The Cycloaddition of Allyl Cations to 1,3-Dienes: General Method for the Synthesis of Seven-Membered Carbocycles

New Synthetic Methods (40)

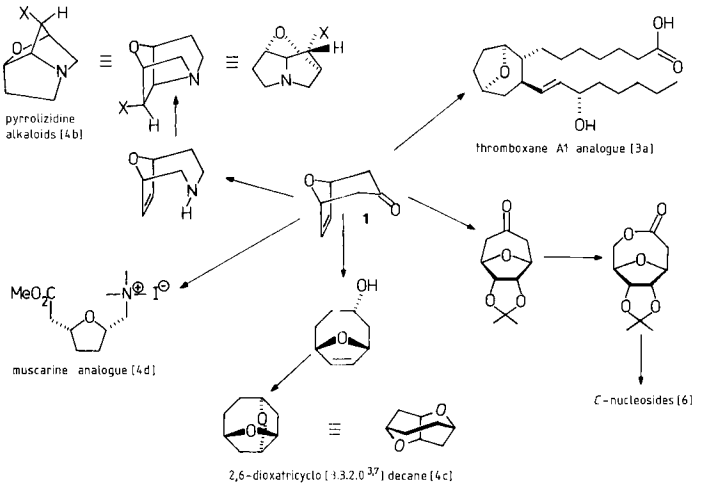
By H. M. R. Hoffmann*

The reaction of allyl cations and 1,3-dienes affords seven-, five-, and six-membered rings as well as products of electrophilic substitution and linear 1 : 1-adducts. In this review article, preparative and mechanistic advances are summarized with special emphasis on the synthesis of seven-membered carbocycles. For the first time, a comprehensive mechanistic description is presented: Three classes A, B, and C correlate product type and stereochemistry with the nucleophilicity of the diene, the electrophilicity of the allyl cation intermediate, and the donor capacity of the group Y attached to the central carbon of the allylic moiety. The problem "allylic resonance versus nucleophilic participation of Y" is discussed and experimental evidence is adduced for some participation of Y as a function of its nucleophilicity. For cyclopentenyl cations, enhanced charge separation and electrophilicity are postulated, even when Y is a good donor, due to the structurally enforced polarity of the π-allyl system.

1. Introduction

1.1. Preparative and Mechanistic Aspects

Common rings (ring size n = 5–7) with novel functionality and stereochemistry occur in many natural products and, for this reason alone, are of great interest. Because of ring strain and also for entropy reasons, seven-membered carbocycles are often more elusive and have been studied less actively than their lower homologues. They are also conformationally more flexible. Many of the compounds described here are bridged seven-membered cyclic compounds containing a five-membered ring or another bridge which more clearly defines overall shape and potentially mobile conformations. Some of the carbocyclic frameworks contain a plane of symmetry—which simplifies NMR spectra—and are aesthetically pleasing. Most importantly, the compounds have found wide application in synthesis. For example, 8-oxabicyclo[3.2.1]oct-6-en-3-one



Scheme 1. Selected transformations of 8-oxabicyclo[3.2.1]oct-6-en-3-one **1**.

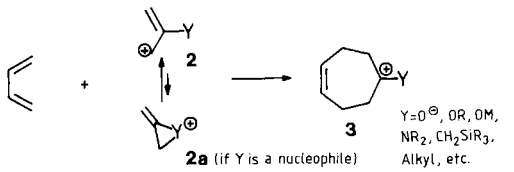
1, which is the prototype of the 2-oxopropano bridged 2,5-dihydrofurans and which we prepared for the first time in 1973[1], has served as starting material for the synthesis of a number of natural products and their analogues and also theoretically interesting molecules (Scheme 1). At least three, simple large-scale preparations of **1** have now been developed[2–4]. In this article I shall concentrate on progress made since the appearance of our first account[5]. The reaction of polybromoketones and carbonyliron compounds has been summarized by *Noyori*[6] and also by others[7].

Allyl cations such as **2** encompass many structural types and variations. Generally, Y is an atom or group which has the ability to stabilize positive charge in the product cation **3** or any other ring that may be formed. If Y is sufficiently nucleophilic, 1,3-interaction with the terminal carbon(s) may ensue with concomitant uncoupling of π-allyl overlap and formation of the cyclic valence tautomer **2a**. Reaction of π systems and **2a** — which is a perpendicular allyl cation if allyl resonance is lost completely—is a stepwise process.

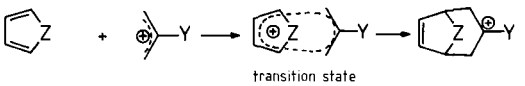


On the other hand, a planar delocalized allyl cation **2** is most likely when Y is less nucleophilic and also when planarity is structurally enforced, *e.g.* in cyclopentenyl-type cations. As we have shown, even the simple 2-methylallyl cation (Y = Me) reacts with cyclopentadiene and cyclohexadiene to give derivatives of **3**[8].

1.2. Classification of Allyl Cation Reactions with 1,3-Dienes

We have found it useful to divide reactions of allyl cations with 1,3-dienes into three categories, here exemplified for reactions of planar delocalized allyl cations and cyclic conjugated dienes.

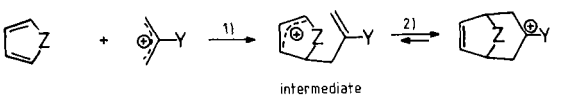
Class A. Concerted bond-formation



Predicted consequences:

1) Products: Bridged seven-membered rings.
2) Stereochemistry: Configuration of allylic cation remains intact. Transition state is "compact" or "extended" (see also Section 4.3.1).

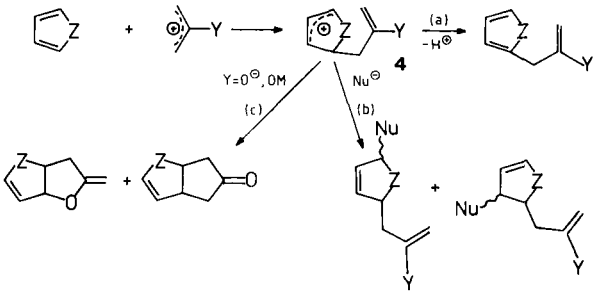
Class B. Stepwise bond-formation



Predicted consequences:

1) Products: Bridged seven-membered rings.
2) Stereochemistry: Configuration of allylic cation may be retained or lost, depending on the lifetime of carbocation **4** (see also Section 4.3.2).

Class C. Electrophilic addition followed by (a) loss of a proton with overall electrophilic substitution or (b) intermolecular- or (c) intramolecular-nucleophilic capture of 4



Predicted consequences:

Products: Five-membered carbocycles and heterocycles; acyclic 1:1-adducts via formation of one σ bond (see also Section 4.3.3).

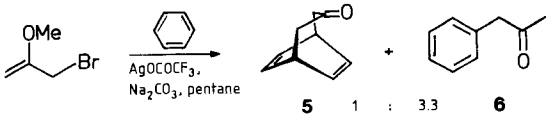
As far as a distinction between class A and class B is feasible, it must rely heavily on stereochemical and physical-organic arguments. From a kinetic viewpoint the class B/class C borderline depends on the rate constant for step 2) and its reverse, which in turn is determined by the lifetime and stability of carbocation **4**. However, the detection of short-lived intermediates such as **4** — let alone the determination of associated rate constants — is often cumbersome and ambiguous, even under favorable circumstances. Fortunately, the mechanistic background has clear phenomenological consequences in predicting a fairly wide range of products, which can generally be isolated and identified easily. Finally, each product type may be assigned to one or at most two of the three classes.

2. Methods for Generating and Capturing Allyl Cations; Survey and Applications in Synthesis

Experimental procedures for generating allyl cations are classified according to type of precursor and structure of electrophilic intermediate:

2.1. Allylic Halides and Lewis Acids

Heterolysis of allyl halides promoted by Lewis acids is the most direct route to allyl cations. The reaction is mechanistically simple, although the structure of electrophilic intermediate(s) may be in doubt when Y is nucleophilic and can interact with the allylic termini. Ambiguities due to ion-pairing may also encroach. The silver salt route remains perhaps the most useful and versatile procedure, especially when very reactive allyl cations are involved and all other methods and Lewis acids fail.



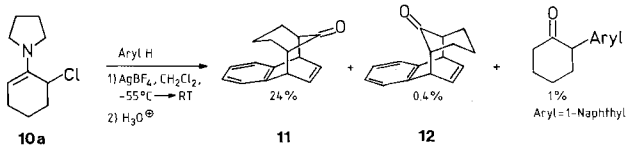
A key experiment which highlights the special driving force of 2-alkoxyallyl cation reactions[9], irrespective of mechanistic detail[10], is the addition of 2-methoxyallyl bromide to benzene to give bicyclo[3.2.2]nona-6,8-dien-3-one **5**. Because of the resonance energy of 36 kcal/mol, cycloadditions to benzene are rare. If the cycloaddition is to succeed, an allyl cation is apparently required which has the proper blend of electrophilicity at the terminal carbons and of nucleophilicity of Y (the simple 2-methylallyl cation **2**, Y = Me, reacts with benzene and furan to give products of electrophilic substitution, *i.e.* class C only). Toluene and *p*-xylene give lower yields of bicyclo[3.2.2]nona-6,8-dien-3-ones and more Friedel-Crafts type, *i.e.* class C, products.

The resulting isomeric bicyclics form π-complexes of different strength with silver ions: For example, on non-aqueous work-up of the reaction mixture from *p*-xylene the remaining silver residues retain preferentially (71%) bicyclic diene **8**, which has two less hindered double bonds than its isomer **7** (Table 1). Parent dienone **5** has also been

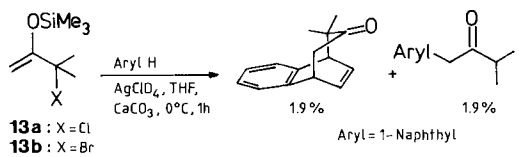
Table 1. Product ratios for the silver trifluoroacetate-promoted cycloaddition of 2-methoxyallyl bromide to 1,4-dimethylbenzene [9].

	[%]		
	7	8	9
Complete work-up	24	7	69
Work-up of Ag^+ residues only (anhydrous)	25	71	4

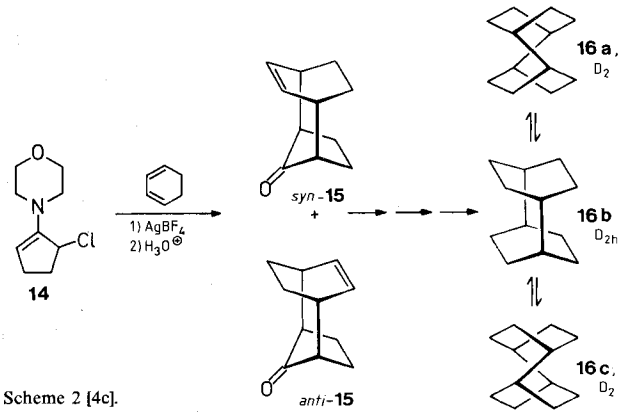
converted into the tricarbonyliron complex, albeit in low yield[5] (complexation of bicyclo[3.2.1]octa-2,6-dienes by silver ion is discussed in Section 2.2).



More recently, cycloadditions to naphthalene have been accomplished with varying success: The cyclic 6-chloroenamine **10a**[11a,b], in which electrophilic and donor strength are well balanced, is clearly superior to acyclic 2-siloxyallyl species **13a**[11c], because it gives not only more cycloadduct (**11** and **12**), but also less product of class C. However, attempts to trap benzene with **10a** and silver salts were not successful[11a,b].

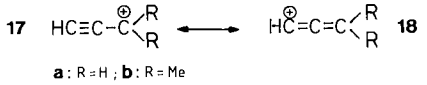


Cycloadditions with cyclopentenyl cations have remained difficult, one reason being the problem of obtaining suitable chloroenamines in reasonable yield. Using *Vilsmaier*'s 2-chloroenamine **14**[58a], *Ernst* and *Ganter* have

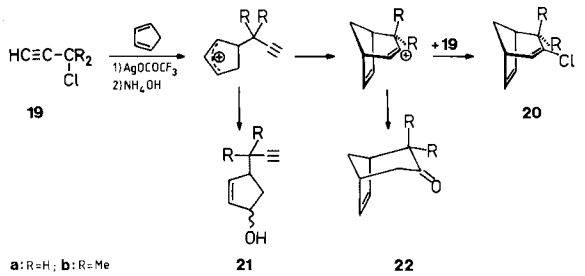


Scheme 2 [4c].

prepared **15** in 30% yield (*syn* : *anti* = 93 : 7)[12]. After hydrogenation and further steps, **15** was transformed into the novel hydrocarbon **16**, which may exist as the achiral D_{2h} conformer **16b** and also as the (presumably) more stable chiral twist conformer **16a** and enantiomer **16c**[12] (Scheme 2). Using the silver salt route *Mayr* et al.[13] have generated a variety of dehydroallyl cations (propargyl cations



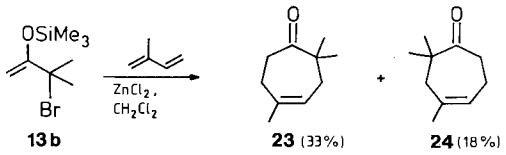
17 ↔ dehydroallyl cations **18**). Even **19a**, the educt from **17a** ↔ **18a**, reacted to give **22a** (7%). Because ions **17** ↔ **18** are likely to be linear, formation of the seven-membered



ring is a stepwise process (class B), which is also consistent with leakage into a product of class C, *i.e.* **21** (see Section 4.2). It should be noted that silver salts remove halide ions such as Br^- and I^- quickly and irreversibly by precipitating insoluble silver halides. Thus, there is no chance of an acid such as HHal being formed, which could destroy reactants and products alike. Furthermore, no free halide ion is generated which might intercept the allyl cation intermediate. Finally, at least for the generation of very reactive allyl cations such as 2-methylallyl, 2-methoxyallyl, and also **17a** ↔ **18a**, it is advisable to use $AgOCOCF_3$ instead of $AgBF_4$: Trifluoroacetate stabilizes the allyl cation, presumably via its weakly nucleophilic fluorine atoms, without significant collapse to covalent trifluoroacetic esters. Also if elimination occurs during the

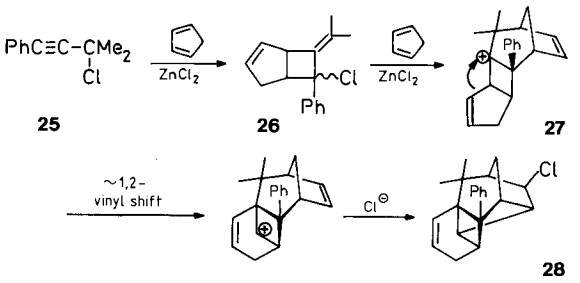
formation of cycloadduct, CF_3CO_2H is less harmful than the stronger acid HBF_4.

Mechanistically, the zinc halide induced heterolysis of allyl halides is related to silver ion induced heterolysis, although two terminal alkyl substituents—or one phenyl substituent—are generally required for ionization to occur. Since $ZnCl_2$ does not dissolve readily in CH_2Cl_2, it is helpful to prepare the ether adduct, which may be used at temperatures as low as -30 to $-50\,^{\circ}C$[14]. A simple example of the use of $ZnCl_2$ is the reaction of the isoprenoid building block **13b** with isoprene, which yields karahanaenone **23** and its isomer **24**[15]. These two monoterpenoids may also be obtained from the appropriate α,α'-dibromoketone with zinc/copper couple[16a] or triethyl borate/zinc dust[16b].



13b **23** (33%) **24** (18%)

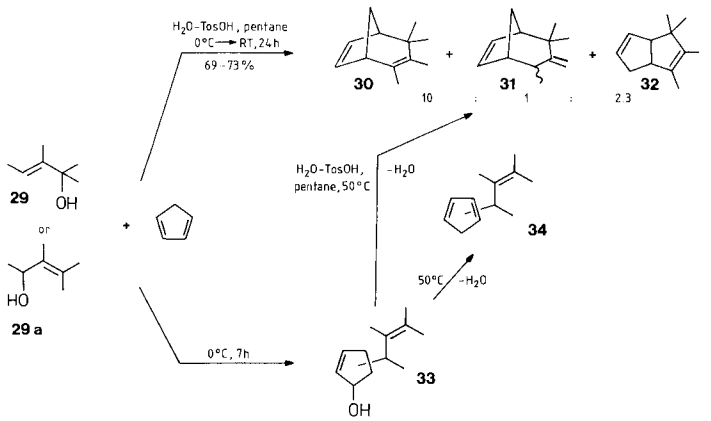
An unusual beginning and conclusion to an allyl cation reaction has been reported by *Mayr* et al.[17]: **26** is the 1:1-adduct of cyclopentadiene and propargyl chloride **25**; with excess cyclopentadiene adduct ion **27** is formed which, however, cannot easily lose a proton and instead rearranges to **28** (52% yield relative to **26**); the structure of **28** was secured by X-ray crystallography.



25 **26** **27** **28**

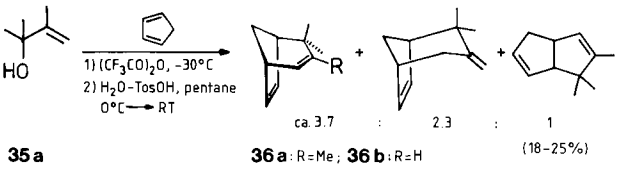
2.2. Activation of Allyl Alcohols and Related Compounds

Allyl alcohols with three terminal methyl groups, such as **29** and **29a**, react with cyclopentadiene under acidic two-phase conditions, *e.g.* in aqueous toluenesulfonic acid/pentane (Scheme 3). The reaction occurs, although cyclopentadiene is acid sensitive in homogeneous solution, to form



Scheme 3 [18].

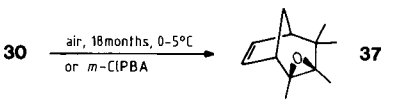
dicyclopentadiene and notorious blue-black polymers. The ratios and yields of adducts **30** and **32** are similar to those observed in the silver salt reaction of the corresponding allylic halide precursor. When the two-phase reaction is run at 0°C and interrupted, allyl-substituted cyclopentenols of type **33** can be isolated, *i.e.* products of class C. Interestingly, on being exposed to aqueous acid/pentane at 50°C, these isomeric cyclopentenols again give **30** and **31** (class B) and **32** (class C)[18].



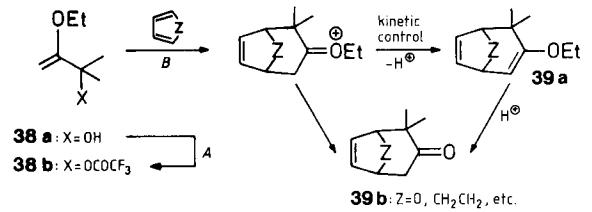
35a **36a**: R=Me; **36b**: R=H

2,3-Dimethyl-3-buten-2-ol **35a**, which clearly is more reluctant than **29** or **29a** to form an allyl cation under standard two-phase conditions, can nevertheless be used by means of a simple trick. On being shaken with trifluoroacetic anhydride at $-30\,^{\circ}C$, it forms the trifluoroacetic ester which on warming with cyclopentadiene under acidic two-phase conditions affords **36a** as the major product. Furthermore, the *exo*-methylene compound and [3.3.0]bicycle corresponding to **31** and **32**, respectively, are now relatively more important products[19].

2,3,4,4-Tetramethylbicyclo[3.2.1]octa-2,6-diene **30** is oily and sensitive to oxygen. On contact with air the crystalline *exo*-epoxide **37** is slowly formed, which can be obtained



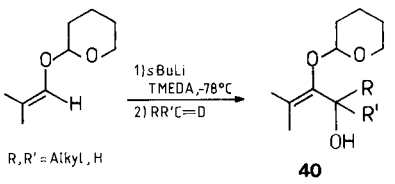
more quickly by epoxidation of **30** with *m*-chloroperbenzoic acid (*m*-ClPBA). A useful method for isolating, purifying and storing strained bicyclo[3.2.1]octa-2,6-dienes such as **30** and **36a,b** is complexation with silver ions. The silver nitrate complex of **30**, *i.e.* $(C_{12}H_{18})_2AgNO_3$ is crystalline (m.p. = 114—115 °C) and can be isolated directly from the mother liquor of the two-phase reaction (Scheme 3). The bicyclic diene **36b**, which has a much less hindered second double bond than **30**, forms a 1:1-complex with $AgNO_3$, *i.e.* $(C_{10}H_{14})AgNO_3$, m.p. = 153 °C. Other complexes, *e.g.* that of **36a** and $AgNO_3$, have a stoichiometry lying between 2:1 and 1:1, *ca.* 1.5:1[20]. Bicyclo[3.2.1]octa-2,6-dienes have served inter alia as model compounds for 9,10-dehydronorzizaenes **46**.



Scheme 4. *A*: $(CF_3CO)_2O$, $EtN(iPr)_2$; *B*: $ZnCl_2$, $EtN(iPr)_2$ (cf. [21]).

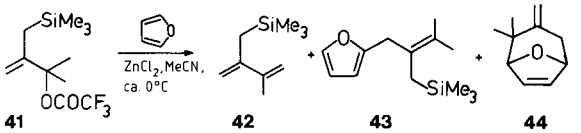
The tertiary allylic alcohol **38a** is readily accessible from pyruvic acid, but is slow to form an ester with common acylating agents, *e.g.* acetic anhydride/pyridine, or with tosylating agents (tosyl chloride/pyridine). Again, trifluoro-

acetic anhydride is a potent acylating agent which reacts with **38a** at −40 °C and below, even in the absence of catalytic 4-dimethylaminopyridine. The resulting trifluoroacetic ester **38b** has been ionized under a variety of conditions. With cyclic 1,3-dienes and in the presence of hindered amine, we have obtained novel bicyclic enol ethers **39a**, *i.e.* products of kinetic control, rather than the thermodynamically more stable bridged cycloheptenones **39b**. Because enol ethers such as **39a** are acid-sensitive, the reaction medium must at least be neutral or even weakly basic. 2-Ethoxyallylic alcohol **38a** is probably more advantageous than the corresponding 2-methoxyallylic species here, because dealkylation of intermediate oxonium ion appears to be less facile; and perhaps also because an ethyl enol ether is more nucleophilic than a methyl enol ether (Scheme 4)[21].



40

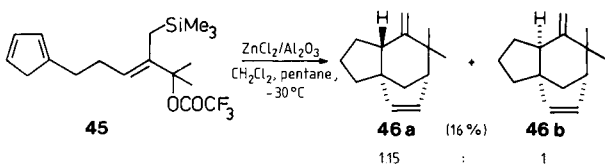
A variety of 2-alkoxyallyl alcohols, *e.g.* of type **40**[22], have also been prepared by oxygen-directed lithiation of enol ethers and subsequent trapping of the vinyllithium intermediate with aldehydes and ketones (TMEDA = tetramethylethylenediamine.)



41 **42** **43** **44**

1 : 6 : 3

The cation derived from educt **41** is much more sensitive toward deprotonation than 2-alkoxyallyl and metal oxyallyl cations (cf. also Section 4.1.1). Thus, in the presence of amine, diene **42** is formed easily from **41**. Nonetheless, in the absence of hindered amine at 0 °C and below, the reaction of **41** with furan has sufficient driving force for formation of bridged methylenetetrahydropyran **44** (class B), in addition to the more conventional products **43** (class C) and **42**[23]. Summing up, the trifluoroacetate method leaves us free to generate structurally complex allyl cations late in a synthesis and also in the presence of other sensitive functionalities. Perhaps the most demanding example described by us so far is the intramolecular "chromatographic cycloaddition" of **45** which was accomplished at

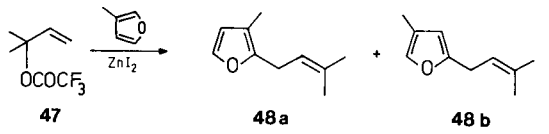


45 **46a** (16%) **46b**

1.15 : 1

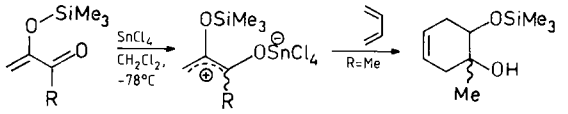
−30 °C and below on an alumina column coated with $ZnCl_2$. A short route to 9,10-dehydro-2-norzizaene **46** and related sesquiterpenes has therefore been opened up[24].

Class C reactions of furans, *e.g.* the formation of **43**, are not necessarily a nuisance, but may be preparatively useful. For example, the reaction of 3-methylfuran with **47** is a simple prenylation, yielding rosefuran **48a** and its hi-



47 **48a** **48b**

therto unknown isomer **48b**[25]. Generally, Friedel-Crafts type alkylations of furans are now feasible using the new methodology for generating sensitive carbocations. It has



49a: R = H
49b: R = Me

50

been reported recently that 2-siloxyacrolein **49a**, but not the less electrophilic **49b** (R = Me), serves as the 1-hydroxy-2-oxidoallyl synthon **50** in the presence of equimo-

Table 2. Reaction of dienes with 2-siloxyacrolein **49a**/$SnCl_4$ as allyl cation component in CH_2Cl_2 at −78 °C [26].

Diene	*t* [h]	Cycloadduct	Yield [%]

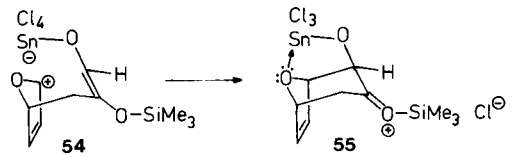
	5	 *endo*-**52** *exo*-**52**	72
	1–6	 **53**	43

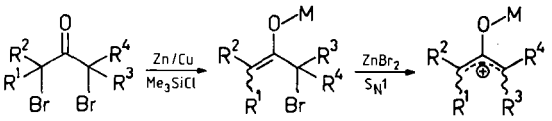
lar amounts of $SnCl_4$ (Table 2). Interestingly, furan affords only the *exo*-adduct[26]. The stereoselectivity can be explained by postulating that the cycloaddition belongs to class B, formation of the second σ bond being late or product-like and being aided by chelation of oxygen (**54** → **55**).



54 **55**

2.3. α,α′-Dihaloketones and Reducing Agents

α,α′-Dihaloketones **56** and reducing agents such as zinc/copper couple generate an α-halogenated zinc enolate of type **57** and subsequently the zinc oxyallyl cation of type **58**. Again, the S_N1-like ionization of **57** to **58** is promoted by $ZnBr_2$ formed in situ, and which may also be added at the outset. The reaction of **56** with zinc/copper couple has

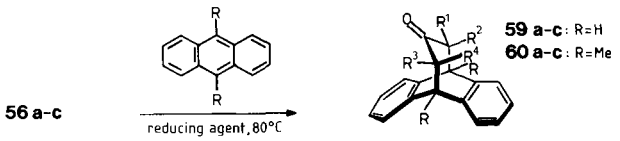


56 57 M = ZnBr, $SiMe_3$, Na 58

	R^1	R^2	R^3	R^4
a	H	Me	H	Me
b	H	Me	Me	H
c	Me	Me	Me	Me
d	H	Br	H	Br
e	H	Me	H	H
f	Me	Me	H	H
g	H	*i*Pr	H	*i*Pr

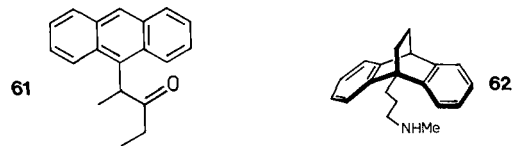
been accelerated and yields have been increased by addition of Me_3SiCl, which leads to formation of the α-halogenated trimethylsilyl enol ether of type **57** and thence to cation of type **58**, which is more electrophilic than **58**, M = ZnBr.

Even catalytic amounts of Me_3SiCl are sufficient, indicating that Me_3SiCl or Me_3SiBr are regenerated during the reaction cycle; in fact, with acid-sensitive dienes such as cyclopentadiene it is advisable to use a relatively small amount of Me_3SiCl[27].



56 a-c — reducing agent, 80°C → **59 a-c**: R = H; **60 a-c**: R = Me

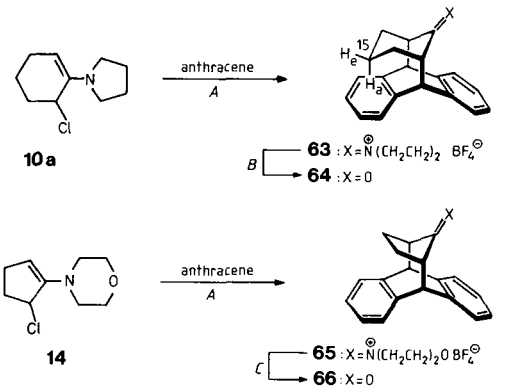
The reaction of α,α′-dibromoketones **56** and reducing agents with anthracene has been studied under three sets of conditions (Table 3)[27,28]. The most electrophilic oxidoallyl species (see Section 4.2), *i.e.* iron oxyallyl, gives somewhat higher yields than siloxyallyl, which in turn is much more effective than zinc oxyallyl. Since anthracene and 9,10-dimethylanthracene are not particularly nucleophilic, it is understandable that the high electrophilicity of the allyl cation is important here. The reaction of **56a,b** with zinc/copper couple and anthracene affords *ca.* 1% of **61** (class C). This fact and the formation of 10% of the *trans* isomer **59b** within the *cis-trans* mixture of isomers **59a** and **59b** suggests that the reaction is on the class B/class C borderline (cf. also Section 4.3.2).



9,10-Propanoanthracene derivatives such as **59** and **60** are structurally related to maprotiline® **62**, a clinically successful antidepressant developed by Ciba-Geigy[29]. Adduct **60c** is unusual in having two CC bonds between two quaternary carbon atoms. Its crystal structure has been determined and is discussed in Section 3.1 (Fig. 1).

Reactions of cyclic allyl cations are generally more demanding preparatively than those of acyclic allyl analogues. In fact, most of the work in this area has been carried out with furan, which also functions as the solvent.

α,α′-Dibromocycloalkanones—which are especially reactive when they are five- and six-membered derivatives—and anthracene react poorly with a variety of reducing agents, and it is advisable to return to preformed allylic species and silver salts (Section 2.1). In his dissertation, *R. Schmid*[11a] has shown that in the presence of $AgBF_4$ and anthracene, cyclic α-chloroenamines **10a** and **14** afford iminium salts **63** and **65**, respectively (Scheme 5). **14** is the only accessible chloroenamine of cyclopentanone at present; it is sensitive and must be used without distillation (*ca.* 60% purity by NMR). Remarkably, the sterically hindered iminium salt **65** is almost inert toward hydrolysis, formation of **66** requiring extreme conditions; on being refluxed



10a — anthracene, *A* → **63**: X = $\overset{\oplus}{N}(CH_2CH_2)_2$ $BF_4^{\ominus}$; *B* → **64**: X = O

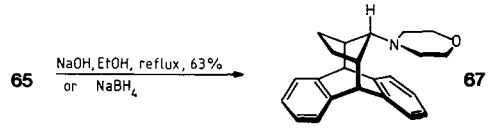
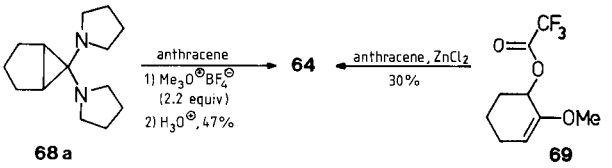
	H	Me	Me	H		**60b**			
56c	Me	Me	Me	Me	Me	**60c**	<2	40	76

[a] **56a** and **56b** are diastereomers which cannot be distinguished in this reaction. [b] Ratio **59a** : **59b** = 90 : 10. [c] *Ca.* 1% of **61** was isolated after chromatography. [d] Ratio **59a** : **59b** = 1 : 1 (equilibrium ratio). [e] Ratio **60a** : **60b** = 95 : 5.



65 — NaOH, EtOH, reflux, 63% or $NaBH_4$ → **67**

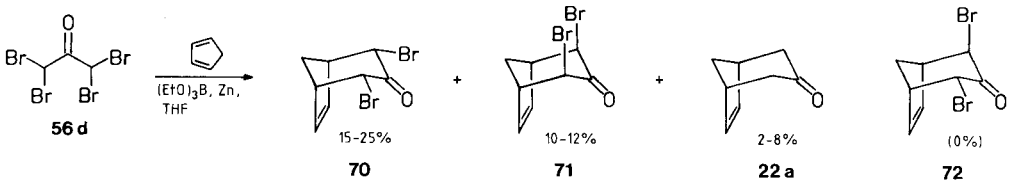
with ethanolic NaOH, **65** does not form **66**, but amine **67**, which can be prepared more readily by reduction of **65** with $NaBH_4$. The mechanism of the reaction of **65** with NaOH is not clear at present. Adduct **64** has also been

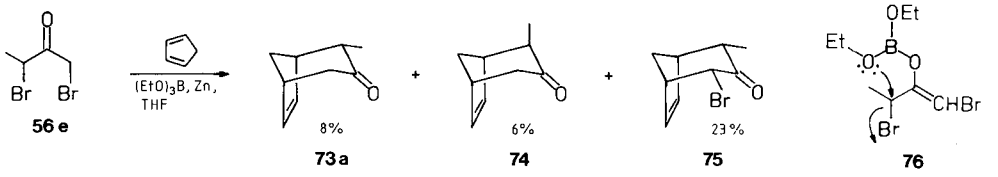


68a **69**

prepared in 46.5% yield using the less electrophilic bicyclic aminal **68a** and $Me_3O^+BF_4^-$[11a,b], and in *ca.* 30% yield from **69** and $ZnCl_2$[30]; in this case anthracene/$ZnCl_2$ and Hünig's base [$EtN(iPr)_2$] were refluxed in CH_2Cl_2 for 30 h, while **69** was slowly added dropwise. The chemistry of the novel double-decker compounds **63**—**67** has hardly been explored. **64** and the corresponding naphthalene adduct show interesting ^{1}H-NMR properties. In **64**, the signals of protons H_e—C(15) and H_a—C(15), which are situated immediately above the aromatic π system, are shifted to high field and appear as broad multiplets at $\delta = 0.8$ and -0.4, respectively (signal width 35—40 and 55—60 Hz, respectively)[11a,b].

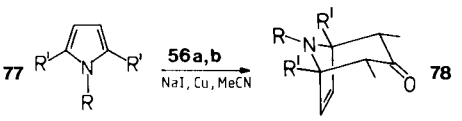
Since siloxyallyl cations, *e.g.* **58**, M = $SiMe_3$, can be generated from α,α′-dibromoketones it is not surprising that boron oxyallyl cations have also been used, even before the current activity on boron enolates in the aldol reaction began. Usually, at least two alkyl groups are required for the generation of metal oxyallyl cations **58** from α,α′-dibromoketones **56** (cf. also Table 3). Important exceptions





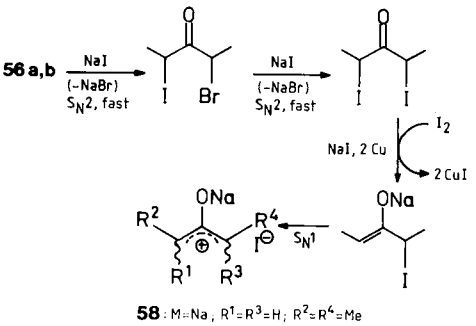
to this rule are reactions of polybromoketones, *e.g.* **56d**, which reacts with triethyl borate, unactivated zinc dust, and cyclopentadiene to give **70**, **71**, and **22a**; **72** is not formed. Brominated products **70** and **71** may be reduced to **22a**. The triethyl borate/zinc procedure is especially useful for structurally simple species including 1,3-dibromo-2-butanone **56e**. Because of the formation of *mono*-debrominated adducts, *e.g.* **75**, from dibromoketone **56e**, the reaction presumably involves initial proton loss from **56e** and formation of boron enolate **76**, which goes on to ionize with intramolecular assistance by oxygen. Consistently, attempts to use tetraalkylated α,α′-dibromoketones, *e.g.* **56c**, which cannot form a boron enolate by proton loss, were not successful[3b].

α,α′-Dibromoketones have also been reduced by iodide ions, especially from sodium iodide, in the presence of metallic copper as a scavenger for the molecular iodine formed. This procedure has been useful in mechanistic studies (Section 4.3) and also in reactions with electron-rich dienes, such as simple pyrroles (**77** → **78**)[31]. The pos-



a R=H, R′=Me;
b R=Me, R′=H

tulated reactive intermediate is sodium oxyallyl **58**, M = Na (Scheme 6)[32]. By comparison, the corresponding zinc oxyallyl species (from **56a,b** + Zn/Cu) and lithium

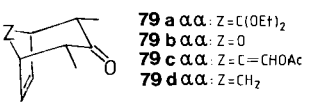


58: M=Na, $R^1=R^3=H$; $R^2=R^4=Me$

Scheme 6. Intermediates in the reaction of **56a,b** with NaI/Cu.

oxyallyl species (from **56a,b** + LiI/Cu) are more electrophilic than **58**, M = Na, and react with pyrroles **77** to give products of class C, *i.e.* electrophilic substitution. If zinc oxyallyl and iron oxyallyl are to react with pyrroles in a manner analogous to the formation of **78a,b**, the substituent R on nitrogen in **77** must be electron-attracting, *e.g.* R = CO_2Me, in order to slow down fragmentation [class B, reverse of step 2)].

The NaI/Cu procedure has also been carried out with the two-phase system acetonitrile/pentane for the capture of the reactive 5,5-diethoxycyclopentadiene (which is prone to dimerization via Diels-Alder reaction) to afford *cis*-diequatorial **79aαα**[32]. A detailed procedure for the

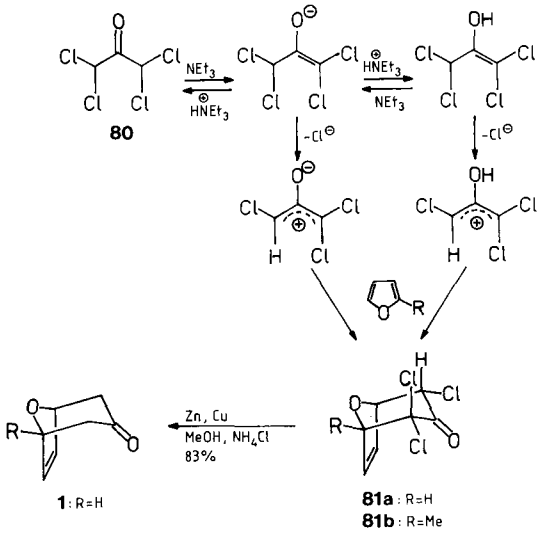


79a αα: Z = $C(OEt)_2$
79b αα: Z = O
79c αα: Z = C=CHOAc
79d αα: Z = CH_2

preparation of **79bαα** has been published in Organic Syntheses[33]. Finally, reaction of 6-acetoxyfulvene affords not only **79cαα**, but also some αβ-isomer (αα : αβ = 5.2 : 1; class B, Section 4.3.2)[32].

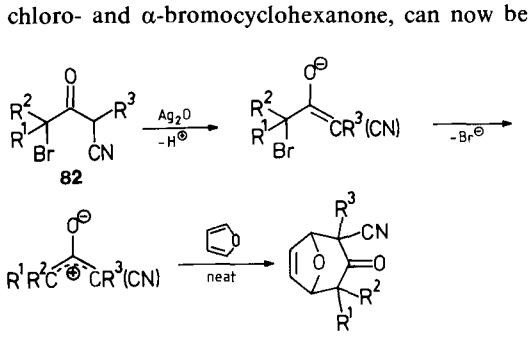
2.4. α-Haloketones and Bases

Although α-monohaloketones are less expensive and easier to handle and prepare than α,α'-dihaloketones, the doubly activated dibromoketones have until recently been much more important preparatively than their singly activated analogues. However, as shown by *Föhlisch,* in particular, α-monohaloketones do have a useful role to play, especially in reactions with electron-rich furans, which may be used in excess, *e.g.* as a co-solvent.



Commercially available 1,1,3,3-tetrachloro-2-propanone **80** or its tetrahydrate reacts with a methanolic solution of furan at room temperature in the presence of triethylamine to give **81a** in 54% yield, which in turn can be reduced to **1**. This sequence is probably the most economic route to **1** at present. With 2-methylfuran, **81b** is formed regioselectively[2], consistent with a class B process in which the less encumbered CC bond is formed in the first, intermolecular step to give the more stable intermediate.

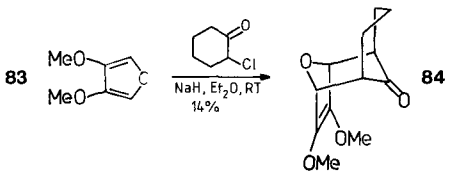
However, for a number of monohaloketones reactions in methanol are slow and hence the latter may compete with furan for electrophilic intermediates. By using 2,2,2-trifluoroethanol (TFE) as solvent—which is much less nucleophilic and has high ionizing power—and triethylamine or sodium 2,2,2-trifluoroethoxide as base, the yields of cycloadducts increase; cyclic α-haloketones, such as α-chloro- and α-bromocyclohexanone, can now be used[34].



Scheme 7.

α-Bromoketones also react with $AgBF_4/NEt_3$ in acetonitrile or neat furan[35], and the more acidic γ-bromo-β-oxonitriles **82** have been dehydrohalogenated with Ag_2O[36] (Scheme 7). A recent variant uses inexpensive $LiClO_4/NEt_3$ in diethyl ether. The progress of the reaction can be monitored by following the precipitation of $NEt_3H^+Cl^-$ or $NEt_3H^+Br^-$, which are insoluble in the reaction medium[37]. Presumably, relatively electrophilic lithium oxyallyl cations (**58**, M = Li) are intermediates in this reaction, because leakage into products of extended attack is quite noticeable (see also Section 4.3.1).

Perhaps the most nucleophilic diene investigated to date, which necessarily must be captured by a very weakly electrophilic allyl cation equivalent if a class C reaction is to be avoided, is the highly sensitive 3,4-dimethoxyfuran



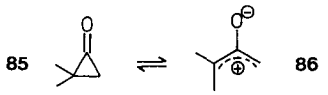
83. Using α-chlorocyclohexanone and the strong base NaH, *Eugster* et al.[38] have prepared **84** in 14% yield.

Summarizing, the base-induced reaction of α-haloketones tends to generate weakly electrophilic intermediates which react specifically with furan and other nucleophilic dienes (see Section 4.3.2 for the special case of **148**).

2.5. Cyclopropanones and Related Species

2.5.1. Cyclopropanones

Cyclopropanones and their cycloadditions are of theoretical interest, but for work on a preparative scale these small ring compounds are impractical, because they are not generally accessible and are too difficult to handle. 2,2-Dime-



thylcyclopropanone **85** is obtained readily from dimethylketene and diazomethane and has been studied most thoroughly: it adds to furan, cyclopentadiene, 6,6-dimethylfulvene, and the relatively nucleophilic *N*-methylpyrrole, but fails to react with anthracene and, of course, butadiene[39]. Parent cyclopropanone cannot be used; in this respect it is similar to the unsubstituted allene oxide (Section 2.5.2) and to 1,3-dibromopropanone/Zn[5] or $Fe_2(CO)_9$[6], but is *unlike* 2-alkoxyallyl bromide/$AgOCOCF_3$[1,9]. The reactive intermediate in cycloadditions involving cyclopropanones—if there is an intermediate—is unlikely to be a planar oxidoallyl cation such as **86**. One reason is that the separation of positive and negative charge in **86** would be energetically too costly (cf. also **148**). An 8-electron transition state with Möbius geometry[5] remains an attractive possibility for concerted cycloadditions of cyclopropanones to dienes. Such a transition state would also be consistent with the failure of cyclopropanones to react with less nucleophilic dienes such as anthracene and butadiene.

2.5.2. *Allene Oxides (Methyleneoxiranes)*

A variety of allene oxides (methyleneoxiranes) have been generated, studied, and characterized in recent years. These highly reactive heterocycles serve as a crude model for a completely bridged ion **2a** and, like the valence tautomeric cyclopropanones, may cycloadd to dienes provided that the developing positive charge can be sufficiently stabilized by substituents. For **87c**, seven-membered adducts have been prepared with cyclopentadiene (**87c** → **73c**), furan, and methyl-1-pyrrolecarboxylate (Table 4). **87a** and cyclopentadiene do not afford **73a**, but instead the product of electrophilic substitution **88a**[40]. This is in contrast to 2-methylcyclopropanone, which cycloadds to cyclopentadiene and furan, although probably in low yield[39]. The regioselectivity of the reaction of cyclopentadiene with **87a** and **87b** is not in accord with a planar oxidoallyl intermediate (cf. also **86**), which should be attacked at the *less* alkylated terminus in a late, product-like transition state. Rather, cyclopentadiene behaves as a nucleophile and attacks the quite electrophilic carbon of the highly strained allene oxide ring[40].

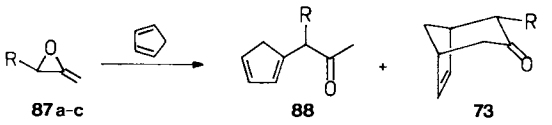


Table 4. Yields in the addition of methyleneoxiranes **87** to cyclopentadiene.

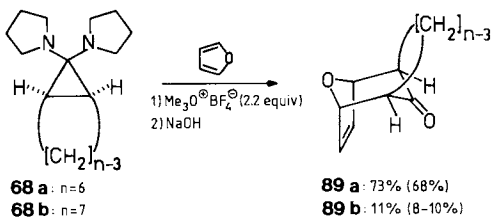
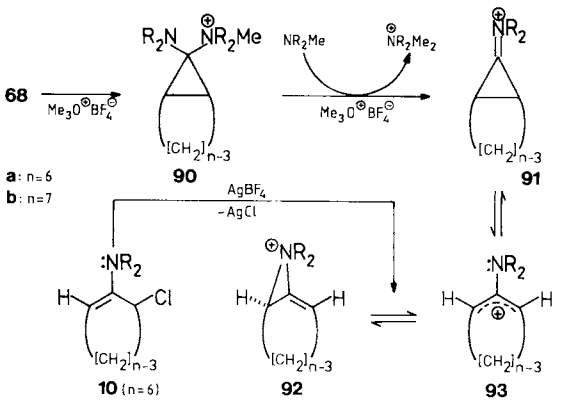
	R	Yield [%] 88	73
a	Me	30	—
b	*i*Pr	48	—
c	Ph	—	66

2.5.3. *Bicyclic Aminals*

The generation of cyclic 2-aminoallyl cations using silver salts has been described in Section 2.1. In his dissertation, *R. Schmid*[11a] has reported a second approach starting from closed, cyclopropyl cation type precursors, *i.e.* bicyclic aminals. Although both procedures may appear to be very similar mechanistically, the silver salt route affords a *higher* yield of cycloadduct **64** with anthracene (cf. **10a** in Scheme 5 as well as **68a**). With the more nucleophilic furan, yields are the same for both procedures (Scheme 8). At first sight, this difference may seem surprising. However, by starting from the monocyclic precursor **10a** and $AgBF_4$, the potentially more electrophilic valence tautomers **92** and **93** are reached earlier than by starting from the bicyclic precursor **68**. In other words, the electrophilicity of the allyl cation intermediate is again crucial for cycloadditions to anthracene—which does not add to less electrophilic cyclopropanones (Section 2.5.1)—but less so for reactions with furan.



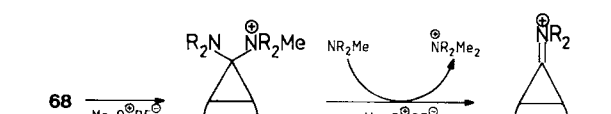
Scheme 8. Tricycles **89** from bicyclic aminals **68** and furan. (Yields in parenthesis refer to α-chloroenamine/$AgBF_4$ procedure [11a, b].)

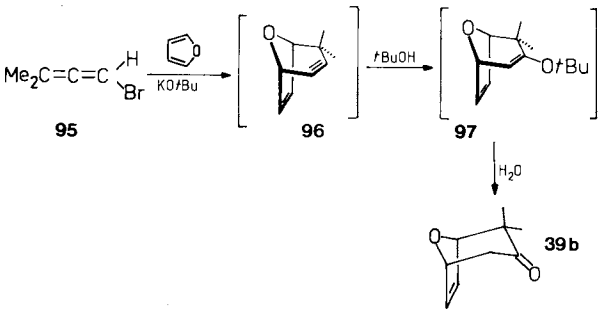


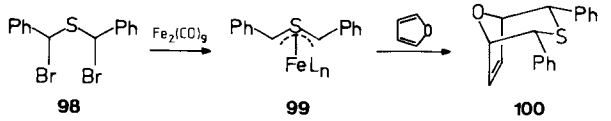
Bicyclic aminals are preparatively useful because they can be purified and stored more readily than the sensitive α-chloroenamines[11a, b].

2.6. Miscellaneous Reactions

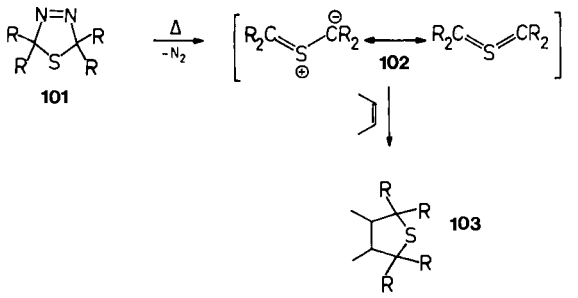
Allenic carbene **94** is isoelectronic with its protonated form **17b** ↔ **18b**, which in turn may be regarded as a didehydroallyl cation (Section 2.1). *Landor* et al.[41] have shown that dehydrobromination of **95** in the presence of furan affords a bicyclic ketone **39b** in 9% yield. Strained alkyne **96** has been postulated as an intermediate, which in the presence of *t*-butyl alcohol is thought to proceed to enol ether **97** and then to a ketone. Another reaction of theoretical interest is the dehalogenation of bis(α-bromobenzyl) sulfide **98** with $Fe_2(CO)_9$ in the presence of furan, affording **100**[42]. As an intermediate, the iron-stabilized sulfur ylide **99** has been proposed. Note that an uncomplexed sulfur ylide **102**, which may be generated by pyrolysis of a 2,5-di-



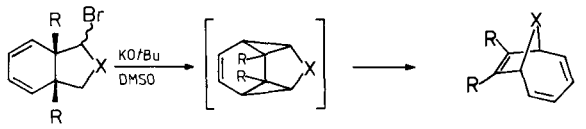




hydro-1,3,4-thiadiazoline **101**, functions as a 1,3-dipole or heteroallyl anion and hence can be trapped by olefins



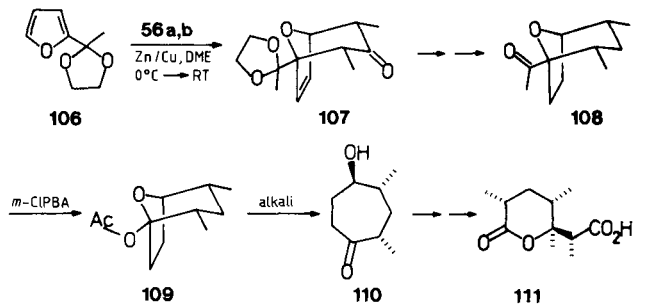
(**102** → **103**) in a 1,3-dipolar cycloaddition. *Hayami*'s work is an interesting example of an umpolung of a heteroallyl anion into a heteroallyl cation. If other 1,3-dipoles could be used in this fashion, seven-membered heterocycles would be accessible in addition to seven-membered carbocycles (cf. *e.g.* **39b**). An intramolecular variant which is possibly related to the reaction **98** → **100** (DMSO = dimethyl sulfoxide) is the base-induced rearrangement of **104** into **105**, studied by *Paquette*[43].



R = H, Me; X = CO, SO_2

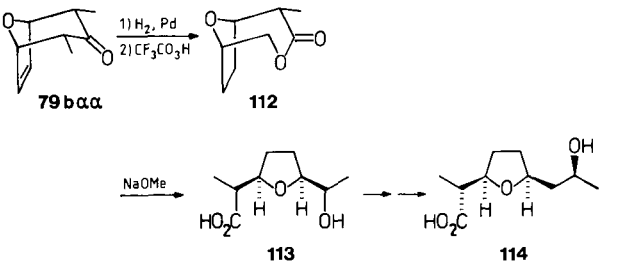
2.7. Further Applications in Synthesis

In dimethoxyethane (DME), ketalized 2-acetylfuran **106** readily affords adduct **107**, containing a bridgehead substituent. **107** has been transformed in several steps into the

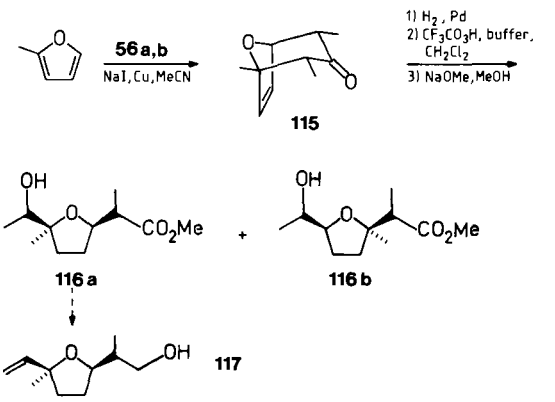


Scheme 9. Stereocontrolled synthesis of **107** and the Prelog-Djerassi lactone **111** [44].

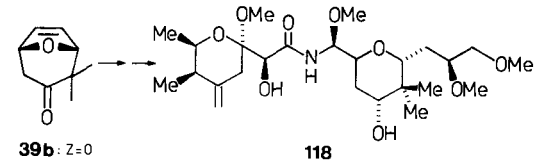
Prelog-Djerassi lactone **111** (Scheme 9)[44]. The sequence demonstrates how opening and removal of the ether bridge in **108** *via* Baeyer-Villiger rearrangement affords functionalized monocyclic cycloheptanes with defined stereochemistry. For entropy reasons it would be much more difficult or impossible to prepare a cycloheptane derivative such as **110** in a stereocontrolled fashion by reaction of an allyl cation with an open-chain diene. *White* et al.[45] have also used **79bαα**, which is simply **107** without a bridgehead substituent, to prepare nonactic acid **114**: Baeyer-Villiger oxidation of 8-oxabicyclo[3.2.1]octan-3-ones and opening of the resulting lactone **112** is clearly the method of choice for preparing *cis*-2,5-disubstituted tetrahydrofurans such



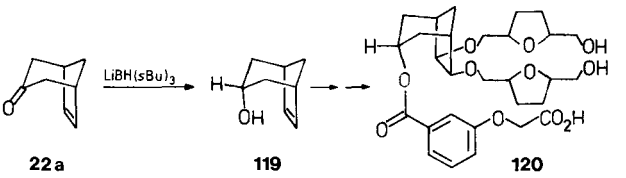
as **113**. We have used the same approach to prepare **116a** and its isomer **116b**; **116a** is a precursor for a stereoselective route to lilac alcohol **117**[46].



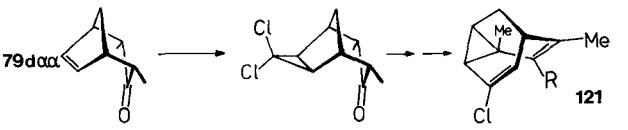
Another bicyclic ketone, namely **39b** (Z = O), has been used as starting material for a multistep synthesis of the "eastern half" of pederin **118**, which is the most complex,



known non-proteinaceous insect defensive compound[47]. The parent [3.2.1]bicycle **22a** has been elaborated in only a



few steps into the noncyclic ionophore **120**, which transports Ca^{2+} efficiently[48]; its 2,4-dimethylated homologue **79dαα** has been used by us as starting material to prepare functionalized barbaralanes **121** (Scheme 10)[49]. The two



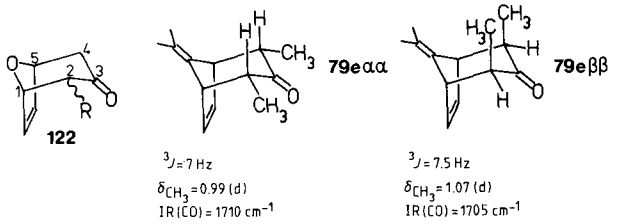
Scheme 10.

methyl groups in **121** serve as convenient "flags" in the ^{1}H-NMR spectra for determining the barrier of the degenerate Cope rearrangement.

3. Structural and Spectroscopic Properties of Bicyclo[3.2.1]oct-6-en-3-ones

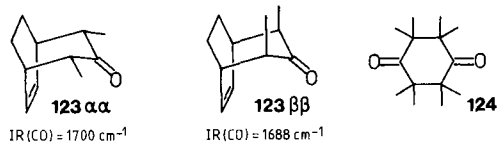
3.1. Flattening of Six-Membered Rings

The configuration of 8-oxabicyclo[3.2.1]oct-6-en-3-ones **122** which are monosubstituted at C-2 (and C-4) can readily be deduced from the coupling constants $^3J_{1,2}$. For *exo* 2-H (or 4-H), $^3J = 4.5-5$ Hz; for an *endo*, $^3J < 1.5$ Hz.



Interestingly, in **79eαα** and **79eββ**, the magnitude of the ^3J coupling constant of the methyl protons is slightly different, depending on whether the methyl groups are present in an α-configuration ($^3J = 7$ Hz) or β-configuration ($^3J = 7.5$ Hz)[32]. The smaller IR carbonyl frequency in **79eββ** can be attributed to partial flattening of the six-membered ring due to *syn*-diaxial Me···Me repulsion.

The sensitivity of the IR carbonyl frequency to conformational changes is also evident in **123ββ**[50]. **123ββ** has the flatter cycloheptanone moiety and hence smaller carbonyl frequency than epimeric **123αα**. The highly crowded,



bridged anthracene adduct **60c** adopts an almost C_{2v} conformation in the crystal: the five contiguous carbon atoms originating from the 2-oxopropanediyl bridge and the two quaternary bridgehead carbons are almost coplanar! A slight pyramidalization of the carbonyl group has also

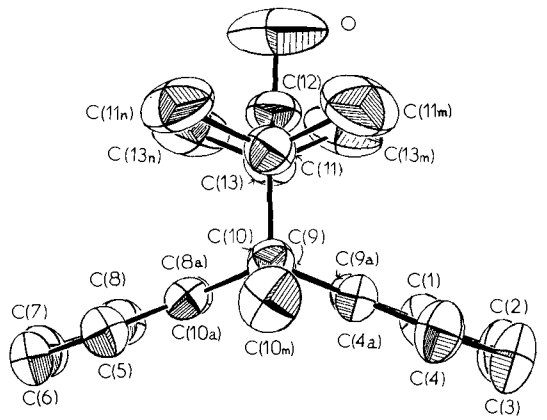


Fig. 1. Structure of **60c** in the crystal; view along the two planes of the benzene rings.

been detected (Fig. 1)[51]. 2,2,3,3,5,5,6,6-Octamethylcyclohexane-1,4-dione **124** also adopts a very flat C_{2v} chair conformation, as can be seen more clearly in the Newman projection (Fig. 2)[52].

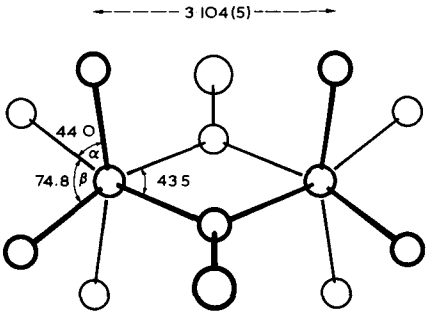

Fig. 2. Newman projection of **124**.

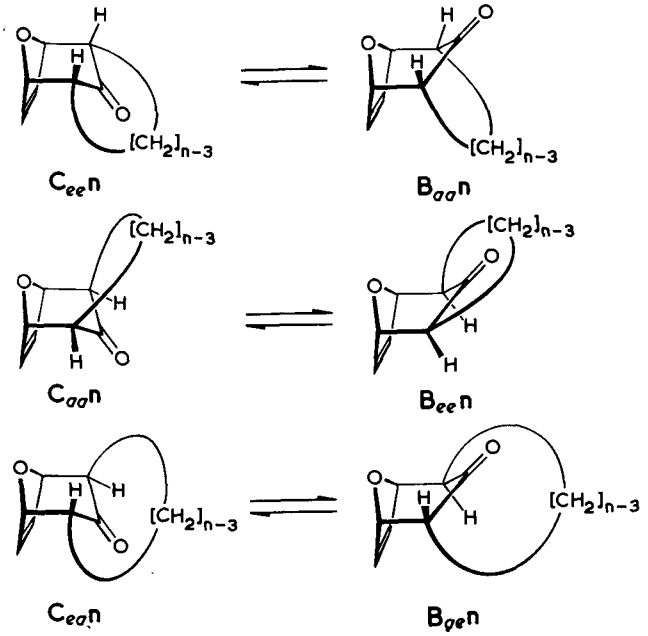
3.2. Conformational Mobility of Six-Membered Rings

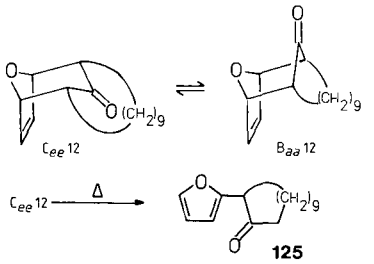
The effect of the methylene chain $(CH_2)_{n-3}$ on the shape of the six-membered tetrahydropyranone moiety can be seen in 2,4-bridged 8-oxabicyclo[3.2.1]oct-6-en-3-ones. A priori, the six-membered ring may be present in a chair conformation C and in a boat conformation B. Depending on the number (n − 3) of methylene groups, the six-membered ring can be deformed in almost predictable fashion. If the methylene chain is long enough (n ≧ 12), it may be attached *cis*-diequatorially (*ee*), *cis*-diaxially (*aa*) and equatorially-axially (*ea*), to either chair C or boat B. Accordingly, we have designated the various stereoisomers and their conformational relationship by simple, self-evident nomenclature (Scheme 11)[53].



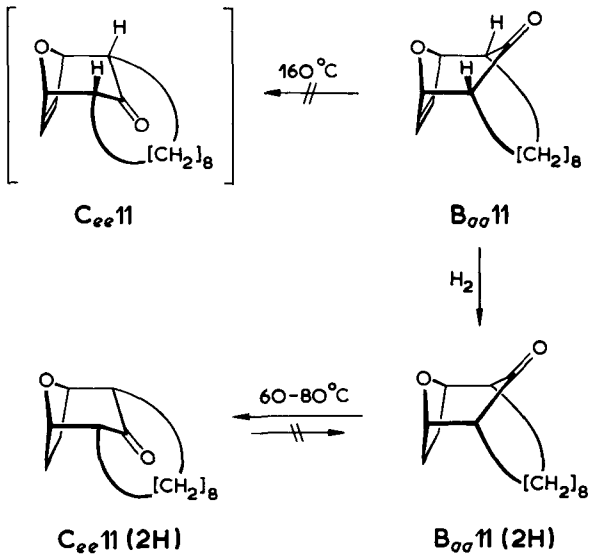
Scheme 11. Nomenclature for conformationally mobile tricycles.

A complete line-shape analysis has demonstrated the dynamic equilibrium $C_{ee}12 \rightleftharpoons B_{aa}12$. In CCl_4, $\Delta G^{+} = 16.0$ kcal/mol and $\Delta S^{+} = 1.5$ cal K^{-1} mol^{-1}, whereas in more polar solvents the more polar $B_{aa}12$ is favored progressively; in fact, the equilibrium $C_{ee}12 \rightleftharpoons B_{aa}12$ can be used as a

criterion for solvent polarity. The existence of $B_{aa}12$ can be ascribed to relief of nonbonding repulsion in $C_{ee}12$, *i.e.* the six-membered ring in $C_{ee}12$ is forced into a strained conformation by the methylene loop, and the carbonyl group is buried below the loop. The strain in $C_{ee}12$ has a chemical consequence, also: on being heated at 70°C, especially under the influence of acid, $C_{ee}12$ fragments to **125**, the product of a class C reaction. In contrast, the epimeric $C_{aa}12$ is comparatively stable under these conditions.

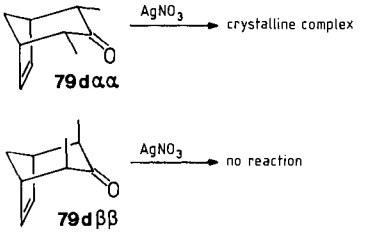


Predictably, the barrier to interconversion of the next higher homologue $C_{ee}13 \rightleftharpoons B_{aa}13$ is substantially lower ($\Delta G^{+} < 9$ kcal/mol), and there is a greater bias towards population of $C_{ee}13$. In contrast, $B_{aa}11$, which has a tighter methylene bridge than $B_{aa}12$, exists as a stable boat and does not show any tendency to spill over into chair $C_{ee}11$ on being heated to 160°C. After hydrogenation of the CC double bond, the crowded $B_{aa}11(2H)$ is isolated; however, on being heated to 60–80°C it is cleanly converted into the more stable chair rotamer $C_{ee}11(2H)$ ($E_a = 26.8 \pm 0.5$ kcal/mol, $\log A = 13.6 \pm 0.1$). A kinetic barrier of this magnitude allows us to describe $B_{aa}11(2H)$ and $C_{ee}11(2H)$ as discrete boat and chair atropisomers, *i.e.* in this case we may isolate two compounds which differ only in the conformation of the six-membered ring (Scheme 12). Hydrogenation of conformationally dynamic $C_{ee}12$ yields conformationally static $C_{ee}12(2H)$, but no $B_{aa}12(2H)$[53].

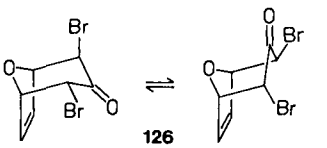


Scheme 12. Boat and chair atropisomers in bridged six-membered rings.

What is the reason for the special conformational behavior of these tricycles? The presence of the unsaturated bridge flattens the six-membered ring and causes concomitant strain in $C_{ee}12$, and more so in $C_{ee}11$. Conversion of the etheno into the ethano bridge lengthens the 2C bridge, and the previously deformed six-membered ring relaxes into a better developed chair.



Half-sided flattening of the six-membered ring by the etheno bridge shows up in another unexpected way: of the epimeric pair **79daα** and **79dββ**, the latter is thermodynamically less stable because of *syn*-diaxial repulsion of methyl groups. The mixture of the two isomers can be separated by treatment with aqueous silver nitrate, which selectively complexes the CC double bond of the thermodynamically *more stable* **79daα**. Presumably, silver nitrate complexation of the ββ-epimer is unfavorable because concomitant lengthening of the CC double bond—similar to hydrogenation of the tricycles—would destabilize it further by increasing *syn*-diaxial repulsion of the methyl groups[20,32].



Finally, **126** has been reported to show two IR carbonyl bands at 1734 and 1747 cm^{-1}[54] ($CHCl_3$). A dynamic equilibrium between chair and boat forms provides a possible rationale.

4. Electrophilic Intermediates and Reaction Mechanisms

4.1. The Nucleophilic Anchor Y

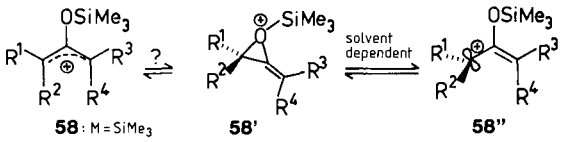
The stabilization of intermediate metal enolates as well as allyl cations by terminal alkyl groups and also by chlorine and bromine atoms (cf. reactions of polyhaloketones) needs no further comment. The exceptional position of 2-alkoxyallyl cations, *e.g.* derived from 2-methoxyallyl bromide, has also been stressed. The yield and type of product are also influenced profoundly by the group Y attached to the central carbon of the allyl system. What is the effect of Y on the structure of the allyl cation? How early or how late does Y intervene as a nucleophile? In the following, a few pertinent examples of groups Y will be discussed.

4.1.1. Oxygen as Heteroatom (Y= OM, OR); Allylic Resonance versus Oxygen Participation

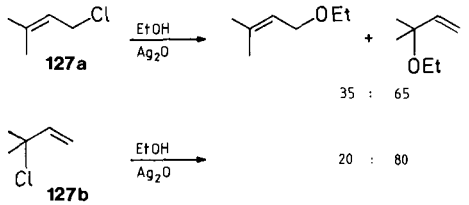
Although we have formulated oxyallyl cations as planar and delocalized (cf. **2**), rotation and a valence tautomeric change to perpendicular **2a** cannot easily be discounted. In fact, two special features of 2-oxidoallyl cations are

consistent with the existence of some oxygen participation in favorable cases.

Resistance to Elimination of Highly Alkylated Metal Oxyallyl Cations: Highly alkylated, conventional allyl cations enter easily into E1-like reactions to form dienes. For example, if the elimination product **42** from **41** is to be avoided, a low temperature and the absence of hindered tertiary amine are required[23] (cf. also conversion of **45** into **46**). In contrast, no significant elimination has been encountered with the 2-ethoxyallylic precursor **38** in the presence of amine under the same conditions[21] nor with permethylated metal oxyallyl cations at higher temperature. Thus, the reaction with anthracene to give **59c** and **60c** gave good yields in refluxing benzene (b.p. 81 °C)! We suggest that an E1 reaction—proton loss under neutral or acidic conditions—of conventional allyl cations is favored by uncoupling the π allyl overlap; in this way the proton to be lost becomes more acidic (see also formation of **143** from **139c** in Section 4.1.4). Such an intended elimination is prevented in metal oxyallyl cations such as **58**, M = $SiMe_3$, because on rotation the positive charge is partially anchored at oxygen as in **58'** and **58''**: **58'** is a valence tautomer and **58''** a rotamer.

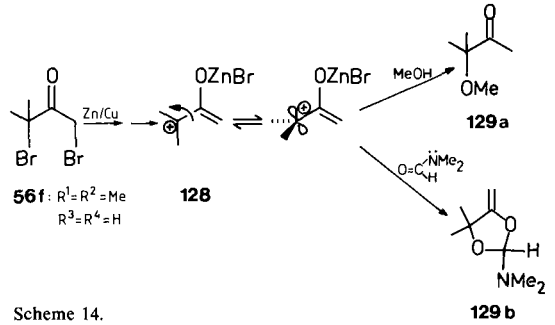


Regioselectivity of Metal Oxyallyl Cation Capture: Generally, solvolysis of unsymmetrically substituted allylic halides, even under S_N1 conditions, affords two regio-isomers. For example, the isomeric precursors **127a** and **127b** give different ratios of product (Scheme 13). The so-called



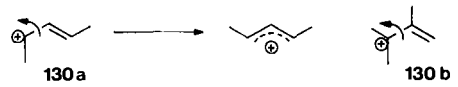
Scheme 13. Regioselectivity of capture of conventional allyl cations under S_N1-like conditions.

product spread, amounting to 15% in this example, is characteristic for conventional allylic halides and is inconsistent with a common intermediate in both reactions[55]. In contrast, the reaction of metal oxyallyl cations with nucleophiles in polar solvents is regioselective; for example,



Scheme 14.

only the more stable tertiary terminus in **128** is uncoupled in methanol[56a] (cf. formation of **129a**) and in *N,N*-dimethylformamide [cf. **129b**, the formation of which involves initial attack by the nucleophilic oxygen of dimethylformamide (DMF)] (Scheme 14)[56b]. Is the postulated perpendicular metal oxyallyl species just a rotamer with a long carbon-oxygen bond (*e.g.* **58''**) or is it a discrete methyleneoxiranium ion (*e.g.* **58'**)? Necessarily, uncoupling of π allyl overlap depends on several factors including temperature, electron demand of the metal, solvent polarity, and substitution pattern. The rotational barrier in **130a** (24

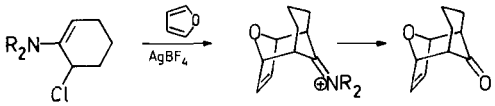


kcal/mol)[57a] and the much lower barrier in **130b** (12.9 kcal/mol)[57b], which contains a tertiary terminus, should be borne in mind. In fact, ion **128**, which is related to ion **130b**, appears to be one of the best candidates for oxygen participation at present[57c].

4.1.2. Nitrogen as Heteroatom (Y = NR_2)

In the series of chloroenamines **10** the nucleophilic center is nitrogen (Y = NR_2), and only the alkyl groups attached to nitrogen vary. Nonetheless, as shown by *Schmid*[11a,b] the yield of furan adduct **132** changes, being highest (68%) for α-chloropyrrolidineenamine **10a**, which works much better than acyclic dimethylaminoenamine **10b**, morpholinoenamine **10c**, and piperidinoenamine **10d** (Table 5). The decreasing yield along this series parallels

Table 5. Cycloadducts **132** by reaction of 2-amino-3-chlorocyclohexenes **10** and furan in the presence of $AgBF_4$ [11a, b].

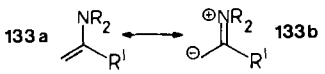


R_2N		$\delta(^1H)$ [a]	**132**, Yield [%]	Ref.
10a		4.4	68	[58a]
10b	Me_2N	ca. 4.5	37	[58b]
10c		4.65	23	[58a]
10d		4.7	20	[58a]

[a] ^{1}H-NMR signal of the olefinic protons.

the ratio of *C*-alkylation/*N*-alkylation of the corresponding enamines (without chlorine) and reflects:

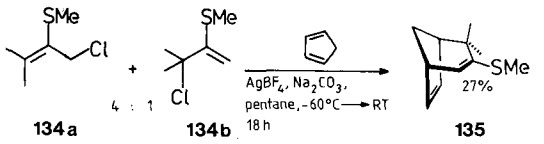
1) the well-known reactivity of enamines toward electrophiles,
2) the ^{1}H-NMR chemical shift of the terminal olefinic protons, and
3) the ^{13}C-NMR chemical shift of the olefinic carbons.



In other words, p,π overlap and carbon nucleophilicity—represented by dipolar form **133b**—drop along this series. Again, the question—early or late intervention of the nucleophilic group NR_2—cannot be answered definitively. Clearly, nucleophilic participation of $Y=NR_2$ depends not only on substituents R, but also on ring size n: it is more favorable for n=6 than for n=5, because strain in the corresponding ammonium ion **92** is smaller.

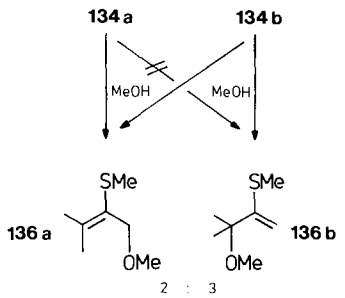
4.1.3. Sulfur as Heteroatom (Y=SR)

From the point of view of synthesizing seven-membered carbocycles, 2-methylthioallylic halides are not promising. By analogy to **40a**, **134a,b** is readily accessible and affords **135**[59], but the yield (27%) is not much better than

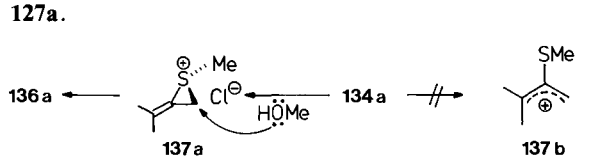


the total yield for the reaction of structurally related **35a** with cyclopentadiene. With furan, **134** affords products of class C only, analogous to the formation of **48a,b** from **47**.

Nonetheless, as *Schöllkopf* and *Riefling*[59] have shown, 2-alkylthioallyl halides are of mechanistic interest since the highly nucleophilic sulfur is able to participate in 1,3-interactions (cf. **2a**). Methanolysis of the primary chloride **134a**

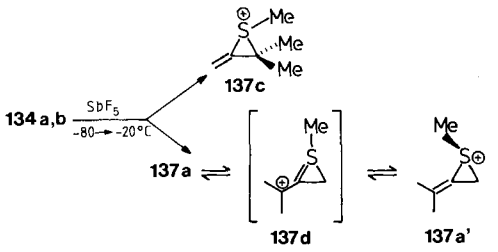


produces the primary ether **136a** regiospecifically, whereas the tertiary chloride **134b** furnishes primary and tertiary ethers in a ratio of 2:3. If methanolysis were to yield planar and delocalized allyl cation **137b** directly, we would expect tertiary **134b** to react about three times faster than its primary isomer **134a**, by analogy to **127b** and **127a**.



In fact, the converse applies: the primary chloride **134a** is solvolyzed about ten times *faster* than tertiary **134b**. Control experiments in the presence of sodium methoxide suggest that it is unlikely that methanolysis of **134a** and **134b** is an S_N2 reaction. Instead, sulfur participation with generation of the methylenethiiranium ion **137a** provides a simple explanation for the enhanced rate of **134a** and regiospecific formation of **136a**. The solvolysis of the tertiary chloride **134b** is more complex mechanistically since **134b** may ionize, at least in part, without participation of sulfur to give the observed mixture of isomeric allyl ethers **136a** and **136b**. Hence, allyl cation **128** and the cations derived from **127a** and **127b** as well as from **134a** and **134b** are all subtly different, although they all have the same basic isoprenoid carbon skeleton.

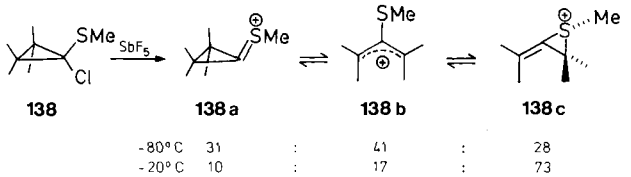
Schöllkopf and *Riefling*[59] have also investigated the ionization of **134a** + **134b** in SbF_5 from −80 to −20°C by ^{1}H-NMR spectroscopy and concluded that two isomeric allene-episulfonium ions **137a** and **137c** are present. The



temperature-dependent ^{1}H-NMR spectrum of **137a** suggests the possibility of a facile inversion at the pyramidal sulfur atom.

The barrier to inversion has been estimated to be *ca.* 8—10 kcal/mol[59], which is *ca.* 16 kcal/mol lower than the normal barriers to inversion of sulfonium sulfur[60]. Inversion appears to be coupled with *E/Z* exchange of the terminal methyl groups. An effective interaction of a vacant d-orbital on sulfur with the olefinic π system probably requires that the sulfonium sulfur attain trigonal planar geometry (cf. **137d**). Again, the planar delocalized allyl cation **137b** is not detectable under these conditions[59].

Finally, the temperature-dependent ^{1}H-NMR spectrum of the cations produced by ionization of **138** (Scheme 15) suggests that all three valence tautomers **138a-c** are present. With increasing temperature **138c** increases at the ex-



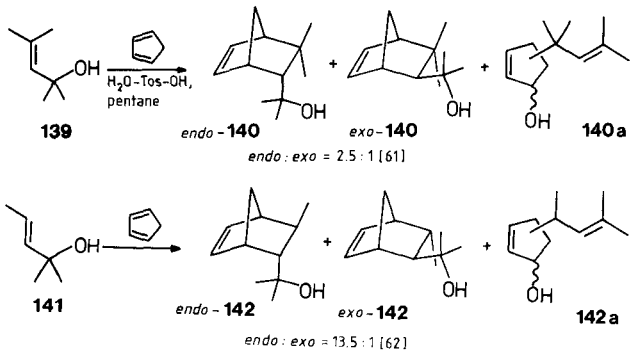
Scheme 15. Ratio of valence tautomers from ionization of **138** at −80°C and at −20°C.

pense of **138a** and **138b** (**138a** → **138b** → **138c**). On the basis of its NMR spectrum, the thiocyclopropyl cation **138a** has been proposed to be *pyramidal* rather than planar at the carbenium center; in this way, $2sp^x$-3p(S) overlap is maximized, with little if any $2sp^x$-2p(S) overlap, which is antibonding[59]. Finally, whereas we have discussed the stabilization of positive charge by 1,3-interactions, the possibility of stabilization by 1,5-interactions has hardly been exploited (cf. **76**).

4.1.4. Allyl Cations as Dienophiles in Diels-Alder Reactions

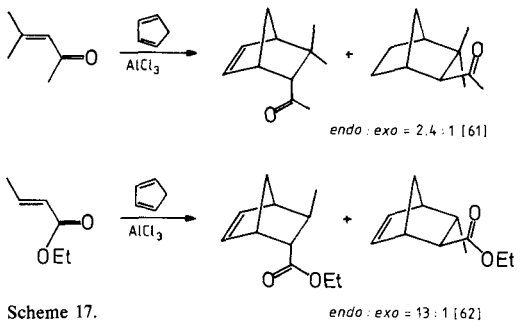
Having dealt with allyl cations containing a very nucleophilic group (Y=SMe), we now turn to the case Y=H.

Clearly, formation of seven-membered rings on reaction with 1,3-dienes is now unfavorable, the hypothetical product being a secondary cation. Instead, the two-phase reaction of allyl alcohols **139** and **141** furnishes six-membered rings, *i.e.* norbornenylmethanols **140**[61] and **142**[62] in addition to **140a** and **142a**, respectively (Scheme 16). Detailed mechanistic investigations suggest that cycloadducts **140** and **142** are formed via stepwise, pull-push Diels-Alder reactions. A stepwise process is also reasonable, because the central carbon atom of a planar allyl cation contains a node in the LUMO, so that there should be no initial bonding to this atom. Interestingly, compounds of type **140a** and **142a**—which are virtually unknown in conventional Diels-Alder additions to cyclopentadiene—correspond to products of class C in the synthesis of seven-membered carbocycles from allyl cations and 1,3-dienes (see *e.g.* Scheme 3).

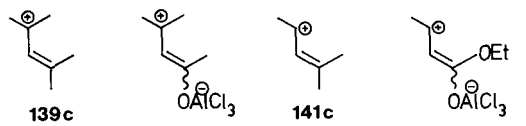


Scheme 16.

The $AlCl_3$-catalyzed Diels-Alder reaction of mesityl oxide or crotonic ester to cyclopentadiene yields *endo/exo* adducts in the ratio 2.4:1 and 13:1, respectively (Scheme 17). Since similar key cationic intermediates (cf. Scheme 18) can be formulated for the reactions in Schemes 16 and 17, and the *endo* selectivity of both sets of dienophiles is almost identical, we have concluded that the two $AlCl_3$-catalyzed Diels-Alder reactions are also stepwise, pull-push processes[61,62].

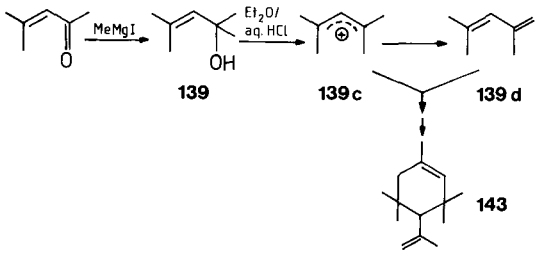


Scheme 17.



Scheme 18.

In the absence of cyclopentadiene, allyl alcohol **139** has been cyclized to tetramethyllimonene **143**, which, starting from mesityl oxide, can be prepared in quantities of at least 60 g per batch (Scheme 19). Although **143** may be regarded formally as the Diels-Alder dimer of 2,4-dimethyl-1,3-pentadiene **139d**, it is, in fact, formed by combination of **139c** and **139d** in a multistep reaction which resembles the biosynthesis of parent limonene[63]. The tetramethylallyl cation **139c**—which must be nonplanar because of steric repulsion of the two *Z*-methyl groups—is readily deprotonated to diene **139d**, *unlike* structurally related metal oxyallyl cations (see, *e.g.* **58**, $M=SiMe_3$; $R^1=R^2=R^3=R^4=Me$ and Section 4.1.1) which have been generated and captured by anthracenes to give **59c** and **60c** at temperatures as high as 80°C.



Scheme 19. Biomimetic one-pot preparation of **143** from mesityl oxide.

4.2. Guidelines for Reactions of Allyl Cations and 1,3-Dienes

Currently known experimental facts and the mechanistic discussion to follow are summarized in the following.

1. Furan, more than cyclopentadiene, favors the compact mode of cycloaddition[5].
2. The electrophilicity of oxyallyl intermediates decreases along the series iron oxyallyl > siloxyallyl > zinc oxyallyl $\gtrsim$ lithium oxyallyl > sodium oxyallyl > cyclopropanone ("oxidoallyl").
3. For reactions within class A and reactions near the A/B border, the more electrophilic allyl cation intermediate has the greater propensity toward extended attack of the diene[5].
4. With increasing electrophilicity of the allyl cation, class B and finally class C reactions are promoted. Conversely, decreasing electrophilicity of the allyl cation requires increasing nucleophilicity of the diene for a class A and class B cycloaddition to occur. Nonplanar allyl cations with poor orbital connectivity must react via classes B and C.
5. A reaction of a structurally defined cation belongs at most to two classes, *i.e.* classes A and B or classes B and C. Thus, formation of class C products precludes class A as a source of cycloadducts and conversely, operation of a class A reaction makes it unlikely that products of class C are formed[*].

4.3. Stereochemistry and Product Type; Criteria and Assignment of Classes A, B, and C

4.3.1. Compact versus Extended Transition States; Class A Requirements

Reaction of 2,4-dibromo-3-pentanone **56a,b** with cyclopentadiene in the presence of three different reducing

[*] This postulate may also be useful for locating Diels-Alder reactions which proceed stepwise; cf. formation of **140a** and **142a**.

agents and under quite different experimental conditions (Table 6) is stereoselective: only *ee*-adducts **79dαα** and *aa*-

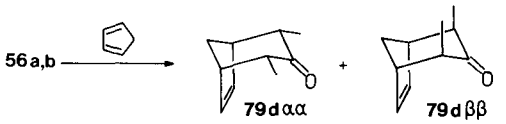


Table 6. Ratios of compact to extended transition states (αα : ββ) in the cycloaddition of cyclopentadiene to 2,4-dibromo-3-pentanone **56a,b** *via* various oxyallyl intermediates.

Method	αα : ββ	Ref.
NaI/Cu, MeCN	6.4 : 1	[32]
2-Bromo-3-pentanone instead of **56a,b**; $LiClO_4$, NEt_3	1.9 : 1	[64b]
Zn/Cu, DME, 0–25 °C	1.7 : 1	[32]
$Fe_2(CO)_9$, C_6H_6	0.89 : 1	[64a]

adducts **79dββ** are formed. There is no leakage into the *ea*-epimer **79aβ**. The $Fe_2(CO)_9$ induced reaction of **56g** ($R^1 = R^3 = i$Pr; $R^2 = R^4 = H$) proceeds analogously, giving *ee*- and *aa*-adducts only, in a ratio 1 : 1[64]. Even the reaction of tetrabromoacetone **56d** with cyclopentadiene via the $(EtO)_3B$/Zn procedure affords *ee*-adduct **70** and *aa*-adduct **71**, but no *ea*-adduct **72**[16b]. These experimental findings are all the more striking when compared with the furan cycloadditions in Section 4.3.2, and they suggest simultaneously that

a) W-configurated allyl cations **58** ($R^1 = R^3 = H$) are generated stereoselectively as the only significant species and
b) these ions are captured by cyclopentadiene via compact and extended transition states[5] in a class A reaction.

In other words, the *ee* : *aa* ratio is identical to the steric course of attack, *i.e.* compact versus extended. Invoking the principle that the more electrophilic allyl cation has the greater propensity toward extended attack (Section 4.2), we conclude that sodium oxyallyl is the weakest electrophile and iron oxyallyl the strongest (Section 4.2). On the basis of this theory, any oxyallyl cation which gives a compact : extended ratio smaller than 0.89 : 1 in the reaction with cyclopentadiene must be considered to be more electrophilic than iron oxyallyl.

4.3.2. Loss of Allyl Cation Configuration; Sufficient Criterion for Class B

In the presence of furan, dehalogenation of **56a,b** with three different reducing agents affords all three epimeric cycloadducts: **79bαα**, **79bββ**, and **79bαβ** in varying amounts (Table 7). The marked loss of allyl cation configuration (21.3% αβ adduct) in the reaction with 3,4-dimethylfuran should also be noted. Leakage into α,β epimeric cycloadducts has been found inter alia for reactions of **56a,b** with *N*-methoxycarbonylpyrrole[64] and with 6-acetoxyfulvene[32] using $Fe_2(CO)_9$ and NaI/Cu, respectively. We have suggested that W-configurated allyl cations are generated initially, but that they partially lose their configuration once an intermediate of type **4** has been generated: attack

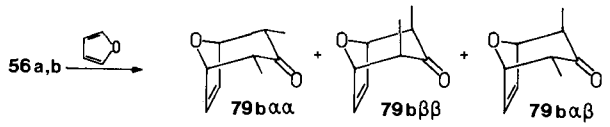

Table 7. Epimer ratios in the cycloaddition of furan and 3,4-dimethylfuran to 2,4-dibromo-3-pentanone **56a,b** in the presence reducing agents.

Reducing-agent	Solvent	Epimer ratios αα	ββ	αβ
NaI/Cu	MeCN	90.9	3.0	6.1

144b, base	53.9	4.1	93 : 7			[37]

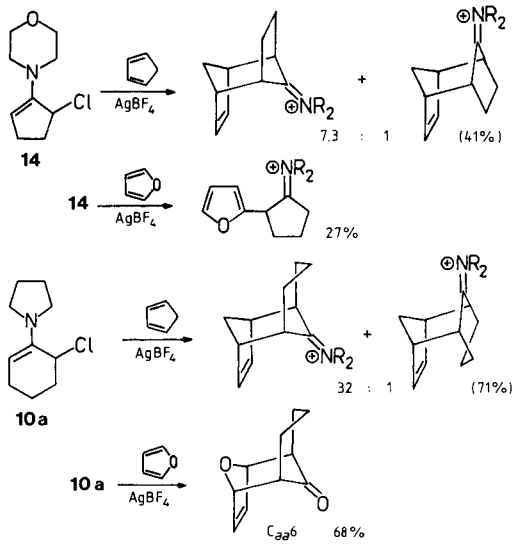
[a] 2-(2-Furyl)cyclododecanone. [b] The numbers are product ratios and not absolute yields. [c] Extended transition state.

The preparation of the conformationally dynamic tricycle $C_{ee}12$ (see Section 3.2) by three different routes is also instructive (Table 8): zinc oxyallyl furnishes $C_{ee}12$ (presumably via a W-configurated allyl cation and a compact transition state) as a major product in addition to $C_{aa}12$ (which probably arises via an extended transition state giving $[B_{ee}12] \rightarrow C_{aa}12$) in a ratio 6 : 1. There is also leakage into $C_{ae}12$ and products of class C. Less electrophilic sodium oxyallyl is more selective (compact : extended = 9 : 1), and the base catalyzed reaction of α-bromocyclododecanone with furan is similar. Thus, the reactivity-stereoselectivity relationship (Section 4.2) holds, although at least some reactions belong without doubt in class B.

On the other hand, the most electrophilic species, *i.e.* iron oxyallyl from the Noyori reaction, does not give any $C_{ee}12$, but mainly $C_{ae}12$ (45%) and some $C_{aa}12$; products of class C are now more prominent than in any of the other procedures (cf. Section 4.2).

A beautiful example linking stereochemistry and product type with electrophilicity of the allyl cation has been

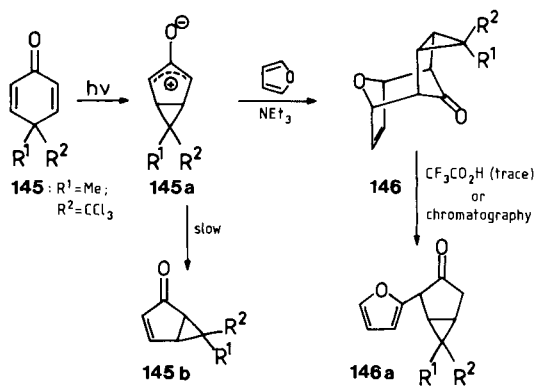
uncovered by *Schmid*[11a,b] in the reaction of cyclic 2-aminoallyl cations with cyclopentadiene and furan (Scheme



Scheme 20. Products of the reaction of 2-aminocyclopentenyl and 2-aminocyclohexenyl cations with cyclopentadiene and furan [11a, b]. Compound **14** was prepared in 80% purity and used further. With cyclohexadiene instead of cyclopentadiene, **14** forms the two stereoisomeric adducts in *ca.* 30% yield: *C. Ganter*, personal communication; see also Scheme 2.

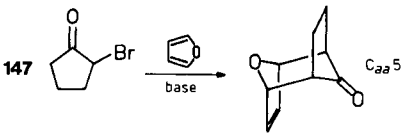
20). As expected, furan favors the compact mode of cycloaddition vis-à-vis cyclopentadiene (Section 4.2). On the basis of the reactivity-stereoselectivity relationship (Section 4.2), the morpholinocyclopentenyl cation derived from **14** (compact : extended = 7.3 : 1) is more electrophilic than the pyrrolidinocyclohexenyl cation derived from **10a** (compact : extended = 32 : 1). It is pleasing to note that this conclusion is consistent with the type of product formed from the corresponding reactions with furan: whereas the more electrophilic cyclopentenyl species affords product of class C, the less electrophilic cyclohexenyl species affords product of class B (or even class A), *i.e.* the compact adduct $C_{aa}6$ (the extended isomer is not detectable).

From a preparative viewpoint it is noticeable that the cation from **14**, *i.e.* the five-membered ring derivative, reacts only reluctantly with cyclopentadiene (41% yield) and also with furan (27% yield, only class C; see also formation of **65**). Irradiation of cross-conjugated dienone **145** generates

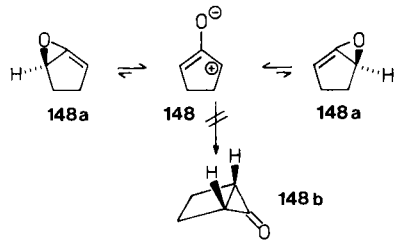


the familiar type of zwitterion **145a**, which is a substituted cyclopentenyl cation. Thanks to the presence of the trichloromethyl group ($R^2 = CCl_3$), the cyclopropane "walk" (**145a** → **145b**) is now a slow process. In the presence of furan and triethylamine, *Samuel* has isolated the highly strained adduct **146**, which is easily transformed into products of class C, *i.e.* **146a**[66].

Although parent $C_{aa}5$ itself can apparently not be made from **14** via the silver salt route (Scheme 20), it has been obtained more recently under basic conditions, *i.e.* by



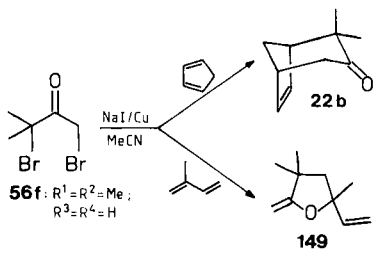
treatment of **147** with base in the presence of furan[37]. Clearly, the 2-oxidocyclopentenyl cation **148** is a special oxyallyl system; because of the high strain energy, the formation of bicyclo[2.1.0]pentan-5-one **148b** from planar **148**



is impossible (note also that polycyclic α-halocyclopentanones derived from **147** undergo base catalyzed Favorsky-type ring contraction only *via* the semibenzilic route, and not via fused cyclopropanones of type **148b**[67]). Since the generation of folded valence tautomer(s) **148a** from **148** also seems difficult, charge separation is structurally enforced: **148** and the cation derived from 2-aminocyclopentenyl chloride **14** should be comparatively electrophilic.

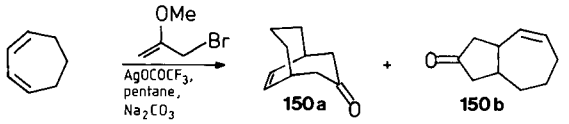
4.3.3. Electrophilic Substitution and Electrophilic Addition with Formation of Five-Membered Carbocycles and Heterocycles; Class C Reactions

The facilitation of electrophilic substitution by an increase in electrophilicity of the allyl cation (Section 4.2) needs no further comment. Likewise, the possibility of forming class C products by fragmentation of class B cycloadducts, especially by Lewis acid catalysis and at higher temperature, has been exemplified several times (*e.g.*, **146** → **146a**, **5** → **6**). Indeed, the formation of products of class C has been used throughout this article to assign class B to any concurrent cycloadditions which afford seven-membered rings (Section 4.2). Conformational factors are often responsible for a change of mechanism: Whereas reaction of **56f** with NaI/Cu and cyclopentadiene yields



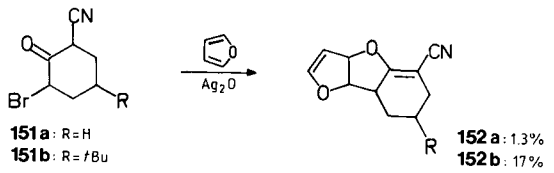
22b, reaction with isoprene affords sensitive α-methylenetetrahydrofurans, **149** being the major regioisomer (class C)[68]. The 2-alkylidenetetrahydrofuran moiety (cf. **149**,

152, and Table 6) occurs in prostacyclins, which show remarkable biological activities[69].—In contrast to the reaction of **56f** with NaI/Cu, the dehalogenation with Zn/Cu furnishes seven-membered and five-membered carbocycles[16a, 70].

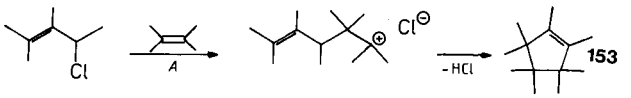


The conformationally flexible cyclohepta-1,3-diene and 2-methoxyallyl bromide yield **150a** (class B), which is a convenient precursor of the theoretically interesting manxane (bicyclo[3.3.3]undecane), as well as hexahydroazulen-2(1*H*)-one **150b** (class C) by the silver salt route[71]. More recently, we have annelated the conformationally rigid cyclopentadiene to a [3.3.0]bicycle (see **32** and analogous reaction from **35a**).

With certain oxyallyl systems, furan also participates in cycloadditions of class C (see also Table 8). In the presence of Ag_2O and furan, 3-bromo-2-oxocyclohexanecarbonitrile **151a** gives a trace of **152a**, whereas **151b** affords



the corresponding tricyclic **152b** in 17% yield[36]. Again, a slight geometric alteration of the σ framework has a pronounced effect on oxyallyl reactivity.



Scheme 21. *A:* $ZnCl_2 \cdot OEt_2$, CH_2Cl_2, −78°C/7.5 h; 25°C/0.5 h, in the presence of gaseous HCl.

Finally, allyl cations may also react with monoolefins. In this way permethylcyclopentene **153** has been prepared recently (Scheme 21)[72].

5. Conclusions

There now exist many procedures for generating and capturing allyl cations, but the question often asked—what is the best, quickest, safest, least expensive and least toxic method—is, in fact, wrongly posed. Instead, we must enquire more specifically: what is the best method for making a particular cyclic compound of interest? Once the structure of the π system and the substitution pattern of the allyl cation have been fixed, we must then decide how electrophilic the allylic component should be. Within these requirements, the silver salt route is especially useful for preparing seven-membered rings, because it allows the generation of highly electrophilic cations while at the same time tolerating nucleophilic groupings such as Y=OR and NR_2. Because of the crucial role played by Y, the reactions described are not only a challenge to preparative carbocation chemistry and to "aliphatic Friedel-Crafts chemistry", but also explose explore (Y=O⁻), metal enolate (Y=OM), enamine (Y=NR_2) and allylsilane chemistry (Y=CH_2SiMe_3), to list a few nucleophilic anchoring groups Y. Even seemingly trivial variations in the allyl cation substituents, including Y, may have a profound effect on the course of the reaction and the yield. Nor have all procedures yet been optimized. As I have tried to show, the formation of seven-membered rings is versatile and subtle from a mechanistic view: the reaction may take a concerted *and also* a stepwise course, depending on the factors discussed. In future, increased mechanistic understanding will stimulate new synthetic work and vice versa.

I thank my coworkers whose names appear in the references for their experimental skills and intellectual contributions, and Miss U. Bültel for the drawings. Our work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the SERC in England, and the Petroleum Research Fund, administered by the American Chemical Society.

[10] Yields of cycloadduct are higher when benzene is diluted with pentane (less polar medium) than in neat benzene (more polar medium). It is therefore possible that benzene is not involved as a free species but rather as a silver π complex and also that perpendicular allyl cations (cf. **2a**) intervene.

Destabilized Carbocations

By Thomas T. Tidwell*

Carbocations are intrinsically reactive species, and in early studies of their generation and properties the more accessible with stabilizing influences were naturally the prime objects of interest. Now, however, it is possible to extend the scope of these studies to include factors which tend to destabilize carbocations. By using the carbocations $CH_3^{\oplus}$ and $C_2H_5^{\oplus}$ as reference ions, such destabilizing factors can be defined; these include various structural factors, antiaromaticity effects, and the presence of electron-withdrawing substituents. Such factors can be studied by their effect on the thermodynamics of carbocations, their effect on reactivities, and by the spectroscopic properties of long-lived carbocations. Destabilized carbocations of this type are receiving increasing attention and promise to remain an active subject of investigation.

1. Introduction

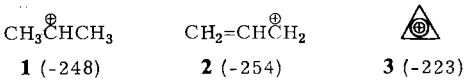
The half century from 1920 to 1970 saw the evolution of carbocations from species that were not considered to be of significance in organic chemistry to familiar intermediates that were routinely implicated in chemical processes and were included in all textbooks on the subject. At the beginning of this period, *Meerwein*[1] set off this development by reasoning that carbocations were involved in the rearrangement of camphene hydrochloride to isobornyl chloride, and were analogous to the long-lived ions formed from triphenylmethyl chloride. At the close of the half century, a five volume review of the field appeared[2] as well as a definitive review article by *Olah*[3] reporting the very extensive research, carried out primarily in his laboratory, on the generation of a diverse array of long-lived carbocations directly observable by spectral methods, most informatively by NMR. During this period the study of carbocations was one of the most actively pursued areas of research in organic chemistry, with a particular concentration of effort being directed to the study of the reaction steps and intermediates involved in solvolyses. As a result of this, the chemistry of carbocations, including their generation, properties, and reactions, progressed from an essentially unknown area to a mature science.

In the intervening decade there has been less emphasis on the study of carbocations, although very important developments have been made, including accurate delineation of the enthalpy of formation of carbocations using solution phase calorimetry[4], measurements of their gas-phase energetics[5], and theoretical investigations of many carbocations[6]. There has also been a significant increase in understanding solvolytic processes and the associated ionic and ion-pair intermediates involved[7,8].

With these accomplishments, it is now possible to consider the chemistry of carbocations as a unified whole[9], and it is the purpose of this review to examine one aspect of this area; namely, the factors which tend to *destabilize* these ions.

The simplest carbocations, consisting only of carbon and hydrogen, which have been directly observed in solution are the 2-propyl **1**[10], allyl **2**[11], and cyclopropenyl **3**[12] cations. These species have been characterized by their NMR spectra and heats of formation[5,13], and each may be considered to be stabilized relative to the ethyl cation using the hydride affinity of this species as a reference value (cf. (a)). The ΔH^0-values for **1**—**3** are given in parentheses, and the greater stability of these species may be attributed to the presence of an extra alkyl substituent, allylic resonance, and aromatic delocalization, respectively. These stabilizing effects are quite familiar, but only in recent years have destabilizing factors been considered systematically.

$$C_2H_5^{\oplus} + H^{\ominus} \longrightarrow C_2H_6\ ;\ \Delta H^{\circ} = -272\ \text{kcal/mol} \qquad \text{(a)}$$



1 (-248) **2** (-254) **3** (-223)

In this review $CH_5^{\oplus}$ and $C_2H_5^{\oplus}$ are considered as unstabilized species, and destabilized carbocations are defined as those with some structural feature that tends to reduce their thermodynamic stability relative to one of the unstabilized ions. In practice, unstabilized ions exist only transiently in solution, and hence almost all the examples of destabilized ions considered here have additional stabilizing influences to counteract the destabilizing effects.

2. Unstabilized Carbocations

An elegant technique which has been used for the study of bona fide free $CT_3^{\oplus}$ in solution is the decay of tritiated methane[14].

$$CT_4 \rightarrow CT_3^{\oplus} + {}^3He + \beta^{\ominus}$$

The course of electrophilic aromatic substitutions undergone by the tritiated methyl cations formed have been monitored by radiochemical techniques. These species, described as "the most powerful carbocations hitherto produced in solution"[14b], display remarkable selectivity.

There have been several studies in which evidence for generation of the relatively unstable $CH_3\overset{\oplus}{C}H_2$ species in solution have been obtained. Deamination of ethylamine labeled with ^{14}C proceeded via substitution accompanied

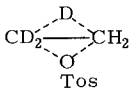
by only 1.5% rearrangement involving hydride migration[15], but solvolysis of CD_3CH_2OTos in FSO_3H gave partial deuterium scrambling without hydrogen exchange with the solvent[16]. This result appears to exclude an elimination-readdition mechanism (b) but does not differentiate between paths involving the ethyl cation (c) and a concerted rearrangement (d). The magnitudes of the observed

$$CD_3CH_2OTos \not\rightleftharpoons CD_2{=}CH_2 + TosOD \qquad (b)$$

$$CD_3CH_2OTos \longrightarrow CD_3CH_2^{\oplus}\ TosO^{\ominus} \longrightarrow {}^{\oplus}CD_2CH_2D\ TosO^{\ominus} \qquad (c)$$

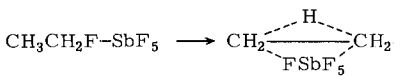


$$CD_3CH_2OTos \longrightarrow \quad \text{or} \quad \longrightarrow TosOCD_2CH_2D \qquad (d)$$

β-deuterium isotope effects on the rate of reaction have been interpreted as simultaneous rearrangement and ionization as shown in (d)[16c].

Olah et al.[17] studied CH_3CH_2F-SbF_5 complexes which undergo rapid intramolecular hydrogen and fluoride exchange with SbF_5 without intermolecular hydrogen exchange with the solvent DF or SO_3DF[17]. This was interpreted as requiring formation of a $C_2H_5^{\oplus}SbF_6^{\ominus}$ ion pair, although it does not appear that a concerted exchange can be excluded.

$$CH_3CH_2F{-}SbF_5 \rightleftharpoons CH_3CH_2^{\oplus}\ SbF_6^{\ominus}$$

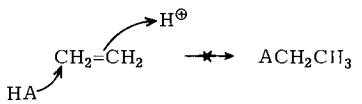


The reaction of HF-TaF_5 with $CH_2{=}CH_2$ and methane in a flow system was proposed to involve formation of ethyl cations which alkylated methane as shown in (e)[18a]. Formation of ethyl cations in solution by protonation of ethane in FSO_3H-SbF_5 or HF-SbF_5 according to (f) has also been proposed[18b].

$$CH_2{=}CH_2 + HF \xrightarrow[-F^{\ominus}]{} CH_3\overset{\oplus}{C}H_2 \xrightarrow[-H^{\oplus}]{CH_4} CH_3CH_2CH_3 \qquad (e)$$

$$CH_3CH_3 \xrightarrow{H^{\oplus}} CH_3\overset{\oplus}{C}H_2 + H_2 \qquad (f)$$

Kinetic evidence for the formation of ethyl cations by protonation of $CH_2{=}CH_2$ in H_2SO_4 was obtained in our laboratory[19]. In general, rates of alkene protonations correlate with substituent effects, and the measured reactivity of ethylene was somewhat less than that predicted by this correlation. This negative deviation emphasized the absence of any good stabilizing mechanism for the ethyl cation compared to more highly substituted carbocations. Intervention of a concerted addition of sulfuric acid to ethene as in (g), bridging, or some other mechanism bypassing formation of $CH_3CH_2^{\oplus}$ would be expected to result in a higher rate than predicted from the linear free energy correlation. The fact that the rates show a marked dependence on solvent acidity but not solvent nucleophilicity also argues against a concerted addition.



$$CH_2{=}CH_2 \not\longrightarrow ACH_2CH_3 \qquad (g)$$

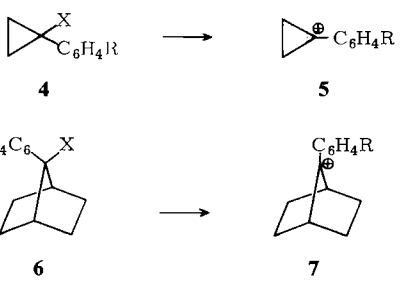
Considering the difficulty in obtaining conclusive evidence for the generation of $C_2H_5^{\oplus}$ in solution, it is not surprising that, except for the radiochemical method mentioned previously[14], evidence for the generation of $CH_3^{\oplus}$ is sparse. Studies of CH_3F ionization and ethane protonation[18b] in "Magic Acid" have, however, been interpreted in terms of $CH_3^{\oplus}$ complexes.

The structure of the ethyl cation in the gas phase and in solution is also of interest. Recent theoretical studies show a modest energetic preference for a hydrogen bridged structure in the gas phase[20a, b], but solvent is expected to interact much more strongly with an open ethyl cation structure, and this is probably favored in solution[20c, d].

Carbocations can be made more stable than $CH_3^{\oplus}$ or $C_2H_5^{\oplus}$ by attaching substituents capable of donating electrons to the positively charged center. Such stabilized carbocations have been the main object of study in the past, but recently there has been increased interest in those species with destabilizing influences. Three classes of these carbocations will be considered; namely those destabilized by structural effects, antiaromatic effects, and by the presence of electron withdrawing substituents[21].

3. Structurally Destabilized Carbocations

Structural distortions that destabilize carbocations arise when the cationic center is prevented from attaining the ideal trigonal geometry. In the solvolyses of the arylcyclopropanes **4** to **5** and the arylnorbornanes **6** to **7**, coplanarity can be attained at the carbocation center, but because the bond angles at the charged atom are constrained to be much smaller than 120° the reactivities are depressed relative to the corresponding cyclohexyl derivative by 2×10^7 for **4** (R = *p*-OCH_3)[22] and 500 for **6** (R = H)[23a, b]. Another example of destabilization of the cations **5** and **7** is the de-



4 **5**

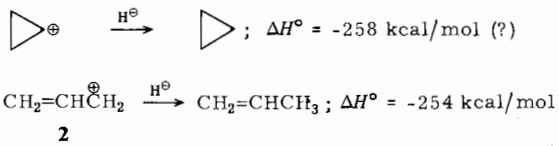
6 **7**

pendence of the reactivities on the aryl substituents; thus the ρ^+ (reaction constant, Brown-Hammett parameter) values for reactions of **4** (X = 3,5-dinitrobenzoate) and **6** (X = Cl) are −7.07[22] and −5.64[23b], respectively, compared to the value of −4.72 for 2-aryl-2-propyl-*p*-nitrobenzoates[22]. The large magnitude of ρ^+ for **4** and **6** was interpreted as arising from a high electron demand originat-

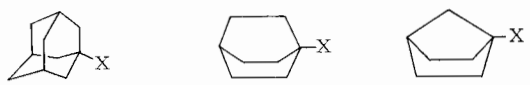
ing from the small bond angles which lead to destabilization of the carbocation.

Comparison of the ρ^+ values of closely related systems is an application of the "tool of electron-demand"[23], and is based on the plausible idea that a less stable carbocation will elicit a greater response from an adjacent substituent. However, the bond angle deformation in **5** or **7** is not relieved by increased electron delocalization from the aryl group. It may be argued that the transition states for these unreactive substrates **4** and **6** are more product-like and hence have greater contributions from the aryl group. Alternatively, the bonds from the carbocation center to the aryl group in **5** and **7** may be somewhat shorter than normal due to the high p character in the endocyclic orbitals, so that more efficient overlap is possible. However, both these explanations are speculative, and this phenomenon is, therefore, worthy of further study.

Calculations using the 6—31G** basis set indicate that the cyclopropyl cation is destabilized by 36 kcal/mol relative to the allyl cation **2**[20e]. However, experimental determination of the proton affinity of cyclopropene gave[24b] a value of 194±3 kcal/mol, which suggests that the $C_3H_5^{\oplus}$ species is only 12 kcal/mol less stable than **2**. If this ion is the cyclopropyl cation, it is not destabilized. On the contrary, it would have a hydride affinity of −258 kcal/mol, which is within the experimental uncertainty of the hydride affinity of **2**. It would appear that the structure and energetics of this system are still not settled and deserve further study.



Bridgehead cations that are geometrically restrained from attaining planarity are also destabilized, as illustrated by the relative solvolysis rates for **8**, **9**, and **10** inter alia[25]. Interestingly, the 1-adamantyl cation derived from **8** is 4



8 (1.0) **9** (10^{-6}) **10** (10^{-11})

kcal/mol more stable in the gas phase than the *tert*-butyl cation[26b]. It was argued[26a] that the destabilization due to strain in the 1-adamantyl cation is not as large as the stabilization provided by the large hydrocarbon framework.

The phenyl cation **11** is structurally destabilized due to the presence of the positive charge in an sp^2 orbital[27,28]. Even although **11** is difficult to form, there is some evidence for the occurrence of this species in reactions of the

11

phenyldiazonium ion inter alia[27,28], including the β-decay method (cf. Section 2)[28a,c].

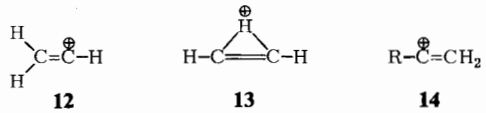
Both thermochemical data[13] and calculations[27c] indicate that the phenyl cation is strongly destabilized. The enthalpy of formation $\Delta H_f^0 = 285$ kcal/mol[13] of $C_6H_5^{\oplus}$ leads to a hydride affinity of −298 kcal/mol, which is of even greater magnitude than that for the conversion of the vinyl cation into ethylene (−287 kcal/mol). It has been suggested[27d] that 270 kcal/mol is a better value for ΔH_f^0 of $C_6H_5^{\oplus}$, but even if this value is adopted the hydride affinity is still comparable to that of $C_2H_3^{\oplus}$.

Vinyl cations are destabilized relative to the corresponding saturated and allylic species as illustrated by the hydride affinities in Table 1[5,29].

Table 1. Hydride ion affinities [kcal/mol] of simple acyclic carbocations [5, 29].

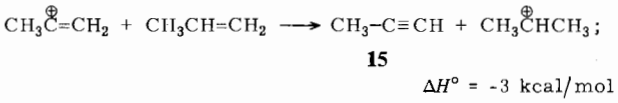
$H_2C{=}\overset{\oplus}{C}H$	−287	$CH_3\overset{\oplus}{C}H_2$	−272
$H_2C{=}\overset{\oplus}{C}CH_3$	−265	$CH_3\overset{\oplus}{C}HCH_3$	−248
$H_2C{=}CH\overset{\oplus}{C}H_2$	−254		

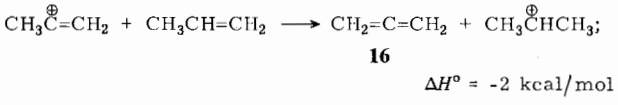
Calculations suggest that in the gas phase the parent vinyl cation $C_2H_3^{\oplus}$ has either the open **12** or bridged **13** structure, separated by a relatively small energy gap[29,30]. The effects of solvation on the preferred geometry are certain to be significant and, hence, it is not possible to predict the preferred structure in solution with confidence. For substituted vinyl cations both calculations and experimental data favor the open ion structure **14**[30–32].



12 **13** **14**

Vinyl cations are particularly readily formed by protonation of alkynes or allenes because of the relatively high ground state energy of the parent hydrocarbons. These effects are illustrated by the small exothermicities of the isodesmic processes for the formation of **15** and **16**[29].





These results are paralleled in solution. Thus in 9.12 M H_2SO_4, propene is protonated only 6.5 times faster than propyne **15** and 37 times faster than allene **16**[31]. A more systematic comparison of alkyne and alkene protonations shows a linear free energy correlation between them (Fig. 1) with a slope $\lg k_{H^+}(\text{alkyne})/\lg k_{H^+}(\text{alkene}) = 1.25$[32]. This correlation is consistent with an open ion structure for the intermediates formed from alkyne protonations, and the slope gives a quantitative measure of the greater effect of substituents in vinyl cations compared to alkyl cations.

Generation of the parent vinyl cation $C_2H_3^{\oplus}$ in solution is an interesting challenge that was first studied by *Ber-*

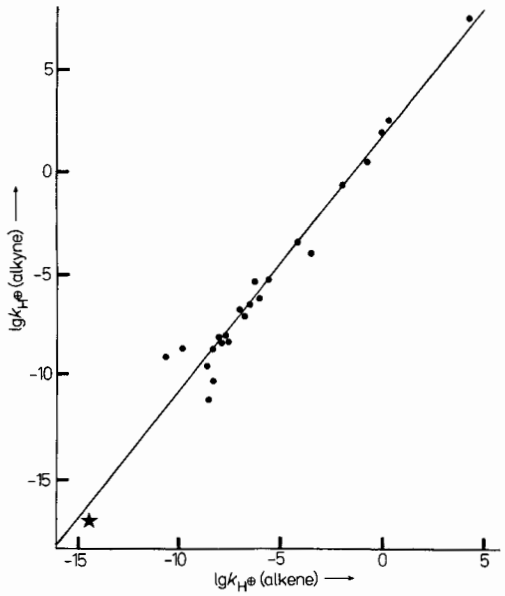


Fig. 1. Linear free energy relationship for protonation of alkenes and alkynes (the star indicates the point for $CH_2=CH_2$ and $CH\equiv CH$).

thelot as long ago as 1862[33]. His studies and those of others over the following 20 years established that in H_2SO_4 acetylene is converted into acetaldehyde, which then reacts further to give crotonaldehyde **17**. More recently, *Olah et al.*[34] showed that the reaction of acetylene with FSO_3H at low temperatures gives the vinyl fluorosulfate **18** which, however, decomposed above $-15\,^\circ C$.

$$HC\equiv CH \xrightarrow{H_2SO_4} CH_3CH=O \longrightarrow CH_3CH=CHCH=O \quad \mathbf{17}$$

$$HC\equiv CH \xrightarrow{FSO_3H} H_2C=CHO_3SF \quad \mathbf{18}$$

We have carried out quantitative studies of the reactions leading to **17** in an attempt to determine whether $C_2H_3^\oplus$ is involved. The ^{1}H-NMR spectrum of $HC\equiv CH$ was recorded at $25\,^\circ C$ in 90—95% H_2SO_4 and observed to display the distinctive signals of acetaldehyde, which is then converted into crotonaldehyde **17**[35]. The formation of crotonaldehyde from acetylene or acetaldehyde can also be monitored by UV spectroscopy under the same conditions. From these results, a relative rate ratio $k(CH_2=CH_2)/k(CH\equiv CH)\approx 200$ for the reaction in strong acid can be estimated. The linear free energy relationship between alkyne and alkene protonations (Fig. 1) predicts a very similar value to this ratio at an acidity $H_0=0$ based on the known reactivity of ethylene[19]. Because an accurate measurement of the acidity dependence of the acetylene reaction is not available, the agreement of the predicted and observed reactivities is only qualitative, but the behavior is certainly that expected from protonation of acetylene to give $C_2H_3^\oplus$.

4. Antiaromatic Carbocations

Carbocations destabilized by antiaromatic effects form a small but important class[36]. Destabilization of the cyclopentadienyl cation **19** in this way is illustrated by its hydride ion affinity of -258 kcal/mol, compared to the value of -225 kcal/mol for **20**[13]. Similarly, the $pK_{R^\oplus}$ of **19** has been reported[36b] to be -40, compared to a value of ca. -20 for the allyl cation. Attempts have also been made to generate **19** by reaction of cyclopentadienyl iodide and

19

20

$Ag^\oplus$, and these experiments showed a kinetic barrier of at least 10^5 relative to the corresponding reaction of cyclopentyl iodide[36d].

5. Electronic Substituent Effects on Carbocations

The most direct measure of the effect of substituents R on the stabilities of ions $RCH_2^\oplus$ is available from gas-phase studies (Table 2)[37] and from calculations (Table 3)[6a]. The data show net stabilization of the carbocation by all substituents studied, except the cyano group. There is good qualitative agreement between the two methods for particular substituents for all cases except fluorine, which is calculated to have only a minor stabilizing effect; in contrast, the gas phase results suggest a stronger influence, almost as great as that of the methyl group.

Table 2. Experimentally measured stabilization energies E_S [kcal/mol] of substituents R in cations $RCH_2^\oplus$ [37a]; values in parenthesis, see [37b].

R	CN	H	F	Cl	CH_3	SCN	Br	I	C_6H_5	OH
E_S	−10 (8)	0 (0)	26	32	35 (42)	42	51	53	55	60 (61)

R	SH	OCH_3	SCH_3	PMe_2	NH_2	NHMe	NMe_2
E_S	64	69 (78)	74	79	95 (95)	99 (108)	106 (110)

Table 3. Calculated stabilization energies E_S [kcal/mol] of substituents R in cations $RCH_2^\oplus$ [6a].

R	H	Li	BeH	BH_2	CH_3	NH_2	OH	F	Ne
E_S	0	79.6	20.4	26.6	29.9	93.3	47.8	2.1	?

More recently there have been a large number of calculations on the effects of particular substituents on cations RCH_2^+[38–41], but perhaps the most comprehensive of these is from *Reynolds, Taft,* and *Topsom* et al.[41]. These authors studied the ability of substituents to donate π electron density to the carbocation centers in $RCH_2^\oplus$ and $RC_6H_4CH_2^\oplus$, as well as in the neutral benzene RC_6H_5, as expressed by the parameter $\Sigma q\pi$ (Table 4). The results indicate that the

Table 4. π-Electron transfer parameters for substituents R in cations $RCH_2^\oplus$ and $RC_6H_4CH_2^\oplus$ [41].

R	NH_2	OH	F	$CH=CH_2$	CH_3
$RCH_2^\oplus$	−566	−486	−353	−427	−113
$RC_6H_4CH_2^\oplus$	−284	−202	−134	−148	− 29
RC_6H_5	−115	− 90	− 70	0	− 8

R	CF_3	CN	CHO	NO_2	H
$RCH_2^\oplus$	− 29	−262	−155	− 76	0
$RC_6H_4CH_2^\oplus$	− 4	− 33	− 20	− 10	0
RC_6H_5	10	21	27	19	0

substituents studied are π electron donors in the cations, with a relatively larger electron donating effect in the $RCH_2^{\oplus}$ system, where electron demand is higher. All the groups that are π acceptors in RC_6H_5 (R = CF_3, CN, CHO, NO_2) are π donors in the cations.

A variety of other aryl systems have been used to study substituent effects, as summarized in Table 5[42–47]. Here, the σ^+ parameters of the substituent R derived[48,49] from the rates of ionization of 2-aryl-2-propyl chlorides ($RC_6H_4CMe_2Cl$) in 90% acetone have been used successfully to correlate the data with the dependence on the substituent parameters measured by the ρ^+ parameter. Comparison of the values of ρ^+ in Table 5 indicates a greater

magnitude of the ρ^+ values in less stabilized systems (*e.g.*, gas versus solution phase; benzene versus styrene protonations; and styrenes versus α-methylstyrenes).

Because the σ^+ parameters have proven so successful in correlating electrophilic reactivity, electronically destabilizing substituents will be defined as those groups with positive σ^+ values. The effects of these substituents in aromatic systems have been thoroughly elucidated, but it is of great interest to examine their effects at the α-position of aliphatic systems such as **21**.

21

For purposes of classification, groups such as CH_2F and CF_3, for which σ^+ parameters from solvolyses of cumyl chlorides are available, are considered as separate substituents, although they could be regarded as β-fluoro- and β-trifluoro-substituents, respectively. A selection of σ^+ parameters is given in Table 6, and recent data are summarized in the following subsections. For some of the substituents, σ_p values are listed because σ^+ values have not been measured. The α-fluoro group, which has a negative σ_p^+ value, is included for purposes of comparison.

Table 6. σ_p^+ Parameters of electron withdrawing substituents [53, 54].

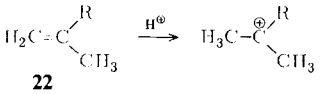
5.1. Halogen Substituents

It is well known from studies of electrophilic aromatic substitution that halogen substituents exhibit two opposing electronic effects on carbocation stability; an inductive electron withdrawal and a π electron donation by resonance. Interestingly, both of these effects decrease along the series F > Cl > Br > I; the inductive withdrawal decreases as the halogen becomes less electronegative, and the conjugative effect diminishes as the CX bond becomes longer and hence the overlap between the 2p orbital on the carbon atom and the p orbital on the different halogen atoms becomes successively smaller. The sum of these effects, as measured by the σ_p^+ values, gives a reasonable prediction of the reactivities in the protonation of the 2-halopropenes **22** in CF_3CO_2H[51] or H_2SO_4[52].

Table 7. Relative rates for protonation of halo-substituted alkenes **22**.



22

R	σ_p^+	CF_3CO_2H [51]	H_2SO_4 [52]
H	0.0	1.0	1.0
F	−0.07	71	54
Cl	0.11	0.35	—
Br	0.15	0.082	0.28

These results contrast with the experimental gas-phase effects of these substituents in $RCH_2^{\oplus}$ ions (Table 2)[37]. In this case, the order of stabilization is I > Br > Cl > F, indicating that strong polarizability effects operate; the stabilizing ability in situations of high demand is therefore determined by the size of the atom. In solution, the electron demand is much less and polarizability effects are not dominant.

Comparison of the results of solvolytic studies of *p*-methoxybenzylidene chloride[53a] with the rates for *p*-$MeOC_6H_4CH_2Cl$[53b] affords a $k(H)/k(Cl)$ substituent effect of 0.1. The greater reactivity of the substrate forming the α-chloro cation is contrary to that expected from the σ_p^+ constant of this group or by analogy with the protonations of **22**.

Similar results were found for $PhCHR_2$ (R = Cl, Br) and for $PhCR_3$[53c]. The rather high reactivity of these latter systems may indicate that ground state strain is significant.

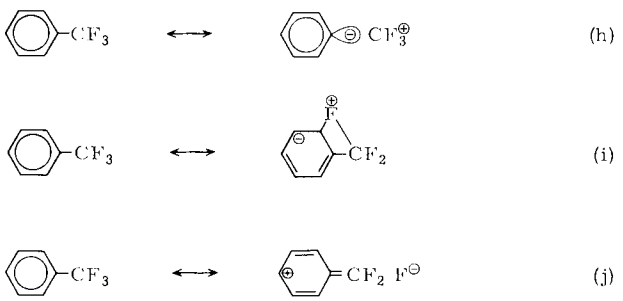
5.2. Halomethyl Groups

The *m*-CH_2F substituent is significantly electron withdrawing as measured by its σ^+ constant[50], whereas the *p*-CH_2Cl substituent is essentially electroneutral[48]. These

groups have not been extensively examined as α-substituents, but the fact that 2-(chloromethyl)propene and propene have approximately the same reactivity in protonations[54] provides powerful confirmation of the applicability of the σ_p^+ parameters derived from aromatic reactivities to aliphatic systems.

The CF_3 group is a strong electron withdrawing substituent as measured by σ_p^+ and has the added virtues of low steric requirements (as measured by van der Waals radii), relative chemical inertness, and wide availability.

According to theoretical studies, the donation of electrons from CF_3 by resonance is predicted to be less than that for other substituents with positive σ^+ values (Table 4)[39,41]. However, there have been two novel proposals for electron donating mechanisms by the CF_3 group: first, to account for the apparent high electron density at the *ipso*-carbon in trifluoromethylbenzene, revealed by photoelectron spectroscopy (cf. (h))[55]; and second the apparent lower electron density at the *para*-relative to the *meta*-positions, which results from the interaction of the n-electrons



(h) (i) (j)

of the F atoms with benzene (cf. (i))[56]—an alternative to the usual hyperconjugative formulation (cf. (j))[57].

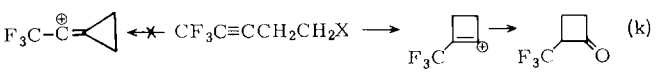
The marked effect of CF_3 on carbocation stability is shown by thermochemical data[58,59], which demonstrate the great destabilizing effect of CF_3 relative to CH_3 and even the H atom.

$$CH_4 + CF_3\overset{\oplus}{C}H_2 \longrightarrow \overset{\oplus}{C}H_3 + CF_3CH_3$$
$$\Delta H_f^{298} = -13 \text{ kcal/mol}$$

$$CH_3CH_3 + CF_3\overset{\oplus}{C}H_2 \longrightarrow CH_3\overset{\oplus}{C}H_2 + CF_3CH_3$$
$$\Delta H_f^{298} = -56 \text{ kcal/mol}$$

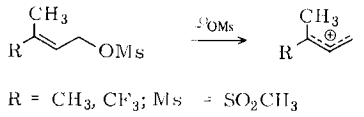
The influence of CF_3 groups on solvolytic reactivity has been studied for more than 20 years, and there is evidence that this substituent is destabilizing in both S_N2[60] and S_N1 reactions[61]. Thus CF_3CH_2I was found to be less reactive than CH_3CH_2I towards attack by C_6H_5SNa by a factor of 1.8×10^4[60a], and $CF_3CH(OBs)CH{=}CH_2$ (Bs = *p*-bromobenzenesulfonyl, "brosyl") was recovered unreacted after 35 d at 50 °C in 70% acetone[61].

The destabilizing influence of the CF_3 substituent also causes the extraordinary long lifetime of the $CF_3CH_2N_2^{\oplus}$ ion in solution[62]. In the reaction of the homopropargyl system in equation (k)[63], only the cyclobutanone derivative was formed, with no trace of cyclopropyl products.



(k)

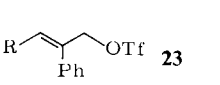
A quantitative measure of the destabilizing influence was provided by the reaction shown in equation (l) where the ratio $k(CH_3)/k(CF_3)$ was found to be 5.4×10^5[64].



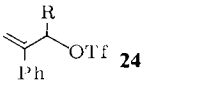
(l)

R = CH_3, CF_3; Ms = SO_2CH_3

Other large rate retarding ratios for CF_3 groups in allylic systems were found by *Harrington* in studies of the systems **23** and **24**[65].



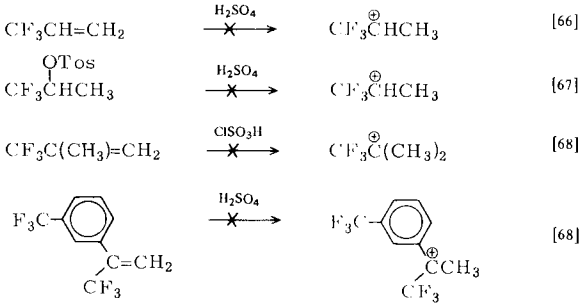
23 $k(H)/k(CF_3) = 3 \cdot 10^3$



24 $k(H)/k(CF_3) = 5 \cdot 10^4$

R = H, CF_3; Tf = SO_2CF_3

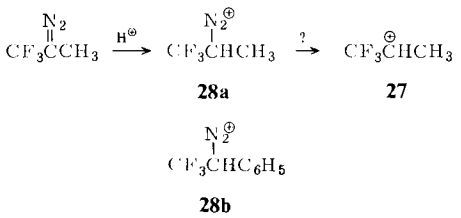
Some seemingly promising methods for forming carbocations presumably failed because of excessive charge destabilization in the ionic intermediates[66–68].



Similarly attempts to generate the ions **25**—**27** for direct detection by NMR spectroscopy were unsuccessful, and only the protonated alcohols were observed[69].

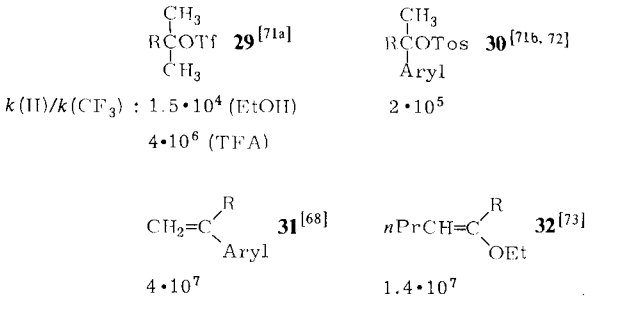
$C_6H_5\overset{\oplus}{C}(CF_3)_2$ **25** $CH_3\overset{\oplus}{C}(CF_3)_2$ **26** $CF_3\overset{\oplus}{C}HCH_3$ **27**

Evidence was obtained[70a] for protonation of 1,1,1-trifluoro-2-diazopropane to give the diazonium ion **28a**, a potential precursor for **27**, but the mode of decomposition of **28a** probably involves solvent displacement. The phenyl derivative **28b** has also been investigated[70b].



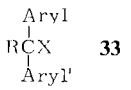
Kinetic studies of CF_3 systems have yielded the $k(H)/k(CF_3)$ rate ratio for solvolysis of the allyl system **24**, as well as those noted for the solvolyses of **29** and **30**, and protonation of **31** and **32**.

Solvolysis of **29** is markedly dependent on the solvent. In this case ionization may not be the rate determining step, but rather formation of an ion pair which undergoes solvent-assisted elimination (cf. (m)). Evidence for the occur-



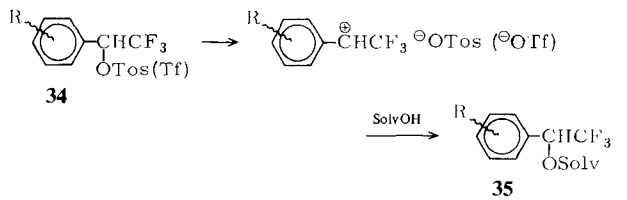
rence of this process includes the lack of correlation between the observed rates and the solvent ionizing power, isotope effects $k(CH_3)/k(CD_3)$, and salt effects in 80% EtOH[71a,b].

The reactions of **30**, **31**, and **32** all involve rate limiting carbocation formation. The solvolysis of **33** has been studied by *Sneen et al.*[74] and found to form carbocations with a $k(H)/k(CF_3)$ ratio of 3×10^6.



33

Efforts to generate secondary carbocations with α-CF_3 substituents by treating alkenes or alcohols with strong acids have been unsuccessful[66,69]. However, reaction of the sulfonates **34** in a variety of solvents evidently involves carbocation intermediates, as indicated by the dependence of the rates on solvent ionizing power ($m_{OTos} = 0.7$ to 1.0), substituents R ($\sigma^+ = -7$ to -12), secondary deuterium isotope effects [$k(H)/k(D) = 1.20-1.35$], and the essentially complete racemization of optically active **34** (OTos, R=H) in the highly ionizing solvents CF_3CO_2H and $(CF_3)_2CHOH$[75]. However, in the more nucleophilic solvent CH_3CO_2H, 40% inversion occurs in the formation of **35**, suggesting that **34** reacts *via* an ion pair which is preferentially attacked by solvent from the back side. The observed ratios of the rate constants determined by polarimetry and spectrophotometry [9 (CF_3CO_2H) and 1.1 (CH_3CO_2H)] are consistent with this interpretation.



Astrologes and *Martin*[76] established that solvolysis of the trifluoromethanesulfonate ("triflate") **36** bearing two CF_3 substituents involves a carbocation intermediate; however, reference data for related substrates were not available and hence no estimate of the destabilization caused by these groups was possible. We have made further studies of **36** as well as of the related tosylates **37**[77].

The reactions of **37** ($R = CF_3$) evidently involve carbocation intermediates, such as **25**, as indicated by the strong effect of *para*-substituents on the reactivity ($\rho^+ = -10.7$) and by the dependence of the rate of solvolysis of **37a** on solvent ionizing power ($m = 0.76$), but surprisingly the rate ratio k(**37b**)/k(**37a**) is only *ca.* 3 in several solvents, and the ratio k(**37f**)/k(**37d**), only 1.1. These results were completely unexpected: H/CF_3 rate ratios usually[71-75] lie in the range 10^4 to 10^7, and H/CN rate ratios are 10^2 to 10^7 (cf. Section 5.4), whereas those compounds with two destabilizing groups have markedly smaller ratios.

	R^1	R^2

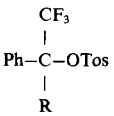
b	H	OMe
c	CF_3	H
d	CN	H
e	CH_3	H
f	H	H

Ground-state steric crowding possibly contributes to the reactivities in these highly substituted derivatives[78,79], but whereas the X-ray crystal structures of **37c—f** reveal[77] significant structural distortions, as evidenced by the bond angles around the central carbon shown in Table 8, the

Table 8. Bond angles [°] in α,α-disubstituted benzyltosylates



R	Ph–C–OTos	Ph–C–CF_3	Ph–C–R

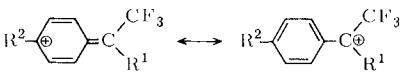
H	—	103	—

structures of all four substrates are rather similar, and no additional strain that would enhance the reactivity of **37c** or **37d** relative to **37f** is apparent. The relationship between structural distortion and the actual energetics of these derivatives is also unknown.

A plausible explanation for the high reactivity of **37a** and **37c** is that for these substrates, as well as for **37f**, the positive charge in the solvolysis transition state largely delocalizes into the aryl ring, as depicted in **38**, and that the rate varies little with the nature of the α-substituent ($R^1 = H$, CF_3). When $R^1 = CH_3$ (**37e**) resonance structure **39** makes a significant contribution and the reactivity is much higher.



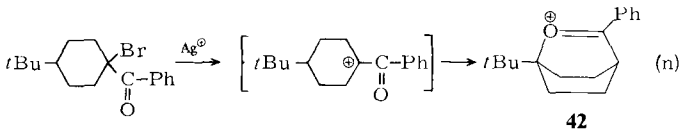
A similar explanation could hold for the high reactivity of **37d** (R^1 = CN); here, charge delocalization to the CN group could also be significant.

5.3. α-Carbonyl Substituents

α-Carbonyl groups have long been used in preparative methodology, and more recently have been the subject of mechanistic studies. An interesting early example[80] was the hydride migration **40** → **41**, which shows a 2.8fold preference for hydrogen over deuterium migration. The acid-catalyzed decomposition of α-diazoketones is the most commonly used reaction to prepare such species[81,82].

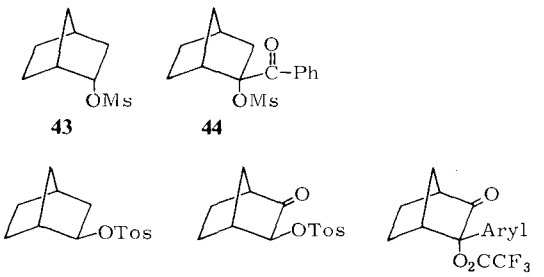
40 **41**

The ionization of α-haloketones has also been the subject of recent studies[83,84], including the example shown in reaction (n)[83], which presumably involves an α-keto carbocation intermediate that rearranges *via* hydride shifts to **42**.



42 (n)

Theoretical studies[39a] suggest that $\overset{\oplus}{C}H_2CHO$ is destabilized less (relative to $\overset{\oplus}{C}H_3$) than $\overset{\oplus}{C}H_2CF_3$ (9.9 and 37.3 kcal/mol, respectively), and kinetic studies[85] also indicate that α-carbonyl groups do not affect solvolysis rates as much as CF_3 groups. Thus, the ratio of rate constants k(**43**)/k(**44**) is *ca.* 8[85c] compared to values of 10^4—10^7 for k(H)/k(CF_3). The ratio k(**45**)/k(**46**) is 6×10^5.



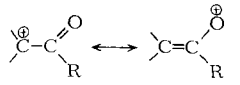
43 **44**

45 **46** **47**

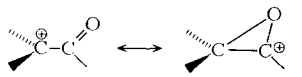
That carbocations occur as intermediates in these solvolyses is supported by ρ^+ values of −7.1 for the acetolysis of **47**[85a] and −5.69 for ethanolysis of the analogous methanesulfonate (mesylate)[85b], and also by the dependence of the rates on the solvent ionizing power (m = 0.67 to 0.91).

Several explanations for the relatively small destabilization by the α-carbonyl group were considered, but the most favored was that delocalization of positive charge to the carbonyl group occurred (**48**)[85c].

This interpretation is supported by theoretical studies[39]. The structure **48** implies that the carbonyl group and the carbocation center are coplanar; calculations on $C_2H_3O^{\oplus}$ suggest that in the gas phase the oxiranyl structure is preferred[85d,e].

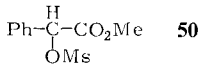


48



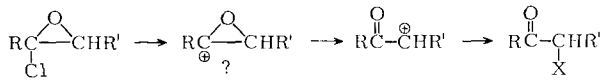
49

Arguments against **49** include the facts that optically active **50** undergoes trifluoroacetolysis with racemization and that acetolysis occurs with 11% net inversion[85c]; in contrast, structure **49** would favor retention. The ions from **46** or **47** are also geometrically precluded by the geometry of **49**. The study of a suitable substrate which cannot undergo the resonance interaction shown in **48** would be of interest in this respect.

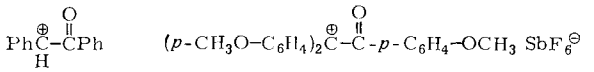


50

The ionization of α-chloroepoxides provides a potentially alternative route to carbocations of the oxiranyl and α-keto type[86]. It was suggested[86b] that in some cases these reactions involve direct ionization to the α-keto structures without the intervention of the oxiranyl ions, but the generality of this mechanism has not been established.



Several long-lived α-carbonyl carbocations have been observed directly by NMR spectroscopy[87], including the secondary species **51**[87c]; **52** has been isolated as a pure crystalline solid[87a].



51 **52**

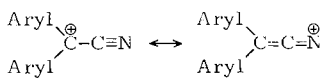
The fact that the values of m for the α-carbonyl derivatives and for the α-CF_3 substituted compounds **34** are less than 1.0 is of interest since a strong dependence of reaction rate on solvent ionizing power might have been expected for these destabilized species. A plausible explanation of this behavior for **34** is that in the transition state significant charge delocalization onto aryl groups occurs and that the influence of the solvent is less. Delocalization of positive charge onto carbonyl as in **48** might similarly result in a rather small value of m for α-carbonyl systems.

The low m-values for the solvolyses of these systems with destabilizing substituents are important for the proposal that low m values observed in certain other systems indicate intervention of the "S_N2-intermediate" mechanism[8] involving back side solvent participation. There is

strong evidence that this mechanism is not involved with these destabilized compounds, including the observation that the optically active **34**[75] and **50**[85c] undergo solvolysis with considerable racemization. Thus, low *m* values *per se* are not diagnostic of mechanisms involving direct solvent participation.

5.4. The α-Cyano Substituent

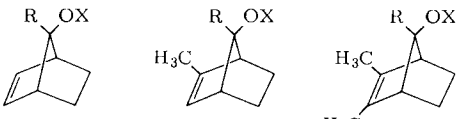
The effect of the α-cyano group has been the subject of several theoretical studies[38-41]. There is general agreement that resonance electron donation by this group will be significant in situations of high electron demand, as illustrated in **53**. Calculations indicate[39,41] that the cyano is a better π donor than the carbonyl group, although the net destabilization by the cyano group is predicted[39a] to be greater because of a greater negative induction effect. The ^{15}N chemical shifts of α-cyano carbocations are consistent with participation of resonance structure **53**, in that substantial positive charge density on nitrogen is detected[88]. Unfortunately, only diaryl derivatives have proven amenable to such NMR studies, and hence the expected higher charge densities on nitrogen in more destabilized systems cannot be established.



53

Solvolysis studies[89-91], as well as the rate of protonation of one cyanoalkene[73] are in accord with variable π electron donation from the cyano group to an adjacent carbocation center, as illustrated by the $k(H)/k(CN)$ ratios for **54—67** (Table 9). A qualitative trend was clear in that the more stabilized systems **59**, **60**, and **65** showed significantly larger $k(H)/k(CN)$ ratios that were comparable to the previously mentioned $k(H)/k(CF_3)$ ratios. This trend was placed[73] on a quantitative basis since a reasonable linear free energy correlation exists between ρ^+ and γ^+ of the cyano group[73]; here the ρ^+ value is derived from the corresponding aryl series and the γ^+ value is defined by $\lg k(CN)/k(Ph)$ versus ρ[92-94]. However, this relation fails badly for **63**, which was reported[91] after the correlation had been published. One reason for this deviation could be a significant steric effect on either the value of ρ^+ or γ^+ for **63**; such an effect would not be accounted for in this treatment.

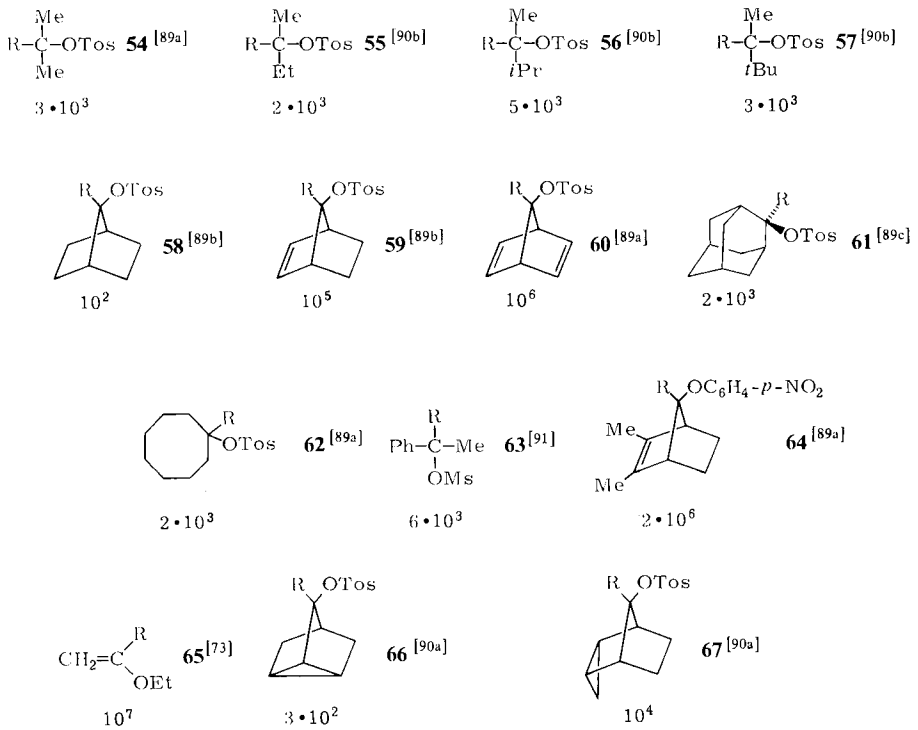
The ρ^+ value for **63** (−6.7) is quite comparable to those found for the α-CF_3 system **30** and the α-carbonyl system **47**. However, the $k(H)/k(CN)$ ratios are significantly larger than the corresponding ratios for the α-carbonyl systems, and in several cases are comparable to the $k(H)/k(CF_3)$ values.



59 **68** **69**

The reactivity of the substrates **59**, **68**, and **69** revealed relative rates of 1:10:150 (R=H) and 1:90:4000 (R=CN). The greater dependence of the system destabil-

Table 9. Ratio of rate constants $k(H)/k(CN)$ for solvolysis of compounds **54-67** (R=H, CN).



54[89a]	**55**[90b]	**56**[90b]	**57**[90b]
$3 \cdot 10^3$	$2 \cdot 10^3$	$5 \cdot 10^3$	$3 \cdot 10^3$
58[89b]	**59**[89b]	**60**[89a]	**61**[89c]
10^2	10^5	10^6	$2 \cdot 10^3$

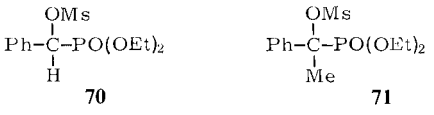
$2 \cdot 10^3$	$6 \cdot 10^3$	$2 \cdot 10^6$	
65[73]	**66**[90a]	**67**[90a]	
10^7	$3 \cdot 10^2$	10^4	

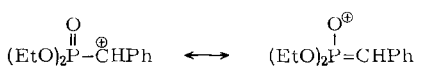
ized by the cyano group on the electron donating ability of the double bond represents another example of the response of such carbocation systems to electron demand.

5.5. The α-Diethoxyphosphoryl Substituent

The σ_p^+ constant of the α-diethoxyphosphoryl group (Table 6) indicates that it is a stronger electron withdrawer than α-carbonyl substituents. Recent experimental studies[95] demonstrate that **70** and **71** react via carbocationic intermediates with $k(H)/k(PO_3Et_2)$ ratios of 10^3 and 2×10^2, respectively. The authors concluded that these differences in rates indicate some electron donation from the phosphoryl group to the carbocation center involving a d orbital on phosphorus (cf. resonance structure **72**). Unfortunately no theoretical studies of this interaction have yet appeared, and hence the interpretation is still tentative.

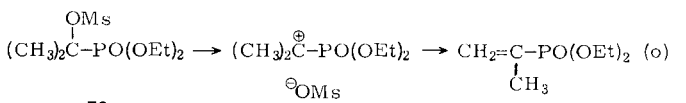


70 **71**



72

Solvolysis of **73** was proposed to occur with the elimination step being partially rate-limiting (cf. (o)). *Creary* et

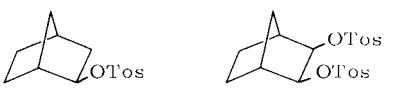


73

al.[95] pointed out this was a cationic analogue to the well known E1cb mechanism and accordingly designated this two-step elimination via a carbocation intermediate as the $E2_{R^+}$ mechanism.

5.6. The Tosyloxymethyl Substituent

No σ_p^+ value is available for the tosyloxymethyl group, but the value is expected to exceed that of the hydroxymethyl group (−0.01). There have been extensive solvolytic studies of 1,2-ditosylates in which one tosyloxy substituent influences the tosylate ionization reactivity[96]. One example is the rate ratio $k(\mathbf{45})/k(\mathbf{74})\approx4\times10^6$.

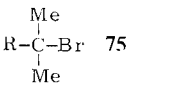


45 **74**

This is comparable to the ratio $k(\mathbf{45})/k(\mathbf{44})$ (cf. Section 5.3), showing that the tosyloxymethyl group has a similar destabilizing effect as the α-carbonyl group.

5.7. α-Silyl Substituents

The σ_p^+ value of 0.02 for the Me_3Si group suggests that this substituent will mildly deactivate a carbocation relative to hydrogen. Relative rate data for solvolysis of **75** in 60% EtOH are shown[97].



75

R	H	Me_3C	Me_3Si
k_{rel}	1	$4\cdot10^4$	1.0

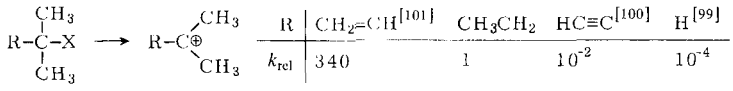
These data demonstrate that Me_3Si is strongly destabilizing relative to Me_3C, but, since the rate of solvolysis of 2-propyl bromide under these conditions is probably increased by nucleophilic solvent participation, it cannot be conclusively stated that Me_3Si favors carbocation formation relative to H. Recent results on the effects of Me_3Si on S_N2 reactivity have been reported[98], but more data are needed on the behavior of this group in S_N1 type reactions. Calculations indicate that $CH_3\overset{\oplus}{C}H_2$ is 13.2 kcal/mol more stable than $SiH_3\overset{\oplus}{C}H_2$, which is in turn 16.1 kcal/mol more stable than $CH_3^{\oplus}$[98].

5.8. The Ethynyl Substituent

A σ_p^+ value of 0.18 has been derived for the C≡CH group based on the solvolysis of the *p*-substituted benzyl chloride **76** in 50% ethanol[99]. However, the ρ^+ value for this solvolysis is only −1.7[99], and it appears highly likely that nucleophilic solvent participation is important in this reaction; the derived σ_p^+ value may, therefore, not be reliable.

76

Relative solvolysis rates for **77**[100,101] show that the order of cation stabilizing ability is $CH_2{=}CH > CH_3CH_2 > HC{\equiv}C > H$.



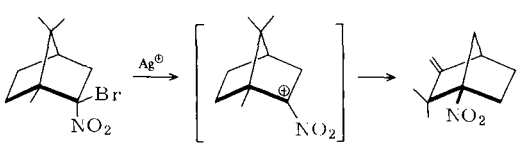
R	$CH_2{=}CH$[101]	CH_3CH_2	$HC{\equiv}C$[100]	H[99]
k_{rel}	340	1	10^{-2}	10^{-4}

77

Taken together, the results for **76** and **77** indicate that the ethynyl group is, at best, a modestly stabilizing group that may be destabilizing in some circumstances. The stabilizing effect of the ethynyl group relative to a hydrogen atom probably represents a minimum value because the reaction rate of the unsubstituted compound is increased by solvent participation.

5.9. Other Substituents

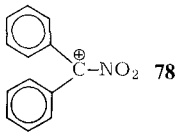
As yet no quantitative data is available for the effects of other destabilizing substituents such as NO_2, $NR_3^{\oplus}$, or SO_3H on the kinetics of formation of carbocation intermediates in aliphatic systems. The reaction of an α-bromonitrobornane [equation (p)] has been observed[102a] and attri-



(p)

buted to intervention of the corresponding α-nitro carbocation.

The long-lived species **78** has also been detected in solution and found to have a significant electron deficiency on the central carbon as indicated by its ^{13}C chemical shift[102b].

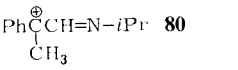


78

Theoretical studies of the $NH_3^{\oplus}$ substituent suggest that some π electron donation from this group is possible[39a,41], and some evidence for this effect has been found in the nitration of benzene substituted with this group[103a].

Two other potentially destabilizing substituents whose effects on carbocations have attracted interest are the isocyano group[103b], which was calculated to be stabilizing relative to hydrogen in **79**, and the α-imidoyl group[103c]; carbocations containing the latter were evidently generated by ionization of the corresponding chlorides to give intermediates such as **80**.

79



80

5.10. β-, γ-, and δ-Substituents

There is abundant evidence that carbocations are also destabilized by electron withdrawing substituents located in the β-, γ-, or δ-positions, or even further removed. Solvolyses of this type have been particularly well examined in the norbornyl system[104], but as this evidence has been recently reviewed[104] it will not be discussed here. It is, however, worth noting that similar effects are observed in alkene protonations[105-107].

$RCH{=}CHOEt \xrightarrow{H^{\oplus}} RCH_2{-}\overset{\oplus}{C}HOEt;\ k(H)/k(CN) = 10^7$

$; k(H)/k(CN) = 10^5$

5.11. Long-Lived Destabilized Ions

Long-lived carbocations substituted with the destabilizing groups CF_3[102b], CN[88], NO_2[102b], CO_2Me[87d], and COPh[87a,d] have been detected by ^{13}C-NMR spectroscopy, and the chemical shifts of their cationic carbon atoms are shown in Table 10, together with some other values[87d] for reference. There is clearly no simple relationship between the destabilizing effect of a substituent and the chemical shift. Thus, based on reactivity studies (cf. Section 5.2) the CF_3 group is more destabilizing than an H atom or the COPh group, although the cationic carbon α to CF_3 is at higher field. However, it is known that even "simple" substituents such as CH_3 affect chemical shifts by more than one mechanism[108a], and there is other evidence for this with a variety of other systems and substituents[108]. There is some indication that chemical shifts are correlated with calculated charges on the cationic carbon[87d], so that a combination of these methods may give a better understanding of these cationic systems.

Table 10. ^{13}C-NMR chemical shifts (δ-values relative to TMS) for the cationic carbon atom in $Ph_2\overset{\oplus}{C}R$.

R	CF_3	CN	NO_2	CO_2CH_3	COPh	H	CH_3
δ	189.6	168.8	189.1	191.2	202.8	199.4	229.3

6. Conclusions and Outlook

Destabilized carbocations have structural features which predestine them to be only transient species. Their study has therefore made valuable contributions to understanding the principles of organic chemistry. In recent years, the study of these species has advanced rapidly through the use of a combination of kinetic studies in solution, theoretical calculations, and structural studies. Several important substituents, most notably NO_2, SO_3R, and $NR_3^{\oplus}$, have been subjected to only minimal quantitative study as destabilizing substituents in aliphatic carbocations and deserve further attention. Many useful applications of destabilized carbocations in syntheses[109] have already been found but many more are to be expected in future. The effort that has been expended in this area has been amply rewarded by the fascinating chemistry that has been revealed, and no less is to be expected for further studies.

The decisive contributions of my coworkers in this area, and the financial support of our research by the Natural Sciences and Engineering Research Council of Canada and the Donors of the Petroleum Research Fund is gratefully acknowledged. Particularly helpful comments were provided by Dr. Dieter Lenoir and Prof. S. P. McManus.

Nodal Nomenclature II—Specific Nomenclature for Parent Hydrides, Free Radicals, Ions, and Substituents**

By Noël Lozac'h and Alan L. Goodson*

Nodal nomenclature is compared with classical organic nomenclature, and the procedure by which an organic compound is given a nodal name is described. Parent hydride—especially hydrocarbon—names are derived from the names of structure graphs and are modified to incorporate descriptions of heteroatoms, unsaturation, free valences, and ionic charges. It is also shown how the substitutive method, though not an integral part of the nodal system, may nevertheless be used as a way to simplify the structure graphs without impairing the logic of the nodal system. For this purpose, it is indicated how to use prefixes or suffixes generally formed according to IUPAC Rules. The rôle of substitution in organic nodal nomenclature is more restricted than in classical nomenclature because many classical substituents are treated as part of the parent hydrides. The concept of "characteristic group" is not used in nodal nomenclature for similar reasons, and the term "principal substituent" is preferred to "principal characteristic group".

1. Preface

The general tendency of classical organic nomenclature, which is the natural outcome of the historical development of organic chemistry, is to consider first the chemical nature of the atoms constituting a molecule and then to indicate how these atoms are connected together. Classical systematic organic names generally correspond to a molecular formula and are sometimes directly derived from this formula (*e.g.*, silane). Nodal nomenclature, on the other hand, can be compared with a technique used for constructing large buildings. It first creates a framework (*i.e.*, a mathematical description of a chemical structure[1]) to which it adds the detail necessary to complete a usable chemical name. Just as new techniques made possible the construction of skyscrapers, so the new concepts of nodal nomenclature facilitate the description of large chemical structures.

The preceding paper[2] of this series, to which we shall refer hereafter as Part I, showed how the framework is created by reducing chemical structures to graphs and then numbering and naming the graphs. This technique of reducing a problem to a graph and then resolving the problem by manipulating the graph is common in graph theory[3,4].

The names of the chemical structures are obtained by supplementing the description of the corresponding graphs, as indicated in Part I, with purely chemical information defining the nature of the atoms and bonds. The objective of this second paper is therefore to describe how parent hydrides—generally organic—as well as their derivatives containing free valences, ionic centers, or substituents can be named by modifying the names of the graphs. For this purpose, it is practical to use, as far as possible, prefixes and suffixes having well known chemical meanings, such as those codified in IUPAC Rules for Nomenclature of Organic Chemistry[5]. To help the reader understand how names of parent hydrides are derived from those of the corresponding graphs, many of the examples in this paper are related to the examples in Part I.

First of all, two important facts should be noted:

1) This paper describes *one* procedure for using nodal nomenclature in organic chemistry, but other procedures such as those involving polynuclear nodes, as in cyclophane nomenclature, can also apply the general method described in Part I, provided that the principles governing the choice of nodes are clearly defined.

2) The Rules concerning substituents, ions, and free radicals show how the main principles underlying IUPAC Rules are applied to parent hydrides named according to the nodal system. In elaborating these Rules, the Authors have drawn great benefit from the work accomplished by the IUPAC Commission on Nomenclature of Organic Chemistry. However, some of these proposals, although consistent with the general methods of IUPAC Rules, represent only the Authors' preference among various possibilities considered by IUPAC.

2. Introduction

It has been argued that the description of the graph, as given in Part I, leads to long strings of numbers and punctuation marks and accordingly is not practical for common use. Some explanations are therefore necessary.

Nodal nomenclature provides a unique and sequential numbering for any graph. The fact that this numbering is unique avoids, in indexes, the scattering of information for compounds having the same carbon skeleton. The fact that it is sequential renders it directly available for construction of a connection table and for substructure retrievals by procedures comparable with those used in the DARC and CAS ONLINE systems. This unique and sequential numbering is intimately connected with the descriptors which were discussed in Part I[2]. The typographical conventions

used for the descriptors were adopted to facilitate understanding of the structure under consideration.

Since we claim that nodal nomenclature is of general use, it is essential for us to show that it works with complicated structures where existing nomenclature rules often do not provide any clear guidance. One should compare only what is comparable, and the "simplicity" of nodal nomenclature should be tested on examples where existing rules provide clear answers. For this reason, we have chosen, for many examples in this paper, compounds that are also used as examples in the IUPAC rules[5]. Thus, nodal nomenclature rules are compared directly with existing IUPAC rules.

There are two questions which must be borne in mind during the further development of nodal nomenclature.

The first is the perennial difference in nomenclature requirements between the primary literature and that of an index.

An essential question for indexing and information retrieval is whether the nomenclature system used leads to a unique and unambiguous name for any given chemical structure. IUPAC Rules often provide various possible names for a substance and, owing to the fundamental inconsistencies of traditional methods, the choice of unique "official names" often requires that the user define his own selection rules. On the other hand, nodal nomenclature can define clearly, for indexing and information storage and retrieval purposes, a unique and unambiguous name for any molecule, provided that the principles governing the choice of nodes and of substituents are clearly defined.

In the primary literature, an author may name a substance to reflect the nature of the work being described. Another author may name the same substance differently because the nature of the work he is describing is different. Therefore, primary literature requires only that names be unambiguous, while indexes require not only unambiguous but, as far as possible, unique names. Some flexibility is built into nodal nomenclature so that while unique names can be derived for indexing purposes, shorter, more convenient names will also be available for use in the literature.

This leads to the second question that must be borne in mind. It is generally recognized that existing nomenclature practices are in need of improvement. When a new nomenclature system is developed and proposed, there is always the potential for conflict between the needs of the chemist and the needs of the information retrieval specialist. It is possible to make minimal (but frequent) changes to existing nomenclature practices and thus retain procedures and names with which the chemist is familiar and with which he therefore feels comfortable. The information retrieval specialist, on the other hand, would prefer a completely systematic nomenclature system that never needs modification and yields unambiguous names as simple as the complexity of structures permits. In developing nodal nomenclature, we are trying to strike a balance between these two extremes and that is why we show how the substitutive method may be used in nodal nomenclature.

Use of the substitutive method is not essential in nodal nomenclature but is advisable for two reasons. The first is that removal of substituents simplifies the graph and, accordingly, its name. The second reason is that chemists will prefer to relate simple substituted structures to the graph of the unsubstituted one; for example, most chemists will prefer to relate a chlorohydrocarbon to the graph of the unsubstituted hydrocarbon. For a similar reason, indexes require that names of related substances be grouped together. For this purpose a compound commonly named as "2-chloro-1-butanol" is frequently given the inverted name "1-butanol, 2-chloro-" in an index. There is no particular problem for applying this procedure to substitutive nodal names.

It is important to remember that the following Rules are modular because of the underlying logic of nodal nomenclature. This means that the various features of a chemical compound are described successively, in a prescribed order, by prefixes and/or suffixes, and that any new feature can influence the numbering of the skeleton only if the preceding features have left a choice.

A parent hydride is named first, and this gives a high priority to unsaturation for the definition of the numbering. The corresponding Rules are particularly detailed as they constitute the basis of any nodal name.

Next comes the description of free valences and ionic centers on skeletal atoms. It should be remarked that any free valence must belong to a skeletal atom and that the use of "onia" replacement prefixes, according to IUPAC **Rule B-6.1**[5], is not recommended because the neutral parent compound should be completely defined before considering ionic centers.

Last comes the naming of substituents, considered in the order of seniority: anionic, cationic, neutral. Nodal nomenclature sets relatively stringent limits to the use of substituents (**Rule N-10.1**) as well as to the rôle of substituents in name selection. For instance, in nodal nomenclature, no substituent plays a rôle as important as the "principal group"[5a] in IUPAC Rules for acyclic compounds. Accordingly, the term "principal substituent" is preferred for a substituent named by a suffix and having priority for low locants only over other substituents.

For sake of consistency, exceptional treatment of various characteristic groups is avoided and substitutive prefixes are used more extensively than in IUPAC nomenclature (*e.g.*, for aldehydes, ketones and nitriles). For the same reason, radicofunctional names are not used at all (*e.g.*, for esters and acyl halides). When appropriate prefixes are not available in current nomenclature, groups of substituents are named with one locant only, such as "(Mercapto, oxo)" for [C](O)SH in *S*-thiocarboxylic acids, "(Amino, oxo)" for [C](O)NH_2 in carboxamides, "(Chloro, oxo)" for [C](O)Cl in acyl chlorides. This procedure has the advantage that the functional group can be identified easily, without departing from the general substitutive method.

3. Glossary

Many terms used in this paper have already been defined in Part I[2a]. Some additional definitions are necessary for specific nodal nomenclature.

Mononuclear Node: (see: Node[2a]) Used principally to distinguish nodes corresponding to single skeletal atoms from polynuclear (contraction) nodes.

Parent Element[6]: An element whose identity is indicated at the end of the name of a saturated parent hydride. Other elements, if present, are denoted by replacement prefixes such as oxa or aza. The parent element is the most, or one of the most, common in the skeleton. When the skeleton contains equal numbers of atoms of more than one element, including carbon, carbon is preferred as the parent element. If carbon is not among the most common elements of the skeleton, then the parent element is the first cited in Table 3. The concept of parent element applies to graphs containing only mononuclear nodes.

Parent Hydride: In organic nodal nomenclature, the element hydride obtained through replacement by hydrogen atoms of all the atoms or groups considered as substituents. According to this definition, while unsaturation endings (*e.g.*, ene, yne) are part of the parent hydride name, suffixes for principal substituents are not, which is different from IUPAC Rules concerning principal characteristic groups. For this reason, in nodal nomenclature, the term "parent hydride" is preferred to "parent compound" in order to avoid confusion with existing IUPAC terminology.

Polynuclear Node: (see: Contraction Node[2a]) Used principally to stress the polyatomic nature of contraction nodes and to distinguish them from mononuclear nodes.

Principal Substituent: A substituent named as a suffix and having priority for low locants over other substituents (see Table 2). The term "principal substituent" is used in nodal nomenclature in order to avoid confusion with the term "principal characteristic group", which has a different use in IUPAC Rules.

Satellite Atom: A univalent atom (usually hydrogen) attached to a skeletal atom and not regarded as part of the structure graph.

Skeleton: The structure resulting when the nodes and lines (or connectivities) of a structure graph are specified. It contains neither satellite atoms nor substituents.

Substituent: An atom or group that replaces a hydrogen atom of a parent hydride. The following may be named as substituents in organic nodal nomenclature (see Tables 1 and 2): a) a heteroatom which may be linked to hydrogen, or b) a group of heteroatoms which may be associated with carbon (as exceptions), which may be linked to hydrogen and which does not need internal numbering for defining its structure. Use of substitution is therefore restricted in nodal nomenclature. The IUPAC concept of characteristic group is not used in nodal nomenclature.

4. General Concepts of Specific Organic Nodal Nomenclature

For naming purposes, a chemical substance can be regarded either as a neutral parent hydride or as being derived from a neutral parent hydride by introduction of free valences, ionic charges, or substituents. Use of nodal nomenclature to name a chemical substance proceeds in four steps:

1) Definition of the Structure Graph;
2) Numbering and Naming of the Structure Graph, according to Part I;
3) Specification of the Nodes and Lines (*i.e.*, naming the neutral Parent Hydride according to **Rules N-11, N-12** and/or **N-13**);
4) Addition of Remaining Information, if any.

4.1. Definition of the Structure Graph

The structure graph is defined by 1) removing the atoms or groups that are to be treated as substituents, 2) removing the satellite atoms (generally hydrogen), 3) ignoring charges, bond values, free valences, and the identity of skeletal atoms, and 4) defining the nodes as either mononuclear (single atoms) or polynuclear (*i.e.*, contraction nodes representing, for example, benzene or pyrrole rings). In this paper we limit ourselves solely to the use of mononuclear nodes.

At this stage, the operation which is most open to discussion is the definition of substituents. As already stated in the Introduction, use of the substitutive method is not essential to nodal nomenclature but may be considered advisable by many users. That is why, in the proposed Rules, two lists of atoms or groups are given which the Authors believe are advantageously treated as substituents in nodal nomenclature. However, it should be stressed that these lists are not limitative and that further development of nodal nomenclature may demonstrate the need to define larger, but limitative, lists of substituents.

It should also be stressed that this graph-based nomenclature precludes the use of radicofunctional names such as those generally used for esters. Binary names of this

kind are reserved for substances, such as salts, comprising a loose association of structurally independent chemical entities.

4.2. Numbering and Naming of the Structure Graph

This step has been described in Part I[2].

4.3. Specification of the Nodes and Lines: Parent Hydrides

Once the structure graph has been numbered and named, the graph name is modified to include information specifying the nodes and lines. For this purpose, the end of the graph name is changed to indicate the nature of the parent element. Other elements, if present, are denoted by replacement prefixes[5b] such as "oxa" and "aza". Unsaturation is indicated by suffixes: either by the traditional terms "ene" and "yne" with their usual meaning of double and triple bond, respectively, or by the new terms "arene" or "axene" denoting unambiguously the presence of the maximum number of noncumulative double bonds. A summary of the Rules indicating how these various features intervene in the choice of the numbering of a substance is given in **Rule N-14.2.** The resulting name is that of the parent hydride, for instance a hydrocarbon.

Only when all the nodes of a graph have been defined and the nature of the lines has been described is hydrogen formally added to satisfy the valence of each skeletal atom. This valence is the "normal valence"[5c] unless otherwise stated[7].

The systematic numbering of structures is a prominent characteristic of nodal nomenclature which endeavors to treat the same problem in the same way, without reference to peculiarities of structure already considered (modularity principle). This uniformity of treatment contrasts with some IUPAC Rules. A particularly important example concerns numbering of heteroatoms in replacement nomenclature. The nodal system retains the method used by IUPAC[5] for acyclic (**Rule C-62.1**) and polycyclic structures (**Rule B-4.2**) but not the method applied to monocycles (**Rule B-4.1**), which is different.

4.4. Addition of Remaining Information

Once the parent hydride name has been formed, the substance name is derived, if necessary, by addition of the remaining information, such as free valences, ionic charges, substituents, stereochemistry, and isotopic modifications. This implies rules for assignment of locants to the diverse features under consideration.

Application of the modularity principle in nodal nomenclature leads unavoidably to rules rather different from those of IUPAC nomenclature. This is particularly significant for principal characteristic groups as defined in the IUPAC Rules. The nodal system treats all unsaturation before considering substituents, even if these are named as suffixes, while IUPAC Rules do not separate these different issues. For instance, according to **Rule C-15.1**[5], indicated hydrogen has priority over principal characteristic groups, which, in turn, have priority over multiple bonds. Apart from this point, the nodal method is rather similar to the one used by IUPAC for polycyclic systems, where, for instance, heteroatoms are considered before principal characteristic groups for assignment of low locants. This is quite different from the IUPAC practice for acyclic systems, where principal characteristic groups have priority over heteroatoms, not only for assignment of low locants (**Rule C-62.1**[5]), but also for determining the principal chain (**Rule C-63.1**[5]).

The rules proposed in this paper show how it is possible to deal with free valences, ionic charges and substituents, but do not consider stereochemistry and isotopic modification, like Sections E and H of the IUPAC Rules[5]. It seems that there is no particular problem in applying these IUPAC Rules to nodal names and one can note only that nodal numbering facilitates their application because each locant occurs only once.

As for specification of free valences, ionic charges, and substituents, two different problems have to be solved: first, the choice of a terminology; second, the definition of the rules governing the numbering of the substance.

For the first problem, the terminology defined in existing IUPAC Rules[5] is available and only minor decisions have to be made. A nonlimiting set of substituent names is given in **Rule N-10**, and terms denoting free valences and ionic charges are recalled in **Rule N-14.3**.

For the second problem, **Rules N-14.3** and **N-14.5** indicate how free valences, ionic charges, and substituents can affect the definitive numbering of a substance.

5. Proposed Rules for Specific Nodal Nomenclature

Rule N-10—Substituents

N-10.1. Substituent groups should not contain an unbranched chain of more than three atoms other than hydrogen and should not need internal numbering. If a hydrogen atom of such a group is substituted with a group containing the parent element, then the resulting group is not regarded as a substituent but as a part of the parent hydride. A nonlimiting list of acceptable substituent atoms and groups cited only as prefixes in nodal nomenclature is given in Table 1.

N-10.2. Substituents are generally named as prefixes, but groups susceptible to losing a proton, and the corresponding anionic atoms or groups, are named as suffixes under the conditions stated in **Rule N-14.1.** If these conditions are not fulfilled, prefixes are used. A nonlimiting list of acceptable hydrogen-containing substituents which may be cited either as prefixes or as suffixes in nodal nomenclature is given in Table 2.

N-10.3. Substitutive prefixes can be derived from the names of mononuclear hydrides (see Table 3) of elements having a nonstandard classical valence bonding[7].

Examples (substituents cited in Table 1):

1. $-ICl_2$ Dichloro-λ^3-iodanyl
2. $-I(OH)_2$ Dihydroxy-λ^3-iodanyl
3. $-SF_5$ Pentafluoro-λ^6-sulfanyl
4. $-SF_2Cl$ Chlorodifluoro-λ^4-sulfanyl
5. $-SCl_3$ Trichloro-λ^4-sulfanyl

Table 1. Acceptable substituents, which are only cited as prefixes in nodal nomenclature when the parent element is carbon.

Substituent	Prefix	IUPAC Rule [5]	Substituent	Prefix	IUPAC Rule [5]
$-F$	Fluoro	C-102.1	$-SCl_3$	Trichlorothio [*]	C-621.2
$-Cl$	Chloro	C-102.1	$-S(O)NH_2$	Sulfinamoyl	C-641.8(b)
$-ClH^+$	Chloronio	C-82.1	$-S(O)_2NH_2$	Sulfonamoyl	C-641.8(b)
$-ClO$	Chlorosyl	C-106.2	$-SNH_2$	Sulfenamoyl	C-641.8(b)
$-ClO_2$	Chloryl	C-106.2	$-SCN$	Thiocyanato [**]	C-833.1
$-ClO_3$	Perchloryl	C-106.2	$=Se$	Selenoxo	C-701.1
$-Br$	Bromo	C-102.1	$-SeH_2^+$	Selenonio	C-82.1
$-BrH^+$	Bromonio	C-82.1	$-SeCN$	Selenocyanato [**]	C-833.1
$-I$	Iodo	C-102.1	$\equiv N$	Nitrilo	
$-IH^+$	Iodonio	C-82.1	$=N_2$	Diazo	C-931.4
$-ICl_2$	Dichloroiodo [*]	C-106.3	$-N_3$	Azido	C-941.1
$-IO$	Iodosyl	C-106.1	$=NH_2^+$	Iminio	C-816.3
$-IO_2$	Iodyl	C-106.1	$-NH_3^+$	Ammonio	C-82.1; C-816.3
$-I(OH)_2$	Dihydroxyiodo [*]	C-106.3	$-NHOH$	Hydroxyamino	C-841.1
$=O$	Oxo	C-311.1	$-NHNH_2$	Hydrazino	C-921.1(b)
$-OH_2^+$	Oxonio	C-82.1	$-NO$	Nitroso	C-851.1
$-OOH$	Hydroperoxy	C-218.1(b)	$-NO_2$	Nitro	C-852.1
$-ONH_2$	Aminooxy	C-841.2(d)	$=NOH$	Hydroxyimino	C-842.1(b)
$-OCN$	Cyanato [**]	C-833.1	$-N(O)OH$	*aci*-Nitro	C-852.2
$=S$	Thioxo	C-532.3	$=NNH_2$	Hydrazono	C-922.1(b)
$-SH_2^+$	Sulfonio	C-82.1	$-NC$	Isocyano [**]	C-833.1
$-SF_5$	Pentafluorothio [*]	C-621.2	$-NCO$	Isocyanato [**]	C-833.1
$-SF_2Cl$	Chlorodifluorothio [*]	C-621.2	$-NCS$	Isothiocyanato [**]	C-833.1
$-SCl$	Chlorothio	C-621.2	$-NCSe$	Isoselenocyanato [**]	C-833.1

[*] These substituents can also be named according to **Rule N-10.3**. [**] Exception to the rule according to which, in organic nodal nomenclature, the parent hydride should contain all the carbon atoms present in the molecule. The use of the carbon-containing substituent cyano (—CN), which is generally linked to the parent hydride by a C—C bond, is not recommended.

N-10.4. The prefixes for anionic substituents formed by loss of a proton from the substituent groups listed in Table 2 are obtained by making the following changes in the names given in the second column of Table 2:

(1a) "-o" to "-onato";
(1b) "-o" to "-ato";
(1c) "Hydroxy" to "Oxido";
(1d) "Mercapto" to "Sulfido";
(1e) "Hydroseleno" to "Selenido".

The suffixes for anionic substituents formed by loss of a proton from the substituent groups listed in Table 2 are obtained by making the following changes in the names given in the third column of Table 2:

(2a) "-ic acid" to "-ate";
(2b) "-ol" to "-olate";
(2c) "-ine" to "-inide".

Anionic substituents have priority for citation as principal substituents over all other substituents. Among anionic

Table 2. Acceptable Substituents, which can also be cited as suffixes in nodal nomenclature when the parent element is carbon. (In descending order of priority for citation as principal substituent, cf. **Rule N-14.1**.)

Substituent	Prefix [**]	Suffix [**]	IUPAC Rule [5]
$-$[C](O)OH	[*]	-oic acid (2a)	C-11.1; C-401.1
$-$[C](O)SH	[*]	-thio *S*-acid (2a)	C-541.1
$-$[C](S)OH	[*]	-thio *O*-acid (2a)	C-541.1

$-OH$	Hydroxy (1c)	-ol (2b)	C-201.1; C-201.2; C-202.1
$-SH$	Mercapto (1d)	-thiol (2b)	C-511.1
$-SeH$	Hydroseleno (1e)	-selenol (2b)	C-701.1
$-NH_2$	Amino	-amine (2c)	C-811.3; C-11.42
$=NH$	Imino	-imine (2c)	C-815.3(a)

[*] When the parent element is carbon, composite substituents are named as prefixes: for instance, $-$[C](O)SH is named "(mercapto, oxo)". [**] (1a) to (1e) and (2a) to (2c): For naming the anionic substituents derived from these groups, as prefixes or as suffixes, see correspondingly numbered instructions in **Rule N-10.4**.

substituents, the priority order is the one adopted for the corresponding nonionized substituent groups.

Examples (for numbering, refer to **Rules N-14.3** and **N-14.5**):

1. 
4-(Mercapto, oxo)[4]tetrane-1-sulfinate

2. 
4-Sulfinato[4]tetrane-1-thioate

3. 
1,5-Bis(mercapto, thioxo)[4.1^2]pentane-4-sulfonate

4. 
4-Sulfonato[4.1^2]pentane-1,5-bis(dithioate)

5. 
2-Oxidocyclo[(06)1 : 7(1)]heptan(1-6)aren-7-oate

(For the name of the parent hydride in Example 5, see **Rule N-12.3**.)

Rule N-11—Saturated Parent Hydrides

N-11.1. Names and bonding numbers for standard mononuclear element hydrides are given in Table 3. Higher homologues of these element hydrides are named by replacing, in the name of the structure graph, the ending "-nodane" by the name of the corresponding mononuclear element hydride given in Table 3.

Table 3. Standard bonding numbers (SBN), names for mononuclear element hydrides and prefixes for elements in replacement nomenclature [5d].

Element		Element Hydride		Replacement
Name	SBN	Formula	Name	Prefix
Fluorine	1	FH	Fluorane [a]	Fluora [a]
Chlorine	1	ClH	Chlorane [a]	Chlora [a]
Bromine	1	BrH	Bromane [a]	Broma [a]
Iodine	1	IH	Iodane [a]	Ioda [a]
Astatine	1	AtH	Astatane [a]	Astata [a]
Oxygen	2	OH_2	Oxidane [b]	Oxa
Sulfur	2	SH_2	Sulfane	Thia
Selenium	2	SeH_2	Selane	Selena
Tellurium	2	TeH_2	Tellane	Tellura
Polonium	2	PoH_2	Polane	Polona
Nitrogen	3	NH_3	Azane	Aza
Phosphorus	3	PH_3	Phosphane	Phospha
Arsenic	3	AsH_3	Arsane	Arsa
Antimony	3	SbH_3	Stibane	Stiba
Bismuth	3	BiH_3	Bismuthane	Bisma
Carbon	4	CH_4	Carbane [c]	Carba
Silicon	4	SiH_4	Silane	Sila
Germanium	4	GeH_4	Germane	Germa
Tin	4	SnH_4	Stannane	Stanna
Lead	4	PbH_4	Plumbane	Plumba
Boron	3	BH_3	Borane	Bora

[a] These names are needed for bonding numbers other than standard (see **Rules N-10.3** and **N-14.1**). [b] "Oxidane" is preferred to "oxane" in order to avoid confusion with Hantzsch-Widman names. [c] For the choice of carbon as parent element, see particular dispositions of **Rules N-11.2** and **N-11.3**.

Examples:

1.  [5.1^3]Hexacarbane

2.  [5.1^3]Hexasilane

3.  [5.1^3]Hexaazane

4.  [4]Tetrasulfane

N-11.2. The systematic names of the higher hydrocarbons are so well known in organic chemistry that the morpheme "carb" can be elided where there is no risk of ambiguity. When a molecule of a saturated hydrocarbon contains less than four carbon atoms, the descriptor is not necessary and the trivial names (*i.e.*, methane, ethane, propane, and cyclopropane) are so firmly entrenched that they can be used as exceptions instead of the systematic names (*i.e.*, [1]carbane, [2]dicarbane, [3]tricarbane, and cyclo[03]tricarbane, respectively). However, the systematic names [4]tetracarbane (or [4]tetrane) and [3.1^2]tetracarbane (or [3.1^2]tetrane) are preferred to the trivial butane and isobutane names because use of the descriptor is necessary to distinguish between the isomers and to define the numbering of the skeleton.

Examples (IUPAC names[5e] are given in parentheses for comparison):

a) Saturated acyclic hydrocarbons

1.  [4]Tetrane [*] (Butane)

2.  [3.1^2]Tetrane (Isobutane)

3.  [6]Hexane (Hexane)

4.  [5.1^3]Hexane (3-Methylpentane)

5.  [10.1^{2}1^{7}1^8]Tridecane (2,7,8-Trimethyldecane)

6.  [9.3^{4}1^5]Tridecane (5-Methyl-4-propylnonane)

7. 
[13.6^{7}6^{7}2^{3}1^{5}1^{9}1^{11}1^{15}1^{17}1^{21}1^{23}]Tetratriacontane (7,7-Bis(2,4-dimethylhexyl)-3-ethyl-5,9,11-trimethyltridecane)

8. 
[12.4^{6}3^{13}2^{9}1^{14}1^{18}]Tricosane (4-Ethyl-7-(1-isobutyl-2-methylbutyl)dodecane)

[*] In this and subsequent examples, the morpheme "carb" is elided.

b) Saturated cyclic hydrocarbons

9. Cyclopropane

10. Cyclo[06]hexane
(Cyclohexane)

11. Bicyclo[04.0^{1,3}]tetrane
(Bicyclo[1.1.0]butane)

12. Bicyclo[07.1^{1,4}]octane
(Bicyclo[3.2.1]octane)

13.  Tricyclo[012.1^{1,7}0^{3,11}]tridecane
(Tricyclo[5.5.1.0^{3,11}]tridecane)
(Perhydo-2,7-methanocyclopenta-cyclononene)

14.  Tricyclo[08.4^{1,1}5^{10,10}]heptadecane
(Dispiro[5.1.7.2]heptadecane)

N-11.3. Heteroatomic hydrides containing atoms of more than one element other than hydrogen are named by replacement nomenclature[5b,f]. Such a structure is first named as though the skeleton contains only the parent element, *i.e.* the most common element other than hydrogen. Atoms of less common elements are then named by means of the prefixes in Table 3, in the order given, with locants to indicate their positions. When a skeleton contains equal numbers of atoms of more than one element, including carbon, carbon is preferred as the parent element. If carbon is not among the most common elements of the skeleton, the parent element is the first cited in Table 3.

If Part I leaves a choice, lowest locants are assigned first to heteroatoms as a complete set, then to heteroatoms in the order of Table 3.

Examples (IUPAC names[5b,f] are given in parentheses for comparison):

a) Saturated acyclic heteroatomic compounds

1. 2,5,8,11-Tetraoxa[13]tridecane
(2,5,8,11-Tetraoxatridecane)

2. 2,6,9-Trioxa[11.2^3]tridecane
(3-Ethyl-2,6,9-trioxaundecane)

3. 13-Oxa-7-thia-10-aza[12.2^4]tetradecane
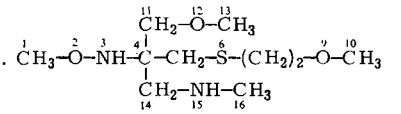
(3-Propyl-2-oxa-6-thia-9-azaundecane)



4.
2,9,12-Trioxa-6-thia-3,15-diaza[10.3^{4}3^4]hexadecane
(4-(Methoxymethyl)-4-[(methylamino)methyl]-2,9-dioxa-6-thia-3-azadecane)

b) Saturated cyclic heteroatomic compounds

5. 1-Oxacyclopropane
(Oxirane)

6. 1-Azacyclopropane
(Aziridine)

7. 1-Oxa-2-thiacyclo[05]pentane
(1,2-Oxathiolane)

8.  4-Thia-1,2-diazacyclo[06]hexane
(1-Thia-3,4-diazinane)
(1-Thia-3,4-diazacyclohexane)

9.  2,6,9-Trioxabicyclo[07.2^{1,4}]nonane
(3,6,8-Trioxabicyclo[3.2.2]nonane)

10.  7-Oxabicyclo[06.4^{1,1}]decane
(1-Oxaspiro[4.5]decane)

11.  from: 
3-Oxa-11-azatetracyclo-[(06.1^{1,4})1 : 9(06.1^{1,4})]tetradecane
(3-(2-Oxabicyclo[2.2.1]hept-4-yl)-1-azabicyclo[2.2.1]heptane)

Tetracyclo[(06.1^{1,4})1 : 9-(06.1^{1,4})]tetradecanodane

Rule N-12—Unsaturated Parent Hydrides: Names Derived from those of Saturated Structures

N-12.1. *Double* and *triple bonds* are indicated by the usual suffixes, *i.e.*, "-ene", "-diene", "-yne", "-diyne", "en...yne", *etc.* In contrast with present usage, the ending "-ane" of the corresponding saturated structure is maintained in the name of the unsaturated compounds, with elision of the final "e" before the vowels "e" or "y"[8]. Locants of two atoms linked by a multiple bond are placed immediately before the appropriate suffix and are cited in ascending order, with the second locant enclosed in parentheses. The second locant is omitted when it exceeds the first by unity. As far as Part I and Rule **N-11.3** leave a choice, lowest locants are assigned first to double and triple bonds as a complete set, even though this may, at times, give "yne" a lower locant than "ene". When there remains a choice, lowest locants are assigned to double bonds.

For the reasons given in **Rule N-11.2**, the IUPAC systematic names "ethene", "ethyne", "propene", "cyclopropene", "propadiene" and "propyne" are retained.

Examples (IUPAC names are given in parentheses for comparison):

a) Unsaturated acyclic hydrocarbons[5e]

1.  [6]Hexan-2-ene (2-Hexene)

2.  [6.1^3]Heptan-5-ene (4-Methyl-1-hexene)

3.  [6.1^3]Heptan-3(7)-ene (2-Ethyl-1-pentene)

4.  [5.2^3]Heptan-2-ene (3-Ethyl-2-pentene)

5.  [6]Hexane-1,4-diene (1,4-Hexadiene)

6.  [5]Pentan-3-en-1-yne (3-Penten-1-yne)

7.  [6]Hexane-1,3-dien-5-yne (1,3-Hexadien-5-yne)

b) Unsaturated cyclic hydrocarbons[5e]

8. Cyclo[06]hexanene (Cyclohexene)

9.  Bicyclo[06.4^{1,1}]decane-2,7-diene (Spiro[4.5]deca-1,6-diene)

10.  Bicyclo[011.0^{1,5}]undecane-1(5),2-diene (4,5,6,7,8,9-Hexahydro-1*H*-cyclopentacyclooctene)

11.  Bicyclo[016.2^{1,4}]octadecane-1,3,17-triene (Bicyclo[12.2.2]octadeca-1(16),14,17-triene)

c) Unsaturated acyclic heteroatomic compounds[5b]

12. 
4-Oxa-13-thia-8,9-diaza[16]hexadecane-1,6,8,10,15-pentaene (4-Oxa-13-thia-8,9-diaza-1,6,8,10,15-hexadecapentaene)

13. 
2,7,10,15,18,22-Hexaoxa[16.4^{8}4^9]tetracosan-8-ene (8,9-Bis(ethoxymethyl)-2,7,10,15-tetraoxa-8-hexadecene)

d) Unsaturated cyclic heteroatomic compounds[5c]

14. 1-Aza-2-arsacyclo[04]tetran-3-ene (1,2-Dihydro-1,2-azarsete) (or 3,4-Didehydro-1,2-azarsetidine)

15.  1-Silacyclo[05]pentan-3-ene (2,5-Dihydro-1*H*-silole) (or 3,4-Didehydrosilolane)

16.  from: 
7-Oxabicyclo[(06.1^{1,4})2:10(4.1^2)]-dodecan-9-ene (2-(1,2-Dimethyl-1-propenyl)-7-oxabicyclo[2.2.1]heptane)

Bicyclo-[(06.1^{1,4})2:10(4.1^2)]-dodecanodane

N-12.2. The presence in a more complex hydride of a part containing the maximum number of noncumulative double bonds is indicated by the suffix "axene" added to the name of the saturated hydride, with elision of the latter's terminal "e". This procedure is applied when the part structure contains at least three noncumulative double bonds.

The position of unsaturation is indicated by locants, preceding the suffix "axene" and describing *all* the skeletal atoms present in the part(s) of the structure concerned. A group of locants such as (1—6) means that all the atoms numbered from 1 to 6 inclusively belong to a part of the compound containing the maximum number of noncumulative double bonds. More than one set of locants may be associated with the suffix "-axene".

Examples:

1. 
[13.1^6]Tetradecan(4-10,14)axene

2.  Bicyclo[016.2^{1,4}]octadecan(1-5,16-18)axene

N-12.3. If the aromatic character of the part containing the maximum number of noncumulative double bonds is to be stressed, the suffix "axene" can be replaced by "arene".

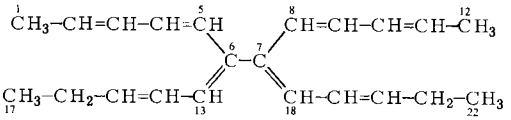
Examples:

1.  Bicyclo[(010.0^{1,6})2:11(2)4:13(2)7:15(2)]-hexadecan(1-10)arene

2. 
11-Azabicyclo[(06)1:7(4)10:11(05)]pentadecan(1-6)arene

N-12.4. If there is a choice, the locants of the "axene" or "arene" suffixes should be as low as possible. All the locants of the atoms belonging to the part with the maximum number of noncumulative double bonds are then considered as one set notwithstanding the fact that some may be explicitly cited while others are implicit, such as 3,4,5,6,7,8,9,10 in (2—11) in the following example.

Example:



[12.5^{6}5^7]Docosan(2-11,13-15,18-20)axene

(NOT: (2—10, 13—15, 18—21), because 2...10, 11, 13... is lower than 2...10, 13, 14...)

N-12.5. When a part of a structure contains the maximum number of noncumulative double bonds while other parts contain either isolated or cumulative double bonds and/or triple bonds, the corresponding suffixes are cited in the order: "-axene" (or "-arene"), "-ene", "-yne". Locants of cumulative and isolated double bonds are cited together when the "-axene" ending is used.

If there is a choice, lowest possible locants are first assigned to the atoms concerning the "-axene" (or "-arene") term, as defined in **Rule N-12.4**; afterwards, if there remains a choice, lowest possible locants are assigned to explicitly cited multiple bonds (double and triple bonds considered together). If there is still a choice, lowest possible locants are assigned to double bonds. This is the pattern set by IUPAC **Rule A-3.3**.

Examples:

1. 
Cyclo[(7)1:8(06)11:14(7)]icosan(8-13)aren-4-en-17-yne

2. 
Cyclo[014]tetradecan-(1-10)axene-11,12,13-triene

(NOT...(5—14)axene-1,2,3-triene, since the suffix "-axene" claims the lowest locants.)

3. 
Cyclo[014]tetradecan-(1-12)axen-13-yne

N-12.6. When, in an "*ortho*-fused" or "*ortho*- and *peri*-fused" polycyclic ring system, the number of double bonds is equal to, or smaller than, two-thirds of the maximum number of noncumulative double bonds, the name is formed from the name of the corresponding saturated ring system *by adding to the ending "ane"* the appropriate "ene", "axene", or "arene" suffixes (see **Rules N-12.1, N-12.2** and **N-12.3**) and associated locant(s).

Examples:

1. 
Bicyclo[010.0^{1,6}]decane-1(6),3-diene (1,2,3,4,5,8-Hexahydronaphthalene)

2.  or

Tetracyclo[016.1^{1,5}0^{6,11}0^{13,17}]-heptadecane-1,3,5(17),6(11)-tetraen
Tetracyclo[016.1^{1,5}0^{6,11}0^{13,17}]-heptadecan(1-6,11,17)axene (5,6,6a,7,8,9,10,11-Octahydro-4*H*-benz[*de*]anthracene)

Rule N-13—Unsaturated Parent Hydrides: Names Derived from those of Structures having the Maximum Number of Noncumulative Double Bonds (Partly alternative to Rule N-12)

N-13.1. The name of an unsaturated hydride containing the maximum number of noncumulative double bonds is obtained by *replacing,* in the name of the corresponding saturated hydride, *the ending "ane" by the suffix "axene".* If the aromatic character of the hydride is to be indicated, the suffix "arene" is used instead of "axene".

The presence of at least one hydrogen atom on a skeletal atom joined to adjacent skeletal atoms by only single bonds is denoted by "indicated hydrogen"[9].

Examples:

1. 
Bicyclo[010.0^{1,6}]decarene (Naphthalene)

2. 
12*H*-Tetracyclo[016.1^{1,5}0^{6,11}0^{13,17}]-heptadecarene (7*H*-Benz[*de*]anthracene)

3. 
Tetracyclo[(06)1:7(06)9:13(06)16:19(06)]tetracosarene

4. 
20*H*-16-Oxa-2,21-diazatetracyclo-[(06)1:7(2)8:9(06)12:15(05)17:20(1)7:21(05)]-pentacosaxene

N-13.2. An unsaturated hydride containing a number of double bonds less than the maximum number of noncumulative double bonds, but larger than two-thirds of this number, can be named by adding a prefix "dihydro", "tetrahydro", *etc.,* to the name of the corresponding hydride having the maximum number of noncumulative double bonds.

Indicated hydrogen has priority over "hydro" prefixes for assignment of lowest possible locants. For this pur-

pose, a structure with the maximum number of noncumulative double bonds, having the lowest possible locant(s) for indicated hydrogen(s) is first selected. Only then, are lowest possible locants assigned to hydro prefixes. This method implies that, eventually, an indicated hydrogen locant may be higher than a hydro locant (see example 4).

Examples:

1. 
2,5-Dihydrobicyclo[010.0^{1,6}]decarene
(1,4-Dihydronaphthalene)

2. 
15,16-Dihydro-14*H*-tetracyclo-
[016.1^{1,5}0^{6,11}0^{13,17}]heptadecarene
(5,6-Dihydro-4*H*-benz[*de*]anthracene)

3. 
9,10,19,20-Tetrahydropentacyclo-
[020.1^{1,5}1^{4,8}1^{11,15}1^{14,18}]tetracosaxene

4. 
17,27-Dihydro-21*H*-tetracyclo-
[(06)1 : 7(3)9 : 10(06)13 : 16(05)17 : 21(1)4 : 22(05)24 : 27(1)]-
heptacosaxene

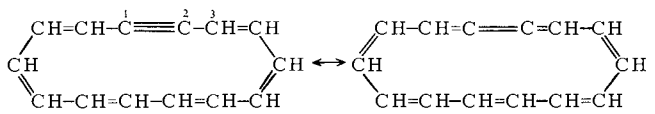
(Only 21*H* and 27*H* correspond to canonical structures having the maximum number of noncumulative double bonds; no 17*H* structure exists.)

5. 
12,13-Dihydro-8,14-diazatricyclo-
[(06)1 : 7(05)8 : 12(2)4 : 14(05)16 : 19(2)]icosaxene

N-13.3. When a parent hydride corresponds to a loss of hydrogen from a structure having the maximum number of noncumulative double bonds, it can be named by adding a prefix such as "didehydro", "tetradehydro", *etc.*, with appropriate locants, to the name of the corresponding hydride having the maximum number of noncumulative double bonds.

It is recommended that the "hydro" and "dehydro" prefixes not be used simultaneously in the same name. Structures for which this circumstance would happen should be named according to **Rule N-12**. For assignment of lowest possible locants, "dehydro" prefixes immediately follow indicated hydrogen.

Example (to be compared with examples 2 and 3 of **Rule N-12.5**):



1,2-Didehydrocyclo[014]tetradecaxene

Rule N-14—Construction of the Name

N-14.1. The various parts of the name occur in the following order:

a) Substituent prefixes, in alphabetical order;
b) Name of the neutral parent hydride, comprising:
   1) Dehydro and hydro prefixes;
   2) Indicated hydrogen;
   3) Replacement prefixes ("a" prefixes), in the same order as in Table 3;
   4) Name of the structure graph in which "nodane" is replaced by an affix denoting the parent element (**Rule N-11**);
   5) Endings indicating unsaturation ("-ene", "-yne", "-axene" or "-arene").
c) *EITHER* One or several ionic and/or free valence suffix(es), in the order: "-ium", "-ylium", "-ide", suffix for anionic principal substituent (**Rule N-10.4**), "-yl";
   OR A suffix denoting a neutral principal substituent (**Rule N-10.2**).

Suffixes denoting free valences ("-yl", "-diyl", *etc.*) are always cited at the end of the name. They preclude the simultaneous presence of a suffix denoting a neutral principal substituent. In nodal nomenclature, these suffixes are used exclusively for free radicals or for substituents which do not need internal numbering (*e.g.*, **Rule N-10.3**: Dichloro-λ^3-iodanyl).

Anionic principal substituents defined in **Rule N-10.4** may be cited after the other ionic suffixes. If there is more than one kind of anionic substituent, **Rule N-10.4** determines the anionic substituent to be cited as a suffix. Other anionic substituents are then denoted by the prefix(es) given in **Rule N-10.3**.

Only one kind of neutral substituent group can be denoted by a suffix (principal substituent). When there is a choice, the principal substituent is the first cited in Table 2. If substituents other than those cited in this table are used, their order of priority is defined by pertinent IUPAC Rules such as **C-10.4**, **C-641.2**, **D-1.31**, **D-1.32**, and **D-1.33**[5].

Atoms or groups which cannot be denoted as a substituent by a suffix or a prefix are expressed as part of the neutral parent hydride.

Examples:

1.  3-(Hydroxy,oxo)propan-1-yl

2.  4-Azacyclo[(06)1 : 7(1)]heptan-4-ium-7-oate

3.  7-Oxo-5-sulfino-8-oxacyclo-[(06)1 : 7(3)2 : 10(1)]decan(1-6)-aren-10-oic acid

(According to Table 2, (C)OOH is preferred to SO_3H as principal substituent.)

N-14.2. According to Part I[2] and to the preceding Rules, the numbering of any structure is determined by the

following criteria, applied successively until a decision is reached:

a) Criteria given in Part I concerning the numbering of the structure graph;
b) Lowest locants for replacement prefixes considered together (**Rule N-11.3**);
c) Lowest locants for replacement prefixes considered in the order of Table 3 (**Rule N-11.3**).

Depending on whether **Rule N-12** or **Rule N-13** is used for indicating unsaturation, locants are then assigned to unsaturation affixes in one of the two following ways:

(**Rule N-12**)—In names derived from those of saturated structures, lowest locants are assigned to:

d_1) "-axene" or "-arene" suffixes (**Rules N-12.4** and **12.5**);
e_1) Explicitly cited multiple bonds as a complete set, then double bonds (**Rules N-12.1** and **12.5**).

(**Rule N-13**)—In names derived from those of structures having the maximum number of noncumulative double bonds, lowest locants are assigned to:

d_2) Indicated hydrogen (**Rules N-13.1** and **N-13.2**);
e_2) "Hydro" or "dehydro" prefixes (**Rules N-13.2** and **N-13.3**), it being understood that these two types of prefixes do not coexist in the same name.

Examples (decisive criteria are indicated within parentheses):

1. (a)  [4.1²]Pentane-1,4,5-triol (2-(Hydroxymethyl)-1,4-butanediol)

2. (a) 
Bicyclo[(010.0^{1,6})3:11(3)2:14(2)8:16(1)]hexadecan-(1-10)arene-13,15,16-trioic acid
(6-Carboxy-1-(carboxymethyl)-2-naphthalenepropionic acid)

3. (a) 
Disodium 4-sulfonato-7,8-diaza-15*H*-bicyclo-[(06)1:7(2)8:9(06)12:15(1)]pentadecaxen-15-oate
(Disodium 4'-sulfonatoazobenzene-4-carboxylate or: Disodium *p*-(*p*-sulfonatophenylazo)benzoate)

4. (b) 
3,5-Dioxo-2,6-dioxa[8]octane
(Ethyl methyl malonate)

5. (c)  2-Oxa-7-thia[6.2³]octane (1-Methoxy-1-(methylthio)butane)

6. (e_1)  Cycloprop-1-en-3-ylium (2-Cyclopropen-1-ylium) [*]

7. (e_1)  Cyclo[06]hexan-1-en-3-ylium (2-Cyclohexen-1-ylium) [*]

8. (e_1) 
1,6-Dioxo[6]hexan-2-en-4-yne
(2-Hexen-4-ynedial)

9. (d_2)  1*H*-Cyclo[07]heptaxen-1-ylium (2,4,6-Cycloheptatrien-1-ylium)

10. (e_2)  3,8-Dihydrobicyclo[010.0^{1,6}]-decarene-5,10-disulfonic acid (3,7-Dihydronaphthalene-1,5-disulfonic acid)

N-14.3. When Part I and **Rule N-14.2** leave a choice for the numbering of the skeleton of a chemical structure, the following criteria are applied successively until a decision is reached, giving the lowest locant to:

a) Free valences, denoted by the suffix "-yl";
b) Anionic skeletal atoms denoted by the suffix "-ide";
c) Cationic skeletal atoms denoted by the suffix "-ylium", corresponding to the loss of an electron at a free valence position;
d) Cationic skeletal atoms denoted by the suffix "-ium", corresponding to the fixation of a proton;
e) Anionic substituents named by a suffix (see **Rule N-10.4**);
f) Anionic substituents named by a prefix (see **Rule N-10.4**);
g) Cationic substituents named by a prefix (see Table 1).

Examples (decisive criteria are indicated within parentheses):

1. (a)  2,5-Diaza[6]hexan-2-yl

2. (a)  [4]Tetrane-2,2-diyl

3. (a)  2,5-Diaza[6]hexan-5-id-2-yl

4. (a)  2,5-Diaza[6]hexan-5-ium-2-yl

5. (b) 2,5-Diaza[6]hexan-2-ide

6. (c) [4]Tetran-2-ylium

[*] As in classical organic nomenclature, free radicals with delocalized free valences, or ions with delocalized charges, can be named by arbitrarily selecting a localized form, *e.g.*, 2-cyclohexen-1-ylium (**Rule C-83.1** [5]). When this procedure is used in nodal nomenclature, it is important to note that the numbering of the neutral parent hydride, including unsaturation, has priority over ionic charges for low locants. This arbitrary numbering may therefore be different from the arbitrary numbering recommended by IUPAC Rules (see examples 6 and 7). Pending publication of IUPAC Rules on delocalized ions and radicals, no attempt to treat this subject is made here.

7. (c)  2,5-Diaza[6]hexan-5-ium-2-ylium

8. (d)  2,5-Diaza[6]hexan-2-ium

9. (d)  6-(Oxido,oxo)-2,5-diaza-[6]hexan-2-ium

(Ionic skeletal atoms having priority for low locants over ionic substituents, it is preferable to use prefixes for the latter.)

10. (e)  Disodium 7-oxo-6-sulfidocyclo-[(06)1 : 7(2)]octan(1-6)arene-3-sulfonate

(The principal substituent SO_3^- has the locant 3, not 5.)

11. (f)  2-Sulfido[4]tetrane-1,4-dioate

12. (g)  2-Ammonio[4]tetrane-1,4-dioate

N-14.4. The description of the skeleton is completed before considering the distribution of hydrogen atoms and of ionic charges. Therefore, a cationic skeletal atom may be denoted by the *suffix* "ium" only if it bears at least one hydrogen atom. If this is not the case, the *suffix* "ylium" is used, associated with the indication of a nonstandard bonding number by a "λ^n" symbol[7].

Examples:

1.  2,5-Diaza[7.1^{2}1^5]nonan-2,5-diium

2.  2λ^5,5-Diaza[7.1^{2}1^2]-nonan-5-ium-2-ylium

N-14.5. When the preceding rules leave a choice for the numbering of the skeleton of a chemical structure, the following criteria are applied successively until a choice is made, giving lowest locants to:

a) Neutral principal substituent, denoted by a suffix;
b) Neutral substituents denoted by prefixes, considered together;
c) Neutral substituents denoted by prefixes, in alphabetical order.

Examples (decisive criteria are indicated within parentheses):

1. (a)  [7.2^4]Nonan-4(8)-en-1-ol (4-Propyl-4-hex-en-1-ol)

2. (a) 
[10.3^{5}1^{8}1^{9}1^{12}]Hexadecane-1,10,13,14,16-pentoic acid (3-(3-Carboxypropyl)-1,1,6,7-octanetetracarboxylic acid)

3. (b)  5-Bromo-2-chlorocyclo-[(06)1 : 7(1)]heptan(1-6)arene

4. (c) $N{\equiv}C{-}CH_2{-}CO{-}CH_2{-}CHO$ 1-Nitrilo-3,5-dioxo[5]pentane (4-Formyl-3-oxobutanenitrile)

6. Conclusion

We have shown that the use of nodal nomenclature (with its structure graphs, mathematical description of chemical structures, unique and sequential numbering, and virtual equivalence of substituents with characteristic groups) simplifies the naming of chemical substances, particularly organic compounds with complex structures. The resulting names are not fragmented and are based upon a single numbering sequence, avoiding the scattering in the name of substitutive affixes and replacement terms.

The present work giving only rather general suggestions for adapting the substitutive method to nodal nomenclature, a more extensive and more detailed treatment of functional groups may deserve a further study. We consider also the extension of nodal nomenclature to other types of chemical substances such as polynuclear coordination compounds.

The Authors wish to thank members of the IUPAC Commission on Nomenclature of Organic Chemistry for their comments and, in particular, Prof. D. Hellwinkel for translating this paper into German.

Note on Part I[2]

Examination of **Rules N-5.3** to **N-5.34** inclusive showed that their selection criteria for numbering and naming assemblies could be simplified and made more exhaustive. The following Rules, denoted **RN-5.3** to **RN-5.34** have therefore been devised in order to replace the preceding **Rules N-5.3** to **N-5.34**.

This new text reproduces many features of the preceding one (including note[23]), sometimes in a different order, and does not affect the name of any example in the original paper.

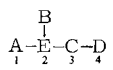
RN-5.3. *Numbering of the module seniority graph, i.e.* assignment of the module seniority numbers, which determines the order of assignment of the definitive sequential numbering of the assembly (see **Rule N-5.1**), begins with the principal module (see **Rule N-4.2**) and proceeds successively through each chain of contraction nodes attached to the principal module. Selection rules for numbering the module seniority graph differ from those applied to acyclic graphs (**Rule N-1**) because module seniority graphs deal with constituent units (modules) which may greatly differ in structural complexity. Accordingly, rules for the module seniority graph take into consideration the nature of the contraction nodes, while, according to **Rule N-1**, the nature of the nodes does not affect the numbering of the graph.

RN-5.31. A module seniority graph is considered as formed by one or more *unbranched chain(s) of modules* which are called *segments* and defined as follows.

RN-5.311. The numbering of a module seniority graph starts from the (one of the) senior module(s), called the *principal module* and continues sequentially according to the following procedure:

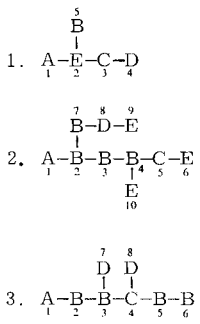
a) In a chain of modules bound to the principal module, the *main segment* is the longest (or one of the longest) attached to the principal module and is numbered sequentially after the principal module.

Example:



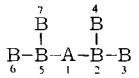
b) Other segments of a chain of modules are numbered sequentially, starting always with the (one of the) longest segment(s) bound to a module already numbered. Segments of equal length are numbered in the increasing numerical order of their locants of attachment.

Examples:



c) Any chain of modules, unbranched or branched, bound to the principal module, is entirely numbered before numbering another chain (if any) bound to the principle module.

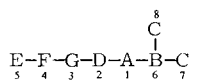
Example:



RN-5.312. When two or more chains of modules are attached to the principal module, the order in which these chains are numbered is decided by the following criteria considered successively until a decision is reached:

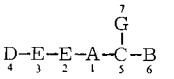
a) Largest number of modules in the entire chain.

Example:



b) Longest unbranched chain of modules (*i.e.*, longest main segment).

Example:



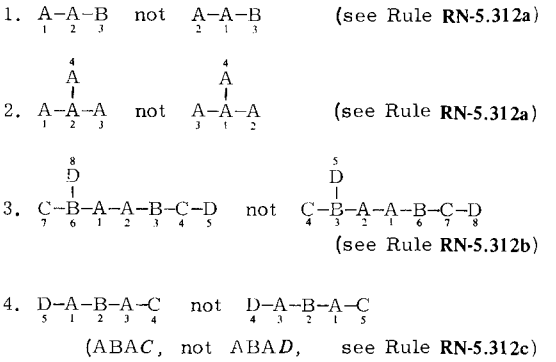
c) Senior module, at the first difference, when the various sets of modules are compared, term by term, in order of decreasing seniority as defined in **Rule N-4.2**, regardless of the positions of the modules in the chains.

Example:

(B*C*, not B*D*)

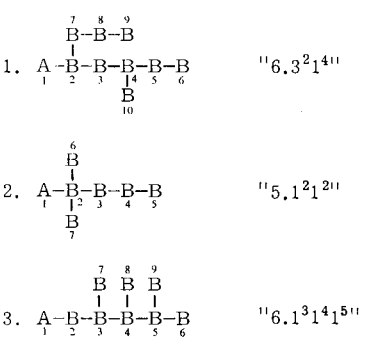
RN-5.313. When a module seniority graph contains two or more modules of highest seniority, *i.e.* with module seniority descriptor A, the *principal module* is that senior module to which is attached the most senior chain of contraction nodes when these chains are compared term by term, in order of decreasing seniority, this order being determined by the criteria described in **Rule RN-5.312**.

Examples:



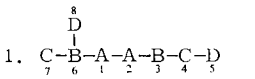
RN-5.32. The *module graph descriptor* consists of quotation marks enclosing: a) an Arabic numeral denoting the number of modules, including the principal one, in the first (main) segment to be numbered; b) a period followed by Arabic numerals denoting the number of modules in each segment, cited in their order of numbering; c) a superscript locant for each segment defined under b), denoting the module, in the part of the graph already numbered, to which the segment is attached.

Examples:

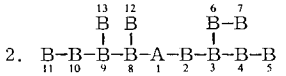


RN-5.33. When there remains a choice for the order of numbering of the chains or for the selection of the principal module, the correct numbering of the module seniority graph is the one corresponding to the module graph descriptor having the preferred numeral at the first difference: if the first difference corresponds to a segment length, the preferred numeral is higher; if the first difference appears in a superscript numeral (locant of a module), the preferred numeral is lower.

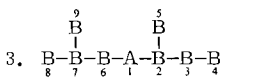
Examples:



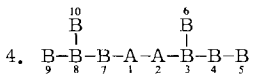
1. "$5.2^{1}1^{6}$" not "$4.1^{3}3^{1}$"



2. "$5.2^{3}4^{1}1^{8}1^{9}$" not "$5.1^{2}1^{3}4^{1}2^{9}$"



3. "$4.1^{2}3^{1}1^{7}$" not "$4.1^{3}3^{1}1^{6}$"



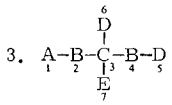
4. "$5.1^{3}3^{1}1^{8}$" not "$5.1^{4}3^{1}1^{7}$"

RN-5.34. If the preceding Rules leave a choice for the numbering, the correct numbering is the one giving the lowest locant, at the first difference, when modules are considered in order of decreasing seniority.

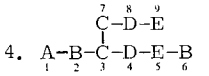
Examples:

1. locants for B: 2,5 not 3,4

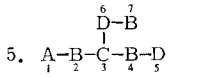
2. locants for B: 2,3 not 3,4



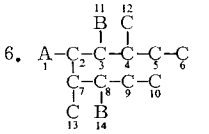
3. locants for D: 5,6 not 5,7



4. locants for B: 2,6 not 2,9



5. locants for B: 2,4,7 not 2,5,6



6. locants for B: 11,14 not 12,13

Rule **N-5.35** and following Rules unchanged.

N,N-Bis(trimethylsilyl)aminomethylation of Grignard Compounds— A Versatile Amine Synthesis

By *Hans Jürgen Bestmann** and *Gerhard Wölfel*

Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday

Sodium bis(trimethylsilyl)amide **1**[1] reacts with primary halides **2** ($R^1=R'-CH_2$, R′=H, alkyl, alkenyl, alkynyl, aryl) to give *N,N*-bis(trimethylsilyl)amines **3**[2]. We have now converted the α-haloethers **4** with **1** into the *N,N*-bis(trimethylsilyl)aminomethyl ethers **5**. These react with the Grignard compounds **6** (R^1, see Table 1) to give the *N,N*-bis(trimethylsilyl)amines **7** and the magnesium alkoxides **8**. Table 1 shows the scope of the reaction. Grignard compounds **6** can be employed in which the MgBr residue is attached to an sp^3, sp^2 or sp hybridized C-atom. In the case of the propargyl moiety (Example **d** in Table 1), use of the aluminum "Grignard compound"[4] has once again[3] proven better than that of the magnesium compound.

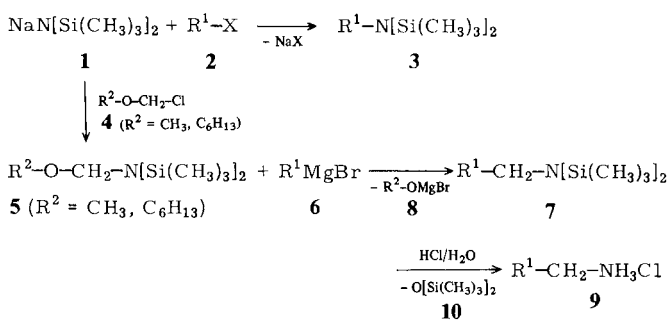

Table 1. Yields and boiling points of the *N,N*-bis(trimethylsilyl)amines **7**.

7	R^1	Yield [%] [a]	B.p. [°C/torr]
a	CH_3	82	60/20
b	$C_6H_5CH_2$	71 [b]	63/0.05
c	$H_2C=CH-CH_2$	70	81/16
d	$HC\equiv C-CH_2$ [c]	52	80/18
e	C_6H_5	64	52/0.1
f	α-Naphthyl	52	64/0.01
g	$H_7C_3-C\equiv C$	65	52/0.1

[a] Not optimized. [b] Same yields also in the reaction with **5b**. [c] The Al-"Grignard compound" was employed.

The silylamines **7** can easily be converted into the amine hydrochlorides **9** in yields of over 90% by treatment with 1 N hydrochloric acid or by passage of gaseous HCl into a solution of **7** in moist diethyl ether; the siloxane **10** is formed concomitantly[1].

Hence, primary halides such as **2** can either be converted into silylated amines such as **3** by nucleophilic substitution with **1** or, after umpolung via a Grignard compound, into compounds such as **7** containing an additional CH_2 group, by electrophilic substitution.

Procedure

5: **4** (0.1 mol) is added dropwise at 0°C to a stirred solution of **1** (18.4 g, 0.1 mol) in hexamethyldisilazane (50 mL). After 8 h at room temperature, NaCl is removed from the reaction mixture by filtration; the solvent is distilled off from the filtrate and the residue is fractionally distilled; **5a**; b.p. 73°C/16 torr; **5b**: b.p. 124°C/16 torr.—**7**: A solution of **5** (0.02 mol) in anhydrous ether (25 mL) is added dropwise to an ethereal Grignard solution of **2** (0.025 mol). After 12 h, precipitated **8** is filtered off and the solvent is removed from the filtrate by distillation. The residue is fractionally distilled. All operations are carried out under nitrogen.—**9**: HCl is passed into a solution of **7** (0.02 mol) in moist ether (25 mL). **9** precipitates out and is recovered by filtration.

Stable Cyclopentadienylium Salts**

By *Rudolf Gompper** and *Heinrich Glöckner*

According to *Breslow*[1], cyclopentadienylium salts are antiaromatic compounds. The parent compound and the pentachloro derivative have a triplet ground state (cf. [2]), and the pentaphenyl and pentakis(*p*-methoxyphenyl) derivatives a low-lying triplet state.

Previously, cyclopentadienylium salts have only been obtained in solution. However, cyclopentadienylium ions can be dramatically stabilized by ring N atoms in a compound with donor substituents: azacyclopentadienylium salts[3] and 1,3-diazacyclopentadienylium salts are extraordinarily thermally stable and display no indication of antiaromaticity. Since the pentakis(*p*-methoxyphenyl)cyclopentadienylium ion is stable in solution at room temperature[5], it should be possible to find combinations of substituents which lead to isolable cyclopentadienylium salts;

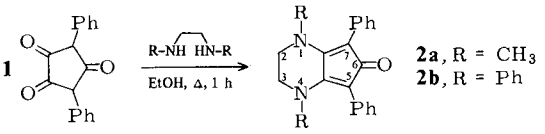
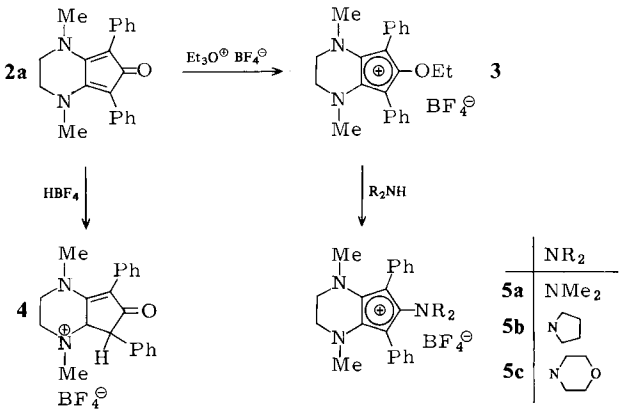
[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

here, we report a route to stable cyclopentadienylium salts.



The diphenylcyclopentanetrione **1** condenses smoothly with *N,N'*-dimethyl- and *N,N'*-diphenylethylenediamine to afford the red cyclopentadienone derivative **2**[7] (for the reaction of **1** with *o*-phenylenediamine, cf. [6]).

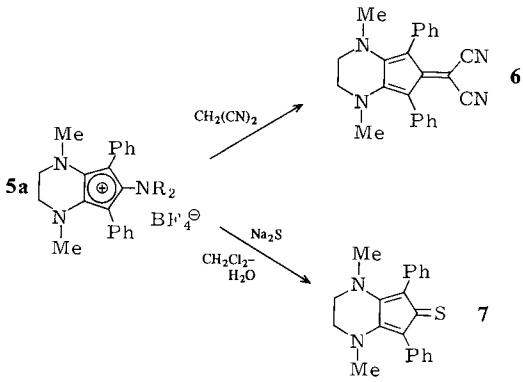
The relatively low CO stretching frequency of **2** suggests that the two amino groups of the piperazine ring are strongly conjugated with the carbonyl group and with an *O*-nucleophile, comparable to simple β-aminovinylcarbonyl compounds.



Protonation of **2a** with tetrafluoroboric acid affords the yellow salt **4** [100%, m.p. = 197 °C (decomp.); IR (KBr): ν = 1707, 1673, 1618, 1600, 1084 cm^{-1}], i.e. instead of the expected *O*-protonation, *C*-protonation occurs. In contrast, only *O*-alkylation occurs in the reaction of **2a** with triethyloxonium tetrafluoroborate (1.2 equiv. freshly prepared $Et_3O^{\oplus}BF_4^{\ominus}$, CH_2Cl_2, 25 °C, 1 h), resulting in formation of the ethoxycyclopentadienylium salt **3** in practically quantitative yield[7] as a green oil which occasionally solidifies amorphously.

3 is stable up to ca. 40 °C, but is very sensitive to moisture. More thermally stable cyclopentadienylium salts are accessible by allowing **3** to react with secondary amines (the reaction solution containing **3** is treated successively with 3 equivalents of amine and water, the dichlormethane separated off, and the mixture dried and covered with a layer of ether). The blue 6-amino-1,4-dimethyl-5,7-diphenyl-1,2,3,4-tetrahydrocyclopentapyrazin-6-ylium tetrafluoroborates **5** result[7]. The synthesis of crystalline, stable cyclopentadienylium salts **5** goes a long way towards stable cyclopentadienylium salts with a triplet ground state. The UV/VIS spectra of **3** and **5** indicate that the longest wavelength absorption maximum corresponding to the calculated (HMO) reduction in the HOMO-LUMO separation is bathocronically shifted (620, 624, 635, 735 nm) as the donor strength of the substituent at the 6-position decreases. Combinations of substituents which allow a triplet ground state should therefore also exist within the framework of the model compounds **3** and **5**.

3 and **5** can be used as starting materials for the synthesis of further cyclopentadiene derivatives. For example, from **5** and sodium sulfide in CH_2Cl_2/H_2O the cyclopentadienethione **7** is obtained [78%, m.p. = 195 °C (decomp.), blue, lustrous lamellae; UV/VIS (CH_3CN):



$\lambda_{max}(\lg\varepsilon)$ = 305 (4.13), 388 (4.49), 645 nm (2.72)]; **7** is the first stable cyclopentadienethione. Using malononitrile (NaH, tetrahydrofuran, Δ, 10 min) the donor-acceptor substituted fulvene **6** is accessible [80%, m.p. = 230 °C (decomp.), blue, lustrous lamellae; UV/VIS ($CHCl_3$): $\lambda_{max}(\lg\varepsilon)$ = 391 (4.58), 4.05 (sh), 510 (sh), 602 nm (2.86)].

Hydroxide Ion-Initiated Deuteration of Very Weak CH Acids under Phase Transfer Catalysis Conditions**

By *Marc Halpern, David Feldman, Yoel Sasson,* and *Mordecai Rabinovitz**

Use of aqueous sodium hydroxide under phase transfer catalysis conditions (PTC/$OH^{\ominus}$ systems) has been ac-

[**] Hydroxide Ion-Initiated Reactions under Phase Transfer Conditions, Part 7. This work is taken in part from the Ph. D. Thesis of *M. Halpern* and the M. Sc. Thesis of *D. Feldman*.— Part 6: *J. Org. Chem. 50* (1984), in press.

cepted as the method of choice for many base catalyzed organic reactions. Thus CH acids have been deuterated in the presence of quaternary ammonium salts[1–4]. Deuteration has, however, been limited to compounds as or more acidic than thiazole[3]. Recently, we showed that the hydroxide ion may be extracted into the organic phase under PTC/$OH^{\ominus}$ conditions[5]. Because of the differences in their relative states of hydration, the basicity of the extracted hydroxide ion is expected to be greater than that of hydroxide ion at the interface. This enhanced basicity may be used to significantly extent the scope of PTC/$OH^{\ominus}$ base catalyzed reactions. Here, we report the deuteration of very weak CH acids (up to pK_a 34)[6e] under extractive PTC/$OH^{\ominus}$ conditions.

When 550 mg (3.27 mmol) of diphenylmethane ($pK_a = 33$)[6a] is stirred magnetically at 27 °C for 16 h in a closed vessel in the presence of 1.5 mL of 18.3 M NaOD/D_2O and 200 mg (0.59 mmol) of tetrabutylammonium hydrogen sulfate (TBA HSO_4), 540 mg of α,α′-dideuteriodiphenylmethane (97%) is obtained after work-up (dilution in dichloromethane/water, washing with water, drying, and evaporation). The methylene singlet at $\delta = 3.72$ totally disappears in the NMR spectrum. The mass spectrum of the isolated compound shows the molecular ion at *m/z* 170.

Allylbenzene ($pK_a = 34$)[6b] was quantitatively isomerized and simultaneously deuterated at 75 °C yielding *trans*- and *cis*-PhCH=$CHCH_2D$. This indicates that isomerization is more rapid than deuterium exchange at the α-position, and that β-methylstyrene is not acidic enough to react further. The product was identified by ^{1}H-NMR spectroscopy and by the characteristic C-D splitting pattern (3 peaks of equal height, $J = 20$ Hz) in the ^{13}C-NMR spectrum. Under the same conditions, toluene ($pK_a = 41$)[6a] does not undergo deuteration. Taking into account the fact that allylbenzene reacts in the given systems, but β-methylstyrene and toluene do not, it may be concluded that the limit of the basicity of the hydroxide ion under these conditions is in the range $pK_a \approx 34-41$.

10,11-Dibenzo[*a*,*d*]cycloheptadiene ($pK_a = 31$)[6a] and xanthene ($pK_a = 27$)[6c] were quantitatively dideuterated at the acidic position after 20 h and 3 h, respectively, in the presence of 10 mol% TBA HSO_4 and 63% NaOD/D_2O (solid material). Under similar conditions the aromatic hydrogens of 1,2,3,4-tetrafluorobenzene ($pK_a = 31.5$[6d] were exchanged to at least 80% for deuterium (^{1}H-NMR CI-MS).

An attempt to deuterate triphenylmethane ($pK_a = 31.5$)[6a] in chlorobenzene surprisingly afforded only 25% deuterium exchange with 10 mol% TBA HSO_4 after 24 h and 70% deuterium exchange with 20 mol% methyltrioctylammonium hydrogen sulfate at 75 °C, the reaction terminating after 2 h due to decomposition of the catalyst. In the presence of tetraoctylammonium bromide no reaction was observed, since $Br^{\ominus}$ apparently suppresses $OH^{\ominus}$ extraction sufficiently to prevent significant deprotonation of the sterically hindered substrate. Chlorobenzene was found to be a suitable solvent for the deuteration of diphenylmethane.

Thus, we believe that it is worthwhile to consider the use of a nonaccessible quaternary ammonium salt paired with a hydrophilic counterion (*e.g.*, NR_4HSO_4) as the catalyst in PTC/$OH^{\ominus}$ reactions requiring strong basic activity.

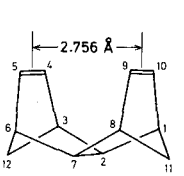
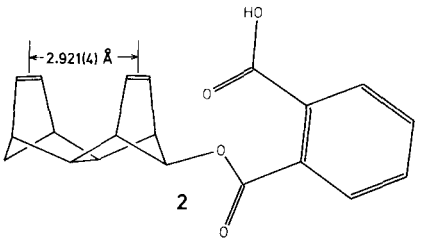
Structure of Tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodeca-4,9-diene: A Diolefin with Close Double Bonds**

By *Otto Ermer**, *Claus-Dieter Bödecker*, and *Hans Preut*

Calculations with our consistent force field gave a C_{2v} symmetric structure for tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodeca-4,9-diene **1** in which the double bonds are only 2.756 Å apart and have almost parallel planes[1]. Here, we report the crystal structure analysis of the derivative **2**, which we performed to examine the computational results (Fig. 1)[2].



1



2

In the crystals of **2**, the tetracyclic carbon framework has, to a good approximation, C_{2v} symmetry. The measured distance between the olefinic double bonds is 2.921(4) Å (corrected for libration 2.933 Å) and thus exceeds the calculated value by 0.165 (corr. 0.177) Å. Correspondingly, the observed (C_{2v} averaged) angle C(1)-C(2)-C(3) is larger than that calculated (125.4(0.3) vs. 121.3°).

The discrepancies between the calculated and observed geometries therefore indicate that the close double bonds in **1** repel each other more strongly than predicted by our force field. The obvious conclusion that the C···C nonbonding potential in our force field is not repulsive enough at short distances, however, *cannot be drawn in general* from the present study. In fact, the larger observed distance between the double bonds in **1** is rather a consequence of orbital symmetry effects as expressed in the rules of *Woodward* and *Hoffmann*[3]. The approach of two parallel double bonds as in **1** is part of a process which in the electronic ground state is energetically particularly unfavorable (symmetry-forbidden) and thus associated with

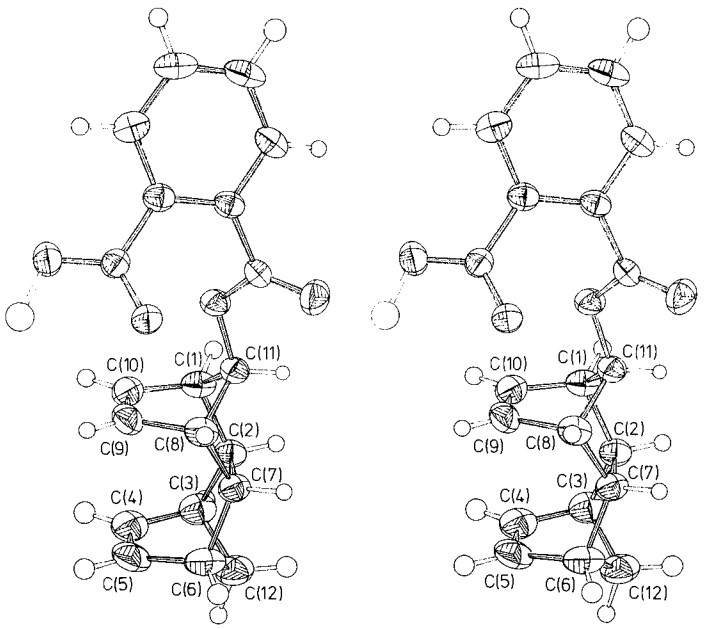
extra non-bonding repulsions. Effects of this nature are not represented in our force field since no data of olefins with close double bonds were available at the time of its calibration. It is noted that *Allinger*'s MM2 force field[4] also gives a smaller distance (2.787 Å) between the double bonds in **1** than that observed for **2**.



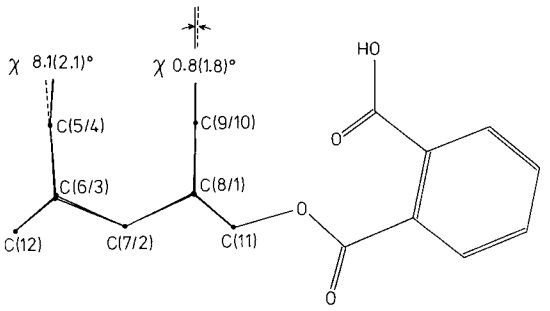


Fig. 1. Crystal structure of **2**. Top: Stereoscopic view with vibrational ellipsoids (35%) for the heavy atoms; for clarity, the isotropic temperature factors of the H atoms are reduced by a common factor. Below: Newman projection along C(7)-C(2).

It is to be expected that in **1** the repulsion between the double bonds is also alleviated by a shift of π electron density from the *endo*- to the *exo*-sides of the norbornene moieties, which is larger than in norbornene[5] itself. The structural consequence should be particularly large pyramidalizations—larger than those calculated for **1** or norbornene with our force field—at the C(sp^2) atoms (symmetric out-of-plane bending) with the H atoms of the double bonds approaching each other. In the crystals of **2**, the double bond C(4)=C(5) is indeed relatively strongly bent inwards by $\chi = 8.1(2.1)°$ (Fig. 1, below); using our force field we calculate only 3.1°[1] for **1** and 4.5° for norbornene. Interestingly, in **2** the double bond C(9)=C(10) is only slightly bent inwards ($\chi = 0.8(1.8)°$). This might be due to the substitution by the electronegative oxygen atom at C(11), which counteracts an accumulation of π electron density on the *exo*-side of the C(9)=C(10) double bond. Quantum chemical calculations on analogous C(7)-substituted norbornenes produced a similar effect[5]. Obviously, these interpretations have to be backed by a more reliable experimental localization of the H atoms in **2** than is possible by X-ray methods.

Our crystallographic results lead to the remarkable conclusion that in the symmetry-forbidden, synchronous dimerization of ground-state ethylene (conservation of overall D_{2h} symmetry, parallel double bond planes) symmetric out-of-plane bending deformations with *inward* displacements of the H atoms occur initially. These displacements are reversed only on closer approach of the ethylene molecules until eventually cyclobutane is formed (Fig. 2). A good quantum mechanical calculation would be of interest to verify this prediction quantitatively. The tetracyclododecadiene **1** with its almost parallel double bonds enforced by the ring fusion, therefore, represents a model for a "frozen" educt geometry in the initial stage of the symmetry-forbidden formation of cyclobutane from two molecules of ethylene.

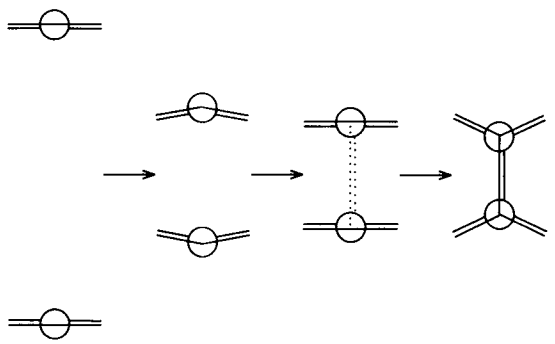

Fig. 2. Proposed qualitative geometry changes (Newman projections) in the course of the symmetry-forbidden dimerization of ethylene (Electronic ground state, overall D_{2h} symmetry).

The computationally underestimated repulsion between the double bonds in **1**, and thus the likewise underestimated total strain, manifests itself also in properties other than structure. Thus the heat of hydrogenation calculated for **1** with our force field (-27.90 kcal mol^{-1} including vibrational corrections[1], hydrogenation of one double bond) has a magnitude more than 6 kcal mol^{-1} lower than the measured value (-34.15 kcal mol^{-1}[6a]). A further indication of the substantial destabilizing interaction between the double bonds comes from the PE spectroscopic finding that **1** is 0.52 eV more readily ionizable than the monoolefin tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodec-4-ene[6h]. Finally, for similar reasons, in the dibenzo compound of **1** smaller distances between the benzene rings are calculated by force field methods[1] than observed crystallographically[6c].

Radical Anion-Substituted Crown Ethers as Cages for Metal Cations**

By *Hans Bock**, *Bernhard Hierholzer*, *Fritz Vögtle*, and *Günter Hollmann*

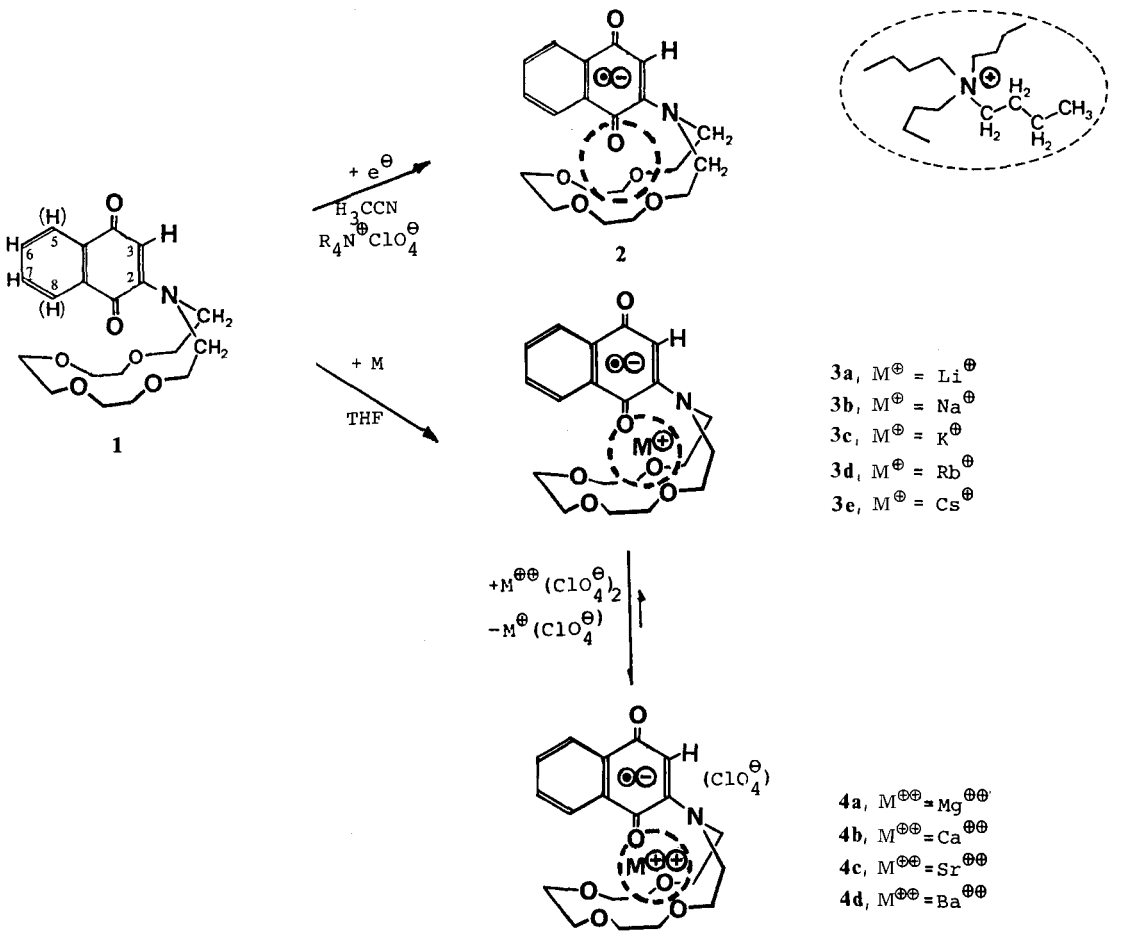
Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday

Exploring membrane transport phenomena, *Frensdorff* and *Pedersen* as well as *Lehn* have demonstrated in classical studies that macrocyclic polyethers selectively form metal cation complexes[1]. Among the various facets of the expansive research area, ion-selective crown ether dyes[2] will be emphasized here; these allow the interactions between metal cations and a structurally fixed solvate cage to be investigated. As a sensitive measurement probe for ion-pair radicals, ESR/ENDOR spectroscopy has been recommended[3]; in the following we report for the first time on the spin distribution in radical anion-substituted crown ethers and its dependence on the charge and radius of the complexed metal cation.

If 1,4-naphthoquinone **1**, substituted in the 2-position with tetraoxomonoaza[15]crown-5, is electrochemically reduced in an acetonitrile solution containing tetra(*n*-butyl)ammonium perchlorate, the azacoronand-naphthoquinone radical anion is generated. This exhibits a vacant solvate cage, for which the counterion tetra(*n*-butyl)ammonium proves to be too bulky.

If, on the other hand, the reduction is carried out using alkali metals in tetrahydrofuran (THF) at room temperature, ion-pair radicals **3** form whose ENDOR spectra (cf. Fig. 1 for $M^{\oplus}=K^{\oplus}$) show the six line-pairs expected for six different types of protons.

The fixation of the metal cation in the solvate cage of the azacoronand-naphthaquinone radical anion is suggested by the following observations:



- On addition of an excess of [2.2.2]cryptand, which complexes $K^{\oplus}$ more strongly[1b], an ESR spectrum results which is identical with that of the electrochemically generated radical anion.
- In the ENDOR spectra of the complexes couplings with metal ions are detected; the coupling constants are, e.g. $a_{Li^{\oplus}}=0.028$ mT for lithium or $a_{Cs^{\oplus}}=0.174$ mT for cesium.

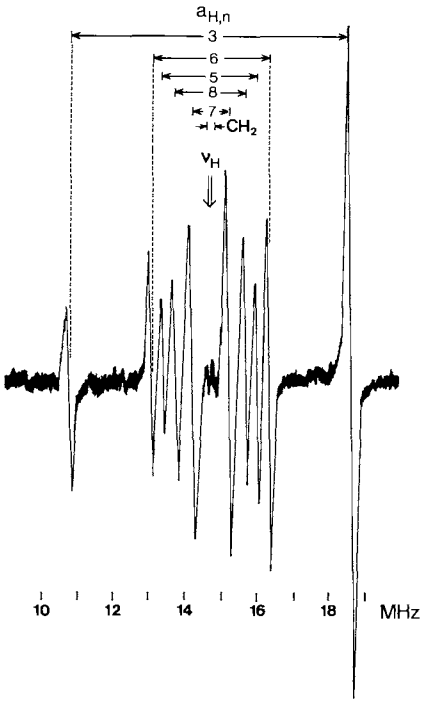

Fig. 1. ^{1}H-ENDOR-spectrum of **3c** at 202 K. Measurement conditions: 9–20 MHz, microwave power 9 dB, radiowave power 150 W, duration of recording 2000 s, time constant 1 s. Assignment according to INDO open-shell calculation for 2-dimethylaminonaphthoquinone radical anion ($a_{H,3} > a_{H,6} > a_{H,5} \approx a_{H,8} > a_{H,7} > a_{HNCH_3}$).

- The ESR spectra of the ion-pairs **3** reported here do not show the temperature-dependence known for quinone radical anions[4]. No ^{14}N-coupling can be observed, a finding, which is consistent with a fixation of the *N*-electron pair in the naphthaquinone π-nodal plane and directed outwards from the solvate cage, and thus with a rigidization of the molecular skeletal framework on metal-cation complexation.
- Addition of anhydrous alkaline-earth perchlorates in THF leads to a significant change in the ESR data, as expected for an increased charge of the complexed cations **4**.

In the ESR/ENDOR spectra of the radical anions of the naphthoquinone-crownether-metal complexes presented here (cf. Fig. 1), the largest coupling, assigned to the proton in position 3, reveals most markedly its dependence on charge and radius of the metal cation (Fig. 2), as is typical for contact ion-pair interactions[3].

The measurement data (Fig. 2), can be rationalized straightforwardly by an increase of the spin population at

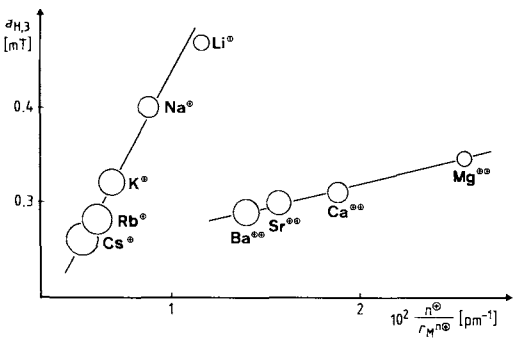

Fig. 2. Correlation of the coupling constants $a_{H,3}$ of the radical anions **3** and **4** with charge $n^\oplus$ and radius $1/r_{M^{n\oplus}}$ of the complexed metal ions.

the center 3 of the naphthoquinone radical anion, caused by the $M^{n\oplus}$-induced electron density flux to the quinone oxygen of the contact ion-pair [π-C→O$^\ominus \cdots M^{n\oplus}$].

Heterometal Binuclear Complexes with Thio- and Selenoformaldehyde as Bridge Ligands**

By *Helmut Werner** and *Wilfried Paul*

Recently, three independent research groups reported the successful fixation of CH_2Se, a molecule which is extremely unstable in the free state, by complexation in transition-metal complexes[1]. *Headford* and *Roper*[1a], like us[1c], used an iodo(iodomethyl)metal compound $L_nM(CH_2I)I$ as starting material and converted this by reaction with NaSeH into the corresponding selenoformaldehyde complex $L_nM(\eta^2\text{-}CH_2Se)$, in which ($L_nM = (PPh_3)_2(CO)_2Os$[1a], $C_5H_5(PMe_3)Rh$[1c]). *Herrmann* et al.[1b] chose another synthetic concept, namely that of methylene addition to bonds between main group elements and transition metals, and thus obtained from (μ-Se)[$Mn(CO)_2C_5R_5$]$_2$ (R = H, Me) and diazomethane the binuclear complex (μ-CH_2Se)[$Mn(CO)_2C_5R_5$]$_2$; in these dimanganese compounds two *identical* metal-complex fragments are bridged by the CH_2Se ligand.

Structurally similar compounds, but with two *different* metal-ligand groups bridged by CH_2Se, are readily obtainable from the mononuclear rhodium complex **1** and the tetrahydrofuran adducts $M(CO)_5 \cdot THF$ (M = Cr, W) or $C_5H_5Mn(CO)_2 \cdot THF$[2]. The structure proposed for the products **2-4** is in good agreement with the spectroscopic data summarized in Table 1. In the ^{1}H-NMR spectra, the occurrence of two signals for the diastereotopic CH_2Se protons is characteristic; they are shifted upfield compared to the signals of **1**[1c]. The difference in the δ-values of the CH_2 signals is substantially greater than in the case of the dimanganese compounds (μ-CH_2Se)[$Mn(CO)_2C_5R_5$]$_2$, in which it is 0.22 (R = H) and 0.70 ppm (R = Me)[1b].

The sulfur atom of a mononuclear (η^2-CH_2S)-metal compound can also function as donor towards a 16-electron complex fragment such as $Cr(CO)_5$: Compound **6** is

2, E = Se, ML_n = $Cr(CO)_5$
3, E = Se, ML_n = $W(CO)_5$
4, E = Se, ML_n = $Mn(CO)_2C_5H_5$
6, E = S, ML_n = $Cr(CO)_5$

formed from **5**[1c] and $Cr(CO)_5 \cdot THF$ under the same conditions as for the reaction **1** → **2**[2]. A corresponding binuclear complex in which a thioformaldehyde ligand bridges two $Mn(CO)_2C_5H_5$ fragments was prepared by *Herberhold* et al. using Herrmann's route[3].

The possible general applicability of the method developed for the synthesis of **1** and **5** is demonstrated by the synthesis of **7**[4] from $C_5Me_5(CO)Rh(CH_2I)I$[5]. The selenoformaldehyde complex **7** also behaves like a Lewis base and reacts with $M(CO)_5 \cdot THF$ (M = Cr, Mo) to give the heterometal binuclear complexes **8** and **9**[4]. This indicates that neutral CH_2S- and CH_2Se-transition-metal compounds presumably react in general as two-electron donors, both towards alkylating agents[1a,c] as well as towards complex fragments such as $Cr(CO)_5$, $Mn(CO)_2C_5H_5$, etc. The cation $[C_5H_5Re(\eta^2\text{-}CH_2S)(NO)PPh_3]^{\oplus}$ does not appear to be capable of this[6], possibly due to the positive charge, and the consequently lower electron density at the sulfur atom.

hydride of the series N_nH_n ("polyazenes"), were long unsuccessful[3].

HN=NH (1) HN=N–NH$_2$ (2) H$_2$N–N=N–NH$_2$ (3)

In each case instead of a silyltriazene, only its thermolysis products dinitrogen and silylamines were found[4].

$$\{R_3Si\text{–}N{=}N\text{–}N\} \longrightarrow N{\equiv}N + R_3Si\text{–}N \quad (a)$$

We have now succeeded for the first time in preparing a silylated triazene stable up to 150 °C—1,3-bis(tri-*tert*-butylsilyl)triazene **4**—by treating tri-*tert*-butylsilyl azide in tetrahydrofuran (THF) first with tri-*tert*-butylsilylsodium[5] and then with methanol.

$$t\mathrm{Bu_3Si\text{–}N{=}N{=}N} \xrightarrow[2)\ +\mathrm{MeOH},\ -\mathrm{NaOMe}]{1)\ +\mathrm{NaSi}t\mathrm{Bu_3}} t\mathrm{Bu_3Si\text{–}N{=}N\text{–}NH\text{–}Si}t\mathrm{Bu_3}$$

4

Apparently, the triazene decomposition is hindered in **4** by the extreme bulk of the two silyl substituents.

The novel compound **4** can be isolated as pale yellow crystals (m.p. = 139—140 °C, subl. = 110 °C/in vacuo), and was identified by elemental analysis, mass spectroscopy (molecular ion: *m/z* 441), and ^{1}H-NMR spectroscopy (90 MHz, C_6D_6; δ = 1.15, 1.28 (Si*t*Bu$_3$), 8.49 (NH); area ratio 27 : 27 : 1). The UV spectrum exhibits an intense $\pi_n \rightarrow \pi^*$ absorption band at $\tilde{\nu}_{max}$(hexane) = 38 600 cm^{-1} (ε = 15 900), which is also observed with other triazenes; however, an additional weak band appears at longer wavelength $\tilde{\nu}_{max}$(hexane) = 26 050 cm^{-1} (ε = 60), which is consistent with an $n \rightarrow \pi^*$ transition—in accord with earlier results[1], which show that the energy of the upper n level of an azo group is increased considerably by substitution of alkyl by silyl substituents—and indicates a comparably high energy for the n level in **4**.

From the coalescence of the proton resonance signals of the two *t*Bu$_3$Si groups of **4** at 55 °C (THF) it follows that the *N*-bonded hydrogen atoms migrates as shown in (b),

$$t\mathrm{Bu_3Si\text{–}N}\underset{\mathrm{N}}{\overset{\mathrm{H}}{\diagdown\!\!\diagup}}\mathrm{N\text{–}Si}t\mathrm{Bu_3} \rightleftharpoons t\mathrm{Bu_3Si\text{–}N}\underset{\mathrm{N}}{\overset{\mathrm{H}}{\diagdown\!\!\diagup}}\mathrm{N\text{–}Si}t\mathrm{Bu_3} \quad (b)$$

4a **4b**

and that the free energy of activation of this 1,3-shift is 78 kJ/mol at 55 °C, corresponding to an average lifetime of the tautomers of ca. 1/8 s. **4** decomposes above 150 °C, inter alia by elimination of N_2, as shown in (a), to afford bis(tri-*tert*-butylsilyl)amine.

[4] Silylated methyl- or phenyltriazenes of the type MeN=N–NMe(SiR$_3$) or PhN=N–N(SiR$_3$)$_2$ could, however, be obtained: N. Wiberg, H. J. Pracht, *Chem. Ber. 105* (1972) 1377, 1388, 1392, 1399; *J. Organomet. Chem. 40* (1972) 289.
[5] The previously unknown reagent NaSi*t*Bu$_3$ was obtained from *t*Bu$_3$SiBr and Na wire in refluxing THF. After removal of the solvent a colorless substance remains, which according to ^{1}H-NMR contains two molecules of THF per sodium atom (assumed formula $[Na(THF)_4]^{\oplus}[Na(Si\mathit{t}Bu_3)_2]^{\ominus}$.

Preparation of Enantiomerically Pure Chiral Alcohols by Asymmetric Alkylation of Glycolates**

By *Günter Helmchen** and *Reiner Wierzchowski*

Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday

The propionates **1c** and **2c** of the chiral reagents **1a** and **2a**, which are readily accessible[1c] from (+)-camphor, can be alkylated with very high diastereoselectivity via lithium enolates[1]. We have now found that this also applies for *O*-protected glycolates such as **1b** and **2b**[2], but, compared to the propionates, a completely different mechanism is involved.

On metalation (−80 °C) with lithium cyclohexylisopropylamide (LICA) in tetrahydrofuran (THF) (conditions A), propionates yield highly selectively (*Z*)-enolates, but in THF-hexamethylphosphoric acid triamide (HMPT) (4 : 1) (conditions B) preferably give (*E*)-enolates[1c], alkylation of which yields products with inverse configuration at C-2′. In contrast, with *O*-benzylglycolates **1b** and **2b** we obtained almost identical product ratios under both conditions (Table 1). If front-side attack of the electrophile R^2–I and an enolate conformation [H–(C-2)–O–(C-1′)–O grouping] corresponding to the given formulas is as-

Table 1. Conversion of the esters **1b** and **2b** with alkylating agents R^2–I *via* lithium enolates into the esters **5** and **6**, and reduction of the dominant diastereoisomer in each case with LiAlH$_4$ (THF) to the alcohols **7**. Metalation: LICA (−80 °C) in THF (A) or THF-HMPT 4 : 1 (B); alkylation at −63 to −40 °C (A), −63 °C (B).

sumed (cf. [1b,c]), it follows from the configuration (C-2′) of each of the dominant products, (2′*R*)-**5b** and (2′*S*)-**6a–c**, respectively, that the enolates **3a** and **4a** are present in the (*E*)-configuration. The preferential formation of the same enolate[3] under both conditions was confirmed in the case of **1b** by reaction of the enolate **3a** with *tert*-butyldimethylsilyl chloride (−63-0 °C) to give the ketene acetal **3b** of ca. 90% purity[4], according to a ^{1}H-NMR spectroscopic analysis.

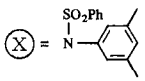
(*S*)-**7a-c**

Bn = Benzyl



The main products (2′*R*)-**5b** and (2′*S*)-**6a–c** can in each case be readily separated preparatively from the C-2′ epimers by medium pressure liquid chromatography (MPLC) and are crystalline; on reduction ($LiAlH_4$/THF) they yield the alcohols **7**, which are presumably enantiomerically pure, since the esters are known to be reduced by $LiAlH_4$ without racemization; furthermore, optical rotations in the case of **7a** and **7c** agree with reliable reference values.

Partially protected 1,2-diols **7** are versatile building blocks for natural product syntheses. Furthermore, it should be noted that glycolate alkylations are "umgepolt" relative to aldol additions regarding the hydroxylated C-atom; that is, glycolates **1b** and **2b** are d^1-ethanol synthetic equivalents[5] which open up interesting possibilities for syntheses with "acyclic control of stereochemistry".

Novel Structures Containing Germanium(II): Germanocene and Dimeric Tricarbonyl(di-*tert*-butoxygermylene)nickel(0)**

By *Mario Grenz, Ekkehardt Hahn, Wolf-Walther du Mont**, and *Joachim Pickardt*

Previously, the coordination chemistry of "carbene analogues" has principally been considered under the aspect "stabilization of low valent species" in the coordination sphere of metal acceptors. We now describe for the first time the structure of a complex that formally appears analogous to the carbene complexes, but which is not sufficiently "internally" stabilized and hence dimerizes *via* heteroatom bridging. Until now, heteroatom bridged structures have only been proposed for some functionally substituted stannylene complexes with associated tin(II) ligands such as *e.g.*, $[Cr(CO)_5Sn(OH)_2]_x$, $[Cr(CO)_5Sn(OMe)_2]_x$, and $[Ni(CO)_3Sn(OtBu)_2]_2$[1]; corresponding complexes containing germanium(II) ligands were previously unknown.

We obtained the first complex with a $Ge(OR)_2$ ligand by cleavage of germanocene **1** with *tert*-butyl alcohol and allowing the di-*tert*-butoxygermanium(II) **2** thus formed to react with tetracarbonylnickel.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

In contrast to reports in the literature, we were able to prepare germanocene **1**, which is described as monomeric in solution but polymeric in the solid state[2–4], in tetrahydrofuran (THF) from sodium cyclopentadienide and the dichlorogermanediyl-dioxane adduct. Colorless crystals of **1** (m.p. = 78 °C) were isolated by sublimation at 10^{-2} mbar (bath temperature 60–80 °C) in 60% yield. The compound is so stable that it can be manipulated like stannocene under an inert gas atmosphere, and can be stored in the refrigerator (−30 °C) for several weeks without noticeable polymerization. Sublimed germanocene crystallizes orthorhombically; the X-ray structure analysis (Fig. 1) establishes that **1** is monomeric and for the first time provides a reliable value for the angle of aperture of the cyclopentadienyl ring planes in germanocene derivatives[5]: 50.4° for **1** contrasted with 45.9 or 48.4° for stannocene[6]. The deviation from a metallocene structure of the D_{5d} or D_{5h} type is therefore larger in germanocene than in stannocene (with the larger central atom!). Remarkable also is the nonequivalence of the Ge–C distances (234.7 to 273.0 pm), which can be described as a displacement of the germanium atom from the point of intersection of the fivefold axis towards the apex at which the Cp ring planes touch. This effect is even more pronounced in **1** than in stannocene and decamethylstannocene[6, 7].

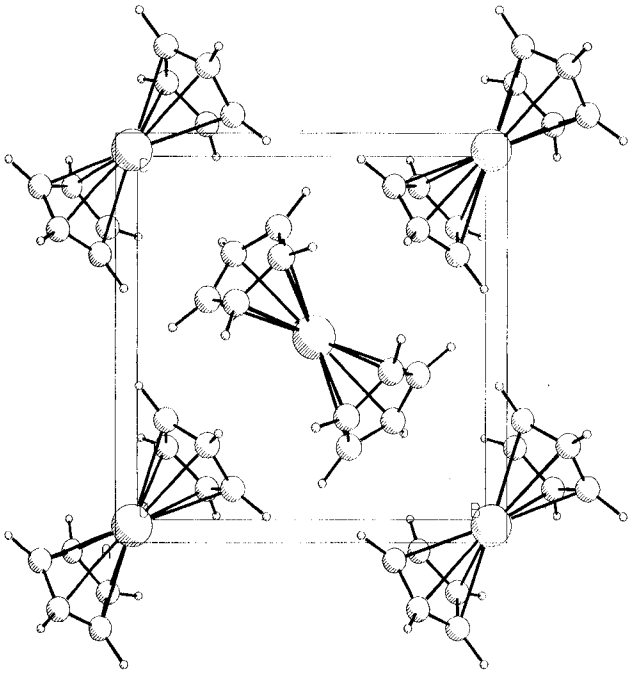

Fig. 1. PLUTO representation of the structure of germanocene **1** in the crystal. Orthorhombic, $P22_12_1$ (nonstandard representation of $P2_12_12$, No. 18), $a = 561.7(28)$, $b = 886.0(19)$, $c = 888.8(30)$ pm, $V = 442.3 \times 10^6$ pm^3, $Z = 2$; $Mo_{K\alpha}$, $2\theta \leq 60°$, solved using Patterson methods, refined (SHELX, anisotropic H atoms with constant temperature factor 8.0×10^4 pm^2) to $R = 0.042$ with 779 reflections with $I > 2\sigma_I$. Important distances [pm]: Ge–C1 258.4(7), Ge–C2 234.7(7), Ge–C3 235.9(6), Ge–C4 256.6(6), Ge–C5 273.0(7), C–C 134.7(12) to 140.2(12) (standard deviations in parenthesis). Data collected at −100(5) °C [10].

Even in the absence of bulky substituents on the cyclopentadienyl rings, **1** is apparently stable enough as a monomer to serve as an excellent educt for the synthesis of Ge^{II} compounds. Hence, alcoholysis of **1** with *t*BuOH affords dimeric "germylene" **2** with a four-membered ring structure, which is also accessible analytically pure by salt elimination methods and multiple recrystallizations[8]. **2** reacts with dimethylbutadiene via typical 1,4-cycloaddition of the carbene-analogous monomeric $Ge(OtBu)_2$[3], and with tetracarbonylnickel *via* CO-elimination to afford dimeric tricarbonyl(di-*tert*-butoxygermylene)nickel(0) **3**. Complex **3** is formed practically quantitatively (NMR), and at −30 °C precipitates out from pentane as colorless crystals (m.p. = 136 °C (decomp.)).

As indicated by the X-ray structure analysis (Fig. 2), **3** contains two *tert*-butyloxo bridges between the coordinating germanium atoms of a bidentate "1,3,2,4-dioxadigermetane" ligand, which is isoelectric with *trans*-diazadiphosphetidines. The transition-metal coordination arises from the 4s electron lone-pair of the "soft" germanium atom. The configuration of the bonds at the tetra-coordinated Ge atoms in **3** deviate markedly from tetrahedral: the OGeO angles are small (74.9 and 95.5°); in contrast, all NiGeO angles are larger than 119° (Fig. 2). The distance

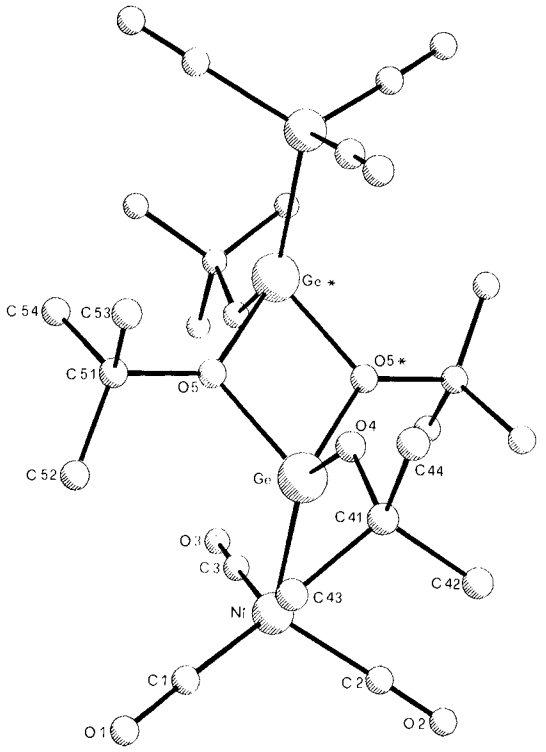

Fig. 2. PLUTO representation of the structure of the binuclear nickel complex **3** in the crystal. For preparation of the crystal cf. [10], data collection at −100(5) °C. Triclinic, $B\bar{1}$ (nonstandard representation of $P\bar{1}$, No. 2, selected because of orthogonality of the cell), $a = 1568.4(41)$, $b = 1028.1(21)$, $c = 1020.5(22)$ pm, $\alpha = 109.69(16)$, $\beta = 91.75(21)$, $\gamma = 89.54(19)°$, $V = 1548.6 \cdot 10^6$ pm^3, $Z = 2$. $Mo_{K\alpha}$, $2\theta \leq 40°$, solved using Patterson methods, refinement (SHELX, anisotropic, CH_3 as rigid group) to $R = 0.055$ with 134.1 reflections with $I > 2\sigma_I$. Most important distances [pm]: Ge–Ni 228.3(2), Ge–$O_{term.}$ 178.0(6), Ge–$O_{br.}$ 193.2(6) and 192.1(6), Ge···Ge 305.9(2).

Ge–Ni is shorter than the sum of the covalent radii as in monomeric germylene complexes, which are closely analogous to carbene complexes, and for which Ge-metal bond orders of up to 1.5 have been proposed[9].

Transition-metal coordination of germanediyls (germylenes), therefore, does not necessarily lead to a preference for structures analogous to those of carbene- or μ-methylene-complexes. We therefore expect that more highly associated Ge^{II} compounds will also exhibit ligand properties. The CO stretching frequencies of **3** (2070, 2000 cm^{-1}) indicate electronic ligand parameters that make O-bridged Ge^{II} compounds comparable to conventional P ligands.

A Novel Aromatic Hydrocarbon with 16π-Electron Periphery: "Cyclic Bicalicene"

By *Shigeo Yoneda, Mitsuhiro Shibata, Shuji Kida, Zen-ichi Yoshida*, Yasusi Kai, Kunio Miki,* and *Nobutami Kasai*

Polycyclic, nonalternant, peripheral 4nπ systems, which may be regarded as perturbated annulenes, should be antiaromatic if they have a planar conformation like pentalene and *s*-indacene[1]. This concept is well established. In contrast, an extremely interesting example of an aromatic, 4nπ system is pentacyclo[11.3.0.0^{2,4}.0^{5,9}.0^{10,12}]hexadeca-1,3,5,7,9,11,13,15-octaene **4** (cyclic bicalicene), which possesses a planar, peripheral 16π-electron structure, and was briefly described at the ISNA-4 conference (Jerusalem, 1981)[2]. Here, we report on novel chemical properties of **4** together with details of its synthesis and structure.

1,2-Bis(*tert*-butylthio)-3,3-dichlorocyclopropene **1** was treated with 2 equiv. lithium cyclopentadienide in tetrahydrofuran at −78 °C for 2 h. The reaction mixture was then chromatographed on silica gel with dichloromethane-petroleum ether and subsequently recrystallized from 1,2-dimethoxyethane to give the 3,11-bis(*tert*-butylthio) derivative **2** (reddish purple crystals, m.p. = 190–200° (dec.), 5% yield). Desulfurizing stannylation of **2** with tri-*n*-butyltin hydride in refluxing benzene in the presence of azoisobutyronitrile gave the 3,11-bis(tri-*n*-butylstannyl) derivative **3** (orange crystals, m.p. = 60–61 °C, 42%). Subsequent treatment of **3** with silica gel (Kieselgel 60PF$_{254}$ Merck) afforded hydrocarbon **4** (orange crystals, m.p. = 125–130 °C (dec.), 40%). **4** is stable for several weeks in air at room temperature.

As indicated by the X-ray structure analysis (Fig. 1), **4** possesses a planar ring skeleton and no bond alternation is observed (D_{2h} symmetry). The ^{1}H-NMR signals of **4** exhibit no upfield shift due to the paramagnetic ring current expected from the 16π system (Table 1), indicating that the

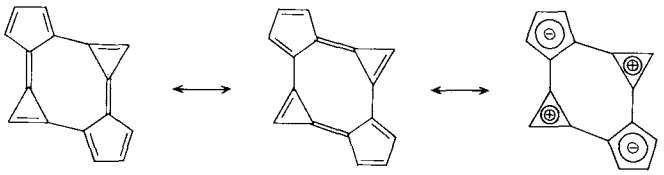
[16]annulene structure does not contribute to its ground state. Also, the percent resonance energy of **4** (0.87) is larger than the aromatic criterion (0.50) defined by *Aihara*[3]. In view of these results, **4** is to be regarded as a peripheral 16π aromatic system.

The charge distribution on each C atom of **4** estimated from the ^{13}C-NMR spectrum is in accord with the calculated charge distribution (MINDO/3, net charge density: C-1,13 −0.12, C-14,16 +0.02, C-15 −0.08, C-2,4 +0.16, C-3 −0.09). These results demonstrate that the negative charge is mainly distributed over C-1,13,15 and the positive charge over C-2,4. We therefore conclude that **4** is stabilized by the resonance of two covalent structures (**4a** and **4b**) and one polarized structure (**4c**) in which the five-membered ring is similar to the cyclopentadienide anion and three-membered ring, similar to the cyclopropenylium cation[4].



4a **4b** **4c**

The chemical properties of this system are consistent with the π-configuration of **4**. Thus, in agreement with no contribution from the peripheral [16]annulene structure, electrochemical or alkali metal reduction of **4** leads to decomposition, in marked contrast to [16]annulene which gives the 18π system by two electron reduction[5]. Also, the HOMO energy level of **4** (MINDO/3) is extremely high (−7.22 eV), suggesting that it should be a good electron donor. On the other hand, although reaction of **4** with $NO^+_2BF^-_4$ and with CF_3COOH affords undefined products (no characteristic absorption of calicene in IR spectra at ca. 1800 and ca. 1550 cm^{-1}), reaction of **4** with *N*-bromosuccinimide in dichloromethane proceeds smoothly to afford the 6,7,8,14,15,16-hexabromo derivative (orange crystals, m.p. = 222–225 °C (dec.), 80%). Nucleophilic substitution of **2** with diethylamine in dichloromethane gives the 3-*tert*-butylthio-11-diethylamino derivative **6** (dark reddish-purple crystals m.p. = 116–117 °C, 36%).

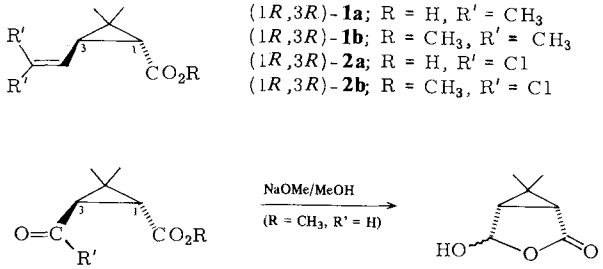
Enzymatic Syntheses of Chiral Building Blocks from Racemates: Preparation of (1*R*,3*R*)-Chrysanthemic, -Permethrinic and -Caronic Acids from Racemic, Diastereomeric Mixtures**

By *Manfred Schneider**, *Norbert Engel*, and *Heike Boensmann*

The physiological activities of pyrethroid insecticides derived from chrysanthemic acid (1*R*,3*R*)-**1a** and permethrinic acid (1*R*,3*R*)-**2a** are closely related to their absolute configurations, making the 1*R*-enantiomers interesting targets for organic synthesis. Important chiral building blocks for the synthesis of optically active pyrethroids are also the caronic acid derivatives (1*R*,3*R*)-**3a** and -**3c** to -**3e**[1]. Simple methods for the preparation of (1*R*,3*R*)-**1a** to -**3a** starting from readily available educts therefore provide an interesting synthetic challenge.



(1*R*,3*R*)-**1a**; R = H, R' = CH_3
(1*R*,3*R*)-**1b**; R = CH_3, R' = CH_3
(1*R*,3*R*)-**2a**; R = H, R' = Cl
(1*R*,3*R*)-**2b**; R = CH_3, R' = Cl

(1*R*,3*R*)-**3a**; R = CH_3, R' = OH
(1*R*,3*R*)-**3b**; R = CH_3, R' = OCH_3
(1*R*,3*R*)-**3c**; R = CH_3, R' = O*t*Bu
(1*R*,3*R*)-**3d**; R = CH_3, R' = H
(1*R*,3*R*)-**3e**; R = *t*Bu, R' = H

4

In contrast to well documented asymmetric syntheses[2] and the resolution of racemic mixtures[1,2], the potential of enzymatic reactions has never been tested in this context. In fact diastereomeric, racemic mixtures of the methyl esters **1b** to **3b** are readily hydrolyzed enzymatically in the presence of porcine liver esterase (Scheme 1). **1b** to **3b** (10–200 mmol) are suspended in 0.1 M phosphate buffer (pH 8) and mixed with the esterase [ca. 70 units (standard ethyl butyrate) = 0.7 mg/g substrate]. The initial enzymatic saponification is indicated by the decrease of pH, which is maintained at pH 8 by the addition of 1 N NaOH solution from an automatic buret. The reactions can be monitored from the consumption of NaOH and can be interrupted after the desired conversion (e.g. 50%). The unreacted esters are removed from the reaction mixtures by extraction (Et_2O). The acids formed, which are present in the aqueous phase as sodium salts, are isolated after acidification to pH 2 by continous extraction with Et_2O. Diastereomeric ratios of all fractions were determined by gas chromatography, and the enantiomeric ratios determined by ^{1}H-NMR spectroscopy and/or gas chromatographic analysis of the diastereomeric (−)-menthyl esters.

The products (1*R*,3*R*)-**1a** to -**3a** can indeed be obtained in good yields with the enantiomeric ratios listed in Table

Product	250 MHz ^{1}H-NMR [e]
(1*R*,3*R*)-**1a**	1.16 (s, 3H, CH_3), 1.31 (s, 3H, CH_3), 1.40 (d, 1H), 1.73 (m, 6H, $2CH_3$), 2.11 (dd, 1H), 4.92 (m, 1H)
(1*R*,3*R*)-**2a**	1.23 (s, 3H, CH_3), 1.35 (s, 3H, CH_3), 1.64 (d, 1H), 2.30 (dd, 1H), 5.65 (d, 1H)
(1*R*,3*R*)-**3a**	1.32 (s, 3H, CH_3), 1.34 (s, 3H, CH_3), 2.27 (AB, 2H), 3.72 (s, 3H, CH_3)

[a] A = enzymatic hydrolysis (% conversion); B = A with recycling after esterification (% conversion); C = recrystallisations from petroleum ether, b.p. = 60–90 °C. [b] Based on converted substrate. [c] Determined by ^{1}H-NMR (with (+)-(*R*)-α-methylbenzylamine or Eu(tfc)$_3$) and GC (±5%). [d] Determined by calibrated GC (±2%). [e] δ-Values, solvent $CDCl_3$ *T* = 25 °C.

1. Clearly, the enzymatic reactions are both *diastereo-* and *enantioselective:*

a) *Diastereoselective hydrolysis:* At the enzyme concentrations used the *cis*-methyl esters (*cis*-**1b** to -**3b**) are not accepted by the enzyme as substrates. They can be recovered unchanged from the reaction mixtures. In contrast, *trans*-**1b** to -**3b** are readily saponified by the enzyme under these conditions. Complete conversions therefore achieve a separation of the *cis*- and *trans*-cyclopropane derivatives (Scheme 1).

b) *Enantioselective hydrolysis:* Enzymatic hydrolysis of *trans*-**1b** to -**3b** at lower conversions (e.g. 50%), produces, after removal of the unreacted (1*S*,3*S*)-**1b** to -**3b**, the optically active acids (1*R*,3*R*)-**1a** to -**3a** (Scheme 1, Table 1). The desired 1*R*-enantiomers are saponified much faster.

The, as yet non-optimized, enantiomeric ratios can be further increased by the usual methods (lower conversion, recycling, recrystallization; cf. examples in Table 1). Chrysanthemic acid (1*R*,3*R*)-**1a** ($[\alpha]_D^{22}$ 16, *c* 1.48, $CHCl_3$) can be obtained from the enzymatic process in 70% *ee*. In contrast, permethrinic acid (1*R*,3*R*)-**2a** ($[\alpha]_D^{25}$ 32.7, *c* 0.86, $CHCl_3$), which is of particular commercial interest, can be obtained almost enantiomerically pure (98 ± 2% (GC), 96% *ee*) after one recrystallization (petroleum ether) of the initial product (80% *ee*). Caronic acid monomethyl ester (−)-(1*R*,3*R*)-**3a** is obtained almost enantiomerically pure (97 ± 2% (GC), 95% *ee*). This ester is not easily accessible by other methods[1,2]. It can also be converted into other building blocks[1] such as (1*R*,3*R*)-**3c** [^{1}H-NMR: δ = 1.28 (s, 6H, $2CH_3$), 1.46 (s, 9H, *t*Bu), 2.16 (bs, 2H), 3.70 (s, 3H, OCH_3); $[\alpha]_D^{25}$ −20.7, *c* 1.07, $CHCl_3$] and (1*R*,3*R*)-**3d** [^{1}H-NMR: δ = 1.32, 1.35 (s, 3H, CH_3), 2.49 (AB, 2H), 3.73 (s, 3H, OCH_3), 9.66 (d, 1H); $[\alpha]_D^{25}$ 15, *c* 1.43, $CHCl_3$]. (1*R*,3*R*)-**3d** can be converted via a known procedure[1,2] into **4**, thereby allowing a synthetic entry into the corresponding *cis*-series.

The chosen reaction times (8-72 h) are dependent on the amounts of substrate and enzyme and depent on the specific activities (10^{-6} mol min^{-1} (mg enzyme)$^{-1}$) [(+)-(1*R*,3*R*)-**1a**: ca. 1.0 (+)-(1*R*,3*R*)-**2a**: ca. 1.7; (−)-(1*R*,3*R*)-**3a**: ca. 7; standard (ethyl butyrate): 100)] of the enzyme towards the substrates, which were determined with the enantiomerically pure (enriched) materials.

The studies are also interesting with respect to enzyme-substrate relations and "in vitro"-investigations of insecticide metabolism in mammals[3].

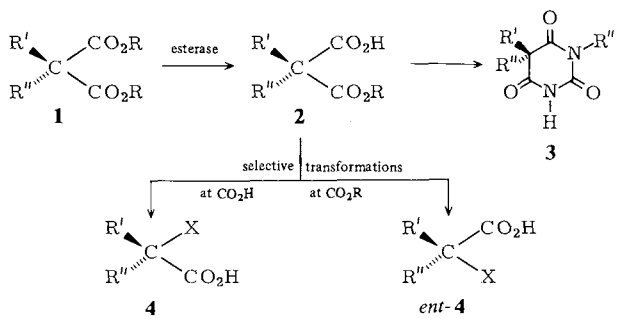
Enzymatic Synthesis of Chiral Building Blocks from Prochiral Substrates: Enantioselective Synthesis of Monoalkyl Malonates**

By *Manfred Schneider**, *Norbert Engel*, and *Heike Boensmann*

Enantioselective conversion of the prochiral dialkyl malonates **1** into their chiral monoesters **2** would produce versatile building blocks for numerous other optically active molecules. Selective transformations (derivatization, degradations, reductions etc.) of the two, now chemically distinguishable, functional groups at the chiral center in **2** would allow optional entry to *both* enantiomeric series of potential target molecules. Optically active barbiturates **3** or α-amino acids **4**/*ent*-**4** (X = NH_2) are examples of possible synthetic applications. A simple method for the enantioselective conversion of the readily accessible, prochiral precursors **1** would therefore be very useful, regardless of the resulting absolute configurations of the products **2**.



1 **2** **3** **4** *ent*-**4**

Enzymes are able to convert prochiral substrates enantioselectively into chiral molecules by enantiotopic group differentiation[1]. Hydrolytic enzymes from microorganisms were used several years ago to convert prochiral dialkyl glutarates into their chiral monoesters[2]. Porcine liver esterase was used in a similar way for a chemoenzymatic synthesis of (*R*)-mevalonolactone[3].

Since porcine liver esterase is easy to handle[4] and conveniently accessible it seemed attractive to use this enzyme for the conversions **1** → **2**. The dialkyl malonates **1a-1f** (10-50 mmol) were suspended in 0.1 N phosphate buffer (pH 8) and mixed with the esterase [70 units (standard: ethyl butyrate) = 0.7 mg/(g substrate)]. The initial enzymatic saponification is indicated by a decrease in pH, which is maintained at pH 8 by the addition of 1 N NaOH solution from an automatic buret. Only one ester group is saponified and the reaction terminates after the consumption of 1 equiv. of NaOH; the reaction mixtures become homogeneous. The monoesters **2a-2f** formed, which are present as sodium salts in the aqueous phase, are isolated in good yields after acidification to pH 2 by continous extraction (Et_2O). The enantiomeric ratios were determined by NMR spectroscopy of the crude products (Table 1).

Table 1. Enzymatic hydrolysis of dialkyl malonates **1** to the monoalkyl esters **2**.

	R′	R″	R	Enantiomer ratio [a]
a	*n*Bu	Me	Et	69 : 31
b	*n*Bu	Me	Me	75 : 25
c	Et	Me	Et	60 : 40
d	*n*Pr	Me	Et	54 : 46
e	Ph	Me	Et	93 : 7
f	Ph	Et	Me	92 : 8

[a] Determined by 250 MHz ^{1}H-NMR with (+)-(R)-α-methylbenzylamine.

From Table 1 it is clear that the enantioselectivities are dependent on the substitution pattern at the chiral centers of **2a-2f** and are largest when the difference in substituent size ΔR′R″ reaches a maximum. Methyl esters, which are preferable also due to their higher rates of hydrolysis, appear to give somewhat higher enantiomeric purities than ethyl esters. The best results from a synthetic point of view were obtained with **1e** and **1f**, which afforded the monoalkyl malonates **2e** and **2f**, respectively, in high enantiomeric ratios; these were further improved to >97:3 (NMR) by recrystallization.

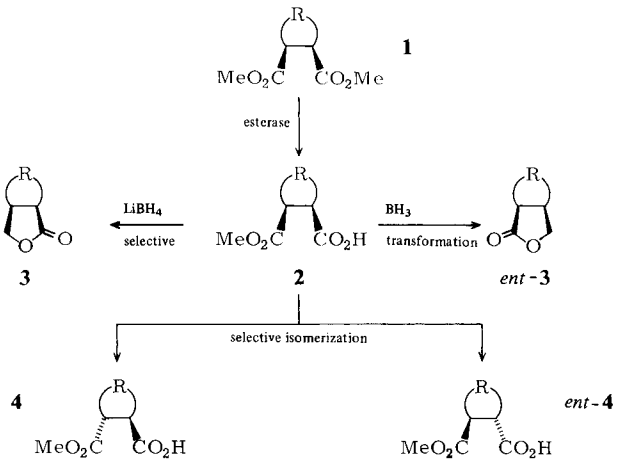
Enzymatic Syntheses of Chiral Building Blocks from Prochiral *meso*-Substrates: Preparation of Methyl(hydrogen)-1,2-cycloalkanedicarboxylates**

By *Manfred Schneider**, *Norbert Engel*, *Petra Hönicke*, *Gerd Heinemann*, and *Helmut Görisch*

Enantioselective hydrolysis of the prochiral *cis*-1,2-diesters **1a–f** to the title compounds **2a–f** would afford versatile chiral building blocks for numerous applications, including natural products synthesis. Regardless of the resulting absolute configurations, the monoesters **2a–f** could serve as potential precursors for all possible enantiomers of these systems by selective group transformations, here exemplified by the selective conversion to the enantiomeric lactones **3** and *ent*-**3**, as well as by selective isomerizations to the *trans*-enantiomers **4** and *ent*-**4** and products thereof.



To make these reactions synthetically useful, **1a–f** should be conveniently accessible isomerically pure and in large amounts. While this is true for **1e**, **f**, the known stereoselective syntheses leading to **1a**, **c**, **d** from readily available starting materials were not satisfactory, and no method of synthesizing **1b** stereoselectively was known. We therefore developed a mild, general method for the concomitant isomerization and cyclization of *trans*-1,2-cycloalkanedicarboxylic acids using $(CF_3CO)_2O$; the *cis*-1,2-anhydrides obtained can be directly converted into **1a—f** using $MeOH/HC(OMe)_3$[2].

Enzymes can convert prochiral substrates into chiral products by enantiotopic group differentiation[1,3]. Porcine liver esterase not only shows high reaction selectivities, but also accepts a broad range of structurally different sub-

[**] Hydrolytic Enzymes in Organic Synthesis, Part 3. Presented at the 2nd International Symposium on Synthesis and Biotechnology of Biologically Active Natural Products, August 14–19, 1983, Budapest. We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support, Bayer AG (Dr. *J. Kurz*) for the determination of optical purities by 250 MHz ^{1}H-NMR spectroscopy and for gifts of chemicals, and Boehringer Mannheim for enzymes. Professor *J. B. Jones*, Toronto is thanked for discussions. – Part 2: [4].

strates[1a,3-5]. It therefore seemed an attractive reagent for the transformations **1**→**2**.

Hydrolysis of **1a—f** catalyzed by porcine liver esterase proceeded in 0.1 M phosphate buffer suspensions. The initial saponification was indicated by the decrease of pH, which was maintained at pH 7 or 8 by addition of 1 N NaOH. Only one ester group is saponified. After acidification, **2a—f** are recovered by extraction (Et_2O). Diastereomeric purities (to check for possible isomerizations) were determined by GC after reacidification (MeOH/$HC(OMe)_3$). Enantiomeric ratios were determined on the crude products by 250 MHz ^{1}H-NMR spectroscopy with (+)-(*R*)-α-methylbenzylamine, independent of, usually unreliable, rotational data of derivatives (Table 1).

The absolute configuration of **2a**[7] was known, that of **2b** was determined by selective base (NaH/dimethyl sulfoxide) isomerization to the known *trans*-enantiomer **4b**, and that of **2c** by conversion to the known[11b] lactones **3c**/*ent*-**3c**. The absolute configurations of **1e, f** were known from X-ray structure determinations[9].

The observed enantiomer ratios are quite high in most cases (somewhat higher at pH 7 than at pH 8, possibly due to some non-enzymatic hydrolysis) and can be further increased by recrystallization. The highest values were found for **2b** and **2f**, which were formed as enantiomerically pure compounds. The only exception was (+)-**2d**, which was formed in very low enantiomeric purity.

The absolute and relative reaction rates (Table 1) were determined under standardized conditions, although the amount of enzyme can be reduced from 100 (or 1000) to 10 units/mmol of substrate.

Whereas **1b—f** are transformed at synthetically useful rates (usually faster at pH 8 by a factor of 2 to 5), **1a** does not function as a substrate under these conditions[4]. Even at high enzyme concentrations the reaction **1a**→**2a** is very slow, making this process unsuitable synthetically despite the relatively high enantiomer ratio.

Because of the favorable enantiomer ratios and reaction rates, the formation of **2b, c, e, f** is of particular synthetic interest. The reactions were therefore scaled-up from the usual 10—50 mmol to 700—1000 mmol. For example, 100 g of optically pure (−)-**2b** can be obtained by this method in a single experiment.

Preliminary studies using esterase on CNBr-activated Sepharose (1.3 mg protein/mL gel; specific activity: 50% of the soluble enzyme) reveal that the enantiomeric purities obtained are identical for both enzyme preparations.

Experimental Procedure

(−)-**2b**: Porcine liver esterase (1000 units) is added to a vigorously stirred mixture of **1b** (15.8 g, 0.1 mol) and 100 mL phosphate buffer (0.1 M, pH 8). The start of the hydrolysis is indicated by a rapid decrease of the pH 8 value. pH 8 is maintained throughout the reaction ($t_{1/2} \approx 25$ h) by addition of 1 N NaOH. After addition of 100 mL (0.1 mol) NaOH the reaction stops. The cooled, stirred reaction mixture is acidified with 5 N HCl to pH 2 and extracted continously with Et_2O. The organic phase is dried, all solvents are removed, and the residue is treated with Et_2O (15 mL) and crystallized first at 0°C and subsequently for 2 d at −30°C. The colorless crystals of (−)-**2b**, 13.5 g (93%), m.p. = 82°C, $[\alpha]_D^{22}$ −13.2 (*c* 1.7, $CHCl_3$), are collected by filtration. Recrystallization from benzene (20 mL) yields 12 g of enantiomerically pure (−)-**2b**, $[\alpha]_D^{22}$ −15.3 (*c* 1, $CHCl_3$); 250 MHz ^{1}H-NMR (solvent $CDCl_3$): δ = 1.36 (m, 1H), 1.72 (m, 1H), 2.14 (m, 2H), 3.74 (s, 3H), 11.36 (bs, 1H).

Hydrozirconation of Nitriles: Proof of a Linear Heteroallene Structure in (Benzylideneamido)zirconocene Chloride**

By *Gerhard Erker**, *Wolfgang Frömberg*, *Jerry L. Atwood*, and *William E. Hunter*

In general, dialkylideneammonium ions adopt a linear heteroallene structure (**1**, sp-hybridized nitrogen). Only exceptionally in cases of extreme stabilization of the carbenium ion center is a bent heteroallyl structure (**2**, *e.g.*, R = NR'_2) more favored[1]. Substitution of the carbenium carbon center by an isolobal, electron deficient metal fragment[2a], *i.e.* formal exchange of $CR_2^{\oplus}$ in **1** by the Cp_2ZrCl moiety[2b], leads to systems for which the structures **1'** and **2'**, analogous to **1** and **2**, respectively, are possible. How-

ever, the preferred ground-state structure of uncharged metal complexes can be determined experimentally much more easily than for the carbenium ion systems.

We obtained the *C*-substituted (methyleneamido)zirconocene chlorides **5a** and **5b** as moisture-sensitive, yellow solids in high yields by hydrozirconation of benzonitrile and acetonitrile, respectively[3]. In addition to the typical absorptions of the bent metallocene, an intense $-C=N$ stretching frequency is observed in the IR spectra of **5a** and **5b** (in toluene; $\nu = 1678$ and 1700 cm^{-1}, resp.). In Schiff's bases with $\geqslant C-N=CHR$ groups this band appears at slightly lower wave numbers[4]. The ^1H- and ^{13}C-NMR spectral data of the $-N=CHR$ moiety in the complex are very similar to those of many comparable organic systems[4]: ^1H, [^{13}C] ([D_6]benzene), **5a**: $\delta = 9.0$ [167.3 (d, $J = 168$ Hz)]; **5b**: $\delta = 8.3$ [167.5 (d, $J = 168$ Hz)]. It is noteworthy that a chemical differentiation of the cyclopentadienyl ligands on the zirconocene moiety, which would be expected for a metalla-allyl structure **2'**, cannot be detected by NMR spectroscopy in **5a**, even at low temperatures [Cp, ^1H [^{13}C] ([D_6]benzene): $\delta = 5.9$ [111.1]) or **5b** ($\delta = 5.8$ [110.7]).

X-ray structure analysis of **5a** (Fig. 1; crystals from toluene) confirms the chemical equivalence of the Cp ligands. The Cp(centr.),Zr,Cp'(centr.) plane is orientated orthogonally to the C(arom.),C1,H1 plane. The most striking feature of the molecular structure of **5a** is the almost linear Zr–N1–C1 moiety (170.5(5)°). The C=N bond distance (1.259(7) Å) is somewhat shorter than that of normal C=N (sp^2) double-bond systems. In contrast, the metal-nitrogen linkage is extremely short: at 2.013(5) Å in **5a** it is, to the best of our knowledge, the shortest Zr–N bond in a molecular zirconium compound known to date[5]. Despite this pronounced Zr–N1 interaction, the N1–Zr–Cl angle (101.1(2)°) and the Zr–Cl bond length (2.497(2) Å) are clearly within the normal order of magnitude[6].

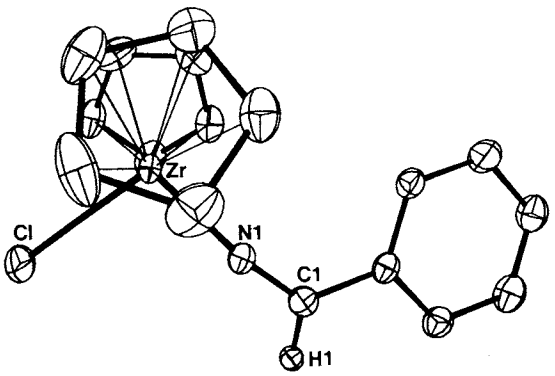

Fig. 1. Molecular structure of **5a** in the crystal. Space group $P2_1/c$; $a = 7.456(6)$, $b = 12.655(7)$, $c = 16.305(8)$ Å, $\beta = 94.09(6)°$, $V = 1534.6$ Å^3, $Z = 4$, 1695 observed reflexions, $R = 0.034$, $R_w = 0.041$. Details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen by quoting the depository number CSD 50559, the names of the authors, and the journal citation.

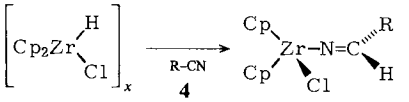
5a can therefore be considered as an organometallic compound with heteroallene structure of type **1'** with sp-hybridized nitrogen. In contrast to the trivalent carbenium ion center in **1**, the incorporation of the isolobal Cp_2ZrCl moiety with tetravalent zirconium could principally lead to stereoisomeric heteroallene systems. However, in the reaction of the nitriles **4** with **3** apparently only one isomer is formed in each case. In **5a**, Cl and H1 are arranged *cis* to the linear Zr–N1–Cl moiety; hydrozirconation usually proceeds with *cis*-stereochemistry[7].



3 **4** **5**

a, R = Ph; **b**, R = Me

The similarity between the structural chemistry of the positively charged organic system **1** and that of the electrically neutral organometallic compound **5** allows us to hope that other examples of "cation chemistry without charges" will be found in the future. Presently, we are investigating whether the resonance interaction between electronically unsaturated, bent, metallocene moieties and organic π systems gives rise to compounds which show reactions similar to resonance stabilized carbocations.

The Scope of Radical CC-Coupling by the "Tin Method"**

By *Bernd Giese**, *Juan Antonio González-Gómez*, and *Tom Witzel*

Alkyl halides undergo CC-coupling on reaction with tributyltin hydride in the presence of electron-deficient alkenes[1]. We have now found that when alkyl iodides are employed in the reaction, the tin salts are necessary only as catalysts; moreover, we have also succeeded in carrying out the reaction with alcohols instead of with halides.

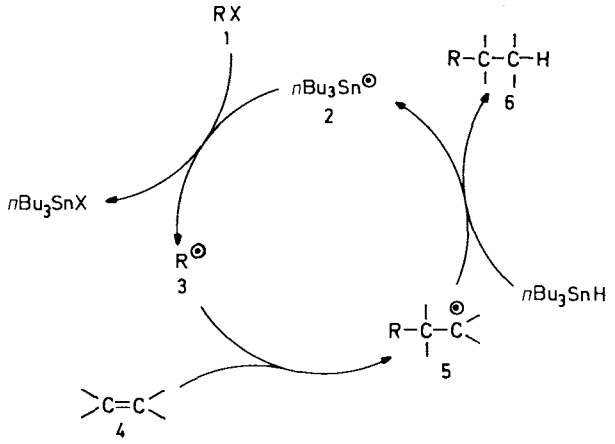
[**] This work was supported by the Fonds der Chemischen Industrie.

With **1** and **4** as educts, a radical chain reaction leads, via the intermediary radicals **2**, **3** and **5**, to formation of the products **6** (Scheme 1).



Scheme 1.

In the case of alkyl iodides the reactions could be carried out with substoichiometric amounts of organotin compounds because the butyltin hydride could be regenerated in situ from the tin halide with $NaBH_4$[2]. Thus, the photochemically initiated reaction of the alkyl iodides **1** (X = I) in ethanol at 25 °C with 0.2 molar equivalents of *n*-Bu_3SnCl and 1.3 molar equivalents of $NaBH_4$ in the presence of the alkenes **4** afforded the products **6** in yields of over 80% (Table 1).

Table 1. Yields of coupling products **6** in the reaction of alkyl iodides and thiocarbonyl compounds **1** (X = I, $OC(S)SCH_3$) with alkenes **4**.

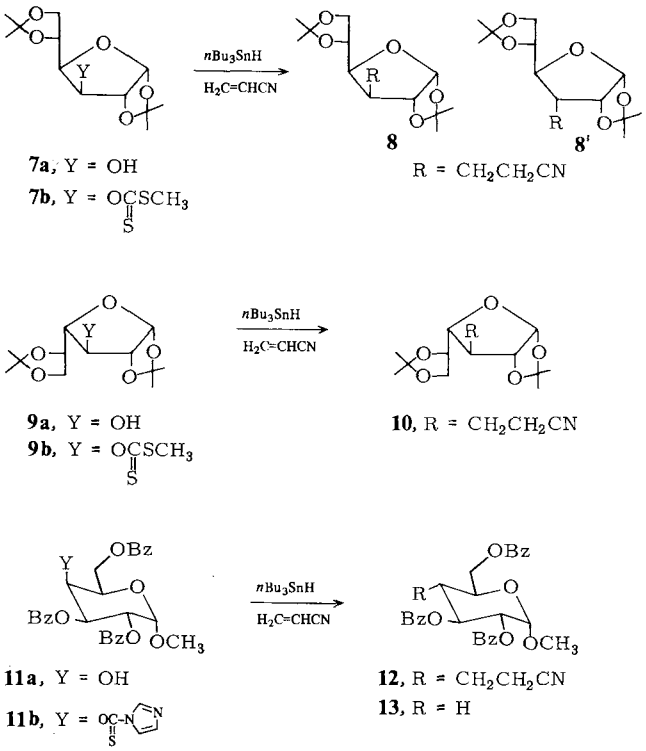
9b	H_2C=CHCN	35 (50)
11b	H_2C=CHCN	30

[a] 45 : 55 *cis* : *trans* mixture. [b] Gas-chromatographically determined yields in parenthesis.

This CC-coupling reaction could also be extended to thioacylated alcohols, analogously to the reduction method of *Barton* et al.[3]. Because of the photolability of the thiocarbonyl compounds, the syntheses were carried out in boiling toluene with azobis(isobutyronitrile) (AIBN) as initiator (Table 1). The versatility of this synthetic method is strikingly revealed on extending its application to carbohydrates: At 110 °C 1,2 : 5,6-di-*O*-isopropylidene-α-D-glucofuranose **7a**, afforded, via intermediary **7b**, the CC-coupling products **8** and **8′** (73 : 27)[4]; in contrast, the 1,2 : 5,6-di-*O*-isopropylidene-α-D-galactofuranose **9a** reacts diastereoselectively to give **10** (via **9b**). Accordingly, acrylonitrile preferably attacks the bicyclic radicals formed from **7b** and **9b** from the *exo*-side. This diastereoselectivity corresponds to the stereoselectivity of the deuteration with tributyltin deuteride[5].



The reaction of the thiourethane **11b** yielded the 4-(2-cyanoethyl)-**4**-deoxyglucopyranoside **12** as the product of CC-coupling. Other than in the unselective deuteration[6], here the equatorial substituents on C-3 and C-5 force an equatorial attack of acrylonitrile at C-4.

Besides the C-branched carbohydrates, about 10% of the corresponding deoxysugars are formed by reduction of the xanthates **7b** and **9b**. In contrast, in the case of **11b** the amount of CC-coupling and reduction, to give respectively **12** and **13**, was about the same.

The Allyl Group as Mildly and Selectively Removable Carboxy-Protecting Group for the Synthesis of Labile *O*-Glycopeptides**

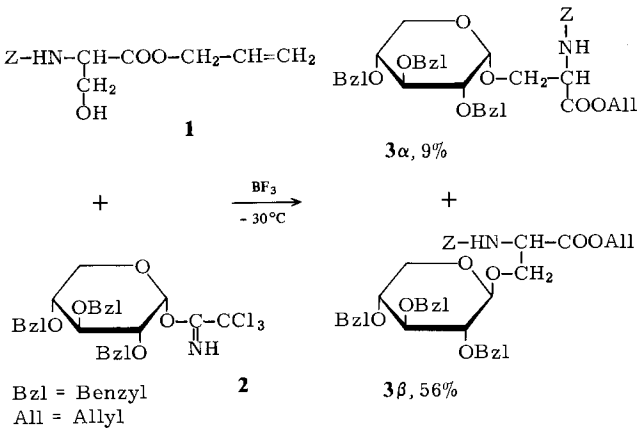
By *Horst Kunz** and *Herbert Waldmann*

Glycoproteins with a *O*-glycosidic bond between serine or threonine and the carbohydrate side chains fulfill important biological functions as membrane, serum, and connective tissue components. The synthesis of typical sections from such molecules is rendered difficult by the fact that the glycosyl-serine and -threonine bonds are both acid-labile as well as base-labile[1].

Selective carboxyl-deblocking and lengthening of the *C*-terminal chain can be achieved in glycosyl-serine derivatives by reductive elimination of the 2-haloethyl esters with zinc[2]. However, loss of material occurs by adsorption on the zinc salts.

We recently found that the allyl group can be used in peptide syntheses as a carboxy-protecting group which can be selectively removed in the presence of the benzyloxycarbonyl (Z) and the *tert*-butoxycarbonyl (Boc) groups under mild neutral conditions. The isomerization of the allyl moiety with tris(triphenylphosphane)rhodium(I) chloride[3] in ethanol/water at 70°C used in this reaction can also be used for liberation of the carboxy function in *N*-glycosylasparagine derivatives[4]. Herein we describe the extension of this method to the synthesis of labile *O*-glycopeptides and, therewith, an even gentler method for the cleavage of allyl esters.

The Z-serine allyl ester **1**, which is obtained by reaction of Z-serine with allyl bromide in 6% aqueous sodium hydrogen carbonate solution/dichloromethane in the presence of methyltrioctylammonium chloride, is first glycosylated with 2,3,4-tri-*O*-benzylxylopyranose according to the trichloroacetimidate method[5].



Unfortunately, the reaction does not proceed with the expected high β-selectivity[5]. The pure β-xylosylserine derivative **3β** can only be obtained by column chromatographic separation on silica gel. It shows a C-1 signal at $\delta = 104.7$ with $J(^{13}C\text{-}H) = 166.2$ Hz ([D$_6$]acetone) in the ^{13}C-NMR spectrum. The C-1 signal of the α-anomer **3α** appears at $\delta = 98.7$ (CD_3OD). Elemental analyses and ^1H-NMR spectra are also consistent with the structures **3α** and **3β**.

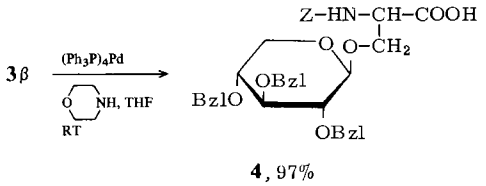
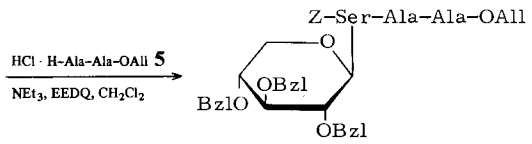
In order not to rupture the very labile *O*-glcoside bond in the glycosylserine derivative **3β**, we searched for an even milder method than the rhodium-catalyzed isomerization for cleavage of the allyl ester, and found this in the palladium(0)-catalyzed allyl transfer which *Trost* et al.[6] have used on several occasions for the allylation of carbanions. On reaction with ca. 10 mol-% of tetrakis(triphenylphosphane)palladium(0) under argon in tetrahydrofuran (THF) at room temperature the allyl residue of **3β** is transferred to morpholine (tenfold excess) as acceptor nucleophile. The cleavage of the allyl ester is almost quantitative.



4, 97%

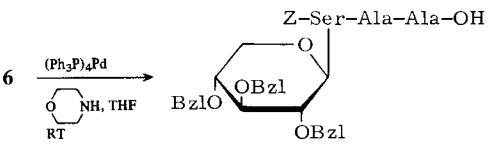


6, 87%

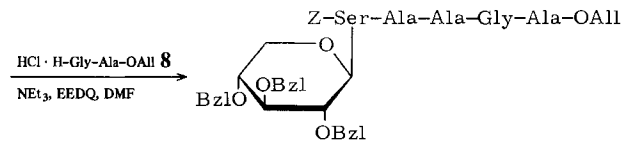
All the remaining functions of the glycosylserine derivative **3β** that are sensitive to acids, bases and to reduction are completely preserved. The carboxy-deblocked product **4** was identified by elemental analysis and by its spectra (^{13}C-NMR: $\delta = 104.9$, C-1; $J_{(^{13}C\text{-}H)} = 164$ Hz (CD_3OD).

For the synthesis of the glycopentapeptide **9**, whose mode of construction is based on data for the linkage region of an extracellular glycoprotein of the alga *Porphyridium crumtum*[7], the lengthening of the *C*-terminal chain of **4** is first undertaken by reaction with the dipeptide allyl ester **5**[4] in the presence of ethyl 2-ethoxy-1,2-dihydroquinone-1-carboxylate (EEDQ)[8]. The glycotripeptide allyl ester **6** is obtained in high yields. This reveals a further advantage of the small allyl group; its low lipophilicity promotes solubility, its sterically less-demanding size the condensation reactions.

It can also be demonstrated on the complex xylosyl-tripeptide ester **6** that the allyl moiety can be selectively and quantitatively removed by palladium(0) catalysis. Further enlargement of the product **7** (^{13}C-NMR: $\delta = 102.8$, C-1 ([D$_6$]dimethyl sulfoxide)) by the dipeptide unit **8** in dime-



7, 97%



9, 61%, $[\alpha]_D^{22} = -24.2$ ($c = 0.5$ CH_3OH)

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 *0570-0833/84/0101-0071 $ 02.50/0*

thylformamide (DMF) afforded the desired glycopentapeptide allyl ester **9**, whose structure was likewise confirmed by elemental analysis and spectroscopic data (^{13}C-NMR: $\delta = 102.9$, C-1, $J_{(^{13}C\text{-}H)} = 163$ Hz (dimethyl sulfoxide)).

The allyl group has thus proven to be a valuable achiral carboxy-protecting group even for difficult peptide and glycopeptide syntheses, and can be used in conjunction with *N*-terminal Z- and Boc-protecting groups. Also noteworthy is that the four glycopeptide allyl esters **3α**, **3β**, **6** and **9** are crystalline.

Procedure

N-Benzyloxycarbonyl-*O*-(2,3,4-tri-*O*-benzyl-β-D-xylopyranosyl)-L-serine **4**:

$(Ph_3P)_4Pd$ (0.15 g, 0.13 mmol) is added under argon at room temperature to a solution of **3β** (0.9 g, 1.32 mmol) in THF (10 mL) and the resulting mixture treated dropwise with 1.15 mL (13 mmol) morpholine. After 30 min the THF is distilled off in vacuo, the residue taken up in dichloromethane (50 mL), and the resulting solution extracted both with 2 N HCl (30 mL) and water, and dried over $MgSO_4$. After removal of the dichloromethane in vacuo, the residue is dissolved in ether, filtered, and the filtrate evaporated down. **4** remains as a colorless, amorphous solid; yield 0.82 g (97%), $[\alpha]_D^{22} = +18.3$ ($c = 1$, $CHCl_3$), ^{1}H-NMR: $\delta = 4.31$ (d, $J_{1,2} = 7.1$ Hz, 1H, H-1).

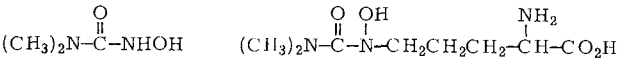
Unusual Components of the Toadstool *Lyophyllum connatum* (Agaricales)**

By *Burkhard Fugmann* and *Wolfgang Steglich**

The white fruiting bodies of *Lyophyllum connatum* are recommended by many field guides on mushrooms as edible and choice[1]. On spraying with aqueous $FeCl_3$ solution the mushroom shows an intense blue-violet color reaction—which prompted us to investigate the substances responsible.

After extraction of the fresh fungi[3] with methanol, evaporation of the solution to dryness and partition of the residue between water and ethyl acetate, the $FeCl_3$-positive compounds remained in the aqueous phase. By repeated gel-chromatography on various separating media, two of the compounds responsible for the color reaction could be obtained in pure form.

The substance present in smaller amounts (0.01–0.02%), m.p. 104–106 °C, proved to be identical with *N'*-hydroxy-*N,N*-dimethylurea **1**[4], a compound previously not found in nature.



1

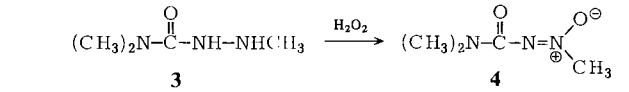
2

The main chromogen, connatin (m.p. 184–188 °C (dec.)) is present in the fresh fungus in amounts of 0.20–0.25%. From the spectroscopic data[5a] it follows that connatin has the formula of a N^{δ}-hydroxy-N^{ω},N^{ω}-dimethylcitrullin **2**. Since **2** affords a 2-trifluoromethyl-5(2*H*)-oxazolone[6] [^{1}H-NMR ($CDCl_3$): $\delta = 6.68$ (qt, $J = 4.6 + 2.3$ Hz, $CH{-}CF_3$)] on reaction with trifluoroacetic anhydride, the α-NH_2-group must be free. The terminal dimethylcarbamoyl group is recognizable in the EI-MS from the fragments *m/z* 104 ($C_3H_8N_2O_2$, 4%), 72 (C_3H_6NO, 94%) and 44 (C_2H_6N, 100%). Hydrolysis of **2** with 5% H_2SO_4 furnishes (*S*)-3-amino-1-hydroxy-2-piperidone[7], whereas with 6 N HCl (*S*)-N^{δ}-hydroxyornithine hydrochloride[8] is formed. The melting points and optical rotations of the two compounds agree with those quoted in the literature, thus proving the *S*-configuration for **2**.

N-Hydroxyamino acids have so far never been isolated from the fruiting bodies of higher fungi. Derivatives of N^{δ}-hydroxyornithine play an important role as sideramines and siderochromes in the transport of iron in microorganisms[9].

A further component, lyophyllin, m.p. 27–28 °C, can be isolated in 0.04% yield from the lipophilic fraction of the crude extract by twofold preparative thin-layer chromatography (silica gel, ethyl acetate).

From the spectroscopic data[5b] and the formation of *N,N*-dimethylurea upon hydrogenolysis, the structure of lyophyllin is *N,N*-dimethylazoxycarboxamide **4**; this has been confirmed by synthesis. Based on the procedure of *Mortarini* et al.[10], 1,4,4-trimethylsemicarbazide **3** was oxidized with 90% H_2O_2/maleic anhydride in dichloromethane (1 h 0 °C, 3 h 40 °C). The compound **4** obtained in 50% yield proved to be identical with the natural product. The stereochemistry of the compound awaits further investigation.



3 **4**

Lyophyllin is the first example of a alkylazoxycarboxamide. From cultures of *Calvatia* species (puffballs), *p*-cyanoazoxybenzoic acid (calvatic acid)[11] has been isolated, which has tumor-inhibiting properties. Simple aliphatic azoxy compounds and natural products of this structural type such as cycasin[12] or elaiomycin[13] are strong mutagens. Since *N*-hydroxyureas also interfere with DNA metabolism[14], a warning must be given about the consumption of this *Lyophyllum* species. After all, 1 kg of this toadstool contains 400 mg of lyophyllin **4** and more than 2 g of connatin **2**[15].

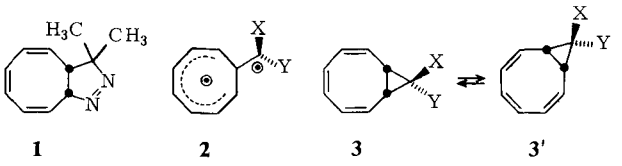
Mechanism of the Cyclopropane "Walk" Rearrangement: Synthesis and Properties of the 2-Diazopropane Adduct of Cyclooctatetraene**

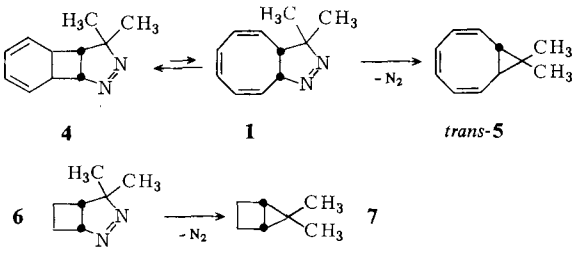
By *Frank-Gerrit Klärner** and *Volker Glock*

Whether the stereospecific cyclopropane "walk" rearrangement of the vinylogous systems bicyclo[2.1.0]pent-2-ene, bicyclo[4.1.0]hepta-2,4-diene (norcaradiene) and *cis*-bicyclo[6.1.0]nona-2,4,6-triene proceed concertedly or in two steps via diradicals cannot be unequivocally decided on the basis of the results of stereochemical and kinetic investigations alone[1]. An attempt was therefore made to generate the possible diradical intermediates via an independent route. We report here on the synthesis and thermolysis of **1**, which is a suitable precursor for a diradical of the type **2**, the potential intermediate of the "walk" rearrangement **3** → **3'**.

Cyclooctatetraene reacts with diazopropane differently than with diazomethane and diazoethane[2]; even at −15 °C the bicyclic dihydropyrazole **1** is primarily produced, which can be separated free of isomer from the tricyclic dihydropyrazole **4**, formed concomitantly as by-product, by reaction with *N*-phenylmaleimide and subsequent column chromatography (Fluorisil, ether-pentane (1:3), −20 °C; yield 7.6% referred to 2-diazopropane)[3]. Similarly, as in the case of other bicyclic cyclooctatriene derivatives[4], the valence isomerization **1** → **4** already occurs at room temperature (25 °C: $\tau_{1/2}$ = 89 min).



1 **2** **3** **3'**



4 **1** *trans*-**5**

6 **7**

Scheme 1. $k_{1,4} = 6.3 \times 10^{11}$ exp [(−21.4 ± 0.4) kcal/RT]; $K = [\mathbf{4}]_\infty : [\mathbf{1}]_\infty \geq 100$; $k_{4,5} = 2.7 \times 10^{15}$ exp [(−34.3 ± 0.7) kcal/RT]; $k_{6,7} = 7.4 \times 10^{15}$ exp [(−39.8 ± 0.5) kcal/RT].

On heating the tricyclic dihydropyrazole **4** at 110 °C, up to 95% N_2-cleavage takes place to give the *trans*- and *cis*-9,9-dimethylbicyclo[6.1.0]nona-2,4,6-triene **5** in a ratio of 149 : 1[5] (gas chromatography). In addition, 5% cycloreversion to 3,3-dimethyl-3*H*-pyrazole[6] and benzene is also observed. The structure of the novel hydrocarbon *trans*-**5**[7] follows unambiguously from its spectral data[3]. From a comparison of the activation parameters of the reactions **4** → **5** and **6** → **7** given in Scheme 1, it emerges that the N_2-cleavage at 110 °C is 500 times more rapid than in the structurally related cyclobutene-diazopropane adduct **6**. This finding indicates that the N_2-cleavage does not occur from the tricycle **4** but from the valence isomeric bicycle **1**.

To gain further insight into the course of the reaction **4** → **5**, the thermal behavior of [1,2-D_2]-**4**, obtainable from

4 by base-induced H/D exchange in tetrahydrofuran (THF), was investigated ($KOt\text{-}C_4H_9$, D_2O-THF, room temperature, 16 h, yield 19%). The deuterium content quoted in Scheme 2 derives from the ^1H- and ^2H-NMR spectra. After partial thermolysis of [1,2-D_2]-**4** (110°C, 140 min, conversion: 50%), the content and position of the deuterium atoms in the recovered educt remain unchanged. According to the ^1H- and ^2H-NMR analyses, the main product consists of equal amounts of the regioisomers *trans*-[1,2-D_2]-**5** and *trans*-[2,3-D_2]-**5**.

The surprising formation of *trans*-**5** from the *cis*-configurated dihydropyrazole **4** can be explained as follows: After the valence-isomerization **4** → **1**, N_2-cleavage starts to take place from the *exo*-conformation of **1** shown in Scheme 2; this conformation of **1** is undoubtedly thermodynamically preferred over the corresponding *endo*-conformation. The structure of the likely diradical intermediates **8** and/or **2** resembles that of the homotropylium ion, and favors ring-closure to the *trans*-configurated bicyclo[6.1.0]nonatriene system. For formation of the *cis*-bicyclo[6.1.0]nonatriene, the intermediate must exist in the *endo*-conformation. Ring inversion obviously competes only to a very limited extent, if at all, with the ring-closure reaction. From the deuterium labeling experiment it can be concluded that the ring-closure between C-9 and C-1 proceeds at the same rate as that between C-9 and C-7. This finding can hardly be reconciled with the diazenyl diradical **8** as intermediate for the ring-closure. For the rear attack on the C atom bearing the diazenyl radical previously discussed in the literature, a preferred ring-closure between C-9 and C-7 would be expected. The experimental result, however, rather requires an intermediate having the symmetry properties of the N_2-free diradical **2**. The observation that the *cis*-configuration is preserved during the "walk" rearrangement in the *cis*-bicyclo[6.1.0]nonatriene system rules out the participation of a diradical intermediate of type **2** in this process.

[8] Review: P. S. Engel, *Chem. Rev. 80* (1980) 99. For the case of the diazenyl diradical **8** as an intermediate the rotation about the C8–C9 bond must be assumed to precede the ring-closure reaction. According to the observed stereoselectivity, conformational processes seem to compete with the ring-closure reaction to only a minor extent.

Macrocycles by Intramolecular Diels-Alder Reaction—Regioselective Synthesis of Anthracycline Precursors**

By *Joaquin Tamariz* and *Pierre Vogel**

The intramolecular Diels-Alder reaction is a powerful synthetic tool and has been applied widely[1]. Usually, the connective chain between diene and dienophile moieties consists of three to five atoms; if longer, the intramolecular reactivity and regio- and stereoselectivity decrease. It is therefore not surprising that this technique has not yet been widely used for the synthesis of medium-ring and macrocyclic compounds[2,3]. We report here an unusual regio- and stereoselective macrocyclic synthesis using an intramolecular Diels-Alder reaction. The method suggests a new approach to the synthesis of anthracycline precursors such as daunomycinone[4].

Mesylate **2**, derived from **1**[5], furnished phenolate **3** upon treatment with KO*t*Bu. Reaction with benzoyl chloride, followed by oxidation with dichlorodicyanobenzoquinone gave **4** (95%, m.p. = 148–149°C). Inspection of simple molecular models indicates that an intramolecular Diels-Alder addition could be possible if, for example, acrylic acid were linked to naphthol **5** through a three-membered chain. Transesterification of **4** (K_2CO_3/CH_3OH) furnishes **5** (m.p. = 194–195°C, 98%). The corresponding naphthoate generated in tetrahydrofuran (THF) using NaH reacts with 3-bromopropanol (molar ratio 1 : 1, 70°C, 3 h) to give **6** (m.p. = 134–135°C, 96%). Esterification with acrylic acid yields 7 (51.5%). When dilute solutions ($< 8 \times 10^{-3}$ M) of **7** in xylene (with or without $ZnCl_2$ or $BF_3 \cdot Et_2O$) are heated to 140–240°C only polymerization was observed. The failure to observe macrocycle formation with **7** led us to choose a longer connecting chain between diene and dienophile.

The sodium naphthoate of **5**, generated using NaH in a mixture of THF and hexamethylphosphoric triamide (1 : 2) reacts with 1,6-dibromohexane (molar ratio 1 : 4, 0°C, 0.5 h) to yield bromide **8** (75%). Treatment with acrylic acid and 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) (molar ratio 2.2 : 2 : 1) in benzene (80°C, 2 h) afforded acrylate **9** as a

colorless oil (63%), which polymerizes rapidly in the condensed state. When **9** was diluted in xylene (1.6×10^{-3} M) containing traces of hydroquinone and the solution heated to 170°C for 23 h, the macrocycle compound **10** was obtained as a homogeneous oil (58% after chromatography on silica gel) together with unreacted **9** and polymeric material. Characteristic data for compounds **7**–**10** are summarized in Table 1.

Table 1. Melting points and selected spectroscopic data of compounds **7**–**10**.

7: m.p. = 109–110°C; UV (CH_3CN): $\lambda = 300$ ($\varepsilon = 3600$), 252 (48100), 218 nm (45800); IR (KBr): $\nu = 1720$, 1595 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 8.16$, 7.67 (2s, 2H), 7.41 (d, $J = 8.2$ Hz, 1H), 7.37 (dd, $J = 7.4$, 8.2 Hz, 1H), 6.83 (dd, $J = 1.0$, 7.4 Hz, 1H), 6.44 (dd, $J = 1.6$, 17.6 Hz, 1H), 6.16 (dd, $J = 10.8$, 17.6 Hz, 1H), 5.85 (dd, $J = 1.6$, 10.8 Hz, 1H), 5.73, 5.70, 5.32, 5.26, 5.23 (5s, 5H), 4.5 (t, $J = 6.4$ Hz, 2H), 4.26 (t, $J = 6.0$ Hz, 2H), 2.32 (m, 2H). MS (70 eV): $m/z = 348$ (M^+, 56), 293 (13), 113 (100).

8: m.p. = 101–102°C; UV (CH_3CN): $\lambda = 302$ ($\varepsilon = 330$), 252 (48000), 218 (44900); IR (KBr): 2950, 1590, 1505 cm^{-1}. ^{1}H-NMR ($CDCl_3$): $\delta = 8.17$, 7.66 (2s, 2H), 7.39 (dd, $J = 2$, 8.0 Hz, 1H), 7.34 (t, $J = 8.0$ Hz, 1H), 6.82 (dd, $J = 2.0$, 8.0 Hz, 1H), 5.74, 5.71, 5.32, 5.26, 5.22 (5s, 5H), 4.13 (t, $J = 6.4$ Hz, 2H), 3.44 (t, $J = 6.6$ Hz, 2H), 1.93 (m, 4H), 1.59 (m, 4H); MS (70 eV): $m/z = 398$ (M^+, 20), 371 (4), 44 (100).

9: UV (CH_3CN): $\lambda = 302$ ($\varepsilon = 3400$), 252 (44700), 218 (42300); IR (film): $\nu = 2940$, 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 8.15$, 7.65 (2s, 2H), 7.37 (dd, $J = 1.0$, 7.2 Hz, 1H), 7.33 (t, $J = 7.2$ Hz, 1H), 6.8 (dd, $J = 1.0$, 7.2 Hz, 1H), 6.40 (dd, $J = 1.3$, 17.2 Hz, 1H), 6.13 (dd, $J = 10.5$, 17.2 Hz, 1H), 5.81 (dd, $J = 13$, 10.5 Hz, 1H), 5.73, 5.69, 5.32, 5.26, 5.23 (5s, 1H), 5.21 (t, $J = 6.6$ Hz, 2H), 4.12 (t, $J = 6.6$ Hz, 2H), 1.95, 1.75, 1.62, 1.52 (4 quintet, $J = 6.6$ Hz, 4×2H); MS (70 eV): $m/z = 390$ (M^+, 75), 335 (25), 236 (100).

10: UV (EtOH): $\lambda = 334$ ($\varepsilon = 420$), 317 (700), 292 (sh, 41000), 280 (sh, 5600), 274 (sh, 5700), 252 (24600), 230 (20200); IR ($CHCl_3$): 3010, 2940, 1735, 1600 cm^{-1}; ^{1}H-NMR ($CDCl_3$): 8.03 (s, 1H, 6-H), 7.51 (s, 1H, 11-H), 7.33 (dd, $J = 7.2$, 8.0 Hz, 1H, 9-H), 7.29 (dd, $J = 1.5$, 8.0 Hz, 1H, 10-H), 6.89 (dd, $J = 1.5$, 7.2 Hz, 1H, 8-H), 5.62 (m, 1H, 12-H), 5.60 (m, 1H, 5-H), 4.32 (t, $J = 5.5$ Hz, 2H, H_2C–OCO), 4.05 (ddd, $J = 3.4$, 5.2, 10.2 Hz), 3.73 (ddd, $J = 3.4$, 10.2, 11.2 Hz, 2H, H_2C–O), 2.58 (dm, $J = 18.0$ Hz, 1H, 1β-H), 2.27 (m, 2H, 2-H, 4β-H), 1.85–1.33 (m, 9H), 1.25 (m, 2H), 0.77 (dddd, $J = 4.0$, 6.0, 10.0, 18.0 Hz, 1H, 3α-H), cf. also text; MS (70 eV): $m/z = 390$ (M^+, 11), 234 (100); MS (CI, CH_4): 391 ($M^+ + H$).

The structure of **10** was determined using 360 MHz ^{1}H-NMR spectroscopy (cf. also Table 1). The distinction between the signals of the aromatic protons 6-H and 11-H is based on NOE measurements. Similarly, the signals of the bridgehead protons 5-H and 12-H was obtained using NOE measurements (proximity to 6-H and 11-H, respectively). A homoallylic ^5J coupling constant of 1.7 Hz was measured between 1β-H and 5-H. This is somewhat larger than expected (1–1.4 Hz) for cyclohexenes annelated to 7-oxanorbornenes[6] and suggests a blocked conformation of the A-ring with 1β-H in an axial position (Fig. 1). The coupling constants $^4J_{12\text{-H},1\beta\text{-H}} = 0.2$–$0.3$ Hz and $^5J_{4\beta\text{-H},12\text{-H}} = 0.2$–$0.3$ Hz were observed, confirming a blocked chair conformation in which 4β-H is equatorial. 2-H couples with 1β-H and 1α-H with relatively *small* vicinal coupling constants (3–4 Hz); 2-H also couples strongly with 3α-H (10 Hz) and weakly with 3β-H (<1 Hz). The measured coupling constants between 3α-H and 4β-H (6 or 4 Hz) and between 3α-H and 4α-H (4 or 6 Hz) are in agreement with structure **10** and the conformation depicted in Figure 1.

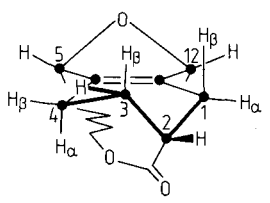

Fig. 1. Conformation of the "right part" of **10** (schematic).

Variation of the concentration of **9** ($1\text{–}4 \times 10^{-3}$ M) did not affect the yield of **10**, as expected for an intramolecular Diels-Alder addition. Inspection of molecular models suggests a preferred attack at the *endo* face, thus requiring the acrylic ester in **9** to adopt an orientation consistent with Alder's *endo* rule. Compound **10** can be viewed as an eighteen-membered ring *ansa*-lactone[7].

The transformation of tetraene **1** into **10** suggests a new approach to the total synthesis of anthracycline precursors involving control of the regiostereoselectivity of the substituents of ring A with respect to those of ring D[8]. Methods for generating **2** in optically pure form and for stereoselective transformation of **10** into daunomycinone[9] are being investigated.

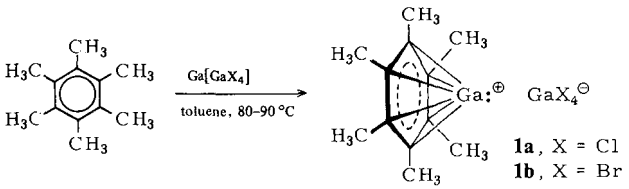
Preparation and Structure of (η^6-Hexamethylbenzene)gallium(I) Tetrabromogallate(III): π-Complex and *nido*-Cluster

By *Hubert Schmidbaur**, *Ulf Thewalt*, and *Theodore Zafiropoulos*

Over a hundred years ago, the discoverer of the element gallium[1] reported the astonishing observation that the preparations which he termed gallium(II) halides of empirical formula GaX_2 (X = Cl, Br) are freely soluble in anhydrous benzene and can be precipitated from solution with "crystal benzene"[2]. Whereas, on the one hand, the dihalides have been characterized in the meantime in the crystalline and molten states by different methods as $Ga^{I}Ga^{III}X_4$[3], and, on the other hand, their dioxane complexes had to be interpreted as compounds, $X_2Ga-GaX_2\cdot(C_4H_8O_2)_2$, with metal-metal bonds[4], the nature of the interaction between "$GaCl_2$" and "$GaBr_2$" and aromatic hydrocarbons remained unclear. It was certainly presumed by many authors that "π-complexes" could be involved[2], but experimental evidence for this remained elusive. The same applied to the benzene adduct of $Tl[AlCl_4]$[5].

Following the elucidation of the benzene-richest phase in the system $Ga[GaCl_4]$/benzene as a tetranuclear complex with two bis(η^6-benzene)gallium(I) moieties[6], we now report the first monoarene complex of gallium(I).

Suspensions of Ga_2Cl_2 or Ga_2Br_4 in anhydrous toluene rapidly become clear upon addition of excess hexamethylbenzene and heating to 80–90 °C; upon cooling the colorless reaction solution crystals of overall composition $Ga_2X_4\cdot C_6Me_6$ precipitate (**1a**, X = Cl, m.p. = 168 °C: **1b**, X = Br, m.p. = 146 °C).



No evidence for other products was found, which is significant in as far as both benzene and 1,3,5-trimethylbenzene form primary products with $(arene)_2Ga^{\oplus}$ structural units[6,7]. Furthermore, it is significant that the hexamethylbenzene added to the toluene is apparently preferred as a ligand. The ^1H- and ^{13}C-NMR spectra of solutions of **1a** in CD_2Cl_2 exhibit signals from the hexamethylbenzene ligand: $\delta(CH_3) = 7.90$, $\delta(CH_3) = 17.15$, $\delta(C) = 136.51$ (rel. TMS).

The X-ray structure analysis of **1b**[8] indicates that a polycoordinated network is present (Fig. 1), composed principally of $Me_6C_6Ga^{\oplus}$ cations and $GaBr_4^{\ominus}$ anions.

Whereas the Ga^{III} center (Ga1) exhibits only a slightly distorted tetrahedral environment of four bromine atoms (Br1 to Br4; cf. Fig. 1), the Ga^{I} center (Ga2) is bonded principally to the hydrocarbon, 2.552 Å vertically above

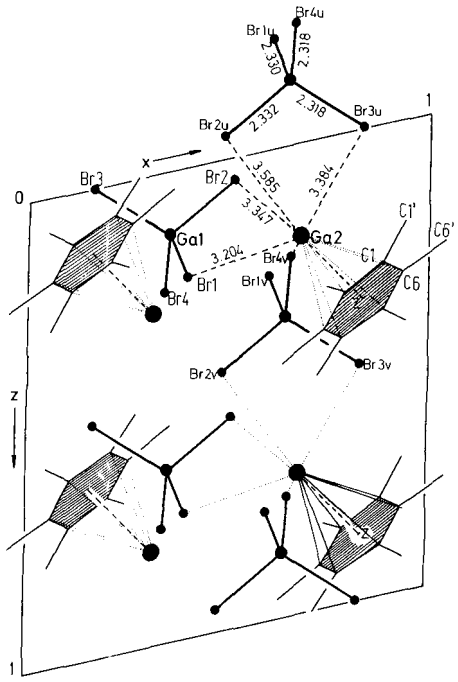


Fig. 1. Projection of the crystal structure of $Ga_2Br_4\cdot C_6(CH_3)_6$ **1b** along the crystallographic y-axis. To clarify matters, the contacts to the neighboring atoms are only shown for two of the Ga^{I} atoms (large circles, Ga2). Supplementary parameters: Ga2–Br4v 3.347, Ga2–C1 2.871, Ga2–C2 2.915, Ga2–C3 2.897, Ga2–C4 2.869, Ga2–C5 2.896, Ga2–C6 2.877. u and v signify the transformations $1-x, -y, -z$ and $1-x, -\frac{1}{2}+y, \frac{1}{2}-z$, respectively. Standard deviations for Ga–C and Ga–Br distances are 0.009 and 0.002 Å, respectively.

the centroid of the six-membered ring. The average Ga2–C distance is 2.888(18) Å. The other sites in the coordination sphere of Ga2 consist of five bromine atoms which originate from three different $GaBr_4$ tetrahedra (Fig. 1). Two of the "ligand tetrahedra" form chelates; one is only monodentate. The associated Ga–2Br distances vary over the range 3.204 to 3.585 Å. The overall coordination of Ga2 can be interpreted as distorted octahedral if the arene (formally its center Z) is assigned to one corner of an octahedron (Fig. 2). The distorsion principally arises because Ga2 is markedly displaced towards the arene.

The complexed hexamethylbenzene displays systematic deviations from planarity: C1 and C4 project out of the "ring plane" in the Ga2 direction; in contrast, C2, C3, and C5 are displaced in the opposite direction. The positions of the CH_3 groups express this pattern particularly clearly[9].

The model of π-complex formation and the cluster formalism both offer theoretical descriptions of the bonding of the arene Ga^{I}. In the qualitative MO scheme the former emphasizes the interaction between the filled bonding orbitals a_1 and e_1 of the arene (C_{6v}) and the empty symmetry-equivalent sp_z and p_x/p_y orbitals of Ga^{I}. The relationship with the known arene complexes of Sn^{II} is discernible from the isoelectronic relationship[10]. Within the framework of the cluster formalism, $Me_6C_6Ga^{\oplus}$ can be considered as the *nido*-form of a polyhedron closely related to the cyclopentadienylgermanium(II) and cyclopentadienyltin(II) cations, which are also well known[11].

Comparison with the $(C_6R_6)_2Ga^{\oplus}$ complexes[6] indicates that the metal-arene bond in **1a, b** is considerably stronger than in bis(benzene)gallium(I) and bis(mesitylene)gallium(I)[7], which have ring centroid-metal distances of 2.764/2.929 and 2.673/2.673 Å, respectively. Since the ar-

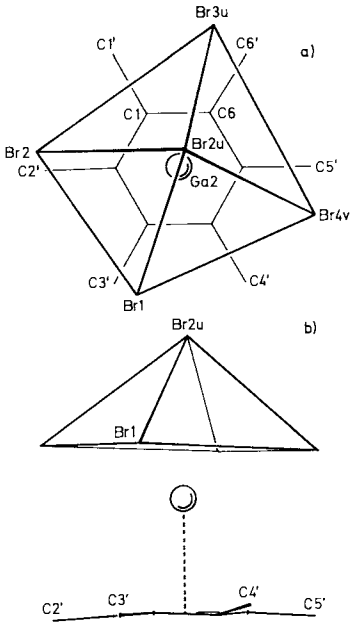

Fig. 2. Coordination sphere of an individual Ga' atom. a) Projection perpendicular to the best plane through the C_6 ring; b) side view of the same moiety.

ene ligand functions as a donor in each case, the shorter distance in **1a, b** can certainly be attributed to the inductive effect of the six methyl groups. The order of stability $C_6Me_6 > C_6H_3Me_3 > C_6H_5Me > C_6H_6$ is therefore not surprising. The C_6H_6 ligand is so loosely bound that it can be removed at room temperature under reduced pressure[6]. However, additional steric effects and symmetry phenomena may predominate over the inductive effect.

Hydrolysis Products of the Monomeric Amine Complex $(C_6H_{15}N_3)FeCl_3$: The Structure of the Octameric Iron(III) Cation of $\{[(C_6H_{15}N_3)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)\}Br \cdot 8H_2O$

By *Karl Wieghardt**, *Klaus Pohl*, *Ibrahim Jibril*, and *Gottfried Huttner*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday

The chemistry of Fe^{III} compounds in aqueous solution is underscored by their tendency to undergo hydrolysis and by the condensation of $Fe(OH_2)_6^{3\oplus}$. Hydroxo- and oxo-bridged oligomers are formed before the precipitation of sparingly soluble $Fe_2O_3 \cdot n\,H_2O$[1]. Nevertheless, the characterization of oligomers containing more than three Fe^{III} centers has so far never been reported. Hydrolysis of the monomeric complex (tacn)$FeCl_3$ **1** (tacn = 1,4,7-triazacyclononane) in the presence of acetate leads to formation of the binuclear complex $[(tacn)_2Fe_2(\mu_2\text{-}O)(\mu_2\text{-}CH_3CO_2)_2]^{2\oplus}$ **2**[2]; in the absence of potential ligands such as acetate the dimeric, green $[(tacn)_2Fe_2(H_2O)_2(\mu_2\text{-}O)_2]^{2\oplus}$ **3** is formed at pH 9, and it can be isolated as the iodide or as the PF_6^- or ClO_4^-salt[3a]. Hydrolysis of **1** at 20°C (pH 9) in the presence of bromide leads within 24 h to precipitation of brown crystals of the compound $[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_8 \cdot 9\,H_2O$ **4**[3b].

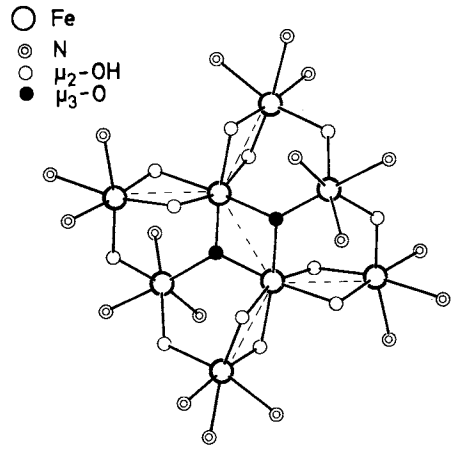

Fig. 1. Skeleton of the octameric cation of **4** (only Fe, O, and N atoms are shown). Mean distances: Fe–N 2.17 Å, Fe–OH 1.98 Å, Fe–(μ_3-O) 1.93 Å. Short Fe···Fe distances (broken lines) 3.05 Å.

The X-ray structure analysis of **4** shows that an octameric Fe^{III} cation is formed[4], in which only six of the eight Fe^{III} atoms are bonded to an amine ligand (FeN_3O_3); two central Fe^{III} atoms are each surrounded by a distorted oc-

tahedral array of six O-atoms. The iron ions are coupled together by twelve μ_2-hydroxo bridges and by two μ_3-oxo bridges (Fig. 1). The cyclic amine ligands form a hydrophobic "surface" of the complex cation (Fig. 2). There are five relatively short Fe···Fe distances (≈305 pm), which arise from edge-to-edge coupling of octahedra via oxo- or hydroxo-bridges, and eight longer ones (≈345 pm). The cation has idealized C_i-symmetry.

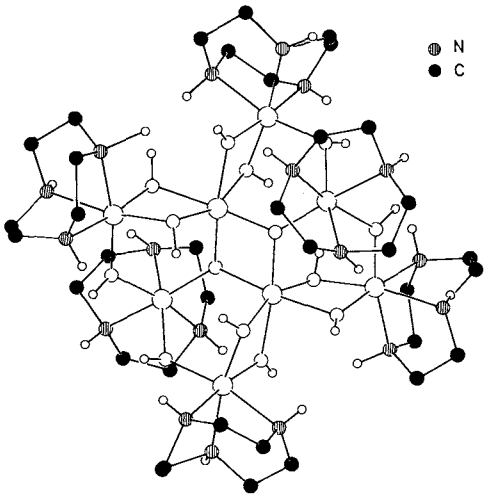

Fig. 2. The complex cation **4** with the 1,4,7-triazacyclononane ligands.

The high ionic charge 8+ in the solid state is almost compensated by seven associated $Br^{\ominus}$ ions. These are bound to the cation by electrostatic forces and hydrogen bonding (via NH-anions and OH-groups (Fig. 3); six of them are arranged pairwise in an idealized centrosymmetric array. Only the pendant to Br7 is missing. This position is occupied by a H_2O-molecule, whereby the C_i symmetry of the cation is destroyed (consequently the space group is also acentric P1 and not $P\bar{1}$). That is, the cation in **4** can be regarded as a bromide ion-carrier complex:

$$\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7 \cdot H_2O\}^{\oplus}$$

The counterion $Br^{\ominus}$ occupies an idealized inversion center (1/2, 1/2, 1/2) and binds eight H_2O molecules, four of which exhibit O—H···Br interactions (Fig. 3); the remaining four H_2O molecules are coupled with the directly coordinated H_2O molecules via O···H—O bonds (O···O distance 270—280 pm).

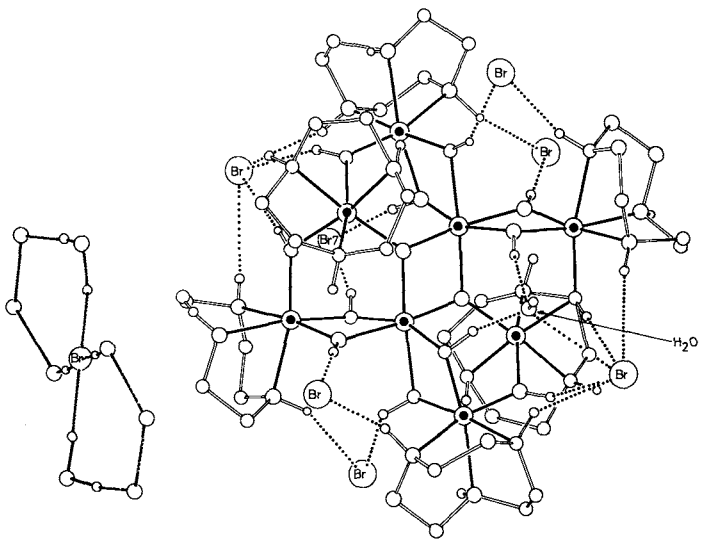

Fig. 3. The structure of $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7 \cdot H_2O\}^{\oplus}$ and $[Br \cdot 8\,H_2O]^{\ominus}$.

The cation-anion lattice of

$$\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7 \cdot H_2O\}^{\oplus}[Br \cdot 8\,H_2O]^{\ominus}$$

is of type AB; it corresponds to a distorted NaCl structure.

[3] Experimental: a) $[(tacn)_2Fe_2(\mu_2\text{-}O)(OH_2)_2]I_2 \cdot H_2O$: 0.25 g (tacn)$FeCl_3$ [2] was dissolved in 20 mL H_2O and 2 mL pyridine at 25°C. After 15 min 1 g of NaI (or KPF_6, $NaClO_4$) was added to the solution. A green precipitate (0.2 g) of the salt containing the cation separated out [μ_{eff}(103 K) = 2.2, μ_{eff}(293 K) = 2.6 μ_B per Fe center].—b) $[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_8 \cdot 9\,H_2O$: An analogously prepared green solution was treated with 5 g NaBr and allowed to stand for 24 h at 20°C. After 12 h the solution turned brown, and over the following 12 h brown crystals separated out (0.15 g). Between 103 and 193 K the magnetic amoment of **4** obeys the Curie-Weiss law ($\mu_{eff} = 3.72\ \mu_B$; $\vartheta = 59.9$ K).—All the salts gave correct elemental analyses.

[4] Crystal structure analysis of **4**: $C_{36}H_{120}O_{23}N_{18}Fe_8Br_8$; P1, $Z=1$; $a = 10.522(7)$, $b = 14.05(1)$, $c = 15.00(1)$ Å, $\alpha = 89.90(6)$, $\beta = 109.65(5)$, $\gamma = 109.27(6)°$, $V = 1956$ Å^3 ($T = -30$°C); $\rho_{calc} = 1.92$ g/cm^3; $Mo_{K\alpha}$, $\lambda = 0.71069$ Å, scan $2.0° < \omega < 29.3°$, $2° < 2\vartheta < 42°$; 4213 reflections (3996 with $I > 2\sigma(I)$); direct methods (SHELX-TL revision 3.0). H atoms of NH- and OH-groups as well as some of those of the H_2O molecules were observed, those of the CH_2-groups ignored. For 450 parameters $R_1 = 0.047$, $R_2 = 0.051$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen on quoting the depository number CSD 50630, the names of the authors, and full citation of the journal.

Stable Olefin Complexes of Pt(II) Containing Trichlorostannate(II) Ligands: Structure of $[Ph_4As][Pt(SnCl_3)_3(1,5\text{-cod})]$**

By *Alberto Albinati, Paul S. Pregosin**, and *Heinz Rüegger*

Olefin complexes of platinum(II) containing the trichlorostannato ligand have been postulated as intermediates in catalytic hydrogenations and hydroformylations[1]; however, these compounds have not been isolated. As part of our program[2], we prepared the stable anionic complexes of type **1** starting from Zeise's salt and analogous Pt^{II} compounds[7].

$$[PtCl_3(olefin)]^{\ominus} + SnCl_2 \xrightarrow{CH_2Cl_2} cis\text{-}[PtCl_2(SnCl_3)(olefin)]^{\ominus}$$

1a, olefin = C_2H_4
1b, olefin = CH_2=CHPh
1c, olefin = *cyclo*-C_8H_{14}
1d, olefin = CH_2=$CHCH_2OH$

Complexes **1a—1d** can readily be characterized using ^{119}Sn-, ^{195}Pt-, and ^{13}C-NMR spectroscopy. Their molecular

[**] We thank the ETH Zürich for financial support and the Johnson-Matthey Research Center, England, for the loan of platinum salts.

geometries were deduced from the values of $^1J(^{195}Pt,^{119}Sn)$, which are dependent on the nature of the trans ligand[3]. **1a** is isolable as its PPN salt $(PPN=(Ph_3P)_2N^{\oplus})$[3] and is interesting in that its trans isomer may be an intermediate in the $SnCl_2$-catalyzed synthesis of Zeise's salt[4].

Addition of more than one equivalent of $SnCl_2$ to **1a** promotes loss of C_2H_4; however, starting from the olefin complex $[PtCl_2(diolefin)]$, the five-coordinate tris(trichlorostannato)platinum(II) complexes **2** and **3** may be isolated in good yield.

$$[PtCl_2(diolefin)] + 2\,SnCl_2 + SnCl_3^{\ominus} \longrightarrow [Pt(SnCl_3)_3(diolefin)]^{\ominus}$$

2, diolefin = 1,5-cyclooctadiene
3, diolefin = norbornadiene

The structure of the anion **2**[5] (see Fig. 1) may be thought of as a distorted square pyramid in which Sn3 occupies the axial position. To our knowledge **2** is the first example of a platinum-tin complex exhibiting a square pyramidal geometry.

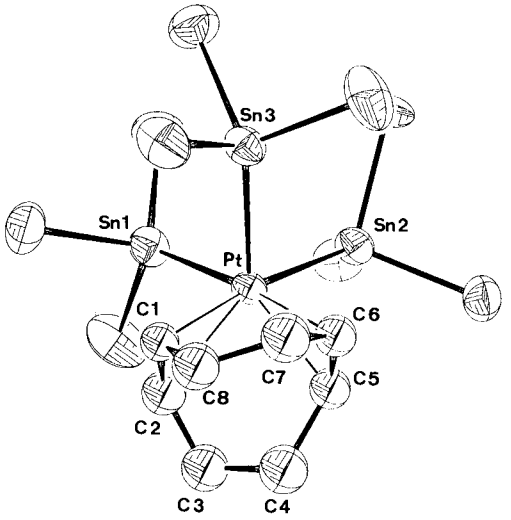

Fig. 1. ORTEP diagram of the complex anion **2** in the crystal of the salt $[Ph_4As][Pt(SnCl_3)_3(1,5\text{-cod})]$. Selected bond lengths [Å] and bond angles [°]: Pt–Sn1 2.568(2), Pt–Sn2 2.546(2), Pt–Sn3 2.643(2), Pt–C1 2.23(2), Pt–C2 2.23(2), Pt–C5 2.27(2), Pt–C6 2.23(2), Sn–Cl (average) 2.355(6), C–C (average) 1.48(3); Sn1–Pt–Sn2 85.90(5), Sn1–Pt–Sn3 94.83(5), Sn2–Pt–Sn3 93.80(5).

All three Pt–Sn distances are relatively long; the value for Pt–Sn3 (2.643 Å) is more than 0.04 Å longer than that observed in either $[Pt(SnCl_3)_5]^{3\ominus}$[6a] or $[Pt(SnCl_3)_3(AsMe_3)_2]^{\ominus}$[6b] and is 0.287 Å longer than the Pt–Sn distance in *cis*-$[PtCl_2(SnCl_3)_2]^{2\ominus}$[6c].

This relatively long Pt–Sn3 distance is compatible with the observation that this complex exhibits a dynamic structure on the NMR scale in solution.

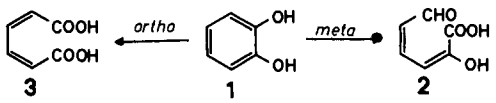
Oxidative Cleavage of Pyrocatechol at the *meta*-Position; A Model Reaction for Cleavage by Pyrocatechol-2,3-dioxygenase?**

By *Rudolf Müller* and *Franz Lingens**

Dedicated to Professor Heinrich Hellmann on the occasion of his 70th birthday

Pyrocatechol **1** can be oxidatively cleaved in two different ways by enzymes: either between the hydroxy groups (*ortho*-cleavage) or adjacent to the hydroxy groups (*meta*-cleavage). The *ortho*-cleavage leads to *cis,cis*-muconic acid **3**, whereas *meta*-cleavage yields the relatively unstable 2-hydroxymuconic acid aldehyde **2**, which is easily recognized by its intense yellow color (λ_{max} (1 N NAOH) = 375 nm). Several model chemical systems have been



3 1 2

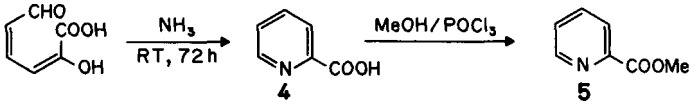
found for the *ortho*-cleavage, the majority of which involve the use of transition-metal complexes[1]. A non-enzymatic *meta*-cleavage, on the other hand, has so far never been reported in the literature. Herein, we wish to report how the *meta*-cleavage can be carried out in a purely chemical way, and how the structure of the unstable product thus formed has been established.

A solution of pyrocatechol in dimethyl sulfoxide (1 mg/mL) was added to a vigorously stirred solution of DMSO saturated with KO_2. The solution immediately turned blue, and after about 10 min at room temperature the color changed via green to yellow. At this point the reaction was terminated by a twofold addition of H_2O. After acidification with HCl the reaction mixture was extracted with CH_2Cl_2; the organic phase was then back-extracted with 0.2 N NaOH. For separation of residual DMSO and purification of the yellow compound, the alkaline solution was diluted tenfold with water and chromatographed on DEAE-cellulose with a NaCl-gradient (0–7.5%). The spectrum between 300 and 400 nm of the yellow fractions thus obtained corresponded to that of the product obtained on

[*] Dr. F. Lingens, Dr. R. Müller
Institut für Mikrobiologie der Universität Hohenheim
Garbenstrasse 30, D-7000 Stuttgart 70 (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie. We thank *G. Schwinger* for recording the mass spectra.

enzymatic *meta*-cleavage of pyrocatechol, both in alkaline solution ($\lambda_{max}=375$ nm) as well as in acid solution ($\lambda_{max}=316$ nm). Since **2** is relatively unstable it was treated with NH_3 for further characterization by the method of *Fujiwara* et al.[2]. After 3 days the yellow color



4 **5**

had disappeared and, as expected, the spectrum of picolinic acid **4** was obtained. The R_f value was identical with that of authentic picolinic acid, both in the thin-layer chromatography (toluene/dioxane/glacial acetic acid, 9:2:0.1) as well as in the HPLC (RP 8, 1% acetic acid). For final proof of the structure, the compound was esterified with methanol/$POCl_3$ according to the method described by *Klosa*[3]. GC-MS gave a peak whose retention time and mass spectrum (*m/z* 137, 4%, M^+; 107, 23%, $M-CH_2O$; 79, 100%, $M-COOCH_2$) were identical to those of methyl picolinate **5**.

The mechanism of the *meta*-cleavage with KO_2/DMSO is still unclear. Since the reaction does not take place under N_2 it can be concluded that not only hyperoxide and pyrocatechol but also molecular oxygen must participate, and that not just a simple reaction of hyperoxide and pyrocatechol is involved.

Several authors have discussed hyperoxide as a possible form of the reactive oxygen involved in dioxygenase reactions[4, 5]. This would infer that the above mentioned reaction could be a model for dioxygenase reactions.

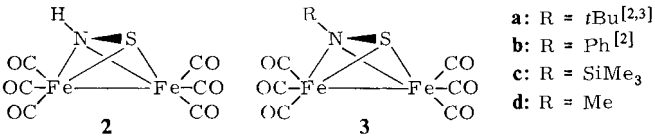
Sulfur Imide as *bisdihapto*-Bridging Ligand in the Complex $Fe_2(CO)_6(HNS)$**

By *Max Herberhold** and *Wolfgang Bühlmeyer*

The triatomic compound HNS is not known in the free state. According to ab initio calculations[1], of the two possible isomers, the sulfur imide **1a** is more stable than the thiazyl hydride **1b**.

1a **1b**

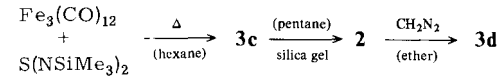
We report here on the binuclear iron complex $Fe_2(CO)_6(HNS)$ **2**, in which the sulfur imide **1a**, the parent of the (unstable) organic thionitroso compounds, is bound as a six-electron ligand.



2 **3**

a: R = *t*Bu[2,3]
b: R = Ph[2]
c: R = $SiMe_3$
d: R = Me

2 was synthesized by the stepwise degradation of bis(trimethylsilyl)sulfur diimide, $S(NSiMe_3)_2$, in the presence of carbonyliron complexes. Compounds of the type $Fe_2(CO)_6(RNS)$ **3** have previously been described[2,3]; the ligand is formed by fragmentation of sulfur diimides $S(NR)_2$ (R = *tert*-butyl[2,3], *p*-tolyl[3]) or sulfinylamines RNSO (R = phenyl[2]). In contrast to the known complexes **3a**, **b** the trimethylsilyl derivative **3c** is readily hydrolyzed; even chromatography on silica gel leads quantitatively to $Fe_2(CO)_6(HNS)$ **2**, which in turn can be methylated with diazomethane to **3d**[4].



Apart from the molecular ion at *m/z* 327 (rel. intensity 21%), the mass spectrum[5a] of **2** exhibits all the fragments $Fe_2(CO)_n(HNS)^+$ (n = 5–0) expected from stepwise cleavage of CO ligands; further fragments are $Fe_2(HNS)^+$ 159 (100%), Fe_2NS^+ 158 (23%), Fe_2S^+ 144 (16%), and Fe_2^+ 112 (10%). In addition to the CO bands, three absorptions at 3365 (s), 984 (m), and 760 (w) cm^{-1} occur in the IR solid-state spectrum (CsI), which are shifted to 2502, 806, and 729 cm^{-1}, respectively, upon deuteration (D_2O/pentane). The very sharp, intense band at 3365 cm^{-1} clearly corresponds to the NH stretching vibration, and we provisionally assign the band of medium intensity at 984 cm^{-1} to a deformation vibration involving displacement of the H-atom at the Fe_2NS tetrahedral skeleton upon variation of the HNS angle[5b]. The weak band at 760 cm^{-1} occurs in the region expected for NS single bond stretching vibrations (850–650 cm^{-1}); it is therefore ascribed to a skeletal vibration with considerable ν(NS) character. For **3a** and **3b** a ν(NS) absorption has been assigned (without supporting arguments) at 705 and 721 cm^{-1}, respectively[2]. Table 1 contains selected spectroscopic data for the new complexes **2** and **3c**, **d**.

Table 1. Spectroscopic data for the diiron complexes **2**, **3c**, and **3d**.

Complex	MS *m/z* (M_r)	IR [a] ν(CO) [cm^{-1}]	NMR [b] $\delta(^1H)$	$\delta(^{13}C)$

[a] In pentane. [b] In $CDCl_3$, rel. TMS. [c] No ^{1}H-NMR signal in $CDCl_3$ (H/D exchange); in [D$_6$]benzene broad singlet at $\delta=2.15$.

The conspicuous similarity of the ν(CO) stretching frequencies and of the mass spectroscopic fragmentation behavior confirms the conclusion drawn from the reaction sequence **3c** → **2** → **3d** that the sulfur imide complex **2** is the parent compound of the thionitroso complexes **3**[6].

[4] Preparation of **3c**: A solution of $Fe_3(CO)_{12}$ (200 mg, 0.4 mmol) and $S(NSiMe_3)_2$ (165 mg, 0.8 mmol) in 150 mL hexane is refluxed for 15 h. After removal of the solvent, **3c** can be isolated from the orange-brown residue by sublimation at 40°C/10^{-2} mbar: air-stable crystals, m.p. = 44—46°C; yield 80 mg (51%). The residue from the sublimation contains some $Fe_3(CO)_9S_2$[7].—Conversion **3c** → **2**: A solution of **3c** (80 mg, 0.2 mmol) in pentane was chromatographed under N_2 on a column (length 1.5 m, diameter 1 cm) packed with silica gel (Fluka, particle size 0.063—0.200 mm). Elution with pentane and crystallization yielded transiently air-stable crystals, m.p. = 46—49°C, which decompose slowly at room temperature. The reaction proceeds to completion.—Conversion **2** → **3d**: A *ca.* 3fold excess of diazomethane (Et_2O solution) is added to a solution of **2** (50 mg, 0.15 mmol) in 10 mL diethyl ether at 0°C and the solution stirred for 0.5 h. Air-stable crystals, m.p. = 30—32°C, can be obtained by sublimation. The reaction proceeds to completion. Yield 48 mg (92%).—The orange, diamagnetic complexes **2**, **3c**, and **3d** are readily soluble in polar and non-polar organic solvents and volatile *in vacuo* (10^{-2} mbar) even at room temperature.

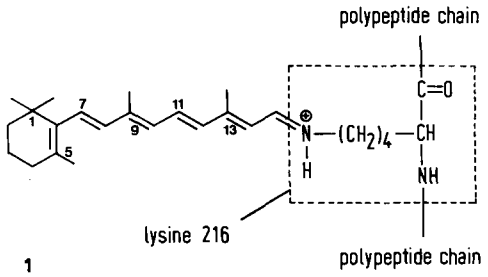
Sterically Fixed Retinal-Analogue Prevents Proton-Pumping Activity in Bacteriorhodopsin

By *Elisabeth Kölling**, *Wolfgang Gärtner*, *Dieter Oesterhelt*, and *Ludger Ernst*

Bacteriorhodopsin (BR), the dominating membrane protein of *Halobacterium halobium*, contains 13-*cis*- and all-*trans*-retinal as prosthetic groups. The retinal molecule forms a protonated Schiff's base (SBH^+) **1**[1] with the ε-amino group of the lysine residue 216 of the apoprotein.

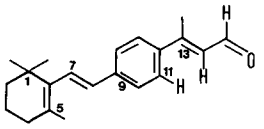


1

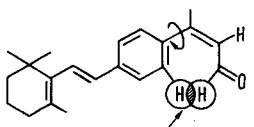
Irradiation of BR ($\lambda_{max} = 568$ nm) induces a photochemical cycle during which numerous intermediates could be detected spectroscopically (BR_{trans}-568 → K-610 → L_{cis}-550 → M_{cis}-412 → O-660 → BR_{trans}-568; absorption maxima in nm)[2]. These species are formed inter alia by deprotonation/reprotonation of the SBH^+ and by all-*trans*-/13-*cis*-isomerization of the retinal molecule[3]. Steric and electronic constraints in the protein permit the thermal back reaction from the 13-*cis*-(M_{cis}-412) to the all-*trans* form (BR_{trans}-568) in the cycle to which a directed proton transport is coupled, i.e. bacteriorhodopsin functions as a "light-driven proton pump".

Modified retinals can be incorporated into the apoprotein isolated from retinal-negative cell mutants and can be tested for their functional activity. As a result, a strong influence specifically associated with substitution at C-13 of the retinal with both chromophore and function of the protein was found. In particular, in analogues carrying no 13-methyl group the reisomerization 13-*cis*- → all-*trans* is so disturbed that the proton transport is drastically retarded[4].

We prepared the retinal analogue **2** (3-[4-[2-(2,6,6-trimethylcyclohexenyl)vinyl]phenyl]-2-butenal) from the acid by reduction ($LiAlH_4$)/oxidation (MnO_2) and characterized it spectroscopically (^{1}H-NMR, IR, MS, UV). **2** can be considered as a 10,11-s-*cis*-fixed retinal bridged between C-9 and C-12, which contains an aromatic ring as novel structural element (atoms numbered as in retinal). Whereas the all-*trans*-isomer **2a** is predominantly planar in solution, the 13-*cis*-isomer **2c** can only be formed because of steric hindrance if simultaneous rotation of the 12,13-single bond occurs, as shown in the formula.



all-*trans*-isomer **2a**



13-*cis*-isomer **2c**

Irradiation of **2a** in isopropyl alcohol affords 7-*cis*-**2b** and the 13-*cis* compound **2c**, which occur in photostationary equilibrium (10 min irradiation) in the ratio 20 : 13 : 67. The assignment followed by 400 MHz ^{1}H-NMR spectroscopy after HPLC separation (Table 1). The 7-*cis*-13-*cis*-isomer could not be detected.

Table 1. ^{1}H-NMR data of compounds **2a** (all-*trans*), **2b** (7-*cis*), **2c** (13-*cis*), and all-*trans*-retinal (in $CDCl_3$). δ-values, J in Hz.

sonance effects an increase in intensity of the aldehyde signal). The low-field shift (ring current effect) of the 13-methyl protons in 7-*cis*-**2b** and in the all-*trans*-isomer **2a** relative to the chemical shift of these protons in the 13-*cis*-form and in retinal itself indicates that the aromatic ring and the 13,14-double bond vinyl group are coplanar. Due to the diamagnetic anisotropy of the carbonyl function, the aryl protons in the 13-*cis*-compound **2c** give rise to an AA'BB' spectrum; in addition, the signal of the aldehyde proton appears at a higher field than that of the all-*trans*-isomer **2a**, in accord with literature data for *cis*- and *trans*-β-methylcinnamaldehyde[6]. The NMR data in Table 1 indicate a conformation for the 13-*cis*-isomer **2c** in which rotation about the 12,13-single bond causes the chain end to protrude out of the plane of the aromatic ring.

Only the all-*trans*-compound **2a** reconstitutes with isolated apoprotein a protonated Schiff's base within a few minutes, which results in a bathochromic shift of the absorption maximum to 490 nm (Table 2). The preparation containing the 13-*cis*-sample **2c** was left at room temperature for several hours and showed only a slow isomerization to the all-*trans*-form, accompanied by the formation of a chromophore with absorption maximum at 490 nm. This could be detected by extraction of the retinal analogues from the protein and subsequent determination of the isomer distribution. Compound **2** is the first retinal analogue which in its 13-*cis*-configuration does not fit into the binding site of bacteriorhodopsin. This can only be explained by the non-planar arrangement of C-11 to C-14. A corresponding thermal isomerization of the 7-*cis*-compound **2b** was not observed; the reconstitution occurred only after irradiation ($\lambda_{max} = 490$ nm). From all of these reconstituted samples, also after irradiation experiments (up to 30 min), exclusively the all-*trans*-isomer **2a** was isolated.

Table 2. Absorption maxima of compounds **2a**, **2b**, **2c**, all-*trans*-retinal, and the associated protonated Schiff's bases *n*-Bu−$\overset{\oplus}{N}$H=CHR with *n*-butylamine and the bacteriorhodopsins.

	Retinal or analogues λ_{max} [nm] (ε) [a]	Prot. Schiff's base λ_{max} [nm] ($\tilde{\nu}_1$ [cm^{-1}]) [a]	Bacteriorhodopsin λ_{max} [nm] ($\tilde{\nu}_2$ [cm^{-1}]) [b]	$\tilde{\nu}_1 - \tilde{\nu}_2$ [cm^{-1}] ([kJ mol^{-1}])
2a	330 (20000)	380 (26320)	490 (20410)	5910 (70.7)
2b	323 (10000)	372	—	—
2c	305 (11000)	365	—	—
Retinal	380 (40000)	440 (22730)	568 (17610)	5120 (61.3)

[a] In isopropyl alcohol. [b] In water.

The absorption of the protonated Schiff's base in the protein is bathochromically shifted relative to the protonated Schiff's base with *n*-butylamine. This decreased energy difference between the ground and the excited state, when estimated by the difference of the according wave numbers—see Table 2—is found to be 5180 cm^{-1} (61.3 kJ·mol^{-1}) for retinal, and 5910 cm^{-1} (70.7 kJ·mol^{-1}) for analogue **2**. From the similar difference in wavenumbers ($\tilde{\nu}_1 - \tilde{\nu}_2$) (cf. Table 2) for retinal and the analogue **2** it can be concluded that similar interactions with the binding site of the protein take place.

As indicated by functional investigations with cell vesicles, the chromophore formed from compound **2** and bacterioopsin does not facilitate proton pumping activity. In addition, no bleaching at 490 nm could be observed in studies of the photocycle with ns laser pulses in the isolated, reconstituted protein. Both those results illustrate the necessity of an all-*trans*-/13-*cis*-isomerization for the function of bacteriorhodopsin. This conclusion is corroborated with retinal analogues whose configuration was fixed at the 13,14-double bond by bridging[7].

Analogue **2a** requires room for the 13-methyl group either above or below the polyene chain in order to isomerize into the 13-*cis* form (**2c**), due to the fixed 10,11-s-*cis* bond and the associated rotation of the 12,13-single bond. This space, however, is apparently not available in the protein (no 13-*cis*-isomer in the protein). Thereby, it can be deduced that—as a prerequisite for proton translocation in bacteriorhodopsin—steric hindrance of the protein permits an all-*trans*/13-*cis*-isomerization upon irradiation and, at the same time, reinforces the thermal reisomerization.

Hexa-*O*-alkanoyl-*scyllo*-inositols, the First Alicyclic, Saturated, Discotic Liquid Crystals**

By *Bernd Kohne* and *Klaus Praefcke**

Dedicated to Professor Alexander Schönberg on the occasion of his 91th birthday

In 1977 the occurrence of a thermotropic mesophase was reported for certain hexaalkanoyloxy derivatives of benzene[1], and hence the possibility of forming mesophases of pure compounds having disc-like molecular structures ("disk-like mesogens") was demonstrated for the first time. Since then, further liquid crystals of compounds with related structures have been prepared[2]; their rigid, planar molecule centers are π-systems of various structures, mainly arenes substituted with flexible side chains. A notable exception is diisobutylsilanediol dimer, whose core consists of a *saturated* but thermolabile hetero-

[**] Liquid Crystalline Compounds, Part 15. Presented in part at the 21st Bunsen Colloquium ("Materialeigenschaften und Ordnungszustände von Flüssigkristallen") at the Technische Universität Berlin (22nd to 23rd September 1983) and at the 4th German-Israeli Center Symposium for Chemistry in Rehovot/Nof Ginossar, Israel (9th to 14th October 1983). This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Technische Universität Berlin. We thank Dr. *R. Eidenschink*, Dr. *B. Scheuble*, and Dr. *L. Pohl*, Merck, Darmstadt, for discussions and for the DSC data for **1a–c** (Table 1).—Part 14: [4c].

cycle formed by conventional hydrogen bonding, which as early as 1955 was described as a liquid crystal[3a], but whose mesophase was first recognized in 1981 as thermotropic discotic[3b].

Substitution of the 1,4-disubstituted phenyl moieties in numerous calamitic liquid crystals ("rod-like" mesogens) by cyclohexyl groups[4], frequently leads to compounds which exhibit improved physical properties for electrooptical applications. This induced us for the first time to study the influence of analogous constitutional changes on the liquid-crystalline properties of *discotic* systems.

We therefore synthesized[5] the first alicyclic, saturated, discotic liquid crystals, the three hexa-*O*-alkanoyl-*scyllo*-inositols **1a–c** — perhydrogenated analogues of known benzene derivatives[1]. Their phase transition data are summarized in Table 1, and their phase transition temperatures are shown in Figure 1 to illustrate the extent of their mesophase regions as a function of chain length.

1a, R = n-$C_5H_{11}CO$
1b, R = n-$C_7H_{15}CO$
1c, R = n-$C_9H_{19}CO$

1b	75.5	198.5	123.0	43.30	9.47
1c	84.0	188.7	104.7	53.07	10.28

[a] Polarizing microscope with Mettler hot stage FP2. [b] DSC Du Pont 1090; phase transitions, crystalline→discotic (C→D) or discotic→isotropic (D→1).

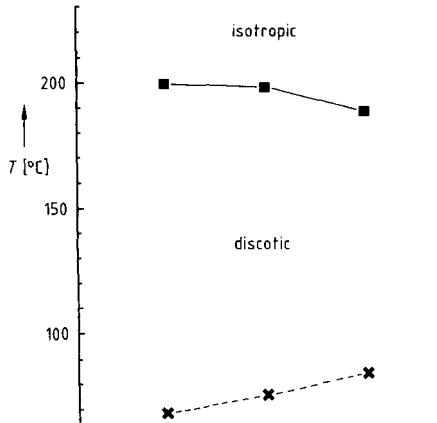

Fig. 1. Phase transition temperatures of the hexa-*O*-alkanoyl-*scyllo*-inositols **1a–c** (× crystalline→discotic; ■ discotic→isotropic; n = number of alkyl carbon atoms of the groups R in **1**).

In contrast to **1a** and **1c**, their benzene analogues are not liquid crystalline; only the benzene analogue of **1b** exhibits a narrow mesophase region ($\Delta T \approx 6$ °C)[1]. The hexasubstituted triphenylene corresponding to **1a** also is not a liquid crystal[6]; whereas the triphenylene derivatives with similar side-chains to **1b** and **1c** exhibit mesophase regions which are only *ca.* half as wide ($\Delta T \approx 60$ and ≈ 50 °C, resp.)[6]. These comparisons demonstrate that the hexasubstituted cyclohexanes with the stereochemistry given in **1** are considerably superior to analogous benzene or triphenylene derivatives in terms of both formation and width (ΔT) of thermodynamically stable mesophases.

Inspection of space filling models indicates that benzene derivatives are considerably less spatially demanding in the middle section than the corresponding cyclohexane compounds **1a–c**, which have an ideal disk shape. According to our findings, the core of a discotic liquid crystalline compound can either be saturated or unsaturated; of greater importance for the formation of discotic mesophases are space filling (minimum dead space), planarity, and rigidity of a molecule.

Hitherto, the type of mesophase formed from **1** has not yet been classified. Preliminary microscopic observations of **1** between crossed polars, however, indicate hexagonal, columnar phases. Heating compounds **1** above their melting points affords viscous highly birefringent phases whose textures are smectic-like phases. Upon cooling the isotropic liquids below the phase transition temperatures (I→D) less birefringent finger- or fan-shaped regions appear in a predominantly black surrounding field in which the molecules are apparently orientated plano-parallel to the surface of the cover slip.

Because of their weak UV absorption (e.g., **1b**: $\lambda_{max} = 211$ nm ($\varepsilon = 357$ L·mol^{-1}·cm^{-1})), these *scyllo*-inositol derivatives **1** may be suitable anisotropic, discotic matrices for the spectroscopic study of aromatic molecules.

The Electrochemical Reduction of Benzene—First Direct Determination of the Reduction Potential**

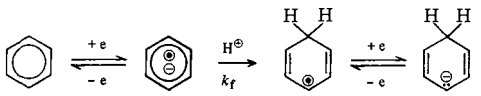
By *John Mortensen* and *Jürgen Heinze**

The physical and chemical properties of benzene have been studied in more detail than those of any other organic compound. It is therefore all the more surprising that its electrochemical reduction potential in solution could not previously be measured directly. This is mainly because of the extremely low electron affinity of benzene[1], which to a great extent precludes reduction in the stability range of the commonly used supporting electrolytes and solvents.

Gerson et al.[2] determined the reduction potential of benzene by extrapolating the electrolytically determined appearance potentials of the radical anions of twenty hydrocarbons. They obtained a value of -3.31 ± 0.12 V vs. SCE. More recently, *Jund, Lemoine,* and *Gross*[3] corroborated the assumption that the reduction potential of benzene lies below -3.3 V.

We have now been able to directly determine the reduction potential of benzene via voltammetric measurements (-60 °C) at a Pt working electrode under "super-dry" conditions in dimethoxyethane (DME) in the presence of tetrabutylammonium hexafluorophosphate ($TBAPF_6$) as supporting electrolyte. Evaluation of the cyclic voltammogram (CV) affords a value of -3.42 ± 0.05 V vs. SCE.

As indicated by the blank voltammogram of the system DME/$TBAPF_6$ at -60 °C, decomposition of the conducting electrolyte commences at -3.46 V, and hence the reduction wave of benzene lies partly in the increasing current range of the conducting electrolyte. This explains why attempts failed to measure the reduction potential directly. At slow scan rates (*ca.* 100 mV/s), the voltammogram indicates a homogeneous chemical follow-up reaction of the initial radical anion **1b**. Presumably, by analogy to other highly charged arene anions[4], the strongly basic anion **1b** attacks the tetrabutylammonium ion and is protonated via Hofmann elimination. The cyclohexadienide **1d**, whose reoxidation can be detected by CV at -0.5 V, is formed from the neutral radical **1c** by further electron transfer.



1a **1b** **1c** **1d**

The observed reduction wave therefore corresponds to a two-electron transfer with a coupled chemical reaction (ECE mechanism); a similar reaction pathway has been observed with [2.2]paracyclophane. Evidence for the ECE mechanism postulated is provided by the fact that the current-function $i/\sqrt{v}$ decreases with increasing scan rate.

Because of the extreme value of the potential for the reduction of **1a** to **1b**, reaction of **1b** with the products arising from the electrochemical decomposition of the tetrabutylammonium ion is, in principle, conceivable. However, in this case the neutral radicals formed from the cation of the conducting salt should decay considerably faster than is observed experimentally. If the scan rate is increased, then at 20 V/s a flat wave appears in the reverse scan of the voltammogram which establishes the increasing stability of the benzene radical anion on the time-scale of the experiment (Fig. 1a). However, because of the low conductivity of the electrolyte system the resulting non-compensated IR-drop strongly distorts the current-potential curves. For this reason, we simulated the cyclic voltammogram assuming a non-compensated resistance of 0.8 kΩ using a newly developed algorithm[5]. Under the given conditions—decomposition of the conducting salt above -3.46 V—there is very good agreement with the experimental results (Fig. 1b). With the aid of the simulation, the rate constant of the follow-up reaction at -60 °C in DME was determined as $k_f = 19 \pm 5\ s^{-1}$.

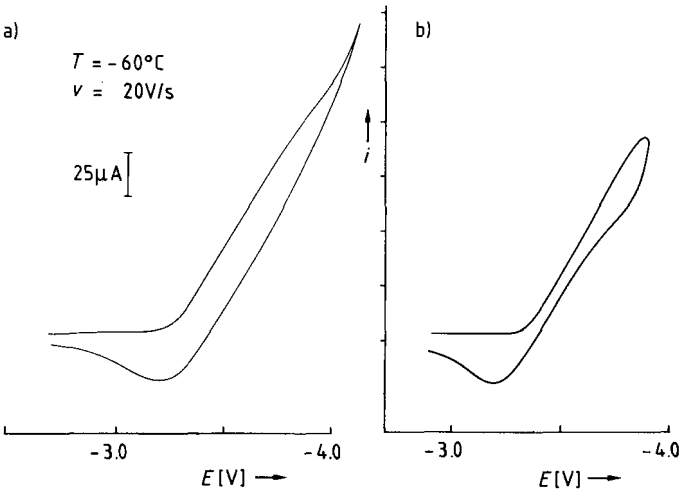


Fig. 1. a) Experimental CV diagram for the reduction of **1a** in DME; b) simulated CV diagram ($v = 20$ V/s, $k_f = 19\ s^{-1}$, $T = -60$ °C) without potential correction, current axis in arbitrary units.

Because of the *iR*-drop, the experimental and simulated values of the potential cannot be directly correlated with the reference electrode (SCE). However, the actual potentials can be deduced from the simulation.

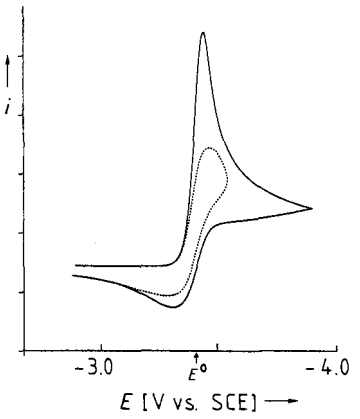

Fig. 2. Potential-corrected, simulated CV diagram ($v = 20$ V/s); -----: without *iR* compensation, ———: with *iR* compensation, current axis in arbitrary units.

Figure 2 shows the simulated CV diagram for the reduction of benzene at 20 V/s, calculated with and without *i*R compensation by "correct" representation of the potential axis. The value of the redox potential can be read directly

BOOK REVIEWS

Atomic Spectrometric Trace Analysis. Edited by *B. Welz*. Verlag Chemie, Weinheim 1982, xvi, 564 pp., bound, DM 148.00

This conference report deals with 55 contributions which were presented at the 1st Colloquium on "Trace Analysis by Atomic Spectrometry" (Konstanz, April 7 to 9, 1981).

The increasing importance of reliable techniques for the determination of low and lowest element concentrations (ng/g to pg/g range) in many areas of the geological, biological, materials sciences and in medicine, as well as environmental control, has made large, close, interdisciplinary exchange of views concerning the currently available methods, their capabilities and their limitations desirable. The conference and the book resulting from it admirably meet these requirements. The conference was organized by an instrument manufacturing company (Bodenseewerk Perkin-Elmer GmbH, Überlingen) rather than by a scientific institute, as is more usually the case. Perhaps, this unusual circumstance is the reason why a valuable evaluation of the actual problems of trace analysis came about. Some important techniques in atomic spectroscopy used today, such as atomic absorption spectroscopy, enabling single element determinations, and optical emission spectrometry with high frequency plasma excitation (ICP-AES) for multielement determinations are considered. Their performance as well as their limitations are discussed, mainly from the point of view of the user. Most of the contributions are devoted to the solution of practical problems. With regard to the type of samples, biological materials and water samples take pride of place. The trace elements concerned tend to be the "old friends", namely Hg, Cd, Pb, Tl, Se and As and the motivation for their determination and analytical strategies to be applied are relatively uniform. Specialized topics concerning trace analysis of Si, As, Sn and organotin compounds, alkyl lead compounds as well as vapor phase lanthanoids and actinoids introdue some variety.

However, there is still a long way to go before universal and, at the same time, reliable and highly characteristic instrumental methods are available which make the direct analysis of solid samples possible. Therefore, decomposition and separation techniques which are employed prior to the actual determination are of great importance. In this connection, the reader will find very informative review articles on the decomposition of organic matrices by *G. Knapp* and on removal of the matrix by *E. Jackwerth*.

From the point of view of the development of instrumental methods of determination, the following contributions are particularly valuable: "A comparison of the various Zeeman systems in AAS" by *L. de Galan* and *M. T. C. de Loos-Vellebregt*, "Forward scattering—a method for multielement determination" by *P. Wirz* and *A. Scharman*, "Loop AAS and AES": a new, highly sensitive micromethod for flame AAS and AES" by *H. Berndt* and *J. Messerschmidt*. A further paper submitted by the editor and his co-workers and relates to improvements in standardization of graphite tube AAS by a better separation of peaks and to the hydride AAS technique.

This conference report is first of all a collection of experiences which can be thoroughly recommended for analysts involved in trace element analysis with the aid of spectroscopy. It further displays inadequacies to be overcome by scientists involved in the development of methods. Finally, it gives a good insight into the multiplicity of current problems in this field; this is useful to those who are less initiated—amongst whom I include the coming generation of analysts. However, the disproportionally high price of the well-edited, photo-reproduced volume will oppose my positive recommendation to acquire it.

The Pyridine Nucleotide Coenzymes. Edited by *J. Everse, N. Anderson,* and *K.-S. You*. Academic Press, New York 1982, xxxv, 389 pp., bound, $ 46.00

Commemorative works are often primarily concerned with the reputation of the commemoratee (and often of the author) and seldom apply themselves to the information requirement of the reader. This book on pyridine nucleotides, published to commemorate the 75th birthday of *Nathan O. Kaplan*, demonstrates that this need not necessarily be the case. *Kaplan* was one of the pioneers of enzymology and, above all, of the synthetic chemical treatment of this class of coenzymes, which *Otto Warburg* discovered in the nineteen thirties. *Kaplan*'s merits in this research area and his efforts as teacher and scientific organizer are introduced by experienced and famous pens. *M. D. Kamen, F.*

Lipmann, W. D. McElroy, and *S. P. Colowick* acquaint us not only with the personality of the scientist, *Kaplan,* but also with the stages of his development and the background against which his remarkable achievements unfolded.

Colowick's remarks introduce the reader in a subtle way to the theme of the book, which, in ten chapters, treats evolutionary aspects of pyridine nucleotides as well as the physico-chemical, synthetic chemical and cell-biological aspects of NAD and NADP. The classical enzymology of the dehydrogenases developed by *Warburg* and his school is scarcely mentioned. This approach is only applied in the case of membrane-bound catalysts and non-redox processes with NAD. The functional aspects are dealt with in terms of X-ray structural analysis together with the application of pyridine nucleotide analogues and of immobilized coenzymes. None of the chapters seeks to be encyclopedic in its completeness, the most important problems are, nevertheless, discussed and enriched with a literature selection that is usually representative.

In the first chapter, *H. B. White III* develops ideas concerning prebiotic origins and the mode of action of pyridine nucleotides in the early stages of evolution. Structural features of dehydrogenases, such as the similarity of their domain structures, are discussed in support of the hypothesis that it was the polypeptide structures that adapted to the primitive pyridine nucleotide "dehydrogenases" (a very plausible but not generally accepted assumption).

The second chapter *(J. B. A. Ross, S. Subramanian, L. Brand)* describes the present state of knowledge concerning the electronic structure of pyridine nucleotides and their analysis by absorption, CD, fluorescence and phosphorescence spectroscopy. The chemistry of NAD and NADH, together with various homologues and analogues as well as their conformations in solution, are dealt with by *N. J. Oppenheimer* in the third, and the synthesis, properties and applications of a large number of synthetic coenzyme analogues by *B. M. Anderson* in the fourth chapter. Since this was *Kaplan*'s field of research for almost 30 years it is not surprising that these topics are given, with more than 80 pages, an importance that seems a little disproportionate.

In the fifth chapter *U. M. Grau* presents, with many clear schemes, a very good description of the interactions of the pyridine nucleotide coenzymes with the apodehydrogenases, insofar as they can be deduced from X-ray structural analysis data. The most important aspects of a fascinating chapter of structural research on enzymes is given in a condensed but up-to-date form.

The sixth chapter *(C.-Y. Lee, A. F. Chen)* offers a valuable review to those who are concerned with the problems of the immobilization of dissociable coenzymes, naturally with special emphasis on NAD and NADP. Synthetic coupling techniques, general aspects of ligand affinity chromatography and numerous examples of application are presented.

The seventh chapter by *H. B. White III* summarizes the present state of knowledge concerning biosynthesis, interconversion, degradation and excretion of pyridine nucleotides and their secondary metabolites. In the eighth chapter *M. B. Grisham* and *J. Everse* deal with the role of pyridine nucleotide oxidases in the formation of activated oxygen species during phagocytosis.

Chapter 9 from the pens of *R. R. Fisher* and *S. R. Earle,* summarizes the available information on membrane-bound transhydrogenases concerned with electron transport in microorganisms and mitochondria, including the problem of energy coupling. In the last chapter *P. H. Pekala* and *B. M. Anderson* discuss those reactions where NAD is not a redox partner but a substrate: the mono- and poly-ADP-ribosyl transfer to proteins. The former concerns, besides the NAD-glycohydrolases, above all the chemical modification of regulatory proteins triggered off by toxins (cholera, diphtheria, *etc.*); the latter processes occurs in the cell nucleus and seems to influence DNA repair and DNA synthesis during differentiation and during the cell cycle.

This well-produced book, which is provided with an index, can offer biochemists, biophysicists and cell biologists new as well as established material in a clear and competently discussed form. Its up-to-date character recommends it to the teacher as well as to the advanced student and the active research worker. The price may be high but not inappropriate for what is offered.

Electron Distributions and the Chemical Bond. Edited by *P. Coppens* and *M. B. Hall.* Plenum Press, New York 1982. ix, 479 pp., bound, $ 55.00

The Spring 1981 Meeting of the American Chemical Society held at Atlanta, GA, included a Symposium dealing with Electron Distributions and the Chemical Bond. This book is the written account of the lectures presented at the Symposium. Its 21 chapters cover a wide range of topics all concerned in one way or another with charge densities in molecules or in extended solids as obtained either experimentally from X-ray diffraction measurements or theoretically from quantum-mechanical calculations. Both of these approaches have made enormous advances over the last decade or so, but each of them also has its own built-in deficiencies. Fortunately, the errors and approximations inherent in the one approach are virtually independent of those in the other, and it is clearly in the confrontation between theory and experiment that the Editors of this book expect its main interest to lie. As far as one can judge, where high-quality comparisons are available for molecular systems containing only light atoms (say, up to F) the results agree rather well. However, the confidence that might be generated by such comparisons does not necessarily extend to studies of systems containing heavier atoms which are much more difficult either to measure or to compute reliably.

As with most books based on Conference proceedings, the quality of the individual chapters is very uneven. Among the more valuable contributions should be mentioned those of *Smith* (on theory), of *Coppens* (on the experimental approach, and including a useful glossary of terms that should help newcomers to follow the jargon), and of *Breitenstein et al.* (on comparison of experiment and theory). The article by *Irngartinger* gives a good idea of what can be learned from careful experimental electron-density studies of organic molecules. At the other end of the scale, some of the contributions appear to be at best of merely anecdotal interest. One article that can hardly fail to raise a few eyebrows is that by *Troup, Extine* and *Ziolo* on electron-density studies on tellurium compounds. Doubtless some people will be impressed by their claim to have obtained experimental evidence for bonding density features such as lone pairs in heavy-atom systems, but many others will find it difficult to see how the conclu-

sions presented by these authors can possibly stand up to critical scrutiny of the evidence. Presumably, the lecture itself provoked some lively discussion, and it seems perhaps a pity that only one side of the story is presented in the printed proceedings.

Several chapters mention the theorem due to *Hohenberg* and *Kohn*, according to which all ground-state properties of any system, including the wave function, are functionals of the charge density distribution, *i.e.* they can be calculated in principle from a knowledge of the charge density. The "in principle" is important, because nobody so far seems to actually know how to calculate these functionals. However, since the charge density is an observable while the wave function is not, the Hohenberg-Kohn theorem and its repercussions (discussed in the chapter by *Parr*) may help to explain why interest among experimentalists and theoreticians in charge-density studies of molecules and extended systems is so lively. The publication of this book is an expression of this interest. From it, the reader can hope to find some of the questions that are being asked in the area as well as some of the answers that are being given.

Covalent Catalysis by Enzymes. By *L. B. Spector*. Springer-Verlag, Berlin 1982, xii, 276 pp., bound, DM 78.00

Covalent enzymic catalysis (double displacement) has been known for a long time. It is accepted as a guiding principle, almost without exception, in the mode of action of vitamins as enzyme cofactors, that the chemical process of substrate reaction takes place on the vitamin unit. Some of these cofactors are covalently bound to their apoenzyme; knowledge of covalent enzymic catalysis stretches back more than half a century.

In 1971 *R. M. Bell* and *D. E. Koshland* compiled a list of 60 enzymes where the application of critical criteria revealed a high likelihood of covalent catalysis. A little later this figure was raised to 140 by *L. B. Spector*, and the much more thorough-going claim was made that all enzyme catalysis proceeds *via* covalent enzyme-substrate intermediates. The present monograph is an attempt to strengthen this concept.

It would have been a good idea to acquaint the reader with the criteria for direct reaction between substrates (single displacement; kinetic sequential; stereochemical inversion of configuration) together with their alternatives (double displacement; kinetic ping-pong; stereochemical retention of configuration; exchange reactions in the absence of the second substrate; isolation of an enzyme substrate complex and demonstration of its kinetic competence). There is only inconclusive kinetic evidence for single displacement without discernible stereochemical consequence. The author founds his assertion that all catalysis is covalent thus: "Single displacement is purely speculative, because no positive evidence in support of it exists. For the documentation of this statement I can do no more than refer the reader to the whole corpus of chemical literature on the chemical mechanism of enzyme action."

The experimenter is faced with a difficult problem in demonstrating direct interaction between the substrates; he must exclude covalent catalysis by every possible test, of necessity this means negative results, thus completing a vicious circle. This, however, does not mean that single displacement reactions do not exist as this author so vehemently insists. Inversions of configuration which indicate direct reaction of the substrates are craftily interpreted by the author as triple displacements. This may be the case but it has not been demonstrated. What is certain is that the examples cited (acetate kinase, adenosine-phosphoribosyl transferase) are insufficient to lead to a conclusion.

It would have been a good idea to acquaint the reader with examples that mimic covalent catalysis: exchange reactions with a substrate may result from a second substrate being firmly attached to the enzyme; a substrate alone may become covalently attached to the enzyme in a side reaction; unphysiological substrate analogues (e.g. suicide inhibitors) may form covalent enzyme substrate bonds when the physiological substrate does not. Finally, some isotope labeling experiments that purport to demonstrate covalent attachment can be attributed to faulty control experiments.

Conclusions that catalysis is covalent are only convincing when all the criteria are fulfilled or when a deviation can be explained. It lies in the nature of a claim that all catalysis is covalent, that the author ignores this critical illumination and does not adequately distinguish experimental demonstration from experimental indications. It can be left to the reader to check the significance of the results described and to decide whether he is reading "covalent catalysis above all" or "above all covalent catalysis".

In this spirit it is possible to recommend this book, which is deliberately provocative, lively and, on occasions, informative, to everyone with an interest in the mechanism of enzymic reactions.

Methods in Stereochemical Analysis I. Stereochemical Applications of NMR Studies in Rigid Bicyclic Systems. By *A. P. Marchand*, Verlag Chemie International, Deerfield Beach 1982, 231 pp., bound, DM 280.00

This book is the first of a new series of monographs to be edited by the author, which is to cover the application of NMR, together with other spectroscopic and physical methods, to stereochemical problems.

This first volume is devoted to the NMR spectroscopy of the bicyclo[2.2.1]heptanes and the [2.2.2]octanes, which have achieved great importance, not only as models for spectroscopic investigation but also for preparative and mechanistic studies, since these rigid molecules are particularly suitable for stereochemical studies.

The book is divided into three chapters. The first chapter presents methods of signal assignment and discusses them in detail using examples. The chapter begins with a study of the application of lanthanoid shift reagents in the evaluation of ^{1}H-NMR spectra, where the theoretical background is largely ignored; then the homo- and heteronuclear nuclear Overhauser effect (NOE) is introduced. A word of criticism is pertinent at this point. Even though this monograph does not aim to discuss measuring techniques, the enormous refinement of NMR techniques in recent years makes it desirable to discuss assignment aids somewhat more fully. This is particularly the case since it

cannot be the aim of this book only to review the methods that have been described for bicyclic systems, but should also stimulate further investigations applying the most modern of possibilities.

The second chapter covers stereochemical applications of chemical shifts in several nuclei (^{1}H, ^{13}C, ^{19}F and ^{31}P); first steric effects then electronic substitution effects are discussed in terms of their dependence on the stereochemistry of the molecule. The tabular presentation of some of the conclusions from investigations on various types of compounds is particularly clear. The correlation of chemical shifts with charge density for a large number of bicyclic carbonium ions is discussed at the end of this chapter; the results are again collected in tabular form.

The third chapter, which makes up by far the largest portion of the book, deals with the measurement and interpretation of spin-spin couplings. A short, general introduction is followed successively by discussions of homo- and heteronuclear coupling over, one, two, three, four and more bonds, with a plentiful supply of data listed to illustrate each case.

There is no doubt that this book fills a vacant niche in the review literature and will provide any chemist who is in some way concerned with compounds of this class with a wealth of valuable information. It should be included in any balanced NMR library. However, it is to be feared that, in the present financial climate, the unusually high price will prevent the wide dissemination that the book deserves.

Metal-Carbon and Metal-Metal Multiple Bonds as Ligands in Transition-Metal Chemistry: The Isolobal Connection

By F. Gordon A. Stone*

A new domain for synthesis has developed following recognition that the metal-carbon and metal-metal multiple bonds present in certain low-valent transition-metal complexes are reactive centers for the attachment of metal-ligand fragments. The products contain metal-metal bonds which may be homo- or heteronuclear in nature. If bridging carbon atoms are present, leading to dimetallacyclopropane or -cyclopropene structures, the organic groups (alkylidene or alkylidyne) have an extensive chemistry. The isolobal connection, developed by *Hoffmann* et al., relating the frontier orbitals of organic groups with those of metal-ligand fragments, has been crucial in guiding the preparative work.

1. Introduction

The growth of organometallic chemistry since the discovery of the cyclopentadienylmetal compounds has been one of the dominant forces in the development of our science. Preparative work leading to new compounds has provided the infrastructure of the field, but in many instances novel products have been synthesised serendipitously. This is not surprising given the variable electronic properties of the d- and f-elements, the remarkable variety of ligand bonding modes, and the kinetic and thermodynamic influences at work. The admission that we lack sufficient predictive power in this area of endeavour is a reaffirmation of the vitality of the research, and not a statement to deplore. The degree of randomness in preparative organometallic chemistry is, however, rapidly decreasing. This is a welcome trend, for which there are several explanations. In this article the thesis will be advanced that by taking into account similarities between the frontier orbitals of metal-ligand fragments and those of particular organic groups, it is often possible to devise logical syntheses of new compounds with metal-metal bonds. Metal cluster compounds represent an active area of research.

2. Early Work

In 1979 we first drew attention[1] to the ability of $Pt(PMe_3)_2$ groups to bond to chromium and to tungsten compounds containing metal-carbon double- or triple-bonds, in a manner long known for alkenes and alkynes (Scheme 1). It thus became evident that the $Cr(CO)_5$ and $W(CO)_2(\eta^5\text{-}C_5H_5)$ groups must have bonding properties similar to those of CH_2(carbene) and CH(carbyne), respectively.

Halpern[2] appears to have been the first to appreciate that certain inorganic and organic groups are electronically equivalent. He drew attention to similarities in the reactivity patterns of alkyl radicals and the pentacoordinate cobalt(II) species $Co(CN)_5^{3\ominus}$, and between carbenes and tetracoordinate d^8-metal complexes. Other seminal work demonstrating electronic equivalence, deserves mention. Through structural studies on $[As_3Co(CO)_3]$ and $[As_2Co_2(CO)_6]$, *Dahl*[3] pointed out the similarity in bonding modes of arsenic atoms and $Co(CO)_3$ groups in tetra-

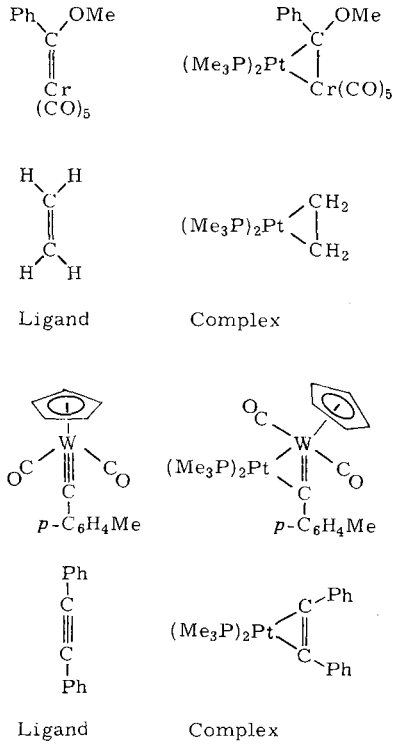

Scheme 1.

hedral clusters. *Hawthorne*[4] elegantly introduced the anion $C_2B_9H_{11}^{2\ominus}$ as a ligand in transition-metal chemistry, following an appreciation of its relationship to $C_5H_5^{\ominus}$. The discovery of the carbaboranes had previously established the equivalence of CH and $BH^{\ominus}$ groups[5,6]. Later, *Wade*[7] and *Mingos*[8] developed a skeletal electron-pair theory which related the structures of certain polynuclear carbonylmetal species with those of polyhedral borane anions, recognizing a similarity in the bonding properties of $Ru(CO)_3$ and BH groups.

3. Synthetic Strategies and The Isolobal Model

Organic chemists have long been accustomed to viewing the synthesis of a compound in terms of a series of one-step interconversions of suitable precursors. The synthetic strategy is conceived by first considering the nature of the organic groups present in the desired product, and then deciding, on the basis of experience, how these fragments may be assembled. In this context, the principle of conservation of orbital symmetry has recently proved to be an exceptionally powerful predictive tool[9]. Concerted reactions proceed readily when there is a similarity in the orbital symmetry properties of reactants and products. Consideration of the frontier orbitals of molecules provided the key to the development of the Woodward-Hoffmann rules.

Recently, *Hoffmann*[10] has elegantly employed frontier orbital similarities to relate the building blocks of hydrocarbon chemistry (CH_3, CH_2, CH, and C) with those of various metal-ligand combinations, thereby accounting for the existence of a range of organometallic complexes. For fragments derived from a metal in an octahedral environment, *Hoffmann* demonstrated the isolobal relationships:

$CH_3 \leftrightarrow Mn(CO)_5$
$CH_2 \leftrightarrow Fe(CO)_4$
$CH \leftrightarrow Co(CO)_3$

Groups are defined as isolobal if the number, symmetry properties, approximate energy and shape of their frontier orbitals, and the number of electrons they contain are similar[10,11]. A "two-headed arrow" with half an orbital below is the symbol used to indicate an isolobal connection.

The derivation by *Hoffmann* et al. of a library of molecular orbitals for metal-ligand fragments which serve as building blocks in organometallic chemistry has provided a sound basis for the correlations noted earlier. Thus, the CH_3 radical is isolobal with the ion $Co(CN)_5^{3\ominus}$ (Co^{II}, d^7), the CH_2 group is isolobal with the platinum fragments PtL_2 (Pt^0, d^{10}; L = PR_3 or CO; L_2 = cod = 1,5-cyclooctadiene), and CH is isolobal with $W(CO)_2(\eta^5\text{-}C_5H_5)$ (W^I, d^5) (Table 1 and Figure 1).

The isolobal analogy is useful in relating the structures of metal complexes with those of simple organic molecules. Compound **1**, for example, which was serendipitously prepared[12], may with hindsight be related structurally to spiro[2.2]pentane. This is because $Fe(CO)_4$ is isolobal with CH_2, and Sn with C. A further interesting comparison involves compounds **2** and **3**, both obtained from the unsaturated molecule $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ by treatment with CH_2N_2[13] or $[Pt(C_2H_4)(PPh_3)_2]$[14], respectively. Compound **2** exists in solution in tautomeric equilibrium with $[Os_3(\mu$-

[a] The list has been compiled to illustrate the chemistry described in the text and is by no means exhaustive. Moreover, it should be noted that the isolobal mapping is not a one-to-one relationship. Thus $Cr(CO)_5$ is isolobal with CH_2 or $CH_3^{\oplus}$ (cf. [10]). The frontier orbitals of the fragments listed are mostly derived by considering the metal to be in a six-coordinate octahedral environment. However, the model can be extended to seven-, eight- or nine-coordinate structures (Table 2); thus, for example, accounting for $Re(CO)_4 \leftrightarrow CH$ or $Mo(CO)_3(\eta^5\text{-}C_5H_5) \leftrightarrow CH_3$. [b] From Table 2 it can be seen that the isolobal property derives from the oxidation state of the metal and the number of ligands. It thus makes no difference whether in a PtL_2 group L is a monodenate ligand such as PMe_3, PPh_3 or CO, or if L_2 is a bidentate ligand such as cycloocta-1,5-diene. Similar considerations apply to anionic electron-pair donors; thus $Cl^{\ominus}$ and $Br^{\ominus}$, or $\eta^5\text{-}C_5H_5^{\ominus}$ and $\eta^5\text{-}C_5Me_5^{\ominus}$ are pairs of equivalent ligands as far as the isolobal connection is concerned. [c] This is an ML_3 (Pt^I, d^9) C_{2v} (T-shaped) fragment with one high-lying orbital, and is thus related to a ML_5 (Mn^0, d^7) fragment derived from an octahedron (cf. [10]). [d] The $Pt(PR_3)_3$ group is also isolobal with CH_2 (see Table 2); however, it is rarely found in complexes, in contrast to the ubiquitous $Pt(PR_3)_2$ fragment. The latter has two high-lying orbitals with two electrons, the remaining eight electrons of Pt^0 (d^{10}) filling the nonbonding d_{z^2} orbital and the t_{2g} set (cf. [10]). Thus $Pt(PR_3)_2$ groups play an important role in the extensive chemistry of platinum in which the metal 'has a 16 shell' or 'functions as a 16 electron species'.

$H)_2(\mu\text{-}CH_2)(CO)_{10}]$, and the latter is the only tautomer present in the solid state. Nevertheless, **2** with its agostic[15] hydrogen atom is well authenticated by NMR studies[13]. The relationship between **2** and **3** lies in the presence of the isolobal fragments CH_3 and $PtH(CO)(PPh_3)$ (ML_3, d^9, essentially C_{2v} symmetry or T-shaped).

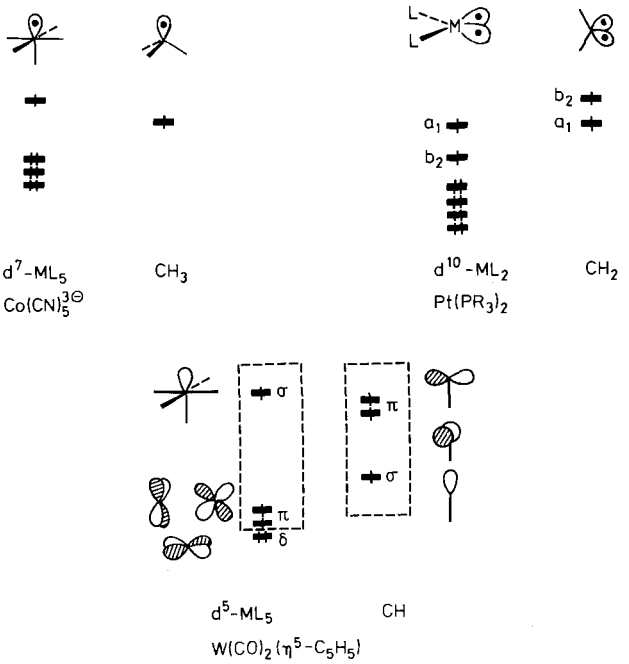

Fig. 1. Isolobal analogies between hydrocarbon and metal-ligand fragments.

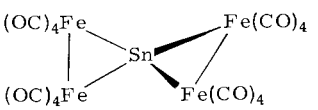
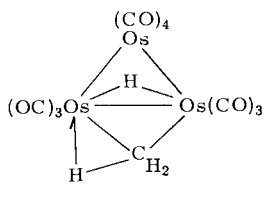
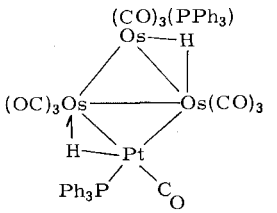
Although the isolobal model[10] has hitherto been primarily used to recognize structural relationships between organometallic and organic molecules, it is now timely to consider its use as a predictive tool for the synthesis of novel compounds. Having conceived a desired molecule as comprising a collection of fragments, one can consider its synthesis via the assembly of appropriate groups, bearing in mind fragment molecular orbital similarities such as those shown in Table 1. The examples in Table 1 are by no



1



2



3

means exhaustive and follow from conclusions drawn elsewhere[10], which have been usefully summarized by *Hoffmann* in the form shown in Table 2.

Before describing some planned synthesis of compounds with metal-metal bonds, it is necessary to point out that isolobal mapping between fragments does not necessarily lead to identical chemical behavior. For example, whereas CH_2 dimerizes to ethylene or polymerizes, the inorganic "methylene" groups $Pt(PR_3)_2$ do not follow this reactivity pattern. It is true that the diplatinum compound $[Pt_2\{tBu_2P(CH_2)_3PtBu_2\}_2]$ exists[16], which is a dimer of the $Pt(PR_3)_2$ species $Pt\{tBu_2P(CH_2)_3PtBu_2\}$, but the Pt_2P_4 core of the complex is not planar as is C_2H_4. Moreover, a Pt=Pt double bonded species would naturally be expected to have the configuration $(\sigma_d)^2(\sigma_d^*)^2(\pi_d)^2(\sigma)^2$; however, in $[Pt_2\{tBu_2P(CH_2)_3PtBu_2\}_2]$ the σ level does not lie below π_d^*, and the actual configuration is $(\sigma_d)^2(\sigma_d^*)^2(\pi_d)^2(\pi_d^*)^2$[17]. Formally, this leads to a zero Pt–Pt bond order, and thus a $Pt(PR_3)_2$ d^{10}-species would not be expected to dimerize[18,19]. Nevertheless, there are Pt–Pt bonding interactions in the diplatinum compound caused by s,p orbital mixing into σ_d and σ_d^* orbitals[17]. If the R groups are bulky, stable $Pt(PR_3)_2$ complexes are known, otherwise these species disproportionate to afford 16- or 18-electron $Pt(PR_3)_n$ (n=3 or 4) complexes and clusters with $Pt(PR_3)$ groups. Hence, a fragment such as $Pt(PMe_3)_2$ is best trapped as the complex $[Pt(C_2H_4)(PMe_3)_2]$, from which ethylene is readily released on treatment with various reagents.

Most of the inorganic species in Table 1 are not stable as dimers under normal conditions. Thus $[Fe_2(CO)_8]$ only exists at low temperatures in a rare gas matrix[20], since with CO it readily affords the thermodynamically more stable $[Fe_2(CO)_9]$. Dimeric forms of $Co(CO)_3$ and $Ni(\eta^5\text{-}C_5H_5)$, with formal metal-metal triple bonds, are also unstable. However, these fragments occur in the polynuclear compounds $[Co_4(CO)_{12}]$[21] and $[Ni_6(\eta^5\text{-}C_5H_5)_6]$[22]. In contrast, $[Rh_2(CO)_2(\eta^5\text{-}C_5Me_5)_2]$[23] and $[W_2(CO)_4(\eta^5\text{-}C_5H_5)_2]$[24] exist as formal analogues of ethylene and an alkyne, respectively. It may be concluded that isolobal metal-ligand fragments only combine with each other or with organic species in kinetically and thermodynamically favorable circumstances and, in combining, these same factors will determine the nature of the final product. Relative energy differences among the frontier orbitals will have a very important influence on the result.

Table 2. Isolobal analogies (after [10]).

Organic fragment	Coordination number of the transition metal on which the analogy is based				
	9	8	7	6	5
CH_3	d^1-ML_8	d^3-ML_7	d^5-ML_6	d^7-ML_5	d^9-ML_4
CH_2	d^2-ML_7	d^4-ML_6	d^6-ML_5	d^8-ML_4	d^{10}-ML_3
CH	d^3-ML_6	d^5-ML_5	d^7-ML_4	d^9-ML_3	

L = neutral two electron ligand.

4. Trimetallacyclopropanes

A multitude of compounds with metal-metal bonds is known, and these often involve atoms of different elements[25]; both for homo- and heteropolynuclear metal complexes a triangular array of metal atoms is a common structural feature. Although in this article we focus on heteronuclear metal species, the homonuclear trirhodium an-

ion **4**[26] is important since its existence prompted development of a useful bonding model[27]. The fragment $Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_5)_2$ has frontier orbitals similar to those of ethylene. Moreover, because $Rh(CO)_2^{\ominus}$ is isolobal with CH_2, the anion **4** is properly described as a trimetallacyclopropane. This analogy is supported by the synthesis of the dimetallacyclopropane **5**[28,29].

It follows that if $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_5)_2]$, with a formal metal-metal double bond, is related to ethylene it should form adducts with a variety of metal-ligand fragments which are isolobal with methylene. The products would then be analogues of olefin-metal complexes. It is not possible to test this idea with $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_5)_2]$ since this compound has not been reported. However, the related complex $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ has fortunately been prepared[23], and we have focussed on its reactions with the fragments PtL_2 ($L=PR_3$, $L_2=$cod) and $M(CO)_5$ (M = Cr, Mo, W); these species are readily accessible from labile complexes containing a weakly bound ligand. Thus, the compounds $[Pt(C_2H_4)(PR_3)_2]$ and $[Pt(cod)_2]$ are sources of $Pt(PR_3)_2$ and Pt(cod), respectively[30]. The $M(CO)_5$ groups may be obtained by UV irradiation of the hexacarbonyls in tetrahydrofuran (THF) or acetonitrile, thereby producing the reactive complexes $[M(CO)_5(THF)]$ (M = Cr, W) and $[Mo(CO)_5(NCMe)]$[31].

As expected, $[Pt(cod)_2]$ reacts with $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ to afford **6**[32], whereas the $[M(CO)_5(ligand)]$ species give the compounds **7**[33]. However, treatment of $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ with $[Pt(C_2H_4)(PPh_3)_2]$ leads to a complex mixture. The major product **8** contains the fragment $Pt(CO)(PPh_3)$ which, although isolobal with CH_2, demonstrates that the reaction is not mechanistically simple, a frequent occurrence in organometallic chemistry.

Protonation of **8** with $HBF_4\cdot Et_2O$ gives the salt **9**[32]. The structure of the cation is of considerable interest in terms of the isolobal analogy, since it is a model for protonated cyclopropane[34]. Moreover, the cation contains a $PtH(CO)(PR_3)^{\oplus}$ group isolobal with $CH_3^{\oplus}$.

The syntheses leading to **6**—**8** can be extended in several ways. For example, *Dahl* et al.[35] have shown that photochemically generated metal fragments, isolobal with methylene, add to the unsaturated dicobalt compound $[Co_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ to afford complexes such as, e.g., $[Co_2Mn(\mu_2\text{-}CO)_3(\mu_3\text{-}CO)(\eta^5\text{-}C_5H_4Me)(\eta^5\text{-}C_5Me_5)_2]$. Recently, the compound $[CoRh(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ has been prepared from the reaction between $[Rh(CO)_2(\eta^5\text{-}C_5Me_5)]$ and $[Co(C_2H_4)_2(\eta^5\text{-}C_5Me_5)]$[36]. This heteronuclear dimetal complex reacts with several carbene-like inorganic fragments to give trimetallacyclopropanes which incorporate three different metallic elements, *e.g.* **10**—**12**.

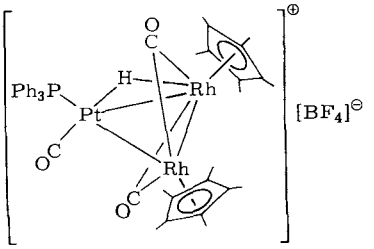
8



9

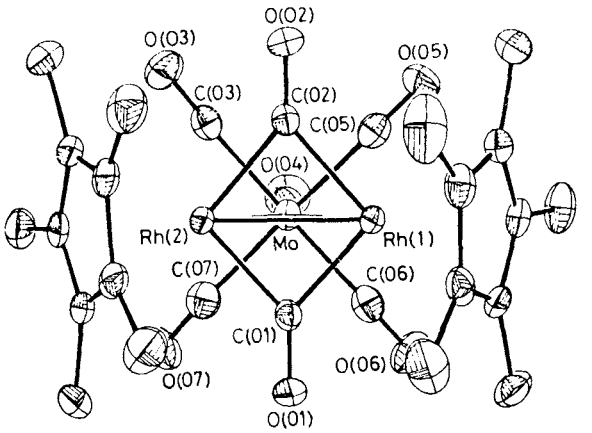


Fig. 2. The molecular structure of $[MoRh_2(\mu\text{-}CO)_2(CO)_5(\eta^5\text{-}C_5Me_5)_2]$ **7b** in the crystal [37].

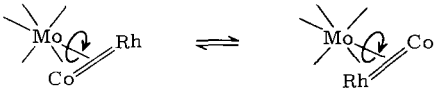
Although it has not proved possible to grow crystals of **12** for X-ray structure analysis, this has been carried out for the closely related compound **7b**, whose structure is shown in Figure 2[37]. At room temperature, the $^{13}C\{^1H\}$-NMR spectra of **7b** and **12** both exhibit two signals for the $Mo(CO)_5$ group (relative intensity 4 : 1). For **12** this implies dynamic behavior involving rotation of the Co=Rh fragment about an axis through the Mo atom and the midpoint of the Co—Rh vector so that the CO sites of the *cis*-$Mo(CO)_4$ group are averaged on the NMR timescale:

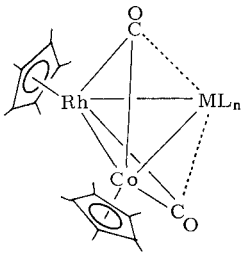


At −60 °C the limiting spectrum for **12** is observed, with the $Mo(CO)_5$ group giving rise to three resonances of relative intensity 2 : 2 : 1. From the coalescence temperature of *ca.* −15 °C, the barrier to rotation for the process is estimated[37] to be 52.3 ± 1.3 kJ mol^{-1}. This $\Delta G^{\neq}$ value lies in the range found for hindered rotation of alkenes in their

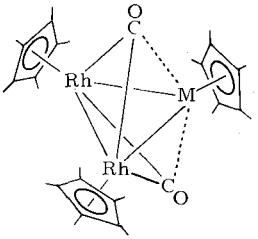
d^6-ML_5 complexes, thus strengthening the analogy between trimetallacyclopropanes such as **6**—**8** or **10**—**12** and $[M(C_2H_4)L_n]$ compounds.

Removal of a proton from **5** would formally yield the cationic methylidyne complex $[Rh_2(\mu\text{-}CH)(CO)_2(\eta^5\text{-}C_5H_5)_2]^{\oplus}$. Although this species is not known, the analogues **13** have been prepared[36] by treating $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ with $[M(C_2H_4)_2(\eta^5\text{-}C_5Me_5)]$ (M = Co, Rh). The latter are sources of $M(\eta^5\text{-}C_5Me_5)$, which are isolobal with $CH^{\oplus}$. The molecular structure of **13b** established by X-ray structure analysis[38] involves CO ligands which are semitriply bridging, as predicted by theoretical considerations[27].

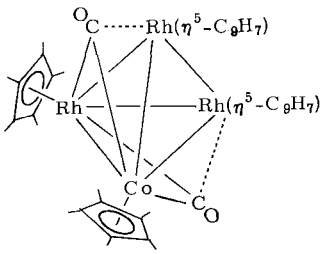
The fragment $Rh(\eta^5\text{-indenyl})$ is isolobal with $Rh(\eta^5\text{-}C_5Me_5)$. However, reaction of $[CoRh(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ with $[Rh(C_2H_4)_2(\eta^5\text{-}C_9H_7)]$ affords the tetranuclear complex **14**, rather than an unsaturated trimetal compound $[CoRh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_9H_7)(\eta^5\text{-}C_5Me_5)_2]$, similar to **13**. This again serves as a caveat that the isolobal model has its limitations when used to predict the final product of a chemical reaction. Nevertheless, if it is borne in mind that the steric effect of ligands or other factors will govern the course of the reaction, either inhibiting it altogether or leading to a thermodynamically more stable product, synthetic strategies based on isolobal connections can be valuable. A further example should illustrate these points. The $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$/ethylene mapping, coupled with the existence of $[Pt(C_2H_4)_3]$ with its easily displaced ethylene ligands, suggested a reaction between the dirhodium compound and tris(ethylene)platinum. Loss of some or all of the ethylene groups should occur to form a rhodium-platinum cluster compound. However, because of the steric requirements of the bulky $\eta^5\text{-}C_5Me_5$ ligands it was believed that a $PtRh_6$ core structure would probably not be formed. In fact, complex **15**, in which all C_2H_4 groups are displaced[39], was produced in virtually quantitative yield.



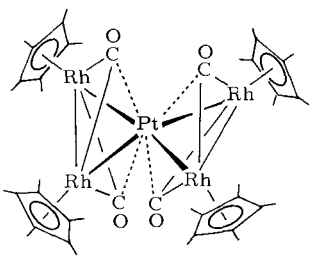
10, ML_n = Pt(cod)
11, ML_n = $Fe(CO)_4$
12, ML_n = $Mo(CO)_5$



13a, M = Co
13b, M = Rh



14



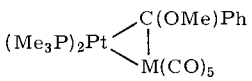
15

Formally, **15** is related to the bulky $Pt(PR_3)_2$ complexes mentioned earlier, but equally well an isolobal correlation could have been made if the product had been $[Pt(C_2H_4)\{Rh_2(CO)_2(\eta^5\text{-}C_5Me_5)_2\}_2]$, analogous to $[Pt(C_2H_4)(PR_3)_2]$.

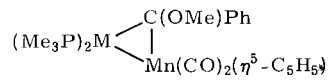
Once the structure of the pentametallaspiro[2.2]pentane **15** had been established, the synthesis of several related species became clear. For example, since Au^I is isoelectronic with Pt^0, the compound $[AuRh_4(\mu\text{-}CO)_4(\eta^5\text{-}C_5Me_5)_4][PF_6]$ was prepared by treating a mixture of $[Rh_2(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)_2]$ and $TlPF_6$ with [AuCl(tht)] (tht = tetrahydrothiophene)[40].

5. Dimetallacyclopropanes

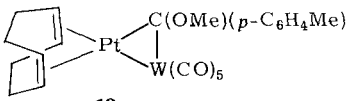
Compounds of type **16** are dimetallacyclopropanes and are readily prepared[41] by using the Fischer[42] carbene compounds $[(OC)_5M{=}C(OMe)Ph]$ (M = Cr, Mo, W) as ligands to displace ethylene from $[Pt(C_2H_4)(PMe_3)_2]$. The $Cr(CO)_5$ fragment is isolobal with CH_2, and since the $Mn(CO)_2(\eta^5\text{-}C_5H_5)$ group is also an ML_5 (d^6) species (Table 2), the syntheses of compounds **17** thus logically followed those of **16**[43].



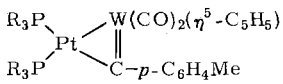
16a, M = Cr
16b, M = Mo
16c, M = W



17a, M = Pt
17b, M = Pd
17c, M = Ni



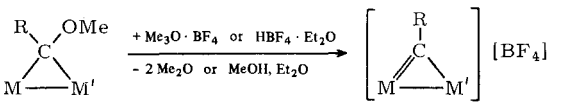
18



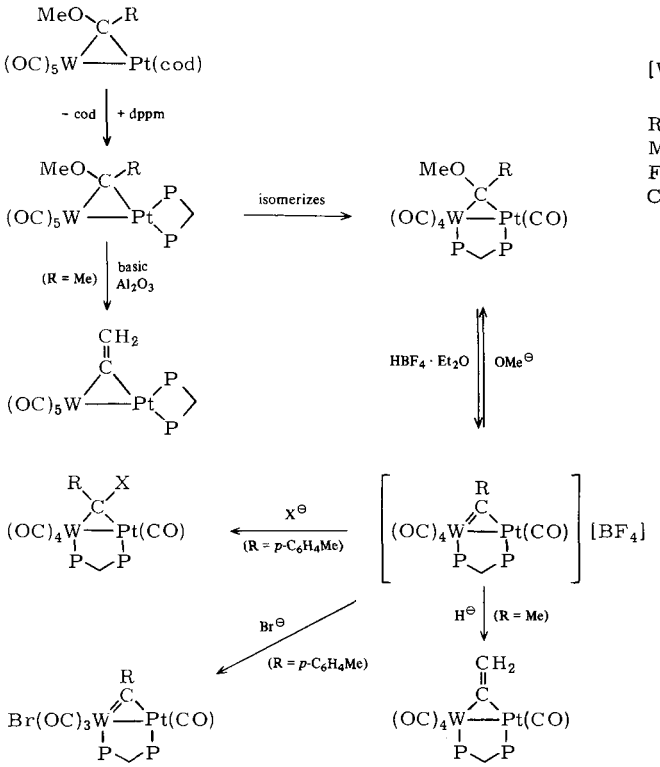
19a, PR_3 = PMe_2Ph
19b, PR_3 = PMe_3

The alkylidene groups in **16** and **17** and in related compounds do not symmetrically bridge the metal-metal bonds. In complex **16c** the μ-C—Pt [2.04(1) Å] and μ-C—W [2.48(1) Å] distances are so disparate that this compound can be viewed as involving a $W(CO)_5$ group coordinated to a $Ph(MeO)C{=}Pt(PMe_3)_2$ moiety. The asymmetry is also reflected in the chemical behavior. Thus, when **16a** is refluxed in toluene it decomposes to afford the triplatinum compounds $[Pt_3\{\mu\text{-}C(OMe)Ph\}_2(\mu\text{-}CO)(PMe_3)_3]$ and $[Pt_3\{\mu\text{-}C(OMe)Ph\}_3(PMe_3)_3]$[41]. Carbene transfer from one metal center to the other also occurs in the reaction of **18** with CO to yield $[Pt_3\{\mu\text{-}C(OMe)R\}_3(CO)_3]$ (R = p-C_6H_4Me)[44].

For compounds containing the μ-C(OMe)R ligand, an important reaction is the removal of the OMe group by methylation or protonation:



The cationic bridged alkylidyne species produced have an extensive chemistry. However, undesired side reactions in-

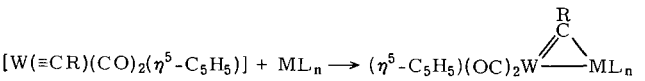


Scheme 2. R = Me, *p*-C_6H_4Me; dppm = $Ph_2PCH_2PPh_2$; X = H, Me, S-*p*-C_6H_4Me.

volving cleavage of the metal-metal bonds and migration of the carbene ligands must not occur. This pathway may be blocked by supporting the metal-metal bond with a bidentate ligand, as illustrated in Scheme 2[45].

6. Dimetallacyclopropenes

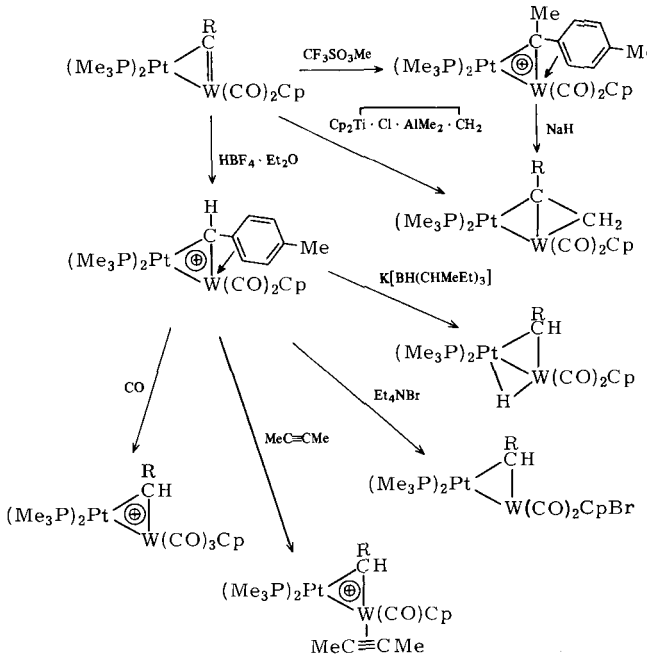
Reference was made earlier to the analogy between the frontier orbitals of CR and $W(CO)_2(\eta^5\text{-}C_5H_5)$ (Scheme 1), first recognized[1,46] in the formation of **19a** by displacement of ethylene from $[Pt(C_2H_4)(PMe_2Ph)_2]$ with



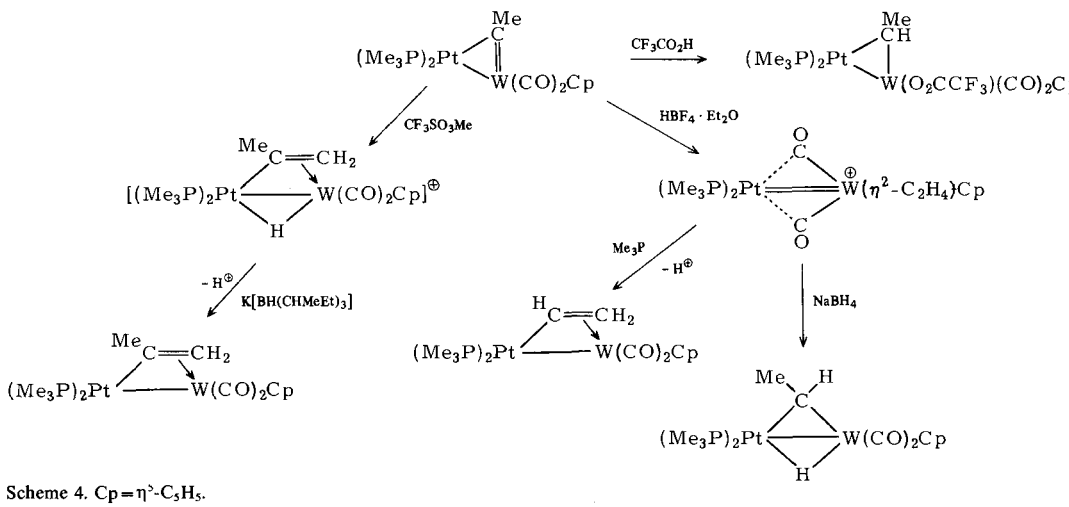
R = *p*-C_6H_4Me; ML_n = $Pt(PR_3)_2$, $M(CO)(\eta^5\text{-}C_5Me_5)$ (M = Co, Rh), $M(CO)(\eta^5\text{-}C_9H_7)$ (M = Rh, Ir), M(CO)(acac) (M = Rh, Ir), $Fe(CO)_4$, $Mn(CO)_2(\eta^5\text{-}C_5H_4Me)$, $Re(CO)_2(\eta^5\text{-}C_5H_5)$, $Cr(CO)_2(\eta^6\text{-}C_6Me_6)$ $Cr(CO)(NO)(\eta^5\text{-}C_5H_5)$, $M(\eta^2\text{-}CO)(\eta^5\text{-}C_5H_5)_2$ (M = Ti, Zr)

$[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta^5\text{-}C_5H_5)]$. An X-ray structure analysis of **19a** showed that the μ-C–W distance (1.967(6) Å) corresponds to that expected for a double bond, and hence the description of the three-membered ring as a dimetallacyclopropene is appropriate.

The reaction which afforded **19a** is remarkably general. A range of metal-ligand fragments isolobal with CH_2 readily form 1:1 adducts with $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta^5\text{-}C_5H_5)]$[47].



Scheme 3. Cp = η^5-C_5H_5, R = *p*-C_6H_4Me.



Scheme 4. Cp = η^5-C_5H_5.

X-Ray structure analysis of several of the bimetal compounds reveal μ-C–W distances which support the dimetallacyclopropene formulation. The synthesis is the most systematic yet devised for preparing complexes with metal-metal bonds between tungsten and another transition metal. The scope of the reaction remains to be established by further experiments. So far, it is known that the R substituent may be alkyl rather than aryl, and it is likely that similar reactions will occur with the chromium and molybdenum derivatives $[M(\equiv CR)(CO)_2(\eta^5\text{-}C_5H_5)]$ (M = Cr, Mo). Whether carbyne complexes of earlier transition metals, such as tantalum, will behave as ligands in a manner similar to $[W(\equiv CR)(CO)_2(\eta^5\text{-}C_5H_5)]$ has yet to be determined. The C≡Os group in the osmium complex $[OsCl(\equiv CC_6H_4Me\text{-}4)(CO)(PPh_3)_2]$ is known to add to copper, silver, and gold centers[48].

Dimetallacyclopropenes containing tungsten may be used as precursors for the synthesis of metal cluster compounds (cf. Section 8); however, interest also focuses on the reactivity of the bridging μ-CR groups. To date, attention has been directed mainly at the tungsten-platinum species, and some of their reactions are outlined in Schemes 3 and 4[49–51]. The very different character of the products obtained with $HBF_4 \cdot Et_2O$, depending on the nature of the μ-CR group (R = *p*-C_6H_4Me or Me), should be noted.

7. Copper, Silver, and Gold

Many cluster compounds containing $Au(PPh_3)$ groups are known, and from structural studies it has been widely appreciated that these groups are isolobal with H or CH_3 since all three species have a frontier orbital containing a single electron[52–54]. Although this analogy recedes in species with two or more $Au(PPh_3)$ groups[55], it remains useful in devising syntheses of compounds containing a single Au atom.

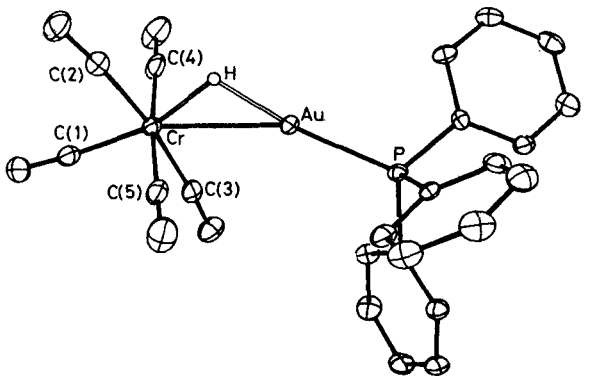


Fig. 3. The molecular structure of $[AuCr(\mu\text{-}H)(CO)_5(PPh_3)]$ in the crystal [60].

The hydrido-bridged anions $[M_2(\mu\text{-}H)(CO)_{10}]^{\ominus}$ (M = Cr, Mo, W) were seminal compounds[56–59] in modern inorganic chemistry since their electron deficient three-center two-electron bridge systems provided a key link between transition-metal chemistry and that of the boranes, for which such bridge-bonding by hydrogen had long been known.

The dichromium anion $[Cr_2(\mu\text{-}H)(CO)_{10}]^{\ominus}$ can be considered to be a combination of the two fragments $CrH(CO)_5^{\ominus}$ and $Cr(CO)_5$, the former fragment behaving as an electron-pair donor and the latter as an electron-pair acceptor, isolobal with $CH_3^{\oplus}$ (Table 1). Because of the isolobal relationship $CH_3^{\oplus} \leftarrow\!\!\circ\!\!\rightarrow [Au(PPh_3)]^{\oplus}$, it follows that the neutral complex $[AuCr(\mu\text{-}H)(CO)_5(PPh_3)]$ might exist, given favorable thermodynamic factors. The desired compound (Fig. 3) has been obtained from the reaction of $[N(PPh_3)_2][CrH(CO)_5]$ and $[AuCl(PPh_3)]$ in tetrahydrofuran[60]. Because of the isolobal relationships $Cr(CO)_5 \leftarrow\!\!\circ\!\!\rightarrow M(CO)_6$ (M = Mo or W), and $Au(PPh_3) \leftarrow\!\!\circ\!\!\rightarrow Ag(PMe_3)$, the related compounds

$[MM'(\mu\text{-}H)(CO)_5(PR_3)]$

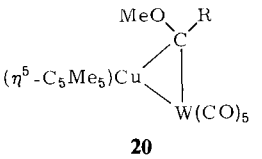
M	M′	R
Mo	Au	Ph
W	Au	Ph
Cr	Ag	Me
W	Ag	Me

have been synthesized by a similar route.

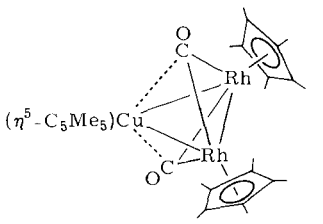
Although several cluster compounds incorporating a copper atom in the framework have been described[25], a reagent capable of supplying a copper moiety in a fragment isolobal with CH_2 or CH could be useful in synthesis. Since $Ni(\eta^5\text{-}C_5H_5)$ (ML_3, d^9) is isolobal with CH, the following relationships hold

$Cu(\eta^5\text{-}C_5H_5)$ (ML_3, d^{10}) $\leftarrow\!\!\circ\!\!\rightarrow CH_2$
$Zn(\eta^5\text{-}C_5H_5)$ (ML_3, $d^{10}\,s^1$) $\leftarrow\!\!\circ\!\!\rightarrow CH_3$

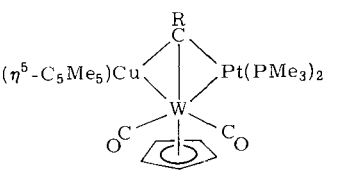
Taking into account that complexes containing $M(\eta^5\text{-}C_5Me_5)$ groups are sometimes more stable than those con-



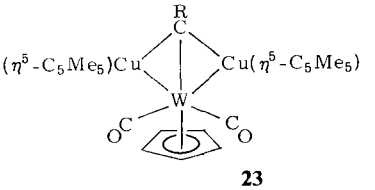
20



21



22

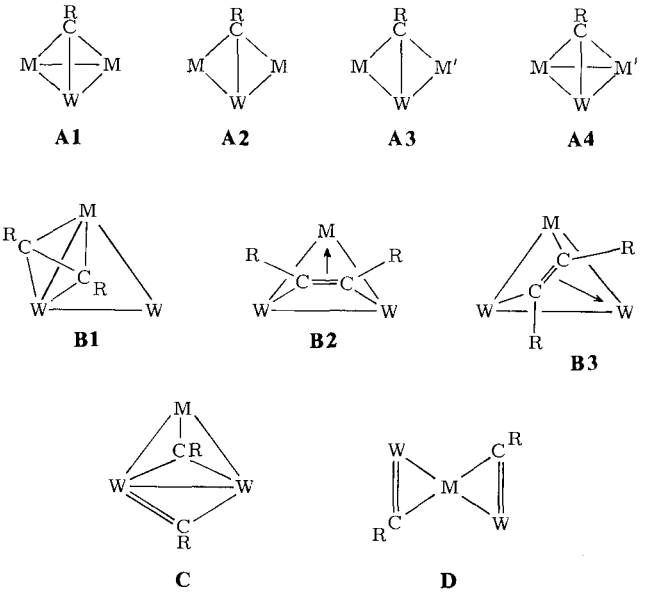


23

taining M(η-C_5H_5), treatment of CuCl with LiC_5Me_5 in tetrahydrofuran affords a reagent which is a ready source of the Cu(η⁵-C_5Me_5) fragment[61]. The latter adds to the unsaturated complexes [W{=C(OMe)R}$(CO)_5$], [Rh_2(μ-CO)$_2$(η⁵-$C_5Me_5)_2$], and [PtW(μ-CR)$(CO)_2(PMe_3)_2$(η⁵-C_5H_5)] to give compounds **20** to **22** (R = *p*-C_6H_4Me).

The analogy between the structure of **22** and that of the CH_2 adduct of [PtW(μ-CR)$(CO)_2(PMe_3)_2$(η⁵-C_5H_5)] depicted in Scheme 3 should be noted.

Interestingly, the reaction between [Cu(η⁵-C_5Me_5)(THF)] and [W(≡CR)$(CO)_2$(η⁵-C_5H_5)] affords the dicopper compound **23** (R = *p*-C_6H_4Me). This should be contrasted with the addition of $Pt(PR_3)_2$ fragments to [W(≡CR)$(CO)_2$(η⁵-C_5H_5)] to give the monoplatinum complexes [PtW(μ-CR)$(CO)_2(PR_3)_2$(η⁵-C_5H_5)][62]. Thus, although Cu(η⁵-C_5Me_5) and $Pt(PR_3)_2$ are isolobal, they show different reactivity patterns towards [W(≡CR)$(CO)_2$(η⁵-C_5H_5)], further illustrating that metal-ligand fragment analogies cannot be applied with certainty in synthesis, although their value as a guide-line in preparative work should be obvious.



Scheme 5. Core structures of trimetal compounds derived from [W(≡CR)$(CO)_2$(η⁵-C_5H_5)]. W = W$(CO)_2$(η⁵-C_5H_5), ligands on M and M′ are omitted for clarity. **A1**: M = Mo, W, Fe, Co, Rh, Ni; **A2**: M = Cu, Pt; **A3**: M = Cu, M′ = Pt; **A4**: M = Fe, M′ = Co, Rh, Pt; **B1**: M = Fe; **B2** and **B3**: M = Ru, Os; **C**: M = Re; **D**: M = Ni, Pd, Pt.

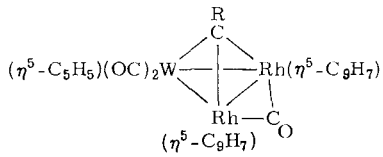
8. Metal-Clusters and -Chains

The dimetallacyclopropenes [MW(μ-CR)$(CO)_2(L_n)$(η⁵-C_5H_5)] (R = *p*-C_6H_4Me) discussed in Section 6 can serve as key building blocks for the synthesis of cluster complexes containing three or more metal atoms[63]. Reactions occur with metal-ligand fragments isolobal with CH_2, CH, or $CH^{\oplus}$ to afford products having a triangle of metal atoms capped by a CR group. Core structures observed for these clusters are of types **A1**—**A4** (Scheme 5). In addition to tungsten these clusters contain either two metal atoms of the same element or two metal atoms of different elements. Moreover, the core structures can be either closed (tetrahedrane) or "butterfly" (bicyclobutane).

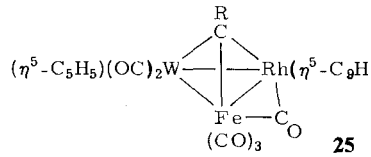
A range of trimetal compounds of type **A** have now been prepared via designed syntheses, and a few examples will suffice to illustrate the approach. The synthesis of compounds **22** and **23**, species with core structures **A3** and **A2**, respectively is described in Section 7.

The binuclear complex [RhW(μ-CR)$(CO)_3$(η⁵-C_5H_5)(η⁵-C_9H_7)] affords **24** when treated with [Rh$(CO)_2$(η⁵-C_9H_7)]. Carbon monoxide is readily released in this reaction, and formally a Rh(η⁵-indenyl)(⟵O⟶CH) fragment has been added to the bimetal complex. The core structure of **24** corresponds to type **A1** (Scheme 5). Addition of an $Fe(CO)_3$ fragment (⟵O⟶$CH^{\oplus}$) to [RhW(μ-CR)$(CO)_3$(η⁵-C_5H_5)(η⁵-C_9H_7)] gives **25**[64], a species which is representative of structure type **A4**. Interestingly, this cluster contains atoms from the 3d-, 4d- and 5d-transition-metal series.

Several clusters of type **A1** have been prepared directly from [W(≡CR)$(CO)_2$(η⁵-C_5H_5)] (R = *p*-C_6H_4Me) and homonuclear dimetal compounds. Thus, the tolylmethylidynetungsten complex reacts with [$Co_2(CO)_8$] to give **26** in essentially quantitative yield[65]. An analogous reaction occurs with [$Mo_2(CO)_4$(η⁵-$C_5H_5)_2$] to afford **27**. The synthesis of **26** and **27** follows directly using the isolobal model as a guide. Both [$Co_2(CO)_8$] and [$Mo_2(CO)_4$(η⁵-$C_5H_5)_2$] were known to add alkynes readily to afford complexes [Co_2(μ-alkyne)$(CO)_6$] and [Mo_2(μ-alkyne)$(CO)_4$(η⁵-$C_5H_5)_2$], which are structurally analogous to **26** and **27**, respectively. However, the formation of **26** and **27**, and also that of the alkyne-bridged complexes, probably proceeds through the



24

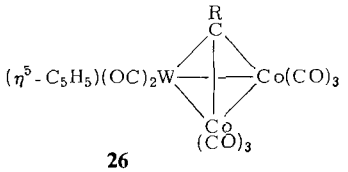


25

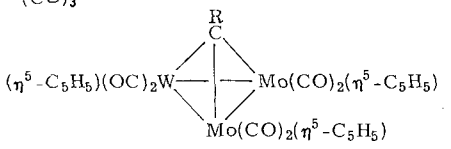
intermediacy of dimetal species which subsequently add $Co(CO)_3$ or $Mo(CO)_2$(η⁵-C_5H_5) fragments[65].

The dimetallacyclopropenes [MW(μ-CR)$(CO)_2(L_n)$(η⁵-C_5H_5)] also react with [W(≡CR)$(CO)_2$(η⁵-C_5H_5)] to give structures of type **B** (Scheme 5), which result from carbyne-coupling. The alkyne ligand thus formed may face- or edge-bridge the metal triangle, as found in species derived from iron, ruthenium, or osmium carbonyls[66].

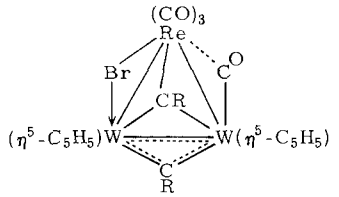
As yet only one example is known of a compound with a core structure of type **C**—the rhenium compound **28** prepared by heating [W(≡CR)$(CO)_2$(η⁵-C_5H_5)] and [$ReBr(CO)_3(NCMe)_2$] in hexane[67]. The acetonitrile complex is a source of $ReBr(CO)_3$, a d^6-ML_4 fragment isolobal with $CH_2^{2\oplus}$ and $CH^{\oplus}$. Hence **28** has 46 cluster valence electrons rather than the customary 48 for a trimetal cluster in which all the metal atoms have 18-electron configurations. The core structure **C** is of considerable interest,



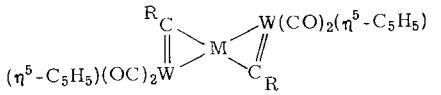
26



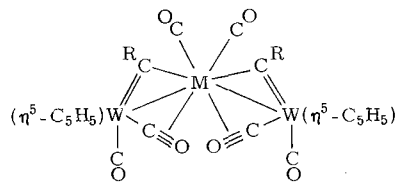
27



28



29a, M = Pt; **29b**, M = Pd; **29c**, M = Ni
29d, M = $Au^{\oplus}$; **29e**, M = $Ag^{\oplus}$



30a, M = Mo; **30b**, M = W

since it would appear to represent an intermediate on a pathway to type **B**.

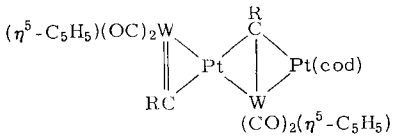
Structures of type **D** were first obtained from reactions between $[W(\equiv CR)(CO)_2(\eta^5\text{-}C_5H_5)]$ (R = *p*-C_6H_4Me) and labile olefin complexes of nickel, palladium, or platinum[68]. Thus $[Pt(C_2H_4)_3]$ afforded **29a** having a *pseudo*-tetrahedral structure. The angle between the two dimetallacyclopropene rings is 83°, and the metal spine is not linear (∢W–Pt–W 165°); however, in **29c** the W–Ni–W angle is 175°. Formation of **29a** parallels the synthesis of a family of $[Pt(alkyne)_2]$ complexes from reactions between $[Pt(C_2H_4)_3]$ and alkynes[69], providing another example of the successful use of the isolobal guide line in preparative work.

Having identified that the complexes **29** possess core structures of type **D** (Scheme 5), we can consider the preparation of related compounds. It is possible that the carbyne-tungsten ligands in **29a** function as four-electron donors to platinum, just as alkynes contribute four electrons to a metal center in certain complexes. In **29** there is some evidence for this in the presence and disposition of two semi-bridging CO ligands[68]. Assuming an 18-electron configuration for platinum in **29a**, albeit without proof, one can consider an isolobal mapping

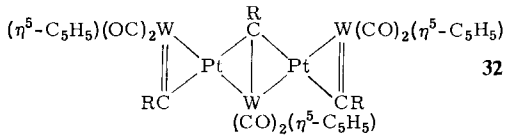
$$Pt^0\,(d^{10}) \leftarrow\!\!\sigma\!\!- C^{4\oplus} \leftarrow\!\!\sigma\!\!- ML_2\,(d^6)$$

with all three species requiring 8 electrons for a filled shell. This prompted synthesis of the compounds **30** from $[W(\equiv CR)(CO)_2(\eta^5\text{-}C_5H_5)]$ and $[M(CO)_3(NCMe)_3]$ (M = Mo, W)[70]. These structures are interesting in two respects. First, the presence of *cis*-$M(CO)_2$ groups necessitates bent W–M–W spines (for **30a**, ∢W–Mo–W = 148°). Second, the complexes contain σ,η^2-CO ligands, and hence the central metal atom (Mo or W) acquires an 18 electron shell without the C≡W ligands functioning as four electron donors.

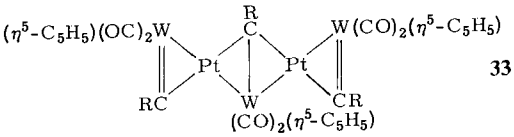
Since Au^I and Pt^0, as well as Ag^I and Pd^0 are isoelectronic pairs, it seemed likely that the cations **29d** and **29e** should exist. These species have been prepared as their $PF_6^{\ominus}$ and $BF_4^{\ominus}$ salts, respectively. Thus treatment of $[W(\equiv CR)(CO)_2(\eta^5\text{-}C_5H_5)]$ with [AuCl(tht)] in the presence of $TlPF_6$ gives **29d**, whereas $[Ag(NCMe)_4][BF_4]$ affords the silver compound **29e**[70b,71]. This readily releases $[W(\equiv CR)(CO)_2(\eta^5\text{-}C_5H_5)]$ in solution, and is less stable in this respect than the gold compound **29d**. In contrast, **29a** is sufficiently robust to be used with some success as a building block in the syntheses of compounds containing a chain of metal atoms, as described below.



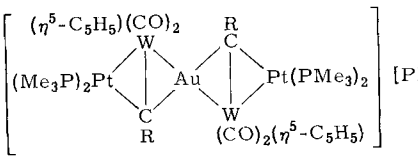
31



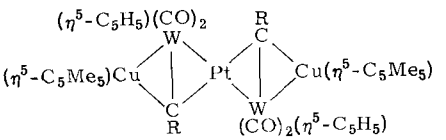
32



33



34



35

Treatment of **29a** with $[Pt(cod)_2]$ results in the stepwise formation of compounds **31** and **32**. Reaction between **31** and one equivalent of $[W(\equiv CR)(CO)_2(\eta^5\text{-}C_5H_5)]$ gives the diplatinumtritungsten compound **33**[71]. The longest metal atom chain made so far in this way contains seven metal atoms with a Pt_3W_4 spine. This compound was prepared from **29a** and $[Pt(C_2H_4)_3]$. In principle, it should be possible to prepare oligomeric or polymeric Pt-W complexes,

but there are experimental difficulties. These include the observation that the chains tend to break to give mixtures of compounds with fewer metal atoms. Variation of the nature of the substituent R group may go some way to inhibit this tendency. Since the chain structures are not planar, the species exist in various conformations, increasing in complexity with chain length, and therefore making spectroscopic characterization very difficult. X-Ray crystallographic studies are crucial whenever single-crystals can be grown.

Nevertheless, despite the obvious difficulties, this is a promising area for research where considerations based on the isolobal model can be helpful. Thus Au^I may be substituted for Pt^0, and $Cu(\eta^5\text{-}C_5Me_5)$ for Pt(cod) or $Pt(PMe_3)_2$. For example, the gold compound **34** has been prepared by treating **19b** with [AuCl(tht)] in the presence of $TlPF_6$, and the copper complex **35** has been synthesized by addition of $[Cu(\eta^5\text{-}C_5Me_5)\cdot THF]$ to **29a**.

9. Conclusion and Outlook

As already stressed by *Hoffmann*[10], predictions based on isolobal analogies are bound to fail from time to time. At various places in this article attention has been drawn to this. Nevertheless, I hope to have demonstrated the value of the isolobal connection for synthesis in organometallic chemistry. Given that countless metal-ligand fragments are available to chemists via complexes containing labile groups (e.g. C_2H_4, THF, NCMe, N_2, etc.), it is possible to define a synthetic objective and the method of attaining it. It then remains to test the preparative pathway experimentally. As a creative area, organometallic synthesis has unlimited horizons!

I am indebted to Professor Roald Hoffmann for helpful discussions, and I thank Dr. Ward Robinson and Gregory Elliott for helpful comments. It will be evident that the work described depended much on stimulating collaboration with X-ray crystallographers, and I am indebted in this respect to Drs. Judith Howard, Guy Orpen, and Peter Woodward. Finally none of the work would have been possible without the able assistance of my co-workers listed in the relevant references.

[29] Whether a structure has bridging or nonbridging CO groups does not cause a major perturbation of the frontier orbitals, at least to a first approximation, (see ref. [10]). Hence the fact that **4** has bridging CO groups in the ground state structure and **5** does not, makes no difference to the isolobal mapping.

Routes to Functional Vesicle Membranes without Proteins

By Jürgen-Hinrich Fuhrhop* and Joachim Mathieu

Fixation of reaction partners at appropriate distances from one another is a structural prerequisite for vectorial reactions and reaction sequences. In biological systems (e.g. the photosynthetically active thylakoid membrane or membrane receptors) the positions of the reaction centers are fixed by membrane-protein complexes, but little is known about the structure of these complexes. Ordered reactive systems in synthetic vesicle membranes were first obtained by employing amphiphiles with reactive head groups as building units, by regioselective incorporation of foreign molecules into the membrane, by alignment of bolaamphiphiles with two head groups of differing solubility or size, and by the formation of domains. Chiral superstructures have also been observed in membranes, and the first stereoselective reactions have been performed in vesicle membranes. The report concludes with a brief discussion of membranes constructed from non-amphiphilic building blocks and problems which still have to be solved.

1. Introduction

Vesicles (lat. vesicula) are sealed, extremely thin (≤ 10 nm), often spherical membranes which enclose aqueous volumes of approximately 1 - 1000 μm^3. Synthetic vesicles formed by aggregation of a single amphiphile can be regarded as extremely simple models of highly organized, multifunctional biological cells[1,2]; for about seven years attempts have been made to equip these structures with properties analogous to those of a single cell. This review describes novel, reactive vesicles without proteins which have been used to try to simulate or modify the individual structural and dynamic properties of biological cells.

As an introduction, the structural units of biological membranes will be briefly dealt with, and their interactions and modes of functioning will be illustrated with the aid of two models. It is shown that the interesting characteristics of membrane reactions (vectorial, selective, rapid) can be accounted for by observable membrane properties which are, however, still not understood. The preparation and properties of protein-free vesicles from phospholipids is then described very briefly to bring in the topic of "synthetic vesicles". In the main part of this report we will only refer to those properties of synthetic vesicles which are not shared by phospholipid vesicles.

Biological cell membranes consist of a molecular bilayer (bilayer lipid membrane, BLM) of lipids (phospholipids, glycolipids) and proteins. According to the currently valid "fluid mosaic" model of *Singer* and *Nicolson*[3] (cf. Fig. 1a), the lipids form a matrix of liquid and liquid crystalline areas whose hydrophobic centers are spanned by proteins ("integral proteins"). Proteins which are associated with the hydrophilic head groups ("peripheral proteins") can be reversibly detached from the cell membrane (e.g. by changing the pH value). Integral proteins can only be isolated from the membrane with retention of their biological activity by using suitable detergents; the membrane is destroyed in the process. Furthermore, integral proteins in the membrane are not, or are only partially, attacked by water-soluble reagents (e.g. hydrolases), whereas peripheral proteins are accessible to these agents. The entire hydrophobic lipid and protein components form a phase which is sharply separated from water, although the distance from the aqueous environment only amounts to a few Ångstroms. Oligosaccharide chains of integral glycoproteins are often found on the outer cell surface and are responsible for (stereo-)selective interactions with substances dissolved in water. Selective interactions also take place between the proteins and the lipid matrix; predominantly negatively charged phospholipids (e.g. phosphatidyl serine) are, for example, closely bound to membrane proteins and form "domains" in the electroneutral phospholipid membranes (see Fig. 1).

The functions of biological membranes correspond with the living processes that occur in the cells: conversion of solar energy into chemical energy (photosynthesis), selective uptake of natural compounds (uptake of nutrients), production of electrical potentials and impulses (nerve excitation, movement), exchange of information with the environment (receptor action), etc. The course of biological reactions at membranes will be illustrated by two models: 1) the receptor action of chiral membrane surfaces and 2) light-induced charge separation at symmetrical membranes.

1) The "fluid mosaic" model for the reaction of a membrane receptor with a peptide hormone (Figs. 1a, b) demonstrates the relative sizes and mobility of the membrane building blocks[3]. Figure 1a shows the BLM with a lipid domain surrounding three integral glycoproteins and a peripheral protein molecule. The oligosaccharide and protein chains on the outer membrane surface are long, flexible arms which can pick up substances dissolved in water. These "arms" are composed of many chiral structures and form the highly specific binding center of the receptor. Association of the signal molecule (membrane ligand) with the receptor (Fig. 1b) changes the positions of the receptor proteins and their tertiary structures. The "signal" is thus conducted through the membrane by the integral proteins

("allosteric effect") and can then trigger off subsequent reactions at the inner surface (e.g. aggregation of actin units to form fibrils).

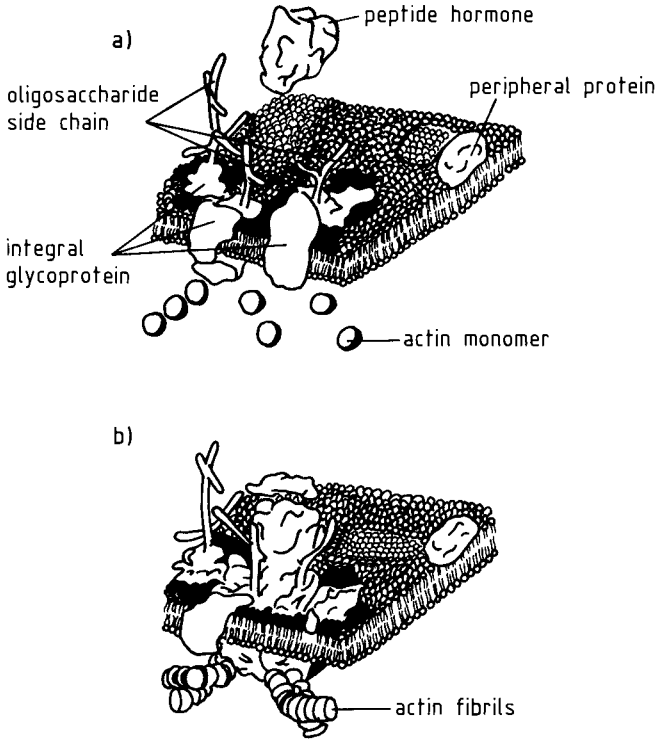

Fig. 1. a) "Fluid mosaic" model of a membrane receptor.—b) Attachment of a peptide hormone (="signal molecule") results in rearrangement of the receptor proteins within a "domain" of the membrane. This triggers subsequent reactions inside the cell (in this case the aggregation of actin molecules). The molecular interactions between the signal molecule and the receptor protein, those within the receptor-protein complex, and also those between the receptor protein and the actin units have not yet been elucidated in detail [3b].

2) The schematic model for the light-induced cleavage of water into hydrogen and oxygen—the most important part of plant photosynthesis—consists of several reaction sequences whose primary result is the enrichment of electrons on the outer membrane surface and the enrichment of protons in the internal aqueous volume ("light-induced charge separation")[4]. Part of this reaction is depicted in Figure 2. A chlorophyll molecule on the inner side of the membrane is excited by visible light and in <1 ns donates an electron via a neighboring pheophorbide molecule to a plastoquinone molecule (X320) situated at the outer side of the membrane.

$$\text{chlorophyll}_{\text{inside}} + \text{plastoquinone}_{\text{outside}} \underset{\geq 200\ \mu s}{\overset{<1\ ns}{\rightleftharpoons}} \text{chlorophyll}^{\oplus}_{\text{inside}} + \text{plastoquinone}^{\ominus}_{\text{outside}}$$

This electron transfer is directional—it only proceeds from the inside to the outside. The three reaction centers so far identified (chlorophyll, pheophorbide, X320) are bound to a lipoprotein (molecular weight: 47000), and their positions and mutual alignment are probably largely fixed during photochemical charge separation. This is a prerequisite for vectorial processes. At least two other proteins are responsible for the subsequent electron transport and prevent the slow back reaction (≥ 200 µs). A quinone anion is

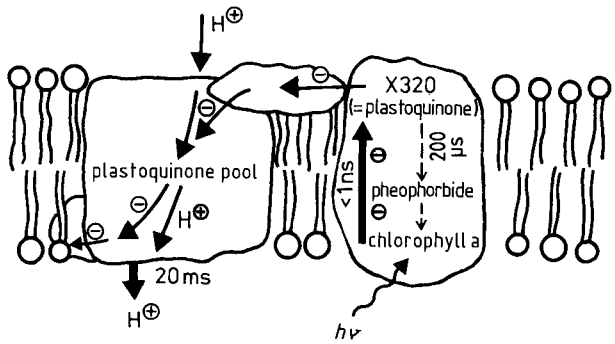

Fig. 2. Part of a model of reaction center II in photosynthesis. Rapid light-induced charge separation is followed by slower proton transport across the membrane. Very little is known about the molecular mechanisms responsible for the vectorial course of the reaction (the forward reactions are much faster than the back reactions).

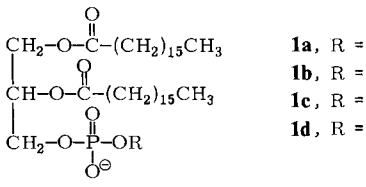
finally protonated by the outer aqueous phase and a proton is transported through the membrane via a plastoquinone pool into the inner aqueous volume. The selective adsorption of dissolved molecules at reactive centers and their action as signals for subsequent reactions, the spatial and time-based organization of reaction centers, and the resulting reversible processes are all fascinating phenomena which are made possible by as yet unknown mechanisms involving the interaction of several membrane proteins; only a few, unsatisfactorily analogous phenomena can be found in bioorganic chemistry.

When compared with the rapidly, selectively reacting proteins, the lipid aggregates constitute a chemically inert filling material. They merely act as a layer separating the two aqueous volumes and as a solvent for the hydrophobic protein moieties. Accordingly, protein-free vesicles have up to now only been studied by physically-orientated chemists[1]. The results of these investigations can be summarized in six points:

1. Phospholipids (such as **1a—d**) or similar water-insoluble amphiphilic natural substances such as **2**[5] aggregate in water to form bilayer liquid crystals which rearrange when exposed to ultrasonic waves to give spherical vesicles (Fig. 3). Natural product vesicles are also called liposomes ("fatty bodies").



1a, R = H
1b, R = $CH_2CH_2\overset{\oplus}{N}(CH_3)_3$
1c, R = $CH_2CH_2NH_2$

2, m + n = 27-31

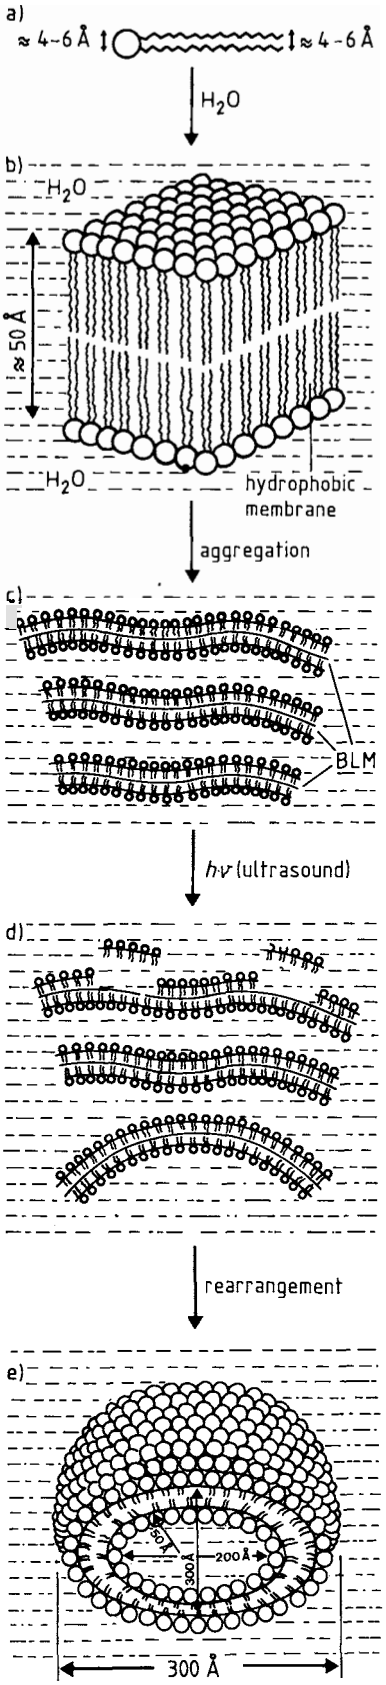

Fig. 3. Vesicle formation by ultrasonic treatment of bilayer membrane (BLM) liquid crystals [24].

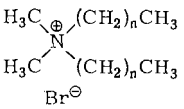
2. The liposome BLMs are extremely thin (thickness ≈ 5 nm).
3. The vesicles are stable for a long time (hours or days) and can be subjected to chromatography and centrifugation.
4. The membrane acts as an efficient barrier for water-soluble compounds but allows water to pass through (osmotic activity).
5. Water-insoluble compounds (e.g. non-polar dyes) can be dissolved in the vesicle membrane.
6. Chemically uniform vesicle membranes display reversible liquid ⇌ liquid-crystalline phase transitions, usually in the temperature range 20–50 °C.

At present it seems that neither the membrane proteins nor the phospholipids will be important topics for future research in organic chemistry. The most important natural phospholipids and their synthetic analogues are known; as far as membrane proteins are concerned, the synthetic problems will be solved by molecular biologists and their structures will be elucidated by spectroscopists. The organic chemist will be limited to helping biophysicists and biochemists (synthesis of pure lipids, systematic cross-linkage of membrane proteins for the structural determination of protein complexes, etc.) or developing artificial vesicle membranes with interesting properties without resorting to the help of nature. This last aspect will be dealt with in the following sections.

2. Reactive Vesicle Membranes

2.1. Head Groups

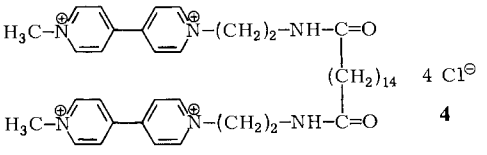
The natural membrane-forming lipids are electroneutral or negatively charged amphiphiles with two fatty acid chains. The breakthrough to other types of membrane-forming compounds was made by *Kunitake* et al. in 1977[6], who demonstrated that tetraalkylammonium salts with two long alkyl residues (e.g. **3**) form vesicles similar to those of the phospholipids. This finding was of importance above all because of its simplicity. It proved that complex interactions between the head groups, which had been studied very intensively in liposomes[7,8], were of little significance in vesicle formation. Furthermore, positively charged vesicles became available for the first time.



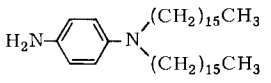
3, n = 11, 15, 17

The development of nitrogen-containing head groups continued by trying to localize reaction centers in the periphery of the vesicle membrane to provide a "substitute" for "inner" or "outer" redox-active chromophores such as chlorophyll and plastoquinone. The paraquat derivatives (*N,N'*-dialkyl-4,4'-bipyridinium salts), which have been used extensively in model systems for water reduction[9–11], were introduced as electron acceptors[12,13]. The amphiphile **4** (see Section 3) has two paraquat head groups and is, for example, suitable for vesicle formation. Paraquat can take over the function of plastoquinone, as shown in the biological charge separation depicted in Figure 2. *N,N*-dialkyl-*p*-phenylenediamine head groups (e.g. in the vesi-

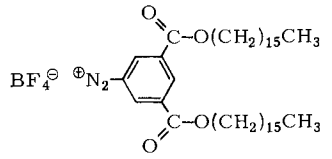
cle-forming compound **5**) act as electron donors in analogy with chlorophyll shown in Figure 2[14,15]. Light-destructable vesicles have also been prepared from amphiphiles with diazonioisophthalic acid head groups (e.g. **6**)[14].



4



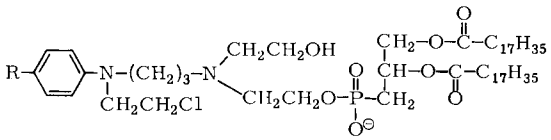
5



6

The reactive vesicles cited here all display the same special feature; they can only react with water-soluble reagents at the outer membrane surface. Paraquat derivatives can be reduced to viologen radicals with dithionite anions, phenylenediamine derivatives can be oxidatively converted into various dyes with water-soluble couplers, and benzenediazonium derivatives can be degraded by visible light after addition of water-soluble sensitizers (cf. Fig. 4). In all cases an almost quantitative yield of a new head group is obtained at the outer surface of the vesicle membrane, whereas the head groups which are on the inner side remain unchanged. Vesicle membranes exhibiting quantitatively asymmetrical arrangement of the head groups have thus become accessible for the first time. In the case of the semi-reduced paraquat vesicles, electron donors are found only on the outside and electron acceptors are located only on the inside; in the coupling reaction of the phenylenediamine vesicles only the outside is dyed oxidatively, and in the benzenediazonium compound nitrogen is at first eliminated solely by the outer surface.

Vesicles with extremely reactive aziridinium head groups can be synthesized if the aniline derivative **10a** is employed as a deactivated precursor in which the nucleophilicity of the nitrogen atom is markedly decreased by the formyl substituent[18]. Intramolecular substitution of the chlorine atom by the aniline nitrogen does not take place. Vesicles from **10a** are then activated by reduction with $NaBH_4$. The aniline methanol **10b** is produced which reacts with nucleophiles (e.g. proteins containing cysteine) due to the formation of the reactive aziridinium compound.



10a, R = CHO
10b, R = CH_2OH

Nitrogen-containing head groups have also been developed which can reversibly take up protons or metal ions. The ylide **11a** forms yellow (λ_{max} = 399 nm) vesicles which become colorless (**11b**, λ_{max} = 256 nm) on addition of acid. The bipyridinium derivative **12** is red (λ_{max} = 470 nm). As these compounds are water-insoluble, they are also suitable for incorporation into foreign vesicles in which the posi-

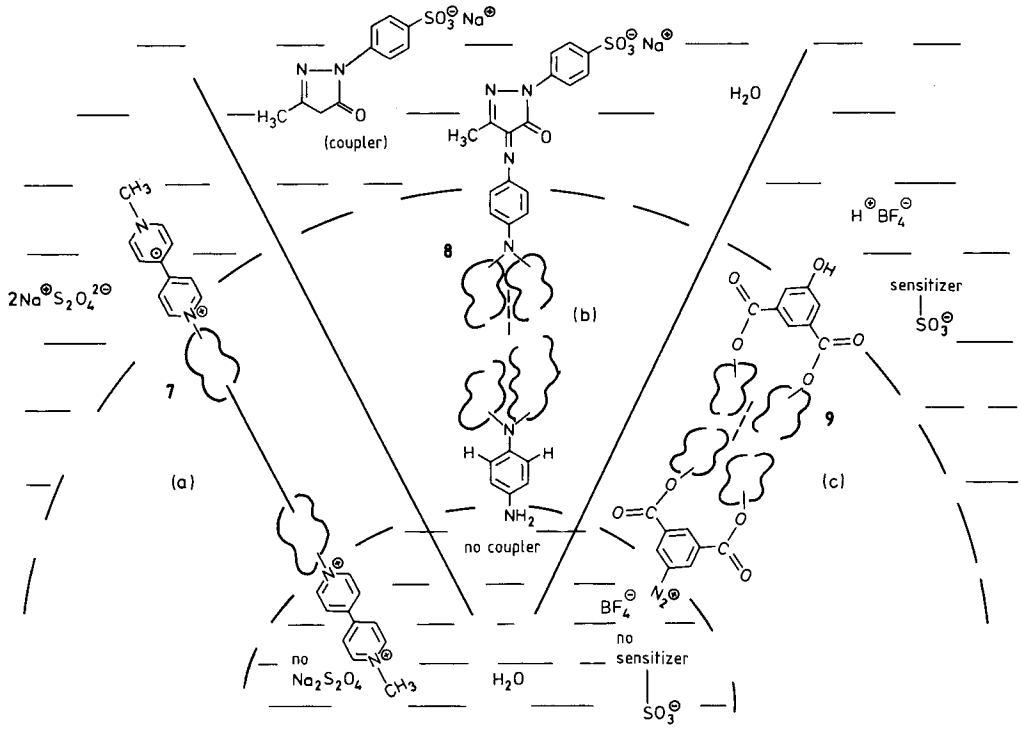


Fig. 4. Examples of reaction products (**7**–**9**) of "exovesicular" head groups of the amphiphiles **4**–**6**. The reactive "endovesicular" head groups are not accessible to membrane-insoluble reagents (examples a, b) or sensitizers (example c).

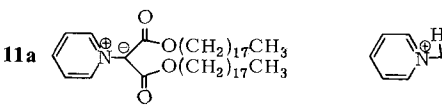
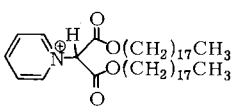
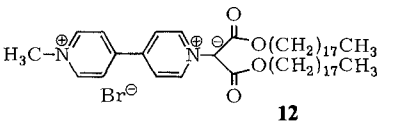
tively charged pyridinium residue lies next to the head groups of the host membrane. The pK_a for protonation of the ylide **11a** is very strongly influenced by the charge of the host groups. In electroneutral vesicles the pK_a value lies close to pH 6, in electropositive vesicles it is pH 4, and in electronegative vesicles it is pH 8[16]. These amphiphilic pH indicators can probably be utilized to detect domains (cf. Section 6).



11a

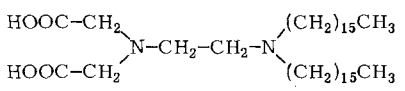


11b

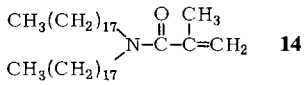


12

The vesicle-forming ethylenediamine diacetic acid derivative **13** complexes metal ions (e.g. $Cu^{2\oplus}$) from the aqueous phase[17]. Since metal ions cannot generally penetrate hydrophobic vesicle membranes, almost any redox-active ions can be fixed on the inner and/or outer membrane surfaces.



13



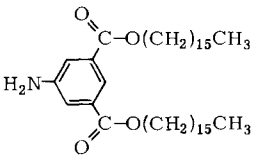
14

Various head groups of vesicle-forming amphiphiles have also been provided with vinyl substituents[19-23]. These terminal groups (e.g. **14**) can be polymerized either solely on the outer vesicle surface with water-soluble radical forming molecules, or on both surfaces with UV light. This does not introduce a new functionality into the vesicles but stabilizes them against the action of detergents and organic solvents (Fig. 5).

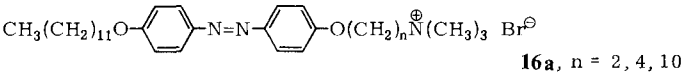
2.2. Hydrophobic Centers

Most synthetic vesicle-forming compounds contain two oligomethylene chains ($n > 8$) per head group in analogy with the phospholipids. The diameters of the hydrated head groups in these amphiphiles correspond to those of the hydrophobic chains and are in each case approximately 6 Å. In aqueous media the bilayer membranes thus only exhibit a low degree of curvature; this is regarded as one of the conditions for vesicle formation[24] (cf. Fig. 3). Fatty acid salts with only one oligomethylene chain and ammonium salts with three oligomethylene chains were known to form micelles without internal aqueous volumes and with a high degree of curvature[25-27]. However, there have also been reports of vesicles composed of mixtures of stearic acid and its salts[28] or of trihexadecyl(methyl)ammonium salts[29]. It is not possible to make reliable predictions about the aggregate structures of a new amphiphilic compound in aqueous media on the basis of the data currently available (cf. Section 8).

Whereas appropriate head groups react equally well and rapidly with water-soluble acids, bases, reducing and oxidizing agents and nucleophiles, reactive groups within the hydrophobic membrane are practically inaccessible for water-soluble reagents. This is reflected, for example, in the acid-stability of vesicle membranes in which the head groups and hydrophobic chains are linked by ester bonds. Vesicles from the amphiphiles **15**[14] and **22**[40] are stable for a matter of weeks in aqueous hydrochloric acid at pH 1.5. Basic dyes ($pK_a \approx 5$) are also not protonated even at pH = 1 if they are in vesicular solution[30].

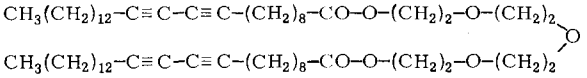


15



16a, n = 2, 4, 10

16b



17

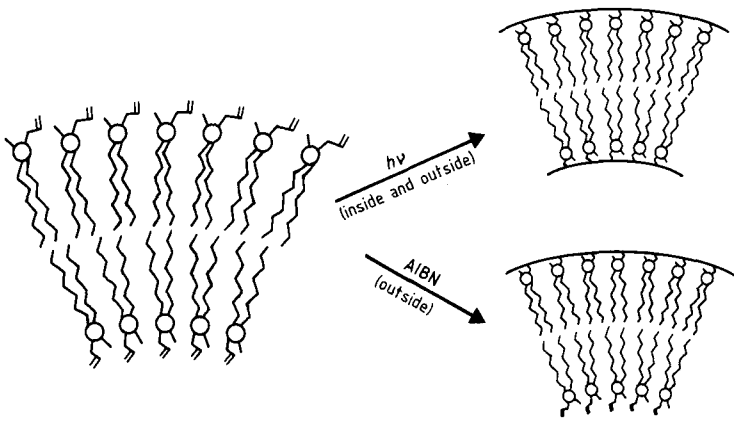


Fig. 5. Polymerization of monomeric amphiphiles at the vesicle surfaces. AIBN = azobisisobutyronitrile (water-soluble radical initiator).

Up to now, light has therefore been used exclusively as a "reagent" for reactions in synthetic hydrophobic membranes. Azomethine[31], azobenzene[45], diene or diyne[20,32-34] chromophores have been employed as reactive centers and were linked to the membrane-forming oligomethylene chains. The *trans*-azobenzene group in vesicles from **16a** underwent 50% isomerization when exposed to ultraviolet radiation to give the *cis* compound, the spherical vesicles simultaneously becoming lamellas. After reverse thermal isomerization, vesicles were reformed, i.e. the enclosed volume of water and the aggregation state of the vesicles undergo reversible changes upon irradiation. In the case of the diyne amphiphile **17** (see Section 8), when liquid crystalline BLMs are subjected to UV radiation (i.e. below the membrane melting point) colored polyene-yne chains are

formed in the middle of both halves of the bilayer. Dye formation does not occur in disordered aggregates.

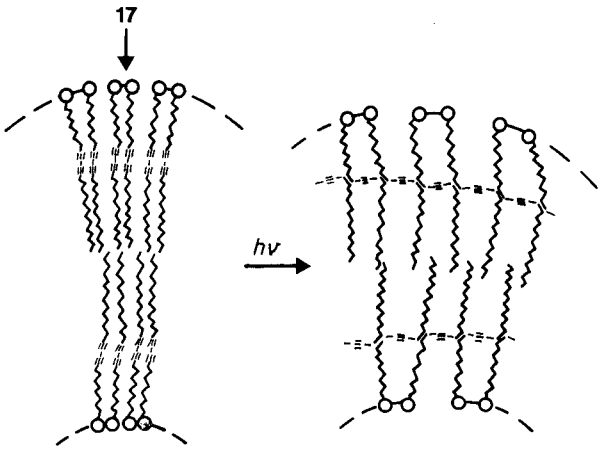

Fig. 6. Polymerization of the monomeric amphiphile **17** to colored polyeneynes in the hydrophobic vesicle membrane.

The membrane interior can be selectively modified in other ways: externally controlled domain formation (cf. Section 6) and regioselective incorporation of foreign molecules (cf. Section 3).

3. Peripheral and Integral Porphyrins in the Nine Regions of Vesicle Solutions

Aqueous vesicle solutions display nine regions or compartments (cf. Fig. 7):

① the outer water volume (bulk volume),
② the aqueous volume in the vicinity of the head groups (hydration sphere, Gouy-Chapman layer),
③ the outer head groups,
④ the hydrophobic membrane close to the outer head groups,
⑤ the interior of the hydrophobic membrane (in bilayer membranes this region can be subdivided into an inner ⑤$_{inner}$ and an outer half ⑤$_{outer}$),
⑥—⑨ the inner regions corresponding to the outer regions ④—①.

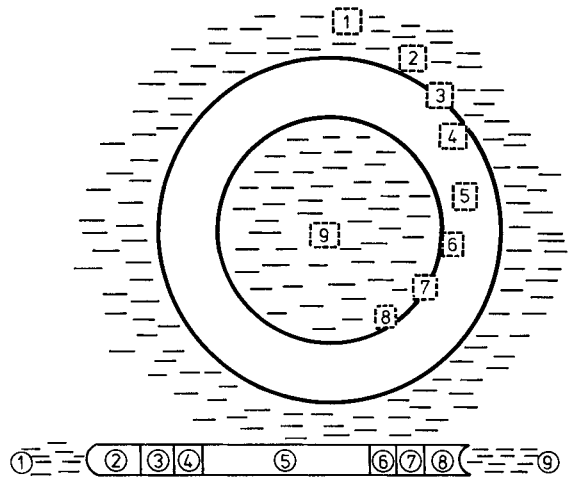

Fig. 7. The nine regions of vesicle solutions.

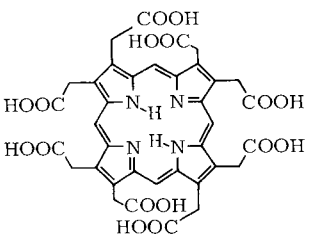
In the case of microvesicles (diameter ≈ 500 Å, amphiphile concentration $\leq 10^{-3}$ M), the volume of the hydrophobic membrane ⑤ and of the enclosed volume of water ⑨ are at least one hundred-fold smaller then the bulk volume ①.

If all or even some of the nine regions defined above could be selectively provided with reaction centers, one of the conditions for synthesizing organized systems without using membrane proteins would be fulfilled. According to Section 2, this has indeed been achieved for the head groups ③ and ⑦ and, in the special case of photochemical reactions, for the hydrophobic compartment ⑤. The other regions can be functionalized by regioselective incorporation of foreign molecules. In vesicles derived from amphiphiles with reactive head groups, the entire surface behaves as a reaction center; the shortest distance to foreign molecules dissolved regioselectively in the membrane is thus fixed, and it is therefore no longer necessary to form domains in order to perform vectorial reactions.

The regioselective incorporation of foreign molecules will now be described using experiments with two water- and membrane-soluble porphyrins as examples; one of these compounds—porphyrin octaacetic acid—is peripherally "attached" to regions ② or ④, the other—mesoviologen porphyrin—is integrally incorporated into the vesicle membrane.

At pH 7, porphyrin octaacetic acid **18**[35] exists in the form of the oligoacetate anion and is water-soluble. The longest wavelength absorbance band (α band) occurs at 616 nm. In the presence of electroneutral or negatively charged vesicles it dissolves in the "bulk" phase ①. When subjected to gel chromatography the porphyrin separates from the vesicle fraction. In solutions of positively charged vesicles the porphyrin oligoanion is bound to the surface of the vesicle membrane region ②. Gel chromatography does not result in separation of the vesicles from the porphyrin. The electronic spectrum of the porphyrin is identical in both cases; the α band is still found at 616 nm.

If aqueous solutions of **18** are acidified (pH 4.5), the porphyrin precipitates out. This precipitation does not occur in the presence of vesicles with surface charge, and the vesicles take up the porphyrin. If the pH is acidified to 5.2, the visible four-band spectrum of the neutral porphyrin chromophore changes to the three-band spectrum of the porphyrin monocation, i.e. one of the two pyrrolenine nitrogen atoms is protonated. Approximately half of the eight acetate substituents should be protonated. The porphyrin monocation is probably still dissolved in either ① or ②. At pH 5 the three-band porphyrin cation spectrum is replaced by the four-band spectrum of the non-protonated porphyrin base. The α band of the visible spectrum is now



18

to be found at 625 nm, which corresponds to the spectrum of porphyrin octaacetate in trichloromethane[36].

It can be concluded from the spectral shift that the porphyrin has migrated from the aqueous medium into the hydrophobic membrane region ④. A protonated nitrogen base is deprotonated on addition of acid. As far as we know, this is the first time that this effect has been observed. The process is completely reversible, i.e. on addition of sodium hydroxide solution the protonated porphyrin cation reappears. If the water-soluble porphyrin octaacetate is enclosed within the inner volume ⑨, acidification results in the same spectroscopic shift 616→625 nm but with some delay because pH equilibration across the membrane requires time (e.g. 15 minutes for lecithin membranes containing cholesterol).

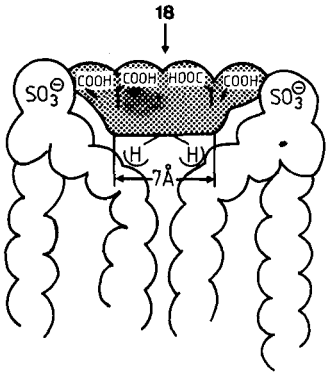


Fig. 8. "Porphyrin octaacetic acid" **18** floats on the hydrophobic surface of the vesicle. The hydrogen atoms directed downwards are from the central NH groups of the porphyrin.

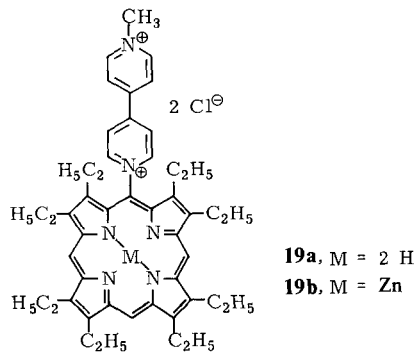
From the reversibility of porphyrin incorporation we deduced that the porphyrin is dissolved peripherally in the membrane (Fig. 8). It is localized in region ④ and not in region ②; this follows from the fact that the porphyrin base is not protonated in strongly acidic media. At pH = 1 the four-band spectrum of the free porphyrin base is still observed. In micellar solutions the pK_a of the porphyrins lies between 4 and 5. Complete formation of the diprotonated porphyrin dication occurs at pH 3 in all cases studied.

"Viologen porphyrin" **19a** is an example of an integral foreign molecule in vesicle membranes[37]. Its zinc complex **19b** is more soluble in water than trichloromethane. In vesicular solutions one would expect **19b** to be localized in regions ① and ②. In fact, the poor reactivity of the porphyrin chromophore towards water-soluble reagents indicates that it is completely taken up by the vesicle membrane. **19a** cannot, for example, be converted into the cation by addition of acid, nor can the metal be removed from the zinc complex **19b**. Since, on the other hand, the substituent in electroneutral or electronegative vesicles can be reduced to a radical by sodium dithionite, it is probably localized on the vesicle surface ③ (cf. Fig. 9). The porphyrin chromophore is accordingly located in regions ④ and ⑤. In analogy with the integral proteins[1,4], it can only be removed from the vesicle membrane if the membrane is destroyed by detergents or solvents.



19a, M = 2 H
19b, M = Zn

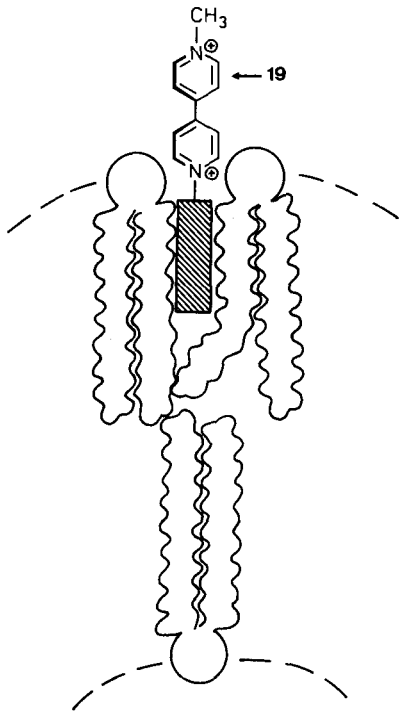


Fig. 9. "Viologen porphyrin" **19** sinks into the hydrophobic membrane of the vesicle.

We have described the special solution behavior of the two porphyrins **18** and **19** in detail to show that vesicular solutions can behave totally differently from micellar solutions or two-phase systems. Dissolved molecules can be localized either entirely within the membrane or in the aqueous medium; distribution between the two phases can be suppressed. This means that another prerequisite for constructing organized systems without proteins has been fulfilled.

4. Monolayer Vesicle Membranes (MLM Vesicles)

If vesicles are prepared using amphiphiles which have hydrophilic head groups at both ends of the hydrophobic chains (trivial name: bolaamphiphiles[38], so called because their shape is similar to that of a South American sling), the resulting membranes consist of a single molecular layer (monolayer lipid membrane, MLM). The MLM vesicles have three advantages compared to the customary BLM vesicles:

1. BLM vesicles grow by fusion and usually precipitate out after a few days. Fusion is hindered in MLM vesicles because the inner hydrophilic head can hardly penetrate the hydrophobic membrane, and it is therefore almost impossible for the amphiphile to migrate from one vesicle to another (cf. Fig. 10). MLM vesicle solutions are stable for a long time under appropriate conditions.

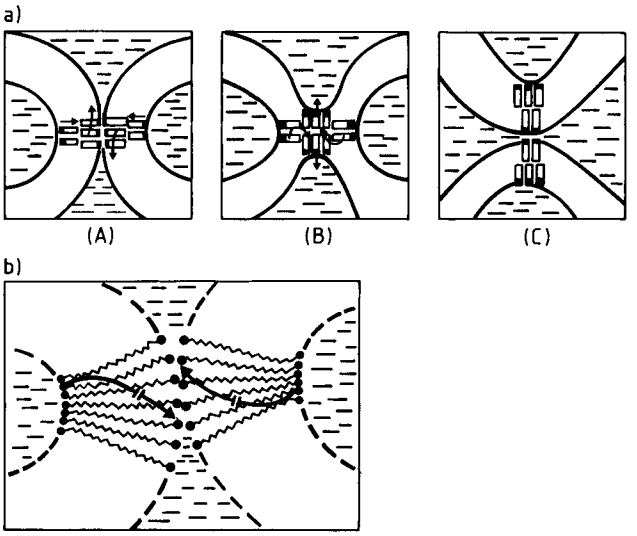

Fig. 10. a) If the vesicle membranes are to fuse, the molecules of the BLM must be able to rotate (or diffuse): (A) aggregate of two vesicles, (B) bridge formation, (C) passage formation (fusion).—b) In monolayer vesicles aggregation is followed by very slow or no diffusion.

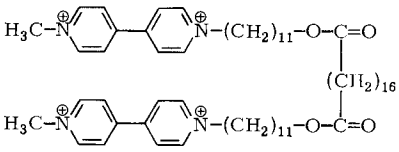
2. Monolayer membranes can be considerably thinner than bilayer membranes. The thickness of the thinnest known MLM including the two head groups is 28 Å; the hydrophobic component is less than 20 Å thick. Such thin membranes are of interest because they can be bridged by 15—20 Å long pore-forming compounds. Short "pore-formers" are synthetically more accessible than the 30—40 Å long, pore formers required for BLMs. Many natural products (e.g. porphyrins, carotenes, steroids) have a molecular length of 15—20 Å. Suitable derivatives and their molecular complexes[2,39] can be employed to construct selective systems for conducting electrons, ions, and water-soluble molecules.
3. α,ω-Bisamphiphiles with two different head groups can form totally asymmetrical vesicle membranes: in MLM microvesicles the large head groups (diameter ≤500 Å) form the outer surface, the small head groups the inner surface[40]. In BLM vesicles composed of two different amphiphiles, one type of molecule can only be partially enriched in one half of the bilayer[41].

4.1. MLM Vesicle Formation by "Partial Precipitation"

Aggregates of the symmetrical bolaamphiphile **20a** with two viologen head groups become asymmetrical and exhibit curvature if the counterions are partially exchanged[13]. If, for example, the water-soluble tetrachloride **20a** is titrated with one mol equivalent sodium perchlorate, microvesicles of uniform size are formed spontaneously. The water-insoluble tetraperchlorate **20c** is produced from the monoperchlorate **20b** by adding three mol equivalents perchlorate, and as is to be expected, the curvature of the vesicles disappears. Monolayer crystals can then be observed under the electron microscope (Fig. 11).



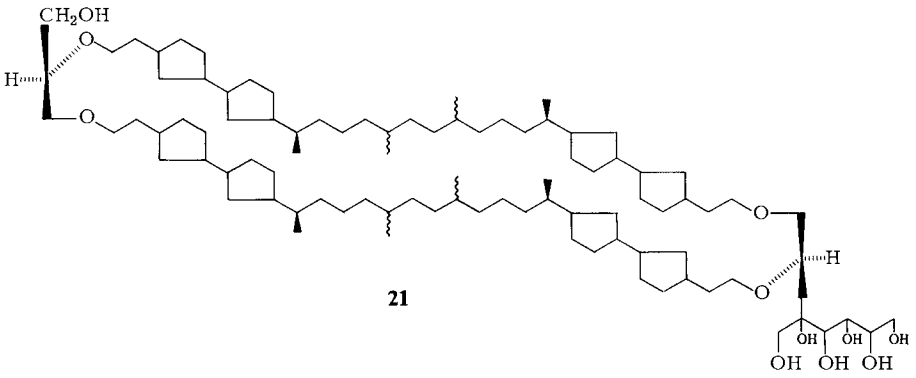
20a: 4 $Cl^{\ominus}$
20b: 3 $Cl^{\ominus}$, $ClO_4^{\ominus}$
20c: 4 $ClO_4^{\ominus}$

f

4.2. Asymmetrical Vesicles-MLMs

The acid- and light-stable membranes of the archaebacterium *Caldariella acidophila* contain the macrocyclic tetraether **21**, which has a (small) glycerol and a (large) nonitol head group. Measurements of asymmetrical current-voltage curves and the specific capacities of black lipid membranes indicate that artificially synthesized membranes are composed of a single molecular layer in which the large heads are localized on one side of the layer and the small heads on the other[43]. This finding seems reasonable in light of the fact that the nonitol terminal with its six hydroxyl groups should crystallize out from *n*-alkane dispersions which are used preferentially for preparing black membranes. Vesicles can be synthesized by means of the partial formation of insoluble salts as described in Section 4.1; similarly, the formation of an asymmetrical membrane begins with the one-sided aggregation of the bolaamphiphile head groups.

The same principle has been adopted for the preparation of an asymmetric membrane consisting of the macro-



21

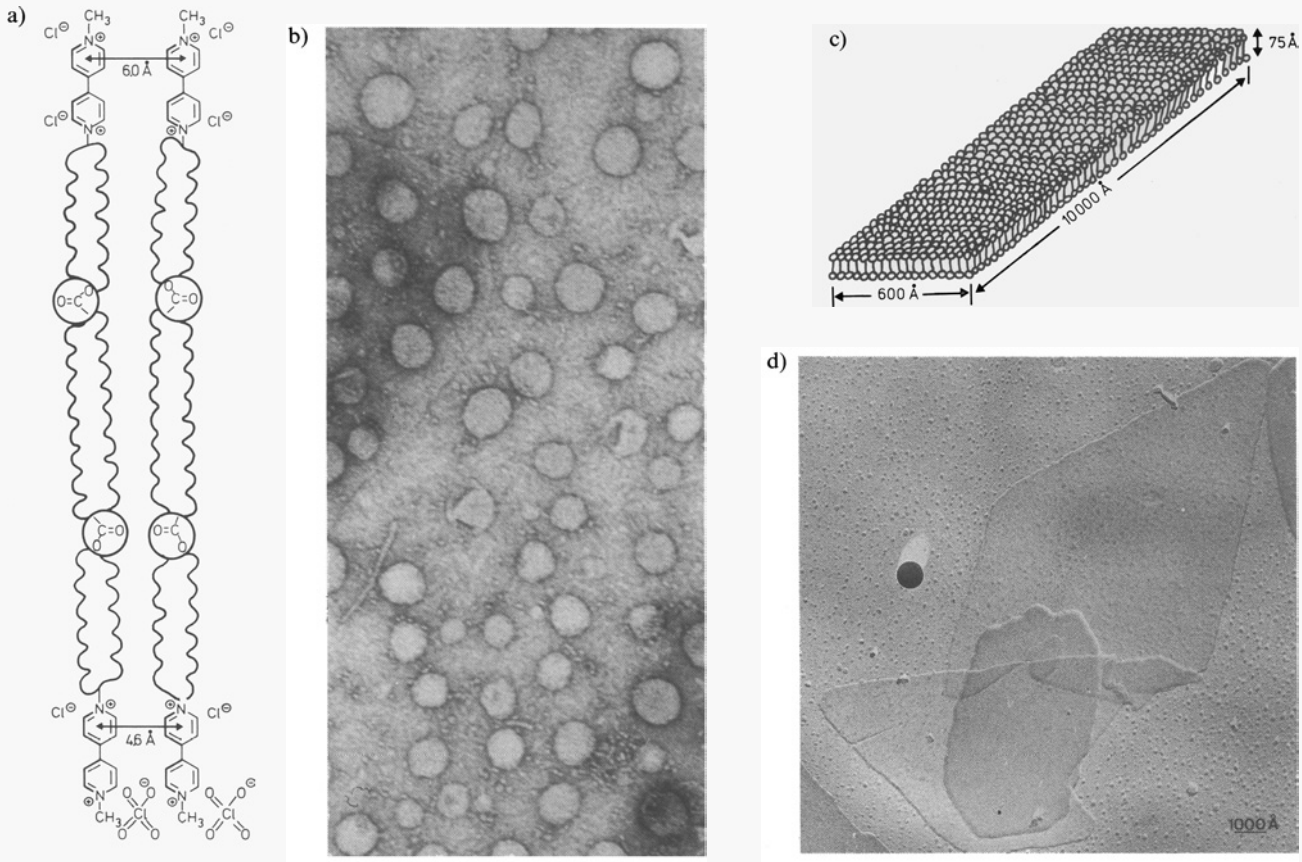


Fig. 11. a) The curvature of monolayer vesicles **20b** is produced by partial formation of insoluble salts (perchlorate inside).—b) Electron micrograph of vesicles from **20b**.—c) The tetraperchlorate **20c** forms monolayer crystals.—d) Electron micrograph of obliquely shadowed monolayer crystals. The white shadow is a measure of the layer thickness. Diameter of latex spheres: 900 Å; thickness of the crystal layer: <100 Å.

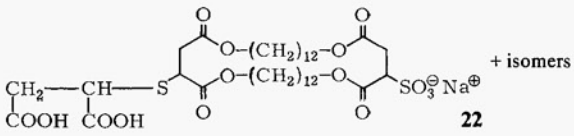
tetrolide **22** with a (small) sulfonic acid and a (large) thiosuccinic acid head group[40]. It has been shown that more than 98% of the sulfonic acid head groups lie on the inner side of vesicles derived from this asymmetrical bolaamphiphile (cf. Fig. 12).



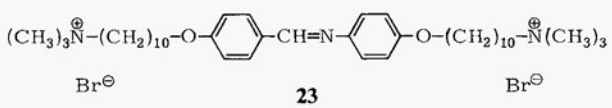
22

This also proves that this membrane is composed of a monolayer[42]. Small-angle scattering measurements with solid **22** gave a thickness of 28 Å for the entire MLM; this corresponds exactly with the all-*anti* conformation of the macrocycle described above. Strangely enough, preliminary ^{1}H-NMR measurements on monolayer vesicles indicate unusually high mobility of the oligomethylene chains at room temperature. This phenomenon is currently being investigated in detail.

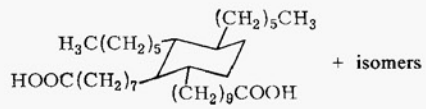
4.3. MLM Vesicles with a "Spacer"

Kunitake et al.[31] were only able to obtain the first vesicles from a symmetrical bolaamphiphile, the bisammonium bromide **23**, when cholesterol was added to the emulsion during ultrasonification. The water-insoluble steroid is dissolved in the membrane and is responsible for the "curvature" of the vesicles. A similar effect has been observed in the cheapest of the bolaamphiphiles, the commercially available dimeric acid **24**. After ultrasonic treatment this compound does not form vesicles, and the milky suspension of **24** does not become clear even at very low

Fig. 12. An asymmetrical monolayer vesicle membrane from the bolaamphiphile **22**.



23



24

concentrations ($\approx 10^{-5}$ M). If, however, a slight excess of the "spacer" cyclohexylamine (cf. Fig. 13) is added, clear vesicle solutions or clear gels are obtained without any difficulty at concentrations of up to 10^{-2} M[44].

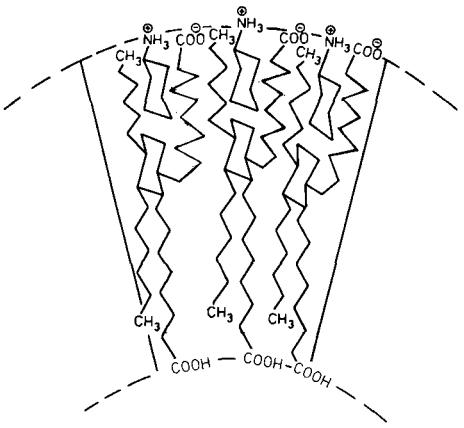


Fig. 13. An example of the "wedge" effect of additives (in this case cyclohexylamine) in the formation of monolayer membranes (in this case from "dimeric acid" **24**).

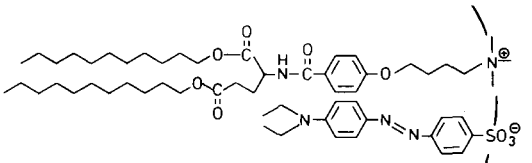
5. Chiral Superstructures

The vesicle membranes from amphiphiles with chiral head groups are of interest because it is to be expected that chiral superstructures on the membrane surface can react stereoselectively with foreign molecules. The liquid-crystalline vesicle surface would thus have acquired one of the properties of biological receptor proteins. *Kunitake* et al.[45] found indications of a chiral superstructure in vesicles from the glutamic acid amphiphile **25**, which has two oligomethylene chains and an aromatic chromophore in its head group. Circular dichoroism (CD) measurements at room temperature reveal maxima with extremely high specific rotation values ($\Theta_{220} = 360\,000$, $\Theta_{260} = -400\,000$). If the vesicle solution is warmed above the phase transition temperature of 32 °C, a single maximum of much lower intensity appears ($\Theta_{245} = 6000$). Non-vesicular aggregates, which are found below the critical vesicle concentration of 5×10^{-6} M, only show slightly elevated specific rotation values ($\Theta_{260} = -22\,000$). Similar effects have been demonstrated in an alanine derivative **26** with a tetraalkyl ammonium head group and a biphenyl chromophore; this compound forms liquid crystalline platelet-shaped aggregates, not vesicles[46].

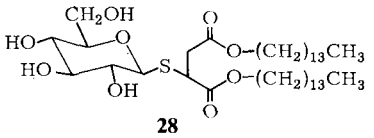
Intensive induced circular dichroism spectra are found when methyl orange is dissolved in chiral vesicles where it is anchored in the membrane by a hydrophobic side chain[47]. The diazo dye head group is probably squeezed into the amino acid surface lattice. Remarkably, an extremely large bathochromic absorbance shift is also observed when methyl orange **27** is incorporated into vesicles from **25**[48]. Below the membrane melting point (20—25 °C) there is a maximum at 488 nm which is displaced to 424 nm at 28—29 °C. This 64 nm shift only occurs when the "hydrophobic spacer" contains a tetramethylene group between the charged head group and the membrane. The methyl orange **27** is probably localized in this ill-defined interspace (region ② or ④?) and fills the gaps left by the narrow "spacer".



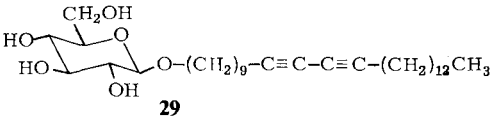
25 **27**

Fig. 14. Regioselective incorporation of methyl orange **27** at the chiral surface of vesicles derived from the glutamic acid amphiphile **25**.

Vesicles with carbohydrate head groups are promising chiral receptors because the cyclic rigid conformation and the existence of at least four centers of asymmetry offer particularly high selectivity. Such vesicles have also been prepared from **28**[49] and **29**[50], but as far as we are aware nothing is known about their interactions with water-soluble compounds.



28

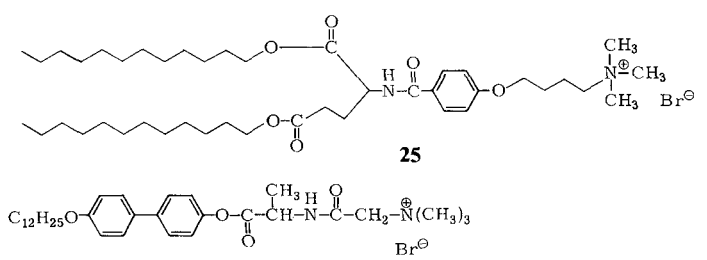


29

6. Domain Formation

If proteins are not employed to synthesize functional vesicle membranes, other membrane building blocks have to be developed which combine with one another within an inert membrane to produce reactive domains. Only when this has been achieved will it be possible to couple two or more reactions in a vectorial reaction chain in synthetic membranes. Mention should be made of the studies of *Kunitake* et al., who succeeded in verifying and deducing the existence of two types of domain formation.

The first method of systematically organizing parts of the membrane interior is the externally controlled displacement of the membrane building blocks. In mixed BLM vesicles from (inert) dihexadecyl(dimethyl)ammonium bromide and the (reactive) azobenzene amphiphile **16b**, the latter compound exists as a protonated monomer at pH 4 ($\lambda_{max} = 355$ nm). At pH 7, **16b** aggregates in vesicles derived from **3**, and the absorbance maximum shifts to 312 nm, i.e. domains are formed. If copper sulfate is ad-



25

26

ded to the solution at pH 4 the maximum is also found at 312 nm[51]. Sodium sulfate has an analogous effect, but copper chloride is ineffective. This formation and dissolution of amphiphile aggregates in a membrane which is controlled by external protons or divalent anions is the first example of (reversible) domain formation in which the head groups act as receptors (cf. Fig. 15).

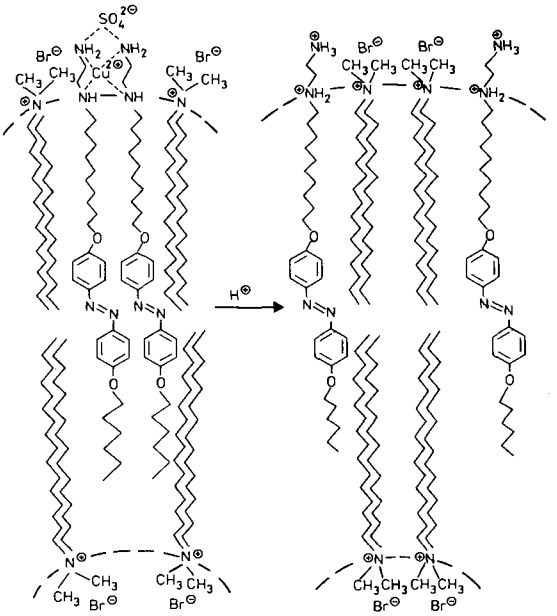


Fig. 15. Domain formation due to the interaction of divalent ions with ethylenediamine head groups. Addition of strong acids destroys the domains.

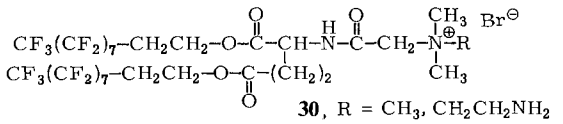
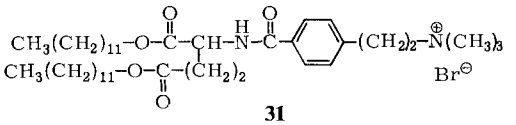
Vesicle membranes from mixtures of amphiphiles with oligomethylene and oligoperfluoromethylene chains also offer interesting possibilities. It has been demonstrated that fluorinated (**30**) and hydrocarbon (**31**) vesicles do not fuse with one another[52]. This is due to the known "lipophobicity" of fluorinated hydrocarbons[53]. It should be possible to introduce perfluorinated domains into hydrocarbon membranes; the hydrocarbon chains would then bring about (irreversible) aggregation.

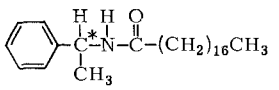


30, R = CH_3, $CH_2CH_2NH_2$



31

Finally, mention should be made of a report by *Arnett* et al.[54] in which he detected the formation of domains of pure enantiomers in a racemic monomolecular surface layer of **32** by surface pressure measurements. Similar phenomena probably occur in vesicles with chiral head groups (cf. Section 5), but as yet no methods are available for proving that this is the case.

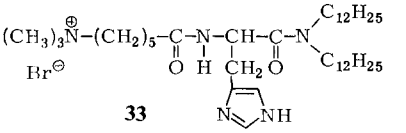


32

7. Vesicle-Specific Reactions

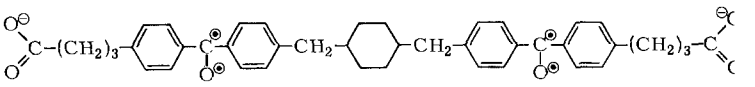
Reactions will now be described which depend on the ordered structure of vesicle membranes. The cholesterol ester of 4-imidazolecarboxylic acid catalyzes the hydrolysis of *p*-nitrophenyl palmitate if the catalyst and substrate are both introduced simultaneously into tetraalkylammonium vesicles. If vesicles containing the catalyst are mixed with vesicles containing the dissolved substrate, catalysis does not take place[55]. Such differences between the rates of inter- and intravesicular reactions are generally found if the reaction partners can only diffuse slowly out of the vesicle membrane.

p-Nitrophenyl acetate is hydrolyzed by vesicles with SH-containing head groups at pH 7.6 and is bound approximately 1600-fold more tightly than by the comparable micelles[56]. The "hardness" of the vesicle membrane as a reaction matrix as compared with the "soft micelles" is also substantiated by the enantiomer-selective hydrolysis of membrane-dissolved phenylalanine esters by the chiral histidine head groups of **33**. The enantiomer selectivity $k_{obs}(L)/k_{obs}(D)$ in vesicles is 4.4, and in micelles 2.7[57]. If the substrate to be hydrolyzed is fixed in the membrane by means of oligomethylene chains, the enantiomer selectivity can reach values of up to 5.7[58].



33

Contrary conclusions about the "hardness" of the vesicle membrane can be drawn from the results of the photochemical incorporation of the benzophenone derivative **34** into oligomethylene chains in vesicles. The excited triplet state of the benzophenone attacks the carbon atoms C6-C12 of a didodecyl phosphate vesicle at random, i.e. **34** takes up the same statistically distributed positions as are found in micelles. The anticipated regioselectivity has only been achieved in planar bilayers[59]. At present there is no plausible explanation for the disordered distribution of **34** in vesicles.



34

8. The Structure of Membrane-Forming Molecules

Both thermodynamic and kinetic models for the formation of vesicle membranes[1,25,60] together with comparison of the structures of molecules and their aggregates in aqueous media[61] assume that only amphiphiles form spherical membranes. We do not want to discuss these preliminary "relationships", which do not lend themselves to generalization, and would rather show that this first limitation ("only amphiphiles form vesicle membranes") is not justified.

For many years, *Chang* has been studying "artificial cells" with membranes composed of various water-insoluble polymers[62-64]. They are prepared by shaking a solution of a water-insoluble polymer (nylon, polystyrene, cellulose nitrate) in organic solvents with a relatively concentrated aqueous hemoglobin solution. Well-defined, spherical membranes having a thickness of 200 Å and diameters of up to 0.1 mm are then found in the aqueous phase. Hemoglobin is enclosed within the interior of these cell-like structures. When the organic solvent is removed the spherical aggregates are stable for a long time. Small polar molecules such as urea, but not proteins, can permeate artificial cells made of nylon. "Artificial cells" make highly suitable dialysis membranes on account of their large membrane surface area.

The mechanism responsible for the formation of "artificial cells" has not, as far as we know, been discussed in the literature. We presume that the hydrophobic regions of the hemoglobin take up the polymers and thus transfer them to the aqueous phase. Here the "hydrophobized" polymer complexes aggregate to form sealed membranes. Once these have been formed they become spherical due to the internal colloid-osmotic pressure exerted by the enclosed hemoglobin: the aggregate surface area increases and the membrane becomes thinner. The internal hemoglobin remains enclosed, the hemoglobin in the outer aqueous phase takes up more polymer, and the process is repeated (cf. Fig. 16).

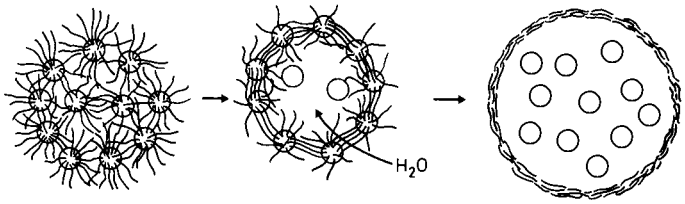


Fig. 16. Hypothetical mechanism for the formation of artificial cells from water-soluble (O) and water-insoluble (∿) polymers.

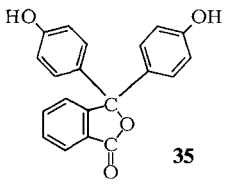
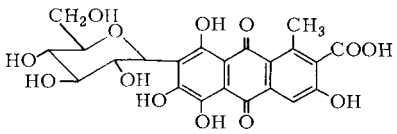
The "microspheres" described by *Fox* are formed analogously; they consist of "proteinoids", and their appearance under the microscope is similar to that of the "artificial cells"[65]. A "protenoid" is a statistically assembled polyamide which is produced by heating α-amino acid mixtures at 100°C in aqueous phosphoric acid. If the mixture is then cooled slowly, the protenoids do not precipitate out but spontaneously form microspheres with a diameter of approximately 0.1 mm. These protenoid aggregates are also osmotically active and are regarded as the simplest model of the "primitive cell"[66]. They may be formed by the aggregation of hydrophobic proteinoids with each other and with hydrophilic components containing ions; the hydrophobic components could float on the surface of the aggregate, in analogy with the mechanism in Figure 16, to form a sealed hydrophobic skin. This skin could then expand to a membrane as a result of penetration of water into the internal electrolyte solution.

Some observations show[67] that low molecular weight non-amphiphiles which are sparingly soluble in water dissolve when treated with ultrasound and appear as spherical membranes under the electron microscope. Phenolphthalein **35** and carminic acid **36** are examples of such compounds (see also **17**).



35



36

The objection can be made that "artificial cells" derived from non-amphiphiles are of minor interest because their membranes are probably in a state of disorder. There should not be any striking differences between the membrane surface and the interior. These membranes are probably unsuitable for the organization of several reaction centers. It is, nevertheless, still important to know that the formation of spherical membranes under phase-transfer conditions or after ultrasonic treatment of aqueous suspensions is an inherent property of many water-insoluble compounds.

9. Summary and Outlook

Some intermediate steps have been made towards the ultimate goal that we have defined as "the synthesis of functional vesicles without proteins":

- electron acceptors and donors (head groups, metal ions) can be fixed at defined distances from redox-active dyes in the membrane (metalloporphyrins)
- light can produce structural changes in the hydrophobic membrane (*trans→cis* isomerization of azobenzene units)
- asymmetrical vesicle membranes are accessible ("monolayer lipid membranes" MLM)
- vesicles with chiral head groups can differentiate between enantiomers which distribute themselves between the aqueous phase and the membrane (stereoselective hydrolysis)
- domains can be produced without involving proteins (complexing head groups)
- "dimeric acid" **24** is a cheap amphiphile which can be used for synthesizing large quantities of vesicles (approximately DM 5.00 per kg).

Using these results as a starting point, it seems that the chances of achieving various targets are promising. Individual, complex, functional vesicle membranes have already been described: in *Shilov*'s system for reducing water with the aid of visible light[9-11] the colloidal platinum, the "sacrificial" reducing agent, the dye, and the paraquat have been localized in different vesicle regions (cf. Section 3) and water cleavage has been studied[68,69]. The efficiency and stability of this system are, however, still unsatisfactory. Modified lecithin vesicles have been tested with a view to studying the organ-selective transport of pharmaceuti-

cals in the bloodstream[70]. We are, however, not aware that they have been used in commercially available preparations. Both problems—the light-induced cleavage of water and the transport of pharmaceuticals—are currently under detailed investigation. It is to be hoped that the new synthetic systems will provide practical solutions.

Some new aspects which have arisen from the results of the previously discussed studies seem even more interesting:

- It should be possible to introduce negatively charged polyelectrolyte cores into positively charged vesicles. Vesicles with a nucleic acid core could be of use, e.g., for transporting genetic material through cell membranes.
- Simple pore-forming compounds[2] can be conceived for vesicles with thin membranes (< 20 Å); these substances aggregate to give an ion-permeable pore which can be controlled either by the pH or by signal molecules. Suitable pores in the membrane should provide water-soluble reagents with access not only to the internal aqueous volume of the vesicle but also to the hydrophobic membrane region surrounding the pore. Bases which can be protonated could then, for example, be reversibly expelled from the membrane. The vesicles would act as extremely small, sealable receptacles.
- Using the novel, water-insoluble amphiphiles it should be possible to coat hydrophobic surfaces (e.g. those of plastics) with polar, monomolecular layers.

Realization of these examples will take several years. In most cases not enough is known about the properties of the new amphiphiles and their aggregates to be able to construct complex systems. It is, however, now already evident that the synthetic membranes prepared by *Kunitake* have opened up an interdisciplinary field with interesting prospects.

Our own studies have been supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Kommission für die Förderung der Forschung und des wissenschaftlichen Nachwuchses of the Freie Universität Berlin, and Henkel KGaA, to whom we are extremely grateful. The following competent and imaginative young chemists are thanked for their individual contributions: Dr. H. Bartsch, Dr. E. Baumgartner, H. H. David, K. Ellermann, D. Fritsch, W. Grabow, D. Hosseinpour, W. Kaufmann, V. Koesling, W. Krüger, F. Kühl, T. Lehmann, A. Link, Dr. U. Meding-Angrick, G. Penzlin, G. Pöschl, J. Rosenberg, G. Schönberger, U. Wanja, and W. Weimann, who in examination projects, Diplomarbeiten and dissertations opened up new scientific territory.

Photochemical Hole Burning: A Spectroscopic Study of Relaxation Processes in Polymers and Glasses

By Josef Friedrich and Dietrich Haarer*

Photochemical hole burning is a special type of saturation spectroscopy in the optical domain having many analogies with NMR methods. The holes, which are burnt with laser irradiation, appear as small indentations in the absorption spectra of dye molecules which are doped into a polymer or glass in minute concentrations. Based on their narrow line width, photochemical holes can be regarded as highly sensitive spectroscopic probes. They can be used to detect small perturbations of the system by external parameters, giving rise to line-shifts and broadenings. Besides the many well documented, spectroscopic applications of hole burning, it may offer interesting future developments for the spectroscopy of biomolecules and for high-density data storage.

1. Introduction

The optical properties of many crystalline and polymeric organic solids are frequently dominated by guest molecules. Guest molecules can either be impurities or doping materials. It has, for example, been known from the early days of low temperature spectroscopy of crystalline organic materials that impurities in low concentrations (10^{-4} mol/mol) can dominate the emission spectra of crystalline host matrices[1,2].

This article deals with hole burning spectroscopy of organic host-guest systems. This spectroscopic method was discovered in 1974 by two Soviet research groups[3-5]. Photochemical hole burning (PHB) spectroscopy is a special kind of saturation spectroscopy: With narrow-band excitation very narrow and stable photochemical holes can be "burned" into the absorption bands of guest molecules. From the line width and line shape of these holes one can obtain information about both the host and guest systems (examples of photochemical holes are shown in Figs. 14, 19, 30, and 31). Most attractive is the very high optical resolution of the hole burning method. In this article we shall mainly focus on the spectroscopy of glasses and polymers, since the high resolution aspects of the new method are especially useful in this field.

In this context we mention that organic host-guest systems are also interesting from the viewpoint of applications. Examples are sunlight-collectors which use organic molecules in polymer or glass matrices to scatter diffuse sunlight into a small solid angle[6,7]. Other, more complex host-guest systems, which are still not completely understood, are polymeric photoconductors[8,9], photographic layers[10], and biological light-harvesting pigments[11].

2. Energy Bands, Localized Excitations, and Phonons

The optical properties of organic solids which are doped with dye molecules are determined both by the absorption

[*] Prof. Dr. D. Haarer, Prof. J. Friedrich
Physikalisches Institut der Universität
Postfach 3008, D-8580 Bayreuth (FRG)

spectrum of the guest and that of the host. The host states are characterized by bands of bandwith B (Fig. 1). The origin of the band states is the close packing of the host molecules leading to a strong molecular interaction. Band states have dispersive character, i.e. the excitation energy is, in most cases, delocalized over many molecules[12,13] (excitonic state). In contrast to the band states, the excited states of the guest molecules are localized. The localized states are referred to as matrix-isolated because they are more or less decoupled from the host states. Many systems which absorb in the visible region are matrix-isolated. The host system is frequently chosen such that its intrinsic absorption is in the UV region of the spectrum. In the following we will focus our attention on matrix-isolated systems and thus do not have to deal with the band-states shown in Figure 1. We will, instead, focus on the states S_1, S_2 which arise from doping and which are termed extrinsic and will investigate their electronic, vibronic (ν), and phonon satellites. Examples of such systems are amorphous polystyrene (matrix) doped with phthalocyanine (guest) or crystalline durene (1,2,4,5-tetramethylbenzene) (matrix) doped with naphthacene (guest). The concentrations of the dopant are usually very low (10^{-4} to 10^{-6} mol/mol).

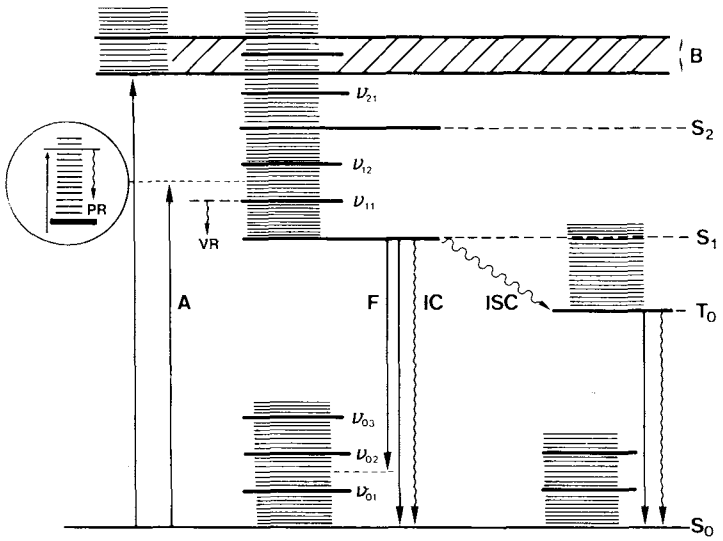

Fig. 1. Energy level scheme of a dye molecule in an organic glass or polymer matrix. B: Electronic band states of the host system (exciton band); S_i, T_i: Singlet and triplet levels of the guest molecule; υ_{ij}: Vibrational levels of the guest molecule in its electronic state i. The levels which appear as a quasi-continuum correspond to phonon states of the host. PR: phonon relaxation; VR: vibrational relaxation; IC: internal conversion; ISC: intersystem crossing; A: absorption; F: fluorescence.

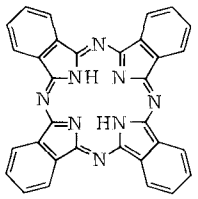
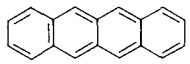
The probability per unit time of an optical transition from the ground state S_0 to an electronic state of the guest molecule (for instance S_1) can be calculated via Fermi's golden rule:

$$P_{10} = \frac{2\pi}{\hbar} |\langle \Psi_1 | \hat{H}_{rad} | \Psi_0 \rangle|^2 g(E - E_1) \tag{1}$$

where Ψ_0 is the electronic wave function of the ground state S_0, Ψ_1 is the wave function of the first excited state, and $g(E-E_1)$ is the normalized absorption line shape



Phthalocyanine



Naphthacene

function. $\hat{H}_{rad}$ characterizes the interaction of the molecule with the radiation field of the light source:

$$\hat{H}_{rad} = -\hat{\mu} \cdot \vec{E}(t) \tag{2}$$

Equations 1 and 2 show that the transition probability P_{10} is proportional to the square of the transition dipole moment $\vec{\mu}_{10} = \langle \Psi_1 | \vec{\mu} | \Psi_0 \rangle$, where $\vec{\mu}_{10}$ is related to the oscillator strength f_{10} of the transition under consideration (see e.g. [14]):

$$|\mu_{10}|^2 = f_{10} [3\hbar e^2/(4\pi m c \bar{\nu}_{10})] \tag{3}$$

where $\bar{\nu}_{10}$ is the optical transition energy in cm^{-1}.

The oscillator strength f_{n0} can be obtained directly from measurements of the extinction coefficient ε_{n0}. The index n labels the transition $n \leftarrow 0$ whose absorption spectrum is being considered. One can write

$$f_{n0} = \ln 10 \cdot \frac{4\varepsilon_0 m c^2}{e^2 N_A \cdot n_0} \int_{-\infty}^{\infty} \varepsilon_{n0} \, d\bar{\nu}_{n0} \tag{4}$$

where N_A is Avogadro's number, n_0 is the refractive index of the material, and ε_0 is the dielectric constant.

So far, only electronic excitations have been considered (with the additional assumption of dealing with allowed transitions). Besides the electronic excitations, molecular spectra also reflect vibrational degrees of freedom. The relative intensity of the electron-vibration bands is given by the Franck-Condon principle, which determines the coupling of the intramolecular vibrations of the guest molecules, which have well-defined energies up to several thousand wave numbers; the same principle also determines the coupling of lattice modes *(phonons)* to the electronic transition. Typical phonon energies lie in the range 10 to 100 cm^{-1}; they have a continuum character (Fig. 1). In the following we consider the coupling of a "normal lattice mode" q_i of frequency Ω_i. Figure 2 shows two electronic energy levels E_0 and E_1. On each of these levels one can build up excitations of harmonic oscillators with energies $\hbar\Omega_i$. As can be seen from the figure, an electronic excitation from E_0 to E_1 leads to a change in equilibrium distance from $q_i = 0$ in the ground state to $q_i = q_{i0}$ in the excited state. The corresponding energy change is proportional to the force constant $K_i = m_i \Omega_i^2$ of the harmonic oscillator with frequency Ω_i and mass m_i:

$$E_{pi} = \tfrac{1}{2} K_i q_{i0}^2 = \tfrac{1}{2} m_i \Omega_i^2 q_{i0}^2 \tag{5}$$

The energy E_{pi} corresponds to half the Stokes-shift between the maxima of the absorption and emission spectra.

If one wants to calculate optical spectra, the transition probabilities to the vibrational levels $\Phi_{ni}(\nu)$ have to be cal-

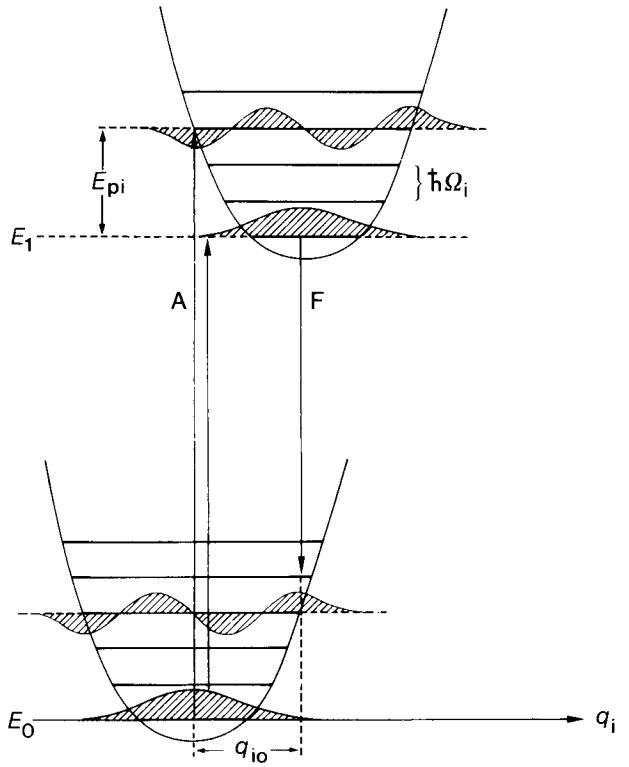


Fig. 2. Energy diagram for interpreting the phonon sideband spectra in terms of configurational coordinates: q_i represents a normal mode of the lattice. The arrows correspond to zero-phonon and three-phonon transitions in absorption and emission, respectively (see text).

culated. Here, the index n stands for the electronic excitation, index i labels the i-th lattice mode of frequency $\hbar\Omega_i$, and v labels the number of excited vibrational quanta in the mode i.

To simplify the calculation, several approximations have to be introduced. The first, is the *harmonic approximation,* which assumes that all lattice modes are independent of another and are described by parabolic potentials; the second, is the *low temperature approximation,* which assumes that in the lowest electronic state only the zero point vibration is excited; the third approximation is the assumption of *linear electron-phonon coupling,* which assumes identical force constants in the ground state E_0 and excited state E_1.

In most experiments the above assumptions are well fulfilled. (Some details have to be modified for calculation of the optical line widths.)

The transition probability $\Psi_1 \leftarrow \Psi_0$ can be calculated using the Franck-Condon principle, which states that the electronic excitation is so rapid that the lattice coordinates q_i cannot follow. Hence, in Figure 2 the optical transitions can be symbolized by vertical arrows. With the above assumptions the transition probability can be calculated from the lowest vibrational state (00) to the vth level of the lattice mode q_i in the excited electronic state

$$P_{1i,00}(v) = \frac{2\pi}{\hbar} |\langle \Psi_1 \Phi_{1i}(v)|\hat{H}_{rad}|\Psi_0 \Phi_{0i}(0)\rangle|^2 g(E - E_1 - v\hbar\Omega_i)$$

$$= \frac{2\pi}{\hbar} |\langle \Phi_{1i}(v)|\Phi_{0i}(0)\rangle|^2 |\langle \Psi_1|\hat{H}_{rad}|\Psi_0\rangle|^2 g(E - E_1 - v\hbar\Omega_i) \quad (6)$$

The line shape function of equation (6) leads to narrow peaks with spacing $\hbar\Omega_i$, characterizing the absorption spectrum of the electronic transition $1 \leftarrow 0$. The intensity of the narrow peaks is given by the overlap of the harmonic oscillator wave functions of Figure 2. Figure 3a shows the transition probability for two modes i and j calculated with the aid of equation (6). For the sake of clarity, we have drawn the absorption and emission spectra separately. In order to obtain the complete spectrum, all modes i have to be summed. Figure 3b shows a spectrum which results from superposition of modes i and j. The *zero-phonon line* ($v=0$) dominates the whole spectrum. There are two reasons for this: First, the zero-phonon lines of all lattice modes i,j... add at the electronic origin $E_1 - E_0$. Second, the width of the zero-phonon line is narrower because its relaxation is prohibited to some extent by the large energy splitting $E_1 - E_0$. The adjacent lattice states spaced by $n\hbar\Omega_i$ and $n\hbar\Omega_j$ relax on a much faster time scale. The envelope of all phonon excitations is termed a *phonon sideband.*

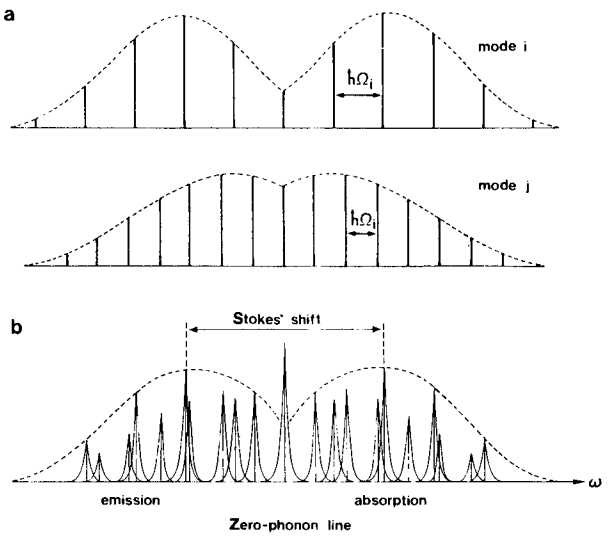

Fig. 3. a) Transition probabilities for two lattice modes i and j [see eq. (6)]; b) superposition of the two modes i and j. The intensities of both modes add up at the zero-phonon frequency (line coincidence); however, they do not add up in the multi-phonon transitions.

We are interested in calculating the line shapes quantitatively. Figure 4 therefore shows a typical line profile of an electronic transition including its phonon sideband (see Section 3). An important quantity is the Lorentzian zero-phonon line $z(\omega)$ with its integrated area α and its line width γ. A second characteristic feature is the phonon sideband $p(\omega)$ with its integrated area $(1-\alpha)$. The line shape of the phonon sideband is given by the overlap integrals of equation (6); these correspond to a Poisson distribution (see e.g. [15]). In many cases an approximation using a Gaussian profile is completely adequate[15, 16, 17]. The total line shape of the $1 \leftarrow 0$ transition is a normalized superposition of $z(\omega)$ and $p(\omega)$. The transition is characterized by the Debye-Waller factor α, which gives the relative intensity I_0 of the zero-phonon line normalized by comparison with the total intensity I_g. Figure 5 shows an experimentally determined guest-host phosphorescence spectrum[18]: In Fig-

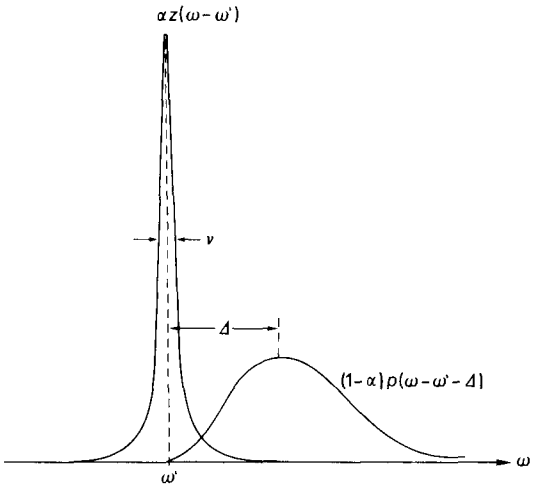

Fig. 4. General line shape function of an electronic excitation of a guest molecule in a solid host matrix: Schematic view of a zero-phonon line and phonon sideband.

ure 5b the zero-phonon line is the dominating feature and in Figure 5a the phonon sideband dominates. The first case is referred to as *weak* electron-phonon coupling and the second, as *strong* electron-phonon coupling. For high-resolution hole burning spectroscopy one needs systems with strong zero-phonon lines to yield the required optical resolution.

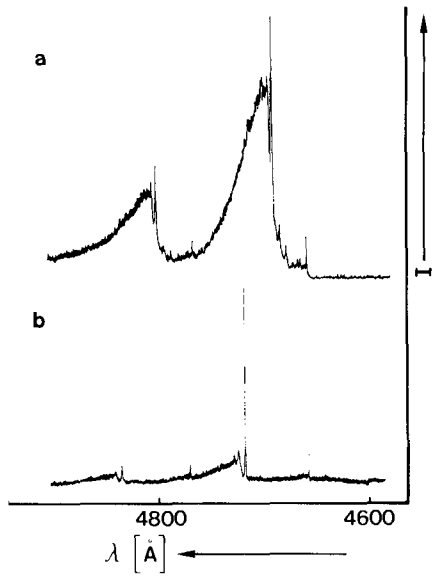

Fig. 5. Phosphorescence spectra of two trap states in the charge-transfer single crystal naphthalene-tetrachlorophthalic anhydride. a) Purified material: The trap state is strongly coupled to the lattice, i.e. the relative intensity of the phonon sideband is large. b) Unpurified material: The trap state is weakly coupled to the lattice; the relative intensity of the phonon sideband is small. A trap-state is a localized excited state of a crystal and can, for example, be produced by doping or by the presence of impurities in natural abundance.

The Debye-Waller factor α is extremely relevant for hole burning experiments. It follows explicitly from equation (6) if one compares the contribution of all modes to the zero-phonon line, namely $\sum_i |\langle \Phi_{1i}(0)|\Phi_{0i}(0)\rangle|^2$, with the total intensity. Since the total intensity is normalized, one obtains

$$\alpha = I_0/I_g = \sum_i |\langle \Phi_{1i}(0)|\Phi_{0i}(0)\rangle|^2 \tag{7}$$

As $T \to 0$, α can readily be calculated (see e.g. [19]), giving

$$\alpha(T=0) = \exp\left(-\frac{1}{2}\sum_i \frac{m_i \Omega_i}{\hbar} q_{i0}^2\right) \equiv \exp(-S) \tag{8}$$

If only a single phonon mode is considered, S has a simple physical interpretation: It corresponds to the number of vibrational quanta which are excited in the maximum of the phonon sideband. If the case shown in Figure 2 is taken, one gets an S-value of 3. The "Franck-Condon gap" Δ_i (half the Stokes-shift) can also be calculated from the one-mode model shown in Figures 2 and 4:

$$\Delta_i = S_i \hbar \Omega_i \tag{9}$$

For S-values >5, one is dealing with strong electron-phonon coupling. In such cases one cannot expect to observe a narrow zero-phonon line [eq. (8)]. Especially in the case of rather strong electron-phonon coupling, the "one-mode" model is quite often good, because usually a single mode couples more strongly than the others and, thus, dominates the optical spectrum.

3. Optical Line Shapes in Perfect Lattices

The optical properties of guest molecules are strongly influenced by the nature of the host lattice. For this reason one can consider a guest molecule as a sensitive probe for the structure and dynamic properties of the host lattice. To exemplify the host-guest interaction we consider a matrix-isolated molecule. Its excited state lifetime T_{10} is given by various relaxation processes, such as fluorescence (F), intersystem crossing (ISC), internal conversion (IC), and vibrational relaxation (VR) (see e.g. [20] and Fig. 1). From Heisenberg's uncertainty relation the *natural line width* γ_0 is

$$\gamma_0 = 1/T_{10} \tag{10}$$

γ_0 is given as the full width at half-height (FWHH) and is expressed in units of $2\pi/s$. For singlet states S_1, lifetimes of 10^{-8} to 10^{-9} s are typically encountered; therefore, the γ_0 values lie in the range 100 MHz to 1 GHz. If one wants to measure natural line widths, typically an optical resolution $\omega_0/\gamma_0 = 10^7$–10^8 is required (ω_0 is the frequency of the optical transition).

So far we have neglected the influence of the lattice, which reduces the lifetime T_{10} to T_1 by introducing new radiationless decay channels[21]. In addition to the relaxation phenomena, the host-guest interaction introduces mechanical strain; it also leads to electrostatic and to van der Waals' interactions, shifting the molecular level by a "solvent shift" D[22]. In the case of a perfect host lattice, all molecules experience identical shifts and, hence, their optical transitions coincide (Fig. 6). The width of this ideal line at $T=0$ is given by its lifetime T_1. Upon increasing the temperature, the thermal motion of the lattice increases and leads to an additional line-broadening mechanism, termed *phase relaxation* (see e.g. [23,24]). We would like to describe

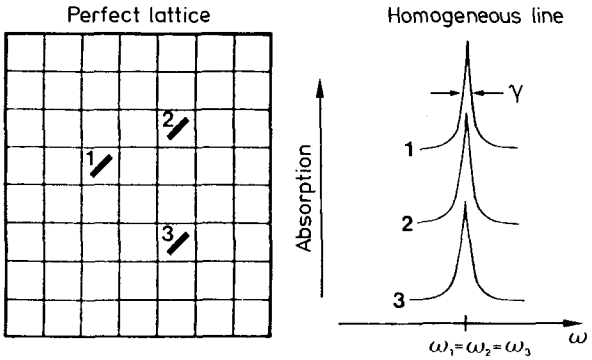

Fig. 6. Schematic view of the optical absorption lines of three (identical) guest molecules in a perfect crystal. The three lines have identical transition frequencies.

this relaxation process on a qualitative level. If a whole ensemble of molecules is excited with a coherent light source, an ensemble of molecules oscillating in phase with each other and with the external light source results. In this way, a macroscopic polarization $\vec{P}$ is induced which can be expressed as a vectorial sum of all molecular transition dipole moments

$$\vec{P}=\vec{P}_0 e^{i[(E_1-E_0)/\hbar]t}; \qquad \vec{P}=\langle\vec{\mu}_{10}(t)\rangle \tag{11}$$

Equation (11) describes a complex vector rotating with the laser frequency

$$\omega_L=(E_1-E_0)/\hbar$$

(In a coordinate system which rotates with frequency $\omega_{01}=(E_1-E_0)/\hbar$, the fast-phase factor of eq. (11) is 1; see Section 6.)

If an individual molecule of the large ensemble is considered, a thermal motion in its neighborhood will change its energies from E_0 to $E_0+\Delta E_0$ and from E_1 to $E_1+\Delta E_1$. As a consequence, the characteristic frequency of the transition moment is shifted by the amount $\varepsilon=(\Delta E_0-\Delta E_1)/\hbar$. This "detuning" leads to a phase loss of the molecule. Since the thermal motions of the lattice have a stochastic nature, ε is also stochastic and thus leads, within the time interval T_2^* *(phase relaxation time),* to a statistical distribution. During this time the various transition moments become out-of-phase and, thus, the macroscopic polarization drops to $\vec{P}_0/e$.

These considerations are only valid if the lattice fluctuations can be regarded as being stochastic, i.e. if a motion at time $t+t'$ is completely independent of one at time t. This is valid for $t'\gg\tau_c$, where τ_c is the correlation time describing lattice fluctuations. If one applies Heisenberg's uncertainty principle to the decay of the macroscopic polarization,

$$\gamma_h=1/T_2\geqslant 1/T_1 \tag{12}$$

results, where γ_h is the *homogeneous line width:* this reflects the dynamic influence of the lattice on the probe molecule. As mentioned previously, $T_2\rightarrow T_1$ as $T\rightarrow 0$ K, which is a consequence of the third law of thermodynamics. At $T=0$ K the stochastic motions of the lattice are "frozen out". The lattice has a "sharp" energy level and thus its entropy is zero.

The lattice fluctuations are caused by phonons, which at thermodynamic equilibrium are created and destroyed with the boundary condition of a mean occupation number $\langle n\rangle$ given by

$$\langle n\rangle=1/(e^{\frac{\hbar\omega}{kT}}+1) \tag{13}$$

One can, therefore, argue that the fluctuations of an excited state are caused by quasi-elastic scattering via phonons[25,26,27]. This is shown schematically in Figure 7: A phonon is absorbed in the ground state Ψ_0 of the scattering center. This changes the energy of the state Ψ_0 by a small amount ΔE_0. If the coupled system of molecule plus phonon absorbs a light quantum, it does so at an energy $(E_1^*-E_0^*)$, which is slightly different from that of a "phonon-less" transition at (E_1-E_0). This is due to a slightly different charge distribution in the probe molecule in the excited state. Since the phonon is re-emitted to the lattice, one refers to the above process as elastic scattering. These scattering processes lead to an increase in line width of the order $(\langle(\Delta E_0-\Delta E_1)^2\rangle)^{1/2}$. Clearly, as $T\rightarrow 0$ K such scattering processes disappear [eq. (13)], since at $T=0$ no thermal phonons are available.

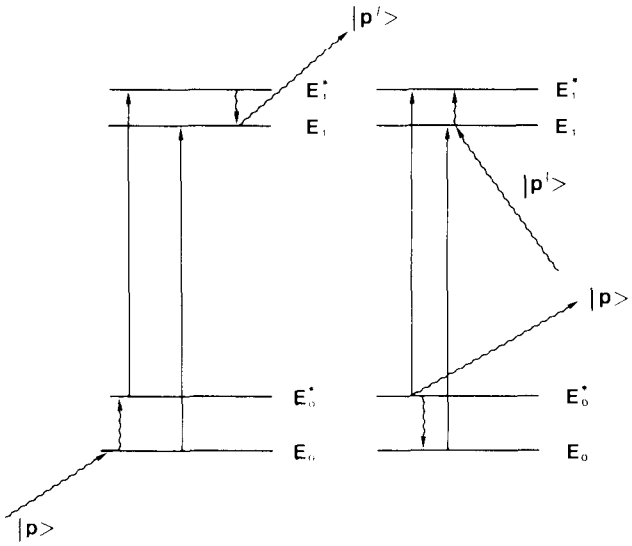

Fig. 7. Energy diagram for elastic phonon scattering involving two different electronic levels (0,1). The electronic transitions are drawn with straight arrows, the phonon transitions with wiggly arrows.

In this case, γ_h is, according to eq. (12), exactly determined by the inverse of the lifetime T_1. The discussion presented here shows that the homogeneous line width as a function of temperature is a characteristic probe for dynamic processes in the lattice.

At this point we want to make some remarks concerning the line widths. We have shown earlier in this section that the phase relaxation is given by the decay of the macroscopic polarization. In mathematical terms, this time dependence is described by the autocorrelation function of the dipole moment[28]:

$$C(t)=\langle\vec{\mu}(0)\vec{\mu}(t)\rangle \tag{14}$$

The autocorrelation function can be viewed as a mathematical scheme which correlates a physical parameter (here the macroscopic dipole moment) at time t with the same quantity at $t=0$. The average brackets in equation (14) reflect that C is a macroscopic quantity. The optical line shape is given by the Fourier transform of the autocorrelation function of the dipole moment:

$$L(E) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} C(t)\, e^{-iEt/\hbar}\, dt \tag{15}$$

The decay of C is given by T_2^* and T_1 for times $t \gg \tau_c$[29]. For exponential decay of C, $L(E)$ is given by a Lorentzian line shape. If only two states are considered (i.e. Ψ_0, Ψ_1), equation (15) yields directly

$$L(E) = |\vec{\mu}_{01}|^2 g(E - E_1) \tag{16}$$

where g is the normalized line shape function introduced in equation (1).

4. Optical Spectra in Glass Matrices

The optical spectra of guest molecules in glassy matrices are very different from those in crystalline matrices. To understand this phenomenon, one has to grasp the basic difference between a crystal and a glass: The glass transition is not a real phase transition, even though many thermodynamic properties exhibit discontinuities there[30-32]. The glass transition has certain kinetic aspects which we will discuss briefly. If the temperature of a host-guest system is lowered through the range in which the glass transition occurs, the intrinsic viscosity of the liquid increases by many orders of magnitude. The liquid finally freezes at a fictitious temperature T_x. To define this temperature, we have to perform a *gedankenexperiment:* We freeze the liquid slowly, maintaining thermodynamic equilibrium. The increasing viscosity of the solution leads to increasing relaxation times and, hence, equilibrium can only be maintained down to a temperature T_x. At this point we quench the liquid to temperatures below which the liquid freezes, i.e. is in a glassy state. We can then assume that the potential distribution of the glass corresponds to that of the liquid at temperature T_x. Clearly, T_x depends on the cooling rate. The thermodynamic properties of a glass therefore depend on the sample's cooling history. Hence, a glass is a *non-equilibrium state*[33]. Each cooling cycle leads to a different point in the configurational space. Figure 8 shows a cross section through the configurational space along a coordinate q. The figure shows that a glass has entropy even at absolute zero[33], since it can occupy various configurations. This is in contrast to the typical situation for a crystal, whose configuration is well defined at $T=0$. In a glass one can think of relaxation processes (e.g. between the states 1 and 2 of Fig. 8) leading to an energy uncertainty, which will eventually be reflected in the optical spectra of glassy materials.

Figure 8 suggests an approach to a quantum mechanical interpretation of the glassy state[34,35]. The random potential given in Figure 8 can be represented as a distribution

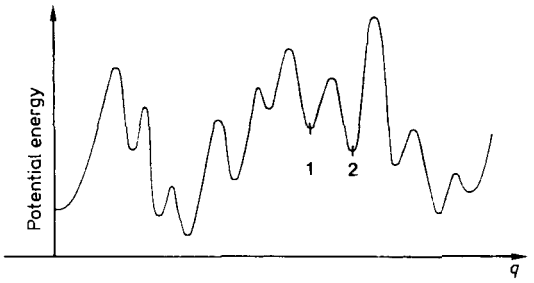

Fig. 8. Cross section through the configurational space of a glass along a fictitious coordinate q (see text).

of double-well potentials. The dynamics of the glassy state can be modeled by the dynamics of double-well potentials whose parameters are determined by an appropriate distribution function. The physics of the systems is determined by this distribution function[36,37]. Measurements of specific heat (C_p) below 1 K allow conclusions to be drawn about the glass distribution function, but only over narrow energy ranges[37,38] (see Section 13).

For double-well potentials the nomenclature of "two-level systems" (TLS) has been used to describe the two lowest eigenstates of the system. The TLS states seem to have a high spectral density at very low energies and this is responsible for the so-called thermal anomalies: At temperatures below 1 K the specific heat increases linearly with temperature (crystal $\sim T^3$) and is time-dependent[39,40] and the thermal conductivity increases with T^2 (crystal $\sim T^3$); both the velocities of sound and that of light in glassy systems are temperature-dependent[41]. In the past few years it has become clear that TLS also influence the optical properties of amorphous materials[42-46].

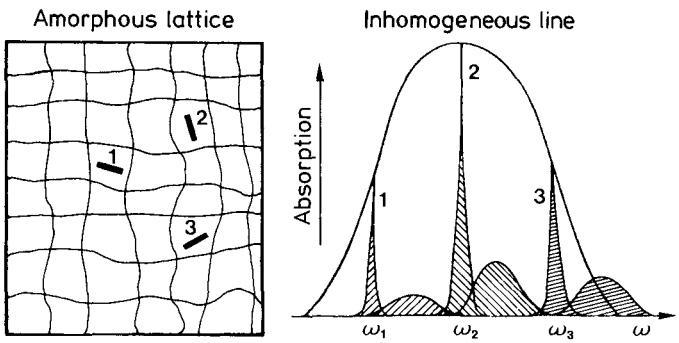

Fig. 9. Schematic view of the optical absorption of three (identical) guest molecules in an amorphous host. In contrast to the situation in a crystalline lattice, the lines appear at different transition frequencies. The broad sidebands represent the phonon spectra of molecules 1, 2 and 3, respectively.

As pointed out previously, the microscopic environment of a "solvent" molecule in a glass is random (Fig. 9). Therefore, the "solvent shift" D is, in contrast to the situation encountered in crystalline systems, not uniform but given by a statistical distribution (site distribution). The latter is usually assumed to be Gaussian:

$$G(D) = 2\sqrt{\frac{\ln 2}{\pi}} \cdot \frac{1}{\Gamma} \exp\left\{-\frac{4(D-D_0)^2 \ln 2}{\Gamma^2}\right\} \tag{17}$$

In organic glasses this distribution can span several hundred wave numbers. Similar distributions are observed for crystals with imperfections; however, in the latter case the line width is only of the order of several wave numbers. The width of the site distribution Γ (full width at half-hight, FWHH) is termed the *inhomogeneous* line width. Figure 9 gives a schematic view of the spatial fluctuations of the site geometry and the corresponding optical absorption profiles. (Besides the spatial fluctuations, there are also fluctuations in the time domain which are responsible for the *homogeneous* line width.) One goal of this article is to discuss methods for measuring individual line shape functions (1, 2, and 3 in Fig. 9) despite the inhomogeneous line broadening phenomena which characterize the glassy state and which, under normal conditions, mask the line shape. A second goal is to relate the line shape profiles to the specific degrees of freedom of the amorphous host matrix (TLS).

5. The Optical Two-Level System Interacting with a Coherent External Field

In the following we briefly compare spectroscopic experiments in the frequency domain (especially optical hole burning) with those in the time domain. Both types of experiments can, under certain conditions, give the same information.

The mathematical framework necessary to describe optical relaxation processes is almost identical with that used in the theory of spin resonance phenomena. This was proved by *Feyman et al.*[47] who described the general equivalence between an optical two-level system and a spin-1/2 system. For the optical two-level system we define the initial and final states as the electronic ground state and the lowest allowed excited state (S_1), respectively. Bearing the basic properties of a spin 1/2 system in mind, we point out some qualitative differences between the optical two-level system and a spin-1/2 system.

a) For optical two-level systems the relation $E_1 - E_0 \gg kT$ holds in general. The longitudinal relaxation time T_1 therefore exists only for the excited state E_1 with a measurable rate. It corresponds to the optical lifetime. The lifetime of the ground state can be assumed to be infinite (i.e. no measurable thermal population of E_1). In other words, the two-level system tends towards a state of complete "polarization" if no radiation is absorbed. A state of complete polarization can, in the case of spin resonance, only be achieved at infinitely high magnetic fields (or infinitely low temperatures). In this highly polarized state all spins are aligned. A completely different picture applies to energy-conserving dephasing processes, which can occur in both the ground *and* excited states. Dephasing processes are usually due to phonon scattering. For optical systems the condition $T_2 = T_1$ is only fulfilled in exceptional cases (i.e. at very low temperatures).
b) In optical systems spontaneous emission processes play an important role. This behavior is quite different from magnetic systems; the ω_{01}^3-dependence of the spontaneous emission clearly favors optical frequencies. The optical spectroscopic methods of fluorescence and phosphorescence are therefore mostly based on spontaneous emission processes. Similar experiments would be difficult, if not impossible, with ESR and NMR spectroscopy. Spin resonance experiments are, thus, based on coherent phenomena as described by the Bloch equations. Only after the advent of lasers as coherent light sources was it possible to perform coherent Bloch-type experiments in the optical region[48].
c) In optical spectroscopy the sample dimensions are, in general, large compared to the wavelength. In addition to the Bloch equations, Maxwell's equations therefore must also be applied. Both sets of equations are often referred to as the Bloch-Maxwell equations.
d) In magnetic resonance phenomena the Larmor frequency of the precessing spin ensemble has a geometric interpretation: The magnetization vector precesses, as long as it has a component perpendicular to the field direction, at the Larmor frequency. It can therefore be detected with appropriate detector coils which pick up an x−y magnetization. The "optical Larmor frequency" $\omega_{10} = (E_1 - E_0)/\hbar$ has no real geometric relevance, i.e. there is no precession in real x, y, z space.

In connection with the above considerations we wish to summarize the basic relations which link optical line width data with the corresponding optical relaxation times. The equations which will be given below can be derived by solving the time evolution of the density matrix of a two-level system driven by a coherent electric field, and represent the optical analogues of Bloch's equations for a precessing spin. They basically describe the phase decay of an ensemble of optically excited molecules (for a review see [49,50]).

If the pure dephasing time of the molecules is defined as T_2^* and the lifetime in the excited state as T_1, one arrives at an effective decay time of the total ensemble of excited molecules

$$1/T_2 = 1/T_1 + 2/T_2^* \tag{18}$$

In contrast to similar expressions derived in spin resonance spectroscopy, equation (18) is not symmetrical in T_1 and T_2^*. The reason for this difference is that for an optical two-level system the excited state cannot be populated thermally. This has as the consequence that only one of the two states (the excited one) can decay with T_1. Scattering processes with characteristic time T_2^* can, however, occur in both the ground and excited states.

Knowing T_1 and T_2, one can calculate the optical line width (FWHH; in units of 2π/s) of an optical two level system as

$$\gamma_h = \frac{1}{T_2}\sqrt{1 + \omega_1^2 T_1 T_2} \tag{19}$$

where ω_1 is the Rabi frequency, proportional to the amplitude of the electric field vector of the light wave. The characteristic time for driving the molecular ensemble from the

ground state to a state with equal population of the ground and excited states is $t=\pi/2\omega_1$; ω_1 is defined as

$$\omega_1=\vec{\mu}_{10}\vec{E}_0/\hbar \tag{20}$$

where $\vec{\mu}_{10}$ is the dipolar matrix element of the optical transition. Equation (19) shows that the optical line width increases at high light-intensities. This line-broadening is referred to as power broadening. In hole burning spectroscopy, one usually tries to avoid power broadening by performing the experiments at low power levels where the following condition holds

$$\omega_1^2 \ll \frac{1}{T_1 \cdot T_2} \tag{21}$$

These lower power levels require longer irradiation times for PHB photochemistry. It should be mentioned that the phenomenon of power broadening is completely different from the so-called "photochemical saturation broadening" (Section 9), which arises from bleaching of the photoactive molecules over a narrow frequency range.

As mentioned previously, excessively high light-intensities in hole burning experiments are avoided since power broadening would otherwise result. However, the methods used in transient spectroscopy, which are summarized in the following section, require high light-intensities. For these experiments equation (21) cannot be fulfilled, and the light field chosen has to be high enough to perform the transient changes in times small compared to T_1 and T_2^* (adiabatic rapid passage, see [51]).

6. Transient Experimental Methods for Determining Optical Relaxation Times

6.1. Free Induction Decay

A very useful method for measuring the optical relaxation time T_2 in the *time domain* is optical free induction decay (FID or OFID). In the FID experiment, a macroscopic polarization is generated in the sample by irradiating it with coherent light. The polarization field of the sample is then superimposed on the incident light field, leading to a beat frequency between the two oscillations. To observe FID experimentally, one has to "switch" the laser frequency fast (compared to T_1, T_2^*) into and out of the molecular resonance frequency. This can be achieved either by Stark-switching the molecular energy levels[52–54] or by rapidly switching the laser frequency[55].

The optimal experimental condition for observing FID arises if the polarization corresponds to equal population of the ground and excited states. This is achieved by irradiating a resonant field during the time interval $t_{\pi/2}$, thereby rotating the polarization by $\pi/2$. To achieve a $\pi/2$-rotation, the condition

$$\omega_1 \cdot t_{\pi/2}=\pi/2 \tag{22}$$

has to be fulfilled.

After generating the above polarization, the laser frequency is quickly shifted from ω_{01} to $\omega_{01}+\delta\omega$. It is important that $\delta\omega$ be several times larger than the homogeneous line width. In this case the beat phenomenon between the (complex) polarization $\vec{P}$ and the external field decays according to the following relation:

$$\vec{P}(t)=\vec{\mu}_{01} N \exp\{i\,\delta\omega\, t\} \cdot \exp\{-t/T_2\} \tag{23}$$

Equations (23) and (24) show no high frequency oscillations with ω_{01}, since they are formulated in a reference frame rotating at frequency ω_{01} (rotating frame description).

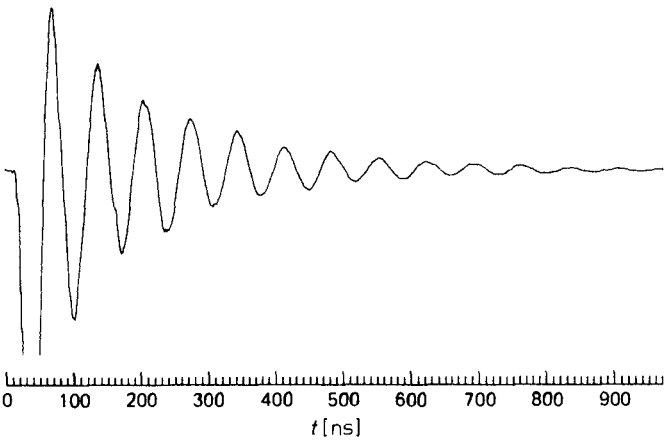

Fig. 10. Optical free induction decay (OFID) of the praseodymium(III) ion in lanthanum trifluoride [56].

In equation (23), N is the number of molecules in the ensemble and $\delta\omega$ is the beat frequency between the sample polarization and the light wave. Figure 10 shows an FID signal of an excited state of the praseodymium(III) ion in a lanthanum trifluoride crystal at 1.5 K. The rapid oscillations correspond to the frequency shift $\delta\omega$. The envelope of the signal corresponds to T_2[*].

6.2. Optical Echo Experiments

In Section 6.1 we assumed for the sake of simplicity that the molecular transitions are narrow (with a width of the order of $1/T_2$). In reality, the transitions are, however, *inhomogeneously* broadened. The time decay of the polarization after a $\pi/2$-pulse is, hence, not given by equation (23) but has to be rewritten (see e.g. [52]):

$$\vec{P}(t-t_{\pi/2})=\vec{\mu}_{01}\left[\sum_j^N \exp\{iD_j(t-t_{\pi/2})\}\right]\exp\{-(t-t_{\pi/2})/T_2\} \tag{24}$$

where D_j characterizes the shifts of the molecular frequencies with respect to the laser frequency caused by inhomogeneity effects [see eq. (17)]. The term in the square brackets of equation (24) decays quickly due to the different molecular frequencies involved. We interpret this decay graphically by describing the polarization vector after a $\pi/2$-pulse in a *fixed* coordinate system. In such a coordinate

[*] In the original paper [56] the envelope corresponds to $1/2\,T_2$, since effects due to the line inhomogeneity have to be taken into account. Inhomogeneity effects are, for simplicity, not included in equation (23) (see Section 6.2).

system the polarization rotates with the Larmor frequency ω_{01}. Ideally in the case of vanishing inhomogeneity, the ω_{01} frequency of all particles, i.e. molecules of the ensemble, is identical and, hence, the length of the polarization vector decays with time constant T_2. Figure 11a shows the situation for two different times τ and 2τ.

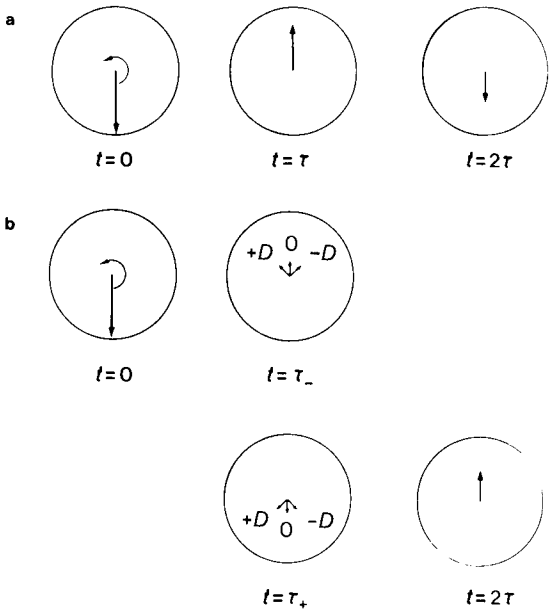

Fig. 11. a) Polarization decay (length of arrow) after a $\pi/2$-pulse. The arrow rotates at the Larmor frequency ω_{01}. The polarization executes $n+1/2$ rotations during the time interval τ and $2n+1$ during the time interval 2τ ($n=\omega_{01}\cdot t/2\pi$). The polarization decays exponentially with characteristic time T_2. b) In the presence of inhomogeneous broadening, the polarization decays faster. The polarization is symbolically composed of three different components: one with the unperturbed Larmor frequency (0) and a faster (D^+) and a slower (D^-) component. τ_- is the time immediately before and τ_+ the time immediately after the 180°-pulse. (The three arrows are all short due to the "spread out" from inhomogeneity.) After $2n+1$ rotations of the polarization the three components refocus and give rise to an echo. (The difference of half a rotation between a) and b) is due to the 180°-pulse.)

Due to the scattering of molecular frequencies in the range $\omega_{01} \pm D$ (inhomogeneous broadening), a decay of the polarization which is much faster than the "true" T_2-decay is also encountered. This is shown in Figure 11b for the time interval $0 \leq t \leq \tau$. For simplicity we consider only three frequency components: An unshifted component at ω_{01}, a fast component at $\omega_{01}+D$, and a slow component at $\omega_{01}-D$. If after a time τ a π-pulse is applied to the system, the slow and the fast components are interchanged as shown in Figure 11b, the slow component preceding the fast (a π-pulse corresponds to an inversion in the two-level system). If one follows the time evolution of the system after the π-pulse, the various Larmor components refocus at $t=2\tau$ and are shifted by 180° (Fig. 11a). The polarization which refocusses at $t=2\tau$ generates an optical echo, which can be detected in a similar way to the OFID signal. The π-pulse has the consequence that at $t=2\tau$ the interference term of equation (24) (square brackets) is equal to unity, as is shown graphically in Figure 11b for two discrete D_j values. Equation (25) describes the decay of the refocussed polarization function, which is measured in an echo experiment.

$$\tilde{P}(\pi/2,\pi,2\tau)=\vec{\mu}_{10}N\exp\{-2\tau/T_2\} \qquad (25)$$

The echo method was first introduced by *E. L. Hahn* in NMR spectroscopy[57]. The first optical echoes were measured in 1964 in ruby crystals[48] (for a survey see [58,49]).

7. Relaxation Spectroscopy in the Frequency Domain

In Section 6.2 we described methods of measuring relaxation times by transient methods in the time domain. With the aid of equation (12) relaxation times can also be measured in the frequency domain. Both methods have advantages and disadvantages and are, in many respects, complementary. In the following we summarize their main differences.

a) Experiments in the frequency domain are difficult to perform for long relaxation times because they require both high frequency resolution and high frequency stability. Practical limits at present are ca. 10^{-4} cm^{-1} (1 MHz)[59,60]. For long relaxation times, FID and echo methods are preferable.
b) Frequency domain experiments are easier at short relaxation times (5 ps $\triangleq$ 1 cm^{-1}). This favors their application to amorphous materials which have short relaxation times, i.e. glasses and polymers[43,45,61]. For these materials transient experiments have so far, with a few exceptions[62], failed. This was mainly due to difficulties in producing sufficiently rapid pulse sequences and high enough Rabi frequencies. At the very high laser powers required, sample heating is often a problem.
c) In contrast to transient experiments, frequency domain experiments can be performed with very low laser powers and are based on a photochemical process in which the sample accumulates the experimental information. Instead of performing an experiment over a short time span under high intensity conditions, the experiments can be extended over a longer time period with correspondingly lower laser intensities. This is principally important for low temperature experiments where sample heating has to be avoided.
d) Due to their advantages at very short relaxation times, frequency experiments are extremely useful for studies of phonon states, which are characterized by very short relaxation times[63,64].
e) A difficulty which arises with experiments in the frequency domain is the interpretation of the line shapes. Line shapes are not always Lorentzian as predicted by simple theories of relaxation. Spectral diffusion processes often have to be considered in addition to straight forward relaxation processes[65]. In the latter case the complementary use of time- and frequency-domain experiments is advantageous.

7.1. The Method of Fluorescence Line Narrowing

As mentioned in Section 4, in the solid state optical line widths are limited by inhomogeneity effects. Figure 9 shows symbolically that sites with different microstructures lead to line broadening. These broadening effects occur in both crystalline and amorphous materials; they are,

however, much more dominant for amorphous systems, leading to line widths of the order of several 100 cm^{-1}. The first investigations suppressing inhomogeneity effects were echo experiments on ruby performed by *Hartmann* et al.[48]. The first fluorescence line narrowing (FLN) experiments were also carried out on ruby by *Szabo*[66], who measured a homogeneous line width of 2×10^{-3} cm^{-1}. The FLN method was subsequently successfully applied to organic systems by *Personov* et al.[63] and to inorganic systems by *Riseberg*[67]. In the context of this article, we do not intend to give an exhaustive review of the FLN work; it is of relevance, however, that the optical spectroscopy of glasses has received new impulses through the introduction of FLN spectroscopy[63,67,68]. The advantage of the FLN method is its high resolution capability; its disadvantage is its off-resonance character. Usually one excites the 0-0 transition via laser stimulation and monitors the fluorescence of vibronic sidebands. Since the vibrational sidebands do not always have a full correlation with the 0-0 band, some line shape information is lost if only the sidebands are detected (see Section 12). Exceptions to these spectroscopic limitations are excited states with long lifetimes (phosphorescence line narrowing)[56,66,69]. In this case the optical spectrum can also be observed at the resonant laser frequency by gating methods (see dotted arrow in Fig. 12). In principle, this gating method can also be applied for short lived singlet states (10^{-8} s). Fast gating experiments are, however, difficult and to date the method has found no practical application.

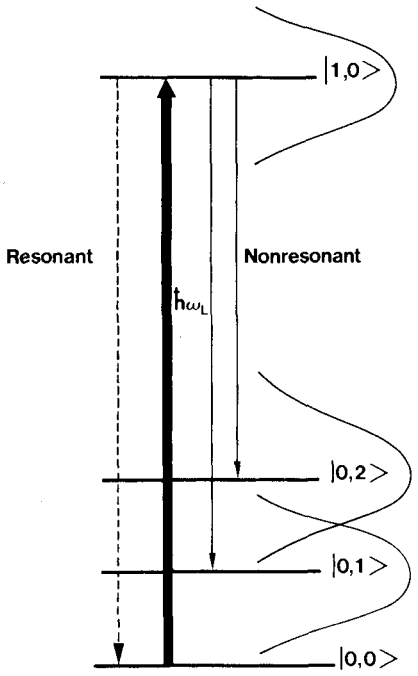

Fig. 12. Energy level scheme of a molecule with resonant and non-resonant fluorescence transitions. The symbol i,j characterizes the i-th electronic and the j-th vibrational level.

7.2. Spectral Hole Burning

The hole burning method was first introduced to NMR spectroscopy by *Bloembergen* et al.[70]. By saturating a two-level system, a hole can be "burned" in an inhomogeously broadened NMR line. The linewidth of the hole is, within a factor of two (vide infra), of the order of $1/T_2$.

Optical hole burning experiments were first performed in the gas phase[71]. The first experiment in the solid state was carried out on ruby by *Szabo*[72].

Transient NMR hole burning is a rather straightforward experiment because of the long T_1-times, which characterize the population decay following partial line saturation. A transient hole burning experiment has to be performed within a T_1-period, which, for nuclei, can be of the order of seconds to hours. Typical optical T_1-times for allowed optical transitions are of the order of 10^{-8} s; transient hole burning experiments in the optical domain are therefore difficult. *Szabo*'s experiment[72] was performed with a comparatively long-lived, forbidden transition in ruby (R_1 band).

Photochemical and *photophysical* hole burning experiments exhibit strong analogies to transient hole burning, but circumvent the difficulty which arises at short T_1-values. Figure 13 gives an extended two-level scheme characterizing both the photochemical and the photophysical experiments. Besides the states $|\Psi_0\rangle = |R\rangle$ and $|\Psi_1\rangle = |I\rangle$ discussed so far, one has to consider a photochemical product state $|P\rangle$ which is populated with quantum yield Φ. The absorption of n quanta transforms $n\Phi$ molecules into the photochemically or photophysically modified state $|P\rangle$. This process leads to a depletion of the ground-state and thus to a permanent hole in the absorption band, provided a back reaction from $|P\rangle$ to $|R\rangle$ is forbidden or infinitely slow. The first experiments on photochemical and photophysical hole burning were published in 1974 by *Rebane* and *Personov* and their respective groups[3,4]. The high resolution of the hole burning experiments was demonstrated two years later in 1976[73,74]. Applications of hole burning to the spectroscopy of glasses were first reported in 1976[42,46].

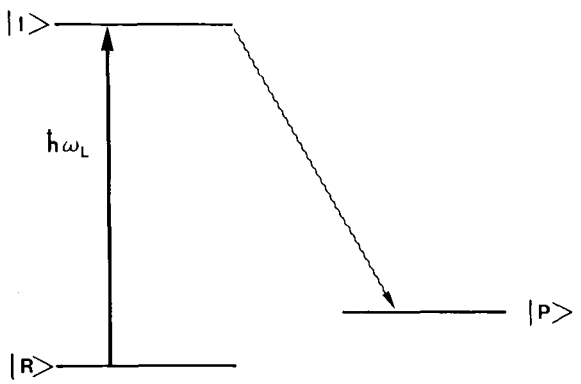

Fig. 13. Energy level scheme for the photochemistry of the hole burning process. $|R\rangle$ is the reactant state, $|P\rangle$ the product state, and $|I\rangle$ an intermediate state (for example the S_1 state).

With the aid of a few examples the difference between photochemical hole burning (PHB) and photophysical hole burning (non-photochemical hole burning, NPHB) will next be described.

In a typical PHB experiment the photoreactive molecules undergo photochemical changes, i.e. the absorption of the photoproduct is, in most cases, spectroscopically

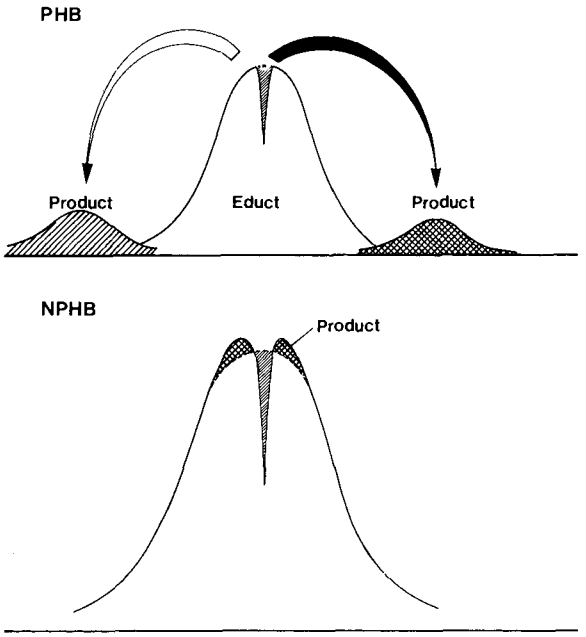

Fig. 14. Spectral distribution of the photoproduct after photochemical (PHB) and photophysical (NPHB) hole burning: The hole in the absorption band is clearly discernible.

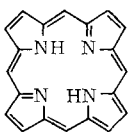
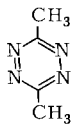
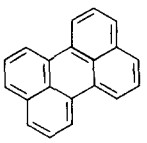
well separated from that of the original absorption (educt). The new absorption can be both blue- and red-shifted (Fig. 14). Examples of reversible PHB processes are proton transfer in metal-free phthalocyanine and in porphin[74] or configurational changes of hydrogen bonds[61]. An example of irreversible PHB photochemistry with large photochromic shift is the two-photon photochemistry of dimethyl-*s*-tetrazine[73,75]. In the latter case, the molecule dissociates into fragments which absorb in the UV range of the spectrum. In all these cases a photoproduct $|P\rangle$ can be defined whose optical absorption is rather different from the spectrum of the pristine molecule. There are also photoactive systems at the border area between transient hole burning and photochemical hole burning; for example, color centers[60]. For such systems the "photochemistry" arises from a reversible, light-induced electron tunneling process. (The back-reaction in the dark usually has a time constant of the order of tens of minutes.)



Porphin



Dimethyl-*s*-tetrazine



Perylene

The NPHB method usually photochemically modifies the molecule-matrix interaction. As "photoactive" molecules usually species such as pyrene[4] or tetracene[43,46] are used, which, under normal conditions, are quite photostable. The light-induced changes of the optical properties depend, by definition, upon properties of the matrix. Matrices which form hydrogen bonds (e.g. ethanol-methanol glasses) seem to be suitable for this kind of photochemistry, whereas saturated hydrocarbons (e.g. *n*-alkanes) seem to be inapt for appropriate host-guest rearrangements. A spectroscopic selection criterion which distinguishes photochemical and photophysical hole burning processes is the position of the absorption of the photoproduct, which for the latter lies very close to the energy of the laser performing the site selection[43]. Therefore, the physical variant can be interpreted as a process which redistributes molecular absorbers within the inhomogeneous band profile. On a microscopic basis this can be envisaged as a process which changes a given molecule-matrix configuration into another which absorbs at a different frequency. Recently NPHB processes have also been observed in amorphous aromatic guest-host systems[76] (see Section 13). It should, finally, be mentioned that NPHB processes have also been observed in the IR spectral range (≈ 1000 cm^{-1})[77].

8. Photochemical Hole Burning: Mechanistic Aspects

In this section we discuss various basic mechanistic aspects underlying hole burning photochemistry. We argue that hole burning photochemistry is a special kind of photochemistry, fulfilling the criterion of "zero-phonon photochemistry"[61]; the latter criterion eliminates many known photochromic systems as good candidates for hole burning.

In Section 2 we discussed the criterion for the appearance of narrow zero-phonon lines in considerable detail, and saw that weak electron-phonon coupling (i.e. small S-values) was the main condition for observing intense zero-phonon lines [(eq. (8)]. A necessary condition for weak phonon coupling was a small change of the equilibrium configuration (q_{i0}) of the lattice in the excited state. Photoreactive molecules, however, are characterized by large changes of their molecular geometry along a reaction coordinate Q (Fig. 15a)[*]. These large changes in the reaction coordinate lead to large changes in the equilibrium positions of the lattice q_{i0}.

In general, photoreactive molecules therefore show strong electron-phonon coupling. The spectra of photoreactive molecules are therefore, on the whole, characterized by broad spectral bands and large Stokes-shifts. Arguments along these lines led to the postulate of proton-transfer processes in the excited state from an analysis of the corresponding molecular spectra[78,79].

From these arguments one can conclude that PHB processes require the existence of mutually exclusive conditions; namely photoreactivity on the one hand and sharp spectral lines on the other. However, for two photochemical reaction schemes, under which most known photoreactions can be categorized, both criteria are fulfilled simultaneously. Figure 15b shows what is termed "*slow photochemistry*". In this case the photoreactive state is not the site-selected state itself, but a third state. This state is mostly populated via radiationless transitions; it can be a triplet state (level crossing in Fig. 15b). The proton-transfer

[*] Q denotes an internal molecular coordinate, whereas q is used throughout this article to denote lattice coordinates.

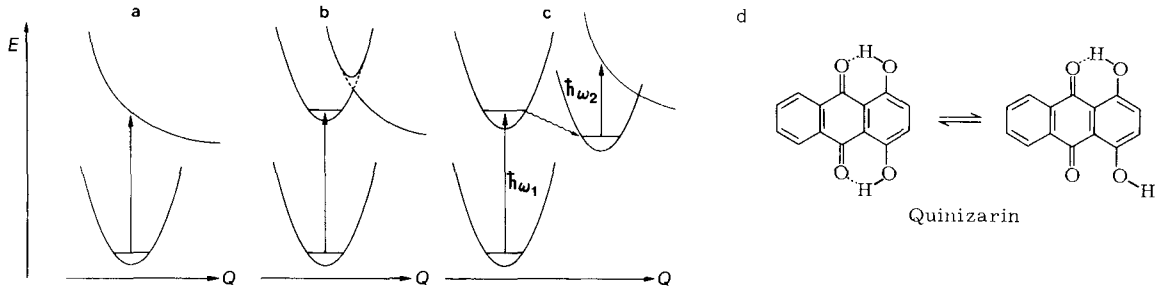


Fig. 15. a)—c) Photochemical model based on a configuration coordinate description of the photochemical process (see text). Q symbolizes an intramolecular coordinate. d) Reaction scheme for the proton transfer in quinizarin.

photochemistry of quinizarin (Fig. 15d) and the photochemistry of H_2-phthalocyanine and -porphin fall into this category. Even photophysical hole burning (NPHB) can be subsumed under this category. In the latter case it seems that the photochemical product state is reached via tunneling processes (see Section 13).

A second possible scheme is based on a *two-photon process*, as observed in the case of dimethyl-*s*-tetrazine[80]. Here, the first photon makes a site-selective transition into a photochemically inactive state, which undergoes relaxation to an intermediate state. The subsequent absorption of a second photon leads to a reactive state which initiates the photochemistry. The intermediate state has to be long-lived to achieve an acceptable quantum yield. Its spectroscopic properties are irrelevant for the hole burning process, whose site selection mechanism occurs during the transition $\Psi_1 \leftarrow \Psi_0$. Figure 15c shows the reaction scheme for a two-photon process[81]. In general, two-photon processes are desirable for technical applications such as optical memories and holographic photochemical applications. The technical advantage is that the first photon acts as a sensitizer, whereas the second photon initiates the irreversible information storage processes (see Section 15).

An important aspect of PHB photochemistry is the role played by the host lattice, which can, for example, cause activation barriers on the energy surfaces, thereby stabilizing various photochemical states[82]. Hence, at low temperatures, certain photochemical pathways may be inaccessible due to activation barriers which cannot be overcome by thermal energy. Such a case has been investigated using the dye molecule quinizarin as the photoreactive system[83]. The molecule undergoes light-induced proton transfer in which an intramolecular hydrogen bond can be opened or closed, depending on the wavelength of irradiation. The experimental results for the back transfer reaction of the proton indicate that the reaction can only occur in an excited phonon state of the lattice. The phonon excitations provide the energy to overcome the barrier of several 10 cm^{-1}, as shown in Figure 16. It should be noted that the phonon excitations needed to overcome the reaction barrier are "automatically" provided by Franck-Condon excitation of molecule-lattice states, as long as the molecule exhibits reasonably strong electron-phonon coupling. The forward reaction in which the hydrogen bond is opened is believed to occur via a low lying triplet state. We are not aware of any other examples of "phonon selective" photochemical reactions at low temperatures; however, no systematic studies of photochemical reactions have been performed at very low temperatures.

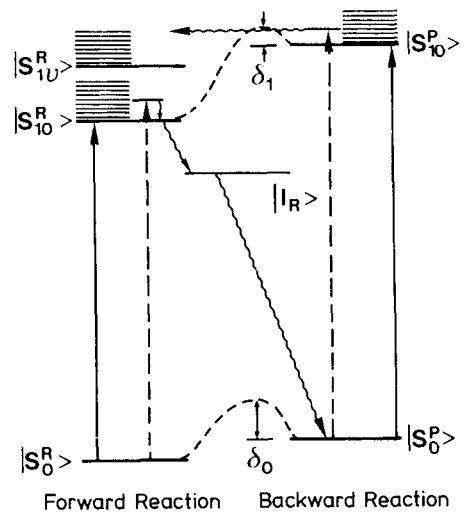

Fig. 16. Energy level scheme for the photoreactive state of quinizarin. $|I_R\rangle$ is a state of a reactive intermediate (most likely triplet); δ_0 and δ_1 symbolize reaction barriers in the ground and excited states, respectively.

9. Model Calculations of Photochemical Hole Burning in Organic Glasses

9.1. Line Shape Equations for Photochemical Hole Spectra

The three-level system shown in Figure 13 accounts for many characteristic features of the hole burning process: The photochemical process leads from the initial state $|R\rangle$ via an intermediate state $|I\rangle$ to the final photoproduct state $|P\rangle$. The excitation energies $\hbar\omega'$ of the initial state are scattered around a center of energy $\hbar\omega_0$ with the width Γ, due to a variation of the D values about D_0 [eq. (17)]:

$$\frac{N(\omega')}{N_0} \equiv \rho(\omega') = 2\sqrt{\frac{\ln 2}{\pi}} \cdot \frac{1}{\Gamma} \exp\left\{-\frac{4(\omega'-\omega_0)^2 \ln 2}{\Gamma^2}\right\} \tag{26}$$

$N(\omega')/N_0$ is the fraction of molecules which absorb in the frequency interval $d\omega'$ centered at ω'. In order to calculate the PHB line shape, the number of molecules at ω' after laser irradiation at ω_L must first be calculated.

It is important to note that a molecule which is centered at ω' absorbs at the laser frequency ω_L via two different processes: through the wings of its zero-phonon line z and through its phonon sideband p (Figs. 17 and 4). The transi-

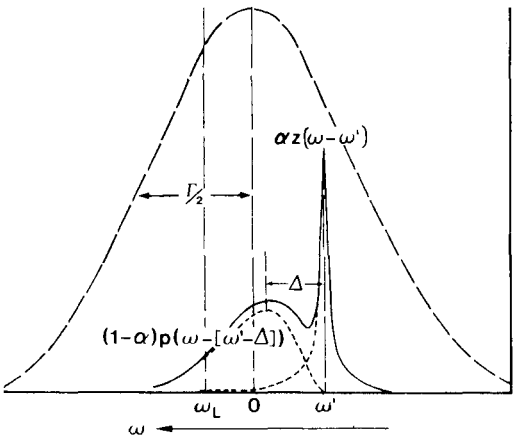

Fig. 17. Inhomogeneous distribution with a half width of Γ (full width at half height; FWHH) and spectral line shape profile of a molecule absorbing at frequency ω': z is the zero-phonon line, p the phonon sideband, ω_L: laser frequency. α: Debye-Waller factor. Δ: half the Stokes-shift. (The zero of the frequency scale corresponds to the frequency ω_0.)

tion probability per time unit can therefore be expressed as the sum of two terms

$$W(\omega_L,\omega') = \frac{\sigma I}{\hbar\omega_L}\{\alpha z(\omega_L-\omega') + (1-\alpha)p(\omega_L-\omega'-\Delta)\} \quad (27)$$

where σ is the absorption cross-section integrated over the frequency space, and $I/\hbar\omega_L$ is the number of incident photons per unit time and unit area. If Φ is the photochemical quantum yield, the change in the relative number of molecules $d\rho$ per time unit dt is given by

$$d\rho = \rho(\omega')\Phi\, W(\omega_L,\omega')\, dt$$

After integration we obtain

$$\rho_\tau(\omega') = \rho_0(\omega')\exp\{-W(\omega_L,\omega')\Phi\cdot\tau\} \quad (28)$$

where τ is the burning time.

A convolution of ρ_τ and the line profile $\alpha z(\omega-\omega') + (1-\alpha)p(\omega-\omega'-\Delta)$ affords the photochemically modified absorption spectrum $A_\tau(\omega)$.

$$A_\tau(\omega) = \sigma \int_{-\infty}^{+\infty} \rho_\tau(\omega')\{\alpha z(\omega-\omega') + (1-\alpha)p(\omega-\omega'-\Delta)\}\, d\omega' \quad (29)$$

The difference $A_0(\omega) - A_\tau(\omega)$ describes the photochemical change in the spectrum, which we refer to as photochemical hole spectrum $L_\tau(\omega)$:

$$L_\tau(\omega) \equiv A_0 - A_\tau = A_0(\omega) - \sigma \int_{-\infty}^{+\infty} \rho_0(\omega')\exp\left\{-\sigma\cdot\Phi\frac{I}{\hbar\omega_L}\tau[\alpha z(\omega_L-\omega') + (1-\alpha)p(\omega_L-\omega'-\Delta)]\right\}\{\alpha z(\omega-\omega') + (1-\alpha)p(\omega-\omega'-\Delta)\}\, d\omega' \quad (30)$$

Since z is a function which is narrow compared to ρ and p, eq. (30) can be resolved into four terms which permit a quite straightforward interpretation (Fig. 18)[84]:

$$zz(\omega) = \sigma\alpha\rho_0(\omega_L)\left\{1 - \int_{-\infty}^{+\infty}\exp\left\{-\frac{\alpha\sigma I\Phi\tau}{\hbar\omega_L}z(\omega_L-\omega')\right\} z(\omega-\omega')\, d\omega'\right\} \quad (31)$$

where $zz(\omega)$ is the narrow zero-phonon hole, whose shape depends on experimental parameters such as laser intensity I and burning time τ.

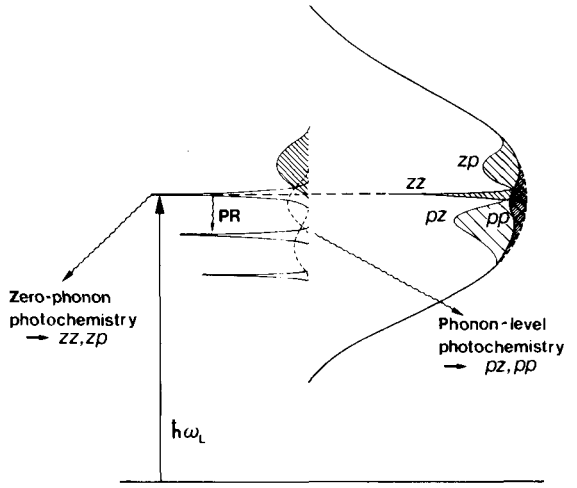

Fig. 18. Graphical scheme representing the four contributions to a photochemically burned hole zz, zp, pz, and pp. PR: phonon relaxation (see text).

The molecules whose electronic energy is centered at the zero-phonon line $zz(\omega)$ give rise to a phonon sideband absorption, which in turn gives rise to a broad hole on the short wavelength side of the zero-phonon hole. This broad hole is called the direct phonon sidehole, because it is a true satellite of the zero-phonon line:

$$zp(\omega) = \sigma(1-\alpha)p(\omega-\omega_L-\Delta)\cdot N_z(I,\tau) \quad (32)$$

The line shape of zp is determined solely by the phonon spectrum p. $N_z(I,\tau)$ is the relative number of molecules which have been changed photochemically by zero-phonon absorption:

$$N_z(I,\tau) = \rho_0(\omega_L)\left\{1-\exp\left[\frac{-\sigma\alpha I\Phi\tau}{\hbar\omega_L\gamma_h}\right]\right\}\gamma_h \quad (33)$$

$N_z(I,\tau)$ is proportional to the homogeneous line width γ_h. The exponent in equation (33) defines a bleaching time τ_b for the zero-phonon line[84]:

$$\tau_B = \gamma_h \Big/ \frac{I\Phi\alpha\sigma}{\hbar\omega_L} \quad (34)$$

τ_b is rather short for low temperatures (≈ 1 K), since γ_h is small. It should, however, be noted that γ_h may increase rapidly with increasing temperature (see Section 10).

Figure 18 shows that in addition to molecules absorbing in their zero-phonon lines, one has to consider molecules with electronic energies lower than $\hbar\omega_L$. These absorb at the laser frequency via their phonon sidebands. This process creates a broad hole at energies lower than $\hbar\omega_L$, which is basically characterized by the line shape of the phonon sideband

$$pz(\omega)=\sigma\alpha\rho_0(\omega)\left\{1-\exp\left[-\sigma(1-\alpha)\frac{I}{\hbar\omega_L}\Phi\tau p(\omega_L-\omega-\Delta)\right]\right\} \quad (35)$$

where $pz(\omega)$ depends on the parameters I and τ used in the experiment. This dependency causes a strong asymmetry in the hole burning line shape as the total light dose $I\cdot\tau$ increases (Fig. 19). We call $pz(\omega)$ a *pseudo-phonon hole,* since

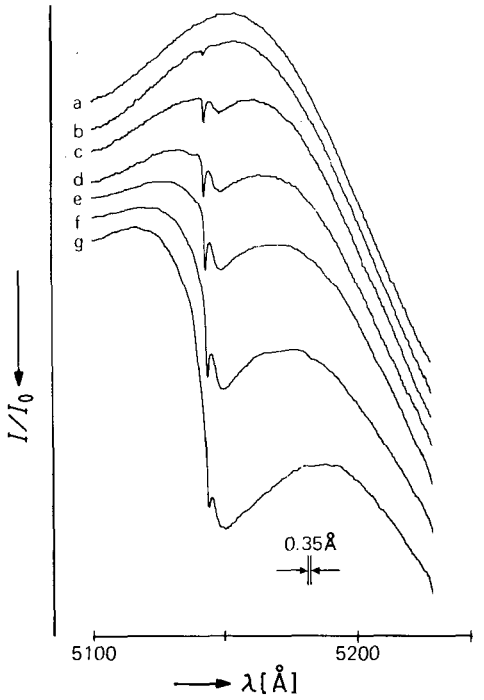

Fig. 19. Growth of a photochemical hole as a function of integrated irradiation time. Quinizarin in ethanol-methanol glass (3 : 1). a) Spectrum prior to irradiation, b) after 1 s, c) after 6 s, d) after 16 s, e) after 1 min, f) after 5 min, and g) after 32 min irradiation time (Argon ion laser, 7 mW/cm^2; T = 1.8 K).

this term does not represent a real phonon sideband belonging to a zero-phonon origin (it is rather a convolution of zero-phonon lines). Finally, the molecules which constitute the pseudo-phonon hole have their own phonon wings. This gives rise to a phonon-phonon term:

$$pp(\omega)=\sigma(1-\alpha)\int_{-\infty}^{+\infty}\rho_0(\omega')\left\{1-\exp\left[-\frac{\sigma I}{\hbar\omega_L}\Phi\tau(1-\alpha)p(\omega_L-\omega'-\Delta)\right]\right\}p(\omega-\omega'-\Delta)\,d\omega' \quad (36)$$

Whereas zp is on the short wavelength side of ω_L and pz is on its long wavelength side, pp has contributions on both sides of ω_L and, for low radiation dose, is symmetric with respect to ω_L (see Section 9.2). For small electron-phonon couplings pp is of minor importance, since the small quantity $(1-\alpha)$ appears both in front of the integral and in the exponent of equation (36).

9.2. Limiting Cases: Short Burning Time Limit

If the burning time τ is considerably shorter than τ_b, the exponent of equation (31) can be expanded into a power series. Neglecting higher terms, the line shape of the zero-phonon hole can then be written as

$$zz(\omega)=\frac{I\cdot\tau}{\hbar\omega_L}\sigma^2\alpha^2\Phi\rho_0(\omega_L)\int_{-\infty}^{+\infty}z(\omega_L-\omega')z(\omega-\omega')\,d\omega';\ \tau\ll\tau_b \quad (37)$$

For most practical cases, $z(\omega)$ is Lorentzian

$$z(\omega)=\frac{\gamma_h}{2\pi}\frac{1}{(\omega-\omega')^2+\gamma_h^2/4} \quad (38)$$

In this case the convolution integral [eq. (37)] can be solved, giving

$$zz(\omega)=\frac{I\cdot\tau}{\hbar\omega_L}\sigma^2\alpha^2\Phi\rho_0(\omega_L)\frac{\gamma_h}{\pi}\frac{1}{(\omega-\omega_L)^2+\gamma_h^2} \quad (39)$$

Equation (39) is also characterized by a Lorentzian line shape; however, with a line width of $2\gamma_h$. The short burning time limit enables one to interpret line widths in terms of the pertinent relaxation times. Equation (37) further predicts a linear growth of the zero-phonon hole with irradiation time τ.

From equations (35) and (36) it can also be concluded that for $\tau\ll\tau_b$ the pseudo-phonon hole and the direct phonon hole have identical shape and depth. $L_\tau(\omega)$ is therefore completely symmetric with respect to the laser frequency ω_L[64].

9.3. Limiting Cases: Photochemical Saturation Limit

With increasing irradiation dose $I\cdot\tau$, photochemical reactions at the center of the line gradually come to a halt because most photoactive molecules have already been converted. Consequently, photochemical reactions shift increasingly to the wings of the line leading to a line broadening, termed photochemical saturation broadening (see Section 9.4). For $\tau\gg\tau_b$, the term N_z in equation (33) does not increase much. In the range of the pseudo-phonon hole, however, the photochemical reactions still progress. This is because many more molecules absorb in the area of the broad pseudo-phonon wing compared to the narrow range of the zero-phonon hole.

The hole spectrum therefore shows a non-linear growth rate (Fig. 19). These considerations make it evident that for a determination of α it is not sufficient to measure the relative intensity of the zero-phonon hole given by equation (7). Instead, a complete computer simulation has to be performed[64]. Only for times $\tau\ll\tau_b$ is the relative area of the zero-phonon hole given by α^2.

9.4. Hole Width and Laser Burning Time

The line width of the zero-phonon hole as a function of τ (or I) can be calculated analytically only for the limiting cases $\tau\ll\tau_b$ and $\tau\gg\tau_b$ using equation (31). As $\tau\to0$, the line width approaches $2\gamma_h$ linearly[85]. For $\tau\gg\tau_b$ the exponen-

tial factor in equation (31) can be omitted from the integral, since it is a function which varies slowly with ω due to photochemical saturation (slow compared to z). Using this approximation, the hole width can be calculated as:

$$\gamma(\tau) = \sqrt{\frac{\alpha\sigma\Phi\gamma_h}{\pi \ln 2 \hbar\omega_L} I\cdot\tau} \qquad (40)$$

The hole width increases with the square root of $I\cdot\tau$. Figure 20 shows a computer simulation of a typical saturation curve[86].

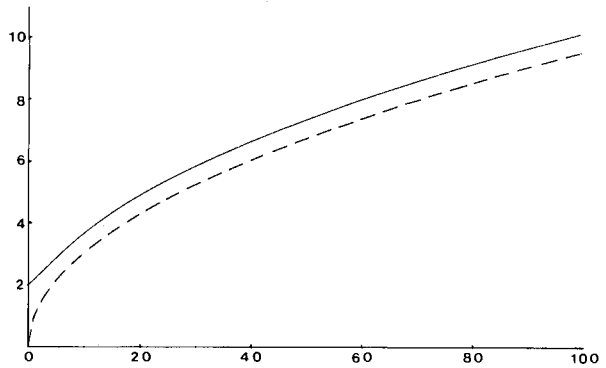

Fig. 20. Computer simulation of a photochemical bleaching curve [86] according to equation (31). Abscissa: Burning time in units of τ_b. Ordinate: Hole width in units of γ_h. The dotted line represents the asymptotic case according to equation (40).

9.5. Temperature Effects on the Emission Spectra of Photoreactive Molecules

At very low temperatures the emission spectra of photoreactive molecules in glasses exhibit a rather strange temperature behavior. In contrast to what one would expect, they do not exhibit narrow zero-phonon lines but show, instead, only broad spectra typical of phonon sidebands (Fig. 21a). At higher temperatures, however, narrow lines appear in the spectra (Fig. 21b). This rather unexpected phenomenon can be explained as follows: At low temperatures the short bleaching times lead to a rapid disappearance of molecules which absorb and emit at the laser frequency. The remaining nonresonant molecules give rise to the observed broad structures. With increasing temperatures, the bleaching time of the zero-phonon lines increases [eq. (34)] and, hence, the resonantly absorbing molecules appear in the spectrum[84]. This unconventional temperature dependence of the observed narrow zero-phonon lines is due to the bleaching effect of the photochemical system which may occur in the time scale of minutes up to several tens of minutes and, hence, may modify the observed fluorescence spectra.

9.6. Limits of the Model and Further Developments

The model which has been presented above makes assumptions which may, in some instances, not be valid. We have, for example, neglected all non-linear effects in the interaction between molecules and the laser field. This seems to be justified, if CW-lasers which operate in the

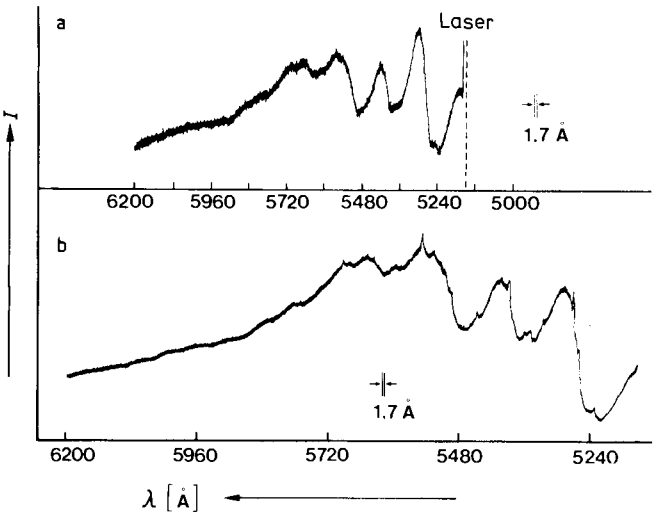

Fig. 21. Emission spectrum of quinizarin in an ethanol-methanol glass (3 : 1) at a) 1.8 K and b) 20 K. Excitation: Argon ion laser, 5145 Å, 7 mW/cm^2 [84].

mW range are used and if one investigates organic molecules in glasses which are characterized by comparatively large line widths. If, however, crystalline systems are studied using pulsed lasers, the non-linear effects may be of importance and have to be included in the theoretical treatment[87,88]. We have further assumed that no states with long lifetimes (e.g. triplet states) are involved in the photochemical cycle. Long-lived triplet states can, for example, give rise to bottlenecks and lead to accumulation of a large fraction of the molecules, thus causing non-linearities[87]. A similar effect can arise from the photochemical equilibrium between the states $|R\rangle$ and $|P\rangle$[5,88] (Fig. 13). Finally, one has to consider tunneling processes in glasses (Section 13), which can occur in the ground state and which can lead to spectral diffusion[65]. This latter effect has not been investigated yet in sufficient detail; however, it seems to have a considerable influence on the measured line widths.

Finally, it must be taken into account that in glasses all physical parameters, such as α, Φ and γ_h, are not characterized by a single, well-defined value, but by distribution functions. In consequence, the measured results may depend on the time-scale of the experiment[64].

10. Experimental Determination of Relaxation Processes in the Frequency Domain

Even in the early stages of photochemical hole burning, workers were aware of the possibility of determining relaxation times[5,73] from measurements of homogeneous line widths as defined by equations (12) and (19). By choosing appropriate experimental conditions, one can select the external parameters such that the following conditions hold

a) $1/T_2^* \ll 1/2T_1$ or b) $1/T_2^* \gg 1/2T_1$

Case a) is, for example, frequently fulfilled if the resonant state is a vibrational state. In experiments conducted using crystals at 4 K, the vibrational relaxations are, in general,

much shorter than the pure dephasing times and hence, vibrational relaxation times can be measured down to the sub-picosecond range. Systematic experiments for various vibrational levels have been published for porphin in *n*-alkane matrices[89]. Figure 22 shows that there is no straightforward relation correlating the relaxation times with the vibrational energies. The measured relaxation times vary over the range 1 to 40 ps. More recent experiments have shown that the vibrational relaxation in porphin strongly depends on the host matrix and on the local molecular environment[90]. Besides the experimental determination of vibrational relaxation times, the relaxation times of purely electronic transitions can also be measured[59,74,91]. These experiments are more difficult, since the relaxation times involved are comparatively long and, hence, the line widths quite narrow. The laser stability required, therefore, has to be better than 10 MHz ($=3\times10^{-4}$ cm^{-1}). In most crystalline systems the line width at 2 K is limited by the lifetime of the excited state [eq. (10)]. (The situation is more complicated in the case of glasses, since the underlying physics is rather complex (see Section 13).) If the temperature is raised, the line width increases rapidly and one approaches the range b), in which the line width is determined by pure T_2^*-dephasing processes.

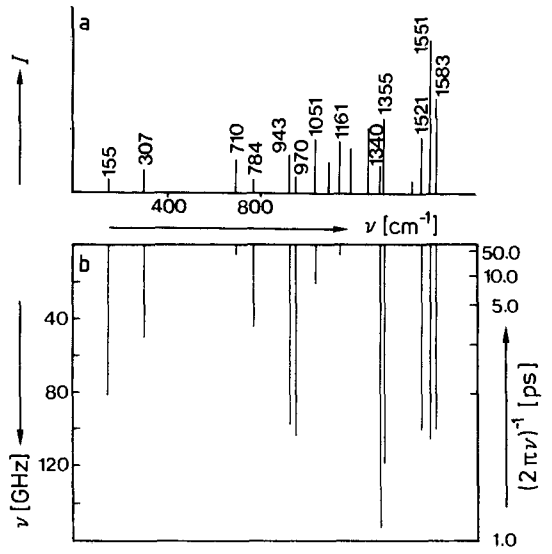

Fig. 22. Line widths of various vibronic states of porphin in *n*-octane [89]. a) Schematic excitation spectrum; b) corresponding line widths. *ν*: Frequency offset from the origin.

As discussed qualitatively in Section 3, phase relaxation is due to elastic phonon scattering processes in the various electronic levels. If these scattering processes are caused by the entire Debye phonon-spectrum (non-resonant scattering), then, well below the Debye temperature Θ, the line width follows a power law proportional to T^7:

$$\gamma_h(T)-\gamma_h(0)=\gamma_2\left(\frac{T}{\Theta}\right)^7 \tag{41}$$

Above the Debye temperature this power law changes to a quadratic law; γ_2 is a constant and is not a function of temperature (see [23]).

If the scattering processes are mainly due to a single, localized phonon state of frequency ω_0 (such as, e.g., a libration of the molecule), it can be shown that the temperature-dependence of the linewidth γ_h is given by the thermal occupation number of the pertinent phonon state, leading to the following relation:

$$\gamma_h(T)-\gamma_h(0)=\gamma_2'\langle n(\omega_0)\rangle(\langle n(\omega_0)\rangle+1) \tag{42}$$

where $\langle n\rangle$ is given by equation (13). In this case one speaks of resonant phonon scattering. For $\hbar\omega_0 \ll kT$, equation (42) leads, to a good approximation, to a quadratic temperature dependence. For $\hbar\omega_0 \gg kT$, one can extrapolate to an exponential behavior $\exp(-\hbar\omega_0/kT)$[74,92].

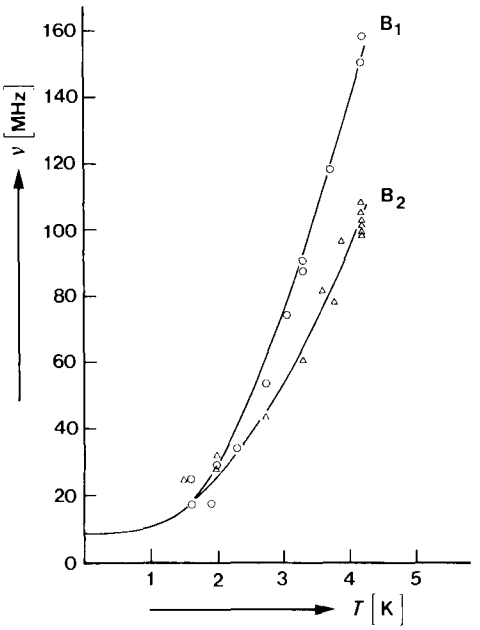

Fig. 23. Temperature dependence of the homogeneous line width of porphin in *n*-octane for the B_1- and B_2-sites [74].

Figure 23 shows the homogeneous line width of porphin in *n*-octane as a function of temperature[74]. The theoretical curves are calculated using equation (42). As $T\rightarrow0$, the line width approaches the limiting value of 9 MHz. This corresponds to the "Heisenberg limit", in which the line width is given by the fluorescence lifetime.

The influence of local lattice vibrations can also be interpreted within the framework of the theory of the optical exchange mechanism[59,93,94]. Figure 24 shows the main features of the model: The optical transition between the two phonon levels shows an energy mismatch Δ with the purely electronic transition. Since the phonon states are, in thermal equilibrium, constantly created and annihilated, the optical line constantly jumps between the two transition frequencies ω and $\omega+\Delta$. This leads to a broadening which for low temperatures ($\hbar\omega_0 \gg kT$) is given by

$$\gamma_h(T)-\gamma_h(0)=2\Delta\tau\frac{\Delta}{1+\Delta^2\tau^2}\exp(-\hbar\omega_0/kT) \tag{43}$$

where τ is the lifetime of the excited phonon state. A characteristic feature of the model is the frequency shift as a function of temperature, which is given by:

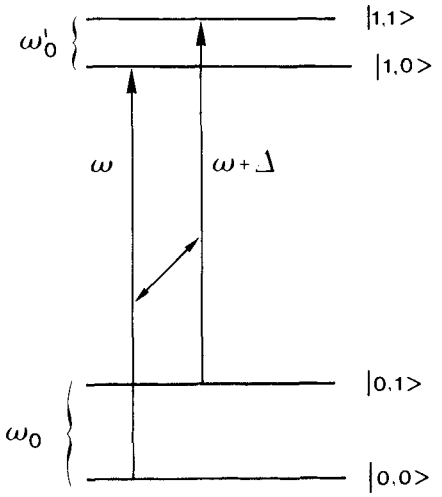

Fig. 24. Four-level scheme on which the optical exchange narrowing model is based (see text).

$$\omega(T)-\omega(0)=\frac{\Delta}{1+\Delta^2\tau^2}\exp(-\hbar\omega_0/kT) \tag{44}$$

Three cases can be distinguished[94]:

Fast exchange: $\Delta\cdot\tau\ll 1$
Slow exchange: $\Delta\cdot\tau\gg 1$
Intermediate exchange: $\Delta\cdot\tau\approx 1$

By measuring both the frequency shift and the line broadening as a function of temperature, one can determine the quantities Δ and τ as well as the energy of the associated phonon state. For porphin in *n*-octane the phonon energy was found to be 15 cm^{-1}; its lifetime was estimated to be 3 ps.

In the slow exchange limit the frequency shift is very small, and $\gamma_h(T)$ is independent of Δ[95].

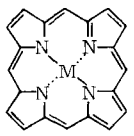
In equations (43) and (44) τ is assumed to be independent of temperature. This assumption may be valid for phonons over a narrow temperature range. Since, however, the exchange can also occur with states other than those of phonons (e.g. TLS), τ can become temperature dependent. In this case, situations in which $\gamma_h(T)$ increases with increasing temperature and those in which it decreases with increasing temperature (optical exchange narrowing; see Section 13) can be encountered.

11. Photochemical Holes in External Fields

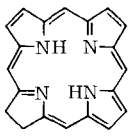
Due to their narrow width, photochemical holes can be regarded as excellent frequency markers which allow one to measure spectral changes of the order of a line width. These small changes would remain undetected, if one were to measure the complete broad inhomogeneous band. Hence, hole burning can be used to increase the experimental accuracy of measured line shifts by several orders of magnitude. This has been used for to measure small Zeeman and Stark shifts in doped crystals and glasses.

11.1. Zeeman Experiments

Zeeman studies of optical transitions of organic molecules were conducted in 1971 using metal porphinates[96]. These molecules have D_{4h} point group symmetry; their S_1-state is characterized by an electronic angular momentum perpendicular to the molecular plane (z-axis), which gives rise to a magnetic moment in the S_1-state. The twofold degeneracy of the S_1-state is removed in the crystal field,



Metal(II)-porphinate



Chlorin

leading to a small splitting. Due to the small splitting, the interaction between the two crystal field states is comparatively large and, therefore, the energy shift ΔE in an external magnetic field is, in case of the S_1-state, larger than the inhomogeneous band width. This large energy difference can readily be detected and allows the determination of the matrix element Λ characterizing the angular momentum:

$$\Delta E=-(\beta\Lambda H_z)^2/(E_2-E_1) \tag{45}$$

$$\Lambda=|\langle S_1|L_z|S_2\rangle| \tag{46}$$

Typical Λ values range between 4.2 and 4.3. Λ is an interesting quantity, because it can be calculated within the framework of structural models. Comparison with experimental data permits a convenient examination of the validity of the molecular models.

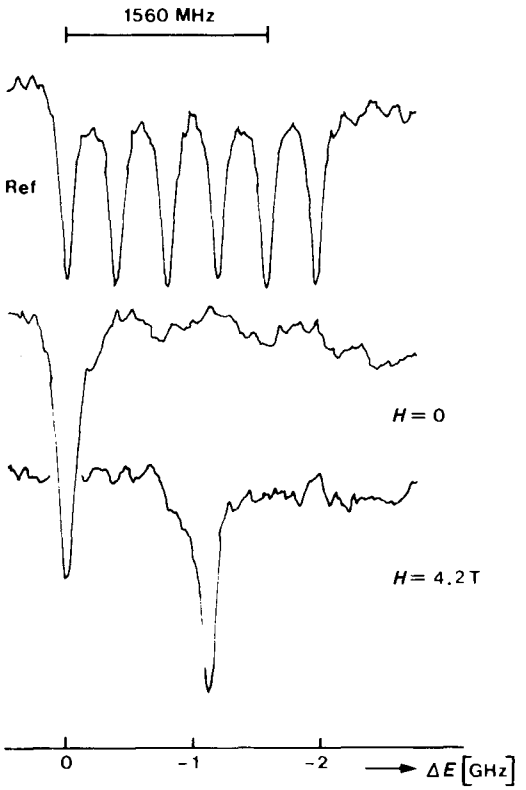


Fig. 25. Zeeman shift of a photochemical hole of porphin in *n*-octane [97] (see text).

These experiments are not feasible with the free base porphin. Because the molecular symmetry is lowered from D_{4h} to D_{2h} the two levels, which were originally split by the crystal field, are now split by the molecular field and are ca. 3000 cm^{-1} apart. Equation (45) shows that the Zeeman-shift is inversely proportional to the energy splitting and, thus, one can expect Zeeman-shifts of 0.03 cm^{-1}, which is about 1/30th of the inhomogeneous line width Γ (Γ in n-alkane crystals is ca. 1 cm^{-1}). Nevertheless, by applying PHB methods it was possible to determine the Zeeman shift[97]. Figure 25 shows the results obtained using two identical samples at 2 K. One of the samples was in a superconducting coil; the other sample was used as a reference wavelength marker into which a series of holes was burnt, which were separated by the laser modes. The "master sample" had only one hole, whose shift with external magnetic field could be measured by comparing it with the hole pattern of the reference sample. Using this high precision method, it could be shown that the Λ-value is much larger for free base porphin relative to those of metal porphins. With the same method one could also perform Zeeman experiments using the two tautomers of chlorin (7,8-dihydroporphin)[98,99]. By comparison of the corresponding Zeeman-shifts in the various "sites" of the *n*-alkane crystal the energy difference E_2-E_1 and Λ for both tautomers could be determined.

Transient optical hole burning experiments were performed using inorganic crystals. Since these crystals do not exhibit "permanent" photochemical states for the hole burning experiment, their nuclear hyperfine states were used as long-lived "hole states", marking the shifts by external fields[100,101]. If hyperfine states are used one can utilize holes as probes for RF-transitions in the spin systems and develop rather sophisticated techniques [optical detection of nuclear magnetic resonance (ODNMR) and optical detection of nuclear quadrupole resonance (ODNQR)].

11.2. Stark Experiments

Similar techniques can be used to study molecular interactions with external electric fields with vastly increased precision. Molecules without centers of inversion possess a permanent dipole moment and, hence, their transition energy changes linearly in an external electric field (linear Stark-shift). Symmetric molecules without permanent dipole moments exhibit a quadratic Stark-shift.

By evaluating these shifts, small changes in the dipole moment and in the polarizability upon electronic excitation can be measured. Frequently these methods also give some insight into the relative orientation between the guest molecule and the host crystal. Figure 26 shows the results of a Stark experiment with chlorin[102]: The hole observed exhibits splitting in an external electric field due to the inversion symmetry of the crystal. Whereas the dipole moment of chlorin only changes its absolute value (0.23 D), its photo-isomer also changes its direction. The directional change of the isomer is also "site dependent", presumably because of the strong S_1, S_2 mixing which occurs due to the small S_1-S_2 energy gap.

A combination of spectral hole burning and Stark effect has also been applied to color centers in NaF[103-105]. The

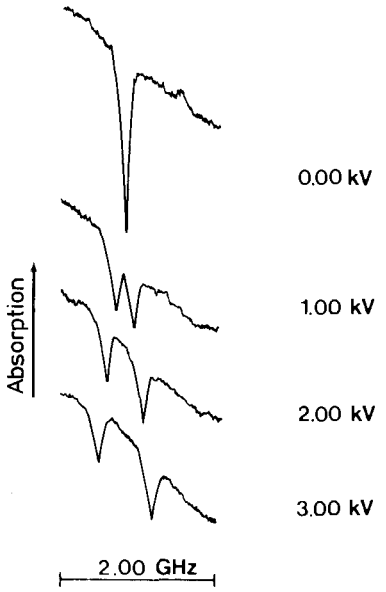

Fig. 26. Stark-shift of a photochemical hole of chlorin in *n*-hexane [102] (see text).

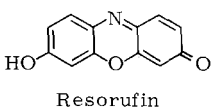
hole burning mechanism presumably involves either photo-ionization or electron tunneling in the excited state. The observed lifetimes of the corresponding photoproducts can be rather long (back tunneling to the original state). Stark experiments allow conclusions to be drawn which clarify both the symmetry and microscopic nature of the corresponding color centers.

Stark experiments in glasses are rather different from those in single crystals. Here, the external field leads mainly to broadening of the observed holes due to the geometry of the isotropic glass. From the increase in line width, the average changes in the electric (or magnetic) dipole moment can be calculated. The initial experiments were performed on the sodium salt of resorufin (Fig. 27) in



Resorufin

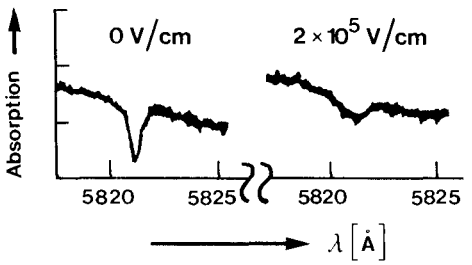


Fig. 27. Stark broadening of a photochemical hole of the sodium salt of resorufin in poly(methyl methacrylate) films [106].

poly(methyl methacrylate) films[106]. From these experiments one could infer a change of the dipole moment of 0.25 D upon excitation to the S_1-state. If holes are burned while an external field is applied[107,108], the hole-spectrum can subsequently be scanned by scanning the external field (Fig. 28). The maximum hole depth is achieved if the field

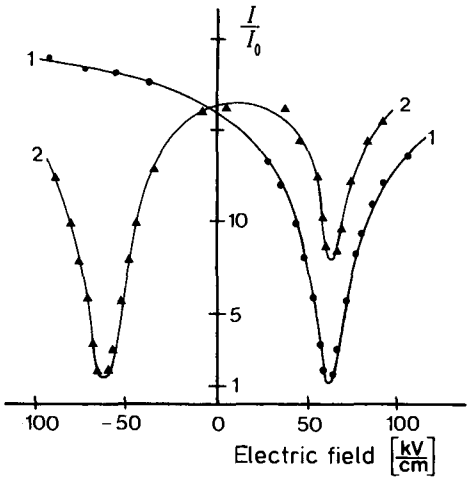

Fig. 28. Line shape of a photochemical hole as a function of the external electric field. System: Perylene in poly(vinylbutyral). 1) Hole burnt at a field of +60 kV/cm. 2) Additional hole burnt at a field of −60 kV/cm [107].

equals that at which the photochemical reaction was performed, in both magnitude *and* direction. The hole can therefore be viewed as a "memory" of the field strength and direction during the PHB photochemistry.

12. Non-Resonant Holes and Correlation Effects

Each photochemical hole burnt at the laser frequency ω_L must, in principle, appear in all other optical bands of the photoreactive molecule. A photochemical hole can therefore be investigated off-resonance at a frequency which is far removed from that of the laser. This experiment raises the question of what information can be gained using such a procedure.

Figure 29 gives an example of non-resonant hole burning: A hole was produced in the first vibrational band of 1,4-dihydroxyanthraquinone at ca. 5030 Å. As a consequence, a whole sequence of holes appears in the 00-band of the molecule. The non-resonant holes in the 00-band are considerably wider than the resonant hole at frequency ω_L. Figures 30 and 31 give a more detailed view of this situation. The occurrence of multiplets of holes was first observed by *Kharlamov* et al.[109]. Multiplets appear because the difference in the frequencies of vibrational states can be smaller than the inhomogeneous band width. Hence, irradiation at ω_L leads simultaneously to photochemical holes at various sites, which appear at different frequencies in the 00-band.

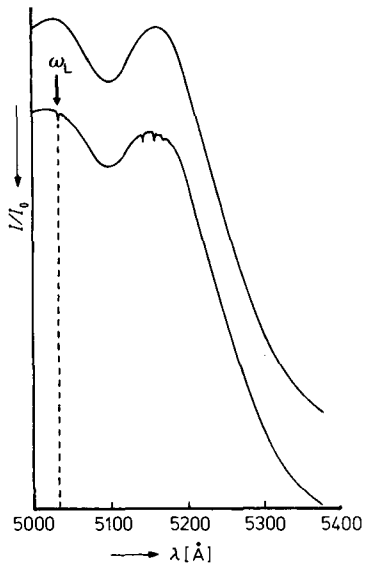

Fig. 29. Absorption spectrum of quinizarin in an ethanol-methanol glass (3 : 1) before and after hole burning at 5032 Å (1 mW/cm², T = 1.8 K). Several satellite holes appear in the 00-band of the spectrum [110].

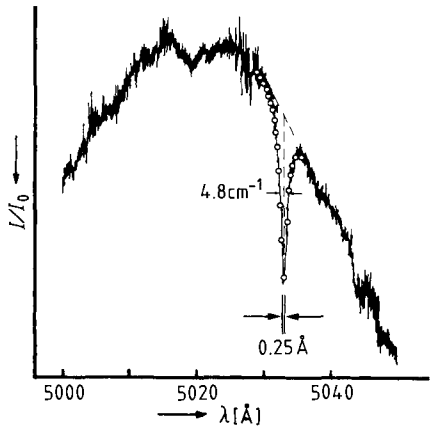

Fig. 30. Enlarged section of the spectrum of Figure 29. Resonant hole [110].

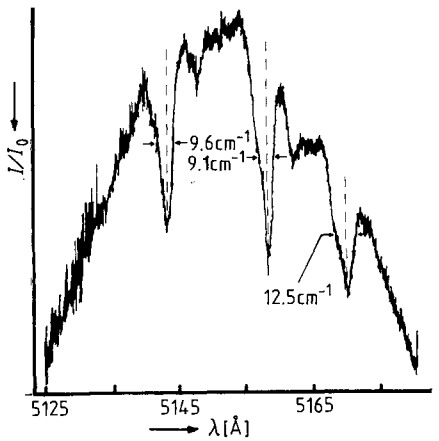

Fig. 31. Enlarged section of the spectrum of Figure 29. Nonresonant satellite holes [110].

If one wants to calculate the hole shape and hole width of the relaxed holes[110], a joint probability distribution must be considered. This distribution determines the probability of detecting a photochemical process at frequency ω_2 (of the inhomogeneous 00-envelope), initiated with laser irradiation into a vibronic transition at ω_1. This is rather analogous to the problem of correlating the errors in two variables[111]. In the simplest case, the distribution function is given by a two-dimensional Gaussian distribution [eq. (47)].

$$G(\omega_1-\omega_n,\omega_2-\omega_0)=\frac{4\ln 2}{\pi\Gamma_0\Gamma_n\sqrt{1-\rho^2}}\exp\left\{-\frac{4\ln 2\cdot(\omega_1-\omega_n)^2}{\Gamma_n^2}\right\}\exp\left\{-\frac{4\ln 2\cdot[(\omega_2-\omega_0)-(\omega_1-\omega_n)\hat{S}]^2}{\Gamma_0^2(1-\rho^2)}\right\} \quad (47)$$

$\hat{S}$ is a scaling factor, which becomes 1 if the inhomogeneous widths Γ_n of the state n (here a vibrational state) and Γ_0 of the state 0 are identical. ρ Characterizes the degree of correlation:

$$\rho\equiv\frac{\langle(\omega_1-\omega_n)(\omega_2-\omega_0)\rangle}{\Gamma_n\Gamma_0};\qquad 0\le|\rho|\le 1 \quad (48)$$

By examining two limiting cases, the significance of ρ becomes apparent. If $\rho=1$ complete correlation results; the second Gaussian function in equation (47) ist a δ-function and there is complete site selectivity in the non-resonant state. The widths of the non-resonant holes in this case are narrow and determined by the pertinent dephasing times. (The fluorescence from the non-resonant state is also narrow.) If the condition $\rho=0$ holds, the second Gaussian function in equation (47) has a width of Γ_0, i.e. a state which had been site-selected in the vibrational level n will be spread over the complete inhomogeneous band characterizing the 00-transition. In the latter case no narrow holes appear at the origin. In reality, one finds the situation of intermediate correlation. Here the hole shape can be calculated by a convolution of the zero-phonon lines $z_n(\omega)$ and $z_0(\omega)$ with the corresponding inhomogeneous profiles given above can be measured. If instead of focussing on a (i.e. to a convolution of a Gaussian and Lorentzian profile). If the homogeneous line widths in the states n and 0 are small compared to the width of the non-resonant holes, the shape of the non-resonant holes is Gaussian and their widths are given by $\Gamma_0(1-\rho^2)^{1/2}$.

By measuring this width (Figs. 30 and 31), one can calculate the loss of correlation between the vibrational state considered and the electronic origin: for quinizarin, $1-\rho\approx 10^{-5}$.

This means that the vibronic transitions are highly correlated with their electronic origin. It is only because of the narrow hole width that correlation losses as small as those given above can be measured. If, instead of focussing on a vibrational state n, one focussed on a different electronic state, for amorphous hosts, a vanishing correlation occurs as a rule. However, there is a possibility in crystalline materials that a certain degree of correlation may still exist even for different electronic states. Experiments probing the degree of correlation can therefore be looked upon as experiments which shed light on the role played by the solvent in optical excitation processes.

To understand the correlation phenomena discussed here, one has to consider a microscopic model. *Gorokhovskii* and *Kikas*[112] assumed that the inhomogeneity not only affects the various electronic levels, but also independently the vibrational levels. Figure 32 reflects this argument for an energy level scheme. If one excites into a vibrational level, two different sites are excited which have slightly different vibrational energies, but which, nevertheless, absorb at the same frequency ω_L. In the 00-transition both sites differ in frequency by the difference of their vibrational energies. If instead of two sites one has a complete site distribution, the above argument leads to an inhomogeneous broadening of the vibrational frequencies. This broadening is, on a relative scale, comparable to the inhomogeneous broadening of electronic levels. Besides correlation effects, using non-resonant holes, one can study the vibrational frequencies of photoactive molecules in the excited state[109,113]. Even in glasses, these frequencies can be studied with great accuracy. These experiments complement FLN techniques which allow the determination of ground state frequencies. By using both PHB- and FLN techniques vibrational frequency changes upon electronic excitation of molecular states can therefore be measured with great accuracy.

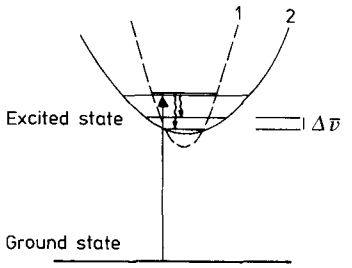

Fig. 32. Microscopic model describing the observed vibrational inhomogeneities. Sites 1) and 2) have slightly different vibrational energies.

13. Amorphous Solids

In 1976 the first fluorescence line narrowing (FLN) experiments were performed using inorganic glasses doped with paramagnetic ions and it was observed that optical properties in crystalline systems were quite different from those in amorphous solids[114]. For example, the homogeneous line width did not increase with T^7 (see Section 10), but increased with a lower temperature exponent. Similar observations were made for ESR and NMR experiments[115-117]. In addition, the observation was made that the homogeneous line width in glasses was much larger than that in crystals[114,118,119].

At first, these results came as a surprise, because it was known that the Debye model could be applied to glasses, and that optical line widths were mainly determined by elastic phonon scattering. A comparison of these new findings with results obtained from experiments on organic glasses created some new aspects. FLN experiments could only partly be evaluated due to the above discussed difficulties concerning correlation effects. Most new aspects therefore came from hole burning experiments[11,45,46,61,106,119] (see also [5]). Even the initial experiments indicated that the optical line widths in organic glasses were larger than those typical of inorganic glasses[46]. The measured hole widths were, even at 2 K, almost a wavenumber; this was an important fact, which had to be taken into account by theoretical considerations. As we have seen in Section 3, the homogeneous line width as $T\rightarrow 0$ is given by the "Heisenberg-limit", i.e. by the lifetime

of the excited state [eq. (10)]. Hole burning experiments, however, showed deviations from the Heisenberg-limit of up to three orders of magnitude, and there was considerable discussion as to the possibility of a residual line width as $T \rightarrow 0$. This discussion was interesting, because some systems, like porphin, allowed an extrapolation to the "Heisenberg-limit" as $T \rightarrow 0$[120-122] (with a power law $T^{1.33}$). Similar results were obtained for chlorin in polymer films[123]. The various conflicting data showing different temperature exponents and different residual line widths stimulated various theoretical model calculations[44,46,119,124,125-129]. One of the salient points of most models was a coupling mechanism of the dye probe molecules to the double-well potentials of the glassy state (Fig. 33a). If coupling to a single double well potential is considered, one has to deal with a total of four levels (Fig. 33b). It is of importance that a glass is, by definition, a system which is not in thermodynamic equilibrium; it has a residual entropy at $T=0$. Therefore, even at this temperature relaxation processes can occur via phonon emission (Fig. 33b), and can contribute to the line width. For a final assessment of this situation, however, a complete knowledge of the microscopic glass parameters would be necessary: Such parameters are barrier heights and energy values of the TLS levels, coupling matrix elements, veclocities of sound, etc. With these parameters still undetermined, the question as to the "true" homogeneous line width has no definite answer, yet.

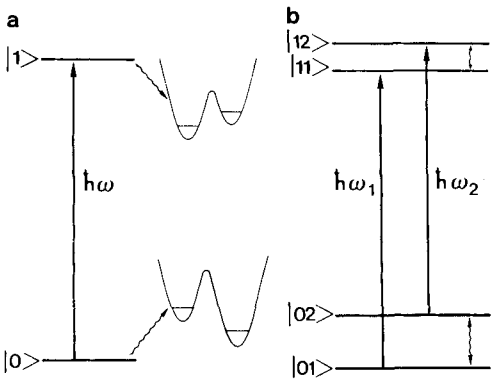

Fig. 33. a) Model describing the coupling of an optical transition to the tunneling potentials of a glass. b) Generalized level scheme. The symbols $|0\rangle$ and $|1\rangle$ correspond to the electronic excitations. The symbols $|01\rangle$, $|02\rangle$ and $|11\rangle$, $|12\rangle$ symbolize the corresponding tunneling states in the ground and excited states, respectively.

New theoretical aspects were introduced by considering "fractal dimensions"[130]. We can visualize this new concept by constructing a glass through areas of solid material, which are statistically interrupted by areas of "free volume". The general topological properties of such a composite system can, in general, not always be described by a three-dimensional model. The topology could, for example, be mainly two-dimensional with some "local defects" pointing into the third dimension. This is important for calculations of the phonon density of states, which can be different from the usual situation encountered in a three-dimensional lattice. The new dimensionality is smaller than three, yet, larger than two: One can speak of "fractal dimensions", whose elementary excitations are termed "fractons". If the TLS-levels are coupled to fractons, instead of to phonons, one can expect different power laws for the optical line width due to the different density of states[131]. Under certain conditions (percolating network, dipole-quadrupole coupling) one arrives at a power law of $T^{1.33}$. There is, however, a limitation to the applicability of fracton excitations. The theory can only be applied above a critical temperature T_c. At the critical temperature the average phonon wavelength is of the length of a structural domain. Therefore, one has to consider domain excitations for $T > T_c$ and thermal phonon excitations for $T < T_c$. In the latter case the domain structure is of little relevance and a simple Debye spectrum can be assumed. A temperature law of $T^{1.33}$ has also been obtained by other theoretical approaches[129,134].

The concept of two-level systems also leads to further, interesting consequences (Fig. 33b): Since the TLS-splitting is, in general, different in the ground and excited states, the transitions 1 and 2 of the four-level scheme are non-degenerate. At low temperatures this difference in TLS-splittings contributes to the optical line width. It can be assumed that, at high temperatures, the relaxation pathways shown in Figure 33b are so efficient that optical "exchange narrowing" takes place. If one were to assume that the relaxation processes slow down at low temperatures, an increase of the line width with decreasing temperature would be expected, as is shown in Figure 34[132]. Line broadening of this type with decreasing temperature is well known in NMR spectroscopy; however, to our knowledge no comparable results have been obtained in the optical domain, other than the preliminary data on amorphous polymers.

The discovery of irreversible contributions to the optical line width of dye molecules in glasses is of considerable importance[45,65]. Similar phenomena are not known from single crystal data and, hence, have to be discussed in some detail.

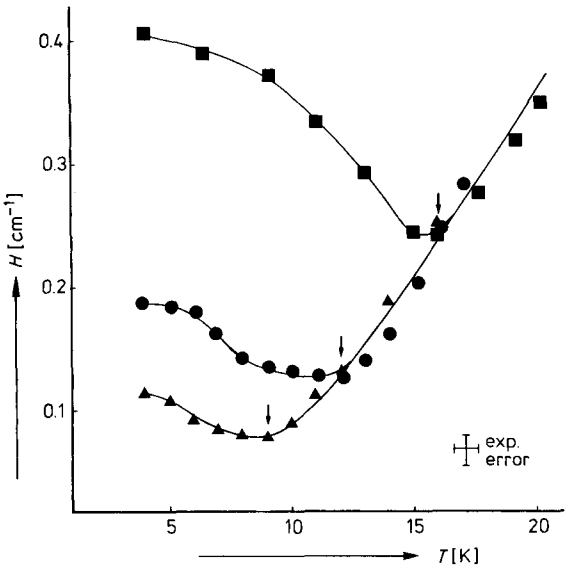

Fig. 34. Hole width as a function of temperature for phthalocyanine in polyethylene. The arrows mark the burning temperature. The increase of line width with falling temperature is rather unusual [132].

We start with the concept that a glass can be described by a distribution of double well potentials. In this model a "particle" can tunnel from the left potential minimum to the right potential minimum: in thermal equilibrium both processes occur. Associated with the tunneling processes are changes in the optical energy of the particles, since the potential curves are different in the ground and excited states (Fig. 33a). It is evident that the tunneling dynamics do not change the total number of molecules absorbing at a given frequency and, hence, the inhomogeneous line profile does not change in time and temperature; in other words the "site population" is in a stationary state.

This situation changes if, by light irradiation, a hole is burnt into the inhomogeneous distribution. The equilibrium is then perturbed and more particles tunnel into the hole relative to those tunneling out of it. This process leads to a change in line width by spectral diffusion[124, 133, 134]. Processes of this kind are always present and can be detected with high sensitivity in hole burning experiments at low temperatures (5 K in Fig. 35a) and by subsequently cycling the temperature. At higher temperatures the rates determining spectral diffusion increase via thermally assisted processes. The glassy state moves towards a state of new quasi-equilibrium. If the temperature is recycled to the low value again, the new state is frozen in and can be evaluated spectroscopically. In the case of quinizarin, the increase in line width is a factor of two. The hole width changes irreversibly with temperature; it becomes dependent on the sample history, a characteristic feature of non-equilibrium systems.

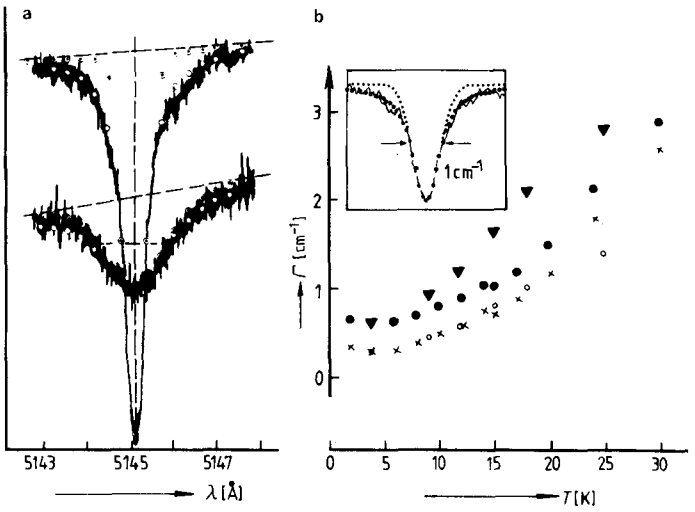

Fig. 35. a) Irreversible contributions to the line width. Both holes were burnt at ca. 5 K. The broad hole was subsequently exposed to a temperature cycle during which the sample was rapidly warmed up to 20 K. System: Quinizarin in ethanol glass [45]. b) Hole width as a function of temperature. ▲: Burning temperature equals temperature of spectroscopic experiment. ●: Burning temperature 2 K. ○, ×: Reduction of both curves to one master curve (good fit up to 20 K) [65]. System: Quinizarin in boric acid [45].

Because of these irreversible diffusion processes, one has to proceed with extreme care if it is desired to measure a homogeneous line width and its temperature dependence. If, for example, a hole is burned at low temperatures and one subsequently investigates the hole at higher temperatures, the result obtained differs from that had the hole burning process been performed at each individual temperature point (Fig. 35b)[45, 65].

At present, the time scale of these diffusion processes is not known exactly. It seems that there are processes which occur on the T_1-time scale, but there are also very slow processes. The different time scales arise because of the different barrier heights and the different tunneling distances and masses.

Hole burning offers a means of investigating the time scale of such diffusion processes. It should be mentioned, however, that spectral diffusion in photochemical hole burning can be due to two different processes: It can be caused from the reorientation of molecules in the ground-state (physical dark process) and can also be caused by a back reaction from the $|P\rangle$ state to the $|R\rangle$ state (Fig. 13) (chemical dark reaction). Both processes may change the hole width in a different way.

The chemical dark reaction has been investigated in only a few systems[135, 136]. It was found for quinizarin in alcohol glasses that the reaction occurs on a logarithmic time scale (Fig. 36)[136]. Between 1.3 and 4.2 K the slopes of the logarithmic decay curves show little temperature dependence, but exhibit a pronounced isotope effect upon deuteration of the sample. We would like to discuss briefly how such a behavior can be understood.

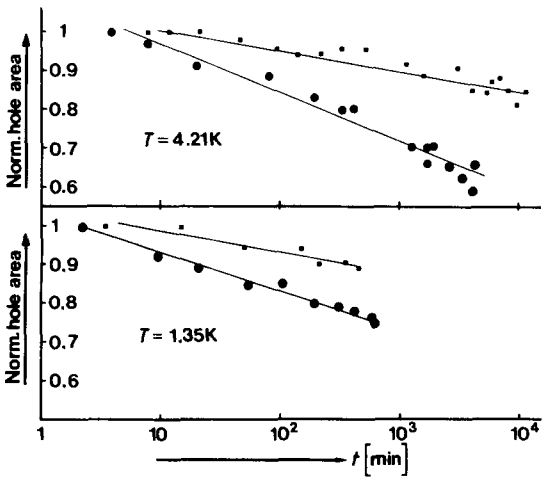

Fig. 36. Hole recovery as a function of time using the system quinizarin in ethanol-methanol glass (3 : 1) ● and in perdeuterated ethanol-methanol glass (3 : 1) ■. The slopes show a pronounced isotope effect [136].

Two main points have to be considered: a) The back reaction occurs via tunneling and b) the distribution of the reaction rates is given by the corresponding tunneling rates, as determined, for example, by measurements of the specific heat. Point a) is corroborated by the experimentally determined isotope effect. Point b) is plausible, since the back reaction, which involves reorientation of a hydrogen bond, is matrix controlled, i.e. depends on the local geometry of the solvent cage. If one accepts these assumptions, the number of molecules which have returned to the educt state after a time t can be calculated by integrating the rate distribution function:

$$\frac{n}{n_1} = N_0 \int_R^{R_1} p(R)\,\mathrm{d}R \qquad (49)$$

where n_1 is the number of molecules in the photoproduct state after a time t_1 has elapsed between hole burning and the first probing experiment. $p(R)$ is the distribution function of relaxation rates, as obtained from specific heat measurements[34-36]:

$$p(R) = \frac{\hat{P}}{2} \cdot \frac{1}{R\sqrt{1-R/R_{max}}} \tag{50}$$

where R_{max} is the fastest relaxation rate, R_{min} is the slowest rate, and $\hat{P}$ is a constant. The constant N_0 normalizes the number of particles. It is clear that for different observation times different relaxation rates $R = 1/t$ are observed. The fastest rate which can be observed in a hole burning experiment is given by $R_1 = 1/t_1$. If it is assumed that $1/t_1$ arises because of the slow time scale of our experiment, i.e. is small compared to R_{max}, then the square root in equation (50) can be neglected. After integrating equation (49), one obtains an expression for the relative hole area which shows a logarithmic time dependence

$$\frac{A}{A_1} = 1 - \left[\ln \frac{R_1}{R_{min}}\right]^{-1} \ln \frac{t}{t_1} \tag{51}$$

From the slope of the hole decay, as given in equation (51), the ratio of the rate constants R_1/R_{min} can be estimated. The ratios vary, for the various experiments, over a vast range, i.e. 8 orders of magnitude for protonated alcohol glass and 19 orders of magnitude for deuterated alcohol glass[136]. A logarithmic decay law corresponds to the slowest possible decay kinetics. The holes therefore persist over very long time intervals.

Finally, the problem of the large optical line width of holes has to be addressed. A typical example is quinizarin, whose hole width in an EtOH/MeOH glass at 1.3 K is 0.55 cm^{-1}. Power- and saturation-broadening can be ruled out. This value is two to three orders of magnitude removed from the "Heisenberg-limit" which should be valid as $T \rightarrow 0$. The question therefore arises as to whether or not this line width can be considered as the homogeneous width. Alternatively the following situation could be conceived: It is feasible that fast spectral diffusion processes set in immediately after the hole burning has created a non-equilibrium situation. This spectral diffusion could, in principle, also mask photochemical saturation (i.e. refilling of a hole which is close to the bottom of the band).

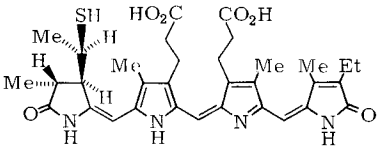
Spectral diffusion can also be initiated by external parameters[42, 137-140]. An ultrasonic pulse, for example, can be partly absorbed by the TLS-levels and, thus, lead to changes in the optical energy levels. Consequently, a spectral hole can be refilled by sound waves. In this respect one can look upon a hole as a "phonon memory"[42].

For a more detailed view of the optical properties of glasses it must finally be considered that not only the TLS-parameters are given by distribution functions, but also most other parameters which enter the model description (Section 9); for example, the Debye-Waller factor, the photochemical yield, and the thermal stability of the photoproduct[64]. Even the homogeneous line width need not be uniform[5]. All these parameters contribute to the spectral properties and to the time dependencies which characterize hole burning. It can therefore be appreciated that optical hole burning can be used as a sensitive tool for investigating subtle aspects of the physics of the amorphous state.

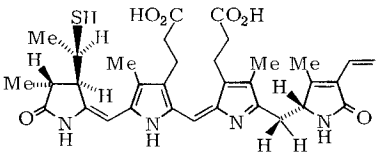
14. Photochemical Hole Burning in Biological Systems: Phycobiliproteins

14.1. Antenna Pigments

Chlorophyll is the most essential part of the photosynthetic reaction center, but has a comparatively low absorption coefficient in the visible spectrum. In photosynthetic organisms a great deal of the sunlight is absorbed by so-called antenna pigments. These channel the absorbed photon energy to the reaction centers. The phycobiliproteins such as phycoerythrin (PE), phycocyanin (PC), and allophycocyanin (APC) (see Fig. 37) characterize a class of antenna pigments. The pigments contain several dye molecules (chromophores) which are coupled via energy transfer processes (see e.g. [11]). The chromophores are covalently bound, at least at one position, to their protein environment and their excitation energy differs both due to the different micro-environment of the protein and their different structures. The energy transfer process between the chromophores is therefore non-resonant.



Phycocyanobilin



Phycoerythrobilin

Conventional optical spectroscopy of antenna pigments is handicapped by low optical resolution due to the large inhomogeneous band width of the pigment spectra. Until

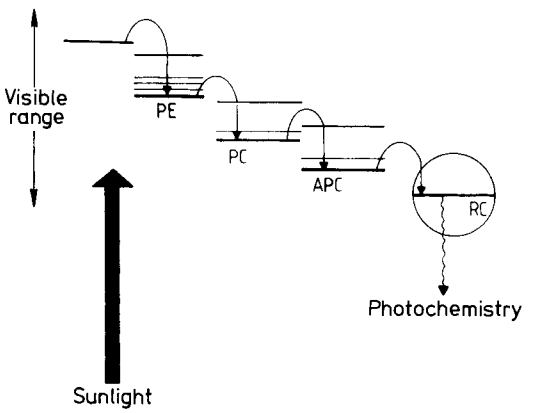


Fig. 37. Energy levels and energy transfer in the antenna pigments. PE: phycoerythrin, PC: phycocyanin, APC: allophycocyanin, RC: reaction center.

now it was therefore impossible to investigate the spectroscopy of the various chromophores selectively. Hole burning is a new approach in this direction, because it increases the optical resolution by several orders of magnitude. The first experiments on isolated antenna pigments were published in 1981[141]. In the following section we summarize the results.

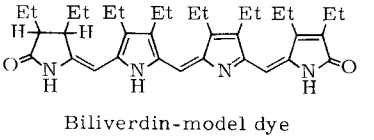
14.2. Low Temperature Photochemistry of Antenna Pigments

Figure 38 shows a sequence of photochemical holes which have been burnt into the visible bands of phycocyanin (6270 Å) and allophycocyanin (6250 Å). The numbers label the sequence of hole burning experiments. The data indicate that the creation of a low energy hole has no influence on a hole previously burned at higher frequency; however, hole burning at high frequencies seems to partly refill holes previously burned at lower frequencies. The creation of hole 3, for example, refills hole 2, but does not affect hole 1.

Fig. 38. Photochemical holes in the lowest energy band of phycocyanin + allophycocyanin. The numbers label the sequence of hole burning events [141]. $T = 1.8$ K, resolution 0.15 Å.

From this it can be concluded that the hole burning process is photo-reversible and that the photoproduct absorbs at energies higher than the absorption energies of the educt. It appears that the photoproduct state cannot be reached directly from the excited educt state (S_1). Most probably it is reached through an intramolecular relaxation process, i.e. intersystem crossing (ISC) to the triplet state T_0. In the latter case the inverse fluorescence lifetime would be an upper bound for the photochemical reaction rate.

We believe that the case considered here is a light-induced proton transfer. This assumption is supported by experiments using a model chromophore. Figure 39 shows an absorption spectrum of a biliverdin dye in an alcohol glass matrix. The spectrum splits into two bands at low temperatures. It is believed that the high energy band is due to the neutral dye molecule and that the low energy band is associated with the protonated species[142]. Only the protonated form, however, exhibits PHB-photochemistry. In general, photochemical hole burning is not possible in all spectral ranges. For example, for phycocyanin within the visible spectral range of absorption, the low energy band shows efficient hole burning, whereas the high energy band exhibits no measurable photochemical yield. Possibly the corresponding chromophore is deprotonated similarly to the model dye.



Biliverdin-model dye

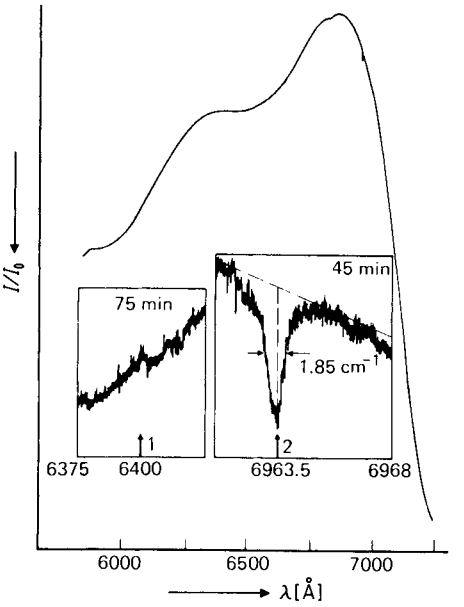


Fig. 39. Hole burning experiments using a biliverdin model dye. Only the protonated species shows measurable photochemistry (see arrow) [141]. Matrix: Ethanol-methanol glass (3:1), $T = 1.8$ K, resolution 0.15 Å.

14.3. Energy Transfer and Satellite Holes

Phycoerythrin behaves similarly to phycocyanin, the main difference being that hole burning occurs in both the high and low energy bands (Fig. 40). It is interesting to note that the creation of one hole at high energies leads to a whole series of holes which are displaced by ca. 600 cm^{-1} to lower energies. At first, one could attribute this phenomenon to vibronic hole burning, as described in Section 12. There are, however, several arguments which can be raised against such an interpretation, the principal one being that no vibrational transitions can be observed in the fluorescence spectrum. It is therefore more likely that the satellite holes are due to energy transfer between the various chromophores of the protein. In this case, one can distinguish three limiting cases.

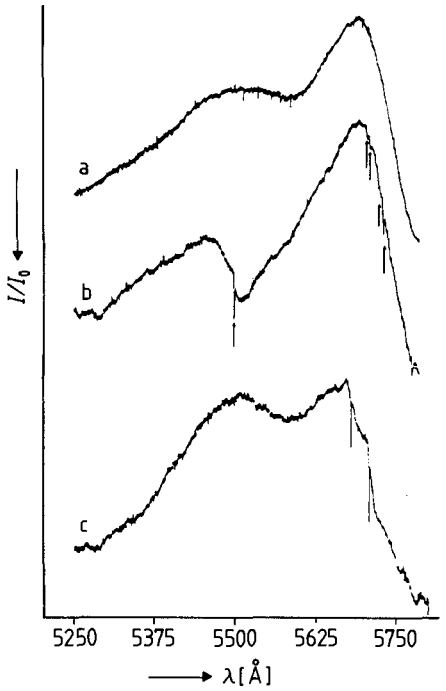

Fig. 40. Hole burning experiments using phycoerythrin [141]. a) Spectrum prior to irradiation. b) Spectrum after irradiation at 5500 Å (1 mW/cm², 10 min). The spectrum shows off-resonant satellite holes (arrows). c) Photochemical hole burning in the low energy band. No satellites appear at higher energies. Matrix: Glycerol/buffer (3:1), $T = 1.8$ K, resolution 0.2 Å.

a) The "fast transfer limit", which is characterized by

$$k_{ET} \gg k_{PR}$$

where k_{ET} is the energy transfer rate and k_{PR} is the rate of the photoreaction. In the "fast transfer limit" the excitation energy is transferred to the energy acceptor before a photoreaction can occur. In this case, only the satellite holes would be observed.

b) The "slow transfer limit", which is characterized by

$$k_{ET} \ll k_{PR}$$

In this case only a resonant hole can be observed.

c) The "intermediate transfer limit", which is characterized by

$$k_{ET} \approx k_{PR}.$$

In the latter case a fraction of the molecules can undergo a photoreaction in the time required for energy transfer to the acceptor molecules. Therefore resonant, as well as off-resonant, holes can be observed.

The PHB experiments in phycoerythrin can, in principle, be explained using the "intermediate transfer limit". As we discussed previously, the fluorescence rate and the photoreaction rate at 2 K must be two competing processes; this assumption is corroborated by fluorescence measurements[143]. Within the framework of the above model it is of special relevance that the satellite holes are rather narrow. This implies a very good correlation between the energy levels of both donor and acceptor molecules ($1-\rho \approx 10^{-4}$). As a consequence, the local molecular environment of the chromophores must be similar, i.e. well correlated from one protein molecule to the other. This would support the concept of a highly structured protein unit with the dye molecules being surrounded by a reproducible local environment (aperiodic crystal). This unit would, to a large extent, shield the inhomogeneities of the solvent cage, at least for some of the chromophores. From these arguments one would also conclude that the energy transfer to the lowest energy chromophore is a relaxation process, which channels the energy downhill along a well defined "energy ladder". The results of polarization experiments seem to support such a view[143].

Based on the sharp structure of the zero-phonon holes, one might conclude that the fluorescence is also structured if observed under FLN conditions. This, however, has not been found for phycoerythrin and phycocyanin[144]. Obviously, there is no high degree of correlation between the absorbing and the fluorescening chromophores, which have, as a rule, the lowest energies. One might speculate that these chromophores lie close to the protein surface and are, therefore, exposed to the inhomogeneous environment of the glass matrix (glycerol/buffer solution).

15. Technical Applications

Photochemical hole burning has potentially interesting applications. Quite evident is the application for creating ultra-narrow optical filters with band widths in the MHz range. Holes could also be used as frequency markers (cf. Section 11) and for stabilizing lasers. It has been reported that holes can be used to modulate optical pulses[145, 146]. A rather attractive application has been pursued since 1978: The use of PHB for ultra-high density storage of data in the optical range[147–149]. Figure 41a shows a possible storage scheme. It consists of a spatial matrix of optical bits which can be scanned by a laser beam. If the laser hits a transmitting spot, it detects a logical 1 (an opaque spot would be 0). The highest storage density of such a scheme would be given by the minimal spot size of the laser focus,

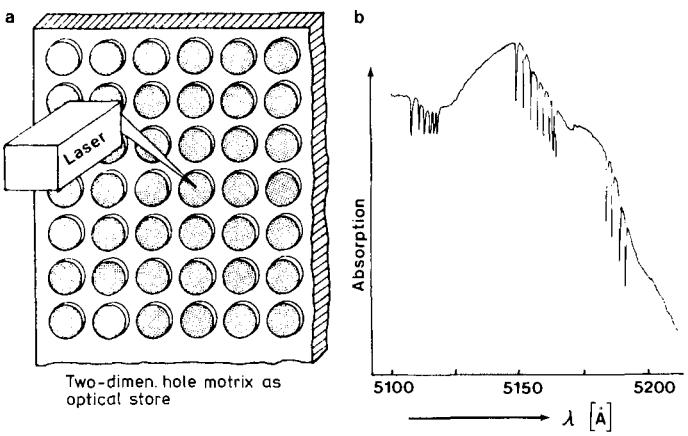

Fig. 41. a) Scheme of an optical store based on photochemical hole burning. b) Photochemical holes as bits (units of information) in the frequency domain. System: Quinizarin in ethanol-methanol glass (3:1, $T = 1.8$ K).

which is in the order of λ^2, where λ is the laser wavelength (diffraction limit). The highest possible storage density using light with the wavelength of 500 nm would therefore be 10^8 bits/cm^2. If the material used in Figure 41a is replaced by one which allows hole burning, one can conceive a frequency selective storage scheme and the bit density can be increased by a factor of 10^3 to 10^4. This factor is roughly given by the ratio of the inhomogeneous line width of the storage material divided by twice the homogeneous line width. Figure 41b shows a sequence of holes burnt into the lowest absorption band of quinizarin in an ethanol/methanol glass. The figure shows that the bits can be stored in a frequency selective fashion.

In PHB-storage the frequency is used as an additional storage dimension, i.e. a two-dimensional spatial store would be three-dimensional. One could even conceive a four-dimensional store by using spatially three-dimensional holograms[150–152]. With such a method one would approach the storage density of the human brain.

The technical problems for hole burning storage are formidable. The least of these is the refrigeration of the storage material to 4 K, whereas the major problems arise from limitations in the speed of reading and writing the information. These speeds are not solely limited by frequency addressing and spatial addressing; they are also limited by the photochemical reaction rate of the photoreactive material. Last but not least, signal to noise considerations have to be discussed in detail[153]. In the technical approach to the problem great success has been achieved using frequency modulation techniques[154, 155]. These methods show the feasibility of data rates in the MHz range. Simultaneous reading and writing in several "frequency channels" could possibly raise the data rates close to the GHz range.

The problems which still bottleneck the method stem from optimizing the photochemical system. It would be desirable to have an active material which operates in the wavelength range of semiconductor lasers (800–900 nm), which are cheap and can be easily tuned and modulated. In this wavelength range color centers in alkali halides have been used as active materials. These systems have the disadvantage of narrow inhomogeneous line widths and of a rather limited hole lifetime (several hours). As a result, the information density, as determined by the factor $\Gamma/2\gamma_h$, is considerably smaller than that of organic materials. Judging from these criteria, organic materials would, in principle, be preferable.

Another problem arises because frequent reading processes gradually bleach the material and, hence, destroy the information. A possible solution to this problem is to use more than one light quantum (two-photon photochemistry)[81, 156]. This is illustrated in the energy level scheme in Figure 42: The frequency selective absorption of the first photon creates an intermediate state $|1\rangle$, most probably the lowest singlet state S_1; it is considered to be photostable. The photoreactive state $|a\rangle$ is reached by absorption of a second photon (Fig. 42a). This can also be reached with a second photon after a relaxation process to a long-lived intermediate state $|2\rangle$ (Fig. 42b).

Depending on the energies $\hbar\omega_1$ and $\hbar\omega_2$, the storage scheme can be designed such that irradiation to level $|1\rangle$ does not destroy the photochemical information. The disadvantage of two-photon schemes is their low quantum yield. Similar schemes have been devised for holographic imaging techniques (two-photon, four-level scheme[156]).

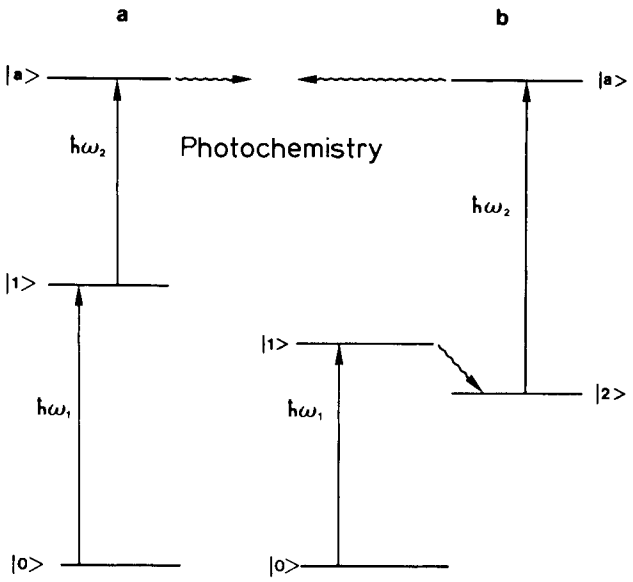

Fig. 42. Energy level scheme for hole burning via a two-photon process. a) Three-level diagram; b) four-level diagram.

From the point of view of the stability of the holes, the use of photochemical hole burning schemes appears safe. Even those photochemical holes which exhibit decay phenomena (see Section 13) decay on a logarithmic time scale, i.e. have the slowest possible relaxation mechanism.

Important results quoted in this article were obtained with the support of the Office of Naval Research and the Stiftung Volkswagenwerk.

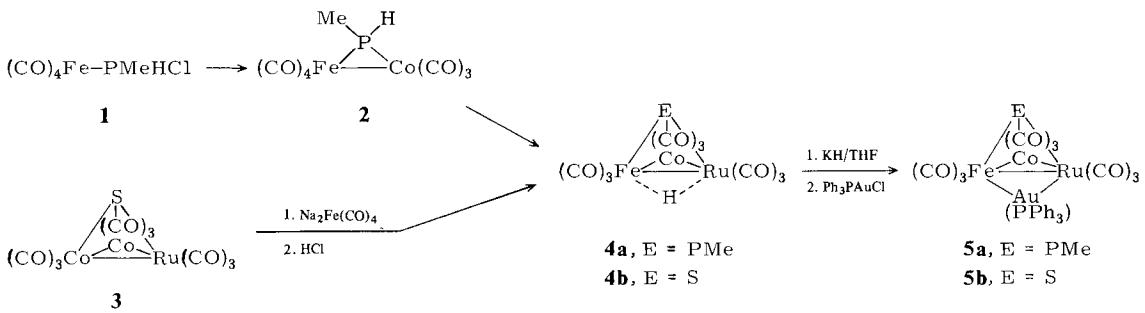
Stepwise Assembly of a Cluster with Four Different Metal Atoms**

By *Klaus Fischer, Manfred Müller,* and *Heinrich Vahrenkamp**

Heteronuclear organometallic clusters lend themselves more readily to systematic synthesis[1] and to mechanistic reactivity studies[2] than homonuclear compounds. Their chemistry still presents many challenges, and we have now met one of these: the stepwise synthesis of a cluster having four different metal atoms from four simple precursors.

The cluster **5a** is formed from the synthetic building blocks $MePCl_2$, $Fe_2(CO)_9$, $KCo(CO)_4$, $Ru_3(CO)_{12}$, and Ph_3PAuCl. We have previously described the reaction sequence reproduced in simplified form in Scheme 1 as far as compound **4a**[3]. Deprotonation of **4a** with KH and subsequent treatment with Ph_3PAuCl led to black **5a**[4]. An alternative route to the cluster type **5**, involving a metal exchange reaction[2,5], has been found for the μ_3-sulfido complex **5b**: **4b** is formed from **3** (cf. Scheme 1) and can be converted into black-red **5b** (yield 37%) by analogy to **4a**[6].

The constitutions of **5a** and **5b** were confirmed by X-ray structure analysis. A simplified molecular structure of **5a** is shown in Figure 1. Because of disorder, in the completely analogous structure of **5b** only the heavy atom framework could be determined unequivocally[7]. Like the hydride ligand in **4a**, the Ph_3PAu moiety preferentially adopts an edge-bridging site, and hence the heteronuclear tetranuclear clusters **5** exhibit a "butterfly" arrangement of the metal atoms.



Scheme 1. Synthetic pathway to the clusters **5**.

5a and **5b** are not the first clusters having four different metal atoms[8], and the reactions in Scheme 1 are also not novel. However, their combination to afford a multistep synthesis of **5a** and **5b** represents a further step in the sys-

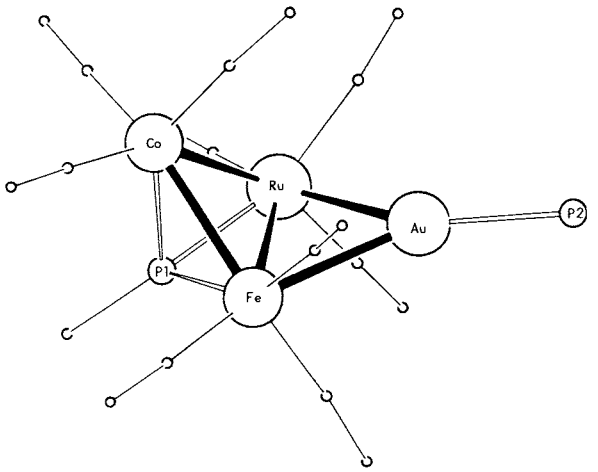

Fig. 1. Molecular structure of the cluster **5a** in the crystal (without the phenyl groups at P2; small circles represent the CO ligands and the methyl group at P1. Important atom distances: Au–Ru 2.729(2), Au–Fe 2.677(2), Ru–Fe 2.914(3), Co–Ru 2.679(3), Co–Fe 2.678(4), Au···Co 3.957(3) pm. Dihedral angle AuRuFe/CoRuFe 122.3(2)°.

tematic development of the chemistry of cluster compounds. That the syntheses can be generalized, which is supported by the bridging effect of the μ_3-E ligand, is clear. Also, the presence of the "catalysis metal" ruthenium as well as the chirality of **5a** and **5b** suggest that these compounds may be useful practically.

A "Cluster-Centered" Acetylene-Vinylidene Rearrangement**

By *Wolfgang Bernhardt* and *Heinrich Vahrenkamp**

The reactions of small hydrocarbon units on solid surfaces and model studies thereof on organometallic polynuclear complexes are of considerable practical significance. An example is the acetylene-vinylidene rearrangement HC≡CR → =C=CHR. Although numerous trimetal clusters with μ_3-alkyne[1] and some with μ_3-alkenylidene ligands[2] are known, corresponding conversions could previously only be postulated[2,3]. We have now succeeded, for one and the same carbonyltrimetal moiety, in isolating and characterizing the μ_3-η^2-alkyne complex and fully characterizing its rearrangement product, the μ_3-η^2-alkenylidene complex.

The 3,3-dimethyl-1-butyne-$RuCo_2$ complex **1** is formed at 5—15°C in 3—4 h *via* a "capping reaction"[4] between $RuCo_2(CO)_{11}$ and the alkyne in *n*-pentane (yield >90% after chromatography on silica gel). If **1** is heated for several hours in hexane at 60°C, it rearranges to the 3,3-dimethyl-1-butenylidene-$RuCo_2$ complex **2** in 81% yield. The constitutions of **1** and **2**, confirmed from their spectra[5],

elemental analyses, and crystal structure determinations[6], prove indirectly that the previously described rearrangements of $RuCo_2$ complexes with acetylene ligands[3] lead to isomers with vinylidene ligands

$RuCo_2(CO)_9(\mu_3\text{-}\eta^2\text{-}HCC\mathit{t}Bu)$ **1** $RuCo_2(CO)_9(\mu_3\text{-}\eta^2\text{-}CCH\mathit{t}Bu)$ **2**

The atomic arrangements in **1** and **2** (Fig. 1) indicate the marked change in the bonding situation caused by the acetylene-vinylidene conversion. The CC multiple bond, which in **1** is parallel to the metal atom triangle, is inclined at ca. 47° to the triangular plane in **2**; and is *ca.* 3 pm longer in **2** than in **1**. The vinylidene ligand can therefore be considered as a M_3C-CHR carbenium ion stabilized by charge delocalization, as discussed previously for the isoelectronic $(CO)_9Co_3C-CHR$ cations[7].

Intermediates involved in the rearrangement of alkyne complexes into isomeric 1-alkenylidene complexes have not yet been observed, even for mono- and binuclear complexes. Initial migration of the acetylenic H atom to the metal to form an acetylide complex, which then tautomerizes to the vinylidene complex, appears plausible[8]. The geometrical relationship between **2** and the acetylide complex **3**[9] corroborates this. And also the ensuing step, the hydrogenation to the alkylmethylidyne complex, which e. g. is possible starting from $H_2Os_3(CO)_9(CCHR)$ to afford **4**[2], requires only slight steric changes. The alkyne-alkene-alkane conversion on a metal surface modeled by the sequence **1**, **3**, **2**, **4** is therefore consistent with a "straightening out" of the C_2 moiety above the metal atom plane.

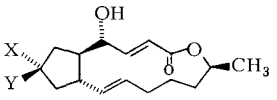
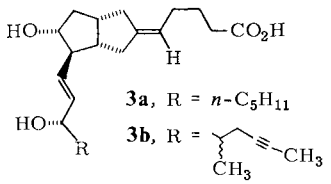
Enantioselective and Enantioconvergent Syntheses of Building Blocks for the Total Synthesis of Cyclopentanoid Natural Products**

By *Hans-Joachim Gais** and *Karl L. Lukas*

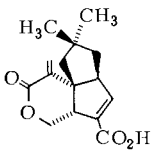
Because of their structures and biological properties, cyclopetanoid natural products and analogues such as brefeldin A **1**[1a], 7-*epi*-brefeldin A **2**[1b], and the 6a-carbaprostacyclins **3a**[1d] and **3b**[1e], and the pentalenolactone E **4**[1c], are rewarding synthetic targets. **1**, **2**[2a], and **3a** and **3b**[2b] have been prepared enantioselectively by total synthesis from the cyclopentenolactone **5**; **4** has not yet been completely synthesized from *ent*-**5**[2c]. We report here two novel efficient routes to **5** and *ent*-**5**, starting from *meso*-tetrahydrophthalic anhydride.



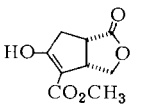
1, X = OH, Y = H
2, Y = OH, X = H



3a, R = n-C_5H_{11}
3b, R =



4



5

Enantioselective saponification of the *meso*-diester **6** with commercial pig liver esterase (PLE) results in practically exclusive attack at the (1*R*)-ester group to afford the enantiomerically pure (1*S*,2*R*)-monoester **7** [99%, ≥99% *ee*, m.p. = 28°C, $[\alpha]_{365}^{20}$ +26.1 (0.89, H_2O)], the reaction proceeding on the mol scale (Scheme 1)[2c, 3a, b]. For the synthesis of 1 mol **7**, ca. 9000 U (90 mg) PLE, 1000 mL phosphate buffer (pH 7.0), 500 mL 2N NaOH, and a reaction time of 4 d at 25°C are required. Enantiomer resolution of *rac*-**7** with ephedrine or dehydroabietylamine enables large amounts of **7** *and ent*-**7** [m.p. = 28°C, $[\alpha]_{365}^{20}$ −25.9 (0.90, H_2O)] to be obtained enantiomerically pure (92%, ≥99% *ee*). The enantiomeric excess (*ee*) of **7** and *ent*-**7** was determined from the diastereomeric excess (*de*) of the ephedrine salts, which in turn was determined by ^{1}H-NMR spectroscopy from the different signals of the ester groups. Within the detection limits (≥1%), admixture of the respective other diastereomer did not occur. The absolute configuration of **7** and *ent*-**7** was established by X-ray structure analysis of the (−)-(1*R*,2*S*)-ephedrine salt of *ent*-**7** [m.p. = 158°C, $[\alpha]_D^{20}$ −35.9 (2.00, MeOH)]. The "pseudosymmetric" structure of **7** and *ent*-**7** permits both their conversion into the lactones **8** [$[\alpha]_D^{20}$ −85.4 (2.63, acetone)] or *ent*-**8** [$[\alpha]_D^{20}$ +85.2 (2.64, acetone)] (enantioconvergence[4]), respectively, and the synthesis of **8** and *ent*-**8**

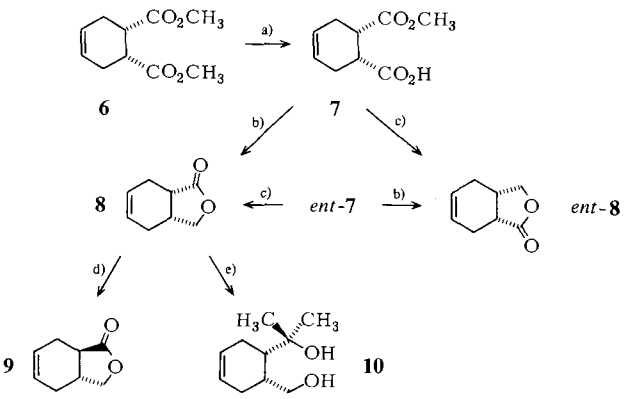
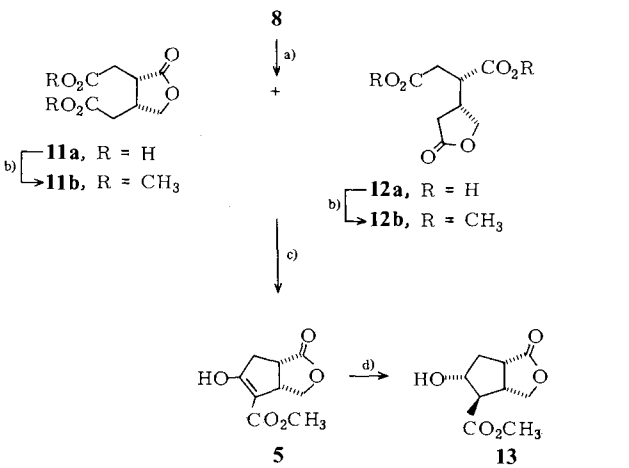
from **7** by optional chemoselective reduction of the ester or carboxy group to the hydroxymethyl group and subsequent lactonization (Scheme 1). For the ester group this proceeds by reduction with sodium and ethanol in liquid ammonia (**7**→*ent*-**8**, 82%) or with $LiBH(Et)_3$ (**7**→*ent*-**8**, 79%) and for the carboxy group via acid chloride and reduction with $NaBH_4$ in ethanol (**7**→**8**, 76%)[5]. Undesired



Scheme 1. a) PLE. b) $(COCl)_2$, $CHCl_3$, 25°C; $NaBH_4$, EtOH, −40°C; TsOH, PhMe, 110°C. c) Na, EtOH, NH_3, −78°C; NH_4Cl; conc. HCl. d) NaOH, H_2O, 100°C, 48 h; conc. HCl. e) MeLi, Et_2O, tetrahydrofuran, −78°C.

epimerization to afford the *trans*-lactones *ent*-**9** and **9**, respectively, in the conversion of **7** into **8** and *ent*-**8**, respectively, can be avoided within the limits of detection (≥1%). For comparison, epimerization of **8** on the preparative scale afforded **9** [m.p. = 98°C, $[\alpha]_D^{20}$ −155.0 (1.90, acetone)] [*ent*-**9**: m.p. = 98°C, $[\alpha]_D^{20}$ +155.1 (1.91, acetone)], whose reduction to the known (1*R*,2*R*)-4-cyclohexene-1,2-dimethanol [m.p. = 54°C, $[\alpha]_D^{20}$ −69.8 (2.97, $CHCl_3$)] allowed determination of the absolute configuration of **8** by a chemical correlation[2c,6] (Scheme 1). The *ee*-values of **8** and *ent*-**8** were determined indirectly on the dimethyldiols **10** [m.p. = 90—91°C, $[\alpha]_D^{20}$ +77.0 (1.68, CH_2Cl_2)] and *ent*-**10** [m.p. = 90—91°C, $[\alpha]_D^{20}$ −76.8 (1.63, CH_2Cl_2)] by ^{1}H-NMR spectroscopy (300 MHz) in the presence of the chiral shift reagent Eu(tfc)$_3$ from the methyl signals to ≥99% [*rac*-**10** + 0.6 equiv. Eu(tfc)$_3$ in $CDCl_3$ exhibits a $\Delta\Delta\delta = 0.12$ ppm][2c,6]. Within the limits of detection (≥0.5%), no admixture of the other isomer was detectable.

Oxidative ring cleavage of **8** leads to the dicarboxylic acids **11a** and **12a** (87%), whose esterification affords a 1:1-mixture of the isomeric lactone diesters **11b** and **12b** (91%). As expected[2c], both the pure diesters and the mixture can be converted regioselectively with KO*t*Bu into the cyclopentenolactone **5** (82%) [m.p. = 120—121°C, $[\alpha]_D^{20} = +190.0$ (2.48, CH_2Cl_2); *ent*-**5**: m.p. = 120—121°C, $[\alpha]_D^{20} = -189.3$ (2.46, CH_2Cl_2)], which exists almost exclusively in the enol form. The structure of **5** is proved by 400 MHz ^{1}H-NMR spectroscopy. A further structural proof was provided by an X-ray structure analysis of the hydroxy ester **13** [m.p. = 98—100°C, $[\alpha]_D^{20}$ +49.3 (1.13, ethyl acetate)] (Scheme 2). Using the strategy we have described here, **5** and *ent*-**5** are accessible rationally and enantiomerically pure by *enantioselective* (7 steps, 50% and 6 steps, 53%, respectively) or *enantioconvergent* synthesis (8 steps, 37%) from *meso*-tetrahydrophthalic anhydride.



Scheme 2. a) O_3, MeOH, −78°C; H_2O_2, HCOOH, 100°C. b) MeOH, $H^\oplus$, 80°C. c) KO*t*Bu, PhMe, 25°C; 50% H_2SO_4. d) $NaBH_4$, MeOH, −78°C.

Stereoselective Synthesis of (*E*)-4-Hydroxy-2-alkenoic Acid Esters from Aldehydes and the d^3-Building Block Ethyl Lithiopropiolate**

By *Hans-Joachim Gais**

The macrolides brefeldin A **1**[1a], 7-*epi*-brefeldin A **2**[1b], colletodiol **3**[1c], and cytochalasin B **4**[1d] contain an (*E*)-4-hydroxy-2-alkenoic acid structure element. For their *direct* synthesis[2] from aldehydes and building blocks which correspond to the d^3-synthon **5**, there are two methods: the

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

d^3-reagents are either the acid **6**[3] or the vinyllithium compound **7**[4]. In this respect, the stereoselective addition of **6** or **7** to aldehydes was not intended. We describe here an efficient method for the stereoselective synthesis of (*Z*)- and (*E*)-4-hydroxy-2-alkenoic acid esters from aldehydes and the d^3-reagent ethyl lithiopropiolate **8** (Scheme 1) and its application to the *E*/*R*-stereoselective transformation of the aldehyde **14**[5].

Addition of the lithioalkyne **8**, generated by deprotonation of ethyl propiolate with lithium diisopropylamide in tetrahydrofuran (THF) at −78 °C[6], to the aldehydes **9** proceeds rapidly, even at −78 °C, to yield the alkynes *rac*-**10** (>90%)[7]. The alkynes *rac*-**11** (>90%) are obtained by attaching the methoxyethoxymethyl (MEM), tetrahydropyranyl (THP), *tert*-butyldimethylsilyl (TBDMS), and benzoyl(Bz) groups to *rac*-**10** (R^2 = Li, H). Stereoselective reduction of the alkynoic acids *rac*-**11** (R^3 = H) to the (*E*)-alkenoic acids *rac*-**13** (R^3 = H) is carried out using $CrSO_4$ in dimethylformamide/water at 20 °C[8]; however, complete conversion of *rac*-**11** (R^3 = H) could not be achieved even with an excess of $CrSO_4$. The alkynoic acid esters *rac*-**10** and *rac*-**11** are not reduced under these conditions.

An efficient alternative to the *E*-stereoselective reduction is provided by the two-step method: *Z*-stereoselective hydrogenation and *E*-stereoselective isomerization. The (*Z*)-alkenes *rac*-**12** (>95%, ≥98% *ds*) are accessible by chemo- and stereoselective hydrogenation of the alkynes *rac*-**11**[9]. Structural proof for *rac*-**12** is provided by their ^{1}H-NMR spectra, which in addition to the signals for the *Z*-olefinic protons ($J \approx 12$ Hz) exhibit the signal of H-4, which is shifted to low field by the anisotropic effect of the *syn*-orientated carbonyl group at $\delta = 5.00-5.20$ (Table 1). Subsequent isomerization of the (*Z*)-alkenes *rac*-**12** to the (*E*)-alkenes *rac*-**13** is effected using ca. 30 mol-% $LiSC_2H_5$ in THF at 0–20 °C (>90%). Within the detection limits of ^{1}H-NMR spectroscopy (≥2%), the (*Z*)-alkenes *rac*-**12** were not found. The $LiSC_2H_5$ should not contain HSC_2H_5 impurities, since otherwise the latter undergoes thiolate-catalyzed addition to *rac*-**12** and *rac*-**13**, respectively; in contrast, no addition is observed upon acidic work-up. Apart from signals for the (*E*)-olefinic protons ($J \approx 16$ Hz), the ^{1}H-NMR spectra of *rac*-**13** now exhibit the signal of H-4 at $\delta = 4.02-4.20$, unaffected by the *anti*-orientated carbonyl group (Table 1). Suitable protecting groups for the hydroxy function are the MEM, THP, or TBDMS groups, but not the Bz group since problems then arise in the isomerization step.

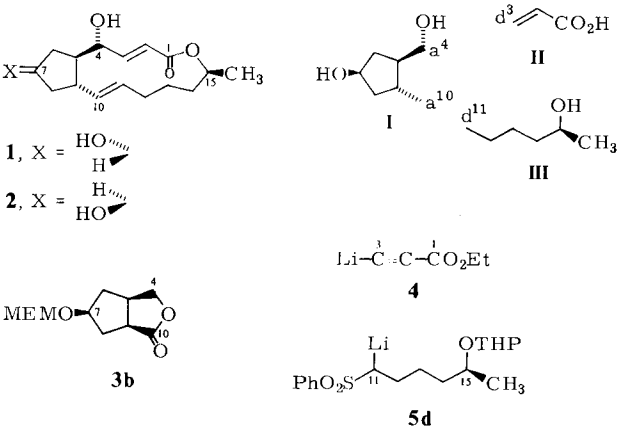
Asymmetric Total Synthesis of the Macrolides Brefeldin A and 7-*epi*-Brefeldin A**

By *Hans-Joachim Gais** and *Thomas Lied*

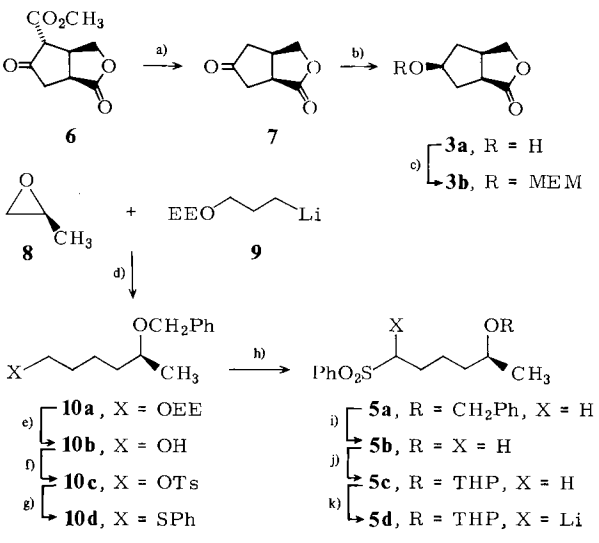
Because of their interesting structures, which resemble those of the prostaglandins, and unusually broad spectrum of interesting biological activity, the macrolides brefeldin A **1**[1a,b] and 7-*epi*-brefeldin A **2**[1c], biosynthesized by *Curvularia lunata*, are attractive target molecules for chemical synthesis[1d]. In 1981 we prepared the intermediate 7-*epi*-**14** (tBuMe$_2$Si for THP)[2], formally the first asymmetric total synthesis of **1**[3a,b]; later, a second asymmetric total synthesis was described[1d]. Here, we report a novel asymmetric total synthesis of **1** and the first of **2**, in which we employ new methods for the stereoselective construction of the C1-C4 structure element and for the macrolactonization. Our synthetic strategy can be deduced from the synthons **I**—**III**; in their connection sequence, the corresponding building blocks are the cyclopentanolactone **3b**, the lithiosulfone **5d**, and the lithiopropiolate **4** (Scheme 1).



Scheme 1. MEM=(2-methoxyethoxy)methyl, THP=2-tetrahydropyranyl.

The synthesis of the cyclopentanoid building block **3b** commences with the cleavage of the β-keto ester **6** (≥99% *ee*)[4] to afford the bicyclic ketone **7**[5a] (96%)[6], which after catalytic hydrogenation yields the β-alcohol **3a**[5b] (97%, 98% *ds*), and which is subsequently protected as the MEM ether **3b**[5c] (91%, ≥99% *ee*) (Scheme 2).

Regioselective ring-opening of (*S*)-propylene oxide **8** (97% *ee*)[7] with the organolithium compound **9** (EE=1-ethoxyethyl)[8] leads via the alcohol **10b**[5d] and the sulfide **10d**[5e] to the sulfone **5c**[5f] (50% overall yield, 97% *ee*)[9] (Scheme 2).



Scheme 2. a) Me_2NCHO, H_2O, NaCl, 120°C. b) H_2, Pd/C, $MeCO_2Me$. c) MEM-Cl, CH_2Cl_2, $EtN(iPr)_2$. d) Tetrahydrofuran (THF), −30°C; $PhCH_2Br$. e) $H^\oplus$, H_2O. f) TsCl, pyridine. g) LiSPh, THF, 25°C. h) *m*-Cl−C_6H_4−CO_3H, $CHCl_3$, −10°C. i) H_2, Pd/C, MeOH. j) Dihydropyran, $H^\oplus$. k) *n*BuLi, THF, −78°C.

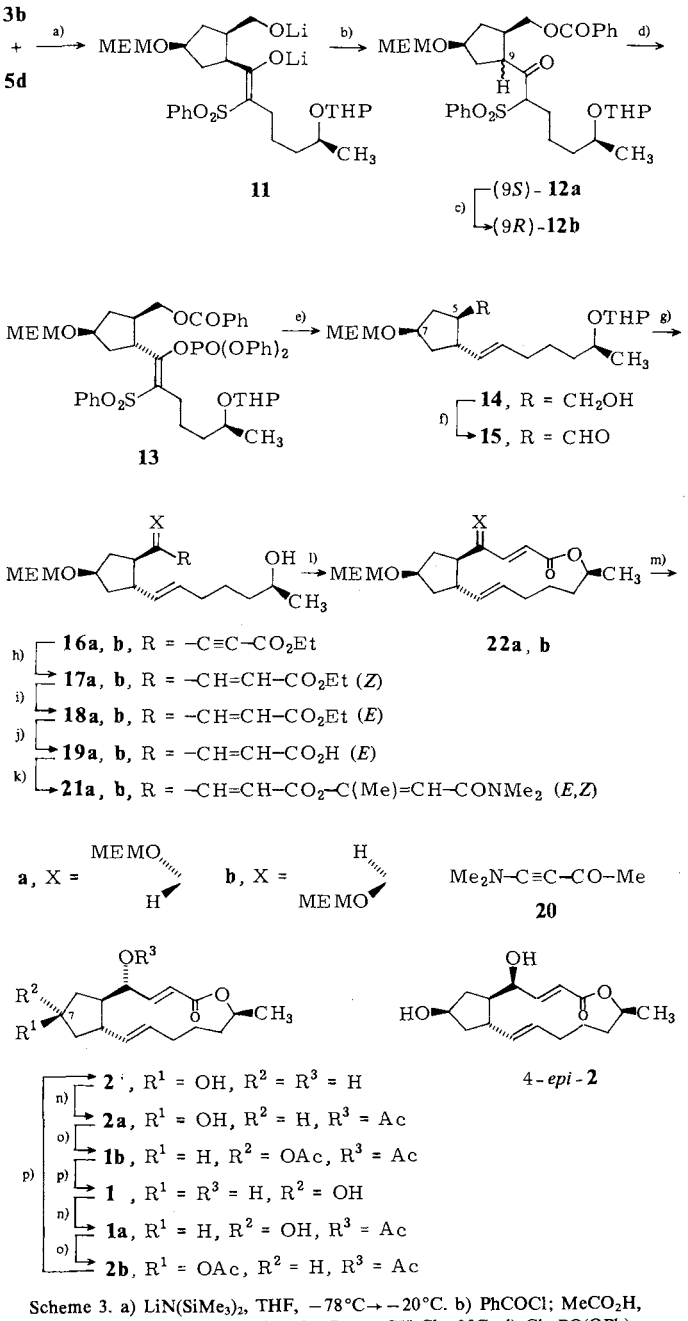
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *A. von Wartburg*, Sandoz AG, Basel, for a sample of brefeldin A from *Penicillium brefeldianum* and Dr. *C. P. Gorst-Allman*, NCRL, Pretoria, for a sample of 7-*epi*-brefeldin A from *Curvularia lunata*.

The C4–C10 building block **3b** is linked smoothly in three steps to the C11–C16 building block with the correct configuration at C9: ring-opening of the lactone **3b** with the lithiosulfone **5d** to give the dilithio compound **11** and chemoselective benzoylation; the initially formed (9*S*)-keto sulfone **12a** is isomerized to the more stable (9*R*)-keto sulfone **12b**[5g] (≥30:1) (Scheme 3). **12b** (90% overall yield) is converted into the enol phosphate **13**[5h] (94%), which was reduced to the (*E*)-alkene **14**[5i] (76%)[10] with concomitant release of the hydroxymethyl function. Oxidation of the alcohol **14** to the aldehyde **15**[5j] (87%) completes the requirements for the coupling of the still absent C1–C3 structure element. A novel, potent method for this[11] starts with the *re*-selective addition of **4** to **15**, which affords, via the alkynes **16**[5k] (90%, 80% *ds*) and the (*Z*)-alkenes **17**[5l] (92%), the (*E*)-alkenes **18**[5m] (91%). Saponification of **18** leads to the seco-acids **19**[5n] (94%), which were lactonized using a novel, efficient method[12]: chemoselective reaction of **19** with the "push-pull" alkyne **20**[13] to give the stable enol esters **21**[5o] (96%) and their $H^{\oplus}$-catalyzed cyclization to the macrolides **22**[5p] (74%) (Scheme 3). These are cleaved to furnish **2** and 4-*epi*-**2** (4:1, 83%), which are separated readily by chromatography. Inversion of the configuration at C 7 of **2a**, prepared by selective acylation of **2**[1c], according to *Mitsunobu*[14], and cleavage of the diacetate **1b** thus obtained lead to **1**. Similarly, the synthesis of **2** from **1** can be carried out via **1a**[1b] and **2b**[1c]. The flexibility of this synthetic strategy for **1** and **2** permits use of the equally readily accessible *ent*-**3b**[4] as educt instead of **3b**, and now with the inversion of configuration 5,7-*epi*-**15**→7-*epi*-**15** leads primarily to **1**. The macrolides brefeldin A **1** [m.p. = 203 °C, $[\alpha]_D^{20}$ +92.1 (0.25, MeOH)] and 7-*epi*-brefeldin A **2** [m.p. = 121–123 °C, [α] +109.6 (0.19, MeOH)] thus obtained are indistinguishable both chromatographically and spectroscopically (300 MHz ^{1}H-NMR) from **1** obtained from *Penicillium brefeldianum* and **2** from *Curvularia lunata*.



Scheme 3. a) $LiN(SiMe_3)_2$, THF, −78 °C→−20 °C. b) PhCOCl; $MeCO_2H$, 0 °C. c) 1,8-Diazabicyclo[5.4.0]undec-7-ene, CH_2Cl_2, 0 °C. d) Cl–$PO(OPh)_2$, MeCN, NEt_3, 4-dimethylaminopyridine. e) Na, NH_3, −78 °C. f) Pyridinium chlorochromate, CH_2Cl_2, 0 °C. g) **4**, THF, −78 °C; MEM-Cl, −78 °C→0 °C; MeOH, $H^{\oplus}$. h) H_2, Pd/$BaSO_4$, quinoline, MeOH. i) LiSEt, THF, 30 °C; 0.1 N HCl, 0 °C. j) LiOH, MeOH; 0.1 N HCl, 0 °C. k) **20**, THF, 0 °C. l) 5 mol-% 10-camphersulfonic acid, PhMe, 80 °C, dilution. m) $TiCl_4$, CH_2Cl, 0 °C. n) Ac_2O, pyridine. o) Ph_3P, diethyl azodicarboxylate, $MeCO_2H$, THF, 0 °C. p) MeOH, K_2CO_3, 0 °C.

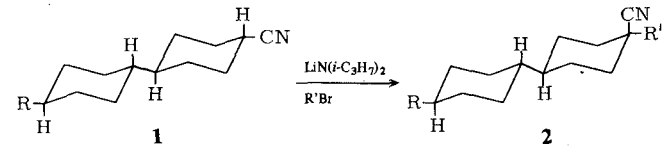
Liquid-Crystalline 4-Bicyclohexylcarbonitriles with Extraordinary Physical Properties

By *Rudolf Eidenschink**, *Günther Haas*, *Michael Römer*, and *Bernhard S. Scheuble*

Liquid-crystalline 4-(*trans*-4-alkylcyclohexyl)benzonitriles[1] and 4'-alkyl-4-bicyclohexylcarbonitriles **1**[2] have achieved considerable importance in display technology. We have now found that 4α,4'α-dialkyl-1α,1'α-bicyclohexyl-4β-carbonitriles **2** also exhibit surprisingly high transition temperatures for conversion from the nematic to the isotropic states (T_{NI}) (Table 1). Compounds **2** were synthesized by the reaction of **1** with an alkyl bromide and lithium diisopropylamide at −50°C in tetrahydrofuran in the molar ratios shown, a variation of a previously described alkylation method[3]. The crude products were purified by column chromatography (silica gel 60, Merck/toluene) and recrystallization from ethanol: yields are between 60 and 70%. The structures are corroborated by elemental analyses and by mass and ^{13}C-NMR spectra[4].



1 **2**

Table 1. Transition temperatures for some 4α,4α'-di-*n*-alkyl-1α,1α'-bicyclohexyl-4β-carbonitriles **2**. C = crystalline, S = smectic, N = nematic, I = isotropic phases.

2	R	R'	T_{CS} [°C]	T_{SN} [°C]	T_{NI} [°C]
a	C_3H_7	C_3H_7	32		(17)
b	C_3H_7	C_5H_{11}	40		49
c	C_3H_7	C_7H_{15}	22	(16)	56
d	C_4H_9	C_4H_9	9	30	38
e	C_5H_{11}	C_5H_{11}	24	(24)	66
f	C_7H_{15}	C_3H_7	38	39	49

The liquid-crystalline, specifically the nematic, behavior of compounds **2** having *axial* CN groups was not predicted by a model[5] which—based on the intermolecular interactions known from the theory of liquids[6]—suggests an association of lengthwise-extended molecular pairs via *equatorial* CN groups arranged in an antiparallel fashion as explanation for the high T_{NI} values of compounds **1**. Also the present findings require that statements correlating chemical structure and T_{NI} be revised[7]. As in **1**[2], smectic phases also occur in **2** (Table 1), however, at comparably lower temperatures.

Clearly, the axial CN groups in **2** are well shielded by the H atoms at the 2- and 6-positions as well as by the geminal alkyl groups. Since the anisotropy of the dielectric constant ($\Delta\varepsilon$)[8] at 20°C lies between −8 and −10 (in **1** with equatorial CN groups, $\Delta\varepsilon$ is +4 to +5), it can be concluded that in **2** the conformation with axial CN groups is largely preferred. Measurement of the (CH) coupling constants[4] confirm this assumption. Because of their $\Delta\varepsilon$ values, stability, and optical anisotropy (birefringence $\Delta n \approx 0.03$), compounds **2** may be of specific interest for electrooptical displays based on the alignment of dichroitic dyes in liquid-crystalline matrices[9].

Aliphatic Polyethers, Basic Building Blocks from Naturally Occurring Humic Substances: Detection by Solid State ^{13}C-NMR Spectroscopy**

By *Ernst Bayer**, *Klaus Albert*, *Wolf Bergmann*, *Kuno Jahns*, *Wolfram Eisener*, and *Hans-Konrad Peters*

Although approximately 60×10^{11} t of organically bound carbon occurs as humic substances[1,2], the structure of these natural products still represents a puzzle. Humic substances contain C, H, and O. The high oxygen content, which leads, according to the age of the humic substance, to a C:O ratio of between 1.6 in recently formed humic substances from waters to 2.5 in the oldest humic acids (lignites) could not be accounted for by previous structural proposals; it is assumed that humic substances contain structural elements predominantly derived from arenes[3]. Since humic substances are often sparingly soluble and alkaline extraction methods can produce changes in the humic acids, non-destructive, structure determining methods have to be resorted to. Cross polarization-magic angle spinning CP-MAS-^{13}C-NMR spectroscopy[4] has recently permitted the exact assignment of the structural elements of solid-state samples.

We have now found that the position of the principal signals in the solution and solid-state ^{13}C-NMR spectra is the same (Fig. 1)[5]. This finding permits reliable statements to be made about the structure of humic substances in the solid state. In contrast to previous hypotheses about the structure, only very weak signals in the arene region ($\delta = 120-160$) occur in both solution and solid-state spectra. Instead, very intense signals from the saturated, aliphatic hydrocarbon chains ($\delta = 10-40$) are observed. Hence, in humic substances from waste water aliphatic structures dominate the basic structure and not aromatics. Intense signals occur at $\delta = 70$ for oxygen containing groups; these can be assigned to the structural element −CHR−O−CHR. In addition, signals arising from ester or carboxy groups ($\delta = 175$) and for acetals ($\delta = 100$) occur in the assigned part of the spectra. Presumably, aliphatic ether groups are the linking structural principle in humic acids; basic building blocks could be polyethers of glycols, e.g. of glycerol. This is also confirmed by the IR spectra (signals in the region of 1120 cm^{-1}). Assuming that the

[**] Dr. *D. Müller*, Bruker Analytische Messtechnik, Rheinstetten, is thanked for the NMR spectra.

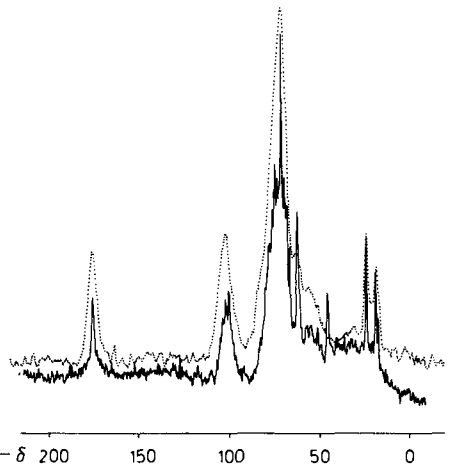

Fig. 1. ^{13}C-NMR spectrum (100.6 MHz) from waste-water humic substances in D_2O solution (—); CP-MAS-^{13}C-NMR spectrum (50.3 MHz) of the same solid waste-water humic substance (....).

ether C atoms and non-functionalized, aliphatic C atoms have similar correlation times, the signal intensity suggests that every second C atom participates in an ether bond. The ether groups should at least be partially hydrolyzable, even if the chemical sluggishness and reduced accessibility in the cross-linked, polymeric humic substances is considered[6]. The signals assigned to the ether C atoms almost completely disappear when the solutions are treated several times with excess 57% boiling hydriodic acid.

Do the part-structures found in waste water humic acids also occur in humic substances from different origins? Previously described NMR spectra of such humic substances suggest this[7]; however, because of the low resolution, weak signals, and possible structural changes caused by the method of isolation, the results are often difficult to interpret[8,9].

In order to avoid structural changes arising from the method of isolation, we initially recorded solid-state spectra of peat. The overlap of the spectrum of the humic acid by that of lignin produces no interference since the latter does not exhibit signals of aliphatic ether groups and aliphatic side chains at $\delta = 70$ and 10—40, respectively[10,11].

The CP-MAS-^{13}C-NMR spectrum of a sample of peat shows the same characteristic signals as the spectra of waste water humic acids (Fig. 2, top). In addition, signal groups typical for lignins at $\delta = 100$—500 (aryl moieties) occur together with a signal for the OCH_3 group at $\delta = 55$. Also for peat—despite the lignin—predominantly aliphatic structural elements occur. A soil humic acid also exhibits a similar solid-state spectrum to that of peat (Fig. 2, middle)[12]; the ether bonds can be cleaved with HI. The structural elements of humic substances from waste water systems, peat, and soils are therefore similar.

In the CP-MAS-^{13}C-NMR spectrum of a humic acid isolated from lignite using caustic soda (Fig. 2, bottom) the signals of the functional groups are much weaker than those of the aliphatic residues ($\delta = 10$—50); however, both the ether and carboxy groups are clearly recognizable. The functionalized C atoms in the humic acids which are relatively young on the geological time scale are apparently converted into alkyl residues as they age (conversion into lignite).

This is interesting since humic substances have been discussed as connecting links in the genesis of fossil fuels[13]. It was never completely understood how humic substances, made up predominantly of aromatic structural elements, could be converted into the aliphatics found almost exclusively in petroleum under the relatively mild conditions associated with its formation. Since the aliphatic structural elements present in humic substances cannot be further degraded microbiologically, this forms the basis for aliphatic geopolymers and petroleum. The greater amount of aromatic structures in coal may therefore arise from products of lignin degradation and not from humic substances. This point of view is also consistent with the various starting substrates for the genesis of petroleum and coal[13]. Petroleum is predominantly formed from lignin-free aquatic biomass[14], and coal from lignin-containing biomass of vegetable origin.

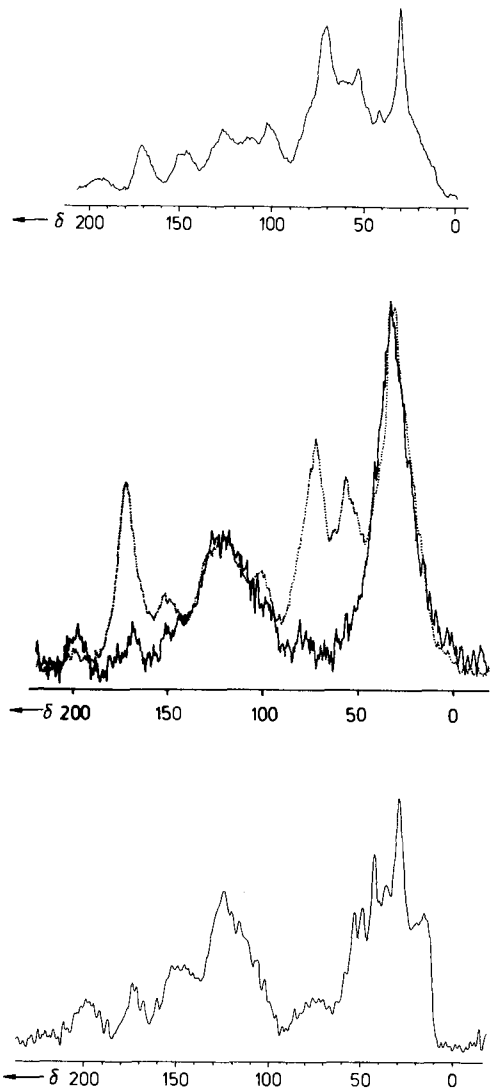

Fig. 2. Top: CP-MAS ^{13}C-NMR spectrum (50.3 MHz) of solid peat (peat bog, Aha/Kreis Rosenheim, FRG).—Middle: CP-MAS-^{13}C-NMR spectra (50.3 MHz) of soil humic acid, before (.....) and after treatment with 57% hydriodic acid (———).—Bottom: CP-MAS ^{13}C-NMR spectrum (50.3 MHz) of solid humic acid from Rhenish lignite.

Summarizing our results therefore suggests that 1) the fundamental framework of these natural products form aliphatic structural elements, and 2) that among the oxygen-containing functional groups the aliphatic ethers assume a dominant position. No statement can be made yet about a total structure. The bacterial sludge obtained from the aerobothermophilic degradation of sewage sludge is particularly suitable for the isolation of humic substances. Ex-

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/0202-0148 $ 02.50/0

traction of this bacterial sludge with water, several precipitations, and membrane filtration lead to isolation of humic substances in over 10% yield (relative to the degraded organic substances). Pure cultures of such thermophilic bacteria could be a route to more homogeneous humic acid preparations.

$(Ph_4As)_2[Cl_5W(\mu\text{-}N_4)WCl_5]$, a μ-Isotetrazenido(4−) Complex of Tungsten(VI)

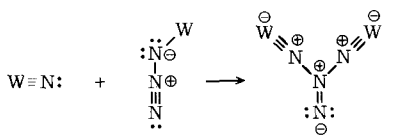
By *Werner Massa, Richard Kujanek, Gerhard Baum,* and *Kurt Dehnicke**

The terminal nitrido ligand in $L_nM{\equiv}N$: transition metal complexes has weakly basic properties and thus often leads to stretched $M{\equiv}N{-}M$ bridge bonding with various M−N bond lengths on complexation[1]. Nitrido complexes are usually synthesized by thermolysis of azido complexes[1,2]. We have now found that the nitride formed in one of these reactions reacts with azide that is still present with formation of the previously unknown tetraanionic isotetrazene bridge ligand:

$$2\,Ph_4AsCl + W(N)Cl_3 + W(N_3)Cl_5 \longrightarrow (Ph_4As)_2[Cl_5W(\mu\text{-}N_4)WCl_5]$$

The binuclear tungsten complex can be isolated as the salt in the form of red single crystals from dichloromethane in the presence of tetraphenylarsonium chloride.

According to the X-ray structure analysis[3] the two WCl_5 groups in the complex anion (Fig. 1) are linked via very short WN bonds (Table 1) with the bridging planar N_4 moiety. This probably arises by nucleophilic attack of the nitrido ligand at the β-N atom of an azido ligand.



[*] Prof. Dr. K. Dehnicke, Doz. Dr. W. Massa, Dr. R. Kujanek, G. Baum
Fachbereich Chemie der Universität
Postfach 1929, D-3550 Marburg 1 (FRG)

The N atom thus attacked becomes sp^2 hybridized (bond angle of 109 to 126° at N2, cf. Table 1). The markedly long N1−N2 and N2−N4 bonds signalize the easy cleavability of a N_2-molecule (N2N3); the N2−N3 bond length of 123 pm corresponds to that of a double bond.

In agreement with the structural findings, the IR spectrum shows a band at 1640 cm^{-1} for ν(N=N)—characteristic for a double bond[6]. Two bands occur at 1224 and 1245 cm^{-1} for $\nu(W{\equiv}N)$, which are assigned to the somewhat different $W{\equiv}N{-}N$ groups; their short-wave position can be ascribed to strong coupling with ν(N−N)[1,6].

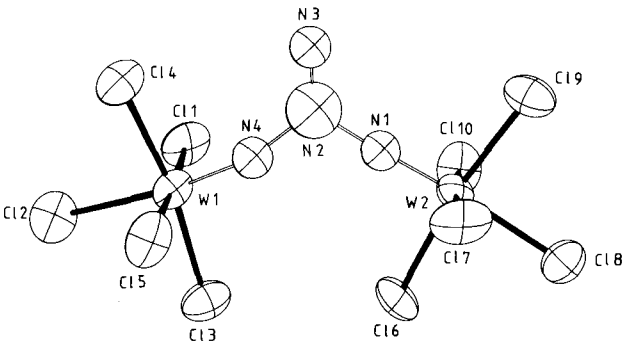


Fig. 1. ORTEP diagram of the $[Cl_5W(\mu\text{-}N_4)WCl_5]^{2\ominus}$ anion in the crystal of the tetraphenylarsonium salt (vibration ellipsoids with 50% probability).

Trifluoroethylidynesulfur Trifluoride, $F_3C-C{\equiv}SF_3$**

By *Brigitte Pötter* and *Konrad Seppelt**

The carbon-sulfur bond in $H_2C{=}SF_4$[1] can be characterized as a weakly polar, genuine double bond; a corresponding triple bond should therefore exist. However, the synthesis of $HC{\equiv}SF_3$ from $H_2C{=}SF_4$ or from another precursor has not been achieved so far, although its existence was confirmed by ab initio calculation[2] and its analogy to $N{\equiv}SF_3$ argues in its favor. Elimination of HF from $H_2C{=}SF_4$ led, in all previous attempts, directly to $S{=}CF_2$[1].

$$H_2C{=}SF_4 \xrightarrow[-HF]{} \{HC{\equiv}SF_3\} \xrightarrow[-HF]{} S{=}CF_2$$

It should be possible to prevent the second elimination step by straightforward substitution at the methylene group. Recently, the substituted compounds $H_3C-CH{=}SF_4$[3] and $F_3C-CH{=}SF_4$[4] have become available, e.g.

$$ROC{\equiv}CH + ClSF_5 \xrightarrow{h\nu} RO-CCl{=}CH-SF_5$$
$$\xrightarrow{Br_2} RO-CClBr-CHBr-SF_5 \xrightarrow[-RBr]{\Delta} OCCl-CHBr-SF_5$$
$$\xrightarrow{H_2O} HOOC-CHBr-SF_5 \xrightarrow{SF_4/HF} F_3C-CHBr-SF_5$$
$$\xrightarrow[-110\,^\circ C]{C_5H_{11}Li} F_3C-CH{=}SF_4$$

The trifluoromethyl derivative eliminates HF practically quantitatively if pumped in the gaseous state at 50–60 °C and 10^{-1} mbar through a 40 cm long quartz tube (12 mm diameter, packed with powdered, dried KOH).

$$F_3C-CH{=}SF_4 \xrightarrow[-HF]{KOH} F_3C-C{\equiv}SF_3$$

The product $F_3C-C{\equiv}SF_3$ is a colorless gas, m.p. = −122 °C, b.p. = −15 to −10 °C (rapid oligomerization). Its composition was determined by high-resolution mass spectroscopy (*m/z* 169.96271, M^+, 13.2%, theor. 169.96250, and numerous smaller fragments).

The isomers $FC{\equiv}C-SF_5$, $F_2C{=}C{=}SF_4$, $F_3C-CF{=}\ddot{S}F_2$, and $F_2C{=}CF-\ddot{S}F_3$ are precluded by the ^{19}F-NMR spectrum: In accord with the structure $F_3C-C{\equiv}SF_3$, two similar quartets are observed in the SF region ($\delta = 65.7$) and in the CF region ($\delta = -43.9$), $J_{F-F} = 19.5$ Hz. The first information about the nature of the carbon-sulfur bond is provided by the IR gas spectrum: In addition to the typical CF and SF stretching vibrations at 1225, 1168, 862, and 730 cm^{-1}, a strong, very broad band occurs at 1740 cm^{-1}, which because of its high absorption frequency can be unequivocally assigned to the CS triple bond. This bond lies ca. 225 cm^{-1} higher than that of the NS triple bond in $N{\equiv}SF_3$, indicating a particularly high bond order in $F_3C-C{\equiv}SF_3$[5]. More details on the molecular structure would result from a complete force field analysis.

The novel compound $F_3C-C{\equiv}SF_3$ does not achieve the extraordinary stability of $F_3C-CH{=}SF_4$, and oligomerizes to a product which is liquid at room temperature but crystalline at low temperatures (according to preliminary NMR results this could be a cyclic dimer).

A New Route to Iron-Sulfur Clusters: Synthesis and Structure of $[(C_2H_5)_4N]_2Fe_6S_6I_6$**

By *Wolfgang Saak, Gerald Henkel,* and *Siegfried Pohl**

The importance of iron-sulfur complexes as models for the active centers in non-heme iron proteins has excited interest in the last few years in the synthesis of a series of clusters of varied structures[1,2]. During investigations of the iron-sulfur-iodine system we found a novel route to iodine-substituted Fe–S clusters, starting from the elements and tetraethylammonium iodide.

We report here on the novel cluster anion $Fe_6S_6I_6^{2\ominus}$, which can be formally synthesized according to

$$6\,Fe + 6\,S + 2\,I_2 + 2\,I^{\ominus} \longrightarrow [Fe_6S_6I_6]^{2\ominus}$$

and isolated as $(Et_4N)_2Fe_6S_6I_6$ **1**[3]. The formation of the complex dianion probably proceeds *via* lower charged species which are readily soluble in CH_2Cl_2 and which so far have never been isolated[3].

According to the X-ray structure analysis of **1** discrete $Fe_6S_6I_6^{2\ominus}$ ions are present in the salt, which, with a symmetry approaching D_{3d}, have C_i crystal symmetry. The hitherto unknown Fe_6S_6 moiety[4] in the series of iron-sulfur clusters consists of two chair-shaped Fe_3S_3 rings which are coupled via six Fe–S bonds (Fig. 1). The three symmetry-independent Fe atoms have almost the same, approximately tetrahedral environment. Hence the formal oxidation number for all iron atoms is +2.67 (bond lengths: Fe–S 224.4(4)–227.1(5), Fe–Fe 271.8(3)–276.4(3), Fe–I 251.8(2)–254.9(2) pm; in each case the shortest bonding contacts in the cluster are given).

The μ_3-S atoms are also similarly coordinated. However, in contrast to the Fe–S–Fe angles in the Fe_4S_4 moiety[5], those in **1** are markedly different (for all three symmetry-independent S atoms: two Fe–S–Fe angles between

73.8(1) and 75.1(1)°, the third between 112.6(2) and 116.3(2)°); the atomic array in **1** rather resembles that of μ_4-sulfur, with the fourth coordination site missing.

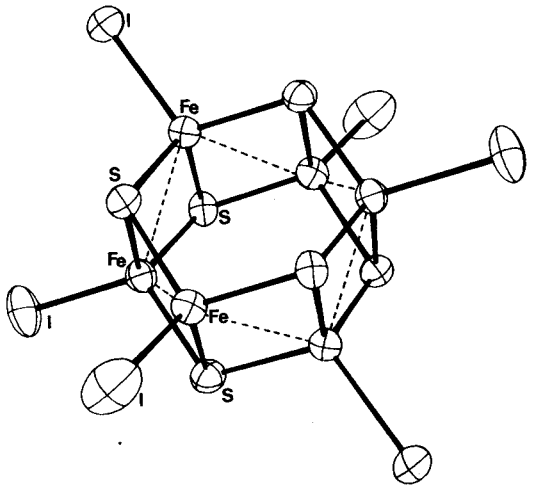

Fig. 1. Structure of the $Fe_6S_6I_6^{2\ominus}$ anion in the crystal of **1** (shortest Fe–Fe contacts shown with dotted lines). Structural data: $P2_1/n$, $a = 802.9(1)$, $b = 1334.1(2)$, $c = 2045.5(3)$ pm, $\beta = 100.04(1)°$, $Z = 2$; 3401 symmetry independent reflections, 2031 observed ($I > 3\sigma(I)$); empirical absorption correction; $R = 0.049$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, on quoting the depository number CSD 50661, the names of the authors, and full citation of the journal.

Depending on the molar ratio of the reactants, further Fe–S–I clusters should be accessible via the synthetic route described for **1**. Thus we were also able to prepare and structurally characterize in an analogous way the complexes $Fe_2S_2I_4^{2\ominus}$ and $Fe_4S_4I_4^{2\ominus}$[7], which had already been synthesized via an alternative route[6].

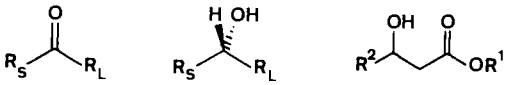
Preparative Microbial Reduction of β-Oxoesters with *Thermoanaerobium brockii*

By *Dieter Seebach**, *Max F. Züger*, *Fabio Giovannini*, *Bernhard Sonnleitner*, and *Armin Fiechter*

The usefulness of chiral, non-racemic starting materials for organic synthesis is increased if both enantiomers are available[1]. The microorganism most frequently used for enantioselective reductions of carbonyl compounds is baker's yeast *(Saccharomyces cerevisiae)*[2]. As with most other microorganisms and isolated enzymes, the hydrogen transfer follows *Prelog*'s rule[3] (see **1** → **2**). Reduction of β-oxoesters[4] produces 3-hydroxycarboxylic acid derivatives **3**, which are especially useful building blocks for syntheses. Depending upon the relative size of the groups R^1 and R^2 in the oxoester substrate, reduction may occur either from the *Re*- or from the *Si*-face[4,5] (see the third column of Table 1).



1 **2** **3**

R_S = smaller, R_L = larger substituent

Table 1. Comparison of the reductions of β-oxoesters and of 2-formylpropionate with baker's yeast (at 30°C) and with the thermophilic bacteria (at 72°C). The specific rotations were measured in $CHCl_3$ (*c* ca. 1.5).

Substrate	Reduction Product		Absol. Config./$[\alpha]_D$/%*ee* [Ref.] Yeast	*Th. brockii*
ethyl 3-oxobutanoate		**3a**	*S*/+41/97 [4]	*S*/+35/80

methyl 4-chloro-3-oxobutanoate		**3c**	*S*/−8/36 [11]	*R*/+21/89
ethyl 3-oxohexanoate		**3d**	*R*/−21/>90 [4]	*S*/+6/25
ethyl 4,4,4-trichloro-4-oxobutanoate		**3e**	*R*/−21/94 [12]	
ethyl 2-formylpropanoate		**3f**	*R*/−13/60 [13]	*R*/−16/72

We now report on the use of thermophilic bacteria[6], which are considered to be especially attractive for practical applications[7], to reduce β-oxoesters—sometimes with reversal of the stereochemical course of the reaction relative to that with yeast[8]. The reductions were carried out in a strictly anaerobic, continuously operated bioreactor of 3 L working volume with a culture of *Thermoanaerobium brockii (Th. brockii)*[9] growing in a TYEG medium (tryptone, yeast extract, glucose) containing sodium sulfide[10]. Charges of 20–100 mmol of the β-oxoesters listed in the

first column of Table 1 were added all at once to the bioreactor. The first 10 L of solution withdrawn from the reactor was filtered, extracted with ethyl acetate, the organic solution dried ($MgSO_4$), the solvent evaporated, and the residue distilled in vacuo. In this way, the hydroxy esters **3** were isolated in yields ranging from 50 to 80%, with the enantiomeric excesses shown in the fourth column of Table 1.

As is evident from a comparison of the last two columns of Table 1, the yet more elaborate reduction by *Th. brockii* may lead to higher enantiomeric excesses than the yeast reduction. For both microorganisms, there are clearly substrates whose enantiotopic faces are poorly differentiated. Thus, the low (*S*)-selectivity of yeast reduction of methyl chloroacetoacetate becomes a high (*R*)-selectivity with the thermophilic bacteria. On the other hand, the hydride transfer by yeast to ethyl acetoacetate and ethyl trichloroacetoacetate occurs in the *same sense*[14]—in spite of the appreciable change of size of the R^2 (see **1**—**3**). The two halogenated β-hydroxy esters (*R*)-**3c** and (*R*)-**3e**, now available in high enantiomeric purity by microbial methods, are valuable starting materials for the synthesis of (*R*)-carnitin[5] and of (*R*)-malic acid[12].

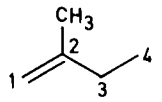
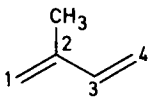
^{13}C-NMR INADEQUATE Spectrum with Broad Band Decoupling by Supercycles

By *Peter Bolte, Martin Klessinger**, and *Konrad Wilhelm*

The INADEQUATE pulse sequence[1] provides access even to small ^{13}C-^{13}C coupling constants in samples of natural abundance, but the experimental possibilities are often considerably limited by large line widths and poor suppression of the main signal. Herein we demonstrate with the spectra of 2-methyl-1-butene **1** and 2-methyl-1,3-butadiene **2** that these difficulties can be circumvented even in routine applications by a combination of the INADEQUATE method with an effective pulse sequence for proton decoupling[2].



1



2

Of the pulse sequences ("supercycles") for proton decoupling MLEV-64, WALTZ-16 and "R7"[3] tested by us, "R7" proved to be most effective for the investigations described here[4]. A comparison of INADEQUATE spectra with broad-band noise decoupling and with "R7" proton decoupling is provided in Figures 1a and b. Since simultaneous computer control of decoupler sequence and double quantum pulse program is not always simple, an external "black-box" decoupler control was developed[5]. To achieve a best possible suppression of the uncoupled ^{13}C-signal the sequence of 128 phase commands given by *Bax*[1] was employed. In the INADEQUATE spectrum of **1** shown in Figure 1b the uncoupled signal of C-3 is almost completely suppressed; the half-width of the lines is 0.25 Hz (corresponding to a line width of 0.12 Hz for one quantum transitions[1]). In addition to the coupling $^1J_{3,4}$=34.6 Hz, the two possible geminal couplings $^2J_{1,3}$=2.6 Hz and $^2J_{3,5}$=4.2 Hz are observable. All the NMR spectra discussed here were recorded with an evolution time τ=0.05 s; according to the relationship $I \sim \sin(2\pi J\tau)$ for the intensity of the doublet components, the coupling $^1J_{2,3}$=41.2 Hz falls in an intensity minimum and is therefore not observable in Figure 1.

The dependence of the signal intensity on the value of the coupling constants and the evolution time τ serves as an important aid for analysis of the spectra. Figure 1c shows the spectrum for C-4 of **1**. Once again, two pairs of signals are observable in addition to the ^1J-coupling with C-3. The two outer signals correspond to the doublet components of the coupling $^3J_{1,4}$=3.4 Hz; according to the expression given above the inner signal pair must, however, on the basis of the intensity, arise from two couplings, namely those of $^2J_{2,4}$=2.3 Hz and $^3J_{4,5}$=2.1 Hz, each of which could be resolved at the coupled nucleus.

All the coupling constants of **1** and **2** are collected in Table 1. Figure 2 illustrates to what degree these coupling constants could still be resolved and individually determined in our experiments. It was possible by extreme Gauss multiplication of the FID, in combination with a

[a] The ^1J couplings were partly determined by conventional measurements.

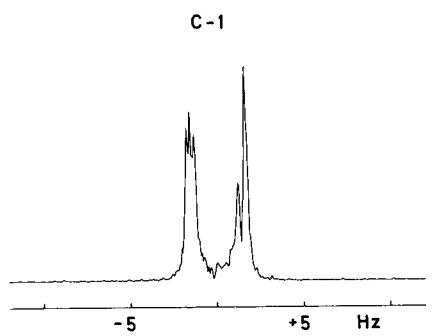

Fig. 2. INADEQUATE spectrum of **1** at 75 MHz. Conditions of measurement as in the case of Figure 1. Gauss multiplication of the FID with the exponents 0.1 and -0.001 and calculation of the "power spectrum".

Combination of the INADEQUATE pulse sequence with an effective broad-band decoupling sequence provides an effective method for the rapid determination of ^{13}C-coupling constants. This combination should thus also extend the possibilities of structural elucidation with INADEQUATE according to *Buddrus et al.*[7], as well as conformation analysis.

Cyclic Carboxylic Acid-Organoboron Compounds with BHB Bridge Bonding**

By *Peter Idelmann, Gerhard Müller, Walter R. Scheidt, Wilhelm Schüssler,* and *Roland Köster**

During investigations on the reduction of D-glucuronic acid with organoboranes $(R_2BH)_2$[1] IR spectroscopic measurements revealed the formation of some novel compounds, namely mixed associates of the unreduced acid with the diorgano-hydro-borane. Such associates are also formed even in solutions of simple monocarboxylic acids and can be preparatively isolated in crystalline form by choosing appropriately substituted educts.

When tetraorganodiboranes(6) $(R_2BH)_2$ [$R_2 = (C_2H_5)_2$, 1,5-C_8H_{14}] are mixed with double the amount of acyloxy(diorgano)boranes R_2BOCOR' [$R_2 = (C_2H_5)_2$, 1,5-C_8H_{14}; $R' = C_6H_{13}$, $C(CH_3)_3$, $CH{=}CHC_3H_7$, C_6H_5] in ether-free solutions at $\approx 20°C$, addition compounds are formed which show broad IR absorption bonds characteristic of a B–(μ-H)–B bond[2]. The mixed association already takes place at $\gtrsim 0°C$: a solution of 1 equivalent diethyl(pivaloyloxy)borane [1755 cm^{-1} ($\nu_{C=O}$); 1600 cm^{-1} ($\nu_{C=O\ldots B}$)] and 0.5 equivalents tetraethyldiborane(6) [1565 cm^{-1} (ν_{BH_2B})] in heptane, prepared at $-10°C$, affords on heating to $\approx 30°C$ the mixed associate [1980 cm^{-1} (ν_{BHB}); 1552, 1499 cm^{-1} ($\nu_{C\ldots OB}$, ring) in quantitative yield. Crystalline mixed associates **4a** and **4b** (melting and decomposition points $> 125-131°C$; temperature interval dependent on the rate of heating) can be prepared in almost quantitative yields from pivalic acid **1** or from 9-pivaloyloxy-9-

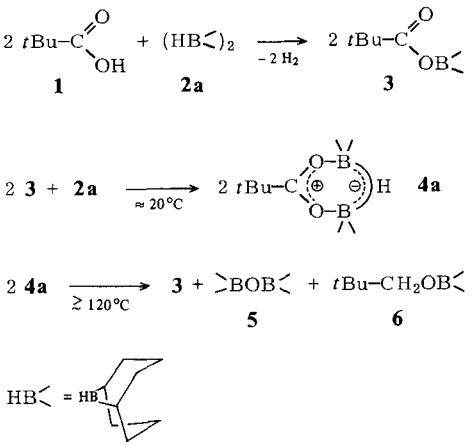
borabicyclo[3.3.1]nonane ("cyclooctane-1,5-diyl(pivaloyloxy)borane") **3** (m.p. = 99 °C) by reaction with bis(9-borabicyclo[3.3.1]nonane) **2a** or bis(9-deuterio-9-borabicyclo[3.3.1]nonane) **2b**, respectively, in heptane or in toluene.

In ethers, and especially in tetrahydrofuran, the species **4** are not stable at $\gtrsim 20$ °C. In hydrocarbons, the carboxylic acid is slowly reduced at $\gtrsim 30$ °C. Because of the formation of intramolecular oxygen-boron bonds, the aldehyde is formed quantitatively from the mixed associate of D-glucuronic acid and tetraethyldiborane(6)[1], whereas almost equimolar amounts of **3** and **6** are obtained from **4a** after cleavage of **5** both in solution as well as in the solid state.



According to the X-ray structure analysis[3] **4a** is made up of two crystallographically independent moieties. Each molecule has two organic bonded boron atoms, which form a six-membered ring with an OCO bridge through a 3c2e BHB bond (Fig. 1). The almost planar COBHBO ring of **4a** corresponds to the planar COBOBO ring in a conformer of the mixed associates of acyloxy-difluoro-boranes and alkoxy-difluoro-boranes[5].

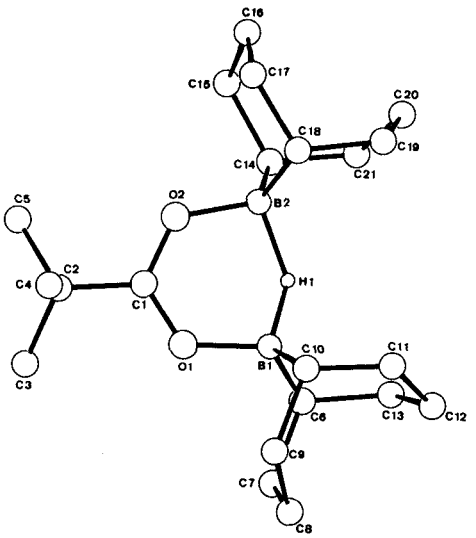


Fig. 1. Structure of **4a** in the crystal (molecule 1) [3, 4].

As can be seen in Figure 2, **4a** forms a layer lattice of molecular units distorted perpendicular to the *ac* plane in the crystal.

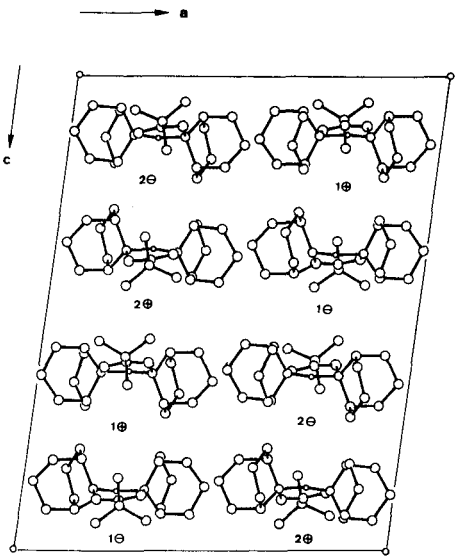

Fig. 2. Projection of the unit cell of **4a** on the *ac* plane. 1 and 2 are crystallographically independent molecules; ⊕ and ⊖ indicate their relative position perpendicular to the plane of projection.

In the solid state, **4a** and **4b** absorb heat at ≈ 80 °C and ≈ 77 °C, respectively (phase transformation), then dissipate heat (reaction) above ≈ 80 °C and ≈ 100 °C, respectively, and finally absorb heat (melting). In the case of **4b** the phase change is completely reversible, whereas in the case of **4a** it is only partially reversible (DSC measurements), because of the reaction that sets in during the phase transformation. The phase change in **4** presumably leads to reorientation of the molecules; this could explain the formation of the products **3**, **5**, and **6** on heating **4** to $\gtrsim 120$ °C.

Procedure

4a: A solution of **2a** (2.4303 g, 10.04 mmol) in heptane (6 mL) is treated with 1.025 g (10.04 mmol) **1** and the mixture stirred at ≈ 20 °C for ca. 19 h. Hydrogen (9.8 mmol, 97%) is slowly evolved. The volatile components are then removed from the white slurry under vacuum (10^{-3} torr) at $\lesssim 20$ °C. **4a** is obtained in 99% yield (3.41 g); from heptane, m.p. = 127–131 °C (decomp.).—MS[6a] (70 eV): *m/z* 344 (M^+), 222, 57 (100%).—^{1}H-NMR[6b] (60 MHz), [D$_8$]toluene): $\delta = 1.97$ (m, 24H), 1.03 (m, 4H), 0.91 (m, 9H).—^{11}B-NMR[6c] ([D$_8$]toluene): $\delta = 18.8$.—^{13}C-NMR[6c] (C$_6$D$_6$): $\delta = 188.24$ (s, 1C), 38.83 (s, 1C), 32.88 and 32.58 (t, 8C), 26.23 (q, 3C), 24.95 and 24.65 (t, 4C), ≈ 23.77 and ≈ 23.66 (br, 4C).—IR (KBr): 1980 cm^{-1} (broad and structured, ν_{BHB}), 1552, 1499 cm^{-1} ($\nu_{C\cdots OB}$, ring)[7].

4b: from heptane, m.p. = 125–130 °C (decomp.).—IR (KBr): 1572 (ν_{BDB}), 1498 ($\nu_{C\cdots OB}$, ring)[7].

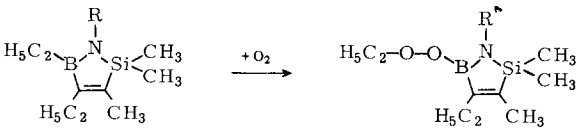
Thermally Stable Ethylperoxyboron Unit by Regioselective Autoxidation**

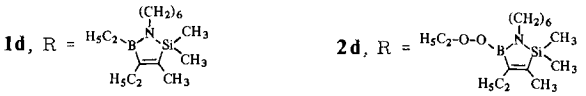
By *Roland Köster** and *Günter Seidel*

The surprisingly thermally stable ethylperoxyboron unit is formed by autoxidation of the heterocycles **1**. In heptane, **1a**—**c**[1] rapidly take up molecular oxygen at ca. 0—20 °C and form 4-ethyl-5-ethylperoxy-1-organo-2,2,3-trimethyl-2,5-dihydro-1*H*-1,2,5-azasilaboroles[***] **2a**—**c** highly regioselectively[2] (yields ≳80%). These can be purified without decomposition by vacuum distillation (see Table 1)[3]. The two heterocycle-containing compounds **1d** correspondingly react regioselectively with exactly **2** equivalents of O_2. Oily **2d** is isolated, and can be stored without decomposition at ≲ −20 °C.



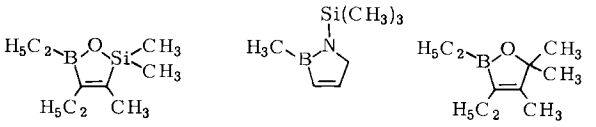
1 **2**

a, R = CH_3; **b**, R = C_6H_5; **c**, R = $CH_2C_6H_5$;



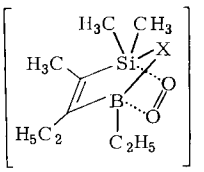
1d **2d**

The autoxidations, which proceed rapidly and afford pure ethylperoxyboron compounds, require the presence of certain atomic groupings in the unsaturated five-membered ring: pentaalkyl-2,5-dihydro-1,2,5-oxasilaboroles[***] such as **3**[4] rapidly take up 1 equivalent of O_2, even at −78 °C. Thermally stable compounds containing an ethylperoxyboron unit cannot however be isolated. In contrast 2-methyl-1-trimethylsilyl-2,5-dihydro-1*H*-1,2-azaborole[***] **4**[5], with an exocyclic trimethylsilyl group, does not react with molecular oxygen up to ≈100 °C. 2,3-Diethyl-4,5,5-trimethyl-2,5-dihydro-1,2-oxaborole[***] **5**[6], which contains the isopropylidene moiety in place of the dimethylsilanediyl group of **3**, is also completely stable towards oxygen up to ≈80 °C.



3 **4** **5**

We assume that the autoxidations of **1** and **3** proceed via oxygen associates **6** having [2.2.1]-structures.



6, X = NR, O

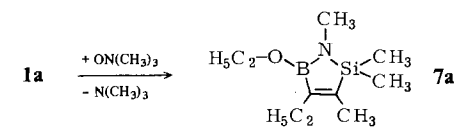
2a—**d** are stable at ≲ −20 °C in the liquid state. The undiluted compounds slowly turn dark brown at ≈20 °C. Presumably intermolecular redox reactions occur. An astonishing feature is the high thermal stability of **2a**—**c** in the gas phase[3]. This could be due to the fact that intermolecular reaction of the exocyclic ethylperoxy group with the BC_{vinyl} bond in the ring is sterically impossible.

2a—**d** are oxidizing agents. Triethylborane reacts with **2a** at ≈20 °C to give ethoxy(ethyl)boranes and 5-ethoxy-4-ethyl-1,2,2,3-tetramethyl-2,5-dihydro-1*H*-1,2,5-azasilaborole[***] **7a** (Table 1).

Table 1. Selected NMR data [7] of the compounds **1a**, **2a**, and **7a**.

	$\delta(^{11}B)$ ($\omega_{1/2}$ [Hz])	$\delta(^{13}C)$ C-5′	C-5″	$\delta(^{14}N)$	$\delta(^{17}O)$ O-5′	O-5″	$\delta(^{29}Si)$ $J(^{29}Si^{13}C)$ [Hz] C-2′	C-3
1a	44.8 (160)	6.8	8.1	−290	—	—	13.6 (76)	(52)
2a	30.0 (180)	71.5	13.2	−325	235.4	263.3	12.95 (73.2)	(53.7)
7a	29.6 (150)	60.1	18.3	−323	71	—	9.65 (75.1)	(53.7)

In analogy to the oxidation of the exocyclic BC bond of **1a**—**d** with oxygen, the oxidation of **1a** with an equimolar amount of trimethylamine *N*-oxide[8] in boiling toluene also proceeds uniformly. **7a** (b.p. = 27 °C/0.001 torr), which is stable to autoxidation, is formed in high yields[9].



1a **7a**

1a, however, is not oxidized by γ-picoline *N*-oxide[8] up to 110 °C. But reaction of the same reagent with **3** leads, exclusively via BC_{vinyl} oxidation, to high yields of 2,6-diethyl-4,4,5-trimethyl-4*H*-1,3,2-dioxasilaborinine[***] **8**. In contrast **3** reacts only slightly regioselectively with trimethylamine *N*-oxide, with formation of 70% **8** and 30% **9**.

The formation of the various O_2- and *N*-oxide products from the unsaturated five-membered rings **1** and **3** demonstrates that the atomic grouping around the acceptor atom

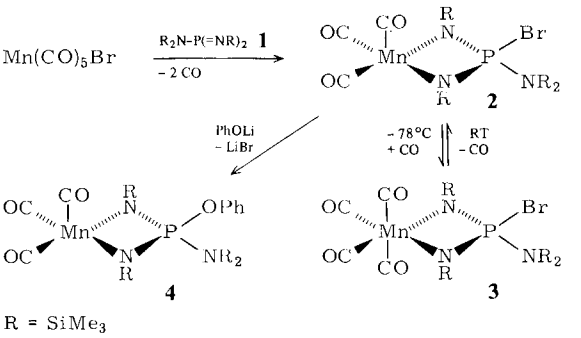
Synthesis and Structure of a Five-Coordinate Manganese(I) Complex**

By *Otto J. Scherer*, Jürgen Kerth,* and *William S. Sheldrick*

Coordination number six and 18-electron system are characteristic for manganese(I) compounds (d^6 complexes)[1]. Five-coordinate 16-electron manganese(I) complexes have hitherto only been detected IR spectroscopically in the matrix[2], and as short-lived, dynamic intermediates in kinetic studies[3]. According to theoretical studies[4], the preferred geometry for d^6 systems (ML_5) is the "flat" square pyramid. However, in the case of the recently characterized $ReCl(Ph_2PCH_2CH_2PPh_2)_2$[5] the crystal structure analysis revealed a trigonal-bipyramidal environment at the rhenium. We have now obtained the isolable five-coordinate manganese(I) complexes **2** and **4** from $Mn(CO)_5Br$ and the double ylide **1**.



R = $SiMe_3$

2 and **4**[6] form permanganate colored crystals, **3** forms yellow-brown crystals, each of which are readily soluble in ether, benzene, *n*-hexane, and dichloromethane. **2** already reacts with carbon monoxide at −78°C to give the tetracarbonyl complex **3** (18-electron system, **2** is regenerated at room temperature and weak vacuum), whereas **4** does not react with CO even at room temperature (normal pressure). In contrast to the extremely air-sensitive **2**, complex **4** can be handled in the open atmosphere for short periods.

In the ^{1}H-NMR spectra (200 MHz, CD_2Cl_2, TMS) a restriction to rotation about the P—NR_2 bond can be de-

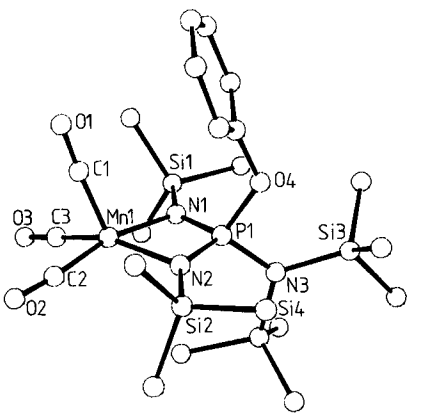


Fig. 1. Structure of **4** (molecule 1) in the crystal. Selected bond lengths [Å] and angles [°] (see also text): Mn1—N1 2.040(5), Mn1—N2 2.013(5), N1—Si1 1.692(5), N2—Si2 1.726(5), N3—Si3 1.805(6), N3—Si4 1.775(6), P1—N1 1.595(5), P1—N2 1.588(6), P1—N3 1.645(6), P1—O4 1.613(5); C1—Mn1—C2 89.1(4), C1—Mn1—C3 88.6(3), C2—Mn1—C3 84.4(4), N1—Mn1—N2 74.4(2), Mn1—N1—P1 91.7(3), Mn1—N2—P1 92.8(3), N1—P1—N2 100.7, O4—P1—N3 97.6(3); sum of angles at N1 360.1, N2 359.8, N3 359.9. Crystallographic data: space group monoclinic, $P2_1/c$; $a = 21.223(4)$, $b = 17.363(4)$, $c = 17.859(4)$ Å, $\beta = 98.63(2)°$; $Z = 8$, $\rho_{calc} = 1.22$ g cm^{-3}. 4207 independent reflections ($Mo_{K\alpha}$, $F_0^2 \geq 3.0\sigma(F_0^2)$, $2\theta \leq 45°$); $R = 0.068$, $R_w = 0.054$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50590, the names of the authors, and full citation of the journal.

Fachbereich Chemie der Universität
Erwin-Schrödinger-Strasse, D-6750 Kaiserslautern (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie (postgraduate grant for *J. K.*).

tected, at room temperature in the case of **4**, at −20°C in the case of **2** and **3**. The fluxional properties of **2** and **4** are visible in the $^{13}C\{^1H\}$-NMR spectrum (CD_2Cl_2, TMS int., 203 K). Even at −70°C only one CO singlet is observed for **2** ($\delta = 227.4$) and **4** ($\delta = 227.1$), whereas for **3** three singlets are observed (217.2 (2CO), 207.7 (1CO), 207.5 (1CO))[7].

In the case of **4** (two independent molecules with no significant difference in bond lengths and bond angles), the crystal structure analysis (Fig. 1, molecule 1) reveals a distorted square-pyramidal environment at the manganese. Whereas the $Mn(CO)_3$ moiety corresponds to the section of an undistorted octahedron, in the chelate moiety a marked widening of the angle is found between the apical CO group and the basal N atoms (C1–Mn1–N1 103.9(3), C1–Mn1–N2 114.2(3)°). In the case of square-pyramidal d^6-complexes, theory[4a] predicts a strengthening of the apical bond for an angle of < 165° between the oppositely situated basal atoms. Molecule 1 of **4** (Fig. 1) with an average value of *ca.* 162° (C2–Mn1–N1 166.7(3), C3–Mn1–N2 157.0(3)°) reveals this trend (Mn1–$C1_{ap}$ 1.748(8), Mn1–$C2_{ba}$ 1.777(9), Mn1–$C3_{ba}$ 1.786(8) Å), whereas molecule 2 does not (average value *ca.* 163°; Mn2–$C1_{ap}$ 1.775(8), Mn–$C2_{ba}$ 1.781(8), Mn2–$C3_{ba}$ 1.751(9) Å). Probably the two angles still lie too near to the limiting value of 165° (moreover, the influence of the twisted NPN chelate moiety is unknown). The Si–N_{ring} bond lengths (average value 1.71 Å) are markedly shorter[8] than the Si–N bond lengths in the P–$N(SiMe_3)_2$ group (average value 1.79 Å). The four-membered ring and the environment of the N atoms are planar. **4** is diamagnetic (susceptibility measurement).

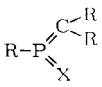
The First Stable Methyleneoxophosphorane**

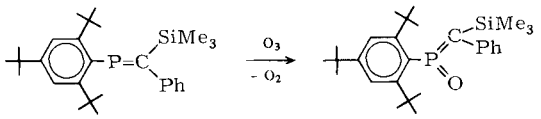
By *Rolf Appel**, *Falk Knoch*, and *Holger Kunze*

Numerous reports have appeared in recent years in which attempts to synthesize the methyleneoxo- and -thioxophosphoranes **1** are described[1,2]. With the exception of a methylenethioxophosphorane substituted at the P atom by a disilylamino group[3], all previous examples of this compound type are highly reactive, transient intermediates and detectable only via trapping reactions.



1a: X = O; **1b**: X = S

We have now found, however, that the phosphaethene **2**, bearing the very bulky 2,4,6-tri-*tert*-butylphenyl group at phosphorus[4], is specifically oxidized by ozone, even at −78°C, to afford the methyleneoxophosphorane **3**. The reaction was followed spectroscopically, since excess ozone leads to secondary reactions.



2 **3**

Colorless crystals of **3** were obtained from acetonitrile. Their composition was determined by elemental analysis and from the mass spectrum, and the structure (Fig. 1) established by X-ray structure analysis[5]. The NMR data[6] are consistent with structure **3**.

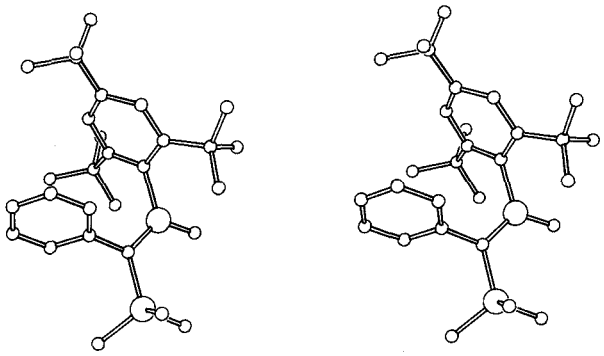


Fig. 1. Structure of **3** in the crystal [5]; stereoscopic projection (without H atoms).

3 slowly reacts with alcohols, the otherwise commonly trapping reagents for these species, to give phosphinic acid esters. The action of sulfur on solutions of **2** in triethylamine affords the corresponding methylenethioxophosphorane of type **1b**.

Procedure

A stream of O_2/O_3 from a commercially available ozone generator is bubbled into a solution of **2** (3.51 g, 8 mmol)

in 50 mL toluene cooled with methanol/dry ice (monitored by ^{31}P-NMR) until the conversion is quantitative. After the solution has been allowed to warm up to room temperature, the solvent is removed in vacuo, the residue taken up in a little acetonitrile, and the spontaneous crystallization completed in the refrigerator at ca. −2°C. Yield: 2.11 g (58%), m.p. = 93°C.

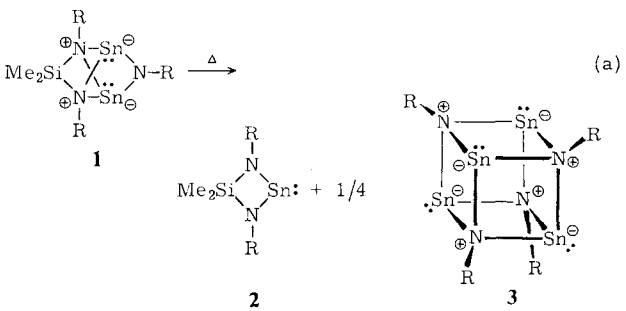
$Sn_3(NtBu)_2(OtBu)_2$, A Molecule with a Novel, Heptaatomic, Polycyclic Framework**

By *Michael Veith** and *Walter Frank*

When strongly heated, the tricyclic compound **1** is quantitatively converted into **2** and **3** (R = *t*Bu)[1].



(a)

1 **2** **3**

The rate-determining step of this reaction follows a first order rate law[1]. We therefore assumed that *tert*-butyliminostannanediyl ("-stannylene") is initially formed as an unstable intermediate, from which the stable tetramer **3** is formed stepwise[2].

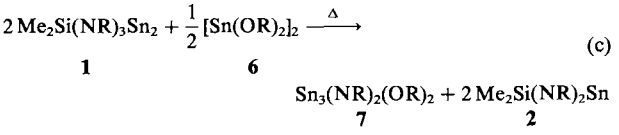
[**] Cyclic Diazastannylenes, Part 20. This work was supported by the Fonds der Chemischen Industrie.—Part 19: M. Veith, M. Grosser, V. Huch, *Z. Anorg. Allg. Chem.*, in press.

To establish the mechanism of reaction we have now repeated the thermolysis of **1** in the presence of a potential trapping reagent for **4** or **5**; we chose for this purpose the dimeric tin(II) bis(*tert*-butoxide) **6**[3], which is loosely bound in solution, for it proved useful in the "trapping" of monomeric thallium(I) *tert*-butoxide with formation of $Tl(OtBu)_3Sn$[4].



(c)

1 **6** **7** **2**

The novel compound **7**[5], which is still stable even above 250°C, is also formed with a twentyfold excess of **6**. Its composition is confirmed by elemental analysis, mass spectrum and ^{1}H-NMR spectrum. As the X-ray structure analysis shows, the molecule **7** has a crystallographic plane of symmetry (cf. Figure 1); the deviation from the higher point symmetry C_{2v} (mm2) is however insignificant, so this symmetry can be assigned to the free molecule. Supporting evidence for this is provided by the ^{1}H-NMR spectrum of **7** [in toluene, $\delta = 1.28$ (s, 18 H) and 1.58 (s, 18 H)], which indicates the same chemical environment for each of the pairs of *tert*-butyl groups at the nitrogen and oxygen atoms independently of the temperature (−80 to +40°C). Purely geometrically, the heptaatomic cyclic moiety in **7**, which to our knowledge is a novelty in the structural chemistry of cage-like polycycles, can be regarded as made up of two trigonal bipyramids (SnN_2OSn) with a common face (SnN_2). Four of the seven atoms forming the "cage" bear *tert*-butyl substituents, which are oriented in the direction of the apices of a distorted bisphenoid.

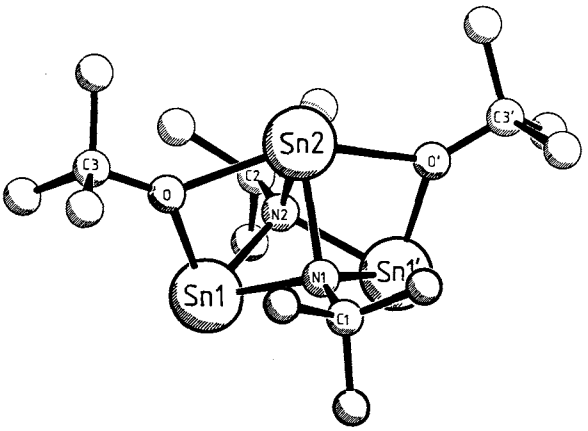


Fig. 1. Molecular structure of **7** in the crystal (orthorhombic, space group Cmca, $a = 1758.6(9)$, $b = 1236.7(9)$, $c = 2192(1)$ pm, $Z = 8$, $\rho_{exp} = 1.81$ g cm^{-3}; 1380 independent reflections/115 parameters, $R = 0.054$). Further details of the crystal structure investigation are available from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, on quoting the depository number CSD 50653, the names of the authors, and full citation of the journal.

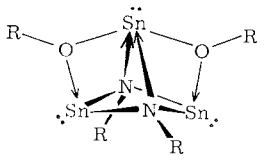
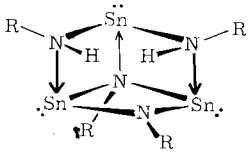
Two of the three tin atoms in **7** are trigonal-pyramidally coordinated, whereas one (Sn2) has four nearest neighbors. Thus, the usual coordination number 3 for Sn^{II} atoms is not only overstepped in larger molecular cages[6] but also in strongly strained systems. The environment at the nitrogen atom is distorted-tetrahedral, that at the oxygen atom trigonal planar. In the chemical formulation of **7** the bonding may simply be described with donor acceptor bonds symbolized by arrows.



7



8

This description of the structure is not only formal (cf. Table 1). The molecule **7** is therefore to be regarded as a Lewis acid-base adduct of **5** and monomeric **6**. Control experiments and kinetic investigations suggest that **5** occurs as intermediate in reaction (a): Thus, e.g., no reaction takes place between **3** and **6**, even under extreme conditions (sealed tube, 270°C).

Other heptaatomic polycycles are known, but their structures mostly derive from the "open" norsecocubane[7]. An example of this type of structure is $Sn(NR)_2(NHR)_2$ **8**[8]. On comparing **8** and **7** there is a very striking similarity in composition, and in a broad sense (replacement of NH by O) they are even isosteric. The sp^3 hybridization brought about in **8** by the hydrogen atoms on the nitrogen atoms leads to the norsecocubane-like structure, whereas in **7** the oxygen atoms are sp^2 hybridized and thus facilitate the formation of the "closed" polycycle.

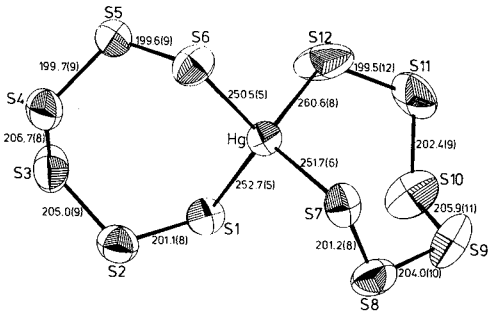
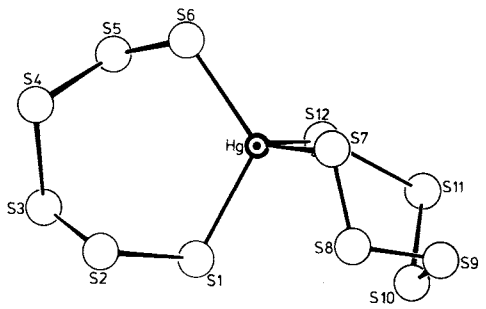
Isolation of a Sulfur-Rich Binary Mercury Species from a Sulfide-Containing Solution: $[Hg(S_6)_2]^{2\ominus}$, a Complex with $S_6^{2\ominus}$ Ligands

By *Achim Müller**, *Jürgen Schimanski*, and *Uwe Schimanski*

The increased solubility of heavy metal sulfides of the "H_2S group" of the analytical separation procedure of the cations (e.g. of HgS) in alkaline sulfide-containing solutions is not only of general chemical interest (possible formation of unusual thiometalates[1,2]) but also of analytical and mineralogical interest[3–5]. Sulfide mineral ores are mainly formed hydrothermally (from post-magmatic fluids); it appears remarkable that the formation of many ore deposits cannot be conclusively explained because of the very small solubility products (e.g. of α-HgS, cinnabar)[3–5]. We have been able to demonstrate that definite novel complexes of metals such as Cu, Ag, Au, and Hg are





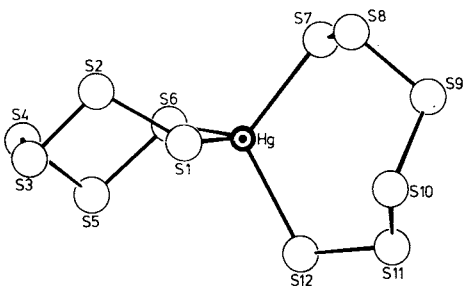


Fig. 1. Structure of the anionic complex **1a** (three projections) in the crystal of the tetraethylammonium salt **1** [space group $P2_1/c$, $a = 1283.1(5)$, $b = 1762.9(7)$, $c = 1455.6(5)$ pm, $\beta = 97.42(3)°$, $Z = 4$; Syntex $P2_1$, $Mo_{K\alpha}$, $R = 0.086$ for 3593 independent reflections ($F_0 > 3.92\sigma(F_0)$)]. Bond angles: S1–Hg–S6 117.0(2), S1–Hg–S7 109.2(2), S1–Hg–S12 99.6(2), S6–Hg–S7 109.6(2), S6–Hg–S12 107.4(2), S7–Hg–S12 113.9(2), Hg–S–S (mean value) 108.4, S–S–S (mean value) 108.6°. formed in polysulfidic solutions which may be of significance in this connection.

Reaction of mercury(II) acetate with methanolic polysulfide solution in the presence of tetraethylammonium iodide leads to formation of orange-colored $(Et_4N)_2[Hg(S_6)_2]$ **1**[6]. In the anionic complex $[Hg(S_6)_2]^{2\ominus}$ **1a**, the first homoleptic complex with bidentate $S_6^{2\ominus}$ ligands, the central Hg atom is surrounded by a distorted tetrahedral array of S atoms (Fig. 1)[8]. The mean Hg–S distance is—as expected—very similar to that in β-HgS with the zinc blende structure (253 pm)[2].

The two $S_6^{2\ominus}$ units in **1a** have a similar conformation, whereas the two HgS_6 heterocycles have a different structure (cf. the three projections in Fig. 1). The coordinating (S1, S6 and S7, S12) as well as the next but one S atoms (S3, S4 and S9, S10) of the hexasulfido ligands each lie almost in a plane; the remaining S atoms (S2,S5 and S8,S11) lie approximately 100 pm above or below these planes. The Hg atom is located almost in the {S1, S3, S4, S6} "plane", but distinctly outside (105 pm) the {S7, S9, S10, S12} plane.

The compound **1** cannot be characterized very well by IR spectroscopy (moderately strong band at 495 and weak band at 485 cm^{-1}) because of the low polarity of all the bonds. However, the characteristic intense main bands at 460 and 196 cm^{-1} in the solid-state Raman spectrum ($\lambda_e = 647.1$ nm) may be used for its detection (assignment: totally symmetric ring breathing and deformation vibration, both practically localized in the $S_6^{2\ominus}$ ligand). The solid-state electronic spectrum (reflectance; dispersion on cellulose) shows a band at 350 nm with two slightly pronounced shoulders at 285 and 402 nm.

On the basis of our findings, it would appear possible that besides sulfido-[4,5] also polysulfidometalates participated in the formation of metal sulfide as for instance cinnabar deposits. The transport of "metals together with sulfur"[4] in the form of soluble polysulfido species could be explained principally in this way.

Novel Clusters of Cobalt and Nickel with Organophosphorus Ligands**

By *Dieter Fenske**, *Ramazan Basoglu*, *Johannes Hachgenei*, and *Friedhelm Rogel*

Reactions of transition metal halides with silylated phosphanes have already been reported on by several authors[1]. In some of these reactions the formation of binuclear metal complexes was also observed[2]. We have now even found a simple entry to polynuclear clusters in this way. When $CoCl_2 \cdot 2PPh_3$ is allowed to react with $(Me_3Si)_2PPh$ in tetrahydrofuran (THF), the tetranuclear cluster **1** can be isolated from the products (yield *ca.* 70%)[3a].

$$CoCl_2 \cdot 2PPh_3 + (Me_3Si)_2PPh \xrightarrow[THF]{293\ K} [Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$$
1

The dark green compound **1** is diamagnetic. In THF solution it can be reversibly oxidized to $\mathbf{1}^{\oplus}$ and $\mathbf{1}^{2\oplus}$[4]. **1** reacts with Br_2 or I_2 to give $CoX_2 \cdot 2PPh_3$ (X = Br, I). $CHCl_3$, CCl_4 and $C_2H_4Cl_2$ oxidize **1** with formation of $\mathbf{1}^{\oplus}Cl^{\ominus}$. Reaction of **1** in toluene with CH_3COCl above 330 K affords a green oil, crystallization of which furnishes the salt-like product **2** having the composition $\mathbf{1}^{\oplus}[CoCl_3(PPh_3)]^{\ominus}$[3b]. Reaction of **2** with $[(C_4H_9)_4N][PF_6]$ leads to formation of $\mathbf{1}^{\oplus}[PF_6]^{\ominus}$ **3**. The compounds **2** and **3** are paramagnetic ($\mu_{eff} = 4.55$ and $2.50\,\mu_B$, respectively, at 300 K)[5].

In the ^{1}H-NMR spectrum of **2**, broad signals are observed for the phenyl protons of the $[CoCl_3(PPh_3)]^{\ominus}$ anion at $\delta = 13.60$, -3.10 and -3.70[6]. A strong deshielding is found for the phenyl protons of the μ_3-PPh ligands in the cation $\mathbf{1}^{\oplus}$ ($\delta = 15.06$, 11.06, and 10.52), which is less marked in the case of the PPh_3 ligand ($\delta = 7.53$, 6.09, and 6.02). The corresponding signals in the spectrum of neutral **1** appear at $\delta = 6.7$–7.6.

As shown by the X-ray structure analysis, **1** crystallizes together with PPh_3 in the ratio 1:1. The molecular structure of **1** contains a Co_4-cluster. Each surface of this tetrahedral cluster is coordinated by a μ_3-PPh ligand, and each Co atom is bound to a PPh_3 ligand. In **1**, the cluster has a threefold axis (the Co1, P1, and P41 atoms occupy the 6c positions, the Co2, P2, and P3 atoms the 18f positions; as a result, the phenyl ring is statistically disordered at P41). **2** contains a cluster of the same structure as cation, and $[CoCl_3(PPh_3)]^{\ominus}$ as anion. Their structures are reproduced in Figures 1 and 2.

In **1** and $\mathbf{1}^{\oplus}$, each Co atom is surrounded by a distorted tetrahedral array of three μ_3-P atoms and one monodentate coordinated P-atom ((μ_3-P)–Co–(μ_3-P) 103–105, P–Co–(μ_3-P) 114–117°). In turn, the Co atoms form a tetrahedron with the following Co–Co distances: (**1**: Co1–Co2 3 × 258.6(2), Co2–Co2A 3 × 257.1(3) pm; $\mathbf{1}^{\oplus}$: Co1–Co2 256.6(3), Co1–Co3 261.1(6), Co1–Co4 259.6(5), Co2–Co3 254.1(6), Co2–Co4 252.7(6), Co3–Co4 254.9(4) pm); the bond angles in the Co_4 cluster are 59.6–60.1(1)° for **1** and 58.6–61.3(1)° for $\mathbf{1}^{\oplus}$. Consistent with the noble gas rule (60 valence electrons), the Co_4 cluster in **1** has al-

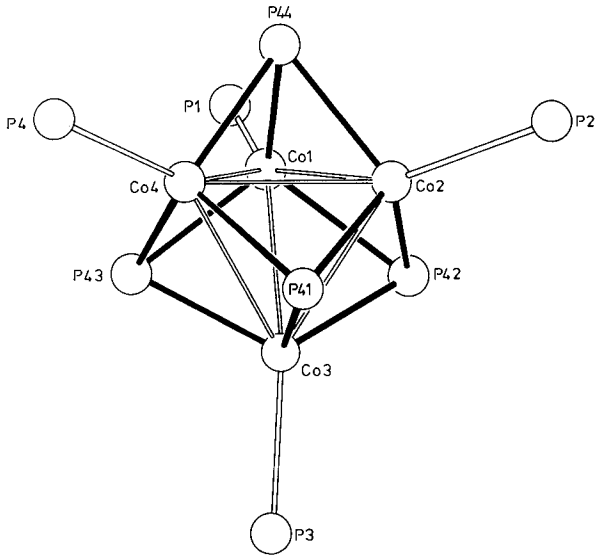

Fig. 1. Molecular structure of **1** and $\mathbf{1}^{\oplus}$ in the crystal (the phenyl groups are not shown for sake of clarity). P1, P2, P3 and P4 signify P-atoms of the $P(C_6H_5)_3$-ligand, P41, P42, P43 and P44 the P-atoms of the μ_3-$P(C_6H_5)$-ligand. **1**: $C_{96}H_{80}Co_4P_8 \cdot P(C_6H_5)_3$, crystals from toluene. Lattice constants (180 K): $a=b=1414.4(3)$, $c=8295.0(30)$ pm, $\alpha=\beta=90$, $\gamma=120°$; space group $R\bar{3}$, $Z=6$. Data collection: Syntex $P2_1$, $Mo_{K\alpha}$ up to $2\theta=45°$; 3098 reflections with $I>1.96\sigma(I)$, empirical absorption correction. Solution of structure: Patterson methods, anisotropic refinement of all atoms (without H) leads with all data to $R_1=0.078$, $R_2=0.066$. **2**: $C_{114}H_{95}Cl_3Co_5P_9$, crystals from ethyl acetate. Lattice constants (293 K): $a=5094.6(31)$, $b=1478.7(4)$, $c=3932.1(11)$ pm, $\beta=132.07(3)°$; space group C2/c, $Z=8$. Data collection: Syntex R3, $Mo_{K\alpha}$, up to $2\theta=45°$; 8703 reflections with $I>1.96\sigma(I)$, empirical absorption correction. Solution of structure: Patterson methods, anisotropic refinement for Co, P, and Cl (rigid phenyl group with C–C 139.5 pm) leads with all data to $R_1=0.084$, $R_2=0.078$ (cf. also Fig. 2) [7].

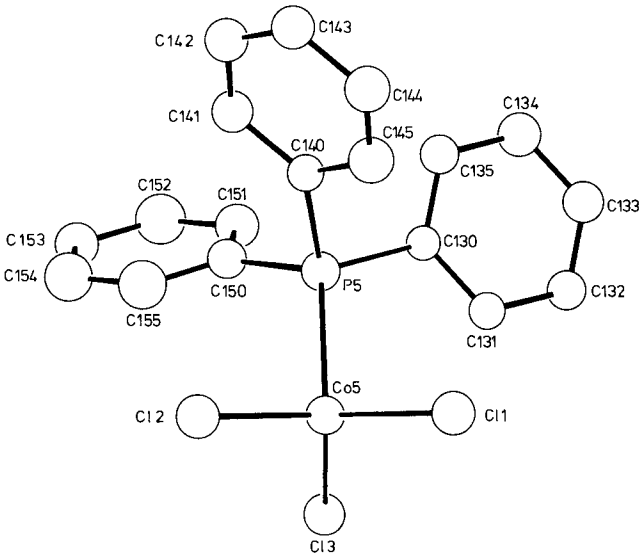

Fig. 2. Molecular structure of the $[CoCl_3(P(C_6H_5)_3)]^{\ominus}$ anion in the crystal of **2**. Bond lengths [pm]: Co5–Cl1 226.9(6), Co5–Cl2 223.8(9), Co5–Cl3 222.2(9), Co5–P5 239.4(8); bond angles [°]: Cl–Co5–Cl 113–116, Cl–Co5–P5 103–105.

most T_d symmetry; in $\mathbf{1}^{\oplus}$ (only 59 valence electrons), on the other hand, the tetrahedron is distorted[8].

In the analogous reaction of $NiCl_2$ with PPh_3 and $(Me_3Si)_2PPh$[3c] the silylphosphane is not completely consumed. Addition of acetyl chloride leads to a change in color from brown to green and formation of a crystalline precipitate. The clusters **4** and **5** can be isolated by fractional crystallization from ethyl acetate.

$[Ni_8Cl_4(PPh)_6(PPh_3)_4]$ **4** $\quad$ $[Ni_8(CO)_4(PPh)_6(PPh_3)_4]$ **5**

The course of the reaction is not known in detail; but the ratio of the products **4** and **5** depends on the reaction time. Apparently **5** predominates in the initial stages of the reaction, and this then reacts with CH_3COCl to give **4**[9]. Conversely, **5** can be prepared by reaction of **4** with sodium amalgam under CO[3c]. Attempts to replace the Cl ligands in **4** by $Br^{\ominus}$ or $I^{\ominus}$ met without success. However, a cluster of the composition $[Ni_8Br_4(PPh)_6(PPh_3)_4]$ can be prepared by reaction of **5** with Br_2[10].

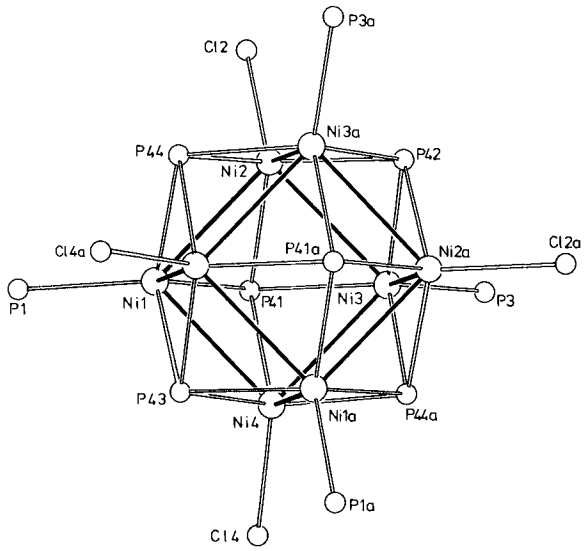

Fig. 3. Molecular structure of the cluster 4 (without phenyl groups). P1 and P3, and P41–P44, respectively, signify the P atoms of the $P(C_6H_5)_3$- and PC_6H_5-ligands. **4**: $C_{108}H_{90}Cl_4Ni_8P_{10}$, crystals from toluene, 4 crystallizes with toluene in the ratio 1:1, space group C2/c. Lattice constants (293 K): $a=1943.7(8)$, $b=2678.4(11)$, $c=2228.8(9)$ pm, $\beta=90.22(3)°$, $Z=4$, $\mu(Mo_{K\alpha})=15.4\ cm^{-1}$. Data collection: Syntex R3, up to $2\theta=45°$; 7695 reflections, 6178 with $I>2\sigma(I)$, empirical absorption correction. Structure solution: Patterson methods, anisotropic refinement of all atoms (without H) lead to $R_1=0.067$, $R_2=0.067$ [7]. Most important bond lengths [pm]: Ni–Ni 259..2–262.1(10), Ni-(μ_4-P) 220.4–222.4(9), Ni1–P1 224.5(9), Ni3–P3 224.7(9), Ni2–Cl2 223.7(9), Ni4–Cl4 225.1(9). Most important angles (±0.2°): Ni–Ni–Ni 89.6–90.3, P1–Ni1–(μ_4-P) 109.5–111.6, (μ_4-P)–Ni–(μ_4-P) 107.5–108.7, Cl2–Ni2–(μ_4-P) 110.3–111.9, Ni–(μ_4-P)–Ni 71.6–72.5.

As can be seen in Figures 3 and 4 the two compounds **4** and **5** each contain a cubic array of eight Ni atoms, each face of which is coordinated by a μ_4-PPh ligand. Ni is surrounded almost tetrahedrally by the ligands bound to it. In **5**, Ni is bound alternately to CO ($\tilde{\nu}CO=1948\ cm^{-1}$) and PPh_3. If the PPh bridge ligand is considered as a 4e-donor, then **5** contains 120 valence electrons and is thus isoelectronic with a cluster of formula $Ni_8(CO)_8(PPh)_6$ already described by *Dahl* et al.[12]. The structure of **4** can be derived from that of **5** by replacing CO by $Cl^{\ominus}$. However, the cluster **4** contains only 116 valence electrons and does not conform to the nobel gas rule. That is, in **4** and **5** there are respectively 20 and 24 electrons available for formation of Ni–Ni bonds. This manifests itself in the Ni–Ni bond lengths, which are markedly shorter in **4** (259.2–262.1 pm) than in **5** (265.3–268.8 pm).

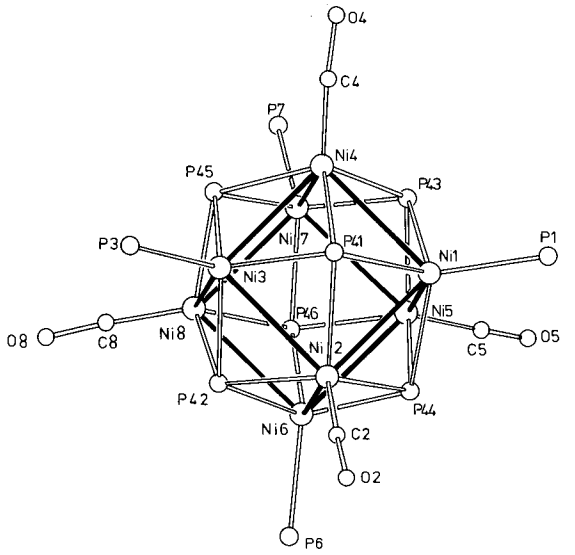

Fig. 4. Molecular structure of the cluster **5** (without phenyl groups). P1, P3, P6, P7, and P41—P46 respectively signify the P-atoms of the $P(C_6H_5)_3$- and PC_6H_5-ligands. **5**: $C_{112}H_{90}O_4Ni_8P_{10}$, crystals from ethyl acetate [11], **5** crystallizes with ethyl acetate in the ratio 1:2, space group $P2_1/c$. Lattice constants (293 K): $a=2471.5(10)$, $b=1561.8(7)$, $c=2893.0(9)$ pm, $\beta=90.45(3)°$, $Z=4$, $\mu(Mo_{K\alpha})=15.2$ cm^{-1}. Data collection: Syntex R3, up to $2\theta=40°$; 11830 reflections, 9350 with $I>2\sigma(I)$, empirical absorption correction. Solution of structure: Patterson methods, anisotropic refinement of all atoms (without H) lead to $R_1=0.088$, $R_2=0.090$ [7]. Most important bond lengths [pm]: Ni—Ni 265.3—268.8(2), Ni—(μ_4-P) 218.0—221.0(3), Ni—P 225.9—228.8(4), Ni—CO 176.2—184.5(15), C—O 109.5—114.2(29). Most important bond angles [°]: Ni—Ni—Ni 88.3—91.5(1), P—Ni—(μ_4-P) 110.7—116.3(1), (μ_4-P)—Ni—C 113.1—116.4(6), Ni—(μ_4-P)—Ni 74.2—76.0(1), Ni—C—O 176.7—179.1(12).

As expected, **5** is diamagnetic; **4**, on the other hand, exhibits paramagnetic behavior and has a temperature-dependent magnetic moment[5] ($\mu_{eff}=2.37$ (300 K), 2.48 (200 K), 2.54 (100 K), 2.44 (25 K), 1.86 (10 K), 1.34 (5 K), $0.94\mu_B$ (4 K)). Formally, the Ni_8 cluster in **4** can be considered to have two different oxidation states: On the one hand, the cluster with the $PPh^{2\ominus}$ and $Cl^{\ominus}$ ligands has the charge $[Ni_8]^{16\oplus}$ and consists of $8\times Ni^{2\oplus}$; on the other, $[Ni_8]^{4\oplus}$ is present if the ligands are regarded as $Cl^{\ominus}$ and PPh^0. In the second case, **4** is a compound which contains nickel in two different oxidation states ($4\times Ni^0$, $4\times Ni^{1\oplus}$), and the magnetic behavior can be explained in terms of an antiferromagnetic coupling of $Ni^{1\oplus}$.

Optically Active α-Arylcarboxylic Acids by Kinetic Resolution: Pyrethroid Acids**

By *Christoph Rüchardt**, *Holger Gärtner*, and *Ulrich Salz*

A recently described method for the preparation of optically active α-arylcarboxylic acids by base-catalyzed reaction of alkyl(aryl)ketenes with optically active alcohols affords good optical yields of the ester that is isolated; however, because of the high reactivity of the ketenes—even when their isolation is circumventable—interfering reactions occur[1,2]. We have now found that optically active α-arylcarboxylic acids **4** and their esters **3** can be obtained in excellent chemical and optical yields if the diastereomeric mixtures of the α-arylcarboxylic acid anhydrides **1** are allowed to react with stoichiometric amounts of the optically active 1-(3-pyridyl)ethanol **2a** or 1-(4-pyridyl)ethanol **2b** in toluene at room temperature.

The results in Table 1 show that the enrichment of an enantiomer of the carboxylic acids can be up to 100% in the esters **3**; in the carboxylic acids **4** formed at the same time, the antipode is enriched. Since the carboxylic acid **4** racemizes again on reconversion into the anhydride **1** with boiling acetic anhydride and pyridine[3], this method is suitable for the complete conversion of a racemic α-arylcarboxylic acid into its optically active ester **3**. A further advantage of the 1-pyridylethanols **2** is that their esters **3** undergo smooth acid-catalyzed hydrolysis without racemization of the alcohol (S_N1) or elimination (E_1); optically pure **2** is recovered[4]. On the one hand, the protonation at nitrogen hinders S_N1 or E_1 reactions in the alcohol moiety,

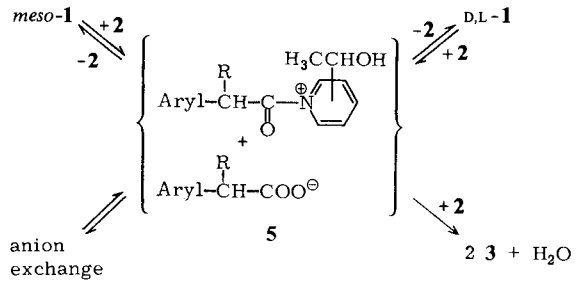
[a] *de* = diastereomeric excess of (*S*,*S*)-**3** (with (*S*)-(−)-**2**) or (*R*,*R*)-**3** (with (*R*)-(+)-**2**) determined by GC; error ±2%. [b] *ee* = enantiomeric excess; with (*S*)-(−)-**2** the (*R*)-carboxylic acid **4** is formed preferentially; determined from $[\alpha]_D$; error ±5%.

and, on the other, increases the quality of the alcohol as leaving group in the ester hydrolysis according to the addition-elimination mechanism ($A_{AC}2$)[5]. Moreover, both enantiomers of the alcohols **2** can easily be obtained by resolution with tartaric acid or dibenzoyltartaric acid[6].

The method is ideally suitable for the production of optically active 2-aryl-3-methylbutyric acids of type **4** (R = 2-C_3H_7, aryl = C_6H_5, 4-Cl-C_6H_4 or 4-CH_3O-C_6H_4), which find use as pyrethroid acids[7] in synthetic insecticides such as the highly effective Fenvalerate[7,8]. The finding that racemic **2** leads to an equal or even somewhat higher diastereomeric excess in **3** than (*S*)- or (*R*)-**2** is indicative of kinetic resolution[3,9]. Kinetic resolution in the reaction of chiral secondary alcohols with an *excess* of α-phenylbutyric acid anhydride in pyridine is already known as the Horeau method for the analytical determination of the absolute configuration of secondary alcohols[3,10]. Conversely it has occasionally also been used for the determination of the configuration of carboxylic acids using optically active menthol as alcohol component[3,10]. The advantage of the 1-pyridylethanols **2** is that, even if only stoichiometric amounts are used, higher optical yields are obtained in the ester **3**, thus making the reaction a preparatively useful one.

To interpret these findings one must assume that the diastereomeric anhydrides **1** equilibrate under the reaction conditions. The essential intermediate for the equilibration and, likewise, for the kinetically decisive acylation step could be **5**. It is even possible that two molecules of **5** participate in the selectivity-determining acylation step. It has not been tested whether base-catalyzed racemization of the anhydride also takes place besides the *meso*-D,L equilibration under the reaction conditions.

Addition of *tert*-amines lowers the optical yields[11]. Lower optical yields are achieved also with amino alcohols such as *N*-methylephedrine or *N*-methylpseudoephedrine[11].



Procedure

2-(4-Chlorophenyl)-3-methylbutyric acid anhydride (4.1 g, 10.0 mmol) is allowed to react with *R*-(+)-**2b** (1.2 g, 10.0 mmol) ($[\alpha]_D^{20} = 46.0$, $c = 0.50$, ethanol, i.e. 92.4 ± 2% *ee*[6b]) in 100 mL toluene for 16 h at 25 °C. Extraction with 2 × 50 mL dil. NaOH, precipitation with conc. HCl, dissolution in ether, washing, drying and removal of the solvent furnishes 1.9 g (82%) (*S*)-(+)-2-(4-chlorophenyl)-3-methylbutyric acid of type **4**, $[\alpha]_D^{20} = 16.5$ ($c = 0.96$, $CHCl_3$), corresponding to an optical yield (*ee*) of 38 ± 5%[7c]. Neutral washing of the toluene solution followed by drying with $MgSO_4$ and removal of the solvent in vacuo affords 2.9 g (96%) 1-(4-pyridyl)ethyl 2-(4-chlorophenyl)-3-methylbutyrate of type **3**, whose diastereomeric ratio was determined by GC (25 m glass capillary SE 20, 200 °C) to be 87 : 13 (*de* = 74%). The product was characterized by elemental analysis, ^{1}H-NMR spectroscopy, and GC.

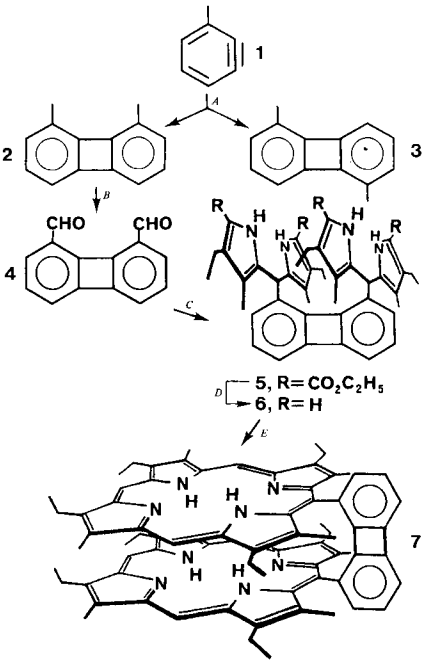
A Biphenylenediporphyrin: Two Cofacially Arranged Porphyrins with a Biphenylene Bridge**

By *Chi K. Chang** and *Ismail Abdalmuhdi*

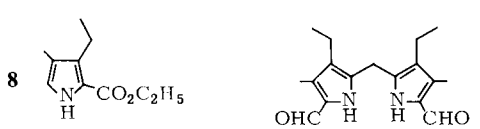
Cofacial diporphyrins and their metal complexes, first synthesized in 1977, have found interesting applications in mediating the 4e path of O_2 reduction on graphite electrodes[1,2] as well as in modeling light-induced charge separation in photosynthetic reaction centers[3]. To date, most cofacial dimers have been prepared by linking two porphyrin rings via an amide (or ester) bond[4]. While this method of covalent linkage is synthetically straightforward, the yields from the lengthy sequence have been low. More serious is the fact that the long-term stability of the amide bond is low in the acid environments present in many potentially useful electrochemical O_2-reduction systems, e.g., fuel cells. It is therefore worthwhile to explore other approaches to synthesize dimeric porphyrins. We report here the synthesis of a novel biphenylene cofacially arranged diporphyrin **7**.

For diporphyrins used in electrocatalytic O_2-reductions, the interporphyrin distance has been shown to be critical. The proven optimum length consists of four C atoms[1,2]. Bearing this in mind, a biphenylene having two porphyrins attached at the 1 and 8 positions should be very attractive. 1,8-Biphenylenedicarboxaldehyde, prepared from the dimethyl precursor, could serve as a convenient starting material. 3-Methylbenzyne **1**[4] was condensed in situ to yield a mixture of 1,8- **2** and 1,5-dimethylbiphenylene **3**. The separation of the two isomers was found to be much simpler if the mixture was converted first to the dialdehydes and then chromatographed. Attempts to condense 1,8-biphenylenedicarboxaldehyde with a mixture of pyrrole and benzaldehyde invariably produced only tetraphenylporphyrin and untractable materials. The 1,8-dialdehyde **4**, however, reacted cleanly with ethyl 3-ethyl-4-methyl-2-pyrrolecarboxylate **8**[6] to give almost quantitatively the bis(dipyrrylmethane) **5**. The tetraester **5** was saponified and the acid **6** decarboxylated. Unlike common α-unsubstituted dipyrrylmethanes, **6** did not yield any porphyrin when allowed to react with dipyrrylmethane-5,5′-dialdehydes such as the (5,5′-diformyl-4,4′-dimethyl-3,3′-diethyl-2,2′-dipyrryl)methane **9** in 0.4% HI/HOAc (MacDonald method). However, if the same reaction was carried out in 0.4% $HClO_4$/methanol, the desired diporphyrin **7** was obtained, surprisingly in nearly 20% yield.



Scheme 1. *A*) See [4b]. *B*) See [5]. *C*) **4** + **8** (molar ratio 1:4), HCl, in EtOH, 1 h reflux. *D*) **5** + NaOH; $H^{\oplus}$; 2-amino ethanol, 180°C. *E*) **6** + **9** in 0.4% $HClO_4$/MeOH, 5 h, RT; *o*-chloranil.

The ^{1}H-NMR spectrum of **7** shows two sharp singlets for the ring methyl groups since the four methyl groups flanking the biphenylene are shielded by the six-membered rings and shifted ca. 0.3 ppm upfield[7]. The magnitude of this shift is notably smaller compared to other *meso*-phenyletioporphyrins (> 1 ppm)[8]. We consider this as unequivocal proof of the theoretical prediction that the six-membered rings in biphenylene should have a comparatively small diamagnetic ring current[9]. The NH protons appear at a position which agrees well with previously studied, closely-spaced cofacial diporphyrins ($\delta \approx -7.6$)[3]. The cofacial configuration of **7** is also indicated by its UV/VIS spectrum which shows a Soret peak at 378 nm (cf. 402 nm for a *meso*-phenyletioporphyrin). Such blue shifts can be understood in terms of exciton interactions in the diporphyrins[3].



The interplanar distance of the diporphyrins may be estimated by studying the dipolar interaction of two Cu^{2+} centers[10]. As shown in Figure 1, the EPR spectrum displays a seven-line parallel hyperfine pattern with a zero-field splitting of 0.043 cm^{-1}, corresponding to a Cu···Cu distance of ca. 4.1 Å. The most unusual feature of the EPR

spectrum, however, is the unexpectedly intense signals associated with the half-field transition ($\Delta M_s = \pm 2$). According to theory, the intensity of the half-field transition is determined by the strength of the dipolar interaction. Recently *Eaton* and *Eaton*[11] calculated that the relative intensity defined by the ratio (intensity of $\Delta M_s = \pm 2$)/(total intensity of $\Delta M_s = \pm 1$) should be approximately $20/r^6$, where r is the interspin distance in Å. Assuming there is no gross distortion of the porphyrin rings, their equation estimates the Cu···Cu distance in the dicopper complex of **7** to be <2 Å, a highly unlikely situation. This issue will have to be resolved by an X-ray structure determination.

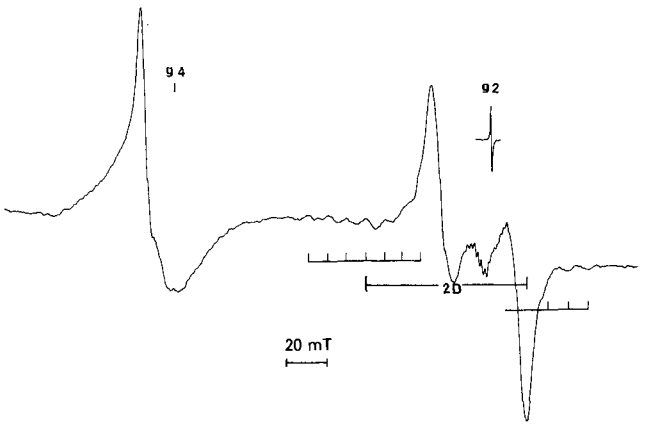

Fig. 1. X-band EPR spectrum of Cu(II)-Cu(II) complex of diporphyrin **7** in toluene at -150°C, $c \approx 1$ mmol/L. Modulation amplitude = 1 mT; $\nu = 9.2$ GHz. D is half the distance between the centers of the parallel absorptions. $g_{\parallel} = 2.18$, $g_{\perp} = 2.05$.

The dicobalt complex of **7** has been synthesized, and preliminary study indicates that a pyrolytic graphite- surface coated by this cobalt diporphyrin is indeed able to reduce O_2 almost exclusively via the 4e path in 0.5 M aqueous trifluoroacetic acid[12].

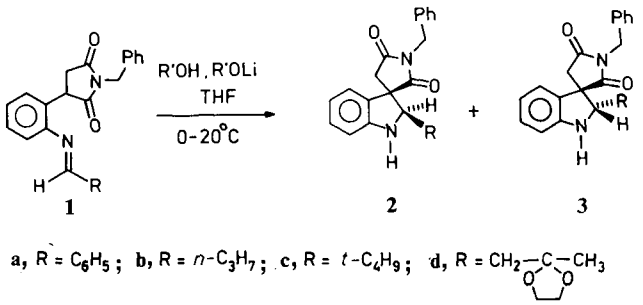
Highly Enantioselective Synthesis of a 2,3-Dihydroindole Mediated by *N*-Methylephedrine

By *Robert Jan Vijn, W. Nico Speckamp*, Bart S. de Jong,* and *Henk Hiemstra*

The single-step synthesis of enantiomerically pure compounds from prochiral educts via the intermediary of a chiral catalyst is the pinnacle of asymmetric synthesis[1]. Reactions that approach such enzymatic processes are still scarce[2]. Here, we wish to communicate the discovery of such a reaction in the course of our investigations of the synthesis of dihydroindoles[3], valuable intermediates in the total synthesis of mitomycins and indole alkaloids[4,8].

Cyclization of azomethines **1** to afford the 2,3-dihydroindoles **2** and **3** proceeds with lithium alkoxide or sodium alkoxide in the presence of the corresponding alcohol in tetrahydrofuran (THF) at 0—20°C. If a bulky secondary or tertiary alcohol is used, the predominant product is the *cis*-2,3-dihydroindole **2**, with less than 10% of the *trans*-isomer **3** being formed[3].

We recently reported[5] that low asymmetric induction (*ee* 17—31%) results if a chiral alcohol, i.e. (−)-menthol or (−)-borneol, is used in this reaction[5]. The degree of enantioselectivity showed little dependence on the structure of chiral alcohol or azomethine, the nature of the cation (Li or Na), or on temperature.



a, R = C_6H_5; **b**, R = n-C_3H_7; **c**, R = t-C_4H_9; **d**, R = CH_2—C(O)(O)—CH_3

We report here the use of chiral β-amino alcohols, which have already been successfully employed as bifunctional catalysts in chiral base catalysis[6]. Although quinine and (*S*)-*N*-methylprolinol gave very low chemical and/or enantiomeric yields, the results with derivatives of ephedrine were good (Table 1). Treatment of the azomethine **1b** with the reagent derived from 1 equiv. of *n*BuLi and 2.5 equiv. of (+)-(1*S*,2*R*)-*N*-methylephedrine **4b** in THF afforded (−)-2,3-dihydroindole **2b** in 50% yield and in more than 95% *ee*[7] (Table 1; entry 4); we were unable to detect the other enantiomer in the ^{1}H-NMR spectrum of the crude product[5,7]. Likewise, (−)-(1*R*,2*S*)-*N*-methylephedrine **5b** yielded the enantiomerically pure (+)-enantiomer of **2b** (entry 5).

An unfortunate feature of this asymmetric synthesis is its extreme sensitivity to small structural variations in substrate and catalyst system. Replacing $Li^{\oplus}$ with $Na^{\oplus}$ leads to a drastic reduction in *ee* (entry 6). Ephedrine **4a** (entries 2, 3) and *N*-benzoylephedrine **4f** (entry 10) are useless as chiral catalysts, whereas substitution of the *N*-methyl group of **4b** with larger groups is also detrimental (entries 7—9). Finally, the nature of R in the azomethine **1** appears to be very important (entries 1, 4, 11, and 12).

12	**1d**	**4b** L = CH_3	**2d**	57	50	(−)

[a] Experimental procedure: [7]. [b] **4a** and **5a** are commercially available; **4b–f** and **5b** were synthesized from **4a** and **5a** by either reductive methylation (**4b**, **5b**) [9] or by acylation (**4f**), followed by $LiAlH_4$ reduction (**4c–e**). [c] Isolated yields except for entry 7, for which the ^{1}H-NMR yield is given. [d] Determined by ^{1}H-NMR spectroscopy using Eu(hfc)$_3$ [5, 7]. [e] Cation: $Na^{\oplus}$.

Mechanistically, this ring-closure reaction must be viewed as a disrotatory 1,5-electrocyclization[3, 10]. To account for the formation of the *cis* product we assume that ring closure occurs from the *Z*-azomethine geometry and that the imide enolate has the enolate oxygen directed toward the azomethine, both moieties being arranged in a helix-type conformation. The favorable influence of the hydroxy group is most probably the result of hydrogen bonding with the azomethine nitrogen (O–H···N) in the transition state. Furthermore, in the highly structured transition state the tertiary amine function of the chiral auxiliary is bound via $Li^{\oplus}$ to the enolate oxygen as shown in **6**. This model accounts for the failure of $Na^{\oplus}$ (entry 6) and of the *N*-benzoyl group (entry 10) to induce high *ee* values. Due to the weak Lewis acidity of $Na^{\oplus}$ and the weak Lewis basicity of an amide nitrogen the interaction between enolate and catalyst is loosened in both cases.

Since the conversion of *rac*-**2d** into *rac*-vindorosine has previously been reported[8], the present result can be formally regarded as an enantioselective synthesis of this alkaloid.

[7] *Procedure:* To a well stirred solution of (1*S*,2*R*)-*N*-methylephedrine **4b** (270 mg, 1.63 mmol) ($[\alpha]_{578}^{RT} = +25$ ($c = 6$, EtOH)) in 5 mL THF under nitrogen at 0°C was added 0.40 mL of a 1.6 N solution of *n*BuLi (0.64 mmol) in hexane. Two minutes later a solution of azomethine **1b** (210 mg, 0.63 mmol) in 1 mL of toluene was added. The resultant blue mixture slowly turned red and was stirred for 45 min at 0°C. 5 mL of 2 N HCl was then added and the mixture extracted with ether (3 × 10 mL). The ether solution thus obtained was dried (Na_2SO_4) and evaporated to leave a light yellow oil (110 mg). Purification via column chromatography [SiO_2 (70–150 mesh), EtOAc, hexane 1:2] afforded 104 mg (0.31 mmol, 50%) of **2b** as light yellow crystals, m.p. 118–119°C (EtOAc/hexane); m.p. (*rac*-**2b**) 125–126°C [3, 8]. $[\alpha]_{578}^{RT} = -71$ ($c = 5.25$, $CHCl_3$); IR (KBr): 3320 (NH), 1760 and 1685 (C=O), 1600, 1385, 1340, 1165, 935, 695 cm^{-1}. ^{1}H-NMR (250 MHz, $CDCl_3$): $\delta = 7.45–6.65$ (m, 9H), 4.70 (d, 1H, $J = 14$ Hz, CH_aH_bPh), 4.61 (d, 1H, $J = 14$ Hz, CH_aH_bPh), 3.85–3.70 (m, 2H, NH and >CH–*n*Pr), 3.17 (d, 1H, $J = 19$ Hz, $-CH_aH_bCON<$), 2.70 (d, 1H, $J = 19$ Hz, $-CH_aH_bCON<$), 1.7–1.1 (m, 4H, CH_2CH_2), 0.79 (t, 3H, CH_3). Addition of Eu(hfc)$_3$ did not change the ^{1}H-NMR spectrum (in the case of the racemic compound the signal originally at $\delta = 3.17$ was split into two doublets of equal intensity).

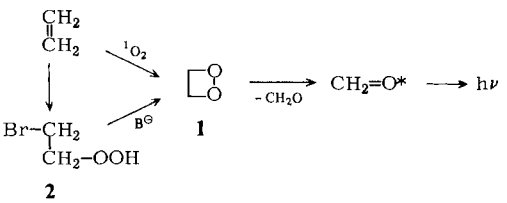
1,2-Dioxetane: Synthesis, Characterization, Stability, and Chemiluminescence**

By *Waldemar Adam** and *Wilhelm J. Baader*

To the best of our knowledge[1], the parent 1,2-dioxetane **1** has been observed only as a transient species in the gas phase via the formaldehyde fluorescence arising from the cycloaddition of singlet oxygen to ethene[2]. The statement ... "isolation and characterization of 1,2-dioxetane still remain a challenge" ...[3] encouraged us to try to prepare the parent 1,2-dioxetane. Here, we report its synthesis, characterization, stability, and chemiluminescence[4].



Synthesis: After photosensitized singlet-oxygenation of ethene in trichlorofluoromethane at −40°C and in the gas phase both failed to produce even traces (monitored by chemiluminescence) of dioxetane **1**, we returned to the now classical Kopecky method[5]. A solution of 2.82 g (20.0 mmol) 1-bromo-2-hydroperoxyethane (**2**)[6] in 20 mL dichloromethane and a solution of 8.00 g (143 mmol) KOH in 20 mL water was vigorously mechanically stirred for ca. 15 min: the mixture was then warmed up from 0°C to 20°C. The organic phase was washed with 10 mL cold water, dried over $MgSO_4$, and the 1,2-dioxetane **1** distilled as a CH_2Cl_2 solution at 0°C/100 torr to 20°C/10 torr. Thin

layer chromatography (silica gel/CH_2Cl_2) gave a peroxide spot at $R_F = 0.58$ (positive KI/HOAc test). Attempts to remove the CH_2Cl_2 by distillative fractionation failed because of the volatility and thermal lability of **1**. In all subsequent operations the dioxetane was therefore handled in CH_2Cl_2 solution. The yield of the dioxetane was estimated as ca. 0.1% by iodometric titration.

Characterization: Solutions of **1** in CH_2Cl_2 exhibited direct chemiluminescence, which was significantly enhanced by the presence of 9,10-dibromoanthracene (DBA). Control experiments with hydroperoxide **2** confirmed that the latter displayed negligible chemiluminescence under comparable conditions. The 400 MHz ^{1}H-NMR and 100 MHz ^{13}C-NMR spectra of a CD_2Cl_2 solution of **1** at -40 °C exhibited the expected signals at $\delta = 5.38$ and $\delta = 76.14$, respectively, which both disappeared after 1 h at 40 °C. The characteristic singlet of formaldehyde (expected decomposition product) was observed at $\delta = 9.60$ in the ^{1}H-NMR spectrum. These data corroborate the proposed dioxetane structure **1**.

Stability: The activation parameters of dioxetane **1** were determined by DBA-enhanced chemiluminescence[7]. Unfortunately, **1** is very prone to catalytic dark decomposition; hence, for reliable and reproducible kinetic data the activation data had to be assessed from the temperature dependence of the initial chemiluminescence intensities[7] (Table 1). Clearly, the normal chemiluminescence method (values in parentheses) results in considerable catalytic dark decomposition, as witnessed particularly by the very low activation entropy. However, the free energy of activation appears to be a more reliable measure of thermal stability (Table 1). At 343 K a half-life $t_{1/2} = 1.1$ min is extrapolated from these rate data. Compared to tetramethyl-1,2-dioxetane **3**, for which $t_{1/2} = 45$ min at 343 K[7], the parent 1,2-dioxetane **1** is, as predicted[8], considerably less stable.

Table 1. Activation parameters and excitation yields for the thermal decomposition of 1,2-dioxetane **1** in toluene and, for comparison, those for tetramethyl-1,2-dioxetane **3** in benzene. For the values in parenthesis see text.

	ΔH^+ [kcal/mol]	ΔS^+ [cal mol^{-1} K^{-1}]	ΔG^+ (343 K) [kcal/mol]	Φ^S [a] $\times 10^4$	Φ^T [b] $\times 10^2$	Φ^T/Φ^S
1	22.1 ± 0.3 [c]	−3.9	23.3	0.03 ± 0.01	0.2 ± 0.05	700
	(18.9 ± 0.8) [d]	(−12.8 ± 1.6)	(23.4)			
3	26.9 ± 0.1	3.7 ± 0.3	25.8	25 ± 14	35 ± 15	140

[a] Determined from DPA fluorescence via Stern-Volmer kinetics [9]. [b] Determined from DBA fluorescence via Stern-Volmer kinetics [9]. [c] Determined from the temperature dependence of the initial chemiluminescence intensities monitored by DBA-fluorescence [7]. [d] Determined from the time profile of the DBA-fluorescence intensity at various temperatures [7]. [e] Taken from [7] and [9].

Chemiluminescence: Direct chemiluminescence could be observed, but was too weak for quantitative measurements. For this reason energy transfer chemiluminescence with 9,10-diphenylanthracene (DPA) was used to determine singlet excitation yields (Φ^S_{DPA}) and DBA to determine triplet excitation yields (Φ^T_{DBA})[9] (Table 1). Unquestionably, the excitation yields are dramatically lower than those of the tetramethyl-1,2-dioxetane **3**; but, like **3**, the spin state selectivity (Φ^T/Φ^S) for triplet excitation is highly favored. The thermal stability and excitation yields increase with methyl substitution.

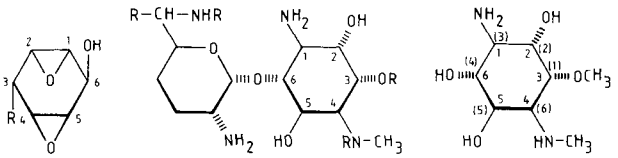
Total Synthesis of a Fortimicin Aglycone**

By *Jürgen Schubert, Reinhard Schwesinger,* and *Horst Prinzbach**

Efficient methods have been developed for the synthesis of a broad spectrum of *cis*-1,3- and *cis*-1,4-(deoxy)inosadiamines using (deoxy)anhydroinositols such as **1** (R = H, OH), which are readily accessible from benzene[1]. Such *cis*-1,4-(deoxy)inosadiamines constitute the aglycone components of several novel, highly effective and structurally simple aminoglycosidic antibiotics (fortimicins **2**[2], istamycins[3], sannamycins[4]).



1 **2** **3**

Herein we report on a convenient entry to enantiomerically pure 3-de-*O*-methylfortamine **11a** starting from 1,2:4,5-dianhydro-*epi*-inositol **1** (R = OH), which is also useful for the total synthesis of chemically modified fortimicins[5]. (In the formula of fortamine **3**, both the "numbering for fortimicin" as well as the "numbering for inositol" is given.) The procedure outlined in Scheme 1 excels in the high selectivity of the epoxide-opening (in **4/5d**) and in the efficient resolution (chromatographic separation of the diastereomeric (*R*)-(+)-1-phenylethylamine adducts **9a/10a**); it makes allowance for the fact that two different *N*-functions could not be selectively introduced via **1** owing to insufficient kinetic differentiation in the separate steps[1,6]. The bisurethane **4** prepared by reaction of **1** with methyl isocyanate (dioxane, 100 °C, 3 h, 95%, m.p. = 203–205 °C[7]), is cyclized regiospecifically by strong, weakly nucleophilic bases, preferably tris(dimethylamino)methyliminophosphorane[8] (acetonitrile, 60 °C, 3 h), with attack at C-1 to give the oxazolidone *rac*-**5a**. The, a priori, possi-

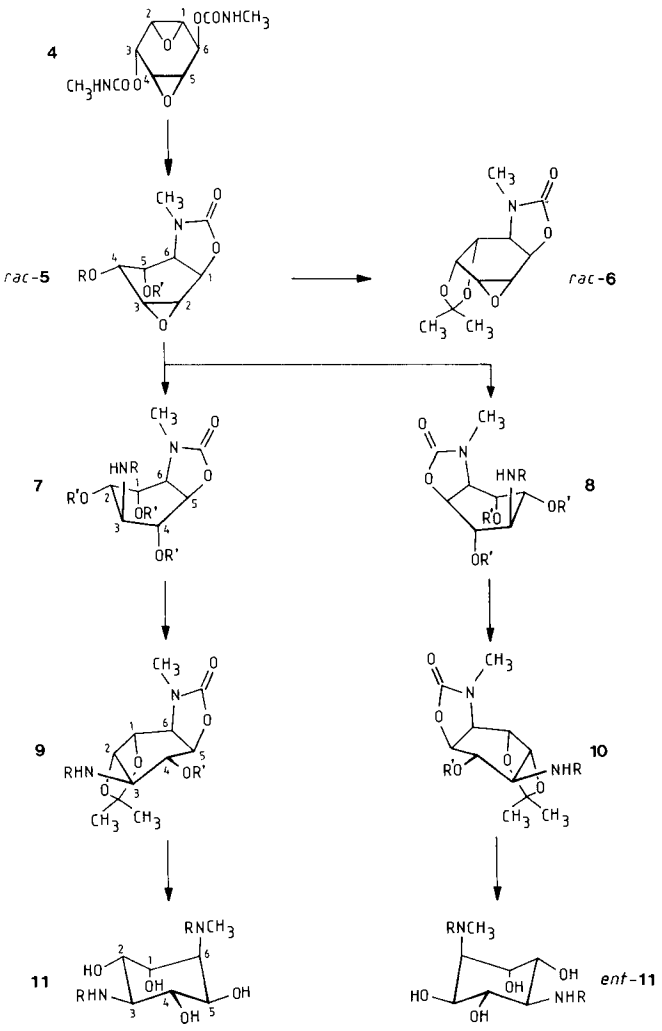
Albertstrasse 21, D-7800 Freiburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

ble competition[9] of attack at C-2 is not at all detectable (<2%). However, transesterification to a mixture of the four components *rac*-**5a**—**d** (together 97%) must be bargained with. Treatment with sodium ethoxide/ethanol (60°C, 1.5 h) furnishes pure *rac*-**5d** (72–75%, m.p. 152–155°C (not optimized), together with up to 5% of the adduct of $C_2H_5O^{\ominus}$ to C-3)[10]. Beyond expectation, is the specificity with which the "half-chair" *rac*-**5d** (D_2O, $J_{3,4}=1.0$, $J_{4,5}=4.0$, $J_{5,6}=3.5$ Hz) is substituted at C-3 by (*R*)-(+)-1-phenylethylamine (and by other nucleophiles such as $C_2H_5O^{\ominus}$, $N_3^{\ominus}$) to give **7a/8a** (boiling 1-propanol, 3 h, almost quantitative). Under the same conditions, the opening of the epoxide ring in the acetal *rac*-**6** is unselective (or more favored at C-2). Separation of the ^{1}H-NMR spectroscopically distinguishable diastereomers **7a/8a** (δ(3-H)=2.80/2.51; $J_{2,3}=4.0/3.0$, $J_{3,4}=9.0/10.0$, $J_{4,5}=8.5/9.5$ Hz), which are also characterized as the triacetates **7b/8b** (δ(3-H)=2.93/2.50; $J_{2,3}=5.0/2.0$, $J_{3,4}=7.5/8.0$, $J_{4,5}=8.5/10.0$ Hz), was accomplished by column chromatography (silica gel, $CHCl_3/CH_3OH$/triethylamine 25:1:1, each isolated in 46% yield); it is, nevertheless, more conveniently carried out via the conventionally prepared (2,2-dimethoxypropane, 1.2 equiv. *p*-toluenesulfonic acid, 2 h, 80°C, 95%) acetals **9a/10a**. After crystallization of ca. 80% **10a** ($CHCl_3$/ether, m.p. = 142°C), pure **9a** (m.p. = 191°C) can be isolated from the mother liquor by "rapid chromatography" (in 10—15 g amounts). According to the ^{1}H-NMR spectra, **9a/10a** and their acetates **9b/10b** preferably exist as the "half-chair" conformers with quasiequatorial substituents on C-3/C-4 ($J_{3,4}=12.0$–12.5 Hz). As in **7a/8a**, the NHR moiety in **9a/10a** also remains unchanged on acetylation.



Scheme 1. Substituents of the compounds *rac*-**5**, **7**, **8**, **9**, **10**, **11** and *ent*-**11**.

rac-**5**	**a**	**b**	**c**	**d**	
R	CONHMe	H	CONHMe	H	
R′	H	CONHMe	CONHMe	H	
7, 8	**a**		**b**		
R	(*R*)-CHMePH		(*R*)-CHMePh		
R′	H		Ac		
9, 10	**a**	**b**	**c**	**d**	**e**
R	(*R*)-CHMePh	(*R*)-CHMePh	(*R*)-CHMePh	H	Cbz
R′	H	Ac	$MeO(CH_2)_2OCH_2$	H	H
11, *ent*-**11**		**a**	**b**		
R		H	Cbz		

The primary amines **9d/10d** (=*ent*-**9d**) (as sulfates) are liberated in pure form ($J_{3,4}=12.5$ Hz) in yields of 89–95% from **9a/10a** by hydrogenation with Pd/C (10%) in methanol (0.3 equiv H_2SO_4, 1 bar H_2, 20°C, 24 h). After selective protection of the NH_2 groups with benzyl chloroformate (acetone/water 1:1, sodium carbonate, 20°C, 1 h, 82%), with **9e/10e** (≡*ent*-**9e**) (m.p. = 93–95°C), derivatives of **11a**/*ent*-**11a** are present in which only the 4-OH group is free (e.g. for glycosidation to **2**).

The (tentative) assignment of the diastereomeric pairs **7/8** and **9/10** in the scheme is based on a comparison of the $[\alpha]_D^{25}$ values for natural fortamine **3** (−88, water, $c=1.0$)[11] and the two de-*O*-methyl derivatives **11a**/*ent*-**11a** (−74, +75) obtained by hydrogenation of **7a/8a** and hydrolysis. The latter are liberated from their sulfates (diammonium salts, D_2O, $J_{1,2}=3.0$, $J_{2,3}=J_{3,4}=9.0$, $J_{4,5}=8.5$, $J_{5,6}=5.0$, $J_{6,1}=4.5$ Hz). There is also a correlation between the $[\alpha]_D^{25}$ values of bis-Cbz-fortamine (+47, methanol, $c=1.0$)[12] and the bis-Cbz-derivatives **11b**/*ent*-**11b** (+56, −57).

The 4-*N*-glycyl moiety, essential for the therapeutic activity of fortimicin A, can be incorporated by specific 4-*N*-acylation[13]. As alternative, reaction of the model compound **12** with lithiated *N*-benzhydrylidenemethylamine[14] has been investigated. In preliminary experiments (3 equiv. reagent, ether, −20°C, 10 min) the protected, oily *N*-glycyl derivative **13** was isolated in 50–60% yield and hydrolyzed to **14** (aq. methanol/HCl). The analogously protected glycyl derivative was obtained (50–60%) from **9c**.

Synthesis of New Amorphous Metallic Spin Glasses M_2SnTe_4 (M = Cr, Mn, Fe, Co): Solvent Induced Metal-Insulator Transformations**

By *Robert C. Haushalter*, Charles M. O'Connor, Jeanne P. Haushalter, Arun M. Umarji,* and *Gopal K. Shenoy*

The physical properties of amorphous materials are often vastly different from those of their crystalline counterparts. Although most amorphous solids are prepared by rapid thermal quenching, or by pyrolytic or sputtering techniques, chemical methods involving rapid precipitation also produce non-crystalline materials[1]. We report a new, potentially general method for the preparation of novel amorphous materials based on the oxidation of main-group metal polyanions[2] by transition-metal cations in solution.

$$n(M_A^{x+}) + m(M_B^{y-}) \longrightarrow (M_A)_n(M_B)_m$$

By adjusting the ratio n : m such that $x + y = 0$, the neutral product precipitates. With this method, the compounds M_2SnTe_4 (M = Cr, Mn, Fe, Co) have been prepared from M^{2+} and $SnTe_4^{4-}$; however, we focus here on the iron system Fe_2SnTe_4.

When solutions of anhydrous $FeBr_2$ and orange K_4SnTe_4 in methanol are mixed at $-20\,^\circ C$, a black precipitate of composition Fe_2SnTe_4 (elemental analysis) immediately forms. X-ray powder diffraction (XRD) studies indicate that the compound is amorphous (Fig. 1a; A). Pressed powder samples of Fe_2SnTe_4 and Co_2SnTe_4 appear metallic and have low resistivities (Fe_2SnTe_4; $\rho \approx 5 \times 10^{-2}\ \Omega \cdot cm$; Co_2SnTe_4: $\rho \approx 6 \times 10^{-4}\ \Omega \cdot cm$ at 300 K). The practically identical ^{57}Fe Mössbauer spectra of Fe_2SnTe_4 and $FeTe_2$ at 77 K (Table 1) are consistent with the formation of Fe–Te bonds. Samples of Fe_2SnTe_4 yield only barely detectable Mössbauer effects (^{57}Fe, ^{119}Sn) at 300 K, presumably due to very large thermal motion in the highly disordered solid. Below 12 K Fe_2SnTe_4 orders magnetically to form a "spin glass"[3] state, characterized by direct current magnetization (Fig. 1b) and alternating current susceptibility behavior and by the dependence of the thermoremanent magnetization on magnetic field, time, and temperature[4]. Mössbauer measurements at 4.2 K indicate magnetic ordering at both the ^{57}Fe and ^{119}Sn sites, showing that both belong to the same phase and not to the respective binary tellurides[4]. Heating to 600 °C for 24 h leads to decomposition

$$Fe_2SnTe_4 \longrightarrow FeTe_2 + FeTe + SnTe$$

to the thermodynamically more stable crystalline tellurides (Fig. 1a: B). Susceptibility measurements on the thermolysis products FeTe and $FeTe_2$ show the expected antiferromagnetic transitions (Fig. 1c).

Strong donor ligands selectively cleave the Fe–Te bonds in Fe_2SnTe_4. When black, metallic Fe_2SnTe_4 reacts with ethylenediamine (en) at 25 °C, the solid gradually turns orange, suggesting "liberation" of $SnTe_4^{4-}$. This process is accelerated by the presence of water. The generation of orange $SnTe_4^{4-}$ and of solvated Fe^{2+} ($3d^6$, high spin), i.e. of $[Fe(en)_3]_2SnTe_4$, is substantiated by the Mössbauer spectra (cf. Table 1); magnetic susceptibility measurements indicate that $[Fe(en)_3]_2SnTe_4$ is paramagnetic with magnetically noninteracting Fe^{II} centers above 5 K. The Raman spectra of both K_4SnTe_4 solutions and $[Fe(en)_3]_2SnTe_4$ display strong bands near 180 and 130 cm^{-1} (intensity ratio $\approx 1:5$), which are assigned to $SnTe_4^{4-}$ on comparison with the Raman spectra of other MX_4^{4-} species. This strongly suggests that the $SnTe_4$ tetrahedral unit is structurally intact in amorphous Fe_2SnTe_4. Thus the metallic network formed from the random, three-dimensional polymerization of Fe^{2+} and $SnTe_4^{4-}$ can be destroyed by reac-

[**] We are grateful to the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Materials Science for financial support (Contract No. W-31-109-Eng-38). We thank Dr. *C. Saw* for the X-ray diffraction data and Dr. *M. Brodsky* for the resistivity measurements on Co_2SnTe_4.

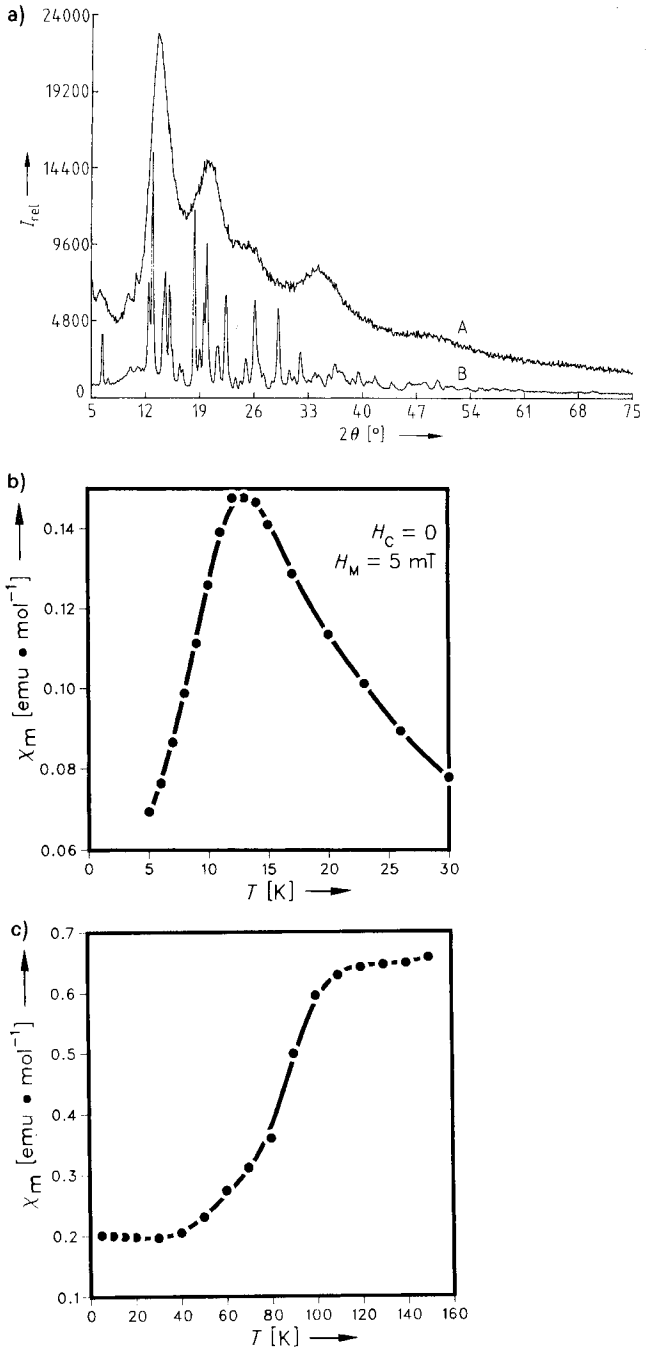

Fig. 1. a) The XRD patterns ($\lambda = 0.7107$ Å) of amorphous Fe_2SnTe_4 (curve A) and of crystalline FeTe, $FeTe_2$, SnTe obtained by heating Fe_2SnTe_4 for 24 h at 600 °C (curve B).—b) Magnetic susceptibility (direct current) of Fe_2SnTe_4 before being heated; c) after heating. Both FeTe and $FeTe_2$ are antiferromagnetic with Néel temperatures of 70 and 83 K, respectively.

tion with certain ligands leading to conversion of the solid into an insulator.

Table 1. Isomer shift (*IS*) and quadrupole splitting (*QS*) in the ^{57}Fe- and/or ^{119}Sn-Mössbauer spectra of some tellurides at 77 K (all values in mm·s^{-1} relative to Fe metal at 300 K or $CaSnO_3$ at 300 K).

Compound	^{57}Fe		^{119}Sn	
	IS	*QS*	*IS*	*QS*
K_4SnTe_4	—	—	1.71(6)	0
Fe_2SnTe_4	0.60(2)	0.48(2)	2.05(2) 3.22(4)	≈0
$[Fe(en)_3]_2SnTe_4$	1.11(2) 1.10(2)	2.32(2) 1.64(2)	1.74(7)	0
$FeTe_2$	0.57(2)	0.50(2)	—	—
SnTe	—	—	3.55(3)	0

The synthesis of amorphous metals from ionic precursors at room temperature utilizing the oxidation of main group polyanions by metal cations should provide a route to metastable materials not readily accessible by other synthetic methods, such as sputtering and thermal quenching. In principle, it should also be possible to vary the physical properties of the solids from those of an insulator (Ca_2SnTe_4) to those of a metal (Co_2SnTe_4) by controlling the amount of electron transfer from anion to cation—either by varying the relative redox potentials of the anion and cation or by incorporating reducible and nonreducible cations ($Ca_xCo_{2-x}SnTe_4$). Even in the series M_2SnTe_4 (M = Mn, Fe, Co) a transition is seen from the metallic and essentially paramagnetic Co_2SnTe_4 to Mn_2SnTe_4 having a higher resistivity and strong spin glass properties.

Methods of Enzymatic Analysis. Volume I. Fundamentals. Edited by *H. U. Bergmeyer, J. Bergmeyer,* and *M. Grasse*. 3rd edit. Verlag Chemie, Weinheim 1983, xxiv, 574 pp., bound DM 170.00 (subscription price until June 30, 1984), thereafter DM 198.00.

For the past twenty years the first step in any enzymatic analysis has been to consult Bergmeyer. The next years will be no different: the updated and enlarged third edition of *Hans Ulrich Bergmeyer*'s "Methods of Enzymatic Analysis" has just commenced publication, and promises to play the same role as previous editions as an indispensable reference for the practicing enzymologist.

The increased interest and importance of enzymatic analysis is reflected in the size of the series: the first edition (1963) consisted of a single volume; the second edition (1974) of four volumes; the current edition is projected to comprise ten volumes. Volume 1 of this series has just appeared, and the entire series is expected to be available by 1986.

The scope of this third edition will be substantially broader than the first two editions. Considerably more background information is included, and some topics covered in the first volume in previous editions have been deferred to later volumes. The introduction—the first of three chapters for volume 1—consists of five sections covering nomenclature and units, reliability of laboratory results and practicability of procedures, standardization in enzymatic analysis, economic considerations in enzymatic analysis, and present status and future prospects for enzymatic analysis. The introduction in the previous edition emphasized the broad applicability of enzymatic analysis; the current volume assumes the reader is already convinced of the importance of the subject matter and covers general background information necessary for the broad range of currently practiced enzymatic analyses. Some specific topics *Bergmeyer* emphasizes (*Bergmeyer* is both the editor in chief of the series and the author of many individual sections in this volume) include the need for standardization of units and nomenclature in enzymology, economic considerations (interestingly, enzyme cost in most analyses is estimated to be less than 2%), and the unique advantages of enzymatic analysis (high specificity and selectivity even in complex mixtures).

The second chapter of volume 1, "Theoretical Considerations," is divided into seven sections: reaction kinetics, determination of Michaelis' constants and inhibitor constants, determination of the catalytic activity of enzymes, determination of metabolite concentration with endpoint methods, determination of metabolite concentrations by kinetic methods, chemical design of indicator reactions for the visible range, and principles of enzyme-linked immunoassays. This chapter contains a wealth of very practical information concerning precision and accuracy in enzymatic methods, and broad considerations necessary for the design of accurate analytical methods. Enzymatic analyses require optimization of many variables (e.g. substrate concentrations, pH, temperature, inhibitors, activators, etc.). This chapter provides the general background required to treat these variables in a knowledgeable way in specific analytical systems. It also discusses certain of the specific characteristics of immobilized enzymes: diffusional limitations, microenvironmental changes and apparent vs. intrinsic kinetic parameters of enzymes. Two new additions in this edition are visualization of enzymatic reactions by coupling to indicators having color changes in the visible range, and principles of enzyme-linked immunoassay.

Enzymatic assays, either directly or indirectly, measure substrate consumption or product formation. The largest and final chapter of volume 1, "Techniques of Measurement, Instrumentation" comprises nine sections, most of which describe the principles and applications to enzymatic analysis of various techniques for measurement. Virtually all of these sections are new or substantially revised and expanded from the previous edition. The sections include volume measurement, absorption photometry, nephelometry, turbimetry, reflectance photometry, fluorimetry, luminometry, other techniques of measurement, mechanization and automation of analysis, microtechniques, and enzymatic analysis with radiobiochemicals. Researchers and technicians using enzymatic analysis have such different backgrounds that a compilation of the basic principles for all techniques associated with enzymatic analysis is both convenient and an essential background to the whole series.

Volume 1 of this edition of *Hans Ulrich Bergmeyer*'s "Methods of Enzymatic Analysis" is a clearly written, amply referenced (over 1300 reference entries) guide to the basic principles and background information underlying enzymatic analysis. It does not contain the detailed data and procedures that one would use on a daily basis in specific enzymatic analyses: this information will be the subject matter of subsequent volumes. This volume should be regarded as a basic reference, and as an introduction to this new edition. This book is strongly recommended for everyone who uses enzymatic analysis. The series will be invaluable to every laboratory involved in enzymology.

ENDOR Spectroscopy—A Promising Technique for Investigating the Structure of Organic Radicals

By Harry Kurreck*, Burkhard Kirste, and Wolfgang Lubitz

The name "ENDOR" has been known since biblical times and denotes a small town close to the Sea of Galilee (ca. 1000 B.C., 1 Sam. 28:7 ff). The acronym "ENDOR" (*E*lectron *N*uclear *DO*uble *R*esonance) characterizes the extension of electron spin resonance to electron-nuclear double resonance spectroscopy, a method that has opened up new dimensions for the investigation of complicated paramagnetic molecules. Only ENDOR spectroscopy, which has achieved technical perfection in the last decade, overcomes the resolution limitations of EPR spectroscopy, thus allowing interesting applications in the field of biochemistry. ENDOR investigations of the primary process of photosynthesis, of the mode of action of derivatives of vitamin E and K, and of the mechanism of the enzymatic catalysis of flavoenzymes in biological redox-chains have opened up new vistas. ENDOR and its extension to the triple resonance experiment TRIPLE offer, for example, the potential for a precise determination of hyperfine coupling constants, including their signs, which are frequently especially interesting. In addition to protons, a multitude of magnetic nuclei can be studied by ENDOR, such as e.g. ^{2}H, ^{13}C, and ^{14}N. The ENDOR technique is not restricted to monoradicals, but can also be applied to polyradicals in spin states of higher multiplicities (triplet, quartet, or quintet state). The experimental data accessible from ENDOR yield information about spin and charge density distributions, and about the geometries of radicals and their internal dynamics; they also provide an excellent test for the accuracy of quantum mechanical calculations.

1. Introduction— Why Electron Nuclear Double and Triple Resonance?

The chemistry of "free radicals" began in 1900 with *Gomberg*'s classical studies on the generation and chemical detection of the triphenylmethyl radical. The first electron paramagnetic resonance (EPR) experiment by *Zavoisky* in 1945[1] can be considered a milestone in the exploration of paramagnetic systems. Nowadays EPR spectroscopy has established itself as the most versatile method for investigating paramagnetic molecules. Applications extend from solid state physics, via studies of structure and dynamics of molecules, to investigations of paramagnetic intermediates in biological systems.

Due to this widespread use, the chemist should already be acquainted with the physical principles of EPR spectroscopy, the more so since the principles of magnetic resonance reveal a close relationship between EPR and the more familiar NMR spectroscopy. Similarly to NMR spectroscopy, where nuclear spin transitions between different nuclear Zeeman levels are induced, in EPR spectroscopy

electron spin transitions between different electron Zeeman levels are stimulated. The observables in an EPR experiment are the electronic g-value, the line shape—and probably most interesting for the chemist—the hyperfine structure, from which the hyperfine interaction parameters can be extracted. By analogy to NMR spectroscopy where local structural information can be obtained from the spin-spin coupling of nuclei in different molecular positions, in EPR spectroscopy the scalar and the dipolar doupling of the unpaired electron (or of unpaired electrons) with magnetic nuclei lead to splitting of the electronic Zeeman levels into hyperfine sublevels and thus to additional EPR transitions. In contrast to NMR spectroscopy, where the spin-spin coupling is usually restricted to nuclei in small fragments of the molecule, delocalization of the unpaired electron in an organic π radical over a larger π system results in its coupling with all magnetic nuclei, producing an (integral) multispin ensemble. Even in the case of a comparatively simple organic doublet radical like triphenylmethyl with one set of three equivalent protons and two sets each of six equivalent protons, this gives rise to a thicket of (theoretically expected) $4 \times 7 \times 7 = 196$ lines. This high density of spectral lines is undoubtedly the greatest handicap of EPR spectroscopy, which makes it of limited utility in investigations of larger organic radicals because of its insufficient resolving power.

One possible way of improving the resolving power of a spectroscopic technique is offered by double resonance methods in which the sample is simultaneously irradiated with *two* resonant fields. In NMR spectroscopy different versions of such double resonance techniques are well-known. Provided the double resonance method is based on a change of level populations, e.g. in the INDOR technique, there exists a certain relationship between extended NMR techniques and the ENDOR experiment, which shall be described in detail in this article.

The *E*lectron *N*uclear *DO*uble *R*esonance (ENDOR) technique was first applied by *Feher* in 1956 to solids[2] and some time later by *Hyde* and *Maki* to organic radicals in solution[3]. This method overcomes the limited resolution of EPR spectroscopy by introducing additional selection rules. Furthermore, by detecting the NMR transitions in the microwave range, the sensitivity is enhanced by several orders of magnitude relative to pure NMR spectroscopy of radicals.

In particular, the drastically improved resolving power compared to EPR spectroscopy makes ENDOR spectroscopy highly attractive for organic chemists and biochemists. Comparison of the EPR and ENDOR spectra of the bis(biphenylylene)allyl radical illustrates this (cf. Fig. 1). Whereas only ca. 400 of the theoretically expected $5 \times 5 \times 5 \times 5 \times 2 = 1250$ lines can be resolved in the EPR spectrum, the ^{1}H-ENDOR spectrum exhibits all five possible line-pairs—one for each set of equivalent protons. The *hyperfine coupling* (HFC) constants can be extracted without difficulty and usually unambiguously without need for computer simulations. A computer simulation of the EPR spectrum with the HFC constants taken from ENDOR then yields the multiplicities. Unequivocal assignments of the HFC constants to individual molecular positions can be achieved by selective isotopic labeling.

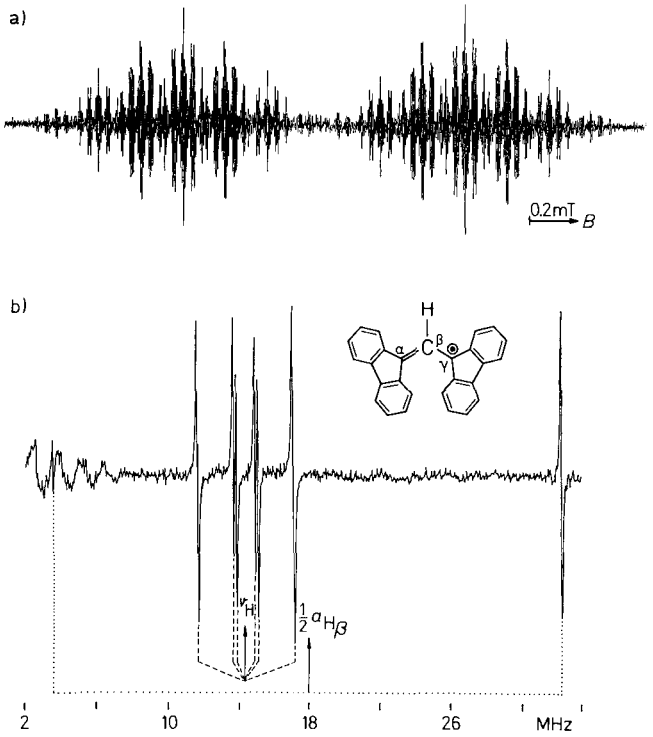

Fig. 1. a) EPR spectrum (in CCl_4, 293 K) and b) ENDOR spectrum (in mineral oil, 330 K) of the bis(biphenylylene)allyl radical. The following points should be noted: that there is a *drastic* decrease in the number of lines in the double resonance experiment (compare ENDOR/EPR); that different conditions (temperature, viscosity of the solvent) are often necessary to obtain optimum EPR and ENDOR spectra; and that the positions of the ENDOR signals—corresponding to the ENDOR resonance condition (eq. (3))—depend on the relative magnitude of the HFC constants with respect to the free nuclear frequency (ν_H); cf. [27].

The extension of ENDOR to electron-nuclear-nuclear triple resonance spectroscopy "TRIPLE" (also termed "double ENDOR"[4]) offers a further increase in resolution and sensitivity[5] and allows determination of the (relative) signs of coupling constants[6].

2. Physical Principles, Instrumentation

Excellent accounts of the theory of electron nuclear multiple resonance may be found in a series of authoritative review articles and monographs[7]. In the following, the ENDOR experiment will be described in a simple phenomenological manner.

2.1. ENDOR

In the ENDOR experiment nuclear spin transitions in paramagnetic molecules are induced by means of a suitable radio frequency (RF) field and are detected by a change in the EPR signal intensity. Figure 2 shows the energy level diagram ("four level scheme") for the simplest case of a radical with one unpaired electron ($S = 1/2$) and one magnetic nucleus ($I = 1/2$), e.g. a proton. The interaction of the electronic and nuclear spin moments with the external magnetic field gives rise to a splitting into two times two levels (Zeeman splitting), the position of which is influenced further by the hyperfine interaction between

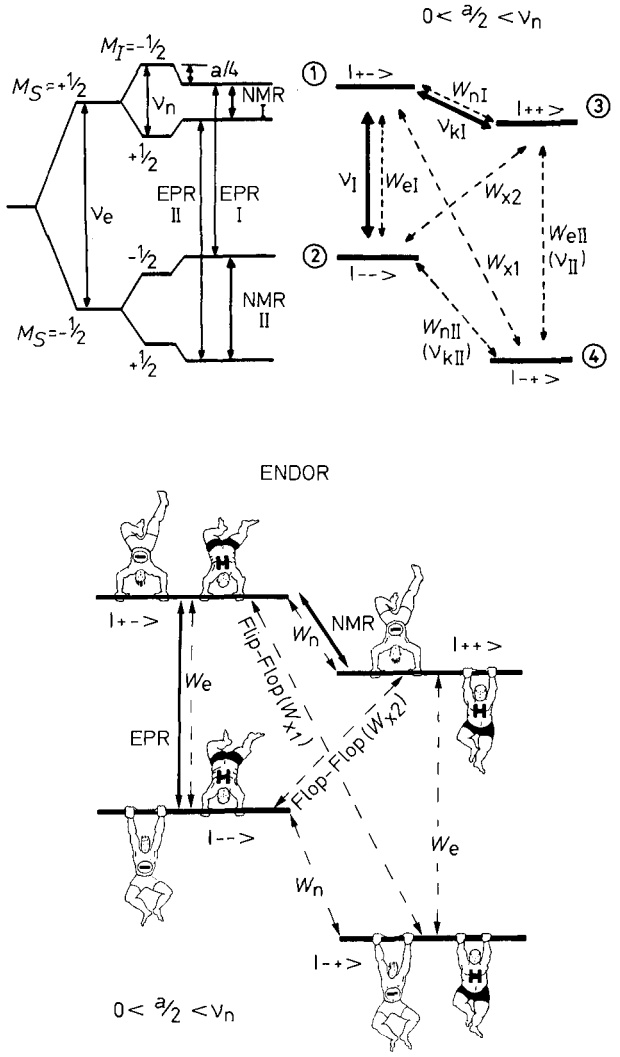

Fig. 2. Energy level diagram and "four-level scheme" for the hyperfine interaction of one unpaired electron ($S=1/2$) with one proton (or another nucleus with $I=1/2$). The solid arrows symbolize the EPR and NMR transitions induced by radiation, respectively, and the broken arrows the relaxation transitions. The bottom scheme should makes plain the "spin acrobatics" in the double resonance experiment).

electron and nucleus. The four levels are denoted by the signs of the magnetic spin quantum numbers, and the energies of the levels are given in frequency units. The solid arrows symbolize the radiation-induced electron and nuclear spin transitions, whereas the dashed arrows characterize the radiationless electron spin (W_e), nuclear spin (W_n) and cross-relaxation processes (W_{X1} and W_{X2}). In the last-mentioned process, simultaneous electron- and nuclear-spin relaxation transitions take place (cf. Section 3). With the selection rules $\Delta M_S = \pm 1$, $\Delta M_I = 0$, the two possible EPR transitions (① ↔ ②, ③ ↔ ④) arise at the frequencies

$$\nu_{EPR} = \nu_e \pm a/2 \tag{1}$$

and with the selection rules $\Delta M_I = \pm 1$, $\Delta M_S = 0$, the two NMR transitions arise at the frequencies

$$\nu_{ENDOR} = |\nu_n \pm a/2| \tag{2}$$

Equation (2) can be written in a general way as the "ENDOR resonance condition":

$$\nu_{ENDOR} = |\nu_n - a M_S| \tag{3}$$

For a monoradical with $M_S = \pm 1/2$, two signals appear in the ENDOR spectrum for each nucleus or set of equivalent nuclei, respectively, either centered about the free nuclear frequency ν_n, separated by the HFC constant a (when $|a/2| < \nu_n$ holds), or equally spaced about $a/2$, separated by $2\nu_n$ (when $|a/2| > \nu_n$ holds).

In the ENDOR experiment, an EPR transition (ν_I) is first irradiated continuously with an intensity high enough that the (spin-lattice) relaxation can no longer compete successfully with the induced rate[8]: The populations of the two levels are almost equalized, the transition is partially "saturated", and the thermal Boltzmann equilibrium distribution is perturbed.

If, additionally, an NMR transition (ν_{kI}) is also irradiated with high intensity, the total transition rate[8] ① ↔ ③ is increased, and level ① is depopulated more efficiently; the relaxation pathway is closed via a W_e (③ ↔ ④) and a W_n (④ ↔ ②) process or via a W_{X2} (③ ↔ ②) process. The desaturation of the EPR transition thus achieved gives rise to an increase in the EPR signal intensity which is recorded as the ENDOR effect. Although the ENDOR effect amounts to only a few percent of the EPR signal intensity, even under the most favorable conditions, there is a sensitivity increase of ca. 10^5 relative to that of NMR spectroscopy, resulting from the detection of the NMR transitions in the microwave frequency range (so-called "quantum transformation").

It can be shown that the magnitude of the ENDOR effect depends critically upon the relative magnitudes of the rates W_e, W_n, W_{X1}, and W_{X2}. Neglecting W_X processes, optimum ENDOR signals are obtained when W_e and W_n are comparable. Since these rates depend differently upon the so-called rotational correlation time τ_R (a measure of the Brownian rotational diffusion of molecules in solution)[9],

$$W_e \propto 1/\tau_R, \quad W_n \propto \tau_R$$

an adjustment of the relaxation rates can often be achieved by temperature variation. This can be understood in terms of the Debye-Einstein equation, which provides a connection between the effective molecular volume (V_{eff} results from the average radius of a molecule considered as a sphere), the viscosity η of the solvent, and the temperature:

$$\tau_R = V_{eff} \cdot \frac{\eta}{kT} \tag{4}$$

With decreasing temperature and increasing viscosity, W_e becomes smaller and W_n larger. The desired ratio $W_n/W_e \cong 1$ can usually be attained through temperature/viscosity optimization of the solution. Since for protons W_n is normally much smaller than W_e, optimum ENDOR signals in solvents of low viscosity such as toluene, tetrahydrofu-

ran (THF) or 1,2-dimethoxyethane (DME) are obtained near the respective freezing points of the solutions.

In summary, fulfillment of the following conditions are necessary for a successful ENDOR experiment:

- (a) An EPR transition and
- (b) an NMR transition have to be saturated; the required microwave and radio frequency powers increase with increasing relaxation rates[10].
- (c) The relaxation rates W_e and W_n have to be of comparable magnitude, or cross-relaxation processes must be effective.
- (d) Finally, it should be emphasized that the quality of the sample (concentration, absence of oxygen) is of crucial importance.

The simplification of the spectra achievable by ENDOR will be illustrated using the hyperfine energy level diagram of the *p*-benzosemiquinone radical anion or, more generally, a radical with one unpaired electron and four equivalent protons (cf. Fig. 3). Whereas the EPR spectrum consists of a quintet of signals with binomial intensity distribution (1:4:6:4:1), the ENDOR spectrum exhibits only two signals. Generally speaking, in EPR spectroscopy the number of signals increases *multiplicatively* with the number of nonequivalent nuclei, whereas in the ENDOR experiment the increase is only *additive*. In a monoradical, each set of equivalent magnetic nuclei gives rise to just *one* ENDOR line-pair, irrespective of the number of nuclei per set.

Figure 4 shows, among others, the EPR and ENDOR spectra of the phenalenyl radical, which contains one set of three and a set of six equivalent protons. Correspondingly, the EPR spectrum consists of $4 \times 7 = 28$ signals and the ENDOR spectrum only of four signals. A more complicated example demonstrating the resolution enhancement of ENDOR more convincingly has already been shown in Figure 1.

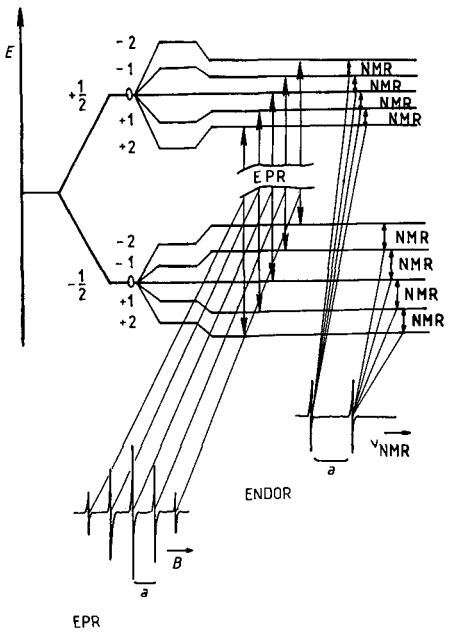

Fig. 3. Energy level diagram of a hyperfine-coupled spin system consisting of one unpaired electron ($S = 1/2$) and four equivalent nuclei ($I = 1/2$).

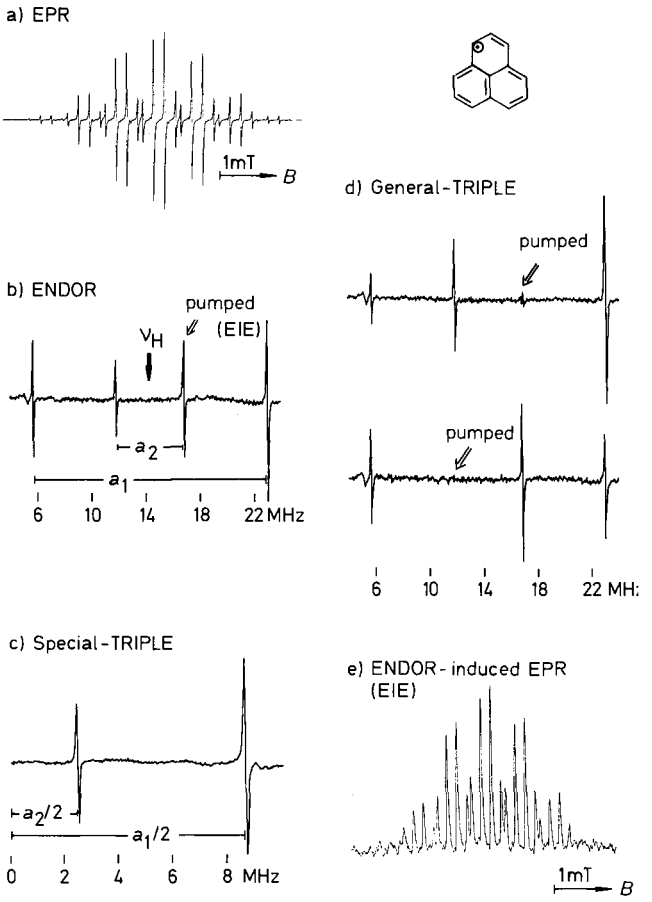

Fig. 4. Spectra of the phenalenyl radical (in mineral oil, 300 K), obtained by application of the magnetic resonance techniques EPR, ENDOR, special TRIPLE, general TRIPLE, and ENDOR-induced EPR (EIE): ENDOR increases the resolution relative to EPR; special TRIPLE resonance extends the range of applicability (temperature, solvent); general TRIPLE resonance yields the signs of the HFC constants; and ENDOR-induced EPR enables the spectra of different radical species in a sample to be recorded selectively.

Whereas the multiplicity, i.e. the number of equivalent nuclei belonging to each set, is reflected in the intensity distribution of a resolved EPR spectrum, this information is lost in an ENDOR spectrum. The reason for this is easily understood, since the ENDOR signal intensity is essentially determined by the individual relaxation properties of the particular nuclei in the respective molecular positions. A systematic decrease of the ENDOR signal intensities is found for small hyperfine couplings[11]. Thus the assignment of individual ENDOR signals to particular molecular positions is more difficult. Moreover, the high-frequency component of an ENDOR line-pair is often more intense than the low-frequency one at the same RF power. This so-called "hyperfine-enhancement effect"[12] becomes more pronounced as the frequency difference between the two components increases. For example, in Figure 1 the high-frequency ENDOR signal (at ca. 33 MHz) is much more intense than the respective low-frequency one and, furthermore, this signal of the single central proton is of the same intensity as the ENDOR lines belonging to the sets of four equivalent protons in the fluorenylidene moieties. The number of equivalent nuclei belonging to a particular HFC constant can be determined by computer simulation of a sufficiently resolved EPR spectrum with the coupling con-

stants obtained from ENDOR. The unequivocal assignment to particular molecular positions is performed by specific isotopic labeling; however, this usually requires considerable preparative effort. Figure 5 illustrates the unequivocal assignment of ENDOR signals by this method using several *m*-terphenyl radical anions[13]. The arrows in the figure indicate the positions of resonance lines in the ^{1}H-ENDOR spectrum that disappear upon deuteration.

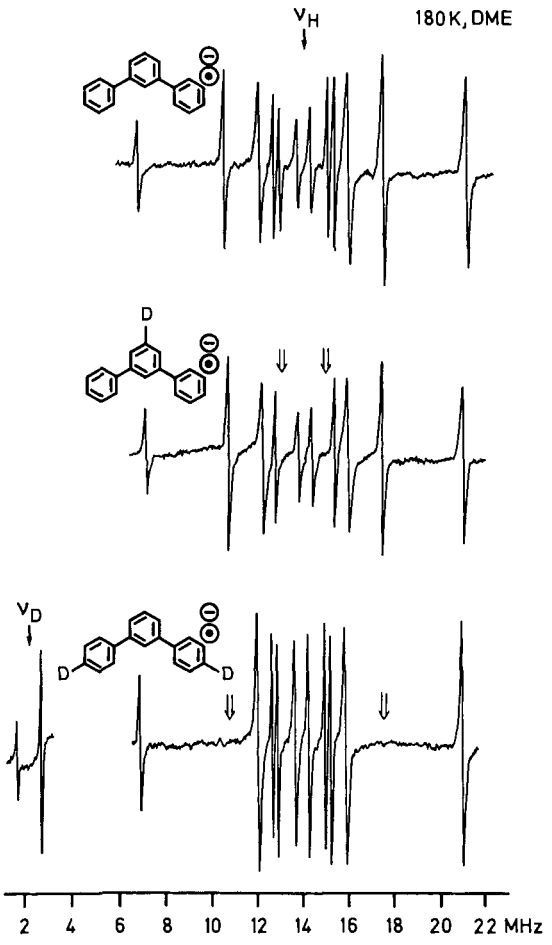

Fig. 5. ^{1}H- and ^{2}H-ENDOR spectra of *m*-terphenyl radical anions. In the spectra of the selectively 5′- or 4,4″-deuterated compounds the respective line pair (marked by arrows) disappears, thus allowing an *unequivocal* assignment of the corresponding HFC constants to these positions in the molecule [13].

2.2. Special TRIPLE Resonance

In Section 2.1 it was demonstrated (Figure 2) that the ENDOR effect can be interpreted as arising from a "short circuit" of a nuclear spin transition. Clearly, this effect should be enhanced substantially if *both* relaxation "resistances" W_{nI} and W_{nII} could be short-circuited simultaneously by means of an additional NMR frequency[5a]. The experimental realization of TRIPLE resonance experiments on organic radicals in solution was first achieved by *Möbius, Biehl, Dinse,* and *Plato*–a group which has played a leading role in the development of ENDOR spectroscopy—in 1974 (special TRIPLE)[5b] and 1975 (general TRIPLE)[6].

In the special TRIPLE experiment the sample is irradiated with *two* RF fields in addition to the "saturating" microwave radiation. By generating side bands around the free nuclear frequency, one RF field is swept to higher, the other to lower, frequencies and thus *both* NMR transitions of each set of equivalent nuclei are always "hit" *simultaneously*. Figure 4c shows that each hyperfine coupling gives rise to just *one* special TRIPLE signal, which appears separated from the origin of the NMR frequency axis ($\nu_{NMR}=0$) by the frequency $|a/2|$. The advantages offered by the special TRIPLE version compared to ENDOR are:

- (a) Enhancement of sensitivity (improved signal-to-noise ratio).
- (b) Improved resolution, as can be shown experimentally and theoretically[5,7c].
- (c) Under favorable experimental conditions (induced rate of nuclear spins $\gg W_e \gg W_n$), the signal intensities reflect the ratio of numbers of equivalent nuclei per set—as in NMR of diamagnetic compounds—because the desaturation of EPR transitions is not primarily determined by the nuclear spin relaxation rate W_n, in contrast to ENDOR.
- (d) This fact (c) also leads to a significantly smaller temperature dependence of the special TRIPLE signal intensity, so that e.g. biological systems can be investigated under (physiological) conditions which do not lend themselves to a measurable ENDOR effect.

The special TRIPLE experiment can be applied in the same way, even to those hyperfine-coupled nuclei for which $|a/2|>\nu_n$ is valid (see Section 2.1), since "negative" frequencies are reflected at the origin. For several reasons (second-order frequency shifts, high relaxation rates W_n), however, in this situation special TRIPLE usually offers no advantage relative to ENDOR experiments.

2.3. General TRIPLE Resonance

Besides pure π conjugation, the different mechanisms of spin density transfer (such as π-π, and π-σ spin polarization or hyperconjugation) can give rise to *positive* as well as *negative* spin densities at the nucleus, and thus via hyperfine coupling to HFC constants with *positive* or *negative* signs, respectively. It is therefore of great interest to be able to determine both the signs of HFC constants *and* their magnitudes. The general TRIPLE technique offers the potential of a simple, elegant and unambiguous method for the determination of the relative signs of HFC constants. In contrast, the applicability of other methods for determination of signs is limited, e.g. wide-line NMR spectroscopy (NMR measurement of the Fermi contact shift) of organic radicals[14] or EPR spectroscopy in liquid crystals (direction of the hyperfine shift on passing from the isotropic to the nematic phase)[15].

In contrast to special TRIPLE, NMR transitions of *different* sets of nuclei of the same kind or of different kinds are saturated *simultaneously* in the general TRIPLE experiment. In practice, one EPR component is saturated, and an

NMR transition is "pumped" with the first (unmodulated) NMR frequency. The whole range of NMR resonances is scanned with the second (modulated) RF field. The additional pumping frequency gives rise to characteristic intensity changes of the signals compared to those of the ENDOR spectrum, and allows the determination of the relative signs of the HFC constants (see Fig. 4d). If, for example, the high-frequency component of the smaller coupling of the phenalenyl radical is pumped (marked by an arrow in Fig. 4d, top), the intensity of the respective *low-frequency* signal increases because this corresponds to a *special* TRIPLE experiment. On the other hand, the *high-frequency* component of the large coupling is enhanced, and the low-frequency component on the other side—with respect to the free proton frequency ν_H—decreases in intensity. This phenomenon allows it to be concluded that the two HFC constants have *opposite signs*. If the corresponding experiment is performed with the pumping frequency set on the low-frequency ENDOR line of the small coupling, these intensity relations are reversed (Fig. 4d (bottom)). This analysis of general TRIPLE spectra is only valid, however, if the gyromagnetic ratios of the nuclei under consideration have the same sign.

In a heteronuclear general TRIPLE experiment between, e.g., ^1H and ^{29}Si[16] or ^1H and ^{15}N[17], these intensity rules have to be reversed. Since this method deals with the determination of *relative* signs, an interpretation of this effect requires at least an eight-level scheme with two different nuclei ($I = 1/2$; $a_1 \neq a_2$). Figure 6 shows such diagrams for equal (left diagram) or opposite signs (right) of the two HFC constants. In both cases ν_2^- denotes the pumping frequency, and ν_1^- and ν_1^+ the monitoring frequencies. An increase in intensity is to be expected if the pumping and monitoring frequencies belong to *different* M_S manifolds. A closer inspection of Figure 6 reveals that only in this situation can a "relaxation loop" be formed which consists exclusively of W_e processes and short-circuited W_n processes; hence, no "bottleneck" W_n is involved. If pumping and monitoring frequencies are irradiated in the same M_S manifold, however, the relaxation loop can only be closed by including W_n processes; the signal intensity is then even smaller than in an ENDOR experiment ("bypass"). Large TRIPLE effects occur if $W_e \gg W_n$, i.e. *outside* the optimum ENDOR range ($W_e \cong W_n$). If the signs of the two HFC constants are the same (in Figure 6 left, positive), *both* low-frequency components ν_2^- and ν_1^- belong to the same M_S manifold. The right-hand diagram in Figure 6 describes, e.g., the TRIPLE experiment on the phenalenyl radical depicted in Figure 4: The HFC constants have opposite signs, and consequently the two low-frequency NMR transitions belong to *different* M_S manifolds. In this case, the ENDOR signal is enhanced if pumping and monitoring frequencies are situated on the same side of ν_H.

In addition to determination of signs, an increase in resolution can occasionally be achieved using the general TRIPLE technique, provided two HFC constants have similar absolute values but opposite signs: The pumping frequency enhances the signal of one set of nuclei but weakens that of the other, thus giving rise to a small shift in the resonance position of the superposed signals. A shift in the opposite direction is achieved by appropriate

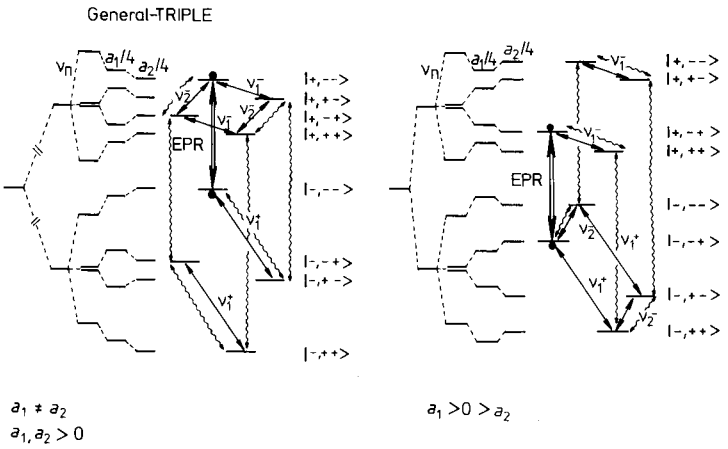

Fig. 6. Energy level diagrams for the hyperfine interaction of one unpaired electron ($S = 1/2$) with two different protons (or two other nuclei with $I = 1/2$) for clarification of the general TRIPLE effect. The HFC constants in the left diagram have the same (positive) signs and in the right one, opposite signs: ν_2^- denotes the NMR pumping frequency, and ν_1^- and ν_1^+ the NMR scan frequencies. *Left:* A closed relaxation loop between the two hyperfine levels of the pumped EPR transition $|-,--> \leftrightarrow |+,-->$ consisting exclusively of W_e and short-circuited W_n processes can *only* occur if ν_1^+ is irradiated. *Right:* For $a_1 > 0 > a_2$ such a relaxation loop—again symbolized by the sinuous line—exists only if ν_1^- is irradiated.

switching of the pumping frequency[13]. Coincident ENDOR signals of HFC constants with opposite signs and equal number of nuclei can be recognized since these lines do not "react" on the TRIPLE effect when the pumping frequency is changed to another NMR transition, i.e. their intensity remains unaltered.

2.4. ENDOR-Induced Electron Paramagnetic Resonance (EIE)

In the chemistry of organic free radicals, it happens occasionally that more than one radical is formed at the same time. Whereas the EPR spectrum of such a mixture—especially when the g-values are similar—often consists of a superposition of the contributing spectra which is difficult to analyze, the individual EPR spectra can be recorded separately using the interesting variant "ENDOR-induced EPR" (EIE), provided separate signals for the different radicals appear in the ENDOR spectrum[18a]. The EIE experiment is illustrated in Figure 4 for the phenalenyl radical: While the NMR frequency is positioned at an ENDOR line (Fig. 4b), the external magnetic field is swept over the range of EPR absorptions, and gives rise to the ENDOR-induced EPR spectrum of phenalenyl depicted in Figure 4e, which, for experimental reasons, has the appearance of an absorption spectrum. The following example serves to illustrate how the EIE technique allows individual species to be selectively studied in a mixture of different radicals: We recently had to decide[18b] whether the ENDOR spectrum of a partially deuterated phenalenyl radical (Fig. 7) could be assigned to a species with H atoms in positions 1 *and* 2, or whether the solution consisted of a mixture of species with only *one* H atom in position 1 *or* 2 (the intensities of the ENDOR signals were ignored). The EIE spectrum gave the unequivocal answer: Depending on the setting of the NMR pumping frequency (Ⓐ or Ⓑ), different EIE spectra (Ⓐ and Ⓑ) were obtained. The solution

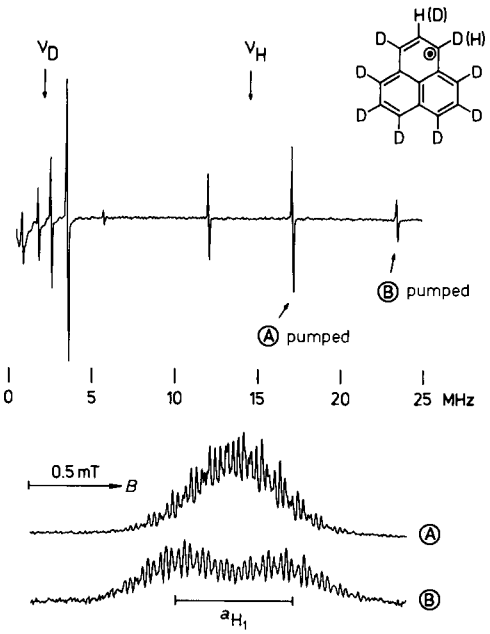

Fig. 7. ENDOR (top) and ENDOR-induced EPR spectra (bottom) of phenalenyl radicals with the same degree of deuteration but different distribution of the isotopes: The EIE spectrum Ⓐ obtained with the NMR pumping frequency set on the high-frequency ENDOR component of the small coupling arises from radicals with the hydrogen atom in position 2; analogously the EIE experiment Ⓑ indicates the presence of phenalenyl radicals with a hydrogen atom in position 1. Furthermore, it can be deduced from the relative intensities of the ENDOR signals that the concentration of the [2-^{1}H] species is larger than that of the [1-^{1}H] species (cf. [18b]).

therefore consisted of a mixture of phenalenyl radicals in which eight of the nine possible positions are always deuterated, with the H atom in either position 1 or 2.

It is worth mentioning that the signal intensity can be increased significantly by using the version "TRIPLE-induced EPR"[19]. In principle, such a selection experiment is also possible using a general TRIPLE experiment. If an ENDOR spectrum exhibits signals from different radicals, of course, only those ENDOR components "react" to the additional pumping frequency which belong to the same level scheme, i.e. to the same radical, as the pumped component.

2.5. Instrumentation and Sample Preparation

Figure 8 shows the block diagram of the spectrometer used in the authors' laboratory. The spectrometer is capable of recording EPR, ENDOR, ENDOR-induced EPR, as well as special and general TRIPLE resonance spectra. The components of the commercial EPR spectrometer (Bruker ER 220 D) are enclosed by the broken lines. The basic features of the broad-band NMR channel have been described previously[7c, 7f, 20].

Sample preparation using the various methods of generating radicals by chemical, electrolytic, and photolytic means is accomplished essentially according to the relevant methods used in EPR spectroscopy[23]. Only a limited number of solvents are suitable for ENDOR spectroscopy; however, those solvents which form a glass on cooling (toluene, ethanol, 2-methyltetrahydrofuran) have proved particularly useful, because the high viscosity thus achievable frequently allows the condition $W_e \simeq W_n$ to be adjusted.

3. Further Nuclei Accessible to ENDOR (ENDOR of Nuclei other than Protons)[25]

Until 1970, ENDOR spectroscopy in solution was applied exclusively to study the protons within the radicals, which are particularly suited for this technique: The mag-

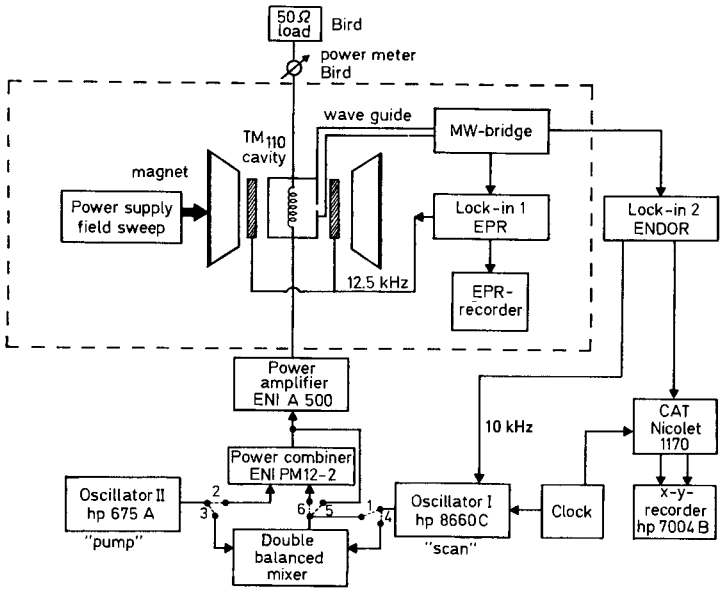

Fig. 8. Block diagram of an ENDOR/TRIPLE spectrometer. The dashed line encloses the EPR spectrometer. For very elaborate EPR measurements (sensitivity, resolution), the ENDOR cavity should be replaced by an EPR cavity. The different modes of operation require the following connections, denoted by 1—6: ENDOR: 1, 5 closed; 2, 3, 4, 6 open. General TRIPLE: 1, 2, 6 closed; 3, 4, 5 open. Special TRIPLE: 3, 4, 5 closed; 1, 2, 6 open. The MW and RF fields are generated by means of a Bruker ENDOR cavity (ER 200 ENB) of TM_{110} type with internal NMR coil, which may have different numbers of turns, and is fixed to a double-walled quartz Dewar. 12.5 kHz field modulation is used for recording the EPR spectra in the field sweep method (Hall probe stabilization). The EPR signals are plotted on the recorder of the Bruker console after phase-sensitive rectification and amplification (lock-in 1). For recording ENDOR spectra, the spectrometer is adjusted to the absorption maximum of the selected EPR line by means of a field frequency lock (Bruker ER 033), and the field modulation is switched off. The frequency generator I (hp 8660 C) generates the 10 kHz frequency-modulated NMR frequency. This is amplified (ENI A 500), passed through the NMR coil in the cavity, and dissipated in a 50 Ω load (Bird 8201) after its power has been measured (Bird Wattmeter 43). The change in the EPR absorption of the sample caused by the NMR transitions undergoes phase-sensitive rectification, is amplified (lock-in 2, Ithaco 393) and stored in a spectrum accumulator (Nicolet 1170). The channel advance of the CAT is synchronized with the change in the oscillator frequency (I) via a clock. The ENDOR signals in the first derivative mode can be plotted versus the NMR frequency on an x,y recorder (hp 7004 B). For performing general TRIPLE experiments, the unmodulated NMR frequency of an ENDOR signal is also irradiated (see Section 2.3). This frequency is generated by oscillator II (hp 675 A) and added to the first (swept, frequency-modulated) NMR frequency using a combiner (ENI PM 12-2). In the special TRIPLE experiment the double balanced mixer (Industrial Electronics SRA-3H) produces two frequency-modulated side bands at ν_{II} (from oscillator II) $\pm \nu_I$ (from oscillator I). Provided the carrier frequency ν_{II} corresponds to the Larmor frequency of one type of nuclei in the radical, the high- and the low-frequency ENDOR transitions for all HFC constants of these nuclei are always irradiated *simultaneously*; this procedure can even be used if $|a/2| > \nu_n$, with the only proviso that the range $\nu_I \cong \nu_{II}$ ($|a/2| = \nu_n$) should be avoided (see Section 2.2). The temperature of the sample is usually adjusted by means of a flow of nitrogen gas (e.g. temperature control unit Bruker VT-1000), but a helium cryostat may be used instead [21]. Slotted cavities allow light irradiation of the sample in situ [7f, 22a, b]. Computerized ENDOR spectrometers are also available; the computer is used, inter alia, to control the field position, the scan oscillator, and the RF power, in addition to data acquisition, and handling and storage of the spectra [7f, 22c].

netic moment of the hydrogen nucleus is relatively large, and therefore the resonant frequency ν_H of the free proton (the "free proton frequency") is situated in an experimentally easily accessible range (13—15 MHz, in the field range of an X-band EPR spectrometer); the π-σ spin polarization mechanism which is operative through the C—H σ bond gives rise to pure s spin density in the proximity of the protons and thus to a comparatively small hyperfine anisotropy; relatively small RF powers are consequently sufficient to saturate the NMR transitions. It was of great interest both for theoretical and applied ENDOR spectroscopy to extend this method to further nuclei such as ^2H, ^{13}C, $^{14,15}N$, and ^{19}F for example, the hyperfine coupling of a ^{13}C nucleus within the π system is expected to be much more sensitive toward changes in the geometry than those of peripheral protons. Finally, all nuclei in the π skeleton not connected to protons are "blind" for purposes of ^1H-ENDOR spectroscopy.

Table 1. Properties of magnetic nuclei from which ENDOR-in-solution signals have been obtained so far, see text (^2H- and ^{15}N-ENDOR spectroscopy were only possible with isotopically enriched radicals.)

Nucleus	Nuclear spin I	Free nuclear frequency [MHz] (B_0=328.8 mT)	Magnetic moment μ_I (in μ_n)	Natural abundance [%]
^1H	1/2	14.00	2.7927	99.99
^2H	1	2.15	0.8574	0.015
^7Li	3/2	5.44	3.2560	92.58
^{10}B	3	1.50	1.8007	19.78
^{11}B	3/2	4.49	2.6880	80.22
^{13}C	1/2	3.52	0.7022	1.11
^{14}N	1	1.01	0.4035	99.63
^{15}N	1/2	1.42	−0.2830	0.37
^{19}F	1/2	13.17	2.6273	100
^{23}Na	3/2	3.70	2.2161	100
^{27}Al	5/2	3.65	3.6385	100
^{29}Si	1/2	2.78	−0.5548	4.70
^{31}P	1/2	5.67	1.1305	100

^{87}Rb	3/2	4.58	2.7414	27.85
^{117}Sn	1/2	4.58	−0.9132	7.61
^{119}Sn	1/2	4.99	−0.9949	8.58
^{133}Cs	7/2	1.84	2.5642	100
^{203}Tl	1/2	8.00	1.5960	29.50
^{205}Tl	1/2	8.08	1.6116	70.50

However, "non-proton" ENDOR spectroscopy faces far greater experimental difficulties than ^1H-ENDOR spectroscopy. Thus, magnetic nuclei occurring in low natural abundance such as ^2H, ^{13}C, and ^{15}N require isotopic labeling[26]. The generally smaller magnetic moment and the lower free nuclear frequency of nuclei other than protons can cause experimental problems (as long as $|a/2| < \nu_n$). Large π spin populations at magnetic nuclei, e.g. at ^{13}C atoms located in the skeleton of aromatic rings, give rise to large hyperfine anisotropies and in the case of heteroatoms (nitrogen, oxygen, halogens) often to large g-value anisotropies. These quantities strongly influence the nuclear- and electron-spin relaxation rates[7d]. In addition, the experimental difficulties of the ENDOR technique increase considerably if high microwave (> 100 mW) and RF powers (> 200 W) are required, in particular, simultaneously. However, nowadays substantial technological improvements allow ENDOR spectroscopy to be performed on a whole series of "non-proton" nuclei (cf. Table 1).

Figure 9 shows the multinuclear EPR and ENDOR spectra of a perdeuterated—except for the proton at the β-carbon atom—and 90% β-^{13}C labeled bis(biphenylylene)allyl radical. Comparison of the EPR spectra in Figures 9 and 1 reveals a drastic decrease in spectral resolution, caused firstly by the smaller gyromagnetic ratio of deuterium (1/6th that of a proton), secondly by its larger spin quantum number ($I_D = 1$, $I_H = 1/2$), and thirdly by enlarged line widths arising from the ^{13}C hyperfine anisotropy. The ENDOR spectrum, optimized for three different kinds of nuclei, however, is completely resolved. The ^2H-ENDOR lines are centered about the free deuterium frequency $\nu_D(|a/2| < \nu_D)$, whereas the ^1H- and ^{13}C-ENDOR signals are equally spaced at about half the respective HFC constant, separated by twice the free nuclear frequency ν_H or $\nu_{^{13}C}$ ($|a/2| > \nu_n$).

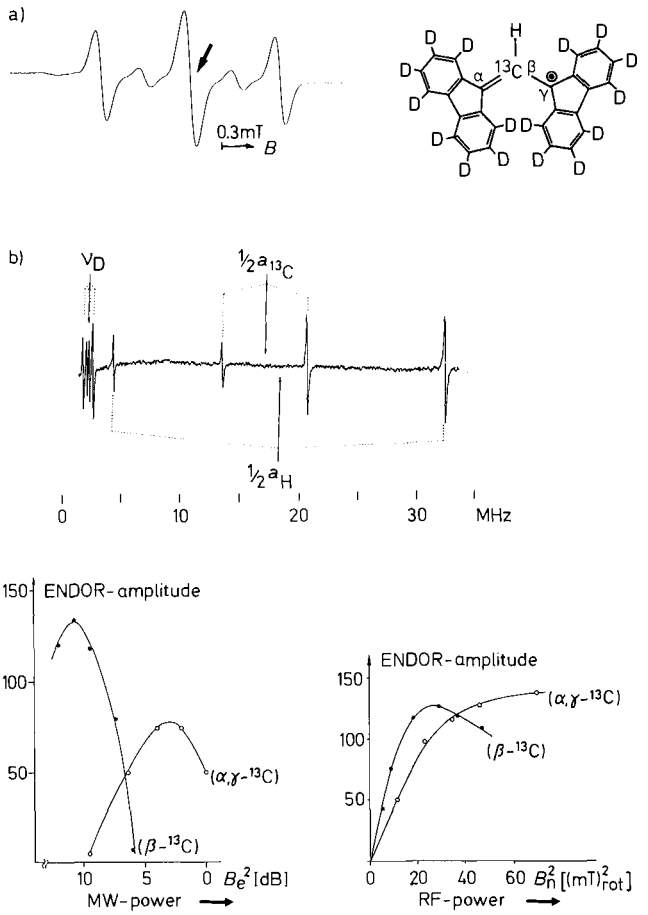

Fig. 9. Multinuclear a) EPR and b) ENDOR spectra (in mineral oil, 360 K) of the selectively deuterated and ^{13}C-labeled bis(biphenylylene)allyl radical. The arrow in the EPR spectrum denotes the field setting for the ENDOR experiment. Note that the experimental conditions were not changed to record the ENDOR spectrum. On the bottom left is plotted the dependence of the signal amplitudes of the high-frequency ^1H-ENDOR signals of the β- and α,γ-labeled compounds, respectively, on the microwave power. On the bottom right, the signal amplitude of the high-frequency ^{13}C-ENDOR lines of these radicals is shown as a function of the radio frequency power. In both cases the α,γ-^{13}C labeled compound requires higher powers to achieve an optimum ENDOR effect because of the larger hyperfine anisotropy (cf. [27]).

The ^{13}C isotope, which is particularly interesting for the organic chemist, will be discussed first. The ^{13}C nucleus in the β-position of the bis(biphenylylene)allyl radical behaves typically in terms of the optimum ENDOR effect, i.e. somewhat higher microwave and RF powers are required compared to those used for the ^{1}H-ENDOR spectrum of the unlabeled compound (Fig. 9). The α- and γ-positions of this molecule exhibit much larger spin populations than the β-position. As expected, ^{13}C-ENDOR spectroscopy requires markedly larger powers and the use of higher temperatures because of the larger hyperfine anisotropy at these positions. Figure 9 (bottom left) shows the dependence of the ENDOR signal amplitudes of the high-frequency proton lines of the two differently labeled molecules on the microwave power; whereas on the bottom right the intensities of the high-frequency ^{13}C-ENDOR signals are depicted as a function of the RF power[27].

Another instructive example is offered by the ^{13}C-ENDOR investigation of ^{13}C-labeled galvinoxyls ("*Coppinger*'s radical")[28]. Whereas the unsubstituted, selectively deuterated and ^{13}C-labeled galvinoxyl radical again exhibits the typical ENDOR behavior, i.e. ^{13}C-ENDOR requires higher temperatures and larger microwave and RF powers compared to ^{1}H- and ^{2}H-ENDOR, the result obtained for the *tert*-butyl substituted and ^{13}C-labeled galvinoxyl radical was completely unexpected (cf. Fig. 10): The optimum ^{13}C-ENDOR intensities are obtained at comparatively low temperatures and powers. Moreover, the low-frequency ^{13}C-ENDOR signal can even be detected in the *unlabeled* molecule, i.e. in natural abundance (1.1%). This signal is also shown in Figure 10 (middle, right). (The high-frequency component, which is certainly more intense because of the "hyperfine enhancement", coincides accidentally with a ^{1}H-ENDOR signal.) Clearly this basically different relaxation behavior of the two ^{13}C nuclei means that the *tert*-butylgalvinoxyl radical, in contrast to many other substituted compounds of this type, no longer behaves like a "genuine" galvinoxyl radical with a completely delocalized π system comprising two equivalent aryl rings. Owing to the *different* twist angles of the rings it has to be described as an equilibrating substituted phenoxyl radical.

This interpretation is confirmed by the investigation of 4-benzoyl-2,6-di-*tert*-butylphenoxyl radical ^{13}C-labeled at the carbonyl carbon which also exhibits such unusual ^{13}C-ENDOR behavior[29]. A natural abundance ^{13}C-ENDOR signal was observed in this radical for the first time. HMO-McLachlan and INDO calculations yielded a very low p_z-spin population at the carbonyl C atom. The ^{13}C hyperfine anisotropy is therefore extremely small in this system, and could be confirmed experimentally by ENDOR investigations in liquid crystals (see Section 4). The ^{13}C hyperfine coupling results almost exclusively from π-σ spin polarization, and the relaxation properties of the ^{13}C nucleus correspond to those of the protons, in full agreement with the experimental observation[30].

The successful detection of a nuclear resonance of ^{13}C in natural abundance by ENDOR spectroscopy testifies convincingly the increase in sensitivity relative to NMR, achievable through quantum transformation. Recently it

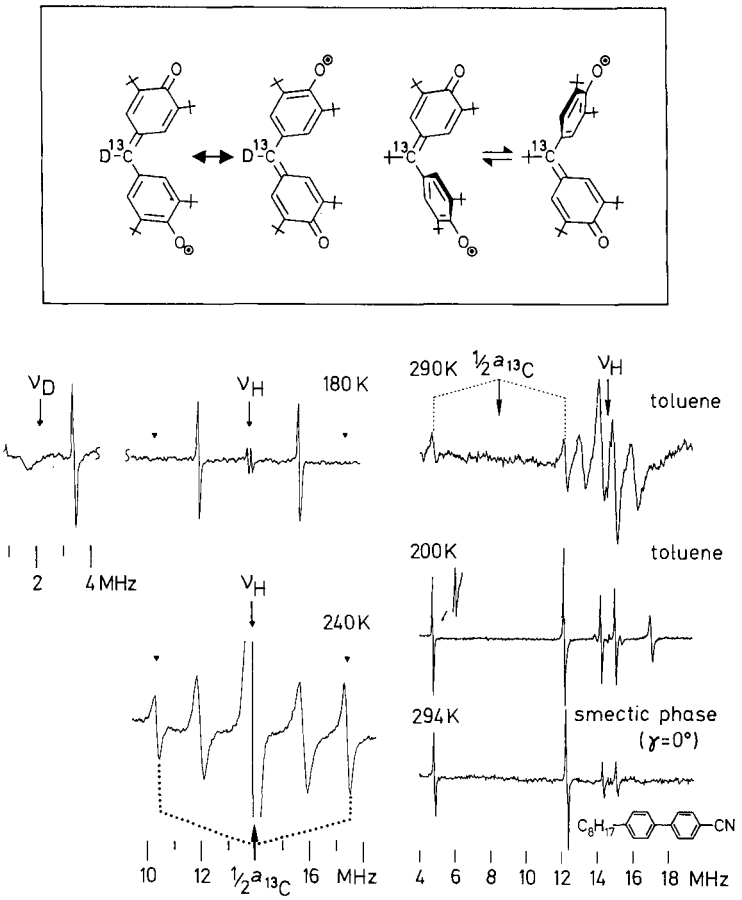

Fig. 10. ^{1}H-, ^{2}H-, and ^{13}C-ENDOR spectra of galvinoxyls. The formulas at the top illustrate that introduction of a bulky substituent converts the galvinoxyl with equivalent aryl rings and a completely delocalized π system into an equilibrating phenoxyl radical with differently twisted aryl rings. Galvinoxyl exhibits typical ^{13}C-ENDOR behavior (bottom left), whereas in the *tert*-butyl compound ^{13}C-ENDOR signals are also obtained at lower temperatures (200 K) or in solvents of high viscosity (smectic phase of a liquid crystal). It is especially noteworthy that the *tert*-butylgalvinoxyl exhibits ^{13}C-ENDOR resonances even in *unlabeled* radicals, i.e. in natural abundance: see the signal at 5 MHz in the ENDOR spectrum at 200 K (middle right) (cf. [28]).

was shown that whole sets of ^{13}C HFC constants could be determined by ^{13}C-ENDOR experiments on unlabeled radicals, provided these are extensively deuterated[31].

In ENDOR investigations of ^{13}C-labeled radicals with a large p_z-spin population, and hence large hyperfine anisotropy, pronounced intensity differences of the ^{13}C-ENDOR line pairs are frequently observed, and it depends on the setting of the external magnetic field in the EPR spectrum whether the high- or the low-frequency ENDOR component is more intense. This effect cannot be accounted for solely in terms of the "hyperfine enhancement" mentioned in Section 2.1, but rather has to be ascribed to so-called "cross-relaxation processes". As can be seen from Figure 2, electron- and nuclear-spin can flip simultaneously. The transition $|+->\leftrightarrow|-+>$ (flip, flop) is denoted W_{X1}, whereas W_{X2} symbolizes the process $|++>\leftrightarrow|-->$ (flop, flop). Evidently the condition $W_e \cong W_n$ for optimum ENDOR signals is no longer valid when W_X processes are efficient ($W_X > W_n$), since a closed "relaxation loop" arises from saturation of *one* NMR transition. Cross-relaxation processes are of importance, espe-

cially at elevated temperatures and large hyperfine anisotropies ($W_{X2} > W_{X1}$) or for time-modulated isotropic HFC constants ($W_{X1} > W_{X2}$)[18b,32]. In Figure 11 the situation is illustrated using the corresponding energy level diagrams for the perdeuterated triphenylmethyl radical which is ^{13}C-labeled to 90% at the central C atom[33]. If, for example, the low-field EPR component is saturated, the high-frequency signal in the ^{13}C-ENDOR spectrum is more intense (case Ⓐ), whereas positioning the external magnetic field at the high-field ESR signal gives rise to an ENDOR spectrum with a more intense low-frequency signal, case Ⓑ. Thus, a W_{X2} process dominates in this system, arising from the large ^{13}C hyperfine anisotropy.

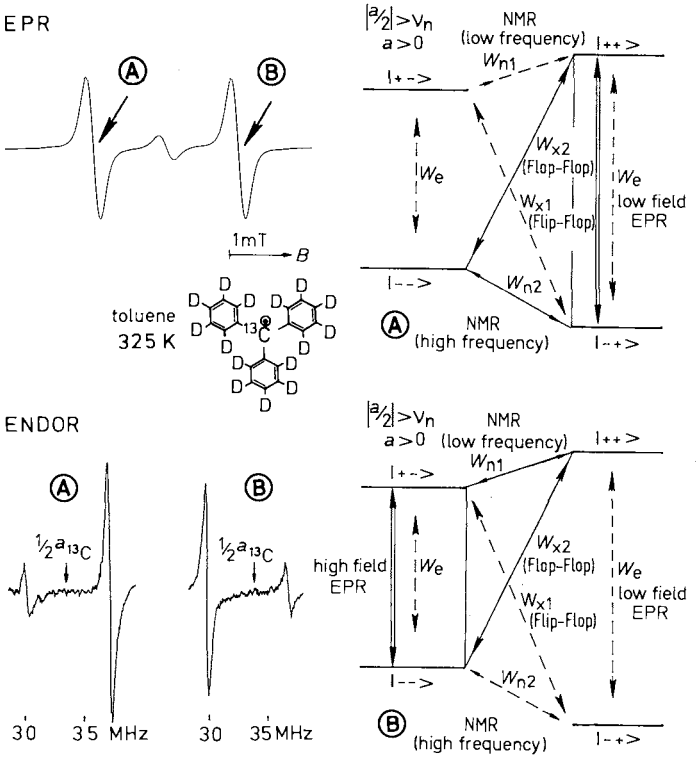

Fig. 11. EPR and ENDOR spectra of the ^{13}C labeled and perdeuterated triphenylmethyl radical. The large ^{13}C hyperfine anisotropy gives rise to a dominant W_{X2} process, so that a closed relaxation loop without inclusion of W_{n1} is obtained with the low-field setting in the EPR spectrum Ⓐ, whereas the NMR transition W_{n2} is avoided with the high-field setting Ⓑ. A closer examination of the two "four-level schemes" reveals that in experiment Ⓑ, the low-frequency, and in Ⓐ the high-frequency ENDOR component is more intense (cf. [33]). This behavior is independent of the sign of the HFC constant.

Interestingly, cross-relaxation processes of nuclei with large hyperfine anisotropies, occurring, e.g., in ^{13}C-enriched molecules, can also be detected through nuclei (e.g. protons) in these molecules which do not normally exhibit cross-relaxation effects because of their low anisotropy. This transfer arises because the unpaired electron in organic radicals couples with all magnetic nuclei to give a multispin ensemble. It should be mentioned that investigations of this type—similar to the general TRIPLE effect—allow determination of the relative signs of HFC constants. For more detailed explanations, the reader is referred to the original literature[18b,34].

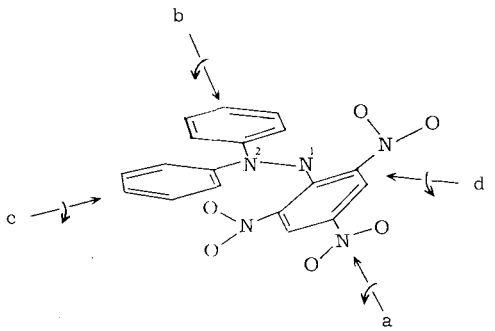
Deuterium (^2H)

In multinuclear ENDOR spectra, deuterons can often be detected with an intensity comparable to that of protons, despite their small magnetic moment (Table 1) (cf. Figures 5 and 9)[19]. Because of the markedly lower hyperfine anisotropy, the optimum ^2H-ENDOR effect occurs at lower temperatures than the ^1H-ENDOR effect. ^2H-ENDOR signals are usually narrower than those of ^1H-ENDOR, which is advantageous for the resolution of, e.g., quadrupole splittings ($I_D = 1$) in liquid crystals (see Section 4).

Nitrogen ($^{14,15}N$)

Since the first successful ^{14}N-ENDOR experiment by *Leniart* et al. in 1970[35], ^{14}N-ENDOR spectroscopy has found growing interest especially in applications to biological systems (cf. also Section 7). The "ENDOR behavior" of a ^{14}N nucleus within a π system is comparable to that of the ^{13}C isotope in a similar environment; the additional quadrupole relaxation of ^{14}N with $I_{^{14}N} = 1$ can, in general, be neglected[7d] since the anisotropic hyperfine interaction provides the main contribution to the relaxation (possible quadrupole effects can be recognized by comparison with ^{15}N-labeled molecules, since this isotope has no quadrupole moment ($I_{^{15}N} = 1/2$)).

Two particularly interesting N-ENDOR investigations will be mentioned here. The first, a study of the "Goldschmidt radical" (*N,N*-diphenyl-*N'*-picrylhydrazyl) by NMR, EPR, ENDOR, and TRIPLE techniques allowed four different dynamic processes to be distinguished on the NMR and ENDOR time scales (denoted by a—d in **1**). The kinetic data were determined by ^1H-ENDOR and ^2H-NMR spectroscopy after ^{15}N-ENDOR and TRIPLE experiments, among others, enabled the complete determination of the HFC constants and their signs[17].



The second, ^{14}N-ENDOR study of the pyrazine radical anion deserves special attention, because here it was shown for the first time that liquid ammonia is well suited for the generation of stable radical anions and for EPR/ENDOR spectroscopy (very good signal-to-noise ratio and efficient TRIPLE and cross-relaxation effects allowing determination of the relative signs of ^{14}N- and ^1H-HFC constants)[34].

Alkali Metal Ions ($M^{\oplus}$)

As is well known, in reactions involving organic ions the influence of the "counterion" on the yield and stereo-

chemistry of the products plays an important role. For this reason, knowledge of type and structure of ion pairs is of considerable interest—also for preparative chemistry. For investigations of *radical* ion pairs, ENDOR spectroscopy has proven especially valuable, because not only the "organic" anionic moiety but also the counterion thus become accessible to direct observation. *Lubitz* et al. were able to detect ^{7}Li-, ^{23}Na-, ^{85,87}Rb-, and ^{133}Cs-ENDOR signals in the metal ketyls of fluorenone[36a] (cf. Fig. 12). The example of the Na ketyl demonstrates how well the heteronuclear TRIPLE resonance effect works[36b]; a proton line is pumped, and the ^{23}Na-ENDOR signals react too! Interestingly, the sign of the sodium HFC constant changes on cooling the solution from ca. 230 K to 170 K. Clearly the structure of the ion pair shows a pronounced dependence on the nature and temperature of the solvent. When contact ion pairs are formed, the spin density changes within the fluorenone ketyl radical and at the metal itself could be correlated with properties of the counterion, and conclusions about the structure of the ion pairs were drawn from INDO calculations.

^{39}K-ENDOR signals can only be detected in chelate complexes with large spin density at potassium because of the very small magnetic moment of ^{39}K (see Table 1). Figure 12 shows the ^{39}K-ENDOR line pair of 1,2-dimesitoylbenzenepotassium[36a]. ^{85}Rb-ENDOR signals were observed for the first time in a similar complex[36c].

Fluorine (^{19}F), Phosphorus (^{31}P), Silicon (^{29}Si), Tin (^{117,119}Sn), Boron (^{10,11}B), Aluminum (^{27}Al), and Thallium (^{203,205}Tl):

Figure 13 represents a small "spectral atlas" of ENDOR signals of nuclei other than protons, not dealt with hitherto. The ^{19}F-ENDOR effect was first mentioned by *Allendoerfer* and *Maki*[37] and discussed later in detail by *Lubitz* et al.[38]. In collaboration with *Haas* et al.[39], we identified the CF_3S-substituted pyrrolyl radical shown in Figure 13 (top left) by ^{14}N- and ^{19}F-ENDOR spectroscopy. ^{31}P-ENDOR spectroscopy was first reported by *Stegmann* et al.[40]. With *Dimroth* et al.[7d,41] we detected ^{31}P-ENDOR signals in a radical generated when 2,4,6-triphenylphosphabenzene was allowed to react with 2,4,6-triphenylphenoxyl (Fig. 13, top right). Whereas the ^{31}P signals can be identified *unambiguously* (line separation $2\nu_{^{31}P}$), the nature of the radical formed is still unknown. In collaboration with *Stegmann* et al.[24,42] we obtained ^{203}Tl- and ^{205}Tl-ENDOR signals for the first time from a complex of an *o*-semiquinone and a diorganothallium(III) compound (Fig. 13, bottom left). In cooperation with *Bock* et al.[16], ^{29}Si-ENDOR signals in organosilicon radicals with natural isotopic abundance were detected for the first time (Fig. 13, bottom right). With *West* we obtained not only ^{29}Si- but also ^{13}C-ENDOR resonances of four- and five-membered cyclosilanes with natural isotopic abundance[43]. The re-

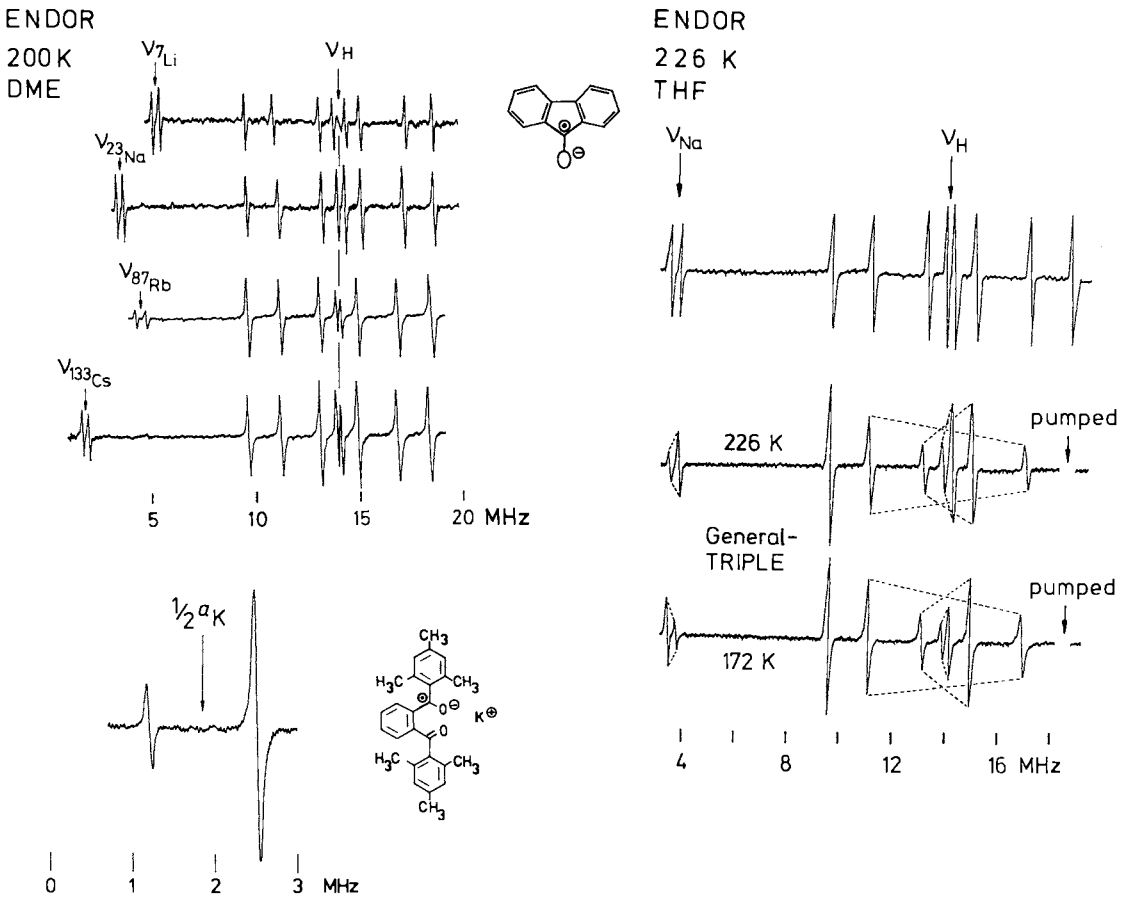


Fig. 12. Alkali metal- and ^{1}H-ENDOR-spectra of fluorenone metal ketyls; for the ^{39}K-ENDOR experiment 1,2-dimesitoylbenzenepotassium was employed. The general TRIPLE spectra of the fluorenone sodium ketyl clearly show that the HFC constant of the ^{23}Na cation changes sign on cooling from 226 K to 172 K (cf. [36a,b]).

sults yielded information about the particularly interesting bonding properties of these systems.

The progress of ENDOR spectroscopy is also revealed in its continuing extension to novel magnetic nuclei. Thus, *Stegmann* et al.[44] recently reported successful ^{117}Sn- and ^{119}Sn-ENDOR experiments on *o*-benzosemiquinones with triphenyltin(IV) counterions. *Kaim* and *Lubitz* observed ^{10}B-, ^{11}B[45a]-, and ^{27}Al[45b]-ENDOR signals for the first time in diazaarene radical anions with the corresponding trialkylmetal species coordinated to the nitrogen atoms.

In a theoretical study of the ENDOR sensitivity of various magnetic nuclei published in 1981[7d], predictions were made about the chances of obtaining ENDOR signals of further, very interesting nuclei such as ^{17}O, ^{33}S, and

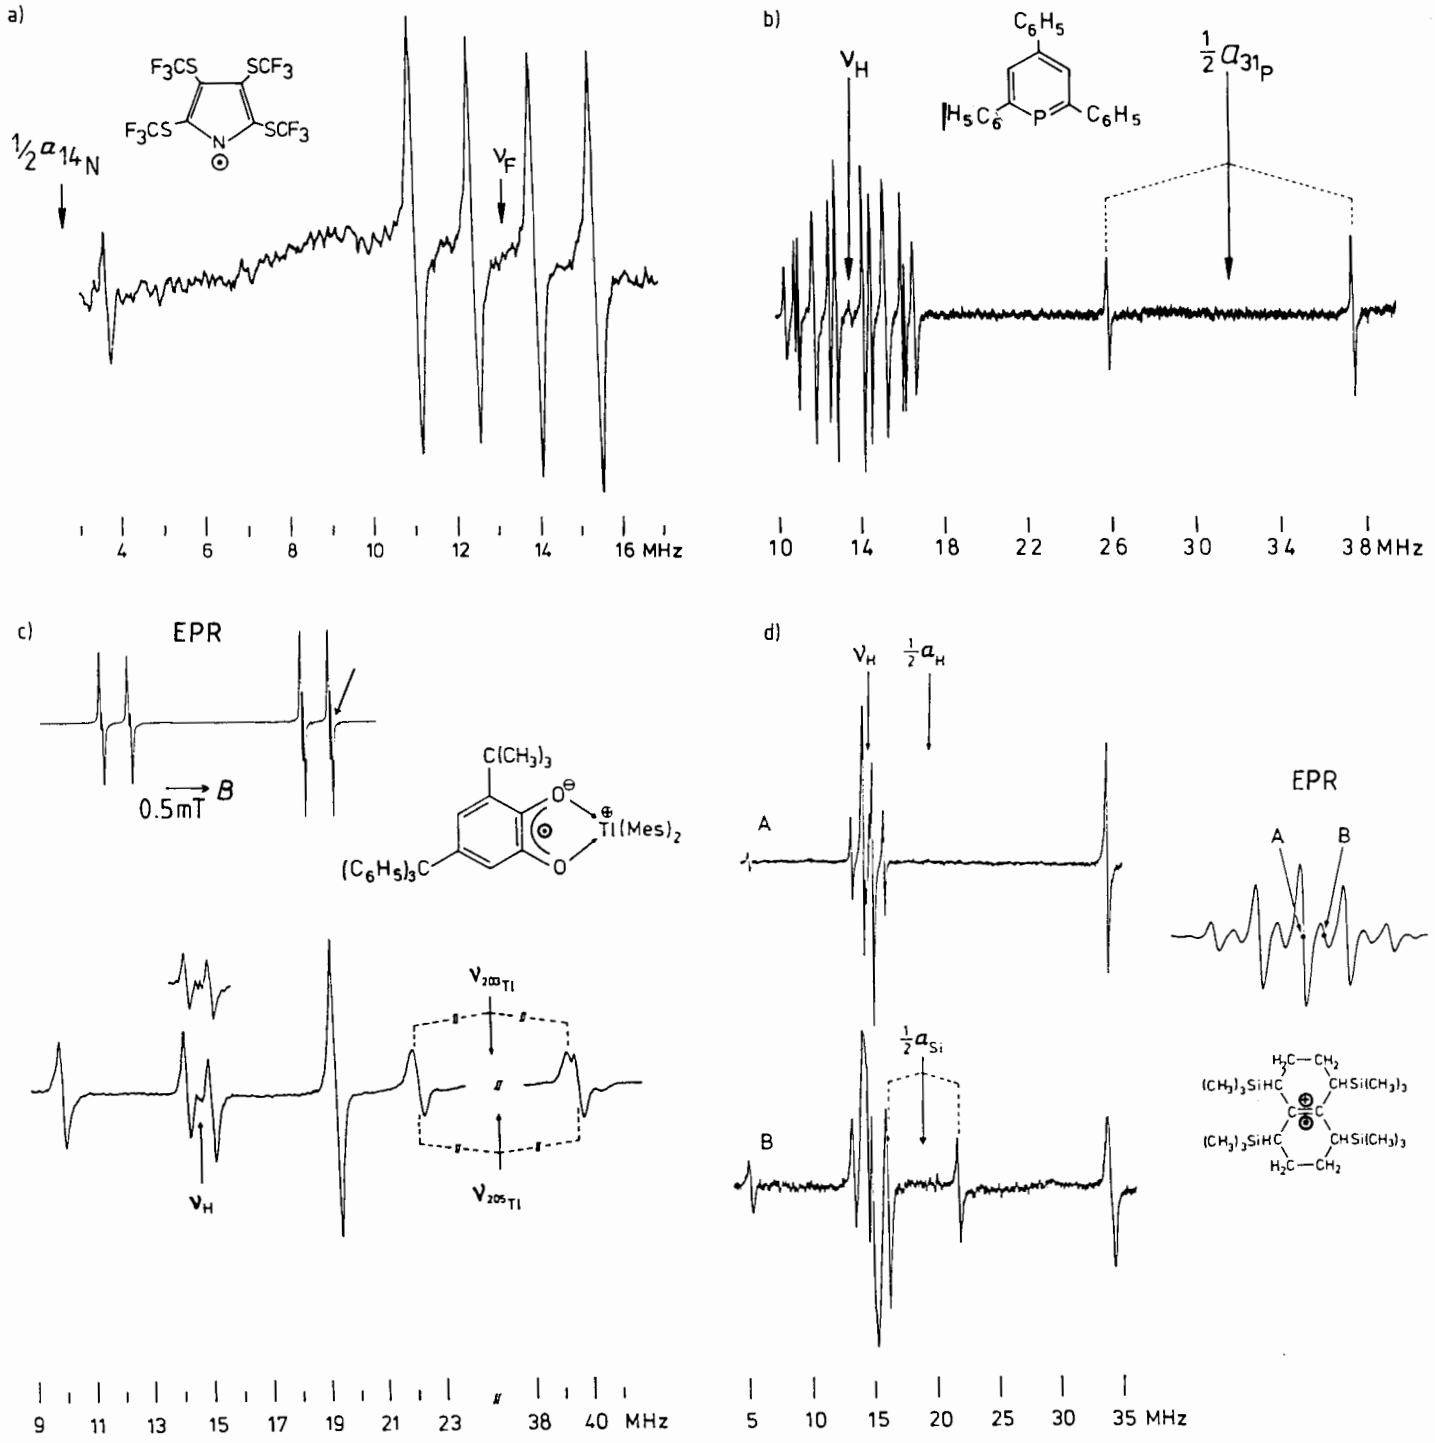

Fig. 13. ENDOR spectra with signals from various nuclei other than protons (see text). Measuring conditions a) ^{19}F: in mineral oil, 330 K; b) ^{31}P: in toluene with 2,4,6-triphenylphenoxyl, 225 K; c) ^{203,205}Tl: in tetrahydrofuran, 260 K; d) ^{29}SI: in dichloromethane, 235 K.

$^{35,37}Cl$ which exhibit usually large quadrupole couplings. It was estimated that ^{17}O- and ^{33}S-ENDOR spectroscopy in solution, which is also biologically relevant, will presumably only be feasible with a few molecules of particularly suitable structure.

4. ENDOR Spectroscopy in Liquid-Crystalline Solutions

The ENDOR experiments in isotropic fluid solution described so far yield—besides the free nuclear frequencies—only *isotropic* HFC constants. To obtain more detailed information about spin density distributions and radical geometries, knowledge of the *anisotropic* hyperfine interactions is often desirable. Although spectroscopy in disordered solids such as powders or glasses can, in principle, afford anisotropic data, the information obtained is rather limited because of the drastic decrease in resolution[46]. On the other hand, all isotropic and anisotropic data are generally accessible from single crystal studies where paramagnetic "guest molecules" are incorporated in sufficient dilution into diamagnetic "host crystals". Nevertheless, apart from the considerable time involved in growing single crystals and their spectroscopic examination, diamagnetically diluted single crystals can be prepared only for a few paramagnetic systems. The use of *liquid crystals* as solvents combines the advantages of spectroscopy in solution (high resolution) and in single crystals (anisotropic interactions are not averaged out). Liquid crystals are suitable as anisotropic solvents because their long-range order is conferred to solute molecules[47]. *Nematic phases* have found extensive applications in NMR[48] and in EPR spectroscopy[15] since they can readily be aligned macroscopically by a magnetic field of about 0.2 T[49]. *Smectic A phases* cannot be aligned directly by a magnetic field, but can in a few cases be aligned indirectly by slow cooling of a precursor nematic phase. "Freezing" the preferential direction then permits investigation of angular dependences[50]. Figure 14 shows schematically the nematic and the smectic A phase of the liquid crystal 4-cyano-4'-octylbiphenyl (8CB). That smectic A phases are well suited for ^1H- and ^2H-ENDOR investigations was shown for the first time using *Coppinger*'s radical[51].

The partial alignment of solute radicals in liquid-crystalline phases, which can be described by an ordering matrix[49], results in a shift Δa of the measured hyperfine coupling constants due to an anisotropic contribution[15]. For the simplest case of axial symmetry about an axis z, the relation is

$$\Delta a = \bar{a}_{nem} - a_{iso} = O_{zz} A'_{zz} \qquad (5)$$

Here O_{zz} is the order parameter, which can have a value between -0.5 and 1 ($O_{zz}=1$ corresponds to complete alignment), and A'_{zz} the axial component of the dipolar hyperfine interaction. Depending on what additional information is available, the experimental data allow conclusions to be made about the degree of ordering, the preferred direction of alignment, or the anisotropic hyperfine interaction. Measurements in liquid crystals can also serve to

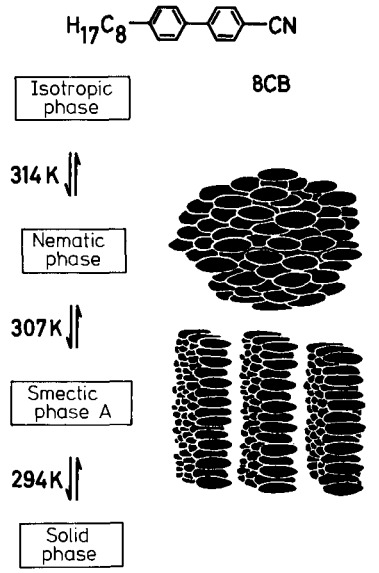

Fig. 14. Schematic representation of different liquid-crystalline phases of 4-cyano-4'-octylbiphenyl (8CB).

lift accidental equivalences of HFC constants, as the ENDOR spectra of the 2-methylphenalenyl radical demonstrate (Fig. 15). In the isotropic phase (top spectrum) the methyl and the small ring-proton HFC constants have coincidently almost the same value. On passing to the smectic A phase (bottom spectrum), however, a marked splitting is observed since the anisotropic shifts act in opposite directions. The splitting which is observable in the region of the large-ring proton HFC constant is due to an additional alignment of the molecules caused by the methyl substituent[52].

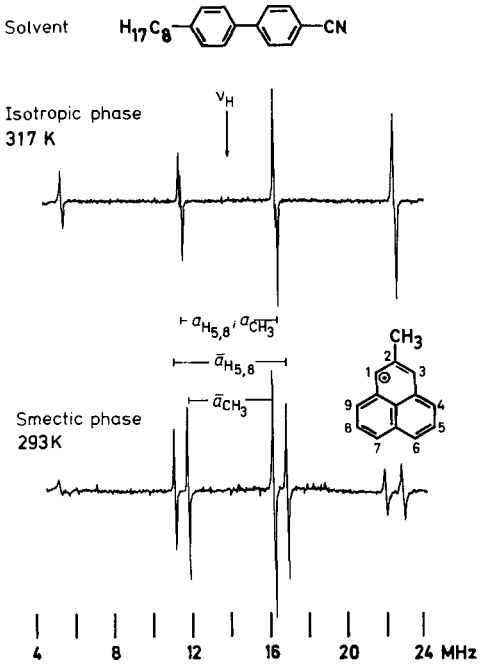

Fig. 15. ENDOR spectra of the 2-methylphenalenyl radical in the liquid crystal 8CB. Whereas the isotropic HFC constants of the methyl protons and the protons in positions 5, 8 are (coincidently) almost equivalent, a marked splitting of the resonance signals appears on passing from the isotropic to the smectic phase (cf. [52]).

In liquid-crystalline solutions the quadrupole interaction of nuclei with spin $I \geq 1$ (^{2}H, ^{14}N) becomes significant. Similarly to NMR spectroscopy, but in contrast to EPR spectroscopy, this interaction gives rise to splittings of ENDOR lines in oriented samples (or in solid solutions). *Dinse, Möbius* et al.[53] detected such quadrupole splittings in ^{14}N-ENDOR lines for the first time in nitroxide radicals in "Licristal Nematic Phase IV". According to the simplified relation (6)

$$\delta_Q \cong \tfrac{3}{2} O_{xx} e^2 q_{xx} Q/h \qquad (6)$$

($I = 1$, neglecting the asymmetry parameter), the quadrupole splittings δ_Q depend on the degree of ordering, the orientation of the bond axes, and the quadrupole coupling constant $e^2 q_{xx} Q/h$[19]. Figure 16 shows ENDOR spectra of the benzil semidione radical anion (unlabeled as well as deuterated in the *para*-positions) in the liquid crystal 8CB[54]. In the ^{2}H-ENDOR spectrum the quadrupole splittings in the smectic phase can be clearly recognized (spectrum center right, $\delta_Q = 160$ kHz). It may be concluded from the magnitude of this splitting that the C–D bond axes are oriented approximately parallel to the director of the liquid crystal, which is only possible if the molecule has a *trans*-configuration. Furthermore, Figure 16 illustrates the strong dependence of the observed hyperfine and quadrupole splittings upon the angle γ between the director of the smectic phase and the magnetic field. Two measurements in a smectic A phase with the sample not rotated ($\bar{a}(0°) = a + \Delta a$) and rotated by 90° ($\bar{a}(90°) = a - \frac{1}{2}\Delta a$) allow the determination of the isotropic HFC constants and the anisotropic shift Δa under the same experimental conditions. On the other hand, the use of nematic phases requires a measurement of the isotropic HFC constants for comparison, either at a higher temperature in the same solvent or in another solvent, which may of course give rise to errors[50].

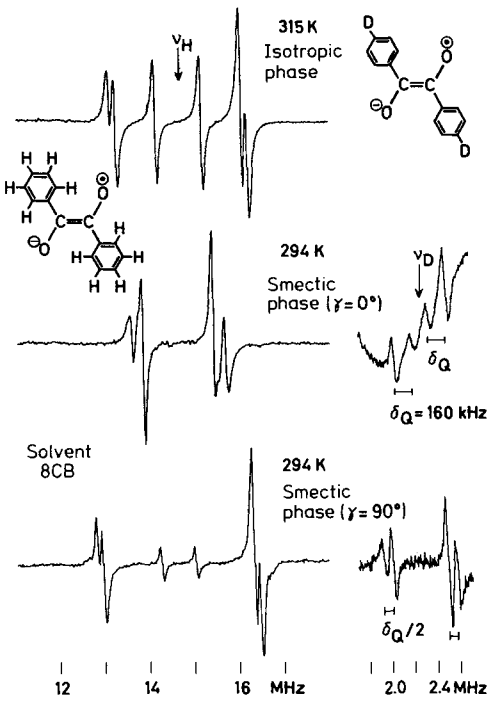

Fig. 16. ENDOR spectra of the benzil semidione radical anion in the liquid crystal 8CB. In the smectic phase, *no* reorientation of the molecules takes place when the sample tube is rotated in the magnetic field—the angular dependence of the resonance positions can be studied, as in single crystals. The selectively deuterated compound shows a pronounced quadrupole splitting (cf. [54]).

Quadrupole splittings of ^{2}H-ENDOR lines were observed for the first time in a deuterated phenalenyl radical[19], and investigations of substituted phenalenyls allowed a determination of the quadrupole coupling constant ($e^2 q_{CD} Q/h = 174 \pm 10$ kHz, asymmetry parameter $\eta = 0.08 \pm 0.04$)[52]. The results available from ^{2}H-ENDOR investigations of radicals and ^{2}H-NMR measurements of diamagnetic molecules[55] show little variation with the ^{2}H-quadrupole coupling constants of C–D bonds. The observed quadrupole *splittings* consequently allow conclusions to be made about radical structures, as has already been discussed for benzil semidione. As another example it should be mentioned that an estimate of the twist angles in the triphenylmethyl radical (ca. 30°) was thus possible[56].

ENDOR investigations of nuclei other than protons (see Section 3) in liquid crystals are subject to severe restrictions because of the high viscosity of nematic, and even more so of smectic, phases. However, ^{13}C-ENDOR signals of high intensity can be obtained in those cases where the ^{13}C-hyperfine anisotropy is exceptionally small, such as in the galvinoxyl and phenoxyl radicals mentioned previously[28] (see Fig. 10). On the other hand, the high viscosity of liquid crystals can sometimes be used to "freeze out" dynamic processes. Thus, in *Coppinger*'s radical a splitting of the ring proton signals, which are normally coalesced in solvents of low viscosity by the rapid rotation of the phenyl groups[51], could be resolved. Another problem is caused by the low solubility of radical ions in liquid crystals. However, it was recently shown[54] that a sufficient concentration of radicals can be achieved in some cases if the alkali metal counterion is complexed by a crown ether or if lipophilic quaternary ammonium counterions are used (cf. also Fig. 16).

5. ENDOR Spectroscopy of Organic Multispin Systems

If a molecule contains more than one unpaired electron, additional magnetic phenomena arise due to *scalar exchange interaction* and *dipolar-electron interaction*. The example of molecules with *two unpaired electrons* will make it clear that the strength of these interactions allows a reasonable classification into "double-doublet radicals", "diradicals", and "real triplet systems". A *diradical* is a species whose spectrum in isotropic fluid solution differs from that of the corresponding monoradical[57]. Thus diradicals are distinguished from *double-doublet radicals*, on the one hand, and real *triplet molecules*, on the other. In the last mentioned, the strong dipolar coupling causes such a large contribution to the electron spin-relaxation that *no* EPR spectrum can be detected in fluid solution[58]. If the exchange interaction is large compared to the hyperfine interaction ($|J| \gg |a|$), rigorous coupling of the unpaired electrons with the spin states $S = 1$, $S = 3/2$, $S = 2$, etc. has to be taken into consideration. The simple "four-level scheme" of a doub-

let radical has to be replaced by the more complicated energy level diagrams shown in Figure 17. The number of EPR hyperfine components increases since the unpaired electrons are formally delocalized over the whole molecule and couple with all magnetic nuclei. Since the total spectral width remains the same, the spectral line density is increased and the resolution decreased relative to that of the corresponding monoradical (cf. Fig. 19). Here the increased resolution achieved by ENDOR spectroscopy is particularly advantageous. The first successful ^{1}H-ENDOR investigation of diradicals (e.g. *p*-phenylenebisgalvinoxyl) in solution appeared in 1975[60]. According to the ENDOR resonance condition [eq. (3)], *three* ENDOR lines are expected for each set of equivalent nuclei in a diradical with $S=1$ ($|J| \gg |a|$) and $M_S = \pm 1, 0$[61]. It was found that the ENDOR lines of such a diradical, consisting of two equivalent monoradical moieties, appear at the *same* positions as those of the monoradical. However, the ENDOR signals display a marked line broadening and different temperature and saturation behavior because of relaxation processes caused by the dipolar electron interaction. The line expected at the free proton frequency, resulting from

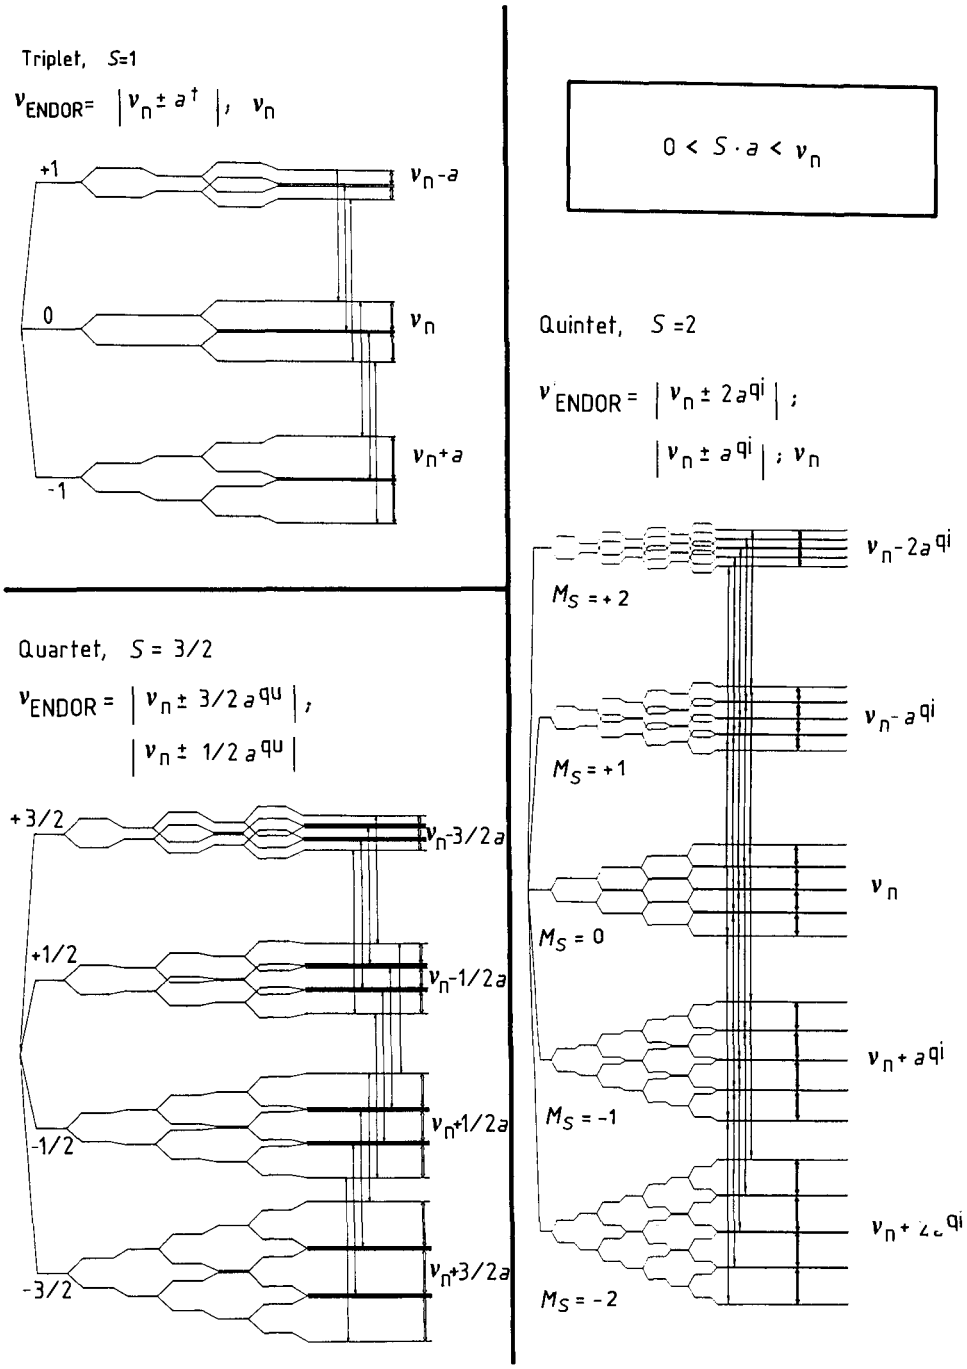

Fig. 17. Energy level diagrams for organic multispin systems in triplet, quartet, and quintet states for the interpretation of the ENDOR spectra reproduced in Figures 18 and 19. Note that the arrows belonging to the EPR transitions $|-1> \leftrightarrow |0>$ and $|0> \leftrightarrow |+1>$ in the diagram of the diradical have the same length (energetically degenerate), see text.

NMR transitions in the $M_S = 0$ manifold, could not be observed. Consequently, the presence of a triplet state cannot easily be established by ENDOR spectroscopic studies in solution, but could be achieved by ^{13}C-labeling[62]. Figure 18 depicts the EPR and ENDOR spectra of the first (doublet) and second (triplet) oxidation steps of the isotopically labeled *p*-phenylenebisgalvinoxyl. As expected (cf. Section 3), only ^1H- and ^2H-ENDOR signals are obtained for the first oxidation step at the lower temperature (210 K), whereas the ^{13}C-ENDOR line pair can only be detected at elevated temperature (250 K) and higher RF power. The pronounced splittings of the signals from the *m*-protons can be accounted for in terms of a sterically induced nonequivalence of these protons. The investigation of the second oxidation step shows *unambiguously* that the spectra have to be assigned to a diradical in the triplet state ($S = 1$) with $|J| \gg |a|$: (a) The EPR spectrum consists of a 1 : 2 : 1 triplet of nonets; hence, each of the two unpaired electrons couples with *all* (eight) *m*-protons and with *both* ^{13}C nuclei. (b) Only mono- and diradicals without a ^{13}C-label or diradicals with two ^{13}C nuclei can absorb in the center of the EPR spectrum. If the external magnetic field is set at the center of the spectrum and ^{13}C-ENDOR signals are observed, then these must arise from doubly ^{13}C-labeled molecules, i.e. diradicals.

Recently, it was shown that ENDOR investigations of unsymmetrical diradicals are also possible[63]. For example, if a nitroxide and a galvinoxyl moiety are linked together, the different *g*-values and HFC constants of the radical moieties have to be taken into consideration. The interpretation of the EPR and ENDOR spectra of such "mixed" diradicals is difficult, especially in the intermediate case $|J| \approx |a|$. A detailed analysis allows the determination of the sign of the exchange integral J[63].

The relaxation processes caused by the dipolar electron interaction give rise not only to line broadening but also to an increase in the electron spin relaxation rate W_e, and thus to a decrease of the ENDOR effect (see Section 2.1). Fluid-solution ENDOR investigations are therefore restricted to diradicals with comparatively small dipolar couplings (zero-field splitting parameter $D \leq 100$ MHz). Measurements in glassy matrices, however, offer an alternative. Here, the dipolar electron interaction is no longer averaged out by Brownian molecular motion but gives rise to a splitting of the EPR transitions $|-1, M_I> \leftrightarrow |0, M_I>$ and $|0, M_I> \leftrightarrow |1, M_I>$[64] which are degenerate in isotropic fluid solution. Incidentally, this degeneracy is responsible for the failure to observe ENDOR lines at the free nuclear frequencies in isotropic fluid solution since both transitions are pumped equally strongly, thus leaving the thermal nuclear spin polarization in the $M_S = 0$ manifold undisturbed (cf. also Fig. 17). In glassy matrices, however, this third ENDOR component can be detected: In general, an intense sharp signal is found at the free proton frequency, and an ENDOR line at the free ^{13}C frequency could even be observed in natural isotopic abundance[65]. Moreover, *one* more, hyperfine shifted ENDOR line, whose position depends on the selection of the pumped EPR component, can be detected for each set of equivalent nuclei. This permits evaluation of the magnitude of the respective hyperfine component together with its sign relative to that of the zero-field splitting parameter[66]. Recently, even investigations of *photoexcited* triplet states (e.g. of naphthalene) were successfully carried out in this way[21].

The example of a triply ^{13}C-labeled trisgalvinoxyl should demonstrate that ^1H- and ^{13}C-ENDOR spectra can also be observed in triradicals[67]. According to the ENDOR resonance condition, *four* ENDOR signals are expected for each set of equivalent nuclei in a quartet state molecule with $S = 3/2$, resulting from NMR transitions in the manifolds $M_S = \pm 1/2$ or $\pm 3/2$ (cf. also Fig. 17). In accordance with theoretical considerations[65], the ENDOR signals belonging to the manifolds $M_S = \pm 1/2$ or $M_S = \pm 3/2$ exhibit different relaxation and saturation behavior. According to the results available so far, threefold symmetry of a quartet state molecule is a prerequisite for a successful ENDOR experiment in fluid solution. If the mutual relations of the individual spin carriers are different (exchange interaction, dipolar coupling), mixed states are formed instead of pure quartet states, which clearly has a crucial influence on the relaxation properties.

Depending on the oxidation state, a molecule with four galvinol moieties can form doublet, triplet, quartet, and quintet states under particular geometrical conditions. A tetraradical with *tetrahedral symmetry* should offer two decisive advantages: The exchange interaction is the same between all pairs of spin carriers, hence the formation of a thermally populated quintet state can be assumed; and the zero-field splitting is equal to zero[68]. These predictions were fully confirmed by the ENDOR investigation of a successively oxidized tetrahedral tetragalvinol, as shown in Figure 19. It can be seen that the resolution of the EPR spectra deteriorates progressively from the doublet to the quintet states (Fig. 19, left), whereas the ENDOR spectra (Fig. 19, right) exhibit all signals expected from the ENDOR resonance condition (eq. (3) with $S = 1/2$ to 2), apart from lines at the free-proton frequency (cf. also Fig. 17).

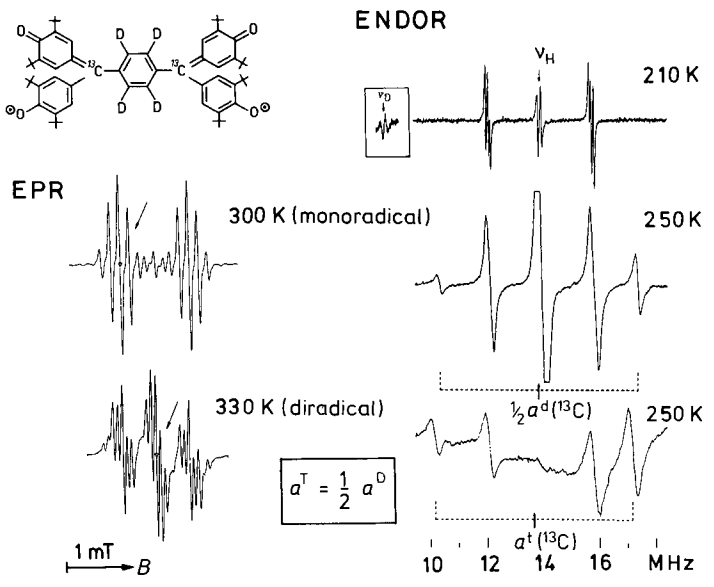

Fig. 18. EPR and ENDOR spectra of the first (monoradical, top and center) and second oxidation step (diradical, bottom) of an isotopically labeled galvinol (cf. [62]). The arrows denote the respective field settings in the ENDOR experiment. The appearance of the ^{13}C-ENDOR signals in the bottom right spectrum establishes the presence of a triplet state (cf. text).

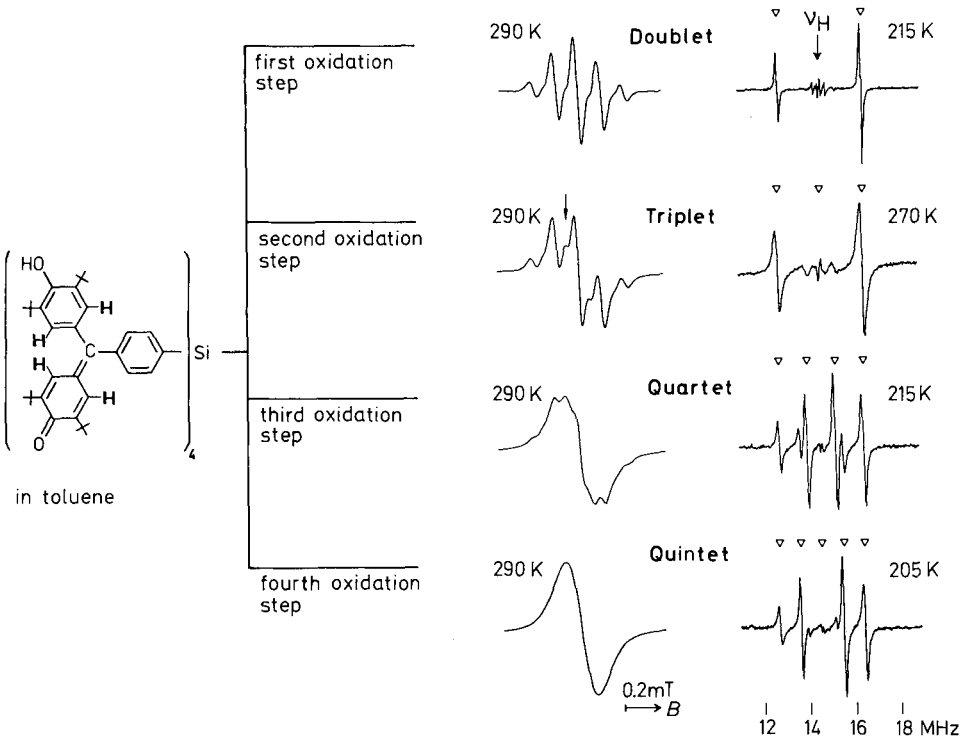

Fig. 19. EPR and ENDOR spectra of the four oxidation steps of a tetragalvinol. Note the deteriorating resolution of the EPR signals with increasing multiplicity, whereas the expected ENDOR signals (marked by triangles) are completely resolved (cf. [68]).

As a matter of fact, only samples from the first and the fourth oxidation steps can be obtained in pure form, whereas the diradical step also contains mono- and triradicals, and the triradical step di- and tetraradicals. The ability of ENDOR spectroscopy to select one species out of a mixture of different paramagnetic molecules can be seen here for the diradical (Fig. 19).

6. Intramolecular Dynamic Processes

ENDOR spectroscopy not only yields information about static molecular properties but may also provide an insight into molecular dynamics, in a similar way to NMR or EPR spectroscopy[7a,69]. Dynamic processes such as hindered rotation of molecular fragments, ring inversions, pyramidal atomic inversions, intramolecular electron transfer, ion-pair interconversions, or torsional oscillations can affect the widths and positions of resonance lines, provided the lifetime of the individual species is of the same order of magnitude as the time scale of the method. The time scale of ENDOR spectroscopy (10^{-9}—10^{-4} s) corresponds to that of EPR, whereas NMR spectroscopy of diamagnetic molecules is a "slower" method (10^{-5}—10^{-1} s). As a typical example, Figure 20 shows the temperature dependence of the high-frequency ENDOR signal of the *ortho*-protons of the 4,4″-dimethyl-*m*-terphenyl radical anion[13]. At high temperatures these protons are spectroscopically equivalent due to rapid rotation of the tolyl groups. With decreasing temperature the signal broadens and splits into two separate signals below the coalescence temperature (157 K), each of which and becomes narrower on further cooling. The rotation of the tolyl groups is now slow compared to the ENDOR time scale, hence the non-

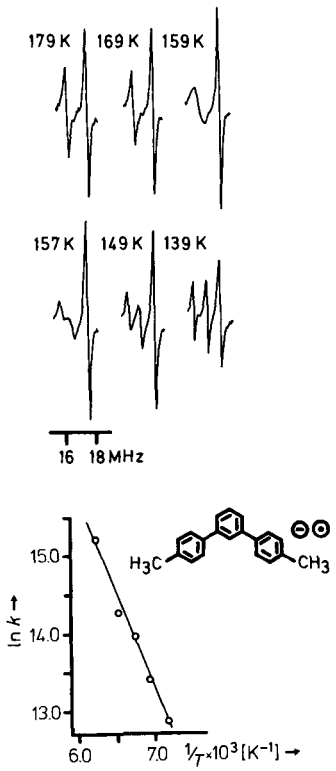

Fig. 20. ENDOR part spectra of the 4,4″-dimethyl-*m*-terphenyl radical anion at different temperatures (coalescence temperature 157 K) in 2-methyltetrahydrofuran. The activation energy and the frequency factor can be taken from the Arrhenius plot (bottom) (cf. [13]).

equivalence of the *ortho*-protons in these groups (twist angle ca. 50°) becomes apparent.

Intramolecular dynamic processes can usually be described as jump processes between two to four distinct species. This implies that the time taken for the jump itself is much less than the mean lifetime of a given species. The determination of rate constants by line-shape analyses is largely analogous to the methods used in dynamic NMR spectroscopy[70]. Line widths or peak separations can be used for the evaluation[71]. The additional line broadening caused by the dynamic effect is (approximately) obtained by comparison with a reference signal of the same sample which does not show this effect. The activation energy E_a of the dynamic process can be determined from the temperature dependence of the rate constant using the Arrhenius equation ($\ln k = -E_a/RT + \ln A_0$; cf. Fig. 20), and the activation enthalpy and entropy are obtained using Eyring's theory (see [72]). In the following, a few applications are mentioned.

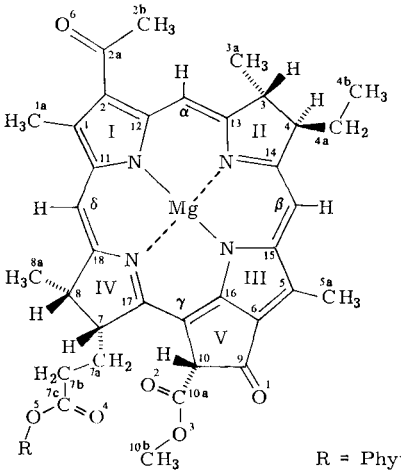
ENDOR spectroscopy was used to investigate the hindered rotation of alkyl side chains in the radical anions of vitamin K_1 and ubisemiquinone[73], as well as of the phenyl groups in silole[72a] and terphenyl radical anions[13,74] and in *N,N*-diphenyl-*N'*-picrylhydrazyl (see Section 3)[17]. In the case of phenylnaphthalene radical anions, a distinction between two types of dynamic processes was possible, namely hindered rotation and ion-pair formation[75]. The hindered rotation of the aroxyl groups in galvinoxyls has been the subject of extensive investigations[28,72b,76], and the mechanism could be largely clarified by systematic variation of the substituents at the central carbon atom and by ^{13}C-labeling experiments (see Section 3). The internal dynamics in tetraaryl- and in bis(biphenylylene)allyl radicals have also been investigated[27,77]. A dynamic process observed in triphenylmethyl derivatives was interpreted as an interconversion of left- and right-handed propeller conformations[78]. The effect of intramolecular cation exchange on ENDOR intensities has been investigated in 2,5-di-*tert*-butyl-*p*-benzosemiquinone ion pairs[79]. A series of papers has dealt with the measurement of temperature dependences of β-proton HFC constants, from which the height of the potential barrier of the hindered rotation was evaluated[80]. As this short survey shows, ENDOR spectroscopy alone or in combination with EPR allows the elucidation of the mechanisms of different kinds of intramolecular dynamic processes as well as the determination of kinetic data and activation parameters or potential barriers.

7. ENDOR Spectroscopy of Biological Systems

Following current developments in many spectroscopic disciplines, ENDOR spectroscopy, too, is increasingly employed to solve biological problems. However, until now ENDOR investigations of biological materials were almost exclusively performed at low temperatures (2—100 K) in powder-like solids; suitable single crystals are rarely accessible[81]. It could nevertheless be shown that interesting structural information can be extracted even from polycrystalline samples by means of ENDOR spectroscopy. This is especially true for protons in freely rotating methyl groups; occasionally ENDOR resonances of protons in other groups and even of nuclei other than protons could also be obtained[82]. Up to now most attention has been paid to paramagnetic derivatives of photosynthetic pigments[83], flavoproteins[84], cobalamins[85], hemo- and myoglobins, and other metalloproteins[81b,82,86].

Undoubtedly ENDOR studies of biological materials would be highly interesting under physiological conditions, i.e. at ambient temperature in aqueous media. According to theory[7d], however, ENDOR investigations of transition metal complexes such as iron-, cobalt-, or copper-containing proteins and coenzymes in solution are *not possible* because of the very unfavorable relaxation properties of these systems. The ENDOR study of metal-free proteins also becomes difficult if the effective molecular volumes are large—because the rotation in solution is no longer fast enough to average out *g*- and hyperfine-anisotropies. For example, a rotational correlation time of 30 ns can be estimated for molecular weights of ca. 100000[87]. As a consequence, only dipolar hyperfine components smaller than 5 MHz are averaged out. Broad and hardly detectable signals similar to powder-type ENDOR spectra are therefore obtained for nuclei with larger anisotropy, even in solution.

Chlorophylls and bacteriochlorophylls play a central role as photopigments in all photosynthetic organisms. As is well known, the photosynthesis consists of a light-induced charge separation, giving rise to the formation of radical cations of primary donors and radical anions of acceptor molecules. ENDOR spectroscopy appears to be a promising method for the identification and structural characterization of these paramagnetic species occurring in the "reaction centers"[88].



Since (bacterio-)chlorophylls and pheophytins participate in the primary step, an investigation of the pigments appeared first to be necessary. As an example, the ^1H-ENDOR spectrum of the radical cation of bacteriochlorophyll a is reproduced in Figure 21 (bottom), from which eleven ^1H-HFC constants can be extracted. The corresponding ^{14}N-ENDOR spectrum yielded all four ^{14}N-HFC constants. Recently ENDOR/TRIPLE studies of the in situ light-induced radical cation of the primary donor $P^{\oplus\odot}$ in the "reaction centers" of several photosynthetic

bacteria were performed in aqueous solution at 25 °C[89,90]. In Figure 21 (top) such an ENDOR spectrum of $P_{870}^{\oplus\ominus}$ (*Rp. sphaeroides* R-26) is depicted. From this "genuine" solution spectrum, seven isotropic ^{1}H-HFC constants could be extracted and were assigned to certain positions in bacteriochlorophyll a by comparison with data from selectively deuterated reaction centers from biosynthetically labeled bacteria. This investigation made a contribution to the contested question of the formation of a "supermolecule"[90] ("special pair" hypothesis[83]).

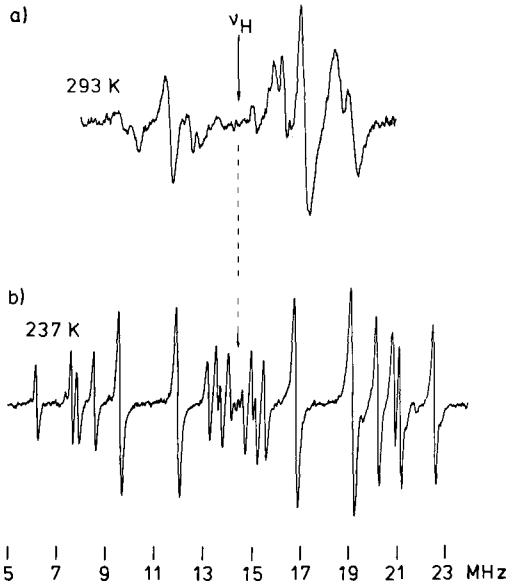


Fig. 21. a) ^{1}H-ENDOR-in-solution spectrum of "reaction centers" from the bacterium *Rp. sphaeroides* R-26 irradiated in situ in the ENDOR cavity; the radical cation $P_{870}^{\oplus\ominus}$ is observed (TRIS buffer, pH = 7.5, lauryl (dimethylamine oxide)). b) ^{1}H-ENDOR spectrum of the radical cation of bacteriochlorophyll a isolated from *Rp. sphaeroides* R-26; generation of the radical cation BCHl $a_p^{\oplus\ominus}$ in CH_2Cl_2/CH_3OH by oxidation with iodine (cf. [89,90]).

Das et al.[73] reported ENDOR-in-solution investigations of the paramagnetic forms of several biologically important quinones such as ubiquinone and vitamins K_3, K_1, E. Four ^{1}H-HFC constants could be determined in electrolytically generated ubisemiquinone-10[91]. Since ubiquinone acts as an electron carrier in many life processes, a comparison with in situ ENDOR spectra of the radical in biological material would be appropriate. However, the solid-solution ENDOR spectrum of ubisemiquinone obtained by *Okamura* et al.[92] from iron-free reaction centers of the bacterium *Rp. sphaeroides* R-26 has not yet been completely analyzed. We were able to determine spin density distributions in radical cations of model compounds of the vitamin E series and observed interesting dynamic effects in ENDOR studies in collaboration with *Sutcliffe* et al.[93].

In the spirit of the introductory remarks to this section, the authors' group has engaged in ENDOR investigations of flavins and flavoenzymes for about two years. These enzymes, as redox catalysts, function as mediators between one- and two-electron transfer steps (more accurately, two one-electron transfer steps) in biological electron-flow processes, e.g. between the NAD/NADH and the ubiquinone system[94]. In fact, the one-electron steps give rise to flavin radicals which can be studied by EPR and ENDOR spectroscopy.

Recently, high-resolution ENDOR/TRIPLE spectra of several model compounds, namely the radical cations of isoalloxazine derivatives, were obtained in solution for the first time. Complete sets of the ^{1}H- and ^{14}N-HFC constants, including their signs, could be determined and assignments made by selective deuteration[95]. Figure 22 shows the ^{1}H-, ^{2}H-, and ^{14}N-ENDOR spectra of the radical cations of several lumiflavins.

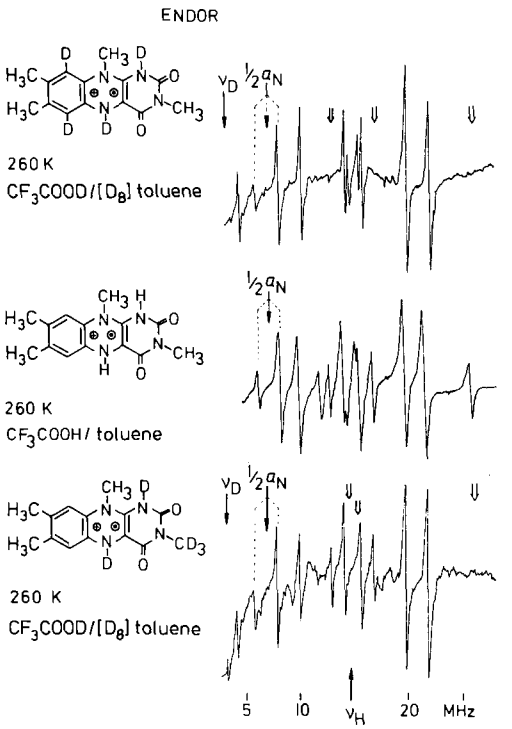

Fig. 22. ENDOR spectra of lumiflavin radical cations. Besides signals from ^{1}H and ^{14}N, ^{2}H-ENDOR signals of selectively deuterated molecules appear in the spectra. The arrows indicate the resonance positions of ^{1}H-ENDOR lines that disappeared upon deuteration (cf. [95]).

Although lumiflavin is considered to be a suitable model system in flavin biochemistry, it is always a challenge to apply the spectroscopic techniques to genuine native, biological material. Since roughly the end of the nineteen-sixties, interesting ENDOR investigations of flavoenzymes in solid matrices have been published, especially by *Hyde* and *Ehrenberg*[84]; these allowed, in part, definite conclusions to be drawn about the nature of the bond between the prosthetic groups and apoproteins. Recently we have been able to perform detailed ENDOR experiments in solid matrices, making use of a substantially improved spectrometer[96]. *Warburg*'s "old yellow enzyme", a NADPH dehydrogenase that can be isolated from brewer's yeast, was investigated[96]. In collaboration with *Kroneck* et al.[96] we studied a methanol oxidase from *Candida boidinii* and an enzyme/pseudosubstrate interaction. Finally, with *Müller*[96] we investigated several flavodoxins (from *Azotobacter vinelandii* and *Megasphaera elsdenii*). For example, Figure 23 shows the EPR, ENDOR, and special TRIPLE spectra of NADPH dehydrogenase, whose radical was generated by irradiation in the presence of ethylenediami-

netetraacetic acid (EDTA) as electron donor. In accord with previous investigations[84a] the radical species could be identified as the radical anion of "flavin mononucleotide" (FMN) by comparison with the authentic model compound. Investigations of the line width as well as the dependence of the line shape of the solid-solution ENDOR spectra of flavoenzymes on the external field setting yielded information about the geometry of the isoalloxazine ring system and about the intramolecular mobility of the prosthetic group in the "pocket" of the apoprotein. However, ENDOR investigations of flavoenzyme radicals in fluid aqueous solution have not yet been successful.

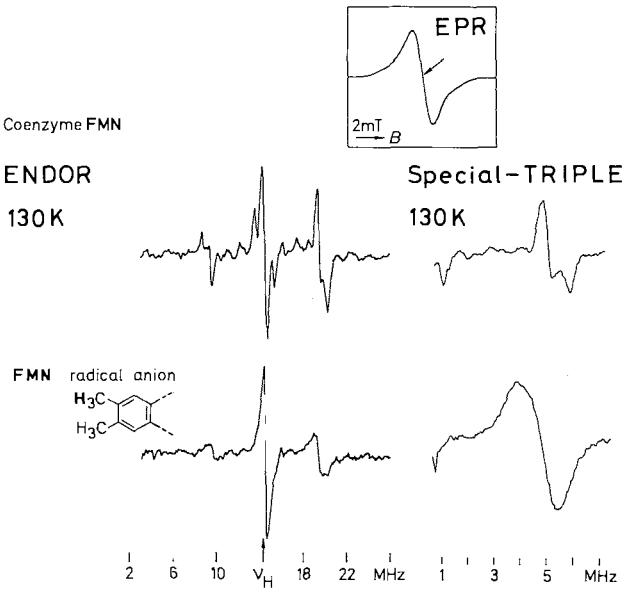

Fig. 23. ENDOR and special TRIPLE spectra of the radical in "old yellow enzyme" (NADPH dehydrogenase from brewer's yeast) generated by irradiation in the presence of an electron donor (20 mM TRIS buffer, pH 9.0, 10 mM EDTA, 80 min irradiation). A comparison with the spectra of the FMN radical anion (below) allows identification of the degree of protonation in the prosthetic group (cf. [96]).

8. Limitations and Outlook

This review indicates that the double resonance method ENDOR with its extensions to TRIPLE is, for many applications, far superior to conventional EPR spectroscopy. In particular, the following points should be emphasized: its high resolving power, its potential as an elegant method of determining the relative signs of coupling constants, its ability to identify different kinds of nuclei and to study their properties individually, the possibility of selecting different species in fluid solution or differently oriented molecules in solid matrices, and finally its ability to determine the spin state, i.e. the multiplicity of organic polyradicals. It has to be borne in mind, however, that applications of the ENDOR technique have so far been limited. Because of their unfavorable relaxation properties, organic radicals with large g-value anisotropies, and/or nuclei with large hyperfine anisotropies or quadrupole couplings, as well as polyradicals with large dipolar electron interactions give rise to scarcely detectable ENDOR effects in solution.

Although the list of references in this article is by no means exhaustive, it is clear that to date less than a dozen research groups have been intensively engaged in ENDOR-in-solution spectroscopy. Not even the development of commercial computer-controlled instruments could change the fact that ENDOR spectroscopy is not a routine method. Successful work still requires long-standing experience; the more so if samples more complicated than "standard" (phenalenyl, galvinoxyl) requiring careful optimization of sample preparation and of spectrometer settings are to be studied. Nevertheless, the ENDOR technique will be used more frequently since it is an indispensable aid to solving difficult structural analysis problems in paramagnetic molecules.

As far as the further development of conventional (continuous wave) ENDOR spectrometers is concerned, an improvement of the ENDOR cavity using the NMR coil—the centerpiece of the spectrometer—appears to be particularly desirable in our opinion.

Whereas pulsed NMR spectrometers have found widespread use, only very recently have pulsed EPR spectrometers become commercially available[97]. It should be mentioned that spin-echo ENDOR experiments on single crystals have already been performed successfully[98]. In this double resonance technique, an RF pulse is applied at a particular time in the electron spin-echo pulse sequence, and a plot of echo intensity versus radio frequency then yields the ENDOR spectrum[99]. The spin-echo technique might extend the range of applicability of the ENDOR method substantially, since its dependence on a critical balance of the RF and microwave powers and the various relaxation rates has been overcome[98]. It should also be possible to perform spin-echo ENDOR experiments in solution, but the short relaxation times and the high powers thus required give rise to experimental difficulties. Finally, it should be noted that the use of flow systems should also allow ENDOR investigations of short-lived radicals. In this context, an increase in sensitivity using spin polarization techniques ("CIDEP-enhanced ENDOR") in the photolytic in situ generation of radicals might be helpful[22b, 100]. However, these novel techniques still demand extensive development efforts and require a more sophisticated experimental set-up. The chances that these highly interesting variants will become routine methods in chemical laboratories in the foreseeable future are therefore even lower than that of conventional ENDOR spectroscopy.

H. K. is grateful to his friends and colleagues from the realms of physics for awakening his—however, not always untroubled (!)—love of ENDOR spectroscopy and for keeping it alive through their readiness to help. In particular, Dr. R. Biehl, Dr. K. P. Dinse, Prof. Dr. K. Möbius, Dr. M. Plato, as well as Dr. F. Lendzian and Dr. C. Winscom should be mentioned. Acknowledgement is also made to the members of our group mentioned in the respective references and to Mrs. E. Brinkhaus and Mrs. J. Krüger for their collaboration. B. K. gratefully acknowledges a Liebig Stipendium from the Fonds der Chemischen Industrie. H. K. thanks the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. W. L. thanks the Deutsche Forschungsgemeinschaft for many years of finan-

cial support (SFB 161, "Hyperfine Interactions") and the Max Kade Foundation (New York) for a research fellowship. Finally, we would like to thank Prof. Dr. R. D. Allendoerfer for reading the manuscript.

[1] E. Zavoisky, *J. Phys. (Moscow) 9* (1945) 245. Unfortunately, as in nuclear resonance, different acronyms are used synonymously for electron spin resonance (EPR: *E*lectron *P*aramagnetic *R*esonance, and ESR: *E*lectron *S*pin *R*esonance). Here we prefer the designation EPR which is finding increasing usage since it includes – in contrast to ESR – both the contribution from the orbital magnetism and from the spin magnetism.

[8] The term "rate" (induced rate, relaxation rate) denotes the number of spin flips per unit time, by analogy to "radioactive decay rate".

[9] The relaxation rates W_e and W_n are, in general, determined by the spin-rotational interaction and the modulation of the dipolar hyperfine interaction, respectively: $W_e^{SR}=B/\tau_R$ and $W_n^{END}=A\cdot\tau_R$. The constant $B\propto\sum_i(g_{ii}-g_e)^2$ depends on the g-value anisotropy, whereas $A\propto Tr A'^2$ contains the magnitude of the hyperfine anisotropy.

[10] The saturation conditions are as follows: $\sigma_e=\gamma_e^2 T_{1e}T_{2e}B_e^2\geqq 1$ and $\sigma_n=\gamma_n^2 T_{1n}T_{2n}B_n^2\geqq 1$, where σ_e, σ_n are the saturation parameters, γ_e, γ_n the magnetogyric ratios, T_{1e}, T_{1n} the longitudinal and T_{2e}, T_{2n} the transversal relaxation times, and B_e, B_n the (effective) field strengths; the subscripts e and n refer to the electron and the nucleus, respectively. [23] The solvents have to be purified carefully, dried (e.g. over liquid Na/K alloy) and freed of oxygen. Sample preparation is best performed at the recipient of a high-vacuum line; residual oxygen can be removed by several freeze-pump-thaw cycles. Good ENDOR spectra can only be obtained if the radical concentration is kept low enough ($\simeq 10^{-4}$ mol/L) to avoid "Heisenberg exchange", but, of course, there is a lower limit to the concentration determined by the signal-to-noise. To exclude "chemical exchange", the diamagnetic precursor should be transformed into the paramagnetic state as completely as possible. To attain an optimum concentration of radicals, sample cells with side arms which allow dilution or concentration of the solution by distillation of solvent under high vacuum have proved suitable[24]. Finally it should be mentioned that whereas solvents with high dielectric constants are often desirable for the study of radical ions (solubility, stabilization), they frequently cause severe dielectric losses in the ENDOR cavity. Small sample volumes have therefore to be put up with. Thus, radicals in concentrated sulfuric acid can only be investigated in capillaries.

[24] W. Lubitz, Habilitationsschrift, Freie Universität Berlin 1982.

[25] The term "ENDOR of nuclei other than protons" cannot be replaced by "heteronuclear ENDOR", since chemists do not denote isotopes such as ^2H or ^{13}C as "heteroatoms".

[26] In ENDOR spectroscopy the Fourier transform (FT) technique, which is commonly used in NMR spectroscopy today, cannot be employed (broadband RF irradiation in the order of kW).

[30] With UV spectroscopy, which is "fast" compared to EPR spectroscopy, this difference between resonance and tautomerism can also be detected: Whereas many differently substituted galvinoxyls show very similar UV spectra, that of *tert*-butyl-galvinoxyl is rather similar in band shape and intensity to the UV spectrum of 2,4,6-tri-*tert*-butylphenoxyl.

[71] The line width $\delta\omega$ in the slow exchange limit is given by $\delta\omega=\delta\omega_0+2/\tau$ and in the fast exchange limit by $\delta\omega=\delta\omega_0+(\Delta\omega_0)^2\tau/4$, where $\delta\omega_0$ is the unperturbed line width (reference line!), τ the mean lifetime of a particular species, and $\Delta\omega_0=\pi|a_1-a_2|$. The peak separation in the slow-exchange range is given by $\Delta\omega=(\Delta\omega_0^2-8/\tau^2)^{1/2}$, and at the coalescence point $\tau\Delta\omega_0=2\sqrt{2}$ is valid. It should be pointed out that the measured line widths have to be extrapolated to vanishing RF power.

Biochemical Aspects of Cholinergic Excitation

By Alfred Maelicke*

In memory of David Nachmansohn (1899—1983)

A prerequisite for every biological system to develop and to continue to function ("to live") is an effective communication between its components, i.e. its cells. This intercellular communication is essentially of a chemical nature: It employs neurotransmitters and hormones as messengers, and receptors as the receivers of transmitted signals. As is typical for all communication systems, biological signal processes usually also utilize only relatively small amounts of material. This general rule, however, does not apply to some synaptic communication systems. One typical exception, for instance, is the nerve-muscle synapse and, in particular, its special form, the nerve-electroplaque synapse of electric fish. These systems, therefore, lend themselves to biochemical studies permitting investigation of the molecular basis of biological communication processes. Thus, the acetylcholine receptor of the plasma membrane of the postsynaptic cell was established as a structurally and functionally rather complicated "transducer system" responsible for both the reception of the chemical message and its conversion into an electrical activity of the receiving cell.

1. Introduction[11]

The central event in the process of chemical excitation is the conversion of the chemical signal into the primary response of the cell. In the case of cholinergic excitation of peripheral muscle cells, a single molecule, namely the nicotinic acetylcholine receptor is responsible for both signal reception and primary response (Fig. 1): through binding of the neurotransmitter acetylcholine released from the associated nerve ending, the receptor receives the chemical message. Short-lived openings of the receptor-integral ion channel constitute the initial reaction to this stimulation, the primary response. This integration of the receiving and the responsive unit into a single protein structure seems to be typical for many ligand-activated ion channel proteins of excitable cells. The acetylcholine receptor, as the biochemically best characterized of all neuroreceptors, may therefore serve as a model system for other ligand-activated ion channels such as those of the central nervous system.

Although the basic reactions in the course of cholinergic excitation and the molecular components participating in these are rather well known (Fig. 1), a molecular mechanism for cholinergic excitation has not yet been established. In particular, it is not yet understood which structural properties enable the receptor to differentiate between agonists (channel activating ligands like acetylcholine) and antagonists (ligands without channel activating properties) and how the binding of the transmitter (or its agonists) is linked on the molecular level to the opening and closing of the receptor-integral ion channel.

In the following these questions will be discussed on the basis of the available biochemical data on the interaction of the receptor with its ligands. Since the acetylcholine receptor is a component of biological systems, such a discussion must also include its physiological role. We shall therefore systematically deal with the physiological, structural, and biochemical aspects of such an interaction. The model finally developed for the mechanism of cholinergic excitation is in good agreement with the existing data.

This article is in no way intended to be comprehensive. When neighboring areas are touched upon the reader is referred to the quoted review articles. Additional information on the biochemical aspects can also be found in several recent reviews[1-10].

2. Electrophysiological Basis

The primary physiological response of the postsynaptic cell to the stimulus exerted by acetylcholine is a brief change in its membrane potential in the region of the synapse. This is caused by openings of a specific ion channel which is an integral part of the receptor protein[12-14]. The channel has an effective pore size of approximately 7 Å and allows all cations with this or smaller ionic radius in the hydrated state to pass through. Thus, under physiological conditions there is a net influx of ions, mainly $Na^{\oplus}$, $K^{\oplus}$ and some $Ca^{2\oplus}$ ions, into the cell during cholinergic excitation.

Macroscopically two types of postsynaptic membrane currents are caused by the presynaptic release of acetylcholine[17-19]: The spontaneous miniature end-plate currents (mepc) are small, have a constant amplitude, and therefore probably result from the release of one "quantum" (often assumed to be the content of one presynaptic vesicle, about 4000—10000 molecules) of acetylcholine. The end-plate currents of usual size (epc) as they are observed after electrical stimulation of the presynaptic nerve ending and the resulting release of acetylcholine, are of larger amplitude and therefore relate to several hundred quanta of transmitter. The half-lives of end-plate currents caused by cholinergic excitation are of the order of millise-

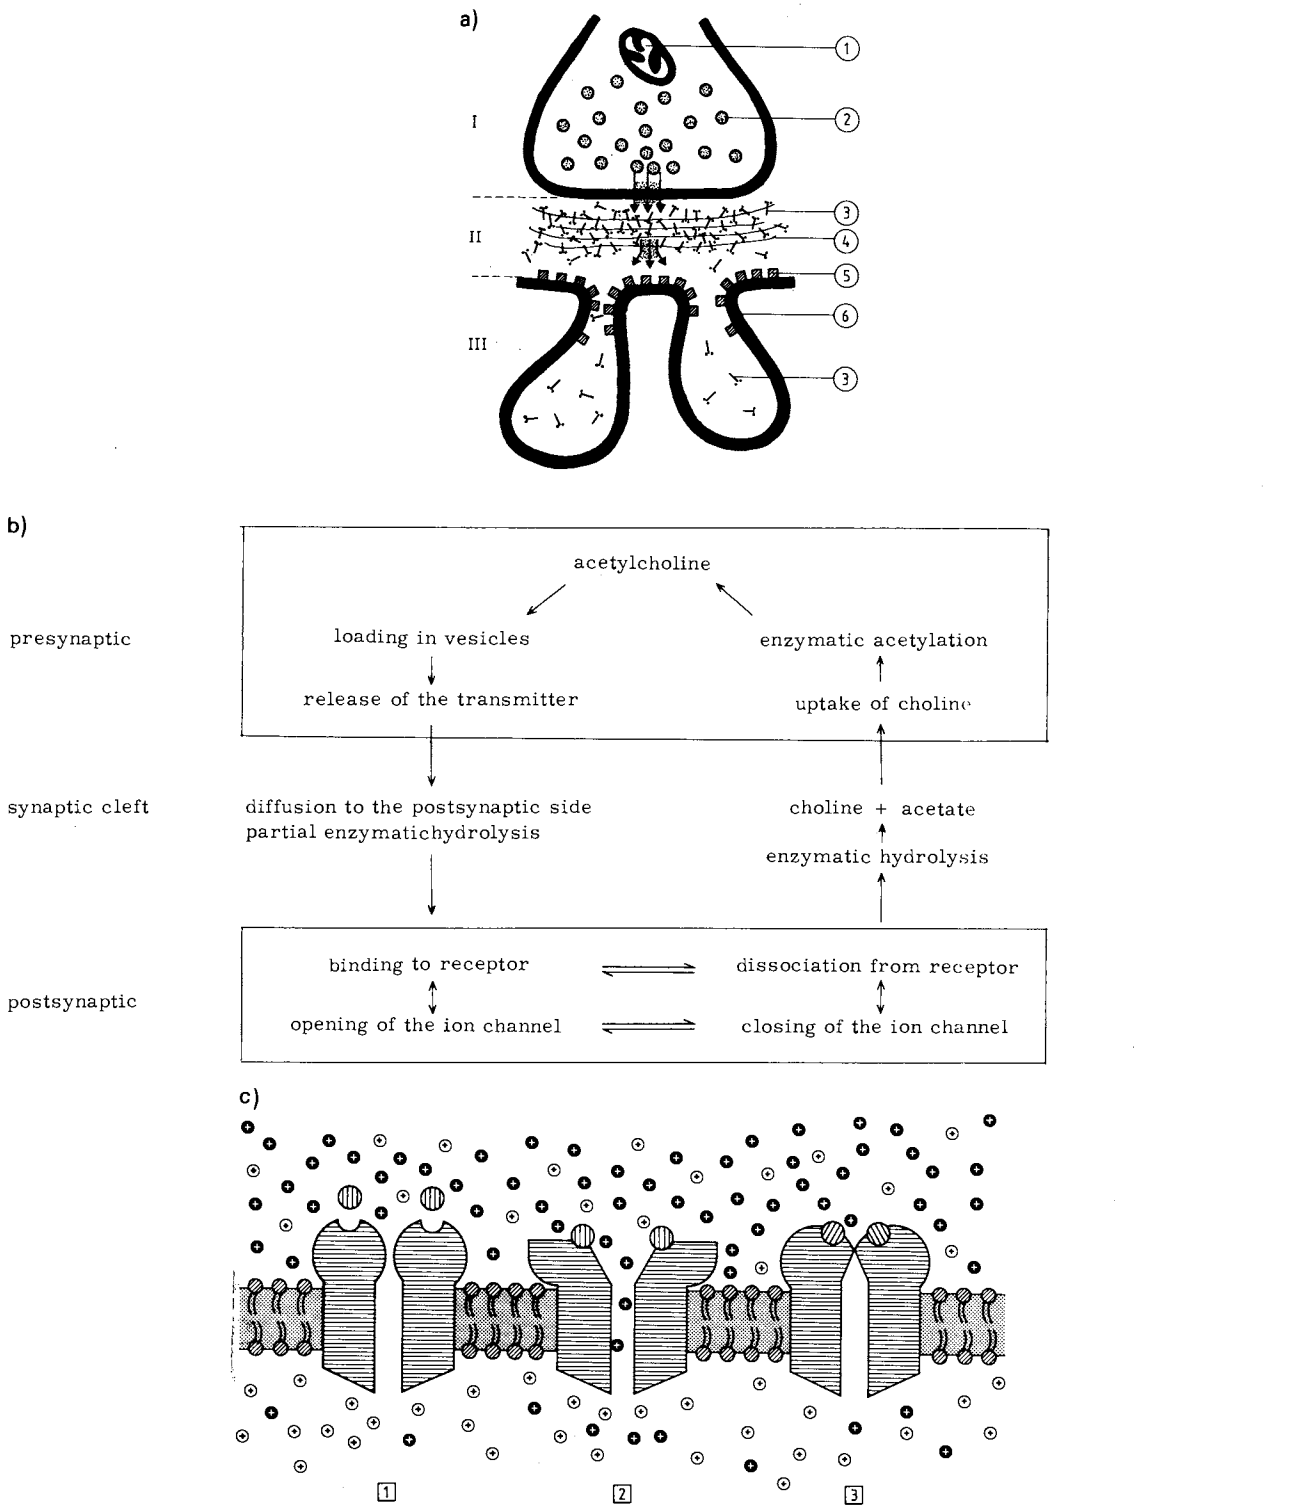

Fig. 1. a) Schematic presentation of a cholinergic synapse. Typical structures of the presynaptic nerve endings I are, apart from the mitochondrion ①, the transmitter-filled vesicles ②. The postsynaptic areas III of mammalian muscle cells are characterized by deep folds: The acetylcholine receptors ⑤ are mostly found in the button-like protrusions of the muscle cell plasma membrane ⑥. Acetylcholine esterase ③ is found in its different forms both in the synaptic cleft and also in the folds of the postsynaptic membrane. The collagen-like tail of some of its forms provides the esterase with additional affinity for the basal lamina ④. It is believed that the contents of one presynaptic vesicle (about 4000–10000 molecules of transmitter) is responsible for the smallest response observed (miniature end plate potential). The synaptic concentrations of acetylcholine receptor and esterase are of the same order of magnitude.—b) Sequence of reactions in the course of an event of cholinergic excitation. An axonal impulse initiates the presynaptic release of transmitter. Following diffusion through the narrow synaptic cleft, acetylcholine binds to its specific receptor, thereby causing short-lived openings and closings of the receptor-integral ion channel. Free and dissociated acetylcholine is hydrolyzed to choline and acetate by the acetylcholine esterase present in the synaptic cleft. Choline is taken up into the nerve ending by the presynaptic choline uptake system, is converted back into acetylcholine by cholineacetyltransferase (with acetyl-CoA and ATP), and reloaded into synaptic vesicles.—c) Model depicting three "states" of the receptor-regulated cation channel. In the absence of transmitter ◍ (or its agonists) the cation channel exists in the closed (*"resting"*) state (State [1]). Through binding of two transmitter molecules the ion channel is briefly opened (*"activated"*), thereby permitting the flow of certain cations along the existing ion gradients (State [2]). Under physiological conditions, predominantly $Na^{\oplus}$ ions flow into the cell thereby causing a depolarization of the plasma membrane. If transmitter remains bound to the receptor over longer periods of time (caused by high concentrations of transmitter as a result of increased transmitter release or of inactivated esterase), the ion channel converts to a persistently closed (*"desensitized"*) state (State [3]).

conds and depend on both the temperature and the existing membrane potential[20–26]. The variations in the synaptic cleft of the transmitter concentration during an event of cholinergic excitation have never been measured directly. On the basis of the existing electrophysiological and biochemical data, however, it appears likely that the observed currents are directly linked to the increase and decrease of transmitter concentration in the synaptic cleft. It can be estimated that after its presynaptic release the concentration of transmitter in the cleft briefly increases from the basal concentration of about 10^{-8} M to 10^{-3} M, and then drops back within a few milliseconds to its original level due to enzymatic hydrolysis and diffusion[10,27–31].

By reducing the area of observation and at the same time increasing the sensitivity of the measurements, it has become possible to directly measure the opening and closing of *single* ion channels in the postsynaptic membrane[32,33] (patch-clamp method Fig. 2). Single channel and noise measurements[34–36] have defined the following properties of the receptor-integral ion channel: The electrical conductivity of the open channel is of the order of 25 pS[37]; each channel contributes about 0.3 μV to the depolarization of the postsynaptic membrane. The opening rates of the channel decrease with increasing transmitter concentration to a few microseconds at saturating concentrations of agonist[38,39]. The closing kinetics of the channel are independent of the transmitter concentration; the mean open times of single channels are therefore constant and, depending on temperature and the nature of the ligand (agonist), are in the range of 0.5—5 msec[12,13,24,32,38,40–43].

The observed jumps in membrane conductivity (Fig. 2b) were originally identified as single channel events[32], for despite the same amplitude they differed from event to event in their duration (open time), showing a Gaussian distribution. Recent results[44–49] indicate, however, that the receptor-integral ion channel can exist not only in two states (one closed and one open) but that there exist several states of both the open and closed channel. These states differ in conductivity and mean open time (states of the open channel) or in their inactivity periods (states of the closed channel). At present, there does not exist structural or biochemical correlates to the distinct states of the receptor-channel defined by physiological measurements.

A further basic property of postsynaptic membranes is their ability to desensitize. Desensitization is defined as a decrease in response, i.e. current amplitude, under conditions of constant stimulation[50–56]. This effect can be viewed as a protective measure of the cell against prolonged depolarization. On the basis of their time constants, a fast (in the region of seconds) and a slow (in the region of seconds to minutes) desensitization can be distinguished. Desensitization is a property of the receptor saturated with transmitter or agonist and is reversed after removal of the inducing ligand. The rate of desensitization increases proportionally with increasing concentration of agonist; the effect is accelerated at increased temperatures[57], low $Na^{\oplus}$, or high $Ca^{2\oplus}$ concentration[58], in the presence of certain non-competitive ligands[57,59,60], and by hyperpolarization of the membrane[57]. Since resensitization can occur either quickly or relatively slowly[56,61] it appears that at least two reaction steps must exist, both for desensitization and resensitization[56]. Single channel experiments show that desensitization is not merely due to a decrease in the number of activated channels at the given agonist concentration, but that the properties of the remaining channels are also altered. The desensitized state is characterized by larger mean open times of the remaining channels, groups of opening and closing events, and long periods of inactivity between them[12,61].

This rather elaborate picture of the electrophysiological properties of postsynaptic membranes indicates that the molecule responsible for these properties must be a rather variable and therefore highly developed signal transducing system. Therefore, profound structural, chemical and biochemical studies are required to fully expose the molecular basis of the different functional states of the receptor. At the present level of molecular analysis, only rough structural correlates are available.

3. Pharmacological Basis

The receptor hypothesis developed by *Langley* et al.[62–64] states that substances which do not penetrate into cells

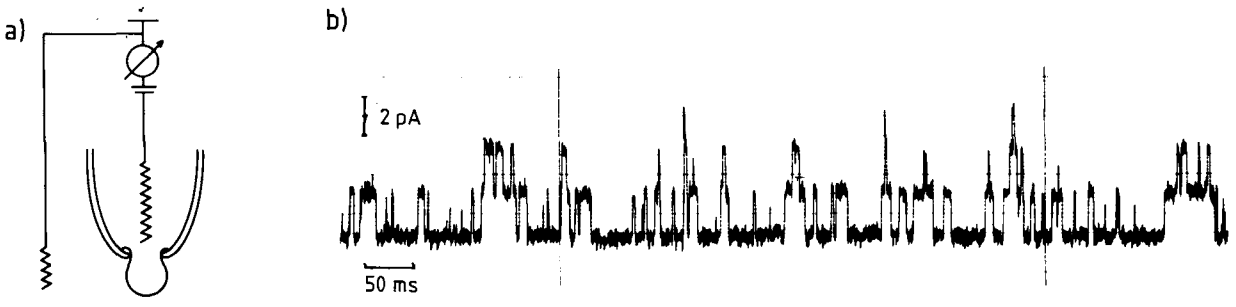

Fig. 2. Acetylcholine-induced changes in the electrical conductivity of single acetylcholine receptor-ion channels. a) According to *Hamill* et al. [33], a small patch of membrane of an embryonic rat muscle cell was sucked into the tip of a measuring pipette in such a way that a seal resistance of several GΩ resulted. The electrical activity of the membrane patch was then recorded under conditions of the voltage-clamp. This method is called "patch clamp" and permits the recording of single channel events from these membranes. The pipette solutions were made as follows: Inner solution 150 mM KCl, 1 mM EGTA, 4 mM HEPES, pH 7.2; outer solution, 150 mM NaCl, 2 mM $CaCl_2$, 2 mM $MgCl_2$, 4 mM KCl, 4 mM HEPES, pH 7.2. The membrane potential was set to −70 mV corresponding to a slight hyperpolarization of the muscle membrane. Temperature 25°C.—b) The measured events were observed after addition of acetylcholine (2 μM) to the outer solution. As can be seen from the different levels of amplitude, double and triple channel events were observed in addition to single channel events (simultaneous activation of two or three receptor channels). These measurements were carried out by Dr. *C. Methfessel*, Universität Bochum.

can influence their function by binding to specific molecular structures on their surface—the receptors. This binding induces physical changes in the receptor (e.g. changes in the conformation or in the charge distribution), which can regulate the properties of the cell membrane or of intracellular reactions.

While pharmacologists view the receptor as a purely operative entity, biochemists link it to the concept of the molecule or molecular complex. This has led to expansions of the pharmacological definition in that for several receptor systems a strong structural link has been established between the actual binding site(s) and the regulatory function affected by these. In the specific system discussed here, the acetylcholine receptor is not only defined as the site or subunit to which the cholinergic ligands bind, but as the whole molecule. This comprises five subunits ($\alpha_2\beta\gamma\delta$) and contains also the cation channel regulated by the ligand binding sites[10-13,31]. As we shall see, this molecular concept of the receptor is advantageous also because there exist several types of ligands of the acetylcholine receptor and these may bind to several structurally distinct binding sites. In contrast, the classical definition of the receptor as a specific binding site could easily lead to confusion if all the different classes of ligands (including modulators) and their binding sites were considered.

According to the classical occupation model[65] there are only two types of ligands which can bind to the same receptor (the same binding site): Agonists whose binding induces a response, and antagonists whose binding does not induce a response but blocks the binding and, thus, the response induced by agonists. On the basis of our present understanding of how receptors function, however, this classification is no longer adequate. Nowadays the following classes of ligands are considered[10,35,36,66-68]:

1) *Agonists*. These, like acetylcholine, briefly increase the conductivity of the end plates for certain cations, thereby reducing the existing membrane potential (they act as depolarizing agents).
2) *Antagonists*. These compete with agonists for binding to the receptor but are not capable of causing an increase in membrane conductivity. Thus, they block in an apparently competitive manner the depolarization induced by agonists.
3) *Partial Agonists*. These possess both antagonist and agonist properties. They cannot produce the maximal increase in conductivity caused by pure agonists.

4a) *Non-competitive Blockers*. These influence the properties of the receptor-regulated ion channel by binding to sites separate from those for pure agonists or antagonists. Typical members of this class of ligands are certain local anaesthetics.

4b) *Direct Channel Blockers*. These block the receptor-regulated ion channel directly, i.e. by binding to site(s) at the channel and separate from those for agonists and antagonists. There does not exist a clear-cut biochemical distinction between direct channel blockers and the previously mentioned non-competitive blockers.

The following models have been developed on the basis of the physiological data to describe the concentration and time dependence of the effects caused by the different types of ligands on the receptor-controlled ion channel:

a) From the concentration dependence of channel activation it is concluded that at least two molecules of transmitter (or agonist) must be bound to the receptor to induce the opening of the integral ion channel. In equation (a) R,

$$R \overset{+A}{\rightleftharpoons} AR \overset{+A}{\rightleftharpoons} ARA \underset{\alpha}{\overset{\beta}{\rightleftharpoons}} (ARA)^* \qquad (a)$$

AR and ARA denote closed (inactive) states; (ARA)* denotes an open (active) state of the ion channel; k_β and k_α are the rate constants for the opening and closing of the channel (the mean open time is determined by k_α). Note that only the last reaction step is physiologically measurable and that data concerning the preceding steps can only be implied from physiological data.

b) Competitive blockers (antagonists) bind at the same sites as agonists, but cannot activate the ion channel ($k_\beta = 0$). They therefore hinder the activation of the channel by agonists [eq. (b)].

$$R \overset{+B}{\rightleftharpoons} BR \overset{+B}{\rightleftharpoons} BRB \qquad (b)$$

c) Non-competitive blockers (local anaesthetics) bind at their own binding sites at the receptor-ion channel already activated by agonists (open channel) [eq. (c)].

$$(ARA)^* + L \rightleftharpoons [(ARA)^*L] \qquad (c)$$

According to *Adams*[35] these binding sites are situated inside the channel, resulting in the following two consequences: firstly, occupation of these sites reduces channel conductivity (partial repolarization); secondly, the open state of the channel is stabilized or "frozen" (longer channel open time, k_α drops).

d) Other non-competitive blockers appear to act through binding to both the open and the closed channel or through binding to only the closed channel conformation[36].

In summary, the major effects of the different ligands on the receptor integral ion channel can be explained by the assumption of several states of the agonist-saturated receptor.

These are the inactive state ARA, the active state (ARA)*, and the modified active state [(ARA)*L]. Considering, however, that by electrophysiological methods several more open and closed states of the receptor channel can be distinguished[44-49], these models can only be a rough approximation of the true situation. The same conclusion can be drawn from a consideration of the structure of the various ligands (Fig. 3): 1) Considerable structural differences exist even within each class of cholinergic ligands. 2) The different affinities and reactivities of cholinergic ligands indicate that even ligands competing with each other probably do not bind to totally identical binding sites. The larger, more hydrophobic or more highly charged ligands have additional binding contacts with the receptor ("subsites"), or they bind to totally different bind-

ing sites with allosteric effects causing the observed competition. 3) The fact that the classification of the individual nicotinic ligands and also their relative potencies differ from one nicotinic system to the next also points to different and/or only partially overlapping points of attachment of the different ligands and the receptor.

This complicated situation is reflected in the models discussed for the interaction of ligands with neuroreceptors. As an alternative to the classical occupation model of pharmacology, in which binding of all ligands to identical binding sites is assumed, allosteric models were proposed rather early[70–74]. According to these, two ligands can still fully compete with each other (mutually exclusive binding), even if they bind to different binding sites. This can happen if binding of one ligand to its binding site alters the structure of the binding site for the other ligand so that its affinity of binding drops by several orders of magnitude[74]. The specific allosteric model[72,73] of *Monod* et al.[75] makes the additional postulate that different states (forms) of the receptor ion channel already exist *in the absence* of ligands, and that ligands merely shift the existing equilibrium of forms in favor of particular forms. Similarly to the other allosteric models, the specific allosteric model can also explain partial agonism in simple terms[76]. None of the existing models has as yet been proven. For a detailed discussion of the various approaches used to describe the dependence of activation on ligand concentration see [1,3,5,7,81,82].

4. Quantitative Pharmacological and Physiological Aspects

4.1. Dose-Response Relationships

These express the quantitative relationship between the magnitude of a physiological response and the concentration of a compound. They are the easier to interpret on a molecular basis the closer the effect under investigation is linked to the binding reaction. For instance, in the case of the cholinergic system, measurements of the changes in membrane conductivity (primary response) are preferable to measurements of muscle contraction (secondary response). Fundamentally, however, dose-response curves can only be interpreted in molecular terms *after* the underlying molecular mechanism—and thus when the true functional relationship between receptor saturation and response—has been established. In addition, there exist many experimental limitations in a system of such functional complexity. At higher concentrations of agonist, for instance, the phenomenon of desensitization becomes increasingly apparent. This is why potencies are often deter-

◀ Fig. 3. Structural formulas of typical ligands of the nicotinic acetylcholine receptor. In the case of salts, only the cations are shown.—a) Structure and favored conformation of the natural transmitter acetylcholine (ACh).—b) Structures of some nicotinic agonists of acetylcholine: **1**: carbamoylcholine, **2**: acetylthiocholine, **3**: thiocholine, **4**: substituted acetylcholines such as bromoacetylcholine (**4a**), acylcholines (**4b**) and "NBD-n-acylcholines" (trimethyl-2-[ω-(7-nitro-4-benzofurazanylamino)-*n*-alkylcarbonyloxy]ethylammonium ion, **4c**), **5**: sulfonium analogue of acetylcholine, **6**: nicotine, **7**: protonated cytisine [69], **8**: "bismethonium compounds" (hexamethyl-*N,N'*-polymethylenediammonium ions) with $n>6$, **9**: suberoyldicholine.—c) Structures of some nicotinic antagonists of acetylcholine: **10**: triethyl analogue of acetylcholine, **11**: acetylcholinamine, **12**: "bismethonium compounds" (hexamethyl-*N,N'*-oligomethylenediammonium ions) with $n\leq 6$, **13**: tubocurarine, **14**: trimethaphane, **15**: β-erythroidine, **16**: gallamine.

mined relative to a standard by comparing at relatively low concentrations (i.e. in a concentration range in which desensitization is negligible) the concentrations producing the same response.

Leaving aside their quantitative reliability, the dose-response curves have been found to be sigmoid in shape for all cholinergic agonists tested[51,77-79], and to yield Hill-coefficients of between 1.5 and 2[51,77,78] or 2.7[79]. Assuming simultaneous binding of the agonist molecules to the receptor, this would imply the presence of two or more agonist binding sites at the receptor with positively cooperative interactions between these sites. Alternatively, non-integer Hill coefficients[*] of less than 2 could be explained by an ordered binding of two agonist molecules to the receptor, since the related Hill plot would initially have a slope of 2, approaching a slope of 1 at very high agonist concentrations[80].

Any interpretation of Hill-coefficients on the basis of the number of binding sites at a receptor molecule implies that receptor saturation and induced response are directly proportional to each other. This is clearly not the case. For instance, all recent physiological data on the acetylcholine receptor-ion channel imply that it is activated only after *two* molecules of agonist have been bound. Thus, if one assumes direct proportionality only between the concentration of the fully saturated receptor (and not of the total number of binding sites) and the induced response, sigmoid dose-response curves could result even if no cooperativity exists between the two binding sites at the receptor[31,81,82]. Consequently, neither the shape of dose-response curves nor the size of the Hill coefficient are of much analytical value with respect to the molecular mechanism underlying the receptor-ligand interaction under study.

In contrast, the concentration of agonist at which half-maximal response is achieved is of important analytical value. Assuming that the response is directly proportional to saturation of both or of the second of the two binding sites per receptor molecule, this concentration is equal to the equilibrium dissociation constant for the saturation of the second binding site. Table 1 lists the half maximal concentrations and the Hill coefficients for some representative cholinergic ligands.

Table 1. Concentrations for half-maximal response and Hill coefficients of some cholinergic agonists [a].

Ligand	K_{app} [μM]	n	n_d
Acetylcholine	27.8	2.7	2
Carbamoylcholine	336	2.2	1.8
Suberoyldicholine	18	—	—
Nicotine	—	1.7	1.5

[a] After *Peper* et al. [79]. The data were obtained at room temperature on frog skeletal muscle fibers. K_{app}: concentration for half-maximal response; n, n_d: Hill coefficients, measured on normal and denervated muscle cell. For further K_{app} values see Table 3.

[*] The Hill coefficient is the slope of the middle, linear part of the curve obtained on plotting $\log z/(z_{00}-z)$ against $\log A$ where z, z_{00} and A denote the response z and maximal response z_{00} effected by the agonist concentration A.

4.2. Maximal Response

According to the classic occupation model[65], the response amplitude solely depends on the degree of receptor saturation, with all agonists therefore producing the same maximal response. This does not apply to the cholinergic system. For instance the maximal response to carbamoylcholine at frog muscle fibers is only about 80% of that to acetylcholine[79]. Agonists with smaller maximal response are called "partial agonists" (see Section 3) and are assumed to possess a smaller "intrinsic activity"[83] or "efficacy"[84] than agonists. *Ariens'* concept[83] keeps the direct relationship between receptor saturation and response and assigns an intrinsic activity of 1 to all full agonists. *Stephenson*[84] assumes that different ligands induce the maximal response by achieving different levels of receptor occupation. Other explanations for the differing maximal responses of agonists and for partial agonism appear to be equally plausible[10]. Consequently, direct studies of receptor-ligand interactions are required to establish the correct mechanism.

4.3. Chemical Modulation of the Response

When *Karlin* and *Bartels*[85] demonstrated in 1966 that the response of the electroplaque end plate to acetylcholine and a few agonists was greatly reduced after incubation with dithiothreitol (DTT) or *p*-chloromercuriobenzoate (PCMP), this was considered important evidence supporting the protein nature of the acetylcholine receptor. Later, it was shown[86,87] that DTT opens a specific disulfide bridge in the immediate vicinity of the binding site for acetylcholine at the receptor. This makes the freed SH-groups excellent targets for irreversible affinity labeling of the receptor—for instance with bromoacetylcholine or [4-(*N*-maleimido)benzyl]trimethylammonium iodide (MBTA). The reaction with DTT also changes the potency and/or the pharmacological classification of some of the cholinergic ligands tested[82,86-91]. For instance, the concentration of acetylcholine required for half-maximal response of the electroplaque cell of the electric eel is increased by approximately one order of magnitude and the cholinergic antagonist **8**, n = 6 (Fig. 3) is rendered an agonist. Equally noteworthy is the fact that many partial agonists are rendered full agonists of acetylcholine after treatment with DTT. The redox state of the disulfide bridges of the receptor also appears to be linked to the phenomenon of desensitization[92]. Chemical modifications at the specific disulfide bridge and their effects on the properties of the receptor have therefore become important tools in the biochemical analysis of the function of the receptor[82,90-95].

5. Biochemical Preparations and the Structure of the Acetylcholine Receptor

The biochemical characterization of nicotinic acetylcholine receptors began with *Lee*'s discovery of the antagonistic effect of the so-called α-toxins in the venoms of the snake family *Elapidae*[96]. These toxins (e.g. α-bungarotoxin, α-cobratoxin) bind with high affinity to and in particu-

lar dissociate extremely slowly from the receptor. They are therefore particularly suitable as affinity ligands. Initially even more important was the specificity of their action. In contrast to all low molecular weight antagonists (and agonists), they do not bind to acetylcholine esterase and, therefore, for the first time enabled unequivocal differentiation between the receptor and this synaptic enzyme. Meanwhile, binding sites for α-neurotoxins have been found in many tissues including the brain[91,97-102], the retina[103-105], sperm[106], and sympathetic ganglia[107] of mammals and other classes of animals[108-112]. In some systems these toxin binding proteins display similarities to the established nicotinic receptors[108,112-114], in others this is not quite as clear[115-117]. Of all the tissues from which acetylcholine receptors have been isolated in a pure form—the electric organs of the electric ray and the electric eel, various types of muscle tissue and cultivated muscle cells[118-131]—we shall limit ourselves here to the electric tissue. While from a medical and biological point of view the acetylcholine receptors of the brain and of mammalian muscle appear to be much more interesting, such larger amounts of receptor can be isolated from electric tissue that for almost all intensive biochemical studies this has been the source of choice.

The critical problem with every subcellular fractionation and purification of the acetylcholine receptor is the control of cellular protease activity. In particular, as SH- and Ca-activated proteases appear to be of importance in this connection[125,127,132,133]. If these are inhibited, sufficiently stable and structurally well defined receptor preparations can be obtained.

5.1. The Membrane-Bound Receptor

Using highly resolved autoradiography after labeling with radioactive α-toxin, the packing density of acetylcholine receptors in the region of the synapses has been shown to be much higher than in the extrasynaptic regions[134]. In synaptic regions the receptor density reaches 30000 molecules per μm^2[134,135], whereas only around 500 molecules per μm^2 are found in the extrasynaptic regions. Since the protein to lipid ratio is unusually high (>1.5)[136] in the subsynaptic regions, such membrane patches can easily be separated from other membrane fragments in density gradients after tissue homogenization. Receptor-rich membrane fragments from *Torpedo* electric organs obtained in this way already contain the receptor as the main protein component.

After removal of some peripheral proteins by alkaline treatment[137], the receptor in these membranes is finally concentrated to approximately 40—50%. Alkaline treatment leaves the fatty acid and phospholipid composition of the membranes largely unchanged[138]: The ratio of cholesterol to phospholipid is close to 0.4[139], that of phosphatidylcholine to phosphatidylethanolamine about 1[138-140]. The most striking result of the alkaline treatment is therefore the removal of a peripheral membrane protein (α', $M_r \approx 43000$) which is closely associated with the receptor and appears to have a structure-stabilizing effect[137,141-143]. After its removal, the receptor displays increased mobility in the membrane[94,163-165].

Electron micrographs after negative staining of such membranes from *Torpedo* show a high density of rosette-like structures (Fig. 4a) which are sometimes ordered in pseudohexagonal rows (not visible in Fig. 4). The doughnut- or horseshoe-like structures have a diameter of 7—9 nm with a heavily stained central pit of about 2 nm. Side views of negatively stained membranes and freeze-fracture experiments, show the receptor to project by about 5 nm on the extracellular side and by about 1.5 nm on the cytoplasmic side out of the membrane. By mathematical correlation and averaging over a large number of particles a structural model of the receptor (Fig. 4) has been developed from these data[143-153]. The results obtained are further supported by small angle X-ray scattering and neutron diffraction experiments[145,154]. From a large number of direct and indirect experiments it can be concluded that the observed ring structures are indeed acetylcholine receptors. Furthermore, it is clear that, at least at the present resolution of the experiments, no larger structural or functional changes have occurred in the receptor due to the use of contrast materials[155]. Raman spectroscopic studies[156] indicate a high content of α-helix structures in the receptor-rich membranes.

SDS gels of receptor-rich membrane fragments from *Torpedo* exhibit before alkaline treatment two, after alkaline treatment one major protein band and several minor bands corresponding to molecular weights of 40000 (43000), 50000, 60000; 68000 and 90000[132,140,157-161]. Of these the 43000-polypeptide is a peripheral membrane protein and the 90000-polypeptide a subunit of ATPase. Belonging to non-receptor proteins, these two bands are not observed in the gels of the purified receptor protein. With the help of selective proteolysis[172] and of antibodies[166,167] it has been shown that all four receptor polypeptides (subunits) protude the lipid membrane, while the 43000 non-receptor polypeptide is only accessible from the cytoplasmic side of the membrane[162].

Receptor-rich membrane fragments represent an unusually highly concentrated "natural" receptor preparation. They are particularly useful for studying the ligand interactions of the receptor (Section 6), the agonist induced changes in membrane conductivity[9], and ion-fluxes[2,6]. They therefore represent the simplest natural systems for the study of cholinergic excitation.

5.2. The Purified Receptor Protein

Being an integral membrane protein, the acetylcholine receptor protein is insoluble in water. It can only be kept dispersed in aqueous solution in association with detergents in the form of micelles. In order not to affect the binding function, non-ionic detergents are usually employed to disperse the receptor. It is common practice to use detergents with a low critical micelle concentration (cmc) for initial solubilization and to replace these by milder detergents during the purification procedure[118-120,125].

Typical purification procedures[125] begin with the homogenization of the electric organ in the presence of suitable protease inhibitors. The membrane fragments are then

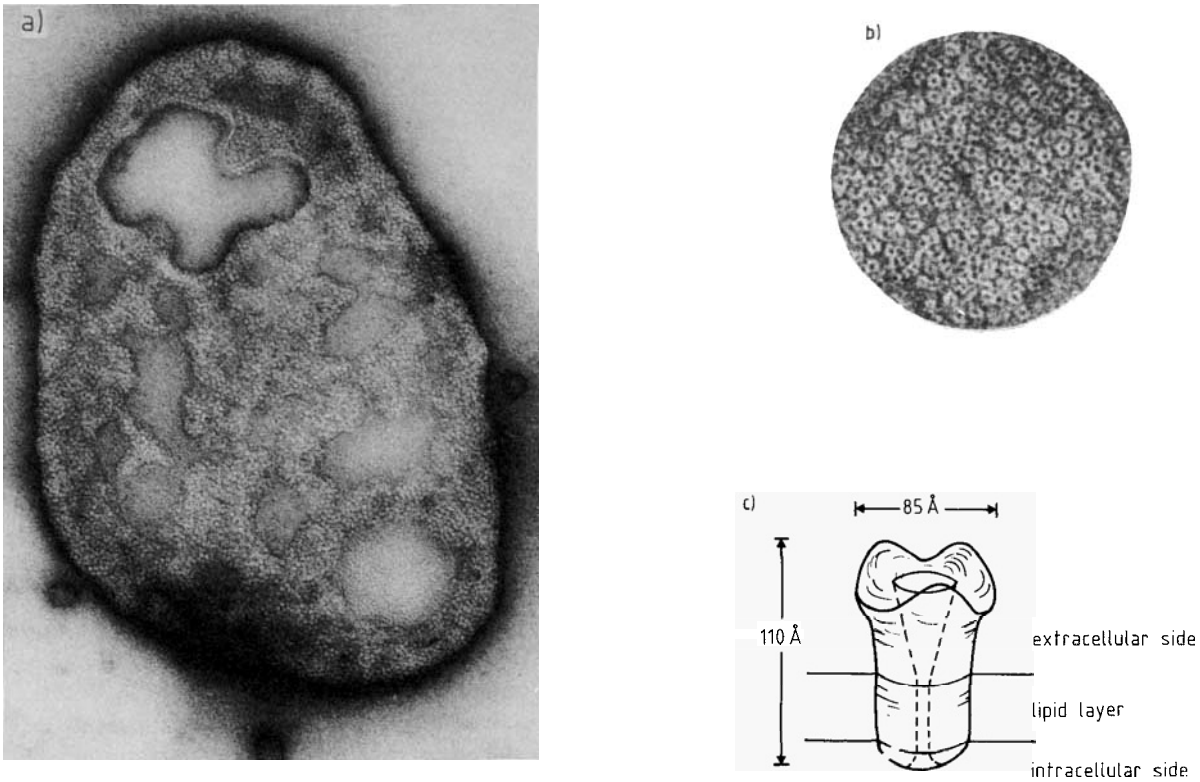

Fig. 4. a) Electron micrographs of receptor-rich membrane vesicles from *Torpedo marmorata*. Membrane vesicles in 20 mM phosphate buffer, pH 7.4 were negatively stained with 1% phosphotungstic acid of the same pH. Magnification ca. 85000 ×.—b) Enlarged section of (a).—c) Three-dimensional model of the acetylcholine receptor based on electron microscopic data. The electron micrograph was obtained by *S. Reinhardt*, Institut für Biochemie der Freien Universität Berlin [155]; the model has been drawn according to *Kistler* et al. [150].

centrifuged and "washed" several times in buffers of differing ionic strength. After removal by filtration of remaining connective tissue, the membrane suspension is incubated with a non-ionic detergent (final concentration 1%) and, after stirring for one hour, is centrifuged in the ultracentrifuge at about 50000 g for 2 hours. The solubilized receptor in the centrifuge supernatant can then be purified by affinity chromatography.

Several alternative procedures are available for affinity chromatography of the receptor: 1) The classical method uses α-neurotoxins as affinity ligands[118–120]. Because of their high affinities and low dissociation rate constants, the α-neurotoxins guarantee an optimal separation of the receptor from contaminating proteins including the acetylcholine esterase. The expected problem of the receptor being difficult to displace from the immobilized ligand owing to the small dissociation rate constants of these complexes does not apply because the dissociation rate of receptor-toxin complexes is accelerated by several orders of magnitude in the presence of higher concentrations of low molecular weight ligands[74, 168, 169]. 2) Since their complexes with the receptor dissociate very rapidly, ligands of low molecular weight are less suitable as affinity ligands. While the stability of their complexes with the receptor appears to increase after immobilization, such affinity columns can not be washed as rigorously as is common practice for toxin affinity columns. Consequently, low molecular weight affinity ligands have proved useful only for preparations which do not require a large enrichment of the receptor[170]. 3) As reversible ligands, monoclonal antibodies against the receptor protein[159, 171–176] are also potentially suitable for the purification of the receptor. Because of the success of the previously mentioned methods, however, they have not yet found broad application with this particular receptor system[177]. 4) Since the receptor is a glycoprotein with significant affinity for certain plant lectins[120, 121, 178–181] it can also be purified by means of immobilized lectins. Such affinity columns, however, have only found application as a second step of the purification procedure and with questionable success[121].

The classical purification procedure by means of toxin affinity columns[119–125, 168] uses α-cobratoxin immobilized on CNBr-activated Sepharose. In order to facilitate the dissociation of the biospecifically adsorbed receptor from the affinity gel, gels of low toxin binding capacity are employed[125, 168]. In this way it is avoided that the majority of receptor molecules is bound to more than one toxin molecule at the gel matrix which would dramatically decrease the probability of dissociation[182]. Affinity gel and membrane extract are mixed slowly with stirring for several hours, and the column is then washed with different buffers. After all contaminating protein is washed out, the receptor is eluted with an antagonist-containing buffer (0.005–0.1 M **8**, $n = 6$[125, 168]). The receptor-containing eluate is applied to a column (hydroxyapatite[119]) whose gel binds the receptor but not the ligand employed for affinity elution. The receptor-free ligand solution is then recycled to the affinity column[119] for further competitive

displacement of the receptor from the affinity matrix. When after a few hours the receptor is completely eluted from the toxin column and bound to the hydroxyapatite column, the latter is disconnected and washed. Finally the receptor is eluted from the hydroxyapatite column with phosphate buffer. In this way 30–100 mg of pure receptor protein can be obtained from 1 kg of the electric organ of *Torpedo*[125]. Employing the standard method the purified receptor protein is contaminated with less than 0.1% of esterase activity[125].

As shown by electrophoresis, isoelectric focussing, sedimentation in density gradients, equilibrium sedimentation studies, and laser light scattering[125, 183–185], the purified receptor is obtained as a mixture of monomers and dimers (Fig. 5). Treatment with disulfide reducing agents or with high concentrations of certain non-ionic detergents completely converts the dimers into receptor monomers[125, 157, 160, 186–189]. Preparations from the electric ray *(Torpedo)* contain much higher concentrations of dimer than those of the electric eel *(Electrophorus)* under the same experimental conditions[125].

The existence of two forms each of the receptor monomer and the receptor dimer from *Torpedo* (Fig. 5, [125]) suggests that the receptor can exist in non-globular forms in solution. These different forms of the receptor appear to be in equilibrium with each other and to be dependent on the nature and concentration of the bound detergent and also on the redox state of some cystein residues (Fig. 5). This multiplicity of forms may have been responsible for the perennial controversies surrounding the hydrodynamic properties and the molecular weight of the receptor[1, 2, 4].

At present the following data seem to be established. The receptor from *Electrophorus* (mostly monomer, see Fig. 5, [125]) dissolved in non-ionic detergent has a Stoke radius of 7 nm[119, 120, 190], the monomer and dimer from *Torpedo* receptor Stoke radii of 7 nm and 8.5 nm, respectively[191, 192]. By measurement of sucrose gradients[193] or sedimentation rates[125], a sedimentation coefficient of about 9 S is found for the eel receptor and of 9.3 and 14.4 S, respectively, for the monomer and dimer from *Torpedo*. Monomer and dimer do not spontaneously interconvert and, therefore, can be investigated separately after separation in density gradients. In this way, ultracentrifuge studies employing the density matching procedure of *Tanford*[194, 195] yielded a molecular weight of $250\,000 \pm 7000$[196] or $275\,000 \pm 15\,000$[125, 185] for the receptor monomer from *Torpedo*. For the receptor monomer from *Electrophorus* a molecular weight of $262\,000 \pm 12\,000$ has been obtained with the ultracentrifuge and of $287\,000 \pm 8000$ by means of laser light scattering[125, 185]. From the known amino acid sequences of all subunits of the *Torpedo* receptor[197–201] and assuming a subunit composition of $\alpha_2\beta\gamma\delta$[202], a molecular weight for the monomer of 268 000 can be calculated. From the translational diffusion coefficient $D_{20,w} = 2.95 \times 10^{-7}$ cm^2 s^{-1} and the sedimentation coefficient $S_{20,w} = 9.29$[125], the ratio of the friction coefficients f/f_0 is calculated as 1.51[*], indicating considerable structural asymmetry of the receptor monomer from *Torpedo* when dissolved in low concentrations of detergent (0.05% Tween

[*] f_0 is the friction coefficient of a spherical object; f/f_0 is therefore a measure of the deviation from sphericity.

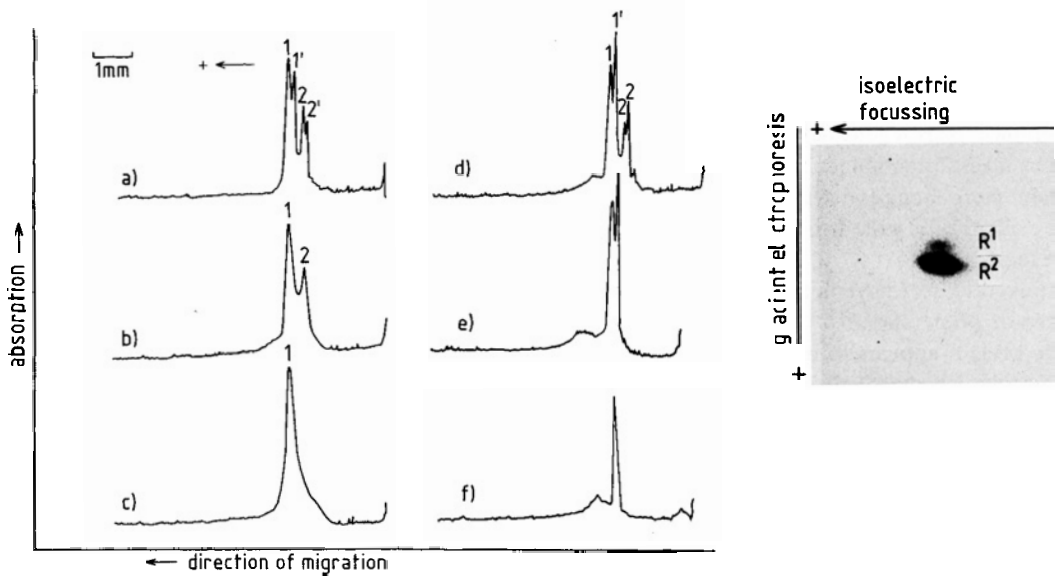

Fig. 5. Gel electrophoresis of the purified acetylcholine receptor from *Torpedo marmorata* under different conditions.—(Left): The receptor was subjected to anodic electrophoresis in the presence of a) 0.1% octylglucoside, b) 20 mM dithiothreitol and c) 20 mM dithiothreitol with 1% Triton X-100. Under non-denaturing conditions in low concentrations of a mild detergent (a), the receptor exists in two forms each of the monomer (1,1') and of the dimer (2,2'). By treatment with disulfide-reducing agents (b), the two dimeric forms are completely converted into the monomeric forms. The two monomeric forms are completely interconvertible if the properties of the receptor-detergent micelle are correspondingly changed through changes in the concentration or type of the detergent (c).—(Middle): Anodic electrophoresis in cylindrical gradient microgels of the purified *Torpedo* receptor in the presence of (d) 0.05% Tween 80, (e) 0.4% Triton X-100 and (f) 2% Triton X-100. In comparison to the experiments described on the left, it is shown that the conversion of dimers into monomers and of the two monomers into a single monomer can also be achieved by non-ionic detergents alone.—(Right): Two-dimensional microelectrophoresis of the acetylcholine receptor from *Electrophorus electricus* and labeling of the bands with ^{125}I-α-bungarotoxin. Two receptor-toxin complexes differing in their size but not in their isoelectric point are observed [125].

80). The relatively low values of $D_{20,w}$ and $S_{20,w}$ for a molecule of this size also point to a relatively loose (e.g. partially unfolded) structure of the receptor in solution.

Comparing the apparent molecular weights of the receptor subunits as obtained by SDS-polyacrylamide gel electrophoresis with the exact data from the protein sequences[197-201], the electrophoretic method turns out to be rather unreliable for this integral membrane protein. From SDS gel electrophoresis the following apparent molecular weights for the subunits (exact values from gene sequencing in brackets) have been obtained: 40000 (50200), 50000 (53681), 60000 (56279), and 67000 (57565). Accordingly, the typical band pattern of the receptor[68, 87, 120, 121, 123, 136, 140, 179, 183, 186, 203, 204] is due to an electrophoretic artifact resulting from either differing affinities for detergent or differences in form and or packing densities of the subunits. The same artificial separation is also observed after cross-linking the subunits with bifunctional reagents[203,204], a technique believed to permit complete introduction of membrane proteins into SDS-micelles. It is therefore unlikely that the erroneous apparent molecular weights of the subunits are due to the use of water-soluble proteins as molecular weight standards[205]. Thus, the irregular deviations from the exact values probably reflect structural differences of the SDS-denatured subunits.

The strong influence of the surrounding detergent—and by inference the surrounding lipids in the membrane-bound state—on the structure of the receptor is also reflected by the fact that *Torpedo* receptor dimers can be converted into monomers merely by the presence of higher concentrations of certain non-ionic detergents (Fig. 5[125,157,205-207]). This implies that the disulfide bridges connecting the δ-subunits of dimers[186-188] can be cleaved *without* external disulfide-reducing reagents. The detergent-induced opening of the δ-δ-disulfide bridge requires, however, the existence of free SH-groups in the receptor structure[125]. Hence, cleavage of this disulfide bridge is probably not a reduction but a rearrangement of disulfide and SH-groups induced by a conformational change of the receptor to accommodate more bound detergent molecules. This is additional evidence for wide structural flexibility of the receptor protein.

Since only δ-subunit linked dimers have been found in the various *Torpedo* receptor preparations[186-188], the formation of these disulfide bridges appears to be a specific event. It is not clear, however, whether their formation is caused by the lattice-like arrangement of receptor molecules in the subsynaptic area[151,152] or whether the presence of certain accompanying membrane components is required[186]. In contrast, cleavage of the disulfide bridges does not appear to require[125] the presence of the postulated[186,187] special membrane component—"a protein that contains SH-groups with unusually low redox potential and with close proximity to the receptor"[186]. Cleavage and re-formation of the disulfide bridge therefore varies with the reaction conditions and can lead to different results[187,189].

It has been postulated that the dimer represents the biologically active form of the receptor[187]. Accordingly, the high content of monomers observed in most preparations of purified receptor[118-131] would have to be the result of side reactions during solubilization of the receptor (caused, e.g., by the exposure of intramolecular SH-groups[188]—about 25% of the receptor's cysteines are free, the others form disulfides[186,188]). Physiological, biochemical and reconstitution experiments[12,14,82,85,90,91], however, contradict this hypothesis; at present only minor if any modulations of receptor properties due to dimer formation appear to be likely. A quantitative comparison of the properties of receptor monomers and dimers has as yet only been carried out for the interaction with α-cobratoxin[125]. For this reaction no fundamental differences were detected.

The purified receptor has a relatively low isoelectric point of $pH_I \approx 5$[118,208,209], with small differences between synaptic and extrasynaptic receptors[210]. All subunits of the receptor are glycoproteins and therefore bind to concanavalin A and other plant lectins[120,162,179,210-212].

While protein sequencing of the receptor subunits has advanced only very slowly[201,213,214], cloning of the genes of all subunits of the *Torpedo* receptor[197-201] and the α-subunits of the calf and human muscle receptors[215] has yielded the complete sequences of these. With these at hand, many basic problems concerning the structure and function of the acetylcholine receptor can be analyzed in quantitative molecular terms. These include the exact sequence positions of the ligand binding sites, of the integral ion channel, of the disulfide bridge near the binding sites for agonists and the positions for phosphorylation[216-223], *N*-glycosylation[224], and methylation[225].

On the basis of the sequence data for the *Torpedo* receptor, hydrophobicity profiles[226] have been calculated and secondary structures[227] postulated. According to these, every subunit of *Torpedo* receptor contains four sequence segments which protrude the membrane and, therefore, could take part in the formation of the receptor-integral ion channel[197,200,201,215]. The strong sequence homologies between the α-subunits of *Torpedo*, calf and human receptors suggest that all these receptors are built into the surrounding membrane according to the same structural principles[215].

Because of the absence of a compartment border, ion fluxes and other electrical responses cannot be measured with solubilized receptor. These preparations are therefore limited to the study of such properties of the receptor that solely require an intact protein structure and do not depend on the membrane potential or the existence of ion gradients. Under these conditions studies with the purified receptor can reach an accuracy comparable with that of biochemical studies of water-soluble proteins such as enzymes.

5.3. The Reconstituted Receptor

Initially, the acetylcholine receptor was purified only as a binding protein for cholinergic ligands[118-132]. This also complied with the classical pharmacological concept of the receptor as specific binding site[62-64]. It was then shown by the reconstitution experiments described below that the affinity-purified receptor molecule not only con-

tains the binding sites for agonists but also the ion channel controlled by these[12]. Reconstitution experiments, therefore, are of fundamental conceptional value. More recently, they have also become useful preparations in the study of the effects of membrane structure and composition on the properties of the receptor and its integral ion channel.

Basically, reconstitution of the acetylcholine receptor is defined as the reincorporation of the purified receptor protein into a lipid membrane and the positive proof of agonist-dependent changes in its electrical conductivity. More stringently defined, a properly reconstituted cholinergic system must display the same single channel characteristics as those typical for natural end plates including pharmacological specificity. The crucial problem then is to define the minimal system still capable of displaying these properties.

The first reconstitution experiments[183,228-240] were aimed at obtaining preparations with similar properties as natural membrane vesicles in order to employ them in ion flux studies[228,241,242]. For this purpose, the solubilized and purified receptor was mixed with artificial lipid vesicles and the detergent removed by dialysis or filtration. These membranes vesicles were then charged with radioactively labeled cations and the discharge kinetics were measured in the presence and absence of cholinergic ligands. Although these methods have only recently reached the time-resolution of physiological events[243,244], the earlier studies already suggested that incorporation of purified receptor protein into artificial membranes leads to a functional ion translocation system with specifically cholinergic pharmacology. These earlier studies, however, were largely qualitative in nature and, therefore, were not capable of establishing the similarities and differences between the reconstituted and the natural system. They demonstrated, however, that the 43000-peptide (cf. Section 5.1) of receptor-rich *Torpedo* membranes initially proposed to contain the ion-channel[141] was not required for ion translocation and that the ion channel is also not a protein component which can be separated from the receptor under non-denaturing conditions. Recent reconstitution experiments[238] could not confirm the claim from earlier studies[244] that the receptor dimer is the only biologically active conformation of the receptor[187].

The receptor has also been reconstituted into planar lipid bilayers according to the methods of *Mueller* et al.[245] and *Montal* and *Mueller*[246]. Using this technique, the first single channel recordings from reconstituted purified receptor protein were obtained[12]. Since at the time of these investigations single channel recordings from intact electroplax cells had not yet been obtained, receptor-rich membrane fragments from *Torpedo* were first incorporated into the artificial lipid bilayers and their electrical properties were compared with those of muscle endplates from rat and frog (Fig. 6). The characteristic, agonist-induced single channel events recorded on the implanted membrane fragments then served as a standard for the reconstitution of purified receptor protein. These experiments showed that the receptor protein purified by affinity chromatography, already as monomer provided the artificial membrane with the electrical properties typical for natural end plates. Therefore, the agonist activated ion-channel

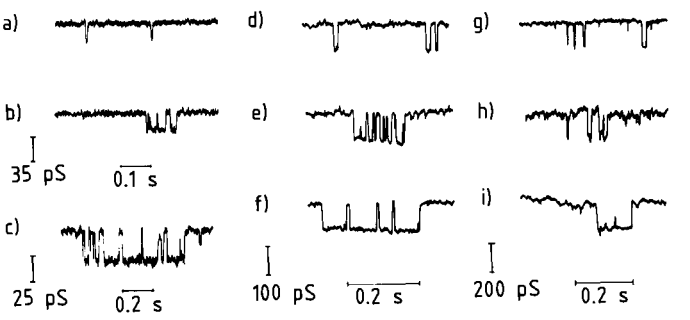

Fig. 6. Acetylcholine-induced single channel events in natural and reconstituted membranes containing acetylcholine receptor [12]. The scale 35 pS/0.1 s applies for a) and b), the scale 100 pS/0.2 s for d)—f) and the scale 200 pS/0.2 s for g)—i). Traces a, b, c show acetylcholine-induced membrane currents recorded with the patch-clamp technique [33] from extrasynaptic membrane regions of chronically denervated rat muscle (a, b) or frog muscle fibers (c): a) Single channel events immediately following addition of acetylcholine; b) multiple channel openings observed after longer incubation times on the same patch of membrane; c) infrequently occurring complicated events ("bursts"), believed to be events of resensitization of single channels. Traces d, e, f are obtained from an SMPC bilayer into which alkaline-treated receptor-rich membrane fragments from *Torpedo marmorata* were incorporated. Traces g, h, i are obtained from an SMPC bilayer into which purified receptor protein was incorporated. Very similar excitation patterns were observed for the natural membrane (a—c), the partially purified *Torpedo* membrane (d—f) and the reconstituted system (g—i).

had to be an integral part of the receptor protein. This is in agreement with recent results published by other groups[13,14,247,248].

The reconstitution experiments of *Boheim* et al.[12,249] are particularly noteworthy for their use of a phospholipid—1-stearoyl-3-myristoylglycero-2-phosphocholine (SMPC)[250]—with unusually high phase transition temperature[251]. Using this lipid the reconstitution of the receptor could be studied under conditions of a frozen membrane matrix. Since the reconstituted system functioned normally under these conditions (Fig. 6[12]), the lipid membrane apparently only functions as compartment border and, therefore, is not required to possess any great fluidity. Thus, the electrical properties of the reconstituted system—and by inference also those of natural muscle end plates—are properties solely of the protein moiety of the receptor. (This is not yet fully established, however, because at present it cannot be ruled out that the purified receptor protein still contains a few tightly bound molecules of natural phospholipids[252].) In any case it is clear, however, that the purified receptor monomer and dimer can function similarly to natural end plates when incorporated into bilayers of an artificial phospholipid. This also proves that solubilization and isolation of the receptor protein can indeed take place without loss of function and that the solubilized receptor therefore represents an intact, i.e., functional receptor preparation[253]. Furthermore, it disproves earlier suggestions that the purified receptor is a desensitized preparation.

Recently[14], single channel recordings have also been obtained from receptor reconstituted into a lipid bilayer at the tip of a pipette[32,33,254] (see Fig. 2a). In this way, and independent of the agonist applied, single channel conductivities of 40 ± 5 pS were measured in a medium containing 0.5 M NaCl; furthermore, two discrete types of single channel events and the typical sequence of events in the course of desensitization were observed[14].

The recently developed reconstituted receptor systems[12-14,249] are noteworthy for their stability and reproducibility. Since they can be biochemically manipulated rather easily (the lipid and protein composition, the relative proportions of monomer and dimer, the structure of the receptor can all be varied), they are particularly useful in connection with the purified receptor for the analysis of cholinergic mechanisms. Since natural membrane vesicles from *Torpedo* have recently become accessible to the patch-clamp method[255,256], there exists an unusual variety of receptor preparations for both biochemical and physiological studies. These (the highly purified receptor protein, the various reconstituted systems, partially purified membrane vesicles, and whole subsynaptic membranes) offer unique possibilities to study the molecular principles of biological signal processes.

6. Interaction of the Acetylcholine Receptor with its Ligands

6.1. Binding Studies

In this section we shall restrict ourselves to the discussion of binding studies only, i.e. we shall for the moment disregard the effects ligand binding may excert on the ion channel. In the same way, however, as response measurements permit implications about the preceding binding steps (see Sections 2 and 4), the biochemical experiments described here permit implications about the accompanying or following activation steps of the receptor-integral ion channel. The central aim of any investigations of the mechanism of cholinergic excitation must be an understanding on the molecular level not only of the binding reaction but also of channel activation and the coupling between these two processes.

Independent of the pharmacological classification of the ligands of the acetylcholine receptors (Section 3), we shall consider them here on the basis of their biochemical properties:

1. Reversible Ligands of low molecular weight: Several hundreds of such ligands (Fig. 3) are known for the receptor. They typically possess relatively large rate constants of association and dissociation and, therefore, are particularly useful for functional studies.
2. Irreversible Ligands of low molecular weight: These are particularly useful for fixing a structure or a state of the receptor.
3. Neurotoxins: These are single chain polypeptides, occurring in the venoms of elapid snakes. They typically possess very high affinities for and extremely slowly dissociate from the receptor. They constitute the most specific ligands of the receptor, and, therefore, are most useful as specific marker molecules, for concentration determinations, and for affinity chromatography.
4. Antibodies: Within the framework of biochemical investigations of the receptor, these ligands are most useful for investigations of receptor structure and membrane topography. By clonal selection of the cells producing a particular (monospecific) antibody it now is possible to obtain specific marker molecules for every antigenic determinant at the surface of the receptor.

6.1.1. *Neurotoxins*

Polypeptide neurotoxins[96,257,258] are small basic proteins with a chain length of between 60 and 75 amino acids. The "short" neurotoxins possess four, the "long" five disulfide bridges. Besides the amino acid sequences of more than 100 neurotoxins, the X-ray structures of two long toxins[259,260] (Fig. 7) and one short toxin are known[261,262].

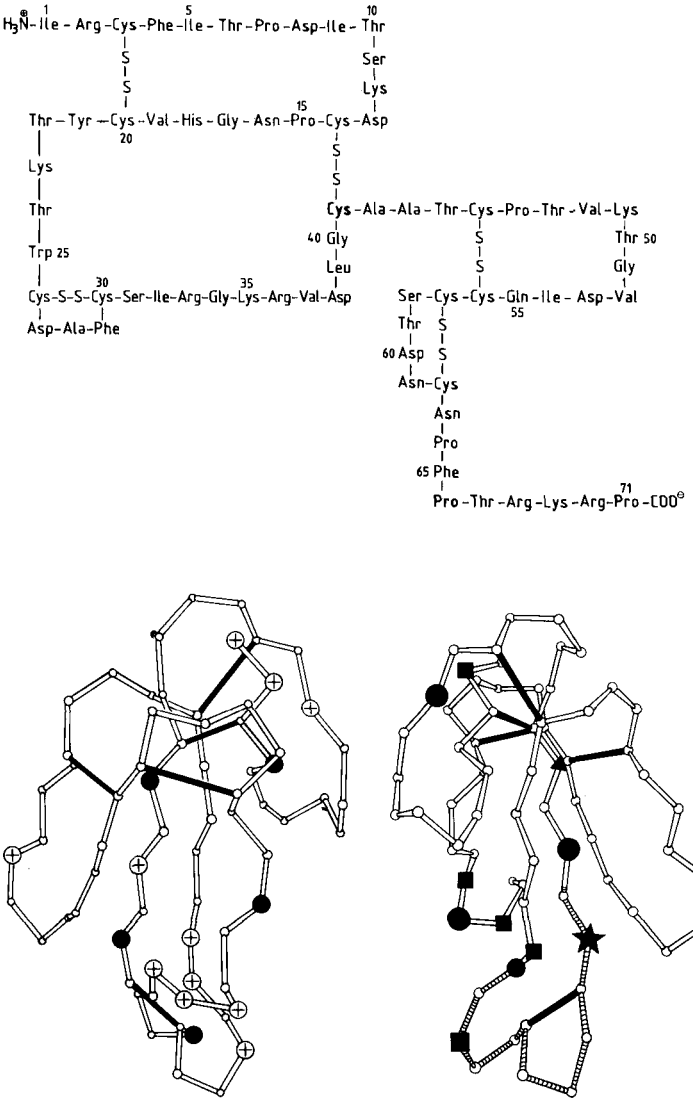

Fig. 7. The structure of α-cobratoxin.—(Above): Amino acid sequence of α-cobratoxin.—(Below, left): Back side view of the three-dimensional structure of α-cobratoxin with the positions of the aromatic (●) and the positively charged (⊕) amino acids indicated.—(Below, right): Front side view of α-cobratoxin with the positions of the amino acids modified by *Martin* et al. [263] indicated: Lysine (●), arginine (■), tyrosine (▲), tryptophan (★). Neither the modification of all lysine residues nor of all arginine residues or of the single tryptophan can completely abolish the toxicity of α-cobratoxin. Even after all five disulfide bridges have been opened and the free SH-groups alkylated, there still remains some residual toxicity. The peptide fragments from the region around the extra disulfide bridge (dotted line in the illustration below, right) also possess some residual toxicity [270—272]. Experimental details see [263, 264]; for a detailed discussion of the three-dimensional structure of α-cobratoxin see [259, 268, 269].

Neurotoxins bind by several attachment points to the receptor, i.e. they do not contain a narrowly defined active site[263,264]. The dissociation of the toxin-receptor complex is unusually slow[168,266,267].

Neurotoxins are easy to purify[96,168,257,258,263,273], to label with radioactive[168,273–276] or fluorescent residues[74,163,277–279], and to couple irreversibly with other proteins[280]. Since toxins are very basic proteins and the acetylcholine receptor is an acidic protein, simple analytical separation procedures can be developed on the basis of filters coated with ion-exchange resins[168,266,267,276]. For instance, filters coated with anion exchanger retain the receptor and the receptor-toxin complexes thereby permitting the determination of the concentration of these complexes. Because of the extremely slow dissociation rates of toxin-receptor complexes, the separation from free toxin can be carried out so completely that high accuracy and reproducibility can be achieved[168,276,281].

As was shown for purified acetylcholine receptor from electric eel and for ^{3}H-labeled α-cobratoxin[168,169,276], the interaction of receptor and neurotoxin cannot be described by one forward and one reverse reaction. Instead, two complexes of different affinity ($K_{D1}=4\times10^{-10}$ M, $K_{D2}=2\times10^{-11}$ M) and dissociation rate constants ($k_1=3\times10^{-3}$ min^{-1}, $k_3=1\times10^{-4}$ min^{-1}) are formed and these can isomerize with each other[168]. The interaction between receptor and toxin is characterized by an unusually high positive reaction entropy ($\Delta S_{298}=99$ cal·mol^{-1} K^{-1}); the activation enthalpy of the forward reaction ($\Delta H^{+}=12$ kcal/mol) is not unusual[168].

The toxin-binding test can also be employed for the study of the binding equilibria between receptor and low molecular weight ligands. Such competition binding studies already showed[168] that the purified receptor protein is capable of discriminating between pharmacologically distinct ligands: Cholinergic agonists and antagonists bind to the same number of binding sites at the receptor in a mutually exclusive fashion. However, antagonists are bound to these sites with only a single affinity, whereas agonists are bound with concentration-dependent affinity indicative of negatively cooperative interactions between pairs of sites (Fig. 8). The competition constants (Tables 2 and 3) for antagonists are in good agreement with the blocking potency in-vivo while for agonists differences of several orders of magnitude to the concentrations for half-maximal response are commonly found. This is not too surprising since the long incubation periods of the equilibrium binding experiment should lead to desensitization of the receptor if agonists are present[12,18,44,50–56].

Two of the observations made by *Maelicke* et al.[168] deserve special attention: In the case of the bismethonium compounds **8**, n=4 to n=10 (cf. Fig. 3), a single class of binding sites was found for the members with n=4—6, and heterogeneous binding (negative cooperativity) for the larger members. This is in agreement with the pharmacological classification of these compounds and demonstrates the sensitivity in response to small differences in ligand structure of the receptor protein. The second unusual observation has to do with the effect of low molecular weight ligands on the dissociation rate of toxin-receptor complexes. Assuming mutually exclusive binding, the added small ligand should only affect the equilibrium concentrations of receptor-toxin complexes but not their kinetics of dissociation. On the contrary, however, (Fig. 9a[74,168,169]) small ligands can accelerate this dissociation several hundredfold. Since the effect is observed only at very high concentrations (much beyond the concentration range used in the competition studies with toxin), yet is saturable, available binding sites for small ligands even in the presence of "saturating" concentrations of toxin are indicated. These show up in the kinetic but not in the equilibrium binding experiments[168]. Thus, the effect probably

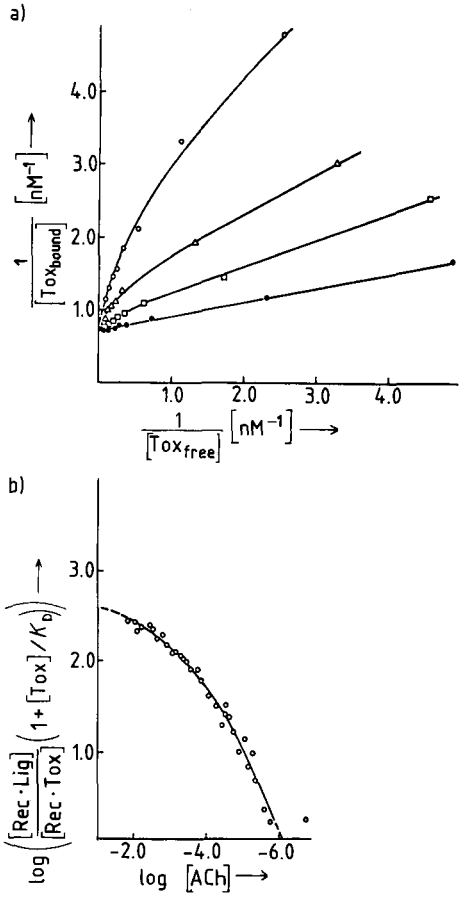

Fig. 8. Competitive binding of ^{3}H-α-cobratoxin and acetylcholine to the purified receptor protein from *Electrophorus* [168]. a) Double reciprocal plot of the concentrations of bound and free toxin. Acetylcholine concentrations: (●) 0, (□) 4.1×10^{-5} M, (△) 2.0×10^{-4} M, (○) 7.5×10^{-4} M.—b) Logarithmic plot according to *Maelicke* et al. [168]: Concentrations of receptor (Rec) and toxin (Tox): $[Rec_0]=1.9\times10^{-9}$ M, $[Tox_0]=2.7\times10^{-8}$ M, sample volume 1.04 mL. All reactions were carried out in the presence of 1.1×10^{-3} M diisopropylfluorophosphate, an inhibitor of acetylcholinesterase. From the initial slope (m=0.95), the same number of competitive binding sites appear to exist for toxin and acetylcholine. Competition constants of the initial binding site $K_{Lig}=7.9\times10^{-7}$ M. The complete functional relationship is as follows:

$$\log\left(\frac{[Rec\cdot Lig]}{[Rec\cdot Tox]}\left(1+\frac{[Tox]}{K_D}\right)\right)=n\log[Lig]-n\log K_{Lig}$$

with [Rec], [Tox] and [Lig] denoting the molar concentrations of toxin binding sites (receptor), toxin, and competitive ligand, respectively, in mol/L. n denotes the ratio of binding sites of the competitive ligand and toxin. K_D is the equilibrium dissociation constant of the toxin-receptor complex, K_{Lig} the apparent inhibition constant for the competitive ligand. Under the experimental conditions used, the concentration of free receptor can be neglected, so that the total concentration of binding sites. [Rec_0] equals the sum of the complexed binding sites ([Rec_0]=[Rec·Lig]+[Rec·Tox]). Thus, all quantities are experimentally accessible.

involves the same binding sites which in the low concentration range are competitive with toxin binding. This implies that structurally distinct binding sites for toxin and the small ligands must exist, and that competition of these ligands is not brought about by mutually exclusive binding to identical sites but is due to allosteric effects (Fig. 9b, see also Section 3). Independently of their structural basis, these low affinity binding sites possess the typical properties of additional regulatory sites[74, 168, 282–285].

Employing radioactively labeled toxins, ligand binding studies have also been performed with other preparations of the purified receptor[93, 286], with membrane vesicles[178, 179, 287–291], and with whole cells[292–298]. In the latter case they were employed in studies of the metabolism of acetylcholine receptors under normal[296, 297] and pathological conditions[298].

6.1.2. *Radioactively Labeled Small Ligands*

These ligands have mainly been used for equilibrium binding studies[137, 186, 230, 299, 304]. Because of their low affinity for the receptor in comparison to the neurotoxins, much higher concentrations of receptor are needed for these experiments. Consequently most of the studies with these ligands have employed receptor-rich membrane fragments from *Torpedo*. Of the methods used—equilibrium dialysis, filtration, centrifugation—only the latter has proved to be dependable. Ultracentrifugation in the airfuge[299, 301] to separate particulate from solute phase is an equilibrium method with comparatively good time-solu-

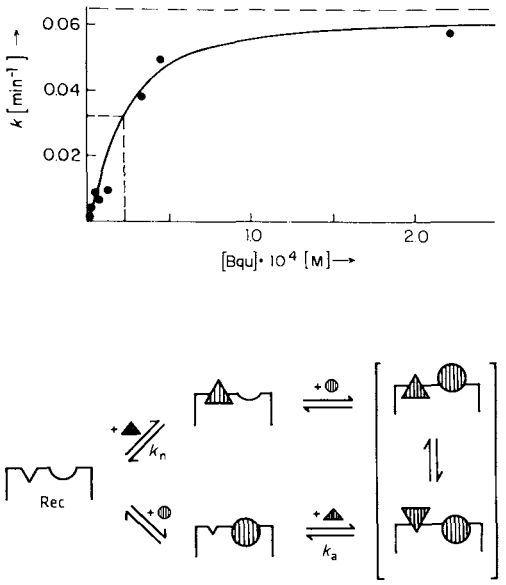

Fig. 9. Accelerated dissociation of toxin-receptor complexes. (Above): Initial rate constants of dissociation of ^{3}H-toxin-receptor complexes in the presence of the cholinergic antagonist benzoquinonium (Bqu).—$k_{max} = 0.065$ min^{-1}, $c(1/2k_{max}) = 2.4\times10^{-5}$ M [168]. Under similar conditions, $c(1/2k_{max})$ values of 1.1×10^{-4} M and 5×10^{-2} M, respectively, were found for tubocurarine and carbamoylcholine [74].—(Below): Allosteric model of accelerated dissociation. The binding sites for toxin and the small ligands are considered to be non-identical but fully competitive over a wide range of ligand concentration. This may happen if binding of toxin to its site at the receptor converts the site for the small ligand into one of much lower affinity. Much higher concentrations of small ligand would then be required for binding to this site. If occupied, however, a conformational change of the receptor is induced leading to accelerated dissociation of the bound toxin [74, 168, 169]. ▲: toxin, ◍: ligand. Dissociation rate constants for normal and accelerated dissociation: k_n and k_a, respectively.

tion (ca. 10 min). In the case of agonists, however, this is still too long to permit studies of the active form of the receptor. The desensitized form which dominates the equilibrium with agonists after the employed incubation times is characterized by relatively high binding affinities for agonists but only small positive cooperativity between the two agonist binding sites per receptor molecule (Fig. 10[303]). Special precautions and assay procedures are therefore required to reproducibly expose the weak positively cooperative interactions of the agonist binding sites at the receptor[303]. This is why the effect was observed in only some[299,300,303] but not all investigations[230,301,305]. In addition, the mathematical basis for the complete analysis of positively cooperative binding to two sites at a macromolecule has only recently been developed[81,82,303].

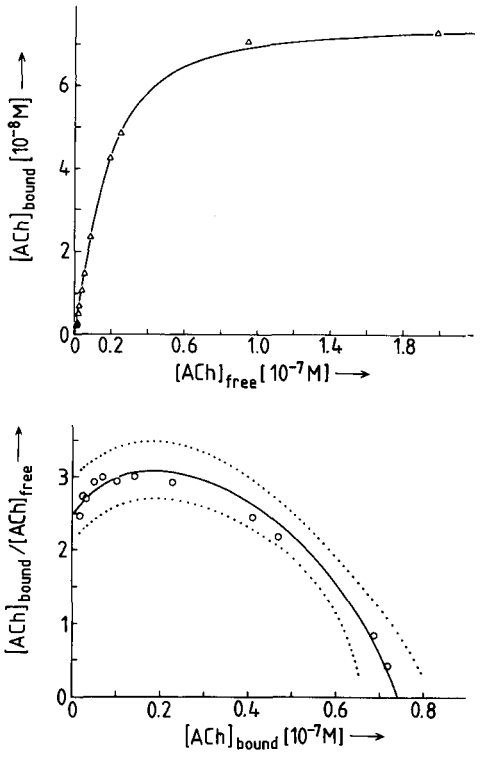

Fig. 10. Equilibrium binding of ^{3}H-acetylcholine to membrane fragments from *Torpedo mamorata* [303]. Binding equilibria were measured in 100 mM NaCl, 2 mM $CaCl_2$, 2 mM $MgCl_2$, 0.1 mg/mL bovine serum albumin, 0.25 mM tetram, 20 mM Tris/HCl, pH 7.2. Concentration of acetylcholine binding sites [Rec_0] = 37 nM. Above: Plot of bound versus free acetylcholine. Below: Scatchard plot of the binding data. 90% of all experimental points from a total of 56 independent binding experiments fall between the two dotted lines K_{D1} = 30 nM, K_{D2} = 6 nM. For data fitting see [303].

In summary, the binding studies with radioactively labeled cholinergic ligands of low molecular weight have produced only limited additional information but are much more difficult to carry out than binding studies with neurotoxins. Most noteworthy, they establish positively cooperative interactions of the binding sites for acetylcholine at the membrane-bound receptor in a non-physiological time-range[303]. This may support but certainly does not prove the earlier postulate[306] that strong positive cooperativity exists between the agonist binding sites of the active (non-desensitized) membrane-bound receptor.

6.1.3. *Irreversible Ligands*

The most thoroughly investigated chemical modification of the acetylcholine receptor is the reduction of a disulfide bridge in close proximity to the binding site for acetylcholine[82,85–95,299,307–311]. This reduction lowers the mean open time and the conductivity of the receptor channel[90,309–311] and the response to agonists with a single center of charge, but increases the response to agonists with more than one center of charge[85,86,307], reduces the Hill coefficients for agonists to 1[73,299], and converts hexamethonium to a cholinergic agonist[88]. With regard to the models of cholinergic excitation (Sections 3 and 7) it is noteworthy that irreversible linking of a single agonist per receptor molecule already suffices for channel activation[89,309,313]. After alkylation of the released SH groups with an affinity ligand—e.g. ^{3}H-bromoacetylcholine or ^{3}H-MBTA (see Section 4.3)—this label is found only in the α-subunit of the receptor. Depending on the reaction conditions and the receptor preparation employed, either only one[93,312] or both[94] of the released SH groups are labeled. While the disulfide reduction and alkylation experiments have identified the particular subunit of the receptor carrying the agonist binding site, no molecular basis exists as yet for the physiological effects of these modifications. This also applies to the discoveries that the irreversible reaction of BAC with single cell preparations of the electric eel leads to permanent depolarization of the membrane (no desensitization although the local concentration of BAC remains very high), and that the amide analogue of BAC, bromoacetylcholamine, under the same conditions also irreversibly binds to but does not activate the receptor[85,314]. These reactions if properly investigated and understood may offer crucial clues to the mechanisms of channel activation and desensitization.

The alkylating agent 3-bromomethyl-3′-trimethylammoniomethylazobenzene is of particular interest within the group of irreversible ligands because it can be photoisomerized from an inactive to a depolarizing ligand[315] and, thus, can be employed in concentration jump experiments. Most noteworthy of the results obtained with this ligand is that irreversible linking of a single molecule per receptor in its agonist conformation appears to suffice for channel activation[89,309,313], and that the rate of agonist binding to the receptor is not rate-determining for channel activation.

6.1.4. *Fluorescent Ligands of Low Molecular Weight*

Ligands with spectroscopic labels enable one to monitor their interaction with the receptor within the physiologically most important subsecond time range. While this is most important for kinetic studies (Section 6.2), these ligands are advantageous also for equilibrium binding experiments.

The chemical structure and spectroscopic and physiological properties of the existing fluorescent probes of the acetylcholine receptor have been discussed in detail[5]. Most suitable, and therefore most extensively used for biochemical studies have been derivatives of acetylcholine in

which the fluorescent moiety is separated from the cholinergic region by a bridge of methylene groups (Fig. 11). Of these, the unmodified NBD-n-acylcholines are pure agonists of acetylcholine[43,82,318–322], whereas the dansyl-n-acylcholines possess additional non-competitive properties[323,324]. Detailed binding studies have only been performed with the NBD-n-acylcholines. With the purified receptor from *Electrophorus* the binding of the fluorescent agonist is accompanied by complete quenching of the ligand's fluorescence[43,82,322]. The quenching is due to the formation of a hydrogen bond between the ω-amino group of the ligand as donor and an unknown acceptor group in a hydrophobic pocket of the receptor protein[322]. While the specificity of binding of the NBD-n-acylcholines is mediated by their cholinergic region[43,322], the changes in fluorescence clearly show that other regions of the fluorescent ligand also take part in the interaction with the receptor. This is why the binding affinity of NBD-n-acylcholines depends on the number of the methylene groups and why both binding affinity and fluorescence are affected by chemical modification of the ω-amino group[322].

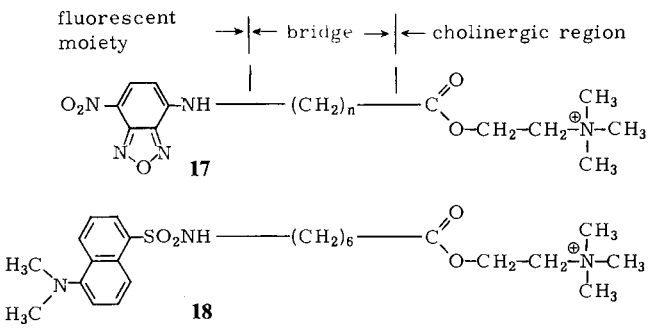

Fig. 11. Structural formulas of fluorescence-labeled acylcholines. **17**: "NBD-n-acylcholines" (systematic name: alkyl(dimethyl)-2-[ω-(7-nitro-4-benzofurazanylamino)-*n*-alkylcarbonyloxy]ethylammonium ion). **18**: "Dansyl-n-acylcholines" (systematic name: 2-[6-(5-dimethylamino-1-naphthalenesulfonamido)hexylcarbonyloxy]ethyl(trimethyl)ammonium ion or *O*-2-[6-(5-dimethylamino-1-naphthalenesulfonamido)hexylcarbonyl]choline. The n in the trivial name stands for the number of CH_2 groups.

The changes in ligand fluorescence caused by the interaction with the receptor permit direct and highly accurate measurements of the binding equilibria with the different receptor preparations[82]. Of particular importance in this context are the results of the competition binding studies with representative cholinergic ligands. They prove that cholinergic agonists and antagonists bind to the same number of binding sites at the purified receptor in a mutually exclusive fashion. The binding sites for antagonists form a single class of sites, those for agonists form two classes of sites with negatively cooperative interactions between each pair of sites. In agreement with electrophysiological observations under the same experimental conditions[85,88,90], incubation with dithiothreitol results in changes in affinity for some agonists; the binding patterns of a partial agonist and an antagonist under non-reducing conditions are changed to those of pure agonists[82].

The most important result of these studies is the proof of two different binding sites for agonists at the receptor. The equilibrium dissociation constants (Tables 2 and 3) obtained for antagonists are in agreement with the physiological data, those for agonists indicate partial or complete densititization of the receptor after the periods of incubation employed. Taken together, the experiments show that the receptor can be solubilized and purified without significant loss in function.

Studies with other fluorescent ligands[323–329] or marker molecules[330,331] were much less informative with regard to the mechanism of ligand interaction. With none of these, however, have more than one class of agonist binding sites or cooperative interactions of sites been observed. On the other hand, the studies of *Heidmann* and *Changeux*[324] and *Schimerlik* et al.[330] provide evidence of several affinity states of the receptor in the presence of agonists and for agonist-induced conformational changes.

6.1.5. Non-Competitive Blockers

Non-competitive blockers influence the response to cholinergic agonists by binding to separate sites at the receptor. While the maximal response to agonists is reduced in their presence, the apparent binding affinity for agonists is increased (smaller concentration required for half-maximal response). Typical members of this group of ligands are local anesthetics with amino groups such as procaine and dibucaine[287,300,338–340], hallucinogens such as phencyclidine[334,341], sedatives such as chloropromazine[335], various detergents[6], neurotoxins such as histrionicotoxin and anatoxin A[342–345], amantadine[346], the lipophilic methyltriphenylphosphonium ion[347] and a number of other natural and synthetic compounds of widely varying structure[348–352]. Electrophysiological studies with these compounds[35,332–334] lead to the suggestion that non-competitive blockers bind to parts of the ion-channel. It is equally probable, however, that they exert their effects through allosteric binding sites or through binding to the lipid phase[6,335–337].

In this context it is noteworthy, that non-competitive blockers do not bind to the purified receptor protein[82,168]. Consequently, only membrane-bound receptors can be used for in-vitro studies of these compounds. In this way, three types of binding sites for non-competitive blockers have been identified: One binding site per receptor molecule with high affinity (K_D in the micromolar range), a larger number of additional binding sites with at least an order of magnitude lower affinity which are probably located at the receptor-lipid boundary, and the binding sites for agonists to which a few of these compounds bind with even lower affinity (20—500 μM)[302,353]. Since all of these ligands possess more or less competitive properties[302,353,354] the name "non-competitive blocker" is confusing and is retained only for purely historical reasons.

All non-competitive blockers provide the membrane-bound receptor with increased affinity for agonists (Fig. 12[339,354]). Kinetic experiments indicate that this increase in affinity is due to conformational changes of the receptor

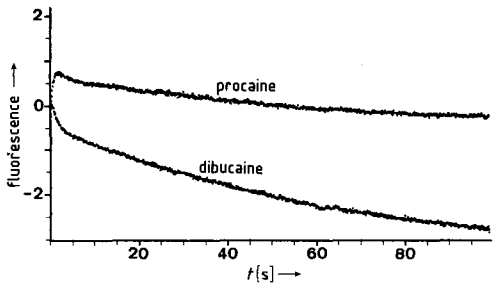

Fig. 12. Effect of non-competitive blockers on the interaction of NBD-5-acylcholine (Fig. 11) with the membrane-bound acetylcholine receptor from *Torpedo marmorata* [354]. The concentrations of membrane fragments [0.08 μM] and of fluorescent agonist employed [0.045 μM] corresponded to about 40% saturation of the available binding sites. Under these conditions, the addition of procaine (500 μM, upper oscilloscope trace) or dibucaine (10 μM, lower trace) induced a decrease in fluorescence, which is equivalent to additional binding of the fluorescent agonist. Binding of dibucaine exclusively causes an increase in the affinity for NBD-5-acylcholine (only a decrease in fluorescence is observed); in the case of procaine, the initial increase in and the equilibrium level of fluorescence both indicate that this local anesthetic can also compete with NBD-5-acylcholine for receptor binding. The rate constant for the decrease in fluorescence ($k = 0.01 \pm 0.005\ s^{-1}$) is reminescent of the slow process of desensitization observed in electrophysical experiments.

and that its time profile resembles that of the electrophysiologically defined phenomenon of desensitization[137,324,338,340,352,354]. Reconstitution experiments[355] suggest that at least some of the functional binding sites for non-competitive blockers are located at the receptor protein. Binding sites at the peripheral 43000-polypeptide[141,157] have been ruled out[137]. When affinity labeled with irreversible, radioactive non-competitive blockers, the label is found dominantly at the δ-subunit[356] but sometimes also at other subunits of the receptor[357].

The effects of non-competitive blockers are often taken as evidence in favor of the special allosteric model of the acetylcholine receptor[2,6,353]. In order to explain their mode of action, however, it already suffices to assume separate binding regions for each type of ligand (cholinergic agonist and non-competitive blocker) and interactions between these. Even the assumption of an allosteric model is not necessarily required, although this is tempting in view of the "modulating" effects of non-competitive blockers.

6.1.6. Antibodies

Antibodies against the acetylcholine receptor are useful tools, inter alia, for the following reasons: 1) Antibodies can be applied to studies of the structure of the receptor. 2) The acetylcholine receptor is a sufficiently simple preparation to quantitatively investigate the principles of antigen-antibody interactions and to analyze the effects of antibodies on the function of the receptor. 3) The molecular basis of the muscle desease *Myasthenia gravis* can be studied with the help of such antibodies. Here we shall concern ourselves mainly with the first aspect, and only just touch upon the others.

Modern approaches to the study of *Myasthenia gravis*[358-378] make use of the following two basic discoveries: The decreased number of functional acetylcholine receptors in the end plates of myasthenic patients[363] is evidence for a pathological change in the receptor concentration; the development of myasthenia-like symptoms after immunization of animals with foreign receptor protein[364] indicates an autoimmune component. In spite of the progress achieved in recent years[358-378], several alternative mechanisms for the induction and the various phases of this immune desease are still being discussed. Accordingly, *Myasthenia* is presently treated largely symptomatically[182,376-380].

Electrophysiological studies of myasthenic rats[370] show that their neurotransmission is reduced due to distinctly lower concentrations of functional receptor channels. In addition, an increase in the concentration of acetylcholine required to elicit half-maximal response (decrease in binding affinity) and changes in the kinetics of muscle excitation have been observed. The single channel properties of the remaining channels appear to be unchanged[370,376]. It has been difficult to show an immediate and direct blockade of receptor function by circulating antibodies[381,382].

Monoclonal antibodies (mAb) are particularly useful for structural studies of the acetylcholine receptor[383] because they are each directed against a single antigenic determinant at the receptor surface. Such determinants consist of only a few amino acids, so that the topography of the receptor can be studied with a high degree of resolution[123, 132, 159, 171-176, 182, 238-240, 369, 373, 380, 384, 385]. By means of the existing banks of monoclonal antibodies against the receptors of the electroplaques[175, 384, 385], at least 30 different surface determinants of the receptor can be distinguished. The most common applications of monoclonal antibodies have been the determination of subunit composition[130,158,386,387] and comparison of structures[175,374,388-390] of receptors from different sources. That much more penetrating investigations of receptor structure and function can be performed with monoclonal antibodies is exemplified in a structural analysis of the ligand binding regions of *Torpedo* receptor[175]. By employing an ELISA test (ELISA = *E*nzyme-*L*inked-*I*mmuno*s*orbent *A*ssay) in the selection of antibody-producing clones[174], monoclonal antibodies were also obtained against the binding regions for cholinergic ligands (agonists and antagonists)[175]. They differed from other antibodies against the receptor protein in that their binding to the receptor was completely blocked by α-cobratoxin. However, not all of these antibodies competed with low molecular weight ligands[175]: Three antibodies (mAbs 2—4) competed with all small ligands tested for binding to the receptor, a further two competed with all except the "bismethonium" compounds (mAbs 1,5), the sixth with all ligands except bismethonium compounds and tubocurarine. On the basis of the classical pharmacological occupational model (see Section 3[65], see also textbooks[391,392]) this implies that there are at least three types of binding sites for cholinergic agonists and antagonists at the receptor. Alternatively, it could be argued that the inability of some antibodies to bind to the receptor in the presence of certain ligands might be the consequence of a conformational change of the receptor induced by these ligands and leading to the disappearance of the appropriate antigenic determinant[175]. In other words, different ligands may cause different conformations of the

receptor; the receptor may not only distinguish between a few classes of ligands (agonist, antagonist, non-competitive blocker), and ligand recognition by the receptor may be of a much more individual nature.

Since all six antibodies competed with polypeptide neurotoxins for binding to the receptor[175], it was natural to assume that the binding sites for small ligands—even if they were different from each other—at least lie within narrow regions. By studying the competition of each pair of the six antibodies for receptor binding, it was shown that two such binding regions existed. Of particular analytical value in this connection was the fact that while antibody mAb 6 completely blocked the binding of the other five to the receptor, these could only partially block the binding of antibody 6. The simplest model accounting for these observations is shown in Figure 13. The essence of the initial data[175] has recently been confirmed by competition binding studies with radioactively labeled acetylcholine[393]. It was shown in this way that mAb 6 can only block half of the binding sites for acetylcholine.

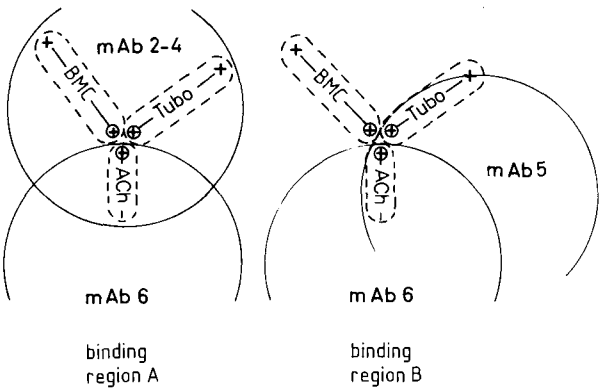

Fig. 13. A plausible model for the competition between monoclonal antibodies and cholinergic ligands [175]. The model assumes two binding regions—region A and region B—each consisting of three distinct ligand binding sites (subsites). Region A is defined by antibodies 2—4, region B by antibodies 1 and 5; the binding sites are defined by the ligands acetylcholine (ACh), tubocurarine (Tubo) and "bismethonium" compound (BMC) **8**, n = 6, 10. Antibody mAb 6 probably recognizes antigen determinants existing in both binding regions.

If such studies are extended to additional receptor functions (binding of non-competitive blockers and channel toxins, ion fluxes and conductivity changes), the surface areas of the receptor participating in these functions could be elucidated. This could lead to the structural localization of the ion channel and the areas involved in the coupling between the receptive and the responsive region(s).

The application of monoclonal antibodies in studies of receptor properties is only in its infancy. The preparation of these specific ligands is still a very new method[383] and basic questions such as the degrees of antibody specificity, the affinities, or the kinetics of interaction of monoclonal antibodies and antigens are still unclear or controversial. Also their basic advantage in comparison to immune sera, namely the reversibility of their action, has not yet been exploited to its full potential. New approaches to the analysis of receptor structure and function by immunological methods can also be expected from the recently available sequence data[197-201]. It now is possible to raise antibodies against synthetic peptides corresponding to particular segments of the receptor's sequence in order to test whether these segments are involved in particular functions of the receptor[197-201, 394, 395].

6.1.7. *Summary of the Equilibrium Binding Studies*

In summary, the equilibrium binding studies discussed here provide the following information on the organization and properties of the ligand binding sites at the receptor: The receptor monomer possesses two binding regions for competitive cholinergic ligands (agonists and antagonists). The two binding regions are structurally distinct[175]. This may explain why not only agonists[303] but also some α-neurotoxins[168] and one antagonist[301] have been found to bind to two classes of sites at the receptor.

In addition, there appear to exist in each of the two binding regions for competitive ligands different subsites for subclasses of these ligands[74, 175, 393]. Mutually exclusive binding of ligands with different subsites must then be due to structural alterations of the subsites for the other ligands after the first ligand is bound. Such model assumptions can also explain the ligand competition patterns of some monoclonal antibodies[175], the accelerated dissociation of receptor-toxin complexes in the presence of cholinergic ligands[74, 168, 169, 182], and other allosteric effects[283-285].

For non-competitive blockers there exist one specific binding site per ion-channel (receptor monomer) and additional binding sites at the boundary between receptor and the lipid environment and in the lipid phase. That the specific binding site for non-competitive blockers disappears with solubilization of the receptor may indicate that a specific protein-lipid-organization is required for the expression of this site. Since competitive and non-competitive ligands differ only in degree in their structure, every ligand of one group also has a certain affinity for the binding sites for the ligands of the other groups. This is more obvious for the non-competitive blockers because these are bound with comparatively low affinity and, therefore, are commonly employed in concentration ranges in which low affinity binding to other sites becomes significant.

The structure of the acetylcholine receptor is characterized by unusual flexibility and is easily influenced by bound ligands—including detergents[125, 168]. This variability in structure corresponds to the complexity of the electrophysiologically observed states of the receptor channel[44-49], and it therefore appears improbable that the functional properties of the receptor can be fully described by the assumption of only two or three states[2, 6, 72, 73]. Such models, therefore, should only be considered as working hypotheses in the phase of transition to a deeper understanding of this biological information transducing system.

The available equilibrium binding data cannot answer the question of how many agonist molecules must be bound to the receptor to activate the integral ion channel. However, under conditions of irreversible attachment of an agonist to the receptor, channel activation seems to require only a single molecule of agonist[309, 313, 316, 317].

6.2. Kinetic Studies

From the equilibrium binding data discussed in the preceding section the following conditions for kinetic studies of cholinergic excitation can be deduced: Since the active (ion conducting) state of the receptor is very short lived, biochemical studies of the molecular properties of this state require methods of similar or better time resolution. Such methods are fluorescent kinetic measurements of the binding reaction[43,324,328–331,396], ion flux measurements with high time resolution[243,344,9], and a combination of both[397]. In view of the complexity of the equilibrium binding studies with this receptor, it seems sensible to begin the kinetic studies with the simplest system available, i.e. purified receptor protein, and then to proceed from there to systems of higher complexity. As was shown by this approach[354,398], the membrane-bound receptor of receptor-rich membrane fragments possesses a much larger functional variability than does the purified receptor protein. This applies in particular to the interaction with non-competitive blockers and the mechanism of desensitization, making the membrane-bound receptor the preparation of choice for such studies[324,328–331,354]. Since ion flux measurements are measurements of the response, they have the same principle limits as have electrophysiological measurements. Since no direct data on the interaction between receptor and ligands can be obtained from such measurements, they will not be considered here in spite of their well developed techniques[9,389].

Of the existing techniques for fast kinetic studies of receptor-ligand interactions, the most suitable ones are those in which receptor and ligand for the first time meet during the actual experiment. This is particularly important for agonists and non-competitive blockers which modify the properties of the receptor within seconds[35,55,61,400]. Thus, methods in which an existing binding equilibrium between receptor and ligand is rapidly shifted[401] are not suited for studies of the active state of the receptor.

Crucial for the validity and significance of the results obtained are the properties of the monitoring effect and the pharmacological properties of the reactants. The monitoring effect should be specific and large in size, the pharmacology of the monitoring ligand should be clear-cut and as simple as possible. These conditions are best fulfilled by ligands—preferentially pure agonist or antagonist—the fluorescence properties of which change drastically and specifically upon binding to the receptor (for a detailed review of such ligands cf. [5]). Because of the considerable functional flexibility of the receptor, all other ligands or marker molecules[326–331] can easily lead to changes in the state of the receptor, thereby severely limiting the significance of such studies with respect to the physiological role of the receptor. As a consequence, we shall describe here mainly only experiments with the pure agonist NBD-5-acylcholine[10,43,318–322,354,396], and the partial agonists *N-n*-propyl-NBD-5-acylcholine[396] and dansyl-6-acylcholine[323–325,353,397] (see Fig. 11).

Binding of NBD-5-acylcholine to the purified receptor of the electric eel is accompanied by complete quenching of the ligand's fluorescence[43,82]. This large and specific effect was employed to study the kinetics of this interaction with the stopped-flow fluorimeter[396]. An initial analysis of the association kinetics showed that they are composed of several reaction steps and, therefore, cannot be analyzed in full detail without additional assumptions. To avoid these in the absence of an established mechanism, initially only the concentration-dependence of the initial rates of the association was analyzed. This yielded a second order forward rate constant of 2×10^8 M^{-1} s^{-1} for physiological buffer conditions at 20 °C and classifies the association reaction as very fast indeed[403] (Fig. 14).

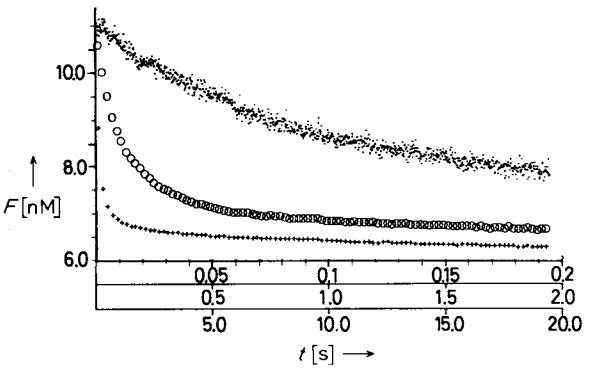

Fig. 14. Kinetics of association of NBD-5-acylcholine and the purified acetylcholine receptor from *Electrophorus electricus* [396]. Equal volumes of receptor (5.1 nM) and NBD-5-acylcholine (10.95 nM) were mixed rapidly in a stopped-flow-fluorimeter, and the decrease in fluorescence F was observed as a function of time t on a digital oscilloscope. Each of the traces shown is the average of four experiments. The three sets of experiments shown differ in their time ranges. These were 0.2—200 ms (•), 2—2000 ms (o), 20—20 000 ms (+). Of the set of experiments with the shortest time range, all 974 data points are shown, of the other two, every 10 points were averaged to one.

The dissociation kinetics were measured in two ways, each of them providing important information on the underlying molecular mechanism: When the kinetics of dissociation were measured after rapid dilution of the NBD-5-acylcholine-receptor complexes in excess of buffer, two kinetic components were observed under all experimental conditions. Since both components remain—even at low receptor saturation when only one of the two binding sites per receptor molecule is occupied—two forms of monoliganded receptor had to exist to account for two reaction steps (two kinetic components) in the dissociation kinetics. Thus, the following two alternative mechanisms could be written for dissociation of the half-saturated receptor [eqs. (d) and (e)].

$$[AR \rightleftharpoons AR^*] \rightleftharpoons R + A \qquad (d)$$

$$\begin{matrix} AR \\ RA \end{matrix} \rightleftharpoons R + A \qquad (e)$$

A = agonist, R = receptor,

(There exist two structurally different binding sites at the receptor; binding to and release from these sites are parallel processes.)

When the dissociation of NBD-5-acylcholine-receptor complexes was initiated by the addition of a large excess of a non-fluorescent competitive ligand, again at least two kinetic components were observed. While the initial rates of dissociation were independent of the type and concentration of the competing ligand and comparable with the first component of the dilution kinetics, the complexes dissociated all the slower in the later stages of the reaction, the higher the concentration of competing ligand (Fig. 15). In fact, the dissociation of complexes could be slowed down "beyond any limit" if only the concentration of competing ligand was increased accordingly (Fig. 15b). This property of the dissociation kinetics cannot be explained by a random mechanism of association and dissociation, not even when additional binding sites[74, 168, 283–285] or an allosteric mechanism[2, 6, 72, 73] are postulated. Under all these conditions the half-life of complexes should never increase beyond that defined by the most slowly dissociating component of the dilution kinetics (τ_2 in Fig. 15b), as is observed at sufficiently high concentrations of competing ligand. The observed dissociation kinetics, however, can be explained by the simplest strictly ordered mechanism [eq. (f)].

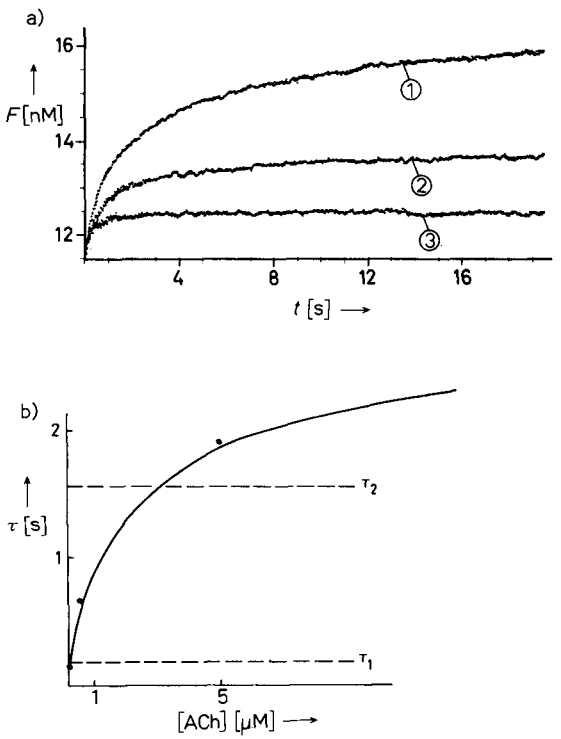

Fig. 15. Dissociation of NBD-5-acylcholine receptor complexes in the presence of a competing non-fluorescent ligand. a) Equal volumes of preformed complexes of NBD-5-acylcholine and the receptor, and of acetylcholine in standard buffer, were rapidly mixed and the increase in the fluorescence was recorded. Each trace shown is the average of four experiments carried out under identical conditions. Concentrations after mixing: receptor 5.05 nM; NBD-5-acylcholine 20.65 nM; acetylcholine 50 nM ③, 500 nM ② and 5000 nM ①. Time after which half of the NBD-5-acylcholine receptor complexes were dissociated: 96 ms in the absence of acetylcholine, 138 ms ③, 636 ms ② and 1900 ms ① in the presence of the concentrations of acetylcholine given above.—b) Half-lives τ of dissociation of NBD-5-acylcholine-receptor complexes plotted versus the concentration of acetylcholine employed. For comparison, the half-lives of dissociation by dilution (τ_1, τ_2) are included in the plot. As can be seen, the half-life of fluorescent complexes in the presence of competing ligands can exceed that of the slowest component of the dilution kinetics. This implies a strictly ordered mechanism, i.e. "first on—last off" of agonist dissociation from the receptor.

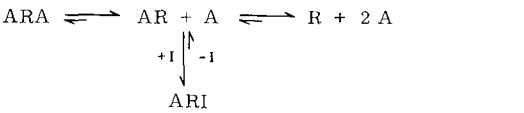
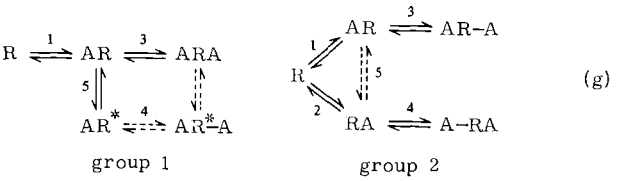


(f)

A = agonist, R = receptor, I = competing ligand

(To simplify the discussion we consider here only a single form of monoliganded receptor, cf. eqs. (d) and (e).) Under conditions of a strictly ordered mechanism, the dissociation of ARA (ARA→AR) (first component) would be independent of the presence of the competing ligand while the dissociation from AR (AR→R) would be hindered by the formation of ARI. The more ARI is formed, the less AR would be available for dissociation of the preformed complexes in the later stages of the reaction (Fig. 15). Hence, the dissociation of the fluorescent ligand-receptor complexes would be slowed down.

Taking together the results of both types of dissociation experiments, the following two groups of schemes are obtained for the interaction of the receptor with its ligands [eq. (g)].



(g)

(As shown by the broken lines, several variations of the basic schemes are possible. Plausible functional models for these reaction schemes are given in Figure 16.)

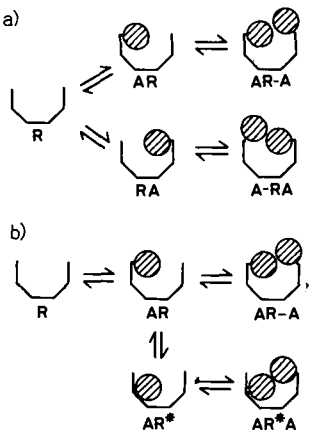


Fig. 16. Plausible models of the reaction schemes derived from fluorescence kinetics with NBD-5-acylcholine and the receptor protein from *Electrophorus* (Figs. 14 and 15). a) Two forms of the monoliganded receptor are formed in parallel from free receptor and free ligand. In the diliganded receptor, the ligand bound last sterically hinders the dissociation of the ligand bound first. Consequently, dissociation of ligands is strictly ordered and in the opposite order of succession as association.—b) Initially only one form of monoliganded receptor is formed (AR) but this form can spontaneously isomerize to a second form (AR*). The ordered dissociation of the diliganded receptor is caused by steric effects similar to those assumed in (a). The described effect of the ligand bound second must not be brought about by steric hindrance of the access to the binding site occupied first. The same effect could also result from allosteric interactions between the two binding sites.

Based on these schemes, simultaneous fits of combined sets of different association and dissociation kinetics and equilibrium binding experiments have been performed[396]. They provide the kinetic constants for all reaction steps considered in the reaction schemes. With these the competition kinetics with acetylcholine (Fig. 15) were fitted to obtain the kinetic constants for the interaction with the natural transmitter. The relevant data are given in Table 4.

Table 4. Reaction parameters for reaction scheme b) of Figure 16, obtained from simultaneous fits of equilibrium and kinetic studies with NBD-5-acylcholine and the purified acetylcholine receptor from *Electrophorus*.

Parameter	NBD-5-acylcholine [a]	Acetylcholine [b]
k_1 [M^{-1} s^{-1}]	4.8×10^8	5×10^8
k_{-1} [s^{-1}]	3.4	740
K_{D1} [M]	7.0×10^{-9}	1.5×10^{-6}
k_3 [M^{-1} s^{-1}]	3.4×10^8	5×10^6
k_{-3} [s^{-1}]	19.4	400
K_{D3} [M]	5.7×10^{-8}	8×10^{-5}
k_4 [M^{-1} s^{-1}]	7.9×10^6	1.5×10^5
k_{-4} [s^{-1}]	0.53	0.09
K_{D4} [M]	6.7×10^{-8}	6×10^{-7}
k_5 [s^{-1}]	0.52	170
k_{-5} [s^{-1}]	0.18	20
K_{D5} [M]	0.35	0.12
K_D (1) [M] [c]	1.8×10^{-9}	1.6×10^{-7}
K_D (2) [M] [c]	6.5×10^{-8}	6.7×10^{-7}

[a] The data for NBD-5-acylcholine were obtained from direct measurements. [b] The data for acetylcholine were obtained from displacement kinetics (cf. Fig. 15) keeping the parameter obtained for NBD-5-acylcholine constant. [c] K_D (1) and K_D (2) are the equilibrium dissociation constants relating to the two classes of sites observed in binding experiments [81]:

$$\frac{1}{K_D(1)} = \frac{1}{K_{D1}} + \frac{1}{K_{D1} \cdot K_{D5}}$$

$$\frac{1}{K_D(1) \cdot K_D(2)} = \frac{1}{K_{D1} \cdot K_{D3}} + \frac{1}{K_{D1} \cdot K_{D4} \cdot K_{D5}}$$

The data show that the two forms of saturated receptor, AR-A and AR*A, have very different properties. AR-A is formed quickly and dissociates quickly, AR*A is formed comparatively slowly and late but is much more stable. Because of its low K_D-value (acetylcholine), AR*A dominates at equilibrium. Since these properties of the two saturated forms of the receptor bear similarities to the active (ion conducting) and the desensitized (inactive) state of the receptor, the related reaction schemes have been proposed as "minimal models" for the mechanism of cholinergic excitation[396, 10]. When an event of cholinergic excitation is simulated on the basis of the kinetic data (Fig. 17), satisfactory agreement of the changes with time in the concentration of AR-A and the electrical events at the muscle end plates is found.

The kinetic study with NBD-5-acylcholine[396] led to the discovery of a strictly ordered mechanism of association and dissociation of agonists with the receptor. This has important consequences for the analysis of receptor kinetics and also for the mechanisms of ligand recognition and channel activation. Because the interaction between agonists and the receptor is ordered, the kinetics of interaction should not be analyzed by means of exponential fits[396, 404]

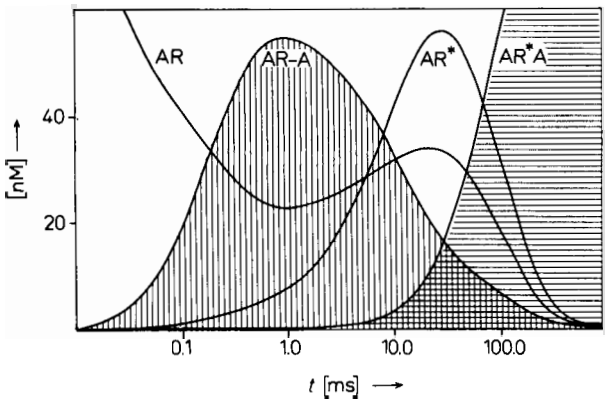

Fig. 17. Simulation of the transmitter binding reaction during an event of cholinergic excitation [396]. The data were calculated on the basis of the reaction scheme illustrated in Figure 16b with the minimal concentrations of acetylcholine receptor (1×10^{-7} M) and transmitter (1×10^{-4} M) present during the course of an excitatory event. The plot shows the intermediate nature of AR-A, its decay into AR* and later into AR*A. It has been postulated [10, 396] that AR-A represent the active state, AR*A are an inactive (desensitized) state of the receptor. In terms of the proposed correlation, the concentration versus time function for AR-A would then mimic the change in conductivity with time of a voltage-clamped muscle cell in the course of an event of cholinergic excitation. The decrease of AR-A with time would relate to the fast process of desensitization.

as was hitherto generally the case[9, 32, 243, 289–291, 323–331, 397, 398–401]. Under these conditions exponential fits not only result in incorrect kinetic constants but also in apparent additional kinetic components. This is why only a few of the previously obtained kinetic data, e.g. the rate constants of the first reaction step, can be compared with the data of ref. [396] without recalculation of the experiments. *Heidmann* and *Changeux*[324] have found a comparable rate constant of second order (9.5×10^7 M^{-1} s^{-1}) for dansyl-6-acylcholine and membrane vesicle from *Torpedo marmorata*. The comparatively low rate constants of other studies[401, 405] of around 1×10^7 M^{-1} s^{-1} are probably related to later reaction steps since they are based on effects which are *induced* but do not parallel the initial binding of acetylcholine to the receptor (corresponding to k_3 for acetylcholine in Table 4). *Heidmann* and *Changeux* have not described reaction steps with comparable kinetic constants. They did observe, however, another bimolecular *slow* reaction step ($k = 3.5 \times 10^5$ M^{-1} s^{-1}) for which there presently does not exist a simple correlation in the activation cycle of the receptor[255, 256, 406]. A further reaction step in the association kinetics of dansyl-6-acylcholine and *Torpedo* membrane vesicles ($k = 0.1$ s^{-1})[324] appears to be typical for the membrane-bound receptor and is also found using NBD-5-acylcholine (Fig. 12) as ligand[354, 398]. Other investigations[329, 331] have also identified similarly slow reaction steps for the interaction of the receptor with its ligands. On the basis of their time ranges, they probably relate to the transition from the active to the desensitized state of the receptor.

In summary, the kinetic studies described above already provide an independent contribution to the understanding of the dynamic properties of the acetylcholine receptor. The strictly ordered mechanism of association and dissociation of agonists probably could not have been found by

mere investigation of the response[7, 9, 24, 28, 35, 47, 49, 79b, 243, 244, 397]; but it has important implications for the mechanism of channel activation. The kinetic constants established from biochemical measurements set a frame for all physiological considerations concerning the relationship between channel activation and receptor saturation. For instance, the biochemical data disprove earlier ideas which saw desensitization as the result of a decrease in the affinity for agonists of the receptor. In contrast, the equilibrium binding and kinetic studies show that two forms of the agonist-saturated receptor exist, one of which being inactive (see Fig. 17). From a comparison of the electrophysiological and the biochemical data, however, it is clear that the latter are still too rough to provide a full molecular basis for all the functional states and substates of the receptor observed in physiological studies.

7. The Acetylcholine Receptor, Integral Signal Transducer of the Muscle End Plate

Rapid cholinergic transmission is a decisive factor for biological survival. Consequently, it must have been an early goal in the evolution of species to optimize the cholinergic synapse to high rates of signal reception, signal response coupling, and signal removal. This is achieved by the advantageous morphology of the synapse, an effective transmitter release system[27, 35, 64], and the combination of a rapid signal transducing (the receptor) with a rapid signal removing system (the esterase). Thus, as a result of the high concentration of acetylcholine esterase in the synaptic cleft[407, 408] and its extremely large turnover number[409] the concentration of acetylcholine fluctuates in the course of an event of cholinergic excitation from its basal to its maximal and back to its basal level within a few milliseconds. Cholinergic transmission is characterized, therefore, by very steep rises and descents of both the overall process and each single reaction step.

Within the reaction cycle of the transmitter[64], excitation of the receptor is only an intermediate side reaction (Figs. 1 and 18). The kinetic investigations with NBD-5-acylcholine (Fig. 11) and the purified receptor protein indicate that a similar mechanistic principle—the functionally significant reaction as an intermediate side reaction—also applies for the actual excitation process (Figs. 16—18). The active state of the receptor-ion channel attained by saturation with agonist is intermediate and short-lived, and rapidly reverts again to an inactive state. Under conditions of fully functional esterase and the usual concentration range of acetylcholine, this inactive state is the partially occupied or the free receptor; in the presence of constantly high concentrations of transmitter it is the desensitized state of the fully occupied receptor.

Since occupation of receptor by agonist is the triggering signal for channel activation, it is improbable that the active state of the receptor can also exist in the *absence* of agonist. Exactly this would be the consequence of the specific allosteric model (see also Section 3)[2, 4, 6, 8, 72, 73], which postulates that the different states of the receptor also exist in the absence of ligand, that they are in equilibrium with each other, and that merely this equilibrium is shifted by appropriate ligands. (According to this model, agonists have a higher affinity for the activated, antagonists a higher affinity for the inactive state of the receptor.) Single channel events, i.e. the activation of single receptor molecules, however, have never been observed in the absence of agonist. In addition, it has been unequivocally shown that a superstructure of the synapse[72] is not a necessary prerequisite for electrical excitation but that isolated receptors (extrasynaptic receptors) also are fully excitable. For these reasons, the specific allosteric model does not seem to be an appropriate basis for a molecular understanding of neuronal excitation processes, although evidence in favor of an equilibrium of states in the absence of agonists has frequently been reported to exist[2, 6, 8, 230, 233, 324, 328].

In contrast to the assumption of various states of the free receptor, it is clear, however, that the receptor saturated with agonist can exist in many states and substates[44–49, 175, 396]. Furthermore, there is strong evidence for allosteric interactions of rather distant regions of the receptor. In this connection it is noteworthy that non-competitive blockers exert their action preferentially on the receptor saturated with agonist. For these reasons it appears more appropriate to stress the plasticity of the *ligand-occupied* receptor in contrast to the free receptor. This is also in accordance with the general biological function of a signal transducer, i.e. to recognize ligands and to specifically re-

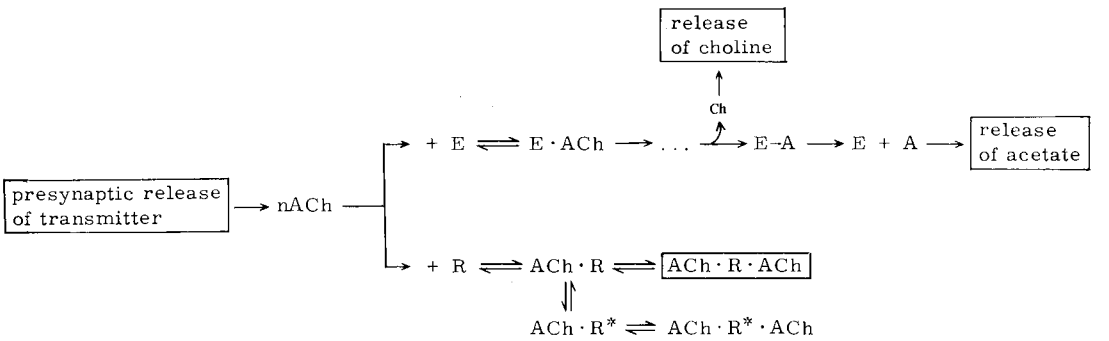

Fig. 18. Competition of acetylcholine receptor R and acetylcholine esterase E for the transmitter (see also Fig. 1b) [412]. From kinetic experiments with receptor and esterase and the fluorescent acetylcholine analogue NBD-5-acylcholine [321] (Fig. 11), the two macromolecules are found to have similar rate constants for initial binding of the transmitter. Consequently, receptor activation and enzymatic hydrolysis of transmitter are parallel reactions. Since receptor activation is a reversible process while transmitter hydrolysis is directed, the activation process can be considered an intermediate side reaction within the reaction cycle of the transmitter.

spond to their message. The fact that this apparently simple receptor system is capable of such a sensible recognition process indicates that it probably already possesses the essential molecular elements necessary for higher neuronal properties such as modulated response, selective information processing, and memory.

The significance of the established strictly ordered mechanism of ligand association and dissociation[396] must be seen in this connection. This mechanism is important, inter alia, for the following two central aspects of cholinergic transmission: 1) Binding of the first of the two agonist molecules per receptor can be fast because the monoliganded receptor is inactive under usual conditions. This is not to say, however, that this particular agonist-receptor complex is of little or no importance for activation. 2) In contrast, it is interesting that the stability of the initially formed agonist-receptor complex is strongly influenced by the occupation of the second binding site (ordered dissociation, "first on—last off"). Taken together, these effects may represent a key to the molecular mechanism of channel activation: Since *two* agonist molecules are required for channel activation, the specificity of excitation is increased; it is further enhanced by the ordered mechanism. In this way, an interaction characterized by low affinities and high forward and reverse reaction rates can obtain the specificity required for any signal receiving system. The periods of occupation of the first binding site may be even more important. To discuss this point, it is useful to depart from the models of rigid binding sites at the receptor and to consider instead models with "moving sites". In an ordered mechanism a shift of the initially bound ligand to a different position in the molecule is quite plausible and is indicated in the mechanism of acetylcholine hydrolysis by acetylcholine esterase[321,410]. If such a structural concept is assumed—binding of the agonist bound second "pushes" the agonist bound first to the activating position and keeps it there—both the usual pathway of receptor activation by two agonist molecules and the unusual activation by one irreversibly bound agonist molecule[89,309,313] can be explained: Activation may be induced by the ligand bound first, but only after this ligand has been shifted to and kept at the "activating position" for which binding of an additional agonist molecule is required. In the case of an agonist that can be linked irreversibly to the receptor, a second agonist molecule is only required for the attachment to the appropriate position but not any more for channel activation (it can be washed out). A plausible scheme demonstrating this mechanism in the context of the observed kinetics is shown in Figure 19. Continuing these arguments, desensitization would remain to be coupled to the periods of receptor occupation by agonist. If agonist remains available for longer periods of time than are defined by the stability of the active form of saturated receptor, the isomeric "desensitized" form of receptor develops. In the context of the above model, the agonist site occupied second (and/or additional "peripheral" sites) is likely to control desensitization: As was shown in experiments with single electroplaques of the electric eel, the irreversible attachment of one agonist per receptor molecule suffices to activate the receptor channel, but the end plate remains depolarized over long periods of time.

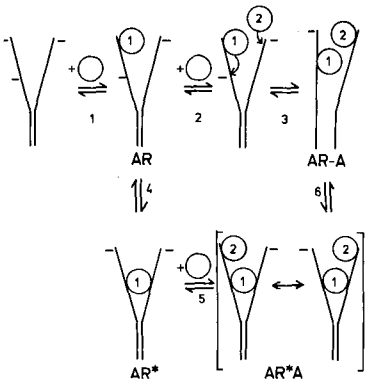

Fig. 19. A plausible model assuming "moving sites" for the agonist-induced activation of the acetylcholine receptor channel. It is proposed that binding of a second molecule of agonist to the receptor requires shifting of the agonist bound first from a peripheral to an inner binding site. This may occur rapidly (k_3, coupled with channel activation) or slowly (after previous isomerization of the receptor, k_4, and without effecting the state of the channel) (see also Figures 16—18). From the fluorescence kinetic studies with NBD-5-acylcholine and the receptor, AR-A is a metastable intermediate which is finally converted into AR*A.

The model conceptions described above are still new and require further testing. Consequently, they should rather be taken as an illustration for the present state of the studies on receptor mechanisms: Initially, the esterase was the subject of choice for the related studies[64], then the receptor was proposed as the central element of the excitation process[72,73], demonstrated and isolated[1,2,4], and subsequently identified as a transducer rather than a receptor of classical definition[12–14]. From the physiological and biochemical studies of recent years, the acetylcholine receptor has emerged as a rather complex system of ligand-modulated properties. With the exception of the resting state, all other states of the receptor appear to be induced and controlled by its ligands.

The structural and functional plasticity of the receptor should not divert from the fact that the basic reactions of receptor activation and inactivation follow well-defined molecular mechanisms. As one model for these mechanisms, ours[396] is based on exclusively biochemical data and does not contain any preconceived model assumptions. Its central element is the strictly ordered association and dissociation of the transmitter and its agonists to and from the receptor. As discussed here, this mechanism can provide molecular explanations not only for the basic electrophysiological observations, but, in addition, also for some experimental facts not understood by the previously available models. This model of cholinergic excitation may therefore be useful also for the investigation of other receptor systems including those of the central nervous system. This article may also illustrate the fact that a purely chemical approach to an understanding of receptor function does not suffice anymore at the present level of analysis, and that additional concepts and methods are required to unravel the molecular mechanisms by which biological cells communicate.

The work carried out in our laboratory was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chem-

ischen Industrie, and the Alexander-von-Humboldt and Fritz-Thyssen Foundations.

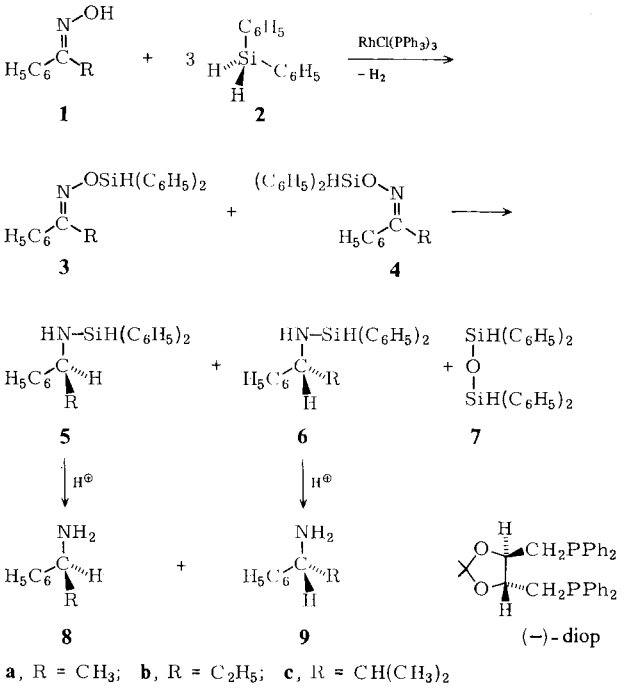
Enantioselective Catalytic Hydrosilylation of Oximes**

By *Henri Brunner** and *Richard Becker*

Whereas the hydrosilylation of alkenes, alkynes, and carbonyl compounds has been intensively investigated[1], only a few references appear in the literature on the corresponding reduction of compounds with CN double bonds[2]. Moreover, these only cover Schiff bases RR'C=NR'', R''≠H, whose hydrosilylation and hydrolysis lead to secondary amines RR'HC–NHR''. In the following, we report a novel method of hydrosilylating the CN double bond in oximes using diphenylsilane and rhodium-phosphane catalysts—a reaction which can also be controlled enantioselectively using optically active catalysts. By means of this novel reaction, oximes, and hence ultimately ketones, can be converted into optically active primary amines.

The reaction of 1 mol acetophenone oxime **1a** and 3 mol diphenylsilane **2** with ca. 1 mol-% $RhCl(PPh_3)_3$ in benzene was monitored by 250 MHz ^{1}H-NMR spectroscopy. After 10 min at −10 °C, the signals of **1a** disappeared. Apart from signals from small amounts of the final products **5a/6a** and **7**, initially only the signals of **3a** appeared [$\delta(CH_3)=2.1$ (s); $\delta(SiH)=6.03$ (s)]. The Rh-catalyzed silylation of **1a** to **3a**, which involves evolution of H_2, proceeds with retention of the *E*-configuration. In the course of the reaction the *E*-isomer **3a** is also converted into the *Z*-isomer **4a** [$\delta(CH_3)=2.2$ (s); $\delta(SiH)=6.05$ (s)]. Both isomers, **3a** more rapidly than **4a**, react to afford the final products **5a/6a** [$\delta(CH_3)=1.27$ (d), $J(CH_3CH)=6.7$ Hz); $\delta(SiH)=5.53$ (d), $J(SiHCH)=2.4$ Hz); $\delta(CH)=4.06$ (2q)] and **7** [$\delta(SiH)=5.85$ (s)]. After 24 h at room temperature only the signals of the final products **5a/6a** and **7** are present.

After addition of acetone and hydrolysis of the reaction mixtures with conc. HCl, 1-phenylethylamine **8a/9a** can be isolated in ca. 60% yield (Table 1) using catalysts generated in situ from $[Rh(cod)Cl]_2$[3] and (−)-diop[3]. The catalyst is still active even at Rh : **1a** ratios of 1 : 500. The best optical induction of 14.4% *ee* for (*R*)-**9a** is achieved with a twofold excess of (−)-diop at an Rh : **1a** ratio of 1 : 100. In order to determine the optical purity, a 1% solution of the trifluoroacetamide in ether, prepared from **8a/9a** using trifluoroacetic anhydride, is gas-chromatographed on a 25m



Chirasil-Val glass capillary[4], giving a base-line separation of the two enantiomers (column 105 °C, injector 230 °C).

Table 1. Hydrosilylation of **1a** (2.19 g), **1b** (2.37 g), or **1c** (2.64 g) with diphenylsilane **2** in 5 mL benzene.

Substrate	Rh : 1	Rh : P	1 : 2	*t* [h]	*T* [°C] [b]	Yield [%]	8/9 *ee* [%] [a]

1c	1 : 200	1 : 2	1 : 3	44	50	30	12.7(*R*)

[a] Reproducibility ca. ±1%. [b] In reactions with **1a**, 1 h at −10 °C, followed by warming to room temperature.

Because of increasing steric hindrance, the analogous reactions with propiophenone oxime **1b** and isobutyrophenone oxime **1c** require either considerably longer reaction times at room temperature or the use of increased temperatures (Table 1).

Further studies should indicate how the novel method measures up against reduction with optically active $LiAlH_4$ reagents[5] and hydrogenation catalyzed by $H_4Ru_4(CO)_8(diop)_2$[6].

Metal Template for the Symmetrical [2+2]-Dimerization of Ketenimines**

By *Rudolf Aumann**, *Heinrich Heinen*, and *Carl Krüger*

Isocyanides insert smoothly into the M=C bond of transition-metal carbene complexes **1** of the Fischer-type to afford ketenimine complexes **2**[1-3], which react with a further equivalent of isocyanide[2] or with pyridine to release previously unknown ketenimines. The reactivity of the ketenimine ligands undergoes an umpolung in the complex: nucleophiles (e.g. CH_3OH) add to the terminal, but not—as in the free ketenimines—to the central carbon atom[2]. Nucleophilic attack results in simultaneous migration of the $Cr(CO)_5$ moiety from the nitrogen to the central carbon atom[1,2], producing aminocarbene complexes. Under certain conditions, aminocarbene complexes can also be obtained without addition of nucleophiles via (radical-induced) isomerization of the ketenimine complexes[1,2].

Thermolysis of **2** leads to novel, symmetrical [2+2]-dimerization of the ketenimine ligands to afford 1,2-bis(imino)cyclobutanes. Apparently this reaction involves participation of a metal template, since dimerization of free ketenimines leads to azetidines, diazetidines, or open-chain products[4]. Even when mildly heated, compounds **2** undergo dismutation to form $Cr(CO)_6$ and deep-blue $Cr(CO)_4$ complexes **3** which contain a 1,2-bis(imino)cyclobutane as chelate ligand. These complexes **3** occur respectively as *cis/trans*-isomer pairs (relative to the bond between the two sp^3 hybridized C atoms of the four-membered ring (cf. Fig. 1). The reaction becomes slower as the spatial demand of the substituent R′ increases and yields with increasing selectivity the *cis*-product.

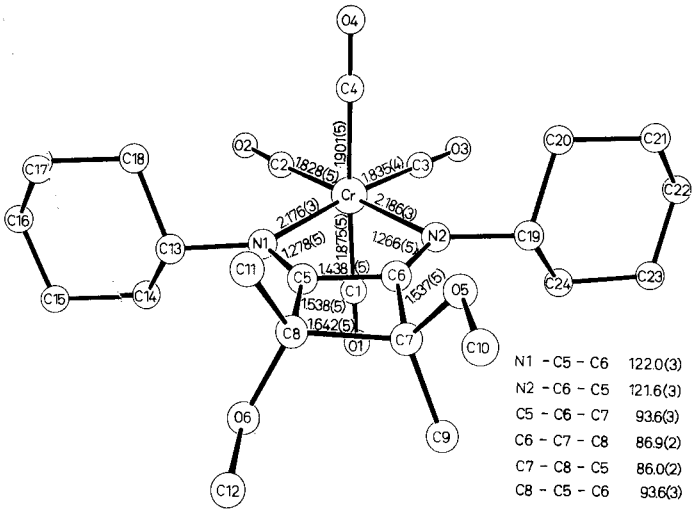

Fig. 1. Molecular structure of the chromium complex **3b′** in the crystal with selected distances [Å] and angles [°]. Crystal data: Space group $P2_1/c$ (No. 14), $a = 14.380(3)$, $b = 9.786(2)$, $c = 19.192(4)$ Å, $\beta = 102.65(2)°$, $V = 2635.20$ Å^3, $Z = 4$, $\rho_{calc} = 1.256$ g cm^{-3}; $\lambda = 0.71069$ Å, $\mu = 4.59$ cm^{-1}, $R = 0.051$, $R_w = 0.056$; 5958 measured reflections, 3283 of which observed ($I > 2\sigma(I)$); 298 refined parameters.—The existence of a high strain in the four-membered ring is expressed both by an extraordinarily long CC bond in the ring (C7–C8 1.642(5) Å) and by a deviation from the planarity of the system N1–C5–C6–N2: C7 −0.09 Å, C8 +0.11 Å. Axial and equatorial metal-carbon distances at the octahedrally coordinated Cr atom differ by 0.06 Å.—Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50679, the names of the authors, and the journal citation.

The spectroscopic data of **3**[5] are consistent with those of other diazabutadiene complexes[6]. Compounds **3** are readily accessible via a one-pot reaction[7] and are relatively stable. They can be considered as depository compounds for 1,2-bis(imino)cyclobutanes and can be used as their synthetic equivalents: e.g., reaction of **3b** and **3b′** with two equivalents of hydroxylamine hydrochloride in methanol (50 °C, 0.5 h) yields the crystalline 1,2-bis(hydroxyimino)cyclobutanes **4b** and **4b′**[8].

[7] Procedure for the synthesis of tetracarbonyl[1,2-bis(cyclohexylimino)-2,3-dimethyl-2,3-dimethoxycyclobutane]chromium(0) (**3b** and **3b′**): $(CO)_5CrC(OCH_3)CH_3$ [1] (250 mg, 1 mmol) is "dissolved" in 1 mL hexane in a 3 mL threaded flask (inert gas atmosphere and with exclusion of moisture), the mixture treated with a solution of cyclohexyl isocyanide (109 mg, 1 mmol) (FLUKA) in 1.5 mL hexane at −78°C and subsequently warmed to 50°C for 4 h. The deep-blue solution is rapidly chromatographed (since the complexes can decompose on the column) on silica gel (column 30 × 1.5 m, petroleum ether/ether = 4 : 1). The elution order is $Cr(CO)_6$, the ultramarine-blue **3b** (main product), and then the azure blue **3b′** (side-product). Total yields after recrystallizations from hexane (−78°C) ca. 200 mg (80%).

[8] **4b** and **4b′** give correct C,H,N values. **4b** (m.p. = 172°C) migrates more slowly than **4b′** (m.p. = 160°C) upon chromatography on silica gel. **4b′**: ^{1}H-NMR ($CDCl_3$, 300 MHz): $\delta = 1.60$ (CCH_3), 3.48 (OCH_3), 8.06 (br, OH); ^{13}C-NMR ([D$_6$]acetone, 75 MHz): $\delta = 13.52$ (CH_3), 54.56 (OCH_3), 78.13 ($C-OCH_3$), 155.56 (C=N); MS (70 eV): *m/z* 185 (6%, *M* − OH), 168 (8, *M* − 2OH), 153 (26, 168 − CH_3), 101 (100, 153 − NC−CN), 73 (56, 101 − CO).—**4b**: ^{1}H-NMR ($CDCl_3$, 300 MHz): $\delta = 1.60$ (CH_3), 3.56 (OCH_3), 8.06 (br, OH); ^{13}C-NMR ([D$_6$]acetone, 75 MHz): $\delta = 17.34$ (CH_3), 54.95 (OCH_3), 86.35 ($C-OCH_3$), 155.66 (C=N); MS (70 eV): **4b′**. The ^{13}C resonance signal of $C-CH_3$ in the *cis*-compound **4b** is observed at lower field than that of **4b′**. This effect was also invoked to explain the configurational arrangement in the complexes **3b** and **3b′**.

Dilithiomethylenecyclohexane—A Stable 1,1-Dilithioalkene**

By *Adalbert Maercker** and *Ralf Dujardin*

Among organopolylithium compounds, the 1,1-dilithioalkenes occupy the center of interest since, according to ab initio calculations on 1,1-dilithioethene[1], an orthogonal (perpendicular) double bond and, moreover, a triplet ground state should be preferred. Furthermore, an extremely low value was calculated for the barrier of rotation to a planar double bond[1]. The synthesis of a 1,1-dilithioalkane[2] suggested that the method used might also be applicable to the preparation of corresponding alkenes.

1,1-Dilithioethane has the disadvantage that, even at room temperature, it decomposes quantitatively in 8 h to afford vinyllithium and lithium hydride[2], a reaction which with 1,1-dilithioethene—assuming that it behaves analogously[1d]—would lead to the even more stable lithium acetylide. Our intention was therefore to synthesize a 1,1-dilithioalkene in which elimination of lithium hydride was precluded.

As starting material for the preparation of dilithiomethylenecyclohexane **4**, we used bis(chloromercurio)methylenecyclohexane **1**[3]. Treatment of **1** at room temperature with lithium powder (molar ratio ≈ 1 : 14) in diethyl ether under argon affords after 1 h a black suspension of **4**, LiCl, and lithium amalgam, which reacts with D_2O (gas chromatographically 81%, by distillation 51%) to form pure dideuteriomethylenecyclohexane **6**; the product is identical with that prepared using a Wittig reaction[4]. Under the conditions used for the deuteriolysis, **1** does not react with D_2O, even in the presence of lithium.

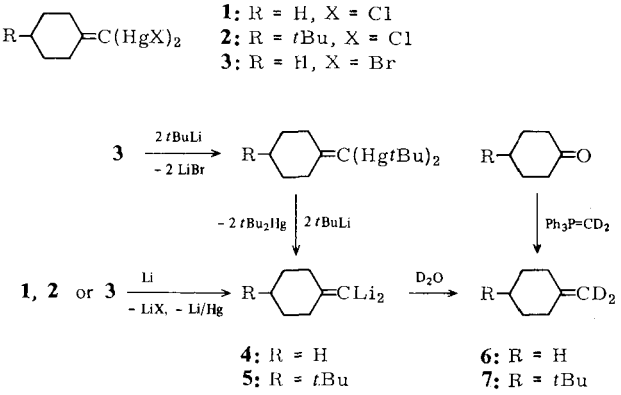
[**] Polylithium Organic Compounds, Part 2. This work was supported by the Fonds der Chemischen Industrie.—Part 1: [2].

An investigation of **4** by NMR spectroscopy has not yet proved possible since the compound is insoluble in ether and hydrocarbon solvents. The introduction of a *tert*-butyl group at the 4-position starting from 4-*tert*-butyl-1-bis(chloromercurio)methylenecyclohexane **2** also did not improve the solubility. **5** was also characterized by deuteriolysis, giving pure **7** (gas chromatographically 95%, by distillation 58%).



The dilithioalkene **4** can be obtained free of lithium amalgam and lithium halide if the bromomercury compound **3** is used and not allowed to react with lithium powder but with *tert*-butyllithium in cyclopentane[5]. This method has previously been used successfully to prepare 1,3-dilithiopropanes[6] and dilithiomethane[2]; however, it fails with the chloromercury compounds **1** and **2** as well as with 1,1-bis(chloromercurio)ethane[2].

[5] *Procedure: tert*-Butyllithium (22 mmol), a large batch of which was previously prepared from di-*tert*-butylmercury and lithium (molar ratio 1 : 10) in cyclopentane, was added dropwise to an ice-cold solution of **3** (7.1 g, 11 mmol) in 30 mL anhydrous cyclopentane under argon. LiBr is filtered off from the clear solution using a filter frit under inert gas atmosphere; *tert*-butyllithium (22 mmol) is added again dropwise to the filtrate at room temperature. After being stirred for 2 h at room temperature, **4** is filtered off under an inert gas atmosphere and washed with anhydrous cyclopentane (5 × 50 mL) to remove di-*tert*-butylmercury and *tert*-butyllithium. For the deuteriolysis 10 mL D_2O is added dropwise at 0°C under argon, the mixture stirred for 10 min at room temperature, and ether added. The organic phase contains **6** (gas chromatographically 91%), which upon distillation affords 0.6 g (57%) pure **6**[4] of b.p. = 102−103°C. **6** was characterized not only by ^{13}C-NMR spectroscopy in $CDCl_3$ (=CD_2: $\delta = 105.8$, quint., $J = 25.4$ Hz) but also by GC/MS (glass capillary, silicon OV-101, length 30 m). The degree of deuteration of the exocyclic methylene group is 91% (MS).

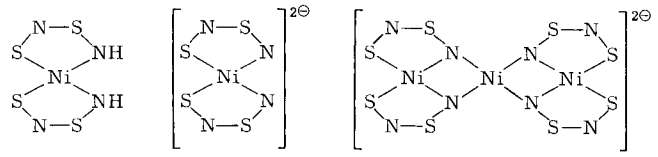
$[Ph_4P]_2[Ni_3N_8S_8]$, a Novel Trinuclear Complex with Sulfur-Nitrogen Ligands**

By *Johannes Weiss**

Alkalis react with the violet, planar complex $[Ni(HN_2S_2)_2]$ **1** to afford brown and red salts of the anions $[Ni(HN_2S_2)(N_2S_2)]^{\ominus}$ and $[Ni(N_2S_2)_2]^{2\ominus}$ **2**, respectively[1]. In turn, **2** can also act as a bidentate ligand in complexes. Thus with, e.g., $Ni^{2\oplus}$ the anion **3** is formed, a trinuclear complex in which two moieties of **2** are linked to each other via a further nickel atom.



1 **2** **3**

3 was isolated as the stable, black tetraphenylphosphonium salt $[Ph_4P]_2[Ni(NiN_4S_4)_2]$ **4**. This compound was initially formed unexpectedly when we attempted to convert the potassium salt of the anion of **2**[1], which only crystallizes with difficulty, into a more readily crystallizing salt with a larger cation by allowing it to react with Ph_4PBr. The initially formed $K[Ph_4P][Ni(N_2S_2)_2]$ recrystallizes from acetonitrile to afford **4**, which can also be obtained from **1** and $NiCl_2$ via directed synthesis[2]. Compound **4** is insoluble in cold water, is sparingly soluble in methanol or acetone, but is reasonably soluble in acetonitrile. Addition of acid to these solutions results in their immediate decomposition to re-form **1**.

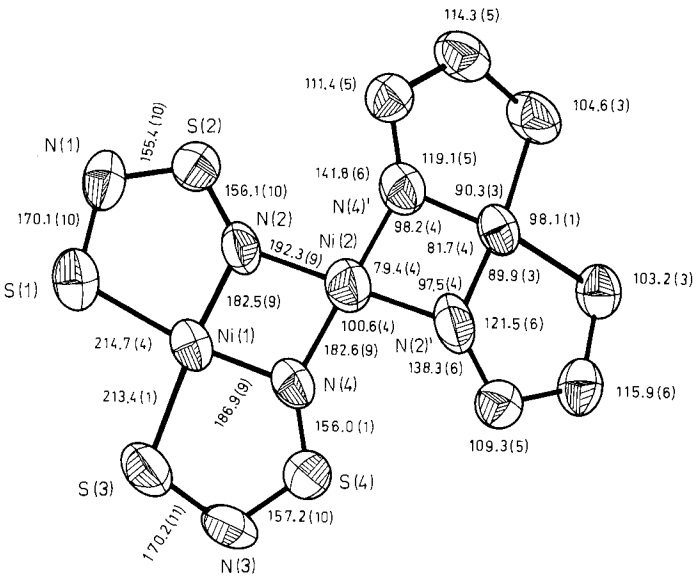


Fig. 1. Structure of the complex anion **3** in crystals of the tetraphenylphosphonium salt **4**. Bond lengths [pm] and bond angles [°], respectively, are shown in the left and right halves of the centrosymmetric anion. Space group $P2_1/a$, $a=1332.8(10)$, $b=1419.5(5)$, $c=1390.0(6)$ pm, $\beta=93.04(3)°$, $Z=2$; 2271 independent reflections with $I>2.5\sigma(I)$, $R=0.065$. Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the depository number CSD 50752, the names of the authors, and the journal citation.

[**] Metal-Sulfur-Nitrogen Compounds, Part 15.—Part 14: H. Martan, J. Weiss, *Acta Crystallogr. C39* (1983) 959.

As indicated in Figure 1, the environment of the central atom Ni(2) in the centrosymmetric anion **3** and of the two peripheral Ni atoms is planar. The atoms of the individual "ligands" deviate only slightly from the best-fitting plane; however, these planes are each inclined by 17° to the coordination plane of Ni(2). The bond lengths and angles in the $[Ni(N_4S_4)]^{2\ominus}$ ligand scarcely differ from those in the complexed molecule **1**[3]. The only main difference is that the angle S(1)–Ni(1)–S(3) is ca. 8° larger and the angle N(2)–Ni(1)–N(4), ca. 11° smaller.

1,2,3-Triaminocyclopentadienide Ions—Preparation via an Unusually Rapid Vinylcyclopropene-Cyclopentadiene Rearrangement**

By *Ekkehard Bartmann** and *Thomas Mengel*

Although cyclopentadienyl derivatives today form a vast class of compounds due to their importance as synthetic building blocks in the chemistry of natural products and as ligands in transition-metal complexes, only one general access to monoamino-substituted systems was previously known[1]. We describe here a facile synthetic pathway to 1,2,3-triamino-substituted cyclopentadienyl compounds, which, at the same time, is mechanistically interesting.

If the tris(dialkylamino)cyclopropenylium salts **1** (which according to *Yoshida* et al. are readily accessible[2]) are mixed with vinyllithium in the molar ratio 1:2 in tetrahydrofuran (THF) below −40 °C and the mixtures are carefully warmed, the salts dissolve with *simultaneous* evolution of ethylene. The reaction temperature is dependent on the steric demands of the cyclopropenylium ion and lies between ca. −10 °C (**1a**, **1c**) and +30 °C (**1b**). The solution contains the lithium salt of the respective 1,2,3-tris(dialkylamino)cyclopentadienide ion **2**, detectable in the NMR spectrum from the singlet exhibited by the ring protons at $\delta \approx 5.1$ as well as from its subsequent reactions.

The reaction can be explained as follows: Vinyllithium attacks **1** to form a vinylcyclopropenetriamine **4**; this immediately rearranges to the cyclopentadienetriamine **5**, which is deprotonated by additional organolithium reagents to afford **2**. The initial step (dissolution of the salt) is apparently the slowest, while the subsequent reaction pro-

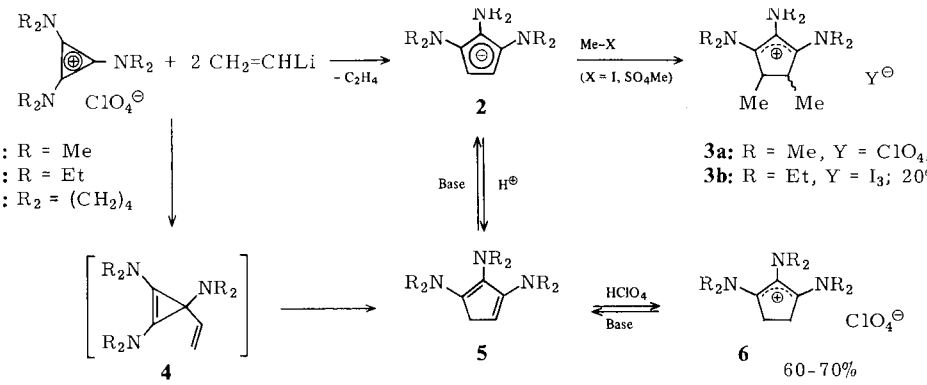
[**] Note added in proof: After completion of this manuscript, a synthesis of 1,2,4-triaminocyclopentadienyl cations was published: R. Gompper, H. Glöckner, *Angew. Chem. 96* (1984) 48; *Angew. Chem. Int. Ed. Engl. 23* (1984) 53.



ceeds extraordinarily smoothly for vinylcyclopropane-cyclopentene or vinylcyclopropene-cyclopentadiene rearrangements. Rearrangements of this type normally require considerably higher temperatures[3] (e.g. for triphenyl(vinyl)cyclopropene: 180°C) or irradiation[4]. The large number of amino substituents in **4** therefore effects a drastic reduction in the activation barrier (in general, highly donor-substituted cyclopropenes very readily undergo ring-opening reactions[5]. However, the rate of the vinylcyclopro*pane*-cyclopent*ene* rearrangement is also markedly increased by the presence of donor rather than alkyl substituents on the three-membered ring[3b,c]).

Upon acidification of the reaction solution, **2** is doubly protonated. The resulting cyclic 1,2,3-triamino-substituted vinamidinium salts **6** can be isolated as perchlorates[6]. The intermediate **5** has not yet been isolated, but its occurrence (possibly mixed with isomers) in solution is implicated: Addition of the weak proton donor *tert*-butyl alcohol to the solution of **2** results in the disappearance of its NMR signals and gives rise to a complicated spectrum; the characteristic signals of **6** appear only after addition of acids[8]. **2** can be re-formed from **6** by the addition of strong bases such as potassium hydride.

2 is also attacked twice by methylating agents to form 4,5-dimethyl-substituted salts **3**[6]. Whereas dimethyl sulfate reacts smoothly (isolation of the perchlorate **3a** starting from **1a**), in reactions with methyl iodide large amounts of by-products are formed (see also, the formation of the triiodide **3b** instead of the normal iodide)[9].

On the basis of preliminary results, the reaction of **1** with vinyllithium described here can be applied to its homologues (e.g. butenyllithium), but not to vinylmagnesium compounds.

Non-Toxic Alternative for a Key Step in Porphyrin Synthesis**

By *Theo Wollmann* and *Burchard Franck**

The oxidative rearrangement of acetylpyrroles such as **1** to pyrrolacetic acids **4** is a key step in the synthesis of porphyrins with "natural" acetic acid side-chains. Until now this rearrangement, whose result is analogous to the Willgerodt reaction, was performed using thallium(III) nitrate[1]. The toxity of this reagent, however, restricts the usefulness of the method and also the application of the synthesized products for medicinal purposes. Here, we describe an efficient, generally applicable method for the rearrangement of acetylpyrroles in the presence of silver nitrate (Scheme 1).

The pyrroleacetic acids **4a** and **4b** are of preparative importance because they permit the biomimetic syntheses of medicinally used porphyrins in a few steps[2]. For example,

[*] Prof. Dr. B. Franck, Dipl.-Chem. T. Wollmann

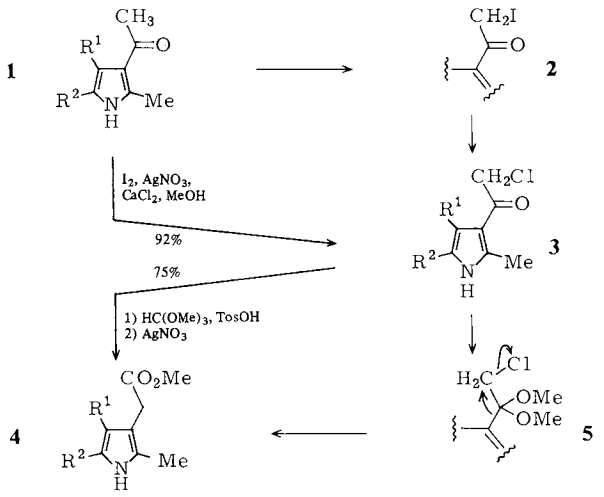
Orléans-Ring 23, D-4400 Münster (FRG)

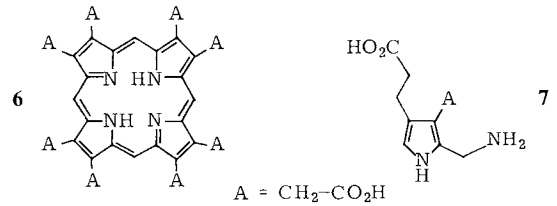
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



a, $R^1 = CH_2{-}CO_2Me$; $R^2 = CO_2Me$
b, $R^1 = CH_2{-}CH_2{-}CO_2Me$; $R^2 = CO_2CH_2Ph$

Scheme 1. Intermediates and possible course of the reaction **1**→**2**→**3**→**5**→**4**.

4a can be converted in three steps into the porphyrinoctaacetic acid **6**, which differs only slightly from the biologically active naturally occurring porphyrins[3]. **4b** can be converted in five steps into the porphobilinogen **7**, a building block in the biosynthesis of red blood pigment[4]; **7** can be condensed biomimetically to afford porphyrins.



Investigations of the mechanism of the oxidative rearrangement of simple aryl ketones indicated that the system thallium(III) nitrate in $MeOH/HClO_4$ can be replaced by $I_2/AgNO_3$[5]. The reaction sequence involves α-halogenation of the ketone, ketalization, and rearrangement of the α-haloketal to the acetate induced by silver ions (**1**→**2**→**5**→**4**).

By fulfilling certain restrictive reaction conditions, we found that using this method the acetylpyrrole **1b** can be converted into the triester **4b**. Because of the formation of side products, which necessitate chromatographic separation the method is still too troublesome for preparative purposes. Furthermore, studies indicated that side products arise because of the instability of the intermediate iodoacetylpyrroles **2**. These problems could be solved by trapping **2** by conversion into the chloroacetylpyrroles **3**. The chloroacetylpyrroles **3a** and **3b**, obtained in high yield, are readily isolable and form good crystals[6].

For the rearrangement, **3a** and **3b** are converted into the ketals **5a** and **5b**, respectively, which are refluxed in the presence of silver nitrate. The yield of the rearrangement step to afford **4a** and **4b**, respectively, is so high that the overall yield starting from **1a** or **1b** is 68–69%. The yields obtained using the new method correspond to those achieved in the rearrangement with thallium(III) nitrate, but the former is preferable because of its non-toxicity. The silver can be fully recovered from the silver halide precipitates.

[6] *Preparation of chloroacetylpyrroles* **3**: $AgNO_3$ (17 g, 100 mmol) and **1** (50 mmol) are added to anhydrous $CaCl_2$ (25 g, 225 mmol) in 150 mL anhydrous methanol. A solution of iodine (12.7 g, 50 mmol) in 100 mL anhydrous MeOH is added dropwise into the refluxing solution over 2 h, the mixture heated for 1 h longer, the solution filtered while hot, and the precipitate washed with hot MeOH. After the filtrate has been diluted with a threefold volume of water, the solution is saturated with NaCl, extracted with $CHCl_3$, the extract concentrated, and the residue recrystallized from $MeOH/H_2O$. 91% **3a**, colorless needles, m.p. = 149–150°C; **3b**, colorless needles, m.p. = 109–110°C.

[7] *Rearrangement of* **3** *into the pyrroleacetic acids* **4**: *p*-Toluenesulfonic acid (200 mg) was added to a solution of **3** (45 mmol) in 175 mL anhydrous MeOH and 50 mL (460 mmol) trimethylorthoformate, the mixture warmed to 50°C, and stirred for 1–2 h under an inert gas atmosphere. After conversion of the starting material into the ketal **5** (TLC monitoring with ether (**3a**) or toluene/acetic acid = 4:1 (**3b**) on silica gel), $AgNO_3$ (11.8 g, 67.5 mmol) is added. The mixture is refluxed for 5–7 h until **5** has been fully converted into **4** (TLC monitoring). After addition of KI (4 g) and cooling, the solution is filtered off, the filtrate diluted with a threefold volume of water, saturated with NaCl, extracted with $CHCl_3$, concentrated, and the oily residue recrystallized from ether/petroleum ether (b.p. 30–60°C). 75% **4a**, m.p. = 92°C; 76% **4b**, m.p. = 78°C.

3-Trimethylsilylacrylic Acid as an Acetylene Equivalent in Diels-Alder Reactions; Olefins via Anodic Decarboxylation-Desilylation**

By *Dieter Hermeling* and *Hans J. Schäfer**

Synthetic equivalents for acetylene which have a greater dienophilicity and lower pressure sensitivity are desirable for the preparation of 1,4-cyclohexadienes by [4+2]-cycloaddition. In this connection, (*E*)-1-benzenesulfonyl-2-trimethylsilylethylene[1] and maleic acid anhydride have proved to be particularly useful. The maleic acid cycloadducts undergo facile anodic bisdecarboxylation to afford olefins[2]. However, low yields and electrode passivation frequently limit the range of application and the scale of the electrolysis. We have now investigated 3-trimethylsilylacrylic acid **1** as an acetylene equivalent. The trimethylsilyl moiety lowers the dienophilicity only marginally[1], and the β-trimethylsilylcarboxylic acid obtained can be converted anodically into an olefin[3].

[a] General procedure: Diene and dienophile were allowed to react neat. Adducts **4**, **5**, **7**, and **8** were extracted with 2N NaOH after acidic impurities had been removed with $NaHCO_3$ (Na_2CO_3 for **7** and **8**). **9**–**11** cannot be extracted with NaOH and after hydrolysis were purified by column filtration (CH_2Cl_2/EtOAc 5:1 to 25:1). Purification of **6**: Extraction with Na_2CO_3, recrystallization from MeOH/H_2O. [b] Data in parenthesis: mol diene per mol dienophile. [c] Data in parenthesis: isomer ratio. [d] After hydrolysis.

Since α,β-unsaturated carboxylic acids cannot be decarboxylated anodically, **6**–**8** were hydrogenated (Pd/C, methanol). **6** afforded **12** quantitatively, whereas **7** gave the three isomeric carboxylic acids **13** in 86% yield together with 9% *p*- and *m*-methylbenzoic acids. With **8** aromatization was even more dominant: In addition to 51% 3,4-dimethylbenzoic acid only 42% of the five diastereomeric acids **14** were formed.—Hydrogenation of **9** yielded **15**.

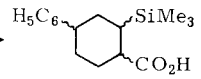
14



15

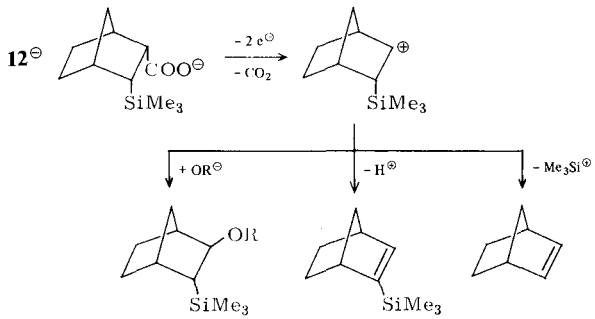
To establish the optimum conditions for formation of olefins, the potassium salt of **12** was electrolyzed under various conditions (Table 2). Formation of the products **16**–**18** indicates the involvement of an intermediate trimethylsilylnorbornyl cation which undergoes solvolysis, deprotonation, and desilylation.

Table 2. Electrolysis [a] of the potassium salt of **12** under various conditions.

Solvent	T [°C]	Cell potential [V]	Product yields [%] [b] **16a**	**16b**	**17**	**18**
pyridine/methanol (5:1)	20	80–150	10	—	45	26
methanol	0	60–80	44	—	13	19
acetonitrile/methanol (5:1)	0	8–20	31	—	7	35
acetonitrile/ethanol (5:1)	0	8–20	—	17	14	51
acetonitrile/ethanol (5:1)	60	8–20	—	9	13	60

[a] 0.2 mmol acid in 20 mL solvent and 4 mL 0.05N KOH in ethanol or methanol were electrolyzed using a graphite anode (8 cm^2) and a platinum foil cathode. Current density 10–20 mA/cm^2. [b] Determined by gas chromatography (capillary column SE-30).

The remaining β-trimethylsilylcarboxylic acids were allowed to react in the most favorable electrolyte (acetonitrile/ethanol (5:1)) (Table 3). In general, the yields were better than with **12**; in contrast to **12**, increasing the temperature caused no increase in yield. With **5** the current consumed should not substantially exceed 2 F/mol since otherwise the product is oxidized to toluene. The other olefins are stable under the electrolysis conditions.



16a: R = CH_3
16b: R = C_2H_5

17 **18**

We believe that the anodic decarboxylation-desilylation is an attractive alternative to anodic bisdecarboxylation. The reaction does not result in electrode passivation and gives good yields. This becomes particularly noticeable

Second Sphere Coordination of Cationic Rhodium Complexes by Dibenzo[3*n*]crown-*n* Ethers**

By *Howard M. Colquhoun, Simon M. Doughty, J. Fraser Stoddart*,* and *David J. Williams*

Dibenzo-crown ethers of the general type DB3*n*C*n* ($n=6-12$) form[1] stable adducts with $[Pt(bpy)(NH_3)_2]^{2\oplus}$ in which the 2,2′-bipyridyl ligand (bpy) participates as a π-acceptor in charge transfer interactions with the benzene rings (π-donors). We have now investigated the structures of 1 : 1 adducts formed between these DB3*n*C*n* receptors[2] and the cationic rhodium(I) complexes[2], $[Rh(cod)(NH_3)_2]^{\oplus}$ and $[Rh(nbd)(NH_3)_2]^{\oplus}$, and discovered that in the case of DB24C8 and DB30C10 the 1,5-cyclooctadiene (cod) and norbornadiene (nbd) ligands also prefer to occupy positions in which they are sandwiched between the two benzene rings of the receptors. In addition to presenting ^{1}H-NMR spectroscopic evidence for this adduct stereochemistry in solution, X-ray structures[3] of the crystalline adducts[2] $[Rh(cod)(NH_3)_2\cdot DB30C10][PF_6]$ **1**, $[Rh(cod)(NH_3)_2\cdot DB24C8][PF_6]$ **2**, and $[Rh(nbd)(NH_3)_2\cdot DB24C8][PF_6]$ **3** provide conclusive proof of a remarkable receptor geometry, clearly much more general in its occurrence than believed previously[1].

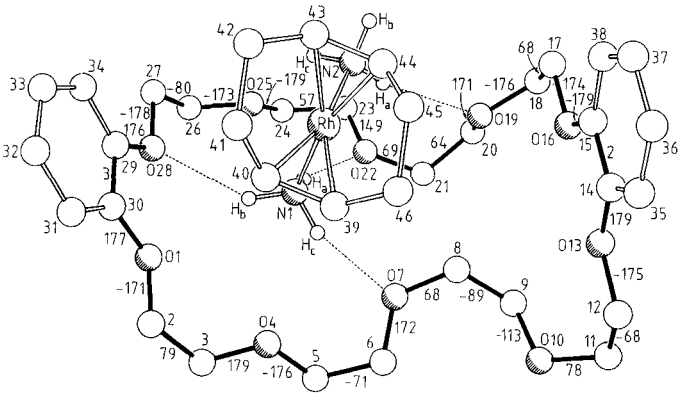

Fig. 1. Structure of the cation of $[Rh(cod)(NH_3)_2\cdot DB30C10][PF_6]$ in the crystal. Torsion angles [°] (O–C–C–O and C–C–O–C) associated with the 30-membered ring are given. Four shortest hydrogen bond distances [Å] [N···O], [H···O], angles [°] between COC planes and HO vectors, and [N–H···O] angles [°]: [N(1)···O(22)]H_a, 3.19, 2.30, 3, 154; [N(1)···O(28)]H_b, 3.16, 2.37, 45, 139; [N(1)···O(7)]H_c, 2.96, 2.06, 42, 155; [N(2)···O(19)]H_a, 3.18, 2.29, 40, 155. Separation [Å] between mean planes of the benzo rings and cod hydrogen atoms: [ring (29/30)···H], H_0 (40), 2.61; H_e (41), 2.98; H_e (42), 3.33; [ring (14/15)···H] H_0 (44), 3.13; H_e (45), 2.87; H_e (46), 3.19.

The solid-state structures (Figs. 1 and 2) of **1**–**3** reveal several surprising features: (a) the preference of the *cis*-NH_3 ligands, without exception, to straddle the side of one of the polyether chains, cf. the solid state structures of $[Pt(bpy)(NH_3)_2\cdot DB3nCn][PF_6]_2$ ($n=8$, 10)[1] which also exhibit this characteristic; (b) the tendency of both NH_3 ligands to underutilize their hydrogen bonding potential towards the polyether chains (only two [N–H···O] distances of less than 3 Å are present in all of the structures), cf. the solid-state structures[4] of transition-metal ammine adducts with 18C6 and DB18C6 where [N–H···O] distances are considerably shorter; and (c) the invariably close juxtaposition of the organic ligands cod and nbd with the benzene rings of DB30C10 and DB24C8, despite the lack of any obvious stabilizing interactions, cf. the charge transfer in $[Pt(bpy)(NH_3)_2\cdot DB3nCn][PF_6]_2$[1]. The distances quoted in Figure 1, together with the three shortest [N–H···O] distances of 3.03, 3.13, and 3.34 Å, and of 2.95, 3.01, and 3.27 Å for **2** and **3**, respectively, suggest that the additive effect of a substantial number of very weak hydrogen bonds and electrostatic interactions confers stability upon the adducts. In both DB24C8 adducts **2** and **3** one of the four phenolic oxymethylene units in the receptor is distorted from its customary coplanarity[1,5] with the benzene ring in order that the O atom can form a hydrogen bond to one of the NH_3 ligands with an approximately trigonal approach to the oxygen atom. It is unclear

whether adduct stability is enhanced by any attractive interactions[6] between either the cod or the nbd ligands in the complexes and the benzene rings in either DB30C10 or DB24C8 since certain nonbonded atoms only just approach the sum of their van der Waals' radii.

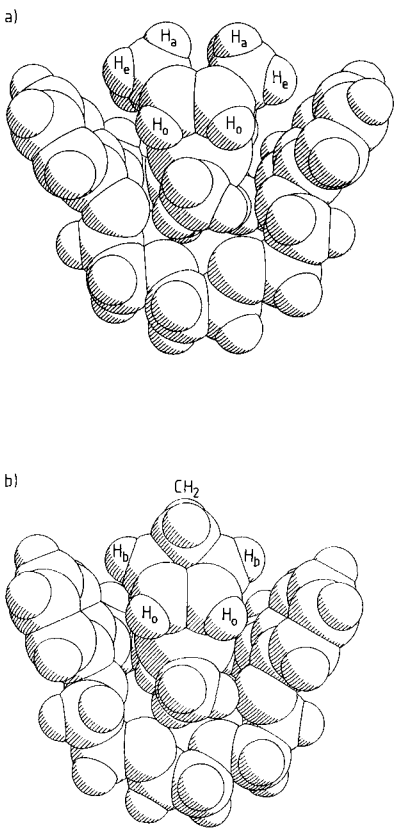

Fig. 2. Computer sketches [(a) and (b)] of space-filling representations of a) $[Rh(cod)(NH_3)_2 \cdot DB24C8]^{\oplus}$ and b) $[Rh(nbd)(NH_3)_2 \cdot DB24C8]^{\oplus}$.

The principal structural features characteristic of the solid state are found to prevail in solution, as judged by the anisotropic diamagnetic shielding effect of the benzene rings upon the chemical shifts of the ^{1}H-NMR signals of cod or nbd ligands. Comparison of the ^{1}H-NMR spectra of $[Rh(L)(NH_3)_2 \cdot DB3nCn][PF_6]$ (L = cod, nbd; $n = 6-12$) with those of the corresponding 1:1 adduct with 18C6 in CD_2Cl_2 reveals substantial upfield shifts for all protons of the cod and nbd ligands (Fig. 3). The shifts assume their greatest magnitude for H_e in the cod ligand and for H_b in the nbd ligand when the receptor is DB24C8. They are accompanied by modest shifts to lower field for the aromatic C_6H_4 protons relative to the singlets observed at $\delta = 6.87-6.90$ for these protons in the free crown ethers. Significantly, this shift also attains its maximum in both series of adducts when the receptor is DB24C8.

Qualitative analysis of nuclear Overhauser effects from difference spectra recorded at 400 MHz confirm that the structure of **2** in CD_2Cl_2 solution is similar to that in the solid state (Fig. 2a). When the signals at $\delta = 1.62$ and 3.54 were irradiated in separate experiments, enhancements of the signal intensities for the C_6H_4 protons at $\delta = 7.03$, as well as for the other cod protons, were observed in both cases. Irradiation of the aromatic protons produced the expected reciprocal effect in the signals at $\delta = 1.62$ and $\delta = 3.54$, but no enhancement in the intensity of the signal at $\delta = 1.41$. These intra- and intermolecular nuclear Overhauser effects also confirm the signal assignments in Figure 3.

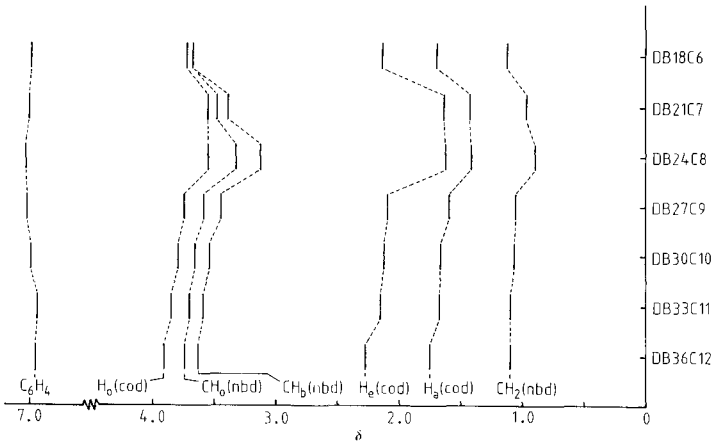

Fig. 3. Partial ^{1}H-NMR line spectra for the complexes $[Rh(cod)(NH_3)_2 \cdot DB3nCn][PF_6]$ and $[Rh(nbd)(NH_3)_2 \cdot DB3nCn][PF_6]$. The ligand protons are designated in Fig. 2 and the signals (singlets) for the benzo-protons refer to $[Rh(cod)(NH_3)_2 \cdot DB3nCn][PF_6]$.

[2] Experimental: The crown ethers DB18C6 and DB24C8 were obtained from Aldrich; DB21C7, DB27C9, DB30C10, DB33C11, and DB36C12 were synthesized by a stepwise procedure (cf. [1]). $[Rh(cod)(NH_3)_2][PF_6]$, m.p. 209–215°, and $[Rh(nbd)(NH_3)_2][PF_6]$, m.p. 159–164°, were prepared from $[Rh(cod)Cl]_2$ (R. B. King, *Organometallic Synthesis 1* (1965) 132) and $[Rh(nbd)Cl]_2$ (E. W. Abel, M. A. Bennett, G. Wilkinson, *J. Chem. Soc. 1959*, 3178), respectively, by treatment of these chloride dimers with NH_3 ($\rho = 0.88$) and then with NH_4PF_6. The crystalline adducts **1**, m.p. 95–100°, **2**, m.p. 135–145°, and **3**, m.p. 118–129°, were obtained by layering Et_2O on top of either CH_2Cl_2 or $(CH_2Cl)_2$ solutions (1:1 stoichiometries). All new crown ethers, complexes, and crystalline adducts gave satisfactory elemental analyses and spectroscopic data.

[3] Crystal data **1**: monoclinic, $a = 9.268(2)$, $b = 34.335(7)$, $c = 13.421(3)$ Å, $\beta = 93.92(2)°$, $V = 4261$ Å^3, space group $P2_1/c$, $Z = 4$, $\rho_c = 1.45$ g cm^{-3}. **2**: monoclinic, $a = 9.195(3)$, $b = 29.380(9)$, $c = 13.900(6)$ Å, $\beta = 93.04(3)°$, $V = 3750$ Å^3, space group $P2_1/c$, $Z = 4$, $\rho_c = 1.49$ g cm^{-3}. **3**: orthorhombic, $a = 15.427(3)$, $b = 18.739(3)$, $c = 25.458(5)$ Å, $V = 7360$ Å^3, space group *Pbca*, $Z = 8$, $\rho_c = 1.49$ g cm^{-3}. Data were measured on a Nicolet R3m diffractometer using the ω-scan routine with graphite-monochromated $Cu_{K\alpha}$ radiation. Structures were solved by the heavy-atom method and refined anisotropically to give R values of 0.034, 0.043, and 0.047, respectively, for 3915, 3401, and 2984 independent observed reflections [$\theta \leq 50°$, $|F_o| > 3\sigma(|F_o|)$]. Further details of the crystal structure investigations can be obtained from the Director of Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW. A Novel Rearrangement of the Azulene Skeleton: Ring Contraction of a Dihydroazulene to an Indene Derivative**

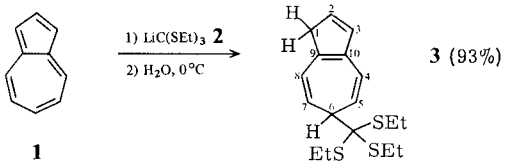
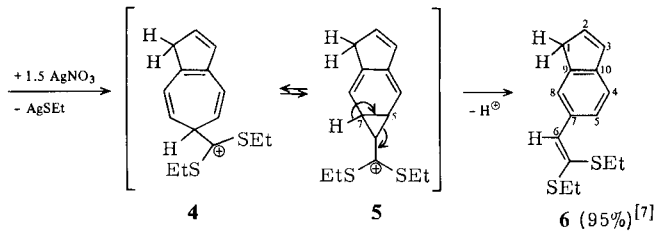
By *Siegfried Hünig** and *Burkhard Ort*

Rearrangements of the azulene skeleton predominantly lead to naphthalene derivatives[2]. Herein we describe the first preparative[3] rearrangement which leads via contraction of the seven-membered ring to an indene derivative.

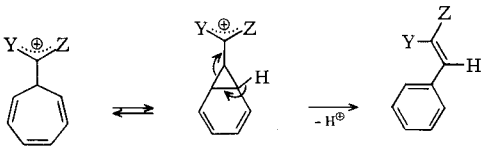
Azulene **1** already reacts at −70 °C in tetrahydrofuran (THF) with the nucleophile **2** generated from triethyl trithioorthoformate[4]. Hydrolysis furnishes a ^{1}H-NMR spectroscopically and chromatographically pure, colorless oil, the 1,6-dihydroazulene derivative **3**[5,6]. When a concentrated solution of silver nitrate in acetonitrile is added dropwise to a solution of **3** in THF, a yellow compound precipitates. Subsequent chromatographic purification of the solution affords 95% 6-[2,2-bis(ethylthio)vinyl]-1*H*-indene **6** as a colorless, undistillable oil[5,7].





Selective decoupling and nuclear Overhauser experiments enable an unambiguous assignment of signals in the ^{1}H-NMR spectrum according to structure **6**[8]. The signals of 1-H_2, 2-H, and 3-H form a A_2MX system, which is almost identical with the corresponding subspectrum of indene[9]. The resonances of the *S*-ethyl groups are very similar, but not exactly the same. The rearrangement is probably initiated by the dissociation of **3** with formation of the cationic cycloheptatriene derivative **4**, which is in equilibrium with the norcaradiene derivative **5**. This finally aromatizes to **6**. If it is assumed that $\delta^\oplus$ charges appear on C-5 or C-7 in the transition state during the cleavage of the three-membered ring, then the regioselective opening to give **6** is understandable: The double bond of the five-membered ring can participate more effectively in the delocalization of the charge if C-5 (and hence C-10) gains $\delta^\oplus$ character.

The transition **5** → **6** is a further example of the cyclopropylmethyl cation/homoallyl cation rearrangement[10], which is realized with several cycloheptatrienes by the reaction sequence **7** → **8** → **9**. However, this rearrangement



7 **8** **9**

only occurs if the carbenium ion is weakly stabilized by Y and Z[11]. The ring contraction in the azulene moiety described here formally appears as a reversal of the classical Plattner azulene synthesis: expansion of the benzene ring in indane by a C_1 unit via a norcaradiene intermediate[12].

$[S_4N_4]^\oplus[FeCl_4]^\ominus$, a Compound with Cyclic Radical Cation

By *Ulrich Müller**, *Elke Conradi*, *Udo Demant*, and *Kurt Dehnicke*

In contrast to the cyclic sulfur-nitrogen cations such as $S_4N_3^\oplus$[1], $S_4N_4^{2\oplus}$[2], $S_4N_5^\oplus$[3] or $S_5N_5^\oplus$[4] with even numbers of electrons, so far only one radical cation $S_3N_2^\oplus$ has been characterized crystallographically in combination with various anions[5–8]: the lattice contains centrosymmetric dimers with long S···S contacts of about 300 pm.

On separating the products formed in the reaction of $FeCl_3$ with $(NSCl)_3$ in dichloromethane by extraction with CH_2Cl_2, we obtained brown, moisture-sensitive crystals of the composition $S_4N_4FeCl_4$, which according to an X-ray

[*] Prof. Dr. U. Müller, Prof. Dr. K. Dehnicke, E. Conradi, Dipl.-Chem. U. Demant
Fachbereich Chemie der Universität
Postfach 1929, D-3550 Marburg 1 (FRG)

structure analysis[9] contain the hitherto unknown radical cation $S_4N_4^{\oplus}$ (Fig. 1). In contrast to the dication $S_4N_4^{2\oplus}$, which occurs as a planar ring (D_{4h} symmetry) with the counterions $SO_3F^{\ominus}$ or $AlCl_4^{\ominus}$ and in the boat conformation (C_{2v}) with the counterion $SbCl_6^{\ominus}$[2], the radical cation $S_4N_4^{\oplus}$ has a puckered eight-membered ring structure in which the S-atoms form an almost ideal square; the N-atoms are located alternately 34, −59, 45, and −38 pm above and below this square. The SN bonds are almost equal in length (average 154 pm), the NSN and SNS angles have mean values of 116.0 and 138.9°, respectively. The SN bond lengths are thus markedly shorter than those in the S_4N_4 molecule (162 pm)[10], but almost the same length as those in the $S_4N_4^{2\oplus}$ cation[2]. The NSN angles in the two cations also differ only slightly ($S_4N_4^{2\oplus}$: average 119°), whereas the SNS angle in the $S_4N_4^{\oplus}$ radical ion, with a value of 139°, is considerably smaller than that in $S_4N_4^{2\oplus}$ (average value 152°[2]).

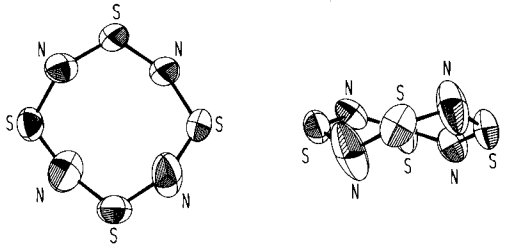

Fig. 1. Structure of the $S_4N_4^{\oplus}$ radical cation (in the crystal of $S_4N_4FeCl_4$) viewed in two directions; ellipsoids of the thermal vibration for 50% probability at 25°C.

The possibility of the presence of $[S_4N_4]^{2\oplus}[FeCl_4]^{2\ominus}$ can be ruled out. The four Fe–Cl bonds in the anion have the same length, namely 219 pm, corresponding exactly to the known value for those in $FeCl_4^{\ominus}$ with various counterions; in $FeCl_4^{2\ominus}$, on the other hand the length is 229 pm[11]. This difference greatly exceeds the limit of error. Equally significant is the IR spectrum: The F_2 stretching vibration of the $FeCl_4^{\ominus}$ anion appears at 388 cm^{-1} (for comparison: $FeCl_4^{\ominus}$ 385 cm^{-1}[12], $FeCl_4^{2\ominus}$ 286 cm^{-1}[13]). Also the IR-active SN stretching vibrations for the $S_4N_4^{\oplus}$ cation were observed at other frequencies than quoted for $S_4N_4^{2\oplus}[S_4N_4(AlCl_4)_2]$: 1091, 1020, 974 cm^{-1}[2]. In accord with the general finding that a smaller positive charge leads to a long-wave shift, the $S_4N_4^{\oplus}$ vibrations appear at 952, 941, 763, 750, and 715 cm^{-1}; the greater number of IR-active vibrations is consistent with the lower C_1 symmetry of the radical cation.

Molecular Structure of 8,11-Dichloro[5]metacyclophane: A Strongly Bent Benzene Ring**

By *Leonardus W. Jenneskens, Johannes C. Klamer, Henricus J. R. de Boer, Willem H. de Wolf, Friedrich Bickelhaupt**, and *Caspar H. Stam*

Of particular interest in the chemistry of the [n]para-[1] and [n]metacyclophanes[2] with short oligomethylene bridges, is the high strain and its effect on the geometry and reactivity of such compounds. Thus, it is conceivable that the sterically enforced bending of the benzene ring could lead to a bond fixation tending towards a cyclohexatriene structure; the increased tendency of some cyclophanes to undergo Diels-Alder reactions has come under discussion in this sense[2d,3]. 8,11-Dichloro[5]metacyclophane **1** is a representative of the meta series with the hitherto shortest bridge[4].

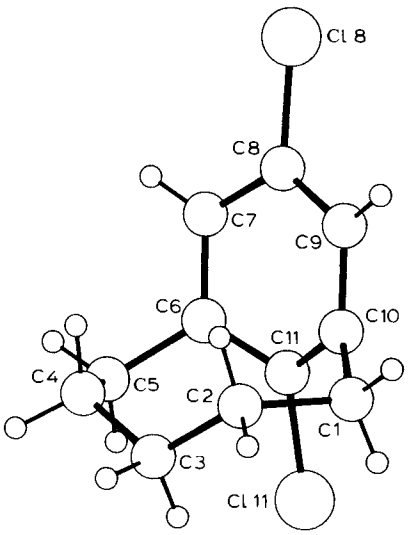

Fig. 1. PLUTO diagram of the structure of **1** in the crystal [5]. Selected bond lengths [Å] and angles [°]: C1–C2 1.569(3), C1–C10 1.506(3), C2–C3 1.566(3), C8–C9 1.389(3), C9–C10 1.400(3), C10–C11 1.391(2), C8–Cl8 1.747(3), C11–Cl11 1.754(3); C2–C1–C10 104.7(2), C1–C2–C3 121.9(2), C2–C3–C4 122.2(2), C7–C8–C9 120.3(3), C7–C8–Cl8 119.5(2), C8–C9–C10 118.8(2), C1–C10–C9 121.8(2), C1–C10–C11 114.8(2), C9–C10–C11 117.4(2), C6–C11–C10 118.7(2), C6–C11–Cl11 119.7.

[**] The investigations were supported by the Netherlands Foundation for Chemical Research (SON) with a grant (*L. W. J.*) from the Netherlands Organization for the Advancement of Pure Research (ZWO).

In the crystal, the molecule has C_s symmetry (Fig. 1); its conformation essentially corresponds to that which, according to MNDO calculations and NMR data, is the more stable of the two conformations in solution[2f]. The benzene ring has an unsymmetric boat conformation, whose most striking characteristic is the marked bending of the "bow" (Fig. 2; $\alpha_1 = 26.8°$); to our knowledge this is the strongest deviation from planarity known so far in a benzene ring. The angle at the "stern" is smaller ($\alpha_2 = 12°$), and the sum $\alpha_1 + \alpha_2 = 38.8°$ is close to that found in the [6]paracyclophane system (41.3°[1a], 38.9°[1b]). A remarkable feature is the large angle $\beta_1 = 48°$; the strain at the bridgehead carbon atoms C-6 and C-10 also manifests itself in marked pyramidalization (sum of the bond angles: 354°).

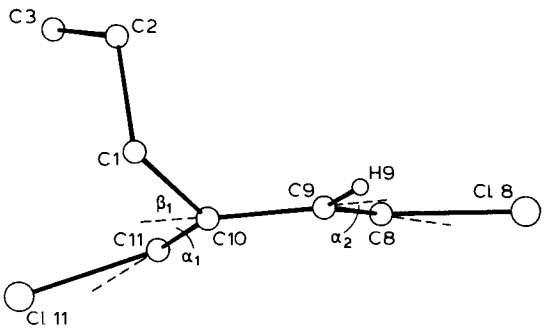

Fig. 2. Side view of the structure of **1** in the crystal [5]. α_1, α_2, β_1, see text.

As has already been observed on several occasions with cyclophanes[6] and acyclic, strongly crowded benzene derivatives[7], the boat conformation is preferred over the—sterically possible—chair conformation. Perhaps this is due to the more favorable π-overlap in the boat form[6b, 7]. This effect also explains the striking finding that all six atoms bound to the benzene ring lie on the same side of the ring, namely the convex side, whereas the substituents in paracyclophynes are, for the same reason, tilted to the concave side[8]. Exceptions to this rule are apparently only found when steric factors counteract such an arrangement, as in the case of the phosphorus atom in bis(2,4,6-tri-*tert*-butylphenyl)phosphinic chloride[7].

The bending of the benzene ring manifests itself in an adjustment of the bond angles in the ring, particularly at C-6, C-10, and C-11. In contrast, the bond lengths in the benzene ring are, surprisingly, completely normal (mean value 1.393 ± 0.007 A). On the basis of this criterion, one must conclude that the aromaticity of the ring is essentially intact. This hypothesis is supported by the ring current effect in the NMR spectra[2f]. These findings are not reconcilable with the postulated cyclohexatriene character, which was considered to explain the high Diels-Alder reactivity[2d, 3]. Apparently, the destabilization of the aromatic ring, which is reflected both in the chemical reactivity and in the UV spectrum[2b, e], is not caused by (partial) bond fixation.

The pentamethylene bridge consists of sp^3-hybridized carbon atoms and is therefore less rigid than the aromatic ring. Consequently, the effects of strain are discernible in the bond lengths as well as in the bond angles. The trend is similar to that in the short-chain [n]paracyclophanes[1]. The angle at the benzylic carbon atom is remarkably small (C10–C1–C2 = 104.7°); the angles at the other bridge atoms (ca. 122°) and the CC bond lengths (1.56–1.57 Å) are somewhat larger than in the [6]paracyclophane system[1b].

Finally, we would like to point out that the MNDO calculations[2f] have predicted the geometry of **1** remarkably well, even though they are not perfect in detail (e.g. $\alpha_1 = 32$, $\alpha_2 = 9$, $\beta_1 = 41°$).

syn-Diastereoselective Homoaldol Reactions: γ-Hydroxyalkylation of (*Z*)-2-Butenyl Carbamates and Synthesis of β,γ-*cis*-Di- and -Trisubstituted γ-Lactones**

By *Dieter Hoppe** and *Florian Lichtenberg*

Diastereoselective homoaldol reactions[1]—they correspond to the hydroxyalkylation of homoenolate ions[2] to give γ-aldols **3**—were first reported very recently. However, the approaches described so far only permit access to *anti*[3,4]-diastereomers **3**[1]. We have now been able to accomplish the first *syn*[3,4]-selective version of the homoaldol reaction, starting from the (*Z*)-2-butenyl carbamate *Z*-**6**.

The *anti*-selective procedures utilize, e.g., α-metalated (*E*)-2-butenyl carbamates[1a–c] *E*-**4a**, (*E*)-2-butenyl ethers *E*-**4b**[1d] or *E*-**4c**[1e], and (*E*)-2-butenylsilanes[1f] *E*-**4d** as homoenolate reagents; the sequences proceed via 1-function-

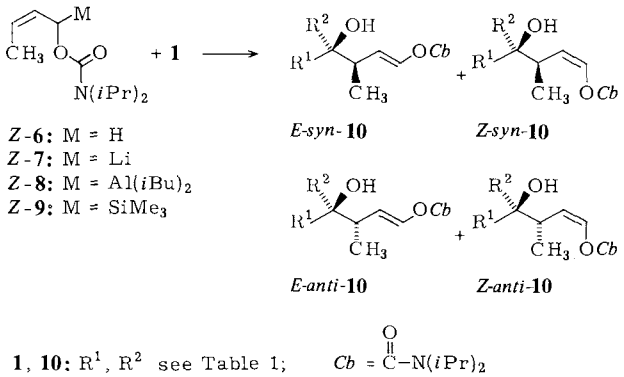
[a] Correct C,H analyses (±0.3%). [b] Diastereomeric mixture **10** after purification by medium-pressure chromatography. [c] In the crude product, determined by capillary chromatography (quartz column SE 30, 50 m, H_2, temperature program 100–230°C, 5–8°C/min); sequence of elution: **11** (diastereomers), *Z-anti*, *Z-syn*-, *E-anti*-, *E-syn*-**10**. [d] Diastereomeric ratio of **10a** achieved with *Z*-**7** : 47 : 15 : 17 : 21; *syn*/*anti* = 62 : 38. [e] Yield of pure *E-syn*-**10a** after recrystallization from pentane, m.p. 76°C.

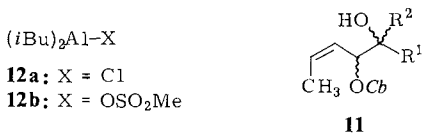
alized 4-hydroxyalkenes[3] of the type *anti*-**5**. *Z*-Configurated derivatives **4** should—as long as the addition of **1** proceeds via a pericyclic transition state with allylic inversion[5]—predominantly yield the racemic[3] diastereomers *syn*-**5**[6]. The problem is the regio- and stereoselective generation of metal compounds of the type *Z*-**4**.

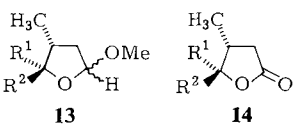
The following procedure proved to be successful: *Z*-**6**[7] is deprotonated with *n*-butyllithium (in pentane, 1.1 equiv. TMEDA, 30 min at −78°C)[2a] to give *Z*-**7**. To check its configurational stability and the α-selectivity of the metal exchange, the solution of *Z*-**7** was kept at −78°C for 2 h and then quenched with chlorotrimethylsilane: the silane *Z*-**9** was formed (yield 95%; <5% *E*-**9**)[8]. Conversely, *E*-**6** afforded pure *E*-**9**[8]. Thus, the lithium compounds **7** prove to be surprisingly stable against torsion of the β,γ-bond.

By exchange[9] of the cation in *Z*-**7** with diisobutylaluminum chloride[1a] (**12a**) or methanesulfonate[10] (**12b**) the alane *Z*-**8** is formed, which adds aldehydes **1** or prochiral ketones **1** (such as acetophenone **1f** or methyl pyruvate **1g**) to give predominantly the diastereomers[3,12] *E-syn*-**10** (see Table 1). Noteworthy is the high γ-regioselectivity of the mesylate procedure[13]: in this way, with aldehydes **1a–e** competing formation of the α-adducts **11** often amounts to <1%.

The mercury(II) acetate-catalyzed methanolysis[1a,c] of *syn*-**10** proceeds—as was observed for the *anti*-diastereomers **10**[1c]—with retention of the relative configurations at C-3 and C-4, and affords the *cis*-γ-lactol methyl ethers **13** (yield ca. 90%). Subsequent Grieco-oxidation[14,15] yields β,γ-*cis*-substituted γ-lactones **14**. Thus *E*/*Z*-*syn*-**10b** furnishes (±)-quercus-lactone b[16] **14b** (yield 84%) and *E-syn*-**10g** the (±)-"*trans*"-methyl crobarbate[17] **14g** (yield 67%).







13b, **14b**: $R^1 = (CH_2)_3CH_3$, $R^2 = H$
13g, **14g**: $R^1 = CO_2Me$, $R^2 = CH_3$

[6] A *syn*-selective synthesis of 1-alkenyldithiocarbamates (*syn*-**5**, $X=SC(S)NMe_2$) has been reported, however hydrolysis to give **3** remains an unsolved problem; cf. T. Hayashi, N. Fujitaka, T. Oishi, T. Takeshima, *Tetrahedron Lett. 21* (1980) 303.

[7] *Z*-**6** (<2% *E*-**6**) was obtained by hydrogenation of the corresponding 2-butynyl carbamate with "P-2-nickel" catalyst/ethylenediamine; cf. C. A. Brown, V. K. Ahuja, *J. Chem. Soc. Chem. Commun. 1973,* 553.

[8] ^{13}C-NMR ($CDCl_3$, δ): *Z*-**9**: 13.60, *E*-**9**: 17.95 (4-CH_3).

[9] For the *syn*-selective carbonyl addition of (*Z*)-butenyldiethylalane, cf. D. B. Collum, J. H. McDonald III, W. C. Still, *J. Am. Chem. Soc. 102* (1980) 2118.

[10] In each case **12b** was freshly prepared from equimolar amounts of diisobutylaluminum hydride and methanesulfonic acid as a 0.25 M solution in hexane/ether (1:3).

[11] General procedure: A 1.6 M solution of *n*-butyllithium (5.5 mmol) in hexane is added dropwise to a solution of *Z*-**6** (5.0 mmol) and tetramethylenediamine (TMEDA) (5.5 mmol) in pentane (15 mL) at $<-70°C$ under N_2. The resulting suspension is stirred for 30 min and then treated with 5.5 mmol **12a** (ca. 25% in toluene) or **12b** [10]. After 1.5 hours' vigorous stirring at $<-70°C$, 5.5 mmol **1** is injected into the mixture and stirring continued for a further 1—3 h (**10f**: 16 h) at $-78°C$. The mixture is then treated with acetic acid (50 mmol), warmed to 0°C, extracted with 50 mL 10% sodium potassium tartrate solution and with 50 mL ether, and worked-up in the usual way [1a]. Isolation of **10** by medium-pressure chromatography on silica gel (ether/petroleum ether).

[12] The stereochemical assignment is confirmed by degradation to known 3-hydroxyalkanoic acids (**10a**, **10d**) [1a] or by conversion into known γ-lactones (**10b** [16], **10f** [1c], **10g** [1f, 17]).

[13] We ascribe the improved regioselectivity with **12b** to increased α-selectivity of the Li/Al exchange.—**12a** reacts with lithiated 2-butenyl ethers to give γ-alanes; cf. M. Koreeda, Y. Tanaka, *J. Chem. Soc. Chem. Commun. 1982,* 845.

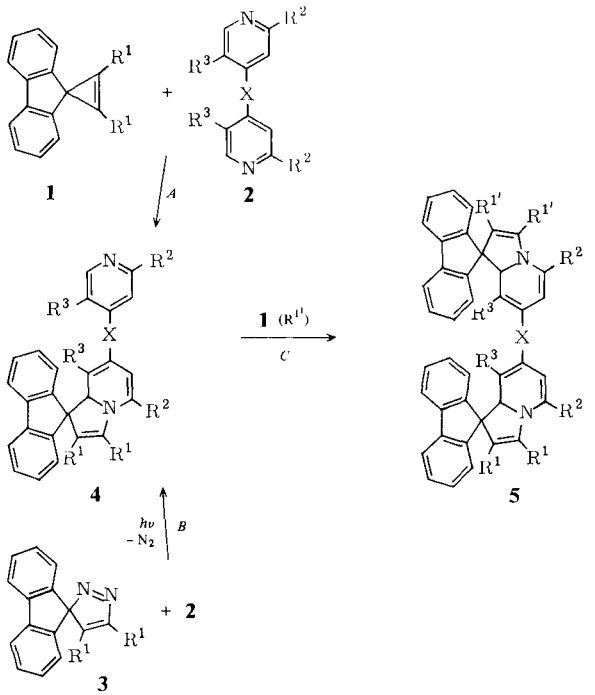
Tailor-Made Photochromic Systems: First Bichromophoric Spiro-1,8a-dihydroindolizines**

By *Peter Spang* and *Heinz Dürr**

Photochromic compounds have attracted a great deal of interest in recent years, largely because they can serve as materials for optical display and data logging[1], as actinometer substances and light filters[2], as well as for solar energy conversion[3]. It has recently been reported that they also appear to be suitable for the frequency-doubling of lasers[3b]. Such applications call for photochromic systems in which long wave absorption ranges, high storage densities, the combination of two colors, and slow or rapid systems can be obtained in a *selective way.*

We have already reported on the photochromic system of the spiro-1,8a-dihydroindolizines[4]. Herein we describe the novel bichromophoric systems **5**, which consist of two 1,8a-dihydroindolizine units, and outline their synthesis and spectroscopic properties.

The bichromophoric species **5** were synthesized by reaction of electrophilic spirocyclopropenes **1** with the bipyridines **2** (X = nothing), 4,4′-ethylenedipyridines **2** ($X=-CH_2-CH_2-$), or 4,4′-vinylenedipyridines **2** (X = −CH=CH−) in the molar ratio 1:1 in ether in the absence of light at room temperature. These reactions afforded mixtures of the yellow 1:1 adducts **4** and the yellow to yellowish orange 2:1 adducts **5** (Table 1), which could easily be separated by column chromatography and recrystallized from ether/*n*-pentane (route *A*). When the molar ratio of the reactants was adjusted to 2:1 the bichromophores **5** were obtained in quantitative yields. Compounds **5** could also be prepared by reaction of **4** and equimolar amounts of **1** (route *C*). Systems containing two different spirodihydroindolizine moieties are accessible via route *C*; these may prove very interesting from the technical point of view. In the case of the thermally unstable spirocyclopropenes **1**, the 1:1 adducts **4** could be synthesized by direct photolysis of the spiro-3*H*-pyrazoles **3** in a 1% ethereal solution of **2** (route *B*)[4].



Reactions *A*—*C* also lead to the formation of betaines[4] as dark colored intermediates which spontaneously cyclize thermally to give the products **4** and **5**. On irradiation (UV/VIS), **5** and **4** undergo electrocyclic ring cleavage with regeneration of the betaines **6** (Table 1) and the analogous intermediates of **4**, respectively. Assignment of the structures of **4** and **5** was possible from the ^1H-NMR, IR, UV, and mass spectroscopic data. The ^1H-NMR data of **5a–f** indicate a symmetric structure. The absorption maxima of **5a–f** lie between 381 and 420 nm, those of the colored forms **6a–f** between 575 and 702 nm. As in the case of the known bichromophoric spiropyran compounds[5], the maxima are markedly broadened in the visible region.

The finding that the extinction coefficients of **5** are about double those of the corresponding coefficients of **4**

Table 1. Some data of the 2:1 adducts **5** and **6**. E = CO_2CH_3. UV data determined at 20°C in CH_2Cl_2.

	R^1	$R^{1'}$	X	R^2	R^3	Yield [%]	M.p. [°C]	**5** λ_{max} [nm]	$\varepsilon \times 10^3$	**6** λ_{max} [nm]	**6**→**5** $k \times 10^{-3}$ [s^{-1}]
a	E	E	—	H	H	39	218	396	20.4	630	6.7
b	Ac	Ac	—	H	H	48	160	420	13.6	575	1.7
c	E	E	—	Me	H	75	220	396	20.9	628	2.1
d	E	E	—	H	Me	69	192	399	14.5	623	17.8
e	E	E	$(CH_2)_2$	H	H	48	126	381	24.6	596	6.9
f	E	E	$(CH)_2$	H	H	73	186	394	15.1	702	4.6
g	E	Ac	—	H	H	37	188	407	16.7	585	2.5
h	E	Ac	—	Me	H	28	138	404	22.3	590	9.0
i	E	Ac	$(CH)_2$	H	H	58	162	401	23.8	650	1.3

suggests the presence of two independent chromophores with additive character in **5**. Thus, the colored forms **6g–i** of the unsymmetric compounds **5g–i** show only one broad maximum, which is centered between the maxima of the corresponding precursors **4**. This long-wave absorption maximum of **6g–i** decreases in the reaction **6**→**5** with a rate constant k which roughly corresponds to the mean value of k in the reaction of the subsystems. In all cases, the rate of the thermal cyclization **6**→**5** is first order. The UV spectroscopic behavior of the unsymmetric species **5g–i** indicates that both spiro systems participate in the photochromism of **5**, i.e. that both dihydropyrrole rings open in an electrocyclic process; this photochromically induced [4n+2]-reaction follows a conrotatory mode.

Thus, **4a** reacts with the spirocyclopropene **1b** (R^1 = Ac) according to route *C*, initially furnishing the red monobetaine **7g** (absorption at λ_{max} = 549 nm), which can be converted by irradiation with light of wavelength 396 nm (λ_1) into the dibetaine **6g** (λ_{max} = 585 nm). Reaction of **4b** with **1a** ($R^1 = CO_2CH_3$), on the other hand, leads to the green monobetaine **7g'** (λ_{max} = 645 nm), which likewise reacts further on irradiation with light of wavelength 420 nm (λ_2) to give **6g**, which thermally recyclizes to **5g**.

The activation parameters of the thermal cyclization **6**→**5** (in CH_2Cl_2 at 25°C) determined by UV have the following values: $\Delta G^{\neq}$ = 16.4–20.3 kcal/mol, $\Delta H^{\neq}$ = 4.2–17.9 kcal/mol, $\Delta S^{\neq}$ = −11.7 to 40.9 cal mol^{-1} K^{-1}.

Thus, molecules with "tailor-made" spectroscopic properties have been synthesized for the first time in the dihydroindolizine series. The selective opening of a particular ring in unsymmetrically substituted compounds **5** is possible by selective monochromatic excitation. These special properties open up a wide spectrum of possible practical applications.

Synthesis of 1,2:3,4:5,6-Trianhydrohexitols with *gluco-*, *manno-*, and *ido*-Configuration**

By *Peter Köll**, *Michael Oelting*, and *Jürgen Kopf*

Dedicated to Professor Kurt Heyns on the occasion of his 75th birthday

Diepoxides of tetritols and hexitols can act both carcinogenically as well as tumorstatically[1]. The physiological action strongly depends on the configuration of the isomer[2,3]. Although these diepoxides have been the subject of intensive studies, to our knowledge the related triepoxides of hexitols have so far never been prepared.

In connection with the preparation of other trianhydrides of hexitols[4], we have now synthesized and characterized for the first time some of the ten possible isomers (four enantiomeric pairs, two *meso* compounds). As starting substances we used the (*E*)-1,2:5,6-dianhydro-3,4-dideoxy-3-hexenitols **1** and **4** with D-*threo*- or *erythro*-configuration described by *Kuszman* and *Sohár*; **1** and **4** are readily accessible in several steps from D-mannitol and D-glucitol, respectively[5]. However, on attempting to synthesize the title compounds by reaction of **1** and **4** with *m*-chloroperbenzoic acid considerable decomposition occurred. Payne epoxidation[6] with H_2O_2 in methanol in the

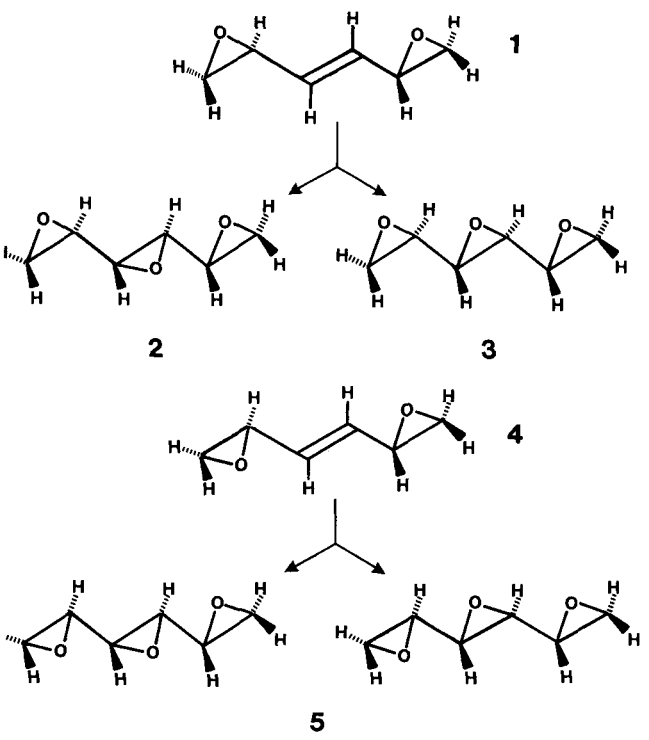
presence of acetonitrile or trichloroacetonitrile[7], on the other hand, led in the case of the D-*threo* isomer **1** to a 1:3 mixture of two enantiomerically pure diastereomers **2** and **3** in 81% yield, having D-*manno*- or D-*ido*-configuration. Both crystallized out after chromatographic separation.



As expected, on epoxidation of the *erythro*-alkene **4** only one optically inactive product is isolable, namely the racemic trianhydroglucitol **5**[8].

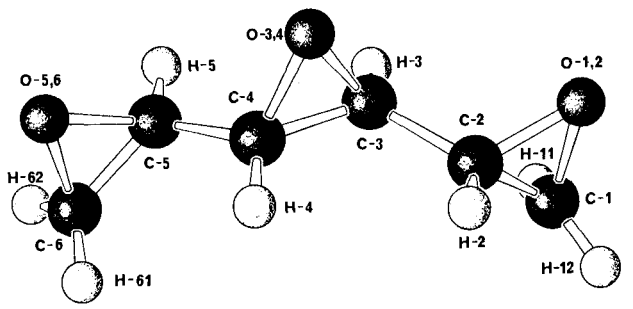


Fig. 1. SCHAKAL diagram [10] of the asymmetric unit of **3**: space group $P2_12_12_1$, $a=460.5(4)$, $b=909.4(7)$, $c=1534.8(9)$ pm, $Z=4$; 912 independent reflections ($I>3\sigma(I)$), $R=0.050$, $R_w=0.027$.—Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50655, the names of the authors, and the journal citation.

The triepoxide structure of the compounds isolated was confirmed by elemental analysis, NMR data, and mass spectroscopy. Moreover, **2** and **3** showed optical activity[9]. However, an unequivocal assignment of configuration was impossible on the basis of this data alone. But a subsequent X-ray structure analysis showed that **3** has the *ido*-configuration, and consequently **2** the D-*manno* configuration. As shown in Figure 1, 1,2:3,4:5,6-trianhydro-D-iditol **3** assumes a crescent shaped conformation with favorable *gauche* orientation of the oxygen atoms. Such an arrangement would also be possible in the alternative zig-zag conformation; in fact, the low values of the coupling constants $J_{2,3}=J_{4,5}=4.4$ Hz indicate that this conformation is adopted in solution too. A much greater value would be expected for the pure bent conformation.

A mixture of the 1,2:3,4:5,6-trianhydrohexitols with *gluco*-, *manno*-, and *ido*-configuration is also obtained when commercially available 1,3,5-hexatriene[11] (ca. 70% *E*- and ca. 30% *Z*-isomer) is oxidized as described above. The reaction is much slower and only racemates are obtained: The DL-*gluco*:DL-*manno*:DL-*ido* ratio is 2:1:4 (overall yield 13% referred to hexatriene used in the reaction).

Small amounts of three further isomers are also obtained; these are presumably formed by triepoxidation of *Z*-hexatriene. The main component could be separated by crystallization (m.p. 80°C). The symmetric ^{13}C-NMR spectrum and the observed polarity indicated this as being 1,2:3,4:5,6-trianhydro-*meso*-galactitol. The other two, as yet preparatively unisolable isomers must have the *meso-allo*- and DL-*altro*-configurations.

Finally, it should be pointed out that the isomeric 1,2:3,4:5,6-trianhydroinositols ("benzene triepoxides") derived from cyclohexane (or benzene) have been known for some time[12].

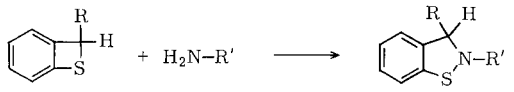
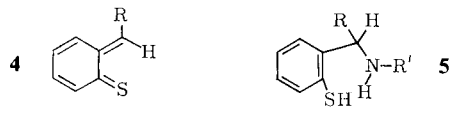
Ring Expansion of Benzothiete to 2,3-Dihydrobenz[*d*]isothiazoles**

By *Kuppusamy Kanakarajan* and *Herbert Meier**

The 2,3-dihydrobenz[*d*]isothiazole (2,3-dihydro-1,2-benzisothiazole) system has acquired special importance through the saccharin molecule[1] and the popular artificial sweeteners that have been developed in recent years[2]. However, very little is known about either the parent compound or the simple (unoxidized) derivatives. We have now discovered a completely new synthetic route to this class of compounds. It belongs to the important class of ring expansion reactions in the synthesis of heterocycles[3]. The starting compounds are the readily accessible[4,5] benzothietes **1**, R = H, CO_2CH_3. Reaction of **1** with primary amines in boiling toluene furnishes the 2,3-dihydro-1,2-benzisothiazoles **3** in good yields (Table 1).



1 **2** **3**



4 **5**

After thermal opening of the four-membered ring in **1** to give the *o*-quinoid system **4**, a 1,4-(or 1,8-)addition takes place, resulting in formation of **5**. A renewed ring closure in the last step follows by autoxidation. The molar ratio of **1** and **2** used in this reaction is 1:4. With a molar ratio of 1:1 the yield of **3** decreases in favor of *N*-substituted 12,13-dihydro-11*H*-dibenzo[*c,h*][1,2,6]dithiazonines **7** and 6,12-dihydro-6,12-iminodibenzo[*b,f*][1,5]dithiocines **9**, a reaction we have monitored in the case of **b–e** (Table 1).

Formation of **9** via the dimer **10** obtained on heating[5] can be ruled out. Heterocycles of type **7** were hitherto unknown, whereas the bridged systems **9** have already been described in the literature as products of the reaction of *o*-mercaptobenzaldehyde with amines[6].

In order to establish the scope of the ring expansion reaction, the higher boiling benzylamine was used in example **f**, while a substituted benzothiete was used in example **g**. The 2,3-dihydrobenz[*d*]isothiazoles **3a–g**, which were isolated by column chromatography on silica gel with petroleum ether 60–90/toluene (2:1), are analytically pure liquids which partially decompose on attempted distillation. In the ^{1}H- and ^{13}C-NMR spectroscopic characterization, the position 3 is the most interesting. During the ring expansion to **3**, the NMR signals shift about 0.1–0.2 and 9–12 ppm, respectively, downfield compared to those of benzothiete **1**, R = H (δ(2-H) = 4.27 and δ(C-2) = 36.5) or methyl benzothiete-2-carboxylate **1**, R = CO_2CH_3 (δ(2-H) = 5.17 and δ(C-2) = 49.2).

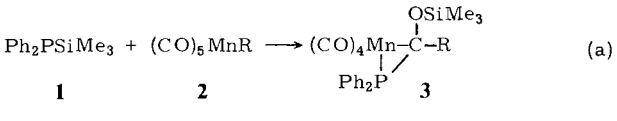
Reactions of Diphenyl(trimethylsilyl)phosphane with Alkyl(pentacarbonyl)manganese; Synthesis of the Ylide Complexes $(CO)_4Mn\overline{Cr(OSiMe_3)}\overline{PPh_2}$ and a New Driving Force for CO Insertion**

By *George D. Vaughn, K. Alex Krein,* and *John A. Gladysz**

Since insertion of CO into an alkyl-metal bond is a key step in many catalytic processes[1], considerable interest has been shown in devising means of kinetically and/or thermodynamically promoting this reaction[2–5]. Recently, it has been demonstrated that Lewis acids[2–4] and ligands which contain Lewis acid sites[5] effect the rapid conversion of alkyl(carbonyl)metal compounds into substituted acylmetal derivatives. We report here that the ligand **1**[4] and alkyl(carbonyl)manganese compounds **2** react to give novel ylide complexes **3** [eq. (a)][5]. In this transformation, an additional driving force—silicon-oxygen bond formation—favors the reaction.



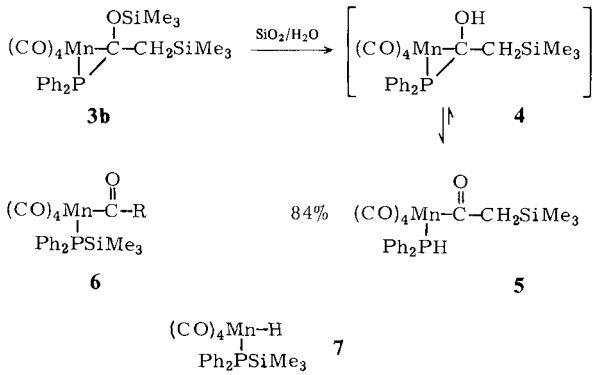
$$Ph_2PSiMe_3 + (CO)_5MnR \longrightarrow (CO)_4Mn(OSiMe_3)(PPh_2)C(R) \quad (a)$$

1 **2** **3**

a, R = Me; **b**, R = CH_2SiMe_3; **c**, R = Ph; **d**, R = 2-Naphthyl

Reaction of **1** with **2a** (molar ratio 1:1.1) in CH_2Cl_2 gave over the course of 12 h complex **3a** in 75% yield (Table 1)[6]. Ylide complexes **3b–d** were prepared in benzene (**3b**: 25°C, 52% yield; **3c** and **3d**, reflux, 67 and 42% yields, respectively) (Table 1)[6].

The following results provide information about the mechanism of complex formation. 1) The rate of disappearance of **2a** was virtually unaffected when triphenylphosphane was substituted for **1**. 2) When **1** and PPh_3 in excess were allowed to compete for **2a**, ca. six times more **1** than PPh_3 was consumed. 3) **1** and the benzoyl complex $(CO)_5MnCOPh$ reacted cleanly to afford **3c** (63% isolated) at a rate ca. four times faster than the reaction of **1** and **2c**. 4) Passage of **3b** through wet silica gel gave the acyclic acyl complex **5**[6] in 84% yield. Presumably **5** is formed via the hydroxy-ylide complex **4**, which, because the O–H bond is weaker than the O–Si bond (103 kcal/mol vs. 106–127 kcal/mol[7]), is thermodynamically unstable with respect to **5**. On the basis of these points, we suggest that the reaction of **1** and **2** to form the ylide complexes **3** proceeds via the substituted acyl complex **6**, which is in turn generated by attack of **1** at the coordinatively unsaturated acyl complex $(CO)_4MnCOR$[8].



3b $\xrightarrow{SiO_2/H_2O}$ **4**

6

84% **5**

7

Remarks relevant to possible extensions of the reaction shown in eq. (a) are as follows: 1) Complex **3a** is inert towards CO (20–25 bar) in CD_3CN or benzene. 2) **1** reacts with the hydride $(CO)_5MnH$ in hexane to afford the complex *cis*-**7** in 76% yield[6]. Hexane solutions of **7** are inert towards CO (ca. 23 bar, 25°C, 3 d). In more polar solvents decomposition occurs. — Equation (a) provides a convenient and distinctly new method[5] for the synthesis of a variety of potentially useful ylide complexes. Extensions to other transition metals can be expected.

Synthesis and Structure of $[Ph_4As][AuS_9]$, a Cyclic Nonasulfidoaurate(I)**

By *Gerolf Marbach* and *Joachim Strähle**

Very little is known about gold sulfides and thioaurates. Au_2S crystallizes in the cuprite structure[1]; the structure of Au_2S_3[2], which hitherto could only be obtained in the amorphous state, is still unknown. References to thioaurates are to be found in older publications[3], according to which gold sulfides dissolve in aqueous sulfide solution with formation of thioaurates. In a systematic study of gold-sulfur compounds we have also attempted the synthesis of thioaurates and to elucidate their structure. Besides other thio- and polysulfidoaurates we were able to isolate the novel, ring-shaped anion $AuS_9^{\ominus}$ with tetraphenylarsonium as counterion.

$[Ph_4As][AuS_9]$ **1** is formed as main product in the form of bright yellow crystalline platelets on reaction of $K[Au(SCN)_2]$ with tetraphenylarsonium polysulfide in absolute ethanol[4]. The nonasulfidoaurate **1** is stable towards air and light. It dissolves in dimethyl sulfoxide to give a red solution; in contrast, it is insoluble in other organic solvents and water. On treatment with acids it undergoes decomposition with formation of Au_2S.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The IR spectrum of **1** shows, aside from the known bands for the cation, the weak bands of the Au–S stretching vibration at 325 cm^{-1}; the S–S vibrations cannot be assigned unequivocally, since the bands arising from them are masked by those of the cation.

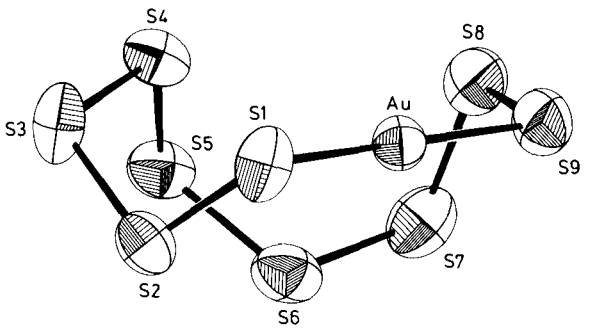

Fig. 1. Structure of the nonasulfidoaurate(I) ion $AuS_9^{\ominus}$. Selected bond lengths [pm] and angles [°]: Au–S1 227.7(1), Au–S9 226.5(3), S–S 203.6(4) to 206.1(5); S–S–S 105.9(2) to 108.2(2), S–Au–S 176.0(1).

As shown by the crystal structure analysis[5] of **1**, the anion consists of a puckered AuS_9 ring (Fig. 1), in which a chain of nine sulfur atoms is bound as chelate ligand to the gold(I) atom. The SAuS angle of 176° is consistent with that expected for linear coordination, which presumably is also decisive for the unusual length of the polysulfide ligand chain. According to model considerations, shorter sulfur chains give rise to less favorable bond angles at the S atoms. In $AuS_9^{\ominus}$ the SSS angles reach the normal value of ca. 107.2°; the S–S bond lengths are on average 204.5 pm. The Au–S distances, with an average value of 227.1 pm, correspond to covalent single bonds. Interactions between the Au atom and the oppositely situated S atoms in the ring can be ruled out, since the distances are too large. Furthermore, there are no short Au–Au contacts like those otherwise frequently observed in Au^I compounds.

The shape of the AuS_9 ring is essentially influenced by the stretched S–Au–S groups. The part of the ring most removed from the Au atom is reminiscent of an "*endo* conformation". In the case of sulfur chains attached as chelate ligands to other transition metals, the smaller bond angle at the central atom leads, in each case, to shorter chains with three, four, five, or six S-atoms. Some typical examples are $[C_5(CH_3)_5]_2TiS_3$[6], $(C_5H_5)_2TiS_5$[7], $[Ni(S_4)_2]^{2\ominus}$[8], $[(S_4)_2MoS]^{2\ominus}$[9], $[Pt(S_5)_3]^{2\ominus}$[10], and $[Hg(S_6)_2]^{2\ominus}$[11].

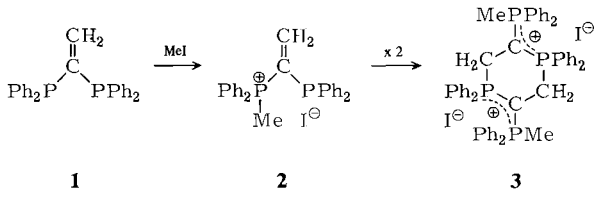
Unexpected Secondary Reaction of the Simple CH_3I-Quaternization of Vinylidenebis(diphenylphosphane)**

By *Hubert Schmidbaur**, *Rudolf Herr*, and *Jürgen Riede*

Vinylidenebis(diphenylphosphane) **1** is the prototype of geminal bis(phosphino)olefins. Its NMR data[1a] and the crystal structure investigation[2,3] have essentially elucidated the conformation and structure, but its reaction behavior (with exception of the chalcogenization[1a,b] has not yet been reported in the literature. Some of the reactions of **1** proceed in an unexpected manner. Thus, we found that even formation of the simple phosphonium salt with alkyl halide leads to a secondary reaction, which, as the first "ylide formation without base", is a remarkable curiosity[4].

Reaction of **1** with methyl iodide (excess) in tetrahydrofuran for 30 min at 20 °C affords the monoquaternary compound **2**, m.p. 128 °C, in more than 75% yield; **2** could be readily characterized by its NMR spectra and by elemental analysis[5]. When solutions of this primary product in methanol are allowed to stand for a few hours at 20 °C, crystals of a novel compound separate out; this, surprisingly, was identified as the head-to-tail [3+3]-cycloaddition product **3** (yield 60%, m.p. 255 °C (decomp.), correct elemental analysis). The ^{31}P-NMR spectrum, in particular, revealed that the two P atoms in each half of the dimeric molecule have become chemically almost equivalent, thus giving grounds for the formulation of **3** as a double semiylide quaternary salt. The spectrum can be simulated as an AA'BB' spin system $\delta(A)=20.17$, $\delta(B)=22.70$; $J(AA')=-5.0$, $J(AB)=39.9$, $J(AB')=23.9$, $J(BB')=11.9$ Hz. In the ^{13}C-NMR spectrum of **3**, the signals of the ylidic C-atoms appear as a doublet of doublets at $\delta=-3.02$ ($J(P_AC)=110.35$, $J(P_BC)=113.28$ Hz)[5].

The FD mass spectrum of **3** shows the line of the dication at m/z 411, as well as the line of the monocation (to which an iodide is still attached) at m/z 949. An analogous behavior has been observed with other 1,3-diquaternary



1 **2** **3**

salts[6]. Correspondingly, the electrical conductivity in CH_3NO_2 also indicates only partial dissociation of **3**: $\Lambda_M=6.45\ \Omega^{-1}\ cm^2$ at 20 °C.

The X-ray structure analysis of **3**[7] shows that the six-membered ring, apparently formed by double intermolecular nucleophilic attack of two non-quaternary P atoms at the terminal C-atoms of the olefinic double bond, has a centrosymmetric chair conformation (Fig. 1). The C=C bond[3] in **1**, which is only 132.7(6) pm long[3], has become the C–C bond in **3**, with a length of 151.3(13) pm. With a P1–C1–P2 valence angle of 125.8 °, the sum of the angles at the bridge C-atom between the phosphorus atoms is 359.7 °, and C1 thus lies in the P1, P2, C2 plane. This arrangement is typical for semiylide quaternary salts $[R_3P{\cdots}CR{\cdots}PR_3]^{\oplus}X^{\ominus}$ with sp^2-hybridized C-atoms.

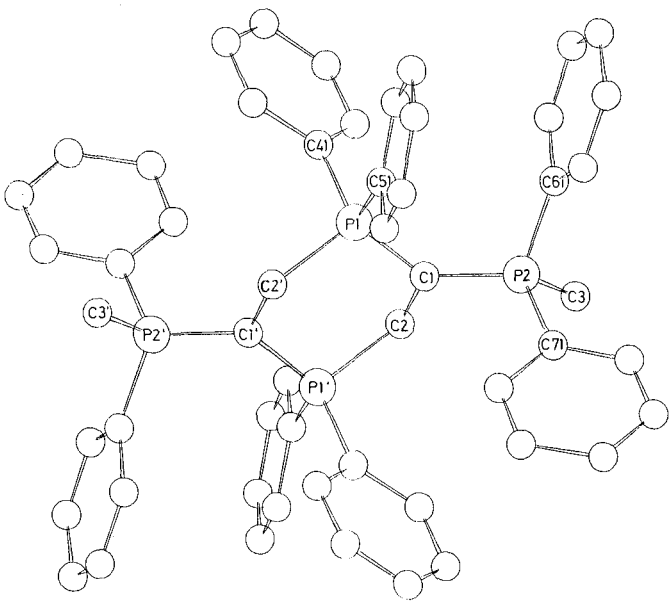


Fig. 1. Structure of the dication in the crystal of the compound **3**. Selected bond lengths [pm] and angles [°]: P1–C1 171.0(8), P2–C1 173.1(8), C1–C2 151.3(13), P2–C3 178.8(11), P1–C2' 182.0(8), P1–C41 178.9(8), P1–C51 178.9(10), P2–C61 180.6(9), P2–C71 179.8)9); P1–C1–P2 125.8(5), P1–C1–C2 116.8(6), P2–C1–C2 117.1(6), C1–P1–C2' 108.3(4), P1–C2'–C1' 113.8(6), C1–P2–C3 109.1(4).

The short P1–C1 and P2–C1 distances of 171.0 and 173.1 pm, respectively, also point to ylidic double bond character (the comparative distances in **1** are 182.9(4) and 183.8(4) pm). The small difference between P1–C1 and P2–C1 in **3** shows that the valence balance in the sense of the formulated mesomeric system is almost complete. The concomitant gain in energy may be regarded as one of the driving forces for the surprising dimerization of **2** to **3** with double ylidization.

The iodide ions in the crystal of **3** have no direct contacts with preferred positions at the dications. Methanol

Lichtenbergstrasse 4, D-8046 Garching (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Priv.-Doz. Dr. *F. R. Kreissl* for recording the FD mass spectra, and Dr. *A. Schier*, Dr. *C. E. Zybill*, and Dipl.-Chem. *S. Schnatterer* for the NMR spectra.

molecules present in the crystal are slightly disordered, but likewise without cation or anion contacts. The dimerization found with **2** also occurs with other counterions ($Br^{\ominus}$, $SO_3F^{\ominus}$) and in other solvents (CH_2Cl_2). On rapid methylation of **1** with an excess of FSO_3CH_3, a bis(phosphonium) salt with even stronger activated C=C double bonding is formed. Further, in a wide sense, related cases of the reaction of phosphanes with activated C=C bonds have already been reported in the literature[4,8].

Diastereoselective Hydroxyalkylation of the 1-Position of 2-Pivaloyl-1,2,3,4-tetrahydroisoquinoline via Magnesium Derivatives

By *Dieter Seebach** and *Max A. Syfrig*

Amide-type derivatives of 1,2,3,4-tetrahydroisoquinolines can be lithiated, and hence alkylated, in the 1-position[1–4]. Whereas an overall enantioselective process could be developed[3], the products of hydroxyalkylation obtained with aldehydes have been reported to be formed with little or no diastereoselectivity[2,4]. We have now discovered[5] that addition of magnesium dibromide ether to solutions of the lithiated 2-pivaloyl-1,2,3,4-tetrahydroisoquinoline in tetrahydrofuran (THF) generates a highly diastereoselective reagent **1**[6].

Thus, addition of benzaldehyde to the solution of the magnesium derivative **1**[6] at −78°C leads to isolation of the *u*-isomer of **2a** (m.p. 160°C) in 83% yield. *l*-**2a** could not be detected by ^{1}H- or ^{13}C-NMR spectroscopy. Furthermore, refluxing a solution of *u*-**2a** in methanol/concentrated hydrochloric acid for 8 h produces the ester *u*-**2b** (b.p. 150°C/0.005 torr). The diastereomeric ester *l*-**2b** (m. p. 76–78°C) is formed by refluxing a solution of *u*-**2a** in trifluoroacetic acid/trifluoroacetic anhydride for 2 h. Both reactions are totally selective as indicated by ^{1}H-NMR spectroscopy and give the esters **2b** in ca. 90% yield[7]. Reductive cleavage of the esters *u*-**2b** and *l*-**2b** with $LiAlH_4$ (6 h reflux) in THF furnishes (ca. 65%) the amino alcohols *u*-**2c** (m. p. 73–75°C) and *l*-**2c** (m. p. 102–105°C), respectively. In contrast, a ca. 2:1-mixture of the amide *u*-**2a** and the ester *l*-**2b** is isolated from the reaction of benzaldehyde with the corresponding lithium derivative of **1**. The configurations *u* and *l*[8] were assigned from the NMR spectra of the four *u*/*l*-diastereomeric pairs of **2a–2d**. Notably, in the *l*-isomers of **2a** and **2c** with intramolecular hydrogen bonds the NMR signals of H-8 show a dramatic upfield shift (up to 1 ppm)[9].

The adducts **3a–3d** with other aldehydes were also formed completely selectively (NMR analysis), and even with acetophenone one diastereomer **3e** was produced in 96% *ds* in 90% yield (see Table 1). The configurations of the compounds **3** were assigned by analogy to those of the benzaldehyde adducts **2**.

Table 1. Products **3** from the magnesium derivative **1** and aldehydes, and a ketone. % *ds* indicates the content of the major diastereomer in the crude product; >97% *ds* means that only one diastereomer could be detected by NMR. The values in parentheses are those obtained with **1**, Li instead of MgBr. All yields are >70%; we assume that the *u*-isomer is formed in excess, except in the case of **3e**, which has *l*-configuration according to the ^{1}H-NMR signal of H-8.

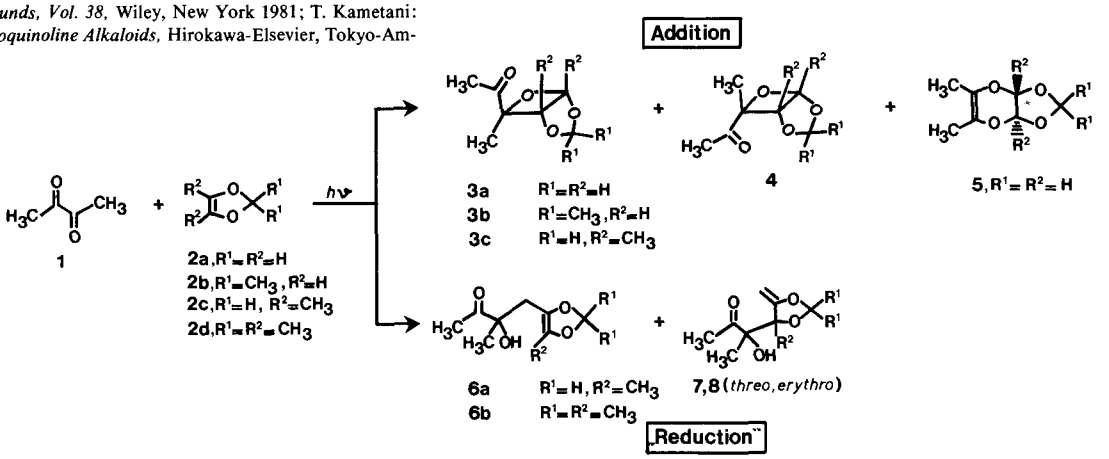
Photoreaction of Biacetyl and 1,3-Dioxole Derivatives: Modification of the Mechanism of the Photoreaction of Carbonyl Compounds with Electron-Rich Olefins**

By *Jochen Mattay**, *Joachim Gersdorf, Hans Leismann,* and *Steen Steenken*

The photoreaction of biacetyl **1** with alkenes usually yields oxetanes and "ene-type" adducts[1]; sometimes enol ("reduction") products formally derived from abstraction of a hydrogen atom from the olefin by the diketone (this corresponds to the first step of the photoreduction)[2]. Generally, exciplexes having some charge transfer (CT) character and diradicals are proposed as intermediates[1,2]. According to *Weller*[3], both locally excited states ($A^*D \leftrightarrow AD^*$) and the CT-configuration ($A^{\ominus}D^{\oplus}$) contribute to the exciplex state formed by excitation of electron donor (D) and acceptor (A) molecules. Stronger electron-donor olefins than those used previously are the substituted 1,3-dioxoles **2**, which have recently become easily accessible[4]. Irradiation of **1** and **2** should lead to formation of exciplexes with more CT-character (contact ion pair according to *Weller*[3]) and also include the possibility of ionic photodissociation in polar solvents[5]. We report here an investigation of the substrate and solvent dependence of the photoreaction and ESR studies under in situ photolysis conditions; the results provide some insight into the effect of charge transfer on the selectivity of this photoreaction.

Preparative irradiation (λ = 400–500 nm) of 1:1 mixtures of **1** and **2** (concentration: 0.1–0.5 mol/L) in cyclohexane or benzene results in formation of the cycloadducts **3–5** and the reduction products **6–8** in 50–70% isolated yields. The product ratio depends strongly on the structure and electron donor abilities of **2**:

1. Only dioxoles containing allylic H atoms (**2c**, **d**) form reduction products;



2. A decrease in oxidation potential ($E^{ox}_{1/2}$) results in increased formation of reduction products, for example $\Phi_{reduction}/\Phi_{addition}$ = 0.07/0.08 (0.22/<0.02) for **1** + **2c** (**2d**);
3. 1,4-Addition is only observed in the reaction of **2a** with **1**; thereby the dihydrodioxin **5** is formed (**3a** : **4a** : **5** = 1.2 : 1 : 1.1 in benzene).

It is noteworthy that photoreactions under S_1- and T_1-conditions yield the same products in the same ratio; neither varying the concentration of **2** (0.05–500 mmol/L, see luminescence quenching rate constants (Fig. 1)) nor sensitizating **1** by addition of benzophenone had any effect on the result[6].

Figure 1 illustrates that charge transfer is important in the luminescence quenching of **1**[6]. However, plots of $\lg k_q/E^{ox}_{1/2}$ with slopes ca. 1/3 of that expected for full elec-

tron transfer ($-17\ V^{-1}$)[7] and the almost complete absence of solvent effects clearly demonstrate that a contact ion pair ($\mathbf{1}^{\ominus\odot}\,\mathbf{2}^{\oplus\odot}$) cannot be formed in this initial step. In order to check the possibility of full electron transfer, ESR experiments were performed under in situ photolysis conditions[8]. In contrast to investigations by *Schaap* et al.[9] of the photooxygenation of dioxenes sensitized by 9,10-dicyanoanthracene electron transfer processes and measurements of transient absorptions in the benzophenone-dioxene system by *Peters* et al.[10], we were able to simultaneously observe both the radical anion $\mathbf{1}^{\ominus\odot}$ and the radical cations $\mathbf{2d}^{\oplus\odot}$ and $\mathbf{2f}^{\oplus\odot}$ during photoreactions of **1** with **2d** and **2f**, respectively, in acetonitrile (Scheme 1). Similar results were obtained in the reaction of **1** with **2b**[11]. These findings strongly support dissociation into free radical ions as an additional reaction path in the photoreactions of **1** and **2**.

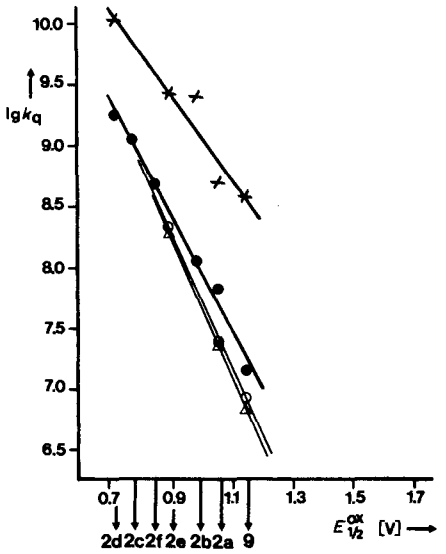

Fig. 1. Rate constants ($\lg k_q$) for the quenching of biacetyl luminescence as a function of the oxidation potential ($E^{ox}_{1/2}$) of the quenchers. (Fluorescence (F) in benzene ×; phosphorescence (P) in benzene ●; in acetonitrile ○, in cyclohexane △). Oxidation potentials (versus SCE) were measured by cyclic voltammetry (Pt working electrode) in acetonitrile; c (quencher) = 1 mM, c ($LiClO_4$) = 0.1 M. The k_q values were calculated using τ_F (benzene) = 9.15 ns and τ_p (benzene) = 284 ± 14, τ_p (cyclohexane) = 180 ± 12, τ_p (acetonitrile) = 358 ± 10 μs, see [6].

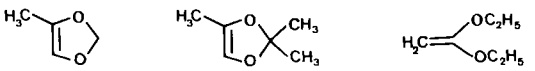
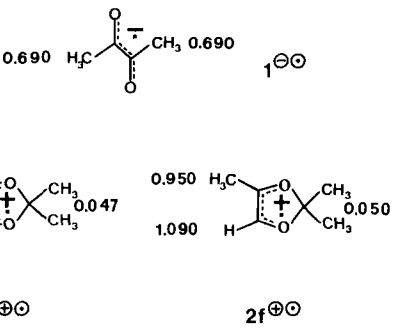


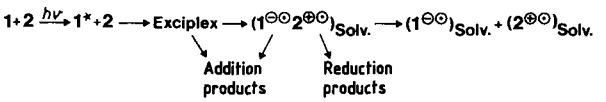
2e **2f** **9**

Recently, we reported[12] the dependence of product quantum yields Φ on solvent polarity in the photoreactions of **1** and **2d** (*Masuhara*'s method[5]). Φ decreases when dissociation into free radical ions becomes exothermic (in solvents with dielectric constant $\varepsilon > 5$). Similar solvent dependences on Φ were observed in all other systems **1** + **2** (Φ decreases by a factor of ca. 2—2.5 when ε is increased from 2 to 37.5). These results together with the ESR studies strongly support the involvement of ionic photodissociation as a competitive reaction path. Moreover, since we are now able to differentiate between an initial step leading to a less polar intermediate ("exciplex"[1]) and a consecutive path yielding radical ions, we propose the mechanism



Scheme 1. ESR coupling constants [mT] of the radical ions $\mathbf{1}^{\ominus\odot}$, $\mathbf{2a}^{\oplus\odot}$, and $\mathbf{2f}^{\oplus\odot}$ in acetonitrile at 0°C.

shown in Scheme 2, an extension of the "exciplex-diradical mechanism" of the Paterno-Büchi reaction[1].



Scheme 2.

Particularly in reactions of strong donors with strong acceptors, H-abstraction seems to proceed via successive transfer of an electron and a proton. Preliminary results with unsymmetrical enol ethers which yield oxetanes of extremely high regioselectivity also indicate participation of polar intermediates in the addition reaction pathway[13]. Other electron donor-acceptor systems (e.g. diketones, aromatic compounds, and electron-rich olefins) exhibit similar reaction selectivities with increasing CT-character.

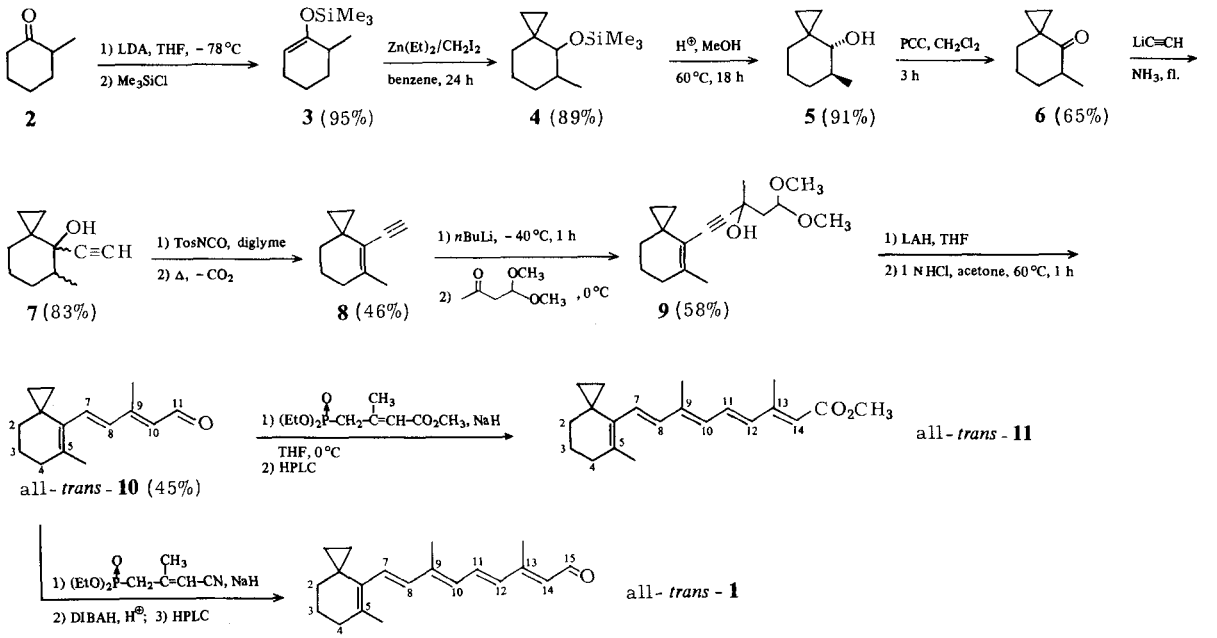
Preparation of Spiroretinal and Related Retinoids**

By *Karin Bartels* and *Henning Hopf**

Retinal ("vitamin A aldehyde") occurs in nature as an essential part of two chromoproteins which fulfill elementary functions in photo-activated processes. Thus in halobacteria light is converted into chemical energy by bacteriorhodopsin, whereas a nerve impulse is triggered via the visual pigment rhodopsin when light falls on the eyes of vertebrates[2]. To study the molecular mechanisms of the two photoreactions, retinals whose substitution pattern is different from that of naturally occurring retinal may be bonded to the apoprotein, and the biochemical properties of the reconstituted, modified rhodopsin probed[2]. In order to be able to clearly distinguish between the steric and electronic effects of a substituent change, the synthesis of vitamin A derivatives („retinoids") is desirable which either deviate in their electronic, but not steric, properties from native vitamin A derivatives, or vice versa.

The spiroaldehyde **1** may belong to the first type of retinoids: Sterically the *gem*-dimethyl groups in the 1-position of the natural product and the cyclopropane ring should differ only slightly from each other; however, the three-membered ring corresponds electronically to a double bond, and hence **1** could be a quasi cross-conjugated polyenal[3].

As the key intermediate for **1** (and other "spiroterpenes"), the enyne **8**, was synthesized first (Scheme 1). For this purpose, the enol ether **3**, obtained from **2** according to the method described by *Murai* et al., was converted into the spiro compound **4**, whose protecting group can readily be removed with methanolic citric acid. Oxidation of the alcohol **5** (trans-arrangement of the methyl and hydroxy groups according to NMR analysis) affords the ketone **6**, which can be ethynylated in good yield to the propargyl alcohol **7** (diastereomeric mixture). Of several reagents for the dehydration **7**→**8**, tosyl isocyanate[6] proved to be the best; convential reagents such as $POCl_3$ and dimethyl sulfoxide gave rise predominantly to products with a cleaved three-membered ring. The chain-lengthening step from **8** to **1** proceeded by means of methods routine in vitamin A chemistry[7]: the "spiro-C_{15}-aldehyde" **10** was obtained as a mixture of the all-*trans*- and 9-*cis*-isomers (2.5 : 1) from the tertiary alcohol **9** via its diastereoselective reduction and subsequent elimination/deblocking. Wittig-Horner olefination of **10** with methyl 4-diethoxyphosphoryl-3-methylcrotonate led to the "spiroretinate" **11** (63%), which according to HPLC (2% ether/cyclohexane) consisted of four isomers: all-*trans*- (84%), 13-*cis*- (23%), 9-*cis* (14%) and 9-*cis*-13-*cis*-**11** (9%)[8]. On the other hand, **10** reacts with 4-diethoxyphosphoryl-3-methylcrotonitrile to form the spiroretinonitrile (63%), which was reduced to a mixture of spiroretinals (41%). From this, all-*trans*-**1** could be isolated by HPLC (relative amount 37%); its structure, as those of the other isomers [13-*cis*- (31%), 9-*cis*- (20%), and 9-*cis*-13-*cis*-**1** (12%)] was determined principally from the high-field NMR spectra (for ^{1}H-NMR data of all-*trans*-**1**, see Scheme 1)[8].



Scheme 1. Abbreviations: LDA = lithium diisopropylamide, THF = tetrahydrofuran, PCC = pyridinium chlorochromate, LAH = lithium tetrahydridoaluminate, DIBAH = diisobutylaluminum hydride. — ^{1}H-NMR of all-*trans*-**1** (400.1 MHz, $CDCl_3$, int. TMS): $\delta = 10.10$ (d, $J_{14,15} = 8.0$ Hz, H-15), 7.11 (pseudo-dd, H-11), 6.37 (d, $J_{11,12} = 15.0$ Hz, H-12), 6.17 (d, $J_{10,11} = 11.5$ Hz, H-10), 6.10 (d, $J_{7,8} = 16.0$ Hz, H-8), 5.97 (d, $J_{14,15} = 8.0$ Hz, H-14), 5.88 (ps-d, $J_{7,8} = 16.0$ Hz, H-7), 2.32 (pseudo-s, 13-CH_3), 2.16 (m, H-4), 1.96 (pseudo-s, 9-CH_3), 1.74 (pseudo-s, 5-CH_3), 1.78—1.70 and 1.48—1.45 (m, H-2, H-3), 0.71 and 0.31 (each pseudo-q, cyclopropyl-H).

Institut für Organische Chemie der Technischen Universität
Schleinitzstrasse, D-3300 Braunschweig (FRG)

[**] Retinoids, Part 3. The novel compounds **1** and **4**—**11** were characterized by elemental analysis or by high-resolution mass spectroscopy and the usual spectroscopic data. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. — Part 2: [1].

The three-membered ring exhibits a weakly hypsochromic influence on the electronic spectrum: Whereas all-*trans*-retinal absorbs at 388 nm (isopropyl alcohol, $\varepsilon = 42900$), the absorption maximum of all-*trans*-**1** occurs at 378 nm (isopropyl alcohol, $\varepsilon = 41300$). The chemical shift of the polyene protons are only influenced if they lie in the spatial vicinity of the three-membered ring. Thus $\Delta\delta$

($\delta_{\text{all-}trans\text{-retinal}} - \delta_{\text{all-}trans\text{-1}}$) for H-7 is 0.48, but in contrast is only 0.08 for H-8; this effect is also exhibited by H-11 and H-12: $\Delta\delta = 0.04$ and 0.0, respectively.

BOOK REVIEWS

Lehrbuch der Physikalischen Chemie. By *G. Wedler*. Verlag Chemie, Weinheim 1982. xxii, 914 pp., bound, DM 98.00

The new textbook "Lehrbuch der Physikalischen Chemie" by *G. Wedler* presents a detailed coverage of physical chemistry in the German language. The author has—in his own words—"tried to write a textbook, which, in spite of the limitation of its subject matter to the presentation of the basic principles, is still sufficient to allow application to particular problems".

The preface is "An Introduction to Basic Physicochemical Concepts and Methods". This includes the material which is presented in the first semester as an introduction to physical chemistry or as part of a general chemistry course. Chemical thermodynamics, the kinetic theory of gases, statistical thermodynamics, quantum theory, chemical kinetics and electrochemistry are summarized prior to the main text. This introduction is followed by five main chapters Chemical Thermodynamics, Structure of Matter, Statistical Theory of Matter, Transport Phenomena, Kinetics and a Mathematical Addendum.

The chapter on "Chemical Thermodynamics" (233 pp.) treats chemical equilibra, phase and surface equilibria as well as electromotive forces in detail, alongside with the basic equations of thermodynamics. The chapter entitled the "Structure of Matter" (161 pp.) begins with the quantum mechanical treatment of simple systems, followed by a discussion of the interaction between radiation and atoms and molecules and ends with treatment of chemical bonding. A section is included covering the behavior of material in electric and magnetic fields.

"The Statistical Theory of Matter" (77 pp.) begins with a comparison of the various sorts of statistics and includes statistical thermodynamics and the kinetic theory of gases.

"Transport Phenomena" (42 pp.) deals with the general equation of transport, with diffusion, internal friction, thermal conductivity, electrical conductivity, as well as electrokinetic phenomena.

"Kinetics" (108 pp.) contains sections on experimental methods, formal kinetics, reaction mechanisms, kinetic theory, solution kinetics, the kinetics of heterogeneous reactions as well as catalysis and the kinetics of electrode processes.

The author has included a detailed Introduction in order to demonstrate how the various areas of physical chemistry are interwoven. However, this intention is not always obvious and the book would be no less attractive if the introductory remarks were included in the relevant chapters.

The five main chapters differ greatly in their breadth and depth. The detailed treatment of chemical thermodynamics reflects the importance of this topic. The section "Matter in Electric an Magnetic Fields" inserted into "The Structure of Matter" is written from a very different point of view than the surrounding material. The section "Interactions between Radiation and Molecules" does not include the laser among the basic considerations. This light source is doubtless an important tool in physical chemistry and it might be asked whether it would not have been advisable to include a section entitled "Photophysics and Photochemistry". The inclusion of the laser alongside fluorescence and phosphorescence under "Emissions by Electronically Excited States" might have been more understandable if the term "Stimulated Emissions" had been chosen instead of "Laser".

The chapter on the statistical theory of matter along with its appropriate introduction in Statistical Thermodynamics deserves special mention. The care which the author has devoted to presenting statistics and explaining their relevance to physical chemistry has undoubtedly been worthwhile. It is appropriate that an illustration from this section graces the book's cover.

The chapters entitled "The Structure of Matter" and "The Statistical Theory of Matter" deal with their subjects in a much more advanced and demanding manner than the chapter entitled "Kinetics". The mathematical addendum and the examples of calculations with solutions will undoubtedly be of value to chemistry students.

The Introduction to Electrochemistry at the beginning of this textbook does not correspond to a chapter on electrochemistry, rather the physical chemistry of electrochemistry is dealt with in several sections. A summary could be helpful for study.

This book enriches the available choice of textbooks which are written in German. When compared with translations and, in particular, with textbooks published in English, where language difficulties aggravate problems with the subject matter, this is an advantage which should not be underrated.

The book is clearly and understandably written; the care taken with the detailed derivations will ease the student's task in learning. This detailed physical chemistry textbook is, at least, as much to be recommended as other good textbooks.

Fragrance Chemistry: The Science of the Sense of Smell. Edited by *E. T. Theimer.* Academic Press, New York 1982. xiii, 635 pp., bound, $ 89.50.

This book sets out to describe the significant classes of fragrance compounds from a chemical point of view. It contains sixteen chapters: *T. V. Getchell, M. L. Getchell,* Physiology of Vertebrate Olfactory Chemoreception, 26 pp.; *J. E. Amoore:* Odor Theory and Odor Classification, 49 pp.; *M. G. J. Beets:* Odor and Stimulant Structure, 46 pp.; *H. Boelens:* Acyclic Monoterpene Alcohols with a 2,6-Dimethyloctane Skeleton, 42 pp.; *P. C. Trass:* Advances in the Chemistry of Some Interesting Cyclic Monoterpene Alcohols, 45 pp.; *V. Herout:* Sesquiterpene Alcohols, 45 pp.; *E. T. Theimer:* Benzene Derived Cyclic Carbinols, 18 pp.; *P. Z. Bedoukian:* Violet Fragrance Compounds, 32 pp.; *H. van den Dool:* Synthesis of Vetiver Oil Components, 32 pp.; *E. P. Demole:* The Fragrance of Jasmine, 48 pp.; *E.-J. Brunke, E. Klein:* Chemistry of Sandalwood Fragrance, 37 pp.; *B. D. Mookherjee, R. A. Wilson:* The Chemistry and Fragrance of Natural Musk Compounds, 61 pp.; *T. F. Wood:* Chemistry of Synthetic Musks I (Non-Benzenoid Musks) and II (Benzenoid Musks), 14 pp. and 34 pp. resp.; *G. Ohloff:* The Fragrance of Ambergris, 40 pp.; and *J. P. Walradt:* Analysis of Fragrance Materials, 42 pp.

The strictly chemical chapters are thus preceded by sections on the physiology of the olfactory system, the mechanism of the sense of smell, and odor-structure correlations in odorous molecules, which, taken together, constitute a fifth of the volume.

Chapter 4 considers the fundamental building blocks of geraniol, nerol, linalool, citronellol, myrcenol and dihydromyrcenol detailing their syntheses and chemical reactions. In the following chapter, the chemistry of menthol, α-terpineol, and borneol receive the prominence they deserve; however the lengthy sections on verbenol, myrtenol, pinocarveol and the boll-weevil pheromones seem out of proportion with their importance to the perfumery industry. The same criticism holds for Chapter 6 where sections on industrially important C15 alcohols such as farnesol, nerolidol, santalol and cedrol rub shoulders with such exotic sesquiterpenes as terrestrol, acorenol and hinesol. Surely, caryophyllene alcohol and acetate, briefly mentioned in the introduction to the chapter, deserve a more detailed treatment.

The editor's own contribution (Chapter 7) covers a curious miscellany—*p-tert*-butylcyclohexyl alcohol, benzyl alcohol, styrallyl alcohol, dimethylbenzylcarbinol and their corresponding acetates, together with 2-phenylethanol. However the comments regarding the different routes to phenylethanol make interesting reading and his exposition on the use of aluminum chloride and Grignard reagents on an industrial scale deserves a wide audience.

Bedoukian's survey of violet odorants rightly emphasizes the importance of the ionones and methylionones in this area, and then briefly touches on irones, damascones, nonadienal and acetylenic esters. In contrast Chapter 9 has only a modest essay on the vetyvenyl acetate of the perfumery industry; it concentrates on α- and β-vetivone, and the history of the structural confusion regarding the latter.

Modern jasmine odorants are described in Chapter 10. The character impact constituents of jasmine oil, *Z*-jasmone, jasmone lactone, and methyl jasmonate, are specified and their syntheses described. Consequently many of the newer synthetic approaches to cyclopentanones are summarized. The chemistry of the sandalwood fragrance follows, in which a good balance between santalols and terpenyl cyclohexanols has been achieved.

The next three chapters cover the various musk odorants. *Mookherjee* and *Wilson*'s contribution contains some interesting unpublished observations on the macrocyclic materials present in natural musk extracts. The synthetic sequences to these materials are subdivided into three groups—intramolecular ring closure, methylation of cyclopentadecanone, and ring expansion and/or contraction, the last including a substantial amount of peripheral material. The monocyclic and polycyclic (indane, tetralin, and isochroman) benzenoid musk odorants and the purely synthetic macrocyclic musks (*e.g.* ethylene brassylate) are covered thoroughly in the other two chapters.

Ohloff, in his chapter on the ambergris odor, covers a dauntingly large number of compounds, but nevertheless demonstrates clearly that the triaxial rule still applies in this area of fragrance chemistry. Finally, *Walradt* summarizes the more recent developments in instrumental analysis and spectroscopy within the context of the perfumery industry.

To sum up, the topics this volume covers, it generally covers well; however, such important fragrance materials as the aliphatic aldehydes, hydroxycitronellal, hexylcinnamic aldehyde, coumarin, heliotropin, and rose oxide receive scarcely a mention.

Lehrbuch der Lebensmittelchemie. *By H.-D. Belitz* and *W. Grosch.* Springer Verlag, Berlin 1982. xxxviii, 788 pp., bound, DM 124.00.

This textbook covers the most important food ingredients (water; amino acids, peptides, proteins; enzymes; lipids; carbohydrates; flavoring; vitamins and minerals) as well as the most important groups of foodstuffs (milk and dairy products; eggs; meat; fish; whalemeat, crustaceans, shellfish and molluscs; edible fats and oils; grain and grain products; legumes; vegetables and vegetable products; fruit and fruit products; sugar, sugar alcohols and honey; alcoholic beverages; coffee, tea, cocoa; spices, salt

and vinegar) in 23 chapters. Because of their topical importance the subjects of the contamination of food and of food additives have a chapter devoted to them.

The authors present a detailed account of the physical and chemical properties of the important food components, in order to emphasize the relationship between structure and properties at both the level of the ingredient and of the foodstuff. This applies particularly in the case of flavoring and taste. In order to limit the size of the book the authors have concentrated on the *chemistry* of foods, and, where possible, impart information in clearly arranged figures and tables. The large number of well-presented formulae and reaction schemes is also worth mentioning and is in favorable contrast to other—particularly older—textbooks. A far-ranging discussion of the nutritional, technological, texicological and legal aspects of the subject has been deliberately avoided. The information concerning commodities and amounts produced, required by the food chemist, is presented in an elegant, tabular review. The book also contains a range of analytical information which is relevant in judging foodstuffs.

In summary it may be said that this book gives a good review of the modern state of food chemistry. The authors have succeeded in presenting the subject synoptically and precisely. It must not remain unmentioned that important themes, such as cosmetics, commodities in relation to food commerce and tobacco products, which are, nowadays, integrated in to food chemistry, are not treated at all. The clear and comprehensive table of contents and index are worthy of praise. This book is both highly suitable for students of food chemistry, chemistry and related subjects and as a reference work and could well become one of the standard works on the subject within a very short time. However, in view of the high price it is questionable whether it will achieve the circulation it deserves.

Reactive Intermediates. Volume 3. Edited by *R. A. Abramovitch.* Plenum Press, New York 1983. xiv, 630 pp., bound, $ 59.50.

Three volumes of this open-ended series have now appeared, in quick succession (Volume 1: 1980; Volume 2: 1982; Volume 3: 1983). The contributions presented are intended to provide the interested reader with in-depth reviews of the present state of relatively new fields of the chemistry of reactive intermediates. The aim is to give the work as a whole—but not necessarily the individual chapters—an interdisciplinary character, dealing with themes from widely separated fields, encompassing atmospheric, biological, and industrial chemistry, as well as inorganic and organic chemistry. Hence, this series has a somewhat different objective from another series of the same name (editors *M. Jones Jr.* and *R. A. Moss,* at present two volumes), which is devoted more to the current knowledge of the conventional intermediates of organic chemistry (carbanions, carbocations, carbon radicals, carbenes and nitrenes).

The present volume, comprising seven chapters, begins with a contribution on the chemistry of selenium and tellurium atoms (*J. R. Marquart, R. L. Belford,* and *L. C. Graciano,* 60 p.). Alongside their generation (excited electronic states included) the reactions of these atoms are described, such as recombination, abstraction, insertion into C–H and Si–H bonds, as well as addition to C–C multiple bonds. A wealth of energetic and kinetic data is assembled into tables. The potential importance of these, to the non-specialist exotic-seeming species, not only in intermediate products and energy storage (lasers), is emphasized; the relationship with the chemistry of the lower chalcogens is often accentuated by comparison.

A reaction type which was formally only of theoretical interest, homolytic aromatic substitution by alkyl radicals, is the subject of the second chapter (*M. Tiecco* and *L. Testaferri,* 61 p.). In this field, considerable strides have been made in recent years in the understanding of polar effects on homolytic reactions. This type of reaction also forms the basis of an interesting preparative technique, in particular for the synthesis of certain substituted aromatic heterocyclics. In the following sections *J. W. Wilt* reports on radical reactions of silanes (85 p.) and *W. G. Bentrude* on phosphoranyl radicals (99 p.). Besides the formation of the radicals, their physical characteristics, isomerization behavior, reactions and synthetic potential are treated in detail.

The fifth contribution, by *G. Szeimies,* covers the numerous developments in the second half of the 1970s in the field of strained olefins with bridgehead double bonds (67 p.). Bridged annulenes and compounds with hetero double bonds are deliberately excluded. Emphasis is rather on the syntheses and characterization reactions for individual members of this class of reactive compounds, which is subdivided into three types. Generalizing answers to the interesting questions concerning the structure of strained C–C double bonds rest on a rather small fundament of experimental structural and energetic data. — The reactivity of alkoxyl radicals and their applications in synthesis are dealt with by *P. Brun* and *B. Waegell* (59 p.). After describing the various routes to these short-lived intermediates, particular emphasis is placed on the various applications of their intra- and intermolecular reactions.

The extensive last chapter (*Z. Rappoport,* 188 p.) is devoted to vinyl cations. In contrast to earlier reviews and to a monograph co-authored by the same author that appeared in 1979, in which vinyl cations were discussed primarily in terms of the method of their generation or the nature of the activating group, a welcome attempt has been made here to emphasize the similarities and differences between ions of different structural families and to view the field as a whole.—The volume concludes with an index (13 p.), appropriate in size and detail to the work. An indication of the reactive intermediates treated in previous volumes would have been desirable, however.

All the chapters are compiled by experts, clearly written and so constructed that even a newcomer to the field can easily follow the latest developments. The relevant literature is covered up to 1980/81. Over 1500 original references illustrate, amongst other things, the depth of treatment of the material. Even though the price of the volume may distract the interest of individuals in acquiring it, this collection of comprehensive reviews belongs in every specialized library. The intention of informing the reader about the importance of reactive intermediates outside his specialized field, has also been fully taken into account by the editor, for intermediates with reactive centers on elements so diverse as C, Si, P, O, Se and Te are included.

Ullmanns Encyklopädie der technischen Chemie. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley †, W. M. Weigert †,* and *E. Weise.* Verlag Chemie, Weinheim 1982. 4th Edition,, Volume 22: Stähle bis Textilfärberei. xiv, 716 pp., price DM 545.00.

Like its predecessors Volume 22 of Ullmann, which is now available, contains a large number of entries that are of interest to every chemist. An example of the synoptical and comprehensive form of the presentation, which is understandable and readable in spite of the wealth of detail, is given by the heading "Tenside" (surfactants) (61 pages). Two introductory sections on surface tension phenomena and historical development are followed by a description of the properties of aqueous surfactant solutions and their correlation with constitution. The groups of surfactants are then described, primarily from the point of view of their properties and the processes conventionally used in their manufacture. There follow sections on the analysis, methods of testing, application, and economic aspects of surfactants. The final section under this keyword ("Tenside in der Umwelt") deals with environmental aspects. Incidentally, eight of the 215 literature references come from 1982, an indication of the topicality of the presentation.

The entries in this volume cover the whole spectrum of applied chemistry. For example, from inorganic chemistry alone we have: strontium, tantalum, tellurium and their compounds, nitrogen; from organic chemistry: styrene, terephthalic acid, terpenes; from materials science: steel (164 pages), stoneware; from applications technology: textile printing (69 pages) and textile dyeing (82 pages); from food technology: sweeteners, tea; entries concerning specific problems of applied chemistry: radiation chemistry (33 pages), superconduction (13 pages); from the field of natural raw materials and derived products: starch (44 pates), tar and pitch (36 pages), tall oil, and tobacco and tobacco products (18 pages). In the last mentioned section one learns, for instance, that tobacco plants are often utilized as bioindicators. Somewhat later comes "heavy metals such as lead and cadmium, which are available to the plant from composted rubbish and activated sludge are taken up by the tobacco plant and stored in the leaves." It is certain that addicted smokers will be just as little impressed by this as by the section on the "toxicology of tobacco smoke", where at the close it is stated hopefully "that in future the mortality ratios (smoker/nonsmoker) will turn out better" (because of, inter alia, the changes made to cigarettes in the last 20 years, e.g. reduction of the tar and nicotine contents by half).

The overall impression gained from this volume is that the "Ullmann quality", in terms of content and presentation, is firmly established.

Liebigs Experimentalvorlesung, Vorlesungsbuch und Kekulés Mitschrift. Edited and commented on by *O. P. Krätz* and *C. Priesner* in collaboration with *O. Kratz, A. Diem,* and *S. von Moisy.* Verlag Chemie, Weinheim 1983. xii, 498 pp., bound, DM 160.00.

It is well known that it was *Justus von Liebig* who initiated the style of modern university chemistry courses with his practice of intimately linking academic teaching with practical instruction in the laboratory. The strand that binds the two main themes of chemical education is the lecture demonstration, and this fact alone is sufficient justification for this volume of Liebig's notes for a demonstration lecture together with a set of student notes derived from it. Furthermore, an insight is given into the knowledge, problems and way of thinking of a leading chemist in the mid-nineteenth century, which is surely not merely of interest to historians of chemistry.

The book of lecture notes which *Liebig* probably had prepared for his son *Georg*—in copybook handwriting with carefully executed drawings of laboratory apparatus—is reproduced in facsimile; the original test is printed alongside and is competently commented upon in many annotations. There is no need for an extensive justification to convince us that such a lecture from the mid-ninteenth century, which has been largely "translated" into present-day chemistry by the editors, constitutes a veritable treasure chest for anyone who wishes to learn more than usual about the first climaxes of classical chemistry. The student's notes on *Liebig*'s lecture were compiled by no less than *August Kekulé.* They are not reproduced here as manuscript copies, but the editors have complemented the printed word with some of *Kekulé*'s original sketches, and have again added some useful, carefully worded comments.

The editors have not seen their task as the simple reproduction of the book of lecture notes and the student's notes; they have created a living picture of *Liebig* and his chemistry in the introductions to the two main portions. The various chapters of both introductions, mainly written by *Otto Krätz,* make gripping reading; the authors command just such a polished style as they rightly attribute to *Liebig,* and with *Liebig* they have a character, who is interesting because he himself inspired interest. Contrary to their own opinion the authors have not failed in their attempt "to produce a sketch of the many faceted *Liebig*", and this, in particular, because they lay the enigmatic personality of this great chemist, with all its contradictions, bare before us. And to boot, we learn a great deal more about *Liebig* himself and the general political and social environment in which he lived—particularly his Bavarian surroundings—and peripherally, but still clearly contoured, about *Liebig*'s son *Georg,* about the Bavarian monarch, *Maximilian II,* about the poet *Paul Heyse,* and not least about *August Kekulé.* The faultless presentation of this book, the excellently chosen photographs and pictures concerning the subject "Liebig" and the often amusing and instructive details, which are to be found in abundance even in the footnotes, do not require any further mention here. It might be added, however, that the authors do not stray into the realms of pure anecdote. Their clear feeling for the times and for the people protects them from that, but their every line vindicates by example the opinion of *Golo Mann* about the writing of history in bloodless, quantitative and sociological terms when he described "the extraordinary entertainment of history".

Phospholipids as Functional Constituents of Biomembranes**

By Hansjörg Eibl*

This article describes new methods for the synthesis of biologically active phospholipids. The physical properties of such compounds are directly related to their chemical structure, the position of the substituents esterified with glycerol not only influencing the physical properties but also the biological function of the phospholipids. Phase transitions can be induced by temperature changes and—in biological systems—by changes in the surface charge or the degree of protonation. In model studies, the properties of lipid phases differ sufficiently to influence and control biological membrane processes. Alkyl glycerides can modify the properties of biological membranes quickly and reversibly to increase the permeation of active compounds. An important example is the improved transport of cytostatic drugs across the blood-brain barrier. Knowledge about the substrate specificity of enzymes that metabolize phospholipids allows the synthesis of tailored cytotoxic phospholipids which selectively accumulate in malignant tissues. Thus, the interplay of chemical synthesis and investigations of physical structure lays a foundation for the understanding of simple membrane processes on a molecular level, and the experience gained with such model systems can, in turn, be used to influence natural membranes, such as those of the blood-brain barrier or of tumors, in a directed way.

1. Introduction[***]

Biological membranes are complex in structure and function. Their quantitatively dominant constituents are phospholipids and proteins that favor the formation of planar bilayer membranes in an aqueous environment. This tendency to aggregate and to form organized structures derives from the architecture and amphoteric character of the phospholipid molecules, which exhibit lipid-soluble, lipophilic or non-polar regions and water-soluble, hydrophilic or polar regions on the same molecule.

The nomenclature of phospholipids[1] is based on a proposal by *Hirschmann*[2]. Naturally occurring phospholipids contain glycerol which is esterified in positions 1 and 2 with fatty acids and in position 3 with phosphate. Thus, the systematic designation of phosphatidic acid (PA) is 1,2-diacyl-*sn*-glycero-3-phosphate (where *sn* means 'stereospecific numbering'). The specific and non-random distribution of substituents over the positions 1, 2 and 3 of the glycerol molecule introduces chirality. The respective (*S*)-enantiomer, 2,3-diacyl-*sn*-glycero-1-phosphate, has not been detected in nature.

In typical membrane phospholipids the phosphate group is esterified with an additional alcohol, for instance in phosphatidylcholine (PC), phosphatidylethanolamine[1b] (PE) and phosphatidylglycerol (PG) (Scheme 1). Depending upon the structure of the polar region, these phospholipid molecules are neutral at pH values of about 7 (zwitter-

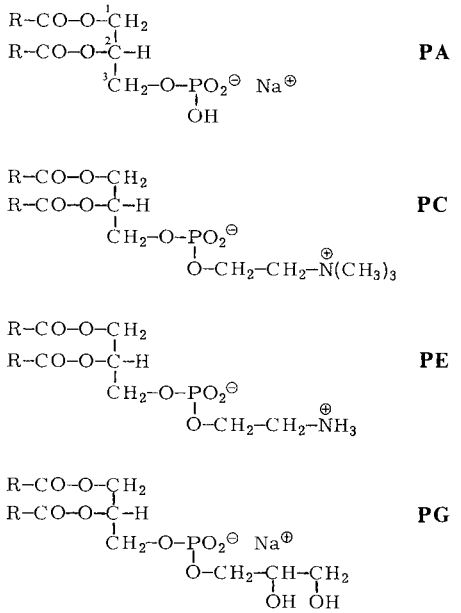
ionic: PC and PE) or exhibit a negative surface charge (PA and PG).



Scheme 1. Typical membrane phospholipids with abbreviations (see text). R represents a long-chain alkyl residue which can contain one or more double bonds. A synthetic analogue of PG is called PP which indicates the lack of a hydroxyl group at C-2 of the glycerol (see Table 5).

In their classic work on the composition of erythrocyte membranes, *Gorter* and *Grendel*[3] were able to show that the phospholipids present in the membrane are sufficient to cover the cell surface with a lipid bilayer. This finding constituted a milestone in biomembrane research and logically became an integral part of all later theories of biological membranes. Surprisingly, the membrane model proposed by *Danielli* and *Dawson*[4] in 1935 has retained its fundamental significance even today: the basic element of biological membranes is the lipid bilayer. The polar regions of the phospholipid molecules are oriented towards the water phase, and the nonpolar parts of the molecules form a hydrophobic phase separating two aqueous regions (Fig. 1). This bilayer structure remained fundamental for many later membrane models such as the 'unit membrane' theory of *Robertson*[5] and in the models of *Finean*[6], of *Singer* and *Nicolson*[7] and of *Lynen*[8]. Only seldom have proteins been proposed as the structural building blocks of biological membranes[9,10].

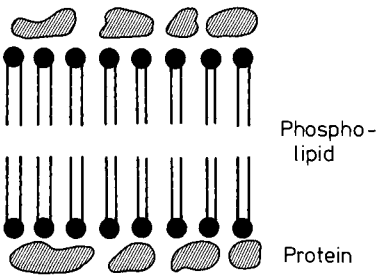


Fig. 1. Membrane model according to *Danielli* and *Dawson* (1935) [4].

Living cells are surrounded by a plasma membrane which defines their extent and insures their integrity by separating the cytoplasm from the surrounding medium. Also, membranes structure the cell interior. Subcellular particles are compartmented by membranes that allow them to operate as separate functional units. For example, the endoplasmic reticulum provides a place for phospholipid[11,12] and protein synthesis[13], and mitochondria are dedicated to the production and storage of energy[10] (ATP-synthesis). It is therefore not surprising that membranes constitute over 90% of a biological cell's dry substance.

The natural border regions of cells and subcellular compartments are membranes which are the main topic of the following discussion. Membranes are composed of a large number of different phospholipid and protein molecules. They form a very complex bilayer matrix and must fulfill multiple functions in close and precise interaction with the environment. The complex structure and the manifold functions normally prevent a detailed study, for example of the interactions between proteins and phospholipids, on a molecular level. Therefore, single membrane processes must be extracted from their natural surroundings and reconstructed in model systems providing a physically and chemically defined lipid environment. Consequently, membrane research involves studies at four levels: 1) synthesis of phospholipids with a well-defined structure and configuration, 2) analysis of the physical properties of phospholipid/water systems, 3) reconstitution experiments, or the reactivation of biological membrane functions in synthetic phospholipid membranes (allowing the study of individual membrane processes), and 4) the selective modification of natural cell membranes.

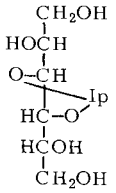
2. Synthesis of Phospholipids

The increasing significance of phospholipids as carriers for drugs with increased bioavailability[14] or as drugs[15] on their own, as well as their importance as membrane model systems[16-18] present a challenge for the synthetic chemist. The growing interest in these chemically variable structures is reflected in the increasing number of publications describing the synthetic or semisynthetic preparation of phospholipids.

The first synthesis of a phospholipid with natural configuration was described by *Rose*[19]. The classical work of *Baer*[20] and of *de Haas* and *van Deenen*[21] followed. More recent techniques have been collected in numerous review articles[22-28].

Hitherto, the usual starting substance for the synthesis of phospholipids has been 1,2-isopropylidene-*sn*-glycerol, whose problematic storage (racemization) and occasionally unsatisfactory optical purity have been criticized[29,30]. We have now developed new routes for the synthesis of phospholipids. The starting material is a stable D-mannitol derivative, 3,4-isopropylidene-D-mannitol **1**, whose synthesis was first described by *Wiggins et al.*[31]. Although stable and easily prepared, this compound was for some reason not often used in lipid work. It is prepared from D-mannitol by reaction with acetone/H_2SO_4. The intermediate, 1,2:3,4:5,6-triisopropylidene-D-mannitol, is con-

verted into 3,4-isopropylidene-D-mannitol **1** by mild hydrolysis with aqueous acetic acid.



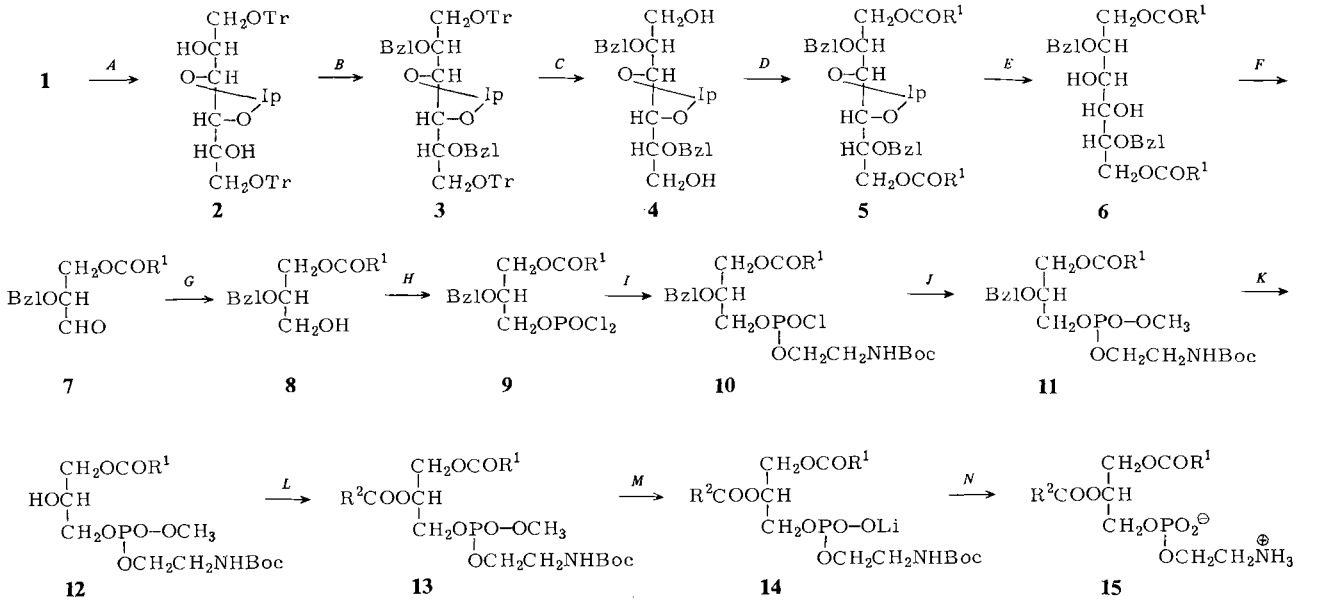
1, Ip = $C(CH_3)_2$

The synthesis of phospholipids starting from 3,4-isopropylidene-D-mannitol is outlined for four different structures of biological significance. The first, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine **15**[28], is an important phospholipid for the induction of ion channels mediated by acetylcholine receptor protein[32,33]. The second, 1-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine **21**[34], is a biological mediator[35] frequently called the 'platelet activating factor' (PAF). The third, 1-octadecyl-*sn*-glycero-3-phosphotrimethylammoniohexanol **27**[27], is a phospholipid with an increased phosphorus-nitrogen separation which alters its metabolism and may impart properties that inhibit tumor growth[36]. The fourth, 1,2-dioleoyl-*sn*-glycero-3-phosphoserine **35**[28], has been found to induce the fusion of liposomes[37].

These four model substances illustrate the close link between the chemical structure and biological function of phospholipids. Small variations in structure can lead to dramatic changes in biological activity. For instance, thrombocytes are activated by 1-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine **21** in a concentration of 10^{-10} mol/L[35]. The corresponding lyso compound (or 2-deacyl compound) is inactive, but exerts an immunostimulating activity like that of 1-octadecyl-2-methyl-*rac*-glycero-3-phosphocholine (cf. **52**, Table 7)[38–40].

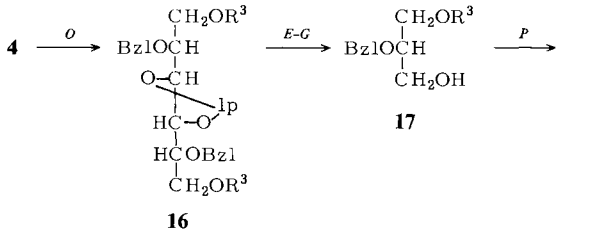
These and other observations have led us to study the relationship between chemical structure and biological activity, and in particular the biologically important interactions between phospholipids and proteins. A prerequisite for such studies is that simple procedures for the preparation and stepwise modification of phospholipid molecules should be available.

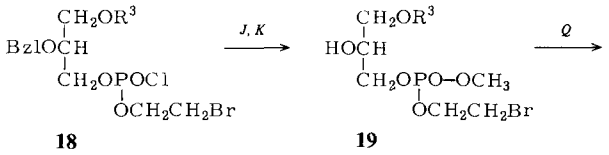
The synthesis of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine **15**[28] is outlined in Scheme 2. Tritylation of 3,4-isopropylidene-D-mannitol **1** with trityl chloride in tetrahydrofuran (THF)/triethylamine (step *A*) furnishes the 1,6-dityrityl derivative **2**, which is then benzylated in positions 2 and 5 to give **3** (step *B*). The trityl groups are then selectively removed from **3** in methanol/2-propanol/H_2SO_4 (step *C*) to give 2,5-dibenzyl-3,4-isopropylidene-D-mannitol **4**. This is esterified in dichloromethane with palmitic acid/dicyclohexylcarbodiimide(DCC)/4-(dimethylamino)pyridine to give 2,5-dibenzyl-1,6-dipalmitoyl-3,4-isopropylidene-D-mannitol **5** (step *D*), in which the palmitoyl group has reached its final position (*sn*-1). Acidic deacetonation of **5** in chloroform/trifluoracetic acid/70% $HClO_4$ affords 2,5-dibenzyl-1,6-dipalmitoyl-D-mannitol **6** (step *E*), the vicinal diol moiety of which in positions 3 and 4 is cleaved with lead tetraacetate in THF (step *F*); the resulting aldehyde **7** is then reduced with $NaBH_4$ (step *G*) to 1-palmitoyl-2-benzyl-*sn*-glycerol **8**. Phosphorylation of **8**—favorably achieved with $POCl_3$ in THF/triethylamine—yields 1-palmitoyl-2-benzyl-*sn*-glycero-3-phosphodichloride **9** (step *H*). Thus, the phosphoester is attached to the *sn*-3 position. All further compounds derived from **9** will therefore have the natural (*R*)-configuration of the phospholipids which are major constituents of all biological membranes. The phosphorylated product **9** is esterified with *N*-*tert*-butoxycarbonylethanolamine to give **10** (step *I*). Subsequent addition of methanol/triethylamine results in formation of **11** (step *J*), the respective phosphotriester. Catalytic hydrogenolysis of **11** in chloroform/methanol

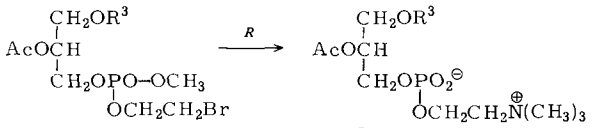


Scheme 2. The synthesis of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine **15**. Boc = $CO-OC(CH_3)_3$; Bzl = $CH_2C_6H_5$; Tr = $C(C_6H_5)_3$; $R^1 = (CH_2)_{14}CH_3$; $R^2 = (CH_2)_7-CH=CH-(CH_2)_7CH_3$. Reaction steps *A* to *N* (see text).

with 10% Pd/C leads to removal of the benzyl group and formation of **12**, which has a free hydroxyl group in the *sn*-2 position (step *K*). Esterification with oleic acid/DCC/4-(dimethylamino)pyridine in dichloromethane affords the 2-oleoyl compound **13** with the oleoyl moiety in the desired 2-position (step *L*). For transformation into the final product, **13** is demethylated in ethyl methyl ketone to **14** (step *M*), from which the *N*-Boc-protecting group is subsequently removed in chloroform/trifluoracetic acid/70% $HClO_4$ (step *N*). The final product **15** is obtained in yields of 40 to 50% based on **1**. Compound **15** is a phosphatidylethanolamine (PE, Scheme 1).



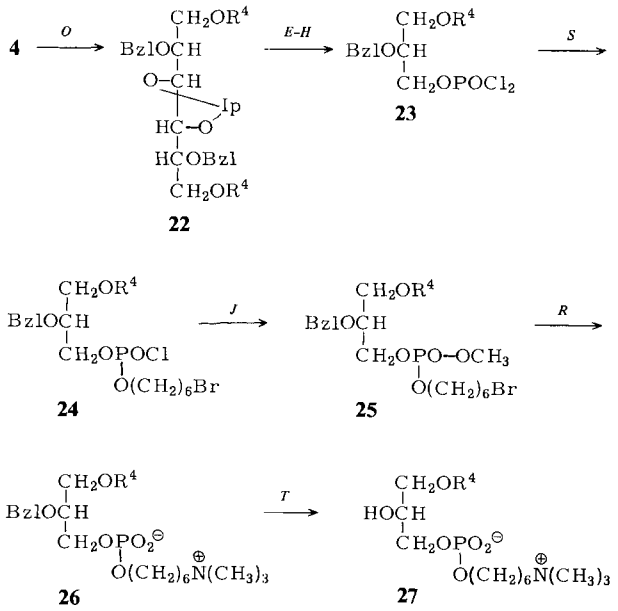




Scheme 3. The synthesis of 1-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine **21**. Ac = $COCH_3$; $R^3 = (CH_2)_{15}CH_3$. Reaction steps *O* to *R* (see text).

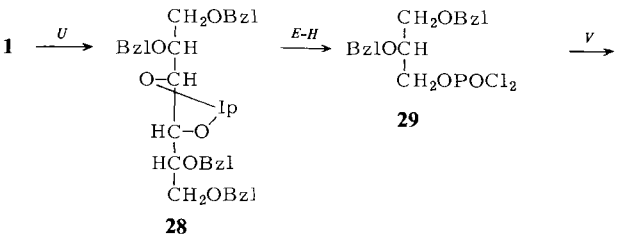
As starting material for the preparation of 1-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine **21** (Scheme 3)[34] we used 2,5-dibenzyl-3,4-isopropylidene-D-mannitol **4**. Alkylation of **4** with 1-bromohexadecane in THF/potassium *tert*-butoxide affords 2,5-dibenzyl-3,4-isopropylidene-1,6-dihexadecyl-D-mannitol **16** (step *O*), which is converted into 1-hexadecyl-2-benzyl-*sn*-glycerol **17** in a sequence of reactions analogous to steps *E* to *G* (Scheme 2). The alkyl chain is thus already in the desired position (*sn*-1). Phosphorylation of **17** with bromoethylphosphoric acid dichloride in THF/triethylamine yields the *sn*-3 phosphoric acid derivative **18** (step *P*) having the natural configuration. **18** is converted, in analogy to step *J*, into the respective methyl ester, which is then debenzylated to **19** in analogy to step *K*. Esterification of **19** in dichloromethane with acetic acid/DCC/4-(dimethylamino)pyridine affords **20**, with the acetyl group in the desired *sn*-2 position (step *Q*). The formation of the final product **21** is then possible in one step (step *R*) by amination and demethylation with trimethylamine in chloroform/2-propanol. The yield is about 40% based on **4**.

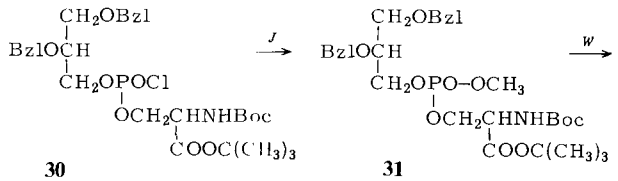
1-Octadecyl-*sn*-glycero-3-phosphotrimethylammoniohexanol **27** (Scheme 4)[27] can also be prepared from compound **4**. In analogy to step *O*, 2,5-dibenzyl-1,6-dioctadec-

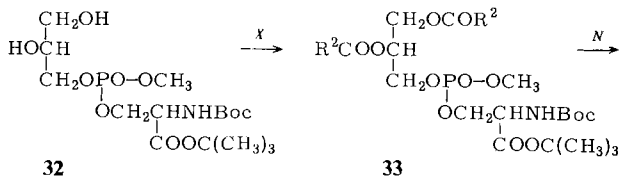


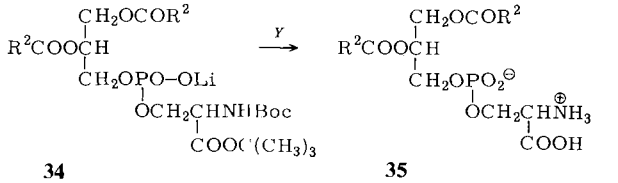
Scheme 4. The synthesis of 1-octadecyl-*sn*-glycero-3-phosphotrimethylammoniohexanol **27**. $R^4 = (CH_2)_{17}CH_3$. Reaction steps *S* and *T* (see text).

yl-3,4-isopropylidene-D-mannitol **22** is obtained using 1-bromooctadecane and is subsequently converted into the phosphoric acid dichloride **23** exactly as shown in steps *E* to *H*. Esterification of **23**, first with bromohexanol result-









Scheme 5. The synthesis of 1,2-dioleoyl-*sn*-glycero-3-phosphoserine **35**. $R^2 = (CH_2)_7–CH=CH–(CH_2)_7CH_3$. Reaction steps *U* to *Y* (see text).

ing in **24** (step *S*) and then with methanol/triethylamine, gives **25** (step *J*). Reaction of **25** according to step *R* provides the phosphocholine analogue **26**. Catalytic hydrogenolysis of **26** in methanol with 10% Pd/C (step *T*) affords **27** in yields of 40% based on **4**.

The synthesis of 1,2-dioleoyl-*sn*-glycero-phosphoserine **35** (Scheme 5)[28] is possible using 3,4-isopropylidene-D-mannitol **1** as starting material. Perbenzylation of **1** in *tert*-butanol/potassium *tert*-butoxide with benzyl chloride (step *U*) gives **28**, which is converted into the phosphoric acid dichloride **29** in analogy to the reaction steps *E* to *H*. **29** is esterified first with *N*-Boc-serine *tert*-butyl ester to **30** (step *V*) and then, in analogy to step *J*, with methanol/ triethylamine to give the phosphoric acid triester **31**. Catalytic debenzylation of **31** with 10% Pd/C in chloroform/methanol under hydrogen (step *W*) yields the phosphotriester **32** which has free hydroxyl groups in positions 1 and 2 of the glycerol molecule. Esterification of **32** with oleic acid/ DCC/4-(dimethylamino)pyridine generates **33** (step *X*). Demethylation in analogy to step *N* with LiBr in ethyl methyl ketone furnishes the protected 1,2-dioleoyl-*sn*-glycero-3-phosphoserine **34**, which is deprotected in one step (*Y*) in chloroform/trifluoroacetic acid/70% $HClO_4$ to give the end product **35**. The yield is about 60% based on **28**.

As shown by examples **15**, **21**, **27** and **35**, tailor-made phospholipids of well-defined structure and configuration can be prepared from simple and stable starting materials in relatively straightforward sequences of reactions. In this way, naturally occurring phospholipids as well as novel structures not found in nature can be synthesized.

The specific, non-random positioning of the fatty acid residues on the glycerol backbone is very important for the physical and biological properties of phospholipids. In natural phospholipids, saturated fatty acids are preferentially found in the *sn*-1 position and unsaturated fatty acids in the *sn*-2 position[41–44]. The physical significance of this finding is discussed in Section 3.

3. Physical Properties of Phospholipid/Water Systems

In water, phospholipids spontaneously assemble into higher molecular aggregates if their concentration surpasses a critical concentration, called the critical micellar concentration (CMC). The type of aggregates formed depends not only on the chemical structure of the lipid but also on physical parameters such as the surface charge, temperature, and the ionic environment. For typical membrane lipids (such as 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine) the CMC values are smaller than 10^{-10} mol/L. Therefore, the concentrations of lipid actually dissolved in the water are negligibly small and the phospholipids are true membrane components.

In view of the different kinds of aggregates observed, the question arises whether the most probable conformation of a particular lipid in water can be predicted from its chemical structure according to some general principle. In fact, relatively simple geometric considerations involving the surface area requirement of the molecule allow quite reliable predictions. The data values required for the relative areas occupied by the two parts of the molecule—the polar and nonpolar regions—are obtained from monolayer studies in a Langmuir trough[45], or from X-ray diffraction analysis of phospholipid single crystals[46–48]. Specific conformations are favored if either the polar or nonpolar regions require more area. In this way, the most important types of organized structures formed by phospholipids (micelles, lamellar bilayer structures, vesicles, and hexagonal structures) can be convincingly explained (Fig. 2).

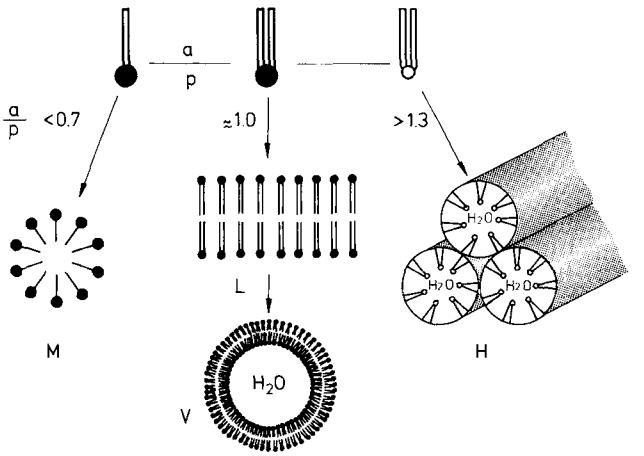


Fig. 2. The organization of phospholipids in water. M: micelle; L: lamellar bilayer; V: vesicle; H: hexagonal structure; a: apolar; p: polar. a/p = ratio of surface requirement of the apolar and the polar region of the molecule.

The decisive parameter is the ratio of the surface requirement of the apolar and the polar regions of the molecule (Table 1). A value near 1 favors the formation of extended lamellar bilayer structures. They can form spheres enclosing water, called vesicles or liposomes. Phosphatidylcholines (lecithins) like **38** are good examples for this behavior (Table 1).

A surface ratio of <0.7 (wedge-shaped molecules with a dominant polar region) leads to the formation of micelles, which differ from vesicles in that the large polar parts of the molecule are oriented towards the water phase and the

Table 1. The surface area (Å^2/molecule) of phospholipids and of the apolar and polar regions of each molecule. The ratio of the respective surface areas apolar to polar allows predictions about the expected orientation in the presence of water. A ratio of about 1 favors structures such as lamellar bilayers (L); a ratio <1 those of micelles (M) and >1 those of hexagonal structures (H). See also Figure 2. H (L) denotes hexagonal or lamellar, depending on temperature (see also Table 3).

Phospholipids [a]	Surface Area			Ratio apolar to polar	Observed organized structure
	Whole molecule	Regions apolar	polar

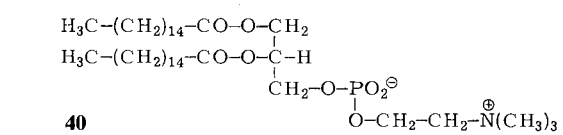
1-Stearoyl-*sn*-G-3-PE **37**	28	20	28	0.71	M (L)
1,2-Distearoyl-*sn*-G-3-PC **38**	44	44	40	1.10	L
1,2-Distearoyl-*sn*-G-3-PE **39**	42	42	28	1.50	H (L)

[a] G-3-PC and G-3-PE denote glycero-3-phosphocholine and glycero-3-phosphoethanolamine, respectively.

fatty acid chains congregate to form an apolar interior. There is no water inside a micelle. Typical micelle formers are monoacylglycerophosphocholines (lysolecithins) like **36**. If the surface ratio is >1.3 (wedge-shaped molecules with larger apolar region), so-called 'inverted micelles' are formed. To avoid confusion with micelles, these structures are now called hexagonal II[*]. Important phospholipids with these properties are the phosphatidylethanolamines (cephalines), as shown in formulas **15**, **37**, and **39**.

Like vesicles, the hexagonal structures enclose an aqueous inner volume. However, in hexagonal structures the aqueous phase is surrounded by a lipid monolayer, whereas in vesicles the aqueous interior is bordered by a bilayer. Lamellar structures can be differentiated from hexagonal arrangements by X-ray analysis.



40

1,2-PP-GPC

In the following discussion we will concentrate on the lamellar bilayer phase, because it is the fundamental structure of biological membranes, and reliable detailed information about it is available. Basic experimental data about phospholipid bilayer structures were obtained with 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (1,2-PP-GPC, **40**). Starting with the innovative experimental work of *Chapman* et al.[49] this phospholipid has been studied most intensively, so that it is the phospholipid whose phase behavior is best understood today. There are several reasons for this: it is relatively easy to synthesize[28], it has biological significance as the major phospholipid of lung alveolar tissue[50,51], and it exhibits thermotropic phase transitions in the experimentally easily accessible temperature range between 10 and 50 °C. It is therefore reasonable to take 1,2-PP-GPC as an example in discussing the characteristic properties of lamellar phases and to study the influence of structural modifications, both in the polar and nonpolar regions, in relation to the properties of this phospholipid.

According to experimental work with 1,2-PP-GPC in aqueous dispersions this lipid exhibits three calorimetric phase transitions[52-55] when heated from 0 to 50 °C. They are called the subtransition I (phase transition temperature T_{S_I}), the pretransition (phase transition temperature T_P) and the main transition (phase transition temperature T_M). The state below the main transition temperature is called the ordered, crystalline or gel-phase (P_β or P'_β phase[**]) and the state above the main transition is called the fluid or liquid-crystalline phase (L_α phase). Thus, for the heating mode, the main transition is a transition from the ordered to the fluid phase, i.e. from P_β to L_α. The two phases differ in the packing density of the hydrocarbon chains. In the ordered phase, the chains are densely packed with an all-*trans* conformation, whereas the fluid phase represents a more loosely packed matrix (*gauche* conformation)[56]. The state below the pretransition temperature is the L_β phase (above T_P is the P_β phase) and the state below the subtransition I is called the L_α phase (above T_{S_I} is the L_β phase; cf. Fig. 3).

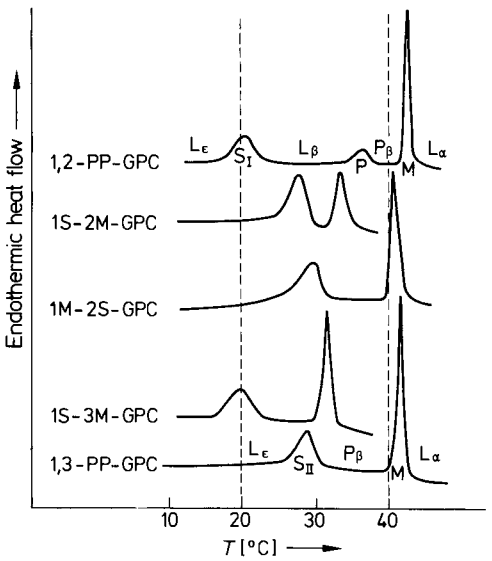


Fig. 3. Calorimetric heating curves of phosphatidylcholines. L_ε, L_β, P_β, L_α: lipid phases; S_I: subtransition I; S_{II}: subtransition II; P: pretransition; M: main transition. Abbreviations for phospholipids see Table 2. A deviation of the heating curve from the base line is observed at a phase transition due to additional heat uptake. The area of the deviation corresponds with the phase transition enthalpy ΔH.

The conformational changes related to the main transition have been directly observed using Laser-Raman spectroscopy[57]. They lead to a considerable contraction of the hydrocarbon chain length (*gauche* conformation) and, accordingly, to a lateral expansion of the bilayer structure. For 1,2-PP-GPC, the following changes were found to accompany the phase change from the ordered to the fluid state (main transition in heating mode): increase in the surface requirement for a single phospholipid molecule from 48 to 70 Å^2[58], shortening of the hydrocarbon chain length by 6 to 7 Å[59], expansion of the bilayer volume by 1 to 2%[59], and onset of rapid lateral diffusion of the lipid molecules due to the decreased van der Waals interaction between the chains above T_M. A lateral diffusion coefficient of 10^{-8} cm^2/s[60,61] was determined for the fluid state, whereas lateral diffusion in the ordered state is immeasurably small.

As demonstrated in reconstitution experiments (Section 4), the main transition is particularly important for biological systems as well as for model studies. It is therefore meaningful to focus attention on the main transition and, because of the amphiphilic nature of the phospholipid molecules, to discuss the influence of the apolar and polar parts of the phospholipid molecule separately. The main transition can react sensitively to small changes in the ionic environment, whereas the subtransition represents a packing change in an already very dense, rigid lipid matrix and thus is isothermally not sensitive to changes in the ionic environment.

[*] Later on, hexagonal is used instead of hexagonal II.

[**] In the work discussed here the tilt angle of the acyl chains to the membrane normal was not estimated. Consequently the primed and unprimed phases were not distinguished. By definition L_ε and L'_ε indicate an orientation of the fatty acid chains parallel to and tilted to the membrane normal, respectively. For simplification, we write L_ε instead of L_ε (L'_ε) etc.

The effects of structural variations in the apolar region were intensively studied with selected phosphatidylcholines. They were of the same molecular weight (Table 2), but differed in the chain lengths of the fatty acid residues[55,62] and also in the respective positions of the fatty acids and phosphocholine along the glycerol backbone[63]. The comparison includes 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (1,2-PP-GPC) and its 1,3-isomer, as well as 1,2- and 1,3-isomers of phosphatidylcholines with stearic acid and myristic acid residues in different but defined positions of the glycerol molecule. The lipids can be subdivided into two groups according to the number of thermotropic transitions and the characteristic X-ray diffraction patterns.

1,2-Diacyl-*sn*-glycero-3-phosphocholines with two identical fatty acid chains are found to be exceptional in showing three calorimetric transitions—subtransition I, pretransition, and main transition (Fig. 3) with their respective transition enthalpies. This behavior was described for 1,2-PP-GPC **40** and for 1,2-distearoyl-*sn*-glycero-3-phosphocholine **38** (Table 1) and is most probably also to be expected for the 1,2-dimyristoyl analogue[63]. The corresponding four lipid phases (L_c, L_β, P_β, and L_α) can be characterized by their respective X-ray diffraction lines (Table 2). The number of reflections in the 4 to 10 Å region increases with increasing packing density of the hydrocarbon chains (L_α to L_c) as a result of the increasing crystallinity of the more densely packed L_c-phase.

Table 2. The physical properties of lamellar bilayers of phosphatidylcholines (see also Fig. 3) with increasing temperature, *T*. Phase transitions are indicated at the respective temperature. S_I: subtransition I; S_{II}: subtransition II; P: pretransition; M: main transition; ΔH: phase transition enthalpy; L_c, L_β, P_β, L_α: characteristic phases of the lamellar bilayer arrangement; *d*: distance of the lamellar periodicities which are composed of the thickness of the lamellar bilayer and of the respective water layer between the bilayer lamellas (long distances from 47 to 70 Å); *s*: distance between fatty acid chains and between single phosphatidylcholine molecules which contain two fatty acids per molecule (short distances between 3.72 to 10.00 Å).

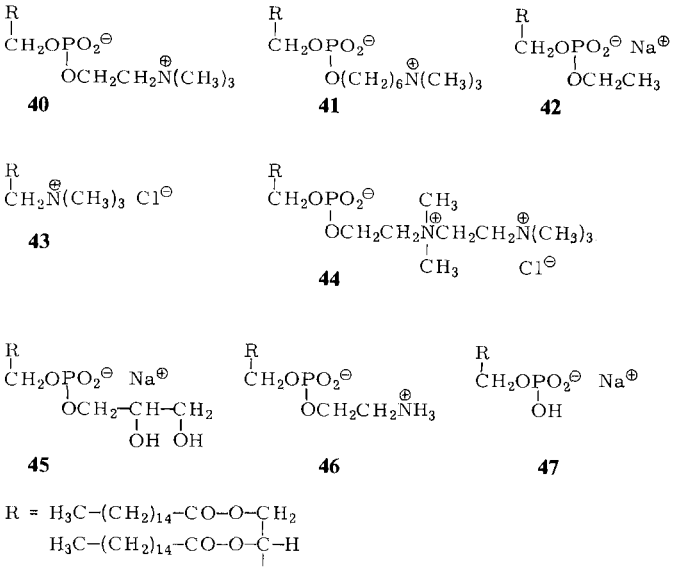
[a] M = myristoyl ($CH_3(CH_2)_{12}CO$), P = palmitoyl ($CH_3(CH_2)_{14}CO$), S = stearoyl ($CH_3(CH_2)_{16}CO$), and GPC = glycerophosphocholine.

All other phosphatidylcholines studied by our group show a different phase behavior. Only two thermotropic transitions are observed, the subtransition II and the main transition. Again, the respective phase transition enthalpies of the lipid phases (L_c, P_β and L_α) and their X-ray diffraction patterns are characteristic for the different lipid phases. The 1,2-diacyl-*sn*-glycero-3-phosphocholines with two different fatty acid residues belong to this class. They are extremely important as naturally occurring biological phospholipids. The same behavior is also observed for 1,3-diacyl-*sn*-2-phosphocholines, independently of whether they contain two identical fatty acid chains or two different fatty acid chains in the same molecule. The most important difference between these two classes of lipids is the absence of the pretransition found for the 1,2-diacyl-*sn*-glycero-3-phosphocholines with two identical fatty acid residues, and most probably the absence of the L_β-phase (for a detailed discussion see [63]).

Biological membranes consist of mixtures of phospholipids which differ in the composition of the fatty acids and also in the surface charge[64]. Therefore structural variations in the polar region of these molecules are studied. *Träuble* and *Eibl*[65] have shown that changes of the surface charge in bilayer membranes can have pronounced effects on the physical properties of the membranes and particularly on the main transition temperature.

The influence of the polar region on the properties of the entire molecule was studied with 1,2-dipalmitoyl-*sn*-glycerol as a constant apolar structural unit. This is advantageous because the discussion in the case of 1,2-PP-GPC can also include the pretransition which is not found for molecules of mixed fatty acid composition. The reference molecule 1,2-PP-GPC **40** was modified as follows: an increase in the phosphorus-nitrogen distance (**41**), removal of the trimethylammonium group (**42**), removal of the phosphate group (**43**), overcompensation of the negatively charged phosphate group by two positive charges (**44**) and substitution of choline by glycerol (**45**). The effect of these extensive structural changes on the physical behavior of phospholipid-water systems at pH 7 is however marginal. The main transition temperatures lie between 40 to 42 °C, and the pretransition occurs at 33 to 36 °C. Thus, the phospholipid bilayer does not respond to these changes in the structure and surface charge of the molecules.

There is, however, another group of lipid molecules for which relatively small changes in structure and/or charge dramatically affect the physical properties. These lipids do not show a pretransition, but are characterized by main transition temperatures far above the main transition temperatures of the aforementioned lipids. For instance, at pH 7 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine **46** and 1,2-dipalmitoyl-*sn*-glycero-3-phosphate **47** have T_M values near 65 °C; in comparison the corresponding phosphatidylcholine **40** has a T_M of 41 °C.



40 **41** **42**

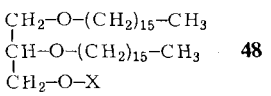
43 **44**

45 **46** **47**

R = $H_3C-(CH_2)_{14}-CO-O-CH_2$
$H_3C-(CH_2)_{14}-CO-O-CH$

In searching for structural analogies between these two groups of molecules which may explain the differences in physical behavior, it appears that the lipids with the higher T_M values (around 65 °C) are protonated. They contain structural and structuring protons within the membrane surface, whereas the lipids with the lower T_M values (near 40 °C) are deprotonated, with the phosphate groups fully charged. Possibly the interplay of forces within the polar region of phospholipid bilayers is decisively influenced by the presence of structural protons within the membrane surface[66,67].

This assumption is easily checked experimentally. If the difference in the degree of protonation, or the degree of dissociation α, is the cause of the drastic differences in the physical properties, similar differences should be found in the transition behavior of one kind of phospholipid molecule at different pH values, above and below the respective pK value. For such studies at extreme pH values from pH 1 to 12 we have prepared phospholipids of type **48** con-



48

taining ether-linked chains instead of the less stable ester bonds, which are subject to hydrolysis. Thus, 1,2-dipalmitoyl-*sn*-glycerol as apolar structural element was replaced by 1,2-dihexadecyl-*sn*-glycerol. The differences in physicochemical behavior between such "ether"- and "ester"-phospholipids have been shown to be small, with the phase transition temperature in the case of the "ether-phosphatidylcholine" increased by about 3 to 4 °C in comparison to the "ester" analogue[68–72].

The phase transition behavior of various "ether-phospholipids" of type **48** was investigated at different pH values, starting at pH 12 and investigating the effect of increasing proton concentration as shown in Figure 4. The deprotonated lipids, 1,2-dihexadecyl-*sn*-glycero-3-phosphocholine, -3-phosphoethanolamine, -3-phosphoglycerol, and -3-phosphate do not differ significantly in their physical properties ($T_M \approx 43$ °C; $T_P \approx 38$ °C). Therefore, the pretransition is not a specific attribute of phosphatidylcholines, but instead is a general property of all phosphocholines with identical chains in the 1 and the 2 position of glycerophosphocholines that are fully dissociated, *i. e.* that do not contain any structural protons within the membrane surface. With increasing proton concentration (lower pH values) the pK values of the polar head-groups become increasingly important[*]. For instance, at pH 11 the amino group of phosphatidylethanolamine binds protons in accordance with its pK value. This drastically changes the properties of the lipid. The pretransition disappears and the main transition is shifted to $T_M > 70$ °C, which is > 30 °C above the main transition temperature of the deprotonated state. The other lipids included in this investigation change their properties with the protonation state in complete analogy to the phosphatidylethanolamine. The pretransition disappears, and the main transition is shifted to higher temperatures. For phosphatidic acid this occurs at pH 9 (pK_2), for phosphatidylglycerol at pH 4 (pK), and for phosphatidylcholine at pH 1 (pK). The physical properties of the "ether-phospholipids" thus depend directly on the degree of protonation; the "ester-phospholipids" behave similarly.

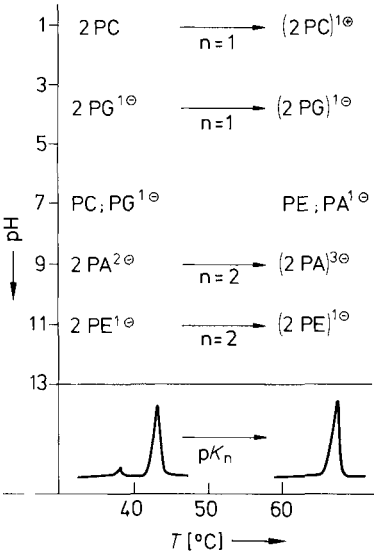


Fig. 4. Influence of the proton concentration on the physical properties of "ether-phospholipids" of type **48**, which were chosen instead of the "ester-phospholipids" because of their better stability. PE, PA, PG and PC stand for 1,2-dihexadecyl-*rac*-glycero-3-phosphoethanolamine, -3-phosphate, -3-phosphoglycerol and -3-phosphocholine. At pH-values > 12 the lipids are all in the deprotonated state and exhibit a pretransition and a main transition. At the pH value of pK_n the main transition temperature is shifted to higher temperatures. A pretransition is no longer detected.

The different pK values of the various phospholipids are therefore of great importance for the function of natural

[*] We have compared the pK values of water soluble glycero-3-phosphate with 1,2-dimyristoyl-*sn*-glycero-3-phosphate [65]. For matrix-bound phosphate residues, the pK values are shifted to higher pH values. For instance glycero-3-phosphate: pK_1 2.0, pK_2 6.0; 1,2-dimyristoyl-*sn*-glycero-3-phosphate: pK_1 4.0, pK_2 9.0. The dissociation of protons from a negatively charged lipid matrix needs more energy than deprotonation of a single molecule.

membrane systems. In the biologically relevant pH region near pH 7, two groups of phospholipids with completely different physical properties coexist: fully dissociated structures and those which are partly protonated. "Ether-phospholipids" with the same apolar region (e.g. 1,2-dihexadecyl-*sn*-glycerol) as the phosphocholine or phosphoglycerol show two transitions with T_M values of about 43 °C and T_P values of about 38 °C, whereas the respective phosphoethanolamines and phosphates exhibit only one transition, namely the main transition at $T_M > 70$ °C (an additional transition to hexagonal also occurs and will be discussed later).

The molecular reason behind the stabilization of the protonated states—higher T_M values due to the more densily packed hydrocarbon chains—is hydrogen bonding between the negatively charged phosphate groups and the positively charged ammonium groups or protonated phosphate residues. Therefore, phosphatidic acid at pH values near 12 (fully dissociated) and near 2 (fully protonated) exhibits a much lower phase transition temperature than in the region between pK_1 and pK_2 (the partially protonated states). Thus, phospholipids with two dissociable protons show a plateau in the phase transition temperature between the pK values. The transition temperatures for the plateau are more than 25 °C higher than the T_M values of the fully dissociated state, and more than 15 °C higher than the T_M value of the fully protonated state (Fig. 5). The extent of the plateau region is determined by the pK values. For "ether-phosphatidylethanolamine" of type **48** it extends from pH 1 to 11, and for the analogous phosphatidic acid from pH 3.5 to 9. For phospholipids with one proton, on the other hand, one expects and finds a maximum in T_M near the pK value; for example, for methyl 1,2-dipalmitoyl-*sn*-glycero-3-phosphate at pH 3.5[73,74].

In addition to the increased T_M values, partly protonated phospholipids like phosphatidylethanolamine may tend to form hexagonal structures (Table 1). For instance, some synthetic phosphatidylethanolamines undergo phase transitions which have been characterized by X-ray analysis as transitions from the lamellar-fluid phase to the hexagonal structure[75]. The dependence of the transition temperatures on the fatty acid chain length differs for the two types of transition. For the transition from lamellar-fluid to hexagonal, T_H decreases with increasing chain length, whereas T_M increases. By contrast, phosphatidic acid cannot form the hexagonal structure at pH 7.

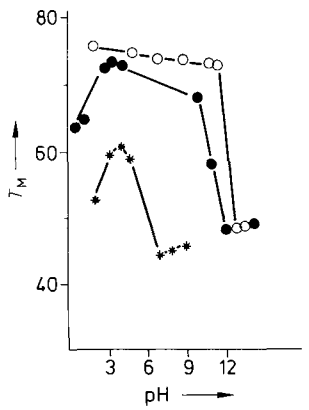

Fig. 5. The pH-dependence of the main transition temperature (T_M) of different phospholipids. ○: 1,2-dihexadecyl-*sn*-glycero-3-phosphoethanolamine (type **48**); ●: 1,2-dihexadecyl-*sn*-glycero-3-phosphate (type **48**); *: 1,2-dipalmitoyl-*sn*-glycero-3-phosphoric acid methyl ester. The extension of the plateau for T_M depends on the difference between pK_1 and pK_n. A phospholipid with only one dissociable proton has a maximum in T_M for the pK value.

In biological systems pH values near 7 are usually maintained, since irreversible damage, such as denaturation of proteins may otherwise result. It is therefore important to search for mechanisms which change the physical properties of lipid-water systems at pH 7 and at constant temperature. A likely 'candidate' is the effect of monovalent and divalent cations on membrane systems.

Monovalent cations may induce the dissociation of protons from the membrane surface[65,74]. A prerequisite for this effect is the presence of partially protonated phospholipids which react sensitively to changes in the concentration of monovalent cations. Then the degree of protonation will change so that T_M for the respective lipid is lowered (deprotonated state). Sensitivity against monovalent cations is thus coupled with the presence of a critical pK value which we generally call the critical pK_n value of a n-proton phospholipid system. Examples are pK_3 of phosphatidylserine (n = 3; pH value near 11), pK_2 for phosphatidic acid (n = 2; pH value near 9) and pK for phosphatidylglycerol (n = 1; pH value near 4) (in the case of phosphatidic acid, pK_1 is not sensitive against monovalent cations and therefore is not a critical pK value, since with increasing concentration of monovalent cations T_M is not lowered—whereas at pK_2, T_M decreases by about 25 °C). In biological membranes at pH 7, natural phospholipids do not show any critical pK values, and thus the influence of monovalent cations on the physical properties is marginal.

The influence of divalent cations, however, is important. At pH 7 and at constant temperatures they can induce phase transitions similar to those which we have described for protons. The sensitivity of the various phospholipids against cations corresponds to their different pK values (Table 3). Phosphatidylcholine and phosphatidylethanolamine are not sensitive. Their characteristic properties, their T_M values, and the particular ability of phosphatidylethanolamine to form hexagonal structures, are unchanged[75,76]. On the other hand, phosphatidylglycerol reacts strongly to the presence of divalent cations such as

Table 3. Influence of cations on the organization of natural phospholipids at pH 7. PC: phosphatidylcholine; PE: phosphatidylethanolamine; PG: phosphatidylglycerol; PA: phosphatidic acid; L: lamellar bilayer; H: hexagonal structure. For a transition from the lamellar to the hexagonal structure the fluid state of the lipid matrix is required. Therefore $T_H > T_M$, since the transition temperature for the transition lamellar fluid to hexagonal is always above the temperature of the transition lamellar gel to lamellar fluid. PE above T_M therefore can arrange in a lamellar or hexagonal structure. The preferred structure depends on the respective temperature. It can be expected that at 37 °C natural PE species prefer the hexagonal arrangement since T_H in most cases lies below the body temperature.

Phospho-lipids	Influence of cations on the structure		
	pH 7	NaCl (1 mol/L)	$CaCl_2$ (0.1 mol/L)
PC	L	L	L
PE	H (L)	H (L)	H (L)
PG	L	L	H (L)
PA	L	L	H (L)

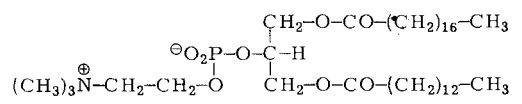
calcium ions, with an increase in T_M by about 24 °C and the ability to undergo the transition to hexagonal structures[76,77]. Phosphatidylglycerol, as calcium salt, behaves very much like phosphatidylethanolamine. In the case of phosphatidic acid T_M is already high, but the binding of calcium additionally allows formation of hexagonal structures at pH 7[76].

Negatively charged phospholipids react stoichiometrically with divalent cations. The binding of magnesium ions leads to an aggregation of vesicles, which retain their integrity and individuality[78]. With the binding of calcium ions aggregation is also observed, but it is followed by fusion[79]. The fusion process results in a profound change in the properties of the system since the individuality of the vesicles is lost. Thus, vesicles of different compositions fuse together, resulting in homogeneous structures[80].

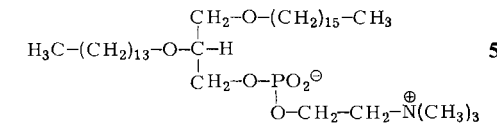
4. Reconstitution Experiments

In reconstitution experiments, biological membrane functions (such as enzyme-catalyzed reactions or membrane transport processes) are extracted from their natural environment, rebuilt in a physically defined system and studied as an individual process. Such experiments can reveal whether specific lipid structures are essential for a particular biological function. The functional constituents of a membrane process are compounds that are inactive in their purified state, but exhibit biological activity when reconstituted in an appropriate functional system. As simple examples we discuss the ion transport through lipid membranes and the biological activity of phospholipid dependent enzymes.

In a pure lipid system, ion transport through a lipid bilayer in the ordered state was first studied by *Boheim* et al.[17]. For these experiments we have synthesized specific mixed-chain phospholipids such as 1-stearoyl-3-myristoyl-*sn*-glycero-2-phosphocholine **49** with T_M near 30 °C (Table 2). These tailor-made phospholipids were found to be ideal film-formers, giving stable planar bilayers both in the fluid and ordered phases, as well as in the transition region. One possible reason for the remarkable properties of these mixed-chain lipids may be the absence of the pretransition.



49



50

Cooling curves of planar bilayer membranes are shown in Figure 6. The pure bilayer membrane made from **48** shows a very low conductance, < 1 nA cm^{-2}. However, spontaneous current fluctuations appear at temperatures close to the phase transition. These fluctuations are obviously related with the phase transition of the lipid. Reorientation of lipid molecules in the transition range causes packing defects which lead to the observed conductance changes. The fluctuations are induced by the temperature change through a melting of the chains in the transition region. Other conductance changes in pure lipid systems may be induced by protonation of the phosphate groups and may thus depend on the proton concentration and the availability of a critical pK value[81].

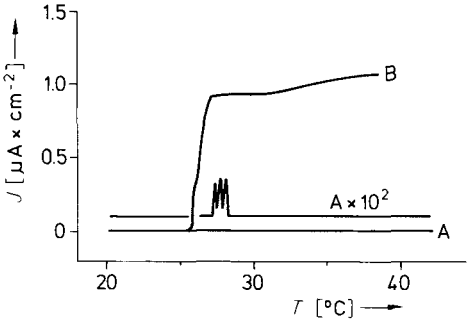


Fig. 6. Changes in conductance of planar lipid bilayers with decreasing temperature (cooling curves). A: current fluctuations of 1-stearoyl-3-myristoyl-*sn*-glycero-2-phosphocholine **49**; A × 10^2: larger scale presentation of A to demonstrate current fluctuations at T_M of the lipid (≈30 °C). B: change in conductance of 1-hexadecyl-2-tetradecyl-*sn*-glycero-3-phosphocholine **50** in the presence of valinomycin and 1 M KCl. In the transition region of the lipid (≈28 °C), a sudden drop of the membrane current is observed.

The influence of the physical state of the lipid matrix on carrier mediated transport processes (Fig. 6) is strong. Conductance values of > 1 μA cm^{-2} are observed in the system 1-hexadecyl-2-tetradecyl-*sn*-glycero-3-phosphocholine **50** in the presence of valinomycin and 1 M KCl if the film is studied in the fluid state at temperatures above T_M (about 28 °C). A sudden decrease in the membrane current is then observed in the transition region: It drops by a factor 10^3 from 1 μA cm^{-2} above T_M to 1 nA cm^{-2} below T_M. Below T_M, the conductance corresponds to that of a film without any carrier. It is reasonable to assume that carrier-induced ion transport depends on the fluid state of the lipid matrix. Like the lateral diffusion of lipid molecules within a monolayer, the rate of ion translocation through the membrane from one monolayer to the other, is undetectably small in the ordered state.

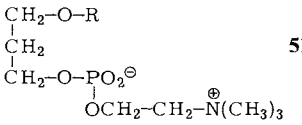
Conductance changes were also found in bilayers made from phospholipid mixtures containing phosphatidylcholine and phosphatidic acid[82]. In the presence of valinomycin and rubidium chloride high conductances are observed. The addition of calcium ions induces a phase separation and produces lipid domains which contain either phosphatidylcholine or phosphatidic acid. Only the phosphatidylcholine domains then contribute to the membrane current, because phosphatidic acid is ordered (below T_M), whereas phosphatidylcholine is in its fluid state (above T_M).

In protein-free lipid systems, carrier-induced ion transport occurs only in the fluid state of the membrane. The reversible phase transition from the ordered into the fluid state and vice versa thus represents a powerful mechanism for regulating membrane currents: a membrane current can flow in the fluid state whereas the current in the or-

dered state is negligibly small. The transition can be induced by temperature changes, but also with calcium ions. In mixtures of lipids containing phosphatidylcholine (insensitive against calcium ions) and phosphatidic acid or other negatively charged phospholipids, the addition of calcium ions may induce phase separation and also increase the main transition temperature T_M.

In lipid-protein systems phase separation can occur via specific interactions between phospholipids and proteins. This is important for the function of D-lactate dehydrogenase from *E. coli*, a phospholipid-dependent enzyme system[83]. The phospholipid composition of the *E. coli* membrane, and probably the properties of the membrane, are imprinted by the dominating role of phosphatidylethanolamines, which represent more than 90% of the membrane lipids. The proportion of negatively charged lipids such as phosphatidylserine and phosphatidylglycerol is small (below 5%). The question arises whether such lipid minorities are of any importance for the biological function.

As shown by *Kovatchev* et al.[84], D-lactate dehydrogenase needs an apolar lipid matrix for its biological function. This was demonstrated with a series of 1-acyl-1,3-propanediolphosphocholines **51** of different chain length. It was possible to measure the activity of the enzyme below and above the CMC of these micelle-forming phosphocholines. As expected, the D-lactate dehydrogenase exerted activity only in the presence of matrix molecules at a higher concentration than the CMC. The activation was clearly a result of the presence of micelles, whereas the monomers



51, R = $CO-(CH_2)_n-CH_3$

Table 4. Critical micelle concentrations (CMC) of 1-acyl-1,3-propanediolphosphocholines **51** in dependence of the chain length of the acyl group. In addition, the concentrations are given which induce a 50% D-lactate dehydrogenase activation (LDH-activation) or 50% hemolysis (of bovine erythrocytes).

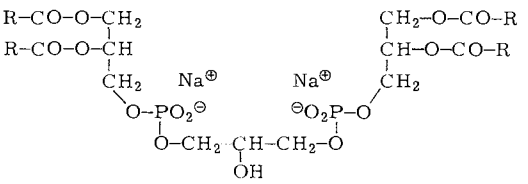
R in **51** [a]	log CMC [mol/L]	log 50% LDH-Act. [mol/L]	log 50% Hemolysis [mol/L]
22:0	−5.05	−5.0	—
20:0	−5.00	−4.50	−4.70
18:0	−4.80	−4.30	−4.70
16:0	−4.70	−4.10	−4.70
14:0	−4.35	−3.70	−4.35
12:0	−3.52	−3.10	−3.60
10:0	−2.46	−2.05	

[a] The acyl groups R in **51** are characterized by the number of double bonds in the fatty acids: 22:0, behenic acid; 20:0, arachic acid; 18:0, stearic acid; 16:0, palmitic acid; 14:0, myristic acid; 12:0, lauric acid; 10:0, decanoic acid.

were virtually inactive. In Table 4, values for the critical concentrations of micelle formation, for the activation of the D-lactate dehydrogenase, and for the hemolysis of bovine erythrocytes are compared for different 1-acyl-1,3-propanediolphosphocholines **51**. These model compounds lack the hydroxyl group in C-2 of glycerol. The close coincidence of the values of the concentration for micelle formation (CMC), for enzyme activation, and for hemolysis is not surprising. These activities all depend on a common property: the surface activity. It induces the formation of micelles and enzyme activation, but also results in a reorientation of the lipid bilayer if the ratio of phospholipid to lysophospholipid falls below 4:1 (hemolysis). Lyso compounds of this type have a free OH group on C-2 of glycerol.

The behavior of D-lactate dehydrogenase in lamellar bilayer structures contributes to an understanding of natural membrane systems. The main phospholipid of the *E. coli* membrane is 1-palmitoyl-2-elaidoyl-*sn*-glycero-3-phosphoethanolamine. Surprisingly, this lipid will not activate the enzyme. Instead, negatively charged phospholipids like phosphatidylserine or phosphatidylglycerol, although only minor constituents of the *E. coli* membranes, do activate the enzyme. This suggests that the native protein in its active state must also be surrounded by negatively charged phospholipids. Thus, the active state of the enzyme in a largely neutral lipid matrix is induced by phase separation, whereas a statistical distribution of the lipids would result in inactivation[84]. Phosphatidylserine and phosphatidylglycerol are therefore functional constituents of *E.-coli* membranes.

Phospholipids are essential for the function of many membrane-bound proteins[85,86]. The requirements for specific lipids, however, are frequently not very stringent. But D-β-hydroxybutyric acid dehydrogenase from bovine cardiac mitochondria[87] needs phosphatidylcholine for enzymatic function[88,89]. In its natural environment, the enzyme is surrounded by phospholipids with highly unsaturated fatty acid residues. The main phospholipids are phosphatidylcholines, phosphatidylethanolamines and bisphosphatidylglycerol (cardiolipin) **52** in a molar ratio of 43:37:20[90,91]. Due to the large number of different fatty acids esterified specifically with the 1- or 2-position of glycerol the diversity of molecular species is large[92].



52, R = $(CH_2)_n-CH_3$

Therefore, it is interesting to inquire what significance the multitude of molecular species, or the presence of bisphosphatidylglycerol **52**, or possible phase transitions from the fluid to the ordered state have for the enzymatic reaction. To answer these questions, we have synthesized many of the various molecular species occurring in the natural membrane, as well as some artificial lipids with the methods described in Section 2. With these structurally and configurationally well-defined molecules we were able to look for some answers to the questions mentioned above.

The results are summarized in Table 5. Although, phosphatidylcholine is essential for the enzymatic activity of D-β-hydroxybutyric acid dehydrogenase, the fine structure of the phosphatidylcholine is of minor importance for the activation process. There is no indication that the presence of highly unsaturated fatty acids in the phospholipids is of

any advantage for the reconstituted systems as long as the lipids are in the fluid state. Almost no activation is found below the main transition temperature; therefore, the fluid state of the membrane is a prerequisite for the activation of the enzyme[93,94].

Table 5. Activation of D-β-hydroxybutyrate dehydrogenase with defined synthetic phospholipid species at 37 °C. Microdispersions of phospholipids were prepared by ultrasonication of PC alone, of PC/PE mixtures (ratio of phosphate 5:4) and of PC/PE/PP mixtures (ratio of phosphate 5:4:1). PC stands for phosphatidylcholines with acyl groups presented in the left column [a]; PE represents phosphatidylethanolamines with the respective acyl groups [a]; PP indicates phosphatidyl-1.3-propanediols with the same acyl groups as in PE (Scheme 1). The numbers give the extent of activation for the enzyme and are based on the activation of the enzyme with the phospholipid extract from mitochondria which is set to 100 per cent. The numbers in parenthesis stand for the effectivity of the phospholipid in the reactivation process (molar ratio of PC to enzyme which results in half-maximal activation). Thus, the smaller the number the better the PC, the PC/PE or the PC/PE/PP mixture. In the case of the natural phospholipid extract of mitochondria an effectivity of 7 was experimentally found. PE or PE/PP mixtures alone do not activate the enzyme.

1,2-Diacyl of PC [a]	PC (alone)	+PE 1-16:0 2-18:1	+PE 1-16:0 2-12:0	+PE/PP 1-16:0 2-18:1	+PE/PP 1-16:0 2-12:0
1-16:0 2-18:1	82 (29)	100 (17)	100 (16)	100 (7)	100 (7)
1-16:0 2-18:2	82 (26)	99 (16)	—	100 (7)	—
1-16:0 2-20:4	85 (27)	100 (13)	—	99 (8)	—
1-22:0 2-18:1	79 (25)	100 (16)	100 (18)	100 (7)	98 (8)
1-16:0 2-14:0	67 (74)	97 (29)	96 (28)	96 (7)	95 (7)
1-16:0 2-12:0	63 (80)	93 (30)	96 (29)	93 (7)	97 (7)

[a] The acyl groups are characterized by the number of carbon atoms and of double bonds, see footnote [a] of Table 4. 20:4, arachidonic acid; 18:2, linoleic acid; 18:1, oleic acid.

Cardiolipin **52** as characteristic phospholipid of the mitochondrial membrane can be substituted by other negatively charged phospholipid molecules without any effect on the kinetic parameters of the enzyme reaction. These experiments allow a clear distinction between phospholipids which are functional components of the enzyme system and others which only provide matrix properties. Phosphatidylcholines are functional constituents of these membranes. However, the matrix properties are also influenced by the phospholipid composition. From the results in Table 5 it is evident that the most favorable matrix properties are obtained in a mixture of phosphatidylcholine/phosphatidylethanolamine/negatively charged phospholipids which closely resembles that found in the natural membrane (except for the fact that the latter contains cardiolipin as the third component).

The large number of different lipid species in the natural membrane does not appear to be important for the enzyme reaction. The only requirements are a fluid state of the lipid matrix and the presence of phosphatidylcholine. Highly unsaturated fatty acids are not essential for the reactivation of this enzyme. In the model system the large number of different lipid species of the natural membrane is replaced by only three different phospholipids which contain only saturated fatty acids in the 1 and the 2 position of the phospholipid molecules. The fluidity of these membranes arises from the use of long-chain fatty acid residues in the 1-position and of short-chain fatty acid residues in the 2-position of the glycerol. For instance, D-β-hydroxybutyric acid dehydrogenase shows optimal activity in a simple lipid matrix composed of 1-palmitoyl-2-lauroyl-*sn*-glycero-3-phosphocholine, -3-phosphoethanolamine and -3-phospho-1,3-propanediol (Table 5, right column, last line). In this mixture phosphatidylcholine is concomitantly a functional constituent as well as a component of the lipid matrix.

Mixtures of phosphatidylethanolamine and phosphatidyl-1,3-propanediol alone (without the phosphatidylcholine) cannot activate the enzyme.

5. Selective Modification of Natural Membranes

The directed modification of natural membranes of cells or subcellular structures is of great medical interest. Methods that allow a selective uptake of drugs by specific organs or organelles have received particular attention. The principles underlying our recent work are illustrated by two specific cases: the problem of the blood-brain barrier and the development of cytotoxic substances that can be detoxified by healthy tissues that lack a specific enzyme.

The blood-brain barrier as a highly selective filter was first described by *Lewandowsky*[95]. It is the reason for the relative resistance of brain metastases against chemical therapy, since an effective concentration of cytostatic substances cannot be reached in the brain. Stimulated by the experiments of *Deuticke*[96] on the influence of short-chain alcohols on the permeability of erythrocyte membranes we have investigated the effect of the physiologically more acceptable alkyl glycerides, such as 1-pentyl-*rac*-glycerol, on the blood-brain barrier.

The method of *Oldendorf*[97] was employed to measure the transport of twelve common cytostatic drugs through the blood-brain barrier. A solution containing a ^{14}C-labeled drug was injected into the right carotid artery of Wistar rats. Following decapitation, the right half of the brain was ashed and its radioactivity determined. The permeability of the blood-brain barrier to the ^{14}C-labeled drugs was measured relative to ^3H_2O as a freely diffusing internal standard. Table 6 summarizes the 'brain uptake index' values determined in this way.

The cytostatics selected differ in their molecular weights (90—1500) and in their oil-water partition coefficients ($\log p$ −3 to +1). According to *Oldendorf*[98], lipophilicity is the decisive parameter determining transport through the blood-brain barrier. According to our results, however, this is correct only for a limited range of molecular weights.

Of the twelve cytostatics tested, only cyclophosphamide (endoxan) and $Et_{18}OCH_3$ can pass the blood-brain barrier in appreciable amounts (about 10%). Cyclophosphamide, however, is not of therapeutic interest because it must be activated in the liver, and the therapeutic value of $Et_{18}OCH_3$ is controversial. Thus, not one of the twelve cytostatics tested meets the requirements for chemotherapy of brain tumors.

Table 6. "Brain Uptake Index" (BUI) values (as ratio of the activities of ^{14}C-labeled drug and free diffusible ^3H_2O as internal standard in the brain and in the injectate times 100) and the oil/water partition coefficients p of cytostatica. The cytostatica are differentiated in three ranges (100 to 500; 500 to 600; 600 to 1500) according to increasing molecular weights (MW). Within each range a subdivision is reached according to increasing lipophilicity. BUI*-values are attained from BUI values by substraction of 3.3 per cent (background of the method). Thus, a BUI value of 3.3 per cent means no uptake. 1-Pentyl-*rac*-glycerol (PeG) was used in physiological concentrations (0.15 M).

Active substance	MW	BUI* value [%] without PeG	BUI* value [%] with PeG	log$p$
5-Fluoruracil	132	0.4	9.7	−2.89
Methotrexate	455	2.0	22.9	−2.44
Cyclophosphamide	262	8.1	50.2	−1.03
Et_{18}-OCH_3 **53** [a]	542	7.4	—	−1.25
Doxorubicin	544	0	—	−1.00
Etoposide	589	0	14.5	−0.62
Daunorubicin	528	0	—	−0.30
Bleomycin	1400	0	2.4	−1.89
Peplomycin	1400	0.9	10.5	−0.74
Vincristine	923	0	—	−0.47
Mitoxantrones	625	0	21.8	+0.13
Vinblastine	909	0	38.3	+0.99

[a] 1-Octadecyl-2-methyl-*rac*-glycero-3-phosphocholine.

A classification of the drugs into three groups is suggested by the results in Table 6. In the range of molecular weights between 90 and 500, the transport properties are determined by the lipophilic properties. The blood-brain barrier acts like a water/oil interface, and the rate of diffusion through the membrane is determined by the oil/water partition coefficient.

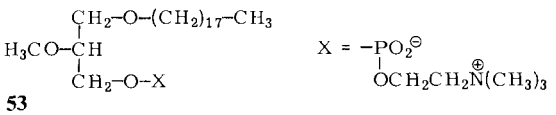
For cytostatics with molecular weights greater than 600, the blood-brain barrier represents a true, impermeable boundary, with the range of molecular weights between 500 and 600 occupying an intermediate position. Such drugs are excluded quite independently of their oil-water partition coefficients. An impressive example is that of vinblastine, which cannot pass the blood-brain barrier[99], in spite of its very favorable partition coefficient (log$p$ +0.99). This experimental result refutes the theory of *Oldendorf*[98], which claims that an oil/water partition coefficient of log$p$ −1 is a sufficient requirement to allow complete delivery of a drug through the blood-brain barrier.

These results suggest that chemotherapy is unlikely to be useful in treating brain tumors because the blood-brain barrier prevents accumulation of an effective concentration of a drug in the brain. However, recently we were able to show that the barrier properties can be favorably influenced by short chain alkylglycerols[100]. Thus, as Table 6 shows, cytostatics with molecular weights below 500 are efficiently transported through the barrier in the presence of 1-pentylglycerol. Indeed, even the transport of drugs with larger molecular weights, up to 1500, is made possible by 1-pentylglycerol. The effect is fully reversible within one minute, which is a major advance over the osmotic shock method of *Rapoport* et al.[101], in which the blood-brain barrier requires several hours to normalize again.

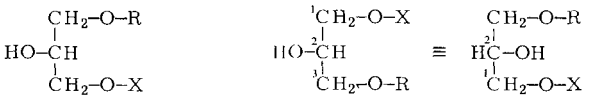
The goal of directing a cytotoxic compound to selected organs or to tumors can thus be achieved by the use of carrier molecules, such as the alkylglycerols in the case of the blood-brain barrier. Since such carriers can only operate above a minimum concentration, they allow transport only in one direction, from the bloodstream into the brain. By dilution in the brain region the concentration falls below the critical minimum value, so that the transported drugs cannot leave the brain area again (cage-effect).

Cytotoxic substances can also be directed to specific organs by exploiting differences in the enzyme pattern. Thus, *Snyder* et al.[102] have observed that tumor cells lack the 1-*O*-alkyl cleavage enzyme found in normal cells. This can be correlated directly with the work of *Westphal, Fischer, Munder* et al.[39,103] on immunostimulating and cytotoxic properties of 1-octadecyl-2-methyl-*rac*-glycero-3-phosphocholine (Et_{18}-OCH_3) **53**. As representative of a possible new class of antitumor agents, Et_{18}-OCH_3 has been intensively studied. It should selectively accumulate in tumor cells and lead there to selective cytolysis. Although the principle of this approach appears convincing, so far it has not been converted into a successful therapy.

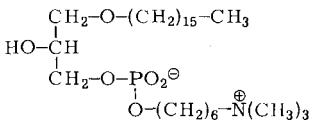
To find out why Et_{18}-OCH_3 **53** is also highly toxic for normal cells, we have studied the properties of related compounds as substrates of the 1-*O*-alkyl-cleavage enzyme from rat liver. As a new assay for the enzyme reaction we have measured the formation of water-soluble phosphate[104], thus circumventing the use of ^{14}C-labeled substrates[105]. The results obtained so far are presented in Table 7. It is noteworthy that Et_{18}-OCH_3 is at best a poor sub-



53



54, R = $(CH_2)_{15}$–CH_3 **55**, R = $(CH_2)_{15}CH_3$



56

Table 7. Substrate specificity of the 1-*O*-alkyl cleavage enzyme of rat liver. A specific activity of <0.2 means that probably no reaction occurs (background level of the method). The values are obtained by determination of water soluble phosphate [104] during the enzyme reaction.

Substrates [a]	Specific activity [nmol (mg protein)$^{-1}$ min^{-1}]
1-Hexadecyl-*sn*-G-3-PC **54**	8.0
1-Hexadecyl-*sn*-G-3-P-trimethylammoniohexanol **56**	7.5
3-Hexadecyl-*sn*-G-1-PC **55**	9.0
1-Octadecyl-*sn*-G-3-PC	5.6
1-Octadecyl-2-methyl-*sn*-G-3-PC **53**	<0.2
3-Octadecyl-2-methyl-*sn*-G-1-PC	<0.2
1-Octadecyl-2-methyl-*rac*-G-3-PC	<0.2
1-Methyl-2-octadecyl-*rac*-G-3-PC	<0.2
1-Hexadecyl-1,3-propanediol-3-PE	7.8
1-Hexadecyl-1,3-propanediol-3-phosphoglycol	3.2
2-Tetradecyl-*rac*-G-3-PE	7.4
1-Octadecyl-1,3-propanediol-3-phosphate	<0.2

[a] G-3-PC and G-3-PE denote glycero-3-phosphocholine and glycero-3-phosphoethanolamine, respectively.

strate for the enzyme, which may explain its high toxicity for normal cells. Analogues with a free hydroxyl group in the *sn*-2 position, like 1-hexadecyl-*sn*-glycero-3-phosphocholine **54**, are better substrates. The enzyme does not exhibit any pronounced stereoselectivity, because the stereoisomer 3-hexadecyl-*sn*-glycero-1-phosphocholine **55** is cleaved approximately at the same rate as the substrate **54** with natural configuration. Neither of the two compounds are useful as antitumor drugs because they are detoxified not only by the 1-*O*-alkyl cleavage enzyme that is only found in normal cells, but also by acyl transferases[106] (for the compound **54** in natural configuration) as well as phospholipases C and D.

By careful study of the phospholipid-metabolizing enzymes of rat liver we were able to construct a cytotoxic lysophospholipid structure that cannot be modified or detoxified by acyl transferases, nor by the phospholipases C and D. This phospholipid, 1-hexadecyl-*sn*-glycero-3-phosphotrimethylammoniohexanol **56**, can only be degraded by the 1-*O*-alkyl cleavage enzyme[36].

At present, this cytotoxic phospholipid with an increased nitrogen-phosphorus separation is undergoing evaluation in animal tests. It is to be expected that the compound will be markedly less toxic for normal cells, which can degrade it biologically, than for tumor cells, which cannot. These examples illustrate how knowledge about the physical and biochemical properties of phospholipids can be used to synthesize tailor-made structures that are optimally designed for highly specific effects.

6. Concluding Remarks

From recent model studies using defined phospholipids, a new understanding of the role of phospholipids in biological membranes has evolved. In contrast with classical views, phospholipids are not merely a matrix that supplies the two-dimensional bilayer required by active membrane processes. They are functional building blocks that interact with other membrane components to induce biological activity. We know that their chemical structure can influence or even control membrane processes, such as ion transport or the activity of phospholipid-dependent enzyme systems. Thus, the physical properties of phospholipids, their phase transitions, and phase separations, become important elements of cellular function and regulation.

The cancer problem is one of the urgent challenges of our time. New therapeutic approaches are opened by simple modifications of phospholipid structures, which are sensitively detected by phospholipid-metabolizing enzymes. This is particularly promising where healthy and malignant tissues differ in their enzymatic equipment.

The therapy of brain tumors may profit from the observation that non-toxic alkyl glycerides can gently increase permeation of active substances across the blood-brain barrier. The range of molecular weights for which transport across the barrier membranes can occur is increased from 500 to 1500. This opens a vast horizon of possibilities for improving the lipophilic and membrane associating properties of drugs by chemical modification.

In closing, I would like to quote from a work written in 1796 and entitled "Die Kunst, das menschliche Leben zu verlängern" (The art of prolonging human life), written by *Christoph Wilhelm Hufeland*, who was the medical adviser to personalities such as *Goethe, Herder, Wieland,* and *Schiller*. In his words, a medicine may be called 'natural' if 'without tangible properties or detectable change of the organism, it quietly and gently, like nature herself, still brings forth the most desirable effects in the organism'. In this sense, *Kunze* et al.[110] have termed lecithin a true natural physic, that 'like sun, light, air, water or earth always acts beneficially, and in very many acute afflictions is indicated as an aid to the physician's treatment'.

Today, we have a more realistic view of the properties of phospholipids. Nevertheless, we are convinced that chemically defined phospholipids are useful model systems for the study of the properties of biological membranes. They help us to recognize transport mechanisms that can improve permeation across the lipid bilayer. Certainly, simple modifications of phospholipids, and the frequently surprising new properties that they bring about, will become important tools in developing new medications.

The continuous support of my work by German research organizations, die Deutsche Forschungsgemeinschaft, die Deutsche Krebshilfe, die Stiftung Volkswagenwerk, die Max-Planck-Gesellschaft und die Technische Universität Braunschweig, is gratefully acknowledged. I am indebted to my wife Brigitte and to my daughter Kirsten for their stimulating appreciation of my work. Last and not least I wish to thank Dr. Christoph Methfessel for carefully reading the manuscript.

Chemical Bonding in Higher Main Group Elements

By Werner Kutzelnigg*

Many concepts used for a qualitative description of chemical bonding that originated in the early days of theoretical chemistry have been vindicated recently by quantum chemical calculations, at least as far as first row elements are concerned. However, many concepts that have been justified for first row elements (Li to Ne) cannot—contrary to widespread belief—be generalized to the higher main group elements. This applies particularly to the concept of hybridization, which should be viewed with considerable caution. The essential difference between the atoms of the first and higher rows is that the cores of the former contain only s-AOs, whereas the cores of the latter include at least s- and p-AOs. As a consequence, the s and p valence AOs of first row atoms are localized in roughly the same region of space, while the p valence AOs of higher row atoms are much more extended in space. This has the consequence that for the light main group elements both lone-pair repulsion and isovalent hybridization play a greater role than for the heavy main group elements. Furthermore, this implies that single bonds between first row elements are weak and multiple bonds are strong, whereas for the second or higher row elements single bonds are strong and multiple bonds weak. The "extended valence" (violation of the octet rule) observed in compounds of higher main group elements has very little to do with the availability of d-AOs but is due rather to the size of these atoms and thus to the reduced steric hindrance between ligands and, to a lesser extent, also to the lower electronegativity of the heavy atoms. A model based on the concept of electron-rich multicenter bonds is certainly closer to reality than one involving hybrids with the participation of d-AOs. The XO bonds in phosphane oxides, sulfoxides, oxo acids and related compounds are better formulated as semipolar rather than as true double bonds, even if they behave in some respects like double bonds.—The growing interest of theorists in compounds of higher main group elements parallels new and, in some instances, spectacular results of experimental research on the chemistry of these elements.

1. Introduction

The molecular chemistry[1] of higher main group elements has advanced in an unexpected and fascinating way in recent years. We point out here the synthesis and characterization of compounds with "genuine"[2] double bonds involving elements such as Si or P[4–16] and which were long thought not to exist, e.g. SiC[7–9], SiSi[10,11], or PP double bonds[12–16]. Furthermore, we mention the relatively young chemistry of phosphorus chains, rings, and polycyclenes[17], e.g. the synthesis of a substituted tetraphosphabicyclobutane[18] and progress in the chemistry of hypervalent compounds with "non-genuine"[2] double bonds, such as OSF_2[19], $RNSF_4$[20–22], H_2CSF_4[23], and even triple bonds as in NSF_3[24].

Parallel to this progress in experimental research, quantum chemistry has also directed its interest to the higher main group elements. This has been possible, on the one hand, due to ab initio programs which are capable of dealing with the large number of electrons in heavy atoms and, on the other, because of the improvement of "pseudopotential methods". In applying the latter methods, the atomic cores are not explicitly considered, and it suffices to study the valence electrons moving in an "effective field"; consequently, a calculation on SnH_2 requires no more computer time than that for CH_2 (cf. also Section 2.4).

Semiempirical procedures (e.g. of the CNDO type), which have proved highly successful for first row atoms, have not performed so well for higher row atoms, mainly because it is highly problematic to fix the parameters for d-AOs. Therefore, reliable information on d-AO participation in the bonding can only be obtained from ab initio calculations.

In the meantime, relativistic calculations have also become feasible and for very heavy atoms, e.g. Pb, these are indispensable. Broadly speaking, relativistic quantum mechanics is a combination of ordinary quantum mechanics and the theory of special relativity. It is well-known that classical mechanics provides only an approximate description of the motion of particles and that the approximation becomes increasingly good the lower the velocity (relative to the velocity of light) and the larger the dimension of the motion (relative to atomic dimensions, e.g. bond lengths). For motions in atomic dimensions (but at low velocities) quantum mechanics rather than classical mechanics must be used, whereas for motions at high velocities (but in macroscopic dimensions) classical mechanics must be replaced by the theory of special relativity. For motions in atomic dimensions with velocities approaching the velocity of light, relativistic quantum mechanics must be used; this

[*] Prof. Dr. W. Kutzelnigg
Lehrstuhl für Theoretische Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (FRG)

includes both ordinary quantum mechanics and the theory of special relativity as special cases.

The 1s electrons in the atoms of elements of the highest rows attain velocities quite comparable to the velocity of light, and hence only relativistic quantum mechanics is appropriate. Its formulation for many-electron systems is still not finally settled[25], although relativistic Hartree-Fock calculations are certainly possible; these clearly indicate that the differences in the chemical behavior of the fourth and fifth row elements (Rb to Xe and Cs to Rn) is determined decisively by relativistic effects. For lighter atoms, however, relativistic effects (of which spin-orbit coupling and the "velocity-mass correction" are most important) play only a minor role. The significance of relativistic effects in chemistry—especially for atoms of the fifth row—has been discussed in several recent articles[26–28].

The exceptional behavior of first row elements, which is of particular concern to us in this review, has nothing to do with relativistic effects.

In view of the renewed interest in molecules of main group elements of the second and higher rows, the question of the bonding in these molecules has again become a topical issue. Long ago, *Pauling*[29] clearly recognized the differences in chemical behavior between first (Li to Ne) and higher row elements and offered a plausible explanation. Yet the theory of chemical bonding, as presented in modern textbooks, still concentrates mainly on the main group elements of the first row (and on the transition elements of the third row). It is customary to regard the bonding of the atoms from Li to Ne as normal and thus to consider the behavior of the heavy elements as "abnormal". Later on in this article we shall reach the conclusion—which we anticipate here—that it is rather the heavy elements which behave normally and not the more familiar elements of the first row.

In this progress report we seek to answer why differences exist in the chemical bonding of main group elements of the first and higher rows in the light of recent data and quantum-chemical calculations. From the wealth of interesting findings and their interpretation, we select a few which appear to be of fundamental importance:

1. For any series of compounds of first row elements, the analogous compounds of higher row elements have different geometries and other physical properties. Examples are provided by the pairs H_2O/H_2S or NH_3/PH_3 and also CH_2/SiH_2.
2. Certain types of bonding commonly found between light atoms occur only rarely in elements of the higher rows, e.g. multiple bonds. The different capabilities of C and Si to form double bonds, which makes the chemistry of carbon and of silicon fundamentally different, is most striking.
3. Certain other types of bonding are found only in heavy atoms, especially in hypervalent compounds such as PF_5 or SF_6.
4. Finally, there are bonds which although formally the same in elements of the first and higher rows are, nevertheless, very different, e.g. the semipolar bonds in R_3NO and R_3PO.

Furthermore, it is worthwhile to study the difference between "genuine" and "non-genuine" multiple bonds[2]. This will be discussed within the context of points 2 and 4.

2. Differences in the Isolated Atoms of Homologous Main Group Elements

2.1. Orbital Energies

The energy levels of s, p, and d atomic orbitals (AOs) for elements of the first, second, and third rows are depicted schematically in Figure 1. In each group a marked jump is apparent in proceeding from the first to the second row, whereas there is little change between the second and higher rows (apart from a larger spin-orbit splitting between the $p_{1/2}$ and $p_{3/2}$ levels for the very highest rows, which we have not documented here).

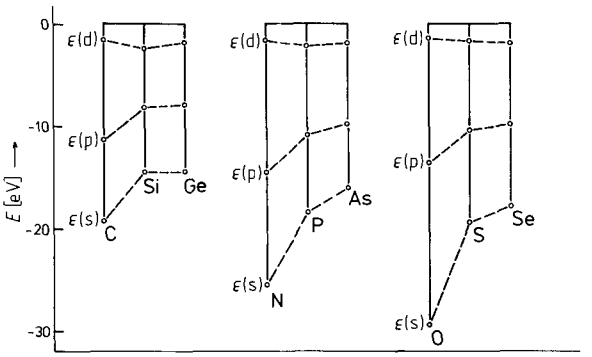

Fig. 1. Energies of s, p and d valence AOs for some main group elements. The ε(p) values given are equal (except for the sign) to the experimental ionization potentials for ionization from a p-AO. ε(s) is equal to ε(p) minus the lowest s→p excitation energy (with conservation of spin multiplicity). Correspondingly, ε(d) is equal to ε(p) plus the lowest p→d excitation energy (with conservation of spin multiplicity). The Hartree-Fock orbital energies differ by only a few eV from the ε(s) and ε(p) used here. All of the data have been taken from *Moore*'s tables [31]. According to *Mulliken* [32], there is a relationship between ionization potentials and electronegativities.

If one assumes that the lower the promotional energy the more readily hybridization occurs, one would expect more hybridization in heavy atoms—contrary to what is observed.

2.2. Size of Atoms

The "size" of an atom is very important for its chemical behavior. A possible measure of this is the expectation value (mean value) $\langle r \rangle$ of the distance of the valence electrons from the nucleus. Quantum-chemically calculated[30] values of $\langle r \rangle$ for s and p valence AOs are depicted in Figure 2.

For elements of the fourth and fifth main groups, the calculated $\langle r \rangle_s$ values agree well with *Pauling*'s[29] covalent radii; however, they vary strongly as a function of the group and are larger in the third and smaller in the seventh group than *Pauling*'s empirically determined radii.

First, it should be noted that $\langle r \rangle_s$ and $\langle r \rangle_p$ for the first row differ little from one another (by ca. 10%), whereas for

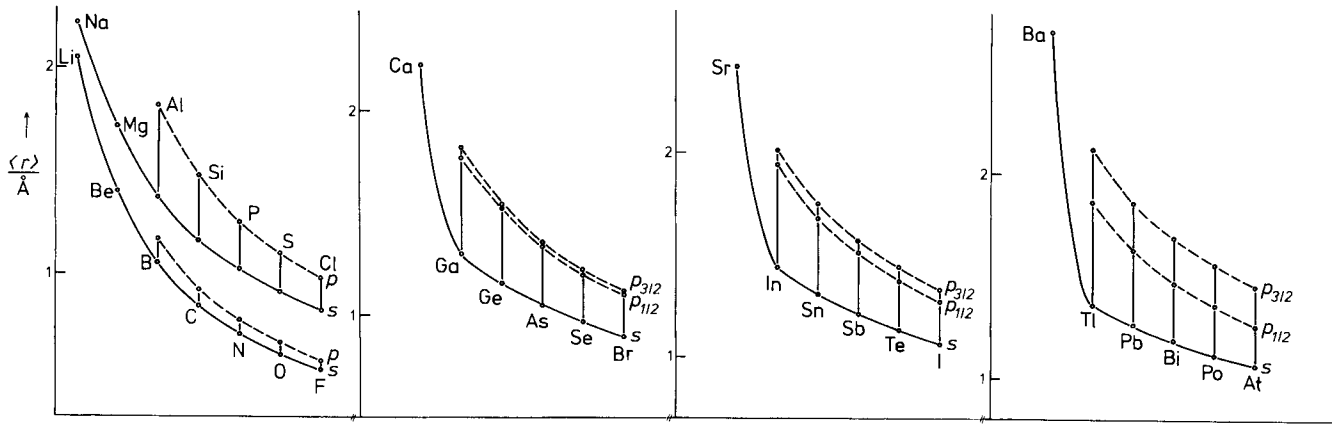

Fig. 2. Expectation values $\langle r\rangle_s$ and $\langle r\rangle_p$ for s and p valence AOs. The indices 1/2 and 3/2 associated with the p-AOs characterize the two components arising from spin-orbit coupling (cf. text). The values given are obtained from relativistic Hartree-Fock calculations by *Desclaux* [30].

higher rows the differences are more pronounced (20—33% for the second row; 24—40% for the third and fourth rows; and 36—55% for the fifth row).

Furthermore, we observe that $\langle r\rangle_{p3/2}$ and $\langle r\rangle_{p1/2}$ differ from each other by less than 2% for the first three rows, by ca. 5% in the fourth row, and by as much as ca. 15% in the fifth row. Within the framework of "ordinary" nonrelativistic quantum mechanics, such as in conventional Hartree-Fock calculations, there is no difference between $p_{1/2}$ and $p_{3/2}$, and the p level is sixfold degenerate (threefold orbital degeneracy and a twofold spin degeneracy). The splitting into a twofold degenerate $p_{1/2}$ and a fourfold degenerate $p_{3/2}$ level is a relativistic effect which depends on so-called spin-orbit coupling. In the fifth row, the two possible p states differ from each other almost as much as the s and p (the effect is even more marked in the orbital energies than in the radii). This relativistic effect has major consequences for the chemical behavior of the very heavy elements[26–28].

In simple terms, it may be said that the s and p valence electrons in first row atoms occupy roughly the same region of space, whereas p-type valence electrons in higher row atoms are considerably more diffuse than the corresponding s-type AOs.

The reason for the different "size" of s and p valence orbitals is not readily understandable[33]. In Section 2.4 we offer a simple explanation in terms of the pseudopotential model.

One should not take the $\langle r\rangle$ values in Figure 2 too literally. These are based on relativistic SCF calculations[30], i.e. although relativistic effects are taken into account, the SCF approximation has been made. Thus, each electron has been assigned a one-electron function (an orbital), and the repulsion between the electrons has only been treated on the average. A precise determination of the electronic interactions is very cumbersome and only tractable within the framework of the configuration interaction (CI) method or the coupled electron pair approximation (CEPA)[34]. The effects neglected in the SCF approximation are designated "electron correlation"[34]. Electron correlation actually has a noticeable influence on the "size" of the atom (i.e. on the mean radii $\langle r\rangle_s$ and $\langle r\rangle_p$), especially for alkali metal and alkaline earth atoms (where the electron correlation reduces $\langle r\rangle$ by 10%[37]), but to a lesser extent for atoms of the fourth to the sixth main groups. At any event, $\langle r\rangle_s$ and $\langle r\rangle_p$ are computed parameters that cannot be directly compared with measured physical quantities.

2.3. Polarizabilities

Another relevant property of an atom is its polarizability (Table 1). Correlation effects have been taken into consideration. Polarizabilities change substantially on proceeding from the first to the higher rows. Even more pronounced is the dependence on the group in the periodic system. If we confine ourselves to groups 3b to 5b, a significant jump in going from the first to the second row is evident.

Table 1. Dipole polarizabilities in atomic units (1 a.u. = 0.1482 Å^3) [a].

Li	Be	B	C	N	O	F	Ne
164.5	37.8	20.5	11.8	7.4	5.4	3.8	2.7
Na	Mg	Al	Si	P	S	Cl	Ar
165.0	71.3	56.3	36.3	24.5	19.6	14.7	11.1
K	Ca	Ga	Ge	As	Se	Br	Kr
287.6	153.9	54.8	41.0	29.1	25.4	20.1	16.7
Rb	Sr					I	Xe
333.0	169					(34)	27.3
Cs	Ba						
416.5	209						

[a] For the atoms from Li to Ca the values are taken from accurate quantum-chemical calculations by *Werner* and *Meyer* [136] or *Reinsch* and *Meyer* [137] (CEPA-calculations, considerating intershell correlation effects); for Rb and Cs they are taken from *Maeder* and *Kutzelnigg* [37] (pseudopotential calculations); for Ge to Br they are from *Miller* and *Bederson* [138]; and for the remaining atoms they are taken from *Teachout* and *Pack* [139]. The experimentally determined values of *Molof* et al. [140] are very similar for the alkali metal atoms.

2.4. Pseudopotentials

The mere existence of a periodic system of the elements suggests that only the valence electrons are directly responsible for the chemical behavior of atoms, whereas the core electrons merely provide a sort of effective potential in which the valence electrons move. *Hellmann*[38] and, independently, *Gombas*[39] were the first to formulate this

quantitatively and to develop simple expressions for the "effective potential". This potential must also account for the Pauli exclusion principle in the sense that the valence AOs must be orthogonal to the core AOs; this can be represented by a repulsion which prevents the valence electrons from "penetrating" into the core and which counterbalances the increased (less shielded) attraction by the nucleus in the neighborhood of the core.

The effective potential "felt" by the valence electrons is usually designated a "pseudopotential" or "model potential"[40].

Although the pseudopotential approximation is not exact—in particular, as far as transferability of atomic pseudopotentials to molecular problems is concerned—it is in most instances an astonishingly good approximation.

According to their analytical form, one can distinguish between three types of pseudopotentials; "local", "semilocal", and "nonlocal". A local pseudopotential is—like a genuine potential—simply a function $V(r)$ of the distance r of the electron from the nucleus (for large r this function behaves like the Coulomb potential for the nuclear charge shielded by the core electrons and for small r allows for "penetration" and "Pauli repulsion"). A nonlocal pseudopotential can be defined only as an integral operator (similar, for example, to the exchange operator in Hartree-Fock theory). Most pseudopotentials used today are of the "semilocal" type

$$V = \sum_l V_l(r) P_l \tag{1}$$

where l counts the angular quantum number ($l=0$ corresponds to s-AOs, $l=1$ to p-AOs, etc.) and P_l is a so-called projection operator on the AOs for that l. For each fixed value of l, the pseudopotential is so-to-speak "local". If $l>2$ (or $l>1$) and $V_l(r)$ is chosen as a simple Coulomb potential independent of l, only $V_0(r)$ (for s-AOs), $V_1(r)$ (for p-AOs) and, if necessary, $V_2(r)$ remain to be determined. In principle, there are two possibilities for determining pseudopotentials (or the parameters which characterize them); namely, either from ab initio calculations which include all electrons or by semiempirical fitting to experimental data.

For example, one can choose a form for V_0 and V_1 containing in each case only one free parameter which can then be determined[37] such that the lowest experimental ionization potentials for s- and p-AOs are correctly reproduced. Using such a semiempirical 2-parameter potential, one can for alkali metal and alkaline earth atoms not only accurately describe the "size", polarizability, frequencies, and oscillator strengths characterizing the electronic spectrum[37] but also use this pseudopotential for calculations on molecules[51].

This indicates that it is quite reasonable to approximately describe the difference in the chemical behavior of homologous atoms in terms of two parameters only. These could, for example, be the different ionization potentials for the s and p valence electrons or the different spatial extension of the s and p orbitals.

From a purely theoretical standpoint, ab initio pseudopotentials are more satisfying than semiempirical model potentials. The first ab initio pseudopotentials have been fitted to all-electron SCF calculations. SCF calculations based on these pseudopotentials and limited to valence electrons reproduced many results obtained using all-electron SCF calculations, resulting in considerably less computational effort[43-46]. However, agreement with experiment was usually less satisfactory than that for semiempirically adjusted pseudopotentials since the latter implicitly include relativistic effects as well as so-called core polarization. Because it is also now possible to obtain relativistic ab initio pseudopotentials[47,48], and ab initio procedures to calculate the core polarization are available[49], we expect that ab initio pseudopotentials will dominate in the future.

All-electron ab initio calculations are still out of the question for higher row elements because of the vast number of electrons involved. Pseudopotentials, however, can be very valuable here. The increasing interest in compounds of the heavy elements and the gain in theoretical insight in the past decade have been accompanied by progress in pseudopotential theory.

Within the framework of the pseudopotential model it is possible, as already mentioned, to rationalize the different, relative spatial distributions for the s and p valence electrons of the first and higher rows. To avoid any discussion of the interactions between valence electrons, we shall consider systems having only a single valence electron, i.e. alkali metal atoms. The wave function $\psi_{nlm}(r)$ is a product of two factors: a radial function $f(r)$ and an angular function $Y_l^m(\theta,\phi)$, a so-called spherical harmonic[52]. The radial function $f(r)$ is the solution of the "radial Schrödinger equation" (in atomic units[52])

$$-\frac{1}{2r^2}\frac{\mathrm{d}}{\mathrm{d}r}r^2\frac{\mathrm{d}f(r)}{\mathrm{d}r} + U_l(r)f(r) = \varepsilon f(r) \tag{2}$$

where the effective radial potential $U_l(r)$ consists of the pseudopotential $V_l(r)$ and a so-called centrifugal potential $Z_l(r)$:

$$U_l(r) = V_l(r) + Z_l(r)\,; \quad Z_l = \frac{l(l+1)}{2r^2} \tag{3}$$

The pseudopotential $V_l(r)$, in turn, can be resolved into a Coulomb potential $-1/r$ (in the field of the nucleus shielded by the core) and an additional potential $W_l(r)$ which takes into account both the partial penetration of the valence electron into the core and the "Pauli repulsion" (or "Fermi repulsion"), i.e. the required orthogonality to the core states.

$$V_l(r) = -\frac{1}{r} + W_l(r)\,; \quad U_l(r) = -\frac{1}{r} + W_l(r) + Z_l(r) \tag{4}$$

Whenever the additional potential $W_l(r)$ is approximately the same for $l=0$ (s-AOs) and $l=1$ (p-AOs), the centrifugal potential $Z_l(r)$ (which vanishes for $l=0$ and is strongly repulsive for $l=1$) ensures that the lowest p valence AO has a significantly higher energy, and is on average markedly further from the nucleus than the lowest s valence AO.

To a very good approximation this holds for Na, K, Rb, and Cs, since here both $W_0(r)$ and $W_l(r)$ are strongly repulsive in the core region because of the orthogonality requirement to the occupied core states with $l=0$ or $l=1$.

This does not apply to Li, where only one s-AO but no p-AO is occupied in the core. As a consequence, $W_0(r)$ is strongly repulsive in the core region, whereas $W_l(r)$ is even weakly attractive owing to the reduced shielding of the nuclear charge in the core region (which is also present in other cases, but is more than compensated for by the Pauli repulsion). The effective radial potentials $U_l(r)$ are now comparably repulsive for s and p, and thus the radial functions are located in roughly the same region of space. Since $W_0(r)$ is of shorter range than $Z_l(r)$, $\varepsilon(2s)$ is distinctly lower than $\varepsilon(2p)$, although in relative terms not as low as in the other alkali metal atoms.

Put simply, atoms of the first row are special because only s-AOs are occupied in their cores and consequently the p-AOs experience no Pauli repulsion from the core. This is not the case for heavy atoms whose cores contain occupied s- and p-AOs.

This difference is fully taken care of within the framework of nonrelativistic quantum mechanics; the pronounced contraction of the 6s orbitals, which is principally responsible for the differences between atoms of the fourth and firth rows, is, however, a relativistic effect[26-28].

3. Electronic Structure and Equilibrium Geometry of Molecules with Normal Valencies

3.1. Hybridization and Valence Configurations

In the following discussion, frequent use will be made of the concept of "hybridization". This was developed during the early days of theoretical chemistry and is still very popular among experimental chemists. Modern quantum chemistry, however, has no real place for it, and many theoretical chemists regard it as problematic or as outdated. Nevertheless, several recent studies indicate a renewed interest in a formal discussion of hybridization[53,54]. The concepts of valence state and of hybridization—which are closely related—arose originally within the context of the valence bond (VB) approximation[55]. In terms of these concepts, it was possible to explain, e. g., the tetravalence of carbon by assuming that the C atom is first "excited" from the ground state (^3P_g) configuration $1s^2 2s^2 2p^2$ into the valence state configuration $1s^2 2s^1 2p^3$ (with all the spins of the valence electrons uncoupled) and then hybridization from sp^3 to te[4] takes place.

In the molecular orbital (MO) approximation, there is no need for ad hoc assumptions about hybridization. In fact, it is possible to manage without this concept at all. For CH_4, for example, if one starts from a so-called minimal AO basis set consisting of one 1s AO per H atom and a $1s,2s,2p_x,2p_y,2p_z$ set for the C atom, the tetravalence of carbon arises automatically.

If desired, the concepts of "valence configuration" (this is preferable to that of the "valence state"[56]) and hybridization may be used in conjunction with MO calculations for an a posteriori interpretation of the results. This is done via a so-called population analysis as described by *Mulliken*[58], although it must not be forgotten that the results of such an analysis are somewhat dependent on the chosen basis set[59]. *Mulliken*'s gross atomic populations (occupancy numbers), $q_s(X)$ or $q_p(X)$, are a measure of the probability of finding an s or p-AO on atom X.

If the occupancy number (gross population) of, for example, the 2s-AO on the C atom in CH_4 has the value $q_s=1.12$ and for all the 2p-AOs together $q_p=3.09$, we can then state that the valence configuration is $2s^{1.12}2p^{3.09}$. It is evident that this configuration deviates substantially from the $2s^2 2p^2$ ground configuration but that it lies close to the "ideal" valence configuration $2s2p^3$[56].

At first sight, this definition may appear to be meaningful only if a "minimal" AO-basis set has been employed. In general, such minimal basis sets yield very poor results. When use is made of larger basis sets, however, it is possible to sum up both s- and p-type populations and thereby express the valence configuration in terms of these total s- and p-AO populations, bearing in mind that two s-AOs or four s-AOs and six p-AOs, etc. must be deducted for the cores. All the valence configurations discussed in this article were determined in this way based on SCF calculations with sufficiently large basis sets[61].

The concept of hybridization is then meaningful in the analysis of the results of MO calculations whenever a description of the molecule in terms of two-center MOs is possible. In fact, it has been found for most "normal" molecules (for limitations see [62]) that the delocalized, so-called canonical MOs can be transformed by means of a unitary transformation[63] (for example, as proposed by *Boys*[65]) to yield localized molecular orbitals (LMOs) which are localized mainly in a bond. The overall wave function is not changed in the procedure[63].

If separate population analyses are carried out for each LMO, statements on the nature of the mixture of s, p, and d valence AOs can be made, i.e. which hybrid AO is involved in a given bond. According to our calculations, the s : p ratio for methane is 1 : 2.76, which is very close to the ratio for a tetrahedral sp^3 hybrid.

Let us suppose that the LMOs for two equivalent XH bonds in an XH_n molecule are as follows

$$\varphi_1=\alpha\,hy_1+\beta\,h_1 \tag{5a}$$

$$\varphi_2=\alpha\,hy_2+\beta\,h_2 \tag{5b}$$

where hy_1 and hy_2 signify two hybrid AOs of the X atom and h_1 and h_2 are two 1s-AOs of H atoms. The LMOs are assumed to be "well localized", i.e. the contributions of the "other" h_k to the φ_l ($k\neq l$) are regarded as negligibly small. Since MOs must be orthogonal, i.e. their overlap integral $\langle\varphi_1|\varphi_2\rangle$ must vanish, it follows that

$$\langle\varphi_1|\varphi_2\rangle=\alpha^2\langle hy_1|hy_2\rangle+\alpha\beta\{\langle hy_1|h_2\rangle+\langle hy_2|h_1\rangle\}+\beta^2\langle h_1|h_2\rangle=0 \tag{6}$$

As a rule, the overlap integrals $\langle h_1|h_2\rangle$ between different H atoms are very small. We regard hybrids as "good" or as "ideally directed" if they bond in only one direction, i.e. if

$$|\langle hy_1|h_1\rangle| \gg |\langle hy_1|h_2\rangle| = \langle hy_2|h_1\rangle. \tag{7}$$

If the overlap integrals $\langle hy_1|h_2\rangle$ for a hybrid AO with the "wrong" H atoms vanish (and if also $\langle h_1|h_2\rangle \approx 0$), it follows from equation (6) that

$$\langle hy_1|hy_2\rangle \approx 0 \tag{8}$$

which implies that the various hybrids on an atom are mutually orthogonal. The orthogonality of the hybrids can be regarded almost as a criterion for "good hybrids". Since the initial AOs on the atom, e.g. the 2s and 2p, are mutually orthogonal, orthogonal hybrids are obtained from these by an orthogonal transformation[63]. This is normally tacitly implied whenever one speaks of hybrids. With the prerequisite that hybrids are mutually orthogonal, it is possible to formulate a relationship between the degree of hybridization and the valence angle[67]. The following relationship holds for an angle θ between equivalent hybrids (i.e. hybrids with the same s contribution)

$$\cos\theta = -a^2/(1-a^2) \tag{9}$$

where a^2 is the s contribution to the hybrid and $1-a^2$ is thus the p contribution.

In the context of this relationship, it is nowadays almost taken for granted that, for example, a bonding angle of 120° implies an s contribution of $a^2 = 1/3$ and accordingly sp^2 hybridization.

As shown in Section 3.3, such conclusions based on the assumption of orthogonal hybrids are fairly reliable for compounds of first row elements only, but are dubious for higher row main group elements. Therefore, equation (9) is a good approximation only for molecules consisting of atoms Li to F.

From the population analyses, information is also obtained about the charges associated with the atoms in molecules and thus about the polarity of bonds. For the previously mentioned calculations on CH_4, one obtains $q_s + q_p = 4.21$ compared to 4 in the ground configuration; accordingly, the C atom bears a formal charge of -0.21[68].

3.2. Bonding Energies of Monohydrides XH and "Saturated" Hydrides XH_n

The bonding energies of a series of monohydrides, XH, together with the energy contributions per XH bond in the "saturated" hydrides, XH_n are shown in Figure 3. It is immediately apparent that the values of the bonding energies per XH bond in XH_n for X = C, N, and O are larger than those in the respective monohydrides by 18, 15, and 10 kcal/mol, respectively. The corresponding "bond strengthenings" for X = Si, P, and S amount to roughly 6 kcal/mol. For BeH_2 compared to BeH and MgH_2 compared to MgH, the bond strengthenings are even higher, but again the effect for Be is substantially larger than that for Mg. It is worth commenting that for the fluorides (cf. Fig. 9) the relationships are quite different, a point which we shall return to in Section 3.9. The bond strengthenings for BeH_2 and MgH_2 are explained in Section 3.4 and those for other compounds in Section 3.6.

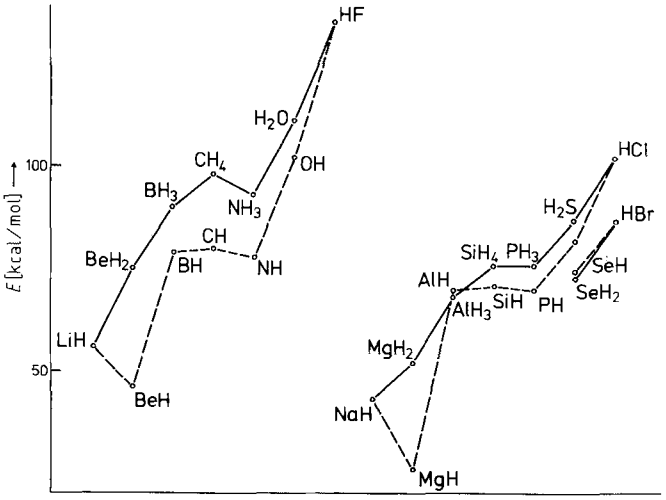

Fig. 3. XH bond energies for monohydrides and saturated polyhydrides of main group elements (for the sources of the values cf. Appendix 1).

Similar trends are found in the bond lengths[69]. Thus, in proceeding from the monohydrides XH to the polyhydrides XH_n the XH bond lengths are reduced by a few percent, both for X from the first and second rows. The effect, however, now varies strongly with the group in the periodic table (5% for BH and CH but only 1% for OH).

3.3. Hybridization and Polarity in the Hydrides BeH_2, BH_3, and CH_4 Compared to MgH_2, AlH_3, and SiH_4

The populations of the s, p, and d valence AOs on the central atom are depicted for the molecules BeH_2, MgH_2, BH_3, AlH_3, CH_4, and SiH_4 in Figure 4. In these XH_n molecules the ratios of the s and p populations lie between the values for the ground configurations (GC) of X without promotion and those for "ideal" sp^{n-1} hybridization. The values for molecules of elements from the first row (Be, B, C) lie much closer to those for ideal hybridization than the values for molecules of elements from the second row (Mg, Al, Si).

If one is accustomed to believe that in a planar XH_3 molecule such as BH_3 or AlH_3 sp^2 hybridization of the central atom is inevitable, one is surprised that in AlH_3 the s : p ratio is only 1 : 1.15, whereas in BH_3 it is at least 1 : 1.64 and not so far removed from the expected 1 : 2.

To analyze the problem more closely, we investigated the molecules BeH_2 and MgH_2. Although these are of less interest to chemists, they can be treated in a formally more straightforward way than XH_3 or XH_4 molecules[72].

MO calculations on BeH_2 or MgH_2 yield, in addition to MOs characterizing the cores of Be ($1s^2$) or Mg ($1s^2 2s^2 2p^6$), canonical valence MOs having the form:

$$\psi_1 = c_1 s + c_2 h_1 + c_2 h_2 \tag{10a}$$

$$\psi_2 = c_3 p + c_4 h_1 - c_4 h_2 \tag{10b}$$

where the s and p valence AOs of the Be or Mg are, respectively, of s or p_z type (z = molecular axis), and h_1 and h_2 represent s-AOs for the two H atoms. Normally, AO basis

sets with more than four functions are employed, though the result can still be presented in the form (10a, b), where s, p, h_1 and h_2 are no longer identical to the corresponding functions in the isolated atoms. Strictly speaking, even h_1 and h_2 in (10a) and (10b) are not identical, but their difference is not of importance here.

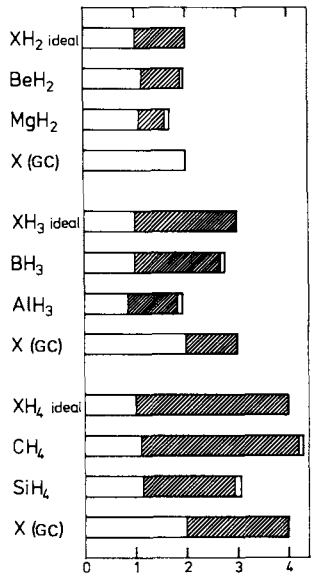

Fig. 4. Mulliken gross populations for the valence AOs of X in XH_n molecules without lone pairs of electrons. From left to right: s, p (hatched), d. The populations given as "XH_n ideal" obtained formally from the valence angles, assuming orthogonal hybrids. X(GC) indicate the ground configuration of the isolated atom. The populations are based on SCF calculations with a 9/5/1 Gauss basis for Be, B, C; an 11/7/1 basis for Mg, Al, Si; and a 5/1 basis for H in triple zeta contraction in each case. The exponents are taken from *Huzinaga* [147]; and for d and p_H from *Ahlrchs* et al. [78, 143].

The total wave function remains invariant[63] if the doubly occupied canonical MOs ψ_1 and ψ_2 are replaced by the so-called equivalent MOs φ_1 and φ_2 which are related to ψ_1 and ψ_2 as

$$\varphi_1 = \frac{1}{\sqrt{2}}(\psi_1+\psi_2) = \frac{c_1}{\sqrt{2}}s + \frac{c_3}{\sqrt{2}}p + \frac{(c_2+c_4)}{\sqrt{2}}h_1 + \frac{(c_2-c_4)}{\sqrt{2}}h_2 \quad (11a)$$

$$\varphi_2 = \frac{1}{\sqrt{2}}(\psi_1-\psi_2) = \frac{c_1}{\sqrt{2}}s - \frac{c_3}{\sqrt{2}}p + \frac{(c_2-c_4)}{\sqrt{2}}h_1 + \frac{(c_2+c_4)}{\sqrt{2}}h_2 \quad (11b)$$

The ideal case where s and p bond "equally" with h_1 and h_2 is characterized by:

$$c_1 = c_3\,; \quad c_2 = c_4 \quad (12)$$

and the equivalent MOs are then

$$\varphi_1 = \frac{c_1}{\sqrt{2}}(s+p) + c_2\sqrt{2}\,h_1 \quad (13a)$$

$$\varphi_2 = \frac{c_1}{\sqrt{2}}(s-p) + c_2\sqrt{2}\,h_2 \quad (13b)$$

i.e. they are genuine two-center MOs formed from one sp hybrid AO and the s-AO of one of the H atoms in each case.

In practice, the relationship (12) is never strictly fulfilled. When the absolute value of the "localization defect"

$$d_l = \frac{c_2-c_4}{c_2+c_4} \quad (14)$$

is small, the description of the molecule in terms of localized two-center bonds is a good approximation, irrespective of whether the "hybridization defect"

$$d_{hy} = \frac{c_1-c_3}{c_1+c_3} \quad (15)$$

is also small. If $|d_{hy}|$ is small, the formulation of (13) with two mutually orthogonal hybrids proves to be a good approximation. However, if $|d_{hy}|$ is not small, the hybrid AOs involved in each XH bond as defined in (11) are not mutually orthogonal, i.e. their overlap integral $\langle hy_1|hy_2\rangle = (c_1^2-c_3^2)/(c_1^2+c_3^2)$ can become quite large.

For BeH_2 and MgH_2 we obtained the following values

BeH_2: $d_l = -0.065$; $d_{hy} = 0.055$; $\langle hy_1|hy_2\rangle = 0.109$; $\langle h_1|h_2\rangle = 0.084$
MgH_2: $d_l = -0.092$; $d_{hy} = 0.183$; $\langle hy_1|hy_2\rangle = 0.354$; $\langle h_1|h_2\rangle = 0.042$

It is evident for all of the hydrides discussed in this section—and this is confirmed by comparisons of BH_3 with AlH_3, and CH_4 with SiH_4—that the magnitude of the localization defects is small. This means that a description in terms of localized XH bonds is justified, although the hybridization defect will be sufficiently small in absolute value only for BeH_2, BH_3, and CH_4 but not for MgH_2, AlH_3, and SiH_4. For the last three molecules, the hybrid AOs are far from orthogonal.

The s component in these hybrids (cf. Fig. 4) is much larger than that calculated from the valence angle given by equation (9). The hybridization defect is especially small in CH_4 ($d_{hy} = 0.08$; $\langle hy|hy'\rangle = 0.017$). Clearly, "good", i.e. optimally directed, hybrids are only possible if the s and p valence AOs are localized in roughly the same region of space. "Good" hybrids are those linear combinations of s- and p-AOs such that on one side of the nucleus the s and p components contribute additively while on the other side they almost cancel. This can only arise if the radial factors of s and p do not differ much.

It is somewhat surprising that the XH bonds in MgH_2, AlH_3, and SiH_4 are highly localized, despite "poor" hybridization.

One explanation for this is that there is a strong displacement of electronic charge from X to H in the XH bonds of MgH_2, AlH_3 and SiH_4. One realizes that for ideal ionic bonding—such as in $Mg^{2\oplus}(H^{\ominus})_2$—the MOs for the MgH bonds are in fact localized, namely on the H atoms, irrespective of the hybridization at the Mg atom (for an ideal ionic bond $q_s = 0$ and $q_p = 0$ and the hybridization ratio is undefined). The s-p ratio at the central atom has little influence on the localizability, as long as the bond is strongly polar (with H the more negative atom), even if it is not ideally ionic. Hybridization has an effect on localizability as well as on the bond strength only in mainly covalent bonds.

3.4. Comparison of BeH and MgH with BeH_2 and MgH_2

The differences in the XH bonding energies shown in Figure 3 are especially striking for BeH and MgH monohydrides, on the one hand, and BeH_2 and MgH_2, on the other. For the sake of simplicity, let us suppose that the valence configuration of the Be and Mg is sp in both molecules (this is not strictly correct according to Section 3.3, cf. also Figs. 5 and 6). We shall also further suppose that promotion to the sp state is necessary to form a BeH or MgH bond. We can then set

$$\Delta E(XH_n) = E_{prom} + n E_{bond};\ n = 1, 2$$
$$E_{bond} = \Delta E(XH_2) - \Delta E(XH)$$
$$E_{prom} = 2\Delta E(XH) - \Delta E(XH_2)$$

where E_{bond} is the energy of a bond and E_{prom} is the promotion energy, and obtain

BeH/BeH_2: $E_{bond} = -104$ kcal/mol, $E_{prom} = 58$ kcal/mol
MgH/MgH_2: $E_{bond} = -78$ kcal/mol, $E_{prom} = 52$ kcal/mol

The lowest s→p excitation energy in Be and Mg atoms is 2.73 eV = 63 kcal/mol and 2.71 eV = 62 kcal/mol, respectively[31], and is of the same order of magnitude as the promotion energy estimated here.

3.5. Isovalent Hybridization in the Monohydrides

In Figure 5 the results of detailed population analyses of the monohydrides LiH to HF and from NaH to HCl are presented. BeH and MgH, which we discussed in Section 3.4, do not fit into the general pattern and nor do LiH and NaH. For these last-mentioned compounds, the valence AOs are essentially of s type, whereas for all the other molecules they are mainly of p type. The relatively strong s→p promotion in LiH and NaH is well understood, although it will not interest us further here.

A comparison of the overall s : p ratios (which are not readily apparent from Fig. 5) for BH to HF and for AlH to HCl reveals that for BH to HF an s→p excitation of ca. 0.1 to 0.35 electrons from the ground configuration occurs, whereas the corresponding excitation for AlH to HCl is ca. 0.0 to 0.23 electrons. As expected, this promotion is small and significantly smaller for second row than for first row atoms. Nevertheless, the conclusion that the promotion, and thus the hybridization, is negligible would be premature. Separate analysis for bonding MOs, unpaired electrons, and lone pairs of electrons (Fig. 5) indicates significant mixing of s components from X into the MO of the XH bond, which is often viewed as a purely p bond and even more mixing of p components into the lone pairs of electrons, which are usually expected to be pure s-AOs.

Any hybridization which does not increase the valence is referred to as isovalent. Essentially, there are two reasons for isovalent hybridization, as schematically illustrated in Figure 7:

(a) Hybrid AOs overlap better and form stronger bonds;

(b) By mixing p components with the lone pairs, the latter are displaced in the opposite direction to the XH bond, thereby reducing the "Pauli repulsion" ("Fermi repulsion") with the XH bonds.

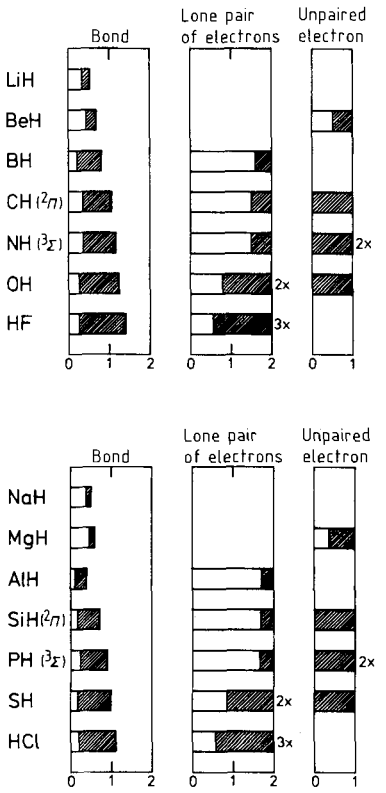

Fig. 5. Mulliken gross populations for the valence AOs of X in the localized MOs of monohydrides XH. Cf. legend to Figure 4. The populations of the d-AOs have not been sketched since they would not appear on the scale used here (they are smaller than 0.02).

The s→p promotion requires energy and there is competition between the gain in energy from hybridization and the loss in energy from promotion.

Of the two reasons given for isovalent hybridization, (a) is well-known[73a], whereas (b) requires some comment.

In the B atom, the (doubly occupied) 2s- and 2p-AOs are mutually orthogonal, i.e. their overlap integral is equal to zero. If an MO is now constructed for the BH molecule from the $2p_z$-AO of the B and an s-AO of the H, this MO is no longer orthogonal to the 2s-AO since the s-AO of H overlaps with the 2s-AO. Because the 2s-AO of B is doubly occupied (as is the MO we have constructed), the usual repulsion between doubly occupied orbitals occurs; this is often designated the Pauli force or exchange repulsion. This repulsion can be reduced by giving the lone pair an opportunity to move partially to the opposite side of the bond.

It is difficult to state whether effect (a) or (b) dominates. That both effects play a less significant role in, for example, AlH and thus contribute less than in BH may be readily seen from the different s : p ratios (cf. Fig. 5). Effect (a) is less important for higher row elements because the s valence AOs are less diffuse than the p valence AOs; mixing

of s components thus does not essentially improve the overlap capability. Moreover, because the s valence AO in AlH is less diffuse and the XH separation is greater than in BH, the Pauli force is also not so large; consequently, the lone pair of electrons is less likely to be displaced.

Since these two effects are less pronounced for the higher main group elements, less isovalent hybridization occurs in these elements. Here, differences in the bond polarities play only a minor role.

Mulliken overlap populations—which provide a measure of the strengths of covalent bonds—have not been documented here. The sh overlap populations are—apart from LiH, NaH, BeH, and MgH—negative and especially so in AlH, SiH, PH, and BH (values lie between -0.10 and -0.20). The interaction of the doubly occupied 2s- or 3s-AOs of the heavy atoms with the 1s-AO of the H atom is, as already explained, certainly repulsive or antibonding.

Since the ph overlap populations are positive and their magnitudes sufficiently large ($+0.30$ to $+0.40$), overall positive X–H overlap populations result with values lying between $+0.17$ (AlH) and $+0.33$ (HCl).

3.6. Pauli Repulsion and Isovalent Hybridization: The Valence Angles in NH_3 and H_2O Compared with Those in PH_3 and H_2S

Among the more spectacular differences between the compounds of elements of the first and higher rows are the geometries of, for example, H_2O and H_2S, H_2Se, etc. or of NH_3 and PH_3, AsH_3, etc. Whereas the valence angles in H_2O and NH_3 are ca. 104° and are thus almost tetrahedral, the valence angles in H_2S, H_2Se, PH_3, and AsH_3 are close to 90°. It is frequently assumed that the bonding in H_2S, PH_3, etc. involves almost pure p-AOs while in H_2O and NH_3 hybrid AOs are involved. This implies that extensive use of isovalent hybridization would be made for H_2O and NH_3 but not for H_2S and PH_3[73b].

Figure 7 demonstrates the reasons for isovalent hybridization. In Section 3.5 we have already mentioned that the effects (a) and (b) are important for diatomic molecules; to these we now add a third:

(c) Increase of the valence angle by hybridization and consequent reduction of the Pauli repulsion between the XH bonds.

That Pauli repulsion between the XH bonds occurs independently of any assumptions about hybridization can be demonstrated, for example, by artificially inhibiting hybridization in a calculation[74] in which the 2s-AO (or 3s-AO) is "frozen in"[75] so that its population remains at $q_s = 2$. Although the XH bonds will then be provided by pure p-AOs, the HOH angle in H_2O turns out to be not 90° but rather 97°, while the HSH angle is not enlarged[74].

This result can be understood as follows: Whereas the two p-AOs, namely p_x and p_y, are both involved in XH bond formation in XH_2 and are mutually orthogonal at the outset, this is no longer true for the MOs formed from a p_x or p_y and an h, since the s-AOs of the H atoms overlap. The nonorthogonality of the MOs leads to a repulsion of the H atoms and thus to a widening of the valence angle (the electrostatic repulsion of the equally charged H atoms is quite negligible compared to this "Pauli force"). The "Pauli force" varies exponentially with the distance. The separation between two H atoms in H_2O or NH_3 for a valence angle of 90° is ca. 1.4 Å and in H_2S or PH_3 is ca. 2.5 Å. It is thus clear why this force is so much weaker for the hydrides of higher row atoms than for elements of the first row and why this leads to a significant increase of the bonding angle in the latter case.

The Pauli force between the XH bonds should weaken the bonding because the HXH angle differs from that between the AOs involved in the bonding. However, a strengthening of the bonding is observed (see Section 3.1) in proceeding from OH to H_2O or from NH to NH_3 (and even to a lesser extent on proceeding from SH to H_2S or from PH to PH_3).

If hybridization is not artificially inhibited, the valence angle can be increased and the bonds simultaneously strengthened. From the population analysis presented in Figure 6, it is apparent that all the molecules discussed in this section make use of isovalent hybridization.

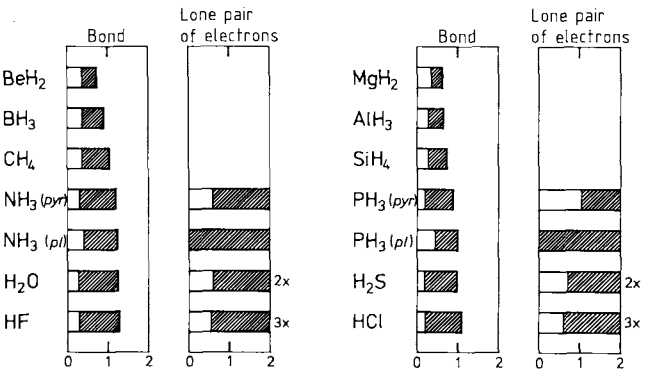

Fig. 6. Mulliken gross populations for the valence AOs of X in the localized MOs of XH_n molecules. Cf. legends to Figures 4 and 5. For NH_3 and PH_3, "pyr" signifies the pyramidal equilibrium configuration and "pl" the optimized planar structure (transition state for inversion).

In H_2O and NH_3 the s:p ratios for the hybrids forming the XH bonds are, respectively, 1:3.81 and 1:2.90. From the observed valence angles, using equation (9) one would expect ratios of 1:3.99 and 1:3.38, which is fairly consistent with the concept of orthogonal hybrids. In both of these molecules the s:p ratios for the lone pairs are, respectively, 1:2.25 and 1:2.37.

For H_2S and PH_3, s:p ratios of 1:4.71 and 1:3.83 are found for the XH bonds, whereas equation (9) yields 1:19.8 and 1:15.1 if one uses the experimental bond angles. There can thus be no suggestion of pure p bonds, nor can the lone pairs be regarded as pure 3s-AOs (s:p = 1:1.182 in H_2S and 1:0.95 in PH_3).

It is noteworthy that the hybrids for the XH bonds of OH and H_2O or SH and H_2S, etc. are not essentially different; this eliminates effect (a), shown in Figure 7 as an explanation of the varying strengths of the XH bonds in XH and XH_n. Effect (c) could at most explain why the bonds in XH_n are not weaker than those in XH. The decisive factor must clearly be effect (b).

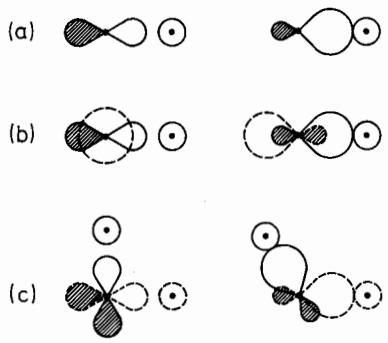

Fig. 7. Depiction of three reasons for isovalent hybridization: (a) Hybrid AOs overlap better; (b) hybridization reduces the repulsion between the XH bond and the lone pairs; (c) hybridization favors larger bond angles.

Because two OH bonds are formed in H_2O, the s→p promotion can be approximately twice as effective as in OH (the total s : p ratio for the O atom is 1 : 2, that for OH 1 : 2.23, and that for H_2O 1 : 2.70). This gives a high p component to the lone pairs, whose centroid in H_2O is displaced considerably further "outwards" from the O atom than in the OH radical. The same effect occurs (in a less pronounced way) in the comparison of H_2S with SH.

That effect (b) is actually more important than effect (c) is also apparent from the magnitude of the overlap populations which are much more strongly negative between the 2s on X and h than between h_1 and h_2. This is also supported by the observation that changes in the HXH angle for H_2O or H_2S have little effect on the valence configuration or the hybridization.

At this point two questions arise:

- Why is isovalent hybridization less used in H_2S or PH_3 than in H_2O and NH_3?
- Why are the valence angles in H_2S and PH_3 close to 90° although significantly larger HXH angles are to be expected from the valence configuration and hybridization?

One answer to the first question is that the three reasons illustrated in Figure 7 for the occurrence of isovalent hybridization in elements of the higher main groups play a less important role. The reason for this is that the 3s-AOs are much less diffuse than the 3p-AOs. Consequently, the Pauli repulsions between the XH bonds and also between the XH bond and the lone pair in H_2S are necessarily weaker than in H_2O. Finally, because of the different $\langle r \rangle_s$ and $\langle r \rangle_p$ values, the hybridization is also less effective in strengthening the bond.

The $\langle s|h \rangle$ and $\langle p|h \rangle$ overlap integrals (for p in the direction of the bond) can be extracted from the population analyses:

H_2O: $\langle s|h \rangle = 0.41$; $\langle p|h \rangle = 0.44$
H_2S: $\langle s|h \rangle = 0.33$; $\langle p|h \rangle = 0.49$

These results also confirm that the 3s-AO in H_2S is located significantly closer to the nucleus than the 3p-AO.

In view of the results obtained in Section 3.3, we should certainly not expect the valence angles calculated from s : p ratios using equation (9) to be relevant since this equation applies only to orthogonal hybrids, which are certainly not realized in H_2S. There is also one further reason for the discrepancy between the observed HSH angle and that predicted from the s : p ratio.

The actual valence angle is determined not only by the Pauli repulsion between the H atoms but also by that between the H atoms and lone pairs of electrons. The latter effect tends to favor small valence angles. When this type of repulsion is predominant, it may be said pictorially that the "lone pair needs more space than the XH bonding orbitals".

In terms of the widely used valence shell electron pair repulsion (VSEPR) model[76], the results of our analysis may be regarded as a confirmation that electron pair repulsion determines the molecular geometry. However, one weakness (among others[74]) of this model is that it completely ignores the role of hybridization in assuming ideal hybridization is always realized[77].

Since comparison of NH_3 with PH_3 leads to a completely analogous result as that of H_2O with H_2S, we need not repeat the same arguments here. It is worthwhile, however, to comment on the analysis of planar NH_3 and PH_3 (cf. Fig. 6). In this instance, the lone pair is necessarily of π type, i.e. a pure p-AO, and one might expect (similarly as in BH_3 or AlH_3) that the sp^2 hybridization for the XH bonds is "enforced". It is found, however, that the s : p ratio for X in the XH bonds in NH_3 and PH_3 is only 1 : 1.5 and 1 : 1.25, respectively.

The inversion barrier for NH_3 is 6 kcal/mol and that for PH_3 around 38 kcal/mol[78]. This enormous difference (cf. Fig. 6) arises because the valence configuration of NH_3 has to change only from $s^{1.53}p^{4.11}d^{0.03}$ to $s^{1.41}p^{4.26}d^{0.01}$ from the equilibrium to the planar structure; in contrast, PH_3 has to change from $s^{1.59}p^{3.04}d^{0.12}$ to $s^{1.32}p^{3.62}d^{0.09}$.

It is not only the strong s→p promotion which requires energy. In planar PH_3 the lone pair is necessarily a 3p-AO which functions better as a valence AO than as a lone pair.

3.7. Comparison of CH_2 with SiH_2, GeH_2, and SnH_2

In its ground configuration s^2p^2, C — like Si, Ge, etc. — is bivalent; accordingly CH_2, SiH_2, GeH_2, etc. in the $^1A_1$ states require no promotion. Population analyses (Fig. 8) and HXH angles[78–80] (CH_2 102.4°, SiH_2 94°, and GeH_2 92°) confirm that in CH_2 as in H_2O or NH_3 use is made of isovalent hybridization (s : p = 1 : 1.56), whereas SiH_2 corresponds rather to H_2S (s : p = 1 : 1.04).

In contrast, formal promotion into the sp^3 valence configuration is necessary for formation of the $^3B_1$ states, since two valence AOs are needed for each XH bond and two further AOs for unpaired electrons. The HXH angles[79–81] are correspondingly considerably larger (CH_2 136°, SiH_2 117.6°, and GeH_2 118.6°), although the s : p ratios deviate markedly from 1 : 3 (CH_2 1 : 2.11 and SiH_2 1 : 1.77).

The assumption of orthogonal hybrids is not justified in all cases. From the degree of hybridization one would expect significantly larger valence angles, especially in SiH_2 but also in CH_2. Admittedly, the potential curves as a function of angle are very flat, particularly for $CH_2(^3B_1)$.

Alternatively, one can interpret the HXH angles in XH_2 molecules using Walsh diagrams[82].

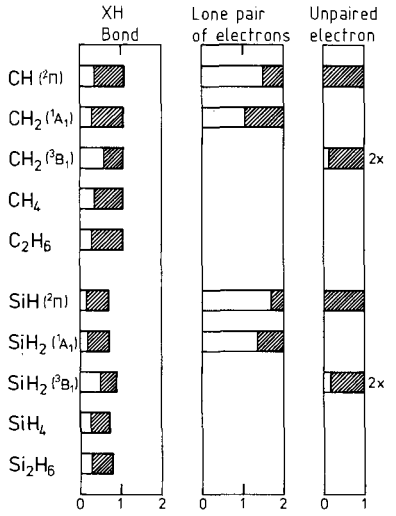

Fig. 8. Mulliken gross populations for the valence AOs of X in the localized MOs of XH_n molecules (X=C, Si). Cf. legends to Figures 4 and 5.

In the series CH_2, SiH_2, GeH_2, SnH_2, the only molecule with a triplet ground state is CH_2. This suggests that the promotion energy for hybridization required for the formation of the $^3B_1$ states is over-compensated by the gain in bond energy only for the C atom.

The effect of substituents on the geometry of XH_2 species and on the singlet-triplet state separation cannot be treated here[80,83].

3.8. Monofluorides and "Saturated" Fluorides

The bonding energies of XF bonds are illustrated in Figure 9. There is a pronounced maximum in the curve for elements of the third main group (B to Tl).

The monofluorides of elements of the first row have stronger XF bonds than the "saturated" polyfluorides; the bond in BF is ca. 30 kcal/mol stronger than a BF bond in BF_3. This trend is also apparent in a less pronounced form in the second row for AlF/AlF_3, whereas the SiF bond in SiF is weaker than that in SiF_4.

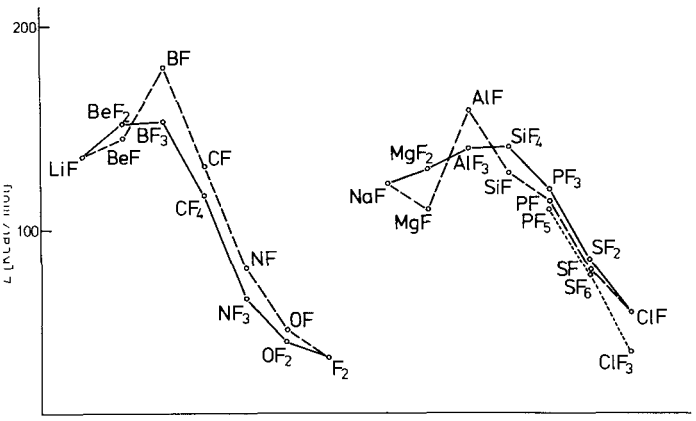

Fig. 9. XF bond energies in monofluorides XF and XF_n molecules (for the sources of these values see Appendix 1).

The extraordinary strength of the bond in BF undoubtedly arises because this compound is isoelectronic with CO and N_2, and some remnant of a triple bond is present. In addition to the σ-bonding in the BF molecule, there is also π-backbonding, although this is much less pronounced than in N_2 or CO since charge has to be displaced from F to B, i.e. against the difference in electronegativity. (In CO only one of the two π-bonds is due to backbonding, whereas in N_2 both are true covalent bonds.) Stabilization of the BF bonds by backbonding is also possible in BF_3 (where the pπ-AO of the B atom is formally unoccupied), but not in CF_4. The high strength of the XF bonds in CF, BF, and OF can be rationalized in a similar way.

The marked difference between the bonds in CF and SiF probably arises, on the one hand, because the π-type backbonding in SiF is much weaker than that in CF (cf. Section 4.1) and, on the other hand, because of possible stabilization even of the SiF_4 by backbonding with the involvement of d-AOs on the Si (cf. Section 5.3). The greater polarity of the SiF bond also plays a role.

The bond lengths[69] (which are not discussed here) tend to support this overall picture. Thus, when X is from the first row, the SF distances increase by ca. 0.03—0.04 Å in going from the monofluorides XF to the saturated, normal-valent polyfluorides XF_n, whereas when X is from the second row, a corresponding shortening of 0.01 to 0.03 Å occurs.

In Figure 9 a number of hypervalent molecules, namely PF_5, SF_6, and ClF_3 (see Section 5.2) are included. The bond energy per XF bond is always smaller in the hypervalent fluorides than in the saturated fluorides, as is apparent from a comparison of PF_5 with PF_3 or of ClF_3 with ClF.

The differences between XH_n and XF_n molecules depend, in part, on the high polarity of the XF bonds and also to an extent on the fact that there are occupied π-electron orbitals on F which permit backbonding.

4. Multiple Bonds in Light and Heavy Main Group Elements

4.1. Bonding Increments

The bond energies for homonuclear diatomic molecules are collated in Figure 10. In going from the first to higher homologous rows, there is a very evident decrease in the bond energies (with the sole exception of F_2 which has a smaller bond energy than Cl_2).

Bond energies of molecules (especially those in which all the bonds are highly localized) can be resolved into (approximately transferable) contributions from the individual bonds. Accordingly, it is entirely reasonable to speak of the energy of a CC single bond or of a CC double bond. Of course, if one wishes to determine the energies in given molecules very accurately by means of an increment system, (transferable) contributions for each of the individual bonds are not sufficient. Then additional increments for interactions, ring strains, etc. are also required[84]. However, we are not concerned here with an increment system which may be used to reproduce any given bond energy, but rather in rationalizing our knowledge of empirical in-

formation on bond energies between main group atoms in a simple and concise way.

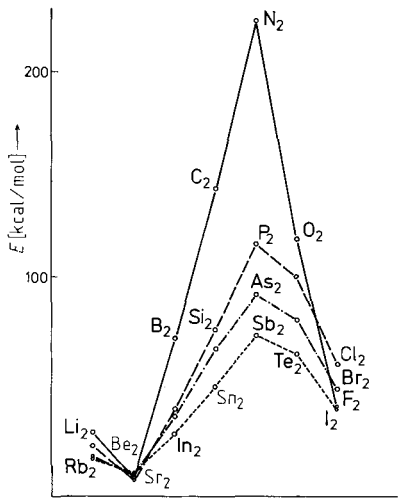

Fig. 10. Bond energies for homonuclear diatomic molecules (for the sources of these values see Appendix 1).

Instead of documenting the energies for single, double, and triple bonds, we resolve them into σ and π contributions (following *Pauling*[129]) and list these in Table 2. This resolution is, to a certain extent, entirely arbitrary. We have, for example, simply identified the CC σ-increment with the energy of a CC single bond (cf. Appendix 2) (the atomization energy of C_2H_6 has been used, with the assumptions that the bond energy of a CH bond in C_2H_6 is the same as that in CH_4 and that non-neighboring interactions or multicenter effects can be ignored). The CC π-increment is then simply the difference between the energy of the CC double bond in ethene and that of the CC single bond in ethane (cf. Appendix 2). No account has been taken of the fact that the σ-bond in ethene is certainly different from that in ethane.

Table 2. Bond increments (in kcal/mol) for σ/π-bonds [a].

CC	NN	OO	FF	CN	CO	NO
80/70	38/94	35/83	37/—	70/65	80/90	45/88
SiSi	PP	SS	ClCl	SiC	PC	SC
46/28	48/34	64/37	58/—	72/33	64/48	67/63
GeGe	AsAs	SeSe	BrBr	SiO	PO	SO
39/26	42/29	50/30	45/—	100/40	80/36	65/60

[a] The sources of these values are cited in Appendix 2.

Table 2 indicates that the π-increments for homonuclear bonds involving first row elements (C to O) are more than twice as large as those involving second row elements. Elements of the second and higher rows differ only little. For the higher rows the σ-increments are significantly larger than the π-increments, exactly the opposite of that found for the first row, namely for N and O (even the small FF σ-increment fits into this pattern). The CC bond is somewhat exceptional in that the σ- and π-increments are of roughly the same magnitude.

These increments reflect that, in general, compounds having OO or NN single bonds are very unstable, and that normally O and N exhibit multiple bonds and exist as O_2 and N_2. Moreover, SiSi, PP, or SS multiple bonds are usually less favored than the corresponding single bonds, and for silicon, phosphorus, and sulfur, structures having single bonds only are preferred.

The enormous variety of organic chemistry is largely due to the fact that CC σ- and π-bonds are competitive with each other. Although the σ-bonds are somewhat stronger—which is why it is justified to speak of molecules with double bonds as "unsaturated"—π-bonds can be stabilized by delocalization. Thus, aromatic molecules are just about as stable as aliphatic molecules, and the cohesive energies of graphite and diamond are virtually identical.

Such a competition between σ- and π-bonds is unique in the periodic system of the elements, notwithstanding recent work[10,11] in which SiSi double bonds have been prepared. Molecules of this type (completely in accord with the increment system in Table 2) are either short-lived or are "kinetically stabilized" by appropriate substitution to prevent oligomerization reactions.

For bonds formed between different atoms, one finds that the π-bonds are stronger when both atoms are from the first row (N-O) or that the σ-bonds or are of comparable strength (C—N, C—O). The NO bond thus behaves analogously to the NN and OO bonds, whereas CN and CO behave like CC bonds, so that the special role of the carbon tends to dominate.

When at least one atom is from the second or a higher row, the σ-increments are much larger than the π-increments—with the exceptions of CS (and possibly also CSe) and SO, for which the σ- and π-increments are comparable.

Single and multiple bonds compete not only in CC bonds but also in CN, CO and CS bonds, which is certainly related to the special role played by nitrogen, oxygen, and sulfur in organic chemistry.

An appropriate measure for the different strengths of π-bonds is also provided by the shortening of the atomic distances in proceeding from single to double bonds (ca. 12% in C, 9% in Si[85a] and 0% in Sn[85b]).

4.2. Electronic Structure of Homonuclear Diatomic Molecules

To understand the notable pattern of the σ- and π-increments (cf. Section 4.1), we consider the overlap of 2pσ- and 2pπ-AOs as a function of the distance between the two atoms (Fig. 11). In view of this overlap it has to be expected that σ-bonds are stronger than π-bonds, at least for distances that are not too small. Elements of the higher rows display in this sense the normal behavior, while those in the first row would represent exceptions.

How is it possible for first row elements to have π-increments which are larger than their σ-counterparts? The key to understanding this surprising result is again found in the relative spatial distributions of the 2s- and 2p-AOs compared to those of the 3s- and 3p-AOs. This type of argument has already been used in Section 3.6 to account for the different geometries of H_2O and NH_3, on the one hand, and H_2S and PH_3, on the other. The relevant mechanism is presented in many textbooks of theoretical chemis-

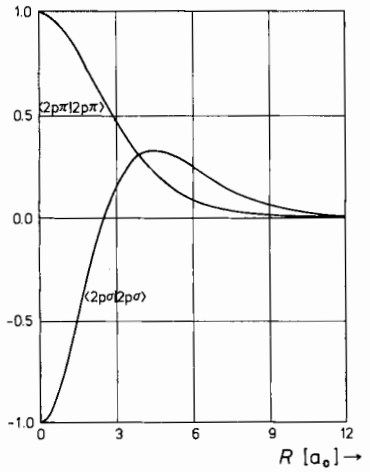

Fig. 11. A comparison of the 2pσ and 2pπ overlap integrals as a function of the distance between the two atoms.

try[86] in the context of the electronic structure of diatomic homonuclear molecules (Fig. 12). If the MOs were constructed from the "pure" 2s- and 2p-AOs of the atoms, the sequence of valence MOs would then be: $2\sigma_g$, $2\sigma_u$, $3\sigma_g$, $1\pi_u$, $1\pi_g$, $3\sigma_u$, where the first two MOs originate from 2s and the last four from 2p orbitals. As a consequence of the interaction of the 2s and 2p orbitals, the energies of MOs of the same symmetry will be shifted away from each other such that the following sequence results: $2\sigma_g$, $2\sigma_u$, $1\pi_u$, $3\sigma_g$, $1\pi_g$, $3\sigma_u$.

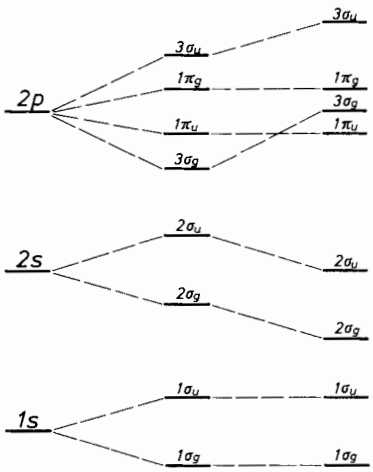

Fig. 12. Schematic representation of the MO levels in homonuclear diatomic molecules.

According to the Aufbau principle, the $1\pi_u$-MO is initially doubly occupied in B_2 and quadruply occupied in C_2 before the $3\sigma_g$-MO is occupied in N_2. Hence, B_2 has a π-bond, C_2 two π-bonds, and N_2 two π-bonds and a single σ-bond.

4.3. Comparison of N_2 with P_2

Since the "mixing" between the s and p valence AOs is less effective for the higher row elements—owing to the greater spatial separation of s and p—than that for first row elements, we would expect the displacement of the levels corresponding to the $2\sigma_g$ and $3\sigma_g$ levels in P_2, for example, to be smaller than that in N_2. This is confirmed by comparing the one-electron energies in the potentials for $N_2^{6\oplus}$ and $P_2^{6\oplus}$ (where the MOs formed mainly from s valence AOs are fully occupied): As shown in Figure 13, the $3\sigma_g$ level in N_2 lies above the $1\pi_u$ and the $5\sigma_g$ level in P_2 is found below the $2\pi_u$, even though in both instances the difference in energy is not very large, namely of the order of 1 eV. It is also found experimentally[87] that the first ionization potential for N_2 corresponds to ionization from the $3\sigma_g$ level (which should thus be the highest occupied MO) and for P_2 to ionization from the $2\pi_u$[88] level.

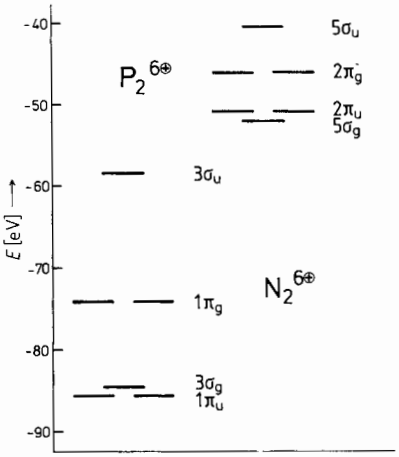

Fig. 13. Energy levels in the field of $N_2^{6\oplus}$ and $P_2^{6\oplus}$.

The MO arguments upon which Figure 13 is based can also be translated into the terminology of hybridization. Thus the nitrogen atom N, for example, is tervalent in its ground configuration $1s^2 2s^2 2p^3$ and can thus form an N_2 molecule with a triple bond. The bond is weakened by Pauli repulsion between the doubly occupied 2s-AOs and between the σ-bond and either of the doubly occupied 2s-AOs. These repulsions can be attenuated by isovalent hybridization, in an extreme model by promotion to the valence configuration $1s^2 di^3 2p^2 = 1s^2 2s^{1.5} 2p^{3.5}$, where di represents a digonal or sp hybrid AO as in equation (13). In this context, di^3 signifies that of the two hybrid AOs di_1 and di_2 one is doubly occupied with a lone pair while the other is available as a valence AO for the NN bond. Isovalent hybridization of this type reduces the Pauli repulsion and also strengthens the NN σ-bond (see Fig. 7), but costs promotion energy. Both of these effects should be less pronounced in P_2, where from the outset the Pauli repulsion is less important.

The valence configuration for N_2 is $s^{1.77} p^{3.17} d^{0.06}$ and that for P_2, $s^{1.82}$, $p^{3.09} d^{0.09}$; the valence configuration in P_2 thus lies rather closer to the ground configuration $s^2 p^3$ (implying less promotion energy), although even for N_2 it is still sufficiently far away from the configuration required for the formation of digonal hybrids, namely $s^{1.5} p^{3.5}$.

The s and p populations for individual MOs are given in Figure 14. The mixing of p into the $4\sigma_g$ and $4\sigma_u$ levels is smaller for P_2 than it is into the $2\sigma_g$ and $2\sigma_u$ levels in N_2. The same holds for the mixing of s into the $3\sigma_g$ or $5\sigma_g$ levels.

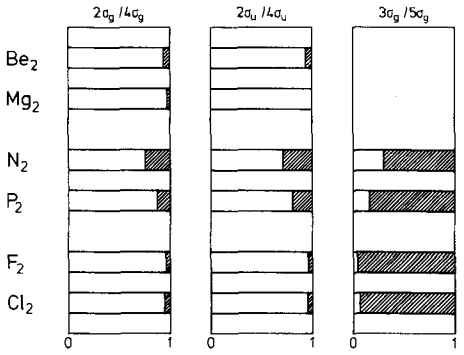

Fig. 14. Mulliken gross populations for the s and p valence AOs in the canonical MOs of X_2 molecules. In each case from left to right: s, p (hatched). The AO bases used are as in Figure 4.

The σ-bonds in N_2 and P_2 lie between pure p-bonds and sp hybrid bonds; they are closer to pure p-bonds, especially in P_2.

Mulliken and *Liu*[90] were the first to point out the role of the different isovalent hybridization. The difference is, however, too small to explain the enormous differences in the σ- and π-increments. Further insight is gained from the overlap populations. The total overlap populations for the XX bond are

N_2: 0.71 P_2: 0.73

and these may be resolved into the following σ and π contributions

N_2, σ:	0.17	P_2, σ:	0.23
π:	0.27	π:	0.25

where "π" indicates the contribution for either of the two π-bonds. The σ-bond in N_2 is evidently weaker than a π-bond, whereas in P_2 both types of bonds should have roughly the same strength. The σ overlap populations can be further resolved into the contributions from the ss, spσ, and pσpσ (and additionally sdσ, pσdσ, dσdσ) overlaps:

N_2 ss:	−0.13	P_2 ss:	−0.04
spσ:	0.05	spσ:	0.00
pσpσ:	0.10	pσpσ:	0.16

The relative weakness of the σ-bond in N_2 clearly results from the negative ss overlap population, i.e. from the repulsion of the 2s-AOs. This is attenuated to some extent by isovalent hybridization, i.e. the repulsion would be even stronger if the lone pairs were frozen-in as pure 2s-AOs. The 3s-repulsion in P_2 is substantially weaker.

Alternatively, the total σ-overlap populations can be resolved into $2\sigma_g$, $2\sigma_u$, and $3\sigma_g$ contributions for N_2 and $4\sigma_g$, $4\sigma_u$, and $5\sigma_g$ contributions for P_2

N_2 $2\sigma_g$:	0.40	P_2 $4\sigma_g$:	0.32
$2\sigma_u$:	−0.19	$4\sigma_u$:	−0.09
$3\sigma_g$:	−0.04	$5\sigma_g$:	0.00

According to this scheme, $2\sigma_g$ or $4\sigma_g$ is strongly bonding, $2\sigma_u$ or $4\sigma_u$ is weakly antibonding, and $3\sigma_g$ or $5\sigma_g$ virtually nonbonding.

On the basis of only the total overlap populations, it might perhaps be expected that the triple bonds in N_2 and P_2 are approximately equal in strength.

However, it is not justified to relate the overlap populations directly to bond energies. The bond energy is also determined by how strongly valence electrons are attached to the core of the free atom, i.e. essentially by the ionization potential. This is larger for p-AOs in N than in P by a factor of 1.3. If the greater s contribution to valence in N is taken into account, the factor should be even slightly larger. Thus, in qualitative terms at least, it is clear why the bond energy in N_2 is significantly greater than that in P_2.

4.4. Comparison of Be_2 with Mg_2

We have seen for N_2 and P_2 that the $2\sigma_g$- or $4\sigma_g$-MOs are strongly bonding, whereas the $2\sigma_u$- or $4\sigma_u$-MOs are weakly antibonding (Section 4.3). If this were true for all X_2 molecules, Be_2 and Mg_2 should be stable molecules.

The Mg_2 molecule has been detected experimentally[91] (equilibrium separation $r_e = 3.89$ Å, bond energy $D_e = 1.2$ kcal/mol). The Be_2 molecule is known only from—albeit very reliable—quantum-chemical calculations[92,93], according to which it should have $r_e = 2.50$ Å and $D_e = 2.0$ kcal/mol, i.e. it should have a stronger bond than that in Mg_2. The Ca_2 molecule has an even stronger bond than Be_2 or Mg_2. The equilibrium separation and bond energy for Mg_2 suggest the presence of a van der Waals' bond, such as occurs between any closed shell systems (e.g. He_2: $r_e = 2.97$ Å, $D_e = 0.02$ kcal/mol; Ne_2: $r_e = 3.07$ Å, $D_e = 0.05$ kcal/mol). In contrast to chemical bonds, the van der Waals' bond (cf. [94]) does not arise from the overlap of orbitals but from the mutual induction of transient dipoles. It can be shown that such a bond will be stronger the greater the dipole polarizability between the atoms or molecules involved. Mg_2 has a very high dipole polarizability (cf. Table 1), which explains why the bonding is much stronger than that in He_2 or Ne_2. From the trend in dipole moments (Table 1), one might expect that the bond strengths should decrease along the sequence Ca_2, Mg_2, Be_2. As already mentioned, however, Be_2 is probably more strongly bound than Mg_2 (in accord with the higher cohesive energy of solid Be compared to solid Mg).

SCF calculations predict that neither Be_2 nor Mg_2 are bound, and not even local minima are found on the potential energy curves. To obtain reliable predictions, one has to treat electron correlation effects[96] in a highly sophisticated manner[92,93]. Nevertheless, even the potential curves obtained from SCF calculations are peculiar.

Whereas strong overlap of atomic orbitals normally results in either marked repulsion or attraction (chemical bonding), for Be_2 in particular (and to a lesser extent Mg_2) one finds only a very weak repulsion when there is strong

overlap. This is because the bonding effect of the $2\sigma_g$ and the antibonding effect of the $2\sigma_u$ largely compensate each other. Normally, an antibonding MO is always much more strongly antibonding than the corresponding bonding MO is bonding. The mixing in of p components into these MOs (cf. Fig. 14) strengthens the bonding character of the $2\sigma_g$ and reduces the antibonding of $2\sigma_u$. It is plausible that this effect is not as pronounced as in N_2, since in the N atom the $2p\sigma$ is occupied but is not in the Be atom.

The bonding in Be_2 is stronger than in Mg_2 because the hybridization of first row elements is more effective than that of higher row elements. Be_2 obviously represents a borderline case between (weak) chemical bonding and (strong) van der Waals' bonding.

One of the strongest genuine van der Waals' bonds occurs in the lowest triplet state of Li_2 ($r_e = 4.2$ Å, $D_e = 0.8$ kcal/mol[95]). This is more comparable with the bond in Mg_2 than that in Be_2. If there were a genuine van der Waals' bond in Be_2, this bond should be substantially weaker than that in the Li_2 triplet because the polarizability of Li (Table 1) is approximately four times that of Be.

4.5. Explanation of the Different σ- and π-Increments

In principle, the σ-bond increments (cf. Appendix 2) have been derived from the molecules C_2H_6, N_2H_4, H_2O_2, F_2, Si_2H_6, P_2H_4, H_2S_2, and Cl_2 assuming that the respective XH bonds are the same as those in CH_4, NH_3, H_2O, SiH_4, PH_3, and H_2S. A comparison of the results of population analyses in Figures 15 and 6 reveals that this assumption is reasonable—at least as far as the s : p ratios for the AOs of X in XH bonds are concerned. The hybridization of the lone pairs in the corresponding molecules also appears to be remarkably similar, even for HF and F_2 or HCl and Cl_2.

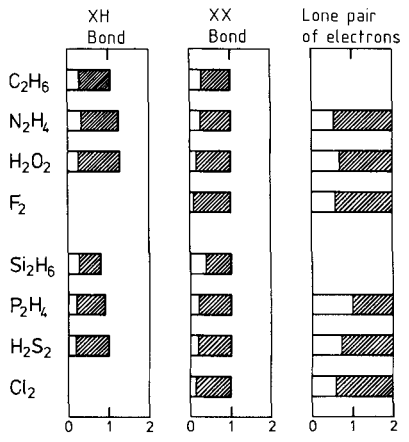

Fig. 15. Mulliken gross populations for the s and p valence AOs of X in the localized MOs of X_2H_{2n} molecules. Cf. legends to Figures 4 and 5.

In addition to Pauli repulsions between pairs of XH bonds and between XH bonds and lone pairs, which we encountered in our discussion of XH_n molecules, there exists in X_2H_{2n} molecules a repulsion between the lone pairs of the two X atoms, as discussed for X_2 molecules (Sections 4.2 and 4.3). While the first two repulsions can be reduced by isovalent hybridization, for the last-mentioned repulsion hybridization is rather less effective (as the comparison of NH_3/N_2 showed). Accordingly, the XX bonds in N_2H_4, H_2O_2 and F_2 are approximately pure p bonds, whereas mixing with s components is more pronounced in the XH bonds.

If the contributions to the XX overlap population from the localized MOs in the XX bond are compared (Table 3) in the series C_2H_6, N_2H_4, H_2O_2, F_2, a smooth variation is observed without any jump between C_2H_6 and N_2H_4. There is a jump, however, in the contributions of the remaining localized MOs to the XX overlap population. The repulsion of the CH bonds in C_2H_6 thus only slightly weakens the CC bond, whereas the repulsion of the lone pairs in N_2H_4, H_2O_2, and F_2 causes substantial weakening of the bond. This weakening is apparently responsible for the jump in the total σ-bond increments in proceeding from C_2H_6 to N_2H_4 (cf. Table 2). Nevertheless, some peculiarities are not easily understood. Why is the weakening of the XX bond through lone-pair repulsion almost the same for N_2H_4, H_2O_2, and F_2 although the number of lone pairs per X is 1, 2, and 3, respectively? A possible explanation is that a bond lengthening from N_2H_4 to F_2 occurs as a result of the lone-pair repulsion and that the net repulsion decreases with the bond length. Furthermore, the empirical σ-increments in Table 2 hardly change in going from NN via OO to FF, whereas the total overlap populations (Table 3) in this series show a distinct decrease. This certainly arises in part (as already discussed in Section 4.3 for the comparison of N_2/P_2) because the bond energy is determined not only by the overlap population but also by the ionization potential of X. The latter increases from N to F and to some extent compensates for the reduction in the overlap population. The fact that the SCF approximation upon which our population analyses have been based becomes increasingly poor along the series $C_2H_6 \ldots F_2$ may also play a role. The effects of electron correlation[96] in this series become increasingly important and lead to a strengthening of the bonding that is not reflected in the population analyses (based on SCF calculations).

Table 3. Mulliken XX overlap populations for X_2H_{2n}-molecules [a].

	C_2H_6	N_2H_4	H_2O_2	F_2
LMO for the XX bond	0.43	0.40	0.30	0.25
Remaining MOs	−0.05	−0.23	−0.22	−0.21
Total	0.38	0.17	0.08	0.04
	Si_2H_6	P_2H_4	H_2S_2	Cl_2
LMO for the XX bond	0.46	0.41	0.36	0.31
Remaining MOs	−0.06	−0.12	−0.16	−0.23
Total	0.40	0.29	0.20	0.08

[a] Cf. Fig. 15.

Let us now compare the X_2H_{2n} molecules of the first with those of the second row! The XX overlap populations arising from the localized MOs for the XX bonds are only slightly larger in the series Si_2H_6, P_2H_4, H_2S_2, Cl_2 (Table 3) than in the series $C_2H_6 \ldots F_2$. In contrast, the contributions of the remaining localized MOs to the total X overlap population, especially in P_2H_4 and H_2S_2, are quite different from the corresponding values for N_2H_4 and H_2S_2. This

confirms the reduced importance of lone-pair repulsion for the elements of the higher rows.

The total XX overlap populations illustrate why the σ-increments for the second row elements are greater than those for first row elements, particularly in comparing NN and OO with PP and SS, although, in general, second row atoms tend to form stronger bonds (cf. Figs. 3 and 10). The change in the overlap populations in going from H_2O_2 to H_2S_2 is so great that the variation in ionization potential from O to S—which operates in the opposite sense—is insufficient to reverse the trend.

Interestingly, the NN σ-overlap population in N_2H_2 (0.17) is almost the same as that in N_2 (0.17) (despite the different bond lengths), whereas in P_2H_4 it is rather larger (0.29) than in P_2 (0.23).

Notwithstanding the significant weakening of the XX bond for X = N or O by the repulsion of the lone pairs, the XX multiple bonds are stronger than for X = P, As or S, Se (cf. Fig. 10). This principally occurs because the valence electrons are bonded—even in the isolated atoms—more strongly in first row than in higher row atoms (cf. Section 4.3 and Fig. 1). Since the lone pair repulsion is included entirely in the σ-increments, the π-increments for the first row are accordingly larger than those for the higher rows.

4.6. Comparison of P_4 with P_8; Ring Strain in Phosphorus Rings

In view of the different σ- and π-bond increments for N and O, on the one hand, and P, S, and As, Se, etc., on the other, it is hardly surprising that the most stable allotropes of nitrogen and oxygen are N_2 and O_2 molecules, respectively, whereas for phosphorus and sulfur larger molecules (e.g. P_4, S_8) having only single bonds are preferred. The relative stability of the P_4 tetrahedron is nevertheless, surprising, for—as in tetrahedrane—considerable ring strain might be expected. Comparison of the atomization energy of P_4 (284 kcal/mol) with six times the PP σ-increment ($6 \times 48 = 288$ kcal/mol) indicates the absence of strain energy. The same conclusion is reached by comparing the thermochemical data for the isodesmic reaction $P_4 + 8\,PH_3 \rightarrow 6\,P_2H_4$ in which the number of PH bonds and PP bonds is maintained. According to calculations carried out by *Schoeller* and *Staemler*[98a], also cyclic $(PH)_3$ exhibits practically no strain energy. The corresponding strain energy in tetrahedrane is, however, 122 kcal/mol[97] and that of cyclopropane, 25 kcal/mol[98b,c].

It should not immediately be concluded that the absence of strain energy implies the absence of ring strain, since the reference energy of the PP single bond in P_2H_4 is already weakened (by repulsion of the lone pairs), even if the same repulsion is also present in P_4 and in $(PH)_3$. It is also rather surprising that a cubic P_8 species is unknown; this would also have only PP single bonds, and the valence angles would be very close to the optimal value for P of 92—94°, which should be more propitious than the tetrahedral angle.

Ab initio pseudopotential calculations[99,100] provide some useful insight[99] in comparing the molecules X_2, X_4, and X_8 (X = N, P, and As). As might be expected, the hypothetical N_4 species has a substantially higher energy than that of $2\,N_2$ (by more than 200 kcal/mol), whereas P_4 lies either close to or slightly below $2\,P_2$ in energy, depending on the level of sophistication of the calculation. The As_4 species is always well below $2\,As_2$ in energy. For P_4 the inclusion of d-AOs is decisive for the stabilization of P_4 with respect to $2\,P_2$, although the relative lowering of the energy by the dAOs amounts to only ca. 30 kcal/mol with a d-AO population of 0.10 in P_4 and 0.06 in P_2 (very similar values are found for N_2/N_4 and As_2/As_4). The role played by the d-AOs here is thus of much less importance than for hypervalent P compounds (cf. Sections 5 and 6), although it is certainly not insignificant. The conclusion reached in earlier work[101a] that the PE spectrum of P_4 can be accurately reproduced even without d-AOs—and that as a consequence the d-AOs are not important—was thus undoubtedly premature.

A calculation without d-AOs indicates that cubic P_8 is more stable than $2\,P_4$ by ca. 10 kcal/mol. Although *Trinquier* et al.[99] were not able to perform a calculation on P_8 with d-AOs, they argued persuasively that the contribution of d-AOs in cubic P_8 should be substantially smaller than that in tetrahedral P_4, with the result that with d-AOs P_8 should not be stable compared to $2\,P_4$. These authors also argue plausibly that parallel PP bonds repel each other and that this repulsion is more important than the ring strain in P_4.

Even though the precise relative energetic position of P_8 with respect to $2\,P_4$ is not known, it can be demonstrated by symmetry considerations similar to the Woodward-Hoffmann rules that the $P_8 \rightarrow 2\,P_4$ reaction is thermally forbidden[101b]. Accordingly, P_8 should not rearrange into $2\,P_4$ or vice versa, at least not unimolecularly. What is more likely to occur is a polymerization of P_8 to black phosphorus in which only a few of the bonds would have to "jump" and the valence angles would need to be increased only by a small amount. The possibility of such a polymerization has yet not been investigated theoretically, and it is not known whether cubic P_8 represents at least a local minimum in the potential hypersurface for the P_8 system.

Similarly, in black phosphorus only PP single bonds with evidently optimal valence angles occur, without any repulsion of parallel PP bonds. Presumably, there is also a metallic (delocalized) bonding contribution which has the effect that the cohesive energy per PP bond of 53 kcal/mol is considerably greater than the PP σ-increment (48 kcal/mol).

4.7. SiC and SiO Double Bonds

The SiC double bond resembles the SiO double bond in that it is less favored energetically than two SiC single bonds. From the bond energy increments we obtain ca. 78 kcal/mol for the dimerization energy of H_2SiCH_2 to the cyclic dimer (with an Si—C—Si—C ring), provided that the strain energy—which is not expected to be large—is neglected. On the basis of an ab initio calculation, *Ahlrichs* and *Heinzmann*[102] obtained a reaction energy of ca. 76 kcal/mol for this process. What is perhaps more interesting is that they found a barrier of only ca. 4 kcal/mol,

which suggests that the thermal dimerization is no longer symmetry—forbidden, unlike that of ethene.

Although the SiC bond is substantially polar, the SiO bond in e.g. oxosilane H_2SiO is even more polar. In fact, it is so polar that a description in terms of a semipolar bond $H_2Si^{\oplus}-O^{\ominus}$ approaches the real situation rather better than the traditional formulation with a double bond $H_2Si=O$[103]. This bond actually has a number of similarities to the genuine semipolar bond, in $H_3P^{\oplus}-O^{\ominus}$. There is even a similar d-AO population on the silicon atom in H_2SiO as that on the phosphorus atom in H_3PO[104] (0.2 and 0.3 electrons, repectively).

5. Molecules which Apparently Violate the Octet Rule

5.1. Hybrids with d-Involvement or Multicenter Bonds?

A significant difference in the chemistry of elements of the first and higher rows is the appearance of compounds such as SF_6, XeF_2, XeF_6, etc. which seem to violate the octet rule.

To describe the bonding in these molecules, two different models have been proposed[104b]:

(a) The involvement of d-AOs leading, for example, to sp^3d^2 hybrids[29,55].
(b) The formation of three-center, four-electron bonds without any significant d-AO contribution[105].

The formation of a three-center, four-electron bond is depicted in the lower part of Figure 16. In XeF_2, for example, three MOs can be constructed as linear combinations of the pσ valence AOs of the Xe on the two F atoms. Of the three MOs, one is bonding (σ_b), one nonbonding (σ_n), and one antibonding (σ_a) (the dσ-AO at σ_n drawn with dashed lines (cf. Fig. 16) should be ignored). Four electrons (two from the Xe and one each from the two F atoms) occupy the σ_b and σ_n MOs, so that overall bonding will occur[106].

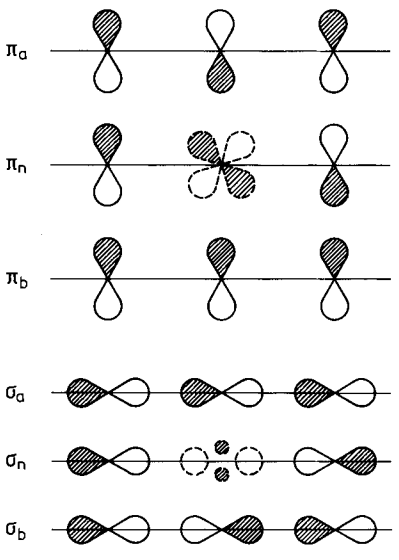

Fig. 16. MOs for a three-center, four-electron σ-bond (lower part of figure) and for backbonding (upper part of figure). The d-AOs not absolutely essential for this bond but which can reinforce it are sketched with broken lines.

The counterpart of this three-center, four-electron bond in VB theory would be mesomerism between two ionic structures

$$F^{\ominus}\cdots Xe^{\oplus}-F \longleftrightarrow F-Xe^{\oplus}\cdots F^{\ominus}$$

This formulation illustrates (as does the MO picture) that each of the F atoms bears approximately half a negative charge and that each XeF bond has a covalent and an ionic component. This bonding situation is favored[106,107] if the central atom (in this case Xe) has a small ionization potential and the outer atom (in this case F) is as electronegative as possible.

When d-AOs on the central atom (dashed lines in Fig. 16) are available for bonding, the σ_n MO can also become bonding, which has the overall effect of stabilizing the bond. In the hypothetical case that both pσ and dσ valence AOs on Xe were equally occupied, it would then be possible to speak of pd-hybrids.

5.2. Comparison of NH_3F_2 with PH_3F_2

It is instructive to compare the hypothetical molecule NH_3F_2 with the known[108] molecule PH_3F_2. This should enable us to understand the different behavior of N and P as respective representatives of the first and higher rows[109].

Both of these molecules may formally be constructed from a planar XH_3 unit and two F atoms such that the π-type lone pair on the XH_3 (similarly to the pσ-AO on Xe) forms a three-center, four-electron bond with the two p-AOs from the F atoms. If our conception of the role of the ionization potential for the central atom is correct, we should expect that an FXF bond is formed in both molecules, since both planar PH_3 and planar NH_3 have ionization potentials (9.9 and 10.9 eV, respectively) lower than that e.g. of Xe (12.10 eV). In fact, in the symmetric D_{3h} configuration (cf. Fig. 17) both PH_3F_2 and NH_3F_2 are stable with respect to planar XH_3 and an F_2 molecule[109].

For NH_3F_2 the stabilization is, however, only a few kcal/mol, whereas for PH_3F_2 it is 170 kcal/mol. The contribution of the d-AOs on the X atom to the bond energy has already been taken into account here (for NH_3F_2 ca. 7 kcal/mol, and for PH_3F_2 ca. 40 kcal/mol).

In this respect there is a clearcut quantitative difference between NH_3F_2 and PH_3F_2 but no qualitative difference. Qualitatively the two molecules behave differently with respect to a lowering of the symmetry from D_{3h} to C_{3v} (cf. Fig. 17). Although the potential hypersurface for PH_3F_2 does indeed have its minimum for D_{3h} symmetry, the energy of NH_3F_2 is lowered if the symmetry is reduced to C_{3v}. The most stable C_{3v} structure corresponds essentially to the ion pair $H_3NF^{\oplus}\cdots F^{\ominus}$[110]. The calculated values of the NF separation and the HNF bond angle in the $NH_3F^{\oplus}$ moiety are 1.41 Å and 107°, respectively, and for the other NF distance 2.06 Å. The NF bonds in the optimal D_{3h} structure appear to be unusually long at 1.70 Å, much too long for covalent NF bonds, which explains why the bonds

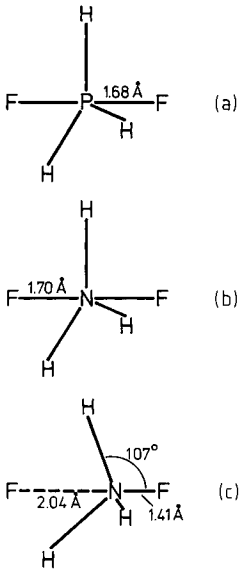

Fig. 17. Geometric structures of PH_3F_2 and NH_3F_2: (a) and (b) with D_{3h} symmetry; (c) lowering of symmetry to C_{3v}.

are only very weak. It is therefore much more favorable if one F atom is covalently bonded (at the normal distance) and the other F atom is correspondingly further away. There is not enough space around the nitrogen atom to accomodate five nearest-neighbors, although there is sufficient space available around the phosphorus atom[111a].

The population of the d-AOs (cf. Table 4) in H_3NF_2 is 0.05 (D_{3h} symmetry), which is the same as that in other "normal valent" compounds; in contrast, in H_3PF_2 the value is 0.27. This is nevertheless much lower than that required by *Pauling*'s sp^3d hybridization model, namely 1 d-electron. *Rundle*'s model based on an electron-rich multicenter bond is certainly closer to the real situation[111b].

Table 4. Mulliken gross population of the d-AOs in analogous molecules with atoms from the first or second rows [a].

	H_3N	H_3NF_2	H_3NO	H_2NOH

at O		0.05	0.01	0.03		

[a] Cf. [104a, 109]; [b] only axial F atoms.

5.3. Backbonding

The MOs shown in the upper part of Figure 16 are linear combinations of the p-AOs perpendicular to the molecular axis. Since all three π-AOs (in each of the two directions) are fully occupied or, in other words, the MOs (π_b, π_n, and π_a) are fully occupied, no overall bond is formed but rather a repulsion results. If, however, a dπ-AO on the central atom participates (dashed line in Fig. 16) and this makes the π_n MO bonding, an overall bonding interaction arises. Because charge is transferred from the central atom to the outer atoms in the σ-bond, whereas in the π-MO the transfer occurs (with d-AO involvement) in the opposite direction, one speaks of backbonding.

In PH_3F_2, the backbonding is relatively weak and corresponds to a population of the dπ-AO of 0.05. It is, however, much stronger in PF_5, where the dπ-AO population is 0.40[112]. Since the σ-bonds in PF_5 remove so much charge from the P atom, the backbonding is particularly effective. In contrast, the population of dσ is hardly larger than that in PH_3F_2 (0.24 as against 0.22 electrons).

To answer the question how realistic *Pauling*'s model is, one need only consider the population of the dσ. The population of dπ, and thus the presence of backbonding, has no place in *Pauling*'s model. The assumption of sp^3d hybrids in PF_5 is thus not even approximately correct and *Rundle*'s model should be given preference in chemistry courses. In this model three equatorial, two-center, two-electron bonds[113] and an axial, three-center, four-electron bond occur in PF_5, together with appreciable stabilization from π-type backbonding.

5.4. PH_5 and SH_4

Unlike PH_3F_2[108], there is currently no experimental evidence for the existence of the parent compound PH_5, although it has been thoroughly investigated quantum-chemically[114, 115]. The D_{3h} structure represents a minimum in the potential hypersurface with a sufficiently high barrier against decomposition into PH_3 and H_2. It should thus at least be metastable. PH_5 is quite a nonrigid molecule; the barrier to pseudorotation (ca. 2 kcal/mol) is of the same order of magnitude as the zero point energy of the vibration which initiates pseudorotation. The probable consequence is that the five H atoms are dynamically equivalent—as in $CH_5^{\oplus}$[116], although this species has an entirely different equilibrium structure.

It is a singularity of the potential surface for the reaction $PH_5 \rightarrow PH_3 + H_2$ that the transition states for a concerted process and for a zwitterionic intermediate $H_4P^{\oplus} \cdots H^{\ominus}$[115] scarcely differ in terms of their energies and that they are not separated by any significant additional barrier.

There is also no experimental evidence for the existence of SH_4. This molecule, too, is metastable with respect to decomposition into $SH_2 + H_2$, i.e. there is only a local minimum in the potential hypersurface. Its equilibrium structure does not, however, have C_{2v} symmetry in analogy with SF_4, as predicted by early quantum-chemical calculations[117], but is rather a flat square pyramid having C_{4v} symmetry with $r(SH) = 1.40$ Å and $\sphericalangle HSH = 155°$[118–120].

5.5. Localizability of Hypervalent Bonds

At first sight it may appear that one major difference between the models of *Pauling*[55] and *Rundle*[105] is that in the former all of the XR bonds, such as those in SF_6, are localized, two-electron, two-center bonds, whereas in the latter model a description only in terms of multicenter bonds is possible. *Hund*'s localization condition[62] is, in fact, ful-

filled if not only the s and p but also the d valence AOs from the central S atom are involved.

If, however, an ab initio calculation is performed and it is attempted to localize the canonical MOs via a unitary transformation according to *Boys*[65], the new MOs formed are astonishingly well localized in each of the bonds, even though *Hund*'s condition is not fulfilled and the occupancy of the d-AOs is substantially smaller than that corresponding to sp^3d^2 (or to sp^3d) hybridization. This observation is quite similar to that made in Section 3.3 in the discussion of the "normal-valent" hydrides MgH_2, AlH_3, and SiH_4, i.e. we observe a marked "hybridization defect" (in this instance a much too small d population) together with a very small "localization defect". As discussed in Section 3.3, this is due to the strong polarity of the XR bonds, i.e. to a significant transfer of charge from X to R. The MOs of the XR bonds are largely localized on the ligands. *Hund*'s localization condition applies strictly only to true covalent bonds. Contrary to *Pauling*'s supposition, the d valence AOs are not needed at all for a description of hypervalent molecules in terms of localized two-center bonds[104c].

6. Semipolar Bonds versus Hypervalence from Multiple Bonds

6.1. Comparison of H_3NO with H_3PO

If one excludes participation of d-AOs from the N or P in the bonding, the bond has to be formulated as semipolar, i.e. as $H_3X^{\oplus}-O^{\ominus}$, in which one electron has been transferred from X to O.

If d-AOs can participate, backbonding is possible in which charge is transferred from O to X. This should make the bond both stronger and less polar. If one full d-AO on X were occupied, one might be tempted to formulate a double bond. However, even in this hypothetical case, the formulation $H_3X=O$ would not be appropriate[66, 134], for there would then certainly not be one σ- and one π-bond (as in $H_2C=O$) but rather one σ-bond and two mutually perpendicular, half π-bonds. It would then be more justified to refer to a partial triple bond rather than to a double bond.

From the results of the population analysis in Table 4, it is seen that the d-AO population in H_3NO is very small and that in H_3PO it is only 0.30. We are thus far removed from the hypothetical case just discussed of a "quasi-double bond".

That an H_3NO species should exist, whereas an H_3NF_2 species does not, arises because the N atom can accomodate four but not five ligands (that the tautomeric H_2NOH is more stable than H_3NO probably explains why H_3NO has not been observed to date, unlike substituted amine oxides R_3NO or F_3NO).

Comparison of H_3NO with H_3PO indicates that the NO bond in H_3NO (1.38 Å) is typical of an NO single bond, whereas the PO bond in H_3PO (1.47 Å) is distinctly shorter than a genuine PO single bond (e.g. a bridging bond in P_4O_{10}: 1.63 Å) and can therefore be viewed as a double bond. If a calculation is performed without any d-AOs, the PO bond length obtained is 1.60 Å, i.e. a single bond, which serves to underline the significance of the d-AOs (despite their relatively small population). The polarity of the PO bond is not consistent with the presence of a double bond (or, more correctly, a partial triple bond). There is an effective charge of +1.33 on the P and −0.97 on the O, which is in much better accord with the presence of a semipolar bond than with that of a double bond (see Table 5).

Table 5. Effective charges (according to *Mulliken*) in analogous molecules with atoms from the first or second rows [a].

	H_3N	$H_3NF_2(D_{3h})$	H_3NO	H_2NOH		
N	+0.16	+0.75	+0.39	+0.08		
O			−0.76	−0.48		
F		−0.65				
	H_3P	H_3PF_2	H_3PO	H_2POH	H_2PF	H_2FPO
P	+0.34	+1.49	+1.33	+0.58	+0.76	+1.82
O			−0.97	−0.56		−1.01
F		−0.56			+0.60	−0.60
	H_2S	H_2SO	HSOH	HClO		
S, Cl	+0.05	+1.05	+0.28	+0.43		
O		−0.92	−0.44	−0.57		

[a] From calculations with d-AOs [104a, 109].

The Mulliken overlap populations (Table 6) and, in particular, the comparison of H_3NO and H_3PO with their respective isomers H_2NOH and H_2POH indicate that the XO bond in H_3NO is weaker than that for a single bond; in contrast, the XO bond in H_3PO is much stronger than that for a single bond. The use of the *Ahlrichs-Heinzmann* population analysis[60], which is here less dependent on the basis set, shows the same trends[109].

Table 6. Mulliken overlap populations for analogous molecules with atoms from the first or second rows [109].

		H_2NOH	H_3NO	H_2POH	H_3PO	HSOH	H_2SO	HClO
without d-AOs	XO	0.54	−0.01	0.20	0.19	0.17	−0.03	−0.16
	XH	0.74	0.73	0.61	0.63	0.54	0.55	0.62
with d-AOs	XO	0.60	0.35	0.35	0.71	0.31	0.47	0.11
	XH	0.74	0.79	0.64	0.75	0.65	0.63	0.69

Table 7 lists the bond energies of a variety of XO bonds both from quantum-chemical calculations[104a] and from thermochemical data[121–124]. The NO and SO bond energies are only slightly larger than the corresponding σ-in-

Table 7. Bond energies for semipolar XO bonds (in kcal/mol).

H_3NO:	53	H_3PO:	111	H_2SO:	59
		H_2FPO:	127	HClO:	−1 [a]

B) Empirical [121–124]

F_3NO:	66	F_3PO:	129		
		$(CH_3)_3PO$:	139	$(CH_3)_2SO$:	87
		$(C_2H_5O)_3PO$:	148		
		Cl_3PO:	122		

[a] HClO is not bound with respect to $HCl+O(^3P)$, although it does represent a local minimum on the potential hypersurface.

crements (Table 2), while the strength of the semipolar PO bond lies between that for a double and a triple bond.

Assessment of all these criteria leads to the conclusion that H_3PO has a semipolar PO bond which is stabilized by some backbonding to such an extent that in many respects it behaves like a double bond (or rather a partial triple bond).

6.2. Bond Strengthening by Fluorine- or Alkyl-Substitution

A marked variation in properties is observed even for the same type of bonds with different substituents. When speaking of the stabilization of bonding by substitution, it must be pointed out that the mechanisms for alkyl- and fluorine-substitution are quite different. Stabilization by methyl groups arises partly from stabilization of the positive charge and partly from destabilization of the unprotonated bases as a consequence of the steric hindrance of the substituents[125]. In order to prepare the lone pair for the addition of a proton (or for the formation of a semipolar bond), the RPR angle need only be opened slightly, at least to a much lesser extent than the HPH angle in H_3PO. The PO bond, as such, is not strongly influenced[104a].

The use of fluorine as a substituent, on the other hand, leads to the removal of electronic charge from P (or N or S), to a lowering of the energy of the d-AOs, and to a reinforcement of the backbonding. This strengthens the PO bond and reduces its length. The net result is a substantial measure of backbonding, even in F_3NO where the NO bond is unusually short (1.16 Å)[126].

6.3. Ylides

The analogy between phosphane oxides, such as H_3PO, and ylides, such as methylene phosphorane H_3PCH_2, is also of interest. In H_3PCH_2 the PC bond is essentially semipolar with some backbonding[127]. It is remarkable that there is almost free rotation of the CH_2 group with respect to the PH_3 group[127].

If the CH_2 group is replaced by BH_3, there is no doubly occupied AO available for backbonding and hence only one semipolar bond can be formed. One then obtains a very low bond energy for XB and, rather surprisingly, a larger bond energy for NB (27 kcal/mol) than for the BP bond (17 kcal/mol)[128].

In principle, F_4SCH_2 is also an ylide, even though the authors who first reported this compound preferred a formulation with a double bond[23]. One of the arguments used was the short SC separation and another was the high rotational barrier. No quantum-chemical calculation has yet been performed which can finally settle the issue of the bonding in this particular case. We may confidently expect, however, that the backbonding will be especially pronounced and stronger than in ordinary ylides. Since backbonding is possible only at right angles to the CH_2 plane, there will be both one σ- and one π-bond present. In this respect, F_4SCH_4 as well as other ylides such as H_3PCH_2 correspond more to π-electron systems in organic chemistry with one σ and one double bond than do molecules such as F_4SO or H_3PO, where two perpendicular π-bonds are possible and where partial triple bonds rather than double bonds are realized.

6.4. Several Semipolar XO Bonds at the Same X Atom

Just as the bonding behavior of many electron-rich fluorides can be understood—at least qualitatively—by attaching three-center FXF bonds to normal-valent molecules[129], we may also attach semipolar XO bonds to normal-valent compounds. Molecules such as HClO, H_2SO, or H_3PO are in fact of this type. One can further add an additional semipolar XO bond to arrive at $HClO_2$ or H_2SO_2, or one can start from OH-substituted molecules, such as HOCl, to obtain HOClO, $HOClO_2$, $(HO)_2SO$, $(HO)_2SO_2$, or $(HO)_3PO$. Many very well-known inorganic compounds may be formally built up in this way. Accordingly, an understanding of the semipolar XO bond is valuable not only in "exotic" compounds such as the phosphane oxides but also for the interpretation of the electronic structures of the best known acids H_2SO_4 and H_3PO_4 and their salts. Should sulfuric acid be represented according to the first or second of the following two formulations?

In the light of quantum-chemical studies[130], the first (semipolar) structure appears to be closer to reality. The backbonding which is superimposed on this semipolar structure is difficult to depict in a structural formula.

A further question which we may pose is: Why are HNO_3, $NO_3^{\ominus}$ or $CO_3^{2\ominus}$ monomeric, whereas $PO_3^{\ominus}$ or $SiO_3^{2\ominus}$ are polymeric—or at least oligomeric—and why do the ortho-anions $NO_3^{3\ominus}$ and $CO_3^{4\ominus}$ not exist?

In $NO_3^{\ominus}$ or $CO_3^{2\ominus}$ the π-bonds are fairly strong and lead to a significant amount of resonance stabilization. In monomeric $PO_3^{\ominus}$ or $SiO_3^{2\ominus}$ both the π-bonds and resonance are weaker and structures possessing only σ-bonds have a lower energy, especially since further stabilization can be attained by backbonding (which is hardly feasible for first row elements) and appropriate Madelung terms.

A special feature of the oxo acids of phosphorus is that in H_3PO_3, for example, an H atom is bonded to a P atom and not to an O atom, as in H_2SO_3. In this context it should be pointed out that quantum-chemical calculations indicate that H_3PO and H_2POH have almost the same energy, while HSOH is significantly more stable than H_2SO[104a].

It is also interesting to note that, although electron-rich fluorides often have inequivalent sets of fluorine substituents, the O atoms in electron-rich oxides, such as SO_2 and SO_3, are always equivalent. In SO_2 the SO bonds are so strong that isovalent hybridization takes place and the OSO angle is ca. 120° (as demanded by sp^2 hybridization), whereas H_2S or SF_2 have bond angles close to 90°.

7. Conclusions and Outlook

The chemical bond is a highly complex phenomenon which eludes all attempts at a simple description. The distinction we made here between the bonds of "light" and "heavy" main group elements is thus only an approximation to the real situation. Accordingly, the central thesis that the differences in the two classes of elements derive from the different relative spatial positions of the p valence AOs with respect to the s valence AOs should not be taken too literally. The more one attempts to provide detailed descriptions, the more nebulous the differences tend to become. Furthermore, one is also confronted with a number of contradictions, such as that concerning the hybridizations found in H_2O and H_2S, where the differences are much smaller than might be expected from the different valence angles.

In our discussion we have not investigated the basic physical mechanism involved in chemical bonding, but have assumed that chemical bonding is principally associated with the overlapping of atomic orbitals. A rigorous analysis[57, 64, 131–133] would certainly make everything much more complicated.

With some reservations, however, it may be said that the differences in the chemical behavior of the main group elements of the first and higher rows can be explained. We claim that it is rather the higher row elements which behave normally and those from the first row which are anomolous. On the one hand, first row elements display a pronounced tendency to hybridize and, on the other, to form multiple bonds which are surprisingly strong.

Hybridization is very effective in the first row because the radial factors for these and p valence AOs strongly overlap (which is not the case in the higher rows). That isovalent hybridization—which does not increase the valence—is made use of, even though it costs promotional energy, is due only partly to a direct strengthening of the bonds (because of the improved overlap of the hybrid AOs) but, mainly to the possibility of reducing the repulsion of lone pairs of electrons by hybridization. Both of these effects influence the valence angle.

The weakness of the σ-bonds for first row elements is largely due to the repulsions of lone pairs of electrons. This repulsion is included in the σ-increments. The apparent strength of the π-bonds results from a combination of several effects. One of these is that the lone-pair repulsions enter the σ-increments but do not affect the π increments.

Ab initio calculations provide some insights concerning the nature of the bonds in molecules which appear to violate the octet rule. *Rundle*'s model[105], in which three-center, four-electron or other electron-rich bonds play a decisive role, reflects the true situation more accurately than *Pauling*'s model[29, 55] in which, e.g., sp^3d^n hybrids are assumed. Although d-type AOs are very important as polarization functions to correctly describe hypervalent molecules even qualitatively, their population is in general much smaller than that required by the hybridization model. Moreover, the d-AOs are largely involved in rather complicated multicenter bonds, especially in backbonding. The XO bond must be viewed as semipolar in terms of its charge distribution not only in the phosphane oxides or sulfoxides but also in most oxo acids, such as H_2SO_4 and their anions. Although the d-AOs have a strongly stabilizing effect, there is no justification for a formulation involving double bonds, as was the case in the early days of chemistry before the octet rule was known[134]. There is no "valence extension" which would justify the formulation, e.g., of the S atom in SF_6 or H_2SO_4 with six valence bonds since this simply does not occur.

Theoretical chemistry has several tasks. Among these is to provide a qualitative understanding of the chemical bond, which has been the primary aim in this article. However, it is also capable of making quantitative statements on the structure and properties of individual molecules, which is of especial interest when the molecules in question are not yet known. For small molecules, in particular, it is simpler nowadays to use a quantum-chemical calculation to decide if they are stable—or at least metastable—and what structures they possess. A number of examples of unknown molecules such as H_3PO, H_2SO, PH_5, and P_8 have been discussed here. Ab initio calculations are often very helpful precisely for those compounds of the higher row main group elements where a paucity of experimental work has been carried out and where intuition cannot be relied upon. Without a good ab initio calculation, one would hardly have guessed that silaacetylene Si_2H_2[135] has a nonplanar, doubly bridged equilibrium structure with C_{2v} symmetry (with H_2SiSi and nonlinear *trans*-HSiSiH as metastable isomers).

The number of colleagues who have contributed to this article with valuable suggestions is too great for me to mention all of them by name here. Of especial value for the successful outcome of this work were the discussions and correspondence held with R. Ahlrichs, H. Kollmar, W. W. Schoeller, W. H. E. Schwarz, and V. Staemmler. All the colleagues mentioned here and those who have not been mentioned by name are thanked for their contributions. I am also grateful to all of my co-workers in Bochum and in particular to M. Schindler and H. Wallmeier. The numerical calculations were carried out on the Cyber 175 and 205 of the computer center at the Ruhr-Universität.

Appendix 1

Sources for the dissociation energies used (D_0^0 values were used, especially for diatomic molecules, whenever available; otherwise ΔH_0 values were used, or in a few cases even ΔH_{298} values when ΔH_0 values were not tabulated. Since the errors usually amount to several kcal/mol, no standardization has been attempted:

Diatomic hydrides XH with X from the first or second row: "Recommended" D_0 values from ab initio calculations by *Meyer* and *Rosmus*[141]. In general, these agree well with the data of Huber and Herzberg[87]. Values for the monohydrides XH with X from the third to fifth row are from *Huber* and *Herzberg*[87], and only RbH is from *Gaydon*[142].

The polyhydrides XH_n with X from the first or second row have values from JANAF[121], but BeH_2[143], MgH_2[78],

and AlH_3[78] are from ab initio calculations by *Ahlrichs* et al. Values for polyhydrides where X is an element from the third and fourth rows are from *Barin* and *Knacke*[122].

For the monofluorides XF the values are taken from the data of *Huber* and *Herzberg*[87], but those for OF, PF, and SF are from JANAF[121], and TeF, BiF are from *Barin* and *Knacke*[122].

The values for polyfluorides XF_n are taken from JANAF[121], but those for MgF_2, GeF_4, AsF_3, AsF_5, SeF_4, SeF_6, TeF_2, TeF_4, and TeF_6 are from *Barin* and *Knacke*[122]; the values for SrF_2 and BaF_2 from *Rossini* et al.[123] and for SeF_2 and XeF_6 from [144].

The values for homonuclear diatomic molecules are taken from *Huber* and *Herzberg*[87].

Appendix 2

Sources for the energy increments in Table 2:

CC-σ: From ΔH for C_2H_6 and CH_4[124], assuming that the CH contributions in both molecules are identical, we obtain the value 78.9 kcal/mol. Values of around 80 kcal/mol are obtained from the ΔH values for other alkanes, while from the cohesive energy of diamond 85.5 kcal/mol is indicated. The dissociation energy for $C_2H_6 \rightarrow 2\,CH_3$ is 88 kcal/mol[145]. This is larger than the increment for the CC bond because the same bonding energy for each of the CH bonds in C_2H_6 as that in CH_4 has been assumed, which is ca. 2 kcal/mol greater than in CH_3.

CC-π: From ΔH for C_2H_5 and CH_3[124], assuming that the CH increments in C_2H_4 and CH_3 are identical, we obtain 148.7 kcal/mol for the energy of the double bond. Using the σ-increment from C_2H_6 and CH_4, we obtain a π-increment of 69.8 kcal/mol. From the dissociation energy of the C_2 molecule with a double π-bond, 72 kcal/mol per CC π-bond is obtained. A π-increment of ca. 65 kcal/mol is estimated from the ΔH value for acetylene. The dissociation energy for $C_2H_4 \rightarrow 2\,CH_2$ amounts to 167 kcal/mol[145], which together with the dissociation energy of C_2H_6 would give a π-increment of 79 kcal/mol. Even the rotational barrier in ethane can be regarded as a measure of the strength of the π-bond; this is 65 kcal/mol[146].

NN-σ: From ΔH for N_2H_4 and NH_3[124], assuming equivalent NH bonds, we obtain 38 kcal/mol. The dissociation energy for $N_2H_4 \rightarrow 2\,NH_2$ is 56 kcal/mol and for $N_2(CH_3)_4 \rightarrow 2\,N(CH_3)_2$, 42 kcal/mol[145]; the NC bonds are obviously less affected than the NH bonds by the dissociation.

NN-π: From the dissociation energy of N_2 and a σ-increment of 38 kcal/mol, we obtain a π-increment of 94 kcal/mol.

OO-σ: From ΔH for H_2O_2 and H_2O[124], assuming identical OH bonds, the value 35 kcal/mol is obtained. The dissociation energy for $H_2O_2 \rightarrow 2\,OH$ is 51 kcal/mol, whereas that for $(CH_3)_2O_2 \rightarrow 2\,CH_3O$ is 36 kcal/mol[145].

OO-π: Combination of the σ-increment of 35 kcal/mol with D_0 from O_2 yields a π-increment of 83 kcal/mol.

SiSi-σ: From ΔH for Si_2H_6 and SiH_4[124], we obtain 46 kcal/mol and from $Si_2H_6 \rightarrow 2\,SiH_3$, 45 kcal/mol[145]. From the cohesive energy of solid Si[121], we arrive at 54 kcal/mol.

SiSi-π: If we assume both a σ and a π-bond in the Si_2 molecule, then using a σ-increment of 46 kcal/mol we obtain a π-increment of 28 kcal/mol.

PP-σ: From ΔH for P_2H_4 and PH_3 or PH_2[124], we obtain a value of 48 kcal/mol and from ΔH for black phosphorus[122] 53 kcal/mol.

PP-π: $D_0(P_2)$ and the above PP σ-increment lead to a value of 34 kcal/mol.

SS-σ: The ΔH value for $(CH_3)_2S$ and $(CH_3)_2S_2$[124] afford a value of 64 kcal/mol and those for H_2S and H_2S_2, 58 kcal/mol. The dissociation energy for $H_2S_2 \rightarrow 2\,HS$ is 66 kcal/mol and from ΔH for S_8[145] we arrive at 64 kcal/mol.

SS-π: From D_0 for the S_2 molecule and a σ-increment of 64 kcal/mol, we obtain 37 kcal/mol.

GeGe: σ-Increment from ΔH for Ge_2H_6 and GeH_4[124] and π-increment from D_0 for Ge_2.

AsAs: σ-Increment from ΔH for As_4, assuming no ring strain, and π-increment from D_0 for As_2 and from the σ-increment.

SeSe: σ-Increment from Se_6[122] and the π-increment from this and from Se_2[122].

CN: σ-Increment from $(CH_3)_3N$ and CH_4; π-increment from HCN[124].

CO: σ-Increment from CH_3OH, CH_4, and H_2O[124] or from the dissociation $(CH_3)_2O \rightarrow CH_3O + CH_3$[145].

NO: σ-Increment from an ab initio calculation on H_2NOH[104] and from ΔH for NH_3 and H_2O; π-increment from NOF and NF_3[121].

SiC: σ-Increment from $Si(CH_3)_4$ and CH_4[124] (from solid SiC[122] one would estimate a value of 74 kcal/mol); π-increment from the SiC molecule[121].

PC: σ-Increment from $P(CH_3)_3$[124] and CH_4; π-increment from the PC molecule, assuming the presence of a 1.5-fold π-bond.

SC: σ-Increment from $(CH_3)_2S$[124] and CH_4; π-increment from an ab initio calculation[103] on H_2CS. From the CS molecule—assuming the presence of a double π-bond—we obtain a π-increment of 58 kcal/mol.

SiO: σ-Increment is rather uncertain and is taken from $(CH_3)_3SiOSi(CH_3)_3$ and $(CH_3)_4Si$[124]; with the ΔH values of other molecules, strongly differing values are obtained. The π-increment is from an ab initio calculation on H_2SiO[103]. From the SiO molecule a value of 45 kcal/mol would be obtained, assuming the presence of a double π-bond.

PO: σ-Increment from an ab initio calculation on H_2POH[104]; π-increment from the PO molecule in which a 1.5-fold π-bond has been assumed. From P_4O_6[121] one would obtain a σ-increment of 99 kcal/mol.

SO: σ-Increment from an ab initio calculation on HSOH[104]; π-increment from the SO molecule.

---

[1] This concept is used as the counterpart of solid-state chemistry. It is not possible here to account for the solid-state chemistry of the higher row main group elements. Much of what is discussed, however, applies to the chemical bonding in solids.

[2] Double bonds will be called "genuine" when, as in ethylene, both a covalent σ- and π-bond is present, and the π component can be constructed from the p-AOs of the atoms involved. "Non-genuine" double bonds are then those consisting of a semipolar σ-bond upon which is superimposed some "backbonding" involving participation of d-AOs, provided certain properties (bond lengths, force constants, etc.) indicate a bond strength corresponding approximately to that of a double bond (cf. Section 7). The double bonds in the molecules C_2 and O_2 play a special role (cf. e.g. [3], p. 131 ff.).

[56] For observable states in free atoms, a distinction is made between the "configuration", e.g. $1s^2 2s^2 2p^2$ and the "term", e.g. ^3P_g. Both of these together characterize the state. A valence state cannot be attained by the free atom. Previously, the valence state of carbon, for example, was viewed as a statistical mixture of the various possible terms for the $1s^2 2s^1 2p^3$ configuration. Such an approach is possible only for configurations having integral occupation numbers. It is our intention to assign no reality to any valence state outside the molecule and thus to permit configurations having nonintegral occupation numbers cf. also [59]. It should be mentioned that *Ruedenberg*[57] distinguishes between the valence state and the promotion state.

[58] R. S. Mulliken, *J. Phys. Chem. 72* (1950) 4493.
[59] It is a fundamental difficulty of all population analyses that any resolution of the charge density in a molecule into atomic contributions is not unique. All of the usual analyses are based on the LCAO approximation and are thus basis-dependent. Accordingly, the population analysis of an individual molecule is, in general, not very meaningful, while the comparison of different molecules with the same or comparable AO-basis sets is significant. It is always of importance that the basis set is balanced, i.e. of comparable quality for all of the atoms involved. A population analysis proposed by *Ahlrichs* and *Heinzmann* [60] exhibits only a small dependence on the choice of the basis set. However, here we have chosen *Mulliken*'s analysis because it is simpler and better known.
[60] R. Heinzmann, R. Ahlrichs, *Theor. Chim. Acta 42* (1976) 33.
[61] The basis sets are specified in the legends to the figures. For a classification of AO basis sets see [66]. Objections can certainly be raised that we are relying on SCF calculations and not using wave functions which account for electron correlation (cf. [34]). The SCF approximation certainly has many drawbacks, although it cannot be denied that it generally provides good values for electron densities—upon which the population analyses are, of course, based.
[62] The Hund localization condition must be fulfilled, i.e. it must hold for each atom that the number of nearest neighbors is equal to the number of valence electrons involved and to the number of available valence AOs. For details see [3], p. 210.
[63] A unitary transformation of MOs is e.g. the conversion of a set ψ_k into a set φ_k according to $\varphi_k = \sum_i U_{kl}\psi_l$, where (provided all parameters are real) $\sum_l (U_{kl})^2 = 1$; $\sum_l U_{kl} U_{ml} = 0$ for $m \neq l$. An example would be $\varphi_1 = \frac{1}{\sqrt{2}}(\psi_1 + \psi_2)$; $\varphi_2 = \frac{1}{\sqrt{2}}(\psi_1 - \psi_2)$. If, within the framework of the SCF approximation, one starts from a wave function for which the ψ_l MOs are doubly occupied, the total wave function is not changed by conversion of the ψ_1 to φ_1 (other than by a physically irrelevant constant factor). For further details see [3], p. 200 or [64].

[67] For a quantitative formulation of this connection see [3], p. 246.
[68] We do not claim that the polarity of the CH bond in methane is such that the C atom bears a negative charge. One can easily select an AO-basis set for which a charge displacement in the opposite direction is found. Only the trends are relevant here, e.g. the comparison of CH_4 with SiH_4 or with NH_3. The question whether the C atom is "really" positive or negative is not very meaningful.
[69] Unfortunately, the bond lengths in the polyhydrides [70] are, in general, not known accurately enough. Moreover, the differences between r_e and r_z [71] and other average distances are of the same order of magnitude as the effects in which we are interested.

[72] For planar XH_3 molecules, equations (10), (14), and (15) must be replaced by

$$\psi_1 = c_1 s + c_2(h_1 + h_2 + h_3)$$

$$\psi_2 = c_3 p_x + \sqrt{2}\, c_4(h_1 - \tfrac{1}{2}h_2 - \tfrac{1}{2}h_3)$$

$$\psi_3 = c_3 p_y + \sqrt{\tfrac{3}{2}}\, c_4(h_2 - h_3)$$

$$d_l = \frac{c_2 - c_4}{c_2 + 2c_4}; \quad d_{hy} = \frac{c_1 - c_3}{c_1 + 2c_3}; \quad \langle hy|hy\rangle = \frac{c_1^2 - c_3^2}{c_1^2 + 2c_3^2}$$

For tetrahedral XH_4 molecules the following relations hold:

$$\psi_1 = c_1 s + c_2(h_1 + h_2 + h_3 + h_4)$$
$$\psi_2 = c_3 p_x + c_4(h_1 + h_2 - h_3 - h_4)$$
$$\psi_3 = c_3 p_y + c_4(h_1 - h_2 - h_3 + h_4)$$
$$\psi_4 = c_3 p_z + c_4(h_1 - h_2 + h_3 - h_4)$$

$$d_l = \frac{c_2 - c_4}{c_2 + 3c_4}; \quad d_{hy} = \frac{c_1 - c_3}{c_1 + 3c_3}; \quad \langle hy|hy\rangle = \frac{c_1^2 - c_3^2}{c_1^2 + 3c_3^2}$$

[88] According to Koopmans' theorem [89], the magnitude of the ionization potentials of a molecule should be roughly equal to the SCF energies of the MOs of corresponding symmetry. Although this is never true quantitatively, the orders of ionization potentials and MO energies do usually agree. In the case of N_2 even this is found not to be true.

[106] Whereas simple MO theory has no difficulty in describing three-center, two-electron bonds such as that in $H_3^{\oplus}$, problems do arise in the description of three-center, four-electron bonds since for $H_3^{\ominus}$ it incorrectly predicts a strong bond with respect to H_2 and $H^{\ominus}$. The failure of simple MO theory for $H_3^{\ominus}$ is not easy to understand (cf. e.g. [3], p. 160). It can be shown, however, that simple MO arguments are reliable in the case of XeF_2 molecules.

A Convenient Method for the Preparation of 1-(*tert*-Butyloxycarbonyl)pyrroles**

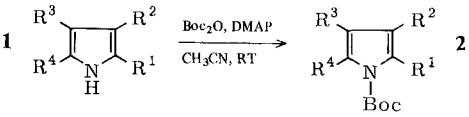
By *Leif Grehn* and *Ulf Ragnarsson**

In connection with structure-activity studies on the antiviral antibiotic distamycin A[1], we prepared analogues without an alkyl substituent on the pyrrole nitrogen and noticed that under certain conditions marked pyrocoll formation occurred[2]. We believed that the *tert*-butyloxycarbonyl (Boc) moiety might serve as a satisfactory protecting group for the pyrrole nitrogen, since deprotection with trifluoroacetic acid (TFA) is compatible with our synthetic scheme[2]. We report here a mild, fast and convenient procedure which gives 1-Boc-pyrroles in excellent yields.

The two Boc derivatives **2a**[3] and **2i**[4] were previously prepared by generating the corresponding anion with a strong base and subsequent treatment with $BocN_3$. Preliminary experiments, however, indicated that treatment of **1h** with $BocN_3$ or Boc_2O in benzene in the presence of KO-*t*Bu/[18]crown-6 resulted in incomplete reaction accompanied with formation of tar. Less severe conditions, successful for protection of tryptophan[5], were also discouraging: Thus, when **1h** was allowed to react with $BocN_3$ in CH_2Cl_2 in the presence of excess solid NaOH and the phase transfer catalyst tetra-*n*-butylammonium hydrogen sulfate, only discolored mixtures of **1h** and **2h** were formed. Even after prolonged reaction time, no trace of **2h** could be detected on treatment of **1h** with $BocF/NEt_3$ in anhydrous ether[6].

An interesting method for the 1-acetylation of pyrrole derivatives has been published[7], and a slight modification (Scheme 1) of this procedure proved successful in converting a wide range of pyrroles into the corresponding 1-Boc-derivatives. When **1h** was allowed to react with Boc_2O in CH_2Cl_2 with NEt_3 as base in the presence of the powerful acylation catalyst 4-dimethylaminopyridine (DMAP)[8–11], pure **2h** was obtained in 89% yield. The reaction also proceeded without base since liberation of CO_2 shifted the equilibrium to the product side. Catalytic amounts of DMAP were, however, required, and Boc_2O could not be replaced by $BocN_3$ in this reaction.

Under these conditions **1b**, **1c** and **1f—1j** reacted smoothly, affording **2b**, **2c** and **2f—2j** in satisfactory yields; however **1a**, **1d** and, particularly, **1e** reacted more slowly and ethyl 5-nitropyrrole-2-carboxylate was completely inert. CH_3CN and CH_2Cl_2 appear to be the solvents of choice and, at least among the more unreactive substrates, CH_3CN was more propitious. Other common solvents seemed less suitable in this reaction.



a, R^1–R^4 = H; **b**, R^1 = CO_2Et, R^2–R^4 = H;
c, R^1 = $COCCl_3$, R^2–R^4 = H; **d**, R^1 = CO_2Et, R^4 = Me, R^2, R^3 = H; **e**, R^1 = CO_2Et, R^2, R^4 = Me, R^3 = H; **f**, R^1, R^3 = CO_2Et, R^2, R^4 = Me; **g**, R^1 = CO_2Bzl, R^3 = NO_2, R^2, R^4 = H;
h, R^1 = CO_2Bzl, R^3 = BocNH, R^2, R^4 = H

1i, Indole; **1j**, 3-Methylindole

Scheme 1.

Table 1. Yields and physical data of the Boc-derivatives **2a—2j** [l].

[a] All new compounds gave satisfactory elemental analyses (C,H,N). [b] For synthesis of starting material, see [14]. [c] Crude product. [d] DEAEA-treatment omitted. The crude product contained a few % Boc_2O (^{1}H-NMR). [e] CH_2Cl_2 as solvent gave 89% yield. [f] Uncorrected. [g] Lit. [3]: 91—92°C/20 torr. [h] From petroleum ether. [i] From CH_2Cl_2/petroleum ether. [j] Lit. [4]: 110°C/0.08 torr. [k] Not consistent with published spectrum [4]. [l] Experimental: DMAP (122 mg, 1.00 mmol) and Boc_2O (2.62 g, 12 mmol) were added to a stirred solution (or suspension) of **1a—1j** (10 mmol) in dry CH_3CN (10—20 mL) at RT. Evolution of gas commenced, and after a few minutes a clear solution was obtained. After 1 h, all starting material had been consumed (TLC); **1a** and, particularly, **1e** required at least 15 h for complete reaction. For **2a—2c**, **2f**, **2i**, and **2j**, excess Boc_2O was destroyed by DEAEA (349 mg, 3.0 mmol) (10 min stirring). The crude products were obtained by partitioning between ether (100 mL) and 1 M $KHSO_4$ (50 mL), washing the ether extract with 25 mL portions of 1 M $KHSO_4$ (5×), water (1×), 1 M $NaHCO_3$, and brine (3×), and subsequent drying ($MgSO_4$). The solids **2g**, **2h** were washed with cold petroleum ether (40/60) to remove excess Boc_2O and then crystallized. The oily **2a—2f**, **2i**, and **2j** were dissolved in petroleum ether, treated with Norite, and evaporated to dryness (**2a** volatile!), affording colorless oils. Products **2a**, **2b**, **2i**, and **2j** were distilled under reduced pressure. Analytically pure samples of **2b—2f** were obtained by crystallization from petroleum ether (10 mL/g, −70°C).

The work-up procedure (Table 1) was sometimes simplified by trapping excess Boc_2O in the reaction mixture by brief treatment with 2-diethylaminoethylamine (DEAEA) followed by acid extraction[12]. Excess DEAEA and extended reaction times should, however, be avoided in these work-ups, since many Boc-pyrroles are decomposed by strong bases. Thus, **2g** decomposed completely within 5 min in CH_3CN at room temperature in the presence of a slight excess of DEAEA.

The TFA-mediated removal of Boc from **2h** proceeded smoothly, affording essentially pure benzyl 4-aminopyrrole-2-carboxylate. By means of our previously described procedure[13], **2f** was reconverted into **1f** in 97% yield. When **2j** was treated with TFA (RT, 2 min), 3-methylindole-1-carboxylic acid could be isolated in 90% yield. Decarboxylation was effected by refluxing in benzene, giving pure **1j** as the sole product.

In view of these findings, the possibility of utilizing the Boc-group for protecting the indole moiety in tryptophan has been considered. Although recent work has suggested the 2,2,2-trichloroethoxycarbonyl (Troc) and the benzyloxycarbonyl (*Z*) groups as suitable tryptophan-protecting groups[5], the Boc-group could be advantageous in some cases.

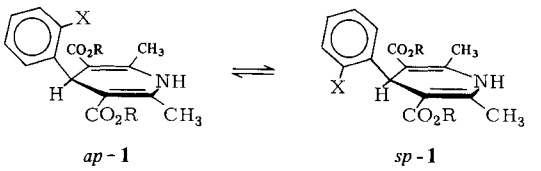
[14] The starting material was prepared from 4-nitro-2-pyrrolecarboxylic acid by analogy to the synthesis of **1h** [2]. The yield of crude product containing a nonpolar impurity was 84%. Recrystallization from toluene (50 mL/g, Norite) afforded pure **1g** as white crystals: m.p. = 149.5–150.5°C; ^{1}H-NMR ($CDCl_3$): $\delta = 7.73$ (q, 1H), 7.40 (pert. s, 6H), 5.35 (s, 2H).

Rotational Barriers of 4-Aryl-1,4-dihydropyridines (Ca Antagonists)

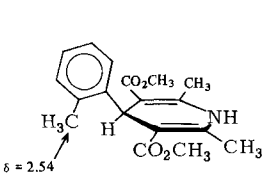
By *Siegfried Goldmann** and *Walter Geiger*

In recent years, 1,4-dihydropyridines **1** have gained considerable importance as calcium antagonists (e.g. nifedipine ($R = CH_3$, $X = NO_2$), the biologically active constituent of Adalat®)[1]. These compounds occur either as the *sp*-rotamer, in which the substituent X and the hydrogen atom at the 4-position are *synperiplanar*, or as the *ap*-rotamer, in which X and the aforementioned hydrogen atom are *antiperiplanar*.

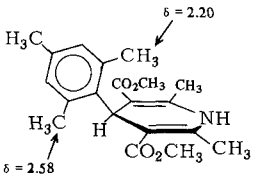


ap-**1** ⇌ *sp*-**1**

Whereas rotamers can be detected in the analogously structured 9-arylfluorenes[2], they have not been observed in the 1,4-dihydropyridines **1**[3]. To gain information about the "pharmacologically active conformer", we synthesized the model compounds **1a**[4] and **2**[5] and showed that the *ap*- and *sp*-forms exist in a rapidly established equilibrium which, however, lies heavily in favor of the *sp*-form.



1a



2

The 200 MHz ^{1}H-NMR spectrum of **2** at room temperature displays a broad singlet at $\delta = 2.39$ ($CDCl_3$) for the two *ortho*-methyl groups. Upon cooling the solution, coalescence occurs at $-18°C$ ($\Delta G^+(-18°C) = 51.1$ kJ/mol), whereas two separate signals ($\delta = 2.20$, 2.58) are observed at $-50°C$. Compared to the analogous fluorene ($\Delta G^+ > 96$ kJ/mol)[2], the dihydropyridine **2**, therefore, has a considerably lower rotational barrier.

Information about the position of the equilibrium *sp*-**1a** ⇌ *ap*-**1a** is provided by the 200 MHz ^{1}H-NMR spectra of **2**[5] and **1a**[4]. The chemical shift of the signal of the methyl group in the 2′-position of **1a** ($\delta = 2.54$) is independent of temperature and agrees well with that of the deshielded methyl group in the low-temperature spectrum of **2** ($\delta = 2.58$). Consequently, **1a** is predominantly present in solution in the synperiplanar conformation[6].

In 1,4-dihydropyridines of structure **1** the *ap*- and *sp*-forms therefore exist in a rapidly established equilibrium resulting from a low rotational barrier; the *sp*-form of the thermodynamically more stable rotamer[7] is even more favored than in 9-arylfluorenes[2].

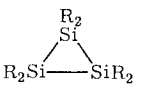
Hexa-*tert*-butylcyclotrisilane, a Strained Molecule with Unusually Long Si–Si and Si–C Bonds**

By *Annemarie Schäfer, Manfred Weidenbruch*, Karl Peters,* and *Hans-Georg von Schnering**

The compounds **1a**[1] and **1b**[2], the first examples of the long sought cyclotrisilanes $(R_2Si)_3$, were recently obtained in low yield; **1a** was also characterized by X-ray structure analysis[1].



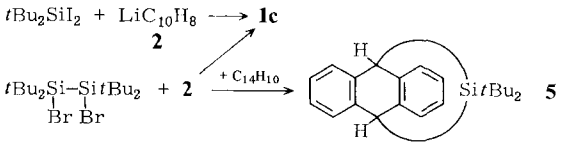
1a, R = 2,6-Dimethylphenyl
1b, R = Neopentyl
1c, R = *tert*-Butyl

Here, we report the synthesis, properties, and structure of hexa-*tert*-butylcyclotrisilane **1c**, which is astonishingly readily accessible and which differs markedly in both its properties and structure from those of **1a** and **1b**. Compound **1c**, which is air-stable and does not decompose even when heated to its melting point of 180°C, is formed by dehalogenation of di-*tert*-butyldiiodosilane with lithium dihydronaphthylide **2** and can be isolated as colorless, prismatic crystals by column chromatography[3].

The high symmetry of **1c** in solution is reflected in the temperature-dependence of the ^{1}H-NMR spectrum, in which, in contrast to those of **1a** and **1b**, the singlet from the methyl protons is not split at −70°C. Irradiation of **1c** in methanol yields equimolar amounts of di-*tert*-butylmethoxysilane **3** and 1,1,2,2-tetra-*tert*-butyl-1-methoxydisilane **4**, which suggests formation of di-*tert*-butylsilanediyl and tetra-*tert*-butyldisilene[4] as initial products of the photolysis.

$$\mathbf{1c} + 2\,CH_3OH \xrightarrow{h\nu} t\mathrm{Bu_2SiH(OCH_3)} + t\mathrm{Bu_2(CH_3O)Si{-}SiH}t\mathrm{Bu_2}$$

Additional evidence for the formation of the silanediyl as an intermediate is provided by the photochemical reaction of **1c** with triethylsilane, from which the insertion product 1,1-di-*tert*-butyl-2,2,2-triethyldisilane can be isolated. The reaction of 1,2-dibromo-1,1,2,2-tetra-*tert*-butyldisilane with **2** also gives access to **1c**; the silanediyl intermediate can be trapped as the product of addition **5** with anthracene[5].



X-ray structure analysis of **1c** revealed unexpected details (Fig. 1). The molecule possesses complete 32 symmetry (D_3) with Si–Si distances of 251.1(3) pm in the three-membered ring—the largest Si–Si distance yet found in a molecule—and also exhibits very large Si–C distances of 197.0(5) pm to the *tert*-butyl groups. These distances exceed those observed in **1a** by 10 and 6 pm, respectively, and, compared to the normal single bond lengths (Si–Si 235 pm, Si–C 188 pm), correspond to Pauling's bond order (PBO) of 0.60 and 0.75, respectively. The Si–Si distance would therefore be equivalent to a C–C distance of 170 pm! In contrast, the peripheral C–C bonds of 153.8 pm are normal and exhibit no counteraction for the loss of bond strength in the central three-membered ring. Accordingly, the molecule is unusually highly strained and energy rich. The strain is also displayed in the bond angles (Fig. 1), e.g. Si–C–C_i (112.1°) > C_i–C–C_j (106.7°), or C–Si–C (105.7°).

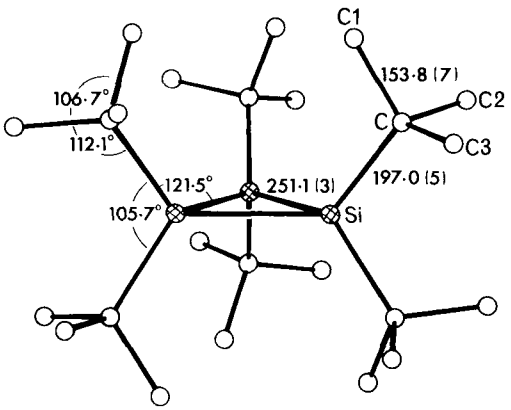


Fig. 1. Structure of the cyclotrisilane **1c** showing bond lengths [pm] and bond angles. The compound crystallizes rhombohedrally, space group $R\bar{3}c$ (No. 167) with a_r = 1745.7(5) pm, α = 33.03(3)° or a_n = 992.4(2), c = 4947.0(10) pm, and Z = 2 or 6 ($Mo_{K\alpha}$ radiation, four-circle diffractometer 722 hkl with $F > 3\sigma(F)$; R = 0.067; no atoms exhibit anomalous deviations from isotropic behavior; H atoms positioned isotropically.

The ease of formation of **1c** can almost certainly be ascribed to the crystallization of LiI, but also to the trisilacyclopropane system which is sterically favorable for directly adjacent bulky substituents. Once formed, the molecule is eminently shielded by its substituents. The substituents sheath the central Si_3 system with optimal special requirements, and thus generate the chirality and rigidity via mutual steric accomodation (Fig. 1). Both enantiomers occur in the crystal. The molecules adopt a cubic close packing of spheres arrangement of periodicity 2 with alternating layers of the two enantiomers.

Synthesis and Structure of a B_6N_7 Phenalene**

Von *Theo Gasparis-Ebeling* and *Heinrich Nöth**

Annelated polycyclic arenes are steps on the route from benzene to graphite. In contrast, in the isoelectronic series of BN heterocycles only B_3N_3-benzene (borazine)[1], B_5N_5-naphthalene[2] are known in addition to boron nitride $(BN)_\infty$[3]. We have now found a surprisingly facile route to a further annelated BN system, a B_6N_7 phenalene.

In the reaction of the distannylamine **1** with tris(methylthio)borane **2**, we expected to isolate the diborylamine **3**. However, the reaction, which commences at 50 °C and which was carried out at 110 °C in the presence of a large excess of **2**, yields the derivative **4** of a B_6N_7 phenalene[4] as shown in (2a). Treatment of **4** with BCl_3 as described by (2b) leads to selective cleavage of the methylthio moieties to give the derivative **5**.

[**] Contributions to the Chemistry of Boron, Part 144. - Part 143: C. K. Narula, H. Nöth, *Inorg. Chem.*, in press.

The 70 eV mass spectrum of compound **4** exhibits an intense molecular ion with correct isotopic pattern. Although **4** and **5** each contain two sets of magnetically nonequivalent B atoms, in the ^{11}B-NMR spectra (64.3 MHz) at room temperature only one signal is observed in each case (**4**: $\delta^{11}B = 39.4$, $w_{1/2} = 530$ Hz, asymm.; **5**: $\delta^{11}B = 31.5$, $w_{1/2} = 320$ Hz)[5]. The structure proposed for **4** and **5** are, however, unequivocally confirmed by the ^{1}H- and ^{13}C-NMR spectra (**4**: $\delta^1H = 0.29$, 2.26 (3 : 1), $\delta^{13}C = 4.61$, 13.31; **5**: $\delta^1H = 0.39$, $\delta^{13}C = 4.61$).

According to X-ray structure analysis[6], **4** possesses the point group symmetry C_3: the threefold rotational axis of the molecule coincides with the threefold crystallographic axis. Although all the ring atoms can be considered to be sp^2-hybridized, the B_6N_7 framework is nonplanar (cf. Fig. 1). This principally arises from the presence of the bulky trimethylsilyl groups, whose effective radii would overlap considerably in a planar structure: the normals to the B_2NSi planes enclose an angle of 94.7°. The central BN distance corresponds to that found in borazines[7]. With the exception of B2—N1′, all the remaining BN distances, in particular the BN(Si) distances to the B1 atom, are longer than the central BN distance. Associated with this is an increase in the exocyclic N2-B1-N1 angle and of the endocyclic dihedral angles (N1-B1-N-B1′ 18.5°, N2-B1-N-B1′ 15.8°, N-B1-N1-Si1 122.8°, N2-B1-N1-Si1 −59.1°, N-B1-N2-Si2 126.9°, N1-B1-N2-Si2 −51.2°, N1-B1-N2-B2 148.6°, N1′-B2-N2-B1 17.9°, S-B2-N2-Si2 39.2°, S-B2-N1′-Si1′ 39.0°). The BN π-interaction should, in consequence, be weaker in this region of the 14π-electron system relative to that in the central BN bonds. Thus, the structure corresponds to a sterically strongly strained periphery, bonded to a "normal" central moiety.

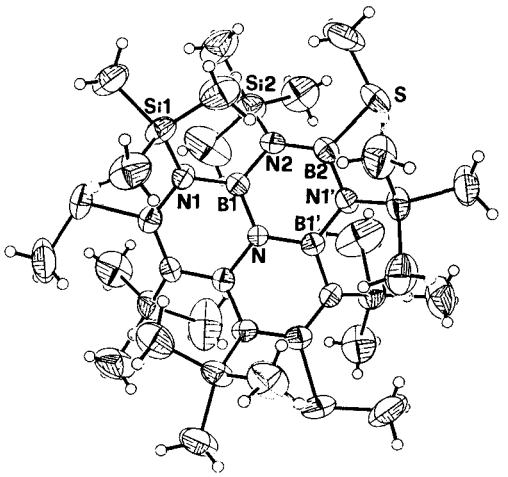

Fig. 1. ORTEP representation of the molecular structure of **4** in the crystal. Selected bond lengths [Å] and angles [°]: N-B1 1.443(2), B1-N1 1.450(4), B1-N2 1.471(5), B2-N1′ 1.434(4), N2-B2 1.448(5), B2-S 1.855(5), N1-Si1 1.788(3), N2-Si2 1.767(3); B1-N-B1′ 120.0(1), N-B1-N1 116.7(3), N-B1-N2 117.5(2), N1-B1-N2 125.7(2), N2-B2-S 123.4(2), N2-B2-N1′ 122.6(3), N1′-B2-S 113.9(3–, B1-N1-Si1 121.0(2), B1-N1-B2′ 115.7(2), Si1-N-B2′ 119.0(2), B1-N2-B2 113.7(2), B1-N2-Si2 116.5(2), B2-N2-Si2 126.2(2).

5 is a propitious educt for the synthesis of the parent compound $B_6N_7H_9$ with the phenalene framework; this compound could be used, inter alia, to test whether, in contrast to **4**, the unsubstituted molecule is planar.

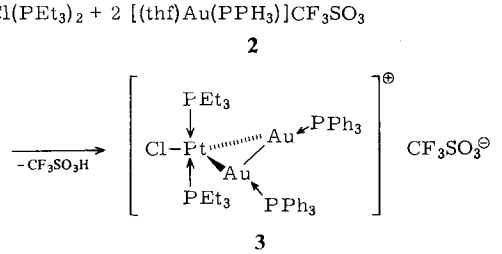
Synthesis of the First Pt-Au Cluster by an Unexpected $H^{\oplus}$-Substitution at *trans*-PtH(Cl)L_2**

By *Pierre Braunstein*, Hans Lehner, Dominique Matt, Antonio Tiripicchio,* and *Marisa Tiripicchio-Camellini*

Monohydrido complexes *trans*-PtH(Cl)L_2 (L = phosphane) are known to undergo easy substitutions either of the chloride with anionic species (carbanions[1], carbonylmetallates[2]), leading to complexes in which the hydride ligand remains attached to the platinum, or of the hydride (e.g. with chloride ions (with HCl))[3]. We report here an unusual example of a substitution in which the hydride ligand is replaced by an Au_2 fragment.



When *trans*-PtHCl$(PEt_3)_2$ **1** is allowed to react with two equiv. $[(thf)Au(PPh_3)]CF_3SO_3$ **2**, (thf) = tetrahydrofuran, the $PtAu_2$ cluster **3** is formed in nearly quantitative yield[9].

The $^{31}P\{^1H\}$-NMR spectrum of **3** shows two sets of resonances centered at $\delta = 42.0$ and 35.7, which correspond to the two PPh_3 and the two PEt_3 ligands, respectively. Both sets of resonances appear as a central triplet ($^3J_{P,P} \approx 4$ Hz) with corresponding platinum satellites ($^1J_{P,Pt} = 2197$ Hz and $^2J_{P,Pt} = 792$ Hz).

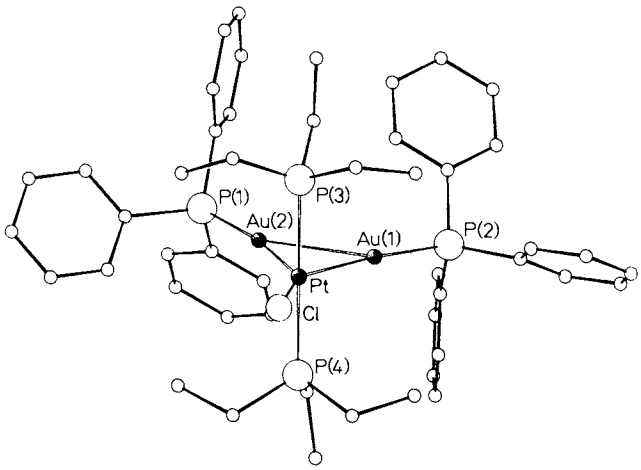


Fig. 1. Structure of **3** in the crystal [4]. Selected distances [Å] and angles [°]: Au1—Au2: 2.737(3), Pt—Au1: 2.600(3), Pt—Au2: 2.601(4), Au1—P2: 2.261(10), Au2—P1: 2.264(7), Pt—Cl: 2.396(11), Pt—P3: 2.298(9), Pt—P4: 2.298(9), Pt—Au1—Au2: 58.2(1), Pt—Au2—Au1: 58.2(1), Au1—Pt—Au2: 63.5(1), Pt—Au1—P2: 173.1(3), Au2—Au1—P2: 128.6(3), Au1—Au2—P1: 136.6(3), Pt—Au2—P1: 165.1(3), P3—Pt—P4: 178.3(4), Au1—Pt—Cl: 148.6(3), Au2—Pt—Cl: 147.9(3).

The X-ray structure determination (Fig. 1)[4] reveals an isosceles triangle for the metal core with a pentacoordinated Pt atom and two tricoordinated Au atoms. The Pt—Au separations (ca. 2.601 Å) are consistent with metal-metal bonds. Although complexes containing Au-transition metal bonds have previously been characterized[5], **3** is, to our knowledge, the first fully characterized compound with a Pt—Au bond. The distance between the two Au atoms (2.737(3) Å) is shorter than in gold metal (2.884 Å) and is one of the shortest reported for Au clusters[6], supporting an Au—Au interaction.

The geometry about the Pt atom is distorted trigonal bipyramidal (P1, P2, Cl, Au1, Au2 and Pt lie almost in the same plane) and is reminiscent of that found recently in bimetallic Pt complexes[7,8]. Together with the short Au—Au distance and the value of the Pt—Au—P angles, this geometry is consistent with the two-electron, three-center (2e3c) bonding shown in Figure 2. **3** is thus similar to the alkyne-metal complexes **4** emphasizing that alkynes RC≡CR and the Au_2 fragment L→Au—Au←L have the same dominant bonding interaction with the Pt center.

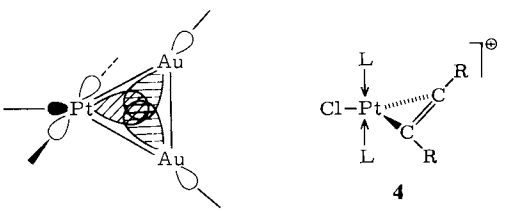

Fig. 2. 2e3c Bond of the metal framework of **3** (left) and structure of the cationic alkyne complex **4**.

[**] We thank the Ministère des Relations Extérieures for a post-doctoral grant to Dr. *H. Lehner,* and Johnson-Matthey Co. Ltd. for a generous loan of $NaAuCl_4$. Financial support from CNRS and from NATO (under Grant 257/83 to *P. B.* and *A. T.*) is acknowledged.

The unexpected reactivity of **1** presumably results from an electron transfer from the Pt atom to $[AuPPh_3]^{\oplus}$ with subsequent elimination of $H^{\oplus}$. The resulting bimetallic PtAu intermediate could then add a further $[AuPPh_3]^{\oplus}$ unit to give **3**. Alternatively, a μ_2-H intermediate might also be involved. This would be relevant to reactivity studies on bimetallic platinum hydride complexes[7].

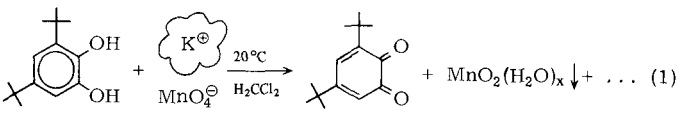
[9] Experimental: All reactions and operations, including the distillation of the solvents, were carried out under N_2. $AgCF_3SO_3$ (0.260 g, 1.01 mmol) was allowed to react with $AuCl(PPh_3)$ (0.500 g, 1.01 mmol) in 20 mL THF. AgCl was filtered off and the solution was added to **1** (0.235 g, 0.50 mmol) in 10 mL THF. The reaction mixture became yellow and acidic (pH monitoring) and after stirring for 1 min was filtered and concentrated. Addition of hexane and cooling to −15 °C produced **3** as white crystals. Suitable crystals for X-ray diffraction were obtained from CH_2Cl_2/pentane at −15 °C. Yield: 0.709 g (92%); m.p. 148 °C (decomp.). Correct elemental analysis (C, H).

Oxidation Reactions with "Naked" Permanganate Ions under Aprotic Conditions**

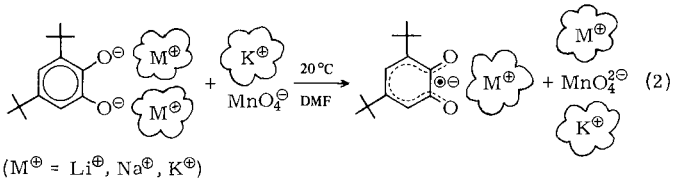
By *Hans Bock** and *Dieter Jaculi*

Dedicated to Professor Heinz Gerischer on the occasion of his 65th birthday

In teaching basic chemistry, water-enveloped $MnO_4^{\ominus}$ anions are introduced as the prototype of pH-dependent oxidation reagents[1a] and are used, inter alia, in "manganometric" analyses. "Naked", i.e. considerably less solvated $MnO_4^{\ominus}$ anions, which occur in aprotic solutions such as "purple benzene", can readily be prepared by lipophilic complexation of the counterions with crown ethers or cryptands and be used for the selective oxidation of organic compounds[1b]; for example, for the synthesis of 3,5-di-*tert*-butyl-*o*-benzoquinone in almost quantitative yield [eq. (1)][1c].



We have reinvestigated[3] this model reaction of catechols, a class of compounds which is also of biochemical interest[2]. Formation of water as a reaction product can be prevented using the dialkali-metal catecholates, obtained either from the catechol by treatment with butyllithium or from the quinone by treatment with sodium- or potassium-amalgam. Under aprotic conditions and with repurified argon as inert gas, reaction (1) proceeds stoichiometrically as a one-electron transfer (2) to yield the semiquinone radical anion, which can be detected in the reaction solution by ESR spectroscopy.



($M^{\oplus}$ = $Li^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$)

Manganese dioxide is not precipitated since the $MnO_4^{2\ominus}$ dianion does not disproportionate under aprotic conditions[1a]. Subsequent reaction of the semiquinone radical anion with excess $MnO_4^{\ominus}$ is not observed.

Numerous measurements corroborate this unexpected result:

- The half-wave potentials of the dialkali-metal catecholates determined by cyclic voltammetry both in the presence and absence of cryptands (Table 1) and especially the ENDOR spectra of the ion pairs which contain the semiquinone radical anion (Fig. 1) illustrate the influence of the alkali-metal cations[2].

Table 1. Half-wave potentials $E_{1/2}$ [V] and ΔE values [mV] for dialkali-metal 3,5-di-*tert*-butylcatecholates in the absence and presence of cryptands in DMF/$R_4N^{\oplus}ClO_4^{\ominus}$, determined at room temperature relative to SCE (scan rate 100 mV/sec).

$A^{2\ominus}$ [a] 2 $M^{\oplus}$ [Cryptand]	$E^{(1)}_{1/2}$	ΔE	$E^{(2)}_{1/2}$	ΔE
$Li^{\oplus}$	−0.29	100	−0.74	100
+[2.1.1]	−0.44	80	−1.1	irrev.
$Na^{\oplus}$	−0.38	90	−0.75	90
+[2.2.1]	−0.44	90	−1.1	irrev.
$K^{\oplus}$	−0.43	80	−0.86	90
+[2.2.2]	−0.45	90	−1.1	irrev.
$nBu_4N^{\oplus}$ [b]	−0.48	100	−1.29	200

[a] $A^{2\ominus}$ = 3,5-$tBu_2C_6H_2$-1,2-$(O^{\ominus})_2$. [b] Determined by reduction of 3,5-di-*tert*-butyl-*o*-benzoquinone in DMF/$nBu_4N^{\oplus}ClO_4^{\ominus}$.

Both sets of data, the potentials $E^{(1)}_{1/2}$ (Table 1) and the radical anion coupling constants $a_{H,M}$ (Fig. 1), can be linearly correlated with the characteristic cation quantity charge/ionic radius[3,4]. After cryptand complexation or with the large cation tetra-*n*-butylammonium as counterion, the half-wave potentials for the catechol dianion

[**] Radical Ions, Part 63. This work was supported by the Land Hessen, by the Deutsche Forschungsgemeinschaft, and the A. Messer-Stiftung. Part 62: H. Bock, B. Roth, J. Daub, *Z. Naturforsch. B*, in press.

and for the semiquinone radical anion in dimethylformamide (DMF), for example, approach -1.29 V (irreversible; presumably due to subsequent reaction) and -0.48 V (quasi-reversible, cf. Table 1; theoretical value for a reversible potential $\Delta E \approx 60$ mV), respectively. The ion-pair interactions detected by cyclic voltammetry or by ENDOR spectroscopy in the redox reaction (2) under the conditions chosen here are therefore reduced to an approximately negligible amount by addition of cryptand.

For the "naked" $MnO_4^{\ominus}$ anion with $K^{\oplus}$([18]crown-6) as counterion, the cyclic voltammogram in DMF affords a quasi-reversible ($\Delta E = 80$ mV) half-wave potential at -0.73 V versus SCE; this is shifted by more than 1 V relative to the value of $+0.32$ V[1] measured in aqueous solution versus the calomel electrode (SCE)! Compared to the $MnO_4^{\ominus}$ reduction in aqueous solution, in which the presumably initially (kinetically controlled) formed $HMnO_4^{\ominus}$ monoanion cannot be observed because of rapid subsequent reactions, the (thermodynamically determined) uptake of an electron to afford the nonprotonated $MnO_4^{2\ominus}$ dianion is therefore considerably handicapped in weakly solvating, organic solvents.

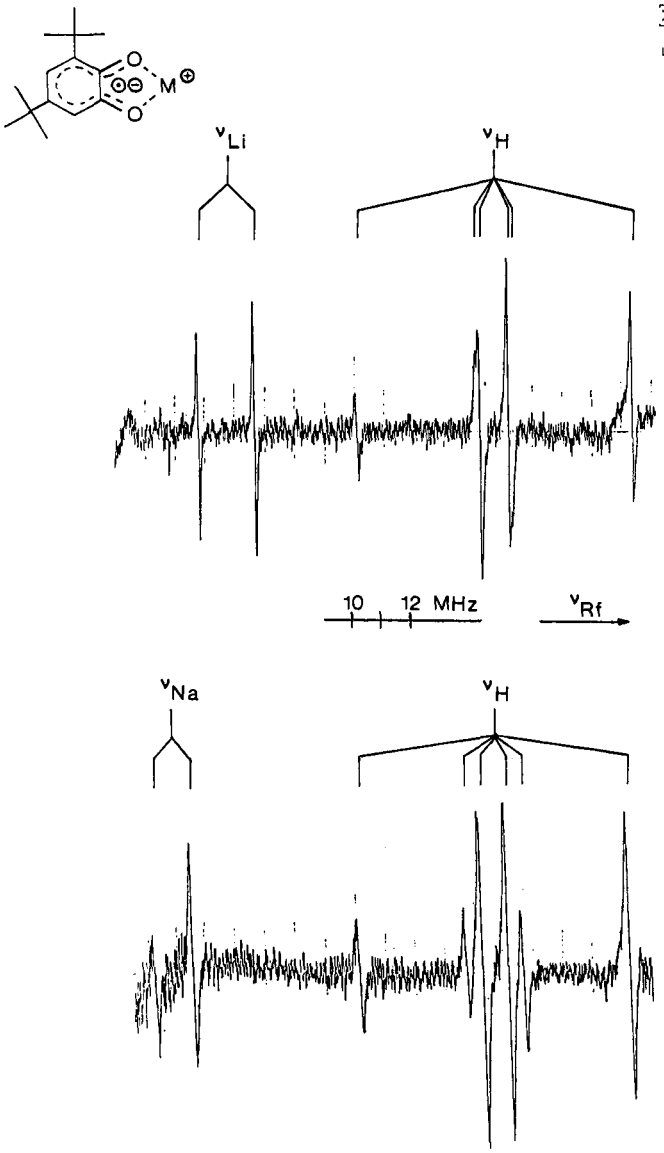

Fig. 1. ENDOR spectra of the Li (upper) and Na salts (lower) of 3,5-di-*tert*-butyl-*o*-benzosemiquinone radical anion at 190 K in tetrahydrofuran.

Under similar, aprotic conditions (Table 1), the half-wave potentials of other redox equilibria, e.g. the hyperoxide ion or the radical anions of cyano-substituted π-systems, were, in part, re-determined[3] in dimethylformamide and arranged in an electrochemical potential series (Fig. 2).

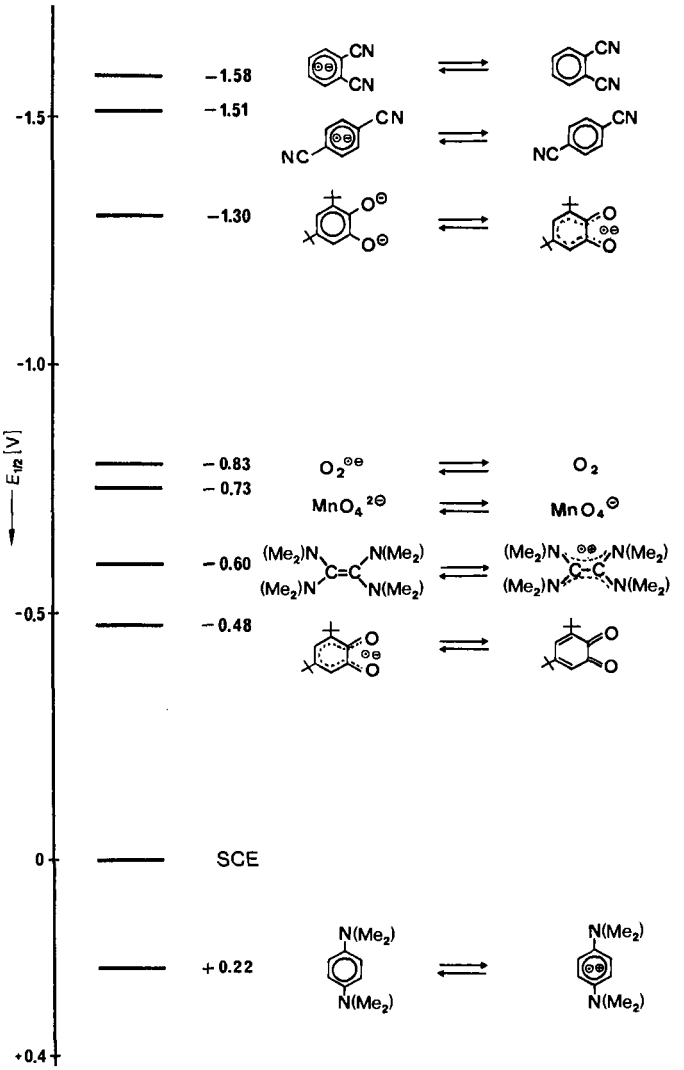

Fig. 2. Electrochemical potential series of redox systems in DMF/$R_4N^{\oplus}ClO_4^{\ominus}$ (0.1 M) at 298 K versus SCE.

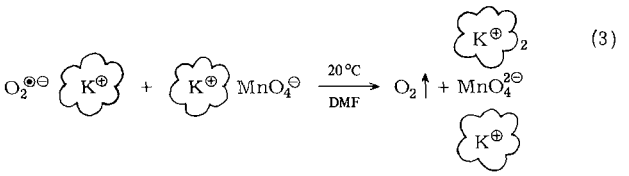
Figure 2 indicates that $MnO_4^{\ominus}$ can indeed oxidize the dianion of 3,5-di-*tert*-butylcatechol, but not the semiquinone radical anion thus formed. Furthermore, electron-rich π systems like tetrakis(dimethylamino)ethene ($IE_1^{\gamma} = 5.95$ eV[5a]) or tetramethyl-*p*-phenylenediamine ($IE_1^{\gamma} = 6.75$ eV[5b]), which form isolable, stable radical cations such as Wursters' blue, are also unable to transfer an electron to $MnO_4^{\ominus}$ in aprotic solutions; traces of e.g. water are required to initiate the $MnO_4^{\ominus}$ reduction [cf. (1)], leading to precipitation of manganese dioxide[3]. In contrast, dicyano-substituted benzene radical anions—characterized by the disappearance of their ESR signals—are immediately discharged to the neutral compound. Deep green solutions of the $MnO_4^{2\ominus}$ dianion in DMF remain in the redox reaction with the hyperoxide radical anion[3].

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/0404-0306 $ 02.50/0



(3)

Many feasible electron transfers between thermodynamically controlled redox systems can be deduced from the electrochemical potential series (Fig. 2), such as the titration of Wursters' blue $[R_2NC_6H_4NR_2^{\odot\oplus}]I^{\ominus}$ with the electron-rich $(R_2N)_2C{=}C(NR_2)_2$ to the neutral compound $R_2NC_6H_4NR_2$ and the radical cation $(R_2N)_2C{=}C(NR_2)_2^{\odot\oplus}$, which can be followed by ESR spectroscopy[3].

Preparation and Crystal Structure of $CuCo(CO)_4$: A Carbonylheterometal Complex Containing a Cu_4Co_4-Ring**

By *Peter Klüfers**

Structural investigations on compounds of the type $E[Co(CO)_4]_n$ in which $n \geq 2$ (E = Zn, Hg, In, Bi) have shown that in the crystalline state monomeric molecules with E–Co bonds are present in which E is of normal valence and fully coordinated[1]. For n = 1 (E = alkali metal, Tl^I), structural parameters are available for ionic compounds $E^{\oplus}[Co(CO)_4]^{\ominus}$ not having short E–Co contacts[2], and for $AgCo(CO)_4$ **2**, a compound with Ag–Co bonds in which coordinative saturation of the Ag atoms is reached in tetrameric molecules with a planar Ag_4Co_4 ring[3].

We have now been able to prepare the lighter homologue $CuCo(CO)_4$ **1** by reaction of $NaCo(CO)_4$ in tetrahydrofuran with a hydrochloric acid solution of CuCl (molar ratio 1:1) and to elucidate its structure[4].

[*] Dr. P. Klüfers
Institut für Anorganische Chemie der Universität
Greinstrasse 6, D-5000 Köln 41 (FRG)

[**] This work was supported by the Landesamt für Forschung, Nordrhein-Westfalen.

Orange colored, monoclinic crystals of **1** contain tetrameric molecules (C_2 symmetry). The sides of a planar, almost square arrangement of Cu atoms are bridged by $Co(CO)_4$ tetrahedra whose edges pointing towards the Cu atoms are greatly lengthened by the formation of Cu–Co bonds. In the Cu_4Co_4 ring thus formed, Co atoms project out oppositely from one another from the Cu_4-plane (48.5(1) and −68.3(1) pm). Two arrays of seven carbonyl groups, one above and one below the metallacycle, form two layers representing fragments of layers in a close packed structure; the two remaining CO groups of a molecule (CO′ groups) are located between these $(CO)_7$-layers (Figs. 1 and 2).

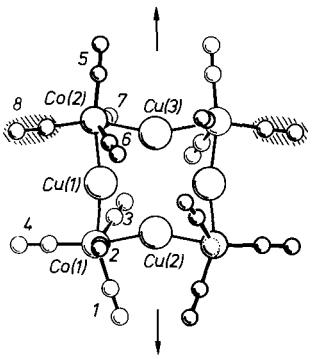

Fig. 1. Molecular structure of the bimetal complex **1** in the crystal. Atomic distances in the heavy-atom skeleton: Co(1)–Cu(1) 237.2(10), Co(1)–Cu(2) 236.0(3), Co(2)–Cu(1) 236.4(9), Co(2)–Cu(3) 236.5(7), Cu(1)–Cu(2) 273.1(4), Cu(1)–Cu(3) 270.3(4). Angles [°] in the Cu_4Co_4 ring at: Co(1) 69.65(6), Co(2) 70.55(4), Cu(1) 167.41(4), Cu(2) 158.07(6), Cu(3) 158.42(8). Bold- and thin-lined CO groups form densely packed layers above and below the Cu_4 plane, respectively. The two CO′ groups not incorporated in the close packing are shaded.

Related compounds with an eight-membered ring of alternately arranged transition- and d^{10}-elements are $[CdFe(CO)_4]_4 \cdot 2(CH_3)_2CO$ and $[(\eta^5\text{-}CH_3C_5H_4)Mn(CO)_2Hg]_4$ **3**[5]. Molecules containing a central Cu_4 unit are known for a series of organocopper(I) compounds, where the Cu–Cu distances are about 30 pm shorter than in **1**[6]. Mutual interaction between the metal atoms should have little if any influence on the molecular structure of organocopper(I) compounds[6], whereas bonding between the Hg atoms has been discussed in the case of the metallacycle **3**.

A comparison of the structure of **1** with that of the silver compound **2** reveals two outstanding differences: firstly, in **2** the metal framework is almost planar, while in **1** the CO atoms are not in the Cu_4 plane; secondly, the $Co(CO)_4$ groups in **2** deviate about 10° more from the tetrahedral structure than in **1**.

The crystal structures must be taken into consideration for an explanation of these effects, which are probably caused by the difference in size of the Cu and Ag atoms. In the structural chemistry of the tetracarbonylcobaltates $ECo(CO)_4$, two types of structure can be distinguished: 1) close packing of E + 4CO, with Co atoms in interstices when E is large; 2) close packing of CO groups alone, with Co and E in interstices when E is smaller[2].

The former type of structure is present in crystals of **2**, whereas the crystal structure of **1** can be derived from a strongly distorted, close packing of CO groups. The $(CO)_7$-fragments of close-packed layers formerly present in the molecule are part of close-packed CO planes in the crystal. These planes are distorted by CO′ groups which group pairwise at one position in the close arrangement (Fig. 2).

 © *Verlag Chemie GmbH, D-6940 Weinheim, 1984* *0570-0833/84/0404-0307 $ 02.50/0*

Thus, the arrangement of ligands resulting from the nonplanarity of the metallacycle in **1** corresponds with the arrangement of the CO groups in the crystal structure. Presumably, therefore, the observed nonplanarity of the individual molecules, even if not brought about by the packing of the molecules in the crystals, is at least stabilized. A greater influence of the crystal structure on the molecular

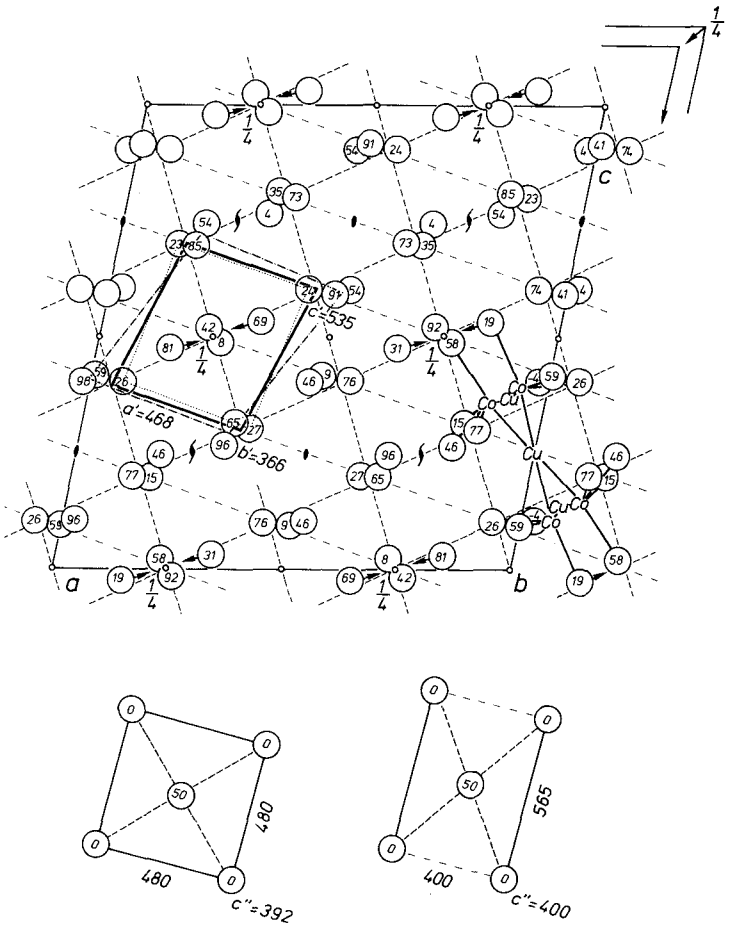

Fig. 2. Top: Crystal structure of **1**, projection on (010). Circles: CO groups, circles with arrows: CO′ groups, showing $y_{CO} \cdot 100$, $y_{CO} = 1/2(y_C + y_O)$. ----- Traces of densely packed layers, layers $(20\bar{1})$ contain the fragments of densely packed CO layers preformed in the molecules. ——, ····· Connecting lines between densely packed particles. —— Mean subunit in CO packing; $b' = b/3$. ·-·-·-·- 1CO+2CO′ subunit, frequency: 1 per unit length in [010]. ····· 2CO subunits, frequency: $2/b$. A complete molecule is indicated about $(0, y, 1/4)$.—Bottom: Measurements (in pm) of equal-volume cells idealized with the average subunit. Left: Tetragonal body-centered close packing, $c/a = \sqrt{2}/\sqrt{3}$, density of packing 0.698, projection on $(001)_{tetr.}$. Right: Cubic close packing, projection on $(01\bar{1})_{cub}$, tetragonal body-centered arrangement $\vec{c}'' = \frac{1}{2}(-\vec{a}_{2,cub} + \vec{a}_{3,cub})$.

structure is discussed for the denser crystal structure of **2** (V/Z [10^6 pm^3]: 169.3 in **1**, 168.6 in **2**). Hence, it is assumed[3] that striking molecular parameters in the neighborhood of the axial CO groups, namely pronounced widening of the $Co(CO)_4$ tetrahedral angle ($\sphericalangle C_{ax}-Co-C'_{ax} = 146.1°$) and unusual deviation of the Co–C–O angle from linearity (171.4°), are not to be considered as indicative of semibridging carbonyl groups, but should be explained in terms of packing effects only in the crystal. The present parameters for **1**, which, with the smaller Cu atom, does not facilitate formation of this type of structure, confirm this presumption ($\sphericalangle C_{ax}-Co-C'_{ax} = 136.7°$, $\sphericalangle Co-(C-O)_{ax} = 174.1°$).

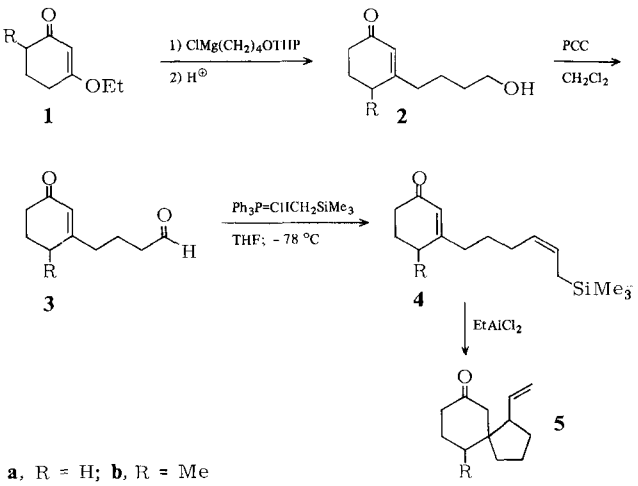
Diastereoselective Synthesis of Spiro[4.5]decanones by Intramolecular Sakurai Reactions**

By *Dieter Schinzer**

The syntheses of complex ring systems, e.g. natural products like lubimin or α-acoradiene which contain the spiro[4.5]decane system, have recently attracted the attention of synthetic chemists[1,2]. We have investigated a new stereoselective route to functionalized spiroketones (**4**→**5**) using Lewis acid-catalyzed cyclizations of allylsilanes **4**, which are readily accessible from 3-ethoxy-2-cyclohexenones **1** as shown in Scheme 1.



Scheme 1. THP = tetrahydropyranyl; PCC = pyridinium chlorochromate.

Of decisive importance for the cyclization of compounds **4** is the choice of Lewis acid: BF_3 and $SnCl_4$, for instance, lead only to protodesilylation, while decomposition occurs with $TiCl_4$. With ethylaluminum dichloride, on the other hand, an intramolecular Sakurai reaction takes place[3], leading to the desired spiroketones **5** in good yields (Table 1)[4].

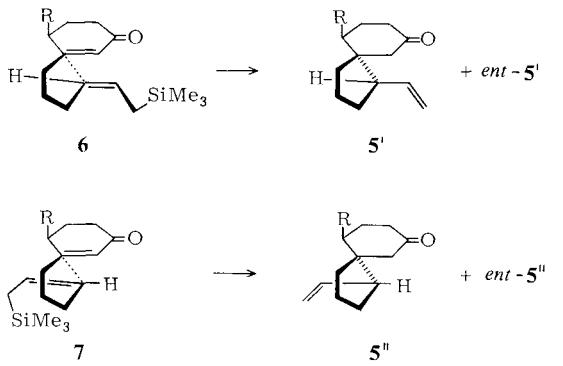

Table 1. Conditions for the conversion **4**→**5**, ratio of the diastereomers **5'** and **5''**, and yields of **5** [a].

4	Conditions	5':5''	Yield [%]
a	CH_2Cl_2, −78°C	2:1	85
a	toluene, 0°C	3:1	77
a	toluene, −78°C	7:1	72
b	toluene, 0°C	5:1 [b]	75
b	toluene, −78°C	7.5:1	70

[a] General procedure, e.g. for **5a**: To a solution of 165 mg (0.66 mmol) **4a** in 30 mL anhydrous toluene is added 0.1 mL (1.1 equiv) ethylaluminum dichloride at 0°C. The mixture is stirred for 30 min at 0°C, treated with 10 mL ice-water, and the phases are separated and extracted twice with 30 mL ether. The combined organic phases are dried over sodium sulfate and evaporated down. Kugelrohr distillation (60°C, 0.1 mbar) affords 90.5 mg (77%) **5a** (**5a'**:**5a''** = 3:1). Physical data of **5a'**: IR (film): ν = 1715 (s), 920 (m) cm^{-1}; ^{1}H-NMR (90 MHz, $CDCl_3$): δ = 1.1–2.5 (m, 15H), 5.1 (m, 2H), 5.7 (m, 1H); ^{13}C-NMR (20.15 MHz): δ = 212.4 (s), 138.5 (d), 116.4 (t), 54.4 (d), 50.2 (s), 47.0 (t), 41.2 (t), 35.8 (t), 29.7 (t), 23.5 (t), 21.4 (t). [b] In addition to the two diastereomers shown, a third occurs (5:1:0.5) of unknown structure.

Interestingly, depending on the temperature and solvent the reaction proceeds diastereoselectively (Table 1), favoring a synclinal transition state **6**. The other diastereomer is formed via an antiperiplanar transition state **7**. Assignment of the configurations of the products followed from known ^{13}C-NMR[5] and ^{1}H-NMR data of the synthesized dimethoxyketals and from NOE experiments[6]. The stereochemistry of the methyl group in **5b** could not be clarified with certainty.

4*H*-1,4-Oxazocine, a Planar, Diatropic 10π-Dihetero[8]annulene?**

By *Bernhard Zipperer, Dieter Hunkler, Hans Fritz, Grety Rihs,* and *Horst Prinzbach**

In the chemistry of π-electron-rich heteroannulenes[1] such as e.g. 1,4-diheterocines **2**, iso-π-electronic with the 10π-cyclooctatetraene dianion **1**, the analysis of the influence of the heteroatoms on the molecular properties remains a topic of current interest[2]. For the 1,4-dihydro-1,4-diazocine **3** the following relationship between *N*-substitution and molecular structure has been observed:

For R=H (donor) **3** is planar with a delocalized 10π system, and for R=SO_2R (acceptor) it is twisted with a localized π-system[3,4]. We show here that a similar relationship between *N*-substitution and molecular structure exists in the 4*H*-1,4-oxazocine framework **4** with the O atom having a lower tendency to n-electron delocalization[2].

1 **2** **3** **4**

X-ray structure analysis (Fig. 1, top)[6] of the recently described *N*-tosyl-1,4-oxazocine **4a**[5] confirms the nonplanar, highly irregular conformation with considerable torsion around the C=C bonds—as expected from the NMR data. It was initially attempted to synthesize donor-substituted derivatives and the parent compound **4b** via the route previously worked out for **4a** (**5**→**6**→**7**→**8**→**4**). **5** actually adds *N*-nucleophiles such as methylamine, aniline, benzylamine, and sodium azide (methanol, $ZnSO_4$, room temperature, 1-2 d)—without side reactions, e.g. S_N2' substitution—to the allylic epoxide position to afford the conduritol derivatives **6b-6e** (80—95%, $J_{1,2}$ = 2-2.5, $J_{2,3}$ = 5.5-6.5, $J_{6,1}$ = 4.5-5.5 Hz, with high 1e,2a,3a,6e-contributions)[7]. However, reaction of **6b-6d** with bases such as diazabicycloundecene (DBU) and potassium *tert*-butoxide in tetrahydrofuran (THF) or with sodium methoxide in methanol (−30 to +50°C)[5] leads under various conditions only to rapid polymerization.

Problems also arose in the attempt to prepare the *cis*-oxaaza-bis-σ-homobenzene **8b** (and from this **4b**) from the epoxy-*trans*-azido alcohol **7e**, isolated in high yield via **6e** (KO*t*Bu, THF, −10°C, 5 min, 90%, $J_{2,3}$ = 2 Hz) and triphenylphosphane[8]. The pure, colorless, powder-like iminophosphorane **9** (86%) precipitates from anhydrous ether. Despite the propitious e,e-position of the OH/NP(C_6H_5)$_3$ groups for *trans*-cyclization to a five-membered ring, the conversion into **8b** proceeds so slowly that considerable decomposition (from **9** and **8b/4b**, the only product identified was the amine **7f**) is unavoidable; the thermally labile parent compound **4b**—even at 20°C, **8b** is not detectable directly (^{1}H-NMR, TLC)—can be separated by chromatography only with high losses.

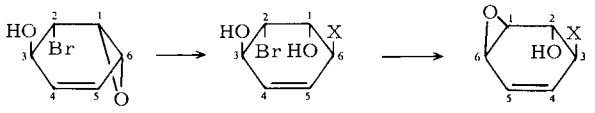
[**] This work was supported by the Deutsche Forschungsgemeinschaft, by the Fonds der Chemischen Industrie, and by BASF AG.

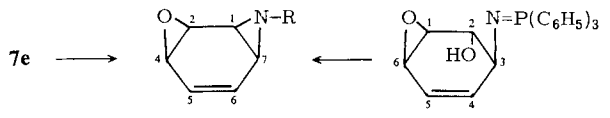
After optimization of the route to **4a**[5], **4b** as well as the derivatives **4c-4i** were prepared via the anion **10** generated by amide-cleavage (K/NH_3, $-33\,^{\circ}C$, orange-yellow powder; extracted with DMSO)[3]. Within the analytical limits (^1H-NMR, 400 MHz), **10** is protonated (deuterated) exclusively to **4b** (**4c**) and **4b**, **4c** do not tautomerize in the presence of strong bases. **4b** crystallizes from ether ($-20\,^{\circ}C$) as pale yellow platelets (m.p. = 32 °C, 65%), which rapidly deliquesce in air and are thermally labile. Like **4b**, **4d-4f** are unstable and, hence, can only be characterized in solution (NMR). The dimethylcarboxamide **4h** and the urethane **4i** are more stable and can be purified by chromatography (75–80%), but not crystallized. This was eventually achieved for the trimethoxybenzyl derivative **4g** (70%, colorless platelets, m.p. = 88-90 °C (decomp.), whose crystals were suitable for X-ray structure analysis.



5 **6** **7**

6,7	a	b	c
X	NHTos	$NHCH_3$	NHC_6H_5

	d	e	f
X	$NHCH_2C_6H_5$	N_3	NH_2



8a, R = Tos
8b, R = H

9

4 **10**

	a	b	c	d	e	f	g
R	Tos	H	D	CH_3	CH_2CH_2CN	$CH_2C_6H_5$	$CH_2C_6H_2(OCH_3)_3$

	h	i
R	$CON(CH_3)_2$	CO_2CH_3

The parent compound **4b**, the anion **10**, and the alkyl derivatives **4d-4g**—less typically **4h**, but not the **4a**-analogous **4i** (N–CO rotation is hindered at 30 °C)—exhibit in the ^1H- and ^{13}C-NMR spectra chemical shifts and particularly $J_{6,7}$- and $^3J_{C,H}$-couplings through the carbon-heteroatom bonds (exemplified in Table 1 with **4a**, **4b**, **4g** and **4i**), which are clearly different from those of the nonplanar **4a** and which make planar conformations probable.

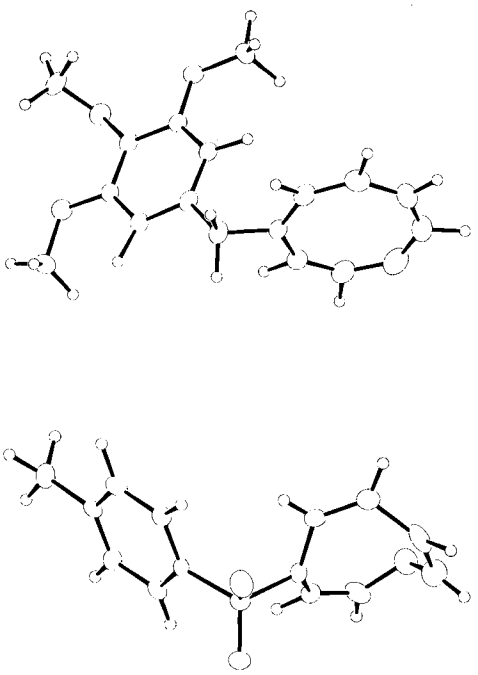


Fig. 1. Molecular structures of **4a** (above) and **4g** (below) in the crystal [6]. Important bond lengths [Å] of **4a** (**4g**): O1-C2 1.362 (1.338), C2-C3 1.293 (1.312), C3-N4 1.421 (1.369), N4-C5 1.412 (1.381), C5-C6 1.328 (1.360), C6-C7 1.527 (1.431), C7-C8 1.296 (1.314), C8-O1 1.385(1.333).

For **4g** a planar molecular structure (average deviation from the ideal plane 0.021 Å; average bond angle in the eight membered ring 135.5°) with a marked decrease in bond length alternation is ascertained (Fig. 1, below)[6]. In contrast to **4a**, which has pyramidal coordination at N4, the substituents at N4 in **4g** are practically coplanar; this satisfies the requirement for efficient n-electron delocalization. Following the arguments presented for **3**[3,4], we interpret these differences in structure and electron distribution, which go parallel with the acceptor or donor character of the *N*-substituents, as proof that cyclic 10π-electron delocalization is responsible, inter alia, for the planarity and that, in consequence, the 4*H*-1,4-oxazocine and its *N*-alkyl derivatives are diatropic[9].

$[Cu_{12}S_8]^{4\ominus}$: A Closed Binary Copper(I) Sulfide Cage with Cuboctahedral Metal and Cubic Sulfur Arrangements**

By *Peter Betz, Bernt Krebs,* and *Gerald Henkel**

Copper is frequently encountered in biological systems, and copper-sulfur bonds have been detected in some metalloproteins[1].

Among the polynuclear copper(I) complexes with complete sulfur coordination and known structure are compounds with Cu_4S_6, Cu_4S_8, or Cu_8S_{12} frameworks which contain trigonally coordinated metal atoms[2]. Distorted, tetrahedral coordination of sulfur occurs, e.g., in the tetranuclear thiourea complex $[Cu_4(tu)_9]^{4\oplus}$ in addition to trigonal coordination[3]. Two pentanuclear compounds are also known in which both trigonal and linear coordination of sulfur are observed[4]. In all these compounds the sulfur atoms are a functional part of thiolates, of unsaturated 1,1- or 1,2-dithiolates (dithiolenes), or of dithiosquarates or thiourea; the tetranuclear Cu_4S_6 moiety is preferentially formed by thiolates and thiourea, whereas the octanuclear Cu_8S_{12} moiety achieves its maximum stability with 1,1- and 1,2-dithiolenes, and dithiosquarates. Di-, tri-, hexa-, and heptanuclear Cu^I–S complexes are not yet known[10].

In the course of systematic investigations of polynuclear metal-thiolate and metal-sulfide-thiolate complexes, we have isolated and structurally characterized the novel hexanuclear cluster $[Cu_6(S_4)_3(S_5)]^{2\ominus}$[5], besides the tetranuclear clusters $[Cu_4(S_4)_3]^{2\ominus}$, $[Cu_4(S_4)_2(S_5)]^{2\ominus}$, and $[Cu_4(S_4)(S_5)_2]^{2\ominus}$ from the copper/sulfur/ethanethiolate reaction system[6]. Under suitable conditions, the trinuclear cluster $[Cu_3(S_4)_3]^{3\ominus}$ and the tetranuclear, mixed-valent anion $[Cu^I_3Cu^{II}(S_4)_3]^{\ominus}$ could be trapped in a $[Ph_4P]_2[Cu_4(S_4)_3]$ matrix[7].

Formation of the stable tetra- and pentasulfido complexes can be avoided by using Li_2S instead of elemental sulfur. We report here the novel anion $[Cu_{12}S_8]^{4\ominus}$ **1**, which with twelve metal atoms in a cuboctahedral arrangement is particularly interesting not only as the largest Cu–S cluster but also as the first isolated Cu^I–S complex with exclusively monosulfido ligands and also because of its closed cage structure. $[Cu_{12}S_8]^{4\ominus}$ is formed in the reaction of $CuCl_2\cdot 2H_2O$ with $EtS^{\ominus}$ (threefold excess) in methanol, followed by cooling to −78 °C and addition of Li_2S. Upon slowly warming the mixture in the presence of Ph_4PBr, an orange, finely crystalline precipitate of $[Ph_4P]_4[Cu_{12}S_8]$ **2** is formed, which can be obtained as wine-red needles from dimethylformamide.

Apart form $Ph_4P^{\oplus}$ cations, crystals of **2** contain discrete $[Cu_{12}S_8]^{4\ominus}$ anions with ideal O_h symmetry, whose centroids occupy crystallographic centers of inversion. The structure of the tetraanion **1** is shown in Figure 1. The closed metal-sulfur cluster has approximately the shape of a cube whose corners are defined by sulfur atoms, whereas the midpoints of the edges are occupied by copper atoms. Thus this structure represents an inverse copper-sulfur arrangement with respect to the Cu_8S_{12} centers of the octanuclear Cu^I dithiolene complexes.

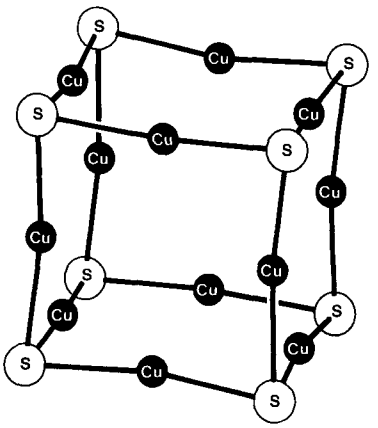

Fig. 1. Structure of the $[Cu_{12}S_8]^{4\ominus}$ cluster **1** in the crystal of salt **2** [monoclinic, $P2_1/n$, $a=13.968(12)$, $b=25.710(23)$, $c=12.681(9)$ Å, $\beta=91.17(7)°$, $Z=2$; Syntex-$P2_1$, four-circle diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, scintillation counter, 2θ-θ scan, $2\theta_{max}=48°$, $T=-130$ °C, 7196 symmetry-independent reflections, 4917 of which with $I>1.96\sigma(I)$; $R=0.046$, $R_w=0.037$]. Range of distances: Cu...Cu 2.774(1) to 2.950(1), Cu–S 2.156(2) to 2.179(2) Å; range of angles: S–Cu–S 166.87(7) to 170.89(7), Cu–S–Cu 79.75(6) to 86.08(6)°. Further details on the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50753, the names of the authors, and the journal citation.

The metal framework of the $[Cu_{12}S_8]^{4\ominus}$ cluster derives from the cubic closest sphere packing of elemental copper, and as a cuboctahedron represents the section of twelve metal atoms around a non-occupied center (cf. Fig. 2). The Cu–Cu distances in **1** range between 2.774(1) and 2.950(1) Å, and the average value (2.845 Å) is ca. 0.3 Å larger than the corresponding value in metallic copper.

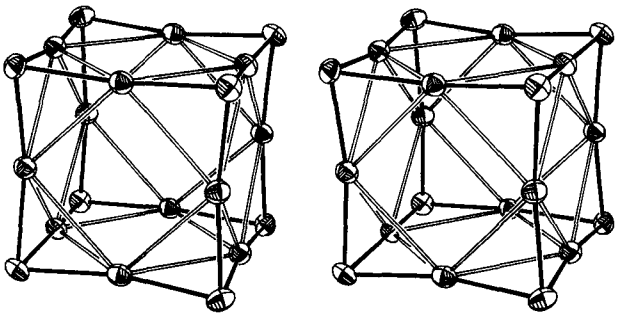

Fig. 2. Stereoscopic projection of the $[Cu_{12}S_8]^{4\ominus}$ cluster **1** with vibrational ellipsoids (50% probability, −130 °C) and sketched metal cuboctahedron.

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.

The copper atoms are displaced slightly from their ideal positions at the midpoints of the edges of the S_8 cube towards the (unoccupied) center; the S–Cu–S fragments are therefore not linear but exhibit angles between 166.87(7) and 170.89(7)° at the Cu atom with bond lengths between 2.156(2) and 2.179(2) Å (average 2.163 Å).

The distorted linear coordination of sulfur observed in **2** is also realized in the highly condensed compounds KCuS (Cu–S 2.155 Å) and $CsCu_3S_2$ (Cu–S 2.166 Å)[8]. However, this is rather the exception in the Cu^IS clusters isolated in which trigonal-planar or tetrahedral sulfur coordination dominates. In addition to trigonal CuS_3 moieties, further examples of distorted linear CuS_2 coordination are found only in the pentanuclear anions $[Cu_5(S\mathit{t}Bu)_6]^{\ominus}$ and $[Cu_5(SPh_7)]^{2\ominus}$[4].

In **1** the S atoms are centered above the triangular faces of the metal cuboctahedron and form μ_3-S bridges with Cu–S–Cu angles between 79.75(6) and 86.08(6)°. Although $(\mu_3\text{-S})M_3$ moieties are frequently observed as basic elements of the $[M_4S_4]$ cubane structure in transition-metal-sulfur chemistry (cf. e.g. [9]), $[Cu_{12}S_8]^{4\ominus}$ is the first complex whose metal centers are coordinated exclusively by μ_3-S ligands. The IR spectrum of **2** exhibits a strong Cu–S stretching frequency at 382 cm^{-1}.

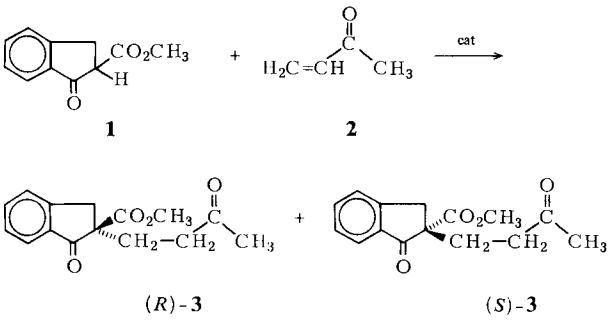
Enantioselective Michael Additions with Optically Active Co^{II}/Diamine Catalysts**

By *Henri Brunner** and *Benedikt Hammer*

CC Bond formations via Michael addition are catalyzed by bases[1]. The use of optically active amines[2] or of optically active crown ethers and bases[3] leads to different degrees of optical induction. 1,3-Dicarbonyl compounds can be preparatively alkylated with α,β-unsaturated systems in particularly high yields if transition metal catalysts such as $Ni(acac)_2$[4] are employed instead of bases.

We have now developed $Co(acac)_2$/(nn), (nn)=(+)- or



(−)-1,2-diphenyl-1,2-ethanediamine, a catalyst system for the enantioselective addition of methyl vinyl ketone **2** to cyclic and open-chain 1,3-dicarbonyl compounds. The optical inductions are, however, markedly dependent on the structure of the CH-active components and for methyl 1-oxo-2-indanecarboxylate **1** reach 66% *ee*.

Treatment of a red-violet solution of $Co(acac)_2$ in toluene with one equivalent of the ligand (nn) results in formation of the red, octahedral Co^{II} complex $[Co(acac)_2(nn)]$, which can be detected as the molecular ion in the mass spectrum (field desorption from toluene). 3 Mol-% of this complex in toluene catalyze the addition of **2** to **1**. The Michael adduct **3** is obtained in 79% chemical yield and 21.3% *ee* after stirring for 40 h at +20°C. At constant chemical yield the optical induction increases continuously with decreasing temperature (Table 1, nos. 3–9) until at −50°C (64 h) a value of 66% *ee* is reached. At lower temperatures the reaction is too sluggish.

Compared to the complex $[Co(acac)_2\{(-)\text{-(nn)}\}]$, the free amine (−)-(nn) is a poorly effective and weakly inductive catalyst (no. 2). In contrast to the complex, which predominantly induces the (*S*)-configuration in the product, the free amine leads preferentially to the (*R*)-configuration. Use of excess (+)-(nn) (no. 12) causes a drastic reduction in the optical induction (Table 1).

In the reaction of methyl vinyl ketone **2** with ethyl 2-methylacetoacetate as CH-acidic component (nos. 13–14) in the presence of the catalyst system $Co(acac)_2$/(nn) at room temperature only 4.5% *ee* (0°C: 2.2%) is obtained. Because of the distillative work-up, chemical yields of the Michael adducts from ethyl 2-methylacetoacetate and **2** are a little lower than for **3**, which after concentration is separated from the catalyst by shaking with dil. hydrochloric acid and chromatography (silica gel).

The (*S,S*)-configuration of the ligand (+)-(nn)[5] gives rise to the λ-conformation in the Co(nn) five-membered ring, as shown in **4**. At the Co atom two methyl 1-oxo-2-indanecarboxylate anions and an (nn) ligand lead to an octahedral complex with Δ- or Λ-configuration. Complex **4**

[a] Relative to *S*-**3a**, $[\alpha]_{578}$ −77.0 ($c=2$, benzene) [2c]. [b] Substrate ethyl 2-methylacetoacetate. [c] Relative to $[\alpha]_D$ −9.6 ($c=1.29$, chloroform) [7].

(one of the two ester ligands is sketched as $\overset{\frown}{OO}$ and the phenyl groups are not shown) has the Δ-configuration. Consistent with the results of conformational analyses of corresponding Co^{III} complexes[6], this Δ-configuration for a given λ-conformation of the Co(nn) five-membered ring is thermodynamically stabler than the Λ-configuration.

Starting from the Δ(λ)-form of **4**, one obtains (*R*)-**3** if it is assumed that the keto-carbonyl group occupies an axial, and the ester carbonyl group an equatorial, position and that in addition the methyl vinyl ketone **2** is directed to the *si*-side of the complexed substrate via a hydrogen bond from the keto oxygen to one of the NH groups. This model accounts for the low optical induction for ethyl 2-methylacetoacetate in terms of a reduced axial/equatorial selectivity of ester and keto-carbonyl groups relative to **1**. The optical inductions attained with (nn)=(+)- and (−)-1,2-diphenyl-1,2-ethanediamine have not yet been achieved with (−)-1,2-diaminocyclohexane and (−)-3-phenyl-1,2-propanediamine Co^{II} complexes.

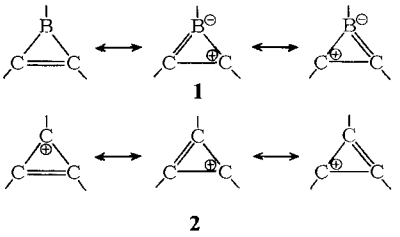
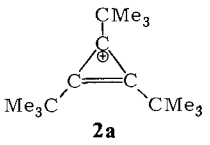
1-*tert*-Butylborirenes**

By *Christine Pues* and *Armin Berndt**

Borirenes **1** are the simplest borarenes isoelectronic with cyclopropenylium ions[1]. Attempts to synthesize compounds **1** remained unsuccessful[2,3] until introduction of sterically demanding substituents recently enabled the preparation of the first derivatives[4-6,10].

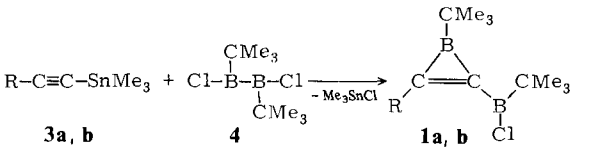




2a

We have now found that the 1-*tert*-butylborirenes **1a**, **b** are accessible in almost quantitative crude yields from the trimethylstannylalkynes **3** and 1,2-di-*tert*-butyl-1,2-dichlorodiborane(4) **4**.

The structures of **1a** and **1b** are consistent with the mass spectra and the ^1H-, ^{13}C- and ^{11}B-NMR data[7]. As was to be expected from the resonance structures of **1**, the B atom of the three-membered ring in **1a** and in **1b** is, in each case, strongly shielded owing to its relatively high π-electron density ($\delta=43$ and 49 compared to $\delta=81$ in boriranes[8]), while the C atoms are markedly deshielded



3a, b **4** **1a, b**

a, R = CMe_3; **b**, R = $SnMe_3$

($\delta=184.3$ and 186.6 in **1a**, 184.8 and 215.3[9] in **1b**). The ring C-atoms of compound **2a**, which is comparable to **1a**, have a chemical shift of $\delta=181.6$. The shielding of the cyclic boron atom in **1a** of 38 ppm compared to that in boriranes is markedly greater than the corresponding shielding of 31 ppm in **1d** ($\delta^{11}B\approx27$)[4] compared to that in dimethylbis(trimethylsilyl)aminoborane[11] ($\delta^{11}B=57.7$)[12]. We conclude, therefore, that the electron gap at the boron in **1d** not only interacts with the π-electrons of the three-membered ring but also with the electron pair at the nitrogen.

1c

1a reacts with 4-*tert*-butylpyridine to give a crystalline adduct **1c**, whose structure is proven by ^{1}H-, ^{13}C-, and ^{11}B-NMR spectra[7]. The addition of the pyridine at the exocyclic B atom follows from the relatively small change in the shift of the ring B-atom compared to that in **1a** ($\delta = 47$ compared to 43). Confirmation of the exocyclic addition is provided by the chemical shifts of the ring C-atoms ($\delta = 182.9$ and 193.1), which are similar to those in **1a**. All attempts to prepare crystals of **1c** for an X-ray structure analysis, to check the calculated[1b,c] bond lengths in borirenes, have so far failed.

Chiral Electron Transfer Compounds: Binaphtho[2,3-*a*]azulenequinone and Binaphtho[2,3-*a*]azulenehydroquinone Derivatives by Oxidative Coupling**

By *Johann Bindl, Georgios Pilidis,* and *Jörg Daub**

Acenazulenediones, like the naphthoazulenequinone **1**, associate on electrochemical reduction in an aprotic medium[1]. The association of light-sensitive compounds plays an important role in electron transfer processes in chemical and biological systems; *poly*functional chiral compounds containing the structural unit **1** are therefore of

[*] Prof. Dr. J. Daub, J. Bindl, Dr. G. Pilidis
Institut für Organische Chemie der Universität
Universitätsstr. 31, D-8400 Regensburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie and by BASG AG. We thank Dr. *T. Burgemeister* for recording the NMR spectra and for valuable discussions regarding their interpretation.

great interest. The racemate of an acenazulenedione has already been described[2]. We now report on the synthesis and stereochemical properties of binaphthoazulenequinones and the corresponding hydroquinone derivatives[3].

Reduction of **1** with sodium dithionite in an alkaline medium and subsequent alkylation with dimethyl sulfate, methoxymethyl chloride, or (−)-3-menthyloxymethyl chloride[4], furnishes the substituted azulenes **2a**, **2b** and **2c**, respectively, in good yields[5]. The oxidative coupling of **2a** leads exclusively to the tetramethoxy compound **3a**, whereas the oxidations of **2b** and **2c** afford product mixtures (Table 1).

4c exists as a diastereomeric mixture of the composition 65:35 ($de = 30\%$) (determined by integration of the OCH_2-absorptions in the ^{1}H-NMR spectrum). In all cases the coupling in the oxidation of compounds **2** takes place only at C-11[6]. The formation of product mixtures in the oxidation of **2b** and **2c** signals the ready oxidative cleavage of the acetal protecting groups, whereby dimerization is obviously difficult in the case of the larger menthyl moiety.

The acid-catalyzed cleavage of the methoxymethyl groups in **3** (tetrahydrofuran, isopropyl alcohol, HCl) and subsequent oxidation with atmospheric oxygen also leads initially to formation of the dione **4b**. With longer reaction times, only the extremely sensitive bisdione **5**[5] is formed.

The ^{1}H-NMR spectra of **3a** and **3b** recorded at different temperatures evidence marked intramolecular interactions in these compounds: In the 250-MHz ^{1}H-NMR spectrum of **3a** at −70°C all the signals are extensively broadened; at +30°C the signals of the ring protons are still extensively broadened. Normal line widths are first observed in spectra recorded above +60°C (Fig. 1). A comparable

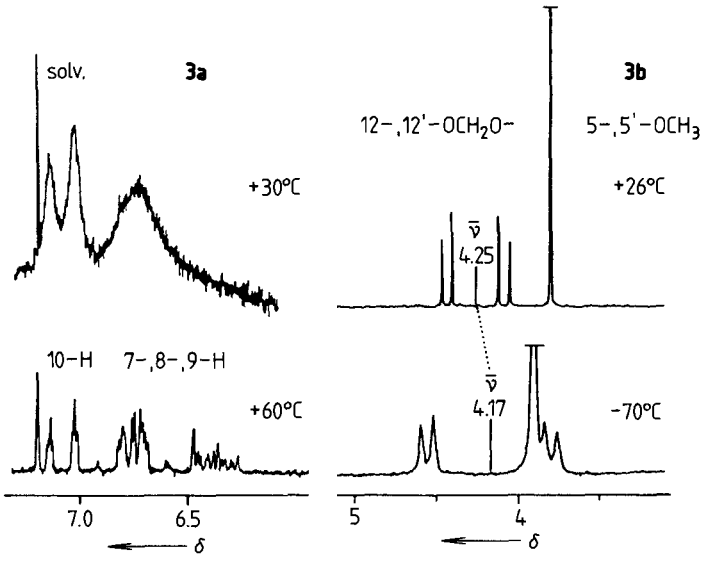

Fig. 1. Parts of the 250-MHz ^{1}H-NMR spectra (in $CDCl_3$) of **3a** and **3b** at various temperatures. **3b**: $\nu_A = 4.08$, $\nu_B = 4.42$, $J_{AB} = 5.7$ Hz.

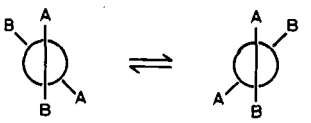
line-broadening is not observable in the ^{1}H-NMR spectrum of the 5,5'-bismethoxy compound recorded at −80°C[7]. In the case of **3b** the protons of two of the four methylene groups give an AB spectrum up to the highest measuring temperature of 152°C (Fig. 1). We ascribe these bands to the "inner" methoxymethyl groups bound to C-12 and C-12'. The same is observed in the case of **4b**. Moreover, the chemical shifts ν_A and ν_B of **3b** are temperature-dependent.



Scheme 1. Atropisomerism of the chiral binaphthoazulenes. Definition for A, B see **3**.

The spectral data of **3a** and **3b** provide proof of the high "racemization threshold", from which stable enantiomers can be expected[8]; however, because of the sparing solubility, a resolution of the enantiomers has not yet been realized. The DNMR spectra of **3a** and **6** indicate an additional restriction to rotation about the C(12)–O and C(12')–O bonding. The "twisted" arrangement of the two halves of the azulenequinone in **5** (see Scheme 1) can be deduced from the electronic spectra: Aside from a weak bathochromic shift of the two long-wave absorption bands in **5** in comparison to **1**, almost a doubling of the extinction coefficients is found over the whole range of measurement (Fig. 2).

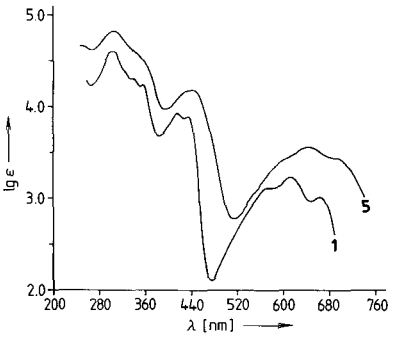


Fig. 2. Electronic spectra of **1** and **5**.

Electrochemiluminescence of Tetrakis(diphosphonato)diplatinate(II)**

By *Arnd Vogler** and *Horst Kunkely*

Intermolecular photoredox reactions of electronically excited transition metal complexes with reducing or oxidizing agents have been the subject of intensive study in recent years[1]. The converse of such processes leads, under suitable conditions, to chemiluminescence (CL). A special case is electrochemiluminescence (ECL). So far only a few investigations have been carried out on the CL[2] or ECL[3] of metal complexes, even though such studies provide important information on the mechanism of redox reactions; hitherto, such investigations have been restricted to complexes which contain 2,2'-bipyridyl or related ligands. The luminescent states are almost exclusively of the charge transfer (metal→ligand)-type. Herein we report on the ECL of $[Pt_2(P_2H_2O_5)_4]^{4\ominus}$ ($A^{4\ominus}$). Both the associated redox processes as well as the ECL itself lead to changes in the metal-metal bonding in the binuclear platinum complex.

In $A^{4\ominus}$ the two Pt^{II} centers are bridged by the dianions of the diphosphonic acid. The metal-metal interaction gives rise to the following series of MOs in order of increasing energy: $1a_{1g}(5d_{z^2}) < 1a_{2u}(5d_{z^2}) < 2a_{1g}(6p_z) < 2a_{2u}(6p_z)$[4]. The a_{1g} orbitals are bonding and the a_{2u} orbitals are antibonding. In the ground state of $A^{4\ominus}$ ($1a_{1g}^2 1a_{2u}^2$) the formal Pt–Pt bond order is therefore 0. At room temperature and in solution, $A^{4\ominus}$ shows an intense photoluminescence of the lowest excited state ($1a_{1g}^2 1a_{2u}^1 2a_{1g}^1$) with bond order 1[4]. Both a weak fluorescence ($\lambda_{max} = 407$ nm) of the singlet $^1A_{2u}$ as well as an intense phosphorescence ($\lambda_{max} = 517$ nm) of the accompanying triplet $^3A_{2u}$ is observed[4].

A 1-cm spectrophotometer cell fitted with two platinum-foil electrodes was used for the ECL investigations. Solutions of $A^{4\ominus}$ as the tetrabutylammonium salt in oxygen-free anhydrous acetonitrile was subjected to an alternating current electrolysis with variable frequency (*sine-wave* generator, Kröncke Mod. 1246) using $nBu_4N^{\oplus}BF_4^{\ominus}$ as supporting electrolyte. With an effective voltage of 4 V and frequency of 280 Hz and a current of 13 mA, a marked green luminescence was observed at one electrode, even with the naked eye. The electrochemiluminescence (Fig. 1) in the long wave region was identical with the photophosphorescence, but no short-wave fluorescence could be observed.

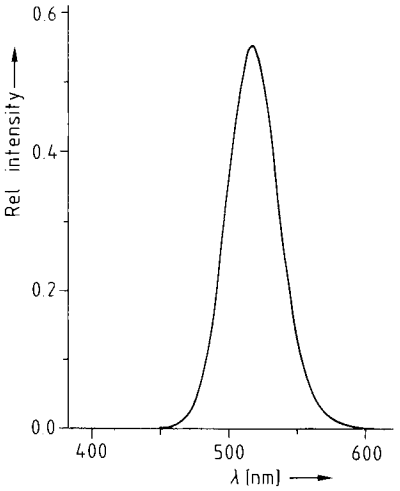

Fig. 1. Electrochemiluminescence spectrum of a solution of 2×10^{-4} M (nBu_4N)$_4$[$Pt(P_2H_2O_5)_4$] and 0.1 M (nBu_4N)BF_4 in CH_3CN; alternating current of 4 V and 280 Hz.

From these observations we conclude that $A^{4\ominus}$ is oxidized to $A^{3\ominus}$ during the anodic phase and reduced to $A^{5\ominus}$ during the cathodic phase. The recombination

$$A^{3\ominus} + A^{5\ominus} \longrightarrow A^{4\ominus *} + A^{4\ominus}$$

furnishes sufficient energy to generate one of the two product molecules in the lowest excited state, the triplet $^3A_{2u}(*)$.

The Pt–Pt bond is strengthened (bond order 1/2), both in the oxidation of $A^{4\ominus}$ to $A^{3\ominus}$ (ground state: $1a_{1g}^2 1a_{2u}^1$) and the reduction to $A^{5\ominus}$ (ground state: $1a_{1g}^2 1a_{2u}^2 2a_{1g}^1$). On the other hand, the recombination involves both a bond-weakening ($A^{4\ominus}$ in the ground state) and bond-strengthening ($A^{4\ominus}$ in the excited state).

Since the ECL spectrum shows only the phosphorescence, and not the fluorescence, the potential difference between $A^{3\ominus}$ and $A^{5\ominus}$ is only sufficient to reach the lowest triplet $^3A_{2u}$ (≈ 2.6 V). The energy of the superposing singlet $^1A_{2u}$ (≈ 3.3 V) is apparently not attained anymore.

The high frequency necessary for observation of the ECL would indicate that the oxidized ($A^{3\ominus}$) or reduced complex ($A^{5\ominus}$), or both, have a very short half-life. This has recently been confirmed: $A^{3\ominus}$ exists only in the solid state in the form of Pt_2 chains which are bridged by halide $X^{\ominus}$[5]; in solution $A^{3\ominus}$ immediately disproportionates into $A^{4\ominus}$ and $AX_2^{4\ominus}$. $A^{5\ominus}$ was generated by pulse radiolysis, but rapidly disappeared ($k = 2.9 \times 10^4$ s^{-1})[6]. It is therefore understandable that it was not possible to determine the redox potentials for the reversible one-electron process by cyclovoltammetry. On attempting to quench the photoluminescence of $A^{4\ominus}$ by electron donors and acceptors, it was however possible to estimate the redox potentials. Donors such as *N,N*-dimethylaniline ($E_{1/2} = 0.78$ V vs SCE) and *N,N*-dimethyl-*p*-toluidine ($E_{1/2} = 0.65$ V) could not quench the photoemission of $A^{4\ominus}$. Even the strong reducing agent *N,N,N',N'*-tetramethyl-*p*-phenylenediamine ($E_{1/2} = +0.24$ V vs SCE) did not effect reduction of $A^{4\ominus}$ in the $^3A_{2u}$ state. It follows, therefore, that the reduction of $A^{4\ominus}$ in the ground state requires at least $E_{1/2} = -2.3$ V vs SCE. In contrast, the phosphorescence of $A^{4\ominus}$ is quenched by relatively weak acceptors[7]. It is estimated that the oxidation of $A^{4\ominus}$ takes place at potentials of less than $E^0 = +1.6$ V vs NHE. The alternating potential of 4 V (2 V

Na_3P_{21} and Li_3P_{21}, the First Polyphosphides with Isolated P_{21}^{3-} Groups**

By *Marianne Baudler*, Doris Düster, Klaus Langerbeins,* and *Joachim Germeshausen*

We recently reported on the synthesis of the polyphosphides Li_3P_7[1] and Li_2P_{16}[2] by nucleophilic cleavage of white phosphorus with lithium dihydrogen phosphide. Salts containing isolated P_n^{m-} anions are of current interest because of their structural relationship with the phosphorus hydrides P_nH_m and organophosphanes P_nR_m and because of their potential use as building blocks for the synthesis of novel polyphosphorus compounds. Herein we report on the synthesis of a trisodium henicosaphosphide and a trilithium henicosaphosphide containing isolated P_{21}^{3-} groups.

Na_3P_{21} **1**[3] is formed on reaction of white phosphorus with substoichiometric amounts of sodium in 1,2-dimethoxyethane or tetrahydrofuran (THF). Other products of the reaction include Na_2P_{16}[4], Na_2HP_7[4], and further, as yet unidentified polyphosphides. The product pattern is strongly dependent on the reaction conditions: The best crude yield of **1** (up to 75 P-% of the soluble reaction products) is obtained at a P : Na ratio of 2 : 1 (not 7 : 1!) in boiling THF. $Na_3P_{21}\cdot 15\,THF$, a solvent adduct of **1**, can be isolated analytically pure by crystallization at −20 °C. On drying, the orange needle-shaped crystals lose a part of the solvent of crystallization with concomitant decomposition to Na_2P_{16} and other polyphosphides. Above −10 °C liquefaction occurs, whereas at room temperature slow disproportionation takes place. The henicosaphosphide is only slightly sensitive to oxidation but strongly sensitive to hydrolysis.

Li_3P_{21} **2** is formed as main product on reaction of Li_3P_7[1,5] with iodine or 1,2-dibromoethane as well as on metalation of P_7H_3[5] with lithium dihydrogen phosphide or *n*-butyllithium under suitable reaction conditions[6]. **2** is also formed on decomposition of LiH_2P_7[7] and Li_2HP_7[7] at room temperature and on nucleophilic cleavage of white phosphorus[8]. Because of the similarity to **1** we have not isolated **2**.

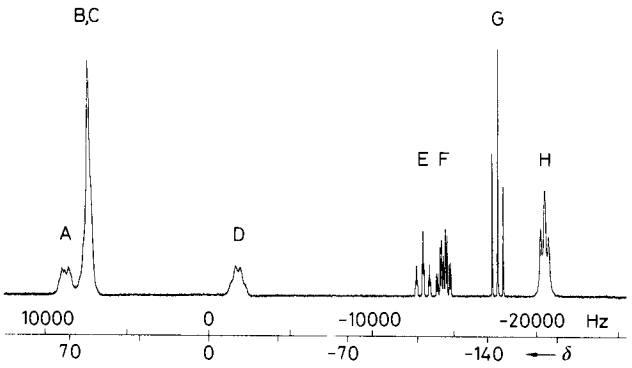

Fig. 1. ^{31}P-NMR spectrum of Na_3P_{21} in tetrahydrofuran/dimethylformamide (ca. 2 : 1) at 243 K (121.497 MHz).

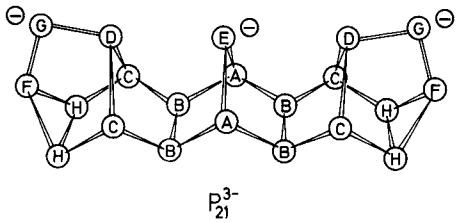
1 and **2** show identical ^{31}P-NMR spectra, in which seven groups of signals occur at $\delta = +72$, $+61$, -15, -108, -118, -146 and -169 (intensity ratio 2 : 8 : 2 : 1 : 2 : 2 : 4) (Fig. 1). The number and intensities of the groups indicate a symmetrical P_{21} skeleton. On the basis of their splitting patterns, chemical shifts and relative



P_{21}^{3-}

intensities the signal groups D, F, G, and H are each to be assigned to five P atoms from two equivalent P_7 cages with nortricyclene structure[9]. As evidenced by the triplet-like signal group E, a P_7-substructure analogous to norbornane with negative charge on the P atom of the P_1-bridge is present as linkage between the two cages. Correspondingly, from the intensities of the remaining signals it follows that the downfield group A arises from the two central bridgehead atoms[10], while the neighboring intense signal B, C arises from the remaining two pairs of four equivalent P atoms.

The constitution of the P_{21}^{3-} ion as decacyclo-[9.9.1.$0^{2,10}$.$0^{3,7}$.$0^{4,9}$.$0^{6,8}$.$0^{12,20}$.$0^{13,17}$.$0^{14,19}$.$0^{16,18}$]henicosaphosphide(3−) is confirmed by the homoscalar-correlated 2D-^{31}P-NMR spectrum (COSY spectrum[11]) of **1** (Fig. 2). All $^1J(PP)$ couplings of the directly linked and non-degenerated P atoms appear as cross-peaks.

The P_{21}^{3-} ion is the largest isolated $P_n(m)$ unit group known so far. In K_4IP_{21} synthesized by *von Schnering* et al.[12] these P_{21}^{3-} groups are linked, after opening of their three-membered rings, to give a polymeric $^2_\infty[P^-_7]$-structure. As a conjuncto-phosphane the isolated $P_{21}(3)$ skeleton is made up of a $P_7(5)$ unit analogous to

[3] Procedure for **1**: Freshly distilled white phosphorus (3.0 g, 0.097 g-atom) and powdered sodium (1.1 g, 0.048 g-atom) in THF (150 mL) are slowly stirred and heated under reflux for 2.5 h under inert gas. The solution turns red, and a fine black precipitate separates out. After removal of the solid by filtration (reduced pressure) at room temperature the filtrate is cooled to −20°C and allowed to stand until completion of crystallization. The crude product is filtered off in the cold (without reduced pressure!) and washed five times with 10 mL of cold THF. Dissolution in 20 mL THF at 0°C and renewed crystallization at −20°C yields pure **1**, which is filtered cold and dried under oil pump vacuum for 15 s; yield 3.0 g $Na_3P_{21}\cdot 15$ THF (36%). Further amounts of **1** can be recovered from the mother liquor.

Stereoselective Total Synthesis of Chlamydocin and Dihydrochlamydocin**

By *Ulrich Schmidt**, *Albrecht Lieberknecht*, *Helmut Griesser*, and *Frank Bartkowiak*

Chlamydocin **8**[1], a cyclic tetrapeptide with extremely high cytostatic activity in vitro, was isolated together with dihydrochlamydocin **7** from culture filtrates of *Diheterospora chlamydosporia*, and its structure and conformation was elucidated in 1976[1,2]. We recently reported[3] on a synthesis of chlamydocin + *epi*-chlamydocin, for epoxidation of the corresponding vinyl ketone proceeded without asymmetric induction by the peptide ring[***]. We now describe the stereoselective total synthesis of **7** and **8** (Scheme 1), in which the *S,S*-configuration at C^8 and C^9 of the substituted aminodecanoic acid is achieved with the aid of (*R,R*)-tartaric acid and the *S*-configuration at C^2 is formed by enantioselective hydrogenation.

Incorporation of the C^7–C^{10} segment of the (2*S*,8*S*,9*S*)-2-amino-8-hydroxy-9,10-epoxydecanoic acid in **7** can be accomplished with the aldehyde **1**, which is readily accessible from (*R,R*)-tartaric acid[4]. Condensation with triphenyl(4-trimethylsiloxybutylidene)phosphorane[7] and subsequent oxidation led to the C_8-aldehyde **2** (*E/Z* mixture), which was condensed with methyl *N*-benzyloxycarbonyl-2-(dimethoxyphosphinyl)glycinate[8] to give the dehydroamino acid ester **3** (diastereomeric mixture). Enantioselective homogeneous hydrogenation of the *E/Z* mixture with the Monsanto catalyst $[Rh(cod)(dipamp)]^{\oplus}BF_4^{\ominus}$[9] led with high enantioselectivity (*ee* > 98%) to the (*S*)-amino acid derivative. Subsequent heterogeneous hydrogenation of the C^6–C^7 double bond, hydrogenolysis of the benzyl ether and benzyloxycarbonyl protecting group, followed by reincorporation of the protecting group, replacement of OH by Cl, and hydrolysis furnished the amino acid **4**, from which the tetrapeptide pentafluorophenyl ester **5** was synthesized by conventional methods. Ring closure by the method previously developed by us[10] afforded the cyclopeptide **6** in high yield. Absolutely no racemization at the proline was observed, for this would have led to a cyclo-

Synthesis of chlamydocin **8**. *a:* $Ph_3P^{\oplus}-(CH_2)_4-O-SiMe_3Br^{\ominus}$ + $(Me_3Si)_2NLi$, −70°C, 30 min→RT, 10 h. *b:* Pyridinium chlorochromate, CH_2Cl_2, RT, 1 h. *c:* Methyl *N*-benzyloxycarbonyl-2-(dimethoxyphosphinyl)glycinate, KO-*t*Bu, CH_2Cl_2, −70°C, 30 min. *d:* [Rh(cod)(dipamp)]$^{\oplus}BF_4^{\ominus}/H_2$, EtOH, RT, 3 d, 3 bar [9]. *e:* Pd/H_2, MeOH, RT, 1 d, 3 bar. *f:* Benzyloxycarbonyl chloride. *g:* 1-Chloro-1-dimethylamino-2-methyl-1-propene + pyridine, CH_2Cl_2, −20°C, 30 min, 40°C, 30 min. *h:* $NaOH/H_2O$/dioxane, RT, NaOH added dropwise over 5 h: pH < 11. *i:* H-Aib-(*S*)-Phe-(*R*)-Pro-OCH_3/DCCD, ethyl acetate, −20°C→RT. *k:* $NaOH/H_2O$/dioxane, RT, 5 h. *l:* C_6F_5OH/DCCD/ethyl acetate, −20°C→RT. *m:* H_2/Pd, dioxane, 95°C, 5 h, reaction at high dilution. *n:* Oxalic acid/dioxane/H_2O, 80°C, 4 h. *o:* K_2CO_3/CH_3OH, RT, 4 h. *p:* DCCD/DMSO/dichloroacetic acid. – Bn: benzyl; Cbz: benzyloxycarbonyl.

tetrapeptide with three (*S*)-amino acids. In this series, such isomers are formed in only extremely small yields and are easy to recognize on chromatographic separation.—Hydrolysis of the ketal and epoxidation yielded dihydrochlamydocin **7**, which was oxidized to the chlamydocin **8** with dicyclohexylcarbodiimide (DCCD)/dimethyl sulfoxide (DMSO)/dichloroacetic acid. The NMR spectra and α_D^{20}-values of the synthetic product were identical with those of the natural product. The agreement in the CD spectra is illustrated in Figure 1.

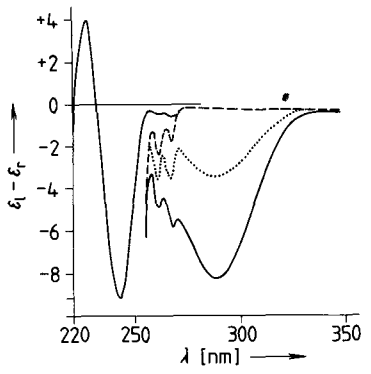

Fig. 1. CD spectra of chlamydocin **8** and epimeric mixtures in ethanol ($c = 3.9 \times 10^{-4}$ mol/L). Absorptions appear in different regions for the peptide ring (220–275 nm) and the epoxyketone group (250–340 nm). (-----): 50% **8** + 50% 9-*epi*-chlamydocin (complete racemization at C^9) [3]; (·····): 70% **8** + 30% 9-*epi*-chlamydocin, obtained by oxidation of **7** with pyridinium chlorochromate; (——): natural chlamydocin **8** and product obtained by oxidation of **7** with DCCD/DMSO/dichloroacetic acid. The curves for $\lambda = 250$–350 nm are tenfold higher than those for $\lambda = 220$–270 nm. 250–350 nm: 2.

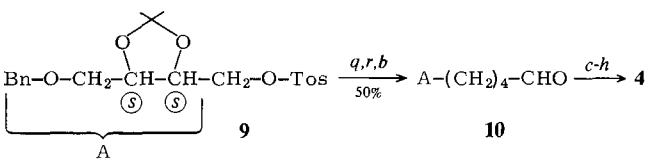
An alternative route to the (*S*)-amino acid **4** involved the use of the tartaric acid derivative **9**[5] and the readily accessible 4-trimethylsiloxybutyl cuprate[11] as starting materials. The coupling product was oxidized to the aldehyde **10**, which reacted analogously to **2** to give **4** (Scheme 2).



Scheme 2. Alternative route for the synthesis of the aldehyde **4**. *q:* $[Me_3Si-O-(CH_2)_4]_2LiCu$, diethyl ether, −70°C→RT. *r:* *n*-$Bu_4N^{\oplus}F^{\ominus}$, acetone, RT, 10 min.—For abbreviations see Scheme 1.

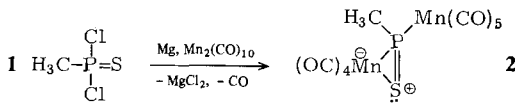
Methyl(thioxo)phosphane: Generation and Trapping Reaction with $Mn_2(CO)_{10}$**

By *Ekkehard Lindner*, Konrad Auch, Wolfgang Hiller,* and *Riad Fawzi*

The generation of diphosphenes by using extremely bulky or electron-rich organic substituents as protecting groups has been reported on a number of occasions just recently[1]. However, to our knowledge, not a single representative of the thioxophosphanes RP=S, which are isoelectronic with diphosphenes RP=PR, has so far been isolated. Owing to its alkene-[2] or alkyne-like[3] behavior, the −P=S function is a valuable building block for the synthesis of numerous heterocycles. We have now been able to trap the intermediate formed on reaction of magnesium[4] with dichloro(methyl)thioxophosphorane **1** in presence of $Mn_2(CO)_{10}$, namely a methyl(thioxo)phosphane[5], whose molecular skeleton remains intact in the complex **2**.



The observation that only traces of the binuclear complex **2** can be detected in the reaction of **1** with $[Mn(CO)_5]^{\ominus}$ points to dehalogenation of **1** by magnesium and thus to an attack of $CH_3P{=}S$ on intact $Mn_2(CO)_{10}$. Attempts to prepare $[Fe_2(CO)_6(P_2tBu_2)]$[6] by analogous addition of RP=S to an $Fe_2(CO)_6$ fragment were unsuccessful; instead, rupture of the P=S bond led to formation of the trinuclear clusters $(\mu_3\text{-}S)(\mu_3\text{-}RP)Fe_3(CO)_9$[7] (R = CH_3, 4-$CH_3OC_6H_4$, C_6H_5).

The air- and moisture-insensitive yellow crystals of **2** (from toluene/*n*-hexane, m.p. 104°C) are readily soluble in polar solvents, but only sparingly soluble in apolar solvents. The binuclear complex was characterized by complete elemental analysis, and by its IR, ^{1}H- and ^{31}P-NMR and mass spectra[8], and an X-ray structure analysis (Fig. 1). Because of the low symmetry of the molecule, nine C≡O absorptions of different intensity are observed for the $Mn(CO)_4$ and $Mn(CO)_5$ fragments in the 5 μm region of the IR spectrum. The CH_3 stretching and deformation vibrations as well as ν(P–C) of the CH_3PS-ligand can be unequivocally assigned.

The X-ray structure analysis of **2** confirms the presence of the methyl(thioxo)phosphane ligand, which is coupled side-on with a $(OC)_4Mn$ complex fragment and end-on via the P atom with a $(OC)_5Mn$ group. The P=S function, with a bond length of 203 pm, should exhibit pronounced π-bonding. The sterically bulky $(OC)_5Mn$ group leads to a noticeable widening of the Mn–P–Mn angle.

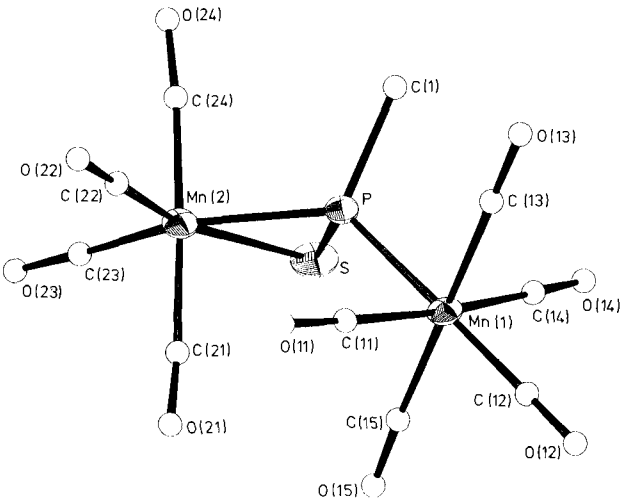


Fig. 1. Molecular structure of **2** in the crystal. Monoclinic, $P2_1/n$, $a = 659.4(3)$, $b = 1520.6(3)$, $c = 1631.2(3)$ pm, $\beta = 93.29(3)°$, $\rho_{calc} = 1.433$ g/cm^3, $Z = 4$, $Mo_{K\alpha}$ radiation. The structure was determined by direct methods (Multan), $R = 0.059$ (1801 symmetry independent reflections with $I \geq 3\sigma(I)$, 4247 measured reflections, 208 refined parameters). Selected bond lengths [pm] and angles [°]: Mn(1)–P 239.4(2), Mn(2)–P 228.9(2), Mn(2)–S 241.4(2), P–S 203.3(2), P–C(1) 184.7(6), Mn(2)–S–P 61.2(1), Mn(2)–P–S 67.6(1), S–Mn(2)–P 51.1(1), Mn(2)–P–Mn(1) 129.4(1), Mn(2)–P–C(1) 117.1(2), Mn(1)–P–S 115.5(1), Mn(1)–P–C(1) 109.3(2), S–P–C(1) 108.7(2). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2 on quoting the depository number CSD 50677, the names of the authors, and the full citation of the journal.

[5] Procedure: All operations were carried out in anhydrous solvents under an inert gas. A solution of **1** (520 mg, 3.5 mmol) in THF (50 mL) was added dropwise within 3 h at 20°C to a mixture of 240 mg (10 mmol) of highly reactive magnesium (prepared from $MgCl_2$ and potassium in THF [4]) and 980 mg (2.5 mmol) $Mn_2(CO)_{10}$ in 100 mL tetrahydrofuran (THF). After filtration over silica gel (P3) and removal of the solvent in vacuo, column chromatographic separation (silica gel, Act. I, $l = 5$ cm, $\varnothing = 25$ mm, eluent *n*-hexane/CH_2Cl_2 5:1) of the residue dissolved in 10 mL $CHCl_3$ yielded pure **2** as second fraction. Yield 78 mg (7%).

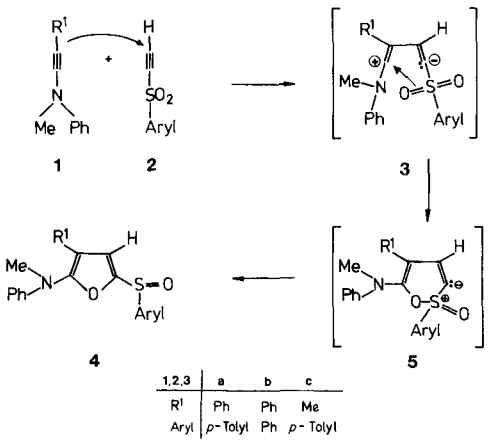
2-Amino-5-sulfinylfurans from Sulfonylacetylenes and Ynamines

By *Gerhard Himbert**, *Steffen Kosack*, and *Gerhard Maas*

Ynamines undergo [2+2]-cycloaddition with electrophilic double bonds to give cyclobutenes which are either stable or spontaneously isomerize[1]. In contrast, reactions of ynamines with acetylenedicarboxylates or nitroacetylenes have been reported not to give cyclobutadienes but benzene derivatives (1:2-addition)[2] and, depending on the structure, also enynamines (aminoethynylmetalation)[3] or nitrile oxides[4]. Also, open-chain 1,4-dipolar species are more likely than cyclobutadienes as intermediates for these products[1]. It was recently reported that *N,N*-diethyl(-1-propynyl)amine should react with phenyl(1-propynyl)sulfone quantitatively to give the corresponding cyclobutadiene[5,6]. We have now found that the reactions of the somewhat less reactive ynamines **1** (these have a methylanilino instead of a diethylamino group) with the sulfonylacetylenes **2** lead smoothly to the 2-amino-5-sulfinylfurans **4**[7].



1,2,3	a	b	c
R^1	Ph	Ph	Me
Aryl	*p*-Tolyl	Ph	*p*-Tolyl

We presume that the reaction is initiated by a nucleophilic attack of the ynamine β-C atom at the terminal C atom of the sulfonylacetylene. The zwitterion **3** thus formed then cyclizes via the S=O bond to give the "ylidic" heterocycle **5**, which finally furnishes the furans **4** in the sense of a Pummerer rearrangement[8].

First indications of the structure of our 1:1 adducts, and thus of the participation of the sulfonyl group in the reaction, were provided by the IR spectra: They are essentially free of bands in the regions characteristic for SO_2 vibrations around 1150 and 1300–1350 cm^{-1}. An intense absorption at about 1045 cm^{-1} (Table 1) points to the presence of a sulfinyl group. Particularly characteristic in the ^{1}H-NMR spectra are the singlet of the proton at position 4 of the furan moiety and the doublet of the corresponding ^{13}C-atom ($^1J_{C,H}=178$ Hz) (Table 1).

Although the furan derivative **4a** can be reduced to the sulfide [yield 10%; m.p. 108–109°C; ^{1}H-NMR ($CDCl_3$): $\delta=7.03$ (s; 1H, furyl-4*H*)] and oxidized to the sulfone [36%; m.p. 137–138°C; ^{1}H-NMR ($CDCl_3$): $\delta=7.46$ (s; 1H, furyl-4*H*); IR (KBr): $\nu=1327$ s, 1161 s, 1141 s cm^{-1} (SO_2 region)], attempted chemical identification by derivatization or hydrolysis has so far met without success. The constitution of **4a** was therefore elucidated by an X-ray structure analysis (Fig. 1)[9].

Table 1. Yields and some physical data of the 2-amino-5-sulfinylfurans **4**.

4	Yield [%] (M.p. [°C]) [a]	IR (KBr) [cm^{-1}] C=C	S=O	^{1}H-NMR ($CDCl_3$; δ values) Characteristic signals [b]
a [d]	52–64 [c] (116–117)	1616 m 1592 s 1578 sh 1509 sh 1488 s	1045 s	2.42 (s; 3H, aryl-*Me*) 3.17 (s; 3H, N*Me*) 7.04 (s; 1H, furyl-4H)
b	67 (114–115)	1611 m 1592 s 1578 sh 1511 sh 1492 s	1048 s	3.16 (s; 3H, N*Me*) 7.09 (s; 1H, furyl-4H)
c	55 (61–62)	1625 m 1595 s 1576 sh 1488 s	1041 s	1.76 (s; 3H, furyl-*Me*) 2.42 (s; 3H, aryl-*Me*) 3.21 (s; 3H, *N*Me) 6.61 (s; 1H, furyl-4H)

[a] Melts with decomposition. [b] The singlet for the furyl proton in position 4 is recognizable with some degree of certainty; in the case of **4a** the assignment is confirmed by the use of deuterated sulfonylacetylene. [c] 87% yield on using a 2.5-fold excess of ynamine. [d] ^{13}C-NMR ($CDCl_3$, 50.28 MHz): $\delta=21.50$ (q; aryl-CH_3), 38.00 (q; N-CH_3), 114.61, 125.06, 126.45, 128.74, 129.06, 130.01 (6d; *o*- and *m*-*C* of the three phenyl rings), 120.18, 127.43, 141.86 (2d+1s; *p*-*C* of the three phenyl rings), 130.70, 138.27, 145.70 (3s; *ipso*-*C* of the three phenyl rings), 116.02 (s; C3), 116.89 (d; $J=178$ Hz; C4), 148.74 (s; C5), 152.51 (s; C2).

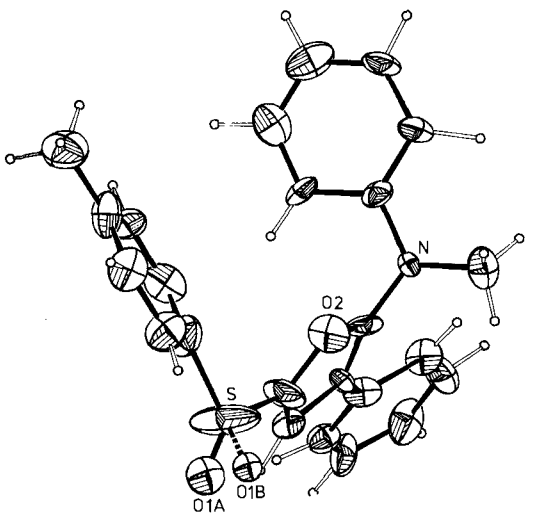


Fig. 1. Structure of an independent molecule of **4a** in the crystal (ORTEP plot). Vibration ellipsoids: 33% probability level. The oxygen atom of the sulfoxide group is disordered (exchange with a lone pair at the sulfur atom). Such a disorder also seems to be present in the second molecule; it could not however be meaningfully refined.

Synthesis and Crystal Structure of the Dicarbido Bimetallic Cluster $[Co_6Ni_2C_2(CO)_{16}]^{2-}$**

By *Aurora Arrigoni, Alessandro Ceriotti, Roberto Della Pergola, Giuliano Longoni*, Mario Manassero*, Norberto Masciocchi,* and *Mirella Sansoni*

Recently, we reported the synthesis and structural characterization of the carbido cluster $[Co_3Ni_9C(CO)_{20}]^{3-}$ **1**[1,2]. We report here the synthesis and crystal structure of a chemically related bimetallic dicarbido cluster, namely the dianion $[Co_6Ni_2C_2(CO)_{16}]^{2-}$ **2**, which is the first simple-hexagonal array of metal atoms whose cavity is completely filled by carbido C atoms.

The dicarbido cluster **2** was originally detected by IR spectroscopy, together with several other species, in the reaction of $[Co_3(CO)_9CCl]$ **3** with $[Ni_6(CO)_{12}]^{2-}$ **4** when **3** and **4** are allowed to react in a molar ratio greater than that used previously to synthesize **1**[1,2]. **2** can be synthesized selectively from **1** and **3** according to equation (a) or by slow addition of **4** to **3** (ca. 1:2 molar ratio) in tetrahydrofuran (THF) [equation (b)]. The dianion **2** has been isolated in more than 70% yield with several tetrasubstituted ammonium or phosphonium counterions; the $Et_4N^{\oplus}$ salt has been crystallized from acetone/heptane[3].

$$2\,[Co_3Ni_9C(CO)_{20}]^{3-} + 4\,[Co_3(CO)_9CCl] \longrightarrow 3\,[Co_6Ni_2C_2(CO)_{16}]^{2-} + 2\,NiCl_2 + 7\,Ni(CO)_4 + 3\,Ni \quad \text{(a)}$$

1 **3** **2**

$$2\,[Co_3(CO)_9CCl] + [Ni_6(CO)_{12}]^{2-} \longrightarrow [Co_6Ni_2C_2(CO)_{16}]^{2-} + NiCl_2 + 3\,Ni(CO)_4 + 2\,CO \quad \text{(b)}$$

3 **4** **2**

The structure of the $Et_4N^{\oplus}$ salt of **2** has been elucidated by X-ray diffraction (Fig. 1)[4]. Dianion **2** has a crystallographic C_i-$\bar{1}$ and an idealized C_{2h}-2/m symmetry and originates from the condensation of two trigonal-prismatic moieties sharing a common square face. An idealized mirror plane is defined by atoms Co1, Co1′, Ni3, and Ni3′. The metal framework of **2** represents a fragment of a simple hexagonal metal lattice, which is stabilized by filling each of the two trigonal prismatic cavities with two carbido C atoms[5]. Previously described clusters having this type of trigonal prismatic building unit are, for instance, $[Rh_6C(CO)_{15}]^{2-}$[6], and the pseudo one-dimensional oligomers $[Pt_3(CO)_6]_n^{2-}$ (n = 2–5)[7].

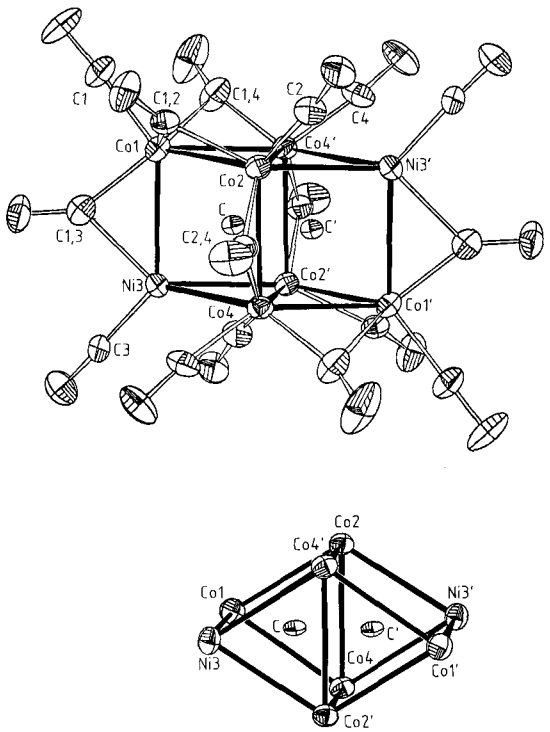

Fig. 1. ORTEP view of the structure of **2** in the crystal. Complete dianion (top) and naked metal framework with the two interstitial C atoms (bottom). Most important distances [Å]: M–M: Co1-Co2 = 2.577(1), Co1-Co4 = 2.528(1), Co1-Ni3 = 2.548(1), Co2-Co4 = 2.775(1), Co2-Co4′ = 2.559(1), Co2-Ni3′ = 2.647(1), Ni3-Co4′ = 2.590(1). – M–$C_{carbido}$: Co1-C = 1.953(5), Co2-C = 2.048(6), Ni3-C = 1.885(5), Co4-C = 2.031(5), Co2′-C = 2.017(6), Co4′-C = 2.023(6). – M–$CO_{terminal}$: Co1-C1 = 1.755(8), Co2-C2 = 1.753(8), Co4-C4 = 1.739(8), Ni3-C3 = 1.774(8). – M–$CO_{bridging}$: Co1-C1,3 = 1.845(8), Co1-C1,2 = 2.317(8), Co1-C1,4 = 2.034(7), Co2-C1,2 = 1.797(8), Co2-C2,4 = 1.956(7), Ni3-C1,3 = 1.967(7), Co4-C1,4 = 1.866(7), Co4-C2,4 = 1.929(7). – C–O: C1-O1 = 1.131(8), C2-O2 = 1.160(8), C3-O3 = 1.117(8), C4-O4 = 1.149(8), C1,3-O1,3 = 1.142(8), C1,2-O1,2 = 1.169(8), C1,4-O1,4 = 1.163(8), C2,4-O2,4 = 1.157(8). – C–C′ = 1.494(11).

In accord with analytical data[3], two atoms of **2** are less coordinated by CO ligands, and we presume that they are Ni atoms. The distance between the two carbido C atoms of 1.49 Å is shorter than typical CC single bonds in hydrocarbons (1.54 Å) and than most C···C interatomic separations in other dicarbido clusters[8,9]. Only the neutral Rh cluster $[Rh_{12}C_2(CO)_{25}]$ and the $[Co_{11}C_2(CO)_{22}]^{3-}$ trianion[10,11], whose metal frameworks originate from condensation of square-antiprismatic and trigonal prismatic moie-

ties, respectively, show comparably short CC interatomic separations (1.48 and 1.62 Å, respectively); an even shorter distance (1.41 Å) is exhibited by the trianion $[Co_3Ni_7C_2(CO)_{15}]^{3-}$[1]. In both $[Rh_{12}C_2(CO)_{25}]$ and $[Co_{11}C_2(CO)_{22}]^{3-}$, the calculated distances between the centers of the two idealized cavities (with edge length equal to the overall mean value of the M–M bonds) are longer than the experimentally determined CC distances (1.98 and 1.80 Å, respectively)[11]. In contrast, in **2** the corresponding calculated and experimental distances (1.49 Å) almost coincide. Such a short interatomic CC separation would be in keeping with the presence of a localized CC bonding interaction in **2**. However, the number of valence electrons (n_{CVE}) of the known carbonylmetal clusters of the first transition series systematically conforms to the relationship $n_{CVE} \geqslant 18N - 2n_{M-M}$ (where N and n_{M-M} are, respectively, the number of metal atoms and M–M bonds). Furthermore, EHMO calculations on a naked cluster having the idealized metal geometry of the title compound predict 58 cluster valence MOs[12]. **2** would therefore require at least 116 cluster valence electrons, which is fulfilled only if each interstitial C atom contributes four skeletal electrons. In accord with this, the thermal ellipsoids of the two carbido C atoms elongated in the CC direction appear to argue against the presence of a localized C–C bond in **2** and suggest a delocalized CC interaction supported by the metal atoms.

X-Ray Spectroscopic Studies of the Surface Species in Co–Mo–Al_2O_3 Hydrodesulphurization Catalysts

By *P. R. Sarode, G. Sankar, A. Srinivasan, S. Vasudevan, C. N. R. Rao*,* and *J. M. Thomas**

Despite a number of investigations of Co–Mo–Al_2O_3 hydrodesulphurization catalysts carried out in recent years[1], a clear understanding of the active sites in these catalysts has not emerged. Accordingly, we have carried out a systematic study of Al_2O_3-supported, sulphided cobalt-molybdenum (Co–Mo) catalysts and their oxide precursors over a wide range of compositions together with a number of model oxides and sulphides of cobalt and molybdenum, including several samples of Co-MoS_2. For this purpose, we have employed X-ray photoelectron spectroscopy (XPS) and X-ray absorption spectroscopy; in the latter, use was made of both X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) to determine coordination numbers and bond distances. The present study shows that Co^{II} and Mo^{IV} are present as sulphides on the surfaces of the active catalysts, each in octahedral coordination; furthermore, our results indicate the presence of disulphide bonds which may play a significant role in the hydrodesulphurization processes.

Co–Mo–Al_2O_3 precursors with Co:Mo ratios between 3:12 and 6:12 exhibit Mo($3d_{5/2}$) binding energies of 232.3 ± 0.1 eV (XPS) and a 3d spin-orbit splitting of 3.1 ± 0.1 eV, characteristic of Mo^{VI} species. The Co($2p_{3/2}$) binding energy is 781.7 ± 0.1 eV with a 2p spin-orbit splitting of 16.0 ± 0.1 eV and a satellite structure separated by ca. 6.2 eV from the main peak, showing that cobalt occurs as Co^{II}. The spectroscopic transition energies determined by XANES spectroscopy are similar to those of Co^{II} and Mo^{VI} oxides. The 1s→nd transitions show that Co is tetrahedrally coordinated whereas Mo is octahedrally coordinated in these oxide precursors. EXAFS spectra of the 4:12 and 6:12 oxide precursors confirm these coordinations and yield Co–O and Mo–O distances close to 2.0 and 1.80 Å, respectively (corresponding distances in CoO and MoO_3 are 2.12 and 1.86 Å).

Sulphided Co–Mo–Al_2O_3 catalysts with Co:Mo ratios between 2:12 and 12:12 show Mo($3d_{5/2}$) and Co($2p_{3/2}$) binding energies (228.9 ± 0.1 eV and 778.8 ± 0.1 eV, respectively) characteristic of Mo^{IV} and Co^{II}. The Co^{II} spectrum shows no satellites. In addition to these Mo^{IV} and Co^{II} species, the sulphided samples generally exhibit additional features due to Mo^{VI} and Co^{II} which are similar to those found in the oxide precursors. The S(2p)/Mo(3d) intensity ratio in XP spectra in the sulphided catalysts increases with increasing Co concentration. The Mo(3d)/Al(2p) intensity ratio also increases as the Co concentration increases, in contrast to the oxide precursors.

XANES spectroscopy suggests an octahedral coordination for both Co and Mo in their catalytically active sulphided state, the spectral transition energies being close to those of CoS and MoS_2. These coordinations are also corroborated by our EXAFS measurements. The Co–S and Mo–S distances found by EXAFS spectroscopy are 2.32 and 2.29 Å, respectively (the Co–S and Mo–S distances in

CoS, $(NH_4)_2MoS_4$, and MoS_2 are 2.39, 2.18, and 2.41 Å respectively).

We have estimated surface compositions of the 4:12 and 6:12 sulphided catalysts using known photoelectric cross sections by assuming the presence of Mo^{IV} and Co^{II}. The compositions thus found generally show the presence of an "excess" of sulphur. The average surface compositions of the 4:12 and 6:12 catalysts are $CoMo_6S_{22}$ and $CoMo_2S_{10}$, respectively. If the excess sulphur is present as disulphide, the two compositions conform to the general formula $CoMo_{2n}(2n+3)S_2^{2-}(2n-2)S^{2-}$.

While some of our results on the sulphided Co–Mo catalysts are in accord with earlier reports in the literature[2–4], what is significant is the possible presence of S_2^{2-} ions on the surfaces of dehydrosulphurization catalysts. Since it seems certain that octahedrally coordinated Co and Mo are present as 2^+ and 4^+ ions, respectively, we suggest that Co at the edges of MoS_2 sheets[5] favors the formation of disulphide linkages. The disulphide ion would be stabilized since the $Mo(d_{z^2})$ band is at a higher energy than the disulphide $3p^6$ band[6]. The S^{2-} $(3p^6)$ band overlaps the highest filled d band in group VIII elements such as Co. Furthermore, group VIII cations do not form strong π bonds as in MoS_2 and would favor disulphide linkages which could well be implicated in pathways for the hydrodesulphurization reaction.

Remarks on *Simon*'s Review Article "Intermetallic Compounds and the Use of Atomic Radii in Their Description"—Cell Dimensions of Phases with a Given Crystal Structure Do Not Generally Form a Homogeneous Data-Set

By *Erwin Hellner** and *William B. Pearson**

In general, the unit-cell dimensions of binary, intermetallic phases with a given crystal structure do not form a homogeneous data-set if the diameter of the component atoms is examined at high precision and attention is paid to the group and period of the component elements in the periodic table. This is demonstrated using examples of phases with the cubic $MgCu_2$- and $SiCr_3$-type structures. The reasons for, and consequences thereof, are noted.

We have read and discussed with much interest *Simon*'s appraisal[1] of atomic radii and interatomic distances in intermetallic and other phases. However, with respect to one of the main aspects of his paper, we feel obliged to emphasize the results of some of our studies[2–4]. In analyzing near-neighbor diagrams[5] for phases with the same structure type according to *Simon*, the general, implicit assumption is that the unit-cell dimensions form an essentially homogeneous set. This generally appeared to be plausible when such diagrams were introduced, and, within the bounds of the relative precision with which the plots were made, some useful "overviews" were obtained[5]. However, we now know that plots such as Figure 6 in *Simon*'s article do not represent a homogeneous data-set with general experimental scatter of data collected from various sources. If in plotting the cell dimension(s) of binary intermetallic phases M_xN_y with a particular structure against the diameter D_M of a variable component M (the other component N is fixed), the choice of M and N is made according to the group and period of the elements in the periodic table, quite a different picture emerges: Different slopes of a versus D_M (dimensional behavior) are observed depending on the selection of the component atoms[2]. Such plots, of course, have considerably higher precision; for example, Figure 1[6] shows the slopes for different groups of phases with the cubic $MgCu_2$ structure (part of the data-set of *Si-*

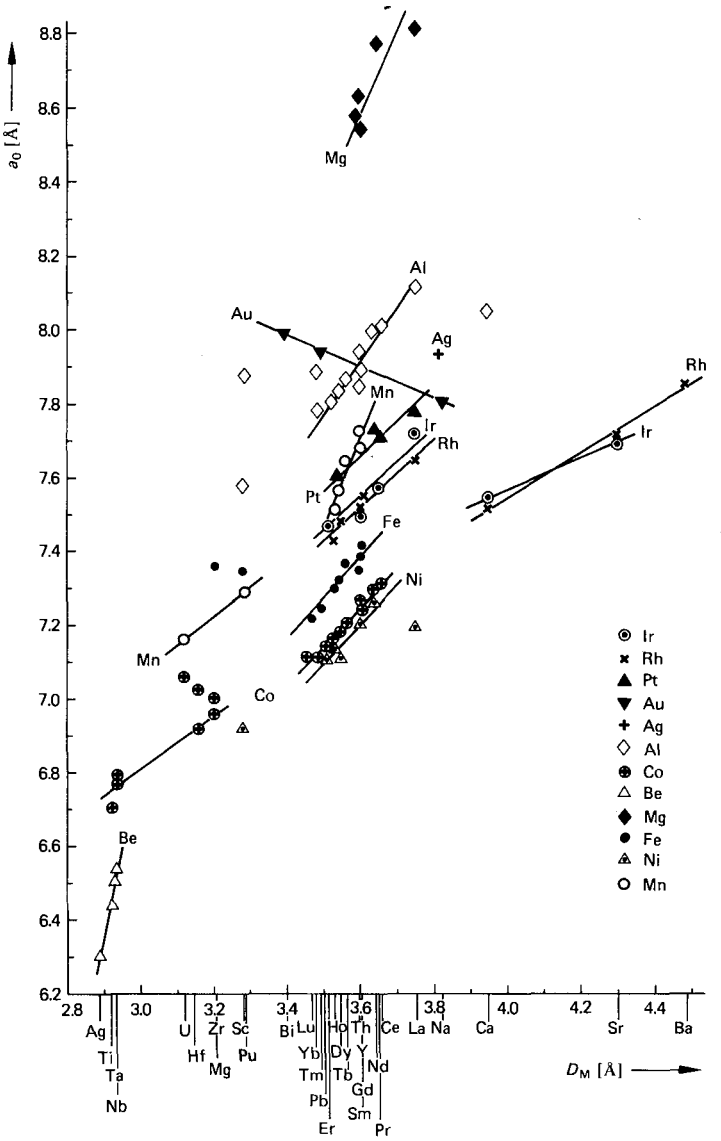

Fig. 1. Various phases (MN_2) with the cubic $MgCu_2$-structure. Plot of the unit-cell edge a_0 against D_M (diameter of the component M) for groups of phases that are formed by the same component N (indicated). The inhomogeneity of the data set is obvious.

mon's Fig. 6, cf. [1]). These slopes vary from ca. 2.5 for lanthanoid/manganese phases to -0.4 for nonlanthanoid/gold phases.

Even when the unit-cell dimensions have been adjusted to ideal stoichiometry and the data-set appears to be extremely homogeneous as in *Simon*'s Figure 17[1], which reproduces *Waterstrat*'s data for MN_3 phases with the cubic $SiCr_3$ structure, the delusion may originate from the low precision or poor selection of the components in the plot. Indeed, *Simon* is not alone in this respect. Recently, but for different and justifiable reasons, *Villars, Girgis,* and *Hulliger*[7] obtained a linear relation between $d_{MN} = a \cdot \sqrt{5}/4$ and $\overline{R} = (R_M + 3R_N)/4$—essentially a versus D_M if N is fixed—calculated for 91 phases with a linear regression factor of 0.989; this would certainly be interpreted as indicating a homogeneous data-set. Nevertheless, with plots of much higher precision obtained using *Waterstrat*'s cell dimensions (i.e. the same data as *Simon*) *Pearson*[4] arrived at a different conclusion.

In these compounds the component N is a transition metal and M may either be a transition metal (T-T phases) or a nontransition metal (B-T phases). When these two groups are considered separately and a is plotted against D_M varying M and the phases of each component N are considered separately then:

1) The slopes of a versus D_M for the B-T and T-T phases of the same N components are not exactly the same; and
2) for both groups of phases the slope of a versus D_M decreases approximately linearly with increasing diameter of component N and is proportional to $-0.4\ (\pm 0.1)\ D_N$.

Conclusions: Taking two structural types as examples analyzed by *Simon*, we have shown that when the data are examined much more precisely and attention is paid both to the choice of the group and period of the components of the phases they may not form an overall homogeneous data-set in terms of dimensional behavior. The recognition of such inhomogeneities requires analytical methods to determine their causes: Indeed, for phases with the $MgCu_2$ structure inhomogeneities in dimensional behavior have long been recognized[8–10], but since the analyses were conducted using radius ratios no interpretation was possible.

- For phases of medium complexity and/or symmetry lower than cubic, the study of atomic volumes provides little more than overall energy considerations.
- Even plots of cell-dimensions a (b, c) against the diameters of the component atoms D_M or D_N are insufficiently diagnostic.
- However, plots of individual interatomic distances relative to the corresponding sums of the atomic diameters (for CN = 12 regardless of the atomic coordination number in the structure[11]) against the atomic diameters D_M or D_N indicate the basic causes of the different dimensional behavior for specific groups of phases with a given structure. These differences do not result per se from the various diameters of the component atoms but from the different interatomic contacts, or combinations thereof, which control the cell dimensions of groups of phases exhibiting different dimensional behaviors. Such information, which is quantitative in nature, should be amenable to firm theoretical analysis (see e.g. data in [12] and [13]).

Our studies also show that in three-dimensional space with D_M and D_N for CN 12 as abscissae and the cell dimension as ordinate all phases with a given structure lie on a planar surface. One exception to this rule has been noted—phases with the $SiCr_3$ structure discussed previously. These phases lie on a curved surface in D_M, D_N, a-space; nevertheless, this surface has the property that phases formed by the same component N and T or B as components M lie along straight lines on it.

Finally, we draw attention to potential difficulties in analyzing near-neighbor diagrams sketched with high precision[14].

Intermetallic Compounds and the Use of Atomic Radii in Their Description—Reply

By *Arndt Simon**

The important remark made by *Hellner* and *Pearson*[1] that phases of one structure type to not represent a homogeneous set is further supported by the occurrence of (1st order) phase transitions which do not involve a change of structure type[2,3]. With this in mind, I stated in my review[4] "that it is not very meaningful to start an analysis of packing effects in a particular structure type on the basis of *all* known representatives". The Laves phases KNa_2, $CsNa_2$ and CsK_2 offer a model system—metallic bonding without significant heteropolarity—to study packing effects. The analysis yields a kind of Vegard rule, i.e. the distances between the atoms are proportional to the sum of atomic radii weighted according to the composition. On this basis, by means of a general approach for the adaption of atomic sizes to coordinations, the interatomic distances in the three phases can be calculated with high accuracy (3‰).

According to *Churcher* and *Heine*[5], such a Vegard-type law can only be plausible when certain assumptions about the interatomic potentials are made; but these assumptions are consistent with the relation between distances and force constants, according to *Badger*'s rule[6]. It must therefore be expected that many intermetallic compounds with topologically close packed structures obey such a Vegard-type law reasonably well. The alkali metal compounds mentioned follow this law extremely well, but all Laves phases of the $MgZn_2$ and $MgCu_2$ type are also reasonably well described by it (Fig. 6 in [4]), at least better than by a

[*] Prof. Dr. A. Simon
Max-Planck-Institut für Festkörperforschung
Heisenbergstrasse 1, D-7000 Stuttgart 80 (FRG)

simple sum of atomic radii ($r_M + r_N$). Nevertheless, the deviations and scatter of the data are significant. In part, they were discussed and by no means were they taken to arise from a "general experimental scatter of data collected from various sources". On the contrary, it is repeatedly pointed out[4] that this scatter is due to interesting influences of chemical bonding. One cannot expect compounds like $CaRh_2$, $SrIr_2$, $AuBi_2$, or $NaAu_2$ to exhibit the same dimensional behavior as KNa_2. A subdivision of compounds into single families as shown in Figure 1[1] and their analysis according to *Hellner* and *Pearson* provides hope of gaining insight into the chemical bonding in these compounds; more precisely, into interatomic potentials and mutual influences of atomic sizes. The same insight might hopefully be gathered from analysis of the deviations of real compounds from Vegard-type behavior, which can be formulated quantitatively.

What does "radius ratios ... are intractable" mean? Radius ratios (r_M/r_N; since $2r = D$, also D_M/D_N) are as good (or bad) as the anticipated atomic sizes D_M and D_N, respectively. These depend on the structure and on the bonding partner. This is clear if the transition of a metal from body centered cubic to face centered cubic packing, on the one hand, and the different sizes of the Cs atoms in CsF and CsK_2, on the other, are considered. Therefore, all representatives in [1], but also in [4] are based on normalized values D_M, D_N for the close-packed elements. We are left with the problem of using near-neighbor diagrams for the representation of all compounds belonging to one structure type[4]. *Hellner* and *Pearson* prefer plots of the lattice constants against D_M or D_N, and they use the experimental distances d_{MM}, d_{NN}, d_{MN} (relative to the normalized values D_M, D_N, or 0.5 $(D_M + D_N)$, e.g., $(D_M - d_{MM})$) instead of the lattice constants for structures with free parameters. The representation $(D_M - d_{MM})/(D_N = f(D_M/D_N)$ chosen in [4], of course, corresponds to the representation of the linear relationships in Figure 1[1], but with a different scale since D_N is a constant for each of these relationships. The problem lies not in the use of near-neighbour diagrams, but in the interpretation of the plot of experimental data. The interpretation given in [4] has a distinctly different basis than previous interpretations[7].

BOOK REVIEWS

Ozonation in Organic Chemistry. Vol. 2: Nonolefinic Compounds. By *P. S. Bailey*. Academic Press, New York 1982. xx, 497 pp., bound, $ 28.50.

"The saga of the many-faceted, many-splendored reactions of ozone with organic groupings is the purpose of this volume". Four years after Vol. 1[*], which deals with the ozonation of olefins, the author presents Vol. 2, which covers the literature until 1980 with 1249 citations.

A small chapter on the still underdeveloped ozonation of the *CC triple bond*—10^4 times slower than that of similarly substituted double bonds—is followed by four chapters dedicated to *aromatic compounds*. The author distinguishes between "bond attack" (O_3 as 1,3-dipole) and "atom attack" (O_3 as electrophile). The justification for applying the Criegee mechanism of olefinic ozonation to the aromatic compounds stems, inter alia, from the interception of the intermediate carbonyl oxides by methanol or acetic acid. These trapping reactions offer preparative access to dialdehydes starting from condensed aromatic systems.

The interaction of ozone with *nucleophiles* (amines, phosphites, thioethers and polysulfides) is the topic of a major chapter. The oxidation of the side chain as well as the oxide formation at the nucleophilic center are interpreted via the same O_3 adduct.

The reaction of ozone with CH and CH_2 groups is comparatively slower than with π systems, providing *tert*-alcohols and ketones, respectively. The initiating step of this important method (235 lit. ref.) is supposed to be a 1,3-dipolar CH insertion with partial carbonium character in the transition state; in superacid medium this insertion is ascribed to the species HO_3^+.

The *technique of ozonation* has made progress. The use of nitrogen as a carrier gas combined with the measurement of O_2 generation is an important analytical tool. In this operation, the ozone adsorbed on silica gel at $-78\,^\circ C$ is driven out by N_2. The "dry ozonation" on silica gel is likewise applied with increasing frequency. Quite justly the author pleads that most synthetic chemists are not sufficiently aware of the advantages of ozone as a reagent. The sewage purification with ozone and the controversy about the stratospheric ozone layer are briefly outlined.

The concluding chapter "Ozonation of Olefins Revisited" reports on the progress achieved (120 lit. ref.) since publication of Volume 1. Among other things, it is noteworthy that an ozonide has been found as a natural product in a fern. Dioxiranes, i.e., the cyclic isomers of carbonyl oxides, have been established at low temperature. The trump card that quantum chemists have predicted this species, is perhaps not so impressive; according to all MO or

VB calculations—except the most sophisticated ones—O_3 should possess the cyclic structure too.

Ozone participates in smog formation. This is the reason why ozonation in the gas phase was developed mainly by kineticists and ecologists. The embarrassing assumption that ozone reacts with hydrocarbons in the *gas phase* in a fundamentally different way than in solution, is becoming extinct. The introductory 1,3-dipolar cycloaddition and the subsequent 1,3-dipolar cycloreversion appear to be the same in gas and liquid phase. It is only the recombination of carbonyl oxide and carbonyl compound forming the ozonide which is replaced in the gas phase by unimolecular conversions of the carbonyl oxide and secondary reactions.

Grousing about a monograph meeting such high standards would be bad style. The quality of presentation deserves recognition. Statements about temperature, solvent and yields on the reaction arrows of the excellent formula blocks would be valuable for the reader. The "diradical structures" in the language of quantum chemists are sometimes falsely associated with reactivity by organic chemists. The notion of the carbonyl oxide occurring as a diradical in the gas phase and as a zwitterion in solution (p. 31) should not be taken verbally.

Whoever has to do with ozonation will find enlightening information in this standard work of reference written by one of the foremost leaders in the field.

der Universität München (FRG)

Protein Folding. By *C. C. Ghélis* and *J. Yon*. Academic Press, New York 1982. xiii, 562 pp., bound, $ 74.50.

The present state of protein structure research is marked by the completed crystal structure analyses of more than one hundred proteins, the elucidation of the mechanism of transcription and translation, as well as the possibilities for the sequencing of proteins and (recently) also the nucleic acids coding them. The result of all this is knowledge concerning the topology and detailed three-dimensional structure of globular protein molecules down to the atomic level and the insight derived therefrom into the catalytic mechanism of enzymes and into their evolutionary relationships.

Basically the functional state of proteins formed spontaneously both in vivo and in vitro represents the (kinetically accessible) state of minimum free energy. Both this structure itself and the process of its formation are described as "folding". It is the last stage in the "translation" of the genetic information stored in the nucleic acid into a covalent amino acid sequence and constitutes the last, largely unexplained, portion of the whole process of protein biosynthesis. Apart from the inborn curiosity of biochemists there are two reasons why interest is concentrated on this problem: Firstly, it is of theoretical importance, because, if the protein folding "code" were known, it would be possible, on the basis of the structure-function relationship, to use the nucleic acid sequences of otherwise uncharacterized proteins (enzymes) to predict their structures and their functions. Secondly, the "code" could be used to design molecules for the optimization of desired catalytic functions.

Both aims can only be envisaged because the three-dimensional structure of proteins is determined solely by the amino acid sequence of their polypeptide chains. This postulate made by *Crick* 25 years ago is based on the observation that protein molecules spontaneously revert to their native conformations after disturbance of their structure (denaturation) and are able to recover their biologically active state of association.

This present volume is devoted to the complex of questions outlined. It provides—apart from a volume of extended symposium contributions of the same name (Elsevier-North Holland, 1980)—the first comprehensive summary, and with its ca. 1500 literature references represents a veritable treasure trove for newcomers in the field.

The authors have attempted to describe the whole breadth and historical depth of the field, whereby they understand folding to have both systematic-descriptive aspects and energetic and kinetic ones. This leads to one of the weaknesses of the book, namely its length (and thus its price) together with a certain lack of criticality; the old and the new are presented side by side, with no attempt to sift and classify.

The book begins with a section on the intracellular environment and the significance of folding (30 pp.). Then follow almost 200 pages dealing with observations on the problem of protein folding from the viewpoint of the characterization of globular proteins. This is followed by 275 pages concerned with experimental methods; the book concludes with a 22-page summarizing commentary.

The above mentioned makeup and subdivision of the book cited and the relative sizes of its parts give some idea of the encyclopaedic proportions of the work. It is basically a detailed survey and not a more profound discussion of chosen examples. This has the consequence for the interested reader that every time "classical" portions of the subject are surveyed, the reader can obtain more detailed information first hand (from the presentations of *J. Richardson, Anfinsen* and *Scheraga, Baldwin, Creighton, Tanford* for example). The qualitative nature of the presentation is particularly regrettable for those parts of the field that become more and more accessible to a solid physicochemical treatment, e.g. intermolecular interactions (somewhat remarkably generally called intramolecular interactions), the structure of water, the thermodynamics and kinetics of unfolding and folding. Here it may also be a case of what the authors themselves call "progressing on shifting sand" with reference to rapidly evolving topics such as peptide processing, topogenic (not topogenetic) sequences and structural flexibility. The quality production of the book and the necessary time span before its appearance demand their price, particularly with respect to topicality.

In general the extraordinary amount of material and the documentation of even the older literature are of assistance to those who wish an effortless introduction to parts of the field. As previously stated a critical sifting of the material and tautening with respect to questions that still remain open would spare the reader some outdated matter. That the reading is not always simple, lies in the problem that "non-natives" who write in English frequently use an unorthodox idiom, that can sometimes only be completely understood after back translation. This remark is directed at the publishers rather than at the authors. This is not the case, however, with the subject index which is not really adequate for a book of this encyclopaedic nature.

It would be out of place here to criticize individual points; however, the occasional aesthetic or teleological

[*] Cf. *Angew. Chem. 91* (1979) 523; *Angew. Chem. Int. Ed. Engl. 18* (1979) 492.

arguments, the not always concise definitions, and the fuzzy distinction in some places between the thermodynamic and the kinetic viewpoint are mentioned as being symptomatic. Critical thinking is necessary on the part of the reader in order to avoid falling into error.

The book can be of good service as a reference work, both with regard to the various aspects of the subject and for particular topics. It is to be hoped that it will arouse biochemists and biophysicists to intensify research in one of the most interesting areas of physical biochemistry today.

Corrigendum

The following corrections should be made to the communication entitled: "Reactions of Diphenyl(trimethylsilyl)phosphane with Alkyl(pentacarbonyl)manganese; Synthesis of the Ylide Complexes $(CO)_4MnCr(OSiMe_3)PPh_2$, and a New Driving Force for CO Insertion" by John A. Gladysz et al., Angew. Chem. Int. Ed. Engl. 23 (1984) 245:

The title should read: "Reactions of Diphenyl(trimethylsilyl)phosphane with Alkyl(pentacarbonyl)manganese; Synthesis of the Ylide Complexes $(CO)_4MnCR(OSiMe_3)PPh_2$, and a New Driving Force for CO Insertion". The heading to column 2 in Table 1 should read $\nu(C\equiv O)$.

Electron Transfer between Metal Complexes— A Retrospective View (Nobel Lecture)**

By Henry Taube*

1. Introduction

This will be an account, in historical perspective, of the development of part of the field of chemistry that I have been active in for most of my professional life, the field that is loosely described by the phrase "electron transfer in chemical reactions". In the short time available to me for the preparation of this paper, I could not hope to provide anything significant in the way of original thought. But I can add some detail to the historical record, especially on just how some of the contributions which my co-workers and I have made came about. This kind of information may have some human interest and may even have scientific interest of a kind which cannot easily be gathered from the scientific journals. For publication there, the course of discovery as it actually took place may be rewritten to invest it with a logic that it did not fully acquire until after the event.

"Simple" electron transfer is realized only in systems such as $Ne/Ne^{\oplus}$. The physics already becomes more complicated when we move to $N_2/N_2^{\oplus}$, for example; and with the metal ion complexes which I shall deal with, where a typical reagent is $[Ru(NH_3)_6]^{2\oplus}$, and where charge trapping by the solvent, as well as within the molecule, must be taken into account, the complexity is much greater. Still, a great deal of progress has been made by a productive interplay of experiment, qualitative ideas, and more sophisticated theory, involving many workers. Because of limitations of space, I will be unable to trace all the ramifications of the field today and will emphasize the earlier history of the subject, when some of the ideas basic to the field were being formulated. This choice of emphasis is justified because, by an accident of history, I was a graduate student at the University of California, Berkeley, about the time the first natal stirrings of the subject of this article occurred, and at a place where these stirrings were most active. As a result, I may be in a unique position to deal knowledgeably and fairly with the early history of the subject. The emphasis on the early history is all the more justified because most of the topics touched on in this article, and also closely related topics, are brought up to date in a very recent volume of the series "*Progress in Inorganic Chemistry*"[1].

Chemical reactions are commonly classified into two categories: substitution or oxidation-reduction (redox). The latter can always be viewed as involving electron transfer, though it is agreed that when we consider mechanisms in solution electron transfer is not as simple as it is in the $Ne/Ne^{\oplus}$ case. Rearrangement of atoms always attends the changes in electron count at each center, and these must be allowed for. I will, however, simplify the subject by considering only processes where the chemistry is simple: those in which electron transfer leaves each of the reaction partners in a stable oxidation state. While substitution reactions can be discussed without concern for oxidation-reduction reactions, the reverse is not true. The changes that take place at each center when the electron count is altered are an essential part of the "electron transfer" process and may be the dominating influence in fixing the rate of the reaction. Moreover, most of the early definitive experiments depended on exploiting the substitution characteristics of the reactants and of the products. Thus, the attention which will be devoted to the substitution properties

of the metal ions is not a digression but is an integral part of the subject.

An appropriate place to begin this account is with the advent of artificial radioactivity. This enormously increased the scope of isotopic tracer methods in chemistry and made it possible to measure the rates of a large number of redox reactions, such as that shown in eq. (a).

$$[^*Fe(aq)]^{2\oplus} + [Fe(aq)]^{3\oplus} \rightleftharpoons {}^*[Fe(aq)]^{3\oplus} + [Fe(aq)]^{2\oplus} \qquad (a)$$

(The first demonstration of a redox exchange was made by *von Hevesy* et al.[2], who used naturally occurring isotopes to follow Pb^{IV}/Pb^{II} exchange in acetic acid.) Because chemists there were involved in the discovery of many of the new isotopes[3], an early interest in this kind of possibility developed in the chemistry community at the University of California, Berkeley, and was already evident when I was a graduate student there (1937—40). In a review article on artificial radioactivity, *Seaborg*[3] mentioned an attempt[4] to measure the rate of $Fe^{3\oplus}/Fe^{2\oplus}$ exchange in aqueous chloride media, the result of this being that the exchange was found to be complete by the time the separation of Fe^{III} from Fe^{II} was made. It was appreciated by many that the separation procedure, in this case extraction of the Fe^{III} chloro complex into ether, might have induced exchange. It was also appreciated that chloride ion might have influenced the reaction rate, possibly increasing it, and that quite different results might be obtained were the experiment done with an indifferent anion.

There were several reasons for the interest among many physical-inorganic chemists in reactions such as described in eq. (a). That the interest in chemical applications of the new isotopes was keen in Berkeley may be traced, in part, to the involvement of much of the research body in teaching the introductory chemistry course. We all had a background of qualitative observations on simple oxidation-reduction reactions—such as, for example, the reaction of $[Ce(aq)]^{4\oplus}$ with $[Fe(aq)]^{2\oplus}$, gained from experience in qualitative or quantitative analysis. Still, to my knowledge, at the time I was a graduate student not a single measurement had been made of the rate of this kind of reaction. That a field of research, which has since grown enormously, was started by studying "self-exchange reactions"[5] such as in eq. (a), rather than net chemical changes ("cross-reaction")[5], may reflect the intervention of a human factor: Measuring the rate of a virtual process such as in eq. (a), today made commonplace for many systems by the introduction of new spectroscopic methods, seemed more glamorous than measuring the rate of oxidation of $[V(aq)]^{2\oplus}$ by $[Fe(aq)]^{3\oplus}$, for example. But I also recall from informal discussions that it was felt that driving force would affect the rate of reaction, and thus there would be special interest in determining the rates for reactions for which $\Delta G^0 = 0$ (except for the contributions to the driving force from entropy).

The interest in the measurement of the rates of self-exchange reactions I witnessed as a graduate student is not reflected in the literature of the years immediately following. Many of those who may have had plans to perform the experiments were engaged in war-related activities. After the war, at least five different studies on the rate of reaction (a), all carried out in non-complexing media, were reported, with conflicting results, some indicating a half-life for exchange on the order of days at concentration levels of 10^{-2} M. The discrepancies led to considerable controversy, and in informal discussions strong opinions were expressed on just what the true rate of self-exchange might be. The basis for this kind of judgment, exercised in the absence of any body of quantitative measurements, is worth thinking about. I believe it reflected an intuitive feeling that there would be a relation between the rates of self-exchange and of the related cross-reactions, and of course each of us had at least some qualitative information on redox rates for the $Fe^{3\oplus}/Fe^{2\oplus}$ couples. The definitive measurements on the rate of reaction (a) in non-complexing media were made by *Dodson*[6]. These measurements were soon extended[7] to reveal the effect of $[H^{\oplus}]$ and of complexing anions on the rate, yielding rate functions such as $[Fe^{3\oplus}][X^{\ominus}][Fe^{2\oplus}]$ (because substitution is rapid compared to electron transfer, this is kinetically equivalent to $[FeX^{2\oplus}][Fe^{2\oplus}]$ and to $[Fe^{3\oplus}][FeX^{\oplus}]$) in addition to $[Fe^{3\oplus}][Fe^{2\oplus}]$, but none specifying a unique structure for an activated complex. Particularly the terms involving the anions provided scope for speculation about mechanism. The coefficient for the simple second-order function was found[7] to be $4\,M^{-1}\,s^{-1}$ at 25 °C, $\mu = 0.5$, and those who had argued for "fast" exchange won out.

Another important experimental advance during the same period, important for several reasons, was the measurement[8] of the rate of self-exchange for $[Co(en)_3]^{3\oplus}/[Co(en)_3]^{2\oplus}$ (en = ethylenediamine) ($k = 5.2 \times 10^{-5}\,M^{-1}\,s^{-1}$ at 25 °C, $\mu = 0.98$). This was, I believe, the first quantitative measurement of the rate of a self-exchange reaction, and it may also have been the first time that the oxidizing capability of a cobalt(III) ammine complex was deliberately exploited. In this publication[8], the rate of the reaction of $[Co(NH_3)_6]^{3\oplus}$ with $[Co(en)_3]^{2\oplus}$ is also reported; this was, I believe, the first deliberate measurement of the rate of an electron transfer cross-reaction. In contrast to the $Fe^{3\oplus}/Fe^{2\oplus}$ system, where both reactants are labile to substitution, $Co(en)_3^{3\oplus}$ undergoes very slow substitution, and thus an important feature of the structure of the activated complex for the $[Co(en)_3]^{3\oplus}/[Co(en)_3]^{2\oplus}$ self-exchange appeared to be settled. In considering the observations, the tacit assumption was made that the coordination sphere of $[Co(en)_3]^{3\oplus}$ does not change on the time scale of electron transfer; hence, it was concluded that the activated complex for the reaction does not involve interpenetration of the coordination spheres of the two reactants. We were thus obliged to think about a mechanism for electron transfer through two separate coordination spheres ("outer-sphere" mechanism)[9].

In 1951, an important symposium on electron transfer processes was held at the University of Notre Dame, and the proceedings are reported in volume *56* (1952) of the *Journal of Physical Chemistry*. Though the meeting was organized mainly for the benefit of chemists, the organizers had the perspicacity to include physicists in the program. Thus, the complete gamut of interests was covered, ranging from electron transfer in the gas phase in the simplest kind of systems, e.g. $Ne/Ne^{\oplus}$, to the kind of system that the chemist ordinarily deals with. Much of the program was

devoted to experimental work, the chemistry segment of which included reports on the rates of self-exchange reactions as well as of reactions involving net chemical change—but none on cross-reactions. Two papers devoted to theory merit special mention: that by *Holstein*[10], whose contributions to the basic physics are now being applied by chemists, and the paper by *Libby*[11], who stressed the relevance of the Franck-Condon restriction[12] to the electron transfer process and applied the principle in a qualitative way to some experimental observations. It was clear from the discussion which several of the papers evoked that many of the participants had already appreciated the point which *Libby* made in his talk. Thus, in the course of the discussion, the slowness of the self-exchange in the aminecobalt complexes was attributed[13] to the large change in the Co–N distances with change in oxidation state, then believed to be much larger than it actually is. During the meeting, too, the distinction between outer- and inner-sphere activated complexes was drawn, and the suggestion was made that the role of chloride ion in altering the rate of the $Fe^{3\oplus}/Fe^{2\oplus}$ self-exchange might be that it bridges the two metal centers[14]. But, of course, because of the lability of the high spin Fe^{II} and Fe^{III} complexes no unique specification of the geometry of the activated complex can be made from the rate laws alone. During the discussion of *Libby*'s paper, a third kind of mechanism was proposed[15] involving "hydrogen atom" transfer from reductant to oxidant.

2. First Efforts

My own interest in the basic aspects of electron transfer between metal complexes became active only after I came to the University of Chicago in 1946. During my time at Cornell University (1941—1946), I had been engaged in the study of oxidation-reduction reactions, and I was attempting to develop criteria to distinguish between $1e^{\ominus}$ and $2e^{\ominus}$ redox changes. As an extension of this interest, I used $1e^{\ominus}$ reducing agents to generate halogen atoms and studied the ensuing chain reactions of the halogens with organic molecules. My eventual involvement in the study of electron transfer between metal complexes owes much to the fact that I knew many of the protagonists personally (*A. C. Wahl, C. N. Rice, C. D. Coryell, C. S. Garner*—the first two were fellow graduate students at Berkeley) and to the fact that I had *W. F. Libby,* with whom I had many provocative discussions, and *J. Franck,* as well as *F. H. Westheimer* as colleagues at the University of Chicago. By the time of the meeting at the University of Notre Dame (in which I did not participate), I appreciated in a general way the special advantages which the $Cr^{3\oplus}/Cr^{2\oplus}$ couple offered in the investigation of the mechanism of electron transfer and outlined my ideas to *N. Davidson* when he visited me en route to the meeting. But the experimental work which led to the first two papers[16,17] was not carried out until 1953. In the interim, I had failed to interest any of my graduate students in the work, because, of course, no one foresaw what it might lead to, and also because it seemed less exciting than other work in progress in my laboratory effects. The bulk of the work reported in these two papers was done with my own hands; I shall now outline the background to those early experiments.

My interest in coordination chemistry did not develop until I elected it as a topic for an advanced course given soon after coming to the University of Chicago. Instead of using the standard textbook material, I used as major source the relevant volume of "Gmelin" in which the chemistry of the cobaltammines is described. At this time, I already had a good background in the literature devoted to substitution at carbon and understood the issues raised in that context, and I soon became interested in raising the same issues for substitution at metal centers. Furthermore, it was evident that the complexes of metal ions which undergo slow substitution were readily amenable to experimental study. I became curious as well about the reasons underlying the enormous differences in rates of substitution for metal ions of the same charge and (approximately) the same ionic radii. The ideas that resulted were presented in my course the next time it was given, but the extensive literature study that led to the paper published in February 1952[18] was not done until 1949, when I was on leave from the University of Chicago as a Guggenheim Fellow.

In this paper, a correlation was made between electronic structure and mainly qualitative observations ("labile" complexes arbitrarily defined as those whose reactions appear to be complete on mixing and "inert" as those for which continuing reaction can be observed) on complexes of coordination number 6. In order to make the correlation, it was necessary to break away from the common practice in the USA of classifying complexes as "ionic" and "covalent" according to electronic structure. Thus, for example, comparison of the Cr^{III} with the high spin and thus "ionic" Fe^{III} convinced me that the bonds to the ligands might actually be somewhat more covalent in the Fe^{III} complexes that in the Cr^{III} complexes. Furthermore, it appeared to me that in earlier discussions of relative rates of substitution, where attempts were made to understand the observations in terms of the existing classification, there was a failure to distinguish between thermodynamic stability and kinetic stability. The affinity of $Cl^{\ominus}$ for $[Cr(aq)]^{3\oplus}$ is considerably less than it is for $[Fe(aq)]^{3\oplus}$, yet the rate of aquation of $[CrCl(aq)]^{2\oplus}$ is much less than it is for $[FeCl(aq)]^{2\oplus}$. Rates, of course, cannot be accounted for by considering ground state properties alone; the stability of the activated complex relative to the ground state must also be taken into account. When the effect of electronic structure on the relative stabilities is taken into consideration, a general correlation of rates with electronic structure emerges. (In the language of ligand field theory, for complexes of coordination number 6, substitution tends to be slow when in the metal ions each of the πd (non-bonding) orbitals, but none of the σd (anti-bonding) orbitals, is occupied. The rate constants for exchange of water between solvent and the hexaaqua ions of $V^{3\oplus}$ (πd^2), $Cr^{3\oplus}$ (πd^3), and $Fe^{3\oplus}$ ($\pi d^3\sigma d^2$) are $1\times10^3\ s^{-1}$, $5\times10^{-6}\ s^{-1}$, and ca. $1\times10^3\ s^{-1}$, respectively)[19].

A shortcoming of this early effort is that the rationalizations of the correlation offered were described using the

binding, because, when I wrote the paper, I did not understand the principles of ligand field theory even qualitatively. The VB approach provides no simple rationale for the difference in rates of substitution of labile complexes, which were found to cover a very wide range thanks to a pioneering study by *Bjerrum* and *Poulson*[20], who used methanol as a solvent to facilitate measurements at low temperatures, and those of *Eigen*[21], who introduced relaxation methods to determine the rates of complex formation of labile systems.

Activated complexes have compositions and structures, and it is necessary to know what these are if rates are to be understood. It is hardly likely that these features can be established for the activated complexes if they are not even known for the reactants, and in 1950 we were not certain of the formula for any aqua cations in water. It seemed to me important, therefore, to try to determine the hydration numbers for aqua cations. Hydration number as I use it here does not mean the average number of water molecules affected by a metal ion as this is manifested in some property such as mobility, but has a structural connotation: how many water molecules occupy the first sphere of coordination? Because the rates of substitution for $[Cr(aq)]^{3\oplus}$ were known to be slow[22], *J. P. Hunt* and I undertook to determine the formula for $[Cr(aq)]^{3\oplus}$ in water[23], with some confidence that we would be successful even with the "slow" method we applied, isotopic dilution using ^{18}O enriched water. That the formula turned out to be $[Cr(H_2O)_6]^{3\oplus}$ was no great surprise—although I must confess that at one point in our studies, before we had taken proper account of isotopic fractionation effects, $[Cr(H_2O)_7]^{3\oplus}$ was indicated, and, faced with the apparent necessity, I was quite prepared to give up my preconceived notions. It was also no great surprise that the exchange is slow ($t_{1/2}$ at 25°, ca. 40 h). Even so, the experiments were worth doing. They were the first of their kind and also attracted the attention of physical chemists, many of whom were astonished that aqua complexes could be as kinetically stable as our measurements indicated, and were impressed by the enormous difference in the residence time of a water molecule in contact with a cation compared with water molecules just outside. That we dealt with hydration in terms of detailed structure rather than in terms of averaged effects may have encouraged the introduction to this area of other methods, such as NMR spectroscopy, capable of making a distinction between cation-bound and free water[19]. As I will now detail, these hydration studies also led directly to experiments on the mechanism of electron transfer[16, 17].

3. The Inner Sphere Activated Complex

R. A. Plane undertook to measure the rate of self-exchange for the pair $[Cr(H_2O)_6]^{3\oplus}/[Cr(aq)]^{2\oplus}$ by using $[Cr(aq)]^{2\oplus}$ as a catalyst for the exchange of water between $[Cr(H_2O)_6]^{3\oplus}$ and solvent. The expected catalysis was found, but, owing to our inexperience in handling the air-sensitive catalyst, the data were too irreproducible to provide a value for the self-exchange rate. Catalysis on electron transfer was expected because the complex $[Cr(aq)]^{2\oplus}$ was known to be much more labile than $[Cr(H_2O)_6]^{3\oplus}$—the lability is now known[24] to decrease by a factor of at least 10^{14} when $[Cr(aq)]^{2\oplus}$ is oxidized to $[Cr(aq)]^{3\oplus}$ (note that $Cr^{2\oplus}$, but not $Cr^{3\oplus}$, has an antibonding electron). It occurred to me in the course of *Plane*'s work that it would be worthwhile to test the potential of the Cr^{III}/Cr^{II} couple as a diagnostic of mechanism with a nonmetal oxidant. Following up the idea, I did a simple test tube experiment, adding solid I_2 to a solution of $[Cr(aq)]^{2\oplus}$ which *Plane* had prepared for his own experiments. I observed that reaction occurs on mixing, that the product solution is green, and that this color slowly fades to produce one characteristic of $[Cr(H_2O)_6]^{3\oplus}$. The fading is important because it demonstrates that $[(H_2O)_5CrI]^{2\oplus}$, which is responsible for the green color, is unstable with respect to $[Cr(H_2O)_6]^{3\oplus}+I^{\ominus}$, and thus we could conclude that the Cr–I bond is established before Cr^{II} is oxidized.

The principle having been demonstrated with a nonmetal oxidant, I turned to the problem of finding a suitable metal complex as oxidant. What was needed was a reducible, robust metal complex with a potential bridging group as ligand, and the idea of using $[(NH_3)_5CoCl]^{2\oplus}$ surfaced during a discussion of possibilities with another of my then graduate students, *R. L. Rich*. Because at that time virtually nothing was known about the rates of reduction of Co^{III} ammines, and they were not considered useful oxidants, I was by no means sanguine about the outcome of the first experiment, which again was done in a test tube. I was delighted by the outcome. Reaction was observed to be rapid (the specific rate has since been measured[25] as $6\times10^5\ M^{-1}\ s^{-1}$ at 25°C), and the green color of the product solution indicated that $[(H_2O)_5CrCl]^{2\oplus}$ is formed. Further work[16, 17] showed that this species is formed quantitatively, and that in forming it picks up almost no radioactivity when labeled $Cl^{\ominus}$ is present in the reaction solution, thus demonstrating that transfer is direct, i.e., $Cl^{\ominus}$ bridges the two metal centers, and this occurs before $Cr^{2\oplus}$ is oxidized. The overall redox process can be described by eq. (b).

$$[(NH_3)_5CoCl]^{2\oplus} + [Cr(H_2O)_6]^{2\oplus} \underset{+H_2O}{\overset{-H_2O}{\rightleftharpoons}} [(NH_3)_5Co^{III}Cl\cdots Cr^{II}(H_2O)_5]^{4\oplus} \longrightarrow$$
precursor complex

$$[(NH_3)_5Co\cdots Cl\cdots Cr(H_2O)_5]^{4\oplus} \longrightarrow \quad \text{(b)}$$
activated complex

$$[(NH_3)_5Co^{II}\cdots ClCr^{III}(H_2O)_5]^{4\oplus} \xrightarrow{H_2O/H^{\oplus}}$$
successor complex

$$[Co(H_2O)_6]^{2\oplus} + NH_4^{\oplus} + [(H_2O)_5CrCl]^{2\oplus}$$

These early results were presented at a Gordon Conference on inorganic chemistry, which was held only a short time after they had been obtained, and they were received with much interest. *E. L. King* was present at the meeting, and together we planned the experiment in which self-exchange by an "atom" transfer mechanism was first demonstrated [eq. (c)][26].

$$[(H_2O)_5{}^*CrCl]^{2\oplus} + [Cr(aq)]^{2\oplus} \rightleftharpoons [{}^*Cr(aq)]^{2\oplus} + [(H_2O)_5CrCl]^{2\oplus} \quad \text{(c)}$$

Note that in a process of this kind, the bridging group will remain bound to a Cr^{III} center, but the auxiliary ligands about the original Cr^{III} center will be exchanged or replaced because of the high lability of Cr^{II}. (Several years later, *King* et al.[27] extended the self-exchange work to include other halides as bridging ligands and still later[28] encountered the first example of "double bridging" [eq. (d)].

$$cis\text{-}[(H_2O)_4{}^*Cr(N_3)_2]^{\oplus} + [Cr(aq)]^{2\oplus} \rightleftharpoons [{}^*Cr(aq)]^{2\oplus} + cis\text{-}[(H_2O)_4Cr(N_3)_2]^{\oplus} \quad (d)$$

A good case can be made for this also being the first demonstration of "remote attack", i.e., inner-sphere electron transfer where more than one atom separates the metal atoms in the activated complex.)

There was a brief hiatus in my work after the early experiments on inner-sphere mechanisms, caused by my taking leave from the University of Chicago in 1956. But before leaving, I hurriedly did some experiments[29], which, though semiquantitative at best, showed that not only atoms but groups such as $N_3^{\ominus}$, $NCS^{\ominus}$, and carboxylates transfer to chromium when the corresponding pentaamminecobalt^{III} complexes are reduced by $[Cr(aq)]^{2\oplus}$, and that there are large differences in rate for different dicarboxylate complexes (maleate much more rapid than succinate). Moreover, it was shown that in being oxidized Cr^{II} can incorporate other ligands, such as $H_2P_2O_7^{2\ominus}$, which are present in solution. In this paper the possibility of electron transfer through an extended bond system of a bridging group was first raised, but was by no means demonstrated by the results. During my leave of absence, *Ogard*[30] began his studies on the rates of aquation of $[(NH_3)_5CrX]^{2\oplus}$ (X = Cl, Br, I) catalyzed by $Cr^{2\oplus}$. By following the arguments made in connection with reaction (b), it can be seen that if an inner-sphere mechanism operates, $[(H_2O)_5CrX]^{2\oplus}$ and $NH_4^{\oplus}$ (acid solution) will be products. The contrast with uncatalyzed aquation is worth noting, where $[(NH_3)_5CrH_2O]^{3\oplus}$ and $X^{\ominus}$ are the expected products.

4. General Progress

The hiatus mentioned previously provides me with a suitable opportunity to outline some of the advances that were being or were soon to be made on other fronts. An important advance was that the rates of numerous self-exchange reactions were being measured. Here, I want especially to mention the contributions from the laboratories of *A. C. Wahl* and *C. S. Garner*. Some of the experiments by *Wahl* et al. made use of rapid mixing techniques—see, for example, the measurement[31] of the rate of self-exchange for $MnO_4^{1\ominus}/MnO_4^{2\ominus}$. An important experimental contributions was made by *N. Sutin*, who introduced the rapid flow method[32] (and later other rapid reaction techniques) into this field of study, and who helped others, including me, to get started with the technique. A spate of activity on the measurements of the rates of cross reactions followed, motivated to a large extent by the desire to test the validity of the cross-reaction correlation[5].

Attempts were being made by theoreticians to account for the barrier to reaction attending encounter and separation, and that contributed by charge trapping within the metal complex and by the surrounding medium. The papers which most influenced the experimentalists, at least during the formative period in question, were those by *Marcus*[33] and *Hush*[34] dealing with adiabatic[35] electron transfer. Other theoretical approaches were being advanced during this period, and, in some, attempts were made to account for nonadiabaticity; the various theories are compared and evaluated by *Marcus*[33]. (The current state of theory can be gathered from a recent article by *Sutin*[36].) Because this very important aspect of electron transfer reactions is not dealt with here, it is essential to mention that the processes occurring at electrodes were not being overlooked.

The correlation of the rates of cross reactions with the rates of the component self-exchange reactions[5] has been widely applied, especially to outer-sphere reactions. The limits of its validity were clearly set down by the author: allowance must be made for the work of bringing the reaction partners together and separating the products, electron delocalization must be great enough to ensure adiabatic behavior, but not so great as to materially reduce the activation energy. (The last condition, it should be noted, does not necessarily limit the applicability of the Marcus equation to outer-sphere processes.) *Hush*'s treatment[34] also leads to a correlation of rates of self-exchange and cross reactions, and also takes into account the contribution of ΔG^0. In fact, the first calculation of the rate of a cross reaction, shown in eq. (e),

$$[Pu(aq)]^{3\oplus} + [PuO_2(aq)]^{2\oplus} \rightleftharpoons [Pu(aq)]^{4\oplus} + [PuO_2(aq)]^{\oplus} \quad (e)$$

from the rates of the self-exchange processes and the equilibrium constant appears in [34].

More qualitative theory also profoundly influenced the development of the field, dealing with the question of how the choice of mechanism and relative rates are to be understood in terms of the electronic structures of the reactants. As is also true for rates of substitution, the observations are so sensitive to electronic structure that even qualitative ideas are useful in correlating observations and in pointing the way to new experiments. Early on, *Orgel*[37] applied qualitative ligand field theory to discussions of the inner-sphere mechanisms for the reduction of Cr^{III} and low spin Co^{III} complexes. When electron transfer takes place through a bridging group, it is important to distinguish a chemical or "hopping" mechanism—here a low-lying orbital of the ligand is populated by the reductant, or a hole is generated by the oxidant in an occupied orbital—from resonance transfer, i.e., electron tunneling through the barrier separating the two metal centers. This distinction was drawn rather early by *George* and *Griffith*[38], who moreover proposed alternative mechanisms for resonance transfer. Shortly thereafter, *Halpern* and *Orgel*[39] gave a more formal treatment of resonance transfer through bridging ligands. Concerns about the relation between electron structure and the observations on electron transfer strongly influenced my own work, but, before tracing this theme, I want to report on the progress made, mainly by others, in

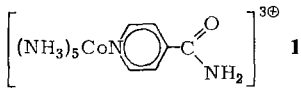
extending the descriptive chemistry of electron transfer reactions.

In a sense, the unambiguous demonstration of an inner sphere mechanism completed a second dimension in the field of electron transfer mechanisms. That in certain systems reaction perforce took place via an outer sphere mechanism had long been known, but until the experiments described in [16, 17] had been performed the inner sphere mechanism was only conjecture, and, as frequently happens in research in chemistry, only after conjecture, however reasonable, is upgraded by proof, is it accepted as a base for further development. That the distinction between the two reaction classes is meaningful, not only for chemical but also for kinetic aspects, will be illustrated by a single comparison: the rate constant of reaction of $[Cr(aq)]^{2\oplus}$ with $[(NH_3)_5CoCl]^{2\oplus}$ is ca. 10^8 greater than with $[Co(NH_3)_6]^{3\oplus}$[40] (the latter can only react by an outer sphere mechanism). The classification of reaction paths as inner sphere or outer sphere on the basis of rate comparisons, involving effects (such as those exerted by non-bridging ligands) established with reactions of known mechanism, became the focus of experiment and discussion when direct proof based on product or intermediate identification was lacking.

Early in the 1960s, new metal centers were added to the roster of those proven to react by inner sphere mechanism. For $[Co(CN)_5]^{3\ominus}$ as reducing agent[41], the demonstration of an inner sphere path again depended on the characterization of product complexes by orthodox means. *Sutin* et al. have been particularly resourceful in using flow techniques to provide direct mechanistic proof for reactions involving oxidizing centers ordinarily considered as labile to substitution: thus, note the proof of inner sphere mechanism for $[FeCl(aq)]^{2\oplus} + [Cr(aq)]^{2\oplus}$[42], $[CoCl(aq)]^{2\oplus} + [Fe(aq)]^{2\oplus}$[43], and even the much studied $Fe^{3\oplus}/Fe^{2\oplus}$ exchange[44]. It was appreciated early[17] that atom or group transfer is not a necessary concomitant of an inner sphere process. Whether the bridging group transfers to reductant, remains with the oxidant, or transfers from reductant to oxidant depends on the substitution labilities of reactants and products. Early qualitative observations[17] on the $[Cr(aq)]^{2\oplus} + [IrCl_6]^{2\ominus}$ system apparently exposed an example of reaction proceeding via an inner sphere mechanism, but which led to no net transfer of the bridging atom. Here, $[(H_2O)_5CrClIrCl_5]$ is formed as an intermediate, but this then aquates to $[Cr(H_2O)_6]^{3\oplus} + [IrCl_6]^{3\ominus}$ (later work[45] has shown that the inner sphere path is minor compared to the outer sphere, and that $Cr(H_2O)_\delta^{3\oplus}$ is the lesser product of the inner sphere path). Experiments[46, 47] with $[V(H_2O)_6]^{2\oplus}$ as reducing agent provided numerous examples of systems in which substitution at the reducing complex is rate determining for the net redox process (note that because of its electronic structure $[V(H_2O)_6]^{2\oplus}$ is expected[18] to undergo substitution relatively slowly). Unstable forms of linkage isomers were prepared by taking advantage of the chemistry of the inner sphere mechanism: $[(H_2O)_5CrSCN]^{2\oplus}$[48] by the reaction of $[Cr(aq)]^{2\ominus}$ with $[FeNCS]^{2\oplus}$[49]; $[(H_2O)_5CrNC]^{2\oplus}$[50] by the reaction of $[Cr(aq)]^{2\oplus}$ with $[(NH_3)_5CoCN]^{2\oplus}$. Oxygen atom transfer was shown to be complete[51] in the reaction of $[(NH_3)_5Co(H_2O)]^{3\oplus}$ with $[Cr(aq)]^{2\oplus}$. (The path involving direct attack on the aqua complex was later[52] shown to be unobservable compared to attack on the hydroxo complex; bridging by H_2O has, to date, not been demonstrated.) The inner sphere path was demonstrated[53] also for net $2e^{\ominus}$ processes in an elegant series of studies involving the reactions of Pt^{IV} complexes with those of Pt^{II}. In an important departure, *Anet*[54] showed that the "capture" property of $[Cr(aq)]^{2\oplus}$ in being oxidized can be exploited to produce complexes in which an organic radical is ligated to Cr^{III}. An entire chapter of the volume referred to in [1] is devoted to the chemistry of similar organochromium complexes[55].

5. Electronic Structure and Mechanism

A major theme in my own research on returning to the University of Chicago was to try to understand the large differences in rate, noted qualitatively in my early work[29], and later made more quantitative, for the reactions of $[Cr(aq)]^{2\oplus}$ with carboxylate complexes of $[(NH_3)_5Co^{III}]$. Many of the ligands were dicarboxylic acids, and, to explain the observation that when a conjugated π system connects the two carboxylates reaction is usually more rapid than it is for the saturated analogue, it seemed reasonable to assume that for conjugated ligands the reducing agent attacks the *exo*-carboxyl (remote attack), the conjugated bond system serving as a "conduit" for electron transfer. In adopting this view, the tacit assumption was made that the reactions are nonadiabatic, and hence the extent of electronic coupling would be reflected in the reaction rate. (In retrospect, this assumption is naive, because the effect of conjugation would be exerted even if the reducing agent attacked the carboxyl groups directly bonded to the metal center).



1

A false start was made in demonstrating remote attack as defined here. Activation effects accompanying electron transfer were reported[56], which if true, would have constituted proof of remote attack for these systems. These effects could not be reproduced[57] in later work (I had by now moved from the University of Chicago to Stanford University). Remote attack with large organic ligands was finally demonstrated[58] in the reaction of **1** with $[Cr(aq)]^{2\oplus}$. This work, which also yielded a measurement of the rate of reaction of $[Cr(aq)]^{2\oplus}$ with the analogous Cr^{III} species, provided the clue to understanding, at least qualitatively, the differences in rate observed for different conjugated ligands. The astonishing result was that the rate of reduction of the Co^{III} complex is only about ten times greater than that of the Cr^{III} complex. When the bridging group is a nonreducible species such as acetate, the corresponding ratio is $> 10^4$. The insensitivity of the rate to the nature of the oxidant suggested that the electron does not transfer directly from Cr^{II} to the oxidizing center but that the mechanism rather involves the $1e^{\ominus}$ reduction[59] of the ligand by the strong reducing agent $Cr^{2\oplus}$, followed by reduction of the oxidizing center by the organic radical—i.e.,

a "hopping" mechanism. This view provided satisfactory rationalizations for most of the rates obtained with organic ligands. For example, that the rate is considerably greater for Co^{III}-fumarate complexes than for Co^{III}-acetate complexes may have little to do with the opportunity Cr^{II} has to attack the remote carboxyl in the fumarate complex, and only reflects the fact that fumarate can be reduced by $[Cr(aq)]^{2\oplus}$. Moreover, the otherwise puzzling observation that the rate for the fumarate complex is increased[60] upon addition of $H^{\oplus}$ is now easily understood; positive charge added to the ligand makes it easier to reduce. That many reactions of the class under consideration proceed by a stepwise mechanism has been convincingly demonstrated and amply illustrated in subsequent work, most of it carried out by *Gould* et al.[61].

The rationalization offered for the operation of the stepwise mechanism in the Co^{III}-Cr^{II} systems is that the carrier orbital on the ligand has π symmetry, while the donor and acceptor orbitals have σ symmetry. This makes it highly improbable that the four following conditions can be fulfilled simultaneously: Franck-Condon restrictions and symmetry restrictions at both centers. Whether or not this is the correct explanation, it led me to search for an oxidizing center among ammine complexes in which the acceptor orbital has π symmetry.

When the important condition that the complexes undergo slow substitution was added, only one couple within the entire periodic table, $Ru^{3\oplus}/Ru^{2\oplus}$ ($\pi d^5/\pi d^6$), qualified[62]. In principle, the $Os^{3\oplus}/Os^{2\oplus}$ couple is also a candidate, but unless some strong π acid ligands are present it is too strongly reducing to be useful. The ruthenium species had the added advantage that much more preparative work had been undertaken on them[63] and, further, that the redox potentials are close to those of the much studied cobalt couples. Since the π orbital on Ru^{III} can overlap with the π^* orbital on the ligand, we expected that the "hopping" mechanism would no longer apply. Reaction with $[Cr(aq)]^{2\oplus}$ is, in fact, much more rapid (2×10^4) than that of the Co^{III} isonicotinamide complex, and, moreover, the rates are quite sensitive to changes in the redox potential of the oxidizing center[64]. The chemistry also differs in an interesting way from that of Co^{III}/Cr^{II}. The bond between Ru and the ligand is not severed when Ru^{III} is reduced to Ru^{II}, and a kinetically stable binuclear intermediate is formed, as expected[18] from the electronic structures of the products—πd^6 for Ru^{II} and πd^3 for Cr^{III}.

Although the main intent of this article is to provide historical background rather than to develop the subject itself in detail, it may be appropriate in concluding this section to illustrate the strong dependence of the reaction properties on electronic structure with a few examples. Effects arising from differences in electronic structure are manifested in several different ways: by affecting the rates of substitution, they can influence the choice of mechanism, and, for an inner sphere reaction path, can determine whether binuclear intermediates are easily observable and whether there is net transfer of a group from one center to another; even after the precursor complex is assembled, orbital symmetry can affect the mechanism itself, as in the example mentioned previously, and can profoundly affect the rate of conversion of the precursor to successor complex.

The Cr^{III}/Cr^{II} ($\pi d^3/\pi d^3\sigma d^1$) and Ru^{III}/Ru^{II} ($\pi d^5/\pi d^6$) couples offer perhaps the greatest contrasts in behavior. It should be noted that the σ electron in Cr^{II} is antibonding, thus accounting for the tetragonal distortion in Cr^{II} complexes and their enormous lability compared to those of Cr^{III}. By contrast, the complexes of both oxidation states of ruthenium undergo slow substitution, with the useful exception of water as ligand, where the residence time on Ru^{II} is a fraction of a second.

The reducing agent Cr^{II} shows preference for an inner sphere mechanism, and this is especially marked if the acceptor orbital has σ symmetry. There is a great economy of motion for electron transfer by an inner sphere path for the σ donor-σ acceptor cases; this arises from the reciprocity at the two centers of the events required to overcome the inner sphere Franck-Condon barrier. This point is illustrated for the $[(H_2O)_5{*}CrCl]^2 + [Cr(H_2O)_6]^{2\oplus}$ self-exchange reaction in Figure 1, where the electronic levels are shown for the precursor complex, for the activated complex, and for the successor complex. Motion of the bridging chloride ion from Cr^{III} to Cr^{II} lowers the energy of a acceptor orbital on Cr^{III} and at the same time raises that of the donor orbital on Cr^{II}, and although other nuclear motions are also required, there is some correlation of the events required for activation to electron transfer, a correlation which is absent with an outer sphere mechanism. The high substitution lability of Cr^{II} of course means that the precursor complex can be formed rapidly.

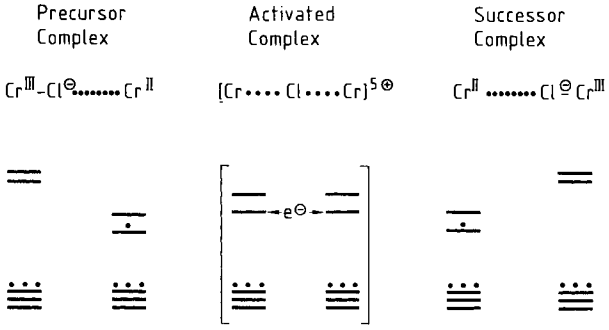


Fig. 1. Electronic structure and "atom" transfer in the self-exchange reaction $[(H_2O)_5CrCl]^{2\oplus} + [Cr(H_2O)_6]^{2\oplus}$.

Comparison of the rates of self exchange for $[Cr(H_2O)_6]^{3\oplus}/[Cr(H_2O)_6]^{2\oplus}$ and $[(NH_3)_5RuH_2O]^{3\oplus}/[(NH_3)RuH_2O]^{2\oplus}$ and how these respond when the higher oxidation state of each couple is converted into the hydroxo complex is quite instructive. The upper limit for the specific rate of self-exchange for the Cr^{III}/Cr^{II} couple is 2×10^{-5} M^{-1} s^{-1}[65,66]; although it has not been directly measured for the ruthenium couple, the specific rate can reasonably be taken to be close to that[67] for $[Ru(NH_3)_6]^{3\oplus}/[Ru(NH_3)_6]^{2\oplus}$, namely ca. 1×10^3 M^{-1} s^{-1}. Because the redox change for the ruthenium couple involves a π electron, it causes only a small change in the dimensions of the complex[68]. Thus, the Franck-Condon barrier to electron transfer arising from inner sphere reorganization is small, and facile transfer by an outer sphere mechanism is observed. By contrast, because Cr^{III} has no antibonding electrons and the electron added on reduction is antibonding, a

large change in dimensions and shape attending the reduction is observed, and the slowness of the self-exchange can be attributed, in part at least, to the inner sphere barrier[69]. Why the water molecule, which as a ligand on the oxidizing agent, which still has an electron pair available for sharing with the reducing agent, is such a poor bridging group is not yet understood.

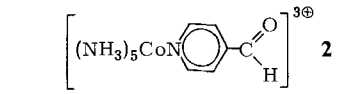
On deprotonation of a water molecule in each oxidant, the inner sphere path for the Cr^{III}/Cr^{II} system opens up, and a marked increase in rate is observed[65] ($k = 0.66\ M^{-1}\ s^{-1}$ at 25 °C)—the increase may be as large as a factor of 10^9[66]. The self-exchange rate for $[(NH_3)_5RuOH]^{2\oplus} + [(NH_3)_5RuOH_2]^{2\oplus}$ has not been measured, but it can be asserted with confidence that the rate via either an inner sphere path or an orthodox outer sphere path will be much less than it is for the aqua couple. The rate via the inner sphere path will be limited by the rate of bridge formation and thus will be no greater than $1 \times 10^{-2}\ M^{-1}\ s^{-1}$ (values of the order of $0.1\ M^{-1}\ s^{-1}$ for substitutions with neutral ligands on $[(NH_3)_5RuOH_2]^{2\oplus}$)[70]. The orthodox outer sphere path now has a composition barrier as well as a Franck-Condon barrier to overcome (the equilibrium constant for the formation of $[(NH_3)_5RuOH]^{\oplus}$ and $[(NH_3)_5RuOH_2]^{3\oplus}$ from $[(NH_3)_5RuOH]^{2\oplus}$ and $[(NH_3)_5RuOH_2]^{2\oplus}$ is ca. 10^{-9}). Reaction by "hydrogen atom" transfer[15] is a reasonable possibility, i.e., electron transfer concomitant with proton transfer from the Ru^{II} complex to the Ru^{III}, and some evidence in support of this kind of mechanism has been advanced to explain observations[71] made in the oxidation of $[(NH_3)_5RuOH_2]^{2\oplus}$ by $Fe^{3\oplus}$ and $[FeOH]^{2\oplus}$. Reaction by such a path might be quite facile and a rate in excess of $1\ M^{-1}\ s^{-1}$ would be strong evidence in its favor.

6. Applications of the Ru^{III}/Ru^{II} Couple

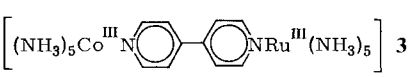
Some unexpected benefits have accrued from introducing Ru^{III}/Ru^{II} ammine couples to the study of electron transfer reactions. Ruthenium(II) participates in back bonding interactions to a degree unprecedented among the dipositive ions of the first transition series. A discovery[72] which forcefully brought this message home is that $[(NH_3)_5RuN_2]^{2\oplus}$ is formed in aqueous solution by the direct reaction of $[(NH_3)_3RuOH_2]^{2\oplus}$ with N_2. When the heteroligand in $[(NH_3)_5RuL]^{2\oplus}$ is pyridine or a derivative thereof, the complexes of both oxidation states undergo slow substitution, and by changing the number of π acid ligands a versatile series of outer-sphere redox couples is made available, spanning a range in redox potential of over 1 V. When derivatives of the Os^{III}/Os^{II} ammines are included, the useful range in aqueous solution is extended by approximately 0.5 V. These reagents are finding wide application in research on redox processes.

6.1. Intramolecular Electron Transfer

In order to arrive at a basic understanding of electron transfer processes, it would be a great advantage if the reactions could be studied intramolecularly rather than, as is commonly done, bimolecularly or intermolecularly, particularly if the geometrical relation between the two metal centers were unambiguously defined. Such systems had been encountered in studies of "induced" electron transfer[73]: when a powerful $1e^{\ominus}$ oxidant reacts with **2**, for example, the resulting coordinated organic radical can undergo intramolecular electron transfer, the oxidation of the ligand to the carboxylic acid being completed by Co^{III}. In some cases, intramolecular electron transfer can be intercepted by reaction of the radical with the external oxidant, but at best, only relative rates were obtained for these systems. In an elaboration of this kind of approach in which pulse radiolysis is used to convert the organic ligand to a radical—usually by reduction—intramolecular transfer rates can be measured[74]. These results are important in their own right, but are no substitute for experiments in which metal-to-metal electron transfer is studied.



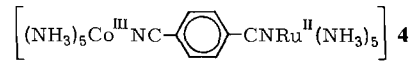
2



3

A strategy for dealing with the metal-to-metal case was devised[75a] which depends on the special properties of the Co^{III}/Co^{II} and Ru^{III}/Ru^{II} couples. The principle is as follows: When a complex[76] such as **3**, which has both metal centers in the oxidized state, is treated with an external reducing agent, Ru^{III} is reduced more rapidly than Co^{III}. This is a direct result of the differences in electronic structure, πd^6 and πd^5 for Co^{III} and Ru^{III}, respectively, the former requiring much more reorganization energy because the incoming electron is antibonding. In a subsequent step, Ru^{II} reduces Co^{II} in an intramolecular process, at least if the solution of the binuclear complex is sufficiently dilute.

The first synthesis[75a] of a $M_A^{III}\ M_B^{III}$ complex is rather ingenious, but it involves many steps and has the disadvantage that $SO_4^{2\ominus}$ rather than NH_3 is trans to the pyridine on Ru^{III}. *Schäffer*[77] has greatly simplified the preparative procedure by taking advantage of chemistry developed by *Sargeson* et al.[78], and has studied intramolecular electron transfer in **4** and in the related complexes with the ortho



4

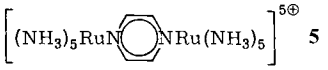
and meta isomers as bridging ligands. Quite independently of our work, *Haim et al.*[79] have carried out experiments similar to those described, but with $[Fe(CN)_5H_2O]^{3\ominus}$ as the reducing agent. Substitution at $[Fe(CN)_5H_2O]^{3\ominus}$ takes place readily, and hence the simple mixing procedure attempted by *Roberts*[75b] can often be used.

A point of interest in all of these studies was to learn how the rate of reaction responds to changes in the structure of the bridging group. For bipyridine complexes the coupling between the pyridine rings was therefore modified[76]; since the immediate environment about each metal

is left unaltered, the driving force for the reaction is but little affected, and changes in rate can then be attributed to changes in electronic coupling. The results obtained in studies of this kind are outlined in a recent review article by *Haim*[80]. Here, I will only mention an extension of this kind of strategy to a system of biochemical interest. *Gray* et al.[81] and *Isied* et al.[82] have succeeded in incorporating the $[(NH_3)_5Ru]$ group into cytochrome c at a position remote from the porphyrin (Ru^{III}-Fe^{III} separation: 15 Å). Different pulse methods were used by the two research groups to reduce Ru^{III} preferentially over Fe^{III}, and though the results of the two studies differ somewhat ($k = 20 \pm 5\ s^{-1}$ and $82 \pm 20\ s^{-1}$, respectively), it is clear that the general strategy is effective.

6.2. Robust Mixed Valence Molecules

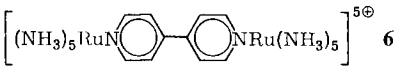
The resurgence of interest[83] in the properties of mixed valence compounds can be traced to review articles[84–86] which appeared in 1967 and to the first deliberate synthesis of a robust mixed valence molecule, species **5**, which is commonly referred to as the Creutz-Taube ion[87]. (Quite



5

independently of our work, *Cowan* and *Kaufman*[88] prepared a molecule based on the ferrocenium/ferrocene couple.) *Peter Ford* and I first synthesized the Creutz-Taube ion in 1967. In undertaking its preparation, we were motivated by simple curiosity rather than by questions which might arise from a deep understanding of the issues raised by the properties of the mixed valence compounds. The fully reduced compound in the (Ru^{II}, Ru^{II}) state is readily prepared by direct substitution using pyrazine and $[(NH_3)_5RuOH_2]^{2\oplus}$, and, in carrying out the project, we were taking advantage of our knowledge of affinities and rates of substitution for both oxidation states of ruthenium. Complexes with Ru^{II} having a bond to a heterocyclic nitrogen atom show very strong absorption in the visible region of the spectrum ($\pi^* \leftarrow \pi d$)[89], and on observing that the color was not significantly altered when the (II,II) species is half oxidized, we did not pursue the matter further. Fortunately, *Carol Creutz* took up the subject again. The electrochemical results which she obtained in about June 1968 showed that the mixed valence state is very stable relative to the isovalent, and this suggested to us that electronic coupling in the mixed valence species is strong. At this stage, the review papers by *Hush*[85] and by *Robin* and *Day*[86] had appeared, and taking their content to heart, we felt certain that an intervalence band must exist, which *Carol Creutz* then located in the near IR ($\lambda_{max} = 1570$ nm), where, of course, it does not affect the color (hereto this region of the spectrum had been little investigated by chemists). Intervalence absorption corresponds to using the energy of a photon to transfer an electron from the reduced to the oxidized metal center, subject to the Franck-Condon restriction. Intervalence absorption confers the characteristic blue color to Prussian blue. The intervalence absorption occurs at longer wavelength for the Creutz-Taube ion than for Prussian blue, because the two iron sites in the latter are not substitutionally equivalent. Thus there is a compositional ground state energy difference attending electron transfer, which is then added to that associated with the Franck-Condon barrier when the process is induced by a quantum of light.

One of my main interests in the field of mixed valence molecules has been to explore and to try to understand the energetics of the systems. I will illustrate the kind of conclusion which we have reached in pursuing these interests, using the localized, mixed valence complex **6** as example, where we have relied on theory introduced by *Hush*[85] and *Mulliken* and *Person*[90], and by *Mayoh* and *Day*[91], the latter providing a correlation between the extent of electron delocalization and electronic structure[92].



6

The stability conferred on the ground state of **6** by charge delocalization is only of the order of 50 cal/mol, far below the upper limit of 5×10^2 cal/mol set by the electrochemical results, which measure the total stabilization of the mixed valent compared to the isovalent state. When the nuclear coordinates about each center are adjusted so that the Franck-Condon condition is met, the energy separating the bonding and antibonding states which arise from electron delocalization is calculated as 2.2 kcal/mol[93]. This is taken to be sufficient to ensure adiabatic transfer[94], in agreement with the conclusion reached in studies of intramolecular electron transfer in Co^{III}/Ru^{II} systems with 4,4′-bipyridine and related molecules as bridging ligands[76]. If electron transfer is assumed to be adiabatic, the specific rate for intramolecular electron transfer is calculated to be $3 \times 10^8\ s^{-1}$, in reasonable agreement with an estimate ($1.6 \times 10^8\ s^{-1}$) obtained from measurements of intermolecular electron transfer rates for pentaammine(pyridine)ruthenium complexes[95].

Mixed valence molecules have been prepared[96] which are delocalized even although the bridging group is so large that direct metal-to-metal orbital overlap cannot be responsible for the delocalization. These molecules have remarkably interesting properties in their own right, and are the subject of current studies[97].

7. Concluding Remarks

In this article, I have focussed rather narrowly on electron transfer reactions between metal complexes. The separation of this subclass from other possible ones which can be assembled from the reactant categories (metal complexes, organic molecules[98], molecules derived from other non-metallic elements, molecules in excited states[99, 100] or electrodes) is not as arbitrary as it might be were it dictated solely by limitations of space. Admittedly, all the possible electron transfer processes are governed by the same principles, at least when these are stated in a general way. But as these principles manifest themselves in the different subclasses, the descriptive chemistry can be quite different,

and these differences are the fabric of chemistry. The subclass treated has perhaps been the most thoroughly studied, yet, as the article by *Sutin* shows[36], our understanding at a basic level is far from complete. Even for the much studied $Fe^{3\oplus}/Fe^{2\oplus}$ self-exchange reaction [eq. (a)], which served to introduce this subject, the important question of whether or not the reaction is adiabatic has not been settled to everyone's satisfaction. Still, a great deal of progress has been made. The descriptive matter has increased enormously since 1940, and our understanding of it, both in scope and depth, has more than kept pace with observations. A great deal of progress has also been made in many of the other subclasses—for example, in the study of electrode processes and in "atom transfer" reactions (as a specific case the use of transition metal species to carry the oxidizing capacity of O_2 to a substrate such as an organic molecule). Both are of the greatest importance in industrial applications, and "atom transfer" reactions in providing an understanding of the chemistry of living cells. Because the subclasses are interrelated, progress in one speeds progress in another.

Many of the co-workers who have contributed to progress in the subject dealt within this article are cited in the references, and this is an implicit acknowledgment of their contributions. Because this account is incomplete, others who have contributed directly to this work have not been cited, nor still others who have had interests that are not reflected in the account I have given. I am grateful to them all for the help they have given, and for what I have learned in the course of working with them. The nature of the contributions made by my coworkers is not evident either from the acknowledgment I have made or from my expression of gratitude. I need to add that I have always relied on the independence of my co-workers, and to a large extent my contribution to the effort has been that of maintaining continuity.

I also wish to acknowledge financial support of my research by the agencies of the U. S. Government, beginning with the Office of Naval Research in about 1950. Later, I derived partial support from the U. S. Atomic Energy Commission, and still later from the National Science Foundation and the National Institutes of Health (General Medical Sciences). The Petroleum Research Fund of the American Chemical Society has also been a source of research support.

[5] This descriptor and that following were introduced by *R. A. Marcus, Faraday Discuss. Chem. Soc. 29* (1960) 21 and *J. Phys. Chem. 67* (1963) 853, in proposing an equation which correlates the specific rate for a "cross reaction" such as $Fe^{3\oplus}+V^{2\oplus}\rightarrow Fe^{2\oplus}+V^{3\oplus}$ with the specific rates of the component "self exchange" reactions $Fe^{3\oplus}/Fe^{2\oplus}$ and $V^{3\oplus}/V^{2\oplus}$. Allowance is made in the equation for the effect of ΔG^0 on the rate.

[9] The descriptor "inner sphere" is used for reactions in which oxidant and reductant metal centers are linked through primary bonds to a bridging group. In the early work, it was assumed that the bridging group would play a special role in electron transfer reactions. However, in more recent work on intramolecular transfer (vide infra) examples have been found of systems in which the bridging group seems to serve only to hold the two partners together. "Inner sphere" or "outer sphere"?

[35] Consider the process

$$\underset{\text{I}}{A\cdot B^{\ominus}} \longrightarrow \underset{\text{II}}{[A\cdot B^{\ominus}]} \longrightarrow A^{\ominus}\cdot B$$

State I is the precursor complex; in state II the energy is independent of whether the electron is on atom A or B, i.e., the Franck-Condon condition has been met. In adiabatic transfer, electron delocalization is great enough so that whenever state II is reached electron transfer can take place, and the rate of the chemical reaction is determined solely by the rate at which state II is reached. In nonadiabatic transfer, the system passes through state II a number of times before electron transfer occurs, and both the Franck-Condon barrier and the rate of electron transfer in state II are rate determining.

"... to make Chemistry more Applicable and Generally Beneficial"—The Transition in Scientific Perspective in Eighteenth Century Chemistry**

By Christoph Meinel*

In 1751, the Swedish chemist *Johan Gottschalk Wallerius* first differentiated between "pure" and "applied" chemistry, a distinction which was quickly adopted by the other branches of science. Behind this was a new scientific concept of chemistry which emphasized the importance of applying chemistry's accumulated knowledge and its capabilities of providing for the general economic benefit. It also provided chemistry with a new position within the hierarchy of the sciences as well as with a new function in society. The reasons behind and causes of the change in scientific perspective associated with this concept point to the social and institutional conditions under which this field has developed into an independent academic discipline.

[*] Dr. C. Meinel

Mathematik und Technik der Universität
Bundesstrasse 55, D-2000 Hamburg 13 (FRG)

[**] Based on a discussion paper "Pure and Applied Chemistry—The Foundation of a New Identity in Eighteenth-Century Chemistry" at the 29th IUPAC-Congress, Cologne, June 6, 1983.

1. The "Chemical Revolution"

During the Age of Enlightenment, chemistry broke with its humble role as an auxiliary adjunct science to medicine, to attain the position of a well-respected and even fashionable science, represented on the faculties of nearly all uni-

versities. The dynamics involved in this process have always attracted the attention of historians of science; for three aspects make this transition worthy of study.

Firstly, even though chemistry had made important practical and theoretical contributions, the "Chemical Revolution" occurred relatively late when measured against the developments in astronomy and physics from *Copernicus* to *Newton,* i.e. in relation to the "Scientific Revolution" as such. *Herbert Butterfield* consequently spoke of a "postponed scientific revolution in chemistry"[1], and strangely enough, the chemists of that time were very conscious of this. In the French Encyclopédie[2], which outranged all other contemporary works as the voice of the Enlightenment, *Gabriel François Venel* (1723—1775) recognized as early as 1753 the necessity of a "new Paracelsus" who would raise chemistry to the rank of a true science: "Il est clair que la révolution qui placeroit la Chimie dans le rang qu'elle mérite, qui la mettroit au moins à coté de la Physique calculée; que cette révolution, dis-je, ne peut être operée que par un chimiste habile, enthousiaste, et hardi, qui se trouvant dans une position favorable, et profitant habilement de quelques circonstances heureuses, sauroit réveiller l'attention des savans, d'abord par une ostentation bruyante, par un ton décidé et affirmatif, et ensuite par des raisons, si ses premières armes avoient entamé le préjugé"[2].

Secondly, the emancipation of chemistry had to do with a fundamental modification of theory. The generally accepted premise up to that time had been that all combustion phenomena could be explained by phlogiston, thought to be a volatile constituent of flammable materials. This theory was replaced by *Lavoisier*'s theory of oxidation. With the acceptance of this new theory, chemistry gained not only a comprehensive theoretical basis, but also a new terminology, making it literally impossible for supporters of the old and new schools of thought to understand one another. For this reason, *Thomas S. Kuhn* views this process as a typical example of scientific revolutions and, at the same time, as confirmation of his controversial thesis that advances in scientific development do not occur on a cumulative-evolutionary basis, but rather take revolutionary leaps and bounds, expressed in changes of paradigms[3]. *Kuhn* is in accord with the older literature on the history of chemistry, maintaining that it was just this replacement of the phlogiston theory by the oxidation theory, which was responsible for chemistry's breakthrough and subsequent scientific success. Developing *Kuhn*'s position, *Elisabeth Ströker*[4] recently examined the prerequisites for crisis and ramifications of this paradigm change on a more theoretically and historically differentiated basis; however, she is almost exclusively concerned with alterations in the cognitive area of chemical knowledge and theories, whereas *Kuhn* alluded to the social components in the process of scientific change.

It is this third aspect which makes the history of chemistry in the eighteenth century so fascinating. For not only did the entire social structure of the scientific community alter itself, but also the position of chemistry within the hierarchy of both the sciences and society was changed. Chemists began to see themselves as representatives of an independent academic discipline, experiencing the necessary acknowledgement from outside their field and forming regional or vernacular communities, enabling them to develop the common forms of scientific communication still in use today. Chemistry can lay claim to the fact that it produced the first specialized journal in a scientific field, published in 1778, and the first international scientists' gathering ever held, in 1786. Not long ago, *Karl Hufbauer* convincingly described this process of breaking away from the "République des Lettres", of its institutionalization, professional integration and communication, using as his example the German chemical community[5].

But neither the alteration of the central paradigm nor the change in the social structure of the scientific community can alone adequately explain the astonishing impetus experienced by chemistry in the eighteenth century. This can least of all be accomplished by means of the traditional allusion to *Lavoisier*'s reform, since pre-*Lavoisier* chemistry can only partially be identified with the phlogiston hypothesis, and in the post-*Lavoisier* period chemistry can only be associated to a limited extent relation to the oxidation theory. In "Elementa Chemiae" (Leyden 1732) by *Herman Boerhaave,* one of the most influential textbooks of its time, the term "phlogiston" does not appear. And as early as the first third of the nineteenth century the relationship between generic and specific properties of substances, an idea central to *Lavoisier*'s reform, had already been dismissed. It is important to note, however, that of the 46 chairs in chemistry not directly related to a medical discipline that were instituted during the eighteenth century in German-speaking countries alone, around 70% had been set up before 1790, a time when it was impossible to speak of any influence of *Lavoisier*'s revolution in Germany.

The rise, establishment, and evolution of sciences are, of course, also social developments which can be traced back to certain groups of scientists. Thus, the intrinsic development of chemical theories, knowledge, and capabilities accompany the crystallization of specific behavior patterns and strategies, the purpose of which is to form the social and institutional basis for their own activities. For this reason the "scientific community" should be understood within the context of argumentation and action in which cognitive elements and institutionalization strategies converge, generating the self-understanding, unity, norms, and values important for just this group on an disciplinary, social and institutional level[6]. I choose to call these collective relationships a scientific orientation complex in order to overcome the unserviceable antithesis of internal and external factors of scientific development, established in 1931 by the Marxist school of science history[7]. It can be demonstrated in the history of chemistry that it was just such a comprehensive orientation complex which in the middle of the eighteenth century experienced a fundamental re-orientation, establishing the direction critical to the evolvement and further development of the discipline.

2. The Status of the Field

The origins of chemistry as an academic discipline lie in the seventeenth century. The Paracelsians had introduced

the therapeutic application of chemical medicines, thereby founding the field of chemiatrics. In 1609 *Johannes Hartmann* (1568-1631) was vested with the first chair in this new area of study at Marburg University. The alchemical leanings of the landgrave no doubt played a part in his appointment. Two generations later this discipline was already to be found at numerous universities, functioning as an auxiliary adjunct to medicine.

Initially, of course, chemistry had no easy position. The representatives of academic science greatly mistrusted the air of alchemical obscurity surrounding it. More important, with chemistry a whole new type of science had penetrated the halls of the traditional educational institution, the University. For chemistry's real place was not at the rostrum, but in the laboratory, where, although no research and experimentation in the modern-day sense was conducted, the work was performed manually with a practical and purposeful intent. This stood in contrast to the other disciplines, including medicine, which supported the inveterate scientific ideal. The professor of chemistry, who first had to brush the soot and dirt from his lab apron before congregating with his more respectable colleagues from other faculties, was a figure who represented a striking contrast to the scholarly ideal of the baroque period, a man to whom in the most literal sense the taint of the non-academic, the crafts, and the unclean adhered.

This situation was not to change very quickly, for the low status of chemistry within the academic hierarchy was institutionally and structurally defined. Professorships exclusively devoted to one particular subject were unknown; instead, each faculty maintained its own specific hierarchy, where advancement was largely based on seniority; here the differences in remuneration as well as the possibilities for lucrative work on the side played no small role. Within the faculties of medicine, this almost always meant that the medical professor of lowest rank lectured on chemistry as well as on pharmacy, botany, or anatomy. As soon as the opportunity arose, this professor then naturally advanced to the next highest position, finally becoming Professor primarius and could then combine his subject with a profitable private practice or with a position as physician to the prince. This system of advancement, a relic from the medieval university, maintained itself long into the eighteenth century. As long as it existed, it prohibited the development of professorships devoted exclusively to one particular science, for a doctor could hardly afford to place his professional aspirations on one of the subordinate subjects.

The reason for chemistry's bad image obviously lay in the concept of science itself, this having concerned itself primarily with a speculative and contemplative scientific ideal, seeing the search for essential truths as its main purpose. Everything else belonged to the arts. Even such a first-class authority on chemistry as *Daniel Sennert* (1572-1637) denied chemistry the status of "scientia" and reserved the right of researching into the causes of natural phenomena to natural philosophy (physica) alone, limiting chemistry to the narrow field of preparative manufacture with the emphasis on a pharmaceutical objective. This judgement was to determine the image of the subject for a considerable time. In 1786 no less than *Immanuel Kant* was still of the opinion that chemistry could be "nothing more than a systematic art or experimental doctrine, but never become a true science, because the principles thereof are solely empirical, envisioning no a priori representation of perception"[8].

As long as the empirical acquisition of knowledge and practical laboratory work stigmatized the subject's general esteem, the road to the autonomous development of the discipline would remain a long one.

The chemists of the Enlightenment, therefore, did everything in their power to weaken the prejudice that their discipline was simply a practical craft, a kind of "ars mechanica", without scientific character. They most certainly had recognized that their own dilemma was not so much a result of inner disciplinary deficiencies as due to the institutional conditions peculiar to their field of study. In this way a special literary tradition of doctrinal publications developed, the goal of which was to solicit support for chemistry as a distinct science in its own right and to make a broader public conscious of its true value[9].

3. Pure and Applied Chemistry

Under the circumstances described here, doctrinal guidelines were formed for the further development of the discipline enabling chemistry to overcome its formalistic division into a theoretical science, on the one hand, and a practical handicraft, on the other, a distinction which was perceived as inhibiting further development; this was the distinction between "pure" and "applied" chemistry, which exists to this day[10]. Actually, this twin notion occurred for the first time in its modern-day sense in the field of chemistry. In the course of the nineteenth century it was adopted by the other sciences. This represented more than a change in terminology, however, and, more accurately, it originated in the desire to formulate a new scientific concept of chemistry in order to endow its level of knowledge and its capabilities with a new purpose. From this time on, the decisive factor in determining the relative worth of the field was not to be the type of work carried out, whether practical or theoretical, but rather the research objective itself and its relevance to society. In the case of pure chemistry, this goal was to delve into the causes and apparent laws governing natural phenomena related to matter; applied chemistry was to exploit these insights for the benefit of mankind by solving concrete everyday problems. The fact that both pure and applied chemistry were to closely ally theoretical reason with experimental practice was seen as an obvious prerequisite.

Fortunately, it is possible to pinpoint the circumstances which led to this new concept of chemistry more precisely. In 1749, the first chair of chemistry was set up at the University of Uppsala. Up to this time, lectures in chemistry had not existed in Swedish universities, despite the fact that this country, rich in mineral resources, exhibited a pragmatically oriented mineral-chemical and metallurgical tradition. The mines at Falun and their state assay office were well-known throughout Europe. The government commission responsible for the institution of the new chair

in chemistry had ordained the integration of the chair into the philosophical faculty, where students of the mining profession, as well as of economics and administrative science, obtained their general education. This was done, even though elsewhere in Europe chemistry was a self-evident part of the faculty of medicine. The appointment offer first went to *Georg Brandt* (1694-1768), director of the laboratory of the Board of Mines in Stockholm and assay master of the Royal Mint. Upon his refusal, the position was offered to *Johan Gottschalk Wallerius* (1709-1785), who had maintained a private chemical and metallurgical laboratory at the University of Uppsala from 1738. He was well-known, even outside Sweden, as the author of a handbook on mineralogy. In July 1750, *Wallerius* accepted his new position as the first professor of chemistry in Sweden. The rector of the University had requested him to expound on the reasons for bestowing the privileges of academia on chemistry in his inaugural lecture—at this time still a controversial topic!

Even though the manuscript of his lecture no longer exists, there is reason to believe that *Wallerius* answered the question in the affirmative, just as *Boerhaave*'s successor in Leyden, *Hieronymus David Gaubius*. In 1731 *Gaubius* had dedicated his "Oratio inauguralis qua ostenditur Chemiam artibus academicis jure esse inserendam" to just this topic and had also had it published. *Wallerius* knew this publication.

Among other duties, the new professor of chemistry was to hold lectures on chemistry, metallurgy, and pharmacy. However, he was also to examine the students of medicine in pharmacy, chemistry, and the art of writing prescriptions. The king himself had insisted that this examination be conducted by a chemist on the philosophical faculty. Understandably, the professors on the faculty of medicine felt this to be a scandalous infringement of their innate scientific and, of course, financial rights, for it meant their forgoing the not unprofitable examination fees, which reduced their not exactly lucrative salaries even further. The spokesman for their cause was none other than *Carl Linnaeus* (1707-1778). Originator of the modern classification system for plants and professor of botany, dietetics, and Materia Medica in Uppsala, he was also president of the Stockholm Academy of Sciences and physician to the king. Nevertheless, his objection remained unsuccessful. The professorship in chemistry stayed with the philosophical faculty, keeping its controversial examination privileges. Thus, its institutional framework was established.

In his autobiography[11], however, *Wallerius* recalls that initially no-one could form a true picture of just exactly what chemistry was. To publicize his field and further his

1751

Min Herre!

Af Min Herres bref, finner jag Eder åstunda någon kundskap om Chemien, des natur och beskaffenhet, samt tillika få weta, hwarutinnan des oumgengeliga nytta består. Jag märker Eder hysa sådana tanckar, som många andra, hwilka hålla chemien endast för en curieux, och, utom den föga nytta den i Medicin skaffa kunde, för en mindre nödig och nyttig Wettenskap. Ar dock, Min Herre, i denna sin tanka drägeligare, än en del andra, hwilka hålla densamma för en skadelig och förderfwelig konst, som endast med Metallernas förädlande hade at syssla. Bägge dessa felacktiga meningar härflyta af idel okunnighet om Chemiens natur och beskaffenhet. Så Eder fördenskul, som Andra til underrättelse, wil jag i korthet derom nu något anföra, en utförligare Chemiens afhandling besparandes til et annat tilfälle.

At årnå någon redig kundskap om Chemien, håller jag begwämligast wara, indela densamma i *Chemiam puram* och *Chemiam applicatam*; på samma sätt som Mathematici indelt sina wettenskaper, förandes en del af dem til *Matheſin puram*, och en del til *Matheſin applicatam*, i hwilken senare, de i den förra abſtracte conſidererade quantiteter och dimenſioner, appliceras til de naturliga kroppar och deras rörelſer.

A 2 CHEMIA

Fig. 1. In this "open letter" by *Johan Gottschalk Wallerius*, dated 10th August 1751, the new and promising distinction between Pure and Applied Chemistry was used for the first time. (Reproduced by permission of the Niedersächsische Staats- und Universitätsbibliothek, Göttingen.)

own cause, he had a small essay printed in Swedish in the form of a letter addressed to an unknown person, in which he introduced the true object of the study, as well as the use and value of chemistry, going into great detail (see Fig. 1). At the very beginning, *Wallerius* coined the conceptual distinction between "pure" and "applied" chemistry. The latter "Chemia applicata" was emphasized by him, and considering the previous events, it is hardly surprising that *Wallerius* was less concerned with the medical and pharmaceutical applications of chemistry than he was with its agricultural, metallurgical, and mineralogical uses, feeling that these areas held the highest economic promise.

Whereas the Swedish "Bref" was directed at students and the general public, *Wallerius* addressed a Latin dissertation "De nexu Chemiae cum utilitate Reipublicae" (Stockholm 1751) of the same year to the academic world and to those politically responsible for the country. Prefacing the work were no less than four Latin, Swedish, and French dedications to eminent personages. The main theme of this work, which was publicly defended by a certain *Lorenz Hiortzberg* under the chairmanship of *Wallerius,* was the distinction between pure and applied chemistry as well as the political and economic uses of the latter. Again, mineral chemistry and metallurgy were the fields in which the fruits of this science seemed closest at hand, while the profitability of chemical medicines was treated rather distantly. In view of the doubtful therapeutical successes achieved by the potent inorganic medicines then administered, this is certainly understandable.

The decisive factor which led to the acceptance and propagation of "pure and applied" chemistry was the general chemistry textbook by *Wallerius* ("Chemia Physica", Stockholm 1759), which he first published in Swedish and then personally translated into Latin, the language of academic Europe (Stockholm, 1760). Shortly thereafter, translations into German also appeared. This work played an important role in the history of chemistry textbooks in that it gave birth to a whole new generation of textbooks, written in the vernacular, the express purpose of which was to represent chemistry as an integral part of the physical natural sciences without reducing it to the level of medical or pharmaceutical interests. Its title "Chemia Physica" was intended to express just this general scientific concern. In this textbook *Wallerius* took the opportunity to develop his scientific concept of chemistry even further, for now he had realized that by consistently classifying the field in accordance with its objective and effect two things would occur: not only would the old separation of theory and practice lose weight, but so would the tiresome dispute over the definition of chemistry as a science or as an art. Instead, he regarded all subdivisions of applied chemistry as independent self-contained sciences which comprised both theoretical and practical aspects.

In choosing the twin concept "pure and applied" chemistry, mathematics had been openly declared as the model, although the mathematical terms had an entirely different meaning. "Pure" mathematics meant that part of the mathematical sciences which dealt with numbers only as intellectually perceptible, incorporeal patterns, whereas "applied" mathematics, according to the literal translation of "mathematica mixta", meant that part of mathematics which dealt with the numerical relationships of real things, perceptible to the senses. The aspect of utility and general benefit which has been connected with the concept of applied science since *Wallerius* was nowhere to be found in "applied mathematics" until the end of the nineteenth century. It is therefore worthy of attention, and most certainly no chance occurrence, that the modern definition of this twin concept originated in chemistry, thereafter spreading to all other sciences and European languages during the nineteenth century. The historical development of its influence will not be expanded upon here[12]. It should be mentioned, however, that the key role in its propagation was played by the Greifswald chemistry professor *Christian Ehrenfried Weigel* (1748-1831). Until 1815 the university at which he lectured was part of the Swedish Kingdom, so that as a result he was exceedingly familiar with the Scandinavian chemical tradition[13]. In addition to translating French and Swedish authors, he was also publicly active as a proponent of an autonomous chemical science by means of his own textbooks and popular writings. He was well-known among his contemporaries as the inventor of the water-jacketed condenser, which today is falsely known as *Liebig*'s condenser.

4. A Concept of Science in the Enlightenment

Wallerius' scientific concept of chemistry would not have been such a sudden and lasting success had it solely originated from a single Swedish chemist. In principle, the idea had been around for some time and it was *Wallerius* who merely succeeded in pinpointing and naming this new orientation of chemistry, which had reached a turning point around the middle of the eighteenth century. For almost simultaneously, it was possible to find *Mikhail Lomonosov* (1711-1765) making very related deliberations in Petersburg, in addition to the circle of authors of the French Encyclopédie. All of these are related by their common attempt to overcome the earlier contemplative ideal of science with its overrating of the theoretical, in order to replace it with a new bourgeois concept of science, which in turn contained the idea of progress and of actively molding the world. This new evaluation of chemistry and the higher status of its range of application was thus an inherent part of the purpose of the Enlightenment in putting rationality and the individual pursuit of happiness into social practice. The reason that this process began earlier and more noticeably in chemistry than in the other natural sciences lies in the fact that applied chemistry had already achieved undisputed successes; and due to its level of development, further useful discoveries could be expected.

Chemistry's understanding of its own role and its status was influenced more and more by utilitarian thought in the eighteenth century. Hardly an author wrote a new work without expressly informing the public of its far-reaching and direct benefits. Even textbooks were laid out according to the widely circulated "Elementa Chemiae" by *Boerhaave,* so that each "processus" was divided into "apparatus" (preparation) and "usus" (application). Seldom have rhetorical elements penetrated so deeply into the inner

structure of a discipline as in this case. Even in defining its objective and essence, the aspect of general benefit, as a rule, played a very important role in determining just what chemistry was. It would be premature to dismiss this only as rhetoric. Of course, it was also a question of safeguarding social and institutional support for their discipline, as well as obtaining new professorships, finances for a laboratory, or funds for an expensive experimental lecture. At the same time, it expressed chemistry's new understanding of its own function. The most respected representatives of the discipline made utilitarianism their own deep concern and stepped forth with treatises on the properties and preparation of foods and industrial goods, on questions of heating and lighting, dyeing and stain removal. It must be remembered that the first scientific publication of *Antoine Lavoisier,* then 21 years of age, was an answer to a question in a contest sponsored in 1764 by the Académie des Sciences as to the best and most economical method of lighting the streets of Paris at night. Working on a wide scale for the benefit of all was considered the final and utmost purpose of scientific work. *Ferdinand Wurzer* (1765-1844), one of the most productive German chemists of his generation, linked his professorship of chemistry and pharmacy at the University of Marburg with a teaching position at its Staatswirtschaftliches Institut, a school of economics. Consequently, he began the introduction to his "Handbuch der populären Chemie" (Marburg an der Lahn 1806) as follows: "People are finally beginning to generally realize how necessary chemistry is in order to handle crafts, factories and matters of economy more effectively, how industry with all its beneficial consequences has risen to an especially excellent level in those countries where knowledge of chemistry and its accomplishments are valued and utilized". And he concluded with this acknowledgement: "It is my deepest wish, with this work, to pay homage to that noble spirit of our time through whose power scientific knowledge is becoming less and less the monopoly of the learned, in that the majority of the latter are everywhere visibly attempting to work for the general benefit, to speak within the grasp of the masses, and to come down to their level"[13a].

Of course, the content of such popular treatises promising to be of directly beneficial use did not always fulfill what the flowery titles and prefaces foretold. Just the same, they must have had a considerable effect. By means of their thematic variety and high circulation, they reached an extraordinarily wide public from gentlemen farmers and manufacturers to ministerial officials. Thus the contribution this kind of scientific literature made to popularizing chemistry and to the public's acceptance of its rational and utilitarian image cannot be overvalued, even if the historiography of chemistry is all too partial to the development of theories and cognitive progress, disapproving of this kind of commercial literature.

5. Chemistry and the Economy

In the German tradition, chemistry's preoccupation with domestic and political economy as well as its leading role in stressing its economic benefit is especially marked. The reason for this is to be found in the discipline's very close ties to cameralism, the German variant of mercantilism, related to the administrative needs of small territories. The goal of the cameralists was the welfare of the state and the "best for all", to whose end mercantile thought and the national quest for power should strive. Their programme of economic reform envisioned increasing the working population as well as the government's intake of revenue by limiting imports and deliberately encouraging trade. By means of accessibility to and better exploitation of domestic raw materials and mineral resources, it was believed feasible to economically strengthen the country, if possible to the point of self-sufficiency. The initial cameralistic encouragement of industry, primarily due to government initiatives in the production of textiles, glass, and ceramics, achieved evident successes. As a result, new problems arose in the production and raw materials sectors, presenting a challenge to chemistry's professional competence.

Johann Joachim Becher (1635-1682), a very versatile man, known to chemists as the father of the phlogiston theory, was also one of the founders of cameralism and at a time when his chemical and alchemical works were almost forgotten, his contributions to cameralistics were still the accepted standard. In 1676 *Becher* founded his "Kunst- und Werkhaus" in Vienna, with the support of emperor *Leopold I,* who was greatly interested in alchemy. It was a technical teaching and research institute meant to enliven Austrian manufacturing methods. Obviously, a chemical laboratory, glassworks, and a metallurgical laboratory were included in its endowment, for encouragement of trade and technological development were accepted as the central mandate of modern government. Around the year 1700, *Georg Ernst Stahl* (1660-1734), the great theorist and respected teacher of a whole generation of German chemists, had expanded on *Becher*'s hypothesis of "fatty earth" to form the phlogiston theory and was thus able to account for a great number of chemical reactions. He had also adopted *Becher*'s doctrine of economically oriented chemical practice. The spiritual environment of Halle's Pietism, to which *Stahl* felt closely allied, had initiated a lively economic boom in that Prussian town even before the turn of the eighteenth century, a boom which resulted in the most modern forms of production and which influenced the building of factories, the establishment of *A. H. Francke*'s Foundations, and the transformation of the Saale into a navigable river. Last but not least, the University of Halle was also founded in this period (1694), to develop a short time later into the leading Prussian university of its time. That same year, *Stahl,* who came from Jena, was made Professor secundarius on the faculty of medicine in the ambitious, newly founded university. He distinguished himself there with treatises on chemical metallurgy, assaying, dyeing techniques and the extraction of saltpeter. His chemical-technical masterpiece "Zymotechnia Fundamentalis" (Halle 1697) laid the foundation for the chemical interpretation of such processes as the brewing of beer, alcoholic fermentation, and the preparation of vinegar. In the year of *Stahl*'s death, 1734, it was recommended by the translator of the German edition as a manual, with the aid of which a clever statesman could save millions in imports

by improving domestic production. It is noticeable that pharmaceutical and medical questions play a relatively minor role in *Stahl*'s chemical publications. His own medical system was based on an animist vitalism and therefore diametrically opposed to the iatrochemical school. *Stahl* believed that chemistry had little to contribute to a better understanding of the physiological and pathological processes occurring within the human organism. This conviction encouraged him to open up new areas of application for chemistry independent of medicine.

Later, it was none other than the Stahlians who carried on this impulse, freeing chemistry from its subordinate role as an auxiliary adjunct to medicine and attempting to integrate it into the economic-cameralistic doctrine of the modern state. The treasury's vital areas of interest made the relationship between economy, production, and science a most important objective of enlightened absolutist thought: mines and foundries, saltworks and porcelain manufactures, mint and glassworks, and finally the production of saltpeter for military purposes presented tasks enough for chemistry. Even the early cameralistics *(Kameralwissenschaft)* which originated from the domestic and rural economy, eventually recognized how much it could profit from chemically founded knowledge of substances and processes. *Johann Gottlieb Eckhardt*'s "Vollständige Experimental-Ökonomie" (Jena 1754) was one of the first works from the tradition of husbandry to apply scientific principles to farming, thus beginning a new epoch in agricultural science which was then to result in a still rather primitive type of agricultural chemistry, as set down in *Johan Gottschalk Wallerius*' "Åkerbrukets chemiska Grunder" (Stockholm 1761; also published in Latin, German, French, and English editions). The theoreticians and reformers of cameralistics in the eighteenth century consciously viewed knowledge of chemical science as a basic prerequisite of their discipline, demanding the establishment of independent teaching positions in chemistry in order to instruct government administration and department of finance employees. In Göttingen, then center of cameralistics in Germany, *Johann Heinrich Gottlob von Justi* (1717—1771), its most important systematist, held lectures on economy, polity and administration, but also on chemistry and mineralogy. In his "Staatswirthschaft", published in 1755, the classic textbook in this field, he demanded that an independent economics faculty be established, in which chemistry, natural history, mechanics, and politics should be instructed on a very practical level with emphasis placed on their social benefits.

It can again be assumed that Sweden was the model in this case, for there, the connection between chemistry and cameralistics had the oldest tradition[14]. As early as 1638, a state Assay Office had been set up in the Stockholm Mines Office, which controlled the education of mining officials as well as the Swedish mines and foundries and the analyses for the Royal Mint. Then in 1750, *Wallerius* was appointed to the first chair in chemistry on the philosophical faculty of the University of Uppsala to give special consideration of the economic interests of the country. Subsequently, the universities of Lund and Åbo linked their new chairs in chemistry to cameralistics and not to medicine. But later, even in Germany, professorships in chemistry existed on the newly-created *Kameralfakultäten* at Lautern/Heidelberg, Giessen, and Mainz.

6. The Emerging Academic Discipline

Thus, chemistry had conquered university territory, where it neither had to assert itself against the overpowering tradition of the medical faculties nor to defend itself against the charge of being only a handicraft. Instead, it could test its knowledge and capacities as a science in accordance with the interests of the respective governments. "To make the gifts of nature easier to use for human benefit", was the way *Johann Georg Menn* (1730–1781) put chemistry's real objective. "Is the real purpose of chemistry not clearly aligned with the most important intention of the State as a whole to work for the common good? Is it not also in agreement with the judgement of those who want nothing more than to see that those sciences prosper which are advantageous to each and every part of the state up to and including the tradesmen?"[15] The shift in orientation within the discipline with regard to its contents can also be followed by studying the change in interests of chemical publications in relation to questions of commercial application.

The persuasive power and success of the new doctrine can be explained by the fact that the capacities of eighteenth century chemistry with regard to knowledge of substances, theoretical interpretation, quality of apparatus and the technical ability to realize its objectives was a great deal better adapted to the new challenges posed by the fields of metallurgy, glass and ceramics manufacture, textile processing and dyeing; better, that is, than the much more complex questions in the medical and pharmaceutical traditions, as they had been posed by *Boerhaave*'s corpuscularian physiology and by the analysis and pharmacology of herbal substances, or by the chemo-cosmological doctrine of Paracelsism. Chemical theory was able to and was also permitted to prove itself, as this practical aspect now met with social approval and enjoyed official support. Chemistry's scientific and economic successes opened perspectives for its development into a profession and for its institutionalization as an academic discipline.

Of course, the ties to the medical faculties still existed, since future medical doctors made up by far the largest part of the students present at chemistry lectures. Only later was there a sudden increase in the number of students of pharmacy, primarily resulting from the introduction of new legal measures, which gave this area increasing importance as a breeding ground for the development of chemistry. Primarily institutional reasons therefore determined that the earliest efforts of the discipline, as "chemia physica" and as a part of general natural science, to break away from the medical faculty and become part of the philosophical faculty seldom met with lasting success. For, along with this transference, the right to examine medical candidates was almost always forfeited, resulting in the loss of a large number of the potential and paying students at lectures. For example, *Johann Friedrich Gmelin* (1748-1804) accepted a full professorship in chemistry on the

philosophical faculty in Göttingen in 1775, which was associated with extraordinary membership of the medical faculty. Three years later, however, he was forced to give up this position to accept a professorship on the medical faculty, despite the fact that his main scientific interests still lay in applied and industrial chemistry. *Friedrich Albert Carl Gren* (1760–1798) suffered a similar fate. He began as an assistant to the professor of mathematics and physics in Halle and was then employed from 1785 onwards as a teacher of political science and economics on the philosophical faculty of the university. In 1788 he accepted a full professorship in science and chemistry which, however, reverted to the medical faculty after a period of just a few months. Jena, with a student body of about 800, was then the third largest German university after Halle and Göttingen, and was simultaneously the first German university to make a lasting institutional differentiation between chemistry and medicine. Due credit for this farsighted appointment policy must be given to the minister responsible at the time, *Goethe*. In 1789 he established a professorship in chemistry, pharmacy and technology there, not without strong objections from the medical staff. He appointed *Johann Friedrich August Göttling* (1755-1809) to this position, an apothecary whom he had sent to study in Göttingen and England at government expense[16].

In surveying the development of chemistry in the eighteenth century, it can be noted that neither a mere improvement in external conditions nor a revolution in *Kuhn*'s sense had enkindled the far-reaching process of transformation enabling the field to liberate itself. In chemistry, the developing scientific community centered its attention not so much on a new and binding doctrine or theory as on a scientific orientation complex composed of rational argumentation and social action, which gave the discipline's level of knowledge and capacities a new direction; this provided chemistry with a more up-to-date form of institutionalization strategy and made a re-evaluation of its cognitive content possible. This shift in orientation equally influenced its objects of study and methods used, its formulation of objectives and self-understanding, its social role, and its institutional integration. At its turning point stood the concept of a "chemia pura et applicata", which set the stage for the autonomous development of the discipline about to take place.

7. Departure from the Chemistry of the Enlightenment

The historical development of chemistry as an academic subject, however, goes beyond its thus attained goal. The climax of the mutual approach of chemistry and cameralistics was reached by the first third of the nineteenth century. The doctrine, which had concentrated on general and economic benefit, had exhausted itself, especially since the hopes of obtaining immediate material advantage in this way were not fulfilled. Finally, the popularization of the subject by the movement started by the Enlightenment occasionally caused the original objectives to seem superficial and trivial. But also with regard to its content, eighteenth century chemistry had come to the limits of its theoretical and methodological capacities when attempting to answer the ever-increasing questions from physiological and organic chemistry which the research programme dealing with quantitative combustion analysis, having received some support from *Lavoisier's* elemental concept, was now at a loss to deal with.

The institutional hurdles had, however, been overtaken. Chemistry had established a firm foothold in the universities. It no longer required any support from outside. In addition, chemists, especially in Germany, influenced by Romantic *Naturphilosophie* as well as by the neohumanistic university reforms, which originated in Berlin in 1810, were increasingly attempting to sever themselves from their utilitarian heritage. The new guiding light was called "pure science", that is, insights gained for the purpose of knowledge and liberal education alone. Applied and technical chemistry had been elevated to the level of a university discipline, only, with a few exceptions, to again depart from the academic arena and regroup in polytechnics. No less a person than *Justus Liebig* (1803-1873), who came from a strong mercantile tradition of chemistry, propagated this new, solely research-oriented concept of education with amazing success and thus initiated a new shift of orientation within his discipline. His fierce attacks on proponents of the old line, including his own teacher *Karl Wilhelm Gottlob Kastner* (1738-1857), often overshot their mark and constituted a part of his campaign against the directly utilizable. The same is true of his polemic remarks on the plight of chemistry in Austria and Prussia, the two countries with the strongest mercantilist traditions: "Most of our statesman only know chemistry and physics as a result of the benefits they have reaped for industry and factories in foreign countries. It is, of course, natural to exploit these benefits; just as chemistry in earlier times was vassal to the doctor, so today it is used as a cog in the wheels of industry. ... It has never been regarded by the state as a means of intellectual education, as a natural science in the true sense of the word. A large number of the well-educated see chemistry consisting of certain simple rules, as an experimental art, useful for making soda and soap, in fabricating better iron and steel, in depositing solid colors on silk and cotton, but as research into nature it is unknown. How strange, then, that the expression education, as understood by the truly enlightened, only extends to include knowledge of classical languages, history, and literature! The question of the causes of natural phenomena and the changes occurring in everything that surrounds us in daily life is so well-adapted to the human spirit that the sciences which are supposed to supply satisfactory answers to these questions influence the cultural level of the mind more than all others"[17].

The challenge which originated in the *Humboldt* reform, with its overevaluation of the "humaniora" and in its new scientific ideal, was a part of chemistry from then on, and was answered in such a way that it held the seed of educational and scientific policy discussions up to the present day.

But let us recapitulate. When *Herman Boerhaave* (1668-1738) accepted the chair of chemistry at the University of Leyden in 1718, he complained anxiously that chemistry

was regarded as "uncouth, repulsive and tiring, excluded from the community of the learned, unknown or mistrusted by scholars; it was supposed to stink of fire, smoke, ash and rubbish, having hardly anything appealing to offer"[18]. Three generations later *Johann Friedrich Gmelin* (1748-1804), professor of chemistry at Göttingen, a supporter of the phlogiston theory and one of the first historians of his field, could already maintain, full of pride, that chemistry was "the idol before which all peoples, all classes, princes and subjects, clergy and secular, learned and unlearned, of high and low rank, kneel down; the favorite science of the great, the practice of which promised mountains of gold, quick reinstatement of ruined finances and of ruined health, ... the retreat of the wise searching for light and enlightenment; the most important aid to the researcher of nature, imparting knowledge to him where other sciences fail; the key to many of the secrets of nature; the chosen guiding light in the labyrinth of countless industries which nurture, bless and enrich people and states; the rational basis for the existence of foundries, of many factories, arts and handicrafts ..."[19].

Hardly eighty years had passed between these two assertions. During these years that far-reaching process of new orientation took place in chemistry, which first created the conditions necessary for its subsequent development as an autonomous academic discipline and for that change of paradigms, which we call the Chemical Revolution.

Liquid Crystals: A Tool for Studies on Chirality

By Guy Solladié* and Richard G. Zimmermann

Nematic liquid crystals are extremely sensitive to optically active molecules, which, at very low concentration, convert them into cholesteric liquid crystals. The purpose of this report is to review recent applications of liquid crystals to chirality studies. A brief discussion of the structure and properties of liquid crystals is followed by a survey of the methods currently being employed for the determination of the pitch and handedness of cholesteric liquid crystals. Of special interest in the formation of induced-cholesteric phases are the twisting powers of optically active compounds and the structural relationships between dopants and nematics. Liquid crystals can be used, inter alia, for the detection of small optical activities and for the determination of thermal racemization barriers and absolute configurations.

1. Introduction

In 1888, while working with cholesteryl benzoate, the Austrian botanist *Reinitzer*[1] discovered a novel state of matter which was later to be termed cholesteric liquid crystal. Actually, *Reinitzer* gave a detailed description of the "two melting points" of this substance[2]. He found that the substance melts at 145.5 °C to give a cloudy but fully liquid melt, which at 178.5 °C suddenly becomes completely clear. On cooling the melt, he observed a violet-blue coloration which quickly disappeared, leaving the substance cloudy but still liquid. On further cooling, the violet-blue coloration reappeared and immediately afterwards the substance solidified to a white crystalline mass. *Reinitzer* sent the specimen to *Lehmann* at Karlsruhe, who initiated a systematic study of this and related phenomena. *Lehmann* coined the term "liquid crystal" and wrote the first monograph on this new topic of interest[3a]. In 1922, *Friedel* published an outstanding paper on the same topic[4] and coined the terms "mesophase", "nematic", and "smectic" phase. The first fully synthetic "liquid crystal", *p*-azoxyanisole (4,4'-dimethoxyazoxybenzene) **2** was prepared by *Gattermann* et al.[3b]. *Vorländer*[3c] was probably the next, and, for a long time, the only person who studied this topic in the organic chemistry sector.

Although liquid crystals have been known for a century or more, it is only in the past 20 years that their unusual properties, especially the color changes that they can undergo, have found widespread application. Liquid crystals have become indispensable for the manufacture of many electrically controlled display devices. Thus, they are the essential material in numerical displays on wrist-watches, pocket calculators, thermometers, and many other electrical and electronic devices. They are also of importance in the development of flat television screens, displays for portable instruments incorporating microprocessors, and in the manufacture of fibers (using macromolecular liquid crystals).

For chemists and physicists studying the theory of matter, liquid crystals are of great interest because of their uniqueness, their not being true solids nor true liquids. However, in this review we will only be concerned with the application of liquid crystals to studies on chirality, a topic which has not been dealt with in detail in monographs[5] or reviews[6] on liquid crystals.

The liquid crystalline or mesomorphic state is intermediate between that of the solid and the liquid state, the associated order being less than that in solids but more than that in liquids. Although liquid crystals exhibit certain aspects of both the solid and liquid states, they also possess properties that are not found in either liquids or solids. Their ordering properties, for example, can be controlled by ordinary magnetic and/or electric fields. In some liquid crystals the optical activity is of an order of magnitude not met with in any solid, liquid or gas. Some liquid crystals change color as a result of the sensitivity of their structure to temperature. These are the properties on which the practical applications of liquid crystals are based. Basically, there are three types of liquid crystals (Fig. 1). Following a proposal by *Friedel*[4], they are designated as smectic, nematic, and cholesteric. Smectic phases have a two-dimensional structure characterized by the packing of molecules in strata or layers. The arrangement of the molecules within the layers may be either random or ordered, in either case the long axes of the molecules in a given layer are parallel to one another. There is a multiplicity of smectic modifications which correspond to various tilted or twisted arrangements of the molecules, including one which has a three-dimensional lattice structure. The physical appearance of the smectic state is that of a highly viscous, turbid fluid.

In the nematic phase the molecules are still oriented in a parallel fashion; however, the layer arrangement no longer exists. The resulting one-dimensional order is therefore less than that in the smectic phase. The nematic phase is turbid but much less viscous than the smectic phase.

The cholesteric phase occurs only in optically active compounds; it corresponds to a twisted nematic, i.e. it has a helical structure. In cholesteric phases there is a local nematic packing of the molecules. The director, however, is

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/0505-0348 $ 02.50/0

not fixed; it rotates spatially about an axis perpendicular to itself, conferring a helical structure on the system (Fig. 2).

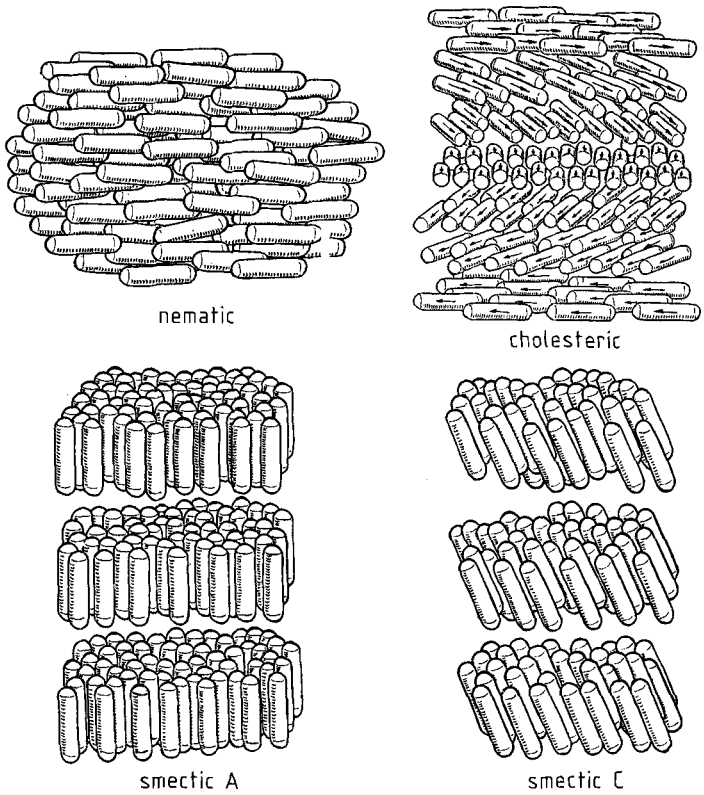

Fig. 1. Arrangement of molecules in thermotropic liquid crystals (see also Table 1).

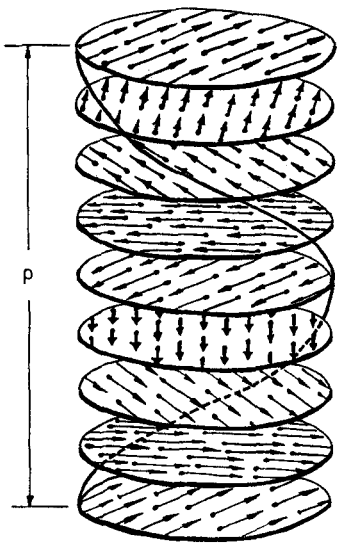

Fig. 2. The cholesteric helical structure. p is the pitch of the helix. The arrows indicate the long axes (or directors of the molecules). The figure shows a left-handed helix (M-helix).

The pitch p of the helix—the thickness corresponding to a 360° rotation of the director of the molecules—is typically of the order of 0.2—2.0 μm. Twisted smectic phases can also be obtained from optically active molecules. The characteristic iridescent color of the cholesteric phase results from the selective reflection of one circularly polarized component of light, as explained by the *De Vries* theory[22]. The behavior of incident light that is plane polarized will change as its wavelength increases. For wavelengths much shorter than the pitch of the helix, the combined wave remains linearly polarized but the direction of polarization is rotated by the spatial rotation of the helix. The molar rotatory power is extremely high; it can exceed 50000. As the wavelength is increased to a value nearly equal to the pitch, the clockwise circularly polarized light is increasingly reflected in the case of a right-handed cholesteric, the reflectivity reaching 100% when the wavelength is about equal to the pitch. In this region, the transmitted wave for a right-handed cholesteric is then solely anticlockwise circularly polarized. Since the width of this region with 100% reflectivity is quite narrow the reflected color appears very pure. For wavelengths longer than the pitch, the reflectivity decreases. Similar color effects seen

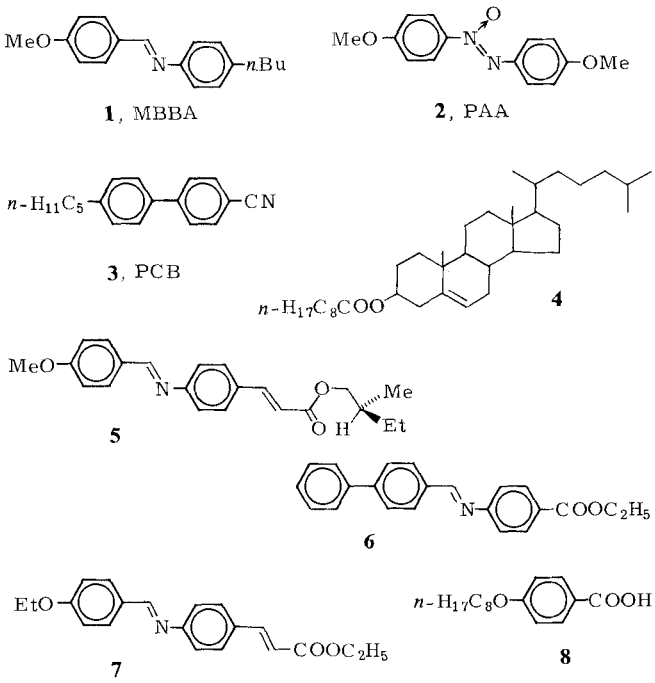

Table 1. Examples of thermotropic liquid crystals [5 h, 7] (cf. Fig. 1).

Compound	Liquid crystalline range [°C]	Liquid crystalline phase [a]
1 4-Butyl-*N*-(4-methoxybenzylidene)aniline (4-Methoxybenzylidene-4′-butylaniline, MBBA)	21–47	nematic
2 4,4′-Dimethoxyazoxybenzene (*p*-Azoxyanisole, PAA)	118.2–135.3	nematic
3 4′-Pentyl-4-biphenylcarbonitrile (4-Pentyl-4′-cyanobiphenyl, PCB)	22.5–35.5	nematic
4 Cholesteryl nonanoate	147–179	cholesteric
5 (−)-(2-Methylbutyl) 4-(4-methoxybenzylideneamino)cinnamate	76–125	cholesteric
6 Ethyl 4-(4-biphenylmethyleneamino)-benzoate	121–131	smectic A
7 Ethyl 4-(4-ethoxybenzylideneamino)cinnamate	77–116	smectic B
8 4-Octylbenzoic acid	108–147	smectic C

[a] Smectic A, B, and C: long axes of the molecules orthogonal (A, B) and tilted (C) to the layer planes, random arrangement (A, C) and hexagonal arrangement (B) within the layers.

in nature, on some beetles wings for instance, are due to the same phenomenon. Temperature, pressure, electric fields, magnetic fields, traces of impurities, and other effects influence the pitch of the helix and thus lead to different changes in color[5e]. Some examples of thermotropic liquid crystals are listed in Table 1.

The identification of mesophases, i.e. the phases of liquid crystals, involves observation of the melting process under a polarizing microscope and the identification of the various birefringent textures that are associated with the respective mesophases[5b]. The simplest texture is one in which the whole liquid crystal appears optically uniform. Nematics can be aligned in parallel by treating the microscope slide with polyvinyl alcohol[5g] or an organosilane[5f] and rubbing in one direction. The molecules tend to align themselves with their long axes in the direction they are rubbed. Helices in cholesteric phases can, in this way, be uniformly aligned with their axes perpendicular to the surface of the slide (planar texture). The color of this structure is caused by Bragg-like reflections associated with the periodicity of the cholesteric helix and can be observed without polarizers. Treatment of the slide with a surfactant such as *N*-cetyltrimethylammonium bromide, on the other hand, will cause perpendicular alignment of the molecules. Nematic liquid crystals not uniformly aligned will appear turbid.

A further method resorted to for the identification of such phases is that of differential thermal analysis, by means of which transition temperatures and specific heats can be determined.

2. Cholesteric Liquid Crystals: Pitch and Handedness

To fully characterize a cholesteric liquid crystal, the pitch and handedness of the helix have to be determined.

In 1922, *Friedel*[4] identified the cholesteric handedness from the sign of the reflected circularly polarized light—a difficult measurement with cholesterics having a large pitch. Later, in 1966, *Fergason*[8], using the helical model for cholesterics proposed by *Oseen*[10] and *De Vries*[22] from the experimental observations of *Mathieu*[9], established that a cholesteric liquid crystal, characterized by the helix pitch p, can reflect light of wavelength λ_0 directly proportional to the pitch:

$$\lambda_0 = \bar{n} \cdot p$$

where $\bar{n}$ is the mean refractive index. This equation holds if a parallel light beam propagating parallel to the helix axis is used for the measurement. The latter condition is easily fulfilled with a cholesteric phase displaying the planar texture (helix axis perpendicular to the object slide). Several papers[11-14] reported pitch determinations by this method, i.e. measurement of the reflection wavelength.

Baessler and *Labes*[15] proposed measurement of the transmitted light instead of the reflected light. This variant is especially valuable in the infrared region for large-pitch cholesterics (0.5 to 5 μm), where reflectance measurements are difficult.

Chiroptical techniques have also been used for pitch determinations. For small-pitch cholesterics, *Stegemeyer* et al.[16-20] determined the reflection wavelength by following the change in optical rotation with wavelength (optical rotatory dispersion, ORD) according to the theoretical predictions of *de Vries*[22].

For induced cholesterics, with pitches of about 10^{-1} to 10^{-2} μm, *Schrader* et al.[23,24] proposed that the infrared rotatory dispersion (IRD) should be investigated, because the reflection band in these cases lies in the infrared region: a positive reflection Cotton effect indicates a left-handed helical structure and vice versa.

Finally *Saeva* et al.[25-27] found that achiral molecules (such as MBBA **1**, naphthalene, or pyrene) dissolved in a cholesteric phase could display induced circular dichroism (ICD) corresponding to their own absorption bands, independently of the CD corresponding to the pitch band (reflection band) of the cholesteric. However, the sign of the liquid crystal-induced circular dichroism (LCICD) was observed to be dependent on the position of the cholesteric pitch band (λ_0) relative to the wavelength of absorption[27]. For induced cholesterics having the pitch band in the infrared, the signs of ICD and pitch CD are always opposite, but are both dependent on the handedness of the helix: a positive ICD band corresponds to a right-handed helix.

For all these spectroscopic measurements, the liquid crystal must be oriented in a planar alignment (axis of helix perpendicular to the slide) and thermostated cells must be used because of the extreme sensitivity of the pitch to temperature.

The other techniques used for determining the pitch and handedness of cholesteric phases involve observations with a polarizing microscope. They are, on the whole simple techniques and require the use of only very small amounts of material.

Some of these methods are variants of the Grandjean-Cano method[28,29], which is based on the observation of the disclination lines occurring in a wedge-shaped cholesteric sample under homogeneous planar boundary conditions. A very simple cell for this determination was recently described by *Berthault, Billard,* and *Jacques*[30]. When a thin layer of a cholesteric liquid crystal oriented in a planar alignment (helical axis perpendicular to the slide) in a cell of variable thickness is observed with a polarizing microscope, dark lines (the Grandjean-Cano steps) and bight lines appear which follow the lines of equal thickness. The distance between two consecutive Grandjean-Cano steps is equal to half of the pitch. If on using monochromatic plane polarized light (wavelength higher than the reflection wavelength) and on rotating the analyzer clockwise the extinction zone is displayed towards the large-thickness area, the helix is right-handed. This method was also recently described by *Gerber*[30c].

Heppke and *Oestreicher*[31,32] modified the method by using a spherical lens of the cholesteric liquid crystal on a glass slide. The spherical lens is first treated to provide a concentric planar surface alignment. Under such conditions the Grandjean-Cano (disclination) lines are spiral, and the sense of the helix screw can immediately be obtained from their handedness. The magnitude of the pitch

is obtained, as in the conventional Cano method, from the radial distance between two consecutive lines[33].

The droplet method[33] is also a very simple technique for determining the pitch. An emulsion of a small amount of a cholesteric liquid crystal in a solvent such as glycerol is prepared and the droplets of the cholesteric phase floating in the isotropic solvent are then observed under the microscope with polarized light. A spiral shaped optical pattern with a radial disclination is observed in each droplet (Fig. 3). The spiral shape is due to the boundary conditions at the surface of the droplet[34]. The optical pattern is actually either a spiral or a series of concentric rings, depending on whether the radial disclination lies in the direction of observation or in a plane perpendicular to it. Usually, both patterns are observed. It was **shown**[33] that the distance between two spirals is equal to half the pitch.

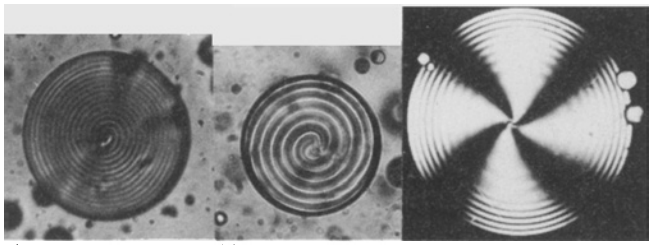

Fig. 3. The droplet method. Droplets of a solution of the diazocine **21** in the liquid crystal Licristal Merck IX. The droplets form an emulsion with glycerol and are observed under crossed nicols. a) Optically pure **21**, b) partially racemized **21**, c) racemic **21**. Licristal Merck IX consists of a mixture of aromatic esters.

Determination of the handedness of the helix by the droplet **method**[35] is based on the finding that a mixture of two cholesterics of opposite handedness and equal pitch gives a compensated nematic and that a nematic droplet displays a characteristic optical pattern[33]: with crossed nicols, a series of concentric rings and an extinction cross are observed, the latter of which rotates when rotating the polarizer and analyzer together (Fig. 3). This cross corresponds to the points on the surface of the droplet where the optical axis is parallel to either the analyzer or the polarizer. However, two reference cholesterics of opposite handedness are needed for this determination[35].

Another way of determining the pitch handedness is by the contact method, which is also based on a comparison with cholesteric phases of known helical sense[36–38]. When the interface of two cholesterics having the same helical sense is observed microscopically, no discontinuity in the texture is visible, i.e. a continuous cholesteric texture is observed from left to right across the field of view. However, when the helical twists are of opposite sense, a narrow band of nematic texture separating two cholesteric regions is observed.

Finally, magnetic resonance techniques can be applied to liquid crystals[39]. As *Gottarelli, Pedulli,* and *Zannoni*[40] have recently shown, EPR spectroscopy enables a rapid and reliable determination of both the pitch and the handedness of induced cholesteric mesophases. The spin probe used was 2,2,6,6-tetramethyl-4-piperidone *N*-oxide.

3. Twisted Nematic Phases: Induction of Cholesteric Phases by Addition of Chiral Compounds to Nematic Phases

More than 60 years ago, *Friedel*[4] described the close relationship between nematic and cholesteric liquid crystals: a small amount of a chiral compound, cholesteryl benzoate, dissolved in a nematic phase induces a cholesteric. The next paper on this topic appeared almost 50 years later, in 1969. *Buckingham* et al.[41] pointed out that a continuous change of a nematic phase to a cholesteric mesophase may be achieved by adding small amounts of optically active molecules, such as D-tartaric acid, which do not in themselves form a mesophase.

Following publication of *Buckingham*'s paper, numerous articles on induced cholesterics appeared in the literature. Two different approaches were developed simultaneously: *Baessler* and *Labes*[42] employed chiral compounds which themselves form cholesteric liquid crystals, while *Stegemeyer* et al.[16] directed their attention to chiral compounds which in themselves do not form liquid crystals.

In 1971, *Goosens*[21] published a molecular statistical theory of the cholesteric phase and of the twisting power of optically active molecules in a nematic liquid crystal. This theory of cholesteric liquid crystals is still of considerable importance (cf. [20d, 48]).

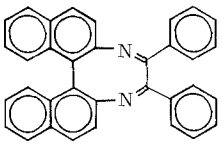
Baessler and *Labes*[42] used a compensated nematic liquid crystal, i.e. a mixture of two cholesteric liquid crystals of opposite handedness (cholesteryl chloride (CC), a right-handed cholesteric, and cholesteryl myristate (CM), a left-handed cholesteric). The extreme sensitivity of the pitch to temperature allowed exact compensation[43, 44], i.e. a nematic phase to be obtained, by a small change in temperature.

Sackmann et al.[43] and *Baessler* and *Labes* et al.[44] were the first to study the helical twisting power β, i.e. the ability of chiral compounds to convert nematic liquid crystals into cholesteric phases, using as example several steroids in the nematic liquid crystal of CC and CM. They showed that the concentration of optically active solute is inversely proportional to the pitch of the helix. For a series of fatty acid esters of cholesterol, the twisting power decreases with decreasing number of carbon atoms in the acyl group. However the helix of the induced cholesteric changes rotational sense if the acyloxy group is replaced by Cl, Br or OH[45]. This finding shows that the *induced helical sense is not only dependent on the chirality of the molecule but, for the same absolute configuration, also on the nature of the substituents.* The first model to explain the mechanism of the twist was proposed by *Baessler, Laronge,* and *Labes*[44]; they considered the side chain at the 3β-position of the steroid ring to be the important factor at the origin of the twist. Similar results were obtained with alkylcholesteryl carbonates[46]. The helical twisting power rapidly reaches saturation with increasing chain length, in accord with the model attributing this twist to the effective length of the alkyl chain.

Nakagiri[47] investigated the pitch in mixtures of nematic and cholesteric material (4-(4-methoxybenzylideneamino)phenylacetate and cholesteryl propionate) as a function

of the concentration of the cholesteric material. He found that the pitch of the helix is inversely proportional to the molar fraction of the cholesteric material only at low concentration. This finding was confirmed for a wide variety of components by *Stegemeyer* et al.[20a] and by *Dekker* et al.[49]. The dependence of the helical twisting power on the molar fraction x of the optically active doping molecule in cholesteric liquid crystals can be considered as linear only at low concentrations.

We now come to the twisting powers of optically active compounds which do not form liquid crystals. The first report in this direction was that published by *Stegemeyer* et al.[16,19], who found that the nematic phase of MBBA **1** is converted into a cholesteric phase by (−)-menthol. He and his co-workers[17,18] also showed that a chiral compound without any asymmetric carbon atom, e.g. diazocine **9**, is also able to transform the nematic MBBA into a cholesteric phase. Both enantiomers of **9** gave cholesteric phases having opposite handedness; the observed pitch was much larger than that in (−)-menthol.



9, DDCO

After this paper, a more quantitative study of the twisting powers of optically active compounds was started by several groups in order to obtain more information about the factors controlling nematic twists. Induced cholesteric phases are characterized by the presence of chiral guest molecules in a nematic host phase. The mole fraction of the chiral component has to be small (< 10 mol-%) in order to get a linear variation of the helix pitch with the concentration. Under such conditions the helical twisting power β_M is defined as:

$$1/p = \beta_M \cdot c$$

The helix pitch p is inversely proportional to the molar concentration c of the solute.

At such low concentrations the chiral molecules are isolated in a matrix of non-chiral nematic molecules. Consequently the helical structure will be induced only by interaction of the chiral molecules with the solvent molecules.

Finkelmann and *Stegemeyer*[20c] studied the helical twisting power as a function of the "chiral character" of the guest molecules. They determined pitches p by the Grandjean-Cano method and β_M from the slopes of the plots $1/p$ vs molar fraction x (in mol-%). The results are listed in Table 2.

From the data given in Table 2 it can be concluded that:

- The strongest twist is induced by the inherently dissymmetric molecule **9** (DDCO) (pitch $p = 1.5$ μm, $x = 0.02$), the weakest by verbenone **10** ($p = 132$ μm, $x = 0.065$).
- Cholesterol derivatives and chiral nematics show higher twisting powers than small molecules with asymmetric carbon atoms.
