 2_s + \sigma 2_a]$ process, a transition state of type **11** can hardly be considered because of geometric limitations. In order to explain formation of the (*Z, E*)-diene **57** a conrotatory ring opening of the diradical **55** was originally suggested[86]. After detailed experimental studies and theoretical calculations the observed stereochemistry was easily explained by conversion of the diradical from the boat- **55** into the chair-conformation **56**[61,88].

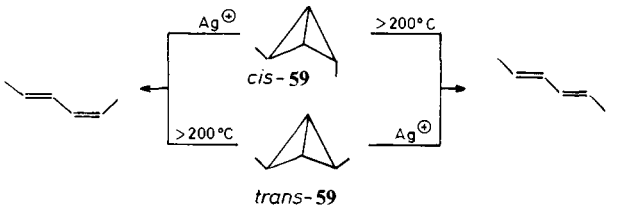


54 55 56 57

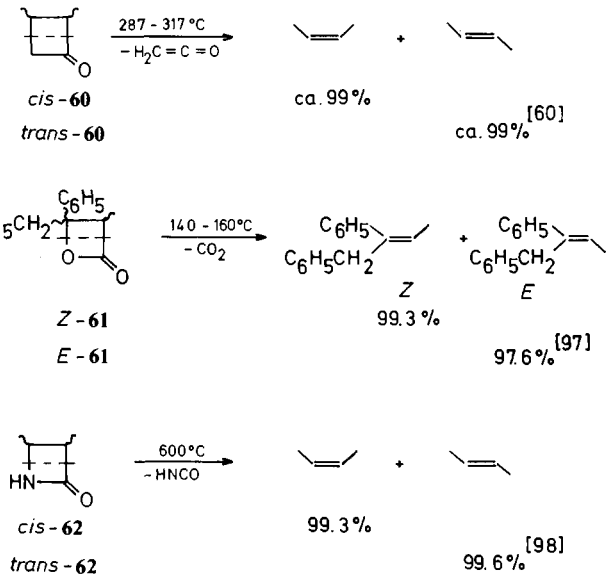
Similar to **54**, thermolysis of *cis*- and *trans*-bicyclopentanes **58** gives, respectively, 83 and 92% inversion of configuration, this has been explained by a conrotatory ring opening[89].



Several groups have studied the stereochemistry of ring-opening of bicyclo[1.1.0]butanes **59**. The central bond is not cleaved but [2+2]-cycloreversion with inversion of configuration at one carbon atom to give 1,3-dienes is observed[90,91–94]. Extensive retention is observed, however, if ring opening is catalyzed by metal ions (cf. Section 3.1.3)[95,96].

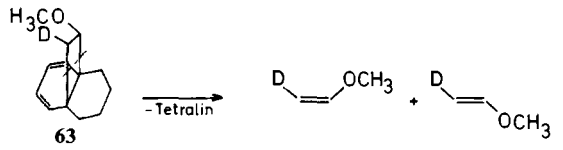


If a carbonyl group forms part of the four-membered ring then the transition state **11** of the $[\sigma 2_s + \sigma 2_a]$ reaction is somewhat more energetically favorable (cf. Section 2.2). In the examples studied a high degree of stereoselectivity is found; this has frequently been demonstrated for 2-oxetanones, in particular[99].



Since the product with the cumulative double bonds is in any case the antarafacial component, the stereoretention observed in the olefin fragment is in agreement with the Woodward-Hoffmann rules[1], and is greater than that with the simple 1,2-disubstituted cyclobutane examples discussed earlier. Alternatively, an intermediate, best formulated as a zwitterion, has been suggested in which interactions between the charged centers are possible, thus hindering rotation about the potential double bond[100]. The criterion "stereochemistry" therefore does not provide unequivocal evidence on the reaction mechanism. The mechanism involving zwitterions, however, fits the general picture better, and the involvement of charges also explains the observed regioselectivity of the cycloreversion (cf. Section 2.4).

For *photochemical* [2+2]-cycloreversions of four-membered rings a higher degree of stereoretention is to be expected because of the "allowed" geometrically favorable transition state **12**. The ratios, however, closely resemble those reported for the thermal process. Here too, the four-membered ring fragmentation usually follows a two-step pathway. If the intermediate diradical is produced with high excess energy, then the "stereochemical leak" can be even greater than in the thermal cycloreversion; this is demonstrated by comparison of the thermal and photochemical fragmentation of **63**.

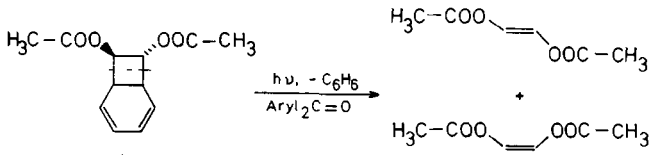


63

314 °C[78]
hν[101]

97:3
88:12

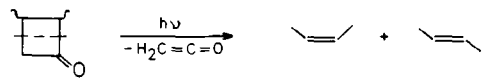
In some cases, the photochemical [2+2]-cycloreversion can be strongly influenced by the photolysis conditions. An extreme example is **64**, which undergoes electrocyclic ring opening upon direct irradiation[102], but which fragments with the expected partial stereoretention when photolysis is performed in the presence of aromatic ketones[103].



64

60 : 40

The medium and wavelength also influence the stereochemical course of the photochemical cycloreversion, as studies with **60** and **65** show.



cis-**60**	>94 : <6	(gas phase)[104]
	80 : 20	(benzene)[105]

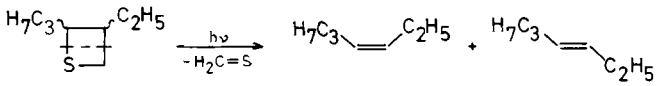
	1 : 99	[$(CH_3)_3COH$][106]



cis-**65**	43:57 (254 nm, Hg)[107]
	34:66 (313 nm)
trans-**65**	22:78 (254 nm, Hg)
	13:87 (313 nm)

2.4. Regioselectivity

Which pair of σ-bonds of a four-membered ring is broken during cycloreversion is a decisive factor for the preparative use of this reaction type. Two effects, at times opposing, are seen from mechanistic studies:

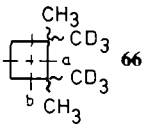
1) The relative strength of the four-membered ring bonds in the ground state.

2) The stability of the diradical or zwitterionic intermediate which can be influenced through substituents or solvent.

In 1,2-disubstituted four-membered rings, the 1,2-bond has the lowest bond order[108] and is ruptured to a relatively stable - on both radical centers secondary - diradical. The preference for cleavage route "a" is most notable with *cis*-**26**. That the interaction of the substituents in the ground state is decisive is demonstrated by the cycloreversion of **33** and **60**: the ratio a/b is not reversed, although cleavage "b" leads to formation of a radical center α to an O atom or carbonyl group that is energetically favored.

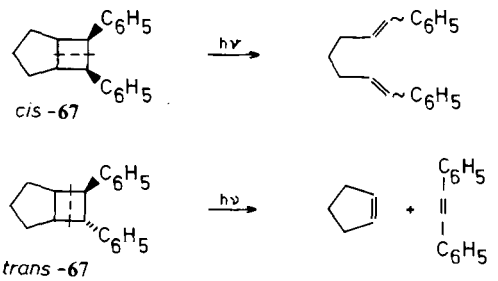
	cis-**26**	*trans*-**26**	*cis*-**33**	*trans*-**33**	*cis*-**60**	*trans*-**60**
X=	CH_2	CH_2	O	O	CO	CO
a/b=	6.8[80]	3.3[80]	2.1[70]	1.2[70]	5.8[96]	1.1[96]

Furthermore, in stereoisomers of **66** in which the 1,2-bond is completely substituted only cleavage by path "a" is observed[109].



66

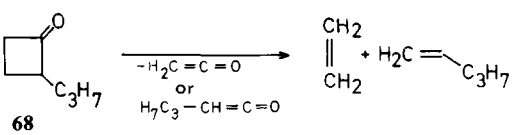
For light-induced [2+2]-cycloreversion of cyclobutanes, numerous examples illustrate that the relief of steric interaction in the ground state determines the regioselectivity of the cleavage. The reaction pathway favored here is also followed even if it leads to a less stabilized diradical[110]. This "*cis*-effect" becomes clear in the different behavior of the *cis*- and *trans*-isomers of the bicycle **67** under direct light-excitation[111].



cis-**67**

trans-**67**

In the photochemistry of cyclobutanones, decarbonylation to give cyclopropanes, and ring expansion to give tetrahydrofuran derivatives compete with the [2+2]-cycloreversion[105, 112, 113]. The regioselectivity of the photochemical cleavage of the four-membered ring can be less marked than in thermolysis shown in example **68**[114].

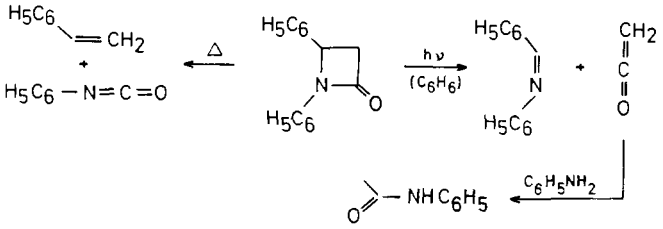


68

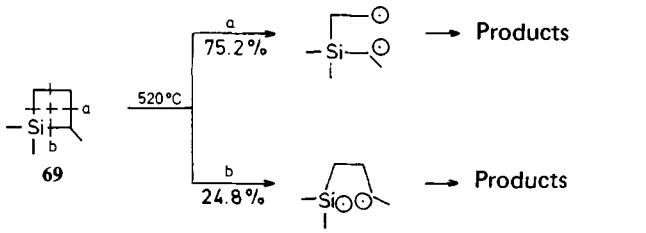
350 °C
hν, 325 nm

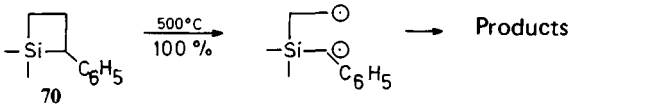
78 : 22
56 : 44

In the photolysis[115] of 2-azetidinones the regiospecificity observed in the thermal[116] cycloreversion is often completely reversed. For both cleavage directions the reaction probably occurs from the excited singlet state[115].

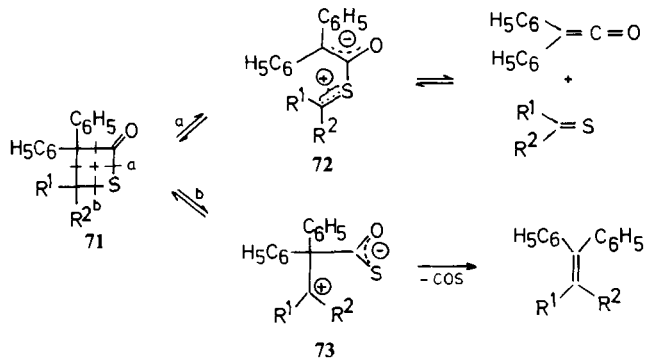


Examples in which the stability of the diradical intermediate determines the regioselectivity of the cycloreversion are found in the chemistry of siletanes. The stabilizing effect of silicon on an unpaired electron in the β-position, despite the "*cis*-effect", facilitates cleavage corresponding to "a" starting from **69**[117]. In **70**, exclusively products resulting from 2,3-bond breaking can be detected[118].





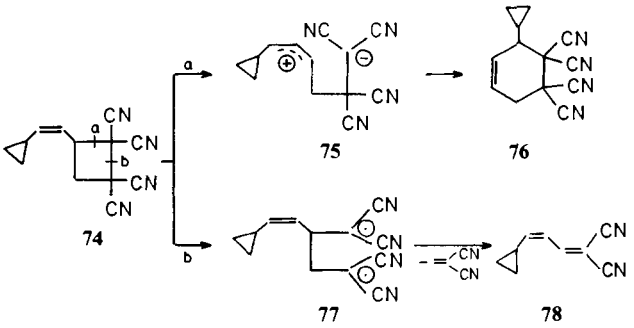
Also, if a possible zwitterionic intermediate is specifically stabilized, this effect can determine the regioselectivity of the cycloreversion. This is indicated by the decomposition of **30**, as well as of **71**. The 2-thietanones **71** resulting from the reaction of diphenylketene and thiobenzophenones generally undergo cycloreversion upon warming to give the educts[119,120]; however, if *both* phenyl residues of the thioketone are substituted by amino groups in the *p*-position, elimination of carbonyl sulfide occurs to give the alkene[119,121]. Apparently the particularly electron-rich groups R^1,R^2 stabilize the positive charge so well that reaction path "b"—irreversible in the last step—can compete with path "a".



Path a: $R^1=R^2=C_6H_5$; $R^1=R^2=4\text{-}CH_3OC_6H_4$;
$R^1+R^2=$  X=O, S;
$R^1=4\text{-X—}C_6H_4$ with X=$(CH_3)_2N$, Cl, $(CH_3)_2CH$,
$R^2=C_6H_5$

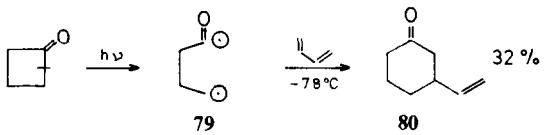
Path b: $R^1=R^2=R^3{}_2N\text{—}C_6H_4$ with $R^3=CH_3$, C_2H_5
$R^1+R^2=$

The solvent effect on the regioselectivity of [2+2]-cycloreversions has only been studied in a few examples. In the decomposition of oxetanes, the effect is slight[122]. The alkenylcyclobutane **74** on the other hand shows a marked dependence of the regioselectivity on the solvent[123]. Bond breaking according to path "a" leads here to an intermediate best formulated as a zwitterion; therefore, in polar solvents this path is taken and a cyclohexene **76** is isolated *via* ring expansion. On the other hand, in the non-polar cyclohexane besides 26% **76**, 67% of the diene **78** is formed *via* the diradical **77**[123].

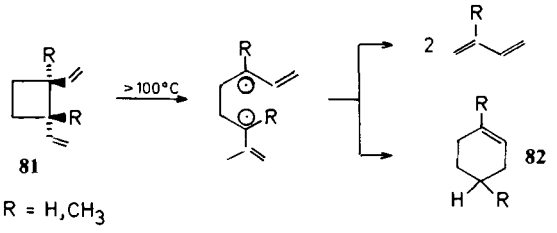


2.5. Trapping and Isolation of the Intermediate

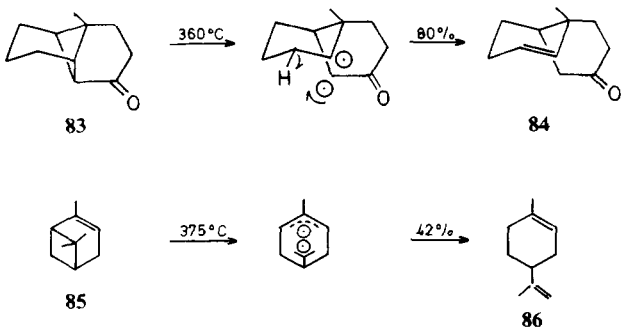
There has been no lack of experiments to trap the presumed 1,4-diradicals in [2+2]-cycloreversions since such reactions deserve study from preparative as well as mechanistic interests. For *inter*molecular trapping reactions, however, there are only a few examples. During photolysis of cyclobutanone in 1,3-butadiene, *Dowd, Gold,* and *Sachdev*[124] found an adduct **80** derived from both components that apparently resulted from reaction of the diene with the diradical **79**. Thus **79** is *mutatis mutandis* to be viewed as the intermediate in the [2+2]-cycloreversion of cyclobutanone.



In view of the usually very short lifetime of the intermediate **13** or **14** the subsequent *intra*molecular reactions are more likely than reaction with trapping reagents. One example, the ring expansion of **75** to **76**, has already been presented. Similarly, a cyclohexene **82** is formed in the thermolysis of *trans*-1,2-divinylcyclobutanes **81**[50,125].

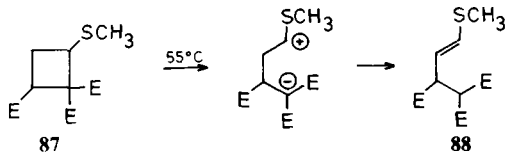


A further possibility for intramolecular stabilization of 1,4-diradicals is hydrogen abstraction. The disproportionation of the diradicals obtained from the tricycle **83**[126] as well as from α-pinene[127] can be mentioned as examples.



83 84 85 86

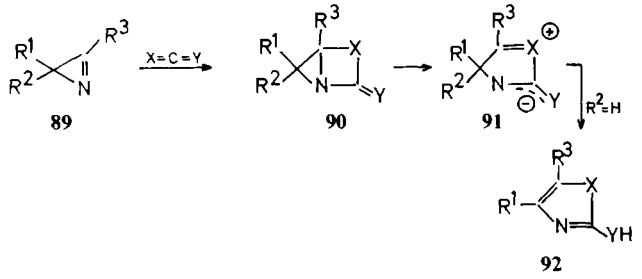
In the 1,4-zwitterions **14** with $R^1 = H$ a 1,3-hydrogen shift occurs particularly easily to the anion moiety. Thus, the cyclobutane **87** is converted into the vinyl sulfide **88** by slight warming[128].



87 88

E = $COOCH_3$

2-Monosubstituted azirines **89a** and **89b** react with cumulative double bonds to give highly strained cycloadducts **90**, which undergo *in situ* four-membered ring opening to produce the zwitterions **91**. Stabilization follows by hydrogen shift to the anionic center. As educts, besides isocyanates[129] carbon disulfide, isothiocyanates[130,131] and thioketenes[132] have been used.

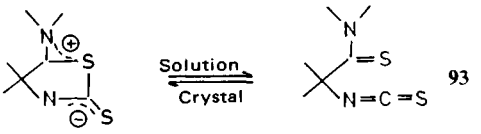


89 90 91 92

89a, $R^1 = CH_3$, $R^2 = H$, $R^3 = C_6H_5$
89b, $R^1 = CON(CH_3)_2$, $R^2 = H$, $R^3 = N(CH_3)_2$
89c, $R^1 = R^2 = CH_3$, $R^3 = N(CH_3)_2$
89d, $R^1 = R^2 = CH_3$, $R^3 = N(C_2H_5)_2$
89e, $R^1 = R^2 = CH_3$, R^3 = morpholino
90—92, X = O, S; Y = S, NAryl, $NCOC_6H_5$, $C(Alkyl)_2$

In 1,4-zwitterions the charge stabilization can be so extensive that they can be isolated[133]. Reaction of the 3-dialkylaminoazirines **89c—e** with benzoyl isothiocyanate[134], carbon disulfide[135—137], carbon diselenide[138], or thioketenes with electron withdrawing substituents[132] yields crystalline, slightly soluble 1 : 1 adducts, which on the basis of spectroscopic data, chemical properties, and X-ray crystallographic analyses[134,135] have the zwitterionic structures **91**. Of particular note is the behavior of the adduct obtained from carbon disulfide: in solution the bifunctional cycloreversion product **93** is detectable, while in the crystal form only the zwitterion is present. The reaction is completely reversible[135].

The corresponding selenium compound behaves in a similar fashion[138].



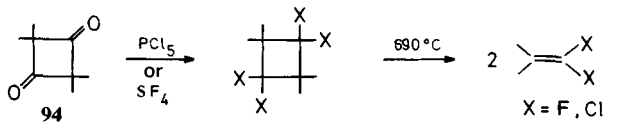
93

3. Applications

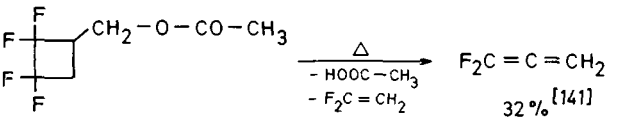
3.1. Cyclobutanes

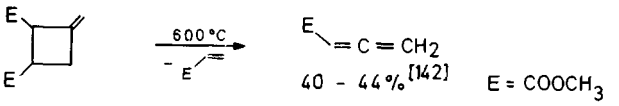
3.1.1. Thermal [2+2]-Cycloreversions of Cyclobutanes

Cleavage of simple cyclobutanes often only leads to trivial products. Exceptions are the preparation of 1,1-dihalo-2-methylpropenes from the easily available cyclobutanedione **94**[139], and of functionally substituted allenes[140—142].

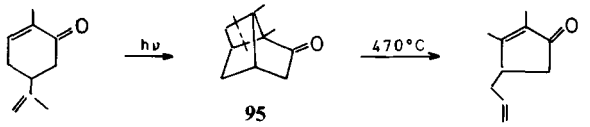


94



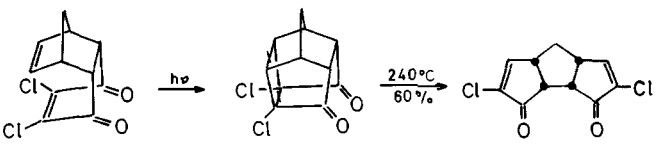


Interesting systems are derived from cycloreversion of four-membered rings that are part of bi- or polycyclic systems. In the simplest case the ring cleavage serves as a structural proof—as with **95**, which resulted from irradiation of carvone with sunlight[143].



95

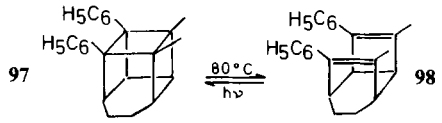
One strategy for preparation of polycyclic cyclopentanoids starts from cage compounds such as **96**[144].



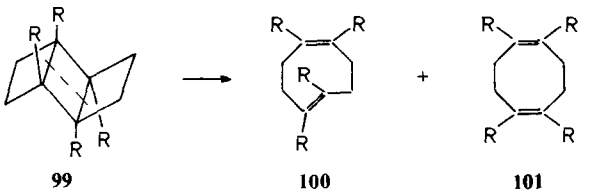
96

Whereas in the case of **96** the thermal cycloreversion proceeds contrary to the photochemical mode of formation, in other cases thermolysis regenerates the starting material. Thus, the cage compound stores light energy and liberates it later as thermal energy. In the case of the polycycle **97**, regeneration of the diene **98** occurs with a Q-

value of 12% at 290 nm[146], characterising the capacity of the energy-storage[145].

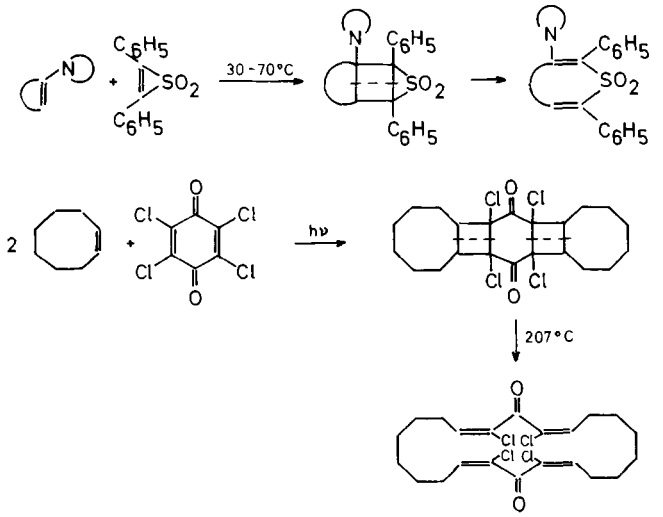


The cycloreversion of the tricycles **99** takes place in the highly strained central ring to give 1,5-cyclooctadienes **100** and **101**. Here, a **56**-analogous diradical intermediate is assumed[61] so that the *cis-trans*-diene **100** predominates and the reaction can be used preparatively for this stereoisomer[48, 147].



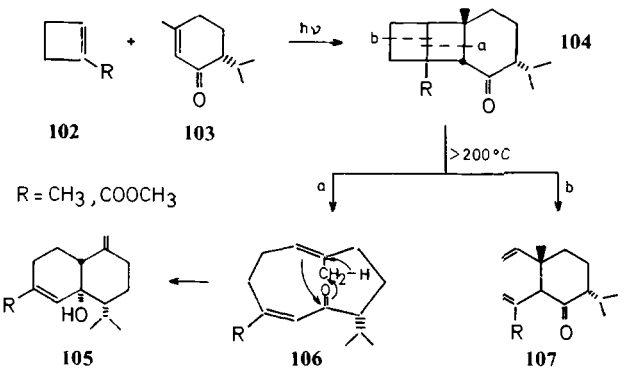
R = CN, $COOCH_3$

Medium S-rings with 9 to 15 members are available thermally from the cycloaddition of 1-aminocycloalkenes with thiirene *S,S*-dioxides and subsequent [2+2]-cycloreversion[148]. With two equivalents of cyclooctene and chloranil the cycloreversion leads to a C_{22} macrocycle[149].



Several groups have used the cycloreversion of tricyclo[4.4.0.$0^{2,5}$]decanes **104** to synthesize sesquiterpenes[150–153]. Here a terpene ketone **103** is first added photochemically to a cyclobutene **102** as an isoprene building block. The cycloreversion then cleaves the central or outer four-membered ring to give **105** or **107**, respectively. With **105** a subsequent facile intramolecular ene-reaction leads to the *trans*-decalins **106**[151b,c]; by changing the thermolysis conditions[150, 153b] or after reduction of the carbonyl group[150b, 151a, 152] the reaction stops at the intermediate stage **105**. **105**—**107** are sesquiterpenes having the germacrane, cadinane, and elenene skeletons, respectively.

The [2+2]-cycloreversion can also serve to modify, as well as to synthesize terpenes. Pyrolysis of compounds

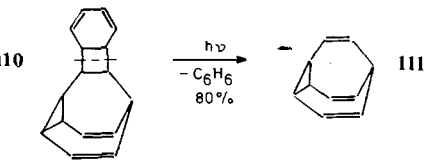


R = CH_3, $COOCH_3$

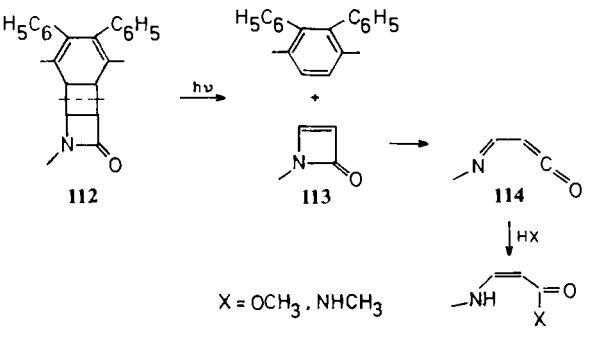
having the pinane skeleton leads to cleavage of the four-membered ring to give 1,6-dienes, which either themselves or subsequent reaction products such as **86** are important in the perfume industry[154]. As a simple example, the cycloreversion of (−)-*cis*-pinane **108** to the diene **109** is given[155]. Pyrolysis of derivatives with hydroxy[156] or carbonyl functions[157] or of pinene **85**[127] also yields useful products.

3.1.2. Photochemical [2+2]-Cycloreversions of Cyclobutanes

Cyclobutanes which are attached to an arene, polyene, or carbonyl group as a chromophore can be easily split photochemically into two olefinic fragments. Photochemical [2+2]-cycloreversions in which one of the fragments can form an aromatic system are especially favored and regioselective. An already classical example of this can be seen in the bullvalene synthesis of *Schröder*[158].



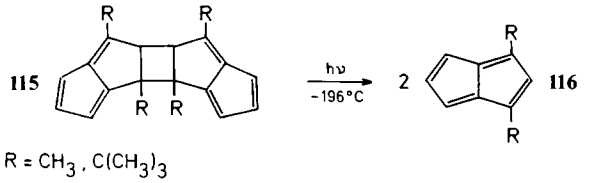
With tricycle **112** cycloreversion of the central ring liberates the azetinone **113**. Under the reaction conditions this unusual heterocycle undergoes electrocyclic ring opening to give ketene **114**, which is finally trapped by added nucleophiles such as methanol or methylamine[159].



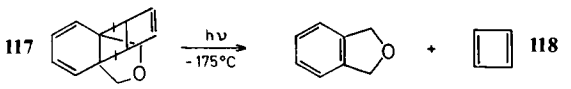
X = OCH_3, $NHCH_3$

Using the matrix technique, high-energy compounds from photochemical [2+2]-cycloreversions can be ob-

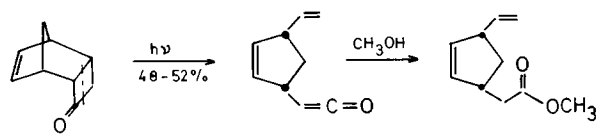
tained and characterized at low temperatures. This holds for preparation of the pentalenes **116** from their dimers **115**[160], as well as for the liberation of cyclobutadiene **118** from various precursors[161] such as the propellane **117**[162].



R = CH_3, $C(CH_3)_3$

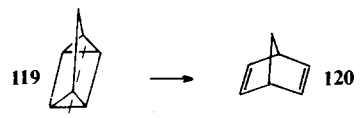


The photochemical [2+2]-cycloreversion of cyclobutanones has been studied primarily from the mechanistic point of view[112, 113]. The reaction finds synthetic application in the preparation of functionalized cyclopentene derivatives[163].



3.1.3. Catalytic [2+2]-Cycloreversions of Cyclobutanes

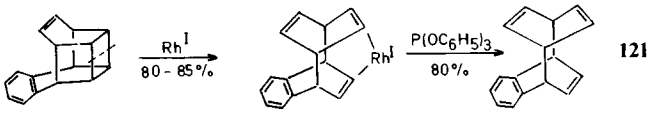
Towards the end of the sixties *Hogeveen et al.* proved that the activation energies for [2+2]-cycloreversion of hexamethylprismane[164] and quadricyclane[165] (Scheme 3) are drastically lowered by rhodium, palladium, or platinum coordination compounds. Subsequently, this aspect of cycloreversions has been intensively studied[166]. In general, metal catalysis is only effective in cases of pronounced ring strain, so that cleavage of cyclobutane proceeds only to a minor extent[167]. On the contrary, catalysis by metal salts or coordination compounds has been used successfully for derivatives of **119**, as well as for bicyclo[1.1.0]butanes like **59**[95, 166a,b,d], for *syn*-tricyclo-[4.2.0.$0^{2,5}$]octanes[166a, 168], and for cage compounds such as cubane[169]. Recent synthetic applications are the indirect synthesis of the *p,p'*-cycloadduct **121** from benzene and naphthalene[170], and the ring expansion of cycloalkenes to 1,3-cycloalkenes, *e.g.* **122**→**126**[166d]. *Paquette et al.* elegantly applied this method in a six-step synthesis of heptalene **127** from naphthalene[171].

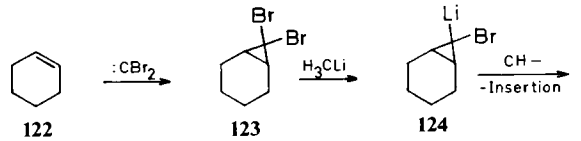


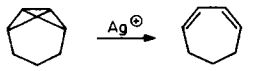
140 °C, without catalyst: $t_{1/2} > 14$ h
−26 °C $[Rh(BCH)Cl]_2$: $t_{1/2} = 45$ min

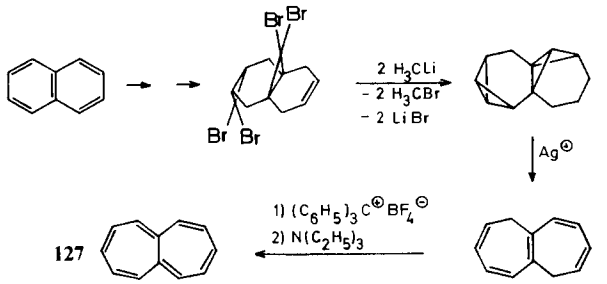
Scheme 3. Half-lives $t_{1/2}$ of the transformation **119**→**120** under different conditions (BCH = bicyclo[2.2.1]hepta-2,5-diene) [165].

In combination with the photochemical formation of four-membered rings the metal catalyzed cycloreversion has been discussed as a method for solar energy storage.

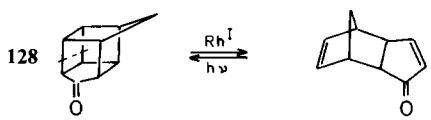




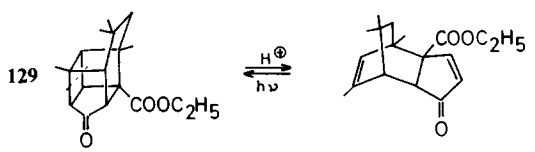




Besides the system **119** ⇌ **120**[172], particularly cage compounds like **128**[173] are being studied for this purpose. So far practical applications remain elusive because of the insufficient stability in multiple reaction cycles.

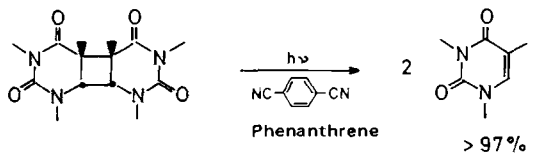


In addition to the use of metal complexes, the energy stored in cage compounds can also be liberated by acids[174]. In the case of the pentacycloundecanone **129** [2+2]-cycloreversion is strongly exothermic by 21.7 kcal/mol, rendering the system particularly interesting from the point of view of energy storage[175].



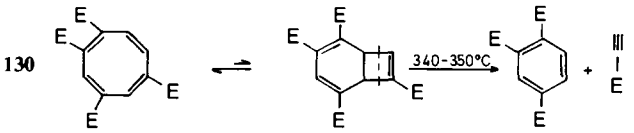
[2+2]-Cycloreversions can also be induced by electron transfer to an acceptor molecule. Formation of the radical cation can take place in the dark by irradiation of the charge transfer complex between four-membered ring compounds and acceptors, or *via* interaction with an electronically excited acceptor[176]. An example for the first-mentioned possibility is found in the cleavage of the *cis-syn* dimer of dimethylthymine which is induced by the phenanthrene radical cation generated in a sensitized pho-

toreaction. The reaction is of interest as a model for the enzymatic photoreactivation of damaged DNA[177].

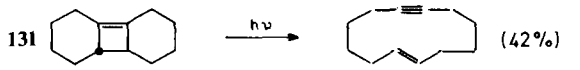


3.2. Cyclobutenes

Cyclobutenes react thermally under electrocyclic ring opening to give butadienes. An exception, the pyrolysis of cyclooctatetraene **130** carried out as a structural proof, can be mentioned[178].



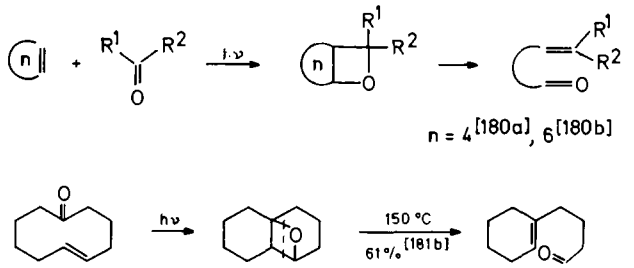
In the photochemistry of cyclobutenes, butadiene formation is less dominant than cycloreversion to an alkyne and an alkene[110a]. This decomposition pathway can even be detected in the parent compound[179a], and is particularly favored if the allowed disrotatory electrocyclic ring-opening would lead to *trans*-cyclohexene, as in tricycle **131**[179b].



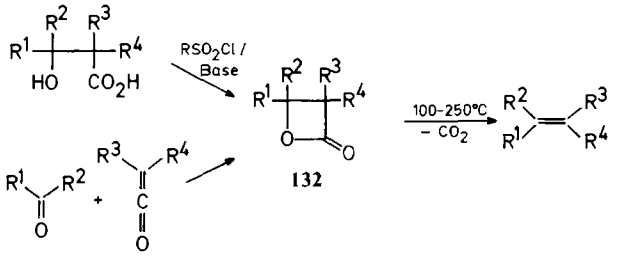
3.3. Four-Membered Rings with One Heteroatom

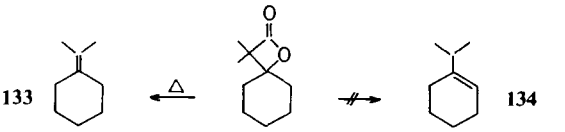
3.3.1. Oxetanes

The cycloreversion of oxetanes is synthetically important if the heterocycle is annelated to a second ring. Such bicycles are easily accessible *via* Paterno-Büchi reaction of cycloalkenes with aldehydes or ketones, and on cycloreversion yield carbonyl compounds with a remote double bond[180]. Intramolecular modifications of the reactions have also been reported[181]. Yields are higher with proton or metal catalysis than in the simple thermolysis[180b].

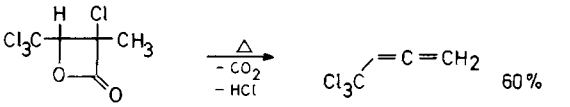


The cycloreversion of 2-oxetanones **132** introduced by *Staudinger* has found broad application[182]. Starting from a 3-hydroxycarboxylic acid or by cycloaddition of a ketene with a carbonyl compound, heterocycles **132** are readily accessible. Because of the stereospecificity of the fragmentation (cf. Section 2.3.) and the smooth formation even of tri- and tetrasubstituted alkenes, the method ably compliments the classical Wittig olefination. Another advantage is that the olefination proceeds without hydrogen shifts, hence **133** can be obtained free of isomers; using a Wittig reaction **134** was also obtained[97].

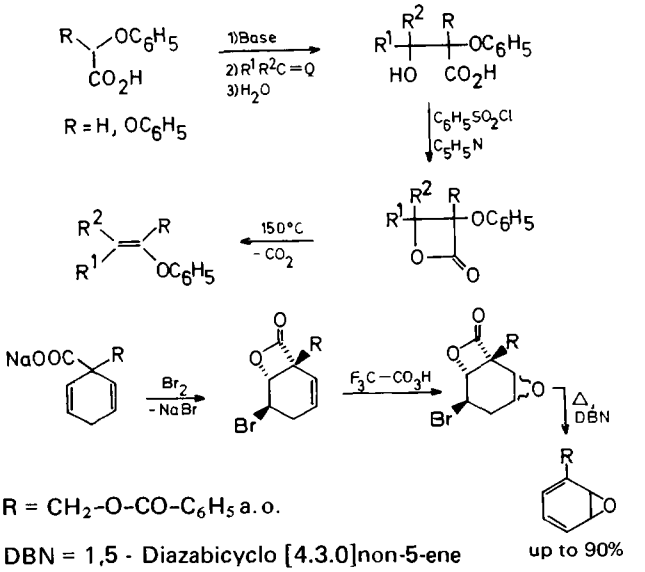




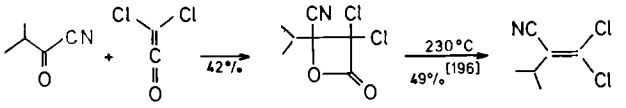
In contrast, decarboxylation of **132** is hindered if R^3 is a silyl residue[183] or by halogen substitution, particularly for $R^1 = CCl_3$[185]; in a ketene generator, however, fragmentation is accomplished in such a case, and leads, with concomitant elimination of hydrogen chloride, to an allene.



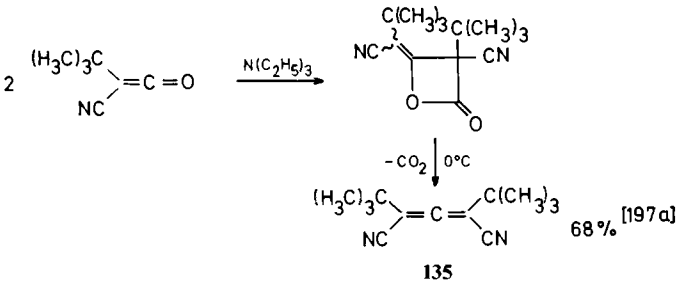
On the other hand, carbon dioxide is eliminated particularly readily if R^1 can stabilize a positive charge at the 4-position of **132**, *i.e.* in 2-oxetanones which result form ketene addition to benzaldehydes[186], cyclopropenones[187], tropones[187b, 188], phenalenone[187b, 189], thiapseudophenalenones[187b, 190], or compounds of the γ-pyrone type[191]. Quinones have also been successfully employed as precursors[192]. Special applications are found in the preparation of aryl enol ethers and ketene diphenyl acetals, which are otherwise obtained only with difficulty[193], and of arene oxides[194].



Attention has been directed to the highly reactive dichloroketene as a particularly interesting ketene component which allows dichloromethylenation of carbonyl compounds even where the Wittig reaction fails[185, 195, 196].

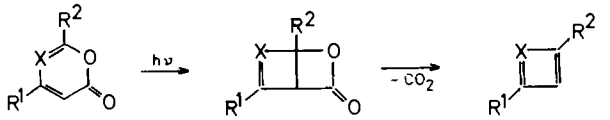


3-Alkylidene-2-oxetanones result from dimerization of ketenes[182a]; their decarboxylation makes symmetric allenes accessible[197], *e.g.* **135** which is strongly electrophilic due to the electron withdrawing nitrile groups[198].



135

On irradiation α-pyrone yields 2-oxabicyclo[2.2.0]hex-5-en-3-one. Its decarboxylation leads to cyclobutadiene **118** which was detected in a matrix at 8 K[199]. Possible formation of azacyclobutadienes **136** using this route has also been invoked[200].



X = CH, $R^1 = R^2 = H$ **118**

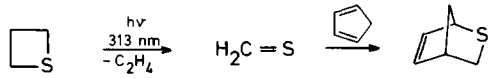
X = N, $R^1 = R^2 = H$ **136a**

X = N, $R^1 = CH_3$, $R^2 = C(CH_3)_3$ **136b**

A special use of the 2-oxetanones lies in the protection of one olefinic double bond in a polyene. This has been used in the synthesis of juvenile hormone analogs[201].

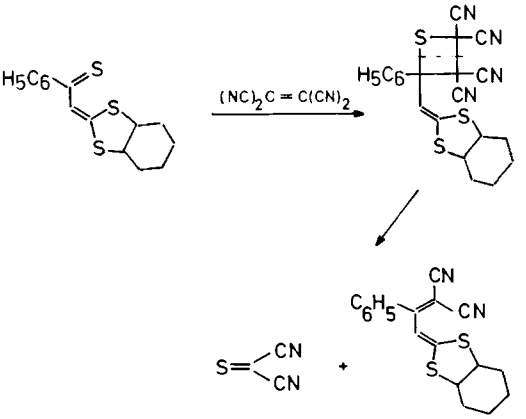
3.3.2. Thietanes

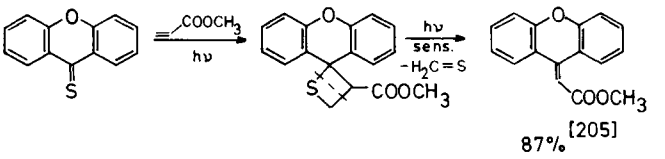
The [2+2]-cycloreversion of thietanes can be thermally or photochemically induced. Thus thioformaldehyde is formed by heating the parent system to 1000 °C[202] or by irradiation[203], and can be detected spectroscopically or trapped by Diels-Alder reaction with cyclopentadiene[203].



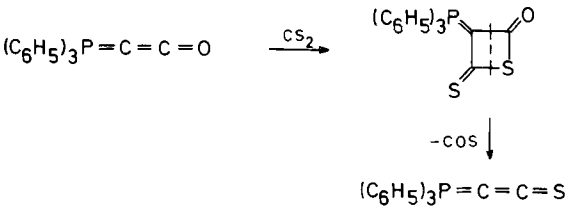
Because the cycloaddition of thiocarbonyl compounds, in contrast to the Paterno-Büchi reaction, often proceeds thermally and with electron-poor alkenes, fragmentation of these thietanes markedly expands the range of olefins available *via* oxetanes (cf. Section 3.3.1.)[204, 205].

Olefinations by reaction of thiocarbonyl compounds with ketenes followed by cycloreversion of the resulting 2-



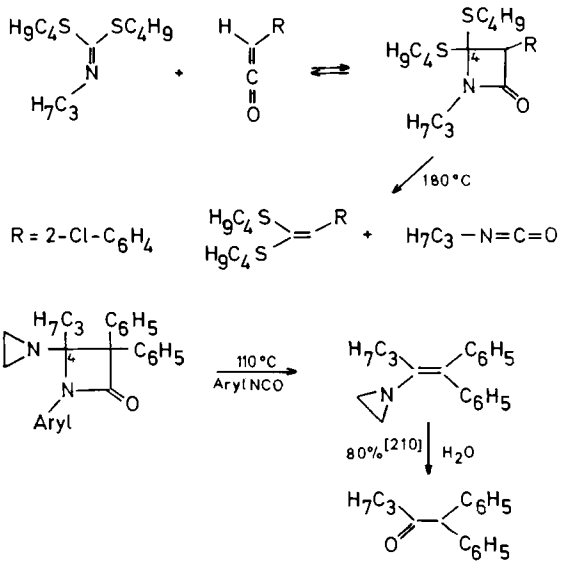


thietanones are possible, but are of synthetic interest only if the carbonyl compounds which serve as the precursors to the thiones do not themselves react with ketenes[119–121]. On the other hand, cycloreversion of 2-thietanethiones opens a route to those thiocarbonyl compounds, especially thioketenes, which are not available by direct sulfurization[206].

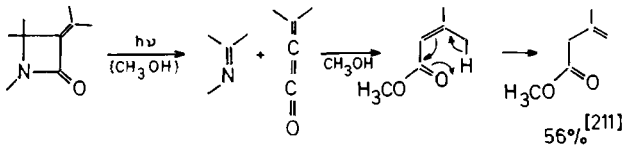


3.3.3. Azetidines

Cycloreversion of unsubstituted azetidine starts only at 400 °C[207], and simple 2-azetidinones ("β-lactams") are thermostable up to 500 °C[98]. As expected, the cycloreversion is significantly accelerated by electron donors in the 4-position[208–210].

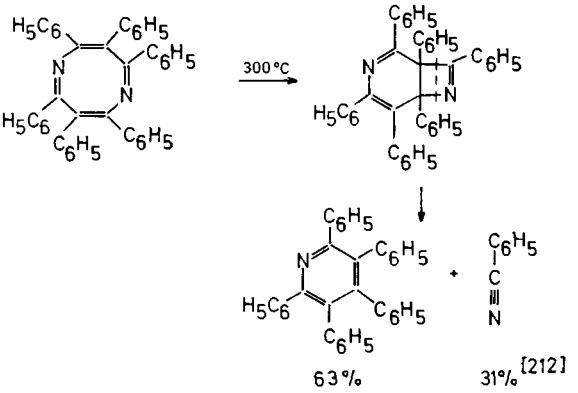


Generally, photochemical cleavage of 2-azetidinones gives fewer side products[115], however, the other cleavage direction occurs (cf. Section 2.4.). Starting from a 3-isopropylidene-2-azetidinone, an alkylideneketene is generated and trapped with methanol[211].



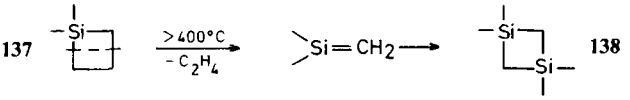
Cycloreversion of the β-lactam moiety of penicillin- and cephalosporin-derivatives catalyzed by trifluoroacetic acid gives a ketene and a thioimidic acid ester fragment[208].

1-Azetines fragment photolytically (cf. **136a, b**) or thermally[212], to afford hydrocyanic acid or a nitrile; electrocyclic ring opening is not observed.

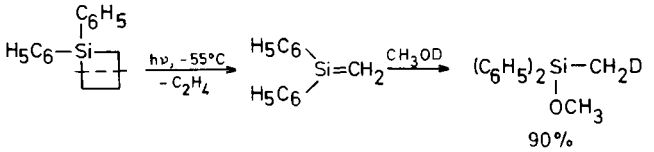


3.3.4. Siletanes

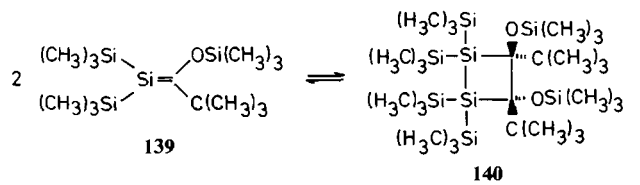
Because of their unique bonding properties, silaalkenes (silenes) are of particular interest. Although assumed for some time not to exist, a species of this type has been obtained through cycloreversion of siletane **137**[35,213].



With phenyl substitution the cycloreversion can also be accomplished by irradiation[214].

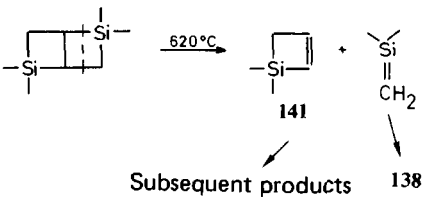


The silaalkene **139** is sufficiently stable that it occurs in solution together with the head-to-head dimer **140**[215].



139 **140**

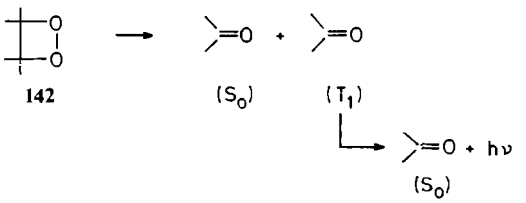
Barton et al. even succeeded in generating a siletene **141** *via* a [2+2]-cycloreversion[216].



3.4. Heterocycles with Two Identical Heteroatoms

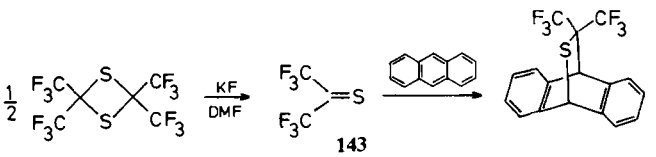
3.4.1. 1,2-Dioxetanes

If a concerted photochemical [2+2]-cycloaddition must follow the $[_\pi 2_s + _\pi 2_s]$ path[1], then a naive expectation for the $[_\sigma 2_s + _\sigma 2_s]$-cycloreversion would be chemiluminescence[217]. In fact, the cleavage of 1,2-dioxetanes such as **142** occurs with chemiluminescence. However, contrary to the expectations of the Woodward-Hoffmann rules, the light is emitted from the triplet acetone[218]. Because of the special interest in chemiluminescent systems, the cycloreversion of 1,2-dioxetanes and 1,2-dioxetan-3-ones has been intensively investigated[219]. At the forefront are mechanistic studies; of particular importance are the roles of 1,2-dioxetan-3-ones in bioluminescence[220] and the "photochemistry without light" studies mainly of *White et al.*, in which photoreactions are induced by heating photolabile substances with **142**[221].

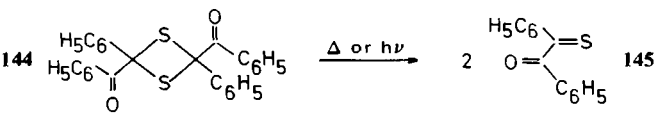


3.4.2. 1,3-Dithietanes

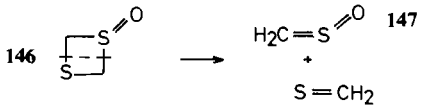
Thiocarbonyl compounds often tend to dimerize to 1,3-dithietanes. This can be an undesired side reaction, but the air-stable, storable 1,3-dithietanes present the possibility of liberating highly reactive C=S compounds by a [2+2]-cycloreversion. Hexafluorothioacetone **143**, prepared from hexafluoropropene and sulfur, dimerizes but can be regenerated in potassium fluoride/dimethylformamide (DMF)[222] or thermally[223], and allowed to react with anthracene in a Diels-Alder reaction.



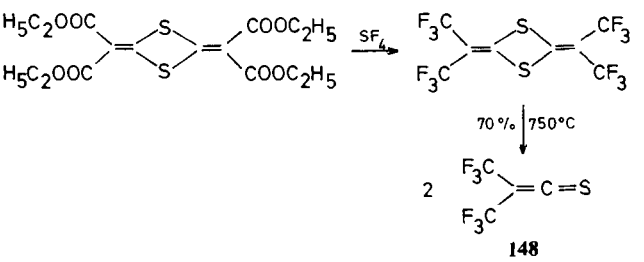
Bak and *Praefcke* reported that the dimer **144** can be converted thermally above 210°C into the monomeric monothiobenzil **145**, but by irradiation even at room temperature[224].



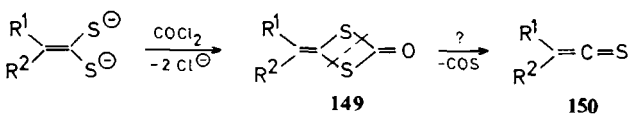
1,3-Dithietane 1-oxide **146** is a source of thioformaldehyde *S*-oxide ("sulfine") **147**, which can thereby be studied by microwave[225] and photoelectron spectroscopy[226].



The cycloreversion of 1,3-dithietanes in the synthesis of heteroallenes containing the thiocarbonyl group is of special preparative interest. The dimers of thioketenes are, however, often insufficiently volatile to be cleaved thermally[227]. An exception is provided by the preparation of the highly reactive bis(trifluoromethyl)thioketene **148** in 70% yield from its dimer[228].

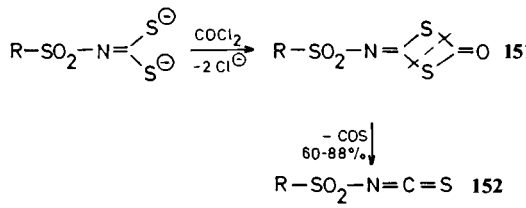


Very often useful as thioketene equivalents are 4-alkylidene-1,3-dithietan-2-ones **149** prepared by reaction of alkene-1,1-dithiolates with phosgene, and they provide access to products with various substituents[132,169,229]. Fragmentation to the thioketene, however, has only been substantiated for **149c**[227]. In the usual trapping reactions the added nucleophiles do not appear to react with the free **150** but first with **149**, and carbonyl sulfide is subsequently lost from the adduct[229d].



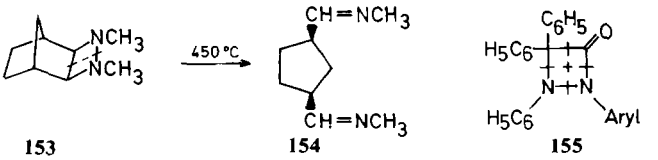
a, $R^1=CN$, $R^2=CO_2CH_3$; **b**, $R^1=CN$, $R^2=CO_2C_2H_5$; **c**, $R^1=R^2=CN$; **d**, $R^1=CH(CH_3)_2$, $R^2=CN$; **e**, $R^1=C(CH_3)_3$, $R^2=CN$

Analogous to **149**→**150** the strongly electrophilic sulfonyl isothiocyanates **152** can be liberated from the dithietanones **151**, and are stable enough to be characterized[230].

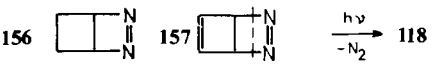


3.4.3. 1,2-Diazetidines and -Diazetines

1,3-Bismethylimino compounds **154** are the products of the flash thermolysis of **153**, in which the relatively weak NN-bond is cleaved regioselectively[231]. The norbornene analog of **153** forms the cyclopentene derivative in the same type of reaction. In the 1,2-diazetidin-3-ones **155**, on the other hand, products of both possible fragmentation pathways are observed[232].

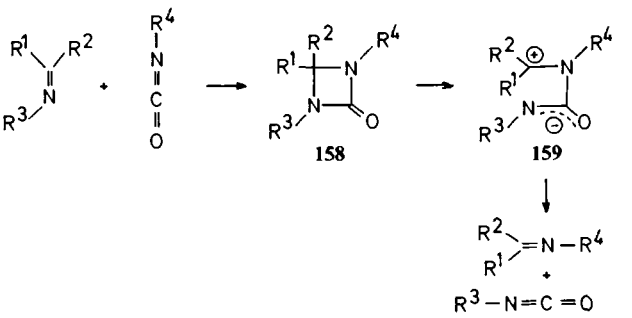


In Δ^1-1,2-diazetines, with the exception of bicycle **156**[233], electrocyclic ring opening is less likely than [2+2]-cycloreversion[28,67,234]. Photolysis of **157** is thus a way to prepare cyclobutadiene **118**[235]. Analogously, azacyclobutadiene can be produced as demonstrated on the basis of its cycloreversion products[200b].

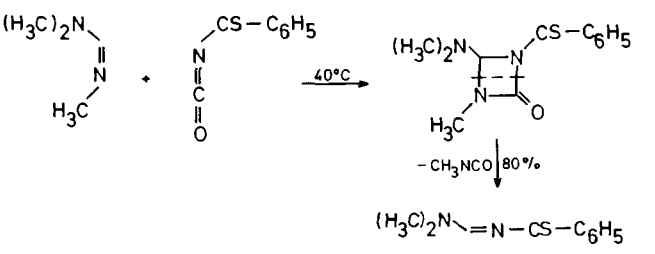


3.4.4. 1,3-Diazetidines

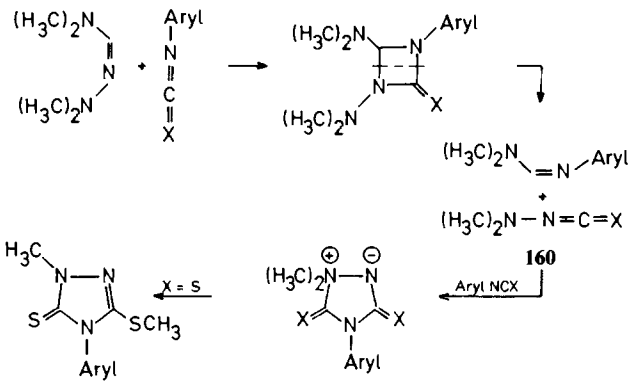
Ingold et al. found that azomethines can dimerize to produce 1,3-diazetidines, which undergo cycloreversion when warmed[236]. With 1,3-diazetidin-2-ones **158** ring cleavage is so favored that it usually occurs *in situ* during preparation from a C=N component and an isocyanate. This is especially true for cases in which R^1 or R^2 can stabilize a positive charge formed in the step **158**→**159**. Especially favorable starting materials for the reaction with isocyanates are therefore imido esters[237], amidines[238], guanidines[11,229d,239], and isothioureas[240]. A C=N compound and an isocyanate are isolated as products, so that this represents an example of an "exchange reaction" (cf. Section 1).



The method is important for preparation of C=N products with electron withdrawing groups R^4, since in this case other methods often fail; formation of **158**, however, is favored because of the high reactivity of the isocyanate component. Using this method *N*-thiobenzoylformamidines can be prepared[239].

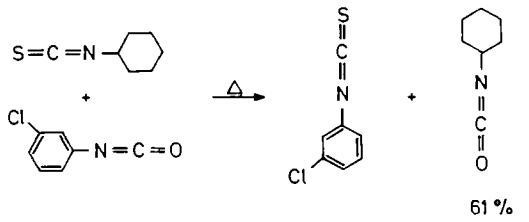


Unusual isocyanates can also be prepared by cycloreversion of **158**. Thus, starting from *N*-(α-pyridyl)azomethines ($R^3 = \alpha\text{-}C_5H_4N$) α-pyridyl isocyanate is formed, which as a highly reactive heteroallene reacts further with the starting isocyanate to give a 1 : 1 adduct[241]. With *N,N*-dimethylhydrazones, isocyanates react *via* **158** to the interesting dimethylamino isocyanate **160a**, which may be trapped as the betaine **161a**[242]. Dimethylamino isothiocyanate **160b** is also formed according to this scheme starting from phenyl isothiocyanate, which here undergoes the relatively uncommon (cf. Section 3.5.3) cycloaddition involving the C=N bond.



a, X = O; **b**, X = S

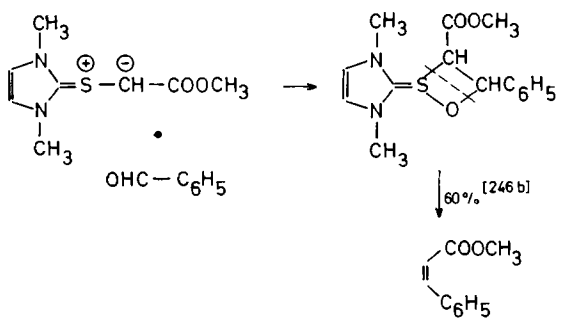
If the starting material serving as the C=N component for **158** is part of a cummulative double bond system, heterocycles **158** having sp^2-hybridization at C-4 are formed; isocyanates and isothiocyanates[243] or carbodiimides and isocyanates[244,256] react *via* exchange of substituents to give an equilibrium mixture. If one of the four participating heteroallenes has a markedly lower boiling point than the others, it can be isolated from the mixture by distillation[243b].



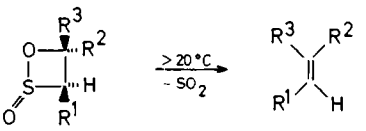
3.5. Heterocycles With Two Different Heteroatoms

3.5.1. 1,2-Oxathietanes

Sulfur ylides do not normally react with carbonyl compounds to give olefins but give oxiranes by methylene transfer[245]. There are, however, cases in which alkene formation is at least a competing reaction[246]; 1,2-oxathietanes are plausible intermediates.

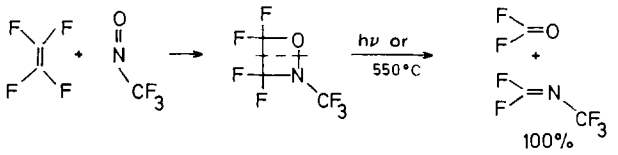


Decomposition of 1,2-oxathietane 2-oxides ("β-sultines") also leads to alkenes; the best yields in this stereospecific reaction are given by trisubstituted systems[62,63].

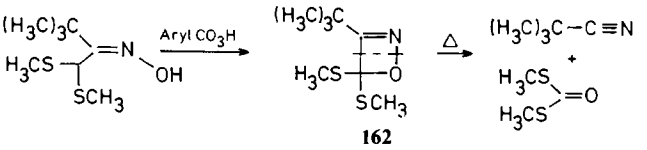


3.5.2. 1,2-Oxazetidines

[2+2]-Cycloadducts of nitroso compounds with alkenes[247], ketenes[248], or ketenimines[249] contain the easily broken NO bond. Usually, cycloreversion occurs on heating, but photochemical excitation can also lead to ring cleavage[247c].

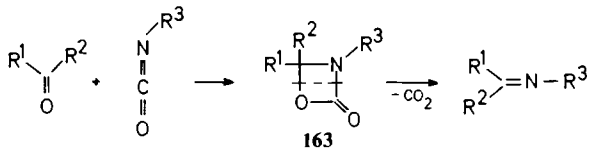


In principle, cycloreversion of 4*H*-1,2-oxazete **162** occurs in the same way, thus confirming the suggested structure[250].



3.5.3. 1,3-Oxazetidines

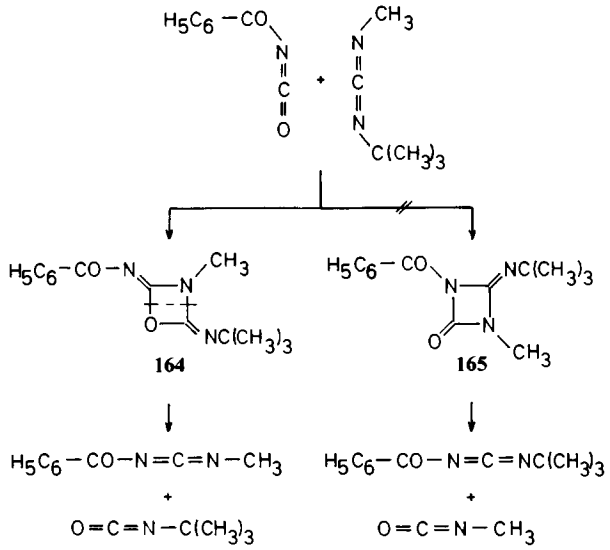
Aldehydes, non-enolizable ketones, amides, and anhydrides react with isocyanates with exchange of the carbonyl for an imino group[10]. As intermediates, 1,3-oxazetidin-2-ones **163** are plausible.



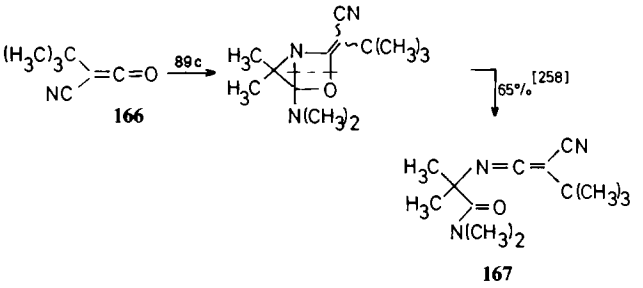
The reaction with isocyanic acid where $R^3 = H$ was even observed by *Liebig* and *Wöhler*[251]. Since the cycloaddition step is favored by increased electrophilicity in the isocyanate, acyl isocyanates[252], arenesulfonyl isocyanates[189,253], and especially chlorosulfonyl isocyanate[254] react under very mild conditions. When catalyzed by 3-phospholene 1-oxides, cycloaddition between two isocyanate molecules can be achieved, thus making carbodiimides available in good yields[255].

The [2+2]-cycloadduct from benzoyl isocyanate and *tert*-butyl(methyl)carbodiimide is thermally cleaved to afford *tert*-butyl isocyanate and an acylcarbodiimide. Therefore, the four-membered ring should be formulated as 1,3-oxazetidine **164**, and the earlier proposed 1,3-diazetidine structure **165**, from which methyl isocyanate would have

to be formed, is excluded[256]. This example demonstrates how useful the [2+2]-cycloreversion is in proving the structure of cycloadducts of unsymmetrical heteroallenes, which is often very difficult by spectroscopic methods. It remains open *a priori* which of the two π-bonds will react with a specific cycloaddition partner, *i.e.* what the *toposelectivity*[257] of the cycloaddition is.

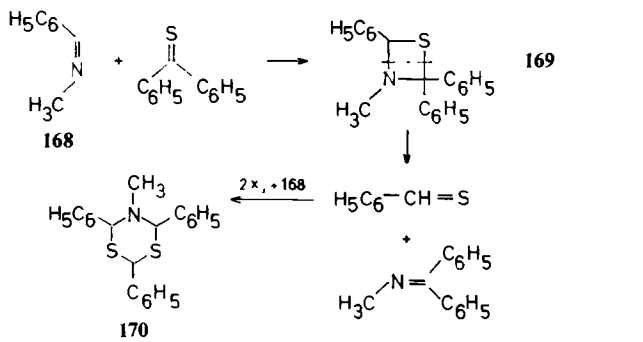


While ketenes normally react with C=N compounds *via* their C=C bond, in the reaction with the strained aminoazirines **89c—e** cycloaddition takes place primarily on the C=O part of the heteroallene[258]. *tert*-Butyl(cyano)ketene **166** reacts with **89c** in this way to form a bicyclic 1,3-oxazetidine, which undergoes *in situ* cycloreversion to the interesting ketenimine **167** containing additional functional groups.

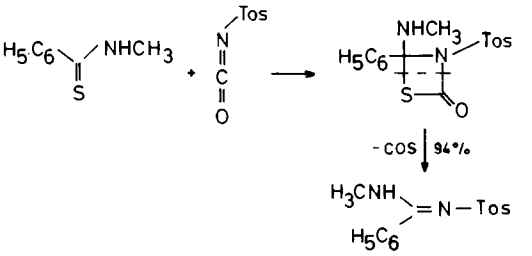


3.5.4. 1,3-Thiazetidines

Thiobenzophenone adds photochemically to benzylidene(methyl)amine **168** to afford a 1,3-thiazetidine derivative **169**, which liberates thiobenzaldehyde *via* cycloreversion. This highly reactive thiocarbonyl compound, incapable of existence in its free form, reacts essentially with unreacted **168** to give the 2:1 adduct **170**[259].

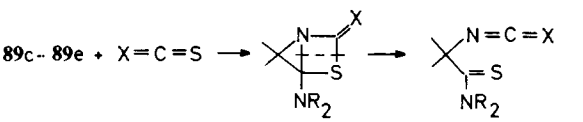


1,3-Thiazetidines also result from thermal reactions, if the imino or the thiocarbonyl group is part of a cumulative system. The four-membered ring compounds then contain at least one sp^2-hybridized ring carbon atom and easily undergo cycloreversion. Thus, exchange of a thiocarbonyl for a tosylimino group is achieved[260].



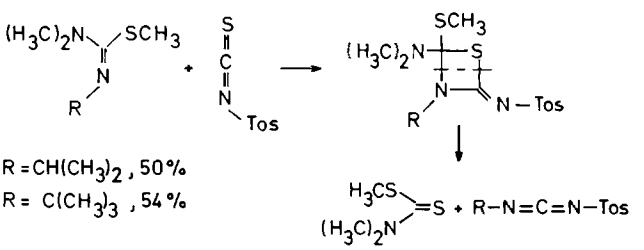
Since the reaction of carbonyl compounds with isocyanates affords imino compounds in the same manner (cf. Section 3.5.3), and the sulfur derivatives must normally be prepared from the corresponding carbonyl compounds, this procedure is generally of no preparative significance.

Interesting applications, however, are found for the cycloreversion of 1,3-thiazetidines available from thiocarbonyl-containing heteroallenes such as carbon disulfide, thioketenes, and isothiocyanates, which often react with imines toposelectively[257] at the C=S bond[10]. This occurs particularly for reactions with the strained C=N bond of the aminoazirines **89c—89e**. As already discussed in Section 2.5 for carbon disulfide (X=S, **89**→**93**) and carbon diselenide (X=Se), new heteroallenes which contain a thiocarbonyl group are obtained from thioketenes ($X=CR_2$)[129] or isothiocyanates (X=N—R)[261,262].



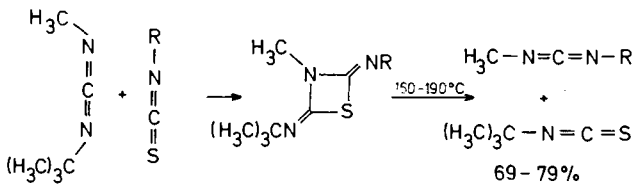
93, X = S
171, X = CR_2
172, X = NR

An example of an *in situ* cycloreversion of a 1,3-thiazetidine obtained from an acyclic C=N component is the reaction of isothioureas with benzoyl or tosyl isothiocyanate. In this case carbodiimides are formed, which, because of the electron withdrawing substituents, demonstrate high reactivity as electrophiles[263].



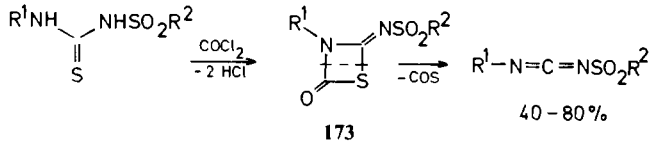
Reaction of two heteroallenes one containing a thiocarbonyl and the second an imino group usually leads *via* a

1,3-thiazetidine to an exchange reaction. The cleavage products produced establish the constitution of the primary heterocycle and in the following case permitted correction of an earlier structural proposal derived from a different toposelectivity in the isothiocyanate[256].



Depending upon substitution, 2,4-bisimino-1,3-thiazetidines can also fragment to the starting compounds[264]. Products of the cycloaddition of carbodiimides **172** and isocyanates do not undergo subsequent cycloreversion but instead zwitterionic addition products or 1:2 adducts are isolated[264].

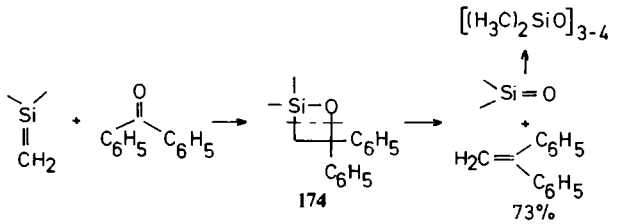
A preparatively useful approach to carbodiimides is the cycloreversion of 4-imino-1,3-thiazetidin-2-ones **173**, which can be viewed as the formal cycloadducts from isocyanates and isothiocyanates but which are available in a simpler way from thioureas and phosgene[265]. This also represents another method for preparation of sulfonylcarbodiimides[266].



173

3.5.5. 1,2-Oxasiletanes

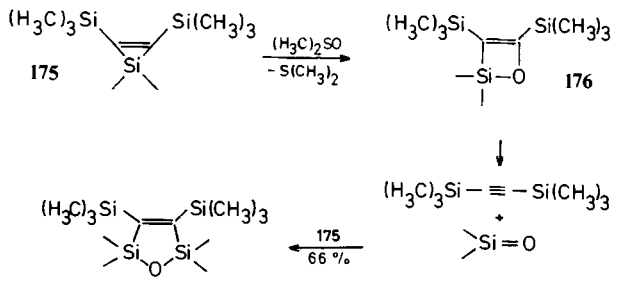
[2+2]-Cycloreversion as a simple method for conversion of a σ- into a π-bond should lead in the case of 1,2-oxasiletanes such as **174** to silanones, which because of the poor overlap of the *p*-orbitals, have a very energy-rich Si=O bond. Because of this special interest in the bonding relationships in silanones, several routes to four-membered rings containing Si—O bonds have been developed. Thus it has been demonstrated that 1,2-oxasiletanes are very unstable and spontaneously fragment to silanones[269]. If no suitable trapping agent is added then the Si=O compounds oligo- or polymerize to siloxanes.



174

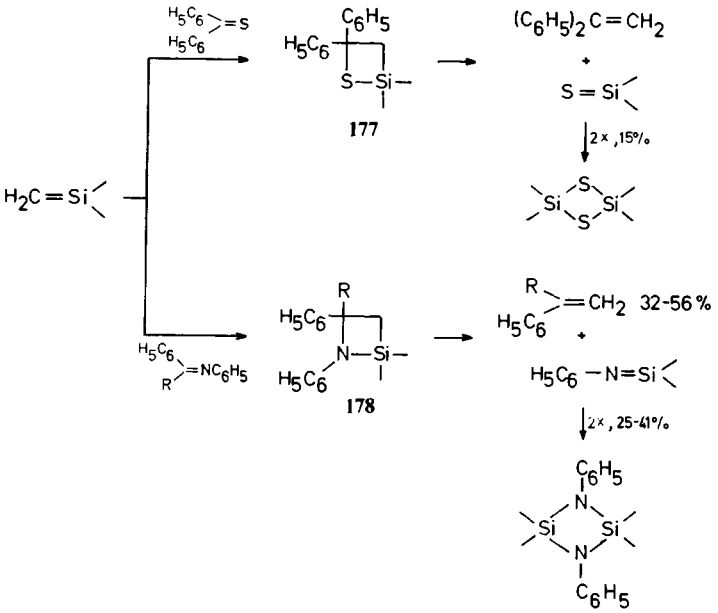
Often the 1,2-oxasiletanes are themselves formed in trapping reactions. Besides the reaction of silandiylenes (silylenes) with epoxides[267] or the intramolecular stabilization of siloxycarbenes[268] one should note especially the [2+2]-cycloaddition of silaalkenes, produced as described in Section 3.3.4, with non-enolizable carbonyl compounds. Benzophenone reacts in this way quite smoothly[270].

In the oxidation of silirene (silacyclopropene) **175** the first product is a 1,2-oxasilete **176** which does not undergo electrocyclic ring opening but reacts further in a cycloreversion step[271].



3.5.6. 1,2-Thiasiletanes and 1,2-Azasiletidines

In the same way that silaalkenes (cf. Section 3.3.4) can be trapped with carbonyl compounds (cf. Section 3.5.5), [2+2]-cycloadditions occur with thioketones or azomethines. In this way thermolabile 1,2-thiasiletanes **177**[272] or 1,2-azasiletidines **178**[273] are formed which react further in cycloreversions to give compounds with Si=S or Si=N bonds, respectively. Stabilization occurs most simply by dimerization.



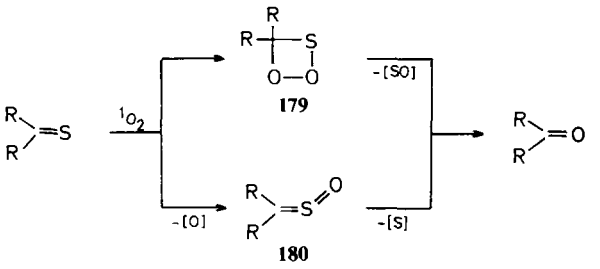
A decomposition analogous to that of **174**, **177** and **178** is observed for the corresponding germanium compounds[274].

3.6. Four-Membered Rings with Three Heteroatoms

Thioketones are desulfurized by singlet oxygen to the corresponding carbonyl compounds[275]. According to theoretical calculations a 1,2,3-dioxathietane intermediate **179** is formed which is stabilized by [2+2]-cycloreversion[276]. Alternatively, the pathway *via* a thioketone oxide **180** should be considered, especially since compounds of type **180** can be isolated starting from thioketenes[277].

Reactions of S=O or S=N systems with C=O or C=N compounds can also be explained by cycloaddition

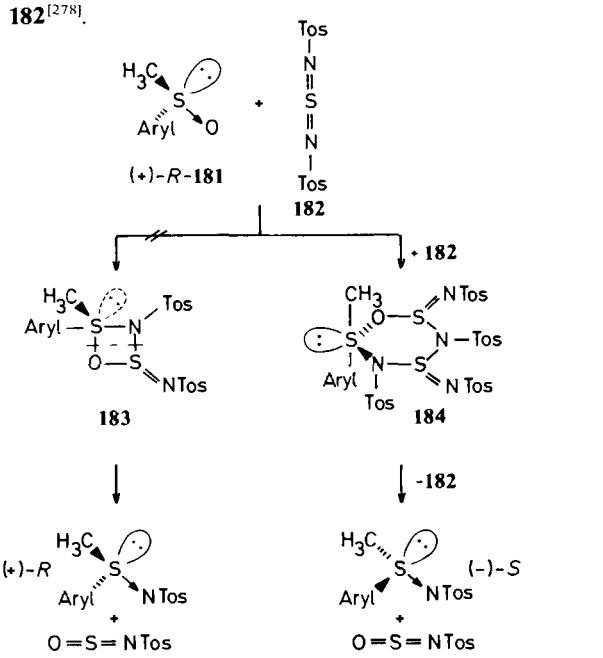
to a four-membered ring with three heteroatoms, followed by cycloreversion. However, a mechanistic study of a related example by *Cram et al.* indicated an intermediate



179

180

184. The optically active sulfoxide **181** reacted with the sulfur diimide **182** with inversion rather than retention as would be expected for the reaction *via* **183**. Furthermore the reaction is second order in the concentration of **182**[278].



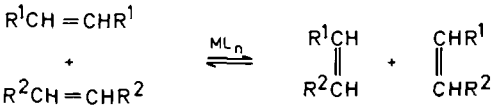
Aryl = 4-$CH_3C_6H_4$

Preparative aspects of the cycloaddition of sulfinylamines and sulfur diimides have been reviewed by *Kresze* and *Wucherpfennig*[279].

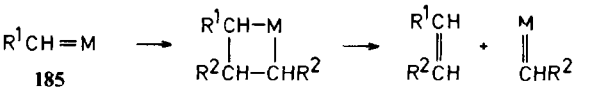
4. Related Reactions

4.1. Metathesis Reactions of Alkenes

The transition-metal catalyzed substituent exchange of olefins can be interpreted in terms of [2+2]-cycloaddition and -reversion processes.



Mechanistic studies, however, have demonstrated participation of metal-carbene complexes of type **185** and a metalacyclobutane intermediate **186**. Thus the overall reaction is a very complex process in which cycloreversion of **186** constitutes only one step[280].

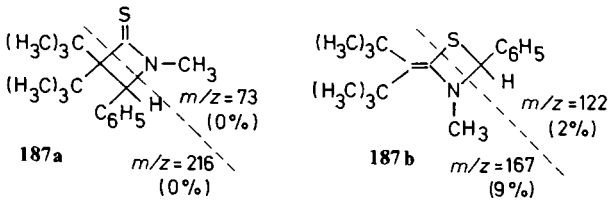


185 **186**

4.2. Electron-Impact-Induced Cycloreversions

During decomposition of four-membered ring compounds in the mass spectrometer, [2+2]-cycloreversions play an important role. This has been extensively observed for 2-azetidinones[281]. Consequently, the mass spectrum might rapidly provide information on the expected regioselectivity of preparative cycloreversions of four-membered ring compounds by thermolysis or photolysis. In fact, there appear, on the basis of theoretical considerations, to be analogies between electron-impact, photochemical, and thermal fragmentation[282]; on the other hand, however, this relationship has been placed in doubt[283]. Here too, one must expect surprises in some instances.

As a method of structure determination, electron-impact fragmentation of four-membered ring compounds can in some circumstances lead to errors. Thus, thioketenes and azomethines form 1:1 adducts, which on the basis of IR and ^{13}C-NMR data as well as decomposition reactions should doubtless be formulated as 2-azetidinethiones (e.g. **187a**) rather than thiazetidines (*e.g.* **187b**)[284]. In the mass spectrum of **187**, besides fragmentation to the starting materials, thioketene (57%), and azomethine (8%), no signals resulting from the alternative, expected fragments, methyl isothiocyanate and 2-*tert*-butyl-3,3-dimethyl-1-phenyl-1-butene are observed. On the other hand a signal is observed at $m/z = 167$, which appears to result from **187b**[284a]. Thus, under the experimental conditions (70 eV) isomerizations may occur which place in doubt the validity of mass spectra to distinguish between isomers such as **187a** and **187b**.



187a **187b**

5. Summary and Prognosis

The review has shown that [2+2]-cycloreversions are involved in many diverse areas of organic chemistry. The range runs from primarily mechanistic research on hydrocarbons *via* their use in heterocyclic synthesis and to natural product chemistry. A well-defined and therefore preparatively valuable pathway is taken by [2+2]-cycloreversions, especially if one fragment is thermodynamically quite stable. In this context aromatic compounds (*e.g.* **110**→**111**), nitrogen (*e.g.* **157**→**118**), carbon dioxide (decomposition of **132**) and carbonyl sulfide (*e.g.* **149**→**150**, **151**→**152**) are included, whereby in the last three cases the volatility of the products make the reversion irreversible, and work-up is facilitated. In these examples formation of

fragments with a labile π-bond is possible. The potential of this reaction principle is far from exhausted. Also valuable is the often high stereoselectivity of these cycloreversions.

Perhaps even more important is the [2+2]-cycloreversion of four-membered rings which form part of a bi- or polycyclic system. Conversion of the aminoazirines **89c**—**89e** into compounds such as **93**, **167**, **171**, or **172**, as well as ring opening of the tricycle **104** provide examples. In future, further interesting uses for the preparation of bifunctional compounds and for ring expansions are to be expected.

The influence of metal- and acid-catalysis on the fragmentation of four-membered rings has so far been extensively studied only with carbocycles. It appears promising for preparative purposes and from the standpoint of solar energy storage to study catalysis in the fragmentation of heterocycles, to increase the yields of known reactions, as well as to broaden the scope of [2+2]-cycloreversions.

Parts of this review were written during a period spent by R. K. at the Universität Hamburg sponsored by the Deutscher Akademischer Austauschdienst and during a guest professorship of E. S. at the University of Wisconsin in Madison. E. S. wishes to thank members of the Chemistry Department at Madison for their hospitality and stimulating discussions, and to express his thanks to the graduate students whose names appear in the references for their engaging collaboration.

Synthesis and Reactions of 4-Chromanones

By Hans-Joachim Kabbe* and Arno Widdig

Dedicated to Professor H. Grünewald on the occasion of his 60th birthday

Many natural products, such as the plant insecticides rotenone and ageratochromene (precocene), some fungitoxic phytoalexins, hashish constituents, vitamin E, and plant pigments, contain the chroman ring system as common structural unit. Some years ago we discovered a particularly simple entry to this class of heterocyclic compounds: The condensation of *o*-hydroxyacetophenones with aliphatic aldehydes and ketones in the presence of pyrrolidine leads to 4-chromanones in good yields. The scope of application and limitations as well as modification of this versatile synthesis are outlined; the accompanying tables give a good indication of the wealth and variety of possible substituents. The reaction of *o*-hydroxyacetophenone, *e.g.* with glyoxylic acid or with α,β-unsaturated ketones, proceeds atypically. The majority of the new chromanones can be used, *inter alia*, for the preparation of chromones, chromenes and chromans, and for the synthesis of tricyclic and larger ring systems.

1. Introduction

Benzopyran compounds[**] are widespread in nature and are found in a variety of forms. Many of them have interesting properties, particularly those belonging to the plant pigments (anthocyanins and flavones) and the biologically active substances, such as the psychotropic constituents of hashish (tetrahydrocannabinol), the insecticidal ageratochromenes (precocenes) and rotenone, fungicidal phytoalexins, vitamin E, as well as coumarin and catechin.

This class of compounds has therefore long been the subject of numerous intensive studies; the many-sided interest shown in such compounds equates directly with an

[**] In Chemical Abstracts, 4-chromanones have for a number of years been referred to as 2,3-dihydro-4*H*-1-benzopyran-4-ones. In this review article we use the IUPAC nomenclature (Rule B-2.12).

advanced state of the art in their syntheses[1]. Nevertheless, many of the methods adopted (see also Section 2.5) leave much to be desired: In some cases variation of the educts is limited, in others severe reaction conditions prevent the synthesis of chromans bearing sensitive substituents. Therefore, new syntheses overcoming these disadvantages are, as in the past, very welcome.

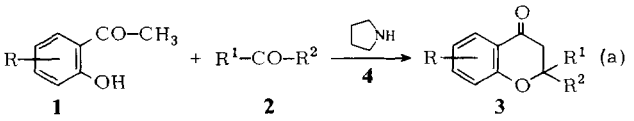
During an investigation[2] of the reactions of *o*-acylphenols with enamines we found that *o*-hydroxyacetophenones **1** undergo cyclization on reaction with aliphatic aldehydes and ketones **2** in the presence of pyrrolidine **4** to give the 4-chromanones **3**[3,4]. This reaction is suitable for the synthesis of a wealth of variously substituted derivatives, since the mild conditions enable reaction of educts containing labile groups. Moreover, because of its simplicity, the synthesis can easily be carried out on a larger scale. It thus opens up the desired entry to new chromans, and frequently provides a useful or better alternative method for the synthesis of known benzopyrans. In the following article the preparative utility of the method and the scope and limitations of the reaction are outlined with the aid of some model examples.

2. Synthesis of 4-Chromanones

2.1. Pyrrolidine-Catalyzed Syntheses

o-Hydroxyacetophenones **1** react with aliphatic aldehydes and ketones **2** in the presence of pyrrolidine **4** to give 4-chromanones **3** [eq. (a)]. Table 1 contains some examples of 4-chromanones **3**, so selected as to demonstrate the scope of possible variation of the substituents[49].

In the simplest model, a mixture of **1**, **2**, and **4** in the ratio of about 1:1:0.5 in toluene is allowed to stand for a while and then heated to boiling in an apparatus fitted with a water separator. The yield is *ca.* 60—90%. Small amounts—usually less than 15%—of 4-pyrrolidinochromenes **34** (cf. Section 2.3.3) are formed at the same time. Therefore, to increase the yield the reaction mixture is hydrolyzed with dilute hydrochloric acid before further work-up and the end products are isolated by distillation or recrystallization[3].



1 **2** **3**

Table 1. 4-Chromanones **3** prepared according to eq. (a).

	R	R^1	R^2	Yield [%]	M.p. [°C] B.p. [°C/torr]
3a	H	H	$CH(CH_3)_2$	93	125/0.07
3b	H	H	$C(CH_3)_3$	78	54-56 [5]
3c	H	H	*n*-C_9H_{19}	79	175/0.1
3d	H	H	$(CH_2)_2C_6H_5$	30	185/0.05
3e	H	CH_3	CH_3	65	88-90 [6]
3f	6-CH_3O	H	*n*-C_6H_{13}	62	53-55
3g	7-OH	—$(CH_2)_5$—		73	170-171
3h	H	—$(CH_2)_4$—		85 [a]	38-39
3i	H	CH_3	$CH(OCH_3)_2$	55 [b]	130/0.1
3k	6-OH	CH_3	$(CH_2)_2CH{=}C(CH_3)_2$	74	79-81
3l	6-Cl	CH_3	COOH	61 [c]	92-94
3m	6-OH 5,7,8-$(CH_3)_3$	CH_3	$(CH_2)_2COOH$	66 [c]	164-166
3n	6-CH_3O	CH_3	$(CH_2)_4COOH$	61 [c]	76-78
3o	H	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	75	185/0.1
3p	6-Cl	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	81	180/0.1
3q	6-CH_3O	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	66	175/0.1
3r	6-COOH	—$(CH_2)_4$—		73	229-231

[a] 86% from previously formed enamine **5** according to eq. (b) [3]. [b] Half-hours' stirring with 2N HCl leaves the acetal group intact. [c] With 1.5 equivalents of pyrrolidine (to neutralize the carboxylic acid group) in toluene, anhydrous.

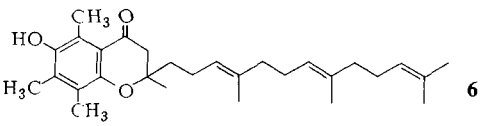
Instead of the carbonyl compounds **2** their enamines (*e.g.* **5**) obtained by reaction with pyrrolidine can also be used [eq. (b)].

This variant yields the chromanones **3** in about the same yields as according to eq. (a) if **1** and the enamine are heated in toluene or methanol[3], but it normally does not offer any advantages.

Acidic groups in **1** and **2** (carboxy- and further phenolic hydroxy groups) must be neutralized beforehand; this is best accomplished by increased addition of pyrrolidine[3] (see **3g**, **3k—n**, **3r** in Table 1).

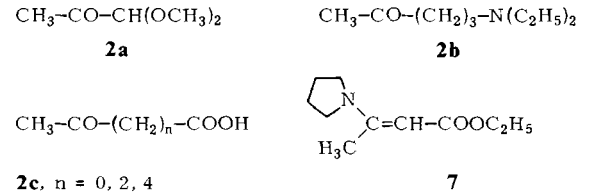
2.2. Scope and Limitations of the Reaction

Table 1 gives an idea of the scope of application of the synthesis. The mild conditions also allow the synthesis of **3** bearing labile substituents. Most of the other chromanone syntheses involve acid catalysis in the final step; *i.e.* they are unsuitable for compounds containing acid-labile groups. Thus, for example, in the case of 4-oxotocotrienol **6** the isoprenoid side-chain is cyclized in the presence of acids[7]; reaction of 2,5-dihydroxy-3,4,6-trimethylacetophenone and farnesylacetone[4] under the conditions of the pyrrolidine-catalyzed chromanone synthesis [eq. (a)] affords **6** in *ca.* 80% yield.



6

Acetal- (**2a**), amino- (**2b**) and carboxy-groups (**2c**) also remain unchanged in this synthesis. Sterically demanding moieties do not hinder reaction, as is demonstrated by the synthesis of 2-*tert*-butyl-4-chromanone **3b** (previously obtained in a four-step synthesis[5]).



Hence there is a large selection of *o*-hydroxyacetophenones **1**, and even a larger one of aliphatic carbonyl compounds available which can be employed (for exceptions see Section 2.3) in this method of synthesis.

Limitations arise where β-dicarbonyl compounds **2** form stable end products with **4**. Thus, *e.g.* the enamine **7**—a vinylogous urethane formed on reaction of ethyl aceto-acetate and pyrrolidine—no longer reacts according to eq. (b).

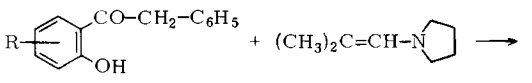
In contrast to the wide selection of **1** and **2** the basic catalyst can hardly be varied. In all cases investigated pyrrolidine proved to be by far the best catalyst; with other secondary amines (piperidine, morpholine, diethylamine) the chromanones are formed much more slowly or even not at all. This special position of pyrrolidine in enamine reactions is already well known[8,9,50].

The use of sodium hydroxide and tertiary amines (triethylamine, diazabicyclononane, *N*-methylpyrrolidine) fails, too. These observations would suggest that pyrrolidine not only reacts as base ("proton captor") but also forms intermediates in the synthesis (see Section 2.4). The relatively narrow restriction to pyrrolidine as catalyst may be the reason why this formally quite simple chromanone synthesis was first discovered as late as 1976.

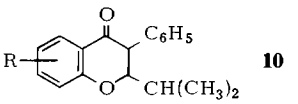
From experience it emerges that the addition of about 30—80 mol-% of pyrrolidine as "catalyst" is necessary in order to achieve satisfactory reaction. This amount can, in principle, be reduced, but at the expense of longer reaction times. It must also be taken into account that a certain amount of the base is consumed in the formation of by-products (*e.g.* 4-pyrrolidinochromenes, cf. Section 2.3.3).

Alteration of the acyl moiety in **1** has several consequences. If 2-acylphenols with longer alkyl chains are used in place of the *o*-hydroxyacetophenones the yields are drastically lowered.

If the methylene group of the acyl moiety is additionally activated, however, as for example in the phenylacetyl group, 2-isopropylisoflavanones **10** can be obtained in satisfactory yields. For this purpose **8** and **9** are heated in the absence of solvent for two to five hours at 100—125 °C. However, this reaction succeeds only with enamines formed beforehand from aldehydes; neither the free carbonyl compounds react with **8**, nor the enamines (*e.g.* **5**) derived from ketones. In **10**, the isopropyl group and the phenyl group are oriented predominantly (*ca.* 75%) in *trans* arrangement.



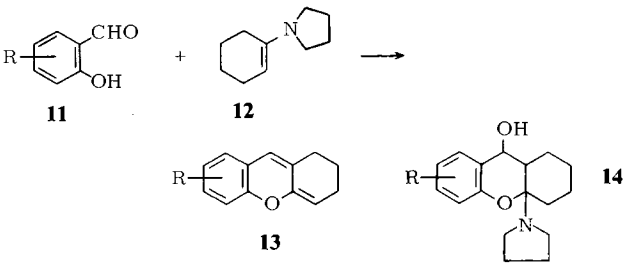
8 **9**



10

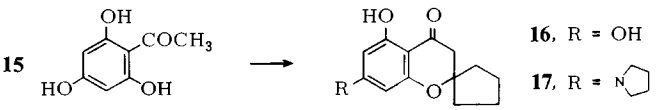
10a, R = H (81%, b.p. 170 °C/0.08 torr)
10b, R = 6-CH_3 (83%, b.p. 170—175 °C/0.1 torr)
10c, R = 7-*i*-C_3H_7O (93%, b.p. 190 °C/0.07 torr)

It should be mentioned here that salicylaldehydes **11** react somewhat differently with some enamines such as **12** derived from pyrrolidine; within relatively narrow limits the xanthenes **13**[2] are obtained, whereby the intermediary hydroxyamines **14**[10] successively split off water and pyrrolidine.



11 **12** **13** **14**

In phloroglucin one or two hydroxy groups can be replaced by other nucleophilic groups[11]. Thus, reaction of **15** with cyclopentanone in the presence of pyrrolidine does not afford the dihydroxychromanone **16** but its substitution product **17** as main product.



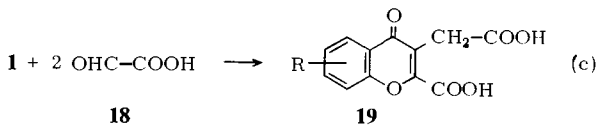
15 **16**, R = OH **17**, R = N

2.3. Special Cases

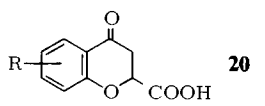
2.3.1. Glyoxylic Acid

It follows from Table 1 that oxocarboxylic acids can be readily converted into chromanones in good yields. Other than in the case of unsaturated ketones (see Section 2.3.2) it is immaterial whether both functions are adjacent (see **3l**) or separated by several methylene groups (see **3m**, **3n**).

In the case of glyoxylic acid **18**, the parent member of the oxoalkanecarboxylic acids, however, the reaction does not terminate with the primary product **20**. Addition of a second molecule of **18**, cleavage of water, and stabilization to the chromone ring system lead to the dicarboxylic acids **19** in good yields[12] (Table 2).



18 **19** (c)



20

Table 2. Dicarboxylic acids **19** prepared according to eq. (c) [a].

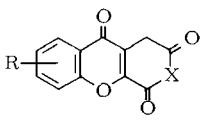
	R	Conditions	Yield [%]	M.p. [°C]
19a	H	6 d/25 °C	92	232–234
19b	7-CH_3	6 d/25 °C	64	147–148
19c	6-Cl	4 h/60 °C	78	253–255
19d	7-Cl	6 d/25 °C	84	150–152
19e	6,8-Cl_2	5 d/25 °C	66	230–232
19f	6-CH_3O	4 h/60 °C	77	219–221
19g	7,8-$(CH_3O)_2$	6 h/60 °C	80	230–232

[a] **1** and **18** are used in a stoichiometric ratio (here 1:2). **18** is neutralized with caustic soda or pyrrolidine **4** and condensation carried out with *ca.* 0.5 equivalents **4**. Water is suitable as solvent, admixed with methanol or isopropanol if necessary. Reaction is complete in 1 h at 70–80 °C; higher yields are obtained if the mixture is allowed to stand for a week at room temperature. – The acids can be precipitated from the aqueous solutions of the salts **19** with dilute hydrochloric acid.

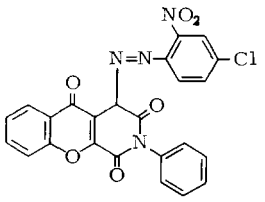
Table 3. Anhydrides **21** and imides **22** prepared from the dicarboxylic acids; **19**; yields based on **19** and **21**, respectively.

	X	R	Yield [%]	M.p. [°C]
21a	O	H	86	230–232
21b	O	6-CH_3	69	229–230
21c	O	6-Cl	83	225–227
21d	O	7-Cl	74	216–218
21e	O	7-CH_3O	79	240 (dec.)
22a	C_6H_5N	H	86	225–227
22b	4-ClC_6H_4N	H	65	225–226
22c	3,4-$Cl_2C_6H_3N$	H	70	240–243
22d	$C_6H_5CH_2N$	6-Cl	53	240–242

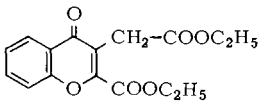
In boiling acetyl chloride (four- to eightfold excess, 10 h 25 °C, 10 h reflux) compounds **19** furnish the anhydrides **21**, from which the imides **22** can be synthesized (Table 3). Their reaction with diazonium salts[13] affords very strongly yellow-colored pigments such as **23**. Esterification of **19a** with ethanol yields the diethyl ester **24**, which has already been prepared as the sole compound of this series *via* an alternative route[14].



21, X = O
22, X = N–R^1



23

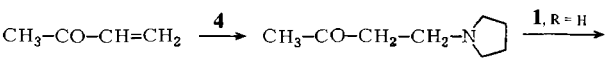


24

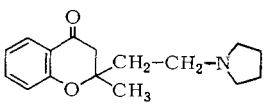
2.3.2. α,β-Unsaturated Carbonyl Compounds

The compounds **3k** and **6** show that double bonds (not in conjugation with the CO group) in the carbonyl components do not hinder benzopyranone ring-closure. However, if α,β-unsaturated aldehydes and ketones are used, the reactions take another course. We have observed two different modes of reaction.

Reaction of **1**, R = H, with methyl vinyl ketone **25** leads to formation of **27** in *ca.* 50% yield. That the primary adduct **26** functions as intermediate can be demonstrated by reaction of **25** (slight excess) with pyrrolidine **4** to give **26**[15], which reacts with **1** and further **4** to give **27**.

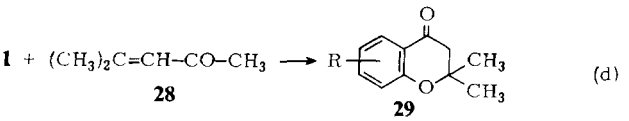


25 **26**



27

Mesityl oxide **28** behaves in a completely different manner. On reaction of **1**, R = H, with **28**, 2,2-dimethyl-4-chromanone **29a** (≡ **3e**) is formed, *i.e.* the same product as with acetone, and indeed in somewhat better yield (75% as compared with 65%). Reaction with **30** also leads to **29**. Table 4 lists some examples for **29**.



28 **29** (d)

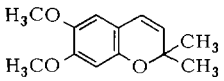
$(CH_3)_2C(OH)–CH_2–CO–CH_3$ **30**

Table 4. 2,2-Dimethylchromanones **29** prepared according to eq. (d) [a].

	R	Yield [%]	M.p. [°C]
29a	H	75	88–90
29b	6-Cl	79	[b]
29c	7-Cl	79	71–72
29d	6,7-Cl_2	63	87–89
29e	7-CH_3	69	68–70
29f	7-C_6H_5	50	98–100
29g	7-CH_3O	40	72–74

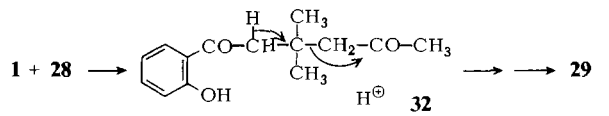
[a] **1**, **28**, and pyrrolidine are dissolved in toluene and the solution is heated to boiling for a few hours. It is then treated as in the isolation of **3** (Section 2.1) with 2N hydrochloric acid, and **29** is isolated by distillation. [b] B.p. = 110–115 °C/0.05 torr.

Both variants provide a base-catalyzed entry to the 2,2-dimethylchroman system frequently occurring in Nature. One example is the insecticidally active ageratochromene (precocene) **31**[16].



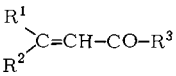
31

Presumably **29** is formed by a sequence of Michael addition (**1** to **28**) and retro-Michael cleavage (of **32**), but detailed information on the reaction is still lacking.



32

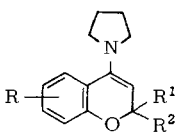
Only one of the two—in the case of **28** and **30** identical!—aldol building blocks is preserved in the final product **29**. Further experiments with unsaturated aldehydes and ketones of type **33** aimed at introduction of only the R^1—C—R^2 moiety into the chromanone met without success; either no definite secondary product could be isolated or the reaction proceeded otherwise (*e.g.* methyl vinyl ketone **25** giving **27**).



33

2.3.3. Pyrrolidinochromenes

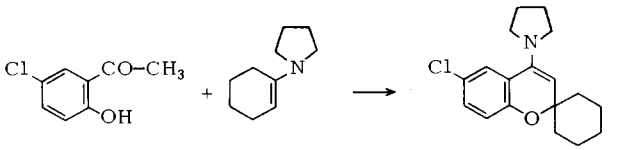
In the synthesis of the 4-chromanones according to eqs (a) and (b) a certain amount (usually less than 15%) of pyrrolidinochromenes **34** is formed as well as **3**. This side reaction is of interest, because the enamines **34** cannot be obtained from 4-chromanones **3** and pyrrolidine[17]. This



34

surprising formation of enamines **34** should therefore enable conclusions to be drawn about the course of the reaction.

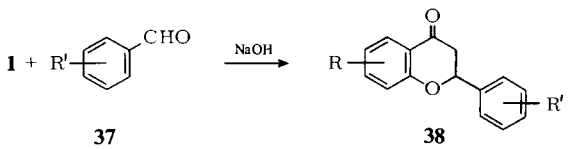
We have not investigated the formation and the amounts of the enamines **34** in detail quantitatively, since they are undesirable byproducts of the synthesis of **3** necessitating an additional hydrolysis step during work-up. In one case however—reaction of the enamine **12** with **35** in the ratio 1.1:1 in petroleum ether, 2d at 25 °C—**36** is obtained in 56% yield[18] (together with *ca.* 15% **3s**); in methanol **36** and **3s** are each formed in *ca.* 40% yield.



35 **12** **36**

2.4. Reaction Mechanism

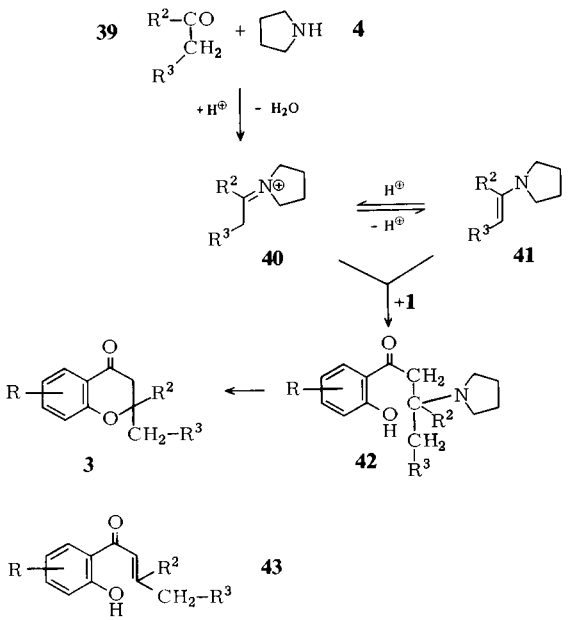
Formally, in our synthesis of chromanones from **1** and **2** only water is split off. One special case of this reaction has been known for a long time: Reaction of **1** with aromatic aldehydes **37** in the presence of caustic soda usually leads to good yields of the flavanones **38**[19]. This synthesis was



37 **38**

optimized a few years ago[20]. With the usual aliphatic aldehydes and the ketones **2**, however, these reaction conditions do not lead to the desired products; no chromanones **3** are obtained on treatment of the reaction mixture with caustic soda[3,21].

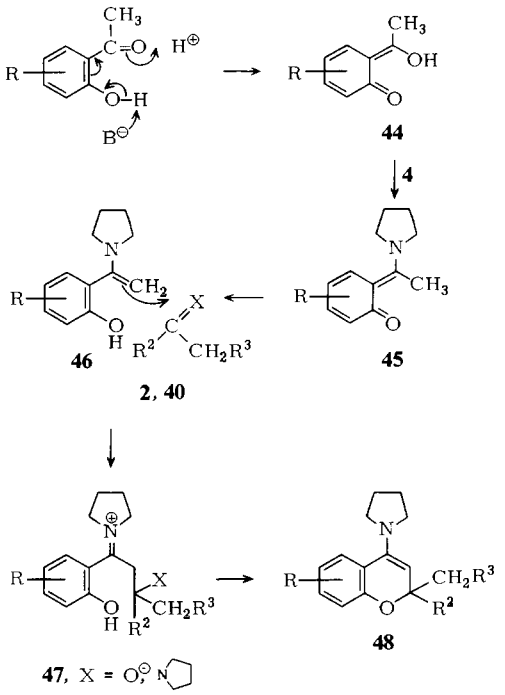
We propose the following reaction mechanism[23]: Reaction of **39** (≡ **2**, $R^1 = R^3CH_2$) with **1** leads to intermediary



Scheme 1.

formation of the addition product **42**, either *via* the enamine **41** or the alkylideneammonium ion **40** (with **1** as proton-donor). Displacement of the amine by the *o*-substituted phenolate ion—possibly after formation of the unsaturated ketone **43**—terminates the reaction to give the chromanone **3** (Scheme 1).

The ready formation of the pyrrolidinochromenes **48** (≡ **34**, $R^1 = R^3CH_2$) may be explained in terms of Scheme 2.



Scheme 2.

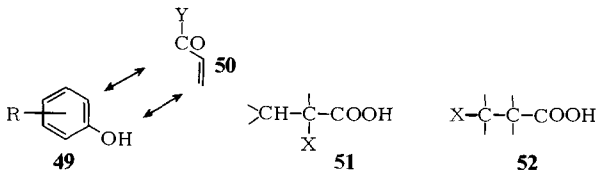
The key intermediate would then be the enamine **46** (formed from **1** and **4** *via* **44**), whose reaction with **2** and/or **40/41** would unproblematically lead *via* **47** to the end product **48**.

2.5. Other Chromanone Syntheses for Comparison

The synthesis of the chromanones according to eq. (a) extends the methods already described in the literature[24]; it enables the synthesis of a large number of hitherto difficultly accessible chromanones, and in many cases provides an advantageous preparative alternative. The following comparison with well known methods described in the literature should facilitate selection of the most suitable method of synthesis.

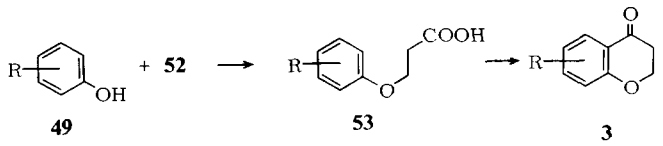
The decisive step in the majority of the chromanone syntheses described in the literature proceeds in the presence of acids (preferably polyphosphoric acid, anhydrous hydrofluoric acid[25], and methanesulfonic acid with phosphorus pentoxide[26]). In principle, a phenol **49** adds to the β-carbon atom of acrylic acids or their derivatives **50** (or their potential equivalents such as α- and β-halopropionic acids **51**, **52**), while the carboxy group acylates the arene *ortho* to the phenol group.

The most variable, and hence most frequently employed methods are: 1. The cyclization of β-phenoxypropionic acids **53**[27]; 2. The reaction of phenols with alkylated acrylic acids[28].

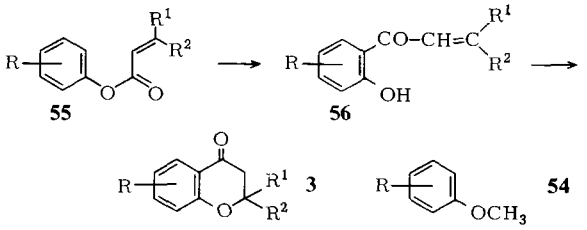


Y = OH, Halogen X = Cl, Br

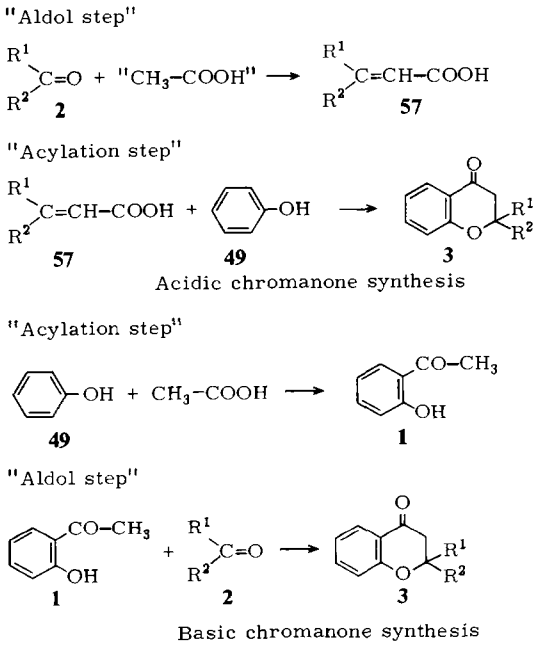
The first synthesis starts from phenols **49** and β-halopropionic acids **52**. The particular advantage lies in the possibility of obtaining C-2 unsubstituted chromanones which are not accessible *via* most of the other methods.



The second method of synthesis can be modified considerably: the phenols **49** can be replaced by their methyl ether derivatives **54**, since they are cleaved under the reaction conditions[29], and the equivalence of **50**, **51**, and **52** has already been pointed out above. Moreover, **3** can also be obtained from **55**, *via* a Fries-shift[6, 30]. The synthesis is most successful when **50**—**52** are alkyl-substituted; 2-alkyl- and 2,2-dialkylchromanones in particular, and, possibly chromanones with additional 3-alkyl groups, are readily accessible by this method. The yield is sometimes poorer because of *p*-acylation of **49**.



Both of these acid-catalyzed chromanone syntheses and the base-catalyzed chromanone synthesis according to eq.



Scheme 3. The substituents R have been omitted.

(a) are presented alongside each other for comparison in Scheme 3, in each case taking into consideration the starting material.

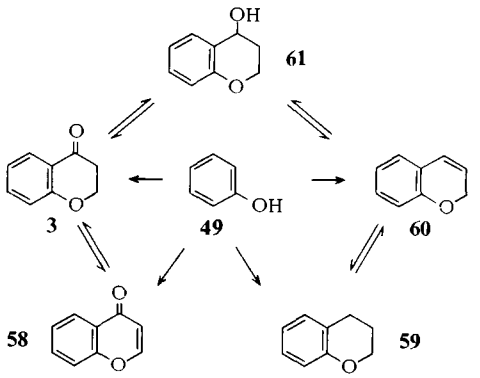
As far as this range of syntheses is comparable (in the acidic synthesis of chromanones the acrylic acids do not have to be formed only by aldol condensation!) the advantages of the base-catalyzed method are obvious: The acidic, unselective acylation step, with its restricted choice of substituents, has been placed into the synthesis of the simple and inexpensive starting materials.

3. Reactions with 4-Chromanones

3.1. Transformation into Benzopyran Derivatives with Other Oxidation States

Chroman derivatives are mainly prepared in one of two ways:

1. Conversion of a phenol **49** by annelation with a C_3- or a C_1- plus a C_2-moiety; 2. Interconversion of compounds containing a benzopyran ring system.



Scheme 4. The substituents R, R^1, and R^2 have been omitted.

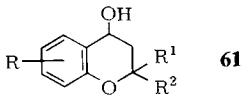
Scheme 4 presents only a few of the most important saturated and unsaturated chroman compounds with and without oxygen substitution. It shows that, *e.g.*,
the direct synthesis can be used at will in the preparation of chromones **58**, chromanones **3**, chromenes **60**, and chromans **59**, and
other benzopyrans—*e.g.* the 4-chromanols **61**—are preferably or exclusively obtained from related compounds having a benzopyran ring system.

From Scheme 4 it can also be inferred that frequently only very simple synthetic steps such as reduction, oxidation, dehydration *etc.* are required for mutual interchange between the individual classes of compounds. For this reason in chroman chemistry very often a direct synthesis with limited yields and choice of substituents is waived in favor of an overall advantageous but indirect synthesis involving several steps. In other words: Each additional entry to *one* of the benzopyran classes also indirectly increases the versatility of the others.

In this sense we have taken our chromanone synthesis according to eq. (a) as key reaction for the synthesis of some other classes of benzopyrans and have investigated the synthesis of chromanols and their direct secondary products such as chromenes, 4-halochromans, 4-aminochromans and 4-alkoxychromans in this way. Some examples are presented in the following sections.

3.1.1. 4-Chromanols **61**

4-Chromanones **3** can generally be reduced quite smoothly to the chromanols **61**. Reactions with complex hydrides ($LiAlH_4$, $NaBH_4$) are just as suitable as the catalytic hydrogenation[31]. Table 5 lists some examples. With dissimilar moieties R^1 and R^2, the compound which can be isolated in crystalline form as main product is that one in which the larger group on C-2 and the hydroxy group on C-4 are arranged equatorially.



61

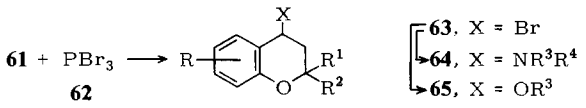
Table 5. 4-Chromanols **61** prepared by reduction of 4-chromanones **3** with $NaBH_4$.

	R	R^1	R^2	Yield [%]	M.p. [°C]
61a	H	n-C_6H_{13}	H	73	48–50
61b	H	—$(CH_2)_4$—		95	56–58
61c	H	CH_3	$(CH_2)_2$-Pyrrolidino	42	100–101
61d	6-Br	CH_3	CH_3	86	97–98
61e	6-Cl	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	88	[a]
61f	7-Cl	CH_3	CH_3	96	82–84
61g	6,8-Cl_2	—$(CH_2)_4$—		96	94–96
61h	7-C_6H_5	—$(CH_2)_4$—		69	91–93
61i	6-CH_3O	n-C_6H_{13}	H	78	66–68
61k	6-OH	n-C_9H_{19}	CH_3	75	112–115
61l	6-OH, 5,7,8-$(CH_3)_3$	3-Cyclohexenyl	H	96	198–200

[a] B.p. = 180 °C/0.2 torr.

3.1.2. 4-Bromo-, 4-Amino-, and 4-Alkoxychromans **63–65**

4-Chromanols **61** are converted with phosphorus tribromide **62** into 4-bromochromans **63**[32]. On warming, compounds **63** readily eliminate hydrogen bromide with formation of the 2*H*-chromenes **60**. The 4-aminochromans **64**[32] can be prepared by reaction of **63** with primary and secondary amines and the 4-alkoxychromans **65** by reaction with alcohols in the presence of triethylamine; the chromenes **60**, which are formed at the same time in small amounts, can easily be separated from the higher boiling end products **64** and **65** by distillation.



61 + PBr_3 → **62**

63, X = Br
64, X = NR^3R^4
65, X = OR^3

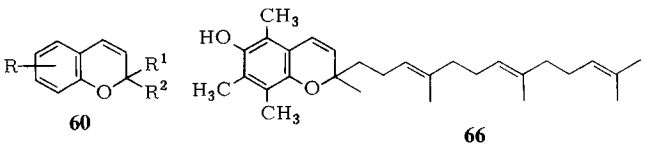
Table 6. 4-Amino- and 4-alkoxychromanes **64** and **65** (yields based on **63**; **63** obtained from **61** in *ca.* 85% yield and crude product used for further work). R^1—R^2 = —$(CH_2)_4$—, in the case of **65a**, however, R^1 = H, R^2 = $CH(CH_3)_2$.

	R	X	Yield [%]	B.p. [°C/torr]
64a	H	$N(C_3H_7)_2$	61	150/0.2
64b	H	NH—C_6H_5	55	[a]
64c	H	NH—$(CH_2)_2$—$N(C_2H_5)_2$	91	145–155/0.1
64d	6,8-Cl_2	NH—$(CH_2)_2$—OCH_3	74	160–165/0.1
64e	6-CH_3O	NH—$CH_2C_6H_5$	56	190–200/0.1
65a	H	OCH_3	79	100–105/0.1
65b	H	O—$(CH_2)_2$—OCH_3	84	140–145/0.05
65c	6-Cl	O—CH_2—C≡CH	78	135–145/0.07

[a] M.p. = 85–87 °C.

3.1.3. 2*H*-Chromenes (2*H*-Benzopyrans) **60**

4-Chromanols **61** are frequently used for the synthesis of 2*H*-chromenes **60**[16] (Table 7). The dehydration can be accomplished by treatment with acidic reagents, whereby the best conditions (*e.g.* reflux in toluene with *p*-toluenesulfonic acid or warming with hydrochloric acid in alcohols) must be ascertained in each individual case. Electron-donating moieties in the arene promote dehydration; thus, 4-hydroxytocotrienol (cf. also **6**) is already converted into 3,4-didehydrotocotrienol **66**[4] during the distillation. Attention has already been drawn to the ready formation of **60** *via* 4-bromochroman **63** (Section 3.1.2).



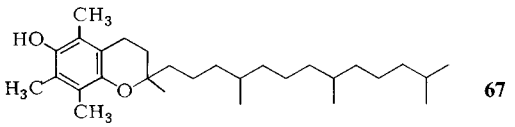
60 **66**

Table 7. Chromenes **60** prepared from 4-chromanols **61** (yields based on **61**).

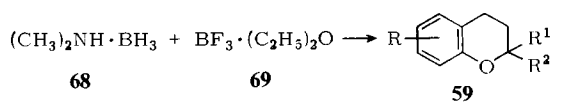
	R	R^1	R^2	Yield [%]	B.p. [°C/torr]
60a	H	—$(CH_2)_4$—		92	100/0.1
60b	H	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	84	115–117/0.1
60c	6-Cl	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	81	120–125/0.06
60d	7-CH_3O	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	70	140/0.03

3.1.4. Chromans **59**

Starting from 4-chromanones **3**, the chromans **59** can also by synthesized *via* the steps **61** and **60**. We have followed this route in the case of the synthesis of vitamin E **67**[4]. More attractive would be a direct conversion of **3** into **59**. Of the known methods, however, only the Clemmensen reaction is practicable[33], while under the strongly basic conditions of the Wolff-Kishner reduction the pyran ring is opened. In the case of chromanones which do not contain any groups that are sensitive towards borane, the reaction with B_2H_6-generating agents is recommended[34]; in the combination of the adducts **68** and **69** we have found a convenient route for directly converting **3** into **59** (see Table 8)[35].



67



3 + $(CH_3)_2NH \cdot BH_3$ (**68**) + $BF_3 \cdot (C_2H_5)_2O$ (**69**) → **59**

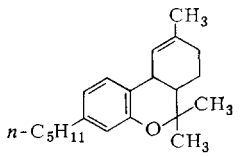
Table 8. Chromans **59** prepared by reduction of 4-chromanones **3** with **68** + **69**.

	R	R^1	R^2	Yield [%]	B.p. [°C/torr]
59a [a]	H	—$(CH_2)_4$—		82	95/0.1
59b	7-CH_3	CH_3	$(CH_2)_3$—$N(C_2H_5)_2$	90	200/0.1
59c	7-OH	CH_3	n-C_9H_{19}	65	185–190/0.1

[a] **59a** can also be obtained from dihydrocoumarin and the bis-Grignard compound prepared from 1,4-dibromobutane [51].

3.2. Higher Ring Systems

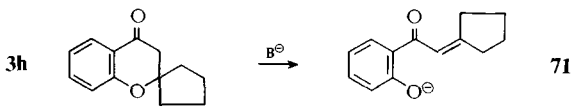
The preparative accessibility of chromane chemistry *via* chromanones **3** is also of interest for introduction of additional rings. As example we have investigated the annelation of six-membered carbocycles to C-3 and C-4 of the chroman ring system. The tricyclic systems which can thus be obtained occur, *inter alia*, in natural products such as tetrahydrocannabinol **70**.



70

Owing to the instability of the chromanones towards alkalis (example **3h**→**71**) the usual base-catalyzed reactions for such additions (Michael addition, Robinson annelation, ester condensation) occasionally proved to be of only limited use or gave unexpected products.

The sensitivity of 2-unsubstituted and 2,2-dimethylated chromans towards alkalis has been known for a long time[36,37]. However, it is only of importance when strong bases are used under severe conditions and then leads to relatively unspecific reactions. In contrast, in the case of the particular chromanones investigated by us, namely those coupled in a spiro-like fashion at C-2 or substituted with long alkyl chains, the pyran ring is particularly easily opened by the action of alkalis and, in fact, all the more rapidly and completely, the stronger the base and the more polar the solvent.



3h **71**

The free phenol **76** (m.p. 49 °C) can be obtained from **71** by careful acidification; however, it rapidly recyclizes in acids. The disadvantages of this behavior for base-catalyzed reactions are: 1) On using larger amounts of base a considerable portion of the chromanone molecules are cleaved and undergo recyclization during the usual acidic work-up; this portion has then apparently "not reacted"; 2) the base considered as catalyst is "consumed" as phenolate of type **71** and thus cannot fulfill its purpose.

3.2.1. Michael Addition and Robinson Annelation

Robinson annelation has proven particularly suitable for the addition of a six-membered carbocycle to C-3 and C-4 of the chroman ring system[38,39]. Attempts to obtain the tricyclic chroman derivative **73** in a one-pot reaction gave unsatisfactory results. Therefore, on the basis of known examples given in the literature, we attempted a stepwise procedure with isolation of the Michael adducts **72** (Table 9).

In order to circumvent the problem of not being able to achieve selective monoaddition of methyl vinyl ketone **25**, we have tried the reversible formylation of **3** before the addition[40]. Such a methodology *via* **74** and **75** is also

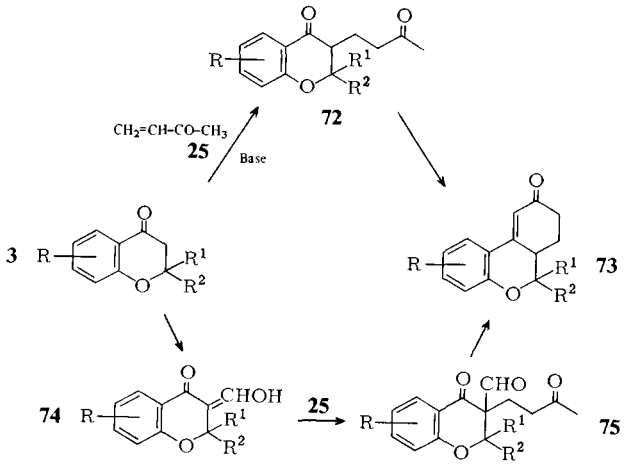


Table 9. 3-γ-Oxobutyl-4-chromanones **72** and 6a,7-dihydro-6*H*-dibenzo[*b*,*d*]pyran-9(8*H*)-ones **73**.

R	R^1	R^2	72 [a] Yield [%]	72 [a] B.p. [°C/torr]	73 [b] Yield [%]	73 [b] M.p. [°C]
H	H	C_3H_7	23	165–170/0.5	68	98–99
H	CH_3	CH_3	32	120–125/0.2	78	75–77
H	—$(CH_2)_4$—		72	158–167/0.14	84	121–123
H	—$(CH_2)_5$—		68	160–170/0.2	78	101–103
7-OCH_3	CH_3	CH_3	25	155–160/0.1	60	103–105
6-Cl	CH_3	CH_3	39	135–140/0.1	58	100–102
7-OCH_3	—$(CH_2)_4$—		52	160–165/0.2	36	105–107
6-Cl	—$(CH_2)_4$—		51	170–175/0.1	63	122–123
6-CH_3	—$(CH_2)_4$—		65	155–165/0.2	75	86–87

[a] Yields (based on **3**) determined gas-chromatographically. Two thirds or more can be obtained pure by distillation; less pure educts also suffice for the cyclization to **73**. [b] Yields based on **72**.

known from chroman chemistry[41,42], but, for the reasons outlined in Section 3.2.2, it cannot be carried out with a number of strongly alkali-labile chromanones.

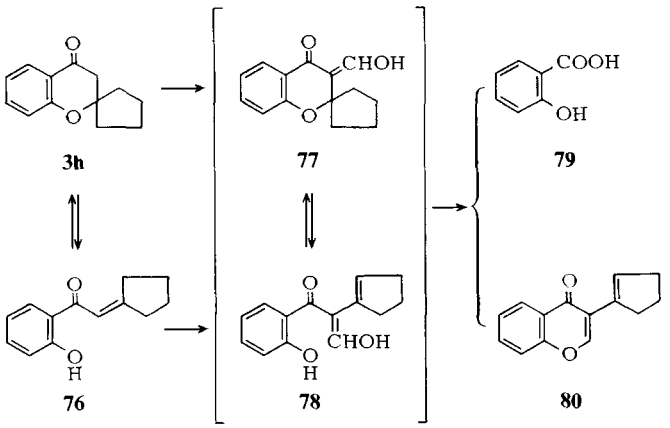
Consequently, in the cases of interest to us we were compelled to search for empirical conditions under which the chromanones **3** are preferably monoalkylated. Strong bases such as sodium hydride, sodium alkoxide, and benzyltrimethylammonium hydroxide mainly proved to be of little use; diazabicyclononene (DBN) and diazabicycloundecene (DBU), on the other hand, were found to be suitable reagents for promoting monoalkylation, particularly when used in the presence of only small amounts of solvent and a large excess (*ca.* fivefold) of **25** at room temperature[43]. In the case of chromanones having longer alkyl chains on C-2 or spirocyclically coupled groups the method leads to satisfactory yields of monosubstituted products. With chromanones containing small substituents (*e.g.* methyl groups) at C-2, 3-mono- and 3,3-disubstituted products are formed in about equal amounts.

The last step for the synthesis of the desired dibenzopyranones **73** (Table 9), the cyclization of the monoadduct **72**, can be achieved with $NaOCH_3$ in methanol (1d at room temperature, **72**: $NaOCH_3$ = 1:1.5, cf.[44]).

3.2.2. Ester Condensation

3-Formylchromanones **75** function as intermediates for the selective monoadditon of methyl vinyl ketone **25** to **3**. Some 2-unsubstituted and 2,2-dimethylated chromanones

have already been converted into tricyclic systems with formic acid esters under the usual alkaline conditions[45–48]. Attempts to extend this procedure to 2,2-substituted chromanones bearing larger substituents failed because of the increased sensitivity of these compounds to bases. Reaction of **3h** gave the result outlined in Scheme 5.



Scheme 5.

Besides up to 60% "unchanged" **3h**, approximately 20–25% of salicylic acid **79** and about the same amount of 3-cyclopenten-1-ylchromone **80a** are obtained. Both compounds could arise from **78**. The expected hydroxymethylenechromanone **77** has not been observed.

The synthesis of the chromones **80** proceeds markedly better with dimethylformamide acetal **82** as formylating agent than with formic acid esters; the novel (cyclo)alkenylchromones **80** are obtained in yields of up to *ca.* 50% on heating the reaction partners in the ratio of about 1:1.5 for several hours (Table 10).

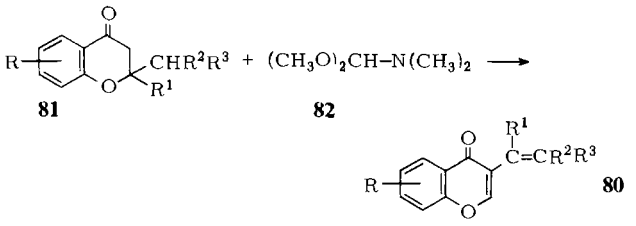


Table 10. Synthesis of 3-alkenylchromones **80** from 2,2-dialkylchromanones **81** and dimethylformamide acetal **82**.

	R	R^1	R^2	R^3	Yield [%]	M.p. [°C]
80a	H	—$(CH_2)_3$—		H	48	115–116
80b	H	H	CH_3	CH_3	47	61–62
80c	H	H	H	$C_6H_5CH_2$	28	105–107
80d	6-Cl	—$(CH_2)_3$—		H	40	156–158
80e	7-CH_3O	—$(CH_2)_3$—		H	52	139–140
80f	7-C_6H_5	H	CH_3	CH_3	53	171–173

4. Closing Remarks

The methods described here for the synthesis of chromanones (and some secondary products) can be made use of in various ways. The reaction itself, besides being of use in the synthesis of individual benzopyrans—such as well known or only recently isolated natural products (*e.g.* 6-acetyl-2,2-dimethyl-4-chromanone[49])—is, in our opinion, of paramount importance for industrial research work on active substances. Characteristically this sector of research is often oriented around naturally occurring "lead compounds"; however, for working out the optimal property-profile of the active substance, syntheses capable of greater variation are necessary. Both of these aspects—the 'natural product approach' and 'preparative flexibility'—appear to us to have been unified to a great extent in the methods presented here.

The authors are grateful to Dr. H. Heitzer, Dr. L. Oehlmann, Dr. D. Wendisch, and Dr. H. Ziemann for their valuable assistance with the investigations and research work presented here.

The Reactivity of Primary Free Radicals and Radical Ions, Mass Transfer, and Electrosorption—The Fundamental Factors for Selectivity in Electrochemical Syntheses of Organic Compounds

By Hartmut Wendt*

Dedicated to Professor Leopold Horner on the occasion of his 70th birthday

In many cases the electrolytic synthesis of organic compounds is rather unselective. This is because the primary radical ions and/or radicals are very often so reactive that they are able to react competitively with several of the different species present in the electrolyte. The aim is to increase the selectivity by rationally altering the process parameters; this demands a knowledge, *inter alia*, of electrosorption effects and of the relationships between mass transfer and chemical reaction, at or in front of the electrodes (in the so-called reaction layer). Four examples will be used to illustrate this theme:

1. The anodic synthesis of triarylsulfonium salts,
2. The addition of anodically generated N_3-radicals to olefins, producing "monomeric" 1,2-diazides and "dimeric" 1,4-diazides,
3. The cathodic synthesis of optically active 1-(2-pyridyl)ethanol,
4. The synthesis of 1,2- and 1,4-diol ethers by anodic oxidation of vinyl compounds in alcoholic solutions.

1. Introduction

The view which used to be frequently expressed that the electrolytic synthesis of organic compounds should be more selective than the "normal" *i.e.* thermally activated synthetic reactions, because the (electrical) energy[**] expended at the beginning of the reaction is very exactly defined by the working potential of the electrode, is in general untrue. The minimal electrical energy required for the primary anodic oxidation or cathodic reduction of organic substrates is usually considerably higher than the free enthalpy of the overall electrochemical reaction.

This can be explained using the cathodic hydrodimerization of acrylonitrile to adipodinitrile (Baizer's synthesis):

$$2\,CH_2{=}CHCN + H_2O \rightarrow (NC{-}CH_2{-}CH_2)_2 + 0.5\,O_2 \qquad (2\,F \text{ consumed})$$

From the cathodic half-wave potential of acrylonitrile[1] and the equilibrium potential of the oxygen electrode at pH 7[2] the minimal expenditure of electrical energy amounts to *ca.* +540 kJ/mol adipodinitrile. The free enthalpy of the overall reaction given above can be roughly calculated from the reaction enthalpy of the hydrogenation

$$2\,CH_2{=}CHCN + H_2 \rightarrow (NC{-}CH_2{-}CH_2)_2$$

(−200 kJ/mol[3,4]) and the free enthalpy of decomposition of water (+240 kJ/mol[5]), at only about +40 kJ/mol adipodinitrile, which is less than a tenth of the minimum expenditure of electrical energy.

[*] Prof. Dr. H. Wendt
Institut für Chemische Technologie der Technischen Hochschule
Petersenstrasse 20, D-6100 Darmstadt (Germany)

[**] The maximal expended electrical energy can be calculated (to a rough approximation) from the difference between the foot potentials of the current-potential curves for the respective anodic and cathodic processes:

$$\Delta E^{el}_{min} \approx (U^{foot}_{anod} - U^{foot}_{cath}) \cdot nF$$

n = The number of electrons consumed per molecule
F = Faraday's constant

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/0404-0256 $ 02.50/0

The initial electrochemical reaction steps [Eqs. (1a) to (1d)] produce undesirably reactive radical ions [Eqs. (1a) and (1b)] from neutral molecules (S) or radicals [Eqs. (1c) and (1d)] from ions ($Cat^{\oplus}$, $An^{\ominus}$):

$$S + e \rightleftharpoons S^{\odot\ominus} \quad (1a)$$

$$S - e \rightleftharpoons S^{\odot\oplus} \quad (1b)$$

$$Cat^{\oplus} + e \rightleftharpoons Cat^{\odot} \quad (1c)$$

$$An^{\ominus} - e \rightleftharpoons An^{\odot} \quad (1d)$$

Because of their high energy content and high reactivity[*] these species can react further in numerous competing parallel reactions, so that at least two and often more products are formed at the same time (Fig. 1). This happens of course irrespective of whether the radicals and/or radical ions are produced electrochemically or by conventional chemical means.

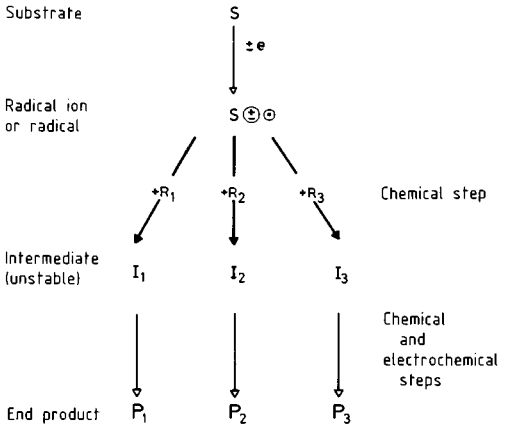

Fig. 1. Schematic representation of the reaction course from initial charge-transfer step, chemical step and further chemical steps or electron-transfer steps. The first chemical step usually determines the structure of the end-product.

Figure 2 shows seven reaction paths by which radical cations formed by anodic oxidation of vinyl compounds can react[6].

One of the aims of the synthetic chemist is to increase the selectivity of such intrinsically non-selective reactions by altering the process parameters (temperature, current density, mass transfer conditions, reactant and depolarizer concentrations *etc.*); to achieve this the rate of formation of the required product must be raised significantly above the rate of formation of the competing products.

In many closely studied examples the first chemical step [Eqs. (2a) to (2c)] which follows the primary charge transfer determines not only the structure of the end-product P_i but also the rate of its formation (r_i):

$$S^{\oplus\odot} + R_1 \xrightarrow{k_1} I_1 \rightarrow P_1 \quad (2a)$$

$$S^{\oplus\odot} + R_2 \xrightarrow{k_2} I_2 \rightarrow P_2 \quad (2b)$$

$$S^{\oplus\odot} + R_3 \xrightarrow{k_3} I_3 \rightarrow P_3 \quad (2c)$$

$$(dc_{P1}/dt)/(dc_{P2}/dt)/(dc_{P3}/dt) = r_1/r_2/r_3 \quad (3)$$

If it can be assumed that the three competing reactions are first order not only with respect to the reactants R_1, R_2, and R_3 but also with respect to the reactive primary species $S^{\oplus\odot}$ then the ratio of formation of the different products is described by Eq. (4a) (N_{P_i} = mol P_i in the product mixture):

$$dN_{P1}/dN_{P2}/dN_{P3} = k_1 c_{R1} c_S / k_2 c_{R2} c_S / k_3 c_{R3} c_S = k_1 c_{R1} / k_2 c_{R2} / k_3 c_{R3} \quad (4a)$$

If the concentrations of R_1, R_2, and R_3 do not change during the electrolysis then the same expression gives the molar ratio of the end-products of a batch electrolysis:

$$N_{Pi}/N_{Pj} = (dN_{Pi}/dt)/(dN_{Pj}/dt) \quad (4b)$$

The selectivity is defined by Eq. (4c)

$$\eta(\mathrm{i}) = \text{selectivity (i)} = N_{Pi}/\sum N_{Pj} \quad (4c)$$

Since the reactions of reactive radicals and radical ions generally exhibit low activation energies, the ratios of the rate constants $k_1/k_2/k_3$ and hence the selectivity η(i) can hardly be altered or improved significantly by changing the reaction temperature[*]. Instead, the selectivity can be influenced significantly better by changing the concentrations of R_1, R_2, and R_3. It must, however, be ensured that

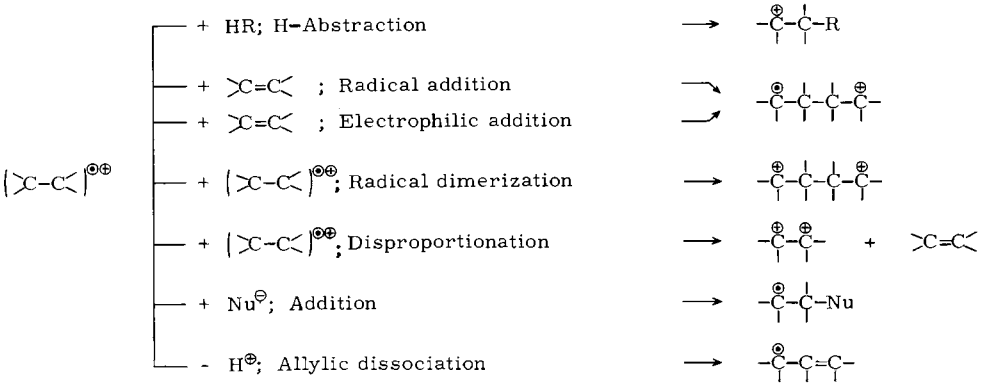

Fig. 2. Seven possible parallel reactions for radical cations, produced by anodic 1e-oxidation of vinyl-compounds. Allylic dissociations are possible only in allylic educts with a β-H atom.

[*] The cathode or anode potentials which are required to produce radical ions and/or radicals by electrochemical reduction or oxidation are an approximate measure of their reactivities [6]; the reactivity depends, additionally, on the nature of the solvent.

[*] Because of the increase in viscosity and the decrease in electrical conductivity with decreasing temperature, the working temperature cannot lie below about −50 °C.

the reactant concentrations are controlled in the "reaction zone". Due to the fast reaction of the primarily formed radicals or radical ions, this reaction zone is located in the boundary layer in front of the electrode or at the electrode surface itself. An important objective of this article is to illustrate how far the reactivity of electrolytically-produced radical ions, radicals and other short-living reactive intermediates controls the thickness of the reaction layer. This is the average distance from the electrode, reached by the reactive intermediates as a result of the competition between chemical reaction and diffusion away from the electrode surface. A knowledge of the site of reaction and details of the reaction kinetics will allow one to optimize the process *i.e.* to maximize its selectivity. If, for example, the key reaction is a surface reaction then the reaction as a whole can be controlled by manipulating the adsorption equilibria.

2. The Reactivity of the Primary Species and Control of the Reaction

2.1. The Boundary Layer Model and the Relationship between the Lifetime of the Primary Species and the Expansion of the Reaction Layer

Figure 3 illustrates the boundary layer model, while Figures 4a to 4c show schematically three cases for concentration profiles of competing reactants in the vicinity of the electrode. The basis for the calculation of such concentration profiles is the analytical or numerical solution of differential equation (5), which describes the concentration distribution of the reactant i in front of the electrode, in terms of convection (1st term), diffusion (2nd term) and reaction (3rd term), under steady-state conditions typical for a normal electrolysis. The solution of equation (5) assumes knowledge of the fluid-dynamic velocity profile in front of the electrode.

$$\frac{d(wc_i)}{dy} + D_i \frac{\partial^2 c_i}{\partial x^2} - r_i = 0 \qquad (5)$$

r_i = rate of consumption or formation of the ith species
w = linear velocity of the electrolyte (usually parallel to the electrode surface)
y = coordinate parallel to the flow vector (in most cases parallel to the electrode surface)
D_i = diffusion coefficient of the ith species

As a consequence of free or forced convection[*] owing to adhesion and viscous friction of the electrolyte in front of the electrode a fluid dynamic boundary layer of thickness δ_w develops (Fig. 3a)[**]. Due to the consumption of the depolarizer or the formation of electrolysis products, spatial concentration profiles of products or the depolarizer are built up between the electrode surface and δ_w. These profiles extend up to $0.33\delta_w$ into the solution (Figs. 3a, 3b).

If the formation of this "concentration boundary layer" is not disturbed by chemical reactions of the species under consideration, it is known as the Nernst diffusion layer of thickness δ_N. The quotient D/δ_N is the mass transfer coefficient k_m, which determines the mass transport velocity to and from the electrode.

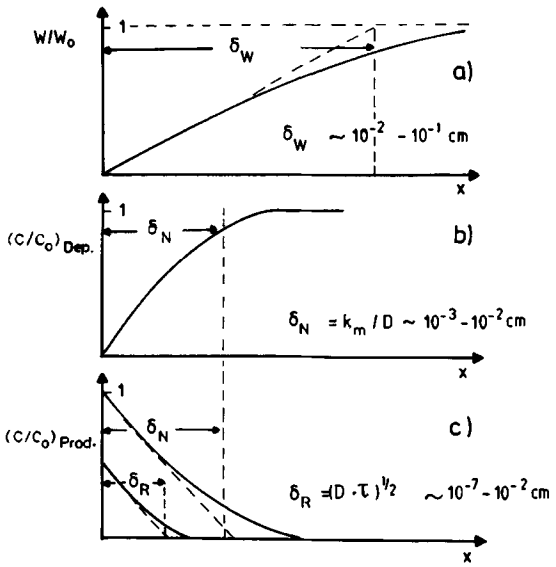

Fig. 3. Representation of the boundary layer model: a) fluid dynamic boundary layer in which a velocity profile is built up at the electrode, caused by wall-adhesion and viscosity; b) Nernst diffusion layer; c) reaction layer; with simultaneous mass transfer and chemical reaction of the primary species the concentration profile in the reaction layer is contracted from δ_N to δ_R. w = linear velocity of the electrolyte, w_0 = velocity in the bulk electrolyte, c = concentration, c_0 = arbitrary reference concentration, k_m = mass transfer coefficient, Dep. = depolarizer, D = diffusion coefficient, τ = half-life of the primary species.

If the species under consideration reacts with other species of the electrolyte during transport to the electrode (depolarizer) or, if it is produced at the electrode, and undergoes reaction on transfer from the electrode into the bulk of the solution, then the concentration profiles resulting from diffusion and convection alone will be contracted, if the reaction velocity is high enough. In particular the rapid consumption of primarily formed species by chemical reaction results in

a) a significant decrease in the spatial extension of the respective concentration profile
b) a decrease in the concentration of the respective species at the electrode (Fig. 3c)[7-9, 12].

A distinction then has to be made between the thickness δ_N of the Nernst diffusion layer—defined in terms of convective diffusion only—and the generally much thinner reaction layer thickness δ_R, which is determined by the competition between chemical reaction and diffusion. δ_R can be estimated using Eq. (6)[*] if the lifetimes τ of the diffusing and reacting molecules are known:

$$\delta_R \approx (D\tau)^{1/2} \qquad (6)$$

[*] A stirrer in the electrolyzer and/or the recirculation of the electrolyte solution causes a "forced" convection; density differences in the electrolyte in the region of the electrode or rising gas bubbles cause "free" convection.

[**] The thickness δ_w is determined by the width of the layer, within which the velocity of the electrolyte decreases continuously towards zero.

[*] If δ_R according to Eq. (6) is less than $1/3\delta_N$, then the first (convection) term in Eq. (5) can be ignored.

If the species under consideration reacts according to a first order rate law with a rate constant k, then $\tau = 1/k$; for a second order reaction $\tau = 1/k c_{max}$ where c_{max} = the maximum concentration in the concentration profile. The thickness of the reaction layer for first and second order reactions can thus be estimated [Eq. (6a) or (6b)]:

$$\delta_R(\text{R.O.1}) \approx (D/k)^{1/2} \quad (6a)$$

$$\delta_R(\text{R.O.2}) \approx (D/k c_{max})^{1/2} \quad (6b)$$

c_{max} = maximal concentration of the reactive species in the concentration profile

For a rate constant k of $10^{-1}\ s^{-1}$, δ_R is 10^{-2} cm and decreases to about 10^{-7} cm when k is increased to $10^{9}\ s^{-1}$.

For $\delta_R < 10^{-7}$ cm it is unrealistic to talk in terms of a "reaction layer thickness", since this is defined just in terms of the kinetics of homogeneous reactions[*]. As the distance from the electrode surface approaches molecular dimensions such reactions ought to be viewed in terms of heterogeneous kinetics (see Section 2.4).

2.2. The Reaction of Long-Living Primary Species in the Bulk Electrolyte

Figure 4 depicts schematically the concentration profiles of two competing reactants, X and Y, which are dissolved in the electrolyte and which are assumed to react with the species formed in the first charge-transfer step. Figure 4a depicts the situation which holds for very long-living, *i.e.* very unreactive radical ions or radicals, whose lifetimes are greater than 10^{-1} s[*]. In such cases most of the intermediates, produced at the electrode, succeed in diffusing away from the electrode into the bulk of the solution, where they react under normal conditions *i.e.* with spatially constant concentrations of the reactants. The "place" of reaction, in this case, is the bulk of the electrolyte. The course of the reaction can then only be influenced (directed) by altering the concentrations of the competing reactants in the electrolyte itself.

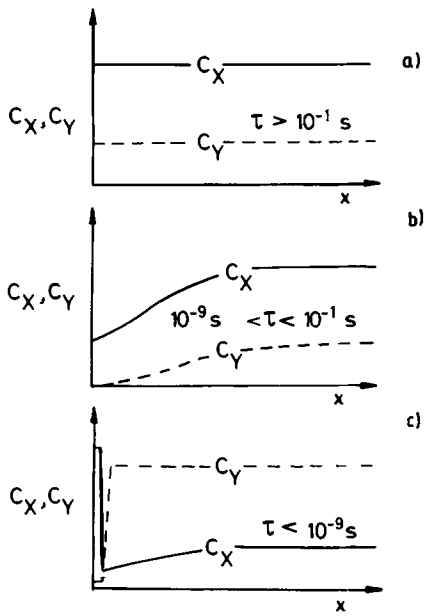

Fig. 4. The dependence of the concentration distribution of reactants X and Y in the reaction or in the diffusion layer on the lifetime τ of the primary species. a) The primary species reacts in bulk solution; the concentration ratio of the reactants X and Y are the same everywhere ($\tau > 10^{-1}$s). b) The primary species reacts homogeneously but close to the electrode surface (10^{-9}s $< \tau < 10^{-1}$s); Y is more reactive than X and the reaction layer is depleted of Y by restricted mass transport. c) Because of their short life-times ($\tau < 10^{-9}$s) or for other reasons (strong adsorption) the primary species reacts heterogeneously. Preferential adsorption can cause the relative concentrations of X and Y to be significantly different from those in the bulk solution. X is therefore favored over Y for heterogeneous reaction.

[*] This is justified, above all, because the composition of the electrolyte in the immediate neighborhood of the electrode is often different from that in the bulk of the solution. This is concerned with adsorption effects and the formation of the electrochemical double layer [10].

2.3. The Reaction of Short-Living Primary Species in the Reaction Layer

2.3.1. Mass Transfer Hindrance as a Method for Influencing the Concentrations of the Competing Reactants

If the lifetime of the primary product of charge transfer is less than 10^{-2} s then, under the usual mass-transfer conditions ($k_m = 10^{-3}$ to 10^{-2} cm/s) for electrolysis, the reaction layer will be thinner than the Nernst diffusion layer ($\delta_R < \delta_N$). Whenever the transport of any reactant, consumed in the vicinity of the electrode, is hindered, its concentration in the reaction layer can fall below that in the bulk of the solution. In an extreme case the concentration of the reactant in the reaction layer even falls to zero (Fig. 4b).

If, for example, the intermediate reacts much faster with Y than with X ($k_Y \gg k_X$) and transport of Y at the place of reaction is therefore hindered, then the reactant Y will be consumed very fast in the reaction layer and the slower reaction between the intermediate and X can successfully compete and under steady state conditions may become the predominant one[**]:

Then, in the reaction layer the following equation holds:

$$k_X \bar{c}_X \gg k_Y \bar{c}_Y \quad (7)$$

where $\bar{c}_X$ and $\bar{c}_Y$ = mean concentrations in the reaction layer

2.3.2. The Influence of the Current-Density on the Concentrations of the Reactive Species

To influence the concentration of the radicals or radical ions, respectively, by varying the current density (i[A/cm^2]) is another very important means for directing reactions. By

[*] In acetonitrile, dimethylformamide, and tetrahydrofuran, which are commonly used as solvents in electrochemical syntheses and which possess neither strongly nucleophilic nor electrophilic properties, such long lifetimes for the intermediates can always be expected if the anodic or cathodic half-wave potential of the depolarizer does not exceed +1 V (anodically) to −0.8 V (cathodically) (versus the aqueous saturated calomel electrode) [11, 42] and the "self-reaction", *i.e.* the radical recombination, for example, is especially slow. This is the case with the radical cation of bis(4-methoxyphenyl) sulfide, for example (see Section 3.1) [43].

[**] In the case of complete mass transfer hindrance of the more reactive reactant, which has a relatively low concentration in the bulk electrolyte, its reaction rate in the reaction layer depends only upon its mass transfer velocity $dN_x/dt = k_m c_x^{\infty}$ towards the electrode. *Fleischmann et al.* described a similar case in 1970 for the anodic oxidation of cyclohexane in the presence of chloride ions [13].

this method, which is typical for electrochemical processes, the rate of production of the reactive intermediate per unit area of surface can be altered almost at will[*]. Thus, it is possible to build up high steady-state concentrations of radicals or radical ions. By this means reactions of higher orders, *e.g.*, radical dimerizations or second order disproportionation reactions are favored over first (or pseudo-first) order reactions. Conversely, reactions of lower order are favored by decreasing the current-density.

In Table 1 the steady-state radical concentrations of anodically generated N_3 radicals (Eq. 8) at the anode ($x=0$) are listed for current-densities between 1 mA/cm^2 and 1 A/cm^2 [Eq. (8a)].

$$N_3^{\odot} - e \longrightarrow N_3^{\odot} \tag{8a}$$

For this calculation homogeneous kinetics and diffusion controlled dimerization of the N_3-radicals [Eq. (8b)][7] are assumed.

$$2\,N_3^{\odot} \xrightarrow{k_d} N_6 \longrightarrow 3\,N_2 \tag{8b}$$

The data in Table 1a were obtained by solution of Eq. (5), neglecting the convection term[7-9, 12].

$$D\left(\frac{\partial^2 c(N_3^{\odot})}{\partial x^2}\right) = k_d c^2(N_3^{\odot}) \tag{9a}$$

with the solution[7-9, 12]

$$c(N_3^{\odot})(x=0) = 1.14\,(i/F)^{2/3}\,(k_d D)^{-1/3} \tag{9b}$$

Table 1b lists the results of a second model calculation based on the assumption that the N_3-radicals react according to a pseudo-first order rate law, for example, by addition to an olefin, available in excess.

In this case the pseudo-first order reaction constant is obtained from Eq. (10).

$$k_{add}^{mono} = k_{add}\,c(\text{olefin})\ [s^{-1}] \tag{10}$$

The values in Table 1b were calculated by means of the differential equation

$$D\left(\frac{\partial^2 c(N_3^{\odot})}{\partial x^2}\right) = k_{add}^{mono}\,c(N_3^{\odot}) \tag{11a}$$

with the solution

$$c(N_3^{\odot})(x=0) = (i/F)\,(k_{add}^{mono} D)^{-1/2}\ [7\text{-}9] \tag{11b}$$

A value of 10^7 s^{-1} was assumed for k_{add}^{mono}[7] (cf. Table 4).

Table 1 shows that even for diffusion-controlled (and hence the fastest possible) bimolecular reaction of the reactive primary radicals and with the moderate current-density of 0.1 A/cm^2 a steady-state radical concentration of about 10^{-4} mol/L can be produced in the immediate neighborhood of the anode.

Table 1. Thickness of the reaction layer (δ_R) and the calculated concentration $c(N_3^{\odot})_0$ of anodically produced N_3-radicals at the electrode surface, where the N_3-radicals
a) undergo diffusion controlled recombination ($k_d \approx 10^{10}$ L mol^{-1} s^{-1})
b) react with styrene, (1 mol/L), according to a pseudo-first order rate law ($k_{add} = 10^7$ L mol^{-1} s^{-1})

a) Diffusion controlled recombination				
i [A/cm^2]	0.001	0.01	0.1	1
$c(N_3^{\odot})_0$ [mol/L]	1.15×10^{-5}	5.31×10^{-5}	2.47×10^{-4}	1.15×10^{-3}
δ_R [cm]	9.00×10^{-6}	4.34×10^{-6}	2.02×10^{-6}	9.30×10^{-7}
b) Addition to styrene				
$c(N_3^{\odot})_0$ [mol/L]	10^{-6}	10^{-5}	10^{-4}	10^{-3}
δ_R [cm]	1.04×10^{-6}	1.04×10^{-6}	1.04×10^{-6}	1.04×10^{-6}

From the ratio of the competing reactions [Eq. (12)]

$$\left\{\frac{r(\text{dimerization})}{r(\text{addition})}\right\}_{x=0} = \frac{k_d c(N_3^{\odot})_{x=0}^2}{k_{add} c(N_3^{\odot})_{x=0} c(\text{olefin})} \tag{12}$$

it can be shown that, at a current-density of 1 mA/cm^2, the pseudo-first order scavenger reaction is doubtlessly predominant, whereas at 1 A/cm^2 the bimolecular recombination reaction and the scavenger reaction proceed at nearly equal rates. In this case both the current density and the concentration of the olefin scavenger (which has a direct influence on the rate of addition) are very effective process variables for controlling the competition between radical addition and radical annihilation.

2.4. Heterogeneous Reactions of Short-Living Species on the Electrode Surface

If the lifetime of the reactive species is less than 10^{-9} s[*], the situation described above (homogeneous kinetics in the region in front of the electrode) is drastically altered: The reactive species no longer have sufficient time to escape from the electrode, the site of their generation. Heterogeneous kinetics can also be favored if the reactive species are strongly adsorbed at the electrode surface.

In these cases the reaction volume shrinks to the electrode/electrolyte interface. Reaction then takes place in a region where the chemical composition of the electrolyte differs, in some cases even to a high extent, from that in the bulk of the solution. In the case of strong adsorption (more precisely electrosorption[**]) of some compounds of the electrolyte the ratio of their surface concentrations (Γ_i) may differ markedly from the ratio of their bulk concentrations[14-16].

Figure 4c demonstrates schematically the effect of the preferential electrosorption of reactant X on the relative concentration of X and Y at the surface. These relative concentrations can often differ by several orders of magni-

[*] The upper limit of the current-density depends on the mass transfer velocity of the depolarizer to the electrode. The diffusion-limited current-density is given by $i_d = nFk_m c^{\infty}$. There is also a practical limit for the lowest applicable current-density, which depends upon the required minimal production rate of the electrolysis apparatus. For technical electrolyzers this limit is about 10 mA/cm^2.

[*] This holds for addition reactions of radicals to radical scavengers if the scavenger concentration amounts to 1 mol/L and a rate constant of more than 10^9 L mol^{-1} s^{-1} (that is nearly diffusion-controlled) reduces their lifetime to below this limit.

[**] The adsorption occurring at the electrode/electrolyte interface is called electrosorption because the adsorption equilibria are significantly affected by the electrode potential.

tude from those obtained in the electrolyte (see Fig. 5 and Fig. 6).

Eqs. (13a) and (13b) formally describe the consequences of this drastic alteration in the concentration ratio at the electrode/electrolyte interface for the selectivity of the heterogeneous reaction (assuming two possible parallel reactions).

$$\Gamma_X/\Gamma_Y \gg c_X^\infty/c_Y^\infty \tag{13a}$$

$$k_X^{het}\Gamma_X/k_Y^{het}\Gamma_Y \gg k_X^{hom}c_X/k_Y^{hom}c_X \tag{13b}$$

$$\text{when: } k_X^{het}/k_Y^{het} \approx k_X^{hom}/k_Y^{hom}$$

It must be mentioned that electrosorption equilibria—in general, adsorption equilibria at the electrode/electrolyte interfaces—are determined to the same extent by the nature of the electrode surface and by the chemical properties of the major components of the electrolyte (the liquid phase in general). Adsorption from liquid phases onto solid surfaces is, of course, always a displacement adsorption [Eq. (14a)]. Solvent molecules, L_{ads}, which were initially adsorbed at the solid surface must be displaced by the dissolved component X_{diss}:

$$\text{surface}\ldots L_{ads} + X_{diss} \rightleftharpoons \text{surface}\ldots X_{ads} + L_{diss} \tag{14a}$$

$$\Gamma_X = \Gamma_{max}\frac{K(X)_{ads}c(X)}{1+K(X)_{ads}c(X)} \tag{14b}$$

$$-RT\ln K(X)_{ads} = G^0(X_{ads}) + G^0(L_{diss}) - G^0(L_{ads}) - G^0(X_{diss}) \tag{14c}$$

Equations (14b) and (14c) describe the adsorption equilibrium in terms of the Langmuir isotherm and do not yet include the dependence of adsorption equilibria on electrode potential, with an arbitrarily variable potential. This dependence on potential is schematically reproduced in Figure 5 for neutral molecules S^0, anions $An^\ominus$ and cations

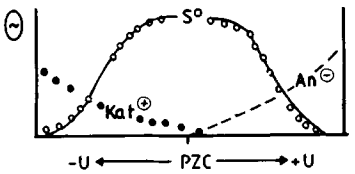

Fig. 5. Schematic presentation of the dependence of the electrosorption of cations ($Cat^\oplus$), anions ($An^\ominus$) and neutral molecules (S°) on the potential: Neutral molecules are most strongly adsorbed in the region of the potential of zero charge (PZC). If the electrode potential U differs sufficiently far from the point of zero charge (PZC ± 300 mV), then neutral molecules are desorbed. Cations are more strongly adsorbed at increasingly negative potentials, anions at increasingly positive potentials.

$Cat^\oplus$, whereby the importance of the potential of zero charge (E_{pzc}) point is to be emphasized. At this point the coulombic interaction between the dipolar solvent molecules normally used in electrolysis, and the electrode is at a minimum. For this reason the displacement of the solvent molecules by electrically neutral surface-active molecules is easiest at the potential of zero charge (E_{pzc}).

The coulombic interaction between the surface charge of the electrode and the solvent dipoles increases with increasing negative and more positive potentials that, ultimately, the adsorbed molecule can be desorbed again, *i.e.* completely displaced by the (usually relatively small) polar solvent molecules. For the same reason cations (anions) are adsorbed, above all, at potentials which are more negative (positive) than the PZC[17].

Figure 6 illustrates the dependence of the surface concentration of protonated strychnine adsorbed at the mercury/aqueous electrolyte interface on the electrode potential[18].

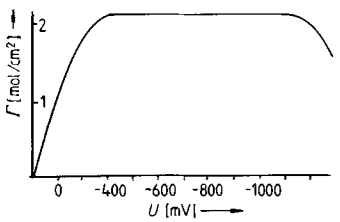

Fig. 6. Strychnine adsorption isotherm on mercury (pH 4.5, $c = 10^{-3}$ mol/L). The surface concentration Γ is plotted against the electrode potential (point of zero charge -400 mV *vs.* saturated calomel electrode (SCE)). At potentials more negative than -400 mV the mercury surface becomes saturated $\Gamma_s = 2.2 \times 10^{-10}$ mol/cm^2.

The importance of the nature of the solid surface can be demonstrated from an older example[19]: ethanol is adsorbed preferentially at polar surfaces (Al_2O_3, SiO_2) from an ethanol/benzene mixture, whereas the benzene is preferentially adsorbed at graphite. The following result makes the importance of the solvent evident: in order to saturate the mercury surface with strychnine, the strychnine concentration in 50/50 v/v aqueous ethanol must be about a hundred times higher than it need be in water alone[20].

Hence it is to be expected that the choice of a suitable electrode material and solvent/electrolyte system will enable deliberate establishment of whether the reactions, following the initial charge transfer, take place under homogeneous or heterogeneous kinetics[*].

The preferential adsorption of the primary species at the electrode surface can often lead to accelerated reaction of these species by heterogeneous catalysis[21] (cf. Section 4.1).

In the following sections the mechanistic and kinetic analysis of four electrosyntheses will be used to illustrate which of the different process variables or methods of controlling the reactant concentrations can be used, depending upon the reactivity and lifetime of the primary species, in order to improve the selectivity of a particular electrosynthesis. Table 2 summarizes the selected examples, which, with the exception of the first, refer to the physicochemical analysis of preparative investigations carried out by other authors.

The first example concerns relatively long-living radical cations, which are formed by the anodic oxidation of diaryl sulfides, and whose consecutive reactions can be very effectively influenced by altering the mass transport conditions[25].

The second case deals with the anodic oxidation of azide ions to N_3-radicals and their addition to olefins. The

[*] A good example of this is the Kolbe synthesis [23], which only takes place without side-reactions at the platinium electrode, while at the graphite anode the Hofer-Moest reaction takes place. The formation of "dimeric" 1,4-diazide compounds, during the oxidation of azide ions in the presence of olefins, at platinum anodes (but scarcely at graphite anodes), is closely related to the Kolbe synthesis [7].

Table 2. Four examples of improved selectivity in electrochemical synthesis.

Synthesis	Form of the first consecutive reaction	Means of improving the selectivity	Ref.
Anodic synthesis of triarylsulfonium ions	Homogeneous-kinetic	a) Altering the reactant concentration in the bulk of the solution b) Inhibition of mass transfer	[41-44]
Anodic additon of N_3-radicals to olefins forming monomeric 1,2- and dimeric 1,4-diazides	Homogeneous-kinetic	a) Choice of anode material (Pt) b) Increasing the olefin concentration c) Lowering the current-density	[7, 46, 47]
Cathodic reduction of 2-acetylpyridine to 1-(2-pyridyl)ethanol with asymetric induction	Heterogeneous-kinetic	a) Electrosorption of the inductor b) Choice of cathode material (Hg, Pb)	[50-55, 57, 58]
Anodic oxidation of vinyl compounds to 1,2- and 1,4-diol ethers	Heterogeneous-kinetic	a) Choice of anode material b) Control of mass-transport	[11, 27-29, 61, 62]

N_3-radicals react according to homogeneous kinetics at platinum anodes[7, 26]. At carbon anodes, however, their reaction is mainly heterogeneous.

The third example derives from the cathodic reduction of 2-acetylpyridine, which leads to pinacols by heterogeneously catalyzed dimerization at the mercury cathode; however, covering the electrode surface with suitable, optically active proton donors enables the synthesis of optically active 1-(2-pyridyl)ethanol[24, 54][*].

The last example deals with the anodic oxidation of olefins—especially of styrene. In this case the heterogeneous kinetics of the consecutive reaction of the primarily formed intermediate make it possible to use either control of mass transport or choice of the anode material to steer the reaction so that either only "monomers" or mainly "dimers" are formed (monomer and dimer refer only to the carbon skeleton)[11, 27-29][**]. In this context it should be mentioned that *Savéant*'s group[30-33] has recently studied the detailed course of the reaction and the selectivity of the overall reaction in the cathodic reduction of aryl halides in organic solvents. *Savéant*'s results, in as far as they deal with comparable cases, confirm the ideas presented here.

3. Improving the Selectivity of Consecutive Reactions having Homogeneous Kinetics

3.1. Triarylsulfonium Ions by Anodic Oxidation of Diaryl Sulfides in Non-Aqueous Solution

The anodic oxidation of diaryl sulfides in aqueous solution leads to the formation of diaryl sulfoxides[38] [Eq. (15)]:

$$R^1\text{—}S\text{—}R^2 + H_2O - 2e \rightarrow R^1\text{—}SO\text{—}R^2 + 2H^{\oplus} \quad (15)$$

R^1, R^2 = alkyl, aryl

In non-aqueous solvents of low basicity (*e.g.* in acetonitrile) and in the presence of an arene, triarylsulfonium ions are formed [Eq. (16)][*]. In this case an anodic SC-coupling reaction takes place instead of an SO-coupling[41] [Eq. (16)]:

$$R^1\text{—}S\text{—}R^2 + HR^3 - 2e \rightarrow R^1R^2R^3S^{\oplus} + H^{\oplus} \quad (16)$$

R^1, R^2, R^3 = aryl

This anodic SC-coupling is, however, non-selective, because the diaryl sulfide competes with the added arene. In the few cases investigated so far this leads to the almost exclusive formation of the unwanted self-coupling product [Eq. (17)]:

$$2R^1\text{—}S\text{—}R^2 - 2e \rightarrow R^1R^2S^{\oplus}\text{—}R\text{—}S\text{—}R^2 + H^{\oplus} \quad (17)$$

R = R^1 minus H

Magno and *Bontempelli* found only the self-coupling product when diphenyl sulfide was oxidized in the presence of benzene or ditolyl sulfide in the presence of toluene[41].

The anodic oxidation of bis(methoxyphenyl) sulfide in the presence of anisole, gives, in contrast, a very good yield of tris(methoxyphenyl)sulfonium ions[42]. The only by-product is bis(methoxyphenyl) sulfoxide, formed from the primary radical cation and the last few traces of water remaining in the solvent (anhydrous acetonitrile).

3.1.1. The Chemical Reaction of the Radical Cations of Various Diaryl Sulfides

Relatively stable radical cations of diaryl sulfides are generated in the first charge transfer step at potentials of between 1 and 1.5 V (*vs.* SCE) according to Eq. (18)[42, 43].

$$R^1\text{—}S\text{—}R^2 - e \rightleftharpoons (R^1\text{—}S\text{—}R^2)^{\odot\oplus} \quad (18)$$

The S-radical cations do not react directly with nucleophiles, such as arenes, water or unreacted diaryl sulfide.

The dication, however, which is constantly supplied by the fast disproportionation equilibrium [Eq. (19)], reacts with nucleophiles; after deprotonation the stable end-product P_i is formed [Eq. (20)][43, 44].

[*] Ketyl radicals, generated by cathodic reduction of 2- and 4-acetylpyridines, dimerize to pinacols in a heterogeneously catalyzed reaction at the mercury cathode. Their adsorption can be inhibited by competitive adsorbants, thus checking the formation of pinacols [24].

[**] The industrial interest in the anodic C—C bond formation reactions of the second and fourth examples is obvious. The first reaction allows use of triarylsulfonium salts as electrolytically regenerable arylation reagents (*e.g.* in the arylation of amines) [34—37]. The third reaction could point the way to easily performed, induced asymmetric synthesis, requiring only catalytic amounts of the inductor.

[*] For arylation using triarylsulfonium salts see [34—37]. However, triarylsulfonium salts can be easily synthesized by non-electrochemical methods (or reactions) like the Friedel-Crafts reaction between diaryl sulfides and aryl halides [39] or the reaction of diaryl sulfides and diaryliodonium salts [40].

$$2(R^1\text{—}S\text{—}R^2)^{\oplus\ominus} \rightleftharpoons (R^1\text{--}S\text{—}R^2)^{2\oplus} + R^1\text{—}S\text{—}R^2 \quad (19)$$

$$(R^1\text{—}S\text{—}R^2)^{2\oplus} + Nu_i \xrightarrow{k_i} (R^1\text{—}S(Nu_i)\text{—}R^2)^{2\oplus} \xrightarrow{-H^{\oplus}} P_i \quad (20)$$

The reaction sequence (18) to (20) is described by the following rate law [(Eq. (21)]:

$$r(P_i) = k_i K_{dis} c^2(\text{rad.-cat}) \times c(Nu_i)/c(\text{diaryl sulfide}) \quad (21)$$

K_{dis} = disproportionation constant

Table 3 summarizes the redox potentials[*] of the charge transfer equilibrium [Eq. (18)] for several diaryl sulfides, as well as the apparent rate constants $k_i^{form} = k_i K_{dis}$ [L mol^{-1} s^{-1}] for coupling reactions between primarily formed radical cations and nucleophiles (as far as they are known). There is a good correlation between the formal rate constants of the consecutive reactions and the redox potentials of the sulfides[**]. The rate is influenced by the nucleophilicity of the coupling partner, just as is expected for electrophilic substitution reactions [Eq. (20)].

Table. 3. Redox potentials E_0 (*vs.* SCE) of the redox pair diaryl sulfide/diaryl sulfide radical cation and apparent constants ($k_i^{app} = k_i K_{dis}$) for the coupling reaction of the radical cation to various partners (23 °C, 0.1 mol/L $NaClO_4$ in acetonitrile).

R in R_2S	E_0 [mV *vs.* SCE]	k_i^{app} [L mol^{-1} s^{-1}] for the reaction of $R_2S^{\oplus\ominus}$ with: H_2O	R_2S	Anisole	Mesitylene	RH
Phenyl	1483	10^7	6×10^7	—	5×10^5	10^4 (Benzene)
4-Tolyl	1380	10^6	5×10^6	—	5×10^6	3×10^4 (Toluene)
Mesityl	1340	—	[a]	—	100	100 (Mesitylene)
4-Methoxyphenyl	1080	80	[a]	240	40	240 (Anisole)

[a] No reaction; $k_i < 100$.

The composition of the product mixture [Eq. (22)] resulting from the simultaneous reaction of the primarily formed radical cation with several nucleophiles can be calculated from Eq. (21).

$$c(P_1)/c(P_2)/c(P_3) = k_1\bar{c}(Nu_1)/k_2\bar{c}(Nu_2)/k_3\bar{c}(Nu_3) \quad (22)$$

$\bar{c}(Nu_i)$ is the average concentration of nucleophile in the reaction layer (δ_R) [Eq. (23)]:

$$\bar{c}(Nu_i) = 1/\delta_R \int_{x=0}^{x=\delta_R} c(Nu_i)\,dx \quad (23)$$

3.1.2. Improving the Selectivity of the Anodic Synthesis of Triarylsulfonium Ions

The anodic synthesis of tris(4-methoxyphenyl)sulfonium ions in acetonitrile avoiding the formation of sulfoxide: the relatively stable radical cation from bis(4-methoxylphenyl) sulfide does not form the unwanted self-coupling product in acetonitrile if more than 10^{-1} mol/L anisole is present. However, even when very carefully dried acetonitrile is used as the solvent bis(4-methoxyphenyl) sulfoxide is formed, since the water content of the electrolyte cannot be reduced to less than about 0.1—0.2% w/w (*ca.* 10^{-1} mol/L). The selectivity of formation, η, of tris(4-methoxyphenyl)sulfonium ions [Eq. (24)] significantly depends upon the concentration ratio c(anisole)/$c(H_2O)$:

$$\eta = \frac{1}{1 + k(H_2O)\cdot c(H_2O)/k(\text{anisole})\cdot c(\text{anisole})} \quad (24)$$

Figure 7 indicates the experimentally determined selectivity for the formation of tris(4-methoxyphenyl)sulfonium ions under the given concentration ratios $c(H_2O)/c$(anisole) (broken line calculated from Eq. (24)). The yields obtained at low water concentrations are better than the calculated values, thus reflecting depletion of water in the diffusion and reaction layers. At current-densities of $i \geq 0.5 i_d$ the selectivity is improved by depletion of water (the more reactive nucleophile) in the diffusion and reaction layers (cf. Fig. 4b).

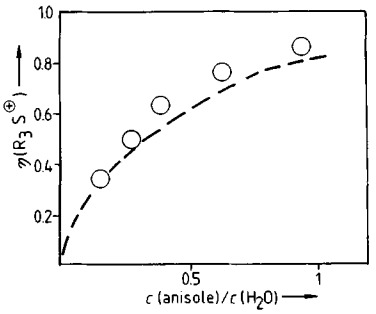

Fig. 7. Dependence of the selectivity (current yield) η for the anodic synthesis of tris(4-methoxyphenyl)sulfonium ions on the relative concentrations of anisole and water in the electrolyte (acetonitrile/$NaClO_4$). Broken line: calculated value according to Eq. (24).

Attempted preparation of tri-4-tolyl and triphenylsulfonium ions: Magno and *Bontempelli*[41] found only anodic self-coupling products in the anodic oxidation of diphenyl and di-4-tolyl sulfides. This is caused by the very different rate constants for the self-coupling and for coupling to benzene or toluene, respectively. In the system di-4-tolyl sulfide/toluene the self-coupling reaction is 100 times faster than the coupling with arene, in the system diphenyl sulfide/benzene more than 1000 times faster (Table 3).

Equation (25) represents the selectivity for the case where coupling to water as a nucleophile can be neglected:

$$\eta(R_3S^{\ominus}) = \frac{dc(R_3S^{\ominus})/dt}{dc(R_3S^{\oplus})/dt + dc(R_2S\text{—}R'SR^{\ominus})/dt} = \frac{k_1\bar{c}(RH)}{k_1\bar{c}(RH) + k_2\bar{c}(R_2S)} \quad (25)$$

$\bar{c}_i$ = mean concentration in the reaction layer
R′ = R minus H

It can be seen immediately from Eq. (25) that the reaction will be the more selective the smaller the concentration of diaryl sulfide and the higher the concentration of the arene in the reaction layer at the electrode.

[*] The redox potentials of the redox pair diaryl sulfide/diaryl sulfide radical cation can be obtained from the half-wave potential for the oxidation of diaryl sulfides, taking into account the chemical kinetics of the reaction.

[**] Higher redox potentials correspond to an increased reactivity of the radical ion; consequently increased rates of reaction are to be expected if a homologous compound has a higher redox potential.

If the current-density i of the working electrode approaches the diffusion-limited current-density i_d then the concentration of the depolarizer, *i.e.* of the diaryl sulfide, at the electrode decreases markedly compared to its concentration in bulk solution. By utilizing this effect it is possible to establish conditions in the reaction layer which are significantly more favorable for coupling with the arene (cf. Fig. 4b). To a good approximation Eq. (26) holds for the diaryl sulfide concentration in the reaction layer region[*]:

$$c_x(R_2S) \approx [1-(i/i_d)]\,c^\infty(R_2S) \qquad (26)$$

$x \leqslant \delta_R$; c^∞ = concentration in bulk solution
x = distance from the electrode

Accordingly, the dependence of the selectivity on the bulk concentration (c^∞) of the diaryl sulfide or the arene and on the current-density is given by Eqs. (25)—(27):

$$\eta(R_3S^\oplus) = \frac{a}{1+a-i/i_d} \qquad (27)$$

$$a = k_1/k_2(c^\infty(RH)/c^\infty(R_2S))$$

In Figure 8a the experimentally determined selectivities for the coupling of di-4-tolyl sulfide with toluene to form tri-4-tolylsulphonium ions are plotted as a function of i/i_d.

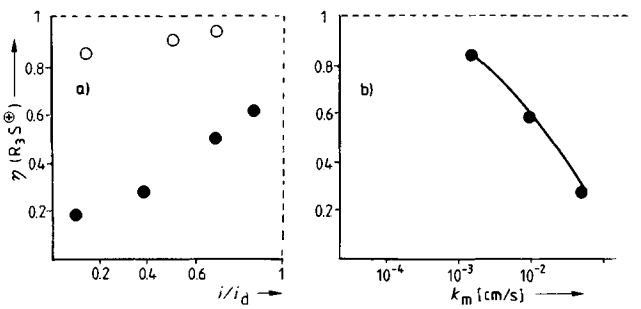

Fig. 8. Selectivity (current yield) η for the anodic synthesis of tri-4-tolylsulfonium ions. a) Dependence on the ratio of the actual current-density i and the diffusion-limited current-density i_d on using platinum (•) or graphite anodes (o). b) The dependence on mass transport coefficient k_m (at 70% i_d).

With platinum anodes, on approaching the diffusion-limited current ($i/i_d \rightarrow 1$) the yield of tri-4-tolylsulfonium, which is about 20% for very low current-densities with a toluene concentration of 1 mol/L and a di-4-tolyl sulfide concentration of 10^{-2} mol/L, can actually be raised to 60% (the full circles in Fig. 8a). Under practical electrolysis conditions it is not easy to adjust the current at the working electrode close to the diffusion-limited current. A somewhat smaller current-density is to be recommended together with a lowering of the concentration of the depolarizer, di-4-tolyl sulfide, within the reaction layer, by use of a mass transfer barrier[**]. The open circles show the results of the same electrosynthesis using carbon instead of platinum electrodes. In this case the kinetics of the reaction are no longer homogeneous but heterogeneous[*] and thus the selectivity is (fortunately) increased. It is not possible—even with carbon electrodes—to produce detectable quantities of triphenylsulfonium ions by the oxidation of diphenyl sulfide in the presence of benzene[43,44].

Fig. 8b shows the calculated and observed dependence of η on the mass transport coefficient k_m.

3.2. Addition of Anodically Produced Radicals to Olefins

3.2.1. Outline of the Reaction

It has been known for more than ten years[46] that radicals formed by the anodic oxidation of the corresponding anions add to olefins. "Dimeric" 1,4-disubstituted and "monomeric" 1,2-disubstituted hydrocarbons are formed [Eqs. (28)—(31)].

$$X^\ominus - e \rightleftharpoons X^\odot \qquad (28)$$

$$X^\odot + R^1R^2C{=}CR^3R^4 \rightarrow R^1R^2XC{-}\overset{\oplus}{C}R^3R^4 \qquad (29)$$

$$R^1R^2XC{-}\overset{\oplus}{C}R^3R^4 + X^\ominus \rightarrow R^1R^2XC{-}CXR^3R^4 \qquad (30)$$

$$2\,R^1R^2XC{-}\overset{\oplus}{C}R^3R^4 \rightarrow (R^1R^2XC{-}CR^3R^4)_2 \qquad (31)$$

Schäfer et al. have exhaustively studied the general applicability of such syntheses[47].

The structures and types of the electrolysis products are determined by the choice of the anode material. At platinum anodes good yields of the dimeric products are achieved [Eq. (31)], while significantly more monomeric disubstituted hydrocarbons are produced at carbon and graphite anodes [Eq. (30)]. The monomeric products formed at carbon anodes often contain different substituents X and Y, where Y is a nucleophilic group which often originates from the solvent molecule[**].

3.2.2. Anodic Addition of N_3-radicals to Olefins

The electrode kinetics of the oxidation of azide ions in non-aqueous solutions at various anodes: The electrode kinetics of the anodic oxidation of azide anions has been investigated at graphite, vitreous carbon, and platinum electrodes, both in the absence and in the presence of various olefins. This reaction provides a very suitable model for the reaction type described by Eqs. (28)—(31).

The technique used made it possible to investigate the kinetics of the chemical reactions of the primarily formed species and to clarify one of the main reasons for the electrolysis at graphite and at platinum electrodes proceeding so differently[7,26]. The study is based on the analysis of steady-state current-voltage curves, which were quantitatively evaluated in terms of the homogeneous kinetic model outlined in Section 2.3. Table 4 contains formal rate constants obtained for the dimerization of N_3-radicals and for the addition of these radicals to various olefins at the three electrode materials mentioned above.

[*] This approximation assumes that the thickness of the reaction layer δ_R is less than 10% of the thickness of the diffusion layer δ_N.

[**] Covering the electrode with either thin felt or cloth can provide a mass transfer barrier and the effective thickness of the diffusion layer is determined by its thickness, so that the diffusion-limited current-density and the space-time yield of the apparatus decrease as the reciprocal of the thickness of the material. In such cases special electrolytic cells, *e.g.* Swiss-roll cells [45], must be used.

[*] It can be shown by analysis of the current-voltage curves that the steady-state radical concentration at carbon anodes is reduced [44], so at the graphite surface the reaction of diaryl sulfide dications is presumably heterogeneously catalyzed.

[**] For electrolyses in alcohols ROH or in acetonitrile, Y = OR or (after hydrolysis) Y = NH—CO—CH_3.

Table 4. Apparent [a] rate constants k_{add} (calculated from the homogeneous-kinetic model) for the addition of anodically produced N_3-radicals to olefins using platinum, vitreous carbon, and graphite anodes (Sigri P 127) [7].

$N_3^{\odot}$ + reactant	k_{add} [L mol^{-1} s^{-1}] Platinum	Methyl radicals [b]	Vitreous carbon	Graphite
$N_3^{\odot}$ [c]	10^{10}	—	5×10^{11}	2×10^{13}
1-Octene	2×10^{5}	(2×10^{3})	3×10^{5}	1.1×10^{9}
cis-Stilbene	1×10^{6}	(4×10^{3})	7.5×10^{6}	8.4×10^{9}
trans-Stilbene	4×10^{7}	(1×10^{4})	4.8×10^{8}	2.1×10^{11}
Styrene	2×10^{7}	(1×10^{5})	1.5×10^{8}	7×10^{10}
1,1-Diphenylethylene	6×10^{7}	(2×10^{5})	6×10^{8}	2×10^{11}
1,4-Diphenylbutadiene	4×10^{8}	—	1.5×10^{10}	6.4×10^{12}

[a] Such values, when calculated from electrode-kinetic data, can be larger than would be expected for diffusion controlled processes ($\approx 10^{10}$ L mol^{-1} s^{-1}), if the reaction is heterogeneously catalyzed. [b] Comparison values for the homogeneously catalyzed reaction of methyl radicals [49a]. [c] Dimerization.

The apparent rate constant k_{add} of the reaction clearly depends on the electrode material. The $N_3^{\odot}$-dimerization, as well as the addition of $N_3^{\odot}$-radicals to olefins, is fastest at graphite, less fast at vitreous carbon, and slowest at platinum anodes.

In several cases at vitreous carbon and especially at graphite anodes the rate constants calculated from the experimentally measured N_3-radical concentrations at the anode are virtually higher than those expected for a diffusion-controlled reaction (10^{10} L mol^{-1} s^{-1}). These observations can only be explained by assuming that the reactions at vitreous carbon and, even more, at the graphite anodes, are heterogeneously catalyzed, while at the platinum anode they mainly follow homogeneous kinetics (*i.e.* in the solution). This is the reason why the apparent rate constants, calculated using a homogeneous kinetic model, are higher than for diffusion-controlled reactions.

For comparison with the rate constants for homogeneous kinetic addition determined at platinum anodes, Table 4 also shows the rate constants for the addition of methyl radicals to olefins[49a]. As a result of the higher reactivity of $N_3^{\odot}$ k_{add} for $N_3^{\odot}$ is, of course, two or three orders of magnitude greater than for $CH_3^{\odot}$, the rate constants, however, are similarly graduated according to the type of the olefin. $N_3^{\odot}$ seems to be more electrophilic than $CH_3^{\odot}$, as shown by the distinctly higher values of the rate constant obtained for addition to phenyl-substituted vinyl compounds.

The different reaction mechanism of N_3-radicals at platinum and graphite electrodes, *i.e.* homogeneous *vs.* heterogeneous kinetics, also explains the different results obtained in preparative electrochemical syntheses at these electrodes[26].

At the platinum electrode the oxidation of azide ions in the presence of styrene can give good yields of 1,4-diazido-2,3-diphenylethane together with only a small amount of 1,2-diazido-1-phenylethane (cf. Fig. 9a):

$$2\,N_3^{\odot} - 2e + 2\,C_6H_5CH{=}CH_2 \rightarrow (N_3CH_2{-}C(C_6H_5)H)_2 \qquad (32a)$$

At the carbon electrode, however, the fraction of this dimeric product is much lower and the monomeric 1,2-diazido-1-phenylethane is the major product.

$$2\,N_3^{\odot} - 2e + C_6H_5CH{=}CH_2 \rightarrow C_6H_5CHN_3{-}CH_2N_3 \qquad (32b)$$

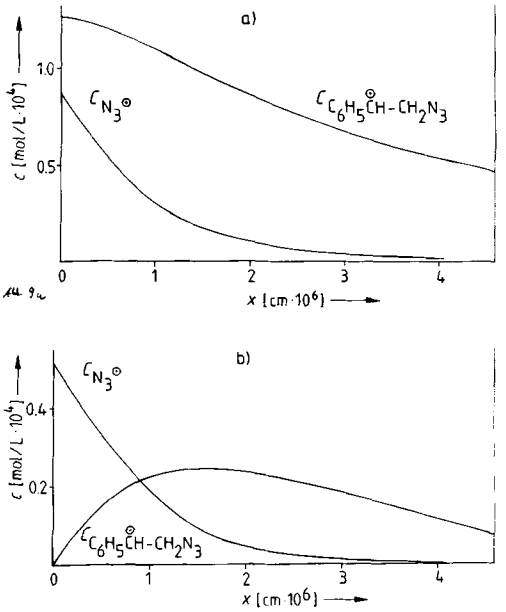

Fig. 9. Calculated concentration profiles for N_3-radicals and secondary *C*-radicals for the anodic oxidation of azide ions in the presence of styrene. The calculation was based on the electro-kinetically measured rate constant for the addition of N_3-radicals to styrene ($k_{add} = 10^7$ L mol^{-1} s^{-1}). The relative current yields η_{rel} given below were calculated from the profiles, and agree satisfactorily with the results obtained experimentally for Fig. 9a (Pt) and to a less extent for Fig. 9b (*C*). $i = 100$ mA/cm^2, $k_{add} \cdot c(\text{styrene}) = 10^7$ s^{-1}. a) Oxidation at the platinum anode, b) oxidation at the carbon anode. In contrast to case (a) it is assumed that the oxidation of the *C*-radical to carbonium ion is not hindered at the carbon electrode.

η [%]	Pt-Anode Calc.	Pt-Anode Obs.	C-Anode Calc.	C-Anode Obs.
Dimer	75.5	70	5.7	10
Monomer	17.4	20	91.6	40
N_2	7.1	10	2.7	50

The reason would appear to be that at platinum anodes a further oxidation of the *C*-radicals formed [Eq. (29)] is inhibited[49b].

$$R^1R^2XC{-}\overset{\odot}{C}R^3R^4 - e \rightarrow R^1R^2XC{-}\overset{\oplus}{C}R^3R^4 \qquad (32c)$$

This results in the preferred dimerization reaction of the *C*-radical [Eq. (31)] produced according to Eq. (29), together with the competitive reaction of the *C*-radical with N_3-radicals to form the monomer [Eq. (30)].

Figure 9a delineates the calculated concentration profiles of N_3- and *C*-radicals at the platinum electrode. The calculations are based on the rate constants of the addition reactions, obtained from the electrode kinetic measurement. The yields, which correspond to the calculated profiles, are in good agreement with those obtained preparatively.

At the carbon anode the addition [Eq. (29)] takes place, to a large extent, according to heterogeneous kinetics and, moreover, further oxidation of the homogeneously produced *C*-radicals to carbonium ions seems to be only slightly inhibited. Figure 9b shows the concentration profiles expected under these conditions for N_3- and *C*-radicals, together with the calculated current yields. Although the agreement between experimental yields and those calculated from kinetic data is worse than in Figure 9a, Figure 9b illustrates the important point: a remarkable in-

crease in the yield of monomer compared to the dimer[*]. When a carbon electrode is used the end-products of anodic addition of N_3-radicals to olefins are mainly monomers. They very likely result from the reaction of the carbocations, produced according to Eq. (32c), with nucleophiles (azide ions, basic solvent, anions of the conducting electrolyte and, in rate instances, unreacted olefin). Three of the possible terminal reactions for the addition of N_3 radicals to styrene at the carbon electrode[26] are presented in Eqs. (33)–(35).

$$C_6H_5\overset{\oplus}{C}H—CH_2N_3 + N_3^{\ominus} \rightarrow C_6H_5CHN_3—CH_2N_3 \quad (33)$$

$$C_6H_5\overset{\oplus}{C}H—CH_2N_3 + Nu^{\ominus} \rightarrow C_6H_5CHNu—CH_2N_3 \quad (34)$$

$$C_6H_5\overset{\oplus}{C}H—CH_2N_3 + CH_3—CN \rightarrow C_6H_5—CH(\overset{\oplus}{N}C—CH_3)—CH_2N_3$$
$$\xrightarrow{\text{solvolysis}} C_6H_5—CH(NH—CO—CH_3)—CH_2N_3 \quad (35)$$

Optimization of the anodic addition of N_3-radicals to styrene, using the platinum electrode: In this case two problems need to be solved:

1) How can the unwanted destruction of the anodically produced N_3-radicals by dimerization [Eq. (8b)] be avoided?
2) How can the highest yield of dimer [Eq. (32a)] be achieved?

Radical dimerization is a second order reaction with respect to N_3-radicals. On the other hand, the addition reaction according to Eq. (29) is first order with respect to N_3-radicals. The annihilation of N_3-radicals can, therefore, be checked by reducing the current-density, and increasing the olefin concentration, if Eq. (36) applies:

$$k_{add}c(\text{styrene}) > k_{dim}c(N_3^{\odot})_{x=0} \quad (36)$$

In order to optimize the yield of dimer it must be taken into account that reactions (30) [≙(38)] and (31) [≙(37)] compete with each other in the reaction layer and that both reactions have diffusion-controlled rates ($k_d \approx 10^{10}$ L mol^{-1} s^{-1}):

$$2\,C_6H_5\overset{\odot}{C}H—CH_2N_3 \xrightarrow{k_d} (N_3CH_2—C(C_6H_5)H)_2 \quad (37)$$

$$C_6H_5\overset{\odot}{C}H—CH_2N_3 + N_3^{\odot} \xrightarrow{k_d} C_6H_5CHN_3—CH_2N_3 \quad (38)$$

The yield of dimer can be increased by raising the olefin concentration, which accelerates the addition [Eq. (29)] and reduces the steady-state concentration of N_3-radicals in the reaction layer, as well as by reducing the anodic current-density i, which has the same effect. Eq. (39) reproduces this correlation formally:

$$\frac{\bar{r}(\text{dimer formation})}{\bar{r}(\text{monomer formation})} \sim (c(\text{olefin})/i)^{1/2} \quad (39)$$

$\bar{r}$ = the reaction velocity averaged over the reaction layer

Eq. (39) holds only approximately and only for the range $0.3 < (1-\eta(N_2)) < 0.7$. Figure 10 shows the dependence of the yields for monomer, dimer, and unwanted nitrogen production on the current-density and on the styrene concentration; Eq. (39) is thus semi-quantitatively verified.

[*] The heterogeneously catalyzed acceleration of the dimerization of $N_3^{\odot}$ at the carbon anode [cf. Eq. (8b)] is not included in the homogeneous kinetic model, used in calculating the data for Figure 9b.

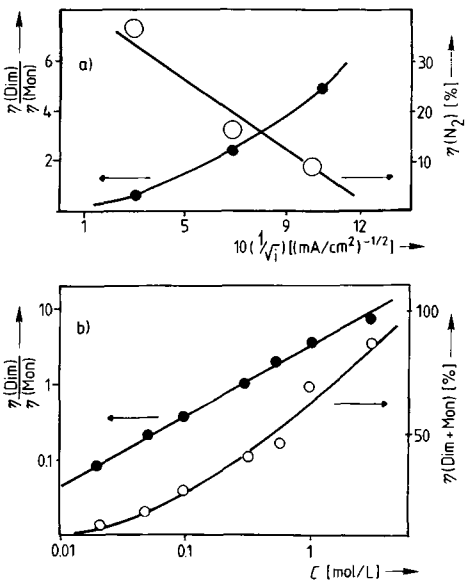

Fig. 10. Competing reactions during the anodic addition of N_3-radicals to styrene. a) Dependence of the ratio of dimer to monomer yield and the yield of N_2 (produced by the annihilation of $N_3^{\odot}$ by dimerization) upon the current-density i. Raising the current-density favors annihilation (c(styrene) = 1 mol/L). b) Dependence of the ratio of the dimer to monomer yield and the total yield on the styrene concentration c. Both the yield ratio and the total yield are improved by raising the styrene concentration (i = 46 mA/cm^2).

4. Improving the Selectivity of Consecutive Reactions having Heterogeneous Kinetics

4.1. The Cathodic Reduction of 2-Acetylpyridine

4.1.1. Asymmetrical Induction by Adsorbed, Optically-Active Species

The work of *Horner et al.*[50,51], *Grimshaw et al.*[52], *Jubault et al.*[53] and *Kariv et al.*[54] has demonstrated that the production of one of the two possible optical isomers can be favored in the cathodic reduction of carbonyl to hydroxyl compounds in the presence of surface-active, optically-active organic compounds. Asymmetrical induction has also been achieved by anodic processes in the presence of surface-active inductors[55]. The best optical yields were obtained by *Kariv et al.* for the reduction of 2-acetylpyridine to 1-(2-pyridyl)ethanol in the presence of protonated strychine at the mercury electrode. The optical yield was up to 50% (75% (+)isomer, 25% (−)isomer).

4.1.2. Polarographic Investigation and Preparative Course of Acetylpyridine Reduction in the Presence and Absence of Strychnine

The polarogram of 2-acetylpyridine in aqueous or aqueous/alcoholic solution at pH values between 0 and 3.5 exhibits two separate one-electron waves (Fig. 11a). The first wave has reversible characteristics and its half-wave potential is pH-dependent. The wave is steeper than would be expected for a "normal" one-electron wave[*].

[*] A normal reversible one-electron wave, as observed in the polarography of, *e.g.*, cobaltocenium ions, has a slope of (60 mV)$^{-1}$ per decade when $\lg[(i_d - i)/i]$ is plotted against U_i; its half-wave potential is pH-independent [56].

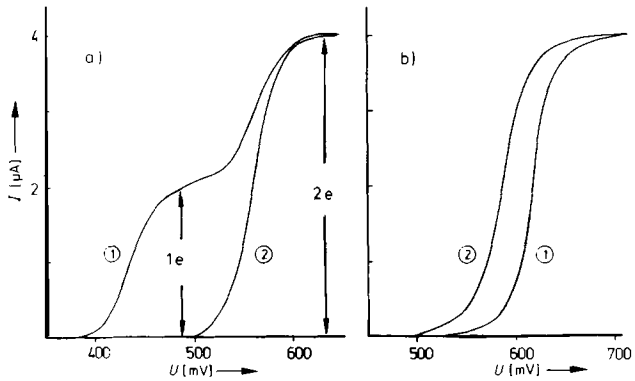

Fig. 11. Polarograms of the cathodic reduction of 2-acetylpyridine. a) pH 2. Curve 1: two separate one-electron waves, aqueous electrolyte without addition of a surface-active agent; Curve 2: one two-electron wave in the presence of 10^{-4} mol/L tetrabutylammonium ion. b) pH 4.4. Curve 1: one two-electron wave in the presence of 10^{-4} mol/L tetrabutylammonium ion; Curve 2: The half-wave potential is displaced to a more positive potential (U *vs.* SCE) when the tetrabutylammonium ion is replaced by the equally strongly adsorbed but strongly protonated strychnine.

A first order reaction with respect to proton concentration is indicated by the pH-dependence and, from the slope of the wave it can be deduced[57] that the ketyl, primarily produced at the cathode [Eq. (40)], is consumed in a heterogeneous second order reaction. It could be assumed that a pinacol is formed under these conditions by dimerization according to Eq. (41).

$$\text{Pyr—CO—CH}_3 + e + H^{\oplus} \rightleftharpoons \text{Pyr—}\overset{\odot}{\text{C}}\text{OH—CH}_3 \quad (40)$$

$$2\,\text{Pyr—}\overset{\odot}{\text{C}}\text{OH—CH}_3 \rightarrow (\text{Pyr—C(OH)(CH}_3))_2 \quad (41)$$

Pyr = 2-Pyridyl

On addition of surface-active but chemically inert substances such as tetrabutylammonium ions, which are strongly adsorbed at the mercury surface, only one reversible two-electron wave is observed instead of two one-electron waves (Fig. 11a). The pH-dependence of its half-wave potential indicates a reaction order of two concerning participation of protons.

On the basis of the electrode-kinetic data the two-electron wave can be assigned to the formation of 1-(2-pyridyl)ethanol, which proceeds according to Eqs. (42) and (43) *via* a preliminary, fast electrochemical/protolytic equilibrium (with the transfer of two electrons) followed by protonization [Eq. (44)] of the intermediate carbanion:

$$\text{Pyr—CO—CH}_3 + e + H^{\oplus} \rightleftharpoons \text{Pyr—}\overset{\odot}{\text{C}}\text{OH—CH}_3 \quad (42)$$

$$\text{Pyr—}\overset{\odot}{\text{C}}\text{OH—CH}_3 + e \rightleftharpoons \text{Pyr—}\overset{\ominus}{\text{C}}\text{OH—CH}_3 \quad (43)$$

$$\text{Pyr—}\overset{\ominus}{\text{C}}\text{OH—CH}_3 + HA \rightarrow \text{Pyr—CHOH—CH}_3 \quad (44)$$

The formation of dimers [Eqs. (40) and (41)] only takes place at the free, unoccupied mercury surface, *i.e.* reaction (41) is a surface reaction in which adsorbed ketyls react with each other. Thus, the dimerization is heterogeneously catalyzed.

If the adsorption of the ketyls is prohibited by competitive adsorption at the mercury surface, then the homogeneous kinetic dimerization[*] is significantly slower than the subsequent reduction [Eq. (43)] and the final homogeneous kinetic protonization [Eq. (44)] to an alcohol. If the inert surface-active tetrabutylammonium ion is replaced by a surface-active, *i.e.* strongly adsorbed, proton donor, *e.g.* protonated strychnine, then this reaction can be greatly accelerated by heterogeneous catalysis. Figure 11b illustrates this effect in the displacement of the half-wave potential of the two-electron reduction of 2-acetylpyridine to more positive potentials (cf. Fig. 6 for the adsorption of strychnine). The displacement corresponds to a 20-fold reduction in the concentration of the reduced partner, as a result of accelerated protonation, in the cathodically produced redox system, that determines the potential. The simplest explanation for this effect is that the homogeneous reaction-steps (42), (43), and (45) become heterogeneous due to participation of adsorbed strychnine, whose local concentration—due to adsorption—is significantly increased.

$$\text{Pyr—}\overset{\odot}{\text{C}}\text{OH—CH}_3 + {}^{\oplus}\text{H—Strych}_{ads} \rightarrow \text{Pyr—}\overset{\star}{\text{C}}\text{HOH—CH}_3 + \text{Strych}_{ads} \quad (45)$$

Figure 6 shows the adsorption isotherm for strychnine at pH 4.5. If the strychnine concentration is 10^{-3} mol/L then the electrode surface is completely covered with strychnine over a wide range of potentials, *i.e.* the condition is fulfilled for the maximum rate of reaction (45).

The adsorbed strychnine does not only act as proton donor for the preestablished equilibrium (42) and the very fast, final reaction (45) but, at the same time, provides the chiral matrix, which leads to the asymmetrical induction. All the conclusions drawn from the electrode-kinetic evidence have been confirmed in preparative electrolysis[57].

The problem of increasing the selectivity of the heterogeneous kinetically-controlled, asymmetrical synthesis has many facets:

Firstly, an inductor must be found that has not only a structure[*] but also an acidity that is optimal for asymmetrical induction.

Furthermore, the pH of the electrolyte must, on the one hand, be high enough to ensure that the protonation, which proceeds homogeneously [Eqs. (42), (43), and (44)], is slower than that proceeding heterogeneously [Eqs. (42), (43), and (45)]. On the other hand, the pH of the electrolyte must always be low enough that the inductor is at least 90% protonated, both in solution and as adsorbant. Finally, a buffer must be present so that the protons, necessary for the reaction sequence (42), (43), (45), can be delivered at the electrode. This last condition means that, in case the current density is close to the diffusion-limited value, the molar concentration of the buffer acid must be as high or higher than that of the depolarizer.

All of these conditions were optimized in *Kariv*'s investigation. Strychnine was used as inductor, whose conjugate acid has a pK_a of 7.5, together with an acetate-acetic acid buffer (pH about 4.5) at a concentration of about 0.5 mol/L. *Köster*[57] has shown that the optical yield decreases drastically, on lowering the pH, since the homogeneous-ki-

[*] This experimental finding is also confirmed by calculation of the homogeneous kinetic reaction rate.

[*] With the inductors chosen by *Horner*, which are closely related to ephidrine, the optimal yield is, almost without exception, much lower than with strychnine.

netic protonation, which only yields racemic product, becomes faster with decreasing pH.

It is to be expected that the nature of the cathode material will be decisive for the success of such induced, heterogeneous-kinetic, optically-inductive syntheses. Table 5 gives examples. Whereas mercury and lead cathodes can produce similar, very high, optical yields, the optical yield

Table 5. The dependence of the optical yield (enantiomeric excess e.e.) in the asymmetrically induced synthesis of 1-(2-pyridyl)ethanol with strychnine as inductor on the cathode material. Electrolyte: H_2O/ethanol, 50% vv., 10^{-1}/L HAc + 10^{-1} mol/L NaAc; 10^{-3} mol/L strychnine, 0.5 mol/L 2-acetyl-pyridine, current-density $i = 50$ mA/cm^2.

Electrode material	e.e. [%]	Electrode material	e.e. [%]
Hg	45	Cd	<1
Pb	40	Zn	<1
Bi	10	C	<1
Sb	3		

falls to about 10% at a bismuth cathode, to about 3% at an antimony cathode, and at cadmium, zinc and carbon it is infinitesimally small. It should be mentioned that the optical yield can be correlated with the position of the respective electrosorption equilibria of strychnine. In other respects the order of optical yield corresponds to the order of increasing hydrophobicity from C to Hg presented by *Trasatti*[24, 58–60].

4.2. Anodic Oxidation of Olefins in Non-Aqueous Solutions

4.2.1. The Composition of the Product Mixture on Anodic Oxidation of Styrene in Methanol

Schäfer et al. found that mainly monomers, *i.e.* methyl ethers of 1,2-diols, and dimers, *i.e.* methyl ethers of 1,4-diols, were formed by the anodic oxidation of vinyl compounds in methanol [Eqs. (46) and (47)][61, 62]:

$$C_6H_5CH{=}CH_2 + 2\,HOMe - 2e \rightarrow C_6H_5CH(OMe){-}CH_2OMe + 2H^{\oplus} \quad (46)$$

$$2\,C_6H_5CH{=}CH_2 + 2\,HOMe - 2e \rightarrow (C_6H_5CH(OMe){-}CH_2)_2 + 2H^{\oplus} \quad (47)$$

By investigating the electrode kinetics[*] *Wendt et al.*[27] were able to show that the adsorption of the vinyl compound precedes the charge-transfer step. Thus, an adsorbed radical cation is produced as a reactive intermediate by electron transfer:

$$(C_6H_5CH{=}CH_2)_{solv} \rightleftharpoons (C_6H_5CH{=}CH_2)_{ads} \quad (48a)$$

$$(C_6H_5CH{=}CH_2)_{ads} - e \rightarrow (C_6H_5CH{-}CH_2)^{\oplus\odot}_{ads} \quad (48b)$$

Investigation of the dependence of the product yields on the various parameters showed that solvolysis of the primary radical cation [Eq. (49)] competes with its electrophilic addition to intact olefin [Eq. (50)]; these reactions lead, on the one hand, to the formation of monomeric, methylated 1,2-diol and, on the other, to dimeric, methylated 1,4-diol.

$$(C_6H_5CH{-}CH_2)^{\odot\oplus}_{ads} + (HOMe)_{ads} \xrightarrow[-H^{\oplus}]{k^{het}_{solv}} C_6H_6\overset{\odot}{C}H{-}CH_2OMe \rightarrow \text{monomer} \quad (49)$$

$$(C_6H_5CH{-}CH_2)^{\odot\oplus}_{ads} + (C_6H_5CH{=}CH_2)_{ads} \xrightarrow{k^{het}_{solv}} C_6H_5\overset{\odot}{C}H{-}CH_2{-}CH_2{-}\overset{\oplus}{C}HC_6H_5 \rightarrow \text{dimer} \quad (50)$$

4.2.2. Controlling the Selectivity of the Anodic Oxidation of Styrene

Reactions (49) and (50) occur as surface reactions at the electrode, for vinyl compounds, that are difficult to oxidize (*e.g.* styrene, vinyl ether and butadiene); the rate and selectivity of their reaction depends upon the surface concentration ratios, Γ, of the reactants, under the specific reaction conditions (concentration in the bulk solution, current-density and mass transfer velocity, electrode, electrolyte) [Eqs. (51a)–(51c)]:

$$dN(\text{mono})/dt = k^{het}_{solv}\,\Gamma_{rad\text{-}cat}\Gamma_{HOMe} \quad (51a)$$

$$dN(\text{dim})/dt = k^{het}_{add}\,\Gamma_{rad\text{-}cat}\Gamma_{olef} \quad (51b)$$

$$\eta(\text{dim}) = 1/[1 + k^{het}_{solv}\,\Gamma_{HOMe}/k^{hed}_{add}\Gamma_{olef}] \quad (51c)$$

It is noteworthy that the surface concentration of olefin dissolved in methanol (maximally 1 mol/L) is determined by the adsorption equilibrium constant K^{ads}_{olef}, which depends on the working potential, as well as the concentration of olefin at the electrode surface, which, in turn, depends on the concentration of the olefin in the bulk of the electrolyte, the mass transfer conditions, and the current-density $\Gamma_{olef} = c^{\infty}_{olef}(1 - i/i_d)K_{ads}$.

By taking these factors into account an overall expression can be derived for the yield of dimer[11]. Thus it is possible to predict that the yield of dimer is maximal at negligible current-densities and that it will decrease to zero when the maximum possible, *i.e.* the diffusion-limiting, current is applied[*]. Under diffusion-limited current conditions each olefin molecule reaching the anode by convective diffusion would, of course, be oxidized, so that with diffusion-limited currents there would never be any olefin available at its surface for the coupling reaction [Eq. (50)].

Figure 12 compares the dependence of the dimer yield for anodic oxidation of styrene at a carbon anode on the current-density used—in terms of the diffusion-limited current-density i—with the theoretically deduced value (solid curve). The results in Figure 12 indicate that at sufficiently high styrene concentrations (1 mol/L) and a vanishingly small i/i_d ratio, almost 100% yields of dimer can be obtained[11].

[*] In this case the current-voltage curves do not show "reversible" waves, but are typical for completely irreversible charge-transfer reactions. In such cases the analysis of the current-voltage curves only yields information concerning the kinetics of the charge-transfer and of the reactions which precede the charge-transfer.

[*] This inference is only correct if the dimerization reaction—as alleged—depends on the nucleophilic attack of the radical cation on a, not yet, oxidized olefin molecule. For radical dimerization as competition to solvolysis, on the other hand, the dimer yield would be maximal under diffusion-limited current conditions.

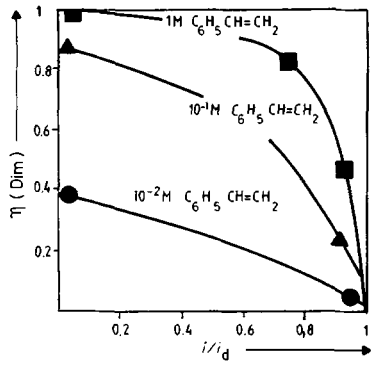

Fig. 12. The dependence of the selectivity (current yield) η for the formation of dimer during the anodic oxidation of styrene at a carbon anode on i/i_d for three styrene concentrations in 0.1 mol/L methanolic $NaClO_4$. The varying yields at negligible current-density ($i/i_d = 0$) correspond to the different surface concentrations Γ of styrene at the C-anode.

In contrast, by using sufficiently low styrene concentrations at current-densities close to the diffusion-limited current-densities, almost 100% selectivity for the monomer is achieved. In principle, it is therefore possible in this case to steer the electrolytic synthesis in either of two directions.

Table 6. The dependence of the relative yield of dimer in the oxidation of styrene on the anode material. Γ_{rel} = relative surface-concentration of styrene. Electrolyte: methanol, 0.1 mol/L $NaClO_4$, 1 mol/L styrene, current-density $i = 50$ mA/cm^2.

Anode material	Rel. yield of dimer	Γ_{rel}
Graphite	1	1
Fe_3O_4	0.2	10^{-2}
PbO_2	0.1	5×10^{-3}
Pt	0.05	2×10^{-3}

Table 6 indicates the strong influence the electrode material has on the olefin electrosorption equilibrium or, to put it another way, the strong relation between the relative rate of the reaction leading to the formation of the dimer, and the anode material. The realizable yields of dimer, under the same electrolytic conditions, are listed in Table 6 for graphite, magnetite, lead dioxide, and platinum anodes, and are compared with the surface concentrations of styrene, calculated from the electrode kinetics[11,21]. This comparison demonstrates that the dimer yield correlates well with the equilibrium constant of the styrene electrosorption.

5. Conclusions and Outlook

The physical chemistry of the electrosynthesis of organic compounds has so far attracted very little interest, for, on the one hand, it has proved difficult to obtain insight into the physicochemical background of such reactions and, on the other, organic chemists are more interested in reactions that "work" than in reactions that do not "work", *i.e.* are not selective enough. However, we are beginning to have a better understanding of the course of such reactions and to recognize what are the most important factors that govern the course and the success of electro-organic syntheses. For all that, the progress made in understanding the individual reactions cannot, as yet, be generalized.

In view of the fact that the industrial electrosynthesis of organic compounds, which had been thought moribund, is finding—albeit modest—application, and further development work in this field is underway, it is to be hoped that the physical chemistry of the reactions involved will, in future, provide the practical chemist with useful ideas, insights and guidelines, and that the synthetic chemist will achieve a better understanding of both his successes and his disappointing results.

I would like to thank those of my co-workers, who are cited in this article, for their work and the results they have made available. Thanks are also due to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Max Buchner Foundation for supporting most of the investigations forming the basis of this paper which have been carried out at the Technische Hochschule Darmstadt. The enthusiastic help provided by Dr. Köster (Technische Hochschule, Darmstadt) in the final preparation of this article is gratefully acknowledged.

Hexagonal Ferrites from Melts and Aqueous Solutions, Magnetic Recording Materials

By Hartmut Hibst*

Dedicated to Professor Werner Reif on the occasion of his 60th birthday

Owing to their particular crystallographic properties, ferrimagnetic hexagonal ferrites exhibit a far greater coercive force than the conventional magnetic pigments. They therefore appear to be suitable for use in magnetic information storage procedures, some of which are novel and are at the development stage. Thus, magnetic tapes of high coercive force containing barium ferrite could be used as master tapes for copying magnetic information or for producing forgery-proof magnetic cards, if magnetic heads having high-order write fields were successfully developed. Moreover, platelet-like ferrite pigments in which the preferred direction of magnetic orientation is perpendicular to the plane of the platelet are of great interest for perpendicular magnetic recording.

In this progress report, the crystal structures, magnetic characteristics of hexagonal ferrites, and chemical processes for their production are discussed. In particular, reactions in salt melts or under hydrothermal conditions produce finely divided pigments whose particles have a pronounced hexagonal, plate-like habit, a narrow particle size distribution, and advantageous magnetic properties. The magnetic properties of the pigments crystallized from salt melts may be adjusted by cation exchange.

1. Introduction

"Ferrites" are oxidic solids which have a high proportion of Fe^{III}. The industrially important ferrites are of three different structural types: those having a spinel-type structure, those having a garnet-type structure, and the so-called hexagonal ferrites[1].

Ferrites with a spinel-type structure have the composition MFe_2O_4, where M is, in general, a divalent cation, *e.g.* Mn, Fe, Co, Ni, Cu, Zn, or Cd. In the "normal" spinels, the oxygen ions have a cubic close packed structure; the divalent cations occupy the tetrahedral sites, and the iron(III) ions occupy the octahedral sites. In the "inverse" spinel structure, in contrast, half the iron(III) ions occupy the tetrahedral sites, while the other half occupy the octahedral sites, together with the M^{II} ions. Ferrites which have an inverse spinel structure, or which have structures intermediate between normal and inverse spinel structures, are ferrimagnetic. These solids are used industrially in the form of polycrystalline powders or ceramics, or in the form of monocrystalline epitaxial films or single crystals. The magnetic properties of ferrites are determined to a great extent by their chemical compositions; the presence of even very small amounts of certain impurities or doping substances, which produce substituted ferrites, can cause a pronounced change in the physical properties. Moreover, the magnetic characteristics of the ferrite powders and ceramics are a function of the distribution of the cations in the crystal lattice, of the shape and size of the crystallites and particles, and of their particle size distribution.

Very finely divided Fe_3O_4 (magnetite) with an inverse spinel structure can be obtained with a mean particle diameter of 50—90 Å by wet-chemical methods, and can thus be processed further to give "magnetic fluids"[2]. By means of "metastable" oxidation, magnetite powders can be converted topochemically, with retention of the crystal habit, into γ-Fe_2O_3, whose spinel type structure has vacancies at tetrahedral and octahedral sites. γ-Fe_2O_3 is currently used on a large scale for the production of magnetic tapes and magnetic disks which are used for the storage of information[3].

Because of their high permeability, and their high electrical resistance in comparison with metallic magnetically soft materials, magnetically soft MnZn ferrites and NiZn ferrites are used for producing magnetic cores. Depending on the composition and the method of production, the magnetic properties of these ferrites may be varied greatly, and thus may be adapted to the particular technical requirements (frequency range, temperature behavior, stability). In general, they are produced by sintering carefully mixed oxides or carbonates. In this process, particularly in the case of Mn-containing ferrites, the splitting off of oxygen on heating and the reoxidation on cooling have to be controlled *via* the partial pressure of the oxygen in the glowing atmosphere. The rate of cooling after sintering may be important, particularly when the distribution of cations in the lattice is very temperature-dependent. Owing to their considerable hardness and their high electrical resistance, these ferrites are also useful materials for magnetic heads used in information storage. By means of vacuum sintering and biaxial or isostatic hot-press techniques, the porosity of the MnZn and NiZn ferrite ceramics can be decreased to less than 0.1% at a particle diameter of *ca.* 10 μm[4]; this makes it possible to produce extremely narrow gaps, and to reduce abrasion of the magnetic head. Monocrystalline MnZn ferrite heads are currently used, in particular, for video recordings. The required MnZn ferrite single crystals are grown by the Bridgman method in platinum crucibles under an atmosphere of oxygen at temperatures above 1600 °C[5].

MnMg ferrites, which are used in toroidal core memories, exhibit a rectangular hysteresis loop at the outset, *i.e.* spontaneously and without orientation of the crystallites, provided they possess the "correct" composition. Because of their high specific electrical resistance, Mg-containing ferrites, in particular, are suitable for microwave applications.

Like the ferrites with a spinel-type structure, those which have a garnet-type structure (composition: $M_3Fe_5O_{12}$, M = Y, Pm, Sm, Eu, Gd, *etc.*) are also of industrial importance. In these structures, which are also cubic, the iron(III) ions occupy tetrahedral and octahedral sites, as in the spinel-type structure; the M^{III} ions are randomly surrounded by eight oxygen ions. Ferrites having a garnet-type structure are employed as magnetic materials for microwave applications. Single crystals, in particular, exhibit advantageous resonance behavior. Ferrimagnetic films which have a garnet-type structure and which have grown epitaxially on nonmagnetic single crystals having a garnet-type or spinel-type structure can form cylindrical, magnetic bubbles when subjected to a magnetic field. This is very important for information storage.

In contrast to the ferrites which have a spinel-type or garnet-type structure, the class of hexagonal ferrites comprises a number of structural types, which are described in more detail in Section 2. The barium and strontium ferrites, which are of very high coercive force and have the magnetoplumbite structure (*M* type, composition: $MFe_{12}O_{19}$, M = Ba, Sr, *etc.*), are now produced industrially in large amounts (world annual production about 70000 tonnes), and are processed further to give permanent magnets[7]. Anisotropic permanent magnetic ceramics which have a higher residual magnetization than isotropic magnets are obtained from "ceramically" produced ferrite powders (cf. Section 4.1) when a magnetic field is applied during shaping to align the magnetic particles of the ferrite powder with their preferred direction of magnetic orientation preferentially in the direction of the field. By far the best degree of orientation is achieved by wet-pressing under the influence of a magnetic field. The pellets are then sintered in air at elevated temperatures (about 1300 °C) to give a magnetic ceramic, and a pronounced anisotropic contraction takes place. Finally, the brittle and very hard crude sintered products are worked with diamond tools, in a cost-intensive process. In contrast, plastoferrite magnets may be produced economically, for example by injection molding, from powders of hexagonal ferrites which are bonded to plastics; although these plastoferrite magnets possess a smaller magnetization than sintered ferrite magnets, they can more readily be processed further by stamping or cutting.

Owing to its high anisotropic field strength, barium ferrite is also a useful material for microwave technology at very high frequencies. The frequency range may be greatly extended by partial substitution of the Fe ions (cf. Section 3.1).

Hexagonal ferrites which have a high proportion of Co, or which are of the *Y* type (see Section 2), possess an almost freely rotatable magnetization vector in the plane of the platelet, perpendicular to the hexagonal *c*-axis, and are accordingly magnetically soft (cf. Section 3.2); they may be used for magnetic cores at very high frequencies.

Furthermore, magnetically hard barium ferrite pigments are important for magnetic recording. The principle of magnetic recording is described in the following[7]: Magnetic tapes and magnetic disks for audio, video and data recording consist of a non-magnetic base and a magnetic storage layer. The magnetic layer contains a magnetic pigment which is uniformly distributed in an organic binder and is in general magnetically orientated. The tape containing the magnetic pigment layer is led past the gap of a horseshoe-shaped iron or ferrite core, the magnetic head of which carries several windings. The information to be stored is converted into an alternating voltage, by means of which, *via* the coil and the core, a magnetic leakage field is produced at the gap, and orientates the magnetic domains of the pigment coating on the tape. The orientation is retained even when the band has left the leakage field.

The strength and permanence of the magnetic recording are determined, in particular, by three parameters: the Curie temperature, the remanent magnetization and the coer-

cive force. The *Curie temperature* is the temperature at which the pigment loses its magnetization as a result of the thermal motion of the spins, and becomes paramagnetic. For practical use, the Curie temperature should be as high as possible. The remanent magnetization and the coercive force are characteristic parameters of the magnetization behavior of a pigment. This behavior is represented as a hysteresis loop. The remanent magnetization M_r is the magnetization remaining when the field has been removed, after magnetic saturation of the pigment by the external magnetic field (M_s = saturation magnetization). The *coercive force* H_c is characteristic of the magnetic field which is required to completely demagnetize the magnetic pigment again, and is a measure of the ability of a pigment to resist demagnetization, *i.e.* to retain the information accepted.

The remanent magnetization and the coercive forces of magnetic pigments are not just material constants of the solids used, but are also greatly influenced by the shape of the pigment particles. The particles of conventional magnetic pigments are acicular, and have a mean particle length of *ca.* 0.5 μm; they consist of ferrimagnetically pure or cobalt-modified γ-Fe_2O_3, or of ferromagnetic CrO_2 or iron[3]. Berthollidic oxides of composition Fe_3O_{4+x} ($x < 0.5$) are also used *inter alia* instead of γ-Fe_2O_3. Whereas magnetic tapes containing pure γ-Fe_2O_3 achieve coercive forces (H_c) of about 30 kA/m, the H_c values of those containing CrO_2 are about 50 kA/m. With cobalt-modified γ-Fe_2O_3 or Fe pigments, H_c values of about 100 kA/m are reached (cf. Fig. 1).

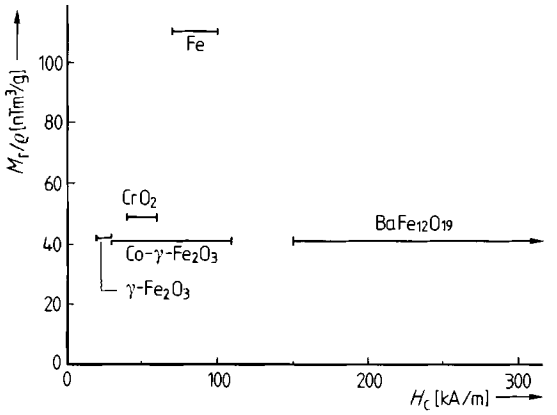

Fig. 1. Coercive force H_c and specific remanent magnetization M_r/ρ of commercially produced magnetic pigments (Fe and CrO_2 non-stabilized; Co-γ-Fe_2O_3 signifies cobalt-substituted γ-Fe_2O_3).

Chromium dioxide is produced hydrothermally by synproportionation of Cr^{III} and Cr^{VI} oxides, and is obtained directly with an acicular particle habit. In contrast, synthesis of acicular, magnetically readily orientatable γ-Fe_2O_3 and Fe pigments with high, defined coercive forces has to be carried out using non-magnetic iron oxide hydroxide (FeOOH) as the starting material; this compound is formed with an acicular habit in the wet-chemical oxidation of iron(II) hydroxide. The resulting FeOOH is dehydrated and reduced with hydrogen at about 350 °C under a defined partial pressure of oxygen to give acicular magnetite (Fe_3O_4), which is converted topochemically into acicular γ-Fe_2O_3 by metastable oxidation. In contrast, the Fe pigment is obtained by reducing FeOOH with pure hydrogen. In the case of γ-Fe_2O_3 and Fe, the art of producing magnetic pigments consists, *inter alia*, in obtaining a magnetic end product with an acicular shape and a particle size which differ very little from those of the non-magnetic FeOOH pigment. High grade magnetic pigments are distinguished by elongated particles of defined size, possess a narrow particle size distribution, are readily dispersible, may readily be oriented in a magnetic field, and have a high chemical stability in the magnetic tape.

Magnetic recordings with carriers containing magnetic pigments of high coercive force should be advantageous in memory technology, particularly at relatively short wavelengths, and this is particularly important for video recording. In addition, an increase in storage density may be expected.

The only pigment of high coercive force ($H_c > 150$ kA/m) which may be used over the whole wavelength without remanent magnetization losses is hexagonal barium ferrite[8] (cf. Fig. 1). In addition, it exhibits desirably low values of the magnetostriction constants[*][9, 10].

Magnetic tapes which have a high coercive force and contain barium ferrite may be used as "master tapes" for copying magnetically stored information[3]. For this purpose, the magnetized master tape is placed in a magnetic field together with unused magnetic tapes of low coercive force, and the information transferred to these tapes.

It is almost impossible to erase magnetically oriented barium ferrite tapes using magnetic fields in the direction of the magnetically hard axis, in contrast to conventional magnetic tapes having the same coercive force[11]. Consequently, it appears that barium ferrite tapes of low coercive force may also be used as master tapes for non-hysteretic contact duplication[12]. In addition, it is thus possible to achieve independent magnetization of each individual layer in dual-layer tapes containing differently oriented barium ferrite layers. Moreover, barium ferrite pigments of high coercive force may be used for producing forgery-proof magnetic cards (credit cards containing strips, identity cards, tickets, *etc.*)[13]. Information carriers of this type are less sensitive to extraneous magnetic fields than the conventional magnetic storage media which have a comparatively low coercive force; in addition, higher packing densities may be employed[14].

However, higher H_c values of the storage layer require magnetic heads with higher gap fields, and the provision of these is difficult due to saturation of the core material. The production of magnetic heads which give sufficiently higher-order write fields remains a thing of the future. Magnetic tapes containing a barium ferrite pigment and having an H_c value of 280 kA/m may still be magnetized if Fe-Co magnetic heads having a high saturation magnetization are used[15]. Suitable alternatives to barium ferrite pigments of high coercive force are $SmCo_5$-metal pigments having an H_c value of 700—900 kA/m. However, even Fe-Co magnetic heads fail to reach such high magnetic fields[16].

Hexagonal barium ferrite is formed as platelets under certain conditions, and the hexagonal *c* axis perpendicular to the plane of the platelet is the easy magnetic direction.

[*] Magnetostriction: Relative elastic change in the length of substance under the influence of a magnetic field (Joule effect).

Thus, barium ferrite would also be suitable as a magnetic pigment for perpendicular recording[*] if it were possible to orient the platelets parallel to the plane of the storage layer. This could be effected either magnetically, as is usual, or mechanically by calendering. Perpendicular recording has advantages over conventional longitudinal recording in processes in which short wavelengths are preferentially stored (video)[8]. In addition it should make very high packing densities possible[17].

As an alternative to particulate barium ferrite layers, non-particulate, magnetically coherent films with vertical anisotropy, for example oxidic barium ferrite or metallic Co-Cr layers applied by a sputtering technique, are suitable for perpendicular recording. It remains to be seen whether it will be possible to produce these films in a sufficiently perfect form, and in the case of the metallic layers, with sufficient resistance to corrosion, or whether particulate barium ferrite layers are more advantageous.

In the following sections the crystal structures and magnetic properties of hexagonal ferrites will be described. Moreover, several chemical methods for the production of finely divided, hexagonal ferrite pigments suitable for the various possible methods of magnetic recording are presented. Salt-melts and hydrothermal syntheses, in particular, give platelet-like pigments having a narrow particle size distribution. By selectively substituting the cations, the magnetic properties of the pigments may be adjusted as desired.

2. Crystal Structures of Hexagonal Ferrites

The crystal structures of the large group of hexagonal ferrites show a number of common features. All structures have a close packed arrangement of oxygen ions, and the barium ions, which are of about the same size, occupy sites analogous to those occupied by oxygen. The substantially smaller M^{II} and Fe^{III} ions occupy the interstitial spaces between the oxygen ions. The magnetoplumbite structure of hexagonal barium ferrite of composition $BaFe_{12}O_{19}$ (M)[18] may be subdivided into so-called M blocks (cf. Fig. 2).

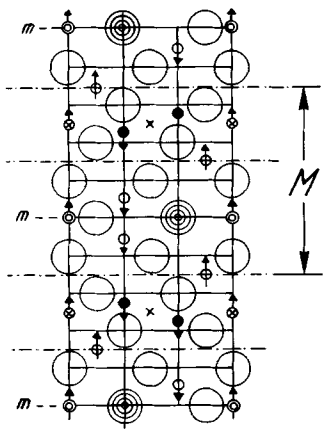

Fig. 2. Cross-section through the magnetoplumbite structure [16] showing an M block and perpendicular c axis. The large blank circles represent oxygen ions and the large filled circles represent barium ions. The small circles associated with arrows represent the distribution of iron(III) ions over the five different sublattice sites, and their spin orientations. Axes of three-fold symmetry are symbolized by lines at right angles, and centers of symmetry by crosses. All layers containing barium ions are located on mirror planes, which have the symbol m.

In these blocks, the Fe^{III} ions occupy five crystallographically different interstitial sites in the oxygen lattice, and some of these sites differ from one another in coordination number. As a result, five magnetic sublattices with different coupling characteristics occur (Table 1)[1].

Table 1. Distribution and spin orientation of the Fe^{III} ions in sublattice sites of $BaFe_{12}O_{19}$ [1].

Sublattice	12k	$4f_1$	$4f_2$	2a	2b
Site	Octahedral	Tetrahedral	Octahedral	Octahedral	Trigonal bipyramidal
Coordination	6	4	6	6	5
Number of Fe^{III}-ions per M Block	6	2	2	1	1
Spin	↑	↓	↓	↑	↑

Another hexagonal ferrite, $Ba_2M_2Fe_{12}O_{22}$(Y), is composed of Y blocks[19,20]. In the blocks, only tetrahedral and octahedral sites are occupied by cations.

The large number of other hexagonal ferrites may be subdivided into two structural families[21]. One relatively large family comprises stacking variations M_pY_n in which the structural building blocks M and Y are stacked along the hexagonal c axis in different, but generally regular, sequences (Table 2).

Table 2. Hexagonal ferrites with M_pY_n stacks [a].

$M:Y$	Stacking sequence	Ideal composition	Symbol
2 : 1	M_2Y	$Ba_4M_2Fe_{36}O_{60}$	U [22]
2 : 2	$MYMY$	$Ba_6M_4Fe_{48}O_{82}$	Z [19]
2 : 3	$MYMY_2$	$Ba_8M_6Fe_{60}O_{104}$	
2 : 4	$MYMY_3$	$Ba_{10}M_8Fe_{72}O_{126}$	
2 : 4	MY_2MY_2		
4 : 3	$MMYMYMY$	$Ba_{10}M_6Fe_{84}O_{142}$	
4 : 5	$MYMYMYMY_2$	$Ba_{14}M_{10}Fe_{108}O_{186}$	
4 : 8	$MYMYMY_3MY_3$	$Ba_{20}M_{16}Fe_{144}O_{252}$	
4 : 8	$MYMYMY_2MY_4$		
4 : 8	$MYMY_2MY_2MY_3$		
4 : 33	$MY_6MY_{10}MY_7MY_{10}$	$Ba_{70}M_{66}Fe_{441}O_{802}$	
6 : 13	$MYMYMYMY_2MY_3MY_5$	$Ba_{32}M_{26}Fe_{228}O_{400}$	
6 : 14	$MYMYMY_2MY_3MY_2MY_5$	$Ba_{34}M_{28}Fe_{240}O_{422}$	
8 : 27	$M_3Y_4MY_7MYMYMY_6MY_8$	$Ba_{62}M_{54}Fe_{420}O_{746}$	

[a] In addition to the structures listed above, 35 other M_2Y_n structures and 6 M_4Y_n structures are known.

The unit cell of M_4Y_{33}, which contains 4100 atoms and has a volume of 47000 Å^3 (c = 1577 Å), is one of the largest cells of all known inorganic compounds[21].

The second, smaller structural family M_nS is obtained by stacking M layers with structural elements (S) from the cubic spinel-type structure MFe_2O_4 (Table 3).

Whereas it has been possible to determine the structures of the majority of the stacking variations by single crystal X-ray methods[25-28], electron-optical methods of investiga-

[*] Perpendicular recording: In conventional longitudinal recording, the direction of easy magnetization lies in the plane of the magnetic tape, in its direction of travel. In contrast, perpendicular recording is possible only with a medium with magnetic anisotropy perpendicular to the plane of the medium.

Table 3. Hexagonal ferrites with M_nS stacks.

M : S	Stacking sequence	Ideal composition	Symbol
1 : 1	MS	$BaM_2Fe_{16}O_{27}$	W [19, 23, 24]
2 : 1	M_2S	$Ba_2M_2Fe_{28}O_{46}$	X [19]
4 : 1	M_4S	$Ba_4M_2Fe_{52}O_{84}$	
6 : 1	M_6S	$Ba_6M_2Fe_{76}O_{122}$	

tion were employed in addition, particularly for the very complicated structures[21,29]. Moreover, it has recently been possible to determine the structures of other exotic "intergrowth phases" M_pY_n by direct, lattice-imaging and high resolution transmission electron microscopy[30,31-33].

Of the large number of known structures, only the basic compounds M ($BaFe_{12}O_{19}$) and Y ($Ba_2M_2Fe_{12}O_{22}$), and the stacking variations having comparatively simple structural patterns (U, Z, W and X) are obtainable as powders in relatively large amounts and can thus be identified on the basis of their X-ray powder diagrams[34]. The relatively simple basic structures M and Y are formed at 800 and 950 °C, respectively, and the stacking variations only at 1150—1300 °C[35].

The other compounds listed above, which have more complicated structures, were isolated only as small single crystals from multi-phase ferrite preparations, powders being obtained from various melts by crystallization[36,37]. It has hitherto been impossible to find a relationship between the conditions of synthesis and the intergrowth phases obtained.

In an analogous system containing strontium instead of barium, only the M, W[38,39], and X phases[40] have been found to date.

3. Magnetic Properties

3.1. Magnetic Properties of $BaFe_{12}O_{19}$

$BaFe_{12}O_{19}$ has a highly anisotropic, hexagonal crystal structure and an anisotropy constant K_1 of 330 kJ/m³[1], and therefore exhibits high magnetocrystalline anisotropy[*], the hexagonal axis being a very strongly preferred direction for the magnetic moment. In platelet-like barium ferrite crystals, the direction of easy magnetization and the hexagonal c axis are perpendicular to the plane of the platelet.

The anisotropic field strength H_A, which specifies the magnetic field theoretically required to simultaneously reverse all spins in a saturated, monocrystalline material, is a measure of the material-specific magnetic rigidity. For $BaFe_{12}O_{19}$, an anisotropic field strength of $H_A = 2K_1/M_s = 1330$ kA/m is obtained. Accordingly, the maximum obtainable coercive force of an isotropic, magnetically non-orientated barium ferrite powder containing magnetic single-domain particles is $H_c = 0.48 \cdot H_A$[41] = 640 kA/m. This value is further decreased by a maximum of 30% by the contribution from anisotropy of shape of the platelet, which has not been taken into account[42]. This contribution depends on the diameter/thickness ratio of the platelet. In addition, the dependence of the coercive force on the density of packing of the pigment must be taken into account[43-45]. Since both the anisotropy constant K_1 and the saturation magnetization M_s decrease uniformly with increasing temperature, H_A, and therefore also the coercive force H_c, are almost temperature-independent up to about 250 °C[1]. The extremely low h_{25} value of only 0.13 is calculated as the switching field distribution[*] for an isotropic distribution of the particle directions[46].

The saturation magnetization M_s is of the same order of magnitude as in other ferrimagnetic iron oxides, and is 478 mT at room temperature.

3.1.1 Decreasing the Coercive Force H_c by Milling Processes

The coercive force actually attained is always smaller than the calculated maximum value. Particularly when barium ferrite powders are milled, the H_c values are greatly reduced (to about 130 kA/m). This is essentially caused by the fact that lattice defects occur in pigment particles when a material is intensively milled[47-50]; however, a small proportion of the decrease in H_c on milling must be attributed to the presence of very fine superparamagnetic constituents[51,52] and to the considerably disturbed surface of the powder particles[50]. The coercive force increases to a maximum of about 350 kA/m on subsequent tempering, and this increase may be explained by the elimination of the lattice defects[47,48] and the combination, by sintering, of the very fine superparamagnetic particles to give larger magnetic single-domain particles[51].

3.1.2. Adjustment of the Magnetic Properties by Substitution

Milling and tempering processes are not the only means of adjusting the coercive force of a barium ferrite powder; it is also possible to change the value of the anisotropy constant K_1 by substitution. The resulting magnetocrystalline anisotropic field strength H_A and the maximum coercive force H_c achievable therewith are, in general, proportional to K_1/M_s. Substitutions have been carried out, *e.g.* on hexagonal ferrites, to adjust the resonance frequency, *via* H_A, to a particular value for high frequency applications[53,54].

Thus, the barium ions in $BaFe_{12}O_{19}$ may be completely replaced by strontium ions[38,55-58] or by lead ions[38,55], or partially replaced by calcium ions[38,55,59-64]. $SrFe_{12}O_{19}$ has an anisotropy constant ($K_1 = 357$ kJ/m³[57]) which is 10% higher than that of barium ferrite, and is therefore particularly suitable for applications requiring high coercive forces. The alkaline earth ions may also be substituted by cation pairs M^I-M^{III} (M^I = Na, K, Rb, Ag, Tl; M^{III} = La, Pr, Nd, Sm, Gd)[65,66].

[*] Magnetocrystalline anisotropy: Crystal anisotropy is associated with crystal energy. This is the energy required to rotate the magnetization vectors from the preferred direction of easy magnetization to the direction of difficult magnetization.

[*] Switching field distribution (h_{25}): Each particle of a magnetic pigment has its direction of magnetization reversed in a magnetic counter-field at a slightly different field strength, which is dependent, for example, on the particle shape and size and the defect concentration. A magnetic pigment containing very similar particles, *i.e.* having a very narrow distribution of particle size, has in consequence a narrow switching field distribution with a small h_{25} value and a comparatively steep ascent of the hysteresis curve. For an exact definition see [152, 153].

The Fe^{III} ions may be replaced by Al^{III} [56, 59, 67–78], Ga^{III} [59, 70, 72, 73, 76–80], Cr^{III} [59, 70, 72, 73, 76, 81–83], In^{III} [76, 77, 84–86], Sc^{III} [77, 85, 87], or Ru^{III} ions[88]. In all cases, the Curie temperature, the saturation magnetization, and the residual magnetization decrease with increasing degree of substitution. The pronounced increase in the coercive force observed on substitution by Cr^{III} and Ga^{III} may be attributed to an increase in the critical single-domain size[76, 83]. Substitution by aluminum additionally gives rise to an increase in the coercive force, owing to an increase in the anisotropic field strength. Indium and scandium ions preferentially occupy sites having trigonal bipyramidal coordination spheres in the crystallographic sublattice 2b, resulting in a pronounced decrease in the anisotropy constants; this gives rise to special magnetic block structures or helical structures[77].

Hexagonal *M* ferrites are also known in which the Fe^{III} ions are partially replaced by a combination of ions of different valencies, giving rise to solids of compositions $BaM^{II}_xM^{IV}_xFe_{12-2x}O_{19}$ and $BaM^{II}_{2x}M^{V}_xFe_{12-3x}O_{19}$. The following cation pairs have been used to date: Zn^{II}-Ti^{IV}[1, 89–93], Ni^{II}-Ti^{IV}[1, 93], Co^{II}-Ti^{IV}[1, 74, 93–100], Cu^{II}-M^{IV}[101], Fe^{II}-Ti^{IV}[102], M^{II}-Zr^{IV}[66], Zn^{II}-Ir^{IV}[103], Zn^{II}-Ge^{IV}[76, 81], M^{II}-Sn^{IV}[66], Zn^{II}-V^{V}, Zn^{II}-Nb^{V}, Zn^{II}-Ta^{V}[76, 81], Cu^{II}-M^{V}[101] and Fe^{II}-Sb^{V}[102]. In all cases, the anisotropy constant, the anisotropic field strength and the coercive force decrease with increasing substitution, the greatest effect being obtained for Co^{II}-Ti^{IV} and Zn^{II}-Ir^{IV}. Thus, the uniaxial anisotropy in the direction of the hexagonal *c* axis vanishes on substitution by Co^{II}-Ti^{IV} for $x > 1.2$[1], and on substitution by Zn^{II}-Ir^{IV} for $x > 0.3$[103], the easy direction of magnetization being tilted in the plane of the crystal platelet perpendicular to the crystallographic *c* axis. In virtually all systems, the Curie temperature and the saturation magnetization decrease with increasing x. A deviation from this behavior was found with Co^{II}-Ti^{IV} substitution, where the saturation magnetization was found to decrease only slightly[1, 74, 95], or even to remain constant[99, 100], in the area of uniaxial anisotropy. For a low degree of substitution by Zn^{II}-Nb^{V}, the magnetization even increases[81]. In the system $BaM_xTi_xFe_{12-2x}O_{19}$, a pronounced temperature dependence of the anisotropic field strength is obtained when M is Co, in contrast to the case where M is Zn or Ni; with Cu, it is possible to achieve a remanent magnetization which is less temperature dependent[101].

Furthermore, it is possible to simultaneously replace Ba^{II} by M^{III} (Y[104], La[102, 104–108], Pr[105, 106], Nd[105], Sm[104, 105], or Eu[105]) *and* Fe^{III} by M^{II} (Co, Ni[106] or Fe). In the system $Ca^{II}_{1-x}La^{III}_xFe^{III}_{12-x}Fe^{II}_xO_{19}$, it is possible to produce magnetically hard ceramics possessing magnetic properties similar to those of barium ferrite[109, 110]. Finally, mixed crystals of composition $BaCo^{II}_xFe^{III}_{12-x}O_{19-x}F_x$ have also been described[111].

3.2. Magnetic Properties of Other Hexagonal Ferrites

In *Y* ferrites of composition $Ba_2M^{II}_2Fe^{III}_{12}O_{22}$ (M^{II} = Mn, Fe, Co, Ni, Zn or Mg), the direction of spontaneous magnetization lies in the platelet plane perpendicular to the hexagonal *c* axis, and is virtually freely rotatable in this preferred plane[112]. These ferrites are therefore magnetically soft and are unsuitable as materials for permanent magnets or magnetic pigments. However, *Y* ferrite is of interest for high-frequency applications[113]. In *Y* ferrites when M is Co the preferred directions of magnetization form a cone with the *c* axis as cone axis at low temperatures[17]. When M is Cu, the *Y* ferrite is magnetically uniaxial at room temperature[114].

The remaining hexagonal ferrite phases *U*, *Z*, *W* and *X*, which may be regarded as stacking variations of the basic structures *M* and *Y*, or *M* and *S* (cf. Section 2) are, like the *M* phase, magnetically uniaxial when M^{II} is Mn, Fe, Ni, Zn, Mg, Cu, or $(Li^{I}+Fe^{III})/2$. The anisotropy constant and the saturation magnetization are dependent on the particular structure and on the M cations, but are in general lower than those of the *M* ferrite[1, 115, 116]. Only the *W* structure with M = Zn has a higher saturation magnetization than the *M* phase[116]. The anisotropic field strength is decreased in all cases by increasing substitution of the M cations by Co, until the uniaxial anisotropy finally becomes planar anisotropy[1, 98, 117, 118]. In the structure Co_2Z ($Ba_3Co_2Fe_{24}O_{41}$) at low temperatures, the preferred directions of the magnetization vector form a cone. In addition, the magnetic properties of the particular ferrite phases may be varied by other substitutions, for example by substituting Fe^{III} ions by Al, Ga, In, or Sc[69, 119], as already investigated in detail for $BaFe_{12}O_{19}$ (*M*).

In order to determine which of the crystallographic sites are occupied in the ferrites obtained by substitution of cations, and to explain the altered magnetic properties, Mössbauer spectroscopy has been used in many cases[75, 79–82, 85, 91, 92, 107, 108, 120, 121].

4. Process for the Production of Powders of Hexagonal Ferrites

4.1. "Ceramic Process"

M-barium ferrite powder, which is processed further, for example, to give plastoferrites, is conventionally produced by the ceramic process. In this process, a mixture of $BaCO_3$ and synthetic or mineral iron(III) oxide in the form of granules is calcined at high temperature (1200–1350 °C) in a rotary tubular kiln. The resulting sintered crystalline agglomerates of $BaFe_{12}O_{19}$ are broken down by a milling process into individual magnetic single-domain particles having a diameter of about 1 μm. The intensive milling required gives rise to crystal structure defects resulting in a comparatively low coercive force. The defects are eliminated in part by tempering, as a result of which the H_c values may increase to a maximum of 350 kA/m (cf. Section 3.1.1). The relatively low coercive forces result from hysteresis characteristics which are determined predominantly by nucleation[122].

The production of the other hexagonal ferrite ceramics is carried out using a similar process, the additionally required M^{II} cations being provided, in general, by using the appropriate oxides or carbonates in the starting mixture.

Ceramic ferrite powders do not appear to be very suitable for use in recording media. Particularly disadvantageous are the particle coarseness, the broad particle size

distribution (cf. Fig. 3) caused by the milling process, and the poor switching field distribution of the powder.

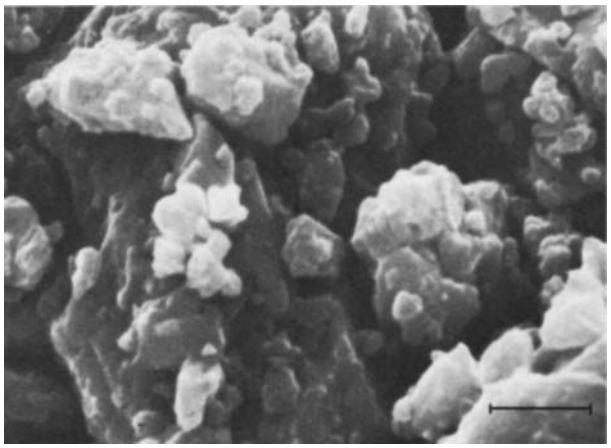

Fig. 3. Ceramically produced and milled barium ferrite (*M*) (the distance indicated corresponds to 1 μm).

4.2. Coprecipitation and Tempering

In contrast to production of ceramics, the coprecipitation process produces finely divided barium ferrite preparations[42, 123–125]. In this process, an aqueous solution of barium chloride and iron(III) chloride is stirred into an excess of an aqueous solution of sodium hydroxide or sodium carbonate. The product of coprecipitation is filtered off, washed thoroughly and dried. Barium ferrite of very high coercive force, with an H_c value of about 450 kA/m, is obtained on tempering, even at 925 °C. The average particle diameter is *ca.* 0.1—0.2 μm (cf. Fig. 4), and the particle size distribution is comparatively narrow. In addition, the coercive force of the ferrites is less temperature-dependent than that of the ceramically produced and milled powders. Microwave absorption spectra have shown that the hysteresis process in the materials obtained by coprecipitation and tempering is determined predominantly by coherent rotation, whereas the reversal of magnetization by nucleation only plays a minor role[126].

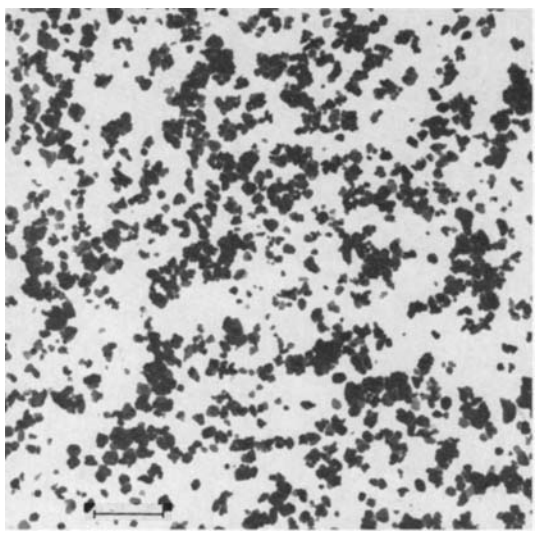

Fig. 4. Finely divided barium ferrite prepared by coprecipitation and tempering (1 h, 925 °C) (the distance indicated corresponds to 1 μm).

In spite of the low reaction temperature in our experiments, the ferrite material is highly agglomerated or even partially sintered. As with the products of the ceramic process, this material requires milling to make it suitable for use as a magnetic pigment. Such a process must be regarded as critical, even when less intensive milling is sufficient. Thus, by means of microwave resonance it could be established that even when the barium ferrite material obtained after tempering is ground gently in a mortar, the number of crystal defects increases, favoring, in turn, noncoherent hysteresis processes[127].

4.3. Synthesis from Melts

4.3.1. Oxidic Fluxes

The growth of $BaFe_{12}O_{19}$ single crystals from BaO-Fe_2O_3 melts (molar ratio 1 : 6) presents problems at atmospheric pressure, owing to the high melting point and elimination of oxygen[23]. The evolution of O_2 begins above 1450 °C, the *M* ferrite decomposing peritectically to form the iron(II)-containing *X* phase. Barium ferrite without an iron(II)-constituent can be crystallised out congruently from a melt at 1540 °C only at a pressure of oxygen of 40 bar or more[128].

The melting point may be lowered by increasing the proportion of Ba or by addition of other oxides, so that Fe^{II} free ferrites may also be obtained at atmospheric pressure. Thus, *Stuijts* has grown large platelet-like single crystals of $BaFe_{12}O_{19}$ by slowly cooling a virtually eutectic BaO-Fe_2O_3 melt[129].

Relatively large $BaFe_{12}O_{19}$ single crystals can be obtained from BaO-Na_2O-Fe_2O_3 melts, even at temperatures below 1250 °C[130]. By adding other oxide components, substituted barium ferrites[65, 70] and other hexagonal ferrite single crystals have also been obtained[36, 37, 131].

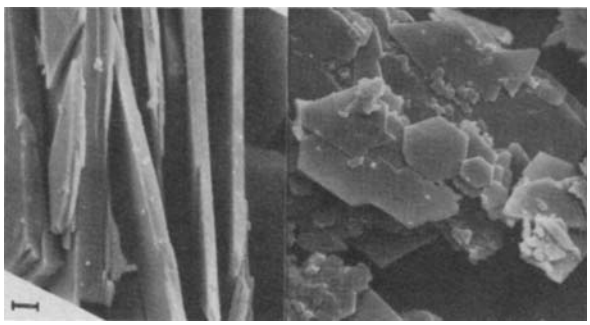

Fig. 5. Magnetically oriented, hexagonal ferrite powder obtained from boric acid melts (the distance indicated corresponds to 2 μm). The magnetic field runs horizontally from left to right in both cases. Left: $BaFe_{12}O_{19}$ (*M*); the preferred direction of magnetization is perpendicular to the plane of the platelet. Right: $Ba_2Zn_2Fe_{12}O_{22}$ (*Y*); the preferred direction of magnetization is in the plane of the platelet.

In addition, the crystals' qualities may be improved by using melts of the system BaO-B_2O_3-Fe_2O_3 (cf. Fig. 5). These melts are advantageous since they possess low volatility, low viscosities, low melting points, and have a negligible corrosive effect on Pt crucibles. Better crystallized

monocrystalline hexagonal ferrites which have only a small number of flux occlusions are obtained[37, 132–135].

Relatively large barium ferrite crystals may be grown by adding PbO and PbF_2 to the BaO-B_2O_3-Fe_2O_3 system, but this flux presents considerable problems due to its high volatility, density, rate of corrosion of Pt, and toxicity[136, 137]. Furthermore, substituted barium ferrites have been crystallized from melts having a high proportion of bismuth oxide[103].

Single crystals of hexagonal ferrites, of considerable size in some cases, have been crystallized from the above melts either by "top seeding" methods of crystal growth or by spontaneous nucleation by very slow cooling. Moreover, ferrimagnetic hexagonal ferrite layers can be grown epitaxially on non-magnetic monocrystalline substrates, particularly from melts containing boric acid, lead oxide, or lead fluoride. The resulting solids are of interest for microwave applications and for use in memories[138, 139].

Inorganic pigments may also be obtained from fluxes[140], the melts being quenched to give amorphous products. When the resulting glass is tempered, the pigment particles crystallize out spontaneously and homogeneously, the particle size in general increasing with temperature. The pigments are subsequently isolated by dissolving the matrix.

Using this process, barium ferrite pigments of high coercive force and narrow particle size distribution may be produced from BaO-B_2O_3-Fe_2O_3 melts[141–143]. A special technique which has been developed for the production of amorphous metals[144] and makes a maximum quenching rate of 10^6 K per second possible is required in this case to quench the above melts to produce amorphous products. This is achieved by pouring the boric acid melt between two metal rollers which are pressed together and rotate very rapidly in opposite directions; the melt is quenched by these rollers to give a glass band about 0.1 mm thick. After the amorphous bands have been tempered at about 850 °C and undergone aftertreatment with acetic acid, a barium ferrite pigment of very high coercive field ($H_c = 425$ kA/m), narrow particle size distribution, and platelet diameter of the order of 0.5 μm is obtained in virtually theoretical yield, based on Fe^{III}. Since the pigment particles crystallize out without being in contact with one another, slightly agglomerated, non-sintered powders are obtained, making it possible to dispense with subsequent milling which causes damage. By introducing other oxides into the boric acid melt, pigments of substituted barium ferrite suitable for magnetic recording are obtained after quenching, tempering, and washing out[145]. A similar method was also subsequently described for the BaO-Na_2O-Fe_2O_3 system[146].

4.3.2. Salt Melts

Alkali metal- and alkaline earth metal-chlorides in the molten state possess a high dissolving power for iron(III) oxide and other oxides[147], and this solubility may be used for growing relatively large single crystals or finely divided pigments. Thus, single crystal platelets of barium ferrite of about 1 mm size are obtained by introducing iron(III) oxide into molten barium chloride or barium fluoride at 1200–1300 °C in the presence of moist oxygen[148, 149]. It is also possible to convert mixtures of $BaCO_3$ and iron oxide hydroxide (FeOOH) in alkali metal salt melts at 1000 °C into barium ferrite powders. By dissolving the alkali metal chloride matrix, barium ferrite platelets of about 1.5 μm diameter with a maximum coercive force of 280 kA/m are obtained[150]. An improved process employs a dispersion of iron oxide hydroxide in aqueous NaCl-KCl, the dispersion being produced by precipitation from an iron(III) chloride solution using solutions of sodium hydroxide and potassium hydroxide, and subsequent heating. Thereafter, solid $BaCO_3$ is added, and a mixture of $BaCO_3$, FeOOH, NaCl, KCl is obtained after spray-drying. Relatively coarse-grained pigments (platelet diameter about 1.0–1.5 μm) are again formed at the temperatures (1000–1050 °C) required for quantitative formation of the ferrite, but these pigments exhibit better H_c values (425 kA/m)[151].

Finely divided products of very high coercive force are obtainable by a novel method which combines the advantages of the coprecipitation process (see Section 4.2) and the salt flux process, and at the same time avoids their disadvantages[152, 153]. Thus, when spray-dried NaCl-containing coprecipitates are heated, single-phase barium ferrite preparations with high H_c values (about 450 kA/m) and small platelet diameters (0.1–0.2 μm) are obtained at remarkably low temperatures (≥730 °C). The pigment particles crystallize from the NaCl matrix as a monodispersion with a pronounced hexagonal platelet habit and narrow particle size distribution, each platelet being separated from its neighbors by a salt layer. After the NaCl has been dissolved in water, a very finely divided, readily dispersible, non-sintered, loose powder is obtained, thereby obviating disadvantageous milling processes to produce more finely divided particles (cf. Fig. 6).

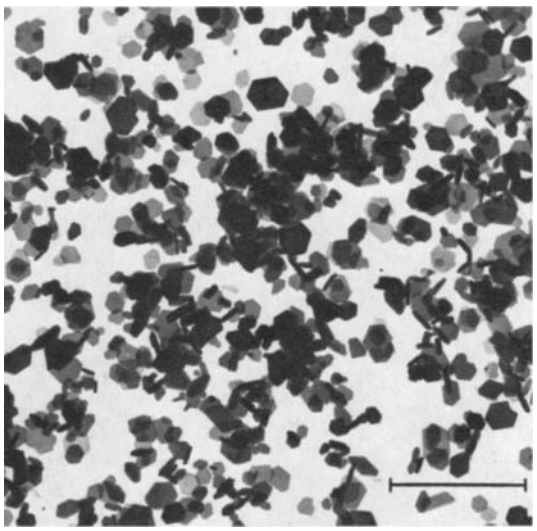

Fig. 6. Finely divided barium ferrite pigment of high coercive force, obtained from an NaCl flux ($H_c = 450$ kA/m; the distance indicated corresponds to 1 μm).

The switching field distribution ($h_{25} = 0.15$) is favorably low and almost reaches the theoretical value of 0.13, indicating a still lower contribution compared to the products obtained by coprecipitation and tempering from undesira-

ble processes involving noncoherent reversal of magnetization. By changing the composition of the coprecipitate, substituted ferrites of type *M* can also be obtained. Thus, magnetic pigments having good properties have been obtained in the $BaM_xTi_xFe_{12-2x}O_{19}$ (M = Zn, Ni, or Co) system, a low defined coercive force being established by altering the degree of substitution (cf. Fig. 7). In addition, magnetically soft *Y* ferrites, crystallizing in pronounced platelet form, are obtainable as powders even at 900 °C[154]. It is remarkable that all other hexagonal ferrite phases are obtained only at higher temperatures, even by this reaction-promoting process[35].

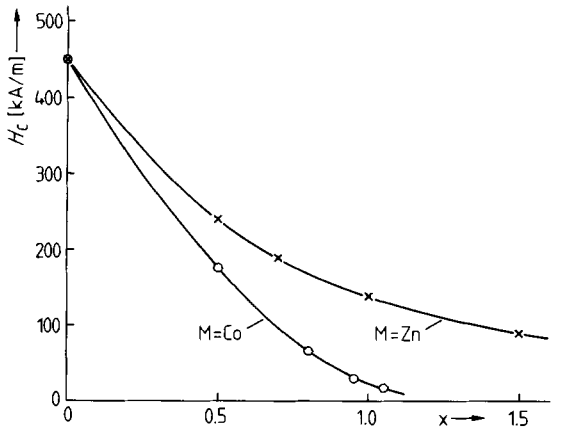

Fig. 7. Variation of the coercive force H_c with the degree of substitution x for $BaM_xTi_xFe_{12-2x}O_{19}$ pigments, where M = Co or Zn.

Platelets of hexagonal ferrites of the *M* and *Y* type may also be produced in a simple manner by directly tempering salt mixtures comprising $BaCO_3$, MCO_3 (*e.g.* "Zn hydroxide carbonate"), $FeCl_3$, Na_2CO_3, and K_2CO_3[155, 156]. In this reaction, finely divided, reactive iron(III) oxide is formed as an intermediate and is continuously dissolved in the eutectic NaCl-KCl melt which forms simultaneously, thus supplying further reaction components. Substituted ferrites are also accessible, and Figure 8 shows a platelet-like *Y* ferrite ($Ba_2Zn_2Fe_{12}O_{22}$).

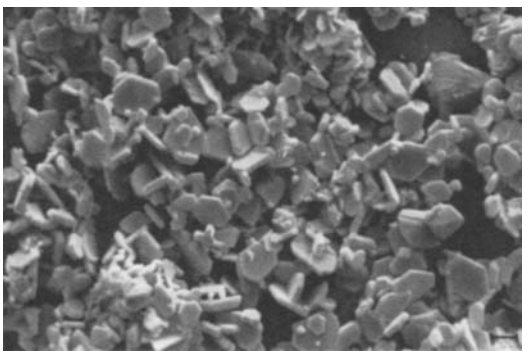

Fig. 8. $Ba_2Zn_2Fe_{12}O_{22}$ (*Y*) obtained by direct tempering of intimate [$BaCO_3$-("Zn-hydroxide carbonate")-$FeCl_3$-Na_2CO_3-K_2CO_3] salt mixtures (the distance indicated corresponds to 2 μm).

In the case of other educts, the two last-mentioned flux processes permit production of ferrite powders with spinel-type structures[157, 158]. Recently other nonmagnetic inorganic solids, *e.g.* lithium aluminate, barium titanate, and alkali metal niobates, have been obtained from alkali metal chloride melts. Ferroelectric lead niobate ceramics containing oriented crystals may be obtained by preparing $PbNb_2O_6$ needles from a eutectic NaCl-KCl melt, followed by doctor blade casting and tempering[159].

In addition to the halides, alkali metal sulfates are also important reaction-promoters for the synthesis of barium ferrite. Thus, $BaCO_3$-Fe_2O_3 mixtures may be converted quantitatively in the presence of a eutectic Na_2SO_4-K_2SO_4 melt at 950 °C into $BaFe_{12}O_{19}$[160]. The disadvantage of this procedure, however, as our own experiments have shown, is that the required excess of barium always forms poorly soluble $BaSO_4$[152].

4.4. Hydrothermal Synthesis of Barium Ferrite Powders

In the hydrothermal preparation of barium ferrite of composition $BaFe_{12}O_{19}$, a dispersion of iron(III) oxide, iron(III) hydroxide, or iron(III) oxide hydroxide is heated for a few hours in an aqueous solution of barium hydroxide to temperatures above the boiling point and below the critical point of water (374 °C). Whereas Fe_2O_3 was initially used as the educt[161], it was possible soon thereafter to obtain improved ferrite preparations by using α-FeOOH (goethite)[162–166]. By this means it is possible to produce barium ferrites having a pronounced platelet habit and mean crystal diameters of about 0.5–2 μm, temperatures above 200 °C being required. The platelet size is dependent on the fineness of the α-FeOOH particles used, and increases with increasing reaction temperature; the crystal diameter may be reduced by using a large excess of barium[166]. According to our own experiments, the products have an extremely broad particle size distribution (see Fig. 9), resulting in a poor switching field distribution.

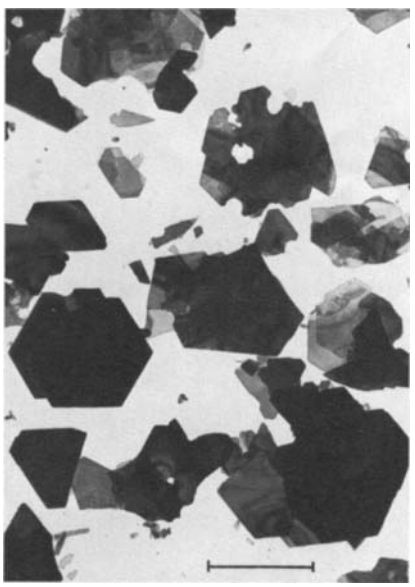

Fig. 9. Hydrothermally produced (300 °C, 8 h, Fe/Ba = 7.9) barium ferrite $BaFe_{12}O_{19}$ obtained from α-FeOOH and $Ba(OH)_2$; specific BET surface area (A_{N_2}) = 3.2 m^2/g (the distance indicated corresponds to 1 μm).

A more recent hydrothermal process starts from $Ba(NO_3)_2$-$Fe(NO_3)_3$-NaOH and involves coprecipitation with excess sodium hydroxide solution[165–167]. Single-

phase, α-Fe_2O_3-free barium ferrite preparations are obtained only in the presence of a small excess of Ba. The required reaction temperature is 150—180 °C, and decreases with increasing alkali concentration. It is remarkable that the particle size may be controlled not only by means of the temperature and the duration of the reaction, but also *via* the barium and NaOH concentrations. Both a high excess of barium and a high excess of NaOH produce, at 160—280 °C, a drastic decrease in the platelet diameter owing to an increased rate of nucleation, and the preparations are obtained with the desired high specific surface areas (cf. Fig. 10)[168]. Unfortunately, the decrease in particle size entails lower coercive forces and specific remanent magnetization and saturation magnetization (cf. Fig. 11). As a result, the material has to be tempered at 500—800 °C to improve the magnetic properties; however, an increase in particle size must be accepted. At 850—1050 °C, maximum H_c values of about 380 kA/m and theoretical values for the magnetizations are attained.

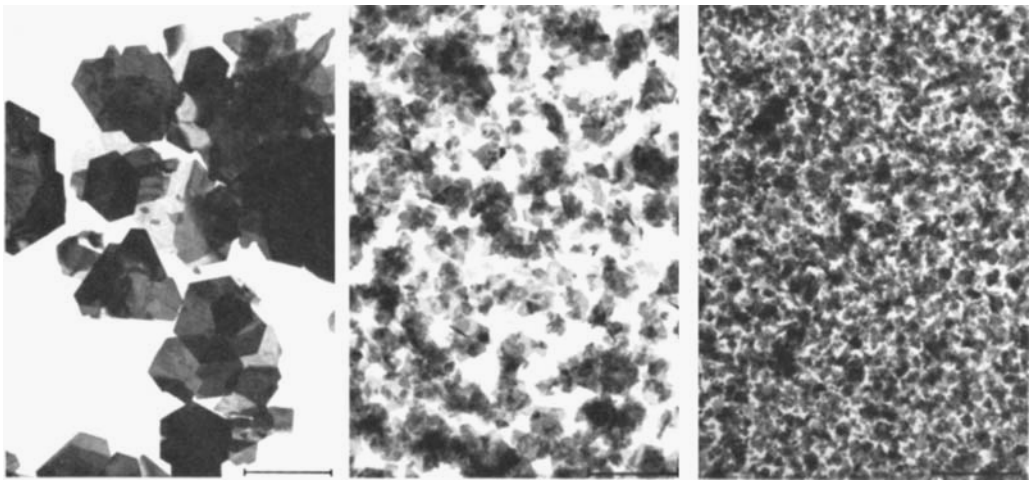

Fig. 10. Hydrothermally produced barium ferrite $BaFe_{12}O_{19}$ obtained from $Ba(NO_3)_2$-$Fe(NO_3)_3$-NaOH coprecipitates (200 °C, 5 h). Left: Fe/Ba = 8.0; NaOH excess = 80 g/L (A_{N_2} = 9 m^2/g). Middle: Fe/Ba = 8.0; NaOH excess = 330 g/L (A_{N_2} = 54 m^2/g). Right: Fe/Ba = 2.9; NaOH excess = 80 g/L (A_{N_2} = 70 m^2/g) (the distance indicated corresponds to 1 μm).

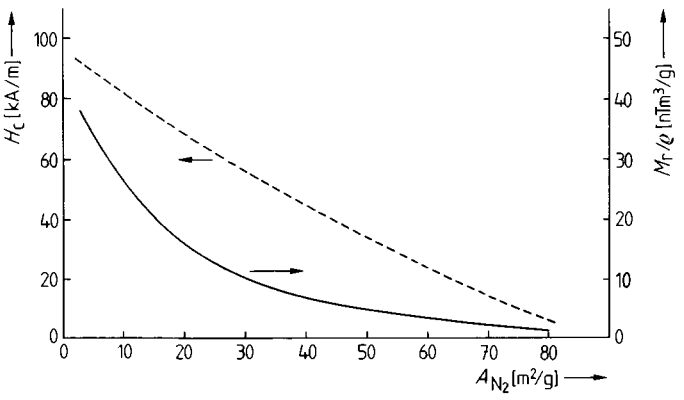

Fig. 11. Decrease in the coercive force H_c (---) and the specific residual magnetization M_r/ρ (—) in hydrothermally produced barium ferrite pigments as a function of the surface area A_{N_2}.

At higher temperatures (300—350 °C), low as well as high concentrations of NaOH give coarse-grained pigments in the hydrothermal process. However, it is remarkable that preparations produced in the presence of high NaOH concentrations are of comparatively high coercive force (almost 300 kA/m) after tempering at 1100 °C, while the powders obtained at low NaOH concentrations give H_c values of only 150 kA/m[168]. The differences in the coercive force may be explained by the narrower particle size distribution of the preparations obtained in the presence of high NaOH concentrations. The hydrothermal production of a substituted *M* ferrite, or of other hexagonal ferrites, has not been described to date.

The hydrothermal synthesis of single-phase $BaFe_{12}O_{19}$ may be complicated by the occurrence of other phases; for example, very finely divided, non-ferrimagnetic particles of composition $BaO \cdot 4.5\,Fe_2O_3$ are formed in the lower temperature range (< 180 °C)[165, 166, 169]. In the preparation of the ferrite from γ-FeOOH and $Ba(OH)_2$, this compound ($BaO \cdot 4.5\,Fe_2O_3$) is formed at the temperature at which γ-FeOOH is usually converted to the α-modification. $BaO \cdot 4.5\,Fe_2O_3$ is also obtained in a well crystallized form by passing air into a strongly alkaline $BaCl_2$-$FeCl_2$-NaOH coprecipitate at atmospheric pressure[170]. Antiferromagnetic hexagonal $BaFe_4O_7$ can be synthesized hydrothermally at 250—300 °C, under a high partial pressure of oxygen[165, 171–174]. Using high concentrations of barium and NaOH, it has recently been possible to isolate a novel metastable compound of composition $BaFe_6O_{10}$ in the form of fine hexagonal platelets[175] (see Fig. 12). The pigment is nonmagnetic and appears to be of interest for producing transparent reddish-orange hues.

Hydrogen may be formed by corrosion when the hydrothermal synthesis is carried out in a steel autoclave, particularly at temperatures in the upper part of the range, and when relatively long reaction times are used. Under the resulting reducing conditions, Fe^{II}-containing ferrites, such as antiferromagnetic $[Ba_8Fe^{II}(OH)_6][Fe^{III}_{12}O_{24}]$[176] and ferrimagnetic $Ba_4[Fe^{III}(OH)_6][Fe^{II}Fe^{III}_7O_{14}]$[177], are formed.

The crystal structure of $[Ba_8Fe^{II}(OH)_6][Fe^{III}_{12}O_{24}]$ is characterized by a three-dimensional network of tetrahedrally linked FeO_4 groups with intercalated $Ba_8Fe(OH)_6^{12+}$ clus-

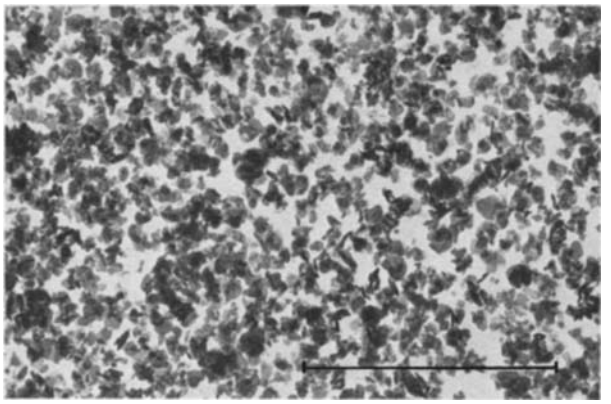

Fig. 12. Hydrothermally produced barium ferrite $BaFe_xO_{19}$ (Fe/Ba = 2.9; NaOH excess = 300 g/L; 170 °C, 8 h) (the distance indicated corresponds to 1 μm).

ters. In contrast $Ba_4[Fe^{III}(OH)_6][Fe^{II}Fe^{III}_7O_{14}]$ exhibits a sheet structure with intercalated Ba^{2+} and $Fe(OH)_6^{3+}$ ions.

In order to suppress corrosive effects, inner vessels of teflon, silver, or platinum have been used, and firmly adhering, pore-free, very thin gold linings produced by explosion plating and applied to the interior wall of the autoclave can also be useful. When silver is used, γ-$AgFeO_2$[179] may also be formed, particularly at high partial pressures of oxygen.

It has been known for some time that ferrites having a spinel-type structure and of composition MFe_2O_4 ($M = Mn^{II}$, Co^{II}, Zn^{II}, Mg^{II}, Fe^{II}, *etc.*) can also be obtained from aqueous solutions at temperatures below 100 °C and under atmospheric pressure. Thus, extremely finely divided isotropic ferrite particles with a spinel-type structure are precipitated when the "neutralization method" or "coprecipitation method" is employed[180, 181], and coarse-grained products of mean particle diameter 0.05 — 1 μm are obtained by the "oxidation method"[182, 183]. However, as shown by our experiments, $BaFe_{12}O_{19}$ cannot be successfully prepared by either method.

5. Prospects

As shown by the example of ferrimagnetic hexagonal barium ferrite, the magnetic properties of a finely divided pigment are determined in the first place by the nature of the bonding, *i.e.* the chemical composition and the crystal structure of the pigment particles. The actual structure of the particles can, in some cases, differ considerably from the ideal crystal structure of the corresponding solid, for example when crystal defects are introduced by milling processes. In addition, the pigment properties are greatly dependent on the state of division of the solid, both the size and shape of the particles and the particle size distribution being of importance. The situation is particularly complicated when the individual pigment particles are not monocrystalline but, in turn, are composed of several monocrystalline regions, and the chemical composition of the monocrystalline regions may differ from those of the grain boundaries.

Finally, the chemistry of the phase boundary solid/binder must also always be taken into account in the development of magnetic pigments in order to achieve, as far as possible, a monodisperse distribution of the pigment particles in the surface-coating, since, when the pigments are used industrially, the physical properties of the information carrier are of decisive importance.

There are therefore two ways of achieving improved or novel pigment properties: on the one hand, chemical preparation of novel solids, and an interdisciplinary investigation of their structural and physico-chemical properties is necessary. On the other hand, methods must be developed by means of which known solids with promising basic properties may be prepared in a pigment form which is optimal for the particular technical requirement. In particular, it is the task of the industrial chemist to work out improved and novel chemical processes and process technologies by means of which the particle geometry and the phase-boundary chemistry may be controlled, and thus the selective adjustment of pigment properties achieved.

I should like to thank Professor Dr. Gruehn for reading the manuscript critically and Dr. Kullmann for the magnetic measurements and discussions.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

A Simple, Highly Variable Route to (1,3-Diynyl)amines**

By *Gerhard Himbert** and *Michael Feustel*

Until now, (1,3-diynyl)amines have practically only been synthesized by base-catalyzed isomerization of (2,4-pentadiynyl)amines and by bromine-amine exchange on 1-bromo-1,3-alkadiynes[2,4]. Both methods have a relatively limited scope of application and necessitate a multistep synthesis of each (1,3-diynyl)amine.

We have now found a route to the (1,3-diynyl)amine system which, in the penultimate step, permits a large variation in the amine residue (see **1**→**2**), and which, in the last step, allows the introduction of a wide choice of electrophiles and electrophilic π-systems into the 4-position of the diynamine (see **2**→[**3**]→**4**). By use of the corresponding lithium amides we have also extended the synthesis of trichlorovinylynamines **2** *via* the readily accessible perchlorobutenyne **1** (only the *N,N*-dialkyl derivatives *e.g.* **2a** had been known before)[7] to compounds with *aryl*amine groups (see **2b** and **2c**) (Table 1).

[a] Hexamethylphosphoric triamide.

The (3-buten-1-ynyl)amines **2** thus obtained are smoothly converted into the lithium compounds **3** using butyllithium (molar ratio 1:2). These are not isolated, but characterized by transformation into **4**; they can be protonated to **4**, alkylated, hydroxyalkylated, acylated[***], carbamoylated, and transformed into heterosubstituted diynamines. Examples are shown in Table 1.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

[***] Note added during revision: In the meantime—independent of us—acylated diynamines ("push-pull diacetylenes") analogous to **4i** have been synthesized using the same route presented here: U. Stämpfli, M. Neunschwander, *Chimia 35* (1981) 336.

The diynamines **4a–k** are thermally stable, mainly crystalline compounds, which are unaffected by storage. The constitution of the diynamines **4**, which with the exception of **4d**[2] are novel compounds, was verified by exact elemental analyses and spectroscopic data: The very intense IR absorptions in the 2188–2228 cm^{-1} region (often accompanied by bands of medium to low intensity at 2065–2153 cm^{-1}), the appearance of the molecular ion in the mass spectra, and of the signals of the four acetylenic C atoms in the sample ^{13}C-NMR spectra of **4c** and **4i** are characteristic. The reactivity of (1,3-diynyl)amines is, with the exception of some hydrolyses[4], unknown; the additions and cycloadditions of electrophilic molecules which we have studied up till now appear to proceed preferentially at the CC triple bond adjacent to the amino group. In contrast, reaction of the stannylated diynamine **4g** with chlorodiphenylarsane afforded the novel diynamine **4j** ($R^3 = AsPh_2$) *via* exchange of the stannyl group.

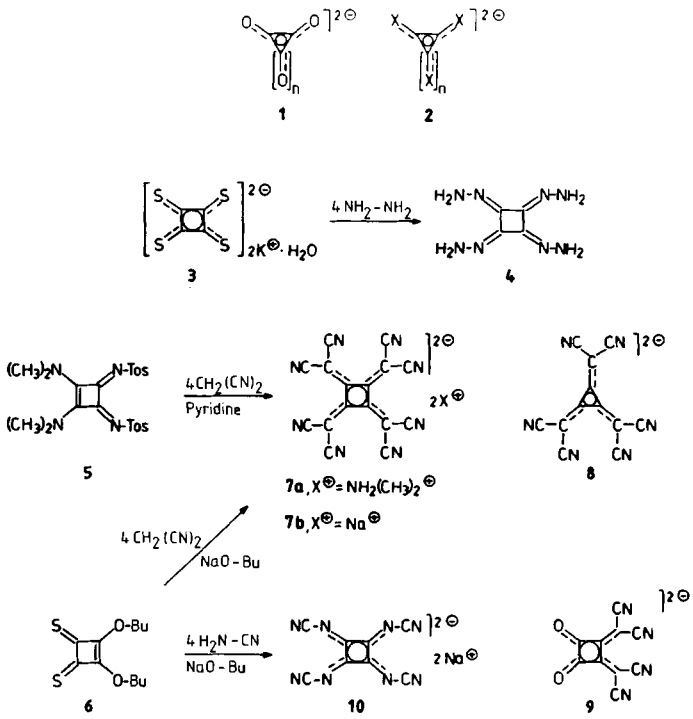
Novel Pseudooxocarbon Dianions of the C_4 Series**

By *Gunther Seitz**, *Rudianto Sutrisno*, *Bernd Gerecht*, *Guido Offermann*, *Roland Schmidt*, and *Werner Massa*

Exchange of the oxygen atoms in oxocarbon dianions **1** by substituents X = S, NR, or =C(CN)$_2$ leads to pseudooxocarbon dianions **2** having similarly delocalized π-electron systems[1]. We have now found that by analogy to the hydrazinolysis of the thiooxocarbon dianion **3** of the C_4 series to give the tetraaza[4]radialene **4**[3], the highly reactive squaric acid derivatives **5** and **6** permit a complete exchange of substituents in only one step with C- or N-nucleophiles. Thereby, novel pseudooxocarbon dianions of the C_4 series such as **7a** and **7b** are formed with malondinitrile and a base, and the first isolable, air-stable salt of the iminocarbon dianion **10**[9a,b] is formed in excellent yield using cyanamide.

The spectroscopic data confirm the high symmetry of these novel aromatic dianions: **7a**: ^{13}C-NMR ([D$_6$]DMSO): δ = 149.6 (four-ring C), 117.6 (CN), 39.7 (*C*—CN), 34.4 (NCH_3); IR (KBr): 2200 (CN), 1440 cm^{-1} (four-membered ring); UV (H_2O): λ_{max} = 484 nm (lgε = 4.69). — **10**: ^{13}C-NMR ([D$_6$]DMSO): δ = 173.2 (four-membered ring C), 117.5 (CN); IR (KBr): 2178 (CN), 1510 cm^{-1}; UV (H_2O): λ_{max} = 376 nm (lgε = 4.6).

A high charge-density on the exocyclic methylene carbon atoms of **7a** is evident from their ^{13}C-NMR shift,



which is comparable to that of the dianion **9**[7] at δ = 38.0; the extreme value of δ = 24.8 for the next lower homologue of **7**, the pseudooxocarbon dianion **8**[8] is, understandably, not reached.

The X-ray structure analysis of **7a** indicates that the point group symmetry of the dianion is only C_2; the two-fold axis lies *in* the plane of the molecule. The dianion is twisted to such an extent that even the four-membered ring is no longer planar (Fig. 1b). Steric hinderance does not

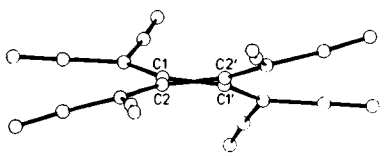


Fig. 1. b) ORTEP representation of the dianion of **7a** in the crystal; view along the two-fold axis.

lead, therefore, to a propeller-like arrangement of the substituents but rather to a tetrahedral distortion. From the bond lengths of the endocyclic [⟨C—C⟩ = 145.3(5) pm] and semicyclic C—C bonds [⟨C—C⟩ = 138.7(9) pm], a π-bond character typical of pseudooxocarbon dianions comparable to that of squarates or tetrathiosquarates, can be derived[1].

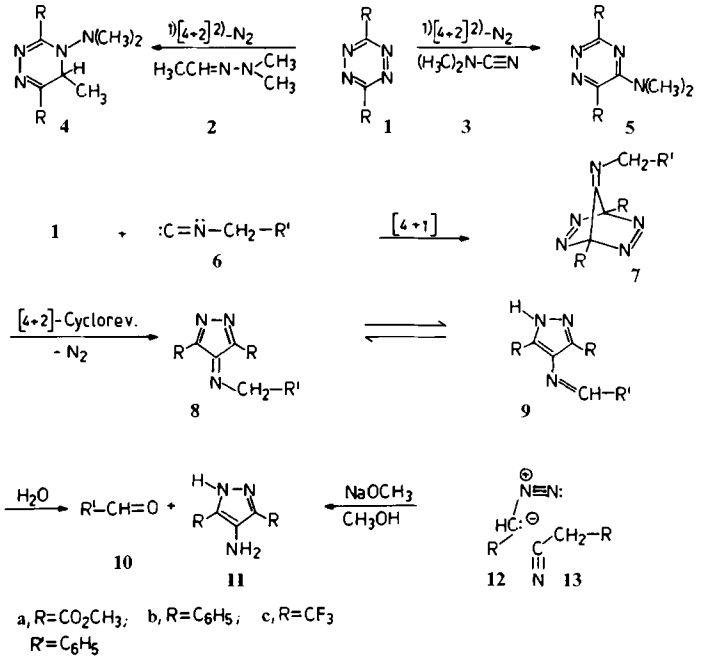
[4+1]Cycloaddition of Isocyanides to 1,2,4,5-Tetrazines: A Novel Synthesis of Pyrazole

By *Peter Imming, Rolf Mohr, Eric Müller, Wolfgang Overheu,* and *Gunther Seitz**

The high reactivity of 1,2,4,5-tetrazines **1** relative to donor-substituted CN multiple bonds[1] such as in the hydrazones **2** or cyanamides **3** makes amine-substituted triazines **4** and **5** respectively, surprisingly readily accessible by Diels-Alder addition with inverse electron demand[2]. We have found that the C=N functionality in isocyanides **6** behaves differently: the reaction of **1a—c** with benzyl isocyanide **6** is the first example of a synthesis in which five-membered heterocycles result from a [4+1]cycloaddition and subsequent [4+2]cycloreversion.



In the initial step, the previously only rarely achieved[3] [4+1]cycloaddition of **6** to **1**, in which the azine system is *s-cis*-fixed, should dominate over a [4+2]cycloaddition. The non-isolable tetraazanorbornadienimine derivative **7**, whose high angular strain causes elimination of nitrogen *via* a [4+2]cycloreversion[4] in a rapid subsequent reaction, is formed; the resulting energy-rich diazacyclopentadienonimine derivative **8** rapidly tautomerizes to the aromatic pyrazole **9**. Hydrolysis of **9a—c** leads quantitatively to the pharmacologically interesting aminopyrazoles **11a—c**. The structures of **11a** and **11b** were confirmed by independent synthesis[5]. Hence, *e.g.*, condensation of **12a** and **13a** also led, after transesterification to **11a**, although in considerably lower yield.

Procedure

9a—c: 1a—c (5 mmol) is dissolved in 20 mL of anhydrous dichloromethane, and a solution of **6** (5 mmol) in 10 mL of dichloromethane added dropwise at *ca.* 0 °C; the mixture is left to react until the red color of **1** has disappeared. **9a** (m.p. = 161 °C, ethyl acetate, yield 65%) as well as **9c** (m.p. = 180—181 °C, carbon tetrachloride, yield 75%) are obtained after concentration; crystals of **9b** (m.p. = 220 °C, ethyl acetate, yield 70%) precipitate out after a short time.

11a, b: 9a is completely hydrolyzed to **11a** (m.p. = 185 °C, ethyl acetate, yield 95%) by addition of water. **9b** is hydrolyzed by heating for a short time in conc. hydrochloric acid. Treatment of the hydrochloride with an aqueous solution of potassium carbonate led quantitatively to **11b** (m.p. = 208 °C, ethanol).—**9** and **11** gave correct C,H,N analysis results and appropriate spectra (MS, IR, ^{1}H-NMR).

A Novel Anionic Five-Coordinate Tris(trichlorostannato)platinum(II) Complex**

By *Alberto Albinati, Ralph Nägeli, Heinz Rüegger,* and *Paul S. Pregosin**

Trichlorostannato complexes of platinum(II) are recognized as useful hydrogenation and hydroformylation catalysts[1]. Although the exact composition of the active species is not clear, it is known that the catalyst functions optimally when the ratio Sn : Pt exceeds five, and therefore poly(trichlorostannato) derivatives may be important intermediates. We have recently shown that mono- and bis(trichlorostannato)platinum(II) complexes containing either tertiary phosphane or arsane ligands are stable in solution[4,6], and now report the synthesis and characterization of the anion

$[Pt(SnCl_3)_3(AsMe_3)_2]^{\ominus}$ **1**

which was isolated as its bis(triphenylphosphorandiyl)ammonium salt ($N(PPh_3)_2^{\oplus}$, PPN).

The PPN salt of **1** and its $AsEt_3$ analog **2** are readily prepared by the reaction of *cis*-$[PtCl_2L_2]$ with $SnCl_2$ (molar ratio 1 : 3) in acetone. Pertinent NMR data for the PPN salt of **1** ($CDCl_3$, −40 °C) are: $\delta(^{119}Sn) = -67$, $\delta(^{195}Pt) = -5364$, $\delta(^{13}C) = 19.7$, $^1J(^{195}Pt,^{119}Sn) = 19037$ Hz, $^2J(^{119}Sn,^{117}Sn) = 17504$ Hz; PPN salt of **2** ([D_6]acetone, −70 °C): $\delta(^{119}Sn) = -79$, $\delta(^{195}Pt) = -5400$, $^1J(^{195}Pt,^{119}Sn) = 19788$ Hz, $^2J(^{119}Sn,^{117}Sn) = 18115$ Hz.

[**] *H. R.* thanks the ETH for a fellowship.

Interestingly, in the related $[Pt(SnCl_3)_3(PEt_3)_2]^{\ominus}$, which we assume has the same structure as **1**, $^1J(^{195}Pt,^{31}P)$ is only 1460 Hz. The Pt- and Sn-NMR parameters are similar to those for **1** and **2**. This $^1J(^{195}Pt,^{31}P)$ value is quite modest when compared to the values of 2400–2600 Hz often found in *trans*-$[PtCl_2(PR_3)_2]$ complexes and still much smaller than the value 2014 Hz found in the five-coordinate tetradentate chelate complex $[Pt(SnCl_3)\{P(o\text{-}AsPh_2C_6H_4)_3\}]$ in which P and Sn occupy pseudoaxial positions. This suggests a relatively weak Pt—P bond in the anion $[Pt(SnCl_3)_3(PEt_3)_2]^{\ominus}$.

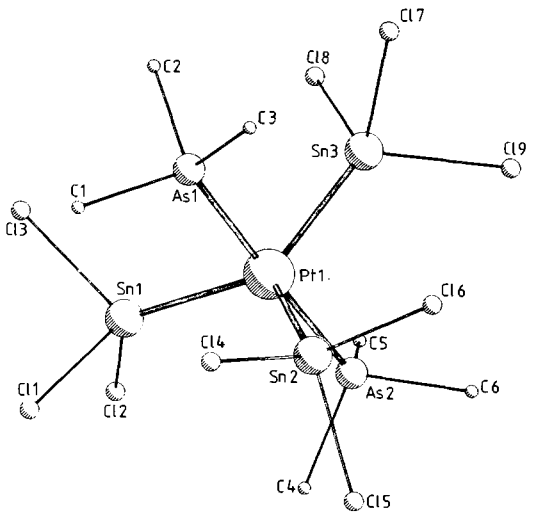

Fig. 1. Structure of anion **1** in crystals of the PPN salt of **1**. Bond lengths [pm]: PtAs1 244.5(2), PtAs2 242.7(2), PtSn1 261.2(1), PtSn2 261.4(2), PtSn3 257.9(1), SnCl 238.0±1.0(7) (average value).—Bond angles [°]: As1PtAs2 177.7(6), Sn1PtSn2 117.1(4), Sn1PtSn3 122.9(4), Sn2PtSn3 119.9(5), As1PtSn1 88.6(1), As1PtSn2 90.7(1), As1PtSn3 88.4(1), As2PtSn1 92.5(1), As2PtSn2 90.6(1), As2PtSn3 89.2(1).

The coordination geometry around the Pt atom in **1** (Fig. 1) is distorted trigonal bipyramidal, with the $AsMe_3$ ligands in axial positions. The average PtSn bond length is 260.2±2.0(1) pm. This is slightly larger than the average equatorial PtSn bond lengths in $[Pt(SnCl_3)_5]^{3\ominus}$ **3** (257.2)[10], but considerably longer than the PtSn bond in $[PtCl(SnCl_3)(PhC(NH_2)=NOH)(PEt_3)]$ **4** (250.1)[11]. The average PtAs distance in **1** is also quite long (243.6±1.3(2) pm) relative to that in the complexes *sym-trans*-$[Pt_2Cl_4(AsMe_3)_2]$ (230.8) and *trans*-$[PtCl_2N(CH_3)=CH-(p\text{-}CH_3C_6H_4)(AsEt_3)]$ (234.6). The SnCl bonds in **1** average 238.0±1.0(7) pm and are in good agreement with the value of 237.2 pm found for the equatorial $SnCl_3$ ligands in **3**, but longer than the SnCl bonds in **4** (234.0).

Given the rather long PtSn and PtAs bond lengths in **1** and the small coupling constant $^1J(^{195}Pt,^{31}P)$ for the PEt_3 complex, ligand dissociation is not unexpected. It is probable but not certain that an $SnCl_3^{\ominus}$ ligand leaves the coordination sphere of Pt to produce the known $[Pt(SnCl_3)_2L_2]$ complex.

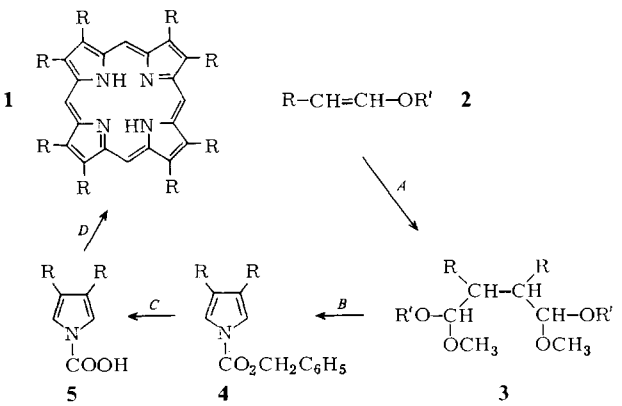
Novel Synthesis of Octaalkyl- and Octaisoalkylporphyrins

By *Henry Jacques Callot**, *Abderrazak Louati*, and *Maurice Gross*

Octaalkylporphyrins and particularly octaethylporphyrin **1a** are the simplest and most useful models for natural porphyrins, and are accessible through multistep syntheses[1]. We have now found an alternative reaction sequence (Scheme 1) which takes advantage of the symmetry of the products and their precursors, and which permits for the first time, the synthesis of an octaisoalkylporphyrin, the isopropyl derivative **1c**.



Scheme 1 (Section). Synthesis of octaalkylporphyrins **1a** and **1b** and octaisoalkylporphyrin **1c** [**a**, R=C_2H_5; **b**, R=*n*-C_4H_9; **c**, R=$CH(CH_3)_2$]. *A*: anodic oxidation in methanol/$NaClO_4$/2,6-lutidine; *B*: benzyl carbamate in acetic acid (isolation of **3** not necessary); *C*: H_2/Pd in methanol; *D*: formaldehyde/O_2/acetic acid/pyridine. R'=C_2H_5.

Anodic oxidation[2] of alkenyl alkyl ethers **2a–c** gave acetals **3a–c**, which were cyclized to afford pyrroles **4a–c** using benzyl carbamate in acetic acid [**4a**, yield 27%, m.p. <20 °C, ^{1}H-NMR ($CDCl_3$): δ=1.15 (t; 6H), 2.36 (q, 4H), 5.28 (s, 2H), 6.99 (s, 2H), 7.35 (s, 5H)]. The unstable acids **5a–c** obtained by removal of the protecting groups react with formaldehyde in presence of air[3] to furnish octaethyl- **1a**, octabutyl- **1b**, and octaisopropylporphyrin **1c** (yields relative to **4**: 52, 35, and 43%, respectively).

One-Pot Synthesis of 1-Alken-5-yne Derivatives[1]

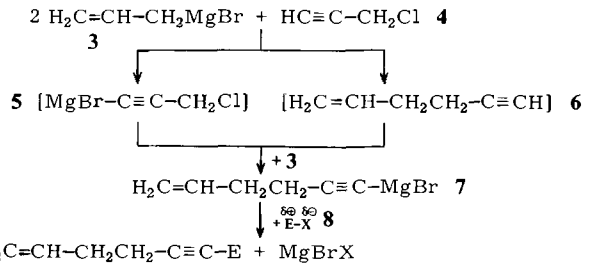
By *Hanno Priebe* and *Henning Hopf**

Propargyl halides **1** metalated in the 3-position are equivalent to the zwitterion **2**, a species suitable for use as a functionalized C_3-synthon for the synthesis of complicated carbon frameworks since it should couple with both electrophilic and nucleophilic substrates:

1 $M-C\equiv C-CH_2-Hal \triangleq {}^{\ominus}C\equiv C-CH_2^{\oplus}$ **2**

As shown by the following one-pot reaction for the synthesis of 1-alken-5-yne derivatives **9**, this is indeed the case even if the reactive centers in **1** are not activated simultaneously, but successively. The compounds (see [2]) can be readily prepared if *two* equivalents of allylmagnesium bromide **3**[3] react first with propargyl chloride **4**[4].

Thereby 5-hexen-1-ynylmagnesium bromide **7** is formed in almost quantitative yield *via* **5** (type **1/2**) or **6**; **7** reacts with electrophilic reagents **8** to give the desired products **9**[5].



E—X **8**	—E in **9**	Yield [%]
H_2O	—H	93
CH_2O	$-CH_2OH$	18
CH_3CHO	$-CH(OH)CH_3$	50
C_2H_5CHO	$-CH(OH)C_2H_5$	32
$(CH_3)_2CH-CHO$	$-CH(OH)-CH(CH_3)_2$	45
$H_2C=CH-CHO$	$-CH(OH)-CH=CH_2$	31
$(CH_3)_2C=O$	$-C(OH)(CH_3)_2$	83
$(CH_2)_4C=O$	$-C(OH)(CH_2)_4$	35
$H_2C=CH-CO-CH_3$	$-C(OH)CH_3(CH=CH_2)$	22
$(CH_3)_2N-CHO$	—CHO	15
$(CH_3CO)_2O$	$-CO-CH_3$	17
CO_2	$-CO_2H$	63
$(CH_2)_2O$	$-CH_2CH_2-OH$	13

A first impression of the scope of application of the method is given by the tabular summary of reactions, whose yields except for the reaction of **7** with acetone have not been optimized. The Grignard reagent **3** and the coupling component **4** can be varied: for example, ethylmagnesium bromide, **4**, and acetaldehyde produce 3-heptyn-2-ol (22%)[5]; 7-octen-3-yn-2,5-diol (36%) is formed from **3**, propionaldehyde, and acetyldehyde.

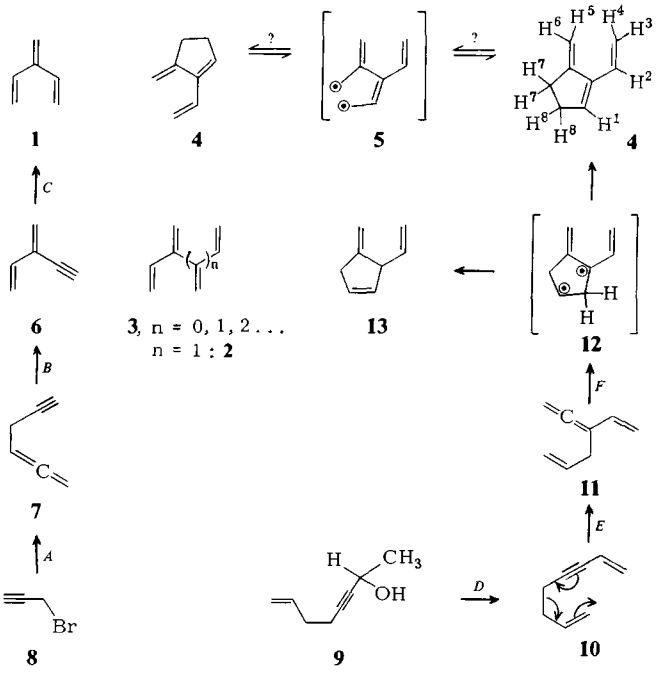
Cross-Conjugated Trienes by Thermal Isomerization of Alkynes[1]

By *Hanno Priebe* and *Henning Hopf**

Although simple cross-conjugated polyolefins such as 2-vinyl-1,3-butadiene **1** and 3,4-bis(methylene)-1,5-hexadiene **2** (≡ **3**, n = 1) have been known for some time, the homologous series of hydrocarbons **3** ("dendralenes") beginning with these substances has been neglected until now[5].

For the synthesis of dendralenes, classical reactions such as eliminations and condensations[5] are preferred. In addition to a novel route to **1**, we also report the synthesis of the conformationally partially fixed 2-vinylbutadiene **4**. Both syntheses are related to each other in the sense that the educts already contain the desired number of π-electrons and carbon atoms. Compound **4** is of interest for the investigation of a novel degenerate 8π-isomerization (automerization) *via* diradical **5**.



A: 1. Mg/ether, 2. CuCl, 3. + **8** (60% total yield); *B*: 500 °C, 49%; *C*: Lindlar-H_2, 60%; *D*: TsOH, 120–150 °C/100 torr, 24%; *E*: 400–500 °C; *F*: 440 °C. ^{1}H-NMR data for **4** ($CDCl_3$): $\delta = 2.43$ (m; $2H^8$), 2.64 (m, $2H^7$), 4.84 (m, H^6), 4.99 (dtt, H^5, $J_{57} = 2.6$, $J_{58} = 1.1$ Hz), 5.17 (dm, H^4), 5.53 (dm, H^3), 6.21 (ps, H^2), 6.39 (dddt, H^1, $J_{13} = 17.6$, $J_{14} = 11.1$, $J_{18} = 0.8$, $J_{12} = 1.1$ Hz).

For the preparation of **1**, propargyl bromide **8** is dimerized to 1,2-hexadien-5-yne **7**, which is subsequently isomerized at 500 °C to 2-ethynyl-1,3-butadiene **6**; Lindlar hydrogenation of **6** then affords **1**[5].

The starting material for **4** is 1,7-octadien-3-yne **10**, which is obtained from the alkenynyl alcohol **9**[9] by acid

[*] Prof. Dr. H. Hopf, H. Priebe
Institut für Organische Chemie der Technischen Universität
Schleinitzstrasse, D-3300 Braunschweig (Germany)

catalyzed dehydration. **10** isomerizes to the allene **11** *via* a Cope rearrangement (400—500 °C). As expected[10] **11** reacts to give the diradical **12**, which stabilizes itself by a 1,2-hydrogen shift to yield **4** and its nonconjugated isomer **13**. Whereas at 440 °C, 44% **4** and 52% **13** are produced (rest **10** and **11**, GC), **13** is practically the only rearrangement product at 500 °C (93%, rest **4**).

The structural assignments for **4** are based on ^{1}H- and ^{13}C-NMR data, as well as on vibrational- and electronic-spectra [acetonitrile, $\lambda_{max} = 252$ nm ($\log\varepsilon = 3.7$)]. In comparison to the conformationally less restricted **1** [$\lambda_{max} = 224$ nm ($\log\varepsilon = 4.4$)], **4** exhibits a bathochromic shift which almost corresponds to that of the completely fixed 3-methylene-1,4-cyclohexadiene [$\lambda_{max} = 242$, sh at 247 nm ($\log\varepsilon = 4.4$[12])].

Pyrolyses of methyl derivatives of **10** result in the corresponding derivatives of **4** and **13**. Moreover, since a further cross-conjugated triene (1,2-dihydropentalene) can be synthesized by thermal rearrangement of 1,2-diethynylcyclobutane, the thermal rearrangement of alkynes promises to become a useful method of preparing branched polyolefins.

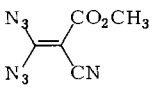
Geminal Vinyl Diazides: Potential Precursors of Functionalized Alkylidenecarbenes; Synthesis and Reactions of 3,3-Diazido-2-cyanoacrylic Acid Methyl Ester**

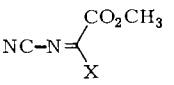
By *Robert Carrié, Daniel Danion, Erich Ackermann,* and *Rolf W. Saalfrank**

So far very little is known about heterosubstituted[4] or functionalized[5] unsaturated carbenes. We have now investigated 3,3-diazido-2-cyanoacrylic acid methyl ester **6** as potential precursor of cyano(methoxycarbonyl)vinylidene **13**.

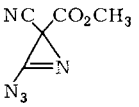
A solution of 0.5 g of 3,3-dichloro-2-cyanoacrylic acid methyl ester[9] in a small amount of acetone is added at −15 °C to an excess of sodium azide dissolved in acetone/water (1 : 1). After a few seconds spectroscopically pure, pale yellow-green crystals of the ester **6** precipitate from the solution [UV (CH_3OH): $\lambda_{max} = 304$, 244 nm ($\lg\varepsilon = 4.34$, 4.10)].



6



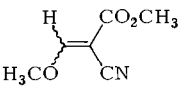
7, X = OCH_3
10, X = CN



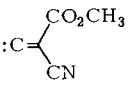
9

On addition to methanol at just below the boiling point **6** decomposes with vigorous evolution of N_2; subsequent removal of methanol and recrystallization of the residue from diethyl ether afford colorless crystalline 2-(*N*-cyanimino)-2-methoxyacetic acid methyl ester **7** [yield 75%; m.p. 54 °C; ^{1}H-NMR ($CDCl_3$): $\delta = 3.96$, 4.00 (s, 6H, CH_3); ^{13}C-NMR ($CDCl_3$): $\delta = 54.36$, 57.94 (q, CH_3; $^1J_{CH} = 150$ Hz), 110.23 (s, CN), 155.38, 164.57 (q, C=N— and C=O resp., $^3J_{CH} = 4$ Hz].

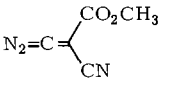
We assume that on heating, **6** initially undergoes a 3,5-ring-closure with N_2-elimination[13]. The resulting azidoazirine **9** then undergoes further loss of N_2 and rearrangement to form the ester **10**[15], which, on addition of methanol and elimination of hydrogen cyanide affords **7**. The intermediate **10** can be trapped with 2,3-dimethylbutadiene to give a tetrahydropyridine derivative *via* a Diels-Alder reaction.



12



13



16

Irradiation (3 h, Original Hanau, high-pressure radiation lamp TQ 150) of **6** in methanol at −30 °C affords **7** (70%) together with the photoproduct **12** (30%).

The 2-cyano-3-methoxyacrylic acid methyl ester **12** probably results from an insertion of the intermediate alkylidenecarbene **13** into the H—O bond of methanol. It is still unclear, however, which other intermediates are involved in the formation of **13**. A further possible route to the vinyl ether **12** is the addition of methanol to the diazoethene **16**[6] to give the corresponding vinyldiazonium methoxide, followed by decomposition.

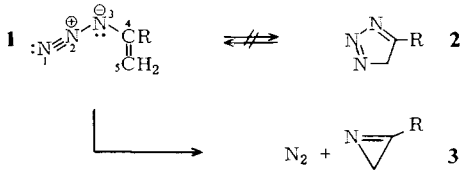
Substituent-Dependent Competition between 1,5- and 3,5-Cyclization in Vinyl Azides; 4*H*-Triazoles from 3,3-Diazido-2-cyanoacrylic Acid Methyl Ester and Primary Amines**

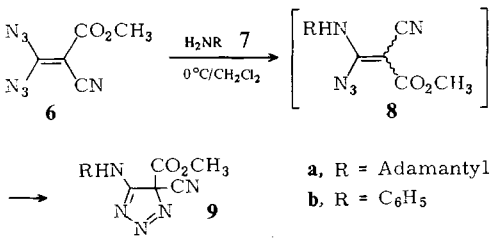
By *Robert Carrié, Daniel Danion, Erich Ackermann,* and *Rolf W. Saalfrank**

Vinyl azides **1** do not generally cyclize to 4*H*-triazoles **2**. Instead, they eliminate N_2 and yield 2*H*-azirines **3**[1,2]. For formation of **3**, a 3,5-ring-closure of **1** with simultaneous N_2-elimination (no free nitrene) is favored.



Introduction of an electron donor into position 4 of **1** leads to increased nucleophilicity at C-5 and lowers the rotation barrier of the CC double bond. Hence, a 1,5-ring-closure should be possible, to give the 4*H*-triazole.

Reaction of 3,3-diazido-2-cyanoacrylic acid methyl ester **6** with amines **7** in dichloromethane at 0 °C leads to the 4*H*-triazoles **9**. We assume that **6** reacts with the amines by nucleophilic substitution to give the donor-substituted vinyl azides **8**, which spontaneously cyclize to **9**[3] [**9a**, yield 60%; m.p. 121 °C (dec.); ^{1}H-NMR ($CDCl_3$): $\delta = 1.66-2.03$ (m, 15 adamantyl-H), 3.73 (s, 3H, CH_3), 9.35 (s, 1H, NH); **9b**, yield 61%; m.p. 84 °C (dec.); ^{1}H-NMR ($CDCl_3$): $\delta = 3.66$ (s, 3H, CH_3), 7.22 (m, 5H, C_6H_5), 10.96 (s, 1H, NH)].



a, R = Adamantyl
b, R = C_6H_5

At 35 °C, **6** reacts completely differently: It rapidly decomposes on heating; double N_2-elimination and rearrangement lead initially to 2-cyano-2-(*N*-cyanimino)acetic acid methyl ester[4], which on addition of aniline or 1-naphthylamine and elimination of hydrogen cyanide affords *N*-aryl-2-(*N*-cyanimino)glycine methyl ester.

Orbital Symmetry Analysis of Triplet-Singlet Spin-Flip during Thermal Isomerization of Tetrahedral to Planar Nickel(II) Complexes**

By *E. Amitai Halevi** and *Rudolf Knorr**

Ni^{II} ($3d^8$) may form (pseudo)tetrahedral, paramagnetic or planar, diamagnetic complexes, whose mutual interconversion requires a spin change of $\Delta S = 1$. Although this might, therefore, be expected to be a slow process, numerous examples[1,2] of such triplet-singlet interconversions have been reported to be immeasurably fast, and in only a few cases could the two species be resolved, or stable enantiomers be detected by ^{1}H-NMR spectroscopy.

We have studied this isomerization by means of Orbital Correspondence Analysis with Maximum Symmetry (OCAMS)[20b,c], extended to reactions which do not conserve spin-multiplicity[21] and with consideration of reduction of symmetry along degenerate displacement coordinates[22a].

The reaction starts by a nuclear displacement belonging to the representation E of the tetrahedral symmetry point group, T_d. Choosing the three equivalent C_2-axes as the Cartesian axes and focusing attention on the z-axis, the two degenerate modes of E-symmetry can be described[22a] as z-compression (S_a) and "z-twist" (S_b) (Fig. 1).

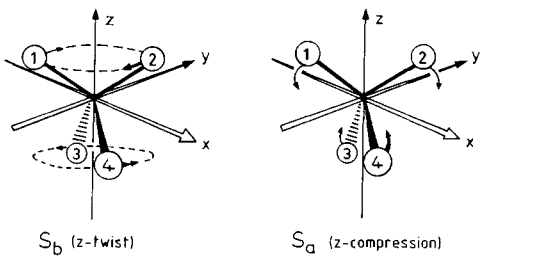

Fig. 1. The two degenerate (e) deformations of a tetrahedral molecule.

The correspondence diagrams for the two pathways are set up in Fig. 2. The *kernel* symmetry, D_2, is either achieved directly by twisting the tetrahedral complex along S_b, or stepwise: $T_d \rightarrow D_{2d}^z \rightarrow D_2$. The first step, S_a^{-1}, in which the angles between ligands ① and ② and between ③ and ④ *decrease* towards 90°, corresponds to chelation. The twist of the resulting bischelate leads to D_{2h} symmetry, and fur-

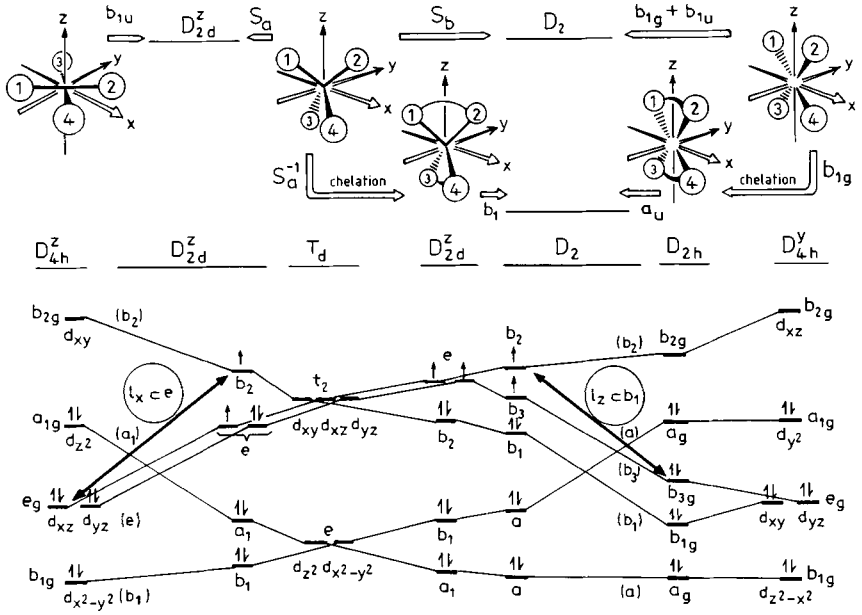

Fig. 2. Correspondence diagrams for tetrahedral to planar isomerization of nickel(II) complexes. Left: along compression coordinate (S_a). Right: along twist coordinate (S_b), with or without chelation (see text).

ther dechelation to the D^y_{4h} point group. Twisting the planar complex in the opposite direction can also be accomplished in two steps. Thus, the correspondence diagram for the S_b pathway is $T_d \rightleftharpoons (D^z_{2d}) \rightleftharpoons D_2 \rightleftharpoons (D_{2h}) \rightleftharpoons D^y_{4h}$. For a nonchelated complex, the group labels enclosed in parentheses can be regarded as "virtual symmetries".

Following the twist pathway S_b we see that three of the doubly-occupied 3d orbitals in the planar complex correspond directly in D_2 with the three doubly-occupied orbitals of the tetrahedral complex. The fourth, d_{yz}, corresponds directly with one of the singly-occupied b_3 orbitals, whereas the other (b_2) corresponds with the empty d_{xz} orbital (b_{2g}). If the ground state of the (pseudo)tetrahedral complex were a *singlet* of the same electron configuration (*i.e.* open shell), OCAMS[20b] would prescribe an *induced* correspondence between $d_{xz}(b_2)$ and $d_{yz}(b_3)$ in order to allow transfer of an electron from one to the other. However, the requisite nuclear displacement along a b_1 coordinate implies the excitation of at least one of the high-energy t_2 vibrational modes of the tetrahedral molecule, which would raise the activation energy of the spin-conservative isomerization, thus rendering it "disallowed".

Since the transfer of an electron between d_{xz} of the tetrahedral triplet and d_{yz} of the planar singlet is accompanied by spin-flip, the b_1 perturbation of symmetry need not be limited to vibrations, but can be a *circulation of charge* in the xy-plane, which generates a magnetic moment about the z-axis and allows formation or annihilation of the z-component of the spin triplet with conservation of total (orbital *plus* spin) angular momentum[21]. Isomerization with spin-flip is "allowed" along the S_b pathway for chelated and nonchelated complexes alike, in the sense that a spin-orbit coupling component exists which has the proper symmetry (b_1 of D_2) to permit the spin-flip to occur.

The compression pathway (S_a) is also "allowed", but—of course—only for nonchelated complexes: as the tetrahedral triplet distorts slightly to D^z_{2d}, the ^3E state, with one electron in b_2 and the other in e, is stabilized. The perturbation required to induce one-electron correspondence between a b_2 and an e orbital would be of symmetry species e. Transfer of an electron from d_{xy} to one of the degenerate e orbitals (d_{xz} or d_{yz}) can be induced by rotation of charge about x or y (also of symmetry species e), annihilating the spin of the x or y component of the triplet[21] and producing the square planar singlet.

Synthesis and Properties of *N*-[1-(Arylcarbonyloxy)alkyl]pyridinium Salts**

By *Ernst Anders** and *Thomas Gassner*

Little is known about the reaction of carbonyl compounds with acyl chlorides in pyridine. Ketones such as acetophenone react only slowly with benzoyl chloride in pyridine to give, particularly, 4-substituted 1-acyl-1,4-dihydropyridines, as well as tar-like by-products in low yield[1]. Addition products of some aldehydes have not been more thoroughly described[2]. We found that the *N*-[1-(arylcarbonyloxy)alkyl]pyridinium chlorides **4** are formed at room temperature in 75—90% yield from aldehydes **3** and arene carboxylic acid chlorides (*e.g.*: **4b**, $R^1 = R^2 = C_6H_5$, m.p. = 169 °C, ν(CO) = 1740 cm^{-1}; **4d**, $R^1 = C_6H_5$, $R^2 = n$-

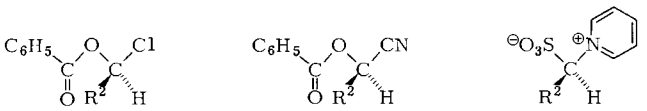
R^1 = Aryl; R^2 = Aryl, Alkyl

C_3H_7, m.p. = 90 °C, ν(CO) = 1730 cm^{-1}). Some of the chlorides **4** are hygroscopic, and frequently can only be prepared in analytically pure form with one mol of water of crystallization. The salts of **4** with BF_4^-, $SbCl_6^-$, and FSO_3^- instead of Cl^-, do not have this property, and can be readily prepared from the chlorides **4**.

The salts **4** can be stored for several months at room temperature, and are readily soluble and stable in aqueous hydrochloric acid. In aqueous alkali (even at room temperature in aqueous $NaHCO_3$) they decompose to the starting materials; the aldehydes **3** can be reisolated in good yield. Secondary reactions of the aldehydes were not observed. Reaction (a) therefore offers a straightforward method of protecting the aldehyde group against attack by acids.

At higher temperature the exchange of the pyridine ring in **4** ($R^1 = C_6H_5$) by chloride ion occurred; the corresponding α-chlorobenzyl benzoates **5a**[6] are distilled out *in vacuo*



5a, R^2 = C_6H_5 **5b**, R^2 = Aryl, Alkyl **6**, R^2 = Aryl

from the reaction mixture. *O*-acylated cyanohydrins **5b** can be prepared under particularly mild conditions (25 °C, water) using KCN, and the novel betaines **6** can be synthesized with $KCN/NaHSO_3$.

With tributyl- or triphenylphosphane[9], instead of pyridine [eq. (a)] we obtained the phosphonium salts **7**, which have not been specifically studied before (**7a**, $R^1 = p$-$CH_3OC_6H_4$, $R^2 = p$-$CH_3C_6H_4$, $R^3 = n$-C_4H_9, ν(CO) = 1730 cm^{-1}; **7b**, $R^1 = R^2 = R^3 = C_6H_5$, ν(CO) = 1740 cm^{-1}). For example, **7a** reacts with cyanide to give an analogue of **5b**.

These salts **7** derived from aldehydes can be deprotonated under mild conditions (**7b** *e.g.* at −55 °C in tetrahydrofuran) using sodium bis(trimethylsilyl)amide to give the phosphorane **8**. **8** *in situ* with aldehydes reacts immediately to give the enol ester **9**, which as expected readily undergoes saponification to afford the ketone **10**. The reaction

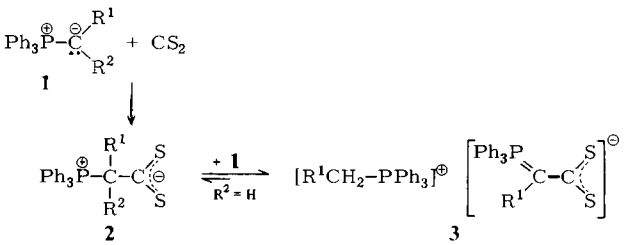
2-Methyl-2-triphenylphosphoniodithiopropionate—A Photosensitive Complex Ligand with Labile P—C Bond**

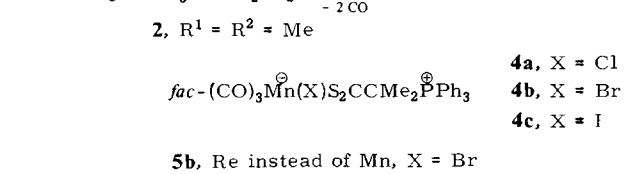
By *Udo Kunze**, *Reinhard Merkel*, and *Werner Winter*

Alkylidenephosphoranes attack heteroallenes nucleophilically[1]. Until now, nothing was known about the complex chemical properties of the initially formed betaines. With carbon disulfide only the disubstituted ylides **1** give stable betaines **2**[4,5]; ylides **1**, R^1 and/or $R^2 = H$, usually react spontaneously to yield phosphonium salts **3**[4].



1 2 3

Reaction of **2**, $R^1 = R^2 = CH_3$, with pentacarbonylmanganese halides (molar ratio 1 : 1 in tetrahydrofuran, 1—3 d stirring) under conditions of strict exclusion of light produces the violet tricarbonyl complexes **4a—c** (*ca.* 75%



2, $R^1 = R^2 = Me$

[**] Coordination Chemistry of Functionalized Phosphorus Ylides. Part 1. This work was supported by the Deutsche Forschungsgemeinschaft.

yield) which are extremely light sensitive in solution and spontaneously decompose when irradiated with a laser (Krypton laser, 647.1 nm, 1 W).

In the carbonyl region, each of the novel complexes **4a–c** exhibits three intense IR absorptions of almost the same frequency, which correspond to a facial arrangement of the carbonyl groups. The analogous rhenium complex **5b** can be prepared from $BrRe(CO)_5$ or, better, from $[BrRe(CO)_4]_2$. The small shifts in the ^{1}H- and ^{31}P-NMR spectra upon coordination indicate similar bonding patterns in the free and coordinated betaine ligands **2**.

In the reaction of the phosphonium salts **3**, $R^1 = CH_3$ or H, with $BrMn(CO)_5$ and $BrRe(CO)_5$, the expected *cis*-tetracarbonyl complexes with anionic ligands (anion of **3**) were detected by IR spectroscopy, but could not be isolated. The more stable cyano(phosphorandiyl)dithioacetato complex, the first example of this structural type, was obtained from **2**, $R^1 = CN$, $R^2 = H$[7].

In order to confirm **4a–c** and **5b** as zwitterionic neutral complexes, X-ray crystallographic structure determinations were performed (Fig. 1). Both complexes crystallize isomorphically in the space group $P2_1/c$, but they decompose at room temperature in the X-ray beam. The reflection data were therefore collected at $-110\,^\circ C$ (no reduction in intensity).

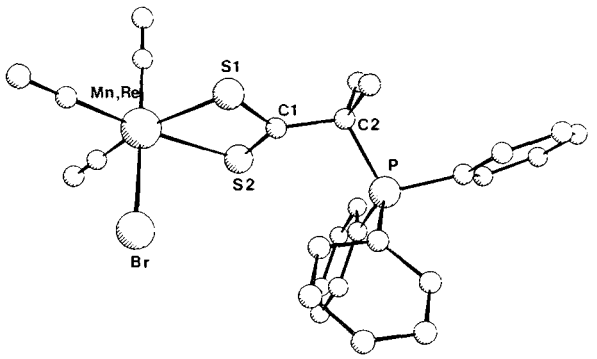

Fig. 1. Molecular structure of **4b** and **5b** at $-110\,^\circ C$ in the crystal. Important distances and angles of **4b**: Mn—S1 2.351(1), Mn—S2 2.380(1), S1—C1 1.691(5), S2—C1 1.675(5), C1—C2 1.522(6), P—C2 1.863(5) Å; S1—C1—S2 112.5(3)°; **5b**: Re—S1 2.488(1), Re—S2 2.503(1), S1—C1 1.717(4), S2—C1 1.664(4), C1—C2 1.526(5), P—C2 1.876(4) Å; S1—C1—S2 113.6(2)°.

The decomposition of the crystals at room temperature upon irradiation presumably results from rupture of the P—C2 bond, *i.e.* from cleavage of PPh_3. Data were measured for both compounds at room temperature (10–20% reduction in intensity within 2–3 d, $R = 0.07-0.10$); the "average" structures obtained from these data clearly show the "drift" of the PPh_3 groups with P—C2 distances of *ca.* 2.0 Å!

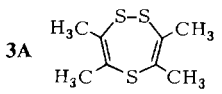
Formation of Bis(isopropylidene)-1,2,4-trithiolane from 2-Methyl-2-triphenylphosphoniodithiopropionate**

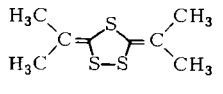
By *Udo Kunze**, *Reinhard Merkel*, and *Werner Winter*

2-Methyl-2-triphenylphosphoniodithiopropionate **1** only reacts with carbonylmanganese and -rhenium halides under strict exclusion of light to afford exclusively *fac*-tricarbonyl complexes **2**[1].

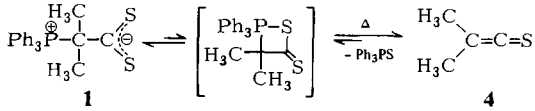
$$BrM(CO)_5 + \underset{\mathbf{1}}{Ph_3\overset{\oplus}{P}CMe_2CS_2^{\ominus}} \xrightarrow[-2CO]{THF,\ 25\,^\circ C} \underset{\mathbf{2},\ M = Mn,\ Re}{fac\text{-}(CO)_3\overset{\ominus}{M}(Br)S_2CCMe_2\overset{\oplus}{P}Ph_3}$$

Reaction of **1** with $BrRe(CO)_5$ in boiling tetrahydrofuran (THF) under the action of light, however, leads to formation of an orange solution in which no new carbonylmetal complex could be detected by IR spectroscopy. Pentacarbonylrhenium bromide precipitates almost completely upon concentrating the solution. After evaporation of the solvent the yellow decomposition product $C_8H_{12}S_3$ **3** could be sublimed out, and this proved to be identical with the product obtained by *Schaumann* and *Grabley*[2] by direct decomposition of **1**.





Of the possible isomers of **3**, *Schaumann* and *Grabley* preferred, on the basis of the two $^{13}C\{^1H\}$-NMR signals [$\delta = 24.22$ (CH_3), 129.19 (C=C)] the 1,2,5-trithiepin structure **3A**. Because of the ^{1}H-NMR signals [$\delta = 1.93$ (s), 2.02 (s)], which are typical of exocyclic isopropylidene groups, and the very intense dimethylthioketene fragment in the mass spectrum (*m/z* 86), the formulation 1,2,4-trithiolane **3B** appeared to us more probable. Trithiolanes are highly stable and are formed in numerous other reactions[3].



Formation of the trithiolane **3B** can be explained by [3+2]cycloaddition of the betaine **1** to the thioketene **4** formed by Wittig reaction. In contrast to the betaine complexes **2**, the elimination of PPh_3 from **1** is thermally activated.

An X-ray structural analysis[4] confirmed the proposed structure **3B** (Fig. 1). The molecule lies on a twofold crystallographic axis (through S1 and the middle of the S2 and S2′ bond); the ring therefore adopts an exact half-chair conformation. In the very similarly constructed bis(cyclo-

The 1,3-Dithian-2-ylmethoxycarbonyl (Dmoc) Moiety—A Protecting Group for the Amino Function in Peptide Synthesis

By *Regina Barthels* and *Horst Kunz**

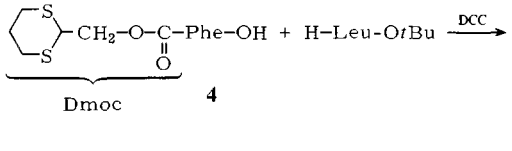
Dedicated to Professor Helmut Zahn on the occasion of his 65th birthday

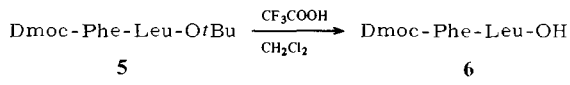
In the synthesis of peptides, and particularly in glycopeptides[8], a sensitive protecting group is required which can be selectively removed under mild conditions. The use of a two-stage protecting group avoids the presence of such sensitive groups during the synthesis: The stable form of the protecting group is converted into a labile form by chemical modification just prior to cleavage.

[*] Prof. Dr. H. Kunz, R. Barthels
Institut für Organische Chemie der Universität
Johann-Joachim-Becher-Weg 18—20, D-6500 Mainz (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

The 2-methylthioethoxycarbonyl (Mtc) group[9] developed by us for the protection of the amino functions in this way in peptide synthesis is quite stable towards bases but not sufficiently so towards strong acids. We therefore converted it into the dithian-2-ylmethoxycarbonyl (Dmoc) group.

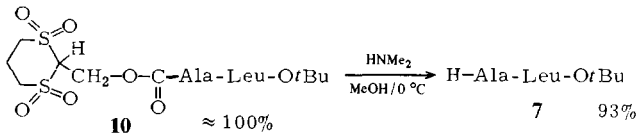




This group can be introduced into amino acid-trimethylbenzylammonium salts *via* the corresponding *p*-nitrophenyl carbonate. With Dmoc amino acids such as **4**, peptide syntheses can be carried out both by the carbodiimide[5] as well as by the mixed anhydride method[6].

Dmoc protection is stable towards trifluoroacetic acid/dichloromethane at 25 °C, so that the *tert*-butyl ester group, *e.g.* in **5**, can be selectively cleaved.

For cleavage, the Dmoc group of the Dmoc-dipeptide ester **9**, which is stable towards acids and bases, is oxidized with peracetic acid to the highly sensitive disulfone **10**.



The protecting group can be completely removed from the oxidized compound **10** with 20% dimethylamine in methanol at 0 °C or with saturated sodium hydrogen carbonate solution according to an E1cB mechanism.

The Dmoc group is thus a reliable amino-protecting group which is stable under the acidic and basic conditions of peptide synthesis, and can be readily removed after simple modification.

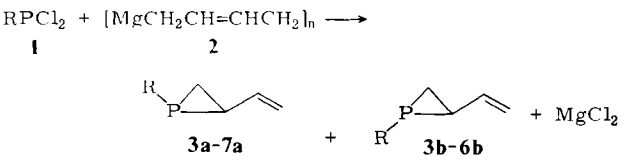
Synthesis of 2-Vinylphosphiranes

By *Wolf Jürgen Richter**

Until now phosphiranes could not be prepared by addition of a phosphanediyl to olefins; both thermolysis of $(PhP)_5$[1] and treatment of organodichlorophosphanes with

[*] Dr. W. J. Richter
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim an der Ruhr 1 (Germany)

magnesium in presence of olefins led to other compounds[2]. Only the reaction of dichloro(phenyl)phosphane with the dipotassium salt of cyclooctatetraene afforded a phosphirane as primary product[3]. Substituted phosphiranes are accessible by reaction of vicinal dihalides with alkali metal phosphides [*e.g.* NaPHR][4]. We describe here a straightforward route to vinyl-substituted phosphiranes by reaction of organodichlorophosphanes **1** with magnesium butadiene **2**[5].



In addition to cyclooligophosphanes, isomeric 1-alkyl- or 1-phenyl-2-vinylphosphiranes **3**—**7** can be isolated.

At low temperatures a *cis*-1,2-disubstituted phosphirane, which epimerizes at higher temperatures to a *cis*/*trans*-mixture, is predominantly formed. The ^{31}P-NMR signals appear in the region characteristic of substituted phosphiranes ($\delta = -160$ to -220, Table 1); the resonances at lower field stem from the *cis*-isomer, and this was confirmed from the ^{13}C,^{31}P-coupling constants.

Table 1. Selected physical data of vinylphosphoranes **3**—**7**.

Cpd.	R	Yield [%]	B.p. [°C/torr]	^{31}P-NMR (δ-values, C_6D_6) a	b
3	*tert*-Butyl	32	60/20	−160.1	−171.0
4	Cyclohexyl	38	55/0.01	−190.2	−190.3
5	Menthyl	36	68/0.01	−190.1	−191.0
				−190.4 [a]	−197.5 [b]
6	Methyl	10	[c]	−216.1	−216.7
7	Phenyl	2	ca. 60/0.1	−204.5	—

[a] Isomer **5c**. [b] Isomer **5d**; structure not yet confirmed. [c] Not determined.

Use of the (−)-menthyl derivative **1** afforded four diastereoisomers, of which the major component (80%, **5a**) is a *cis*-isomer (^{31}P-NMR: $\delta = -190.1$); the other *cis*-phosphirane (**5c**, $\delta = -190.4$) is formed in *ca.* 8% yield. Consequently, the asymmetric induction amounts to *ca.* 82% de.

The vinylphosphoranes isomerize above 150 °C to yield phospholenes; this reaction also occurs photochemically and under Ni^0 catalysis.

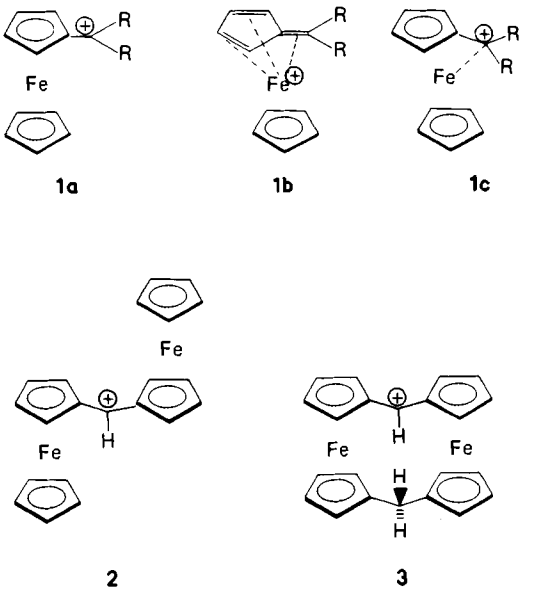
Influence of Conformational Rigidity on the Stabilization of α-Ferrocenyl Carbocations: A *cis*-Fixed Diferrocenyl Carbenium Ion

By *Ulrich T. Mueller-Westerhoff**, *Adel Nazzal*, *Wolfram Prössdorf*, *James J. Mayerle*, and *Russell L. Collins*

To explain the unusual stability of α-ferrocenyl carbenium ions **1**, contributions by structures of different geometries such as **1b** and **1c** have often been proposed. A precise structure determination for the ferrocenyl(diphenyl)carbenium ion **1**. $R = C_6H_5$, indicates[7] that this can best be described by **1c**. On the other hand, *Cais et al.*[8] found that the tetrafluoroborate of the ferrocenyl carbenium ion crystallizes in a *trans*-conformation **2**; both undistorted ferrocenes are, however, bent towards the positively charged central C atom. The structural results leave open the question of how much the bending reflects the stabilization of the isolated molecule as opposed to crystal packing effects.



In the *cis*-fixed diferrocenyl carbenium ion **3** the bridging CH_2 group effectively eliminates twisting and rotation. Any major bending of the carbenium ion center towards one or both of the Fe atoms would be an energetically very unfavorable process. With these constraints is **3** destabilized relative to **2**?

The tetrafluoroborate salt of **3** can be prepared from [1.1]ferrocenophane[15] as shiny black needles, which dissolve in CH_2Cl_2 to give a deep blue-green colored solution. In the UV spectrum the longest wavelength band is in methylene chloride shifted 140 nm bathochromically relative to the corresponding band in **2**. While in [1.1]ferroceno-

phane rapid exchange between two equivalent *syn*-conformations occurs, the carbenium ion **3** has a rigidly fixed *syn*-conformation: in the ^{1}H-NMR spectrum (CD_2Cl_2) a singlet for the CH proton occurs at $\delta = 7.71$, the bridging CH_2 group appears as two sharp doublets ($\delta = 2.05$ and 2.49, $J = 22$ Hz) and all eight different ferrocene protons can be distinguished.

From the twelve signals in the ^{13}C-NMR spectrum only those of the carbenium C atom ($\delta = 162.3$) and the adjacent C atoms ($\delta = 108.1$) show a significant downfield shift (remaining signals: $\delta = 70-90$).

This conformational rigidity of cation **3** must be attributed to conjugation between the positively charged C atom and both ferrocene units. Nevertheless, the Mössbauer spectra of these two carbenium ions show that **3** has no more positive charge residing on the Fe atoms than its non-bridged counterpart **2**; each ferrocene has accepted one-third of the charge. This reduction in charge on the CH group also can explain the absence of hydride transfer in **3**, whose structure would appear to predestine it to such an exchange. In the corresponding carbanion, rapid proton transfer is known to occur[18].

The X-ray structure of the tetrafluoroborate of **3** shows that: 1) the cation is in a fixed *syn*-conformation; 2) all cyclopentadienyl rings are planar within 1 pm; 3) in the two ferrocene units, the rings are not coplanar but tilted by 6.6 and 7.5°, respectively, opening towards the center of the cation; 4) the Fe—C distances average 206 ± 2 pm and indicate that the Fe atoms are located essentially symmetrically with respect to their ligands; 5) the positively charged C atom is noticeably displaced towards the center of the molecule, lying *ca.* 20 pm below the intersection of the two adjacent cyclopentadienyl rings, with Fe-C$^{\oplus}$ distances of 296 and 301 ± 2 pm. In this way, any overlap between the $2p_z$ orbital of the carbenium C atom and the d orbitals at the iron atoms tends to be maximized, but the rigidity of the cation allows this to happen only to a very limited degree. In contrast to the earlier crystallographic work, we may be confident that, because of the cyclic structure, crystal packing forces cannot contribute significantly to the structural deformation in **3**. The displacement of the carbenium C atom towards the Fe atoms must therefore be associated with the stabilization effect alone.

The three main factors in α-ferrocenyl carbenium ions are therefore: charge distribution from the carbenium C atom to ferrocene, conjugative interaction between the carbenium C atom and the adjacent π-system, and direct Fe—C$^{\oplus}$ bonding. The first two stabilizing factors do not require geometrical changes as in **1b** and **1c**; since the third type of stabilization is significant in **3** (with deformation), we assume that carbenium ions of type **1** can, on the whole, be described by **1c**.

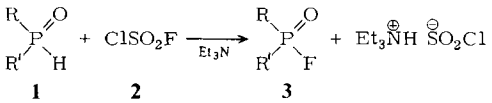
Novel Application of Sulfonyl Chloride Fluoride in the Synthesis of Organophosphorus Fluorine Compounds: Direct Conversion of >P(O)H and >P(O)OH Groups into >P(O)F Groups

By *Andrzej Łopusiński* and *Jan Michalski**

The readily available[1] sulfonyl chloride fluoride **2** has found extensive use as solvent in the spectroscopic investigation of carbocations[2] and is occasionally used in organic synthesis[3]. Recently the organophosphorus fluorine compounds RR'P(O)F and R_3PF_2 have been prepared from sulfides and selenides >P=X[4].

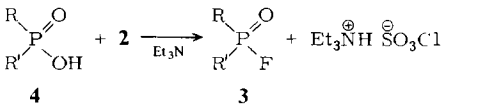
Compounds containing the >P(O)H and >P(O)OH part structures such as **1** and **4**, respectively, show the ability to act as proton donors. We now describe a novel method for their conversion into acid fluorides >P(O)F **3** by the action of **2** under extremely mild conditions.

Dialkyl phosphites and compounds of type **1** react at −40 °C in dichloromethane with **2** in the presence of tertiary amine to give the corresponding fluorides **3**. The most important discovery was that in dichloromethane **2** reacts smoothly at −60 °C with tetracoordinate phosphorus acid salts **4** to give fluorides **3** in very high yield. At higher temperatures the chlorides RR'P(O)Cl are formed in addition to **3**. Presumably the reaction proceeds *via* the mixed anhydrides $RR'P(O)OSO_2Cl$ as reactive intermediates.



1 **2** **3**

a, R = R' = OEt



4 **3**

b, R = *t*Bu, R' = Ph

Experimental

3b: **2** (1.5 g, 0.012 mol) was added to a solution of *tert*-butyl(phenyl)phosphinic acid **4b** (1.9 g, 0.01 mol) in 15 mL of CH_2Cl_2 and Et_3N (1.0 g, 0.01 mol) at −65 °C. The reaction mixture was stirred at −55 °C to −60 °C for 2 h and held at 0 °C for additional 6 h. The solution was washed with 15 mL of H_2O and the organic layer dried over $MgSO_4$. Distillation gave 1.5 g (75%) of *tert*-butyl(phenyl)phosphinic acid fluoride **3b**, b.p. = 68−70 °C/0.2 torr, $\delta(^{31}P) = +58.63$, $J_{PF} = 1048$ Hz, $\delta(^{19}F) = +98.34$ ($CFCl_3$ int.).

3a: Diethylfluorphosphate **3a** was obtained in a similar procedure from **1a** (1.3 g, 0.01 mol), Et_3N (1.0 g, 0.01 mol), and **2** (1.5 g, 0.012 mol) at −40 °C in 85% yield: b.p. = 59−60 °C/12 torr, $\delta(^{31}P) = -9.4$, $J_{PF} = 964$ Hz.

Relaxation Studies on the Stabilization of Trityl Cations by Acids**

By *Franz L. Dickert** and *Helmut Fackler*

Superacids enable the preparation of extremely reactive carbenium ions[1]. The well stabilized trityl cations $Trt^{\oplus}$, on the other hand, are already obtained from triphenylmethanol by acids of the strength of usual mineral acids[2]. Thus, in the case of ionogenic trityl trifluoroacetate Trt(TFA) the conductivity in acetonitrile increases considerably on addition of trifluoroacetic acid H(TFA)[3a]. This is not due to the conductivity of the acid, which is practically undissociated in acetonitrile[3b], but to formation of trityl cations:

$$Trt(TFA) \underset{k_{12}}{\overset{k_{21}}{\rightleftharpoons}} Trt^{\oplus} + TFA^{\ominus} \qquad (1)$$

To explain this increase in conductivity we carried out a series of relaxation studies[4] (pressure-jump method with conductivity detection and optical observation). The findings in Figure 1[3c] indicate that ion-pair formation can be

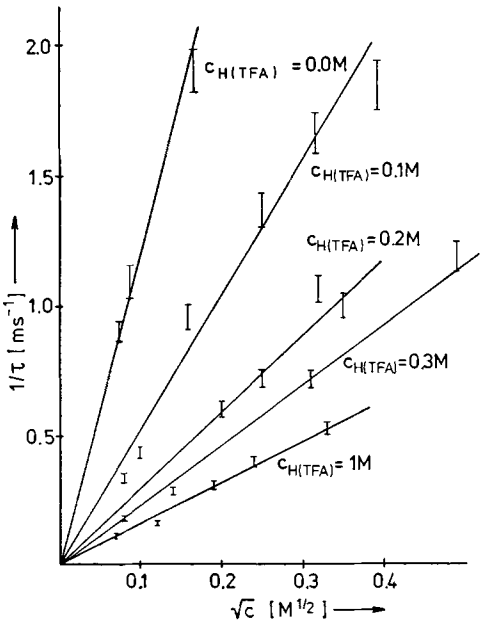

Fig. 1. Reciprocal relaxation times $1/\tau$ as a function of the total concentrations of trityl trifluoroacetate in acetonitrile (273 K) at variable concentrations of added trifluoroacetic acid.

neglected as preliminary step during ion recombination according to eq. (1).

Egerlandstr. 3, D-8520 Erlangen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The rate constants and activation parameters are listed in Table 1. k_{21} was determined by ^{19}F-NMR measurements independently of the relaxation investigations[3b]. The shift of the dissociation equilibrium (1) in favor of the formation of trityl cations on addition of acid is due to a drastic reduction in k_{12}. Trifluoroacetic acid, having an acceptor number AN = 105.3 on the Gutmann scale[5], solvates anions extremely effectively *via* hydrogen bonding; hence, the nucleophilicity of the trifluoroacetate ions is reduced more and more with increasing acid concentration. Addition of acid has little effect on k_{21}. As already observed in previous experiments[3b], trityl trifluoroacetate and trifluoroacetic acid form a 1:1 complex. This leads to a slight increase in k_{21} (Table 1).

Accordingly, eq. (1) must be modified by two additional solvation equilibria:

$$\begin{array}{l} Trt(TFA) + n\ H(TFA) \\ \quad\uparrow\downarrow \\ Trt(TFA)\ldots H(TFA) + (n-1)\ H(TFA) \\ \quad\downarrow\uparrow \\ Trt^{\oplus} + (TFA)^{\ominus}\ldots[H(TFA)]_n \end{array} \qquad (2)$$

Hence, rapid desolvation of the anions precedes ion recombination. In agreement with this hypothesis is the finding that ΔH_{12}^{+} increases on addition of acid (Table 1). The experimentally determined activation enthalpy ΔH_{12}^{+} is then made up of the positive anion-desolvation enthalpy ΔH_{12}^{0} and the activation enthalpy $\Delta H_{12}^{+}(0)$ in absence of acid:

$$\Delta H_{12}^{+} = \Delta H_{12}^{0} + \Delta H_{12}^{+}(0) \qquad (3)$$

From eq. (1) and the results in Table 1, a value of 16 kJ/mol is obtained for ΔH_{12}^{0} in 1 M trifluoroacetic acid solution. This enthalpic effect outweighs the increase in activation entropy in the temperature range investigated and leads to strongly reduced ion-recombination rate constants k_{12}.—In this way the formation of carbenium ions is favored when solutions of ionogens are treated with acid.

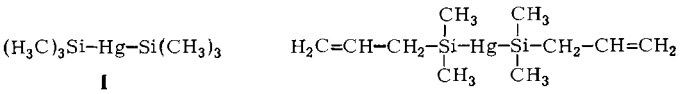
(R_1^{CSA}) not only depends on the correlation time τ_c but also on the magnetic flux density B_0[1]:

$$R_1^{CSA} = (2/15)\gamma_I^2 B_0^2 [\Delta\sigma^2]\tau_c$$

If R_1^{CSA} is the most important parameter for a given magnetic nucleus, the high magnetic fields available today from cryomagnets, may lead to very rapid relaxation. In the case of spin-spin coupling this can cause line broadening for neighboring nuclei or even spin, spin-decoupling.

Heavy metal nuclei such as ^{199}Hg in linear molecules of the type R—Hg—R exhibit relatively high chemical shift anisotropies, whose significance for the observed relaxation behavior has recently been stressed[2]. We show here that with silylmercury compounds, high-field NMR spectroscopy can lead to the disappearance of ^{199}Hg, ^{1}H-spin,spin coupling and, in consequence, to a loss of information.



1

2

3

The ^{1}H- and ^{13}C-NMR spectra of bis(trimethylsilyl)mercury **1**, respectively, at 1.88 T ($\nu_0(^1H) = 80$ MHz), show the expected satellite lines (Fig. 1) due to $^3J(^{199}Hg,^1H)$ and $^2J(^{199}Hg,^{13}C)$ spin-spin coupling. When the same sample is measured at 9.4 T ($\nu_0(^1H) = 400$ MHz) selective line broadening occurs, which in the ^{1}H-NMR spectrum practically leads to loss of the coupling. The same effect was observed with bis(allyldimethylsilyl)mercury **2**, and even with di-*tert*-butylmercury **3**.

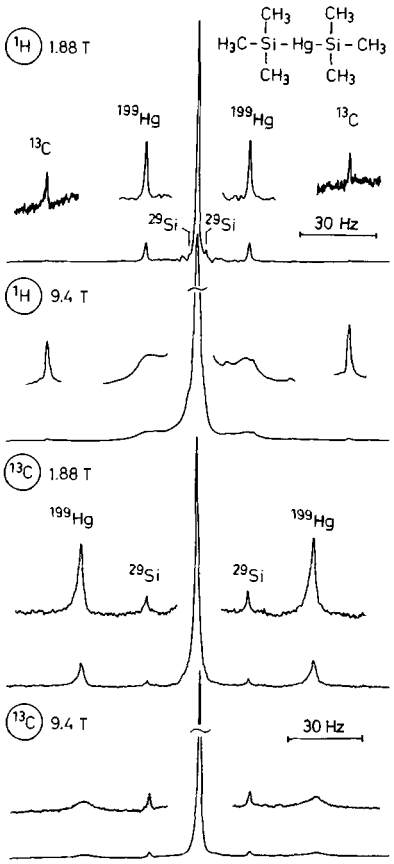


Fig. 1. ^{1}H- and ^{13}C-NMR spectra of bis(trimethylsilyl)mercury **1** [5] at 1.88 and 9.4 T; the ^{13}C-NMR spectrum is broadband decoupled. The following coupling constants are obtained from the satellite spectra: $^1J(^{13}C,^1H) = 119.6$; $^2J(^{29}Si;^1H) = 6.6$, $^3J(^{199}Hg,^1H) = 40.7$; $^1J(^{13}C,^{29}Si) = 40.1$, $^2J(^{13}C,^{199}Hg) = 92.1$ Hz.

That enhanced spin-lattice relaxation of the ^{199}Hg nucleus is indeed involved is shown by the fact that the satellite lines produced by $^1J(^{13}C,^1H)$- and $^1J(^{13}C,^{29}Si)$ coupling remain sharp (Fig. 1)[3a]; it also becomes apparent from the T_1 data. As shown in Table 1 the T_1 values measured at three different field strengths closely follow the ratio $(B_0^{(i)}/B_0^{(j)})^2$, so that even at 1.88 T, R_1^{CSA} must provide the predominant contribution to the relaxation of the ^{199}Hg nucleus[3b].

Table 1. ^{199}Hg spin-lattice relaxation times T_1 [ms] for **1**, **2**, and **3** at various magnetic flux densities B_0[T] [a].

B_0	1.88	6.35	9.40
1	460	45.4	21.5
2	310	29.1	18.6
3	1280	136	63.5

[a] Measured using the inversion recovery method [1] with Bruker WP 80, WH 270, and WH 400 spectrometers; $\nu_0(^{199}Hg) = 14.3$, 48.2 and 71.7 MHz, respectively; solvent C_6D_6/C_6H_6 (9:1); conc.: 30 wt.-%

Since R_1^{CSA} is also of significance with other metal nuclei[4], the possibility of enhanced spin-lattice relaxation must be considered in high-field NMR studies of organometallic compounds in order to prevent erroneous assignments, particularly since broad residual signals can disappear in the noise.

$(\mu\text{-H})_3[C_5H_5RhP(iPr)_3]_2^+$: A Dinuclear (Rh—Rh) Complex with Three Bridging Hydrido Ligands

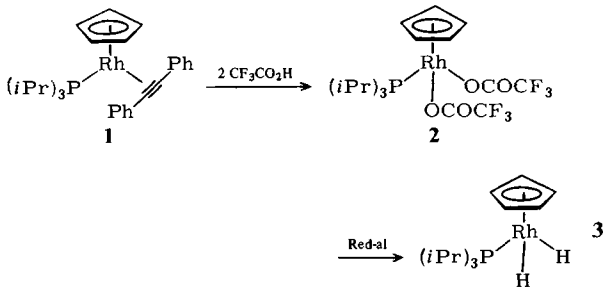
By *Helmut Werner** and *Justin Wolf*

Hydrido(phosphane)rhodium compounds play an important role as catalysts or as intermediates in catalytic hydrogenations (*e.g.* with $Rh(PPh_3)_3Cl$)[1]. Recently, we have been particularly interested in the behavior of the Lewis basic alkyne(phosphane)complexes $C_5H_5Rh(C_2R_2)P(iPr)_3$ with Brønsted acids[2], and in this connection have attempted preparation of the dihydrido(phosphane)complex **3** from $RhClH_2[P(iPr)_3]_2$[3] and NaC_5H_5. However, only small amounts of **3** are formed in this reaction.

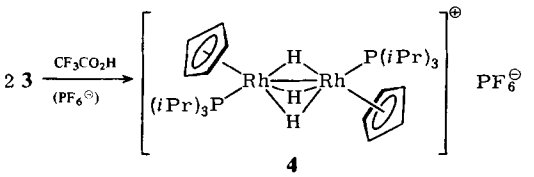
[*] Prof. Dr. H. Werner, J. Wolf
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

 © Verlag Chemie GmbH, 6940 Weinheim, 1982 0570-0833/82/0404-0296 $ 02.50/0

Another method has proved to be considerably more propitious: Compound **1**, which reacts with an equimolar amount of trifluoroacetic in diethyl ether to give $C_5H_5Rh(CPh{=}CHPh)(OCOCF_3)P(iPr)_3$[2], reacts with excess CF_3CO_2H at 40 °C to afford the bis(trifluoroacetato)complex **2** [^{1}H-NMR ($CDCl_3$): $\delta = 6.09$ (dd, $J_{PH} = 1.7$, $J_{RhH} = 0.6$ Hz (C_5H_5)); IR (KBr): $\nu(CO) = 1680$ cm^{-1}]. Treatment of **2** with $Na[AlH_2(OC_2H_4OMe)_2]$ ("Red-al") in toluene/ether at 20 °C gives the colorless, highly air-sensitive dihydridorhodium compound **3** in 36% yield which melts below room temperature [^{1}H-NMR (C_6H_6): $\delta =$ 5.55 (m(C_5H_5)); −14.73 (dd, $J_{PH} = 33.5$, $J_{RhH} = 27.5$ Hz (RhH_2)); IR (hexane): $\nu(RhH) = 2045$ cm^{-1}]. In a similar manner *Maitlis et al.*[4a] and *Bergman et al.*[4b] recently synthesized the complexes $C_5Me_5RhH_2PR_3$ (R = Me, Ph) starting from $C_5Me_5Rh(OCOCH_3)_2PMe_3$ and $C_5Me_5RhCl_2(PPh_3)$, respectively, and starting from $C_6Me_6Ru(OCOCF_3)_2PR_3$ we synthesized the complexes $C_6Me_6RuH_2PR_3$ ($R_3 = Me_3$, $MePh_2$, Ph_3)[4c].



Whereas **3** is inert towards alkenes (*e.g.* C_2H_4) or alkynes (*e.g.* C_2H_2, C_2Ph_2) under standard conditions, a rapid reaction takes place with CF_3CO_2H in methanol in presence of NH_4PF_6. The violet crystalline solid **4**, which is air-stable for a short time but which decomposes fairly rapidly in solution, is formed accompanied by evolution of H_2. Elemental analysis, conductivity (in MeOH: $\Lambda = 103$ cm$^2\,\Omega^{-1}$ mol^{-1}), and NMR data confirm the composition. In addition to the ^{1}H-NMR spectrum [(CD_3NO_2): $\delta = 5.64$ (d, $J_{PH} = 1.1$ Hz (C_5H_5)), −17.75 (tt, $J_{PH} = 13.1$, $J_{RhH} = 13.1$ Hz (RhH_3Rh))] the ^{31}P-NMR (in CD_3NO_2) supports the structural proposal: a 6 line signal corresponding to an XAA'X' spin system (AA' = Rh; X, X' = P) is observed for the phosphane P atoms at $\delta = 80.22$; the coupling constants are $^1J_{RhP} = 141.1$, $^3J_{RhP} = 1.8$, $J_{RhRh} = 11.4$ Hz.



To the best of our knowledge **4** is the first dinuclear (Rh—Rh) complex with three bridging hydrido ligands. By considering an M—M bond, each rhodium atom (which is in oxidation state III) achieves the 18 electron configuration. The cation $[(C_5Me_5Ir)_2(\mu\text{-}H)_3]^+$, with a very short Ir—Ir distance, is known for iridium(III); the dinuclear rhodium cations $[(C_5Me_5Rh)_2(\mu\text{-}H)_2(\mu\text{-}OCOR)]^+$ and $[(C_5Me_5Rh)_2(\mu\text{-}H)(\mu\text{-}OCOR)_2]^+$ ($R = CH_3$, CF_3) are similar in this respect[5]. The reactivity and structural data of these two complexes suggest[5] that the hydrido bridges stabilize the dinuclear structure, and this undoubtedly also applies to **4**.

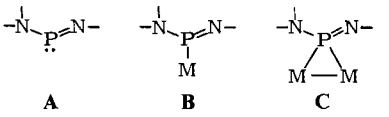
λ^3-Phosphazenes as Bridging η^1-Ligands**

By *Otto J. Scherer*, Rainer Konrad, Ernst Guggolz*, and *Manfred L. Ziegler*

By analogy to metal complexes with *e.g.* CO- or RNC-ligands, λ^3-phosphazenes **A** [amino(imino)phosphanes] should be capable also of participating in terminal (**B**) as well as in bridging (**C**) coordination schemes.



Until now, phosphazene complexes characterized by structure-analytical methods with ligands of type **A** exhibit, without exception, the end-on ligand arrangement **B**[1,2]. The platinum trinuclear clusters **2** and **3**, in which a σ^2, λ^3-phosphorus compound[3] participates in μ-*P* coordination **C** have been realized for the first time. They can be prepared in good yield from PtL_3 **1**[1] and isocyanides, and carbon monoxide, respectively.

2, which can also be obtained from $Pt_3(\mu\text{-}CNR)_3(CNR)_3$[4] and λ^3-phosphazene L, forms orange crystals which are highly soluble in benzene, ether, and dichloromethane, and moderately soluble in pentane. **3** is sparingly soluble in benzene, and moderately soluble in CCl_4 and CH_2Cl_2 (whereby **3** decomposes faster than **2**). In the IR spectrum of **2** (in CH_2Cl_2) the RNC bands occur at 2150 vs, 2080 w (terminal), and 1775 s, 1730 sh cm^{-1}

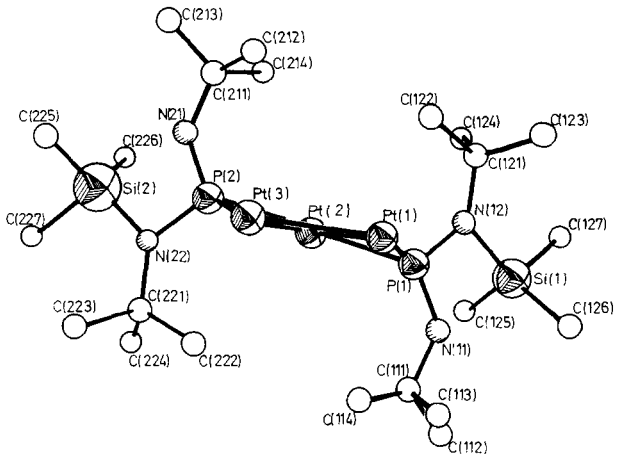

Fig. 1. ORTEP representation of complex **2** (side view without RNC ligands; thermal vibration ellipsoids with 50% probability). Most important bond lengths [pm] and angles [°] of the μ_2,η^1-phosphazene ligands: P(1)—Pt(1) 231.9(6), P(1)—Pt(2) 233.8(7), P(2)—Pt(2) 236.8(8), P(2)—Pt(3) 231.9(7), P(1)—N(11) 157.7(3), P(1)—N(12) 166.0(2), P(2)—N(21) 151.2(3), P(2)—N(22) 169.6(3); N(11)—P(1)—N(12) 97.3(1), N(21)—P(2)—N(22) 95.8(2); sum of angles at N(12) 359.9, N(22) 358.8.

(both br., bridging). In **3** (KBr disc) νCO appears in the region expected for terminal ligands (2045 vs, 2000 w, 1980 sh cm^{-1}). The structures of **2** and **3** were confirmed by crystal structure analysis (Fig. 1).

In **2** and **3** the distances and angles in the comparable parts of the cluster framework deviate only slightly from those in $Pt_3(\mu\text{-}CNR)_3(CNR)_3$[4]. Figure 1 illustrates the *trans*-orientation of both imino groups and the *trans*-configuration of the residue on the P=N bond necessary for migration of the $(CH_3)_3Si$ group (readily detectable by NMR spectroscopy). Compared to free L (104.9°)[12] and PtL_3 (average value *ca.* 104°)[2] an unusually small NPN angle (average value 96.5°) is exhibited by L in **2**. This angle opens slightly in **3** (average value 101.5°) whose *P*-imino groups are arranged mutually *trans/cis/trans*.

In comparison to the $^{31}P\{^1H\}$-NMR spectrum of the noncoordinated λ^3-phosphazene L ($\delta = 327.5$) that of **2** ($\delta = 286.7$) shows a weak, and that of **3** ($\delta = 237.3$), a strong high-field shift.

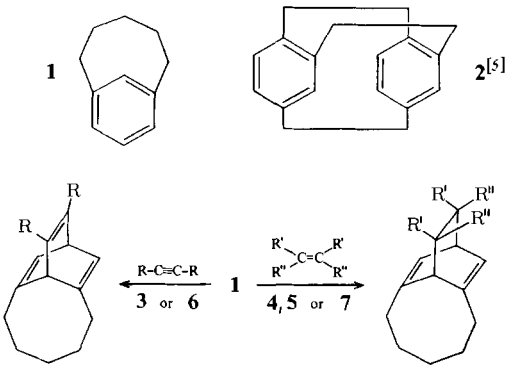
Diels-Alder Reactions of [5]Metacyclophane

By *Lucas A. M. Turkenburg, Pieter M. L. Blok, Willem H. de Wolf,* and *Friedrich Bickelhaupt**

[5]Metacyclophane **1**, the smallest compound of its class known so far[8], is highly strained and thus can be expected to show a markedly reduced aromaticity. To check this, we investigated its reactivity in Diels-Alder reactions. Dienophilic alkynes such as **3** and **6** (Table 1) add to **1** as anticipated with formation of the 2,6-pentamethylenebarrelenes **8a** and **8b**, respectively, while reaction of **4**, **5**, or **7** and **1** affords the 2,6-pentamethylene-7,8-dihydrobarrelenes **9**; in no case were byproducts observed.



8a, R = CF_3
8b, R = $COOCH_3$

9a, R' = R'' = CN
9b, R' = H, R'' + R'' = CO—O—CO
9c, R' = H, R'' = $COOCH_3$

Table 1. Diels-Alder reactions of **1** and **2** [5].

Dienophile	**1**	**2**
4-Phenyl-1,2,4-triazoline-3,5-dione		C_6H_6, 20 °C, 3 h, 79%
Hexafluoro-2-butyne **3**	$CDCl_3$, 20 °C, < 1 h, 100%	
Tetracyanoethene **4**	$CDCl_3$, 20 °C, 15 min, 100%	C_6H_6, 20 °C, 20 h, 59%
Maleic anhydride **5**	$CDCl_3$, 20 °C, 15 min, 100%	C_6H_6, 100 °C, 10 h, 53%
Acetylenedicarboxylic acid dimethyl ester **6**	$CDCl_3$, 20 °C, 5 h, 100%	C_6H_6, 170 °C, 1 h, 61%
Dimethyl maleate **7**	C_6H_{12}, 65 °C, 25 h, 77%	C_6H_6, 100 °C, 10 h, 0%
Cyclopentene	C_6D_{12}, 80 °C, 64 h, 0%	

In Table 1 the results of the Diels-Alder reactions of **1** are compared with those of the reactive, likewise mononuclear benzene derivative [2$_3$](1,2,4)cyclophane **2**[5]. It emerges that **1** is considerably more reactive than **2**. This is strikingly demonstrated by its behavior towards the two weakly dienophilic compounds **6** and **7**. **6** reacts quantitatively with **1**, even at room temperature, whereas for reaction with **2** a temperature of 170 °C is necessary. In the case of **7**, **2** apparently stays below the limit of reactivity, while a satisfactory reaction rate is still observed for **1** at 65 °C. Only with cyclopentene, which is just about three times less reactive than **7** towards 9,10-dimethylanthracene in dioxane[9], could a reaction no longer be established for **1**, even at 80 °C.

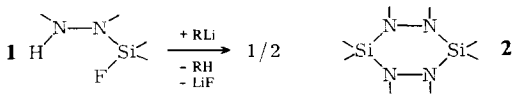
A Stable Diazasilacyclopropane**

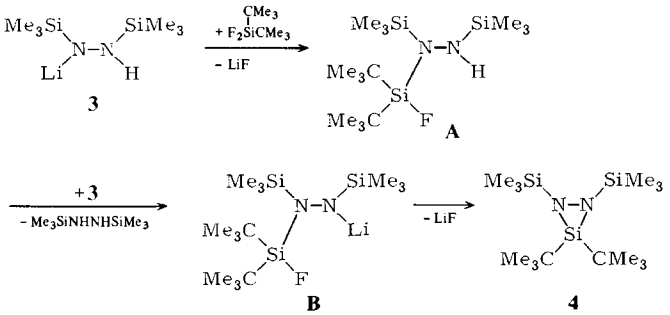
By *Johann Hluchy* and *Uwe Klingebiel**

The first synthesis of a three-membered, silicon-containing ring, azadisilacyclopropane, was reported by *Fink* in 1963[1]. In the meantime the synthesis of other silicon-element three-membered ring systems have been accomplished[2–4]. We now report the synthesis of a diazasilacyclopropane.



Fluorosilyl-substituted hydrazines **1** react with bases such as butyllithium to give preferably six-membered heterocycles **2**[7].

The bulky di-*tert*-butyl(fluoro)silyl group of the hydrazine derivative **A**, which is formed on reaction of singly lithiated *N,N'*-bis(trimethylsilyl)hydrazine **3** with di-*tert*-butyldifluorosilane, reacts with excess **3** with formation of the diazasilylcyclopropane **4**.



The intermediate **A** is not isolated; it reacts with **3**, undergoing transmetalation *via* the lithium salt **B** to give the product **4**. Above +80 °C, and on attempted distillative or gas-chromatographic purification of **4**, di-*tert*-butylbis(trimethylsilylamino)silane $(Me_3SiNH)_2Si(CMe_3)_2$ is formed. The diazasilacyclopropane **4** can be purified by repeated recrystallization from *n*-hexane at −15 °C.

The upfield shift of the ^{29}Si-NMR signal of the silicon-containing small ring compounds is also observable in the case of **4** (in C_6F_6, TMS int.: $\delta = -30.73$)[2,4].

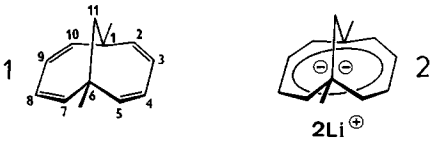
A Bishomocyclooctatetraene Dianion**

By *Walter Huber, Klaus Müllen**, *Ralf Busch, Wolfram Grimme*, and *Jürgen Heinze*

According to recent studies it would appear that homo- and bishomoconjugation[1] are of little or no significance in neutral and anionic π systems[2,3]. In the 1,6-dimethylbicyclo[4.4.1]undeca-2,4,7,9-tetraene **1**[4], a vinylogue of norbornadiene, "through-space" interaction of the p_π orbitals at centers 2 and 10, and at 5 and 7 enables formation of a monocyclic conjugated π-system. We describe here the long sought bishomocyclooctatetraene dianion **2**, which has been generated by reduction of **1**.



A degassed solution of **1** in [D$_8$]tetrahydrofuran ([D$_8$]THF) reacts at −78 °C with lithium to give a deep-red solution of the diamagnetic dilithium compound **2**. Methylation leads to formation of an isomeric mixture of dimethyl derivatives ($C_{15}H_{22}$), and confirms the existence of a doubly negative hydrocarbon system; the ^{1}H- and ^{13}C-NMR spectra of **2** are characteristic of a symmetry which leaves no doubt that the original molecular ring system has remained intact.

The NMR signals of the ring protons of **2** are shifted upfield compared to those of **1**, though to a lesser extent than would be expected as a result of charge effects (see Table 1). This finding and the upfield shift for 11-H (about 3.3 ppm) are consistent with a diatropic 10π-system.

Further evidence for the expected π-bond delocalization is provided by exact analysis of the AA'BB' spin system of the ring protons and correlation of the coupling constants of the vicinal protons with π-bond orders. Accordingly **1** is a diene system with fixed double bonds, while **2** exists as a π-bond delocalized species.

δ_C	**1** [c]	44.4	140.8	122.3	31.6	50.8
	2 [d]	41.9	95.2 [e]	88.8 [e]	41.9	49.0
		J_{23}	J_{24}	J_{25}	J_{34}	
	1	11.60	0.58	0.97	7.19	
	2	8.61	1.21	0.16	7.93	

[a] $CDCl_3$, 400 MHz, 35 °C [19]. [b] [D_8]THF, 90 MHz, −20 °C. [c] $CDCl_3$, 20 MHz, 35 °C. [d] [D_8]THF, 22 MHz, −20 °C. [e] Assignment not confirmed.

A comparison of the ^{13}C-NMR spectra of **1** and **2** reveals the upfield shift of the signals of **2** characteristic for a dianion.

If the formation of **2** is accompanied by pronounced conjugative stabilization, then transfer of the second electron (conversion of the radical anion into the dianion) should be facilitated. The transfer of two electrons, and an ECE mechanism, could be demonstrated cyclovoltammetrically (THF, 0.2 M $NaBPh_4$, Ag as quasi-reference electrode). In a reversible E-step ($E_1^0 \cong -2.1$ V) a radical anion is formed which is then converted in a rapid irreversible C-step into a conjugatively stabilized π system. This conversion favors formation of the dianion, and the redox potential of the second electron transfer shifts anodically ($E_2^0 \cong -1.8$ V; *i.e.* $E_2^0 > E_1^0$). Conversely, in the case of reduction of two neighboring butadiene moieties, E_2^0 would be shifted cathodically compared with E_1^0.

There are convincing arguments against a bishomoconjugation in the neutral and anionic π system considered earlier[1-3]. Our findings clearly show that, for steric and electronic reasons—equal "through space" coupled π fragments are present—**2** is a bishomoconjugatively-stabilized species with ten π electrons.

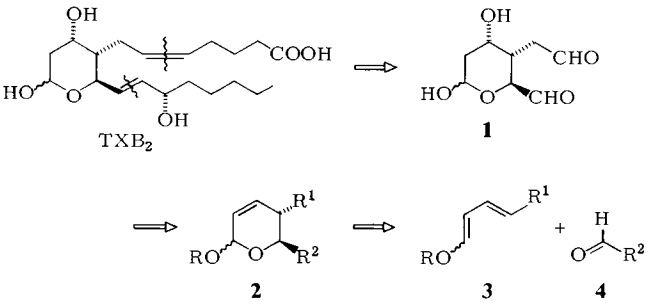
Hetero Diels-Alder Reactions for the Synthesis of Thromboxane Intermediates**

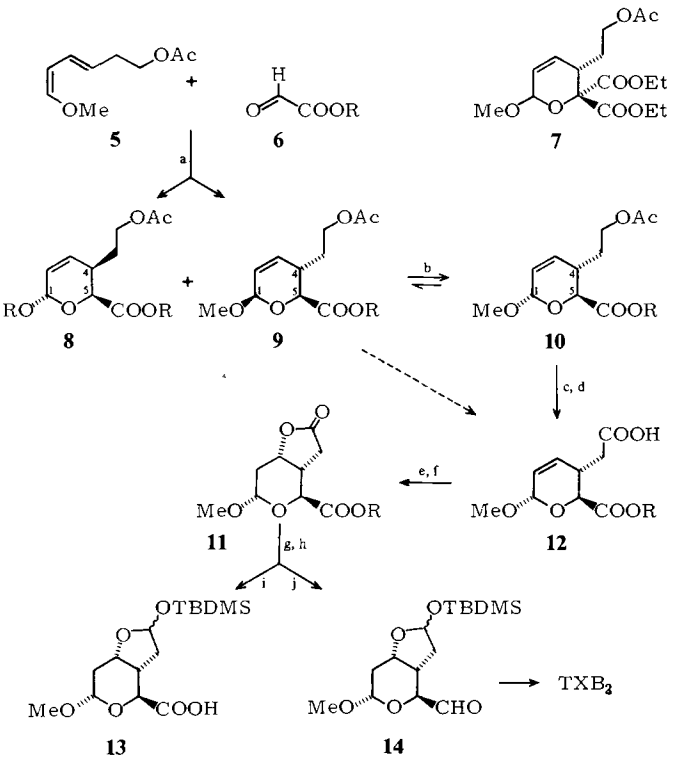
By *Richard R. Schmidt** and *Wolfgang Abele*

Reactive pseudoglycals, which are useful intermediates for the synthesis of modified carbohydrates, have been synthesized by hetero Diels-Alder reactions[1]. This type of reaction should also be useful for the synthesis of the carbohydrate-derived thromboxanes such as TXB_2 (Scheme 1).



Scheme 1.

Exploitation of the hetero Diels-Alder reaction for the synthesis of the target molecule **2**, which has a pseudoglycal structure, requires: (i) a 1-alkoxy-1,3-diene **3** bearing a substituent R^1 which contains two C-atoms and enables stereospecific incorporation of the OH group at C-3 in **2** as well as coupling of the side chain, and (ii) a carbonyl compound **4**, whose substituent R^2 increases the dienophilicity and allows construction of the second side chain.



6, **8**–**12**, R = (−)-Menthyl

Scheme 2. Only the D-isomers are shown. TBDMS = *tert*-butyl(dimethyl)silyl. a: C_6H_6, 120 °C, 72 h; yield 62% (**8**: 31%, **9**: 26%, **10**: 5%) or CH_2Cl_2, 60 °C, 96 h, 8.5 kbar; yield 71% (**8**: 35%, **9**: 30%, **10**: 6%). b: Et_2O, $BF_3 \cdot OEt_2$, RT; yield 100% **10**, colorless oil. c: MeOH, Na_2CO_3, RT, 12 h; yield 75%. d: Dimethylformamide (DMF), pyridinium dichromate, RT, 8.5 h; yield 57% **12**, m.p. 166—168 °C (*n*-hexane). e: Tetrahydrofuran (THF), KI/I_2, RT, 5 h; yield 94%. f: Toluene, *n*-Bu_3SnH, 80 °C, 30 h; yield 92% **11**, colorless oil. g: Toluene, DIBAH, −70 °C, 20 h; yield 70%. h: DMF, TBDMS-Cl, 40 °C, 1.5 h; yield 92%. i: NaOH, EtOH, 40 °C, 24 h; yield 77% **13**, colorless oil. j: Toluene, DIBAH, −70 °C, 12 h; yield 54% **14**, colorless oil.

Cycloaddition of the (*Z*,*E*)-1-methoxy-1,3-hexadiene **5**[5], which bears a functionalized C_2 substituent at C-4, with menthyl (−)-glyoxylate **6** affords a mixture of the pseudoglycaluronates **8**, **9**, and **10** that can be easily separated. A 1 : 1 mixture of **8** and **9** can also be obtained in good yield from the mesoxalate adduct **7**[5]. **9** is catalytically converted with boron trifluoride-ether into the α-

[**] De novo Synthesis of Carbohydrates and Related Natural Products, Part 8. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 7: [1c].

anomer **10** in quantitative yield. The higher thermodynamic stability of **10** is due to the anomeric and allylic effects[6], which are effective in the $^0H_5$ conformation of **10**[7]. The compounds **9** and **10** have the necessary relative stereochemistry at C-4 and C-5. After conversion[8] into the lactone **11**, reduction with equimolar amounts of diisobutylaluminum hydride (DIBAH) at $-70\,^\circ C$ affords the lactol. After reaction with *tert*-butyl(dimethyl)silyl chloride (TBDMS-Cl), the carboxylic acid **13** is obtained by ester hydrolysis, and the aldehyde **14**—an analogue of **1**—by repeated reduction with DIBAH. The compounds **11**, **13** and, in particular, **14** are valuable intermediates for thromboxane syntheses.

Hydroxylation of Acyclic Alkanes by Oxygen Atoms O(^{3}P)—Comparison of Ozone and O(^{3}P) Oxidations of Alkanes**

By *Elazar Zadok* and *Yehuda Mazur**

Ozone oxidation of saturated compounds leads to introduction of OH groups at tertiary positions[3]. This method is generally applicable to saturated cyclic hydrocarbons, but not to acyclic hydrocarbons which give comparatively large amounts of ketones derived from cleavage of C—C bonds[6].

Looking for an alternative method, we utilized ground state oxygen atoms (O(^{3}P) atoms) generated by low-pressure microwave discharge of a CO_2/He mixture in a flow system[2]. We have recently found that O atoms produced in this way convert saturated cyclohexane derivatives mainly into tertiary alcohols and epoxides[1].

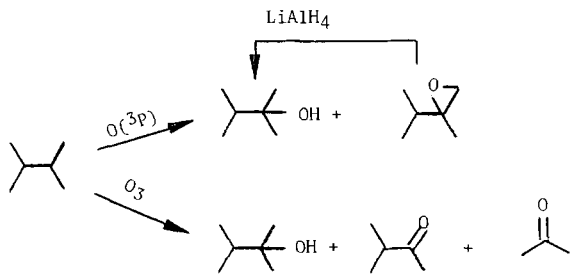
We have now applied this oxidation method to five acyclic hydrocarbons and have found that also in these cases the major products were tertiary alcohols and tertiary epoxides (Table 2). Since reduction of these epoxides with $LiAlH_4$ leads to the same tertiary alcohols, the reduction of the total mixture of products gave the alcohols in comparatively high yields. The amounts of ketones derived from C—C bond cleavage is considerably lower than in the ozone oxidation (Table 2).

Table 2. Product distribution [%] in the reaction of O(^{3}P) with acyclic hydrocarbons.

Substrate	Tertiary alcohols [a]	Secondary and primary alcohols + ketones	Epoxides	Ketones (by C—C cleavage) [b]
	64 (97)	2	34	— (65)
	55 (73)	21	20	4 (42)
	52 (75)	13	24	12 (50)
	45 (82)	15	40	— (57)
	51 (67)	32	17	— (77)

[a] In parenthesis: relative yields after reduction of reaction mixture with lithium aluminium hydride. [b] In parenthesis: relative yield of C—C cleavage products formed in the ozone oxidation.

This may be exemplified by the oxidation of 2,3-dimethylbutane, which results in 2,3-dimethyl-2-butanol (64%) and 1,2-epoxy-2,3-dimethylbutane (34%), and after reduction with lithium aluminium hydride in 97% of the tertiary alcohol (Scheme 1). Reaction of 2,3-dimethylbutane and O_3 gave only 35% of the tertiary alcohol in addition to acetone (37%) and 3-methyl-2-butanone (28%)[6].



Scheme 1.

Although both ozone and O(^{3}P) hydroxylate saturated hydrocarbons, they operate by different mechanisms. Ozonation of hydrocarbons involves electrophilic attack of O_3 on C—H bonds, leading to reversible formation of a dipolar intermediate from which alcohols (C—H cleavage) or ketones (C—C cleavage) are formed. Steric effects play an important role in the ozone oxidation and are responsible in acyclic hydrocarbons for the fact that not only C—H- but also C—C-bonds can readily be attacked.

The mechanism for the reaction of O(^{3}P) with hydrocarbons probably involves H atom abstraction to form a radical pair[1]. Radical combination in a solvent cage leads to alcohols, while disproportionation of the radicals gives olefins which are then epoxidized by O atoms. This reaction, which occurs when the O-atom is colinear with the C—H bond, has comparatively small steric demands[10] and does not differentiate between cyclic and acyclic hydrocarbons.

Phanes Derived from 1,5- and 1,7-Dihydro-*s*-indacene**

By *Peter Bickert, Virgil Boekelheide,* and *Klaus Hafner**

Frontier orbital analysis of two conjugated, cyclic polyenes held face-to-face in close proximity suggests that when both polyenes have $4n\pi$-electron systems the interaction will be stabilizing, whereas when both have $(4n+2)\pi$-electron systems the interaction will be destabilizing[1]. To test this prediction experimentally it would be of especial interest to examine phanes having nonbenzenoid aromatic and also antiaromatic decks as model compounds.

In the course of experiments directed toward a synthesis of [2.2](2,6)-*s*-indacenophane, we have now prepared, *inter alia*, the tetrahydro-*s*-indacenophane **4** by means of a cyclization method not previously employed in phane chemistry.

The 2,6-disubstituted dihydro-*s*-indacene, needed as a precursor for this synthesis, was prepared in a straight-forward fashion from dimethyl 2,5-bis(bromomethyl)terephthalate[2]. On reaction with diethyl malonate in the presence of excess sodium ethoxide it was converted in 85% yield into diethyl 1,5-dioxo-1,2,3,5,6,7-hexahydro-*s*-indacene-2,6-dicarboxylate (m.p. = 158–161 °C (dec.)), which after reduction with $NaBH_3CN$/acetic acid followed by elimination of water using TsOH/$CHCl_3$ gave diethyl 1,5-dihydro-*s*-indacene-2,6-dicarboxylate[3a] as stable colorless needles (m.p. = 186–187 °C), intensely fluorescent under long wavelength UV light. Reduction of this with diisobutylaluminum hydride gave 1,5-dihydro-*s*-indacene-2,6-dimethanol[3b] as air-sensitive, colorless crystals (m.p. = 197–199 °C (dec.)) which was converted by treatment with $SOCl_2$ into a mixture of 2,6-bis(chloromethyl)-1,5-dihydro-*s*-indacene **1** and its 1,7-dihydro isomer (m.p. = 137–140 °C (dec.)). The overall yield from the bis(β-keto ester) was 50%.

[**] This work was supported by the National Science Foundation and the Fonds der Chemischen Industrie.

Treatment of **1** with 4,4′-biphenyldimethanethiol under high dilution conditions gave the corresponding dithia[3](4,4′)biphenylo[3](2,6)dihydro-*s*-indacenophane **2** (colorless crystals, dec. > 250 °C)[3c], and desulfurization by irradiation in a solution of trimethyl phosphite/benzene gave the [2.2]phane **3** (colorless crystals, dec. > 250 °C) in 33% yield[3d].

Attempts to prepare tetrahydro-*s*-indacenophane **4** from **1** by standard methods of cyclophane synthesis failed. However, when **1** was treated with tetracarbonylnickel in *N,N*-dimethylformamide, following the procedure of *Corey et al.*[4] for converting allyl halides into macrocycles, the desired phane **4** was formed in 10% yield as a mixture of double bond isomers (air-sensitive, colorless crystals, dec. > 100 °C)[3e]. Catalytic hydrogenation of **4** readily gave the novel, bridged "cyclophane" **5** (colorless crystals, m.p. = 204–206 °C (dec.))[3f].

The intermediate diethyl 1,5-dioxohexahydro-*s*-indacene-2,6-dicarboxylate has also been shown to be a useful precursor for a logically-designed synthesis of 1,5- and 1,7-dihydro-*s*-indacene, interesting molecules for which there are other known literature procedures[5]. Hydrolysis and decarboxylation of the bis(β-keto ester) with TsOH/acetic acid gave tetrahydro-*s*-indacene-1,5-dione (m.p. = 230–231 °C)[3g], which on reduction with $NaBH_4$ to the corresponding 1,2,3,5,6,7-hexahydro-*s*-indacene-1,5-diol followed by dehydration using TsOH in $CHCl_3$/tetrahydrofuran gave 1,5(1,7)-dihydro-*s*-indacene in 56% overall yield.

Active Transport of Amino Acid Anions by a Synthetic Metal-Complex Carrier

By *Hiroshi Tsukube**

Although membrane transport of amino acid anions, ATP, and other compounds has been recognized to play important roles in biology, and to have wide applications in separation science, very few artificial carriers have been reported for the selective transport of these anionic species[3,4].

Here we report that a new series of transition-metal complexes of the macrocyclic polyamine 1,4,7,10-tetrabenzyl-1,4,7,10-tetraazacyclododecane (tbcyclen) display nov-

el, characteristic functions for the active transport of amino acid anions[6]. Advantageous are that tbcyclen is easily prepared, that its metal complexes can coordinate substrates, and that the benzyl groups of tbcyclen offer the excellent hydrophobic properties required of an effective carrier.

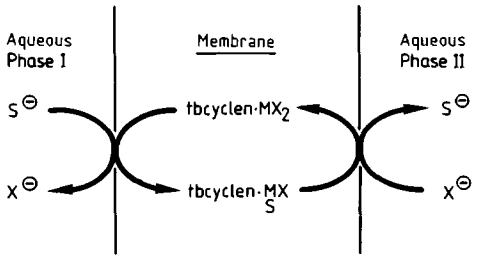

Fig. 1. Active transport of amino acid anions (substrate anion $S^{\ominus}$) through a membrane; M = metal ion, $X^{\ominus}$ = antiport anion, tbcyclen = 1,4,7,10-tetrabenzyl-1,4,7,10-tetraazacyclododecane.

Table 1 (Extract). Active transport of amino acid anions by a metal-complex carrier. Initial concentrations: Aqueous phase I: 0.250 mmol substrate in 5 mL of 0.05 N NaOH. Aqueous phase II: 0.250 mmol substrate and 5.0 mmol antiport anion salt in 5 mL of 0.05 N NaOH. Membrane: 0.056 mmol metal-complex carrier in 12 mL of $CHCl_3$.

Substrate	Antiport Anion	Equilibrated Substrate Distribution [mmol] [a]		
		Aq. Phase I	Membrane	Aq. Phase II

Bz-Val	$Cl^{\ominus}$	0.105	0.040	0.355

[a] Determined spectroscopically after 24 h's experiment. Bz = benzoyl.

Some amino acids anions were effectively transported against their concentration gradients with the aid of these metal-complex carriers *via* an anion exchange mechanism[4] (Fig. 1, Table 1). The transport selectivity and efficiency of the system could be regulated by the nature of the ligand, as well as by the type of coordinated metal ion, and antiport anion:

- The novel carrier, tbcyclen-$CuCl_2$, showed different transport selectivities from those displayed by previously reported copper complexes and lipophilic organic carriers[4]. This indicates that coordination character and lipophilic properties of the ligand essentially influence the transport behavior.
- tbcyclen-$CuCl_2$ and -$CoCl_2$ were found to facilitate transport of amino acid anions more effectively than the corresponding $NiCl_2$ complex.
- The influence of the antiport anion on the transport rates clearly shows that $Cl^{\ominus}$ is more effective than $ClO_4^{\ominus}$ or $SCN^{\ominus}$ in this respect.

Hence, the metal-complex carriers discussed here may provide a simple model for biological transport as well as prototypes for the separation of anions by membranes.

Electrochemical Reduction of [2.2]Paracyclophane

By *Rodolphe Jund, Paul Lemoine*, and *Maurice Gross**

[2.2]Paracyclophane exhibits enhanced basicity compared to other cyclophanes[6] and its reduction potential, $E_{1/2}$, which has only been determined indirectly to date (-3.05 ± 0.12 V *vs.* SCE) is, as expected, more negative than that of other cyclophanes[1]. We have now determined this potential directly using a dropping mercury electrode in the system *N,N*-dimethylformamide (DMF)/tetrabutylammonium perchlorate: $E_{1/2} = -3.00 \pm 0.05$ V *vs.* SCE. Attempts to determine the electrochemical reduction of benzene under the same conditions failed, even at $-35\,^{\circ}C$. Reduction of [2.2]paracyclophane can also be studied cyclovoltammetrically. Whereas no anodic peak is observed at low potential scan rates (5–20 V/s), at higher rates (> 50 V/s) such a peak is observed (Fig. 2). This indicates that the reduced species rapidly decomposes.

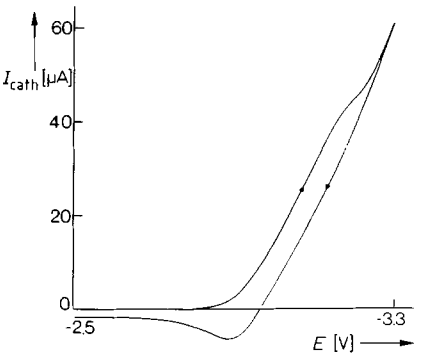

Fig. 2. Cyclovoltammogram of [2.2]paracyclophane (7×10^{-3} mol/L). Solvent DMF. Conducting salt: tetrabutylammonium perchlorate (0.2 mol/L). Electrode: mercury. Potential scanning rate: 100 V/s. Triangular sweep between -2.5 and -3.3 V (*vs.* SCE).

The number of electrons transferred in the reduction could not be determined by potentiostatic coulometry. However comparison of the height of the polarographic reduction wave of [2.2]cyclophane with those of "similar" compounds (naphthalene, phenanthrene, anthracene) suggests that the reaction is a two electron transfer process. The experimental results are certainly consistent with the hypothesis that the electrochemical reduction of [2.2]paracyclophane generates a diradical—bromination of [2.2]paracyclophane to afford 4,12-dibromo[2,2]paracyclophane is also in accord with this—but the involvement of a dianion cannot be excluded.

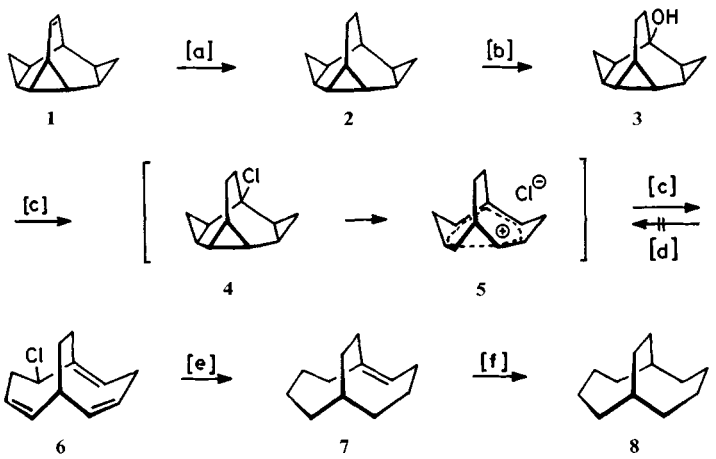
Bicyclo[4.4.2]dodeca-1-ene—The First "Hyperstable" Bridgehead Olefin**

By *Hanspeter Kukuk, Ehrhardt Proksch*, and *Armin de Meijere**

Bridgehead olefins have long lost their uniqueness[1]. On the basis of force field calculations the possible existence of "hyperstable" bridgehead olefins has recently been predicted, yet no experimental evidence of such species has so far appeared in the literature[2]. We therefore describe the surprising result of unsuccessful attempts to prepare a bridged trishomocycloheptatrienyl cation, which unexpectedly led to the formation of the hyperstable compound **7** (Scheme 1).

Catalytic hydrogenation of the *exo,exo*-bishomobullvalene **1**[3] afforded pentacyclo[4.4.2.0^{2,4}.0^{5,7}.0^{8,10}]dodecane **2**, an ethano-bridged *cis*-trishomocycloheptatriene. **2** can be oxidized to the bridgehead alcohol **3** (42% yield) by dry ozonation[4] on silica gel deactivated with 5 wt-% of potassium hydroxide. Reaction of **3** with sulfinyl chloride in the presence of diethylaminomethylpolystyrene does not lead



Scheme 1. [a] PtO_2/H_2, MeOH, RT; [b] O_3/SiO_2-KOH; [c] $SOCl_2$, polymer base, CH_2Cl_2, −40 °C to RT; [d] SbF_5, SO_2ClF, −110 to −78 °C; [e] PtO_2/H_2, Et_2O, 24 h; [f] as [e], but 72 h.

to the expected bridgehead chloride **4**, even under mild conditions (−40 to +20 °C). Rather, according to its ^{1}H- and ^{13}C-NMR spectra the product (61%) is the 10*exo*-chlorobicyclo[4.4.2]dodeca-1,4,7-triene **6** [δ(^{1}H) = 5.82 (dddd, H-5), 5.52—5.65 (m, H-2,4,7), 5.12 (dddd, H-8), 4.37 (ddd, H-10^{endo}); δ(^{13}C) = 140.5 (C-1), 5 doublets at 138.1, 131.7, 130.8, 128.8, 117.9 (C-2,4,5,7,8)].

Institut für Organische Chemie und Biochemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen.

Obviously **4** is so labile that it rearranges in a [$_\sigma$2$_s$ + $_\sigma$2$_s$ + $_\sigma$2$_s$]-cycloreversion *via* the bridgehead cation to **6**, even in the weakly polar solvent dichloromethane. Several attempts by spectroscopic investigation to directly demonstrate the presumed intermediary formation of the bridged trishomocycloheptatrienyl cation **5** as the first representative of its kind[5] have failed. Under superacidic conditions (HSO_3F/SbF_5 or SbF_5/SO_2ClF) only polymers were obtained, both from **3** as well as from **6**.

6 is a bridgehead olefin of the hitherto little known bicyclo[4.4.2]dodecane system. Such bridgehead olefins should, according to molecular mechanics calculations, exhibit less strain energy than the corresponding saturated hydrocarbons[2]. **6** can be reductively dehalogenated over prehydrogenated platinum dioxide in ether, and selectively hydrogenated to the monoolefin **7** [δ(^{1}H) = 5.35 (br. dd, H-2); δ(^{13}C) = 142.26 (s, C-1), 126.95 (d, C-2), 10 signals between 36.84 and 24.35]. The finding that further hydrogenation to bicyclo[4.4.2]dodecane **8** requires at least three times longer reaction time, seems to indicate that there is a "hyperstability effect"[2] in **7**.

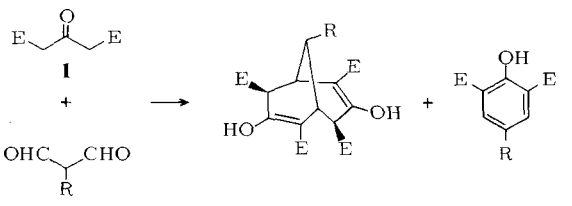
Synthesis of Bicyclo[3.3.1]nonane Derivatives under Physiological Conditions

By *Steven H. Bertz** and *Gary Dabbagh*

Prelog et al. prepared a variety of phenols from 1,3-dicarbonyl compounds and diethyl 3-oxoglutarate or ethyl acetoacetate in hot ethanolic sodium ethoxide[1a]. It has been shown that in some cases better yields can be obtained by conducting the reaction at room temperature in aqueous solution containing 0.1 to 1 equivalents of NaOH (pH 7—8) and methanol cosolvent[1b]. Organic chemists often refer to such buffered[1c] aqueous solutions as "physiological conditions"[1d]. We wish to report that when they are treated with dimethyl 3-oxoglutarate **1** under these



2, R = H
3, R = *n*-C_5H_{11}
E = CO_2CH_3

4 **5** **6** **7**

[*] Dr. S. H. Bertz, G. Dabbagh
Bell Laboratories
600 Mountain Avenue, Murray Hill, New Jersey 07974 (USA)

conditions, malondialdehyde **2** and *n*-pentylmalondialdehyde **3** yield bicyclo[3.3.1]nonane derivatives **4** (67%) and **5** (21%), respectively. This new reaction is reminiscent of the formation of tropinone derivatives from 3-oxoglutarate, succindialdehyde, and methylamine[1d].

The yields of **4** and **5** fall off as the pH is raised above 8 or lowered below 7. The yield of phenol **6** obtained from **1** and **2** is maximal (43%) at pH 4.5. In contrast, the yield of phenol **7** is maximal (26%) at pH 7, which explains why the yield of **5** is lower than that of **4**. Remarkably, under *Prelog*'s conditions only **4** is produced from **1** and **2**, although the yield (49%)[2] is lower than under physiological conditions. Only 10% of **7** and no **5** is observed with **1** and **3** under these conditions. Thus, compounds **4**, **5**, and **7** are all best prepared under physiological conditions.

The preferred formation of **6** at low pH has been adduced as supporting evidence for the intermediacy of dimethyl 2-oxo-5-hydroxy-3-cyclopentene-1,3-dicarboxylate in the Weiss reaction of **1** with glyoxal at pH 5[3a]. Given the precedents[1a] for phenol formation and the driving force of aromatization, it is surprising that **1** and **2** proceed to afford **4** in analogy to the formation of bicyclo[3.3.0]octane[3b] or bicyclo[3.3.2]decene[3c] derivatives from **1** and glyoxal or *o*-phthalaldehyde, respectively. In neither of these cases is a six-membered ring intermediate possible, thus our work bridges this gap between five- and seven-membered ring compounds and clarifies when the driving force of aromatization is effective.

In order to prove the structure, **4** was hydrolyzed and decarboxylated[4a] to yield bicyclo[3.3.1]nonane-3,7-dione[4b] (83%) in what is also a very convenient preparation of this useful compound[4c]. Similarly, after hydrolysis and decarboxylation **5** furnished the novel 9-pentylbicyclo[3.3.1]nonane-3,7-dione (100%)[4d].

Ethyl 2-formyl-3-oxopropionate[5a] reacts with **1** to give only the mixed ester of 2-hydroxy-1,3,5-benzenetricarboxylic acid at pH 5 (65%) and pH 7 (70%, 78% as the Na salt). No transesterification is observed under our mild conditions. Bromomalondialdehyde gave neither phenol nor bicyclo[3.3.1] derivative at pH 5 or 7; no product was observed by *Prelog et al.* either[1a].

This new reaction furnishing bicyclo[3.3.1]nonane derivatives is significant because of the large increase in molecular complexity[5b] brought about under very mild conditions, which are not likely to affect other functional groups.

Experimental

5: Dimethyl 3-oxoglutarate (7.0 g, 0.04 mol) was dissolved in 10 mL of methanol and 10 mL of 1.0 M NaOH added, followed by 1.7 g (0.01 mol) of the sodium salt of **3**[6]. The final pH was 8. After being stirred for 4 days at ambient temperature, acidification to pH 3 gave 1.9 g of crude material, which was isolated by decanting the aqueous layer and drying the organic residue *in vacuo*. (Extraction of the aqueous layer with CH_2Cl_2 gave 4.5 g of **1**.) Crystallization from $CHCl_3$ yielded 0.95 g (21% relative to **3**). Recrystallization from $CHCl_3/CH_3OH$ (1:1) gave an analytically pure sample, m.p. = 129–131°.

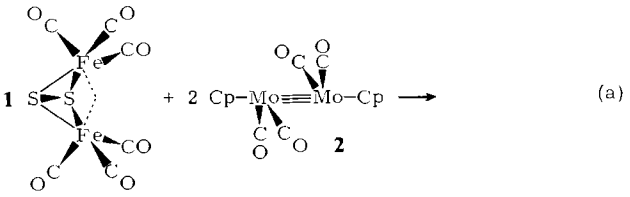
A New Type of Iron-Molybdenum-Sulfur Cluster: Synthesis and Structure of $[Fe_2Mo_2(\eta^5\text{-}C_5H_5)_2(\mu_3\text{-}S)_2(\mu_3\text{-}CO)_2(CO)_6]$**

By *Pierre Braunstein**, *Jean-Marc Jud*, *Antonio Tiripicchio*, *Marisa Tiripicchio-Camellini*, and *Enrico Sappa*

Iron-molybdenum-sulfur clusters[1] are of interest, *inter alia*, because of their occurrence in nitrogenase[2]. We have now prepared a new cluster of this type, namely **3**, with the unprecedented framework stoichiometry $\{Fe_2Mo_2S_2\}$, by reaction of the diiron complex **1**[3] with the dinuclear molybdenum compound **2** ($Cp = \eta^5\text{-}C_5H_5$) in toluene.



$$Fe_2Mo_2Cp_2(\mu_3\text{-}S)_2(\mu_3\text{-}CO)_2(CO)_6 + [CpMo(CO)_3]_2$$
3 **4**

Reaction (a) is the third example[4] for the formation of a heterotetranuclear cluster from **1** and a dinuclear species. The high reactivity of the MoMo triple bond in **2** towards electrophiles and nucleophiles[5] facilitates reaction under very mild conditions.

[**] This work is part of a CNR-CNRS cooperation program and was supported by an Italian C.N.R. Grant (No. 7902133).

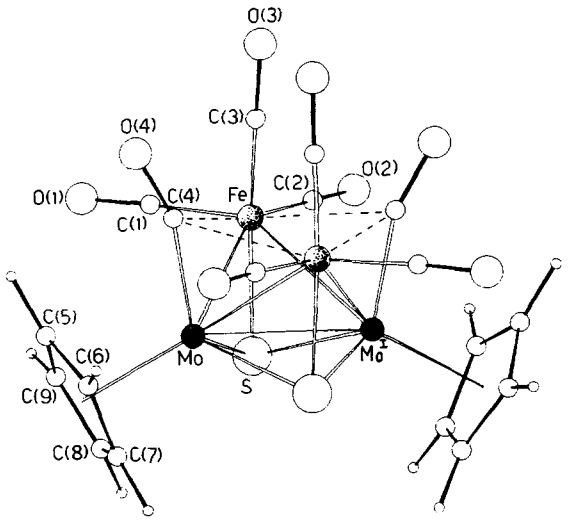

Fig. 1. Molecular structure of **3** in the crystal. C2/c; $Z=4$; $a=17.927(10)$, $b=8.316(4)$, $c=15.978(8)$ Å; $\beta=114.31(5)°$; $V=2171(2)$ Å^3, $\rho_{calc}=2.209$ g cm^{-3}; 1485 independent reflections ($3°<\theta<23°$), Nb-filtered $Mo_{K\alpha}$ radiation, 504 reflections ($I>2\sigma(I)$) were used in structure solution and refinement; $R=0.052$. Selected bond distances (Å) and angles (°): MoMo' 2.846(5), MoFe 2.818(5), MoFe' 2.815(5), MoS 2.335(9), MoS' 2.327(9), FeS 2.165(8), MoC4 1.90(4), FeC4 2.62(3), Fe'C4 2.64(3); FeMoFe' 85.8(1), FeMoMo' 59.6(1), FeMo'Mo 59.7(1), MoFeMo' 60.7(1), MoSMo' 75.3(3), FeSMo 77.4(3), FeSMo' 77.5(3), MoC4O4 159(3), FeC4O4 119(2), Fe'C4O4 116(2). I indicates the transformation $-x, y, 1/2-z$. **3** has forced C_2-symmetry, but it is almost C_{2v}.

The X-ray structure analysis of **3** (Fig. 1) (cf. [6a]) revealed a "butterfly arrangement" of the four metal atoms with the two molybdenum atoms in the hinge position (butterfly angle: 104.1°). A four-electron donor sulfur atom is μ_3-bonded on each $FeMo_2$ wing, confirming the tendency of sulfido-ligands to assist cluster formation[1b, 3b]. Noteworthy is the unusual nature of the two CO-bridges. The IR spectrum suggests presence of μ_3-bonding [ν(CO) (KBr): 2043 m, 2010 s, 1982 s, 1975 s, 1956 m, *1791* ms cm^{-1}], but this situation usually occurs for CO ligands capping a closed trimetallic face, whereas the arrangement of $MoFe_2$ is open (Fe···Fe' = 3.833(5) Å).

One can visualize the formation of **3** as a formal "insertion" of the MoMo triple bond of **2** into the Fe_2S_2 core of **1** accompanied by Fe—Fe and S—S bond breaking. This would reduce the metal-metal bond order; the Mo—Mo distance in **3** (2.846 Å) is indeed intermediate between that in **2** (2.448 Å[6b]) and in **4** (3.235 Å[6c]).

Experimental

All reactions and operations were carried out under nitrogen. Solvents were dried and distilled under nitrogen before use. A solution of **1**[6d] (0.47 g, 1.4 mmol) in toluene (25 ml) was added at 0°C to a solution of **2**[5a] (1.20 g, 2.8 mmol) in the same solvent (75 ml). This mixture was stirred for 0.25 h at 0°C. The residue obtained after filtration and evaporation under reduced pressure was chromatographed on a silica gel column. Elution with pentane gave a red-brown solution of $Fe_3S_2(CO)_9$ (0.03 g). Further elution with toluene/pentane (3:10) furnished a red solution of **4** [0.25 g (0.5 mmol) ≙ 21% based on Mo, after recrystallization from CH_2Cl_2/pentane]. Using a toluene/pentane (1:1) eluent afforded a red-brown solution of **3**, from which dark-red monoclinic crystals were obtained with CH_2Cl_2/pentane [0.325 g ≙ 33% based on Fe; m.p. > 140°C (decomp.)]. Elution with THF afforded a dark-brown compound which has not yet been characterized.

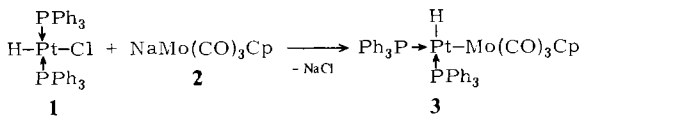
Synthesis and Structure of a Heterodimetallic Complex Containing a Terminal Hydrido Ligand: $[(PPh_3)_2(H)PtMo(CO)_3(\eta^5\text{-}C_5H_5)]$**

By *Odile Bars* and *Pierre Braunstein**

Dinuclear hydridocarbonyl complexes are considered to be interesting model compounds or intermediates in CO reduction, and much work is presently directed towards the synthesis and characterization of such systems[1].

We have envisaged synthesizing such complexes by reaction of *trans*-$PtH(Cl)(PPh_3)_2$ **1** with carbonylmetalates. Simple chloride exchange would indeed afford the desired product, but, in view of our previous results in the field[2], more complicated pathways cannot be ruled out. Thus it was open to speculation whether the phosphane ligands in (**1**) would remain coordinated or not to the platinum during the envisaged reaction.

In the reaction of **1** with **2** we were able to isolate the complex **3** ($Cp=\eta^5\text{-}C_5H_5$).



3, IR (KBr): ν(PtH): 2103 m, ν(CO): 1916 s, 1828 s, 1797 vs cm^{-1}; ^{1}H-NMR ([D$_8$]toluene, −40°C): $\delta=-5.73$ [d, H1, ^2J(H1,P2) = 170 Hz, ^1J(Pt,H1) = 678 Hz]; 5.44 [s, 5H, Cp]; ^{31}P[^{1}H]-NMR ([D$_8$]THF, −40°C); $\delta=31.9$ [d, P1, ^2J(P1,P2) = 6 Hz, ^1J(Pt,P1) = 3690 Hz], 35.5 [d, P2, ^1J(Pt, P2) = 2653 Hz].

[**] Organometallic Complexes with Metal-Metal Bonds, Part 17. This work was supported by the Centre National de la Recherche Scientifique.— Part 16: P. Braunstein, D. Matt, O. Bars, M. Louër, D. Grandjean, J. Fischer, A. Mitschler, *J. Organomet. Chem. 213* (1981) 79.

The $^{31}P\{^1H\}$-NMR spectrum of the two non-equivalent phosphorus atoms appears as an AB pattern; the magnitude of $^2J(P1,P2)$ indicates a *cis*-type of orientation of the phosphane ligands. The ^1H-NMR spectrum in the hydride region shows a doublet with ^{195}Pt-satellites, thus indicating a Pt-bonded hydrido ligand in a terminal position (because of the high $\nu(Pt—H)$ frequency). The fact that $^2J(P1,H)=0$ was confirmed ^{31}P-NMR spectroscopically by an off resonance experiment.

From the NMR spectra it follows that a dynamic behavior occurs above 0 °C, and is being further investigated.

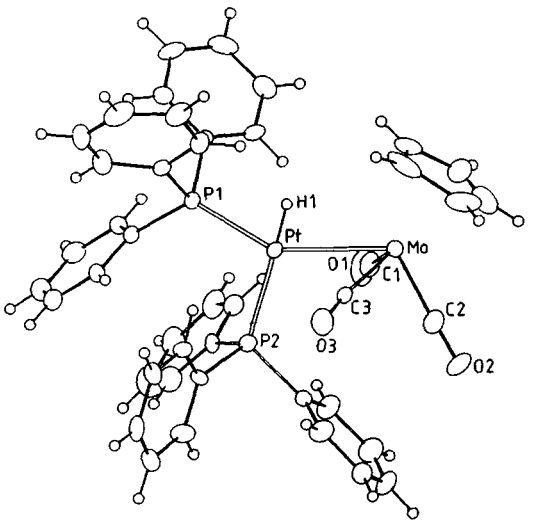

Fig. 1. Molecular structure of **3** in the crystal. $P2_1/n$, $Z=4$; $a=15.42(1)$, $b=16.44(1)$, $c=16.50(2)$ Å; $\beta=103.13(5)°$; $V=4076$ Å^3, 4159 reflections ($I>3\sigma(I)$), $Mo_{K\alpha}$ radiation, $R=0.053$. Selected bond distances [Å] and angles [°]: PtMo: 2.839(1), PtP1: 2.264(3), PtP2: 2.355(3); MoPtP1: 149.1(1), MoPtP2: 108.8(1), P1PtP2: 101.3(1).

According to the X-ray structural analysis of **3** (Fig. 1) the Pt atom is located in the plane defined by P1, P2 and Mo, but the usual square-planar environment found for Pt[1] complexes is strongly distorted in order to minimize steric repulsions between the bulky groups. The terminal hydride could not be located on the Fourier difference map and H1 was placed at 1.6 Å from Pt[3] on the bisector of the large P1—Pt—Mo angle, leading to a P2—Pt—H1 angle of 183.4°. The Pt—Mo distance in **3** appears to be the first value of its kind reported for such a bond in a bimetallic complex[4] and is intermediate between the value 2.889 Å found in the trimetallic carbene complex[5] *trans*-$Pt(C_6H_{11}NC)[(C_6H_{11}NH)C(OC_2H_5)][Mo(CO)_3Cp]_2$ and of 2.813 Å (average value) in the tetrametallic cluster[2a] $Pt_2Mo_2Cp_2(CO)_6(PEt_3)_2$.

Experimental

All reactions and operations were carried out under nitrogen. Solvents were dried and distilled under nitrogen before use. To a suspension of **1** (1.89 g, 2.5 mmol) in THF (20 ml) at −40 °C was added a THF solution (30 ml) of **2**, prepared from $[Mo(CO)_3Cp]_2$ (0.613 g, 1.25 mmol). When the reaction temperature was slowly raised to 0 °C, the solution turned red. The reaction mixture was stirred for 1 h at 0 °C and then filtered to remove NaCl. An equal volume of pentane was added to this solution and after cooling to −20 °C, an orange powder precipitated which was recrystallized from toluene/pentane, affording orange crystals of the product **3** [yield 1.0 g, 41.4% based on Pt; m.p. 158 °C (decomp.)].

A Stereocontrolled Synthesis of the Pheromone 4-Methyl-3-heptanol: Novel and Selective CC-Linking Reactions**

By *Manfred Schlosser** and *Katsuramaru Fujita*

Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday

The (*S,S*)-enantiomer of 4-methyl-3-heptanol is the major constituent of the aggregation pheromone of the elm bark beetle *Scolytus multistriatus* Marsham[2]. The synthesis of the racemate described here illustrates the utility of two novel, stereoselective methods for CC-linking: Addition of dimethyl (*Z*)-2-alkeneboronates to aldehydes, and transfer of alkyl groups to olefinic double bonds with titanium reagents.

After torsional isomerization in tetrahydrofuran (THF) 2-butenylpotassium assumes the (*Z*)-configuration (*"endo"* form) to the extent of more than 99%[3b]. Condensation with fluorodimethoxyborane at −75 °C affords almost pure dimethyl (*Z*)-2-buteneboronate **1**[4]. This reacts as ex-

pected[5] with propanal to give the *"erythro"*-4-methyl-5-hexen-3-ol **2**, the adduct having the (*R**,*R**)-configuration. The reaction proceeds rapidly (1 h at −75 °C, 30 min at 25 °C), stereoselectively (*erythro*/*threo*-ratio between 95 : 5 and 99 : 1, depending on the temperature profile), and with satisfactory yields (>60%). Thus, their is no need for the alternatively proposed indirect route[5c] *via* 2-butenylbis(dimethylamino)borane and 2-(2-butenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane.

For chain-extension, **2** is dissolved in THF and treated with trimethylaluminum (or methyllithium) and titanium tetrachloride (molar ratio 1 : 2 : 1). After 30 min at 0 °C, the solvent is removed by distillation under nitrogen and the residue heated to 120 °C for 3 h. Subsequent hydrolysis affords *"erythro"*-(5*E*)-4-methyl-5-hepten-3-ol **3** (b.p. 67–69 °C/15 torr) as sole volatile product (32%), besides traces of unreacted **2**. Catalytic hydrogenation of **3** leads quantitatively to the pheromone constituent 4-methyl-3-heptanol **4** (b.p. 51–54 °C/15 torr).

Evidence for Intermediates in the Cycloaddition of Singlet Carbenes**

By *Bernd Giese**, *Woo-Bung Lee*, and *Carola Neumann*

Singlet carbenes have a vacant p-orbital and an occupied σ-orbital. Cycloadditions with alkenes therefore depend upon electrophilic properties (p/π-interaction) and nucleophilic properties (σ/π* interaction) of the carbenes[1]. Because of the smaller energy difference between the interacting orbitals[1] in reactions of CBr_2 and CCl_2 the electrophilic p/π interaction is greater than the nucleophilic σ/π* interaction. Substituents on the alkene which raise the energy of the π orbital increase the p/π interaction and should therefore lower the activation energy of the cycloaddition. This is not the case, however, as the data determined in competition experiments show (see Table 1).

Table 1. Influence of varying the substituents in 2-methylpropene (R = CH_3) on the activation enthalpies [kJ·mol^{-1}] and activation entropies [J·mol^{-1} s^{-1}] of cycloadditions with CBr_2 and CCl_2.

Alkene	CBr_2		CCl_2

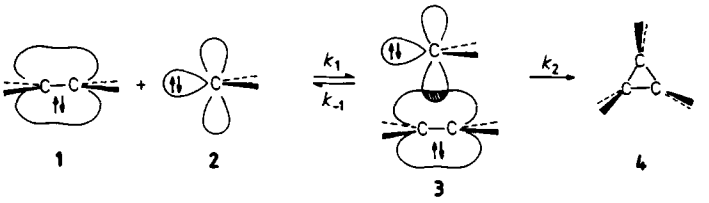
Methyl, methoxy, and phenyl groups on the alkene increase the activation enthalpies of the cycloadditions of CCl_2 and CBr_2. This cannot be explained by steric effects, because the activation enthalpies of the CBr_2 cycloadditions remain unchanged on replacing a methyl group by an ethyl or isopropyl group on the alkene (Table 1). Therefore, the substituent effects show that the nucleophilic σ/π* interaction plays a decisive role in the cycloadditions of the electrophilic carbenes CBr_2 and CCl_2. This contradiction is resolved if an intermediate **3** is postulated for the reaction of the alkene **1** with the carbene **2**[2].



In the case of a rapid equilibrium **1** + **2** ⇌ **3** the experimentally determined activation enthalpy $\Delta H^{\neq}_{exp}$ is equal to the reaction enthalpy ΔH^0 of complex formation and the activation enthalpy of the nucleophilic reaction step:

$$\Delta H^{\neq}_{exp} = \Delta H^0 + \Delta H^{\neq}_2$$

Methyl and methoxy substituents raise the energy of the π* orbitals, whereby the σ/π* distance increases and hence also the activation enthalpy $\Delta H^{\neq}_2$. Evidently for cycloadditions of CCl_2 and CBr_2 this effect is more significant than the influence of substituents on the equilibrium **1** + **2** ⇌ **3**.

The increase in reaction rate of the alkene due to methyl, methoxy, or phenyl substituents[3] is thus effected *via* an increase in the activation entropies[4].

Synthesis, Structure, and Reactions of Primary Adducts of Sulfur or Selenium with Hexaphenylcarbodiphosphorane**

By *Hubert Schmidbaur**, *Christian E. Zybill*, and *Dietmar Neugebauer*

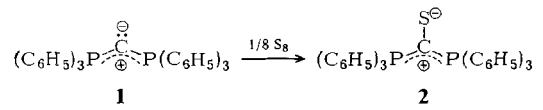
Double ylides of the carbodiphosphorane[3] type afford preparatively versatile phosphacumulene ylides as secondary products upon reaction with sulfur[4]:

[*] Prof. Dr. H. Schmidbaur, C. E. Zybill, Dr. D. Neugebauer
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

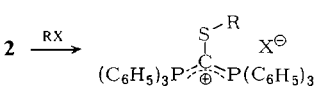
$$R_3P{=}C{=}PR_3 \xrightarrow{S_8} 2\ R_3P{=}S + CS_2 \xrightarrow{R_3P=C=PR_3} R_3P{=}C{=}C{=}S$$

Using particularly mild conditions we have now been able to show, using hexaphenylcarbodiphosphorane **1** as example, that this reaction proceeds *via* an isolable primary adduct **2** in which the carbanionic center of the ylide bonds as a donor to a sulfur atom.



1 **2**

2 forms from the components in tetrahydrofuran at $-50\,^{\circ}C$ in almost quantitative yield as a red solid, which decomposes at room temperature. Because of the strongly nucleophilic thiolate functionality, **2** reacts with methyl fluorosulfonate, benzyl chloride, or chlorotrimethylstannane to yield the colorless salts **3a–c**.

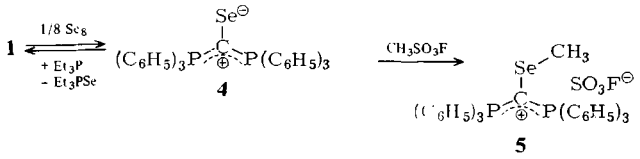


3a: R = CH_3, X = SO_3F
3b: R = $CH_2C_6H_5$, X = Cl
3c: R = $Sn(CH_3)_3$, X = Cl

2 is desulfurized by triethylphosphane at $-15\,^{\circ}C$ to reform **1**:

$$2 + P(C_2H_5)_3 \rightarrow 1 + (C_2H_5)_3P{=}S$$

Addition of selenium to the ylide **1** proceeds quantitatively, even at $-15\,^{\circ}C$, in an analogous manner to formation of **2** and affords a stable red product **4**, whose structure could be determined by single-crystal diffraction studies (Fig. 1).



4 **5**

The P=C=P framework of **1** changes only slightly on incorporation of the Se atom: the P=C bond lengths (162.9(5) or 163.8(5), depending on the modification) are lengthened to only 169.4(12) and 170.2(12) pm, and consequently the multiple bonding character remains intact. The PCP angle (130.1(6), 131.7(3) or 143.8(6)° in **1**)[5] amounts to 135.9(7)° in **4**.

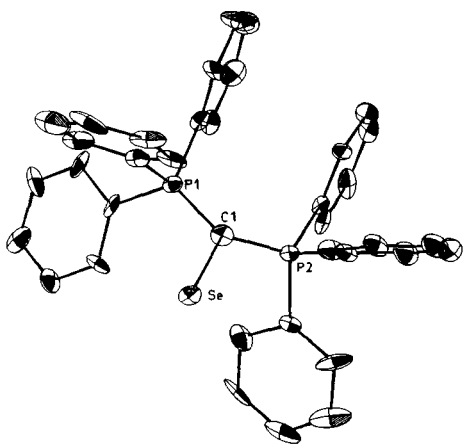


Fig. 1. Molecular structure of the selenium adduct **4** in the crystal.

The C—Se bond length (199.0(11) pm) signifies loose bonding of the selenium[6], yet the ylide carbon atom has a planar configuration (sum of angles 360°). These results clearly indicate that in carbodiphosphoranes the electron distribution and structure[5,7] can best be expressed as in formula **1**.

The selenium addition can be reversed using $(C_2H_5)_3P$. Methylation of **4** with CH_3SO_3F yields **5**.

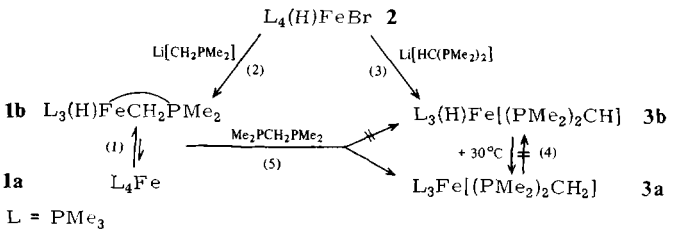
A Pentakis(phosphane)iron(0) Complex by Reductive Elimination**

By *Hans Heinz Karsch**

Earlier investigations[1a,c] on complex formation in the trimethylphosphaneiron(0) system showed that a spontaneous C—H cleavage leads to an equilibrium (1) between the Fe^0- and Fe^{II}-complexes **1a** and **1b**. This reaction proceeds intramolecularly, at least in the presence of an excess of phosphane[1a]. In solution the equilibrium (1) is largely on the side of **1b**, in the solid state only **1b** is present. We have now found that **1** can also be prepared from the Fe^{II}-complex **2**[1b] *via* path (2).



In an analogous way $[(D_3C)_3P]_4Fe(D)I$ **2'**[2a] can be converted into $[(D_3C)_3P]_4(D)FeCH_2PMe_2$ **1'** in Et_2O at $-30\,^{\circ}C$. The IR spectrum (Nujol solution, 20 °C) of **1'** initially shows only one ν(Fe—D) band, but after *ca.* 30 min it also shows a ν(Fe—H) band[1a] with rapidly increasing intensity as a result of exchange according to Eq. (1). Thus, we have the first proof of such a "cyclometalation equilibrium" as an intramolecular process.

[*] Dr. H. H. Karsch
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstr. 4, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Furthermore, **1** in combination with $Me_2PCH_2PMe_2$ serves as an ideal model system for investigating various influences on such cyclometalation reactions.

2 reacts with lithium bis(dimethylphosphino)methanide according to route (3) to give the pentakis(phosphane)iron(II) complex **3b**[2b], which, in contrast to **1b**, is unstable; it rearranges irreversibly (rapidly on warming) into **3a**[2c]. Such a reductive elimination, with the additional attribute that an atom (*i.e.* the methanide carbon) not directly bonded to the metal takes over the leaving ligand, has so far not been reported. The reverse reaction, namely the metalation of complexed methylenebis(diorganophosphane), on the other hand, is well known[3]. Other than in the case of **1**, with **3** the Fe^0 complex is favored (the proportion of which, increases with increasing temperature, in the case of **1**).

Since, according to

$$Me_2PCH_2PMe_2 + Li[CH_2PMe_2] \rightarrow Li[HC(PMe_2)_2] + PMe_3$$

PMe_3 is less acidic than $Me_2PCH_2PMe_2$ it is clear that not the acidic character (stability of the anion) is decisive for a C—H cleavage, but—e.g. in the case of **1a** (cf. [3])—the coordinatively unsaturated character. $Me_2PCH_2PMe_2$ is less space-demanding than two PMe_3 ligands and is therefore more effective for coordinative saturation (according to IR studies on corresponding $L_2Cr(CO)_4$ complexes electronic effects are not decisive). The few pentakis(organophosphane)iron(0) complexes previously described in the literature have *two* (likewise sterically favorable) $Me_2PCH_2CH_2PMe_2$ ligands[4].

Thus, **3a**, which is also accessible *via* route (5), is the first such complex with three monodentate organophosphane ligands. In solution (−90 °C) it is fluxional, in the crystalline state it has a square-pyramidal structure[5], which also distinguishes it from other P_5Fe^0 complexes[1a,c] and possibly facilitates the rearrangement (4).

[5] From the cell parameters (tetragonal, Laue group 4, $a = b = 796$, $c = 920$ pm, $Z = 1$, no systematic absences) it follows that the Fe atom is localized on a tetradentate axis of rotation; this requires ligand disorder: U. Schubert, private communication.

Ring Contraction 6—5/3 by Oxidative Addition to a Ferrabicycle having Novel Structural Units**

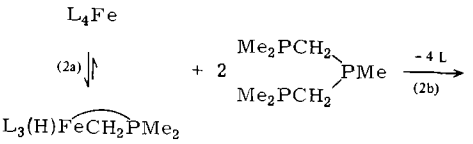
By *Hans Heinz Karsch** and *Dietmar Neugebauer*

To our knowledge cyclometalation reactions with ring contractions of type (1) have so far never been reported in the literature.

(1)

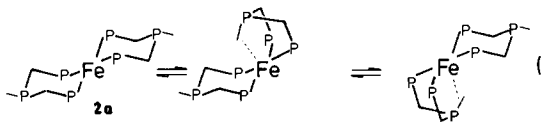
We have now been able to isolate an iron complex whose mode of formation, spectroscopic data[1], and X-ray structure analysis affords evidence of such a type of reaction.

Ligand exchange with $(Me_2PCH_2)_2PMe$[2] at the iron(0) complex **1a**, which is in equilibrium (2a) with its hydridoiron(II) isomer **1b**, leads *via* route (2b) to the product **2**.



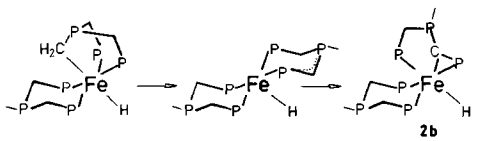
L = PMe_3 "$[MeP(CH_2PMe_2)_2]_2Fe$" **2**

Since the complex **2a** analogous to **1a** should, as coordinatively unsaturated Fe^0 compound, have an adequately long lifetime (flexible chelate angle, shielding by "free" phosphorus at position 4) to enable cleavage of C—H, *e.g.*



(3)

via equilibrium (3), it is not surprising that such an oxidative C—H addition actually occurs at the Fe center. Surprisingly, however, the primary product of this reaction is not isolated, but, due to increased CH acidity in the six-membered ring, a "diphosphinomethanide" moiety is formed in a (presumably intramolecular) acid-base secondary reaction (4)[3,4].



(4)

Of the novel structural moieties in **2b**—a six-membered M—PCPCP ring and a five-membered M—CPCP ring with annelated three-membered M—CP ring—the carbon atoms of the two smaller rings are disordered in the crystal and the positional parameters of the dotted atoms in Figure 1 could not be determined accurately.

[*] Dr. H. H. Karsch, Dr. D. Neugebauer
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstr. 4, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

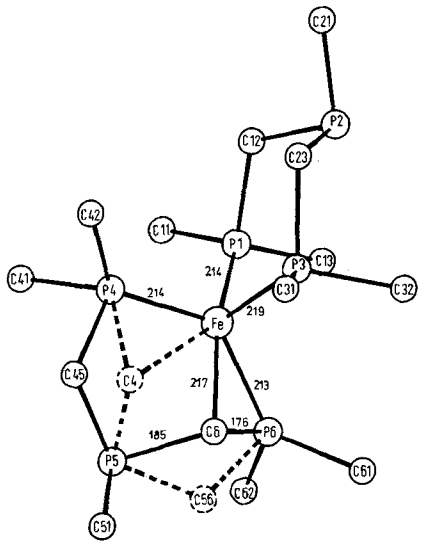


Fig. 1. Molecular structure of **2b**; the hydrido ligand could not be located with certainty. Ratio in the crystal: dotted/undotted = 2:3. Monoclinic, $P2_1/n$, $Z=4$, $a=935.9(6)$, $b=1625.8(10)$, $c=1552.1(8)$ pm, $\beta=94.69(5)°$, $V=2353.7\times10^6$ pm^3, $\rho_{calc}=1.26$ g/cm^3, $C_{14}H_{38}FeP_6$. 2116 structural factors ($F>4.5\sigma_F$; $2°\leq2\theta\leq48°$), $Mo_{K\alpha}$ ($\lambda=71.069$ pm, graphite monochromator), $R_1=0.115$, $R_2=0.118$ (Syntex $P2_1$/XTL).

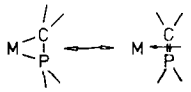
The six-membered ring has chair conformation, and also the five-membered ring is not planar (P5 and C45 lie 117 and 12 pm respectively above the Fe—P4—C6 plane). The three-membered ring is oriented at an angle of 154.6° to this plane. The short P6—C6 distance favors a bonding description



which would reduce ring strain and explain the high tendency for formation of M—CP three-membered rings, and also suggests an analogy to η^1,η^2-alk-4-enyl complexes[5]. In contrast, the Fe—C6 and Fe—P4 bond lengths are "normal" for sp^3 bonds[4]. More meaningful from a coordination-chemical point of view is formulation as a 5/3 ring system. The NMR data indicate a *cis*-H—Fe—C arrangement with a phosphorus atom *trans* to an H-atom, which would allow **2b** to be termed an analogue of **1b**, despite its unusual mode of bonding and properties.

BOOK REVIEWS

Comprehensive Treatise of Electrochemistry. Vol. 2: Electrochemical Processing Edited by *J. O'M. Bockris, B. E. Conway, E. Yeager,* and *R. E. White*. Plenum Press, New York, 1981. xxii, 616 pp., bound, $ 57.50.

This is the second in a series of four volumes[*] dealing with applied or industrial electrochemistry. In the space of eleven chapters, nineteen authors attempt to describe the most important industrial processes with an electrochemical basis. The individual contributions are as follows: 1) Electrolytic Production of Hydrogen (104 pp., 133 refs.), by *B. V. Tilak, P. W. T. Lu, J. E. Colman,* and *S. Srinivasan*; 2) Production of Chlorine (62 pp., 118 refs.), by *D. L. Caldwell*; 3) Inorganic Electrosynthesis (84 pp., 371 refs.), by *N. Ibl* and *H. Vogt*; 4) Electro-Organic Syntheses (49 pp., 99 refs.), by *K. Köster* and *H. Wendt*; 5) Electrometallurgy of Aluminum (25 pp., 79 refs.), by *W. E. Haupin* and *W. B. Frank*; 6) Electrolytic Refining and Winning of Metals (54 pp., 77 refs.), by *V. A. Ettel* and *B. V. Tilak*; 7) Electroplating (17 pp., 34 refs.), by *C. J. Raub;* 8) Electrochemical Machining (122 pp., 370 refs.), by *J. P. Hoare* and *M. A. LaBoda*; 9) Theory of the Structure of Ionomeric Membranes (15 pp., 15 refs.), by *A. J. Hopfinger* and *K. A. Mauritz*; 10) Electrodeposition of Paint (33 pp., 123 refs.), by *F. Beck,* and 11) Mineral Flotation (25 pp., 60 refs.), by *R. Woods*.

It is a wide field, ranging from the electrosynthesis of inorganic and organic substances to specific industrial processes with an electrochemical basis, such as mineral flotation. Quite correctly, the currently most important electrochemical winning processes (of chlorine and aluminum), and hydrogen production, which may well be important in the future, have whole chapters devoted to them. The contributors are authorities in their fields, and the editors deserve credit for the fact that, despite the large numbers of authors and contributions, they managed to produce a homogeneous work. Virtually all the chapters begin with an introduction to the problem and economic significance of the process, follow this with a brief survey of the thermodynamic and kinetic aspects, and finally give practical solutions.

The book contains a wealth of technical details, exact numerical data, and references which will certainly make it a useful reference work for the subject specialist; at the same time, it is this very wealth of technical detail (*e.g.* plant dimensions) that will divert the newcomer from the essentials. Overall, the work is a success; one limited criticism is that it has missed the chance of consciously establishing the relationships with fundamental electrochemical problems, or making a stronger link with Volume 1 of the series. The opportunities were surely there; we have only to think of the chapter on metal winning and refining. Relating this to the corresponding problems in basic research (*e.g.* adsorption, nucleation, overvoltage, undervoltage deposition) would have opened the eyes of both the electrochemist working in basic research and the student to the problems of industrial electrochemistry. Nevertheless, the book gives an interesting insight into the problems of electrochemistry, even to those not directly concerned.

[*] *Angew. Chem. 93* (1981) 840; *Angew. Chem. Int. Ed. Engl. 20* (1981) 817.

Like Volume 1, Volume 2 is distinguished by excellent layout and painstaking typography. The extensive use of photographs and drawings is a great help in the clarification of practical aspects. This second volume can also be highly recommended to libraries specializing in this area as an enrichment of the electrochemical literature.

Dieter M. Kolb [NB 558 IE]

Liquid Phase High Pressure Chemistry. By *N. S. Isaacs*. J. Wiley & Sons, Chichester 1981. vii, 414 pp., bound, £ 33.00.

As the author explains in his preface, this is not a book for the specialist but rather for someone interested in becoming better acquainted with the details and application of a technique that is not too widely known. In this aim the author has been completely successful. In six chapters the reader is presented with a readily understandable survey on high-pressure chemistry in the liquid phase.

The author starts by describing the methods used to produce and measure high pressures, including many valuable characteristic materials data and tips on the construction of high-pressure equipment. This is supplemented by an instructively and abundantly illustrated description of selected high-pressure equipment for different analytical techniques as described in the literature.

The chemists and physicists engaged in practical work will find useful data on materials, *e.g.* compressibilities and pressure coefficients of optical and electrical properties, collected together or derived in Chapter 2.

Logically, it is only after providing this helpful material that the author turns to describe the influence of high pressures on chemical equilibria and reactions. The examples are drawn predominantly from the realm of organic chemistry, reflecting both the many organic systems that have been studied and the author's own interests. Isaacs succeeds in providing a critical appraisal of the molecular interpretation of volume effects, and also the use of these parameters derived from the pressure dependence in the discussion of mechanisms.

The increasing use of high-pressure techniques to study biochemical systems is acknowledged; this is discussed in a separate chapter. The survey is rounded off by the description of pressure effects on photophysical and photochemical phenomena.

More than 1200 literature references give an opportunity to check on details.

It is a pity that the book probably will not reach a wide circle of readers—including students—because of its high price.

Anomalies of Liquid Water

By Elmar Wolfgang Lang and Hans-Dietrich Lüdemann*

Water at low temperatures ($T<300\,K$) reveals a multitude of unusual physico-chemical properties, which originate from the strong directivity of the hydrogen bonds. This directivity forces the molecules into a tetrahedral arrangement of first neighbors and thus leads to a poor packing efficiency. All anomalies of the liquid become more pronounced in the metastable range below the melting pressure curve. In the following article, methods for the investigation of the supercooled range are presented. A few anomalous static and dynamic properties are described and compared with the properties of normal liquids. The experimental results are discussed in the context of computer simulations and the more recent theories on cold water. It can be concluded that the anomalies of water, for instance the density maximum of the liquid phase and the initial decrease in viscosity with pressure, are confined to the pT-range: $T<300\,K$, $p\lesssim 200$ MPa. At these pressures, lowering the temperature leads to an unexpected behavior of almost all physical properties. They seem to approach a phase transition at $T\simeq(T_M-50\,K)$, the nature of which has not yet been fully characterized. This phenomenon has hitherto been observed only in supercooled water.— In the future it will be possible to use supercooled aqueous solutions for kinetic studies, thus expanding the available dynamic range for the investigation of aqueous solutions considerably.

1. Introduction

Water is the most abundant liquid on earth. Its high specific heat and the high energy of fusion of ice diminish the daily and seasonal variations of temperature at the surface of the earth and determine the climate. The unusual physical properties of water at temperatures around 300 K and atmospheric pressure, together with the unique chemical behavior of hydrocarbon compounds are the two prime essentials for a successful prebiological and biological evolution on the surface of the earth[1–4].

The pronounced tendency of the water molecule to participate with its two protons and two lone electron pairs in four hydrogen bonds simultaneously as donor and as acceptor, creates in the pure liquid a tetrahedral arrangement of first neighbors. This unusual open structure is the origin of all anomalies of liquid water and the ice polymorphs. The anomalies are also apparent in the high probability of the formation of irregular aqueous solutions of apolar compounds and in the occurrence of microheterogeneities in the distribution of dissolved non-electrolytes[5,6].

In aqueous solutions, proteins and nucleic acids can form ordered structures like helices or pleated sheets. For the generation of these structures, both intramolecular interactions as well as intermolecular interactions with the solvent water are of equal importance[7,8].

The contribution of the water molecules to the stability of these structures consists in the formation of intermolecular hydrogen bonds with the polar groups of the biopolymers and in the hydrophobic interaction, which forces

apolar hydrocarbon groups into the interior of the polymers or leads *via* hydrophobic hydration to a change in water structure at the interface between apolar groups and solvent[9, 10].

The tendency to prefer a local arrangement of first neighbors with a tetrahedral geometry, resulting in a poor packing efficiency, increases with falling temperature and causes the density maximum in light water at 277 K and in deuterium oxide at 285 K. The unusual properties of water are much more pronounced at temperatures below the density maximum.

Unfortunately, the temperature of the density maximum is very close to the melting temperature. In the region of thermodynamic stability only a small range of temperatures is accessible to experiments. Thoroughly purified, clean water, which is free of all ice-nucleating impurities can be supercooled with avoidance of heterogeneous nucleation, and kept in the metastable state for long periods of time.

Supercooled water becomes easier to handle the smaller the metastable samples are, since the reduction in volume lowers the probability of the occurrence of heterogeneous nuclei. Therefore, most investigations of supercooled water have dealt with water contained in narrow capillaries[11], with small droplets of water in dust-free cloud chambers[12], or with droplets of water emulsified in a water-insoluble apolar carrier[13]. Such emulsions are stabilized by the addition of a water-insoluble emulsifying agent and can be kept in the supercooled, metastable state for periods of months. The emulsified aqueous phase can be supercooled to 233 K at atmospheric pressure[14]. The same homogeneous nucleation temperature T_H is found if water droplets are allowed to sink in a temperature gradient[12].

Water/cycloalkane-emulsions are suitable for the investigation of the pressure dependence of T_H. *Kanno, Speedy,* and *Angell*[15, 16] have studied T_H for H_2O and D_2O up to pressures of 300 MPa by differential thermal-analysis. The results of these studies (see Figure 1) show that T_H drops even faster with pressure than the melting temperature T_M and reveal that water can be supercooled to $-92\,^{\circ}C$ at 200 MPa. Increasing pressure thus enlarges the metastable range considerably.

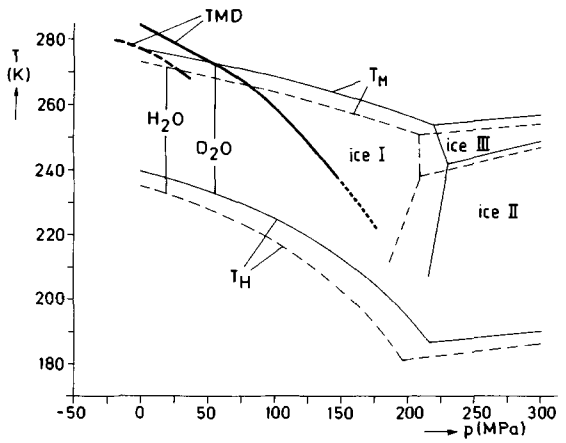

Fig. 1. *p-T*-projection of the phase diagram of H_2O and D_2O. T_M = melting temperature, T_H = homogeneous nucleation temperature [15, 16]. Also included is the temperature of maximum density (TMD) [87–90] (see Section 3.1).

In the following it will be shown using several examples, that the properties of metastable water are a continuation of the behavior observed in the range of thermodynamic stability, and that all anomalies of liquid water become considerably more pronounced in the supercooled region. A comprehensive review of the physical properties of supercooled water has been given by *C. A. Angell* in volume 7 of the series: "Water—A Comprehensive Treatise" edited by *F. Franks*[81].

2. The Equilibrium Structure of Liquid Water

2.1. Introductory Remarks

In principle one may calculate the macroscopic properties and the structure of a liquid from the physical properties of their molecules and the interactions between them. A rigorous quantum-mechanical treatment of a system with $\approx 10^{23}$ degrees of freedom is impossible and does not appear sensible since the microstates have energy differences of only $\Delta \approx \exp(-10^{23})$ erg and one can not decide by experiment which microstate the system acquires at any instant. Analogously it is impossible in classical mechanics to define the initial conditions for the equations of motion for a system of $\approx 10^{23}$ particles. In statistical mechanics macroscopic properties are expressed as averages weighted with proper distribution functions. The application of standard integral equations of statistical mechanics[17] to the description of liquid water has been attempted with relatively modest success[18–20]. In computer simulations[21] the averages are calculated numerically. Limited computer capacity and computer time permit these investigations on rather small systems with $\lesssim 10^3$ particles only. Two different methods of calculation are in current use: the molecular dynamics method (MD) solves the classical Newton-Euler equations of motion and forms time averages. The Monte-Carlo method (MC) forms ensemble averages. In systems of maximal 10^3 particles boundary effects play a major role; both methods thus apply either periodical boundary conditions and a cut-off radius for the interaction between the molecules or the Ewald summation[22, 23]. Besides these simulations, which will be discussed in the following, models describing liquid water as chemical equilibria between two or more possible states of the free or bound hydroxyl groups are presented in the literature and have been applied successfully[24, 25].

2.2. Model Potentials and Computer Simulations

The form of the intermolecular potential in the liquid phase is needed for MC- and MD-calculations. In simple liquids it is sufficient to consider pairwise interactions only. Quantum-mechanical calculations reveal however[26–28], that many-body interactions cannot be neglected in the case of liquid water. Since the exact form of the interaction potential in the liquid phase is unknown, computer simulations apply model potentials[29–32]. Such potentials are:

a) effective molecule pair potentials[33–35] which are constructed from point charge models and simple parame-

trized functions. The parameters in these functions are optimized to fit a few experimental properties (*e.g.* BNS[36-38], ST2[39-43], *Rowlinson*[44-46], TIPS methods[47]). These models do not take into account internal degrees of freedom and dissociation effects. If the electrostatic interaction between point charges is replaced by an electrical multipole expansion, one obtains non-additive potentials, which incorporate polarization effects[32].

b) parametrized functions (Coulomb potentials, exponential functions), which are fitted numerically to quantum-mechanical *ab initio* calculations of the dimer potential (*e.g.* MCY method[48-51,31,52,53]). These models do not take into account the influence of many-body forces.

c) empirical atom pair potentials between H- and O-atoms carrying the charge $\pm\eta e$ (*e.g.* CF methods[54-56]). These can also describe internal degrees of freedom and dissociation effects. The incorporation of non-additive interactions between delocalized charges, chosen in analogy to classical electrostatics leads to model potentials, which incorporate polarization effects[60-66].

The equilibrium structure of a molecular liquid is described by its atom pair correlation functions $g_{\alpha\beta}(R)$[29]. These can be determined by scattering experiments and calculated with computer simulations. Figure 2 gives

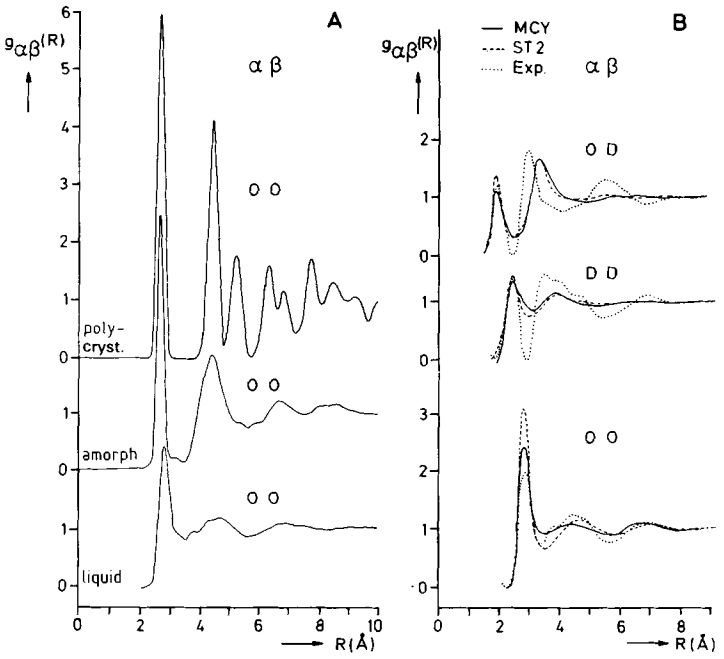

Fig. 2. Atom pair correlation functions $g_{\alpha\beta}(R)$ of liquid water. A) Comparison of the $g_{OO}(R)$ derived from X-ray studies for polycrystalline, amorphous, and liquid water (300 K) [74]; B) comparison between the calculated and the averaged experimental results $g_{\alpha\beta}(R)$ [182, 183] (MCY [48-51], ST2 [39-43] see text).

$g_{OO}(R)$ for H_2O in its various condensed phases. From the atom pair correlation functions one can derive that:

a) position and number of first neighbors is similar to the crystalline phases (tetrahedral coordination). The positions of the second neighbors show a broad distribution of O—O—O angles with the highest probability centered at the tetrahedral angle. Spatial correlations disappear for distances $R \gtrsim 8$ Å;

b) the maxima in $g_{OH}(R)$ and $g_{HH}(R)$ occur at distances expected for almost linear hydrogen bonds (for a detailed discussion see [29-32]).

At high hydrostatic pressures[43,67] $g_{OO}(R)$ becomes similar to the distribution functions of simple liquids.

The variations in the different $g_{\alpha\beta}(R)$ with increasing density reveal a bending of the hydrogen bonds and the formation of interpenetrating hydrogen bond networks. Taken together these results indicate that the equilibrium structure of liquid water is best described as a disordered network with more or less strained and bent hydrogen bonds. The topology of this network has been studied very thoroughly[39,53,68,69]. Classifying the molecules according to the number of hydrogen bonds formed, yields in all calculations a unimodal distribution. The distribution of polygons shows, that even and odd membered rings are found with comparable probabilities, the largest non-short-circuited rings containing 11 molecules. The analysis of the quasi-component distribution functions for hydrogen bond indices leads to a probability maximum for nonlinear H-bonds[53,69]. Furthermore, the degree of polymerization of a given configuration of water molecules and the structure and distribution of clusters with n water molecules has been investigated recently[70]. The statistical state of the H-bond network has been analyzed in terms of the average number of H-bonds per molecule ($\bar{n}$). At room temperature and at $\rho = 1\ g \cdot cm^{-3}$ the H-bond network exhibits for $\bar{n} \approx 1.3$ a bond-percolation threshold[*]. All estimates previously made for $\bar{n}$ under these conditions are significantly higher than this value, indicating that water is at any instant a space-filling network of H-bonded molecules. The time averaged mole fraction of loop-forming H-bonds is only greater than zero for $\bar{n} > 1.3$. This shows, that ring formation is a significant feature of the random H-bond network of liquid water[69].

The results discussed hitherto deal with the instantaneous structure (I-structure[71]) as obtained by the computer simulations. *Hirata et al.*[72] and *Belch et al.*[73] averaged the center of gravity- and angular-coordinates for a time of 0.2 ps, corresponding approximately to the period of hindered translations and librations, and created a structure comparable to the vibrationally averaged structure (V-structure) introduced by *Eisenberg* and *Kauzmann*[71]. This structure differs from the I-structure by:

a) a pair correlation function $g_{OO}(R)$ with a steeper and higher first maximum,

b) a stronger preference for almost linear hydrogen bonds,

c) a significant increase in the number of hydrogen bonds,

d) a strong increase in the number of non-short-circuited polygons of various size ($n = 3-11$).

[*] A bond percolation threshold is the first appearance of a H-bond network penetrating the whole sample.

These results are not very sensitive to the period of averaging. The stabilization of the disordered network in the V-structure is equivalent to the removal of mean thermal energy $k_B T$ from the I-structure. The hindered translations and librations can thus be understood as thermal excitations of the random H-bond network.

2.3. The "Random Network" Model[74]

The main result of the computer simulations is that liquid water presents a space-filling, random network of molecules interacting mainly through directional H-bonds of variable bonding energy and length. The network rearranges continuously on the time scale of diffusion processes, and for higher frequency vibrations it appears quasistatic. This picture has been combined with experimental data from the crystalline, the amorphous, and the liquid state to develop the "Random Network Model"[75,76].

In addition to the average distance between first neighbors R_{OO}, the quasistatic structure of the random H-bond network is described by the distribution of first neighbor distances ΔR_{OO}^2 and the deviation from a linear H-bond geometry θ_H^2 (θ_H = H-bond angle). Hindered translations and librations are treated as thermal excitations of this quasistatic network.

Sceats and *Rice*[77] completed their structural characterization of the disordered network in the RNM by the development of an interaction potential for the water molecules. Since this potential is derived from spectroscopic data it is obvious that it can only be valid for a rather limited range of the configuration space. However, it samples those configurations near the energy minimum, where the H-bond interactions strongly determine the mutual position of the molecules. The random network potential (RNP) is generated as a function of displacement from a standard reference configuration *via* a power series expansion. Only two coordinates are used, the first neighbor distance R_{OO} and the hydrogen bond angle θ_H.

The effective RNP is used together with the RNM for the calculation of thermodynamic potentials and static response functions[*]. The results are in good agreement with experimental data[73,78–80].

3. Static Properties of Supercooled Water

Only a few selected thermodynamic quantities are discussed in the following. It is shown, that the properties of the supercooled phase are a continuation of the behavior observed in the stable liquid phase. It is not attempted to approach encyclopedic completeness, but rather it is the intention to describe using a few examples the unique behavior of cold liquid water. A more comprehensive and extensive description of the state of the art is given by *Angell*[81]. His group has obtained many of the results described here.

[*] Static response functions are, *e.g.*, the thermal expansion coefficient α, the isothermal compressibility κ_T or the heat capacity at constant pressure C_p.

3.1. The Density ρ

The density at 0.1 MPa has been determined in thin capillaries of *ca.* 10 μm diameter for H_2O down to 239 K and for D_2O down to 244 K[82]. The resulting densities are in good agreement with data obtained in supercooled emulsions[14]. These data are given together with the results found in the region of thermodynamic stability[83] as reduced quantities ρ_r, T_r in Figure 3. In light water a density

	ϱ_{crit} (kg·m^{-3})	T_{crit} (K)	T_M (K)
H_2O	305	647	273
D_2O	338	645	277
NH_3	236	406	196

Fig. 3. ρ_r-T_r-diagram of H_2O and D_2O at 0.1 MPa and of NH_3 at saturation pressure. T_M: melting temperature.
$\rho_r \equiv \rho_{p,T}\rho_{crit}^{-1}$; $T_r \equiv TT_{crit}^{-1}$

maximum is observed at 277 K followed by a slight decrease of ρ on further lowering the temperature to the melting point. In the supercooled range this decrease in density is much more pronounced, and one would expect that $\rho_{liq}(T)$ becomes equal to the density of ice Ih[*] between 220—240 K. The expansion of volume starts much earlier in D_2O ($T_{\rho max} = 285$ K). At temperatures below ≈ 310 K, ρ_r of D_2O is lower than the reduced density of H_2O.

For a comparison Figure 3 gives the temperature dependence of ammonia[84,85], which as usual increases with falling temperature. Also the crystallization of this compound is accompanied by an increase in density.

Kanno and *Angell*[86] studied the pressure dependence of the density in supercooled D_2O to 243 K and 140 MPa. Figure 1 shows the pressure dependence of the temperature of maximum density (TMD) obtained from these measurements, together with previous studies on H_2O[87–89] which have been extended recently by *Henderson* and *Speedy*[90] to a negative pressure of −16 MPa. Extrapolation of the data obtained for D_2O implies, that the TMD becomes lower than T_H at pressures > 200 MPa. This anomaly of the supercooled liquid will thus not be observed at high pressures.

3.2. The Isothermal Compressibility κ_T

The isothermal compressibility of a substance is defined by

[*] Ice Ih is the hexagonal modification of ice thermodynamically stable at low pressures.

$$\kappa_T = -\left(\frac{1}{V}\right)\left(\frac{\partial V}{\partial p}\right)_T$$

In all simple liquids κ_T decreases rapidly with falling temperature.

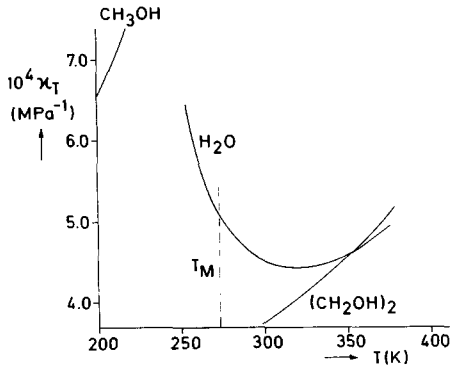

Fig. 4. Temperature dependence of the isothermal compressibility κ_T of H_2O at 0.1 MPa [91-93]. For comparison: κ_T of methanol [94] and glycol [95]. T_M: melting temperature.

In Figure 4 the compressibility of water at atmospheric pressure is given[91,92]. In the supercooled range the data were obtained by *Speedy* and *Angell* using a thin capillary. κ_T passes through a minimum at 320 K, a temperature well above the TMD (277 K), and increases below this minimum rapidly with falling temperature. On inspection of this diagram it becomes obvious, that the anomalies of the supercooled liquid are a steady continuation of the anomalies observed in the region of thermodynamic stability. For comparison, the compressibility of methanol[99] and glycol[95] are also included in the diagram. *Kanno* and *Angell*[86,96] succeeded in studying the compressibility of supercooled H_2O and D_2O at pressures up to 190 MPa down to a temperature of 243 K. They could show, that the increase in compressibility with falling temperature is still observed at the highest pressure studied, but it is less pronounced than at ambient pressure.

3.3. The Heat Capacity at Constant Pressure C_p

A supercooled liquid usually possesses a higher molar heat capacity than the corresponding crystalline phase. On further lowering the temperature more entropy is thus removed from the liquid than from the crystal.

The entropy of melting, which has remained in the supercooled liquid phase, is thus continuously removed on further cooling. From the third law of thermodynamics it must be inferred that the difference in molar heat capacity of the crystal and the metastable liquid is reduced with falling temperature. This is just what is observed in normal supercooled systems such as alcohols[97-99].

Figure 5 shows that C_p of ethanol and propanol decreases with falling temperature, and finally drops very rapidly, in a fairly narrow temperature interval in the range of the glass temperature T_g, to the value found for the crystalline phase.

Below a minimum temperature (T_{min} H_2O: 308 K, D_2O: 373 K) C_p^{Liq} of H_2O[100,101] and D_2O[102,103] increases with

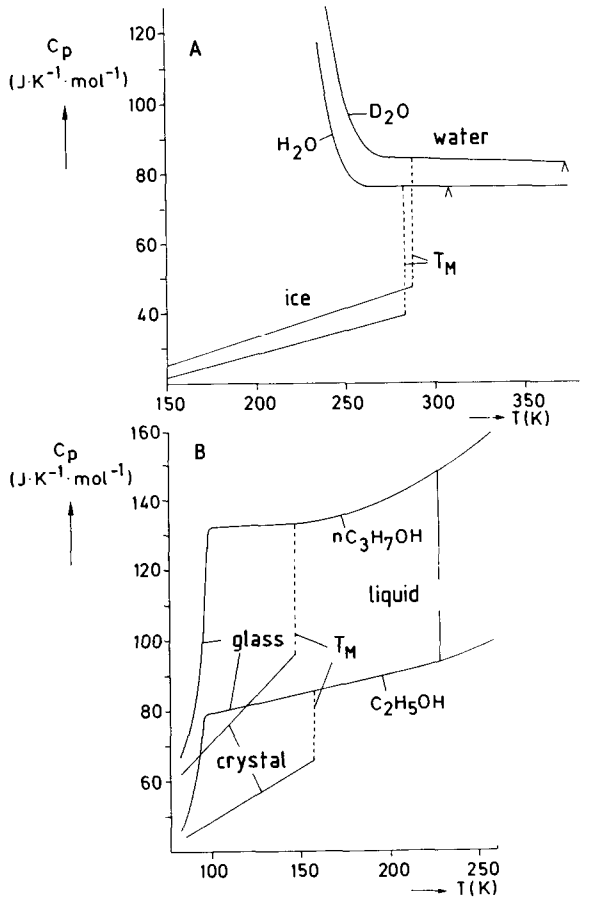

Fig. 5. Temperature dependence of the molar heat capacity at constant pressure C_p; A) of H_2O and D_2O [100-108], B) of 1-propanol and ethanol [97-99]. T_M: melting temperature.

falling temperature and this increase becomes very steep in the metastable region in the vicinity of the homogeneous nucleation temperature[104-108] (Fig. 1). Amorphous solid water, prepared by slow condensation of H_2O vapor under high vacuum conditions, has a glass temperature of $\approx 130-140$ K[109-110]. It is thermodynamically impossible that the decrease in C_p^{Liq} of supercooled water occurs in the vicinity of this glass temperature. The temperature dependence of C_p in the unstable interval of temperature is thus still a matter of controversy[107,108,111-113]. *Johari*[111] asserts that there is no continuity of states between the supercooled liquid phase and the amorphous solid phase prepared by low temperature condensation, while *Rice et al.*[113] propose the contrary. Recently, it has been claimed that a liquid emulsion was directly transferred into the glassy state by jet-cooling[114]. It is to be expected, that caloric studies on this phase will settle this controversy.

3.4. The Static Dielectric Constant ε_0

Figure 6 compares the temperature dependence of the static dielectric constant ε_0 of water in the range between 237 and 373 K[115,116] with the results obtained for methanol[117,118] and ammonia[119-122]. The data given for supercooled water were calculated from the dielectric constant of emulsions with low water content. Compared to the strong increase in ε_0 for methanol with falling temperature, supercooled water does not reveal any anomalies. The sug-

gestion[123] that supercooled water might approach a ferroelectric transition at temperatures around 220 K is thus rather improbable.

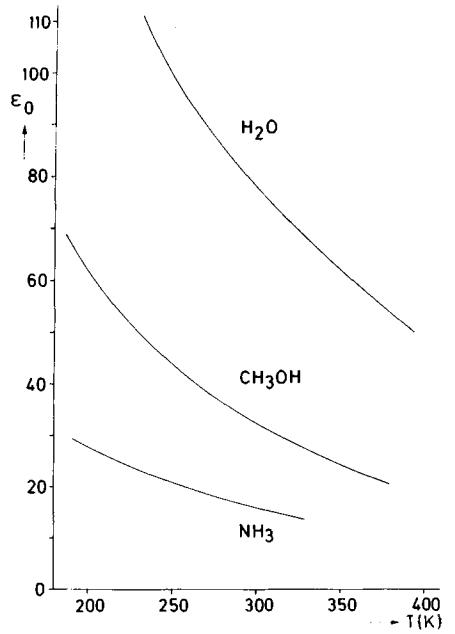

Fig. 6. Temperature dependence of the static dielectric constant ε_0 of H_2O [115, 116], methanol [117, 118], and ammonia [119–122] at 0.1 MPa.

The measurement of the static dielectric constant averages the dipole orientation in water over dimensions large compared to the particle diameter. The absence of a pronounced anomaly in ε_0 is thus an indication that the peculiarities of the structure of supercooled water are restricted to rather small domains, *i.e.* to the arrangement of the closest neighbors.

3.5. The Speed of Sound v

Several groups have studied the temperature dependence of the speed of ultrasound in liquid water into the supercooled region[112, 124–126]. *Trinh* and *Apfel*[127] could extend their measurements down to 240 K. The thermodynamic speed of sound v ($\nu \rightarrow 0$) is given by:

$$1/v^2 = \rho[\kappa_T - (TV\alpha_p^2/C_p)] \quad (1)$$

$$\left(\alpha_p = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_p\right)$$

It thus follows from anomalies of ρ, κ_T, and C_p, discussed above that v should exhibit unusual properties, too. It is found that v decreases at $T \leq 347$ K with falling temperature[128], and apparently this decrease continues to the lowest temperatures studied[129] (Fig. 7). The results obtained by *Bacri et al.*[126] imply that the speed of sound continues to decrease rapidly with falling temperature and tends to zero, while the studies by *Trinh* and *Apfel*[127] indicate a minimum of the speed of sound at temperatures around 243 K. It must be emphasized, that the measurements in the supercooled region encounter considerable experimental difficulties, and it is not to be expected that they can have the precision of the investigations in the region of thermodynamic stability.

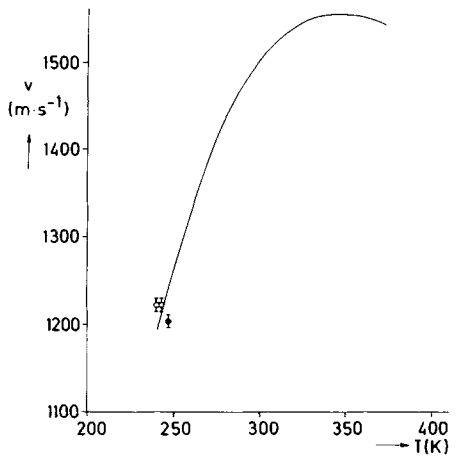

Fig. 7. Temperature dependence of the speed of sound v in supercooled water. Only the experimental points obtained at the lowest temperatures are given. • [126], ○ [127].

Recently *Dietz et al.*[194] estimated the heat conductivity λ in the supercooled range by application of a lattice model. Extrapolation of the experimental data for λ obtained at $T \geq 273$ K to lower temperatures by combining the experimental ρ, C_p, and v data yields the result that λ passes through a minimum at temperatures around 250 K and starts to increase on further cooling. Since this minimum is calculated for temperatures well above T_H, it would be interesting to verify this calculation by experiment, since then it could be decided which of the various models presented in the literature (see Section 4) quantitatively describes the properties of liquid water at temperatures approaching T_H and T_S (T_S is the singularity temperature, see Section 4.1 and Fig. 12).

4. Discussion of the Static Properties of Supercooled Water

4.1. The Speedy-Angell Singularity of Supercooled Water

The experimental findings given in Section 3 deal with the anomalies of water at constant pressure. These anomalies are almost completely suppressed if the properties of the liquid are studied at constant volume. The heat capacity at constant volume C_V, which can be calculated from the data given above by:

$$C_V = C_p - VT(\alpha^2/\kappa_T) \quad (2)$$

shows a quite normal behavior at atmospheric pressure.

Furthermore, it can be derived from the data that all anomalies of water are suppressed by high hydrostatic pressure ($p > 200$ MPa). It is thus the topology of the open, random three-dimensional H-bond network, which causes the anomalous behavior. This can be seen from the interrelations between the functions C_p, κ_T, α_p and the fluctuations of the thermodynamic variables in the (TPN)-ensemble[*]:

[*] A (TPN)-ensemble is a thermodynamic many particle system in which the temperature T, the pressure p, and the number of particles N are kept constant.

$\kappa_T \sim \langle(\delta\bar{V})^2\rangle$, $C_p \sim \langle(\delta S)^2\rangle$, and $\alpha_p \sim \langle\delta\bar{V}\delta S\rangle$.

It follows from the relations that the experimental pressure- and temperature-dependence of these quantities is determined by the density, enthalpy, and entropy fluctuations, which have strongly increasing amplitudes with falling temperature. From these observations *Speedy* and *Angell*[93] deduced the existence of a thermodynamic singularity in supercooled water at the temperature T_S. The latter is found only a few degrees below the homogeneous nucleation temperature T_H and, like T_H, is shifted with increasing hydrostatic pressure to lower temperatures (see Fig. 12). T_S is interpreted by the authors as a lower limit of mechanical stability of the supercooled liquid. This interpretation implies a divergence of the thermodynamic response functions in the vicinity of $T_S(p)$. The molecular origin of these anomalous fluctuations is seen in the formation of highly ordered clusters of the tetrahedral network with linear H-bonds.

Hydrostatic pressure opposes the formation of linear H-bonds, which correspond to the configuration with the lowest energy but with the largest volume requirements. Application of pressure thus leads to a decrease in the amplitudes of the anomalous fluctuations and to a rapid approach of the temperature of maximum density (TMD) towards the homogeneous nucleation temperature $T_H(p)$ (see Fig. 1). Currently (see als Section 10), two theoretical models exist for the description of the anomalous properties of supercooled water. The percolation model, proposed by *Stanley et al.*[130] (see Section 4.2), associates the conjectured thermodynamic singularity with a percolation threshold of the four-bonded water molecules in the random H-bond network. *Stillinger*'s[131] proposal, applying statistical mechanics of finite systems, shows that deep supercooling can eventually lead to a "thermodynamic catastrophe".

4.2. The Percolation Model

Stanley et al.[130, 132, 133], using the correlated site percolation theory, developed a concept for the qualitative description of the anomalies observed. This concept is, moreover, in quantitative agreement with computer simulations on model water. In this model, the water molecules are classified by the number of their hydrogen bonds. A fraction p_B of intact H-bonds is distributed randomly between the molecules. The fraction f_j of molecules of the species j is then given by the binomial distribution:

$$f_j = \binom{4}{j} p_B^4 (1-p_B)^{4-j} \tag{3}$$

Because $f_4 = p_B^4$, this model has a built-in amplification mechanism, which leads to a rapid nonlinear increase of four-bonded molecules with increasing p_B ($\triangleq$ falling temperature).

Although intact H-bonds are assumed to be distributed randomly between the molecules, a clustering tendency is observed especially for molecules of the species $j=4$. Obviously the local physical properties of the clusters of four-coordinated molecules, cannot be derived from the considerations given. They have to be introduced as plausible assumptions. Computer simulations show that clusters of tetracoordinated water molecules possess a density and entropy lower than the mean value of the liquid phase. This leads to density and entropy fluctuations larger than in a homogeneous network.

A direct experimental proof of the existence of these density fluctuations could be given by small-angle scattering experiments, since the structure factor $S(q)$ of a liquid is proportional to the Fourier transform of the density correlation function[134]. An increase in the correlation length ξ of the density fluctuations leads to an increase of $S(q)$ for $q \rightarrow 0$, and thus to a higher scattering intensity at small angles. *Bosio, Teixeira,* and *Stanley*[135] performed small-angle X-ray scattering experiments in supercooled H_2O and D_2O, which indeed showed this enhancement at small angles. At $T=253$ K the correlation length ξ of the density fluctuations amounts to approximately 8 Å.

4.3. The Differential Geometric Model[131]

This model starts with the partition function Z_N in the (TPN)-ensemble:

$$Z_N(\beta,p) = Z_N^{(0)} \langle \exp(-\beta\theta)\rangle_{TPN}; \quad \beta = kT^{-1} \tag{4}$$

where θ is the sum of the potential energy ϕ of the water molecules and the product pV. It is assumed, that the molecular configurations can be described by two independent parameters, the potential energy ϕ and the structural order parameter Ψ. The latter specifies the number of bound bicyclic octamers, which in a molecular dynamics calculation with the polarization model were found to represent a global minimum in the configurational space[63]. A system described by these parameters possesses essentially two stable states at low temperatures. The solid phase, characterized by a large Ψ and a small θ, and the liquid phase, for which θ becomes large while Ψ remains small.

Removal of thermal energy from such a system can lead eventually to a catastrophe, *i.e.* to a divergence of the order parameter Ψ for the liquid phase. Just this situation may arise in supercooled water at the temperature T_S. Since Ψ is a measure of the number of bound bicyclic octamers, which represent open structures with linear H-bonds in the irregular H-bond network, the fluctuations of the order parameter are consequently associated with density fluctuations of the H-bond network. Diverging density fluctuations imply a divergence of the functions κ_T, α_p, and C_p.

An important implication of both the differential geometric model and the percolation model is, that the aggregation of ordered regions, or analogously the percolation of four-coordinated clusters of molecules, creates an irreversible situation, leading to the destruction of the liquid phase, *i.e.* to homogeneous nucleation. It will thus be fairly difficult to follow experimentally the temperature dependence of physical properties to the immediate vicinity of T_S.

A significant difference between the two model-considerations given above should be emphasized once more: While the proposals by *Speedy* and *Angell*[93] and by *Stillinger*[131] (Section 4.1) lead to a divergence of the static prop-

erties (κ_T, C_p, α_p) on approaching T_S, the ideas developed by *Stanley* and *Teixeira*[132] lead to the conclusion, that these properties should show in their percolation model no divergence when the percolation threshold T_S is approached.

As explained by *Bosio, Teixeira,* and *Stanley*[135] scattering experiments at very small scattering angles at temperatures above T_H could decide whether the correlation length (ξ) of the density fluctuations diverges at T_S or runs through a maximum above T_H.

5. Dynamic Properties of Liquid Water

In statistical mechanics the dynamic properties of liquids are described by time correlation functions of dynamic variables[136]. The theoretical calculation of these functions for molecular liquids is exceedingly complicated. Many time correlation functions have, however, been calculated explicitly in computer simulations of model water.

5.1. Molecular Dynamic Calculations

Only the molecular dynamics method can yield dynamic properties. Contrary to the investigations of the structural aspects of liquid water the dynamic properties of this liquid have been studied by computer simulation in a few cases only.

In statistical mechanics, translational motions in a liquid are described by velocity autocorrelation functions $\varphi(t)=\langle\vec{v}(0)\vec{v}(t)\rangle$. The velocity correlation function for the center of gravity of the molecule $\varphi_{CM}(t)$ has been determined over a wide range of temperatures for "BNS-water"[37,38] and "ST2-water"[40,41]. At low temperatures this function shows pronounced oscillations around $\varphi_{CM}(t)$ for short times ($t<0.5$ ps). The spectral density function reveals significant maxima at ≈ 40—$60\ cm^{-1}$ and 190—225 cm^{-1} at low temperatures. These are shifted with rising temperature to lower frequencies. These bands have been identified as the O—O—O bending and the O—O stretching vibrations, respectively. Though these oscillations—compared to simple liquids—are very pronounced, they are still strongly damped, and $\varphi(t)$ decreases to zero after approximately 1 ps. As emphasized by *Rahman* and *Stillinger,* these oscillations do not imply diffusional jumps from one discrete equilibrium position to another. The translational motions of the water molecules rather occur as a continuous process within the perpetual rearrangement of the labile, disordered H-bond network. The self diffusion coefficient D is a quantitative measure characterizing the diffusive motion of the center of gravity of the molecules in a homogeneous liquid. By application of a Green-Kubo relation it can be described with the correlation function $\varphi(t)$:

$$D = (1/3)\int_0^\infty \langle\vec{v}(0)\cdot\vec{v}(\tau)\rangle\,d\tau \qquad (5)$$

The temperature dependence of D is significantly weaker for BNS-water and ST2-water than found experimentally. Incorporation of long range interactions *via* a reaction field leads to a calculated diffusion coefficient twice as large as the experimental result[137]. Molecular dynamic calculations with CF-potentials[55] yield at room temperature diffusion coefficients which are a factor of 2 to 3 too low. *Rapaport* and *Scheraga*[50] performed molecular dynamic calculations with the MCY-potential. The diffusion-coefficients obtained are for slightly supercooled water $\approx 67\%$ too large, and at 377 K $\approx 12\%$ too small. As in the case of BNS-water and ST2-water they also show a temperature dependence weaker than that observed by experiment. Thus it can be concluded, that all model potentials are unable to describe correctly the strong decrease of D in the supercooled range. The only determination of D from molecular dynamic calculations of ST2-water under high pressure[43] yields at 370 K for an increase in density by 35% a lowering of D by $\approx 10\%$. Experimentally a reduction by this amount is already seen for a change of density by $\approx 6\%$, indicating that ST2-water reveals much smaller pressure effects than real water. It is still an open question, whether molecular dynamic calculations will show the increase of D with pressure which is observed experimentally at low temperatures and medium pressures (<250 MPa).

In addition to the translational motions the molecules in a liquid possess rotational mobility. These rotations are described in statistical mechanics by the functions

$$G_l(t)=\langle P_l[\vec{u}_j(0)\cdot\vec{u}_j(t)]\rangle$$

which describe the time dependence of the orientational correlation of a unit vector $\vec{u}$ in the molecule j. The functions for l = 1, 2 are closely related to measurable quantities[138]. *Rahman* and *Stillinger*[37,38] studied the orientational relaxation of water molecules in molecular dynamic calculations applying the BNS-potential. $G_1(t)$ as well as $G_2(t)$ reveal librational motions for $t<0.1$ ps. For longer time spans both functions decay nearly exponentially. The effective time constants τ_1 and τ_2 of the exponential decay decrease with falling temperature. *Van Gunsteren et al.*[137] determined τ_1 and τ_2 for ST2-water with a reaction field, while *Rapaport et al.*[50] calculated τ_1 by application of the MCY-potential. Both latter groups obtain significantly smaller time constants than found for ST2-water, which yields the best agreement with experiment. With the exception of the data for supercooled water, the temperature dependence of τ_1 and τ_2 is in good agreement with experimental results.

The librational behavior of the molecules has been further investigated by *Rahman* and *Stillinger*[37,38] by studying the angular velocity autocorrelation function

$$f_\alpha(t)=\langle\omega_\alpha(0)\omega_\alpha(t)\rangle;\quad \alpha=x, y, z$$

A weak time dependence of $f_\alpha(t)$ implies a relatively free rotation, while fast oscillations of this function indicate that the molecule is kept in a fixed orientation by its neighbors. All three functions show strong oscillations, which, however, decay very rapidly ($<10^{-13}$ s at 307 K). The first neighbor molecules are thus unable to retain a "cage molecule" in its orientation for times $t>10^{-13}$ s. Increasing

temperature weakens the oscillations, the periods of oscillation becoming longer under these conditions.

5.2. Statistical Mechanics and Hydrodynamics

In 1978 *Chu* and *Sposito*[139] studied the motion of the center of gravity of the water molecules with a time-dependent perturbation theory by application of classical statistical mechanics. The authors start with the so-called "relaxing-cage" model[140] for the dynamic structure of an atomic liquid and generalize it for the case of liquid water. Ice Ih is chosen as the undisturbed reference system, yielding the normal modes for the lattice dynamics of the system. The calculation of the velocity autocorrelation function

$$\varphi(t)=\langle\vec{v}(0),\vec{v}(t)\rangle$$

starts at a time $t=0$ with a liquid possessing a first neighbor order corresponding to ice. This first neighbor arrangement is assumed to have the same normal modes as ice Ih. The destruction of this arrangement through the thermal motion of the neighboring molecules causes the decay of the normal modes. Collisions with neighboring particles leads to a continuous loss of correlation for the velocity of the particles. After a short period of time the cage structure is almost intact, and the central molecule oscillates. The thermal motion of the neighbors destroys the first neighbor arrangement and the oscillating motion of the central particle is transformed into a diffusive motion. By suitable choice of the lifetimes of the normal modes, the spectral density function of this model can satisfactorily reproduce the power spectrum derived from molecular dynamic calculations.

Sposito[141] shows in a subsequent paper, with data from the literature for the self-diffusion coefficient D, the dielectric relaxation time, τ_d and the NMR-orientational correlation time τ_2, that at low temperatures and pressures the single particle motion in liquid water can be adequately described with a hydrodynamic model. In the hydrodynamic approximation one obtains with $f=\beta a/3\eta$:

$$D=\frac{k_B T}{4\pi\eta a}(1+f)/(1+3/2f) \tag{6}$$

$$\tau_d \simeq \tau_1=\frac{4\pi\eta a^3}{k_B T}f/(1+f) \tag{7}$$

$$\tau_2=\frac{4\pi\eta a^3}{3k_B T}f/(1+f) \tag{8}$$

where η is the shear viscosity, a the van der Waals radius of the water molecule, which is assumed to be spherical, and the parameter β characterizes the boundary conditions at the surface of the sphere[142]. The equations imply $\tau_1/\tau_2=3$, and thus the validity of the rotational diffusion model[143]. Using experimental viscosity data and $a=1.44$ Å one can reproduce the experimental results for D, τ_1, and τ_2 very well, under the assumption that for translational diffusion $\beta\simeq 0$ and for rotational diffusion $\beta\rightarrow\infty$.

6. Transport and Relaxation Properties of Supercooled Water

6.1. The Shear Viscosity η

The viscosity η describes the transport of linear momentum in a liquid. Kinetic processes as well as intermolecular forces contribute to this transport. Theory shows, that the viscosity summarizes the influence of short-lived processes, decaying on the time scale of the mean collision time τ_c[144], upon the dynamics of the system at long times.

Experimental investigations of the temperature- and pressure-dependence of the shear viscosity have been performed with high accuracy in the region of thermodynamic stability of the liquid[145-147]. The strong temperature dependence of the viscosity in cold water is amplified further in the metastable supercooled phase. At ambient pressure, η could be measured down to 238 K for H_2O and to 242 K for D_2O[148,149] (Fig. 8).

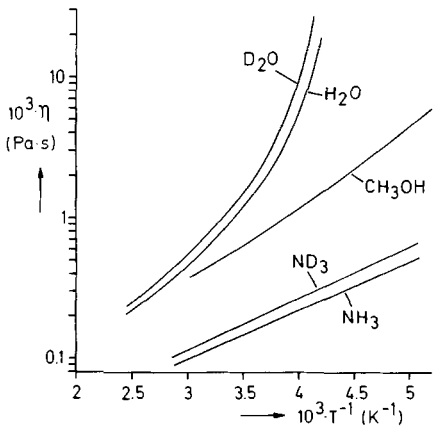

Fig. 8. Temperature dependence of the shear viscosity η of H_2O, D_2O [145-149], methanol [188], NH_3, and ND_3 [184-187].

The pressure dependence of the viscosity reveals anomalous behavior in cold water (H_2O: $T\leq 312$ K, D_2O: $T\leq 317$ K[150]), since in water—contrary to simple liquids—η decreases with increasing pressure and passes through a minimum. The minimum pressure increases with falling temperature, and the minimum becomes narrower[151,152]. Measurements at elevated pressures $p>0.1$ MPa have not been published for the metastable phase. An interpolation between the experimental results obtained down to 258 K at high pressures and the results at ambient pressure indicates a drastic drop in the viscosity with increasing pressure. The ratio $[(\eta(D_2O))/(\eta(H_2O))]_{T,p}$ increases rapidly with falling temperature.

6.2. The Self Diffusion Coefficient D

The self diffusion coefficient D describes the motion of the center of gravity for the particles in a liquid. In the thermodynamically stable region of the liquid phase, nu-

merous measurements of the temperature- and pressure-dependence of D are published for H_2O as well as for D_2O[145, 146]. For the metastable supercooled phase only the temperature-dependence of the diffusion coefficient at normal pressure is known to 242 K[153] (see Fig. 9).

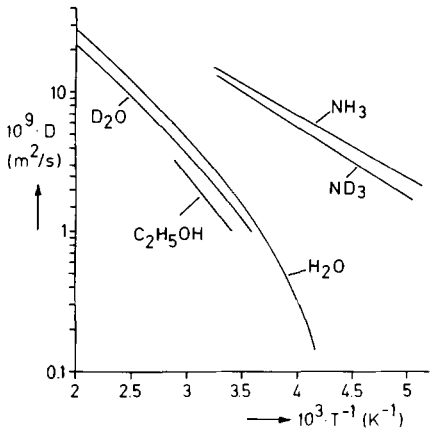

Fig. 9. Temperature dependence of the self diffusion coefficient D of H_2O, D_2O [145, 146, 153–156], ethanol [192], NH_3 and ND_3 [184–191] at saturation pressure.

The viscosity η as well as D do show a pronounced temperature dependence[154], which is even more pronounced in the supercooled liquid[155]. In cold water D passes with increasing pressure through a maximum[154–156], which, with falling temperature, is shifted to higher pressures[152].

6.3. The Spin Lattice Relaxation Rate R_1

Determination of the nuclear magnetic spin-lattice-relaxation rate R_1 offers a possibility of collecting information about molecular motions in liquid water. Application of a semiclassical theory yields[157]:

$$R_1 = \frac{1}{T_1} \approx \sum_{m=1,2} c(m) J^{(m)}(m\omega_0) \qquad (9)$$

where T_1 is the spin lattice relaxation time determined experimentally, $J(\omega_0)$ the spectral density of the autocorrelation function $G(t)$ at the observing frequency ω_0. The factors $c(m)$ characterize the type and strength of the interaction between spin system and lattice. The time dependence of the fluctuation function $G(t)$ can often be described by a microscopic correlation time τ, characterizing the molecular motion.

Spin lattice relaxation times T_1 have been measured in water for the isotopes ^1H, ^2H, and ^{17}O over a wide range of pressures and temperatures[158–166]. Until now the proton- and deuteron-T_1 are the only physical quantities that could be studied in the whole metastable region of the liquid phase down to temperatures $T \geq T_H$ (see Fig. 10) and up to pressures of 300 MPa[164, 165].

In non- or weakly-associated liquids[167] T_1 can normally be described by a simple Arrhenius equation. For water a non-linear temperature denpendence is seen in the Arrhenius diagram, the deviations being most pronounced in the supercooled region. Hydrostatic pressure leads to a smaller

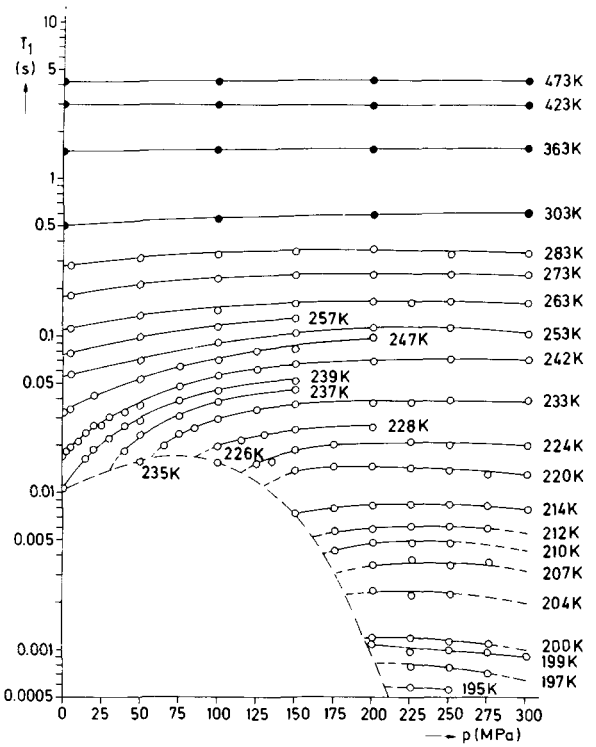

Fig. 10. Pressure dependence of the isotherms of the deuteron spin-lattice relaxation time T_1 in D_2O. • [151, 152], ○ [165].

isobaric temperature-dependence of T_1[165]. The isothermal pressure-dependence of T_1 in cold water reveals—as found for the pressure coefficients for η and D—an extremum[168]. With falling temperatures this anomaly becomes,

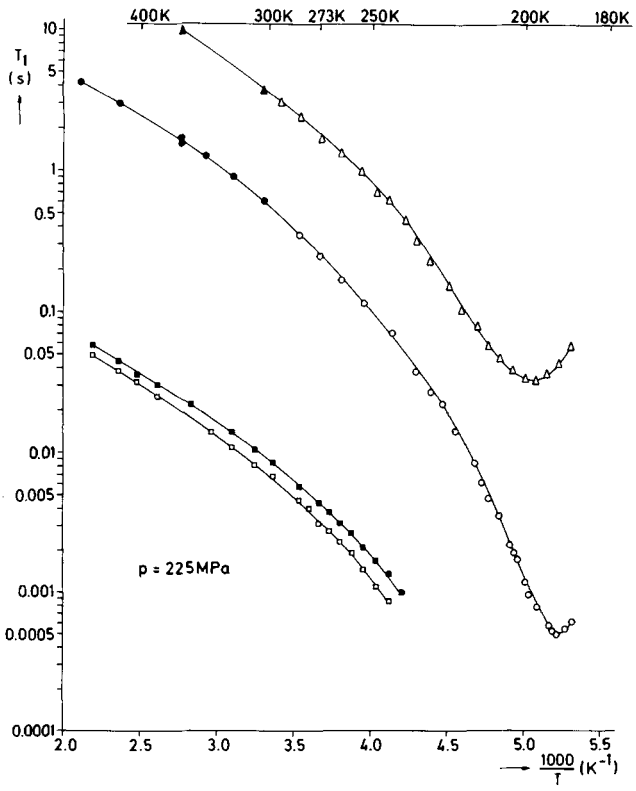

Fig. 11. Temperature dependence of the 225-PMa isobars of the spin-lattice relaxation time T_1. ▲ [193], △ [164] (^1H-T_1 in H_2O); ● [193], ○ [165] (^2H-T_1 in D_2O); ■ [166] (^{17}O-T_1 in H_2O); □ [166] (^{17}O-T_1 in D_2O).

compared to the range of thermodynamic stability, much more pronounced in the supercooled region at medium pressures ($p < 200$ MPa)[164-167]. At very low temperatures ($T < 220$ K), because of the pressure dependence of the homogeneous nucleation temperature T_H this means necessarily higher pressures, T_1 decreases monotonously with pressure, as observed in simple liquids[167, 169-171].

A minimum in the high-pressure T_1-isobars for the proton- and deuteron-relaxation was observed close to the homogeneous nucleation temperature T_H (see Fig. 11). Such minima occur if the microscopic time constant becomes approximately equal to the observing frequency ($\omega_0 \tau \simeq 1$), since at high temperatures $R_1 \approx \tau$ and at low temperatures $R_1 \approx (\omega_0^2 \tau)^{-1}$, and since τ increases monotonously with falling temperature. Measurements of the relaxation time T_1 at various frequencies in this temperature region could provide the possibility of determining details of the form of the spectral density function $J(m\omega_0)$. An interpretation of microscopic correlation times τ, derived from the T_1-measurements, will be given in Section 7.

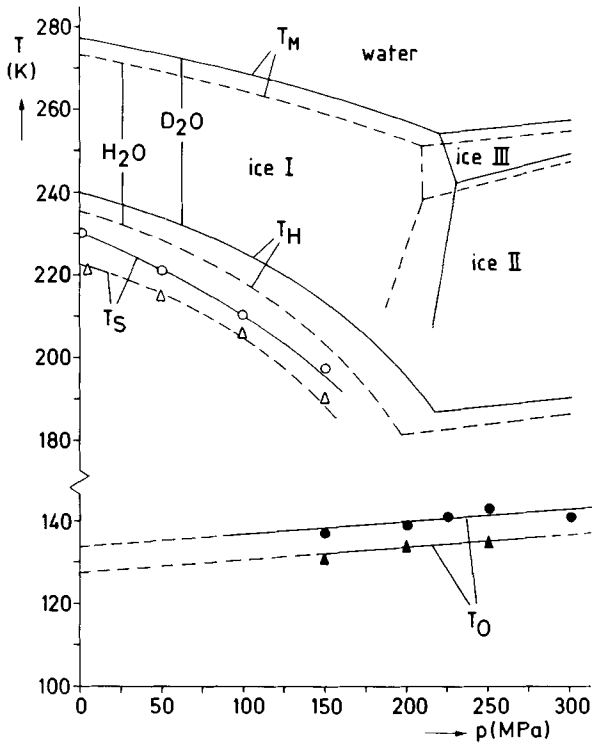

Fig. 12. p-T-Projection of the phase diagram of H_2O and D_2O, including: T_S = temperature of singularity, T_0 = ideal glass transition temperature. △, ▲: H_2O; ○, ●: D_2O. T_S was obtained by fitting the τ_2 data to the Speedy-Angell equation.

7. Discussion of the Dynamic Properties of Supercooled Water

The discussion of the static and dynamic properties of liquid water shows that water at elevated pressures reveals the behavior of a normal viscous liquid[172]. The isobaric temperature-dependence of the dynamic properties of many viscous liquids is described quantitatively by the Vogel-Tammann-Fulcher equation[173-175].

$$X = X_0 \exp\left(\frac{B}{T - T_0}\right) \quad \text{(VTF equation)} \tag{10}$$

This equation indicates that the dynamic quantity X diverges on approaching the temperature T_0. In viscous liquids this occurs if the liquid is transformed into the amorphous glassy state, in which molecular mobility is frozen out. The temperature T_0 is called the ideal glass transition temperature. It has been shown[165, 166], that at high hydrostatic pressures ($p \geq 200$ MPa) the isobaric temperature dependence of the orientational correlation time τ_2 of liquid water can be described quantitatively by the VTF equation. The parameters t_0, B, T_0 obtained from least squares fitting of the experimental τ_2 to the VTF equation are compiled in Table 1. The ideal glass temperatures $T_0(p)$ found show a small positive linear pressure-dependence (Fig. 12). These data, as well as their extrapolation to normal pressure are in good agreement with published T_0-data[176]. Comparison of the results obtained in light and in heavy water reveals a significant isotope effect. In D_2O, T_0 is higher by about ≈ 6 K than in H_2O, in accordance with the lower zero point energy of heavy water. The two other parameters of the VTF-equation also reveal an isotope effect. It appears interesting to compare the dependence of the pre-exponential factors τ_0 on the isotopic composition. The reciprocal values τ_0^{-1} have the dimension of a frequency and correspond in the energy spectrum of liquid water to the librations of the molecules, originating from the hydrogen bonding interaction with its neighbors. This interaction confines a molecule for a short period in its orientation and forces it to oscillate about the equilibrium position. In accordance with the isotope-dependence of the librational bands, one finds a ratio

$$\frac{\tau_0^{-1}(D_2O)}{\tau_0^{-1}(H_2O)} \simeq \sqrt{\frac{I(D_2O)}{I(H_2O)}} = 1.38 \tag{11}$$

equal to the square root of the mean moments of inertia I of the molecules. *Sceats et al.*[75] interpreted the librational

motions as thermal excitations in the quasistatic hydrogen bond network. Therefore, τ_0^{-1} characterizes the high-frequency orientational fluctuations of the molecules in the potential wells. The exponential factor summarizes the influence of the topological reorientation of the disordered H-bond network caused by the thermal fluctuations.

Removal of thermal energy decreases the probability for configurational fluctuations and thus leads to an increase in the orientational correlation times τ_2. It is to be expected, that at high pressure these fluctuations also determine the temperature dependence of the self-diffusion coefficient and the shear viscosity, and that these are described also by the VTF-equation. But the experimental data on deeply supercooled water at high pressures required in order to test this suggestion are still lacking.

For lower pressures ($p < 150$ MPa), it could be shown[165, 166] that the orientational correlation time τ_2 decreases with falling temperature much faster than predicted by the VTF-equation. As the discussion of the static properties showed, their temperature dependence is determined by a thermodynamic singularity at the temperature T_S. It has to be checked whether this description is also applicable to the dynamic properties of cold liquid water. The isobaric temperature-dependence of the orientational correlation time τ_2 at low pressures ($p \leq 150$ MPa) is quantitatively described by equation (12) proposed by *Speedy* and *Angell*[93]:

$$X = A_X \left(\frac{T - T_S}{T_S}\right)^{-\gamma_X} \quad \text{(Speedy-Angell equation)} \qquad (12)$$

which is known from the theory of critical phenomena. The parameters obtained from a least squares fit of the experimental data to equation (12) are given in Table 2. From the data it becomes apparent that the change from H_2O to D_2O influences the singularity temperature T_S only. Fig. 13 shows, that the τ_2 for both liquids fall in a reduced diagram ($\ln \tau_2 \leftrightarrow \ln(T - T_S)$) upon a single straight line. The dynamic behavior of the water molecules in both liquids is thus identical at equal distance from the singularity temperature ($T - T_S$). The frequencies τ_S^{-1} derived from the factors τ_S ($\equiv A_X$) correspond in the spectrum of liquid water to the O—O—O bending vibrations. The ratio of these hindered translational vibrations on isotopic H-D-substitution is given by the ratio of the square root of the molecular masses ($= 1.05$). It is thus understandable that no isotope effect outside the limits of error is found for τ_S.

The results suggest, that fluctuations in the H-bond bending vibrations are the driving force for the anomalous density fluctuations. The growth and decay of these vibrations controls the orientational correlation function $G(t)$ at low temperatures and pressures.

From the definition of the orientational correlation time by

$$\tau_2 = J(\omega = 0) = \int_0^\infty G(t)\,dt \qquad (13)$$

it follows, that the orientational fluctuations are determined by low frequency excitations of the random network.

H-bond bending vibrations can develop the better, the more open and ordered the random H-bond network is. They are thus dependent upon the presence of ordered patches with almost linear H-bonds. The discussion of the static properties suggested that the cooperative order-disorder fluctuations of the random H-bond network reflect the formation of such open-structured, low density clusters on approaching T_S. These processes also hinder the reorientation of the molecules, and cause the orientational correlation time τ_2 to increase drastically in the vicinity of T_S.

It is interesting to check whether the temperature dependence of D or η also is described by equation (12). At ambient pressure the dynamic properties D (self-diffusion coefficient), η (shear viscosity) and τ_2 (orientation correlation time) of liquid water can be quantitatively represented by the Stokes-Einstein equation (14) and the Debye equation (15):

$$D = kT/4\pi\eta a \tag{14}$$

$$\tau_2 = 4\pi a^3\eta/3kT \tag{15}$$

The result of this test is that the correlations $\tau_2 \sim \eta/T \sim 1/D$ are also valid for the supercooled phase. After introduction of the corresponding temperatures $(T - T_S)$, all dynamic properties of H_2O and D_2O fall onto a single straight line. Within the limits of error all lines have identical slopes $\gamma = -1.9 \pm 0.1$, the plausible explanation being that the development of ordered patches in the random H-bond network slows down the reorientation and self diffusion of the molecules and increases the shear strength of the H-bond network.

8. Supercooled Aqueous Salt Solutions

The influence of solutes upon the structure and dynamics of water must become more pronounced in the supercooled region. Figure 14 collects some deuterium-T_1 measurements on supercooled salt solutions[176]. The specific influence of the ions upon T_1 is much more pronounced at 238 K than at 283 K. In this context it appears interesting that at low temperature and low pressure, all ions increase the mobility of the water molecules. Under these conditions magnesium and lithium ions cause the breaking of water-structure.

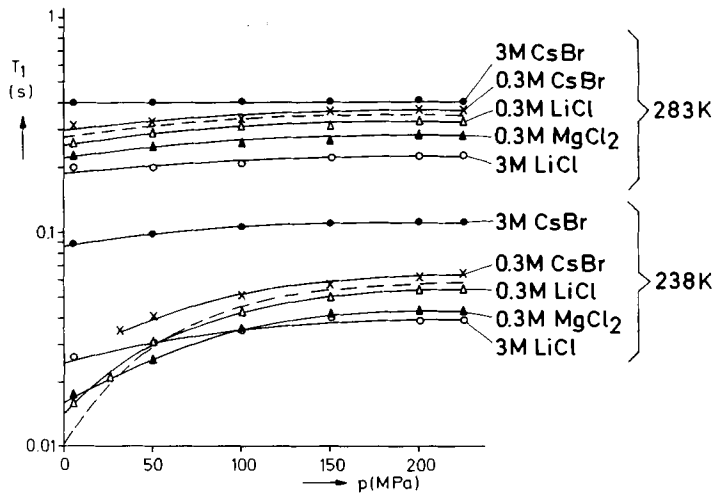

Fig. 14. Pressure dependence of the isotherms of the deuterium spin-lattice relaxation time T_1 of some salt solutions in D_2O.

9. Concluding Remarks

In the preceding chapters it has been shown that liquid water has to be regarded as a three-dimensional random H-bond network. Locally, an almost tetrahedral arrangement of nearest neighbors is preferred in this network. A broad distribution of O—O—O angles leads to a loss of spatial correlation between more distant molecules. The network possesses thermal excitations in the form of hindered translations and librations. The structural rearrangements occur on the time scale of diffusion processes. Removal of thermal energy stabilizes linear H-bonds and favors a network topology with open structure and low density. Especially in supercooled water, these patches have a tendency to clump together.

The consequence of these cooperative processes is that many thermodynamic and dynamic properties possess a very strong temperature dependence in the metastable region. It cannot be decided, as yet, whether a second-order phase transition, or a percolation threshold, or a stability limit is approached with falling temperature. Hydrostatic pressure destabilizes the hydrogen bonds and leads to a denser packing of the molecules in the network. The formation of ordered low density patches becomes more difficult, and is thus suppressed by increasing pressure. Under high hydrostatic pressure the properties of water reveal a pressure- and temperature-dependence similar to many simple viscous liquids. So far only a few measurements of the physical properties of deeply supercooled water at high pressure are available. Considerable experimental difficulties are encountered in the metastable range, particularly if the experiments cannot be performed on the relatively stable alkane/water emulsions.

No computer simulations for deeply supercooled water have been performed hitherto, since the considerable increase in the microscopic time constants on approaching T_H, the temperature of homogeneous nucleation, increases the computer time required enormously. Calculations in the metastable region would, on the other hand, show whether the potential functions applied are able to reproduce the cooperative behavior of the molecules. The anomalies, which are much more pronounced in the supercooled water, present an important test case for all simulations.

It is to be expected that experiments with supercooled aqueous solutions of biopolymers, apolar solutes, and electrolytes will contribute substantially to our understanding of these solutions in their respective regions of thermodynamic stability[177-181]. The investigation of the dynamic properties of water in supercooled aqueous solutions of biopolymers should yield new insights into the hydration of these substances, since large deviations from the behavior of pure water are to be expected. The investigation of the kinetic activity and of the spectroscopic properties of enzymes under these conditions extends the observ-

able dynamic range of enzymic reactions by some orders of magnitude[195]. Unstable reaction intermediates could be accumulated and investigated spectroscopically[180, 181]. During the winter season many cold-blooded, polar animals produce antifreeze agents, most of which are glycoproteins[196–199]. The formation of these compounds enables the animals to survive for long time spans at a few degrees below the melting point of their body fluid. The physics of this freeze-protection mechanism is not completely understood and it should be possible to check some of the currently discussed mechanisms with the help of spin-lattice relaxation time measurements of the water molecules in deeply supercooled solutions of these compounds.

Furthermore, one can expect that the investigation of supercooled aqueous emulsions with apolar solutes will increase our knowledge about hydrophobic solvation and hydrophobic interactions.

10. Appendix

After submission of this review article for publication, *Wu, Whalley,* and *Dolling* published high-pressure data up to 1560 MPa for neutron scattering in D_2O[200]. It emerges that the number of nearest neighbors increases about 50% between 0.1 MPa and the highest pressure achieved. The first O—O distance, on the other hand, remains practically unchanged. In addition, further work published by *Angell, Sichina,* and *Oguni*[201] revises C_p values for supercooled H_2O and D_2O. However, the basic conclusions of Section 3.3 are not affected by this revision. Finally, *Speedy*[202] has succeeded in describing the behavior of supercooled and superheated liquid water assuming a closed mechanical stability limit for the liquid.

We thank Prof. C. A. Angell (W. Lafayette, Ind., USA), Dr. A. Geiger (Aachen), Prof. R. J. Speedy (Wellington, N. Z.), and Prof. H. E. Stanley (Boston, Mass., USA) for sending us manuscripts prior to publication. Our contributions to this field have been supported by generous grants from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Transition Metal Complexes with *cyclo*-Triphosphorus (η^3-P_3) and *tetrahedro*-Tetraphosphorus (η^1-P_4) Ligands

By Massimo Di Vaira and Luigi Sacconi*

Salts of 3d, 4d, and 5d metals in the presence of the ligands 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) or tris(2-diphenylphosphinoethyl)amine (np_3) react with white phosphorus P_4 (or yellow As_4) to produce several mononuclear sandwich and dinuclear triple-decker sandwich complexes, which contain the unprecedented *cyclo*-triphosphorus (or *cyclo*-triarsenic) unit acting as a *trihapto*-ligand. In these complexes the metal atoms are bonded to the three phosphorus atoms of the phosphane ligand and to the three atoms of the *cyclo*-P_3 or *cyclo*-As_3 unit. The complexes are diamagnetic or have μ_{eff}-values corresponding to one or two unpaired electrons. The *cyclo*-P_3 ligand is coordinatively unsaturated as proved by the fact that the mononuclear sandwich compounds may form Lewis-base adducts with electron-acceptor fragments. Reaction of the complexes $(np)_3M$ (M = Ni, Pd) with white P_4 leads to formation of diamagnetic compounds $[(np_3)M(\eta^1\text{-}P_4)]$, in which the metal atom is bonded to the three phosphorus atoms of the np_3-ligand and in addition to one P atom of the intact P_4 molecule, which behaves as a *monohapto*-ligand. This article contains a review of the syntheses and structures of these complexes as well as a unified, albeit qualitative, approach to their bonding and properties.

1. Introduction

Very few metal complexes containing P_2, P_3, or P_4 groups bonded to the metal atom were known until recently. Some rather unstable compounds of the types $[RhCl(ER_3)_2(P_4)]_2$ (E = P, As; where E represents an element with donor properties)[1], $[Fe(CO)_4]_3P_4$, and $[Fe(CO)_3P_2]_n$[2] had been reported, but definitive conclusions about their structures were not reached. Unstable tetrahedral clusters $P_n[Co(CO)_3]_{4-n}$ (n = 1, 2, 3) had been reported and structures proposed for some of them on the basis of indirect evidence[3].

Recently however, stable compounds containing the *cyclo*-triphosphorus (P_3) unit or, only in two cases, the *tetrahedro*-tetraphosphorus (P_4) molecule as ligands have been obtained by allowing some hydrated salts or complexes of transition metals to react with white phosphorus in presence of appropriate polyphosphanes under mild conditions. X-ray structure determinations performed on some of these compounds have shown that the tetrahedral P_4 molecule in the complexes hitherto obtained behaves as a *monohapto*-(η^1) ligand and is coordinated to *one* metal atom, whereas the *cyclo*-triphosphorus group acts as a *trihapto*-(η^3) ligand and is either (a) coordinated to *one* metal atom or (b) to *two* metal atoms, or (c) is η^3-bonded to *one* metal atom and *in addition* is η^1-bonded to one to three other metal centers.

The *cyclo*-triphosphorus complexes of type (a) have the general formula $[LM(\eta^3\text{-}P_3)]^{n+}$, where L = 1,1,1-tris(diphenylphosphinomethyl)ethane, $(CH_3C(CH_2PPh_2)_3$, triphos) or tris(2-diphenylphosphinoethyl)amine, $(N(CH_2CH_2PPh_2)_3$, np_3), M = metal and n = 0, 1[4-7]. They may be considered as "sandwich" compounds in a generalized sense, since their LM moieties are isolobal[9, 10] with the η^5-C_5H_5M fragment which is present in some of the classical sandwich compounds[8]. The dinuclear metal complexes of type (b) are formed by the triple-decker sandwich complexes $[LM(\eta^3\text{-}P_3)M'L]^{n+}$[4, 11], in which the *cyclo*-triphosphorus unit forms the "filling" between the molecular fragments ML and M'L. Several complexes of this type are paramagnetic and have provided, with the analogous *cyclo*-triarsenic derivatives, the first examples of paramagnetic triple-decker sandwich complexes[4, 12]. The polynuclear complexes of type (c) have less simple structures than those of types (a) and (b) (see Section 5).

2. Metal Complexes with *tetrahedro*-Tetraphosphorus Ligands

2.1. Synthesis and Structure

Reaction of the trigonal pyramidal nickel(0) complex $(np_3)Ni$[13] with white phosphorus in tetrahydrofuran (THF) at *ca.* 0 °C leads to the diamagnetic compound $[(np_3)Ni(\eta^1\text{-}P_4)]$, which readily precipitates[14]. This is slightly air-sensitive and is insoluble in all common organic solvents. On substitution of $(np_3)Pd$ for $(np_3)Ni$, the $[(np_3)Pd(\eta^1\text{-}P_4)]$ complex is obtained by the above procedure[15]. This is isomorphous with the nickel analog, whose structure has been determined[14].

The metal atom in $[(np_3)Ni(\eta^1\text{-}P_4)]$ is bound to the three P atoms of the np_3 ligand and to one P atom of the P_4 unit in a nearly regular tetrahedral coordination geometry (Fig. 1). The molecule has crystallographic C_3 symmetry, with the threefold axis passing through the metal atom, the coordinated P_4 phosphorus atom, and the nitrogen atom of the np_3-ligand, which is uncoordinated. In the educt compound this nitrogen donor is linked to the metal: its detachment upon coordination by one phosphorus atom of the competing P_4 ligand results from the flexibility of the

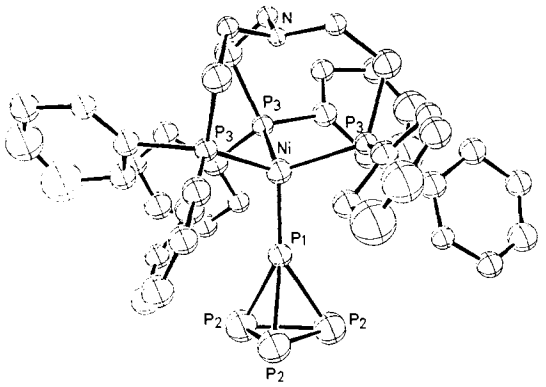

Fig. 1. Perspective view of [(np$_3$)Ni(η^1-P$_4$)] in the crystal.

np$_3$ molecule[16, 17], and is probably determined by the electronic factors described in Section 2.2. Upon coordination, the P_4 unit undergoes a small distortion from regular tetrahedral geometry with PP bond distances of 2.21 Å[18], to form a slightly elongated trigonal pyramid, with the apex pointing toward the metal atom: the P_{basal}—P_{apical} distances of 2.20(3) Å are significantly longer than the P_{basal}—P_{basal} of 2.09(3) Å, even though there is a rather large uncertainty on such values due to the limited diffraction data available for structure determination. Such deformations of the tetrahedral P_4 unit and the short Ni—P bond (1.99(1) Å) are indicative of considerable interaction between the (np$_3$)Ni moiety and the P_4 group, although it has to be stressed that the energy required to change the length of PP bonds is rather small.

The formation and stability of these P_4 adducts are probably due to properties of the np^3-ligand, such as its flexibility, the nature of its donor atoms, and its ability to impose a proper symmetry on the metal environment, as well as to the stability of the 18-electron configuration of the metal atom, existing both in the educt and in the product. In fact, at variance with most of the reactions leading to formation of η^3-P$_3$ complexes described in Section 3, the formation of the present P_4 adducts involves no change in the oxidation number of the metal atom. It appears that a moderate conformational rearrangement of the ligand molecule is sufficient to lengthen, *via* the simplest reaction path, the NiN bond with formation of the new NiP bond by the incoming P_4 molecule. This transformation leads to an almost regular tetrahedral environment of nickel(0), formed by four phosphorus atoms, which should be more favorable than the less symmetrical and inhomogeneous arrangement of the parent compound.

2.2. MO Description of the Bonding

A qualitative description of the electronic structure of the *tetrahedro*-P_4 derivatives is provided by the "fragment molecular orbital" (FMO) approximation[19, 20]. The nature of the valence orbitals of a conical fragment such as the (np$_3$)M moiety with uncoordinated nitrogen atom has been extensively investigated and described at length[9, 21]: this will be described briefly here, since it is relevant to most of the following discussion. The HOMO (Fig. 2a) consists of a doubly-degenerate 3e orbital set (the electron count is appropriate for the d^{10} configuration, although assigning electronic configurations to molecular fragments is to some extent arbitrary) having high metal nd and low (n+1)p character. Due to the low "pyramidality"[9] (PMP ≈ 109°) of the (np$_3$)Ni fragment, the orbitals forming the "lower d block", *i.e.* the 1a$_1$ (z^2, σ-type) and the 2e set, are located only slightly below this. As a further consequence of the large PMP angle, mixing of the (xz,yz) and (xy,x^2-y^2) sets of metal orbitals occurs in the 2e and 3e MO's which therefore have less pronounced δ- and π-bonding character, respectively, than in more pyramidal (*e.g.* in the (triphos)M) fragments. Lower-lying orbitals have predominantly ligand character. The LUMO, 2a$_1$, is an important σ-bonding hybrid orbital with metal (n+1)s and (n+1)p character.

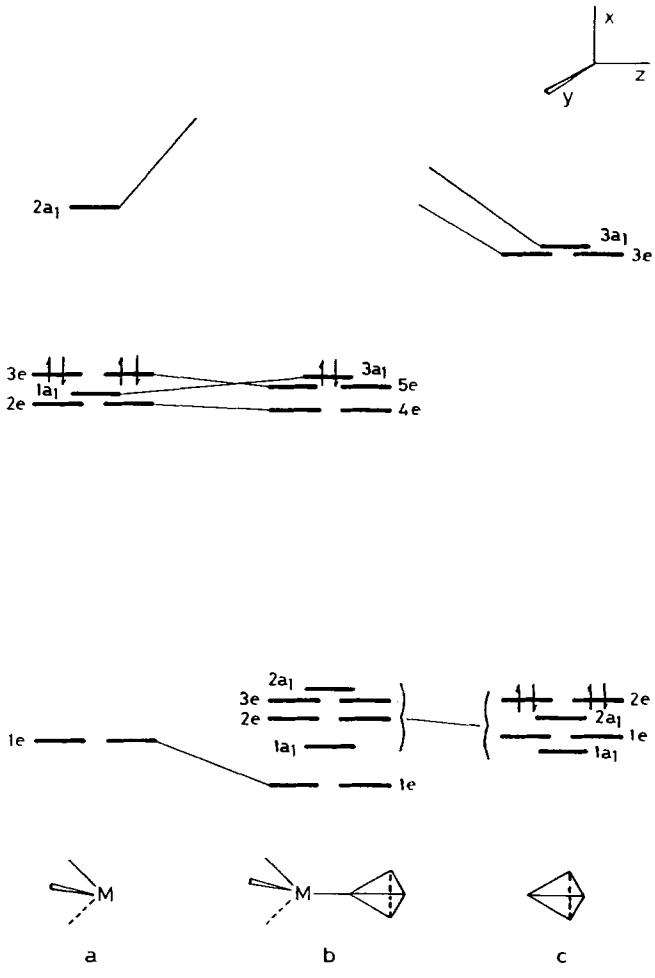

Fig. 2. MO correlation diagram for [LM(η-P$_4$)] complexes (C$_{3v}$ symmetry); a, b, c see text.

This MO correlation diagram (Fig. 2), as are those in Figures 5 and 10, is based on extended-Hückel (EH) calculations[22] performed using computer programs, which we wrote following procedures described by *Hoffmann et al.*[9, 10, 19–22] with parameters from this or other sources[23]. Both iterative calculations, to self-consistency in charge and configuration (SCCC), and noniterative ones, in which the effects of geometrical deformations were investigated, were performed. In the simplified molecular models, the triphosphane in the (np$_3$)M or similar LM fragments was idealized as a set of three properly oriented PH_3 groups.

The energies of the important orbitals of the P_4 group, which in the calculations was assigned the distorted geometry in $[(np_3)Ni(\eta\text{-}P_4)]$, are shown on the right-hand side of the interaction diagram (Fig. 2c). Even when the effects of the small decrease from T_d symmetry are taken in account, their order does not match the energy sequence reported by *Van Wazer et al.* based on accurate calculations on the isolated P_4 molecule[24]; the corresponding energies, on the other hand, all lie rather close together.

None of the interactions between valence orbitals on the two fragments appear to be particularly strong (Fig. 2b), in contrast to what would be anticipated from consideration of the bond lengths (Section 2.1). Important stabilizing effects in these adducts are due to the sp hybrid orbital on the metal atom, as well as to additional vacant orbitals on both fragments. There are indications that the empty d orbitals on the phosphorus atoms play a role in redistributing the electron density throughout the whole molecule. However such effects can hardly be quantified, because of the lack of reliable parameters for virtual orbitals.

The largest contribution to the bonding in the P_4 adducts is provided by the σ-type $2a_1$ orbital (Fig. 2b) having metal z^2, z contributions, and above all apical-phosphorus s and z contributions. The bonding and antibonding π-interactions between the two fragments largely cancel each other out, and hence contribute slightly to the overall $MP(P_4)$ overlap population (which is, however, appreciably larger than that of the $MP(np_3)$ bonds). Allowing the apical nitrogen atom, treated as an NH_3 group, to approach the metal atom more closely results in an increase in the $NNiP(np_3)$ angle and causes a steep rise in the energy of a σ orbital, which is antibonding with respect to the $MP(P_4)$ bond. This reillustrates the validity of the 18-electron rule.

The increasing difficulty in obtaining $[(np_3)M(\eta^1\text{-}P_4)]$ compounds on going from nickel to palladium, and then to platinum (the platinum derivative has not been obtained as yet using the previously mentioned procedure) is presumably due to increasing mismatch of the orbital energies of the two fragments involved.

The electronic spectra of these d^{10} complexes show a band at 26000–27000 cm^{-1}, which may be due to a $M \rightarrow L$ charge-transfer (CT) transition. The absence of lower-energy excitations suggests that bands appearing at much lower energies in the spectra of the η^3-P_3 derivatives (see Section 3.4) may have some d-d character.

3. Mononuclear Metal Complexes with *cyclo*-Triphosphorus Ligands

3.1. Synthesis

If hydrated cobalt(II) complex salts with "non-coordinating" anions such as BF_4^- are allowed to react under mild conditions with white phosphorus in presence of triphosphanes, mononuclear single- or dinuclear triple-decker sandwich complexes are obtained, depending on the stoichiometric ratio of the reagents. Both types of complexes contain the *cyclo*-P_3 group as ligand. This group, originating from the P_4 molecule, behaves as a *trihapto*-ligand both when it is coordinated to *one* metal atom and when bridging between two metal atoms. The mononuclear sandwich complexes are obtained using an excess of white phosphorus dissolved in THF[5,7]; the hydrated metal salts employed in the reactions are generally dissolved in ethanol whereas the triphosphane is in THF solution. The complexes are stable in air but only moderately stable in organic solvents.

The structure of $[(triphos)Co(\eta^3\text{-}P_3)]$[7], which is typical of complexes of this sort, is shown in Figure 3. The metal

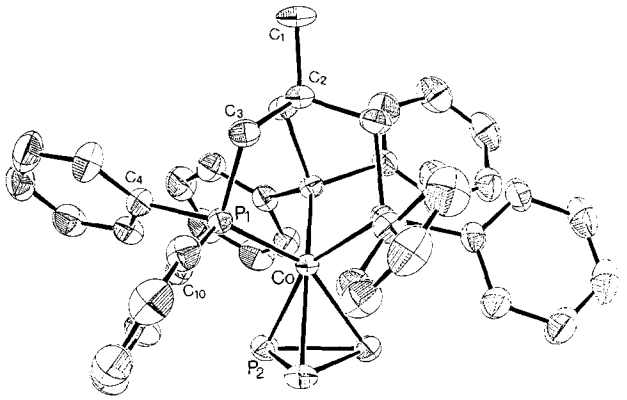

Fig. 3. Perspective view of $[(triphos)Co(\eta^3\text{-}P_3)]$ in the crystal.

atom is coordinated by six phosphorus atoms, three of which are provided by the triphos ligand, the other three by the *cyclo*-P_3 group. Viewed along the molecular C_3 axis the two sets of donor atoms are nearly staggered, yielding a very distorted octahedral coordination. A closely similar molecular geometry exists in $[(np_3)Co(\eta^3\text{-}P_3)\cdot 0.5\,C_4H_8O]$ (Fig. 4), in which the np_3 nitrogen atom is not coordinated[5]. Simple electron counting (Section 3.2), shows that removal of the nitrogen lone pair from the coordination sphere of the metal allows this to attain the 18-electron configuration.

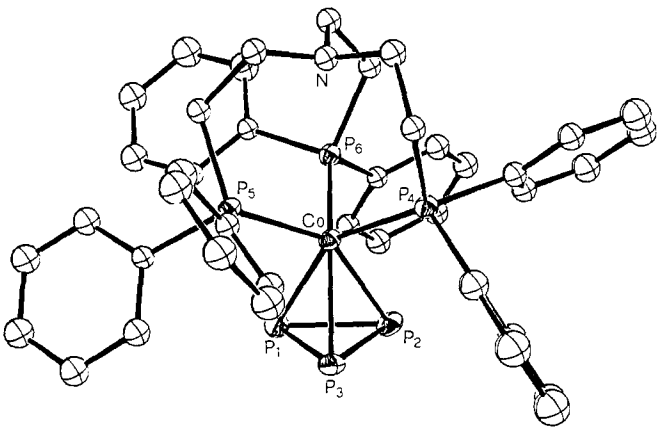

Fig. 4. Perspective view of $[(np_3)Co(\eta^3\text{-}P_3)]$ in the crystal.

The rhodium and iridium analogs of $[(triphos)Co(\eta^3\text{-}P_3)]$ have been obtained by allowing the complexes $[Rh(C_2H_4)_2Cl]_2$ and $[Ir(PPh_3)_2(CO)Cl]$, respectively, to react with P_4 in presence of triphos[6]. These complexes are isomorphous with each other as well as with the cobalt complex[6].

Starting from the $[(MCl_2PBu_3)]_2$ complexes (M = Pd, Pt), the first cationic sandwich complexes of *cyclo*-P_3, $[(triphos)M(\eta^3\text{-}P_3)]^+$ (M = Pd, Pt), have been obtained[15]. The structures of their BF_4^- salts, which are mutually isomor-

phous, have been determined[15,25]. Although the coordination geometry is closely similar to that of the Co, Rh, and Ir neutral complexes, the MP and PP distances show significant differences between the two sets of compounds. Selected structural data for all of the mononuclear complexes are listed in Table 1. The main features of the structures are shortly discussed in Section 3.3 using a simplified approach to the bonding.

At variance with the η^1-P_4 complexes, in the mononuclear η^3-P_3 compounds substantial interaction occurs between the upper d-block orbitals, 2e, of the LM fragment and properly oriented orbitals, e″, of the η^3-P_3 fragment. Stabilizing effects of the sp hybrid orbital on the metal atom and of additional virtual orbitals are again important. The appreciable contribution to the bonding by the metal (n + 1)s and (n + 1)p orbitals increases on going from

Table 1. Structural data for the mononuclear [LM(η^3-P_3)] complexes [a, b].

[(triphos)Co(η^3-P_3)]	2.186(1)	2.301(1)	2.141(2)	93.55(4)	55.43(5)	[7]
[(np_3)Co(η^3-P_3)]	2.254(9)	2.315(8)	2.135(6)	102.7(6)	54.9(2)	[5]
[(triphos)Rh(η^3-P_3)]	2.294(1)	2.418(2)	2.152(2)	91.25(4)	52.86(5)	[6]
[(triphos)Ir(η^3-P_3)]	2.277(2)	2.436(2)	2.159(4)	91.22(7)	52.60(8)	[6]
[(triphos)Pd(η^3-P_3)]BF_4	2.37(1)	2.412(8)	2.115(8)	91(2)	52.0(1)	[15]
[(triphos)Pt(η^3-P_3)]BF_4	2.339(8)	2.433(5)	2.155(9)	91(1)	52.6(3)	[25]

[a] L = triphos or np_3. [b] The average bond-lengths (chemically equivalent bonds) [Å] and -angles [°] are reported; standard deviations are calculated using the formula $[\Sigma_i|\Delta_i|^2/(n-1)]^{1/2}$, where n is the number of bonds or angles and Δ_i are deviations of individual values from the mean. [c] Angle involving P atoms of L. [d] Angle involving the P atoms of *cyclo*-P_3.

It should be noted that formation of mononuclear *cyclo*-P_3 derivatives by the procedures exploited up to now, invariably involves reduction of the metal atom relative to its oxidation state in the parent compound. The mechanisms of the reactions have not yet been ascertained. We recall at this point that a *cyclo*-P_3 cobalt derivative with formula $[(CO)_3CoP_3]$ had been obtained previously by different procedures using more drastic conditions[3].

3.2. MO Approach to the Bonding

Among the possible simplified approaches to the bonding in the mononuclear *cyclo*-P_3 derivatives the following two seem to be particularly appropriate. According to the first viewpoint the compounds may be considered to originate from the tetrahedral P_4 molecule by replacing one of the phosphorus atoms with an LM (M = Co, Rh, Ir; L = triphos, np_3) or an LM^+ (M = Pd, Pt) group. Such substituent groups are three-electron donors according to *Wade*'s rules[26]: in this sense they are equivalent to the phosphorus atom of P_4 that they are considered to replace. This is essentially the approach followed by *Dahl et al.* in their pioneering work on metal carbonyls containing the As_3 or As_2 group as ligands[27,28]. In a more detailed approach the bonding pattern is investigated by the FMO approximation (see Section 2.2).

The orbital correlation diagram for an [LM(η^3-P_3)] complex is shown in Figure 5. The orbitals of the LM conical fragment (Fig. 5a) have already been described (Section 2.2, Fig. 2); the triphosphane lone pairs, lying lower in energy, do not appear in the diagram. Orbitals of the *cyclo*-P_3 group having suitable energy to interact with those of the other fragment are shown on the right hand side (Fig. 5c): those labeled a_1' and e′ lie in the plane of the ring, whereas a_2'' and e″ represent π orbitals of the fragment, *i.e.* normal to its plane. The energy levels of the complex are sketched in Figure 5b.

complexes with 3d and 5d metals. The large separation between the HOMO and LUMO is in good qualitative agreement with the diamagnetism of the compounds and with their electronic spectra, which exhibit transitions only at high energies (see Section 3.4).

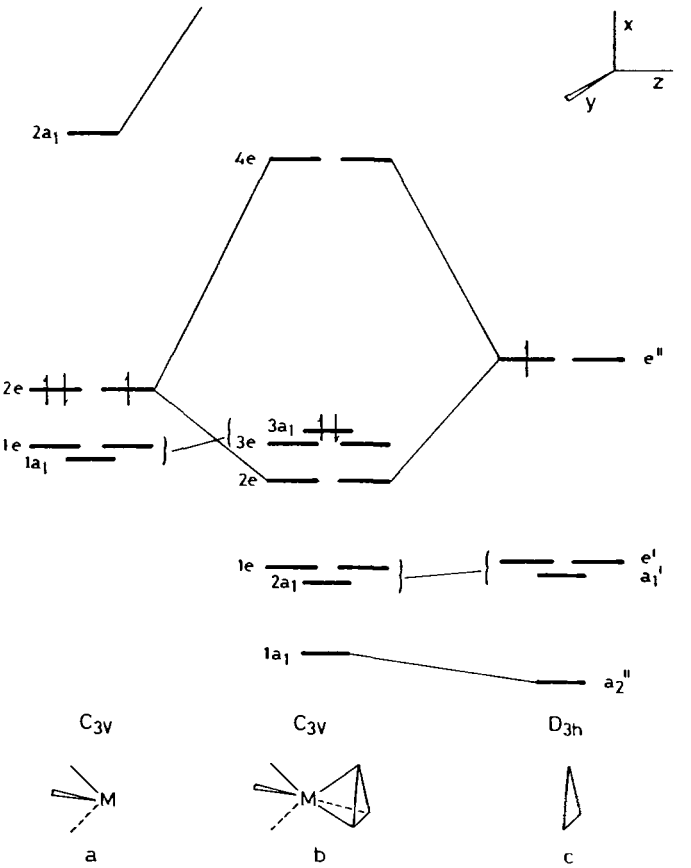

Fig. 5. MO correlation diagram for $[LM(\eta^3\text{-}P_3)]^{n+}$ complexes; a, b, c see Text.

It is a useful approximation for electron-counting purposes to consider the η^3-P_3 group as a three-electron donor both in the mononuclear and in the dinuclear complexes. This assumption is based on the fact that among the highest-occupied orbitals of the *cyclo*-P_3 group, those (a_2'' and e'' in Fig. 5c) which undergo most of the interaction with orbitals of the other fragment(s), are allocated three electrons. From a complementary point of view, such assumption is consistent with the assignment of the stable 18-electron configuration to all the mononuclear *cyclo*-P_3 derivatives, nine electrons being provided by the metal atom or ion, six by the triphosphane lone pairs and the remaining three by the neutral *cyclo*-P_3 group[*].

Iterative SCCC calculations indicate that there is an overall shift of electron density toward the *cyclo*-P_3 group in η^3-P_3 complexes. Although the amount of this shift may not be reliable, as it may be largely an artifact of the calculational procedure, the trend however should be correct (it is supported by comparisons with $[(CO)_3M(\eta^3\text{-}P_3)]$ and $[Cl_3M(\eta^3\text{-}P_3)]$ model systems). The general shortening of the PP distances in these compounds (Table 1) from the value of 2.21 Å found for the isolated P_4 molecule[18], can, therefore, hardly be attributed to decreased electrostatic repulsions between lone pairs on the phosphorus atoms. It may originate from an overall increase in bonding and/or decrease in antibonding interactions within the ring upon coordination to the metal atom. Remarkably, the $MP(P_3)$ overlap integral is two to three times smaller than that of "normal" MP bonds, such as those formed by the phosphane (L) donor atoms. The PP overlap population is almost twice as large as that of an MP(L) bond.

3.3. Structural Trends

Turning to a consideration of structural features of the mononuclear compounds, the fact that the $MP(P_3)$ bonds are generally longer than the MP(L) bonds (cf. Table 1) may be traced to the above differences in the overlap integrals. A further point is that the close similarity in the PP and $CoP(P_3)$ distances in the two cobalt compounds $[(triphos)Co(\eta^3\text{-}P_3)]$ and $[(np_3)Co(\eta^3\text{-}P_3)]$ (cf. Table 1) is surprising in view of the differences both in their CoP(L) bond lengths (0.07 Å) and in the PCoP angles (9°) formed by the phosphane donor atoms. The difference in the angles, *i.e.* in the "pyramidality" of the LM fragments, in particular, would be expected to have appreciable stereochemical consequences[10,29]. It appears that the conformational preferences of the two LM fragments are inhibited by the strict bonding requirements of the "rigid" *cyclo*-P_3 ring. Calculations on two model systems, which correspond to each of the complexes mentioned, provide similar bonding patterns. There is a small decrease in the $CoP(P_3)$ bond overlap population from the triphos to the np_3 derivative, due to unfavorable mixing of the metal 4s orbital, which might be related to the small (mean) elongation observed for such distances in the np_3 complex.

In the series of $[(triphos)M(\eta^3\text{-}P_3)]$ compounds (M = Co, Rh, Ir) the PP distances increase a little (2.141 Å to 2.159 Å) on going from the 3d to the 5d metal complex. Both the $MP(P_3)$ and the MP(triphos) distances increase noticeably (*ca.* 0.11 Å) from the cobalt to the rhodium compound. Although such distances change only little on proceeding from the rhodium to the iridium compound as a consequence of the lanthanoid contraction, they however exhibit the following interesting trend: while the $MP(P_3)$ bonds lengthen by *ca.* 0.02 Å, those formed by the triphos donor atoms shorten by a corresponding amount. An analogous trend is observed for the two cationic Pd and Pt complexes (*cf.* Table 1) even though each differs from the corresponding neutral compound in having longer (*ca.* 0.07 Å) MP(triphos) distances.

Such a trend is indicative of competing conformational preferences of the two conical fragments—(triphos)M and $M(P_3)$—having their apices at the metal atom position. Which conformation is preferred should in turn be determined by properties of the metal atom, *e.g.* the size and energy of its valence orbitals, which do not vary linearly on going from first to third transition series[23]. It has been verified using the approximate atomic parameters available[23] that the important $\langle d(M)|P(P_3)\rangle$ overlap integrals do not vary linearly with the principal quantum number of the d orbitals, but reach a maximum for M = Rh. However, detailed conclusions on the origin of the above structural trend may hardly be drawn, because of the large number of possible factors involved and uncertainty in the values of parameters to be used in the calculations. As a final note, the extremely short PP distances (average 2.115 Å) in the palladium complex cation (*cf.* Table 1) again point to the importance of the electronic requirements of the individual metal atoms.

3.4. Electronic Spectra

The lowest-energy transition which is observed in the electronic spectrum of $[(triphos)Co(\eta^3\text{-}P_3)]$, *i.e.* before the onset of CT bands, is a shoulder at *ca.* 24000 cm^{-1}. With reference to Figure 5b, such a transition provides an estimate of the separation between the $2e\text{-}3a_1$ group of energy levels and the excited 4e level. In addition to this transition, a shoulder at lower wavenumber (20400 cm^{-1}) appears in the spectrum of $[(np_3)Co(\eta^3\text{-}P_3)]$. This could be due to small alterations in the pattern of energy levels caused by the lower "pyramidality" of the $(np_3)Co$ moiety relative to (triphos)Co, or to a contribution of the uncoordinated nitrogen atom to the axial ligand field strength in the np_3 derivative. As noted in the previous section, however, neither of these effects is indicated by the approximate calculations. As expected on consideration of the increasing ligand field strength, there is a high-energy shift of the bands on going from the cobalt to the rhodium complex (27000 cm^{-1}); in the spectrum of the iridium com-

[*] This electron partitioning is based on the concept of a closed-shell 18-electron configuration which, in general, cannot be readily reconciled with a delocalized MO picture of the bonding in the compound. In the present case, however, nine doubly occupied MO's which are mainly responsible for the closed-shell environment of the metal atom, may be identified: the 3e and $3a_1$ orbitals in Figure 5b, having predominantly metal character, the $1a_1$ and 2e orbitals, having metal and $\pi(P_3)$ contributions, and a set of three orbitals, not shown in the figure, mainly consisting of the phosphane "lone pairs".

pound no transitions are observed before the CT bands at *ca.* 28000 cm^{-1}. An analogous trend is exhibited by the spectra of the cationic derivatives, that of the Pd complex having a shoulder at 22600 cm^{-1} and bands in the region 25500–28500 cm^{-1}, whereas that of the Pt complex shows no bands below 28000 cm^{-1}[30].

4. Triple-Decker Sandwich Complexes of *cyclo*-Triphosphorus and *cyclo*-Triarsenic Ligands

4.1. Syntheses and Structures

The dinuclear triple-decker sandwich complexes containing the *cyclo*-triphosphorus group as ligand, or in some cases the *cyclo*-triarsenic group, have been obtained up to now by the following procedures:

a) By allowing stoichiometric amounts of P_4 (or As_4), the hydrated metal salt, and the phosphane ligand to react in solution. THF solutions of P_4 (or As_4) and of the ligand have generally been used, the hydrated metal salt being dissolved in ethanol. By this procedure only symmetric, *i.e.* having identical halves of the sandwich, triple-decker sandwich compounds are obtained.

b) By allowing a mononuclear complex [(triphos)M(η^3-P_3)] (M = Co, Rh, Ir) to react with a hydrated metal salt or metal complex in solution, in presence of the phosphane ligand. All reactants are generally dissolved in dichloromethane, except for the hydrated metal salts, which are dissolved in ethanol. In this way both symmetric and asymmetric complexes are obtained. In the latter, the metal atoms and/or the external ligands may be different.

c) By reducing the dinuclear *cyclo*-P_3 complexes described in a) or b), *e.g.* with $NaBH_4$ in acetone/ethanol.

If equimolar amounts of $[Co(H_2O)_6](BF_4)_2$ (or $[Ni(H_2O)_6](BF_4)_2$), the triphos ligand, and white phosphorus are allowed to react as described in procedure a), the complexes [(triphos)M-μ-(η^3-P_3)M(triphos)]$(BF_4)_2$ (M = Co, Ni) are isolated[11]. Their BPh_4 salts, which are generally suitable for structural investigations[11,31], were obtained by recrystallization from acetone/butanol, after adding $NaBPh_4$ to acetone solutions of these complexes. The *cyclo*-triarsenic derivatives [(triphos)M-μ-(η^3-As_3)M(triphos)]X_2·solvent (M = Co, Ni; X = BF_4, BPh_4) were analogously obtained using a solution of As_4 in THF[11,32]. Finally, the dinuclear palladium complexes [LPd-μ-(η^3-P_3)PdL]X (L = np_3, X = BF_4; L = triphos, X = BPh_4) were prepared by reaction of $[PdCl_2PBu_3]_2$ with white phosphorus in presence of the appropriate ligand L[15].

Following procedure b), the triple-decker sandwich complexes [(triphos)Co-μ-(η^3-P_3)M(triphos)]$(BPh_4)_2$·solvent (M = Co, Ni) are obtained by allowing the mononuclear cobalt complex [(triphos)Co(η^3-P_3)] to react with equimolar amounts of $[Co(H_2O)_6](BF_4)_2$ (or $[Ni(H_2O)_6](BF_4)_2$) and triphos, followed by addition of solid $NaBPh_4$[11]. By allowing [(triphos)Co(η^3-P_3)] to react with hydrated salts of divalent metals in presence of the alkyl-substituted tertiary phosphane 1,1,1-tris(diethylphosphinomethyl)ethane ($CH_3C(CH_2PEt_2)_3$, etriphos), mixed-ligand complexes [(triphos)Co-μ-(η^3-P_3)M(etriphos)]X_2 (M = Fe, Co or Ni, and X = PF_6 or BPh_4)[33] have been synthesized. In this manner, the iron-cobalt compound, a triple-decker complex with 30 valence electrons could be obtained[*].

Reaction of the rhodium complex [(triphos)Rh(η^3-P_3)] with hydrated metal salts and triphos affords the triple-decker heterometallic complexes [(triphos)Rh-μ-(η^3-P_3)M(triphos)]X_2·solvent (M = Co or Ni, and X = BF_4 or BPh_4)[34,35], which contain metal atoms of different transition-metal series. The above mononuclear rhodium complex also reacts with $[Rh(C_2H_4)_2Cl]_2$ (or $[Rh(CO)_2Cl]_2$) to yield the symmetric dirhodium derivative [(triphos)Rh-μ-(η^3-P_3)Rh(triphos)]BPh_4·$(CH_3)_2CO$[35]. Finally, starting from [(triphos)Ir(η^3-P_3)] the mixed iridium-cobalt complex [(triphos)Ir-μ-(η^3-P_3)Co(triphos)]$(BF_4)_2$·CH_2Cl_2 was obtained analogously[35].

The mononuclear educt complexes acting as synthetic building blocks in procedure b) were incorporated, undecomposed, into the dinuclear product complexes. Such behavior may be due on the one hand to efficient shielding of the η^3-P_3 core by the phenyl groups of the triphos ligand, which imposes constraints on the reaction path in such a way that disruptive transformations of the initial compound are prevented. On the other hand, the *cyclo*-P_3 phosphorus atoms are readily attacked, since they have considerable electron density in energetically accessible orbitals, and, in addition, have vacant orbitals at relatively low energies. It should also be noted that no change in the mean oxidation number of the metal atoms involved in the above synthetic processes occurs. In this respect formation of dinuclear complexes by procedure b) shows similarities to formation of the P_4 adducts, discussed in Section 2.1. On the other hand, it differs considerably from reactions of type a), in which redox processes invariably occur and the molecule of the P_4 reactant fragments.

Many of the triple-decker complexes can be oxidized or reduced, to some extent without decomposition. The complexes [(triphos)M-μ-(η^3-E_3)M(triphos)]BPh_4 (M = Co, Ni; E = P, As) have indeed been obtained by reduction of the corresponding dicationic compounds with $NaBH_4$[11]. This has been classified above as procedure c) for preparation of the triple-decker sandwich complexes. Redox processes in solution have been also performed on some of these compounds by cyclic voltammetric techniques[36], as is briefly described in Section 4.3.

All of the triple-decker complexes are stable in the solid state; most of them are also stable in solution, the exceptions being essentially due to the unsymmetrical compounds formed by two metal atoms of different transition-metal series. The nickel-rhodium complex, having VEN = 32 and low-lying excited states (see below) is particularly unstable.

In all of these triple-decker complexes the external "layers" are formed by the triphos, etriphos, or np_3-ligands, whereas the internal layer is formed by the *cyclo*-P_3 or *cyclo*-As_3 group. Each metal atom is bonded to the three phosphorus atoms of one external ligand and to the three

[*] The triple-decker sandwich complexes are assigned a valence-electron number (VEN) by straightforward extension of the criteria specified in Section 3.2 for mononuclear complexes, *e.g.*, the cobalt-nickel dication complex has VEN = 32 and the nickel-nickel monocation complex, described below, has VEN = 34.

atoms of the bridging η^3-E_3 group in a very distorted six-coordinate arrangement. A typical example is provided by the structure of the dication in the complex [(triphos)Ni-μ-(η^3-P_3)Ni(triphos)]$(BPh_4)_2 \cdot 2.5(CH_3)_2CO$, shown in Figure 6. Actually, four complexes out of a total of eight compounds of this type whose structures have been determined are isomorphous to the nickel complex:

[(triphos)Co-μ-(η^3-P_3)Co(triphos)]$(BPh_4)_2 \cdot 2CH_2Cl_2$[31]
[(triphos)Co-μ-(η^3-P_3)Ni(triphos)]$(BPh_4)_2 \cdot 2(CH_3)_2CO$[11]
[(triphos)Co-μ-(η^3-P_3)Rh(triphos)]$(BBh_4)_2 \cdot 2(CH_3)_2CO$[35] and
[(triphos)Co-μ-(η^3-As_3)Co(triphos)]$(BPh_4)_2$[11]

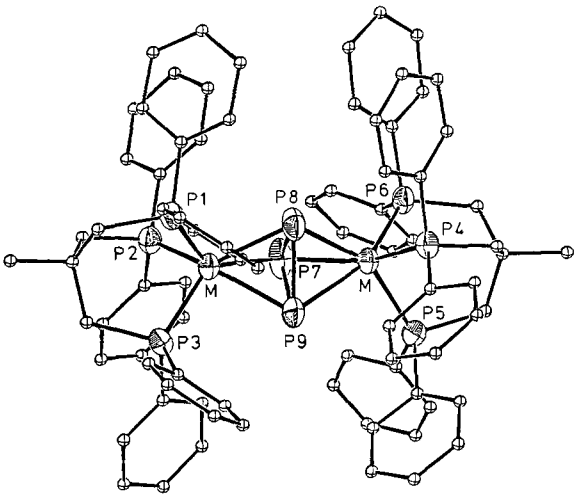

Fig. 6. Perspective view of the [(triphos)Ni-μ-(η^3-P_3)Ni(triphos)]$^{2+}$ cation (M = Ni) in the crystal.

Although the dication in each of these compounds has no crystallographic symmetry, its inner skeleton closely approaches C_3 symmetry. As shown in Figure 7a, the external ligands are rotated from the eclipsed position by *ca.* 30° about the pseudothreefold axis, whereas the phosphorus atoms forming the "inner triangle" are almost eclipsed

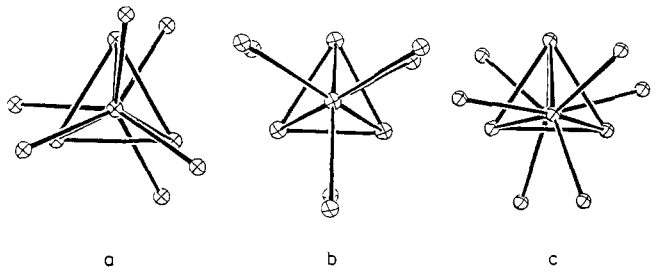

Fig. 7. Views along the molecular axis of the $P_3MP_3MP_3$ inner skeletons of representative triple-decker complexes: a) [(triphos)-Ni-μ-(η^3-P_3)Ni(triphos)]$^{2+}$; b) [(triphos)Pd-μ-(η^3-P_3)Pd(triphos)]$^+$; c) [(triphos)Ni-μ-(η^3-P_3)Rh(triphos)]$^{2+}$.

with those of one of the external layers. The inner coordination geometry in the cation of [(etriphos)Fe-μ-(η^3-P_3)Co(triphos)]$(PF_6)_2 \cdot CH_2Cl_2$[33] (Fig. 8) is closely similar to that of the above complexes, even though this iron-cobalt compound is not isomorphous to these. The [LPd-μ-(η^3-P_3)PdL]$^+$ (L = triphos, np_3) complexes have so far provided the only examples of a more regular arrangement[15,30] having the inner layer staggered with respect to the outer layers, so that the coordination geometry about each metal atom is a distorted octahedron (Fig. 7b). The nitrogen atoms of the two np_3-ligands in the cation

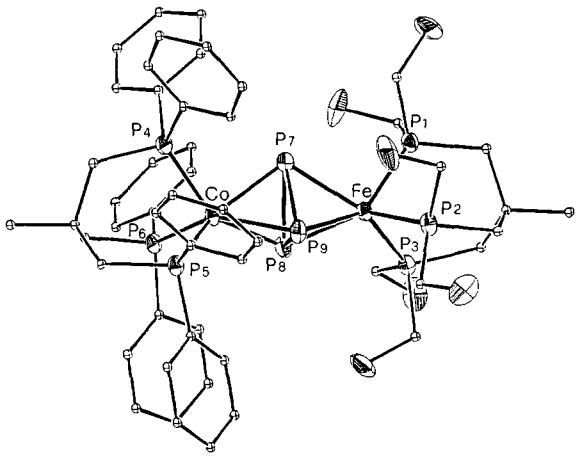

Fig. 8. Perspective view of the [(etriphos)Fe-μ-(η^3-P_3)Co(triphos)]$^{2+}$ cation in the crystal.

[(np_3)Pd-μ-(η^3-P_3)Pd(np_3)]$^+$ containing 34-valence electrons are uncoordinated (Fig. 9) and lie at 3.32 Å (average) from the metal atoms[30]. Finally, the structure of [(triphos)Ni-μ-(η^3-P_3)Rh(triphos)]$^{2+}$ shows significant deviations from the idealized C_3 symmetry[35]. In particular, the *cyclo*-triphosphorus group in such a complex forms an isosceles triangle, whose centroid is displaced away from the line joining the two metal atoms, with the vertices of the triangle lying in a plane perpendicular to this line (Fig. 7c). Relevant structural data for the above dinuclear complexes are listed in Table 2. Detailed consideration of the most significant features of these structures will be undertaken in the light of the following section on the bonding in these compounds in Section 4.4.

4.2. MO approach to the Bonding

The essentials of the orbital correlation diagram for a [LM-μ-(η^3-P_3)ML]$^{n+}$ model compound are shown in Figure 10. Although it is derived for idealized D_{3h} symmetry, in which adjacent layers are mutually staggered, it applies with only minor alterations, noted below, to the C_3 effective symmetry possessed by the majority of triple-decker complexes. The energy levels of the two LM fragments, separated by rather large distances of 3.8–4.3 Å, are shown on the left-hand side (Fig. 10a): the groups of orbitals originating from the upper- and lower-d blocks, and from the higher-lying sp hybrid orbital of an LM monomer fragment are readily identified. The important orbitals of the *cyclo*-P_3 group are sketched on the right-hand side (Fig. 10c). Valence orbitals of the dinuclear model compound appear in Figure 10b, with the occupancy appropriate for the VEN value of 33, which corresponds to the nickel-nickel dication.

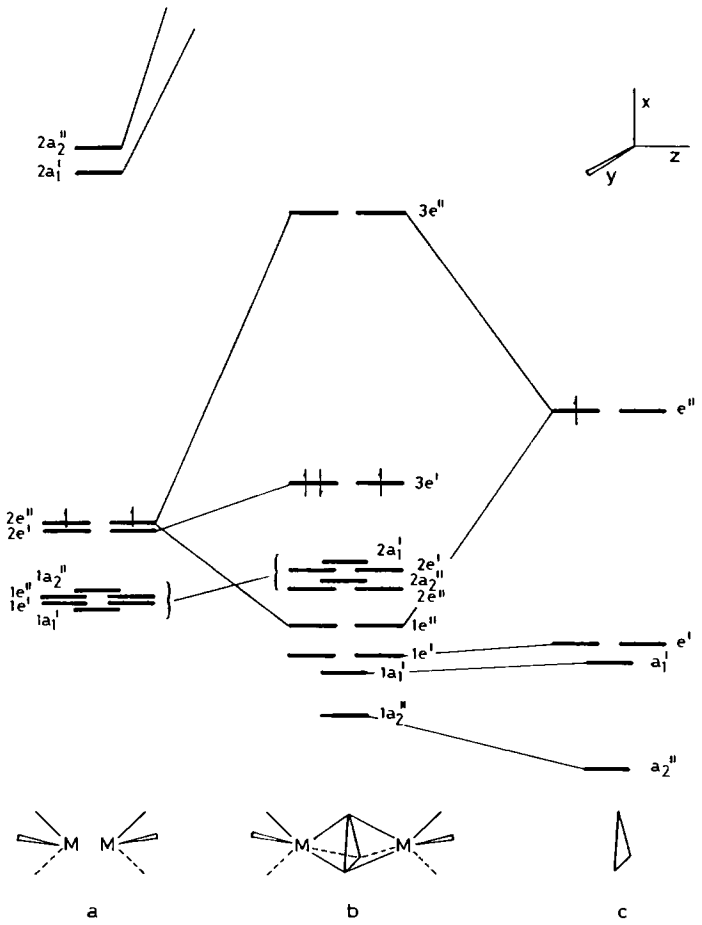

Fig. 10. MO correlation diagram for [LM-μ-(η^3-P_3)ML]$^{n+}$ complexes (D_{3h} symmetry); a, b, c see text.

The principal stabilizing interaction involves the metal xz and yz orbitals, which contribute to both e'' combinations of the LM...ML system, and the phosphorus z orbitals forming the e'' set of the *cyclo*-P_3 fragment. The occupied orbitals resulting from this interaction form the 1e'' set in Figure 10b. Interactions between the metal orbitals and those lying in the plane of the *cyclo*-P_3 group become more and more important as the distance between the two LM fragments decreases below *ca.* 3.8 Å. In particular, the cluster of the essentially metal 2e''-2a$_1'$ orbitals spreads considerably with decreasing M...M separation, whereas the 1a$_1'$ and 1e' combinations, predominantly localized in the plane of the *cyclo*-P_3 unit, are stabilized. The energies of all these orbitals are also affected by rotating the LM and P_3 molecular fragments about the threefold axis. The 3e' set forming the HOMO in most of these complexes has antibonding character in the interactions between the metal d orbitals and those of the phosphorus atoms lying in the plane of the *cyclo*-P_3 group. At the MM separation in the nickel-nickel dication, 76% metal and 12% *cyclo*-P_3 contributions to the HOMO are indicated by SCCC calculations in qualitative agreement with the electrochemical data.

4.3. Magnetic Properties and Redox Behavior of the Complexes

The redox behavior of the triple-decker sandwich complexes has been investigated electrochemically[36]. The reversible three-step cyclic voltammogram of the dicobalt complex [(triphos)Co-μ-(η^3-P_3)Co(triphos)](BF$_4$)$_2$ shown in Figure 11 indicates that a one-electron oxidation and two one-electron reduction processes may be performed on the 31-electron starting compound in acetonitrile. Therefore the range of VEN values from 30 to 33 is spanned by removing or adding electrons to the 3e' orbitals in the diagram in Figure 10. The diamagnetic bright green [(triphos)Co-μ-(η^3-P_3)Co(triphos)]$^{3+}$ species has been generated in solution by bulk oxidation of the dication at a controlled potential[36].

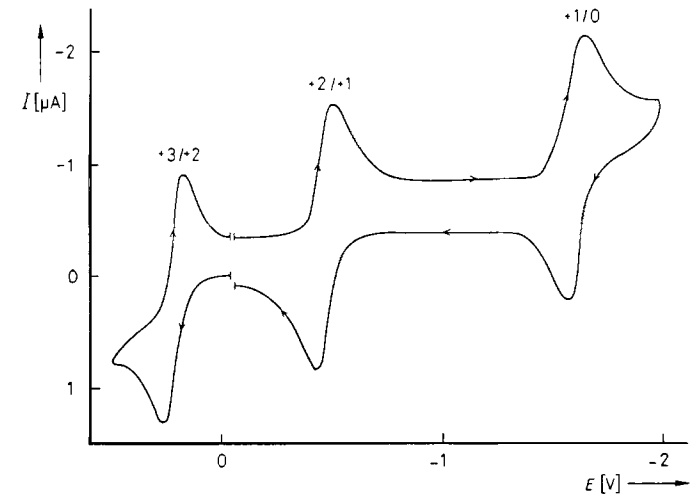

Fig. 11. Cyclic voltammogram of [(triphos)Co-μ-(η^3-P_3)Co(triphos)]$(BF_4)_2$: potential relative to Ag/Ag^+ (0.01 M).

The electrode potentials of the [(triphos)M-μ-(η^3-E_3)M(triphos)]$^{2+}$ (M = Co, Ni; E = P, As) complexes, reported in Figure 12, show that: a) oxidation processes occur at higher potentials for the nickel complexes than for the cobalt ones, in agreement with the trend in metal ionization potentials, which are of course embodied in the parameters used in the semiempirical calculations[23], and b) *cyclo*-As_3 complexes are more readily oxidized than the *cyclo*-P_3 derivatives. The latter result, being in accord with the expected trend from atomic ionization energies of group V atoms, indicates that the nature of the HOMO is influenced to some extent by that of the *cyclo*-E_3 unit.

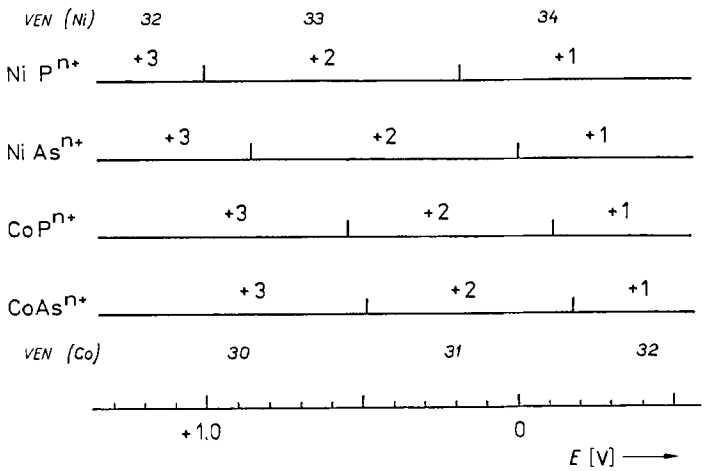

Fig. 12. Electrode potentials for the redox transitions of triple-decker sandwich complexes (*e.g.*, NiP^{n+} in the figure stands for [(triphos)Ni-μ-(η^3-P_3)Ni(triphos)]$^{n+}$, *etc.*). VEN = number of valence electrons; potential measured relative to saturated calomel electrode (SCE).

The magnetic properties of the triple-decker sandwich complexes formed by 3d metal atoms can be rationalized as follows: a) The 3e′ level is separated by large energy gaps both from the lower levels and from the successive 3e″ level. The electronic spectra suggest that the first of these energy separations is probably underestimated by the approximate calculations, or is an unsuitable indicator of the separation between the actual molecular states originating from the one-electron configurations; b) the 3e′ doubly-degenerate level is either empty, or completely filled, respectively, in the diamagnetic triple-decker sandwich complexes having VEN = 30 or 34; c) the 3e′ set is progressively occupied in paramagnetic complexes with VEN ranging from 31 to 33, which have a doublet (VEN = 31 or 33), or a triplet ground state (VEN = 32).

The magnetic behavior of 32-electron complexes formed by 4d or 5d metal atoms, such as the distorted nickel-rhodium derivative (Fig. 7c), deviates from the general trends; it is considered in more detail in Section 4.6.

4.4. Structural Features

Before examining the possible trends revealed by the structural data listed in Table 2 for these triple-decker sandwich complexes, it has to be noted that in the lattices of all the heteronuclear compounds investigated so far (except for the iron-cobalt compound having a highly asymmetric cation, cf. Fig. 8) the position of the complex cation is affected by twofold orientational disorder, so that each metal site is populated with almost equal probability by each of the metal atoms. Therefore, in these structures only average values of bond distances and angles about the two metal centers have been measured.

From the data listed in Table 2 it appears that in the series formed by the iron-cobalt, cobalt-cobalt, cobalt-nickel, and nickel-nickel dications, which are 3d complexes with VEN increasing along the series from 30 to 33, both the $MP(P_3)$ and MP(L) distances increase smoothly from 2.29 Å to 2.35 Å, and from 2.20 Å to 2.25 Å, respectively (the MM distances correspondingly increase from 3.80 Å to 3.99 Å). It should be noted that such trends are the opposite to those expected on the basis of the variations in the metal atom radii. The PP distances in the *cyclo*-P_3 group on the other hand exhibit the opposite trend, decreasing from 2.23 Å to 2.16 Å as VEN increases from 30 to 33. Moreover, this reduction is not linear, since the contraction between VEN = 30 and VEN = 32 is greatest.

The increase in the $MP(P_3)$ distances with increasing VEN values is evidently related to the antibonding character of the HOMO with respect to such MP interactions. Trends in the other distances are, however, less easily rationalized, due to the large number of potentially effective interactions. SCCC calculations using a fixed geometry were used for the model complexes (VEN = 30—33, dicationic; VEN = 34, monocationic), and indicated that the overlap populations of *all* MP bonds decrease, whereas those of the PP bonds increase slightly with increasing VEN. Such results are consistent with the observed structural trends but cannot be readily traced to a few dominant interactions, except for the variation in the $MP(P_3)$ distances. Complementary information has been obtained by calculations in which both the LM...ML and the PP distances were systematically varied. They indicated that a decrease in the MM distance entails a considerable increase in valence-orbital antibonding interactions between the metal atoms and the *cyclo*-P_3 group. Such interactions are somewhat relieved by an increase in the size of the η^3-P_3 ring. This may provide a rationalization for the trend in the PP distances if the contraction of the $MP(P_3)$ bonds

with decreasing VEN is assumed to be the dominant effect.

The distances between atoms of the *cyclo*-P_3 group in the dinuclear complexes (Table 2) are generally shorter, as are those in the mononuclear complexes, than the PP distance of 2.21 Å in the isolated P_4 molecule[18] (the distorted nickel-rhodium derivative[35] is not considered here). As already noted for the mononuclear complexes, a contraction of this type is probably due to a decrease in the antibonding interactions between the phosphorus atoms, rather than to a shift of electron density from the inner slice to the outer parts of the complex. The PP overlap population parallels the decrease in bond length, increasing by *ca.* 30% from the P_4 molecule to the *trihapto cyclo*-P_3 group bonded to one metal atom. It increases slightly in the dinuclear complexes relative to that in the mononuclear.

The mean AsAs distance of 2.43 Å in [(triphos)Co-μ-(η^3-As_3)Co(triphos)]$(BPh_4)_2$ (**8** in Table 2), matches that in the As_4 molecule[18] as well as that found for an organocyclotriarsane[37]. On the other hand it is longer than the distance of 2.372(5) Å found in $[As_3Co(CO)_3]$[27].

Triple-decker sandwich complexes formed by metal atoms of different transition series would be expected to exhibit appreciable differences in the bond lengths about the two metal centers. Although such differences have not been directly observed to date because of disorder in the lattice, it should have been possible to notice some of their effects, such as abnormal shapes of thermal ellipsoids of the atoms in the coordination sphere. However, anomalies of this type have not been detected (see compound **5** in Table 2). Focusing on the position of the inner slice in the complex, the above results suggest that this group may maximize its interactions with the outer fragments by lying closer to the heavier metal atom than would be expected by consideration of bond distances in the corresponding mononuclear complexes. Actually, calculations on a cobalt-rhodium model compound indicate that the minimum in the total energy for motion of the inner layer along the metal-metal axis lies close to the middle point of this axis (it is even slightly shifted toward the side of the heavier atom).

An interesting problem is posed by the conformation of the triple-decker sandwich complexes, since the orientation of the three slices is not unique for such compounds and in the most common conformation the three moieties are rotated with respect to each other about the molecular pseudo-threefold axis in an apparently random fashion.

The angles used to describe such rotations are defined in Figure 13. As already noted, the majority of complexes listed in Table 2 attain a conformation close to that shown in Figure 7a, with $\alpha \approx 30°$ and $\beta \approx 0°$, exceptions being complexes **6** and **7** (Table 2), whose inner skeletons are respectively sketched in Figures 7c and 7b.

Excluding lattice effects, because not all of the compounds with the arrangement shown in Figure 7a are isomorphous to each other, the possible factors determining the mutual orientation of the three slices are non-bonding interactions within the cation and electronic bonding effects.

There are indeed numerous close contacts between substituent groups on the phosphorus atoms of the outer ligands although none of the distances are very short. It has to be noted in this connection that the triphos ligand undergoes a conformational rearrangement going from the mononuclear to the dinuclear compounds, involving shifts of the phenyl groups (some carbon atoms are shifted by as much as 1 Å) away from the central part. While the above mentioned interactions probably determine the mutual orientation of the external layers (they may fix the angle α to *ca.* 30° not only in the five isomorphous compounds **2—5** and **8** listed in Table 2 but also in the nickel-rhodium derivative **6** which differs in other structural features: cf. Fig. 6 and Table 2), additional short contacts (<3.5 Å) between the atoms of the inner layer and the phenyl carbons

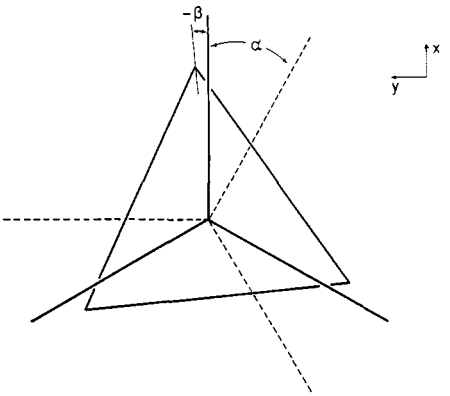

Fig. 13. Schematic representation along the pseudo-threefold axis of the inner skeleton of a triple-decker sandwich complex: angles α and β measure rotations of one on the outer layers and of the internal slice, respectively, from the reference position of the second outer layer.

in *ipso*-positions appear to fix the arrangement of all three slices. These interactions, in particular, should be responsible for the fact that the heteroligand dication [(etriphos)Fe-μ-(η^3-P_3)Co(triphos)]$^{2+}$ (Table 2), which has a short M...M′ distance, has the same conformation (Figs. 7a and 8) as the majority of the homoligand dications. The higher symmetry of the inner skeletons of the PdPd complexes (Figs. 7b and 9) may result from the absence of all above steric hindrances, caused in turn by the very long PdP distances (cf. Table 2).

The possible role of electronic factors in determining the conformation of the triple-decker sandwich complexes has been probed by a cursory examination of the barriers to rotation of the three fragments about the molecular axis in model compounds. In short, the arrangement with D_{3h} symmetry should be favored both in terms of total energy and of overlap populations of the MP bonds. The rotational barriers show a moderate and smooth increase with VEN, so that the conformation of a 34-valence electron complex, such as the dipalladium derivative, would not be expected to differ substantially from that of the other complexes on consideration of the electronic factors alone[*].

[*] The orbitals mostly affected by the rotations are those having large MP(L) character, in addition to those already mentioned, *i.e.* the $1a_1'$ and 1e′ orbitals (Fig. 10b) and the 2e″-2a′ orbitals of the d block. Considering that the "tilting" [21] of the highest-occupied degenerate orbitals of the ML fragments is partly removed in forming the dinuclear complex, and that purely π-type combinations do not set rotational barriers, it is not surprising that the most notable effects of the rotations are due to the closed-shell interactions between the MP(L) bonds and the *cyclo*-P_3 unit.

The height of the rotational barrier of the inner slice with fixed LM...ML framework decreases steadily with increasing values of α (Figs. 14a and 14b), becoming quite small for $\alpha = 60°$. Finally, the height and shape of the barriers are strongly dependent upon the orientation of the PH_3 groups of the model molecule about their MP axes (Fig. 14c), in such a way that it would be possible, by choosing appropriate orientations of such groups, to produce a minimum energy conformation matching the experimental one. The last result emphasizes that nonbonding interactions are more important than bonding effects in determining the geometry of the compounds. In particular, it suggests that in a more fundamental approach to this problem, the geometric requirements of the phosphane ligands should not be neglected.

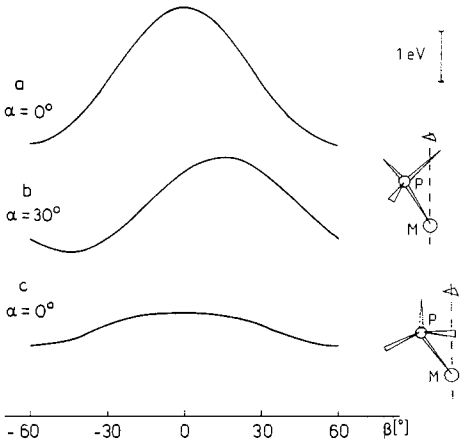

Fig. 14. Barriers to rotation of the *cyclo*-triphosphorus group, with fixed LM...ML frame, about the threefold axis in triple-decker sandwich complexes. The orientation of the PH_3 groups about the MP axes (see sketches at right: a) and b) 60° apart from c), is consistent with D_{3h} symmetry of the model molecule at $\alpha = 0°$.

4.5. Spectral Properties

The main features of the electronic spectra of the triple-decker sandwich complexes formed by 3d metals may be understood by firstly considering the spectra of the compounds with the "extreme" VEN values of 30 and 34. Bands lying in the region 11000—17000 cm^{-1} of the spectrum (Fig. 15a) of the only available 30e compound[33] should have substantial d-d character due to transitions from the 2e''-2a'$_1$ group of one-electron levels (Fig. 10b) to the 3e' level, which is the LUMO for this compound. On the other hand, the lowest-energy d-d bands (17000—22000 cm^{-1}) in the spectra of the 34e monocations[11] (a representative spectrum is shown in Figure 15c) should be assigned as 3e'→3e'' (such bands show a considerable high-energy shift going from the 3d to the 4d metal complexes)[30]. Both types of transitions are active for complexes with VEN in the 31-33 range, as may be verified by comparison of the spectrum in Figure 15b with those in Figures 15a and 15c and considering that a) the regions of the d-d spectrum containing bands of the above two types should only marginally overlap (Fig. 15a and 15c) and b) that both sets of transitions should shift to higher energies with decreasing VEN, due to the decrease in MP distances and the parallel increase in metal-ligand interactions.

$^{31}P\{^1H\}$-NMR spectra have been reported recently for the two triple-decker sandwich complexes [LPd-μ-(η^3-P_3)PdL]X (L = triphos, X = BPh_4; L = np_3, X = BF_4; VEN = 34) and for the mononuclear complexes [(triphos)M(η^3-P_3)]BF_4, with M = Pd, Pt[15]. The former exhibit

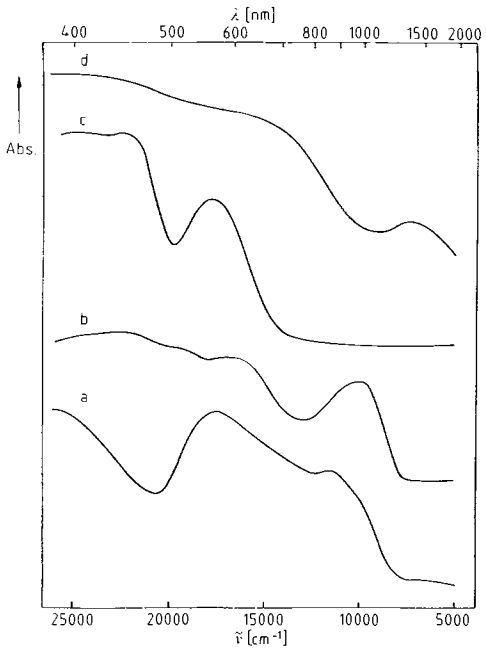

Fig. 15. Reflectance spectra of representative triple-decker sandwich complexes (VEN values in parenthesis):
a) [(etriphos)Fe-μ-(η^3-P_3)-Co(triphos)]$(PF_6)_2 \cdot CH_2Cl_2$ (30);
b) [(triphos)Ni-μ-(η^3-P_3)Ni(triphos)]$(BPh_4)_2 \cdot 2.5(CH_3)_2CO$ (33);
c) [(triphos)Ni-μ-(η^3-P_3)-Ni(triphos)]$(BPh_4) \cdot (CH_3)_2CO$ (34);
d) [(triphos)Ni-μ-(η^3-P_3)-Rh(triphos)]$(BF_4)_2 \cdot C_4H_8O$ (32).

an A_3X_6 pattern and the latter an A_3X_3 pattern. The large chemical shift of the *cyclo*-P_3 phosphorus atoms increases from the monometal to the dimetal complexes. The ^1J(M,P) value for the *cyclo*-P_3 phosphorus atoms is more than one order of magnitude smaller than that of the triphos P atoms. Such a reduction in going from σ-bonded to π-bonded systems is not unusual[15].

4.6. Properties of Complexes with VEN = 32

The spectral and magnetic properties of the 32e complexes containing at least one 4d or 5d metal atom, which have been synthesized to date, differ significantly from those of the isoelectronic complexes formed solely from 3d metals[35]. These "mixed" complexes have a singlet ground state, rather than the spin triplet which would be expected for the $(3e')^2$ configuration, or exhibit small residual paramagnetism. Moreover, bands at unusually low energies are present in their electronic spectra (Fig. 15d). Such properties have been correlated with the known structure of the nickel-rhodium dication, in the light of the proposed bonding pattern for the dinuclear complexes. Generalizing, it has been assumed[35] that the distortion which is observed (a stabilizing Jahn-Teller distortion in which the effective symmetry of the inner-skeleton is lowered from C_3 to C_2; cf. Fig. 7c) is caused by the higher field strength and larger spin-orbit coupling constants of the heavier metal

atom(s). Although EH calculations, which do not include the repulsive two-electron and higher terms in the Hamiltonian, are not expected to provide a definitive answer about this point, they do, however, give the following indication, partly consistent with the above hypothesis: the contributions to the highest-occupied MO's of the complex by the bridging phosphorus atoms increase considerably with the atomic number of the metal atoms (by *ca.* 100% from 3d to 4d metals), *i.e.* with increasing covalency. Such an increase is significant, because the *cyclo*-P_3 group has the greatest effect on the distortion (Fig. 7c). These complexes which even in the ground state are distorted, and the presence of low-lying excited states, revealed by the spectra, may account for the fact that their synthesis has proved so far to be rather elusive, that their magnetic properties are somewhat dependent on the nature of the counterion and even on the preparation of the sample, and that the complexes decompose rapidly in solution.

5. Adducts of Mononuclear *cyclo*-Triphosphorus Metal Complexes

As has already been stressed, the *cyclo*-P_3 unit bonded to one metal atom as a *trihapto*-ligand may form additional bonds to new metal atoms or to other centers with Lewis acid properties. In other words it imparts Lewis base properties to the mononuclear metal complexes. This property has been exploited to form triple-decker sandwich complexes from the mononuclear *cyclo*-P_3 derivatives (Section 4.1). The affinity of the monometal *cyclo*-P_3 complexes for electron-acceptor groups has moreover been tested by allowing than to react with metal carbonyls or related compounds.

The [(triphos)Co(η^3-P_3)] complex dissolved in THF reacts with solid $Cr(CO)_6$ under UV irradiation according to the following scheme:

$$[(\text{triphos})\text{Co}(\eta^3\text{-}P_3)] + n\,\text{Cr(CO)}_6 \xrightarrow{h\nu} [(\text{triphos})\text{Co}(\eta^3\text{-}P_3)]\{\text{Cr(CO)}_5\}_n] \quad (n = 1, 2)$$

The dinuclear or the trinuclear complex is obtained, depending on the stoichiometry and the conditions[7,38]. No compound with more than two $Cr(CO)_5$ groups attached to the *cyclo*-P_3 unit has been obtained by this procedure.

The structure of the [(triphos)Co(η^3-P_3)$\{Cr(CO)_5\}_2$] complex is shown in Figure 16. Bond distances within the *cyclo*-triphosphorus group are essentially unchanged relative to those in the parent compound[7]. The chromium atoms are displaced from the plane of the *cyclo*-P_3 unit on the opposite side to that of the cobalt atom, the two CrP bonds forming angles of *ca.* 65° and 70° with the normal to this plane. The CrP bond lengths, which fall in the range observed for such distances in phosphane-substituted chromium complexes, and the CO stretching frequencies are indicative of metal-phosphorus interactions comparable to those of phosphane complexes[7].

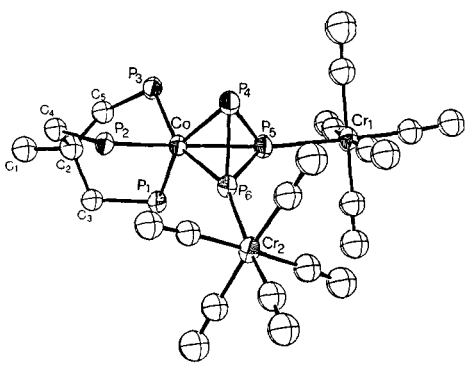

Fig. 16. Skeleton of the [(triphos)Co(μ-(η^3-P_3))$\{Cr(CO)_5\}_2$] molecule in the crystal.

A tetranuclear adduct, in which each phosphorus atom of the *cyclo*-P_3 unit of the parent [(triphos)Co(η^3-P_3)] complex is linked to a metal center, has been synthesized using a substituent group with similar electronic properties but lower steric requirements than pentacarbonylchromium. Hence [(triphos)Co(η^3-P_3)] reacts with $Mn(C_5H_5)(CO)_3$ in THF under UV irradiation to afford the [(triphos)Co(η^3-P_3))$\{Mn(C_5H_5)(CO)_2\}_3$] complex[39]. The structure of the compound is shown in Figure 17. The mean value of the PP distances in the tetrametal complex is practically unchanged relative to the parent compound. The MnP bonds are tilted from the plane of the *cyclo*-P_3 unit essentially by the same amount on average as the CrP bonds in the previous trimetal complex.

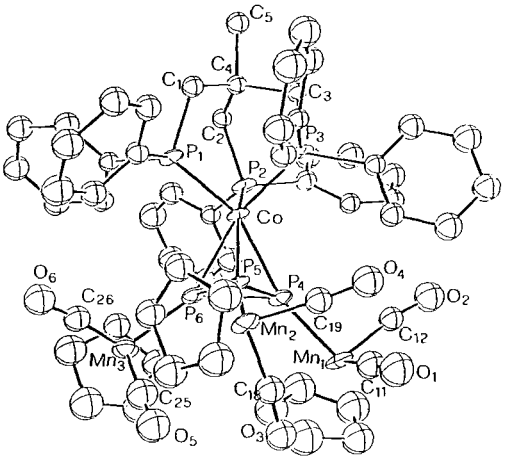

Fig. 17. Perspective view of [(triphos)Co(η^3-P_3))$\{Mn(C_5H_5)(CO)_2\}_3$] in the crystal.

Calculations at the EH-SCCC level performed on a [LCo(η^3-P_3))Cr(CO)$_5$] model compound have indicated that the bonding pattern in the valence-orbital region is not considerably modified from that of the original cobalt complex, because the electronegative $Cr(CO)_5$ fragment has relatively low-lying occupied orbitals available for interaction. This allows the diamagnetism of the dichromium and trimanganese adducts and their spectra, which are similar to those of the mononuclear cobalt complexes (bands characteristic of the appended chromophores are expected to occur in the CT region in the spectra of the polymetal species) to be rationalized. In spite of the fact than an additional strong bond is formed in the model compound between a *cyclo*-P_3 phosphorus atom and the new metal center (the overlap population of the CrP bond is practically identical to that of a CoP(L) bond) and that an overall shift of electron density takes place toward the chromium moiety, the mean value of the PP overlap popu-

lation is almost identical to that calculated for the parent compound. No optimization of the geometry was performed in the above calculation. A separate set of calculations in which the angle between the CrP bond and the threefold axis of the cobalt fragment was varied yielded a minimum-energy conformation essentially matching the experimental one. It therefore appears that the arrangement of the attached groups in these polymetal adducts is determined by electronic factors, rather than by steric effects.

A very recent result is the synthesis of the heterometal triple-sandwich complex [(triphos)Co(P_3)($CuBr)_6$(P_3)Co(triphos)], formed by allowing a solution of [(triphos)Co(η^3-P_3)] in dichloromethane to react with a suspension of CuBr[40]. The internal slice in such compounds, formed by a hexagon of copper atoms bridged in pairs by bromine atoms, is sandwiched by the *cyclo*-P_3 groups of the two external (triphos)Co(P_3) units (Fig. 18). The inner core may be alternatively described as a cuboctahedron of six copper and six phosphorus atoms.

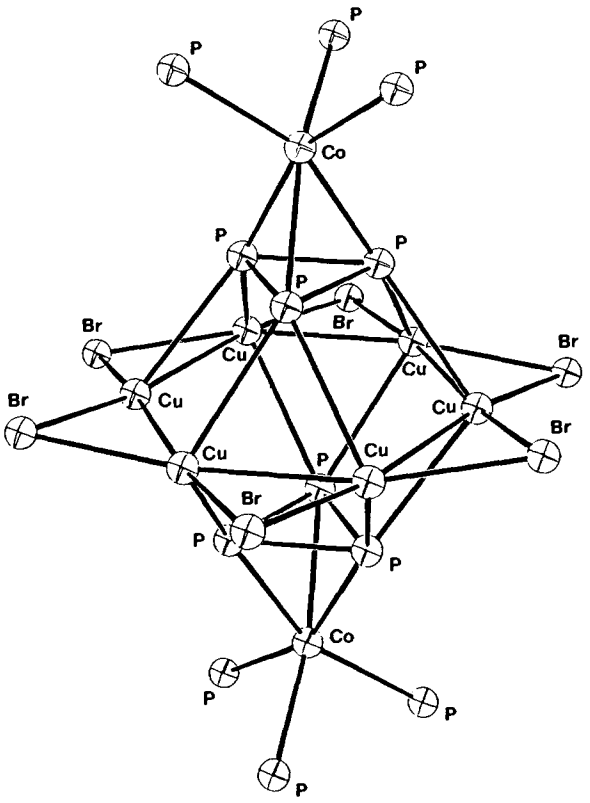

Fig. 18. Skeleton of [(triphos)Co(P_3)($CuBr)_6$(P_3)Co(triphos)] in the crystal.

It is evident that in spite of the work already performed in this field, much has still to be done. In particular, the mechanisms of the most important processes are still obscure. On the synthetic side, the chemistry of additions at η^3-coordinated *cyclo*-triphosphorus units is an open field, possible limitations to the nature of products probably arising only from the geometric constraints imposed by the "ancillary" phosphane ligands.

Topical Problems in the Biosynthesis of Red Blood Pigment**

By Burchard Franck*

Uroporphyrinogen III plays a key role in the biosynthesis of heme, the red pigment of blood. *In vivo* studies with specifically ^{14}C- and ^{3}H-labeled precursors have revealed that the formation of uroporphyrinogen III in the organism follows several primary and subsidiary pathways. Model experiments on the pattern of biosynthesis have led to simple and effective methods of synthesizing uroporphyrin analogs and have shown that their production is strongly favored thermodynamically. The biologically important porphyrins thus available permit a mechanistic explanation of the light-induced dermatoses in porphyria diseases and suggest promising medical applications in diagnosis and therapy.

1. Introduction

Each cubic centimeter of human blood contains 5 billion erythrocytes (Fig. 1), the most important component of which is the conjugated protein hemoglobin. The five liters of blood circulating within the body of an adult contain almost one kilogram of hemoglobin, which can bind and transport 1.3 liters of oxygen. The red blood pigment heme **1** can be cleaved off hemoglobin by acid hydrolysis. The human body contains some 30 g of heme, which is renewed by biosynthesis within a period of 120 days.

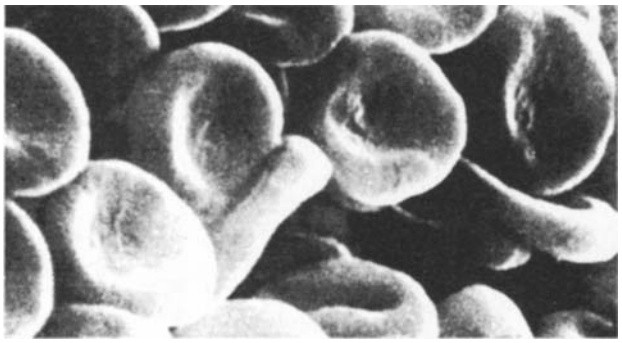

Fig. 1. Human erythrocytes in a scanning electron microscope (magnification about 4000) (from [1]).

Thus, every year the world's human population biosynthesizes some 400000 tons of heme, this being almost equal to the annual global industrial production of organic dyes. Because of the vital functions of heme, its biosynthesis—a process controlled by a large number of enzymes—occupies a central position in the body's metabolism[2].

Research into heme biosynthesis has enabled

1) the key biogenetic compounds to be pinpointed
2) simple biomimetic syntheses to be developed, and finally
3) some metabolic diseases to be understood and treated.

Re 1: The key biogenetic compounds—themselves produced by fairly simple enzymatic reactions—are the precursors for the biosynthesis of a large group of other natural products[3].

Re 2: By following the biosynthetic pattern, particularly simple and effective laboratory syntheses of complicated natural products can often be developed[4]. Such "biomimetic syntheses" need not be performed under the exact conditions of the biosynthesis[*].

Re 3: The principal biogenetic compounds are the nodes or junctions in the network of metabolic pathways. Any disturbance in the formation or conversion of these compounds leads to the development of metabolic diseases, *e.g.* porphyrias are caused by disturbances in heme biosynthesis[5-7].

The discussion that follows will be centered around the above three points. Our current understanding of heme biosynthesis will first be outlined, with special consideration of the key biogenetic compounds. This will be followed by a description of applications of this knowledge in organic chemistry and medicine.

2. The Biosynthesis of Heme

The basic skeleton of the red blood-pigment heme **1** is termed porphyrin **2**, a stable, cyclically conjugated [18]annulene system. Under the influence of mild reducing agents the deep-red porphyrins can be converted into the colorless porphyrinogens **3** *via* addition of six H atoms. Porphyrinogens are more reactive than porphyrins, atmospheric oxygen, for example, being sufficient to dehydrogenate them back to porphyrins.

Approximately 30 biologically active, cyclic tetrapyrroles of the porphyrin type are now known; as far as man is concerned, apart from heme, the cytoheme of the cytochromes and the chlorophylls are the most important compounds[8]. Considering its comparatively complex structure, it is astonishing that heme is produced in the body from two very simple building blocks, glycine **5** and succinic acid **4**[9,10]. Because of their methodological origi-

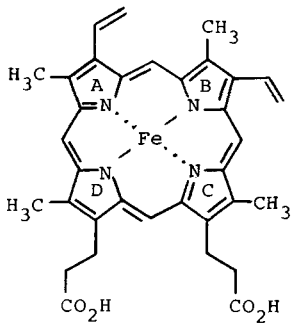
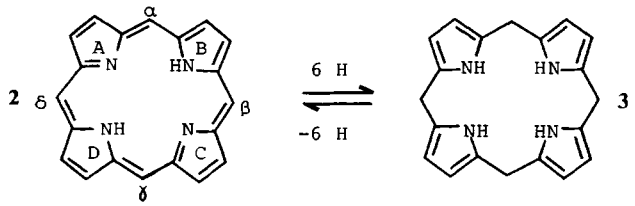
[*] "Biomimetic chemistry is the branch of organic chemistry which attempts to imitate natural reactions and enzymatic processes as a way to improve the power of organic chemistry" (*Breslow* [4d]).

nality and impact, this discovery and the clarification of the subsequent course of the condensation by *Shemin et al.* rank among the greatest pioneering achievements of biosynthetic research, and have never been disputed[9,4c].



1

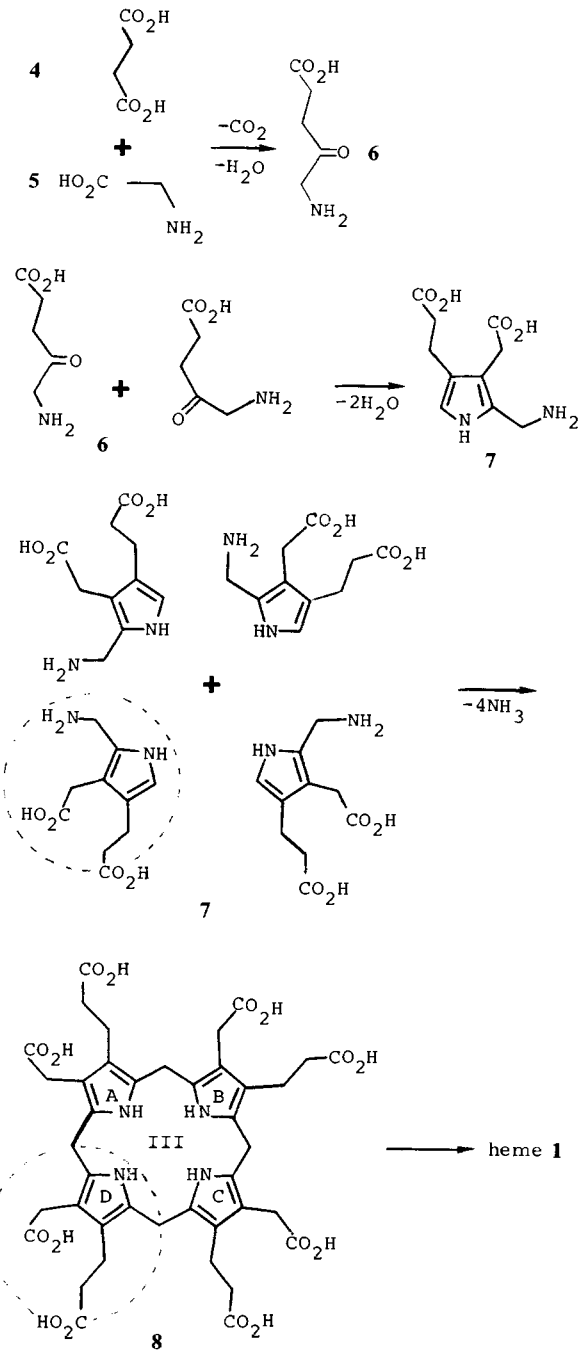


2 **3**

Shemin started with the incorporation of [^{15}N]glycine into his own bloodstream and subsequently devised a reliable method using hemolyzed duck blood. He was thus able, as long as 35 years ago, to describe accurately the biosynthesis of the heme molecule from eight molecules of glycine **5** and eight of succinic acid **4**. **5** and **4** first condense *via* decarboxylation to form 5-aminolevulinic acid **6**, two molecules of which condense further to form the monopyrrole compound porphobilinogen **7**[25]. With the release of ammonia, four porphobilinogen units next combine to afford uroporphyrinogen III **8**. For a long time the clarification of heme biosynthesis went no further than this stage, because little promise was seen in radioactively labeling a compound as large and complicated as **8** and exposing it to the enzyme system involved in heme biosynthesis. In 1972 we brought about the first total synthesis of a specifically ^{14}C-labeled uroporphyrinogen III **8**[11]. Using hemolyzed duck blood, this product could be converted into heme in surprisingly high yield[12]. Rearrangements could be ruled out by a determination of the labeling positions in the radioactive hemin thus obtained (**1**, FeCl instead of Fe). Subsequently *Scott et al.*[13] were able to demonstrate that **8** is also the starting point for the microbial synthesis of vitamin B_{12}. It is therefore probable that all the natural cyclic tetrapyrroles known so far stem from uroporphyrinogen III, which thus proves to be a key biogenetic building block[3].

3. The Problem of "Pyrrole Inversion"

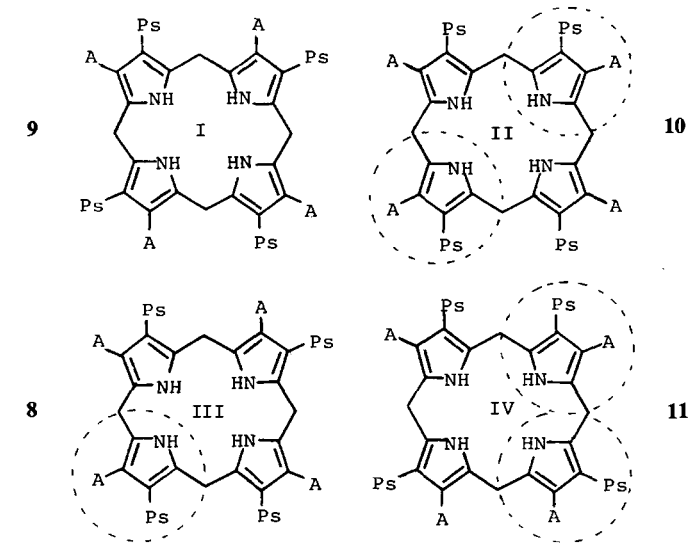
Many and sometimes contradictory hypotheses have been put forward in the last twenty years concerning the mechanism of the biosynthesis of uroporphyrinogen III **8** from porphobilinogen **7**, which includes the inversion of a pyrrole ring (in the dotted circle)[10]. The puzzling feature here was that only one pyrrole unit was inverted. However,



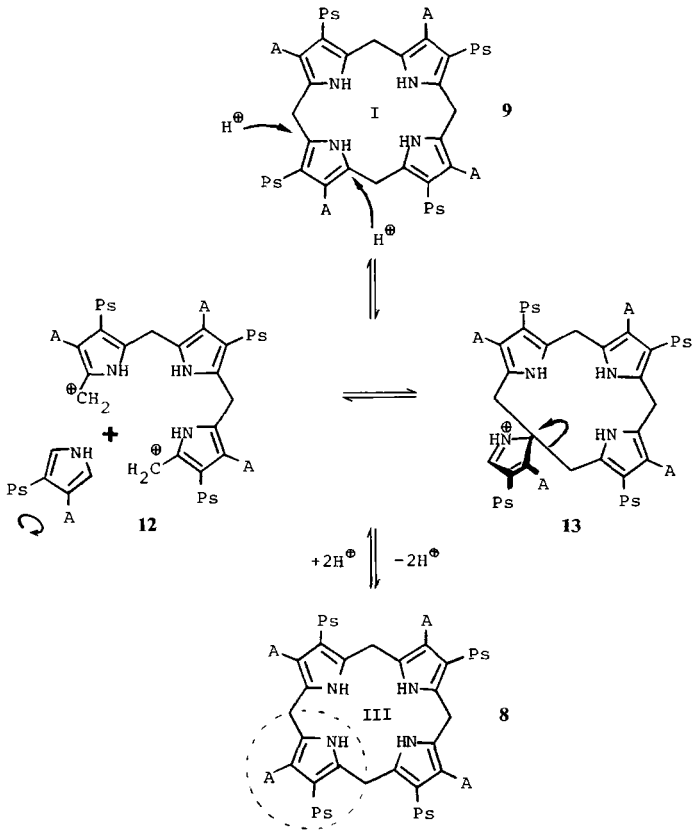
it is relatively easy to show that this is not nearly so remarkable as it first seemed.

In all there are four isomeric uroporphyrinogens (**8**–**11**), characterized by Roman numerals. In uroporphyrinogen I **9** all four pyrrole rings are arranged "in series", *i.e.* the acetic acid and the propionic acid side chains, denoted by "A" and "Ps" respectively, alternate regularly. In the heme precursor **8** one pyrrole ring is inverted (dotted circle). The remaining uroporphyrinogens II **10** and IV **11**, each with two inverted pyrrole rings, in contrast to isomers I and III have not yet been found in nature[8].

In their high reactivity the isomeric uroporphyrinogens resemble Mannich bases and are readily mutually interconverted under mild acid catalysis (Scheme 1). By protonation of the α-positions of the pyrrole rings the porphyrinogen system can be opened at one or more places. During

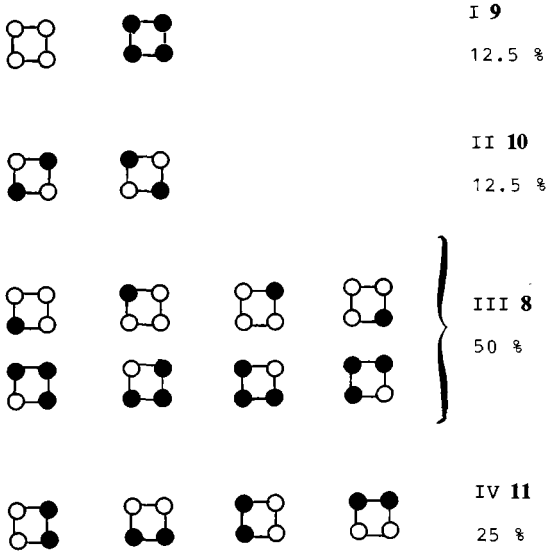


the proton-catalyzed intramolecular isomerization, inversion of all the pyrrole rings can occur *via* open-chain **12** or spirocyclic **13** intermediates[14].



Scheme 1. Proton-catalyzed isomerization of uroporphyrinogens exemplified by **9** and **8**.

Since the four isomeric uroporphyrinogens have practically identical stability, the composition of an equilibrium mixture is determined by the number of permutations that give rise to each isomer (Scheme 2)[15]. Of the 16 possible permutation products, eight are identical with uroporphyrinogen III **8** and only two with uroporphyrinogen I **9**. According to the permutation scheme an isomer ratio of 2:2:8:4 is expected for an equilibrium mixture of uroporphyrinogens I, II, III, and IV. *Mauzerall*[16] was first to be able to confirm this experimentally in the acid-catalyzed condensation of porphobilinogen **7**: uroporphyrinogen III **8** and/or its dehydrogenation product uroporphyrin III were the main products (50%).

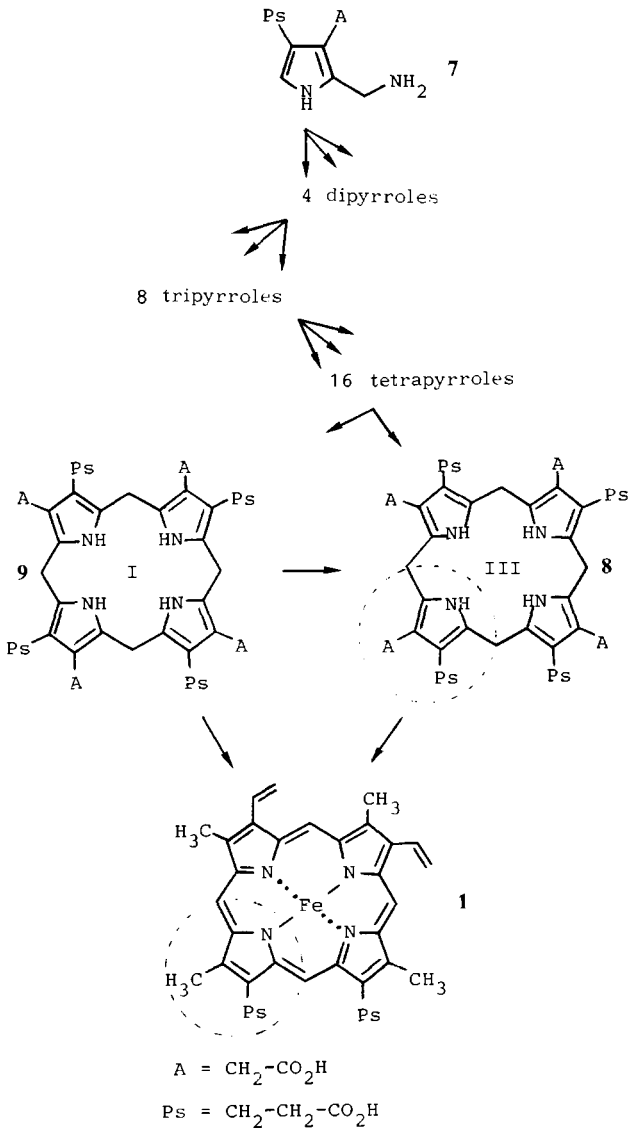


Scheme 2. The 16 possible permutations in the acid-catalyzed isomerization of uroporphyrinogens I—IV (**8**–**11**). Inverted pyrrole rings are shown as filled-in circles.

Considered in this light, the formation of uroporphyrinogen III **8** during the biosynthesis of heme is not puzzling[17–20]. The participant enzymes only increase the proportion of the reaction product that is considerably favored thermodynamically over its isomers. Similar phenomena are known in the biosynthesis of alkaloids[21,22].

The biosynthesis of the blood-pigment heme **1** from porphobilinogen **7** is summarized in simplified form in Scheme 3. Condensation of **7** leads *via* dipyrroles and tripyrroles to reactive tetrapyrroles, which are cyclized to uroporphyrinogens. Isomerizations with the inversion of one pyrrole unit can occur in each condensation step.

To check whether the pyrrole inversion occurs in somewhat preferred manner in certain parts of a kinetically controlled, enzymatic reaction sequence it would be necessary to isotopically label the rearranged and nonrearranged oligopyrroles (a total of 28 oligopyrroles) and then investigate their incorporation. This extensive and elaborate program has been partly realized by the efforts of several research groups[23–29]. To this end, isotopically labeled pairs of mono-, di-, and tripyrroles[25–29,45] and of uroporphyrinogens[30] have been synthesized in Münster. In each of these oligopyrrole pairs only one component contained an inverted pyrrole ring. In addition, the two components of each pair differed in that one was labeled with ^{14}C and the other with ^{3}H. By labeling with different isotopes it was possible to compare the incorporation of the components very reliably in one and the same experiment.



Scheme 3. Intermediates in the biosynthesis of heme **1** from porphobilinogen **7**.

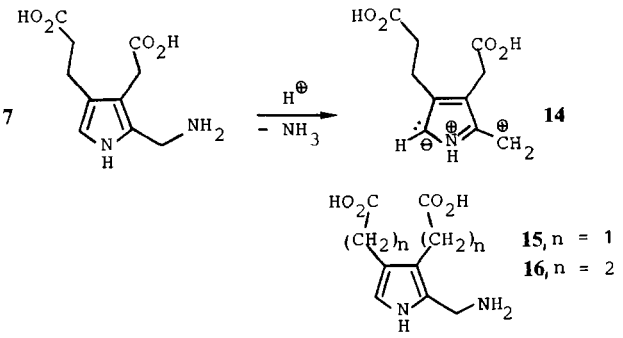
The biosynthesis experiments were carried out with the enzyme system from duck blood (*Shemin*[9]) on a scale which afterwards provided enough radioactive hemin — about 100 mg — for thorough purification to constant radioactivity. Without going into all the details of these extended chemical and enzymatic investigations some of the most important results will be mentioned. The ^{14}C- and ^{3}H-radioactivities of the hemin samples for both components of the pairs of isomers fed, revealed a significant although more or less differing incorporation into the blood pigment. This difference was especially conspicuous for the isomeric monopyrroles. In this case the incorporation rate for porphobilinogen **7** was 10—15 times higher than that of isoporphobilinogen (**7** with exchanged side chains "Ps" and "A"). As no chemical isomerization of the two monopyrroles was observed under the feeding conditions, the low incorporation of the isoporphobilinogen must be ascribed to some non-specificity of the enzyme system. A substantially higher non-specificity was observed in the incorporation of isomeric di- and tripyrroles.

Furthermore it is instructive that the incorporation rates of the monopyrroles and uroporphyrinogens are about 20 times higher than those of the highly reactive di- and tripyrroles. This gives rise to the assumption that the latter are especially strongly bound in the enzyme complex so that the labeled precursors supplied from outside can only be exchanged to a small extent. — In all these experiments the possibility of chemical condensation was critically taken into account.

Therefore, in the heme biosynthesis the condensation of porphobilinogen **7** *via* open-chain and cyclic oligopyrroles is accompanied by enzymatic isomerizations with inversion of individual pyrrole rings. The oligopyrroles are a kind of substrate pool for formation of the thermodynamically favored uroporphyrinogen III **8** and its further transformation into heme. These conclusions are applicable to biosynthetic experiments performed with fresh duck blood under *in vivo* conditions, which may more closely approach the situation prevailing in the organism than experiments with isolated enzymes. Recently, similar ideas on the participation of isomeric oligopyrrole precursors have also been suggested from experiments with isolated enzymes[31].

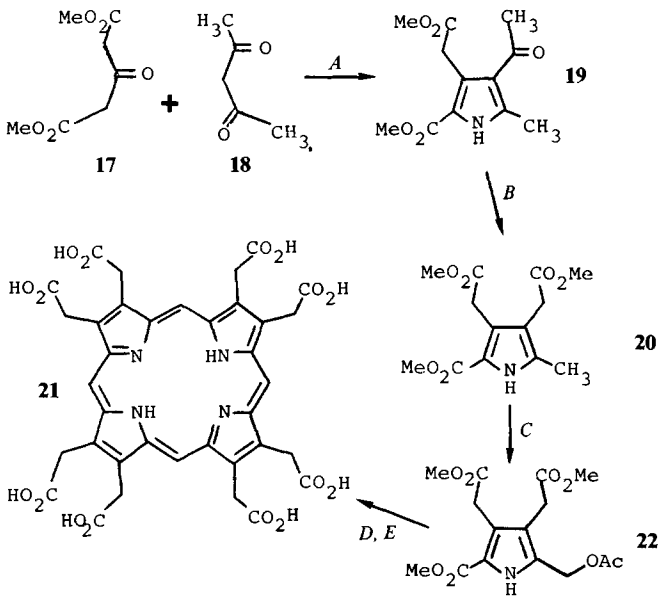
4. Biomimetic Syntheses

The question confronting the organic chemist is whether heme biosynthesis can serve as a pattern for the development of simple and effective porphyrin syntheses. In view of the central position of porphyrins in metabolism it would be highly desirable for biologically active porphyrins to be made more readily accessible than previously, *via* biomimetic syntheses of this kind. Thus, the uroporphyrinogen III **8** required for medico-diagnostic investigations currently still necessitates a 22-step total synthesis, and is marketed at the cost of $ 450 for 50 mg (*ca.* 500 times the price of gold). Among the reactions of heme biosynthesis, the cyclizing condensation of the monopyrrole porphobilinogen **7** is of particular significance for the development of biomimetic syntheses. **7** is a very reactive, bifunctional compound. On the one hand it can react with nucleophiles as a Mannich base at the aminomethyl group, and on the other has centers open to electrophilic attack at the α-positions of the activated pyrrole ring. Thus, under mild acid catalysis, intermolecular condensation with the release of ammonia can be expected *via* intermediate **14**, without the need for enzymes.



In fact, as *Cookson* and *Rimington*[32] had already established, under acid catalysis a mixture of isomeric uroporphyrins in which the biologically important isomer III **8** predominates is produced *in vitro* from **7** in high yield.

The formation of isomeric mixtures can be prevented if, in place of 7, similar pyrrole derivatives with two identical side chains at C-3 and C-4 are condensed. We therefore synthesized derivatives of the norporphobilinogen **15** and the homoporphobilinogen **16**[33], which under acid catalysis can be converted with good yields into homogeneous, readily crystallizing porphyrins[34]. A particularly simple and practical method is the synthesis of porphyrinoctaacetic acid **21** from the readily available acetonedicarboxylic acid ester **17** and acetylacetone **18**, a process which requires only a small number of steps (Scheme 4).



Scheme 4. Five-step synthesis of porphyrinoctaacetic acid **21**. *A:* Knorr condensation; *B:* $Tl(NO_3)_3$/MeOH; *C:* $Pb(OAc)_4$; *D:* Boiling in 20% HCl; *E:* Oxidation with O_2.

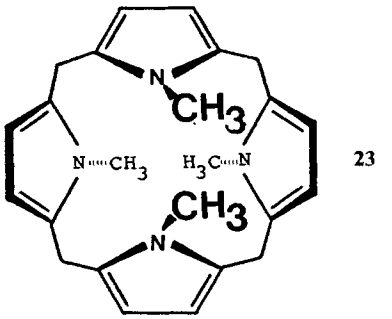
The porphyrinoctaacetic acid **21** differs from uroporphyrinogen III **8** only by the shortening of the four side chains by one C atom each. Because of the "natural" acetic acid side chains, also present in natural porphyrins, **21** is just as suited as **8** for many investigations of the chemical and physiological behavior. The same is true of the analogously synthesized porphyrinoctapropionic acid[34] (for further details see also **43** in Scheme 7).

Up to now octaethylporphyrin **24** was the porphyrin used most often as a model compound[35], but despite essential improvements in the syntheses[36-38] it does not satisfy the requirement for a more easily accessible and better water-soluble derivative[*].

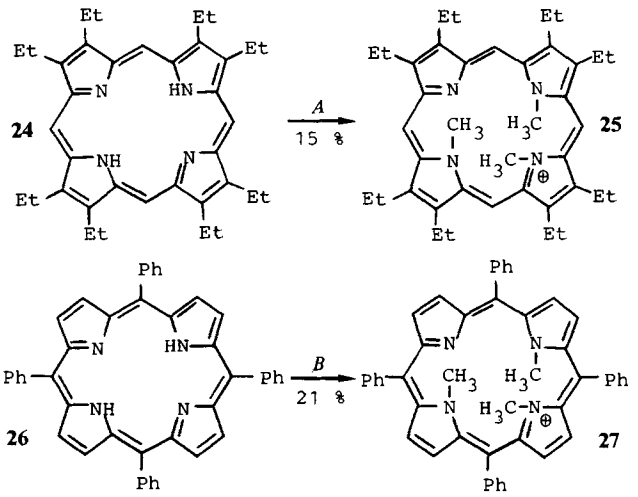
It has also been possible to make use of the strong tendency of porphobilinogen **7** to cyclotetramerize in the biomimetic synthesis of unusual porphyrins[40], such as sterically strained porphyrinogens and porphyrins containing alkyl groups on the nitrogens, *e.g.* **23**.

[*] *J. B. Kim et al.* [39]: "*Dolphin et al.* [38] have recently developed an improved and reliable synthesis of octaethylporphyrin, but the reader is warned that even this synthesis is necessarily long and that in inexperienced hands the final product, rather than lustrous purple crystals, is often an intractable black polymer".

Since *N,N',N'',N'''*-tetraalkylporphyrinogens and porphyrins of this kind may be able to provide revealing information on the stereochemistry, aromaticity, spectroscopic properties, and structure-biological activity relationships of the porphyrin system, their synthesis was attempted by *Corwin* and *Quattlebaum* as early as 1936[41], and subsequently by several other groups. In their remarkable investigations, *Jackson, Johnson et al.*[42,43] succeeded in incorporating up to three *N*-methyl groups into the two chemically robust porphyrins **24** and **26** under vigorous experimental conditions (Scheme 5). Since *N,N',N'',N'''*-tetramethylporphyrins could not be obtained, it was assumed that these cannot exist because of the extreme strain on the methyl groups directed toward the center of the molecule.

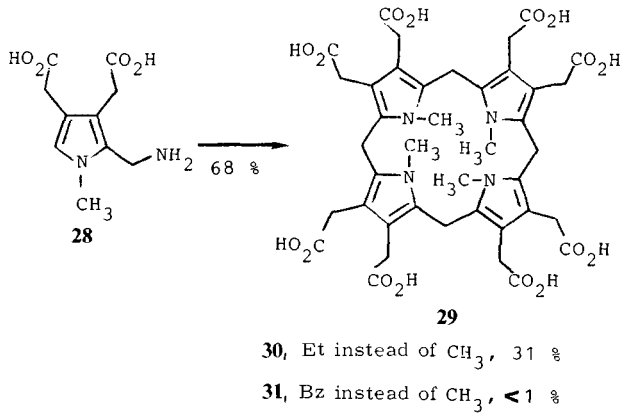


23



Scheme 5. *N*-Methylation of chemically robust porphyrins under vigorous conditions [42, 43]. *A:* CH_3SO_3F, 100°C, 120 h; *B:* CH_3I, $CHCl_3$, 60°C, 96 h.

Our attempts to prepare *N,N',N'',N'''*-tetramethylporphyrinogen **29** by a biomimetic synthesis exceeded all expectations. *N*-Methylnorporphobilinogen **28** served as the starting compound. After only 30 min of boiling in 0.5 N hydrochloric acid a product crystallized out in a high yield. After purification *via* the octamethyl ester, this product was found to be the desired compound **29** (Scheme 6). Encouraged by the practicability of the biomimetic principle, we were also able to obtain the tetraethyl and tetrabenzyl analogs **30** and **31** in the stated yields, which were lower as a result of increasing steric hindrance. According to model considerations, in porphyrinogens of this kind the pyrrole rings, including the *N*-alkyl groups, are rotated alternately "upward" or "downward" out of the porphyrin



Scheme 6. Biomimetic synthesis of **29**. 0.5 N HCl, 100 °C, 30 min. **30** and **31** can be obtained in analogous fashion.

plane. X-ray structure analysis[44] revealed that **29** in fact has a propeller-like structure (Fig. 2).

The non-planar structure of the *N,N',N'',N'''*-tetraalkylporphyrinogens is the reason for their unusual oxidation behavior. Whereas normal porphyrinogens are quickly dehydrogenated to dark-red aromatic porphyrins in the presence of atmospheric oxygen or iodine, the tetraalkyl derivatives remain unchanged under these conditions. Dehydrogenation is only possible with strong oxidizing agents such as cerium(IV) sulfate or bromine[45,36], whereupon green porphyrins such as **33** with two quaternary ammonium groups and interesting spectroscopic properties are obtained. Although, like the corresponding porphyrinogens, the *N,N',N'',N'''*-tetraalkylporphyrins cannot have a

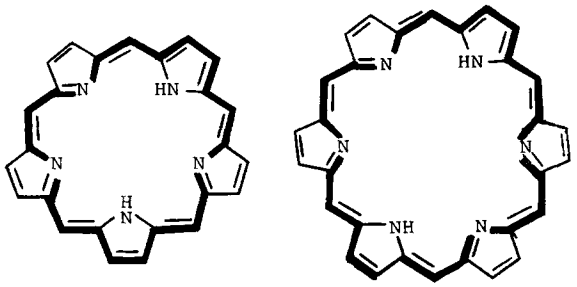
planar structure because of steric interaction of the *N*-alkyl groups, the aromatic character of their 18π-electron system is apparently hardly impaired. This can be seen very clearly from a comparison of the ring-current influenced ^{1}H-NMR signals of the bisquaternary *N,N',N'',N'''*-tetraalkylporphyrins **33** and **34** with those of the *N*-unsubstituted, planar porphyrin **35** and the *N,N',N'',N'''*-tetramethylporphyrinogen **32** (Table 1).

5. Extreme Selectivity of Porphyrin Formation

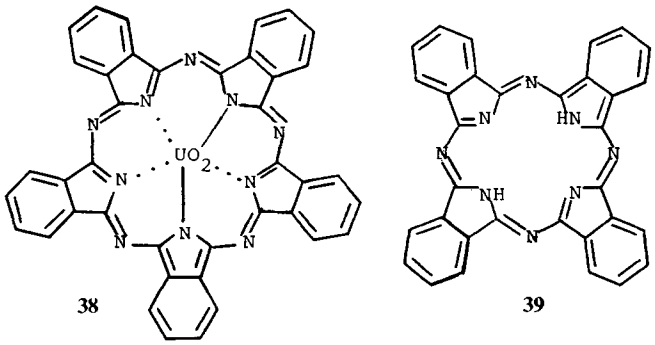
The biomimetic cyclotetramerization of the monopyrrole porphobilinogen **7** and its derivatives deserves closer consideration. Thus, careful chromatographic analyses revealed only the formation of porphyrins and hardly any by-products. In the condensation of a bifunctional compound of type **7**, in addition to the cyclic tetrapyrroles one would normally expect to find open-chain oligopyrroles and higher cyclic oligomers, such as cyclic pentapyrroles or hexapyrroles. The higher cyclic oligopyrroles could, like the porphyrins, all have aromatic, ring-conjugated annulene structures; the hypothetical [22]- and [26]annulenes **36** and **37** are examples.

Whereas porphyrins with more than five pyrrole rings are still unknown, *Day et al.*[47] succeeded in synthesizing a phthalocyanine of this kind, **38**, which because of its remarkable properties was called "superphthalocyanine". Its synthesis from phthalodinitrile was carried out using the



36 37

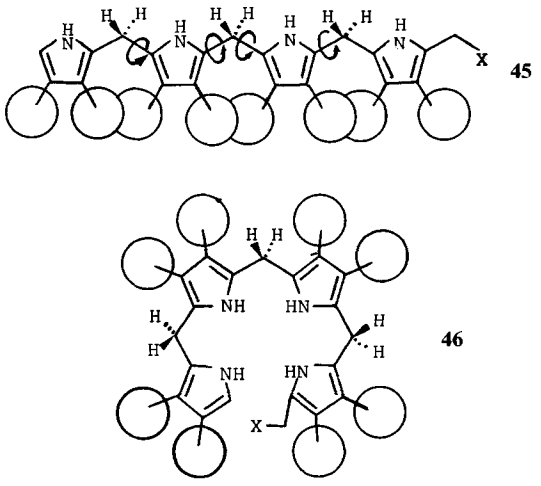
large uranyl cation as a complexing matrix. The dark-green superphthalocyanine is characterized by the fact that its longest-wavelength absorption maximum is displaced into the near infrared (953 nm) relative to the normal phthalocyanine complexes. Under the influence of trifluoroacetic acid at room temperature[48] or of $CuCl_2$[49], **38** decomposes into phthalodinitrile and phthalocyanine **39** or its copper complex. The formation of the cyclic tetramer is accordingly also strongly preferred in the phthalocyanines.



38 39

To acquaint ourselves with the selectivity of the formation of porphyrins and with the degree of instability of the higher cyclic oligopyrroles ("superporphyrins"), we carried out directed syntheses[50-52] based on the aldol-like condensation of the dialdehyde **40** with linear oligopyrroles (Scheme 7).

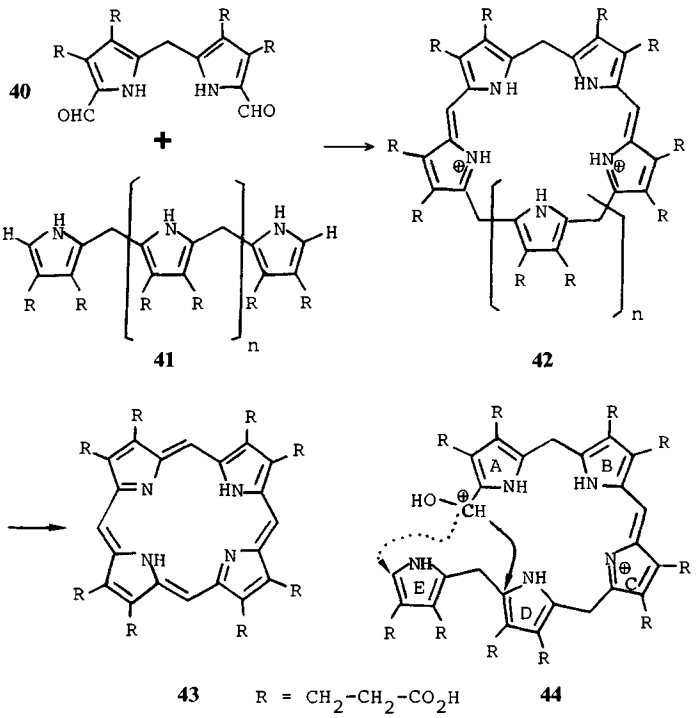
This reaction leads to cyclic oligopyrroles **42** with two pyrromethene structures which stabilize the ring system against further dehydrogenation. The propionic acid side chains also present in natural porphyrins were selected for the protection of the β-positions of the pyrrole rings and because of their favorable solubility characteristics. The four linear oligopyrroles **41a—41d** were synthesized by a simplified method that avoids the conventional use of ester protecting groups at the α-positions of the pyrrole rings[51]. Coupling the dialdehyde **40** with linear dipyrroles, tripyrroles, tetrapyrroles, and pentapyrroles **41a—41d**, as a result of which pyrrole-homologous porphyrins with respectively four, five, six, and seven pyrrole rings had been expected, gave a surprising result: under the very mild conditions used (0.25% hydriodic acid in glacial acetic acid at room temperature) only one cyclic tetrapyrrole was formed in each case, and this was oxidized to the porphyrin **43**[52]. This is conclusive proof of the very strong preference for porphyrins compared to other condensation products. An explanation of this preference can be derived by considering the possible conformations of open-chain tetrapyrrole porphyrin precursors (Fig. 3)[29,52].



45 46

Fig. 3. Linear **45** and helical conformations **46** of an open-chain porphyrin precursor [29]. X = electronegative leaving group.

In the linear conformation **45** there is a strongly destabilizing steric interaction of the side chains in the β-position. In the helical conformation **46**, which differs from the linear by rotation around single bonds (shown by circular arrows), only a small interaction of this kind is found; this conformation provides the optimal prerequisites for ring closure to afford porphyrins. Although other conformations between the extremes represented by **45** and **46** can be envisaged, such considerations reveal a steric preference for the porphyrin-forming helical conformation **46**. This makes it possible to derive the mechanism of preferred porphyrin formation illustrated by **44** in the reaction of **40** with linear oligopyrroles **41a—41d** (Scheme



43 R = CH_2-CH_2-CO_2H 44

Scheme 7. Course of the reaction of dialdehyde **40** with linear oligopyrroles **41a—41d**. **a, b, c, d:** n = 0, 1, 2, 3.

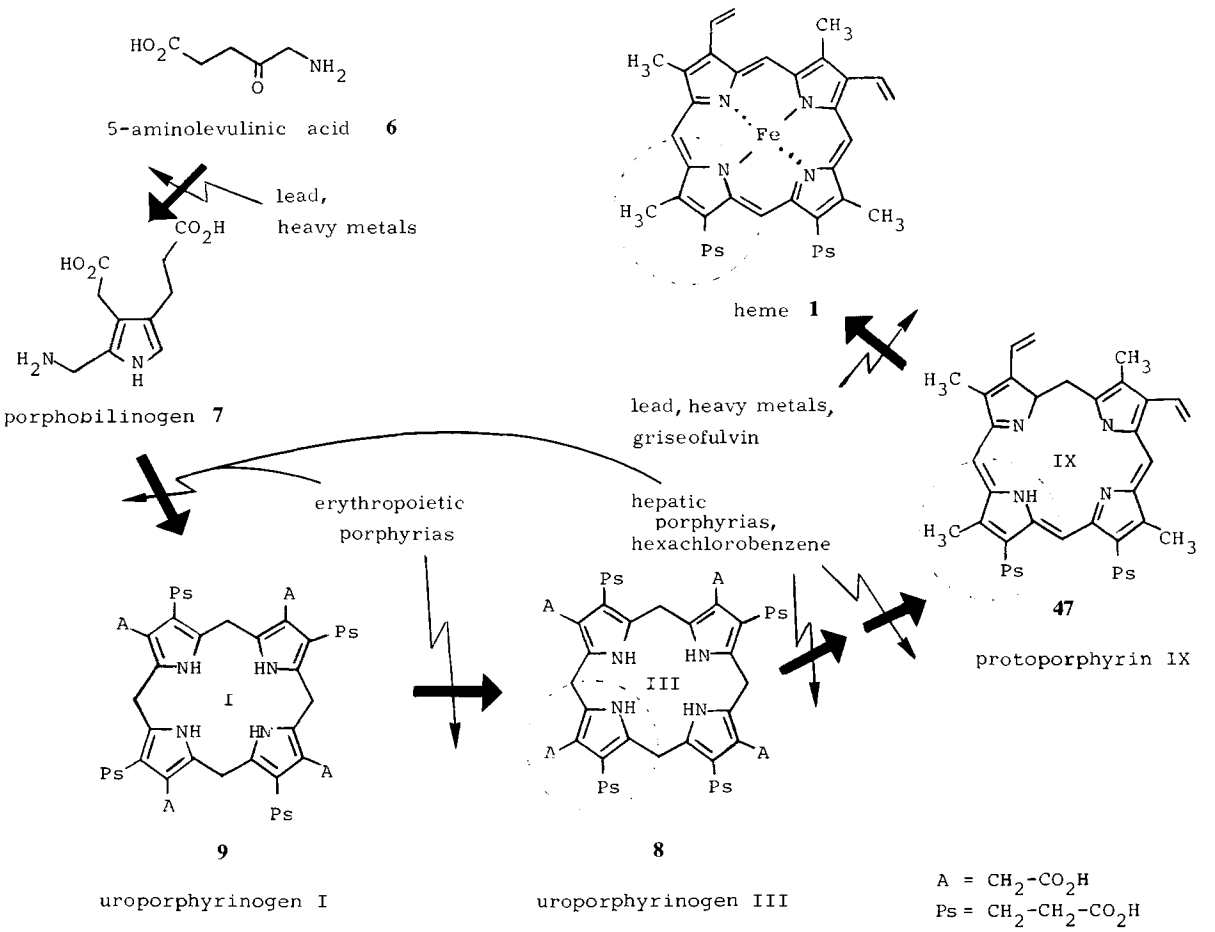
7). For example, if **40** reacts with **41b** in an acid medium, a linear pentapyrrole **44** with a protonated aldehyde group is formed first. As the arrows show, there are two possibilities for electrophilic attack of the carbocation at the electron-rich α-positions of the adjacent pyrrole rings. Because of the cyclic conformation of **44**, attack at the fourth pyrrole ring D is favored over that at the fifth pyrrole ring E. The product thus formed then stabilizes itself by elimination of one pyrrolylmethyl cation, to furnish the cyclic tetrapyrrole (porphyrin) **43**.

In these investigations, as in biomimetic syntheses, the porphyrins proved to be the products of an extremely selective and thermodynamically-favored cyclization proceeding in high yields, even in the absence of enzymes. It is therefore not surprising that porphyrins are also found among the reaction products of a simulated "primeval atmosphere"[53-55]. Porphyrins can thus be included among the prebiotic compounds, *i. e.* those that were already present before the emergence of life on Earth. In the evolution of organisms they proved to be advantageous ligands for catalytically-active heavy-metal ions in enzymes, and were also particularly advantageous because the favored formation of porphyrins is relatively insensitive to enzymatic interference.

6. Explanation of the Metabolic Disease Porphyria

The biosynthesis of the red blood pigment is a central metabolic process whose normal operation is regulated by many enzymes, and an inhibition of individual enzymes as a result of endogenous or exogenous influences gives rise to serious disorders (Scheme 8). Thus, lead poisoning is accompanied by inhibition of δ-aminolevulinic acid dehydratase, the enzyme responsible for the condensation of 5-aminolevulinic acid **6** to porphobilinogen **7**. Lead poisoning is recognized, among other effects by an increased concentration of **6** in the urine. When enzymes from later stages of the heme biosynthesis are inhibited, porphyrins that cannot be converted accumulate further and the urine assumes a reddish color. Metabolic disorders of this kind are known as porphyrias[5-7]. In the comparatively rare, congenital erythropoietic porphyrias the inhibition mainly affects the enzymes causing the production of uroporphyrinogen I **9** and its conversion into uroporphyrinogen III **8**. In hepatic porphyrias the inhibition affects decarboxylases which in heme biosynthesis convert the uroporphyrinogen III **8** into protoporphyrin IX **47** *via* coproporphyrinogen III. Porphyrias can also be triggered by a variety of metabolic toxins and by drugs. In one critical clinical evaluation this was found to be the case for more than 100 drugs, including barbiturates, sulfonal, ergot alkaloids, griseofulvin, estrogen, and also ethanol[55].

The porphyrins produced in porphyrias, which cannot be converted into heme, accumulate in all organs of the



Scheme 8. Inhibition of heme biosynthesis in porphyrias and under the influence of toxins (after [5]).

body. Among other symptoms, this is recognizable by deep-red staining of the tooth roots and the teeth themselves. The severe damage that light can inflict upon affected persons is characteristic. Because of the photosensitizing action of uroporphyrin excreted in the skin, the patient suffers from blisters which are easily infected and leave scars. This can ultimately result in leprosy-like damage to facial skin and in mutilation of the extremities *e.g.* the fingers (Fig. 4).

Fig. 4. Skin and tissue damage in a porphyria patient (from [65]).

In pathophysiological studies on porphyrias it is noted that the biochemical mechanism of the action of light on skin sensitized by porphyrins has not yet been clarified[56,57]. It seemed to us important to help toward the resolution of this medical problem by model chemical investigations. In particular we wanted to consider the possibility—hitherto hardly considered—of the involvement of singlet oxygen. As a result of the biomimetic syntheses[33,34] and labeling experiments[11,27,30], physiologically relevant porphyrins were available for us in adequate supply. We asked ourselves three questions about photodermatosis in porphyrias:

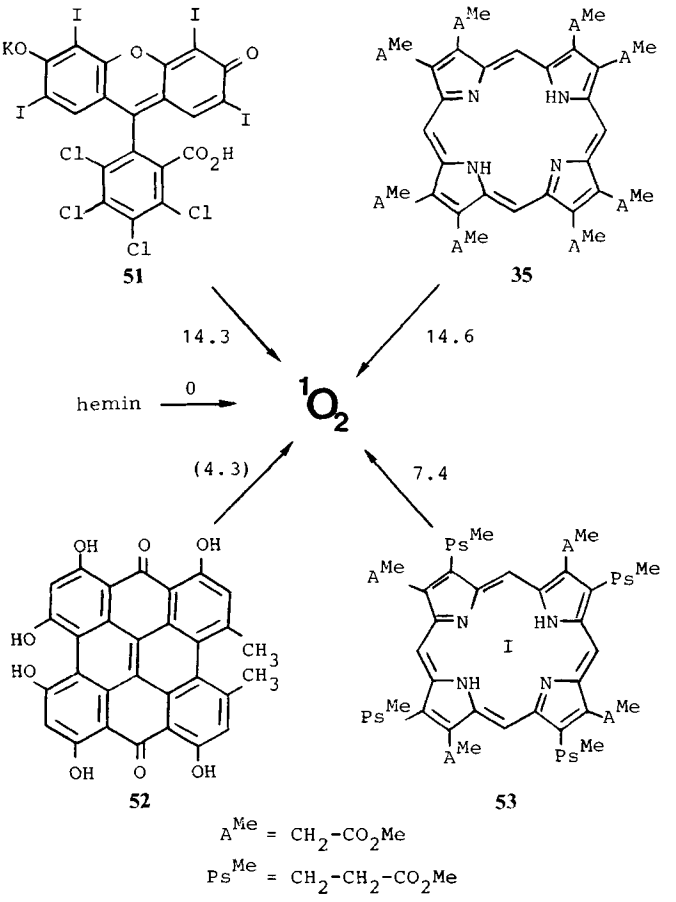
1) How suitable are porphyrin intermediates in heme biosynthesis as sensitizers for the formation of singlet oxygen?

2) Do such porphyrins accelerate the photochemical degradation of vitamin A?

3) What are the structure and the biological activity of products of the reaction between vitamin A and singlet oxygen?

Re 1: The formation of singlet oxygen by porphyrins and other photodynamically active natural products should be compared as quantitatively as possible with that of known photosensitizers under standardized conditions.

Cycloaddition of $^1O_2$ with 2,5-dimethylfuran **48**[58] is suitable for this purpose, since it permits the singlet oxygen to be captured and determined as a crystalline, solvolyzed adduct **50**. Some of the results are summarized in Scheme 9[60] Uroporphyrin I **9**, which is deposited in the tissue in porphyrias in the form of its octamethyl ester **53** is almost as good a generator of singlet oxygen as bengal rose **51**. The same is true of the porphyrin **35** produced by biomimetic synthesis[34]. As expected, hemin did not form any singlet oxygen.

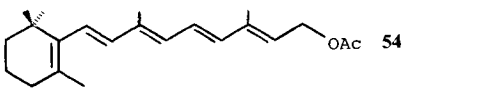


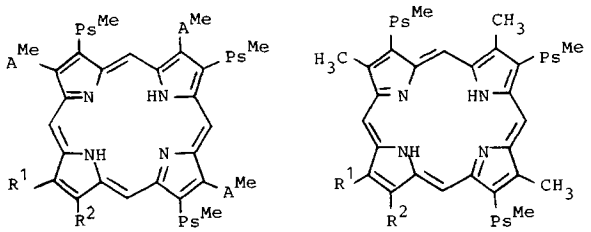
Scheme 9. Comparison of formation of singlet oxygen (in mmol) by hemin and by the four photosensitizers **35**, **51**, **52**, and **53** under standardized conditions (5 μmol of the sensitizer in methanol, 20 min irradiation). Hypericin **52** yielded the value given in parentheses only when used in 10 times higher concentration at double the irradiation time [60].

The behavior of hypericin **52** is remarkable. As a photodynamically active substance from the common hypericum (St. John's wort) *Hypericum perfovatum*, it causes the dermatoses known as hypericism in grazing cattle[59]. In sunny regions these dermatoses are so serious that in addition to total eradication of the plant, which is not without its problems, pasturing by night and staining the cattle a dark

color as a protection against sun light are actually practiced[59]. The ability of **52** to form singlet oxygen is, however, much smaller than that of the porphyrins and only becomes noticeable after a considerable increase of its concentration and prolongation of the illumination period (Scheme 9). The porphyrins deposited in a pathological disturbance of heme biosynthesis are therefore more dangerous than hypericin **52**, which has long been known as a photodynamically active substance.

Re 2: We investigated to what extent physiologically important porphyrins accelerate the photochemical conversion of the epithelium-preserving vitamin A *via* the production of singlet oxygen[60]. Again using standardized conditions, we studied how long it takes 60 mg of vitamin A acetate **54**—nearly an adult's monthly requirement—to be photochemically degraded or converted to half and to one-tenth of the initial quantity in the presence of various sensitizers (Table 2). It should be particularly noted that on illumination, very small quantities (1 μmol) of the porphyrins tested, corresponding to about only 1/1000 of the quantity occurring in porphyria patients, were sufficient to destroy a month's supply of vitamin A within minutes.





53, R^1 = Ps^{Me}, R^2 = A^{Me} **56**, R^1 = Ps^{Me}, R^2 = CH_3

55, R^1 = A^{Me}, R^2 = Ps^{Me} **57**, R^1 = CH_3, R^2 = Ps^{Me}

A^{Me} = CH_2-CO_2Me; Ps^{Me} = CH_2-CH_2-CO_2Me

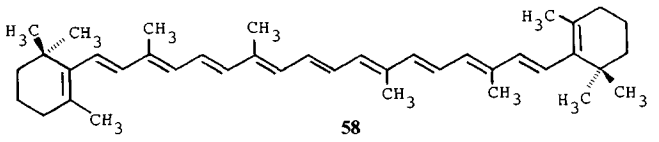


Table 2. Conversion of vitamin A acetate **54** by singlet oxygen under standard conditions (60 mg of **54**, 1 μmol of sensitizer). The times given are those after which the amount of **54** falls to 50% ($t_{1/2}$) and to 10% ($t_{10\%}$) of the original amount [60].

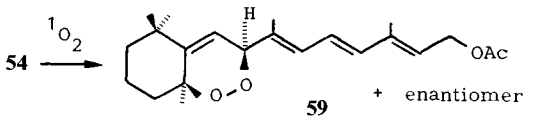
Sensitizer	$t_{1/2}$ [min]	$t_{10\%}$ [min]
Bengal rose **51**		12
Uroporphyrin-I-octamethyl ester **53**	13	41
Uroporphyrin-III-octamethyl ester **55**	9	25
Coproporphyrin-I-octamethyl ester **56**	8	23
Coproporphyrin-III-octamethyl ester **57**	7	22
Blank experiment	36	
53 + β-Carotene **58**	> 50	

The formation of singlet oxygen and thereby the destruction of vitamin A acetate **54** was thought to be preventable by the addition of a singlet oxygen quencher[61] such as β-carotene **58**. This indeed proved to be the case (Table 2). This result provides a mechanistic explanation of the clinical use of **54** in doses of 50 to 100 mg per day in the treatment of photodermatosis in porphyrias[62,63]. Our experiments permit the conclusion that, on exposure to light, the porphyrins deposited in skin in porphyrias form singlet oxygen, whose reaction with vitamin A gives rise to a local avitaminosis, destroying the epithelium.

Re 3: We isolated the endoperoxide **59** in 60% yield as the main product of the conversion of vitamin A acetate **54** induced by pathological porphyrins as $^1O_2$ generators (see Table 2). The structure of this peroxide corresponds to that of analogous endoperoxides obtained from vitamin A derivatives by photosensitization with bengal rose **51**[64]. The endoperoxide **59** obtained from vitamin A acetate has no Vitamin A activity in the chicken test and is non-toxic when administered orally to mice[60].



7. Outlook

The porphyrin skeleton in the red pigment of blood is one of the oldest organic molecules on Earth, probably older than life itself. Model experiments with simulated primeval atmospheres[53,54] suggest that porphyrins arose even in the prebiotic era. Their formation was later enzymatically optimized when living organisms made use of them to complex catalytically active metal ions. The biosynthesis of heme and the porphyrins has since become a principal strand in the metabolic network of organisms. It may be likened to a silk thread on which our life hangs, increasingly endangered by forces of heredity and the effects of civilization. Thus medicine imposes important future tasks on the organic chemist in the field of porphyrins, an area which is just beginning to become accessible by simple biomimetic syntheses.

I am indebted to all my coworkers mentioned in the cited studies for their creative and stimulating collaboration in the broadly-based study of heme biosynthesis. I am also grateful to colleagues in the field all over the world who led us to undertake intensive work in this field—not really so complicated as it sometimes seems—both by enlightening and puzzling contributions. The work has been generously and patiently supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

N-(Pentafluoro-λ^6-sulfanyl)iminosulfur Tetrafluoride by Reaction of Thiazyl Trifluoride with Fluorine**

By *Alfred Waterfeld* and *Rüdiger Mews**

Reaction of NSF_3 and fluorine at room temperature yields SF_6 and N_2:

$$\underset{\mathbf{1}}{NSF_3} + 3/2\,F_2 \rightarrow SF_6 + 1/2\,N_2 \qquad (1)$$

No products containing nitrogen-fluorine bonds are formed, and therefore the reaction could be used for the fluoro-calorimetric determination of the enthalpy of formation of **1**[1].

We have now found that even under controlled, mild reaction conditions no [2] products with N—F bonds are formed, but instead the title compound **2**, SF_6, and N_2:

$$\mathbf{1}_{exc} + F_2 \xrightarrow{-196 \rightarrow -78 \rightarrow 20\,^\circ C} \underset{\mathbf{2}}{F_5SNSF_4} + SF_6 + N_2 \qquad (2)$$

Reaction commences at about $-78\,^\circ C$, recognized by a slow drop in pressure (the number of molecules decreases).

A drastic change in the experimental conditions, *e.g.* rapid heating or addition of BF_3 or HgF_2, leads to explosive-like reaction; SF_4 and N_2 are formed.

Reaction (3) is strongly exothermic (-415.9 kJ/mol):

$$\mathbf{1} + 1/2\,F_2 \rightarrow \{NSF_4^{\oplus}\} \rightarrow SF_4 + 1/2\,N_2 \qquad (3)$$

Thus, **2** is formed only under kinetic control in liquid **1** at temperatures slightly above $-78\,^\circ C$. The yield of **2** (maximum 50% referred to reacted fluorine) is higher, the smaller the ratio F_2 : **1**.

We assume that **1** is oxidized by fluorine radicals *via* short-lived intermediates to the radical $SF_5^{\oplus}$, which not only reacts with F_2 to give SF_6, but also with the solvent **1** to give $F_5SNSF_3^{\oplus}$. The latter stabilizes with formation of **2** and a fluorine radical, which continues the chain reaction:

$$\underset{\mathbf{1}}{SF_5^{\oplus} + NSF_3} \rightarrow \{F_5SNSF_3^{\oplus}\} \rightarrow \underset{\mathbf{2}}{F_5SNSF_4} + F^{\oplus} \qquad (4)$$

2 is a stable, colorless liquid (b.p. $49\,^\circ C$, m.p. $< -100\,^\circ C$) at room temperature, and can be heated to $60\,^\circ C$ in metal or Kel-F vessels, but decomposes in glass—particularly in the presence of traces of moisture—to F_5SNSOF_2[3].

The IR spectrum of **2** (gas) shows, aside from ν(SN) at 1299 cm^{-1} (s), strong bands at 922 (vs), 841 (s), and 794 cm^{-1} (s), which can be assigned to the stretching vibrations of the SF_5- and SF_4-groups. The ^{19}F-NMR spectrum at $0\,^\circ C$ is of AB_4X_4 type ($\delta_A = 70.4$, $\delta_B = 78.1$); the NSF_4 group gives a broad singlet ($\delta = 77.75$)[4]. On lowering the temperature, a further broadening occurs; at $-70\,^\circ C$ only the AB_4 part for the SF_5-group is observed ($\delta_A = 70.65$, $\delta_{B_4} = 77.96$, $J_{AB} = 155.6$ Hz).

The NSF_4 group in **2** can function both as fluoride donor and as fluoride acceptor:

$$\mathbf{2} + AsF_5 \xrightarrow[-50 \rightarrow -20\,^\circ C]{SO_2ClF} \underset{\mathbf{3},\ \text{m.p. } 103\,^\circ C}{F_5SNSF_3^{\oplus}AsF_6^{\ominus}} \qquad (5)$$

$$\mathbf{2} + CsF \xrightarrow[14\,d]{20\,^\circ C} \underset{\mathbf{4}}{Cs^{\oplus}[N(SF_5)_2]^{\ominus}} \qquad (6)$$

The salt like structure of **3** follows from the ^{19}F-NMR spectrum.

The IR spectroscopically characterized salt **4**, whose anion contains two geminal pentafluoro-λ^6-sulfanyl groups, opens up an entry to bis(pentafluoro-λ^6-sulfanyl)amides[9].

Bis(pentafluoro-λ^6-sulfanyl)amines**

By *Alfred Waterfeld, Heinz Oberhammer*, and Rüdiger Mews**

$F_2C(SF_5)_2$[1] and F_5SOSF_5[2,3] are the only compounds with two geminal pentafluoro-λ^6-sulfanyl groups to have been reported in the literature so far. The *N*-(pentafluoro-λ^6-sulfanyl)iminosulfur tetrafluoride **1** prepared by us[4] now opens up access to bis(pentafluoro-λ^6-sulfanyl)amines. Thus, addition of hydrogen fluoride to **1** affords $(SF_5)_2NH$ **2** in quantitative yields:

$$\underset{\mathbf{1}}{F_5SNSF_4} + HF \rightarrow \underset{\mathbf{2}}{(SF_5)_2NH} \quad (1)$$

The colorless liquid **2**, b.p. 60.4 °C, is stable at room temperature in glass; at elevated temperature in presence of alkali-metal fluorides, it loses HF with re-formation of **1**. **2** is a weak acid; with large cations, salts such as $Ph_4P^{\oplus}N(SF_5)_2^{\ominus}$ **3** can be precipitated.

The *N*-halobis(pentafluoro-λ^6-sulfanyl)amines **5** and **6** are accessible in 91 and 87% yield, respectively, *via* the cesium salt **4**[4]:

$$\underset{\mathbf{4}}{Cs^{\oplus}N(SF_5)_2^{\ominus}} + F_2 \rightarrow \underset{\mathbf{5}}{FN(SF_5)_2} + CsF \quad (3)$$

$$\mathbf{4} + ClF \rightarrow \underset{\mathbf{6}}{ClN(SF_5)_2} + CsF \quad (4)$$

5 and **6**, b.p. 51.6 and 78 °C, respectively, are stable, colorless liquids at room temperature. Owing to the polarity of the Cl—N bond, **6** is considerably more reactive than **5**; **6** is rapidly decomposed by halide ions (Cl^-, Br^-). Since the two SF_5 groups couple with each other, the NMR spectra of the bis(pentafluoro-λ^6-sulfanyl)amines are quite complicated ($AA'B_4B_4'$ or $AA'B_4B_4'X$ spectra).

The structures of **2** and **5** were determined by electron diffraction.
