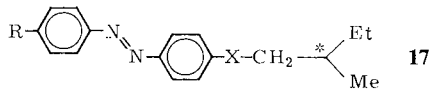
- Helical structures of cholesteric systems built up by esters of cholesterol are much more twisted than can be achieved by chiral molecule-host interactions (pitch $p \approx 0.2$ μm).
- The influence of nematic host phases on the induction of the helical structure is rather small and increases

along the series EBPA < EBBA < MBBA. However, these host phases are quite similar.

The "chirality character" of the guest molecule is not simply related to its optical rotation. **9** (DDCO) has undoubtedly the highest rotation ($[\alpha]_D$ +2000) and also the highest twisting power, but the β_M value of carvone **11** exceeds that of verbenone **10** by a factor of 20, while the optical rotation of verbenone ($[\alpha]_D$ +237) is higher than that of carvone ($[\alpha]_D$ +62.2). Geometrical factors probably also play a role.

Nematic azobenzene derivatives of type **17** with asymmetric side chains have been systematically investigated[51] in order to establish the influence of the structure on the pitch and handedness of the helix. Some of the results are listed in Table 3.



17

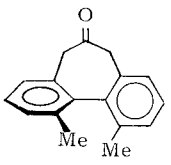
[a] The twisting powers $\beta = 1/(0.2p)$ relate to concentrations in g/100 g and not in mol/L. A positive sign refers to a right-handed helix and vice versa. The pitches were determined by the Grandjean-Cano method and the helical sense from the sign of the optical rotation in the visible region.

Noteworthy in Table 3 is that:

In the upper part of the table, the pitches increase gradually with the chain length, as observed with cholesteryl esters[42,45,46] in compensated nematic and in optically active naphthoxyalkanoic acids in tolans and aromatic esters[30].

In the lower part of the table, the handedness of the helix changes when a 2-methylbutyl side chain is replaced by a 2-methylbutoxy side chain or both side chains are replaced by an ethoxy and a 3-methylpentyl side chain. This implies that the helical sense depends on the number of atoms in the side chain and not only on the chirality, a fact which has been confirmed by *Gray* et al.[38] with non-steroid cholesteric liquid crystals.

We have investigated more closely the influence of the structure of nematic liquid crystals on the twisting power of optically active compounds[52]. The pitches were determined by the droplet method. Table 4 lists the twisting powers of the optically active ketone **18** in several nematic phases. The results suggest that there is a close relationship between the host compound and the optically active guest compound. *Twisting powers are higher when the chiral molecule has a structure similar to the nematic:* A chiral bridged biphenyl such as **18** has a stronger twisting power in a biphenyl-like nematic phase such as PCB. As follows from Table 2, molecules having only one asymmetric carbon atom show high β_M values when they exhibit a close structural similarity with MBBA **1**; this is true for PAC **14**, MBAC **13**, and α-phenylethylamine (after amine-exchange reaction with the solvent).



18

Table 4. Twisting powers β of 4,5-dimethyl-9,11-dihydrodibenzo[*a*,*c*]cycloheptan-10-one **18** in nematic liquid crystals [52]. **18**: $[\alpha]_D^{20}$ +617. We also investigated the twisting powers of the optically active diazocines **19** to **23** in MBBA **1**[53]. Table 5 lists the results, including our values for (−)-menthol and cholesteryl propionate (CP), which are in good agreement with the values reported by *Stegemeyer* et al.[20c] (Table 2).

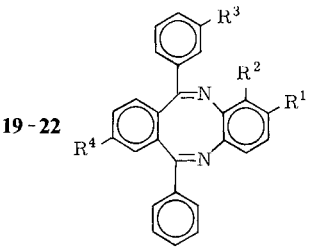
Table 5 shows that diazocines have very strong twisting powers in MBBA and that the location of the aldehyde



19-22

function, which is at the origin of the molecular dissymmetry, is very important: R^3 appears to have the greatest influence. In addition, it is shown that the twisting power of diazocine **22** in PBC **3** is only half that in MBBA **1**, whereas with the biphenyl ketone **18** the opposite is the case.

These findings emphasize once again that a close structural analogy between the chiral guest and the nematic host is necessary to achieve a large twist, probably because of a better intermolecular arrangement and therefore a better chirality transfer. Figure 4 shows the structural similarity between diazocines and MBBA, which is due to the tub-like conformation of the eight-membered heterocycle.

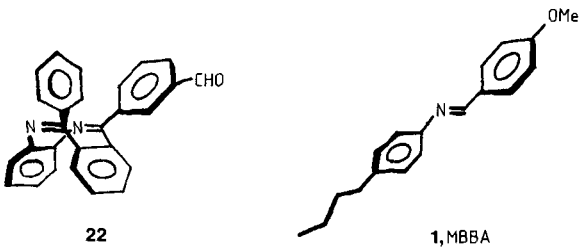

Fig. 4. Structural analogy between diazocines such as **22** and MBBA **1**.

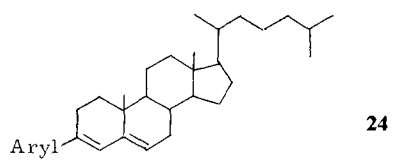
The twisting powers of stereoidal molecules are also strongly dependent on the structure of the nematic host[54].

If we compare our results with those obtained in a compensated nematic phase (mixture of cholesteryl chloride and cholesteryl myristate)[42,45,46], it is evident that cholesterol esters in PCB **3** do not show any significant variation in β_M values with the chain length ($\beta_M = -9.1$ to -9.7 μm^{-1} (mol-%)$^{-1}$, but certainly do so in steroidal nematics ($\beta_M = +2$ to -7.5). These twisting powers are even higher in other nematics[35]: for cholesteryl myristate, $\beta_M = -25.2$ in MBBA **1** and -16.7 in MBAB (4-butyl-4′-methoxyazoxybenzene).

Finally, substituted cholestadienes **24** with various aryl groups on C-3 showed an interesting change in helix handedness in aromatic nematic phases[54] (Table 6).

While all the cholesterol esters displayed left-handed helices in these aromatic nematic phases, we observed right-handed twists with 3-arylcholestadienes when there was no *o*-substituent on the aromatic ring. Therefore the coplanarity of the aromatic ring and the double bonds in the steroid moiety, in other words the *conformation of the molecule, also appears to be an important factor.*



24

Table 6. Twisting powers β_M of 3-arylcholestadienes **24** in aromatic nematic phases [54]. MBAB = 4-butyl-4′-methoxyazoxybenzene.

Aryl	β_M [μm^{-1} mol^{-1}]		
	PCB **3**	MBBA **1**	MBAB
2-Me–C_6H_4	−3.2	− 1.7	−2.7
4-Me–C_6H_4	+6.8	+12	+5.1
4-MeO–C_6H_4	+8.1	+15.6	+2.7
4-Ph–C_6H_4	+8.2	+ 7	+3.1

In summary it emerges that:

- A small amount of an optically active molecule will twist any nematic liquid crystal to a cholesteric phase.
- Two enantiomers will twist a nematic phase to cholesterics of opposite handedness.
- The resulting pitch is inversely proportional to the concentration of the optically active compound and to its optical purity (at least at low concentrations).
- The magnitude and sign of the twisting power of an optically active molecule in a nematic result from solute-solvent interactions.

Therefore, aside from geometrical factors, structural analogies between solute and solvent, and conformational factors, the type of chirality involved is very important. As shown by *Jacques* et al.[30b,55], globular molecules such as camphor and verbenone or small molecules having only one asymmetric carbon atom[49,56,57] will generally show very low twisting powers. However, derivatives of such compounds having a similar structure to the nematic will display higher twisting powers[56]. Inherently asymmetric or dissymmetric molecules, such as biphenyl and diazocine derivatives, will show high twisting powers if a suitable nematic is used and if geometrical factors are compatible (β-values of spiro compounds were found to be very low[58]). The sense of twist does not only depend on the absolute configuration of the molecule. In a given series of molecules having the same chirality, the handedness of the twist can be modified by geometrical factors, by conformational factors, or by using another type of nematic phase.

4. Applications of Liquid Crystals to Studies on Chirality

The extreme sensitivity of nematic liquid crystals to optically active compounds enabled stereochemical information to be obtained by generation of induced-cholesteric liquid crystals.

4.1. Detection of Very Small Optical Activities

A cholesteric liquid crystal is characterized by a very high macrostructural chirality. Therefore optical activity which is not detectable by polarimetric methods, owing to the small quantity of material available and/or very low rotatory power, can be amplified by the phenomenon of induction of a cholesteric mesophase. The induced-cholesteric can then be easily identified even in the case of large pitch by the Grandjean-Cano method, by the droplet method, by IRD (infrared dispersion), or even by measuring the rotatory power on a microscope[59].

This approach was already used in 1968 by *Jacques* et al.[55] to follow spontaneous resolution of conglomerates.

Korte[60a] showed that induced cholesteric could be used to detect the optical activity of 3 μg of tyrosine methyl es-

ter by IRD. He also showed that 70 μg of optically active cyclophosphamide, an anticancer drug, could easily be detected by IRD of a solution in 4-butyl-4′-methoxyazoxybenzene. This finding made the study of the metabolism of cyclophosphamide easier. A polarimetric study would have necessitated a total 24h sample of urine from the patient, which is about 100 times more than that required by the liquid crystal technique. A similar method was recently proposed by *Gottarelli* et al.[60b] for the determination of traces of heroin.

Gottarelli et al.[61] used induced cholesterics to characterize chiral compounds obtained by deuterium substitution. Such species generally exhibit a very low optical rotation. The twisting powers of these chiral deuterated compounds were small (Table 7)—about two orders of magnitude smaller than those observed with chiral secondary alcohols—but pitch and handedness in the helices of the corresponding induced-cholesterics could be determined by the Grandjean-Cano method.

25   *ent*-**25**

Table 7. Twisting powers β_M of chiral deuterated compounds of type **25** and *ent*-**25** in a 1:1 mixture of MBBA **1** and EBBA **15**.

R	R′	β_M [μm^{-1} mol^{-1}]	
		25	*ent*-**25**
Ph	$OCOC_6H_4NO_2$-*p*	+0.093	−0.096
$PhCH_2CH_2$	OH	+0.079	−0.075
Ph	$CH_2NMeCOPh$	−0.113	+0.109

Both enantiomers always gave β_M values of opposite sign. The twist handedness changes, in spite of the same absolute configuration.—The method requires only two drops of liquid crystal and a very small amount of chiral compound.

4.2. Determination of Thermal Racemization Barriers

The pitch of induced cholesterics is inversely proportional to the concentration of the optically active solute and its enantiomeric purity r[71]:

$$1/p = \beta_M r c$$

Consequently, it should be possible to follow the kinetics[62a] of thermal racemization of optically active compounds by merely measuring the variation in pitch of a cholesteric mesophase, prepared by doping a nematic with the thermally racemizing optically pure compound, as a function of time. The higher the twisting power of the solute, the smaller the quantity of material necessary for the study. The host phases must be nematic at room temperature and stable at the racemization temperature, since the racemization occurs in the isotropic phases.

We first studied the racemization of diazocine **21** brought about by inversion of the eight-membered heterocycle[62b]. The pitch, as determined by the droplet method, typically varies during the racemization between 5 μm and 50 μm. The nematic used was a mixture of aromatic esters (Licristal Merck IX, nematic between −20 and +60 °C). The racemization, a first-order reaction, follows the relation

$$\ln(1/p) = -2kt + \ln(1/p_0)$$

where p_0 is the pitch in the starting material. The free enthalpy of activation for the racemization $\Delta G^{\neq}$ is 39 ± 1 kcal/mol at 188 °C, a value consistent with the barrier determined by NMR spectroscopy[63].

This method of determining thermal racemization barriers has two main advantages:

- Only extremely small quantities of optically active material are needed (less than 10 mg).
- The determination of rate constants from pitch variations is very accurate. The pitches are determined by the droplet method. It is not necessary to weigh exact quantities of material (the main source of error in the polarimetric method).

Recent results which we obtained on optically active atropisomers are collected in Table 8. They illustrate the wide range of temperature which can be used.

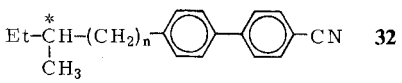
4.3. Determination of the Absolute Configurations

Addition of enantiomers to nematic liquid crystals produces cholesteric phases of opposite handedness. It has been known for some time[42] that cholesterol esters give left-handed, while cholesteryl chloride gives right-handed

cholesterics. More recently *Gray* and *McDonnell*[38] reported that in the case of optically active biphenyl liquid crystals having one chiral center in the side chain, the helical handedness cannot be simply correlated with the absolute configuration of the chiral center. (*S*)-**32**, with an even number of carbon atoms between the asymmetric center and the benzene ring gave a right-handed helix, whereas with an odd number of carbon atoms, a left-handed helix was formed. (This is also the case when some of the CH_2-groups are replaced by oxygen atoms.) We also found[54] that opposite twist can be obtained from the same enantiomer in different nematics, probably through conformation effects due to the substituents.



32

Therefore, the use of liquid crystals for the determination of the absolute configuration of optically active solute from the handedness of the resulting cholesteric helix requires a far better knowledge of the mechanism of the twist of nematics by chiral molecules. *Saeva*[69] was actually the first to recognize this. He added the compounds (*S*)-**33**, (*S*)-**34**, (*R*)-**35**, and (*S*)-**36**, which contain one simple chiral center of known configuration, to the nematic mesophases MBBA **1** and BPC [butyl-[4-(4-ethoxyphenoxycarbonyl)phenyl] carbonate]. The chirality of the resulting cholesteric mesophase was determined by LCICD[25-27] (Table 9).

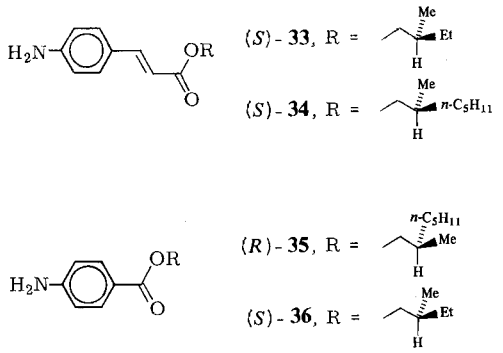


Table 9. Chirality of cholesteric mesophases produced from the nematic phases MBBA 1 or BCP and chiral compounds [69]. BCP is butyl [4-(4-ethoxyphenoxycarbonyl)phenyl] carbonate.

Chiral compound	Helical sense of the induced cholesteric phase
(*S*)-**33**	right-handed
(*S*)-**34**	left-handed
(*R*)-**35**	right-handed
(*S*)-**36**	right-handed

The 2-methylbutyl group in the aminocinnamate (*S*)-**33** and in the aminobenzoate (*S*)-**36** induces a right-handed helix, both in MBBA and in BPC. However, on going from (*S*)-2-methylbutyl to (*S*)-2-octyl aminocinnamate (*S*)-**34**, cholesteric mesophases of opposite handedness are produced. From these results, *Saeva* concluded that different diastereoisomeric interactions in the nematic-solute complex lead to an energy difference in the helical structures and, thus, to a preference of one helical sense over the other. Prediction of the helical sense of the induced cholesteric mesophases requires detailed energy calculations for the guest-host complex. However, enantiomers always appear to generate cholesteric mesophases with different helical sense.

For these reasons, many exceptions can be found to the correlation proposed by *Schrader* et al.[70-72]. These authors investigated over one hundred compounds having only one chirality center in an equimolecular mixture of MBBA **1**-EBBA **15** or in 4-butyl-4′-methoxyazoxybenzene (Licristal Merck IV). The induced cholesteric handedness was determined from the reflection Cotton effect in the IR region[24] (IRD). *Schrader* et al. proposed characterization of the absolute configuration of these chiral molecules by a sequence of ligand parameters in analogy to the Cahn-Ingold-Prelog nomenclature, but based on the "effective volumes" of the substituents of the asymmetric carbon atom, and to correlate this nomenclature to the sign of the Cotton effect observed in the IR region. Although this correlation is suitable for a larger number of molecules, it doesn't explain the observations of *Saeva*[69] (Table 9), some of the results of *Tsukamoto* et al.[51] (Table 3), the results obtained on compounds having several chiral centers, the dependence of the twist sense on the structure of the nematic phase, and the effect of the length of side chain observed by *Gray*[38].

As pointed out by *Gottarelli* et al.[73], the effective volume approach is an oversimplification which can at best only function within a single series of compounds or a favorable set of molecules. These authors studied numerous optically active sulfoxides. To explain the observed twist sense, the effective volume rule requires one to consider that the ethyl group is smaller than phenyl in 4-butyl-4′-methoxyazoxybenzene but larger in MBBA **1**. The benzyl group must also be considered as being smaller than all other groups, methyl included. The authors therefore concluded that the sequence of effective volumes does not agree with the observed twist sense, at least for a whole set of sulfoxides.

In order to obtain a correlation, additional experimental information about the specific interactions of the solute with the liquid crystal and the orientational properties of the solute is necessary. *Gottarelli* et al.[74] were the first to determine the twisting powers of a set of alcohols and amino alcohols of known absolute configuration in MBBA **1**; the chirality of the resulting cholesterics was determined by CD at the band edge of the MBBA absorption (the reflection band lay in the IR).

As shown in Table 10, for the aromatic compounds **37** to **45** there is indeed a correlation between the chirality of the induced helix and that of the inducing compound: for all the compounds having the same absolute configuration the sign of the CD band is the same. Even **41** and **42** fit in the scheme if the nitrogen atom is not taken into consideration; (*R*)-**41** and (*S*)-**42** would then be present. However, the correlation seems to be more complicated in the case of aliphatic molecules.

However, *Gottarelli, Samori,* and *Stremmenos*[75] obtained some additional information about the solute orien-

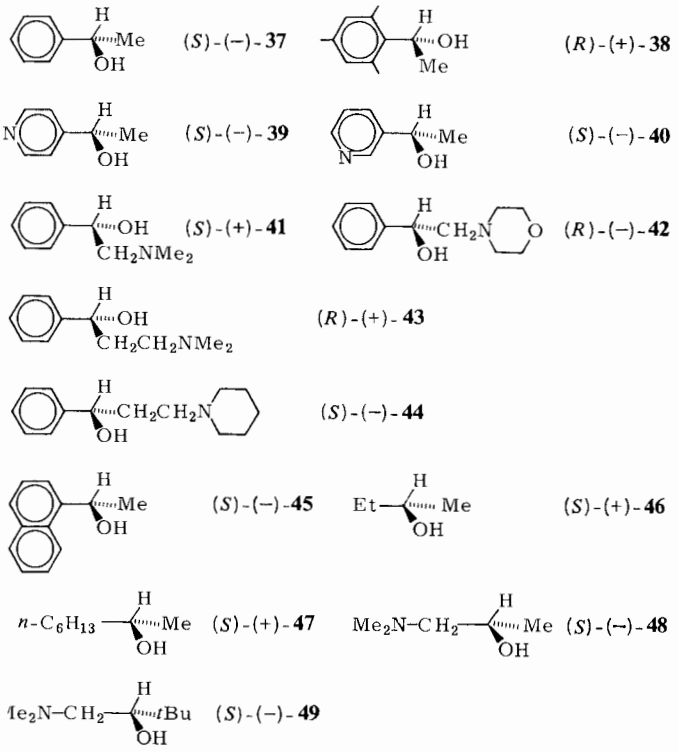

Table 10. CD-signs of cholesteric mesophases produced from MBBA **1** and chiral alcohols and amino alcohols [74].

tation in the liquid crystal phase. From the IR spectra of α-phenylethanol in MBBA **1**, they demonstrated that the hydroxy group was hydrogen bonded to the nitrogen in MBBA—a result which is at the origin of a possible explanation of why (*S*)-(−)-α-phenylethanol induces a right-handed helix in MBBA. In the model by *Gottarelli* et al. (Fig. 5), the phenyl group of α-phenylethanol is in a preferred conformation and superimposed onto a phenyl ring of MBBA. The bulkiness of the methyl group, which in the two possible stackings of α-phenylethanol and MBBA lies farther from the centroid of the MBBA molecule and therefore causes less steric interactions with MBBA, prevents parallel covering of a second molecule of MBBA; thus a right-handed helix is formed with (*S*)-α-phenylethanol.

To form an ideal helix, one molecule of MBBA should interact with one molecule of alcohol. Therefore, at the very low concentrations used there must be a twisted area around the dopant molecules as well as undisturbed zones. Such a model is consistent with the inverse dependence of the pitch with concentration[76].

This model is valid for many aromatic alcohols or *N,N*-disubstituted amino alcohols[77], as shown in Table 11.

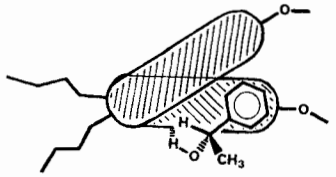

Fig. 5. Model for the interaction between (*S*)-α-phenylethanol and MBBA **1**. The central region of MBBA is represented by the dashed area. It forms a right-handed helix.

Only one exception has so far been reported: 2,2,2-trifluoro-1-phenylethanol. This compound has a very small twisting power, which (because of the presence of a phenyl group and a trifluoromethyl group on the asymmetric carbon atom) is probably due to competitive orientations of the solute in the nematic phase. When the phenyl ring is replaced by a naphthyl group, which will be much better aligned parallel to the nematic director, the twisting power is higher, and the twist sense is still in agreement with the model. The same effect was observed by *Pirkle* and *Rinaldi* with the 9-anthryl group[78]. However, these authors slightly modified the Gottarelli model to correlate the configuration of alcohols having a trifluoromethyl group in the absence of strongly orienting substituents such as naphthyl or anthryl. They proposed, in addition to the hydrogen bonding between the hydroxy group and the nitrogen lone-pair (an experimental fact), a bonding interaction of the α-hydrogen atom with one of the aromatic rings of MBBA. This double bonding interaction results in a conformation in which both the aryl and alkyl substituents are quasi-perpendicular to the long axis of MBBA. Such a conformation is certainly not favored in liquid crystals, the aromatic groups having the property to align in a liquid crystalline matrix with their long axes parallel to the nematic director[79].

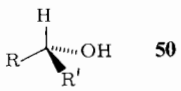

Table 11. Chirality of cholesteric mesophases produced from MBBA **1** and chiral arylmethanols **50** [77]. The helical sense of the induced cholesteric phase is given as "helicity" (*P* = right-handed, *M* = left-handed).

R	R′	Abs. config.	Induced helicity	β_M [μm^{-1} mol^{-1}]
Phenyl	CF_3	*S*	*P*	+0.2
	CH_3	*R*	*M*	−1.0
	Et	*R*	*M*	−1.3
	*i*Pr	*R*	*M*	−1.4
	*t*Bu	*R*	*M*	−1.5
1-Naphthyl	CH_3	*R*	*M*	−7.7
	CF_3	*S*	*M*	−8.5
2-Naphthyl	CF_3	*S*	*M*	−8.1

More recently, *Rinaldi* et al.[80] used MBBA **1** to correlate the absolute configurations of α-substituted benzylamines **51**. A number of years ago *Stegemeyer* et al.[20] and *Labes* et al.[50] pointed out that optically active α-phenylethylamine displayed very high twisting powers in MBBA because of a transamination reaction; hence, the sense of the induced helix in MBBA was brought about by interactions between MBBA and optically active Schiff-bases. *Ri-*

naldi et al. confirmed that synthetic Schiff bases **52** displayed a LCICD behavior in MBBA very similar to that observed with the corresponding amines **51** in MBBA. Therefore, the correlation of the absolute configurations (Table 12) must be described in terms of an interaction model very similar to the one proposed by *Gottarelli* for benzylic alcohols.

51   **52**

Table 12. Chirality of cholesteric mesophases produced from MBBA **1** and chiral α-substituted benzylamines **51** and Schiff bases **52** [80]. The liquid crystal induced circular dichroism (LCICD) was negative in all cases.

The Schiff bases **52** will align with their long axes parallel to the long axis of MBBA (Fig. 6). In (*S*)-**52**, the large R′ group leads to formation of a left-handed helix.

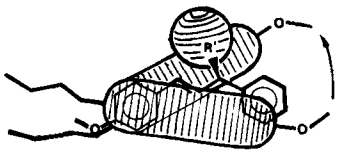

Fig. 6. Model for the interaction between chiral Schiff bases of type (*S*)-**52** and MBBA **1**. The central region of MBBA is represented by the dashed area. It forms a left-handed helix.

Recently, *Rinaldi*[81] extended these studies to β-amino alcohols **53**, which are also transaminated in MBBA. In addition, some hydrogen bonding between the hydroxy group and MBBA can contribute to the orientation of the solute in the solvent (Table 13).

Rinaldi et al.[81] proposed an interaction model of the type depicted in Figure 6 for these compounds. However, two exceptions to this model were found: the compounds in which R is a methyl and an isobutyl, respectively. Hence, the simple prerequisites of the model do not suffice to deal with the real situation. For example, in the preceeding discussion, the MBBA molecules were assumed to be planar, which in reality is not true. The *p*-substituted benzylideneaniline-type compounds such as MBBA **1** or EBBA **15** are known to be non-planar[82]; the angle between the planes of the two phenyl groups lies between 41 and 55°. Such a conformation is stabilized by electronic interactions between the nitrogen lone-pair and the π-electrons. Recent work on EBBA **15** in the crystalline[83] and in the liquid crystalline state[84] confirms this conformation.

At this point, in collaboration with Professors *Gottarelli* and *Samori*, we reached the following conclusions:

- Any future interacting model should take into consideration that MBBA has a skewed non-planar conformation.
- Such studies should be done only with molecules having high twisting powers (i.e. with good organization within the liquid crystal matrix).
- Experimental data about the solute orientation in the liquid crystal matrix should be obtained.

Optically active *trans*-stilbene oxides and analogous compounds were investigated[85], and it was shown that *trans*-diaryl molecules such as **55** have a much higher twisting power in MBBA than in any other liquid crystal (Table 14). This is a further example of the influence of structural and conformational similarity on the twisting powers. The results listed in Table 15 confirm this statement.

Information about the orientation of guest molecules in the liquid crystalline matrix were obtained by measurement of the linear dichroism (LD). The liquid crystalline matrix must be transparent in the UV/VIS region.

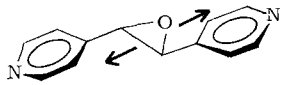
[a] [μm^{-1} mol^{-1}].

Two types of information can be obtained[86-88]:

If the orientation of the long axis of the guest molecule is known, data concerning the electronic states involved becomes available.

If the polarizations of the transitions are known, their orientation with respect to the nematic director can be established.



55

63

The linear dichroism[85] of racemic **55** and **63** in the nematic phase ZLI 1167 shows that the molecule **55** is aligned with the long axis parallel to the nematic director, while **63** behaves approximately like a disk-shaped molecule: orientation of the phenyl group with its long axis parallel to the director is slightly favored.

The higher twisting power of **55** in MBBA than in any other liquid crystal is the result of close structural and conformational analogies (cf. Table 14). Several reports on phenyloxiranes reveal a preferred conformation for such a molecule. An X-ray structure analysis of 1-(4-bromophenyl)-1,2-epoxycyclohexane demonstrated that the phenyl group adopts a quasibisected conformation in the crystal[89]. MO calculations on phenyloxirane **63**[90] likewise point to a quasi-bisected conformation, with the plane of the phenyl group rotated towards the C–O bond of the oxirane ring. In this type of conformation the two aryl groups of (*R*,*R*)-(+)-*trans*-stilbene oxide **56** and analogous molecules are distorted and display a sort of left-handed two-bladed propeller helicity (Fig. 7).

It is quite interesting to note that the chirally distorted conformation (*M*-helicity) of substituted stilbene oxide fits very well into an *M*-distorted conformation of MBBA (Fig. 7).

This may explain the process of chirality transfer from the optically active solute such as **55** and **56** to the solvent such as MBBA: the chiral conformation of the solute as

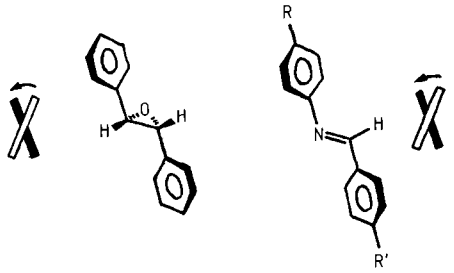


Fig. 7. Similarity between *trans*-diaryl epoxides such as **56** and MBBA **1**, R = *n*Bu, R' = MeO.

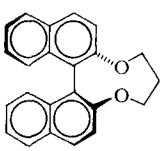
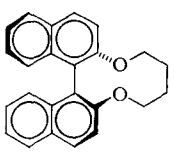
well as its analogy with MBBA may induce a chiral conformation of the solvent, and thus the formation of the cholesteric helix. Modification of the inducing compounds decreases their similarity to MBBA and thereby reduces the dynamic interactions with the solvent molecules; consequently the twisting power should decrease drastically, e.g., in globular molecules such as **63**.

In order to confirm this model, the compounds **29-31** and **67-76**, having a chiral cyclic binaphthyl or biphenyl structure with non-planar conformation and distinct helical configuration, were investigated[91]. Because of their biaryl geometry, the highest twisting powers were expected to occur in biphenyl-type nematic phases, which was indeed found to be the case for **30** and **31** (Table 16).



(*S*)-(+)-**30**



(*S*)-(+)-**31**

Table 16. Twisting powers β_M of the chiral binaphthyl derivatives **30** and **31** in nematic liquid crystals.

Liquid crystals		Type	β_M [μm^{-1} mol^{-1}] **30**	**31**
3	PCB	Biphenyl	+79	+80
1	MBBA	Schiff base	+65	+56
	1052	Aromatic ester	+42	+38
	ZLI 1167	Bicyclohexyl		+35

On the strength of this finding, the chiral compounds **29-31** and **67-76** were studied in biphenyl-type nematic phases (Table 17). All the absolute configurations are expressed in terms of helicity.

It is certainly gratifying to notice from Table 17 that, despite the important differences in the chemical structures of the compounds, *P*-helicity or *M*-helicity always leads to positive or negative values, respectively, for the twisting power (i.e. to right-handed or left-handed helices). In other words, the main factor determining the chirality of the induced mesophase is the twist sense of the biaryl moiety.

The very high values of β_M were somehow expected, since bridged biaryl compounds are conformationally ri-

gid, and, being structurally very similar, should interact very well with the biphenyl-type liquid crystals.

Furthermore, it was shown[91] by linear dichroism measurements that the binaphthyl **31** was oriented with the axis joining the two naphthyl groups parallel to the nematic director, i.e. to the long axis of the molecules in the nematic phase.

In nematic liquid crystalline solution, 4,4′-disubstituted biphenyl derivatives show non-planar conformations with torsion angles of 30 to 80°, depending on the substituents[92,93]. It is therefore reasonable to assume that such non-planar conformations exist also in biphenyl-type liquid crystals such as PCB **3** or E_7. In the nematic phase, pairs of mirror-image conformations are equally probable, but rapidly interconvert. The chiral biaryl inducer, with its biaryl axis aligned parallel to the biphenyl axis of the solvent, can have close contact and interact only with molecules having the same chirality (the same chiral conformation) (Fig. 8). At the very low experimental concentrations of the inducing compound it seems unrealistic, for statistical reasons, to postulate a model in which one molecule of solvent interacts with two molecules of solute. The chirality is therefore transferred from the inducer to a near molecule of solvent and from this to the next near one and so on, via *chiral conformations*. A biaryl derivative with *P*-helicity leads to a cholesteric phase of the same P-helicity.

These findings underline the importance of conformational effects on the twist mechanism.

Fig. 8. Model for the interaction between chiral biaryl derivatives and nematic liquid crystals of the biphenyl type [91].

Therefore, as long as there is no ambiguity about the solute orientation in the liquid crystal matrix (linear dichroism is a very informative in this domain), models can be established from solute-solvent interactions to correlate absolute configurations and twist sense, the correlation being much more certain in the case of strong solute-solvent interactions, i.e. in the case of high twisting powers.

Finally, a few more words must be added about the complementary phenomenom, i.e. induction of optical activity by a cholesteric liquid crystal. It was already shown in Section 2 that it is possible to induce a Cotton effect within the absorption bands of achiral molecules with the aid of a cholesteric liquid crystalline solvent. It has also been shown[94–96] that optical activity can be chemically induced by running an asymmetric synthesis in a cholesteric solvent. Since the chirality transfer is mainly the results of solute-solvent interactions, only low enantiomeric excesses have been obtained so far.

5. Concluding Remarks

In recent years many modern analytical techniques have been modified in order to obtain stereochemical information. Historically, the method most commonly used for obtaining information about chirality was polarimetry. Circular dichroism (CD) and optical rotatory dispersion (ORD) are now more powerful than polarimetry. The introduction of chiral shift reagents in NMR spectroscopy was probably one of the most spectacular improvements in the field of enantiomeric purity determinations.

The results reviewed in this report show that the extreme sensitivity of liquid crystals to optical activity makes them suitable for stereochemical studies. It is possible by very simple experiments to detect low optical activities and to determine the kinetics of racemization. Important contributions have also been made to the correlation of absolute configurations: the liquid crystal technique resembles the NMR technique, correlating absolute configurations to chemical shifts induced by chiral complexes, or chromatography, correlating retention times to the configurations of diastereoisomeric species. A better understanding of the nature of the interactions between chiral molecules and liquid crystals should lead to better models for solute-solvent interactions, so that the liquid-crystal technique could some day complement the ORD and CD techniques.

G. S. wishes to thank Professor H. M. Walborsky for his hospitality at Florida State University during the summer of 1983, for providing facilities for writing this paper, and for many stimulating discussions and suggestions. Thanks are also due to the CNRS for financial support (ATP NSF-CNRS n° 0782). The authors are also indebted to Dr. S. Candau (Université Louis Pasteur, Strasbourg), Professors Gottarelli and Samori (Università di Bologna) for their invaluable collaboration in this work, and to their co-workers who are individually recognized in the cited references. Finally, a joint grant for us and our Italian colleagues from NATO (Grant n° RG081-81) is gratefully acknowledge.

Isolation of the First Six- and Seven-Membered Selenium-Sulfur Rings and Mechanism of their Conversion into Other-Sized Rings**

By *Ralf Steudel** and *Eva-Maria Strauss*

Cyclic selenium sulfides Se_xS_y have previously only been isolated in the ring sizes $x+y=8$ or 12[1]. We now report the isolation of compounds SeS_5 and Se_2S_5 as well as the decomposition of Se_2S_5 in solution, for which we propose a novel mechanism that is also relevant to other chalcogen compounds.

Titanocene pentasulfide, which contains a TiS_5 ring, reacts smoothly with S_2Cl_2 to afford S_7[2a], and with Se_2Cl_2—as we have now found—just as smoothly to yield the analogous heterocycle 1,2-Se_2S_5[3a].

$$(C_5H_5)_2TiS_5 + Se_2Cl_2 \xrightarrow[20°C]{CS_2} Se_2S_5 + (C_5H_5)_2TiCl_2 \qquad (a)$$

1,2-Se_2S_5 could be detected in CS_2 solution by high performance liquid chromatography (HPLC) and isolated as needle-shaped, dark orange crystals (density 2.69 g/cm^3 (25°)[3b] by rapidly covering the solution with pentane and cooling to −78°C. The solid compound completely decomposes at 25°C in 5 h but can be stored for several months at −78°C with no sign of decomposition. Upon heating, decomposition occurs above 99°C and melting at 111–113°C.

The SeSe bond of Se_2Cl_2 is retained in 1,2-Se_2S_5 as unequivocally indicated by the Raman spectrum, which exhibits one SeSe stretching frequency and only two SeS stretching frequencies (Fig. 1). If the conformation observed in the S_7 homocycle[2b] is also assumed for the Se_2S_5 ring, the spectrum is only consistent with the isomer shown in Figure 1; the three other feasible isomers with a SeSe bond can be ruled out for the following reasons: The two SeS stretching frequencies (339 and 304 cm^{-1}) are, respectively, 30 and 65 cm^{-1} wavenumbers lower than in SeS single bonds (e.g. in the rings Se_nS_{8-n}[4]) and must, therefore, be associated with two weak (long) bonds. These can only be the two bonds which in S_7 are 210 and 218 pm long and are, therefore, markedly longer than an SS single bond (205 pm). In contrast, for the SeSe stretching frequency of Se_2S_5 (271 cm^{-1}) a somewhat larger value is found than for a single bond (250 cm^{-1}); this can be accounted for by the conformation shown, since the corresponding bond in S_7 is slightly shorter than a single bond. The four SS stretching frequencies of Se_2S_5 appear at almost the same

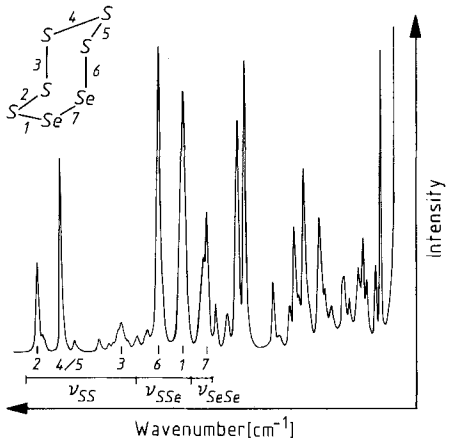

Fig. 1. Correlation of molecular structure and Raman spectrum (−110°C) of 1,2-Se_2S_5. The bonds 1–7 lead to the Raman lines of corresponding numbers (4 and 5 are the symmetric and asymmetric SS stretching frequencies of the bonds 4 and 5, respectively). Wavenumbers [cm^{-1}]: *511*, 505, *479*, 459, 425, 393, 372, 357, *339*, *304*, 276, *271*, 259, 242, *228*, *219*, 179, 155, *149*, *136*, *113*, 98, 79, 72, 59, *52*, 47, 34, *27* (most intense lines are shown in italics). Due to the different sizes of the S and Se atoms, bonds 2 and 7 are probably not coplanar, in contrast to S_7, i.e. the torsion angle at the bond 1 differs from zero.

[**] Sulfur Compounds, Part 87. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie; results were presented at the International Symposium on Liquid Chromatography in Baden-Baden (3rd—6th May 1983).—Part 86: R. Steudel, R. Strauss, *J. Chem. Soc. Dalton Trans.*, in press.

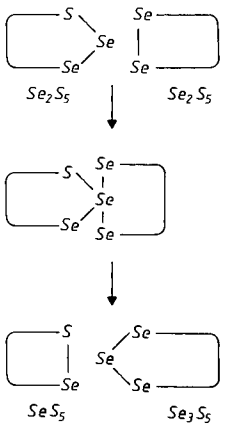
wavenumbers as the corresponding stretches of S_7[5]. Since a clear relation exists between the wavenumber $\tilde{\nu}_{SS}$ and the nuclear separations of the associated bonds[6], the SS bonds in Se_2S_5 must be almost as long as the corresponding bonds in S_7.

Reversed phase HPLC on octadecylsilane[7] indicates that Se_2S_5 decomposes in CS_2 solution at 25 °C according to

$$2\ 1,2\text{-}Se_2S_5 \longrightarrow SeS_5 + 1,2,3\text{-}Se_3S_5 \qquad (b)$$

At a concentration of 1 mmol/L the half-life of the reaction is ca. 1 h; disproportionation is complete after 2.5 h. Whereas the eight-membered ring Se_3S_5 has been isolated previously, we have now been able to obtain small amounts (ca. 20 mg) of the six-membered ring SeS_5 by cooling (−78 °C) a solution whose HPLC exhibited peaks of approximately the same size for the three rings in equation (b); the crystals were subsequently sorted according to their shape under the microscope. During this process Se_2S_5 remains in solution, Se_3S_5 crystallizes as orange needles, and SeS_5 is obtained as yellow, square crystals—similar to S_6 and Se_6, which are both known in pure crystalline form. The Raman spectrum of SeS_5 can be assigned to a six-membered ring with two SeS bonds[9]. As expected, the HPLC retention times of the compounds increase with the ring size: SeS_5 2.95, Se_2S_5 3.4, Se_3S_5 4.7 min (dead time 1.4 min; eluent: methanol/cyclohexane 90/10 v/v).

Formation of SeS_5 and 1,2,3-Se_3S_5 from 1,2-Se_2S_5 can be accounted for by the reaction mechanism shown in Scheme 1, in which a spirocyclic intermediate structurally related to SeF_4 is postulated. This species forms by insertion of an Se atom into the reactive SeSe bond of a second molecule and subsequent decomposition to SeS_5 and Se_3S_5, a reaction of this type is allowed by orbital symmetry.



Scheme 1.

Sulfur homocycles probably interconvert in an analogous way upon heating in CS_2 solution to 130–155 °C[10] or in the melt[11]; the corresponding interconversion of the selenium homocycles Se_8, Se_7, and Se_6 proceeds rapidly in solution even at 20 °C[12], and can be explained by the higher reactivity (lower bond energy) of the SeSe single bond. Decomposition, i.e. interconversion of sulfanes R–S_n–R (R = H, halogen, organyl) involving alteration of the chain length n, probably proceeds via a sulfurane SX_4 as reactive intermediate[13]. The mechanism proposed here thus deals with an important type of reaction in the chemistry of chalcogens.

^{15}N-^{15}N Coupling Constants and Rotational Barriers of Nitrosamines**

By *Heinz Bandmann, Peter Heymanns, Carola Siem,* and *Paul Rademacher**

The spin-spin coupling constant ^1J characterizes the electron distribution in the individual bonds of a molecule[1]. Whereas because of the predominance of the Fermi contact term simple relations exist between ^1J and the electronic structure of the respective bonds for ^{13}C-H and ^{13}C-^{13}C coupling constants, for example, a correlation of this type for NN bonds is still not completely unequivocal due to the orbital and spin-dipolar terms, which can no longer be neglected, as well as the different influences of the lone pairs of electrons[3]. We have now found that for nitrosamines[4] linear correlations exist between the ^{15}N-^{15}N coupling constants and the π bond order of the NN bond, as well as with calculated values for the barrier to internal rotation ΔH^*.

Compounds **1**–**6**, whose NO group is ^{15}N-labeled (99%), were studied; the amino group contains ^{15}N in natural abundance[5]. The results are summarized in Table 1. Within experimental error, the δ-values for **1**, **4**, and **5** are in accord with those measured by *Gouesnard* and *Martin*[7] on unlabeled compounds; however, for **6** we found larger deviations[7]. According to theoretical investigations[8], ^1J is negative. For 1-phenylpyrazole, whose NN bond is similar to those in nitrosamines, $^1J_{N,N} = -12.91$ Hz was found[9]. We determined the absolute values.

As indicated by the resonance structures $R_2N-N=O$ and $R_2N^{\oplus}=N-O^{\ominus}$, the NN bond in nitrosamines exhibits

[a] Varian XL 200 spectrometer at 20.28 MHz. Measurement temperature for **2**, −40°C, otherwise 23°C. INEPT pulse sequence (R. Benn, H. Günther, *Angew. Chem. 95* (1983) 381; *Angew. Chem. Int. Ed. Engl. 22* (1983) 350). [b] Relative to NH_3(l) at 25°C. External standard: nitromethane, conversion factor +380.23 Hz [6]. N^1 = amino-, N^2 = nitroso-N atom. [c] Error limits for **1** and **4** ±0.2 Hz, otherwise ±0.6 Hz.

partial double bond character. A measure of this was taken to be the rotational barrier of the NN bond determined by dynamic NMR spectroscopy[7, 10]. The contribution made by the polar resonance structure to the electronic ground state of the molecule is governed by the donor ability of the amino group. In this respect, for compounds **1**–**6** the ring size is of paramount importance[11]. If the ^{15}N-^{15}N coupling constant is a function of the electron distribution in the NN bond, a correlation should exist between ^1J and the π bond order as well as the rotational barrier and, possibly, also with other structural parameters, such as the NN bond lengths. A correlation between the ^{15}N-^{15}N coupling constants and structural parameters is, however, not possible since, to date, only the structure of **1** has been determined[12]. No correlation is apparent between ^1J and NN bond lengths calculated by the MNDO method.

The linear relationship expressed by equation (a), with correlation coefficient $r^2 = 0.91$, exists between ^1J and the π bond order p of the NN bond[13]. And an excellent correlation ($r^2 = 0.97$) is obtained with equation (b) for ^1J and the enthalpy of activation ΔH^* of rotation about the NN bond[13]. Since the experimental values of ΔH^*[7, 10] for **2** and **6** are not known and those for **1**, **4**, and **5** are equal within experimental error, for the relationship (b) we used ΔH^* values calculated by the MNDO method[14, 15].

$$p = 0.020\ ^1J + 0.91 \quad \text{(a)}$$

$$\Delta H^* = 1.44\ ^1J + 39.4\ \text{[kcal/mol]} \quad \text{(b)}$$

Hence, in nitrosamines both the ^{15}N-^{15}N coupling constant and the rotational barrier can be used as a measure of the NN double bond order. In particular, this may offer advantages for thermolabile compounds such as **2**[16], which are not suitable for dynamic NMR studies. Moreover, the relationships offer a further possibility of studying this class of substances which are important in view of their carcinogenic activity[17]. It remains to be established whether the relationships (a) and (b) only apply to nitrosamines or are more general.

Synthesis of Tetrahydro-3-thienylacetic Acid Esters by Consecutive Photo-Induced Reactions**

By *Elke Anklam* and *Paul Margaretha**

Irradiation of five-membered cyclic α,β-unsaturated carbonyl compounds, such as 2-cyclopenten-1-one[1], 2(5*H*)-, and 3(2*H*)-furanones[2, 3] usually leads to formation of tricyclic dimers. In addition, in solvents such as 2-propanol or cyclohexane photoreduction products are also obtained[4]. The [2+2]-photocycloaddition of such enones to olefins is one of the most important preparative photochemical reactions[5].

2(5*H*)-Thiophenone **1**, which is readily accessible from thiophene[6], behaves quite differently. Upon irradiation ($\lambda = 300$ nm) of **1** in benzene or cyclohexane in either the presence or absence of olefins, no products are detected, even after long irradiation times. In contrast, irradiation of **1** in alcohols leads selectively and in good yields to the 4-mercaptocrotonates **2**[7]. The fact that the rate of formation of **2** from **1** is not lowered by addition of 2,5-dimethyl-2,4-hexadiene, suggests a reaction proceeding from the S_1 state of **1**.

Irradiation of **1** in alcohols *in the presence* of 2,3-dimethyl-2-butene leads, in turn, to formation of the 4,4,5,5-tetramethyltetrahydro-3-thienylacetates **3**[7]. In this case, a

[*] Prof. Dr. P. Margaretha, E. Anklam

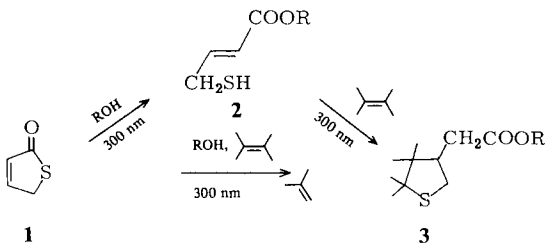
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

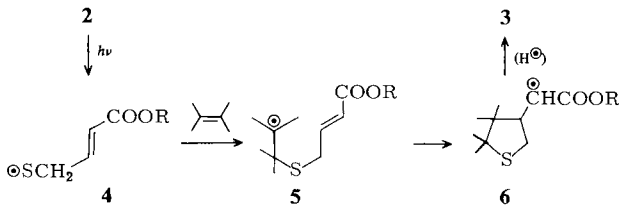
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

consecutive photoreaction is involved, since compounds **3** are also formed by irradiation of **2** in the presence of the olefin.



R = CH_3, C_2H_5, $(CH_3)_2CH$, $(CH_3)_3C$

The reaction **1*** + ROH → **2** involves photosolvolysis (ring opening does not occur in the dark). The esters **2**, which are readily accessible in this way, are interesting synthetic intermediates. The formation of **3** from **2** can be explained as follows: generation of the alkylthio radical **4** either by homolysis of the SH bond in the excited thiol[8] or H abstraction by the carbonyl oxygen of the ester group; stepwise [3 + 2]-cycloaddition[9] of **4** and olefin via **5** to afford the radical **6**; reaction of **6**, e.g., with **2** to give the final product **3**—in this case re-forming **4**.



This mechanism is corroborated by the results on the irradiation of **1** (or **2**) in the presence of 2-methylpropene. In this case, the products **8** analogous to **3** are formed; use of a large excess of olefin also leads to formation of the 2-(tetrahydro-3-thienyl)-4-methylpentanoic acid esters **11**. Alkylthio radicals add to olefins in *anti*-Markovnikoff orientation[8]. The fact that **8** (and **11**), but not the corresponding regioisomers, e.g. **9**, are formed exclusively suggests the involvement of an intermediate alkylthio radical. However, radical **7**, which is analogous to **6**, also reacts with 2-methylpropene to give **10** and, hence, compound **11**. The corresponding reaction of **6** with 2,3-dimethyl-2-butene does not occur—presumably for steric reasons. **8** and **11** can be separated by chromatography (SiO_2, CH_2Cl_2). The ^{1}H-NMR data of **2**, **3**, **8**, and **11** (in each case R = CH_3) are summarized in Table 1.

[7] *Procedure*: **2**: After 12 h irradiation (λ = 300 nm, Rayonet-RPR-100 photoreactor) of a N_2-degassed solution of **1** (1 g, 0.01 mol) in 100 mL alcohol, the solvent is distilled off. Unreacted **1** (40%) is separated from **2** (50—60%) by chromatography (SiO_2, Et_2O/pentane 1.1). Since at λ = 300 nm the extinction coefficient of **1** is only twice that of **2** (ε_{300} = 60), the yield of **2** is reduced at longer irradiation times.—**3**: A N_2-degassed solution of **1** (1 g) and 2,3-dimethyl-2-butene (5 g) in 100 mL alcohol is irradiated for 48 h. After removal of the solvent in vacuo, the residue is purified by kugelrohr distillation (150—160 °C/0.01 torr) (yield 80—85%).

Enantioselective Synthesis of β-Substituted Primary Amines; α-Alkylation/Reductive Amination of Aldehydes via SAMP-Hydrazones**

By *Dieter Enders** and *Heinrich Schubert*

SAMP-hydrazones have proven to be useful reagents for the asymmetric synthesis of carbonyl compounds[1]. They allow, through alkylation, the formation of α-substituted aldehydes and ketones[2] and, through Michael addition, the synthesis of β-substituted δ-keto esters[3] with high enantioselectivity. Optically active amines are equally of interest as chiral building blocks and as compounds with a wide variety of biological activity.

We now report on the highly enantioselective synthesis of β-substituted primary amines **5**. The aldehydes **1** are

[**] This work (part of planned dissertation by *H. S.*) was supported by the Fonds der Chemischen Industrie, by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, by the Deutsche Forschungsgemeinschaft, and by Degussa AG, BASF AG, Bayer AG, and Hoechst AG.

converted into SAMP-hydrazones (*S*)-**2**, which are metalated with lithium diisopropylamide (LDA) in ether and alkylated with dimethyl sulfate or alkyl bromides to give **3**. According to ^{1}H-NMR shift experiments [methoxy singlet, Eu(fod)$_3$], the diastereomeric excess (*de*) is greater than 95%. Reduction with catecholborane (CB) in ether leads to the hydrazines **4**, whose reductive N–N cleavage with Raney nickel/hydrogen in methanol affords the β-substituted primary amines **5** in good overall yields (41–63%) (Table 1). (*S*)-2-methoxymethylpyrrolidine [(*S*)-**6**], which is also formed in this reaction, permits, after being separated off, the recovery of the chiral auxiliary SAMP[4] by nitrosation/reduction or *N*-amination with KOCN/Hofmann degradation[5]. The enantiomeric excesses of the amines **5** (*ee* ≥ 95%) are consistent with the *de* values obtained at the hydrazone stage **3**. They were determined polarimetrically (**5e**) and NMR spectroscopically via the 3,3,3-trifluoro-2-methoxy-2-phenylpropionamides (MTPA)[6] (^{19}F, ^{1}H) and by shift experiments with Eu(hfc)$_3$.

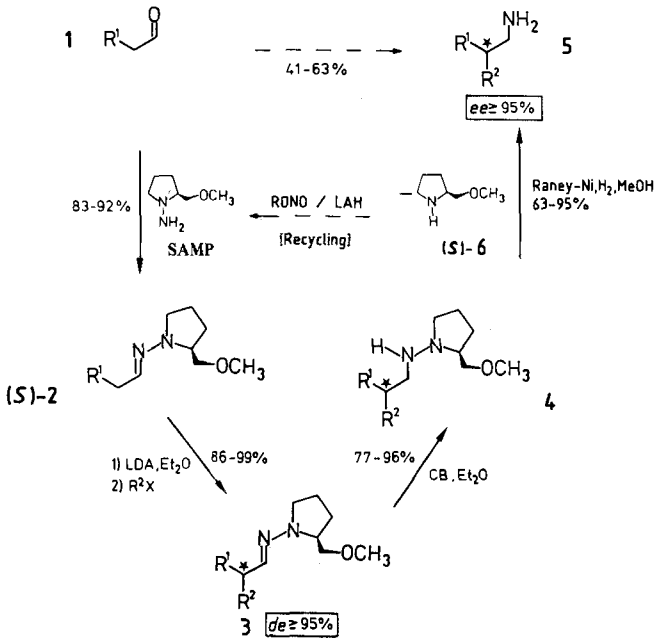

Table 1. Primary amines **5** prepared via SAMP-hydrazones from aldehydes **1** by alkylation/reductive amination.

5	R^1	R^2	B.p. [°C/torr] [a]	Total yield [%]	$[\alpha]_D^{22}$ (neat)	*ee* [%]
(*S*)-**5a**	CH_3	n-C_6H_{13}	75/15	63	− 8.4°	>95
(*R*)-**5a**	n-C_6H_{13}	CH_3		56	+ 8.1°	>90[b]
(*S*)-**5b**[c]	CH_3	$C_6H_5CH_2$	100–110/15	52	− 9.6°	>90[b]
(*R*)-**5b**	$C_6H_5CH_2$	CH_3		41	+10.8°	>95
(*S*)-**5c**	CH_3	$(CH_3)_2CH(CH_2)_3$	74/15	48	−10.6°[d]	>95
(*R*)-**5d**	n-C_9H_{19}	CH_3	78–84/1.5	53	+ 6.7°[e]	>95
(*R*)-**5e**	C_6H_5	CH_3	90/15	61	+32.7°[f]	95

[a] Data for short-path distillation. [b] According to NMR spectroscopic determination (MTPA-amides) *ee* ≥ 95%. [c] Alkylation in tetrahydrofuran. [d] $[\alpha]_D^{22}$ (c = 1.8, EtOH). [e] $[\alpha]_D^{22}$ (c = 1.1, C_6H_6). [f] $[\alpha]_D^{22}$ (c = 1.0, EtOH); (*S*)-**5e** [7]: $[\alpha]_D^{22} = -33°$ (c = 1.0, EtOH) corresponding to 96% *ee*.

Depending on the choice of nucleophilic and electrophilic building blocks, the C–C coupling procedure permits both enantiomers of an amine **5** to be prepared with high enantioselectivity by simply changing the priority of R^1 and R^2. This "opposite enantioselectivity by synthon control" is demonstrated in Table 1 for the enantiomeric pairs (*S*)-**5a**/(*R*)-**5a** and (*S*)-**5b**/(*R*)-**5b**. The absolute configurations of the new, optically active amines **5a–d** follow from the known selectivity in SAMP-hydrazone alkylations[1]; the absolute configuration of (+)-**5e** was already known[7].

The novel method of α-alkylation/reductive amination of aldehydes via SAMP-hydrazones[8] thus opens up an efficient and general entry to both optical antipodes of β-substituted amines **5** of high enantiomeric purity[10, 11].

[8] *Procedure:* To a solution of 20 mmol LDA (from 12.5 mL 1.6 M *n*-butyllithium in *n*-hexane and 2.9 mL diisopropylamine) in 20 mL ether is added 20 mmol (*S*)-**2** under argon at 0°C and the mixture stirred for 4–5 h. After cooling to −120°C, the mixture is treated dropwise with R^2X, stirred for a further 3 h, and then allowed to warm to room temperature (RT). Work-up and distillation affords the hydrazones **3**, which are dissolved in 50 mL ether and treated under argon at 0°C with two equivalents of CB. Warming to RT within 12 h, washing with water and several times with 1 N NaOH, drying over $MgSO_4$, removal of solvent, and short-path distillation, affords the hydrazines **4**. These are dissolved in methanol (50 mL) and hydrogenated in a Parr hydrogenation apparatus with freshly prepared alkaline Raney nickel [9]/H_2 (3.5–3.8 bar, 20–40°C). After filtering off the catalyst, the filtrate is evaporated down, taken up in 50 mL ether, refiltered, treated with 1.5 equivalents of *p*-nitrobenzaldehyde, and stirred for 12 h at RT. The Schiff bases that are formed ($R_f \geq 0.9$) are separated from (*S*)-**6** ($R_f \leq 0.2 \rightarrow$ recycling) by column chromatography (SiO_2, ether); their ethereal solution (50 mL) is stirred with 50 mL 1 N HCl for 2 h. The aqueous phase is separated off, covered with a layer of ether (50 mL), and rendered alkaline with KOH pellets. After shaking, the ether phase is dried over $MgSO_4$, evaporated down, and the amines are distilled.

Configurational Stability of Vinyllithium Derivatives with 1-Trimethylsilyl and 1-Alkoxy Substituents**

By *Rudolf Knorr** and *Therese von Roman*

Considerable preparative interest[1, 2, 4] has been directed towards vinyllithium derivatives with silyl[1–3] and alkoxy[1, 4, 5] functions in the α-position. Qualitative observations on 1-silyl-1-alkenyllithium compounds (**1**, $R^1 = R_3Si$, $R^2 \neq H$) indicate that the *E*/*Z*-isomerization (**a** ⇌ **b**) in alkane solvents in the presence of 1,2-bis(dimethylami-

no)ethane (TMEDA) at +25 °C[3a] or in diethyl ether (Et_2O) above −35 °C[3b,c] occurs rapidly; only at temperatures below −65 °C is the configurational stability in ether[3c] and in tetrahydrofuran (THF)[2b,c] sufficient for stereospecific syntheses, but detailed rate data are not known. By direct observation of the *E/Z*-diastereotopomerization **1a** ⇌ **1b**[6] using dynamic NMR spectroscopy, we have now been able, for the first time, to determine the rate constants and activation parameters.

	R^1	R^2
1	$Si(CH_3)_3$	H
2	OC_2H_5	H
3	OCH_3	H
4	OC_2H_5	CH_3

The ^{1}H-NMR spectrum[8] of a THF solution[7] of 1-trimethylsilylvinyllithium **1** exhibits the AB splitting pattern of the olefinic CH_2 group (Table 1). As the solution was warmed to above room temperature, considerable line broadening was observed which was found to be reversible on cooling. Line-shape analysis[9] between +26 and +70 °C gave an activation enthalpy $\Delta H^{\neq} = 7.4$ (±1.5) kcal/mol and activation entropy $\Delta S^{\neq} = -32$ (±4) cal K^{-1} mol^{-1}. The half-life of the *Z/E* permutation in THF at +48 °C is therefore 0.11 s and, by extrapolation, ca. 0.5–15 min at −70 °C.

At room temperature, solutions of **1** decompose slowly (Table 1). In the absence of TMEDA, **1** cannot be generated in a similar way[7] in pentane; rather, as with the analogous (1-chlorovinyl)trimethylsilane[10], (3,3-dimethyl-1-butenyl)trimethylsilane is formed in addition to *tert*-butyltrimethylsilane. In TMEDA (by-product, *N,N*-dimethylvinylamine) the half-life of the *Z/E*-diastereotopomerization at +61 °C is considerably greater than 15 s. Since this solvent dependence and the previously mentioned activation parameters of **1** are in accord with those of 1-arylvinyllithium compounds[11], an ionic mechanism, as proposed[11] for the latter compounds, involving stabilization of charge by silicon[3c] can be presumed.

Table 1. ^{1}H-NMR data and stability of vinyllithium derivatives **1**–**4** in 0.05–0.5 M solutions, $\tau/2$ = half-life of the decomposition.

2a, b	Et_2O/THF [f]	+25	4.91	4.06	0	≫ 2 d
2a, b	TMEDA [g]/alkane [h]	+25	5.07	4.47	[i]	—
3a, b	C_6D_6/THF [g]	[k]	5.39	4.56	0	[k]
4a, b	THF	+25	5.48 [l]	4.45 [m]	—	≫ 9 d
4a, b	[D_8]THF/TMEDA [g, n]	+25	5.44 [l]	4.32 [m]	—	≫ 17 h

[a] Assignments for **1**–**3** interchangeable. [b] With ca. 15 vol.-% hexamethylphosphoric triamide (HMPT). [c] Ca. 57 vol.-% pentane/hexane. [d] Same NMR parameters at +61 and −32 °C. [e] Almost the same δ-values with 50 vol.-% pentane at +25 and −50 °C, with $(CH_3OCH_2)_2$ or with 83 vol.-% TMEDA. [f] 20 vol.-%. [g] One mol. equivalent. [h] 90 vol.-% pentane/hexane. [i] Very broad. [k] Lit. [12a]. [l] q with $^3J = 6.5$ Hz (*E*-isomer). [m] q with $^3J = 6.0$ Hz (*Z*-isomer). [n] Methyl doublets at $\delta = 1.57$ (*E*) and 1.47 (*Z*), respectively.

1-Alkoxy-1-alkenyllithiums $R^2HC{=}C(OAlk)Li$[6] are formed and react in THF below −78 °C[4c, 5a, b] up to ca. −20 °C[5c] with retention of configuration; we investigated their previously unknown degree of configurational stability spectroscopically[8, 12]. The positions of the ^{1}H-NMR signals of the vinyl protons of 1-ethoxyvinyllithium **2**, which show up as sharp singlets in ethereal solutions[13], are consistent with the values given[12a] for **3** and are strongly solvent-dependent (Table 1); up to +106 °C, line broadening does not occur in TMEDA, but rather decomposition is observed. Since (*E*)-1-ethoxy-1-propene in the *E/Z* mixture[13] reacts considerably more rapidly with *tert*-butyllithium to afford **4a** than the (*Z*)-isomer to give **4b**, reduction of the amount of *tert*-butyllithium allows the selective formation of different *E/Z*-mixtures (1 : 3 to 3 : 1) of 1-ethoxy-1-propenyllithium **4**. *These ratios remain constant* for more than 13 days at +25 °C in THF; therefore, the compounds **4** (as well as **9**) are stable with respect to *Z/E*-isomerization.

We propose that the vanishingly small coupling constant of **2** and the unusually strongly positive one of **1** are due to the σ-inductive effects of R^1 and Li, which operate in opposite directions in **2** but in the same direction in **1**[14].

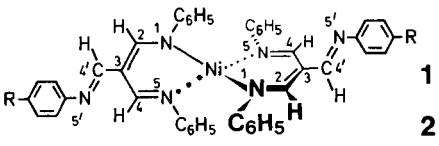
Detection of Intramolecular Linkage Isomerization of a (Pseudo)tetrahedral Nickel(II) Bis(chelate)**

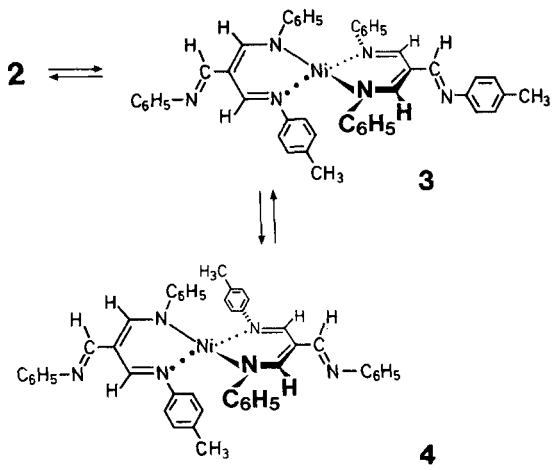
By *Rudolf Knorr** and *Friedrich Ruf*

The monomolecular interconversion of tetrahedral and planar isomers of tetracoordinated nickel(II) bis(chelates) such as **1** could proceed either as a thermally allowed, synchronous process[1] or, instead, in two steps involving reversible opening of a chelate ring. We found that a model (pseudo)tetrahedral nickel(II) compound[2] closely related to **1** undergoes slow inversion of configuration at 25°C[3,4], possibly involving transient formation of the planar (not detectable) form. We now wish to report that a spontaneous chelate opening is possible, using evidence of linkage isomerization of **2** to **3** and **4**.

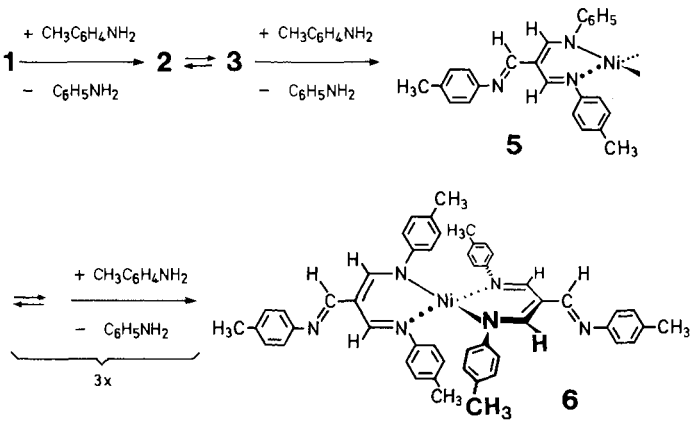


1: R = H

2: R = CH_3



Exchange of the two exocyclic phenylimino substituents of **1**[5] for *p*-tolylimino substituents, leading to **2**, is complete after less than 5 min at room temperature[6]. The ^{1}H-NMR spectrum[7a] of a solution of the purified nickel complex **2** in $CCl_4/DCCl_3$ (3:1) initially exhibits no extraneous signals; however, in the course of a few days at first one, and then a second, methyl singlet[7b] appear for **3** and **4**, arising from incorporation of the *p*-tolyliminomethyl groups into the chelate ring. In addition, a novel triplet for the *p*-hydrogen atom of the previously coordinated phenylimino group is observed. Consumption of **2** is measured by the reduction in intensity of the methyl signal of the exocyclic tolylimino groups and the *p*-absorption of the coordinated phenylimino groups[7a]. The final equilibrium of **2**, **3**, and **4** corresponds to the statistical distribution (1:4:4). The rate constant[8] $k_{iso} = 38(\pm 5) \times 10^{-8}\ s^{-1}$ at 24.5°(±1)°C refers to only one of the four equally probable linkage isomerizations of **2**. A parallel experiment using a twofold initial concentration yields the same value within experimental error; in this inert solvent the isomerization is, therefore, a first order reaction[9].



The very rapid formation of **2** from **1** permits an independent measurement of the rate constant under irreversible conditions. The ^{1}H-NMR spectrum recorded immediately after mixing the nickel complex **1** (0.175 M) with *p*-toluidine (3.73 M) in $DCCl_3$ shows only the nickel complex **2**. Intermediate products (e.g. **3**) of the linkage isomerization may be present in only very small steady-state concentrations, since they react immediately and almost completely with the remaining *p*-toluidine to form **5** by substitution of the now exocyclic phenylimino groups released from the chelate. The repeated interplay of bonding isomerization and exocyclic substitution leads eventually via three additional intermediates[8] to **6**, the sole final product[7c,10]. The increase in intensity of the methyl signal ($\delta = +26.6$) for the coordinated *p*-tolylimino group at the expense of that of the *p*-hydrogen signal of **2** ($\delta = -11.4$)[7a] was studied as a function of time and gave $k_{iso} = 64(\pm 20) \times 10^{-8}\ s^{-1}$, assuming the same rate constant for each of the conceivable linkage isomerizations. Within the limits of experimental error, this value is consistent with the forementioned rate constant and proves that free *p*-toluidine does not measurably accelerate the linkage isomerization.

Considering that the catalytically efficient donor property of *p*-toluidine should not be smaller than that of the solvents used in the two experiments, we suggest that the linkage isomerizations are initiated by *mono*molecular rupture of the N^5Ni bond in **2**[11].

Since the subsequent C^2C^3 rotation presumably contributes to the free energy of activation ($\Delta G^{\neq} = 26.0(\pm 0.3)$ kcal/mol) of the linkage isomerization, the similar values of k_{iso} and the rate constant for inversion of configura-

[8] Formal kinetic formulation in [4].
[9] The problem of intermolecularity found for an octahedral cobalt(III) tris(acetylacetonate), designed with a similar concept, thus does not occur here: cf. J. P. Collman, J.-Y. Sun, *Inorg. Chem. 4* (1965) 1273; F. Basolo, R. G. Pearson: *Mechanisms of Inorganic Reactions*, 2nd edit., Wiley, New York 1967, p. 319, 320.
[10] Isolation of **6**: After removal of *p*-toluidine in vacuo, the residue is dissolved in anhydrous benzene and **6** precipitated by addition of anhydrous ethanol; m.p. (crude product) = 276–279°C.—Independent synthesis of **6**: yield 79%, m.p. = 296–298°C, spectra identical.
[11] Compare also the "swinging gate" mechanism of a planar Pd chelate which, however, involves solvent participation: W. G. Rohly, K. B. Mertes, *J. Am. Chem. Soc. 102* (1980) 7939.—Instead of an intermediate with tricoordinated nickel, one could, following the suggestion of a referee, also assume temporary formation of $\sigma(N^1)$-π(azaallyl)chelates in which the nickel atom is initially bonded to the $\pi(C^3C^4N^5)$- and then to the $\pi(C^3C^{4'}N^{5'})$-system. Differentiation between these two models is not yet feasible.

Strong 1,3-Interaction in 1,2-Dihydroboretes: Homoborirenes**

By *Rolf Wehrmann, Harmut Klusik,* and *Armin Berndt**

Cyclobutenyl cations **1** exhibiting 1,3-interaction have been described as homocyclopropenylium ions[1]. Herein we report on an experimental entry to the isoelectronic 1,2-dihydroboretes (boracyclobutenes) **2**, for which strong 1,3-interaction is demonstrated, so that the designation homoborirenes seems to be justified[2].

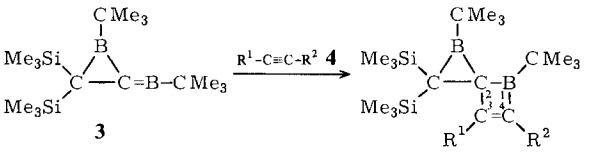
[**] This work was supported by the Fonds der Chemischen Industrie.

The 2-*tert*-butylborandiylborirane **3**[3] reacts with 2-butyne **4a** and 3,3-dimethyl-1-butyne **4b** below −50°C to give the 1,2-dihydroboretes **2a** and **2b**, respectively[4]. The addition of **4b** proceeds regioselectively, such that the *tert*-butyl group evades steric hindrance by a trimethylsilyl group of the three-membered ring. The structures of the compounds **2a** and **2b** follow from the ^{1}H-, ^{13}C- and ^{11}B-NMR spectra[5].



3 **2**

a: $R^1 = R^2 = Me$; **b**: $R^1 = H$, $R^2 = CMe_3$; **c**: $R^1 = R^2 = Ph$

The strong 1,3-interaction in **2a** and **2b** is concluded from the pronounced shielding of the boron atoms in the four-membered ring ($\delta = 34.5$ and 40 resp.), the shielding ($\delta = 143.2$ and 135.1, resp.) and broadening of the signals of the C^3 atom at 25°C, which indicate a bonding relation to B^1, and from the deshielding of the C^4 atom ($\delta = 185.5$ and 195.0, resp.). For normal interaction with a conjugated double bond, a chemical shift of ca. 75 is to be expected for the boron atom B^1, a *sharp* signal at ca. 175 at 25°C for the C^3 *not* bound to boron, and a chemical shift of ca. 140 ppm for the C^4 bound to boron[6].

In the case of the diphenyl derivative **2c**[3,4], neither the ^{11}B-NMR shift nor the broadening of the signal of C^3 can be measured at 25°C; the chemical shift of C^4, $\delta = 180.1$, however, indicates a strong 1,3-interaction.

The ^{13}C-NMR shift of C^4 in **2a** ($\delta = 185.5$) is as amazingly similar to the shift of a comparably substituted homocyclopropenylium ion ($\delta = 186.2$)[1b], as that of the ring C-atoms in the *tert*-butyl substituted borirenes to that in the tri-*tert*-butylcyclopropenylium ion[7].

2a and **2b** undergo transformation into products of still unknown structure more slowly than **2c**[3]. The low stability of **2a–2c** is consistent with the results of ab initio calculations[8], according to which the unsubstituted spirocyclic **2** represents a particularly energy-rich $C_4B_2H_6$ system.

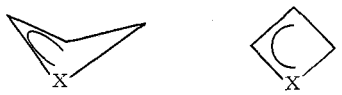
1,2-Dihydroborete: Structure of a Potential Homoaromatic System**

By *Dieter Cremer**, *Jürgen Gauss*, *Paul von Ragué Schleyer*, and *Peter H. M. Budzelaar*

Experimental and theoretical studies of cyclobutenyl cations **1** indicate that, due to relatively strong 1,3-interactions, the nonplanar form **1a** is more favorable than the planar form **1b**[1–3]. On the basis of quantum chemical model calculations, we now show that similar structural behavior is expected for 1,2-dihydroboretes **2**, which are isoelectronic to **1**.



a **b**

1, X = $CH^{\oplus}$
2, X = BH

Complete optimization of the geometry of **2** using the MINDO/3 method[4] leads to the nonplanar form **2a**, which is 6.1 (5.3) kcal/mol more stable than **2b**[5]. The corresponding value for **1** is 9.8 kcal/mol[3] (experimental value: 8.4 kcal/mol[1]).

Reinvestigation of the equilibrium structure determined for **2a** using ab initio calculations of the Hartree-Fock (HF) type with an extended 6-31G* basis set[6] led to the structural data summarized in Figure 1. Hence, the fold angle α in **2a** (152°, cf. Figure 1) is only slightly different from the calculated value of 148° for **1a** (HF/6-31G*[3]; exp.: 148.5°[2]). The 1,3-distance of 1.90 Å is somewhat longer than that in **1a** (HF/6-31G*: 1.79 Å[3]; exp.: 1.78 Å[2]). The relatively long B1C4 bond and the relatively short C3C4 bond indicate that delocalization of the two π electrons in the B1C4C3 region is not fully established[7].

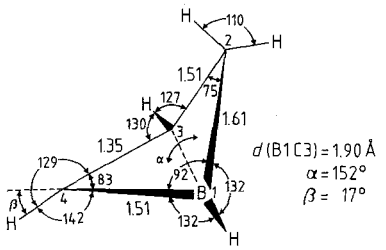


Fig. 1. Calculated structural parameters for the 1,2-dihydroborete **2a** (all values obtained from 6-31G* calculations; bond lengths [Å], bond angles [°]). The fold angle α is the angle between planes B1C2C3 and C3C4B1. Angle β measures the deviation of the bond vector C4H from the plane B1C4C3. Further parameters: B1H = 1.19, C4H = 1.07, C3H = 1.07, C2H = 1.08 Å, ∢ C2C3C4 = 103°.

The degree of 1,3-interaction can be determined by analysis of the one electron density distribution $\rho(r)$[8]. In proceeding from **2b** to **2a**, $\rho(r)$ between B1 and C3 increases by 20%; at the same time, the gross electron population at B1 and C3 grows, while that at C4 decreases. Although accumulation of $\rho(r)$ in the X1C3 region (X = B) is substantial, it is less than in **1a** (X = $C^{\oplus}$). This result, together with the inversion barrier calculated for **2a**, is an index for the 1,3-interaction, which is weaker than in **1**. In contrast to the homotropylium ion[8], accumulation of $\rho(r)$ between the interacting atoms in **1** and **2** does not lead to a saddle point in the electron density distribution[9].

In terms of an exactly defined model for homoconjugation based on the properties of $\rho(r)$, neither **1** nor **2** involve completely extended homoaromatic 1,3-bonding[8]; however, if the term *homoaromaticity* is used merely qualitatively to signify a change in structural and spectroscopic properties relative to those of a given reference state, without intending to specify quantitatively the difference between bonding and nonbonding 1,3-interactions, then both **1** and **2** can be described as homoaromatic[10].

Preliminary calculations with a minimal basis set (HF/STO-3G[11]) on the spirocyclic 1,2-dihydroborete **3**, several derivatives of which have recently been synthesized[12], also indicate a nonplanar structure for the dihydroborete ring (Fig. 2).

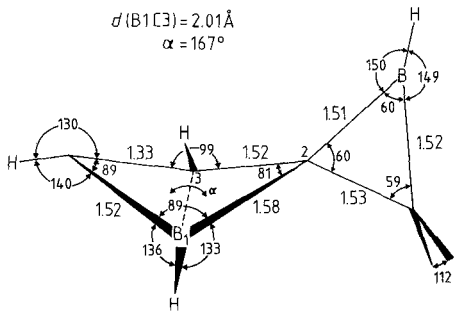

Fig. 2. HF/STO-3G parameters for the spirocyclic 1,2-dihydroborete **3** (bond lengths [Å], bond angles [°]). The fold angle α is the angle between the planes B1C2C3 and C3C4B1. Further parameters: B1H = 1.16, C3H = 1.09, C4H = 1.08, B5H = 1.15, C6H = 1.08 Å, ∢ C2C3H = 128, ∢ C4C3H = 132, ∢ B1C2B5 = 134, ∢ C3C2B5 = 131, ∢ B1C2C6 = 131, ∢ C3C2C6 = 129°.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *P. H. M. B.* thanks the Netherlands Organization for the Advancement of Pure Research (Z. W. O.) for support.

Since the endocyclic angle at C2 in **3** is strongly compressed, forcing the B1C2C3 angle to widen, the nonplanarity of **3** represents further evidence for the presence of strong 1,3-interactions in compounds of type **2**.

[9] In all molecules investigated to date (ca. 100), a saddle point in the electron density distribution $\rho(r)$ occurs between the bonded atoms, i.e. $\rho(r)$ possesses a minimum at a point between the atomic nuclei along the nuclear-nuclear axis, but has a maximum value for all directions perpendicular to this. Such a saddle point for $\rho(r)$ does not occur between the nonbonded atoms. This therefore suggests that the presence of a saddle point in $\rho(r)$ is associated with a chemical bond [8, 10].

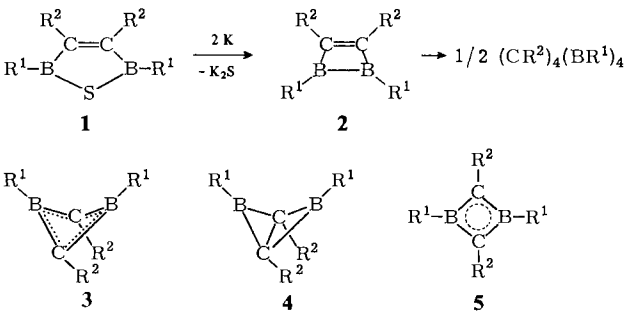
Synthesis and Structure of a 1,3-Dihydro-1,3-diborete**

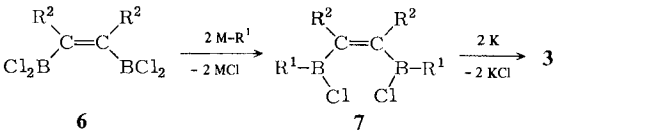
By *Manfred Hildenbrand, Hans Pritzkow, Ulrich Zenneck,* and *Walter Siebert**

We have postulated that desulfuration of the 2,5-dihydro-1,2,5-thiadiborole **1** (R^1 = Me, R^2 = Et) with potassium proceeds via an intermediary labile $(CR^2)_2(BR^1)_2$-molecule **2** which subsequently dimerizes to the *nido*-carbaborane $(CR^2)_4(BR^1)_4$[1]. However, attempts to stabilize the intermediate using electronically effective substituents in **1** only led to the formation of colored anions $\mathbf{1}^{\odot\ominus}$ and $\mathbf{1}^{2\ominus}$ (R^1 = OEt, O*i*Pr, OPh, Ph; R^2 = Et)[2].



1 **2** **3** **4** **5**

We report here on the first 1,3-dihydro-1,3-diborete **3a** (R^1 = NMe_2, R^2 = *t*Bu) whose structure has been elucidated by X-ray crystallography, and thus confirm the results of ab initio calculations[3] which indicate that the puckered four-membered ring **3** should be the most stable of the $(CR^2)_2(BR^1)_2$-isomers **2**–**5** (R^1 = R^2 = H). Reaction of B_2Cl_4 with 2,2,5,5-tetramethyl-3-hexyne (di-*tert*-butylacetylene) yields the *cis*-3,4-bis(dichloroboryl)-3-hexene derivative **6a** (R^2 = *t*Bu; yield 83%), which reacts with Me_3SiNMe_2 to give **7a** (R^1 = NMe_2, R^2 = *t*Bu; yield 70%). Dehalogenation of **7a** with K/Na in benzene (80°C, 75 h) leads to the formation of the colorless, relatively air-stable 1,3-dihydro-1,3-diborete **3a** (m.p. 68–70°C) in 65% yield.



6 **7**

The spectroscopic data[4] are consistent with the structure **3**. Since no C=C stretching vibration is observed in the Raman spectrum, and according to the NMR data (^{1}H, ^{13}C) the *N*-methyl groups are equivalent, a 1,2-dihydro-1,2-diborete **2** can be ruled out. In the ^{13}C-NMR spectrum, the signal for the ring C-atoms occurs at δ = 90.8, which is inexplicable in terms of either "unsaturated" (in **2**, cf. also **6a**) or "saturated" C-atoms (in the 2,4-diborabicyclobutane **4**); the chemical shift lies between those of the tetra-*tert*-butyl derivatives of cyclobutadiene (δ = 152.70) and tetrahedrane (δ = 10.20)[5]. On the basis of the ^{11}B-NMR spectrum (δ = 33.0), a diboratetrahedrane (as the first member of the *closo*-carbaboranes $(CH)_2(BH)_n$ with 10 skeletal electrons) can also be ruled out; the chemical shift, compared to that of other diorganoaminoboranes[6], suggests partial π-character in the BN and BC bonds. The ^{1}H-NMR spectrum shows no change in the singlets of the Me_2N and Me_3C substituents (δ = 2.92 and 1.11, respectively) in the temperature range −93 to +90°C. The mass spectrum shows the isotopic patterns expected for the molecular ion and the main fragments; a fragment with half the molecular mass is not observed. Reduction of **3a** with potassium in tetrahydrofuran yields a radical anion which shows a broad septet in the ESR spectrum (g = 2.0029, $a(^{11}B)$ = 10.3 G). This radical disappears after a short time at 20°C. An electrochemical reduction could not be achieved in CH_2Cl_2 up to −2.3 V.

Recently, on reacting di-*tert*-butylacetylene with $MeBBr_2$ and C_8K a mixture of products containing not only the corresponding borirene but also the 1,3-dihydro-1,3-diboretes **3b** and/or **5b** (R^1 = Me, R^2 = *t*Bu) has been obtained[7]. Other derivatives[8] give almost identical spectroscopic data as **3a**.

The X-ray structure analysis[9] shows a puckered ring structure for **3a**, which is in agreement with the calculations made for $(CH)_2(BR^1)_2$, R^1 = H[3] or NH_2[12]. A comparison with tetra-*tert*-butylcyclobutadiene shows that the bulky substituents in **3a** cannot be responsible for the strong puckering of the ring[10]. The molecule exhibits C_{2v} symmetry, and only the methyl groups deviate slightly

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by BASF AG.

therefrom (Fig. 1). The angle between the normals to the two planes through C1,B1,C2 and C1,B2,C2 is 52° (calculated values[3] 54.9, 48.2°). The dimethylamino groups lie almost in these planes (deviation 2–3°, calculated 5 and 6°), whereas the *tert*-butyl groups are shifted towards each other by about 12° (calculated 11.4 and 12.1°) from the planes through B1,C1,B2 and B1,C2,B2.

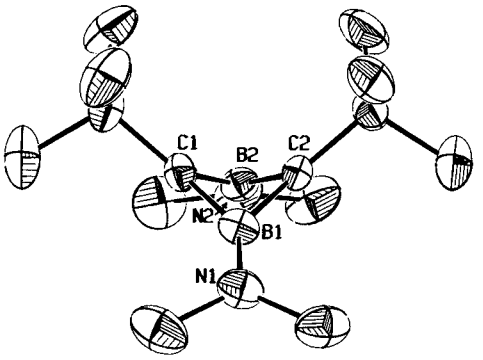

Fig. 1. Molecular structure of **3a** in the crystal. Vibrational ellipsoids correspond to 30% probability. Important distances [Å] and angles [°] (standard deviations 0.005 Å and 0.2°, resp.): C1–B1 1.501, C1–B2 1.503, C2–B1 1.505, C2–B2 1.506, C1–C2 1.814, N1–B1 1.415, N2–B2 1.404; B1–C1–B2 91.8, B1–C2–B2 91.6, C1–B1–C2 74.2, C1–B2–C2 74.2.

Due to the puckering, the C1–C2 distance in **3a** is reduced to 1.81 Å (calculated[3] 1.75 and 1.86 Å), while the B1–B2 distance of 2.16 Å is not much greater than in the planar ring **5**. The B–C distances of 1.50–1.51 Å (calculated[3] 1.48 and 1.51) are about 0.05 Å shorter than for single bonds. This suggests π-character in the four BC bonds, for which there are only two π-electrons available. On the basis of our findings (B–C 1.51, C···C 1.81 Å; $\delta(^{13}C)=90.8$) we favor a non-planar formulation **3** with delocalized π electrons rather than a diborabicyclo[1.1.0]butane structure **4**, for which C–C 1.40–1.50, B–C 1.55 Å and $\delta(^{13}C)=0$–20 are to be expected.

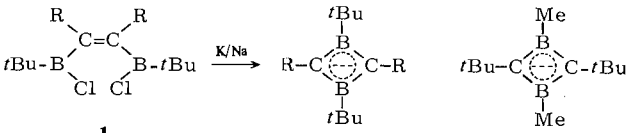
1,3-Dihydro-1,3-diboretes and Their Radical Anions**

By *Rolf Wehrmann, Christine Pues, Hartmut Klusik,* and *Armin Berndt**

1,3-Dihydro-1,3-diboretes **2** are derivatives of the, according to ab initio calculations, lowest energy $C_2B_2H_4$ system[1]. Experimentally, the 2,4-di-*tert*-butyl-1,3-dimethyl derivative **2e** was previously obtained in admixture with other compounds[2]. We report here on novel routes to 1,3-dihydro-1,3-diboretes and on their radical anions, which are isoelectronic with radical cations of cyclobutadienes[3].

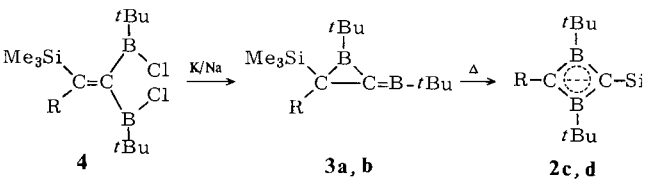
The derivative **2a**, isomeric with **2e**, can be prepared by reaction of the 1,4-dichloride **1a**[4a] with K/Na alloy in pentane. The analogous reaction of **1b**[4a] leads to **2b**[4b].



1 **2a, b** **2e**[2]

a: R = Me; **b**: R = Et

The derivative **2c** is formed in admixture with **3a** on reacting the 1,3-dichloride **4a**[4a] with K/Na alloy in boiling pentane. Heating the mixture to 170°C leads to isomerization of **3a** to **2c**. Correspondingly, **3b**[5] isomerizes to **2d** at 170°C ($\Delta G^{\ddagger}_{3\to 2}\approx 34$ kcal/mol).



4 **3a, b** **2c, d**

a, c: R = CH_2-*t*Bu; **b, d**: R = $SiMe_3$

The structure of the new compounds **2a**–**2d**[6] follows from the ^{1}H-, ^{13}C- and ^{11}B-NMR spectra and the Raman and mass spectra. The fragment ions with half the molecular mass observed in the mass spectra of **2e** (rel. int. 34%)

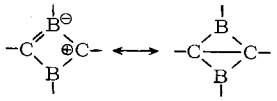
do not appear in the spectra of **2c** and **2d**, and only weakly in the spectra of **2a** and **2b** (rel. int. 2.6 and 1.4%, respectively). Since the Raman spectra of **2a—2d** do not contain bands in the region for CC double bonds, the structure of the isomeric 1,2-dihydro-1,2-diboretes can be ruled out.

Table 1. NMR shifts (δ values, $CDCl_3$) of the skeletal atoms of **2a—2d** and ESR coupling constants (in $G = 10^{-4}$ T) of the corresponding radical anions ($g = 2.0028$).

Cpd.	**2a**/**2a**$^{\odot\ominus}$	**2b**/**2b**$^{\odot\ominus}$	**2c**/**2c**$^{\odot\ominus}$	**2d**/**2d**$^{\odot\ominus}$	**2e** [2]
$\delta(^{11}B)$	41.2	40.3	42.4	45.0	35.9 or 38.5 [7]
$\delta(^{13}C)$	124.8	126.2	105.9 107.7	81.5	127—133 [2] 86.9 [7]
$a(^{11}B)$	9.5	9.4	9.4	8.9	—
$a(H)$	14.3	11.7	7.8	—	—
$a(^{29}Si)$	—	—	8.8	7.0	—

The chemical shifts for the boron and carbon atoms in the ring skeleton of **2** (Table 1) rule out the structure of a 2,4-diborabicyclobutane, for which $\delta(^{11}B) \approx 80$—as in the case of boriranes[5]—and $\delta(^{13}C) \approx 10$—as in the case of bicyclobutanes[8]—are to be expected. The shielding of the boron atoms reflects the π-charge density corresponding to **A** (one of four equivalent resonance formulas), while the shielding of the ring C-atoms compared to systems with partial positive charge on the carbon atom (1-*tert*-butylborirenes: $\delta(^{13}C) \approx 185$[9a], homoborirenes: $\delta(^{13}C) \approx 190$[9b]) reflects a 1,3-interaction corresponding to **B**.



A **B**

This interaction has been predicted theoretically[1], and the puckering of the ring associated with it has been experimentally confirmed by an X-ray structure analysis of the 2,4-di-*tert*-butyl-1,3-bis(dimethylamino)-1,3-dihydro-1,3-diborete[10]. The increase in shielding of the ring C-atoms on successive replacement of alkyl by trimethylsilyl substituents is indicative of an increasing 1,3-interaction, and thus also of the puckering as a result of increasing steric hindrance.

The 1,3-dihydro-1,3-diboretes **2a—2d** can be reduced to radical anions with K/Na alloy in dimethoxyethane/tetrahydrofuran. The large ESR coupling constant of the methyl protons in **2a**$^{\odot\ominus}$ (14.3 G; cf. 26.9 G in $^{\circ}CH_2CH_3$) indicates that the unpaired electron resides almost exclusively on the carbon atoms of the ring. The large ^{11}B-coupling constants compared to those in **5**$^{\odot\ominus}$ ($a(^{11}B) = 1.2$ G)[11] must, therefore, be essentially due to spin polarization as a result of high spin density on C^2 and C^4, and must have negative signs. The electronic structure of the radical anions **2a**$^{\odot\ominus}$—**2c**$^{\odot\ominus}$ is thus described in terms of **C** (one of the four equivalent resonance formulas), 1,3-interaction corresponding to formulation **D** is not involved, the radicals are planar.

According to calculations[3a,12], the radical cations **6**$^{\odot\oplus}$ of cyclobutadienes, which are isoelectronic with **2**$^{\odot\ominus}$, are also planarized compared to the puckered dications **6**$^{2\oplus}$[13]. Strong steric hindrance leads to puckering and 1,3-interaction: The increase of $a(^{11}B)$ from -9.4 to -8.9 G and the decrease of a (^{29}Si) to 7.0 G in **2d**$^{\odot\ominus}$ compared to 8.8 G in **2c**$^{\odot\ominus}$ indicate a shift of spin density from the carbon to the boron. A four-membered ring structure deviating from planarity is also assumed for the strongly sterically hindered radical cation of tetra-*tert*-butylcyclobutadiene[3a].

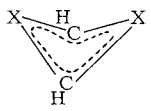
Puckered Structures of 1,3-Dihydro-1,3-diboretes and Bicyclobutane-2,4-dione: Nonplanar Hückel 2π-Electron Aromatic Molecules**

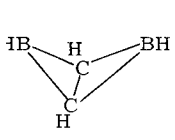
By *Paul von Ragué Schleyer**, *Peter H. M. Budzelaar*, *Dieter Cremer*, and *Elfi Kraka*

Krogh-Jespersen's[1a] calculational discovery that the cyclobutadiene dication prefers a puckered **1** rather than a planar structure initiated interest in the isoelectronic 1,3-dihydro-1,3-diborete **2**. Ab initio molecular orbital theory predicted a nonclassical folded geometry for this molecule as well[1b].

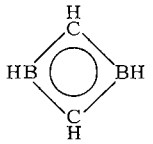


1, X = $CH^{\oplus}$
2, X = BH

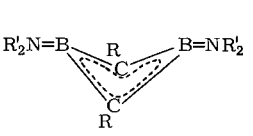
Structure **2**, calculated (4-31G basis set) to have an unusual C–C distance of 1.86 Å, was favored over classical **3** and planar Hückel 2π aromatic **4** alternatives. The repulsive 1,3-interactions in **4** are reduced or eliminated in **2**. Due to orbital mixing, other electronic features of **2** are also more favorable than those in **4**[1b].



3

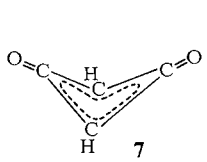


4

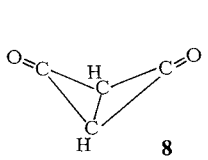


5, R = $C(CH_3)_3$, R' = CH_3
6, R = R' = H

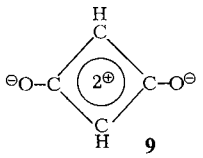
Quite recently the first syntheses of 1,3-dihydro-1,3-diborete derivatives were achieved in three different laboratories[2–4], and the first X-ray determination carried out. *Siebert*'s puckered structure of **5**[4] is in remarkably close agreement with our 1981 predictions of **2** (Table 1). Thus the experimental distance, 1.81 Å, is much longer than the normal C–C bond length found in bicyclobutane (1.50 Å)[5]. The short exocyclic BN bonds in **5** (1.41 Å) indicate considerable B=N double bond character. Nevertheless, the very good π-donor $N(CH_3)_2$ substituents in **5** evidently alter the geometry of **2** only to a small extent. To examine this matter further, we have now calculated the structure of **6**, a simple analog of **5**, with the 3-21G basis set[6]. The geometry of **2** was redetermined at that level. The work has been further extended to the isoelectronic "organic" counterpart of **6**, bicyclobutane-2,4-dione **7**.



7



8



9

As can be seen from the data collected in Table 1, the calculated structure of **6** agrees even more closely than that of **2** with the experimental structure of **5**[4]. The long C···C and the B=N distances are essentially identical, and the calculated puckering angle, α, is only 4° smaller than the experimental value. In view of the bulky substituents in **5**, better agreement could hardly be expected.

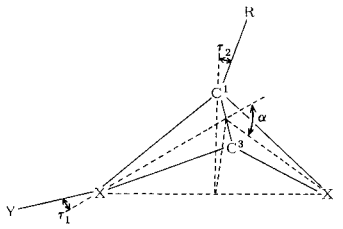


Table 1. Comparison of calculated and experimentally determined structures.

Compound	Data source [a]	Distances [Å] $C^1\cdots C^3$	C^1-X	Angles [°] HCC	α	τ_1	τ_2
1 (D_{2d})	4-31G opt. [1a]	1.973	1.431	160.6	35.8		1.5
	6-31G* opt. [1a]	1.928	1.414	157.1	42.6		1.6
2 (C_{2v})	STO-3G opt. [1b]	1.754	1.477	140.6	54.9	6.2	7.4
	4-31G part. opt. [1b]	1.858	1.510	141.0	48.2	5.2	11.4

5	exp. [4]	1.814	1.504 [c]	52		2–3	12
6 (C_{2v})	3-21G opt.	1.794	1.528 [d]	133.9	48.4	6.4	16.7
7 (C_{2v})	3-21G opt.	1.762	1.464 [e]	139.4	45.8	6.9	13.3
Bicyclo-butane	exp. [5]	1.497	1.498	128.3	58.3	−0.7	11.5
	3-21G opt.	1.484	1.513	134.7	61.8	1.4	3.0
	6-31G* opt. [f]	1.466	1.489	132.5	59.9	1.4	6.0

[a] The basis sets used for geometry optimizations are indicated. STO-3G is a minimal basis, 3-21G and 4-31G split valence bases, and 6-31G* a polarization basis. The accuracy of the results obtained at these levels are generally expected to increase in the order given. [b] T. Clark, unpublished. [c] BN distance 1.410 Å av. [d] BN distance 1.403 Å, CH 1.075, NH 1.000 Å; angles, BNH 122.6°; CBNH 171.8°. [e] CO distance 1.196 Å (in **9** 1.208 Å), CH 1.066 Å. [f] For 4-31G and 6-31G* geometries see K. B. Wiberg, *J. Am. Chem. Soc. 105* (1983) 1227.

The donation of ca. 0.2π electron from nitrogen to boron in **6** only results in a decrease of ca. 0.04 e in the C→B donation. The inversion barrier though the planar structure increases by 4 kcal/mol (**2** vs **6**) as a consequence, but the other effects are small. Because of the electropositive character of boron, other electronegative substituents (like OR or F) also are not expected to alter the geometry appreciably.

We now predict that bicyclobutane-2,4-dione **7**[7], like **1**, **2**, **5**, and **6**, will also prefer a nonclassical folded structure (Table 1). The 3-21G optimized central C1···C3 distance in **7** (1.76 Å) excludes the classical formulation **8**. This distance is halfway between that in bicyclobutane (1.50 Å)[5] and that calculated for planar **9** (2.01 Å). Analysis of the electron distribution $\rho(r)$ reveals a considerable build-up of negative charge between C1 and C3 in going from **9** to **7**. The properties of $\rho(r)$ in **7** are typical for a situation preceding the formation of a C–C bond[8]. The C–O electronegativity difference is nearly the same as that between B

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *P. H. M. B.* expresses his gratitude for a Fellowship sponsored by the Netherlands Organization for the Advancement of Pure Research (Z. W. O.). We thank Dr. *T. Clark* for the 3-21G calculations of **2** and general assistance.

and N; the bonding situations in **6** and **7** are rather similar.

As suggested by the formal structure **9**, a planar form would be expected to benefit from the Hückel 2π character of the four-membered ring. Nevertheless, **9** is 14.6 kcal/mol less stable than **7** with the larger 6-31G* basis set (13.2 kcal/mol; 3-21G). The inversion barrer for **6** is indicated to be even larger, 20.6 kcal/mol (6-31G*//3-21G; 18.4 kcal/mol, 3-21G). According to the properties of $\rho(r)$, electron delocalization in puckered **6** and **7** is still large and is supported by the now favorable 1,3-interaction. Both π and σ effects contribute to the stability of the puckered forms[1]. Once again, our calculational observations emphasize that an aromatic 2π electron ensemble does not necessarily imply planarity of a four-membered ring like **1**, **2**, **5**, or **6**.

Our results on **7** are pertinent to a large number of squaric acid derivatives, e.g., the "squaraines" ("quadrains")[7]. While examples with good π donor substituents are planar[9], we are attempting to find cases with non-planar structures. Groups with C=N or C=C double bonds[10] when substituted at C2 and C4 of bicyclobutane may also lead to partially opened structures like **7** with elongated C1–C3 bonds[11].

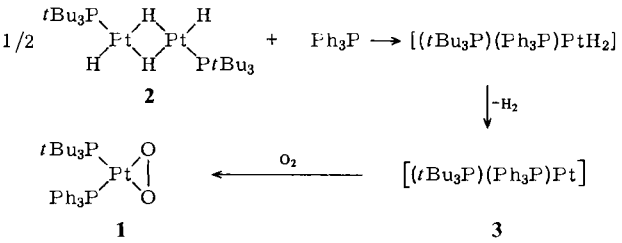
Novel Synthesis of an Unsymmetrical $Pt(\eta^2\text{-}O_2)$ Complex

By *Anil B. Goel** and *Sarla Goel*

Studies of the nature of the bonding in $M(\eta^2\text{-}O_2)$ complexes (M = low-valent platinum group metal) and the reactivity of the η^2-dioxygen ligand have received considerable interest[1,2]. To the best of our knowledge, all these systems deal with the symmetrical complexes and no low-symmetry platinum dioxygen complex with dissimilar ligands has ever been reported. Low-symmetry complexes of platinum metals and ligands having different electronic and steric parameters should be useful in studying the *trans*-effect of the ligands, asymmetric synthesis, and homogeneous catalysis[3]. Here, we report the isolation of the first unsymmetrical square-planar $(\eta^2\text{-}O_2)$-platinum complex containing mixed phosphane ligands, $[t\mathrm{Bu_3P}(\mathrm{Ph_3P})\mathrm{Pt}(\eta^2\text{-}O_2)]$ **1**.

Our initial attempts to synthesize unsymmetrical complexes $LL'Pt(\eta^2\text{-}O_2)$ by successive reduction of $PtCl_2(L)(L')$ and reaction with oxygen resulted in excessive decomposition (for sterically less bulky phosphanes, cone angle $\leq 130°$) and gave a mixture of two symmetrical complexes (L_2PtO_2 and L'_2PtO_2). Interestingly, the addition of one equivalent of Ph_3P per Pt atom to a solution of the hydrido-bridged dinuclear platinum complex **2**[4] in benzene resulted in a vigorous reaction with evolution of H_2. The solution, which presumably contained the Pt^0 complex **3**, yielded the desired unsymmetrical complex **1**[5,7] upon exposure to air.



The IR spectrum of **1** shows a medium intensity band at ca. 838 cm^{-1} due to $\nu(O_2)$. The ^{1}H-NMR spectrum (60 MHz, $CDCl_3$, 25 °C) exhibits, in the ratio 9:5, a doublet from the *tert*-butyl groups ($\delta = 1.31$, $J_{PH} = 12.7$ Hz) and two multiplets from the phenyl groups centered at $\delta = 7.38$ (*m*-, *p*-protons) and $\delta = 7.7$ (*o*-protons) in the ratio 3:2). The ^{31}P-NMR spectrum (24 MHz, CH_2Cl_2/C_6D_6, 25 °C) shows two singlets at $\delta = 72.4$ ($t\mathrm{Bu_3P}$) and $\delta = 9.85$ (Ph_3P) with Pt satellites ($K_{Pt,P} = 3940$ and 4443 Hz, respectively), consistent with a *cis*-disposition of the two phosphanes.

$Pt(\eta^2\text{-}O_2)$ complexes are known to react with electrophilic olefins to form the related cycloadducts $L_2PtOOCR_2CR'_2$ via formal Michael addition of a ring-opened platinum peroxide[2a]. However, reaction of complex **1** with electrophilic acetylenes, e.g. dimethyl acetylenedicarboxylate (dma) in benzene, yields the five-membered metallacycle **4**[8] by unique rupture of the O–O bond (supporting evidence—disappearance of IR band at 838 cm^{-1} [$\nu(O_2)$] and appearance of 1580 cm^{-1} band [$\nu(C{=}C)$])[2b].

1 4

The ^{1}H-NMR spectrum (60 MHz, $CDCl_3$, 25 °C) exhibits two singlets from the methyl ester groups ($\delta = 3.42$ and 3.70) arising from the nonequivalent methyl groups (different *trans*-effects). Upon hydrolysis with trifluoroacetic acid **4** affords dimethyl dihydroxymaleate in ca. 35% yield. The structure of a diolate complex similar to **4**, obtained by reaction of $[(cyclo\text{-}C_6H_{11})_3P]_2PtO_2$ with dma, has been confirmed by X-ray crystal structure analysis[6].

Silver-Catalyzed Formation of Crown Ethers; Synthesis and Structure of $[Ag([12]crown\text{-}4)_2][AsF_6]$**

By *Peter G. Jones*, Thomas Gries, Hansjörg Grützmacher, Herbert W. Roesky, Jürgen Schimkowiak,* and *George M. Sheldrick*

Dedicated to Professor Werner Schultheis on the occasion of his 80th birthday

Few isolable complexes of Ag^I with oxygen ligands have been reported[1]. The formation of crown ethers from ethylene oxide in the presence of cations and Lewis acids was known[2], but no crystalline silver complex had been described. We recently succeeded in obtaining the crystalline complex $[(CH_2O)_6Ag_2][Ag][AsF_6]_3$ by reaction of $(CH_2O)_3$ with $AgAsF_6$ and in determining its structure; it contains a macrocyclic $(CH_2O)_6$-ring[3].

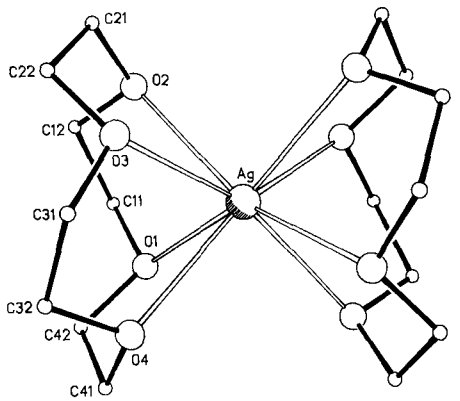

Fig. 1. Structure of the $[Ag([12]crown\text{-}4)_2]^{\oplus}$ cation. Crystal data of the AsF_6 salt: space group $C2$, $a = 1047.1(3)$, $b = 1153.9(3)$, $c = 980.1(3)$ pm, $\beta = 91.83(3)°$, $Z = 2$, $R = 0.070$ for 1854 absorption-corrected reflections with $F > 4\sigma(F)$. Silver and arsenic atoms lie on the twofold axes 0, y, $\frac{1}{2}$ and 0, y, 0 respectively. The average Ag–O bond length is 257 pm. The structure determination was made more difficult by the fact that the positions of the Ag, As, and F atoms all correspond to the centrosymmetric space group $C2/m$. Further details of the crystal structure can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the deposition number CSD 50760, the names of the authors, and the journal citation.

We have now found that reaction of $AgAsF_6$ with ethylene oxide in liquid SO_2 leads to a crystalline complex of composition $[Ag(OCH_2CH_2)_8][AsF_6]$ **1**[4]. The crystal structure analysis of **1** (Fig. 1) shows a "sandwich" structure with eight-coordinated Ag^I. The coordination geometry at silver corresponds to that of a cube, two opposite faces of which are rotated through ca. 30°. (A 45° rotation would give rise to an Archimedean antiprism.) The ligands are two molecules of 1,4,7,10-tetraoxacyclododecane ([12]crown-4)[5] with non-crystallographic C_4 symmetry (torsion angles g^+g^+a in the O–C–C–O moieties[6]). This conformation is known for other complexes of [12]crown-4[6].

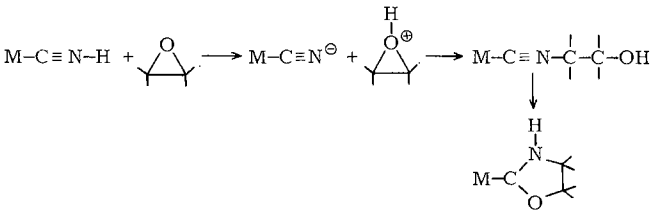
Reactions of the Cyanometal Acids $H_4M(CN)_6$ (M = Fe, Ru, Os), $H_2Pt(CN)_4$, and $HAu(CN)_2$ with Epoxides: β-Hydroxyalkyl Isocyanide- and Oxazolidine-2-ylide-Metal Complexes**

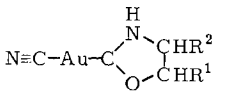
By *Wolfgang Beck**, *Wolfgang Weigand, Ulrich Nagel,* and *Matthias Schaal*

"Cyanometal acids" such as $H_4Fe(CN)_6$ are classical complexes in which isohydrocyanic acid, the parent compound of the isocyanides, is stabilized as a ligand at the metal atom (M–C≡N–H). In the solid state these compounds contain hydrogen bonds of the type M–C≡N–H...N≡C–M[1]. As early as 1901, *von Baeyer* and *Villiger*[2] investigated the reaction of $H_4Fe(CN)_6$ with ethylene oxide in connection with studies of the "basic properties of oxygen". The ice-like product obtained was initially held to be a hydrate of ethylene oxide, and its more precise characterization was postponed until a "cooler time of the year"[2].



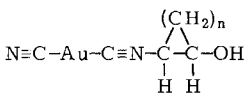
Since the reaction of $H_4Fe(CN)_6$ with α,β-unsaturated carbonyl compounds leads to novel γ-oxoisocyanide complexes[3], we were interested in the reaction of cyanometal acids with electrophiles. We have now found that with epoxides under heterogeneous conditions (in $CHCl_3$), metal complexes are formed with β-hydroxyalkyl isocyanide- or oxazolidine-2-ylide ligands. Ring cleavage is effected by attack of the nucleophilic N atom of a cyano group at the *O*-protonated oxirane[4].

In this way, the carbene complexes **1a** or **1b** are formed from $HAu(CN)_2$ and propene oxide or styrene oxide.



1a: R^1 = Me, R^2 = H
1b: R^1 = H, R^2 = Ph

In contrast, reaction with cyclopentene and cyclohexene oxides affords complexes **2a** and **2b**, respectively, with open-chain β-hydroxyalkyl isocyanide ligands. Ring opening proceeds *trans*-diaxially in these bicyclic epoxides[5], and hence with **2a**, **b** precludes ring closure to the oxazolidine derivatives.



2a: n = 3
2b: n = 4

Fehlhammer et al. obtained a series of complexes with ligands such as in **1** and **2** directly from β-hydroxyalkyl isocyanides and metal compounds[6]. Complexes of the type XAu(carbene) have been isolated using other routes, as described by *Bonati* et al. as well as by *Fischer* et al.[7]. The structures of **1** and **2** have been corroborated by spectroscopic data (Table 1 and 2).

Table 1. Characteristic IR bands [cm^{-1}] for complexes **1**–**3** (in KBr).

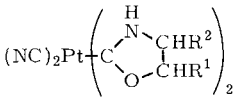
[**] Pseudohalometal compounds, Part 63. This work was supported by the Fonds der Chemischen Industrie as well as by Bayer AG, Leverkusen, BASF AG, Ludwigshafen, Hoechst AG, Gendorf, and Chemische Werke Hüls, Marl.—Part 62: W. Beck, H. Nöth, *Chem. Ber. 117* (1984) 419.

The 1,3-oxazolidine ring is completely planar (±1 pm) and the Au atom is only 13 pm above this plane, i.e. the carbene C atom has practically a trigonal-planar environment.



3a: R^1 = Me, R^2 = H
3b: R^1 = H, R^2 = Ph

The bis(carbene) complexes **3a** and **3b** were synthesized from $H_2Pt(CN)_4$ and propene or styrene oxides, respectively. In the IR spectrum (Table 1), **3a** exhibits one ν(CN) band and **3b** two ν(CN) bands corresponding to the *trans*- and *cis*-configurations, respectively.

The reactions of epoxides with the hexacyanometal acids $H_4M(CN)_6$ of iron, ruthenium, and osmium are more complex. As indicated by HPLC analysis [reversed phase C_{18} column, eluent EtOH/H_2O (7:3), UV detection (λ = 260 nm)], a mixture of at least seven complexes with similar product distribution for the Fe^{II}, Ru^{II}, and Os^{II} compounds is formed in reactions with styrene oxide. Elemental analysis indicates that 1.2—1.5 ethylene oxide moieties are added on average per CNH moiety, i.e. oligo(ethylene glycol) groups such as

also form at the isocyanide ligand.

In the mass spectrum of the iron complex obtained with styrene oxide, $[FeCNCH(Ph)CH_2O]^{\oplus}$ appears as the ion with the highest mass (*m/z* 202) [IR (KBr); 3280 br, ν(OH); 2150, ν(CNR); 2085 cm^{-1}, ν(CN)].

The reactions described here of the MCNH group with epoxides to afford carbene complexes are comparable to those of carbonylmetal compounds with three-membered heterocycles (epoxides, aziridine), which also lead to cyclic carbene ligands[9]. However, in the latter case, nucleophilic attack of the hetero-ring atom at the carbonyl carbon atom has been postulated.

$[Cu_5I_7]^{2\ominus}$—An Isopolyanion with Cyclic Face-to-Face Linking of CuI_4 Tetrahedra**

By *Hans Hartl** and *Farbod Mahdjour-Hassan-Abadi*

In our studies on iodocuprates(I) $R_mCu_nI_p$ with various organic cations $R^{\oplus}$ we demonstrated the existence of a series of unusual polyanions[1a,b]. Further investigations with tetra-*n*-propylammonium as cation have now revealed the existence not only of a binuclear planar anion $[Cu_2I_4]^{2\ominus}$[1c] and a polymeric chain-like anion $^1_\infty[Cu_3I_4]^{\ominus}$[1b] but also of an oligomeric anion $[Cu_5I_7]^{2\ominus}$ with a fascinating structure: seven $I^{\ominus}$ ions form a pentagonal bipyramid with only slight deviations from C_{5h} symmetry; the five face-to-face linked iodide tetrahedra of the pentagonal bipyramid contain Cu^I ions (cf. Fig. 1).

Following the successful synthesis of $R^1_\infty[Cu_2I_3]$ (R = $[(C_2H_5)_4N]^{\oplus}$ or $[(CH_3)_2N{=}CH{-}N{=}CH{-}N(CH_3)_2]^{\oplus}$)[1a] and $[(C_3H_7)_4N]^1_\infty[Cu_3I_4]$[1b] with unusual face-to-face linking of two and three CuI_4 tetrahedra, respectively, an iodocuprate(I) with five cyclic condensed CuI_4 tetrahedra could be isolated in $[(C_3H_7)_4N]_2[Cu_5I_7]$ **1**[2].

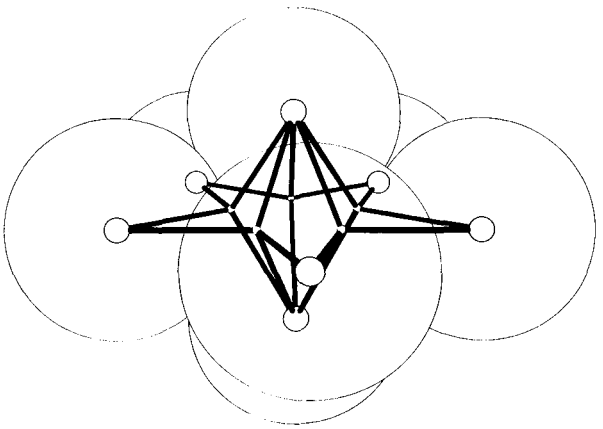

Fig. 1. Structure of the $[Cu_5I_7]^{2\ominus}$ anion in the crystal of **1** (idealized).

A pentagonal bipyramid can be regarded as a section of a centered icosahedron and is a structural unit which frequently occurs in the $AgI/I^{\ominus}$ system[3], but which has also been found in a halocuprate(I), $[pyH]_2[Cu_5Br_7]$[4]. In this compound, however, the pentagonal bipyramids of $Br^{\ominus}$ ions are not isolated, but are linked together edge-to-edge in a three-dimensional arrangement. As a result, additional tetrahedral cavities are formed; the Cu^I ions are statistically distributed with different population parameters over the greater number of tetrahedral cavities. $[pyH]_2{}^3_\infty[Cu_5Br_7]$ is a solid state ion-conductor. In contrast, only five tetrahedral vacancies are available for the five Cu^I ions in **1**. The Cu atoms are not located exactly in the centers of the tetrahedra, since this arrangement would lead to extraordinarily short distances d_{Cu-Cu} = 0.41 × length of tetrahedron edge ≈ 185 pm[5]; they are therefore dislocated in the direction of a tetrahedron face, above or below the plane of the

I_5 ring. The temperature factors of the Cu atoms showed unusually large coefficients for the direction perpendicular to the plane of the I_5 ring; this anisotropy disappeared on refinement of the Cu positions as split atom sites. The alternative population of two crystallographically independent positions within each of the CuI_4 tetrahedra is possible. In three tetrahedra these two possible positions have a distance of approx. 68 pm, in the remaining two tetrahedra a distance of approx. 96 pm (Fig. 2). An alternating distribution of the Cu^I ions at positions above or below the I_5 ring is impossible because of the uneven number of ring members; the arrangement shown in Figure 2 leads to plausible Cu–Cu distances (mean value 258 pm). Each Cu atom shows three short and one longer Cu–I distances. The distances from the Cu atoms to the I atoms of the I_5 ring vary between 251(2) and 257(2) pm (mean value 253 pm), those to the I atoms at the apices of the pyramids between 264(2) and 277(2) pm (mean value 270 pm) and between 314(2) and 342(2) pm (mean value 325 pm), respectively. The intramolecular I–I distances of 416.7(2) between the apices of the pyramids are distinctly shorter than the remaining I–I distances, which vary between 435.8 and 459.3(2) pm (mean value 445 pm).

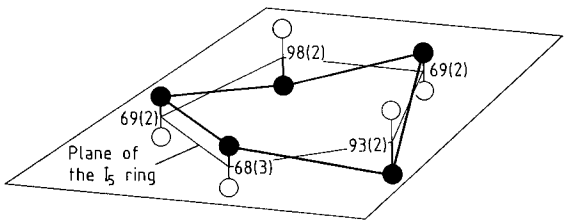

Fig. 2. Distribution of the Cu atoms of the $[Cu_5I_7]^{2\ominus}$ anion over the ten possible split atom positions [6]. The split atoms are located above or below the plane of the I_5 ring. The numerical values indicate the distance between the two possible Cu positions within the respective I tetrahedra; the alternative arrangements—black and white spheres, respectively—enable Cu···Cu contacts of 257–263 pm (mean value 259 pm) and 247–262 pm (mean value 257 pm).

A ring-shaped coupling of five MX_4 tetrahedra in a plane is also found in compounds containing the $^1_\infty[Ag_5I_6]^\ominus$ anion[3a,b]; but here the tetrahedra are linked edge-to-edge, and the rings are additionally linked via common tetrahedron corners to give a column-like structure. A face-to-face linkage of AgI_4 tetrahedra in analogy to $[Cu_5I_7]^{2\ominus}$ is not to be expected for steric reasons ($r(Ag^\oplus) > rCu^\oplus$))[5].

As_4tBu_2—The First Bicyclo[1.1.0]tetraarsane**

By *Marianne Baudler** and *Stefan Wietfeldt-Haltenhoff*

Small-ring compounds have played a major role in preparative nonmetal chemistry for many years. Following the synthesis of the monocyclic arsenic three-membered ring compound $(AstBu)_3$[1] and the bicyclo[3.3.0]octaarsane As_8tBu_6[2], the question arose as to whether also organoarsanes with a bicyclic skeleton of two annelated three-membered rings are capable of existence and whether or not they are isolable. Such compounds would be formally regarded as primary cleavage products of the As_4 tetrahedron. We have now succeeded in synthesizing 2,4-di-*tert*-butylbicyclo[1.1.0]tetraarsane **1**, the first compound with an $As_4(2)$ ring skeleton.

1 is formed in the dehalogenation of a mixture of *tert*-butyl(dichloro)arsane and arsenic(III) chloride with lithium hydride below 0 °C:

$$2\,tBuAsCl_2 + 2\,AsCl_3 + 10\,LiH \longrightarrow \underset{\mathbf{1}}{As_4tBu_2} + 10\,LiCl + 5\,H_2$$

Other products formed in the reaction include monocyclic and chain-shaped *tert*-butylarsanes and, above 0 °C, increasingly polycycles with higher arsenic content. The product pattern is strongly dependent upon the reaction conditions (solvent, temperature, molar ratio and concentration of the reactants, and reaction rate). Under suitable reaction conditions (optimized by ^{1}H-NMR spectroscopic monitoring), **1** can be obtained free of arsenic-containing by-products and, by work-up at low temperature, can be isolated in analytically pure form[3].

At −40 °C, **1** is a reddish-orange to dark-red, moldy smelling solid which is stable in the absence of air and light at −196 °C. It is readily soluble in tetrahydrofuran and in aliphatic and aromatic hydrocarbons; at −78 °C, the solutions slowly undergo decomposition. At room temperature, or when exposed to light, **1** disproportionates to arsenic metal, $(AstBu)_4$, and other *tert*-butylarsanes. **1** is only slightly sensitive to hydrolysis, but extremely sensitive to oxidation. Its composition is confirmed by correct elemental analysis and the mass spectrum (10 eV, 180 °C), in which M^+ (m/z 414) as base peak and a signal group with highest mass numbers are observed. The IR spectrum, un-

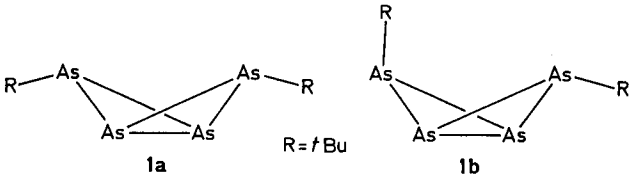
[**] Contributions to the Chemistry of Arsenic, Part 6. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie.—Part 5: M. Baudler, P. Bachmann, *Z. Anorg. Allg. Chem. 485* (1982) 129.

like those of other *tert*-butylarsanes, shows three bands at 400 (s), 371 (s), and 299 (m) cm^{-1}.



1a **1b**

The constitution of **1** follows from the ^{1}H-NMR spectrum ([D$_6$]benzene, 24°C), which shows a singlet at $\delta = 0.91$ for the *tert*-butyl groups. The strong shielding of the ^{1}H-nuclei, which is even greater than in (As*t*Bu)$_3$ ($\delta = 1.16$, 1.41[1]), proves the presence of the highly strained bicyclo[1.1.0]tetraarsane system. Also consistent with the presence of the bicyclo[1.1.0]tetraarsane system are the high- and low-field positions of the singlets for the primary and tertiary C atoms in the ^{13}C{^{1}H}-NMR spectrum ([D$_6$]benzene, 24°C) at $\delta = 23.48$ and 44.03, respectively, which have previously never been observed in the case of a *tert*-butylarsane. Since the NMR spectroscopic findings reveal that the two *tert*-butyl groups are equivalent, it follows that the sterically more favorable *exo/exo*-isomer **1a** (symmetry C_{2v}) is present[4]. Probably, the *endo/exo*-isomer **1b** is also formed initially, but already decomposes under the reaction conditions.

[3] *Procedure:* A solution of *tert*-butyl(dichloro)arsane (9.18 g, 45.2 mmol) and arsenic(III) chloride (8.64 g, 47.7 mmol) in tetrahydrofuran (THF) (60 mL) is cooled to −35°C and added dropwise with vigorous stirring within 4–4.5 h at −35°C to a suspension of lithium hydride (1.96 g, 247 mmol) in THF (60 mL). The mixture is stirred for a further 15 min, rapidly filtered at −35°C, and the solvent removed from the filtrate as quickly as possible in vacuo ($< 10^{-2}$ torr) at the same temperature. The orange-yellow solid residue is treated with 500 mL *n*-pentane and the mixture stirred for 3 h at −78°C. After filtration at −40°C, the residue is washed three times with 20 mL cold pentane, the filtrates are combined, and the solvent is removed at −40°C; yield 4.8 g **1** (51% referred to *t*BuAsCl$_2$), purity 100% (^{1}H-NMR). All operations must be carried out in the absence of air and light.

[4] In principle, the *endo/endo*-isomer would also appear possible, but according to model considerations this can be ruled out.

Synthesis of *N*-(Arylmethylene)dehydroalanine Esters**

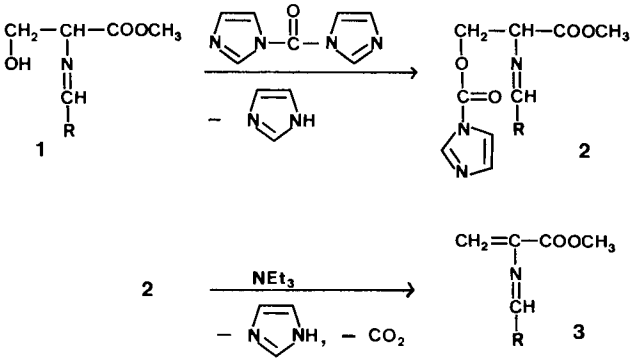
By *Günter Wulff** and *Helmut Böhnke*

Dehydroamino acids play an important role in nature[1]. For example, in the biosynthesis of some amino acids, *N*-pyridoxylidenedehydroalanine is formulated as a reactive intermediate which undergoes Michael additions with nucleophiles. By analogy, *N*-(arylmethylene)dehydroalanine esters could serve as a valuable equivalent for the synthon $^{\oplus}CH_2-CH(NH)_2-COOH$ in a biomimetic synthesis of α-amino acids.

[*] Prof. Dr. G. Wulff, Dipl.-Chem. H. Böhnke
Institut für Organische Chemie II der Universität
Universitätsstrasse 1, D-4000 Düsseldorf (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

Whereas *N*-(arylmethylene)dehydroamino acid esters substituted at the CC double bond are known and are stable[2,3], the preparatively interesting, highly reactive parent compounds (e.g. the *N*-benzylidenedehydroalanine methyl ester **3a**) have previously only been detected in solution by ^{1}H-NMR spectroscopy[3].



a, R = C_6H_5; **b**, R = 4-(C_6H_5)C_6H_4

Using a very straightforward route, we have now succeeded in preparing and characterizing the reactive compounds **3a** and **3b**[4]. **3** was synthesized from the Schiff base of the serine methyl ester **1**[5] by modifying a recently published method[6]: the urethane **2**—detected by ^{1}H-NMR spectroscopy—obtained from **1** and *N,N'*-carbonyldiimidazole—reacts quantitatively (NMR spectroscopy) with triethylamine in a few minutes at room temperature to afford the dehydro compound **3**. After separation of imidazole, **3a** and **3b** can be obtained by crystallization at lower temperature; however, they could be further directly reacted in solution[7].

Whereas upon warming to room temperature **3a** decomposes to a colorless, viscous liquid, **3b** is a white, crystalline solid which can be manipulated at room temperature and can be stored in a refrigerator for some time under an inert gas atmosphere. Compound **3b** is therefore suitable for further studies of the properties of *N*-(arylmethylene)dehydroalanine esters. Under the same experimental conditions, **3b** adds diethylamine ten times faster than the more stable *N*-acetyldehydroalanine methyl ester[8]. A further increase in reactivity can be achieved by introducing substituents into the aryl group[9]. An additional advantage of using compounds of type **3** is that the protecting group for the amine function can readily be removed, e.g. by an equimolar amount of HCl in water/diethyl ether at room temperature.

[4] The ^{1}H-NMR spectrum of **3a** is consistent with that described in [3]. The structure of **3b** was determined by ^{1}H-NMR and mass spectroscopy as well as by elemental analysis.

[5] **1a** was prepared using the method described by J. W. Davis, US-Pat. 3718688 (1973); **1b** was prepared analogously. The structures were determined by ^{1}H- and ^{13}C-NMR spectroscopy as well as by elemental analysis. Although racemic serine can, in principle, also be used L-serine was used on grounds of cost.

[6] R. Andruszkiewicz, A. Czerwiński, *Synthesis 1982*, 986.

[7] *Experimental procedure* using the example of **3b**: **1b** (560 mg, 2.0 mmol) [5] and an equimolar amount of *N,N'*-carbonyldiimidazole were dissolved in 10 mL anhydrous diethyl ether and 2 mL anhydrous tetrahydrofuran under N_2. After addition of 1 mL triethylamine, the mixture was stired for 2–3 min at room temperature, 50 mL cold *n*-pentane added, and the resulting mixture cooled for 30 min at −15 °C and filtered at this temperature. **3b** crystallizes at −90 °C; yield: 325 mg (62%); m.p. (in sealed ampule) = 60–61 °C (decomp.).

[8] E. Rothstein, *J. Chem. Soc. 1949*, 1968.

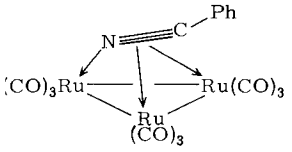
[9] Attempts to prepare the *N*-salicylidenedehydroalanine methyl ester indicated that this is considerably more reactive than **3a**.

Stepwise Hydrogenation of Benzonitrile on a Ru_3-Cluster**

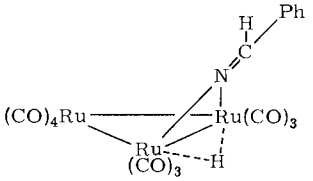
By *Wolfgang Bernhardt* and *Heinrich Vahrenkamp**

Nitriles can be reduced to amines by H_2 under pressure using metal catalysts, e.g. Raney nickel. Single steps of this reaction have been studied in an exemplary way for Fe_3-clusters[1]. Here, we report other part-steps which occur on Ru_3-clusters.

With the aim of obtaining the μ_3-η^2-benzonitrile complex **1**, we passed H_2 into a mixture of $Ru_3(CO)_{12}$ and PhCN in ligroin for 30 min at 130 °C using the conditions described by *Keller* et al.[2] for the corresponding Fe_3-complex[1]. However, instead of **1** we isolated the orange-yellow μ_2-η^1-complex **2** in 41% yield after chromatography on silica gel[3].



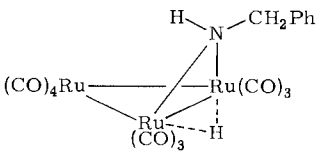
1



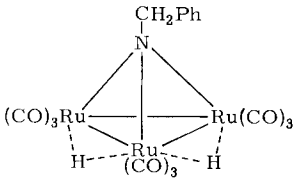
2

The CN-containing ligand in **2** is derived from benzylideneamine, the initial product of hydrogenation of benzonitrile. For this reaction to occur under the very mild hydrogenation conditions, coordination of the substrate to the cluster is a prerequisite. Whether complex **2** is formed from a precursor related to **1** is not yet clear. The constitution of **2** is determined by crystal structure analysis[4]. The C=N bond length in **2** (127 pm) is in the double bond region; the C≡N bond in benzonitrile is 13 pm shorter[5]. All the atoms of the benzylidenamino ligand and the two bridged ruthenium atoms are coplanar, and this plane forms an angle of 109° with the Ru_3 plane.

Further hydrogenation of **2** should afford the recently described **3**[6]. However, renewed reaction of **2** with H_2 as described above gave 49% of the orange-yellow μ_3-η^1-complex **4** after 90 min. The composition of **4** results from elemental analyses and the EI mass spectrum, and its structure can be deduced from the relationship between its spectra[3] and those of other $H_2Ru_3(CO)_9(\mu_3\text{-}X)$ complexes[7]. **4** is the product of oxidative addition of the NH moiety of the benzylamino ligand in **3** to the free ruthenium atom, resulting in CO elimination. The assumption that **3** is an intermediate on the route from **2** to **4** is corroborated in that under the chosen reaction conditions pure **3**[6] is converted into **4**.



3



4

The bonding and activation of the substrate by several metal atoms in these complexes is an example for the cluster-surface analogy. In contrast to the Fe_3/nitrile system[1], in which the key steps occur on μ_3-bonded, CN-containing ligands, the present case demonstrates that complete hydrogenation of the CN bond at atmospheric pressure is possible with coordination involving only the nitrogen and two metal atoms. We are presently attempting to obtain the precursor complex of **2** containing unaltered benzonitrile and to find a method of cleaving the benzylamine from **4**.

Dialkylboryl-Substituted Triphenylphosphonium Ylides

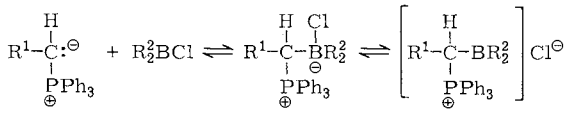
By *Hans-Jürgen Bestmann** and *Thomas Arenz*

The hydrogen atom in triphenylphosphonium ylides of type **1** can be exchanged[2,3] via transylidation by reactions with halogen compounds in the molar ratio 2 : 1[1]. So far these reactions have only been carried out with halides of elements of the 4th–7th main groups of the Periodic System[2,3].

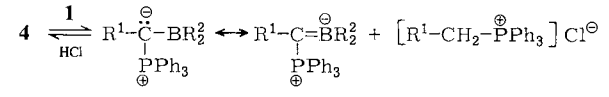
It can be expected that ylides in which an element of the 1st to 3rd main groups is bonded to carbon are more stable

[*] Prof. Dr. H. J. Bestmann, Dipl.-Chem. T. Arenz
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (FRG)

than **1**. We therefore examined reactions of the readily accessible dialkylchloroboranes **2**[4] with phosphoranes **1**[5].



1 **2** **3** **4**



5A **5B** **6**

In boiling benzene the reaction proceeds as expected with transylidation and formation of the α-dialkylboryl-substituted triphenylphosphonium ylides **5**[6] (Table 1) and the phosphonium salts **6**, which precipitate from the solution. We assume that the adduct **3** is initially formed[7] and is subsequently converted into **4**. The products **5** and **6** are obtained by reaction of **1** with **3** as well as **4**.

[a] In C_6D_6, H_3PO_4 as external standard. [b] Cyclopentyl. [c] Cyclohexyl. [d] In C_6D_6 at RT; Et_2O-BF_3 as external standard. [e] In [D_8]toluene, 80°C, Et_2O-BF_3 as external standard. [f] Extremely flat bands. [g] Intensity in molecular ion region.

The new ylides, which can be described in terms of the mesomeric formulations **5A** ↔ **5B**, are crystalline compounds which decompose without melting sharply over a wide temperature interval on heating. The ^{1}H-NMR data of **5** are consistent with expectation. In the ^{13}C-NMR spectrum the absorption of the C atoms directly bonded to boron is characterized by strong line-broadening. The ^{11}B-NMR spectrum shows a broad signal in the region $\delta = 50$ (diethyl ether/trifluoroborane as external standard), whereas trialkylboranes absorb at $\delta = 80$. The ^{31}P-NMR signal appears at $\delta = +20$ to $+27$ (H_3PO_4 as external standard) and is thus shifted downfield into the resonance region of stabilized phosphonium ylides compared to that of the ylide **1**. We ascribe the upfield shift of the ^{11}B-NMR signals compared to those of trialkylboranes and the downfield shift of the ^{31}P-NMR signals compared to those of the phosphorane **1** to participation of the mesomeric form **5B** with partial B=C double bonding.

When anhydrous hydrogen chloride is passed into a solution of **5** in ether or tetrahydrofuran the title compounds decompose to the starting compounds **1** and **2**. **3** is formed on addition of HCl, but it cannot be established whether the phosphonium chloride **4** occurs as intermediate. **3** decomposes in an equilibrium reaction into **2** and **1**. Compound **1** reacts with further HCl to give the phosphonium salt **6** and is thus removed from the equilibrium. The chloroborane **2** formed in the reaction was detected by reaction with methanol and subsequent conversion of the dialkyl borinate into the ketone[8].

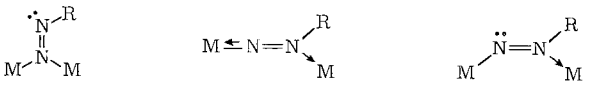
A Binuclear Molybdenum Complex with Two μ-Hydrazido(3−) *N*-Ligands

By *Rainer Mattes** and *Heinz Scholand*

Alkyl dithiocarbazates $NH_2NHC(S)SR$ are versatile ligands: thus, complexes with *N*-, *S*-, or *N,S*-coordinated neutral ligands are known, as are also chelate complexes of the singly (at N^α) or doubly (at N^α and N^β) deprotonated ligands[1]. Alkyl dithiocarbazates can also be used as starting substances for the synthesis of diazenido complexes[2]. In mononuclear compounds of this type the N_2R' group functions either as formal 3-electron donor with linear M−N−N arrangement or as 1-electron donor with angular M−N−N arrangement. For binuclear complexes with diazenido bridge-ligands, structure types **A**−**C** are conceivable; examples for all three cases are already known[3].



A **B** **C**

On attempting to convert the diazenido-hydrazido(1−)molybdenum complex **1**[2] into the corresponding hydrazido(2−) complex by protonation, we have now obtained the neutral, diamagnetic binuclear complex **2**[4].

The molybdenum complex **2** represents a novel example for the versatile ligand properties of alkyldithiocarbazates. As shown by an X-ray structure analysis[5] (cf. Fig. 1) the two molybdenum atoms in **2** are linked together via two N_2R' groups (R′ = C(S)SEt) analogously to the general type **A**; concomitantly, however, the two $N_2C(S)SEt$ groups function as N,S chelate ligands via the terminal sulfur atom. The bonding is best described in terms of the me-

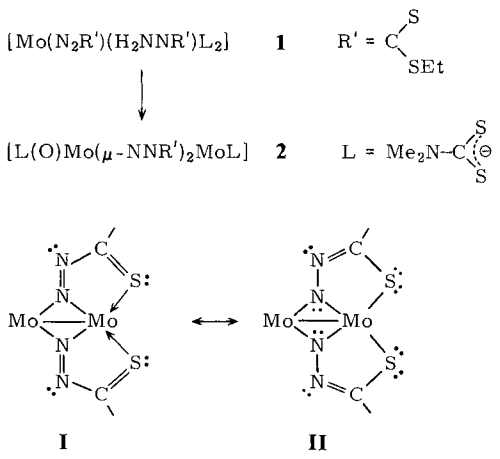
Corrensstrasse 36, D-4400 Munster (FRG)



someric formulations **I** ↔ **II**. The coordination of the sulfur atoms lead to a preference for **II**. Therefore, in comparison to the previously known μ-diazenido *N*-complexes, the NN bond in **2** is elongated by more than 10 pm from 123 ± 1 pm to 135.0(8) pm. The novel complex **2** is thus to be designated as a hydrazido(3−)- and not as a diazenido-complex.

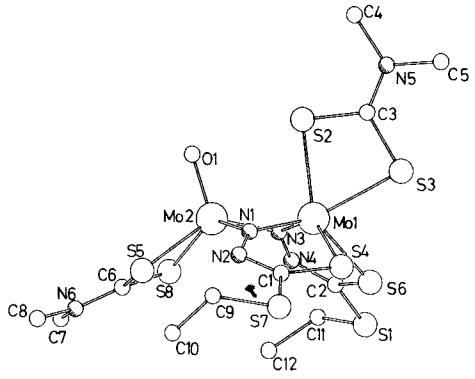


Fig. 1. Molecular structure of the binuclear molybdenum complex **2** in the crystal. Selected bond lengths [pm]: Mo1–Mo2 267.2(1), Mo1–N1 192.9(7), Mo1–N3 194.1(7), Mo1–S4 241.7(3), Mo1–S6 242.2(3), Mo2–N1 199.0(7), Mo2–N3 197.7(7), N1–N2 1.361(11), N2–C1 126.9(13), C1–S4 173.3(10), N3–N4 1.339(11), N4–C2 128.7(13), C2–S6 170.8(10); selected bond angles, mean values [°]: MoNMo 85.97(2), NNMo1 134.31(4), NNMo2 135.1(9), NMoN 91.0(3), dihedral angle NMo1N/NMo2N 152.5°. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50792, the names of the authors, and the journal citation.

Further structure parameters support this hypothesis: The N^{β} atoms (N1 and N3) are not sp^2 hybridized. The sum of the bond angles to them is 353.9(5) and 357.0(5)°, respectively. The N^{α} atoms (N2 and N4) lie 30 and 40 pm, respectively, outside the Mo, N^{β}, Mo planes. The mean values of the N–C and C–S distances in the hydrazido ligands are 127.8(9) and 172.0(7) pm, and thus correspond to the values of CN double and CS single bonds, respectively. For hydrazido(3−) ligands the formal oxidation state of the central atoms of **2** is +5. Actually, the structural array with the Mo–Mo distance of 267.2(1) pm corresponds to that of numerous binuclear Mo^{V} complexes with metal-metal bonding and central $Mo_2O_2(\mu\text{-}O_2)$ groups[6]. However, as observed here for the first time, one of the two molybdenum atoms of **2** has no terminal oxygen or sulfur ligands; this coordination site is occupied rather by the two sulfur atoms of a $Me_2NCS_2^{\ominus}$ ion, without essentially changing the structure. The molybdenum atom concerned (Mo1) is surrounded by a trigonal-prismatic arrangement of four S atoms and two N atoms. To a good approximation **2** has C_s symmetry; the mirror plane is defined by the atoms O1, Mo1, and Mo2.

Exhaustive Oxidative Decarbonylation of Metal Carbonyls by Light and Oxygen: The Example of $(\eta^5\text{-}C_5Me_5)ReO_3$**

By *Wolfgang A. Herrmann**, *Ricardo Serrano*, and *Hans Bock*

The photosensitivity of carbonylmetal compounds has been exploited for some considerable time to synthesize substituted derivatives[1]. To this end, one frequently selects the indirect route via photochemical generation of solvent-stabilized intermediates which are open for introduction of the desired ligands in subsequent dark reactions. A typical example of general preparative importance is the photochemistry of cymantrene, $(\eta^5\text{-}C_5H_5)Mn(CO)_3$, which via this method affords complexes of type $(\eta^5\text{-}C_5H_5)Mn(CO)_2L$ (L = two-electron ligand) that are frequently not accessible along other routes[1,2]. Whereas in the intermediate complex $(\eta^5\text{-}C_5H_5)Mn(CO)_2(THF)$ the cyclic ether ligand can readily be exchanged for better π-acceptors, in the analogous rhenium complex the considerably greater stability of the metal-oxygen bond renders further substitution reactions more difficult[3]. The much

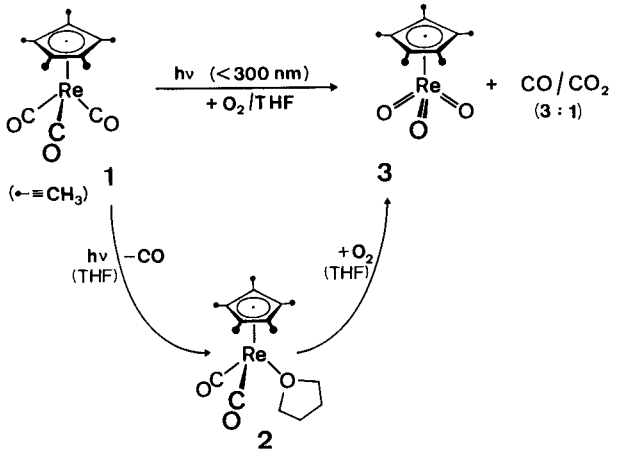
higher oxophilicity of rhenium relative to that of manganese accounts for the remarkable formation tendency of the novel title compound **3**, too.



Irradiation of a solution of the half-sandwich complex **1** in tetrahydrofuran (THF) under rigorous exclusion of oxygen (argon atmosphere or vacuum, quartz glass, Hg high-pressure lamp) effects CO-elimination with formation of the THF complex **2**; the latter species has not yet been isolated in substance but its identity has been established from subsequent reactions with phosphanes. Whereas analogous manganese complexes decompose in the presence of atmospheric oxygen, **2** eliminates CO and CO_2 (GC) to form the carbonyl-free product **3**, which after work-up by means of column chromatography is obtained as air-stable, lemon yellow, sublimable crystals in up to ca. 40% yield[4]. **3** has the unexpected constitution of a mononuclear trioxo complex (MS, IR, Raman, NMR); elemental analysis and determination of M_r by vapor osmometry indicate the formula $C_{10}H_{15}O_3Re$ with only one Re atom[4]. **3** is derived from the educt **1** by oxidative substitution of the entire set of carbonyl groups by oxo ligands. The latter can be identified by their intense ν(Re=O) stretching bands (IR, Raman); the π-coordination of the pentamethylcyclopentadienyl ligands follows from the ^{1}H- and ^{13}C-NMR spectra, which even at -120°C ($CHFCl_2$) only exhibit simple signal patterns[4]. In terms of bonding theory, it is significant that the metal center in **1** is present in the oxidation state +1 (d^6-Re^I), but in **3**, for the first time in a half-sandwich complex, as Re^{VII} having a d^0 configuration. This enormous difference in the d-electron bookkeeping is reflected in the spectra. Thus, replacement of the CO by the oxo groups leads to a drastic deshielding ($\Delta\delta > 20$ ppm) of the C atoms of the ring ligands bonded to the metal in the ^{13}C-NMR spectrum, indicating a markedly reduced charge density. More impressive is that the PE spectra convincingly show the change in oxidation state: In the d^6 complex **1** (Fig. 1b) the first group of bands centered around 8 eV is assigned to the ionizations of metal d electrons, and the second at 9.2 eV to the almost degenerate π ionizations of the ring ligand[5]. As expected, for the trioxo complex **3** no further ionizations bands which could be assigned to metal d electrons are found in the low energy region of the PE spectrum (Fig. 1a)[6].

The results of a preliminary X-ray structure analysis indicate that the ring ligand is symmetrically π-bonded in the crystal[7]. Among the reactions of **3** investigated to date is its partial deoxygenation by triphenylphosphane. This is of

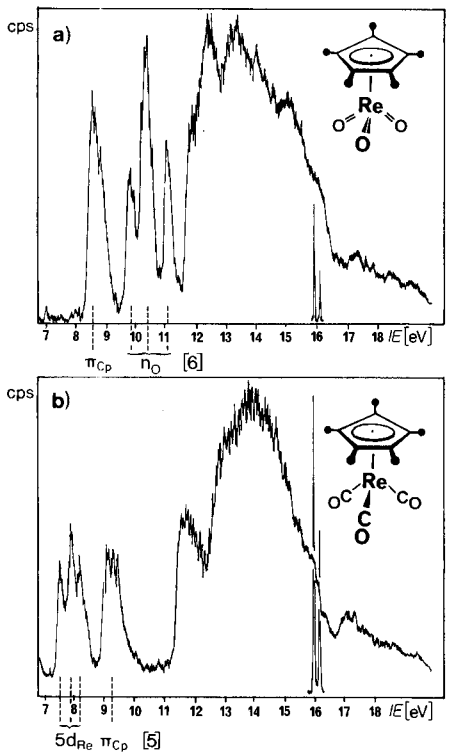


Fig. 1. He(I) PE spectra of a) trioxo- and of b) tricarbonyl(η^5-pentamethylcyclopentadienyl)rhenium recorded using a Leybold-Heraeus UPG 200 spectrometer at 10^{-5} mbar and 500 K (a) and 410 K (b). Calibrated with the $Ar(^2P_{3/2})$ peak at 15.76 eV; for assignment cf. [5, 6].

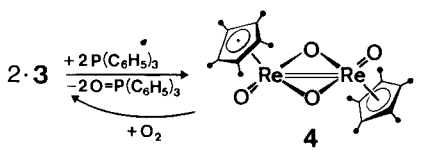
particular importance in that the binuclear derivative **4** is formed quantitatively and that this cleaves thermally into (η^5-C_5Me_5)ReO_2 fragments and hence makes secondary reactions accessible. Even in the solid state **4** rapidly rearranges in air to form the educt **3** (quantitative yield); this process corresponds to the formal change in oxidation state $Re^V \rightarrow Re^{VII}$[8]. Compound **4** reacts smoothly with bromine at -78°C in CH_2Cl_2 to give the mononuclear green complex (η^5-C_5Me_5)$ReOBr_2$ (air-sensitive), whereas reaction with CO (20 bar, toluene, 70 h) affords the title compound **3** as well as the carbonyl complex **1** and (η^5-



$C_5Me_5)_2Re_2(\mu\text{-}CO)_3$. Compound **3** also undergoes reductive carbonylation if it is allowed to react with (η^5-$C_5H_5)_2Ti(CO)_2$; in this case the rhenium-containing product is the crystalline, red oxo-complex (μ-O)[(η^5-C_5Me_5)$Re(CO)_2]_2$ (X-ray structure). The novel complex **3** is certainly comparable stoichiometrically with the tetrahedrally configurated derivatives CH_3ReO_3[9a] and $XReO_3$ (X = F, Cl, Br)[9b] but represents the first half-sandwich

[4] *Procedure:* **1** (1.01 g, 2.5 mmol) is dissolved in 100 mL THF in a quartz glass Schlenk tube ($l = 25$ cm, $\varnothing = 3.4$ cm). The reaction vessel is sealed and evacuated until the solution foams up. Subsequently, the vessel is placed at ca. 4 cm distance from a water-cooled lamp housing (quartz glass) in which an Hg high-pressure lamp (TQ 150, Original Hanau) is located. The solution is stirred and irradiated for 8 h (solution temperature 30–40°C). At 2 h intervals the mixture is filtered *in air* and the clear, yellow-brown filtrate is stored in an open flask for 15 h, subsequently concentrated in vacuo, and the residue chromatographed on a silica gel column (Merck 7734, Act. II–III; $l = 40$ cm, $\varnothing = 1.2$ cm). Small amounts of unreacted **1** as well as unidentified side products are eluted with benzene. **3** is then eluted in a bright yellow zone using toluene/diethyl ether (1 : 2 v/v). The crude product is washed with 20 mL *n*-hexane and recrystallized from diethyl ether/dichloromethane (2 : 1 v/v; +25 ... −35°C); by this means, **3** forms as refractive, lemon-yellow needles, which are both stable in air and up to temperatures above 140°C (slow decomposition with brown coloration upon prolonged heating in the temperature range 150–200°C; no definite melting point). Yield 296–379 mg (32–41%); insoluble in aliphatic hydrocarbons, very soluble in CH_2Cl_2, toluene, and THF. ^{1}H-NMR (270 MHz, C_6D_6, 26°C): δCH_3 1.63 (s); ^{1}H-NMR (270 MHz, CD_2Cl_2, −80°C): δCH_3 2.08 (s); no signal broadening at this temperature.—$^{13}C\{^1H\}$-NMR ($CDCl_3$, 28°C): δCH_3 10.24, δC_5Me_5 120.35.—IR (KBr): 909 s-vs, 878 vs, [ν_{as}(Re=O)]; further bands 334 w, 393 m, 797 w-m, 960 w, 1024 m, 1073 w, 1362 m, 1373 m, 1381 m, 1440 m (br), 1472 w (br), 1504 m; 2920–3000 w-m [ν(CH)].—IR [CS_2; ν_{as}(Re=O)]: 922 s-vs, 892 vs.—Raman [solid; ν(Re=O)]: 907 vs, 889 m, 874 w-m (C_s-symmetry).—MS (Varian MAT CH7; 12 eV $T_Q = 100$°C, $T_E = 120$°C, ^{187}Re): $M^{\oplus\odot}$ (*m/z* 370, rel. int. 100%), $[M-O]^{\oplus\odot}$ (354, 32), $[M-2O]^{\oplus\odot}$ (338, 40), $C_{10}H_{15}^{\oplus\odot}$ (135, 96; with decomposition spectrum, $m/z < 135$).—FD-MS: 370 (parent ion, ^{187}Re).—Correct elemental analysis (C, H, Re, O).

[5] D. C. Calabro, J. L. Hubbard, C. H. Blevins II, A. C. Campbell, D. L. Lichtenberger, *J. Am. Chem. Soc. 103* (1981) 6839, and literature cited therein. The PE spectrum of **1** was assigned by comparison of the radical cation state with those of the similar complexes $CpRe(CO)_3$, $CpMn(CO)_3$, and $Me_5CpMn(CO)_3$ on the basis of the observed vibrational fine structure and with parameter-free Fenske/Hall model calculations: Accordingly, the group of bands around 8 eV contains the metal d-states $\tilde{X}(^2E_{3/2})$ and $\tilde{B}(^2E_{1/2})$ split by spin/orbit coupling to $\tilde{A}(^2A_1)$ under the local C_{3v} symmetry, and the second group of bands at ca. 9.2 eV the states $\tilde{C}(^2E'')$, which are almost degenerated under the local D_{5h} symmetry, with predominant π Cp contribution.

[6] Because of the unexpectedly large relaxation and correlation effects, the PE spectra of organometallic compounds cannot usually be assigned on the basis of MO calculations and Koopman's theorem (cf. e.g. M. C. Böhm, *Inorg. Chem. 22* (1983) 83, and literature cited therein). For the novel title compound, comparison of the radical cation state with similar complexes is also not possible. Qualitative considerations—starting from the intensity ratio 2 : 1 : 2 : 1 of the four PE bands of lowest energy and the C_5H_5 π-system as well as the oxygen lone-pairs n_O, which are the most electron-rich sites in the Re(d^0) compound **3**, and which can each be subdivided into three parallel (∥) and three horizontal (⊥) components—lead to the proposed assignment $\pi_{Cp}(e) < n_O^{\perp}(a_2) < n_O^{\parallel}(e) < n_O^{\perp}(a_1)$. The missing degenerate combination $n_O^{\parallel}(e)$ should be stabilized by overlap with d_{xz}(Re) and d_{yz}(Re). An EHMO-approximation calculation for the (still) fictitious $CpMnO_3$ with program-specific standard parameters reproduces this qualitative MO sequence.—Cf. J. C. Green, S. E. Jackson, B. Higginson, *J. Chem. Soc. Dalton Trans. 1975*, 403.

Dextran-Linked N^6-(2-Isopentenyl)adenosine—A Polymer-Bound Antimetabolite with a Predetermined Cleavage Position**

By *Helmut Rosemeyer* and *Frank Seela**

N^6-(2-Isopentenyl)adenosine [6-(3-methyl-2-butenylamino)-9-ribosylpurine, i^6A], **1**, is a modified nucleoside which exhibits cytokinine activity and stimulates cell division and cell differentiation. It is found in the *t*RNA's of many organisms and, furthermore, shows strong antitumor activity in transformed cells, animals, and man[1].

The covalent attachment of **1** to biopolymers (e.g. dextrans) is expected to increase the circulatory lifetime (plasma half-life) of **1** and would alter the uncontrolled distribution of the pharmacon over the compartments of the organism. Furthermore, polymer-linked anticancer drugs should show an enhanced tumor cell selectivity since the latter possess an increased pinocytic uptake activity compared to normal cells[2].

Dextrans which contain linear chains of 1→6—linked α-D-glucopyranose residues as the dominant structural feature have proven valuable as biopolymeric carriers for biologically active compounds since they can be slowly hydrolyzed by dextranases in vivo. Dextran is used as a blood-volume expander in the molecular-weight range 4×10^4–8×10^4[3].

We report here on the covalent attachment of **1** via a cyclic acetal side chain to activated dextran T 80 bearing a spacer with a disulfide bridge as a predetermined cleavage position. Furthermore, we describe the chemically controlled release of the derivative **3b** of **1** from the polymer **5** by reduction of the disulfide bridge of the spacer using dithiothreitol. This can serve as a model reaction for a drug delivery by reducing enzymes like glutathione reductase.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and die Regierung des Landes Nordrhein-Westfalen.

Alkylation of (*R*)-2′,3′-*O*-(3-ethoxycarbonyl-1-methylpropylidene)adenosine[4] with 1-bromo-3-methyl-2-butene in dimethylformamide (DMF) leads to **2**. Dimroth rearrangement with simultaneous saponification of the ester function in the acetal side chain yields the acid **3a**[5]. Its structure could be confirmed by ^{1}H- and ^{13}C-NMR spectroscopy. The ribose ring conformation of **3a** was determined from the observed vicinal proton coupling constants [$J_{2',3'}$ and $(J_{1',2'}+J_{3',4'})$], which allow an estimation of the corresponding pseudorotational parameter (P, τ_m) using the nomograms in ref. [6]. The parameters were found to be: $P_N=231°$; $P_S=219°$; $\tau_m=42°$. From these data the S-conformer population ([S], C-3′-*exo*) was calculated to 50%, which corresponds to a $^4_3$T conformation. The data of the unmodified nucleoside, however, imply a ^{2}E-conformation which demonstrates the altered sugar puckering caused by the chemical modification[7].

The modified dextran **4** bearing a spacer with a predetermined "breaking point" was prepared by carboxymethylation of dextran using chloroacetate in a strong alkaline medium to form carboxymethylated dextran T 80 (CM-dextran). Reaction of CM-dextran with cystamine in water using *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC) as coupling reagent yielded the polymer **4**, which could be isolated as a water-soluble and fluffy solid after dialysis and lyophilization[8].

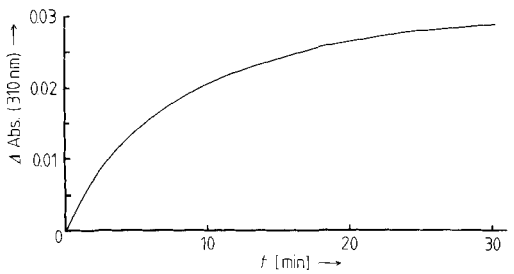

Fig. 1. Dithiothreitol cleavage of **5** as a function of time in Sørensen phosphate buffer (0.07 M, pH 7.6, 10^{-3} M EDTA) with dithiothreitol (10 μL of an 0.5 M aqueous solution, 10^{-3} M EDTA). The formation of 1,2-dithiane-4,5-diol was monitored at $\lambda=310$ nm.

The activated dextran **4** was coupled with the acid **3a** to give **5**[10]. As can be seen from Figure 1, the half-life of the reduction is about 15 min and the reaction does not show simple first-order kinetics. This implies that an in vivo release of the ligand **3b** by reducing enzymes like glutathione reductase can be accomplished—a process which may be of general importance for the delivery of pharmacologically active compounds.

[10] **5**: The acid **3a** (50 mg, 0.12 mmol) was dissolved in water/dioxane (20 mL, 1:1) and **4** (0.35 g) was added. After shaking for 5 min at room temperature EDC·HCl (250 mg, 1.3 mmol) was added. After shaking for another 12 h at room temperature the solution was chromatographed on Sephadex G-50 (2.5 × 60 cm). Lyophilization yielded **5** (0.35 g). The ligand concentration was determined spectrophotometrically at 268 nm using the extinction coefficient of **3a**, and was found to be 12.9 μmol of **3a**/g of dextran.

Bis(1,3,5-trimethylbenzene)indium(I) Tetrabromoindate(III), the First Arene Complex of Indium

By *Jan Ebenhöch, Gerhard Müller, Jürgen Riede,* and *Hubert Schmidbaur**

Dedicated to Professor Jan Thesing and the occasion of his 60th birthday

Arene complexes of transition metals[1] have played an important role in organometallic chemistry ever since the discovery of bis(benzene)chromium[2], yet rarely has any attention been paid to the fact that some main group elements in low valency states also readily form coordination compounds with aromatic hydrocarbons. It was first demonstrated by *Amma* et al.[3] that, e.g., Sn^{II} atoms, like transition metal atoms, can coordinate centrally to a benzene ring. However, until quite recently, elucidation of the structure of such compounds has been restricted to mono(arene) complexes.

In continuation of a systematic study on this new class of compounds we have been able to prepare, besides the (η^6-hexamethylbenzene)gallium(I) ion, both the bis(benzene)gallium(I) complex as well as the bis(mesitylene)gallium(I) complex and to examine them X-ray crystallogra-

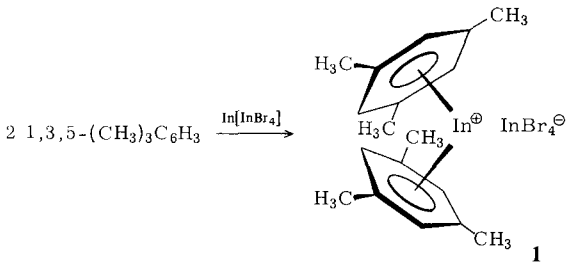
[+] X-ray structure analysis.

phically[4]. Herein we report on the title compound **1**, the first compound containing a bis(arene)-complex of indium.

Anhydrous mesitylene (1,3,5-trimethylbenzene) saturated with nitrogen rapidly takes up considerable amounts of $In(InBr_4)$ on heating; the $In[InBr_4]$ may be generated separately or in situ[5]. On cooling such solutions, colorless crystals are formed whose elemental analysis reveals a ratio of reactants of 2 : 1. The product is sensitive to air and light and—particularly on reducing the pressure—soon loses a part of its arene content.



1

The X-ray structure analysis of **1**[6] shows that the compound in the crystalline state is a coordination polymer whose helical chains run along the y axis; complex cations and anions are coupled in such a way that the tetrabromoindate(III) tetrahedra are bidentate chelate-forming on one side and monodentate-bridging on the other (cf. Fig. 1).

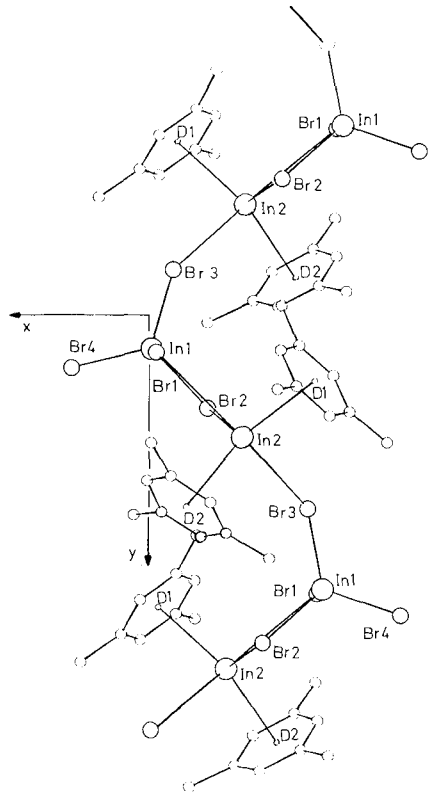


Fig. 1. Projection of a section of the crystal structure of **1** on the x,y plane.

The environment of each In^{I} center (In2) is completed by two mesitylene rings, which are inclined to each other at an angle of 47.3°. Their centroids are at about the same distance from the metal atom, which is located almost perpendicularly over the center of the ring (Fig. 2). The three bromine atoms are arranged in a plane bisecting the angle between the hydrocarbon rings in such a way that the BrInBr angles are almost equal, even though two of the halogen atoms (Br1, Br2) are coordinated as part of a chelate ligand (Fig. 2 and 3).

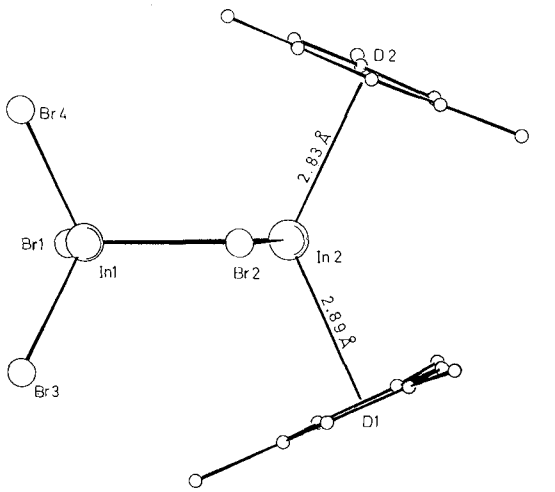

Fig. 2. Sideview of a monomeric unit of **1**.

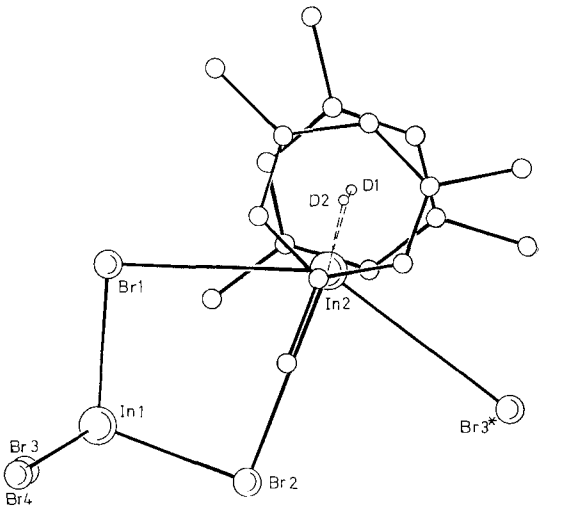

Fig. 3. Projection of the molecule **1** on the plane through In2, Br1, Br2, Br3 (cf. Fig. 1). Selected bond lengths [Å] and angles [°]: In1–Br1 2.494(1), In1–Br2 2.500(1), In1–Br3 2.482(1), In1–Br4 2.466(2), In2–Br1 3.446(1), In2–Br2 3.503(1), In2–Br3* 3.527(1); Br1–In1–Br2 106.3(1), In1–Br1–In2 92.4(1), In1–Br2–In2 91.0(1), In2–Br3*–In1* 146.0(1), Br1–In2–Br2 70.2(1), Br2–In2–Br3* 74.1(1).

The structure of **1** reveals many analogies to transition metal arene complexes[1]. However, because of the electronic configuration $5s^25p^04d^{10}$ of the main group element indium, a completely different situation arises for a theoretical description. Simple model concepts such as the noble gas rule must therefore be replaced in this instance and in related problems by the cluster formalism[7] or a specific MO consideration[8]. We have also obtained crystals of the arene complexes $[1,3,5\text{-}(CH_3)_3C_6H_3]_2In^{\oplus}AlBr_4^{\ominus}$ and $[(CH_3)_6C_6]In^{\oplus}InBr_4^{\ominus}$, whose characterization is still under

way. Unsubstituted benzene is so loosely bound to In[1] that the adducts could so far not be isolated.

Bonding Attitudes in Crystalline SeF_4 and TeF_4**

By *Rüdiger Kniep*, Lutz Korte, Rainer Kryschi,* and *Wolfgang Poll*

Selenium tetrafluoride: In solution, the SeF_4 molecule has a pseudo-trigonal-bipyramidal structure; with increasing concentration, the molecules become increasingly associated via intermolecular fluorine bridges[1]. We have now succeeded in determining the crystal structure of SeF_4 and are able to comment on the type of intermolecular interactions and the molecular structure. From the very beginning, it could not be ruled out that crystalline SeF_4 is also polymeric, like TeF_4. Since the structure analysis of TeF_4 reported in the literature[2] (film technique) gave only relatively inaccurate bond lengths and angles, we have also redetermined the structure of TeF_4, a comparison of the bonding in SeF_4 and TeF_4 thus becoming more informative.

SeF_4 and TeF_4 were prepared by reactions of SeO_2 and TeO_2, respectively, with SF_4 in an autoclave[3,4], and were subsequently purified by distillation or vacuum sublimation. In the case of TeF_4 (m.p. 130°C), single crystals for the structure analysis were already obtained on sublimation, while in the case of SeF_4 (m.p. $-10°C$) they were cultivated from the melt on the single-crystal diffractometer. Determination of the lattice parameters and measurement of the reflection intensities were carried out on both compounds at $-110°C$. SeF_4 and TeF_4 crystallize with similar lattice metrics in the space group $P2_12_12_1$; remarkable, however, is that the *c*-axis in TeF_4 is considerably shorter than that in SeF_4[5].

The molecular structure and coordination of the compounds are shown in the top part of Figure 1. In SeF_4 the

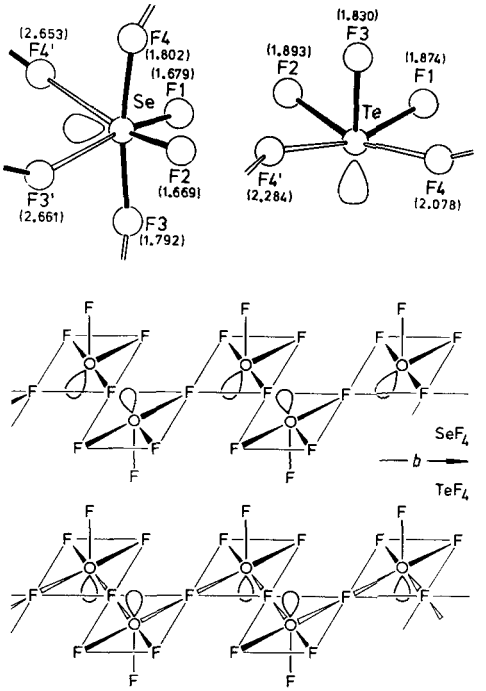

Fig. 1. *Top:* Molecular structure and coordination in SeF_4 and TeF_4 with bond lengths (standard deviations 0.006 and 0.005 Å, respectively). Bond angles (standard deviations 0.3 and 0.2°, respectively): F1SeF2 96.9, F1SeF3 85.7, Fe1SeF4 87.2, F1SeF3' 171.0, F1SeF4' 77.1, F2SeF3 85.5, F2SeF4 87.5, F2SeF3' 78.5, F2SeF4' 169.5, F3SeF4 169.3, F3SeF3' 86.3, F3SeF4' 102.5, F4SeF3' 100.3, F4SeF4' 83.6, F3'SeF4' 108.6, SeF3Se' 150.1, SeF4Se'' 139.9.—F1TeF2 86.8, F1TeFe3 87.6, F1TeF4 83.9, F1TeF4' 162.5, F2TeF3 84.2, F2TeF4 161.3, F2TeF4' 88.2, F3TeF4 79.2, F3TeF4' 75.3, F4TeF4' 95.9, TeF4Te' 154.1.—*Bottom:* Polymeric structure in TeF_4 and position and sequence of monomers in a corresponding section of the SeF_4 structure (schematic representation).

selenium is bonded to four fluorine atoms in such a way that, with the pair of electrons on the selenium atom also taken into consideration, a distorted pseudo-trigonal bipyramid with longer axial Se–F bonds results. In accord with the electron pair repulsion (VSEPR) model the F_{ax}–Se–F_{ax} array is not linear but angular (169.3°), with the Se–F_{ax} bonds tilting away from the lone pair on Se; in the same way, the F_{eq}–Se–F_{eq} angle is smaller than 120°. The coordination of neighboring molecules in the second sphere is increased via the axial fluorine atoms (distorted octahedral fluorine coordination); according to the size of the F···Se distance, the intermolecular interactions are to be rated as being so weak that they do not significantly influence the bonding in the SeF_4 molecule. The bonding in TeF_4 is different (see also [2]). Here the tellurium is bonded to five fluorine atoms (distorted tetragonal pyramid), two of which (*cis*-oriented in the tetragonal plane) bridge a further neighboring tellurium atom each. The bridge bonds, are, however, distinctly shorter than the intermolecular F···Se contacts in SeF_4. It is to be expected that the lone pair on the tellurium completes a pseudo-octahedral coordination of the central atom; consistent with this expectation the tellurium atom is located 0.3 Å below the plane of the four fluorine atoms. The differences in the bonding in crystalline SeF_4 and TeF_4 can be ascribed to the respective degrees of hybridization of the chalcogen, and can be described in terms of sp^3d (SeF_4: pseudo-trigonal-bipyramidal) and sp^3d^2 states (TeF_4: pseudooctahedral). The polymeric structure of TeF_4 in the [010] direction and the position and sequence of SeF_4 monomers (also in the [010] di-

[*] Prof. Dr. R. Kniep, Dr. L. Korte, Dipl.-Chem. R. Kryschi, Dr. W. Poll

[**] This work was supported by the Fonds der Chemischen Industrie.

rection) in a corresponding section of the SeF_4 structure are reproduced schematically at the bottom of Figure 1. The shortening of the *c*-axis in TeF_4 is due to the strong fluorine bridges within the polymeric structural assemblage. The fundamental similarity of the arrangements of the structural units of SeF_4 and TeF_4 in the [010] direction also exists in the three-dimensional crystal arrays. The possibility of a structural transformation in SeF_4 by a closer (pressure-induced) proximity of the axial fluorine atoms to selenium atoms of neighboring molecules cannot be ruled out.

The chemical similarity of SeF_4 and SF_4[6] seems to be further confirmed by the—albeit up to -160 °C disordered—crystal structure of SF_4[7], from which a formation of fluorine-bridged associates in crystalline SF_4 is not to be assumed.

Mixed Crystals Containing the Diamagnetic Complex $[Mo_2(SO_2)(S_2)(CN)_8]^{4\ominus}$ and the Paramagnetic Complex $[Mo_2(SO_2)(S_2)(CN)_8]^{5\ominus}$

By *Achim Müller**, *Werner Eltzner*, *Rainer Jostes*, *Hartmut Bögge*, *Ekkehard Diemann*, *Jürgen Schimanski*, and *Heiko Lueken*

Paramagnetic multinuclear and, particularly, binuclear complexes of the heavy transition metals (4d and 3d elements) are rare. We have now been able to isolate a compound which contains the isostructural anions $[(Mo^{III/IV})_2(SO_2)(S_2)(CN)_8]^{5\ominus}$ **1a** (paramagnetic) and $[(Mo^{IV})_2(SO_2)(S_2)(CN)_8]^{4\ominus}$ **1b** (diamagnetic)[1] *together* in a mixed crystal compound.

Passage of oxygen into an aqueous solution of $[(Mo^{III})_2(S)_2(CN)_8]^{6\ominus}$ **2**[2] leads to the formation of a blackish violet mixed-crystal compound of the composition $K_{4+x}[(Mo^{III/IV})_2(SO_2)(S_2)(CN)_8]_x[(Mo^{IV})_2(SO_2)(S_2)(CN)_8]_{1-x} \cdot 4H_2O$ **1** ($x = 0.3$) **1**[3]. **1** was characterized magnetochemically and spectroscopically (ESCA, ESR, IR, UV/VIS/NIR), and by an X-ray structure analysis (Fig. 1)[4].

In the crystal, the complexes **1a** and **1b** are located at two crystallographically independent positions *A* and *B* (Fig. 1). The structures of **1a** and **1b** differ only slightly; in both complexes each molybdenum atom is surrounded by an approximately pentagonal-bipyramidal array of four $CN^{\ominus}$ and three sulfur atoms of the bridging ligands $SO_2^{2\ominus}$[1] and $S_2^{2\ominus}$[5]. However, markedly different Mo–Mo bond lengths are observed for the positions *A* and *B* (279.0 and 268.4 pm, respectively). Since the greater Mo–Mo distance is to be expected for **1a** (see below), this complex obviously preferably occupies the position *A*; but since the crystal contains only ca. 30% of **1a**, the geometric parameters cannot exclusively arise from **1a**, at least in the case of *A*.

By ESCA measurements[6] it was possible to demonstrate that mixed valence Mo species are present in **1**. Moreover, from the hyperfine structure of the ESR spectrum (solution of **1** in water, addition of Na_2SO_3[7], room temperature) it unequivocally follows that an unpaired electron in **1a** interacts with the nuclear spin of two chemically equivalent Mo atoms (^{95}Mo and ^{97}Mo with $I = 5/2$). The measured parameters $\bar{g} = 2.012$ and $\bar{A}(^{95}Mo) = 19.2$ G

point to a strong delocalization of the unpaired electron (e.g. in comparison to that in $[Mo_2(SO_4)_4]^{3\ominus}$[8]).

The electronic absorption spectrum of **1** in aqueous solution (addition of Na_2SO_3[7]) reveals the presence of both **1a** (980, 340 (sh), 305 nm) and **1b** (900, 550, 410 (sh), 340, 280 (sh), 230 nm)[9]. The time-dependent measurement of the IR spectra of an aqueous solution of **1**, through which O_2 is passed, permits monitoring of the conversion of **1a** (ν(CN): 2103 cm^{-1}) into **1b** (ν(CN): 2134 cm^{-1}); the ESR signal of **1a** correspondingly disappears.

The proportion of the binuclear unit **1a** in the mixed crystal was estimated from susceptibility measurements (Faraday method) to be 31%[10].

An SCCC-EH-MO calculation on **1b** showed that the species can be best described as a $(Mo^{IV})_2/SO_2^{2\ominus}/S_2^{2\ominus}$ complex with a metal-metal double bond (two occupied MOs with pronounced Mo-4d character, configuration approximately $\sigma^2\pi^2$); formally, the 18-electron rule is fulfilled. The additional electron in **1a** occupies a weakly Mo–Mo antibonding MO ($\sim\delta^*$), from which the greater atomic distance is feasible.

Also remarkable is the reaction path leading to **1**. Passage of O_2 into a solution of **2** leads to successive formation of $[(Mo^{IV})_2(S)_2(CN)_8]^{4\ominus}$ **3**[11], **1a**, and **1b**:

$$\mathbf{2} \xrightarrow[(a)]{O_2} \mathbf{3} \xrightarrow[(b)]{(O_2)} \mathbf{1a} \xrightarrow[(c)]{O_2} \mathbf{1b}$$

Under the given conditions[3], **1a** and **1b** crystallize out together in the mixed-crystal compound **1**. In the case of reactions (a) and (c) the conversion of isostructural species with different electron populations takes place via two- and one-electron oxidation processes, respectively (detection by CV measurements on **2** and **3**[11] and **1b**: $E_{1/2} = 0.06$ V relative to the potential of the normal hydrogen electrode), whereas reaction (b) involving formation of the $SO_2^{2\ominus}$ and $S_2^{2\ominus}$ bridging-ligands is more complicated and not understood.

According to *Robin* and *Day*[12], the salt **1** can be classified as a mixed-valence compound of type I, while the anion **1a** can be assigned to the type III (complete delocalization).

[1] The oxidation states of the molybdenum atoms are based on the assumption of $SO_2^{2\ominus}$ and $S_2^{2\ominus}$ ligands. Supporting evidence for the presence of a $SO_2^{2\ominus}$ ligand [cf. also D. M. Hoffman, R. Hoffmann, *Inorg. Chem. 20* (1981) 3543] is provided by ESCA data (very low value for $E_b(S2p_{3/2})$) and IR data (low ν(SO) value, especially in the case of **1a**, corresponding to large S–O distances; solid-state spectrum (CsI pellet) of **1**: 960, 1055 (**1a**); 1016, 1131 cm^{-1} (**1b**) [cf. R. R. Ryan, G. J. Kubas, D. C. Moody, P. G. Eller, *Struct. Bonding (Berlin) 46* (1981) 47]; the intensity of the ν(CN) band of **1b** in aqueous solution is almost as large as that of $[Mo_2^{IV}(S)_2(CN)_8]^{4\ominus}$, cf. [11]).

[2] E. Crepaz, *Gazz. Chim. Ital. 58* (1928) 391; P. Christophliemk, Diplomarbeit, Universität Göttingen 1969; M. G. B. Drew, P. C. H. Mitchell, C. F. Pygall, *Angew. Chem. 88* (1976) 855; *Angew. Chem. Int. Ed. Engl. 15* (1976) 784.

[3] Oxygen is bubbled into a solution of $K_6[Mo_2(S)_2(CN)_8]\cdot 4H_2O$ [2] **2** (2 g) in H_2O (20 mL) and glacial acetic acid (0.5 mL) for 3 h. The reddish brown precipitate is filtered off and further oxygen passed into the filtrate until a violet solution is obtained (ca. 2 h). After renewed filtration the solution is transferred to a crystallizing dish and allowed to evaporate down to ca. 5 mL in a desiccator over P_4O_{10}. After about a week the colorless byproducts are filtered off and the filtrate (covered with a watch glass) is allowed to stand for 1–2 weeks at room temperature in presence of air. The large, blackish violet crystals of **1** which separate out (ca. 0.2 g), are dried between filter papers.

[4] Space group $P\bar{1}$, $a = 1051.9(2)$, $b = 1581.6(4)$, $c = 1616.6(4)$ pm, $\alpha = 106.68(2)$, $\beta = 95.10(2)$, $\gamma = 101.61(2)^\circ$, $Z = 2$; $R = 0.061$ for 6990 independent reflections ($F_0 > 3.92\sigma(F_0)$), $Mo_{K\alpha}$ radiation, Syntex $P2_1$. The binuclear anions are grouped in pairs that are located almost parallel to each other in the crystal lattice (Mo positions of *A* and *B*: Mo1 −0.1491, 0.2770, 0.2934; Mo2 0.1209, 0.3352, 0.2983 and Mo3 0.0344, 0.2888, 0.7166; Mo4 −0.2251, 0.2227, 0.7029). The $K^\oplus$ cations are distributed over nine lattice sites of the asymmetric unit, of which three are not fully occupied.

[5] The molecular structure of diamagnetic **1b** in the $PPh_4^\oplus$ salt [C. Potvin, J. M. Brégeault, J. M. Manoli, *J. Chem. Soc. Chem. Commun.* 1980, 664] corresponds to that found here.

[6] Hewlett-Packard 5950A spectrometer, monochromatic $Al_{K\alpha}$ radiation, standard: $K2p_{3/2} = 292.2$ eV; $Mo3d_{5/2}$ 228.0 and 229.2, $S2p_{3/2}$ 163.4 ($S_2^{2\ominus}$) and 165.1 eV ($SO_2^{2\ominus}$).

[7] The addition of Na_2SO_3 provides an easy way of preventing the oxidation **1a** → **1b** by traces of oxygen, without any reduction **1b** → **1a** taking place (checked by measurements on carefully degassed solutions).

[8] F. A. Cotton, B. A. Frenz, E. Pedersen, T. R. Webb, *Inorg. Chem. 14* (1975) 391.

[9] The two complex anions could be identified on the basis of the pure diamagnetic compound $(PPh_4)_4[Mo_2(SO_2)(S_2)(CN)_8]\cdot 6H_2O$ and the $K^\oplus$ salts of **1a** (contaminated with K_2SO_4) and **1b**, now prepared by us, too.

[10] The magnetic behavior between 10 and 300 K can be described by the relationship $\chi = C/T + \chi_0$ (with $C = 0.2939 \times 10^{-5}$ m^3 K mol^{-1} and $\chi_0 = 191 \times 10^{-11}$ m^3 mol^{-1}; SI units). The Curie term of **1a** ($s = 1/2$) is determined under the formal assumption of strong antiferromagnetic interactions between the Mo atoms in the binuclear units. From its magnitude (and using $\bar{g} = 2.012$ obtained from the ESR experiment) the given composition can therefore be determined. The positive χ_0 value indicates contributions from temperature-independent paramagnetism (measurements at the Technische Hochschule Aachen).

All-*cis*-[5.5.5.5]fenestrane**

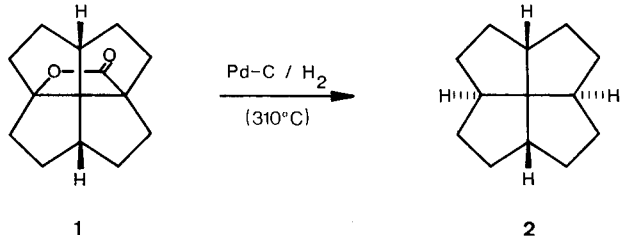
By *Marcel Luyten* and *Reinhart Keese**

Dedicated to Dr. Ulrich Weiss on the occasion of his 75th birthday

Fenestranes are of particular interest because they belong to the class of compounds which contain tetracoordinate carbon with planoid configuration[1]. We now wish to report that reductive decarboxylation of **1**[2] gave the saturated hydrocarbon **2**, the all-*cis*-[5.5.5.5]fenestrane[3,4].

Because of the specific structural properties and the steric hindrance it seemed unlikely that **1** could be transformed into **2** by typical multistep methods used for decarboxylation of lactones. In particular, ring-opening reactions, potentially leading from **1** to a γ-hydrocarboxylate or a corresponding derivative, could be excluded, because of the high tendency of lactone formation in similar cases[5].

We have now found that **1** can be reductively decarboxylated to **2** in presence of hydrogen and Pd as a catalyst[6].



1 **2**

[*] Prof. Dr. R. Keese, M. Luyten
Institut für organische Chemie der Universität
Freiestrasse 3, CH-3012 Bern (Switzerland)

[**] This work was supported by the Swiss National Science Foundation (project No. 2.421-0.82).

The structure of **2** is supported by spectroscopic data[7]. The configuration of **2** is based upon the following considerations: Of the six stereoisomeric [5.5.5.5]fenestranes[8], only the all-*cis*- and the all-*trans*-isomer, strained by 762 kJ/mol[1], have a symmetry compatible with the ^{13}C-NMR spectrum, which exhibits three lines with s, d, and t coupling patterns, respectively. Since extensive H/D exchange can be expected to take place on decarboxylation of **1** in presence of deuterium[9], it can be assumed that the all-*trans* isomer, if formed at all, should be converted into the all-*cis* isomer **2**. The capillary-GC[10] of the crude product shows—apart from **1** and solvent—only one signal; hence, it is concluded that **2**, the most stable isomer, is formed exclusively. The decarboxylation of carboxylic acids and reductive decarboxylation of lactones such as **1** is of general importance[8].

$[Mo_4(\mu_3\text{-}S)_4(\mu\text{-}S_2CNEt_2)_2(S_2CNEt_2)_4]$, a Compound Containing a Cubane-Like Mo_4S_4 Cluster

By *Thomas C. W. Mak, Khalid S. Jasim,* and *Chung Chieh**

Molybdenum and iron are key transition metals in nitrogenase, an enzyme responsible for nitrogen fixation. The iron may be present as Fe_4S_4 clusters, yet the state of molybdenum is still to be identified[1]. Over the years, a large number of molybdenum complexes with dithioic acids and dithiophosphates have been prepared and their structures determined, but so far only a few compounds are known to contain a cubane-like Mo_4S_4 cluster[2]. The cluster in **1** and **2** has approximate D_{2d} symmetry with only two Mo–Mo bonds of 2.862(2) and 2.881(3) Å, respectively[3]. On the other hand, the structures of the organomolybdenum compounds **3**, reported lately, contain cubane-like Mo_4S_4 clusters with six Mo–Mo bonds[4]. Recently, in our studies on molybdenum chemistry **4** was prepared, its crystal structure determined, and other properties measured. The structural analysis revealed that this compound contains a cubane-like cluster in which there are six Mo–Mo bonds. Although the present results have no direct connection with the study of nitrogenase, the existence of a cubane-like Mo_4S_4 cluster, and the unusual oxidation state of 3.5 for each Mo atom, as compared to the existence of the cluster $Fe_2Mo_2S_4$ are of considerable interest[5].

$[Mo(NC_6H_4Me)(\mu_3\text{-}S)\{S_2P(OEt)_2\}]_4$ **1**
$[Mo(NC_6H_4Me)(\mu_3\text{-}S)(S_2CN\textit{i}\text{-}Bu_2)]_4$ **2**
$[Mo(\eta\text{-}C_5H_4\textit{i}\text{-}Pr)(\mu_3\text{-}S)]_4^{n+}$ **3**, n = 0, 1, 2
$[Mo_4(\mu_3\text{-}S)_4(\mu\text{-}S_2CNEt_2)_2(S_2CNEt_2)_4]$ **4**

$Et_2N-\overset{\overset{S}{\|}}{C}-S-S-\overset{\overset{S}{\|}}{C}-NEt_2$ **5**

Brown, Glass, and *Jasim*[6] mentioned that during the preparation of $Mo_2(S_2CNEt_2)_6$ from $Mo(CO)_6$ and tetraethylthiuram disulphide **5** a black by-product was produced. We have now isolated this by-product in pure crystalline form and found that it can also be prepared by prolonged heating of the solution in the absence of light and air[7]. Complex **4** is insoluble in aliphatic and aromatic hydrocarbons, but sparingly soluble in cold acetone and chlorinated solvents. Recrystallization over more than one month from $CHCl_3$ gives square or rectangular black plates. Upon exposure to air, the crystals lose $CHCl_3$ in a few minutes (strong odor) and then disintegrate into a powder.

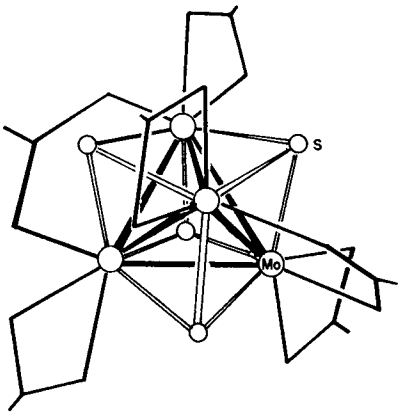

Fig. 1. The molecular structure of **4** in the crystal. For clarity, only the CS_2 groups of the dithiocarbamates are shown. The single crystal used for structure determination was kept in a chloroform atmosphere and held stationary against the wall of the capillary with petroleum jelly. Crystals of **4** are tetragonal, space group $P4_12_12$, $a = 12.442(3)$, $c = 40.30(1)$ Å and $Z = 4$; 1099, $R = 0.094$. However, the C atoms of the $CHCl_3$ and one terminal C atom of an ethyl group were not located from the difference map, and the $CHCl_3$ molecules of crystallization are randomly orientated [8].

The key features of the structure of **4** are given in Figure 1. A novel feature of the molecular structure of **4** is that it contains a cubane-like Mo_4S_4 cluster, which is similar to that of Fe_4S_4, except that all four Mo atoms are mutually bonded via single Mo–Mo bonds; in contrast, in Fe_4S_4

there is no Fe–Fe bond. The two Mo–Mo bonds involving metal atoms bridged by $S_2CN(C_2H_5)_2$ ligands are 2.732(5) Å, slightly shorter than the other four which range from 2.858(5) to 2.870(7) Å giving an average value of 2.861(6) Å[4]. In contrast to the two short and four long Mo–Mo distances present in **4**, **3** (n = 0), has two long Mo–Mo distances (2.912(1) Å) and four short ones ranging from 2.892(1) to 2.905(1) Å (average 2.900(6) Å)[4]. Most Mo–S distances in the Mo_4S_4 cluster are close to 2.35(3) Å. The S–Mo–S angles are obtuse (101.6–107.8°) but the Mo–S–Mo angles are acute (71.5–75.2°). The molecule has a two-fold symmetry axis coinciding with that of the space group.

If the Mo–Mo bonds are ignored, the coordination geometry about each metal center is a distorted octahedron, the S–Mo–S angles being constrained by the cubane-like arrangement and by the "bite" of the chelate $S_2CN(C_2H_5)_2$ ligand. The "chelate angles" are 68.5(5) and 70.0(4)°, respectively, for angles centered at Mo1 and Mo2. Generally speaking, the Mo–S (ligand) bonds are longer than the Mo–S ("cubane") bonds, and the dithiocarbamate structural parameters are normal.

Compound **4** exhibits a single C=S stretching vibration at ca. 1000 cm^{-1} with no splitting due to a bidentate mode of bonding for the S_2CNEt_2 groups in the molecule. However, the strong bands at 565 and a shoulder at 551 cm^{-1} indicate that the C=S groups, although similar, are different, perhaps due to the inequivalence of S_2CNEt_2 groups. The Mo–S stretching bands lie between 300–360 cm^{-1}, in good agreement with the wide range of Mo–S distances in the structure.

The ^{1}H-NMR spectrum of **4**·toluene shows two triplets for the methyl groups at $\delta = 1.32$, 1.23, 1.14 and 1.29, 1.21, 1.12 ppm, respectively, in the expected intensity ratio 2:1.

The total molar magnetic susceptibility of **4**·toluene corrected for ligand diamagnetism is $\chi_m = 10.6\ m^3\ mol^{-1}$. The effective magnetic moment per Mo atom is $\mu_{eff} = 0.71\ \mu_B$, a value close to the spin-only value of two unpaired electrons. The ESR spectrum of solid **4** shows a triplet with $g_1 = 1.994$, $g_2 = 1.981$, and $g_3 = 1.977$. All these data suggest the presence of two unpaired electrons per molecule. Since the four Mo atoms are mutually bonded and their chemical states are equivalent, the unpaired electrons are not localized in any particular bond or atom, but delocalized throughout the entire cluster, in excellent agreement with the observed Mo–Mo bond lengths.

BOOK REVIEWS

The Formation of the German Chemical Community (1720–1795). By *K. Hufbauer*. University of California Press, Berkeley 1982. viii, 312 pp., paperback, $ 19.45.

This volume has its origins in a dissertation published in 1970 that had already set a precedent in the history of chemistry. It deals with the astonishing ascent of chemistry in the German-speaking world from the modest status of being an adjunct to medical science to being a science "in fashion" at the end of the century in question; a change that is very difficult to explain solely in terms of the development of chemical knowledge and its practical effects. *Hufbauer* correctly seeks to probe its historical roots into a background of social structures and mentalities. The result is a fascinating case study of social, institutional and cognitive changes as scientific consequences of the enlightenment.

Rationalism and utilitarianism were the decisive arguments for the new self-confidence of the subject. Rhetoric and strategies of institutionalization marked the moulding and acceptance of the discipline. The success can be measured in the increasing material support, in the establishment of new chairs, and in the building of laboratories. In this the medical aspect waned in comparison with those impulses which chemistry received from economic and administrational sources. The education and professional careers of the eighteenth century chemists are analyzed in detail. They were first amalgamated into a German chemical community by the brilliant scientific journalist *L. von Crell*, when he created an adequate forum of communication with the prototype of a specialized scientific journal. The origins of the contributors and subscribers emphasizes the national character of the undertaking and the role of the protestant territories of central and northern Germany as the nursery of chemical science. That nationalistic motives were another basis of the alliance became evident when the chemistry of *Lavoisier* from France brought into question the very foundations of the domestic German traditions and thus fed the consciousness of a national identity, which, however, led to rather a scientific ideology then to a paradigm in *Kuhn*'s sense. The first phase of almost unanimous rejection was followed, between 1790 and 1793, by an examination of the antiphlogistic theory, whose experimentum crucis was the reaction of HgO to yield mercury and oxygen, an examination that was every

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/0505-0392 $ 02.50/0

bit as intensive as it was free from nationalistic bias. The degree of methodological agreement and the speed with which the controversy was pursued and put aside, indicate that the formation of the German chemical community had been completed by this time.

The history of this, until now, unwarrantably neglected chapter is of great general historical interest. Additionally the historian of chemistry will discover in the volume a veritable treasure trove for the history of his subject. What the 147 page appendix with biographical profiles of 65 chemists means in terms of detailed historical research can only be appreciated by those who have worked in the same field. Thereby remain some uncertainties which the abundance of chronological data concerning education and careers should not be allowed to obscure. Those who are familiar with this relatively scattered material will not be surprised. The same applies to the histories of the 59 institutions studied, for it is often impossible to conclude a great deal from the nominal incumbency of professorial chairs in the 18th century. Professorships of special subjects and courses of study did not exist in the present-day sense. For instance, under the University of Halle the too formalistic presentation results, unbelievably, in the omission of *G. E. Stahl,* the scholastic mentor of a whole generation of German chemists, simply because he formally held chairs for physiology, pathology, materia medica, botany and philosophia naturalis, but not for chemistry. Nevertheless, the priceless material contained in the appendices and footnotes, and from which by no means the last drops have been squeezed, will make the volume indispensable for future workers on the history of eighteenth century chemistry.

The reviewer would have liked to have seen more discussion of three themes. The first is the structure and peculiarities of the German academic landscape, which made possible the blossoming of the discipline on such a wide front; the second concerns the local learned societies or associations for the encouragement of industry and their part in the spreading and realization of the declared utilitarian aims of chemistry. Thirdly, the relationship of the subject to cameralism, the German form of mercantilism, should have been made plainer since the key position of chemistry in economic and financial reform was alloted to it from just this quarter. According to the cameralist theorists, chemical knowledge was an essential armament for an administrative career. This ensured public approval and support for the subject.

The reviewer is sceptical of the tendency of the presentation to attach wide-ranging labels to historical diversity. This begins with "cultural nationalism" and "national community". Just what sort of chimera could represent the German nation during the period under discussion when geographically the concept is stretched to cover both Budapest and Strasbourg as well as Graz, Kiel and Königsberg? In the cases of Greifswald (Swedish until 1815) and Kiel (Danish until 1864) there is no mention of the important consequences of the bonds with the mineralogical-analytical traditions of Scandinavian chemistry. The lasting influence of *H. Boerhaave*'s "Elementa Chemiae" is also ignored as is the increasing number of works by Scandinavian and French authors that were translated into German. If these had been included in the analysis then the social structure of the German chemical community could well have seemed less closed than it appears here. Similar remarks apply to the unspecified division into protestant and catholic territories.

The thesis that the specialist journals of *L. von Crell* moulded chemists into a close-knit, discipline-oriented, national, specialist community loses its ability to convince when it turns out later that the decisive debate concerning *Lavoisier*'s theories took place not so much in *Crell*'s "Annalen" as in the "Intelligenzblatt der Allgemeinen Literaturzeitung" which was dedicated to a much wider public.

Whether the subsequent path of chemistry was as smooth as it portrayed in the short epilogue is to be doubted. The decisive steps, however, in the formation of a scientific discipline, the breaking up of the *République des Lettres* into individual scientific communities structured along the language and subject boundaries has been pregnantly depicted by *Hufbauer* using German chemistry as an example. It is easy to criticize pioneering work. He who breaks new ground has to leave much undone. It is evidence of the superiority of this work, which is original both in subject and method, that it opens up so many questions. It will stimulate further research and already provides a wealth of material thereto.

Hexachlorcyclohexan als Schadstoff in Lebensmitteln. Published by the Deutsche Forschungsgemeinschaft (DFG). Verlag Chemie, Weinheim 1983. 288 pp., paperback, DM 70.00.

This research report with a foreword by *H.-J. Hapke* (President of the DFG Senate Commission for the Investigation of Residues in Foodstuffs) contains 30 original contributions from two colloquia organized by this commission on November 28 and 29, 1979 and on March 6, 1980.

The title of this report seems too specialized since the volume not only contains a survey of the presence of hexachlorocyclohexane in the food *chain,* but also covers the following topics in an interdisciplinary and wide-ranging manner: historical development, manufacture, applications, properties (chemical, physical, physicochemical), analysis (including isomers in biological matrices), decomposition, transformations, residue situation and toxicology. This applies both to the insecticidally active γ-isomer (Lindane) and to the α- and β-isomers, which have attracted considerable attention in recent years.

Since the aim of the meetings was the evaluation of the material as it concerned human health, the effects of hexachlorocyclohexane isomers on the animate and inanimate human environment were not discussed.

It is particularly satisfactory, however, that not only real time monitoring (RTM) of aquatic, terrestrial, urban ecosystems and border areas was discussed but the latest experiences with the environmental specimen bank programme (ESBP), in this case the environmental bank of human samples, have also been included.

The broad disciplinary range of the 39 authors (pharmacology, toxicology, hygiene, industrial medicine, pharmacy, chemistry, food chemistry, biochemistry, ecological chemistry) and the participation of the German federal authorities and federal research institutions together with representatives of the chemical industry and international toxicological characterization and evaluation organiza-

tions should mean that this report is of interest to a much wider circle of readers than its title would lead one to suppose.

Protein Folding and Protein Association

By Rainer Jaenicke*

Dedicated to Professor Max F. Perutz on occasion of his 70th birthday

The biosynthesis of proteins leads to linear chain molecules with a well-defined amino acid sequence that is unambiguously determined by a corresponding polynucleotide sequence at the level of the gene. The underlying mechanism of transcription and translation is based upon the complementarity of pyrimidine and purine bases, on the one hand, and the genetic code, on the other. As indicated by denaturation/renaturation experiments, the one-dimensional structural information encoded in the polypeptide chain generates a unique three-dimensional structure. In consequence, one would expect a "folding code" to exist which governs the spontaneous acquisition of the thermodynamically stable "native" structure of a given protein. The rate of folding (in vivo as well as in vitro) is fast, despite the astronomically high number of potential conformations. The mechanism of folding must therefore be kinetically controlled. Whether the native structure represents the "global" or a "local" minimum on the energy hyperspace is an open question. Above a critical size, protein molecules tend to be organized as assemblies made up of identical or non-identical subunits. The observed uniformity of a given "quaternary structure" requires a close correlation of folding and association as well as a high specificity of subunit recognition. Both are corroborated by in vitro reconstitution experiments.

1. Introduction

As indicated by their name, *proteins* are the most abundant organic molecules in cells. Due to the characteristic structure-function relationship in biomolecules, their central role in all aspects of cell structure and function is reflected by a great diversity in their spatial structure.

The conformational characteristics of each individual protein depend both on the specific sequential order of amino acids in the polypeptide chain and on the chemical environment of the molecule. The sequence is generated as the "translation" product of the corresponding homologous nucleotide sequence on the DNA. Evidently information transfer from the gene to the functional product of its expression is mediated by two "codes", the "genetic" one, which translates the m-RNA polynucleotide sequence into the linear polypeptide chain, and the "folding code", which governs the transition from the one-dimensional information contained in the amino acid sequence into the specific three-dimensional structure of an individual structural protein or enzyme.

While the genetic code has been deciphered as a degenerate triplet code with 64 combinations of 4 letters, the code of protein folding is still totally unknown. What is known is that folding occurs in a spontaneous and autonomous way without catalytic or other cellular effectors being involved. Observations corroborating this come from in vitro reconstitution experiments: the acquisition of the native structure of proteins in the course of a denaturation/renaturation cycle allows structure formation in vivo

to be mimicked with respect to both the final product and the rate of folding[1,2].

The following discussion is based mainly on reconstitution studies, which *Max F. Perutz* has called "unboiling an egg"[3]. One reason for this approach is the fact that there is no direct way of unraveling the single steps in the folding mechanism of the nascent polypeptide chain. In addition, the free choice of variables in reconstitution experiments allows us to uncouple first-order folding reactions from second-order association reactions, thus providing a means of analyzing the correlation of subunit folding and assembly in the case of oligomeric or multimeric "superstructures".

In the following section, we shall first discuss the hierarchy of protein structure and the aims of folding and reconstitution studies; subsequent sections deal with the mechanism and kinetics of folding and association and finally with their relationship gained from in vitro experiments.

1.1. Hierarchy of Protein Structure

The term "protein folding" has come to refer to both the detailed description of the spatial arrangement (topology) of the amino acid residues in the functional protein and the mechanism or kinetics by which the unordered (nascent) polypeptide chain achieves its native conformation[4].

We shall focus on the second of these definitions. However, in order to provide a sound basis for a detailed discussion of structural transitions it may be appropriate to give a brief summary of the principles of the spatial structure of proteins[5,6].

As concluded from the vast amount of experimental data obtained from well over one hundred distinct structures of globular proteins, the three-dimensional structure of proteins may be characterized by a hierarchy of structural levels of organization[7-10].

The *primary structure*—the specific amino acid sequence along the covalent polypeptide chain—is the basic level of organization. The *secondary* and *supersecondary structures* define regular arrangements of the polypeptide backbone, e.g. helices and β structures, and their energetically and topologically preferred aggregates in terms of clusters of helices, coiled coils, βξβ units, β meanders and other preferences in β sheets etc. The *tertiary structure* refers to the three-dimensional chain fold, with structural and functional "*domains*" as spatially separated entities, sometimes with a specific function such as (allosteric) effector binding or intrinsic catalytic activity. The *quaternary structure* describes the stoichiometry and geometry of assemblies built up from subunits characterized by the foregoing levels of structural organization. Beyond a critical size of polypeptide chain, association may be considered a general structural principle, extending the molecular description into the microscopic and macroscopic range. In this structural hierarchy, "*folding*", as the transition from the one-dimensional to the three-dimensional structure, corresponds to the formation of the native secondary and tertiary structures, and "*association*" refers to the acquisition of the native quaternary structure. Both folding and association must be properly coordinated because the formation of the native quaternary structure requires that the surfaces of the structured monomers be preformed in the correct way such that specific recognition of the subunits is achieved. In fact, the specificity of association to form the native quaternary structure is exceedingly high (cf. Section 5.2).

The question as to whether folding in vivo occurs as a cotranslational or posttranslational process is still unresolved[11]. What is certain is that structural domains as well as antigenic sites are formed during translation; however, these results cannot be generalized because different systems in different compartments of the cell do not show identical patterns[11-16]. The question is essential because of the vectorial character of protein biosynthesis: if the nascent polypeptide chain acquires its biologically active form on the polysome, folding must occur stepwise from the *N*- to the *C*-terminal end. If, on the other hand, structure formation does not start until the protein is released into the cytoplasm or the lumen of the endoplasmic reticulum, folding is expected to start from the fully synthesized polypeptide chain in its random conformation. From the given alternatives, the question arises whether the products of cotranslational and posttranslational folding may differ from each other, or—to put it another way—whether the thermodynamically stable state of the native protein might be determined kinetically. There are three types of experiments which clearly indicate that the native structure of a protein molecule is determined exclusively by its primary structure (independent of its folding pathway): 1) in vitro reconstitution experiments after prior denaturation (cf. Section 3.3); 2) solid-phase peptide synthesis (from the *C*- to the *N*-terminus)[17,18]; and 3) semi-synthetic linking of protein fragments[19,20]. All three approaches seem to generate the protein in its native conformation.

1.2. Aims of Folding Studies

1.2.1. Folding Code

In view of both the "anatomy" of the known structures of globular proteins and the previously mentioned relationship between the amino acid sequence and the corresponding spatial structure of a polypeptide chain, the stage is set for elucidating the mechanisms of folding and the code by which the one-dimensional primary structure of a protein specifies its three-dimensional structure. This code will not only aid in engineering changes in protein structure (using recombinant DNA techniques), but also provide a tool to specify hypothetical functions for given amino acid sequences gained from DNA sequence analysis.

In a preliminary stage, the code of protein folding may be deduced only from small single-chain proteins. As the next step, multi-domain proteins should be included, and finally assembly systems have to be considered. Evidently with increasing size and complexity, structure predictions are complicated by the fact that both tertiary and quaternary structure are stabilized by the same types of weak intermolecular interactions[4-8,21-24].

1.2.2. Mechanism and Specificity

The formation of the native structure of proteins is strongly influenced by their aqueous or nonpolar environments (for cytoplasmic or membrane proteins, respectively). In this context, the entropic tendency to exclude water molecules from hydrophobic surfaces has three significant consequences: 1) the tertiary and quaternary structures of globular proteins favor a tightly packed state with nonpolar side chains in the interior and polar or ionized ones at the periphery of the molecule; 2) the inner "core" of the protein is unsolvated (except for very few strictly localized water molecules); 3) association leads to maximum structural complementarity of the subunit interfaces, so that all three, stoichiometry, geometry, and intermolecular interactions in a given quaternary structure, are highly specific. In order to achieve the unique fit of the subunit interfaces in oligomeric proteins, the pathway of quaternary structure formation must include well-populated, folded intermediates capable of "subunit recognition".

As in monomeric systems, where structural intermediates may be used to analyze the folding pathway, intermediates during association allow the identification of single events in the multistep folding/association process leading to oligomeric proteins. In this connection, kinetic experiments provide a means of separating both processes due to the different reaction orders of isomerization and association reactions[25,26]. By investigating the assembly pathway, we can characterize both the specificity of subunit interactions and the physicochemical and enzymological properties of kinetic intermediates. Questions that are of interest in this connection concern the structure, stability, and catalytic activity of "structured" monomers, dimers, etc., compared to the corresponding properties of the fully assembled native oligomers. For enzymes, the results may provide us with criteria for the structural prerequisites of catalytic and regulatory functions.

1.2.3. Analysis of Complex Macrostructures

Within the hierarchy of levels of protein structure, oligomeric proteins may be regarded as model systems for multimeric assemblies of higher complexity. The specificity achieved by complementarity of surface shapes, hydrophobic "patches", hydrogen bond donors and acceptors, and ion pairs is expected to hold for both oligomeric and multimeric systems. However, in many cases a detailed structural analysis of the latter is not amenable to high resolution X-ray crystallography. Oligomeric systems then may provide a key to some clearer understanding of the energetics and kinetics of association as well as the structural principles at atomic resolution.

Tobacco mosaic virus (TMV: $M_r \cong 40 \times 10^6$) may serve as an example (Fig. 1). The rodlike nucleoprotein of ca. 300 nm length and ca. 18 nm diameter consists of a single-stranded RNA-helix (ca. 6400 nucleotides) surrounded by a protein coat of ca. 2100 subunits (TMVP: $M_r = 17\,500$) [27–29]. The determination of the three-dimensional structure of the complete virion at atomic resolution has not been successful so far[27,28]. However, the RNA-free "double disc" consisting of 2×17 protein subunits turned out to be amenable to high resolution X-ray analysis[29,30]. Apart from the tertiary structure of the monomer, it provides us with certain mechanistic details of the protein-nucleic acid interaction within the virus[30,31]: only those parts of the polypeptide chain covering the RNA on the outside are found to be structured. Due to a high degree of structural flexibility of the inner part, the hole in the middle of the disc appears to be much bigger than in the whole virus.

Upon inserting the RNA, the polypeptide chain loses its flexibility, forming the rigid and highly stable nucleoprotein complex. The example illustrates the potential use of oligomeric intermediates in the structural and mechanistic analysis of complex systems; at the same time, it stresses the importance of the molecular dynamics of protein struc-

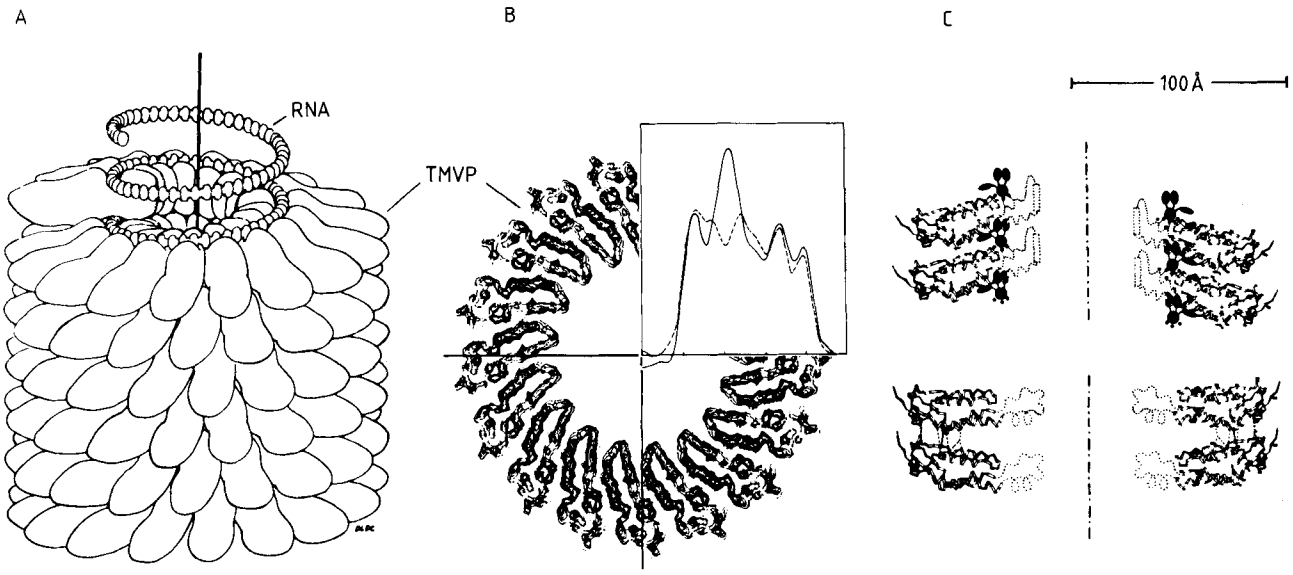

Fig. 1. Tobacco mosaic virus (TMV) as an example for a heterogeneous multimeric quaternary structure (TMVP = TMV coat protein). A) Section of about 1/20 of the length of the complete virion [27a]. B) Electron density of the double disc of TMVP and radial distribution of electron density of TMV (—) and TMVP (--) [30]. C) Side view of the TMV helix and the TMVP double disc. Dotted line: flexible part of the tertiary structure [28]. Filled circles represent the position of the RNA helix within the complete virion.

ture, which are fundamental in understanding biological function.

In the case of TMV, the double disc represents an intermediate of morphogenesis (at least in vitro): to initiate helix formation, a hair-pin loop of RNA is inserted into the double disc. "Elongation" seems to occur via (bidirectional) addition of further discs (and protein subunits) until the whole RNA strand is "coated"[32,33]. The sequential assembly reaction may be considered a model case as far as thermodynamics and kinetics are concerned[25].

With increasing complexity of the structure, an ordered assembly mechanism or specific "morphopoietic factors" may be required. This holds especially in cases where covalent modification is essential for structure formation (e.g. components of the cytoskeleton, complement system, etc.).

2. Methods

The experiments underlying the following discussion are based on the methods commonly applied to characterize macromolecules in solution (Table 1). As far as structure determination in vitro is concerned, these methods make use of the reversibility of protein denaturation focusing on *re*folding, *re*association, and *re*activation rather than folding and association. The reason is that so far no direct approach is available to study the acquisition of the native structure of the nascent polypeptide chain with sufficient resolution either in vivo or in vitro[*]. This holds especially because sensitive methods, like binding of ligands or specific antibodies, may be perturbed because the reporter molecules themselves may induce structural changes interfering with the folding process[36] (cf. Section 5.1.3).

One reason why denaturation itself is not used to unveil the structure-function relationship has previously been mentioned: dissociation and deactivation run strictly parallel (Fig. 2).

Table 1. Experimental approaches to the folding and association of proteins.

Equilibrium measurements	
State of association	Electron microscopy, ultracentrifugation, (elastic and inelastic) light scattering, gel permeation chromatography, SDS-polyacrylamide gel electrophoresis (with and without cross-linking).
Conformation	Spectroscopy (absorption, fluorescence, optical rotatory dispersion, circular dichroism, nuclear magnetic resonance), hydrogen-deuterium-(tritium) exchange, stability towards denaturation or proteolysis, binding of ligands (coenzymes, substrates, etc.) [a], chemical modification ("group specific labels")
Function (Activity)	Enzymatic assays, ligand binding (affinity chromatography)
Kinetic measurements [b]	
Assembly (Association)	Turbidity, light scattering, chemical cross-linking, hybridization
Folding	Spectroscopy (absorption, fluorescence, circular dichroism), hydrogen-deuterium exchange, limited proteolysis (Fragment analysis using gel electrophoresis), ligand binding (antibodies, allosteric effectors, etc.) [a]
Function (Activity)	Enzymatic assays, ligand binding (coenzymes, substrates) [a]

[a] Ligand binding may cause artifacts by shifting equilibria or stabilizing intermediates. [b] Depending on the time range, methods include manual mixing, stopped flow, quench stopped flow (double jump), relaxation techniques (temperature jump, pressure jump, etc.).

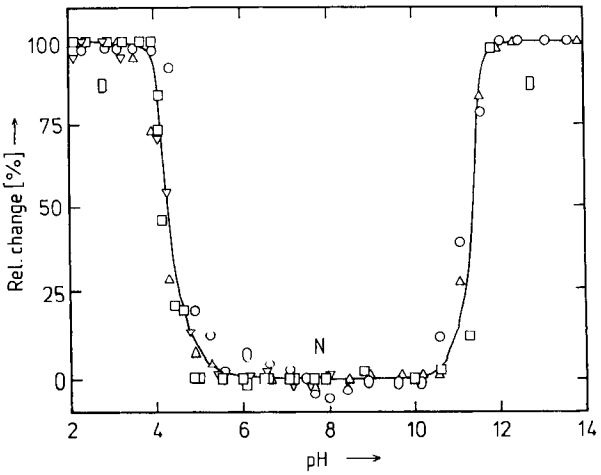

Fig. 2. pH-Dependent dissociation, denaturation, and deactivation of aldolase from rabbit muscle. N, D = native and denatured states, respectively. □ Sedimentation coefficient; △ maximum of the relative fluorescence emission ($\lambda_{exc} = 275$ nm); ▽ circular dichroism $\Theta(281$ nm); ○ specific activity [26].

Being first-order processes, they cannot be distinguished kinetically. On the other hand, the reverse reaction can be easily manipulated by varying the protein concentration, such that at low concentration the bimolecular association is rate-limiting, while at high concentration unimolecular folding gains importance. Thus, kinetic analysis allows us to gain insight into possible mechanisms of folding and association[26,37]. In order to prove or disprove such mechanisms, a variety of techniques has been devised. Determinations of the conformation and the particle distribution make use of spectroscopic methods, on one hand (absorption, fluorescence, circular dichroism, etc.), and hybridization or chemical cross-linking (e.g. with glutaraldehyde[38]), on the other (Fig. 3). Under certain conditions, intermediates of folding or quaternary structure formation may become accessible at low denaturant concentrations or by using limited proteolysis. The occurrence of such intermediates may then be used to characterize the folding pathway directly and in a detailed way[39-42]. Stability data and association enthalpies may be deduced directly from calorimetry (ΔH_{cal}) or indirectly from equilibrium constants ($\Delta H_{van't\,Hoff}$). $\Delta H_{cal} \simeq \Delta H_{van't\,Hoff}$ may be used as a criterion to prove the two-state model[43-45]. Differential scanning calorimetry has been applied successfully, especially to the study of endothermic "entropy-driven" processes[46]. In this context, measurements involving high hydrostatic pressure as well as solvation changes ("water release") may provide some deeper understanding of the thermodynamic data[23,47,48].

[*] Certain special cases (immunoglobulin [12], collagen [34], tail-spike protein of bacteriophage P22 [35]) have provided some insight into the mechanism of folding in vivo.

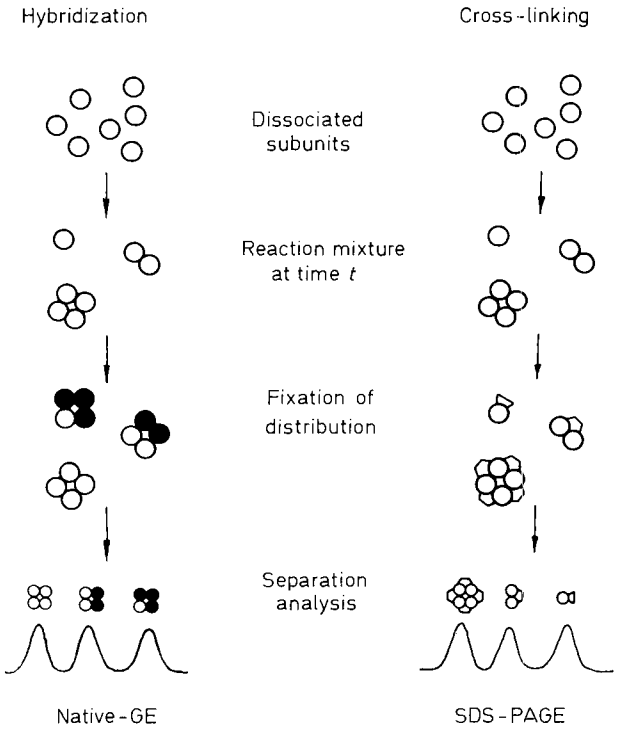

Fig. 3. Hybridization and chemical cross-linking as methods to monitor reassociation [26, 38, 115]. Native-GE = native gel electrophoresis; SDS-PAGE = SDS-polyacrylamide gel electrophoresis.

3. Nature of the Native and Unfolded States

To be able to understand the process of folding of a protein from its unordered to its active state, we have to try to describe the unfolded (D) and native (N) states. The "pathway" connecting both represents the sequence of all intermediates and transition states between D and N.

The complexity of the problem becomes obvious if we consider that "the denatured state" represents the sum of numerous heterogeneous conformations of closely similar energy which (at least in early stages of folding) belong to different folding paths. An estimate of the number of different conformations for a protein with an average molecular weight of ca. 20000 yields a figure of the order of 10^{80}[5]. Thus, the problem of the folding pathway in the sense of the previous definition is meaningless. On the other hand, the description of N and D and the characterization of intermediate states (sufficiently populated to be detectable with one of the methods mentioned) seem to be challenging, yet solvable problems[49-53].

3.1. Native State

Detailed models of the native state of proteins are obtained by X-ray analysis of crystals. Schematic representations of the "anatomy" of the polypeptide backbone[6] of a number of proteins discussed in the following paragraphs are depicted in Figure 4. Except for a certain degree of flexibility of side chains or loops in the periphery of a globular molecule, one may assume that the conformations in solution and in the crystal are identical[54,55].

Each of the topologies given in Figure 4 represents a specific way of minimizing the hydrophobic surface area, while, at the same time, forming a maximum number of stabilizing intramolecular interactions. Although the inner

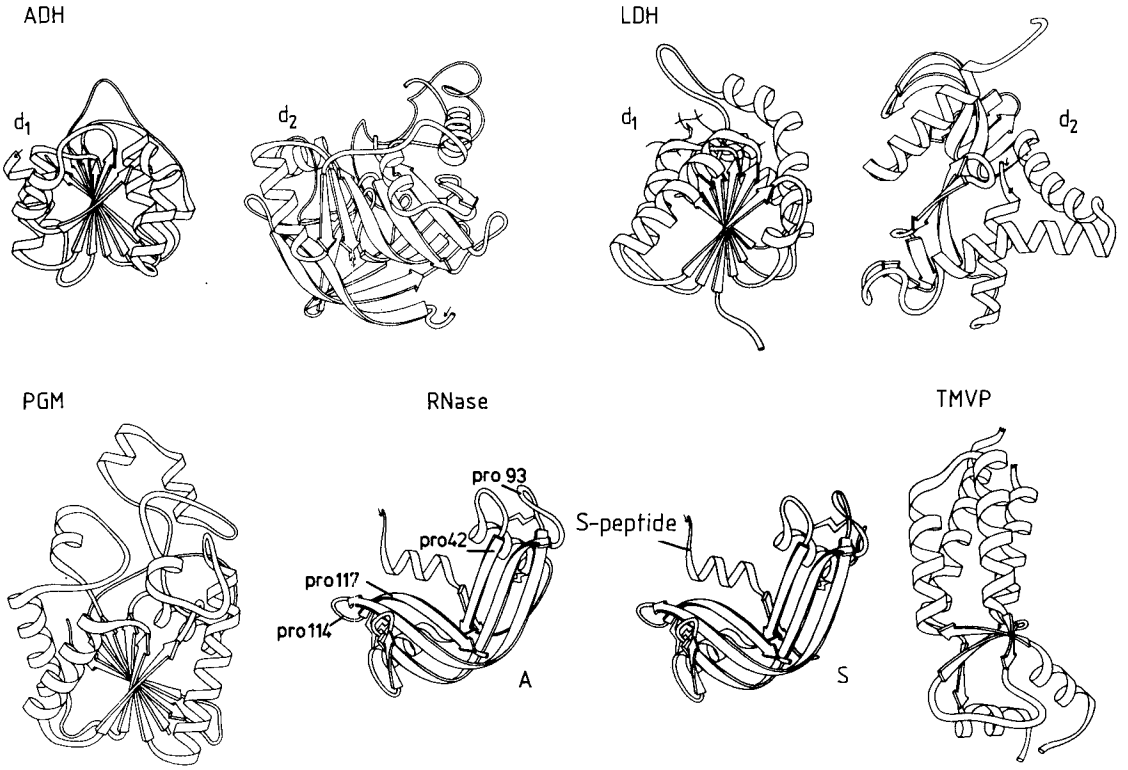

Fig. 4. Tertiary structure of selected proteins (according to Richardson [6]). ADH = liver alcohol dehydrogenase; LDH = lactate dehydrogenase; PGM = phosphoglycerate mutase; RNase = ribonuclease (RNase A includes the position of proline residues; RNase S, subtilisin-treated enzyme); TMVP = tobacco mosaic virus protein. d_1, d_2 signify the structural domains of the dehydrogenases 1 and 2, respectively.

core of the molecules resembles the crystal lattice of small amphipathic molecules with regard to the packing density and compressibility[55–57], the free energies of stabilization are small compared to the sum of the stabilizing intermolecular forces ($\Delta G_{stab} \cong 40$ kJ/mol). Clearly, the stabilizing and destabilizing contributions more or less compensate each other, so that at temperatures encountered in vivo kT is sufficient to provide the conformational flexibility required to optimize the biological function[58,59]. The size of the molecule has no significant influence on the free energy of stabilization. Domains or subunits therefore favor folding, flexibility, and transport without affecting stability.

The examples provided by NAD-dependent dehydrogenases[60] suggest that a given tertiary structure may tolerate a great number of amino acid exchanges without its topology being changed significantly ("degenerate folding code"). On the other hand, there exist only a limited number of amino acid sequences yielding a well-defined stable tertiary structure. Both observations are considered to be responsible for the surprisingly small number of "folding topologies" that have been deduced from the more than 100 crystal structures solved so far[6]. In this context, one has to keep in mind that (apart from the astronomically high number of possible conformers, ca. 10^{80} for $n \cong 170$) the 20 natural amino acids may give rise to $20^n \cong 10^{220}$ different sequences with the given chain length[*]. Clearly, there exist many "non-coding sequences" which do not generate a defined stable three-dimensional structure.

3.2. Unfolded State

The native state of a given protein requires a certain "quasi-physiological" environment. If this is changed, e.g. by varying the pH, the hydrostatic pressure, or the temperature, or by adding solubilizing agents, e.g. urea, guanidine·HCl, detergents, etc., "denaturation" occurs. In a good solvent, as a limiting case, the polypeptide chain will approach the randomly coiled state[61]. In the native state, rotation about the various bonds along the chain is restricted by the preferred trans-configuration of the peptide bond[62] and by van der Waals limitations with respect to the N–C_α and C_α–C bonds[63], which leave no more than 25% of the Ramachandran space available for attainment of the energetic optimum[*]. Part of these restrictions remain unaffected even at maximum solubilization in 6 M guanidine·HCl, so that the unfolded state may not represent an ideal random coil in the sense of the statistical theory of polymers[64,65]. Circular dichroism or (intrinsic) fluorescence may be used to measure unfolding. Both approaches clearly show that dissociation and deactivation, e.g. at acidic pH or high hydrostatic pressure, may occur without drastic changes in the native secondary and tertiary structures. Under certain experimental conditions, unfolding and dissociation may be totally "uncoupled"; the corresponding reconstitution experiments may then provide a means of studying the formation of "structured monomers" and their assembly as separate processes.

3.3. Reconstitution

For small single-chain proteins, denaturation has been shown to proceed as an equilibrium reaction

$$N \rightleftharpoons D \qquad \text{(a)}$$

where N and D are the native and the denatured states, respectively. The product of renaturation does not differ from the initial native state (Fig. 5A); the transition may be adequately described by the two-state model ($\Delta H_{cal} \cong \Delta H_{van't\,Hoff}$)[43].

Multi-domain proteins and proteins with quaternary structure usually exhibit complex behavior[26,66]: the renaturation yield is decreased, and the profiles of denaturation and renaturation do not coincide (Fig. 5B). "Wrong

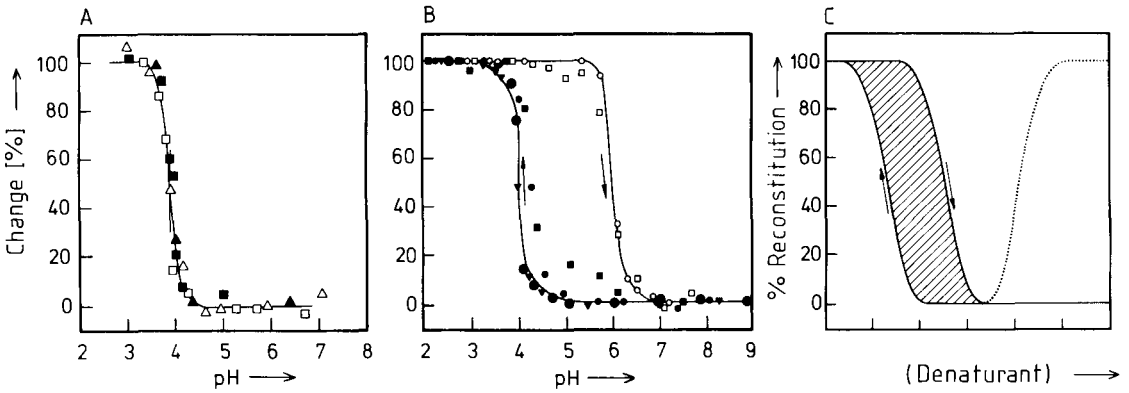

Fig. 5. Denaturation-renaturation of monomeric and oligomeric proteins [25, 26]. Open symbols: denaturation (deactivation); closed symbols: renaturation (reactivation). A) Staphylococcal nuclease: (□, ■) reduced viscosity; (△, ▲) circular dichroism Θ (220 nm). B) Lactate dehydrogenase from porcine skeletal muscle (LDH-M_4): (●) sedimentation coefficient $s_{20,w}$; (○, •) specific activity; (□, ■) maximum of relative fluorescence; (▼) circular dichroism Θ (192 nm). C) Competition of reconstitution and aggregation during the reassociation of oligomeric proteins. Hatched area: Range of metastability (aggregation) range between denaturation (↑) and renaturation (↓). The dotted curve gives the reactivation yield in the absence of the denaturant (after incubation at the given denaturant concentration) [26].

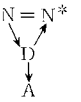
[*] An estimate of the probable number of atoms in the universe yields 10^{79} [5, 49].

[*] Crystallographic analysis has revealed that in native proteins each proline residue usually occurs as a unique *cis*- or *trans*-isomer. Release from the conformational constraint (e.g. by denaturation) yields an equilibrium distribution of *cis*:*trans*-isomers of ca. 20:80. The relaxation time of the isomerization reaction, as determined for model peptides or small proteins, varies at room temperature from seconds to a few minutes; the energy of activation is ca. 85 kJ/mol [10].

aggregation" due to intermolecular interactions of groups exposed in the N→D transition is the main reason for the observed perturbation[66–69]. For oligomeric enzymes, the inverse concentration dependence of reconstitution and aggregation (Fig. 6) clearly proves that kinetic competition prevails between the two reactions, according to

$$A \longleftarrow D \longrightarrow N^* \qquad (b)$$

where A, D, N* represent the aggregated, denatured, and reconstituted states of the protein, respectively. At high protein concentrations, aggregation governs the coupled folding-association reaction so that under unfavorable conditions "irreversible denaturation", i.e. complete aggretation, occurs[69]. The effect may easily be reversed by resolubilizing the aggregates (e.g. in 6 M guanidine·HCl) and subsequently renaturing the protein under optimum reconstitution conditions[69][*]. The final product of reconstitution (N*, after separation from A) has been shown to be indistinguishable from the initial native state N by all available physicochemical and enzymological criteria (Table 2). Thus the complete denaturation-renaturation cycle may be written as follows.



(c)

This result is crucial for two reasons: 1) the "reversibility" of denaturation corroborates the assumption that the native state is thermodynamically stable and unambiguously defined with respect to its three-dimensional structure; 2) the fact that renaturation leads back to the native state (N* = N), encourages us to consider reconstitution experiments in vitro (D→N*) as model reactions for folding and association in vivo, as far as structure, energetics and kinetics are concerned[*].

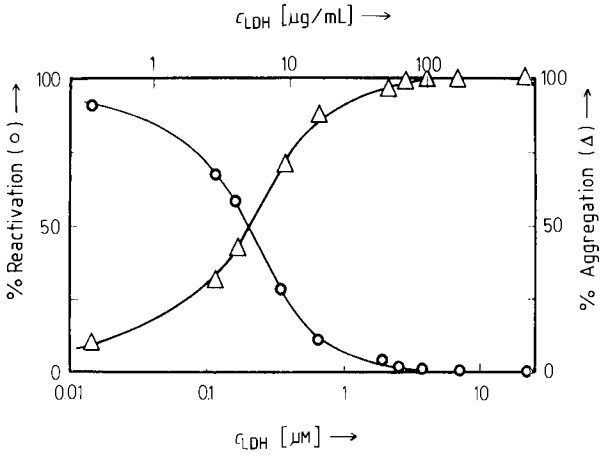


Fig. 6. Kinetic competition of reconstitution (○) and aggregation (△) for lactate dehydrogenase from porcine skeletal muscle (LDH-M_4) [69].

4. Folding

Ribonuclease may be taken as an example of the simple case of a single-chain, one-domain protein[49–53]. As derived from renaturation experiments, the half-life of the formation of the native structure is of the order of 10 s. In view of the exceedingly great number of possible conformations with a polypeptide chain of 124 amino acids, this time is extremely short. If folding implied a stochastic process, the time required to probe all possible conformations in search of the global minimum of potential energy would be about 60 orders of magnitude longer[72]. The discrepancy may be explained by kinetic and configurational constraints, defining the thermodynamically stable state as the "kinetically accessible state of minimum energy"[11]. A

[a] Enzymes: ALD = aldolase from rabbit skeletal muscle; LDH-M_4 = lactate dehydrogenase from pig skeletal muscle; s-MDH, M-MDH = cytoplasmic, mitochondrial malate dehydrogenase from pig; ODH = octopine dehydrogenase (isoenzymes A + B) from *Pecten jacobaeus*. N, D, and N* = native, denatured, and renatured states, respectively (D_S: denaturation in 1 M glycine/H_3PO_4, pH 2; D_G: denaturation in 6 M guanidine·HCl). $s^0_{20,w}$ = sedimentation constant, M_r = molecular weight, λ_{max} = maximum of fluorescence emission (λ_{exc} = 280 nm), F_{rel} = relative fluorescence. θ_{208}, θ_{222} (degrees·cm^2·dmol^{-1}) = molar ellipticity (mrw = 113) at 208 and 222 nm, respectively. K_M (K_D) = Michaelis constant, (dissociation constant) for NADH as coenzyme; $K_{M,substrate}$ = Michaelis constant for pyruvate (LDH, ODH) and oxaloacetate (MDH).

[*] Reconstitution after prior denaturation (aggregation) may be applied as a purification step in the isolation of proteins. For example, proteases may be separated from high molecular weight subunits or insoluble cellular protein by fractionation under denaturing conditions. Fractions may then become accessible after solubilization in urea, guanidine·HCl, or sodium dodecyl sulfate (SDS), etc. [69, 70].

[*] The folding of proteins with an average molecular weight $M_r \cong 100000$ takes seconds to minutes. For the total enzyme pattern, e.g. of *Escherichia coli*, the upper limit for the time required for transcription, translation, folding, and association is the generation time of the bacterium (ca. 20 min).

plausible way of most efficiently reducing the number of structural intermediates would be a unique folding pathway with stereochemically well-defined intermediates[53].

4.1. Models

"Hierarchical models" describing folding as a sequential process start from short-lived unstable microdomains and proceed via "embryos" to increasingly higher substructures. They are primarily based on short-range interactions within the folding chain. Correspondingly, such models lead to helices, (twisted) β structures or β hair-pins as intermediates; tertiary structures are then formed from these by the action of long-range stabilizing forces[73-75]. Early intermediates are assumed to be involved in isomerization equilibria favoring the less stable levels within the structural hierarchy. "Nucleation sites" may be α helices, hydrophobic clusters, antiparallel β structures (hair-pins), and β bends[74-78]. For a more detailed discussion of topological and statistical mechanical theories see [4, 53, 75].

The models of protein folding proposed so far can only claim to be of heuristic value. Experimental data are only available for phase transitions of model peptides. These data confirm the high rates observed for elementary processes such as α helix formation (ca. 10^{-6} s); for the formation of hydrophobic "clusters" (ca. 10^{-3} s) and β structures (< 1 s), only estimates can be given[49, 74].

4.2. Ribonuclease

Most theoretical studies on protein folding refer to bovine pancreatic trypsin inhibitor (BPTI, $M_r = 6500$) because of its small size. From the experimental point of view, ribonuclease (RNase, $M_r = 13\,700$) has been the most extensively studied system. Consisting of 124 amino acid residues, the enzyme has the typical size of a single folding domain. It contains all structural elements characteristic of globular proteins, including 4 disulfide bridges stabilizing the three-dimensional structure. The equilibrium of folding-unfolding U ⇌ N (Fig. 5A) fits the two-state model on thermodynamic criteria. On the other hand, the kinetics of the U→N transition are complex, requiring at least three species to fit the data quantitatively. The corresponding minimum scheme (d)

$$U_S \overset{\text{slow}}{\rightleftharpoons} U_F \overset{\text{fast}}{\rightleftharpoons} N \qquad (d)$$

can be considered as a first approximation. Stopped flow experiments allow the amplitudes as well as the kinetic constants of the two sequential steps to be determined[79, 80]

$U_S \longrightarrow N$ (80%) $\tau_{1/2} = 12$ s
$U_F \longrightarrow N$ (20%) $\tau_{1/2} = 30$ ms, 25 °C
activation energy ($U_S \rightleftharpoons U_F$): 85 kJ/mol

The relative amplitudes of the fast and slow folding species do not change at high temperatures or high denaturant concentrations; i.e. both U_S and U_F are unfolded polypeptide chains which (in the denatured state) are at equilibrium in the ratio 80 : 20. In view of the two-state situation, U_S and U_F can only differ in entropy; energetically they must be closely similar, if not identical.

These observations are consistent with the characteristics of the *cis-trans*-isomerization of X-proline peptide bonds[81-84] (cf. [*] on p. 400). A more detailed analysis of the kinetic data shows that U_S is not a homogeneous species, but rather a mixture of at least two components differing in the number and/or the position of their non-native X-proline states[85].

As mentioned previously, eq. (d) holds only in the equilibrium transition range. Under native conditions, the folding reaction $U_S \rightarrow N$ requires a more complex kinetic scheme with at least two intermediates[81, 84-86]:

$$U_S \longrightarrow I_1 \longrightarrow I_N \longrightarrow N \qquad (e)$$

Compared with the kinetics of proline isomerization in the unfolded state, I_1 is formed in a rapid reaction. It is characterized by an open conformation with a high amount of secondary structure[87]. As expected (cf. Section 4.1), this is formed at an early stage of folding[*].

I_N is a native-like intermediate with at least one "wrong" proline isomer; it contains a hydrophobic "core" and exhibits normal cytidine 2'-monophosphate (2'-CMP) binding and high catalytic activity. However, it is less stable than the native enzyme[85, 88]. Clearly, the folding of ribonuclease is not blocked by proline isomers in their non-native configuration. The secondary structure is generated in a fast reaction, preceding the formation of the native tertiary structure via I_1 and I_N. The detailed description of the folding pathway in terms of the sequential formation of defined intramolecular interactions along the polypeptide chain has not yet been obtained. In this respect, information is expected to come from folding studies involving limited proteolysis and from investigations of homologous enzymes with definite amino acid replacements. Initial results have shown that the *C*-terminal end of the polypeptide chain becomes inaccessible at an early stage of folding[42].

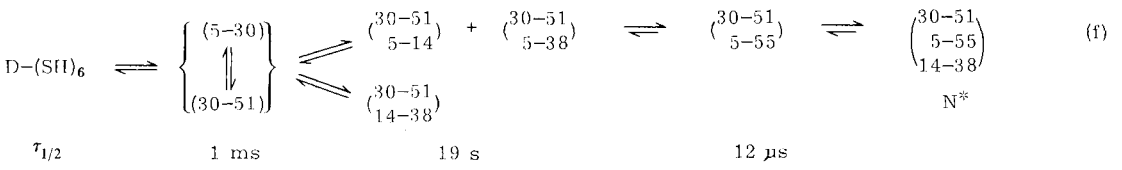
The hypothesis that folding is in principle determined by non-native proline isomers does not take into account the specific neighborhood of the proline residues within a given sequence. Energy calculations as well as folding experiments indicate that this hypothesis has to be limited to "essential" (in contrast to "non-essential") proline residues[89, 90]: Estimates of the decrease in stabilization energy induced by non-native proline residues yield a range of $\Delta\Delta G_{stab}$ between ca. 5 and ca. 85 kJ/mol, depending on the folding conditions and the position of X-proline bonds within the sequence[89]. Only those residues contributing significantly to destabilization are considered to be essential in the folding process. On investigation of homologous ribonucleases with varying proline content, neither the folding properties nor the stability of the molecules were found to be changed. Evidently the enzyme contains non-essential proline residues, and the folding pathway has

[*] Whether I_1 and N have identical secondary structures or whether a certain degree of intramolecular reshuffling occurs [73] is still unknown. A number of observations point to a close similarity.

been conserved during evolution, despite considerable alterations in the primary structure[90]. In summary, the results seem to confirm the hierarchical model of protein folding: the all-*trans* polypeptide chain synthesized on the ribosome generates, at an early stage of folding, elements of secondary structure in a fast reaction. These may be considered as "microdomains" or "embryos", which at later stages form native-like intermediates (I_1, I_N) stabilized by long-range interactions. The final product is the native enzyme (N). Additives stabilizing the native structure may accelerate the folding reaction by shifting early equilibria (e.g. $U_S \rightarrow I_1$). Clearly, the final stages ($I_1 \rightarrow N$) are not blocked by incorrect proline isomers. These are always positioned in β bends, i.e. in the periphery of the molecule, so that their *trans→cis* isomerization may occur after establishing the native-like state I_N. The flexibility of the "hinge residues" involved may serve the purpose of allowing the nascent molecule to ultimately achieve its compact native structure.

The experimental results discussed in this section were obtained using ribonucleases with unmodified disulfide bridges. As shown by *Anfinsen* et al.[91], the reduced enzyme may be completely reactivated by reoxidation. Since the cross-bridges involve cysteine residues distributed over the whole polypeptide chain, it is a plausible assumption that the formation of cystine bridges in vivo is a posttranslational event. The redox-equilibrium depends on the level of reduced and oxidized glutathione; under physiological conditions within the cell as well as in blood plasma, it is shifted towards the oxidized, i.e. the active state, of the enzyme[92].

For the trypsin inhibitor BPTI, which contains three cystine bridges, 15 different combinations of the thiol groups may occur in the reduced polypeptide[2]. In this case, careful reduction-reoxidation indicated that there exists a series of redox-equilibria on the folding pathway, such that wrong intermediates formed in preequilibria are corrected to generate finally the native state[49]. The folding pathway, showing the positions of cysteine residues involved in intermediary disulfide bonds with their respective number, may be represented schematically by eq. (f).



(f)

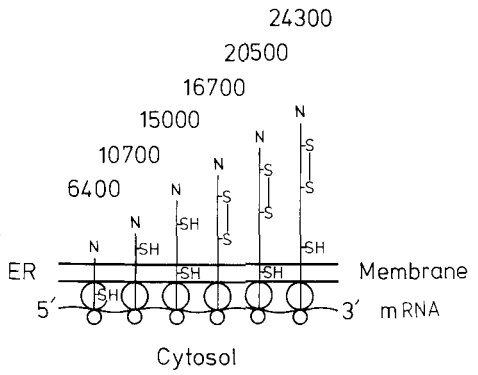


Fig. 7. Cotranslational folding of the nascent polypeptide chain of immunoglobulin. Formation of intramolecular disulfide bonds within the structural domains of the light chain of MPC 11 still fixed to the polyribosomal complex. ER = endoplasmic reticulum. The numbers refer to the molecular weight of the growing polypeptide chain (after [12]).

ments in vitro, these interactions may cause the same kind of side-reaction mentioned previously in connection with "wrong aggregation" upon subunit association (cf. Section 3.3). For this reason, the single-chain octopine dehydrogenase (as an NAD-dependent oxidoreductase, a typical multi-domain protein) exhibits a reaction yield of only ca. 70%[94]; the remaining 30% is lost due to the occurrence of incorrect intermolecular interdomain interactions[*]. The enzyme is deactivated at low guanidine concentrations in a highly cooperative monophasic process; in contrast to this simple transition, denaturation shows a biphasic profile which may be attributed to two domains, or (more probably) to the secondary and tertiary structure of the enzyme. The kinetics of renaturation also exhibit a two-step profile, since the rapid regain of native fluorescence precedes the rate-limiting reactivation, according to

$$\mathscr{M} \xrightarrow{\text{fast}} M' \xrightarrow{k_1} M \qquad (g)$$

where $\mathscr{M}$, M', and M represent the denatured, "structured", and native monomer, respectively, and k_1 is the first-order rate constant of reactivation ($k_1 = 6.6 \times 10^{-4}\ s^{-1}$).

4.3. Proteins with Domain Structure

The folding of multi-domain proteins seems to occur as a cotranslational process. For example, in vivo translation of the light and heavy chains of immunoglobulin (which is a typical multi-domain protein), clearly proves that domain folding and disulfide cross-bridge formation parallel the synthesis of each single domain[12] (Fig. 7). By making use of this kind of vectorial folding mechanism ("folding by parts"[11,93]), the nascent polypeptide chain is able to avoid wrong inter-domain interactions. In folding experiAs in the case of ribonuclease, the rapid reorganization of the secondary structure and the acquisition of the native tertiary structure follow each other.

Folding units that are integrated into the native molecule as structural domains may be considered obligatory kinetic intermediates on the pathway of folding. Apart from eliminating "wrong aggregation", they may be of se-

[*] The fact that the yield of reactivation is independent of the time of denaturation may be considered to indicate that proline isomerization in the unfolded state is not responsible for the incomplete reactivation.

lective advantage because they enhance the folding rate of long polypeptide chains ($M_r > 20000$) considerably, thus avoiding proteolytic degradation (turnover) of the nascent molecules[93].

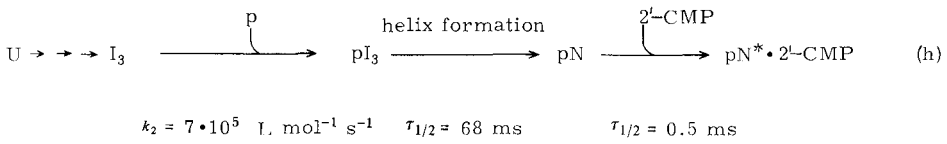
If various domains in a given molecule possess different enzymatic activities, e.g. the tetrameric aspartokinase homoserine dehydrogenase I, the local domain structure may be of additional importance because the allosteric function of the whole molecule may be used to optimize separate steps in sequential or concerted reaction mechanisms involving single domains[95]. Corresponding denaturation-renaturation experiments allow us to determine the structure-function relationship of the complex and its constituents. In this connection, the independence of domains is stressed by comparing the bifunctional complex with its proteolytically separated domains: both differ only slightly in their folding properties[96,97].

4.4. Fragments

Folding studies on protein fragments may be used to answer a number of questions: What is the minimum length of a polypeptide chain that is required for enzyme function? To what extent can separate domains or other substructures associate to form functional proteins? What is the significance of specific sequences in a given polypeptide chain for subunit assembly or for a complex reaction sequence? Can fragments be used to analyze the pathway of folding and association? At which stage in translation do folding, processing, and conjugation[*] (e.g. with carbohydrates, lipids, or nucleic acids) occur?

Fragmentation of a given polypeptide may be brought about at the level of the gene, as well as during or after translation. A few examples may serve to illustrate the alternatives: in vivo folding studies using proteins from mutants or homologous proteins from different sources differing in the sequence and length of their polypeptide chains [35, 93]; in vitro translation of manipulated structural genes, e.g. of aminoacyl tRNA synthetase (ala) which proves the "modular" organization of single activities along the polypeptide chain[98]; cotranslational cross-bridge formation between thiol groups in nascent proteins[12] (see Fig. 7); posttranslational modification applying limited proteolysis to study the folding and association of single-chain, as well as oligomeric proteins[41,42].

In studies of the correlation of folding and association, protein fragments and their reconstitution may be used as a model in two ways: on the one hand, suitable fragments may provide us with stable intermediates of folding or reconstitution which are below the limits of detection for the complete chain (cf. Section 5.3). On the other hand, the mutual effect of subunits on each other in the process of association may be simulated by applying the reconstitution of fragments. Again ribonuclease may serve as an example. The endoprotease subtilisin splits RNase A specifically, producing inactive S-peptide (p) (amino acids 1—20) and inactive S-protein (amino acids 21—124)[99]. Reconstitution of the two fragments yields a stable complex (RNase S) with full enzymatic activity (cf. Fig. 4). Under standard folding conditions, the S-peptide has a random conformation; its α-helical structure is stabilized only after reconstitution[100-102]. An analysis of the kinetics of the assembly (S-protein + p → RNase S) proves that the S-peptide binds to an early structural intermediate. However, this binding alone is insufficient to stabilize its helical conformation. It is only after the S-protein has acquired its final backbone structure that S-peptide as well as the whole complex (RNase S) are fixed in their specific active conformation. The late events in the pathway of reconstitution are summarized in eq. (h).



U, I_3, and N, N* = unfolded state, intermediate, and native states of the S-protein, respectively; p = S-peptide; k_2 = second-order rate constant of association; $\tau_{1/2}$ = half-life of transconformation.

The final product pN* exhibits properties of the native enzyme. For its recombination, the formation of the proper "recognition site" (U → I_3) is a necessary requirement. The resulting uni-bimolecular reaction sequence: *folding → association → function* provides a model for the general mechanism observed for oligomeric systems.

5. Association of Oligomeric Proteins

The model reaction discussed in Section 4 differs from the situation during folding and association of oligomeric proteins in two ways: Firstly, quaternary structure formation refers to polypeptide chains of comparable size, which in principle exceed the subdomain size, so that solvent interactions enforce a certain intrinsic backbone structure to the entities undergoing association. Secondly, subunits of oligomeric proteins (in contrast to small single-chain, one-domain systems) exhibit the previously mentioned competition between intra- and intermolecular interactions, which gives rise to incomplete reconstitution due to "wrong aggregation" (cf. Section 3.3). In consequence, the formation of "structured monomers" must precede any assembly reaction in order to achieve high yields of native oligomers (cf. Fig. 6). Specific association requires comple-

[*] Processing and conjugation specify covalent modifications of polypeptides produced by partial proteolysis and linkage of non-protein components, respectively.

mentary surface structures to be formed before subunit association occurs.

5.1. Folding and Association

In vitro reconstitution depends on the state of denaturation and the relative rates of folding and association. Because dissociation, deactivation, and denaturation of oligomeric enzymes, and the respective reverse reactions are coupled processes (Fig. 2), association cannot be totally separated from folding. Investigations of the equilibrium properties in the oligomer-monomer transition range are therefore unsuited to answering the question of whether or not isolated monomers of oligomeric proteins possess biological function or maintain at least part of the specific structural properties essential for the native state. The only way to gain insight into the correlation between folding and association is by kinetic analysis of the reconstitution reaction under a variety of folding conditions and/or starting from different stages of unfolding[37,68,91].

5.1.1. Reconstitution of Structured Intermediates

There have been successful attempts to dissociate oligomeric proteins without drastic perturbation of the native backbone structure of the constituent subunits. For the previously mentioned uni-bimolecular mechanism, this is clearly indicated by the fact that rate-limiting, first-order folding reactions become insignificant.

A few examples may serve to illustrate the wide range of approaches possible:

1) By varying the temperature, dissociation equilibria may be shifted, yielding well-defined assemblies or "structured monomers" (cf. intermediates in the endothermic polymerization of tobacco mosaic virus protein[32], cold-inactivation of enzymes[55], and other entropy-driven processes[103]).

2) High hydrostatic pressure (ca. 1 kbar) is known to induce denaturation and deactivation of oligomeric proteins, accompanied by subunit dissociation[48,55]. The complete reversibility of the reaction after decompression to normal atmospheric pressure[104–106] arises because hydrophobic side chains involved in intersubunit contact areas are reversibly buried in the interior of the subunits in the process of high pressure dissociation[106]. The exposure of charges (dissociation of ion-pairs) and their corresponding electrostrictive effect on the solvent allow the pressure-induced denaturation to be explained in terms of Braun-Le Chatelier's principle.

3) By addition of stabilizing ions (e.g. 1 M Na_2SO_4) to the denaturant, "structured monomers" may be preserved even at extremes of pH[26].

4) Dissociation by dilution (according to Ostwald's law) is expected to be the most protective approach. Evidently, it is only applicable if the dissociation constant is sufficiently high for accurate measurements to be feasible. For most oligomeric proteins this condition is not fulfilled. In addition, the reverse reaction is inaccessible to kinetic approaches. Results may therefore only be used to characterize certain equilibrium properties. In this context, the technologically important binding of proteins to a matrix is an interesting variant[107]. Using low protein concentrations, one can readily succeed in linking oligomers via single subunit contacts to the column so that denaturation-renaturation leads to separate matrix-bound monomers[108]. In certain cases, their properties were shown to resemble those of the oligomeric system. However, it appears that the matrix may "mimic" the subunit interface present in the native quaternary structure; another explanation may be the mobility of the fixed monomers due to the flexibility of the chain molecules forming the gel matrix.

5) Finally, quasi-native intermediates of association may become accessible at medium denaturant concentrations[39] or as metastable products of reconstitution[109] or limited proteolysis[110]. As shown in Section 5.3, they are highly instructive in illustrating the correlation of quaternary structure and biological function.

5.1.2. Mechanism of Reconstitution

Kinetic analyses of the concentration dependence of reactivation, renaturation, and reassociation of oligomeric proteins prove that the overall process of in vitro reconstitution is a superposition of (unimolecular) isomerization reactions with a sequence of (bimolecular) association steps according to

$$n\,M' \longrightarrow n\,M \longrightarrow \frac{n}{2}\,D' \longrightarrow \frac{n}{2}\,D \longrightarrow \frac{n}{4}\,T' \longrightarrow \frac{n}{4}\,T \longrightarrow \cdots \qquad \text{(i)}$$

Because of the "quasi-physiological conditions" commonly used in reconstitution experiments, this scheme implicitly includes three assumptions: 1) because of the stability of the native quaternary structure, reverse reactions are omitted; 2) fast folding steps preceding the formation of M′ are not included because they are not rate limiting [cf. eq. (g)]; 3) for the reconstitution of tetramers, trimers (only present in insignificant amounts) are ignored.

The strategy in evaluating the mechanism of reconstitution involves the determination of rate-limiting steps and the characterization of sufficiently populated intermediates in the given scheme. Using the time course of regaining enzyme activity and fluorescence to monitor reconstitution, one can obtain unambiguous kinetic data. Independent evidence comes from parallel cross-linking and hybridization experiments. In summary, the recovery of the native structure and function can be directly correlated with individual steps in the general scheme in eq. (i). By inspection of the kinetic reconstitution profiles, the concentration-dependent sigmoidal patterns immediately indicate that both folding *and* association are rate limiting. Both follow simple exponential functions, and concentration is a means of establishing association[26,37].

For native *dimers*, reconstitution consists of only one association step ($2M \rightarrow D'$), apart from two isomerization reactions at the level of the monomer and the dimer ($M' \rightarrow M$ and $D' \rightarrow D$). Which of these reactions is rate limiting cannot be predicted a priori. Depending on whether the formation and assembly of "structured monomers" or the reshuffling of the dimer is rate limiting, a uni-bimole-

cular or a simple unimolecular mechanism is expected to hold.

Two closely related enzymes, cytoplasmic (s-MDH), and mitochondrial malate dehydrogenase (m-MDH), illustrate the two alternatives[94, 111]. Both enzymes are synthesized in the cytoplasm as products of different nuclear genes. They are composed of identical subunits of equal size, but widely differing primary structure. Their dimeric quaternary structure is highly stable ($K_{ass} > 10^9$ L/mol) and, hence, reconstitution experiments may be performed over a wide concentration range.

Denaturation in 6 M guanidine·HCl and subsequent renaturation by dilution leads to totally different reconstitution kinetics for the two enzymes (Fig. 8). Only the fast early steps ($\mathcal{M} \rightarrow$ M′) show comparable rates. s-MDH (though chemically homogeneous) is characterized by two separable, slow, first-order reactions without any detectable concentration dependence. m-MDH, on the other hand, exhibits the typical uni-bimolecular reaction pattern. For both enzymes, the product of reconstitution is indistinguishable from the initial native state (N* = N) (Table 2).

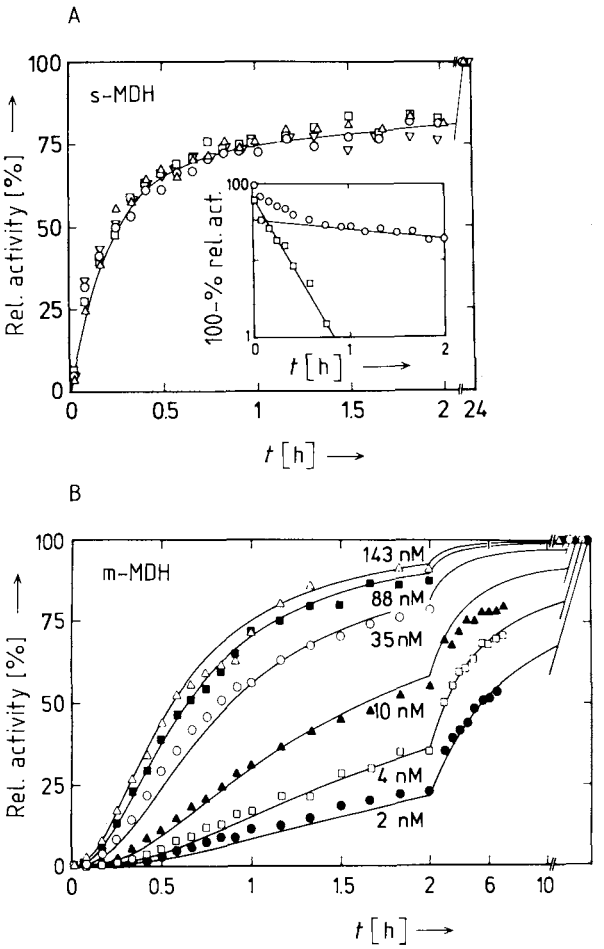


Fig. 8. Kinetics of reconstitution of dimeric porcine malate dehydrogenase (MDH) after denaturation in 6 M guanidine·HCl or 1.0 M glycine/H_3PO_4, pH 2.3. Reactivation by dilution in 0.1 M sodium phosphate, pH 7.6. For experimental details see [94, 111]. A) Cytoplasmic MDH (s-MDH). Reconstitution at c_{MDH} [μg/mL] = 1.3 (○), 3.7 (△), 6.4 (□), 12.9 (▽). Profile calculated according to eq. (j) using $k_1 = 13 \times 10^{-4}\ s^{-1}$ (68%) and $k_1' = 7 \times 10^{-5}\ s^{-1}$ (32%). Inset: linearization using 1st order kinetics to determine k_1 and k_1' (c_{MDH} = 1.3 μg/mL). B) Mitochondrial MDH (m-MDH). Reconstitution at c_{MDH} [μg/mL] = 0.07 (●), 0.14 (□), 0.35 (▲), 1.2 (○), 3.1 (■), 5.0 (△). Profile calculated according to eq. (k) using $k_1 = 6.5 \times 10^{-4}\ s^{-1}$ and $k_2 = 3 \times 10^4$ L mol^{-1} s^{-1} [111].

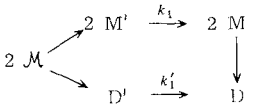
For s-MDH, the kinetic analysis of reactivation together with synchronous, chemical cross-linking experiments allow the following explanation of the results: The main amplitude (ca. 70%), with a half-life of ca. 9 min, represents the rate-determining folding to generate "structured monomers", which then assemble in a diffusion-controlled step ($k_2 > 10^6$ L mol^{-1} s^{-1}) to form the active dimer. The remaining ca. 30% yield the same final product with "wrong dimers" as intermediates and with subsequent reshuffling (D′ → D) as the rate-limiting step. For both pathways



(j)

reactivation and dimerization run parallel, so that neither the monomer nor folded association-intermediates can possess any significant enzymatic activity (Fig. 8 A).

The reconstitution properties of m-MDH differ from those described for s-MDH [eq. (j)]. Reactivation as well as the regain of native fluorescence are concentration-dependent, exhibiting sigmoidal kinetics (Fig. 8 B). The data may be adequately described by the above consecutive uni-bimolecular reaction scheme with one single pair of rate constants [eq. (k)]

$$2\,\mathcal{M} \xrightarrow{\text{fast}} 2\,M' \xrightarrow{k_1} 2\,M \xrightarrow{k_2} D \qquad (k)$$

The overall kinetics do not depend on the mode of denaturation (acid, urea, guanidine·HCl). Since each of these denaturants leads to a different conformational state, it is obvious that M′ must be a common structured intermediate on the pathway of reconstitution[94, 111].

In proceeding from dimers to *tetramers*, a number of new questions arise: Do intermediates of association accumulate during reconstitution? Are they catalytically active and resistant towards proteolysis? Is the dimerization of M or D the rate-limiting step in the obligatory sequential assembly pathway?

The questions may be answered using the glycolytic enzyme lactate dehydrogenase (LDH) as an example, because its three-dimensional structure is known and its reconstitution has been studied in detail[26, 37–41, 66, 68–71, 94, 104–106, 112]. Both isoenzymes, LDH-H_4 and LDH-M_4, from heart and skeletal muscle, respectively, corroborate the uni-bimolecular mechanism [eq. (i)]. For LDH-M_4 concentration-dependent reactivation kinetics yield eq. (l).

$$4\,\mathcal{M} \xrightarrow{\text{fast}} 4\,M' \xrightarrow{k_1} 4\,M \xrightarrow{\text{fast}} 2\,D \xrightarrow{k_2} T \qquad (l)$$

where $k_1 = 8 \times 10^{-4}\ s^{-1}$ and $k_2 = 3 \times 10^4$ L·mol^{-1}·s^{-1} (Fig. 9), by analogy to the mechanism obtained for dimeric m-MDH (cf. Fig. 8 B).

As shown by cross-linking experiments, dimer formation predominates in the early phase of reconstitution (Fig. 9). The corresponding decrease in monomer concentration obeys first-order kinetics with a rate constant

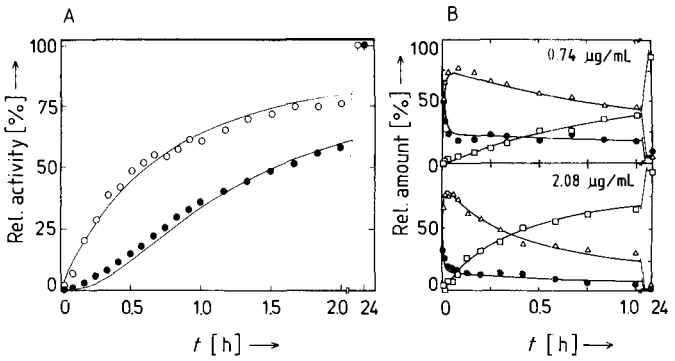


Fig. 9. Kinetics of reconstitution of tetrameric porcine skeletal muscle lactate dehydrogenase (LDH-M_4). 0.1 M sodium phosphate, pH 7.6, 20 °C. A) Reactivation after denaturation in 6 M guanidine·HCl ($c_{LDH} = 1.7$ µg/mL). Activity measured in standard assay (•). (Profile calculated according to eq. (l) with $k_1 = 8 \times 10^{-4}$ s^{-1}, $k_2 = 3 \times 10^4$ L mol^{-1} s^{-1}) and in the presence of 1.5 M $(NH_4)_2SO_4$ (○). Profile calculated with the same kinetic constants k_1, k_2, but assuming 50% dimer activity.) B) Reassociation of "structured monomers" after dissociation and deactivation in 0.1 M H_3PO_4, 1 M Na_2SO_4. Determination of the relative amount of monomers (•), dimers (△), and tetramers (□) applying SDS-polyacrylamide gel electrophoresis after chemical cross-linking with 1% glutaraldehyde. Profiles calculated according to $4\,M \overset{K}{\rightleftharpoons} 2\,D \xrightarrow{k_2} T$ with $K = 3.3 \times 10^8$ L mol^{-1} and $k_2 = 3 \times 10^4$ L mol^{-1} s^{-1}, assuming inactive monomers and dimers; the reactivation parallels tetramer formation [38, 113].

$k_1 = 8.0 \times 10^{-4}$ s^{-1}, in excellent agreement with the computer simulation of the time- and concentration-dependent reactivation profiles. The systematic deviation in Figure 9 may be explained by the fact that the dimerization of M represents a fast equilibrium reaction with $K = 3 \times 10^8$ L mol^{-1} and a rate close to that of a diffusion controlled reaction[38, 113]. Hence, the complete kinetic scheme may be described by eq. (m).

$$4\,\mathscr{M} \xrightarrow{\text{fast}} 4\,M' \xrightarrow{k_1} 4\,M \overset{\text{fast}}{\rightleftharpoons} 2\,D \xrightarrow{k_2} T \qquad \text{(m)}$$

As with monomeric and dimeric proteins, the slow M′→M transition is preceded by fast folding steps restoring ≅75% of the native ellipticity. On addition of stabilizing ions such as 1 M Na_2SO_4 to the denaturant (e.g. H_3PO_4 pH ≈ 2), unfolding may be kept to a minimum, thus giving rise to "structured monomers" (M). As expected, their reassembly obeys simple second-order kinetics with $k_2 = 3.0 \times 10^4$ L mol^{-1} s^{-1}, confirming the second rate constant in the uni-bimolecular scheme shown in eq. (l)[113].

The proposed reconstitution mechanism has been confirmed by several independent lines of evidence. 1) Reconstitution of dimeric intermediates (obtained e.g. at 1 M guanidine·HCl) yields precisely the same reactivation kinetics as observed for the monomer→tetramer assembly, thus proving that the 2 D→T transition is the rate-limiting step in the overall reactivation of LDH[39]. 2) Limited proteolysis using thermolysin during reconstitution generates artificial "stable dimers"[40]. Adding the protease at various reconstitution times again proves the dimer→tetramer transition to be rate limiting for both reassociation and reactivation. 3) Hybridization of isoenzymes at different reconstitution times enables us to calculate the concentrations of all species (M, D, and T) during reconstitution. The result confirms the mechanism given in eq. (l)[115].

A number of other tetrameric enzymes have been found to show reconstitution properties similar to those described above, so that the sequential uni-bimolecular folding-association mechanism may be considered to be the general kinetic scheme underlying the formation of the native quaternary structure[25, 26, 66, 71, 94]. In going from tetrameric to *multimeric* systems, successful attempts to achieve reconstitution of complex biological systems, such as phages, viruses, ribosomes, multienzyme complexes, etc. clearly prove that no fundamental differences occur. New facets may be a stringent assembly pathway, cooperative phenomena, and "morphopoetic factors" regulating the correct geometry and/or stoichiometry.

Three examples may illustrate the different levels of complexity.

1) *Homogeneous multimers* such as tobacco mosaic virus protein show different kinetic mechanisms depending on the mode of assembly. In this connection, the pH determines the structure with extremely high cooperativity[32, 117, 118]. Slow nucleation steps causing overshoot reactions may generate non-equilibrium states[119]. However, to a first approximation the "polymerization" may be expressed in terms of Flory's condensation polymerization [eq. (n)] using the isodesmic mechanism

$$2\,A_1 \overset{K}{\rightleftharpoons} A_2;\ A_2 + A_1 \overset{K}{\rightleftharpoons} A_3;\ A_3 + A_1 \overset{K}{\rightleftharpoons} A_4 \ldots \qquad \text{(n)}$$

where A is the polymerizing unit and K the equilibrium constant[120]. The endothermic nature of the reaction holds under all conditions which favor association. The corresponding increase in entropy is caused by release of water upon polymerization[47].

2) *Heterogeneous multimers*, e.g. multienzyme complexes, raise the question as to whether structure formation in the case of complex assemblies is an "assembly line" process with neighboring chains providing a matrix for the folding and association of other components of the multimeric system.

As with monomeric and multimeric multi-domain proteins (which are known to show independent folding of their domains[121–123]), there is no indication that multienzyme complexes require either external factors or structured components of the complex in order to accomplish proper folding. The simplest example is the tetrameric tryptophan synthase bienzyme complex from *Escherichia coli*. The two components (α and β_2) catalyze the two-step reaction shown in eq. (o).

$$\text{Indole-3-glycerol p} \xrightarrow{\text{glyceraldehyde}} \text{indole} \xrightarrow{\text{serine}} \text{tryptophan} \qquad \text{(o)}$$

"Channeling" of the common intermediate (indole) in the $\alpha_2\beta_2$ complex increases the catalytic efficiency of the partial reactions by two orders of magnitude. The α-subunit is enzymatically active; accordingly, its reactivation follows first-order kinetics. The same holds for β_2, although in this case the dimer is the active species; evidently, rate-limiting folding steps precede the diffusion-controlled assembly of the structured monomers. The reactivation of the two com-

ponent enzymes with respect to their individual activities is kinetically independent. The re-establishment of the native quaternary structure (monitored by activity and spectral analysis) obeys a complex uni-bimolecular scheme, with the increased turnover at the level of the tetramer[121, 124, 125]. Aspartate transcarbamoylase from *E. coli* (a dodecamer composed of two "catalytic" trimers (C) and three "regulatory dimers" (R)) exhibits a far more complex reconstitution pattern. The enzyme regulates the biosynthesis of pyrimidines using ATP/CTP as allosteric effectors. Both its stability and conformational flexibility depend on specific "binding domains" within the C-trimers and R-dimers, as well as between C and R. They are also responsible for the practically complete reconstitution of the enzyme after dissociation, denaturation, and deactivation.

In the concentration range 1—5 mg/mL, folding and association take a few seconds. The first step in the mechanism of reconstitution is the mutually independent folding and association of the subunits to form C and R; in a subsequent reaction both the trimeric and dimeric intermediates assemble in a heterologous fashion yielding the native enzyme ($c_6r_6 \triangleq C_2R_3$). The recombination of c_3 and r_2 (without considering homologous association) requires ten kinetic equations; it is therefore obvious that we are far removed from a definitive proof of the mechanism[126, 127].

3) *Giant molecules.* The multienzyme complex pyruvate dehydrogenase may serve as one further example. This enzyme is the connecting link between glycolysis, Krebs cycle, and fatty acid synthesis. It contains three enzyme components: pyruvate decarboxylase (E1), lipoate acyl transferase (E2), and lipoamide dehydrogenase (E3), organized as an E2 core surrounded by peripheral E1 and E3 units. The complexes from different organisms differ widely in their physical properties. The enzyme from the thermophile *Bacillus stearothermophilus,* the biggest multienzyme complex known so far ($M_r \approx 10^7$), may be only partially disassembled to functional protomers. Partial reconstitution is accomplished by means of "joint denaturation-renaturation" of the whole complex. Its time course is governed by first-order rather than second-order kinetics, thus indicating that rate-limiting folding reactions at the monomer or multimer level determine the overall mechanism of reconstitution, while bimolecular association reactions are fast. By attributing the first-order reaction to the intramolecular rearrangement ("reshuffling") of the whole complex, the mechanism shown in eq. (p) is tentatively proposed.

$$n\,M_i \xrightarrow{\text{folding}} n\,M_i' \xrightarrow[\text{fast}]{\text{association}} (M_i')_n \xrightarrow{\text{reshuffling}} N^* \qquad (p)$$

As shown in Figure 10, the folding and reactivation of the components E2 and E3 do not affect the overall reconstitution. Both are fast and independent of each other; addition of core particles (E2) during reconstitution does not alter the overall reactivation pattern[94, 128].

The fact that highly complex multienzyme systems can be reconstituted in vitro proves that even in the case of giant molecules, folding and association occur spontaneously, without necessarily requiring external factors or a specific reaction sequence. This conclusion cannot be generalized: conjugated proteins or systems as complex as ribosomes or certain phages and viruses require either "morphopoetic factors", or specific "assembly programs" to achieve their correct final structure[129–131].

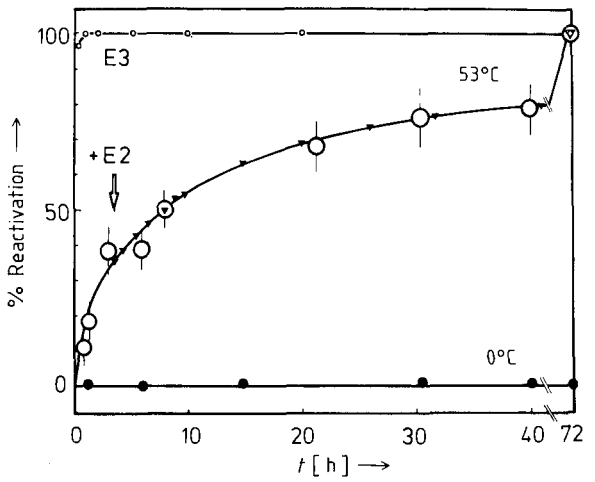

Fig. 10. Reconstitution of the pyruvate dehydrogenase multienzyme complex from *Bacillus stearothermophilus* and its components E2 (lipoate acyl transferase) and E3 (lipoamide dehydrogenase). Denaturation in 1.0 M glycine/H_3PO_4, pH 2.3. Reconstitution in 0.2 M sodium phosphate, pH 7.0, 53°C (filled circles, 0°C). ○ and the respective profile illustrate the reactivation of the complex, which is found to be independent of protein concentration in the range $40 < c_{PDH} < 160$ μg/mL. Addition of E2 at ↓ (▼) does not affect the kinetics of the overall reactivation; reactivation of E3 (○) precedes that of the complex.

5.1.3. *Ligand Effects*

Specific ligands such as cofactors, substrates, or solvent components may stabilize or destabilize the native structure of proteins. For certain enzymes, the attainment of their functional state depends on the presence, e.g., of metal ions or other ligands. In connection with the present discussion, the question arises as to whether, and at which stage, specific ligands may affect the folding and association of proteins.

In principle, effectors may influence the kinetics of reconstitution in two ways. Firstly, association of the effector with some intermediate state of reconstitution may lower the activation energy of subsequent rate-limiting steps. Secondly, binding of the effector molecule to the native or a quasi-native structure may lower the free energy of this state compared to the local minima of non-native conformations in the free energy hyperspace, in this way shifting the equilibrium towards the native structure. Thus, the effector can influence the reconstitution rate by accelerating rate-limiting steps, or by stabilizing either folding intermediates or the final product of reconstitution. Apart from the rate enhancement, both mechanisms may increase the yield of reconstitution.

In the case of NAD-dependent dehydrogenases, which have been the subject of extensive studies, the coenzyme (NAD) has often been considered as a "nucleating agent" which enhances the rate of folding and association[67]. Thorough *kinetic* analyses have shown, however, that this effect is at best small[66, 71, 111, 132] (as predicted from the high complexity of the domains involved[60]). As far as the

yield is concerned, the formation of the holoenzyme may significantly increase the reconstitution.

An example illustrating this is the effect of zinc ions on the reconstitution of liver alcohol dehydrogenase (L-ADH)[133, 134]. The ions play a double role: as a Lewis acid in catalysis and in stabilizing the structure of the dimeric enzyme. In the absence of Zn^{2+}, neither reassociation nor reactivation occur (Fig. 11). Instead, partial refolding takes place, which is easily detectable as a first-order regain of native fluorescence. Competing "wrong aggregation" is quenched immediately after Zn^{2+} is added; at the same time, enzymatic activity is recovered in a second-order reaction, which indicates that subunit assembly is required for catalytic activity.

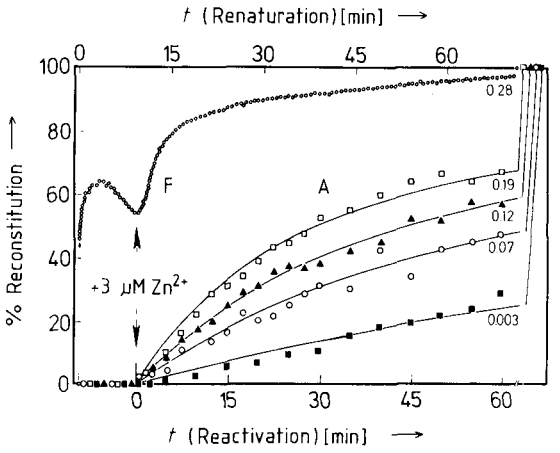

Fig. 11. Effect of Zn^{2+} and enzyme concentration on the reconstitution of horse liver alcohol dehydrogenase (L-ADH). Denaturation and subsequent removal of Zn^{2+} by gel chromatography in the presence of 6 M guanidine·HCl. Renaturation in 0.1 M sodium phosphate, pH 7.6 at 25°C, $c_{ADH} = 10$ μg/mL [0.28 μM]. F = regain of native fluorescence ($\lambda_{exc} = 275$ nm, $\lambda_{em} = 330$ nm). A = reactivation at given enzyme concentrations [μM]. Profiles calculated according to eq. (q) with $k_1 = 7 \times 10^{-3}\ s^{-1}$, $k_2 = 1.6 \times 10^3\ L\ mol^{-1}\ s^{-1}$, and $K = 0.17\ \mu L\ mol^{-1}$ [134].

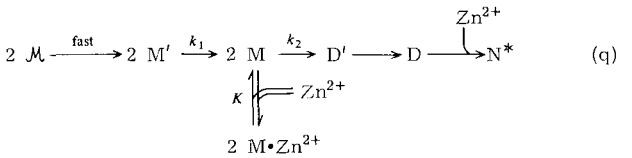
Folding and association may be analyzed independently by adding Zn^{2+} after completion of the slow folding step (Fig. 11). Under these conditions, the formation of dimers (D) rather than "structured monomers" (M) becomes rate-limiting for the reactivation reaction. The kinetic scheme (q) describes the overall reaction.



(q)

At the same time, the scheme provides a plausible explanation for the antagonistic effects of Zn^{2+} at high and low concentrations: trapping of inactive monomers, on the one hand, and shifting the reaction sequence towards N*, on the other.

In summary, the example indicates a three-fold role for the ligand: participation in catalysis (as Lewis acid); fixation of folding intermediates; and stabilization of the native quaternary structure.

5.2. Specificity

The most fascinating aspect of "ligand effects" on protein folding and protein association is the specificity of subunit recognition, i.e. the question of whether or not other proteins may interfere with the formation of the native quaternary structure. The folding of a nascent polypeptide takes place in the presence of high concentrations of other proteins, including other chains coded by the same structural gene. From this fact, the question arises whether "chimeric" assemblies may exist at least as intermediates of association. Earlier negative results (which ignored the different reconstitution rates of different enzymes) did not provide an unequivocal answer[135].

The fact that closely related enzymes may form hybrids is well-established. For example, the two different polypeptide chains of the tetrameric lactate dehydrogenases LDH-H_4 and LDH-M_4 form five physiologically distinct isoenzymes, including the three hybrids H_3M, H_2M_2, and HM_3. A similar hybridization has also been observed for other enzymes. Reconstitution experiments using pyruvate dehydrogenase (Fig. 10) have shown that the individual components of the multienzyme complex are independent with respect to their folding and association kinetics. On the other hand, different enzyme complexes have been found to share certain components[94].

In order to investigate the phenomena with regard to possible kinetic intermediates or hybrid end-products, synchronous reconstitution experiments were performed using closely-related enzymes with characteristic differences in their physicochemical properties. LDH-H_4 and m-MDH (mitochondrial malate dehydrogenase) should be good candidates in this respect[60]. As shown by kinetic and equilibrium measurements, neither subunit exchange in the native state nor (intermediate) hybrid formation (LDH·MDH or $(LDH)_2 \cdot (MDH)_2$) could be detected[136]. However, these experiments are not completely unambiguous, because under the given conditions of synchronous reactivation, LDH-*dimers* as intermediates (cf. Section 5.1.2) must hybridize with MDH-*monomers*, forming trimeric hybrids. Since these are unstable, analogous experiments should be devised combining two dimeric enzymes, e.g. LDH from *Limulus* and porcine m-MDH. Both enzymes obey the same uni-bimolecular reconstitution mechanism with similar rate-constants. The outcome is precisely the same: the time course and concentration dependence, as well as the yield of reactivation in the absence and presence of the prospective partner in hybridization, remain unchanged (Fig. 12). Similarly, equilibrium measurements (using chromatographic and electrophoretic techniques) do not indicate any exchange of subunits[137].

Hence, the conclusion may be drawn that also in the case of dimeric LDH reconstitution experiments clearly disprove hybrid formation. This holds for the stable end product as well as for inactive kinetic intermediates. Evidently, the association of oligomeric enzymes is highly specific owing to complementary intersubunit binding interactions. In order to permit "recognition" of the respective interfaces, the individual subunits must not collide until they have reached a certain level of backbone structure[138]. For large subunits in vivo this requirement is presumably ful-

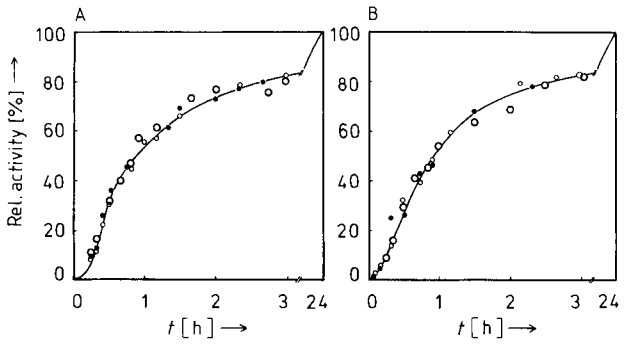


Fig. 12. Specificity of association of two dimeric dehydrogenases: Synchronous reconstitution of D-lactate dehydrogenase (D-LDH) from *Limulus polyphemus* and porcine mitochondrial malate dehydrogenase (m-MDH) [137]. A) Reactivation of 2 μg/mL D-LDH in the presence of 0.2 (•), 0.5 (○), and 1.0 (○) μg/mL m-MDH. Profile: Reactivation of D-LDH in the absence of m-MDH calculated according to eq. (k) with $k_1 = 6 \times 10^{-4}\ s^{-1}$ and $k_2 = 1.5 \times 10^4$ L $mol^{-1}\ s^{-1}$. B) Reactivation of 2 μg/mL m-MDH in the presence of 0.2 (•), 0.5 (○), and 0.9 (○) μg/mL D-LDH. Profile: Reactivation of m-MDH in the absence of D-LDH, using the kinetic constants given in Figure 8.

filled by cotranslational folding of the nascent polypeptide chain. The respective intermediate states in the folding process must be sufficiently well-defined so that even in the heterogeneous system of the cytoplasm no compartmentation is required to guarantee correct quaternary structure formation. It should be noted that the coalescence of structural domains shows a similar degree of specificity to that observed for quaternary structure formation. By analogy to the reconstitution of intact subunits, domains and/or proteolytic fragments of subunits may associate to form "nicked" assemblies which may resemble the oligomer or multimer in its functional state[93,97,110,121,122].

5.3. Structure-Function Relationship

The observation that the native structure and function of proteins does not necessarily require the full integrity of the polypeptide backbone leads back to the notion of "essential" and "non-essential residues" within a given amino acid sequence (cf. Section 4.2). In the present context, one may ask whether in the case of oligomeric enzymes the native quaternary structure is a prerequisite for catalytic function or whether intermediates of folding and association or even nicked molecules can be enzymatically active. A tetrameric enzyme such as lactate dehydrogenase is expected to provide an answer because dimeric, or sometimes even monomeric intermediates are easily accessible to structural and functional analysis.

Equilibrium data obtained from denaturation studies on a large number of oligomeric enzymes indicate that full enzymatic activity and allosteric regulation require the native quaternary structure. On the other hand, matrix-bound subunits of a number of oligomeric enzymes have been shown to be at least partially active, and certain monomeric enzymes, such as α-amylase or ribonuclease seem to exhibit allosteric properties. Kinetic experiments involving second-order steps in the reconstitution of oligomeric enzymes prove unequivocally that catalytic function requires association. Beyond the level of the dimer, additional experiments are required to determine the state of association where activity is achieved. As mentioned in Section 5.1.2, chemical cross-linking together with reactivation kinetics may provide a solution to this problem (cf. Fig. 9). Reconstitution experiments starting from well-defined intermediates of dissociation may be used as an independent method[37–40]. Attempts to solve the problem by comparing homologous enzymes with identical catalytic function but different quaternary structure were unsuccessful. For example, phosphoglycerate mutase, which occurs either as a tetramer, a dimer, or a monomer in different organisms, exhibits totally different reconstitution properties at the various levels of quaternary structure[116].

In the present context, limited proteolysis is expected to be a promising approach. Due to the non-equivalence of subunit interactions, many oligomeric enzymes may be regarded as "dimers of dimers" or "dimers of trimers" etc. For example, lactate dehydrogenase is stabilized as a "dimer of dimers" by an *N*-terminal "arm" of 20 amino acids. By cleaving off this arm using limited proteolysis during reconstitution (cf. Section 5.1.2), artificial "dimers" may be prepared that are sufficiently stable to allow detailed structural analysis.

Table 3. Comparison of native lactate dehydrogenase ($LDH\text{-}M_4$) and proteolytic "dimers" as intermediates of reconstitution [a].

	native enzyme	"dimer"
Molecular weight ($M_r \cdot 10^{-3}$)		
sedimentation equilibrium	140 ± 4	65 ± 3
gel permeation chromatography	140	70
SDS-polyacrylamide gel electrophoresis	35	34 (60%)
		18 (20%)
		12 (20%)
Sedimentation coefficient $s_{20,w}$ (*S*) [b]	7.6 ± 0.3	3.4 ± 0.2
N-terminus	acetylated	Leu, Val, Ile, Gly
Rel. fluorescence at 340 nm [$\lambda_{exc} = 280$ nm]	100	55 ± 5
Ellipticity $\Theta_{208\,nm} \cdot 10^{-3}$ [degr · cm² · dmol⁻¹]	−12.0	−11.5
Absorption $A^{0.1\%}_{280\,nm}$ [cm² · mg⁻¹]	1.4	1.8
Spec. activity [units/mg]		
standard assay	550 ± 70	2 ± 2
in the presence of 2 M $(NH_4)_2SO_4$	445 ± 65	106 ± 15

[a] Limited proteolysis using thermolysin after 1 min reconstitution. For experimental details cf. [40, 109, 110]. [b] Sedimentation analysis at $c_{LDH} = 0.2$ mg/mL; analysis of the "dimer" using activity transport [139] in the presence of 1.0–2.0 M $(NH_4)_2SO_4$.

The outcome is instructive in many respects (Table 3). Denaturation (e.g. in 6 M guanidine) and subsequent reconstitution lead back to the initial "dimer". The fact that no tetramers emerge proves that the "dimer" does not trap unmodified monomers. On the contrary, there is a high percentage of "nicking" to smaller fragments ($M_r \approx$ 12000 and 19000), reflecting the domain structure of the LDH subunits. That even the fragments retain the potential for generating the correct tertiary structure corroborates the idea that protein folding may be understood as "folding by parts" followed by "merging of domains"[111]. Clearly, the domains contain sufficient structural information (even without the connecting stretches of the polypeptide chain) to establish the specific intramolecular contacts required to stabilize the native tertiary structure[110]. Similar results have been reported for β-galactosidase, lyso-

zyme, penicillinase, tryptophan synthase, and other enzymes[140-144].

Compared with the native tetramer, the "dimer" obtained after limited proteolysis shows decreased thermal and proteolytic stability. That it binds to an NAD-specific affinity column indicates that the active center of the native enzyme must already be present at the level of the dimer, although it does not show enzymatic activity under standard test conditions. The structure must be too flexible in the dimeric state to permit catalytic activity.

This hypothesis is in good agreement with the weaker ligand affinity of the "dimer" compared to that of the tetramer. It is emphasized by the effect of stabilizing solvent conditions: after addition of "structure-making ions" such as 2 M $(NH_4)_2SO_4$ to the test mixture, up to 50% of the native tetramer activity is induced without altering the dimeric state[94, 110]. This recovery of activity is also observed for the intact dimeric intermediate on the pathway of reconstitution. If activity is measured in the presence of $(NH_4)_2SO_4$, the regain of enzymatic activity precedes tetramer formation, due to intrinsic dimer activity, and in contrast to the result obtained under standard conditions (cf. Fig. 9)[109].

In view of the structural and functional similarity of lactate dehydrogenase in its dimeric and tetrameric states, it is not surprising that the reconstitution of the $M_r \approx 34000$ subunit of the "dimer" is adequately described by the kinetic scheme given in eq. (l). By monitoring reconstitution as reactivation (with Na_2SO_4 in the enzyme assay), the overall process is determined by the same rate-limiting first-order rate constant ($k_1 = 8 \times 10^{-4}$ s^{-1}) obtained previously for the folding of the intact polypeptide chain in the reconstitution of the tetramer. By using "p" to denote the proteolytically modified chain, scheme (r) may be written:

$$2\,\mathscr{M}_p \xrightarrow{\text{fast}} 2\,M'_p \xrightarrow{k_1} 2\,M_p \xrightarrow{\text{fast}} D_p \qquad (r)$$

Comparing this scheme with eq. (l), we see that the unchanged rate constant clearly proves that the *N*-terminal "arm" is not involved in rate-limiting folding steps at the monomer level. Its functional role is the stabilization of the dimers to form the native tetramer[109]. The tetrameric quaternary structure provides optimum stability with respect to solvent parameters and turnover. At the same time, it maintains the structural flexibility required for enzyme catalysis and regulation[59, 145].

6. Concluding Remarks

We are only beginning to understand the elementary processes involved in protein folding. Thus we are still far away from unraveling the "folding code", one of the aims of systematic folding experiments and energy calculations. What has been clarified in recent years is the folding pathway of single-chain, one-domain proteins and the folding-association mechanism of oligomeric proteins in vitro.

In principle, the formation of the native, three-dimensional structure of proteins proceeds via rapidly formed structured intermediates, whose reshuffling is rate-limiting for the acquisition of the functional state.

In the case of oligomeric proteins, structure formation involves a sequence of well-defined folding and association steps. Kinetic methods have been devised to elucidate the sequential mechanism in terms of distinct unimolecular and bimolecular reactions. Such methods provide a means of determining the particle distribution during the reconstitution process, and of characterizing intermediates of association with respect to their structural and functional properties.

As a result, fast folding reactions are found to restore a considerable amount of the secondary structure. The rate-limiting process is the slow formation of correctly structured monomers, which then can associate in a highly specific way to form the native quaternary structure.

Side reactions competing with folding and association are the formation of "wrong aggregates" of partially folded subunits, on the one hand, and cotranslational or post-translational chemical modification (glycosylation, processing, etc.), on the other. The in vitro approach differs inevitably from folding of the nascent polypeptide chain in vivo with respect to the unfolded state, which may simply not exist in vivo, at least for proteins beyond a certain size. Cotranslational domain-folding may prevent the incorrect interactions which are responsible for aggregation and for slow reshuffling steps during in vitro reconstitution, thus speeding up the folding process considerably.

Our own work cited in this review was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. I would like to thank Drs. P. Bartholmes, P. Orlean, R. Rudolph, and F. X. Schmid for fruitful discussions and collaboration. The experimental help of my coworkers, the technical assistance of Mrs. Ingrid Fuchs, Eva Gregory, and Brigitte Teuscher, as well as the skilled cooperation of the mechanical workshop, especially Mr. G. Wiesener, K. Zweckerl, and R. Knott are gratefully acknowledged.

Synthesis of Anti-Inflammatory α-Arylalkanoic Acids by 1,2-Aryl Shift

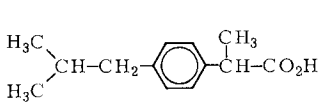
New Synthetic Methods (42)

By Claudio Giordano*, Graziano Castaldi, and Fulvio Uggeri

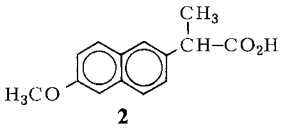
α-Arylalkanoic acids have acquired importance as anti-inflammatory agents and are now in great demand on the pharmaceutical front. Hence, the need has arisen for new and improved, economical synthetic procedures suitable for their preparation and manufacture on an industrial scale. For many years the synthetic approach to this class of compounds was restricted to the Willgerodt and Darzen reactions. More recently, several methods have been developed which are based on the 1,2-aryl shift in acetals of α-functionalized alkyl aryl ketones. This new approach starts from the oxythallation of alkyl aryl ketones first described by *Taylor* and *McKillop* in 1971. Asymmetric syntheses of some important arylalkanoic acids have also been developed on this basis. The highly toxic thallium salts may be replaced, inter alia, by catalytically effective metal salts.

1. Introduction

For almost a century, aspirin has dominated the drug armamentarium of mild anti-inflammatory, analgesic and antipyretic agents. Over the last few decades there has been a steadily increasing demand for aspirin-like drugs having higher therapeutic activity and exhibiting reduced side effects. α-Arylalkanoic acids, particularly the α-arylpropionic acids, have already proved to be suitable compounds which may fulfill these requirements[1]. In fact, some of them, like Ibuprofen **1** and Naproxen (*S*)-**2**, have already been extensively used in medical practice[1b].



1



2

Most of the syntheses of α-arylalkanoic acids start from arylcarbonyl compounds[1], which can be prepared in high yields by selective electrophilic acylation and converted, by many different routes, into α-arylalkanoic acids.

Initially, the Willgerold-Kindler reaction was the method of choice to achieve this conversion[2]. Its synthetic utility is, however, limited by (a) the reaction conditions, which involve high temperatures and frequently also high pressures, (b) the tedious and rather complicated isolation technique, and (c) the yield of the products, which, in many cases, is modest and variable. Attention was then directed toward the Darzens reaction[3], i.e. the base-promoted condensation of an aldehyde or a ketone with an α-halo ester to give an α,β-epoxyester, which, in turn, is converted by a multistep process into the desired acid.

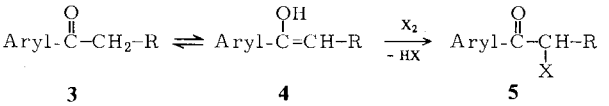
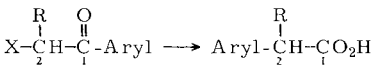
Subsequently, more convenient syntheses of α-arylalkanoic acids were found, based on the rearrangement of α-halo, α-thallio(III), α-tosyl, or α-diazoalkyl aryl ketones **5**.



3 **4** **5**

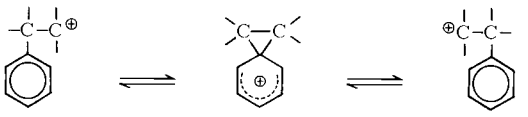


5 **6**

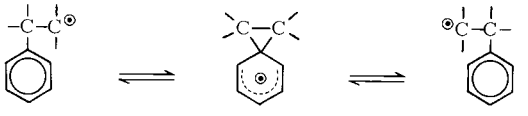
In general, these processes are characterized by two fundamental steps: a) attack of an electrophile on the enol form **4** of the non-functionalized ketone **3**; b) rearrangement of the α-functionalized ketone **5** thus obtained to the acid **6**.

Since the first step can be accomplished in many convenient ways, the success of the synthesis is mainly determined by the factors which govern the 1,2-shift of the aryl moiety.

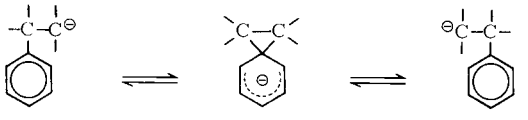
In principle, 1,2-aryl shifts can occur with β-arylalkyl cations[4], β-arylalkyl radicals[5], β-arylalkyl carbanions **7**, **8** and **9**[6], and β-arylalkyl carbenes[7] (with these last substrates, however, the reaction is not general and occurs with very low selectivity, since hydrogen migration prevails over aryl migration). In all cases it has been established that the process is intramolecular.



7



8



9

For the synthesis of α-arylalkanoic acids, the rearrangement of β-arylalkyl cations such as **11**, derived from α-functionalized alkyl aryl ketones **5**, is undoubtly the most interesting of these possibilities. In fact substrates having the correct oxidation state give directly the carboxylic acids derivatives, whereas the rearrangement of free radicals or carbanions has to be followed by oxidation.

The participation of the aryl group in the electrophilic rearrangement of β-haloarylalkanes is well established: Electron-withdrawing groups decrease and electron-donating groups increase the reaction rate[8].

Molecular orbital calculations carried out for the benzenium ion $C_6H_7^{\oplus}$ using EHT, CNDO/2, and ab initio methods also support participation of the aryl group. It has been concluded[9] that CNDO/2 overestimates the stability of cyclic structures (the energy of **10** is 119.4 kcal/mol lower than that of **11**), whereas EHT underestimates the stability of the cyclic structures (the energy of **11** is 20 kcal/mol lower than that of **10**). Ab initio calculations[10] with a contracted STO-3G basis set indicated that the bridged structure **10** is more stable, by 35—50 kcal/mol, than any possible conformations of the open chain species **11**.

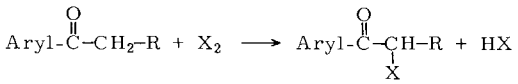
10 **11**

When a carbonyl group replaces the benzylic methylene group in the substrate, 1,2-migration of the aryl group should be less favored, since the geometry of the sp^2 carbonyl carbon "resists" the attainment of the spiro, cyclopropyl-like transition state[11]. However, the favorable sp^3 geometry of the benzylic carbon can be easily restored by masking the carbonyl group as an acetal, which, destabilizing the incipient carbenium center, should favor participation of the aryl group[8].

Accordingly, in all the successful synthetic applications of this strategy the masking of the carbonyl group as an acetal has been the expedient to obtain the desired 1,2-aryl migration.

2. Rearrangement of α-Haloalkyl Aryl Ketones

Halogenation is an inexpensive and simple way to functionalize alkyl aryl ketones **3** in the α-position to give **5**. However, solvolysis of phenacyl halides such as **12** leads only to the substitution products **13**[12]; all attempts to obtain rearrangement products remained unsuccessful[12].



3 **5**

12 **13**

Instead, in the silver-ion assisted solvolysis of α-halobenzyl aryl ketones and of α-halo-*tert*-alkyl aryl ketones a 1,2-shift of the aryl group was observed. In most cases substitution or elimination reactions[13-15] occurred together with the rearrangement.

In the silver ion-assisted methanolysis of α-bromo-*prim*- and α-bromo-*sec*-alkyl aryl ketones **14** both substitution (formation of **15**) and rearrangement (formation of **16**) occur, and the ratio **16/15** is strongly affected by the acidity of the reaction medium[16]. The 1,2-aryl shift is favored by electron-donating substituents on the aryl group (Table 1).

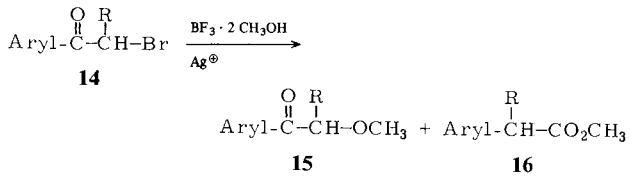


Table 1. Reaction of the ketones **14** to give **15** by substitution or to give **16** by 1,2-aryl shift; influence of substituents in the aryl group.

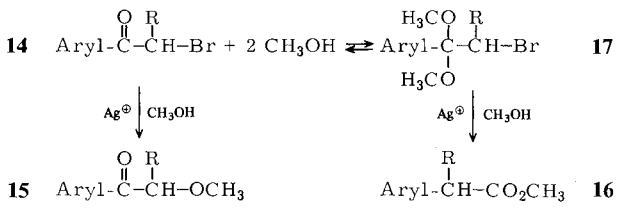
Aryl	R	Yield [%] 15	16	16/15
4-Methoxyphenyl	H	11.6	58	5
Phenyl	H	40	8	0.2
4-Methoxyphenyl	CH_3	8.7	78	9
Phenyl	CH_3	25.5	51	2
6-Methoxy-2-naphthyl [a]	CH_3	5.7	85	15

[a] Methyl ester of **2**.

When the rearrangement of 2-bromo-4′-methoxyacetophenone (R = H, Aryl = 4-methoxyphenyl) was carried out in CD_3OD, ^{1}H-NMR analysis revealed the presence of the starting ketone, the corresponding enol ether, and the acetal **17**[16b]. This observation suggested that the acetal was responsible for the rearrangement product.



In order to verify this hypothesis, acetals of α-halo-*prim*- and α-halo-*sec*-alkyl aryl ketones were reacted with silver salts in methanol[11]: quantitative yields of rearrangement products were obtained (Table 2).

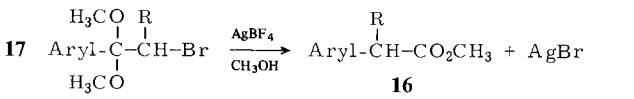


Table 2. Reactions of the acetals **17** with $AgBF_4$ in methanol involving 1,2 aryl shift to give **16** and AgBr.

Aryl	R	t [h]	Conversion [%]	Yield [%]
4-Methoxyphenyl	H	2	95	98
4-Methylphenyl	H	6	85	98
3-Chlorophenyl	H	48	17	98
4-Methoxyphenyl	CH_3	1.5	96	98
6-Methoxy-2-naphthyl [a]	CH_3	1	98	98

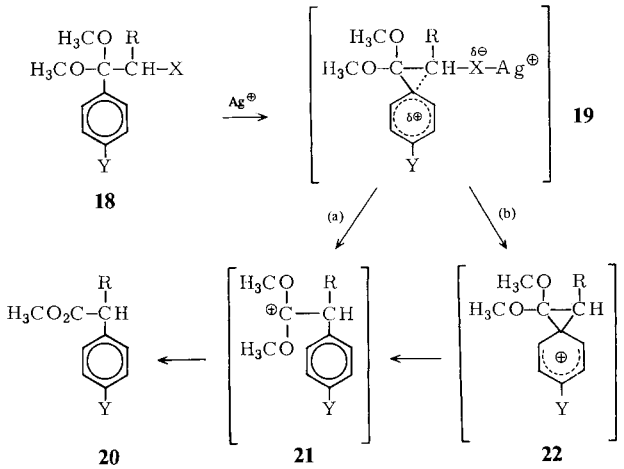
[a] Methyl ester of **2**.

Kinetic investigations revealed that the reaction is first-order in $AgBF_4$ and in the α-bromo acetal **17**, indicating that the rate-determining step is the interaction between **17** and $Ag^{\oplus}$.

A good Hammett correlation between σ^+ of the substituents and the corresponding rate constants was found ($\rho = -3.29$). Thus, the rearrangement is strongly influenced by the polar character of the substituents.

This behavior contrasts with the silver ion-assisted ethanolysis of phenacyl bromides[12a], where only substitution products (ethers) are formed and the reaction is insensitive to the substituents on the phenyl ring. This explains the effect of the substituents on the product pattern when the acetal is in equilibrium with the ketone: the rate of substitution of the ketones is not affected by the substituents in the aromatic ring, whereas the rearrangement rate of the acetals strongly increases with the electron-releasing ability of the groups present on the phenyl ring.

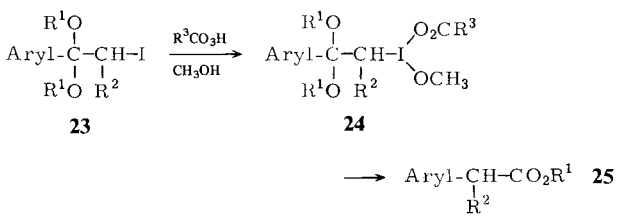
The strong polar effect found in the rearrangement of α-bromo acetals indicates that in the transition state the aryl group assists the development of the positive charge on the α-carbon. Moreover, the order of reactivity of the α-halo acetals (I > Br > Cl) is that expected on the basis of the carbon-halogen bond energies, showing that this bond is broken in the rate determining step. A reaction mechanism based on the above observations is depicted in Scheme 1.



Scheme 1.

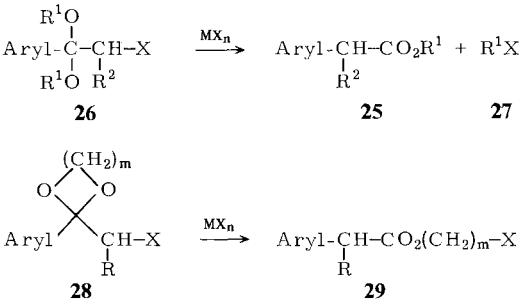
Depending upon the electron density on the aryl ring, the reaction of the acetal **18** via **19** to the cation **21** proceeds either via a synchronous pathway (a) (Y = electron-withdrawing group) or through pathway (b), which involves the intermediacy of **22** (Y = electron-releasing group).

The use of stoichiometric amounts of silver salts makes the method less attractive for large-scale preparation and unsuitable for industrial processes. Therefore, a large effort was devoted to overcoming the synthetic limits related to the use of silver salts. To this end, α-iodo acetals **23** were oxidized by peracids to iodine(III) derivatives **24**; these compounds rearrange spontaneously to **25**, since the iodine(III) species are very good leaving groups[17].

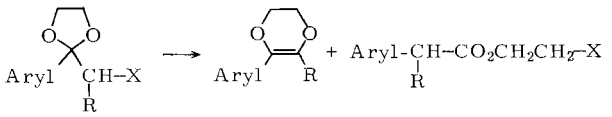


Very recently, *Thomas* and *Higgins*[18] have used the same approach and obtained similar results. These authors also reported[18] that all attempts to promote the rearrangement of α-halo acetals with a variety of Lewis acids had failed. However, under appropriate experimental conditions[19,20], acidic catalysts ("soft and borderline" Lewis acids) that—like the silver ion—are capable of polarizing to some extent the carbon-halogen bond of α-haloalkyl aryl acetals and have a poor affinity for the oxygen atoms of the acetal, lead to the desired rearrangement.

Actually, zinc, tin, copper, mercury, palladium, cobalt, antimony, bismuth, and iron salts were found to promote the conversion of alkyl acetals of α-haloalkyl aryl ketones **26** into alkyl esters of α-arylalkanoic acids **25** and into alkyl halides **27**; several solvents, including hydrocarbons, were used[20]. With cyclic acetals **28**, ω-haloalkyl esters **29** were formed.



Generally, in reactions involving ethylene acetals of α-halo-*sec*-alkyl aryl ketones **28a** devoid of electron-donating substituents on the aryl ring, sizeable amounts of 5-alkyl-6-aryl-2,3-dihydro-1,4-dioxin **30** besides **29a** were formed as a result of the oxygen migration[21].



Classical Lewis acids, such as aluminum trichloride and boron trifluoride, and, in general, "hard" acids are less effective toward the rearrangement because they strongly complex the oxygen atoms of the acetal group, favoring the conversion of the acetal into the corresponding ketone or enol ether. Some significant results, including those related to commercially important compounds, are listed in Table 3.

The main advantage of this method is the use of merely catalytic amounts of inexpensive metal salts. Accordingly, it has been the method of choice for the manufacture of some α-arylpropionic acids on an industrial scale.

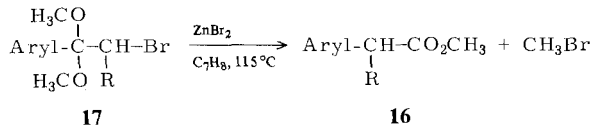


Table 3. $ZnBr_2$-catalyzed reaction of the acetals **17** in toluene at 115 °C with 1,2-aryl shift to give **16**.

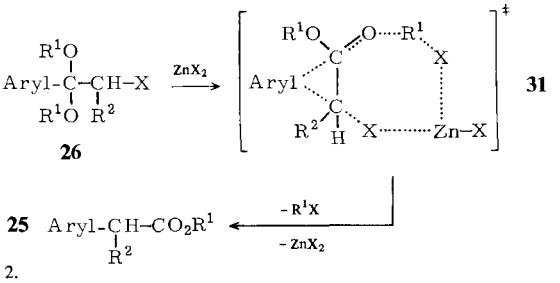
Aryl	R	*t* [h]	Yield [%]
4-Methoxyphenyl	H	1	95
4-Methylphenyl	H	8	80
4-Methoxyphenyl	CH_3	0.5	98
4-Methylphenyl	CH_3	1.5	96
4-Chlorophenyl	CH_3	24	78
6-Methoxy-2-naphthyl [a]	CH_3	0.5	98
4-Isobutylphenyl [b]	CH_3	4	94

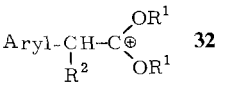
[a] Methyl ester of **2**. [b] Methyl ester of **1**.

Investigations on the mechanism of the reaction proved that the role of "soft and borderline" Lewis acids parallels that of silver salts in promoting the 1,2-aryl shift (Scheme 2).



Scheme 2.

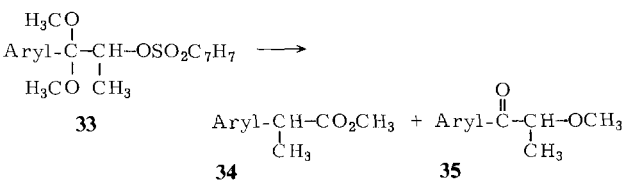
The interaction between the substrate and the catalyst causes a progressive polarization of the carbon-halogen bond with concomitant migration of the aryl group to give **31** as a possible transition state. The conversion of the transition state **31** into the products can be either a synchronous or a two-step process via cation **32**.



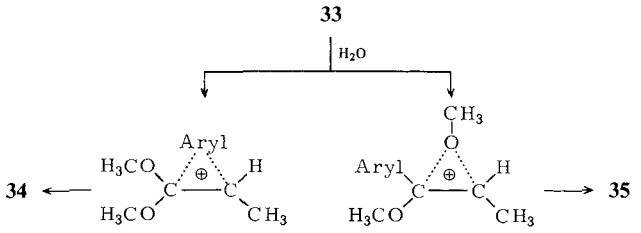
More recently it has been reported that acetals of α-haloalkyl aryl ketones **26** rearrange to esters of α-arylalkanoic acids **25** when heated in polar protic solvents under neutral conditions *in the absence of metal catalysts*[22,23].

3. Solvolysis of the Acetals of 1-Aryl-2-sulfonyloxy-1-alkanones

Solvolysis of the acetals of 2-tosyloxypropiophenones **33** in aqueous methanol in the presence of a weak base furnishes methyl α-arylpropionates **34** and 2-methoxypropiophenones **35**[24].

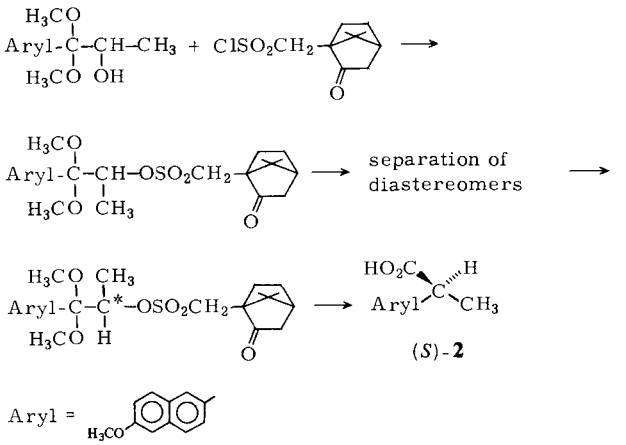


Formation of **34** and **35** has been ascribed to an intramolecular displacement of the tosyloxy group by the neighboring aryl and methoxy group, respectively.



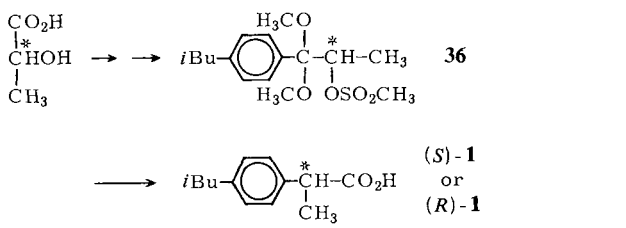
The polar effect of the substituents on the aryl group in CH_3OH/H_2O has been studied; it has been found that both the rate and the selectivity of the reaction towards ester formation are enhanced on increasing the electron density on the aromatic ring.

This method has allowed the direct synthesis of one specific enantiomer of α-arylalkanoic acids by rearrangement of an optically pure α-sulfonyloxy acetal[25]. This result is important, because it has been found that for some α-arylalkanoic acids only one enantiomer exhibits a high anti-inflammatory activity. A well-known example is that of 2-(6-methoxy-2-naphthyl)propionic acid **2**, whose *S*-isomer (Naproxen) is 28 times as active as the *R*-isomer. Naproxen has been synthesized according to the reaction sequence outlined in Scheme 3.



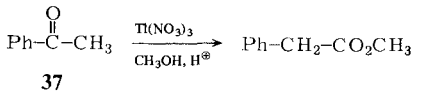
Scheme 3.

It is worth emphasizing that the 1,2-rearrangement proceeds with 100% inversion of configuration, consistent with a S_N2 mechanism. On this basis, an asymmetric synthesis of α-arylalkanoic acids, e.g. the enantiomers of **1**, has been developed[26]; it involves the intermediacy of an enantiomerically pure acetal **36**, obtained in a multistep process from lactic acid (*R* or *S*).



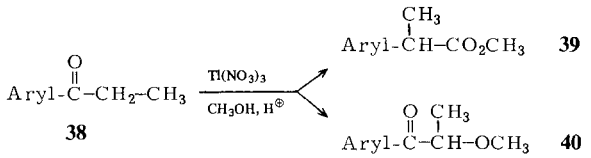
4. Reaction of Alkyl Aryl Ketones with Thallium(III) and Lead(IV) Salts

A direct method for converting alkyl aryl ketones into esters of α-arylalkanoic acids by thallium(III)-promoted rearrangement was first reported by *McKillop, Swann,* and *Taylor* in 1971[27]. This oxidative rearrangement of alkyl aryl ketones is a smooth reaction[28]. Acetophenone **37**, for instance, is rapidly converted into methyl phenylacetate with thallium(III) nitrate in acidic methanol at room temperature.

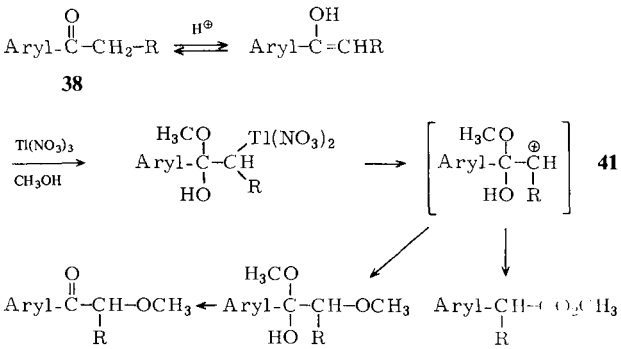


However, acetophenones having the aromatic ring deactivated by electron-withdrawing groups react slowly, giving methyl arylacetates in low yields.

With propiophenones **38** a mixture of products is obtained, among which the expected esters **39** and α-methoxypropiophenones **40** are the major components.



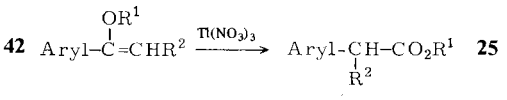
The reaction mechanism is shown in Scheme 4: the individual steps are acid-catalyzed enolization of the ketone **38**, oxythallation of the C=C bond thus formed, and oxidative rearrangement by 1,2-aryl migration with simultaneous reduction of thallium(III) to thallium(I). The substantial amounts of α-methoxy derivatives found in the case of propiophenones were explained by the authors in terms of an increased stabilization of the cation **41** by the methyl group (R = CH_3).



Scheme 4.

Later on, the use of thallium(III) nitrate in trimethyl orthoformate/methanol[29] or of "anhydrous thallium(III) nitrate" (adduct with $3CH_3OH$) on a solid support[30] al-

lowed high conversion of propiophenones into esters of α-arylalkanoic acids, with the virtual exclusion of α-methoxy derivatives. The results of this study suggested that in trimethyl orthoformate the reaction might proceed via oxidation of the enol ether formed in situ. In agreement with this prediction, it was found[31] that enol ethers **42** undergo rearrangement with high selectivity to the esters **25**.



More recently, the mechanism of oxythallation of alkyl aryl ketones was further investigated by *Thomas* and *Higgins*[18,32]. In spite of some minor discrepancies, all authors agree that the rearrangement products stem from α-thallated hemiacetals or acetals, whereas the substitution products (i.e. α-alkoxy derivatives) are formed from α-thallated ketones. This conclusion emphasizes the close similarity between this rearrangement and that of α-haloalkyl aryl ketones.

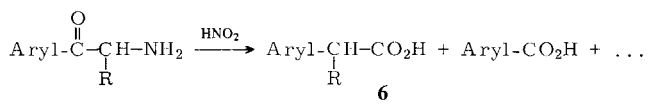
Two main aspects limit the industrial development of this synthesis: the cost of the thallium salts and their toxicity. Successful studies have been reported on the use of oxidants capable of regenerating the thallium(III) species in a continuous process[33]. Nevertheless, besides the technological problems involved in the production, doubts remain as to whether government authorities would permit the use of drugs manufactured via a thallium-based route.

Many efforts have been made to avoid the use of thallium salts. For instance, the reaction between alkyl aryl ketones and lead(IV) acetate has been investigated[34,35]. The results resemble those obtained with thallium(III) compounds, and the mechanism seems to involve the rearrangement of an α-oxyplumbated hemiacetal.

Esters of α-arylalkanoic acids have also been obtained by reacting α-haloalkyl aryl ketones and thallium(III) nitrate in the presence of trialkyl orthoformate[36]. In this case the thallium(III) salt probably acts as a Lewis acid.

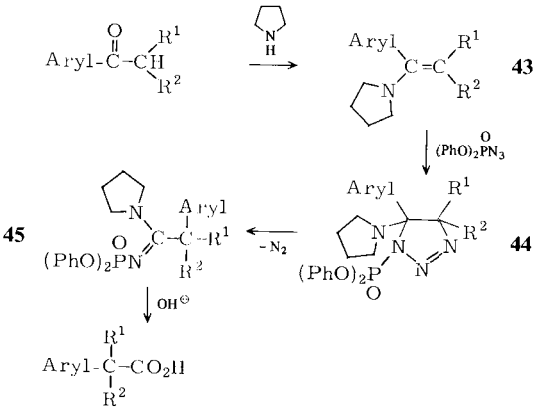
5. Miscellanea

The solvolysis of α-diazoalkyl aryl ketones is not selective and provides rearrangement products **6** in low yield[37].



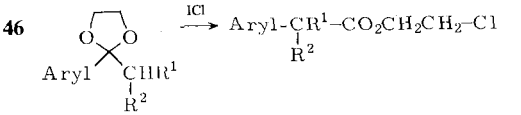
Recently, high selectivity towards the rearrangement has been achieved by masking the carbonyl group as an acetal[18], and an enantioselective synthesis of α-arylalkanoic acid has been accomplished starting from optically active acetals of α-aminoalkyl aryl ketones[38].

Another interesting approach is the three-step process shown in Scheme 5[39]: a) conversion of the ketones with pyrrolidine into enamines **43**, b) 1,3-dipolar cycloaddition of diphenyl azidophosphate to the enamines to give **44**, followed by aryl migration to give **45**, and c) hydrolysis of the resulting *N*-phosphorylated amidines.



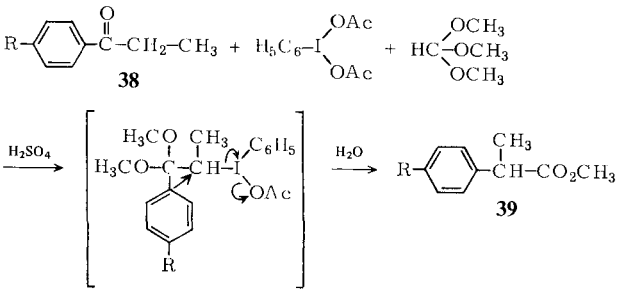
Scheme 5.

Esters of α-arylalkanoic acids have also been obtained by reacting 2-alkyl-2-aryl-1,3-dioxolanes **46** with iodine (I) monochloride in dichloromethane[40], a process which is quite similar to the rearrangement of cyclic acetals of the α-haloalkyl aryl ketones, e.g. **28**.



The oxidative rearrangement of acetylpyrroles is a key step in the synthesis of porphyrins with "natural" acetic acid side-chains. Generally, this rearrangement has been performed using thallium(III) salts. *Franck* et al. have now succeeded in rearranging acetals of suitable α-halogenoalkyl aryl ketones in the presence of silver ions[41].

Oxidation with *m*-chloroperbenzoic acid of the ethylene acetals of α-phenylseleno- or α-phenyltelluroethyl aryl ketones affords hydroxyethyl 2-arylpropanoate in moderate to good yields via aryl group migration[42]. Very recently it was reported that the reaction of ethyl aryl ketones **38** with (diacetoxyiodine)benzene in trimethyl orthoformate in the presence of sulfuric acid leads to methyl 2-arylpropanoates **39** in good yield (Scheme 6)[43].



Scheme 6.

6. Conclusions

Several syntheses of important α-arylalkanoic acids are based on the rearrangement of α-functionalized alkyl aryl ketones. A key point of all these processes is the change of

the hybridization of the carbonyl carbon atom from sp^2 to sp^3, realized by masking it as acetal. Among the various methods available, the most simple appears to be the rearrangement of α-haloalkyl aryl ketones, which has been developed on an industrial scale. The rearrangement can be promoted either by a catalytic amount of metal salts[20], or by protic solvents[22,23]; both methods overcome toxicity problems related to the use of thallium(III) salts[33].

In our opinion, the rearrangement of α-functionalized alkyl aryl acetals to derivatives of α-arylalkanoic acids, thanks to its simplicity, high yields, and clean S_N2 mechanism in the key step, is promising for the direct synthesis of enantiomerically pure compounds.—The present review, constituting a meaningful contribution to the chemistry of "benzenium ions", will hopefully further stimulate synthetic and theoretical studies in the field.

We thank Prof. F. Minisci and Dr. A. Garbesi for helpful discussions.

Pyrylium Mediated Transformations of Primary Amino Groups into Other Functional Groups**

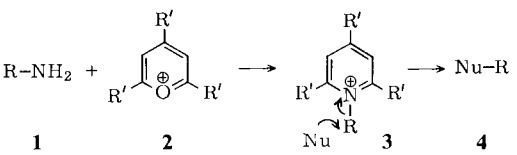
New Synthetic Methods (41)

By Alan R. Katritzky* and Charles M. Marson

The first pyrylium salt was isolated some 80 years ago, yet up to the 1950s only moderate interest was taken in the preparation, properties and uses of such salts. However, the past thirty years has seen a phenomenal growth in the literature pertinent to this area of chemistry: the importance of pyrylium salts as intermediates has been realized. They are readily prepared by a variety of generally applicable routes, and they are highly reactive towards nucleophiles. Together, this enables the convenient synthesis of a great variety of acyclic and heterocyclic compounds. We have used highly substituted pyrylium salts for the two-step conversion of the amino group in alkylamines RNH_2 into numerous other functionalities. In the first step, the pyrylium salts are converted with the amines into *N*-substituted pyridinium salts, which, in the second step, react with $Nu^{\ominus}$ to give the desired products RNu. In some cases the R moiety is also changed, e.g. by elimination. Studies of the reactions of these pyridinium salts have allowed interesting insights into the mechanisms of nucleophilic substitution, in addition to rendering aliphatic amines important synthetic intermediates. Thus, the method complements the diazotization procedure for the transformation of arylamines.

1. Introduction

For the last eight years, first at the University of East Anglia in England and more recently at the University of Florida, our research team has been engaged in investigations aimed at transforming primary amino groups into other functional groups using pyrylium salts as reagents. By 1980, when this work was first reviewed[1], it was already possible to replace primary amino groups in compounds of the type RNH_2 by a large number of functionalities by means of the reaction sequence **1** + **2** → **3** → **4** (Scheme 1).



Scheme 1. Conversion of amines **1** with pyrylium ions **2** via pyridinium ions **3** into the compounds **4** and pyridine derivatives.

Over the past four years, our work has concentrated on the definition of conditions under which both steps of the sequence could be carried out under mild conditions. It has also been concerned with elimination reactions, radicaloid reactions, intramolecular reactions, replacement of NH_2 groups of arylamines by other functionalities, and possible applications to biologically important molecules, particularly in aqueous solution. It is with these aspects that this review covering the period 1980 to 1984 will be principally concerned.

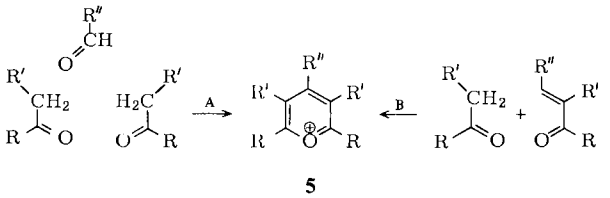
[**] Unless the contents demand otherwise, the qualifiers primary, secondary, and tertiary used in this article refer explicitly to the nature of the alkyl group attached to the amino functionality, and not to the degree of substitution of the latter.

A comprehensive monograph on pyrylium chemistry has appeared in the interim[2].

2. Preparation of Pyrylium Salts

Particularly in connection with our search for good leaving groups for nucleophilic displacements, we have synthesized many dozens of salts containing pyrylium ions **5**. In most cases we have used one of the two routes shown in Scheme 2.

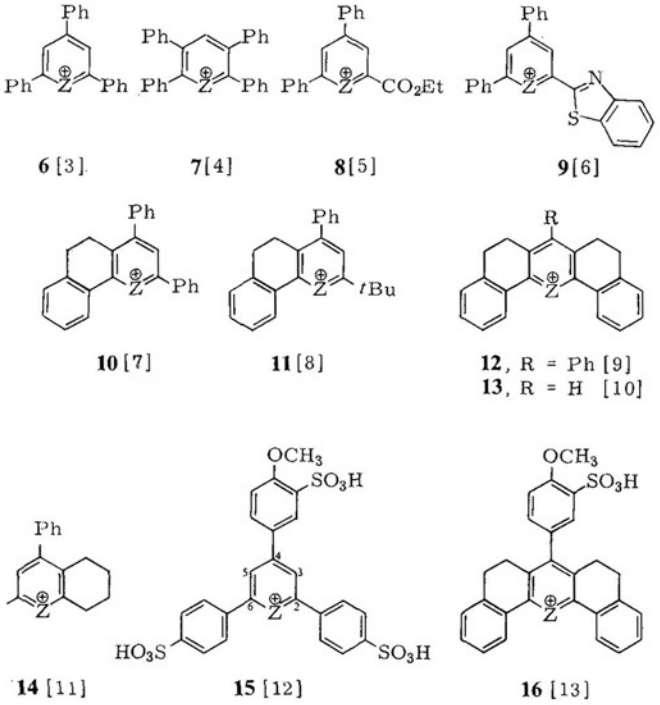


Scheme 2. Preparation of *A*) symmetrical and *B*) symmetrical or unsymmetrical pyrylium ions **5**.

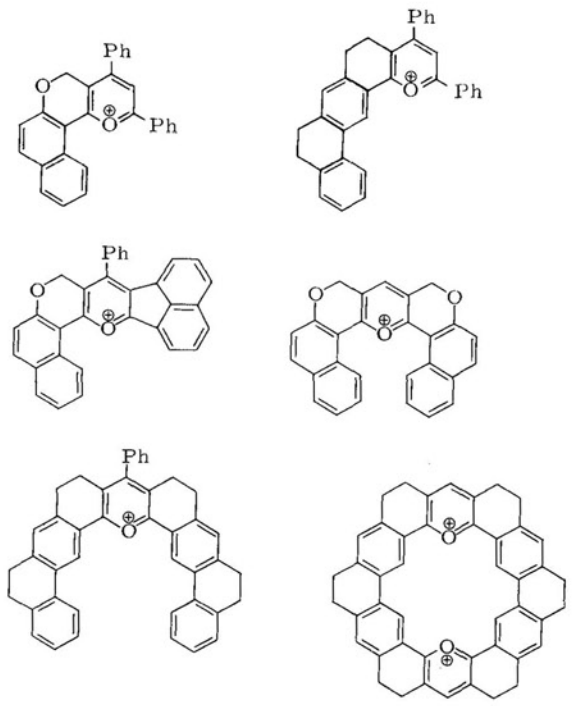
The species **6a**—**16a** shown in Scheme 3 count among the most useful pyrylium salts: their particular uses are mentioned later in this review. Further pyrylium ions that have been investigated are presented in Scheme 4.

3. Conversion of Amines into Pyridinium Salts

^{13}C-NMR spectroscopy has proven very useful for investigating the mechanism of the conversion of amines with pyrylium salts into pyridinium salts. It has been possible to assign all the signals in the ^{13}C-NMR spectra of pyrylium salts, 2*H*- and 4*H*-pyrans, divinylogous amides, diketones, pyridinium salts, pyridines, and anilines[14]. With this information it could be shown that *prim*- and *sec*-alkylamines, RNH_2 and RR'NH, respectively, react with 2,4,6-



Scheme 3. Useful pyrylium ions **6a** – **16a**, Z = O, and corresponding pyridinium ions **6b** – **16b**, Z = NR. References are given to preparative methods of the pyrylium salts.

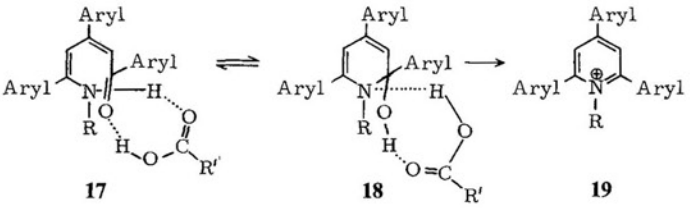


Scheme 4. Polycyclic pyrylium ions.

triarylpyrylium ions by fast ring opening to yield vinylogous amides, which, in the former case slowly cyclize to pyridinium salts[15].

More precise kinetic investigations have been carried out with the aid of ultraviolet spectroscopy. These have shown that the initial reaction with pyrylium ions to give the vinylogous amides is fast under all conditions in the case of strongly basic *prim*-alkylamines, whereas base catalysis is necessary in the case of weakly basic amines[16].

The acid-catalyzed ring-closure of the intermediate divinylogous amides **17** to give the pyridinium derivatives **19** is subject to steric and electronic hindrance. The preferred catalysts are carboxylic acids[17]. Probably the rate-determining, acid-catalyzed step is an electrocyclic ring closure **17** → **18**.



The information gained from these mechanistic and kinetic investigations made it possible to find mild preparative conditions under which amines can be rapidly converted into pyridinium salts at room temperature in only mildly acidic or basic media[18]. The correct preparative conditions have been investigated for reactions of *prim*-alkylamines in which the alkyl group is either primary or secondary as well as (including weakly basic) *prim*-arylamines with a variety of types of pyrylium salts, including those containing bulky α-substituents[19].

4. Nucleophilic Attack on Pyridinium Salts—Mechanisms and Reaction Rates

Extensive mechanistic investigations on the reaction of *N*-substituted pyridinium salts with nucleophiles have shown that the *N*-substituents can be displaced by any of the four routes and five mechanisms depicted in Scheme 5[20]. It is not possible to discuss the mechanistic and kinetic work in detail here in the space available; this will be reviewed elsewhere[21].

The S_N2 rates of reactions of *N*-substituted pyridinium salts with piperidine in chlorobenzene serve as a measure of the reactivity of such salts. Based on a wide range of kinetic results, the following conclusions have been reached:

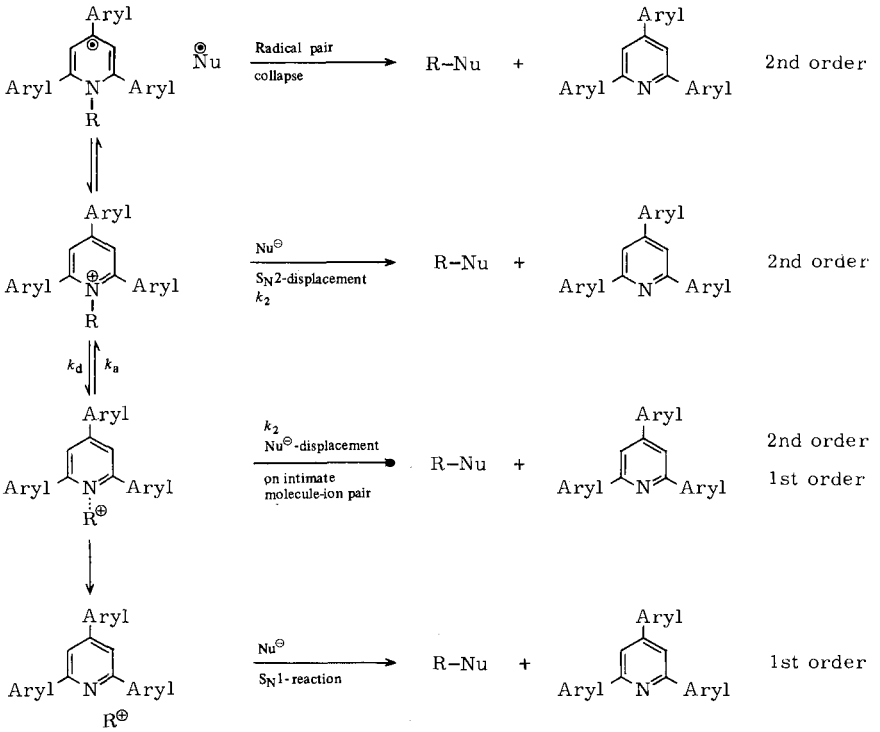
a) In **6b**, *N*-benzyl and *prim*-*N*-alkyl groups are displaced exclusively by S_N2 reactions, whereas *sec*-*N*-alkyl groups undergo displacement by both S_N1 and S_N2 mechanisms.

b) Replacement of α-phenyl groups in **6b** by methyl, *tert*-butyl, or H leads to considerably slower displacement rates.

c) Constrainment of the α-phenyl group to near planarity as in **10b** and **12b** markedly increases the displacement rates. Increased rates are also found for electron-withdrawing substituents, as in **8b** and **9b**.

5. Further Examples of the Transfer of *N*-Alkyl Substituents from Pyridinium Salts to Nucleophiles by S_N2 Reactions

It is now possible to transform primary amino groups into many other types of functionality via intermediate pyridinium ions. Leading references are given in Table 1. Most of the more recent work along these lines has con-



Scheme 5. Alternative mechanistic pathways for the nucleophilic displacement of *N*-substituents from pyridinium ions.

Table 1. Reactions of amines according to the "pyrylium method". The products mentioned in the four vertical columns arise via exchange with nucleophiles from the 4th, 5th, 6th, and 7th main groups of the periodic table.

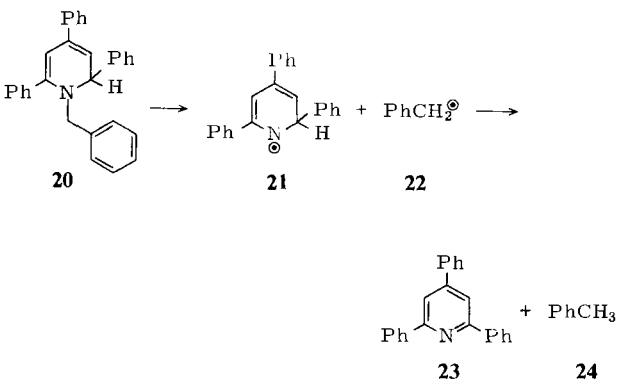
centrated on obtaining such conversions under mild conditions in solution. It has been shown that the use of the pentacyclic pyridinium compound **12b** and phase transfer catalysis permits conversion of *prim*-alkylamines RCH_2NH_2 into primary alcohols (sodium (*o*-hydroxymethyl)benzoate is used as nucleophile and phthalide is eliminated), sulfones (from sulfinate ions), thioethers, and ethers at below 100°C in solution[22]. Nitrate ion in refluxing dioxane similarly gives alkyl nitrates[23], while tertiary amines form quaternary compounds[24], and dichromate oxidation yields carbonyl compounds[24]. Under phase transfer conditions, sodium nitrite and the pentacyclic derivatives **12b** give mixtures of nitro compounds and the corresponding alcohols or alkyl nitrites[25].

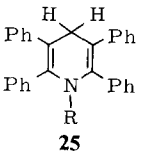
These methods have made it possible to use *N*-neopentyl derivatives of the tricyclic pyridinium compound **10b** and, thus, to prepare neopentyl halides, trifluoroacetate and thiocyanate in good yields without rearrangement[26]. Dialkylamino *prim*-alkylamines are converted by pyrylium salts into the corresponding pyridinium derivatives; these react as aminoalkylating agents with *O*-, *S*-, *N*-, and *C*-nucleophiles and therefore represent safe substitutes for nitrogen mustards[27].

Further work has also been carried out on the replacement of the amino group by hydrogen. Deuterium labeling experiments have demonstrated that the conversion **20** → **23** + **24** proceeds *via* the radical intermediates **21** and **22** (Scheme 6)[29]. The conversion of alkylamines into alkanes can be achieved with the 2,3,5,6-tetraphenylpyridinium ion **7b**[29] or the pentacyclic derivatives **12b** or **13b**[52].

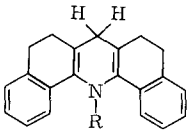


Scheme 6. Thermolysis of 1,2-dihydropyridines **20** to 2,4,6-triphenylpyridine **23** and toluene **24**.

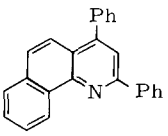
The *N*-alkylated 1,4-dihydropyridines **25** and **26**, which are derived from **7b** and **13b**, thermolyze at approximately 180 and 160 °C, respectively, to give the corresponding alkanes RH. In contrast, however, salts of the pyridinium ion **12b** already give the alkane on heating in solution with diazabicyclononene (DBN)[52]. For the analogous exchange of NH_2 for H in arylamines and heteroarylamines the preferred method is pyrolysis of the tricyclic *N*-aryl and *N*-heteroaryl pyridinium fluorides **10b** $F^{\ominus}$ to give ArH and **27**[53].



25



26

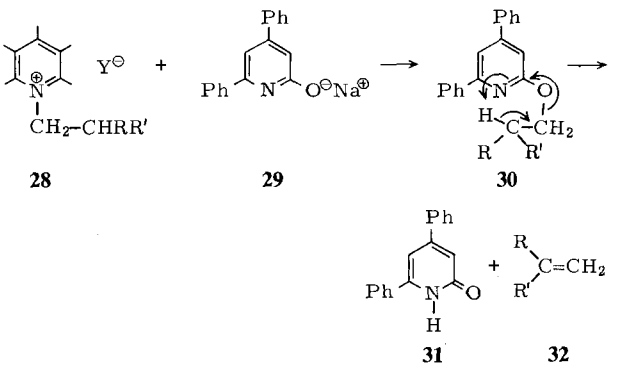


27

6. Formation of Olefins

Since the publication of the previous review[1], conditions for the conversion of primary amines RNH_2 into olefins have been defined. *prim*-Alkylamines are heated with the pentacyclic triflates **12b** at 150 °C in the presence of triphenylpyridine as non-nucleophilic base. In this way olefins can be obtained in yields of 80% or more[42,54]. Nonterminal olefins (20—30%) accompany the terminal olefins. It is believed that the reaction involves an E1 mechanism and that rearrangement of the primary carbonium ion intermediate occurs. *sec*-Alkylamines are converted by the pentacyclic pyrylium ion **12a** directly at 20 °C into olefins via the corresponding secondary carbocations[43]. Thus, cyclohexene (isolated as dibromide in 90% yield) is obtained from cyclohexylamine. These reactions proceed via secondary carbocations and hydrogen shifts are observed. For instance, 3-aminopentane gives some 1-pentene in addition to *cis*- and *trans*-2-pentene.

An alternative method for the preparation of olefins is to heat a pyridinium salt **28** with the sodium salt **29** of 4,6-diphenyl-2-pyridone. The intermediate ether **30** decomposes to pyridone **31** and the olefin **32** (Scheme 7)[55].



28 **29** **30** **31** **32**

Scheme 7. Synthesis of olefins such as **32** from pyridinium salts **28** using the sodium salt **29** of 4,6-diphenyl-2-pyridone.

7. *C*-Alkylation using Pyridinium Salts: Non-Chain Radicaloid Reactions

The *C*-alkylation of nitroalkane anions such as **34** has been developed into a useful preparative procedure. With the pyridinium ions **33**, unsubstituted and substituted benzyl groups can be transferred to the anions **34** in refluxing ethanol; with nitromethane anions the yields of **36** average 65%. The reaction proceeds much faster in dimethyl sulfoxide as solvent; heating at 100 °C was needed for alkylation, 50 °C sufficed for benzylation. The best yields under these conditions are achieved with 2-nitropropane anions; they are somewhat lower with nitroethane anions, and still lower with nitromethane anions, probably because of further reaction in the last two cases[56]. However, high yields can be achieved if the tricyclic derivative **11b** is used for the transfer of *prim*-alkyl groups and the tricyclic derivative **10b** for the transfer of *sec*-alkyl groups[31].

The following modifications to the 2-phenyl group in 2,4,6-triphenylpyridinium salts do not greatly affect the rate of radicaloid nucleophilic displacement of the *N*-benzyl group by the anion of 2-nitropropane: insertion of a *p*-nitro, *p*-methoxy, or *o*-methyl group, or replacement of phenyl by α- or β-naphthyl[57].

R = $ArylCH_2$

Scheme 8. Reaction of pyridinium ions **33** with nitroalkane anions **34** via the radicaloid intermediate **35**.

There is considerable evidence in favor of a non-chain radicaloid reaction (Scheme 8). Aside from other observations, the following arguments favor participation of radicals rather than a S_N1- or S_N2-type mechanism:

a) *Type of products.* In S_N2 reactions, nitroalkane anions generally give *O*- and not *C*-alkylation products[58].

b) *Dependence of the reaction rate on the N-substituent.* In S_N2 reactions, the rate decreases in the order benzyl > methyl > *prim*-alkyl and *sec*-alkyl. In the radicaloid reactions considered here, however, we find that the *sec*-alkyl derivatives react considerably faster than the *prim*-alkyl and methyl analogues.

c) *Influence of p-substituents in the benzyl moiety.* In the alkylations mentioned here, even this is quite different from the pattern found in "normal" S_N2 reactions with piperidine as nucleophile. In reactions of piperidine with *p*-substituted benzyls the rates decrease along the series methoxy > methyl > hydrogen > nitro. In contrast, in the radicaloid reaction the nitro derivative shows the fastest rate, followed by the methoxy compound and methyl, with the unsubstituted derivative showing the slowest rate. This latter sequence is that expected for radical stabilization.

d) *Dependence of reaction rate on the nucleophile.* The rate of formation of an intermediate charge transfer complex is dependent on the structure of the nucleophile.

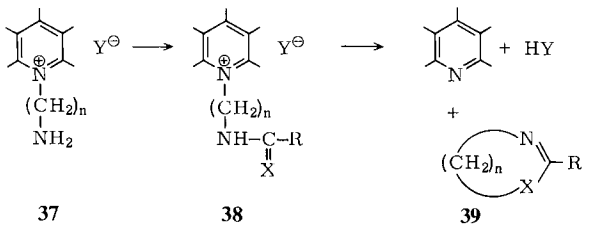
e) *Absolute values of reaction rates and activation parameters.* The absolute reaction rates of the 2-nitropropane anion are much greater than those of piperidine. The activation entropies for the radicaloid reaction are large and negative.

f) *ESR evidence.* ESR spectra show that a charge transfer complex **35** is formed[59].

There is also considerable evidence against a chain-reaction mechanism. First and foremost, clean kinetics are found. It is further significant that initiators and inhibitors do not alter the rates greatly[59][*]. Polarography of pyridinium ions also supports the mechanism described above[61].

8. Intramolecular Reactions with Participation of the *N*-Alkyl Substituents of Pyridinium Salts

The pyridinium ion **12b** derived from 5-aminopentanol was cyclized to tetrahydropyran in 78% yield[62]. Although ethylene oxide was obtained from **6b**, R = 2-hydroxyethyl[63], the pyridinium salts (**6b**, **12b**) derived from other 2-hydroxyamino compounds gave aldehydes or ketones via a 1,2-hydrogen or methyl group migration[62]. The ω-aminoalkylpyridinium salts **37** obtained from diamines can be acylated and converted into ureas or thioureas **38**. On heating in solution, these products cyclize to 4,5-dihydrothiazoles, 5,6-dihydro-4*H*-1,3-thiazines, 4,5-dihydro-1,3-oxazoles, 5,6-dihydro-4*H*-1,3-oxazines, or 4,5,6,7-tetrahydro-1,3-triazepines **39** (Scheme 9)[62].

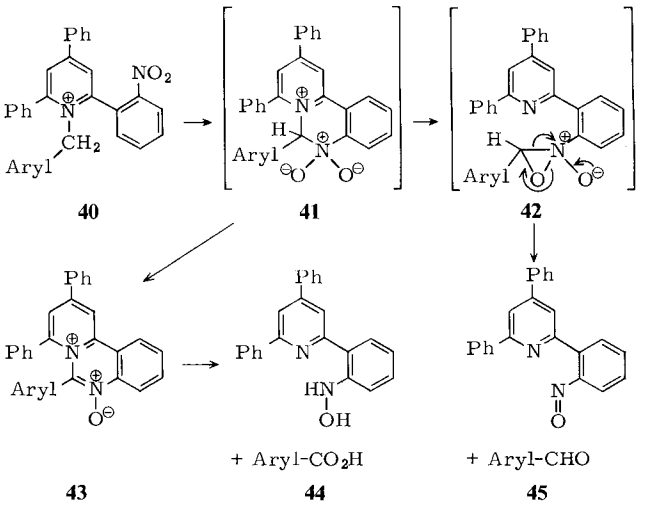


Scheme 9. Intramolecular reactions of *N*-(ω-aminoalkyl)pyridinium salts **37**.

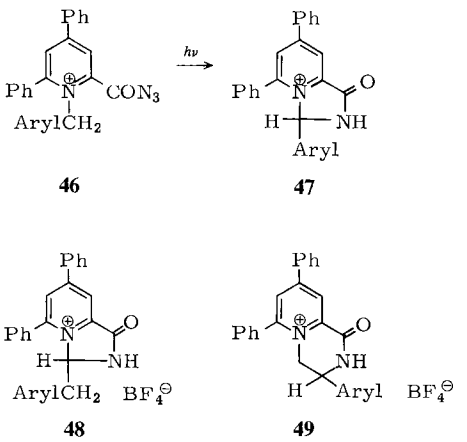
Intramolecular cyclizations between the *N*-substituent and an α-substituent on the pyridine ring are known which proceed via both radical and ionic mechanisms. Pyridinium compounds **40** derived from the 2-(2-nitrophenyl)-4,6-diphenylpyrylium ion and benzylamines undergo intramolecular redox reactions to give mixtures of benzaldehydes (**41** → **42** → **45**) and benzoic acids (**41** → **43** → **44**) according to Scheme 10[64].

On photolysis, the 2-azidocarbonyl-*N*-benzylpyridinium ions **46** are converted via imidazole derivatives **47** into benzaldehydes. Under the same conditions, the *N*-phenethyl derivatives give mixtures of phenylacetaldehydes (via **48**) and benzaldehydes (via **49**)[65].

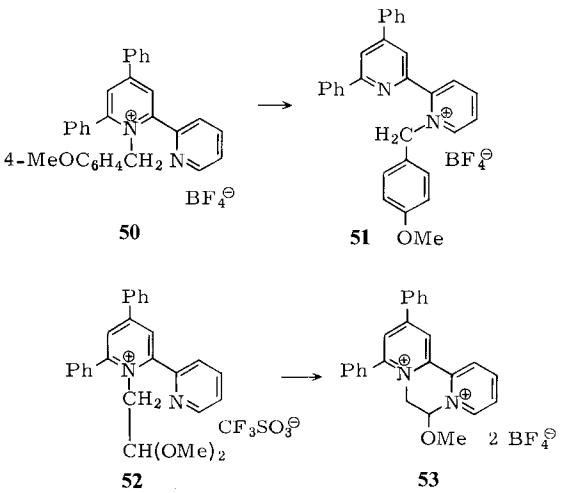
[*] This mechanism was originally referred to in our preliminary communication [30] as the $S_{RN}2$ mechanism. At the time we submitted this communication such a designation had not been previously used. However, in a paper that appeared after submission, but before publication, of our manuscript, *Bunnett* [60] used it in a different way, and we have therefore discontinued its use [59].



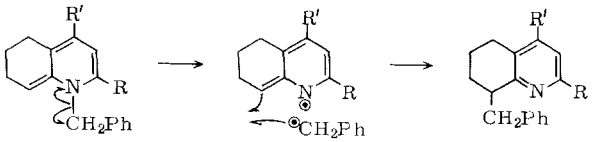
Scheme 10. Conversion of *N*-benzyl-2-(2-nitrophenyl)-4,6-diphenylpyridinium ions **40** into benzaldehydes **45** and benzoic acids **44**.



The transformation **50** → **51** has also been achieved; here a 4-methoxybenzyl group migrates from the pyridinium ring to the nitrogen atom of an α-(2-pyridyl) substituent[66]. This is likely to be an S_N1 process with the benzyl carbocation being trapped by the second nitrogen atom. Concerted intramolecular S_N2 displacement is unlikely, considering the geometric requirements[66]. The cyclization **52** → **53** has also been observed[66].



Considerable work has been carried out on "pyridinium anhydrobases" such as the 2,4-disubstituted 1-benzyl-1,5,6,7-tetrahydroquinolines **54**[67]: On thermolysis of these compounds, *N*-benzyl and *N*-ethyl groups migrate to the neighboring methine carbon atom C-8. Crossover experiments indicate an intermolecular process, probably involving the homolysis shown in Scheme 11[68].

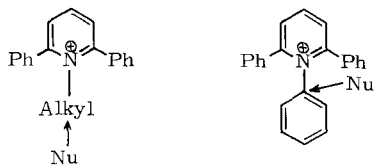


54 **55** **56**

Scheme 11. Rearrangement of "pyridinium anhydrobases" such as **54**.

9. Conversion of the NH_2-Group in Arylamines and Heteroarylamines into Other Functional Groups

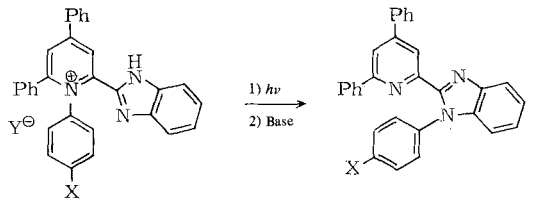
In our previous review we showed that *N*-arylpyridinium salts normally do not undergo nucleophilic displacement reactions[1]. Exceptions are the pyrolysis of the iodides of **6b** (R = aryl) at temperatures above 200 °C[51] and the thermolysis of the thiocyanate of **10b** (R = aryl) above 220 °C[39].



57 **58**

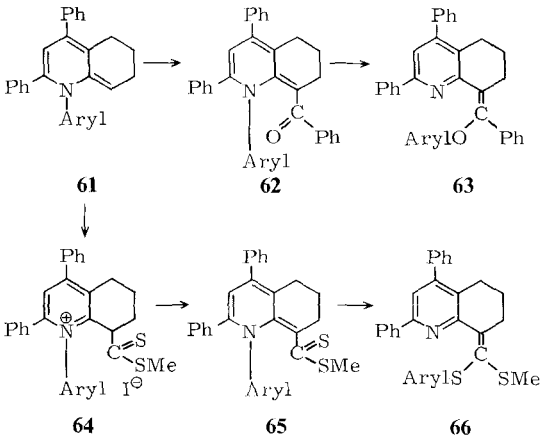
Scheme 12. Difference in steric approach of nucleophiles to *N*-alkyl- and *N*-arylpyridinium ions.

The stereoelectronic requirements for intermolecular nucleophilic displacements of *N*-aryl groups are not favorable, as seen on comparing **58** with **57** (Scheme 12). By way of contrast, however, intramolecular displacement of an *N*-aryl moiety to a suitable α-substituent on the pyridine ring should be possible. The first example of this kind of displacement was found in the photochemical rearrangement **59** → **60**[69].



59 **60**

More recently, it has been possible to demonstrate a series of non-photochemical rearrangements of this type. Such reactions are related to the well-known Smiles rearrangement[70], but our reactions occur under milder conditions and, in particular, do not require activating substituents in the displaced aryl ring.

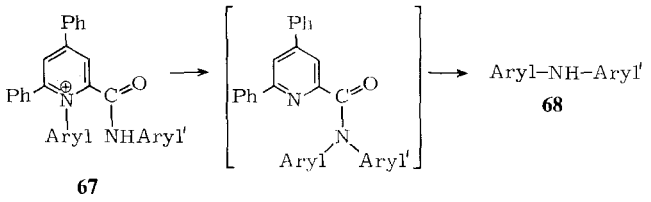


61 **62** **63** **64** **65** **66**

Scheme 13. Rearrangement of *N*-aryldihydropyridines such as **62** and **65**.

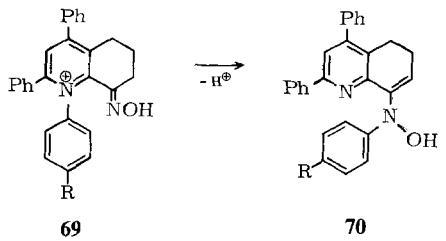
Thus, anhydrobases **62** (obtained from **14b** via **61**) rearrange at 150 °C into the isomeric aryl enol ethers **63**, which can be readily hydrolyzed to the corresponding phenols[71]. Alternatively, the compounds **61** can be converted by carbon disulfide and methyl iodide into the thio derivatives **64**, which afford the new anhydrobases **65**. These rearrange thermally into ketene-*S*,*S*-dithioacetals **66** (Scheme 13)[72].

Reaction of 2-ethoxycarbonyl-4,6-diphenylpyrylium ions **8a** with ring-substituted anilines leads, via the pyridinium ions **8b**, to the carboxamides **67**, which react with



67 **68**

sodium hydride in refluxing toluene to give diarylamines **68** in overall yields of ca. 30%; this compares favorably with other methods for the synthesis of diarylamines lacking active substituents[73]. The second amine used to form the amide can also be *tert*-butylamine or neopentylamine[74].

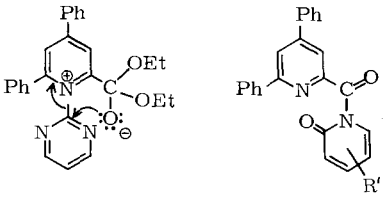


69 **70**

Another reaction in which a fragment of a molecule is transferred to nitrogen is the conversion of *N*-aryl-8-hydroxyimino-5,6,7,8-tetrahydroquinolinium ions **69** into **70**[74]. Attempts to transfer *N*-aryl groups to carbon atoms are still in progress[75].

An intermolecular nucleophilic displacement of the 2-pyridyl group in 2,4,6-triphenyl-, 2,4-diphenyl-, or 4-phenyl-*N*-(2-pyridyl)pyridinium salts under mild conditions has so far not been achieved[76]. However, it was found that

the 2-ethoxycarbonyl-4,6-diphenyl-*N*-(2-pyrimidinyl)pyridinium ion **8b** smoothly rearranges in the presence of ethanolic sodium ethoxide to give the corresponding 2(1*H*)-pyrimidinone via intramolecular attack, as shown in formula **71**[76].



71 **72**

Following this work it was shown that the cations **8b**, which are readily accessible from substituted 2-aminopyridine, are converted by dilute sodium hydroxide at 25°C into the corresponding *N*-pyridylcarbonyl-2-pyridones **72**, which, in turn, readily hydrolyze to 2-pyridones[77].

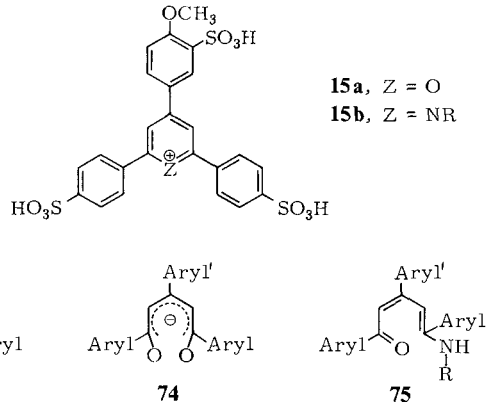
10. Biological Applications: Reactions in Aqueous Solution

Pyrylium salts show several potential advantages for the modification of the primary amino groups of complex natural products in the presence of other functional groups.

Thus, pyrylium ions react specifically with amines of the type RCH_2NH_2; on the other hand, no irreversible reaction occurs with compounds of the type RCO_2H, ROH, RCHO, RSH, R_2NH, RCONHR′, $RCONH_2$, RSR′, etc. Amino groups bound to *prim*-alkyl residues react at very different rates with the same pyrylium derivative, depending on the chemical environment. The method is therefore suitable for semi-synthetic transformations of natural products provided the reaction $RNH_2 \rightarrow$ pyridinium salt in presence of H_2O is possible, and provided the pyridinium moiety can be displaced by other substituents under mild conditions.

Preliminary attempts to react amino acids with triphenylpyrylium salts were unsuccessful owing either to the inactivation of the pyrylium salts by rapid formation in water of insoluble enedione pseudobases, or to the insolubility of amino acids in the common organic solvents (e.g. dichloromethane or absolute ethanol) normally used for the preparation of pyridinium salts. Although primary amines react with triphenylpyrylium ions in solvents of high polarity (e.g. triethylamine/carboxylic acid mixtures or phenols) to give the usual pyridinium salts, α-amino acids suffer spontaneous decarboxylation under these conditions, yielding *N*-alkylpyridinium salts. However, formation of pyridinium salts without further decomposition occurs with the ω-amino and terminal amino groups of lysine and glycylglycine, respectively, which serve as models for amino residues in polypeptides and proteins[78].

Alkyl esters of α-amino acids likewise react with pyrylium salts; however, the *N*-(α-ethoxycarbonylalkyl)-2,4,6-triphenylpyridinium salts thus formed are very unreactive towards nucleophilic substitution[79]. This is ascribed to stereoelectronic effects: the normal activating influence of an α-carbonyl group on the displacement of say a bromine atom is due to the possibility of overlap between the incoming nucleophile and the anti-bonding orbital of the carbonyl group. Models indicate that this is impossible in the pyridinium derivatives just mentioned[79].



15a, Z = O
15b, Z = NR

73 **74** **75**

For these reasons, it was decided to prepare water-soluble pyrylium salts. Tris(sulfophenyl)pyrylium ions such as **15a** co-exist in aqueous solution with the soluble enedione pseudobase **73**, and the anion **74**. The kinetics and equilibria of these species and the corresponding 2*H*-pyran and hydroxydienone have been elucidated over a wide pH range[12]. The pyrylium ion **15a** reacts with amines in aqueous solution to give mixtures of divinylogous carboxamide **75** and pseudobase **73**. The two products are formed by kinetic control in quantities which then equilibrate. **75** cyclizes to pyridinium ions **15b**; more pyridinium ion is then slowly formed from the pseudobase **73**. Rate constants were measured for reactions with lysine and other typical primary amines[80].

Other water-soluble triarylpyrylium salts and zwitterions containing two or three carboxylic or sulfonic acid groups and 2,6-diaryl-4-carboxypyridinium derivatives have been prepared[81,82].

In order to determine the best conditions for maximizing the yields of pyridinium salts from pyrylium salts and amines, the equilibria and kinetics of representative water-soluble pyrylium salts have been measured in aqueous solution, and the competing reactions with amines, water molecules and hydroxide ions elucidated and rationalized[83].

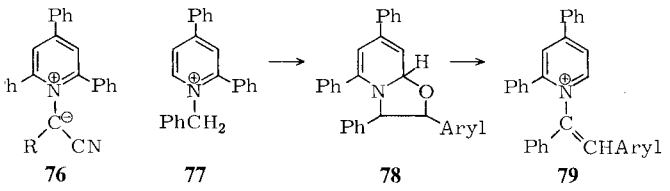
The reactions of gelatin and chymotrypsin with 4-(4-methoxy-3-sulphophenyl)-2,6-bis-(4-sulphophenyl)pyrylium ions **15a** in aqueous buffer have been investigated. The first-order ring-closure of the divinylogous carboxamide groups thus formed proceeds at a rate comparable with that of the reaction of **15a** with free lysine[84].

Kanamycins A and B react exclusively at the 6-amino groups with a variety of water-soluble pyrylium ions in aqueous solution to give the corresponding pyridinium ions in high yields. Neomycin reacts at the 1-amino group[85].

The ω-amino group of lysine has been replaced by PhS and $PhCH_2S$ groups via intermediates of the type **16b** in two-step reactions in aqueous solution, and at temperatures not exceeding 75°C. The terminal amino group of glycylglycine can be replaced in an analogous way by a PhS function[13]. These reactions provide models for the selective conversion of the ω-amino group of lysine side chains and the terminal groups of glycine residues, respectively.

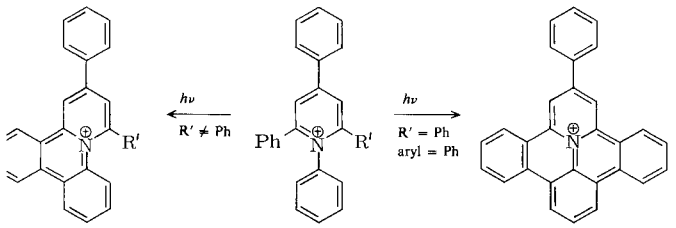
11. Other Reactions of the *N*-Substituents of Pyridinium Salts

Pyridiniomethanides have been utilized in various syntheses by *Kröhnke*[86]. We have also investigated such ylides. When another electron-withdrawing group is situated on the carbon atom, the ylide becomes quite stable, as, e.g., the compounds **76** derived from *N*-(cyanomethyl)pyridinium salts[87]. *N*-Benzyl-2,4-diphenylpyridinium ions **77** react with benzaldehydes to give the oxazolopyridines **78**, which can be dehydrated to the *N*-(β-styryl) derivatives **79**[5]. (4,6-Diphenyl-2-pyridinio)formates react with *p*-nitroso-*N*,*N*-dimethylaniline to give nitrones in an extension of the Kröhnke reaction[88].



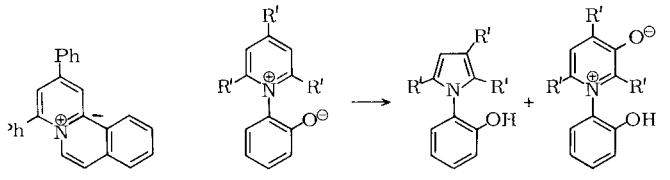
76 **77** **78** **79**

Pyridiniomethanides also add to carbonyl groups in aldol-type reactions, and to active CC double bonds in Michael reactions[89]. 1,2,4-Triarylpyridinium ions **81**, R ≠ Ph, undergo photocyclization and 1,2,4,6-tetraarylpyridinium



80 **81** **82**

cations **81**, R′ = Ph, photobiscyclization to form condensed ring systems **80** and **82**, respectively[90,91]. These compounds form pseudobases very readily[92]. Somewhat similar ring-systems (e.g., **83**) have been obtained by cyclization of pyridinium salts derived from 2,2-dimethoxyethylamine[93].

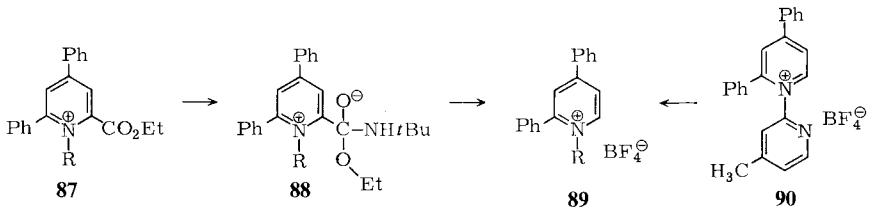


83 **84** **85** **86**

2-(2,4,6-Triaryl-1-pyridinio)phenolates **84** (and the corresponding 1-substituted 2-naphtholates) are oxidized by H_2O_2: mixtures of tetraarylpyrroles **85** and 3-pyrimidiniooxides **86** are formed. 2,4,6-Triaryl-*N*-phenylpyridinium salts react with H_2O_2 to give β-(arylcarbonylamino)chalcones[94]. *N*-(α-Methylallyl)pyridinium salts rearrange to the *N*-(γ-methylallyl)-analogues.

12. Preparation of Pyridinium Salts without α-Substituents

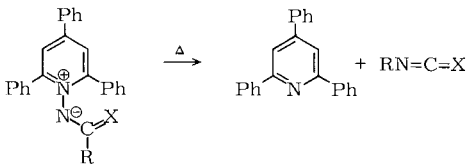
Some of the work described in this review has required the availability of pyridinium derivatives with unsubstituted α-positions. Such compounds cannot be prepared directly from pyrylium precursors, since ring-closure to the pyridinium derivative does not occur very readily in this case. However, we have found that α-ethoxycarbonyl substituents in pyridinium salts are removed completely by refluxing with *tert*-butylamine (e.g., **87** → **88** → **89**). With other amines, $S_NANRORC$ reactions compete[95]. This method has been utilized for the preparation of 1,4-diarylpyridinium salts[96]. An alternative method involves utilization of *N*-(4-methyl-2-pyridyl)-2,4-diphenylpyridinium tetrafluoroborate **90**, which reacts with a variety of amines to give the corresponding *N*-substituted 2,4-diphenylpyridinium salts **89** directly[97].



87 **88** **89** **90**

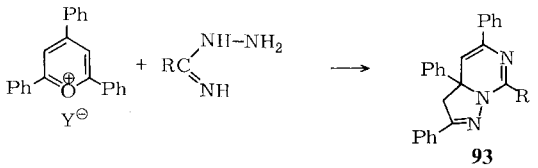
13. *N*-Amino-Substituted Pyridinium Salts

Scheme 14 shows the previously described conversion of *N*-(1-pyridinio)carboxamidates **91** into isocyanates[46] and of *N*-(1-pyridinio)carboxamidinates into carbodiimides[48] (for further details see [1]). More recently we have found that the compounds **92** are conveniently accessible from *N*-aminopyridinium salts and imidoyl chlorides[98]. However, *N*-unsubstituted amidrazones react with 2,4,6-triphenylpyrylium salts to give, via ring-opening and cyclization, the corresponding pyridines, namely the dihydropyrazolo[1,5-*c*]pyrimidines **93**[98].



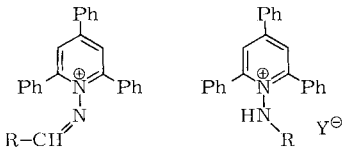
91, X = O
92, X = NR

Scheme 14. Preparation of isocyanates (X = O) and carbodiimides (X = NR) from the pyridiniocarboxamidates **91** and pyridinioamidinates **92**.

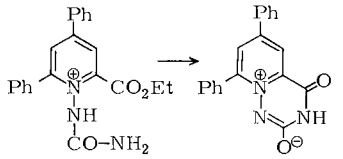


93

N-Amino-2,4,6-triphenylpyridinium tetrafluoroborate reacts with aldehydes to give **94** and with active halides[99] and other electrophiles to give **95**[100].



94 **95**



96 **97**

The copious and widely scattered pertinent literature on the reactions of pyrylium salts with hydrazines has been reviewed. Not only are the reactions of alkyl, dialkyl, and arylhydrazines dealt with but also the chemistry of the acid hydrazides and other electron-withdrawing, substituted hydrazines, and hydrazones[101]. In suitable cases, these reactions, in which a large variety of *N*-aminopyridinium derivatives is formed, are also followed by a cyclization, e.g. **96** → **97**[101].

14. Physical Measurements

Solution and gas-phase basicities of pyridinium salts with bulky α-substituents have been compared with their nucleofugacity[102, 103]. Restricted rotation occurs in polysubstituted pyrylium ions[104]. The gas-phase behavior of these pyridinium ions is currently being investigated by mass spectroscopy[105].

15. Summary and Outlook

In the preceding sections, the particular suitability of pyrylium salts for transforming amino groups into other functionalities has been described. It would now seem appropriate to summarize the disadvantages as well as the advantages of the method. Because of the high molecular weights of the pyrylium reagents, the method is unlikely to be much used for the transformation of simple amines which can be conveniently carried out with analogous halides R-Hal or alkyl tosylates R-Tos. The method will most likely be resorted to,

a) when transformations cannot be carried out at all, or less conveniently, with the corresponding halides or tosylates. Examples here include the *C*-alkylation of nitroalkane anions, the preparation of alkyl and benzyl fluorides, and the conversion of amines into olefins,
b) when the amino compounds are more easily accessible (e.g. from natural sources) than the corresponding halides or alcohols,
c) when amino groups are to be converted selectively. Pyrylium salts do not react with most other functional groups of common natural products. With the new water-soluble pyrylium salts, specific transformation of protein NH_2-groups becomes feasible under mild conditions in aqueous solution. Future work in this area could have important consequences for biological chemistry,
d) when the diazotization of arylamines, despite the usefulness of this method for many transformations, cannot be resorted to without difficulty. Thus, attachment of C-linked functionalities other than CN by diazotization is difficult. In the case of many heteroarylamines diazotization of the normal type is not easily achieved. An example of a possible application of the new alternative method is the mild conversion of nucleic acid NH_2-groups into oxo-groups (via tautomerizing hydroxy groups); the selectivity could be considerably greater than that in the diazotization with nitrous acid.

The kinetic studies outlined in this review made it possible to determine the optimum conditions for amino-group transformations. Moreover, they have shed new light on the mechanism of such transformations. Studies on the solvolysis of pyridinium ions are of importance for the formulation of general theories of nucleophilic substitution in both aliphatic and aromatic systems.

The reactions proceeding via radicaloid intermediates, exemplified here by nitroalkane anions **34**, are being studied in more detail. In particular, we are interested in the conditions which favor the formation of σ-adducts over charge-transfer complexes, and in the possible extension of this reaction to C_{aryl}–C bond formation.

The present work has emphasized the potential importance both of steric acceleration and of the possibility of fast intramolecular reactions of normally unreactive substrates. The field offers considerable potential for molecular design: the pyrylium cation can be considered as a template into which the amine is introduced, and on which any desired functionality can be arranged to facilitate intramolecular transformations of types which are reminiscent of those which apply in enzymes.

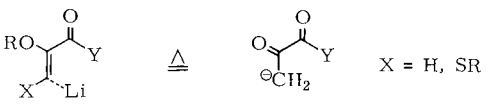
Synthesis of 3-Deoxy-D-*manno*-2-octulosonic Acid (KDO)**

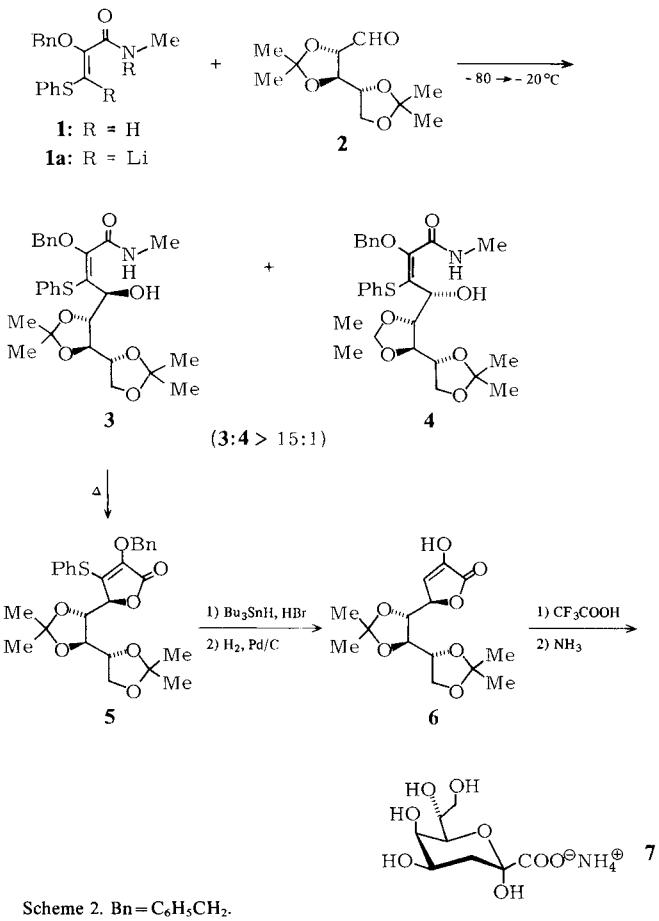
By *Richard R. Schmidt** and *Rainer Betz*

KDO (ammonium salt: **7**) is an integral component of the lipopolysaccharides of gram-negative bacteria[1]. In all the published syntheses, the construction of the D-*manno* structure from D-mannose derivatives with chain lengthening by Wittig reaction required additional steps for the incorporation or liberation of the 2-keto group[1–3]. In the case of its construction from D-arabinose and derivatives, the formation of diastereoisomers and their separation prove to be disadvantageous[4]. The special interest in the chemistry of KDO[1] was the reason for developing, in analogy to the biosynthesis[1], a productive synthesis on the basis of *C*-lithiated, functionally substituted acrylic acid as pyruvic acid-equivalent C_3-building block and D-arabinose as C_5-building block (Scheme 1).



Scheme 1.

A suitable C_3-synthetic building block was found to be 2-benzyloxy-3-(phenylthio)acrylic acid *N*-methylamide **1**[5], which reacts with lithium diisopropylamide in the molar ratio 1:2 directly and almost quantitatively to give the dilithiated species **1a** (Scheme 2). Reaction of **1a** with the readily accessible 2,3:4,5-di-*O*-isopropylidene-D-arabinose **2**[6] as electrophile furnished, in very good yields and with high diastereoselectivity, the desired D-*manno* product **3** (in tetrahydrofuran (THF)/hexamethylphosphoric triamide: 85%, **3**:**4** > 15:1; in THF: 75%, **3**:**4** = 8:1), which recrystallized from the mother liquor in isomerically pure form (m.p. 113–114°C, 75%). Hence, the problem of separating diastereoisomers was solved in an easy way. The diastereofacial selectivity can be explained in terms of the Felkin model[7]. Steric and stereoelectronic influences favor *Re*-attack in the case of **2A**, to give the D-*manno* product, rather than *Si*-attack to give the D-*gluco* product **4** (Scheme 3). In the case of **2B** *Re*- and, in particular, *Si*-attack are handicapped owing to the spatial requirement of the 4,5-*O*-isopropylidene group.



Scheme 2. Bn = $C_6H_5CH_2$.

On heating in petroleum ether (b.p. 110–140°C), **3** was converted almost quantitatively into butenolide **5**[8], which was obtained as a colorless oil after filtration over silica. Cleavage of the phenylthio-group was accomplished by reaction with tributyltin hydride and hydrogen bromide (73% after filtration over silica)[9]. The benzyl group was removed hydrogenolytically with palladium on active charcoal in ethyl acetate; the known KDO intermediate **6** was thus formed as colorless crystals [95%; m.p. 100–104°C, ref. [2] 102–104°C; $[\alpha]_{589}^{25}$ 57.2 ($CHCl_3$, $c = 1$); ref. [2] $[\alpha]_D^{22}$ 56.7 ($CHCl_3$)]. According to ^{1}H-NMR data (250 MHz,

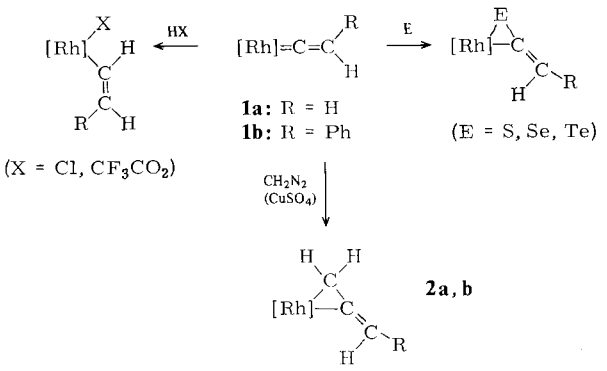
Ambidentate Behavior of Mononuclear Vinylidenerhodium Complexes—Novel C–C Coupling of a Methyl to a Vinylidene Group

By *Helmut Werner*, Justin Wolf, Gerhard Müller,* and *Carl Krüger*

Dedicated to Professor Jan Thesing on the occasion of his 60th birthday

Besides carbenemetal complexes $L_nM{=}CRR'$, the related vinylidenemetal complexes $L_nM{=}C{=}CRR'$ have also attracted increasing interest in recent years[1]. As confirmed by X-ray structure analyses[1], they contain a cumulated π-electron system and may therefore be regarded as "metallaallenes". In the complexes with $L_nM = C_5H_5(iPr_3P)Rh$ and $CRR' = CH_2$, CHMe, CHPh recently prepared by us[2a,b], the M=C and not the C=C bond is the preferred site of attack for electrophiles, as can be seen from the examples given in Scheme 1[2c].

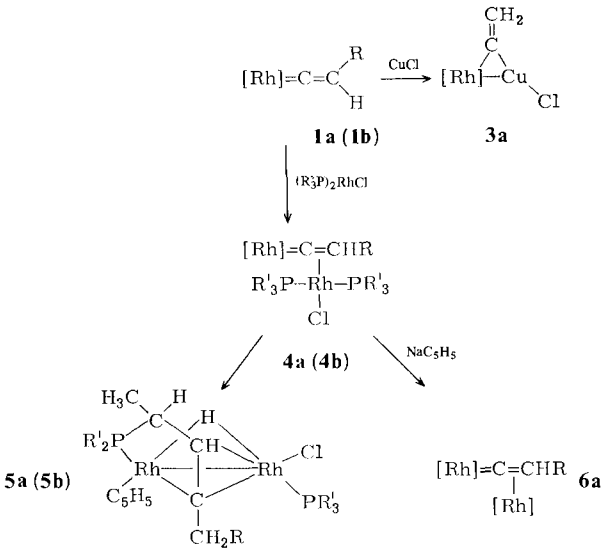
We have now discovered that on using CuCl instead of $CuSO_4$ for the transfer of CH_2 from diazomethane to **1a**, yet another η^5-C_5H_5Rh-containing compound of the composition **3a** is formed in addition to **2a**; it is obtained directly from **1a** and CuCl in tetrahydrofuran (THF) at room temperature in 71% yield[3]. The new complex contains a μ-$C{=}CH_2$ bridge between two different metal atoms, only



Scheme 1. $[Rh] = C_5H_5(iPr_3P)Rh$.

one example of which has so far been reported in the literature[4].

Attempts to prepare a $(\mu\text{-}C{=}CH_2)Rh_2$ complex with a 16-electron fragment $C_5H_5(L)Rh$ on each side of the vinylidene bridge by reaction of **1a** with $C_5H_5Rh(L)CO$ ($L = CO$, PMe_3) or $C_5H_5Rh(PMe_3)C_2H_4$ failed, owing to the poor reactivity of the starting compounds $C_5H_5Rh(L)L'$. However, **1a** reacts rapidly with the 14-electron species $(iPr_3P)_2RhCl$ (pentane, 25°C, 10 min; yield 56%) to give the binuclear complex **4a**[3], in which the "metallaallene" is bound to the square-planar coordinated rhodium atom, similarly to an alkene[5] or an alkyne[2a,b].



Scheme 2. $[Rh] = C_5H_5(R'_3P)Rh$, $R' = iPr$ (P atom of the $C_5H_5(R'_3P)Rh$ group designated as P^1 in the ^{31}P-NMR spectrum of **4a** [3]); **a**: R = H; **b**: R = Ph.

Solid **4a** is stable under inert gases. In solution, elimination of phosphane occurred (at 25°C after several days, at 50°C after 2–3 h), and a binuclear complex containing a hydrido bridge was formed which could not be isolated in analytically pure form; however, both the NMR data as well as the mass spectrum [M^+ at m/z 652 (^{35}Cl), 654 (^{37}Cl)] support formulation of the complex as **5a** (Scheme 2).

Reaction of **1b** with $(iPr_3P)_2RhCl$ (benzene, 25°C, 30 min) leads rapidly (via the ^1H-NMR spectroscopically detectable intermediate **4b**) to the corresponding phenyl derivative **5b** (yield 63%)[3]. The elimination of iPr_3P from **4b** is apparently promoted by the phenyl substituents on the β-C atom of the vinylidene ligand.

The result of the X-ray structure analysis of **5b** is shown in Figure 1[6]. Double H-transfer from a CH_3 group of a triisopropylphosphane ligand to the Rh_2-moiety and the CHR carbon atom leads to formation of a CH group which is linked to the α-C atom of the original vinylidene ligand and the Rh atom of the starting compound $(iPr_3P)_2RhCl$. The Rh1,P1,C3,C2 fragment of the resulting C_3PRh five-membered ring is planar; the bridging atom Cl is at a distance of 0.39 Å from this plane. The C1–C2 bond length of 1.417(4) Å suggests partial double-bond character, i.e. the bonds drawn between the CC unit and Rh in Scheme 2 are to be regarded as representing a resonance formula. The Rh–Rh bond length of 2.7602(3) Å can be interpreted in terms of a weak Rh–Rh interaction[7]. The Rh1–C1 and Rh2–C1 distances are very similar to those in other, comparable Rh_2 complexes[8]; the Rh2–C2 distance, however, is slightly longer (Fig. 1). Even the values for the Rh–H–Rh bridge differ very little from those of other singly H-bridged systems[9].

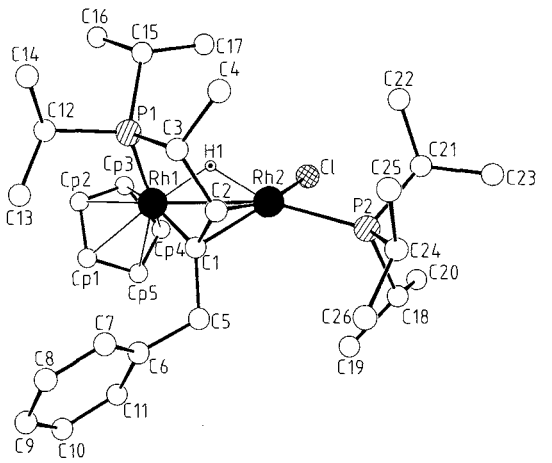

Fig. 1. Structure of the complex **5b** in the crystal. Selected bond lengths [Å] and angles [°]: Rh1–Rh2 2.7602(3), Rh1–H1 1.61(3), Rh2–H1 1.72(3), Rh1–C1 2.053(3), Rh2–C1 2.021(3), C1–C2 1.417(4), C2–C3 1.526(4), C3–C4 1.527(4), C1–C5 1.526(4), Rh2–C2 2.140(3), Rh1–P1 2.230(1), Rh2–P2 2.308(1), Rh2–Cl 2.392(1); Rh1–H1–Rh2 112(2), Rh1–C1–Rh2 85.3(1), Rh1–C1–C2 116.4(2), Rh2–C1–C2 74.7(2).

Reaction of **4a** with NaC_5H_5 (THF, 25 °C, 20 min) leads quantitatively to the binuclear compound **6a**[3], in which the two $C_5H_5(iPr_3P)Rh$ moieties are unequally coordinated to the $C{=}CH_2$-group. Proof of the structure follows from the ^{1}H-NMR spectrum, but principally from the ^{13}C-NMR spectrum (in C_6D_6), in which in addition to the signals for the phosphane and the cyclopentadienyl carbon atoms a signal is found at $\delta = 310.37$ (ddd, $J_{Rh^1C} = 70.6$, $J_{Rh^2C} = J_{PC} = 23.0$ Hz), i.e. in the region typical for carbene and α-vinylidene carbon atoms[1,2a,b]. Attempts to rearrange **6a** into the symmetrical isomer $[C_5H_5(iPr_3P)Rh]_2(\mu\text{-}C{=}CH_2)$ have so far been unsuccessful.

With the synthesis of **4a**, **b** and **6a**, it is shown for the first time that not only the M=C- but also the C=C-bond of a vinylidene complex can react with a coordinatively unsaturated metal species. Thus, complexes of the type $L_nM{=}C{=}CRR'$ behave in an ambidentate way, as demonstrated by the formation of the structurally different binuclear compounds **3a** and **4a** from **1a**.

Ring-Opening of Methylene-Bridged Dimetal Complexes by Bases**

By *Wilhelm Keim**, *Michael Röper*, *Heinz Strutz*, and *Carl Krüger*

Dimetallacyclopropane complexes are of special interest for the mechanistic explanation of the Fischer-Tropsch synthesis[1]. Ring-opening to well-defined derivatives has hitherto only been accomplished by reaction with strong acids[2]. We have now found that ring-opening of the three-membered ring moiety can also be induced by bases when such complexes contain CO ligands. Reaction of $[Fe_2(\mu\text{-}CH_2)(CO)_8]$ **1**[3] with sodium methoxide leads to the unstable polynuclear methyl metallaacetate complex **2**,

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

so far characterized only by IR spectroscopy[4]. Cation exchange with $(Ph_3P)_2N^{\oplus}Cl^{\ominus}$ (PPNCl) afforded the more stable compound **2a**, which, however, could not be isolated in analytically pure form[5]. However, on warming **2a** (in DMSO, 80 °C) the pure, isolable mononuclear product **3** is formed[6].

$$\underset{\mathbf{1}}{Fe_2(\mu\text{-}CH_2)(CO)_8} + NaOCH_3 \xrightarrow{THF} \underset{\mathbf{2}}{Na^{\oplus}[Fe_n(CO)_m(CH_2COOCH_3)]^{\ominus}}$$

$$\xrightarrow[2.\ 80\ °C/18\ h]{1.\ PPN^{\oplus}Cl^{\ominus}} \underset{\mathbf{3}}{PPN^{\oplus}[(CO)_4Fe(CH_2COOCH_3)]^{\ominus}}$$

The geometric data of the central moiety in the anion of **3** (Fig. 1) correspond to those of tetracarbonyl(propyl)ferrate[7].

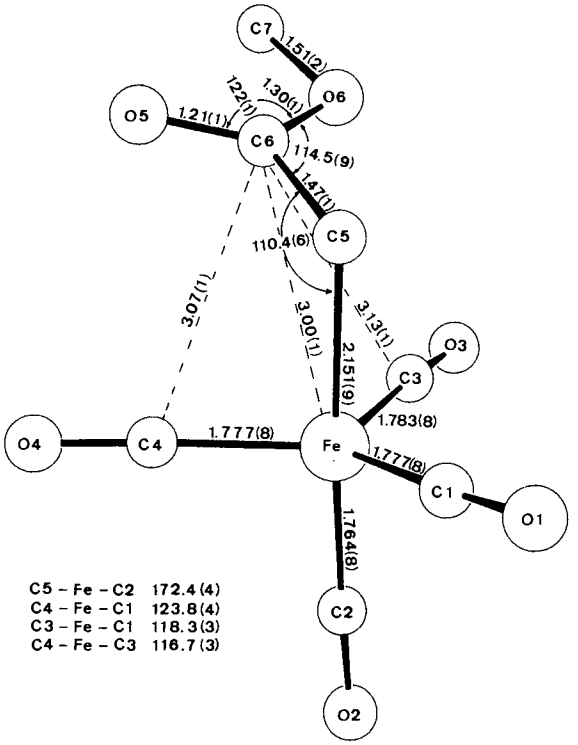

Fig. 1. Structure of the anion of **3** in the crystal, with important atomic distances [Å] and angles [°]. Space group $P2_1/n$ (No. 14). $a = 24.798(5)$, $b = 9.483(2)$, $c = 35.606(4)$ Å, $\beta = 108.23(1)°$, $V = 7952.51$ Å^3, $\rho_{calc} = 1.302$ g cm^{-3}, $Z = 8$ (4 × 2 molecules); $\lambda = 0.71069$ Å, $\mu(Mo_{K\alpha}) = 5.02$ cm^{-1}, 13891 reflections, 5923 observed ($I > 2\sigma(I)$), refined parameters 913, $R = 0.0599$, $R_w = 0.0739$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50744, the names of the authors, and the journal citation.

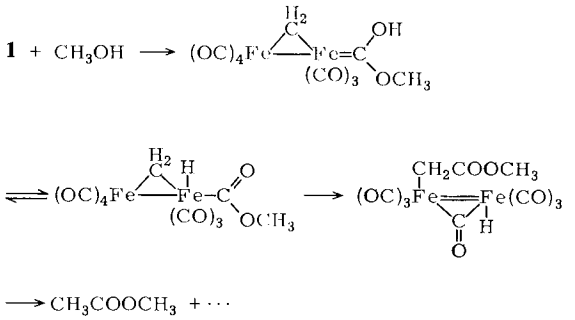
The intermediate product **2** is formed by nucleophilic attack of the methoxide base at a CO ligand of **1**, and its subsequent coupling with the CH_2-bridge ligand. Such a reaction sequence is also supported by the detection of $Li^{\oplus}[Fe_2(\mu\text{-}CH_2)(CO)_7(COR)]^{\ominus}$ **4** (R = Me, *n*-Bu) as product of the reaction of **1** with methyl- or butyllithium[8a]. Reaction of **4** with trifluoroacetic acid in tetrahydrofuran leads to acetaldehyde and acetone (yield 3.4 and 3.6% referred to **1**, R = Me) or to valeraldehyde and 2-hexanone (yield 4.8 and 2.1%, respectively, referred to **1**, R = *n*Bu).

The formation of **3** from **1** corresponds to a homologation of the methylene function within the coordination sphere of a complex. The cobalt complex $[Co_2(\mu\text{-}CH_2)Cp_2(CO)_2]$[9] reacts analogously, whereas the iron complex $[(Fe_2(\mu\text{-}CH_2)(\mu\text{-}CO)Cp_2(CO)_2]$[10] does not react with sodium methoxide. **1** reacts with phenyllithium or $KHB[CH(CH_3)C_2H_5]_3$ to give respectively the IR spectroscopically characterized, polynuclear metalated acetophenone $Li^{\oplus}[Fe_n(CO)_m(CH_2COPh)]^{\ominus}$ **5** or acetaldehyde $K^{\oplus}[(Fe_n(CO)_m(CH_2CHO)]^{\ominus}$ **6**[8b].

Protolysis of **2** furnishes methyl acetate in high yields (ca. 50%); as expected, with deuterated acids such as CF_3COOD, methyl acetate monodeuterated in the acetyl function is formed. Reaction of **1** with methanol also leads to almost quantitative yields of methyl acetate[11]. A "base reaction mechanism" according to Scheme 1 also appears plausible for the reaction with alcohols.



Scheme 1.

Our findings would suggest at least an indirect interaction of the CH_2-bridge with a terminal CO ligand[2]; we thus may have a model here for explaining the formation of oxygen-containing products by the "methylene-oligomerization mechanism" in the Fischer-Tropsch synthesis[13].

Structure of a Novel μ_3-Oxo-$Fe_2^{III}Cr^{III}$-Glycine Complex**

By *William Clegg, O. Mi Lam,* and *Brian P. Straughan**

Several crystal structures have been determined for trinuclear oxo-centered carboxylates of vanadium[1], chromium[2], manganese[3], and iron[2]. Their structures are of great interest because mixed-valence species as well as mixed-metal triangular complexes have been confirmed. A key question in connection with the mixed-valence species is whether they show valence trapping or a symmetrical structure with equivalent metal atoms. No crystal structure has so far been determined for mixed-metal carboxylate systems of the type $(M_A^{III})_2M_B^{III}$.

The structure of the μ_3-oxo-Fe_3^{III}-alanine complex **1** is of biochemical interest as a model for the ferritin iron core[4]. The L-alanine in **1** is present as a zwitterion, and the nitrogen atoms are not involved in the iron-ligand bonding.

$[Fe_3(\mu_3\text{-}O)(\text{L-alanine})_6(H_2O)_3][ClO_4]_7 \cdot x\,H_2O$ **1**
$[Fe_2Cr(\mu_3\text{-}O)(\text{glycine})_6(H_2O)_3][ClO_4]_7 \cdot 6\,H_2O$ **2**

During the course of our own studies on metal complexes with carboxylates and amino acids, we found that very large (1–1.5 cm) deep red-brown crystals of **2** were deposited when a warm aqueous solution (60°C) of $Cr(ClO_4)_3$, $Fe(ClO_4)_3$, and glycine (molar ratio 1:2:6) was set aside with occasional maceration for a period of two months. Satisfactory elemental analyses (C, H, N, and Fe) were obtained, and a single-crystal X-ray diffraction study has confirmed the trinuclear structure (Fig. 1).

Examination of the structure of **2** and comparison with other *triangulo*-complexes lead to the following conclusions:

1) The Fe_2Cr-arrangement is *ordered* in the crystal structure of **2**, as indicated by the thermal parameters; refinement with three Fe atoms gives a considerably higher temperature factor for one atom. The four symmetry-equivalent cations in each unit cell are arranged such that all the Cr–(μ_3-O) bonds are aligned in two directions inclined at only 35.4° to each other. This alignment implies the presence of magnetic ordering.

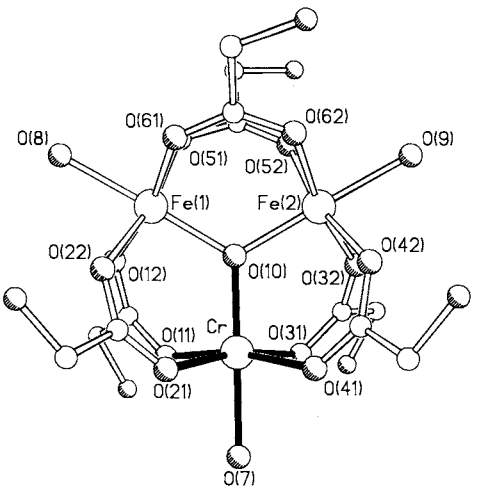

Fig. 1. Structure of the complex cation $[Fe_2Cr(\mu_3\text{-}O)(\text{glycine})_6(H_2O)_3]^{7+}$ of **2** in the crystal. Space group Cc, $a = 19.576(5)$, $b = 14.555(3)$, $c = 19.812(5)$ Å, $\beta = 106.80(2)°$, $Z = 4$, $R = 0.074$ for 6632 reflections with $F > 4\sigma(F)$. Key distances [Å]: Cr–O10 1.900(2), Fe1–O10 1.910(2), Fe2–O10 1.921(4), Cr–O7 2.043(9), Fe1–O8 2.053(6), Fe2–O9 2.079(7), Cr···Fe1 3.322(3), Cr···Fe2 3.288(3), Fe1···Fe2 3.316(3), mean Cr–O(glycine) 2.03(2), mean Fe–O(glycine) 2.01(1) Å. Further details on the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50867, the names of the authors, and the journal citation.

2) Substitution of an Fe atom by a Cr atom in the cation introduces virtually no deviation from the ideal threefold symmetry in the central core. The less symmetrical arrangement of the glycine ligands is a consequence of the lower symmetry of the overall crystal structure.

3) The triangular structure of these complexes is largely independent of the precise nature of the other oxygen-containing ligands coordinated to the trinuclear unit (carboxylate, amino acid, water, etc.) and of the nature of the counterion ($ClO_4^{\ominus}$, $NO_3^{\ominus}$, etc.).

The $Fe_2Cr(\mu_3\text{-}O)$-glycine complex **2** has an average M···M separation of 3.309(3) Å. An interesting comparison can be made with analogous acetate complexes of Cr^{III} and Fe^{III}[2]. Crystal structure data for these indicate very similar average M···M distances, in the range 3.274–3.307 Å. Mixed-valence analogues (M^{II}/M_2^{III}) of ruthenium[5], chromium[6], and manganese[7] exhibit slightly longer average M···M distances, in the range 3.329–3.363 Å. In the absence of direct metal-metal bonding, the central geometry of these complexes seems to be dictated mainly by the size of the (μ_3-O) atom. In contrast, the average M···M distance in $[Pd_3^{II}(\text{acetate})_6]0.5\,H_2O$[8], a complex with no central oxygen atom, is only 3.15 Å, even though there is no recognized formal direct metal-metal interaction. For doubly oxo-capped trinuclear structures of molybdenum[9] and tungsten[10] with acknowledged metal-metal interactions, the M–M bond lengths are considerably shorter (2.766 and 2.745 Å, respectively), and the presence of a central in-plane oxygen atom is presumably impossible for steric reasons.

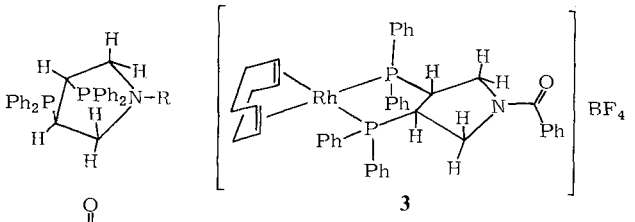
Asymmetric Hydrogenation of α-(Acetylamino)cinnamic Acid with a Novel Rhodium Complex; the Design of an Optimal Ligand**

By *Ulrich Nagel**

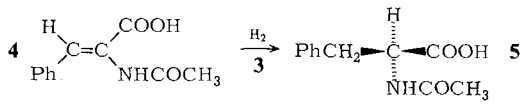
Rhodium complexes of optically active bisphosphanes facilitate the asymmetric hydrogenation of prochiral olefins, in some cases in high optical yields[1]. The new 1,2-bisphosphane **1** (benzoylpyrphos) is presented here as a ligand especially suited for the hydrogenation of α-(acylamino)acrylic acids to (*S*)-*N*-acylamino acids.



3

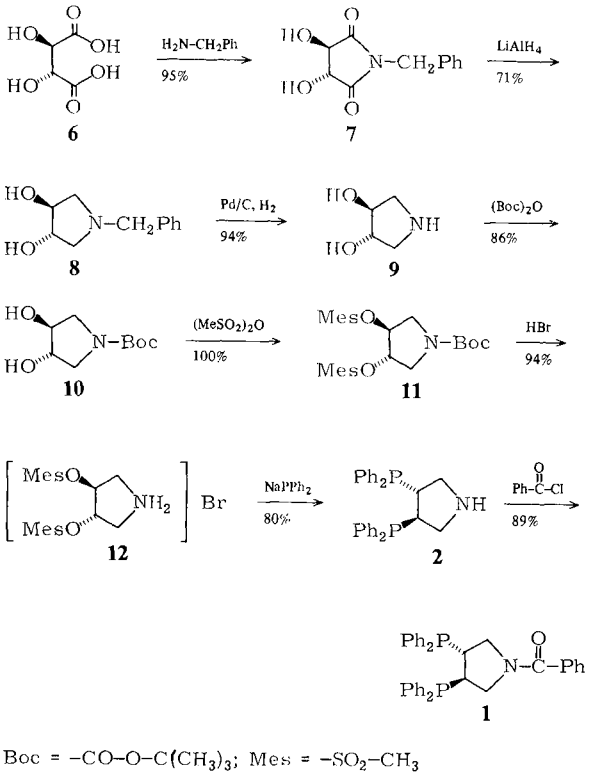
1, R = $-\overset{O}{\overset{\|}{C}}-Ph$
2, R = H

The novel rhodium complex {(*R,R*)-*P,P'*-[*N*-benzoylpyrrolidine-3,4-diyl]bis(diphenylphosphane)}-1,5-cyclooctadienerhodium tetrafluoroborate **3** catalyzes the hydrogenation of α-(acetylamino)cinnamic acid **4** to (*S*)-*N*-acetylphenylalanine **5** with 99% *ee*. In contrast to hydrogenations with other enantioselective catalysts, this hydrogenation can be carried out under pressure without loss of selectivity. The reaction rate increases linearly with the hydrogen pressure (0.8 min^{-1} at 1 bar, 40 min^{-1} at 50 bar). Even high substrate to catalyst ratios (10000 : 1) can be used without lowering the selectivity and, at 50 bar hydrogen pressure, such conversions are achievable in only 10 h.



All structural units known to increase the optical yield in the hydrogenation of acryl acid derivatives were incorporated in the ligand **1**. The ligand is chemically stable under the conditions used for the catalysis. It does not contain any P–O or P–N bonds, which undergo solvolysis on prolonged reaction[2], and it imposes a markedly rigid conformation (λ-conformation) on the five-membered metallacycle[3].

Variation of the substituents on the nitrogen atom of **1** has no marked influence on the catalytic activity and the selectivity of the resulting rhodium complex. Only in the case of **2** (R = H) is the catalytic hydrogenation slower, which could be due to an oxidative addition of N–H to Rh^I. Even substituents on the phenyl group of **4** have little influence on the optical yield; thus, e.g., the 4-hydroxy-, 4-methoxy-, 4-hydroxy-3-methoxy-, or 3,4-methylenedioxy-derivatives all give over 95% *ee*.



Boc = $-CO-O-C(CH_3)_3$; Mes = $-SO_2-CH_3$

Scheme 1.

1 was obtained in eight steps from natural (*R,R*)-(+)-tartaric acid **6** (overall yield 36%) (Scheme 1). Attempts to prepare (*S,S*)-3,4-dihydroxypyrrolidine **9** via the tartrimide met without success; *N*-benzyltartrimide was therefore used. The Boc-moiety in **11**, which was obtained via the sequence **7** → **8** → **9** → **10** → **11**, must be removed since reaction of **11** with sodium diphenyl phosphide leads to elimination products. The reaction of **12** is critical and only affords satisfactory yields when carried out in dimethylformamide (DMF)[5].—So far the only optically active 3,4-dihydroxypyrrolidine described in the literature since we completed our studies has been the *N*-phenyl derivative[2].

A particular advantage of the new ligand is that the *N*-substituent can be varied, i.e. the ligand itself can be tailored according to its intended use. Two polymer-bound chiral bisphosphanes (DIOP and PPM) are known[1,4].

Preliminary experiments with **2** bonded to Merrifield resin or silica gel furnished heterogeneous catalysts which hydrogenate **4** in methanol with 95% *ee*—an enantioselectivity which has so far never been achieved in heterogene-

ous catalysis. The hydrogenation with the silica-bound catalyst is only slightly slower than in solution; after filtration, the catalyst could even be used again without reducing the selectivity.

[5] Procedure: A solution of $NaPPh_2 \cdot 2$ dioxane (10.5 g, 27.5 mmol) in DMF (60 mL) is treated at −35 °C with 2.6 g (7.6 mmol) **12** and the mixture stirred for ca. 12 h at −12 °C. After removal of the solvent, dissolution of the residue in water, and extraction of the aqueous solution with ether, 2 N HCl is added to the ether extract to precipitate **2** as the hydrochloride. Treatment of **2** with benzoyl chloride affords **1** [colorless, m.p. 180—182 °C; $[\alpha]_D^{22}$ +153 (c = 2.84, toluene), reprecipitation from toluene/hexane]. **1** reacts with $[Rh(cod)_2]BF_4$ to give **3** [yellow, readily soluble in methanol, reprecipitation with ether]. Typical experiment: A solution of **4** (2.05 g, 10 mmol) in methanol (30 mL) was treated with 1 mg (0.0012 mmol) **3** and the mixture stirred in a 50 mL steel autoclave under an average pressure of 40 bar H_2 (ca. 12 h at RT). After addition of 1 mL 0.1 N HCl, the solution was evaporated to dryness, the residue taken up in NaOH, and the catalyst removed by extraction with dichloromethane. The aqueous solution was acidified and extracted with ethyl acetate. After removal of the ethyl acetate, pure **5** was obtained in quantitative yield. According to polarimetric measurements the optical purity was 99%; the rotation of a recrystallized sample agreed to within 0.1 with the value quoted in the literature [6] $[\alpha]_D^{20}$ +47.4 (c = 1.95%, ethanol), and was taken as reference.

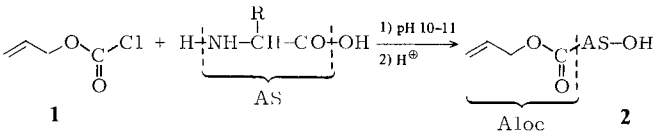
The Allyloxycarbonyl (Aloc) Moiety—Conversion of an Unsuitable into a Valuable Amino Protecting Group for Peptide Synthesis**

By *Horst Kunz** and *Carlo Unverzagt*

For the synthesis of sensitive peptides and glycopeptides, we have used the allyl moiety to block carboxy groups reversibly[1,2]. This protecting group can be rapidly removed under mild, practically neutral conditions either via rhodium(I)-catalyzed isomerization[3] or by palladium(0)-catalyzed allyl transfer[4]. In attempting to use these advantageous properties also for the protection of the *N*-terminal group, we became aware of the allyloxycarbonyl (Aloc) protecting group, which *Stevens* and *Watanabe*[5] investigated with D,L-amino acids. These authors established that hydrogenolytic cleavage of the Aloc moiety leads to marked hydrogenation, forming noncleavable propoxycarbonyl groups. Also, reduction with sodium in liquid ammonia (yield 65—85%) and cleavage with phosphonium iodide in glacial acetic acid (yield 70—75%) affords only incomplete deblocking. The Aloc moiety therefore appeared to be less than suitable for peptide synthesis[6].

We have now found, however, that the combination of the Aloc amino-protecting group with a novel cleavage method is highly propitious.

Although the Aloc moiety can be introduced using the allyl chloroformate **1** under Schotten-Baumann conditions[5], it is more advantageous to use the pH-stat method at pH 10—11. The Aloc-amino acids **2** (**2c** forms a crystalline hydrate, m.p. = 52 °C), which are generally oily, were identified by elemental analysis and by ^{1}H-NMR spectroscopy[7]. The advantage of the small Aloc protecting group is demonstrated by the condensation reactions. In the presence of ethyl-2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ)[8], Aloc-amino acids **2** react with *tert*-butyl amino acid esters to afford the Aloc-dipeptide *tert*-butyl esters **3** in high yield.



1 **2**

2a, AS = Phe, 84%; **2b**, AS = Met, 80%;
2c, AS = Ser, 79%; **2d**, AS = Ala, 77%

2 **3**

3a, AS–AS′ = Met–Phe, 92%
3b, AS–AS′ = Phe–Ser(*t*Bu), 95%
3c, AS–AS′ = Ala–Ser(*t*Bu), 94%

The *tert*-butyl esters **3** can be smoothly and selectively decomposed with trifluoroacetic acid, without the Aloc group being attacked. The latter group survives even the considerably lengthened reaction times required for the complete cleavage of the *tert*-butyl ether of serine.

3a **4a**, 84%

3b **4b**, 83%

For the cleavage of the Aloc moiety from the esters **3**, we chose catalytic allyl transfer with tetrakis(triphenylphosphane)palladium(0)[2]. However, as allyl acceptor, we used 5,5-dimethyl-1,3-cyclohexanedione (dimedone) instead of morpholine.

The CH-acid dimedone (pK_a = 5.2) can readily be separated from liberated amine. *C*-allyl substituted dimedone is an acid which can also be readily separated. Dimedone, especially if it is used in a 7- to 8-fold excess, protonates the free amino function ($pK_a \approx 8$) to such an extent that the latter can neither function as an allyl acceptor nor is able to form an enamine with dimedone within the reaction time[9].

By means of this method[10], the Aloc protecting group can be completely removed from the dipeptide esters **3** in 30 min in tetrahydrofuran (THF) at room temperature using 5–10 mol-% of catalyst.

The thioether function of methionine influences neither the activity of the palladium catalyst nor is itself alkylated. The very mild and highly selective deblocking method is therefore widely applicable.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

The advantages of the small allyloxycarbonyl (Aloc) protecting group are demonstrated by the high yield (95%) in which the protected tetrapeptide *tert*-butyl ester Aloc–Met–Phe–Ala–Ser(*t*Bu)–O*t*Bu, is obtained from **4a** and **5b** in THF with EEDQ. By virtue of the cleavage method described here, the long-known allyloxycarbonyl (Aloc) moiety has become transformed into an effective and highly selective tool for the synthesis of sensitive peptide derivatives.

Transfer of Chirality in the Addition of Chiral α-Chloroallylboronate Esters to Aldehydes**

By *Reinhard W. Hoffmann** and *Bernd Landmann*

Optically active homoallyl alcohols have previously been prepared in moderate to excellent enantiomeric purity by addition of chirally modified allylmetal compounds to aldehydes[1]. An attractive route to these compounds is presented by the use of chiral α-substituted allylmetal compounds, which upon addition to aldehydes transfer the chirality to the newly formed stereocenter[2]. The sign and extent of the transfer of chirality depend to what extent the reaction proceeds uniformly via one of several stereoisomeric transition states (e.g. **5** or **6**)[3]. We report here on the addition of chiral α-chloroallylboronates **4** to aldehydes, which leads to homoallyl alcohols **8** with ≥90% transfer of chirality.

Chiral α-substituted boronic esters are accessible using the method described by *Matteson* et al.[4]. Thus, the cyclic dichloromethaneboronate **1** derived from (*R,R*)-2,3-butanediol was allowed to react with vinylmagnesium chloride and $ZnCl_2$ to give the α-chloroallylboronate **2**. Its diastereomeric purity could not be ascertained from the ^{13}C-NMR spectrum, but should be ≥90% (vide infra). The absolute configuration of **2** was determined as (*S*) by converting it into the 2,3-pinanediyl ester **3**, whose ^{1}H-NMR spectrum differs in a known and characteristic way from that of the diastereomer[5].

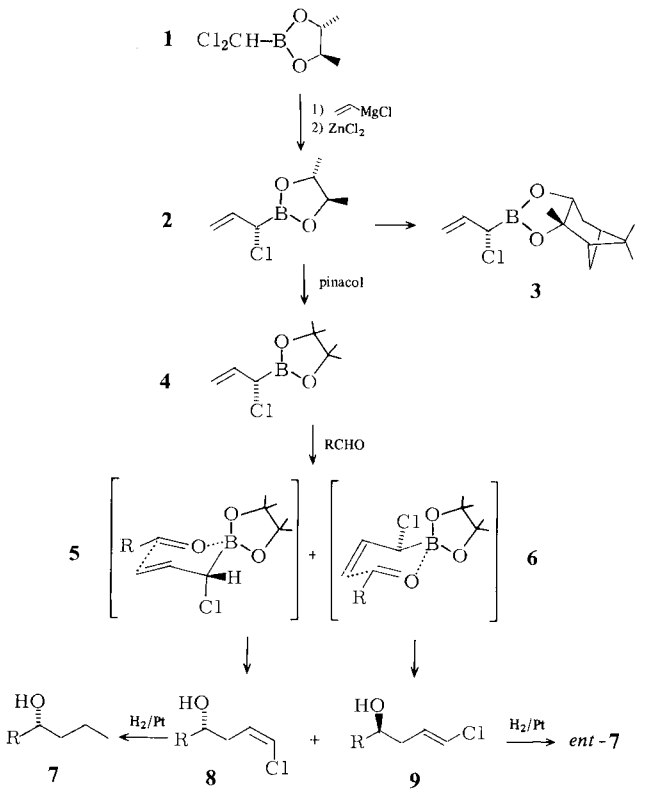

Table 1. Formation of **8** and **9** from **4** and aldehydes: conversion of **8** into **7**. *o.p.* = optical purity

	R	**8** : **9**	**8**: *ee* [%]	**7**: Conf. [a]	*o.p.* [%]
a	CH_3	93:7	90–93	*S*	—
b	C_2H_5	94:6	90–93	*S*	76
c	$(CH_3)_2CH$	96:4	90–93	*R*	—
d	C_6H_5	95:5	90–93	*R*	76

[a] Determined from the rotation value of **7**.

In order to achieve a high *Z/E*-ratio of the products **8/9** in the addition of **2** to aldehydes[6], **2** was first converted into the pinacol ester **4**. The latter, as previously described for the racemic series[6], adds to aldehydes (cf. Table 1) to give homoallyl alcohols (**1** → **8**, **9**) in an overall yield of ca. 50%. The enantiomeric purity of the major component **8** was determined from the ^{19}F-NMR spectra after esterification with Mosher's reagent. The absolute configuration of **8** was obtained by converting it into the known alcohols **7** via hydrogenolysis of the C–Cl bond and hydrogenation of the double bond on Pt/C in methanolic KOH[7].

The relative configuration of the educt **4** and product **8** are once again[3] in accord with the reaction proceeding via a cyclic six-membered transition state **5** in the chair conformation. Inasmuch as the by-product **9**, with *E*-configurated double bond, is formed via the same type of transition state, i.e. **6**, the new center of chirality in **9** must exhibit the opposite configuration to that of **8**. This becomes notable, e.g., if the double bond is removed or cleaved[8]. In this way, hydrogenation of the diastereomeric pair **8/9** leads to an enantiomeric pair **7**/*ent*-**7**. For example, the phenyl derivative **7d**, obtained from **8d/9d**, had a lower enantiomeric purity (76%) than that of the starting material **8d**. The *Z/E*-ratio of the homoallyl alcohols **8/9** is there-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

fore decisive for the enantiomeric purity of the products derived therefrom, and hence in this respect efforts at improvement must be made. In contrast, the problem of obtaining educts **4** in high enantiomeric purity can be regarded as being solved: The constant *ee* values of 90—93% for **8a—d** prove that **4** exhibits at least this *ee*-value. Furthermore, the constancy of the *ee*-value for the compounds **8** examined indicates that the transfer of chirality from **4** to **8** is cogent.

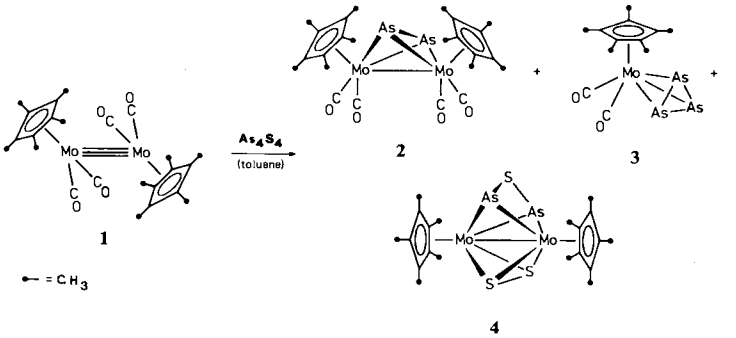
Ligand Extrusion from the As_4S_4-Cage by $[C_5Me_5(CO)_2Mo]_2$: Formation of $(C_5Me_5)_2Mo_2(CO)_4(\mu,\eta^2\text{-}As_2)$, $C_5Me_5(CO)_2Mo(\eta^3\text{-}As_3)$, and $(C_5Me_5)_2Mo_2As_2S_3$**

By *Ivan Bernal, Henri Brunner, Walter Meier, Heike Pfisterer, Joachim Wachter**, and *Manfred L. Ziegler*

The chalcogenide-rich binuclear complexes of the type $(C_5Me_5)_2Mo_2X_4$ (X = S, Se) can be prepared by complete exchange of the CO groups of $[C_5Me_5(CO)_2Mo]_2$ **1**, which contains one Mo≡Mo bond, by reaction with elemental sulfur or selenium[1]. Since a similar synthetic principle has also been found for $(C_5H_5)_2Mo_2As_5$, a combination of arsenic with sulfur or selenium should lead to previously unknown arsenide/chalcogenide ligands. In fact, realgar (As_4S_4), which is moderately soluble in organic solvents, proves to be a suitable synthetic reagent. Surprisingly, reaction of As_4S_4 with **1** also gives rise to a η^3-As_3 complex which belongs to the still less researched monosubstituted derivatives of yellow arsenic.

The two arsenic-containing complexes **2** and **3** as well as the arsenic- and sulfur-containing complex **4** are formed by heating an equimolar mixture of **1** and As_4S_4 in toluene[3]; no complex containing only sulfur could be detected. The compositions of all the products have been verified by elemental analysis (C, H, As, S) and mass spectroscopy. The spectroscopic data of **2** [IR: ν_{CO} = 1976, 1913, 1897, 1823 cm^{-1} (toluene solution); ^{1}H-NMR: δ_{CH_3} = 1.98 ($CDCl_3$)] indicate a tetrahedral Mo_2As_2 cluster, as previously established by X-ray crystallography for $(C_5H_5)_2Mo_2(CO)_4(\mu,\eta^2\text{-}As_2)$[4].



X-Ray structure analysis of **3**[5] indicates that the Mo atom forms the apex of a tetrahedron with a practically equilateral As_3 triangle as base (cf. Fig. 1). A crystallographically stipulated mirror plane through the atoms As1, Mo, C2, and C3 bisects the bonds As2—As2′ and C6—C6′ as well as the angle C1—Mo—C1′. Just as in $As_3Co(CO)_3$, the As—As distances (2.375 Å) are shorter than in the free As_4 molecule[6]. In order to account for this result, a reduction in the mutual repulsion of the lone pairs of electrons by transfer of electron density to the central metal atom and the other ligands[6] or an increase in bonding and a decrease in antibonding interactions within the As_3-ring by coordination to the metal[7] have been postulated.

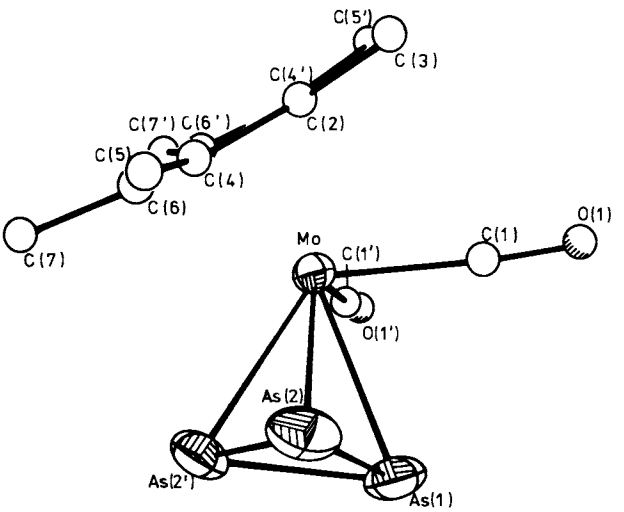


Fig. 1. Molecular structure of the complex **3** in the crystal (ORTEP representation). Selected bond lengths [pm] and angles [°]: Mo—As1 270.6(2), Mo—As2 263.9(1), Mo—C1 200.7(7), Mo—C2 227(1), Mo—C4 233(1), Mo—C6 239(1), As1—As2′ 237.2(1), As2—As2′ 237.7(2); As2—Mo—C1 87.4(2), C1—Mo—C1′ 90.5(4), C_5Me_5(cent)—Mo—As_3(cent) 136(2), C_5Me_5(cent)—Mo—C1 96.4(4), As_3(cent)—Mo—C1 113.5(2), As2—As1—As2′ 60.2(1), As1—As2—As2′ 59.9(0).

Experimental proof for an increased charge density at the central metal is provided, for the first time, for **3** by comparison with the isoelectronic complex $C_5Me_5Mo(CO)_2NO$[8]. Correspondingly, in **3** a more "obli-

[**] Reactivity of the M-M Multiple Bond in Metal Carbonyl Derivatives, Part 9. – Part 8: J. Wachter, J. G. Riess, A. Mitschler, *Organometallics*, in press.

quely" arranged C_5Me_5-ring is found in which the distances of the atoms C6 and C6′, which are *cis* to the As_3-ligand, to Mo are ca. 0.12 Å more than that of C2, and the Mo–C distances for the CO ligands are at least ca. 0.065 Å longer. The ν_{CO} frequencies in **3** [1964, 1904 cm^{-1} (KBr)], which are over 20 cm^{-1} lower, are consistent with this.

To date, single crystals of the air-sensitive, red-violet complex **4** have eluded isolation. In addition, the IR spectrum—weak absorptions at 422 and 388 cm^{-1} suggest Mo-ligand bridging functions—cannot be interpreted in more detail; nevertheless the ^{1}H-NMR spectrum [$\delta_{CH_3}=2.03$ in $CDCl_3$/[D_8]toluene (1:2) at −26 °C] indicates a symmetric structure. By analogy to the previously known structures of $(C_5Me_5)_2Mo_2(\mu,\eta^2\text{-}S_2)(\mu\text{-}S)_2$[1a] and $(C_5Me_5)_2Mo_2(\mu,\eta^2\text{-}As_3)(\mu,\eta^2\text{-}As_2)$[2], **4** probably contains a μ,η^2-AsSAs and a μ,η^2-S_2 ligand, which should both lie in a plane between the two Mo atoms. The sum of valence electrons from all the ligands therefore amounts to 10 per Mo atom, which enables the latter to attain the nobel gas configuration upon inclusion of the corresponding metal d-orbitals. This scheme is corroborated by studies on the reactivity. Thus, no weakly bonded sulfur is eliminated by PPh_3, for example, and, even under mild conditions, S_8 displaces the As_2S ligand to form the blue complex $(C_5Me_5)_2Mo_2(\mu,\eta^2\text{-}S_2)(\mu\text{-}S)_2$[1a].

No statements can be made at present about the mechanism of fragmentation of the As_4S_4-cage since the complexation of intact realgar has not yet proved possible. However, the novel compounds **2**–**4** appear to be relatively thermodynamically stable, as also indicated by the decomposition of the structurally totally different P_4S_3 into $C_5Me_5(CO)_2MoP_3$, $(C_5Me_5)_2Mo_2P_2S_3$, etc.[9].

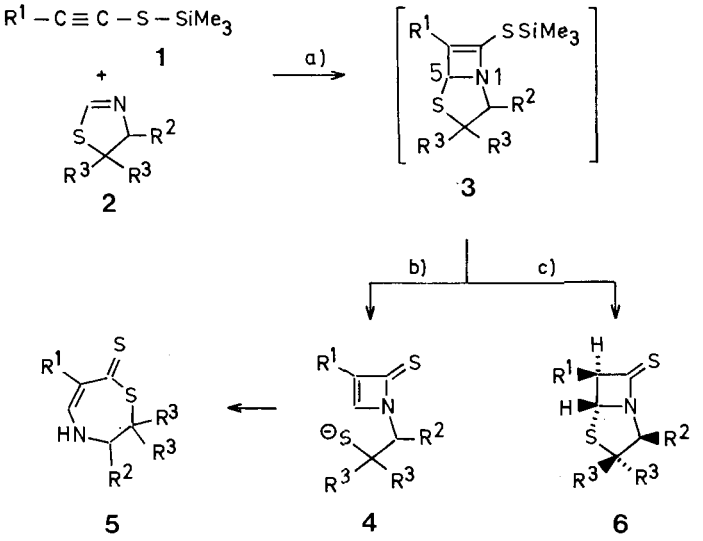
Thiopenam Derivatives from Alkynyl Silyl Sulfides and 4,5-Dihydrothiazoles**

By *Ernst Schaumann**, *Wolf-Rüdiger Förster*, and *Gunadi Adiwidjaja*

Although β-lactam antibiotics have been modified in a variety of ways[1], the replacement of the oxo group in the four-membered ring by hetero-substituents has so far not been studied in detail. As previously described in the literature, a tosylimino group can easily be introduced[2], whereas the sulfuration of biologically active β-lactams



Scheme 1. a) 20 °C, 7 d, without solvent; b) H_2O, CsF or SiO_2; c) Ultrasonication (20 min), then H_2O.

	R^1	R^2	R^3		R^1	R^2	R^3
1a	*t*Bu			**5a, 6a**	*t*Bu	H	H
1b	Ph			**5b**	Ph	H	H
2a		H	H	**5c**	*t*Bu	COOMe	H
2b		COOMe	H	**5d, 6b**	*t*Bu	COOMe	Me
2c		COOMe	Me	**5e**	Ph	COOMe	Me

gives only poor yields of the desired sulfurated products[3]. We have now investigated the possibility of obtaining β-thiolactams as part of a penicillin skeleton ("thiopenam derivatives") by reaction of the readily accessible alkynyl silyl sulfides **1a**, **b**[4], which are highly reactive toward nucleophiles, with the 4,5-dihydrothiazoles **2a**, **b** and (*S*)-**2c**[5].

The alkynes **1** react with the heterocycles **2** at room temperature to give adducts which may be formulated as silylthio derivatives **3**. Desilylation by hydrolysis, cesium fluoride or silica gel does not furnish the thiopenam system **6**, but leads, with cleavage of the S4–C5 bond, via **4** to dihydro-1,4-thiazepinethiones **5**.

[3] An equimolar mixture (1.60 mmol) of $[C_5Me_5(CO)_2Mo]_2$ **1** and As_4S_4 in 100 mL of toluene is stirred for 17 h at 100 °C. After being concentrated to 10 mL, the mixture is filtered and chromatographed on SiO_2 (column 30 × 4 cm). An orange and a dark-red zone are eluted with toluene. Low pressure chromatography (Merck LiChroprep Si60) of the orange zone with toluene/pentane (1:2) as eluent afforded yellow **3** and orange **2** in 12 and 4% yield, respectively. Analytically pure **4** is obtained in 26% yield from the dark-red zone by washing the red-violet crude product with pentane (2 × 10 mL) and chromatography on SiO_2 using toluene/pentane (2:1) as eluent. The complexes **2**, **3**, and **4** can be recrystallized from Et_2O/pentane (3:1) and toluene/pentane (3:1), respectively.

[9] The reaction of P_4S_3 with **1** proceeds under the same conditions as that of As_4S_4; we were able to isolate $(C_5Me_5)_2Mo_2P_4S$ as additional product (unpublished results).

Table 1. Yields, melting points and some NMR data of the compounds **5** and **6**.

Product	Yield [%]	M.p. [°C]	NMR [a] δ(=CH)	δ(H-5)	δ(H-6)	δ(^{13}C=S)
5a	60	123	6.89 (d, 8.4)	—	—	217.5 [b]
5b	77	150	6.89 (d, 9)	—	—	212.7 [b]
5c	74	oil	6.97 (d, 9) [b]	—	—	[c]
5d	50	135	7.05 (br. s)	—	—	[c]
5e	79	129 (dec.)	7.03 (d, 9)	—	—	[c]
6a	80	oil	—	2.82 (d, 1.5)	5.13 (d, 1.5)	215.0
6b	55	64	—	2.93 (d, 1.2)	5.53 (d, 1.2)	212.2

[a] Including the multiplicity, $^3J_{HH}$ [Hz]; in $CDCl_3$, if not otherwise stated. [b] In $(CD_3)_2SO$. [c] Not measured.

For penicillins, this rearrangement is already well-known[6]. However, the ring-opening can be suppressed if the *tert*-butylsubstituted sulfide **1a** is used as starting material and the reaction mixture is concomitantly treated with cesium fluoride and subjected to ultrasonication. The constitution of the stereochemically uniform thiopenam compounds **6a** and **6b** obtained with **2a** and (*S*)-**2c**, respectively, is confirmed by the spectroscopic data (Table 1) and by an X-ray structure analysis of **6b** (Fig. 1)[7].

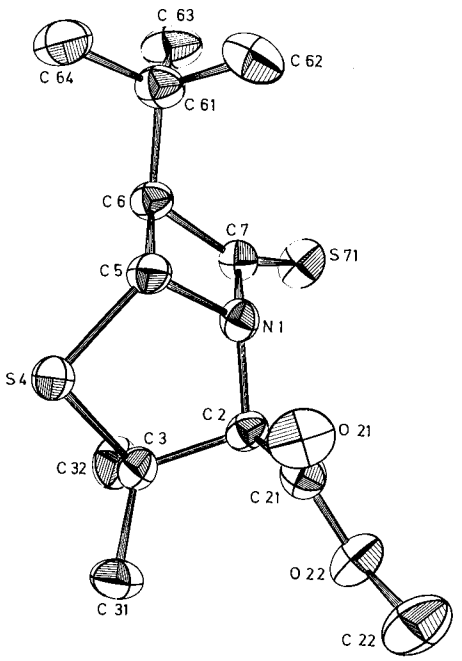

Fig. 1. ORTEP plot of the structure of **6b** in the crystal. Selected bond lengths [pm] and angles [°] (average values of two independent molecules): N1–C5 146.8(4), N1–C7 136.3(4), C6–C7 152.7(5), C7–S71 162.6(3); C5–N1–C7 95.6(3), N1–C7–C6 92.0(2).

The X-ray structure analysis shows that the carboxylic function and H-5 are *cis*-oriented, as in natural penicillins, whereas H-5 and H-6 are arranged *trans* to each other, as also indicated by the relatively small $^3J_{HH}$ coupling (Table 1); thus, the whole molecule has a (2*S*,5*R*,6*R*)-configuration. The N1–C7 distance (136.3(4) pm) is shorter than the average value (139.5 ± 2.6 pm[8]) found on X-ray spectroscopic analysis of 33 penam derivatives. The higher ring strain implied by this finding is further supported by a flatter nitrogen pyramid: the distance from N1 to the C2–C5–C7 plane (3.61 pm) is smaller than in the corresponding β-lactam derivatives (average distance 3.94 pm[8]).

A Photochemical Entry to Macrocyclic Mono- and Dilactones**

By *Gerhard Quinkert**, *Gerd Fischer, Uta-Maria Billhardt, Jürgen Glenneberg, Ulrich Hertz, Gerd Dürner, Erich F. Paulus,* and *Jan W. Bats*

Dedicated to Professor Jan Thesing on the occasion of his 60th birthday

On irradiation of 2,4-cyclohexadien-1-ones at low temperature the resulting dienylketenes can be trapped and identified spectroscopically[1], provided any strong nucleophile is absent. If not, the characteristic UV/VIS spectrum of the dienylketene in question is superseded by a new absorption (see Fig. 1).

If the strong nucleophile is protic, the respective carboxylic acid derivative is formed. If, however, the strong nucleophile is aprotic, it may promote the reaction of an additionally present weak protic nucleophile which alone would not form the corresponding carboxylic acid derivative (see Figs. 2 and 3).

[**] This work was supported by the Deutsche Forschungsgemeinschaft, by the Fonds der Chemischen Industrie, and by Hoechst AG.—Abbreviations: DABCO = 1,4-diazabicyclo[2.2.2]octane; MOM = methoxymethyl; THP = tetrahydropyranyl; TFE = 2,2,2-trifluoroethanol.

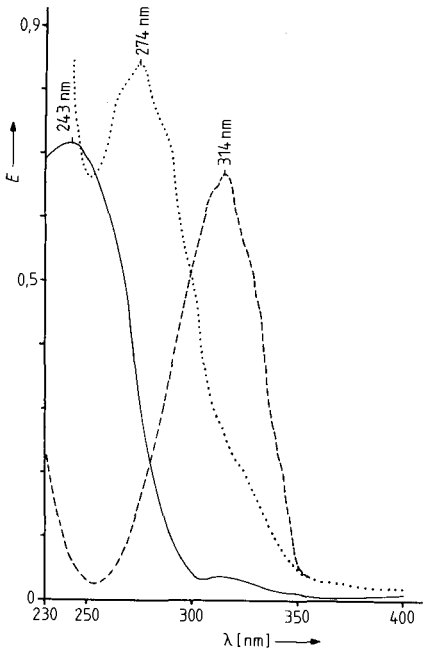

Fig. 1. UV/VIS spectra (at −90 °C in methylcyclohexane/isopentane (1 : 4)). Before irradiation of **1** (8.56×10^{-5} M) with 313 nm light (---); after irradiation of **1** with 313 nm light in the absence of DABCO (—); after irradiation of **1** (8.36×10^{-5} M) with 313 nm light in the presence of DABCO (· · ·).

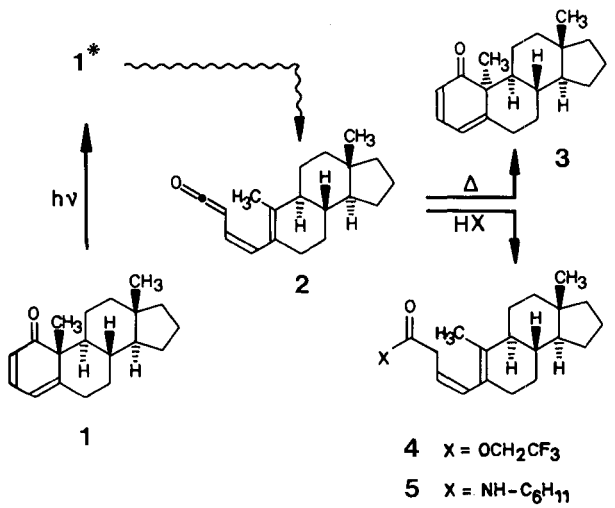

Fig. 2. Photoepimerization (to give **3** in TFE) or adduct formation (to give **4** in TFE after addition of DABCO in the molar ratio 1 : 12 or to give **5** in ether after addition of cyclohexylamine in the molar ratio 1 : 110 instead of DABCO) on exposure of **1** to light of wavelengths > 340 nm.

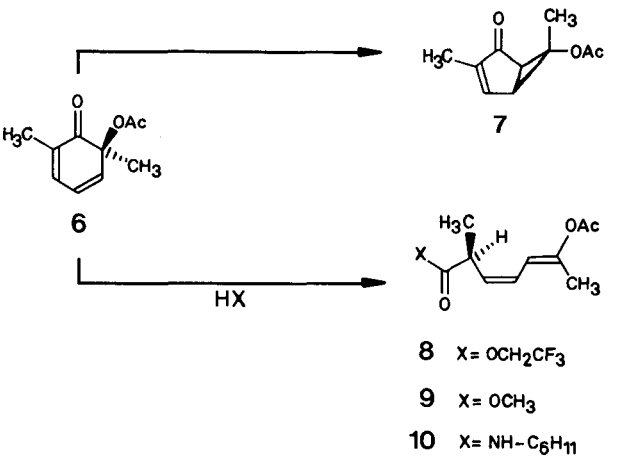

Fig. 3. Photocyclization (to give *rac*-**7** in TFE) or photochemical adduct formation (to give *rac*-**8** in TFE after addition of DABCO in the molar ratio 1 : 1.2 or to give *rac*-**9** in methanol or *rac*-**10** in ether in the presence of cyclohexylamine in the molar ratio 1 : 21) on exposure of *rac*-**6** to light of wavelengths > 340 nm.

When an ethereal solution of *rac*-**11a**[3] is irradiated with light of wavelength > 340 nm in the presence of DABCO (molar ratio 1 : 1.3-5), the 22-membered dilactone **14**[14] is formed in almost 30% yield, and the 33-membered trilactone **15**[3] in a good 6% yield. Under the same reaction conditions, *rac*-**11c**[5] furnishes the 16-membered monolactone *rac*-**13a** in almost 30% yield[6]. That the new method of cyclization can lead to the formation of macrolides in remarkably high yield (73%) is indicated by the conversion of *rac*-**11e** into *rac*-**13b**[7]. Constitution, ligand-orientation at the CC double bonds, and conformation of *rac*-**13a** and **14** have each been determined by single-crystal structure analysis[8-10]. The UV, IR, and NMR data of *rac*-**13a**, *rac*-**13b**, and **14** support the constitution and relative configuration formulated in Scheme 1.

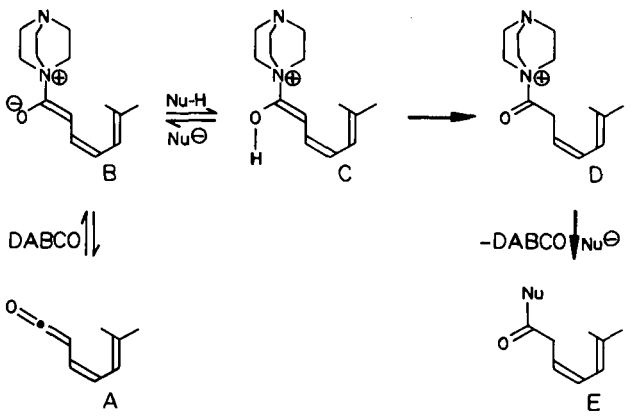

Fig. 4. DABCO-activated addition of a weak protic nucleophile (Nu–H) to a dienylketene. A: dienylketene; B: zwitterionic adduct of DABCO and A, which causes the new absorption (see Fig. 1); C: enol of D formed on uptake of a proton (from Nu–H); D: extremely reactive acylammonium compound; E: carboxylic acid derivative formed on replacement of DABCO by $Nu^{\ominus}$ (possibly also after deprotonation of Nu–H by DABCO).

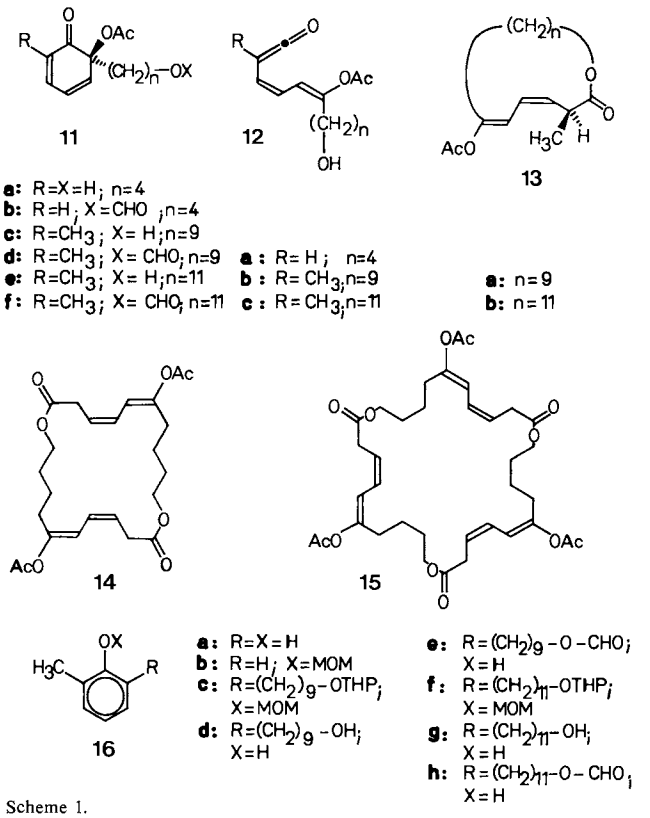
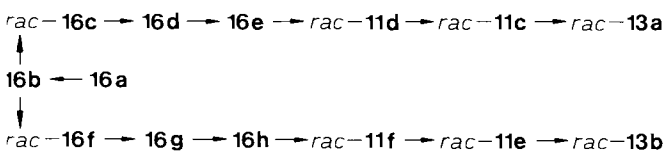
DABCO is an efficient reagent for this purpose[2]. It activates the appropriate ketene (and perhaps also the protic addendum). The acylammonium compound expected to be formed finally, reacts smoothly with the (deprotonated) nucleophile (see Fig. 4).

When activation by DABCO is used in the case of compounds of type **12**, which contain both a ketene and a hydroxy group at a suitable distance from each other, macrocyclic mono- or di-(and tri-)lactones are formed (Scheme 1).



Scheme 1.



Scheme 2.

Scheme 2 outlines how *rac*-**13a** or *rac*-**13b** is accessible lastly from **16a** and the corresponding ω-bromoalkanols.

Adducts of the Ketene (1*E*,3*Z*)-1,2,3,4,5-Pentamethyl-6-oxo-1,3,5-hexatrienyl Acetate

By *Gerhard Quinkert*, Uta-Maria Billhardt, Erich F. Paulus, Jan W. Bats,* and *Hartmut Fuess*

The structures of some adducts of dienyl ketenes and protic nucleophiles have been determined unambiguously: by chemical conversion into known compounds[1], by directed synthesis[2], or by X-ray structure analysis[3]. In most cases, however, the structures have been deduced from the various spectroscopic data characteristic for certain partial structures. Such spectroscopic assignments are to be used with care if the linear adduct is highly branched: for instance, in the case of adducts of the title compound,

$$O{=}C{=}CMe{-}CMe\overset{Z}{=}CMe{-}CMe\overset{E}{=}CMe{-}O{-}COCH_3$$

which is kinetically unstable under normal conditions.

After irradiation of cyclohexylamine-containing ether solutions of *rac*-**1**[4] with UV light (> 340 nm) the two crystalline adducts *rac*-**2b**[5] and *rac*-**3**[6,7] can be isolated. In neither case can it even be established from the data obtained by conventional spectroscopic methods whether the isomer is a 1,2-, 1,4-, or 1,6-adduct. According to the NMR spectra, *rac*-**2b** consists of two rotamers in solution[8]. From the products of ozonolysis[9] it must have been formed by 1,2-addition to the title compound. The single-crystal structure analysis[10,11] confirms this and, moreover, establishes the orientation of the ligands at the CC double bonds (see Fig. 1).

A comparison of the crystal structures of *rac*-**4**[11,12] (see Fig. 2) and *rac*-**2b** reveals the influence of the methyl

groups on the conformations: An intramolecular H-bridge between the amide nitrogen and the ester carbonyl oxygen explains the anomalous properties[13] of *rac*-**2b** compared to *rac*-**4**[1a].

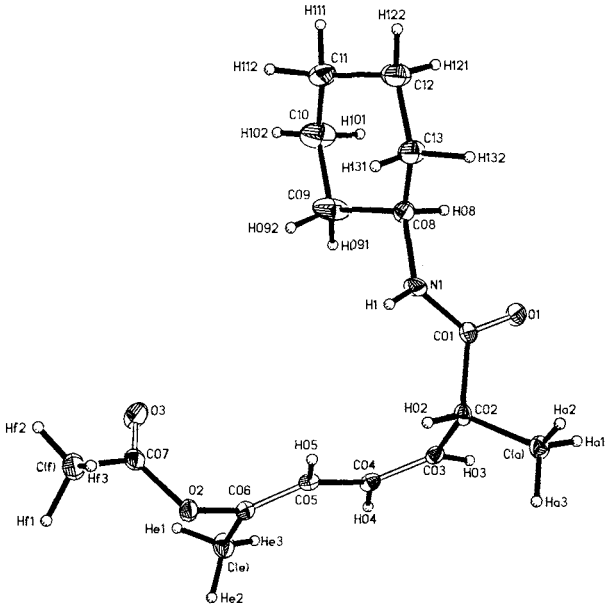

Fig. 2. Structure of *rac*-4 in the crystal [11, 12].

Received: February 24, 1984 [Z 721 1E]
German version: *Angew. Chem. 96* (1984) 432

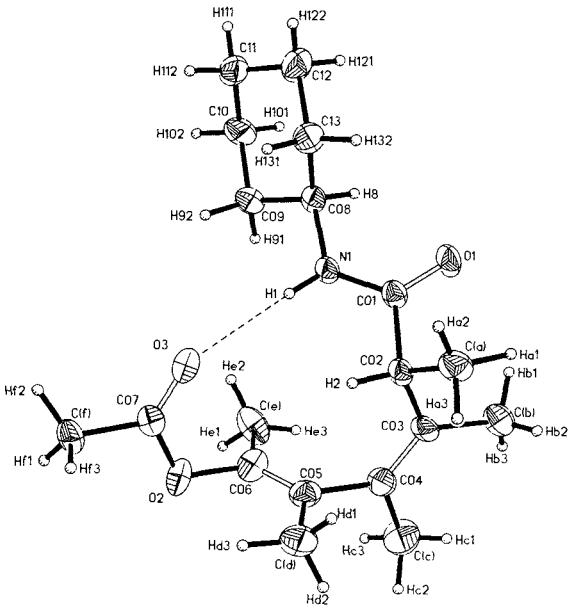

Fig. 1. Structure of *rac*-**2b** in the crystal [10, 11].

rac-**3** has been recognized[15] as a 1,4-adduct by a new two-dimensional NMR technique for the determination of connectivity[14]. All the signals of the C-atoms 1 to 7 and of the protons of the methyl groups a to f are assigned by this method. Measurements at 500 MHz have provided evidence of nuclear Overhauser effects (NOE) only between a and b (2.5% in both directions) or the methine proton on C-4 and e (from e: 4%): hence, it follows that *rac*-**3** has the 2*Z*,5*E* configuration. The 3*Z*,5*E*-configuration of *rac*-**2b** and the 2*Z*,5*E* configuration of *rac*-**3** are consistent with the view how these adducts are formed from the title compound[16].

[7] In an earlier work only one adduct was isolated, which, correctly, was regarded as a 1,2-adduct; see [4].
[8] Since this is also the case in *rac*-**2a**, the torsional isomerism established here is caused by an increased barrier to rotation about the C-4/C-5 bond and not about the C—N bond of the amide. The rotamer dominant under normal conditions corresponds, according to the low-temperature NMR spectrum (see [14]), to the conformation prevalent in the crystal.

Determination of Connectivities via Small Proton-Carbon Couplings with a New Two-Dimensional NMR Technique**

By *Horst Kessler**, *Christian Griesinger*, and *Jörg Lautz*

The scalar spin-spin couplings observable in NMR spectra are brought about by bonding and thus provide information about atomic linkages. Hitherto, only carbon-carbon (INADEQUATE)[1] or proton-proton couplings (H,H-COSY)[2] have been used for establishing the connectivity of carbon atoms in organic compounds (Fig. 1). If

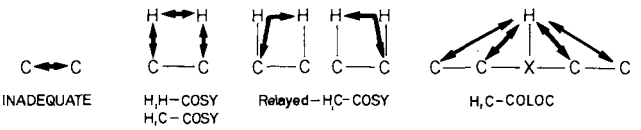

Fig. 1. NMR spectroscopic methods for locating carbon linkages.

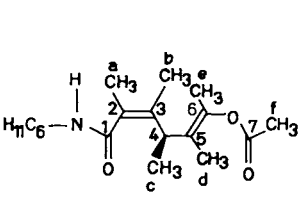
proton couplings are used, this information is obtained in an indirect way via an additional H,C-COSY spectrum[3]. If relevant signals overlap, the relayed H,C-COSY technique[4] often enables an unequivocal assignment. Herein we describe the use of two-dimensional heteronuclear shift correlation via small couplings (H,C-COLOC = *CO*rrelation spectroscopy via *LO*ng range *C*ouplings). The conventional H,C-COSY pulse sequence[3] has the disadvantage that the intensity of the cross peaks not only depends on $^2J_{CH}$ and $^3J_{CH}$ couplings of differing sizes but also on couplings between the protons themselves and the direct CH coupling ($^1J_{CH}$). An optimization of the parameters prior to carrying out the two-dimensional experiment is not possible in the conventional sequence. We therefore propose the following pulse sequence H,C-COLOC[5], in which the evolution time (t_1) is incorporated in the time in which H,C-couplings develop (Δ_1):

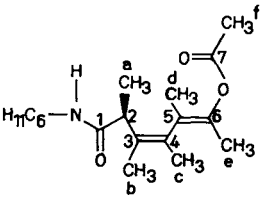
$$\begin{array}{lllll} ^1H & (\pi/2)_{\phi_1}, t_1/2, & (\pi)_{\phi_2}, & (\Delta_1 - t_1/2), & (\pi/2)_{\phi_3}, \Delta_2, BB \\ ^{13}C & & (\pi)_{\phi_4}, & & (\pi/2)_{\phi_5}, \quad AQ_{\phi_{det}} \end{array}$$

Compared to conventional H,C-COSY, the H,C-COLOC sequence has the advantage of an easy optimization of the Δ_1 and Δ_2 delays for development of small couplings by INEPT measurements[6]. Because of the constant length of the pulse sequence, the parameters so determined are also valid for the whole 2D experiment. In addition, an improved signal-to-noise ratio results from the pulse sequence shortened by t_1 and the homonuclear broad-band decoupling in t_1[5].

The following two examples demonstrate the application of the new technique. On irradiation of *rac*-(1,2,3,4,5-pentamethyl-6-oxo-2,4-cyclohexadienyl) acetate (*rac*-6-acetoxy-2,3,4,5,6-pentamethyl-2,4-cyclohexadien-1-one) in the presence of cyclohexylamine as protic nucleophile, the two adducts *rac*-**1**[7] and *rac*-**2**[7,8] are formed. An NMR-spectroscopic characterization of the two isomers by 2D-INADEQUATE is not very attractive because of the large



1



2

amounts of substance necessary for the measurement and the large spectral range of the ^{13}C-NMR signals (ca. 150 ppm) with various $^1J_{CC}$ coupling constants. Techniques which are designed for the measurement of carbons directly bonded to protons cannot be used because of the missing protons at the olefinic carbons. In the COLOC spectrum of *rac*-**1**, elucidation of the constitution via determination of the connectivities is possible (Fig. 2): Cross peaks are visible for all cases where the carbon atoms couple with protons via several bonds.

It is convenient to start the interpretation of the spectrum with the downfield carbonyl signals. Signal 7 shows only one cross peak with the signal of the protons of the methyl group f. The latter do not couple with any other olefinic C-atom; f can thus be assigned to the acetyl moiety. The carbonyl carbon 1 couples with the protons of the methyl group a, which, in turn, exhibit couplings with the olefinic C-atoms 3 and 2. Of these, only C3 couples with the protons of the methyl group c, which are easily identified as a doublet in the ^{1}H-NMR spectrum. C5 also couples with c. The signals 5 and 6 form cross peaks with d and e. It follows from the cross-sections through C5 and C6 (not shown here) that the cross peaks of C5 with d and of C6 with e are the most intense. C,H couplings via two and three bonds are, of course, of the same order of magnitude; however, it is seen from the higher intensity of 2-a and 3-b compared to 2-b and 3-a that in the case of the parameters chosen here, the geminal coupling is more developed than the vicinal coupling. The protons of the methyl groups d and e can also be assigned under these assumptions. The experiment thus enables the sequencing and assignment of the signals of all the olefinic carbon atoms and methyl protons. Hence, all the requirements for determining the configuration at the two double bonds by NOE difference spectroscopy are fulfilled[7]. Noteworthy is the sharpness of the cross peaks 3-c and 5-c, which results from homonuclear proton decoupling.

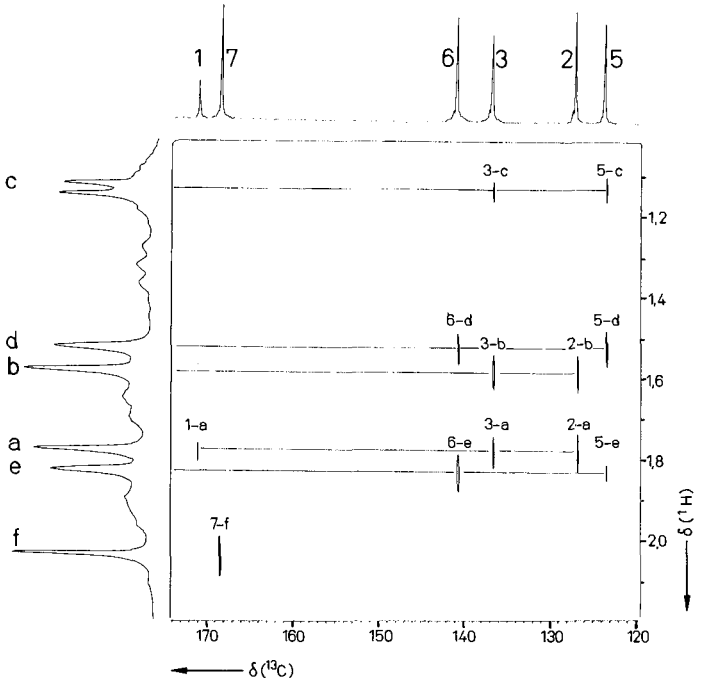

Fig. 2. Section of the H,C-COLOC spectrum of *rac*-**1** for the olefinic carbon atoms and the carbonyl groups, in the proton region of the methyl groups. Spectrometer: Bruker WH 270. Measuring conditions: 150 mg in 2 mL $CDCl_3/C_6D_6$ (5:1); $\Delta_1=\Delta_2=40$ ms; spectral width in $\omega_1=1850$ Hz, in $\omega_2=3625$ Hz. Total duration of a scan 1.5 s. 140 increments of 1 K with 192 scans each. Total recording time: 12 h. The phases of the 90°-^{1}H-pulse were cycled independently of one another in 90° steps with respect to the receiver phase ($\phi_1=k\times90°$, $\phi_{det}=-k\times90°$, $k=0, 1, 2, \ldots$ and $\phi_3=m\times90°$, $\phi_{det}=-m\times90°$, $m=0, 1, 2, \ldots$; $\phi_2=\phi_4=\phi_5=0$).

The spectrum of *rac*-**2** (Fig. 3) reveals the presence of two conformers in solution, of which the dominating one has the conformation determined in the crystal. This was proven by dissolution at −80 °C in CD_2Cl_2 and immediate ^{1}H-NMR measurements[9]. The conformation occurring on warming the solution is formed through steric hindrance of rotation about the single bond between C4 and C5[7]. The H,C-COLOC spectrum of the dominating conformation can be interpreted completely analogously to that of the isomeric *rac*-**1**.

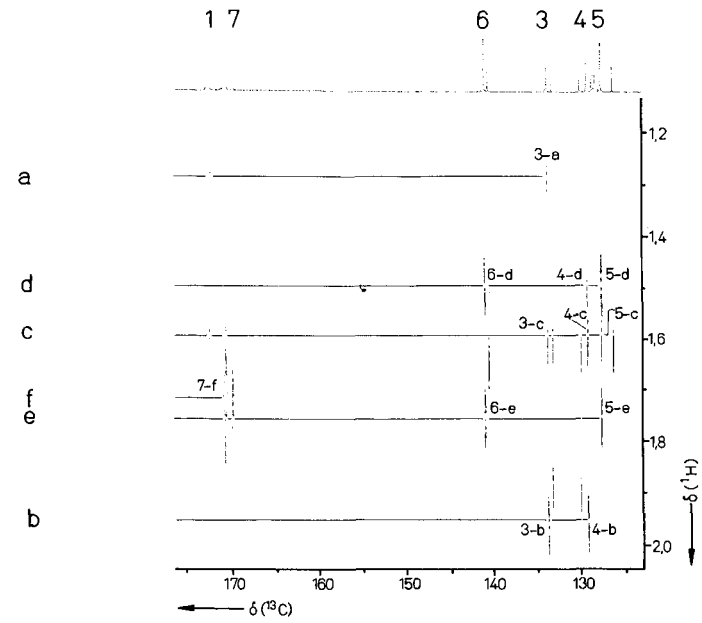

Fig. 3. Section of the H,C-COLOC spectrum of *rac*-**2**. Spectrometer: Bruker AM 500. Measuring conditions: 240 mg in 2 mL C_6D_6. $\Delta_1=60$ ms, $\Delta_2=40$ ms; spectral width in $\omega_1=3800$ Hz, in $\omega_2=6670$ Hz. Total duration per scan 1.5 s. 180 increments of 4 K with 128 scans each. Total recording time: 10 h. Other than for the spectrum in Figure 2, the phase of the 90°-^{13}C-pulse was also cycled with respect to the receiver phase ($\phi_5=n\times90°$, $\phi_{det}=n\times90°$, $n=0, 1, 2, \ldots$; $\phi_2=\phi_4=0$). This led to a better suppression of spectral artefacts.

The method presented here, which employs H,C-couplings via two and three bonds, can be used with advantage for the assignment of quaternary carbon atoms, whose environment is thus also determinable. For its application to aliphatic carbon atoms we recommend the use of a low-pass J filter[10] for suppressing the direct C–H cross signals[11]. The new pulse sequence enables a convenient and, other than the conventional H,C-COSY sequence, effective optimization of the delay for the whole experiment. It is especially suitable, therefore, for the investigation of complex molecules, where intensity maximization is of importance due to scarcity of substance or short relaxation times.

The sensitivity of the experiment described here, like that in the relayed H,C-COSY technique, can be rated between that of H,C-COSY and 2D-INADEQUATE.

[**] Fungal Pigments, Part 44. This work was supported by the Deutsche Forschungsgemeinschaft. We thank Dr. *M. Schmitz*, Bonn, for recording the X-ray emission spectra and Dr. *G. Wolf*, Bruker, Karlsruhe for high-field NMR measurements.—Part 43: W. Steglich, B. Oertel, *Sydowia Ann. Mycol.*, in press.

tion with methanol-acetone. The separation and purification of the pigments can be achieved by multiple chromatography on Sephadex LH20 with methanol as eluent; besides the main products badion A **2a** and norbadion A **4a**, bisnorbadioquinone A **5a** and *O*-methylpulviquinone A **6b** are also obtained. The pigments can be easily recognized on TLC plates by their color reaction with ammonia vapor (Table 1).

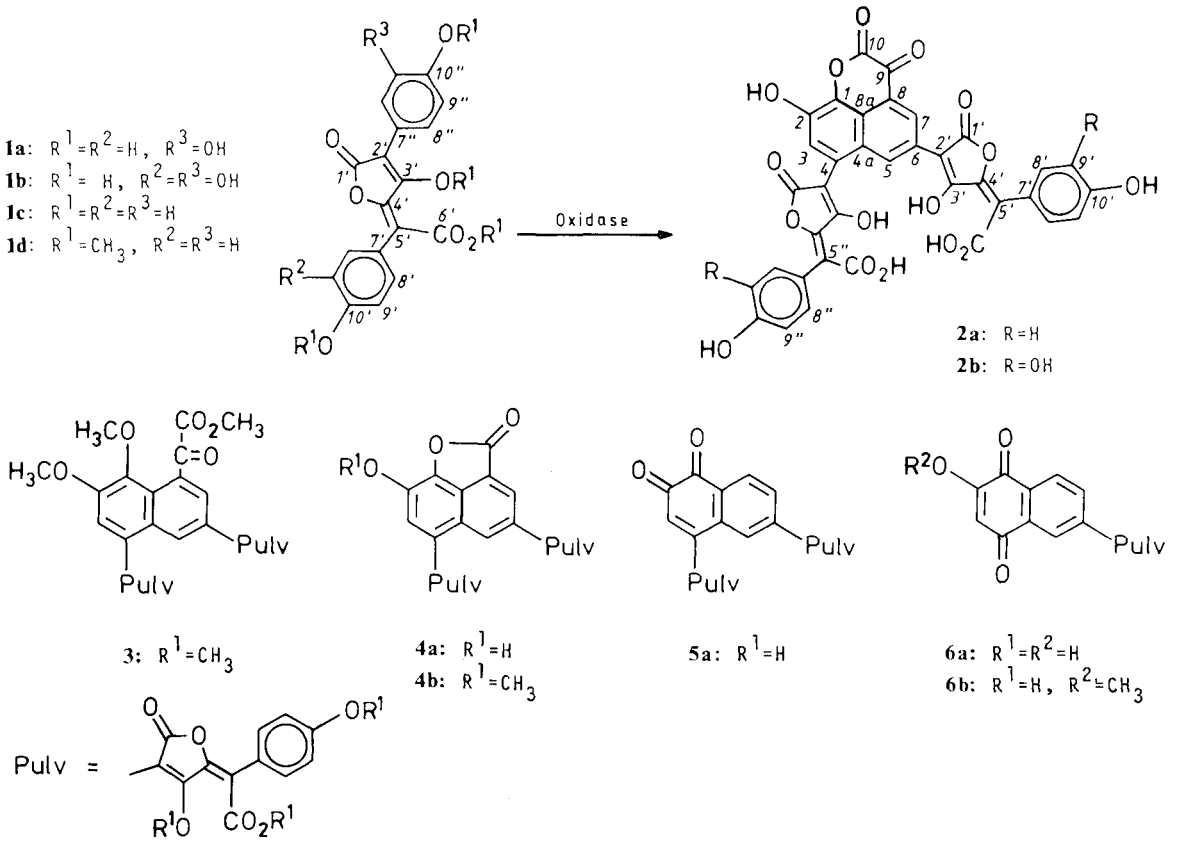

Table 1. Thin-layer chromatographic characterization of the cap cuticle pigments.

Pigment	R_F [a]	Color	Color over NH_3	Rel. amount [b]
2a	0.83 (I)	brown	green	100
4a	0.89 (I)	yellow-brown	salmon color	30
5a	0.83 (I)	brown	violet	10
6b	0.24 (II)	yellow-brown	red-violet	2

[a] I: TLC-Al foil aluminum oxide 150 F_{254} Merck, impregnated with saturated ethanolic ascorbic acid solution (eluent: 2-butanone/formic acid/water = 15 : 3 : 2); II: TLC-Al foil silica gel 60 F_{254} Merck (eluent: benzene/ethyl formate/formic acid = 10 : 5 : 3). [b] Referred to **2a** = 100.

Badion A **2a** forms blackish brown, shiny microcrystals, which decompose without defined melting point above 250°C and do not furnish any molecular ions with the usual MS techniques (EI, FD, FAB). According to elemental analyses and the X-ray emission spectra both **2a** as well as **4a** contain potassium, which can be removed only with difficulty, even by washing with dilute hydrochloric acid. The reddish brown solution of **2a** in methanol shows absorption maxima at $\lambda_{max} = 260$, 368, and 482 nm (sh). The ^{1}H-NMR spectrum ([D]$_6$DMSO) shows a singlet at $\delta = 7.31$ (1H) and two 1.5 Hz doublets at unusually low field ($\delta = 9.06$ and 9.26, 2H) besides the signals for two *p*-hydroxyphenyl moieties. Methylation with dimethyl sulfate/potassium carbonate in acetone affords a lemon-yellow nonamethyl derivative **3**, m.p. 255—257°C, which, according to high resolution MS, has the empirical formula $C_{45}H_{38}O_{17}$.

This indicates **2a** as having a C_{36} skeleton, and thus a biogenesis by oxidative dimerization of xerocomic acid **1a** ($C_{18}H_{12}O_7$). **1a** has already been isolated from the bay boletus[1] and recognized as a component responsible for the blue coloration of the flesh on being damaged[2]. Indeed, it is found on comparing the coupled ^{13}C-NMR spectra of **2a** and **3** with those of atromentic acid **1c** and its permethyl derivative **1d** that **2a** contains two pulvinic acid substructures (Table 2). Systematic selective decouplings, paying special attention to long-distance coupling, shows that the two pulvinic acid moieties in **3** are located at the 4,6-positions of a naphthalene nucleus bearing two methoxy groups in the 1,2-position and a CH_3O_2C—CO moiety at the 8-position.

Since the low-temperature ^{1}H-NMR spectrum ([D$_6$]acetone, 170 K) of **2a** shows only signals for three protons at $\delta = 9.51$, 9.63, and 10.70 in the region characteristic for phenolic OH groups, i.e. between $\delta = 9.5-11$, it must be present as naphtho[1,8-*bc*]pyrandione[4]. Hence, the methylation of **2a** to **3** proceeds via opening of the lactone ring. The structure **2a** fully explains the downfield position of the NMR signals of H-5 and H-7, since these protons are exposed to the deshielding effect of both the 9-carbonyl group as well as that of the pulvinic acid moiety on C-6[5].

Methylation of norbadion A **4a** furnishes a heptamethyl derivative $C_{42}H_{32}O_{15}$ **4b**, m.p. 247—249°C. The ^{1}H-NMR spectrum of **4a** is almost the same as that of **2a**[6], and, according to the ^{13}C-NMR data, it contains a dihydroxy-

3: 1-OCH_3 (60.5, Q, J=146.4 Hz), 2-OCH_3 (56.7, 145.0), 10-OCH_3 (52.9, 148.1), 3′/3″-OCH_3 (60.8/61.8, 148.4/148.4), 6′/6″-OCH_3 (52.7/52.8, 147.6/147.6), 10′/10″-OCH_3 (55.32/55.33, 144.2/144.2); **1d**: 3′-OCH_3 (60.9, Q, J=147.7 Hz), 6′-OCH_3 (52.7, 147.7), 10′/10″-OCH_3 (55.3, 144.6)

[*] Assignment may be reversed. [**] Signals for double the number of C atoms.

naphthalene moiety with two pulvinic acid side chains. The side chain at the 8-position, however, is one carbon atom shorter than the other, and forms a γ-lactone with the 1-OH group (^{13}C-NMR: δ(9-CO)=167.12, d, J=3.5 Hz, in [D$_6$]DMSO).

Apparently, the component **2a** of the fungus is capable of further degradation; in bisnorbadioquinone A **5a**[6] the side chain at the 8-position is missing, and the hydroxy groups are oxidized.

Formation of pulviquinone A **6a** from **5a** by oxidative elimination of the pulvinic acid chain at the 4-position is conceivable. The brownish red pigment is isolated as the methyl ether **6b**, which is most likely formed during the extraction with acidified methanol. In order to demonstrate the role of xerocomic acid **1a** as a biogenetic precursor of badion A **2a**, a portion of the cap cuticle was removed from a bay boletus and the underlying white flesh treated with aqueous xerocomic acid solution. The resulting yellow spot became bluish green within a few minutes and gradually turned brown in color. After extraction and chromatographic separation of the resulting pigment, **2a** could be detected ^{1}H-NMR spectroscopically. Thus, the enzymes necessary for the oxidative dimerization of **1a** appear to be fixed to the cap cuticle. Badion A **2a** is also the pigment of *Boletus pinicola* Vitt., a close relative of the cep. Interestingly, in *Boletus erythropus* (Fr. ex Fr.) Pers. it is replaced by badion B **2b**, which is biogenetically derived from variegatic acid **1b**[7].

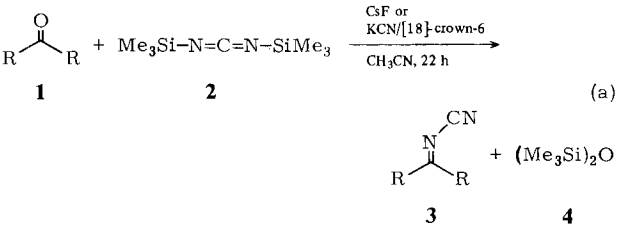
One-Step Entry to *N*-Cyanimines and to *N,N′*-Dicyanoquinonediimines, a Novel Class of Electron-Acceptors**

By *Alexander Aumüller* and *Siegfried Hünig**

N-Cyanimines **3** are accessible from alkenes and cyanazide[1], as well as from certain carbodiimides and isothiocyanates[2]. Hitherto all reactions in which ketones have been used as starting substances have involved several steps[3]. Herein we describe the one-step conversion $>C=O \rightarrow >C=N-CN$, which can be applied to (non-enolizing) ketones and to *p*-quinones. The crucial reagent is bis(trimethylsilyl)carbodiimide **2**[4], which converts, e.g., benzophenone (62—70%)[5] and fluorenone (75%)[5] into **3** in the presence of fluoride or cyanide catalysts according to equation (a).



1 **2** (a) **3** **4**

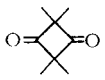
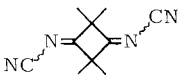
[**] This work was supported by the Stiftung Volkswagenwerk, by the Fonds der Chemischen Industrie, and by BASF AG.

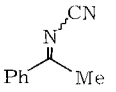
However, under these basic conditions the reaction fails in the case of, e.g., **5** (acid cleavage) and quinones **8**. These tend to undergo 1,4-addition and are more readily reduced than anthraquinone **8i**, which affords 62% **9i** with **2** and CsF.



5

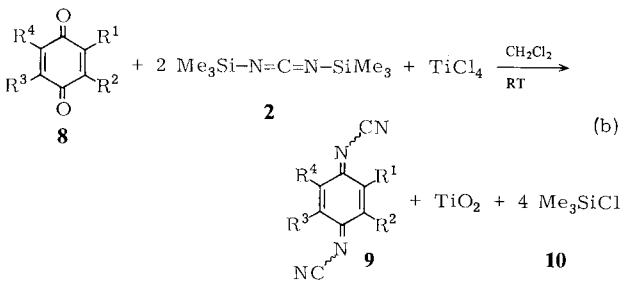


6 (47%)



7 (23%)

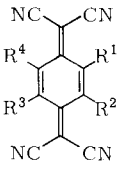
This problem can be overcome, however, by using titanium tetrachloride as auxiliary reagent. For example, **6** (47%, m.p. 143–144°C) can then be prepared quite smoothly, and even the enolizable acetophenone affords 23% **7**[3a], while *N*-cyanocyclohexanimine[1] is not detectable. Presumably the silyl groups are not eliminated as **4** in the presence of $TiCl_4$, but as **10** [cf. eq. (b)].



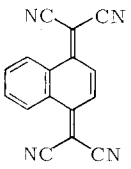
8 + 2 $Me_3Si-N=C=N-SiMe_3$ + $TiCl_4$ $\xrightarrow[RT]{CH_2Cl_2}$ **2** (b)

9 + TiO_2 + 4 Me_3SiCl **10**

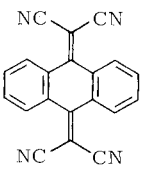
The first synthesis of the *N,N'*-dicyanoquinonediimines **9**[6] counts among the few reactions involving condensation at the carbonyl group of the quinones **8**. The selected examples **9a–i** demonstrate the broad spectrum of quinone substituents tolerated with regard to changes in potential and spatial requirements (Table 1).



11



11h



11i

sured in $\lg K_{SEM}$ values—frequently exceed even those of the quinone systems **8**. Because of the chemical analogy between the groups $=C(CN)_2$ and $=N-CN$[7], the systems **9** ("DCNQI") have acquired considerable importance as alternatives to derivatives of tetracyanoquinodimethane ("TCNQ") **11**, $R^1-R^4=H$, being acceptor components for electrically conducting CT complexes[8]. X-ray structure analyses of all the compounds reveal that the planarity required for this purpose is assured in the case of **9h**[8], and probably also in the case of **9a–g** and **9i**, but is not so in the analogues of **9h** and **9i**, the dicyanomethylene derivatives **11**[9] and **11i**[10].

Crystal Structure and Conductivity of a Novel Charge-Transfer Complex of *N,N'*-Dicyano-1,4-naphthoquinonediimine and Tetrathiafulvalene

By *Alexander Aumüller, Erich Hädicke, Siegfried Hünig*, Albin Schätzle,* and *Jost Ulrich von Schütz*

The discovery that the CT-complex **3** formed from tetracyanoquinodimethane (TCNQ) **1** and tetrathiafulvalene (TTF) **2**[1] exhibits high electrical conductivity has stimulated the synthesis and study of numerous variants[2]. Besides the introduction of substituents in **1** and **2**, the heteroatoms in the donor **2** have also been exchanged (S→Se), with the acceptors always containing $=C(CN)_2$ groups. The synthesis of a new class of quinonoid acceptors in which the $=C(CN)_2$ groups are replaced by $=N-CN$[3], allowed the construction of novel, potentially conductive CT-complexes (cf. Table 1).

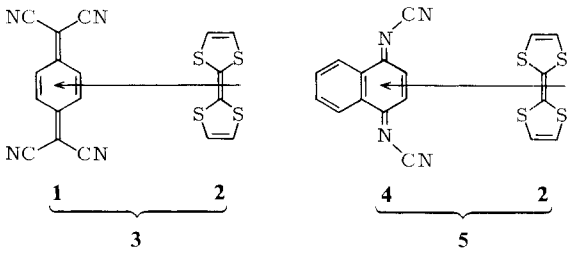

Table 1. Comparison of **3** with **5**.

	3	**5**
Conductivity [Ω^{-1} cm^{-1}]	192–652 [1a]	25
Distances in stack [pm]	317/347 [7]	329/353
Smallest distances between stacks [pm]	320 [7]	318, 324
Angle between acceptor- and donor-planes [°]	58.5 [7]	9

As first example, we describe here the CT-complex **5**[4], obtained from **2** and *N,N'*-Dicyano-1,4-naphthoquinonediimine **4**[3], which exhibits high conductivity and shows an ESR signal for ca. 10^{-2} mol/mol unpaired spins. Characteristically, the tetracyanonaphthoquinodimethane analogue of **4** does not form a CT complex with **2**, apparently due to the twisting of the molecule enforced on it by the Y-shaped $=C(CN)_2$ groups. This deformation does not take place in the *syn*-configurated **4**[4]. Thus, **5** obeys the rules outlined by *Cowan* et al.[5] for metallic conductivity of CT-complexes, both in the case of the reaction partners and, as shown by the crystal structure analysis, in the case of the crystal lattice (Fig. 1).

5 consists of separated, oblique stacks of almost planar donor and acceptor moieties, which are equidistant at room temperature. Since the distances in the stacks are only slightly greater than in **3**[7], there are also interactions here (distances between the moieties in solid **2**: 362 pm[7]). Contrary to **3**, the planes of the molecules in donor and acceptor stacks deviate very little from each other in **5**. An interaction between the negatively polarized N-atoms of the acceptor **4** and the positively polarized S-atoms of the donor **2** may be responsible for this, since the distance between these is the shortest in the stacks. The two terminal N-atoms of *one* acceptor molecule **4** are so coordinated with the S-atoms of *two* neighboring donor molecules **2** that the stacks form left- and right-handed helices in the crystal (Fig. 2).

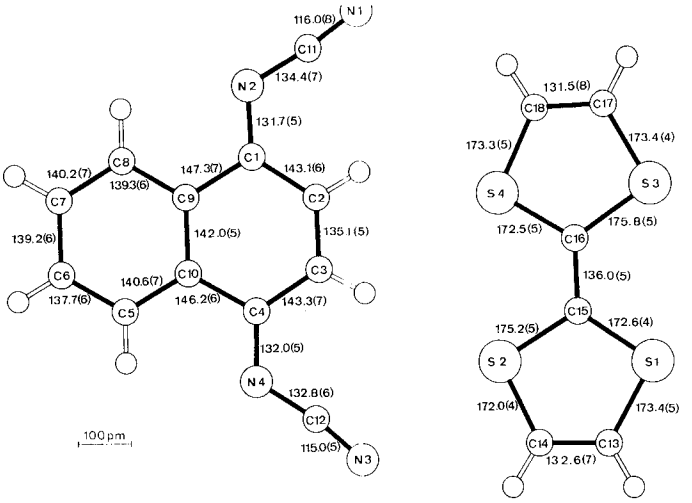

Fig. 1. Bond lengths [pm] of **4** and **2** in crystalline **5**.

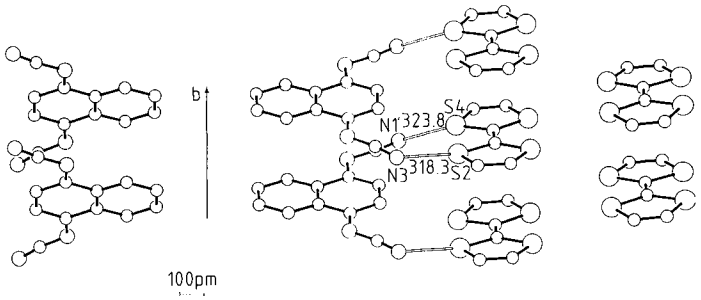

Fig. 2. Intermolecular contacts in crystalline **5** [pm].

The *syn*-configuration of **4** and the "inactivity" of the unsubstituted part of the naphthalene skeleton may be responsible for the special arrangement of the stacks: Two

parallel, "back-to-back" rows containing stacks of **4**; "on the front side" there are two parallel rows of stacks of **2** (Fig. 3).

Figure 4 shows the temperature-dependence of the conductivity of **5**. The conductivity steadily increases with decreasing temperature down to a phase-transition temperature $T_c = 140$ K, and then decreases by several orders of magnitude down to 50 K. The temperature range above T_c is ascribed to metallic behavior, and that below T_c to semiconducting behavior with an activation of 0.08 eV (band gap 0.16 eV).

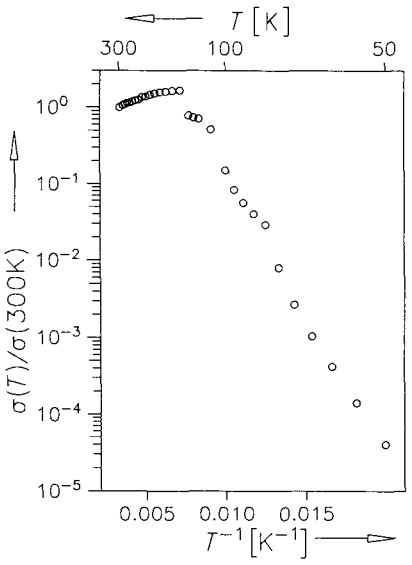

Fig. 4. DC conductivity of **5**. Four-point measurements on thin needles with single crystal domains.

The concentration of the mobile charge carriers, which could be deduced from the intensity of the ESR signal, was found to be ca. 10^{-2} spins/mol **5**, i.e. consistent with the values recorded for other similar salts.

Peptide Structures of the Alamethicin Sequence: The *C*-Terminal $\alpha/3_{10}$ Helical Nonapeptide and Two Pentapeptides with Opposite 3_{10} Helicity**

By *Roland Bosch, Günther Jung*, Heribert Schmitt, George M. Sheldrick,* and *Werner Winter**

Alamethicin and its analogues are model compounds for the exitability of nerve membranes[1]. Voltage-dependent, ionophoric membrane pore formers of the icosapeptide antibiotic alamethicin-type contain numerous α-aminoisobutyric acid residues (Aib) which reduce considerably the conformation space. In oligopeptides with Aib residues, predominantly a tendency to form β-turns and 3_{10}-helical conformations (several consecutive β-turns III) is observed[2]. However, the structures of alamethicin[3] and of an *N*-terminal model undecapeptide[4] are α-helical. According to the flip-flop gating model[1], a rigid, preferably α-helical dipole is the only prerequisite for pore formation. Thus lipophilic peptide segments such as the sequential polymers Boc-(L-Ala-Aib-L-Ala-Aib-L-Ala)$_n$-OMe (n = 1–4) and the pentapeptide Boc-Aib-L-Ala-Aib-L-Ala-Aib-OMe **7** induce also voltage-dependent membrane pores since they form conformationally stable helix-dipoles in the lipid bilayers[1b].

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 76) and by the Fonds der Chemischen Industrie.

In the crystal, the pentapeptides **1** and **7** (Fig. 1) form 3_{10}-helices, each with three intramolecular (4→1) hydrogen bonds. Whereas **7** exhibits a *right-handed* helix with torsion angle combinations in the region $\phi = -60°$, $\psi = -30°$[2a], the helix in **1** is *left-handed* with $\phi = +60°$, $\psi = +30°$ (Fig. 2), although the chiral amino acids in both peptides have L-configuration. The assumption that the L-proline residue could cause the unusual left-handed helicity in **1** is not in harmony with the 3^r_{10}-helix of tetrapeptide **10**[2b].

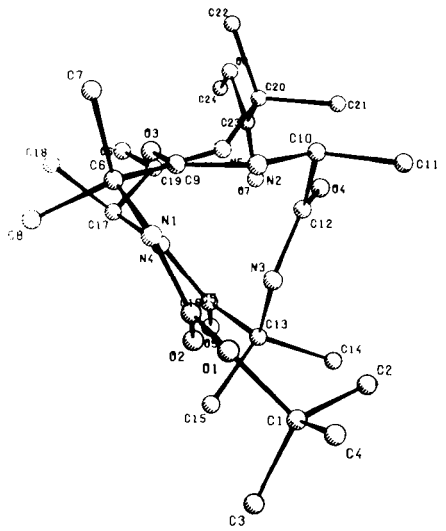
Handedness: , 3^l_{10} - Helix



7: Boc-Aib-Ala-Aib-Ala-Aib-OMe

Handedness: , 3^r_{10} - Helix

Fig. 1. Comparison of the inverse helical structures of **1** and **7**·2 H_2O [2a] (view direction: from N- to C-terminus, *N*-Boc protecting group at the bottom right corner). Structure solution of **1**: direct methods ($P2_12_12$, $Z=4$, $a=18.839(3)$, $b=18.776(7)$, $c=9.179(1)$ Å; CAD-4 diffractometer, $Cu_{K\alpha}$ radiation, room temperature); anisotropic structure refinement for C, N, and O (H isotropic); $R=0.056$ ($R_w=0.057$) for 2429 reflections with $F>0$.

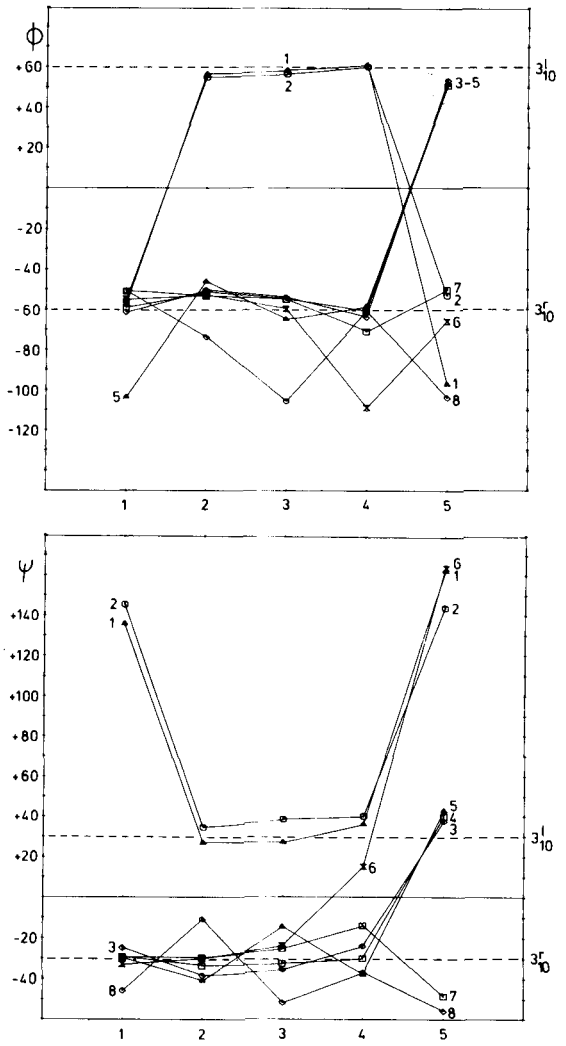


Fig. 2. Torsion angles ϕ and ψ [°] for Aib-containing pentapeptides: **1** (▲), **2** (○) [2e], **3** (◇) [2h], **4** (□) [2c], **6** (△) [2f], **5** (⧖) [2d], **7** (□) [2a], and **8** (◇) [2g].

In **1** the Boc-Pro urethane group is *trans*-orientated, although it normally prefers the *cis*-orientation[5]. According to model considerations, formation of the 3^l_{10}-helix from the *cis*-form would be impossible. Apart from **2**[2e], which is also a left-handed helix, no 3^l_{10}-structures are yet known. Protecting groups at the *N*- and/or *C*-terminus usually have only a slight effect on the secondary structure, as we find, inter alia, with **11a** and **11b**[6]. Particularly the segment Ala-Aib-Ala[6] appears to determine the structure of **1**, as indicated by comparison of the Aib torsion angles of **1** with those of the anomalous β-turn type of the tripeptides **11**: Aib^2 in **11** and Aib^4 in **1** have precisely the torsion angles of a 3^l_{10}-helix. Further evidence of the structural similarities is provided by the positive Cotton effects at $\lambda < 230$ nm for **11**[6]. The 3^l_{10}-helix of **1** (and its methyl ester) also shows small positive Cotton effects at $\lambda < 225$ nm and negative Cotton effects at $\lambda > 225$ nm, whereas the 3^r_{10}-helix of **7** shows qualitatively a mirror imaged CD curve.

The single intermolecular H-bond of **1** connects the molecules to linear chains in a head-to-tail fashion along [010], similar to that in **7**. However, the pentapeptide **7**, in contrast to **1**, forms a left-handed superhelix[2a]. Only lipophilic contacts occur between these parallely oriented,

one-dimensional superstructures; membrane-bridging, head-to-tail aggregates of this type might, therefore, also be the reason for the experimentally determined membrane pore formation by **7**. On the basis of CD and ^{13}C-NMR studies, we supposed earlier that for alamethicin-like sequences, e.g. $(Aib\text{-}Ala)_n$, a reorientation of the 3_{10}- to the more stable α-helix should occur in the region between the hepta- and the nonapeptide.—A recently described 3_{10}-helical decapeptide[2i] has a sequence which is less similar to that of alamethicin.

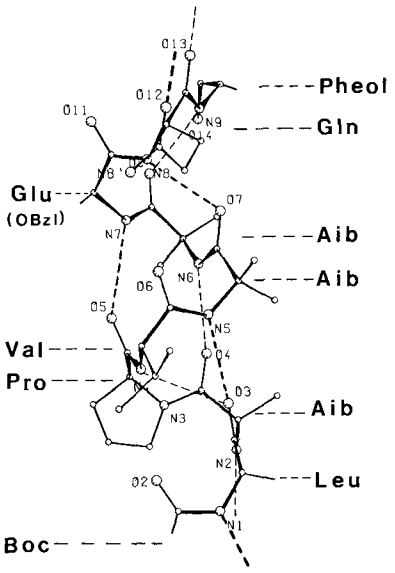

Fig. 3. Perspective view of the secondary structure of **9**. H-bonds are indicated by dashed lines, and bulky side groups are omitted. Structure solution: direct methods (SHELX 84 [7], refinement with SHELX 76 [7]; $P2_12_12_1$ $Z=4$, $a=15.666(6)$, $b=16.192(2)$, $c=25.876(3)$ Å); anisotropic structure refinement (H atoms isotropic), $R=0.063$ ($R_w=0.053$) for 5857 reflections with $F>0$). Four H_2O molecules per unit cell participate in the H-bonding scheme.

The structure of the *C*-terminal nonapeptide segment **9** of alamethicin in the crystal displays the interesting formation of 3_{10}- *and* α-helix regions in a longer Aib peptide (Fig. 3). Moreover, in connection with the α-helix of the *N*-terminal model undecapeptide **12** of alamethicin, which we described earlier[4], a direct structural comparison between the complete peptide antibiotic[3] and two structure-determining, longer segments is possible for the first time. The excellent agreement is illustrated in Figure 4. The right-handed helix extends beyond the proline residue over the total peptide length, as in alamethicin. Apart from two H-bonds, all the others are considerably longer than the ideal value of 2.9 ± 0.1 Å. In addition, two bifurcated H-bonds, which form both a C_{10}- as well as a C_{13}-turn, are observed. Of these, only the stronger components are shown in Figure 4. As in **12**[4], the individual molecules of **9** are linked head-to-tail by two intermolecular H-bonds to form antiparallel chains along [100]. An additional weak H-bond perpendicular to the helix results in the formation of a type of a layer-like structure; again only hydrophobic contacts occur between the layers.

NMR and CD studies indicate that, at least in chloroform and alcoholic solvents, this $\alpha/3_{10}$ helical conformation is retained. Negative Cotton effects at 223 and 207 nm form a CD spectrum which is typical for the dominant α-helix. We therefore postulate that the partial structure **9**, like alamethicin itself, also induces voltage-dependent ion-conducting membrane pores.

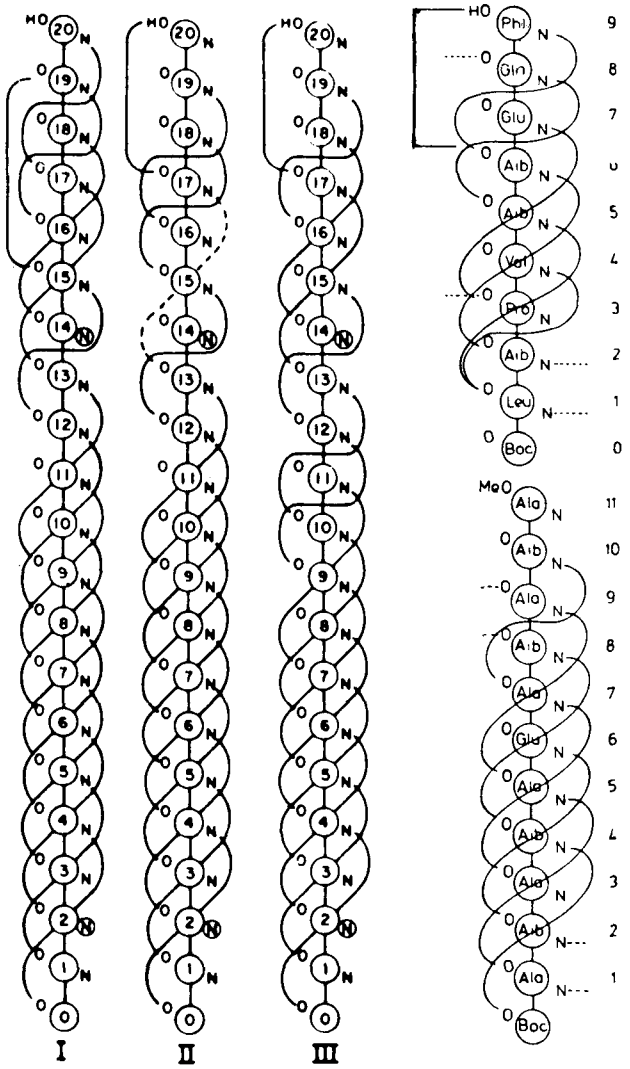

Fig. 4. H-bonding scheme for the three individual molecules of alamethicin (I, II, III) [3] compared with a combination consisting of the *N*-terminal model undecapeptide **12** [4] and the *C*-terminal nonapeptide **9** with natural sequence.

Our results, i.e. that alamethicin has predominantly an α-helical conformation, not only in the *C*-terminal part but also in the segment 12—20, should refute a recently published model[8]. In this model, a *C*-terminal, parallel β-pleated sheet structure was proposed on the basis of ^1H-NMR data, speculations having no experimental evidence, and the neglect of many known facts[1,3,4].

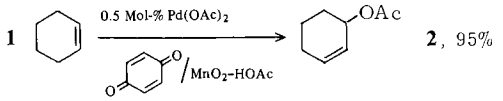
Oxidation with Palladium Salts: Catalytic Preparation of Allyl Acetates from Monoolefins Using a Three-Component Oxidation System**

By *Andreas Heumann** and *Björn Åkermark**

Because of their potential applications for the synthesis of complicated organic molecules[1] or merely of allylamines[2], the synthesis of allyl acetates is a topical problem, but is, however, only partly solved[3a]. In particular, the direct, metal-catalyzed oxidation of readily accessible monoolefins—a series of metals has been intensively studied[3b]—cannot be carried out in a selective and general way, although some alkenes can be converted in a highly designed way[3c].

We recently reported that, in the presence of a $PdCl_2$-$CuCl_2$ oxidation catalyst, 4-vinylcyclohexene derivatives react regio- and, in part, stereoselectively to afford allyl acetates[4]. A vinylic double bond appeared to be necessary for the successful, and in comparison to cyclohexene[5], very selective reaction (stabilization by intramolecular chelate). We have now found that monoolefins also react to give allyl acetates if another—combined with Pd^{II}—redox system is added[6]. Table 1 shows some experimental details for the reaction with cyclohexene **1**[7].



Other cycloalkenes (C_5, C_7, C_8, C_{12}) can also be converted into allyl acetates in the presence of 5% $Pd(OAc)_2$, but in somewhat lower yields (60—90%). Nonterminal aliphatic alkenes (e.g. *trans*-5-decene: 87%) also react similarly; however, in this case more regio- and configurational-isomers are obtained.

Table 1. Catalytic preparation of 2-cyclohexenyl acetate **2**.

Catalyst	mol-%	Reoxidant	*T* [°C]	*t* [h]	Yield **2** [%]
$Pd(OAc)_2$	5	MnO_2	60	72	5
	5	*p*-benzoquinone	60	17	29
	5	*p*-benzoquinone/MnO_2 [a]	60	17	97
	0.5	*p*-benzoquinone/MnO_2 [b]	60	48	95
	5	chloranil/MnO_2 [c]	25	70	72
$PdCl_2$/AgOAc	5/10	TeO_2/*t*-BuOOH	25	72	32—44 [d]
$PdCl_2$		$CuCl_2$	75	2	88 [e]

[a] Pd : benzoquinone = 1 : 4. [b] Pd : benzoquinone = 1 : 10. [c] Pd : chloranil = 1 : 2. [d] Lit. [6b]: product contains varying amounts of 2-cyclohexen-1-one. [e] Lit. [8], Pd : Cu = 1 : 100, reaction up to 5% conversion of **1**.

p-Benzoquinone, a well-known reoxidation reagent for Pd^{II}-catalyzed functionalizations of conjugated dienes[9a], has only been used with moderate success with simple cycloalkenes[9b]. As found by *Bäckvall* et al. for the oxidation of conjugated double bonds[9a,c], addition of MnO_2[10], which under the reaction conditions is only capable of oxidizing the hydroquinone formed, but not Pd^0 or an alkene, permits the use of much smaller amounts of *p*-benzoquinone. Table 1 shows that *p*-benzoquinone markedly accelerates the reaction of monoolefins. Interestingly, substituted quinones can also be employed. Comparison with other acetoxylation reactions catalyzed by Pd indicates at least similar selectivities for cyclohexene and considerably higher selectivities for other cycloalkenes[5,6,8].

As is frequently observed for Pd-catalyzed oxidations[11], in this case the reoxidation system is of paramount importance. Quinone reacts highly probably as a ligand *and* reoxidant, and only the additional oxidizing agent (MnO_2) prevents—by rapid re-formation of the quinoid system—removal of the ligand from the palladium catalyst and hence precipitation of Pd^0.

These types of combined oxidation systems, which are often involved in biological processes, and by means of which two (or more) compounds that react extremely slowly and nonselectively with each other (olefin and acetic acid) are induced to react via a series of multiple catalyzed reactions, appear to be gaining more and more importance in organic chemistry[12].

Photochemical Generation of Triphenylsilylboranediyl ($C_6H_5)_3SiB$: from Organosilylboranes**

By *Bernd Pachaly* and *Robert West**

Organoboranediyls ("organoborylenes") are interesting in connection with questions of chemical bonding in hypovalent molecules and as reactive species. They have been postulated as intermediates in the photolysis of tri-1-naphthylborane[1] and in the dehalogenation of methylboron dibromide[2].

By photolyzing organobis(triphenylsilyl)boranes, such as **1** and **2**, or tris(triphenylsilyl)borane **3** in a hydrocarbon matrix at −196 °C, we have succeeded in generating triphenylsilylboranediyl and in detecting it via its subsequent reactions. This method had already proved useful for the preparation of hypovalent species in the chemistry of silicon[3].

Methyl-**1** and mesitylbis(triphenylsilyl)borane **2** can be obtained by reaction of the corresponding organoboron dibromides with triphenylsilyllithium.

$$RBBr_2 + 2\,Ph_3SiLi \xrightarrow[-10\,^\circ C]{THF/heptane} RB(SiPh_3)_2 + 2\,LiBr$$

1, R = CH_3
2, R = C_9H_{11}

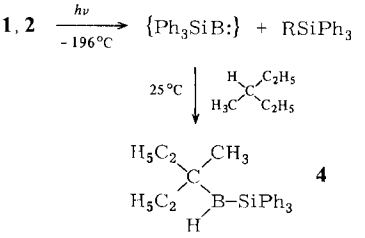
Tris(triphenylsilyl)borane **3** was prepared analogously[4].

$$BBr_3 + 3\,Ph_3SiLi \xrightarrow[-70\,^\circ C]{THF/heptane} B(SiPh_3)_3 + 3\,LiBr$$

3

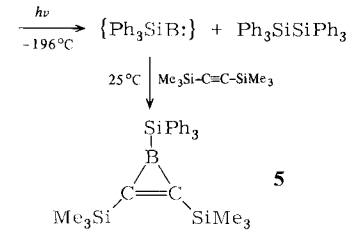
The organosilylboranes **1**–**3** are colorless, moisture-sensitive solids which melt above their decomposition point (ca. 200 °C). Their IR spectra exhibit the characteristic stretching bands of the B–Si bond around 500 cm^{-1}[5]. In the mass spectrum[6], molecular ions and/or parent ions appear for all three compounds. Stepwise hydrolysis of **1** leads initially to cleavage of the B–C bond and subsequently to cleavage of the first B–Si bond, whereas mesitylboric acid is formed upon cleavage of the B–Si bonds of **2**; hydrolysis of **3** leads to boric acid.

Irradiation of **1** and **2** was performed in a 3-methylpentane matrix at −196 °C at $\lambda = 254$ nm. The absorption spectra of the irradiated matrix exhibited no characteristic new bands, except for a weak new band around 250 nm. In both cases, the insertion product 3-methylpentyl(triphenylsilyl)borane **4** was isolated and characterized as a reaction product[6].



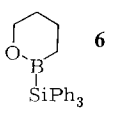
4

Compound **3** was irradiated in the presence of trapping reagents[7]. Upon cophotolysis with bis(trimethylsilyl)acetylene, 1-triphenylsilyl-2,3-bis(trimethylsilyl)borirene **5** can be isolated[6,8,9].



5

Analogous photolysis of **3** in the presence of tetrahydrofuran affords the insertion product, 2-triphenylsilyl-1,2-oxaborinane **6**[6].



6

The reaction behavior of silylboranediyls indicates that they do not tend to dimerize, but that in the presence of trapping reagents insert, e.g. into the C–H or C–O bonds of solvent molecules.

The photochemical generation of this species could have application in the synthesis of organoboranes, possibly with boron-element double bonds—as indicated by the preparation of the borirene **5** and the oxaborinane **6**.

[4] *Procedure:* A solution of BBr_3 (2.97 g, 0.012 mol) in 40 mL hexane is added dropwise to a solution of chlorobiphenylsilane (13.25 g, 0.045 mol) in 100 mL tetrahydrofuran (THF) containing lithium (3.15 g, 0.45 mol)—corresponding to approximately 0.04 mol Ph_3SiLi. After being stirred for 24 h at room temperature, the solvent mixture is removed, the residue taken up in 150 mL hot heptane and filtered. Upon cooling the filtrate to −15 °C, 6.0 g (64%) of **3** precipitates out as a white solid, and is recrystallized several times from heptane until a flame test indicates a Li-free product. In contrast, in the analogous preparation of **1** and **2**. Ph_3SiLi is added to the organoboron dibromides.

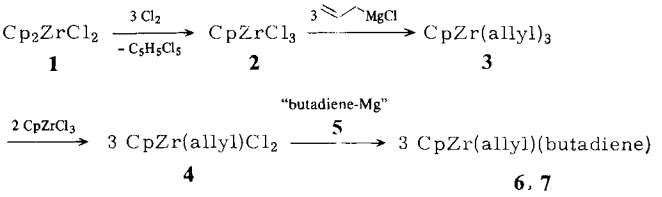
(η^3-Allyl)(η^4-butadiene)(η^5-cyclopentadienyl)-zirconium, a System of Isomeric Monocyclopentadienylzirconium(II) Compounds**

By *Gerhard Erker*, Klaus Berg, Carl Krüger, Gerhard Müller, Klaus Angermund, Reinhard Benn,* and *Gerhard Schroth*

Electronically unsaturated early transition-metal complexes are interesting substrates for the development of active catalysts for the CC coupling of olefins. Current examples contain the small number of compounds of the organometallic fragments (η-cyclooctatetraene)M and (η-pentamethylcyclopentadienyl)M (M = Ti, Zr, Hf)[1]. We have recently found a novel, general route to the mono(η-cyclopentadienyl)zirconium system[2]. This allowed us to synthesize the (η^3-allyl)(η^4-butadiene)(η^5-cyclopentadienyl)zirconium compounds **6**, **7**, to our knowledge the first isolated and structurally completely characterized mono(η-cyclopentadienyl)zirconium(II) system.

The radical chain chlorination of zirconocene dichloride **1** at 20—25°C in CCl_4 leads to $CpZrCl_3$ **2** (amorphous solid, 96%)[2]. Reaction with allylmagnesium chloride in ether at −40°C in a 1:3 molar ratio affords triallyl(η-cyclopentadienyl)zirconium **3**[3], isolated in 65% yield after extraction with pentane (−35°C) and crystallization (−78°C).

Above −10°C, **3** decomposes thermally. In the presence of zirconium halides it undergoes ligand exchange. A rather slow (72 h) comproportionation of **3** with $CpZrCl_3$ (molar ratio 1:2) at −40°C produces allyl(η-cyclopentadienyl)zirconium dichloride **4** (Scheme 1). The latter was not isolated, but reacted directly with "butadiene-magnesium" **5**[4b]. After usual work-up at room temperature and crystallization (pentane, −78°C), **6** is obtained as dark-red crystals (70% yield).



Scheme 1.

The molecular structure of **6** (Fig. 1) is derived from a square pyramidal geometry with an apical η-Cp ligand (Zr–C(Cp) = 2.512(7) Å) in which the η^3-allyl and the η^4-butadiene ligand both occupy basal positions. The molecular symmetry in the crystal is C_s. Normals to the planar carbon frameworks of all three π-ligands lie in the molecular mirror plane. As is often the case in complexes of this structural type[5], the open-chain π-ligands open towards the apex of the pyramidal framework. Parameters typical of the (η^3-allyl)Zr moiety are found[6] (Zr–C3 2.443(7), Zr–C4 2.446(8), C3–C4 1.440(8) Å, C3–C4–C3* 119.9(9)°). As expected for a zirconium complex, the bond lengths of the (*s-cis*-η^4-diene)metal moiety differ considerably from those of the corresponding moieties with more electron-rich late transition metals. However, values of 1.384(7) (C1–C2), 1.358(8) (C2–C2*), 2.360(5) (Zr–C1) and 2.463(5) Å (Zr–C2) point to a σ-complex character of **6** being decidedly less pronounced than in (*s-cis*-η^4-diene)$ZrCp_2$ complexes[7].

The NMR spectra of **6**[8] in addition to the ^{1}H-NMR-NOE difference spectra indicate that **6** adopts an analogous structure in solution. Dynamic behavior of the allyl

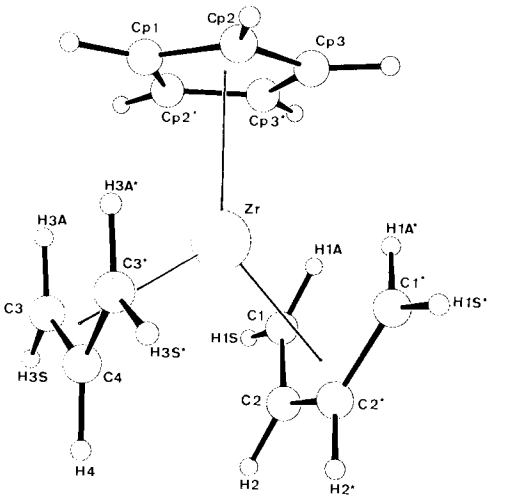


Fig. 1. Molecular structure of **6** in the crystal. Space group $P2_1/m$; $a = 7.412(1)$, $b = 11.335(2)$, $c = 7.5916(8)$ Å, $\beta = 117.699(7)°$, $V = 564.759$ Å^3, $Z = 2$, 1561 observed reflections, 64 parameters refined, $R = 0.051$, $R_w = 0.068$. Further details on the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50786, the names of the authors, and the journal citation.

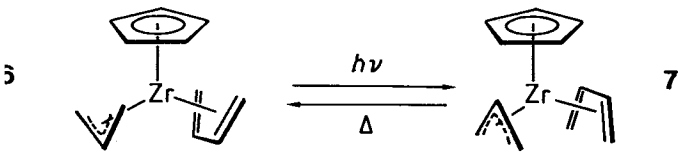
ligand is detected by ^{1}H-NMR spectroscopy (60 MHz) at high temperature (AA'BB'X→A_4X pattern, $\Delta G^{\ddagger}_{105\,°C} = 19.1 \pm 0.3$ kcal/mol, as estimated from the coalescence of the methylene protons[4a]).

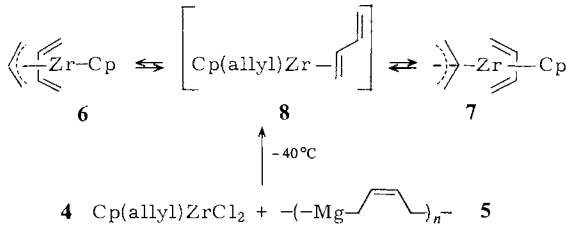
Photolysis of **6** (Philips HPK 125, Pyrex filter, toluene, −40 °C) leads to **7** in practically quantitative yield. Formation of this isomer can be monitored by the appearance of a new Cp singlet shifted to lower δ-values. Both the (*s-cis*-η^4-butadiene) ligand as well as the π-allyl moiety can be assigned by NMR[8]. According to the NMR data and the ^{1}H-NMR-NOE difference spectra, **6** and **7** are principally different with regard to the arrangement of the allyl and butadiene moieties relative to the Cp group: Both open-chain π-ligands in **7** open towards the base of the pyramidal framework (Scheme 2)[1a,9].



Scheme 2.

7 is only observed at sufficiently low temperature. Upon heating, **6** is re-formed in a smooth reaction. The thermally induced isomerization **7**→**6** follows a first-order rate law with $\Delta G^{\ddagger}_{10\,°C} = 22.1 \pm 0.2$ kcal/mol.

Reaction of CpZr(allyl)Cl_2 **4** with "butadiene-magnesium" **5** below −30 °C features a somewhat different result: even in the dark reaction **7** is formed in addition to **6** (55 : 45). Presumably, this reaction proceeds via intermediate **8**[10], which under kinetic control is stabilized by forming both isomers **6** and **7** with an almost equal probability (Scheme 3). It is possible that the thermally induced isomerization **7** ⇌ **6** might also proceed via **8**. However, from the experimental material presented it cannot unequivocally be distinguished between this mechanism of diene rotation and one involving a ring inversion process[7,11].



Scheme 3.

As shown by the example of the isolated complexes **6** and **7** in Scheme 1, a system of isomeric mono(η-cyclopentadienyl)zirconium(II) compounds of a square-pyramidal structural type has become readily available. These compounds become chiral[12] upon substitution at C1, C2, or C3 (see Fig. 1). Therefore their use in catalytic CC coupling reactions of the Ziegler-Natta type should be of particular interest.

Ferrocenium Salts— The First Antineoplastic Iron Compounds**

By *Petra Köpf-Maier**, *Hartmut Köpf*, and *Eberhard W. Neuse*

Dedicated to Professor Ernst Otto Fischer

Metallocene dihalides of d-electron deficient transition metals such as $(\eta^5\text{-}C_5H_5)_2MX_2$ with M = Ti, V, Nb, Mo[1,2] or octahedral complexes such as *cis*-dihalobis(1-phenyl-1,3-butanedionato)titanium(IV)[3], for which antineoplastic activity has previously been detected, are neutral complexes and contain a *cis*-configurated MX_2 group; they are

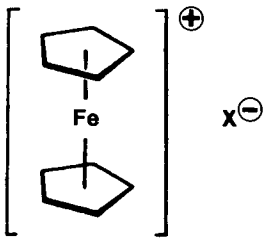
[**] This work was supported by the Fonds der Chemischen Industrie.

capable of releasing two neighboring coordination vacancies at the site of action, and, hence, fulfill structural conditions recognized as essential for cytostatic action and which are also realized by other inorganic or organometallic cytostatics[4,5].

In contrast, the ferrocenium salts $(\eta^5\text{-}C_5H_5)_2Fe^{\oplus}X^{\ominus}$ **1**[6,7], with the d-electron richer transition-metal iron as central atom, represent another type of coordinatively largely saturated complex in which the cyclopentadienyl ligands are not inclined to each other, but rather are arranged parallel to one another[8]. We have now surprisingly found that the cation in the salts **1** has antineoplastic activity.



1a: $X^{\ominus} = Cl_3CCOO^{\ominus} \cdot 2\,Cl_3CCOOH$[9]
1b: $X^{\ominus} = 2,4,6\text{-}(NO_2)_3C_6H_2O^{\ominus}$[7]
1c: $X^{\ominus} = FeCl_4^{\ominus}$[10]

To test the antineoplastic activity, we intraperitoneally (i.p.) implanted female CF1 mice with approximately 6×10^6 Ehrlich ascites tumor cells. After 24 h, the animals were administered various doses of **1a**, **1b**, or **1c** (20, 40, 60 ... 500 mg/kg; six animals per dose); the salts, which are readily soluble in water, were applied i.p. in physiological saline solution. Twelve control animals received an i.p. injection of 0.5 mL pure saline solution 24 h after implantation of the tumor cells. The animals were observed for 90 days after tumor transplantation; evaluation of the experiment was carried out as described in [4].

All three ferrocenium salts investigated had an inhibiting effect towards Ehrlich ascites tumor and, in optimal doses, cure 60 to 100% of the animals treated (cf. Fig. 1 and Table 1; for comparison, *cis*-$(NH_3)_2PtCl_2$, 10 mg/kg: 100% cure rate[4]); in the optimal dose range, the increase in mean survival time until the key-date is statistically highly significant (two-sided U-test, after *Wilcoxon*) relative to that of the untreated animals (15.3 d). Antineoplastic properties were neither detected for ferrocene $(\eta^5\text{-}C_5H_5)_2Fe$ **2** itself, nor for the tetrachloroferrates(III) $[(CH_3)_4N]^{\oplus}[FeCl_4]^{\ominus}$ **3a** and $[C_6H_5CH_2(C_2H_5)_3N]^{\oplus}[FeCl_4]^{\ominus}$ **3b**.

Our results permit the following conclusions to be drawn: 1) Not only metallocenes of the "early", but also of "middle" transition elements, such as iron, can effect cytostatic activity. 2) A coordination-gap releasing MX_2 group is not absolutely necessary for the realization of antineoplastic properties by metal complexes. 3) For this purpose, the occurrence as a neutral complex is also not a conditio sine qua non; in contrast, the excellent solubility of the salts in water, caused by the ionic character of **1**, proves to be propitious for applications in biological systems.

Highly Enantioselective Alkylation of Tetrahydroisoquinolines via a Valine Chiral Auxiliary; Asymmetric Synthesis of (*S*)-Isoquinoline Alkaloids

By *A. I. Meyers**, *Michael Boes*, and *Daniel A. Dickman*

The utilization of natural amino acids as a source of chirality for the preparation of various enantiomerically enriched compounds has been reviewed recently[1]. We have reported that tetrahydroisoquinolines, via their *N*-iminomethyl derivatives (i.e. as formamidine derivatives), are metalated and alkylated to give 1-alkyltetrahydroisoquinolines in good yields[2,3], while enantioselective alkylations via chiral formamidines provide these products in high enantiomeric excess[4]. These enantioselective alkylations were performed using the disilyl ethers of (1*S*,2*S*)-(+)-2-amino-1-phenyl-1,3-propanediol, whose availability and stability posed some technical problems. We now report that the *tert*-butyl ether **8d** of valinol **8a** can not only be conveniently prepared, but also leads to higher enantioselectivity than the propanediol derivative when transformed into the formamidine **9**. By simple exchange between the isoquinolines **1** or **2** and **9**, the chiral formamidines **3a** or **3b** are obtained in 70—90% yield[5]. Metalation with lithium diisopropylamide (for **3a**) and *tert*-butyllithium (for **3b**) gave the lithiated formamidines, which were alkylated with alkyl halides and then hydrazinolyzed to remove the iminomethyl group[6]. The high efficiency of this process is outlined in Table 1. The enantiomeric excesses of **4** were determined by chiral-column HPLC analysis, as developed by *Pirkle*, and applied to chiral *N*-heterocycles and other amines[7,8]. The optical rotations in Table 1 were obtained on purified **4**. The amines were released from the recrystallized hydrochlorides **4** · HCl, converted into *N*-(α-naphthoyl)amides, and resubjected to HPLC analysis. These derivatives showed >99% enantiomeric purity, and thus the rotations are for pure materials. Clearly, recrystallization of the hydrochlorides increased the optical purity of **4**.

Several naturally occurring isoquinoline alkaloids were prepared using this method. Thus (−)-salsolidine **4f**[9] was formed from **3b** and MeI (Table 1), whereas (−)-norcoralydine **6** ($[\alpha]_D$ −273, $c = 1.17$, $CHCl_3$) was obtained in 98.5% *ee* by cyclizing **4g** (from **3b** and dimethoxybenzyl bromide) with formaldehyde and 2 N HCl (reflux, 30 min)[10]. The alkaloid (*S*)-(+)-homolaudanosine **7**, recently isolated[11], was readily prepared from **3b** and dimethoxyphenethyl iodide to give the corresponding 1-substituted isoquinoline, which was *N*-methylated (46%, ethyl formate, $LiAlH_4$) to the natural material [(α]$_D$ 10.4°, $c = 0.2$, $CHCl_3$). Finally, the benzoquinolizidine **5**, a degradation product of securine, was prepared by treatment of **3a** with 1-bromo-4-chlorobutane, which cyclized to **5** concurrently

Table 1. Synthesis of (*S*)-1-alkyl-1,2,3,4-tetrahydroisoquinolines **4** [6].

Educt [a]	R′X	Product	Yield [%] [b]	$[\alpha]_D$ [c]	*ee* [%] [d]
3a	MeI	**4a**	50	−71.3° (0.64)	99
3a	*n*BuI	**4b**	56	−78.4° (0.96)	96
3a	AllylBr	**4c**	63	−83.1° (0.61)	96
3a	$PhCH_2Cl$	**4d**	66	−62.2° (1.24)	98
3a	$PhCH_2CH_2Br$	**4e**	67	−23.5° (5.71)	93
3b	MeI	**4f**	61	−56.5° (4.15) [e]	95
3b	$3,4\text{-}(MeO)_2PhCH_2Br$	**4g**	75	[f]	99
3b	$3,4\text{-}(MeO)_2PhCH_2CH_2I$	**4h**	75	[f]	95

[a] **3a** was metalated with 1.05 equiv. $LiN(iPr)_2$ in THF at −78°C; **3b** was metalated with 1.1 equiv. *t*BuLi (2.3 M in THF). [b] Based on overall yield for **3**→**4**. [c] Based on amine released from hydrochloride salts after recrystallization. The values reflect optical purities >99%, as determined by chiral HPLC analyses of the *N*-(α-naphthoyl)amides. [d] Determined by chiral HPLC analyses of the *N*-(α-naphthoyl)amides from products obtained by metalation-alkylation *before* purification of hydrochloride salts. [f] In EtOH; cf. [9]. [f] Not determined since **4g** and **4h** were carried forward to **6** and **7**, respectively. Enantiomeric excess was determined through the *N*-(α-naphthoyl)amides and comparison with the rotation values of the natural products [10, 11].

with hydrazinolysis (50—60%, $[\alpha]_D$ −206°, c = 0.017, pyridine, 93—95% *ee*)[12].

The asymmetric synthesis described here provides the (*S*)-enantiomer of all the products obtained, as indicated by comparison of the absolute configuration of the natural isoquinolines, and should provide ready access to a wide variety of enantiomerically pure isoquinoline alkaloids.

[5] Procedure for **9** and **3**: Valinol **8a** was treated with excess ethyl formate (reflux, 3 h) and concentrated to afford crude **8b**, which was stirred with excess isobutene (0°C, dioxane, trace of H_2SO_4, 3 equiv. $BF_3 \cdot OEt_2$) for 3 h and gave, after kugelrohr distillation, the ether **8c** (92%, $[\alpha]_D^{25}$ −55.7, c = 1.08, tetrahydrofuran (THF)). Hydrolysis of **8c** with 1:1 of 50% KOH ethanol (reflux, 4 h) gave the crude amine **8d**, which was dried prior to addition of 1.1 equiv. $Me_3NCH(OMe)_2$, and heated at 50° for 12 h. Concentration and kugelrohr distillation (70°C/0.03 torr) gave **9** (80% $[\alpha]_D^{25}$ −15.9°, c = 0.98, THF). **3a** and **3b** were formed by heating **1** or **2** with 10—50% excess **9** in toluene for 48 h and concentrating the solution. The residue was first chromatographed (silica gel, 5% Et_3N-hexane) and then distilled (kugelrohr) to give **3a** and **3b** as oils. Correct elemental and spectral analyses were obtained; $[\alpha]_D$ −3.96, c = 1.06, THF, and −30.3, c = 2.7, $CHCl_3$, respectively.
[6] Procedure for **4**: A 0.03 M solution of **3** in THF was lithiated at −78°C. The deep red solution was cooled to −100°C and the alkyl halide added. After 30 min the reaction was quenched in CH_2Cl_2–H_2O, and the organic layer dried (K_2CO_3) and concentrated. The residue was dissolved in 60% aqueous ethanol (3 mL/mmol) and 3—5 equiv. hydrazine and 3—5 equiv. acetic acid added. After being stirred at 25°C or refluxed overnight, the mixture was quenched in CH_2Cl_2–H_2O. The organic layer was dried (K_2CO_3), concentrated, and distilled (kugelrohr). For *ee*-determinations, the *N*-(α-naphthoyl)amides of **4** were prepared and analyzed by HPLC [7].

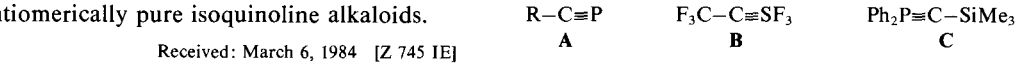
First Evidence for an Intermediate Nitrilo-λ^5-phosphane $>P\equiv N$**

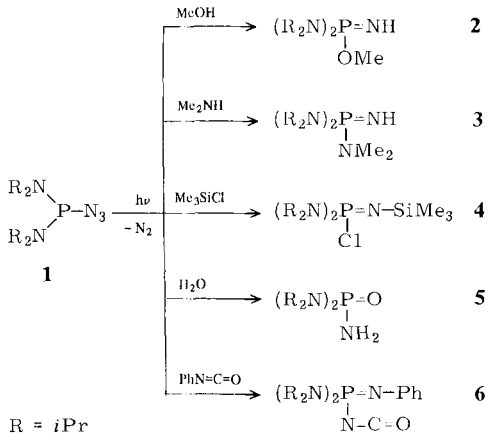
By *Ghislaine Sicard, Antoine Baceiredo, Guy Bertrand**, and *Jean-Pierre Majoral**

During the last twenty years, one of the most fascinating areas in the chemistry of the heavier main group elements has been the synthesis and reactivity of p_π-p_π multiply bonded compounds[1]. Whereas a number of investigations have been devoted to double bonded derivatives, in contrast, only a few reports have appeared on compounds possessing a triple bond between elements of the first and the second rows of the periodic table: some phosphaalkynes **A**[1c], the trifluoroethylidynesulfur trifluoride **B**[1f], and only one transient λ^5-phosphaacetylene **C**[2].



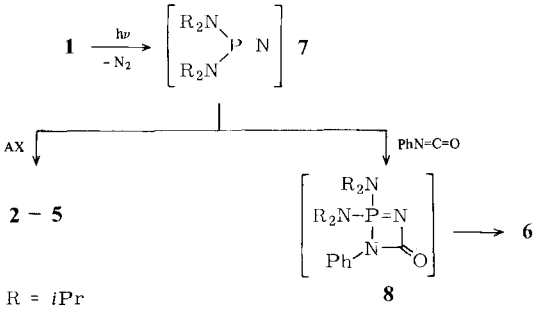
Recently, ab initio effective potential calculations indicated that the structure of singlet λ^3-phosphinonitrene H_2P–N is better formulated as a nitrilo-λ^5-phosphane $H_2P\equiv N$ due to delocalization of the lone pairs $n_\pi(P) \rightarrow p_\pi(N)$ and $n_\pi(N) \rightarrow d_\pi(P)$[3]. These findings prompted us to investigate the possibility of generating a "λ^3-phosphinonitrene–nitrilo-λ^5-phosphane" by photolysis of an azidophosphane.

We chose to study the photochemical behavior of azidobis(diisopropylamino)phosphane **1**[4] in order 1) to prevent Staudinger reactions by steric effects[5], and 2) to avoid formation of a tricoordinated λ^5-phosphane R_2N–$P(=NR)_2$[6] by using poor migrating groups.



1 was photolyzed at room temperature in benzene at λ = 300 nm[7] in the presence of a stoichiometric amount of trapping agent AX. Products **2** to **6** were obtained in near quantitative yield[8].

It seems reasonable to postulate that compounds **2** to **5** result from 1,2-addition of the trapping agent AX to the phosphorus-nitrogen triple bond of an intermediate bis(diisopropylamino)nitrilo-λ^5-phosphane **7**. The diamino(imino)isocyanato-λ^5-phosphane **6** probably arises from [2+2]-cycloaddition of phenyl isocyanate to **7** followed by ring opening of the resulting strained cyclic adduct **8**.



1,1-Adducts of type **9** were not observed, and we therefore note that they cannot be the precursors of products **2**

9

to **5**. Moreover, no trapping reactions occurred when monoolefins, conjugated dienes, or dimethyl sulfide were used. These results, as a whole, showed that the λ^3-phosphinonitrene reacts as a nitrilo-λ^5-phosphane. This is in perfect agreement with the calculated structure with a polarized phosphorus-nitrogen triple bond[3]. It is noteworthy that, in contrast to tetra- or pentacoordinated phosphorus azides[9], no Curtius rearrangement takes place, supporting the stabilization of the nitrene.

Nickel-Catalyzed Reduction of Carbon Monoxide by Hexamethyldisilane: a New Reaction Leading to a Novel Synthesis of Siloxanes**

By *K. Peter C. Vollhardt** and *Zhen-Yu Yang*

The oxophilicity of silicon[1] has been exploited in a number of organic transformations[1,2]. Particularly intriguing are reports on the oxidation of disilanes with a variety of oxidizing agents to furnish siloxanes[3]. These observations, in conjunction with the hydrogen-like reactivity of disilanes in the presence of transition metals[2,4], suggested the attractive possibility of utilizing hexamethyldisilane **1** as a reducing agent for carbon monoxide, a fundamentally new transformation potentially analogous to the Fischer-Tropsch reaction[5], but leading to silicon-containing products. We report that 50% nickel on kieselguhr does indeed mediate this reaction, furnishing siloxanes and surface-deposited carbon:

$$\underset{\mathbf{1}}{R_3Si{-}SiR_3} + CO \longrightarrow \text{"C"} + \underset{\mathbf{2}}{R_3SiOSiR_3} + R_3SiOSiR_2OSiR_3 \cdots$$

In the presence of hydrogen this carbon is converted into methane. The results of a series of experiments and the experimental conditions are delineated in Table 1.

Table 1. Major products from the reaction of CO and $Me_3SiSiMe_3$ **1** in the presence of 50% Ni-kieselguhr [a, b].

Run	Changes in conditions	Conversion of **1** [%]	$(Me_3Si)_2O$	Yield [%] Siloxane (total)	CH_4 (in gas phase)
1	—	62.4	25.8	35.6	7.3
2	170°C	[c]	4.1	6.5	[c]
3	250°C	72.0	33.2	41.8	[c]
4	no CO, (carrier gas N_2)	12.6	2.0 [d]	3.6 [d]	trace
5	with H_2 ($CO:H_2 = 1:1$)	91.8	59.0	68.0	42.1 [e]
6	batch reaction [f, g]	26.1	10.3	18.8	6.0
7	Et_3SiH instead of **1**	94.0 [h]	57.0 [i]	57.0	10.3 [j]

[a] United Catalysts Inc.; C46-7-01. [b] Conditions: flow system; catalyst 8.0 g; 200°C; 1 bar; HMDS 1.6 mL h^{-1}, added by syringe pump; CO 900 mL h^{-1}; time on stream: 2 h. [c] Not quantified. [d] Impurity in commercial **1** (Alfa). [e] Yield based on CO. [f] Solvent, xylene (10 mL), 100 mL Fischer-Porter glass bomb; catalyst 1 g; 180°C; $p(H_2) = p(CO) = \approx 2.45$ bar at RT; **1**: 0.73 g; reaction time 20 h. [g] A similar result was observed using decalin as solvent. [h] Conversion of triethylsilane. [i] Yield of hexaethyldisiloxane. [j] In addition to methane, ethane was formed.

The major silicon-containing product in most cases (exceptions are runs 4 and 6, cf. Table 1) was hexamethyldisiloxane, but, clearly, substantial amounts of higher molecular weight products were formed. Careful analysis (GC-MS; preparative GC; spectral identification by comparison with authentic materials) revealed the presence of higher siloxanes. A typical product distribution (run 1) was: tetramethylsilane (0.2%), hexamethyldisiloxane (38.3%), unreacted hexamethyldisilane (46.9%), hexamethylcyclotrisiloxane (5.0%), octamethyltrisiloxane (5.2%), and decamethyltetrasiloxanes (1.3%), in addition to traces of other materials. The proportions of these products do not change, but the activity of the catalyst decreases with time. The observation of higher siloxanes is important in light of the commercial significance of silicones[6]. We do not know yet whether these products are generated through direct oxidative Si–C bond cleavage or catalyzed redistribution[7]. In this connection, we have found that doping the reaction with hexamethyldisiloxane gave relatively more of the higher siloxanes.

In the absence of CO, only a certain amount of decomposition of **1** was noted[8] (run 4). The efficiency of siloxane formation increased dramatically in the presence of added H_2 (run 5), with the concomitant emergence of me-

[**] This work was supported by the National Science Foundation (CHE-82-00049) and by equipment funds of the Director, Office of Energy Research, Office of Basic Energy Sciences, Chemical Sciences Division of the U.S. Department of Energy (Contract DE-AC03-76SF00098). *K. P. C. V.* was a Camille and Henry Dreyfus Teacher-Scholar (1978–1983).

thane in good yield. A similar increase in activity was observed when using triethylsilane (run 7), which furnished only hexaethyldisiloxane as oxidation product[9]. On the other hand, a batch reaction revealed decreased catalyst efficiency in terms of conversion of **1**, although a much higher production of higher siloxanes (run 6) was noted, in a ratio similar to that obtained under flow conditions.

In order to pinpoint the origin of the component atoms in the methane formed, as well as that of the oxygen in the siloxanes, several labeling experiments were performed. Execution of run 5 (Table 1) with D_2 instead of H_2 gave mainly CD_4 (84%) in addition to some protic (predominantly CH_3D) methane. None of the silicon-containing products (and **1**) showed incorporation of deuterium. Similarly, use of ^{13}CO gave mainly $^{13}CH_4$ (84.4%) and revealed the absence of ^{13}C in the other product molecules. Thus, clearly, the major contributors to methane formation are CO and H_2, minor amounts arising from **1** and siloxane decomposition or as part of the pathways which lead to higher siloxanes.

Since it was of interest whether the oxygen in the siloxane product was, in fact, somehow derived from the kieselguhr support or other oxygen sources, an additional control was carried out involving $C^{18}O$. This experiment revealed completely clean incorporation of ^{18}O into all isolated siloxanes.

Mechanistically, it is tempting to formulate surface pathways analogous to those found in the Fischer-Tropsch reaction[10], involving not only CO and H–H, but also Si–Si and Si–C activation on the nickel surface. Current work is directed at further mechanistic elucidation of the pathways controling these unprecedented transformations and at finding other substrates for the carbon left after it has been stripped of its oxygen by **1**.

BOOK REVIEWS

The Chemistry of the Allenes. Edited by *S. R. Landor*. Academic Press, London 1982. Vol. 1: Synthesis, p. 1–234, bound, $ 66.00; Vol. 2: Reactions, p. 235–578, bound, $ 86.00; Vol. 3: Stereochemical, Spectroscopic and Special Aspects, p. 579–882, bound, $ 86.00. Each volume contains index to whole work (pp. 26).

The subjects of all three volumes are presented in a short introduction (Chapter 1, 17 pp.) in Volume 1 by *S. R. Landor*. The remainder of the first volume is devoted to *P. D. Landor*'s description of allene synthesis. Chapter 2 deals with the synthetic methods for the hydrocarbons, for halogenated allenes, then for allenes containing alcohol, ether, aldehyde, ketene, carboxylic acid and carboxylic acid derivative functions, and finally for allenes bearing heteroelements (B, Si, Sn, N, P, S, Se, Te). The shorter, third chapter covers the synthesis of allenes containing additional olefinic, acetylenic or allenic functions. Each class of substance is dealt with in a separate section with an independent reference list. It is here that the need for an additional author index (with reference number and page number) becomes apparent, with which to keep track of allenes with several functional groups and to keep a better check on the comprehensiveness of the literature citations. This applies not only to this volume devoted to synthesis, but to the whole series, since a complete author index allows the rapid tracking down of a whole range of publications which describe not just the synthesis of allene derivatives but also their reactivities and/or other properties. Random sampling of the synthesis volume revealed that the literature citations (up to 1980), though not comprehensive, do at least cover the most important literature. The text does not reveal whether comprehensiveness or a review of the most important methods was the intention. Nor are the somewhat older but excellent reviews of various aspects of allene chemistry referred to. In the interests of a clearer conspectus the reviewer would like to have seen a distinction made in the various sections between reactions in which allenes merely undergo transformations without the cumulene being affected or altered and syntheses where the cumulene is actually created. A classification according to mechanism would have been preferable to the formal one used: For instance, Section 2.3.1 on the synthesis of allenic alcohols ("Reduction Methods") deals with the addition of hydride ions to 1,3-enynes, the addition of a hydride ion to the carbonyl group of allenic ketones and the nucleophilic substitution (S_N2') of halogen atoms in the propargyl position by hydride ions, while in Section 2.3.4 ("Use of Organometallic Reagents") the reaction of allenic Grignard reagents with ketones, of Grignard reagents with allenic ketones, and the fragmentation of tosyl hydrazones by butyllithium are discussed as well as the reaction of organometallic compounds with propargyl halides and suitable epoxides. The addition of organometallic compounds to 1,3-enynes is dealt with separately in Sec-

tion 2.3.3. The hydroxyalkylation of an allene ether with butyllithium and 3-pentanone described at the end of this section does not belong here. This criticism, however, applies only to the arrangement and not to the content. The author has presented the methods scientifically correctly and has also given a critical indication of the limits and applicability of the methods.

S. R. Landor covers the substitution reactions of 1- or 3-, 4-, and 5-halo-1,2-alkadienes in Chapter 4 (Volume 2). The most interesting reactions are those of the 1-halogen derivatives with geminal hydrogen atoms, since these can yield allenic carbenes by 1,1-elimination under the influence of strong bases. These carbenes can react with nucleophiles by undergoing 1,1- or 1,3-addition or are captured by olefins (see also Section 2.1.1, c) with the formation of allenylidenecyclopropanes. After the relatively short but informative report by *H. Hopf* on sigmatropic rearrangements of stable allenes, *T. L. Jacobs* discusses the transition metal complexes of the allenes. A list with literature citations and commentaries makes possible a rapid overview of the allenic complexes that have so far been isolated; then follows a discussion of their synthesis, structure and stereochemistry. The oligomerization and polymerization reactions of the metal complexes described at the end should be of interest to organic chemists, too. It can be seen from the reference list that this is a very new field; most of the references appeared in the 1970s, the majority of them towards the end of the decade. Chapter 5 (Volume 2) summarizes practically all the types of allene additions and cycloadditions: First *S. R. Landor* reports briefly on reactions with carbenes, which lead to a wide range of interesting cyclopropanes, and then on the nucleophilic addition of hydride ions and organometallic compounds. After a short section on radical additions *T. L. Jacobs* presents the large field of electrophilic additions. The tables which summarize the reactions with protonic acids, sulfenyl chlorides, halogens and with mercury salts are very useful for gaining a preliminary overview. These are followed by the mechanistically interesting epoxidation reactions; the methyleneoxiranes formed initially are only isolable with bulky residues. The last three sections of Chapter 5 contain a survey of allene cycloadditions. While the number of reactions with 1,3-dipoles is relatively limited *(S. R. Landor)*, [2+2]-cycloadditions seem of greater importance. Their preparative and mechanistic development between 1970 and 1979 is described by *H. Hopf*; he cites reviews on earlier work. In the section on [4+2]-cycloadditions he points out that vinyl-substituted allenes and bisallenes react as dienes, while simple allenes function as dienophiles.

Chapter 6 in Volume 3, concerning the stereochemistry of allenes, is particularly worthy of mention. In it *W. Runge* first of all explains the phenomenon of allene chirality, then takes up the synthesis of chiral allenes, and finally mentions some chosen reactions whose course is influenced by configuration. However, instead of retaining the confusing *cis* and *trans* nomenclature for some of the trisubstituted olefins the author should have adopted the *E/Z* nomenclature. In Chapter 7 *S. R. Landor* informs in a lively manner about all the naturally occurring allenes so far isolated and about the successful and unsuccessful attempts at their synthesis. *A. Claesson* discusses the known biologically active allenes in Chapter 8 (93 references). In Chapter 9 entitled "Allenic Intermediates in Organic Synthesis", *A. Claesson* and *L.-J. Olsson* describe the reactions of stable and also unstable allenes only appearing as reaction intermediates, from the point of view of the type of compound synthesizable. Thematically this section would fit better into the second volume where a large proportion of the reactions are already described. Chapter 10, written by *W. Runge* and concerning spectroscopic properties, ought to be of great value to spectroscopically inclined synthetic chemists; here at last is a good collection of UV, IR, photoelectron, NMR and mass spectroscopic data, in contrast to books concerning spectroscopic methods in organic chemistry, where the allenes are usually shortchanged. In the last, very brief chapter *P. D. Landor* reports on the methods of synthesis of nine specialized, variously functionalized allenes; an expansion of this section would have been desirable.

This three volume monograph is very readable, because the text is copiously illustrated with structural formulas. The typesetting of the text and formulas is very good and, apart from a few unimportant exceptions that were perhaps unavoidable in a first edition, free from errors. The great value of this work is based on two facts: The individual sections are written by leading specialists and, for the first time, a complete picture is given of practically every aspect of allene chemistry. (The whole thing ought to have been published as one volume, which would undoubtedly have lowered the price.)

Even taking into account the small imperfections mentioned here, this monograph, consisting of three books can be warmly recommended to all who are concerned with or wish to be concerned with the chemistry of allenes and who require a comprehensive overview. The high price will certainly prevent many people from acquiring a personal copy; however, it ought to be available in departmental libraries to ensure its accessibility to undergraduates and graduate students alike. This work offers the specialist a solid basis, which covers all significant publications up to 1980 and from which he can research the literature of the last few years for himself. This is very necessary because we are at present in a phase of rapid development in the field of allene chemistry.

Gerhard Himbert [NB 613 IE]
Fachbereich Chemie der

Encyclopaedia of the Terpenoids. Vol. 1: A—H, Vol. 2: I—Z. By *J. S. Glasby*. John Wiley, Chichester 1982. 2646 pp., bound, £ 250.00.

The systematic coverage of the vast field of naturally occurring terpene derivatives is, without doubt, a very useful and urgent task, particularly since the work by *Devon* and *Scott* only covers the literature up to 1971. The present comprehensive summary unfortunately only covers the literature up to the end of 1979, but nevertheless includes more than 10000 compounds. It is, however, questionable whether all the substances included belong here, since substances such as thelepine, for example, are included although it can scarcely be described as a terpenoid. (Thelepine is 3′,5′,7-bromo-5-hydroxymethyl-2-spiro[benzofuran-2(3*H*),1′-cyclohexa-2′,5′-diene]-4′-one.) Furthermore, the indole alkaloids are also regarded as terpenoids, which is perhaps defensible on the grounds of their biogenesis from loganine, even though it does not seem very useful. Neither does the inclusion of substances whose structure is completely unknown seem to serve any useful purpose.

The formulas are very clearly presented and great care has been taken in the indication of stereochemistry. There

are literature references as well as spectroscopic and other data for each substance. The melting point and optical rotation are given in as far as they are available. The source plant from which the substance was isolated is also always reported. It would perhaps have been of value to have included the family as supplementary information.

The arrangement of the work is problematical. The decision was taken to list the compounds alphabetically without regard to their belonging to particular compound classes. This leads, on the one hand, to problems with the many terpenes that do not possess a trivial name and, on the other hand, makes it very difficult to search for a particular substance whose trivial name is unknown, in spite of the presence of a formula index. Since one often wishes to establish whether a certain compound is already known or not, classification according to substance type would have been very helpful.

It is only natural that a work of this magnitude should contain errors, as can be illustrated by a couple of accidentally found examples. Thujopsine and thujopsadiene lack ring three and yomogiartemine and δ-yohimbine both lack a carbon atom.

All in all this present work is a useful supplement to the somewhat out-of-date compilation of *Devon* and *Scott*. The very generous, but not very compact printing, unfortunately means that the price is relatively high, so that this "encyclopaedia" is only mainly intended for libraries.

Enrichment Techniques for Inorganic Trace Analysis. By *A. Mizuike*. Springer-Verlag, Berlin 1983. viii, 144 pp., bound, DM 72.00.

Enrichment techniques in combination with powerful detection methods are extraordinarily important for the proper and sure analysis of trace elements. It is, therefore, praiseworthy that a book devoted to this theme has been included in the informative series "Introduction to chemical laboratory practice". Starting from the increasing importance of trace elements in science and technology and the, thereby, increasing demands on trace analysis, the author, who is professor of analytical chemistry at the University of Nagoya, provides a review of the principles and methods of chemical and physical enrichment techniques for trace components in materials in various states of aggregation.

The foundation-laying introductory chapters treat the general concepts such as yield, enrichment factors and, in particular, the most important sources of systematic errors, that is, contamination and loss of material. Sensible and practical suggestions are made for minimizing these errors, which are particularly important in ultra trace analysis.

The main portion of the book consists of the presentation of the fundamentals and application possibilities (studded with many important practical hints) of the most important "unit operations" for the enrichment of trace elements: Evaporation (from solutions, solids and molten salts), liquid-liquid extraction (in its many varieties), selective dissolution, precipitation reactions, electrochemical separation and dissolution, sorption, ion exchange and liquid chromatography, flotation, freezing-out and zone melting, filtration, centrifugation, particle removal from gases, gas separation.

Each basic operation is described in detail and its potentialities and limitations illustrated with examples. Apart from this, the author attempts to assist the reader with the solution of his own problems by including a large number of references (a total of 785 citations), many case descriptions, and individual exercises. Although this book is not a laboratory manual, I have no doubt of its usefulness for all workers confronted with practical problems in the enrichment of trace elements.

In summary, this book makes an excellent impression. It contains a wealth of information, is clearly written, comprehensive and interesting. It can be recommended without reservation not only to students and teachers but also to practical workers in the field of trace analysis.

Chemistry and Biology of β-Lactam Antibiotics. Edited by *R. B. Morin* and *M. Gorman*. Academic Press, New York 1982. Vol. 1: Penicillins and Cephalosporins. xl, 453 pp., bound, $ 73.00; Vol. 2: Nontraditional β-Lactam Antibiotics. xii, 408 pp., bound, $ 64.00; Vol. 3: Biochemistry. xiv, 424 pp., bound, $ 64.00.

In 1982, ten years after the monograph "Cephalosporins and Penicillins" edited by *E. H. Flynn* and published in 1972, a new three volume work was published, which summarizes in about 1300 pages the enormous advances that have been made in the intervening period in the field of β-lactam antibiotics.

The work, which is dedicated to the memory of *R. B. Woodward*, begins with the personal reminiscences of *Abraham* on the developments in penicillins and in his main field of cephalosporins.

In the first volume *Cooper* and *Koppel* treat penicillin sulfoxides comprehensively, while *Kukolja* and *Chauvette* discuss modifications at the 3-position of cephalosporins, and *Gordon* and *Sykes* deal with the cephamycin antibiotics. *Webber* and *Wheeler* survey the antimicrobial and pharmacokinetic properties of the newer penicillins and cephalosporins, particularly those of the third generation. The first volume concludes with an interesting chapter by *Boyd* covering theoretical and physicochemical studies of β-lactam antibiotics.

In the second volume *Nagata, Narisada* and *Yoshida* discuss the partial synthesis of cephalosporin analogues with modified nuclei, particularly the synthesis of the highly biologically active 1-oxocephems. *Holden* describes progress in the total synthesis of penicillins, cephalosporins and their analogues with nuclear modifications. *Kamiya, Aoki* and *Mine* discuss the new monocyclic nocardicins which are active against gram-negative bacteria; their synthesis is also covered. *Ratcliffe* and *Albers-Schönberg* discuss the chemistry of the new thienamycins and other carbapenem antibiotics, while the penems, which were first studied intensively at the Woodward Institute in Basle, are discussed by *Ernest*. The second volume concludes with a review by *Cherry* and *Newall* of the chemistry and chemical modification of clavulanic acid, a highly active inhibi-

tor of β-lactamases which has a synergetic effect, e.g. in combination with ampicillin and cephaloridin.

In the third volume *Queener* and *Neuss* discuss the biosynthesis of β-lactam antibiotics; *Elander* and *Aoki* cover the β-lactam-producing microorganisms, while *Sykes* and *Bush* outline the physiology and biochemistry of β-lactamases and their deactivation, e.g. by clavulanic acid. *Waxman* and *Strominger* summarize present knowledge concerning biochemical mechanisms of the biological action of the β-lactam antibiotics, while *Kammer* attempts to cover the overwhelming importance of β-lactam antibiotics to present-day clinical medicine in only 13 pages. *Schockman, Daneo-Moore, McDowell* and *Wong* complete the third volume with a survey of the relationship between the inhibition of cell wall synthesis and the lethality towards bacteria.

Then follows a chapter by *Koster, Cimarusti* and *Sykes*, which evidently belongs to Volume 2, concerning the new monocyclic monobactams, which are largely resistant to β-lactamases and are often highly active against gram-negative bacteria.

An appendix lists all β-lactam antibiotics that are currently commercially available.

Finally, exact experimental details are given for the difficult and interesting introduction of the 7-methoxy group into cephalosporins, the total synthesis of amino-β-lactams, and the cell-free enzymatic conversion of penicillin N into cephalosporins.

The authors from many industrial organizations and several universities provide a very good survey of the whole field, the importance of which for the control of infectious diseases cannot be overestimated. These volumes are also a treasure chest for the nonspecialist—for everyone who, for example, is concerned with the total synthesis and modification of natural products, for the sulfur chemist (cf. the chapter by *Cooper* and *Koppel* on penicillin sulfoxides), or for biochemists and microbiologists. The volumes are carefully printed and bound and largely free from errors. Unfortunately the quality of reproduction of the numerous chemical formulas, which seem in part to have been provided by the authors and directly reproduced, is variable.

Taken as a whole the work is to be recommended to all natural product and sulfur chemists and, of course, all libraries should acquire it.

Schering AG, Berlin

Electron and Ion Microscopy and Microanalysis. By *L. E. Murr*, Marcel Dekker, Basel, 1982. xiv, 793 pp., bound, SFr. 185.00.

This book is an extension and revision by the author himself of his book "Electron Optical Applications in Material Science" published in 1970. The present work addresses two groups: First, university lecturers and advanced students who teach or take part in courses on electron and ion microscopy, electron and ion microscopical applications, or microanalysis. The presentation of all of the material would take up at least two semesters. A suggestion for distributing the material among individual lectures and laboratory demonstrations is given at the end of the book and offers a framework that can, if necessary, be supplemented.

The second group addressed consists of scientists and engineers in the various disciplines of materials science—physicists, chemists, metallurgists, ceramists—who wish to characterize materials by electron- and ion-microscopy. One of the major concerns of the author has been to create an awareness of the diversity of available investigation techniques, discussing their advantages and disadvantages, pointing out differences, and giving reasons for difficulties of interpretation.

The author describes all the relevant techniques that are known: conventional transmission electron microscopy at medium and high voltages, scanning transmission electron microscopy and scanning transmission ion microscopy, X-ray microscopy, emission microscopy using photo and field electron emission, and field ion microscopy. He compares the suitabilities of one-stage, two-stage and extraction replicas for the representation of surfaces with reflection electron microscopical imaging and the various methods of operating surface scanning electron microscopes or the information capabilities of electron mirror microscopes. He treats electron diffraction with slow and fast electrons, as well as channelling and Kikuchi diagrams. Just as complete is his discussion of microanalysis with electron, ion or atom probes: the spectroscopy of characteristic X-rays (both wavelength and energy-dispersive), Auger and photoelectrons, electron energy loss spectrometry and the mass spectrometry of scattered or secondary ions.

The basic theory is treated thoroughly and comprehensively, without becoming either too theoretical or too general; the immediate relevance to practice is always emphasized. Nevertheless, this is not simply a book concerned with the description of instruments; the methods of operation and the properties of the instruments and their components are described only so far as is necessary for judging their applicability to the solution of a particular problem. The text is supplemented by numerous electron micrographs from many areas of application and by many carefully thought-out and very clear drawings.

For a complete understanding of the bulk of the book, the reader should have a mathematical background equivalent to that required in engineering courses, including differential equations and matrix algebra.

At the end of each chapter the reader will find a number of exercises suitable for testing the level of understanding he has reached. This is particularly useful for those who wish to engage in private study. The exercises cover just those problems which confront the practitioner daily, so that everyone will enjoy working through them. The author provides solutions at the end of the book.

Each chapter contains a list of references cited in the text and, separately, suggestions for supplementary reading (the wide range of material, of course, precludes any possibility that the list is exhaustive).

An appendix deals with the basic theory of crystallography, which is necessary for the understanding of several sections and knowledge of which has been assumed. Also in the appendix there is a compilation of the most usual methods of sample preparation. The included computer programs for the analysis of diffraction diagrams and the tables of material data will be accepted as welcome aids by the practicing scientist and engineer.

Analysis of Enzyme Structure and Activity by Protein Engineering**

By Alan R. Fersht*, Jian-Ping Shi, Anthony J. Wilkinson, David M. Blow, Paul Carter, Mary M. Y. Waye, and Greg P. Winter

Structure-activity relationships of enzymes can now be analyzed for the first time by the systematic alteration of protein structure. Recent developments in the chemical synthesis of DNA fragments and recombinant DNA technology enable the facile modification of proteins by highly specific mutagenesis of their genes. Kinetic analysis of the mutant enzymes combined with high-resolution structural data from protein X-ray crystallography allow direct measurements on the relationships between structure and function. In particular, the strength and nature of enzyme-substrate interactions and their detailed roles in catalysis and specificity can now be studied. We have developed such analysis of enzyme structure-function by site-directed mutagenesis of the tyrosyl-tRNA synthetase from *Bacillus stearothermophilus*, concentrating so far on the subtle role of hydrogen bonding in both substrate specificity and catalysis. We find that the energetics of tyrosine and ATP binding must be analyzed in terms of an exchange reaction with solvent water. Based on this idea and structural data, we have engineered an enzyme of improved enzyme-substrate affinity, and there thus appear to be real prospects of engineering proteins of new specificities, activities, and structural properties. We are also using protein engineering to gather direct information on the nature of enzyme catalysis. For example, we find the catalysis of formation of Tyr-AMP from Tyr and ATP is due largely to electrostatic and hydrogen bonding interactions that are stronger in the transition state than in the ground state—a "strain" mechanism rather than acid-base or covalent catalysis.

1. Introduction

The study of enzymes has been revolutionized by two major developments: knowledge of three-dimensional protein structure from X-ray protein crystallography and the ability to produce large quantities of sometimes otherwise inaccessible enzymes by genetic engineering. These methods are now being combined to produce enzymes having novel properties by the new discipline of "protein engineering".

Protein crystallography has provided, over the past twenty years, the necessary structural information for modifying enzymes, but the ability to change structure has been the stumbling block to producing new enzymes. Although there have been some isolated examples of synthesizing enzymes de novo by classical peptide synthesis, this procedure is too laborious and too limited to be of general use for producing novel enzymes. Further, synthetic proteins often do not fold into their native structures. The logical way to tackle the problem of protein synthesis is to copy nature and work at the level of DNA: DNA is the natural

[**] The review article is based on a lecture presented at The Third European Symposium on Organic Chemistry (ESOC III) in September, 1983. This work was supported by the Medical Research Council of the UK.

genetic material and can be used indefinitely to generate more supplies of protein; the simple rugged structure of DNA causes no problems of folding; DNA may be mutated and recombined in vitro to generate novel genes in a way analogous to the generation of new structures during evolution. This process of producing new activities by mutation of existing structures is how the problem of producing novel enzymes is presently being approached. Although it is not yet possible to design new enzymes ab initio, since the rules governing the folding of protein chains are not sufficiently well understood, it is possible to make variations on existing structural themes by controlled mutation of the gene encoding the relevant protein. In this article, we outline the results obtained from experiments on one particular enzyme and indicate the diversity and wealth of information that can be obtained on enzymes and enzymic catalysis.

2. Oligodeoxynucleotide-Directed Mutagenesis

The current method of generating specific mutations in DNA uses a chemically synthesized fragment of DNA that directs the mutation—oligodeoxynucleotide-directed mutagenesis. The mutator DNA fragment contains the codon (or its complementary codon) for the amino acid that is to replace the target amino residue in the native protein. The procedure was introduced in 1973[1]. The determination of the DNA sequence of a bacteriophage (ΦX174) by *Sanger*'s laboratory in 1976–1978[2] enabled the method to be put into practice. Oligodeoxynucleotide-directed mutagenesis was used in 1978 to create point mutations in bacteriophage ΦX174[3,4], and has subsequently been fashioned into a precision tool[5]. At the end of 1982, three papers were published reporting, for the first time, the site-directed mutagenesis of amino acid residues in the structural genes of enzymes of defined mechanism[6,7,8]. One of these examples involved an enzyme of known three-dimensional structure, the tyrosyl-tRNA synthetase from *Bacillus stearothermophilus*[6], and so it was possible to analyze the results in terms of structure and to initiate a systematic programme for dissecting the structure and activity of an enzyme.

The method of mutating amino acid residues in the tyrosyl-tRNA synthetase is illustrative[6,9] (Fig. 1). The gene coding for the enzyme was cloned into the bacteriophage vector M13 (this is a single-stranded DNA bacteriophage and is thus ideal for several of the following manipulations); a short oligodeoxynucleotide primer (12 to 20 residues) was synthesized that is complementary to the sequence of the DNA to be mutated, apart from a single mismatch; the mismatch was designed to convert the codon for the target amino acid into that for the desired mutant amino acid residue; the oligodeoxynucleotide was an-

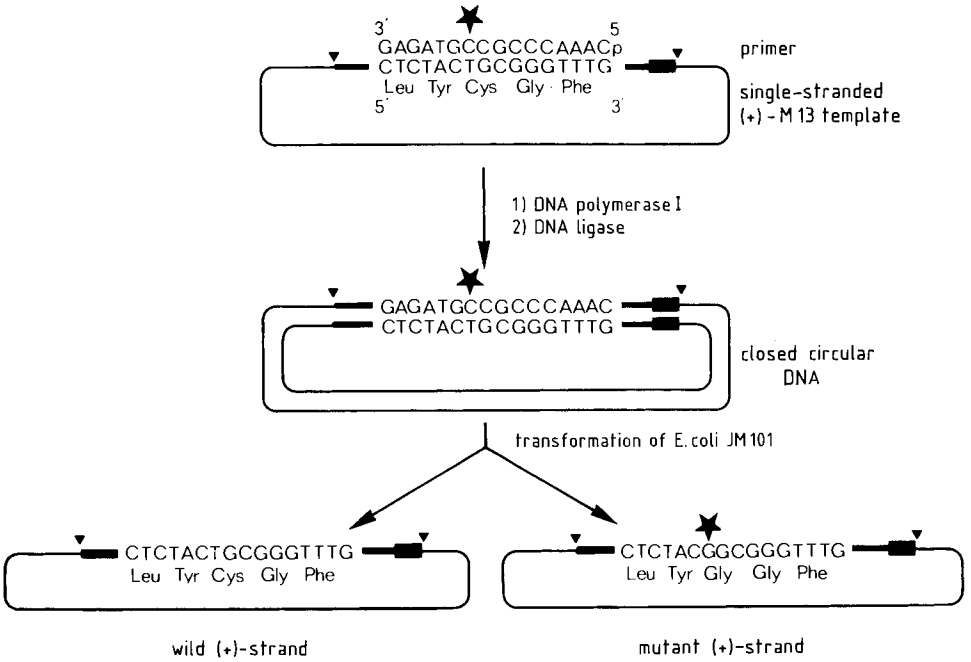

Fig. 1. Schematic representation of oligodeoxynucleotide-directed mutagenesis. The mismatched primer is designed to convert the codon for cysteine (TGC) into that for glycine (GGC). The gene for mutation must be obtained in the form of single-stranded DNA before the primer can be annealed. This was done for the tyrosyl-tRNA synthetase gene by subcloning it from the plasmid pBR322 into bacteriophage M13, a parasitic bacteriophage that does not destroy its host. ▼ Indicates the limits of the insert; the thickened line indicates the *B. stearothermophilus* DNA; ■, the portion of pBR322. The genome of this filamentous bacteriophage is a covalent circle of single-stranded DNA that becomes a covalent double-stranded circle (termed RF) during its replication in *E. coli*. The subcloning is performed on the double-stranded form, and the mutation on the single-stranded. A mutant gene is formed by copying the DNA of the bacteriophage and cloned gene from the 3′ end of the mismatched primer using DNA polymerase and ligating to the 5′ end with DNA ligase. The resultant heteroduplex is introduced into *E. coli* (strain JM101 in this case) to yield clones of cells; some contain the bacteriophage with the gene for the wild-type enzyme, others the gene for the mutant. The clones may be screened as described in the text. The clones produce large quantities of tyrosyl-tRNA synthetase. For further details see [6, 9].

nealed to the single-stranded DNA and used as a primer for replication catalyzed by a DNA polymerase; the new strand was ligated using DNA ligase to produce a heteroduplex of wild-type and mutant DNA; host cells of *Escherichia coli* were transformed by the heteroduplex to give clones containing mutant or wild-type vector. Mutant clones were identified using the ^{32}P-labeled mutagenic primer as a probe in a hybridization assay, since it binds preferentially to the mutant DNA[10]. The frequency of mutants varies from 1 to 50%. Mutant enzymes are produced in high yield from the clones.

Oligodeoxynucleotide mutagenesis has been extended to make deletions and insertions of sequences. For example, a mutator DNA fragment containing an additional codon somewhere in its middle anneals to the target with the three additional bases looping out. After replication, the synthetic strand contains the extra codon. Conversely, a longer primer, e.g. a 24-mer, may be synthesized in which the first 12 residues are complementary to one region of the gene and the other 12 to a distal region. On annealing the primer to the gene, the intervening section of the gene is looped out. After replication, the synthetic strand lacks the looped-out section. There are also more sophisticated methods of causing deletions[11].

3. The Tyrosyl-tRNA Synthetase from *B. stearothermophilus*

The enzyme studied most extensively so far by oligodeoxynucleotide-directed mutagenesis is the tyrosyl-tRNA synthetase (TyrTS)[*] from *B. stearothermophilus*. To date, we have prepared and analyzed some 20 mutants involving single mutations, double mutations, and extensive deletions.

This enzyme catalyzes the aminoacylation of $tRNA^{Tyr}$ in a two-step reaction [eqs. (a) and (b)][12].

$$E + Tyr + ATP \longrightarrow E\cdot Tyr\text{-}AMP + PP_i \quad (a)$$

$$E\cdot Tyr\text{-}AMP + tRNA^{Tyr} \longrightarrow Tyr\text{-}tRNA^{Tyr} + AMP + E \quad (b)$$

It is a symmetrical dimer of $M_r = 2 \times 47\,500$[13,14]. The nucleotide sequence of the gene has been determined from a clone in the vector pBR322[15]. X-ray crystallographic studies on the enzyme at 0.3 nm resolution have been published (Fig. 2)[16a], and in subsequent work refinement has been extended to a nominal 0.21 nm[16b]. Most importantly, the crystal structure of the enzyme-bound tyrosyl-adenylate complex has also been solved[17] so that there is the rare opportunity of direct knowledge of the interactions of the enzyme with a substrate (Fig. 3).

Aside from this, the tyrosyl-tRNA synthetase has convenient kinetic properties that render it a suitable target for mutagenesis studies: the enzyme is readily assayed by active-site titration, and hence accurate and reproducible steady-state kinetic measurements may be made[18]; the partial reaction of activation [eq. (a)] and the overall charging reaction are readily determined by straightforward assays; the pre-steady state kinetics of activation may be followed by stopped-flow fluorescence studies[19] and those of the transfer step [eq. (b)] by rapid quenching methods[12]. The enzyme also has interesting properties since it is a dimer. Kinetic studies show that the two active sites interact so that in solution[20] only one tyrosine as well as one $tRNA^{Tyr}$[21,22] and one tyrosyl adenylate are bound tightly per two active sites[23].

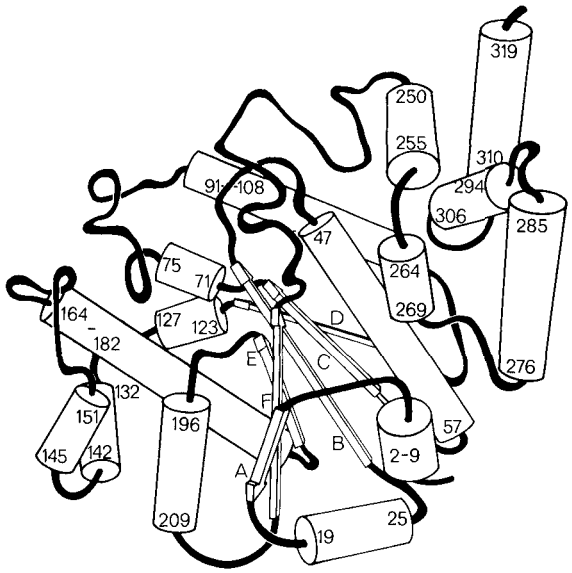

Fig. 2. Crystal structure of one of the symmetrical subunits of the tyrosyl-tRNA synthetase. Note that the tyrosyl adenylate (see Figs. 3 and 4) makes hydrogen bonds with side chains from the helices spanning residues 47–57 and 164–182, and the strand of β-sheet B.

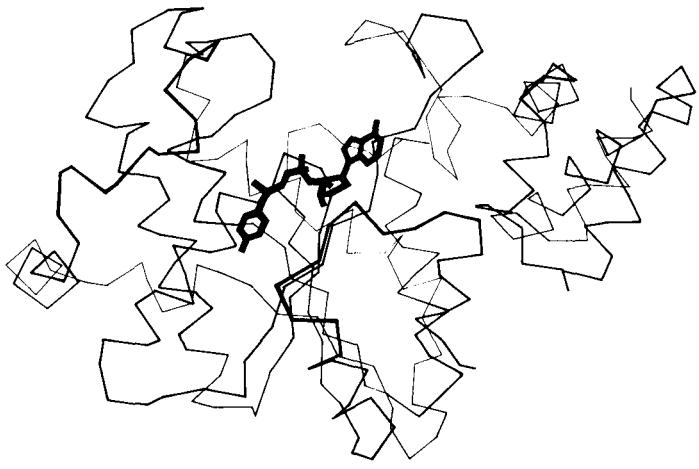

Fig. 3. Tyrosyl-tRNA synthetase forms a stable, enzyme-bound tyrosyl adenylate complex. On addition of tyrosine and ATP to the crystals of the enzyme, they first crack and then reanneal to produce the intermediate which is stable in the absence of tRNA or high concentrations of pyrophosphate. The sketch shows the backbone of the enzyme and the bound substrate which were determined directly by X-ray diffraction studies.

The tyrosyl-tRNA synthetase from *B. stearothermophilus*—a thermophilic organism—has one further very important property: the enzyme is thermostable and loses no activity on prolonged incubation at 56 °C, unlike the enzyme from *Escherichia coli* which is rapidly denatured. As the mutant tyrosyl-tRNA synthetases used in the studies

[*] Abbreviations: TyrTS = tyrosyl-tRNS synthetase; mutants are indicated thus: TyrTS(Cys35-Ser35) = TyrTS containing the mutation Cys-35 to Ser-35; k_{cat} and K_M are the catalytic and Michaelis constants, respectively, in the Michaelis-Menten equation.

are produced from the clones in *E. coli*, provided the mutation does not reduce thermostability, any background native enzyme from *E. coli* can be readily removed by heating. Thus, weakly active mutants may be studied without interference from active native enzyme.

4. Strategy for Studying Structure-Activity Relationships

The utilization of binding energy is at the heart of enzyme catalysis and specificity. There is a simple equation relating the rate constant k_{cat}/K_M of the Michaelis-Menten equation to the binding energy of the enzyme and substrate[24,25] [eq. (c)]

$$RT\ln(k_{cat}/K_M) = RT\ln(kT/h) - \Delta G^{+} - \Delta G_s \qquad (c)$$

where ΔG_s is the binding energy between the enzyme and substrate, ΔG^{+} is the energy of activation, and k and h are the Boltzmann and Planck constants, respectively.

Using site-directed mutagenesis, we are able to alter the binding energy term ΔG_s by changing the side chains of the amino acid residues that interact with the substrate. The changes in binding energy may be calculated from k_{cat}/K_M using eq. (c) and the importance of the interaction evaluated. This provides an experimental means of measuring ΔG_s for the interactions. Theoretical considerations[24,25] show that reaction rate is optimized when the binding energies of these interactions are realized in the enzyme-transition state complex rather than the enzyme-substrate complex—the concept of transition-state stabilization. Furthermore, hydrogen bonds should be particularly important in mediating such differential binding effects because the strength of hydrogen bonding varies strongly with interatomic distance and hence is sensitive to the movement of atoms during the reaction. Accordingly, the initial strategy of our experiments was to alter residues that form hydrogen bonds with the substrates.

5. Nature of Hydrogen Bonding of Enzymes with Substrates

The mutation of Cys-35 to Ser-35 in tyrosine-tRNA synthetase was the very first experiment in which a residue at the active site of an enzyme of known three-dimensional structure was specifically mutated by protein engineering, leading to an enzyme of altered activity[6]. As shown in Figure 4, Cys-35 forms a hydrogen bond with the 3′-hydroxyl of the ribose moiety of Tyr-AMP. The mutation experiment changes −SH to −OH in the amino acid side chain. Although the *absolute* strength of the hydrogen bond −OH···O− is greater than that of −SH···O− in simple intermolecular associations, it is found on comparing the wild-type TyrTS with the mutant TyrTS(Cys35-Ser35) (Table 1) that the former enzyme has a higher affinity (1.2 kcal mol^{-1}) for the ATP substrate [calculated from eq. (c)]. There are two reasons for this:

1) It is not the absolute strength of a hydrogen bond in an enzyme-substrate complex that affects the enzyme-substrate dissociation constant that is important; rather it is

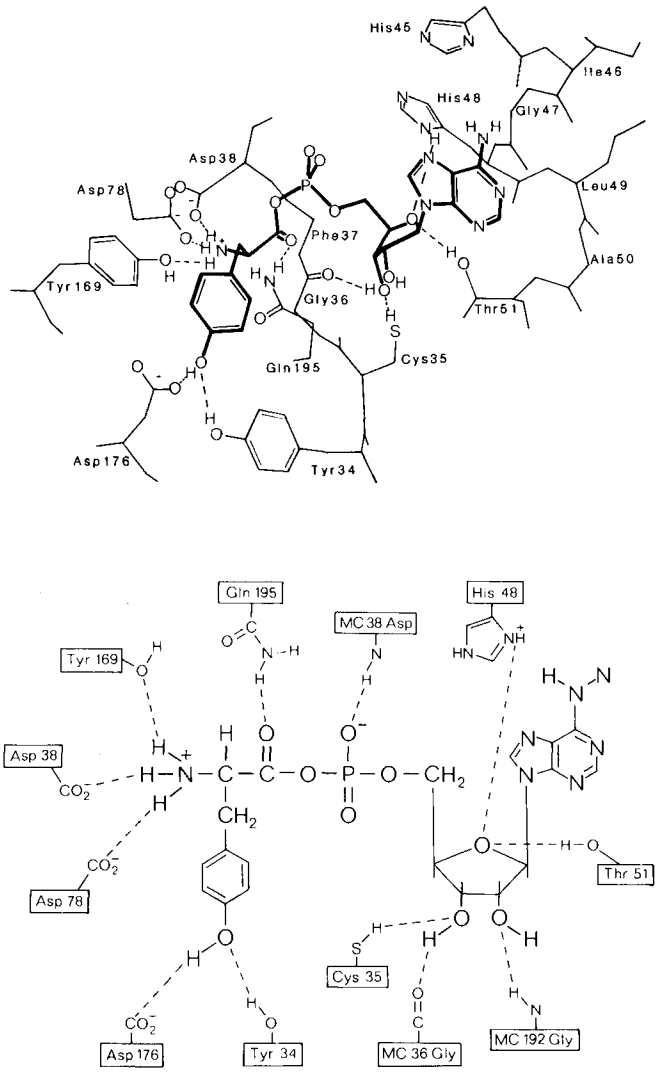

Fig. 4. Active site of the tyrosyl-tRNA synthetase with the bound tyrosyl adenylate. Top: an expanded and more detailed view of Figure 3. Bottom: schematic sketch of residues that probably form hydrogen bonds. These interactions are tentative at the resolution of the structure, but most have now been confirmed by site-directed mutagenesis.

Table 1. Activation of tyrosine by TyrTS-wild type and mutants at 25°C (details see [9]).

Enzyme	k_{cut} [s^{-1}]	K_M (ATP) [mM]	K_M (Tyr) [μM]	k_{cat}/K_M (ATP) [$s^{-1}\,M^{-1}$]
TyrTS	7.6	0.9	2.4	8400
TyrTS(Cys35-Gly35)	2.8	2.6	2.7	1120
TyrTS(Cys35-Ser35)	2.4	2.4	2.6	1000

the *difference* in energies of the hydrogen bond donor/acceptor in the free enzyme and the acceptor/donor in the free substrate when they are separately hydrogen-bonded to solvent water relative to the situation when they are hydrogen-bonded to each other [eq. (d)]:

$$E\cdots OH_2 + S\cdots HOH \longrightarrow E\cdots S + HOH\cdots OH_2 \qquad (d)$$

2) There are geometrical constraints on hydrogen-bond formation in enzyme-substrate complexes because the donor and acceptor groups are held at fixed distances from each other. For example, the S–O distance in SH···O

bonds is 0.5 nm longer than the O–O in OH···O. The substitution of the side-chain hydroxy group of a serine for a cysteine residue is thus energetically unfavorable because the O–O distance is too long in a rigid active site[9]. Comparison of TyrTS(Cys35-Ser35) and another mutant in which the side chain has been completely removed, TyrTS(Cys35-Gly35) (Table 1), shows that the serine side chain contributes no apparent binding energy with the substrate and, if anything, the presence of the side chain actually weakens binding.

It is concluded that the presence of a poor (too long) hydrogen bond in an enzyme-substrate complex can increase the dissociation constant and the value of k_{cat}/K_M. Perhaps the removal of a weak hydrogen bond by site-directed mutagenesis could be used to increase the affinity of an enzyme for its substrate.

6. Improving the Affinity of the Enzyme for ATP

Preliminary crystallographic studies indicated that Thr-51 makes a long hydrogen bond with the tyrosyl adenylate (Fig. 4). Furthermore, although all the other side chains illustrated in Figure 4 are conserved in the *E. coli* enzyme, it has a proline residue in this position that cannot possibly make a hydrogen bond with the substrate and will also distort the secondary structure in this region. Accordingly, in the light of the conclusion of the last section, we changed Thr-51 first to Ala-51 to determine the effect of deleting the hydrogen bond, and then to Pro-51 to examine the results of causing a larger structural change[26].

Table 2. Increase in affinity for ATP in tyrosine activation by TyrTs upon mutation of Thr-51. Reaction at 25 °C (details see [26]).

Enzyme	k_{cat} [s^{-1}]	K_M (ATP) [mM]	K_M (Tyr) [μM]	k_{cat}/K_M (ATP) [s^{-1} M^{-1}]
TyrTS	7.6	0.9	2.4	8400
TyrTS(Thr51-Ala51)	8.6	0.54	2.0	15900
TyrTS(Thr51-Pro51)	12.0	0.058	—	208000

The results for activation of tyrosine by these mutants are listed in Table 2. It is seen that the K_M for ATP of TyrTS(Thr51-Ala51) is two times lower than that of the wild type. It appears, in fact, that the interaction of threonine with the substrate is very weak and hence lowers the affinity of the enzyme for the substrate. Site-directed mutagenesis is thus a good fine-structure probe for hydrogen bonding.

Mutation of the wild type to TyrTS(Thr51-Pro51) causes a massive increase in the value of k_{cat}/K_M, involving both an increase in k_{cat} and a decrease in K_M (for ATP). Thus, engineering a single point-mutation has caused a significant improvement in enzymic activity and, hence, shows that there are real biotechnological possibilities of engineering the activities of enzymes in vitro.

What is the reason for this dramatic improvement in affinity of the enzyme for ATP? Thr-51 is located in an α-helix (amino acid residues 47–57) (Fig. 2), and the introduction of a proline would be expected to distort the helix structure between residues 47–50. The improved affinity

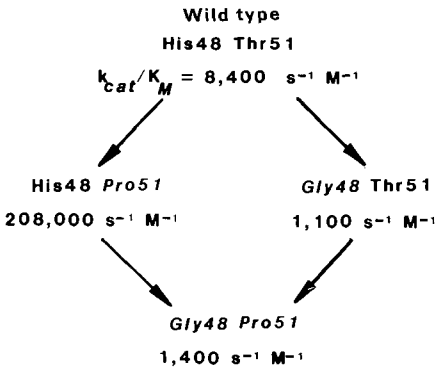

Fig. 5. Use of double mutants for investigating structural changes. (Mutated residues are shown in italics.) The high value of k_{cat}/K_M for the mutant TyrTS(Thr51-Pro51) requires the presence of both His48 *and* Pro51. If His48 is first converted into Gly48 (right), mutation of Thr51 to Pro51 to generate the double mutant TyrTS(His48-Gly48, Thr51-Pro51) at the bottom leads to little increase in the rate constant.

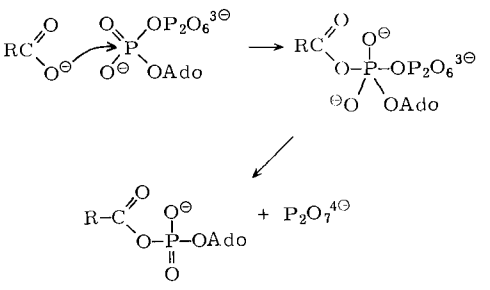
might thus result from a new contact formed between enzyme and substrate, from an improved interaction at an existing contact, or from a direct interaction of the substrate and the pyrrolidine ring of the proline. An earlier mutagenesis experiment had shown that His-48 forms an H-bond to ATP which only gains 1.2 kcal mol^{-1}. We were therefore interested whether the effect of proline was to distort the polypeptide backbone and thereby improve the interaction of His-48 with the substrate. To prove this, we constructed a double mutant TyrTS(His48,Thr51-Gly48,Pro51). This mutant has approximately the same activity as the TyrTS(His48-Gly48) mutant, indicating that the effect of Thr-51 is mediated via the imidazole group of His-48 (Fig. 4). From the cycle shown in Figure 5, we can calculate, using equation (c), that the imidazole group of His-48 contributes 1.2 kcal mol^{-1} to binding energy in the wild-type enzyme and 3 kcal mol^{-1} in the Pro-51 mutant. This result shows how a second mutation introduced into the active site of an enzyme can be used as a probe of the structural change introduced by the first mutation.

7. Evidence for Transition-State Stabilization in the Activation Reaction

How is the attack of the tyrosyl carboxy group on ATP [eq. (a)] catalyzed? This reaction involves an associative in-line displacement of pyrophosphate from ATP [eq. (e)][27].



(e)

General base-catalysis of the nucleophilic attack is not possible since the carboxylate is fully ionized. Nucleophilic catalysis by a group on the enzyme forming an inter-

mediate with AMP is unlikely since ATP is already an "activated" compound containing a good leaving group (pyrophosphate). The remaining possibilities are electrostatic catalysis and transition state stabilization, whereby certain groups on the enzyme make stronger interactions with the substrate transition state. For transition state stabilization it is predicted that when a group on the enzyme is removed, as in a site-directed mutagenesis experiment, the affinity of the enzyme for the substrate will be decreased to some extent, but the affinity for the transition state will be decreased to a much greater extent than if the transition state had been stabilized. This means that the value of K_M may be increased to a greater or lesser extent but the value of k_{cat} will fall, as shown in Table 3. Particularly noteworthy is the change from His-45 to Asn-45 leading to a 2000-fold drop in k_{cat}, whilst the values of K_M are hardly affected (*J.-P. Shi*, unpublished). Similarly, the rate of attack of pyrophosphate on the tyrosyl adenylate complex is lowered 2000-fold in TyrTS(Hys45-Asn45) (unpublished data). His-45 does not interact with the tyrosyl adenylate in the crystal structure (Fig. 4). Model building studies by Dr. *R. J. Leatherbarrow* (unpublished) show that the γ-phosphoryl group of the pentacovalent intermediate in eq. (e) can make a hydrogen bond with His-45[*].

Table 3. Influence of various mutations on the activation of tyrosine.

Mutant	k_{cat} [s^{-1}]	K_M (ATP) [mM]	k_{cat}/K_M [s^{-1} M^{-1}]
TyrTS [a]	7.6	0.9	8400
TyrTS(cys35-Gly35) [a]	2.8	2.6	1120
TyrTS(Cys35-Ser35) [a]	2.4	2.4	1000
TyrTS(His48-Gly48) [b]	1.6	1.4	1140
TyrTS(His45-Asn45) [b]	0.003	1.0	3
TyrTS(Gln195-Gly195) [b]	0.16	2.5	64

[a] Ref. [9]. [b] Unpublished results.

Geometrical changes that occur during the activation reaction may be inferred from some of the mutations in hydrogen-bonding groups we have engineered based on the following reasoning. If an amino acid residue on the enzyme hydrogen bonds with the substrate equally well in the enzyme-transition state complex as in the enzyme-substrate complex, removal of that residue will affect only K_M and not k_{cat} (see [25] pp. 244–247). Similarly, removal of a residue that hydrogen bonds better in the enzyme-transition state complex will lower k_{cat}. We have found that k_{cat} for the activation reaction is sensitive to all changes made so far in residues that hydrogen-bond with ATP. Conversely, k_{cat} is insensitive to changing a residue that forms a hydrogen bond with the tyrosine hydroxy group (Tyr-34 to Phe-34 in Figure 4, (unpublished)). This suggests that during the activation reaction the bound tyrosine side-chain may move relatively little, but that the bound ATP moves towards the tyrosine carboxy as it makes a nucleophilic attack on the α-phosphoryl group of ATP. Since the strength of the hydrogen bonding of the enzyme with ATP increases as the transition state is reached, the enzyme must presumably be compressing the ATP and the tyrosine together.

[*] As indicated in Table 3, changes in k_{cat} and K_M may also arise from mechanisms such as "induced fit" and "non-productive binding". Because of this, the results of previous kinetic studies on structure-reactivity relationships from studies where the structure of the substrate has been altered have usually failed to provide unambiguous evidence for "strain" mechanisms (transition-state stabilization) [21]. However, the changes induced by site-directed mutagenesis of the tyrosyl-tRNA synthetase are more amenable for producing unambiguous analysis for the following reasons: 1) It will be possible to solve the structures of the native enzyme and enzyme-substrate complexes for the mutants by X-ray crystallography. 2) Many of the structural changes will be sufficiently small that the binding energetics may be calculated. Even in the absence of precise structural data, the combination of chemical intuition and inspection of the enzyme structure by computer graphics strongly suggests that transition-state stabilization by electrostatics and hydrogen bonding is operating.

8. Optimization of the Rate of Enzymic Reactions during Evolution

Various proposals have been made as to how enzymic rate constants should respond to selective pressure in evolution to maximize the overall rate of reaction[20,21,28]. One way of testing the validity of these models is by site-directed mutagenesis. Although the mutants we have generated are not necessarily the evolutionary precursors of the present native enzyme, they are possible forms of the enzyme that have been rejected during evolution, since the rate of spontaneous mutation is sufficiently high for them to have arisen and hence been tested. One simple theory for the effects of selective pressure on the evolution of maximum rate[20,21] predicts 1) that the catalytic term k_{cat}/K_M tends to a maximum (this is the consequence of the enzyme being complementary to the transition-state structure of the substrate) and 2) that values of k_{cat} and K_M tend to increase in parallel so that the value of K_M lies above the normal concentration of the substrate encountered in vivo. The net result is that the term $[S]_p k_{cat}/(K_M+[S]_p)$ is maximized in eq. (f), which gives the rate in vivo, where $[S]_p$ is the concentration of substrate in vivo. This is achieved by low-

$$v\ (\text{in vivo}) = [E]_0[S]_p k_{cat}/(K_M+[S]_p) \qquad (f)$$

ering the complementarity of the enzyme with the substrate in its unreacted structure while maintaining complementarity with the transition-state structure. Experimentally, the value of K_M for ATP in the aminoacylation reaction of native enzyme is 2.5 mM, a value close to the 2–3 mM found for the concentration of ATP found in vivo for many organisms. The full intrinsic binding energy of ATP and a protein is clearly not utilized here—the K_M for ATP and myosin is 10^{-13} M, for example[29]. In general, the values of k_{cat}/K_M for the mutants are lower than that for wild-type. The notable exception is the mutant TyrTS(Thr51-Pro51), where k_{cat}/K_M for the mutant is much higher (Table 4). However, the high value for k_{cat}/K_M is achieved by compensation of a low value of k_{cat} by a very low value of K_M for ATP. At physiological concentrations of ATP (2–3 mM), the native enzyme is more active than the mutant (as calculated by substituting the experimental values of k_{cat}, K_M, and [ATP] into eq. (f)). At lower concentrations of ATP, however, the mutant TyrTS(Thr51-Pro51) is more active. This illustrates the importance of enzymes maximizing their rate by adjusting their K_M values to the concen-

Table 4. Kinetics of the aminoacylation of tRNA [a].

Enzyme	Different ATP conc.			[ATP] [mM]

trations of substrates in vivo. One other mutant TyrTS(Thr51-Ala51) has similar activity to the native enzyme at 25°C in vitro.

9. Structural Organization of the Tyrosyl-tRNA Synthetase

The crystal structure of the enzyme consists of a well-ordered *N*-terminal domain comprising residues 1—319 that binds tyrosyl adenylate, while the remaining 100 residues of the *C*-terminus are disordered[16]. The fragment of gene coding for the *N*-terminal domain has been prepared by a gene-deletion procedure, and the truncated protein isolated[11]. The truncated enzyme is fully active in the activation reaction [eq. (a)], but does not catalyze the transfer of tyrosine to tRNA or bind Tyr-tRNA. The structural division of the tyrosyl-tRNA synthetase is thus also a functional one in which an *N*-terminal domain is responsible for amino acid activation and a *C*-terminal domain for tRNA binding. A series of more general mutational experiments on the alanyl-tRNA synthetase, an enzyme of unknown three-dimensional structure, shows that this protein also has distinct regions for activation and transfer reactions[30].

10. Summary and Outlook

Although we know from personal communications from our colleagues that many other enzymes are now being studied by oligodeoxynucleotide-directed mutagenesis, there is little published work at present relating changes in activity to changes in structure. The work on β-lactamase[7,8] cannot be extended at present because the three-dimensional structure of the enzyme is not known; however, crystallographic work is in progress. Three mutants of dihydrofolate reductase have been prepared[31], and further work is in progress by other groups. However, we anticipate that in the next year or two there will be a plethora of exciting data published.

Protein engineering appears to be the answer to an enzymologist's prayer. The prospects are quite open-ended. At the purely academic level, the relationship between structure and activity of enzymes is now being analyzed directly: in the most basic experiments, groups directly involved in catalysis are being identified; in more sophisticated experiments, the role of enzyme-substrate interactions in catalysis and specificity is being studied. Future experiments will explore long-range effects of structural changes on activity and the transmission of the effects of substrate and effector binding through protein subunits. Experiments are being planned in various laboratories to change the thermostability of enzymes and to learn the structural basis of enzyme stability. Undoubtedly, protein engineering will be used to study enzyme folding. At the commercial level, protein engineering will be used to alter the physical properties of enzymes, such as their thermostability, solubility, pH optima etc., and hence optimize their use in biotechnological processes in vitro. Protein engineering will also be used to alter kinetic properties, such as the values of k_{cat} and K_M for substrates, and to change even the specificities of enzymes. The ultimate goal is to design tailor-made enzymes for every reaction.

Organolanthanoid Compounds**

By Herbert Schumann*

Up to little more than a decade ago organolanthanoid compounds were still a curiosity. Apart from the description of an isolated number of cyclopentadienyl and indenyl derivatives, very few significant contributions had been made to this interesting sector of organometallic chemistry. However, subsequent systematic studies using modern preparative and analytical techniques, together with X-ray single crystal structure determinations, enabled the isolation and characterization of a large number of very interesting homoleptic and heteroleptic compounds in which the lanthanoid is bound to hydrogen, to substituted or unsubstituted cyclopentadienyl groups, to allyl or alkynyl groups, or even to phosphorus ylides, trimethylsilyl, and carbonylmetal groups. These compounds, which are all extremely sensitive to oxygen and water, open up new possibilities in the field of catalysis and have great potential in organic synthesis—as recent studies with pentamethylcyclopentadienyl derivatives, organolanthanoid(II) compounds, and hexamethyllanthanoid complexes have already shown.

1. Introduction

"Those elements whose valence electrons possess the same principal quantum number yield typical alkylelement compounds; all other elements which do not comply with this condition are not able to form such compounds". With this statement, which he made in 1926, *Aristid von Grosse* contested the ability of the transition metals as well as the lanthanoids to form stable organometallic compounds[1].

This postulate was based on the knowledge that a main group element forms stable compounds if its valence shell, consisting of s and p orbitals and covering completely occupied inner shells, acquires a total of eight electrons. To achieve such a stable noble-gas configuration, the transition metals require 18 electrons, while the lanthanoids and actinoids require as many as 32 electrons of different principal quantum numbers. Hence, all compounds which do not fulfill this requirement are unstable to a greater or less extent, but, at the same time, highly chemically reactive. The first example of a transition metal-to-carbon σ bond was demonstrated in an organotitanium compound in 1952[2].

The first indication of the existence of organolanthanoid compounds was furnished by the observation that methyl radicals react with lanthanum[3]. The reputed synthesis of triethylscandium and triethylyttrium, the first alkyl derivatives of the "rare earth metals", however, proved to be erroneous[4]. All the attempts made by *Gilman* et al. to prepare the first phenyllanthanum derivative, in connection with the separation of ^{235}U from ^{238}U via volatile uranium compounds, also met without success. Both the reaction of lanthanum trichloride with phenyllithium as well as that of lanthanum with diphenylmercury furnished only biphenyl[5].

The major breakthrough in organo-transition metal chemistry followed the discovery of ferrocene and other sandwich complexes in the second half of the 20th century. For instance, in their search for π-complexes of the lanthanoids in 1954, *Wilkinson* and *Birmingham* were able to synthesize the first tricyclopentadienyl derivatives of scandium, of yttrium, and of almost all of the other lanthanoids[6]. Fourteen years later, the first indenyl derivatives[7] and, in 1969, the first cyclooctatetraene complexes were described[8]. There then followed, in 1968/1970, the synthesis of triphenylscandium[9] and of lithium tetraphenyllanthanate(III) and praseodymate(III), the first homoleptic compounds of the lanthanoids[10]. However, it was not until the late seventies that these compounds became known on a broad front. Nowadays, numerous teams of chemists all around the world are engaged in studies relating to these new compounds and their fascinating properties.

The present article reviews two important aspects of this area of chemistry: 1) The methods which have proven most successful for the preparation of organolanthanoid compounds, and 2) the molecular structures of these compounds. For completeness, the derivatives of scandium and yttrium are also taken into consideration. Finally, the increasing importance of these compounds in preparative organic chemistry is outlined.—A number of review articles covering this field of chemistry have been published in recent years. Three of them, which reflect the latest state of research in more detail than is possible here, should be given special mention[11-13].

2. Organometallic Compounds with Lanthanoids in the Oxidation State +3

2.1. Tricyclopentadienyllanthanoid Compounds

The tricyclopentadienyl complexes of the lanthanoids were the first organometallic compounds of these "inner"

[**] In this review article the types of compounds have been numbered systematically; lower case letters after the numbers signify the respective metal that is present: **a** stands for Sc, **b** for Y, **c** for La, ... **r** for Lu (see, e.g., Table 1). Ln signifies Sc, Y, La—Lu. Cp means cyclopentadienyl, as well as with substituents.

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/0707-0474 $ 02.50/0

transition elements to be prepared and have remained, until this day, the most intensively investigated derivatives. They are best prepared by the reaction of sodium cyclopentadienide **1** or potassium cyclopentadienide **2** with anhydrous lanthanoid trichlorides **3** in tetrahydrofuran (THF) under an inert gas[6,14]. The pure, THF-free compounds, $(C_5H_5)_3Ln$ **4**, are isolated by sublimation of the crude products in a high vacuum at temperatures above 200°C. Only in the case of the thermally sensitive $(C_5H_5)_3Eu$ **4i** are difficulties encountered with the removal of THF. These difficulties can, however, be overcome, either by using benzene as solvent[14] or, as could be shown in the preparation of **4i** from $C_5H_5EuCl_2\cdot(THF)_3$ **5i** and **1** in THF, by taking special care during the removal of THF[15]. The synthesis of the radioactive species $(C_5H_5)_3Pm$ **4g** was accomplished by reaction of $PmCl_3$ **3g** with molten $(C_5H_5)_2Be$ or $(C_5H_5)_2Mg$[16,17]. Compound **4g** had already been detected in 1967 in the matrix of $(C_5H_5)_3Nd$ **4f** after bombardment with neutrons[18].

Lu	**4r**	colorless	264	[a]	[14]

[a] Diamagnetic.

All compounds **4** are air- and moisture-sensitive. Their colors, melting points, and magnetic moments are summarized in Table 1. Various spectroscopic investigations suggest strong ionic bonding between the lanthanoids in the oxidation state +3 and the negatively charged cyclopentadienyl ligands[19]. X-ray structure analyses of solvent-free **4a**[20] and **4h**[21] revealed the presence of chains in which di(η^5-cyclopentadienyl)lanthanoid units are bridged by the remaining C_5H_5 ligands, which, in turn, are η^5-bound to one lanthanoid atom and η^1-bound to the next. $(CH_3C_5H_4)_3Nd$ **6f** is tetrameric, but with the same arrangement of the rings within the crystal[22]. The structure of $(C_5H_5)_3Pr$ **4e** (Fig. 1) consists of a uniform polymer-chain with three η^5-coordinated cyclopentadienyl rings and one η^2-coordinated bridging ring for every Pr atom, thus resulting in a formal coordination number 11 for praseodymium[23].

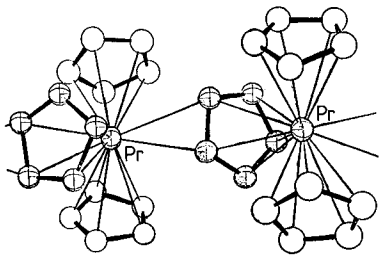

Fig. 1. Structure of $(C_5H_5)_3Pr$ **4e** in the crystal [23].

The unsaturated character of the compounds **4**, which is reflected in their structures, is also manifested in their behavior towards coordinating solvents such as THF[24-31], ammonia[6,26], pyridine[32], isocyanides[25,33,34], and phosphanes[25,35]. With these solvents they form remarkably stable 1:1 complexes in which the solvent molecule is bonded to the metal via oxygen, nitrogen, carbon, or phosphorus. As before, the three C_5H_5 rings are η^5-bonded. The compounds **4** also behave as Lewis acids towards phosphorus ylides[36] and carbonyl- or nitrosyl-complexes of the transition metals[37].

Only two substituted cyclopentadienyl ligands have so far been used successfully for the synthesis of triorganyllanthanoid compounds. Tris(methylcyclopentadienyl)metal compounds **6** of practically all lanthanoids can be obtained[28,37-40]. Furthermore, La, Pr and Nd form compounds of the type $(i\text{-}C_3H_7C_5H_4)_3Ln$ **7**[41]. With more bulky ligands, such as the pentamethylcyclopentadienyl, the trimethylsilylcyclopentadienyl, or even the bis(trimethylsilyl)cyclopentadienyl moiety, only the disubstituted derivatives could be obtained.

2.2. Cyclopentadienyllanthanoid Halides $(C_5H_5)_2LnCl$ and $C_5H_5LnCl_2\cdot(THF)_3$

A key role in the synthesis of organolanthanoid compounds with η^1-bonded organyls is played by the cyclopentadienyllanthanoid halides. The first species of type **8** were obtained by reaction of the lanthanoid trichlorides **3** with **1** in the molar ratio 1:2 or by comproportionation between **3** and **4**[42].

$$\underset{\mathbf{3}}{LnCl_3} + 2\,\underset{\mathbf{1}}{C_5H_5Na} \xrightarrow{THF} \underset{\mathbf{8}}{(C_5H_5)_2LnCl} + 2\,NaCl$$

Ln = Y (**8b**), Sm (**8h**), Gd (**8k**), Tb (**8l**), Dy (**8m**), Ho (**8n**), Er (**8o**), Tm (**8p**), Yb (**8q**), Lu (**8r**)

$$\underset{\mathbf{3}}{LnCl_3} + 2\,\underset{\mathbf{4}}{(C_5H_5)_3Ln} \xrightarrow{THF} 3\,\underset{\mathbf{8}}{(C_5H_5)_2LnCl}$$

Ln = Sm (**8h**), Gd (**8k**), Dy (**8m**), Ho (**8n**), Er (**8o**), Yb (**8q**)

$(C_5H_5)_2ScCl$ **8a** has been prepared from **3a** and $(C_5H_5)_2Mg$[43], while **8h** and **8q** were respectively obtained from **4h** and **4q** and NH_4Cl in benzene[44]. The cleavage of one Ln–C bond of the tricyclopentadienyllanthanoids **4**

by HCl has also been used for the synthesis of several of the species **8**[42]. With the exception of **8c**, **8d**, **8e**, **8f**, and **8g** all other compounds of this type could be isolated. In THF they form 1:1 complexes, $(C_5H_5)_2LnCl\cdot(THF)$ (**9**)[45-47], whereas in benzene solution or in the solid state the compounds form dimers in which the metal atoms are bridged by two chlorines, as could be deduced from the results of the X-ray structure analysis of **8a** (Fig. 2)[48]. Because of the larger ionic radii of the lighter lanthanoids La to Pm, a coordinative saturation of the metal will obviously not be reached with such a structure, thus making the isolation of these compounds from solutions impossible.

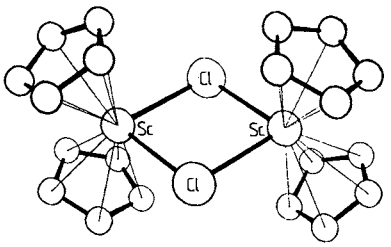

Fig. 2. Molecular structure of $[(C_5H_5)_2ScCl]_2$ **8a** in the crystal [48].

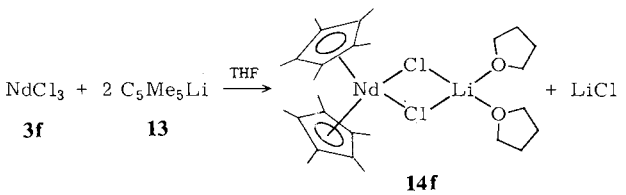
This situation changes if substituted cyclopentadienyl ligands are used. Although the only compounds of the type $(CH_3C_5H_4)_2LnCl$ **10** known so far are those from **10m**[37,42,49] onwards (there have been no reports concerning the corresponding derivatives of the remaining metals **a** to **l**), the observation that bis(pentamethylcyclopentadienyl)neodymium chloride **11f**[50] is an extremely stable compound which does not melt below 220°C, and the fact that the series of compounds of the type $[(Me_3Si)_2C_5H_3]_2LnCl$ **12**[51] is almost complete, unequivocally demonstrate the high screening effect of these bulky, substituted cyclopentadienyl ligands. Hence, compounds of the type Cp_2LnCl should also be stable in the case of the lighter metals.

The tendency of these metals to favor higher coordinative saturation leads to the compounds forming complexes with alkali metal halides[50,52-54] in which the lanthanoid and the alkali metal are bridged twice, in each case by an halogen atom, and in which the alkali metal is electronically further saturated by additional donor molecules such as THF or ether. An example is **14f**.



At this point two reactions should be mentioned. Firstly, the oxidation of $(C_5Me_5)_2Yb\cdot(dme)$ **15q** with $[(C_5H_5)_2Fe][PF_6]$, which leads to purple crystals of the composition $(C_5Me_5)_2YbPF_6\cdot(dme)$ **16q**[53], and, secondly, the reaction of ether-free $(C_5Me_5)_2Yb(\mu\text{-}Cl)_2Li$ **17q** with Al_2Cl_6, leading to the blue complex $(C_5Me_5)_2Yb(\mu\text{-}Cl)_2\text{-}AlCl_2$ **18q**, which loses aluminum chloride in THF and is converted into the complex $(C_5Me_5)_2YbCl\cdot(THF)$ **19q**[53] (dme = dimethoxyethane).

The use of the bis(trimethylsilyl)cyclopentadienyl ligand, introduced into synthesis by *Lappert* et al.[51,55], also enables the preparation and isolation of diorganometal chlorides **12**, even of the lighter lanthanides. Almost all lanthanoid trichlorides **3** react with bis(trimethylsilyl)cyclopentadienyl lithium **20** in THF to give complexes of the type $[(Me_3Si)_2C_5H_3]_2Ln(\mu\text{-}Cl)_2Li(THF)_2$ **21**, which decompose above 140°C with formation of the solvent-free derivatives **22**.

The X-ray structure analysis of **12e** as well as those of the isostructural scandium and ytterbium compounds, **12a** and **12q**, respectively, confirm the dimeric nature of the molecules with distorted tetrahedral ligand coordination around each lanthanoid atom. These dimers react with compounds RCl (R = large cation) to give very stable ionic complexes **23**—**26**[56,57].

$$RCl + 1/2\{[(Me_3Si)_2C_5H_3]_2LnCl\}_2 \rightarrow R^{\oplus}\{[(Me_3Si)_2C_5H_3]_2LnCl_2\}^{\ominus}$$
12 **23—26**

$R = N(PPh_3)_2$, Ln = Y (**23b**)
$R = PPh_4$, Ln = Pr (**24e**), Tm (**24p**)
$R = AsPh_4$, Ln = Nd (**25f**)
$R = PPh_3(CH_2Ph)$, Ln = Nd (**26f**), Dy (**26m**)

Finally, some analogous complexes with trimethylsilylcyclopentadienyl ligands have also been described, for example: $(Me_3SiC_5H_4)_2Y(\mu\text{-}Cl)_2Li\cdot L_x$ [L = THF, x = 2 (**27b**); L = tmed, x = 1 (**28b**)][58], the red-brown dimers $[(Me_3SiC_5H_4)_2YbX]_2$ [X = Cl (**29q**), I (**30q**)][59], and the complexes $(Me_3SiC_5H_4)_2Yb(\mu\text{-}Cl)_2Li(Et_2O)_2$ **31q** and $(Me_3SiC_5H_4)_2Lu(\mu\text{-}Cl)_2Li$ **32r**[54] (tmed = tetramethylenediamine).

The cyclopentadienyllanthanoid dichlorides **5**, which are prepared by reaction of **3** with **1** or by comproportionation of **3** and **4**[60], are monomeric. If they are prepared in THF, three solvent molecules remain in the coordination sphere of the metal. Figure 3 shows the arrangement of the ligands in compound **5o**[61]. La, Sm, Eu, Tm, and Yb also form complexes of the type $C_5H_5LnCl_2\cdot(THF)_4$ **33**[62]. The structure of the pentamethylcyclopentadienyllanthanoid dihalide-alkali halide complexes such as $C_5Me_5Nd(\mu\text{-}Cl)_3\text{-}Na\cdot(Et_2O)_2$ **34f**[50], $C_5Me_5Ln(\mu\text{-}Cl)_3Li\cdot(Et_2O)_2$ (Ln = Yb (**35q**[53], Lu (**35r**)[54]), $C_5Me_5Yb(\mu\text{-}Cl)_3Li\cdot(THF)$ **36q**[54], and $C_5Me_5Yb(\mu\text{-}I)_3Li\cdot(Et_2O)_2$ **37q**[53,54] is formulated with three halogen bridges.

Table 2 lists the most important data of the compounds **8** and **5**.

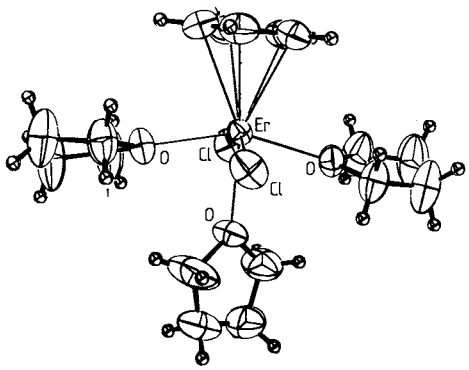


Fig. 3. Molecular structure of $C_5H_5ErCl_2\cdot(THF)_3$ **5o** in the crystal [61].

Elementary iodine reacts with **4o** with substitution and formation of the pink $(C_5H_5)_2ErI$ **38o**[42]. The compounds $(C_5H_5)_2NdCN$ **39f** and $(C_5H_5)_2YbCN$ **39q** have been prepared by reaction of **4f** and **4q**, respectively, with HCN[67].

Finally, it should be mentioned that $[(C_5H_5)_2YCH_3]_2$ **40b** reacts with CH_3AlCl_2 with cleavage of the Y–CH_3 bond and formation of the stable complex $(C_5H_5)_2Y(\mu\text{-}Cl)_2Al(CH_3)_2$ **41b**[63], and that the reaction of **8b** with AlH_3 in ether or in triethylamine yields the complexes $[(C_5H_5)_2YCl]_2\cdot AlH_3\cdot Et_2O$ **42b**[68] and $[(C_5H_5)_2YCl\cdot AlH_3\cdot NEt_3]_2$ **43b**[69], respectively.

2.3. Alkyl- and Aryl(dicyclopentadienyl)lanthanoid Complexes

Alkyl- and aryl(dicyclopentadienyl)lanthanoid complexes are accessible by reaction of **8** with Grignard reagents or alkyl- and aryllithium compounds. Generally speaking, such compounds are dimers, **44**, and not monomers as initially postulated by *Tsutsui* and *Ely*[70,71]. Monomeric molecules must be stabilized, either intramolecularly by a chelating ligand, as is the case in $(C_5H_5)_2ScC_6H_4CH_2NMe_2$–(*o*) **45a**[72], or intermolecularly by coordinating solvents.

Accordingly, the species **8** react with lithium tetraalkylaluminates in toluene to give the complexes **46** or **47**, respectively[73,74]. These complexes are converted by pyridine into the dimeric dicyclopentadienyl(methyl)lanthanoid complexes **44**, which compensate their electron deficiency by forming methyl bridges between the two lanthanoid atoms (Fig. 4)[63,75]. In contrast, reaction of **46a** with pyridine does not furnish **44a**, but the monomeric dicyclopentadienyl(methyl)pyridinescandium **48a**[63,75].

8r reacts with alkyl- and aryllithium compounds in tetrahydrofuran to give monomeric 1 : 1 complexes of the alkyl- and aryl(dicyclopentadienyl)lutetium derivatives with THF, respectively. **49r**, **50r**, **51r**, and **52r** can only be detected by NMR at room temperature, whereas the corresponding compounds with more or less bulky alkyl or aryl ligands can be isolated as colorless to light-yellow, needle-like crystals[76–78]. Analogous THF-complexes have also been obtained with yttrium[49], samarium[77,79], gadolinium[80], erbium[49,77,80], thulium[77,79], and ytterbium[77,79,80]:

R = $CH_2C_6H_5$,	Ln = Lu (**56r**)
R = $C_6H_4CH_3$-(*p*),	Ln = Gd (**57k**), Er (**57o**), Yb (**57q**), Lu (**57r**)
R = C_6H_4Cl-(*p*),	Ln = Er (**58o**)

In compounds **49r** to **57r** the lutetium atom is located at the centroid of a distorted tetrahedron formed by the centers of two cyclopentadienyl ligands, the η^1-bonded carbon atom, and the oxygen atom of the THF (Fig. 5)[77].

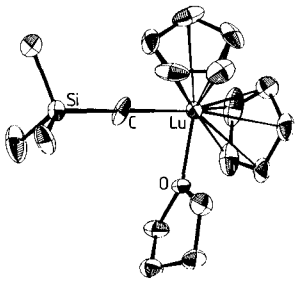

Fig. 5. Molecular structure of $(C_5H_5)_2LuCH_2SiMe_3 \cdot (THF)$ **55r** in the crystal [77].

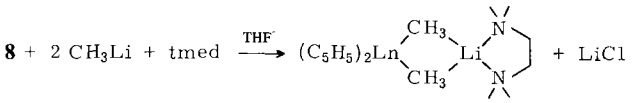
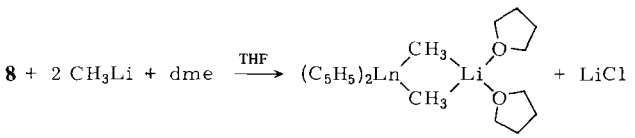
8o and **8r** react with an excess of methyllithium in THF in the presence of tmed to give complexes **59**, in which the two methyl groups bridge the lanthanoid and the lithium, and which are further stabilized by coordination of a tmed molecule to the lithium.

If dme is used instead of tmed, the complexes **60** containing two molecules of the solvent THF are formed[81].



Ln = Er (**59o**), Lu (**59r**) **59**



Ln = Er (**60o**), Lu (**60r**) **60**

The X-ray structure analysis of **59o** shows a tetrahedrally coordinated erbium atom and a lithium atom which is also coordinated tetrahedrally by two methyl groups and the two nitrogens of the tmed ligand (Fig. 6)[81].

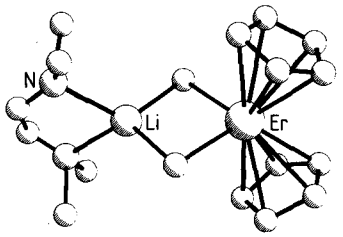


Fig. 6. Molecular structure of $(C_5H_5)_2Er(\mu\text{-}CH_3)_2Li \cdot (tmed)$ **59o** in the crystal [81].

The pentamethylcyclopentadienyl derivatives $(C_5Me_5)_2Yb(\mu\text{-}Cl)(\mu\text{-}CH_3)Li \cdot (Et_2O)_2$ **61q** and $(C_5Me_5)_2Yb(\mu\text{-}CH_3)_2Li \cdot (Et_2O)_2$ **62q** have been obtained by reaction of $(C_5Me_5)_2Yb(\mu\text{-}Cl)_2Li \cdot (Et_2O)_2$ **63q** with CH_3Li in THF[53].

The corresponding lutetium derivatives, especially **64r**, the first monomer not stabilized by solvent molecules, can be used as novel Ziegler-catalysts. They promote the formation of longer alkyl chains from olefins[82,83] and activate C–H bonds[84,85]. Thus, **64r** reacts with H_2 to form **65r**, which in turn reacts with benzene with elimination of H_2 to yield the compounds **66r** and **67r**[84]. The reactions of

2.4. Allyl- and Alkynyl(cyclopentadienyl)lanthanoid Compounds

The allyl(dicyclopentadienyl) derivatives of scandium[43], samarium, holmium, and erbium[86], which are readily accessible from **8** and allylmagnesium chloride, have a fluctional allyl group. However, the exact structure of these compounds is still unknown. According to NMR investigations, $(C_5Me_5)_2LuCH_2C(CH_3)=CH_2$ **72r**, which is formed as a decomposition product of $(C_5Me_5)_2Lu\text{–}i\text{-}C_4H_9$ **71r**, also has a fluctional structure[83].

The first alkynyl derivatives of the lanthanoids, the scandium[43], gadolinium, holmium, erbium, and ytterbium derivatives $(C_5H_5)_2LnC{\equiv}CC_6H_5$ **73**[71,87] as well as $C_5H_5Ho(C{\equiv}CC_6H_5)_2$ **74n**[71], have been prepared from $(C_5H_5)_2LnCl$ **8** and $C_5H_5HoCl_2 \cdot (THF)_3$ **5n** and alkali metal phenylacetylide, respectively. Reaction of **4f** or **4q** with acetylene derivatives likewise affords species of this kind (**75**–**78**)[88]:

$$(C_5H_5)_3Ln + HC{\equiv}CR \longrightarrow (C_5H_5)_2LnC{\equiv}CR + C_5H_6$$

4 **73, 75–78**

Ln	R = C_6H_5	*n*-C_4H_9	*n*-C_6H_{13}	*c*-C_6H_{11}	$C_5H_5FeC_5H_4$

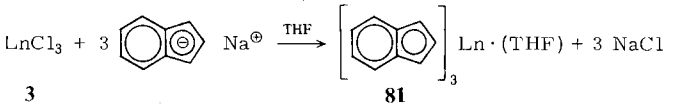
80h

2.5. Compounds with Indenyl, Cyclooctatetraenyl, and other π-Ligands

Triindenyllanthanoids were first prepared in 1968 by *Tsutsui* by the reaction of **3** with indenylsodium and were isolated as THF-adducts **81**[7,92]:



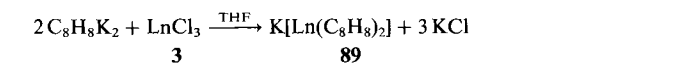
Ln = La (**81c**), Sm (**81h**), Gd (**81k**), Tb (**81l**), Dy (**81m**), Yb (**81q**)

Solvent-free $(C_9H_7)_3Sm$ **82h** is formed on reaction of **3h** with $(C_9H_7)_2Mg$ in benzene. The X-ray structure analysis of this compound shows that the samarium atom is surrounded, in a trigonal planar manner, by the centers of the five-membered rings of the three indenyl moieties[93]. The structure of $(C_9H_7)_3Ce \cdot (C_5H_5N)$ **83d**, which is prepared by the reduction of $Ce(O\text{-}i\text{-}C_3H_7)_4 \cdot (C_5H_5N)$ with triethylaluminum in indene, confirms the π-complexation for the indenyl derivatives. The π-bonded five-membered moieties of the three indenyl ligands and the σ-bonded nitrogen atom of the pyridine are arranged tetrahedrally around the cerium atom[94].

Depending on the stoichiometry, reaction of **3** with heptamethylindenylsodium in THF affords $(C_9Me_7)_3Ln$ **84**, $(C_9Me_7)_2LnCl$ **85**, or $C_9Me_7LnCl_2$ **86**, which are coordinated with different amounts of THF[95].

Fluorenyl derivatives of the lanthanoids have been described by two research groups: the bright yellow trifluorenyl cerium **87d** was reported first[96], and then the complexes $(C_{13}H_9)_2Ln(\mu\text{-}Cl)_2Li \cdot (THF)_2$ **88** with Ln = La (**88c**), Sm (**88h**), and Ho (**88n**)[97].

Compounds of the lanthanoids in the oxidation state +3 with cyclooctatetraene were first reported in 1970[98]. The reactions of **3** with $C_8H_8K_2$ in tetrahydrofuran afford the complexes **89**, which are stable up to ca. 160 °C but sensitive towards air and moisture[98–100].



Ln = Sc (**89a**), Y (**89b**), La (**89c**), Ce (**89d**), Pr (**89e**), Nd (**89f**), Sm (**89h**), Gd (**89k**), Tb (**89l**)

Infrared, Raman, visible and ultraviolet spectra[101], semiempirical LCAO calculations[102], and the chemical behavior are consistent with strong ionic bonding between lanthanoid and cyclooctatetraene.

Cerium complexes with the potassium cation additionally coordinated by one monoglyme[103] or diglyme molecule[104] have also been described. The X-ray structure analysis of the diglyme complex **90d** shows a discrete $[Ce(C_8H_8)_2]^{\ominus}$ anion with planar C_8H_8 rings. The potassium cation is coordinated by the diglyme on one side and by one of the cyclooctatetraenyl rings on the other side (Fig. 7).

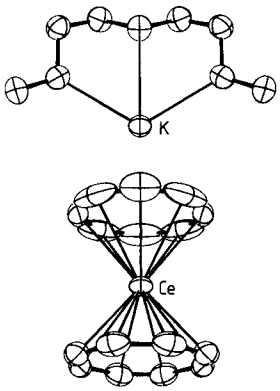


Fig. 7. Molecular structure of $[K(diglyme)][Ce(C_8H_8)_2]$ **90d** in the crystal [104].

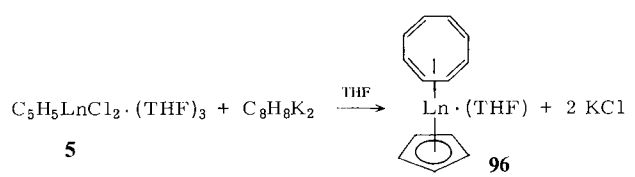
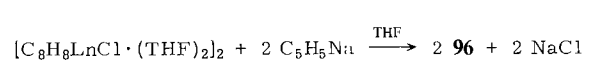
The reactions of **3** in THF with only one equivalent of $K_2C_8H_8$ afford complexes of the type $[C_8H_8LnCl \cdot (THF)_2]_2$ **91**[99,105,106]. Investigation of the structure of the cerium complex **91d** provided proof of its dimeric nature, and showed that the two cerium atoms are bridged asymmetrically by two chlorine atoms and are each coordinated to one cyclooctatetraenyl ring and two THF molecules[107]. The complexes lose the tetrahydrofuran on heating above 60 °C in vacuo. Reaction of **91r** with Me_3SiCH_2Li or *o*-$Me_2NCH_2C_6H_4Li$ in THF afforded the first cyclooctatetraenyl(organyl)lutetium compounds $(C_8H_8)LuR \cdot (THF)$ with $R = CH_2SiMe_3$ **92r** or $C_6H_4CH_2NMe_2$-(*o*) **93r**, respectively[108].

Cocondensation of La, Ce, Nd, or Er metal atoms with cyclooctatetraene at 77 K and subsequent extraction of the reaction product with THF furnished the binuclear complexes $[C_8H_8Ln(THF)_2][Ln(C_8H_8)_2]$ **94**[109]. The neodymium compound **94f** crystallizes with an asymmetrically bridging cyclooctatetraenyl ring between the two neodymium atoms[109,110]. A triple-decker sandwich structure is assumed for the green microcrystalline $(C_8H_8)_3Ce_2$ **95d**[103] formed on reaction of $Ce(O\text{-}i\text{-}C_3H_7)_4$ with triethylaluminum in presence of cyclooctatetraene.



Ln = Y (**96b**), Sm (**96h**), Ho (**96n**), Er (**96o**)



Ln = Y (**96b**), Nd (**96f**)

Sandwich complexes **96** with two different 'flaps' can be obtained either by reaction of **5** with $C_8H_8K_2$, or of **91** with **1**, in THF[65].

The analogous scandium compound **96a** is formed in a solvent-free state from $C_8H_8ScCl\cdot(THF)$ and **1** as a yellowish, air-sensitive powder[100,106].

Dicyclopentadienyllanthanoid chlorides in which the cyclopentadienyl rings are bridged one with the other are formed when **3** is allowed to react with the disodium salt of 1,3-dicyclopentadienylpropane in THF[111,112]. With this new ligand it was possible for the first time to synthesize dicyclopentadienyllanthanoid chlorides of the earlier lanthanoids praseodymium and neodymium as THF-complexes **97**. The THF ligand can be exchanged for other bases, such as for instance 2,2'-bipyridine[113].

$$\underset{\mathbf{3}}{LnCl_3} + NaC_5H_4(CH_2)_3C_5H_4Na \xrightarrow{THF} \underset{\mathbf{97}}{LnCl\cdot(THF)} + 2\,NaCl$$

Ln = La (**97c**), Ce (**97d**), Pr (**97e**), Nd (**97f**), Gd (**97k**), Dy (**97m**), Ho (**97n**), Er (**97o**), Yb (**97q**), Lu (**97r**)

Finally, it should be pointed out that **3f** and 2,4-dimethylpentadienylpotassium react in tetrahydrofuran to yield the, so-to-speak 'open' pentadienyl complex **98f** as a brilliant green, ionic compound. The molecule contains a ring-shaped array of three almost planar pentadienyl ligands, each of which has two methyl groups in the 2- and 4-positions protruding out from the plane and bent away from the neodymium atom[114].

$$\underset{\mathbf{3f}}{NdCl_3} + 3\,C_7H_{11}K \xrightarrow{THF} \underset{\mathbf{98f}}{Nd} + 3\,KCl$$

2.6. Homoleptic Organolanthanoid Compounds

The simplest organometallic compounds of the lanthanoids in the oxidation state +3 are the species $(CH_3)_3Ln$. Since the inner transition elements strive to reach high coordination numbers it can be expected that these compounds exhibit a high reactivity. Hence, for a long time, only indirect evidence could be found for the existence of simple homoleptic organolanthanoid compounds; the isolation and characterization of compounds belonging to this class were first achieved in the last decade[115].

2.6.1. Neutral Homoleptic Organolanthanoid Compounds

3a and **3b** react with methyl- or phenyllithium with formation of air-sensitive products, of which only the phenyl derivatives **99** could be characterized by analysis, IR spectroscopy, and reactions with $HgCl_2$, CO_2 or benzophenone[9,10]:

$$\underset{\mathbf{3}}{LnCl_3} + 3\,C_6H_5Li \xrightarrow{THF} \underset{\mathbf{99}}{(C_6H_5)_3Ln} + 3\,LiCl$$

Ln = Sc (**99a**), Y (**99b**)

Bulky ligands such as *tert*-butyl, neopentyl, or trimethylsilylmethyl can improve the stability of homoleptic organolanthanoid compounds considerably. However, whereas the trimethylsilylmethyl derivatives **100** and **101** still require THF as additional stabilizing ligand, the complexes **102b** and **103a** are stable as monomers without any coordinated solvent molecules[116,117]. The complexes **100**, prepared by reaction of $ErCl_3$ or $TmCl_3$ with Me_3SiCH_2Li in THF at −78 °C, lose one THF ligand when warmed to 0 °C and yield the fivefold coordinated complexes **101**[118,119] With the corresponding ytterbium or lutetium derivative this transition from sixfold to fivefold coordination takes place even at −25 °C[58,119].

$$\underset{\mathbf{3}}{LnCl_3} + 3\,Me_3SiCH_2Li \xrightarrow{THF} \underset{\mathbf{100}}{(Me_3SiCH_2)_3Ln\cdot(THF)_3} + 3\,LiCl$$

Ln = Er (**100o**), Tm (**100p**)

$$\mathbf{100} \xrightarrow{-25\,^\circ C} \underset{\mathbf{101}}{(Me_3SiCH_2)_3Ln\cdot(THF)_2} + THF$$

Ln = Er (**101o**), Tm (**101p**), Yb (**101q**), Lu (**101r**)

$[(Me_3Si)_2CH]_3Y$ **102b**
$[(o\text{-}CH_3OC_6H_4SiMe_2)_2CH]_3Sc$ **103a**

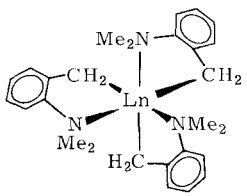
The ^1H- and ^{13}C-NMR data of **101r** are consistent with a trigonal bipyramidal structure with the THF ligands occupying the axial positions. On prolonged standing at 40 °C in an inert atmosphere, **101o** and **101r** split off not only the two residual THF ligands but also tetramethylsilane to give the pyrophoric, polymeric carbene complexes **104**[119].

$$\mathbf{101} \xrightarrow[-2\,THF]{40\,^\circ C} 1/n[Ln(CH_2SiMe_3)(CHSiMe_3)]_n + Si(CH_3)_4$$
$$\mathbf{104}$$

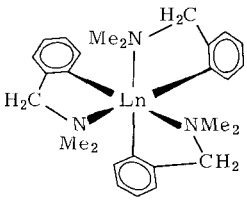
Ln = Er (**104o**), Lu (**104r**)

The products of the reactions of YCl_3 or $NdCl_3$ with $C_6H_5CH_2Li$, $C_6H_5C(CH_3)_2CH_2Li$, or Me_3SiCH_2Li decompose in a similar manner. The compounds expected to be formed, namely $(C_6H_5CH_2)_3Ln$ **105**, $[C_6H_5C(CH_3)_2CH_2]_3Ln$ **106**, and $(Me_3SiCH_2)_3Ln$, respectively, could not be isolated[120–122].

By using ligands containing built-in chelating groups, such as terminal amino groups, it is possible to synthesize solvent-free homoleptic organolanthanoid compounds. Thus, *o*-$Me_2NC_6H_4CH_2Li$ and *o*-$Me_2NCH_2C_6H_4Li$ react with **3a**, **3b**, **3c**, **3f**, and **3o** to give the sixfold coordinated compounds **107** and **108**, respectively[72,123].



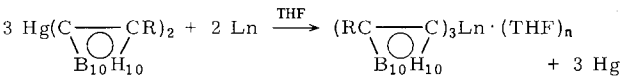
107



108

The carbaboranyl derivatives **109** and **110** of La, Tm and Yb were obtained by reaction of the *C*-mercurio deriv-

atives of methyl- and phenylcarbaborane with the metals in THF at 20°C[124]. A carbaboranyl derivative with a thulium-boron bond, **111p**, has also been described[125].



109, **110**

R = CH_3, Ln = Tm, n = 3 (**109p**); Yb, n = 2 (**109q**)

R = C_6H_5, Ln = La, n = 1 (**110c**); Tm, n = 3 (**110p**); Yb, n = 2 (**110q**)

111p

2.6.2. *Anionic Homoleptic Organolanthanoid Compounds*

$LaCl_3$ and $PrCl_3$ react with phenyllithium to give the homoleptic organometallic compounds **112** in which four phenyl groups are bound to the metal[10].

3 **112**

Ln = La (**112c**), Pr (**112e**)

A tetrahedral ligand arrangement is suggested for the anion $[Ln(C_6H_5)_4]^{\ominus}$; such an arrangement has already been established in the case of the anion of the analogously prepared $[Li(THF)_4][Lu(C_6H_3Me_2)_4]$ **113r** (Fig. 8)[126].

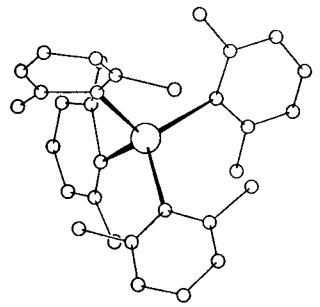


Fig. 8. Structure of the anion of $[Li(THF)_4][Lu(C_6H_3Me_2)_4]$ **113r** in the crystal [126].

In 1978, the first permethylated complexes of the lanthanoids could be synthesized with the aid of tmed as stabilizing base[127]. In the meantime, the hexamethyl complexes **114** of nearly all the lanthanoids have been synthesized by reaction of stoichiometric amounts of **3**, $LiCH_3$, and tmed[128–130]. The radioactive element promethium was the only lanthanoid not included in these investigations, while $EuCl_3$ is reduced by $LiCH_3$ to europium(II) compounds of unknown structure[130]. Analogous, but thermally less stable complexes **115** can be prepared by using dme instead of tmed[130, 131].

3 **114**

3 **115**

Table 3. Physical properties of hexamethyllanthanoid derivatives **114** and **115**.

$[Li(tmed)]_3[Ln(CH_3)_6]$ **114** Ln		Color	Dec. [°C]	Ref.

Er	**115o**	pink	82–84	[131]
Lu	**115r**	colorless	84–88	[131]

Table 3 lists the colors and decomposition points of these compounds. The X-ray structure analyses of **114o**[128], **114n** (Fig. 9)[129], and **115r**[131] show that the lanthanoid atoms are surrounded by six methyl groups in a slightly distorted octahedral arrangement. All Ln–C bonds are of equal length, and the six methyl groups bridge the lanthanoid atom pairwise with the three lithium atoms. The lithium atoms are each located at the center of a tetrahedron formed by the two bridging methyl groups and the two nitrogen or oxygen atoms of the tmed or dme ligand.

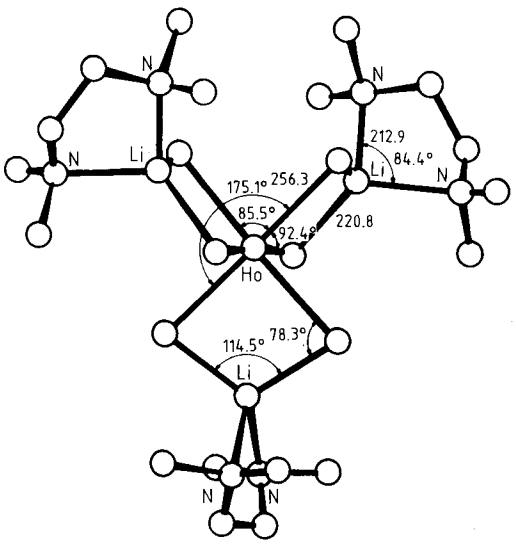

Fig. 9. Molecular structure of $[Li(tmed)]_3[Ho(CH_3)_6]$ **114n** in the crystal [129].

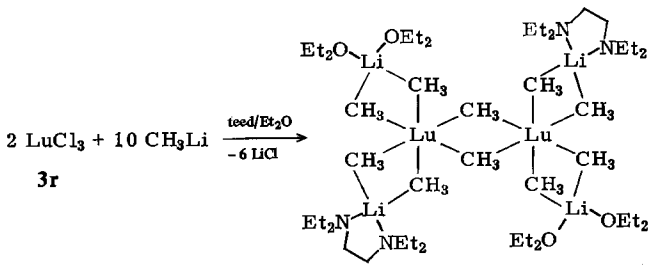
Even polynuclear methyl derivatives of the lanthanoids are capable of existence, as is demonstrated by compound **116r**, which could be isolated on reaction of **3r** with

CH_3Li. In this compound there are methyl bridges not only between lutetium atoms and lithium atoms but also between two lutetium atoms (teed = tetraethylethylenediamine)[131].



116r

Lanthanoid trichlorides **3** or *tert*-butoxides react with *t*-C_4H_9Li to give tetrahedrally structured complex anions, with the lithium ion coordinated by three or four THF, four Et_2O, or two tmed molecules, depending on the solvent used in the reactions[129,132,133].

$$LnCl_3 + 4\,t\text{-}C_4H_9Li \xrightarrow{THF} [Li(THF)_x][Ln(t\text{-}C_4H_9)_4] + 3\,LiCl$$
3 → **117, 118**

Ln = Yb, x = 3 (**117q**); Ln = Er, x = 4 (**118o**)

$$LnCl_3 + 4\,t\text{-}C_4H_9Li \xrightarrow[Et_2O]{pentane} [Li(Et_2O)_4][Ln(t\text{-}C_4H_9)_4] + 3\,LiCl$$
3 → **119**

Ln = Tb (**119l**), Er (**119o**), Lu (**119r**)

$$Ln(O\text{-}t\text{-}C_4H_9)_3 + 4\,t\text{-}C_4H_9Li \xrightarrow[tmed]{pentane} [Li(tmed)_2][Ln(t\text{-}C_4H_9)_4] + 3\,t\text{-}C_4H_9OLi$$
120

Ln = Er (**120o**), Lu (**120r**)

Complexes of the type $[LiL_4][Ln(CH_2SiMe_3)_4]$ with L = THF **121** or Et_2O **122** or L_2 = tmed **123** are formed in the reaction of Me_3SiCH_2Li with either the neutral, homoleptic compound **101** or with **3**[58,119].

$$(Me_3SiCH_2)_3Ln\cdot(THF)_2 + Me_3SiCH_2Li \xrightarrow{THF} [LiL_4][Ln(CH_2SiMe_3)_4]$$
101 → **121, 123**

L = THF, Ln = Y (**121b**)
L_2 = tmed, Ln = Y (**123b**), Er (**123o**), Yb (**123q**)

$$LuCl_3 + 4\,Me_3SiCH_2Li \xrightarrow{Et_2O} [Li(Et_2O)_4][Lu(CH_2SiMe_3)_4] + 3\,LiCl$$
3r → **122r**

$$\mathbf{122r} + 2\,tmed \longrightarrow [Li(tmed)_2][Lu(CH_2SiMe_3)_4] + 4\,Et_2O$$
123r

The complexes **122** and **123** also decompose slowly at room temperature with loss of tetramethylsilane and formation of products in which not only CH_2SiMe_3 but also $CHSiMe_3$ and $CSiMe_3$ groups are fixed to the lanthanoids[134].

$ErCl_3$ and $YbCl_3$ react with $(Me_3Si)_2CHLi$ in THF to give complexes of the type $[Li(THF)_4]\{Ln[CH(SiMe_3)_2]_3Cl\}$ **124**. On heating in hexane solution, the erbium compound **124o** is converted into a lithium salt containing the $\{Er[CH(SiMe_3)_2]_4\}^{\ominus}$ anion[58].

2.7. Organolanthanoid Hydrides

Organolanthanoid hydrides were first prepared in 1981/82 by hydrogenolysis of alkyl(dicyclopentadienyl)lanthanoid derivatives[47,49]. The X-ray structure analyses of **126b**[49], **126o**[49], and **65f**[135] confirm a hydrogen-bridged dimeric structure. In the case of **65h** the bulky pentamethylcyclopentadienyl ligands prevent coordination of additional solvent molecules.

$$[(C_5Me_5)_2SmC(H_5C_6)=C(C_6H_5)Sm(C_5Me_5)_2] + H_2 \longrightarrow [(C_5Me_5)_2SmH]_2$$
65h

$$2\,Cp_2LnR\cdot(THF) + 2\,H_2 \xrightarrow{toluene} [Cp_2LnH\cdot(THF)]_2 + 2\,RH$$
125, 126

Cp = C_5H_5, R = *t*-C_4H_9, Ln = Y (**125b**); R = *t*-C_4H_9, Ln = Er (**125o**); R = *t*-C_4H_9, $CH_2C(CH_3)_3$, CH_2SiMe_3, $CH_2C_6H_5$, Ln = Lu (**125r**)
Cp = $CH_3C_5H_4$, R = *t*-C_4H_9, Ln = Y (**126b**), Er (**126o**), Lu (**126r**)

The hydrides **65**, **125**, and **126** undergo very interesting reactions. Thus, **126b** reacts with *t*-C_4H_9NC to yield $[(CH_3C_5H_4)_2Y(HC{=}N\text{-}t\text{-}C_4H_9)]_2$ **127b**[136], and **65r**, which according to its NMR spectrum rapidly equilibrates with the monomeric species at 25 °C, catalyzes the polymerization of olefins and activates C–H bonds, even in $Si(CH_3)_4$[82–84].

$$2\,(C_5Me_5)_2LuCH_3 + 2\,H_2 \xrightarrow[20°C]{hexane} [(C_5Me_5)_2LuH]_2 + 2\,CH_4$$
64r → **65r**

$$(C_5Me_5)_2Lu(\mu\text{-}H)_2Lu(C_5Me_5)_2 \rightleftharpoons 2\,(C_5Me_5)_2LuH$$
65r

$$(C_5Me_5)_2LuH \xrightarrow[-H_2]{+Si(CH_3)_4} (C_5Me_5)_2LuCH_2SiMe_3$$
69r

The tetrahydridoborates **128** and **129** are readily accessible by reaction of the corresponding chlorides with $NaBH_4$ in tetrahydrofuran[56,77,137].

$$Cp_2LnCl\cdot(THF) + NaBH_4 \xrightarrow{THF} Cp_2LnBH_4\cdot(THF) + NaCl$$
128, 129

Cp = C_5H_5, Ln = Sm (**128h**), Er (**128o**), Yb (**128q**), Lu (**128r**)
Cp = $(Me_3Si)_2C_5H_3$, Ln = Sc (**129a**), Y (**129b**), La (**129c**), Pr (**129e**), Nd (**129f**), Sm (**129h**), Yb (**129q**)

The IR spectra of **129c**, **129e**, **129f**, and **129h** suggest a tridentate BH_4 ligand, whereas the spectra of **129b** and **129q** are better interpreted in terms of a bidentate BH_4 ligand[56]. The structure determinations carried out on solvent-free **129a** unequivocally prove the presence of a rigid bidentate BH_4 ligand[56].

Novel types of polynuclear organolanthanoid hydrides are formed when Cp_2LnR derivatives decompose by β-elimination. The compounds $[Li(THF)_3][\{(C_5H_5)_2LuH\}_3H]$

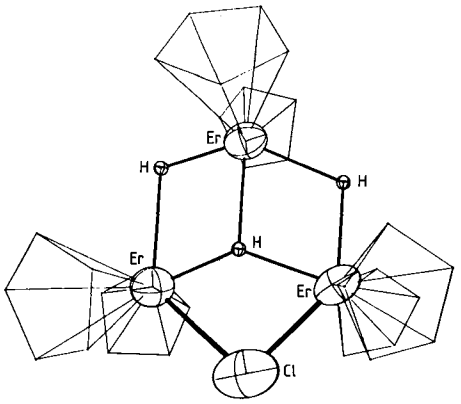


Fig. 10. Structure of the anion of $[Li(THF)_4][\{(C_5H_5)_2ErH\}_3Cl]$ **131o** in the crystal [138].

130r and $[Li(THF)_4][\{(C_5H_5)_2ErH\}_3Cl]$ **131o** (Fig. 10) have been obtained in this way[138]. **8r** reacts with NaH in THF in a way not yet clear, to yield $[Na(THF)_6][\{(C_5H_5)_3Lu\}_2H\cdot(THF)_2]$ **132r** (Fig. 11)[139]. Finally, it should be mentioned that the condensation of Sm, Er, or Yb vapor with 1-hexyne at 77 K affords catalytically active polymers which contain $[(n\text{-}C_4H_9C{\equiv}C)_2SmH]$, $[(n\text{-}C_4H_9C{\equiv}C)_2ErH]$, or $[(n\text{-}C_4H_9C{\equiv}C)_3Yb_2H]$ moieties, respectively[140].

2.8. Ylide Complexes of the Lanthanoids

The first ylide complexes **133** of the lanthanoids were synthesized in 1976 using trimethyl(methylene)phosphorane as starting material; they are very sensitive to air and moisture[141].

The complex ^{1}H-NMR spectra suggest a temperature-dependent equilibrium between the monomeric species **133** and the oligomeric and polymeric species. This could be demonstrated by means of ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra (Fig. 12) in the case of the analogous complex

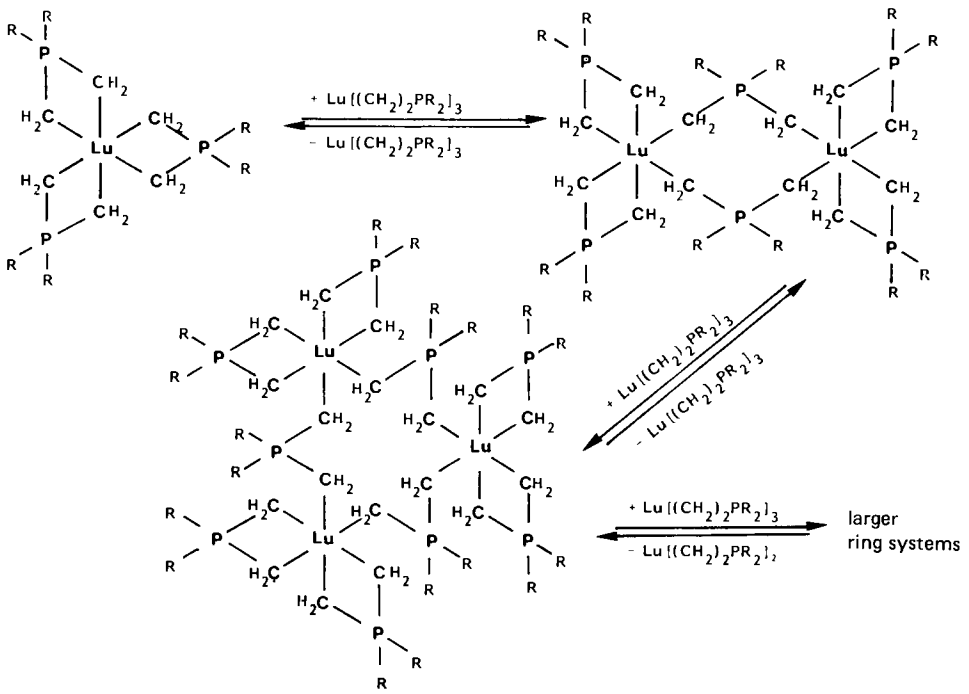

Fig. 12. Oligomerization equilibrium in $Lu[(CH_2)_2P(t\text{-}C_4H_9)_2]_3$ **134r** [142]; $R = t\text{-}C_4H_9$.

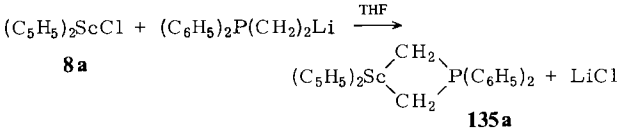
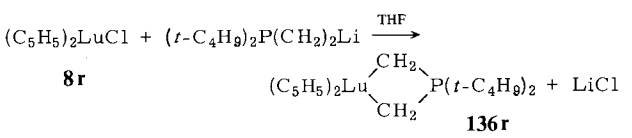
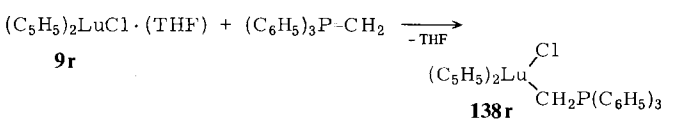
134r, which is accessible from $LuCl_3$ **3r** and $(t\text{-}C_4H_9)_2P(CH_2)Li$[142].

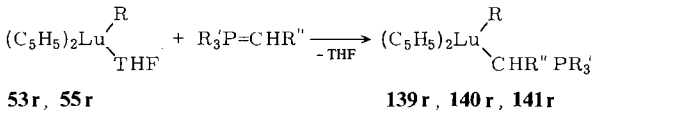
Dicyclopentadienyllanthanoid ylide complexes, such as **135a**[143] and **136r**[142], which are prepared in THF, are, however, monomeric in benzene.





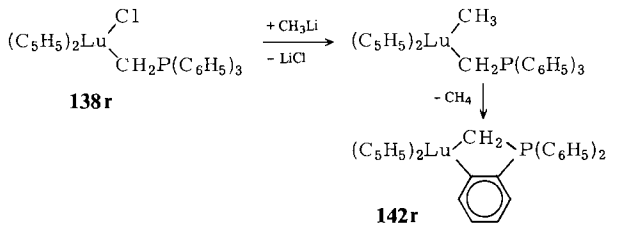
Phosphorus ylides can replace THF as stabilizing base in organolanthanoid compounds, as is shown by the following exchange reactions of **4r**·(THF), **9r**, **53r**, and **55r**, which already proceed at low temperatures in THF or toluene solution[36, 144, 145].





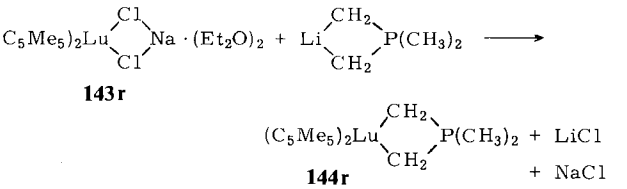
R = t-C_4H_9, R' = C_6H_5, R'' = H (**139r**)
R = CH_2SiMe_3, R' = C_6H_5, R'' = H (**140r**)
R = t-C_4H_9, R' = CH_3, R'' = $SiMe_3$ (**141r**)

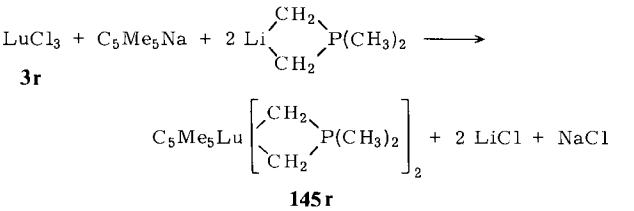
Of special interest is the zwitterionic complex **138r**, which is stable up to 172°C, hydrolyzes with cleavage of all Lu–C bonds, and is converted by an intramolecular metalation of one phenyl ring into **142r** on reaction with $LiCH_3$ at −78°C[36, 146].



The cyclic ylide **142r** is also accessible from **138r** and NaH, or by the reaction of **9r** with t-C_4H_9Li in the presence of $(C_6H_5)_3P{=}CH_2$[36, 146]. Reaction of **64** or **65** with $(C_6H_5)_3P{=}CH_2$ also yields a cyclic ylide complex (**70**)[84].

Pentamethylcyclopentadienyllutetium complexes with $(CH_2)_2P(CH_3)_2$ as chelating ligand are remarkably thermally stable[147].





The composition and structure of the complex **144r**, which melts with decomposition at 205°C, could be confirmed by X-ray structure analysis (Fig. 13)[147].

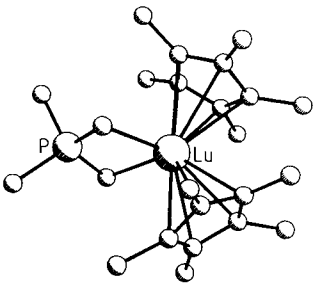


Fig. 13. Molecular structure of $(C_5Me_5)_2Lu(CH_2)_2P(CH_3)_2$ **144r** in the crystal [147].

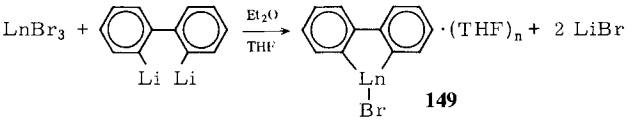
2.9. Organolanthanoid-Element Compounds

2.9.1. Compounds with Lanthanoid-Main Group Element Bonds

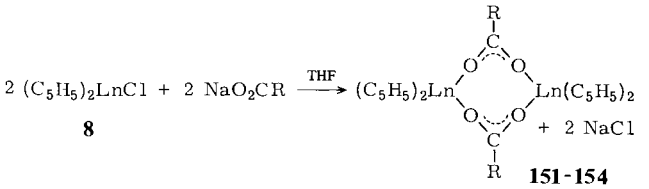
Shortly after the first synthesis of the tricyclopentadienyl derivatives **4**, the cyclopentadienyllanthanoid halides **5** and **8** were prepared as the first organolanthanoid compounds with additional bonds between the lanthanoid and another element other than carbon. They are the most important starting materials for the synthesis of other organolanthanoid derivatives with bonds between the lanthanoids and other elements of the periodic table. Besides the cyclopentadienyl-, indenyl-, fluorenyl- and cyclooctatetraenyllanthanoid halides and the compound $(CH_3)_2C{=}C(C_6H_5)$-$ScCl_2\cdot(THF)_3$ **146a**, first mentioned in 1979[148], the following organolanthanoid halides have been described: the triphenylmethyllanthanoid dichlorides of La (**147c**)[149], Pr (**147e**), Nd (**147f**), Gd (**147k**), and Ho (**147h**)[150], the fluorenyl derivatives $(C_{13}H_9)_2Ln(\mu\text{-}Cl)_2Li\cdot(THF)_2$ of La (**148c**), Nd (**148f**), Sm (**148h**), Ho (**148n**), and Lu (**148r**)[151], and the methyl- and phenylcarbaboranyllanthanoid chlorides of La, Tm, and Yb[125]. Even metallacycles **149** have also been reported[152].



Ln = Pr (**149e**), Gd (**149k**), Ho (**149n**), Yb (**149q**)

Dicyclopentadienyllanthanoid alkoxides were prepared from **8** and the corresponding sodium alkoxides[42,77], or, as shown for $(C_5Me_5)_2LuOC_2H_5$ **150r**, by ethanolysis of **64r**[84].

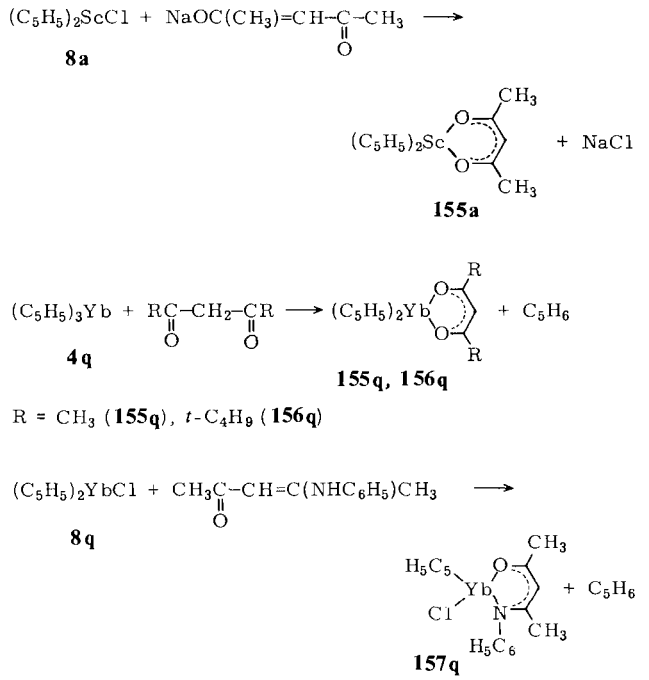
The dicyclopentadienyllanthanoid carboxylates **151**—**154**, which can be prepared from **8** and alkali metal carboxylates, are dimeric in boiling benzene[42,43,88].



8 **151-154**

R = H; Ln = Er (**151o**), Yb (**151q**)
R = CH_3; Ln = Sc (**152a**), Er (**152o**), Yb (**152q**)
R = *n*-C_4H_9; Ln = Yb (**153q**)
R = C_6H_5; Ln = Yb (**154q**)

Reaction of **8a** with sodium acetylacetonate[43] or of **4q** with β-diketones[153] affords the dionates **155a**[43], **155q** and **156q**, respectively[153]. β-Aminoketones react with **8q** analogously to give **157q**[153].



8a **155a**

4q **155q, 156q**

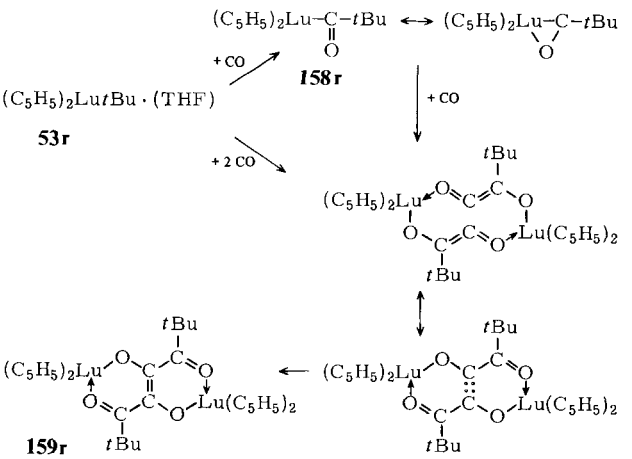
R = CH_3 (**155q**), *t*-C_4H_9 (**156q**)

8q **157q**

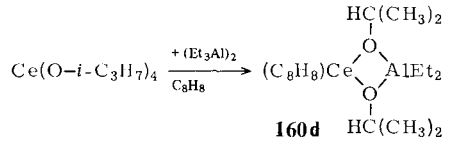
53r reacts with CO to give a yellow acyl complex **158r**, which, after insertion of a second CO molecule, dimerizes to the complex **159r**, the structure of which has been confirmed X-ray crystallographically. It has been suggested that ketene-carbene intermediates are formed during the course of this reaction[154].

Reduction of $Ce(O-i-C_3H_7)_4$ with triethylaluminum in the presence of cyclooctatetraene yields the yellow cerium(III) complex **160d** with two alkoxy bridges between Ce and Al[155].

The first organolanthanoid sulfur compounds have recently been obtained by reaction of bis(pentamethylcyclopentadienyl)neodymium or -ytterbium chloride with sodium dithiocarbamate. In the ytterbium derivative **161q** the dithiocarbamate group functions as a bidentate ligand (Fig. 14)[156].



53r **158r** **159r**



160d

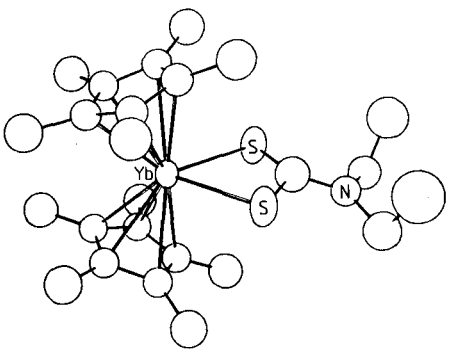


Fig. 14. Molecular structure of $(C_5Me_5)_2YbS_2CNEt_2$ **161q** in the crystal [156].

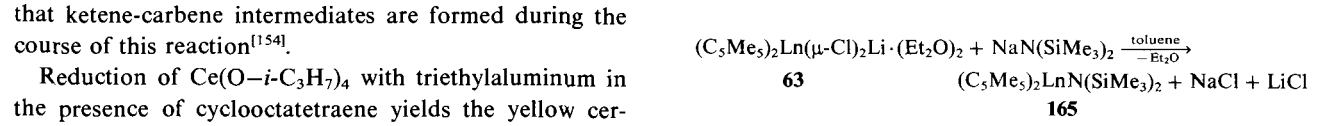
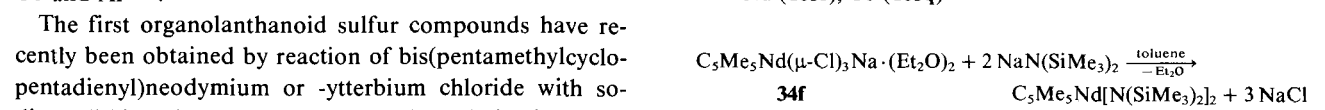
The first organolanthanoid-nitrogen compound was prepared as long ago as 1963 by reaction of **8o** with $NaNH_2$[42]. A couple of years later, it could be shown that $(C_5H_5)_2YbNH_2$ **163q** is the product of the thermal decomposition of $(C_5H_5)_3Yb\cdot(NH_3)$ **162q** at 250 °C[25]. Furthermore, besides the well known homoleptic compounds $Ln[N(SiMe_3)_2]_3$ **164**[157], the bis(trimethylsilyl)amido derivatives **165** and **166** have also been described[50].



63 **165**

Ln = Nd (**165f**), Yb (**165q**)



34f **166f**

Like its analogue **127b**, the formimidoyl complex **167b** (Fig. 15), which is formed on reaction of **125b** with *t*-C_4H_9NC, also contains a Y–N bond[136].

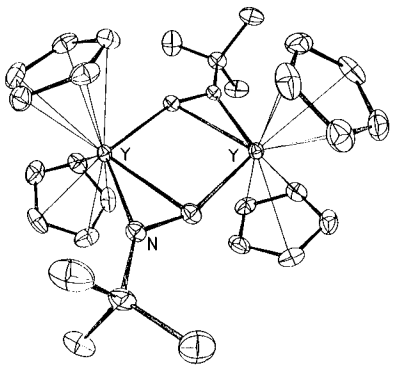


Fig. 15. Molecular structure of $[(C_5H_5)_2Y(HC{=}N{-}t\text{-}C_4H_9)]_2$ **167b** in the crystal [136].

The first dicyclopentadienyllanthanoid phosphides **168** and **169** have been prepared, starting from $LiP(t\text{-}C_4H_9)_2$[64,158] and $LiP(t\text{-}C_4H_9)(C_6H_5)$[158], respectively.

$$(C_5H_5)_2LnCl + LiP(t\text{-}C_4H_9)R \xrightarrow{THF} (C_5H_5)_2Ln{-}P(t\text{-}C_4H_9)R + LiCl$$

8 **168**, **169**

Some diphenyl-[35,91] and dicyclohexylphosphane derivatives[35] as well as homoleptic compounds of the type $Ln[P(t\text{-}C_4H_9)_2]_3$ **170**[159] and their arsene analogues $Ln[As(t\text{-}C_4H_9)_2]_3$ **171**[160] have also been described. However, no exact determinations of the structure of these compounds have been carried out as yet.

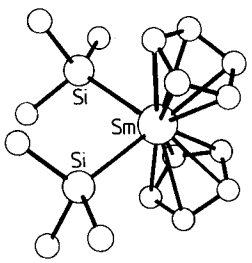

Fig. 16. Structure of the anion in $[Li(dme)_2][(C_5H_5)_2Sm(SiMe_3)_2]$ **172h** in the crystal [161].

The X-ray structure analysis of the first compound containing a Ln–Si bond (**172h**) (Fig. 16) shows that an ionic complex containing two Sm–Si bonds is formed on reaction of **8h** with $LiSiMe_3$ in dme, even when a molar ratio of 1:1 is used[161]. The corresponding compounds of germanium (**173**) and tin (**174**) can also be prepared[162]. These compounds, as well as the complexes of the type **175**, are extremely sensitive to oxygen[163–165].

2.9.2. Compounds with Lanthanoid-Transition Metal Bonds

Very few organolanthanoid compounds containing lanthanoid-transition metal bonds have so far been described in the literature. The first experiments aimed at the preparation of such compounds, carried out as long ago as 1973, showed that $(C_5H_5)_3Ln$ **4** reacts with carbonyl- or nitrosyl metal compounds, but, the composition and the structure of the reaction products are still unknown[37,166]. The infrared spectra of the complexes formed on reaction of **4h** with salts of the manganese-containing anions $[Mn(CO)_5L]^{\ominus}$ have been interpreted in terms of Sm–Mn bonds[167]. On the other hand, well-defined complexes **176** and **177**, which are stable up to 220 °C, can be prepared from **8** and **10**[37].

$$Cp_2LnCl + Na[W(C_5H_5)(CO)_3] \xrightarrow{THF}$$
8, **10**

$$Cp_2Ln{-}W(C_5H_5)(CO)_3 + NaCl$$
176, **177**

Cp = C_5H_5, Ln = Dy (**176m**), Er (**176o**), Yb (**176q**)
Cp = $CH_3C_5H_4$, Ln = Dy (**177m**), Ho (**177n**)

The two complexes with Yb–Co (**179q** (Fig. 17)) and Yb–Fe bonds (**180q** (Fig. 18)) were obtained by reaction of $(C_5Me_5)_2Yb\cdot(Et_2O)$ **178q** with $Co_2(CO)_8$[168] and **178q** with $Fe_2(CO)_9$ or $Fe_3(CO)_{12}$[169], respectively.

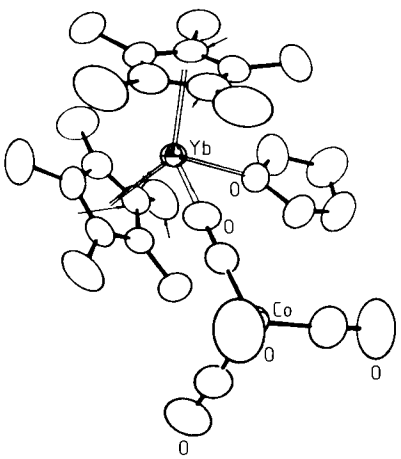

Fig. 17. Molecular structure of $(C_5Me_5)_2YbCo(CO)_4\cdot(THF)$ **179q** in the crystal [168].

Pure lanthanoid-transition metal compounds without any organic ligand on the lanthanoid atom, e.g. $Er[Co(CO)_4]_3\cdot(THF)_4$ **181o**[170], $[(CO)_4Co]HoCl_2\cdot(THF)_4$ **182n**[171], $\{[(C_6F_5)_3Ge]_7Cd_2\}Pr\cdot(dme)_3$ **183e**[172], and $[(C_6F_5)_3Ge]_7Hg_2Ho\cdot(dme)_3$ **184n**[173] have been synthesized

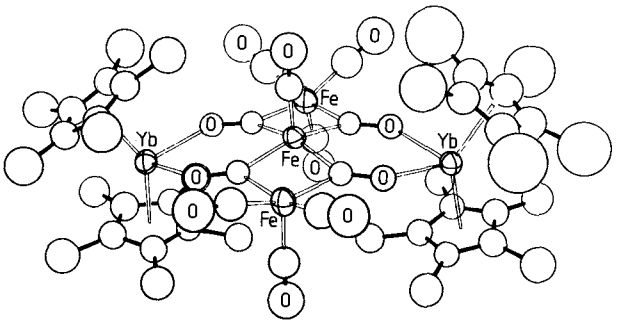

Fig. 18. Molecular structure of $[(C_5Me_5)_2Yb]_2[Fe_3(CO)_{11}]$ **180q** in the crystal [169].

by reaction of $LnCl_3$ **3** with carbonylmetal derivatives, or by reaction of lanthanoid amides or alkoxides with organomercury compounds.

3. Organometallic Compounds with Lanthanoids in the Oxidation State +2

When, in 1964, the blue solution of metallic europium in liquid ammonia was allowed to react with cyclopentadiene, and the crude product of the reaction was sublimed at 400 °C in vacuo, the ammonia-free sandwich complex **185i** was obtained as the first organometallic compound of a lanthanoid in the oxidation state +2[174]. The ytterbium complex **185q** has been prepared in an analogous way[14].

$$Ln + 3\,C_5H_6 \xrightarrow{\text{liq. } NH_3} \underset{\textbf{185}}{(C_5H_5)_2Ln} + C_5H_8$$

Ln = Eu (**185i**), Yb (**185q**)

In the meantime, other routes have been used successfully for the synthesis of **185q** as well as **186h**, **186i**, and **186q**[26,66,175].

$$\underset{\textbf{8q}}{(C_5H_5)_2YbCl} + Na \xrightarrow{THF} \underset{\textbf{185q}}{(C_5H_5)_2Yb} + NaCl$$

$$3\,\textbf{8q} + Yb \xrightarrow{THF} 3\,\textbf{185q} + YbCl_3$$

$$\underset{\textbf{4q}}{(C_5H_5)_3Yb} + Na \xrightarrow{THF} \underset{\textbf{185q}}{(C_5H_5)_2Yb} + C_5H_5Na$$

$$m\,Ln + (C_5H_5)_2Hg \xrightarrow{THF} (m-1)Ln/Hg + \underset{\textbf{186}}{(C_5H_5)_2Ln\cdot(THF)_n}$$

Ln = Sm (**186h**), Eu (**186i**), Yb (**186q**)

185i was one of the first compounds to be investigated by ^{151}Eu Mössbauer spectroscopy[176,177]. The green complex **185q** dissolves in THF to give a red solution, from which the yellow THF-complex **186q** can be isolated[26]. A red form of $(C_5H_5)_2Yb$ is also described in the literature[178,179].

$(C_5H_5)_3Sm$ **4h** is reduced by naphthalene potassium in the presence of THF to the purple, pyrophoric **186h**[180]. Ytterbium reacts with TlC_5H_5 in dme and in the presence of a little mercury to give the complex $(C_5H_5)_2Yb\cdot(dme)$ **187q**[31], in which the Yb atom is tetrahedrally surrounded by the centers of the two cyclopentadienyl rings and the two oxygen atoms of the dme molecule[181]. The yellow complex $(CH_3C_5H_4)_2Yb\cdot(THF)$ **188q**, which has been synthesized via several different routes, shows a helical chain structure consisting of $(CH_3C_5H_4)Yb(THF)$ units which are bridged by a further methylcyclopentadienyl ligand (Fig. 19)[182].

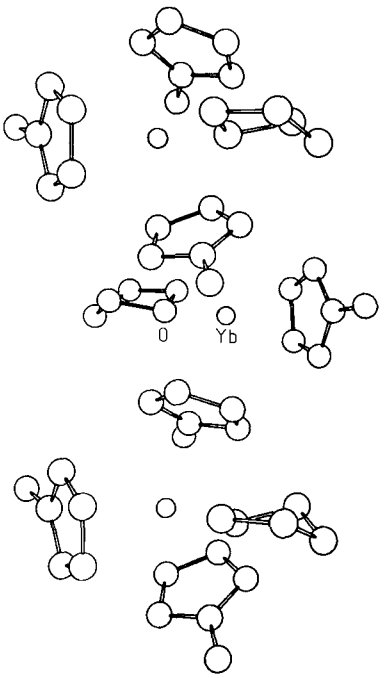

Fig. 19. Chain arrangement of the ligands in $(CH_3C_5H_4)_2Yb\cdot(THF)$ **188q** in the crystal [182].

Reduction of $[(Me_3SiC_5H_4)_2YbCl]_2$ **29q** with sodium amalgam in tetrahydrofuran yields the purple diamagnetic complex $(Me_3SiC_5H_4)_2Yb\cdot(THF)_2$ **189q**, which, on heating in vacuo, loses both THF ligands to give the green, solvent-free complex **190q**. Reaction of **189q** with tmed leads to formation of blue $(Me_3SiC_5H_4)_2Yb\cdot(tmed)$ **191q**[59].

Complexes $(C_5Me_5)_2Ln\cdot(L)$ (L = THF (**192**) or Et_2O (**178**)) of Sm^{II}, Eu^{II}, and Yb^{II} are formed on reaction of $LnCl_2$ or $LnCl_3$ with C_5Me_5Na in THF or Et_2O[183].

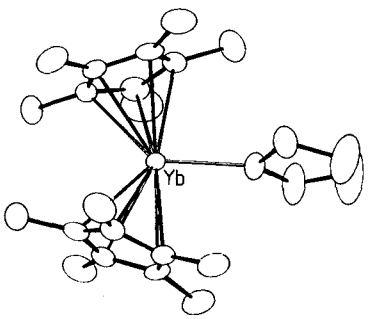

Fig. 20. Molecular structure of $(C_5Me_5)_2Yb\cdot(THF)\cdot(CH_3C_6H_5)_{1/2}$ **193q** in the crystal. The toluene not coordinated to Yb is not shown [183].

When **192q** is recrystallized from toluene, the hemitoluene complex $(C_5Me_5)_2Yb\cdot(THF)\cdot(C_6H_5Me)_{1/2}$ **193q** (Fig. 20) precipitates, the molecules of which form an

open sandwich structure with the ytterbium atom coordinated to the two C_5Me_5 rings and to the oxygen atom of the THF molecule, but not to the toluene[183]. Compounds of the type $(C_5Me_5)_2Yb \cdot L_2$ (L = THF (**194q**), Et_2O (**195q**); L_2 = dme (**15q**)) were synthesized from $YbBr_2$ and C_5Me_5Na. On heating, the red complex **194q** is converted via loss of a THF ligand into the orange complex **192q**[53]. The samarium derivative **194h** could be obtained by metal-atom synthesis from Sm and C_5Me_5H in hexane at

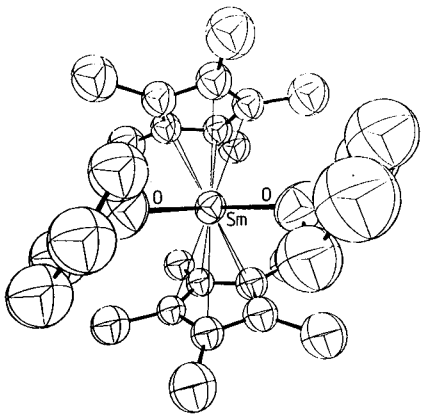

Fig. 21. Molecular structure of $(C_5Me_5)_2Sm \cdot (THF)_2$ **194h** in the crystal [184].

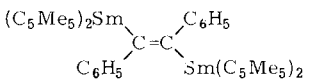
−120°C. The purple crystals show a sandwich structure with the THF-coordinated samarium atom located between the two pentamethylcyclopentadienyl rings (Fig. 21)[184]. **194h** reacts with diphenylacetylene to yield the black enediyl compound **196h**, which upon hydrolysis generates pure *trans*-stilbene[136].

$$(C_5Me_5)_2Sm \cdot (THF)_2 + C_6H_5C{\equiv}CC_6H_5 \xrightarrow{-THF}$$

194h



196h

Pyridine and *P,P'*-methylene- and *P,P'*-ethylenebis(dimethylphosphane) coordinate via N and P respectively to $(C_5Me_5)Ln$, as could be shown by the synthesis and elucidation of the structure of $(C_5Me_5)_2Yb \cdot (C_5H_5N)_2$ (**185q**)[185] and $(C_5Me_5)_2Ln \cdot L$ (Ln = Eu and Yb; L = $Me_2PCH_2PMe_2$ (**197**) or $Me_2PCH_2CH_2PMe_2$ (**198**))[186].

The orange compounds **199i** and **199q** are formed when europium and ytterbium, respectively, are allowed to react with cyclooctatetraene in liquid ammonia[8,109].

$$Ln + C_8H_8 \xrightarrow{\text{liq. } NH_3} (C_8H_8)Ln \quad \mathbf{199}$$

Ln = Eu (**199i**), Yb (**199q**)

Even cerium can be stabilized as Ce(II) by C_8H_8 ligands, as is shown by the reduction of $(C_8H_8)_2Ce$ **200d** with potassium in monoglyme. The green, microcrystalline **201d** is formed[103].

$$\underset{\mathbf{200d}}{(C_8H_8)_2Ce} + 2K \xrightarrow[30°C]{\text{monoglyme}} \underset{\mathbf{201d}}{[K(\text{monoglyme})]_2[Ce(C_8H_8)_2]}$$

Europium, samarium, and ytterbium react with alkyl or aryl iodides in THF between −20 and +30°C to yield the organolanthanoid(II) iodides **202**—**206**.

$$Ln + RI \xrightarrow{THF} R{-}Ln{-}I \quad \mathbf{202-206}$$

R = CH_3 (**202**); C_6H_5 (**203**), $C_6H_4CH_3$-(*p*) (**204**), $C_6H_3(CH_3)_2$-2,6 (**205**), $C_6H_2(CH_3)_3$-2,4,6 (**206**); Ln = Eu, Sm, Yb

The colored solutions, from which no well-defined compounds can be isolated, behave like Grignard compounds[187,188]. Thus, **203q** reacts with ketones and aldehydes to give alcohols, with esters to give alcohols and ketones, and with nitriles, albeit in low yields, to give ketones[189]. In contrast to the corresponding Grignard reaction, the reaction of **203q** with benzoyl chloride selectively affords benzophenone[190]. Both **203i** and **203q** react with $C_6H_5CF{=}CF_2$ in THF to yield *trans*-α,β-difluorostilbene[191].

Europium and ytterbium react with acetylene derivatives such as 1-propyne[192], 1-hexyne[193], or phenylacetylene[194] as well as with $Hg(C{\equiv}CC_6H_5)_2$[194], forming the isolable lanthanoid(II) compounds **207**—**209**. The compound **209q**, which is also obtainable from **210q** and $C_6H_5C{\equiv}CH$[194], reacts with aldehydes R'CHO and ketones R'_2CO to give (after hydrolysis) the alcohols $(C_6H_5C{\equiv}C)R'CHOH$ and $(C_6H_5C{\equiv}C)R'_2COH$, respectively. Benzophenone is reduced to benzopinacol[195].

$$Eu + 2CH_3C{\equiv}CH \xrightarrow{\text{liq. } NH_3} \underset{\mathbf{207i}}{(CH_3C{\equiv}C)_2Eu} + H_2$$

$$Ln + (RC{\equiv}C)_2Hg \xrightarrow{THF} \underset{\mathbf{208,\ 209}}{(RC{\equiv}C)_2Ln} + Hg$$

R = *n*-C_4H_9, Ln = Eu (**208i**); Yb (**208q**)
R = C_6H_5, Ln = Yb (**209q**)

$$\underset{\mathbf{210q}}{(C_6F_5)_2Yb} + 2HC{\equiv}CC_6H_5 \xrightarrow{THF} \underset{\mathbf{209q}}{(C_6H_5C{\equiv}C)_2Yb} + 2C_6HF_5$$

210q[196–198] and **210i**[198] are formed by transmetalation from $(C_6F_5)_2Hg$ and Yb or Eu, respectively. Of the less stable complexes $(C_6HF_4)_2Ln$ **211**, with the hydrogen in the 2- or 4-position of the phenyl ring, only the ytterbium derivative but not that of samarium could be isolated in a pure state[197,198].

$$Yb + (C_6F_5)_2Hg \xrightarrow{THF} \underset{\mathbf{210q}}{(C_6F_5)_2Yb} + Hg$$

210q is a useful reagent for incorporating the C_6F_5 group into transition metal complexes[198,199].

The metal exchange reaction between mercury and ytterbium has even enabled the preparation of ferrocene- **212q** and cymantrene- **213q**[200] as well as the carbaborane-derivatives **214q**—**216q**[124,152,201].

R = CH_3 (**214q**), C_6H_5 (**215q**)

216q

Finally, it should be mentioned that organomercurioytterbium(II) iodides **217q**[202] and carbonyl derivatives of Sm, Eu, and Yb (**218**)[203] are also known.

217q

R = CF_3, C_5H_5, n = 2–4

218

Ln = Sm, Eu, Yb; n = 3, 4

4. Organometallic Compounds with Lanthanoids in the Oxidation State +4

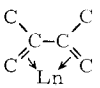
If there is any chance of being able to isolate organometallic compounds of the lanthanoids in the oxidation state +4, it should be possible in the case of cerium, where the electron configuration of the noble gas xenon is achieved on giving up four electrons. The first paper referring to the successful synthesis of $(C_5H_5)_4Ce$ and $(C_9H_7)_4Ce$[204] was published in 1971. In 1983, however, it could be proven that the reaction of C_5H_5Na with $[C_5H_6N]_2[CeCl_6]$ in THF yields exclusively $(C_5H_5)_3Ce$ **4d**, and not the long contested $(C_5H_5)_4Ce$[205]. Moreover, the reputed synthesis of $(C_9H_7)_4Ce$[206] is also in doubt, for it could never be repeated[103]. Therefore, compounds of the type $(C_5H_5)_3CeX$ or $(C_9H_7)_2CeX_2$ with X = H, BH_4, Cl, N_3, CN, NCO, NCS, NO_2, NO_3, OR, O_2CR, SR, NH_2, alkyl or aryl, whose existence likewise remains unproven, should only be remarked upon in passing[207].

The only organocerium(IV) compound whose existence still appears plausible is the pyrophoric and amazingly water-stable $(C_8H_8)_2Ce$ **200d**. It has been obtained by reaction of $Ce(O-i-C_3H_7)_4$ with triethylaluminum in excess cyclooctatetraene. Its ^{1}H-NMR spectrum shows only one sharp signal at $\delta = 5.6$. The X-ray structure data, which are said to prove a uranocene-like sandwich structure for **200d**, have so far not been published. Reduction of **200d** with alkali metals furnishes the anion $[Ce(C_8H_8)_2]^{2\ominus}$ **201d**[103].

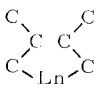
5. Organometallic Compounds with Lanthanoids in the Oxidation State Zero

Typical ligands for organometallic compounds of the transition metals in lower oxidation states are CO and olefins. There has therefore been no lack of attempts to synthesize such carbonyl and olefinic complexes with elements of the third subgroup and the lanthanoids. Whereas carbonyllanthanoid compounds have so far only been detected in a matrix[208], evidence has been obtained for the existence of olefinic complexes in the free state.

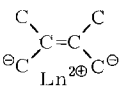
Thus, the cocondensation of La, Nd, Sm, or Er with butadiene or 2,3-dimethylbutadiene at 77 K affords brown solids, which, on extraction with toluene or THF, yield paramagnetic compounds for which the formulas **219**, **220** and **221** are under discussion (H atoms not shown)[209].



219



220



221

Samarium, erbium and ytterbium also react with ethene, propene or 1,2-propadiene at 77 K with formation of orange to black products, the hydrolytic decomposition of which affords the hydrocarbons methane, ethane, propene, propane, butene, butane, allene, or propyne. However, the only compound to have been isolated and characterized is the erbium complex $(CH_3CH{=}CH_2)_3Er$ **222o**[210]. The cocondensation of Sm, Er, or Yb with 3-hexyne at 77 K yields brown solids which upon extraction give the isolable complexes $C_6H_{10}Sm$, $C_{18}H_{30}Er_2$, or $C_6H_{10}Yb$. The structure of these compounds, which are useful as hydrogenation catalysts, is still unknown[133,211].

6. Reactive Behavior and Application in Catalysis and Organic Synthesis

Organolanthanoid compounds, most of which are highly reactive, count among the most novel and versatile tools in the chemist's armamentarium.

A systematic investigation of the chemical behavior of these compounds has not yet been possible, since, in most cases, the synthesis and characterization of the compounds themselves still raise difficulties. On the basis of the studies carried out so far, however, it can be assumed that these compounds should provide interesting new possibilities in catalysis and organic syntheses.

The first indication of the catalytic ability of the organolanthanoid compounds was provided by the observation that oxides, halides, and alkoxides of almost all lanthanoids in the presence of alkylaluminum, alkyllithium, or other organometallic compounds catalyze cracking reactions, oligomerizations, and polymerizations[11,212]. **4h** catalyzes the dimerization of diphenylacetylene[213]; several alkyl(dicyclopentadienyl)lanthanoid[214,215], cyclooctatetraenylcerium, and allyllanthanoid complexes[212] catalyze the polymerization of olefins such as ethene or butadiene.

Initial studies on the reaction of **64r** with propene, which reveal an insertion-elimination equilibrium, provide an insight into the mechanism of such catalytic reactions[82,83].

$$(C_5Me_5)_2LuCH_3 + CH_2{=}CHCH_3 \rightleftharpoons (C_5Me_5)_2LuCH_2CH(CH_3)_2$$
64r

Organolanthanoid hydrides[135,140,210,216], cyclopentadienylytterbium(II) derivatives[182], as well as the cocondensation products of lanthanoids with alkynes[133,211,217] catalyze the hydrogenation of alkenes and alkynes.

Organocerium compounds, which are generated in situ from CeI_3 and alkyllithium, convert ketones into tertiary alcohols in high yields at $-65\,^{\circ}C$. At $0\,^{\circ}C$, an additional reductive coupling is observed[218]. Organocerium compounds are also useful for the synthesis of allyl alcohols[219] and pinacols[220], for aldol reactions with ketones or sterically crowded aldehydes[221], and for the reduction of alkynes and mono- or disubstituted alkenes[222]. These investigations show that organolanthanoid compounds are sometimes helpful in solving chemical problems which cannot be resolved with organic derivatives of main group elements or with transition metal compounds[223].

The homoleptic methyl derivatives **114** methylate α,β-unsaturated aldehydes and ketones in yields of more than 80%, the formation of 1,2-adducts being favored[129].

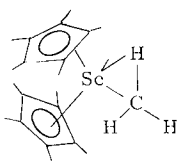
The organolanthanoids are particularly efficient at activating C–H bonds. The compounds **64b**, **64r** (R = CH_3) and **65b**, **65r** (R = H) even cleave the C–H bonds in methane, benzene and tetramethylsilane. By using ^{13}C-labeled methane it was possible to prove that the first step in the substitution reaction is the following exchange reaction, suggesting intermediate formation of the transition state **223r**[85].

$$(C_5Me_5)_2LnR + {}^{13}CH_4 \rightleftharpoons (C_5Me_5)_2Ln{-}{}^{13}CH_3 + RH$$
64b, **r**, **65b**, **r**

$$(C_5Me_5)_2LuCH_3 \underset{-CH_4}{\overset{+CH_4}{\rightleftharpoons}} (C_5Me_5)_2Lu\begin{matrix}CH_3\\ \diagdown\\ \diagup\\ CH_3\end{matrix}\!\!\cdots H$$
64r **223r**

$$(C_5Me_5)_2LuCH_3 + C_6H_6 \longrightarrow (C_5Me_5)_2LuC_6H_5 + CH_4$$
64r **66r**

The most recent investigations show that **64a** also has the ability to activate methane. The "agostic"[224] methyl group is said to be the active center of this compound[225].



64a

The reaction of **53r** with CO in THF, which yields the acyl complex **158r**, proves that even CO is activated by organolanthanoid compounds[154] (see Section 2.9.1).

7. Outlook

The synthesis of a respectable number of organometallic compounds of all the lanthanoids in the last 15 years has filled—albeit tentatively—one of the largest remaining gaps in organometallic chemistry. The fundamental prerequisites for this development have been the easier accessibility of "elemental pure" lanthanoids, the improvements of methods of preparation, and, in particular, the better opportunities for carrying out exact structure determinations within a short time.

Even today, the major concern in this area of chemistry is the problematical and often very troublesome synthesis and characterization of the compounds themselves. However, in the near future, it should be possible to answer at least some of the many questions which are posing themselves as more and more progress is being made regarding the chemistry of organolanthanoid compounds. Some of these questions are: How does the stability of homologous compounds change in going from scandium to lutetium? Are organocerium(IV) compounds able to exist? Is it possible to isolate definite carbonyl, phosphane, or olefinic complexes of the lanthanoids? Is it possible to synthesize organolanthanoid compounds containing lanthanoid-lanthanoid bonds? How useful are organolanthanoid compounds in organic synthesis? Will the organolanthanoid compounds—because of the nontoxicity of their hard-acid lanthanoid ions—oust the ecologically objectionable heavy metal compounds from some fields of application? And last, but not least, is this sector of organometallic chemistry not a real bonanza for theorists?

The author's work cited in this review could not have been carried out without the inspiring and engaging cooperation of Ilse Albrecht, Ursula Kieper, Norbert Bruncks, Dr. Manfred Cygon, Manfred Dettlaff, Dr. Georg-Michael Frisch, Dr. Wolfgang Genthe, Ekkehardt Hahn, Dr. Sigurd Hohmann, Dr. Hartmut Jarosch, Gerald Jeske, Harald Lauke, Dr. Jochen Müller, Sigbert Nickel, Dr. Friedrich-Wilhelm Reier, and Klaus-Dieter Ziep. I thank them all for their invaluable help. The crystallographic investigations supporting this work were undertaken in collaboration with Prof. Dr. Joachim Pickardt. I also wish to thank the Senator für Wirtschaft und Verkehr des Landes Berlin, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie, for financial support of this work.

Mycotoxins from Mold Fungi—Weapons of Uninivited Fellow-Boarders of Man and Animal: Structures, Biological Activity, Biosynthesis, and Precautions**

By Burchard Franck*

In addition to the antibiotics, mycotoxins represent a second large group of biologically active substances of microbial origin. Over 300 mycotoxins are so far known and can be subdivided into 25 structural types. They are formed by approximately 350 molds of which there are 10000 different strains. As mycotoxin-producing molds tend to spread aggressively on foodstuffs, they can cause epidemic mycotoxicoses.—The mycotoxins have been isolated, their structures determined, and their biological activities investigated; their biosynthesis has now also largely been elucidated. Accordingly, mycotoxins are derived from only three groups of key biogenetic building blocks: polyketides, isopentenyl pyrophosphate, and amino acids. Mycotoxins are mainly non-polar, chemically stable, are formed in high concentrations, and do not contain—unlike antibiotics—any sugars. Mycotoxins display an enormous variety of toxic-pharmacological activities, e.g. liver degradation, hemorrhages, carcinomas. The identification of mycotoxicoses is impeded by their long incubation periods and the fact that the mycotoxins tend to accumulate in the mammalian organism, which means that even very low concentrations in food are a potential danger. The particularly dangerous aflatoxin B_1 **1** may not exceed a limit in food of 5 ppb (5 μg/kg), which is difficult to control.

1. Introduction

Everyone knows what happens when fruit juice is left to stand unprotected for a few days (Fig. 1). Mold colonies are formed from the germs present in the air, usually Aspergillus and Penicillium species. We then do not feel like drinking the juice, our instinct warns us to be careful, and this is important because many of these fungi produce poisonous metabolic products which are dangerous for man and mammals. These poisonous substances are called mycotoxins.

The biological activities of the mycotoxins differ from those of the antibiotics produced against bacteria. The mycotoxins and antibiotics provide the microorganisms with effective means of driving other living organisms away from their sources of food. In Figure 1 the molds have already won this battle, as man can now no longer enjoy the foodstuff they have covered.

Some typical features of mycotoxins and antibiotics are compiled in Table 1. Mycotoxins are synthesized by the rapidly growing, aggressively spreading molds; antibiotics are mostly formed by Streptomycetes. Whereas the Streptomycetes are satisfied with residual substances such as cellulose and chitin, which are difficult to degrade, molds compete with higher organisms for their foodstuffs and fodder. Man and mammals are thus greatly endangered by mycotoxins.

Penicillin G and streptomycin are the most important antibiotics, whilst aflatoxin B_1 **1** is the most dangerous representative of the mycotoxins.

The danger posed by the mycotoxins and the diseases they cause, *mycotoxicoses*, were underestimated for a long time, which is why they are also referred to as the "neglected diseases"[1]. This situation changed suddenly from 1960 onwards with the epoch-making discovery of the

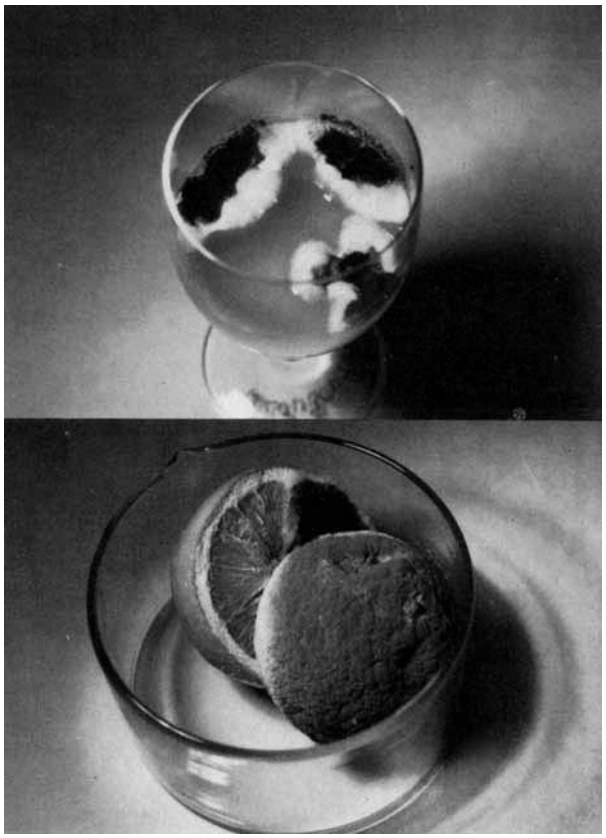

Fig. 1. *Aspergillus niger* growing on orange juice (above) and a mixed infection of Aspergillus and Penicillium species on an orange (below).

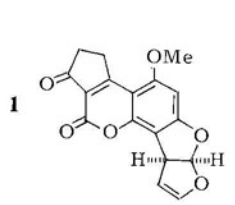
mass poisoning of young turkeys by moldy peanut fodder on farms in South and East England[2,3]. The peanut meal was infected with the mold *Aspergillus flavus*, which produces aflatoxins that are highly toxic (for man as well), causing liver cancer[3]. Since then, intensive interdisciplinary studies have demonstrated that further mycotoxins are responsible for dangerous illnesses. As a result the physiological, toxicological, and food-chemical classification of mycotoxins progressed rapidly[4–11]. Many unpredictable findings were made which had a stimulating influence on large areas of bioorganic chemistry. Three main aspects and important research targets can be distinguished and are dealt with here: 1) Structures and biological activity, 2) biosynthesis of the mycotoxins, 3) protection against their toxic effects.

Table 1. Comparison of mycotoxins and antibiotics.

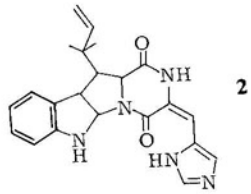
	Mycotoxins	Antibiotics
Active against:	Higher organisms (e.g. mammals)	Bacteria (e.g. pathogenic bact.)
Produced predominantly by:	Molds	Streptomycetes
Preferred nutrient media:	Easy to degrade (e.g. foodstuffs)	Difficult to degrade (e.g. cellulose, chitin)
Typical examples	Aflatoxin B_1 1	Streptomycin, penicillin G

2. State of Development of Mycotoxin Research

More than 300 mycotoxins are so far known and can be subdivided into 25 structural types[4]; they are synthesized by 350 different molds, each of which has up to 100 strains. A total of approximately 10000 mycotoxin producers thus threaten our foodstuffs. This still represents, however, a modest start comparable to the state of antibiotic research 30 years ago[12].



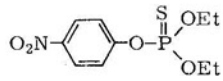
Aflatoxin B_1[3,14]
(Aspergillus flavus)
LD_{50} (OR, rat) 7.2 mg/kg[4]



Roquefortin[15,16]
(Penicillium roqueforti)
LD_{50} (IP, mouse) 10–20 mg/kg[4]

As_2O_3

Arsenic
LD_{50} (OR, rat) 15 mg/kg[13]



Parathion (E 605)
LD_{50} (OR, rat) 4–13 mg/kg[13]

Fig. 2. Structures and toxicities of two typical mycotoxins and comparable toxins. (OR = oral, IP = intraperitoneal administration).

Figure 2 shows two typical mycotoxins, aflatoxin B_1 **1**[3,14] and roquefortin **2**[15,16]. The toxicities of two well-known poisons, arsenic and parathion, are also given for comparison. The roquefortin-producing mold *Penicillium roqueforti* is used in the preparation of many types of blue cheeses. Mycotoxins are thus not only limited to those molds which occur as avoidable infections of foodstuffs. Fortunately, the roquefortin content of normal blue cheeses is so low (<7 ppm)[17] that the lethal adult dose is only reached after eating 200 kg of the cheese.

Mycotoxins with more than twenty different activities (see Table 5) can be isolated from the molds found in human food; they are often threatening to life and many of them cause cancer[4,6]. According to an estimate of the International Agency on Cancer[18], 80% of cancers are caused by environmental factors, mycotoxins making a considerable contribution to this.

Practically all foodstuffs may contain toxin-producing molds. The mycotoxin contents of the majority of the foodstuffs listed in Table 2 are checked continuously in many countries.

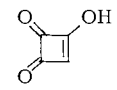
Table 2. Foodstuffs particularly threatened by mycotoxin-producing molds.

Nuts	Cereal products	Fruit products	Foodstuffs of animal origin
Peanuts	Rice	Tomato juice	Milk
Brazil nuts	Maize	Apple juice	Cheese
Walnuts	Rye	Orange juice	Egg products
Hazelnuts	Wheat	Wine	Sausage meats
Almonds	Soybeans	Fruit purees	Liver
Pistachio nuts	Cornflakes	Fruit jellies	Kidney

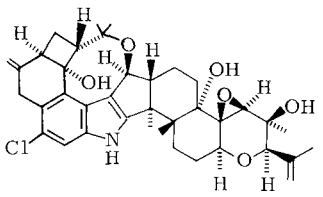
Man is threatened in two ways by mycotoxins. First of all directly by the consumption of foodstuffs which are infected with toxin-producing molds. Secondly in an indirect manner by the meat, milk, and eggs of animals whose fodder contained mold colonies (carry-over) due to the high persistence of the mycotoxins in metabolism. This applies especially to liver and kidney, where mycotoxins can be accumulated[19].

3. Structures, Biological Activity, and Mycotoxicoses

As is typical for natural products of secondary metabolism, mycotoxins mainly occur as groups of structurally related compounds containing numerous components, many of which are regioisomers, diastereomers, or enantiomers. The mycotoxins also display a wide variety of structures and chemical properties. This is demonstrated, for example, by the readily water-soluble, highly toxic moniliformin **3**[20] from *Fusarium moniliforme* and the complex, hydrophobic, tremorgenic penitreme A **4** from *Penicillium crustosum*[21,22]. The isolation and purification of mycotoxins thus require intensive use of the most modern separation methods[23].



3



4

3.1. Ergotism

The structural elucidation of the mycotoxins began with the causative agent of the longest known mycotoxicosis, *ergotism*. This disease is caused by the filamentous fungus *Claciceps purpurea*, which is to be found on ears of grain where it forms the black sclerotia known as ergot[24]. These found their way into the bread cereals and caused epidemic, mass poisoning which has been known in Europe since the Middle Ages[25,26]. Chemical investigations performed for well over one hundred years finally led to the elucidation of two mycotoxin groups—the ergot alkaloids[27] (e.g., ergotamine **5**) and the yellow ergochromes[28] (e.g., secalonic acid A **6**) (Fig. 3).

The mycotoxicosis ergotism is associated with burning pains in the extremities and was previously called St. Anthony's fire. Pilgrimages to the grave of St. Anthony in Padua indeed often resulted in the ergotism being cured since the afflicted persons had left the area where the bread was contaminated with ergot[29].

The fact that the action of ergot involves not only the long-known ergot alkaloids[27] but also the more toxic ergochromes[28,30,31], which are present in larger quantities[32], was appreciated at a relatively late stage after the structure of this new group of natural products had been established. This is because the ergochromes possess six to ten centers of chirality, and thus mixtures of diastereomers occur which could only be separated by modern chromatographic methods. Between 1964 and 1966 our group purified nine sterically uniform ergochromes and determined their structures, including the absolute configurations at a

total of 78 centers of chirality[33-35]. The studies of other groups of workers produced a further five ergochromes[36]. *Steyn*[37] in Pretoria made a surprising discovery when he isolated an enantiomer of secalonic acid A **6**, the secalonic acid D **7**, as the toxic principle of the maize fungus *Penicillium oxalicum*. **7** possesses the opposite configurations to those of **6** at all six of its centers of chirality (Fig. 4). This

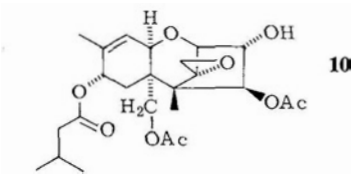
unique finding is as remarkable as if the enantiomer **9** of a steroid hormone (e.g., cortisone **8**) had been isolated as a natural compound.

3.2. Alimentary Toxic Aleukia (ATA)

Alimentary toxic aleukia (ATA) is another serious mycotoxicosis which is caused by a mold growing on cereals[38]. This disease is characterized by progressive damage of the hemopoietic system, which is responsible for the formation of the red and white blood corpuscles. ATA begins with destruction of the skin, hemorrhaging, inflammation, and sepsis (Fig. 5). In the terminal stages the bone marrow atrophies, and the leukocytes and erythrocytes decrease markedly. The mortality of this mycotoxicosis is 60%.

Fig. 5. Initial stage of alimentary toxic aleukia (ATA) in a 15 year old boy (from [41a]).

ATA was identified as a mycotoxicosis as a result of studies on a widespread outbreak of the disease in 1944 in the southern Ural region of Russia which extended over 500 km. The food cereals were infected with toxigenic Fusaria species which synthesize type "T-2 toxin" **10**[39] mycotoxins (Fig. 6).



10

T-2 toxin[39]

(Fusarium culmorum)

hemorrhaging, sepsis, decrease in red and white blood corpuscles,

bone marrow atrophy,

inhibition of protein synthesis (similar to the alkylating agents such as nitrogen mustard gas), damage to the hemopoietic system[4,38].

Fig. 6. Alimentary toxic aleukia: causative agent, its origin and mode of action.

The T-2 toxin **10** inhibits protein synthesis by a mechanism similar to that of nitrogen mustard gas. Since the first representative of this group of mycotoxins was isolated by *Freeman* and *Morrison*[39b] from *Trichothecium roseum*, they were called the "trichothecenes". The more than 50 trichothecenes so far known constitute one of the most important groups of mycotoxins[40]. If there are bottlenecks in the purity control and supply of foodstuffs, especially in tropical climates, the mycotoxicosis ATA caused by the trichothecenes represents a considerable source of danger to the population; this is apparently now the case in Cambodia[41].

3.3. Aflatoxicosis

Aflatoxicosis was the third epidemic mycotoxicosis to be recognized after ergotism and ATA, and is the most dangerous. As soon as the aflatoxins of the mold *Aspergillus flavus* had been identified as the cause of the "turkey X disease"[2,3], intensive studies were undertaken to establish whether these highly active mycotoxins were also responsible for human mycotoxicoses[42,43]. This required a complicated, comprehensive screening program. For example, the daily consumption of aflatoxins was determined by analyzing a large number of food samples collected from markets and domestic households[44]. A significant statistical relationship between the incidence of liver cancer and the intake of aflatoxins was established. Some typical examples are compiled in Table 3.

Table 3. Incidence of liver cancer (cases per 100000 people per annum) and aflatoxin intake (ng/kg body weight per day) in Africa and Asia [44].

Region	Incidence of liver cancer	Aflatoxin intake
Kenya—highlands	0.7	3.5
Thailand—Songkhla	2.0	5.0
Swaziland—highlands	2.2	5.1
Kenya—medium altitude	2.9	5.8
Swaziland—medium altitude	4.0	8.9
Kenya—lowlands	4.2	10.0
Thailand—Ratburi	6.0	45.0
Swaziland—lowlands	9.7	43.1
Mozambique—Inhambane	13.0	222.4

The normal incidence of liver cancer is two cases per 100000 people per annum. This frequency was observed in dry highlands where it is relatively simple to keep the mold infection of food and thus their aflatoxin content at a low level. The daily aflatoxin intake in these regions is less than 5 ng/kg body weight. If the aflatoxin intake is doubled to 10 ng/kg, as is the case in the more humid lowland areas of Kenya, the average incidence of liver cancer increases by 100%. Although the linear relationship to cancer incidence is not maintained at higher levels of aflatoxin intake, the effect of these mycotoxins is still evident. Similar to the situation in liver cancer, there also seems to be a relationship between aflatoxin intake and the "childhood cirrhosis" encountered in India (Fig. 7)[46].

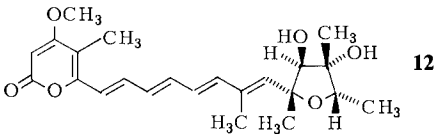
(milk from animals whose fodder contains aflatoxin B_1 1)

Fig. 7. Human aflatoxicoses: Causative agents, their origins and modes of action. 1 and 11 cause liver cancer and Indian childhood cirrhosis, respectively. After being converted into the 15,16-epoxides 1 and 11 bind to RNA and other vitally important macromolecules [47].

Of the approximately 20 aflatoxins so far known, special attention should be paid to aflatoxin B_1 1 and the equally carcinogenic aflatoxin M_1 11; the latter is a hydroxylation product formed in the metabolism of mammals whose food contains 1. Aflatoxin M_1 11 in cows' milk may be the cause of severe liver cirrhosis observed in young children in India and Africa. The mechanism of action of the aflatoxins, which includes a 15,16-epoxide and involves cytochrome P-450, is currently under intensive investigation[47,48].

3.4. "Cardiac Beriberi"

A fourth mycotoxicosis is caused by a toxin of the East Asian rice fungus *Penicillium citreoviride*[49], the polyene lactone citreoviridin **12**[50] (Fig. 8). This mycotoxicosis is



12

Citreoviridin

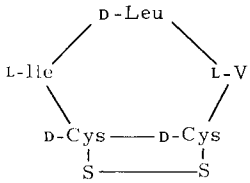
Fig. 8. "Cardiac beriberi": Causative agent, its origin and mode of action.

referred to as "cardiac beriberi" because its symptoms resemble those of the avitaminosis beriberi which results from a deficiency of vitamin B_1. The disease begins with disturbances of cardiac function and progresses with difficulty in breathing (dyspnea), nausea, and vomiting. Cardiac beriberi was endemic among the rice-eating population of South East Asia until its cause was identified and largely eliminated by preventing fungal infection of rice. Previously, for example in 1908[48], more than 10000 deaths from "cardiac beriberi" were registered annually in Japan alone. Under certain conditions the action of citreoviridin, which evidently[52] involves inhibition of mitochondrial ATP synthesis, can be overcome by administration of vitamin B_1[49].

Until recently it was assumed that citreoviridin **12** was only to be found in the South East Asian rice fungus; in 1980 we discovered[51], however, that this dangerous mycotoxin and two new structurally related mycotoxins are also produced by the mold *Aspergillus terreus* which occurs in soil, on cereals, and sugar-containing foodstuffs. The citreoviridin contents of *A. terreus* reach extremely high levels—up to 2% of the dry mycelium weight.

The finding that *Aspergillus terreus* synthesizes mycotoxins is also important because this mold is used for the biotechnological production of, for example, itaconic acid[53,54]. As is the case with other "useful molds" which simultaneously form mycotoxins, the useful product must be purified with particular care. This also applies to the mold *Aspergillus niger* employed to obtain citric acid[54]; it synthesizes a group of toxic cyclopeptides, e.g. the stereochemically interesting malformin A_1 **13**[55].

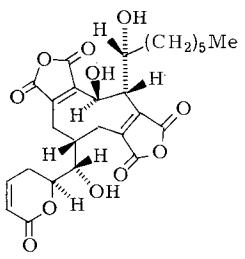


13

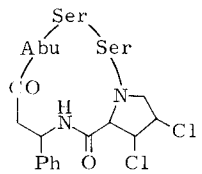
Malformin A_1 [55] *(Aspergillus niger)*: LD_{50} (IP, mouse) 3.1 mg/kg [4, 55].

3.5. Other Mycotoxicoses

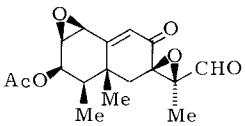
In addition to those mycotoxins which are known to be responsible for epidemic mycotoxicoses, due attention should be paid to other identified and not yet identified mold toxins. On account of their special structures and dangerous biological activities (see Table 5), rubratoxin B **14**[56], islanditoxin **15**[57], PR toxin **16**[58,59], and cytochalasin E **17**[60] (Abu = 2-aminobutyric acid) should be mentioned.



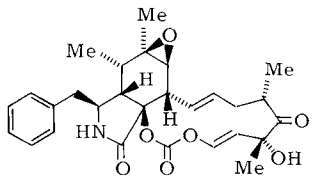
14



15



16



17

4. Criteria for the Effectiveness of the Mycotoxins

It would be desirable to classify the mycotoxins so far studied according to their biological activities. On closer consideration, however, this is not so simple because a variety of criteria have to be taken into account (Table 4).

Table 4. Criteria for evaluating the biological activity of mycotoxins.

1) Acute toxicity (LD_{50})
2) Specific pharmacological actions
3) Carcinogenic and mutagenic actions
4) Accumulative effects
5) Aggressiveness of the mold producing the mycotoxin
6) Cause of mycotoxicoses

The acute toxicity is undoubtedly very informative for evaluating a mycotoxin. However, the toxic effects of the mycotoxins commence at levels far below their lethal concentrations, so that their dangerous potency is primarily determined by the nature of their pharmacological actions. The way in which the LD_{50} is determined is also of importance. Somewhat lower toxicities are generally found for oral administration (OR), which is particularly informative for mycotoxins, than for intraperitoneal (IP), intravenous (IV), or subcutaneous (SC) testing. Despite this, listing the mycotoxins in the order of their acute toxicities (as shown in Table 5 for 18 of the mycotoxins discussed in this article) provides a useful guide.

The carcinogenic and mutagenic effects of the mycotoxins are other criteria of their biological activity which cannot be inferred from their acute toxicities. Furthermore, a mycotoxin which can accumulate at sensitive sites in the organism may be much more dangerous on a long term basis than would be expected from its possibly low toxicity. The production of mycotoxicoses is of particular importance. This depends on additional factors such as the ability of the mold synthesizing the mycotoxin in question to spread aggressively on foodstuffs. The mycotoxins ergotamine **5** and secalonic acid A **6** of the ergot fungus *Claviceps purpurea* are typical examples. Although their acute toxicities are comparatively low, they are responsible for the devastating mycotoxicosis ergotism which terrorized the population of Europe for many centuries. Finally, the biological activities of the mycotoxins should not be regarded as being solely of negative value.

In appropriate doses, some mycotoxins have therefore found useful medicinal and other applications. Under the name Gynergen®, the tartrate of ergotamine **5** is used in obstetrics and, because of its α-blocking, vascoconstrictive action, as a remedy for migraine[97]. As indicated by Japanese patent applications, ergochromes formed by ergot fungi and other mold fungi, e.g. the secalonic acids A **6** and D **7**, are being tested as antineoplastic agents. According to the particularly extensive, most recent application[98], secalonic acid derivatives with phthalimidomethyl and maleimidomethyl groups in the 4,4′-position exert antineoplastic activity. One of these derivatives was able, e.g. to increase the survival rate of mice implanted with Ehrlich ascites tumor by over 300%.

Zearalenone **32**, which, despite low acute toxicity, is classed with the mycotoxins, is used in animal husbandry because of its estrogenic and anabolic effects[99, 100]. The compound can markedly accelerate the increase in weight of young animals. A commercially available mixture of epimeric zearalenols prepared from **32** (Ralgro®) produces, e.g. as a 12 mg implant in lambs, a weight increase of ca. 23% and reduces the amount of feeding required. Because of its high persistence and carry-over into meat, this use of zearalone, which gives rise to concern, is difficult to control since both dosage and detection sensitivity (Table 8) are low.

5. Biosynthesis

The mold mycotoxins are secondary metabolic products which have many novel structures and thus provide a wealth of information about the biosynthesis of natural products[61]. This has improved the understanding both of metabolic relationships and of the functions of the key biosynthetic building blocks[62]. This in turn, opens up ways of performing simple biomimetic syntheses for organic chemistry[63].

5.1. Key Building Blocks of Mycotoxin Biosynthesis

Research into mycotoxin biosynthesis began at a time when the necessary methodology had reached a high level due to the development of efficient labeling syntheses, the availability of stable radioactive isotopes, and modern methods for determining their positions. Furthermore, mold fungi proved to be excellent subjects for biosynthetic experiments because their metabolite production was, by comparison, particularly reliable and reproducible; the enzymes of intact cells were also highly accessible to the labeled precursors.

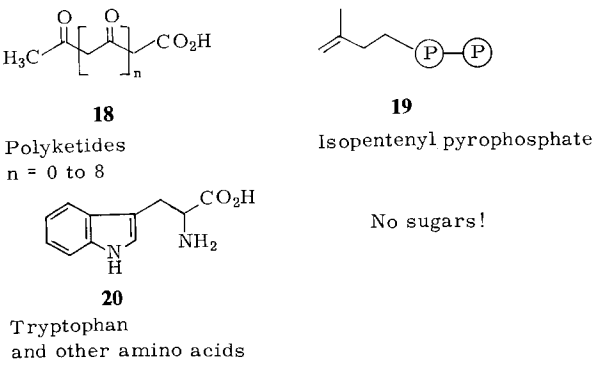

Fig. 9. The most important key building blocks in mycotoxin biosynthesis.

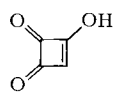
Progress was therefore rapid. The most important result was that the biosyntheses of all 300 known mycotoxins are based on a small number of biogenetic key building blocks, which are summarized in Figure 9. The di- to decaketides **18**, which contain two to ten acetic acid units, are exceedingly important, and mycotoxins with a wide range of biological activities can be constructed from these polyketides in an extremely versatile way. Moreover, many mycotoxins are formed either from isopentenyl pyrophosphate **19**, either alone or in combination with tryptophan **20** and other amino acids.

One of the characteristic features of mycotoxin biosynthesis is that, unlike other products of microbiological origin, e.g. the antibiotics, practically *no sugars* are used as biosynthetic precursors or building blocks.

5.2. Biosynthesis of Moniliformin

Until recently a tetraketide (**18**, n = 2) was held to be the first member of the natural product series formed by the cyclization of polyketides. According to recent labeling experiments performed by our group, however, a diketide (**18**, n = 0) may act as a precursor in the biosynthesis of the structurally particularly simple mycotoxin moniliformin **3**[67].



3

Moniliformin (*Fuarium moniliforme*, *Gibberela fujikuroi*): LD_{50} (OR, cockerel) 4.0 mg/kg [4]: pK_a 0.88 ± 0.03 [66].

The highly acidic moniliformin **3** was first isolated by *Cole* et al.[20] and its structure was elucidated by *Springer* et al.[65]; **3** is formed in high concentrations (up to 33 g/kg[64]) by the mold *Fusarium moniliforme* which is particularly common in maize fodder. This amount would be sufficient to kill 200000 cockerels. *Fusarium moniliforme* and *Gibberella fujikuroi* only produce moniliformin on a solid maize culture medium on which they grow aggressively, transforming it rapidly and completely into a white mycelium.

In order to test the biosynthesis suggested by the structure of moniliformin **3** from a ketide precursor such as **22**, we fed solid cultures of *G. fujikuroi* with [1-^{14}C]-, [2-^{14}C]acetate, and [2-^{14}C]malonate[67]. We also tested another biosynthetic pathway (Fig. 10), and in connection with this

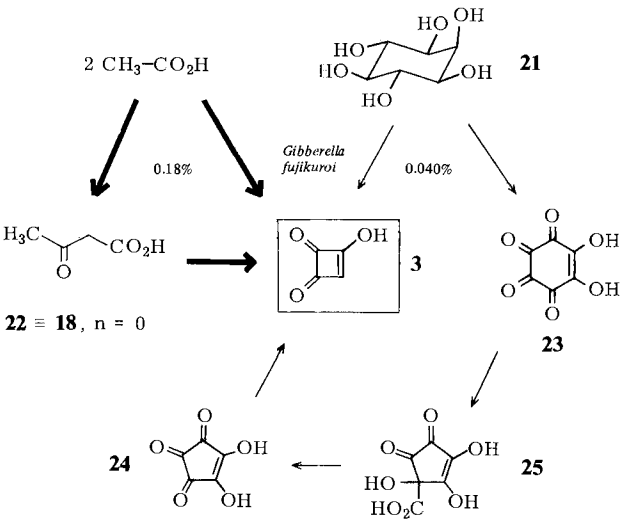


Fig. 10. Biosynthetic pathways and incorporation results for the mycotoxin moniliformin **3**.

checked the incorporation of an additional series of radioactively labeled precursors to rule out the possibility of alternative synthetic routes. Formation of moniliformin from mesoinositol **21** (which is found in many fungal molds) via rhodizonic acid **23** and croconic acid **24** was considered as an alternative biosynthetic pathway. **23** and **24** may be produced by oxidative conversion and benzilic acid rearrangement and are also known natural products. Incorporation experiments with [U-^{14}C]mesoinositol **21** and other precursors, however, only gave very low incorporation levels so that the biosynthetic route via the diketide **22** ≡ **18** (n = 0) seems to be the most likely. The incorporation value of 0.18 for acetate is two orders of magnitude greater than the significance level; this is comparatively high and convincing in view of the many metabolic pathways which require acetate and the fact that the precursors were administered to a solid culture.

The biosynthesis of moniliformin **3** from acetate thus probably proceeds via malonyl coenzyme A **26** and 1,3-butanedione **27** (Fig. 11). Oxidation of the reactive methylene groups of **27** would yield the intermediate described by the tautomeric forms **28a**–**28c**, which could be dehydrated to give moniliformin **3**. Oxidative degradation of radioactive moniliformin **3** obtained after feeding *Gibber-*

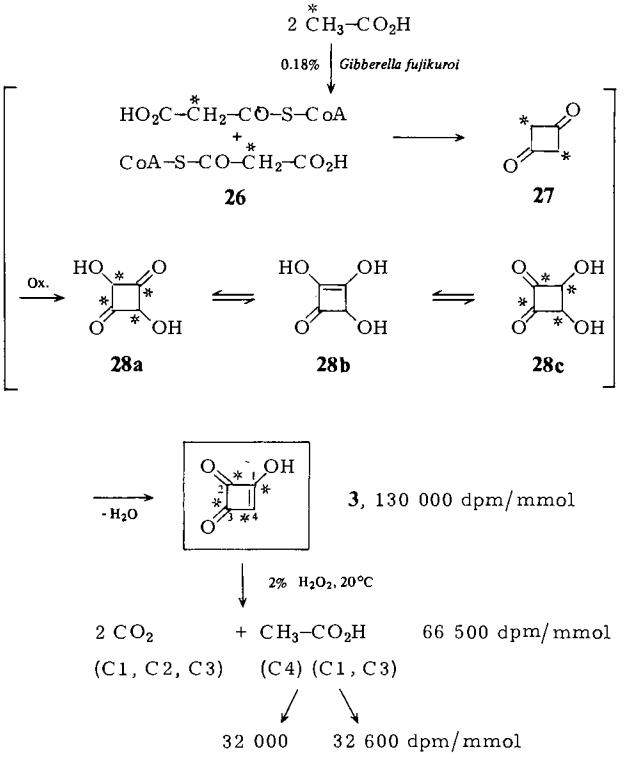

Fig. 11. Formation and degradation of radioactive moniliformin **3** from [2-^{14}C]acetate [67]. dpm = disintegrations per minute *Giberella fujikuroi*.

ella fujikuroi with [2-^{14}C]acetate gave the same specific radioactivities for all the C atoms. This is in accord with the biosynthetic pathway (Fig. 11) involving the tautomeric intermediate **28**.

5.3. Mycotoxins from other Polyketides

Figure 12 summarizes the biosynthesis of two more mycotoxins which are formed from tetra- and pentaketide precursors (**18**, n = 2 and 3, respectively) by consecutive functional changes: the carcinogenic mycotoxin patulin **29** from *Penicillium patulum*[68], which is found in apple juice, and the hepatotoxic ochratoxin **30** from *Aspergillus ochraceus*[69].

The variety of possible condensations undergone, for example, by the nonaketide **31** (≡ **18**, n = 7) is much greater than that of these smaller polyketides. Two bicyclic mycotoxins are shown in Figure 13 as examples; they are derived from two differently folded conformations **31b** and **31c** of the open-chain nonaketide precursor **31a**. These are the polyene mycotoxin citreoviridin **12**, which causes "cardiac beriberi" (Fig. 8), and zearalenone **32**, which has strong estrogenic activity. Incorporation experiments with ^{14}C-labeled acetate and methionine were performed with *Penicillium citreoviride* to clarify the biosynthesis of citreoviridin **12**[70]. These studies demonstrated that the four *C*-methyl groups at positions 4, 12, 14, and 16 are derived from methionine and that some of the chain C atoms are formed from acetic acid; this supports the polyketide concept. After we discovered that citreoviridin **12** is also synthesized in particularly high concentrations by the mold *Aspergillus terreus*, we used this finding for the incorporation of [1-^{13}C]- and [2-^{13}C]acetate and subsequent evaluation by ^{13}C-NMR spectroscopy[51]. Administration of the precursors in the nutrient solution of the mold cultures at the comparatively high concentration of 0.2% gave high incorporation rates of 17.6 and 25.7%, respectively, for the ^{13}C-labeled acetates, thus allowing reliable determination of the position by ^{13}C-NMR spectroscopy.

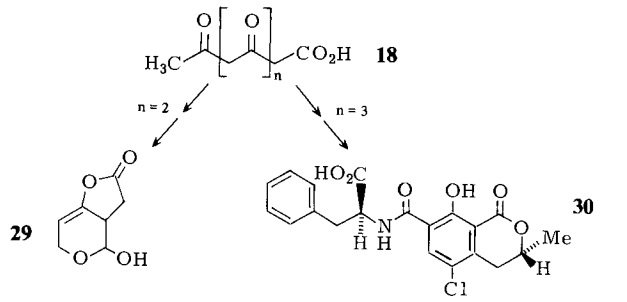

Fig. 12. Polyketide precursors of the mycotoxins patulin **29** and ochratoxin **30** [61].

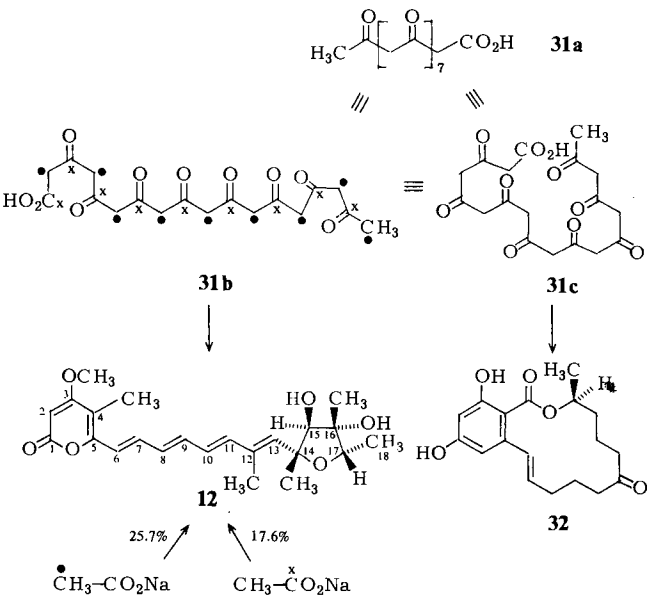

Fig. 13. Biosynthesis of the mycotoxins citreoviridin **12** and zearalenone **32** [72] from the nonaketide **31** (≡ **18**, n = 7). ●, × see text.

According to these studies, all the evenly numbered C atoms (●) of the polyketide chain of the precursor of citreoviridin **31b** are derived from the methyl groups of the acetate building blocks and the unevenly numbered C atoms (×) from the carboxy groups. The C atoms of the *C* methyl and methoxy groups of **12** did not exhibit any significant signals in the ^{13}C-NMR spectrum, which is consistent with their origin in the C_1 pool of the organism. These findings have recently been confirmed in *P. citreoviride*[71].

5.4. Secoanthraquinones

Elucidation of the biosynthesis of mycotoxins of the octaketide type **33**(≡ **18**, n = 6) led to the discovery of previously unknown ring-opening reactions of the anthraquinones (Fig. 14). The toxic emodin **34** of the rice fungus *Penicillium islandicum* is formed from the octaketide **33b**[73] (see Table 5). We were able to prove the hypothesis

that the ergochromes (e.g. secalonic acid A **6**) are produced from an octaketide via **34** shortly after having determined the structure of these mycotoxins[74,75].

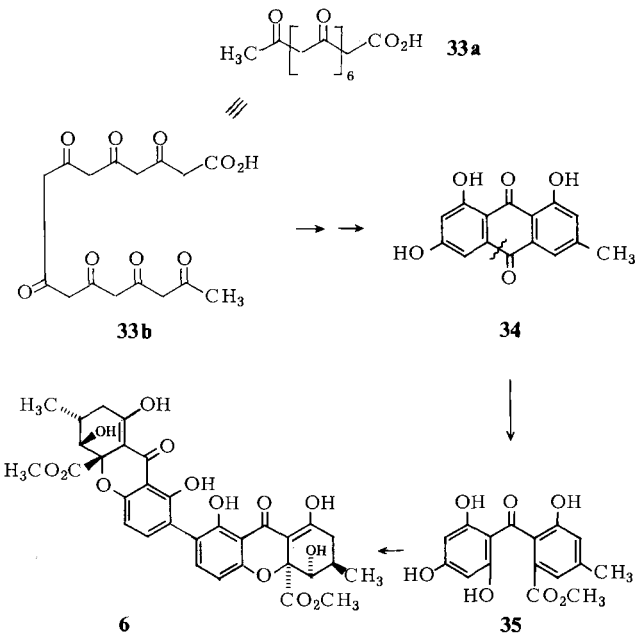

Fig. 14. Biosynthesis of the mycotoxins emodin **34** and secalonic acid A **6** from the octaketide **33** (≡ **18**, n=6).

Oxidative ring-opening of the anthraquinone first yields a benzophenone carboxylic acid **35** which, after functional transformations, cyclizes to the xanthone derivative and finally undergoes oxidative dimerization to give **6**. Figure 15 shows a few of the many incorporation experiments performed to prove the ergochrome biosynthesis[63]. These studies also helped to show whether emodin **34** or emodinanthrone **36** is the better biosynthetic precursor, which was important to explain the ring-opening mechanism.

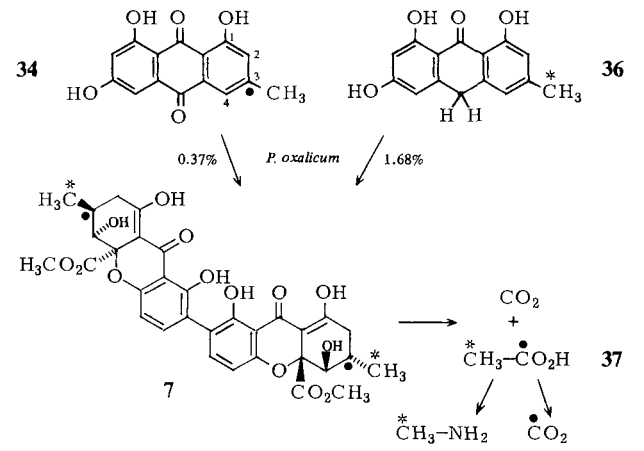

Fig. 15. Incorporation experiments on the biosynthesis of the ergochrome secalonic acid D **7** in the mold *Penicillium oxalicum* [76].

Comparative experiments were carried out to determine the incorporation ratio of emodin **34** and emodinanthrone **36** independent of fluctuations in the growth of the fungal cultures (Fig. 15). For this purpose we prepared emodin **34** and emodinanthrone **36**, labeled with ^{14}C at C-3 and the methyl group, respectively, by total syntheses; a mixture of these compounds was then fed to the mold *Penicillium oxalicum*.

The labeling positions of **34** and **36** were chosen such that their radioactivity could be cleaved from the subsequently isolated biosynthetic product secalonic acid D **7** by Kuhn-Roth oxidation in the form of acetic acid. The desired information about the incorporation values of emodin **34** and emodinanthrone **36** was stored in the respective radioactivities of the carboxy and methyl groups of the "Kuhn-Roth acetic acid" **37**. After Schmidt degradation of the acetic acid to CO_2 and methylamine and oxidation of the latter to CO_2, the incorporation levels were found to be 0.37% and 1.68%, respectively. The radioactivity of the carbon dioxide produced during the Kuhn-Roth oxidation, in addition to the acetic acid, was below the limit of significance. This demonstrated that the ergochrome secalonic acid D **3** is derived directly from two molecules of an anthraquinone by ring opening, whereby emodianthrone **36** proved to be a 4.5-fold better precursor than emodin **34**.

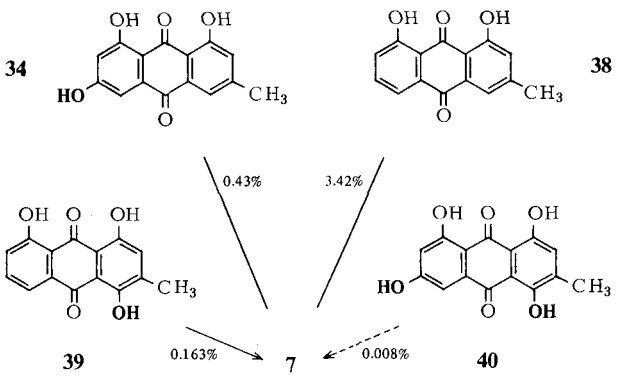

Fig. 16. Competitive incorporation of emodin **34** and three similar anthraquinone precursors **38**—**40** into the ergochrome secalonic acid D **7** in *Penicillium oxalicum* [77].

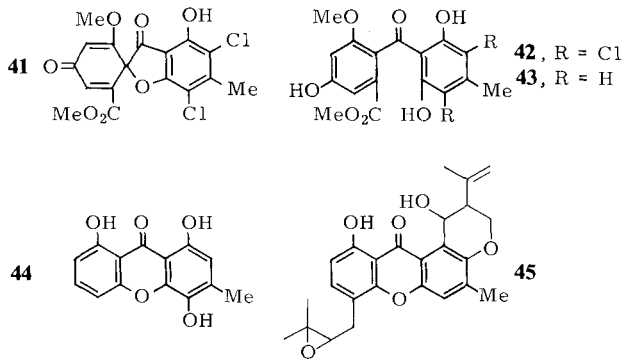
The incorporation of related anthraquinone natural products **38**—**40** was compared with that of emodin **34** by similar competitive incorporation experiments using natural anthraquinone compounds labeled with different isotopes and *Penicillium oxalicum* (Fig. 16)[63,77]. Chrysophanol **38** was shown to outclass **34** as a biosynthetic precursor of secalonic acid D **7**, whereas islandicin **39**, although its hydroxylation pattern is very similar to that of **37**, was incorporated to a lesser extent. Catenarin **40**, however, could be completely ruled out as a precursor. As is the case in other biosynthetic studies, it is apparent that the synthesis of natural compounds in the organism involves main and subsidiary pathways which combine to produce a *metabolic network* in which the biogenetic *key building blocks* occupy the cross-over points[62,78].

The oxidative ring-opening first discovered by us in 1968 in ergochrome biosynthesis[74,75] demonstrated that the natural anthraquinones are reactive metabolic intermediates. This was subsequently confirmed manifoldly by the fact that other natural products, such as the spirocyclic an-

tibiotic geodin **41**[63,79], the benzophenones dihydrogeodin **42**[79] and sulochrin **43**[80], and the xanthones ravenelin **44**[81] and thajixanthone **45**[82] are derived from anthraquinone precursors and thus form a novel biogenetic group of natural products, the *secoanthraquinones*.



Finally, the impressive studies of several groups of workers on the biosynthesis of the aflatoxins[83] revealed that their basic skeleton is also produced by oxidative ring opening of an anthraquinone precursor (Fig. 17). In this way, the anthraquinone versicolorin A **47** is formed from a decaketide **46** (≡ **18**, n = 8), via its folded conformation **46b**, in a multistep reaction sequence. Oxidative ring opening of **47**, internal rotation of the benzophenone intermediate, and xanthone ring closure yield sterigmatocystin **48**[84,85]. Oxidative transformations at the phenol ring of **48** then furnish the coumarin system of aflatoxin B_1 **1**.

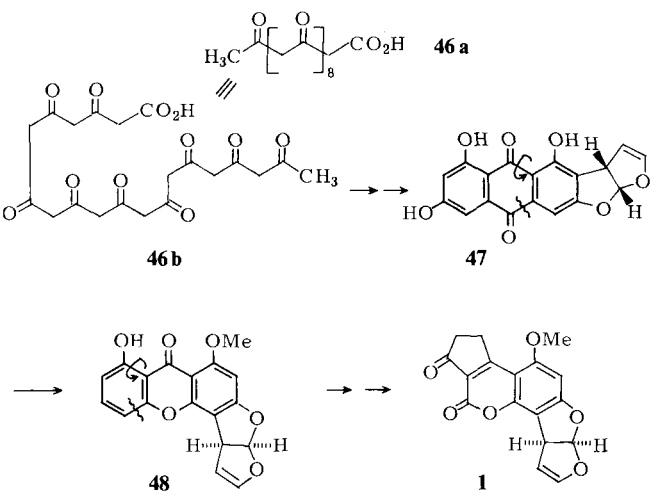


Fig. 17. Biosynthesis of aflatoxin B_1 **1** from the decaketide **46** (≡ **18**, n = 8).

5.5. Isoprenoid Mycotoxins

Compared with mycotoxins derived from polyketides (**18**, n = 0...8), those formed from other biosynthetic precursors are somewhat less important as regards their number and structural diversity, but not their physiological significance. The T-2 toxin **10**[86] from *Fusarium culmorum* and PR toxin **16**[87] from *Penicillium roqueforti*, shown in Figure 18, are two examples of mycotoxins derived from isopentenyl phosphate **19**, the next most common biosynthetic precursor. The biosynthesis of these sesquiterpene mycotoxins, which are constructed from three isoprene building blocks, commences with the differently-folded isomers **50** and **51** of farnesyl pyrophosphate **49**. Enzymatic elimination of the pyrophosphate induces ring closure to give **52** and **54**, respectively[86,87]. This is followed by methyl migration, the introduction of more functional groups, and the formation of the physiologically active epoxide groups to yield T-2 toxin **10** and PR toxin **16**.

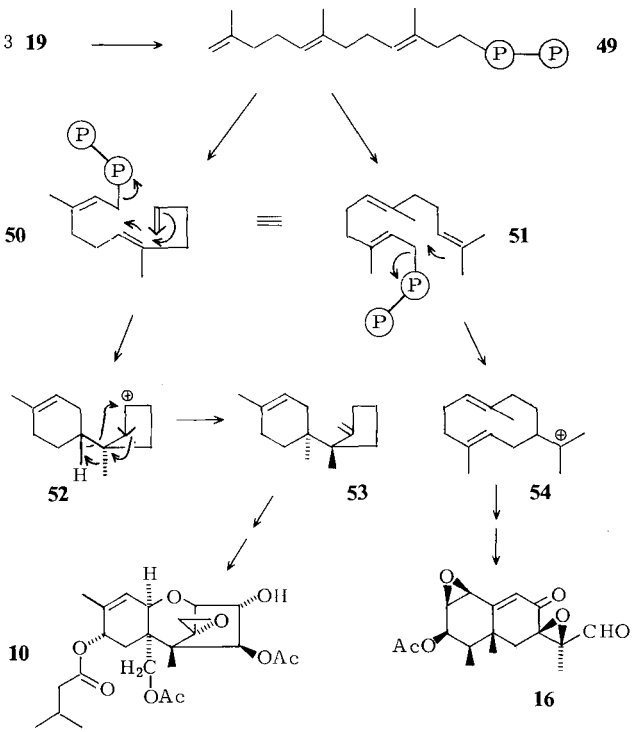

Fig. 18. Biosynthesis of the sesquiterpene mycotoxins T-2 toxin **10** and PR toxin **16** [86, 87].

After the polyketides **18** and isopentenyl pyrophosphate **19**, the third group of mycotoxin biosynthetic building blocks are the amino acids, especially tryptophan **20** (Fig. 9). The usually cyclic peptide mycotoxins (e.g., malformin A_1 **13** or roquefortin **2**) often exhibit lipophilic behavior since they only possess a few polar groups or are substituted with isoprene building blocks (prenyl groups). This represents a further general difference between mycotoxins and antibiotics (Table 1): whereas many antibiotics are readily water-soluble because they are glycosides or possess other polar structures, the mainly nonpolar character[*] of the mycotoxins is further enhanced by prenyl groups which almost appear to be like "antisugars".

Roquefortin **2** from *Penicillium roqueforti* is a typical example of a nonpolar, prenyl-substituted peptide mycotoxin (Fig. 19). The most interesting step in its biosynthesis[80,89] is the introduction of a dimethylallyl group into the diketopiperazine **56**, formed from tryptophan **20** and histidine **55**, coupled to a further ring closure. This may be accounted for, according to analogous chemical reactions[90],

[*] The highly polar mycotoxin moniliformin **3** is an exception.

by the enzymatic introduction of an isopentenyl residue with **19** at the nitrogen or at C-2 of the indole moiety, followed by sigmatropic rearrangement of the isopentenyl residue to C-3 and cyclization of the 3*H*-indole to afford the aminal arrangement of roquefortin **2**.

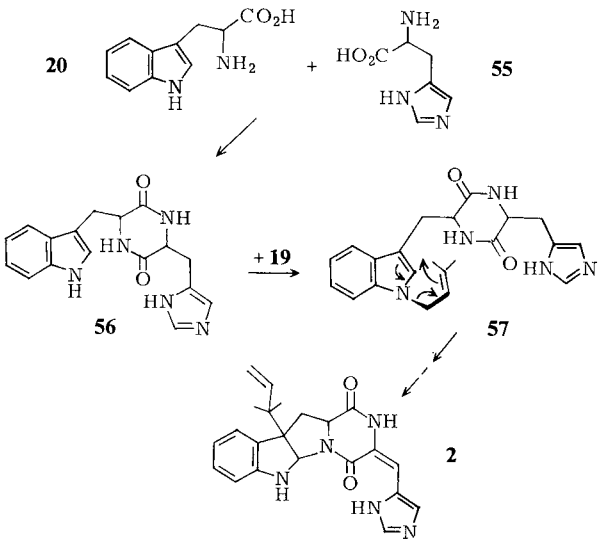

Fig. 19. Building blocks and biosynthetic pathway of roquefortin **2**.

6. Protection against Mycotoxins

An awareness of the causes of mycotoxicoses has led to the development of a wide range of protective measures against mycotoxins in foodstuffs[7] (Table 6).

Table 6. Measures for the prevention and deactivation of mycotoxins in foodstuffs.

1) Protection against toxin-producing molds
2) Culling of infected fruit
3) Chemical deactivation
   - heating
   - UV irradiation
   - oxidizing agents
   - acidification
   - addition of bases
4) Biological deactivation
   - reaction with food constituents
   - passage through domestic livestock and animals for slaughtering
   - degradation by microorganisms
   - interaction with inhibitors in metabolism

The prevention or minimization of toxin-producing molds in foodstuffs and the resulting elimination of mycotoxins are certainly the most important[91]. Compared to this the three other measures involve a great deal of technical effort and entail serious disadvantages such as incompleteness, production of changes in taste, and the possible formation of daughter products which are toxicologically difficult to control. Over the past few years, many countries have laid down limits for the maximum concentrations of the particularly dangerous aflatoxins in foodstuffs (Table 7).

The aflatoxin limiting values cited are based on the state-of-the-art in analytical detection and the so-called

Table 7. Legal control of aflatoxins in 10 countries (state in 1977; according to [92]).

Country	Foodstuff	Aflatoxin limit [μg/kg] [a, b]
Denmark	Peanuts and Brazil nuts	0
Federal Republic of Germany	All foodstuffs	5 B_1
		10 G
France	All foodstuffs	5 B_1
Great Britain	Peanuts	50 B_1
India	Peanut meal	30 B_1
Italy	Peanut products	50 B_1
Japan	All foodstuffs	0
Netherlands	Peanut products	0
Poland	All foodstuffs	0
USA	Peanut products	15 G

[a] B_1 = maximum limit for aflatoxin B_1 **1**. [b] G = maximum limit for the total aflatoxin concentration.

"no effect level" which, according to the evaluation of animal experiments by *Friedmann*[93], corresponds to a daily intake of 9.6×10^{12} molecules per kg body weight = 5 ng/kg.

If it is accepted that a threshold value for carcinogenic activity exists, for aflatoxin B_1 **1** this would be 375 ng for an adult weighing 75 kg. 100 g of food which complies with the limits prescribed by various countries (Table 7) can, however, contain up to 5000 ng aflatoxin B_1 **1**. It is thus evident that the understanding of the threshold value of aflatoxin activity and its analytical control urgently require further development.

A comprehensive review of the methods available for multimycotoxin analysis in foodstuffs has been published by the *"IUPAC Commission on Food Chemistry"*[123]. Accordingly, the analysis of a foodstuff sample, which must amount to at least 25 g, consists of five equally important procedures: extraction, concentration, separation, identification, and quantitative determination. The most important separation methods, usually associated with identification, are thin-layer chromatography, high performance liquid chromatography (HPLC), and FDI mass spectrometry.

Fortunately, the identification method described by *Patterson* and *Roberts*[101], which has proved to be particularly effective, can be used "on the spot" without requiring complicated apparatus. It consists of a combination of two-dimensional, thin-layer chromatography systems on silica gel. Because of its higher sensitivity, the method should be superior to HPLC methods and is distinguished by the fact that it gives the individual mycotoxins good "chromatographic windows". The detection limit varies with the mycotoxin and the foodstuff being investigated (Table 8). Thus, e.g. for aflatoxin B_1 in milk concentrates,

Table 8. Detection limits in ng/kg for mycotoxins in foodstuffs according to *Patterson* and *Roberts* [101].

Foodstuff	Aflatoxin B_1 **1**	Sterigmatocystin **48**	T-2-Toxin **10**	Zearalenone **32**
Peanut flour	100	—	—	—
Maize	100	1000	20000	2000
Wheat	200	1000	20000	2000
Milk concentrate	300	2000	20000	10000

a lowest detection limit of 300 mg/kg has seen found, which corresponds more or less to the "no-effect level".

Somewhat higher aflatoxin limits are allowed for animal fodder (in the FRG 10—50 μg/kg)[94], since the activity of the aflatoxins is calculated to be reduced by a factor of 100 after "carry-over" into the milk and meat of domestic livestock. This is due to excretion of the aflatoxins and their metabolic detoxification. Figure 20 summarizes some of the weakly toxic metabolic products of aflatoxin B_1 **1** which have been detected in animal experiments[4].

It is remarkable that hydroxylation or release of hydroxy groups at the C atoms 5, 8 and 16 considerably reduces the acute toxicity of aflatoxin B_1 **1**; unfortunately, hydroxylation of **1** at C-14 to aflatoxin M_1 **11** in cows' milk hardly decreases its toxicity or tendency to cause liver carcinoma[95,96].

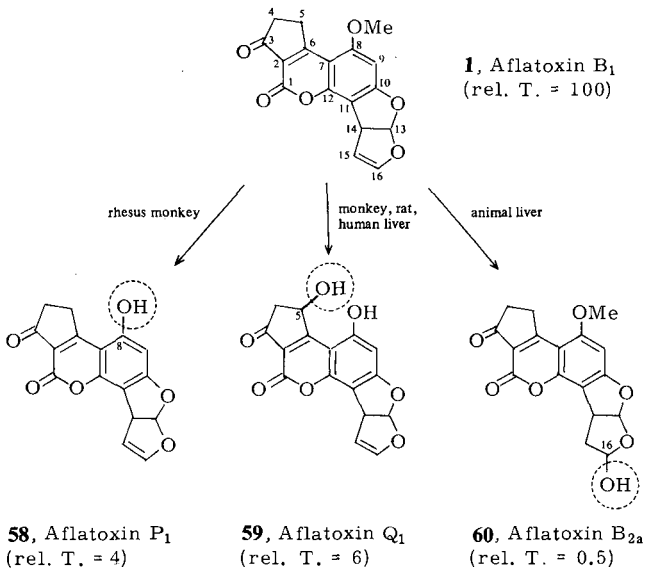

Fig. 20. Structures and relative toxicities (rel. T.) [4] of some metabolites of aflatoxin B_1 **1**. Structural changes are indicated by the broken circles.

7. Outlook

Although research on mycotoxins (e.g. the ergot alkaloids) started before the era of antibiotic chemistry, it has not been pursued with the same intensity until recently. More interest was shown in the medically useful antibiotics. The situation began to change, however, after it was appreciated that, besides the diseases which can be cured by antibiotics, there are many others which can be eliminated by being aware of and preventing mycotoxins.

It should actually be easier to stop molds from infiltrating into food and fodder than to prevent human bacterial infections. This is, however, hindered by the traditional generosity and inexperience we show when dealing with the aggressiveness of food molds. Furthermore, because of their long incubation periods some mycotoxicoses can only be identified by modern statistical methods and did thus only gained importance with the decrease of other diseases and increase of average life expectancy.

I would like to thank my coworkers who are named in the literature published by our group and our microbiologist, Frau Cornelia Peters, for their successful cooperation. The investigations were generously supported by the Landesamt für Forschung in Nordrhein-Westfalen, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.

Thin-Layer Chromatographic Enantiomeric Resolution via Ligand Exchange

By *Kurt Günther, Jürgen Martens**, and *Maren Schickedanz*

Today, gas[1] and liquid chromatography[2] are the methods of choice for the resolution of enantiomeric organic compounds in analysis. However, these methods necessitate the use of expensive apparatus and, in part, derivatization of the samples. Chiral amino acids are increasingly gaining importance as building blocks for the preparation of biologically active peptides in asymmetric syntheses[3] and as pharmaca[4]. A simple and rapid method of monitoring optical purity is therefore desirable.

A glass plate covered with hydrophobiated silicic acid (RP 18-TLC) is immersed (1 min) in a 0.25% copper(II) acetate solution (methanol : water = 1 : 9 v/v) and subsequently dried. The plate is then immersed in a 0.8% methanolic solution of the *chiral* selector (1 min). A suitable selector is (2*S*,4*R*,2′*RS*)-4-hydroxy-1-(2′-hydroxydodecyl)-proline **1**[5]. After being allowed to dry in the air, the plate is ready for chromatography.

1

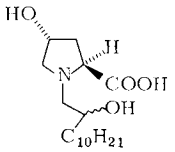

Table 1. Enantiomeric resolution of amino acids by thin layer chromatography [a].

Amino acid	R_f value (configuration)	Eluent [b]
Isoleucine	0.37 (2*R*,3*R*)	A
	0.44 (2*S*,3*S*)	
Phenylalanine	0.38 (*R*)	A
	0.45 (*S*)	
Tyrosine	0.26 (*S*)	B
	0.34 (*R*)	
Tryptophan	0.39 (*R*)	A
	0.45 (*S*)	
Proline	0.40 (*R*)	B
	0.59 (*S*)	
Glutamine	0.37 (*S*)	A
	0.53 (*R*)	
3-Thiazolidine-4-carboxylic acid	0.42 (*S*)	A
	0.52 (*R*)	

[a] Development distance 14 cm. Saturated chamber. [b] A: methanol/water/acetonitrile = 50/50/200 (vvv); B: methanol/water/acetonitrile = 50/50/30 (vvv).

[+] Present address: Unternehmensplanung und -entwicklung, Degussa AG
Postfach 110533, D-6000 Frankfurt am Main 11 (FRG)

Using the plates thus impregnated, we have succeeded in performing thin-layer chromatographic enantiomeric resolution via ligand exchange: 2 μL of each of the racemic α-amino acids in Table 1 was applied as a 1% solution to the TLC plates and eluted with the given eluent (30—45 min). After drying, the spots were visualized using 0.1% ninhydrin reagent. The resolution of the enantiomers was so good that the respective antipodes could be determined at trace levels; the lowest level of detection was found to be ≥ 1%, although this value can probably be improved.

Topological Charge Stabilization and the Equilibrium between P_4S_3 and As_4S_3**

By *Benjamin Gimarc** and *P. J. Joseph*

Recently, *Blachnik* and *Wickel*[1] reported the results of their experimental studies on the equilibrium system P_4S_3/As_4S_3. When the reactants are mixed in the stoichiometric ratio (1 : 3), the equilibrium lies predominantly to the side of PS_3As_3 [eq. (a)].

$$P_4S_3 + 3\,As_4S_3 \rightleftarrows 4\,PS_3As_3 \qquad (a)$$

P_4S_3 and As_4S_3 are cage or end-capped triangular prism structures with a unique apical atom, three equivalent bridging atoms, and three atoms in the equilateral triangular base[2,3]. In these molecules the sulfur atoms occupy the bridging positions, while atoms of the less electronegative group 5B elements are located at apical and basal sites. Presumably the particularly stable equilibrium product PS_3As_3 has a similar structure, with a P atom at the apex, bridging S atoms, and basal As atoms. *Blachnik* and *Wickel* attribute the stability of this product to the greater strength of PS compared to AsS bonds and to the increase in the number of PS bonds from 6 in the educt to 12 in the product PS_3As_3.

We report here an alternative explanation. The stability of PS_3As_3 is a beautiful example of the operation of the rule of "topological charge stabilization"[4]. The $P_7^{3\ominus}$ ion is isoelectronic and isostructural[5] with P_4S_3, As_4S_3, and

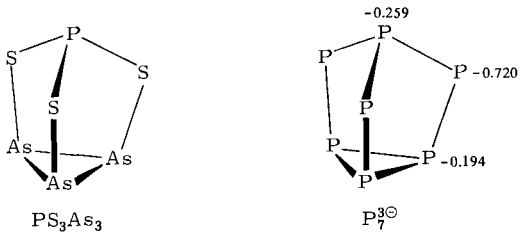
PS_3As_3. Because all the atoms of $P_7^{3\ominus}$ are alike, we call this the uniform reference frame for the end-capped triangular prism structure. The connectivity of atoms and the number of valence electrons cause the three different kinds of atomic positions in $P_7^{3\ominus}$ to have different charge densities, which we calculated using the extended Hückel (EH) method.



PS_3As_3 $P_7^{3\ominus}$

Scheme 1. Structures of PS_3As_3 and $P_7^{3\ominus}$ (charge densities shown).

The largest charge densities are in the bridging positions with smaller densities at apical and basal sites. The rule of topological charge stabilization states that *particularly stable structures result from the substitution of electronegative heteroatoms at sites where electron charges are more negative in the homoatomic, isoelectronic uniform reference frame.* Application of this rule to PS_3As_3 with the charge density distribution in $P_7^{3\ominus}$ (Scheme 1) suggests that in PS_3As_3 the electronegative S atoms should occupy the bridging positions, the less electronegative P atom the apical site, and the still less electronegative As atoms should prefer the basal positions, as confirmed by its structure[6]. The rule of topological charge stabilization has been shown to predict the correct order of relative stabilities for a wide variety of planar, two-dimensional, conjugated molecules[4]. PS_3As_3 is one of a number of examples that demonstrate the operation of this rule for three-dimensional structures[7,8].

Although charge densities obtained from EH calculations are generally regarded as too large, the relative ordering of charges—all that is required for the operation of our rule—is probably reliable. The charge densities in $P_7^{3\ominus}$ were obtained using 3d AOs in the basis set. Without d AOs, but using the extended Hückel, charge-iteration procedure, the same qualitative trend results: the highest charge density is located on the bridges, followed by the apex, and finally by the triangular base. It should be borne in mind that our conclusions depend on the pattern of charges for the homoatomic system that is isoelectronic and isostructural with the heteroatomic system of interest. The unperturbed charge distributions in the homoaromatic reference system may not be the same as those obtained for the heteroatomic structure. For example, *Paddock* et al.[9] report that in P_4S_3 the apical P atom is slightly positive relative to the basal P atoms—opposite of what we find for the homoatomic $P_7^{3\ominus}$ ion. From the heteroatomic results, one would conclude that the most stable product of atomic exchange would be AsS_3P_3 with an apical As atom. But it is the charge distribution in the unperturbed or homoatomic system that determines the first-order perturbation correction to the energy of the heteroatomic analogue[7]. Our concept makes no assumptions about the mechanism that exchanges P and As atoms in the system P_4S_3/As_4S_3 [eq. (a)].

$[(Me_2N)_2SF_2]^{2\oplus}$, a Sulfur(VI) Dication**

By *Hartmut Henle, Reinhard Hoppenheit,* and *Rüdiger Mews**

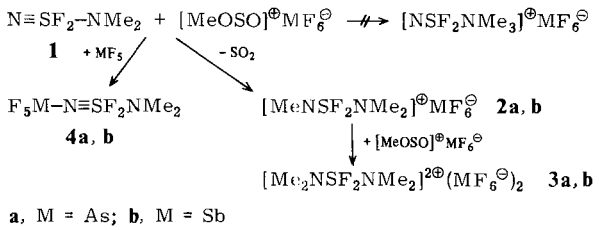
Salts containing sulfur(VI) monocations can be prepared by abstraction of $F^\ominus$ from hexa-[1,2] or pentacoordinated species[3,4], by oxidative addition to S^{IV} derivatives[5], or by addition of cations to species having SN multiple bonds[6]. Similar methods have been developed for the synthesis of sulfur(IV) monocations[3,4,7]; abstraction of $F^\ominus$ from bis(dimethylamino)difluorosulfurane has even led to a sulfur(IV) dication[8].

Alkylation of $N{\equiv}SF_3$ and its derivatives $N{\equiv}SF_2R$ presents a convenient route to sulfur(VI) monocations:

$$N{\equiv}SF_2R + \text{alkyl-OSO}^\oplus MF_6^\ominus \xrightarrow[-SO_2]{} [\text{alkyl-NSF}_2R]^\oplus MF_6^\ominus$$

$R = F$[6a], $NSOF_2$, $CF(CF_3)_2$, $C(CF_3)_3$[6c]

Exclusively the thiazyl nitrogen atom is alkylated, even in the presence of other nucleophilic positions, e.g. a dimethylamino group as in **1**. The synthetic potential of the $MeOSO^\oplus$ cation[9] is convincingly demonstrated by its ability to alkylate even the monocation in **2**. This leads to the salts **3**, which contain the dication $[(Me_2N)_2SF_2]^{2\oplus}$.



a, M = As; **b**, M = Sb

When **1** and $(MeOSO)^\oplus MF_6^\ominus$ are allowed to react in the molar ratio 1:2 in liquid SO_2 at room temperature, salts **3** are formed in quantitative yield[14]. The adducts **4**[10] or the salts **2** of the monocation $[MeNSF_2NMe_2]^\oplus$[11] may occur as impurities.

The course of the reaction indicates how the reactivity of the N≡S triple bond is influenced by substituents bonded to N and S. For the formation of dications the presence of ligands at the nitrogen atom having a +I-effect (such as the methyl group) is necessary; protonation of **1** in the superacid medium HF/AsF_5 leads only to the monocation **5**[14].

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

$1 + HF/AsF_5 \longrightarrow [HNSF_2NMe_2]^{\oplus}AsF_6^{\ominus}$ **5**

$NSF_3 + HF/AsF_5 \longrightarrow [F_5S{-}NH_3]^{\oplus}AsF_6^{\ominus}$ **6**

In contrast, NSF_3 reacts with HF/AsF_5 to afford the stable and isolable pentafluorosulfanylammonium salt **6**[12, 14]. The dimethylamino group in **5** reduces the electrophilicity of the central sulfur atom to such an extent that $F^{\ominus}$ can no longer add to increase the coordination number; in this way, all subsequent steps to a product analogous to **6** are blocked.

The salts **3** are stable, colorless solids (m.p. = 101 °C (**3a**), 103 °C (**3b**)) that are readily attacked by nucleophiles, e.g. H_2O or $X^{\ominus}$ of NaCl- and KBr-IR plates. They were characterized by elemental analysis and by IR and NMR spectroscopy (Table 1). Bands at 945 and 910 cm^{-1} in the IR spectrum are assigned to the $\nu_{as}(SF)$ and $\nu_{sym}(SF)$ vibrations.

Table 1. NMR data of salts **3** and **5** [a] as well as the neutral S^{IV} derivative $(Me_2N)_2SF_2$ [13].

	^{19}F [a] $\delta(SF_2)$	^1H $\delta(CH_3)$	^{13}C {b} $\delta(CH_3)$	$^4J_{HF}$ [Hz]	$^3J_{FC}$ [Hz]
3a	38.6 [c]	4.20 (t)	48.19 (t)	4.75	2.1
3b	37.9 [c]	4.22 (t)	48.21 (t)	4.80	2.1
5	54.7 (sept.)	3.16 (t) (N–H 7.37)		2.89	
$(Me_2N)_2SF_2$	7.5 (br. s)	2.72 (br. s)	37.71 (s)	—	—

[a] ^{19}F-NMR (**3a**, **3b**: 60 MHz, SO_2, 301 K; **5**: 75.4 MHz, SO_2, 253 K), ^{13}C-NMR (20.15 MHz, SO_2, 309 K), ^1H-NMR (80.13 MHz, SO_2, 304 K). [b] Proton decoupled. [c] Of the 13 lines expected only 11 were observed.

The NMR data for the cations of salts **3** and **5** as well as the neutral S^{IV} derivative $(Me_2N)_2SF_2$[13] are shown in Table 1; nevertheless, a direct comparison of the cations with the neutral compound is not without problems since in this the sulfur atom has trigonal-bipyramidal coordination, but in the cation the sulfur atom is tetrahedral. The nature of the anion in **3** does not influence the spectroscopic data of the dication; no interaction therefore appears to be present in solution.

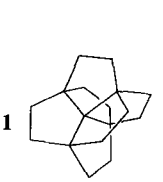
[14] General Procedure: **3**: SO_2 (5–10 mL) is condensed onto 2–3 mmol MF_5 (**a**: M = As; **b**: M = Sb) and CH_3F (slight excess); the mixture is warmed slowly to -30 °C and held at this temperature for 2–3 h until formation of $(MeOSO)^{\oplus}MF_6^{\ominus}$ is complete. The solution is then cooled again to -196 °C and **1** condensed in; the mixture is warmed slowly to room temperature and stirred for 2 d. After removal of the solvent **3a** and **3b** are isolated in quantitative yield as analytically pure solids.—**5** and **6**: 5 mL HF and MeF_5 are condensed into a cold trap (Kel–F) containing 1–2 mmol **1** or NSF_3 (molar ratio NSF_3: $AsF_5 < 1:2$) at -196 °C. After removal of the volatile products, **5** and **6** remain as almost analytically pure substances. Purer products can be obtained by dissolving the Lewis acid adducts $F_5M \cdot N{=}SF_2(NMe)_2$ or $MF_5 \cdot NSF_3$ in HF.

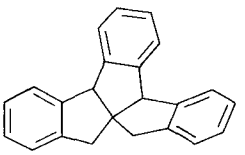
A Facile Route to Benzoannelated Centrotriquinanes

By *Dietmar Kuck**

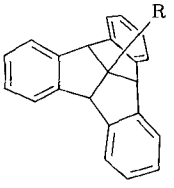
Centropolyquinanes[1] are a fascinating group of compounds, which, as polycondensed cyclopentane hydrocarbons, have been intensively studied in recent years[2–4]. They are characterized by a central C atom shared by all cyclopentane rings. The centrohexaquinane ("C_{17}-hexaquinane") **1** represents a challenging synthetic target molecule[5].



1



2



3a, R = CH_3
3b, R = $CH_2C_6H_5$
3c, R = $CH(C_6H_5)_2$

We report here a facile synthesis of benzoannelated centrotriquinanes of type **2** and **3**[6], which can be used as educts for the synthesis of higher centropolyquinanes. Key reaction in the synthesis is the double cyclodehydration of the 2,2-disubstituted 1,3-indanediols **5**, which can readily be prepared by reduction of the corresponding 1,3-indanediones **4**.

Whereas the tribenzotricyclo[6.3.0.$0^{1,5}$]undecane **2** is obtained in excellent yield[14], the 10-alkyltriben-

zo[5.2.1.0^{4,10}]decanes **3** have, up till now, only been accessible in moderate yields (Table 1). We attribute this to the prochirality of the benzhydryl group and, in particular, to the susceptibility of the 1,3-diol system to cleavage under acidic conditions. Moreover, the ring opening is certainly favored by the steric hindrance of the quaternary center. Of greater note therefore is the double cyclization, specifically of **5** ($R^1=R^2=CH(C_6H_5)_2$) to **3c**, whose structure, like those of other centrotriquinanes, is consistent with the spectroscopic data (Table 1)[7].

Table 1. Centrotriquinanes **2** and **3a**—**3c**. Yields, melting points, and some ^{1}H- and ^{13}C-NMR data (in parentheses) [a].

	Yield [%]	M.p. [°C]	NMR Data C(*quart*)	C(*tert*)	C(*sec*)	C_α(R)
2	92	148	(62.8)	4.44 (62.1)	3.15 [b] (44.5) 3.34 [b]	—
3a	33	239	(60.7)	4.47 (63.7)	—	1.68 (27.6)
3b	18	243	(65.2)	4.80 (61.3)	—	3.33 (45.7)
3c	26	318	(68.7)	5.10 (60.8)	—	4.60 (59.7)

[a] 80 (300) MHz, δ in $CDCl_3$. The number of signals from the aromatic groups as well as the integrated intensities and multiplicities reflect the symmetry of the compounds. [b] $^2J=-16.4$ Hz.

Under relatively mild conditions (e.g. p-$CH_3C_6H_4SO_3H$/C_6H_6) predominantly products of ring-opening form, e.g. compounds **6** and **7**[8]. However, under conditions of acid catalysis, **6** is converted into a mixture of **7** and **2**. It can therefore be assumed that the tricycles **2** and **3** are, at least in part, formed via *acyclic* intermediates of type **6**. In the UV spectra[9] of the tribenzocentrotriquinanes **3**, which have C_{3v} symmetry, the α-bands display a slight bathochromic shift relative to indane[10] ($\Delta\lambda_{max}=2.0-3.5$ nm) and have a threefold greater molar extinction in each case. In contrast, this effect is absent in **2** ($\Delta\lambda_{max}<0.5$ nm). Extensive interactions between the benzene chromophores are therefore—as in other centrotriquinanes of this type[6]—not present.

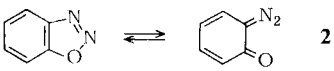
[14] Procedure: **2**: 2,2-Dibenzyl-1,3-indanedione 4 [11] is obtained in quantitative yield from 1,3-indanedione and benzyl bromide with KF/celite 545 (Fluka) in CH_3CN, by analogy to a procedure described by *Bloch* and *Orvane* [12], and reduced with $LiAlH_4$ in tetrahydrofuran (THF) using standard methods to afford the *trans*-1,3-diol **5** ($R^1=R^2=CH_2C_6H_5$) [13] (crude yield quantitative).—A solution of this diol (3.3 g, 10 mmol) in 120 mL xylene is refluxed with 85% H_3PO_4 (1.6 g) for ca. 15 h in a water separator. The reaction solution is then washed with dilute Na_2CO_3 solution and water and dried over Na_2SO_4. After removal of the solvent an oil is formed from which **2** is obtained as fine, white needles by recrystallization from EtOH.

1,2,3-Benzoxadiazole—Detection in an Argon Matrix and in Solution**

By *Reinhard Schulz* and *Armin Schweig**

The notion that compounds such as **1** with 1,2,3-oxadiazole structures are not capable of existing[1,2] was refuted for the first time by PE spectroscopic studies on 6-diazo-2,4-cyclohexadienone **2**[3]. We report here independent experiments in a noble gas matrix and in solution which corroborate the presence of an equilibrium between 1,2,3-benzoxadiazole **1** and 6-diazo-2,4-cyclohexadienone **2**, and remove any doubts[4] surrounding our previous work[3].



If—as indicated by the results of PE spectroscopy—the diazoquinone **2** and the oxadiazole **1** both exist in the gas phase, it should be possible to freeze out both components at low temperature. The condensate formed from condensation of diazocyclohexadienone vapor **2** (vaporized at room temperature and ca. 4×10^{-2} mbar) and excess argon in a vacuum flow system at 15 K exhibits intense IR absorptions originating from a compound, which, even during recording of the spectrum, is re-converted into **2**. This retro-isomerization cannot only be followed by IR spectroscopy, but also by the naked eye due to a marked deepening of the color of the originally light yellow matrix (λ_{max} of **2** in hexane: 407 nm). The IR-induced isomerization to **2** at 15.4 K exactly follows first-order kinetics ($\tau_{1/2}=6.2$ min). By inserting a filter which transmits only

IR radiation of long wavelength ($\lambda > 4500$ nm), the reaction could be suppressed. Only in this way could the IR spectra of the condensate in the region from 2200 to 350 cm^{-1} be recorded without simultaneous disappearance of the absorptions of the isomer.

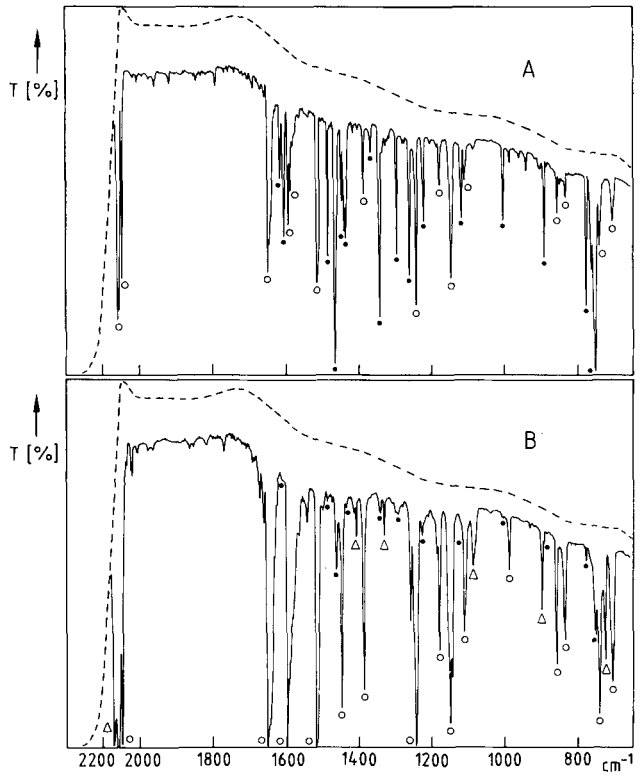

Fig. 1. IR spectra of the cocondensate of 6-diazo-2,4-cyclohexadienone **2** (20°C, $p < 0.1$ mbar) and excess argon. A: In the absence of radiation ($\lambda < 4500$ nm), B: After irradiation (60 min) by the Nernst glower of the IR spectrophotometer (Beckman IR 4250). The background caused by the IR long-pass filter is shown by the broken curves. **1**: •; **2**: ○ and **5**: △. T = transmission.

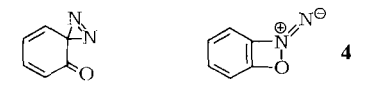
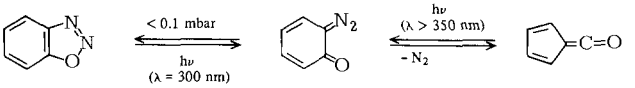
Figure 1 shows the IR spectra obtained before and after 60 minutes' irradiation with the Nernst glower of the IR spectrometer. The IR absorptions, which because of the changes in intensity are assigned to the component in equilibrium with **2**, are summarized in Table 1 and suggest a 1,2-disubstituted benzoid structure. Because of the absence of a carbonyl absorption, the diazirine **3** can certainly be ruled out. Of the remaining possible isomers of **2**, compound **4** is also precluded because of its high energy content (MNDO enthalpies of formation [kcal/mol]: **1**: 38; **2**: 49; **3**: 108, and **4**: 124). Accordingly, here—as indicated by the PE spectroscopic results in the gas phase[3]—an equilibrium between 1,2,3-benzoxadiazole **1** and the diazocyclohexadienone **2** can be assumed.

Table 1. IR absorptions of **1**, **2**, and **5** in an argon matrix.

1	1615 (m), 1605 (m), 1485 (m), 1465 (s), 1440 (m), 1437 (m), 1365 (w), 1342 (s), 1295 (m), 1261 (m), 1222 (m), 1119 (m), 1005 (m), 892 (m), 777 (m), 763 (m), 752 (s), 543 (m), 493 (m), 421 (m), 372 (m)
2	2113 (s), 2091 (m), 1650 (m), 1594 (m), 1589 (m), 1513 (m), 1446 (m), 1388 (w), 1243 (m), 1179 (w), 1147 (m), 1110 (w), 858 (w), 835 (w), 740 (m), 707 (m)
5 [7]	2138 (bs), 2080 (m), 1582 (w), 1459 (m), 1448 (m), 1407 (m), 1329 (m), 1079 (m), 899 (s), 725 (s), 634 (m), 573 (m), 518 (w)



Irradiation with light of wavelength $\lambda > 350$ nm results in selective, quantitative cleavage of the diazocyclohexadienone **2** into N_2 and 6-fulvenone **5** without decomposition of the benzoxadiazole **1**. Upon subsequent irradiation (300 nm, interference filter, width at half-height 10 nm) of the colorless matrix thus obtained, the intensities of the bands of the oxadiazole **1** decrease, and the diazocyclohexadienone **2** reappears with renewed yellow coloration of the matrix. Accordingly, **1** absorbs at ca. 300 nm and undergoes ring-opening; even the irradiation[5] of the Nernst glower ($\lambda > 2300$ nm) causes the isomerization.



1 **2** **5**

This interpretation is confirmed by UV/VIS spectroscopic studies in solution. Figure 2 shows the UV/VIS spectra of **2** in solution (A: methanol/*n*-hexane (95:5); B: *n*-hexane). Both spectra differ so markedly in the positions of the bands and their intensities that solvatochromic effects can be precluded as the reason for these differences. In contrast, the spectra are consistent with a strong solvent-dependent equilibrium between **1** and **2**, whereby

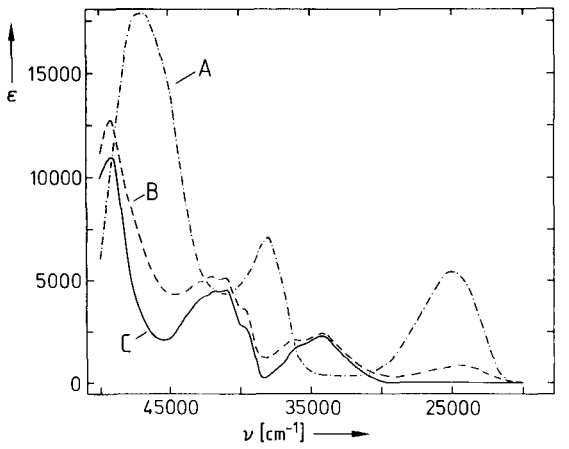


Fig. 2. UV/VIS spectra of a solution ($c = 5.83 \times 10^{-5}$ mol L^{-1}) of 6-diazo-2,4-cyclohexadienone **2** in methanol/*n*-hexane (95:5) and *n*-hexane (A and B, respectively). C: Spectrum of 1,2,3-benzoxadiazole **1** calculated from A and B.

predominantly 1,2,3-benzoxadiazole **1** occurs in apolar *n*-hexane and almost exclusively the diazoquinone **2** in methanol. From the intensity ratio of the UV/VIS bands at 400 nm, a composition of 84% **1** and 16% **2** is calculated in *n*-hexane[6]. This value is consistent with the composition determined by PE spectroscopy in the gas phase (80-90%, **1**, 10-20% **2**)[3]. The UV/VIS spectrum of **1** obtained by spectral subtraction is also shown in Figure 2 (C). Maxima occur at $\lambda = 203$, 244, and 295 nm ($\varepsilon = 11000$, 4500, and 2200, respectively) and it is very similar to the UV spectrum of 1,2,3-benzothiadiazole [λ_{max} (*n*-hexane) = 215 ($\varepsilon = 19000$), 256 (4700), and 310 nm (2300).

[5] The isomerization is a genuine photochemical process; warming the matrix from 15 K to 30 K does not influence the IR spectrum.

[6] In CCl_4 both **1** and **2** can be detected by UV (λ_{max} = 293 nm) and IR spectroscopy (ν = 1482, 1461, 1338, 1290, 1256, 1000, and 888 cm^{-1}, cf. Table 1); however, **1** cannot be detected in $CHCl_3$.

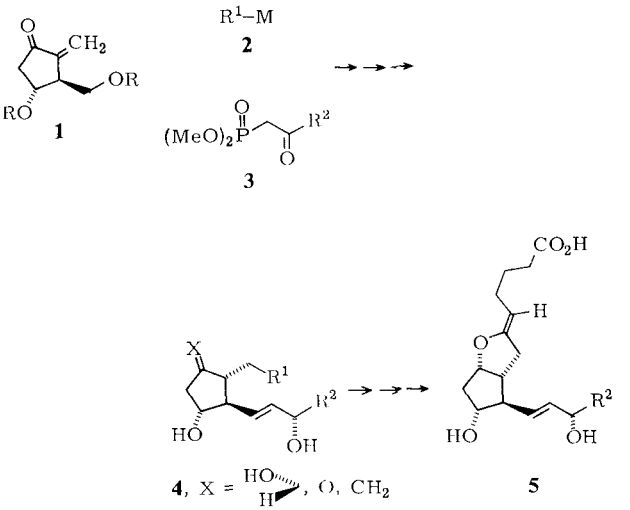
Asymmetric Synthesis of a Novel Enantiomerically Pure Prostaglandin Building Block**

By *Hans-Joachim Gais**, *Thomas Lied*, and *Karl L. Lukas*

Their specific biological effects have again moved prostaglandins into the focal point of medical[1] and chemical[2] interest. 16,16-Dimethylprostaglandin E_2 **4** (X = O, R^1 = CH=CH–$(CH_2)_3$–CO_2H (*Z*), R^2 = $C(CH_3)_2$–$(CH_2)_3$–CH_3) effects cytoprotection of the gastrointestinal tract against aggressive agents[1a], while the prostacyclin **5** (R^2 = *n*-C_5H_{11}) is the most potent endogenous inhibitor of human platelet aggregation[1b].

We have developed an asymmetric synthesis of the novel, enantiomerically pure prostaglandin building block **1**, which with alkyl-, alkenyl-[3a], alkynyl-[4], and arylmetal compounds **2**[3b] as well as phosphonates **3**[2] permits attachment of various side chains R^1 and R^2 in a *1,4-addition, carbonyl-olefination strategy* and, hence, should open a general enantioselective access to prostaglandins **4** and **5**[5] (Scheme 1).



Scheme 1.

The starting material for **1** is the enantiomerically pure keto ester **6**, readily accessible by asymmetric synthesis[6]. Stereoselective reduction of **6** with $NaBH_4$ affords the hydroxy ester **7a**[6] in 91% diastereoselectivity (*ds*), in addition to 4-*epi*-**7a** (96% total yield). Recrystallization readily affords diastereomerically pure **7a** (76%); 4-*epi*-**7a** can be isomerized to **7a** using NaOMe (MeOH, 0°C). The conversion **6** → **7a** (71%) via catalytic hydrogenation is preparatively even simpler. Saponification of **7a** to the carboxylic acid **7b**[7] (92%) and its chemoselective reduction with borane-tetrahydrofuran (BH_3·THF)[8] leads to the diol **8a**[7] (78%), which is protected as the bissilyl ether **8b**[7] (91%) (Scheme 2). The decisive introduction of a hydroxy group at C-6a of **8b** to give the hydroxylactone **10**[7] (73%) is carried out by oxidation of the enolate **9**, generated by metalation of **8b** with lithium diisopropylamide (LDA), with the oxodiperoxymolybdenum-pyridine-hexamethylphosphoric

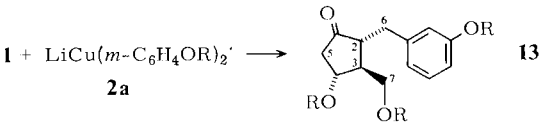
triamide complex (MoOPH)[9a] or with O_2/$P(OMe)_3$[9b]. With the reduction of **10** to the triol **11**[7] (92%), the requirements are met for the final construction of the enone structural element in the synthesis of **1**. **11** is oxidized with $NaIO_4$ to the stable hydroxy ketone **12**[7] (93%), which is then converted by $MeSO_2Cl$ (MsCl) and triethylamine into the crystalline, enantiomerically pure methylenecyclopentanone **1**[7] (89%) (Scheme 2).

A first demonstration of the synthetic potential of **1** is offered by 1,4-addition of the cuprate **2a**[3b], which affords the enantiomerically pure cyclopentanone derivative **13**[7] (88%) (Scheme 3). Comparison of the relevant ^{1}H-coupling constants of **13** ($J_{2,3}=9.0$, $J_{2,5\beta}=0.7$ Hz) with those of **12** ($J_{2,3}=10.0$, $J_{2,5\beta}=1.0$ Hz) and PGE_2 ($J_{8,12}=11.6$, $J_{8,10\beta}=1.2$ Hz) establishes the 2α-configuration. **13** is an interesting precursor for 4,5,6-trinor-3,7-*inter*-*m*-phenylene-3-oxaprostaglandins E_1 **4** (X=O, $R^2=m$-C_6H_4-OCH_2CO_2H)[3b], which are being clinically tested as selective bronchodilators for treatment of asthmatic attacks[10].



R = *t*BuMe$_2$Si

Scheme 3.

The stereoselective synthesis of **8d**[7] (total yield 70%) from **8a** via **8c**[7] demonstrates the method planned for the introduction of ω-side chains to analogous diols, which are obtained by addition of **2** to **1** via appropriate transformation of the ring-carbonyl function and removal of the protecting groups R[11] (Scheme 2).

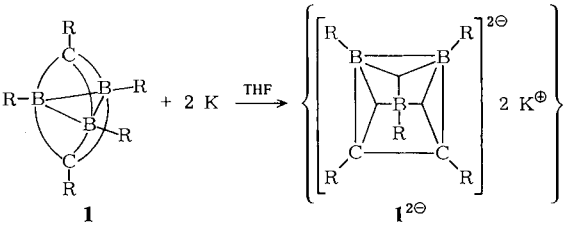
The First C_4B_6 Carbaborane**

By *Roland Köster**, *Günter Seidel*, and *Bernd Wrackmeyer*

In an investigation of the reaction of diethylborane Et_2BH with acetylene twenty years ago, we discovered a synthetic route to the first peralkylated C_2B_3 carbaborane[1] having a trigonal-pyramidal framework. Equally unexpected is our present finding that starting from pentaethyl-1,5-dicarba-*closo*-pentaborane(5) **1**[2a,b], we can prepare perethylated carbaborane **2**, which has a novel C_4B_6 skeleton.

Reaction of **1** with potassium in tetrahydrofuran (THF) at room temperature leads slowly to the formation of a dark brown solution; the metal does not react faster when the mixture is heated. If ≥0.5 mol potassium per mol **1** are taken up, two ^{11}B-NMR signals, which are shifted to high field ($\delta\approx -14$, -37; intensity ratio 2:1), appear in the ^{11}B-NMR spectrum of the weakly paramagnetic solution. The intensity of the ^{11}B-NMR signal of **1** ($\delta=+13.5$[2c]) decreases to ca. 50% after reaction of ≥1 mol potassium per mol **1**. Correspondingly, we presume that $\mathbf{1}^{2\ominus}$ is formed from a pentaethyl-*nido*-dicarbapentaborate(2$^-$) $\mathbf{1}^{2\ominus}$ (Scheme 1).



R = C_2H_5

$$2\ (\mathbf{1}^{2\ominus}K_2^{2\oplus}) + 2\ I_2 \xrightarrow[-4\ KI]{THF} (H_5C_2)_4C_4B_6(C_2H_5)_6$$
Isomers **2**

Scheme 1.

A solution of reduced **1** in THF reacts with iodine, rapidly becoming lighter in color and leading to quantitative precipitation of potassium iodide. Colorless, crystalline **2**[3] (crude yield >60%, isolated ≤25%)[4] is obtained from the yellow liquid, in addition to unreacted **1** (30–40%).

[**] Boron Compounds, Part 60.—Part 59: R. Köster, G. Seidel, *Angew. Chem. 96* (1984) 146; *Angew. Chem. Int. Ed. Engl. 23* (1984) 155.

Comparison of the mass spectra[5] of **1** and **2** indicates that in the spectrum of **2** the peaks for the mass fragments M^+-15 and M^+-29 are practically absent; dominant are the peaks in the region of the molecular ion. At ca. 20°C, the ^{11}B-NMR spectrum of **2** consists of four signals[3]. In the ^{13}C-NMR spectrum in [D$_8$]toluene, three types of skeletal C atoms ($\delta = +37.4$, $+29.2$, and -6.3) can be observed in the ratio 1 : 2 : 1[3,6].

Compound **2** is stable to iodine and oxygen at room temperature, but in THF it is attacked by potassium to form a pale yellow solution. **2** reacts analogously to **1**[7] with anhydrous trimethylamine *N*-oxide[7] above 75°C. In refluxing toluene, 1 mol **2** liberates more than 16 mol trimethylamine from the *N*-oxide. **2** is readily soluble in aliphatic, aromatic, and many other solvents (e.g. $CHCl_3$), and can be recrystallized from diethyl ether or refluxing ethanol. On being heated from -50°C to >300°C, solid **2** undergoes endothermic and reversible phase transformations, respectively, at -21.5°C and -1.4°C (DSC[8]); because of this phase change or valence isomerization it has not yet proved possible to obtain crystals suitable for the determination of the molecular structures.

As decaethyltetracarbadecaborane(10), **2** is a valence isomer of the unknown decaethyl-2,4,6,8,9,10-hexaboraadamantane[9]; presumably the 24 valence electrons in the C_4B_6 skeleton of **2** do not, as in C_4B_6 adamantane, distribute themselves over twelve 2e2c bonds but rather over six nonlocalized 2e2c and 2e3c bonds, respectively.

2, which consists of two asymmetrically fused C_2B_3 "halves", is the first C_4B_6 carbaborane. The dimerization[10,11], which mechanistically has yet to be clarified, may be applicable to the synthesis of other organocarbaboranes with known and novel $C_xB_yH_{(x+y)}$ skeletons and of C_xH_x hydrocarbons having novel structures. The organic residues in the dimerization assume a protecting function by means of which the cluster fusion is facilitated without intermolecular condensations[12].

Compound **2** (n = 10) is an important extension to the series of carbon-rich carbaboranes $C_4B_{n-4}R_n$[10]. One possible structure for **2** is the bicapped Archimedian antiprism shown in Figure 1a; however, because of the 2n+4 skeletal electrons[13], this *closo*-type is unlikely. On the contrary, a *nido*-structure is expected for **2** (Fig. 1b). The distribution of the skeletal atoms was determined by homoscalar (^{11}B^{11}B)- and heteroscalar (^{13}C^{11}B)-correlated ^{11}B- and ^{13}C-NMR spectroscopy, respectively. By this means, using a 2D-NMR experiment (COSY[14,15]), measurable cross-peak intensities were obtained for the scalar coupling $J(^{11}B,^{11}B)$[16]. In order to explore the ^{13}C/^{11}B neighborhood, ^{11}B was selectively decoupled in the ^{13}C-NMR spectrum[17].

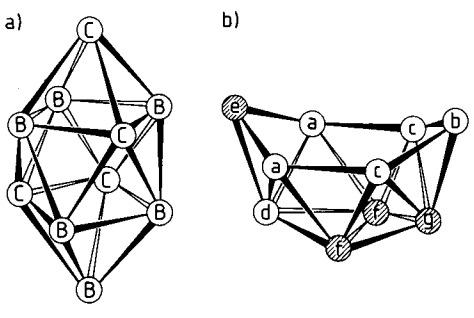

Fig. 1. a) Unlikely skeletal structure of **2**; b) Presumed skeletal structure of **2** in solution.

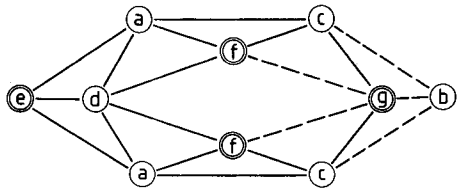

Fig. 2. Connectivities in the C_4B_6 carbaborane skeleton **2** [a].

^{11}B-Skeletal atoms $\delta(^{11}B)$		Intensity	^{13}C-Skeletal atoms $\delta(^{13}C)$		Intensity
ⓐ	−20.7	2	ⓔ	−6.3	1
ⓑ	− 6.3	1	ⓕ	29.2	2
ⓒ	6.7	2	ⓖ	37.9	1
ⓓ	50.3	1			

[a] Solid lines = detected connectivities; COSY: [14–16] ⓐ–ⓓ, ⓐ–ⓒ, ^{13}C{^{1}H, ^{11}B} [17]: ⓐ–ⓔ, ⓐ–ⓕ, ⓓ–ⓒ, ⓓ–ⓕ, ⓒ–ⓖ; broken lines = presumed connectivities.

The results of the (^{11}B^{11}B)- and (^{13}C^{11}B)-δ-correlations are shown in Figure 2. Only for boron atom ⓑ can no unequivocal connectivity be detected[18]. The number and intensities of the NMR resonances for the skeletal atoms and the linkages detected are consistent with the structure shown in Figure 1b, which is formally derived from decaborane(14) by fourfold BH_2/CEt substitution. On the basis of the present data, no statement can be made about the number and type of opened triangular faces of the polyhedron. At room temperature and above, the ^{13}C-NMR signals of the C(e,g) ethyl groups are particularly broad, which suggests a fluxional structure for the C_4B_6 skeleton.

[17] A 50.3 MHz $^{13}C\{^1H$- broad band$\}$-NMR spectrum of **2** was recorded in $CDCl_3$ (ca. 5%) at 28°C. The following were compared: a) $^{13}C\{^1H,^{11}B(50.3)\}$: effect at ^{13}C (29.2), weak at $^{13}C(-6.7)$ and clear at $^{11}B(50.3)$-$^{13}CH_2$; b) $^{13}C\{^1H,^{11}B(+6.7)\}$: effect at ^{13}C (37.9), weak at ^{13}C (29.2), and clear at ^{11}B (+6.7)-$^{13}CH_2$; c) $^{13}C\{^1H,^{11}B(-6.3)\}$, effect clear only at ^{11}B (−6.3)-$^{13}CH_2$; d) $^{13}C\{^1H,^{11}B(-20.7)\}$, effect at ^{13}C (−6.7), weak at ^{13}C (29.2), and clear at ^{11}B (−20.7)-$^{13}CH_2$.
[18] This arises from relatively small scalar couplings $^1J(^{13}C^{11}B)$ and $^1J(^{11}B^{11}B)$; cf. [16].

$[Cu_6I_{11}]^{5\ominus}$—a Polyanion with Trigonal-Prismatic Arrangement of Six Metal Atoms**

By *Farbod Mahdjour-Hassan-Abadi, Hans Hartl**, and *Joachim Fuchs*

By allowing Cu to react with I_2 in the presence of organic iodides RI in polar organic solvents, we were able to prepare a series of compounds having unusual iodocuprate(I) ions[1]. Recently, with $Et_4N^{\oplus}$ as counterion, we isolated a monoclinic and a hexagonal compound of empirical formula $[Et_4N]CuI_2$[2], in addition to $[Et_4N]^1_\infty[Cu_2I_3]$[1a]. The vibrational spectra in the monoclinic phase lead one to expect the planar binuclear moiety $Cu_2I_4^{2\ominus} = [ICu(\mu\text{-}I)_2CuI]^{2\ominus}$, which was previously found in compounds with $[Ph_4P]^{\oplus}$, $[Pr_4N]^{\oplus}$, or $[Bu_4N]^{\oplus}$[3]. The hexagonal phase, from which the monoclinic phase forms upon solidification of the melt, corresponds—as indicated by the X-ray structure analysis—to the formula $[Et_4N]_6[Cu_6I_{11}]I$; in the crystal, the isolated anions $[Cu_6I_{11}]^{5\ominus}$ and $I^{\ominus}$ are therefore present in the ratio 1:1 (Fig. 1). The polyanion $[Cu_6I_{11}]^{5\ominus}$ of approximate $\frac{3}{m}2\,m$ (D_{3h}) symmetry consists

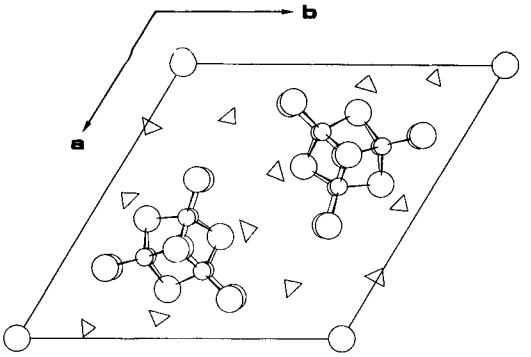

Fig. 1. Crystal structure of $[(C_2H_5)_4N]_6[Cu_6I_{11}]I$, viewing direction [001]; I: large circles, Cu: small circles, $Et_4N^{\oplus}$: triangles. Hexagonal, $P6_3/m$ (No. 176), $a = 1947.4(2)$, $b = 1212.9(3)$ pm, $Z = 2$, $\rho_{calc.} = 2.24$ g cm^{-3}; $R = 0.046$, $R_w = 0.051$ ($Mo_{K\alpha}$, Zr filter, 2723 reflections, 2153 of which with $I > 2\sigma(I)$, absorption and extinction correction, $\mu = 63.6$ cm^{-1}, anisotropic temperature factors for Cu, I, C, N; 127 refined parameters, positions of H atoms not refined). Further details of the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50871, the names of the authors, and the journal citation.

of a trigonal prism of six Cu atoms; the five faces and six corners are bound to a total of eleven I atoms (Fig. 2). In this way, the Cu atoms achieve tetrahedral coordination, and the six CuI_4 tetrahedra are each condensed via three common edges to di-μ_3-iodo-tri-μ_4-iodohexakis(iodocuprate(I) $[CuI_{1/1}I_{1/3}I_{2/4}]_6^{5\ominus} = Cu_6I_{11}^{5\ominus}$.

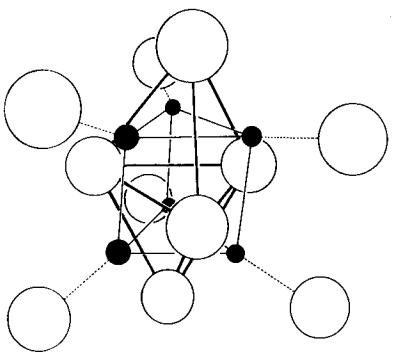

Fig. 2. Structure of the anion $[Cu_6I_{11}]^{5\ominus}$. The trigonal Cu_6-prisms and the trigonal I_5-bipyramids, respectively, are indicated by faint and bold lines. Important distances: Cu–I 256.7(3), Cu-μ_3I 270.7(2), Cu-μ_4I 273.1(2) or 274.9(2), Cu–Cu 296.1(3) (prism edge) and 341.1(3) pm (triangular side), respectively.

A trigonal-prismatic arrangement of six metal atoms without occupation of the polyhedral gaps by a further atom[4] is rare[5]; Cu_6 octahedra are the rule[6] in copper compounds. The trigonal-prismatic arrangement in $[Cu_6I_{11}]^{5\ominus}$ is not attributable to bonding Cu–Cu interactions; structure-determining is rather the close packing of the I atoms. Five I atoms form a trigonal bipyramid over whose six triangular faces six CuI_4 tetrahedra are positioned. In this way, the two tetrahedral voids in the trigonal I_5 bipyramid remain unoccupied. The Cu–Cu distances of 296.1(3) and 341.1(5) pm are considerably longer than e.g. in the anion $[Cu_5I_7]^{2\ominus}$[1c]. The additional $I^{\ominus}$ anion is separated from the anion $[Cu_6I_{11}]^{5\ominus}$ by the $Et_4N^{\oplus}$ cations.

[2] Procedure: Tetraethylammonium iodide (2.57 g, 0.01 mol) and copper powder (2.54 g, 0.04 mol) are heated in 100 mL acetone. After addition of iodine (2.54 g, 0.01 mol), the mixture is heated until it becomes slightly yellow (N_2 stream) and is filtered hot. White needle-shaped crystals of composition $[Et_4N]Cu_2I_3$ (m.p. = 175–178 °C) precipitate out from the filtrate after a few days. Slow, dropwise addition of ether, leads to precipitation of white, needle-shaped crystals of $[Et_4N]CuI_2$-*A* (monoclinic), m.p. = 122–124 °C. Addition of benzene to the cold filtrate (ca. 5 °C) affords white, needle-shaped crystals of $[Et_4N]CuI_2$-*B* (hexagonal) (m.p. = 122–124 °C). Precipitation with benzene at room temperature gives a mixture of *A* and *B*.

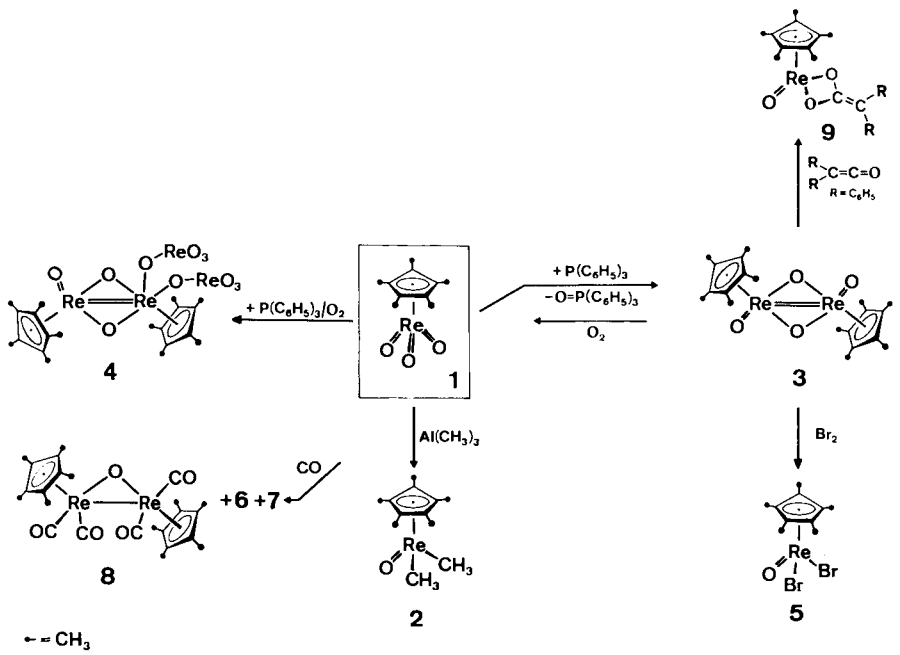
route to trioxo half-sandwich complexes[1]. The d^0-Re^{VII} complex $(\eta^5\text{-}C_5Me_5)ReO_3$ **1**, surprisingly easily accessible from the isostructural tricarbonyl complex by the action of light and oxygen, can be modified in a variety of ways. We report here first examples of typical functionalization and aggregation reactions and demonstrate that both Lewis acids and Lewis bases induce partial deoxygenation processes with concomitant reduction of the metal center to yield derivatives that are very reactive.

Excess trimethylaluminum reacts instantaneously with **1** even at low temperature (−80 °C, toluene/*n*-hexane) to afford the dark red, water-stable crystalline Re^V complex **2** (> 55% isolated yield), which contains two methyl groups bonded to the metal (Scheme 1) and is sensitive to oxidation in solution[2]. Presumably an intermediate complex adduct of the oxophilic Lewis acid $Al(CH_3)_3$ is formed; subsequent transfer of methyl groups to the transition metal then leads to **2**. This reaction is general and works also with higher trialkylaluminum compounds. In contrast, the Lewis base triphenylphosphane only causes a 1:1 abstrac-



Scheme 1.

Chemistry of the Novel Oxo Half-Sandwich Complex $(\eta^5\text{-}C_5Me_5)ReO_3$: Functionalization and Aggregation**

By *Wolfgang A. Herrmann*, Ricardo Serrano, Ulrich Küsthardt, Manfred L. Ziegler, Ernst Guggolz,* and *Thomas Zahn*

In memoriam, Earl L. Muetterties

By means of exhaustive oxidative decarbonylation of metal carbonyl complexes, we have recently opened up a tion of the oxo ligands of **1**; thus, in tetrahydrofuran (THF) solution, the brown, crystalline, readily oxidizable binuclear Re^V derivative **3**, whose bridged structure is broken in air via complete reversion to the parent complex **1**, is formed slowly at room temperature; in this way, we synthesized the isotopically labeled derivatives $(\eta^5\text{-}C_5Me_5)ReO_2(*O)$ (**1**-*O; *O = ^{17}O, ^{18}O)[2]. In the presence of little atmospheric oxygen, triphenylphosphane reacts with **1** (THF, room temperature) to afford the light brown, crystalline, air-stable, diamagnetic, tetranuclear complex **4**; after recrystallization from dichloromethane/diethyl ether, the isolated yield was 40–50% (CH_2Cl_2-adduct). The surprising structure of **4** derives from that of compound **3** in that one of the terminal oxo ligands is replaced by two perrhenate groups (Fig. 1)[2].

These perrhenate groups are each bonded unsymmetrically via an oxygen atom and form an obtuse angle with the strongly distorted square-pyramidally configurated metal center Re(2). It is to be noted that the Re(1)–Re(2) distance is comparatively short (265.1(1) pm), which, al-

[**] Multiple Bonds between Main Group Elements and Transition Metals, Part 8. This work was supported by the Deutsche Forschungsgemeinschaft, Degussa AG, and VARTA Batterie AG.—Part 7: W. A. Herrmann, R. Serrano, A. Schäfer, U. Küsthardt, M. L. Ziegler, E. Guggolz, *J. Organomet. Chem.*, in press.

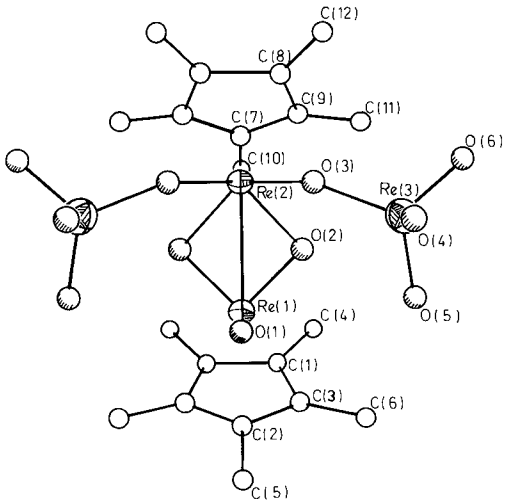

Fig. 1. Molecular structure of the tetranuclear Re^{V}/Re^{VII} complex **4** in the crystal. Rhombic, space group D_{2h}^{16}-Pcnm, $R_{iso}=0.074$, $R_w=0.036$. Important bond lengths [pm] and angles [°]: Re(1)–Re(2) 265.1(1), Re(1)–O(1) 172(1), Re(1)–O(2) 189(1), Re(2)–O(2) 199(1), Re(2)–O(3) 209.6(9), Re(3)–O(3) 177(1), Re(3)–O(4,5,6) 171(1); Re(2)–Re(1)–O(1) 95.5(5), Re(1)–Re(2)–O(3) 91.5(3), Re(1)–O(2)–Re(2) 86.2(4), Re(2)–O(3)–Re(3) 143.1(5).

though according to the noble gas formalism strongly indicates a d^2-d^2 metal-metal double bond, does not constitute strict proof of its presence[3]. In contrast, there is no doubt that the terminal oxo ligand O(1) forms a double bond with the pseudo-tetrahedrally configurated Re^{V} center[4]. The central Re_2O_2 structure is folded along the Re(1)–Re(2) vector (122°). Compound **4** has a mirror plane through the atoms Re(1), Re(2), and O(1).

The binuclear oxo complex **3** also undergoes halogenation and carbonylation reactions: elemental bromine (−80°C, CH_2Cl_2) reacts smoothly with **3** to give the green, mononuclear Re^{V} complex **5**[2]. Carbon monoxide under pressure (15 bar, THF, room temperature) effects reductive deoxygenation to afford the Re^{I} compounds (η^5-C_5Me_5)$Re(CO)_3$ **6** and (η^5-C_5Me_5)$_2Re_2(\mu$-CO)$_3$ **7**[5] in >90% total yield; in addition, traces of the novel μ-oxo complex **8**, which can be prepared better by other routes[2,6], are also produced. The structure of **8**, which has approximate C_2 symmetry, exhibits an isosceles triangular Re_2O skeleton with a Re–Re single bond of 281.7(1) pm (Fig. 2).

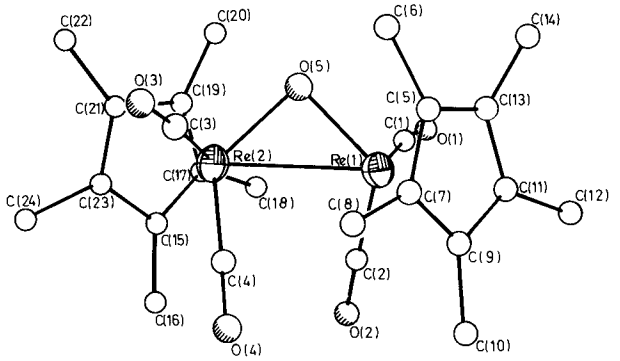

Fig. 2. Molecular structure of the (μ-oxo)carbonyl complex **8** in the crystal. Triclinic, C_i^1-$P\bar{1}$; $R_{iso}=0.068$, $R_w=0.031$. Selected bond length [pm] and angles [°]: Re(1)–Re(2) 281.7(1), Re(1)–O(5) 197.3(6), Re(2)–O(5) 197.2(8), Re–CO 186–189, C–O 115–121; Re(1)–O(5)–Re(2) 91.1(3), Re(1/2)–Re(2/1)–O(5) 44.4(2); interplanar angle between the planar C_5Me_5 ligands: 2.0°.

Further proof of the chemical lability of the bridged structure of **3** is provided by its smooth cleavage by heterocumulenes. With diphenylketene (THF, room temperature) the dark red, mononuclear complex **9** is formed quantitatively[2,7]. The dioxametallacyclobutane structure (Fig. 3) of this unprecedented compound can be attributed to a novel type of [2+2]-cycloaddition of the heterocumulene to one of the Re=O functions. The analogous reaction occurs when the trioxo complex **1** is treated with diphenylketene; here, the adduct of composition (η^5-C_5Me_5)$ReO_2[O_2CC(C_6H_5)_2]$ is formed.

Although the multiplicity of reactions undergone by the trioxo complex **1** has not yet been defined, the model reactions delineated here indicate a broad spectrum of products which should basically be realizable via deoxygenation and redox processes.

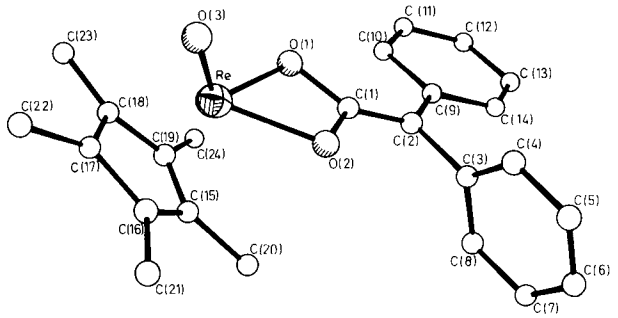

Fig. 3. Molecular structure of the dioxametallacyclobutane **9** in the crystal. Monoclinic, $P2_1/c$; $R_{aniso}=0.036$, $R_w=0.029$. Selected bond lengths [pm] and angles [°]: Re–O(3) 167.4(5), Re–O(1) 199.0(4), Re–O(2) 198.0(4), C(1)–O(1) 135.0(8), C(1)–O(2) 135.7(6), C(1)–C(2) 135.4(9); Re–O(1)–C(1) 94.7(3), Re–O(2)–C(1) 94.9(3), O(1)–Re–O(2) 65.3(1), O(1)–C(1)–O(2) 104.5(5), O(1)–C(1)–C(2) 131.9(5), O(2)–C(1)–C(2) 123.5(5), O(1)–Re–O(3) 113.3(2), O(2)–Re–O(3) 109.4(2), C(1)–Re–O(3) 118.2(2)°. The metallacycle is slightly folded along the O(1)–O(2) vector (172.7°).

[2] **2**: Recrystallized from *n*-hexane/toluene at −78°C. IR [cm^{-1}]: ν(Re=O) = 965 vs, 955 s-vs (sh) [KBr]; 969 vs [CS_2]; ^{1}H-NMR (270 MHz, C_6D_6, 28°C): δ($C_5(CH_3)_5$) = 1.42 (s, 15H), δ($ReCH_3$) = 1.95 (s, 6H); EI-MS (70 eV): *m/z* 366 (M^+, ^{185}Re); molecular mass 372 (osmometry, C_6H_6). — In solution **3** can only be handled under conditions of strict O_2-exclusion (glove box, <1 ppm O_2). IR [cm^{-1}] (KBr): ν(ReO) = 930 s (terminal), 634 s, and 614 m (bridging); ^{1}H-NMR (270 MHz, CD_2Cl_2, 28°C): δ(CH_3) = 2.03 (s); EI-MS (70 eV): *m/z* 352 peak of highest mass ($C_5Me_5ReO_2^+$); FD-MS (toluene): *m/z* 704 (M^+, ^{185}Re). — **4**: IR [cm^{-1}] (KBr): ν(ReO) = 973 m, 934 vs (br), 899 s, 855 m (sh), 827 s (br), 729 m, 700 w, 688 w-m; ^{1}H-NMR ($CDCl_3$, 28°C): δ(CH_3 = 1.93 and 2.21 [2s, 30H], δ(CH_2Cl_2) = 5.32 (s, 2H); FD-MS (CH_2Cl_2): *m/z* 1186 (M^+, ^{185}Re); molecular mass 1180 (osmometry, $CHCl_3$). — **5**: IR [cm^{-1}] (KBr): ν(Re=O) = 965 vs, 950 sh; ^{1}H-NMR ($CDCl_3$, 28°C): δ(CH_3) = 2.28 (s); FD-MS (toluene): *m/z* 494 (M^+, ^{79}Br, ^{185}Re); molecular mass 478 (osmometry in $CHCl_3$). — **8**: IR [cm^{-1}] (KBr): ν(CO) = 1966 s, 1923 vs (br), 1865 vs (br); ^{1}H-NMR ($CDCl_3$, 28°C): δ(CH_3) = 1.98 (s); EI-MS (70 eV): *m/z* 768 (M^+, ^{185}Re). — **9**: IR [cm^{-1}] (KBr): ν(CO) = 1630 vs, 1625 vs, ν(Re=O) = 925 vs, 889 vs; ^{1}H-NMR (C_6D_6, 28°C): δ(CH_3) = 1.46 (s, 15H), δ(C_6H_5) = 7.67, 7.26, 7.03 [mc, 10H]; FD-MS (toluene): *m/z* 546 (M^+, ^{185}Re); molecular mass 550 (osmometry, C_6H_6). — Correct elemental analyses were obtained for **2**–**9**. The reagents and complexes that are air- and moisture-sensitive must be handled in an efficient glove box, particularly for the preparation of spectroscopic samples.

[3] According to the same formalism, a Re=Re double bond, as typically found in $Re_2(\mu$-$CSiMe_3)_2(CH_2SiMe_3)_4$ [*d*(Re=Re) = 255.7(1) pm], can be assumed to be present in the simpler derivative **3**: cf. M. Bochmann, G. Wilkinson, A. M. R. Galas, M. B. Hursthouse, K. M. Abdul Malik, *J. Chem. Soc. Dalton Trans. 1980*, 1797. — In principle, it also seems possi-

ble that the two oxo bridges cause the observed contraction of the Re(1)–Re(2) distance (single bond lengths normally > 280 pm); however, multiply oxygen-bridged Re complexes with considerably larger and nonbonding ReRe distances are also known (e.g., W. A. Nugent, R. L. Harlow, *J. Chem. Soc. Chem. Commun. 1979*, 1105). Cf. also the following discussions for organometallic molybdenum and tungsten complexes as well as for molybdate structures: a) M. H. Chisholm, *ACS Symp. Ser. 155* (1981) 17ff., American Chemical Society, Washington D. C. 1981; b) R. E. McCarley, T. R. Ryan, C. C. Torardi, *ibid.*, p. 41ff.; c) F. A. Cotton, D. DeMarco, L. R. A Rational Synthetic Method for 2*H*-Isoindoles**

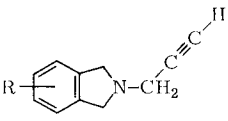
By *Richard P. Kreher** and *Norbert Kohl*

Dedicated to Professor Jan Thesing on the occasion of his 60th birthday

A straightforward synthetic concept proposed by *Thesing* et al. in 1964[1a] enabled, shortly afterwards, the first synthesis of 1*H*-isoindole **1a** and stimulated intensive studies to detect[1b] and isolate the tautomeric 2*H*-isoindole **2a**[2]. Base-induced 1,2-elimination of methanesulfinic acid from 2-mesylisoindolines is a particularly suitable method of preparing solutions containing **2a**[3]. Thermolytic methods[2] are propitious if the *o*-quinonoid hetarene is to be isolated and characterized spectroscopically; in this respect, the preparative difficulty is the time-consuming procedure of obtaining the starting materials for the thermally induced, cyclo-elimination or cycloreversion reactions. The retro-ene reaction[4] of isoindolines **3** bearing a propynyl group at the *N*-atom opens a facile route to 2*H*-isoindoles.

a, R = H; **b**, R = 5-*t*Bu, **c**, R = 4,7-Me_2

The 2-[2-propynyl]isoindolines **3** can be prepared using a simple procedure from 1,2-bis(bromomethyl)benzene, or corresponding derivatives, and 2-propynylamine by cyclizing *N*-alkylation (NEt_3, benzene, 1–8 d/room temperature)[6]. The following ^{1}H-NMR data (60 MHz, $CDCl_3$) are characteristic for **3**: δ = 3.95–4.10 (s, 4H, benzylic CH_2-groups), 3.52–3.63 (d, J = 2 Hz, 2H, propargylic CH_2-groups). Thermolysis of the isoindolines **3** (500°C/2×10^{-6} torr)[6] leads, via the—not detected—1*H*-isoindoles **1**, to the 2*H*-isoindoles **2**. In addition to ^{1}H- and ^{13}C-NMR data, the Diels-Alder reaction with *N*-(4-methylphenyl)maleimide establishes the presence of the *o*-quinonoid structure **2**. Isoindoles are also formed by cleavage of allene from **3** in the mass spectrometer.



3a, R = H(54%)
3b, R = 5-*t*Bu(57%)
3c, R = 4,7-Me_2(43%)
3d, R = 5-CO*t*Bu(68%)

According to findings on the mechanism of the retro-ene reaction[5], the intramolecular hydrogen transfer should proceed via a six-membered transition state involving an isoindoline methylene group and the CC triple bond. Activation of the CH_2-group by the benzene ring appears to be essential for the reaction. Preliminary investigations suggest that side chains having a terminal CC- or CO-double bond are less suitable for the thermolytic method, although the steric requirements for a cyclic transition state are more favorable; a non-concerted process is, therefore, not ruled out.

The facile and rational preparative method for 2*H*-isoindoles **2** combines the advantages of the thermolytic methods[2]—volatile accompanying products—with those of the base-induced elimination reaction[3]—straightforward preparation of the starting compounds—and permits the synthesis of 2*H*-isoindoles **2** with a specific substitution pattern and with anellated systems.

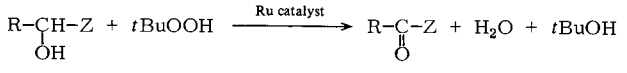
[6] **3**: A solution of 1,2-bis(bromomethyl)benzene (40–50 mmol) in 100 mL anhydrous benzene under argon at 0°C is stirred with 2-propynylamine (40—50 mmol) and triethylamine (100–125 mmol) at room temperature. After extraction with water (3 × 20 mL), the organic phase is dried with $MgSO_4$, filtered, and concentrated in vacuo; the residue is digested in 100 mL anhydrous ether and filtered. The ethereal filtrate is concentrated in vacuo and the residue dried; yields: 43–68%. The crude product **3** is distilled using a kugelrohr at 120–170°C/0.05 torr (**3a**, **b**, **d**) or fractionally recrystallized from ether (**3c**).—**2**: **3** (3 mmol) is vaporized at 45–65°C, pyrolyzed in a quartz tube (2.5 × 30 cm) at 500°C/2×10^{-6} torr, and the pyrolyzate condensed on a cold finger at −196°C. After thawing, the pyrolyzate is dissolved in 10 mL ether, *N*-(4-methylphenyl)maleimide added (2 mmol), and the mixture filtered after 24 h. The 1 : 1-adducts isolated (yield ca. 80%) are practically analytically pure.—Spectroscopic data: **2a**: ^{1}H-NMR ([D$_6$]acetone/300 MHz): δ = 6.78–6.86 (m, H-5, H-6), 7.26 (d, J = 2.9 Hz, H-1, H-3), 7.48–7.57 (m, H-4, H-7). ^{13}C-NMR ([D$_8$]dioxane/300 MHz): δ = 107.98 (d, C-1, C-3), 120.45 (d, C-4, C-7), 120.92 (d, C-5, C-6), 124.71 (s, C-3a, C-7a). 1,2,3,4-Tetrahydro-1,4-iminonaphthalene-2,3-dicarboxylic acid-*N*-(4-methylphenyl)imide: yield 82%, m.p. = 230°C (decomp.), isomer ratio: 40% *endo*- and 60% *exo*-adduct.—**2b**: ^{1}H-NMR: δ = 1.33 (s, C(CH$_3$)$_3$), 6.97–7.01 (m, H-6), 7.18–7.19 (m, H-1, H-3), 7.43–

7.48 (m, H-4, H-7). 6-*tert*-Butyl-1,2,3,4-tetrahydro-1,4-iminonaphthalene-2,3-dicarboxylic acid-*N*-(4-methylphenyl) imide: yield 83%, m.p. = 209–210°C (decomp.); isomer ratio 50:50.—**2c**: ^{1}H-NMR (60 MHz) δ = 2.38 (s, CH_3), 6.53 (s, H-5, H-6), 7.22 (d, J = 3 Hz, H-1, H-3), 10.15–11.85 (br., NH). 1,2,3,4-Tetrahydro-5,8-dimethyl-1,4-iminonaphthalene-2,3-dicarboxylic acid-*N*-(4-methylphenyl)imide: yield 75% (fractional crystallization), 30% *exo*-adduct, m.p. = 197–200°C (decomp.) and 45% *endo*-adduct, m.p. = 187–190°C.

α-Keto Esters and α-Keto Nitriles via Ruthenium-Catalyzed Dehydrogenation of α-Hydroxy Esters and Cyanohydrins with *tert*-Butyl Hydroperoxide

By *Masato Tanaka**, *Toshi-aki Kobayashi*, and *Toshiyasu Sakakura*

α-Keto acid derivatives are versatile intermediates in organic synthesis. Previously, we have described several methodologies for the synthesis of these compounds, including cyanation of acyl chlorides, cyanocarbonylation of organic iodides, and double carbonylation of organic halides in the presence of *sec*-amines[1–4]. We have now found that dehydrogenation of α-hydroxy esters and nitriles can be effected smoothly by *tert*-butyl hydroperoxide under very mild conditions in the presence of catalytic amounts of ruthenium compounds (Table 1).



1 **2**

a: R = Ph, Z = CO_2Et; **b**: R = 2-furyl, Z = CO_2Et;
c: R = (*E*)–PhCH=CH, Z = CO_2Et; **d**: R = CH_3, Z = CO_2CH_3;

1e:  ; **2e**:  ; **f**: R = Ph, Z = CN;

g: R = 2-thienyl, Z = CN; **h**: R = (*E*)–PhCH=CH, Z = CN

National Chemical Laboratory for Industry
Yatabe, Tsukuba, Ibaraki 305 (Japan)

As the reactions of ethyl mandelate **1a** show (runs 1–10), the dehydrogenation is catalyzed by a variety of Ru^0, Ru^{II}, and Ru^{III} compounds; the reaction could also be effected in air as well. The Ru/C catalyst exhibited almost the same catalytic activity (No. 9) when a second reaction was run (No. 10) using recovered catalyst.

The new dehydrogenation is applicable to aromatic, heteroaromatic, and vinylic compounds; no side-products were formed. Of note is that the olefinic bond in **1c** and **1h** was not epoxidized (runs 13 and 20). This is a remarkable contrast to the well-known Sharpless oxidation, which efficiently epoxidizes allylic alcohols[5]. Fully aliphatic α-hydroxy esters, such as **1d** and **1e**, could also be dehydrogenated, albeit with somewhat low reactivity; however, α-hydroxyvaleronitrile gave only butyric acid under similar conditions.

In summary, the new procedure offers a facile synthetic route to α-keto acid derivatives from readily available starting materials.

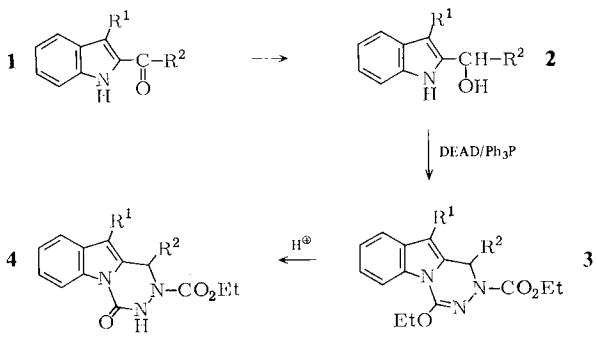
Synthesis of Substituted, Partially Hydrogenated [1,2,4]Triazino[4,5-*a*]indoles and Pyrrolo[1,2-*d*][1,2,4]triazines

By *Henning Böttcher** and *Bernd Arzt*

Dedicated to Professor Jan Thesing on the occasion of his 60th birthday

The Mitsunobu reaction, namely intermolecular dehydration with diethyl azodicarboxylate (DEAD) and triphenylphosphane, has found wide application in organic synthesis[1]. Azodicarbonyl compounds undergo cycloaddition reactions with dienes, monoenes, and 1,3-dipolar compounds[2]. We have now succeeded in preparing substituted, partially hydrogenated [1,2,4]triazino[4,5-*a*]indoles **3** and **4** by a novel cycloaddition reaction using the Mitsunobu reagent DEAD/Ph_3P. Generalization of this synthesis could lead to new interesting heterocyclic sytems.



a, $R^1 = R^2 = CH_3$; **b**, $R^1 = C_6H_5$, $R^2 = CH_3$;
c, $R^1 = CH_3$, $R^2 = CH_2\text{–}CH_2\text{–}N(CH_3)_2$,
d, $R^1 = C_6H_5$, $R^2 = CH_2\text{–}CH_2\text{–}N(CH_3)_2$

On reduction with $NaBH_4$ in methanol (or 2-propanol) or $LiAlH_4$ in tetrahydrofuran (THF), the 2-acylindoles **1** are converted into the 2-(1-hydroxyalkyl)indole derivatives **2**. The 2-(3-dimethylaminopropionyl)indoles **1c** and **1d** are obtained from the 2-acetylindoles **1a**[3] and **1b**[4], respectively, by Mannich reaction with formaldehyde and dimethylamine. Reaction of **2** with DEAD/Ph_3P (molar ratio 1:1) in THF leads, in all cases, to crystalline products, which, according to elemental analyses, contain 1 mol of incorporated DEAD. Even addition of nucleophiles (e.g. phenol) did not lead to the substitution products to be expected in a Mitsunobu reaction. ^{1}H-NMR, IR, and mass spectroscopic data (Table 1) showed that a cycloaddition to give ethyl 1-alkyl-4-ethoxy-1,2-dihydro[1,2,4]triazino[4,5-*a*]indole-2-carboxylates **3** takes place. These can be converted by treatment with acid into the ethyl 1-alkyl-1,2,3,4-tetrahydro-4-oxo[1,2,4]triazino[4,5-*a*]indole-2-carboxylates **4**.

8: as for **7**, 5%, m.p. 169–171 °C (HCl). IR (KBr): 1700 (C=O). ^{1}H-NMR ([D_6] DMSO): 7.1 (m, 1H), 6.3, 6.25 (2m, 2H), 5.6 (t, 1H), 4.35, 4.15 (2q, 4H), 2.95 (m, 2H), 2.65, 2.7 (2s, 6H), 1.95 (m, 2H), 1.25, 1.35 (2t, 6H). MS: *m/z* 308 (M^+, 5), 279(14), 136(28), 58(100)

9: NaOEt/EtOH, 6h, reflux, 20%, m.p. 199–200 °C (HCl). IR (KBr): 1700 (C=O). ^{1}H-NMR ([D_6] DMSO): 10.55 (s, 1H), 7.22 (m, 1H), 6.26, 6.19 (2m, 2H), 5.42 (t, 1H), 4.12 (q, 2H), 3.08 (t, 2H), 2.75 (2s, 6H), 1.95–2.3 (m, 2H), 1.20 (t, 3H). MS: *m/z* 207 (M^+ –73, 4), 58(100)

The scope of the reaction can be demonstrated by the reaction of DEAD/Ph_3P with dimethylamino-1-(2-pyrrolyl)-1-propanol **6**, which is obtained from the Mannich product **5**[5] by reduction with $LiAlH_4$. Under the conditions given in Table 1, **6** affords a mixture of the open-ring diethyl *N*-[3-dimethylamino-1-(2-pyrrolyl)propyl]hydrazodicarboxylate **7** and the cycloadduct **8**, which can be separated by column chromatography. **7** reacts with sodium ethoxide in ethanol with cyclization to give the ethyl 1-(2-dimethylaminoethyl)-1,2,3,4-tetrahydro-4-oxopyrrolo[1,2-*d*][1,2,4]triazine-2-carboxylate **9**.

Application of the Mitsunobu reaction to 2-(1-hydroxyalkyl)pyrrole and -indole derivatives thus leads to the cycloaddition of the DEAD reagent and opens up a facile synthetic route to novel annelated 1,2,4-triazines.

Synthesis of Enantiomerically Pure 1,7-Dioxaspiro[5.5]undecanes, Pheromone Components of the Olive Fly *(Dacus oleae)***

By *Hartmut Redlich** and *Wittko Francke*

Recently, spiroacetals have awakened increasing interest as chemical communication substances[2]. Mass spectroscopic studies of this class of compounds[3] have led to the identification of 1,7-dioxaspiro[5.5]undecane as the major component in the pheromone bouquet of the female olive fly *(Dacus oleae)*[4]. However, the absolute configuration of this chiral substance of C_2 symmetry remained unknown. A few syntheses of optically active spiroacetals have been described[5], and *Schurig* et al. have succeeded in enan-

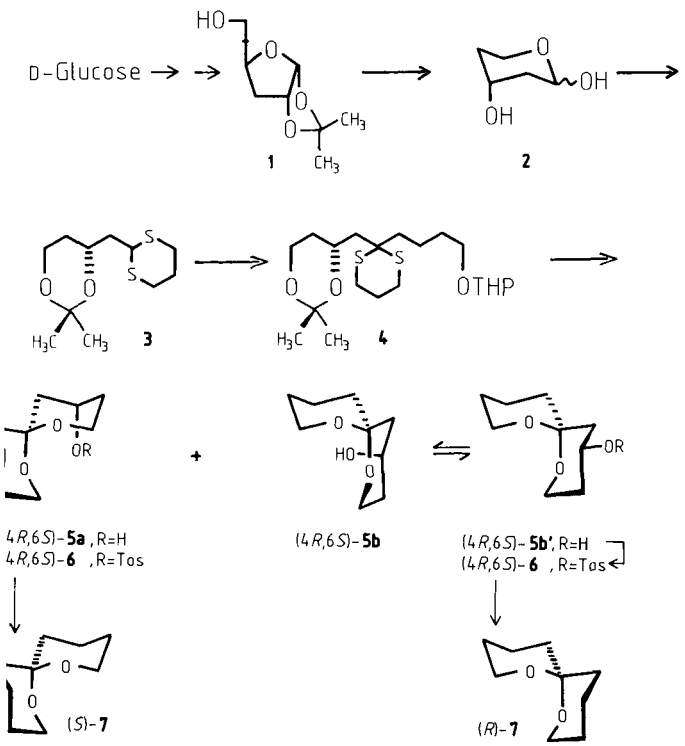
tiomeric separation of spiroacetals using complexation gas chromatography on optically-active metal complexes[6].

We have synthesized optically pure (*S*)- *and* (*R*)-1,7-dioxaspiro[5.5]undecane **7** starting from D-glucose[7]. However, since **7** possesses only one chiral center, the synthesis of the pure enantiomers using further chiral elements[1] is not possible. Instead, we used the anomeric effect, which is particularly pronounced in the 1,7-dioxaspiro[5.5]undecane system[8].

Starting material for the synthesis is the dideoxy compound **1**[5f], obtained from D-glucose. Removal of the isopropylidene group (0.5 N HCl, room temperature) by periodate cleavage (ethanol/water (1:1), $NaIO_4$ in water, 0°C) affords the free 2,4-dideoxy-D-*glycero*-pentapyranose **2**. After conversion of the latter into the open-chain dithiane (chloroform, 3 equiv. 1,3-propanedithiol, conc. HCl, 0°C), the isopropylidene compound **3** is synthesized (acetone, $CuSO_4$, catalytic amount H_2SO_4, $[\alpha]_D^{20}$ −31.5 (c=0.85 in MeOH), yield >80% for all steps). Reaction of **3** with the tetrahydropyranyl (THP) ether of 4-chlorobutanol [5g] using the Corey-Seebach method[9] [tetrahydrofuran (THF), 1.1 equiv. BuLi, −70→−20°C, 1 h, then Cl−$(CH_2)_4$−OTHP, 1 d at 0°C, 0°C→RT, 1 d, $[\alpha]_D^{20}$ −16.4 (c=1.0 in MeOH), yield 75%] affords the fully protected C_9-framework **4**.



The protecting groups in **4** can be removed in one step (acetone/water (99:1), $CuCl_2$/CuO (1:1), yield >95%). The free trihydroxy ketone cyclizes to the diastereomeric spiroacetals (4*R*,6*S*)-**5a** and (4*R*,6*R*)-**5b**/**5b**′. In (4*R*,6*S*)-**5a** the two pyran oxygen atoms are arranged in such a way that the anomeric effect is active in both pyran rings. In (4*R*,6*R*)-**5b** the anomeric effect is only active in the unsubstituted pyran ring; however, by changing its conformation to (4*R*,6*R*)-**5b**′, this molecule can also achieve an arrangement at the spirocenter in which the oxygen atoms adopt diaxial positions. Because of the equatorial position of the hydroxy group in (4*R*,6*R*)-**5b**′, this arrangement is more stable overall and this is expressed in the isomer ratio (4*R*,6*S*)-**5a**: (4*R*,6*R*)-**5b**′=3.5:6.5.

The two pure enantiomers (*S*)-**7** and (*R*)-**7** can be obtained by removal of the hydroxy group from (4*R*,6*S*)-**5a** and (4*R*,6*R*)-**5b**′, respectively. The diastereomeric hydroxy spiroacetals (4*R*,6*S*)-**5a** and (4*R*,6*R*)-**5b**′ are separated by chromatography on silica gel (ether/petroleum ether), whereby **5a**, the compound with the axial hydroxy groups, is considerably more mobile[10]. **5a** reacts slowly with tosyl chloride in pyridine to give the tosylate (4*R*,6*S*)-**6** ($[\alpha]_D^{20}$ +60.0, c=1.92 in $CDCl_3$), conversion after 3 d ca. 50%), whereas the reaction to the diastereomer (4*R*,6*R*)-**6** ($[\alpha]_D^{20}$, −56.3 (c=2.46 in $CDCl_3$) proceeds smoothly. The width of the ^{1}H-NMR signal for 4-H in (4*R*,6*S*)-**6** (400 MHz ^{1}H-NMR-spectrum, solvent $CDCl_3$, five lines at δ=4.78, overall width 14.6 Hz, corresponding to 2×a:e and 2×e:e), and in (4*R*,6*R*)-**6** (nine lines at δ=4.87, overall width 36.8 Hz, corresponding to 2×a:e and 2×a:a) confirms the assignment, which indirectly also fixes the configuration of the respective spirocenter. Elimination of the tosyl group[11] (ether, Al_2O_3, 4 h for (4*R*,6*S*)-**6**; 3—4 d for (4*R*,6*R*)-**6**) and subsequent hydrogenation (filtered ether solution, Et_3N (catalytic amount), then Pd/C/H_2, total yield >95% in each case, determined by gas chromatography) affords (*S*)-**7** and (*R*)-**7** in an optical purity of more than 95%[12]. The, to date, largest rotation value was determined for the *R*-configurated compound: $[\alpha]_D^{19}$ −122.8 (c=3.2 in pentane). Similar to 1,6-dioxaspiro[4.4]nonanes[5a], 1,7-dioxaspiro[5.5]undecane racemizes relatively easily, catalyzed by traces of acid[13].

Nitrosoferrocene**

By *Max Herberhold** and *Ludwig Haumaier*

Among the ferrocene (Fc) derivatives with simple N-containing substituents[1], nitrosoferrocene has so far never been synthesized. Unsuccessful attempts to synthesize it were first described in the literature in 1959[2]. Fc-NO was postulated as a product of the electrochemical oxidation of Fc-NHOH[3], but it was neither isolated nor characterized. We have now succeeded in generating Fc-NO as a ligand in a metal complex and in isolating it for the first time after removal from the metal.

Ferrocenyllithium, Fc-Li, reacts with the η^5-cyclopentadienyl(Cp)-chromium complex $CpCr(NO)_2Cl$ under nucleophilic addition of the ferrocenyl moiety to the N atom of a nitrosyl ligand. The primary product of unknown structure can be converted into the nitrosoferrocene complex **1** using *tert*-butyl isocyanide.

$$CpCr(NO)_2Cl \xrightarrow[\text{THF}]{\text{1. Fc-Li, 2. } t\text{BuNC}} CpCr(NO)(t\text{BuNC})(\text{Fc-NO}) \quad \mathbf{1}$$

Oxidative degradation of **1** with H_2O_2 leads to liberation of nitrosoferrocene **2**. The reaction must be controlled carefully, because **2** is gradually oxidized to nitroferrocene **3** on too prolonged a treatment with H_2O_2. In contrast to **3**[4], **2** gradually decomposes at room temperature in the solid state. The violet solutions of **2** in pentane or CH_2Cl_2, on the other hand, are stable for days, even at room temperature. Starting from **2**, novel ferrocenyl compounds of the type Fc–N=X can be obtained; examples are the reactions with malonodinitrile or triethylphosphane to give **4** and **5**, respectively.

The spectroscopic data of **2**—**5** are listed in Table 1. The ^{1}H-NMR spectra show the typical pattern for ferrocenyl groups[5], and the ^{13}C-NMR spectra indicate that C-1 is much more strongly deshielded in **2** than in **3**. A similarly large difference in the chemical shift of the ring atoms C-1 (bearing the substituents) is also found in the benzene derivatives Ph–NO (δ(C-1) = 165.63) and Ph–NO_2 (δ(C-1) = 148.3)[6]. The mass spectra of **2**—**5** all show the molecular ion as a very intense peak.

Experimental

1: 15 mL tetrahydrofuran (THF) is added to solid Fc-Li[7] (400 mg, 2.1 mmol) at −78 °C and the mixture is treated with a solution of $CpCr(NO)_2Cl$ (425 mg, 2.0 mmol) in THF (15 mL). After warming to room temperature, 0.45 mL (4.0 mmol) *tert*-butyl isocyanide is added and the mixture heated under reflux for 15 min. The solvent is removed, the residue dissolved in CH_2Cl_2, and the resulting solution chromatographed on a 6 × 2 cm column packed with silica gel (Fluka, particle size 0.063—0.200 mm). Ferrocene and a small amount of **2** are eluted with CH_2Cl_2, while the main product **1** is washed from the column with THF. Crystallization from CH_2Cl_2/hexane gives dark violet, almost black crystals, m.p. 151 °C (decomp), yield 750 mg (84%)[8].

2: A solution of **1** (445 mg, 1.0 mmol) in CH_2Cl_2 (20 mL) is treated with 1 mL of a 10% aqueous solution of H_2O_2 and the mixture stirred vigorously. The course of the reaction is followed by thin-layer chromatography (eluent CH_2Cl_2; **1** does not elute, **2** only slowly, **3** rapidly). As soon as **1** has completely disappeared (ca. 45 min), the reaction mixture is transferred to a column (20 × 2 cm) packed with dry silica gel. A small amount of **3** is first eluted as a pale pink zone with CH_2Cl_2, followed by **2** as a blue zone. On leaving the column **2** changes color; the eluate is violet. **2** crystallizes from pentane as violet, temperature-sensitive crystals, m.p. 110 °C (decomp.), yield 140 mg (65%).

4: **2** (82 mg, 0.38 mmol) and malonodinitrile (75 mg, 1.14 mmol) are dissolved in 20 ml THF. On addition of ca. 10 mg KO*t*Bu the solution turns blue. After removal of solvent the residue is taken up in CH_2Cl_2 and the solution chromatographed on silica gel. Crystallization from pentane affords dark blue crystals of **4**, m.p. 114 °C, yield 23 mg (23%).

5: A solution of **2** (60 mg, 0.28 mmol) and triethylphosphane in pentane (20 mL) is stirred for 30 min at room temperature. The yellowish brown solution is evaporated to dryness (for removal of excess PEt_3). The residue is extracted with pentane, the extract concentrated and cooled to −20 °C. **5** crystallizes as light-brown needles, m.p. 88 °C, yield 42 mg (47%). The residue from the extraction contains a small amount of azoxyferrocene, Fc–N=N(O)–Fc, which can be purified by chromatography on silica gel (eluent CH_2Cl_2) and crystallized from CH_2Cl_2/hexane; M_r = 414 (MS).

Pentamethylcyclopentadienyllutetium Derivatives of Dimethylphosphoniobis(methanide)**

By *Herbert Schumann*, Ilse Albrecht, Friedrich-Wilhelm Reier,* and *Ekkehardt Hahn*

Among the first organometallic compounds of the f-elements were the homoleptic ylide complexes, obtained in 1976 by reaction of the trichlorides of La, Pr, Nd, Sm, Gd, Ho, Er, and Lu with trimethylphosphoniomethanide and butyllithium. These compounds are polymeric and difficult to characterize, even in solution[2]. Use of tBu_2MePCH_2[3] or Ph_3PCH_2[4–6] allowed unequivocal spectroscopic characterization of lutetium derivatives of these ylides. Using pentamethylcyclopentadienyllutetium compounds, we have now succeeded for the first time in both synthesizing the first lutetium derivative of $[(CH_3)_2P(CH)_2]^{\ominus}$ that is configurationally stable even in solution and in performing an X-ray structure analysis of an ylide complex of the lanthanoids.

[**] Organometallic Compounds of the Lanthanoids, Part 21. This work was supported by the Fonds der Chemischen Industrie and by the Technische Univerität Berlin (materials for new technologies). We thank Prof. Dr. *H. G. von Schering* Stuttgart, for a valuable gift of Lu_2O_3.— Part 20: [1].

Reaction of $(C_5Me_5)_2Lu(\mu\text{-}Cl)_2Na(Et_2O)_2$[7] with $Li[(CH_2)_2P(CH_3)_2]$ (tetrahydrofuran (THF), 25 °C, argon) affords the complex **1** in 65% yield. Complex **1**, which is extremely sensitive to air and moisture, crystallizes from pentane or ether as colorless needle-like crystals. The similarly colorless ylide complex **2** is formed analogously from $LuCl_3$, NaC_5Me_5, and $Li[(CH_2)_2P(CH_3)_2]$. The NMR spectra of **1** and **2**[8] confirm the proposed structure. Both derivatives are configurationally stable at room temperature.

The complex $Lu[(CH_2)_2P(CH_3)_2]_3$ obtained on reaction of $LuCl_3$ and $Li[(CH_2)_2P(CH_3)_2]$ in THF at 25 °C does not show a simple NMR spectrum, even at −78 °C. As in the case of $Lu[(CH_2)_2P(t\text{-}C_4H_9)_2]_3$[3], an exchange equilibrium is established between the monomeric and oligomeric association products.

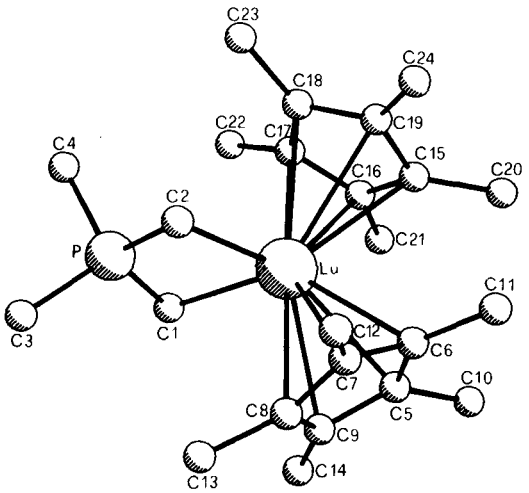

Fig. 1. Molecular structure of **1** in the crystal [9]. Selected bond lengths [Å] and angles [°]: LuCl 2.344(15), Lu-C2 2.378(15) P-C1 1.769(16), P-C2 1.782(15), P-C3 1.816(22), P-C4 1.823(23), Lu-Cp1 2.360(14), Lu-Cp2 2.493(10) (Cp1 and Cp2 are the calculated centroids of the cyclopentadienyl groups with the atoms C5 to C9 and C15 to C19), Lu-P 2.872(5); Cp1-Lu-Cp2 128.2(5), C1-Lu-C2 76.0(5), C1-P-C2 109.9(8), C1-P-C3 112.2(9), C1-P-C4 107.4(8), C2-P-C3 113.2(7), C2-P-C4 110.9(9), C3-P-C4 102.8(10).

The X-ray structure analysis shows that the Lu atom in **1** (Fig. 1 and 2)[9] is surrounded by a distorted tetrahedral array consisting of the centroids of two pentamethylcyclopentadienyl rings and two methylene carbon atoms. The Lu-C1 (2.344(15)Å) and Lu-C2 (2.378(15)Å) bond lengths lie within the range of lengths previously determined for Lu-C σ-bonds [2.376(17)Å in $(C_5H_5)_2LuCH_2Si(CH_3)_3(thf)$

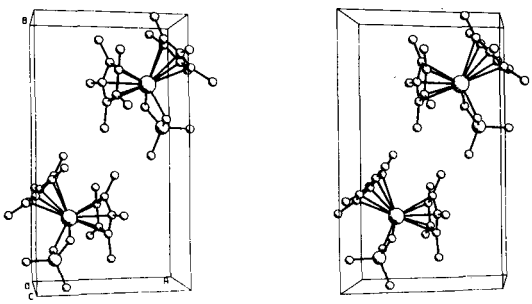

Fig. 2. Stereoview of the unit cell of **1** [9].

and 2.345(39) Å in $(C_5H_5)_2Lu$-p-C_6H_4-$CH_3(thf)$[10], yet are significantly shorter than in $[Li(dme)]_3[Lu(CH_3)_6]$ (dme = dimethoxyethane)[11], the permethylated homoleptic compound of lutetium (2.53(2) Å). The distances between the lutetium atom and the centroids of the cyclopentadienyl groups are markedly different (Lu-Cp1 2.360(14), Lu-Cp2 2.493(10) Å); however, the Lu-Cp1 distance is in good agreement with the values already known for dicyclopentadienylmetal derivatives[10]. This distortion does not occur in bis(pentamethylcyclopentadienyl) compounds of the type Cp'_2LnR_2 which have a similar structure to **1**[7]. The different Lu-Cp′ distances must therefore be interpreted in terms of electronic effects of the chelating ylide ligands and not in terms of steric interactions between the pentamethylcyclopentadienyl ligands. All the methyl groups of the C_5Me_5 ligands lie outside the planes of the C_5 rings, in each case on the side away from the lutetium (maximum deviation 0.307 Å for C13 in Cp1 and 0.437 Å for C20 in Cp2). The bond lengths P–CH_2 (1.769(16) and 1.782(15) Å) and P–CH_3 (1.816(22) and 1.823(23) Å) are in very good agreement with comparable bond lengths in ylide complexes of Ni and Co (P–CH_2 1.736(3), P–CH_3 1.825(4) and 1.795(4) Å for $[(CH_3)_2P(CH_2)_2]_4Ni_2$; P–$CH_2$ 1.734(9) and 1.717(8), P–CH_3 1.793(8) Å for $Co(CH_3)_2[P(CH_3)_3]_2[(CH_3)_2P(CH_2)_2]$[12]. The C1LuC2 angle (76.0(5)°) deviates the most from a tetrahedral angle; the phosphorus atom shows almost exact tetrahedral coordination (102.8(10)–113.2(7)°).

Mechanism of the Cyclocotrimerization of Diethyl(hydrido)thiophosphorus with Alkynes**

By *Ekkehard Lindner*, Claus-Peter Krieg, Wolfgang Hiller,* and *Riad Fawzi*

The cyclotrimerization of alkynes on transition metal complexes proceeds via metallacyclopropenes and -cyclopentadienes; depending on the alkyne, the products are metallacycloheptatrienes or -bicycloheptadienes[1]. Cyclocotrimerization (mixed cyclotrimerization) of alkynes and nitriles on cobalt complexes leads to pyridine derivatives[2]. The alkyne-like behavior of the P=S group (comparable atomic radii and electronegativities of P and S), which is suitable for the synthesis of otherwise difficultly accessible or even inaccessible highly substituted P- and/or S-containing heterocycles, has already been demonstrated[3].

We have now succeeded for the first time in detecting all the intermediates **2-5** participating in the cyclocotrimerization of η^2-P=S-compounds with electron-deficient alkynes. They could be characterized by elemental analyses, by their IR, ^{31}P-NMR and mass spectra (Table 1), and, in the case of **3** and **4c**, also by crystal structure investigations[4] (Fig. 1 and 2). All the intermediates contain the complex fragment $(\sigma\text{-}C_3F_7)Fe(CO)_2$.

[**] Preparation and Properties of, and Reactions with, Metal-Containing Heterocycles, Part 41. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 40: E. Lindner, C.-P. Krieg, *J. Organomet. Chem. 269* (1984) 65.

previously *no* example in the series of 3d elements[5], is soluble in *n*-pentane. When $L_nM = Mn(CO)_4$[6a] and CpNi[6b] only the dimeric complexes $[L_nM(SPMe_2)]_2$ can be isolated, while the extremely unstable cleavage product $L_nM\overline{SP}Me_2$ has been trapped with alkynes. Consistent with the short-wave position of ν(PS) in the IR spectrum of **3**, the P–S distance of 201 pm (Fig. 1) reflects significant π-bonding character. The P–Fe contact is recognized by the PF couplings in the $^{31}P\{^1H\}$-NMR spectrum. The –I effect of the perfluoropropyl group in the *trans*-position to the sulfur atom stabilizes the three-membered ring **3** to such an extent that it can be isolated and identified. Oligomerization or dimerization is not observed in solution, even at 50 °C.

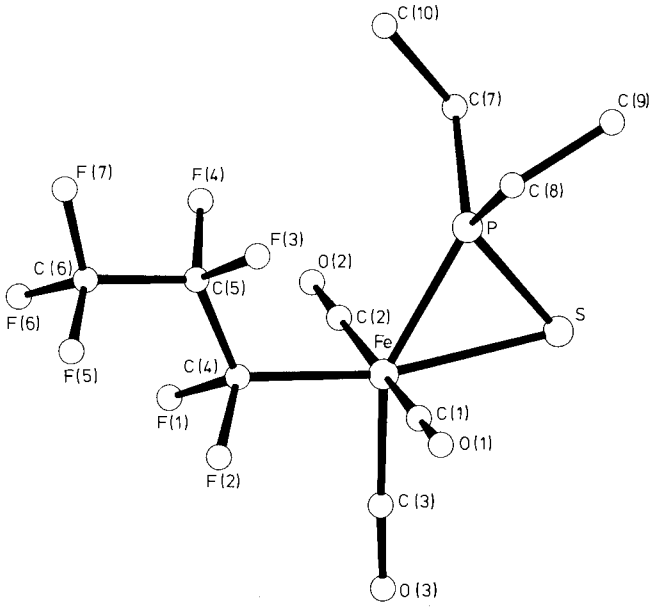

Fig. 1. Molecular structure of **3** in the crystal. Selected bond lengths [pm] and angles [°]: Fe-P 223.0(1), P-S 201.1(1), Fe-S 241.4(1), Fe-C(4) 200.1(3); P-Fe-S 51.13(3), Fe-P-S 69.16(3), Fe-S-P 59.71(3).

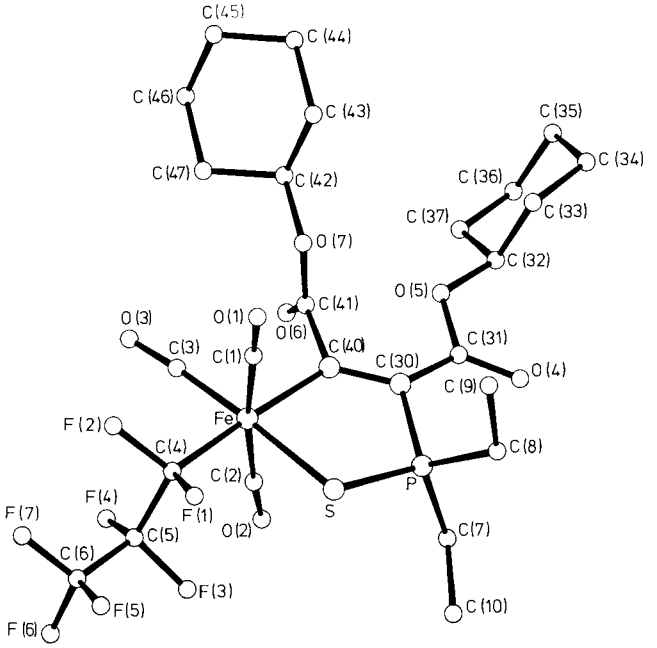

Fig. 2. Molecular structure of **4c** in the crystal. Selected bond lengths [pm] and angles [°]: Fe-S 235.6(2), S-P 200.1(3), P-C(30) 182.8(5), C(30)-C(40) 135.6(9), Fe-C(40) 200.5(7), Fe-C(4) 198.6(7); C(40)-Fe-S 87.4(2), Fe-S-P 100.9(1), S-P-C(30) 105.7(3), P-C(30)-C(40) 114.1(6), C(30)-C(40)-Fe 129.0(4).

In spite of the reduced reactivity it was demonstrated that **3** can be regarded as an intermediate of the cyclocotrimerization with electrophilic alkynes. When **3** is warmed to 50 °C in *n*-hexane, the alkyne is inserted into the Fe-P bond with formation of the bright-yellow, thermally stable ferracyclopentadienes **4a-c**. "P-Isomeric" species[5] do not occur. Typical for the almost planar metallacyclopentadiene **4c** (Fig. 2) are the short P–S and C(30)–C(40) distances, which correlate with the frequencies of ν(PS) and ν(CC) in the IR spectrum. In **4c**, the C_3F_7 group occupies the position opposite C(40).

The three CO ligands in **2-4** are always arranged meridionally, the middle CO molecule being located in the *trans*-position to the sulfur (**2, 4**) or phosphorus atom (**3**). Accordingly, the IR band which is to be assigned to this CO molecule is shifted to the long- and short-wave side, respectively, of the most intense ν_{as}(CO) band. **4a-c** react with alkynes with loss of CO to give the bright-yellow ferracycloheptadienes **5a-c**, which are only sparingly soluble in nonpolar solvents[7]. The structure follows from comparison of their analytical and spectroscopic data with those of the manganese analogues[8].

[7] Typical procedure: A solution of Et_2HPS (3.0 mmol) in Et_2O (30 mL) is added dropwise at –18 °C to a solution of **1** (3.0 mmol) in Et_2O (50 mL). The stirred mixture is slowly warmed to 25 °C within 12 h. After removal of solvent and recrystallization from *n*-hexane at –30 °C, pure **2** is obtained in 70% yield. A powerful stream of NH_3 is passed through a solution of **2** (2.5 mmol) in *n*-hexane (100 mL) for 15 s, and, after removal of the solvent, two-fold extraction of the residue with 50 mL *n*-pentane, and filtration of the extracts over silica gel (5 mm), the resulting solution is evaporated down to ca. 30 mL. **3** crystallizes at –30 °C as yellow needles (yield 50%). A solution of **3** (2.5 mmol) in *n*-hexane (100 mL) and alkyne (3.0 mmol) is stirred for 6 h at 50 °C. Subsequent work-up by medium-pressure liquid chromatography with $CHCl_3$/*n*-hexane (1:5) affords **4a-c** in 15% yield and small amounts of **5a-c**. If further alkyne (3 mmol) is added to the reaction solution and stirring continued for 3 h at 60 °C, bright yellow **5a-c** are obtained after chromatographic purification (yield 20%).

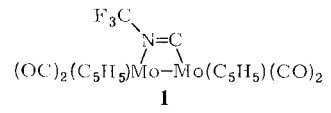
$F_3CN{=}C{=}C{=}NCF_3$, a New Bridge Ligand: Formation by CC Linkage of Two CF_3NC Ligands and Cleavage of a Mo≡Mo Bond

By *Dieter Lentz**, *Irene Brüdgam*, and *Hans Hartl*

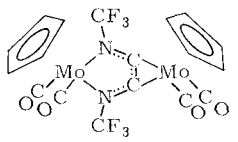
Vibrational spectroscopic investigations have shown[1] that trifluoromethyl isocyanide CF_3NC, recently used for the first time as a complex ligand, behaves both as σ-donor and as strong π-acceptor; it thus resembles the carbonyl ligand more than other isocyanide ligands[2]. In competition with CO, CF_3NC seems to prefer the bridge position; this is demonstrated, for example, in $Fe_3(\mu\text{-}CNCF_3)(CO)_{11}$[3]. In the binuclear molybdenum complex $[Mo(\eta\text{-}C_5H_5)(CO)_3]_2$[4], the CO ligands take up exclusively the terminal positions. We have now tried to synthesize the analogous CF_3NC complex in order to check whether the CF_3NC ligand is terminally or bridge coordinated.

$$(OC)_2(C_5H_5)Mo{\equiv}Mo(C_5H_5)(CO)_2 + F_3CNC \xrightarrow[25\,^\circ C]{CH_2Cl_2}$$



1

$$\mathbf{1} + n F_3CNC \xrightarrow[25\,^\circ C]{CH_2Cl_2}$$



$+ Mo_2(C_5H_5)_2(CO)_3(CNCF_3)_3$

2 **3**

Reaction of $[Mo(\eta\text{-}C_5H_5)_2(CO)_2]_2$ with CF_3NC in the molar ratio 1:1 leads to formation of $Mo_2(\eta\text{-}C_5H_5)_2(CO)_4(\eta^2\text{-}\mu\text{-}CNCF_3)$ **1**. According to the spectroscopic data[5], **1** has the same structure as the analogous phenyl isocyanide complex[6], in which the η^2-bonded isocyanide bridge ligand functions as a four-electron donor. If an excess of CF_3NC is employed, the complexes **2** and **3** are formed; these can be separated by column chromatography (silica gel, petroleum ether 40—60/CH_2Cl_2 4:1). The IR, MS, and 60 MHz ^{1}H-NMR data of **2**[5] indicated a dimeric structure analogous to that of $[Mo(\eta\text{-}C_5H_5)(CO)_3]_2$ with a molybdenum-molybdenum bond and terminal ligands. The high resolution ^{1}H- and ^{13}C-NMR spectra[5], however, showed a double set of signals for the C_5H_5-ligands, thus indicating the presence of an unsymmetrical structure. The X-ray analysis of **2**[7] gave a surprising result (Fig. 1): **2** is a complex of 1,1,1,6,6,6-hexafluoro-2,5-diaza-2,3,4-hexatriene, $F_3CN{=}C{=}C{=}NCF_3$, a molecule unknown in the free state.

Addition of a second CF_3NC molecule to **1** dimerizes the ligand via CC bond linkage and MM bond cleavage; this has hitherto rarely been observed in the Mo≡Mo system[8]. The new $F_3CN{=}C{=}C{=}NCF_3$ ligand bridges two $Mo(\eta\text{-}C_5H_5)(CO)_2$ fragments, one of which forms a five-membered MoNCCN metallaheterocycle with the bridge ligand. The second $Mo(\eta\text{-}C_5H_5)(CO)_2$ fragment is linked to the C atoms of the bridge ligand. The molybdenum, nitrogen, and carbon atoms lie in a plane (maximum deviation from the least squares plane 5 pm). The C(4)—N(1) bond length of 132.3(8) pm lies between the lengths of the CN single bonds (141.4(7) pm) and CN double bonds (127.7(7) pm) in CF_3NCHF[9]. The C(4)—C(4′) bond length of 137.6(9) pm corresponds to the length of a CC double bond. These findings indicate a strong electron delocalization in the $Mo_2(\mu\text{-}F_3CNCCNCF_3)$ system.

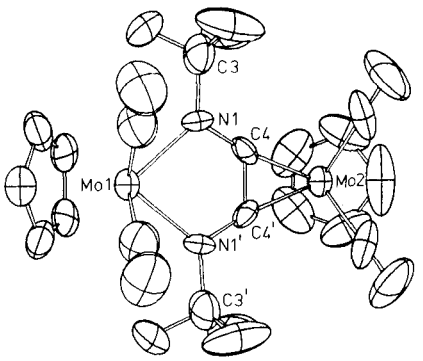


Fig. 1. Molecular structure of $[(CO)_2(\eta\text{-}C_5H_5)Mo(\mu\text{-}F_3CNCCNCF_3)Mo(\eta\text{-}C_5H_5)(CO)_2]$ **2**. Selected bond lengths: C(3)—N(1) 142(1), C(4)—N(1) 132.3(8), C(4)—C(4′) 137.6(9), Mo(1)—N(1) 223.9(6), Mo(2)—C(4) 205.6(7) pm.

The sole example known to date in which a dimeric isocyanide occurs as ligand is the complex $Cl_2(t\text{BuNC})_4Nb(\mu\text{-}t\text{BuNCCN}t\text{Bu})NbCl_4$[10]; it contains the metal atoms in different coordination spheres and oxidation states, and formation of the ligand is less easily understood than in **2**.

The composition of **3** has been determined mass spectroscopically, but insufficient reliable data are as yet available about its structure. The ^{19}F-NMR spectrum shows three signals for the three different trifluoromethyl groups, two of which couple with a small coupling constant. According to the ^{13}C-NMR spectrum, the two cyclopentadienyl groups are not equivalent.

Table 1. ESR coupling constants of the radicals $\mathbf{1}^{\odot\oplus}$–$\mathbf{3}^{\odot\oplus}$.

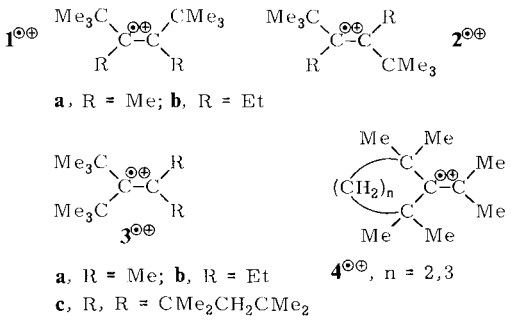
Radical	Oxidation method [a]	T [°C]	$a^{H}_{CMe_3}$ [G]	a^{H}_{R} [G]
$\mathbf{1a}^{\odot\oplus}$	A	− 85	1.7 (6H)	14.2 (6H)
$\mathbf{1b}^{\odot\oplus}$	B	− 90	1.6 (6H)	23.0 (2H) 1.6 (2H)
$\mathbf{2a}^{\odot\oplus}$	B	− 110 to − 40	0.65 (18H) [b]	14.8 (6H) [b]
$\mathbf{2b}^{\odot\oplus}$	B	− 61	0.65 (18H)	15.9 (2H) [c] 9.3 (2H) [c]
$\mathbf{3a}^{\odot\oplus}$	A, B,	− 90	2.5 (6H)	12.5 (6H)
	B	− 45	0.87 (18H)	12.5 (6H)
$\mathbf{3b}^{\odot\oplus}$	B	− 110	2.5 (6H)	13.2 (2H) [c] 9.5 (2H) [c]
$\mathbf{3c}^{\odot\oplus}$	A	− 88	2.9 (6H)	—

[a] A: electrochemically, B: with $AlCl_3$. [b] In [10], these data have been erroneously assigned to $\mathbf{3}^{\odot\oplus}$. In the meantime we have found that **3a** isomerizes to **2a** in the presence of $AlCl_3$. [c] Line-broadening effects by hindered rotation of the ethyl groups.

Hindered Rotation of *tert*-Butyl Groups in Radical Cations of Highly Substituted Alkenes**

By *Horst Eierdanz, Siegfried Potthoff, Rudolf Bolze,* and *Armin Berndt**

Hindered rotation of *tert*-butyl groups bound to sp^2 C-atoms has hitherto only been observed in 1,8-di-*tert*-butylnaphthalenes[1] and has been predicted for *Z*-1,2-di-*tert*-butylethene **1** (R = H) on the basis of force field calculations[2,3]. Herein we describe with the radical cations $\mathbf{1}^{\odot\oplus}$ and $\mathbf{3}^{\odot\oplus}$ the first examples of hindered rotation of sp^2 C-bonded *Z*-vicinal and geminal *tert*-butyl groups.



The radicals $\mathbf{1}^{\odot\oplus}$-$\mathbf{3}^{\odot\oplus}$ were generated by electrochemical oxidation of the corresponding alkenes[7] on a gold spiral as anode (platinum wire as counter electrode) or by oxidation with $AlCl_3$ in dichloromethane at −80 to −100°C. The ESR coupling constants are collected in Table 1.

In the radicals $\mathbf{1}^{\odot\oplus}$ and $\mathbf{3}^{\odot\oplus}$ only six of the eighteen *tert*-butyl protons lead to a splitting in the ESR spectrum at low temperatures. Only $\mathbf{3a}^{\odot\oplus}$ is stable enough to be investigated in the temperature range of the intermediate and fast exchange of the six with the remaining twelve γ protons. The analysis of the ESR spectra of $\mathbf{3a}^{\odot\oplus}$ (Fig. 1) gives a rotation barrier of E_A = 4.7 kcal/mol[11]. By replacing one of the six methyl groups of the *tert*-butyl groups in $\mathbf{3}^{\odot\oplus}$ by a trideuteriomethyl group we were able to prove that the phenomenon under investigation involves a hindered rotation of the *tert-butyl groups* and *not of the methyl groups* as in the neopentyl radical[12]. The ESR spectrum of the deuterated radical shows a splitting at −90° by six *tert*-butyl protons, while in the case of hindered rotation of the methyl groups a splitting by only five *tert*-butyl protons is to be expected[13].

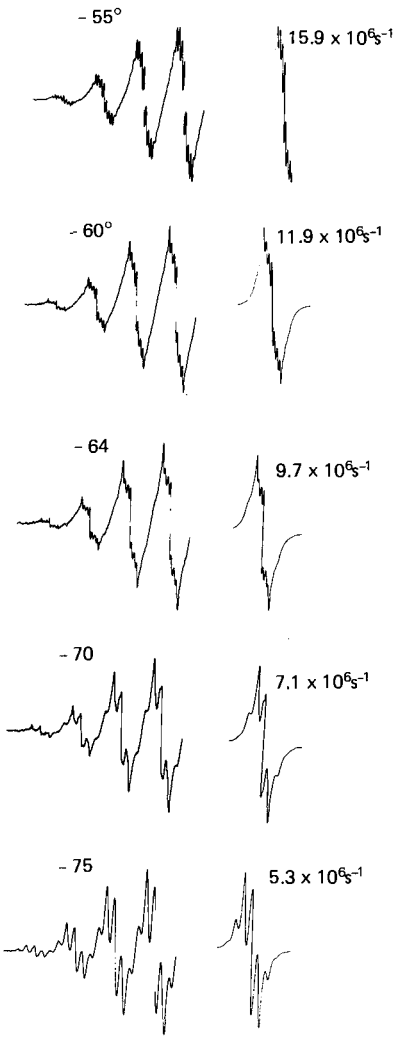


Fig. 1. Downfield halves of the ESR spectra of $\mathbf{3a}^{\odot\oplus}$ at various temperatures (left) and simulations of the central multiplet with the pertinent rate constants of the exchange (right).

The hindered rotation of the *tert*-butyl groups in $3^{\odot\oplus}$ is consistent with the relatively high barriers of ring inversion which we have recently demonstrated for the radicals $4^{\odot\oplus}$[10, 14].

The free rotation down to -110°C of the *tert*-butyl groups of the radicals $2^{\odot\oplus}$ of *E*-1,2-di-*tert*-butylalkenes, isomeric to $1^{\odot\oplus}$, shows that hindered rotation of sp^2 C-bonded *tert*-butyl groups occurs only when two *tert*-butyl groups are in close neighborhood (1,1-, *Z*-1,2-, or "*endo*"-1,3-position in $3^{\odot\oplus}$, $1^{\odot\oplus}$, and 1,8-di-*tert*-butylnaphthalenes). This finding is consistent with the assumption of a correlated rotation[2] of the two *tert*-butyl groups.

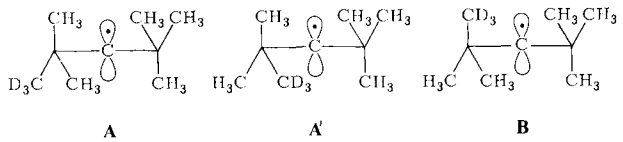
[5] Hindered rotation of the $CH(CH_3)_2$ groups in the radical cation of tetraisopropylethene, which we have generated electrochemically at -80°C, follows from the coupling constants of the β-protons: $a_\beta^H = 2.28$ G (2H), 0.4 G (2H); $a_\gamma^H = 0.57$ G (24H).
[6] Hindered rotations of the ethyl groups in the ethenes **1b**, **2b**, and **3b** follow from line-broadening effects in the ^{1}H-NMR spectra. *syn-anti*-Isomers are detectable for **1b** and **2b** below -50 and -115°C, respectively.
[7] **1a** and **2a** were prepared as described by *Rice* et al. [8], **1b**, **2b** and **3a**–**c** according to the method of *Barton* et al. [9]. The *Z*-, *E*-isomers were separated by gas chromatography.
[8] J. E. Rice, Y. Okamoto, *J. Org. Chem. 47* (1982) 4189.
[9] T. G. Back, D. H. R. Barton, M. R. Britten-Kelly, F. S. Guziec, Jr., *J. Chem. Soc. Perkin Trans. 1 1976*, 2079, and references cited therein.
[10] H. Eierdanz, A. Berndt, *Angew. Chem. 94* (1982) 716; *Angew. Chem. Int. Ed. Engl. 21* (1982) 690; see also footnote [b] of Table 1.
[11] Hindered rotation of the *tert*-butyl groups in the ethene **3a** follows from the marked broadening of the corresponding ^{13}C-NMR signal at -155°C. Since neither the temperature range of the coalescence nor that of slow exchange was accessible, only an upper limit can be estimated for the barrier. Assuming $\Delta\delta = 100-400$ Hz, ΔG^+ must be less than 5 kcal/mol.
[12] K. U. Ingold, J. C. Walton, *J. Am. Chem. Soc. 104* (1982) 616.
[13] In the case of hindered rotation of the *tert*-butyl groups, only the six protons of the two "axial" methyl groups of the conformations **A** and **A'** lead to splitting into a 1:6:15:20:15:6:1 septet with $a^H = 2.5$ G. The additional ESR spectrum of the conformation **B** is not resolved, since each line of the 1:3:3:1 quartet (2.5 G) of the axial CH_3 group is split into a 1:3:6:7:6:3:1 septet with $a^D = 2.5/\approx 6.5 \approx 0.4$ G, while the line width is 1.7 G.



A **A'** **B**

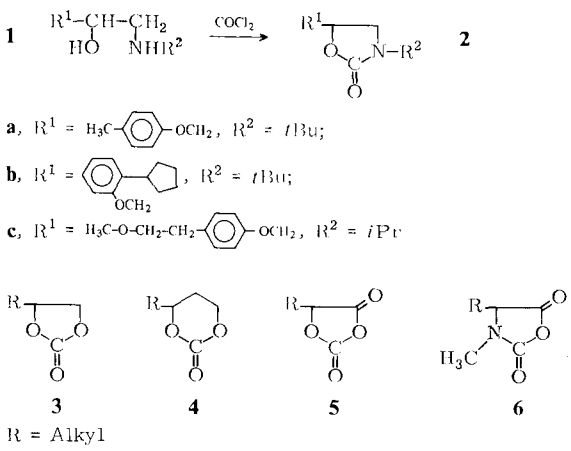
On hindered rotation of the methyl groups only five protons would lead to splitting, since one deuterium of the CD_3 group always adopts a position which would lead to coupling.

[14] The similarity of $3^{\odot\oplus}$ and $4^{\odot\oplus}$ is also reflected in the size of the ESR coupling constants of the γ-protons (2.3 and 2.5 G in the case of $4^{\odot\oplus}$, 2.5-2.9 G in the case of $3^{\odot\oplus}$).

Phosgene as a Reagent for the Enantiomeric Resolution of 1,2- and 1,3-Diols, α-Amino Alcohols, α-Hydroxy Acids, and *N*-Methyl-α-Amino Acids by Gas Chromatography**

By *Wilfried A. König**, *Eberhard Steinbach*, and *Karin Ernst*

Isocyanates have proved to be versatile reagents for the preparation of carbamate, urea, and amide derivatives of chiral hydroxy, amino, and carboxy compounds which can be resolved by gas chromatography[1]. We now report on the use of phosgene as a reagent for enantiomeric resolution. Phosgene-containing solutions react with α-amino alcohols (such as **1**) to give the oxazolidin-2-one **2**[2], with 1,2- and 1,3-diols to give the cyclic carbonates **3** and **4**[3], respectively, with α-hydroxy acids to give the 1,3-dioxolane-2,4-diones **5**[4], and with *N*-methyl-α-amino acids to give the *N*-methyloxazolidine-2,5-diones **6**[5].



1 **2**

a, R^1 = H_3C–⟨○⟩–OCH_2, R^2 = *t*Bu;
b, R^1 = ⟨○⟩(OCH$_2$), R^2 = *t*Bu;
c, R^1 = H_3C–O–CH_2–CH_2–⟨○⟩–OCH_2, R^2 = *i*Pr

3 **4** **5** **6**

R = Alkyl

With 30–50 μL of phosgene solution (20% in toluene) and between 0.1 and 1 mg of starting material in dichloromethane or ether, the reactions afford good yields at room temperature in 30–60 min. When ammonium salts are used, addition of a small amount of 0.5 M NaOH is advantageous. α-Hydroxy acids react particularly well in dioxane in the presence of a trace of pyridine. The derivatives, obtained from racemic compounds, can be readily resolved into their enantiomers by gas chromatography (glass or fused silica capillary columns, stationary phase: polysiloxane XE-60-L-valine-(*R*)-α-phenylethylamide[6]) (Table 1). The derivatization proceeds without racemization.

Aliphatic 1,2- and 1,3-diols (Fig. 1)—frequently used chiral building blocks for the synthesis of natural products[7] and for which various enantioselective synthetic methods have been developed[8]—could previously hardly be resolved into enantiomers by gas chromatography; this could only be achieved with aryl-substituted 1,2-diols via perfluoroacylated derivatives[9]. Diols and α-amino alcohols with additional functional groups can also be resolved as cyclic carbonates and oxazolidin-2-ones, respectively. By this means, racemic tartaric acid and *N*-methylthreonine were resolved after esterification of the carboxy groups with isopropanol and subsequent reaction with phosgene.

[a] The diols were kindly supplied by Dr. *K. Günther*, Degussa AG, Hanau. [b] Order of elution was not determined. [c] Separation on XE-60-L-valine (*S*)-α-phenylethylamide. [d] Bupranolol was supplied by Sanol Schwarz-Monheim GmbH, penbutolol by Hoechst, Frankfurt, and metoprolol by Hässle, Gothenburg, Sweden. [e] As isopropyl ester.

For tartaric acid, the resolution on the XE-60-L-valine-(*S*)-α-phenylethylamide phase[6] is better than on the diastereomeric phase. Particularly large separation factors α are obtained for the alicyclic *trans*-1,2-diols (Table 1). For alicyclic *trans*-1,3-diols, cyclic carbonates do not form for steric reasons.

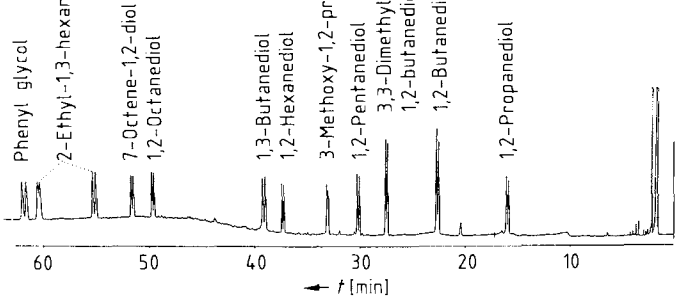

Fig. 1. Enantiomer resolution of the cyclic carbonates of 1,2- and 1,3-diols. 35m fused-silica capillary, coated with XE-60-L-valine-(*R*)-α-phenylethylamide; column temperature 90°C, temperature program 1°C/min up to 110°C, then 2.5°C/min up to 170°C. Carrier gas H_2, 0.9 bar.

Oxazolidine-2-ones from amino alcohols of the ephedrine type are also readily resolvable and configurationally stable derivatives[10]. This also applies to amino alcohols, which have considerable importance as β-receptor blockers in the treatment of cardiac-circulation diseases, but could previously not be resolved[11]. Today, β-blockers are largely used in the form of racemates; however, because of the, in part, extremely different action of the enantiomers the pure enantiomers are sought.

Compared to the derivatives prepared by reaction of isopropyl isocyanate with 2-hydroxy acids or *N*-methyl-α-amino acids[1], those derivatives obtained by reaction with phosgene offer the advantage of considerably higher volatility. Phosgene is therefore an alternative and/or extension to the isocyanates for the derivatization of chiral, polyfunctional compounds for resolution by gas chromatography.

High-Pressure Phases of KSi, KGe, RbSi, RbGe, CsSi, and CsGe with the NaPb-Type Structure**

By *Jürgen Evers**, *Gilbert Oehlinger*, *Gerhard Sextl*, and *Armin Weiss*

The compounds $SrGe_2$[2], $BaSi_2$ and $BaGe_2$[2], which crystallize in the $BaSi_2$-type structure[1] at normal pressure (NP), are characterized by two unusual properties: (i) their Si or Ge sublattice is reminiscent of the P_4 tetrahedron of white phosphorus, (ii) they are semiconductors[3]. The semimetal sublattice of these phases contains isolated Si_4- or Ge_4-tetrahedra of three-bonded atoms which can be formulated ionically as

$\geqslant Si:^{\ominus}$ and $\geqslant Ge:^{\ominus}$

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

with fully occupied octets; they contain the same number of valence electrons as phosphorus. Fully occupied valence shells confer non-metallic properties on the solid species.

At high pressures and temperatures (e.g. 4 GPa, 1000 °C) the isolated tetrahedra in $SrGe_2$[4], $BaSi_2$[5] and $BaGe_2$[6] can be transformed into layer or three-dimensional network arrays of three-bonded atoms, with concomitant loss of semiconducting properties. This transformation is most impressive in the case of $BaGe_2$; its "high pressure/high temperature (HPHT) phase", which can be kept in the metastable state at normal pressure, is superconducting (critical temperature: 4.9 K)[7].

The structures of the compounds formed from the alkali metals K, Rb and Cs and the Group IV elements Si, Ge, Sn, and Pb also consist of isolated tetrahedra at normal pressure. The silicides and germanides of K, Rb and Cs crystallize in the cubic KGe-type structure[8], the corresponding stannides and plumbides[9] in the tetragonal NaPb-type structure[10]. In this paper we report on transformations of the silicides and germanides at high pressures and high temperatures.

The cubic NP-phases were synthesized from the elements under argon. The alkali metals (10% excess) were fused together with semiconductor silicon (or germanium) in a corundum crucible. Due to the considerably high vapor pressure of the alkali metals at the synthesis temperature (650—750 °C), the corundum crucible was heated in a copper-sealed iron container. Both the alkali metals and their silicides and germanides are extremely sensitive to air and moisture; therefore all operations with open crucibles had to be carried out in a glove box under very pure argon. The HPHT experiments were performed in boron nitride crucibles in a Belt type apparatus at 4 GPa and 600—700 °C.

We were able to quench six high-pressure (HP) phases of the alkali metal silicides and germanides to ambient conditions. When heated to about 400 °C at NP, these phases were transformed into the thermodynamically stable phases with the cubic KGe-type structure in exothermic reactions. Chemical analyses of the new phases of KSi gave no indication of a change in the 1:1 composition. The pycnometrically determined densities and those calculated from X-ray data were in good agreement. All six HP-phases are isotypic. Their X-ray powder diagrams (Debye-Scherrer method, $Cu_{K\alpha}$, 114.6 mm) can be indexed tetragonally. Intensities of the reflections were calculated with the "Lazy Pulverix"[11] program (position parameters: single-crystal data of KSn[9]) and found to be in good agreement with the NaPb-type structure.

Table 1. Lattice parameters of the tetragonal NaPb-type phases AB (A = K, Rb, Cs; B = Si, Ge, Sn, Pb).

Compound	Phase [a]	a Axis [pm]	c Axis [pm]	Axial ratio c/a
KSi	HP	1057	1710	1.62
KGe	HP	1069	1737	1.62
KSn	NP [9]	1142	1857	1.63
KPb	NP [9]	1150	1876	1.63
RbSi	HP	1083	1758	1.62
RbGe	HP	1104	1787	1.62
RbSn	NP [9]	1171	1909	1.63
RbPb	NP [9]	1184	1942	1.63
CsSi	HP	1123	1834	1.63
CsGe	HP	1138	1850	1.63
CsSn	NP [9]	1219	1987	1.63
CsPb	NP [9]	1226	1999	1.63

[a] HP = high-pressure phase, NP = normal-pressure phase; the standard deviations of the lattice parameters in the HP-phases are a: ±3 pm, c: ±5 pm.

In Table 1 the a and c axes of the six new phases of the silicides and germanides of potassium, rubidium and cesium are compared with those of the known NP-phases[9] of the corresponding stannides and plumbides. The c/a ratio of all twelve phases has a constant value of 1.62—1.63, convincingly indicating a geometrical relationship as for the NaPb-type structure. This value corresponds to:

$$c_{tetr.}/a_{tetr.} \approx (0.96 a_{cub}\sqrt{2})/(0.96 \cdot 0.5 a_{cub}\sqrt{3}) \approx \tfrac{2}{3}\sqrt{6} \approx 1.63$$

In comparison to the cubic KGe-type structure of the NP-phases, the HP-phases are about 4% more densely packed. Whether this increase in density is associated with a slight increase in the coordination numbers must remain open until an accurate determination of the positional parameters has been carried out. Thus, isolated tetrahedra are still stable in the HP-phases of the alkali metal silicides and germanides up to 4 GPa. A transformation into layer or network arrays is probably rendered difficult here because of the metal content being twice as high as in the alkaline earth metal silicides and germanides.

Hydridoplatinum(II) Complexes with Phosphites and Phosphonites and their Reactions with Methyl Acrylate**

By *Werner R. Meyer* and *Luigi M. Venanzi**

While hydrido complexes of the type *trans*-$PtHXL_2$ (L = tertiary phosphane, X = halide) have been known for a long time[1], the analogous compounds with $L = P(OR)_3$, $PR'(OR)_2$, or $PR'_2(OR)$ have not been reported hitherto, although $PtHCl[P(OPh)_3]_2$ has been postulated as a co-catalyst for the isomerization of randomly unsaturated to conjugated compounds[2]. We report here the facile synthesis of *trans*-$PtHCl[P(OMe)_3]_2$ **1**, *trans*-$PtHCl[PMe(OMe)_2]_2$ **2**, and their reactions with $CH_2{=}CH{-}CO_2Me$.

Compound **1** is formed in high yield by allowing *cis*-$PtCl_2[P(OMe)_3]_2$[3] to react with $NaBH_4$ in acetonitrile. The colorless solid product ($\nu(Pt{-}H) = 2050\ cm^{-1}$) is obtained

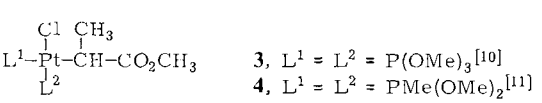
from the reaction medium by addition of diethyl ether. As a dry solid, complex **1** decomposes rapidly forming a mixture of products in which *cis*-$PtCl_2[P(OMe)_3]_2$ and $Pt[P(OMe)_3]_4$[4] can be identified from their ^{31}P-NMR parameters. However, solutions of compound **1** are stable at room temperature for several hours even in air.

Characterization of compound **1**[5] follows from its NMR spectra[6]. While the ^1H-NMR data of the hydrido ligand are very similar to those of *trans*-$PtHCl[PEt_3]_2$[7], the ^{31}P-NMR data are typical of $P(OR)_3$-complexes, i.e. low field $\delta^{31}P$ values and large $^1J_{P\text{-}Pt}$ values[8].

The thermally more stable **2** can be prepared similarly[9].

Compounds **1** and **2** react rapidly with $CH_2{=}CH{-}CO_2Me$ in acetone at room temperature to give the insertion products **3** and **4**, respectively.



3, $L^1 = L^2 = P(OMe)_3$[10]
4, $L^1 = L^2 = PMe(OMe)_2$[11]

There are three notable features to this insertion reaction:

1) It proceeds smoothly, even though chloride is coordinated to the platinum atom in contrast to *trans*-$PtHCl[PEt_3]_2$, which does not react with methyl acrylate[12].
2) Complexes **3** and **4** have the usual *cis*-geometry, but do not rearrange to their respective *trans*-isomers as found for the corresponding PEt_3-complexes[13].
3) Only a branched alkyl chain is formed, irrespective of the nature of solvent used for this reaction, in contrast to the behavior of the PEt_3-complexes where the branched is always accompanied by the linear isomer and the ratio of these two forms is solvent-dependent[14].

In summary, hydridoplatinum(II) complexes with phosphites or phosphonites can be obtained and show very high reactivity and regioselectivity towards alkene insertion. Thus, they could prove to be useful reagents and/or catalysts for organometallic reactions.

Synthesis and Determination of the Absolute Configuration of (+)-Delesserine, a Metabolite of the Red Marine Alga *Delesseria sanguinea* (Lamouroux)

By *Dieter Seebach**, *Matthias Dust*, *Reto Naef*, and *Markus Bänziger*

Delesserine **6** is a γ-lactone isolated from the algae *Delesseria sanguinea* (Lamouroux). The relative configuration was determined by an X-ray crystal structure analysis[1], Aqueous extracts of *Delesseria sanguinea*, an alga occurring on the European Atlantic coast, are powerful anticoagulants for human blood[2].

We describe here a short synthesis of enantiomerically pure, natural delesserine **6** starting from diethyl (*R,R*)-(+)-tartarate[3] and demonstrate the relationship of delesserine to the (L)-series of C_6-carbohydrates, which had previously only been conjectured.

The key reaction in the synthesis is the addition of the lithium enolate of the phenyl lactic acid derivative **1** to the aldehyde **2** [acetonide and benzyl-protected (L)-threose], which was synthesized in four steps from diethyl tartarate[3–5]. Information about the formation of this C–C linkage, which completes the assembly of the carbon skeleton, and about further reactions is given in Scheme 1. Alcohol **3** (four diastereomers) was oxidized directly, without isolation, to the β-keto ester **4**, which was present in two forms epimeric at the α-C atom. After hydrolysis of the acetonides, a 1:2 mixture of lactones **5a** and **5b** was obtained, from which isomer **5a** could be isolated as ana-

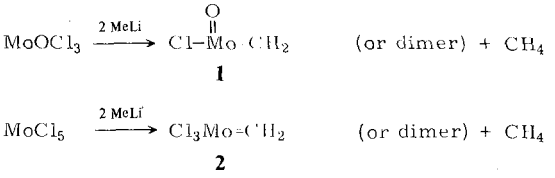
Carbonyl Olefinations with Methylenemolybdenum Reagents in Aqueous or Ethanolic Media**

By *Thomas Kauffmann**, *Petra Fiegenbaum*, and *Raphael Wieschollek*

Among the known transition metal reagents that have been used for carbonyl olefinations[2,3], the molybdenum complexes first reported by us[2c,d] deserve special attention, since they are the most easily accessible and are comparable in their carbonyl selectivity to the titanium-containing alkylating reagents[4].

We report herein that the Mo-compounds **1** and **2** accessible according to Scheme 1 are—other than the titanium-containing Tebbe-reagent[2a] and the structurally related Zr-reagents of *Schwartz* et al.[2b]—suitable for carbonyl olefination in aqueous or ethanolic solvents[5], which could prove advantageous in the case of hydrophilic substrates.



Scheme 1.

The reagent prepared in anhydrous tetrahydrofuran (THF) (5 mmol in 50 mL) according to Scheme 1 is treated with the carbonyl compound dissolved or suspended in water, ethanol/water mixture, or ethanol (in each case ca. 20 mL) (Table 1). If this is carried out at −70 °C, the mixture is allowed to warm to room temperature within 12 h; if the addition is carried out at 0 °C, then the mixture is kept at this temperature for 1 h.

Reactions with **1**: The yields of alkene (Table 1) on addition of the substrate in ethanol or ethanol/water at −70 °C are practically the same as on addition of the substrate in anhydrous THF, with one exception: for some unknown reason **1** reacts better with benzaldehyde in the presence of water or ethanol. Thus, as a rule, the carbonyl olefination is more rapid than a replacement of the Cl substituents in **1** by OEt or OH. If, however, water is added at 0 °C there is a distinct loss in reactivity.

Reactions with **2**: In ethanol or aqueous THF the yields of alkene are substantially lower than in anhydrous THF (Table 1). The drastic reduction in yield of alkene on addi-

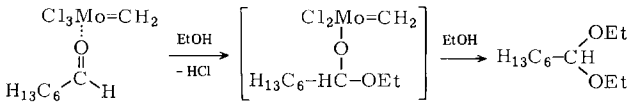
tion of ethanol in the reaction with heptanal can be ascribed, in part, to the fact that its diethyl acetal **4** (13%) is formed. Since **4** is undoubtedly formed via a semiacetal-like intermediate and a lot of heptanal is recovered after hydrolysis, presumably some of the heptanal of the carbonyl olefination is removed by formation of **3**.



3 **4**

Table 1. Carbonyl olefinations in THF with added EtOH, H_2O or EtOH/H_2O. Molar ratio of reagent: carbonyl compound = 2:1, in competition reactions 2:1:1. Yields in brackets refer to the reaction in anhydrous THF.

[a] Referred to carbonyl compound used. Determined gas-chromatographically. [b] Preferred olefination of the aldehyde.

Stability of **1** and **2** toward protic solvents: We treated the THF solution of these reagents with 20 mL ethanol or water, added a carbonyl compound after prescribed times, and determined the yields of alkene. As shown in Figure 1, **1** and **2** are still rather active after 30 min at 0 °C and 30 min at −70 °C, respectively, despite a large excess of water (molar ratio: H_2O:**1** = 220:1) or ethanol (C_2H_5OH:**2** = 70:1). According to the activity curve a new stable species is formed from **2**.

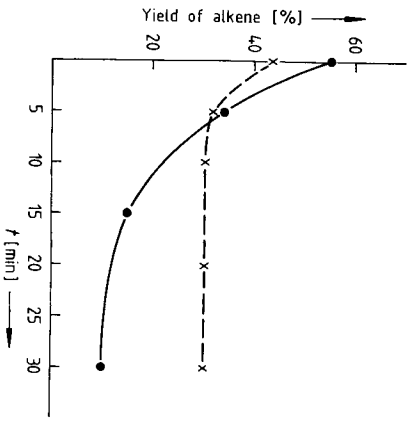

Fig. 1. Loss of reactivity of **1** (——) and **2** (- - - -) on addition of H_2O or ethanol, respectively; reactions of **1** with 4-MeO–C_6H_4–CHO at 0 °C and of **2** with Ph–CHO at −70 °C, respectively. Points on the ordinates: protic solvent and carbonyl compound given simultaneously.

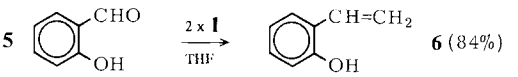

6 (84%)

Since **1** and **2** are relatively insensitive towards compounds containing OH-groups, it was expected that hydroxyaldehydes can be readily olefinated with these reagents. The reaction **5** → **6** does indeed proceed quite smoothly in anhydrous THF[6].

[5] Carbonyl olefinations in aqueous medium were first observed by R. Wieschollek (Universität Münster).
[6] Procedure: **6**: Dissolution of $MoCl_5$ (1.37 mg, 5 mmol) in anhydrous THF at room temperature leads (within 2 h) to formation of the complex $(THF)_2MoOCl_3$ [7]. The solution is stirred with 10 mmol MeLi (ca. 1.5 M in ether) at −70 °C for 1.5 h and then treated with 305 mg (2.5 mmol) *o*-hydroxybenzaldehyde. The mixture is allowed to warm to room temperature within 12 h, hydrolyzed with 20 mL water, and rendered neutral with $NaHCO_3$. The aqueous phase is extracted three times with 20 mL hexane. The combined organic phases are shaken with a $K_4[Fe(CN)_6]$ solution (2 g in 20 mL H_2O) to give a water-soluble Mo-complex, washed twice with water, and dried. After evaporation to dryness, the alkene is separated by column chromatography (silica gel, 13 × 4 cm, $CHCl_3$); yield 228 mg (76%).

Selective Synthesis of Carbonyl Olefinating or Alkylating Reagents from $MoCl_5$ and MeLi by Changing the Solvent or the Rate of Addition of MeLi**

By *Thomas Kauffmann** and *Gudrun Kieper*

Reaction of methyllithium (MeLi) with $MoCl_5$, $(EtO)_3MoCl_2$ or $O=MoCl_3$ leads to the formation of carbonyl olefinating reagents[1,2]. We have now found, in the case of MeLi and $MoCl_5$, that the rate of addition of MeLi and the solvent have a surprisingly marked influence on the product pattern.

Reactions in tetrahydrofuran (THF): When a solution of 3 or 4 mol equivalents of MeLi in diethyl ether (ca. 1.5 M solution) is added dropwise and *slowly* (1 drop per 7–10 s) to a solution of $MoCl_5$ (5 mmol) in THF (ca. 40 mL) under argon at −70 °C and the mixture is kept at this temperature

for a further 2—4 h, in each case an *olefinating reagent* is formed, which we formulate as **1** and **2** (or dimers thereof), respectively. Both compounds react with benzaldehyde or 4-methoxybenzaldehyde to give alkenes in good yields (Table 1). In competition reactions with 4-methoxybenzaldehyde/acetophenone the reagent **1** olefinates practically only the aldehyde.

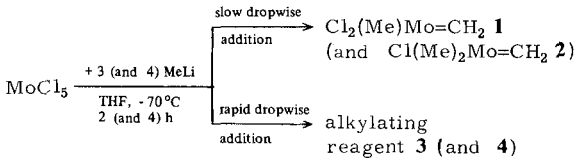

Table 1. Olefinations with **1** and **2**.

Reagent	Carbonyl compound	Mol. ratio Reagent/Substrate	Solvent	Yield [%] [a] Alkene	Alcohol	Recovered carbonyl compound
1	Ph–CHO	2:1	THF	71	0.2	16
1	Ph–CHO	2:1	Et_2O	92	0	0.4

[a] Referred to carbonyl compound used. Determined gas-chromatographically. [b] Preferred olefination of the aldehyde.

If the MeLi solution is added *rapidly* (1 drop per second) to the solution of $MoCl_5$ in THF under otherwise the same conditions and the mixture is kept at −70 °C for 2—4 h, the *alkylating reagents* **3** and **4**, respectively, are formed, of which **4** is the most reactive since it also reacts with ethyl butyrate (Table 2). The high reactivity of **4** is likewise reflected in the low selectivity of the competition reaction with aldehyde/ketone.

Table 2. Alkylations with **3** and **4** in THF.

Reagent	Carbonyl compound	Mol. ratio Reagent/Substrate	Yield [%] [a] Alcohol	Alkene	Recovered carbonyl compound
3	Ph–CHO	2:1	86	1	0.4
4	Ph–CHO	2:1	91	0.2	1
4	Ph–CHO	1:1	81	4	1
4	C_6H_{13}–CHO	2:1	75	1	0.2

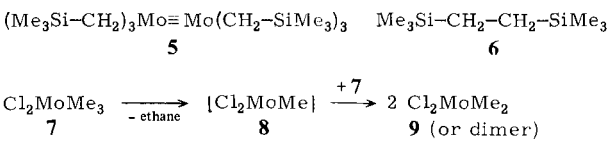
4	C_3H_7–COOEt	2:1	51 [b]	0	30
3	Ph–CN	2:1	0	—	97
4	Ph–CN	2:1	0	—	83
4	4-MeO–C_6H_4–CHO + Ph–CO–Me	2:1:1	87 / 91	3 / 1	0 / 0.3
4	C_6H_{13}–CHO + Et–CO–Et	2:1:1	77 / 95	1 / 0	0 / 0

[a] Referred to substrate used, determined gaschromatographically. [b] Alcohol C_3H_7–C(OH)Me_2; methyl propyl ketone is not found.

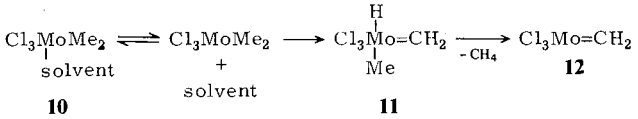
The methylations cannot be ascribed to unconsumed MeLi, since, before addition of the electrophile, stirring of the mixture at −70 °C was prolonged in each case (2—4 h) until the Gilman test with *Michlers* ketone was negative and attack of benzonitrile was no longer possible.

Reactions in diethyl ether: When $MoCl_5$ is allowed to react with 3 mol equivalents of MeLi in diethyl ether instead of in THF the olefinating reagent **1** is formed in each case, irrespective of whether the MeLi is added slowly or rapidly (Table 1). On the other hand, for some unexplained reason the olefinating reagent **2** is obtained in diethyl ether only on slow addition of the MeLi solution.

Mechanistic interpretation: Since $MoCl_5$ reacts with 5.5 mol equivalents of trimethylsilylmethylmagnesium chloride to give the Mo^{III} compound **5** (isolated yield 15%)[3] with formation of **6** (ca. 30%)[4], presumably the trimethyl compound **7** was formed on *rapid* addition of MeLi to $MoCl_5$ (3:1) in THF and reduced by ethane-elimination to the Mo^{III} compound **8**. The yield of ethane, however, is only ca. 50%[5], thus indicating the likelihood of disproportionation of **8** with any **7** that is still present to give the Mo^{IV} compound **9** (hypothetical structure of reagent **3**).



On *slow* addition of MeLi to $MoCl_5$ (3:1) in THF there is sufficient time for the initial product of methylation to be converted with evolution of methane into **12**, which is methylated by excess MeLi into **1** or **2**. If the reaction path **10** → **11** → **12** is assumed for the formation of the



Mo=C double bond, then it is understandable that this is slower in THF than in diethyl ether, which, as the weaker donor (solvent) is more susceptible to coordination.

^{25}Mg-NMR: A Method for the Characterization of Organomagnesium Compounds, their Complexes, and Schlenk Equilibria

By *Reinhard Benn**, *Herbert Lehmkuhl*, *Klaus Mehler*, and *Anna Rufińska*

Although organomagnesium compounds are exceedingly important in preparative chemistry, until now ^{25}Mg-NMR data have only been available for ionic compounds and biological systems[1]. In the course of our investigations of the metal resonances and syntheses of and with organomagnesium compounds[2], we have studied such compounds using ^{25}Mg-NMR and, as far as we are aware, determined the range of their chemical shifts for the first time. We show here, that ^{25}Mg chemical shifts and line widths ($W_{1/2}$) can be used to clarify the multiple bonding, coordination, and association behavior of organomagnesium compounds, and report our studies of methyl-, ethyl-, allyl-, cyclopentadienyl(Cp)magnesium derivatives and of the Schlenk equilibria of organomagnesium halides.

The compounds R_2Mg, RMgHal (R = alkyl, aryl) and $MgBr_2$ are monomeric in tetrahydrofuran (THF) over a wide range of concentrations[3]. The $\delta(^{25}Mg)$ values of these compounds lie between 0 and +100 (Fig. 1, Table 1). The signals of CpMg derivatives lie outside this range.

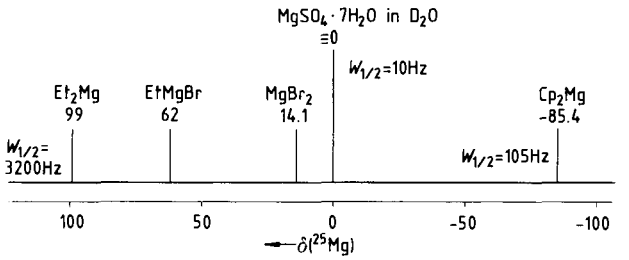

Fig. 1. Range of chemical shifts for ^{25}Mg derivatives. For details, see text and Table 1.

[+] NMR Spectroscopy.

Cp_2Mg **17** is a volatile compound that dissolves as a monomer in nonpolar solvents[5] and has a sandwich structure[6,7] which is isotypic with ferrocene and nickelocene. Despite numerous spectroscopic[8,9] and theoretical studies[7,8], the bonding relationships between Mg and Cp are the subject of controversy, and are described variously as more ionic or predominantly covalent. The ^{25}Mg-NMR parameters of Cp_2Mg suggest largely covalent character for the Mg–Cp bonds.

	X/X X
8	TMED
10	TMBD
11	THF
13	1,4-dioxane
14	DME
15	PMe_3
16	Et_2O

Because of the narrow line width of the Cp_2Mg signal, the complexation of Cp_2Mg with Lewis bases [eq. (a)] can be studied by ^{25}Mg-NMR spectroscopy. If Lewis bases are used as solvent, $\delta(^{25}Mg)$ increases with the complexation strength of the base: $(i\text{Pr})_2O \approx NEt_3 <$ anisole $< Et_2O < PMe_3 <$ 1,4-dioxane $<$ DME $<$ THF $<$ TMED.

Bis(2-methylallyl)magnesium **2** gives a signal at $\delta = 70.4$ ($W_{1/2}$ = 2000 Hz); Mg must therefore be preferentially η^1-bonded. A similar result is found for allylmagnesium bromide **5**. Previously, this could only be determined by time-consuming, isotopic-labeling techniques[10].

$$2\ RMgBr \rightleftharpoons R_2Mg + MgBr_2 \qquad (b)$$

The ^{25}Mg-NMR spectra of organomagnesium halides (Grignard compounds) are a function of the concentration and temperature. With EtMgBr, three species of the Schlenk equilibrium [eq. (b)] can be detected concurrently at 310 K (Fig. 2). The resonances for EtMgBr ($\delta = 62$) and $MgBr_2$ ($\delta = 12$) are resolved, and the broader signal of **1** is superposed by the signal group for EtMgBr. Direct evi-

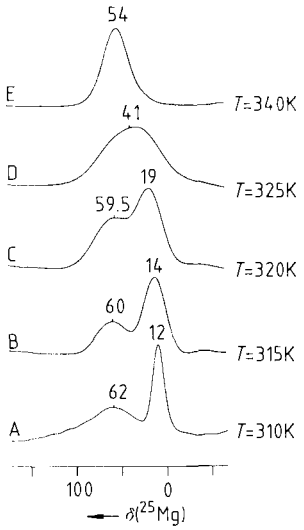

Fig. 2. ^{25}Mg-NMR spectra (24.49 MHz) of a 0.36 M solution of EtMgBr **4** in THF at various temperatures. At 310 K (A) the RMgX and MgX_2 species are directly identified in the presence of one another. The presence of R_2Mg follows from the coalescence behavior (B–D) and the high-temperature spectrum (E).

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/0707-0534 $ 02.50/0

dence for this is provided by the spectrum at 340 K. In accord with the shift in equilibrium in the direction of EtMgBr[3, 11], an average signal is found at $\delta = 54$. Since the equilibrium constant for the methyl compound MeMgBr $K \approx 30$[11] is larger than that for EtMgBr ($K = 5.1$)[3], **3** displays an averaged signal ($\delta = 67.8$), even at 300 K.

In the case of CpMgBr **9**, the ^{25}Mg signal is further removed from that of $MgBr_2$ and the line width is narrow enough to allow the Schlenk equilibrium to be studied quantitatively. Signals at $\delta = 16.3$ (1—2% **6**) and at $\delta = -26.8$ ($\approx$98% **9**) are observed for 1.38 M solutions of **9** in THF. The same chemical shifts and line widths are found when Cp_2Mg and $MgBr_2$ are mixed in the ratio 1 : 1 in THF. The signal intensities allow a value for the equilibrium constant to be estimated which is in good agreement with the value ($K = 10^5$)[12] obtained by extrapolation to 298 K.

In comparison with ^{1}H- and ^{13}C-NMR spectroscopy[10, 11, 13], ^{25}Mg-NMR spectroscopy has considerable advantages in the study of the Schlenk equilibria, since all three species can be recorded and identified directly from their typical chemical shifts. The large range of ^{25}Mg chemical shifts (ca. 200 ppm) permits unequivocal statements to be made about the bonding behavior such as, e.g., in **17** and **2**.

BOOK REVIEWS

Chemical and Biological Generation of Excited States. Edited by *W. Adam* and *G. Cilento*. Academic Press, New York 1982. xi, 388 pp., bound, $ 59.50.

The first seven chapters of this book give a detailed survey of the diverse aspects of the generation of excited states in chemical systems. Several sections are devoted to the chemistry of dioxetanes, covering the topics of synthesis, chemical characterization, activation (chemi- and photoenergization) and photophysical and photochemical transformations of the excited states. A critical and systematic survey of the techniques for their detection and calculation of excitation yields is presented. Without losing in originality, the chapter by *W. Adam* offers a useful and comprehensive introduction to the chemistry of dioxetanes, which enables the reader to go easily over other topics treated in this book. In addition, the activation parameters of over 50 well-studied 1,2-dioxetanes are summarized. In general, the chemical reports on these four-membered ring peroxides are sustained by common basic concepts that permit the reader to establish rapid comparisons, e.g., evaluation of dioxetane chemiluminescence in solution and in the gas phase. Solution-phase chemiluminescence resulting from electron-transfer reactions (electrochemiluminescence) is analyzed here on theoretical basis, and mechanistic implications for the production of the emitting state and experimental techniques are presented. These accounts on the chemistry of some excited states (mainly concerned with excited carbonyl compounds derived from dioxetane energization) give a synopsis of general and important concepts without being simplistic or falling into a long listing of observed details. They provide valuable up-to-date information for the chemist or biologist interested in the generation of excited states.

The final four chapters treat the generation of excited species in biological systems. The possible formation of singlet oxygen in some enzymatic reactions is discussed along with a short examination of the processes that can mimic singlet oxygen. At variance with the native chemiluminescent systems, the fluorophor-mediated chemiluminescence is also considered and the advantages of the use of such chemiluminigenic probes in the study of biological oxidations are listed. However, the disdavantages inherent in the addition of a foreign compound to a biological system are not taken into account. An outstanding contribution is the chapter on "Electronic Excitation in Dark Biological Processes". The author, *G. Cilento*, and his team have long been committed to a systematic study of the production of excited molecules which give the cell the potentialities of photochemistry in the absence of light. The section deals with the occurrence and generation of excited states and puts forward their role in biological processes. The possibility that one of the roles of peroxidases and some internal monooxygenases might be the formation of an electronic excited state product is exploited here on sound experimental grounds. No doubt the biologist could feel himself attracted to the discipline of "photobiochemistry in the dark" after these serious attempts for its characterization and definition.

In summary, the book gives an up-to-date account of the field and can be recommended to those interested in the occurrence of excited states in chemistry and biology.

Enrique Cadenas [NB 622 IE]
Institut für Physiologische Chemie
der Universität Düsseldorf (FRG)

Vitamin B_{12}. Vol. 1: Chemistry; Vol. 2: Biochemistry and Medicine. Edited by *D. Dolphin*. Wiley Interscience, Chichester 1982. xiv, 671 pp., bound/xiv, 505 pp., bound, together £90.00.

This two-volume work, which is the most comprehensive up to now covering vitamin B_{12}, fulfills its claim to cover the chemistry, biochemistry and medicine of this group of compounds. It has been possible to recruit leading scientists for each of the topics to which a chapter is devoted.

Volume 1 with almost 600 pages of text is devoted to chemistry. A historical introduction *(Folkers)* and a summary of the nomenclature *(Cohn)* are followed by an extensive third chapter (84 p.) by *J. Pickworth-Glusker* devoted to the structures of corrinoids and containing a wealth of data not all of which had previously been published. The numerous tables and figures and the detailed discussion concerning structure-activity relationships make the few slight errors on p. 77 and 78 seem unimportant. The impressive advances made recently are described by *Battersby* and *McDonald* in a fascinating chapter on the biosynthesis of the corrin macrocycle. In chapter 5 there follows the biosynthesis of the cobalamine coenzyme (*Huennekens* et al.). The chapter on "The total synthesis of Vitamin B_{12}" by *Stevens* which is obligatory for any book on the subject presents this complex project, which has been the subject of previous reviews, in a very informative manner. The long needed summary of the rich chemistry of the corrin ligand by *Bonnett* is just as useful; here too, results are quoted that were until now only available in dissertations. Then follow two chapters concerning the synthesis *(K. L. Brown)* and reactivity *(Hogenkamp)* of organocobalt complexes. Chapters 10, 14, and 15 are particularly devoted to the central theme of coenzyme B_{12} chemistry, the reactivity of the Co–C bond. Chapter 10 by *Pratt*, engagedly and colorfully written, is detailed (68 p.) and contains an attempt to formulate a basic unified mechanistic view of the vitamin B_{12}-dependent isomerases that is not completely established and unchallenged in all aspects. Chapters by *Halpern* and by *Golding* close the first volume with discussions of the models and theories for coenzyme B_{12} catalyzed reactions. Chapters 11 (*Giannotti:* UV/VIS, CD, MCD), 12 (*Pilbrow:* ESR), and 13 (*Williams* et al.: NMR), which contain many data which had previously been scattered throughout the literature or were unpublished, are somewhat arbitrarily interposed between the contributions on the above range of topics.

The second, smaller volume covers biochemistry and medicine. Chapter 5 on metal-free corrinoids *(Koppenhagen)* is rather misplaced here and it would have been better to include it in the first volume. The "medical" chapters 1–4 *(Beck, Bradbeer, Nexø* and *Olesen)* which cover intrinsic factor, cobalamine transport and determination are easily readable and understandable for an organic chemist. A short informative chapter (15 p.) on methyl transfer reactions *(J. M. Wood)* is followed by one concerned with a discussion of acetate biosynthesis which goes beyond the bounds of corrin chemistry, by *Ljungdahl* and *H. G. Wood*. The second half of the volume contains seven detailed treatments of coenzyme B_{12}-catalyzed enzyme reactions. The common "design" (history, sources, isolation, measurement of the enzymes' activity; substrates and mechanism of the enzyme reaction) is enriched by the varied presentations of the authors *(Baker* and *Stadtman, Toraya* and *Fukui, Babior, Switzer, Taylor, Rétey, Blakley)*. The possibly unavoidable repetition of material already presented in chapters 9, 10, 14, and 15 of the first volume is not too disturbing.

Both volumes contain detailed subject and author indexes. The quality of the illustrations and the print is very high; the price is high but reasonable in comparison with similar works. These books can be highly recommended; not only are they a "must" for every scientist working in the vitamin B_{12} field but are also important, for example, for chemists dealing with organometallic compounds, bioorganic chemistry, or heterocyclic natural products. Apart from the well-done presentation of the "state of the art", the importance of this work lies in the fact that the many controversies and "unwritten chapters" in this long and intensively studied field are brought before our eyes.

Laboratorium für Organische Chemie der
Eidgenössischen Technischen Hochschule Zürich

Ullmanns Encyklopädie der technischen Chemie. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley †, W. M. Weigert †*, and *E. Weise*. Verlag Chemie, Weinheim 1983. 4th Edition. Volume 23, Textilhilfsmittel bis Vulkanfiber. xv, 750 pp., bound, DM 545.00.

With the publication of the 23rd Volume of the 4th Edition of Ullmann[*] only one further volume and the general index are required to complete the series. This means that, on average, two volumes per year have been produced, a marvellous performance on the part of the editors and publishers, which is the more imposing if one takes the trouble to ascertain the number of authors involved in the production of a single volume. There were more than 80 for this volume.

Once again the subjects included in the volume are drawn from every area of industrial chemistry; that is, from inorganic chemistry: thallium, thorium, titanium, vanadium, and uranium together with their alloys and compounds, then the transuranic elements (excepting plutonium which is discussed in its own right in Volume 18) and some inorganic sulfur compounds (thiocyanic acid and thiourea); from organic chemistry come: vinyl compounds, toluene, toluidines and a range of organosulfur compounds (thiazoles, isothiazoles, benzothiazoles, organic thiocyanates and isocyanates, thioles, sulfides, polysulfides, thioglycolic acid, thiophene and benzothiophene); from application technology come: textile additives (102 p.), nonwovens, inks and other writing fluids, separating agents, drying agents, drying oils; from the area of raw materials come: composites, clay and clay minerals, pottery; then vitamins (108 p.), veterinary medicines, tri- and diarylmethane dyestuffs, peat. Then come two articles of particular topicality, namely thermo- and photoelectricity (28 p.) and the saccharification of starch and cellulose-containing materials (42 p.). Both these articles are concerned with topics touching on possible future forms of en-

[*] Cf. *Angew. Chem. Int. Ed. Engl. 23* (1984) 255.

ergy production, that is from solar cells and from natural polysaccharides (starch and cellulose). In both cases the decisive step is the utilization of solar energy, and Ullmann contains information for each topic concerning the present state of the art, possible developments and, above all, concerning the cost. Naturally the scientific basis is also outlined, i.e. the significant physical relationships in the case of solar cells and the chemistry and process technologies of the various methods and variants for the saccharification of starches and cellulose. A further example of the topicality of the contents is the article on thallium, where the problem of the environmental dangers of thallium emissions from industrial plants is discussed on the basis of recent knowledge in the section on toxicology.

The volume naturally contains much more that is worthy of note alongside such particularly topical information. Apart from the descriptions of manufacturing processes and possibilities for application and a great deal of statistical information it is the clear and concise information concerning the chemical and physical properties of individual compounds that make this volume, like its predecessors, of interest to chemists. The production is, as ever, excellent (readable type, clear and easily understandable graphics, perfect printing), so that it is a joy to pick up the volume and leaf through it.

Abteilung Chemietechnik der Universität Dortmund

Technische Chemie I. Grundverfahren. By *W. Brötz* and *A. Schönbuchen.* Verlag Chemie, Weinheim 1983. xvi, 338 pp., bound, DM 68.00.

The first volume of this two-volume work presents the general basic principles of chemical engineering. Based on the "Lehrprofil Technische Chemie" of the Dechema training committee of May 1981 this clearly planned text book is particularly designed for comprehensibility. The authors present a survey of the three main branches of chemical engineering that are usually covered in technical universities by mechanical process technology, thermal process technology and chemical reaction technology.

In advance of the presentation of the unit processes of these three branches the first part of the book delivers the necessary basic knowledge from physics and physical chemistry, fluid dynamics and thermodynamics of material and thermal transport. A large number of tabular presentations ranging from units of measurement via dimensionless numbers, resistance values, diffusion and material transfer coefficients, to aids for the calculation of heat transfer and heat diffusion coefficients help give this volume the character of a reference book.

The section on mechanical unit processes includes all those unit operations which proceed without material alteration (chemical reaction). With the aid of numerous diagrams and cross-sectional drawings of apparatus, detailed accounts are given on storage, transport, the mixing of liquids, gases and bulk solids, the separation of disperse systems (solid/liquid, solid/gaseous) and the classification, sorting and comminution of bulk solids. Under the major headings of bulk solid/fluid and fluid/fluid contact,the type and layout of apparatus are introduced that find application in thermal and reaction engineering processes. Thus, the most important variables affecting the design of solid beds, fluidized beds, stirrers, and rotating drums are given, together with their main fields of application. The same applies to fluid-fluid contacting equipment such as fluid film contactors, packed columns, spray towers, bubble columns and plate columns.

The section on thermal processes first gives a detailed treatment of the problems of heating and cooling. The section dealing with the production of process heat and cooling and thermal transport media, is followed by a large section on the actual equipment used in heat exchange and its construction. The following sections covering unit operations, distillation and rectification, absorption, extraction, adsorption, drying, and crystallization are laid out in a way that the presentation of the thermodynamic basis of the operation is followed by details of the construction of the plant; this makes fundamental information easily available. The presentation of drying and, in particular, the application of the Mollier diagram is particularly thorough.

The unit processes in reaction engineering are subdivided into thermal, electro-, photo-, and biochemical reactions, the largest amount of space being dedicated to thermal reactions. The concept of the thermal reaction utilized here is justified in that the resistance to reaction is overcome by the choice of the temperature of the reacting mass. A discription of the various types of reactors is then followed by a discussion of the methods of calculation and the fundamental behavior of stirred reactors (continuous and batch) and tube reactors in terms of a simple first order reaction; this is followed by a clear comparison of productivities. Residence time distributions and the techniques for their measurement are then discussed, as are also complex reactions. The influence of thermal and material transport on the course of the reaction and the consequences for the choice and dimensioning of the reactor are presented in a very easily understandable form. The electro-, photo-, and biochemical reactions are outlined in a very few pages.

This book is also likely to be of interest to those chemists employed in industry who require an optimal introduction to the unit processes of chemical engineering. Used as a textbook the work can provide the new student of chemical engineering and process technology with an easily understandable survey of the major aspects of his course. The copious references to the more advanced literature are invaluable for more detailed study.

Isotopeneffekte bei chemischen Reaktionen. By *Alfred V. Willi,* Georg Thieme Verlag, Stuttgart 1983. x, 180 pp., bound, DM 80.00.

Because several exhaustive books are already available covering this topic the particular aim of the author has been to close a gap in the German-language chemical literature with a short treatment.

Thus the reader proceeds from the 1st Chapter "The theory of isotope effects in chemical reactions" (p. 5—29) to the 2nd Chapter "Isotope effects in chemical equilibria" (p. 32—61). The third chapter deals with the topic "Kinetic isotope effects and mechanism" (p. 62—135), while the title of the last chapter is "Kinetic isotope effects and the transition state" (p. 139—159). The text is completed by 443 literature references and an index (5 1/2 pages) that is almost too short.

There is no doubt that the book fulfills its purpose: Anyone dealing with isotope effects for the first time can find

all the significant aspects mentioned within the compass of not too many pages and also a rapid entry into the original literature. Its limitation consists of the lack of an adequate discussion of the isotopic perturbation method, a nuclear magnetic resonance technique by *M. Saunders* et al. (*J. Am. Chem. Soc. 93* (1971) 2558; *ibid. 105* (1983) 3571, and references cited therein) which, above all, allows a decision as to whether rapidly equilibrating molecules (ions) or a symmetrical delocalized molecule (ion) is being studied.

Cobalt-Mediated [2+2+2]-Cycloadditions: A Maturing Synthetic Strategy

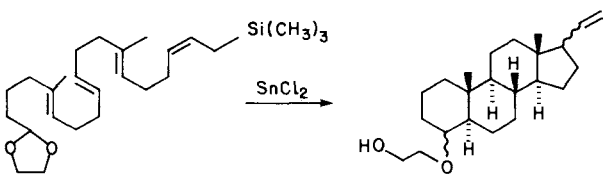
New Synthetic Methods (43)

By K. Peter C. Vollhardt*

Dicarbonyl(η^5-cyclopentadienyl)cobalt functions as a matrix on which a variety of unsaturated organic substrates undergo mutual bond formation. In this way α,ω-diynes cocyclize with monoalkynes to give annelated benzenes, while *o*-diethynylbenzenes furnish biphenylenes, and α,ω-enynes lead to the formation of complexed bi- and tricyclic dienes. Nitriles cocyclize with two alkynyl groups to give pyridines and other heterocycles, isocyanates allow access to annelated 2-pyridones, and incorporation of carbon monoxide provides complexed cyclopentadienones. In many cases remarkable chemo-, regio-, and stereoselectivity are observed, partially facilitated by use of the trimethylsilyl substituent as a controlling group. The scope and level of maturity of the method are demonstrated by the synthesis of a series of hitherto inaccessible, novel, and theoretically interesting molecules, and by its utilization in several unique approaches to a variety of natural products, e.g. protoberberines, steroids, vitamin B_6, and camptothecin.

1. Introduction

The discovery and control of new bond formations are two of the primary tasks of the synthetic organic chemist. The arsenal of current synthetic methods has already allowed the construction of even the most complex natural products and most remarkable, "unnatural" molecular assemblies. Nevertheless, despite these advances, there remains much room for improving and particularly simplifying synthetic strategies. This can be done by either cleverly manipulating existing methodology or, probably more successfully, by finding new methods through which simple materials are converted into structures of greater complexity. In this connection we deem it especially important to design new reactions in which a maximum change of topological complexity[1] can be effected with the highest degree of efficiency and selectivity. Many cycloaddition reactions fall into this category, because at least two bonds may be formed in one step while steric and electronic factors reduce the number of options available to the substrates en route to the products. A striking example is the cyclization reaction of *Johnson* et al.[2] in which a stereospecifically constructed polyene undergoes acid-catalyzed multiple ring closure to the steroid nucleus (Scheme 1).



Scheme 1. Polyene cyclization according to *Johnson* et al. [2].

Perhaps the most widely used cycloaddition reactions are the Diels-Alder cyclizations (Scheme 2) and their various modifications[3]. Typically, six-membered rings are generated by two CC bond formations with the potential

[*] Prof. Dr. K. P. C. Vollhardt

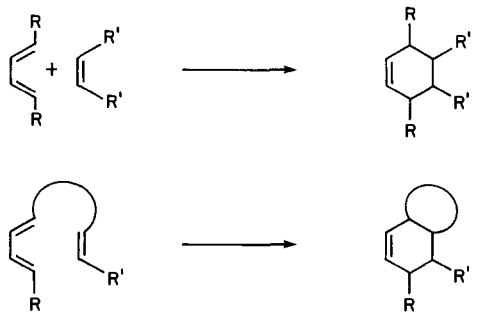
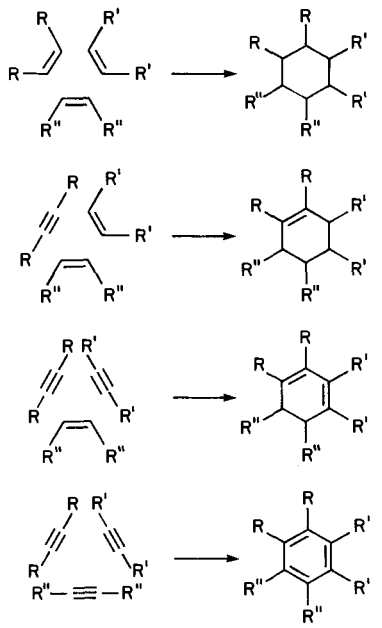
to construct four chiral centers. More complex topological changes may ensue on application of its intramolecular version (Scheme 2)[4]. The power of this method lies in its extraordinary specificity: it is chemoselective, in other words the dienophile prefers to react with the diene, and neither of the starting materials react competitively with themselves; it is regioselective, unsymmetrical dienes choosing only one sense of cycloaddition to unsymmetrical dienophiles; and it is stereoselective, mostly following the *endo*-rule.



Scheme 2. Inter- and intramolecular Diels-Alder reactions.

A simple analysis shows that a potentially more powerful strategy would be one based upon the [2+2+2]-cycloaddition of three unsaturated moieties (Scheme 3). Now three new bonds would be constructed in one step, constituting a considerably larger change in molecular complexity, and up to six chiral centers could be generated from completely achiral starting materials.



Scheme 3. Prototypical [2+2+2]-cycloadditions.

Employment of varying proportions of cycloaddends containing double and triple bonds would provide access to six-membered, partially or completely unsaturated rings. As in the Diels-Alder reaction, one could also envisage the use of heteroatomic units furnishing various heterocyclic systems[5] and a plethora of partially or completely intramolecular versions.

It is surprising that, although symmetry-allowed[6], and in most cases strongly exothermic[7], there is a paucity of examples of purely thermal [2+2+2]-cycloadditions. It is possible that entropic and, in some cases, enthalpic[8] activation energy contributions account for the relative rarity of these transformations. This report will describe how the use of a transition metal, particularly cobalt in the form of the dicarbonyl(η^5-cyclopentadienyl) derivative $CpCo(CO)_2$ as a catalyst or reagent may lead to the successful execution of a variety of [2+2+2]-cycloadditions of the type depicted in Scheme 3. The many previously unattainable molecules generated in this way have been used as starting materials for the preparation of several unnatural and natural products of theoretical and/or medicinal-synthetic interest.

2. α,ω-Diyne Cyclizations in the Preparation of Annelated Benzene Derivatives: Control of the Substitution Pattern

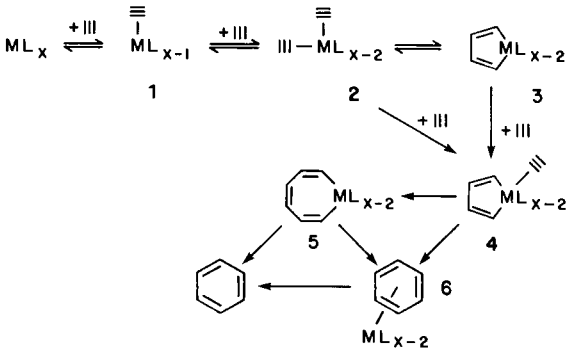
2.1. Background

Berthelot reported in 1866 on the thermal cyclization of acetylene to benzene[10]. High temperatures (ca. 400 °C) are required and a mixture of products is formed[11]. In 1949, *Reppe* et al. described the first transition metal catalyzed version of this transformation, in which nickel was employed, and which under certain conditions leads to the predominant formation of cyclooctatetraene[12]. Subsequently, it was found that a large number of transition metal systems catalyze the cyclotrimerization of substituted, frequently functionalized alkynes to benzene derivatives[13]. At the outset of the work described in this account, comparatively little was known about the utilization of these reactions in organic synthesis, particularly when employing oligoynes, even though such reactions would hold considerable potential in complex molecule construction. The validity of this premise was indeed demonstrated earlier when it was shown that a variety of oligocycles were obtainable by cyclization of α,ω-diynes[14]. Furthermore, in a series of over 40 papers, *Müller* et al. showed that stoichiometric amounts of rhodium complexes could be used in the "diyne reaction" to generate a multitude of rhodacycles capable of varied reactivity to furnish quinones, carbocycles, and heterocycles[15]. Although the method has its limitations with respect to scope, generality, and expense, it clearly pointed out some of the possibilities in store. Very recently, other groups have become interested in this problem[16].

2.2. General Mechanistic Considerations

Based on the results of several investigators, the general Scheme 4 may be formulated for the mechanism of cyclotrimerization of acetylene to benzene catalyzed by low valent transition metal complexes[17]. Initially, one and then two alkyne moieties sequentially displace two ligands on

the metal to form alkyne complexes **1** and **2**. Oxidative coupling may occur to give the coordinatively unsaturated metallacyclopentadiene **3**, in which the metal has adopted a formal oxidation state two units higher than in its precursor **2**. This change appears to facilitate chemoselectivity in

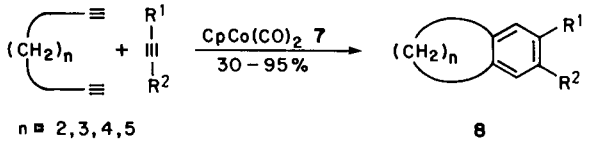


Scheme 4. Mechanism of cyclotrimerization of acetylene.

certain cases. Complex **3** may then coordinate a third molecule of alkyne to give **4**. On the other hand, calculations show that the direct conversion of **2** into **4** should be kinetically more advantageous[18], since coordinative unsaturation is avoided. Species **4** appear to be very reactive, since, in contrast to **2**, **3**, **5**, and **6**, derivatives of which have been characterized, it has so far eluded isolation. This is unfortunate, because its preparation could provide crucial information with respect to the next step in the catalytic cycle: either an alkyne-insertion to form the metallacycloheptatriene **5** or a Diels-Alder type addition to furnish the benzene complex **6**. Precedence exists for the conversion of either species into the free arene[17], and perhaps both options are viable.

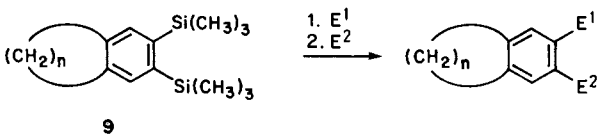
2.3. Cobalt-Catalyzed Cocyclizations to Benzocycloalkenes

Approximately 10 years ago, it was found that $CpCo(CO)_2$ **7** catalyzes a variety of [2+2+2]-cycloadditions involving α,ω-diynes to give annelated benzenes **8** as shown in Scheme 5[19]. The reaction works best for n=3 and 4 and tolerates a wide variety of substituents, such as R=H, alkyl, aryl, vinyl, CO_2R', CH_2OH, CH_2OR', COR', C=NOR', NR'_2, SR', and $Si(CH_3)_3$. In some cases there is a problem of chemoselectivity in as much as alkynes of comparable bulk or electronic make-up tend to undergo random cyclizations. The presence of substituents at the terminal position of the diyne may also lead to diminished yields when bulky groups such as $Si(CH_3)_3$ are involved[20]. Although the reaction is poor for the preparation of benzocycloheptenes **8**, n=5, it is capable of generating strained four-membered rings, thus providing a fairly general synthetic entry to the 1,2-dihydrocyclobutabenzenes (benzocyclobutenes) **8**, n=2, which are useful synthetic intermediates (see Section 3.1). Functional groups such as NO_2, alkyl halides, and reactive vinyl and aryl halides are detrimental to the catalyst, presumably due to facile oxidative addition processes[17]. On the other hand, chlorophenylalkynes are readily cyclized according to Scheme 5[20].

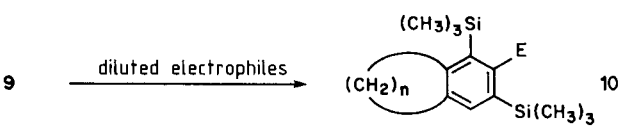


Scheme 5. $CpCo(CO)_2$-catalyzed cocyclotrimerization of α,ω-diynes with alkynes.

In order to circumvent the aforementioned problems of chemoselectivity, bulky alkynes may be employed, particularly trimethylsilylalkynes which are too sterically hindered to autocyclize but not so encumbered not to cocyclize. Their application (usually in excess) frequently results in excellent yields of the corresponding annelated arenes[19–21]. The trimethylsilyl group in the products functions as an excellent leaving group in electrophilic aromatic substitution reactions[22]. This is particularly advantageous when employing bis(trimethylsilyl)acetylene (BTMSA) in the cyclization reaction, since the resulting *o*-bis(trimethylsilyl)benzene derivatives **9** can be substituted selectively and in high yield in a step-wise manner (Scheme 6)[19,20]. Even in the case of deuteriodesilylation the first silyl group is more reactive than the second by a factor of about 40[19c]. Another interesting feature of compounds **9** is their ability to rearrange to the *m*-bis(trimethylsilyl) derivatives **10** when exposed to dilute electrophiles (Scheme 7)[19c,23]. This phenomenon appears to be caused by the slow rate of desilylation of the cationic intermediate formed during electrophilic aromatic substitution relative to 1,2-silyl migration, relieving steric strain, followed by rapid deprotonation.

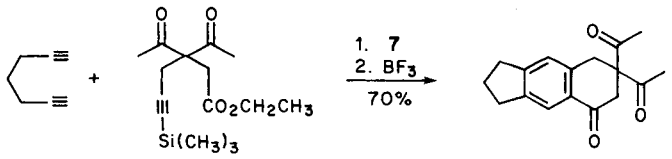


Scheme 6. Selective electrophilic aromatic substitution of *o*-bis(trimethylsilyl)arenes.



Scheme 7. Rearrangement of *o*-bis(trimethylsilyl)arenes (E=H, Br).

An example of the use of the cobalt-catalyzed cocyclization reaction, incorporating a silicon-directed intramolecular regioselective Friedel-Crafts acylation[21], is illustrated for the synthesis of a linear annelated tricycle in Scheme 8.



Scheme 8. Formation of a linear annelated tricycle by $CpCo(CO)_2$-catalyzed cyclization and silicon-directed intramolecular Friedel-Crafts acylation.

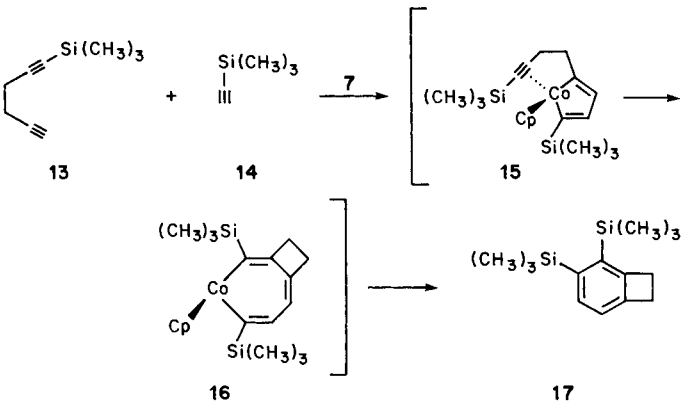
2.4. Specific Mechanistic Considerations

If we recall the discussion in Section 2.2 and apply its conclusions to the case of $CpCo(CO)_2$, there are two cobaltacyclopentadiene intermediates of the type **4** to be considered, namely **11** and **12** (Scheme 9). The mechanism of the reaction of $CpCo(CO)_2$ with alkynes to give cobaltacyclopentadienes and ultimately benzene derivatives has been well investigated[17,24,25]. Intermediates such as those of the type **11** (but not **12**) have been isolated[26], except for n=2, although a related iron compound is known[27]. Cyclobutadiene complexes derived from both **11** and **12** are obtained as by-products in catalytic reactions employing α,ω-diynes[19,20,28] and are responsible for some of the catalyst depletion, since they appear to be unsuitable as precursors for any catalytic intermediates[29,30]. On the basis of previous findings, neither of the two possible intermediates **11** or **12** can be ruled out; indeed, either one or both may be formed depending on the reaction conditions and substrate structures.

Scheme 9. Proposed cobaltacyclopentadiene intermediates in the cocyclization of α,ω-diynes with alkynes.

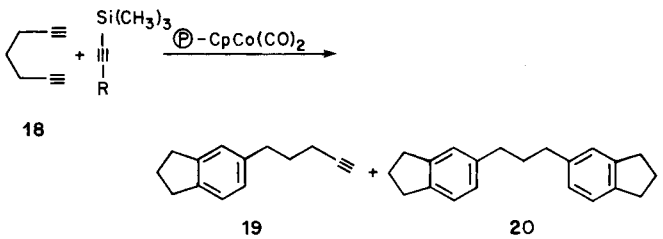
The structure of **12**, with the alkynyl group in the α-position, is in accord with expectations based on steric arguments[24a]. These arguments also predict that R^1 should be larger than R^2. Electronic factors, in particular the polarization of the alkyne π* orbital, are, however, thought to favor the preferential emergence of alkyl substituents in the β-position, whereas the trimethylsilyl group should, according to both theories, occupy the α-position[31]. The inconsistency of some of the predictions with the experimental results[24a] may simply be due to thermodynamic factors. Since the oxidative coupling of two complexed alkynes to a cobaltacyclopentadiene proceeds endothermically (by an estimated 14 kcal/mol), this step may well be reversible; hence, the observed regioselectivity of the cyclization may not in any way reflect the initial course of the reaction. In the specific case of systems of the type **12**, it may also be that additional involvement of the appendant alkyne group in the transition state for oxidative coupling (modelled by **2**→**4** in Scheme 4) controls the outcome of the process.

The trimethylsilyl group, which is used extensively for controlling the chemo- and regioselectivity, has a pronounced tendency to α-selectivity in the metallacycle (vide infra), as can be concluded from product isolation studies. An example of how this effect may be synthetically exploited in the formation of **17** as the sole isomer on cocyclization of 1-trimethylsilyl-1,5-hexadiyne **13** and trimethylsilylacetylene **14** is shown in Scheme 10[19c]. On steric grounds the kinetically favored metallacycle is expected to be **15**, which, after insertion of the complexed alkyne to give **16**, can only lead to **17**.



Scheme 10. Exclusive formation of the regioisomer **17** in the cyclization of **13** with **14**.

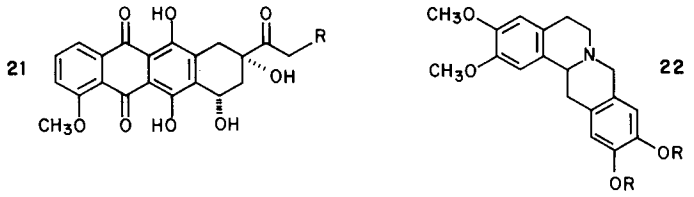
A mechanistically curious and synthetically unexploited result was obtained when attempts were made to catalyze cocyclizations of the type shown in Scheme 5 with polystyrene-supported $CpCo(CO)_2$[32] (Scheme 11). The monosubstituted acetylenes were not incorporated into the aromatic products, and only diyne dimers, such as **19** (major product), and trimers, such as **20**, were isolated. Since homogeneous $CpCo(CO)_2$ converts **18** exclusively into **20**, indicating that the catalyst is transferred intramolecularly from the benzene ring in **19** to the appendant alkyne unit, which is next to be cyclized, and since $CpCo(CO)_2$ also cocyclizes trimethylsilylalkynes, the polystyrene-supported or similar catalysts may offer an opportunity for interesting shape-selectivity in some of these transformations.



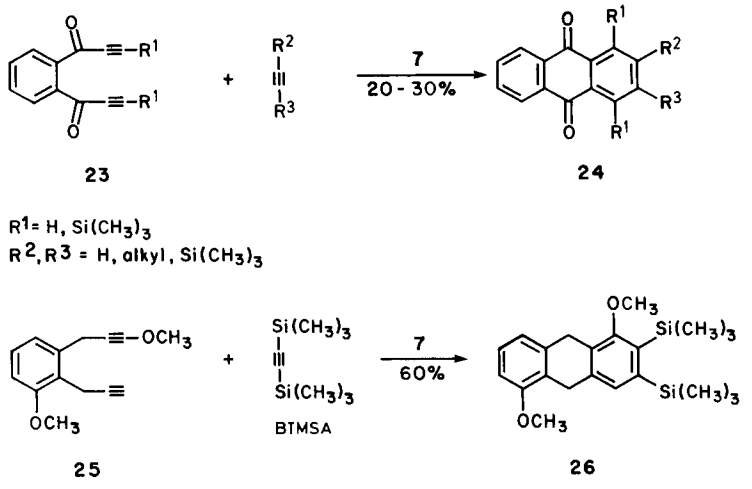
Scheme 11. Catalytic cyclization of 1,6-heptadiyne by polystyrene-supported $CpCo(CO)_2$. Ⓟ = polystyrene.

2.5. Synthetic Applications: Anthracycline Antibiotics and Protoberberine Alkaloids

The $CpCo(CO)_2$-catalyzed [2+2+2]-cycloaddition of three alkyne units could in principle be applied to the total synthesis of a variety of natural products containing annelated benzene rings. Two target molecules which require 1,7-octadiyne structures as cooligomerization precursors are the antitumor anthracycline aglycones **21**[33] and the protoberberine alkaloids **22**[34]. Both systems have already been synthesized via a multitude of approaches, none, however, involving the retrosynthetic disconnection made possible by the "cobalt-way". Two strategies are currently being employed en route to anthraquinone type antibiotics

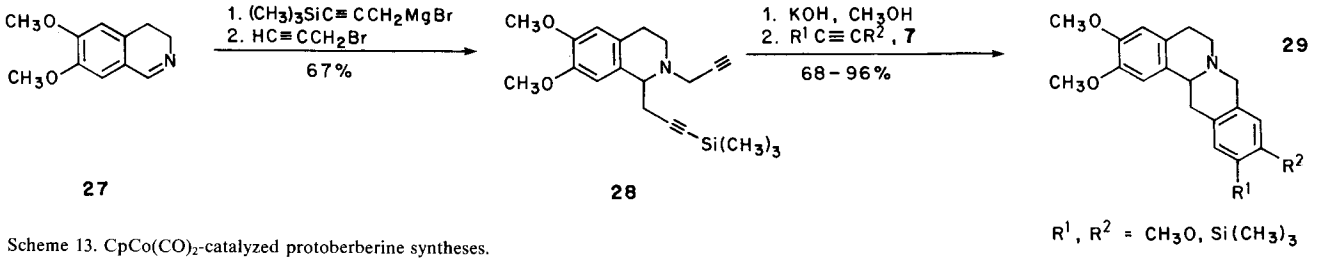


(Scheme 12), one involving the cyclization of aromatic bis(alkynylketones) **23** to furnish directly the desired framework **24**, albeit in only moderate yields[19c], the other utilizing dipropargylbenzenes of the type **25** to assemble initially a dihydroanthracene nucleus as in **26**[35].



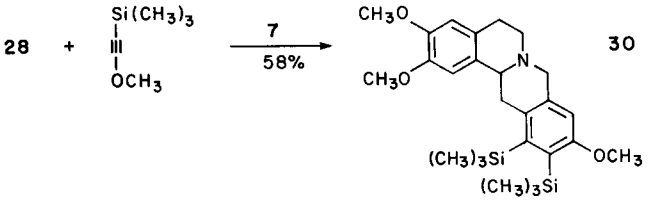
Scheme 12. Two cyclization strategies for the preparation of anthraquinones.

The protoberberines **29** are readily accessible by the sequence of reactions shown in Scheme 13[36]. For example, **29**, $R^1=R^2=Si(CH_3)_3$, is formed in 96% isolated yield by cocyclization of **28** with bis(trimethylsilyl)aceylene (BTMSA). Unfortunately, but perhaps not unexpectedly, unsymmetrical alkynes [$R^1=CH_3O$, $R^2=Si(CH_3)_3$] cyclize non-regioselectively. However, such selectivity is attainable starting from **28**, again the sterically more demanding



Scheme 13. $CpCo(CO)_2$-catalyzed protoberberine syntheses.

arene, e.g. **30**, being generated exclusively (Scheme 14)[36]. Finally, the trimethylsilyl substituents in the compounds **24**, **26**, **29**, and **30** can function as leaving groups in electrophilic aromatic substitution reactions.

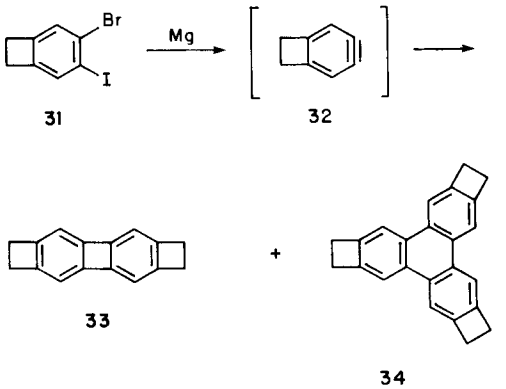


Scheme 14. Regioselective protoberberine synthesis.

3. Theoretically Interesting Molecules

3.1. 1,2-Dihydrocyclobutabenzenes (Benzocyclobutenes)

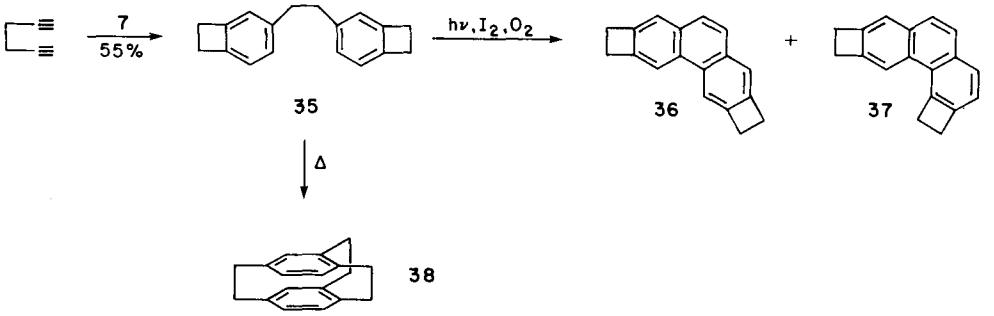
The ready access to functionalized 1,2-dihydrocyclobutabenzenes according to Scheme 5 has enabled their use in the construction of a host of theoretically interesting, strained ring activated, benzenoid hydrocarbons[37]. Thus, 4-bromo-5-iodo-1,2-dihydrocyclobutabenzene **31** (Scheme 15) functions as a precursor of **33**[38] and **34**[39] *via* the intermediacy of 1,2-dihydro-4,5-didehydrocyclobutabenzene



Scheme 15. Generation and oligomerization of 1,2-dihydro-4,5-didehydrocyclobutabenzene.

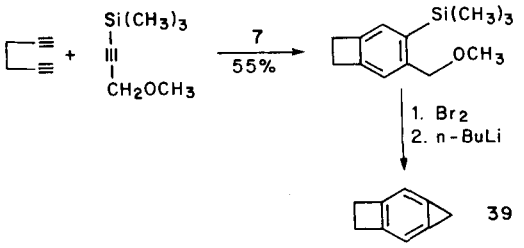
32. The activating effect of the four-membered ring is reflected in the physical and chemical properties of the products. Thus, e.g., both **33** and **34** are rapidly hydrogenated over platinum at ambient pressures. In a similar sequence, compound **17** afforded 1,2-dihydro-3,4-didehydrocyclobutabenzene, predicted by bond fixation arguments to be more reactive than **32**[40].

Hydrocarbon **35**, readily prepared in one step by trimerization of 1,5-hexadiyne, undergoes oxidative photocyclization to give the two isomeric dicyclobutaphenanthrenes **36** and **37** (Scheme 16)[41]. In contrast to **36** and phenanthrene itself, the more reactive **37** is mutagenic in the Ames test, and thus constitutes the first substance in which such physiological activity is increased by ring strain. Flash vacuum pyrolysis[42] of **35** results[43] in diastereoselective cycloaddition to give cyclophane **38**; the conceivable alternative isomer (±)-[2.2.2](1,2,4)(1,2,5)cyclophane[44] could not be detected. This preparation of **38** is clearly the method of choice[45].



Scheme 16. Synthesis of strained ring systems from **35**.

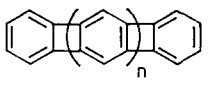
The currently most severely strained simple annelated benzene derivative is probably[46] **39**, which can be prepared rapidly as in Scheme 17[47]. This sequence is comparable in effectiveness with an alternative route[48] because of its speed, even though the last cyclization step is poor (≈5% yield).



Scheme 17. $CpCo(CO)_2$-catalyzed synthesis of 3,4-dihydro-1*H*-cyclobuta[*a*]cyclopropa[*d*]benzene **39**.

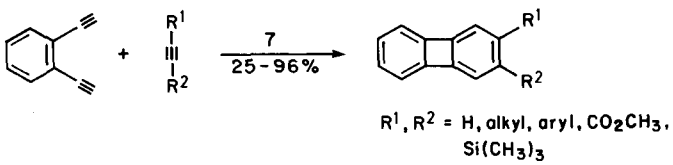
3.2. Multiphenylenes and Related Hydrocarbons

Cobalt-catalysis has opened up an iterative synthetic approach to the preparation of a novel series of cyclobutadienoid[49] aromatic polycyclic hydrocarbons **40**, termed multiphenylenes (biphenylene, terphenylene, etc.), in analogy to the multiphenyls (biphenyl, terphenyl, etc.). Curiously, the series is alternating with respect to the π-electron count of the individual members between formally antiaromatic and formally aromatic. Theory predicts[50] a rapidly narrowing HOMO-LUMO gap with increasing n. Therefore, these compounds might have potential as novel materials with conductive behavior[51].

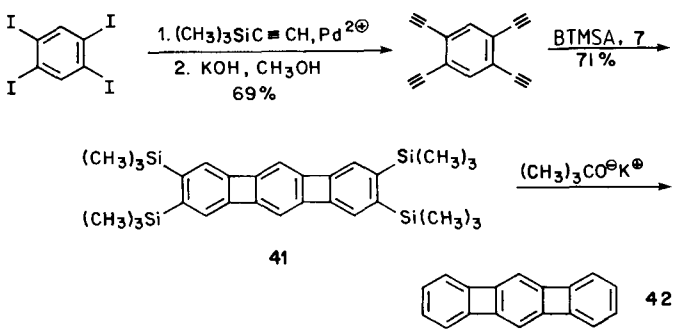


40

The synthetic strategy is based on the palladium-catalyzed ethynylation of halobenzenes[52], on the cobalt-catalyzed cotrimerization of *o*-diethynylarenes with alkynes to give biphenylenes (Scheme 18)[53], and on the ability of the trimethylsilyl group to function as a masked halogen. Scheme 19 depicts the rapid construction of terphenylene **42**, the first new member in the series[54].



Scheme 18. A $CpCo(CO)_2$-catalyzed biphenylene synthesis.

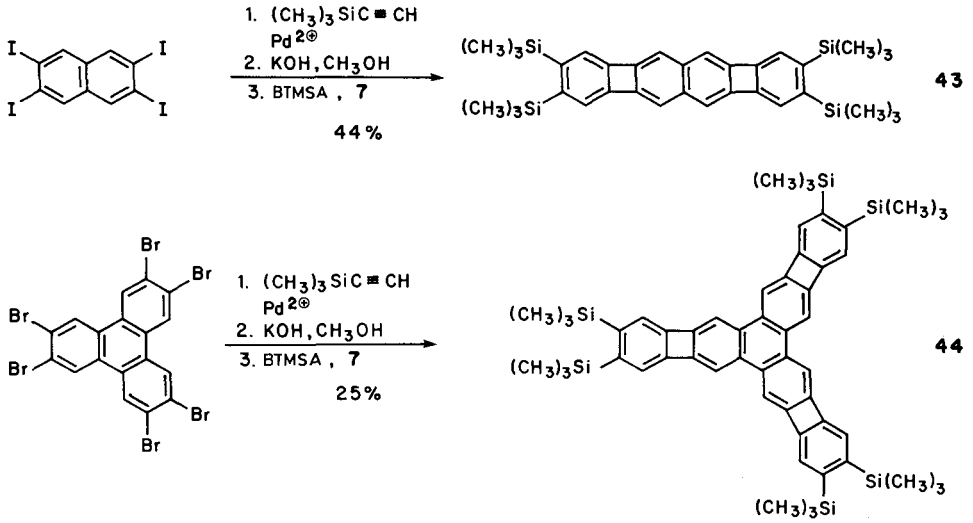


Scheme 19. Synthesis of terphenylene.

The cyclization of 1,2,4,5-tetraethynylbenzene to **41** is the first reaction to form four rings in one step. Even though terphenylene has 18 π-electrons, the system does not behave like an [18]annulene, either physically or chem-

ically. Although the two outer benzene rings show considerably more bond alternation than the central ring, as revealed by an X-ray crystallographic investigation[55], it is the central "cyclohexatriene" which exhibits unusual reactivity: it hydrogenates (all-*cis*) faster than a normal alkene and it adds both electrophiles and alkyllithium reagents. The dianion is surprisingly diatropic[55], suggesting that the system avoids antiaromatic circuits[56].

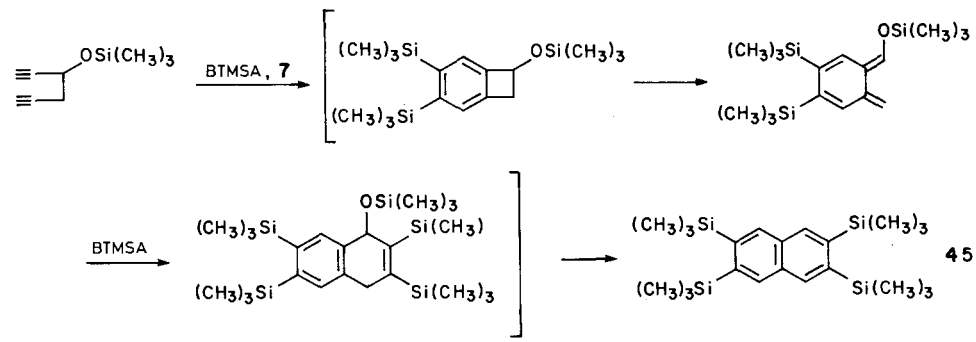
cocyclization of 1,5-hexadiynes with alkynes can be utilized in the construction of more complex assemblies by exploiting their ability to ring-open thermally to the reactive *o*-quinodimethanes, which subsequently undergo Diels-Alder cycloadditions[19,20]. A particularly interesting example is shown in Scheme 21; five of the carbon-carbon bonds of the naphthalene **45** are made in one step[58]. The product **45** not only enables a facile synthesis of otherwise



Scheme 20. A novel synthesis of hydrocarbons containing biphenylene units.

The methodology for the preparation of **42** is of general utility, as shown by the additional examples in Scheme 20[57]. Its effectiveness becomes apparent when one reflects that eleven (!) of the bonds present in **43** are formed by cobalt catalysis; the precursor of **43**, 2,3,6,7-tetraiodonaphthalene, is prepared by iodination of **45** (Scheme 21). The cyclization furnishing **44** constructs a record number of, e.g., six rings in one step.

inaccessible 2,3,6,7-tetrasubstituted naphthalene derivatives[57,59], but its preparation also demonstrates the feasi-

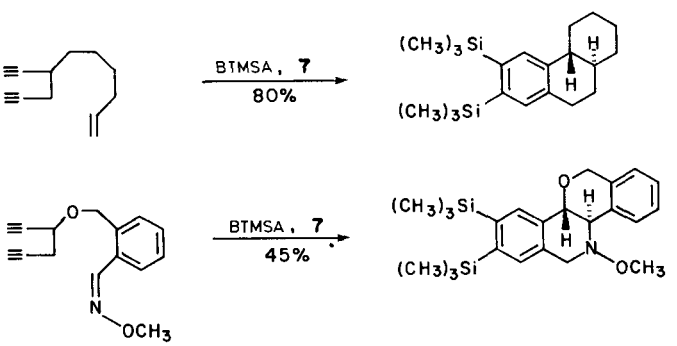


Scheme 21. A one-pot synthesis of naphthalenes according to the "tandem principle".

4. Coupling of Alkyne Cooligomerizations and *o*-Quinodimethane Cycloadditions: The "Tandem Principle"

4.1. A One-Pot Synthesis of Polycycles

Aside from their use in the synthesis of strained ring systems, the 1,2-dihydrocyclobutabenzenes generated by the



Scheme 22. One-pot syntheses of polycyclic compounds according to the "tandem principle".

bility of executing tandem cyclization-cycloaddition reactions. When the latter are carried out intramolecularly[58b,60], polycyclic systems are assembled chemo-, regio- and stereoselectively with remarkable ease. Two of several examples are shown in Scheme 22. The observed stereoselectivity appears to be controlled by the intermediacy of an *o*-quinodimethane formed by conrotatory outward opening of the initially generated 1,2-dihydrocyclobutabenzene, followed by an *exo*-Diels-Alder closure[58b,60]. Control experiments demonstrate that the metal is not involved in the latter.

4.2. The Cobalt-Way to (±)-Estrone: the D→ABCD Approach

Based on the above model systems, a $CpCo(CO)_2$-catalyzed steroid synthesis may be designed as in Scheme 23[61], in which in the crucial step the ABC portion of the steroid nucleus is fused onto the D-ring already present. The salient features of this synthesis are:

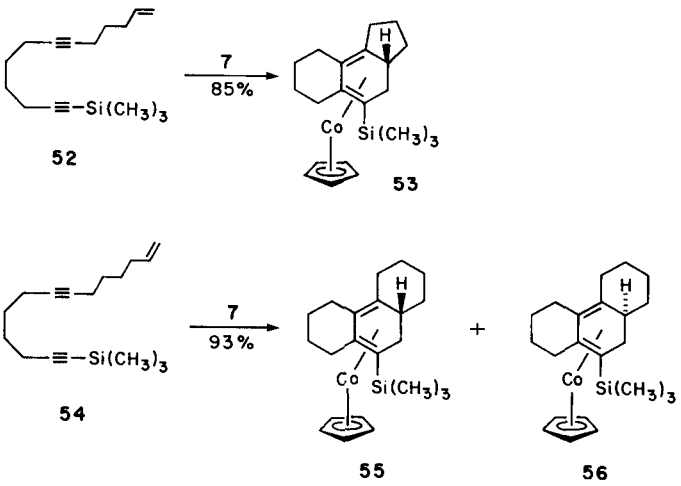
1. the regiospecific alkylation of 1,5-hexadiyne to furnish **46** and ultimately **47**,
2. the stereoselective alkylation of the lithium enolate derived from **48** with **47** to give **49** (two diastereomers),
3. the stereoconvergent cocyclization of **49** to construct steroid **50** stereospecifically,
4. the regiospecific protodesilylation at C-2 of **50**, and
5. the oxidation of ring A to furnish racemic estrone.

The target molecule **51** is formed in five steps from 2-methylcyclopentenone (21% overall yield), and in six steps from 1,5-hexadiyne (14%). The ketal derived from **49** gives even better cyclization yields. Unfortunately, a more direct approach to the A-ring phenol present in estrone by cocyclization of **49** with alkoxyalkynes was not regioselective and suffered from catalyst depletion by cyclobutadiene formation[61].

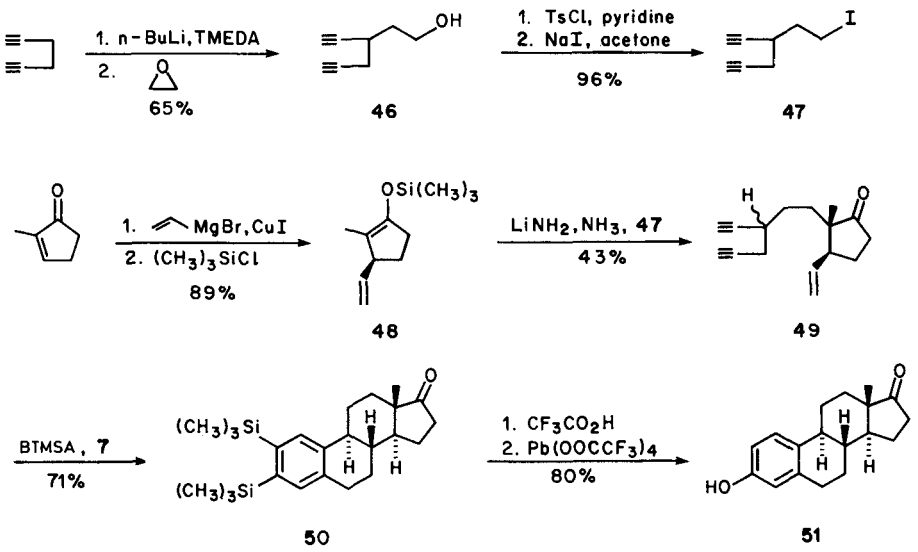
5. [2+2+2]-Cycloadditions of Enediynes: Stereospecific One-Pot Synthesis of Tri- and Tetracyclic Diene Complexes

5.1. Intramolecular Cyclizations of Enediynes with a Terminal Double Bond

Entry 3 in Scheme 3 indicates the potential utility of a cocyclization in which an alkene is employed. The synthetic versatility of such a transformation becomes apparent when one realizes that stereochemical consequences, e.g., ensue upon transformation of a stereochemically defined double bond. There are indeed various organometallic compounds which catalyze such reactions[29], one of which is based on the stoichiometric reaction of $CpCo(CO)_2$ leading to cyclohexadiene complexes[62]. In order to establish the utility of such a method, purely intramolecular cyclization reactions were chosen involving terminal alkenes. Scheme 24 shows examples of the success-

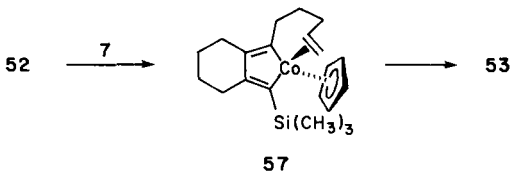


Scheme 24. Intramolecular cyclizations of enediynes with terminal double bonds.



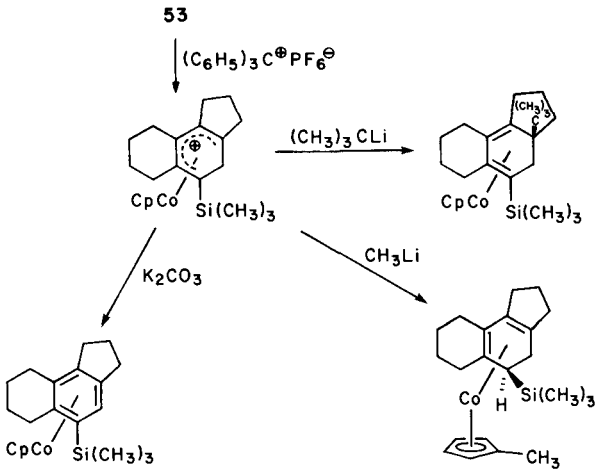
Scheme 23. A $CpCo(CO)_2$-catalyzed synthesis of (±)-estrone.

ful outcome of these attempts[29,63]. Interestingly, complete stereoselectivity is observed in some cases, its utter absence in others. Thus, **52** leads only to diastereomer **53**, whereas the homologue **54** gives an equimolar mixture of **55** and **56**. Why this is so remains a mystery. It is attractive to invoke an *exo*-Diels-Alder type mechanism involving a metallacycle of the type **57** leading to **53** (Scheme 25). However, insertion pathways and kinetic metallacyclopentene[64] formation cannot be ruled out as alternatives, and it is not clear why merely extending the appendant sidechain by one carbon should completely eradicate any selectivity. More puzzling, the desilylated analogue of **52** is equally unselective in its reactions.



Scheme 25. Diels-Alder-like mechanism for the reaction **52**→**53**.

Regardless of this mechanistic question, the method provides an efficient preparation of hitherto inaccessible polycyclic dienes, liberated almost quantitatively from their complexes by oxidative demetalation[63]. Some preliminary indication has been gathered that dienylsilane moieties such as those present in the cyclization products **53**, **55**, and **56** may be useful masked functional groups, for example α,β-unsaturated enones[63].

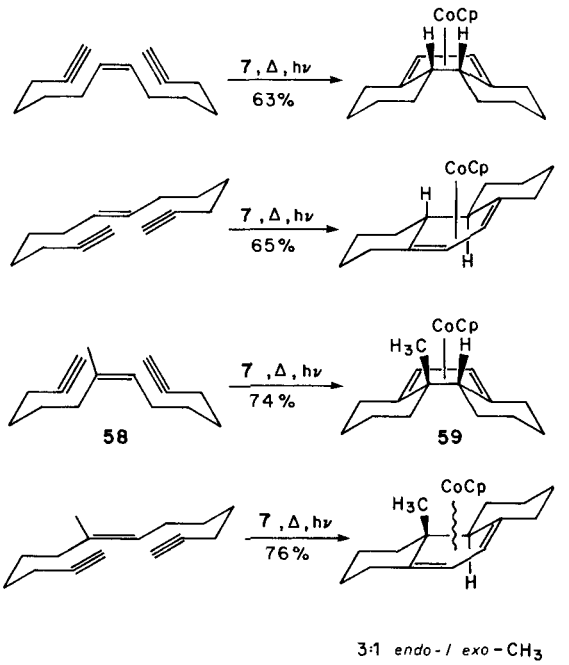


Scheme 26. Attack by nucleophiles on CpCo-cyclohexadienyl cations.

The presence of the metal may be beneficial. It protects the diene from rearrangements, polymerization, and (when applicable) protodesilylation. As observed for the analogous isoelectronic tricarbonyliron systems[65], hydride abstraction can be effected with trityl hexafluorophosphate to give cations which are subjectable to nucleophilic attack (Scheme 26). However, the regioselectivity[66] appears unpredictable.

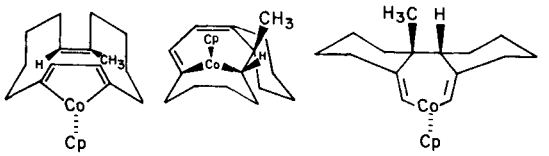
5.2. Intramolecular Cyclizations of Enediynes with Internal Double Bonds: Stereochemistry of the Double Bond

With the demonstration of the successful cyclization of terminal enediynes, it became necessary to establish the scope of the reaction by testing more highly substituted systems, particularly those in which the stereochemical fate of the double bond could be determined. For this purpose a series of internal enediynes was subjected to the cyclization conditions, altered to include photochemical acceleration of CO dissociation (Scheme 27)[67]. It can be seen that



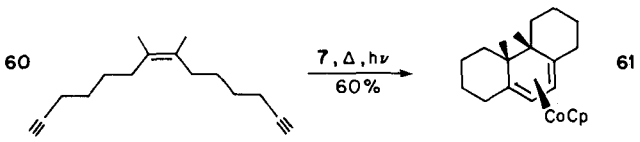
Scheme 27. Intramolecular cyclizations of enediynes with internal double bonds.

these transformations proceed relatively efficiently and with remarkable stereoselectivity, both with respect to the stereochemistry of the original double bond and the stereochemistry at cobalt. For example, of the four possible diastereomers, the enediyne **58** forms only one, namely **59**. The observed selectivity is consistent with mechanisms in which either an enyne unit or the two ethynyl groups undergo initial coupling. Subsequent incorporation of the third unsaturated moiety may then occur by Diels-Alder or insertion pathways. Some possible crucial intermediates arising from the reaction of **58** are depicted in Scheme 28, illustrating the variety of options. It appears in all cases that steric arguments can be invoked to explain the observed stereochemical results. It also transpires that, unlike



Scheme 28. Possible intermediates in the cyclization of **58**.

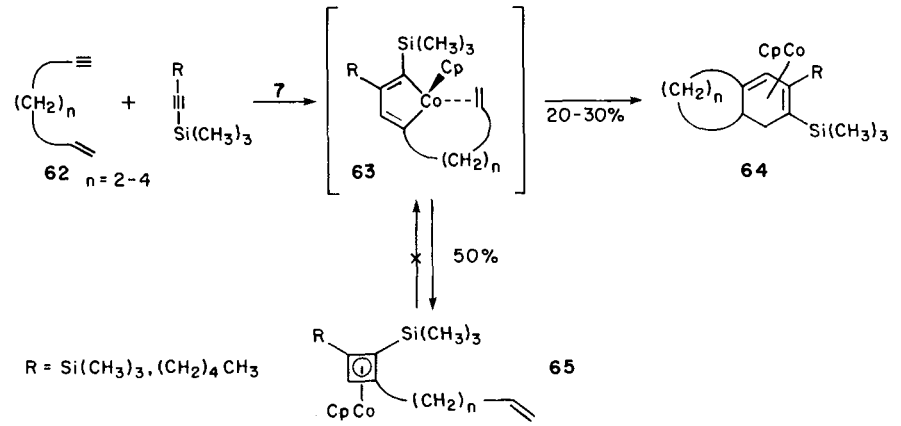
the Diels-Alder and numerous other cycloaddition reactions, the steric encumbrance of the double bond has little influence on the successful outcome of the reaction. The cyclization can therefore be used to accomplish a traditionally very difficult synthetic task: the introduction of quaternary carbon atoms into polycyclic frameworks, particularly those bearing angular methyl groups[68]. Currently, the most impressive demonstration of this potential is the conversion of the substrate **60**, which contains a tetrasubstituted double bond and, under standard conditions (see Scheme 29), affords the tricyclic diene **61** bearing two adjacent quaternary carbon atoms[69]. Surprisingly, and perhaps attesting to the (sterically induced?) relatively greater sensitivity of complex **61**, filtration through silica gel gave the free ligand in high yield.



Scheme 29. Cyclization of **60** to **61** with two adjacent quaternary centers.

5.3. Intermolecular Cyclizations of Enynes

Intramolecular [2+2+2]-cycloadditions of enediynes have found a fair amount of applications, whereas their intermolecular variants have so far been little exploited. Part of the problem appears to be the occurrence of a competing rapid valence tautomerization of the intermediate metallacyclopentadiene to give cyclobutadiene complexes. For example, cooligomerization of the α,ω-enynes **62** with BTMSA gave mainly **65** and only moderate amounts of the desired bicycle **64**[29,70] (Scheme 30). Moreover, only

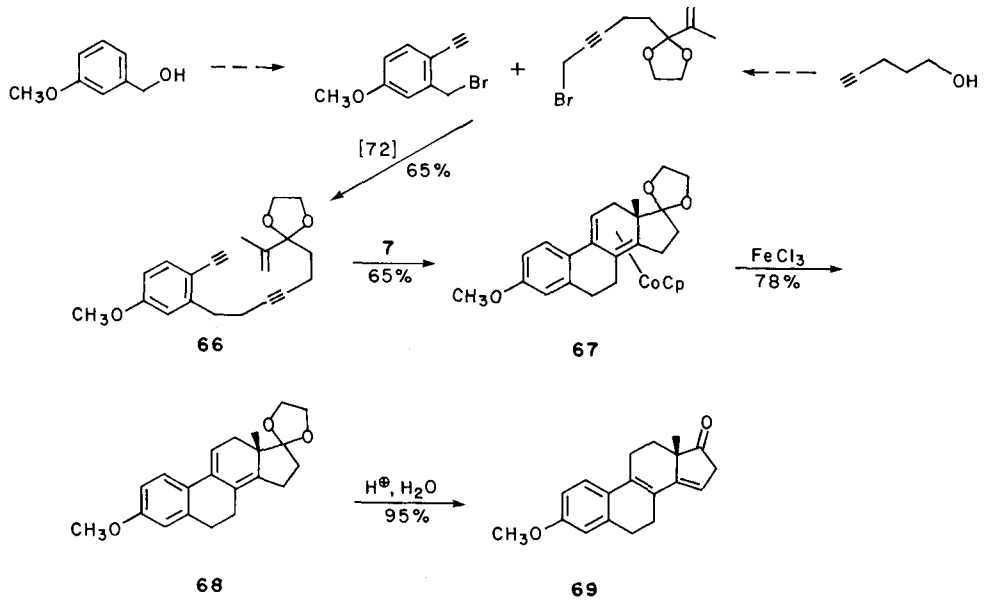


Scheme 30. Cocyclizations of α,ω-enynes with alkynes.

in the case of **64** (n=2) was stereoselectivity observed in the product. The cyclobutadienes **65** cannot, unfortunately, be induced to re-enter the cyclization manifold, regardless of the application of photochemical, thermal, or oxidative degradation methods. It appears that **63** undergoes relatively slow alkene incorporation. Complete regioselectivity is observed when 1-trimethylsilyl-1-heptyne is cocyclized with **62** (n=3, 4), suggesting that the trimethylsilyl group, as expected, prefers the α-position to the metal upon oxidative coupling to the metallacycle **63**. Improvement of the yields awaits the outcome of experiments designed to probe further the stereoelectronic aspects of the reactions.

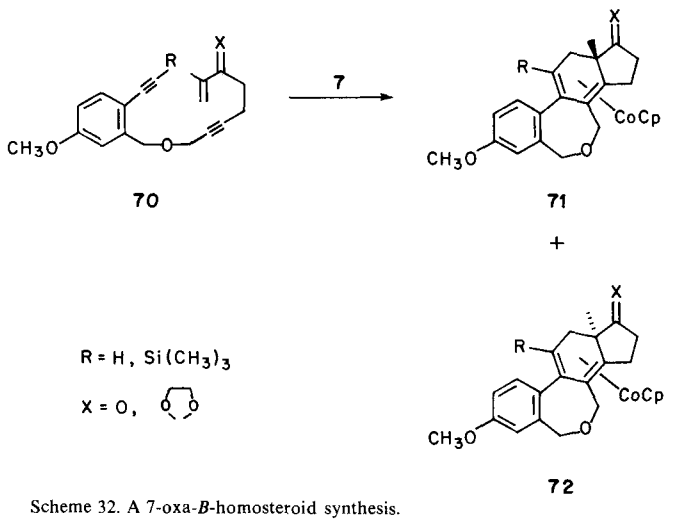
5.4. The Cobalt-Way to (±)-Estrone: the A→ABCD Approach

The effectiveness of the cycloadditions depicted in Scheme 24 suggested further application to the total synthesis of steroids in which the BCD portion of their framework would be fused to a pre-existing aromatic A-ring. This approach also provided the opportunity to test the [2+2+2]-cycloadditions of a 1,1-dialkylated olefin. With this aim in mind, the crucial enediyne precursor **66** was synthesized (Scheme 31)[71], utilizing in the key step a dihydrothiazole-mediated coupling of benzyl and propargyl halides[72]. Reaction of **66** with 7 gave the steroid complex **67** completely stereospecifically, the methyl group at C-13 being positioned *exo* to the metal. It was surprising to find that the steroidal pentaene ligand **68** had not been described in the literature prior to the present synthesis. There appear to be two reasons for this: firstly, the ligand **68** obtained on oxidative demetalation of **67** is very sensitive, turning into colorless, flocculent, insoluble material on exposure to air; secondly, the position of the diene moiety in **68** is thermodynamically disfavored over that present in **69**, into which it can be converted by acid treatment. Compound **69** is the Torgov intermediate in the synthesis of estrone[73]; its novel preparation as in Scheme 31 constitutes another formal total synthesis of the racemic natural product. Mechanistically, one could again invoke a Diels-Alder cycloaddition of the type depicted in **57** to account for the stereoselectivity observed. The added bulky ketal group would ensure that the chain connecting diene to dienophile would be placed *exo*.



Scheme 31. Steroid synthesis by enediyne cyclization.

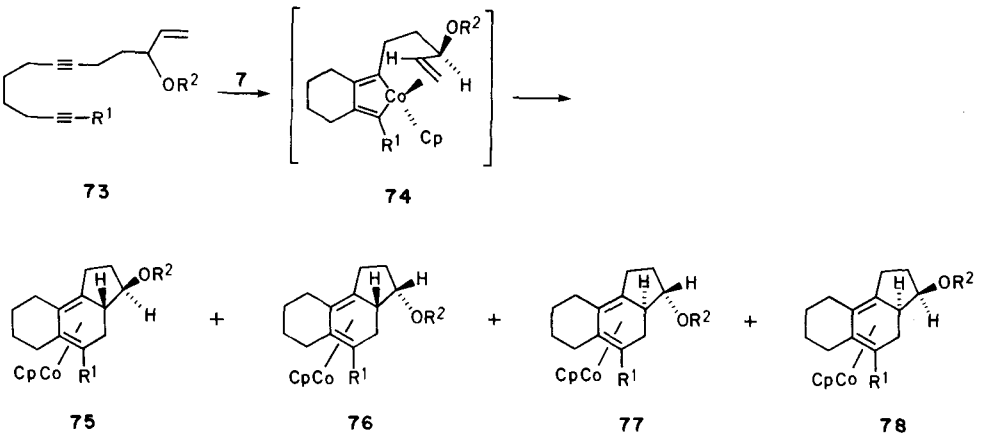
Similar arguments could be advanced to explain the changes in selectivity encountered in the transformations of **70** into the 7-oxa-*B*-homosteroid complexes **71** and **72** (Scheme 32)[71]. For example, when $R=(CH_3)_3Si$, the ketalized system **70** ($X=OCH_2CH_2O$) produces only **71** (analogous to the conversion of **66** into **67**), whereas the ketone **70** ($X=O$) leads to a mixture of **71** and **72** in which the latter predominates. This finding is possibly a consequence of the preferred *endo*-arrangement of the carbonyl group in the transition state for addition.



Scheme 32. A 7-oxa-*B*-homosteroid synthesis.

5.5. Diastereoselective Cyclizations of Chiral Substrates

Since the [2+2+2]-cycloaddition of achiral enediynes leads to the formation of ligands containing new chiral centers, it was of interest to investigate the potential diastereoselectivity of such a process with chiral substrates. In particular, it was hoped that a mechanistic insight might be gleaned from the reaction of **73**, for, if a Diels-Alder-like process involving **74** was operating, steric arguments would have to place the substituent OR^2 *exo* (as shown and as seen in general in intramolecular reactions of this type), ultimately furnishing only **75** (Scheme 33) at the ex-



Scheme 33. Diastereoselective cyclizations of enediynes.

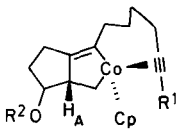
pense of the other three possible diastereomers **76**—**78**. However, as the results in Table 1 show[74,75], the outcome

Table 1. Yields of Complexes **75**–**78**.

R^1	R^2	Relative yields [%]				Isolated	t
		75	**76**	**77**	**78**	yields [%]	[h]
$Si(CH_3)_3$	CH_3	71	26	—	3	88	4
$Si(CH_3)_3$	$C_6H_5CH_2$	73	23	—	4	85	4
$Si(CH_3)_3$	CH_3OCH_2	69	24	—	7	91	4
$Si(CH_3)_3$	tBuSi$(CH_3)_2$	36	52	—	12	94	6
$Si(CH_3)_3$	$Si(i$Pr$)_3$	37	39	6 [b]	18 [b]	88	24
$Si(CH_3)_3$	tBuSi$(C_6H_5)_2$	33 [b]	47 [b]	—	20 [b]	[a]	[a]
tBuSi$(CH_3)_2$	tBuSi$(CH_3)_2$	35	50	—	15	91	6

[a] 44% conversion after 24 h. [b] Not isolated; presence ascertained by NMR spectra.

of this experiment appears to confuse the issue rather than to clarify it. Thus, although the first three entries appear to bear out the premise of Scheme 33, introduction of bulkier OR^2-groups, expected to maximize the intermediacy of a species of the type **74** and hence the yield of **75**, has exactly the opposite effect. Whether this phenomenon is general for non-silicon-containing groups has yet to be ascertained. The observed results, at odds with the simple Diels-Alder picture, might be more readily explained by invoking **79** as an intermediate formed by initial enyne coupling. Models show that **79** adopts a pseudo-chair config-

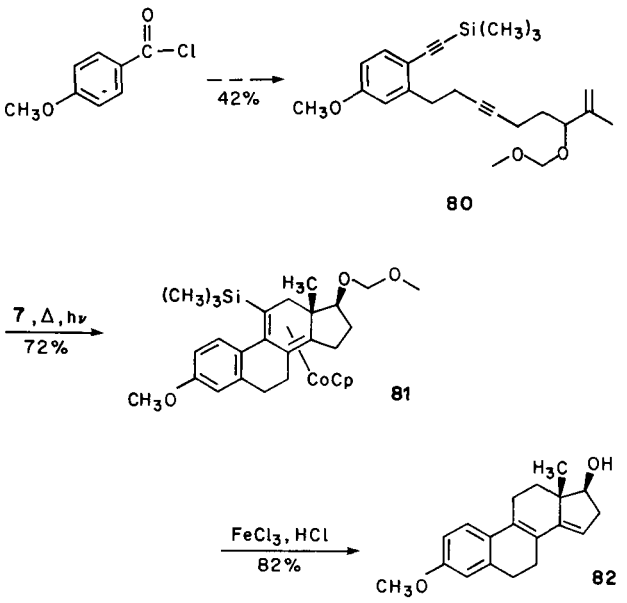


79

uration, placing the OR^2 substituent in an initially favorable equatorial position. Upon oxidative coupling, this group emerges severely eclipsed with H_A. This effect would lead to the OR^2-moieties increasingly preferring to be positioned axially with increasing bulkiness, or to the formation of a boat-shaped transition state in which the prochiral vinyl hydrogen points towards the metal (giving appreciable amounts of **77** and **78**, in addition to **75** and **76**, as observed).

5.6. A Diastereoselective Steroid Synthesis

The fairly selective outcome of at least some of the examples in Table 1 can be exploited in a diastereoselective steroid construction as shown in Scheme 34[75]. The required precursor **80** is readily prepared in good overall yield starting from *p*-methoxybenzoyl chloride. Cyclization gives mainly **81** (72%) in addition to its 17α-isomer (20%). Oxidative demetalation under acidic conditions converts **81** directly into the known estrapentaenol **82**[76], by (presumably in this sequence) loss of metal, diene isomerization, protodesilylation, and removal of the alcohol protecting group. The free ligand is also obtainable from **81** (81%), and in contrast to **68**, is air stable. A curious feature



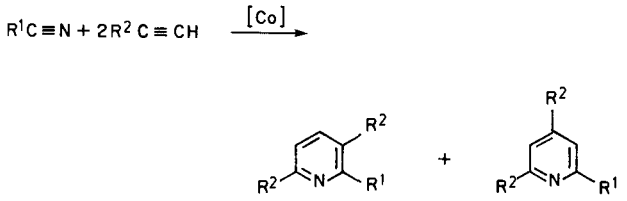
Scheme 34. Diastereoselective steroid synthesis.

of complex **81** (but not observed in the free ligand) is the presence of hindered rotation of the trimethylsilyl group ($\Delta H^{+} = 18.8$ kcal/mol) on the NMR time scale, the first such impaired mobility observed for a vinyltrimethylsilane[77], obviously caused by the bay-region hydrogen at C-1.

6. The Cobalt-Way to Heterocyclic Systems

6.1. Cocyclization of α,ω-Diynes with Nitriles: Synthesis of Cycloalka[1,2-*c*]pyridines and a Total Synthesis of Vitamin B_6

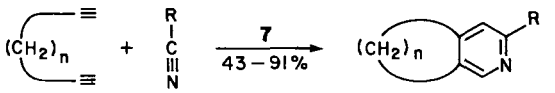
In the early 1970s, several groups independently discovered that cobalt complexes could cocyclize alkynes with nitriles to furnish pyridines in stoichiometric and catalytic reactions (Scheme 35)[78]. *Bönnemann* et al. have carried



Scheme 35. Cobalt-catalyzed pyridine synthesis.

out a comprehensive study of the scope and limitations of this reaction[79]. Although good control of chemoselectivity is obtained in the preparation of 2-substituted pyridines, product mixtures are formed in the cocyclization of unsymmetrical alkynes (Scheme 35)[79]. This potential prob-

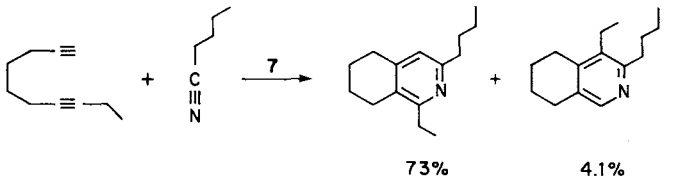
lem can be avoided by the use of α,ω-diynes (Scheme 36),



n = 3–5, R = alkyl, aryl, CH_2OCH_3, $CH_2CO_2C_2H_5$

Scheme 36. Cocyclization of α,ω-diynes with nitriles.

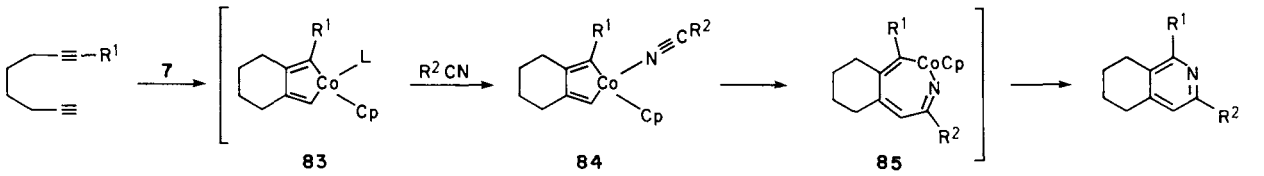
in which regioselectivity is controlled by the chelating nature of the alkyne component and by steric effects, whereas chemoselectivity is apparently controlled by electronic interactions[80]. Unsymmetrical diynes lead to predominant generation of the sterically less encumbered substitution pattern (Scheme 37). With electron-deficient ni-



Scheme 37. Regioselective cocyclization of unsymmetrical diynes with nitriles.

triles, the reaction fails to give satisfactory yields of pyridines, furnishing instead diyne oligomers. On the other hand, with other nitriles it is remarkably chemospecific, requiring only equimolar amounts of starting materials[80].

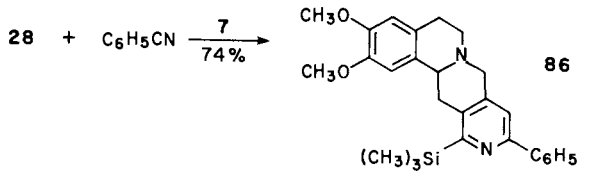
Mechanistically, the above results are readily accommodated by invoking initial formation of the metallacycle **83** (Scheme 38). The Co(III) center may now be postulated to



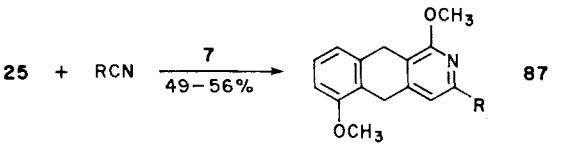
Scheme 38. Mechanism postulated for the formation of annelated pyridines.

select for nitrile by ligation through its lone pair[81], as in **84**, an interaction which becomes noncompetitive with alkyne complexation in the case of electron-deficient nitriles. Insertion into the less hindered cobalt-carbon bond, placing the nitrogen next to cobalt (**85**), eventually furnishes the observed products. This mechanism is consistent with the finding that isolated cobaltacyclopentadienes react like **83**[78a] and lead to substituent patterns similar to those observed in normal pyridine formation[79]. However, there is no conclusive evidence ruling out other pathways.

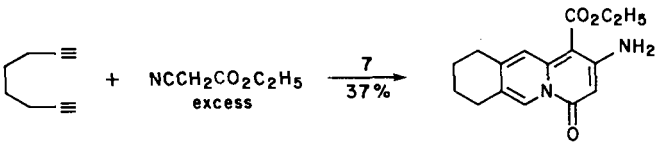
Irrespective of the mechanistic questions, the cocyclization depicted in Scheme 36 is potentially synthetically useful. For example, the diyne **28** cotrimerizes regioselectively



with benzonitrile to give **86**[36], an example of the rare isoquino[2,1-*b*]-2,6-naphthyridine nucleus. Similarly, the 2-azaanthracene framework **87** is accessible from **25**[35].



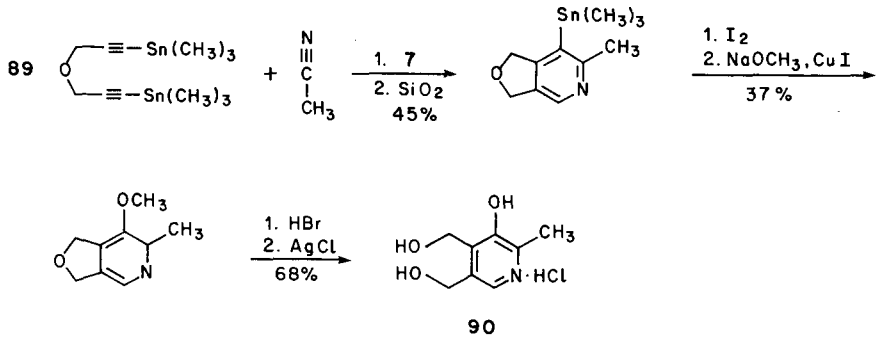
Employment of excess ethylcyanoacetate in the cocyclization with diynes can lead to further condensation of the intermediate 2-pyridylacetic esters[82]. This facilitates the one-pot synthesis of annelated quinolizinones such as **88**[35,80].



Dipropargylamines[83] and dipropargyl sulfides[83a] have been successfully cocyclized to give the corresponding 1,3-dihydropyrrolo- and thieno[3,4-*c*]pyridines. Based on this principle, but using dipropargyl ether **89** as starting material, a regioselective synthesis of vitamin B_6 **90** has been accomplished (Scheme 39)[84]. The cyclizations of **89** are the first to employ stannylalkynes, necessary in this case to ensure the successful outcome of electrophilic aromatic substitution on the resulting stannylpyridine.

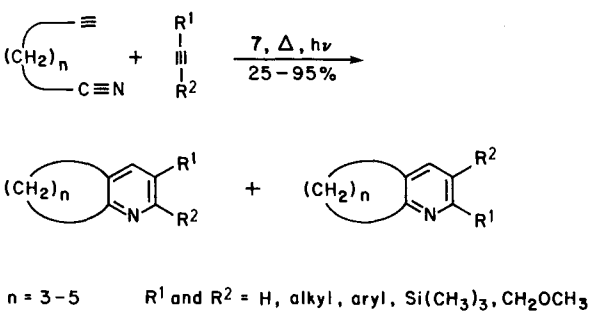
6.2. Cocyclization of ω-Alkynyl Nitriles with Alkynes: Synthesis of Cycloalka[1,2-*b*]pyridines

Scheme 40 shows a complementary cyclization strategy which enables the preparation of [*b*]annelated pyridines[85]. Regioselectivity is again attained in the case of unsymmetrical alkynes, the bulky substituent emerging next to the nitrogen. The successful outcome of this reaction appears

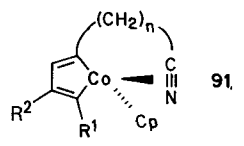


Scheme 39. A cobalt-catalyzed synthesis of vitamin B_6.

to depend on the efficiency of oxidative coupling to **91**, the larger group on either of the original alkynes being located in the α-position to the metal. The trimethylsilyated pyridine derivatives can be further functionalized by electrophilic aromatic substitution. A recent extension of Scheme 40 has involved the cyclodimerization of two ω-alkynyl nitrile molecules to give the corresponding cyanoalkyl-substituted cycloalka[*b*]pyridines[86]. Finally, it should be pointed out that cyclopentadienylcobalt does not appear to be capable of coupling more than one nitrile group in these transformations. This contrasts with $Fe_2(CO)_9$, which facilitates the cocyclization of adiponitrile with nitriles to give 1,2,4-triazines[87].



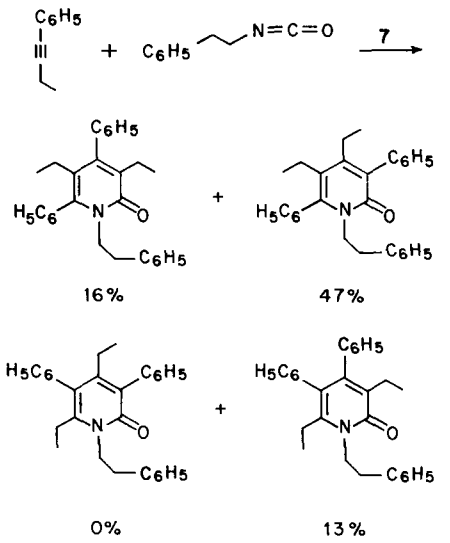
Scheme 40. Cocyclization of ω-alkynyl nitriles with alkynes.



91

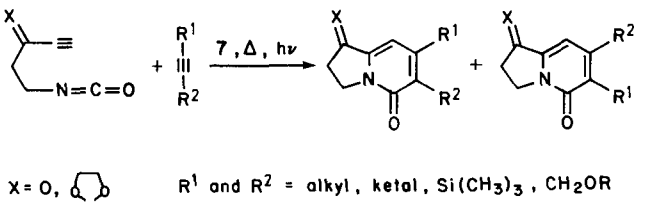
6.3. Cocyclizations of ω-Alkynyl Isocyanates: a Total Synthesis of Camptothecin

In analogy to the topological change occurring when going from alkynes to alkenes in [2+2+2]-cycloadditions, the employment of an imine unit instead of a nitrile in cocyclizations with alkynes could provide a ready synthetic entry to dihydropyridines. Moreover, if the C=N-substructure were to be incorporated into an α,ω-doubly unsaturated chain, its cyclization could lead to the rapid construction of polyheterocyclic systems incorporating bridgehead nitrogen atoms. Although this goal remains to be realized with simple imines[88], isocyanates appear to be suitable substrates in such an endeavor[79,89]. In simple cocyclizations leading to substituted pyridones (Scheme 41)[88]



Scheme 41. Product distribution in the cocyclization of β-phenethyl isocyanate with 1-phenyl-1-butyne.

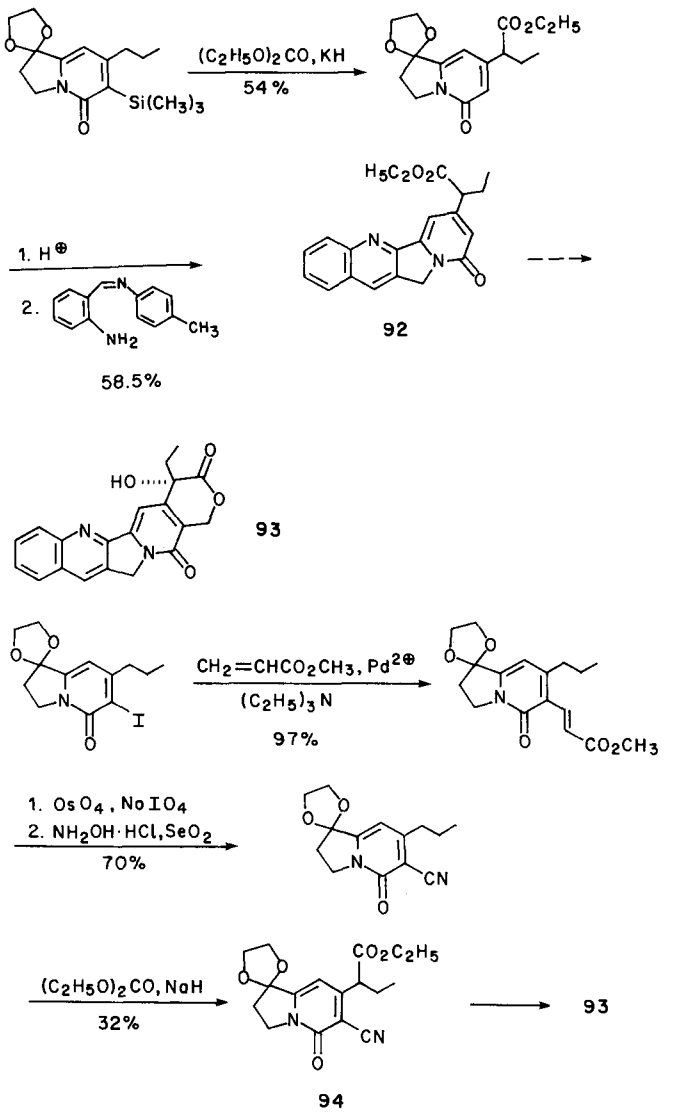
there is a potential problem of regioselectivity[79,88,89]. However, it may be circumvented by the use of ω-alkynyl isocyanates (Scheme 42)[90]. Good chemo- and regioselectivity are observed, the latter favoring the bulky substituent (particularly trimethylsilyl) taking up the α-position to the carbonyl group. An intermediate of the type **91** is indicated, but bearing an appendant complexed isocyanato rather than a nitrile group. Unexpectedly, based on steric



Scheme 42. Cocyclization of ω-alkynylisocyanates with alkynes.

considerations, the trimethylsilyl group always wins out and takes over the α-position, even when in competition with a *tert*-butyl group. This finding clearly indicates the operation of both steric and electronic effects with the silyl substituent (see Section 2.4). The silyl moieties in the product allow for selective halodesilylations at C-6[90]. In contrast, the halogenation of ordinary 2-pyridones leads to mixtures[91]. Finally, carbon-carbon bond formation is possible at C-6 by employing palladium-catalyzed coupling reactions of the corresponding 6-iodides[52,92].

Application of the above methodology has led (Scheme 43)[90] to two formal syntheses of the antitumor alkaloid camptothecin **93**[93]; one proceeds via the intermediate **92**[94], the other via **94**[95].



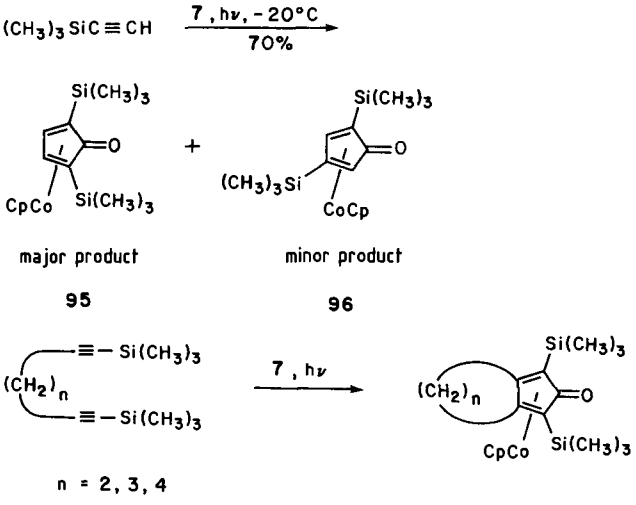
Scheme 43. Two total syntheses of camptothecin.

It is interesting to note that bis(η^4-cyclooctadiene)nickel, another catalyst reported to catalyze the formation of pyridones from alkynes and isocyanates[96], gives not only a different product distribution in the case depicted in Scheme 41, but is also a much poorer catalyst than the cobalt system in the presence of terminal alkynes[88]. Evidently, a different mechanism is operating in this system.

7. [2+2+2]-Cycloadditions Involving Carbon Monoxide: Cyclopentadienone Formation

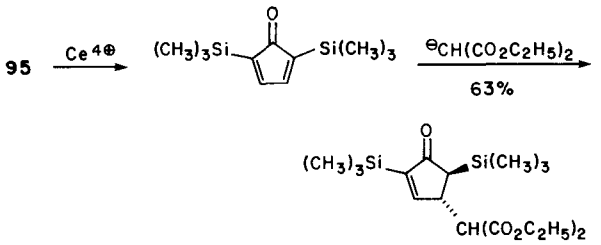
7.1. Synthesis of Cyclopentadienones

An alternative to the mode of cyclization depicted in Scheme 3 is provided by cyclization partners with "carbenoid" atoms, such as isocyanides[97] and carbon monoxide[13c,98]. If multiple insertion pathways could be avoided and product selectivity were controlled, the CpCo moiety should enable a [2+2+2]-cycloaddition to give five-membered ring systems in the presence of either substrate[13e,99]. Although isocyanides have not yet proven successful[100], it has been found that trimethylsilylalkynes undergo such reactions under low-temperature photolytic conditions in the presence of stoichiometric amounts of $CpCo(CO)_2$ **7** to furnish complexed cyclopentadienones regioselectively (Scheme 44)[101].



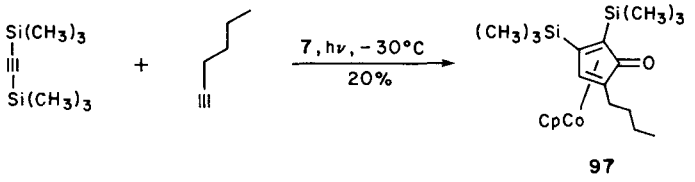
Scheme 44. Formation of cyclopentadienone complexes.

The utility of these complexes lies in their ready decomplexation ($Ce^{4\oplus}$) to give the free monomeric cyclopentadienones, which function as extraordinarily reactive substrates in further transformations (Scheme 45)[102].



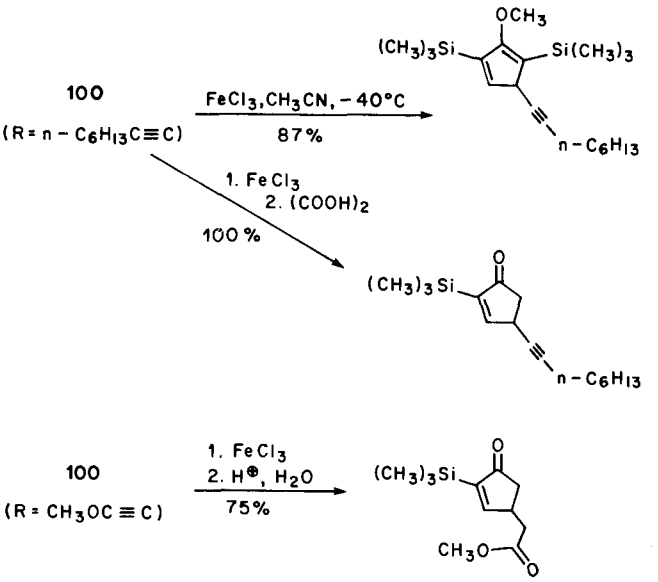
Scheme 45. Nucleophilic addition to 2,5-bis(trimethylsilyl)cyclopentadienone.

Metallacyclopentadienes[17,26], metallacyclobutenones[98,103], and more complex intermediates[103] have been invoked in the formation of cyclopentadienones from alkynes and carbonylmetal compounds. All are consistent with the observed product regioselectivity. For example, **95** is the major product in the cyclization of trimethylsilylacetylene with 7 (Scheme 44). On the other hand, when $(CH_3)_5C_5Co(CO)_2$ was employed, the corresponding 2,4-disilylated product predominated[101].



97

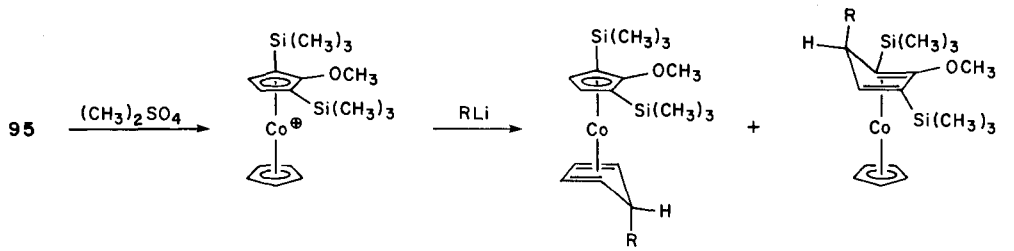
Cocyclization of 1-hexyne with BTMSA results in **97** as the exclusive cotrimer[102], indicating further synthetic potential, although the yield is, as yet, unsatisfactory.



Scheme 47. Oxidative decomplexation of the substituted ligands in **100**.

7.2. Cobaltocenium Salts as Precursors of Substituted Cyclopentadienes and Cyclopentadienones

Cyclopentadienone complexes of the type **95** can be exploited synthetically if they are activated by methylation to give cobaltocenium salts[104]. In the case of **95**, the resulting cation **98** can be ring-selectively and regioselectively attacked by organolithium reagents to give predominantly either **99** (R = bulky substituent, alkyl) or **100** (R = small substituent, alkynyl) (Scheme 46)[105]. It is the latter which



98 99 100

Scheme 46. Nucleophilic additions to cobaltocenium salts.

commands synthetic attention, because highly substituted and functionalized cyclopentadienes or cyclopentenones may be liberated from these species under mild oxidizing conditions (Scheme 47)[105]. Five-membered ring compounds of this type should be useful in the construction of cyclopentanoid natural products[106].

8. Conclusions and the Future

It is clear that the present methodology has not only provided some powerful simplifications in approaches to the construction of natural and medicinal products, but has also given access to novel structures of theoretical and synthetic interest. Chemo-, regio-, and stereospecific cyclizations in conjunction with the use of auxiliary groups, such as for example silicon- or tin-based substituents, allow for the rapid build-up of polycyclic ring systems with extensive control of ring-substitution. However, much remains to be done. The synthetic potential of such [2+2+2]-cycloadditions, as outlined in Scheme 3, has only barely begun to be explored. Many additional unsaturated organic (and organometallic?) substrates could be envisaged to participate in such a reaction. The possible stereochemical complexity of cyclizations involving increasing numbers of double-bonded partners should be elucidated. There must be a host of other catalysts, waiting to be discovered, which might exhibit specific selectivities. The use of optically active ligands in enantioselective transformations should be explored. Novel structures incorporating unusual strain-related and electronic features will become available, and their chemistry should provide further insight into the theories of bonding, delocalization, and aromaticity. Finally, why stop at [2+2+2]? There are many other combinations of one, two, and higher atomic synthons which might be induced to undergo multiple bond-formations in the presence of the appropriate catalyst to supply structures of increasingly higher complexity. Such will be the task of future investigators and collaborators.

I wish to thank my devoted, enthusiastic, and readily stimulated collaborators mentioned in the references. This work was supported by the National Institutes of Health (GM 22479 and in part CA 20713) and in part by the National Science Foundation (CHE 76-01783, 79-03954, and 82-00049).

Chelation or Non-Chelation Control in Addition Reactions of Chiral α- and β-Alkoxy Carbonyl Compounds

New Synthetic Methods (44)

By Manfred T. Reetz*

The addition of C-nucleophiles such as Grignard reagents or enolates to chiral α- or β-alkoxy aldehydes or ketones creates a new center of chirality and is therefore diastereogenic. In order to control stereoselectivity, two strategies have been developed: 1) Use of Lewis-acidic reagents which form intermediate chelates, these being attacked stereoselectively from the less hindered side *(chelation control)*; 2) use of reagents incapable of chelation, stereoselective attack being governed by electronic and/or steric factors *(non-chelation control)*. Generally, the two methods lead to the opposite sense of diastereoselectivity. It is possible to predict the outcome by careful choice of organometallic reagents containing elements such as Li, Mg, B, Si, Sn, Cu, Zn, or Ti.

1. Introduction

The two π-faces of a carbonyl compound having at least one chiral center are diastereotopic. Addition of C-nucleophiles such as Grignard reagents or enolates can therefore lead to unequal amounts of diastereomers. Reactions involving such 1,n-asymmetric induction[1b,c] have been termed "diastereofacially selective"[2]. Although this phenomenon was observed as early as 1894[1], it was not until the work of *Cram* et al. that some degree of systematization was attempted[3]. In what is now known as Cram's rule[1], an α-chiral aldehyde (or ketone) such as **1**[*] is assumed to adopt a conformation in which the largest of the three α-substituents is antiperiplanar to the carbonyl function, nucleophilic attack then occurring from the less hin-

[*] Prof. Dr. M. T. Reetz

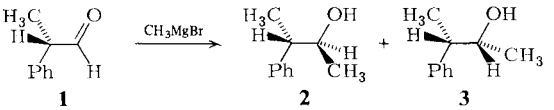
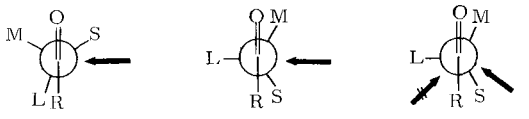
Hans-Meerwein-Strasse, D-3500 Marburg (FRG)

[*] Only one enantiomer is shown, although a racemate was used leading to racemic products.

dered side. In the case of CH_3MgBr, the ratio of Cram to anti-Cram products **2** : **3** turned out to be ca. 66 : 34[1,3]. Besides the Cram model (cf. Newman projection **4**), other explanations have been offered[1]. *Felkin* et al. assumed a reacting conformation **5**[4], a model which has been refined by *Anh*, who postulated *non-perpendicular* attack (Bürgi-Dunitz trajectory), as shown in **6**, on the basis of molecular orbital considerations[5].



1 **2** **3**

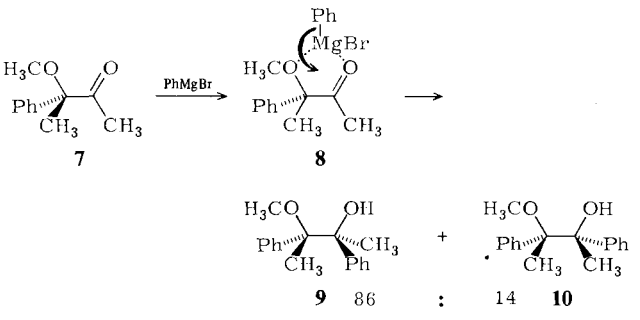


4 **5** **6**

L = large, M = medium, S = small substituent

For carbonyl compounds with α-halogen substituents, *Cornforth* et al. proposed an electrostatic model in which the electronegative group points away from the polar carbonyl function, i.e., it takes the place of L in **4**[1,6]. In contrast, *Felkin et al.* stated that "polar effects stabilize those transition states in which the separation between the incoming nucleophile and the electronegative group is greatest", as in **5** (L = electronegative group)[4]. *Anh*'s MO calculations show that **6** (L = chlorine) is, in fact, the most reactive conformation because $\pi^*_{C=O}$-σ^*_{C-Cl} interaction provides a low-lying LUMO. Attack *anti* to L avoids certain anti-bonding interactions which occur in a *syn*-trajectory (see arrows in **6**)[5].

For α-alkoxy or hydroxy carbonyl compounds, the electronegative oxygen substituents exert potentially analogous effects. However, a different phenomenon is also possible, namely chelation, which makes the *opposite* π-face sterically more accessible. In such cases, *Cram*'s cyclic model pertains[1,3] (see **8**)[7].

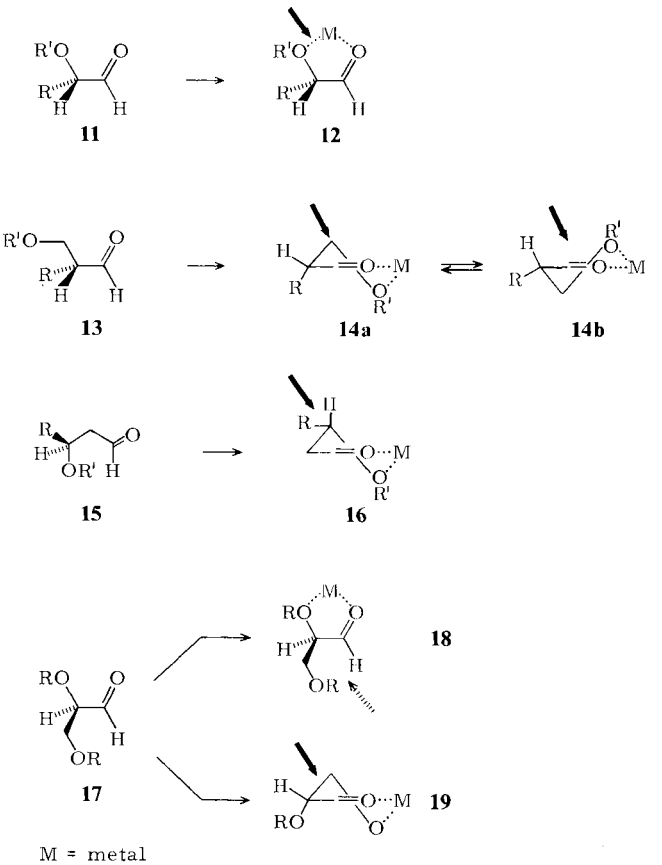


7 **8**

9 86 : 14 **10**

This review focuses on recent developments in controlling chelation or non-chelation in diastereogenic additions to α- and β-alkoxy (and -hydroxy) aldehydes and ketones. Several reviews covering certain aspects of chelation as well as other types of "acyclic stereoselection" have appeared elsewhere[1,8,9].

We shall call the respective dominant diastereomer chelation controlled or non-chelation controlled (Felkin-Anh products)[*]. The aldehydes **11**, **13**, and **15** (and the analogous ketones) react with Lewis acids to give the chelates **12**, **14a**, and **16**, respectively, the arrows indicating the preferred direction of attack. Instead of **14a**, the other half-chair conformation **14b** can also be invoked. With the dialkoxy aldehyde **17**, α-coordination leads to **18** and β-coordination to **19**, in which opposite diastereotopic faces of the carbonyl group are exposed. Chelation in **19** is analogous to that in **14a**, but diastereoselectivity might be expected to be enhanced because the non-complexed RO group facilitates an "Anh-effect". For non-chelation control, it is clear that reagents *not* capable of bidentate complexation are necessary.



11 **12**

13 **14a** **14b**

15 **16**

17 **18** **19**

M = metal

Besides 1,n-asymmetric induction, a different type of stereochemical problem may arise. If a C-nucleophile such as an enolate is prochiral, addition to an *achiral* aldehyde creates two new chiral centers by linkage of two sp^2-hybridized C atoms. Diastereodifferentiation in such a process has been termed "simple diastereoselectivity", and forms the basis of most of the recent work on aldol reactions[10] and related additions of crotylmetal compounds[11].

If the aldehyde is *chiral*, such as **11**, **13**, **15**, or **17**, this type of stereoselection and the problem of diastereofacial selectivity (chelation or non-chelation) are both relevant. Thus, a maximum of *four* diastereomers may be formed. In the absence of special effects, the rules for predicting sim-

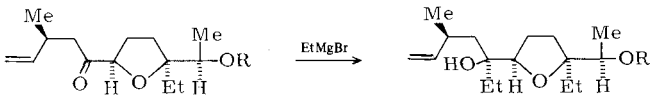
[*] The latter has sometimes been called the anti-Cram product. However, this may cause confusion because the term was first used for *Cram*'s acyclic model (e.g., **1**→**2**).

ple diastereoselection for achiral aldehydes[10,11] also apply to chiral compounds. Efficient methods for stereoselective Grignard and aldol additions to chiral alkoxy carbonyl compounds are of importance for the synthesis of natural products, e.g. ionophores, pheromones, and carbohydrates[2,8,9].

2. Chelation-Controlled 1,2-Asymmetric Induction

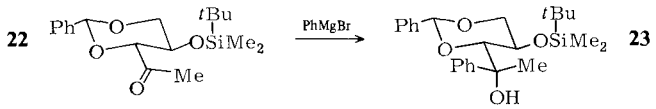
2.1. Grignard, Alkyllithium, and Cuprate Reagents

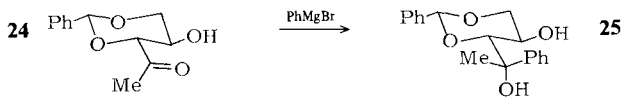
In early work *Cram* et al.[3,7] and later *Stocker* et al.[12] studied the addition of RMgX and RLi to α-alkoxy (and hydroxy) carbonyl compounds and were able to rationalize most of the data by assuming chelation of the type **12**. The ratio of chelation- to non-chelation-controlled products ranged between 55:45 and 96:4. Exceptions were "explained" by invoking competition between cyclic, dipolar, and open-chain models. Thereafter, further examples of more or less useful levels of diastereoselectivity became known[1,13]. Generally, low temperatures are beneficial, although the converse has been observed[14]. An example involving complete chelation control was reported by *Kishi* et al., **20** → **21** being one of the key steps in their synthesis of the isolasalocid ketone[15].



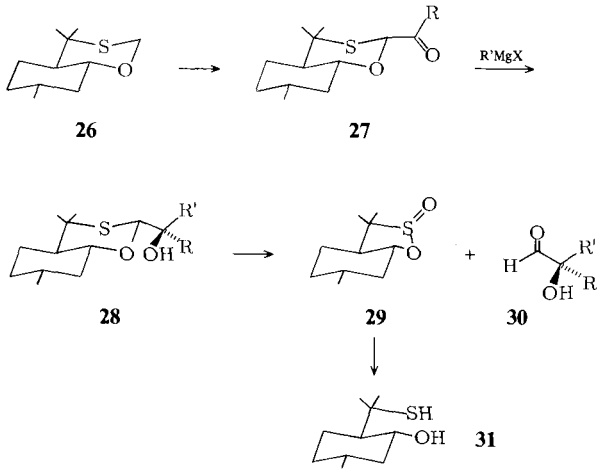
20 **21**

Horton et al. have described reactions in which the choice of protecting groups controls the sense of stereoselectivity[16]. Ketone **22** reacts with phenylmagnesium bromide to form **23** via α-coordination; the β-oxygen carries a bulky silyl group which prevents competitive β-coordination. In case of **24**, use of excess Grignard reagent first deprotonates the hydroxy group, the intermediate Mg-alkoxy moiety then inducing β-chelation. A number of α-alkoxy and α-hydroxy aldehydes and ketones in steroids have been shown to undergo pronounced chelation-controlled Grignard-type additions[8,17], but exceptions are known[18].

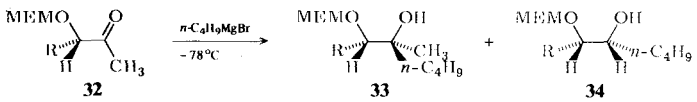




In all these cases, the old and the newly created chiral centers form part of the target molecule. It is also possible to destroy the original chiral center via some sort of cleavage (sacrificial asymmetric synthesis). For example, several groups have reported stereoselective Grignard additions to certain carbohydrates followed by oxidative cleavage, a sequence which creates a new chiral center at the expense of the old one[1,9,19]. However, if the chiral adjuvant is expensive, this is unacceptable. Recently, *Eliel* et al.[9,20] and *Mukaiyama* et al.[21] have devised ingenious systems which solve this problem. The starting point of *Eliel*'s strategy is the conversion of **26** (available from (+)-pulegone) into **27**. Grignard addition then occurs stereoselectively via α-oxygen chelation to form **28**. The fact that α-sulfur coordination does not compete was explained using the HSAB principle. Aldehyde **30** (>90% *ee*) can be liberated and the chiral starting material **31** recovered. Other 1,3-oxathianes have also been described[9]. In the system studied by *Mukaiyama* et al., α-amino ketones in which proline derivatives are incorporated form the basis of chelation control[21].



Since chelation control is *not always* efficient[1,9,18], *Still* et al. carried out systematic studies in which the type of alkoxy group, the carbon nucleophile, solvent, and temperature were varied[22]. It was found that ketones of the type **32** fail to react stereoselectively with alkyllithium reagents (e.g., *n*-butyllithium), in contrast to Grignard compounds, and that these reactions show dramatic solvent effects, tetrahydrofuran (THF) being the medium of choice.



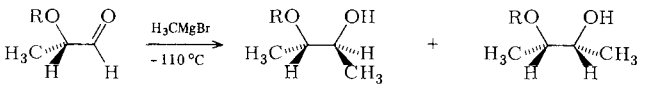
32 **33** **34**

R = *n*-C_7H_{15}
MEM = $CH_2OCH_2CH_2OCH_3$

ether	90	:	10
THF	>99	:	<1
CH_2Cl_2	94	:	6
n-C_5H_{12}	90	:	10

The methoxyethoxymethyl (MEM) group has two additional oxygen atoms, so that chelation involving a "crown-ether effect" is conceivable. However, this appears not to be necessary, since α-benzyloxy groups also facilitate complete chelation control. In their synthesis of the polyether antibiotic monensin, *Still* et al. made use of these generalities to construct one of the building blocks[23]. Another elegant application pertains to the total synthesis of (+)-zoapatanol by *Nicolaou* et al.[24]. RLi sometimes reacts more selectively than RMgX, a phenomenon which has not yet been explained mechanistically[1,9].

Unfortunately, the extremely high levels of 1,2-asymmetric induction observed with ketones do *not* extend to analogous aldehydes[25], in line with previous studies[8,9,18]. Perhaps this is due to the lower Lewis basicity of aldehydes. Thus, addition of CH_3MgBr to aldehyde **35** affords

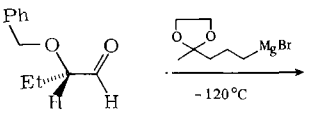


35 **36** 91 : 9 **37**

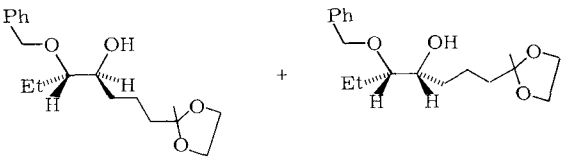
R = CH_2OCH_2Ph

36 and **37** in the ratio 91:9. Since this was the only aldehyde studied, it is not clear whether the benzylmethoxy group is necessary for the attainment of this level of selectivity.

Later experiments showed that the choice of reaction conditions, type of protecting group, and Grignard reagent are crucial, as evidenced by the fact that the α-benzyloxy analogue of **35** reacts with CH_3MgI fairly unselectively (60:40 ratio)[26]. Addition of Grignard reagents to **38** provides another example[27].



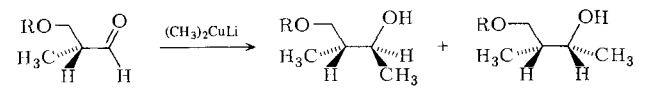
38



39 60 : 40 **40**

Recently, further examples of low levels of chelation control in the addition of Grignard reagents to chiral α-alkoxy aldehydes have been reported; these include compounds having various types of alkoxy groups such as methoxymethyl (MOM) and pyran moieties[13,28]. Clearly, other approaches to this problem are necessary (Section 2.3).

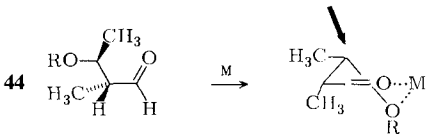
If we now consider β-coordination (see **14**), compounds of the type **41** do not react stereoselectively with RMgX or RLi, in contrast to cuprates[25]. For example, $(CH_3)_2CuLi$ adds to **41a** to afford **42a** and **43a** in the ratio 97:3. The benzyloxy analogue **41b** reacts only slightly less selectively. However, chelation-directed diastereoselectivity is not observed if the oxygen atom in the alkoxy residue is sufficiently hindered, as in the *O*-trityl derivative **41c**[25].



41 **42** **43**

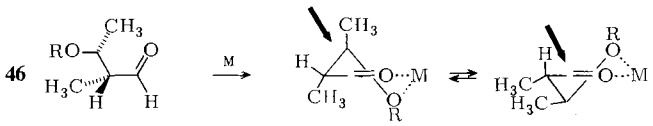
a, R = CH_2OCH_2Ph	97	:	3
b, R = CH_2Ph	95	:	5
c, R = CPh_3	≈ 33	:	67

It is unclear why cuprates, but not RMgX or RLi, lead to efficient β-chelation[25]. Nevertheless, **14** is a useful model since it also predicts stereoselectivity for compounds having an additional chiral center at the β-position. Thus, **44** shows the usual diastereofacial selectivity with $(CH_3)_2CuLi$ (>95:5), whereas **46** gives a product ratio of 2:1[25]. Although the authors do not provide a reason for this dramatic difference, chelation of **46** in a manner analogous to **45** gives rise to **47a**, in which the axial β-methyl group hinders the incoming nucleophile. An alternative conformation **47b**, in which the two methyl groups are equatorial, is also likely to react less stereoselectively than **45**.



44 **45**

R = CH_2OCH_2Ph



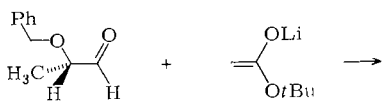
46 **47a** **47b**

R = CH_2OCH_2Ph; M = metal

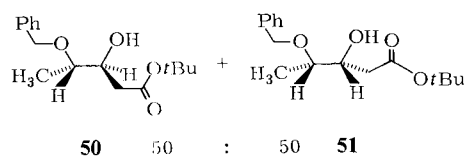
In summary, notable advances have been made in inducing chelation with the aid of RMgX, RLi, and R_2CuLi. However, a number of problems persist, and the present level of mechanistic understanding is unsatisfactory. The role played by the aggregation state of the reagents or type of solvent are poorly understood. In carbohydrate chemistry (Section 5), the situation is sometimes even less clear.

2.2. Aldol Additions with Lithium- and Magnesium-Enolates

With a few exceptions, lithium enolates add to α-alkoxy aldehydes either completely unselectively or show some degree of non-chelation control[10] (Section 4). For example, **48** reacts with the ester enolate **49** without any diastereofacial selectivity[10].

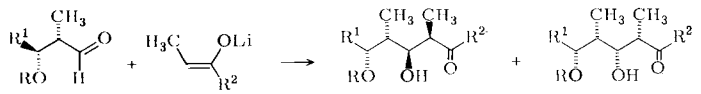


48 **49**



50 50 : 50 **51**

In contrast, certain β-alkoxy aldehydes having centers of chirality at the α- or β-position display useful levels of chelation control, as shown by *Masamune* et al.[29]; since they used prochiral enolates, simple diastereoselectivity is also involved. Several aldehydes **52** were allowed to react with



52 **53** **54** **55**

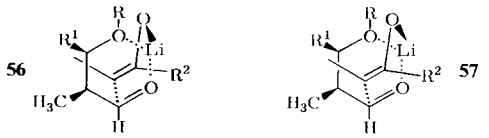
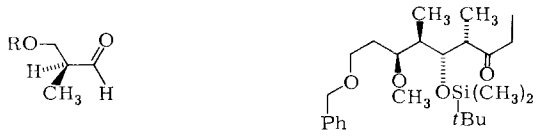
*t*BuMe$_2$SiOCH$_2$CH$_2$	*cyclo*-C_6H_{11}	95	:	5



56 **57**

enolates **53**, leading mainly to **54** and **55**, in addition to small amounts of the other two possible diastereomers. The preferred formation of **54** was explained by assuming coordination of the lithium cation by *three* oxygen atoms, as shown in **56**, rather than the sterically less favorable transition state **57**. This hypothesis neglects the state of aggregation of the enolates, but is nevertheless useful. Simple diastereoselectivity is *syn* (Masamune nomenclature) and depends upon the configuration of the enolate[10].

Chelation control in the reaction of **58** with the lithium enolate of ketone **59** is not as efficient (product ratio 75 : 25)[29]. Apparently, stereoselectivity is only pronounced if the system is "loaded" with additional groups at the β-position, as in **52** (R^1 = alkyl). This is plausible on the basis of the model shown in **56**. Chelation control is expected to decrease if the relative stereochemistry of the two chiral centers in **52** is reversed, but this has not been tested (cf. **44** vs. **46**).



58, R = $CH_2OCH_2CH_2SiMe_3$ **59**

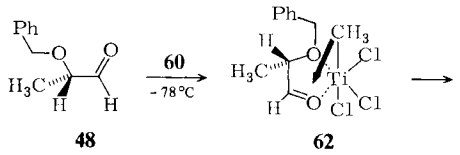
Why do α- and β-alkoxy aldehydes show such different behavior in classical aldol additions? Perhaps the Masamune decalin-like transition state in the β-case is energetically favored relative to the more strained hydrindane-like transition state which would have to be transversed in case of α-alkoxy aldehydes. It should be noted that lithium enolates derived from esters generally do not show chelation effects in reactions with β-alkoxy aldehydes (Section 4), the reason for this being unclear[10]. Systematic studies involving magnesium enolates have not appeared[23], although in one case chelation seems to be slightly better compared to the lithium analogue[29].

2.3. Other Organometallic Reagents

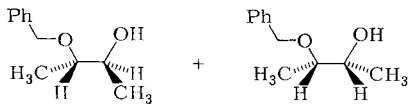
In early studies devoted to the application of organotitanium reagents to organic synthesis, we discovered that **60** undergoes chemo- and stereoselective C-C bond forming reactions with carbonyl compounds[30] and S_N1-active alkyl halides[31]. Some of these reactions depend upon the pronounced Lewis acidity of **60**. Furthermore, **60** as well as titanium tetrachloride **61** readily form octahedral complexes with two donor molecules (e.g., ether, THF) or with bidentate ligand systems[32-34]. These observations set the stage for testing Lewis-acidic titanium reagents in chelation-controlled reactions of alkoxy carbonyl compounds.

60 H_3CTiCl_3 $TiCl_4$ **61**

Addition of **60** (prepared quantitatively from dimethylzinc and $TiCl_4$ in CH_2Cl_2) to the aldehyde **48** led to **63** and **64** in the ratio 92 : 8, consistent with an intermediate of the type **62**[26].



48 **62**



63 92 : 8 **64**

48 can also be "tied up" by $TiCl_4$ and selectively alkylated by adding mild C-nucleophiles such as dialkylzinc, allylsilanes, or allylstannanes which do not destroy chelation (e.g., **48** → **65**)[26]. For comparison, allylmagnesium chloride reacts with **48** to afford **65b** and **66b** in the ratio 60 : 40. In the addition of allylsilanes, we found the somewhat milder $SnCl_4$ to be equally well suited[35,36], as also reported by *Heathcock* et al.[37]. $TiCl_4$ and $SnCl_4$ are similar in that both are capable of forming six-coordinate octahedral complexes[34]. Interestingly, $MgBr_2$-etherate in CH_2Cl_2 (−30 °C/3 h) also promotes this reaction, but the stereoselectivity (70 : 30) and conversion (ca. 50%) are inferior[36]. One equivalent of Al_2Cl_6 ($AlCl_3$ is dimeric in solution) affords **65b** and **66b** in the ratio 85 : 15 (CH_2Cl_2/−78 °C/3 h; ca. 80% conversion)[36]. In contrast, BF_3 is incapable of chelating, and in fact causes reversal of diastereoselectivity (Section 4).

	65		**66**
a, R = *n*Bu	90	:	10
b, R = $CH_2CH{=}CH_2$	>93	:	<7
c, R = $CH_2C(Me){=}CH_2$	>95	:	<5

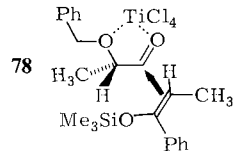
Silyl enol ethers **67** are also excellent C-nucleophiles[26]. This is synthetically important, because they constitute the

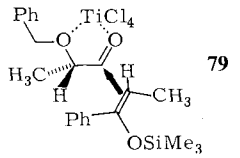
	67	68		69
a, R^1 = H, R^2 = Ph		96	:	4
b, R^1 = H, R^2 = *t*Bu		>95	:	<5
c, R^1 = CH_3, R^2 = OCH_3		>97	:	<3

only currently known class of compounds for chelation-controlled aldol additions to α-alkoxy aldehydes.

In view of this, it was of interest to determine how prochiral silyl enol ethers behave. In the reaction of the complex **48**/$TiCl_4$ with pure **70a**, *essentially only one of four possible diastereomers is formed*[26]. The X-ray structure determination of **71** shows that it is the chelation-controlled product in which simple diastereoselectivity is *syn*. Since the Mukaiyama aldol addition involving normal aldehydes is known to be non-selective[38] (e.g., **70a** reacts with propanal/$TiCl_4$ to form a 66:34 *syn/anti*-mixture[39]), this stereoselection is remarkable. **48**/$SnCl_4$ + **70a** gives the same result[26]. Activation of an aldehyde RCHO by Lewis acids is generally assumed to occur by complexation to the carbonyl group *anti* to the R group (Section 6); however, chelation necessarily involves *syn*-complexation, and this may be the determining factor for the unexpectedly high simple diastereoselectivity. This special effect was first observed in reactions of β-chiral, β-alkoxy aldehydes[39] (Section 3) and thus appears to be general. Indeed, the influence of chelation on simple diastereoselectivity is also apparent in the reaction of the *achiral* aldehyde **75**. For α-chelation, $SnCl_4$ is often more efficient than $TiCl_4$[40].

The lithium (*Z*)-enolate corresponding to **70a** shows non-chelation control (**71** : **72** : **73** : **74** = 10:60:30:0), and the zinc analogue is non-selective (11:23:50:16 ratio). Addition of preformed trichlorotitanium enolate (generated by adding $TiCl_4$ to **70a**) results in chelation control: (**71** : **72** : **73** : **74** = 89:8:3:0). In order to gain further mechanistic information, **48**/$TiCl_4$ was allowed to react with the (*E*)-isomer **70b**[40]. The product distribution 85:0:0:15 shows that complete chelation control again pertains, and that the sense of simple diastereoselectivity is *independent* of the configuration of the silyl enol ether. This suggests participation of the open-chain transition states **78** and **79**.





Although this and alternative models correctly predict chelation control, the prediction of the sense of simple diastereoselectivity is more difficult[26,40]. Not only the methyl group of the enolates **70**, but also the relative steric bulk of the other two enolate substituents exert steric influence. For example, replacing the phenyl group in **70a** by ethyl, reverses simple diastereoselectivity, i.e., the (*Z*)-silyl enol ether from 3-pentanone reacts with **48**/$TiCl_4$ with complete chelation control, but the simple diastereoselectivity is *anti* (*anti/syn* = 82:18)[36]. Furthermore, a (*Z*)/(*E*)-mixture of 66:34 leads to an *anti/syn* distribution of 56:44. The influence of different enolate substituents is also apparent in ester additions (Table 1)[36]. Included are the lithium enolates, which afford Felkin-Anh products

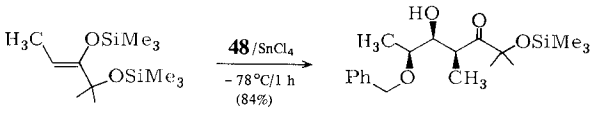
$TiCl_4$	90	:	10
$SnCl_4$	95	:	5

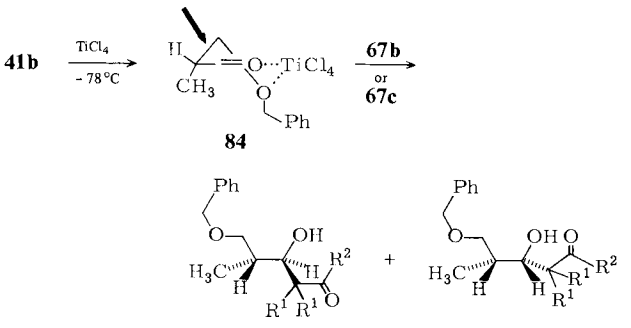
preferentially (titanium enolates are better suited, as discussed in Section 4).

An important example illustrating the usefulness of the present methodology involves the addition of silyl enol ether **82** to **48**/$SnCl_4$, which results in a single diastereomer **83**[40]. The lithium enolate affords a mixture[10], and **48**/$TiCl_4$/**82** fails to react[40].



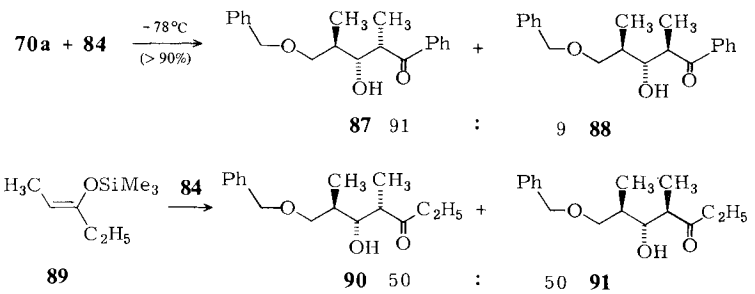
82 **83**

In the β-alkoxy series, chelation-controlled aldol additions involving **84** are also possible, e.g., by using the silyl enol ethers **67b** and **67c** from pinacolone or isobutyric acid ester[41]. Allylsilane additions are slightly less selective[35,37,41].

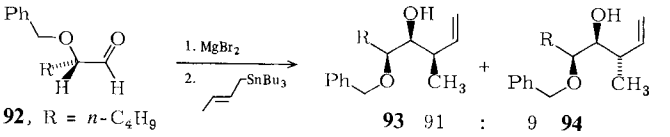


a, R^1 = H, R^2 = *t*Bu 95 : 5
b, R^1 = CH_3, R^2 = OCH_3 >97 : <3

Prochiral **70a** adds to **84** with complete chelation control, simple diastereoselectivity also being excellent (*syn* : *anti* = 91 : 9)[40]. The other two diastereomers are not formed. Again, chelation boosts simple diastereoselectivity. **89** also adds to **84** with chelation control, but not with any degree of simple diastereoselectivity[36].



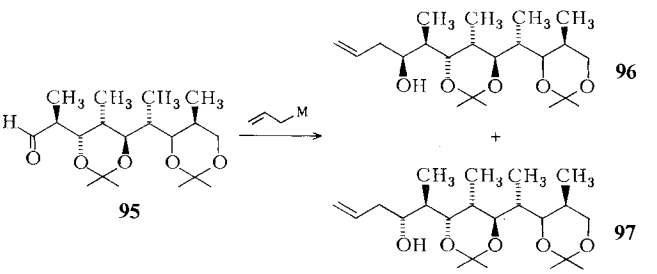
In summary, $TiCl_4$- or $SnCl_4$-induced additions of R_2Zn, silyl enol ethers, or allylsilanes to α- and β-alkoxy aldehydes have emerged as a powerful synthetic tool, and further progress involving other nucleophiles and/or more complicated aldehydes and ketones with two chiral centers is likely. In fact, allyl- and crotylstannanes add to α-alkoxy aldehydes in chelation-controlled processes mediated by Lewis acids such as $TiCl_4$, MgX_2, or ZnX_2, as recently



92, R = *n*-C_4H_9 **93** 91 : 9 **94**

shown by *Keck* et al.[42]. Since the stereochemistry of Lewis acid-mediated addition of crotylstannane to achiral aldehydes is known to be *syn*[11], good chelation control *and* simple diastereoselectivity in the reaction of **92** to **93/94** come as no surprise.

A $ZnBr_2$-mediated Grignard reaction has been reported, but its generality is unknown[43]. Allylzinc or -tin reagents (in the absence of catalysts) have not been investigated in a systematic way, but *Kishi* et al. reported interesting results for aldehydes of the type **95**[44]. Depending on its state of purity, diallylzinc reacts with **95** to afford **96** and **97** in the ratios 82 : 18 to 94 : 6. The CH_2=$CHCH_2I$/$SnCl_2$ system is



even more selective (96 : 4). A chair *trans*-decalin-type of transition state **98** is believed to be involved, in contrast to the energetically less favorable boat analogue **99** or *cis*-decalin-like conformations[44]. In **95** and in similar compounds, the relative configuration of the chiral centers is expected to influence the degree of chelation control. Such effects are indeed observed and can be rationalized[44].

With the exception of RLi and RMgX, little is known about the addition of organometallics to alkoxy *ketones*. Methylzirconium and -titanium reagents add to α-alkoxy ketones with levels of chelation control which equal or surpass analogous reactions with RMgX[45,46].

3. Chelation-Controlled 1,3- and 1,4-Asymmetric Inductions

Control of 1,3-asymmetric induction in Grignard and aldol additions to acyclic carbonyl compounds of the type **100** is not possible using reagents such as RMgX, RLi, R_2CuLi, lithium enolates, or allylboron compounds[25,39,47]. We were able to solve this problem in the same manner as in 1,2-stereocontrol, i.e. by employing Lewis-acidic titanium reagents (Section 2.3). Thus, **100** is converted into **102** with unprecedented diastereofacial selectivity[39] (Table 2). Based on these observations, it was subsequently found that $SnCl_4$ is also a useful Lewis acid for allylsilane additions[35,37].

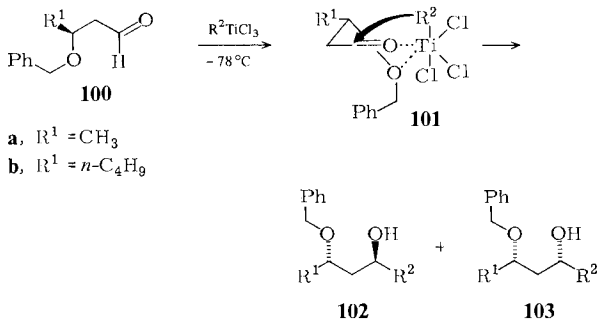


Table 2. 1,3-Asymmetric induction in addition reactions of **100** [39].

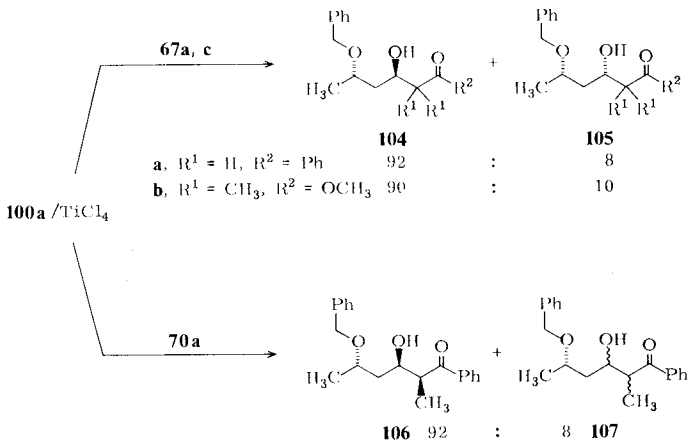
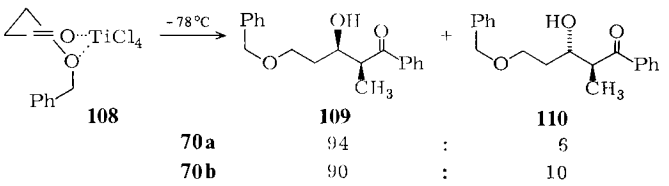
[a] All reactions at −78 °C in CH_2Cl_2; for $TiCl_4$, complexation and reaction at −78 °C.

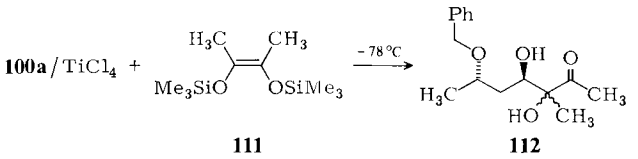
The use of silyl enol ethers facilitates 1,3-asymmetric induction in aldol reactions for the first time[39]. Remarkably, **70a** adds to **100a**/$TiCl_4$ to provide essentially only one (**106**) of four diastereomers. Simple diastereoselectivity is *syn*. **100a**/$SnCl_4$ affords three diastereomers; β-chelation is thus more effective with $TiCl_4$.



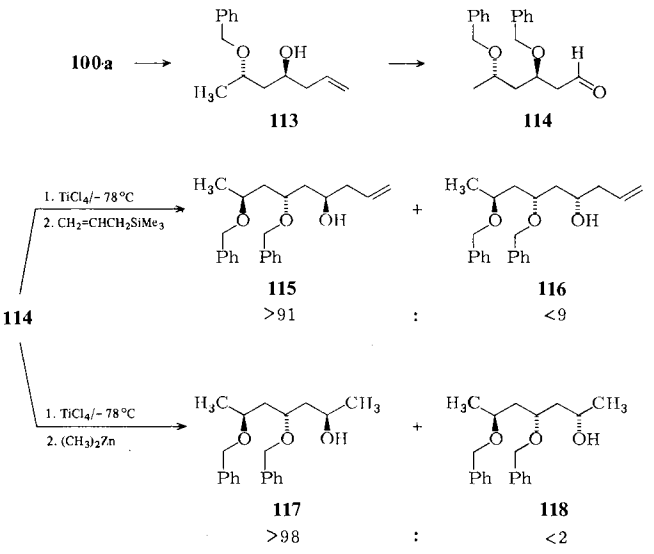
In order to explore the effect of chelation on simple diastereoselectivity, reactions of chelated achiral 3-benzyloxypropanal **108** with (*Z*)- and (*E*)-**70** were preformed. Stereoselectivity is independent of the enolate configuration. This is in accord with an "acyclic" approach of the silyl enol ether to **108** (see Section 2.3), but certainly does not prove such a mechanism.



Complete 1,3-asymmetric induction is also possible using the bis(trimethylsilyl) enol ether **111**, which adds to **100a**/$TiCl_4$ to afford only two of four possible diastereomers (>70:30). Both products are chelation controlled, but the simple diastereoselectivity has not been elucidated[36].

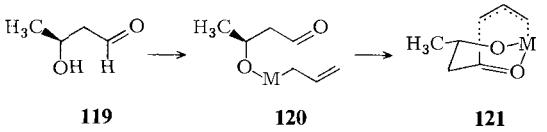


The idea that allyl- and crotylmetal reagents can be used as "masked enolates" has been developed by *Hoffmann* et al.[11,48]. We have applied this strategy to perform iterative additions. For example, the allyl adduct **113** (prepared on

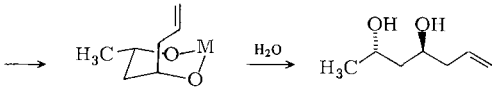


an 80 mmol scale in 92% yield and in >99% isomeric purity after one distillation) was *O*-benzylated and ozonized, and the product **114** again subjected to chelation-controlled additions (−78 °C/5 min; conversion >85%)[36]. Repetitive 1,3-stereorelations involving hydroxy groups occur in certain natural products[49].

Strategies relating to *intramolecular transfer* of C-nucleophiles, such as **119** → **123**, are beginning to be considered. **119** reacts with tetraallylzirconium to afford **123** in 81% diastereoselectivity[39].

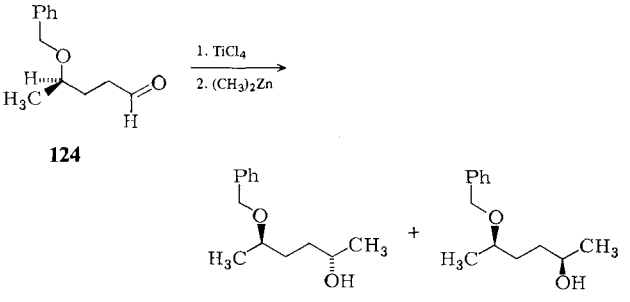


119 **120** **121**



122 **123**

Several cases of 1,4-asymmetric induction based on seven-membered chelates have been studied[26,45], e.g., **124** → **125** + **126**[26]. Allylsilane addition to **124** is 75% stereoselective[36].



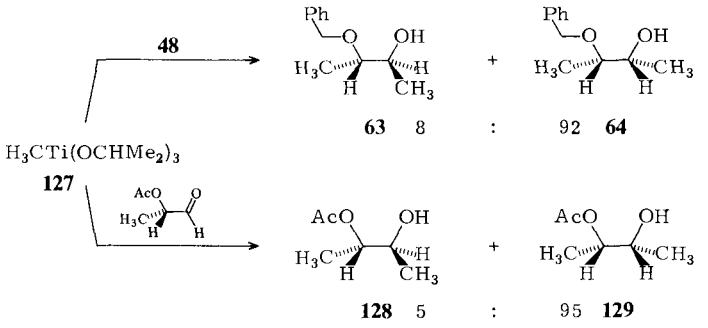
124

125 85 : 15 **126**

4. Non-Chelation-Controlled Additions

Non-chelation control is a formidable task because there is no general way to reduce the number of degrees of freedom of non-complexed molecules. Reagents incapable of chelation must be used and electronic and/or steric factors relied upon, notably those defined by the Felkin-Anh or Cornforth (dipolar) models. In fact, up till now reversal of diastereoselectivity in favor of non-chelation has only proved feasible for 1,2-asymmetric induction.

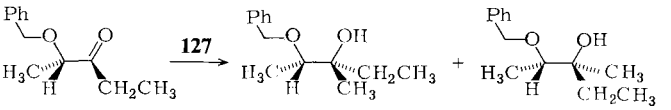
Since the Lewis acidity of alkyltitanium reagents decreases drastically in going from $RTiCl_3$ to $RTi(OR')_3$[50,51], we speculated that the latter might be *incapable* of chelation. Indeed, the complex $CH_3Ti(OCHMe_2)_3$ **127** reacts with **48** to afford preferentially the Felkin-Anh product **64** (**63** : **64** = 8 : 92)[26]. Presently, this is the only CH_3-metal compound known which permits non-chelation control. Thus, chelation or non-chelation control is possible in a predictable way simply by varying the ligands at titanium (CH_3TiCl_3 affords a 92 : 8 ratio; Section 2.3). For α-acetoxy aldehydes, stereo- and chemoselectivity is observed, as in the formation of **129**[50]. This methylation method is general and has been applied to carbohydrates (Section 5). The Felkin-Anh model (or possibly the Cornforth hypothesis) provides a satisfactory explanation.



63 8 : 92 **64**

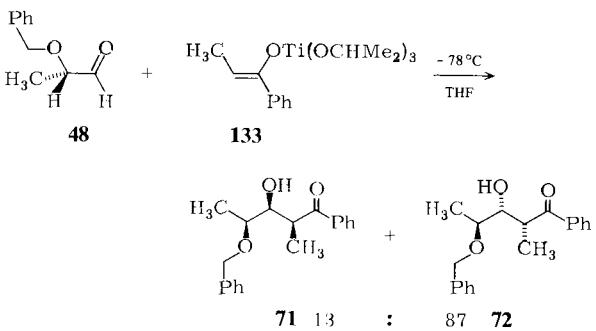
128 5 : 95 **129**

In view of these results, reaction of **127** with ketones such as **130** came as a surprise[46]. In this case the ratio of products **131** and **132** (>98 : <2) is the same as in the addition of CH_3TiCl_3 or CH_3MgCl to **130**! Either ketones are such strong Lewis bases that even **127** participates in chelation, or some other conformation is involved. Actually, theory predicts greater 1,2-asymmetric induction (Felkin-Anh-products) for ketones compared to aldehydes, because the π^*_{ketone} MO lies higher in energy than the $\pi^*_{aldehyde}$ MO, making $\pi^*_{C=O}$-σ^*_{C-X} mixing more important[52].



130 **131** >98 : <2 **132**

Titanium enolates of low Lewis-acidity react with chiral α-alkoxy aldehydes via non-chelation control[26]. A case in point is the addition of **133** to **48**, which affords only two of the four possible diastereomers[*]. This is another example of reversal of diastereoselectivity by substitution of chloro by alkoxy ligands at titanium. Simple diastereoselectivity is *syn*, as in reactions with achiral aldehydes[30,50].

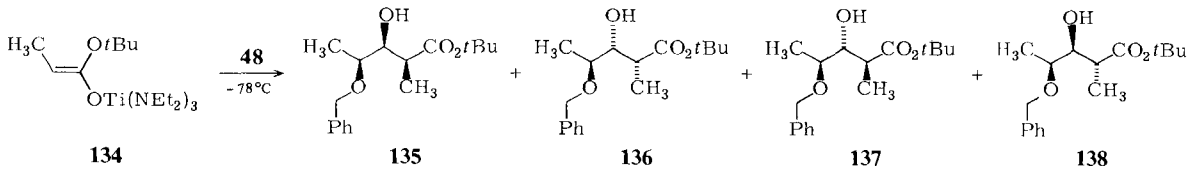


48 **133**

71 13 : 87 **72**

Sometimes tris(diethylamino)titanium enolates are better suited. With **134**, 93% non-chelation control and >90% simple diastereoselectivity are observed[36]. The corresponding Li-enolate affords all four diastereomers (Table 1), as does the triisopropoxytitanium analogue (**135** : **136** : **137** : **138** = 14 : 33 : 35 : 18)[36]. Other Li-enolates show modest levels of non-chelation control[10]. In these

[*] The configurational assignment with regard to simple diastereoselectivity in the formation of the major isomer **72** has now been ascertained by chemical correlation [41].



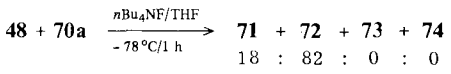
134 **135** **136** **137** **138**

(chelation/*syn*) (non-chelation/*syn*) (non-chelation/*anti*) (chelation/*anti*)

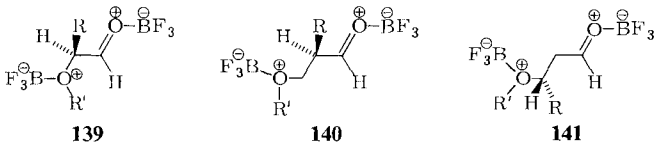
7 : 85 : 8 : 0

cases, *Heathcock* et al. have performed elegant experiments involving optically active enolates in order to increase diastereofacial selectivity[53]. The principle of double stereodifferentiation seems promising in this area.

A different approach to non-chelation control involves ammonium enolates. Using Noyori's method of fluoride ion induced aldol additions[54], we allowed **48** to react with **70a** under conditions of kinetic control and observed only two of the four diastereomers with 82% non-chelation control and 100% simple diastereoselectivity (*syn*)[41]. It remains to be seen to what extent this method can be generalized.



A third strategy makes use of Lewis acids which are incapable of chelation. By using two equivalents of gaseous BF_3, double complexation of **11**, **13**, and **15** might be expected to result in formation of adducts **139**, **140**, and **141** with rigid conformations due to electrostatic repulsion[41]. Nucleophilic attack from the less hindered side in **141** simulates chelation control, and this has been verified experimentally[35]. In contrast, **139** and **140** are expected to form products of non-chelation control.

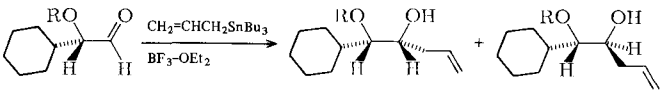


139 **140** **141**

R = CH_3, R' = CH_2Ph

Indeed, addition of allyltrimethylsilane or the silyl enol ethers **67b** and **67c** to **139** (−95°C/1 h) results in significant levels of non-chelation control (**65b** : **66b** = 20 : 80, **68b** : **69b** = 10 : 90 and **68c** : **69c** = 16 : 84)[41]. Addition of **67b** to **140** results in a product distribution **85a** : **86b** = 12 : 88, which is again synonymous with non-chelation control[41]. $BF_3 \cdot Et_2O$ is considerably less efficient. Besides the "Cornforth conformations", **139** and **140**, the results are also consistent with Anh's theory[41].

Keck et al. have shown that allylstannanes also undergo BF_3-mediated non-chelation-controlled additions[42]. For the bulky aldehyde **142**, the *tert*-butyldimethylsilyl protecting group results in higher selectivity than the benzyl group. However, useful stereoselectivity is not observed with other α-alkoxy or α-siloxy aldehydes (e.g., α-siloxy pentanal). For α-chiral, β-siloxy aldehydes, reaction with crotylstannanes results in excellent non-chelation control and simple diastereoselectivity (*syn*)[42].



142 **143** **144**

a, R = CH_2Ph 61 : 39

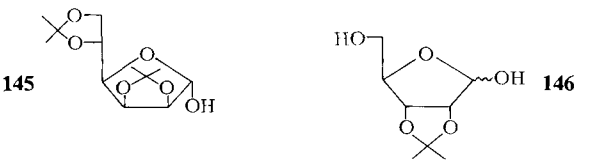
b, R = $SitBuMe_2$ >91 : <9

Although allylboron compounds might be expected to exhibit non-chelation control, selectivity in the reaction of α-benzyloxy propanal **48** with 2-allyl-4,4,5,5-tetramethyl-1,3,2-dioxaborolane is meager (**65b** : **66b** = 35 : 65)[55]. However, in sugar chemistry, aldehydes react very selectively with certain allylboron compounds (Section 5).

Finally, several special cases of non-chelation control in the addition of Li- and Mg-enolates to certain α-chiral, β-alkoxy (or siloxy) aldehydes have been reported. These include key steps in the synthesis of erythromycin A by *Woodward* et al.[56], maytansinoids by *Meyers* et al.[57], and monensin by *Still* et al.[23]. Nevertheless, there are not enough data to draw up general guidelines for enolate reactions of this type[10]. For non-chelation, Cram's rule may be applied.

5. Addition Reactions in Carbohydrate Chemistry

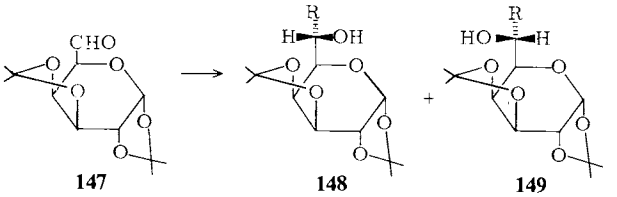
Although some of the general points mentioned in this article also apply to carbohydrate aldehydes and ketones, additional factors often have to be considered. Surprises and mechanistic uncertainties prevail in a number of situations. For example, Grignard additions to the mannofuranose **145** follow different stereochemical pathways, depending upon whether EtMgBr or HC≡CMgBr is used[58]. In contrast, **146** reacts with benzylmagnesium chloride to provide a single diastereomer having the D-*allo*-configuration[59].



145 **146**

In other cases, interpretation of the stereoselectivity using *Cram*'s cyclic model is straightforward. For example, several groups[60,61] have described chelation-controlled

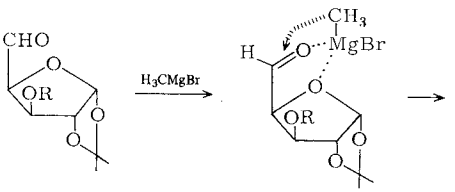
Grignard additions to D-galactose derivatives (e.g. **147**)[61]. According to *Schöllkopf*, α-chelation with the oxygen atoms of the carbonyl group and the pyran ring determines the sense of diastereofacial selectivity[61].



147 **148** **149**

H_3CMgBr	80	:	20
	>98	:	<2

Similarly, *Hanessian* et al.[62a] and *Inch*[62b] postulate chelation of the type shown in **151** to explain the preferred formation of **152** in the Grignard addition to **150**[62]. Coordination with the less basic β-benzyloxy group cannot compete effectively. In order to "turn off" chelation and thus to reverse diastereofacial selectivity, we performed the reaction with $CH_3Ti(OCHMe_2)_3$[26]. Exclusive formation of the Felkin-Anh product **153** is in accord with the non-chelation control observed with other aldehydes (Section 4), and documents the synthetic value of this methodology[26,50].

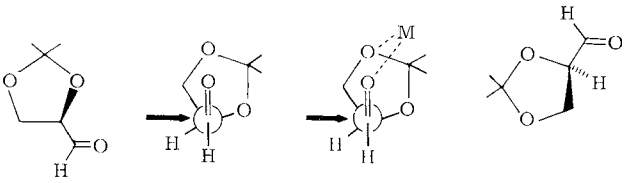


150, R = CH_2Ph **151**

	152		**153**
H_3CMgBr	88	:	12
$H_3CTi(OCHMe_2)_3$	<1	:	>99

2,3-*O*-Isopropylidene-D-glyceraldehyde **154** or its enantiomer as well as similar compounds have been allowed to react with a large number of Grignard reagents and enolates. Up to about 1980, most of the reactions reported were fairly unselective[10,63]. Since then enormous progress has been made by careful choice of reagents and conditions. These reactions are often the starting point of natural products syntheses. The diastereofacial selectivity of the reactions is *anti* (Masamune nomenclature)[*] and has generally been explained by the Felkin-Anh model **155**

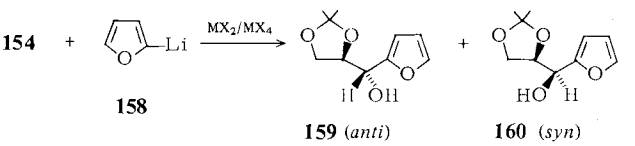
[*] The *syn/anti*-nomenclature is used both for the diastereofacial selectivity and for simple diastereoselectivity [1c].



154 **155** **156** **157**

without any complexation to the α- or β-oxygen. β-Chelation **156** has also been postulated and leads to a synergistic effect (type **19**). However, a Cornforth-type of conformation **157** also accommodates the data.

Mukaiyama et al. have published a series of papers in this area[64]. For example, in their synthesis of D-ribulose, addition to **154** constitutes the key step[65]. Table 3 shows that ZnX_2-mediated reactions are best. Although the nature of the actual reacting organometallic species is not known, **156** (M = Zn) was postulated.



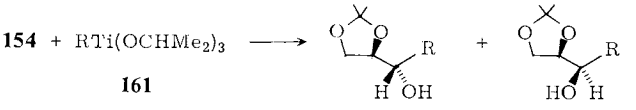
158 **159** (*anti*) **160** (*syn*)

Table 3. Stereoselective reaction of **154** to **159**/**160**.

MX_2/MX_4 [a]	*T* [°C]	Yield [%]	**159** : **160**
—	−78	68	40 : 60
$MgBr_2$	0	49	50 : 50
$SnCl_4$	0	58	95 : 5
$ZnCl_2$	0	60	90 : 10
$ZnBr_2$	0	75	95 : 5
ZnI_2	0	57	95 : 5

[a] All reactions in THF, except the $SnCl_4$-mediated addition (toluene).

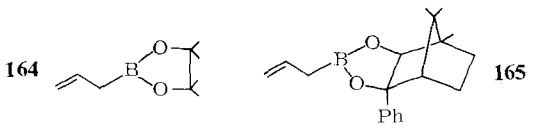
The stereoselective introduction of methyl groups into **154** is very difficult[63]. We therefore employed $CH_3Ti(OCHMe_2)_3$ in the hope of effecting non-chelation control. The ratio of *anti*:*syn*-adducts was in fact 75:25 (THF/−78 °C/5 h; >85% conversion)[66], which is not exceedingly good, but better than in previous methods[63]. *Mulzer* et al. have used organotitanium reagents to add other groups[67]. Oddly, the phenyltitanium reagent **161d** favors the *syn*-adduct **163d**, which is a rare exception in nucleophilic additions to **154**. *Mulzer* et al. have also studied other organometallic reagents (Li, Mg, Zn, and Cr) and discuss various models, including tridentate chelation involving the aldehyde function and both alkoxy groups[67].



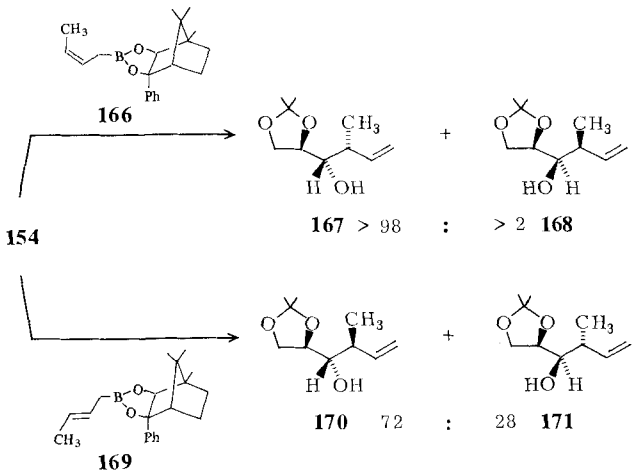
161 **162** **163**

a, R = CH_3	75	:	25
b, R = *n*Bu	90	:	10
c, R = CH_2=$CHCH_2$	71	:	29
d, R = Ph	9	:	91

Considerable effort has gone into adding allyl groups to **154**. Although diallylzinc affords a 91:9 ratio of **162c** : **163c**[67], a better result is reached using boron reagents. *Hoffmann* et al. have shown that switching from **164** to optically active **165** increases the **162c** : **163c** ratio from 80:20 to 96:4[68].

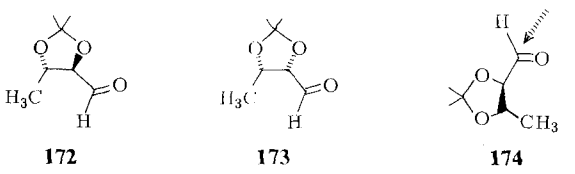


The optically active crotylboron reagents **166** and **169** have also been tested[68]. The former delivers one (**167**) of four diastereomers, the latter a mixture of **170** and **171**. Whereas simple diastereoselectivity depends in a predictable way on the configuration of the crotyl double bond[11,48], the phenomenon behind the different degrees of diastereofacial selectivity is not easily pinpointed. With racemic **169**, the **170** : **171** ratio dropped to 67:33, which shows that double stereodifferentiation is involved. Preliminary reactions involving other aldehydes indicate that the Anh model is *not* necessarily the optimal explanation[69]. Perhaps the reactions of allylboron compounds can be viewed as cycloadditions in which there is little flow of electron density from the reagent to the aldehyde[69].

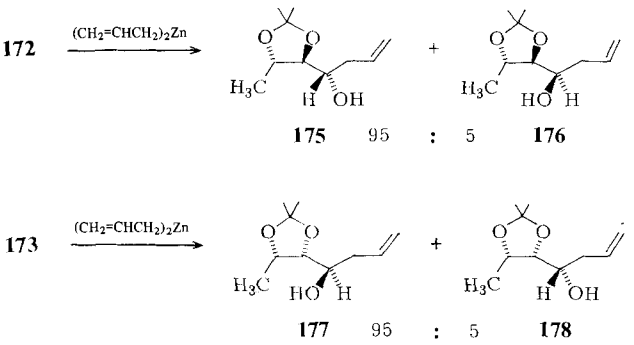


154 has also been used in other stereoselective additions[70]. Certain enolates are *anti*-selective to a greater or lesser extent[10,53]. Electrochemically generated dichloroacetate enolates add very selectively, as described by *Shono* et al.[71]. In all cases the Felkin-Anh model **155** was invoked to explain the stereoselectivity.

anti-Stereochemistry is also generally observed for β-substituted substrates of the type **172** and **173**. For the *trans*-isomer **172**, the same phenomena should operate as in **154**. The *cis*-compound **173** is different, because transition states of the type **155** or **156** would involve unfavorable steric interactions between the incoming nucleophile and the methyl group, an aspect which has not been discussed in the literature. It seems that a Cornforth-type of conformation **174** is a more plausible explanation for the observed *anti*-selectivity.



Fuganti et al. have reported many elegant additions of diallylzinc or propargylzinc reagents to **172** and **173** as well as to imine analogues[72]. The stereoselective formation of **175** and **177** are typical examples.

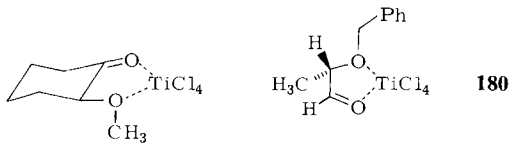


This method has been used for the synthesis of various natural products. An outstanding example is the synthesis of the amino sugars L-daunosamine and L-ristosamine from the phenylsulfenimines derived from **172** and **173**, respectively[73]. *Roush* et al. used allylboron compounds[11] to synthesize D-fucose derivatives[74]. An exception to the general rule regarding *anti*-stereoselection has recently been published, but not explained[75]. Also, *ketones* related to **154** react with RMgX to form preferentially *syn*-adducts[76]. Perhaps this involves chelation of the more basic ketone oxygen and the α-alkoxy group.

Finally, a number of related processes have been reported. These include hetero-Diels-Alder reactions of **154** as described by *Danishefsky* et al.[77]. Furthermore, Wittig reactions of **154** yield olefins, which have been used in stereoselective Diels-Alder reactions[78], 1,3-dipolar cycloadditions[79], cyclopropanation induced by phosphorus ylides[80], as well as Michael additions[81]. The observed 1,2-asymmetric induction can be explained on the basis of the Houk-model[82], which has some similarity to the Anh-theory.

6. Mechanistic Studies

Despite the synthetic progress in chelation and non-chelation control, shortcomings persist in terms of the mechanism. For example, the products of chelation control are usually rationalized solely on the basis of the stereochemical outcome. Until recently, no direct physical evidence for intermediate chelates had been presented. Although X-ray structural data on such species have not yet been completed, ^{1}H- and ^{13}C-NMR spectroscopic studies have been performed[26,66]. Thus, the NMR data for **179** (which reacts 100% stereoselectively with allylsilanes)[26] and **180** are consistent with the proposed structures.



179 **180**

Although a host of Lewis acid adducts with carbonyl compounds are known[34], no X-ray crystallographic data on ketone or aldehyde complexes are available[83]. Since the question of *syn*- or *anti*-complexation of aldehydes is of mechanistic importance, *Rademacher* et al. performed some MNDO calculations on the BF_3-adduct of acetaldehyde[84]. The difference in energy between the *anti*- (**181**) and *syn*-adduct (**183**) is only ca. 2 kcal/mol. The linear form **182** shows no minimum, but π-coordination has not yet been explored. Recently, *Helmchen* came upon the latter phenomenon in an X-ray crystallographic study of a $TiCl_4$-diester adduct[85]. Clearly, more work is necessary before details of mechanistic hypotheses become meaningful.

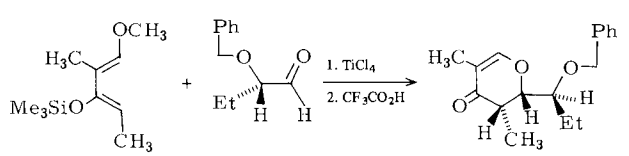
7. Conclusions and Addendum

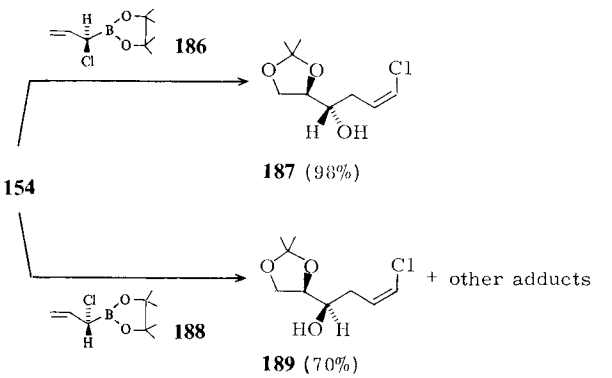
A variety of reliable methods for chelation control in nucleophilic additions to chiral α- and β-alkoxy carbonyl compounds are available. Further elaborations are certain to follow, including the use of synthetically useful C-nucleophiles not previously tested. A more difficult task is the development of new and better ways of non-chelation control. As far as predictive guidelines for the latter are concerned, any one of the qualitative models (Felkin, Anh, or Cornforth) may be used. It is a challenge to devise experiments which illuminate the real mechanism in a given case.

Since the submission of this manuscript, further progress has been made. A steroidal α-alkoxy aldehyde has been allowed to react with a lithium dienolate under conditions of chelation control, and the aldol adduct converted into withanolide D[86]. In an extension of their work on cyclocondensations of aldehydes with dienes of the type **184**, *Danishefsky* et al. have reported chelation-directed asymmetric C–C-bond forming reactions, e.g. the synthesis of **185**[87].



184 **38** **185**

Finally, *Hoffmann* et al. have carried out reactions based on the principle of double stereodifferentiation[69]. Whereas the optically active allyl boronate **186** reacts with **154** to form the *anti*-adduct **187**, diastereofacial selectivity is reversed if the enantiomer **188** is employed!



Our work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. I would like to thank Prof. R. W. Hoffmann for helpful discussions. My thanks are also due to my co-workers, especially K. Kesseler, A. Jung, S. Schmidtberger, and R. Steinbach.

Microbial Asymmetric Catalysis—Enantioselective Reduction of Ketones

New Synthetic Methods (45)

By Charles J. Sih* and Ching-Shih Chen

Microbial asymmetric reduction of ketones is a method widely used for the preparation of chiral alcohols. The present progress report deals with the basic concepts that govern enantioselectivity of enzymes and intact cells. Strategies to control the stereochemical course of microbial reductions of carbonyl compounds and the relationship of substrate structure to enantioselectivity are considered.

1. Introduction

The asymmetric reduction of carbonyl compounds by microorganisms, a method outside the traditional arena of chemical synthesis, is now well-recognized as an invaluable tool for the preparation of chiral alcohols. Because a single microorganism contains a number of oxidoreductases, it can mediate the reduction of a variety of artificial ketones to produce chiral alcohols of remarkable optical purity. Hence, in recent years reductions of this type have been used for the introduction of the key chiral centers in target molecules in numerous total syntheses[1]. In contrast, enantioselective reduction of ketones using "chemical" catalysts (e.g., organometallic compounds) has not been widely applied to asymmetric syntheses[2]. This is because of the difficulties associated with the design of such catalysts, which is still largely empirical and requires much chemical intuition.

In this article, the underlying principles of enantioselection for isolated enzyme systems and for intact cells will be addressed first, since the dependence of rates and enantioselectivities on structural features of substrates is based on a mechanistic understanding of these concepts. Also, this background facilitates the subsequent coverage of the examples on microbial enantioselective reduction of achiral ketones. This brief overview should provide the synthetic chemist with a useful guide for the application of this simple but powerful technique, now central to modern synthetic organic methodology.

2. Theory

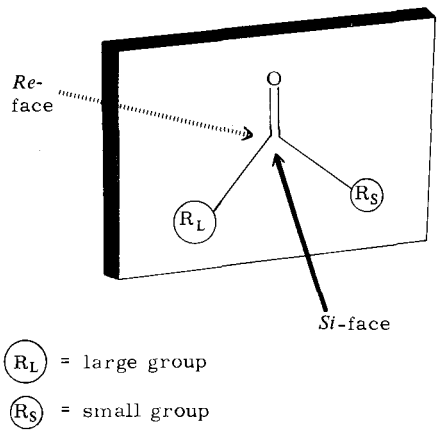
Although the present state of knowledge concerning asymmetric catalysis does not allow the prediction of the sense of chirality and the extent of asymmetric induction for a given substrate, there are certain important mechanistic concepts contributing to the process of enantioselection that merit attention. In general, asymmetric catalysis occurs because the chiral catalyst (enzyme) and prochiral substrate form diastereomeric transition states which differ in energy; the magnitude of their energy difference, $\Delta\Delta G^{\neq}$, determines the enantiomeric excess *ee*[3]. Unfortunately, this simplification has deterred many chemists from gaining a detailed understanding of the kinetic laws governing asymmetric induction. In the following, we shall attempt to discuss the origin of enantioselectivity using enzymic, enantioface discrimination as an example, but the same principles can be applied to asymmetric catalysis in general (enzymic and non-enzymic).

2.1. Isolated Enzyme Systems

Consider a prochiral ketone with enantiotopic faces *Re* and *Si*, and which is reduced to a chiral alcohol. Complexation of the chiral catalyst, the enzyme, on the *Re*-face leads to one enantiomer, whereas the other enantiomer is formed with the same probability through complexation on the *Si*-face. If the enzyme is unable to discriminate between the two faces, the resulting alcohol will be obtained as a racemate. High enantioselectivity is achieved only when the enzyme is capable of discriminating between the two enantiotopic faces. The enantioselectivity is generally expressed by the enantiomeric excess *ee*,

$$ee = ([R]-[S])/([R]+[S])$$

where $[R]$ and $[S]$ are the amounts of the enantiomers.



The reduction of a prochiral ketone by an isolated oxidoreductase generally requires the presence of either NADH or NADPH[4] as cofactors; these molecules furnish the reducing equivalents in the reaction. With the assumption that this reaction proceeds via an ordered mechanism and that NADH is used as the coenzyme, the en-

[*] Prof. C. J. Sih, C.-S. Chen

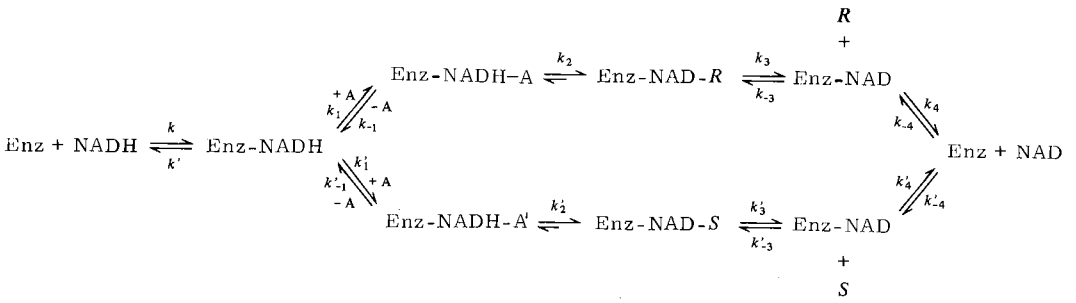
zyme first forms the complex Enz-NADH. Subsequently, the prochiral ketone A then binds to this complex either from the *Re*- or the *Si*-face with equal probability ($k_1 = k'_1$) to generate two ternary complexes (Scheme 1); the two complexes are held together with different degrees of tightness ($k_{-1} \neq k'_{-1}$). These complexes then undergo catalytic reduction to yield the (*S*)- and (*R*)-enantiomers, which are still bound to the enzyme-cofactor complex (Scheme 1).

$$RT\ln\frac{\left(\frac{k_{cat}}{K}\right)_1}{\left(\frac{k_{cat}}{K}\right)_2} = -(\Delta G^{\neq}_{T_1} - \Delta G^{\neq}_{T_2}) = -\Delta\Delta G^{\neq} \quad \text{(e)}$$

$$E' = \frac{\left(\frac{k_{cat}}{K}\right)_1}{\left(\frac{k_{cat}}{K}\right)_2} = \exp\left(-\frac{\Delta\Delta G^{\neq}}{RT}\right) \quad \text{(f)}$$



Scheme 1. Reaction mechanism for enzyme-catalyzed reductions.

Whereas Scheme 1 contains multi-step reactions, for enantioselection only those steps leading up to and including the first irreversible step (k_{cat}/K) are important. k_{cat}/K is the rate constant for the reaction of enzyme and substrate A at infinitely low substrate concentration ([A]→0). Thus, the enantioselectivity, E', of the system in Scheme 1 is dependent on the ratio k_{cat}/K [eq. (a)].

$$E' = \frac{\left(\frac{k_{cat}}{K}\right)_A}{\left(\frac{k_{cat}}{K}\right)_{A'}} = \frac{\frac{k_1}{1+C_r}}{\frac{k'_1}{1+C'_r}} \quad \text{(a)}$$

$C_r = k_{-1}/k_2$ and $C'_r = k'_{-1}/k'_2$.

According to the transition state theory[5], the equilibrium constant for the equilibrium between the transition state EnzA$^{\neq}$ and Enz+A is proportional to $\Delta G^{\neq}_T$, which is related to $\Delta G^{\neq}$, the activation energy of the bond-forming and -breaking steps, and ΔG_C, the (negative) complexation energy [eq. (b)].

$$\Delta G^{\neq}_T = \Delta G^{\neq} + \Delta G_C \quad \text{(b)}$$

These interrelationships are depicted in the energy-profile diagram (Fig. 1).

It can be shown that the kinetic constant, k_{cat}/K, is related to the thermodynamic term, $\Delta G^{\neq}_T$[6], as shown in equation (c).

$$RT\ln\left(\frac{k_{cat}}{K}\right)_1 = RT\ln\left(\frac{kT}{h}\right) - \Delta G^{\neq}_{T_1} \quad \text{(c)}$$

$$RT\ln\left(\frac{k_{cat}}{K}\right)_2 = RT\ln\left(\frac{kT}{h}\right) - \Delta G^{\neq}_{T_2} \quad \text{(d)}$$

k is the Boltzmann constant and h is Planck's constant. Subtracting equation (d) from equation (c), one obtains equation (e), which may be rearranged to yield equations (f) and (g).

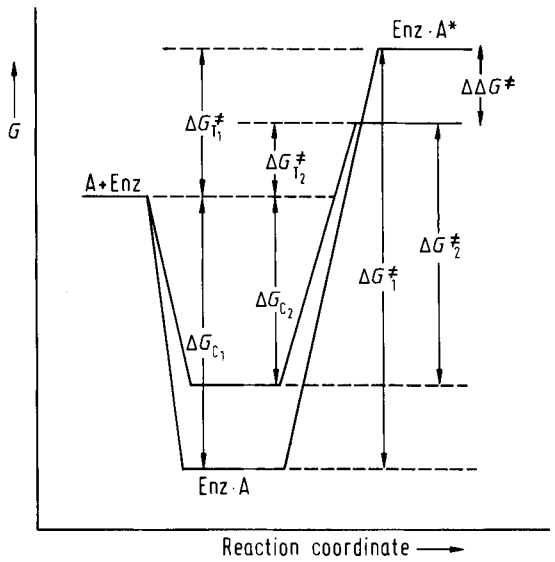


Fig. 1. Energy profile of a hypothetical enantioselective reaction.

$$\Delta\Delta G^{\neq} = -RT\ln E' \quad \text{(g)}$$

The dependence of E' and $\Delta\Delta G^{\neq}$ on the rate constants (barrier heights) of the competing reactions is shown in Table 1. These simulations provide a useful overview of the quantitative correlation between changes in the magnitude of each rate constant with the value of E'.

2.1.1. *High Enantioselection*

When the substrate (A and A') undergoes rapid and reversible exchange with Enz-NADH ($k_2 \ll k_{-1}$, $k'_2 \ll k'_{-1}$ (C_r and $C'_r \gg 1$), equation (a) simplifies to equation (h).

$$E' = \frac{k_1 C'_r}{k'_1 C_r} = \frac{C'_r}{C_r} \quad \text{(h)}$$

Table 1. Dependence of enantioselectivity E' and $\Delta\Delta G^{+}$ on the rate constants of two competing reactions (assumption: $k_1 = k'_1 = 10^6$).

No.	k_{-1}	k_2	k'_{-1}	k'_2	C_r	C'_r	E'	$-\Delta\Delta G^{+}$ (25 °C) [cal/mol]
1	0.01	100	0.01	10	0.0001	0.001	1.00	—
2	0.1	100	0.1	10	0.001	0.01	1.01	5
3	10	100	10	10	0.1	1	1.81	354
4	100	100	100	10	1	10	5.50	1010
5	100	10	100	1	10	100	9.18	1313
6	10	1	100	1	10	100	9.18	1313
7	1000	100	10	0.1	10	100	9.18	1313
8	100	1	100	0.1	100	1000	9.91	1358
9	100	1	1000	0.1	100	10000	99.0	2721
10	100	10	1000	0.1	10	10000	909.0	4034

The second-order rate constants k_1 lie typically in the range 10^6 to 10^8 M^{-1} s^{-1} for low molecular weight substrates[7]; these values are close to those for diffusion-controlled processes. Hence, the tightness of substrate binding is determined in most cases by the values of k_{-1}. Since the complexation of Enz-NADH with either A or A′ occurs with the same probability ($k_1 \simeq k'_1$), the enantioselectivity, E', is mainly dependent on the ratio of the reverse commitment to catalysis, C_r/C'_r. High enantioselection is achieved only when there is a rapid interconversion of the diastereomeric enzyme-ketone-coenzyme complexes compared with the rates of the subsequent catalytic step. The examples Nos. 1 and 4 in Table 1 illustrate this. While changes in either k'_{-1} or k'_2 alter the value of E', it is noteworthy that commitment to catalysis (C_r) is independent of the energy levels of the enzyme-substrate complex. In other words, when k'_{-1} and k'_2 are changed, but not their ratio (C'_r), the value of E' remains the same (Nos. 6 and 7 in Table 1).

2.1.2. *Poor Enantioselection*

When the substrate (A and A′) binds tightly to the enzyme complex, Enz-NADH ($k_2 \gg k_{-1}$; $k'_2 \gg k'_{-1}$; C_r and $C'_r \ll 1$), equation (a) simplifies to equation (i).

$$E' = \frac{k_1}{k'_1} \qquad \text{(i)}$$

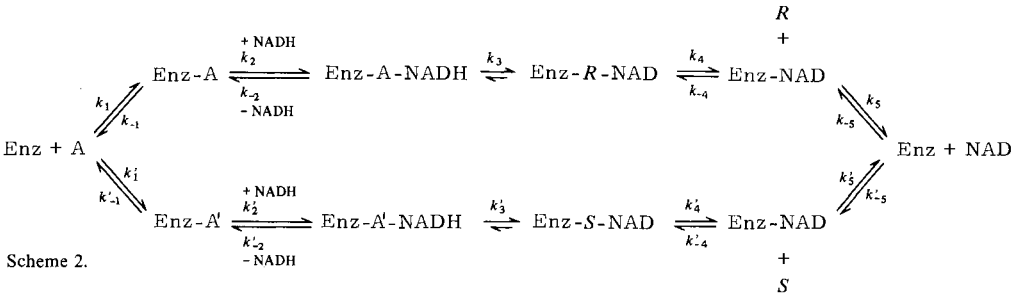
The enantioselectivity, E', is therefore now dependent on the ratio k_1/k'_1. Intuitively, this condition may be conceived as follows: during the first catalytic cycle, free enzyme proceeds through the upper and lower pathways (Scheme 1) to produce equal amounts of Enz-NADH-A and Enz-NADH-A′. Because $k_2 > k'_2$, more enzyme will proceed through the upper pathway than the lower to regenerate free enzyme. In each of the successive catalytic cycles, some Enz-NADH-A′ remains from the previous cycles (held back by slower k'_2) and continues to increase until the reaction attains a steady state, at which time

$$[\text{Enz-NADH-A}]k_2 = [\text{Enz-NADH-A}']k'_2$$

Hence the relative flow through the upper and lower pathways will be the same if $k_1 = k'_1$[8], because of the compensatory shift of the enzyme complexes in the steady state. In this situation, poor enantioselection results (Nos. 1 and 2 in Table 1).

For most oxidoreductases[9], the larger NAD(P)H does indeed bind first to the enzyme followed by the smaller ketone substrate. In these instances, enantioselectivity is independent of NAD(P)H and ketone concentrations. This treatment also holds for those oxidoreductases which obey the Theorell-Chance mechanism[10].

As the size of the artificial ketone increases, it may bind to the enzyme more tightly, and the mechanism could shift from ordered to random[11], as reported for some alternative substrates with the enzyme yeast alcohol dehydrogenase. For illustrative purposes, let us discuss what happens when the enzyme combines first with the prochiral ketone A and then with NADH (Scheme 2).



Scheme 2.

High enantioselection is attained only when there is rapid equilibration of the enzyme complexes

$$\text{Enz-A-NADH} \rightleftharpoons \text{Enz-A'-NADH}$$

In this case, the enantioselectivity, E', is related to the kinetic rate constants by equation (j).

$$E' = \frac{\left(\frac{k_{cat}}{K}\right)_A}{\left(\frac{k_{cat}}{K}\right)_{A'}} = \frac{\frac{k_1}{k_{-1}R + [\text{NADH}]}}{\frac{k'_1}{k'_{-1}R' + [\text{NADH}]}} \qquad \text{(j)}$$

where $R = \frac{k_{-2} + k_3}{k_2 k_3}$ and $R' = \frac{k'_{-2} + k'_3}{k'_2 k'_3}$

When the concentration of NADH is very low, equation (j) simplifies to equation (k), and E' is not affected by the low concentration of NADH.

$$E' = \frac{k_1 k'_{-1} R'}{k'_1 k_{-1} R} \qquad \text{(k)}$$

However, it should be noted that enantioselection decreases as the concentration of NADH is increased, since this reduces the reverse commitment to catalysis (C_r and C_r'); equation (j) then simplifies to equation (i). Enantioselectivity is not affected by the concentration of the prochiral ketone, but the concentration of NADH should be kept relatively low in preparative enzymic enantioselective reductions, especially when the artificial substrate can compete in size or binding affinity with NADH.

2.2. Intact Cells

One major complication in using intact cells for the catalytic reduction of ketones is that the process is often only partially enantioselective. This can be interpreted in two ways. 1) The ketone may be reduced by a single oxidoreductase which interacts with both faces of the carbonyl group to form two diastereomeric transition states, one of which is more favored than the other. 2) Two or more competing oxidoreductases in intact cells may generate alcohols of opposite configuration at different rates (depending on v_{max} and K). These two possibilities may be readily distinguished from each other by conducting the reduction at different substrate concentrations. In case 1), the enantioselectivity is independent of changes in substrate concentrations, whereas in case 2) it is not[12]. In our experience, virtually all partial enantioselective reductions emanate from the combined action of competing enzymes of opposite chirality in intact cells.

Despite the many enantioselective microbial reductions of ketones that have been reported, in most instances the enzyme(s) responsible for the catalytic reduction has (have) not yet been identified. Consequently, at present it is not possible to predict the configuration or the extent of asymmetric induction with any degree of confidence. Although there are a number of possible approaches to directing the stereochemical course of microbial reductions of carbonyl compounds, the one most suited to the synthetic chemist is to design substrates whose kinetic constants (apparent v_{max} and K (Michaelis constant)) for the competing oxidoreductases are considerably different. In theory, by making strategic changes in the structural features of substrate molecules, it may be possible to prepare optically pure alcohols of either configuration.

In the enantioselective reduction of ketones by two or more competing enzymes of intact cells, the three variables of interest to the synthetic chemist are A_0, the initial substrate concentration; C, the extent of conversion; and *ee*, the enantiomeric excess of the product alcohol. These key parameters are of course related to the apparent kinetic constants (v_{max} and K) of the competing enzymes. Although several methods are available for the determination of v_{max} and K of mixed enzyme systems in crude cell extracts, these apparent kinetic constants do not take into account additional variables: the number, relative concentration, and compartmentalization of competing enzymes; effective coenzyme concentration; permeability factors, etc. Hence, the apparent K and v_{max} values thus secured do not apply to intact cells.

Because of the difficulty of acquiring accurate initial rate measurements using intact cells at low substrate concentrations, especially for substrates which are not miscible with water, a time-independent method was developed to estimate the apparent kinetic constants (K and v_{max}) of intact cell systems.

The relationship of the three parameters, *ee*, A_0, and C to the apparent kinetic constants v_{max} and K is given by equation (l)

$$ee = 1 - 2\frac{A_0 C + (K_R - x)\ln\dfrac{A_0 + x}{A_0(1-C)+x}}{(1+y)A_0 C} \qquad (l)$$

where $x = \dfrac{yK_S + K_R}{1+y}$ and $y = \dfrac{v_{max(R)}}{v_{max(S)}}$

and $v_{max(R)}$, $v_{max(S)}$ and K_R, K_S denote maximal velocities and Michaelis constants for *R*-enzyme(s) and (*S*)-enzyme(s), respectively.

Two assumptions were made in the derivation of equation (l)[13]: the reaction is virtually irreversible and no product inhibition occurs. Both of these criteria are met since microbial reduction of ketones is generally irreversible when sufficient amounts of reducing equivalents are available, as is the case when the incubation mixture contains an exogenous source of either sucrose or glucose. Secondly, no product inhibition is observed until very late stages of the reaction.

Thus, by experimentally determining the values of *ee* and C at several initial concentrations A_0, the three unknowns, y, K_R, and x may be solved by numerical analyses using equation (l). This then allows one to obtain two useful dimensionless constants

$$z = [(v_{max(R)}/K_R)/(v_{max(S)}/K_S)] \quad \text{and} \quad y = v_{max(R)}/v_{max(S)}$$

which dictate the stereochemical course of the reduction; z is the ratio of the apparent first-order rate constants for the binding of substrate to the enzyme when $A_0 \ll K_R$ and K_S, and y is a measure of the ratio of catalysis by the competing enzyme systems. Knowing the values of $v_{max(R)}/v_{max(S)}$, $v_{max(R)}/K_R$, and $v_{max(S)}/K_S$, one can calculate *ee* as $A_0 \to 0$ [eq. (m)] and as $A_0 \to \infty$ (saturation) [eq. (n)].

$$ee = \frac{\dfrac{v_{max(R)}}{K_R} - \dfrac{v_{max(S)}}{K_S}}{\dfrac{v_{max(R)}}{K_R} + \dfrac{v_{max(S)}}{K_S}} \qquad (m)$$

$$ee = \frac{v_{max(R)} - v_{max(S)}}{v_{max(R)} + v_{max(S)}} \qquad (n)$$

These values provide a useful overview of the upper and lower limits of optical purity that are theoretically obtainable for each substrate. Moreover, structural changes in substrates can be quantitatively correlated to changes in z and y, which serve as measures of the relative changes in binding and catalysis of competing enzyme systems. Optimization of enantioselectivity is dependent on the maximization of z.

3. Enantioselective Reductions

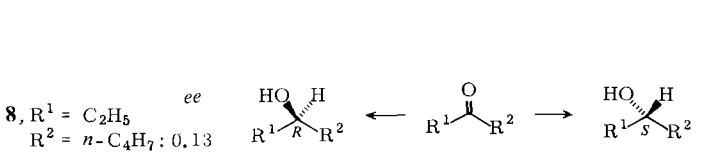
Much of the early work on the microbial reduction of ketones and keto acids or keto esters has been amply de-

scribed and reviewed[14]. Hence, we shall confine our treatment here to more recent studies on enantioselective reductions of prochiral ketones, highlighting the relationship of substrate structure to enantioselectivity; diastereoselective reductions will not be discussed.

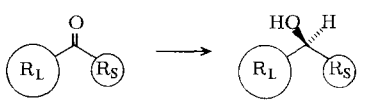
3.1. Alkanones

The purified NADPH-specific dihydroxyacetone reductase of *Mucor javanicus*[15], an enzyme that transfers hydrogen exclusively to the *Si*-face of the carbonyl group of most substrates, has been extensively investigated by the Prelog school. The unique structure of the active site of this enzyme allows it not only to possess broad substrate-specificity but also high enantioselectivity. Although the value of k_{cat}/K decreases markedly on changing the substrate from dihydroxyacetone to 2-alkanones such as acetone, the reaction rate is enhanced significantly when the alkyl chain is increased in length. Product analysis demonstrated that with the exception of 2-butanone, where the racemic alcohol was obtained, the higher homologues were reduced with high enantioselectivity ($ee = 0.94$) to the (*R*)-alcohols—(*R*)-2-pentanol, (*R*)-2-hexanol, and (*R*)-2-octanol. From this, it was concluded that the ethyl group of 2-butanone is too short to create the necessary hydrophobic interactions. Hence, 2-butanone is attacked by hydrogen at both the *Si* and *Re*-face to yield racemic 2-butanol.

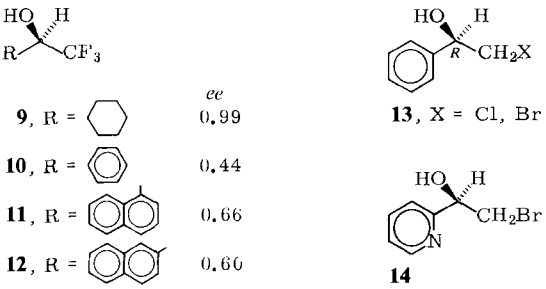
The first systematic study of the stereochemical course of reduction of acyclic ketones by bakers' yeast *(Saccharomyces cerevisiae)* was reported by *MacLeod* et al.[16]. They examined the reduction of a series of ketones with all combinations of the substituents methyl, ethyl, *n*-propyl, *n*-butyl, and phenyl. With the exception of the alcohol derived from butyl ethyl ketone **8**, where the *R*-configuration is preferred, the secondary alcohols **1**—**7** possess the *S*-configuration in excess. The more sterically hindered ketones, including *n*-butyl *n*-propyl ketone, *t*-butyl methyl ketone, isobutyl isopropyl ketone, and *n*-amyl phenyl ketone, were not reduced by yeast. Similar results were obtained by other groups[1b, 17].



These results suggested that the stereochemical course of reduction proceeds in contrast to that with dihydroxyacetone reductase from *Mucor javanicus*, via hydrogen transfer to the *Re*-face of the prochiral ketone, R_S and R_L represent the smaller and larger group, respectively.



This is now known as the Prelog rule[18], and was initially postulated for the reduction of decalones by *Curvularia lunata*. Subsequently, however, this rule has been widely used to predict the stereochemistry of alcohols produced in microbial reductions. In accord with this rule, the *R*-configurated trifluoromethyl alcohols[19] **9**—**12** are obtained in excess by reduction of the corresponding ketones with baker's yeast. A similar stereochemical trend is observed in other microbial reductions of aryl α-halomethyl ketones, which yield (*R*)-halohydrins **13** ($ee \geq 0.80$)[20]. It thus appears that monosubstituted methyl groups are effectively smaller than a phenyl ring. Apparently, the presence of a heteroatom in the aromatic system, as in **14**, does not influence the stereochemical course of the reduction.



Two alternative explanations have been proposed to account for the partial enantioselective reductions of ketones by fermenting yeast[16]. The yeast alcohol dehydrogenase (YADH) reduces ketones, but is partially enantioselective with unnatural ketones. Alternatively, more than one oxidoreductase exists (including YADH and/or a yet unknown oxidoreductase) which produces alcohols of opposite configuration at different rates. *MacLeod* et al.[16] favor the first of these two explanations, but it is not possible at present to draw definite conclusions. Although crystalline YADH has been shown to reduce most of the aforementioned acyclic ketones at different rates[27], until the alcohols obtained from each of these substrates have been isolated, purified, and the optical purities defined, generalizations cannot be made about this complex system, especially since other enzymes in yeast may also competitively reduce these ketones.

3.2. β-Keto Esters and Acids

The asymmetric reduction of ethyl acetoacetate by bakers' yeast is a well-established method for the synthesis of (*S*)-ethyl 3-hydroxybutanoate **15**, a valuable chiral building block. However, the yield (60—80%) and the optical purity ($ee = 0.85$—0.97) of the product vary depending on the procedure used[21]. The most critical factor affecting the enantioselectivity of this reduction is the substrate concentration, because of the presence of competing enzymes

of opposite chirality in bakers' yeast. The optical purity of the product drops significantly when the concentration of ethyl acetoacetate is greater than 5 g/L[22]. Because the (*S*)-enzyme(s) has (have) a competitive advantage by virtue of having a higher v_{max}/K ratio than that of the *R*-enzyme(s), optically pure (*S*)-ethyl 3-hydroxybutanoate can be obtained by limiting the concentration of ethyl acetoacetate in the reaction medium via continuous, slow addition of the substrate[22]. If the apparent values of y, K_R and x are determined, one may calculate the *ee* for any substrate concentration[13] [eq. (l)]; in turn, this allows the definition of the optimum rate of continuous substrate addition.

Whereas ethyl acetoacetate[21] and acetoacetic acid[23] are reduced mainly to their corresponding (*S*)- (or L)-isomers, ethyl 3-oxopentanoate[24], 3-oxohexanoic acid[23], 3-oxoheptanoic acid[23], and 3-oxo-6-heptenoic acid[1a] are all preferentially converted into their respective (*R*)-(or D)-isomers **16**—**19**. These results suggest that by extending the length of the hydrocarbon chains of the β-keto carbonyl molecule the stereochemical course of yeast reduction may be altered from L to D. The reduction of ethyl 4-chloroacetoacetate to (*S*)-ethyl 4-chloro-3-hydroxybutyrate **20**[25] and of ethyl benzoylacetate to (*S*)-ethyl 3-hydroxy-3-phenylpropionate **21**[26] are also consistent with this supposition. The *S*-configuration of **20** and **21** is a consequence of the sequence rule.

The enantioselectivity of the reduction of β-keto carbonyl compounds by yeast is also strongly influenced by

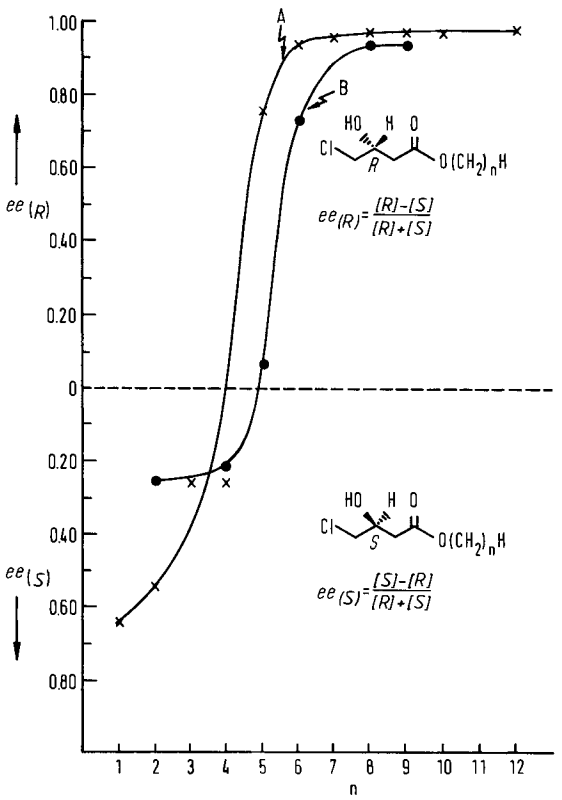

Fig. 2. Enantiomeric excess (*ee*) as a function of the size of the ester group of 4-chloro-3-oxobutanoate. Curve A: 0.045 M; curve B: 0135 M. See also text.

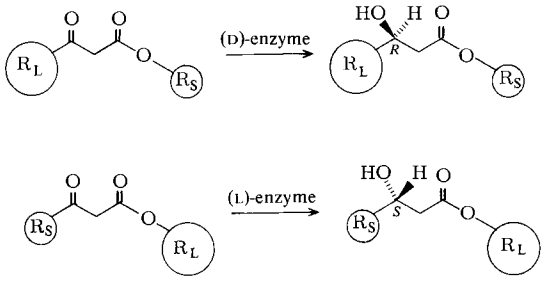
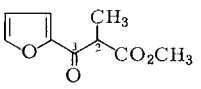
changes in the carboxy substituents (R^1). Along a homologous series of C_1- to C_{12}-esters of 4-chloroacetoacetic acid as substrates, a dramatic shift in the stereochemistry of the alcohol products was observed as the size of the ester group was enlarged (Fig. 2). Curve A depicts that the methyl ester was reduced to its corresponding (*S*)-enantiomer ($ee_{(S)}=0.65$), whereas the octyl ester was reduced to its (*R*)-enantiomer ($ee_{(R)}=0.97$). Notably, the $ee_{(R)}$-value of the pentyl ester dropped from 0.76 to 0.07 when the concentration of the substrate was raised from 0.045 M to 0.135 M (curve B)[25]. Similarly, octyl 3-oxopentanoate and octyl 3-oxohexanoate were reduced in excess to their corresponding (*S*)-isomers **22** and **23**, respectively[27].

Substrates with aromatic substituents at the carboxy end (R^1) are also transformed by bakers' yeast predominantly into (*R*)-configurated alcohols. *N*-Phenyl 4-chloro-3-oxobutanamide (3 mg/mL) was reduced to (*R*)-*N*-phenyl 4-chloro-3-hydroxybutanamide **24** ($ee_{(R)}=0.97$), but at 8 mg/mL the optical purity of the alcohol dropped drastically ($ee_{(R)}=0.04$)[27]. Hence, the stereochemical course of the reduction of β-keto carboxylic acid derivatives by yeast is influenced by substituents at both ends of the molecule. While the enantioselective reductions are dependent on the ratio of the apparent v_{max}/K-values of the two types of competing enzymes of opposite chirality, the enzyme(s) affording (*S*)- (or L)-alcohols appear to prefer large hydrophobic substituents at the carboxy end, whereas the (D)-enzyme(s) appear to prefer those at the hydrocarbon end (R^2). Recent results also support this contention[28].

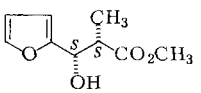


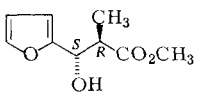
There are many oxidoreductases in bakers' yeast that could be responsible for catalyzing the reduction of these β-keto carboxylic acid derivatives. However, crystalline YADH I (EC 1.1.1.1) and purified yeast L-LDH (EC 1.1.1.27) do not reduce ethyl or octyl 4-chloroacetoacetate[27]. On the other hand, β-hydroxyacyl CoA dehydrogenase from porcine heart[29] (EC 1.1.1.35), an enzyme involved in the degradation of fatty acids, reduced both keto esters in the presence of NADH to their respective (*R*)-4-chloro-3-hydroxybutyrates (*ee* = 0.98)[27]. Furthermore, we have recently found that purified fatty acid synthetase from bakers' yeast[30] readily reduces both ethyl and octyl 4-chloroacetoacetates in the presence of NADPH to their respective (*S*)-4-chloro-3-hydroxybutyrates (*ee* = 0.98)[31]. The purification of the β-hydroxyacyl CoA dehydrogenase from bakers' yeast is currently in progress. These two enzymes are probably the major ones responsible for the reduction of these unnatural β-keto carboxylic acid esters, since the normal physiological substrates of β-hydroxyacyl CoA dehydrogenase (a mitochondrial enzyme) and the β-keto reductase component of fatty acid synthetase are the structurally analogous acetoacetic thiol esters. Furthermore, the first enzyme generates alcohols having an (L)-configuration, whereas the second generates alcohols having a (D)-configuration. It is interesting to note that mammalian fatty acid synthetase[32] appears to possess a very relaxed substrate specificity, because the keto reductase component of this complex also reduces cyclic ketones.

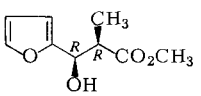
Reduction of ethyl acetoacetate with *Geotrichum candidum* leads to (*R*)-ethyl 3-hydroxybutyrate of moderate optical purity (*ee* = 0.89) in an overall yield of 36%[22]. However, this reaction is highly dependent on the metabolic state of cells, and the optical yield was poorly reproducible, again suggesting the presence of competing enzymes with the (*R*)-type dominating in this case. On the small scale, it is probably more convenient to prepare (*R*)-ethyl 3-hydroxybutyrate by using either the dihydroxyacetone reductase of *Mucor javanicus* or the commercially available D-β-hydroxybutyrate dehydrogenase (EC 1.1.1.30) of *Pseudomonas lemoignei*[27]. Both enzymes catalyze the reduction of ethyl acetoacetate with high enantioselectivity (*ee* > 0.97), but an NADH-regenerating system[33] must be included in the incubation.

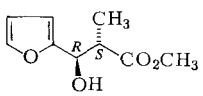


25



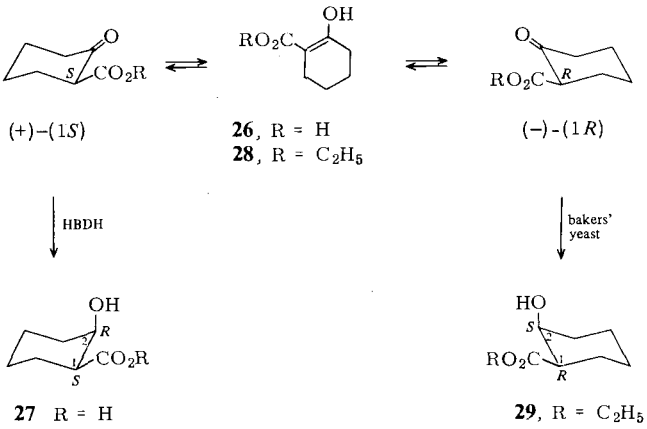






Because the α-methyl-β-hydroxy structural element appears in a variety of natural products, α-methyl-β-keto esters are attractive substrates for asymmetric reduction. The action of a wide variety of microorganisms on methyl 3-(2-furyl)-2-methyl-3-oxopropionate **25** has been studied[34]. All four possible stereoisomers were prepared by selecting the appropriate microorganism. With most microorganisms, a mixture of the (2*R*,3*R*)-ester (*ee* = 0.49—0.90) and the (2*S*,3*R*)-ester (*ee* = 0.23—0.91) was obtained in a ratio of ca. 1:1 to 4:6. The exception was *Candida albicans* KSY-36 which gave only the (2*S*,3*R*)-ester (*ee* = 0.99), but in 23% yield. In contrast, *Kloeckera saturnus* KSY-7 afforded a ca. 1:1 mixture of the (2*S*,3*S*)-ester (*ee* = 0.68) and the (2*R*,3*S*)-ester (*ee* = 0.46) in 29% yield. Ethyl α-methylacetoacetate was reduced by bakers' yeast to afford a 9:91 mixture of the (2*R*,3*S*)- and (2*S*,3*S*)-esters in 65% yield, whereas ethyl α-allylacetoacetate was reduced to a 96:4 mixture of the (2*R*,3*S*)- and (2*S*,3*S*)-esters in 84% yield[35]. Bakers' yeast also reduces several ethyl α-formylpropionates to yield predominantly the (−)-(*R*)-ester (*ee* = 0.60—0.65), which may be crystallized via the 3,5-dinitrobenzoate to give the enantiomerically pure ester[36].

Since 2-oxocyclohexanecarboxylates are conformationally constrained analogues of acetoacetate, it was anticipated that compounds of this type might also serve as substrates for those enzyme systems that reduce acetoacetate. With purified D-3-hydroxybutyrate dehydrogenase (HBDH) from *Rhodopseudomonas spheroides* in the presence of NADH, it was shown that 2-oxocyclohexanecarboxylic acid **26** was reduced exclusively to *cis*-(1*S*,2*R*)-2-hydroxycyclohexanecarboxylic acid **27** in 77% yield, indicating that the (+)-(1*S*)-enantiomer was selectively reduced by HBDH[37]. On the other hand, bakers' yeast,



which reduces ethyl acetoacetate to (*S*)-ethyl 3-hydroxybutyrate, would be expected to selectively attack the (−)-(1*R*)-enantiomer. In fact, ethyl 2-oxocyclohexanecarboxylate **28** was indeed reduced to the (1*R*,2*S*)-isomer **29** in 69% yield and 2-oxocyclopentanecarboxylic acid was similarly transformed into its corresponding (1*R*,2*S*)-isomer in 80% yield[26]. Similar results were obtained with the corresponding tetrahydrothiophene analogues[38]. The alternative possibility involving the stereospecific reduction of the enol, which is known to be the major species in the equilibrium mixture, is unlikely in light of results on the reduction of related compounds[39].

3.3. Other Keto Esters and Acids

Derivatives of 2-aryl-2-oxoacetic acid are generally reduced by bakers' yeast to give satisfactory yields of optically pure α-hydroxy acids **(30–33)**[26]. Thus, methyl 2-oxo-2-phenylacetate gave (−)-(*R*)-methyl 2-hydroxy-2-phenylacetate **30** in 59% yield; 2-oxo-2-phenylacetamide gave (−)-(*R*)-2-hydroxy-2-phenylacetamide **31** in 70% yield; and ethyl-2-thienylacetate gave (−)-(*S*)-ethyl 2-thienylacetate **33** in 49% yield. In contrast, reduction of methyl 2-oxo-3-phenylpropionate yielded only racemic methyl 2-hydroxy-3-phenylpropionate **34**. Also, 2-oxoalkanoic acid esters did not produce optically pure alcohols. Ethyl pyruvate was reduced to (+)-L-ethyl lactate (*ee* = 0.92), but this was racemized in the reaction medium, suggesting the presence of a racemase. The enzymology of the reduction of these α-keto acid derivatives has not been investigated, but bakers' yeast is known to contain L- and D-lactate dehydrogenases that are known to react with α-hydroxy acids. Furthermore, purified YADH in the presence of NADH reduced pyruvate to (−)-D-lactate[40]. An NADH-dependent 2-oxocarboxylate reductase has been found in several anaerobic bacteria, and this enzyme produces (2*R*)-hydroxy acids[41].

		ee

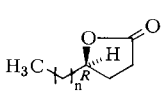
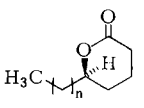
Optically-active hydroxy acids (isolated as (+)-lactones) may be readily prepared by yeast reduction of γ- and δ-keto acids. With the bacterium *Sarcina lutea* and the mold *Cladosporium butyri*, the corresponding (−)-lactone was obtained by reduction of δ-ketohexanoic acid[42]. The (*S*)-configuration was assigned to (−)-γ-valerolactone since the (+)-γ-lactones should have the (*R*)-configuration[43].



n = 4-7

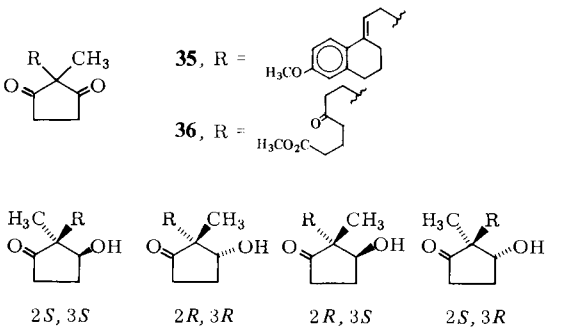


n = 2-5

The enzyme in yeast responsible for the reduction of 5-oxodecanoid acid occurs in the mitochondrial fraction, is NADPH-dependent, and the reaction is strongly stimulated by the addition of ATP and Mg^{2+}, but to a lesser extent by coenzyme A[44]. It is not yet known whether this enzyme is 3-hydroxyacyl CoA dehydrogenase, although the latter is NADH-dependent.

3.4. Cyclic Diketones

The asymmetric reduction of cyclopentane-1,3-diones with 2,2-dialkyl substituents has been examined in considerable detail[45], because this reaction has found application in the industrial total synthesis of steroid hormones. The stereochemical course of this reduction depends on the relative size of the 2,2-dialkyl substituents and on the microorganisms, and can be carried out with a high degree of enantioselectivity. For example, *Saccharomyces uvarum*



(CBS 1508) reduces **35** to give the (2*R*,3*S*)-isomer in 74% yield, accompanied by a small quantity of the (2*S*,3*S*)-isomer as by-product. In contrast, the bacterium *Bacillus thuringiensis* transformed **35** into predominantly the (2*S*,3*S*)-isomer in 87% yield. With most microorganisms, alcohols of the 3*S*-configuration are produced, although some strains of *Kloeckera* afforded alcohols of the *R*-configuration[45].

Similarly, yeasts of the genera *Schizosaccharomyces* and *Saccharomyces* convert **36** into the (2*R*,3*S*)-isomer as the major product, with the (2*S*,3*S*)-isomer as the only by-product. It is notable that a variety of α,β-unsaturated ketones, e.g. acrolein, methyl vinyl ketone, ethynyl methyl ketone, 2-cyclohexen-1-one, and also allyl alcohol, are capable of enhancing the rate and extent of formation of the (2*R*,3*S*)-isomer and reduce the level of (2*S*,3*S*)-isomer formation[46]. Although the mechanism of action of these "enhancers" is not known, one possibility could be that they act as "suicide substrates" for the oxidoreductase which forms the undesired (2*S*,3*S*)-isomer, for allyl alcohol has been reported to be a suicide substrate for YADH[47].

In a more recent study, *Brooks* et al.[48] conducted investigations designed to establish a relationship between enantioselectivity and size differences of both alkyl substituents in the 2-position. As expected, whereas (*S*)-alcohols were produced in both series, the enantioselectivity of the reaction was found to be strongly dependent not only on the alkyl substituents but also on the ring size. In the cyclopentane series, the (2*S*,3*S*)-isomers **37a**—**39a** were the major species, whereas the (2*R*,3*S*)-isomers **40b**—**43b** predominated in the cyclohexane series.

4. Outlook

Microbial, enantioselective reduction of ketones is now recognized as a method of great value for the preparation

of chiral alcohols. Since the stereochemical course of reduction is dependent on the nature of the substituents attached to the carbonyl group, the Prelog rule has been applied with some degree of success to predict the stereochemical outcome for microbial reductions. However, in intact cell systems the ketone substrate may be acted upon by competing oxidoreductases of opposite chirality, and the rates of production of unequal quantities of enantiomeric alcohols are dependent on the kinetic parameters (K and v_{max}) of the respective competing enzymes. Hence, it is often feasible to regulate the stereochemical course of reduction by designing suitable substrates with significant differences in v_{max} and/or K values for the competing enzyme systems.

It is to be expected that major efforts in the near future will focus on the isolation and characterization of the relevant oxidoreductases, and that a correlation of substrate structure with the kinetic parameters v_{max} and K of these enzymes will be made. This information should not only provide a conceptual framework for better interpretation of the complexity of microbial reductions of ketonic substrates, but also aid in the development of strategies to control enantioselectivity. Selective inhibitors such as "suicide substrates" may then be designed to inhibit the dominant interfering enzyme. Furthermore, various mutants may be selected, and hence chiral alcohols of either configuration and high optical purity may be made accessible in larger quantities.

Mercury(II)- and Palladium(II)-Catalyzed [3,3]-Sigmatropic Rearrangements

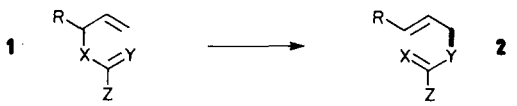
New Synthetic Methods (46)

By Larry E. Overman*

Mercury(II) and palladium(II) salts have found broad applications as catalysts for [3,3]-sigmatropic rearrangements leading to formation of C–O, C–N, C–S, and C–C σ bonds. Increases in reaction rate are often very large (10^{10}–10^{14} at 1 M catalyst concentration) and allow many previously difficult transformations to be conducted at or near room temperature, often with attendant increases in stereoselectivity and decreases in by-product formation. The mechanism of these catalyzed transformations is briefly discussed, and evidence is summarized to suggest that many follow a cyclization-induced rearrangement mechanism.

1. Introduction

[3,3]-Sigmatropic rearrangements[1,2] (Scheme 1) are among the more important transformations in the arsenal of modern synthetic organic chemistry[3]. These reactions allow the allylic interchange of functionality X and Y (**1**→**2**), and often fashion the newly formed CC double bond with high levels of stereocontrol[3c,4].



Scheme 1. The newly formed C-Y bond is sketched with a bold line.

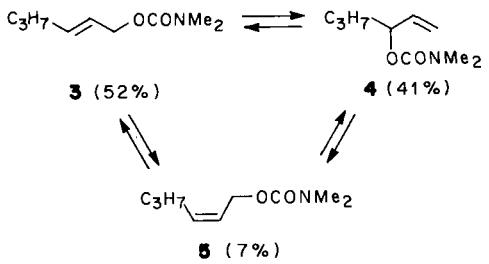
It is not surprising that the development of catalytic methods[5] for these important transformations has attracted widespread attention, and this area has recently been reviewed comprehensively by *Lutz*[6]. Acid-base catalysis has been most extensively investigated and requires the presence of an acidic or basic heteroatom substituent. The most important transformations of this type are Brønsted and Lewis acid catalyses of aromatic Claisen, aromatic amino-Claisen and Cope rearrangements, as well as base-catalysis of the oxy-Cope rearrangement and the Claisen rearrangement of allylic esters[6]. Catalysis of [3,3]-sigmatropic rearrangements by a variety of metals and organometallic reagents has also been described[6]. A representative, though certainly not complete, list of metal "catalysts"[5] includes Ni^0, Pd^0, Ag^I, Ni^{II}, Pd^{II}, Pt^{II}, Hg^{II}, and Al^{III} compounds.

Perhaps the most versatile of the metal catalysts are the "soft"[7] metal salts of Hg^{II} and Pd^{II}. These effectively catalyze a wide variety of [3,3]-sigmatropic rearrangements which form C–O, C–N, C–S, and C–C bonds (C–Y, Scheme 1). Catalyzed transformations of this type occur under extremely mild conditions (neutral pH and at, or near, room temperature) and often afford yields and regio- and stereoselectivities which far exceed those of their thermal counterparts.

This review briefly summarizes recent advances in the catalysis of [3,3]-sigmatropic rearrangements with Hg^{II} and Pd^{II} salts. Excluded are the many useful [3,3]-sigmatropic rearrangements effected with Pd^0 complexes[6,8,9].

2. Allylic Ester Rearrangements

Catalysis of the equilibration of allylic esters by mercury(II) salts was first reported by *Overman* and *Campbell* in 1976[10,11]. Allylic carbamates equilibrated more readily than allylic anisoates or acetates[10,12], and *anhydrous* mercury(II) trifluoroacetate[11] was found to be the catalyst of choice. For example, treatment of the hexenyl carbamates **3** and **4** with mercury(II) trifluoroacetate in the molar ratio 1:0.4 gave the equilibrium mixture of **3**, **4**, and **5** within 4 h at room temperature (Scheme 2). However, the (*Z*)-



Scheme 2.

isomer **5** reacted much more slowly and could not be fully equilibrated with **3** and **4**[11,13]. Comparison of the initial rate of the mercury(II) trifluoroacetate-catalyzed isomerization of **3** in tetrahydrofuran (THF) with the thermal, gas-phase isomerization of several 2-butenyl esters[13] indicated a rate enhancement of 10^{12}–10^{13} (1 M catalyst concentration) for the mercury(II)-catalyzed transformation.

A number of other mercury(II) trifluoroacetate-catalyzed allylic ester rearrangements are summarized in Scheme 3. The only limitation reported to date is the unreactivity of 2-alkylallylic esters, e.g. **6**[11,14]. This method for equilibrating allylic alcohol derivatives, which typically affords high yields, has significant advantages over classical acid-catalyzed procedures which proceed via allyl cation intermediates[15]. Thus, *N,N*-dimethyllinalyl carbamate

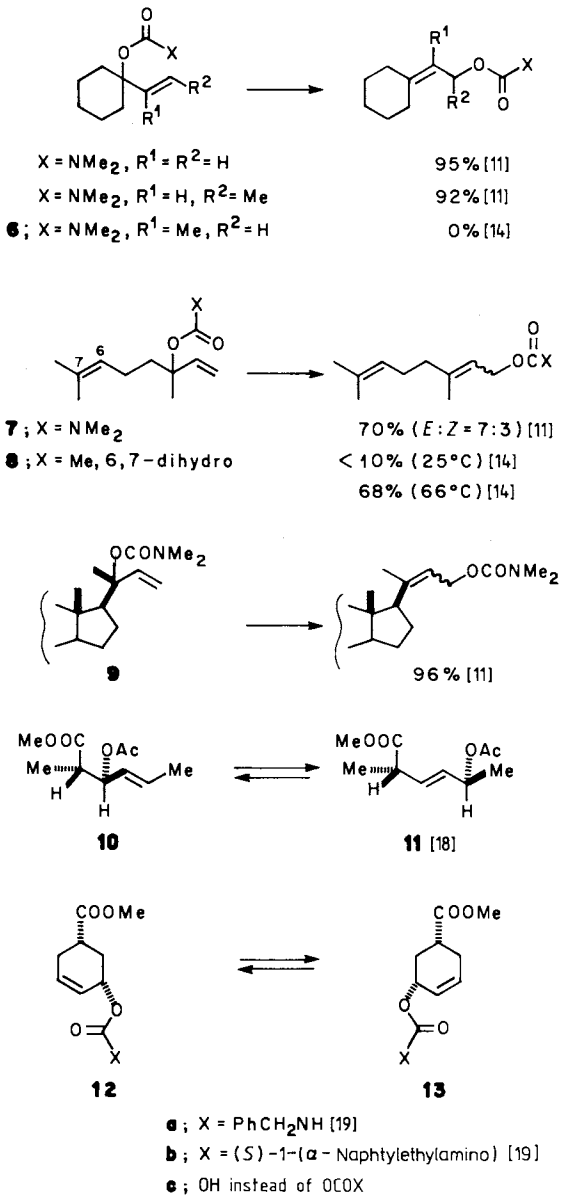
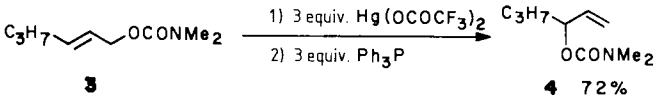


Scheme 3. Representative examples of mercury(II) trifluoroacetate-catalyzed allylic ester rearrangements [a] (in THF at 25—66°C; molar ratio allylic ester : $Hg(OCOCF_3)_2$ = 1 : 0.25—0.4).

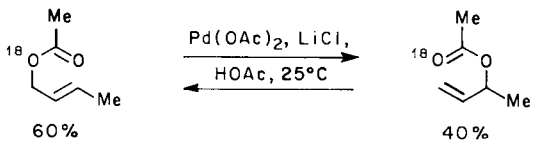
7 was converted[11] into the geranyl and neryl isomers without competing cyclization[16], and the allylic rearrangement[11] of the steroidal ester **9** was accomplished in nearly quantitative yield without complicating dehydration or skeletal rearrangement[17]. Of equal significance is the clean suprafacial chirality-transfer of mercury(II)-catalyzed allylic ester rearrangements[18,19]. This feature was demonstrated by *Eschenmoser* et al.[18] in the stereospecific interconversion of acetates **10** and **11**, and by *Trost* et al.[19] in the mercury(II)-catalyzed racemization of the optically pure cyclohexenyl carbamate **12a**. Mercury(II) trifluoroacetate-catalyzed equilibration of the mixture of diastereomeric carbamates formed from *rac*-methyl *cis*-5-hydroxy-3-cyclohexenecarboxylate and (*S*)-1-(α-naphthyl)ethylisocyanate yielded **13b** and **12b** in the ratio 2 : 1. Chromatographic separation of **13b** followed by re-equilibration of the unwanted diastereomer **12b** provided a new method for converting a symmetrical allylic alcohol racemate into a single enantiomeric product[19]. Enantiomerically pure alcohol **13c** obtained in this way was used by *Trost* et al.[19] to prepare optically pure prostanoid analogues.

Use of an excess of mercury(II) trifluoroacetate followed by treatment of the reaction mixture with triphenylphosphane provides a method of achieving "contra"-thermodynamic allylic isomerizations (see Scheme 4)[11,12]. However, this approach is limited in scope and works well only when the two isomers have similar energies[11,20].



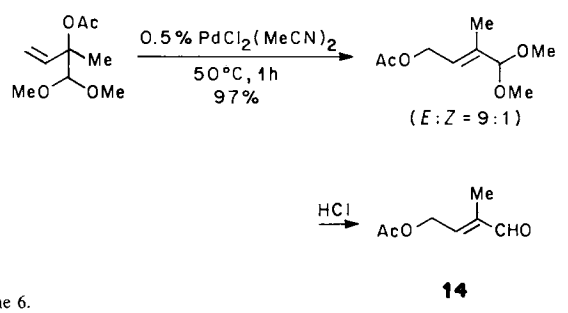
Scheme 4.

Palladium(II) salts are even more effective than mercury(II) salts for equilibrating allylic esters[21]. Catalysis by palladium(II) was first recognized by *Winstein* et al.[22] in their investigations of the oxidation of alkenes with palladium acetate in acetic acid. Subsequently, this reaction was studied extensively by *Henry*[23,24], who convincingly demonstrated the involvement of two equilibration processes which proceed with and without exchange of the ester acyl group with acetic acid. The intramolecular equilibration reaction was found to occur 500 times faster with propionate than with trifluoroacetate esters, and with complete 1,3-shift of the oxygen atoms (Scheme 5)[24b]. Allylic esters are also equilibrated at higher temperatures (70—100°C) by palladium acetate or palladium acetylacetonate in the presence of phosphane ligands[25].



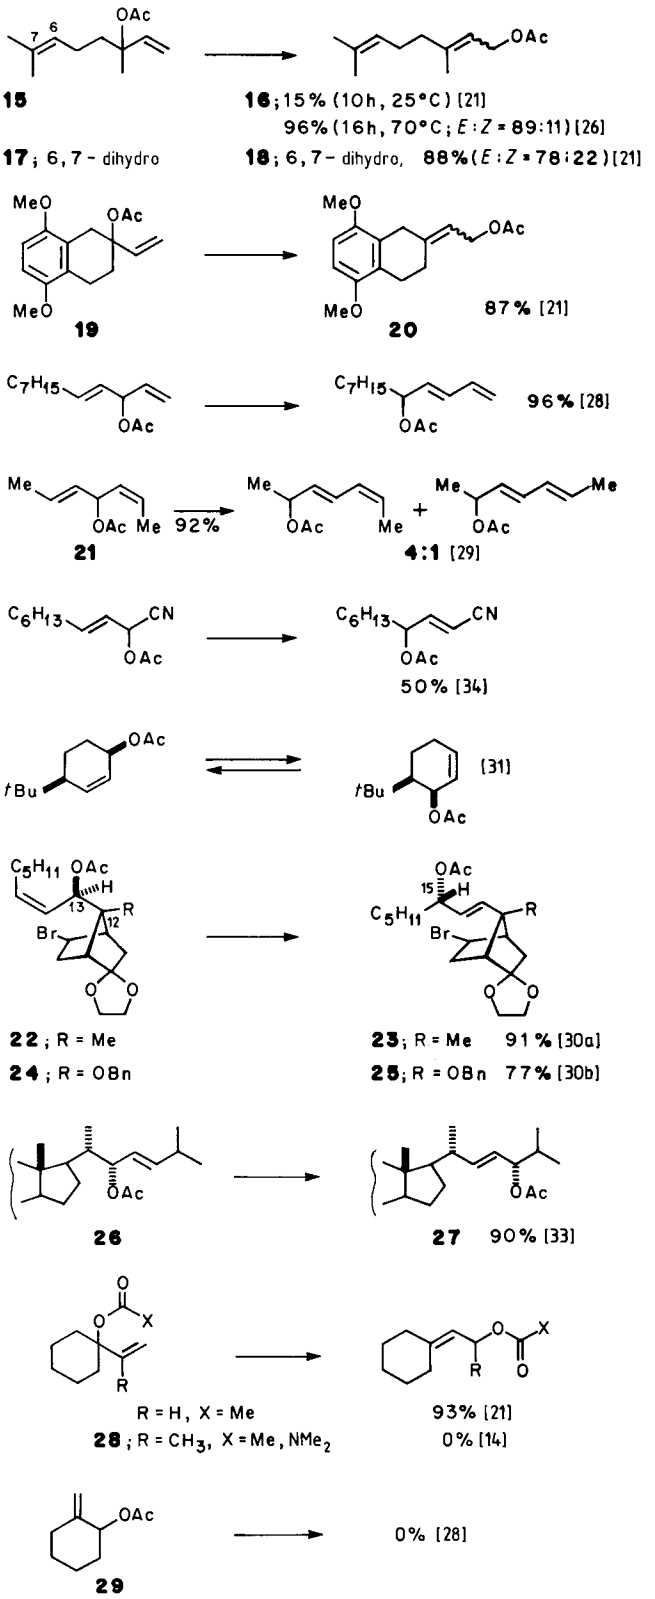
Scheme 5.

For preparative purposes the most convenient method for equilibrating allylic esters is to use the palladium(II) chloride complexes of acetonitrile or benzonitrile in inert solvents such as THF, benzene, dichloromethane, or dichloroethylene. This procedure was first described by *Meyer*[26], and his synthesis of the terpene intermediate **14** is shown in Scheme 6. This method was further developed by *Overman* and *Knoll*[21], who showed that a variety of al-



Scheme 6.

lylic acetates could be conveniently equilibrated at room temperature in the presence of 4 mol-% of $PdCl_2(MeCN)_2$. Measurements of the initial rate[27] of the palladium(II) chloride-catalyzed rearrangement of (*E*)-2-hexenyl acetate at 25°C in THF showed that this conversion was ca. ten times faster than the rearrangement of hexenyl carbamate



Scheme 7. Representative examples of palladium(II) chloride-catalyzed allylic ester rearrangements [a] (at 25°C; molar ratio allylic ester : $PdCl_2(RCN)_2 = 1 : 0.01-0.08$).

3 under similar conditions, but catalyzed by mercury(II) trifluoroacetate. This experiment allowed a rate enhancement of $10^{13}-10^{14}$ (1 M catalyst concentration) to be estimated[11,14] for $PdCl_2$-catalysis.

A representative selection of allylic ester equilibrations catalyzed by palladium(II) chloride is summarized in Scheme 7. These results reveal that carbamates rearrange more rapidly than acetates[14,28], which in turn react somewhat faster than carbonates[28]. In contrast to the facile rearrangement of **17** with $PdCl_2$ (4 mol-%, 2 h, 25°C), this ester was unchanged after one week at room temperature in the presence of 20 mol-% of tetrakis(triphenylphosphane)palladium(0)[14]. Like the corresponding mercury(II)-catalyzed equilibrations, allylic ester rearrangements catalyzed by palladium(II) chloride are not complicated by skeletal rearrangements, cyclizations (cf. clean conversion of **15** into **16**), or elimination processes (e.g. clean conversion of **19** into **20**) which often plague[11,16,17] acid-catalyzed equilibrations[15]. There are many other similarities between the Hg^{II}- and Pd^{II}-catalyzed reactions. Thus, (*Z*)-alkenes rearrange much slower[14,28,29] than the corresponding (*E*)-isomers (note selective rearrangement of **21**) in the presence of palladium(II) chloride, and with clean suprafacial stereochemistry[30-33]. This latter feature has been exploited by *Grieco* et al.[30] to obtain the desired stereochemistry at the C-15 center of prostanoids. A key step in this prostaglandin synthesis was the palladium(II) chloride-catalyzed rearrangement of **22** and **24** to give the rearranged (*E*)-allylic acetates **23** and **25**, respectively, which were subsequently converted into 12-methyl-$PGF_{2\alpha}$ and 12-hydroxy-$PGF_{2\alpha}$[30]. Importantly, the rearrangement of the C-13 epimer of **22** (not shown in Scheme 7) was also demonstrated to be suprafacial and cleanly yielded the C-15 epimer of **23**[30]. The apparent irreversibility of these rearrangements was suggested[30] to be a consequence of destabilizing steric interactions of the acetate group with the *exo*-bromine and the quaternary C-12 center. *Ikekawa* et al.[33] have reported a similar, apparently irreversible transfer of chirality from C-22 to C-24 (e.g. **26** → **27**) in steroidal side chains.

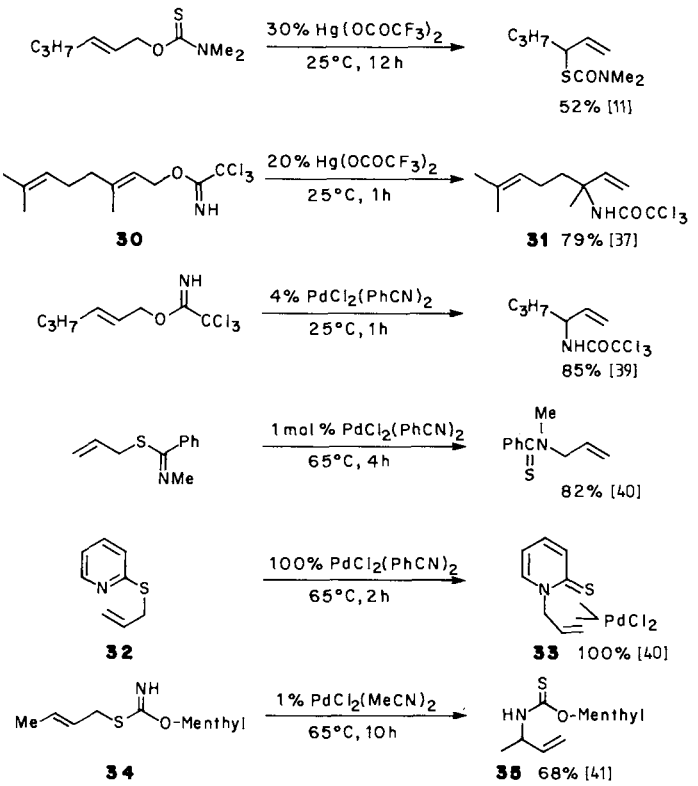
Like the mercury(II)-catalyzed reaction, allylic ester rearrangements catalyzed by palladium(II) chloride are limited to allylic esters which are unsubstituted at the C-2 position of the allyl group (e.g. **28** and **29** do not react). Another limitation would appear to be the failure of propargylic allylic acetates (1-ethynylallyl acetates) to rearrange in the presence of palladium(II) chloride[28,35,26].

In summary, it would appear that for most applications palladium(II) chloride should be the catalyst of choice, since allylic rearrangements are faster than with mercury(II) salts and can be accomplished using less catalyst. A possible exception would be substrates which contain ligands that coordinate strongly to palladium(II), such as dienes[21] and alkynes[28,35].

3. Other Hetero-Cope Rearrangements

A variety of other hetero-Cope rearrangements are catalyzed by mercury(II) and palladium(II) salts, and representative examples are summarized in Scheme 8. Catalysis of

[3,3]-sigmatropic rearrangements by mercury(II) compounds was first discovered in our laboratory ten years ago during studies of the allylic imidate→allylic amide conversion (e.g. **30**→**31**)[37,3e]. This transformation can also be brought about by salts of platinum(II)[38] and palladium(II)[3e,39]. *Yoshida* et al.[40] have reported several examples of the conversion of *S*-allylthioimidates into *N*-allylthioamides catalyzed by palladium(II) chloride. In this case, palladium(II)-catalysis is particularly important since the corresponding thermal reactions often afford entirely different products[40]. Particularly noteworthy is the conversion of **32** into the palladium(II) chloride complex **33**, which demonstrates the use of palladium complexation to shift an unfavorable equilibrium [1-allyl-2-thiopyridone (non-complexed **33**) is less stable than **32**][40]. This would



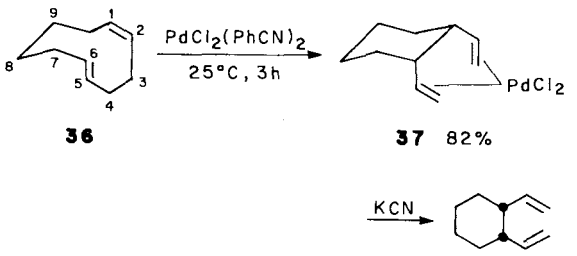
Scheme 8. Representative examples of mercury(II)- and palladium(II)-catalyzed hetero-Cope rearrangements.

appear to be a strategy which is potentially more generally applicable. The $PdCl_2$-catalyzed rearrangement of *S*-allyl-(*O*-(−)-methyl) iminothiocarbonates (e.g. **34**→**35**) to *N*-allyl *O*-((−)-menthyl) thiocarbamates has also been described[41]. Unfortunately, these conversions are of little use for preparing optically active amines, since the rearrangements occur with very low diastereoselectivities (3—5%)[41].

There are no reported examples of mercury(II) or palladium(II) catalysis of [3,3]-sigmatropic rearrangements of 3-hetero-1,5-dienes. We explored without success the use of mercury(II) trifluoroacetate as a catalyst for the aliphatic Claisen rearrangement and attribute this failure to irreversible binding of the catalyst to the strongly nucleophilic vinyl ether functionality[67].

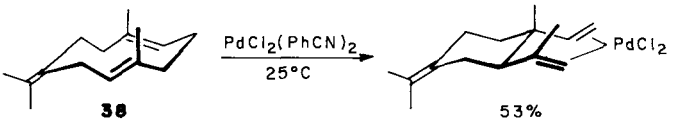
4. Cope Rearrangements

The first example of a metal-promoted Cope rearrangement was reported by *Jonassen* et al.[42], who in 1966 described the preparation of the crystalline palladium(II) chloride complex of *cis*-1,2-divinylcyclohexane **37** from the reaction of excess *cis,trans*-1,5-cyclodecadiene **36** with bis(benzonitrile)palladium(II) chloride (Scheme 9). Reaction of **37** with aqueous potassium cyanide liberated *cis*-



Scheme 9.

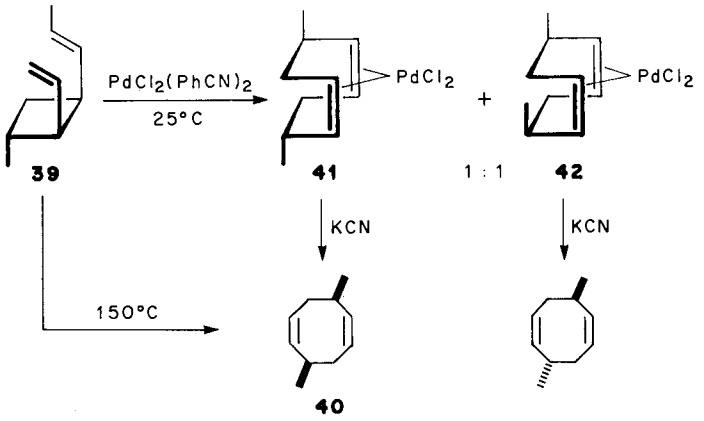
1,2-divinylcyclohexane, the product of thermal Cope rearrangement of **36**. A similar conversion occurred in the presence of sodium hexachloroplatinate, but proceeded much more slowly[42]. The rearrangement of a variety of substituted *cis,trans*-1,5-cyclodecadienes was subsequently studied by *Heimbach* and *Molin*[43]. Mixtures of cyclodecadienes were employed in this study and only solid complexes were isolated, experimental procedures[43] which somewhat complicate the interpretation of the results. Cyclodecadienes **36** with methyl substituents at C-1, C-2, or C-6 did not undergo rearrangements promoted by palladium(II) chloride at 20°C, whereas dienes **36** with substituents at C-3, C-4, C-7, C-8, or C-9 were successfully transformed in the presence of $PdCl_2$[43]. The related transformation of the germacrane **38** (a 1,5-dimethyl-*trans,trans*-1,5-cyclodecadiene) to the palladium(II) chloride complex of the corresponding triene of the elemane structure has also been described (Scheme 10)[44]. In all these cases, the preference for a chair conformation observed for the palladium(II)-promoted rearrangements was identical with that found in the corresponding thermal reactions at elevated temperatures.



Scheme 10.

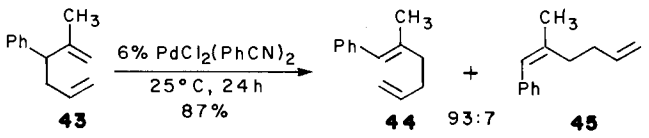
A detailed study of the rearrangement of a variety of *cis*-1,2-divinylcyclobutanes into palladium(II) chloride complexes of *cis,cis*-1,5-cyclooctadienes has also been reported by *Heimbach* and *Molin*[45]. The stereochemistry of the reaction is quite complex and the rearrangements promoted by palladium(II) chloride often occurred with less stereoselectivity than the corresponding thermal rearrangements. For example, thermal rearrangement of **39** gave only cyclooctadiene **40**, while the palladium(II)-induced

reaction afforded nearly equal amounts of the palladium(II) chloride complexes **41** and **42** (Scheme 11)[45].



Scheme 11.

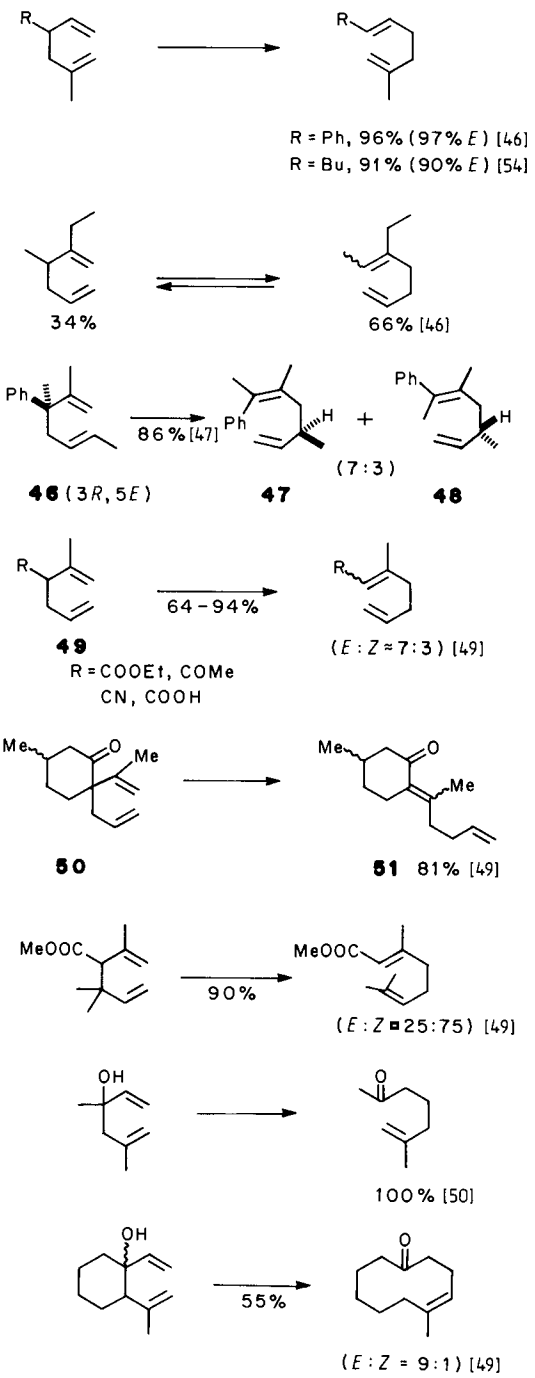
In 1980, *Overman* and *Knoll*[46] reported for the first time that Cope rearrangements could be conducted catalytically using $PdCl_2$ to provide the rearranged diene, rather than the diene-$PdCl_2$ complex. In marked contrast to the facile palladium(II)-catalyzed reaction (Scheme 12), thermal



Scheme 12.

Cope rearrangement of diene **43** required elevated temperatures ($t_{1/2}$ = 13 h at 177 °C) and proceeded much less stereoselectively (**44** and **45** were produced in the ratio 3 : 1). The catalyzed rearrangement of **43** was faster in benzene or dichloromethane than in THF, and a catalytic rate enhancement of 10^{10} (1 M $PdCl_2$) was estimated for the rearrangement of **43** in benzene catalyzed by palladium(II) chloride[46]. Palladium acetate, $Pd(Ph_3)_4$, and mercury(II) trifluoroacetate were not effective catalysts under comparable conditions[46].

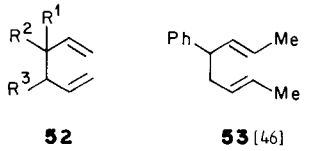
Palladium(II) chloride-catalyzed Cope rearrangements of a representative group of substituted, acyclic 1,5-dienes are shown in Scheme 13. Of particular note is the rearrangement of the optically active diene **46** (99% *ee*) with virtually complete 1,4-transfer of chirality[47]. The observation that only the (2*Z*,5*R*)- and (2*E*,5*S*)-dienes **47** and **48**, respectively, were produced in this rearrangement proves[47] that Cope rearrangements of acyclic dienes catalyzed by palladium(II) chloride occur preferentially with the same chair conformation as thermal Cope rearrangements[47,48]. As the rearrangements of **49** and **50** demonstrate, a number of heteroatom substituents are compatible with this catalytic method[49]. Palladium(II) chloride-catalyzed oxy-Cope rearrangements of tertiary alcohols have also been described[50,51] (see Scheme 13). The advantages of the palladium(II) chloride-catalyzed Cope rearrange-



Scheme 13. Representative examples of palladium(II) chloride-catalyzed Cope rearrangements [a] (at 25–40 °C, molar ratio allylic ester : $PdCl_2(RCN)_2$ = 1 : 0.1).

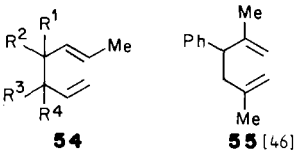
ment are illustrated by the catalyzed rearrangement of diene **50**[49]. Thermal rearrangement of **50** at 220–300 °C gave significant amounts of the β,γ-unsaturated isomer of **51** as well as ene-cyclization products[52].

Unfortunately, the palladium(II) chloride-catalyzed Cope rearrangement has significant limitations. For example, the failure of this catalytic method with substituted 1,5-hexadienes **52**–**55** has been reported by several investigators[46,50,51,53]. Successful palladium(II) catalysis appears to require that the C atoms 2 and 5 of the substituted acyclic 1,5-hexadiene have one hydrogen and one "non-



52 **53** [46]

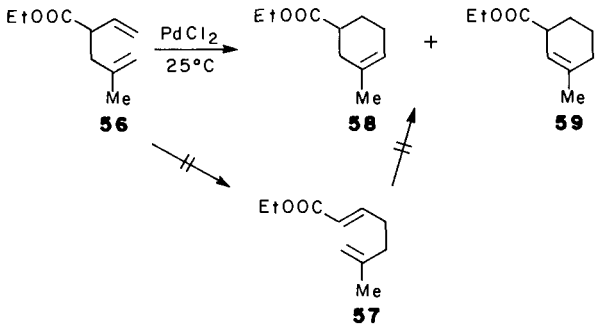
R^1 = Ph [46], OH [50,51]
R^2, R^3 = H, Me



54 **55** [46]

R^1 = Ph [46], OH [51], OMe [51]
R^2, R^3, R^4 = H, Me, Ph

hydrogen" substituent (cf. dienes in Scheme 3 with **52**—**55**)[46]. This feature will be discussed in Section 5. A further limitation is seen in the reaction of diene **56** with palladium(II) chloride, which did not yield the Cope product **57**, but rather cyclohexenes **58** and **59** (Scheme 14)[55].



Scheme 14.

Mercury(II) is much less effective as a Cope rearrangement catalyst than palladium(II) chloride[46]. Nonetheless, a two-step mercury(II)-based method for effecting oxy-Cope rearrangement of tertiary alcohols has been developed by *Gore* et al.[56]. In this approach (see Scheme 15), the diene is treated with mercury(II) trifluoroacetate (molar ratio 1 : 1) at room temperature to yield the rearranged α-mercurated ketone, which is subsequently demercurated with $NaBH_4$[56].

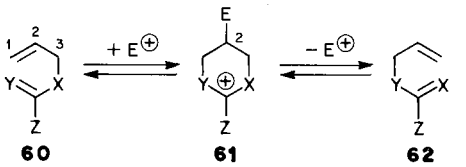
5. Cyclization-Induced Rearrangement Catalysis. A Conceptual Model or a Real Mechanism?

Our efforts to develop methods for catalyzing [3,3]-sigmatropic rearrangements have been guided by the mechanistic paradigm we have termed *cyclization-induced rearrangement catalysis* (Scheme 16)[11]. We expected that soft[7] electrophiles would react with molecules such as **60**



60 **61** **62**

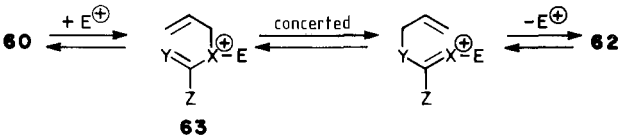
Scheme 16.

at a "soft" carbon-carbon π-bond, rather than a harder heteroatom, and thus promote a polyene-like cyclization[57] to yield **61**[58] (or a nucleophile-trapped equivalent). Alternative Grob-type fragmentation[59] of **61** would afford the rearranged product **62**. For catalysis of this type to be effective, both the cyclization and fragmentation steps have to be rapid, and the cyclic intermediate must be less stable than **60** and **62**. At the time our work began, ample indications existed in the literature that mercury(II)[60] and palladium(II)[61] salts rapidly and reversibly promoted the addition of a variety of nucleophiles to carbon-carbon double bonds. To our knowledge, a cyclization-induced rearrangement mechanism was first suggested by *Henry*[23] for intramolecular allylic ester rearrangements catalyzed by palladium acetate (see Scheme 5).

The present article illustrates that Hg^{II} and Pd^{II} salts are able to catalyze a wide variety of [3,3]-sigmatropic rearrangements involving the making and breaking of C—O, C—N, C—S, and C—C bonds. These diverse, catalyzed transformations show a remarkable number of similarities, and it is appropriate to briefly consider whether or not a cyclization-induced rearrangement mechanism is, in fact, a proper mechanistic description of *all* these catalyzed reactions.

For the Hg^{II}- and Pd^{II}-catalyzed allylic ester and hetero-Cope rearrangements there is ample evidence to preclude mechanisms involving allyl cation or η^3-allylpalladium intermediates. In all cases studied, the catalyzed transformations proceed without scrambling of the allyl fragments (i.e. no competing [1,3]-shifts) and with clean suprafacial stereochemistry. In contrast, several related reactions which are catalyzed by palladium(0) and probably involve η^3-allyl intermediates do *not* show similar clean regio-[8d,e,29] or stereochemical control[8b].

Mechanistically, a cyclization-induced rearrangement (Scheme 16) or concerted charge-induced rearrangement[6,62] (Scheme 17) would be consistent with these observations. Both mechanisms involve intramolecular reorganization of a catalyst-substrate complex and thus could exhibit stereo- and regioselectivities similar to an intramo-



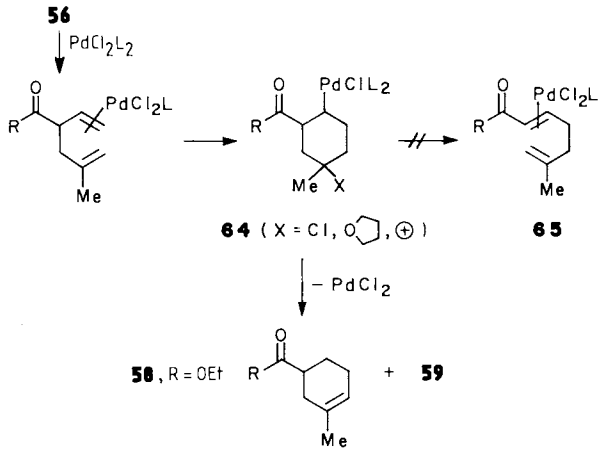
63

Scheme 17.

lecular thermal rearrangement. There is strong evidence, primarily from *Schmid*'s group[62] that acid-catalyzed, aromatic Claisen and amino-Claisen rearrangements occur via charge-induced rearrangement pathways. However, the evidence accumulated to date is quite persuasive in favoring a cyclization-induced rearrangement mechanism for mercury(II)- and palladium(II)-catalyzed allylic ester and hetero-Cope rearrangements. Some of the key observations are: 1) the soft electrophiles[7] mercury(II) and palladium(II) are much more effective than hard Lewis or Brønsted acids in catalyzing the rearrangement of allylic imidates and allylic esters[11,37]; 2) the general requirement[10,11,21,28,40] that substrates **60** have a H atom at C-2 is consistent with the bonding of a bulky metal at this carbon. Alkyl substitution at this site should not dramatically decrease[3d,63] the rate of a concerted [3,3]-sigmatropic rearrangement of complex **63**; 3) intermediate **61** rationalizes the rate of rearrangement of allylic esters in both mercury(II)-catalyzed ($Z = NR_2 > 4$-methoxyphenyl $> CH_3$)[10-12] and palladium(II)-catalyzed ($Z = NR_2 > OR > CH_3 > CF_3$)[21,28] reactions, since these relative rates directly parallel the stability of carbocation **61**.

The mechanistic picture is less clear for $PdCl_2$-catalyzed Cope rearrangements. In particular, the reactivity patterns observed for cyclic and acyclic 1,5-dienes are quite different. Thus, $PdCl_2$-catalyzed Cope rearrangements of acyclic dienes require[46,49-51] an alkyl substituent at C-2 (or C-5). On the other hand, 2-methyl-*cis,trans*-1,5-cyclodecadiene apparently does not rearrange[43] in the presence of $PdCl_2$, while *cis,trans*-1,5-cyclodecadiene does[42,43]. The palladium(II)-catalyzed rearrangements of *cis*-1,2-divinylcyclobutanes are different still, since products other than those of the thermal Cope reaction are sometimes obtained[45]. Transformations of *cis*-1,2-divinylcyclobutanes may be considered special cases due to the strain of the four-membered ring and the enforced boat conformation of intermediates or transition states whose formation involves bond-formation concerted with (or prior to) bond cleavage. However, the significance of the apparent differences between the rearrangements of substituted *cis,trans*-1,5-cyclodecadienes and substituted acyclic 1,5-dienes is unclear at present.

The evidence available to date on $PdCl_2$-catalyzed Cope rearrangements of acyclic 1,5-dienes is compatible[47,58] with a cyclization-induced rearrangement mechanism[64]. In particular, the requirement[46,49-51] for one "non-hydrogen" substituent at C-2 or C-5 of a 1,5-hexadiene is rationalized by the importance of this group (Z in **61**) in stabilizing the positive charge developed in the cyclization step. The failure of the 2,5-disubstituted hexadiene **55** to rearrange would then reflect the difficulties in forming a bond between the bulky metal catalyst and a sterically hindered tertiary carbon. Since a cyclohexyl intermediate is the key feature[58] of a cyclization-induced rearrangement mechanism, the many examples[55,65] of palladium(II)-promoted cyclizations of 1,5-dienes to form six-membered ring products provide further support for this mechanism. For example, the formation of cyclohexenes from the reaction of diene **56** with $PdCl_2$ (Scheme 14) is best interpreted as a "trapping" of cyclic intermediate **64** (Scheme 18), although the mechanistic details for the conversion of **64** into the cyclohexene product are currently unclear. Fragmentation of **64** to alkenepalladium(II) complex **65** is presumably not favored in this case because of the relative instability[66] of $PdCl_2$-complexes of electron deficient alkenes.



Scheme 18.

6. Conclusion and Outlook

Mercury(II) and palladium(II) salts have broad applications for the catalysis of [3,3]-sigmatropic rearrangements. The accelerations in rate brought about are dramatic: 10^{10}- to 10^{14}-fold for a 1 M solution of the catalyst. Catalytic effects of this magnitude allow many previously difficult transformations to be conducted at or near room temperature, often with attendant increases in stereoselectivity and decreases in formation of by-products. Perhaps of greater significance is that these compounds can be used to catalyze [3,3]-sigmatropic rearrangements which have no useful thermal counterparts. Salts of mercury(II) and palladium(II) tolerate a wide variety of functionalities, with the important exception of groups which bind these soft metal salts tightly. Of particular significance is that catalysis of a large number of diverse [3,3]-sigmatropic rearrangements which form a variety of C–X bonds (C–O, C–N, C–S, C–C) has already been demonstrated. It seems likely that in the future many additional applications will appear.

The concept of cyclization-induced, rearrangement catalysis has served well as a framework for our studies. Although some important mechanistic questions remain unanswered, particularly with regard to $PdCl_2$-catalysis of Cope rearrangements, there is now a considerable body of evidence to support the cyclization-induced rearrangement mechanism for many mercury(II)- and palladium(II)-catalyzed [3,3]-sigmatropic rearrangements.

The results described in this article from this laboratory were, to a large extent, the work of four talented doctorate students: Curtis Campbell, Fredrick Knoll, E. Jon Jacobsen, and Alfred Renaldo. Our efforts in the area of catalysis have been supported from their inception by grants from the U.S. National Science Foundation, with additional assistance being provided by the Camille and Henry Dreyfus Foundation.

[1] This nomenclature [2] refers to the overall bonding changes which occur in a rearrangement and implies nothing about the *mechanism* of the process. Although the sigmatropic rearrangement nomenclature was originally used by *Woodward* and *Hoffmann* for "uncatalyzed intramolecular process" [2], it has been widely employed in recent years to characterize reactions which are not of this mechanistic type. We feel the term is now best used in a non-mechanistic sense.

[53] The trivial explanation that forcing enough conditions were not employed with dienes **52**–**55** is probably not correct. We have investigated in some detail the reaction of several of these dienes with $PdCl_2(RCN)_2$ and other palladium(II) catalysts under a variety of conditions. Forcing conditions lead to other products. For example, reaction of **54** ($R^1 = R^2 = H$, $R^3 = Ph$, $R^4 = Me$) with the more soluble catalyst bis(hexanenitrile)palladium(II)chloride in refluxing THF for 17 h gave substituted cyclopentenes as the major products [54].

[58] Clearly, the reaction **60** → **62** could involve other intermediates. However, the formation at some point on the reaction pathway of the σ-bonded cyclic intermediate **61** is the key feature of this mechanism. For example, in the $PdCl_2$-catalyzed Cope rearrangement, intermediate **61** could be reached by a two-step process involving initial bond formation between Y and Pd^{2+} followed by insertion of the 1,2-π bond into the PdY σ bond. This mechanism has been suggested by *P. M. Henry*, personal communication.

Carbene Complexes in Organic Synthesis

New Synthetic Methods (47)

By Karl Heinz Dötz*

Transition metals are finding increasing use in organic synthesis on the borderline between "organic" and "inorganic" chemistry. Advantage is taken thereby of the fact that metal-induced CC bond formation often takes place with remarkable selectivity. The rapid development that has taken place in this area of chemistry is clearly demonstrated by the carbene complexes, examples of which are now known for almost all transition elements, and which have transformed from organometallic curiosities into synthetically useful reagents in less than two decades since the first studies of *E. O. Fischer*. They are not only suitable as carbene-transfer agents but also undergo interesting cycloadditions with other ligands in the co-ligand sphere. Their manipulation requires techniques no more complicated than those for Grignard reactions. Thus, carbene complexes can also be used in the synthesis of natural products such as vitamins or antibiotics.

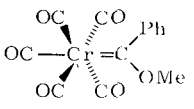
1. Preliminary Remarks

One of the most outstanding properties of transition metals is their ability to stabilize short-lived molecules as ligands in coordination compounds. There are two advantages to this: Firstly, a reactive molecule can be studied and characterized as the ligand of a complex that is much more easily handled. This will especially appeal to the chemist who is interested in mechanism, spectroscopy, and structure. Secondly, the metal fragment can also be considered as a protecting group, which can be cleaved off when so desired. If the complex can be "bottled" and stored, it offers the synthetically oriented chemist a source of short-lived molecules that can be tapped at any time. The easier the complex is to prepare, the more likely it will be used.

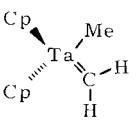
Carbenes—derivatives of divalent carbon—are a widely used building block in organic synthesis[1]. In particular, they are used in the synthesis of small rings. Classical sources of carbenes are diazo compounds and ketenes[2–4], which readily undergo thermal, photochemical, or metal-induced cleavage. In addition, organometallic precursors such as trihalomethylmercury compounds[5] and α-haloalkyllithium compounds[6] have also proven useful. The reactivity of the carbene species is dependent on both the choice of precursor and the method of generation. Truly free carbenes are only to be expected in gas-phase reactions; for example, by thermolysis or photolysis of ketenes. In contrast, one must reckon in solution with a broad spectrum of more or less stabilized carbene species, the reactive behavior of which can only be vaguely defined by the term "carbenoids".

2. Carbene Complexes—Classification and Pattern of Reactivity

Carbene complexes contain metal-stabilized carbenes[7]. These compounds can be divided into two classes: the "Fischer-type"[8] and the "Schrock-type"[9], named after their discoverers. Subdivision into "carbene complexes" and "alkylidene complexes", which is encountered now and then, makes little sense didactically and has at most only historical significance.

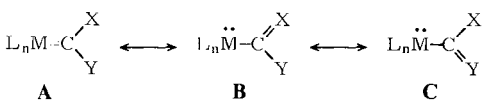


1



2

"Fischer-type" compounds such as **1** contain a metal from Groups VI to VIII. It is present in a low oxidation state, which is stabilized by a series of other ligands with pronounced acceptor properties (e.g., carbon monoxide). A typical representative is pentacarbonyl[methoxy(phenyl)carbene]chromium **1**, the first carbene complex that was characterized by X-ray crystallography[10]. The carbene carbon in this compound is considered to be sp^2-hybridized; the distances between it and its substituents, especially the heteroatoms, are short relative to single bonds. The bonding must therefore be described by the three resonance structures **A**—**C**, the relative importance of which may differ in individual cases. For reasons of graphic depiction, exclusively resonance structure **A** will be used in the following discussion.



A **B** **C**

Complexes of the "Schrock-type" such as **2** (Cp = cyclopentadienyl) are characterized by an early transition metal.

The reactive behavior of the "Fischer" carbene complexes is illustrated by **3** in Scheme 1[11]. Characteristic is the electrophilicity of the carbene carbon atom, which, therefore, is the preferred site of attack for nucleophilic

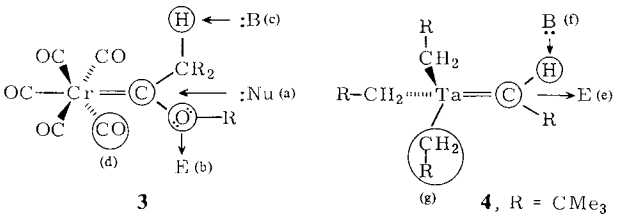
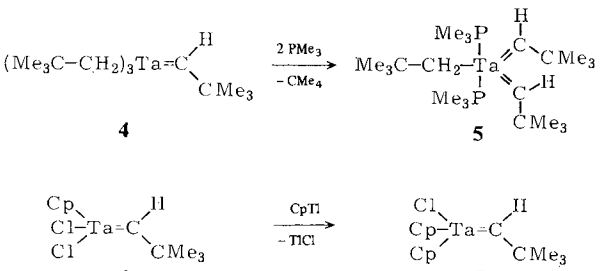
reagents :Nu [route (a)]. In contrast, electrophiles E are coordinated to the carbene heteroatom [route (b)]. This offers an easy access to carbyne complexes[7, 12]. The acidity of the C–H groups in the α-position of the carbene ligand offers a further reaction possibility. Thus, alkylcarbene complexes are deprotonated by bases :B and converted into carbenemetal anions, which can undergo bond formation with a series of electrophiles [route (c)]. Finally, as is known from the chemistry of carbonylmetal compounds, other ligands can be substituted for carbon monoxide [route (d)].



3 **4**, R = CMe_3

Scheme 1. Pattern of reactivity of "Fischer" and "Schrock" carbene complexes **3** and **4**, respectively. (a)–(g), see text.

The polarity of the metal-carbon bond is reversed in going from the "Fischer" carbene complexes **3** to the "Schrock"-type compounds **4** (Scheme 1)[9]. Consistent with a charge distribution $\overset{\delta\oplus}{M}-\overset{\delta\ominus}{C}$, electrophiles add to the carbon [route (e)]. Likewise, strong bases result in deprotonation; thus, this takes place in the neopentylidene ligand of **4** directly on the metal-coordinated carbon [route (f)]. Reactions in the co-ligand sphere show clearly that the number of valence electrons of the metal can vary widely: For example, reaction of **4** with trimethylphosphane and of **6** with thallium cyclopentadienide take place with retention of the alkylidenemetal structure to give compounds **5** and **7**, respectively [route (g)]. Compounds **5** and **4**, in which the central metal atom has 14 and 10 valence electrons, respectively, contrast with the 18-electron complex **2**.



4 **5**

6 **7**

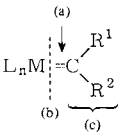
In addition to the complexes with terminal carbene ligands, alkylidene-bridged binuclear complexes have recently become known, especially through the studies of *Herrmann*. These compounds, as well as metal-coordinated vinylidenes and propadienylidenes, will not be dealt with in the following discussion since these classes of compounds have recently been reviewed elsewhere in the literature[13, 14].

3. Synthesis and Functionalization of the Carbene Ligand

3.1. Strategies for the Synthesis of Carbene Complexes

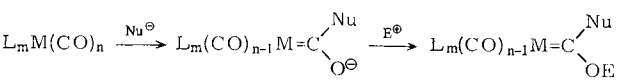
Since the first directed synthesis of a stable carbene complex by *Fischer* and *Maasböl*[15] in 1964, a large number of methods have been developed, providing access to several hundred compounds involving nearly all the transition metals. The rapid expansion of this area of research is reflected in a series of recent comprehensive reviews[7, 16–18]. Therefore, only a few characteristic synthetic examples will be selected here from the abundance of material available. Basically, three strategies are used for the preparation of carbene complexes (Scheme 2):

a) The transformation of a metal-carbon bond that is already present,
b) the addition of a carbene precursor to a coordinatively unsaturated metal complex, and
c) the modification of a carbene complex that is already available.



Scheme 2. Strategies for the synthesis of carbene complexes. (a)–(c), see text.

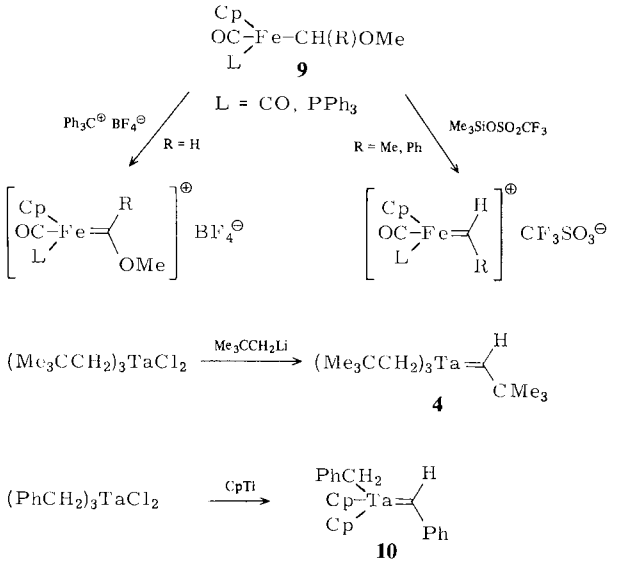
Route (a) has the greatest potential, in particular, because the commercially available carbonylmetal compounds can be used as starting materials. In this method a carbonyl ligand is converted into an alkoxy- or aryloxycarbene ligand by successive addition of a nucleophile and an electrophile. Organolithium compounds have proven to be especially useful as nucleophiles. Even at low temperatures they add rapidly enough and are preferred to the Grignard reagents[19], both for this reason and because of better yields. The rate of addition depends on the electrophilicity of the carbonyl carbon and on steric factors, which are determined by the number and kind of co-ligands. Thus, methyllithium reacts with $W(CO)_6$ about 230 times faster than with $(CO)_5WP(OPh)_3$, about 380 times faster than with $(CO)_5W(PPh_3)$, and about 660 times faster than with $(CO)_5WP(c\text{-}C_6H_{11})_3$[20]. The acyl metallates **8** are preferably alkylated with oxonium salts or fluoroalkanesulfonates; as a rule, the neutral carbene complexes are formed in 70–90% yields[21].



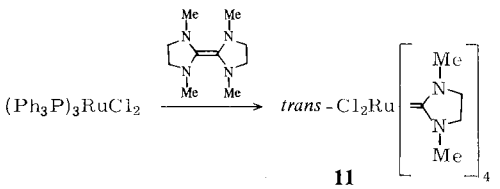
8

Besides additions to ligands, the elimination of substituents from the α-position of alkyl ligands also leads to carbene complexes. In the carbonyl(cyclopentadienyl)iron complexes **9**, a hydride or a methoxy substituent is eliminated by trityl tetrafluoroborate or trimethylsilyl trifluoro-

methanesulfonate, respectively[22,23]. The synthesis of "Schrock-type" compounds is based on the elimination of an α-hydrogen from neopentyl and other similar ligand systems[9]. Steric overcrowding of the ligand sphere is considered to be the driving force for the formation of the alkylidene complexes **4** and **10**. The stability of these compounds is therefore also increased by the introduction of cyclopentadienyl ligands.



The preparation of carbene complexes from carbene precursors has so far mainly been applied to diazo compounds[24] and electron-rich alkenes[25]. By cleavage of tetraaminoethene derivatives, several carbene ligands can be coordinated to a metal, as in **11**[26].

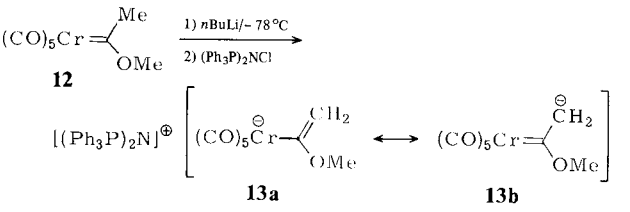


3.2. Functionalization of the Carbene Ligand

The metal-carbene bond is usually stable enough to permit a subsequent functionalization within the carbene ligand. To that end, deprotonation reactions as well as addition reactions have been applied to the series of carbonyl-carbene complexes.

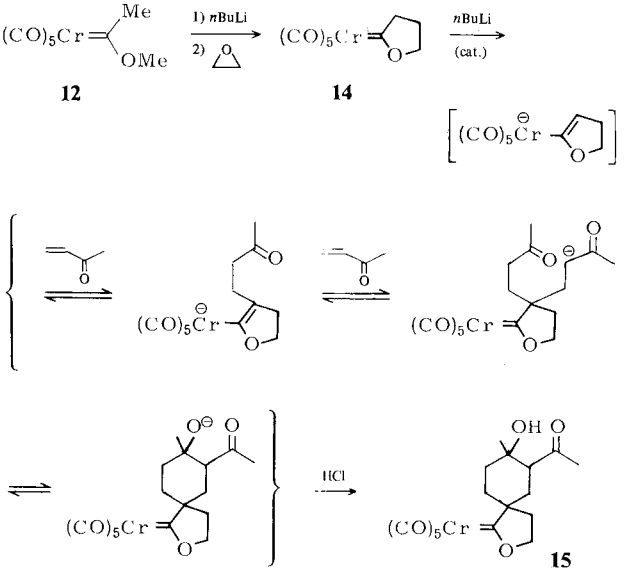
3.2.1. Carbene-Complex Anions

Complexes whose carbene substituents have hydrogen atoms in the α-position show considerable acidity[27]. Thus, pentacarbonyl[methoxy(methyl)carbene]chromium **12** has a pK_a value of ≈8[28]. The conjugate base obtained by deprotonation, which can be isolated as the bis(triphenylphosphoranediyl)ammonium salt, is, according to spectroscopic findings, better regarded as the vinylchromium anion **13a** than as carbanion **13b**.



The reaction of carbene-complex anions with electrophiles is frequently used for C–C bond formation. The anions are smoothly alkylated with allyl and benzyl bromides, α-bromo esters, aldehydes, and α,β-unsaturated carbonyl compounds[29–31]. Dialkylation as well as monoalkylation can occur[31,32], the degree of alkylation being controlled by the use of stoichiometric or catalytic amounts of base. This is illustrated by the example in Scheme 3.

The tetrahydro-2-furylidene ligand in **14** is synthesized by nucleophilic ring opening of oxirane with the anion **13**, which is generated from the carbene complex **12** using stoichiometric amounts of *n*-butyllithium[31]. It can be further functionalized in the presence of methyl vinyl ketone and a catalytic amount of base to give the spirocyclic system **15**[33].

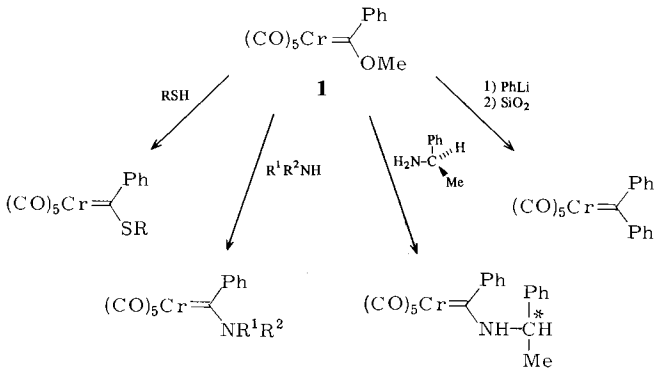


Scheme 3. Functionalization of carbene ligands via carbene-complex anions.

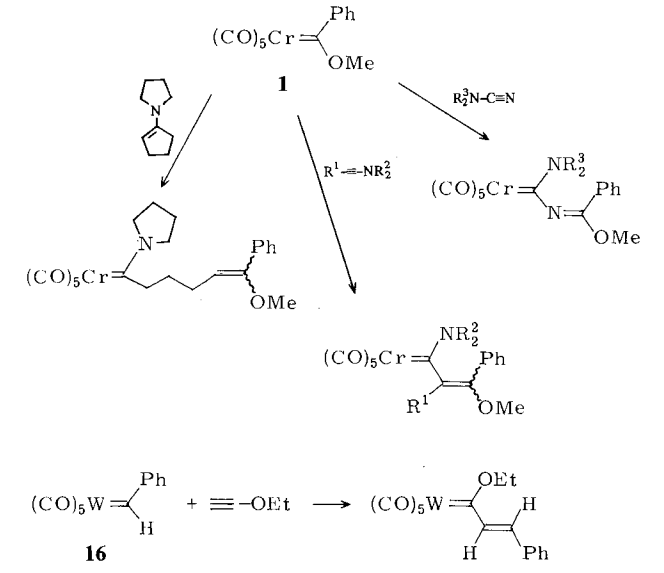
3.2.2. Addition to Carbene Ligands

Mulliken population analyses[34,35] and ESCA studies[36] have shown for "Fischer"-type compounds that the carbon atom in the carbonyl ligand bears a larger positive charge than the carbene carbon. In contrast, extensive experimental evidence confirms that the addition of nucleophiles takes place at the carbene carbon. Apparently, the course of these reactions is not charge-controlled but rather orbital-controlled. Thus, MO calculations on methoxy(methyl)carbene complex **12** show that the lowest unoccupied molecular orbital (LUMO) is spatially and energetically localized mostly on the carbene carbon atom[34]. The nucleo-

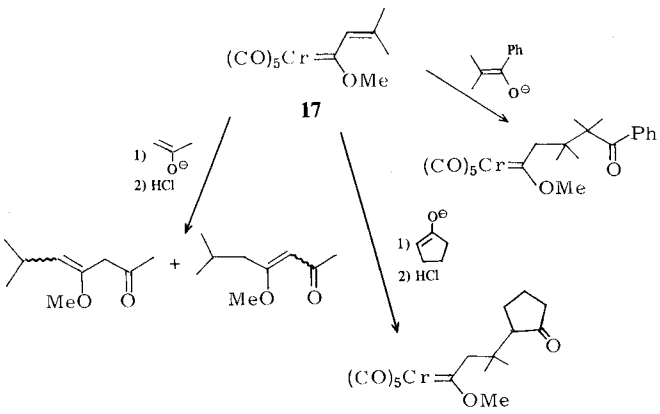
philic addition at the carbene carbon has found wide application in the modification of carbene ligands; the alkoxycarbene complexes, which are obtainable directly from the carbonylmetal compounds, function as intermediates. Thiols[37], primary and secondary amines[38], and aryllithium compounds[39,40] react by substituting for the methoxy group, leading to alkyl- (or aryl)thio-, amino- and arylcarbene ligands, respectively. The mechanism of the aminolysis of alkoxycarbene complexes is similar to that of the aminolysis of esters[41]. By using chiral amines, the reaction can be exploited for the synthesis of optically active carbene complexes[42,43]. These examples show that alkoxycarbene complexes can thus be regarded as organometallic ester equivalents.



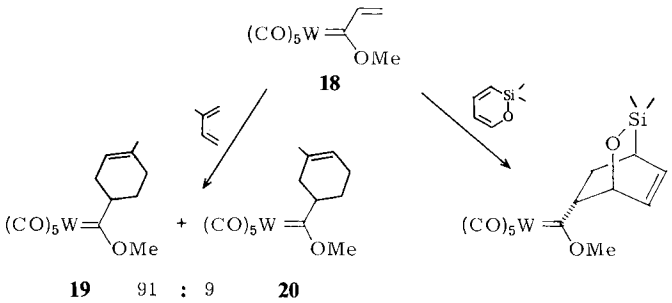
In nucleophilic multiple bond systems, not only the primary addition but also an insertion into the metal-carbene bond takes place. Enamines, ynamines, and cyanamides react smoothly with alkoxycarbenes of type **1**[44–47], whereas ynyl ethers require that the carbene carbon be more electrophilic, as is the case for the thermally labile benzylidene compound **16**[48]. The formation of the CC double bond always takes place stereospecifically to give predominantly or even exclusively the *E*-configuration.



In the case of vinylcarbene complexes **17**, direct attack at the carbene carbon atom competes with a conjugate addition to the olefinic double bond[49,50]. In the process, steric factors play a role, as shown by the example of enolate addition: the less bulky enolate of acetone attacks the carbene carbon atom. Decomposition of the addition product leads to a mixture of isomeric enones. In contrast, the more bulky enolates of cyclopentanone and isobutyrophenone are added at the terminal vinyl position.



Vinylcarbene ligands behave as dienophiles in the sense of a Diels-Alder reaction. The cycloaddition of **18** with isoprene is superior in terms of yield to the $AlCl_3$-catalyzed reaction of the ester analog methyl acrylate—the regioselectivities and reaction rates being comparable[51]. The method is also suitable for the synthesis of bicyclic systems.



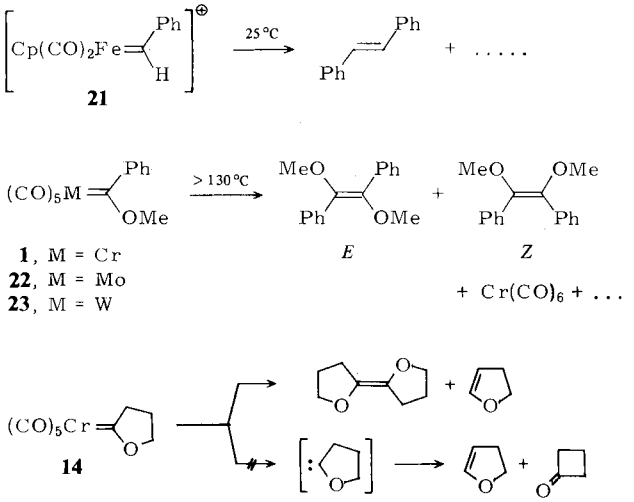
4. Carbene-Transfer Reactions

For some time it remained an open question whether the cleavage of the metal-carbene bond resulted in "free" carbenes. Although numerous different preparative methods have been used for the release or transfer of the carbene ligand, there has so far been no evidence for the appearance of a "free" carbene. In contrast, the influence of the metal on the product distribution has often been demonstrated.

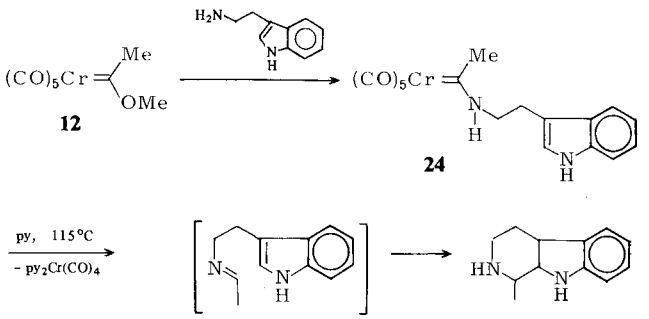
4.1. Cleavage of the Metal-Carbene Bond

The thermal decomposition of carbene complexes usually results in dimerization of the carbene ligand[52,53]. As expected, the cleavage of the metal-carbene bond is facilitated by the absence of stabilizing heteroatoms in the carbene ligand. Thus, the benzylidene ligand in the iron

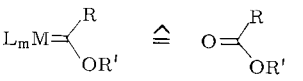
complex **21** already dimerizes at room temperature[54]. In contrast, the cleavage of the α-methoxybenzylidene ligand in **1**, **22** and **23** only begins above 130°C[52,55]. The elimination of carbon monoxide proved to be the initial step of the reaction. The metal must be involved in the formation of the C=C bond, as shown by the change in *E/Z* ratio within the series chromium, molybdenum, and tungsten. The thermolysis of the cyclic carbene complex **14** leads to a similar result: the reaction mixture contains no cyclobutanone, which is known to be a characteristic stable rearrangement product of metal-free 2-tetrahydrofurylidene[56].



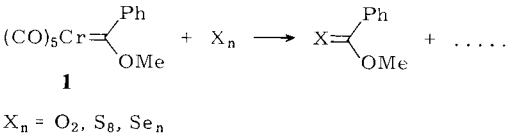
Ligand substitution is a more gentle method of cleaving the metal-carbene bond. Carbon monoxide[38], tertiary phosphanes[57,58], and amines[53,59] are suitable as substituting ligands. When using amines, the acidity of carbene complexes must be taken into account. Alkylcarbene ligands do not dimerize: instead, a base-induced 1,2-hydrogen shift takes place, which can be exploited for the preparation of enol ethers and azomethines. A reaction in the alkaloid series serves as example: the methoxy compound **12** is converted into the aminocarbene complex **24** by aminolysis with tryptamine. Subsequent cleavage of the carbene ligand in pyridine affords tetrahydroharmane in 17% yield[60].



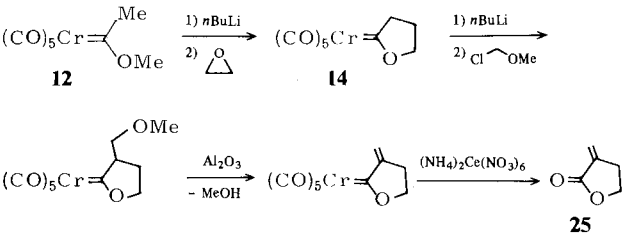
As shown by their aminolysis, alkoxycarbene complexes can be regarded as ester equivalents, the metal fragment corresponding to the carbonyl oxygen:



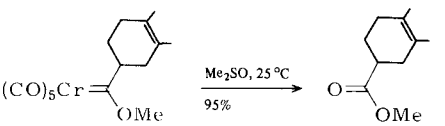
This analogy suggests the possibility of an oxidative cleavage of the metal-carbene bond. In early studies, oxygen was used directly as the oxidizing agent[61]. However, since it is not a clean reaction, the method has not achieved preparative significance. Nevertheless, it can be used for the preparation of difficultly obtainable thio or seleno esters, using sulfur or selenium as oxidizing agents[62].



Cerium(IV) compounds are versatile reagents for the transformation of carbene ligands into carbonyl compounds[29,63]. The oxidation does not affect multiple bonds and generally proceeds in high yield, so that it is also suitable for the characterization of carbene ligands in labile complexes. An example of its preparative use is the synthesis of the α-methylene-γ-butyrolactone skeleton **25**, which is a component of several natural products and has been synthesized via **14** in an overall yield of 20% from the methoxy(methyl)carbene ligand bonded to the chromium center of **12**[64].



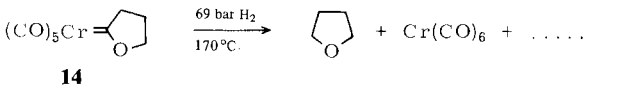
Mild reaction conditions during the oxidation are ensured using dipolar reagents such as amine oxides, sulfoxides, thioamide *S*-oxides, or iodosylbenzene[51,65,66], of which especially the use of dimethyl sulfoxide has become established.



In contrast to the oxidation, the reductive cleavage of the metal-carbene bond has achieved no preparative significance.

Hydrides reduce carbene complexes merely to alkylmetal compounds[67]. The cleavage of the carbene ligand with hydrogen, resulting in formation of the saturated hydrocarbon, requires drastic conditions. In order to suppress competing carbene dimerization, low concentrations of the

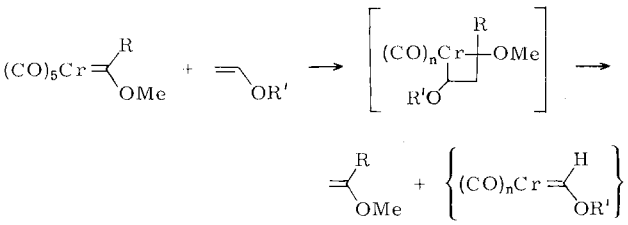
carbene complex, as well as relatively high hydrogen pressure, have to be used[51,68].



14

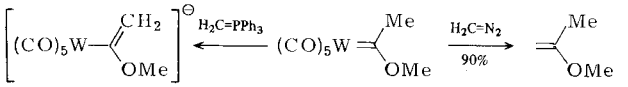
4.2. Alkenylation Reactions

Carbene (alkylidene) ligands can be used for the synthesis of olefinic double bonds. Thus, the electrophilic carbene carbon of "Fischer" complexes reacts with nucleophilic multiple bond systems such as enol ethers, enamines, diazoalkanes, or phosphorus ylides to give alkenes[69–73]. This type of reaction is a model for the metathesis of olefins (Section 7.1). Four-membered metallacycles are assumed to be intermediates, the cleavage of which affords, in addition to the olefin **26**, a coordinatively unsaturated carbene-complex species.

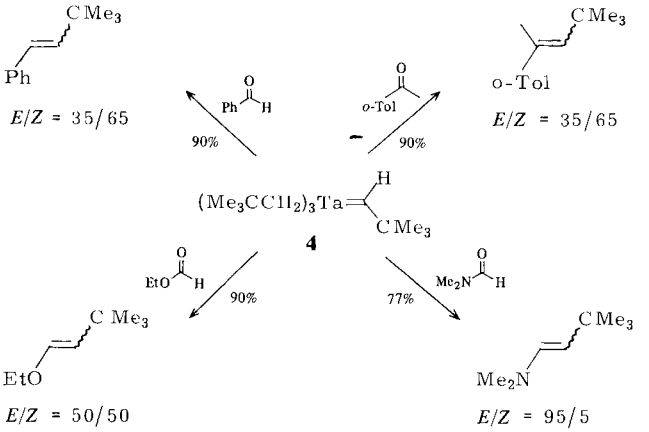


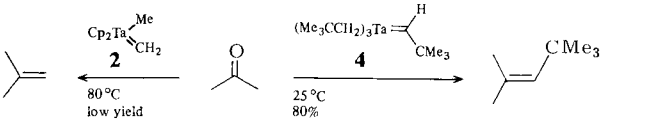
26

The alkenylation of the carbene ligand is dependent on the steric demands as well as on the basicity of the nucleophile. Thus, in contrast to ethylidene(triphenyl)phosphorane, the bulkier isopropylidene compound no longer undergoes C=C bond formation. For alkylcarbene complexes, phosphorus ylides effect a competing deprotonation, hence it is better to resort to the less basic diazoalkanes.

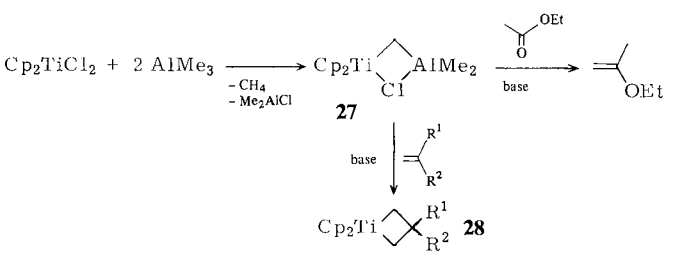


"Schrock"-type complexes which contain an early transition metal can be regarded as transition-metal analogs of ylides as far as their reaction behavior is concerned[9]. Accordingly, they react with carbonyl compounds in Wittig-type reactions to form C=C bonds. Thus, the tantalum-neopentylidene complex **4** converts ketones and aldehydes into *tert*-butyl-substituted olefins. The metal forms an oxo compound, which presumably is polymeric. Of great preparative significance is the discovery that these complexes—in contrast to the phosphorus ylides[74]—also alkenylate esters and even amides[75]. The reason for this is to be seen in the pronounced oxophilicity of the early transition elements. The rate of alkylidene transfer is determined not only by steric factors in the electrophile (acetophenone reacts immediately at room temperature, pivaldehyde only very slowly over several hours), but also by the electronic configuration of the metal. The 18-electron complex **2** reacts with acetone to give only small amounts of isobutylene, whereas the 10-electron compound **4** gives the corresponding olefin in 80% yield. This result supports the assumption that coordination of the carbonyl carbon to the metal precedes transfer of the alkylidene ligand.

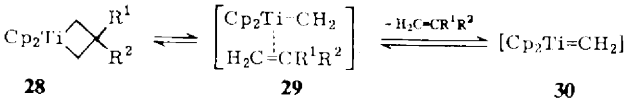




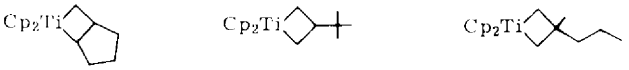
Compounds of titanium are especially suitable for the transfer of methylene. Starting from dicyclopentadienyltitanium dichloride and trimethylaluminum, a titanium-methylene complex is obtained that is stabilized as the Me_2AlCl-adduct **27** ("Tebbe compound")[76]. Although this species can be used directly for methylene transfer, for example, for conversion of ethyl acetate into ethyl isopropenyl ether[76], an indirect route via the titanacyclobutane intermediate **28** has proven to be advantageous. This compound is obtainable from **27** and an olefin and—in contrast to the aluminum reagent—can even be handled as a solid for a short time in air[77–79].



Labeling experiments and kinetic studies suggest that the titanacyclobutane can be cleaved to the alkene-methylene complex **29** and thus can be used as a source of dicyclopentadienyl(methylene)titanium **30**[79,80]. The thermal stability of the metallacycle **28** depends on the substituents. Bicyclic or sterically-shielded systems such as **28a** or **28b** are relatively stable (up to ca. 50—60°C); the methylene complex **30** is released from the most widely used dialkyl derivative **28c** at 0°C and from the aluminum reagent **27** even above −40°C[81].

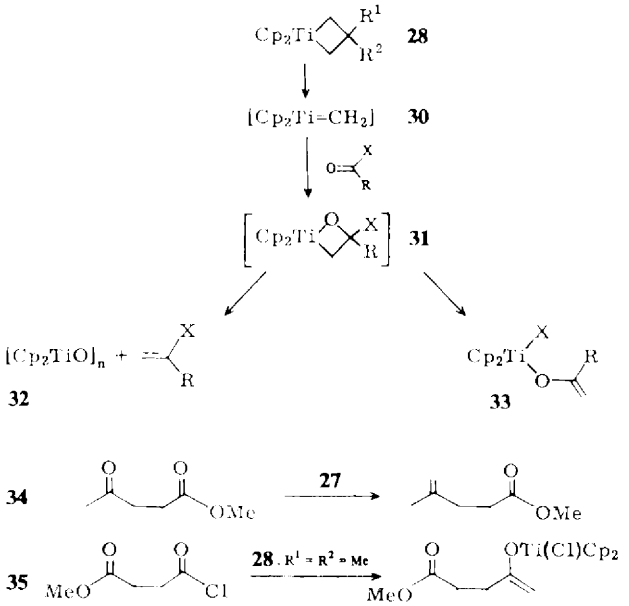


28 29 30



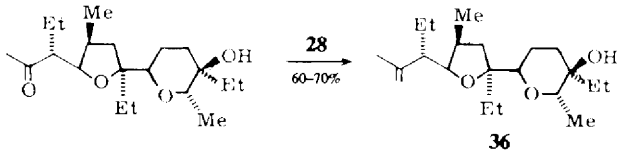
28a 28b 28c

The reaction of the titanacycles with carbonyl compounds can proceed by two pathways. An oxametallacycle **31** is assumed to be a common intermediate, which can be cleaved to give the olefin. The formation of the oxatitanocene **32** is regarded as the driving force for this cleavage. In this way, aldehydes, ketones, esters, and amides can be converted into the corresponding alkenes[79,82]. However, if the carbonyl component contains a good leaving group, as, for example, in acid chlorides or anhydrides, then the titanium enolate **33** is formed by migration of this group to the metal[83,84]. Competition experiments using 1,4-dicarbonyl compounds show considerable regioselectivity. Thus, methylene transfer decreases along the series ketone > acid chloride > ester.



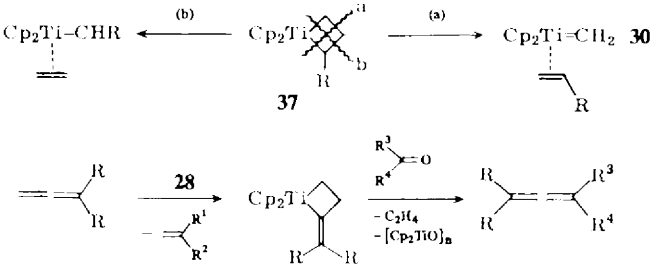
28 30 31 32 33 34 35

The titanacyclobutanes **28** enable an alkylidene transfer under non-basic conditions. They are thus suitable for reactions with enolizable ketones, there being no danger of racemization of asymmetric centers, and are therefore a good complement to the phosphorus ylides. Their synthetic use is illustrated by a step in the synthesis of Lasalocid A[85].



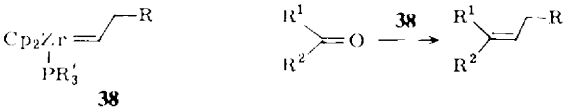
36

The extension of this reaction principle from the transfer of methylene to the transfer of alkylidenes, in general, poses difficulties. By all means, a whole series of α-substituted titanacyclobutanes **37** can be synthesized; however, their cleavage proceeds predominantly with formation of the more highly substituted olefin and the methylene complex **30** [path (a)][81]. The reasons for this are apparently steric and electronic. Thus, the direction of cleavage in the metallacycle can only be reversed if the ring substituents are small and the alkene formed is destabilized [path (b)]. In this way, the substitution of allenes is possible[86].



37

A more general method of alkenylation is based on zirconium complexes of the type **38**. It gives high yields with ketones and lactones, especially when the alkylidene substituent is sterically demanding[87].



38

4.3. Cycloaddition Reactions

The most useful reaction of carbenes from a synthetic point of view is their [2+1]-cycloaddition to alkenes[1]. Early studies on carbene complexes of the elements of Group VI already showed that metal-coordinated carbenes could also be used as cyclopropane building blocks[69,88,89]. They can be transferred to electron-deficient as well as electron-rich alkenes. To achieve this, different conditions are necessary; therefore, a single reaction mechanism is unlikely. In no case so far has evidence for the appearance of "free" carbenes been found. Moreover, since the product distribution is metal-dependent, the metal must be involved in the product-determining step. This is also shown by the transfer of chirality from carbene complex **39**, the optical activity of which is due to the phosphane ligand, to the cyclopropane **40**. The cyclopropanation proceeds stereospecifically; the addition of the α-methoxybenzylidene ligand of complexes **1**, **22**, and **23** to unsymmetrically substituted alkenes such as crotonates gives a pair of *syn/anti* stereoisomers **41a/b**, the ratio of which increases along the series M = W, Cr, Mo[89]. The temperature necessary for reaction (≥90°C) would indicate the cleavage of a CO ligand as initial step, followed by coordination of the alkene. A reductive elimination via a metallacyclobutane **42** leads to the cyclopropane. The cyclopropanation of electron-rich olefins such as enol ethers or enamines can be achieved at lower temperatures, but only under CO pres-

sure[69,90]. Instead of an initial cleavage of CO, a nucleophilic addition of the alkene to the carbene carbon is therefore assumed. As shown by the dependence of the product ratio **43a/b** on the metal, the central metal atom must also be involved in the subsequent course of the reaction.

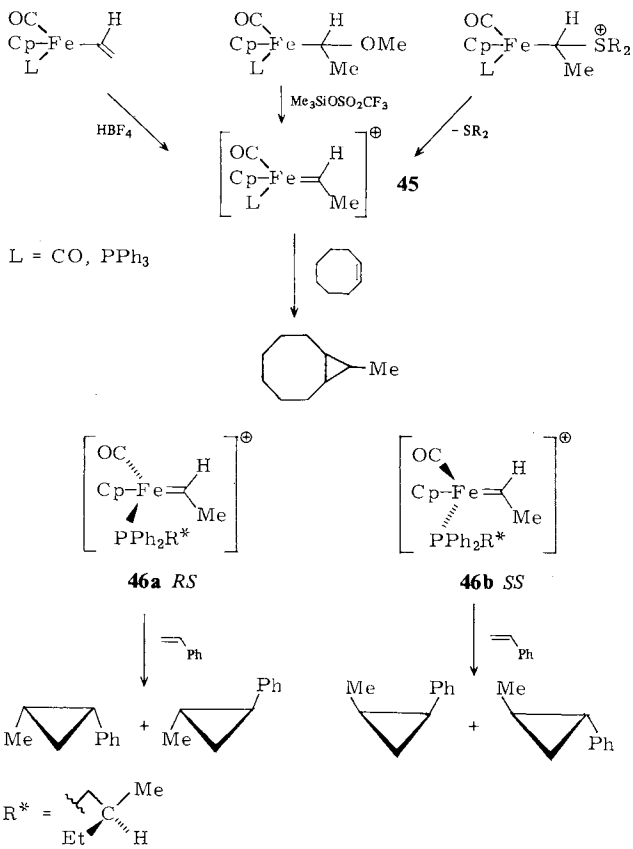
Carbene ligands that are not stabilized by heteroatoms in the α-position can also be transferred to non-activated olefins. Studies on the phenylcarbenetungsten complex **16**, a thermally labile compound which already decomposes at −56 °C with a half-life of 24 min, show that the cyclopropanation is favored by increasing electron density in the alkene[48]. Thus, in competition experiments at −78 °C, isobutene reacts about 320 times faster than propene and about 3500 times faster than ethene. Since the CO exchange in the carbene complex should be markedly slower at this temperature than the carbene transfer to the olefin, a direct attack of the pronouncedly electrophilic phenylcarbene ligand on the less substituted carbon atom of the alkene has been suggested. Surprisingly, with some olefins, such as *cis*-2-butene or 2-methyl-2-butene, the thermodynamically less stable *syn*-cyclopropanes **44a** are preferably formed, a result that has not yet been satisfactorily explained[48,91].

16 **44a** **44b**

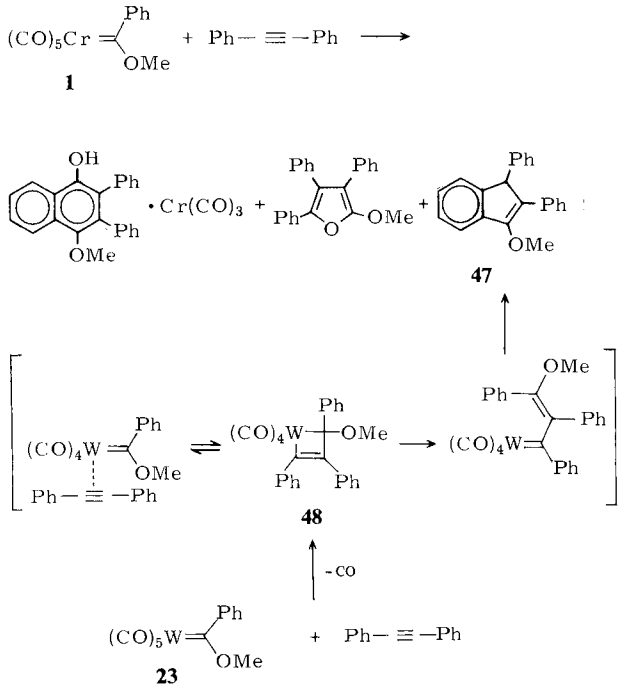
R = H	37	1
R = Me	90	1

In addition to the elements of Group VI, iron also offers an entry to strongly electrophilic carbene ligands. These are obtained from alkenyl, alkoxyalkyl, or dialkylsulfonium-alkyl ligands[23,92,93] and have been transferred to a series of non-functionalized olefins[93-96]. The cyclopropanation takes place, like that for the tungsten complex **16**, with favored formation of the *syn*-configuration[94]. The alkylidene transfer can be made enantioselective by introduction of a chiral phosphane ligand into **45**[97]. The complex cation **46** is obtainable as a pair of diastereomers. Since the diastereomers **46a** and **46b** give cyclopropanes with opposite configurations and, indeed, in practically the same enantiomeric purity, the chirality at the metal is primarily responsible for the optical induction.



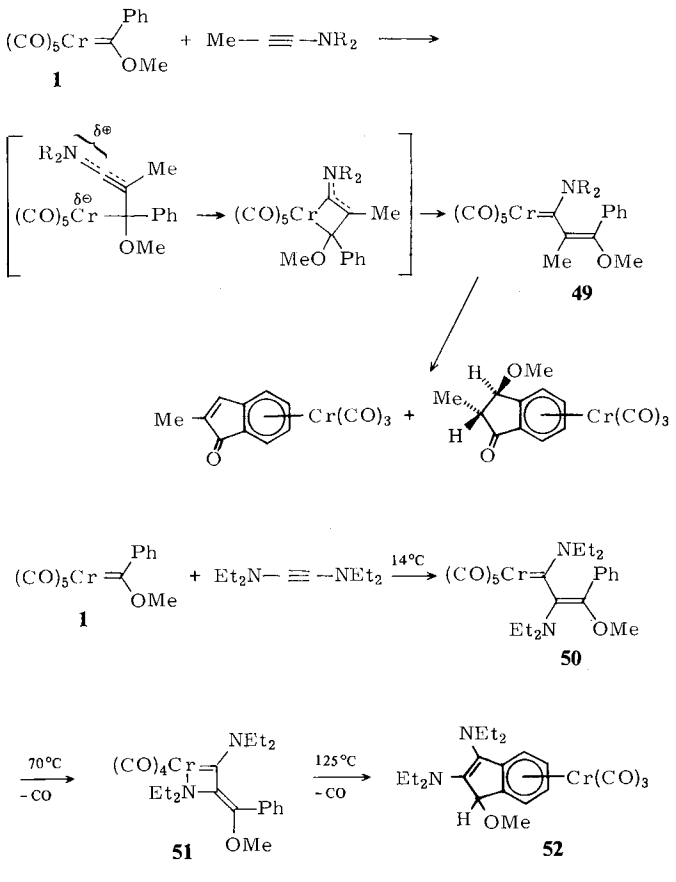
46a *RS* **46b** *SS*

In special cases, phenylcarbene ligands can be annelated by alkynes to give indenes. The first example of this type of reaction was the reaction of the carbene complex **1** with tolane in a poorly coordinating solvent[98]. In addition to other products such as naphthohydroquinone derivatives and furan derivatives, which are formed by cycloaddition of the methoxy(phenyl)carbene ligand, CO ligand, and alkyne, the indene **47** is formed, which is the formal [2+3]-cycloadduct of the alkyne and the carbene ligand. This reaction can be carried out selectively if the chromium

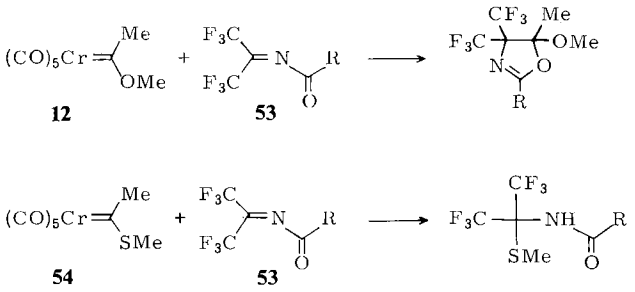


compound **1** is replaced by the analogous tungsten complex **23**[99]. In this case, the stronger metal-carbonyl bond ($\overline{\Delta H}_{W-CO} = 178$ kJ mol^{-1} in contrast to $\overline{\Delta H}_{Cr-CO} = 108$ kJ mol^{-1})[100] prevents insertion of carbon monoxide into the reaction product.

The formation of the indene skeleton could take place via insertion of the alkyne into the metal-carbene bond. Such a reaction sequence has been demonstrated for nucleophilic alkynes. Ynamines and ynyl ethers add to the carbene carbon and are inserted into the metal-carbene bond, possibly via a four-membered metallacycle[45,47,48]. The *E*-styrylcarbene ligand in **49** can be cyclized only in small yield to the indanone and indenone skeleton, probably because of the flexible alkenyl side chain[101]. The course of the reaction can be better controlled if the freedom of motion of the alkenyl side chain is restricted by coordination to the metal. This is clearly demonstrated by the example of an ynediamine, which undergoes 1,3-addition to the phenylcarbene ligand, forming the diaminoindene complex **52** via the isolable intermediates **50** and **51**, the course of the reaction being temperature-controlled[102,103].

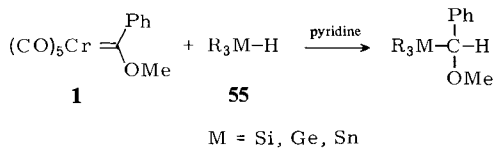


So far, only one example of a [4+1]-cycloaddition is known. *N*-Alkylideneamides **53** react with alkoxy- and aminocarbene ligands, as they do with carbenes or isocyanides, to give dihydrooxazoles[104]. In contrast, the thiocarbene complex **54** undergoes cleavage of the carbene-sulfur bond, and the methylthio group is added to the imine carbon.

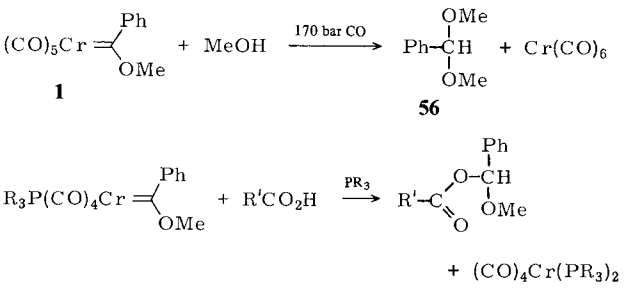


4.4. Insertion Reactions

In addition to cycloadditions to unsaturated compounds, insertion reactions are also a characteristic feature of carbene chemistry which can provide information on the nature of the carbene species. So far, there is no known example for the insertion of a metal-coordinated carbene into a C–H bond. This reaction is regarded as the criterion for the appearance of a "free" carbene[1]. In contrast, carbene ligands insert into the more reactive silicon-, germanium-, and tin-hydrogen bonds[105–107]. The reaction is favored by the presence of a base (e.g. pyridine), which finally replaces the carbene ligand. Kinetic investigations with alkoxy- and aminocarbenechromium complexes and triorganometal hydrides **55** have shown that a dissociative first-order component competes with a predominant, associative contribution that is due to nucleophilic attack of the hydride on the carbene carbon[108,109]. The rate of reaction increases along the series Si < Ge ≪ Sn, which has been interpreted in terms of an increasing tendency towards pentacoordination.



Insertion reactions are also known for oxygen-hydrogen bonds; in the presence of carbon monoxide or phosphanes, the carbonylmetal fragment becomes coordinatively saturated. Thus, the complex **1** reacts with methanol in a CO atmosphere to give the acetal **56**[110], while carboxylic acids are esterified[111].

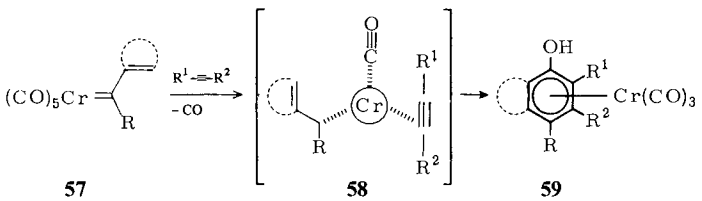


5. Carbonyl-Carbene Transfer Reactions

Carbonylcarbene complexes contain complex-bonded carbon monoxide in addition to the carbene ligand. The wide use of carbonylmetal compounds in carbonylation reactions[112,113] would suggest that the carbonyl ligand in the carbene complex might also be used for syntheses. The bifunctional behavior of this class of compounds is manifested in their reactions with alkynes and Schiff bases.

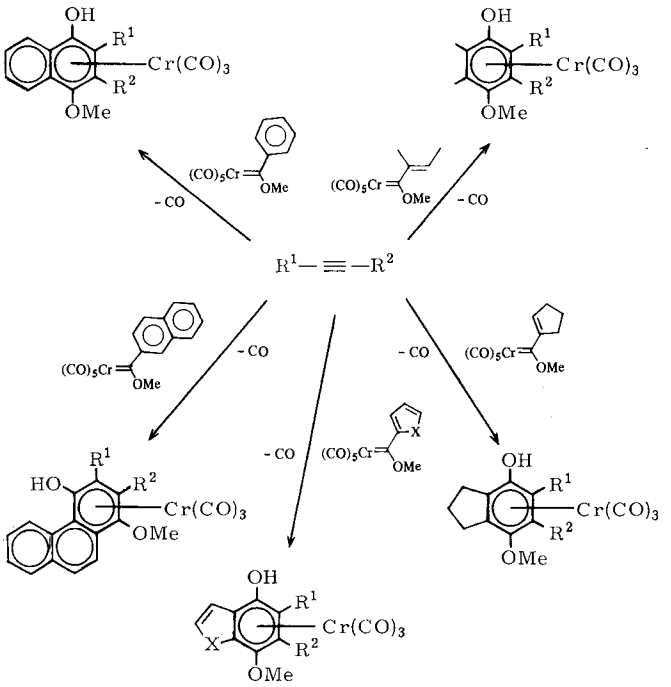
5.1. Cocyclization with Alkynes

Bond formation of carbenes *and* carbon monoxide with alkynes can be carried out at a chromium center[114]. The prerequisite is that the three components have to be directly coordinated to the metal. If pentacarbonylcarbene complexes and alkynes are used, the free coordination site required can be created by a thermally or photochemically induced cleavage of a CO ligand. The CO cleavage depends on the donor-acceptor ability of the carbene ligand and parallels the electrophilicity of the carbene carbon atom, e.g., along the series $:C(NR_2)Ph < :C(OR)Ph < :CPh_2$. In the octahedrally arranged pentacarbonylcarbene complexes, four *cis*-CO ligands and one *trans*-CO ligand can be differentiated. In accordance with the relative donor-acceptor properties of carbene and carbonyl ligands, the elimination of a *cis*-CO ligand is expected to be favored; this is confirmed by CO-exchange studies[115]. Starting with complex **57**, which contains an unsaturated carbene ligand, the addition of the alkyne to the free coordination site leads to a facial alkyne-carbene-carbonyl complex **58**. This reactive intermediate has not yet been isolated. It undergoes rather a clean cycloaddition reaction to give an aromatic six-membered ring which is π-bonded to the metal (Scheme 4)[116].



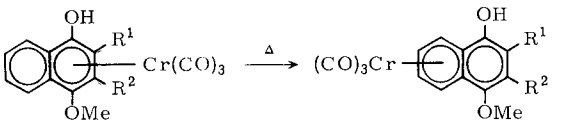
Scheme 4. Cycloaddition of alkyne, carbene, and carbonyl ligands bonded to a chromium center. Ⓒr = Cr(CO)$_3$.

The alkyne is incorporated into the 2,3-position of the hydroquinone derivative **59**. The C-4—C-6 ring positions come from the carbene ligand, whereas C-1 is contributed by the carbonyl ligand. The cycloaddition takes place in donor solvents (e.g., ethers) under mild conditions (40—60°C); the yields are usually 60—90%. The formation of the arene complex **59** is not limited to vinyl-[117] and phenylcarbene substituents[114,118,119]. Carbocycles, heterocycles, and polycyclic arene ligands[120] can also serve as carbene ligands for the synthesis of complexes with benzoannelated arenes (Scheme 5). The metal is always bonded to

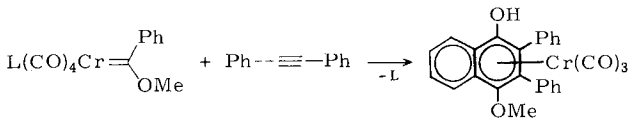


Scheme 5. Benzoannelation of carbene ligands.

the newly formed aromatic ring under conditions of kinetic control. However, in the naphthalene complexes **60** metal migration to give the thermodynamically more stable 4a-8a-η^6-compounds **61** occurs if longer reaction times and higher reaction temperatures are used.



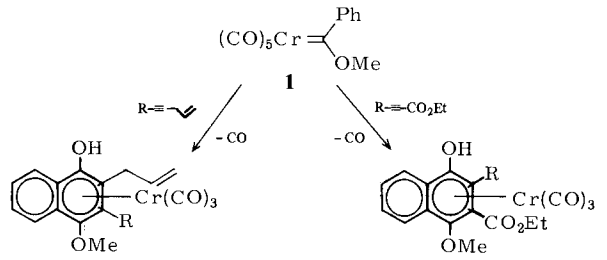
The formation of a free coordination site in the carbonylcarbene complexes can be influenced by other ligands. It is facilitated by good acceptor ligands, as shown by the series of carbene complexes **1**, **62a**, and **62b**. Thus, the



1, L = CO	3 h/45 °C	62%
62a, L = P(*p*-FC$_6$H$_4$)$_3$	2.5 h/60 °C	61%
62b, L = P(*n*Bu)$_3$	2.5 h/90 °C	11%

yield for the reaction with tolane decreases to ca. 1/6 when carbon monoxide or tris(*p*-fluorophenyl)phosphane is replaced by the weaker acceptor tributylphosphane[120].

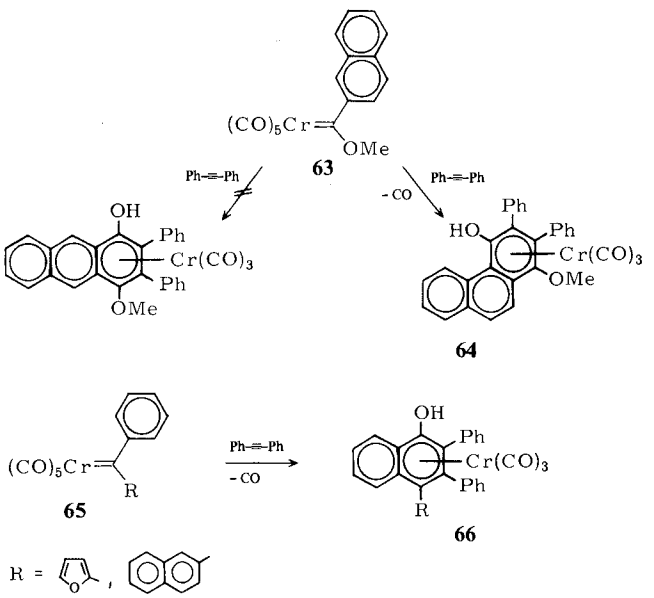
In addition to aliphatic and aromatic alkynes, functionalized derivatives can also be used as the alkyne component. Besides alkynoates[118,121], non-conjugated enynes[122] are suitable since the bond formation between the carbene ligand and the C≡C bond in the cycloaddition proceeds appreciably faster than the cyclopropanation. For this reason, the cycloaddition is also interesting for the synthesis of more complex structures.



An important criterion for the value of a cycloaddition is its regioselectivity. In the present case, the regioselectivity relates to

a) a carbene substituent which offers two possibilities for annelation[120],
b) a competing annelation, such as expected for diarylcarbene ligands[120], and
c) the incorporation of unsymmetrical alkynes into the aromatic ring[117,119,120,123].

The regioselective annelation of a carbene substituent is exemplified by the 2-naphthylcarbene complex **63**. The new ring can, a priori, be joined to either the 1-position or the 3-position. Exclusively the phenanthrene complex **64** is isolated from the reaction with tolane. Only when the 1-position is blocked by substitution is the anthracene system obtained[124]. Similarly, in the diarylcarbene complexes



65, which bear a furyl or a naphthyl substituent in the carbene ligand in addition to a phenyl ring, annelation of the phenyl ring is preferred, so that naphthol complexes **66** are formed.

The regioselectivity of the alkyne incorporation depends strongly on the alkyne. In the reaction with methoxy(phenyl)carbene complexes such as **1**, it increases in going from diaryl- to dialkylalkynes and to terminal alkynes (Scheme 6)[119,123]. This trend also holds for vinylcarbene complexes[117]. Tolane derivatives that are partly selectively substituted in the *p*-position give both possible regioisomers **A** and **B** in approximately equal amounts. With 2-al-

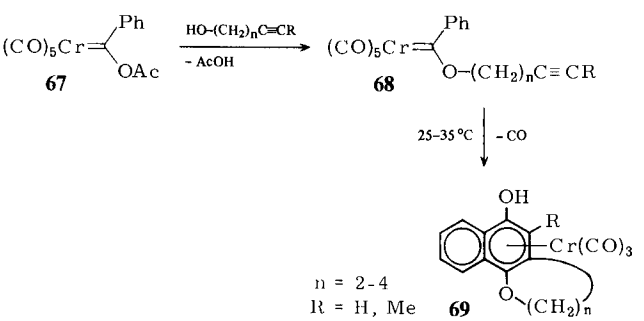
kynes, the isomeric ratio increases to about 2:1. Isomer **A**, in which the longer side chain is adjacent to the hydroxy group, always predominates. The example of methylphytylacetylene shows that the length of the side chain has no effect. In contrast, the regioselectivity is improved by α-substitution in the alkyne (e.g. in 4,4-dimethyl-2-pentyne). Another point to consider is the incorporation of the alkyne component into the carbene ligand[125]. The cycloaddition can thereby take place intramolecularly, which consequently reduces the conformational freedom. The required alkynyloxycarbene complex **68** can be obtained by nucleophilic addition of the alkynol to the acetoxycarbene compound **67**, which can be regarded as an organometallic analog of an anhydride. The cycloaddition of **68** proceeds smoothly with internal triple bonds (R = Me), providing a good extension of the intermolecular variant of the reaction. Carbene substituents with terminal alkyne functions (R = H), however, give only moderate yields of the tricyclic compounds **69**. On the other hand, terminal

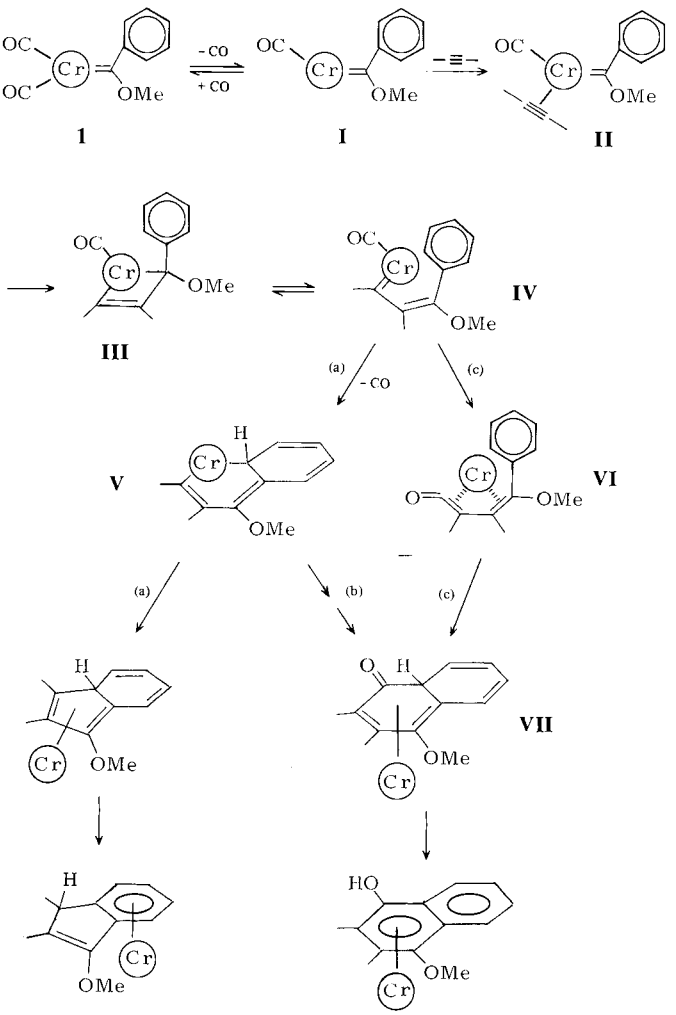


alkynes, as well as the arylalkylacetylene 1-phenyl-1-propyne, are incorporated regiospecifically even in the intermolecular reaction within the detection limits of NMR spectroscopy (±3%). Only isomer **A**, in which the sterically more demanding alkyne substituent is present in the more accessible 2-position, can be observed. This finding indicates that the regioselectivity of alkyne incorporation is mainly controlled by steric factors, which favor bond formation between the carbene carbon and the spatially less-shielded alkyne carbon atom.

5.2. Vinylketenes as Intermediates

Initial studies on the reaction mechanism had shown that the cycloaddition is suppressed by the presence of carbon monoxide[118]. This finding pointed to cleavage of CO in the first step, which was later confirmed by a more thorough kinetic study[126]. Accordingly, the kinetic parameters found for the reaction of the methoxy(phenyl)carbene complex **1** with tolane, a relatively high activation enthalpy ($\Delta H^{+} = 108 \pm 2$ kJ mol^{-1}) and a positive activation entropy ($\Delta S^{+} = 26 \pm 6$ J mol^{-1} K^{-1}), are characteristic of substitution reactions in carbonyl carbene complexes that take place by a dissociative mechanism[127]. The elimination of carbon monoxide gives a coordinatively unsaturated tetracarbonyl carbene complex, for which the alkyne and the cleaved CO ligand compete (Scheme 7). The re-addition of the carbon monoxide takes place faster than complex formation with the alkyne. The rate of alkyne coordination increases with increasing electron density in the alkyne function. Thus, in CO-saturated dibutyl ether, the coordination of 1-phenyl-1-propyne takes place about 5 times faster than that of the more electron-deficient tolane; it is, however, still 40 times slower than the addition of carbon monoxide. Since the CO substitution takes place preferably in the position *cis* to the carbene ligand[115,128], an intermediate **II** is formed in which the metal fixes the three different ligands in a facial configuration, i.e. on an octahedral surface. In comparison with the first two reaction steps, the subsequent steps proceed so fast that the kinetics of the reaction provides no further information about them. Nonetheless, it is plausible to assume bond formation between the alkyne and carbene ligands in the next step to give chromacyclobutene **III**, the ring opening of which results in a coordinatively unsaturated alkenylcarbene complex **IV**. From here, several reaction pathways are conceivable[7,116]:

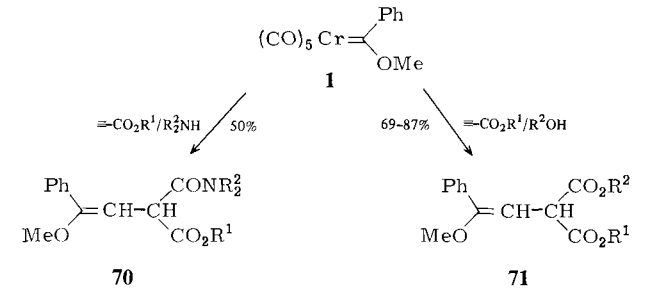
a) The oxidative addition of the phenylcarbene substituent to the metal gives a chromacyclohexadiene **V**, which via σ-π rearrangement, re-aromatization, and metal migration results in an indene complex.
b) The chromacyclohexadiene **V** could undergo a CO insertion into the metal-carbon bond and give, via σ-π rearrangement, a chromium-coordinated cyclohexadienone **VII**, which then isomerizes to the naphthol complex.
c) Alternatively, the formation of the naphthol skeleton can take place via carbonylation of the alkenylcarbene carbon in **IV** to give the vinylketene complex **VI**, which undergoes an electrocyclic 1,6 ring-closure involving the phenyl substituent and gives the naphthol complex via cyclohexadienone **VII**.



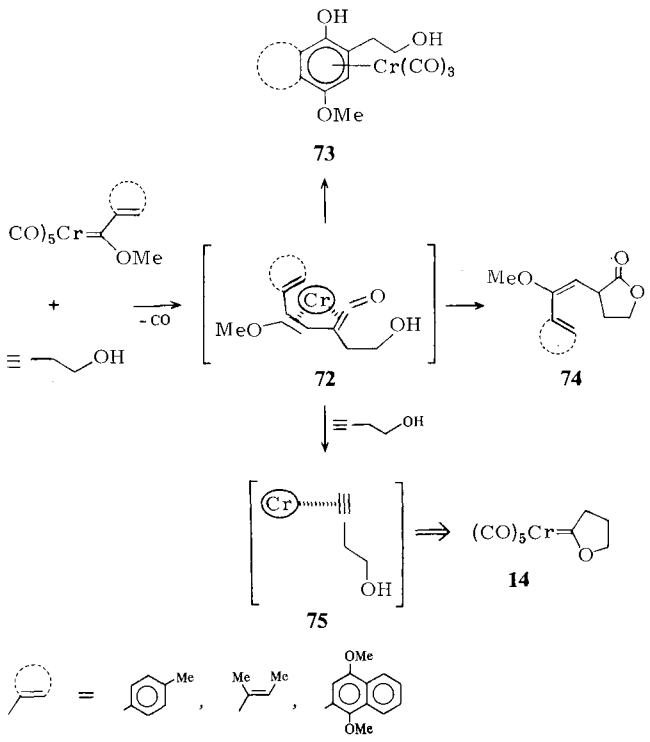
Scheme 7. Discussion of the reaction mechanism. (a)—(c), see text. Cr ≡ Cr(CO)$_3$.

According to Scheme 7, the chromacyclobutene **III** and the vinylketene **VI** are key intermediates. Thus, the observed regioselectivity of the alkyne incorporation and of the annelation of diarylcarbene ligands can be traced back to a selective formation of the metallacycle from alkyne and carbene ligands as well as to a selective ring opening. The occurrence of coordinatively unsaturated intermediates demonstrates that a donor solvent is necessary for a smooth reaction.

Of the suggested reaction pathways, the vinylketene route (c) is supported by a series of experimental results. Thus, bond formation between carbene and carbonyl ligands in iron[129] and manganese compounds[130] is well known and has recently also been shown for pentacarbonyl(diphenylcarbene) complexes of chromium and tungsten[131]. Because of its diene-like coordination to the metal, the vinylketene ligand in **VI** should exist in the *s-cis*-conformation. Hence, a 1,4 ring closure to give cyclobutenone is expected to take place if the phenyl ring is replaced by a carbene substituent that cannot undergo annelation. This is confirmed by the reaction of methoxy(methyl)carbene complex **12** with tolane[132].



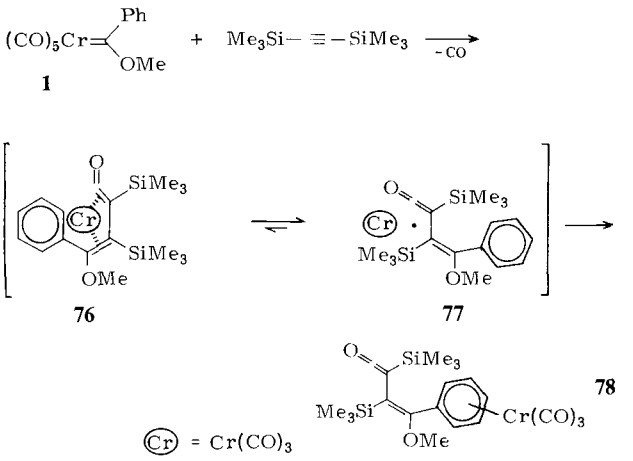
Bond formation between alkyne, carbene, and carbonyl ligands to give vinylketenes is further supported by trapping experiments. Thus, the carbene complex **1** reacts with propiolate in the presence of amines or alcohols to give the α,β-unsaturated 1,3-dicarbonyl compounds **70** and **71**, respectively[133]. The relative rates of such trapping reactions and of the cycloaddition should be determinable if alkyne and alcohol functions are combined together in the form of alkynols: A vinylketene intermediate **72** will then be formed, which can undergo annelation of the carbene substituent to give the arene skeleton **73** as well as addition of the alcohol to the ketene group to give the lactone **74**. This competition can be controlled by the choice of carbene ligands (Scheme 8)[134]. Both ring-closure reactions take place at comparable rates when *p*-tolylcarbene complexes are allowed to react with 3-butyn-1-ol. However, with the *E*-2-butenylcarbene complex, only the hydroquinone **73** is isolated. In contrast, the annelation of the naphthylvinylketene **72** proceeds so slowly that only the lactone **74** is obtained. On ring closure of the vinylketene **72** to give lactone **74**, the carbonylchromium fragment is set free. It adds to excess alkynol to give **75** and can be isolated as the



Scheme 8. Annelation (**73**) *versus* lactone formation (**74**).

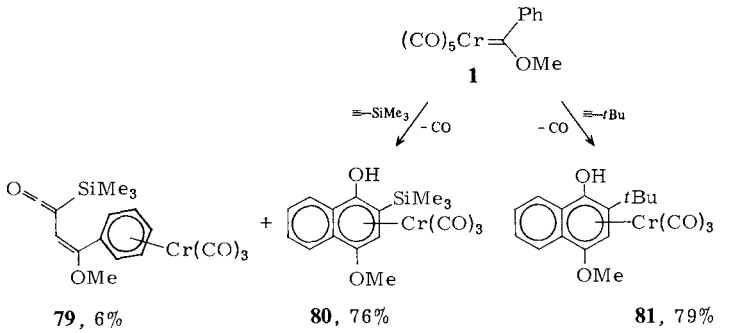
tetrahydro-2-furylidene complex **14**. This reaction course is confirmed by reaction of the alkynol with solvent-stabilized carbonylmetal fragments such as $(CO)_5Cr \cdot OEt_2$[135].

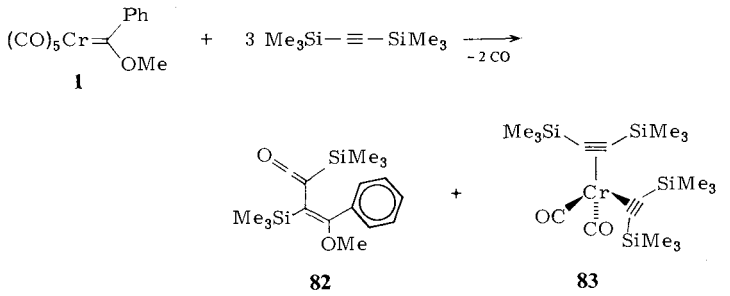
Besides trapping reactions, the isolation of stable compounds also supports the appearance of vinylketenes. These experiments are based on the argument that the *s-cis* conformation **76** of the vinylketene ligand will be forced by sterically demanding substituents R of the central C–C bond to assume an *s-trans* conformation **77** and thereby be prevented from undergoing a subsequent ring closure. The central C–C bond is derived from the alkyne; therefore, bis(trimethylsilyl)acetylene was chosen as the alkyne component. Arylvinylketenes that are coordinated by the aryl group to the metal are thus obtained from a series of arylcarbene complexes[136, 137]. They are sufficiently stabilized by the silyl substitution to allow investigation of their stereochemistry and bonding by X-ray analysis. It was shown for the phenyl compound **78** that the ketene and olefin moieties are separated by a pure CC single bond (1.51 Å) and form a dihedral angle of 77° along this axis[138]. Any



electronic interaction is thus obviated. The isolation of the vinylketene can be traced back to the steric and electronic properties of the trimethylsilyl group. Thus, in the case of trimethylsilylacetylene, the formation of the vinylketene **79** can hardly compete any longer with the cycloaddition to give the naphthohydroquinone skeleton **80**[137], and, if the even bulkier *tert*-butyl group is substituted for the trimethylsilyl function, only the hydroquinone **81** is obtained[119]. The diene-like coordinated vinylketene in **76** is displaced by excess bis(trimethylsilyl)acetylene. In this way, metal-free vinylketenes **82** and isolable bis(alkyne)dicarbonylchromium **83** are obtained[139].

Spectroscopic studies indicate that the vinylketene system is practically unaffected by the complexation of the aryl ring. Its reactivity is markedly lower in comparison with silyl-free vinylketenes[140], which usually cannot be isolated. The addition of nucleophiles, such as amines and alcohols, to give carboxylic derivatives is relatively slow, and, even with typical ketenophiles such as enol ethers and enamines, no cycloaddition takes place[141]. With the more strongly nucleophilic ynamines, addition to the C=C bond competes with addition to the C=O bond (Scheme 9)[142, 143]. The reaction products, cyclohexadienone **86** and

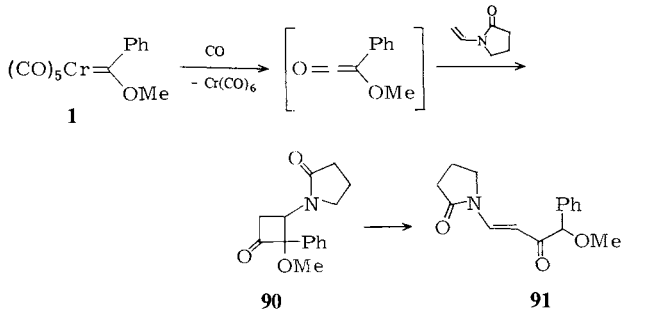




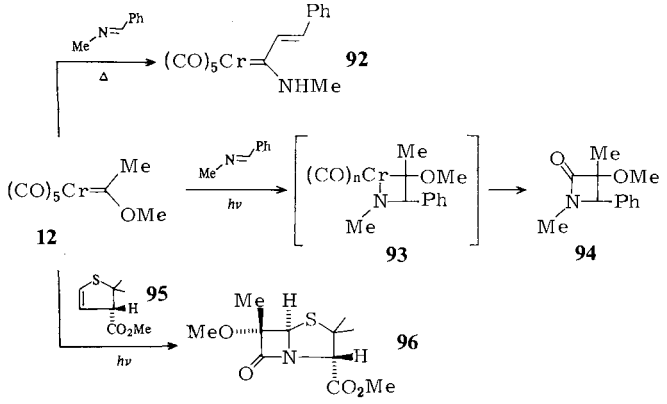
endo-R-bicyclo[3.1.0]hexenone **87**, can be traced back to the common cyclobutenone and dienylketene intermediates **84** and **85**, respectively; the formation of allenamide **89** is explained by an intermediate dihydrooxete **88**.

5.3. Cocyclization with Enamines and Schiff Bases

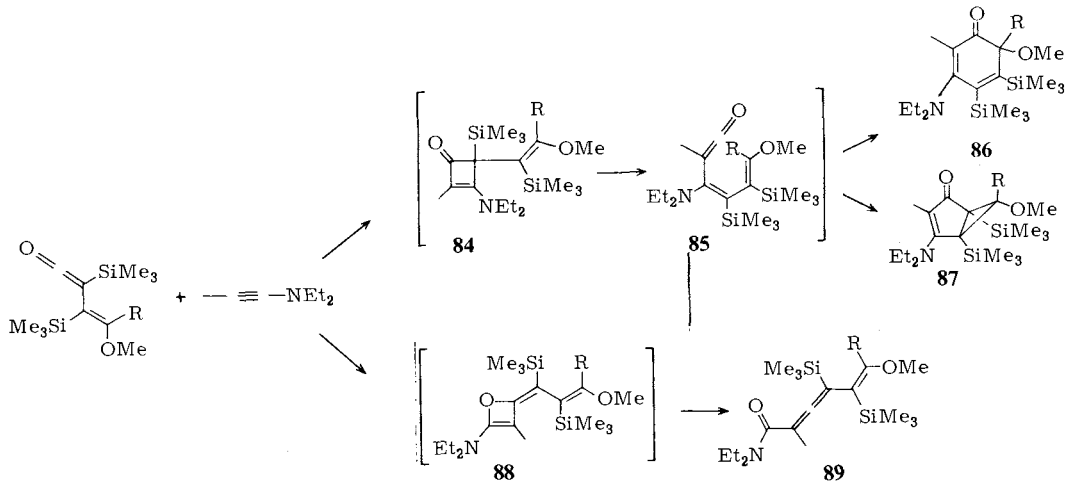
Besides alkynes, several double bond systems are known that undergo bond formation with carbene and carbonyl ligands. On heating with *N*-vinylpyrrolidone, the methoxy(phenyl)carbene ligand in **1** is alkenylated to give α-methoxystyrene[72], whereas bond formation between the alkene, carbene, and carbonyl components takes place under additional CO pressure. The enamino ketone **91** is obtained, albeit in modest yield, via ring opening of the pyrrolidonecyclobutanone **90**, a complex that can be isolated by using 2,2-disubstituted vinylpyrrolidones[144]. Methoxyphenylketene, formed by carbene-carbon monoxide coupling, is assumed to be an intermediate.



The reaction conditions prove to be a critical factor in the reaction of the methoxy(methyl)carbene complex **12** with Schiff bases[145-147]. Under thermal conditions, the acidity of the methylcarbene substituent, which is functionalized to give the alkenyl(amino)carbene system **92**, dominates. On the other hand, cycloaddition to give β-lactam **94** takes place upon UV irradiation. The formation of the four-membered ring appears to proceed stereospecifically; according to NMR spectroscopic analysis, only *one* diastereomer is formed. The (*S*)-dihydrothiazole ester **95** is converted into the diastereomerically pure penam system **96** according to the same criterion. Acyclic Schiff bases, however, effect a smaller asymmetric induction. A



Scheme 10. Photo-induced cycloaddition of carbonylcarbene complexes and Schiff bases.



Scheme 9. Competing pathways for the addition of ynamines to bis(silyl)vinylketenes.

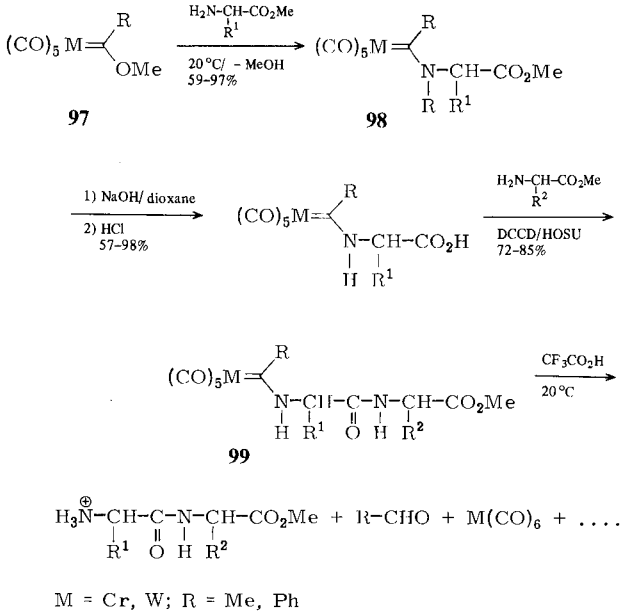
reaction mechanism cannot involve the nucleophilic attack of the imine nitrogen on the carbene carbon since this step would lead to a 3-azetidinone ring instead of a β-lactam (2-azetidinone) structure. Instead, reversal of the polarity of the metal-carbene bond in the photo-excited state is proposed. This should react with the Schiff base to give the β-lactam **94** via the chromacycle **93** (Scheme 10).

6. Synthesis of Natural Products

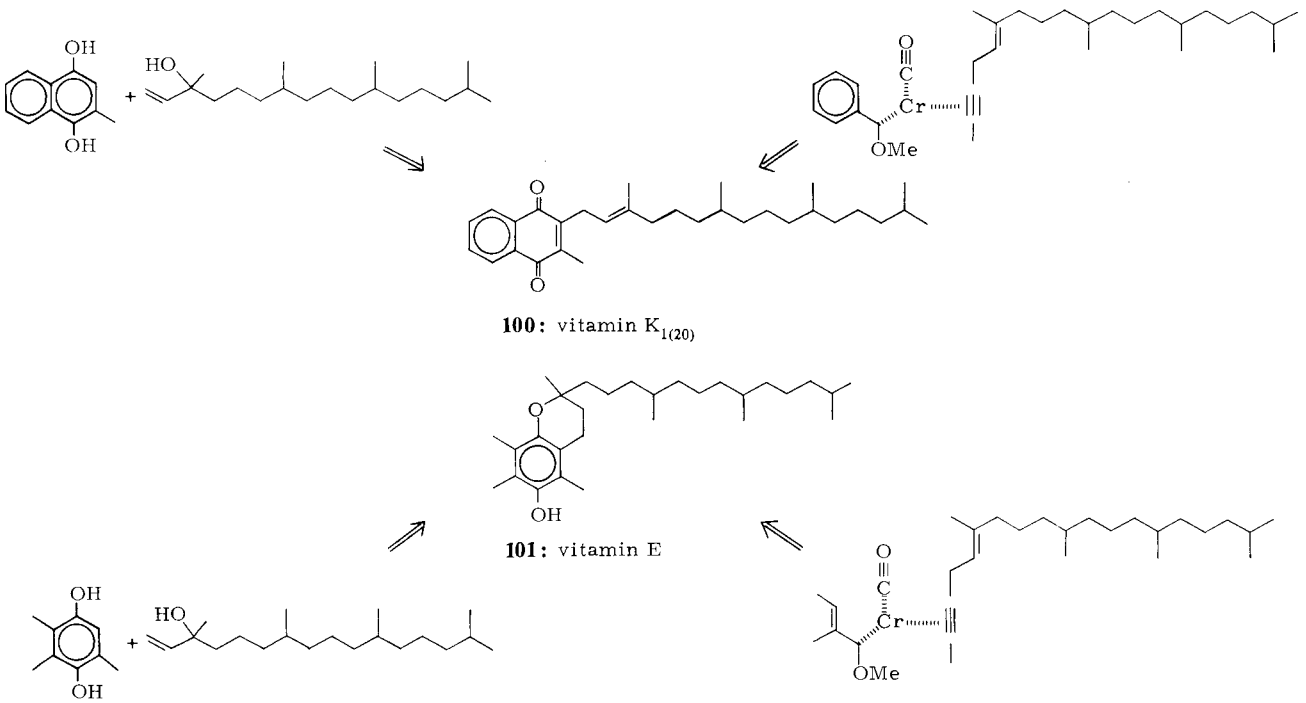
The simple preparation of alkoxycarbenecarbonyl complexes, their easy manipulation, and the possibility of functionalizing them make these reagents of interest in natural product synthesis. The examples so far known are based on the electrophilicity of the carbene carbon, on the one hand, and on the cycloaddition of alkyne, carbene, and carbonyl ligands to form the hydroquinone skeleton, on the other.

6.1. Peptide Synthesis

The smooth aminolysis of alkoxycarbene complexes was the impetus for the use of the "metalcarbenyl" function as a protecting group in the synthesis of peptides. Similarly to primary or secondary amines, amino acid esters react with pentacarbonyl(methoxycarbene) complexes of chromium and tungsten **97** to give the aminocarbene complexes **98**[148,149]. Because of the nucleophilicity of carboxylate ions, the amino acids have to be protected by esterification. However, no further protection is necessary for other groups, such as hydroxy groups or heterocyclic nitrogen groups in serine and histidine esters. The aminolysis is not limited to α-amino substituents; both the α- and the ε-amino groups in lysine react because of their similar nucleophilicity, so that lysine derivatives protected on N^{α} and N^{ε} by carbene complexes are formed. In order to form the peptide bond, the conventional method is used, namely saponification of the ester followed by coupling of the second amino acid ester component in the presence of dicyclohexylcarbodiimide/*N*-hydroxysuccinimide (DCCD/HOSU method)[150]. The cleavage of the amino protecting group from **99** is accomplished under mild conditions at 20°C with trifluoroacetic acid (Scheme 11). This step proceeds most cleanly with phenylcarbenechromium complexes. The utility of the method has been demonstrated by the stepwise synthesis of the tetrapeptide Gly-Gly-Pro-Gly-OMe, which is present as sequence 14—17 in the human proinsulin C-peptide[149].



Scheme 11. Metalcarbenyl functions as *N*-terminal protecting groups in peptide synthesis. The last step can also be carried out with acetic acid at 80°C (74—83% yield).

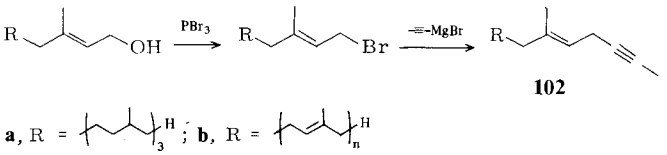


Scheme 12. Synthetic strategies for the synthesis of vitamins K and E.

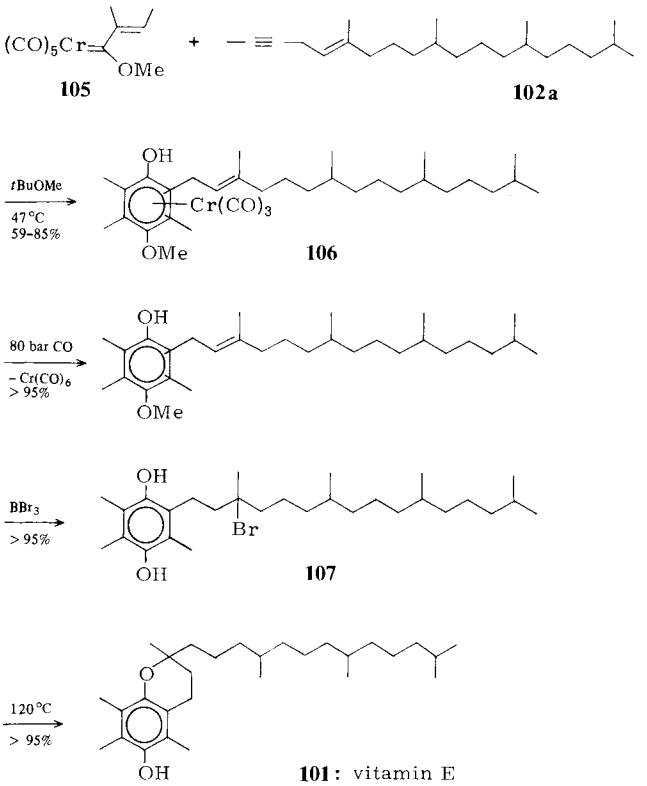
6.2. Synthesis of Vitamins K and E

The conventional synthesis of vitamins K **100** and E **101** is based on the condensation of isoprenoid alcohols with hydroquinones[151]. In contrast, a carbene-complex route to these compounds aims at the formation of the hydroquinone ring within the coordination sphere of chromium(0) (Scheme 12)[116].

The synthesis of vitamins of the K series starts with the methoxy(phenyl)carbene complex **1** and the enynes **102**, which are easily obtainable from the commercially available isoprenoid alcohols via the bromides using a Grignard propynylation[152, 153]. The cycloaddition in a low-boiling



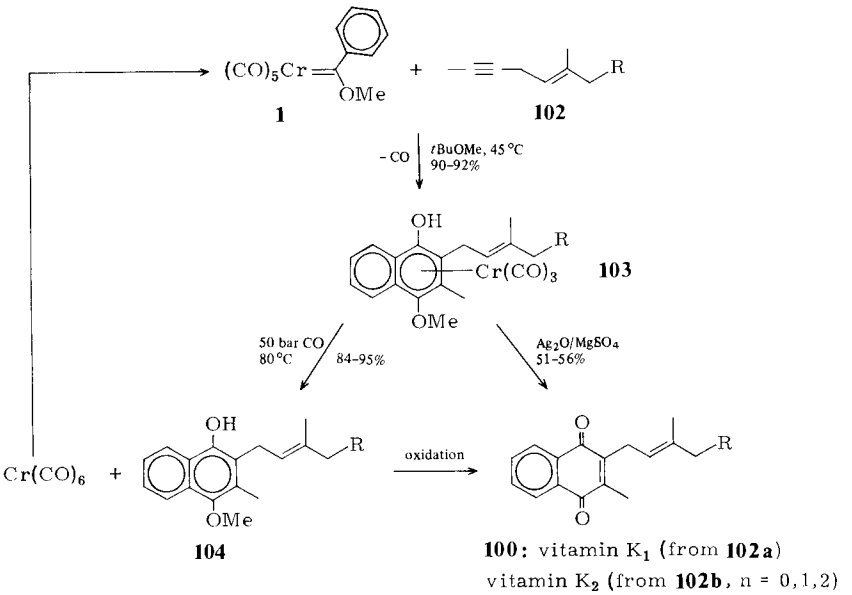
ether gives a 2:1 mixture of regioisomers of the dihydrovitamin K monoether complex **103** in 90% yield. The isomers can be separated by column chromatography using silica gel; however, this is not necessary for the subsequent course of the synthesis. Cleavage of the metal-arene bond is basically possible in two different ways: by oxidation or by ligand exchange. Oxidation with silver(I) oxide gives vitamin K directly. However, the yield is only about 55% and the chromium is converted into valueless chromium(III). These disadvantages can be avoided by a ligand substitution under CO pressure. The $Cr(CO)_3$ fragment is released practically quantitatively as hexacarbonylchromium, which serves as starting compound for the preparation of the carbene complex and can therefore be reused in a cyclic process. The oxidation of the dihydro-vitamin K intermediate **104** is then carried out using the conventional procedure (Scheme 13). In contrast to the condensation route, in which partial isomerization of the allylic double bond cannot be avoided because of the acidic medium required, the cycloaddition takes place with retention of con-



Scheme 14. Carbene-complex route to vitamin E.

figuration. This is important insofar as only the *E* isomer of vitamin $K_{1(20)}$, the most important K vitamin, is biologically active[154].

Vitamin E can also be synthesized according to a similar reaction sequence. A suitable starting material is the *E*-2-butenylcarbene complex **105**, which is obtained stereospecifically from *E*-2-bromo-2-butene[155]. The cycloaddition with the C_{23}-enyne **102a** gives the tricarbonylchromium complex **106** as a 70:30 mixture of the two regioisomers, from which the metal is cleaved as $Cr(CO)_6$ under CO pressure. In order to use both regioisomers for a ring clo-

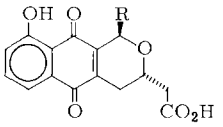


Scheme 13. Carbene-complexes route to the vitamins of the K series.

sure to give the chromane skeleton, cleavage of the ether is necessary. This is best achieved with boron tribromide, the allylic double bond being hydrobrominated simultaneously. The cyclization of the bromine derivative **107** to give vitamin E **101** can be carried out in the presence of Lewis acids according to the method of *Karrer* et al.[156] or, in practically quantitative yield, by heating to 120°C (Scheme 14)[157].

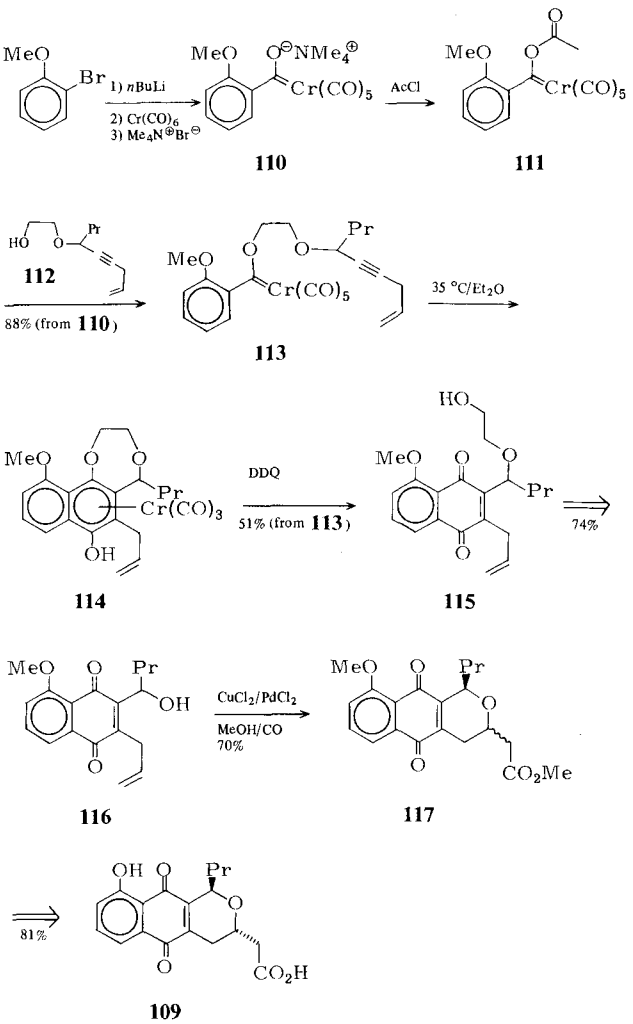
6.3. Synthesis of Antibiotics

The naphthoquinone skeleton appears as a part of the structure of a series of antibiotics. For example, it is combined with a dihydropyran ring in nanaomycin A **108** and deoxyfrenolicin **109**. A carbene-complex route to this

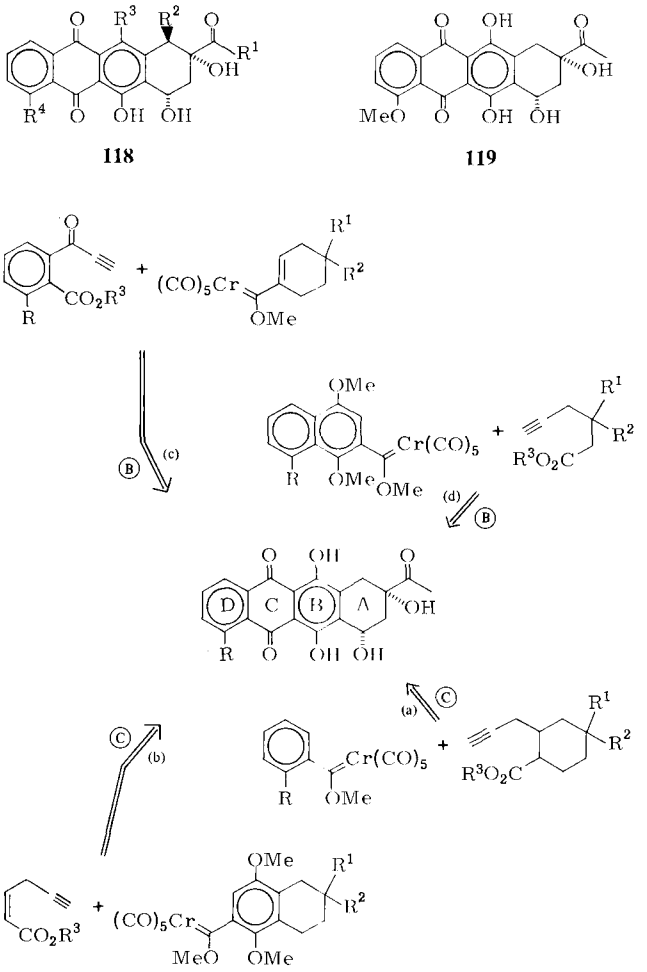


108, R = Me
109, R = Pr

compound is based on two key reactions: the formation of the quinone ring by a cycloaddition reaction, and the intramolecular alkoxy carbonylation of a hydroxy alkene to give the oxygen-containing heterocycle[158].



Scheme 15. Synthesis of deoxyfrenolicin **109** by intramolecular carbene addition and alkoxycarbonylation.



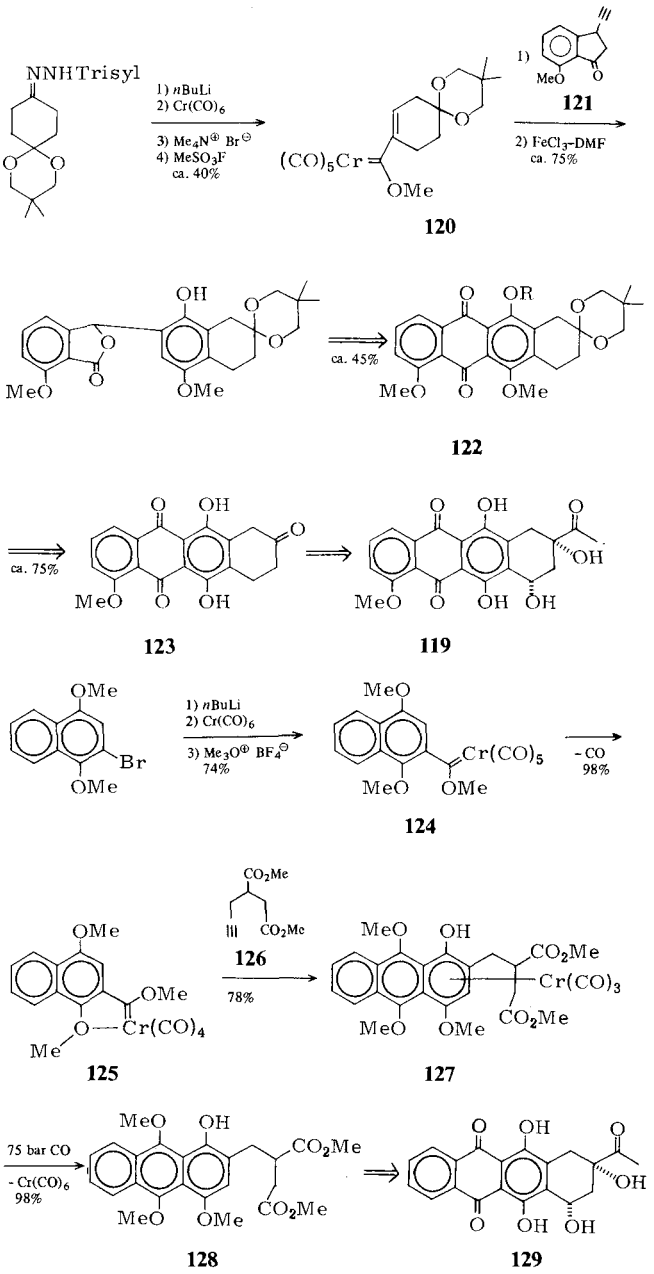
Scheme 16. Carbene-complex strategies to the daunomycinone skeleton. (a)—(d), see text.

The acyl chromate, which is storable and easy to handle as the tetramethylammonium salt **110**, is obtained by addition of 2-lithioanisole to hexacarbonylchromium. Its acetylation gives the acetoxycarbene complex **111**, which, since it is an "anhydride analog", is cleaved by the hydroxyenyne **112**. The alkynyloxycarbene compound **113** undergoes an intramolecular cycloaddition to give the hydroquinone complex **114**. It is oxidized with 2,3-dichloro-5,6-dicyanoquinone (DDQ) to give directly the quinone **115**, which is finally isolated in 51% yield. After cleavage of the alcohol protecting group, a hydroxyalkene structure is present in **116** which enables a palladium-catalyzed alkoxycarbonylation to give the dihydropyran. Thereby, **117** is formed as a *cis/trans* mixture (25:75). However, during the subsequent demethylation with boron tribromide, a complete isomerization to the natural *trans*-configuration takes place (Scheme 15).

Anthracyclinones offer an ideal target for the carbene-complex route. They are the aglycones of the anthracyclines, which at present are being intensively studied and which have proven to be effective anti-tumor agents[159]. They have a basic tetracyclic skeleton **118**, which always has a quinoid ring C and, in many cases, including the most important representative of this series, daunomycinone **119**, a hydroquinone system B. The synthesis of daunomycinone can follow four independent routes, each

starting with a carbene complex and an alkyne (Scheme 16). Thus, the quinone ring C might be formed either from the anisylcarbene complex and an alkyne ester containing ring A [route (a)] or from the bicyclic carbene complex and a 1,4-enyne ester [route (b)]. Alternatively, a ring closure to give the hydroquinone ring B may be considered. The basic principle of route (c) is realized in the cycloaddition of the cyclohexenylcarbene complex **120** and the ethynyl lactone **121**[160]. The C and D ring components can, however, be introduced via the carbene ligand. Following annelation of the carbene ligand with the alkyne ester to give the hydroquinone, the A ring must be closed in the next step [route (d)][161].

The cyclohexenylcarbene complex **120** was prepared from the hydrazone[160]. The cycloaddition with an acylacetylene according to route (c) (Scheme 16), however, proceeded in only small yield; it proved more advantageous, therefore, to use the lactone **121** as alkyne component. **121** is readily obtainable from 2-methoxybenzamide and propargyl aldehyde. After oxidative cleavage of the $Cr(CO)_3$ fragment, ring C is closed and oxidized to the quinone, using a protecting group for the hydroxy function. A dealkylation in the hydroquinone ring finally affords the triketone **123**, the A ring of which can be further functionalized to give daunomycinone **119**[162] (Scheme 17).



Scheme 17. Carbene complex route to daunomycinone **119** and derivatives such as **129**. DMF = dimethylformamide.

An alternative route consists of the annelation of the CD-ring building block, which is introduced by the carbene ligand, prepared from 2-bromo-1,4-dimethoxynaphthalene[124]. Arylcarbene complexes with alkoxy functions in the *ortho* position, such as **124**, readily undergo displacement of a *cis* CO ligand by the arylalkoxy group[163]. A tetracarbonyl complex **125** containing a chelating carbene ligand is thereby formed quantitatively. Such compounds are practically air-stable and therefore very useful as storable starting materials. As shown by the X-ray structure analysis of the analogous methoxy(*o*-methoxyphenyl)carbene complex, the chromium-oxygen bond is about the same length as in the labile $(CO)_5Cr$-ether adducts[164] and therefore easily opened. Thus, metallacycles of this kind represent a stabilized form of the coordinatively unsaturated tetracarbonyl species. **125** reacts smoothly with the alkyne ester **126**, which is obtainable in two steps from methyl acetoacetate, to give the anthracene complex **127**. This compound is very sensitive toward oxidation, but easy to separate because of its sparing solubility; under CO pressure, it is quantitatively cleaved to give the aromatic ligand **128** and hexacarbonylchromium, which can be reused in the synthesis of the carbene complex. The anthracenyl ester **128** is a suitable intermediate in the preparation of 4-demethoxydaunomycinone **129** (Scheme 17).

7. Catalytic Reactions

Although the emphasis in this discussion is on the stoichiometric use of carbene complexes, the catalytic reactions will be considered in this final section, using some characteristic examples. Here, only those processes will be considered that are initiated by isolable, well-defined complex compounds.

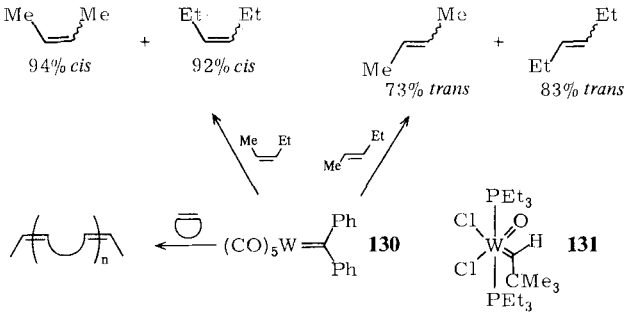
7.1. Olefin Metathesis

Ever since the discovery of metal-catalyzed alkylidene exchange in alkenes, i.e. of "olefin metathesis"[165,166], its mechanism

$$2\,RCH{=}CHR' \xrightarrow{\text{catalyst}} RCH{=}CHR + R'CH{=}CHR'$$

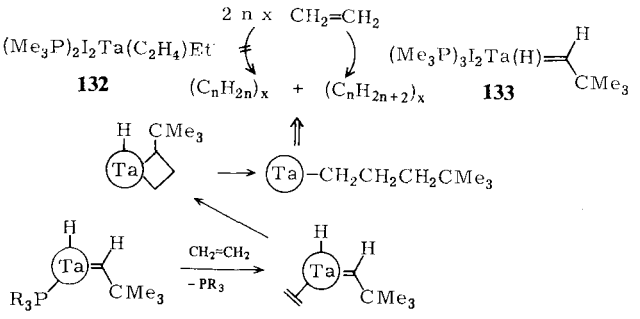
has been the object of controversial discussion. At present, the view is generally accepted that the key step involves bond formation between a carbene and an alkene ligand to form a metallacyclobutane[167]. This conclusion could be arrived at largely because of the fact that the isolable carbene complexes provided well-characterized starting materials, the catalytic effectiveness of which could be studied in model reactions. Compounds of tungsten, which is

known as a "metathesis-active" metal, proved especially useful. Whereas the methoxy(phenyl)carbene complex **23** only reacts with the more reactive cyclic olefins such as norbornene[168], giving a polymeric norbornene with an average molecular weight $\overline{M}_r$ of ca. 1.1×10^5, the diphenylcarbene complex **130** also reacts with open-chain alkenes[169–171]. In contrast to most conventional catalyst systems, a high stereoselectivity is observed. Thus, cyclic and acyclic *cis*-olefins give more than 90% *cis*-products. The configuration of *trans*-alkenes such as *trans*-2-pentene, however, is not so well preserved. In addition to the "Fischer-type" compounds, "Schrock-complexes", such as **131**, have also proven to be metathesis-inducing. However, Lewis acids have to be added in this case in order to achieve turnover numbers of ca. 50[172,173].



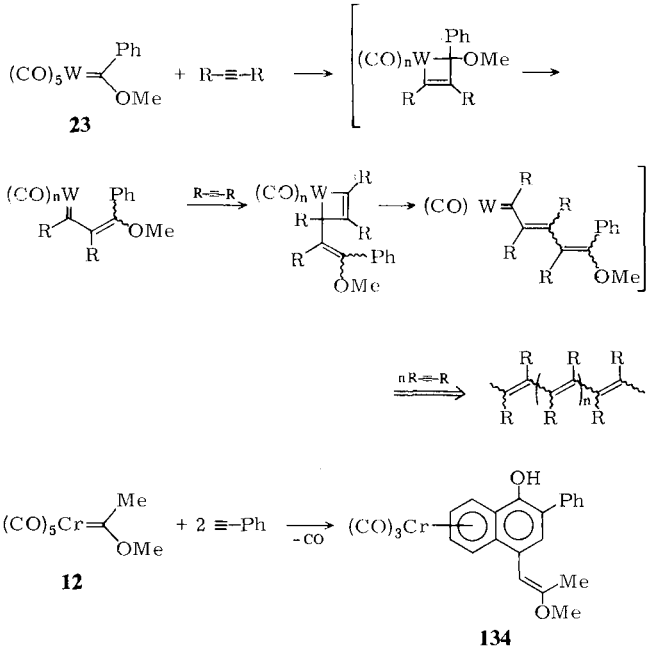
7.2. Polymerization of Alkenes and Alkynes

The Ziegler-Natta polymerization of alkenes is generally thought to be due to insertion of the olefin into a metal-alkyl bond[174,175]. This contrasts with a recently made suggestion that carbene-hydride complexes should be effective as catalysts[176]. Such species are known for tantalum and thus provided the opportunity to test this hypothesis[177,178]. Interestingly, it was observed that—in contrast to the alkene-alkyl compound **132**—the neopentylidene-hydride complex **133** is able to polymerize ethylene. After hydrolysis of the initial product alkenes and alkanes are obtained. The chain growth is explained by the formation of a metallacyclobutane which is opened to give the alkyl complex (Scheme 18).



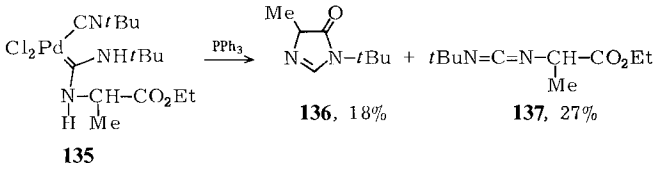
Scheme 18. A mechanism proposed for the polymerization of ethylene catalyzed by carbene-hydride complexes. (Ta) = $(R_3P)_2I_2Ta$.

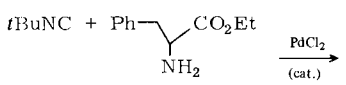
Carbenetungsten complexes of the "Fischer-type" have also proven to be effective catalysts in the polymerization of alkynes[179]. The reactions initiated by **23** or **130** proceed slowly but give comparatively pure products. Unbranched terminal alkynes give good yields (50—75%). Dialkylalkynes such as 2-butyne, whose polymerization by conventional catalyst systems is described only for isolated cases, react more poorly, as expected; characteristic $\overline{M}_r$ values are about 25000. In accord with the preferred mechanism of the olefin metathesis reaction, the chain growth is described by repeated addition of the alkyne to the metal-carbene bond to give the metallacyclobutene followed by its ring opening to give the alkenylcarbene complex. Coupling of two alkyne units with a carbene ligand and a carbonyl ligand to give the alkenylnaphthol **134** can also be explained in terms of repeated formation and opening of a metallacyclobutene[180].

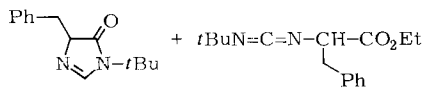


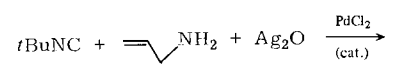
7.3. Synthesis of Heterocycles

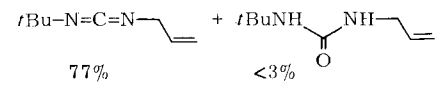
By introduction of an amino group, the carbene carbon is usually so stabilized that it can no longer be used in specific reactions. In the palladium series of complexes, however, diaminocarbene ligands, which can be synthesized by addition of α-amino acid esters or β-amino alcohols to coordinated isocyanides, have proven to be precursors of some N- and N,O-heterocycles, respectively[58]. Thus, the carbene ligand in **135** is cleaved by substitution with phosphanes or by oxidation and modified to give the imidazolone **136** or the carbodiimide **137**. The reaction can also be carried out directly starting with isocyanides and using catalytic amounts of palladium chloride. The main product resulting after oxidation with silver(I) oxide is the carbodiimide[181] or, if β-amino alcohols are used, the aminooxazole.

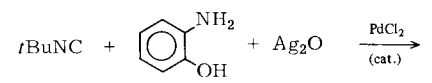


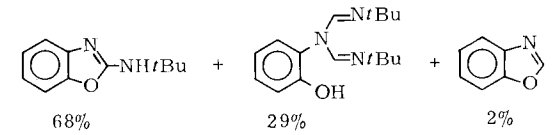












8. Outlook

Only two decades ago carbene complexes were still regarded as exotic compounds in organometallic chemistry. Today, numerous carbene complexes can be synthesized with various metals and with a broad range of substitution patterns. They offer a broad potential for synthetic use. In this review it has been shown that not only those reaction types are encountered which are transferable from "organic" carbene chemistry. On the contrary, by the additional interaction of ligands within the coordination sphere of the metal, the scope is enlarged to allow bond formation between specific ligands; so far, however, this has only been explored in individual cases. In particular, the cocyclization of carbene ligands with several other ligands or compounds, which has proven useful in the synthesis of natural products, promises to find broad application. Here, the metals show pronounced specificity, as shown by the chromium-induced formation of hydroquinone, so that the use of other metals should lead to further interesting results. Moreover, a "fine tuning" is possible by variation of the co-ligand sphere.

My thanks are due, above all, to a series of committed and enthusiastic co-workers who are mentioned in the cited references. I would also like to thank the Deutschen Forschungsgemeinschaft and the Fonds der Chemischen Industrie for generous support of this work.

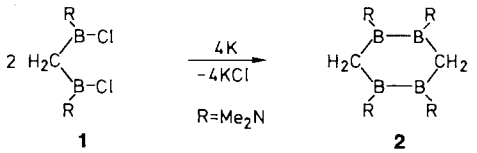
Synthesis and Structure of a 1,2,4,5-Tetraborinane**

By *Herbert Fisch, Hans Pritzkow,* and *Walter Siebert**

Dedicated to Professor Margot Becke on the occasion of her 70th birthday

Due to a deficiency of electrons, the derivatives of the B–C-compounds $(RB)_4(CR')_2$, $(RB)_4(CR')_2H_2$, and $(RB)_2(CR')_4$, with R, R′ = H, alkyl, exhibit carbaborane structures[1]. $(RB)_2(CR')_4$ is stabilized as a 1,4-diboracyclohexadiene derivative by electron donating substituents on the boron atoms, a stabilization that was first accomplished with the fluoro compound $(FB)_2(CR')_4$[2]. The stability of *cyclo*-organoborane/*nido*- or *closo*-carbaborane has been studied in detail by PRDDO calculations on $(RB)_2(CR')_4$, $(RB)_3(CR')_2$, and $(RB)_4(CR')_2$[3].

We report here a novel B_4C_2 ring **2**, stabilized by dimethylamino groups, whose parent compound $B_4C_2H_8$ is expected to have a *nido*-structure. The slightly air-sensitive compound **2** is formed upon dehalogenation of the



1 **2**

bis(aminoboryl) derivative **1**, obtained from bis(dichloroboryl)methane and $Me_3Si–NMe_2$, with Na/K alloy[4]. On the basis of the ^{1}H-NMR data [$\delta = 0.91$ (d, $J = 10.3$ Hz, 2H), 1.50 (d, 2H), 2.80 (s, 12H), 2.83 (s, 12H)], a planar ring can be ruled out. Neither the CH_2- nor the CH_3-signals coalesce below 105 °C (in [D_8]-toluene), thus indicating a relatively rigid conformation and strong (BN)-π-bonding. The ^{11}B-NMR signal at $\delta = 53.7$ is typical for a diborane containing alkyl- and Me_2N-substituents[6]. The isotopic pattern characteristic for four boron atoms appears at $m/z = 248$ ($M^{\oplus}$, 100%) in the mass spectrum. $M^{\oplus}/2$ is observed at $m/z = 124/125$ (50%). Preparative evidence for the 1,2-bis(dimethylamino)diborirane, the corresponding three-membered ring, could not be found.

1,2,4,5-Tetrakis(dimethylamino)-1,2,4,5-tetraborinane **2** crystallizes in the triclinic space group $P\bar{1}$ with two crystallographically independent, centrosymmetric molecules which differ only slightly from each other (Fig. 1)[7]. The ring lies in the chair-conformation. The angle between the

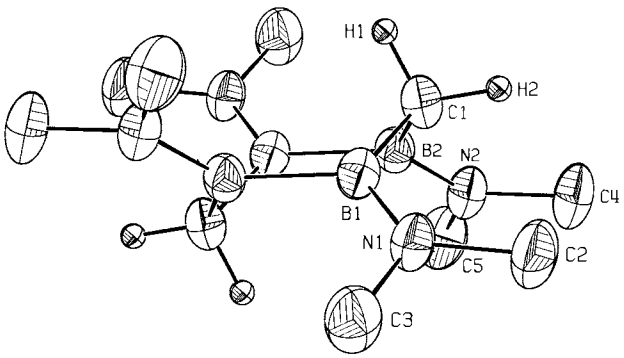


Fig. 1. ORTEP diagram of one of the two molecules of **2** in the crystal (vibration ellipsoids with 40% probability, for methylene-H atoms arbitrary; for sake of clarity the methyl-H atoms are omitted). Bond lengths [Å] and angles [°] (averaged values for both molecules, standard deviations 0.002 Å and 0.1°): B–B 1.711, C–B 1.590, B–N 1.405, N–C 1.457; B–C–B 105.5, C–B–B 113.3, C–B–N 122.2, B–B–N 124.0, C–N–C 111.3, B–N–C 124.1 [7].

plane through the four boron atoms and the plane through B1-C1-B2 is ca. 50°. The boron and nitrogen atoms are planar coordinated, whereby the boron atoms deviate slightly more from the respective planes (up to 0.05 Å). The angle of twist between the planes NBBC and BNC_2 is small (2—6°) so that a good π-interaction with a resulting short B-N distance is possible. The bond lengths in the ring correspond to the values for single bonds.

A comparison with hexakis(dimethylamino)cyclohexaborane[8] and 2,3,5,6-tetrakis(dimethylamino)-1,4,2,3,5,6-dithiatetraborinane[9] shows that the B-B and B-N distances in all three compounds are equal and that the planarity of the XBB–NC_2 group is preserved. The cyclohexaborane, like the tetraborinane **2**, exhibits a chair-conformation, whereas the dithiatetraborinane adopts a twist-conformation.

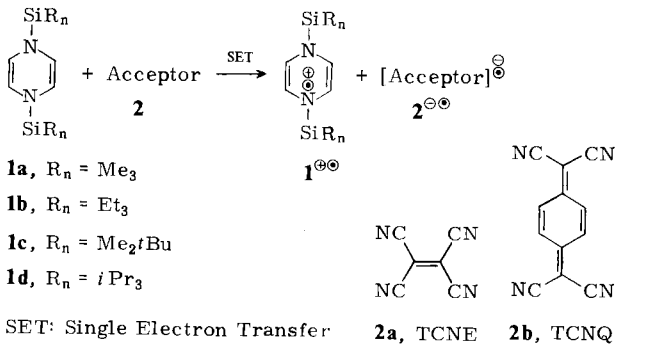
Isoelectronic Radical Ions from Single-Electron Transfer Reactions: Direct Observation of Persistent Solvent-Separated Radical Anion/Radical Cation Pairs**

By *Wolfgang Kaim**

The possibility of electron transfer mechanisms being involved in reactions of organic compounds with organometallic reducing agents has recently been discussed in the literature[1]. Although evidence indicating the involvement of such mechanisms has been reported on several occasions, some of the findings have been misinterpreted, particularly regarding the identity of the long-lived radical species observed[1,2]. The primary product of a "single electron transfer" (SET) between diamagnetic closed-shell reactants, the pair of oppositely charged radical ions, is generally very reactive owing to the instability of simple organometallic radical cations[3].

N-Silylated 1,4-dihydropyrazines **1** are electron-rich[4] reducing agents[5] forming stable radical intermediates[4,6]. We have now been able to observe both radical ions simultaneously on allowing **1** to react with the acceptors tetracyanoethylene (TCNE) **2a** or tetracyanoquinodimethane (TCNQ) **2b**.



This is the first *direct* evidence of thermal single-electron transfer involving main group organometallic reductants; earlier claims of this sort have proven invalid[2].

Variation of the organometallic component[4,7] shows that steric effects play an essential role, aside from electronic stabilization by the pyrazine system: the larger the substituents R on the silicon atoms, the more stable are the radical ion "pairs" in solution; in the case of the bis(triisopropylsilyl) compound **1d**, both species can be readily observed at room temperature (Fig. 1).

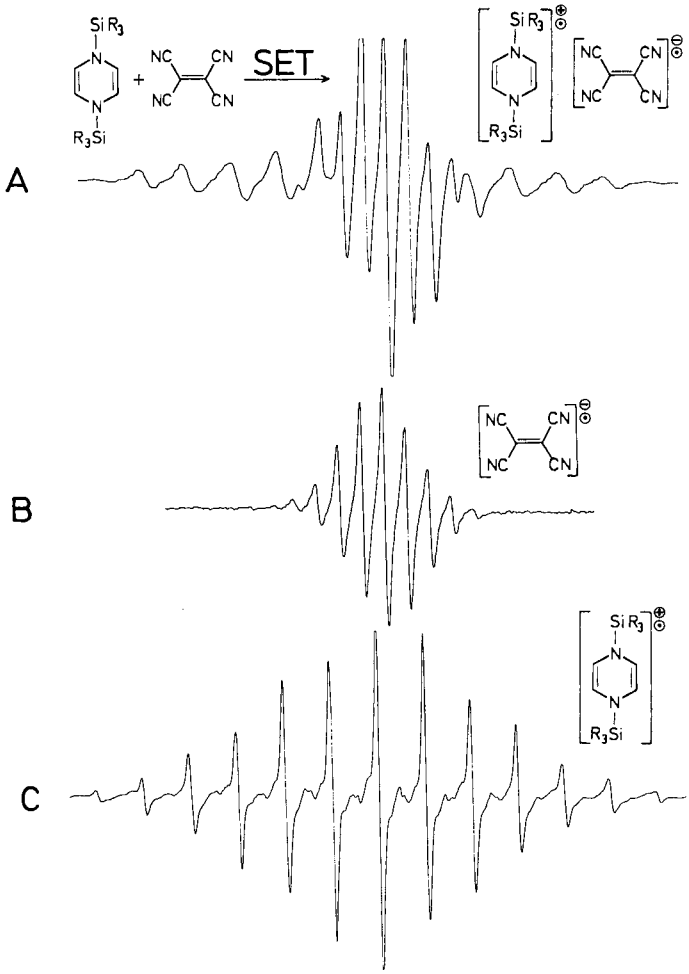


Fig. 1. According to the potential difference between **1d** ($E_{ox}=-0.35$ V) and TCNE **2a** ($E_{red}=+0.33$ V vs. SCE), single electron transfer occurs during the reaction in dichloromethane. The primary products, the radical ions $\mathbf{1d}^{\oplus\odot}$ and $\mathbf{2a}^{\ominus\odot}$, can be detected simultaneously as persistent solvent-separated ions; the ESR spectrum of the reaction solution (A) is a superposition of spectra of the components $\mathbf{2a}^{\ominus\odot}$ (B) and $\mathbf{1d}^{\oplus\odot}$ (C) [4]. Particularly characteristic is the loss of inversion symmetry in (A) because of the slightly different g factors of the components ($\mathbf{2a}^{\ominus\odot}$: $g=2.0029$; $\mathbf{1d}^{\oplus\odot}$: $g=2.033$); the line-broadening in (A) compared to (C) could arise through weak association.

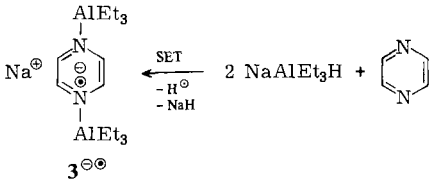
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

From the point of view of the pyrazine system, the direction of this electron transfer is reversed relative to that in the reaction of the oxidized pyrazine with organometallic reducing agents[8], e.g. to give $3^{\ominus\odot}$.



$3^{\ominus\odot}$

The occurrence of iso-π-electronic radical ions[9] such as $1^{\oplus\odot}$ and $3^{\ominus\odot}$ demonstrates the excellent suitability of the pyrazine system for studies of electron transfer phenomena.

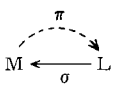
π-Back Bonding and Stability of the Oxidation States in Tetracarbonyldicyclopentadienyl-(μ-pyrazine)dimanganese(I) Complexes**

By *Renate Gross* and *Wolfgang Kaim**

Transition metals with low-spin d^6-configuration such as Fe^{II}, Ru^{II}, Os^{II} or Cr^0, Mo^0, and W^0 are capable of back-bonding with π-acceptor ligands L:



Characteristic of such complexes are intense MLCT (metal-to-ligand charge transfer) bands[1,2]—often in the visible region of the spectrum—and a typical, well documented[3] photochemistry. Support of an MLCT assignment, i.e., for an electron transition (Scheme 1) into a ligand π* orbital can be obtained by electrochemical and ESR studies[4].

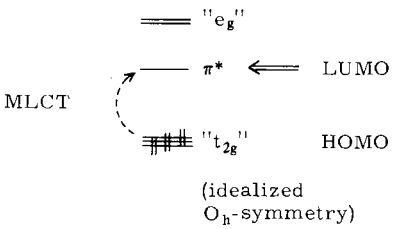
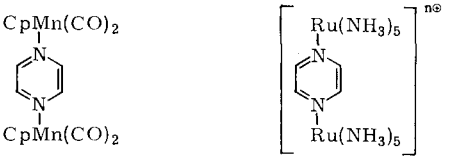
Niederurseler Hang, D-6000 Frankfurt am Main 50 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We wish to thank Frau *A. Veltmann* for help with the electrochemical measurements.



Scheme 1.

Few such studies have been carried out on manganese(I) complexes[5], even though the coordination chemistry of the fragment $MnCp(CO)_2$ is extensive, and has led to the stabilization of some unusual ligands[6,7].



1a, Cp = η^5-C_5H_5
1b, Cp = η^5-$C_5H_4CH_3$
1c, Cp = η^5-$C_5(CH_3)_5$

2, n = 4,5,6

In our effort to study organometallic analogues of the Creutz-Taube system **2**[8], we have prepared the binuclear pyrazine complexes **1**[9] and examined them both electrochemically and spectrocopically. A comparison with related Ru^{II}, Fe^{II}, and Cr^0 complexes reveals quite clearly the remarkable position of the Mn^I complexes (Table 1):

Table 1. MLCT absorption maxima E_{MLCT} [eV] and redox potentials $E_{ox/red}$ or peak potentials [d] [V vs. SCE] for μ-pyrazine complexes with low-spin d^6-metal fragments; pz = pyrazine.

Complex	E_{MLCT}	E_{ox}	E_{red}
2, n = 4 [8] [a]	2.27	+0.12	[b]
$\{pz[Fe(CN)_5]_2\}^{6\ominus}$ [10] [a]	2.45	≈0.0	[b]
$pz[Cr(CO)_5]_2$ [c]	2.41	+1.1 [d]	−1.05 [d]
1a [c]	1.94 2.14 [e]	+0.37 [d]	−1.36
1b [c]	1.88 2.12 [e]	+0.34 [d]	−1.37
1c [c]	1.80 2.03 [e]	+0.25 [d]	−1.40

[a] Measurements in water. [b] Not observed. [c] Absorption measurements in benzene [2] or toluene; cyclovoltammetry in dimethylformamide/0.1 M tetrabutylammonium perchlorate. [d] Peak potential for irreversible redox behavior (cyclovoltammetry, scan rate 100 mV/s). [e] Two bands due to lower symmetry [5].

- The Mn^I complexes **1** absorb at even longer wavelengths than the Ru^{II} compounds **2**[1,8]; this quantitative evidence of unusual π-back-bonding behavior may be related, e.g., to the stability of the corresponding N_2 complexes[7].
- Twofold coordination of $MnCp(CO)_2$ to pyrazine facilitates the reduction of the ligand by about 0.7 V.
- Acquisition of an electron affords relatively stable (Cp!) radical anion complexes (Fig. 1), whose ESR data confirm the ligand character of the singly occupied molecular orbital (Scheme 1)[4c]; however, a noticeable interaction already occurs with the coordinated metal fragments. From the relative size of the g factor of the radical anions ($g_{complex} < g_{electron} = 2.0023$), it can be de-

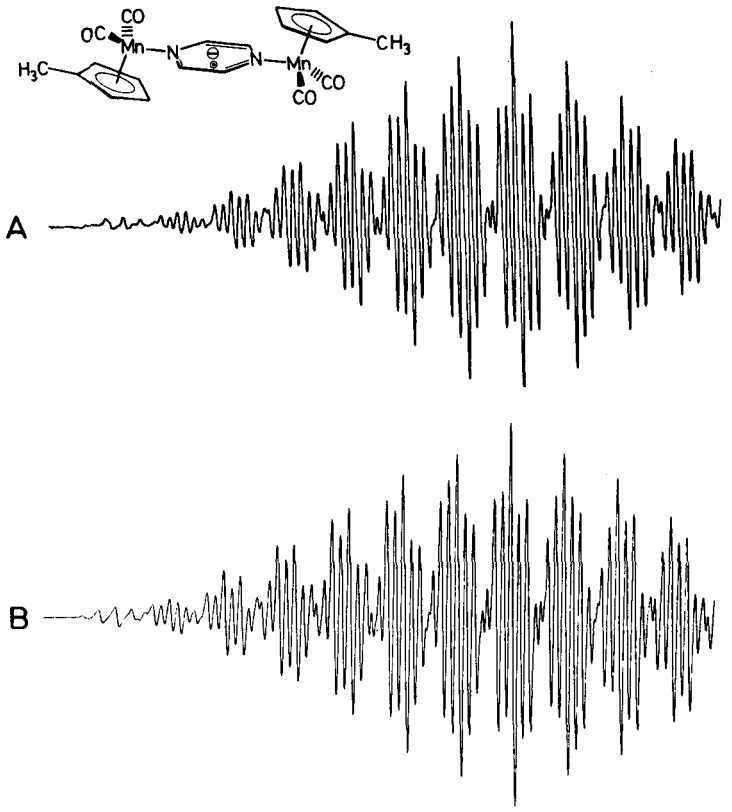


Fig. 1. Low-field section (A) of the ESR spectrum of complex $\mathbf{1b}^{\ominus\ominus}$ in THF, generated by reduction with potassium. Computer controlled spectra-synthesis (B) with the coupling constants [μT]: 227 (4 H), 865 (2 N), 747 (2 Mn) and with a line width of 60 μT; 275 theoretical lines, $g = 1.9997$.

duced[4d] that a further unoccupied orbital must be close-by; consistent with this, the compounds are very light-sensitive. Obviously, an effective photoreaction takes place from a state other than the MLCT excited state[5].

The oxidation of the complexes **1**, which should lead to a mixed valence system analogous to the Creutz-Taube ion **2**, n = 5, is dissociative under the electrochemical conditions employed—apparently due to electrocatalytic substitution by the solvent[11].

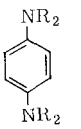
p-Phenylenediboranes: Mirror Images of *p*-Phenylenediamines?

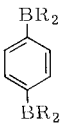
By *Wolfgang Kaim** and *Andreas Schulz*

The *p*-phenylenediamines **1**, the prototypes for electron-rich organic compounds, can act as components of donor-acceptor complexes[1a], and their one-electron oxidation products, the radical cations, have been known[1b] as *Wurster's salts* for more than a century. The strong donor function of an amino group should find its counterpart in the acceptor capability of boryl substituents, and there are some relatively stable radical anions $BR_3^{\ominus\ominus}$[2]; in the case of boranes, however, complications can arise because of their sensitivity toward oxidation and their tendency to cleave BC bonds and to form *ate* complexes.



1

R = Alkyl, Aryl



2, R = 
3, R = Ph

4, BR_2 =

We have prepared the *p*-phenylenediboranes **2**–**4**[3] which are analogous to *p*-phenylenediamines and investigated their redox behavior both chemically and electrochemically. As in the case of simple boranes BR_3[2c], no reversible electrochemical reduction is observed with alkyl (**4**) and phenyl derivatives **3** (Table 1); however, introduction of the bulky dimesitylboryl substituents[4] precludes the aforementioned side reactions, ensures effective inter-

Table 1. Electrochemical reduction potentials *E* [V vs. SCE] of aromatic boranes [a].

action[4] of the unoccupied *p*-orbitals on the boron atoms with the π-system of the central benzene ring, and thus causes **2** to behave diametrically opposite to the *p*-phenylenediamines:

The cyclovoltammogram in dimethylformamide (DMF) shows two reversible reduction steps to the radical anion and to the dianion (Fig. 1); the separation of 0.69 V corresponds to a rather large radical formation constant of 5×10^{11}. The oxidation of **1** also occurs in two reversible steps, albeit with a somewhat smaller separation of 0.44 V[5].

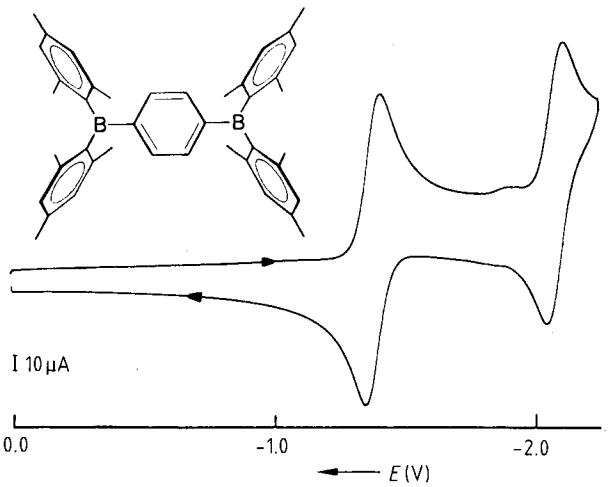

Fig. 1. Cyclovoltammogram (reduction) of *B,B,B',B'*-tetramesityl-*p*-phenylenediborane **2** in dimethylformamide (10^{-3} M).

The (negative) reduction potential of **2** is very high for a *p*-disubstituted benzene derivative (Table 1); the value of −1.39 V vs SCE is exceeded only by that of −0.57 V for *p*-nitrobenzene[6]. In comparison to benzene ($E_{red} = -3.42$ V[7a]), this signifies facilitation of the reduction by ca. 2.0 V; a similar difference of about 2.2 V exists between the oxidation potential of benzene (≈ +2.4 V[7b]) and that of **1** (≈ +0.25 V[5]).

Unfortunately, the ESR spectrum of the radical anion $\mathbf{2}^{\ominus\ominus}$ is no longer resolved due to the number 511875 (!) of theoretical lines ($g = 2.0025$). However, electron nuclear double resonance (ENDOR)[8] yields a largest ^{1}H-coupling of only 119 μT, which is assigned to the phenyl protons and indicates considerable delocalization of the unpaired electron. Once again, a comparable effect is only shown by the *p*-nitrobenzene system (a_H = 112 μT[9]).

These results illustrate quite convincingly that the acceptor dimesitylboryl[4] is only surpassed by the NO_2 substituent, both energetically as well as with respect to the delocalization of negative charge, and, despite their steric requirements, compounds like **2** or **3** should be suitable as components of donor-acceptor complexes.

Sequential Lithiation and Silylation of Stannocene**

By *Alan H. Cowley**, *Peter Jutzi**, *Franz X. Kohl*, *Jonathan G. Lasch*, *Nicholas C. Norman*, and *Ewald Schlüter*

It has been noted that the properties of Me_3Si-substituted cyclopentadienyl ligands are complementary to, yet distinct from, those of the more familiar $Me_5C_5^{\ominus}$ moiety[1]. The existing methodology for introducing the silylated ligands involves treatment of e.g. $(Me_3Si)_2C_5H_3Li$ with metal halides. We have now found a new route to polysilylated cyclopentadienyl compounds which starts from the parent metallocene.

Treatment of $(C_5H_5)_2Sn$ with *n*BuLi (molar ratio 1:2) in tetrahydrofuran (THF) at −78 °C affords 1,1'-dilithiostannocene[2], which can be quenched with Me_3SiCl to give $(Me_3SiC_5H_4)_2Sn$ **1**. Repeated treatments of this kind lead sequentially to 1,1',3,3'-tetrakis(trimethylsilyl)stannocene **2** and 1,1',2,2',4,4'-hexakis(trimethylsilyl)stannocene **3**.

$$(C_5H_5)_2Sn \xrightarrow[2)\ 2\,Me_3SiCl]{1)\ 2\,n\text{BuLi}} \underset{\mathbf{1}}{(Me_3SiC_5H_4)_2Sn} \xrightarrow[2)\ 2\,Me_3SiCl]{1)\ 2\,n\text{BuLi}}$$

$$[(Me_3Si)_2C_5H_3]_2Sn \xrightarrow[2)\ 2\,Me_3SiCl]{1)\ 2\,n\text{BuLi}} \underset{\mathbf{2}}{[(Me_3Si)_2C_5H_3]_2Sn} \qquad \underset{\mathbf{3}}{[(Me_3Si)_3C_5H_2]_2Sn}$$

The identification of **2** is based on elemental analytical and high-resolution mass spectroscopic data (M_r (calc.) 536.1381; M_r(found) 536.1392). Moreover, **2** can be prepared independently by reaction of $(Me_3Si)_2C_5H_3Li$ with $SnCl_2$. The NMR data for **2**[3] establish that, as in the case of lanthanide complexes[1], each η^5-cyclopentadienyl ring is 1,3-silyl substituted.

Compound **3**, which can also be synthesized from $(Me_3Si)_3C_5H_2Li$ and $SnCl_2$, was characterized by X-ray analysis (Fig. 1)[4]. Unfortunately, the crystals of **3** were only of poor quality, and hence the geometric parameters

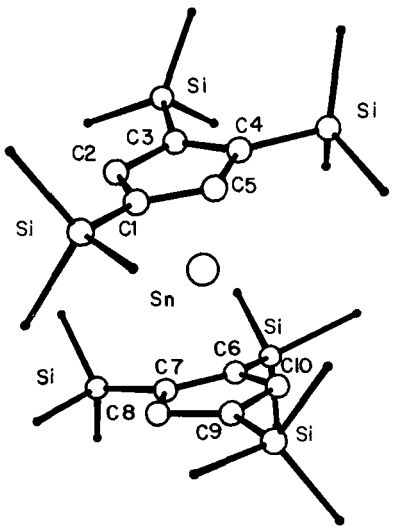

Fig. 1. Structure of **3** in the crystal. Selected bond lengths [Å]: C1-C2 1.42(3), C1-C5 1.49(4), C2-C3 1.56(3), C3-C4 1.54(3), C4-C5 1.48(4), C6-C7 1.57(4), C6-C10 1.54(3), C7-C8 1.50(2), C8-C9 1.54(2), C9-C10 1.53(4).

are not very accurate. However, two comments can be made about the structure: 1) The 1,2,4-substitution of the cyclopentadienyl rings is similar to that in the complexes $(Me_3Si)_3C_5H_2Li\cdot base$[5]; 2) the ring centroid-Sn-ring centroid angle is 162(2)°. This is considerably larger than the corresponding (average) angles in $(\eta^5\text{-}C_5H_5)_2Sn$ (145.8)[6] and $(\eta^5\text{-}Me_5C_5)_2Sn$ (144.1)[7].

High-Pressure Syntheses: The Henry Reaction**

By *Kiyoshi Matsumoto**

The Henry or nitroaldol reaction is one of the most important methods of CC bond formation, in particular since the nitro group of the nitroaliphatic compounds formed can be converted into other functional groups such as amines, alcohols, aldehydes, and ketones[1]. However, this reaction is sensitive to steric factors and "becomes less and less satisfactory the more substituents there are attached to the C atoms to be linked together"[2]. Yields are very low except for those reactions involving nitromethane itself, though a few important improvements have been reported[2,3]. Thus, Henry reactions of nitroalkanes with 2-methylcyclohexanone are unsuccessful, and higher nitroalkanes give low yields of nitroalcohols with 3- and 4-methylcyclohexanones[4]. We now report that some of these difficulties can be surmounted by the combined use of high pressure and nBu$_4$NF as catalyst[5,6].

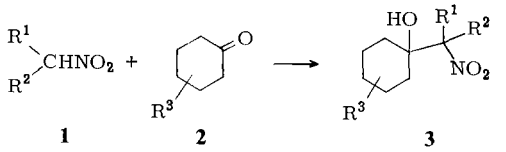

Table 1. Formation of nitroalcohols **3** [a] from nitroalkanes **1** and ketones **2** (9 kbar, 30°C, 4 d) [6].

R^1	R^2	R^3	Yield [%] [a]	B.p. [°C/torr] M.p. [°C]
H	H	2-CH_3	50 (0) [4])	68—69/2
		3-CH_3	61 (29 [4])	79—80/2
CH_3	H	2-CH_3	41 [b] (0 [4])	78—79/2
		3-CH_3	87 [c] (10 [4])	74—75/2
		4-CH_3 [d]	60 (14 [4])	73—75/2
C_2H_5	H	2-CH_3	40 (0 [4])	88—89/2
		3-CH_3	81 (5 [4])	84—85/2
		4-CH_3	89 (10 [4])	85—86/2
		[e]	86 (40 [7] 20 [8])	90—92/9
CH_3	CH_3	H	74 (45 [8])	56—57 [f]
		[e]	53 (19 [8])	66—70 [g]

[a] Yields not optimized. Correct elemental analyses obtained for all new nitroalcohols; all products gave satisfactory spectroscopic data (IR and ^{1}H-NMR spectra). Literature yields in parentheses. [b] 14% with piperidine as catalyst. [c] 52% with piperidine as catalyst. [d] 6 kbar, 30°C, 4 d. [e] Acetone was used as ketone. [f] Recrystallized from *n*-pentane. [g] Sublimed at 70—75°C (bath temperature)/9 torr.

The results are summarized in Table 1. Even 2-methylcyclohexanone affords moderate yields of the corresponding nitroalcohols, and with 3- and 4-methylcyclohexanones the yields are greatly improved[9]. n-Bu$_4$NF has proven to be a better catalyst than piperidine (see footnotes [b, c] to Table 1). Thus, the use of elevated pressure has extended the scope and potential utility of the Henry reaction.

[5] For a description of the high pressure apparatus employed in this study, see K. Matsumoto, A. Sera, T. Uchida, *Synthesis*, in press; most recent review on high pressure reactions: P. Welzel, *Nachr. Chem. Techn. Lab. 31* (1983) 148; W. J. le Noble, *Chem. Unserer Zeit 17* (1983) 152.
[6] Procedure: A mixture of the ketone **2** (16 mmol) and the nitroalkane **1** (24 mmol) is diluted with 1 M solution of nBu$_4$NF in tetrahydrofuran in a 10 mL Teflon capsule, which is then stored for 4 d at ca. 30 °C and 9 kbar. The reaction mixture is diluted with 97 mL benzene and 3 mL acetic acid and extracted several times with water to remove the catalyst. The organic layer is dried over $MgSO_4$. After removal of the solvent and unchanged starting materials under reduced pressure, the residue is either distilled in vacuo or recrystallized (see Table 1).

[9] Most of these reactions can also be enforced by the use of lithium α-lithionitronates Li$^{\oplus}$[RCLi=NO$_2^{\ominus}$] [7] instead of high pressure.

Molecular Structure of a 1,3-Diphosphaallene: (2,4,6-tBu$_3$C$_6$H$_2$)P=C=P(2,4,6-tBu$_3$C$_6$H$_2$), a Phosphorus Analogue of Carbon Disulfide**

By *Hans Heinz Karsch**, *Hans-Ulrich Reisacher*, and *Gerhard Müller**

The current interest in (p-p)$_\pi$ bonding systems with elements of higher rows has only recently led to the isolation of phosphacumulenes **1** for the first time[1-3]. However, the structural parameters of these compounds are not yet known.

R–P=C=X

1a, X = O[1]; **1b**, X = NR[2]; **1c**, X = CR$_2$[3]

R–P=C=P–R **2**, R = 2,4,6-tBu$_3$C$_6$H$_2$

S=C=S **3**

R–P=P–R **4**, R = 2,4,6-tBu$_3$C$_6$H$_2$

The most recently synthesized 1,3-diphosphaallene **2**[4] is now the first example of a structurally characterized phosphacumulene (see also [4c]). Its structural parameters are particularly interesting for a comparison with those of carbon disulfide **3**[5] and of the diphosphene **4**[6].

The X-ray structure analysis of **2** (synthesized as described[4a], recrystallized from toluene, colorless air-stable crystals) indicates that in the crystal, isolated molecules are present[7]. Two RP groups are bonded to an almost linearly-coordinated C atom (Fig. 1). The P=C bonds (1.635(8) and 1.630(8) Å) are markedly shorter than isolated P=C bonds with an sp^2-hybridized C atom (1.68–1.72 Å[8]). This shortening presumably reflects the special electronic characteristics of the heteroallene system and the smaller bond radius of the sp-hybridized C atom.

In carbon disulfide **3**, the CS bond length (d(C=S) = 1.554(5) Å[9]) is ca. 0.06 Å shorter than in thiocarbonyl compounds[10]. For P=C and P≡C systems, the Pauling bond radii lead one to expect bond lengths of 1.67 and 1.53 Å, respectively[11]. The PCP angle of 172.6(5)° indicates a slight but, nevertheless, significant deviation from linearity; angular deformations of this magnitude frequently result from packing effects. However, inspection of molecular models suggests that in this case the angular contraction reduces the interactions between the extremely bulky 2,4,6-tBu$_3$C$_6$H$_2$ moieties. Their mutual orientation is almost orthogonal with respect to the PP axis and approach each other to a greater extent than in R–P=P–R, where they adopt *trans*-positions relative to the P=P bond[6]. This orthogonality of the P-substituents is an important criterion for describing the P=C=P bonding system as a heteroallene, since allenes exhibit comparable geometry. Notable deviations with respect to allenes occur, however, with the CPC angles (100.3(4) and 99.9(4)°), which are similar to those in diphosphenes[6] and diarsenes[12] and can be interpreted as arising from approximately sp-hybridized P atoms; the bonding of the substituents via one p orbital in each case then accounts for the small CPC angle[13].

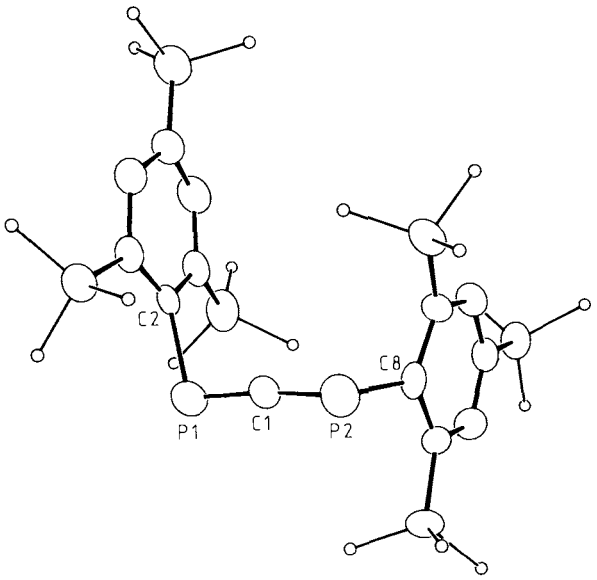

Fig. 1. Structure of **1** in the crystal (ORTEP; thermal ellipsoids 40%). The H atoms are omitted; the Me groups are shown with arbitrarily small radii. Plane angle C2P1P2/C8P2P1 = 83.0° [7].

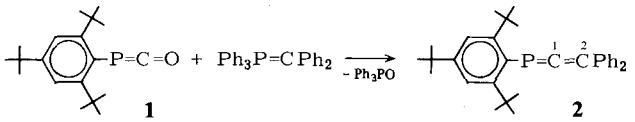
Phosphaallenes**

By *Rolf Appel**, *Peter Fölling*, *Bernhard Josten*, *Mustafa Siray*, *Volker Winkhaus*, and *Falk Knoch*

Dedicated to Professor Margot Becke on the occasion of her 70th birthday

So far, the only known representatives of the heterocumulenes R–P=C=X are those with X = NR'[1] and O[2], as well as the 1-phosphaallene **2** (X = CPh_2) recently described by *Yoshifuji* et al.[3]. We now report an independent synthesis of **2** using phosphaketene **1** and diphenylmethylenetriphenylphosphorane, an approach based on analogy to the Wittig reaction[4].



1 **2**

The IR and NMR data of **2** (m.p. = 165 °C) are consistent with the values given in [3] and fit the structure determined by X-ray diffraction studies (Fig. 1)[5].

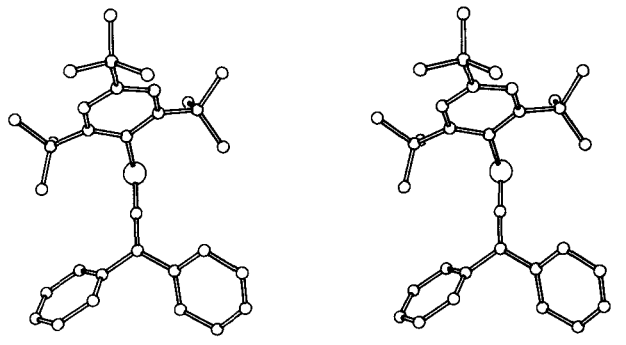


Fig. 1. Stereoscopic projection of the molecular structure of **2** in the crystal [5].

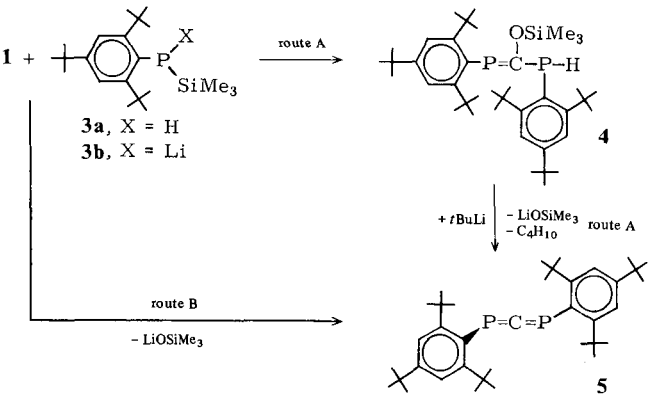
The phosphaketene **1** can also be used for the synthesis of the 1,3-diphosphaallene **5**. Addition of the silylphosphane **3a** to **1** (route A) leads initially to the isolable diphosphapropene **4**, which undergoes cleavage of lithium trimethylsilanolate with *tert*-butyllithium to afford the 1,3-diphosphaallene **5**[6]. By analogy to the carbodiphosphoranes[7], **5** can also be described as a carbodiphosphane. Alternatively, **5** can also be obtained directly via a Peterson olefination[8] by reaction of the lithium phosphide **3b** with **1** (route B)[6].



Because of the steric hindrance of the 2,4,6-tri-*tert*-butylphenyl substituents, **5** is so stable towards air and moisture that it can be purified by column chromatography. The composition and structure of the 1,3-diphosphaallene are based on the elemental analysis, a determination of the molecular mass, as well as MS and NMR data[9–11]. The synthesis of phosphaallenes **2** and **5** provides new evidence for the relationship between the PC and CC double bonds.

[4] Preparation of **2**: **1** (3.04 g, 0.01 mol) is placed in 80 mL anhydrous toluene and a solution of (diphenylmethylene)triphenylphosphorane (4.28 g, 0.01 mol) in 140 mL benzene added dropwise under an inert gas atmosphere with ice cooling. Subsequently the mixture is stirred for 3 h at room temperature. The solution is then evaporated to dryness and the residue purified by column chromatography (silica gel, hexane). Yield: 1.36 g (30%); m.p. = 165 °C.

[5] Molecular structure of **2**: Monoclinic, $P2_1/n$, a = 1097.9(3), b = 1730.8(4), c = 1458.0(4) pm, β = 90.06(2)°, V = 2770.6 × 10^6 pm^3, ρ_{calc} = 1.09 g/cm^3, Z = 4. Direct methods (SHELXTL), 2664 reflections, R = 0.078 (R_w = 0.070). Bond angles [°]: C_{aryl}PC1 104, PC1C2 167, torsion angle: C_{aryl}PC1C2 172; bond lengths [pm]: PC1 163, C1C2 131 (aryl = 2,4,6-tri-*tert*-butylphenyl). Further details on the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50913, the names of the authors, and the journal citation.

[6] Preparation of **5** (route A): **4**: To a solution of **1** (1.52 g, 5 mmol) in 15 mL toluene is added dropwise an equimolar amount of silylphosphane **3a** (1.75 g, 5 mmol) at room temperature under an inert gas atmosphere. After 30 min, ca. 30 mL acetonitrile is added and the mixture cooled on an ice bath; the diphosphapropene **4** precipitates out and is washed with acetonitrile. Pale yellow crystals are obtained, yield: 2 g (61%), decomp. = 142 °C. $^{31}P\{^1H\}$-NMR (32.19 MHz, C_6D_6, standard 85% H_3PO_4): δ = −46.0 (dd, ^2J(P,P) = 66.3, ^1J(PH) = 220.6 Hz; P=C–*P*), 171.2 (dd, ^2J(P,P) = 66.3, ^3J(P,H) = 20.1 Hz; *P*=C–P); ^{1}H-NMR (90 MHz, C_6D_6):

$\delta = 0.22$ (s, $Si(CH_3)_3$), 1.35–1.73 (*t*Bu), 6.04 (dd, $^1J(P,H) = 220$, $^3J(P,H) = 20$ Hz; P*H*), 7.47–7.62 (aromat.); $^{13}C\{^1H\}$-NMR (20.0 MHz), $CDCl_3$): $\delta = 1.6$ (d, $^4J(P,C) = 2.9$ Hz; $Si(CH_3)_3$), 31–38 (*t*Bu), 121–156 (aromat.), 192.7 (dd, $^1J(PC) = 39.5$, $^1J(PC) = 90.8$ Hz; P=*C*–P). MS (20 eV/110°C, selected peaks): *m/z* 597 ($M^{\oplus} - t$Bu), 540 ($M^{\oplus} - 2t$Bu), 451 ($M^{\oplus} - 2t$Bu–$OSi(CH_3)_3$), 319 (arylPCP$^{\oplus}$), 276 (arylP$^{\oplus}$).—**5**: To a solution of **4** (2 g, 3 mmol) in 40 mL ether is added dropwise an equimolar amount of a 1.5 M solution of *tert*-butyllithium at −60°C, the contents of the flask mixed well and then warmed rapidly to +30°C. The solution becomes red. After addition to trimethylsilyl chloride to remove the base formed in the reaction and concentration of the reaction solution, the product is purified by column chromatography (silica gel, hexane) and recrystallized from hexane; m.p. = 202–204°C, yield: 0.81 g (48%).

Preparation of **5** (route B): **3b** (2.5 mmol) in 8 mL ether is added to a stirred solution of **1** (750 mg, 2.5 mmol) in 5 mL toluene. When the reaction ceases (30 min), 2.5 mmol trimethylsilyl chloride is added and the mixture stirred for 15 min. Undissolved residues are filtered off and the solvent removed using an oil pump. The residue is then taken up in benzene, and precipitation with acetonitrile gives 0.49 g **5** (35%).

[9] MS (70 eV): *m/z* 564 ($M^{\oplus}$, 3%), 507 ($M^{\oplus} - t$Bu, 43%); ^{31}P-NMR (32.2 MHz, C_6D_6, 25°C): $\delta = +141.2$; ^{1}H-NMR (90 MHz, CD_2Cl_2, 25°C): $\delta = 1.25$ (br. s), 7.25 (s); ^{1}H-NMR (CD_2Cl_2, −40°C): $\delta = 1.0$ (s, *o*-*t*Bu), 1.2 (s, *p*-*t*Bu), 1.55 (s, *o*-*t*Bu), 7.25 (d, aryl); ^{13}C-NMR (20 MHz, $CDCl_3$, 25°C): $\delta = 276.2$ (t, $J(PC) = 58$ Hz).

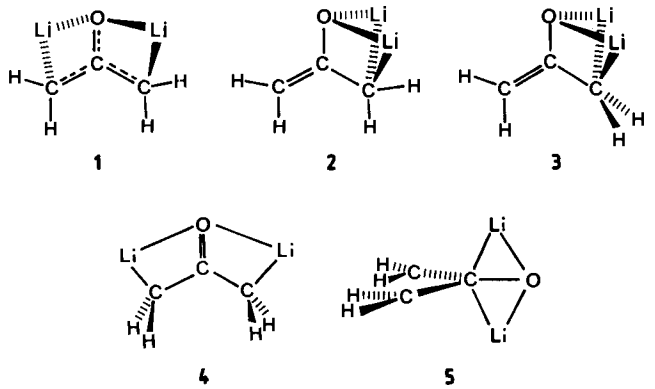
[10] The phosphaallene **5** was prepared independently and at the same time by another route: H. H. Karsch, H.-U. Reinacher, G. Müller, *Angew. Chem. 96* (1984) 619; *Angew. Chem. Int. Ed. Engl. 23* (1984) 618.

[11] Note added in proof: In the meantime, *Yoshifuji* et al. have also reported a synthesis of **5**: M. Yoshifuji, K. Toyota, N. Inamoto, *J. Chem. Soc. Chem. Commun. 1984*, 689.

The ab initio Calculation of the Structure of 1,3-Dilithioacetone**

By *Alexander J. Kos, Timothy Clark,* and *Paul von Ragué Schleyer**

In cases where enolate anions react sluggishly, the reactivity and the nucleophilicity of the α-carbon atoms can be enhanced greatly by a second metallation. Hence, α,α′-keto dianions (in reality, dimetalated intermediates) are often employed in synthesis[1]. An NMR investigation[2] of the dilithium salt of the dibenzyl ketone dianion showed the high negative charges at the two benzylic C atoms typical of "Y-conjugated" systems[2]. We report here ab initio calculations with the split-valence 3-21G basis set[3] on the α,α′-keto dianion salt prototype, 1,3-dilithioacetone.



With the assumption that the Li atoms bridge the O and α-C atoms, there are two possible structures for the monomer. Structure **1** is chiral (C_2 point group symmetry) and has two enol moieties[4] and equivalent terminal C atoms. The lithium cations bridge above and below the dianion molecular plane, and some twisting of the CH_2 groups results (Fig. 1). This "opposite side" arrangement of two Li atoms, which is also found in several dilithiated conjugated hydrocarbon systems[5,6], is more favorable electrostatically (lower dipole moment) than the alternative with both Li atoms on the same side of the dianion moiety. Isomer **2** exhibits a different double bridging arrangement with both Li atoms attached to the same α-C atom. This C atom becomes much more negative than the α′-C atom, which is more olefin-like. The ab initio calculations (Table 1) indicate that **1** is 13.9 kcal/mol more stable than **2**. All the C, O, and H atoms in **2** lie in the same plane; this favors charge delocalization. Rotation of the carbanionic center by 90° gives isomer **3**, which has reduced conjugation. Nevertheless, only a small energy disadvantage results; **3** is 4.2 kcal/mol less stable than **2**. The loss of conjugation in **3** is partially compensated by the electrostatically more favorable orbital orientation at C_α. This is characteristic of 1,3-dilithium doubly bridged structures and has already been discussed in detail for other systems[7].

Complete removal of the Y-conjugation in **1** by 90° rotation of both CH_2 groups (isomer **4**) costs 33.1 kcal/mol. This high energy precludes the possibility of racemization of chiral α,α′-dilithio ketone derivatives by simultaneous rotation of both C–C bonds. Racemization involving exchange of Li atoms may occur instead through structures like **5**, which retain Y-conjugation. The energy difference between **1** and **5** is calculated to be only 16.3 kcal/mol.

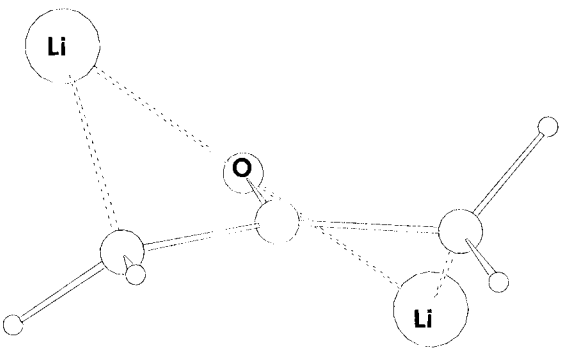


Fig. 1. 3-21G Optimized structure of 1,3-dilithioacetone **1**. Bond lengths [Å]: C–C 1.400; C–O 1.407; C–H 1.073 (*exo*), 1.083 (*endo*). Bond angles [°]: CCO 114.6; CCC 130.7; CCH 119.3 (*exo*), 116.8 (*endo*). Dihedral angles [°]: CCOLi 38.4; OCCH 186.9 (*exo*), 40.3 (*endo*).

Table 1. Calculated 3-21G energies for 1,3-dilithioacetone isomers **1**–**5**.

Isomer	E_{tot} [a.u.]	E_{rel} [kcal/mol]
1	−204.57903	0.0
2	−204.55693	13.9
3	−204.55019	18.1
4	−204.52317	33.1
5	−204.55306	16.3

The geometry of **1** corresponds remarkably well with the X-ray structure of 1,3-dilithiodibenzyl ketone[8]. The pre-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *H. Dietrich* for his interest.

ferred locations of the Li atoms are the same. The main differences between **1** and the X-ray result can be attributed to the presence of the coordinating tetramethylenediamine (TMEDA) molecules in the experimental structure[6]. The lower lithium coordination in **1** is reflected by the shorter Li–O and Li-α-C distances (0.1 and 0.4 Å, respectively). In addition, the C–O bond in **1** is 0.07 Å longer than that in the X-ray structure of 1,3-dilithiobenzyl ketone.

The experimentally observed structures of mono-enolate anions correspond to dimers and tetramers without Li–C interactions[4b,9]. In contrast, 1,3-lithium bridging between C and O atoms is found to be structure- and reactivity-determining in α,α′-keto dianions[8].

Structure of a "Y-Conjugated" Dilithium Salt of an α,α′-Keto Dianion: 1,3-Dilithiodibenzyl Ketone-$(Me_2NCH_2CH_2NMe_2)_2$**

By *Hans Dietrich**, *Waruno Mahdi*, *Dieter Wilhelm*, *Timothy Clark*, and *Paul von Ragué Schleyer*

Although the enolates commonly used in syntheses are usually regarded as anions, their structures are complex and involve counterions and aggregated clusters[1]. Consideration of organoalkali metal structures as they really are, rather than as oversimplified models, is necessary to understand their reactivity and stereochemistry as well as the selectivity of their reactions[2]. We report here the first X-ray structure analysis of a monomeric dilithium salt of an α,α′-keto dianion. Both the position of the lithium counterions and the geometry of the carbodianion moiety are of interest. The ab initio structures of the parent Y-conjugated[3] system, 1,3-dilithioacetone, have been reported[4]. We compare here the experimental results on 1,3-dilithiodibenzyl ketone **1** with those obtained by MNDO calculations (Fig. 2)[5]; the preparation and NMR spectra of **1** and MNDO calculations on the corresponding dianion have already been discussed[6].

The X-ray structure of **1**[7] shows that the benzyl groups adopt *exo,exo* orientations, in agreement with the MNDO results on the dianion, but not with the results of NMR measurements in tetrahydrofuran (THF), which indicate a 65% *exo,endo*- and 35% *exo,exo*-mixture[6]. Both phenyl groups are twisted ca. 20° in opposite directions out of the plane of the central atoms; the MNDO findings indicate 21° for the dilithium salt (Fig. 2) and nearly the same value in the dianion[6]. Comparison of Figures 1 and 2 indicate that the X-ray and MNDO structures agree very well in their general features. As in the case of the parent system[4], other alternatives were examined calculationally, but were found to be less stable. With approximate C_2 symmetry, the dilithium salt is chiral, which may be significant in synthetic applications.

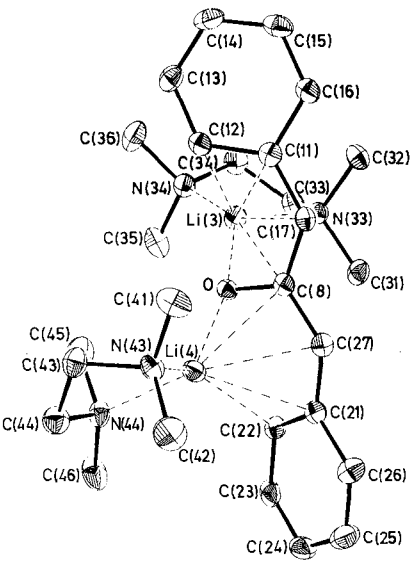

Fig. 1. Structure of 1,3-dilithiobenzyl ketone·$(TMEDA)_2$ in the crystal. The hydrogen atoms have been omitted. Important bond lengths [Å]: C(8)–O 1.334(1), C(8)–C(17) 1.413(2), C(8)–C(27) 1.402(2), C(11)–C(17) 1.424(2), C(21)–C(27) 1.434(2), C(11)–C(12) 1.423(2), C(21)–C(22) 1.433(2), C(12)–C(13) 1.386(2), C(22)–C(23) 1.395(2), C(13)–C(14) 1.376(2), C(23)–C(24) 1.381(2), C(14)–C(15) 1.388(2), C(24)–C(25) 1.391(2), C(15)–C(16) 1.374(2), C(25)–C(26) 1.375(2), C(16)–C(11) 1.430(2), C(26)–C(21) 1.421(2); Li(3)–O 1.849(2), Li(4)–O 1.870(2), Li(3)–C(12) 2.469(2), Li(4)–C(22) 2.425(2), Li(3)–C(11) 2.653(2), Li(4)–C(21), 2.505(2), Li(3)–C(17) 2.731(2), Li(4)–C(27) 2.550(2), Li(3)–C(8) 2.150(2), Li(4)–C(8) 2.415(2).

The C–O bond is lengthened due to coordination with the two Li atoms. The C–O distance of 1.334 Å (X-ray analysis, 117 K) is comparable to that found in aggregated lithium enolates[1] and phenolates[8,9]. The MNDO value for **1** (1.337 Å) is in good agreement with the experimentally determined value, in contrast to the shorter length calculated for the dianion (1.247 Å)[6]. The distances between the carbonyl and the benzylic carbon atoms (average 1.408 Å) are slightly shorter than those between the benzyl carbon atoms and the phenyl rings (1.429 Å). The lengths

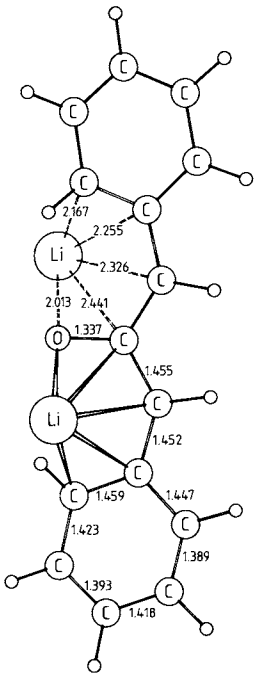

Fig. 2. Calculated (MNDO) structure of 1,3-dilithiodibenzyl ketone **1** (bond lengths in [Å]).

of these bonds in the calculated and experimental structures indicate the importance of conjugation in the dilithium compound.

The two Li atoms, each solvated by tetramethylethylenediamine (TMEDA), occupy bridging positions on opposite sides of the α,α'-keto dianion system. In addition to the strong coordination to oxygen (d(Li–O) = 1.86 Å), each Li atom is in close contact with four C atoms (Figs. 1 and 2). The LiC distances determined at 117 K by X-ray crystal structure analysis range between 2.42 and 2.73 Å.

The structure of **1** can be regarded as consisting of two fused enolate units with a common C–O bond. The lithium enolate units then correspond to the bridged form of acetaldehyde lithium enolate, which is indicated by ab initio calculations to be slightly less stable than the structure with a linear C–O–Li linkage[10]. This bridged form has not been observed for monoenolate aggregates, but is clearly favored for "dienolates"[4].

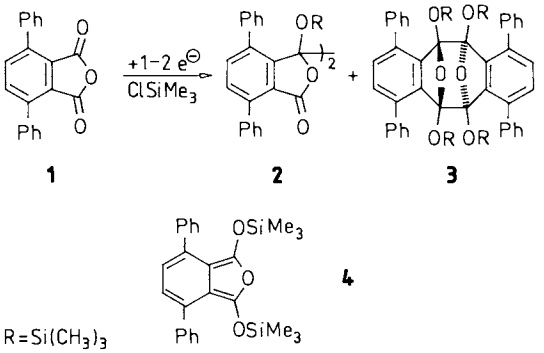
1,4,7,10-Tetraphenyldibenzo[*a*,*e*]cyclooctene-5,6,11,12-tetrone from 3,6-Diphenylphthalic Anhydride**

By *Theodor Troll**, *Georg W. Ollmann*, and *Helga Leffler*

Electrochemical reduction of *N*-phenyl- and *N*-methylphthalimide under aprotic conditions in the presence of trimethylchlorosilane leads to formation of 1,3-bis(trimethylsiloxy)isoindoles[1,2]. The reaction offers an extremely facile entry to 1,3-bis donor-substituted isoindoles[3]. Transfer of this reaction to phthalic anhydride affords exclusively bislactone ethers[1].

In the reduction of 3,6-diphenylphthalic anhydride **1** under the same conditions, however, we obtained, in addition to 4,7-diphenyl-3-hydroxyphthalide (7% yield) and the dimers **2** (34%, two diastereomers), the acetal **3**.



Reduction of **1** at the potential E^1 ($E_{1/2}=-1.32$ V vs. SCE, reversible formation of the radical anion) leads to isolation of **3** in 13% yield; at the potential E^2 ($E_{1/2}=-2.10$ V, reversible formation of the dianion), the yield increases to 25%. A reductive cyclization of **2** can be ruled out, since no reduction step was found in the potential range available. Hence, a bis donor-substituted isobenzofuran **4** has been obtained for the first time as an intermediate; previously, only 1-alkoxyisobenzofurans have been described[4].

Presumably **3** adopts the sterically more favorable configuration with *anti*-oxygen bridges, as in the dimeric parent compound[5]. No distinction could be made by complexation with NMR shift reagents. Potassium fluoride in ace-

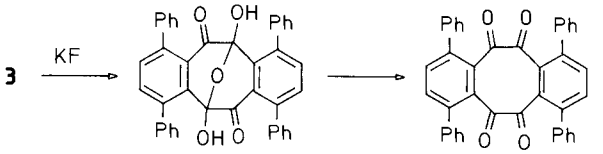
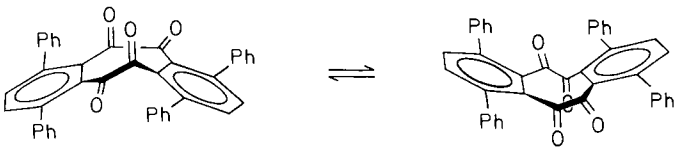
tonitrile converts **3** into **5**, which undergoes acid-catalyzed dehydration to yield the tetraketone **6**, the first member of this class of compounds[6].



5 **6**

Of note is the similarity between the UV spectra of **5** and **6** (Table 1). The two additional carbonyl groups in **6** effect practically no shift of the absorption maximum. The position of the long-wavelength maximum of **6** is consistent with that of 1,2-dicarbonyl compounds having orthogonal carbonyl groups[7,8]. On the basis of these data, the eight-membered ring adopts a twisted boat conformation. Two carbonyl groups are coplanar and hence are able to undergo conjugation with the neighboring terphenyl system; the two remaining carbonyl groups are perpendicular to this plane and are arranged parallel to each other. Inspection of a molecular model indicates that the change in



6a **6b**

conformation from **6a** to **6b** proceeds via pairwise exchange of carbonyl groups. For tetrahydrodibenzo[*a,e*]cyclooctene and some of its derivatives, a twisted boat conformation has been detected[9].

This conformational change, which proceeds rapidly even at room temperature, is also apparent from the ^{13}C-NMR spectrum, which up to $-80\,^{\circ}C$ displays only one signal for the carbonyl carbon atoms (Table 1). An X-ray structure analysis of **6** was unsuccessful because of the small number of observed reflections.

Table 1. Melting points and spectroscopic data for **3**, **5**, and **6**. ^{13}C-NMR: **3** and **6** in $CDCl_3$, **5** in CD_2Cl_2. UV: in CH_2Cl_2.

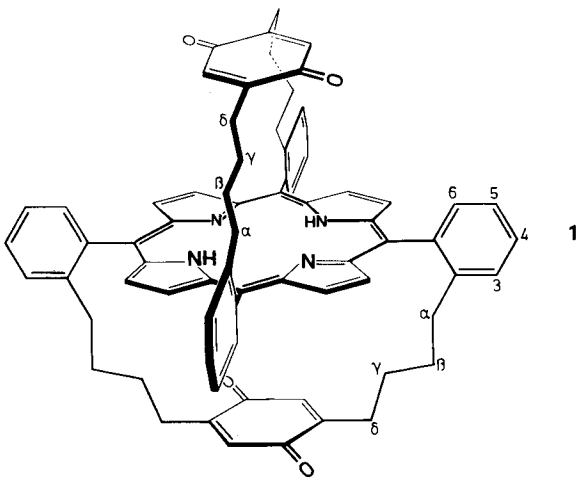
Synthesis of a Porphyrin Sandwiched between Two Parallel *p*-Benzoquinone Units

By *Jürgen Weiser* and *Heinz A. Staab**

Because of the considerable biochemical importance of electron-transfer reactions between porphyrins and *p*-benzoquinones, various intramolecular porphyrin-quinone systems have recently been synthesized in order to study the spatial requirements of such reactions[1]. In most cases, however, the covalent linkage between porphyrin and quinone involves either one single chain or two relatively long heteroatomic bridges, neither systems leading to porphyrin-quinone systems of well-defined geometry. In view of these studies, we wish to report on compound **1**, whose synthesis we began independently[2] in connection with our work on intramolecular charge-transfer interactions. In **1** a porphyrin is sandwiched between two *p*-benzoquinone units which, due to four hydrocarbon bridges, are kept in a fairly rigid arrangement above and below the center of the porphyrin moiety.



1

For the synthesis of **1**, the key precursor was 2,2′-[2,5-dimethoxy-1,4-phenylenebis(tetramethylene)]dibenzaldehyde **2**, which was prepared in the following way: 3,3′-

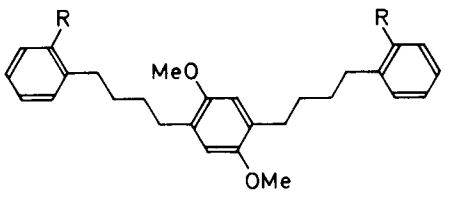
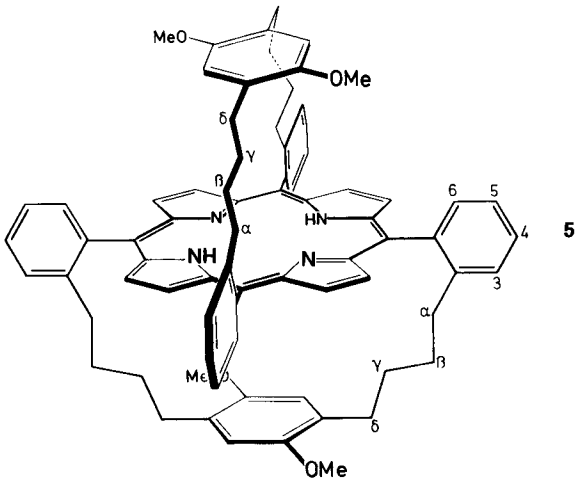
(2,5-dimethoxybenzene-1,4-phenylene)di-1-propanol[3] was oxidized (pyridinium chlorochromate, dichloromethane, 3 h, 20°C; 68% yield) to the corresponding dialdehyde (m.p. = 85–87°C)[4]. Wittig reaction with (2-methoxycarbonylbenzyl)triphenylphosphonium bromide (MeONa, MeOH, 60°C; 65%) yielded dimethyl 2,2'-[2,5-dimethoxy-1,4-phenylenebis(3-butenylene)]dibenzoate (*Z/E* mixture)[4], which was hydrogenated (Pd/C, methanol/ethyl acetate; quantitative) to the diester **3** (m.p. = 79-81°C)[4]. Reduction ($LiAlH_4$, tetrahydrofuran, 3 h reflux; 92%) led to the dialcohol **4** (m.p. = 128–130°C)[4], oxidation of which (pyridinium chlorochromate, dichloromethane, 3 h, 20°C; 90%) afforded dialdehyde **2** (m.p. = 90-92°C)[4].



2 : R = CHO
3 : R = COOMe
4 : R = CH_2OH

By analogy to the synthesis of tetraphenylporphyrin (TPP)[5], **2** was allowed to react with pyrrole (molar ratio 1 : 2, 4 h) in boiling propionic acid. Not unexpectedly, considering the bifunctionality of **2**, the majority of products of this reaction were oligomers and polymers which, however, could be separated on the basis of their insolubility and by chromatography (silica gel, toluene). Thin layer chromatography of the porphyrin fraction (silica gel, toluene/cyclohexane, 3 : 1) revealed that three different products, corresponding apparently to the three modes of condensation[6], are present. By repeated column chromatography (silica gel, toluene/cyclohexane, 3 : 1), fraction A ($R_F \approx 0.27$) was obtained pure (yield ca. 0.1%), whereas of the other two fractions, B and C, only the latter ($R_F \approx 0.15$) could be enriched to about 95% purity (yield ca. 0.5%)[7].

Compound A forms violet microcrystals (m.p. = 267-269°C, from dichloromethane/methanol). The elemental analysis, absorption spectrum (very similar to that of TPP), and mass spectrum [$m/z = 1106$ ($M^{\oplus}$, 100%), 1092 (8), 1091 (8), 1079 (16), 1078 (19), 553 ($M^{\oplus}/2$, 40)] are strongly indicative of a doubly bridged porphyrin. Furthermore, the ^{1}H-NMR data reveal that, out of the three isomeric structures, A has indeed structure **5** in which the two bridges diagonally link two opposite *meso*-positions of the porphyrin and, consequently, are arranged on either side of the porphyrin plane [^{1}H-NMR (360 MHz, CD_2Cl_2): $\delta = -2.79$ (s, 2H, NH), 0.09-0.14 ('dd', 8H, δ-CH_2), 0.40-0.47 (m, 8H, γ-CH_2), 0.78-0.84 (m, 8H, β-CH_2), 1.97 (s, 12H, OCH_3), 2.07-2.09 ('dd', 8H, α-CH_2), 4.31 (s, 4H, dimethoxy-subst. rings), 7.52-7.54 ('d', $J = 7.5$ Hz, 4H, 3-H), 7.57-7.61 ('dd', $J \approx 7.4$ Hz, 4H, 5-H), 7.67-7.71 ('dd', $J \approx 7.4$ Hz, 4H, 4-H), 8.18-8.20 ('d', $J \approx 7.3$ Hz, 4H, 6-H), 8.55 (s, 8H, β-pyrrole-H)]. From these data the following points can be made: The eight β-pyrrole protons exhibit only one singlet; methylene protons which correspond to each other on the four bridges are equivalent, and compared to the respective protons in **2** are increasingly shielded by the porphyrin anisotropy in going from the periphery to the aromatic rings above and below the porphyrin center; the four aromatic protons of these two rings are equivalent and give rise to a singlet at $\delta = 4.31$ which is shifted upfield $\Delta\delta = 2.33$ relative to **2**; the four methoxy groups are also equivalent and their singlet at $\delta = 1.97$ shows an upfield shift $\Delta\delta = 1.79$ ppm relative to **2**. These data very strongly indicate the highly symmetrical structure **5** with the two aromatic rings arranged parallel to the porphyrin plane (cf. the ^{1}H-NMR data for compound C[7]).



5

Demethylation of **5** under mild conditions (BBr_3, dichloromethane, 3 h, −40°C, exclusion of light) and subsequent oxidation with 1,2-dichloro-4,5-dicyano-*p*-benzoquinone (DDQ) [dichloromethane/methanol (1 : 1), 1 h, 20°C] yielded the bisquinone **1** in 41% yield after chromatography (neutral alumina Brockmann 2–3, toluene) and crystallization from toluene/hexane.

1 forms violet needles of m.p. = 281–282°C[4]. In the mass spectrum the molecular ion $m/z = 1046$ forms the base peak; compared to **5**, however, there is much more pronounced fragmentation which is clearly due to the lability of the quinone rings. The ^{1}H-NMR spectrum closely resembles that of **5** and, thus, strongly supports the arguments put forward for the spatial structure of these systems [^{1}H-NMR (360 MHz, CD_2Cl_2): $\delta = -2.82$ (s, 2H, NH), 0.13-0.16 ('dd', 8H, δ-CH_2), 0.28-0.30 (m, 8H, γ-CH_2), 0.84-0.86 (m, 8H, β-CH_2), 2.29-2.31 ('dd', 8H, α-CH_2), 4.04 (s, 4H, quinone-H), 7.54-7.56 ('d', $J \approx 6.8$ Hz, 4H, 3-H), 7.61-7.64 ('dd', $J = 6.8$ Hz, 4H, 5-H), 7.68-7.70 ('dd', $J \approx 6.8$ Hz, 4H, 4-H), 8.41-8.43 ('d', $J \approx 6.3$ Hz, 4H, 6-H), 8.64 (s, 8H, β-pyrrole-H)].

Conversion of **1** into metalloporphyrins and the study of electron-transfer reactions, which because of the specific structure of the doubly quinone-shielded **1** must involve quinone-porphyrin interactions, are presently being investigated by optical and EPR spectroscopy.

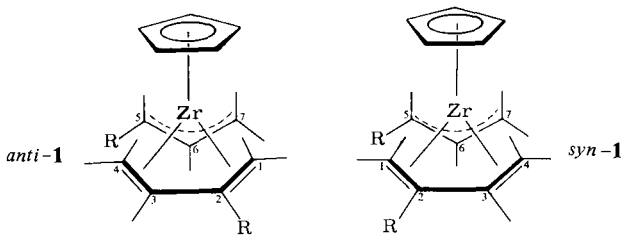
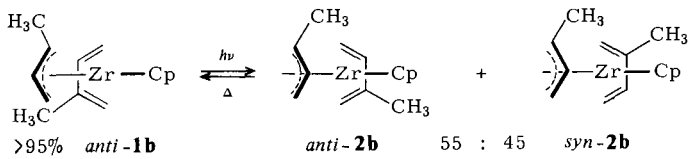
Diastereoselective Formation of Substituted (η^3-Allyl)(η^4-diene)ZrCp Complexes by Intramolecular Ligand Interaction**

By *Gerhard Erker**, *Klaus Berg*, *Reinhard Benn*, and *Gerhard Schroth*

Most of the catalysts in use today have been developed empirically. However, there has been no lack of attempts to synthesize homogeneous catalysts according to plan[1]. A basic problem in directed syntheses is the control of selectivity. A prerequisite for a specific product formation at the metal center is a pronounced intramolecular interaction between different ligands[2]. We have recently synthesized the isomeric (η^3-allyl)(η^4-diene)ZrCp complexes **1** and **2**[3], which, because of the different arrangement of the three π-ligands, can be expected to exhibit different intramolecular ligand interactions.

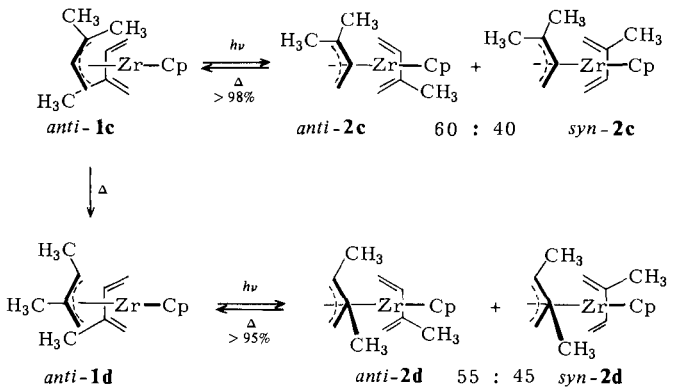




Scheme 1.

In the thermodynamically more stable isomer **1** the η^3-allyl and η^4-diene moieties open towards the apical cyclopentadienyl (Cp) ligand. According to an X-ray structure analysis and the ^{1}H-NMR-NOE difference spectra of the parent system[3] (η^3-allyl)(η^4-butadiene)(η^5-cyclopentadienyl)zirconium **1a**, the hydrogen atoms at C-2 of the diene and in the *syn*-position at C-5 of the allyl ligand come spatially very close (see Scheme 1); with respect to the C-2, C-5 vector they are almost eclipsed. The introduction of substituents at these positions leads to the formation of diastereomers. A strong repulsive interaction between these ligands should result in a preferential occurrence of *anti*-**1** over *syn*-**1** under equilibrium conditions. We could demonstrate this effect by introduction of methyl groups at the 2- and 5-positions to give the (η^4-isoprene)(η^3-1-methylallyl)ZrCp system **1b/2b**.

1b/2b was synthesized via the route previously described by us for **1a/2a**[3,4]: $CpZrCl_3$ **3**[5] is allowed to react with 2-butenylmagnesium chloride **4**; subsequent comproportionation with two equivalents of the starting material and reaction with "isoprene-magnesium" **7**[6] gives **1b/2b** in ca. 10% total yield as a red solid which is very sensitive to air and moisture. The material isolated at room temperature is photolyzed (Philips HPK 125, Pyrex filter) in toluene (≈5% solution) at −50 °C; the compounds *syn*-**2b** and *anti*-**2b** are obtained in a 45:55 ratio (^{1}H-NMR). Both



Scheme 2.

isomers rearrange on heating—within the range of accuracy of the measurement (^{1}H-NMR) at equal rates ($\Delta G^{\ddagger}_{10\,°C} = 21.7 \pm 0.3$ kcal/mol)—to give essentially one product (diastereoselectivity >95%), which according to the NMR analysis is the expected isomer *anti*-**1b**[7,8].

This effect is not limited to the system **1b/2b**. The (1,1-dimethylallyl)(isoprene)ZrCp system **1c/2c** as well as (1,2-dimethylallyl)(isoprene)ZrCp **1d/2d**, readily available therefrom by a thermally induced hydrogen-shift, behave analogously[9]. The formation of the photoisomers **2c** and **2d**, in which the allyl and diene moieties open towards the basis of the skeletal framework, is unselective. The thermal rearrangement affords only the thermodynamically more stable diastereomers *anti*-**1c** and *anti*-**1d**, respectively.

Therefore, it seems promising to us to attempt the development of catalyst systems for stereoselective syntheses using the chiral building blocks (η^3-1-methylallyl)ZrCp, (η^4-isoprene)ZrCp[3b] or metal-complex fragments of similar structure[11].

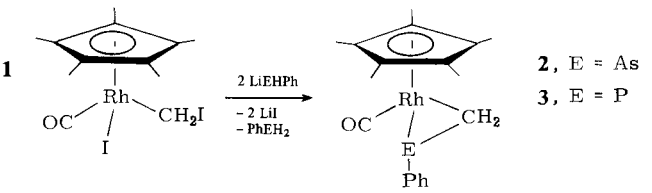
Complexation of PhAs=CH$_2$ and Synthesis of a Novel RhAs$_3$-Metallaheterocycle**

By *Helmut Werner**, *Wilfried Paul*, and *Ralf Zolk*

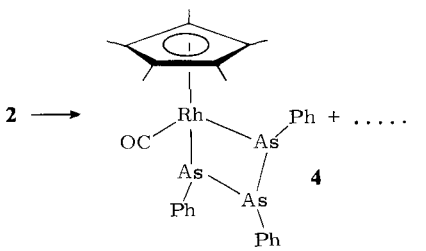
So far only one methylenephosphane RP=CH$_2$, the extremely reactive compound with R = 2,4,6-*t*Bu$_3$C$_6$H$_2$, is known[1a]. Analogous compounds R−E=CR$'_2$ with R$'$ = *t*Bu or OSiMe$_3$ were first prepared and structurally characterized by *Becker* et al.[1b], and subsequently also by other groups[1c]. With regard to their stability, particularly for methylenearsanes R−As=CR$'_2$, it appears that an almost complete shielding of the polar As=C bond by bulky groups R is of great importance. Convincing support for this statement comes from the work of *Bickelhaupt* et al.[2], who observed a striking difference in reactivity between (2,4,6-Me$_3$C$_6$H$_2$)As=CPh$_2$, which is stable at room temperature, and Ph−As=CPh$_2$, which immediately polymerizes under the same conditions.

Following the same method of synthesis which recently enabled us to prepare thio-, seleno- and telluroformaldehyde complexes of cobalt and rhodium[3], we have now succeeded in generating and stabilizing Ph−As=CH$_2$, a compound unknown in the free state, in the coordination sphere of a transition metal. The synthesis makes use of complex **1**, formed from C$_5$Me$_5$Rh(CO)$_2$ and CH$_2$I$_2$[3c]. **1** reacts with LiAsHPh[4a] in Et$_2$O/tetrahydrofuran at room temperature to produce **2**[5a]. Evidence for the proposed structure with an η^2-coordination of the methylenearsane via As *and* C emerges from the ^{1}H-NMR spectrum[5b], in which two well separated signals for the CH$_2$-protons are observed, as in C$_5$Me$_5$Rh(η^2-CH$_2$Se)CO[3c].



Reaction of **1** with LiPHPh[4b] follows a similar course. Compound **3** has not as yet been characterized analytically, but on basis of the spectroscopic data there is no doubt about its composition and structure. *Bickelhaupt* et al.[6a, b] as well as *Nixon* et al.[6c, d] have prepared complexes of Cr, Mo, W, Rh, and Pt with (2,4,6-Me$_3$C$_6$H$_2$)P=CPh$_2$ as ligand; spectroscopic measurements and X-ray analysis showed in nearly all cases that the diphenylmethylenephosphane molecule is linked *only via phosphorus* to the metal. Evidence for coordination via P *and* C has been found only in the platinum(0) complex [(2,4,6-Me$_3$C$_6$H$_2$)P=CPh$_2$]Pt(Ph$_2$PCH$_2$)$_3$CMe[6e] and in the nickel complexes [(2,6-Me$_2$C$_6$H$_3$)P=CPh$_2$]Ni(bpy)[6f] and [(Me$_3$Si)$_2$HCP=C(SiMe$_3$)$_2$]Ni(PMe$_3$)$_2$[6g], in which, as in **3**, an electron-rich metal is present.

Attempts to obtain single crystals of **2** from pentane led to a yellow microcrystalline powder (**2** according to mass spectroscopy) as well as to some orange-red crystals **4**, which are formed from **2**[5b]. At present, no detailed mechanism for the formation of **4** can be formulated. The X-ray structure analysis (Fig. 1)[7] shows the presence of a nonplanar, four-membered RhAs$_3$-ring in which the angle between the planes Rh, As1, As2 and Rh, As3, As2 is 25.9° and that between the planes Rh, As1, As3 and As1, As2, As3 is 23.1°. The As−As distances correspond to single bonds and are only slightly different from those in *cyclo*-(AsCF$_3$)$_4$ (245.4(1) pm)[8a] and *cyclo*-(AsPh$_6$) (average distance 245.9 pm)[8b]. The angle As1-As2-As3 (82.97(5)°) is also similar to that in *cyclo*-(AsCF$_3$)$_4$ (83.6(1)°).



4 is the second example of a heterocycle derived from a *cyclo*-(AsR)$_4$ ring system in which one AsR unit is replaced by a transition metal moiety (C$_5$Me$_5$(CO)Rh). The first example was described by *Köpf* and *Görges*, who isolated the complex (C$_5$H$_5$)$_2$Ti(AsEt)$_3$[9]. More recently, *Shaver* et al. reported the synthesis and crystal structure of the compound (C$_5$Me$_5$)$_2$TiS$_3$, which also contains a four-membered ring (though somewhat more bent than in **4**) formed from one transition-metal and three non-metallic atoms[10].

Chemical Bonds without Bonding Electron Density—Does the Difference Electron-Density Analysis Suffice for a Description of the Chemical Bond?**

By *Dieter Cremer** and *Elfi Kraka*

Carefully executed X-ray diffraction experiments on peroxides[1,2] have indicated that the difference electron-density distribution $\Delta\rho(r)$ in the region of the OO bond is negative. The $\Delta\rho(r)$-distributions in certain CC, CN, CO, and CF bonds in various organic molecules are also surprisingly small[2,3]. Since $\Delta\rho(r)$ provides at least a qualitative measure for the accumulation of electron density in the bonding region[4], bonding models in which the existence of a covalent bond is dependent upon a finite bonding electron density $\Delta\rho(r)$ appear somewhat dubious[2]. We report here a novel approach to the description of the chemical bond, which confirms that the formation of covalent bonds does not necessarily bring about an increase in electron density in the bonding region.

The analysis of difference or deformation electron-densities $\Delta\rho(r) = \rho(r) - \rho'(r)$, although experimentally quite useful, is problematic since it requires the definition of an appropriate reference density $\rho'(r)$[4,5]. Therefore, we have analyzed the electron-density distribution $\rho(r)$ directly from its assigned Laplace field $\nabla^2\rho(r)$. It is an important property of the Laplace field to indicate concentrations of its associated scalar field without requiring a reference field[6]. The "Laplace concentration" reflects the behavior of the principle curvatures λ_i (i = 1, 2, 3) of $\rho(r)$ in the three directions of space (λ_i: eigenvalue of the matrix of second derivatives of $\rho(r)$). The curvature λ_1 along the bond is always positive since $\rho(r)$ has a minimum there. The curvatures λ_2 and λ_3 perpendicular to the bond axis are negative, corresponding to an increase in $\rho(r)$ towards the bond axis. If the charge concentration perpendicular to the bond axis is predominant ($|\lambda_2| + |\lambda_3| > |\lambda_1|$), a negative value for $\nabla^2\rho(r)$ results, synonymous with a concentration of $\rho(r)$ in the bonding region.

The Laplace fields $\nabla^2\rho(r)$ determined by HF/6-31G* calculations for some selected bonds are shown in Figure 1 in the form of contour line diagrams. The broken lines occur in regions with charge concentrations ($\nabla^2\rho(r) < 0$) which, on the basis of simple chemical concepts, can be assigned to bonding and lone-pair electrons[7]. The concentration of $\rho(r)$ in the bonding region decreases along the series CC, CN, CO, CF and CC, OO, FF, respectively (see Fig. 1 and Table 1), which qualitatively goes hand in hand with a decrease in covalent bond strength[8].

Chemical Bonds without Bonding Electron Density—Does the Difference Electron-Density Analysis Suffice for a Description of the Chemical Bond?**

By *Dieter Cremer** and *Elfi Kraka*

Carefully executed X-ray diffraction experiments on peroxides[1,2] have indicated that the difference electron-density distribution $\Delta\rho(r)$ in the region of the OO bond is negative. The $\Delta\rho(r)$-distributions in certain CC, CN, CO, and CF bonds in various organic molecules are also surprisingly small[2,3]. Since $\Delta\rho(r)$ provides at least a qualitative measure for the accumulation of electron density in the bonding region[4], bonding models in which the existence of a covalent bond is dependent upon a finite bonding electron density $\Delta\rho(r)$ appear somewhat dubious[2]. We report here a novel approach to the description of the chemical bond, which confirms that the formation of covalent bonds does not necessarily bring about an increase in electron density in the bonding region.

The analysis of difference or deformation electron-densities $\Delta\rho(r) = \rho(r) - \rho'(r)$, although experimentally quite useful, is problematic since it requires the definition of an appropriate reference density $\rho'(r)$[4,5]. Therefore, we have analyzed the electron-density distribution $\rho(r)$ directly from its assigned Laplace field $\nabla^2\rho(r)$. It is an important property of the Laplace field to indicate concentrations of its associated scalar field without requiring a reference field[6]. The "Laplace concentration" reflects the behavior of the principle curvatures λ_i (i = 1, 2, 3) of $\rho(r)$ in the three directions of space (λ_i: eigenvalue of the matrix of second derivatives of $\rho(r)$). The curvature λ_1 along the bond is always positive since $\rho(r)$ has a minimum there. The curvatures λ_2 and λ_3 perpendicular to the bond axis are negative, corresponding to an increase in $\rho(r)$ towards the bond axis. If the charge concentration perpendicular to the bond axis is predominant ($|\lambda_2| + |\lambda_3| > |\lambda_1|$), a negative value for $\nabla^2\rho(r)$ results, synonymous with a concentration of $\rho(r)$ in the bonding region.

The Laplace fields $\nabla^2\rho(r)$ determined by HF/6-31G* calculations for some selected bonds are shown in Figure 1 in the form of contour line diagrams. The broken lines occur in regions with charge concentrations ($\nabla^2\rho(r) < 0$) which, on the basis of simple chemical concepts, can be assigned to bonding and lone-pair electrons[7]. The concentration of $\rho(r)$ in the bonding region decreases along the series CC, CN, CO, CF and CC, OO, FF, respectively (see Fig. 1 and Table 1), which qualitatively goes hand in hand with a decrease in covalent bond strength[8].

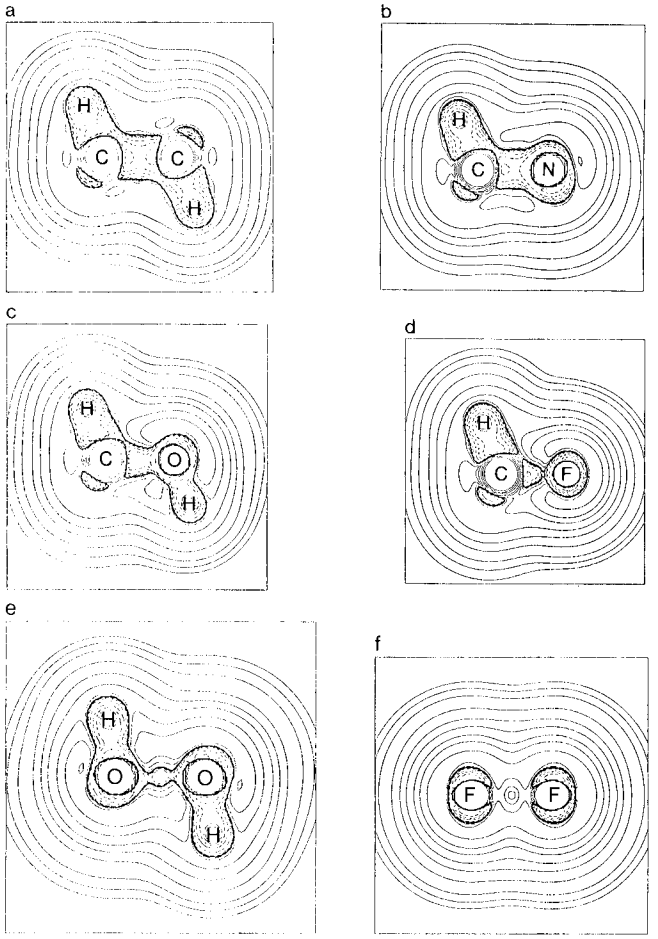

Fig. 1. Contour line diagram of the Laplace field $\nabla^2\rho(r)$ (HF/6-31G* calculations) for a) C_2H_6 (staggered), b) CH_3NH_2 (staggered, HCN *trans*), c) CH_3OH (staggered, HCOH *trans*), d) CH_3F, e) H_2O_2 (trans), and f) F_2. Broken lines indicate regions with charge concentrations. Atoms lying outside the reference plane are not shown.

In contrast to the results of the analysis of $\Delta\rho(r)$[1], the Laplace field of $\rho(r)$ indicates that charge is concentrated in the region of the OO bond. Apparently, the quantity $\nabla^2\rho(r)$ is a more sensitive measure for the description of charge accumulation than $\Delta\rho(r)$. The experimental observation that bonding electron density can be absent for specific covalent bonds is, however, confirmed in the case of the FF bond[9]. Clearly, a characterization of the covalent bond by $\nabla^2\rho(r)$ is insufficient. The chemical bond can only be satisfactorily described if in addition to electrostatic also energetic aspects are considered[10].

Bond formation is associated with a gain in molecular energy, and this gain is a result of a complex interplay of changes in potential and kinetic energy[11]. One possibility to analyze these changes in the bonding region is provided by the relation $2G(r)+V(r)=\frac{1}{2}\nabla^2\rho(r)$, derived by *Bader*, which connects the kinetic energy density $G(r)$ and the potential energy density $V(r)$ with the Laplace field of $\rho(r)$[12]. Pointwise analysis of $G(r)$ and $V(r)$ indicates that for covalent bonds the local energy density $H(r)=G(r)+V(r)$ at sites of maximum concentration of $\rho(r)$ is always negative (stabilizing)[12b, 13]. This also applies to the F–F bond: Although electron density flows out of the internuclear region upon bond formation, the residual density is sufficient to contribute towards bond stabilization via an increase in $|V(r)|$ (Table 1).

Table 1. Characterization of covalent bonds by electron density and energy density [a].

Molecule	Bond	$\rho(r_C)$ [e·Å^{-3}]	$\nabla^2\rho(r_C)$ [e·Å^{-5}]	$G(r_C)$	$V(r_C)$ [Hartree·Å^{-3}]	$H(r_C)$
C_2H_6	C–C	1.880	−24.844	1.032	−3.803	−2.771

CH_3F	C–F	1.769	−10.517	1.199	−3.134	−1.935
H_2O_2	O–O	1.837	−4.753	1.190	−2.713	−1.523
F_2	F–F	2.335	2.908	2.247	−4.292	−2.045

[a] HG/6-31G* calculations with optimized geometries. The point r_C corresponds to the maximum density in the bonding region.

The condition $H(r)<0$ in the bonding region holds for all covalent bonds studied to date (ca. 100)[13]; not, however, for ionic bonds, H bonds, or van der Waals bonds. Thus, specifically those bonds which exhibit either zero or a very small bonding electron density should be investigated with the aid of the local energy density $H(r)$. For this purpose, analysis of the local property $H(r_c)$ is adequate for a qualitative description of bonding, whereas for a quantitative treatment the behavior of $H(r)$ in the whole bonding region must be considered[13].

[5] Difficulties arise, inter alia, in the investigation of ions with delocalized charge, e.g. cations or anions of cyclopolyenes.
[6] The significance of the Laplace field can be understood from the definition of the second derivative. In the one-dimensional case

$$\lim_{\Delta x\to 0}\{\rho(x)-\tfrac{1}{2}[\rho(x-\Delta x)+\rho(x+\Delta x)]\}=$$
$$-\tfrac{1}{2}\lim_{\Delta x\to 0}\{[\rho(x+\Delta x)-\rho(x)]-[\rho(x)-\rho(x-\Delta x)]\}=-\tfrac{1}{2}(\rho/\mathrm{d}x^2)\cdot\mathrm{d}x^2$$

is valid.
If the second derivative, and hence the curvature of ρ, is negative, $\rho(x)$ is larger than the average value of ρ at all neighboring points; P. M. Morse, H. Feshbach: *Methods of Theoretical Physics, Bd. 1*, McGraw-Hill, New York 1953, p. 6.

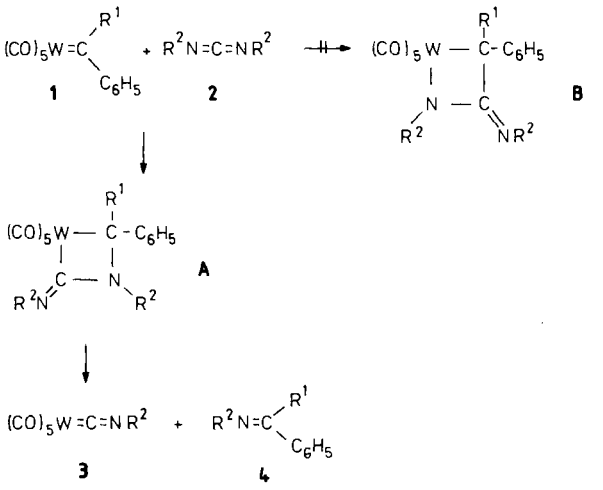
Stoichiometric and Catalytic Metathesis of Carbodiimides and Pentacarbonylcarbenetungsten Complexes**

By *Karin Weiss** and *Petra Kindl*

The carbene complexes pentacarbonyl(diphenylcarbene)tungsten **1a**[1] and pentacarbonyl[methoxy(phenyl)carbene]tungsten **1b**[2] exhibit low activity as metathesis catalysts and so are especially suitable for the investigation of stoichiometric model reactions such as, e.g., metathesis with alkenes or vinyl ethers[2,3]. Stoichiometric or catalytic metathesis reactions have so far been achieved with cyclic or acyclic alkenes, which only in exceptional cases contained substituents bearing heteroatoms. Metathesis reactions of heteroallenes with carbene complexes were hitherto unknown. Isocyanates react as heteroallenes with carbonyl compounds as catalysts to give carbodiimides and CO_2[4], a metathesis which has so far not been recognized as such. On reaction of the model catalysts **1** with the heteroallenes dicyclohexylcarbodiimide **2a** and diisopropylcarbodiimide **2b**, we obtained the metathesis products pentacarbonyl(cyclohexylisocyanide)tungsten **3a** or pentacarbonyl(isopropylisocyanide)tungsten **3b**, as well as the Schiff bases *N*-(diphenylmethylene)cyclohexylamine **4a**, *N*-(diphenylmethylene)isopropylamine **4b** and *N*-(α-methoxybenzylidene)isopropylamine **4c**. The reactions (in pentane at 20 °C) were monitored spectroscopically (IR: ν-N=C=N–). Reaction of complex **1a** was complete after 3 h, whereas **1b** was completely converted only after 24 h[5].

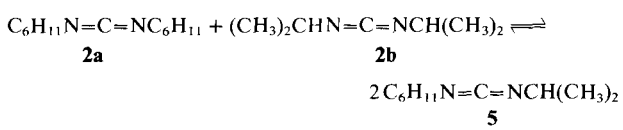


Reaction	R^1 (from **1**)	R^2 (from **2**)	Yield [%] **3**	**4**
1a + **2a** → **3a** + **4a**	Ph	*c*-Hex	98	95
1a + **2b** → **3b** + **4b**	Ph	*i*Pr	88	93
1b + **2b** → **3b** + **4c**	OMe	*i*Pr	79	90

The course of the metathesis can be easily explained in terms of an azatungstacyclobutane intermediate. Similar metallacyclobutane intermediates are postulated for metathesis reactions of alkenes[6]. Two different orientations of the carbodiimides with respect to the W=C(carbene) bond are conceivable (A and B). From the reaction products it follows that there is a clear selectivity for orientation A; a pentacarbonyl(imido)tungsten should be formed from B (cf. [7]).

In metathesis reactions with carbene complexes of the Fischer-type, cyclopropanes are often also formed in a competing reaction by formal [2+1]-cycloaddition of the olefins with the carbene ligands[6]. However, in the reaction of the carbodiimides **2** with the carbene complexes **1** cycloadducts were not observed, only the products resulting from metathesis.

At 20 °C, the carbene complexes **1** are not active as catalysts for the metathesis of symmetrical carbodiimides, e.g. **2a** and **2b**.



Rather, the isocyanide complexes **3** and the Schiff bases **4** are formed stoichiometrically. The carbene complexes **1** and **2** catalyze the metathesis of **2a** and **2b** at temperatures greater than or 140 °C to give "mixed" carbodiimides **5**. That is, the isocyanide complexes **3**, formed in the course of the reaction from **1** and **2**, are thought to be the actual catalysts for the carbodiimide metathesis (2nd generation catalysts). Indeed, under these conditions (i.e. at 140 °C) **3a** and **3b** show the same catalytic activity as the carbene complexes **1**.

Since **1** and **3** catalyze both the forward as well as the reverse reaction, the conversion proceeds only until equilibrium is established, as in the case of the metathesis of acyclic olefins[8,9].

The course of the reaction can be readily explained in terms of an (not detected) azatungstacyclobutane intermediate. With the exception of the formation and decomposition of the intermediates, the partial reactions can also be monitored stepwise. If, e.g., **3b** is allowed to react at 140 °C with excess dicyclohexylcarbodiimide **2a**, then **3a** as well as **3b** can be detected in the reaction mixture by mass spectrometry. Correspondingly, **3a** reacts with excess diisopropylcarbodiimide **2b** to give **3b**. These findings support the postulated reaction course as proceeding via isocyanide complexes, which are newly formed in each reaction step. The metathesis of two symmetrical carbodiimides to give "mixed carbodiimides" such as **5** with pentacarbonyl(isocyanide)tungsten complexes **3** as catalysts provides a facile route to these compounds, which can be used for numerous organic syntheses[10].

This first *catalytic* metathesis of carbodiimides shows that not only alkenes and alkynes undergo metathesis reactions, but that heteroallenes are also capable of doing so in the presence of suitable catalysts.

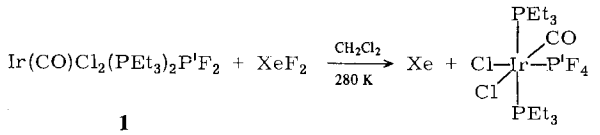
An Iridium(III) Complex Containing a PF_4-Group Bound to the Metal

By *E. A. V. Ebsworth*, John H. Holloway, Nicholas J. Pilkington,* and *David W. H. Rankin*

Compounds containing metal atoms bound to pentacoordinated P, As, or Sb atoms are rare[1-3]. We recently[3] described the complex $Ir(CO)Cl_2(PEt_3)_2(P'Cl_4)$ and characterized it by NMR spectroscopy and elemental analysis; however, the characterization of P' as pentacoordinated was based on the failure of solutions to conduct. By treating **1** with XeF_2, a valuable, mild, fluorinating agent[4], we have now synthesized $Ir(CO)Cl_2(PEt_3)_2(P'F_4)$, whose ^{19}F- and ^{31}P-NMR spectra unequivocally show the presence of the Ir–P'F_4 group.



1 **2**

The reaction is very slow at 220 K but rapid at or above 280 K. The product, which appears to be stable at room temperature in the absence of air or moisture, has been isolated as a white solid and characterized by partial elemental analysis and by NMR spectroscopy. The ^{31}P{^{1}H}-NMR spectrum in CD_2Cl_2 at 300 K consists of a broad quintet of triplets due to the P' nucleus (see Fig. 1a) and a narrow

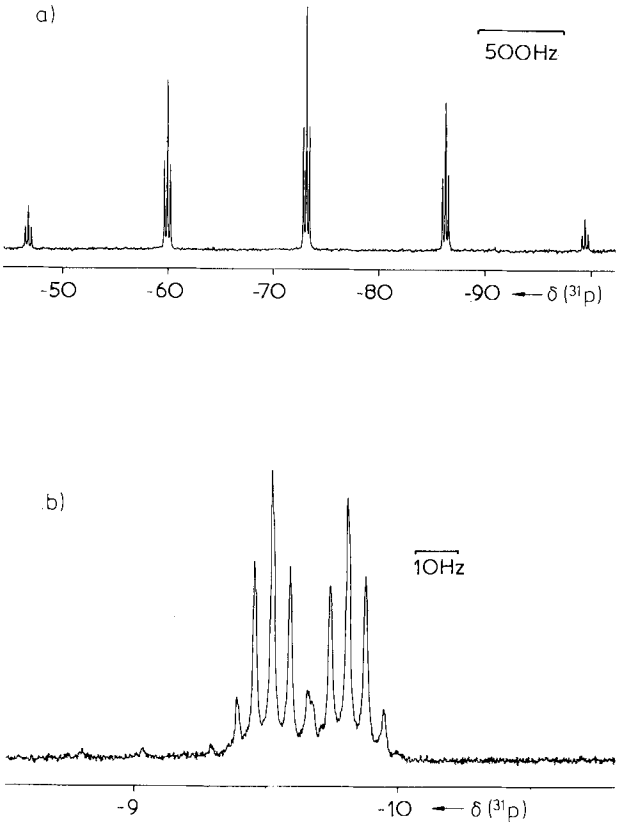


Fig. 1. Part of the 80.1 MHz ^{31}P{^{1}H}-NMR spectrum of **2** at 300 K in CD_2Cl_2; a) is assigned to the P' nucleus and b) to the P nuclei.

doublet of quintets due to the *P* nuclei (see Fig. 1b); the ^{19}F-NMR spectrum at 220 K in the same solvent is a broad doublet of triplets. The ^{31}P{^{19}F}-NMR spectrum is sharp at 220 K, but becomes very broad at 190 K, showing that the molecule is fluxional and that there must be at least two different F sites in the static structure.

Temperature Dependence of the UV Spectrum of 1,5-Dimethyl-2,6-semibullvalenedicarbonitrile; Evidence for an Equilibrium with a Delocalized, Homoaromatic Isomer**

By *Helmut Quast** and *Josef Christ*

In our search for delocalized bishomoaromatic systems of the Dewar-Hoffmann type[1], we have now found, for the first time, experimental evidence for the existence of a semibullvalene of this type; we report here on the surprising temperature dependence of the UV spectrum of the 2,6-semibullvalenedicarbonitrile **1c**[1b,c,2], which suggests an equilibrium with the isomer **2**, and on the thermal isomerization of **1c** to the cyclooctatetraene **5c**.

	R^1	R^2	R^3
1a,4a,5a,7a	H	H	H
1b,4b,5b	CH_3	H	H
1c,5c,7c	CH_3	CN	H
1d	CH_3	CO_2CH_3	CO_2CH_3
1e	H	CN	CN

The 2,6-semibullvalenedicarbonitrile **1c** has the lowest of all previously determined Cope activation barriers ($\Delta G^{\neq}_{115} = 13.0 \pm 0.5$ kJ mol^{-1}[1c]). It forms sublimable crystals which are pale lemon-yellow at room temperature and which completely decolorize reversibly on cooling to 180 K. The UV spectrum of **1c** in solution is temperature dependent in the same way between 180 and 370 K (Table 1, Fig. 1): In butyronitrile at 180 K, the absorption in the near UV of a sample carefully degassed at 10^{-5} torr has virtually disappeared, whereas on warming to 300 K a new band is formed as a markedly pronounced shoulder at 360 nm, which amplifies on further warming to 366 K. If the thermal expansion of the solvent is taken into consideration, two isosbestic points are found at 291 and 241 nm. The changes in the spectrum with temperature are completely reversible. The absorption at 360 nm also occurs in non-degassed solutions and on using other solvents (Table 1), and does not depend on the concentration between 10^{-2} and 10^{-4} M. Since no impurities were detectable by gas chromatography[3] they could be ruled out as the cause of the temperature-dependent occurrence of the long-wavelength band.

Cyclooctatetraenes are generally yellow; we therefore checked the possibility of a thermal isomerization of the 2,6-semibullvalenedicarbonitrile **1c** to a cyclooctatetraene. This isomerization was accomplished by vacuum pyrolysis of the parent compound, the semibullvalene **1a**, and some alkyl-substituted semibullvalenes, e.g. **1b**[4]. **1c** is indeed isomerized in a yield of 98% (capillary GC) in solution, but only at 130°C in a slow irreversible first order reaction (benzene, $k_{403} = 3.0 \times 10^{-5}$ s^{-1}, $t_{1/2} = 6.5$ h); the product is a *colorless* cyclooctatetraene which, according to its NMR spectra, has the structure **5c**[5]. Therefore, the phenomenon cannot be interpreted in terms of this isomerization either.

Table 1. UV data of 10^{-3} M solutions of the semibullvalenedicarbonitrile **1c** and the barbaralanedicarbonitrile **9**.

Cpd.	Solvent	T [K]	λ_{max} (logε) [nm]			λ_{min} (logε) [nm]
1a	Cyclohexane[a]	293	212(3.927)	245(3.809)	360(1.792)(sh)	232(3.751)
	Butyronitrile	293	211(3.922)	246(3.831)	360(1.807)(sh)	232(3.750)
		178[b]		247(3.848)	—	232(3.720)
		297[b]		245(3.831)	360(1.779)(sh)	232(3.753)
		366[b]		243(3.825)	360(2.127)(sh)	232(3.776)
	Acetonitrile	293	211(3.913)	246(3.824)	360(1.797)(sh)	232(3.741)
	Ethanol	293	211(3.920)	245(3.828)	360(1.837)(sh)	232(3.751)
9	Butyronitrile	293	201(4.087)	239(3.926)		222(3.717)

[a] 10 mL Solution contained 0.050 mL acetonitrile. [b] Sample degassed at 10^{-5} torr. The temperature dependence of the volume was taken into account by means of the density of butyronitrile (178, 0.886; 297, 0.7885; 366 K, 0.720 g cm^{-3}).

The reversible temperature-dependent appearance of a new long-wavelength band in the UV spectra of **1c** can best be explained in terms of an unstable, optically readily excitable species in equilibrium. This species occurs in significant amounts only at higher temperatures. Since **1c** does not absorb at 360 nm, the apparent extinction coefficients ε_1 and ε_2 measured at 360 nm and at the temperatures T_1 and T_2 are proportional to the concentrations of the unstable species. The energy difference ΔE between stable and unstable structure can therefore be calculated

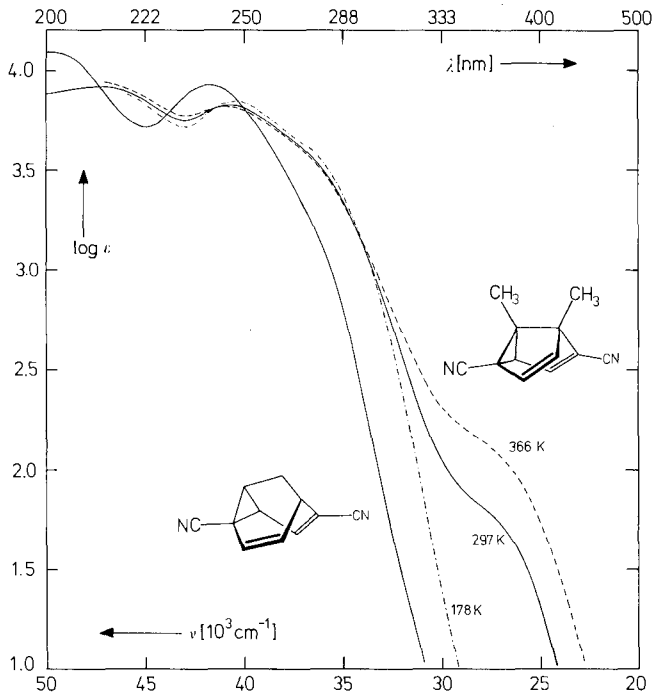

Fig. 1. UV spectra of the 2,6-semibullvalenedicarbonitrile **1c** (at 178, 297 and 366 K) and of the 2,6-barbaralanedicarbonitrile (**9**) (at 293 K) in butyronitrile.

on the basis of the Boltzmann distribution function[6] from the values in Table 1 according to $\varepsilon_1(1+\exp\Delta E/RT_1) = \varepsilon_2(1+\exp\Delta E/RT_2)$. This gives a value of 10.7 kJ mol^{-1}, which is ca. 2 kJ mol^{-1} smaller than the Cope activation barrier determined ^{13}C-NMR spectroscopically at 115 K[1c]. From the energy difference ΔE, equilibrium constants of $K_{178}=0.07\times10^{-2}$, $K_{297}=1.3\times10^{-2}$, and $K_{366}=2.9\times10^{-2}$ are obtained. Accordingly, only ca. 3% of the unstable species is present, even at 366 K. Its extinction coefficient in the near UV ($\varepsilon_{360}=4700$ L mol^{-1} cm^{-1}) corresponds to that of a $\pi^*\leftarrow\pi$ transition.

We propose that the unstable species isomeric to **1c** be assigned the *delocalized, bishomoaromatic* structure **2**. The UV spectroscopically detectable species **2** corresponds to a well-defined molecule in a shallow local minimum on the potential energy hypersurface, and *not* to the transition state of the Cope rearrangement of **1c**. Opening of the central bond C1–C5 of **2** at higher temperature leads to the cyclooctatetraene **5c**. Analogous intermediates **4** have been assumed for the thermal isomerizations **1a**→**5a**, **1b**→**5b**, **5a**→**3**[4], and **7a**→**1a**[7].

Because of the relatively long-wavelength absorption of the unstable semibullvalene isomer **7a** in the near UV[7b], structure **7c** must be considered as the unstable isomer of **1c**. As in **7a**[7c], the orthogonal π-systems of **7c** interact through the bonds of the cyclobutane ring. On the other hand, the tricyclo[3.3.0.0^{2,6}]octadiene structure, which is isomeric to **7c** but has the cyano groups attached to C5 and C6, lacks stabilization by conjugation between cyano groups and double bonds and, therefore, may be ruled out as a plausible alternative for **2**. However, the observation that the isomerization of the unstable isomer fails to produce the more stable[8] semibullvalenes **6** and **8**, besides **1c**, argues against the structure **7c**.

Consistent with the hypothetical existence of long-wavelength absorbing, unstable isomers in the case of semibullvalenes *with particularly low Cope activation barriers*, the crystals of the semibullvalenetetracarboxylate **1d** are brilliant yellow[9], whereas all other semibullvalenes, especially derivatives with electronegative substituents[10] and 2,6-barbaralanedicarbonitrile (**9**), do not absorb in the near UV. From the results obtained with **1c**, an analogous temperature dependence can be predicted for the UV spectrum of **1d**. Furthermore, it is remarkable in this connection that the most recent MNDO-CI calculations for the localized and the delocalized structure of the semibullvalenetetracarbonitrile **1e** indicate an energy barrier between both structures[8].

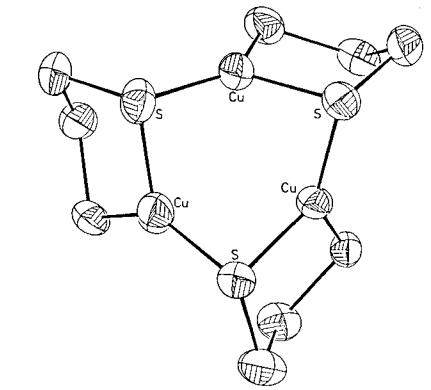
[**] Note added in proof: In the meantime, several compounds containing the $[AgS_9]^-$ ring system could be obtained too, for example, orange $(Ph_3P)_2N[AgS_9]\cdot S_8$ ($P\bar{1}$, $Z=2$, $a=1383.8(4)$, $b=1429.5(4)$, $c=1540.5(5)$ pm, $\alpha=62.38(2)$, $\beta=68.05(2)$, $\gamma=65.86(2)$) having a symmetrical $[AgS_9]^-$ ring (with approximate C_2 symmetry).

ters has already been outlined. In view of the large variety of Cu–S minerals, it had been presumed[4] that numerous polynuclear complexes and clusters exist in the $Cu^{n\oplus}/S_x^{2\ominus}$ system. We have so far synthesized salts of the anions $[Cu_3(S_6)_3]^{3\ominus}$[4], $[Cu_4(S_5)_3]^{2\ominus}$[2], $[Cu_4(S_5)_2(S_4)]^{2\ominus}$, $[Cu_4(S_5)(S_4)_2]^{2\ominus}$[2,3a], $[Cu_4(S_4)_3]^{2\ominus}$[5], and $[Cu_6(S_5)(S_4)_3]^{2\ominus}$[6]. Herein we report the synthesis and characterization of the polynuclear complex ions $[Cu_3(S_4)_3]^{3\ominus}$ **1** (Fig. 1, above) and $[(S_6)Cu(S_8)Cu(S_6)]^{4\ominus}$ **2** (Fig. 1, below).



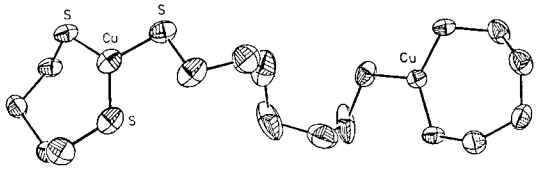


Fig. 1. Above: Structure of **1**. Bond lengths S–S 201.7(9)–212.4(8), Cu–S (in the Cu_3S_3 ring) 219.5(5)–229.8(6), Cu–S (outside of the Cu_3S_3 ring) 222.5(6)–224.1(6), Cu–Cu 295.0(3)–318.5(3) pm; bond angles (selected): S–Cu–S (CuS_4 ring) 105.5(2)–106.2(2), S–Cu–S (Cu_3S_3 ring) 116.3(2)–119.0(2), Cu–S–Cu 81.8(2)–90.6(2), Cu–S–S (in the CuS_4 ring) 98.9(3)–100.7(3), S–S–S 104.5(3)–105.6(4)°.—Below: Structure of **2**. Bond lengths: S–S (ring): 200.7(9)–208.9(9), S–S (chain) 197.0(12)–211.8(12), Cu–S 220.8(7)–226.1(6) pm; Bond angles (selected): S–Cu–S (ring) 130.9(3) and 128.1(2), S (ring)–Cu–S (chain) 112.9(3)–118.8(3), S–S–S (ring) 107.0(4)–111.9(4), S–S–S (chain) 103.9(5)–109.6(4)° [8].

The diamagnetic salts $[(C_6H_5)_4P]_2[NH_4][Cu_3(S_4)_3]\cdot 2CH_3OH$ **1a** (orange) (which can crystallize under slightly varying conditions, e.g. in the case of different H_2S flow rates, without solvent molecules (**1b**); for crystal data of **1b** see [7]) and $[(C_6H_5)_4P]_4[(S_6)Cu(S_8)Cu(S_6)]$ **2a** (reddish brown)[7] have been characterized by X-ray structure analysis and UV/VIS, IR, and Raman spectroscopy[9, 10]. **1** consists of three CuS_4 five-membered rings with half-chair conformation and a central Cu_3S_3 six-membered ring with alternating short and long Cu–S bond lengths and chair conformation (Fig. 1, above). In MS_4 ring systems one finds both the aforementioned half-chair conformation as well as the envelope conformation. The anionic complex has almost C_3 symmetry.

2 consists of two CuS_6 seven-membered rings with different conformations (having approximately C_2 and C_s symmetry, respectively) which are linked via an $S_8^{2\ominus}$ ligand. The Cu atoms are trigonal-planar coordinated. So far, neither a complex with an $S_8^{2\ominus}$ ligand nor a salt with an isolated $S_8^{2\ominus}$ ion has been reported in the literature[1]. A longer $S_x^{2\ominus}$ ligand has hitherto only been found in the anion $[AuS_9]^{\ominus}$[11].

The above-mentioned, previously synthesized trinuclear and tetranuclear clusters (the short Cu–Cu distances point to metal-metal interactions and justify the term cluster) with $S_4^{2\ominus}$ and $S_5^{2\ominus}$ ligands are orange or deep orange ($\lambda_{max} < 400$ nm), whereas **2a** is reddish-brown; this color can be ascribed to an internal ligand transition in the $S_8^{2\ominus}$ chain (shoulder at ca. 470 cm[9]).

[5] The deep orange compound $[(C_6H_5)_4P]_2[Cu_4(S_4)_3]\cdot CH_3CN$ is formed in pure form on passing H_2S (0.5 min) into NH_3-saturated acetonitrile (100 mL) and treatment of this solution with a solution of 1 g $Cu(CH_3COO)_2\cdot H_2O$ in CH_3CN (50 mL) in the presence of oxygen and a trace of sulfur.

[6] A. Müller, M. Römer, H. Bögge, E. Krickemeyer, D. Bergmann, *J. Chem. Soc. Chem. Commun. 1984*, 348; G. Henkel, P. Betz, B. Krebs, *ibid. 1984*, 314.

[7] *Procedure:* **1a**: NH_3 was passed into a suspension of 1.0 g $Cu(CH_3COO)_2\cdot H_2O$ in 30 mL CH_3OH for 10 min (formation of a blue solution). After addition of 0.5 g sulfur and 0.5 g $[(C_6H_5)_4P]Br$, H_2S was passed into the reaction solution for 0.5 min (flow rate 6 L/h (precipitated copper sulfide was filtered off). The orange crystals of **1a** which precipitated from the filtrate after 2 d (closed vessel; 5°C) were washed with methanol and toluene and dried in air. Yield: 0.3 g.—**2a**: NH_3 was passed into 200 mL CH_3CN (analytically pure; dried) for 20 min. After addition of 5.0 g $[(C_6H_5)_4P]Br$ and 2.0 g sulfur, H_2S was passed for 2 min (6 L/h) into the vigorously stirred mixture (color change from blue through green to brown). The vigorously stirred reaction mixture was treated with a mixture of 2.0 g $Cu(CH_3COO)_2\cdot H_2O$, 4.0 g $[(C_2H_5)_4N]I$, and 50 mL (analytically pure) CH_3CN (which was stirred for 20 min), restirred for 0.5 min, and filtered. After 1-3 d (closed vessel; Ar atmosphere; 20-25°C) reddish brown **2a** and sulfur precipitated from the brown filtrate; the precipitate was filtered off and washed several times with toluene (alternatively with water, isopropanol and toluene). Yield: 1.8 g.
Under the experimental conditions quoted in [5], but after addition of 0.8 g sulfur, $[(C_6H_5)_4P]_2[NH_4][Cu_3(S_4)_3]$ **1b** precipitated out after 1d; crystallographic data: $P\bar{1}$, $Z=2$; $a=1266.0(5)$, $b=1489.6(6)$, $c=1493.6(6)$ pm, $\alpha=74.72(3)$, $\beta=86.40(3)$, $\gamma=77.52(3)°$, $V=2652.9\times10^6$ pm^3. After 4 d **2a** crystallized from the filtrate.

[8] X-ray structural analyses: **1a**: $P2_1/c$, $a=2317.4(7)$, $b=1458.4(4)$, $c=1843.1(5)$ pm, $\beta=108.68(2)°$, $V=5901.0\cdot10^6$ pm^3, $Z=4$; $R=0.101$ for 3817 independent reflections ($F_0>3.92\sigma(F_0)$).—**2a**: $P\bar{1}$, $a=1058.7(8)$, $b=1342.3(10)$, $c=3733.9(28)$ pm, $\alpha=92.38(6)$, $\beta=97.72(6)$, $\gamma=110.06(6)°$, $V=4917.5\cdot10^6$ pm^3, $Z=2$; $R=0.104$ for 4835 independent reflections ($F_0>3.92\sigma(F_0)$). Both measurements were carried out with a Syntex $P2_1$ diffractometer and $Mo_{K\alpha}$ radiation. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50869, the names of the authors, and the journal citation.

[9] Characteristic IR, Raman, and UV/VIS bands of **1a** (of **2a** in brackets): IR (CsI): weak bands of the ν(S–S) vibrations at 468, 455 and 437 cm^{-1} (484 and 456 cm^{-1}); *Raman* (solid state, $\lambda_e=647.1$ nm): ν(S–S) = 469, 435, 425 cm^{-1}; further bands at 287, 252, 198, 148 cm^{-1} (ν(S–S) 485, 452, 406 cm^{-1}; further bands at 287, 258, 223, 204 cm^{-1}); ν(S–S) bands, all strong (except that at 485 cm^{-1} (m)), the others with weak to moderate intensity; UV/VIS (reflection; cellulose as standard): $\lambda=325$ nm (340, ca. 470 nm (sh)).

[10] $[Cu_3(S_4)_3]^{3\ominus}$ was detected alongside $[Cu_4(S_4)_3]^{\ominus}$ in a matrix of $[(C_6H_5)_4P]_2[Cu_4(S_4)_3]$: G. Henkel, P. Betz, B. Krebs, Chemiedozententagung, Konstanz 1984; cited in P. Betz, B. Krebs, G. Henkel, *Angew. Chem. 96* (1984) 293; *Angew. Chem. Int. Ed. Engl. 23* (1984) 311.

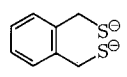
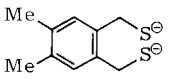
Thiolate Chemistry of the Iron Group Elements: Synthesis and Structure of the Complexes $[Co_2\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2\ominus}$ and $[Ni_3\{o\text{-}(SCH_2)_2C_6H_4\}_4]^{2\ominus}$**

By *Wolfgang Tremel, Bernt Krebs,* and *Gerald Henkel**

The trinuclear clusters **1**—**4**[1,2] as well as the thiolate ions **5** and **7**[2,3], i.e. both metal thiolate sulfides and pure metal thiolates, could be isolated from the reaction system $MCl_2/X/Y$ [M = Fe, Co, Ni; X = *o*-xylene-α,α′-dithiolate (S_2-*o*-$xyl^{2\ominus}$), durene-α,α′-dithiolate (S_2-$dur^{2\ominus}$); Y = $S^{2\ominus}$, S, $SPh^{\ominus}$, S_2-*o*-$xyl^{2\ominus}$, 1,1-dithiolate]. Complexes containing both thiolate and $S_n^{2\ominus}$-ligands ($n \geq 2$) were hitherto unknown[15].



S_2-*o*-$xyl^{2\ominus}$



S_2-$dur^{2\ominus}$

$[Fe_3S(S_2\text{-}dur)_3]^{2\ominus}$ **1**
$[M_3S(S_2\text{-}o\text{-}xyl)_3]^{2\ominus}$ **2**, M = Fe; **3**, M = Co; **4**, M = Ni
$[M_2(S_2\text{-}o\text{-}xyl)_2(SPh)_2]^{2\ominus}$ **5**, M = Fe; **6**, M = Mn
$[M_2(S_2\text{-}o\text{-}xyl)_3]^{2\ominus}$ **7**, M = Fe; **8**, M = Mn
$[M_2(S_2\text{-}o\text{-}xyl)_2(R_2dtc)_2]^{2\ominus}$ **9**, M = Fe; **10**, M = Mn

The Fe_3S_4 skeleton of **1** and **2** is, together with the analogous fragment of the mixed valent cluster $[Fe_6S_9(SR)_2]^{4\ominus}$[4], of interest as a structural model of the centers in [3 Fe-4S]-proteins[5]. The studies were extended to manganese, the first result being the synthesis of the manganese complexes **6** and **8**, the analogues of **5** and **7**, respectively[6]. The thiophenolate species **5** and **6** can be derivatized to give the anions **9** and **10**, respectively ($R_2dtc^{\ominus}$ = dialkyldithiocarbamate)[7], in which the monodentate $PhS^{\ominus}$ group is replaced by a bidentate $R_2dtc^{\ominus}$ group. We were also able to isolate the novel thiolate ions $[Co_2(S_2\text{-}o\text{-}xyl)_3]^{2\ominus}$ **11** and $[Ni_3(S_2\text{-}o\text{-}xyl)_4]^{2\ominus}$ **13**.

$[Co_2(S_2\text{-}o\text{-}xyl)_3]^{2\ominus}$ **11**
$[Me_4N]_2[Co_2(S_2\text{-}o\text{-}xyl)_3]\cdot 5\,MeOH$ **12**

The binuclear anion **11**, which is isostructural with **7** (Fig. 1), is formed on reaction of $CoCl_2$ with S_2-*o*-$xyl^{2\ominus}$ (in the ratio 2:3) in methanol and precipitates as the crystalline salt **12** on addition of Me_4NCl[8,9]. The Co_2S_6 center of **11**, as a section of the M_3S_7 center of **1**, **2** or **3**, consists of edge-sharing MS_4 tetrahedra, one of the three S_2-*o*-$xyl^{2\ominus}$ groups not functioning as a chelate ligand but spanning the Co_2S_4 fragment in a handle-like fashion. The S atoms of this group thus occupy opposite terminal coordination sites of the Co_2S_6 center. The rigid 1,4-dithiolate ligand cannot bridge a planar $Co_2(\mu\text{-}S)_2$ moiety. The S5...S6 distance within this ligand (4.264(3) Å) leads to a folding of the moiety along the S2...S4 vector and, thus, to a concomitant lengthening of the distance between the corresponding terminal atoms S1 and S3 (6.629(3) Å). The folding of the $M_2(\mu\text{-}S)_2$ moiety in **7** and **11** leads to a significant shortening of the metal-metal distance by ca. 0.1 Å

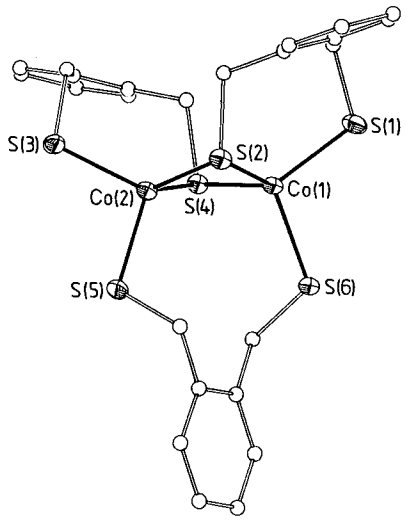


Fig. 1. Structure of the anion **11** in the crystal of **12** with thermal ellipsoids of the Co and S atoms (50% probability, without H atoms, −130°C). Important bond lengths [Å]: Co1...Co2 2.786(1), S1...S3 6.629(3), S5...S6 4.264(3), Co1-S1 2.271(2), Co1-S2 2.294(2), Co1-S4 2.290(2), Co1-S6 2.308(2), Co2-S3 2.261(2), Co2-S2 2.310(2), Co2-S4 2.299(2), Co2-S5 2.306(2); range of angles [°]: S-Co-S 99.77(8) to 122.20(8); Co-S-Co 74.47(7) and 74.74(7).

with respect to comparable complexes with a planar $M_2(\mu\text{-}S)_2$ structure[2,10]. The mean M-S and M-M distances of 2.292 and 2.786 Å in **11** are about 0.04 and 0.09 Å shorter than in the analogous Fe complex **7**, which corresponds to the sums of the ionic radii (Co^{II} 0.72, Fe^{II} 0.77 Å[11]). In principle, three isomers are possible in the case of complexes with non-planar $M(\mu\text{-}SR)_2M$ moieties. Due to the restrictive geometry of the S_2-*o*-$xyl^{2\ominus}$ ligands, **7** and **11** belong to the rare *syn-exo*-type complexes[12].

$[Ni_3(S_2\text{-}o\text{-}xyl)_4]^{2\ominus}$ **13**
$[Et_4N]_2[Ni_3(S_2\text{-}o\text{-}xyl)_4]\cdot 2\,MeOH$ **14**

Reaction of $NiCl_2$ with S_2-*o*-$xyl^{2\ominus}$ in the ratio 1:2 to 1:4 in methanol leads to formation of the trinuclear cluster ion

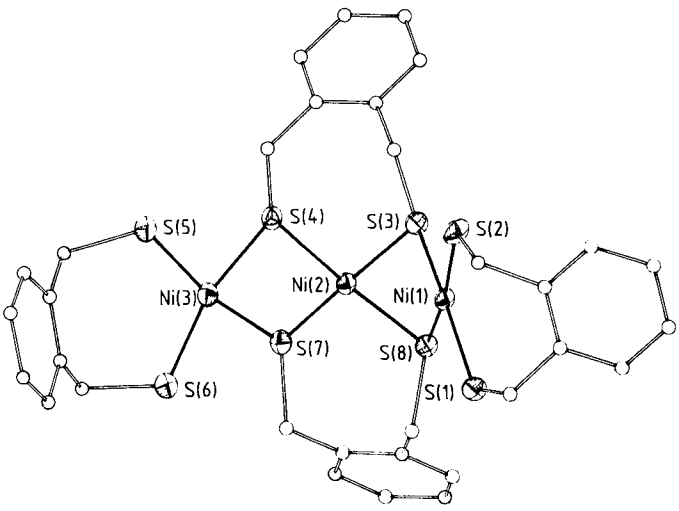

Fig. 2. Structure of the anion **13** in the crystal of **14** with thermal ellipsoids of the Ni and S atoms (50% probability, without H atoms, −130°C: Important bond lengths [Å]: Ni1...Ni2 3.131(1), Ni2...Ni3 3.016(1), S3...S8 2.687(2), S4...S7 2.735(2), Ni1-S1 2.185(2), Ni1-S2 2.177(2), Ni1-S3 2.228(2), Ni1-S8 2.226(2), Ni2-S3 2.206(2), Ni2-S4 2.193(2), Ni2-S7 2.208(2), Ni2-S8 2.192(2), Ni3-S5 2.185(2), Ni3-S6 2.193(2), Ni3-S4 2.219(2), Ni3-S7 2.229(2); range of angles [°]: Ni1...Ni2...Ni3 131.34(4), S-Ni-S(*cis*) 74.22(7) to 105.19(8), S-Ni-S(*trans*) 164.01(8) to 173.34(8), Ni-S-Ni 85.66(7) to 90.26(7).

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.

13 (Fig. 2), which crystallizes as the salt **14**[8,9]. The metal-sulfur skeleton of **14** resembles the corresponding moiety of the cyclic complex $[Ni(SEt)_2]_6$[13]. The three Ni atoms in **13** are arranged at an angle of 131.34(4)°, with four of the eight S atoms lying above and the other four lying below the plane of the metal atoms. The coordination of each Ni atom is approximately square-planar. In the center of the cluster, Ni2 is surrounded by the S atoms of two chelate ligands at a distance of 2.200 Å (mean value), which, as μ_2-substituents, form bridges (mean Ni-S 2.226 Å) to the terminal Ni atoms. The coordination of these metal centers is completed by the S atoms of terminally bonded chelate ligands (mean Ni-S 2.185 Å). Like **11**, **13** is also folded along the S...S vectors of the $M_2(\mu\text{-}S)_2$ moieties, whereby the distances S4...S7 (2.735(2) Å) and S3...S8 (2.687(2) Å) are strikingly short. Interactions due to oxidative S...S coupling and involving partial metal reduction could be in effect here[12]. The Ni-Ni distances lie outside of the range for direct metal-metal interactions. The Ni-S-Ni valence angles are about as large as in the cyclic compound $[Ni(SEt)_2]_6$[13].

Thus, it emerges that there are pronounced structural analogies in polynuclear thiolate- and thiolate-sulfide complexes of the electron-rich bivalent transition metals.

[8] Experimental (all operations carried out under N_2 in degassed solvents): **12**: A solution of $CoCl_2 \cdot 6H_2O$ (4.76 g, 20 mmol) in methanol (50 mL) was treated dropwise with a solution of sodium (1.38 g, 60 mmol) and *o*-xylenedithiol (5.10 g, 30 mmol) in methanol (60 mL). The mixture was stirred overnight, evaporated at room temperature in vacuo to ca. 70% of its original volume, treated with 2.20 g (20 mmol) solid Me_4NCl, and cooled to −30°C. After a few days, greenish-brown crystals of **12** precipitated (yield 4.6 g, 55%).—**14**: A suspension of $NiCl_2$ (3.91 g, 30 mmol) in methanol (50 mL) was treated with a solution of sodium (1.38 g, 60 mmol) and *o*-xylenedithiol (5.1 g, 30 mmol) in methanol (60 mL). When the initial precipitate was treated with a solution of sodium (0.69 g, 30 mmol) and thiophenol (3.1 mL, 30 mmol) in methanol a blackish-brown solution was obtained, from which, on addition of 4.97 g (30 mmol) Et_4NCl, black crystals of **14** separated in the course of a few days. **14** was recrystallized from dimethylformamide/MeOH, yield: 2.7 g (37%); $\lambda(\varepsilon)$ [nm]: 356 (14900), 423 (8000).

[9] Crystal structure analysis: **12**: $P2_1/n$, $a = 13.651(3)$, $b = 15.629(3)$, $c = 22.552(5)$ Å, $\beta = 105.18(2)°$, $Z = 4$, $\rho_{calc} = 1.332$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 10.4$ cm^{-1}, 7322 reflections, 4921 observed ($F_o > 3.92\sigma(F_o)$; isotypic with $[Me_4N]_2[Fe_2(S_2\text{-}o\text{-}xyl)_3] \cdot 5\,MeOH$ [2]; 453 variables; $R(R_w) = 0.066$ (0.064).—**14**: $P\bar{1}$, $a = 13.131(3)$, $b = 15.148(4)$, $c = 16.694(4)$ Å, $\alpha = 110.26(3)$, $\beta = 99.41(3)$, $\gamma = 110.25(3)°$. $Z = 2$, $\rho_{calc} = 1.409$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 13.4$ cm^{-1}, 8497 reflections, 6777 observed (vide supra), 586 variables, $R(R_w) = 0.058$ (0.059). Syntex $P2_1$ four-circle diffractometer; graphite monochromator, scintillation counter, 2θ-scan, $2\theta_{max} = 48°$; −130°C; empirical absorption corrections, refinement of the non-H atoms (with exception of disordered solvent molecules) with anisotropic temperature factors (block diagonal matrix least squares); H atoms calculated or from difference Fourier syntheses, all H atom coordinates fixed ($B = 5.0$ Å^2); further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50963, the names of the authors, and the journal citation.

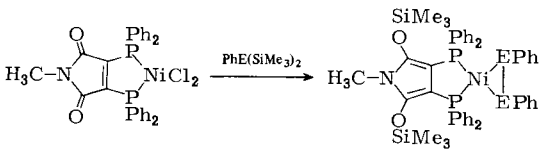
[14] Lane et al. describe a complex $[Et_4N]_2[Ni_2(S_2\text{-}o\text{-}xyl)_3]$ [3] which was obtained in a similar way.—However, it differs from **13** in its spectroscopic properties.

[15] *Note added in proof (July 13, 1984):* Following the synthesis of the X-ray crystallographically characterized complex salt $(PPh_4)_2[Ni_4(S)_2(SCH_2CH_2S)_4] \cdot MeOH$, we have in the meantime succeeded in gaining access to the first mixed thiolate-disulfide complex anion.

The Reaction of [2,3-bis(diphenylphosphino)-*N*-methylmaleimide]nickel(II) Chloride with $PhE(SiMe_3)_2$ (E = P, As)**

By *Dieter Fenske** and *Kurt Merzweiler*

Phosphane complexes of $NiCl_2$ react with silylated phosphanes in various ways. For example, diphosphene complexes are obtained in the reaction of $(R_3P)_2NiCl_2$ ($R = C_2H_5$) and $LiP(SiMe_3)_2$[1]. In contrast, the reaction of $NiCl_2$ and PPh_3 with $PhP(SiMe_3)_2$ leads to $Ni_8X_4(PPh_3)_4(\mu_4\text{-}PPh)_6$ ($X = Cl^{\ominus}$, CO)[2]. To prepare clusters of this type with bidentate phosphane ligands, we allowed the $NiCl_2$ complex **1**[3] of 2,3-bis(diphenylphosphino)-*N*-methylmaleimide to react with $PhP(SiMe_3)_2$. In this way, the yellow diphosphene complex **2** is formed in 60% yield[4]. Under analogous conditions, reaction of **1** and $PhAs(SiMe_3)_2$ affords a compound isostructural to **2** with a PhAs=AsPh ligand[4].



1 **2**, E = P; **3**, E = As

According to ^{31}P-NMR spectroscopic studies, the silylphosphane reacts initially with the maleimide ligand. The diphosphene moiety at the nickel is presumably formed subsequently via a complex with two terminal $PhP(SiMe_3)$ groups, by analogy to reactions of $(R_2PCH_2CH_2PR_2)NiCl_2$ with $LiP(SiMe_3)_2$ and $R'P(SiMe_3)_2$[5] (R = Et, *cyclo*-C_6H_{11}; R' = Me, Ph, *t*Bu).

In the IR spectra of **2** and **3**, ν(C=C) bands are observed at 1542 and 1522, and 1534, 1555, and 1572 cm^{-1}, respectively. In the ^{31}P-NMR spectrum of **2**, the P atoms of the PPh_2 and PPh ligands exhibit a triplet ($J_{PP} = 30$ Hz) at $\delta = +36.5$ and -4.9, respectively[6].

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Institut für Kristallographie (crystallographic data). We thank Prof. Dr. *H. Schäfer* (Karlsruhe) for assistance in the discussion of the ^{31}P-NMR spectra.

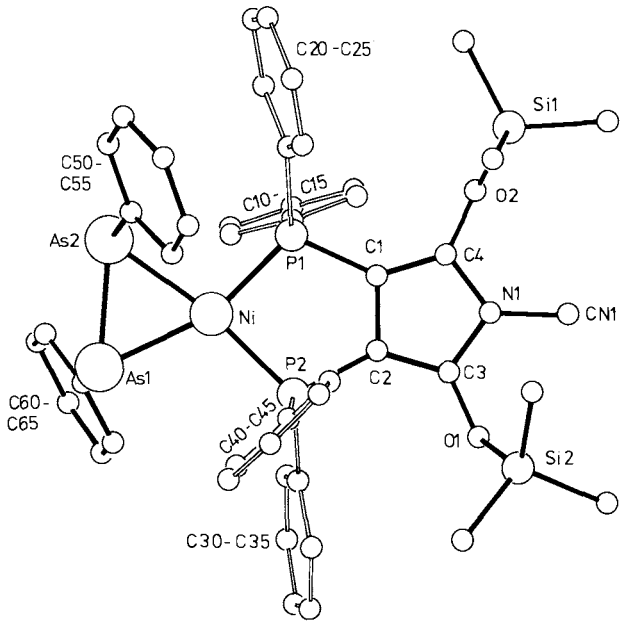

Fig. 1. Molecular structure of **3** [8] in the crystal [13]. Important bond lengths [pm]: Ni-P 214–215.0(2), Ni-As1 236.0(1), Ni-As2 236.4(1), As1-As2 237.2(1), C1-C2 145.9(9), C2-C3 137.1(9), C-O 134.5(8), C-N 139.6(8), C1-C4 135.5(8), Si-O 169.0(2), Si-C 185.0(1), As1-C60 199.0(8), As2-C50 197.0(7); important bond angles [°]: P1-Ni-P2 92.9(1), As2-Ni-P1 100.5(1), As1-Ni-P2: 106.7(1), As1-Ni-P1 160.4(1), As2-Ni-P2 160.0(1), As2-Ni-As1 59.9(1), Ni-As1-As2 59.9(1), As2-As1-Ni 59.8(1), C60-As1-Ni 90.9(2), C50-As2-Ni 95.0(1), As2-As1-C60 93.4(2), As1-As2-C50 101.0(2). Important bond lengths [pm] and bond angles [°] for the analogous structure of **2** [7]: Ni-P1 215.4(1), Ni-P2 215.7(1), Ni-P3 225.7(1), Ni-P4 225.3(1), P3-P4 214.0(1), the remaining bond lengths correspond to those of **3**, within the standard deviation. P1-Ni-P2 92.9(1), P4-Ni-P1 159.0(1), P2-Ni-P4 106.8(1), P1-Ni-P3 105.0(1), P2-Ni-P3: 160.9(1), P3-Ni-P4 56.7(1), Ni-P3-P4 61.6(1), Ni-P4-P3 61.8(1), Ni-P3-C50 94.6(1), Ni-P4-C60 99.5(1), P4-P3-C50 100.7(1), P3-P4-C60 101.3(1) (P3 ≙ As2; P4 ≙ As1).

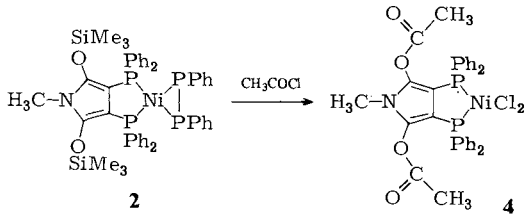
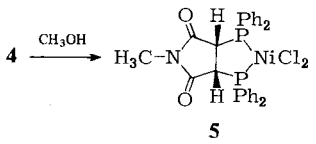
The crystal structure analysis indicated that **2**[7] and **3** (Fig. 1)[8] have practically the same molecular structure. In the diarsene complex **3**, the Ni is approximately planar-coordinated by the As atoms of the PhAs=AsPh ligand and by the P atoms of the PPh_2 groups. With 214.0(1) and 237.2(3) pm, respectively, the P–P and As–As distances in the PhE=EPh ligands of **2** and **3** are markedly shorter than an E–E single bond and correspond to the values found in other complexes with side-on coordinated PhE=EPh[9].

The PhE=EPh ligand in **2** and **3** has a *trans*-configuration, and the atoms C50-P3-P4-C60 and C50-As2-As1-C60 are almost coplanar. The dihedral angles C50-P3-P4-C60 and C50-As2-As1-C60 are 175.7° and 178.3°, respectively. If it is assumed that Ni^0 is involved, together with the two PPh_2 and the PhE=EPh ligands Ni has a total of 16 valence electrons. As a consequence of the $SiMe_3$-transfer to the CO group of the *N*-methylmaleimide, a PPh_2-substituted derivative of 2,5-bis(trimethylsiloxy)-*N*-methylpyrrole is formed. This can be seen clearly from the bond lengths in the planar five-membered ring. Reaction of **2** and CH_3COCl leads to formation of the red acyl derivative **4**; simultaneously, the diphosphane ligand is displaced and the Ni^0 oxidized to $Ni^{2\oplus}$.

The IR spectrum of **4** exhibits a ν(CO) band at 1782 cm^{-1} and a band for ν(C=C) at 1542 cm^{-1}. On the basis of the crystal structure analysis, Ni is coordinated in a distorted square-planar manner by two P atoms and two $Cl^{\ominus}$[10]. The Cl ligands lie respectively 48 pm above and below the plane formed by the Ni and P atoms. As in **2** and **3**, the pyrrole ring is planar.





With CH_3OH, **4** undergoes hydrolysis and rearrangement to yield **5**. Presumably **5** is formed via an unstable derivative of 2,5-dihydroxypyrrole which isomerizes via keto-enol tautomerism. This observation corresponds to the fact that hydroxypyrrole can also readily rearrange to the keto form[11]. As shown by the crystal structure analysis, the H-shift gives rise to the *cis*-isomer **5**[12]. Ni is planar coordinated by the two P atoms and two $Cl^{\ominus}$ ligands; one P atom lies 88 and the other 188 pm above the mean plane of the succinimide ring. **5** can also be formed from **2** by recrystallization from a mixture of $1,2\text{-}C_2H_4Cl_2$ and CH_3OH.

Transallenation of 1,3-Bis(dialkylamino)-1,3-diethoxyallenes with Disubstituted Malonyl Chlorides**

By *Rolf W. Saalfrank**, *Walter Rost*, *Franz Schütz*, and *Ulrike Röss*

Tetraethoxyallene **1a**—synthetic equivalent of the dianion of diethyl malonate—reacts with phosgene to afford bis(ethoxycarbonyl)ketene and with succinyl chloride and its higher homologues to give lactones[1]. However, an attempt to convert malonyl chloride into diethyl (4-oxo-2-oxetanylidene)malonate was unsuccessful due to the acidity of the methylene protons of malonyl chloride.

We have now allowed **1a**[2] to react with oxalyl chloride **2** and with the dialkylmalonyl chlorides **6a—c**, thereby obtaining 3-chloro-4-(ethoxycarbonyl)maleic anhydride **3** (yield 60%; m.p. = 76 °C) and the diethyl (3,3-dialkyl-4-oxo-2-oxetanylidene)malonates **8a—c** (yields 88, 68, 73%; m.p. = 43 °C, b.p. = 88 °C/0.05 torr, m.p. = 43 °C).

The constitution of the novel anhydride **3** is based on its spectroscopic data and on its Diels-Alder reaction with 2,3-dimethyl-1,3-butadiene **4** to afford 1-chloro-2-(ethoxycarbonyl)-4,5-dimethyl-4-cyclohexene-1,2-dicarboxylic acid anhydride **5** (yield 86%, m.p. = 54 °C).

The oxetanones **8** are "mixed ketene dimers", only a few examples of which are known[5].

The spectra of **8a—c** are as expected. In contrast, the ^{1}H- and ^{13}C-NMR spectra of the oxetanones **8d—g** (yields 61, 51, 52, 64%; m.p. = 83, 92, 80, 89 °C), obtained from 1,3-bis(dialkylamino)-1,3-diethoxyallenes **1b**, **c**[6], and dialkylmalonyl chlorides **6a**, **c** are temperature dependent. Apparently, the C_s symmetry in **8d—g** is perturbed by the steric interactions between the substituents R^2/R^3 and the neighboring dialkylcarbamoyl group.

[**] 1,3-Donor/Donor-Substituted Allenes in Synthesis, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 1: [1].

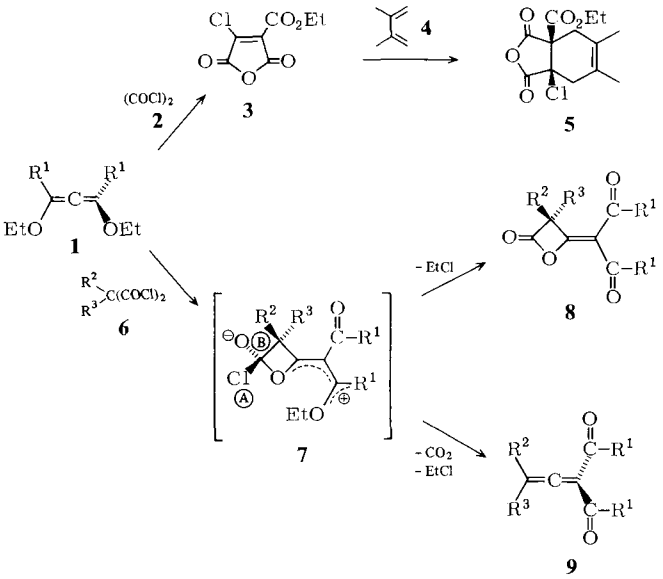
Allene **1b** does not form oxetanones with the malonyl chlorides **6b**, **d**; rather, allenes **9a**, **b** result (yields 52, 61%; m.p. = 75 °C/0.05 torr, m.p. = 177 °C) (Table 1).

Table 1. Spectroscopic data for the allenes **9**.

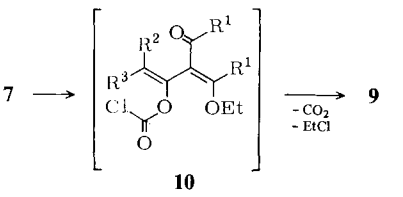
9a, IR (film): 1950 (=C=), 1635 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): $\delta=1.13$ (t, 6H, CH_3), 2.17 (q, 4H, CH_2), 3.17 (s, 12H, NCH_3); ^{13}C-NMR ($CDCl_3$): $\delta=12.38$ (CH_3), 25.30 (CH_2), 35.37 and 38.86 (NCH_3), 100.47 and 113.42 (=C), 165.36 (C=O), 198.90 (=C=)

9b, IR (KBr): 1950 (=C=), 1635 cm^{-1} (C=O); ^{1}H-NMR (C_6D_6): $\delta=2.63$ (s, 6H, CH_3), 2.73 (s, 6H, CH_3), 7.13 (mc, 6 arom. H); 7.50 (mc, 4 arom. H); ^{13}C-NMR ($CDCl_3$): $\delta=35.43$ and 38.95 (CH_3), 100.35 and 114.79 (=C), 128.38, 128.74 and 133.84 (arom. C), 164.30 (C=O), 202.21 (=C=)

9c, IR (KBr): 1970 (=C=), 1630 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): $\delta=1.12$ (t, 12H, CH_3), 1.75 (s, 6H, CH_3), 3.36 (q, 8H, CH_2); ^{13}C-NMR ($CDCl_3$): $\delta=12.68$, 14.01 and 17.78 (CH_3), 39.74 and 43.26 (CH_2), 96.65 and 100.04 (=C), 164.90 (C=O), 196.82 (=C=)



In the reaction of allene **1c** with dimethylmalonyl chloride **6a**, allene **9c** is obtained (yield 21%; m.p. = 68 °C) (Table 1), in addition to **8f**. Since **8f** does not decarboxylate to **9c** under the reaction conditions[9], the betaines **7**[10] can be considered to be the common precursors of **8** and **9**.



Reaction	R^1 (from **1**)	R^2	R^3 (from **6**)
1a + **6a** → **8a**	OEt	Me	Me
1a + **6b** → **8b**	OEt	Et	Et
1a + **6c** → **8c**	OEt	$-(CH_2)_3-$	
1b + **6a** → **8d**	NMe_2	Me	Me
1b + **6c** → **8e**	NMe_2	$-(CH_2)_3-$	
1c + **6a** → **8f** + **9c**	NEt_2	Me	Me
1c + **6c** → **8g**	NEt_2	$-(CH_2)_3-$	
1b + **6b** → **9a**	NMe_2	Et	Et
1b + **6d** → **9b**	NMe_2	Ph	Ph

Depending on the steric interaction between R^1 and R^2/R^3, **7** decomposes to afford **8** (route Ⓐ: cleavage of a C–Cl bond) or the butadienes **10** (route Ⓑ: cleavage of a C–C bond). Spontaneous elimination of CO_2 and ethyl chloride from **10** lead exclusively to the allenes **9**.

11   **12**

Transallenations have previously hardly played a role in the chemistry of allenes. The novel transallenation method leading to the allene-1,1-dicarboxamides **9**[11] is widely applicable given the choice of suitable combinations of substituents. The readily accessible allenes **1b, c** function as synthetic equivalents for the dianions **11** of malonamide, and the disubstituted malonyl chlorides **6a, b, d** as equivalents of 1,1-vinylidene dications **12**.

CP/MAS-^{13}C-NMR Spectra of Sclerotized Insect Cuticle and of Chitin**

By *Martin G. Peter*, Lothar Grün,* and *Hans Förster*

During the sclerotization of the exoskeleton, which is a vital process for insects, the *N*-acylated catecholamines ("diphenols") *N*-(3,4-dihydroxyphenethyl)acetamide (*N*-acetyldopamine)[1] and 3-amino-*N*-(3,4-dihydroxyphenethyl)propionamide (*N*-β-alanyldopamine)[2] are oxidized in the cuticle to give reactive intermediates. It is thought that such intermediates involve *o*-quinones and/or *p*-quinonemethides, which can lead, in an addition-oxidation-condensation sequence[3], to the covalent cross-linking of proteins and/or chitin[4]. Sclerotized cuticle is almost completely insoluble under nondestructive conditions, and consequently there is no convincing proof for the postulated structures of the cross-linkages[5]. Solid state ^{13}C-NMR spectroscopy has proven most useful for the non-destructive analysis of complex insoluble biopolymers. Using this technique we have now succeeded in obtaining struc-

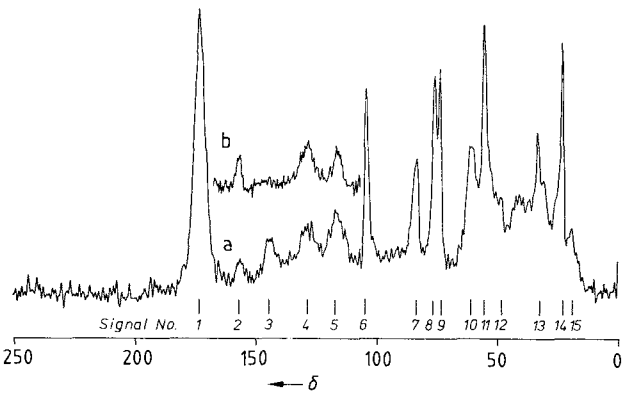

Fig. 1. a) CP/MAS-^{13}C-NMR spectrum of the pupal cases (exuviae) of *Manduca sexta*; b) aromatic region of the CP/MAS-^{13}C-NMR spectrum of *Blaberus giganteus* (exuviae). Spinning side-bands have been suppressed. Conditions of measurement: Bruker CXP 300, at 75.46 MHz, ^{1}H-^{13}C-cross polarization with sample rotation about the magic angle, 15—20 G decoupling field strength, 4.9—5.1 KHz rotation frequency, 1 ms contact time. The sclerotized cuticle was broken down in ice-cold, 0.1 M phosphate buffer (pH 6.8) using an Ultra-Turrax at maximum revolution. After filtration, the sample of cuticle was washed with water, ethanol, and ether, and dried over P_4O_{10}.

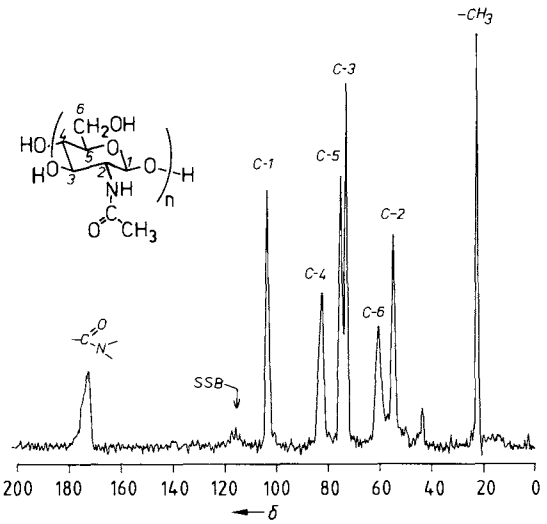

Fig. 2. CP/MAS-^{13}C-NMR spectrum of chitin. Spinning side-bands have not been suppressed. The cuticle of *Manduca sextra* larvae was treated twice in the following way: immersed for 1 h in 10% NaOH at 80°C, washed with water, immersed for 1 h in 98% HCOOH at 22°C, washed with water, dried over P_4O_{10}, remaining chitin cut into smaller pieces with scissors.

tural information about the completely sclerotized, native cuticle of insects.

Figure 1a shows a CP/MAS-^{13}C-NMR spectrum of solid, deep-brown colored pupal cases (exuviae) of the tobacco hornworm *Manduca sexta*. A comparison of this spectrum and that of chitin (Fig. 2) immediately allows assignment of the signal groups 1, 6 up to 11, and 14 (see Table 1 and [6]), which can be seen to arise from 2-deoxy-2-acetylaminoglucopyranosyl moieties.

Comparison with the spectrum of bovine serum albumin (Fig. 3) reveals a contribution by proteins in the signal groups 1, 2, 4, 5 and 10 to 15 (see Table 1 and [7]). What can now be deduced about the fate of the *N*-acylated catecholamines which are incorporated into the cuticle during sclerotization? In the signal groups 1 and 14 the resonances of the *N*-acetyl groups superimpose those of chitin. The signals of the aliphatic C-atoms of the side-chain, which coincide with those of amino acid residues, are likewise not observable separately. In contrast, the region of aromatic C-atoms has great diagnostic value. Comparison with a solid-state ^{13}C-NMR spectrum of *N*-acetyldopamine[8] reveals that the signal groups 3 and 5 observed in the spectrum of the sclereotized cuticle are mainly derived from diphenolic partial structures. Most likely these are polyphenols formed by oxidative coupling. The absorption regions of the groups 3 and 5 are very much broader than the chitin resonances, thus indicating the presence of a large number of aromatic C-atoms with different chemical environments. The assignment of the signal groups 1 to 4 to quaternary C-atoms also follows from a spectrum that was recorded with a NQS pulse sequence, by which the remaining resonances are suppressed.

The observation that the transformation products of the sclerotizing agents in the cuticle are present in the *reduced* state is at first sight surprising, since it contradicts the hypothesis of a covalent cross-linking of proteins via aminoquinone imines. The absorptions of imino C-atoms are to be expected in the region of $\delta \approx 150-160$. The phenoxy C-atoms of tyrosine and guanidino C-atoms of arginine also appear in this region[7]. A comparison of the intensities of the signal groups 2 in the cuticle spectrum (Fig. 1a) and in the protein spectrum (Fig. 3) with those of the groups 4 gives no indication of larger amounts of aminoquinone imine partial structures. Exuviae of the migratory locust *Locusta migratoria* have an analogous solid state ^{13}C-NMR spectrum. In contrast, in the exuviae of the cockroach *Blaberus giganteus* one finds substantially smaller amounts of diphenols (Fig. 1b). Apparently, the molecular principles of the sclerotization of the cuticle are different in at least this insect species.

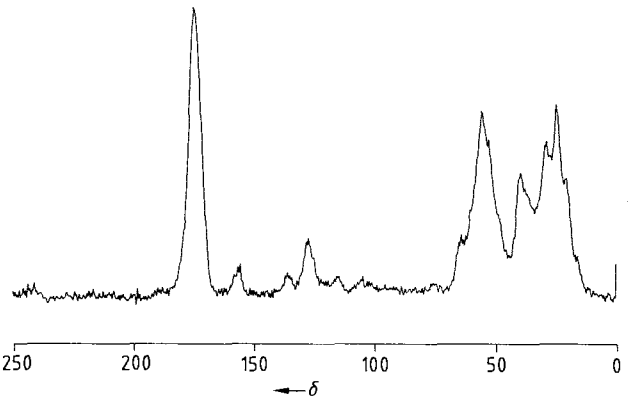

Fig. 3. CP/MAS-^{13}C-NMR spectrum bovine serum albumin (Sigma). Spinning side-bands were suppressed. Conditions of measurement as in Fig. 1.

Table 1. Assignment of the signal groups in the CP/MAS-^{13}C-NMR spectra of sclerotized cuticle (Fig. 1), of chitin (Fig. 2) and of bovine serum albumin (Fig. 3).

[a] Spinning side-band of group 1. [b] Chitin cannot be obtained completely free of protein.

The question whether covalent protein-diphenol linkages are formed by addition of nucleophiles to *p*-quinomethides cannot be answered without the use of isotopically labeled compounds.—The above results are consistent with the hypothesis that the sclerotization of the cuticle occurs by a denaturation of structure proteins by polyarenes. This would suggest analogies to the tanning of proteins by catechin-type polymers or to the stabilization of plant structures by lignin[9].

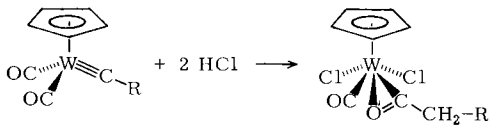
Acid-Induced Carbyne-Acyl Rearrangement—an Unexpected CC Coupling Reaction**

By *Fritz R. Kreissl**, *Werner J. Sieber*, *Mathias Wolfgruber*, and *Jürgen Riede*

In the homogeneous- or heterogeneous-catalyzed reduction of carbon monoxide, carbene, carbyne, or carbide ligands are thought to be linked intramolecularly to coordinated CO[1,2]. Examples are 1) the thermal decomposition of diphenylcarbene complexes of chromium and tungsten[3], 2) the base-induced, intramolecular carbonylation of dicarbonyl(η^5-cyclopentadienyl)carbene complexes of molybdenum and tungsten[4], as well as 3) the carbonylation of carbide clusters[5].

We have now obtained the η^2-acyl complexes **2a**, **b** via protonation and CC-coupling reaction sequence of the carbyne complexes **1a**, **b** with an ethereal solution of hydrogen chloride[6]. Similar compounds are formed by the carbonylation of $[MCl(CH_2SiMe_3)(PMe_3)]$ (M = Mo[7], W[8]) or by reacting the anion $[Mo(CO)_3\{HB(3,5\text{-}Me_2C_3HN_2)_3\}]^{\ominus}$ with aryldiazonium salts[9].



a, R = CH_3; **b**, R = p-$CH_3C_6H_4$

2a, **b** are orange-red, diamagnetic crystals, which are readily soluble in dichloromethane or acetone, but insoluble in diethyl ether and pentane. Their compositions and structures were determined by elemental analysis and by IR, ^{1}H-, and $^{13}C\{^1H\}$-NMR spectroscopy[10], as well as by X-ray structure analysis. On this basis, **2a** can be discribed as a pseudosquare pyramid in which the acyl ligand occupies a coordination site (Fig. 1). Its η^2-coordination follows from the W–C3 distance of 199.9(8) pm, which is shorter than a W–C single bond, and from the W–O3 bond length of 216.7(6) pm. At the same time, the C3–O3 double bond is lengthened. The geometry of the acyl-C3 deviates from that of an sp^2-hybridized carbon; the W–C3–O3 angle is similar to the corresponding angle in $[(CO)_2Cl(PMe)W(\eta^2\text{-}COCH_2SiMe_3)]_2$[8].

The acid-induced carbyne-acyl rearrangement is a novel reaction of transition metal-carbyne complexes; it confirms the nucleophilicity of the carbyne carbon atom in η^5-cyclopentadienyl-substituted carbyne complexes predicted by *Fenske* et al.[12]. A few examples are known for the probable first step in the reaction, leading to the as yet non-isolated carbene complex $(\eta^5\text{-}C_5H_5)(CO)_2ClW{=}CHR$ (R = CH_3, p-$CH_3C_6H_4$): protonation of $(PMe_3)_4ClW{\equiv}CH$[13], $CO(PPh_3)_2ClOs{\equiv}CR$[14], $(CO)_2[HB(C_3H_2N_2)_3]W{\equiv}C\text{–}SCH_3$[15] and $(\eta^5\text{-}C_5H_5)(CO)_2W{\equiv}C\text{–}NEt$[16].

A further reaction step could be protonation of this carbene complex followed by a formal CO insertion to give rise to **2**. An alternative mechanism might be a metal-induced, carbonyl-carbene coupling. The intermediate η^2-ketene complex could then undergo renewed addition of HCl to yield the η^2-acyl complex **2**.

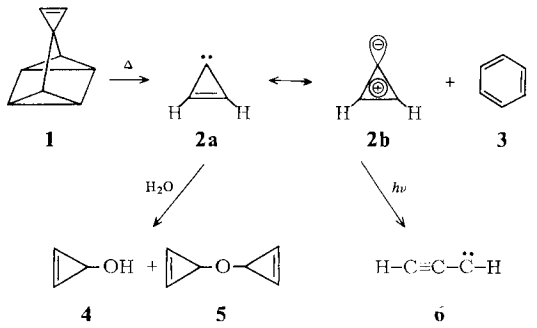
Cyclopropenylidene**

By *Hans Peter Reisenauer, Günther Maier*, Achim Riemann,* and *Reinhard W. Hoffmann**

Cyclopropenylidene **2a** ↔ **2b** is of considerable theoretical interest[1]. Until now, only the diphenyl[2] and bis(dialkylamino) derivatives[3] had been detected indirectly in trapping reactions. We report here the generation of cyclopropenylidene **2** by flash thermolysis and its matrix isolation.



The quadricyclane derivative **1**[4] was heated to 523 K under conditions of preparative vacuum flash pyrolysis at 1 torr. The products, which were trapped at 77 K, underwent exothermic polymerization upon thawing; in addition, benzene **3** was isolated in almost quantitative yield. If water was not completely excluded from the reaction, cyclopropenol **4** and dicyclopropenyl ether **5** were formed[5]. This indicates that in the pyrolysis of **1** a C_3H_2-fragment having an intact cyclopropene ring is cleaved off.

If the product of the pyrolysis is condensed with a large excess of argon[6] onto a window at 10 K immediately after it leaves the hot zone, the IR spectrum shows, apart from the bands from benzene, four additional absorptions (Table 1). Within the normal variations of calculations of this type (the calculated frequencies are ca. 10% too high), the frequencies and relative intensities are consistent with those of the four most intense IR bands predicted for **2**[1a]. Four other bands are too weak to be observed under our experimental conditions.

Table 1. Experimental and calculated [1a] IR spectrum of cyclopropenylidene **2**.

[**] Small Rings, Part 51. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 50: G. Maier, K. Euler, H. Irngartinger, M. Nixdorf, *Chem. Ber.*, in press.

The presence of cyclopropenylidene **2** is confirmed by the following experiment: Upon irradiation ($\lambda > 360$ nm) of the matrix-isolated pyrolysis product of **1**, only the four IR bands belonging to **2** disappear. Simultaneously, new absorptions at 3390, 3366, 412, 405, 261, and 248 cm^{-1} appear, whose frequencies correspond to the known values for matrix-isolated propynylidene **6**[7].

The photolytic conversion of **2** into **6** can also be observed using ESR spectroscopy. In accord with the singlet ground-state of **2**[1], the ESR spectrum of the matrix-isolated product of pyrolysis exhibits no triplet signal. After irradiation, the known spectrum[8] of the triplet carbene **6** is obtained, consistent with the results of IR studies.

2 does not react when the matrix is tempered for several hours at 35—40 K. After evaporation of the argon, a brown, polymeric residue remains. Evidence for the formation of the interesting dimer of **2**, 1,1-bicyclopropenylidene, could not be obtained.

Summary: Cyclopropenylidene **2** is stable in an argon matrix at 10 K and has, as predicted[1], a singlet ground-state.

Direct Photochemical Cleavage of the Cyclobutane Ring in Bicyclo[4.2.0]octane on 185nm Irradiation in Solution**

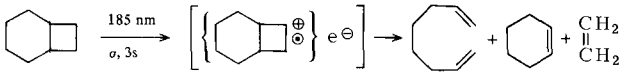
By *Waldemar Adam** and *Thomas Oppenländer*

By analogy to cyclopropanes, which recently have been shown to exhibit interesting and diversified photochemistry on 185 nm irradiation in solution[1], cyclobutanes are

[*] Prof. Dr. W. Adam, Dipl.-Chem. T. Oppenländer [+]
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)
[+] Doctoral fellow of the Fonds der Chemischen Industrie.

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

also expected to be photoactive in the far UV region since they possess appreciable absorption below 200 nm ($\sigma^* \leftarrow \sigma$ and Rydberg excitations)[2]. Cyclobutane rings can be cleaved efficiently by photochemical electron transfer with quinones as electron acceptors[3]. This photo-cleavage, which involves radical cation intermediates, plays a central role for the dissociation of thymine dimers in photodamaged DNA by photo-repairing enzymes[4]. Since $\sigma^* \leftarrow \sigma$-Rydberg excitation does lead to intermediates with radical cation character[2], it appeared important to explore the possibility of promoting direct photochemical cleavage of cyclobutanes that are devoid of chromophoric substituents by means of 185 nm irradiation in solution. That this cleavage indeed occurs is demonstrated using bicyclo[4.2.0]octane **1** as example.



1 **2**

Irradiation of a 0.044 M solution of **1** in *n*-pentane with the full output of a mercury low-pressure lamp (Gräntzel, Karlsruhe) affords 1,7-octadiene, cyclohexene, and ethylene. These photo-products were identified by co-injecting authentic materials onto three different capillary GC columns (86 m polypropylene glycol, 50 m OV-101, and 50 m Carbowax 20 M). In addition, 1,7-octadiene and cyclohexene were identified by their characteristic fragmentation patterns on capillary GC/MS analysis. Finally, 1,7-octadiene was collected by preparative gas chromatography (packed glass column 1.5 m × 8 mm, 10% β,β′-oxydipropionitrile on Chromosorb WHP, 100/200), and its 90 MHz ^{1}H-NMR spectrum found to be identical to that of an authentic sample.

Control experiments revealed that not even traces of cyclooctene were produced in the 185 nm photolysis, and at 254 nm (the major output of the mercury low-pressure lamp) **1** was completely photo-stable. Quantitative capillary GC analysis (50 m SE 30) gave a relative product composition of 1,7-octadiene: cyclohexene = 70:30, with a mass balance of >98% during the first 40 min of 185 nm irradiation. The quantum yields determined using the (*Z,E*)-isomerization of cyclooctene as actinometer[5] were $\Phi_S = 0.12 \pm 0.01$ for substrate consumption and $\Phi_P = 0.10 \pm 0.01$ and $\Phi_P = 0.030 \pm 0.003$ for 1,7-octadiene and cyclohexene, respectively.

In comparison, vacuum flash pyrolysis of **1** (18 torr, distillation through a Quartz tube, 450 °C) led to a relative product composition of 1,7-octadiene : cyclohexene = 11 : 89[6]. Ethylene was also formed, but the amount was difficult to quantify.

There are no analogous photoreactions of **1** at higher wavelengths because this alkyl-substituted cyclobutane[7] has no UV absorption above 200 nm. Mercury-sensitized irradiation of cyclooctene at 254 nm leads to **1**, postulated to be formed via cyclization of the intermediate tetramethylene diradical 1,4-cyclooctanediyl[8]. The fact that cyclooctene is not formed in the 185 nm photolysis of **1** precludes this 1,4-diradical as reactive intermediate, at least in its ground state. For example, in the thermolysis of the azoalkane 7,8-diazabicyclo[4.2.2]dec-7-ene, in which a ground state 1,4-cyclooctanediyl intervenes, both **1** and cyclooctene are produced[9]. Finally, the fact that the vacuum flash pyrolysis of **1** leads mainly to cyclohexene and ethylene[6] is evidence against the involvement of the 1,4-cyclooctanediyl as preferred intermediate in the 185 nm photolysis of **1**.

Since cyclobutane rings are efficiently cleaved in the electron-transfer photolysis of thymine dimers with quinones via intermediary radical cations[3], we postulate that the observed cleavage of **1** into 1,7-octadiene and cyclohexene in the 185 nm photolysis proceeds via (σ,3s)-Rydberg excitation. Promotion of an electron into a 3s Rydberg molecular orbital generates a species **2** with radical cation character[11], which on cyclobutane ring-cleavage and electron demotion would be expected to afford the observed products. Orbital symmetry arguments[11] also suggest that such cleavage processes should be facile. The demonstration that cyclobutane rings can be directly cleaved by 185 nm excitation provides novel opportunities for mechanistic investigations.

Formation of Phenanthrenequinone from Benzil: A Novel Reaction of Graphite-Potassium Intercalates

By *Dov Tamarkin, Daphna Benny*, and *Mordecai Rabinovitz**

Reactions of the highly ordered potassium-graphite intercalate C_8K have evoked recently much interest. Due to its structure it reacts in a different mode, as compared with non-intercalated dispersed potassium[1]. Recently, we reported that *vic*-dibromides undergo with C_8K a stereospecific debromination reaction, and ketones undergo a bimolecular reduction in high yields to the respective pinacols. It has been suggested that the "layer-edge mechanism" is responsible for the specific reactivity of this reagent[2]. According to this mechanism ketones which are linked to adjacent potassium atoms at the graphite layer edge, form radical anions. These radical anions can then undergo a C–C bond formation reaction at those carbons bearing high spin density[2b].

1, R = H
2, R = CH_3

3, R = H
4, R = CH_3

We now wish to report a novel reaction that α-diketones undergo with C_8K. Benzil **1** and *p,p'*-dimethylbenzil **2** with C_8K afford phenanthrenequinone **3** and 3,6-dimethylphenanthrenequinone **4**, respectively. This reaction involves an intramolecular carbon-carbon bond formation. The products are obtained in good yields and high purity, while experiments with dispersed potassium under similar conditions afforded only trace amounts of the respective quinone. Graphite-potassium intercalate C_8K is formed by heating to 200 °C potassium metal and dry graphite (B.D.H.) with magnetic stirring[3]. To freshly prepared C_8K (12.5 mmol in 20 mL dry THF), 2.5 mmol of benzil **1** (0.525 g, Fluka AG in 30 mL of THF) was added and stirred at room temperature (5 h, inert atmosphere). During this period of time hydrogen gas evolves. The red reaction mixture was quenched carefully with water and filtered, extracted with CH_2Cl_2 and evaporated. Phenanthrenequinone **3** (3.7 g, 70%, m.p. 208 °C(EtOH)[4] was obtained. Similarly, 3,6-dimethylphenanthrenequinone **4** was prepared from *p,p'*-dimethylbenzil in 72% yield (m.p. 216 °C/MeOH)[4]. The same reactions can also be performed in benzene or cyclohexane and the yields are 35% and 32%, respectively[5].

This novel C–C bond formation reaction provides a new synthetic pathway for the preparation of phenanthrenequinone-type compounds and their derivatives, especially in view of the easy affordability of substituted benzil derivatives from the corresponding benzaldehydes.

The evolution of the hydrogen gas was followed and measured. The rate of the gas evolution was found to be constant. This observation may indicate that the process is "layer-edge" controlled, i.e. the rate is determined by the surface area of the graphite lattice which contains ordered potassium atoms available for the reaction. This is consistent with the mechanism that we have previously described for the bimolecular reduction of ketones[2b]. The mechanistic behavior of C_8K reactions with ketones, diketones and their analogs is under further investigation.

BOOK REVIEWS

Organotransition Metal Chemistry: Applications to Organic Synthesis. By *S. G. Davies*. Pergamon Press, Oxford 1982. x, 411 pp., bound, $ 85.00.

The use of transition metal complexes for the formation of carbon-carbon bonds is not in itself new; the classical investigations of *Roelen* and *Reppe* are nearly half a century old. Since then, however, the tremendous growth of organometallic chemistry has opened up a variety of reactions that have greatly augmented the armory of the synthetically oriented organic chemist.

The author of the present monograph has aimed at acquainting the organic synthesis-oriented reader with the possibilities of organometallic chemistry. The basic principles are dealt with in an introductory chapter, which, possibly because of space constraints, is so short that a list of references for further reading would have been appropriate. A review of the synthesis of various types of complexes and methods of ligand elimination follows a section concerned with the role of organometallic fragments as protective groups and as stabilizing functions. The central chapters deal with organometallic complexes as electrophilic and nucleophilic reaction partners; coupling and cyclization reactions, isomerization, redox and carbonylation reactions are also described. Each section is provided with a rich selection of literature examples. It is a pity that, nevertheless, such established reagents as organocopper compounds, which play such an important role in the formation of C–C bonds remain unmentioned—possibly because they are the subject of a recently published monograph by *G. Posner*. In addition to established catalytic processes, the main treatment is of stoichiometric reactions that are seen as a potential basis for new synthetic methods. The literature is covered up to mid-1980. The majority of the 700 references, which unfortunately are not without error, stems from the last five years.

The same theme has been the subject of several monographs lately. Nevertheless, this book by *Davies* is a welcome addition. It is clearly set out according to mechanistic principles and is thus of value as a primary reference source. It is well constructed from an instructional standpoint and gives a contemporary survey of the synthetic potentiality of organometallic chemistry. It will be of use to all those who seek an "organometallic" solution of their synthetic problems. Why this book, which is directly reproduced for the sake of topicality, is so expensive, is quite another question.

Karl Heinz Dötz [NB 623 IE]

der Technischen Universität München (FRG)

Molecular Biology of the Cell. By *B. Alberts, D. Bray, J. Lewis, M. Raff, K. Roberts,* and *J. D. Watson*. Garland Publishing, New York 1983. xxxix, 1142 pp., bound, £ 33.95.

This textbook, which has been written by a group of authors, deals with only one subject, the cell, from various

points of view, thereby abandoning the usual compartmentation according to subject. The cell is the building block of all life. It is the host for subcellular life forms such as viruses and virus-like structures, it can also organize itself into a supracellular assemblage, losing some of its autonomy. A cell is not a temporal or structural continuum, but distinguishes itself by its functional complexity and its ability to adapt to its surroundings. Differentiation can be genetically programmed; it can, however, also be a response to environmental influences.

The first chapter of the book deals with the basic principles of cytology, by leading the reader from simple biomolecules up to multicellular organisms. The following section explains the techniques by which cellular structure and functions are currently investigated. Even complicated techniques such as cell fusion, the production of monoclonal antibodies, DNA cloning and cell sorting are explained in a very clear, albeit simplified, manner. The following chapter deals with the compartmentation of cells, cell growth and cell division and with cellular communication. The last chapter is even more topical than its predecessors. This covers the topics of heredity, fertilization and of cellular differentiation using the immune and nervous systems as examples and last of all the molecular biology of plants.

The individual contributions are written by specialists, who quote material published in their field up to about the end of 1982. The good didactic presentation and the courage to simplify are worthy of mention. Every contribution has been checked by a second expert for its factual content and comprehensibility. Each section ends with a summary and short list of literature references.

The quality of the illustrations is superior even to that of the text; for example, simplified schematic drawings are almost always placed alongside electron micrographs. The illustrations are not squeezed into the text on the principle of maximum utilization of space but each individual page is suitably graphically laid out even taking superscripts and subscripts into account.

Which readership is this book suitable for? It is to be recommended to each and every scientist in the fields of education, biology, chemistry and medicine who wishes to refresh and bring up-to-date his knowledge of cellular biology.

It is only suitable for students of biology or chemistry after they have completed the first part of their undergraduate courses, since the biological facts in the text and illustrations are somewhat schematized. Since the quantitative chemical-mechanistic aspect is neglected, the dominance of the illustrations leads to an overemphasis of static structures.

All in all an excellent book, that is currently unsurpassed in content and production.

Experimental and Theoretical Nuclear Astrophysics; The Quest for the Origin of the Elements (Nobel Lecture)**

By William A. Fowler*

Ad astra per aspera et per ludum

I. Introduction

We live on planet Earth warmed by the rays of a nearby star we call the Sun. The energy in those rays of sunlight comes initially from the nuclear fusion of hydrogen into helium, deep in the solar interior. *Eddington* told us this in 1920, and in 1939 *Hans Bethe* developed the detailed nuclear processes involved in the fusion. For this he was awarded the Nobel Prize in Physics in 1967.

All life on earth, including our own, depends on sunlight and thus on nuclear processes in the solar interior. But the sun did not produce the chemical elements which are found in the earth and in our bodies. The first two elements and their stable isotopes, hydrogen and helium, emerged from the first few minutes of the early high-temperature, high-density stage of the expanding Universe, the so-called "big bang". A small amount of lithium, the third element in the periodic table, was also produced in the big bang, but the remainder of the lithium and all of beryllium, element four, and boron, element five, are thought to have been produced by the spallation of still heavier elements by cosmic radiation in the interstellar medium between stars. These elements are, in general, very rare, in keeping with this explanation of their origin, as reviewed in detail by *Audouze* and *Reeves*[1].

California Institute of Technology, Pasadena
California 91125 (USA)

[**] Copyright © The Nobel Foundation 1984.—We thank the Nobel Foundation, Stockholm, for permission to publish this article.

Where did the heavier elements originate? The generally accepted answer is that all of the heavier elements from carbon, element six, up to long-lived radioactive uranium, element ninety-two, were produced by nuclear processes in the interior of stars in our own Galaxy. The stars we see at the present time in what we call the *Milky Way* are located in a spiral arm of our Galaxy. In Sweden, it is called *Vinter Gatan*, the Winter Street. Our eyes see only a small fraction of the one hundred billion stars in the Galaxy. Astronomers use almost the full range of the electromagnetic spectrum and thus can observe many more Galactic stars and even individual stars in other galaxies.

The stars which synthesized the heavy elements in the solar system were formed or born, subsequently evolved or aged, and eventually ejected the ashes of their nuclear fires into the interstellar medium over the lifetime of the Galaxy *before* the solar system itself formed, four and one-half billion years ago.

The lifetime of the Galaxy is thought to be more than ten billion years but less than twenty billion years. In any case, the Galaxy is much older than the solar system. The ejection of the nuclear ashes or newly formed elements took place by slow mass-loss during the old age of the star, called the *giant* stage of stellar evolution, or during the relatively frequent outbursts which astronomers call *novae*, or during the final spectacular stellar explosions called *supernovae*. Supernovae can be considered to be the death of stars, but the white dwarfs, neutron stars, or black holes that they leave behind may represent a form of stellar purgatory.

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/0909-0645 $ 02.50/0

In any case, the sun, the earth, and all the other planets in the solar system condensed under gravitational and rotational forces from a gaseous solar nebula in the interstellar medium consisting of "big bang" hydrogen and helium mixed with the heavier elements synthesized in earlier generations of Galactic stars. All of this is illustrated in Figure 1.

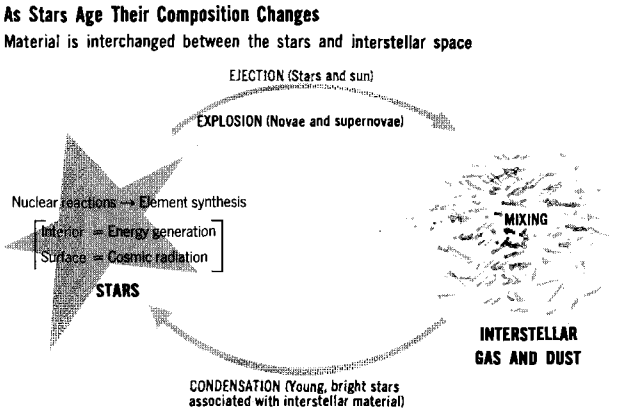

Fig. 1. Synthesis of the elements in stars.

The idea can be generalized to successive generations of stars in the Galaxy with the result that the heavy element content of the interstellar medium and the stars which form from it increase with time. The oldest stars in the Galactic halo, that is, those we believe to have formed first, are found to have heavy-element abundances less than one percent of the heavy-element abundance of the solar system; the oldest stars in the Galactic disk have approximately ten percent. Only the less massive stars among those first formed can have survived to the present as so-called Population II stars. Their small concentration of heavy elements may have been produced in a still earlier but more massive generation of stars, Population III, which rapidly exhausted their nuclear fuels and survived for only a very short lifetime. Stars formed in the disk of the Galaxy over its lifetime are referred to as Population I stars.

We speak of this element building as nucleosynthesis in stars. It can be generalized to other galaxies such as our twin, the Andromeda Nebula, and so this mechanism can be said to be a universal one. Astronomical observations on other galaxies have contributed much to our understanding of nucleosynthesis in stars.

We refer to the basic physics of energy generation and element synthesis in stars as Nuclear Astrophysics. It is a benign application of nuclear physics, in contrast to reactors and bombs. For the nuclear physicist, this contrast is a personal and professional paradox. However, there is one thing of which I am certain. The science which explains the origin of sunlight must not be used to raise a dust cloud which will black-out that sunlight from our planet.

As for all physics, the field of Nuclear Astrophysics involves experimental and theoretical activities on the part of its practitioners, and hence the first part of the title of this lecture. This lecture will emphasize nuclear experimental results and the theoretical analysis of those results almost, but not entirely, to the exclusion of other theoretical aspects. It will not in any way do justice to the observational activities of astronomers and cosmochemists, which are necessary to complete the cycle: experiment, theory, observation. Nor will it do justice to the calculations by many theoretical astrophysicists of the results of nucleosynthesis of the elements and their isotopes under astrophysical conditions during the many stages of stellar evolution.

My deepest personal interest is in experimental data, in the analysis of the data, and in the proper use of the data in theoretical stellar models. I continue to be encouraged in this regard by the one-hundred-and-and-ten-year-old quotation from *Mark Twain:*

There is something fascinating about science. One gets such wholesale returns of conjecture out of such a trifling investment of fact.

— Life on the Mississippi 1874

For me, *Twain*'s remark is a challenge to the experimentalist. The experimentalist must try to eliminate the word "trifling" through his endeavors in uncovering the facts of nature.

Experimental research and theoretical research are often very hard work. Fortunately, this is lightened by the fun of doing physics and in obtaining results which bring a personal feeling of intellectual satisfaction. To my mind, the hard work and the resulting intellectual fun transcend in a way the benefits which may accrue to society through subsequent technological applications. Please understand—I do not belittle these applications, but I am unable to overlook the fact that they are a two-edged sword. My subject matter resulted from the hard work of a nuclear astrophysicist, which when successful brought him joy and satisfaction. It was hard work, but it was fun. Thus, I have chosen as subtitle for this lecture—"*Ad astra per aspera et per ludum*", which can be freely translated "To the stars through hard work and fun." This is in keeping with my paraphrase of the biblical quotation from *Matthew* "Man shall not live by work alone".

With that in the record, let us next ask what are the goals of Nuclear Astrophysics? First of all, Nuclear Astrophysics attempts to understand energy generation in the sun and other stars at all stages of stellar evolution. Energy generation by nuclear processes requires the transmutation of nuclei into new nuclei with lower mass. The small decrease in mass is multiplied by the velocity of light squared, as *Einstein* taught us, and a relatively large amount of energy is released.

Thus, the first goal is closely related to the second goal that attempts to understand the nuclear processes which produced, under various astrophysical circumstances, the relative abundances of the elements and their isotopes in nature; whence the second part of the title of this lecture. Figure 2 shows a schematic curve of atomic abundances as a function of atomic weight. The data for this curve was first systemized from a plethora of terrestrial, meteoritic, solar and stellar data by *Hans Suess* and *Harold Urey*[2], and the available data has been periodically updated by

A. G. W. Cameron[3]. Major contributions to the experimental measurement of atomic transition rates needed to determine solar and stellar abundances have been made by my colleague, *Ward Whaling*[4]. References [3] and [4] occur in a monograph, Essays in Nuclear Astrophysics, which reviews the field up to 1982. In the words of one of America's baseball immortals, *Casey Stengel*, "You can always look it up".

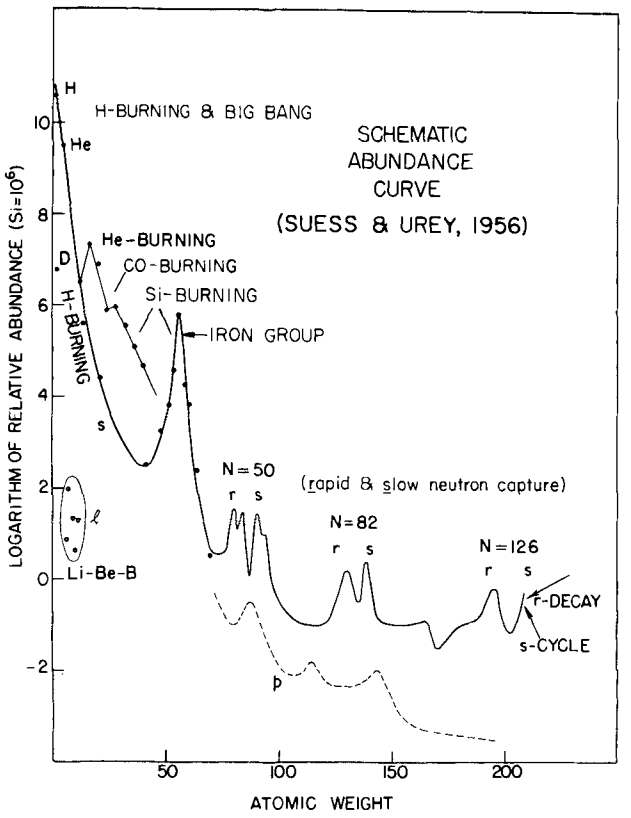

Fig. 2. Schematic curve of atomic abundances relative to $Si = 10^8$ versus atomic weight for the Sun and similar Main Sequence stars.

The curve in Figure 2 is frequently referred to as "universal" or "cosmic", but in reality it primarily represents relative atomic abundances in the solar system and in main sequence stars similar in mass and age to the sun. In current usage, the curve is described succinctly as "solar". It is beyond the scope of this lecture to elaborate on the difficult, beautiful research in astronomy and cosmochemistry which determined this curve. How this curve serves as a goal can be easily explained. In the sequel it will be noticed that calculations of atomic abundances produced under astronomical circumstances at various postulated stellar sites are almost invariably reduced to ratios relative to "solar" abundances.

II. Early Research on Element Synthesis

George Gamow and his collaborators, *R. A. Alpher* and *R. C. Herman*[5], attempted to synthesize all the elements during the big bang using a nonequilibrium theory involving neutron (n) capture with gamma-ray (γ) emission and electron (e) beta-decay by successively heavier nuclei. The synthesis proceeded in steps of one mass unit at a time, since the neutron has approximately unit mass on the mass scale used in all the physical sciences. As they emphasized, this theory meets grave difficulties beyond mass 4 (^{4}He) because no stable nuclei exist at atomic masses 5 and 8. *Enrico Fermi* and *Anthony Turkevich* attempted valiantly to bridge these "mass gaps" without success and permitted *Alpher* and *Herman* to publish the results of their attempts. Seventeen years later, *Wagoner, Fowler,* and *Hoyle*[6], armed with nuclear reaction data accumulated over the intervening years, succeeded only in producing ^{7}Li at a mass fraction of at most 10^{-8} compared to hydrogen plus helium for acceptable model universes. All heavier elements totaled less than 10^{-11} by mass. *Wagoner, Fowler,* and *Hoyle*[6] did succeed in producing ^{2}D, ^{3}He, ^{4}He, and ^{7}Li in amounts in reasonable agreement with observations at the time. More recent observations and calculations are frequently used to place constraints on models of the expanding universe and in general favor open models in which the expansion continues indefinitely.

It was in connection with the "mass gaps" that the W. K. Kellogg Radiation Laboratory first became involved, albeit unwittingly, in astrophysical and cosmological phenomena. Before proceeding, it is appropriate at this point to discuss briefly the origins of the Kellogg Radiation Laboratory, where I have worked for 50 years. The laboratory was designed and the construction supervised by *Charles Christian Lauritsen* in 1930 through 1931. *Robert Andrews Millikan*, the head of Caltech, acquired the necessary funds from *Will Keith Kellogg*, the American "cornflakes king". The Laboratory was built to study the physics of 1 MeV X-rays and the application of those X-rays in the treatment of cancer. In 1932, *Cockcroft* and *Walton* discovered that nuclei could be disintegrated by protons (p), the nuclei of the light hydrogen atom ^{1}H, accelerated to energies well under 1 MeV. *Lauritsen* immediately converted one of his X-ray tubes into a positive ion accelerator (they were powered by alternating current transformers!) and began research in nuclear physics. *Robert Oppenheimer* and *Richard Tolman* were instrumental in convincing *Millikan* that *Lauritsen* was doing the right thing. *Oppenheimer* played an active role in the theoretical interpretation of the experimental results obtained in the Kellogg Laboratory in the early crucial years.

Lauritsen supervised my doctoral research from 1933–1936, and I worked closely with him until his death. It was he who taught me that physics was both hard work and fun. He was a native of Denmark and was an accomplished violinist as well as physicist, architect, and engineer. He loved the works of *Carl Michael Bellman*, the famous Swedish poet-musician of the 18th century, and played and sang *Bellman* for his students. It is well known that many of *Bellman*'s work were drinking songs. That made it all the better.

We must now return to the first involvement of the Kellogg Radiation Laboratory in the mass gap at mass 5. In 1939, in Kellogg, *Hans Staub* and *William Stephens*[7] detected resonance scattering, by ^{4}He, of neutrons with orbital angular momentum equal to one in units of $\hbar$ (p-wave) and energy somewhat less than 1 MeV, as shown in Figure 3. This confirmed previous reaction studies by *Williams,*

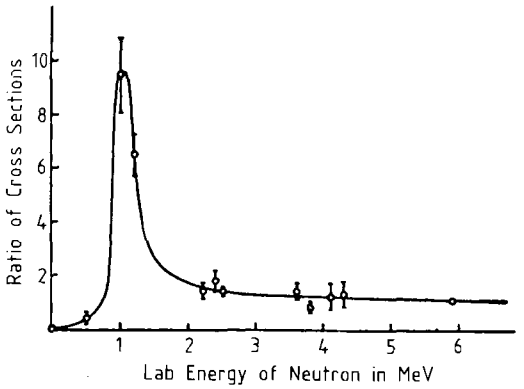

Fig. 3. The ratio of the backward scattering cross section of helium to hydrogen as a function of the laboratory energy of the incident neutron in MeV.

Shepherd, and *Haxby*[8] and showed that the ground state of ^{5}He is unstable. As fast as ^{5}He is made it disintegrates! The same was later shown to be true for ^{5}Li, the other candidate nucleus at mass 5. The Pauli exclusion principle dictates for fermions that the third neutron in ^{5}He must have at least unit angular momentum and not zero as permitted for the first two neutrons with antiparallel spins. The attractive nuclear force cannot match the outward centrifugal force in classical terminology. Still later, in the Kellogg Radiation Laboratory, *Tollestrup, Fowler,* and *Lauritsen*[9] confirmed, with improved precision, the discovery of *Hemmindinger*[10] that the ground state of ^{8}Be is unstable. They found the energy of the ^{8}Be break-up to be 89 ± 5 keV compared to the currently accepted value of 91.89 ± 0.05 keV! The Pauli exclusion principle is again at work in the instability of ^{8}Be. As fast as ^{8}Be is made it disintegrates into two ^{4}He-nuclei. The latter may be bosons but they consist of fermions. The mass gaps at 5 and 8 spelled the doom of *Gamow*'s hopes that all nuclear species would be produced in the big bang one unit of mass at a time.

The eventual commitment of the Kellogg Radiation Laboratory to Nuclear Astrophysics came about in 1939 when *Bethe*[11] brought forward the operation of the CN-cycle as one mode for the fusion of hydrogen into helium in stars (since oxygen has been found to be involved, the cycle is now known as the CNO-cycle). *Charles Lauritsen,* his son *Thomas Lauritsen,* and I were measuring the cross sections of the proton bombardment of the isotopes of carbon and nitrogen which constitute the CN-cycle. *Bethe*'s paper[11] told us that we were studying in the laboratory, processes which are occurring in the sun and other stars. It made a lasting impression on us. World War II intervened, but in 1946, on returning the laboratory to nuclear experimental research, *Lauritsen* decided to continue in low-energy, *classical* nuclear physics with emphasis on the study of nuclear reactions thought to take place in stars. In this, he was strongly supported by *Ira Bowen,* a Caltech Professor of Physics, who had just been appointed Director of the Mt. Wilson Observatory, by *Lee DuBridge,* the new President of Caltech, by *Carl Anderson,* Nobel Prize winner 1936, and by *Jesse Greenstein,* newly appointed to establish research in astronomy at Caltech. In Kellogg, *Lauritsen* did not follow the fashionable trend to higher and higher energies which has continued to this day. He did, however, support *Robert Bacher* and others in establishing high energy physics at Caltech.

Although *Bethe*[11], in 1939, and others, still earlier, had previously discussed energy generation by nuclear processes in stars, the grand concept of nucleosynthesis in stars came from *Fred Hoyle*[12]. In two classic papers, the basic ideas of the concept were presented within the framework of stellar structure and evolution with the use of the then known nuclear data.

Again, the Kellogg Laboratory played a role. Before his second paper, *Hoyle* was puzzled by the slow rate of the formation of ^{12}C-nuclei from the fusion ($3\alpha \rightarrow {}^{12}$C) of three alpha-particles (α) or ^{4}He-nuclei in Red Giant Stars. *Hoyle* was puzzled because his own work with *Schwarzschild*[13] and previous work of *Sandage* and *Schwarzschild*[14] had convinced him that helium burning through $3\alpha \rightarrow {}^{12}$C should commence in Red Giants just above 10^8 K rather than at 2×10^8 K, as required by the reaction rate calculation of *Salpeter*[15]. *Salpeter* made his calculation while a visitor at the Kellogg Laboratory during the summer of 1951 and used the Kellogg value[9] for the energy of ^{8}Be in excess of two ^{4}He to determine the resonant rate for the process ($2\alpha \leftrightarrow {}^8$Be), which takes into account both the formation and decay of the ^{8}Be. However, in calculating the next step, $^8\text{Be} + \alpha \rightarrow {}^{12}\text{C} + \gamma$, *Salpeter* had treated the radiative fusion as nonresonant.

Hoyle realized that this step would be speeded up by many orders of magnitude, thus reducing the temperatures for its onset, if there existed an excited state of ^{12}C with energy 0.3 MeV in excess of $^8\text{Be} + \alpha$ at rest and with the angular momentum and parity ($0^+, 1^-, 2^+, 3^-, \ldots$) dictated by the selection rules for these quantities. *Hoyle* came to the Kellogg Laboratory early in 1953 and questioned the staff about the possible existence of his proposed excited state. To make a long story short, *Ward Whaling* and his visiting associates and graduate students[16] decided to go into the laboratory and search for the state using the ^{14}N $(d,\alpha)^{12}$C reaction. They found it to be located almost exactly where *Hoyle* had predicted. It is now known to be at 7.654 MeV excitation in ^{12}C or 0.2875 MeV above $^8\text{Be} + \alpha$ and 0.3794 MeV above 3α. *Cook, Fowler, Lauritsen,* and *Lauritsen*[17] then produced the state in the decay of radioactive ^{12}B and showed that it could break up into 3α and thus, by reciprocity, could be formed from 3α. They argued that the spin and parity of the state must be 0^+, as is now known to be the case.

The $3\alpha \rightarrow {}^{12}$C fusion in Red Giants jumps the mass gaps at 5 and 8. This process could never occur under big bang conditions. By the time the ^{4}He was produced in the early expanding Universe, the subsequent density and temperature were too low for the helium fusion to carbon to occur. In contrast, in Red Giants, after hydrogen conversion to helium during the Main Sequence stage, gravitational contraction of the helium core raises the density and temperature to values where helium fusion is ignited. *Hoyle* and *Whaling* showed that conditions in Red Giant stars are just right.

Fusion processes can be referred to as nuclear burning in the same way we speak of chemical burning. Helium burning in Red Giants succeeds hydrogen burning in Main Sequence stars and is in turn succeeded by carbon, neon, oxygen, and silicon burning to reach to the elements near iron and somewhat beyond in the periodic table. With these nuclei of intermediate mass as seeds, subsequent processes similar to *Gamow*'s involving neutron capture at a slow rate (*s*-process) or at a rapid rate (*r*-process) continued the synthesis beyond ^{209}Bi, the last stable nucleus, up through short-lived radioactive nuclei to long-lived ^{232}Th, ^{235}U, and ^{238}U, the parents of the natural radioactive series. This last nucleus requires the *r*-process which actually builds beyond mass 238 to radioactive nuclei which decay back to ^{232}Th, ^{235}U, and ^{238}U rapidly at the cessation of the process.

The need for two neutron capture processes was provided by *Suess* and *Urey*[2]. With the adroit use of relative isotopic abundances for elements with several isotopes, they demonstrated the existence of the double peaks (*r* and *s*) in Figure 2. It was immediately clear that these peaks were associated with neutron shell filling at the magic neutron numbers $N=50$, 82, and 126 in the nuclear shell model of *Hans Jensen* and *Maria Goeppert-Mayer*, who won the Nobel Prize in Physics just twenty years ago.

In the *s*-process, the nuclei involved have low capture cross-sections at shell closure and thus large abundances to maintain the *s*-process flow. In the *r*-process, it is the proton-deficient radioactive progenitors of the stable nuclei which are involved. Low capture cross-sections and small beta-decay rates at shell closure lead to large abundances, but after subsequent radioactive decay these large abundances appear at lower A values than for the *s*-process, since Z is less and thus $A=N+Z$ is less. In *Hoyle*'s classic papers[12], stellar nucleosynthesis up to the iron group elements was attained by charged particle reactions. Rapidly rising Coulomb barriers for charged particles curtailed further synthesis. *Suess* and *Urey*[2] made the breakthrough which led to the extension of nucleosynthesis in stars by neutrons unhindered by Coulomb barriers all the way to ^{238}U.

The complete run of the synthesis of the elements in stars was incorporated into a paper by *Burbidge, Burbidge, Fowler,* and *Hoyle*[18], commonly referred to as B^{2}FH, and was independently developed by *Cameron*[19]. Notable contributions to the astronomical aspects of the problem were made by *Jesse Greenstein*[20] and by many other observational astronomers. Since that time, Nuclear Astrophysics has developed into a full-fledged scientific activity including the exciting discoveries of isotopic anomalies in meteorites by my colleagues *Gerald Wasserburg, Dimitri Papanastassiou,* and *Samuel Epstein* and many other cosmochemists. What follows will highlight a few of the many experiments and theoretical researches under way at the present time or carried out in the past few years. This account will emphasize research activities in the Kellogg Laboratory, because they are closest to my interest and knowledge. However, copious references to the work of other laboratories and institutions are cited in the hope that the reader will obtain a broad view of current experimental and theoretical studies in Nuclear Astrophysics.

This account cannot discuss the details of the nucleosynthesis of all the elements and their isotopes, which would, for a given nuclear species, involve discussing all the reactions producing that nucleus and all those which destroy it. The reader will find some of these details for ^{12}C, ^{16}O, and ^{55}Mn.

It will be noted that the measured cross-sections for the reactions are customarily very small at the lowest energies of measurement, for $^{12}C(\alpha,\gamma)^{16}O$ even less than one nanobarn (10^{-33} cm^2) near 1.4 MeV. This means that experimental Nuclear Astrophysics requires accelerators with large currents of well focussed, monoenergic ion beams, thin targets of high purity and stability, detectors of high sensitivity and energy resolution, and experimentalists with great tolerance for the long running-times required, and with patience in accumulating data of statistical significance. Classical Rutherfordian measurements of nuclear cross-sections are required in experimental nuclear astrophysics, and the results are in turn essential to our understanding of the physics of nuclei.

A comment on nuclear reaction notation is necessary at this point. In the reaction $^{12}C(\alpha,\gamma)^{16}O$ discussed in the previous paragraph, ^{12}C is the laboratory target nucleus, α is the incident nucleus (^{4}He) accelerated in the laboratory, γ is the photon produced and detected in the laboratory, and ^{16}O is the residual nucleus which can also be detected if it is desirable to do so. If ^{12}C is accelerated against a gas target of ^{4}He and the ^{16}O-products are detected but not the gamma rays, then the laboratory notation is $^4He(^{12}C,^{16}O)\gamma$. The stars could not care less. In stars, all the particles are moving and only the center-of-momentum system is important for the determination of stellar reaction rates. In $^{12}C(\alpha,n)^{15}O(e^+\nu)^{15}N$, n is the neutron promptly produced and detected and e^+ is the beta-delayed positron which can also be detected. The neutrino emitted with the positron is designated by ν.

As an aside at this point, I am proud to recall that I first spoke to the Royal Swedish Academy of Sciences on "Nuclear Reactions in Stars" on January 26, 1955. It does not seem so long ago, and some of you in the audience heard that talk!

III. Stellar Reaction Rates from Laboratory Cross Sections

Thermonuclear reaction rates in stars are customarily expressed as $N_A\langle\sigma v\rangle$ reactions per second per (mole cm^{-3}) where $N_A=6.022\times10^{23}$ mole^{-1} is Avogadro's number and $\langle\sigma v\rangle$ is the Maxwell-Boltzmann average as a function of temperature for the product of the reaction cross section, σ, in cm^2, and the relative velocity of the reactants, v in cm sec^{-1}. Multiplication of $\langle\sigma v\rangle$ by the product of the number densities per cm^3 of the two reactants is necessary to obtain rates in reactions per second per cm^3. N_A is incorporated so that mass fractions can be used, as described in detail by *Fowler, Caughlan,* and *Zimmerman*[21]. These authors also describe procedures for reactions involving more than two reactants and give analytical expressions for reactions mainly involving γ, e, n, p, and α with nuclei having atomic mass number $A\leq30$. Bose-Einstein statistics

for γ have been necessarily incorporated, but the extension to Fermi-Dirac statistics for degenerate e, n, and p and the extension to Bose-Einstein statistics for α are not included. Factors for calculating reverse reaction rates are given.

Early work on the evaluation of stellar reaction rates from experimental laboratory cross sections was reviewed in *Bethe*'s Nobel Lecture[11]. *Fowler, Caughlan,* and *Zimmerman*[21] have provided detailed numerical and analytical procedures for converting laboratory cross sections into stellar reaction rates. It is first of all necessary to accommodate the rapid variation of the nuclear cross sections at low energies, which are relevant in astrophysical circumstances. For neutron-induced reactions this is accomplished by defining a cross section S-factor equal to the cross section (σ) multiplied by the interaction velocity (v) in order to eliminate the usual v^{-1} singularity in the cross section at low velocities and low energies.

For reactions induced by charged particles such as protons, alpha particles, or the heavier ^{12}C, ^{16}O ... nuclei, it is necessary to accommodate the decrease by many orders of magnitude from the lowest laboratory measurements to the energies of astrophysical relevance. This is done in the way first suggested by *E. E. Salpeter*[22] and emphasized by *Bethe* in 1967[11].

Table 1. Definition of the S-Factor (*Bethe* 1967 [11]) as a function of reaction energy E.

$\sigma(E) = \pi\lambda^2 \times P \times$ intrinsic nuclear factor
$\pi\lambda^2 \propto E^{-1}$ (λ = de Broglie wavelength/2π
$P(E)$ = Gamow penetration factor
$\propto \exp(-E_G^{1/2}/E^{1/2})$; $E_G \approx Z_0^2 Z_1^2 A$ [MeV]
$\Rightarrow S(E) \equiv E\sigma(E)\exp(+E_G^{1/2}/E^{1/2})$
$S(E)$ { permits more precise extrapolation from lowest energy measurements in laboratory to very low effective stellar energies

Table 1 shows how a relatively slowly varying S-factor can be defined by eliminating the rapidly varying term in the Gamow penetration factor governing transmission through the Coulomb barrier. The cross section is usually expressed in barns (10^{-24} cm^2) and the energy in MeV (1.602×10^{-6} erg), so that the S-factor is expressed in MeV-barns, although keV-barns is sometimes used. In Table 1 the two charge numbers and the reduced mass in atomic mass units of the interacting nuclei are designated by Z_0, Z_1, and A. Table 2 then shows how stellar reaction rates can be calculated as an average over the Maxwell-Boltzmann distribution for both nonresonant and resonant cross sections. In Table 2 the effective stellar reaction energy is given numerically by $E_0 = 0.122(Z_0^2 Z_1^2 A)^{1/3} T_9^{2/3}$ MeV, where T_9 is the temperature in units of 10^9 K. Expressions for reaction rates derived from theoretical statistical model calculations are given by *Woosley, Fowler, Holmes,* and *Zimmerman*[23].

It is true that the extrapolation from the cross sections measured at the lowest laboratory energies to the cross sections at the effective stellar energy can often involve a decrease of many orders of magnitude. However, the elimination of the Gamov penetration factor, which causes this decrease, is based on the solution of the Schroedinger equation for the Coulomb wave functions in which one can have considerable confidence. The main uncertainty lies in the variation of the S-factor with energy, which depends primarily on the value chosen for the radius at which formation of a compound nucleus between two interacting nuclei or nucleons occurs, as discussed long ago in [18]. The radii used by my colleagues and I in recent work are given in [23]. There is, in addition, the uncertainty in the *intrinsic nuclear factor* of Table 1, which can only be eliminated by recourse to laboratory experiments. The effect of a resonance in the compound nucleus just below or just above the threshold for a given reaction can often be ascertained by determination of the properties of the resonance in other reactions in which it is involved and which are easier to study.

Table 2. Stellar reaction rates as functions of temperature (T).

$\langle\sigma v\rangle_{MB} = f(T) \propto T^{-3/2} \int S(E) \exp(-E_G^{1/2}/E_{1/2} - E/kT)\,dE$
MB ≡ average over Maxwell-Boltzmann distribution maximum in integrand occurs at E_r and at
E_0 ≡ effective stellar reaction energy $\propto E_G^{1/3} T^{2/3}$

Nonresonant rate
$\langle\sigma v\rangle_{nr} \propto S(E_0) T^{-2/3} \exp(-3E_0/kT)$; $E_0/kT \propto T^{-1/3}$

Resonant rate
$\langle\sigma v\rangle_r \propto S(E_r) T^{-3/2} \exp(-E_r/kT)$
E_r = energy at resonance

IV. Hydrogen Burning in Main Sequence Stars and the Solar Neutrino Problem

Hydrogen burning in Main Sequence stars has contributed at the present time only about 20 percent more helium than that which resulted from the big bang. However, hydrogen burning in the sun has posed a problem for many years. In 1938, *Bethe* and *Critchfield*[24] proposed the proton-proton or *pp*-chain as one mechanism for hydrogen burning in stars. From many cross section measurements at Kellogg and elsewhere, it is now known to be this mechanism, rather than the CNO-cycle, which operates in the sun.

Our knowledge of the weak nuclear interaction (beta decay, neutrino emission, and absorption, etc.) tells us that two neutrinos are emitted when four hydrogen nuclei are converted into helium nuclei. Detailed elaboration of the pp-chain by *Fowler*[25] and *Cameron*[26] showed that a small fraction of these neutrinos, those from the decay of ^7Be and ^8B, should be energetic enough to be detectable through interaction with the ^{37}Cl nucleus to form radioactive ^{37}Ar, a method of neutrino detection suggested by *Pontecorvo*[27] and *Alvarez*[28]. *Raymond Davis* and his collaborators[29] have attempted for more than 25 years to detect these energetic neutrinos employing a 380000 L tank of perchloroethylene ($C_2{}^{35}Cl_3{}^{37}Cl_1$) located one mile deep in the Homestake Gold Mine in Lead, South Dakota. They find only about one quarter of the number expected on the basis of the model-dependent calculations of *Bahcall* et al.[30].

Something is wrong — either the standard solar models are incorrect, the relevant nuclear cross sections are in error, or the electron-type neutrinos produced in the sun are converted in part into undetectable muon neutrinos or taon neutrinos on the way from the sun to the earth. There have indeed been controversies about the nuclear cross sections, which for the most part, however, have been resolved, as reviewed in *Robertson* et al., *Osborne* et al.[31], and *Skelton* and *Kavanagh*[32].

It is generally agreed that the next step is to build a detector which will detect the much larger flux of low energy neutrinos from the sun through neutrino absorption by the nucleus ^{71}Ga to form radioactive ^{71}Ge. This will require 30 to 50 tons of gallium at a cost (for 50 tons) of approximately 25 million dollars. An international effort is being made to obtain the necessary amount of gallium. We are back at square one in Nuclear Astrophysics. Until the solar neutrino problem is resolved, the basic principles underlying the operation of nuclear processes in stars are in question. A gallium detector should go a long way toward resolving the problem.

The chlorine detector must be maintained in low level operation until the chlorine and gallium detectors can be operated at full level simultaneously. Otherwise, endless conjecture concerning time variations in the solar neutrino flux will ensue. Moreover, the results of the gallium observations may uncover information that has been overlooked in the past chlorine observations.

The CNO-cycle operates at the higher temperatures which occur during hydrogen burning in Main Sequence stars somewhat more massive than the sun. This is the case, because the CNO-cycle reaction rates rise more rapidly with temperature than those of the *pp*-chain. The cycle is important because ^{13}C, ^{14}N, ^{15}N, ^{17}O, and ^{18}O are produced from ^{12}C and ^{16}O as seeds. The role of these nuclei as sources of neutrons during helium burning is discussed in Section V.

V. The Synthesis of ^{12}C and ^{16}O and Neutron Production in Helium Burning

The human body is 65% by mass oxygen and 18% carbon, with the remainder mostly hydrogen. Oxygen (0.85%) and carbon (0.39%) are the most abundant elements heavier than helium in the Sun and similar Main Sequence stars. It is little wonder that the determination of the ratio ^{12}C/^{16}O produced in helium burning is a problem of paramount importance in Nuclear Astrophysics. This ratio depends in a fairly complicated manner on the density, temperature, and duration of helium burning, but depends directly on the relative rates of the $3\alpha \rightarrow {}^{12}$C process and the ^{12}C$(\alpha,\gamma)^{16}$O process. If $3\alpha \rightarrow {}^{12}$C is much faster than ^{12}C$(\alpha,\gamma)^{16}$O, no ^{16}O is produced in helium burning. If the reverse is true, no ^{12}C is produced. For the most part, the subsequent reaction ^{16}O$(\alpha,\gamma)^{20}$Ne is slow enough to be neglected.

There is general agreement about the rate of the $3\alpha \rightarrow {}^{12}$C process, as reviewed by *Barnes*[33]. However, there is a lively controversy at the present time about the laboratory cross section for ^{12}C$(\alpha,\gamma)^{16}$O and about its theoretical extrapolation to the low energies at which the reaction effectively operates. The situation is depicted in Figures 4, 5, and 6, taken with some modification from *Laganke* and *Koonin*[34], *Dyer* and *Barnes*[35], and *Kettner* et al.[36]. The Caltech data obtained at the Kellogg Laboratory is shown as the experimental points in Figure 4, taken from *Dyer* and *Barnes*[35], who compared their results with theoretical calculations by *Koonin, Tombrello,* and *Fox*[35]. The Münster data are shown as the experimental points in Figure 5, taken from *Kettner* et al.[36], in comparison with the data of *Dyer* and *Barnes*[35]. The theoretical curves which yield the best fit to the two sets of data are those of *Laganke* and *Koonin*[34].

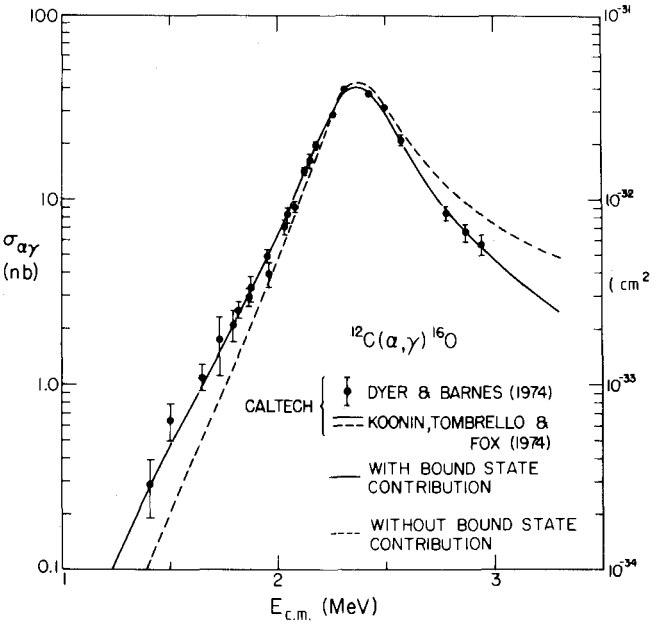

Fig. 4. The cross section σ in nanobarns (nb) versus center-of-momentum energy in MeV for ^{12}C$(\alpha,\gamma)^{16}$O, measured by *Dyer* and *Barnes* [35] and compared with theoretical calculations by *Koonin, Tombrello,* and *Fox* (see [35]).

The crux of the situation is made evident in Figure 6, which shows the extrapolations of the Caltech and Münster cross section factors from the lowest measured laboratory energies (≈ 1.4 MeV) to the effective energy ≈ 0.3 MeV, at $T = 1.8 \times 10^8$ K, a representative temperature for helium burning in Red Giant stars. The extrapolation in cross sections covers a range of 10^{-8}! The rise in the cross section factor is due to the contributions of two bound states in the ^{16}O nucleus just below the ^{12}C$(\alpha,\gamma)^{16}$O threshold, as clearly indicated in Figure 4. It is these contributions plus differences in the laboratory data which produce the current uncertainty in the extrapolated *S*-factor. Note that *Laganke* and *Koonin*[34] increase the 1975 extrapolation of the Caltech data by *Fowler, Caughlan,* and *Zimmerman*[21] by a factor of 2.7 and lower the 1982 extrapolation of the Münster data by 23%. There remains a factor of 1.6 between their extrapolation of the Münster data and of the Caltech data. There is a lesson in all of this. The semiempirical extrapolation of their data by the experimentalists *Dyer* and *Barnes*[35] was only 30% lower than that of *Laganke* and *Koonin*[34] and their quoted uncertainty ex-

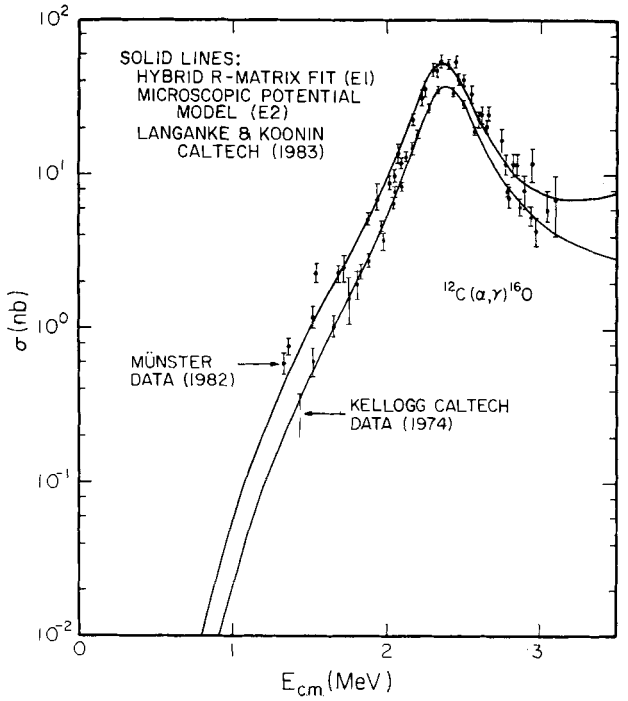

Fig. 5. The cross section σ in nanobarns (nb) versus center-of-momentum energy in MeV for $^{12}C(\alpha,\gamma)^{16}O$. The Münster data was obtained by *Kettner* et al. [36] and the Kellogg Caltech data, by *Dyer* und *Barnes* [35]. The solid lines are theoretical calculations made by *Laganke* and *Koonin* [34].

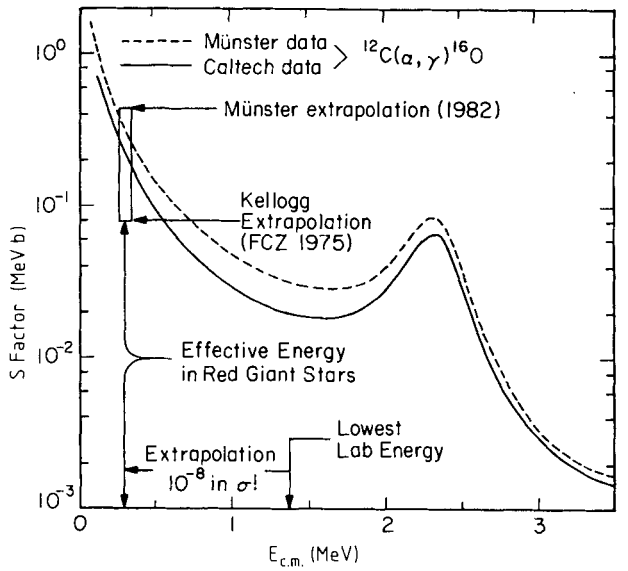

Fig. 6. The cross section factor S in MeVb versus center-of-momentum energy in MeV for $^{12}C(\alpha,\gamma)^{16}O$. The dashed and solid curves are the theoretical extrapolations of the Münster and Kellogg Caltech data by *Laganke* and *Koonin*, respectively [34].

tended to the value of *Laganke* and *Koonin*[34]. *Caughlan* et al.[21] will tabulate the analysis of the Caltech data by *Laganke* and *Koonin*[34].

With so much riding on the outcome, it will come as no surprise that both laboratories are engaged in extending their measurements to lower energies with higher precision. In the discussion of quasistatic silicon burning in what follows, it will be found that the abundances produced in that stage of nucleosynthesis depend, in part, on the ratio of ^{12}C to ^{16}O produced in helium burning, and that the different extrapolations shown in Figure 6 are in the range crucial to the ultimate outcome of silicon burning. These remarks do not apply to explosive nucleosynthesis.

Recently, the ratio of ^{12}C to ^{16}O produced under the special conditions of helium flashes during the asymptotic giant phase of stellar evolution has become of great interest. The hot blue star PG 1159-035 has been found to undergo nonradial pulsations with periods of 460 and 540 seconds and others not yet accurately determined. The star is obviously highly evolved, having lost its hydrogen atmosphere and leaving only a hot-dwarf of about 0.6 solar masses behind. Theoretical analysis of the pulsations by *Starrfield* et al. and *Becker*[37] requires substantial amounts of oxygen in the pulsation-driving regions where the oxygen is alternately ionized and deionized. Carbon is completely ionized in these regions and only diminishes the pulsation amplitude. It is not yet clear that sufficient oxygen is produced in helium flashes, which certainly involve $3\alpha \rightarrow {}^{12}C$, but may not last long enough for $^{12}C(\alpha,\gamma)^{16}O$ to be involved. The problem may not lie in the nuclear reaction rates according to [37]. We shall see!

In what follows in this paper, β^+-decay is designated by $(e^+\nu)$ since both a positron (e^+) and a neutrino (ν) are *emitted*. Similarly, β^--decay is designated by $(e^-\bar{\nu})$ since both an electron (e^-) and antineutrino $(\bar{\nu})$ are *emitted*. Electron capture (often indicated by ε) is designated by (e^-,ν), the comma indicating that an electron is captured and a neutrino emitted. The notations $(e^+,\bar{\nu})$, (ν,e^-) and $(\bar{\nu},e^+)$ should now be obvious.

Neutrons are produced when helium burning occurs under circumstances in which the CNO-cycle has been operative in the previous hydrogen burning. When the cycle does not go to completion, copious quantities of ^{13}C are produced in the sequence of nuclear reactions $^{12}C(p,\gamma)^{13}N(e^+\nu)^{13}C$. In subsequent helium burning, neutrons are produced by $^{13}C(\alpha,n)^{16}O$. When the cycle goes to completion, the main product (>95%) is ^{14}N. In subsequent helium burning, ^{18}O and ^{22}Ne are produced in the sequence of reactions $^{14}N(\alpha,\gamma)^{18}F(e^+\nu)^{18}O(\alpha,\gamma)^{22}Ne$, and these nuclei in turn produce neutrons through $^{18}O(\alpha,n)^{21}Ne(\alpha,n)^{24}Mg$ and $^{22}Ne(\alpha,n)^{25}Mg$. However, the astrophysical circumstances and sites under which the neutrons produce heavy elements through the *s*-process and the *r*-process are, even today, matters of some controversy and much study (see Section XI).

VI. Carbon, Neon, Oxygen, and Silicon Burning

The advanced burning processes discussed in this section involve the network of reactions shown in Figure 7. Because of the high temperature at which this network can operate, radioactive nuclei can live long enough to serve as live reaction targets. In addition, excited states of even the stable nuclei are populated and also serve as targets. The determination of the nuclear cross sections and stellar rates of the approximately 1000 reactions in the network has involved and will continue to involve extensive experimental and theoretical effort.

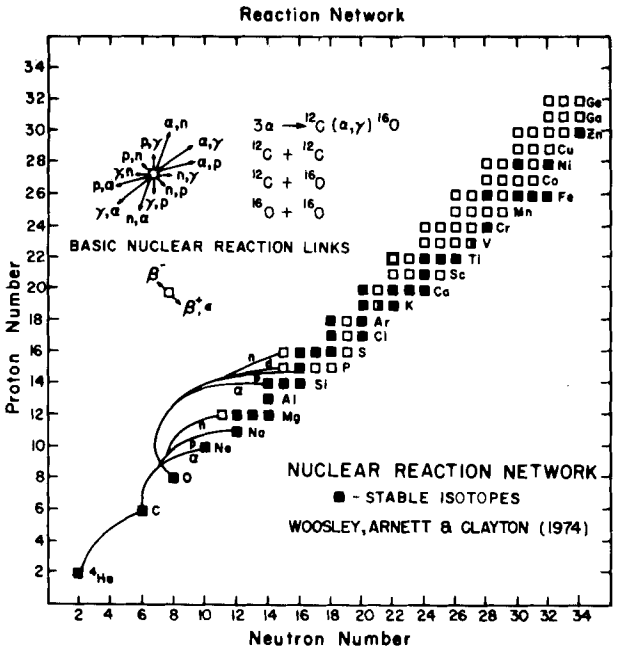

Fig. 7. The reaction network for nucleosynthesis involving the most important stable and radioactive nuclei with $N=2$ to 34 and $Z=2$ to 32. Stable nuclei are indicated by solid squares. Radioactive nuclei are indicated by open squares.

The following discussion applies to stars so massive enough that electron degeneracy does not set in as nuclear evolution proceeds through the various burning stages mentioned in this section. In less massive stars, electron degeneracy can terminate further nuclear evolution at certain stages, with catastrophic results leading to the disruption of the stellar system. The reader will find Figure 8, especially Figure 8a, instructive in following the discussion in this section. Figure 8 is taken from *Woosley* and *Weaver*[38], and a much more detailed recent version is shown in Figure 9, from *Weaver, Woosley,* and *Fuller*[39]. Figure 8a applies to the preexplosive stage of a young (Population I) star of 25 solar masses and shows the result of various nuclear burnings in the following mass zones: 1) $>10\,M_\odot$, convective envelope with the results of some CNO-burning; 2) $7-10\,M_\odot$, products mainly of H-burning; 3) $6.5-7\,M_\odot$, products of He-burning; 4) $1.9-6.5\,M_\odot$ products of C-burning; 5) $1.8-1.9\,M_\odot$, products of Ne-burning; 6) $1.5-1.8\,M_\odot$, products of O-burning; 7) $<1.5\,M_\odot$, the products of Si-burning in the partially neutronized core are not shown in detail but consist mainly of ^{54}Fe as well as substantial amounts of other neutron-rich nuclei such as ^{48}Ca, ^{50}Ti, ^{54}Cr and ^{58}Fe. ^{54}Fe, ^{48}Ca and ^{50}Ti have $N=28$, for which a neutron subshell is closed. Both Figures 8a and 8b have been evaluated shortly after photodisintegration has initiated core collapse, which will then be subsequently sustained by the reduction of the outward pressure through electron-capture and the resulting almost complete neutronization of the core.

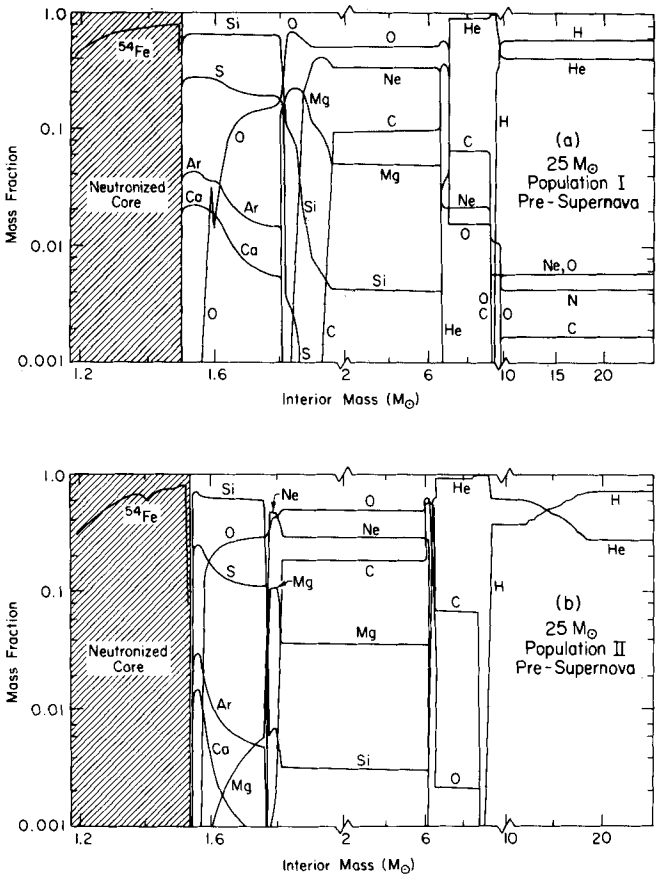

Fig. 8. Pre-supernova abundances by mass fraction versus increasing interior mass in solar masses $M_\odot$, measured from zero at the stellar center to $25\,M_\odot$, the total stellar mass from *Woosley* and *Weaver* [38]. a) (above) Population I star. b) (below) Population II star.

It must be realized that the various burning stages took place originally over the central regions of the star and finally in a shell surrounding that region. Subsequent stages modify the inner part of the previous burning stage. For example, in the 25 solar mass Population I star of Figure 8a, C-burning took place in the central 6.5 solar masses of the star, but the inner 1.9 solar masses were modified by subsequent Ne-, O-, and Si-burning.

Helium burning produces a stellar core consisting mainly of ^{12}C and ^{16}O. After core contraction, the temperature and density rise until carbon burning through $^{12}C+{}^{12}C$ fusion is ignited. The S-factor for the total reaction rate shown in Figure 10 has been taken from page 213 of [33] and is based on measurements in a number of laboratories. The extrapolation to the low energies of astrophysical relevance is uncertain, as Figure 10 makes clear, and more experimental and theoretical studies are urgently needed. At the lowest bombarding energy, 2.4 MeV, the cross section is ca. 10^{-8} barns. For a representative burning temperature of 6×10^8 K, the effective energy is $E_0=1.7$ MeV, and the extrapolated cross section is ca. 10^{-13} barns. The main product of carbon burning is ^{20}Ne produced primarily in the $^{12}C(^{12}C,\alpha)^{20}Ne$ reaction. The reactions $^{12}C(^{12}C,p)^{23}Na$ and $^{12}C(^{12}C,n)^{23}Mg(e^+\nu)^{23}Na$ also occur, as well as many secondary reactions such as $^{23}Na(p,\alpha)^{20}Ne$. When the ^{12}C is exhausted, ^{20}Ne and ^{16}O are the major remaining constituents. As the temperature rises, from further gravitational contraction, the ^{20}Ne is destroyed by photodisintegration, $^{20}Ne(\gamma,\alpha)^{16}O$. This occurs because the alpha-particle in ^{20}Ne is bound to its closed-shell partner, ^{16}O, by only 4.731 MeV. In ^{16}O, for example, the binding of an alpha-particle is 7.162 MeV.

The next stage is oxygen burning through $^{16}O+{}^{16}O$ fusion. The S-factor for the total reaction rate is shown in Figure 11 and is based entirely on data obtained in the Kellogg Laboratory at Caltech. The work of *Hulke, Rolfs,*

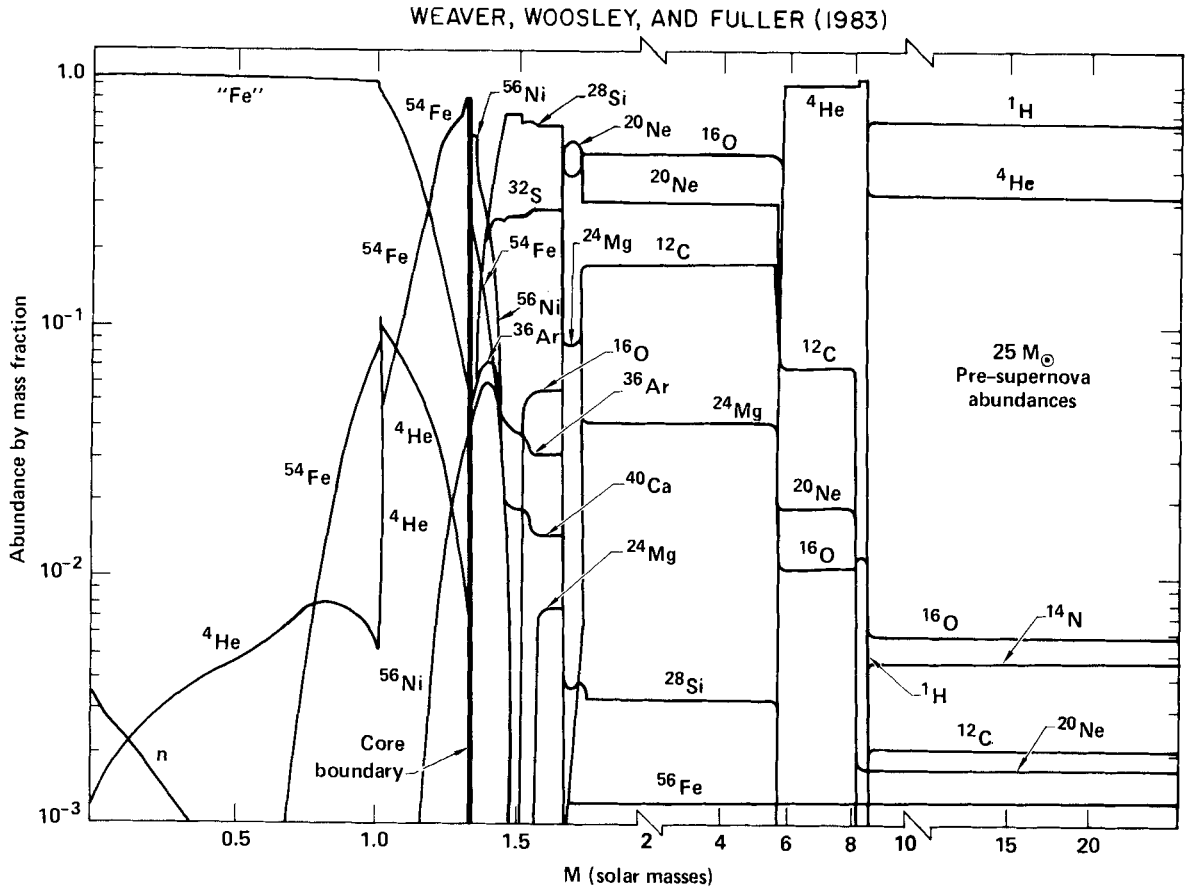

Fig. 9. Pre-supernova abundances by mass fraction versus increasing interior mass for a Population I star with total mass equal to 25 $M_\odot$ (from *Weaver, Woosley,* and *Fuller* [39]).

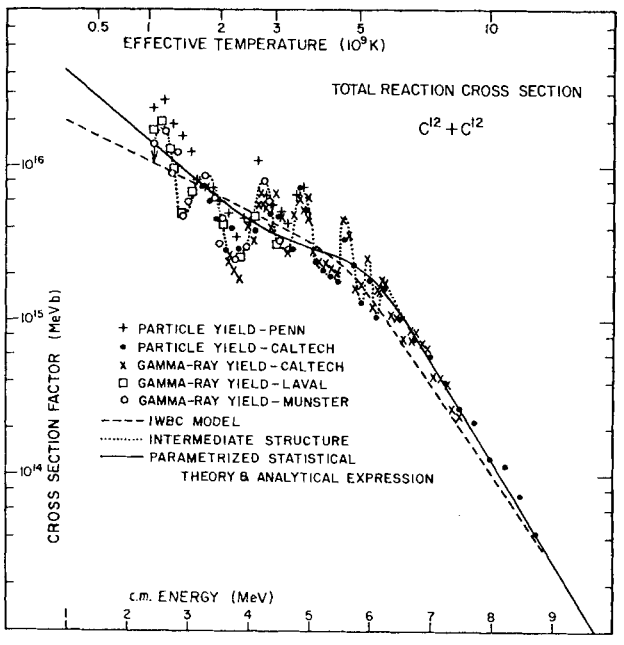

Fig. 10. The total cross-section factor in MeVb versus center-of-momentum energy in MeV for the fusion of ^{12}C and ^{12}C. The experimental data from several laboratories are shown along with schematic intermediate structure in the dotted curve. Two parametrized adjustments to the data, ignoring intermediate structure, are shown in the dashed and solid curves.

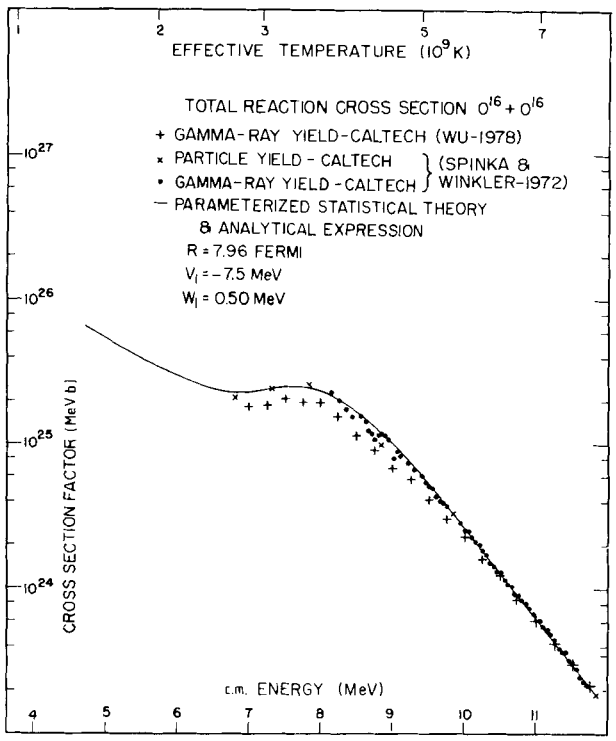

Fig. 11. The total cross-section factor in MeVb versus center-of-momentum energy in MeV for the fusion of ^{16}O + ^{16}O. The experimental data from several measurements at Caltech are shown and compared with a parametrized theoretical adjustment in the solid curve.

and *Trautvetter*[40] using gamma-ray detection is in fair agreement with the gamma-ray measurements at Caltech. As in the case of $^{12}C + ^{12}C$, the extrapolation to the low energies of astrophysical relevance is uncertain, although only one of many possible extrapolations is shown in Figure 11. The main product of oxygen burning is ^{28}Si through the primary reaction $^{16}O(^{16}O,\alpha)^{28}Si$ and a number of secondary reactions. Under some conditions, neutron-induced reactions lead to the synthesis of significant quantities of ^{30}Si. Oxygen burning can result in nuclei with a small but important excess of neutrons over protons.

The onset of Si-burning signals a marked change in the nature of the *fusion process*. The Coulomb barrier between two ^{28}Si nuclei is too great for fusion to produce the compound nucleus ^{56}Ni directly at the ambient temperatures ($T_9 = 3$ to 5) and densities ($\rho = 10^5$ to 10^9 g cm^{-3}). However, the ^{28}Si and subsequent products are easily photodisintegrated by (γ,α), (γ,n) and (γ,p)-reactions. As Si-burning proceeds, more and more ^{28}Si is reduced to nucleons and alpha particles, which can be captured by the remaining ^{28}Si nuclei to build through the network in Figure 7 up to the iron group nuclei. The main product in explosive Si-burning is ^{56}Ni, which transforms eventually through two beta-decays to ^{56}Fe.

In quasistatic Si-burning, the weak interactions are so fast enough that ^{54}Fe, with two more neutrons than protons, is the main product. Because of the important role played by alpha particles (α) and the inexorable trend to equilibrium (e) involving nuclei near mass 56, which have the largest binding energies per nucleon of all nuclear species, B^2FH[18] broke down what is now called Si-burning into an α-process and an e-process. Quasi-equilibrium calculations for Si-burning were made by *Bodansky, Clayton,* and *Fowler*[41], who cite the original papers in which the basic ideas of Si-burning were developed. Modern computers permit detailed network flow calculations to be made, as discussed in references [38] and [39].

The extensive laboratory studies of Si-burning reactions are reviewed in [33]. Figures 12 and 13, adapted from *Zyskind* et al.[42], show the laboratory excitation curves for $^{54}Cr(p,n)^{54}Mn$ and $^{54}Cr(p,\gamma)^{55}Mn$ as examples. The neutrons produced in the first of these reactions will increase the number of neutrons available in Si-burning, but will not contribute directly to the synthesis of ^{55}Mn as does the second reaction. In fact, above its threshold at 2.158 MeV the (p,n)-reaction competes strongly with the (p,γ)-reaction, which is of primary interest, and produces the pronounced *competition cusp* in the excitation curve in Figure 13. Competition in the disintegration of the compound nucleus produced in nuclear reactions was stressed very early by *Niels Bohr*, so perhaps the cusps should be called *Bohr cusps*. They arise from the same basic cause but are not the long known *Wigner cusps*. It will be clear from Figure 13 that the rate of the $^{54}Cr(p,\gamma)^{55}Mn$ reaction at very high temperature will be an order of magnitude lower, because of the cusp, than would otherwise be the case.

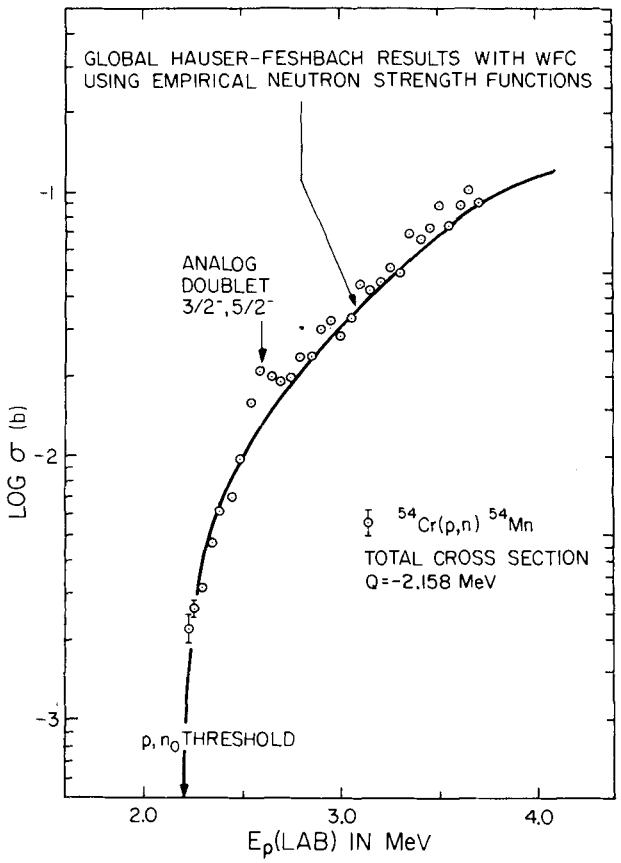

Fig. 12. The total cross section in barns integrated over all outgoing angles versus laboratory proton energy in MeV for the reaction $^{54}Cr(p,n)^{54}Mn$. The data of *Zyskind* et al. [42] are compared with unnormalized global Hauser-Feshbach calculations made by *Woosley* et al. [23].

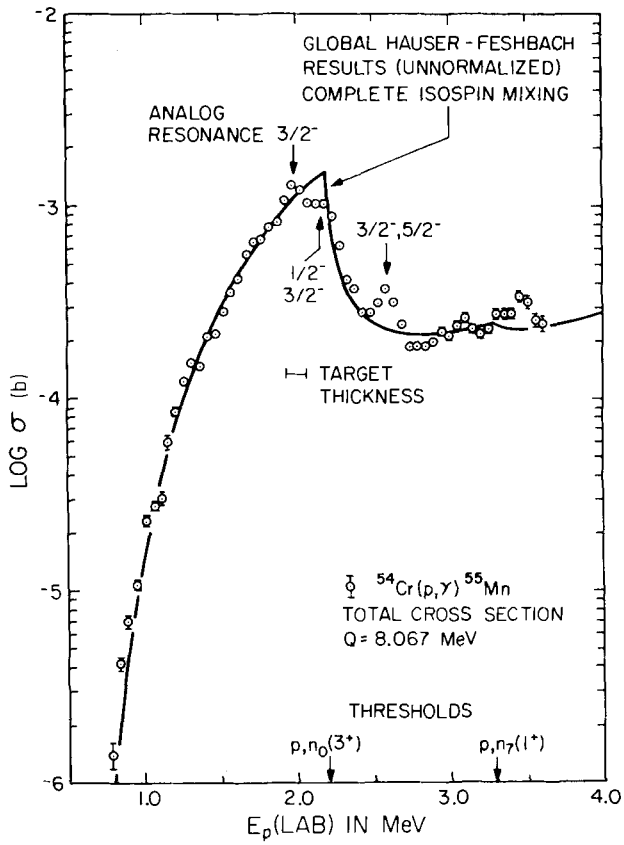

Fig. 13. The total cross section in barns integrated over all outgoing angles versus laboratory proton energy in MeV for the reaction $^{54}Cr(p,\gamma)^{55}Mn$. The data of *Zyskind* et al. [42] are compared with unnormalized global Hauser-Feshbach calculations made by *Woosley* et al. [23].

The element manganese has only one isotope, ^{55}Mn. The manganese in nature is produced in quasistatic Si-burning, most probably through the ^{54}Cr$(p,\gamma)^{55}$Mn-reaction discussed in the previous paragraph. The reaction network extends to ^{54}Cr and then on through ^{55}Mn. ^{51}V$(\alpha,\gamma)^{55}$Mn and ^{52}V$(\alpha,n)^{55}$Mn may also contribute, especially in explosive Si-burning. The overall synthesis of ^{55}Mn involves a balance in its production and destruction. In quasistatic Si-burning, the reactions which destroy ^{55}Mn are most probably ^{55}Mn$(p,\gamma)^{56}$Fe and ^{55}Mn$(p,n)^{55}$Fe, which are discussed and illustrated by *Mitchell* and *Sargood*[43]. ^{55}Mn$(\alpha,\gamma)^{59}$Co, ^{55}Mn$(\alpha,p)^{58}$Fe, and ^{55}Mn$(\alpha,n)^{58}$Co may also destroy some ^{55}Mn in explosive Si-burning. In the figures discussed in Section VIII, it will be noted that calculations of the overall synthesis of ^{55}Mn yield values in fairly close agreement with the abundance of this nucleus in the solar system. Unfortunately, the same can not be said about many other nuclei.

The laboratory measurements on Si-burning reactions have covered only about 20% of the reactions in the network of Figure 7 involving stable nuclei as targets. Direct measurements on short-lived radioactive nuclei and the excited states of all nuclei are impossible at the present time. In this connection, the production of radioactive ion-beams holds great promise for the future. *Richard Boyd* and *Haight* et al.[44] have pioneered the development of this technique.

Figures 14 and 15 show the beam transport system developed by *Haight* et al.[44], which has produced accelerated beams of ^{7}Be and ^{13}N and successfully determined the cross section of the reaction ^{2}H(^{7}Be,^{8}B)n to be 59 ± 11 mb for 16.9 MeV ^{7}Be-ions. The equivalent center-of-momentum energy for the ^{7}Be$(d,n)^{8}$B reaction is 3.8 MeV. It is my view that continued development and application of radioactive ion-beam techniques could bring the most exciting results in laboratory Nuclear Astrophysics in the next decade. For example, the rate of the ^{13}N$(p,\gamma)^{14}$O reaction, which will be studied as ^{1}H(^{13}N,γ)^{14}O, is crucial to the operation of the so-called fast CN-cycle.

In any case it has been clear for some time that experimental results on Si-burning reactions must be systematized and supplemented by comprehensive theory. Fortunately, theoretical average cross sections suffice in many cases. This is because the stellar reaction rates integrate the cross sections over the Maxwell-Boltzmann distribution. For most Si-burning reactions resonances in the cross section are closely spaced and even overlapping, and the integration covers a wide enough range of energies that the detailed structure in the cross sections is automatically averaged out. The statistical model of nuclear reactions developed by *Hauser* and *Feshbach*[45], which yields average cross sections, is ideal for the purpose. Accordingly, *Holmes, Woosley, Fowler,* and *Zimmerman*[46] undertook the task of developing a *global, parametrized* Hauser-Feshbach theory and computer program for use in Nuclear Astrophysics. An extension of this work is reported in [23]. The free parameters are the radius, depth, and compensating reflection factor of the black-body, square-well equivalent of the Woods-Saxon potential characteristic of the interaction between n, p, and α with nuclei having $Z \geq 8$. Two free-parameters must also be incorporated to adjust the intensity of electric and magnetic dipole transitions for gamma radiation. Weak interaction rates must also be specified, and ways of doing this will be discussed later in Section VII.

The parameters originally chosen for N, p, and α-reactions were taken from earlier work of *Michaud* and *Fowl-*

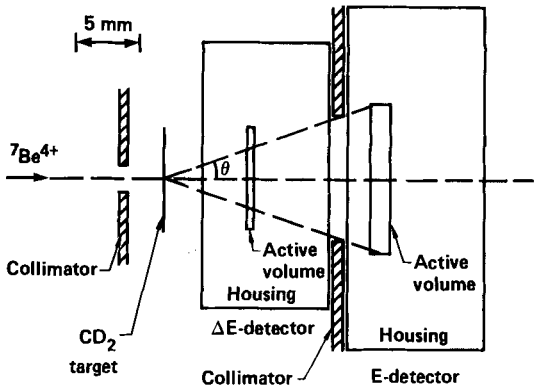

Fig. 15. Detail of the target and detector in the radioactive beam transport system developed by *Haight* et al. [44].

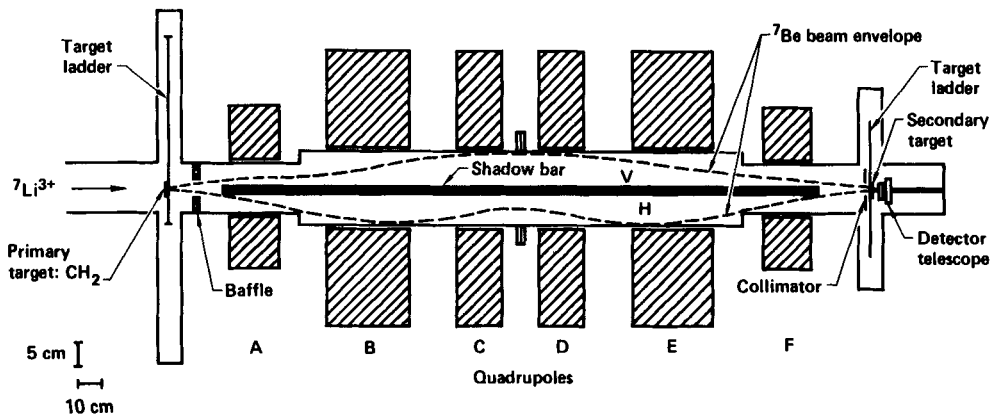

Fig. 14. Radioactive beam transport system developed by *Haight* et al. [44].

er[47], who depended heavily on studies by *Vogt* (see [47]). These parameters and those chosen for electromagnetic and weak interactions have survived comparison of the theory with a plethora of laboratory measurements. More sophisticated programs have been developed which use experimental neutron strength functions instead of that from the equivalent square well or which use realistic Woods-Saxon potentials for all interactions, as done by *Mann*[48]. In addition, marked improvement in the correspondence between theory and experiment is found when width-fluctuation corrections are made, as described in *Zyskind* et al.[49].

It is well known that the free parameters can always be adjusted to fit the cross sections and reaction rates of any one particular nuclear reaction. This is not done in a *global* program. The parameters are, in principle, determined by the best least-squares fit to all reactions for which experimental results are available. For example, see the figure on p. 307 of [46]. It is on this basis that some confidence can be had in predictions in those cases where experimental results are unavailable.

The original program[23,46] has produced reaction rates, either in numerical or analytical form, as a function of temperature. Ready comparison with integrations of laboratory cross sections for target ground states are possible. Using the same *global* parameters which apply to reactions involving the ground states of stable nuclei, the theoretical program calculates rates for the ground states of radioactive nuclei and for the excited states of both stable and radioactive nuclei. Summing over the statistically weighted contributions of the ground and known excited states or theoretical level density functions, we obtain the stellar reaction rate for the equilibrated statistical population of the nuclear states. After summing, division by the partition function of the target nucleus is necessary. Analytical parametrized expressions for the partition functions of nuclei with $8 \leq Z \leq 36$ are given in Table II A of [23] as a function of temperature over the range $0 \leq T \leq 10^{10}$ K.

Sargood[50] has compared experimental results from a number of laboratories for protons and alpha particles reacting with 80 target nuclei, which are, of course, in their ground states, with the theoretical predictions made in [23]. Ratios of statistical model calculations to laboratory measurements for 12 cases are shown in Table 3 for temperatures in the range 1 to 5×10^9 K. The double entry for $^{27}Al(p,n)^{27}Si$ signifies ratios of theory to measurements made in two different laboratories. It is fair to note that the theoretical calculations match the experimental results within 50% with a few marked exceptions. In American vernacular "You win some and you lose some". For the rather light targets in Table 3, especially at low temperature, the global mean rates can be in error whenever more and stronger resonances or fewer and weaker resonances than expected on average occur in the excitation curve of the reaction at low energies.

Sargood[50] has also compared the ratio of the stellar rate of a reaction with target nuclei in a thermal distribution of ground and excited states with the rate for all target nuclei in their ground state. The latter is of course determined from laboratory measurements. A number of cases are tabulated for $T = 5 \times 10^9$ K in Table 4. In many cases, notably

Table 3. Statistical model calculations versus measurements: Ratio of reaction rate (ground state of target) from *Woosley, Fowler, Holmes,* and *Zimmerman* [23] to reaction rates from experimental yield measurements (1970–1982) at Bombay, Caltech, Colorado, Kentucky, Melbourne, and Toronto.

for reactions producing gamma rays, the ratio of stellar to laboratory rates is close to unity. In other cases the ratios can be high by several orders of magnitude. This can occur for a number of reasons. It frequently occurs when the ground state can interact only through partial waves of high angular momentum resulting in small penetration factors and thus small cross sections and rates. This makes clear a basic assumption in the prediction of stellar rates: a statistical theory which works well predicting ground state results is assumed to do equally well in predicting excited state results. This assumption is frequently not valid. *Bahcall* and *Fowler*[51] have shown that in a few cases laboratory measurements on inelastic scattering involving excited states can be used indirectly to determine reaction cross sections for those states.

Ward and *Fowler*[52] have investigated in detail the circumstances under which long-lived isomeric states do not come into equilibrium with ground states. When this occurs it is necessary to incorporate into network calculations the stellar rates for both the isomeric and ground state. An example of great interest is the nucleus ^{26}Al. The ground state has spin and parity, $J^{\pi}=5^{+}$, and isospin $T=0$, and has a mean lifetime for positron emission to ^{26}Mg of 10^6 years. The isomeric state at 0.228 MeV has $J^{\pi}=0^{+}$, $T=1$ and mean lifetime of 9.2 seconds. *Ward* and *Fowler*[52] show that the isomeric state effectively does not come into equilibrium with the ground state for $T<4\times10^8$ K. At these low temperatures, both the isomeric state and the ground state of ^{26}Al must be included in the network of Figure 7.

VII. Astrophysical Weak-Interaction Rates

Weak nuclear interactions play an important role in astrophysical processes in conjunction with the strong nuclear interactions, as indicated in Figure 7. Only through the weak interaction can the overall proton number and neutron number of nuclear matter change during stellar evolution, collapse, and explosion. The formation of a neutron star requires that protons in ordinary stellar matter capture electrons. Gravitational collapse of a Type II supernova core is retarded as long as electrons remain to exert outward pressure.

Many years of theoretical and experimental work on weak-interaction rates in the Kellogg Laboratory and elsewhere have culminated in the calculation and tabulation by *Fuller, Fowler,* and *Newman*[53] of electron and positron emission rates and continuum electron and positron capture rates, as well as the associated neutrino energy loss rates for free nucleons and 226 nuclei with mass numbers between $A=21$ and 60. Extension to higher and lower values for A is now underway.

These calculations depended heavily on experimental determinations in Kellogg by *Wilson, Kavanagh,* and *Mann*[54] of Gamow-Teller elements for 87 discrete transitions in intermediate-mass nuclei. The majority of the experimental matrix elements for both Fermi and Gamow-Teller discrete transitions as well as nuclear level data were taken from the exhaustive tabulation of *Lederer* and *Shirley*[55]. Unmeasured matrix elements for allowed transitions were assigned a mean value as described in the second reference in [53]. These mean values were $|M_F|^2=.062$ and $|M_{GT}|^2=.039$, corresponding to $\log ft=5$, where f is the phase-space factor and t is the half-life for the transition. Nuclear physicists traditionally think in terms of $\log ft$-values in connection with weak interaction rates.

Simple shell model arguments were employed to estimate Gamow-Teller sum rules and collective state resonance excitation energies. These estimates have been shown to be fair approximations for $T^{<}$-nuclei and $T^{>}$-nuclei by recent high resolution measurements on *p,n*-reactions and ^3T,^{3}He-reactions by *Goodman* et al. and *Ajzenberg-Selove* et al., respectively[56]. Here $T^{<}$, with $T\equiv|N-Z|$ represents, for example, ^{56}Fe with $T=2$ in ^{56}Fe$(e^-,\nu)^{56}$Mn or ^{56}Fe$(n,p)^{56}$Mn. Similarly, $T^{>}$ designates ^{56}Mn with $T=3$. The work described in [53] emphasizes the great need for additional results for $T^{>}$-nuclei using the *n,p*-reaction as well as the ^3T,^{3}He-reaction from which matrix elements for electron capture can be obtained.

Moment method shell model calculations of Gamow-Teller strength functions have been performed by *S. D. Bloom* and *G. M. Fuller*[57] with the Lawrence Livermore National Laboratory's vector shell model code for the ground states and first excited states of ^{56}Fe, ^{60}Fe, and ^{64}Fe. These detailed calculations confirm the general trends in Gamow-Teller strength distributions used in the approximations in [53].

The discrete state contribution to the rates, dominated by experimental information on the Fermi transitions, determines the weak nuclear rates in the regime of temperature and densities characteristic of the quasistatic phases of presupernova stellar evolution. At the higher temperatures and densities characteristic of the supernova collapse phase, which is of such great current interest, as discussed in detail in *Brown, Bethe,* and *Baym*[58], the electron-capture rates are dominated by the Gamow-Teller collective resonance contribution.

The detailed nature and the difficulty of the theoretical aspects of the combined atomic, nuclear, plasma, and hydrodynamic physics problems in Type II supernova implosion and explosion were brought home to us by *Hans Bethe* during his stay in our laboratory as a Caltech Fairchild Scholar early in 1982. His visit plus long-distance interaction with his collaborators resulted in the preparation of two seminal papers, *Bethe, Yahil,* and *Brown*[59] and *Bethe, Brown, Cooperstein,* and *Wilson*[60].

Current ideas on the nuclear equation of state predict that early in the collapse of the iron core of a massive star the nuclei present will become so neutron-rich that allowed electron capture on protons in the nuclei is blocked. Allowed electron capture, for which $\Delta l=0$, is not permitted when neutrons have filled the subshells having orbital angular momentum, l, equal to that of the subshells occupied by the protons.

This neutron shell blocking phenomenon, and several unblocking mechanisms operative at high temperature and density, including forbidden electron capture, have been studied in terms of the simple shell model by *Fuller*[61]. Though the unblocking mechanisms are sensitive to details of the equation of state, typical conditions result in a con-

siderable reduction of the electron capture rates on heavy nuclei, leading to significant dependence on electron capture by the small number of free protons and a decrease in the overall neutronization rate.

The results of one-zone collapse calculations carried out by *Fuller*[61] suggest that the effect of neutron shell blocking is to produce a larger core lepton fraction (leptons per baryon) at neutrino trapping. In keeping with the Chandrasekhar relation that core mass is proportional to the square of the lepton fraction, this leads to a larger *final*-core mass and hence a stronger post-bounce shock. On the other hand, the incorporation of the new electron capture rates during precollapse Si-burning reduces the lepton fraction and leads to a smaller *initial*-core mass and thus to a smaller amount of material (*initial*-core mass minus *final*-core mass) in which the post-bounce shock can be dissipated. The dissipation of the shock is thus reduced. This is discussed in detail in [39].

Recent work on the weak interaction has concentrated on making the previously calculated reaction rates as efficient as possible for users of the published tables and the computer tapes, which are made available on request. The stellar weak interaction rates of nuclei are in general very sensitive functions of temperature and density. Their temperature dependence arises from thermal excitation of parent excited states and from the lepton distribution functions in the integrands of the decay and continuum capture phase space factors.

For electron and positron emission, most of the temperature dependence is due to thermal population of parent excited states at all but the lowest temperatures and highest densities. In general, only a few transitions will contribute to these decay rates and hence the variation of the rates with temperature is usually not so large that rates cannot be accurately interpolated in temperature and density with the standard grids provided in [53]. The density dependence of these decay rates is minimal. In the case of electron emission, however, there may be considerable density dependence due to Pauli blocking for electrons where the density is high and the temperature is low. This does not present much of a problem for practical interpolation since the electron-emission rate is usually very small under these conditions.

The temperature and density dependence of continuum electron and positron capture is a much more serious problem. In addition to temperature sensitivity introduced through thermal population of parent excited states, there are considerable effects from the lepton distribution functions in the integrands of the continuum-capture phase-space factors. This sensitivity of the capture rates means that interpolation in temperature and density on the standard grid to obtain a rate can be difficult, requiring a high-order interpolation routine and a relatively large amount of computer time for an accurate value. This is especially true for electron capture processes with a threshold above zero energy.

We have found that the interpolation problem can be greatly eased by defining a simple continuum-capture, phase-space integral, based on the parent ground-state to daughter-ground state transition Q-value, and then dividing this by the tabulated rates[53] at each temperature and density grid point to obtain a table of effective *ft*-values; these turn out to be much less dependent on temperature and density. This procedure requires a formulation of the capture phase-space factors which is simple enough to use many times in the inner loop of stellar evolution nucleosynthesis computer programs. Such a formulation in terms of standard Fermi integrals has been found, along with approximations for the requisite Fermi integrals. When the chemical potential (Fermi energy) which appears in the Fermi integrals goes through zero, these approximations have continuous values and continuous derivatives.

We have recently found expressions for the reverse reactions to e^-, e^+-capture, (i.e., $\nu,\bar{\nu}$-capture) and for $\nu,\bar{\nu}$-blocking of the direct reactions when $\nu,\bar{\nu}$-states are partially or completely filled. These reverse reactions and the blocking are important during supernova core collapse when neutrinos and antineutrinos eventually become trapped, leading to equilibrium between the two directions of capture. General analytic expressions have been derived and approximated with computer-usable equations. All of these new results described in the previous paragraphs will be published by *Fuller, Fowler* and *Newman*[62], and new tapes including $\nu,\bar{\nu}$-capture will be made available to users on request.

VIII. Calculated Abundances for $A \lesssim 60$, with Brief Comments on Explosive Nucleosynthesis

Armed with the available strong and weak nuclear reaction rates which apply to the advanced stages of stellar evolution, theoretical astrophysicists have attempted to derive the elemental and isotopic abundances produced in quasistatic presupernova nucleosynthesis and in explosive nucleosynthesis occurring during supernova outbursts.

The various stages of preexplosive nucleosynthesis have been discussed in Sections IV, V, and VI, and it is fair to say that there is reasonably general agreement on nucleosynthesis during these stages. On the other hand, explosive nucleosynthesis is still an unsettled matter, subject to intensive study at the present time, as reviewed, for example, by *Woosley, Axelrod,* and *Weaver*[63].

The abundances produced in explosive nucleosynthesis must of necessity depend on the detailed nature of supernova explosions. Ideas concerning the nature of Type I and Type II supernova explosions were published many years ago by *Hoyle* and *Fowler*[64] and *Fowler* and *Hoyle*[65]. It was suggested that Type I supernovae of small mass were precipitated by the onset of explosive carbon burning under conditions of electron degeneracy where pressure is approximately independent of temperature. Carbon burning raises the temperature to the point where the electrons are no longer degenerate, and explosive disruption of the star results. For Type II supernovae of larger mass it was suggested that Si-burning produced iron-group nuclei, which have the maximum binding energies of all nuclei so that nuclear energy is no longer available. Subsequent photodisintegration and electron capture in the stellar core lead to core implosion and ignition of explosive nucleosynthesis in the infalling inner mantle which still contains nuclear fuel. These ideas have "survived" but, to say the

least, with considerable modification over the years, as indicated in the excellent review by *Wheeler*[66]. Modern views on Type II supernovae are given in [39-60] and on Type I supernovae by *Nomoto*[67].

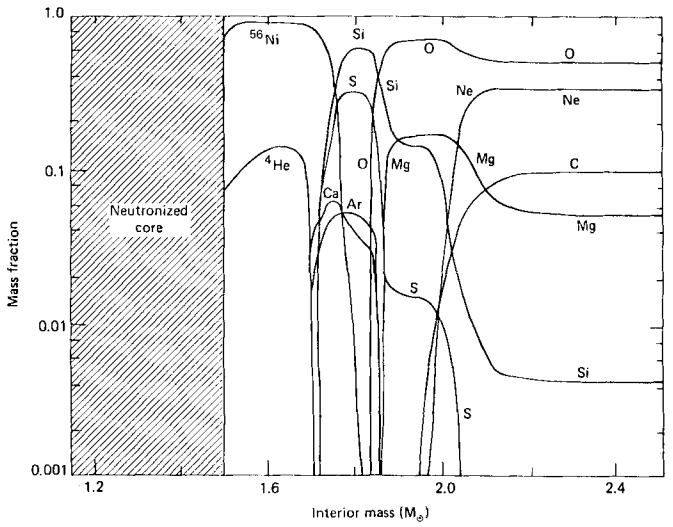

Fig. 16. Final abundances by mass fraction versus increasing interior mass in solar masses, $M_\odot$, in Type II supernova ejecta from a Population I star with total mass equal to $25M_\odot$, from *Woosley* and *Weaver*[38].

We can return to the nuclear abundance problem by reference to Figure 16, taken from [38], which shows the distribution of the final abundances by mass fraction in the supernova ejecta of a $25M_\odot$ Population I star. The presupernova distribution is that shown in Figure 8a. The modification in the abundances for the mass zones interior to $2.2M_\odot$ is very apparent. The mass exterior to $2.2M_\odot$ is ejected with little or no modification in nuclear abundances. The supernova explosion was simulated by arbitrarily assuming that approximately 10^{51} ergs was delivered to the ejected material by the shock generated in the bounce or rebound of the collapsing and hardening core.

Integration over the mass zones in Figure 16 for $1.5M_\odot < M < 2.2M_\odot$ and over those in Figure 8a for $M > 2.2M_\odot$ enabled *Woosley* and *Weaver*[38] to calculate the isotopic abundances ejected into the interstellar medium by their $25M_\odot$ Population I simulated supernova. The results relative to solar abundances (the reader should refer to the last paragraph of Section I) are show in Figure 17, which is taken from [38]. The relative ratios are normalized to unity for ^{16}O, for which the overproduction ratio was 14, i.e., for each gram of ^{16}O originally in the star, 14 grams were ejected. This overproduction in a single supernova can be expected to have produced the heavy-element abundances in the interstellar medium just prior to formation of the solar system, given that supernovae occur approximately every one hundred years in the Galaxy. The ultimate theoretical calculations will yield a constant overproduction factor of the order of 10.

The results shown in Figure 17 are disappointing if one expects the ejecta of $25M_\odot$ Population I supernovae to match solar system abundances with a relatively constant overproduction factor. The dip in abundances from sulfur to chromium is readily apparent. *Woosley* and *Weaver*[38] point out that calculations must be made for other stellar masses and properly integrated over the mass distribution for stellar formation, which varies roughly inversely proportional to mass. *Woosley, Axelrod,* and *Weaver*[63] discuss their expectations of the abundances produced in stellar explosions for stars in the mass range $10M_\odot$ to $10^6M_\odot$. They show that a $200M_\odot$ Population III star produces

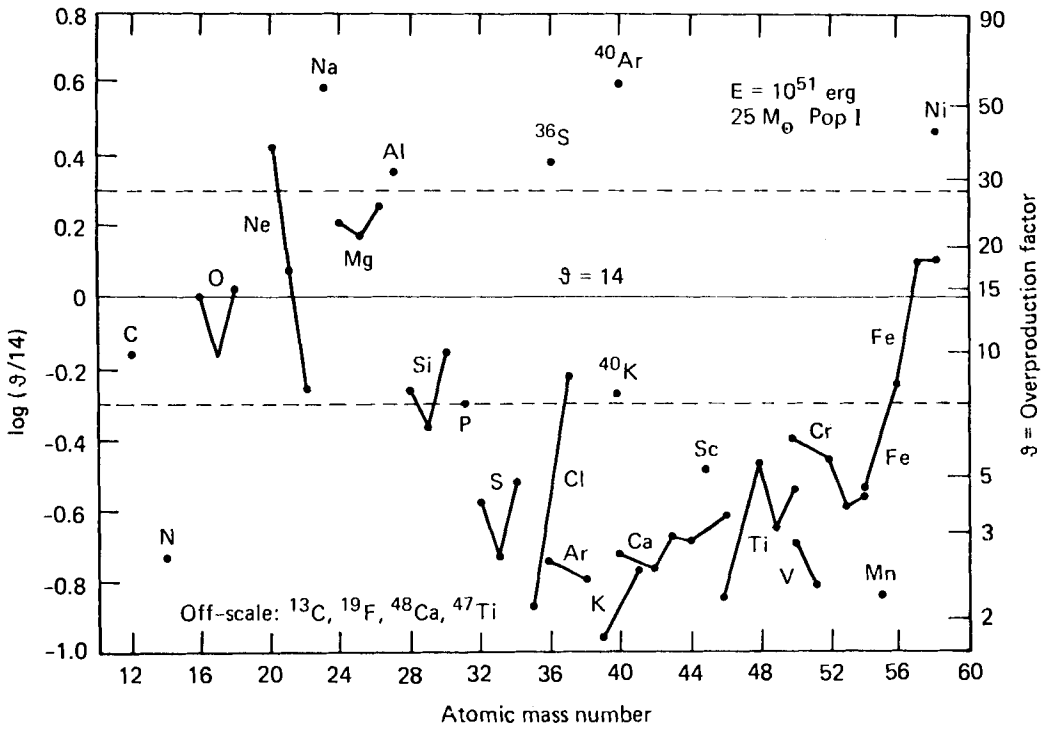

Fig. 17. Overabundance (ϑ) relative to 14 times solar abundances versus atomic mass number for nucleosynthesis resulting from a Type II, Population I supernova with total mass equal to $25M_\odot$, from *Woosley* and *Weaver* [38].

abundant quantities of sulfur, argon, and calcium which possibly compensate for the dip in Figure 17. Population III stars are massive stars in the range $100\,M_\odot < M < 300\,M_\odot$, which are thought to have formed from hydrogen and helium early in the history of the Galaxy and evolved very rapidly. Since their heavy element abundance was zero, they have no counterparts in presently forming Population I stars as well as no counterparts among old, low-mass Population II stars.

Other authors have suggested a number of solutions to the problem depicted in Figure 17. *Nomoto, Thielemann,* and *Wheeler*[68] have calculated the abundances produced in carbon deflagration models of Type I supernovae. By adding equal contributions from Type I and Type II supernovae, they obtain Figure 18, which can be considered somewhat more satisfactory than Figure 17. On the other hand, *Arnett* and *Thielemann*[69] have recalculated quasistatic presupernova nucleosynthesis for $M \approx 20\,M_\odot$, using a value for the $^{12}C(\alpha,\gamma)^{16}O$ rate equal to three times that given in [21]. This would seem to be justified by the recent analysis of $^{12}C(\alpha,\gamma)^{16}O$ data in [34], as discussed in Section V. These authors then assume that explosive nucleosynthesis will not substantially modify their quasistatic abundances and obtain the results shown in Figure 19. The average overproduction ratio is roughly 14, and deviations are in general within a factor of two of this value. However, their assumption of minor modification during explosion and ejection is questionable.

I feel that the results discussed in this section and those obtained by numerous other authors show promise of an eventual satisfactory answer to the question where and how did the elements from carbon to nickel originate. We shall see!

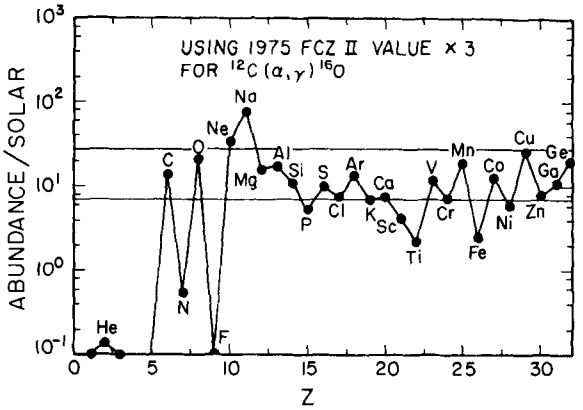

Fig. 19. Over-abundance yields relative to solar versus atomic number, Z, resulting from the explosion of a Type II supernova with mass approximately equal to $20\,M_\odot$, from *Arnett* and *Thielemann* [69]. The horizontal lines are a factor two higher and lower than the average overabundance equal to 14. It is assumed that the presupernova abundances were not modified during the supernova explosion. The reaction rate for $^{12}C(\alpha,\gamma)^{16}O$ of *Fowler, Caughlan,* and *Zimmerman* [21] was multiplied by a factor of 3, in accordance with the theoretical analysis by *Laganke* and *Koonin* [34].

IX. Isotopic Anomalies in Meteorites and Observational Evidence for Ongoing Nucleosynthesis

Almost a decade ago, it became clear that nucleosynthesis occurred in the Galaxy up to the time of formation of the solar system or at least up to several million years before its formation. For slightly over one year, it has been clear that nucleosynthesis continues up to the present time or at least within several million years of the present. The decay of radioactive $^{26}Al(\bar{\tau} = 1.04 \times 10^6$ years) is the key to these statements, which bring great satisfaction to most ex-

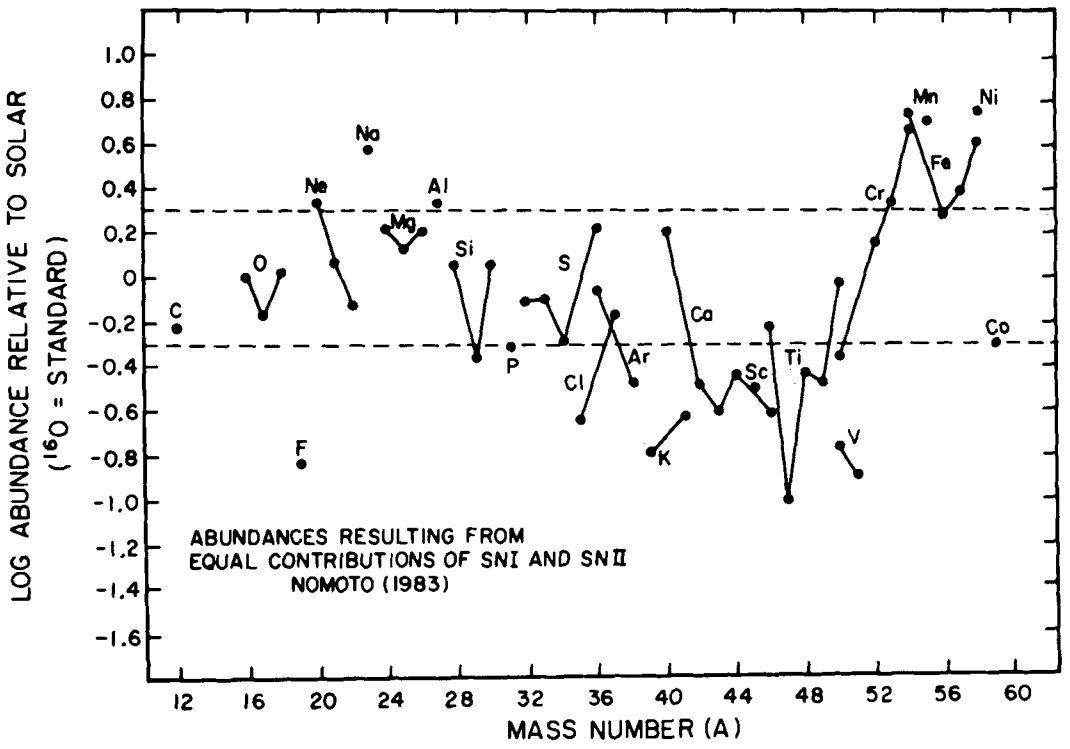

Fig. 18. Abundances relative to solar with the abundance of ^{16}O taken as standard produced by equal contributions from typical Type I and Type II supernovae, from *Nomoto, Thielemann,* and *Wheeler* [68].

perimentalists, theorists, and observers in Nuclear Astrophysics. For the record, it must be admitted that the word "clear" is subject to certain reservations in the minds of some investigators, but as a believer, "clear" is clear to me.

Isotopic anomalies in meteorites produced by the decay of short-lived radioactive nuclei were first demonstrated in 1960 by *Reynolds*[70], who found large enrichments of ^{129}Xe in the Richardson meteorite. *Jeffery* and *Reynolds*[71] demonstrated in 1961 that the excess ^{129}Xe correlated with ^{127}I in the meteorite and thus showed that the ^{129}Xe resulted from the decay in situ of ^{129}I ($\bar{\tau} = 23 \times 10^6$ years). Quantitative results indicated that $^{129}I/^{127}I \approx 10^{-4}$ at the time of meteorite formation. On the assumption that ^{129}I and ^{127}I are produced in roughly equal abundances in nucleosynthesis (most probably in the *r*-process) over a period of ca. 10^{10} years in the Galaxy prior to formation of the solar system, and taking into account that only the ^{129}I produced over a period of the order of its lifetime survives, *Wasserburg, Fowler,* and *Hoyle*[72] suggested that a period of free decay of the order of 10^8 years or more occurred between the last nucleosynthetic event which produced ^{129}I and its incorporation into meteorites in the solar system. There remains evidence for such a period in some cases, notably ^{244}Pu, but probably not in the history of the nucleosynthetic events which produced ^{129}I and other "short"-lived radioactive nuclei such as ^{26}Al and ^{107}Pd ($\bar{\tau} = 9.4 \times 10^6$ years).

The substantiated meteoritic anomalies in ^{26}Mg from ^{26}Al, in ^{107}Ag from ^{107}Pd, in ^{129}Xe from ^{129}I, and in the heavy isotopes of Xe from the fission of ^{244}Pu ($\bar{\tau} = 117 \times 10^6$ years; fission tracks also observed), as well as searches in the future for anomalies in ^{41}K from ^{41}Ca ($\bar{\tau} = 0.14 \times 10^6$ years), in ^{60}Ni from ^{60}Fe ($\bar{\tau} = 0.43 \times 10^6$ years), in ^{53}Cr from ^{53}Mn ($\bar{\tau} = 5.3 \times 10^6$ years), and in ^{142}Nd from ^{146}Sm ($\bar{\tau} = 149 \times 10^6$ years; α-decay) are discussed exhaustively by my colleagues *Wasserburg* and *Papanastassiou*[73]. They espouse in situ decay for the observations to date, but my former student *D. D. Clayton*[74] argues that the anomalies occur in interstellar grains preserved in the meteorites and originally produced by condensation in the expanding and cooling envelopes of supernovae and novae. *Wasserburg* and *Papanastassiou*[73] write on p. 90: "There is, as yet, no compelling evidence for the presence of preserved presolar grains in the solar system. All of the samples so far investigated appear to have melted or condensed from a gas, and to have chemically reacted to form new phases". With mixed emotions I accept this.

Before turning to some elaboration of the $^{26}Al/^{26}Mg$ case, it is appropriate to return to a discussion of the free-decay interval mentioned above. It is the lack of a detectable anomaly in ^{235}U from the decay of ^{247}Cm ($\bar{\tau} = 23 \times 10^6$ years) in meteorites, as shown by *Chen* and *Wasserburg*[75], coupled with the demonstrated occurrence of heavy Xe anomalies from the fission of ^{244}Pu ($\bar{\tau} = 117 \times 10^6$ years), as discussed, for example, by *Burnett, Stapanian,* and *Jones*[76], which demands a free-decay interval of the order of several times 10^8 years. This interval is measured from the "last" *r*-process nucleosynthesis event (supernova?) which produced the actinides, Th, U, Pu, Cm and beyond, up to the "last" nucleosynthesis events (novae?, supernovae with short-run *r*-processes?) which produced the short-lived nuclei ^{26}Al, ^{107}Pd, and ^{129}I before the formation of the solar system. The fact that the anomalies produced by these short-lived nuclei relative to normal abundances are all of the order of 10^{-4}, despite a wide range in their mean lifetimes (1.04 to 23×10^6 years), indicates that this anomaly range must be the result of inhomogeneous mixing of exotic materials with much larger quantities of normal solar-system materials over a short time, rather than the result of free decay. The challenges presented by this conclusion are manifold. Figure 14 from [73] shows the time scale for the formation of dust, rain, and hailstones in the early solar system and for the aggregation into chunks and eventually the terrestrial planets. The solar nebula was almost but not completely mixed when it collapsed to form the solar system. From ^{26}Al, it becomes clear that the mixing time down to an inhomogenity of only one part in 10^3 (see below) was the order of 10^6 years.

Evidence that ^{26}Al was alive in interstellar material in the solar nebula which condensed and aggregated to form the parent body (planet in the asteroid belt?) of the Allende meteorite is shown in Figure 20, taken with some modification from *Lee, Papanastassiou,* and *Wasserburg*[77]. The Allende meteorite fell near Pueblito de Allende in Mexico on February 8, 1969 and is a carbonaceous chondrite, a type of meteorite thought to contain the most primitive material in the solar system *unaltered since its original solidification.*

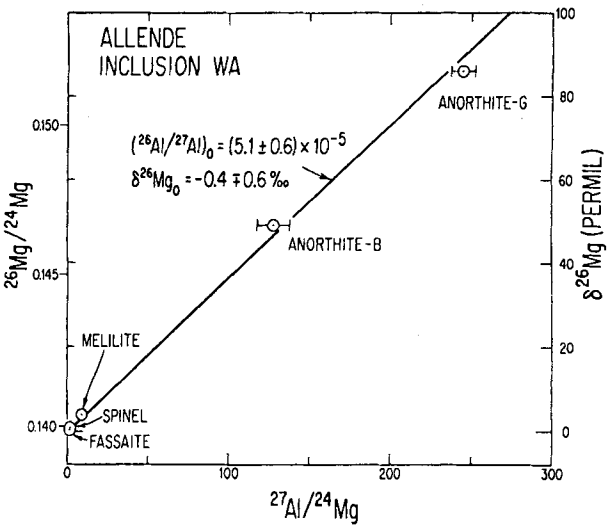

Fig. 20. Evidence for the in situ decay of ^{26}Al in various minerals in inclusion WA of the Allende meteorite from *Lee, Papanastassiou,* and *Wasserburg* [77]. The linear relation between $^{26}Mg/^{24}Mg$ and $^{27}Al/^{24}Mg$ implies that $^{26}Al/^{27}Al = (5.1 \pm 0.6) \times 10^{-5}$ at the time of formation of the inclusion with ^{26}Al considered to react chemically in the same manner as ^{27}Al.

Figure 20 depicts the results for $^{26}Mg/^{24}Mg$ versus $^{27}Al/^{24}Mg$ in different mineral phases (spinel, etc.) from a Ca-Al-rich inclusion called WA obtained from a chondrule found in Allende. It will be clear that excess ^{26}Mg correlates linearly with the amount of ^{27}Al in the mineral phases. Since ^{26}Al is chemically identical with ^{27}Al, it can be inferred that phases rich in ^{27}Al were initially rich in ^{26}Al, which subsequently decayed in situ to produce excess ^{26}Mg. ^{26}Al was alive with abundance 5×10^{-5} that of ^{27}Al

in one part of the solar nebula when the WA inclusion aggregated during the earliest stages of the formation of the solar system. The unaltered inclusion survived for 4.5 billion years to tell its story. Other inclusions in Allende and other meteorites yield $^{26}Al/^{27}Al$ ratios from zero up to $\approx 10^{-3}$, with 10^{-4} a representative value. The reader is referred to [73] for the rich details of the story and the importance and significance of non-accelerator-based contributions to Nuclear Astrophysics.

Evidence that ^{26}Al is alive in the interstellar medium today is shown in Figure 21, taken from *Mahoney, Ling, Wheaton,* and *Jacobson*[78], my colleagues at Caltech's Jet Propulsion Laboratory (JPL). Figure 21 shows the gamma-ray spectrum observed in the range 1760 to 1824 keV by instruments aboard the High Energy Astronomical Observatory, HEAO 3, which searched for diffuse gamma-ray emission from the Galactic equatorial plane.

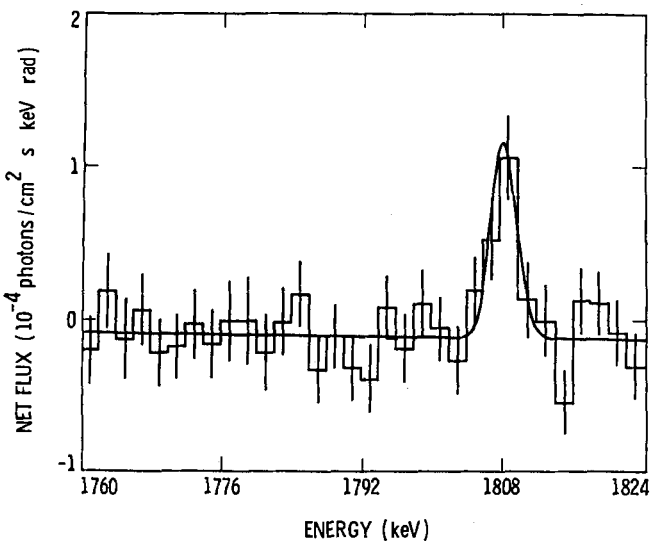

Fig. 21. The High Energy Astrophysical Observatory (HEAO 3) data on gamma rays in the energy range 1760 to 1824 keV emitted from the Galactic equatorial plane, from *Mahoney* et al. [78]. The line at 1809 keV is attributed to the decay of radioactive $^{26}Al(\bar{\tau} = 1.04 \times 10^6$ years) to the excited state of ^{26}Mg at this energy.

The discrete line at 1809 keV, detected with a significance of nearly five standard deviations, is without doubt due to the transition from the first excited state at 1809 keV in ^{26}Mg to its ground state. Radioactive ^{26}Al decays by $^{26}Al(e^+\nu)^{26}Mg^*(\gamma)^{26}Mg$ to this state and thence to the ground state of ^{26}Mg. This gamma-ray transition shows clearly that ^{26}Al is alive in the interstellar medium in the Galactic equatorial plane today. Given the mean lifetime (1.04×10^6 years) of ^{26}Al, this shows that ^{26}Al has been produced no longer than several million years ago and is probably being produced continuously. It is no great extrapolation to argue that nucleosynthesis in general continues in the Galaxy at the present time. Quantitatively, the observations indicate that $^{26}Al/^{27}Al \approx 10^{-5}$ in the interstellar medium. This value averages over the Galactic plane interior to the sun at the present time. This average value was probably much the same when the solar system formed, but the variations in $^{26}Al/^{27}Al$ for various meteoritic inclusions show that there were wide variations in the solar nebula about this value ranging from zero to 10^{-3}.

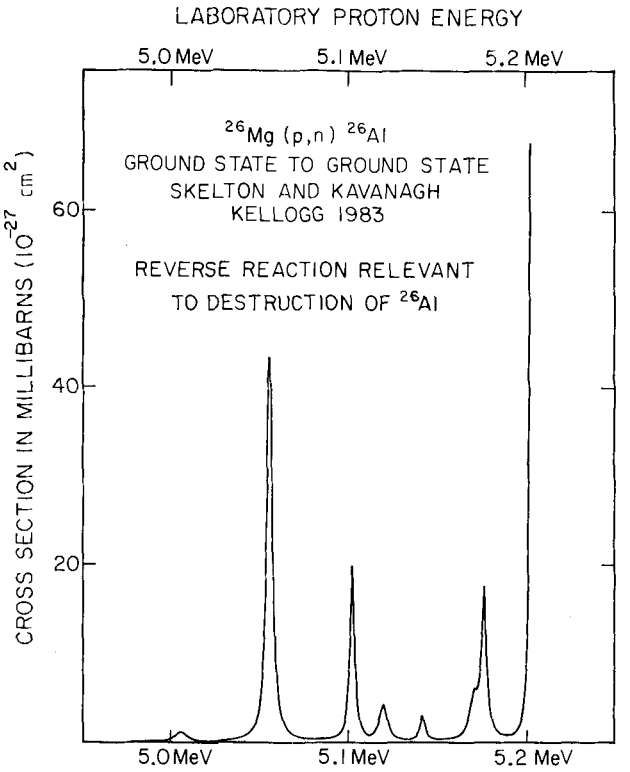

Fig. 22. The cross section in millibarns versus laboratory proton energy for the ground-state to ground-state reaction $^{26}Mg(p,n)^{26}Al$, from *Skelton, Kavanagh,* and *Sargood* [79].

The question immediately arises, what is the site of the synthesis of the ^{26}Al? Since the preparation of reference[52], I have been convinced that ^{26}Al could not be synthesized in supernovae at high temperatures where neutrons are copiously produced because of the expectation of a large cross section for $^{26}Al(n,p)^{26}Mg$. This expectation has been borne out by the measurements on the reverse reaction $^{26}Mg(p,n)^{26}Al$ in the Kellogg Laboratory by *Skelton, Kavanagh,* and *Sargood*[79]. Figure 22 is taken from Figure 1a of these authors and shows the great beauty of high-resolution measurements in experimental Nuclear Astrophysics. Until the ^{26}Al-targets just recently available can be bombarded with neutrons, it is necessary to supplement the laboratory measurements on $^{26}Mg(p,n)^{26}Al$, perforce involving the ground state of ^{26}Mg, with theoretical calculations involving excited states[23], in order to calculate the stellar rate for $^{26}Al(n,p)^{26}Mg$. There is little doubt that this rate is very large indeed.

In [74] and [78] and in *Arnould* et al.[80] it is suggested that ^{26}Al is produced in novae. This is quite reasonable on the basis of nucleosynthesis in novae as discussed by *Truran*[81]. In current models for novae, hydrogen from a binary companion is accreted by a white dwarf until a thermal runaway involving the fast CN-cycle occurs. Similarly, a fast MgAl-cycle may occur with production of $^{26}Al/^{27}Al \gtrsim 1$, as shown in Figure 9 of [52]. The recent experimental measurements cited in [52] substantiate this conclusion. *Clayton*[74] argues that the estimated 40 novae occurring annually in

the Galactic disk can produce the observed $^{26}Al/^{27}Al$ ratio of the order of 10^{-5} on average. He assumes that each nova ejects 10^{-4} $M_\odot$ of material containing a mass fraction of ^{26}Al equal to 3×10^{-4}.

Another possible source of ^{26}Al is spallation induced by irradiation of protoplanetary material by high energy protons from the young sun as it settled on the main sequence. This possibility was discussed very early by *Fowler, Greenstein,* and *Hoyle*[82], who also attempted to produce D, Li, Be and B in this way, requiring such large primary proton and secondary neutron fluxes that many features of the abundance curve in the solar system would have been changed substantially. A more reasonable version of the scenario was presented by *Lee*[83], but without notable success. I find it difficult to believe that an early irradiation produced the anomalies in meteorites. The ^{26}Al in the interstellar medium today certainly cannot have been produced in this way.

Anomalies have been found in the abundances of the stable isotopes of many elements in meteorites compared with in normal solar system material; namely: O, Ne, Mg, Ca, Ti, Kr, Sr, Xe, Ba, Nd, and Sm. The possibility that the oxygen anomalies are non-nuclear in origin has been raised by *Thiemens* and *Heidenreich*[84], but the anomalies in the remaining elements are generally attributed to nuclear processes.

One example is a neutron-capture/beta-decay ($n\beta$) process studied by *Sandler, Koonin,* and *Fowler*[85]. The seed nuclei consisted of all the elements from Si to Cr with normal solar system abundances. When this process operates at neutron densities $\approx 10^7$ mole cm^{-3} and exposure times of $\approx 10^3$ s, small admixtures ($\lesssim 10^{-4}$) of the exotic material produced are sufficient to account for most of the Ca and Ti isotopic anomalies found in the Allende meteorite inclusion EK-1-4-1 by *Niederer, Papanastassiou,* and *Wasserburg*[86]. The anomalies in stable isotope abundances are of the same order as those for short-lived radioactive nuclei and strongly support the view that the solar nebula was inhomogeneous and not completely mixed with regions containing exotic materials up to 10^{-4} or more of normal material.

Agreement for the ^{46}Ca and ^{49}Ti anomalies in EK-1-4-1 was obtained only by increasing the theoretical Hauser-Feshbach cross sections for $^{46}K(n,\gamma)$ and $^{49}Ca(n,\gamma)$ by a factor of 10, on the basis of probable thermal resonances just above threshold in the compound nuclei ^{47}K and ^{50}Ca, respectively. In a CERN report, which subsequently became available, *Huck* et al.[87] reported an excited state in ^{50}Ca just 0.16 MeV above the $^{49}Ca(n,\gamma)$ threshold, which can be produced by *s*-wave capture and fulfills the requirements made in [85].

Reference [85] suggests that the $\approx 10^3$ s exposure time scale is determined by the mean life-time of $^{13}N(\bar{\tau} = 862$ s), produced through $^{12}C(p,\gamma)^{13}N$ by a jet of hydrogen suddenly introduced into the helium burning shell of a Red Giant star where a substantial amount of ^{12}C has been produced by the $3\alpha \rightarrow {}^{12}C$ process. The beta decay $^{13}N(e^+\nu)^{13}C$ is followed by $^{13}C(\alpha,n)^{16}O$ as the source of the neutrons. All of this is very interesting, if true. More to the point, [85] predicts the anomalies to be expected in the isotopes of chromium. Attempts to measure these anomalies are underway now by *Wasserburg* and his colleagues. Again, we shall see!

X. Observational Evidence for Nucleosynthesis in Supernovae

Over the years, there has been considerable controversy concerning elemental abundance observations in the optical wavelength range on Galactic supernovae remnants. To my mind, the most convincing evidence for nucleosynthesis in supernovae has been provided by *Chevalier* and *Kirshner*[88], who obtained quantitative spectral information for several of the fast-moving knots in the supernova remnant Cassiopeia A (approximately dated 1659, but a supernova event was not observed at that time). The knots are considered to be material ejected from various layers of the original star in a highly asymmetric, nonspherical explosion. In one knot, labelled KB33, the following ratios *relative to solar, designated by brackets,* were observed: [S/O] = 61, [Ar/O] = 55, [Ca/O] = 59. It is abundantly clear that oxygen burning to the silicon group elements in the layer in which KB33 originated has depleted oxygen and enhanced the silicon group elements. Other knots and other features designated as filaments show different abundance patterns, albeit, not so easily interpreted. The moral for supernova modelers is that spherically symmetric supernova explosions may be the easiest to calculate but are not to be taken as realistic. Admittedly they have a good answer: it is expensive enough to compute spherically symmetric models. OK, OK!

Most striking of all has been the payoff from the NASA investment in the High Energy Astronomy Observatory (HEAO 2), now called the Einstein Observatory. Using this satellite, *Becker* et al.[89] observed the X-ray spectrum in the range 1 to 4 keV of *Tycho Brahe*'s supernova remnant (1572) shown in Figure 23. An X-ray spectrum is much simpler than an optical spectrum. For me it is wonderful that satellite observations show the K-level X-rays ex-

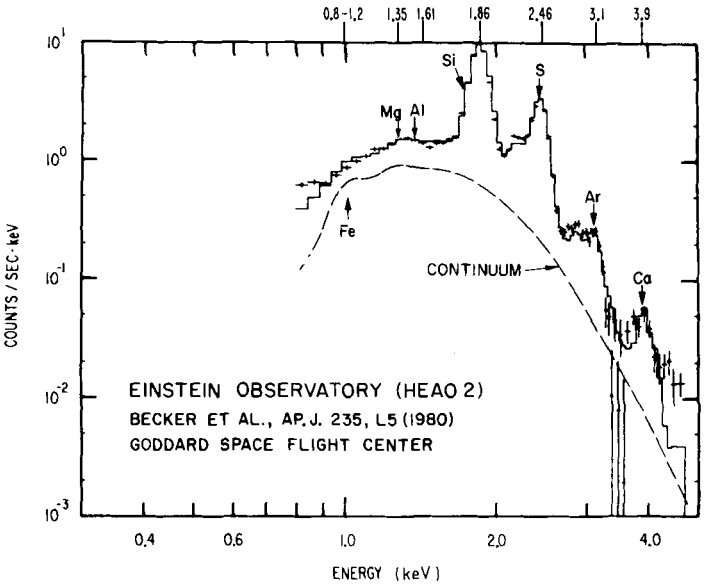

Fig. 23. The Einstein Observatory (HEAO 2) data on the X-ray spectrum of *Tycho Brahe*'s supernova remnant, from *Becker* et al. [89].

pected from Si, S, Ar and Ca just where the Handbook of Chemistry and Physics says they ought to be! Such observations are not all that easy in a terrestrial laboratory.

Shull[90] has used a single-velocity, non-ionization-equilibrium model of a supernova blast-wave to calculate abundances in *Tycho*'s remnant *relative to solar, designated by brackets,* and finds: [Si]=7.6, [S]=6.5, [Ar]=3.2 and [Ca]=2.6. With considerably greater uncertainty, he gives [Mg]=2.0 and [Fe]=2.1. He finds different enhancements in *Kepler*'s remnant (1604) and in Cassiopeia A. One more lesson for the modelers: no two supernovae are alike. Nucleosynthesis in supernovae depends on their initial mass, rotation, mass-loss during the Red Giant stage, the degree of symmetry during explosion, initial heavy element content, and probably other factors. These details aside, it seems clear that supernovae produce enhancements in elemental abundances up to iron and probably beyond. Detection of the much rarer elements beyond iron will require more sensitive X-ray detectors operating at higher energies. The nuclear debris of supernovae eventually enriches the interstellar medium from which succeeding generations of stars are formed. It becomes increasingly clear that novae also enrich the interstellar medium. Sorting out these two contributions poses interesting problems in ongoing research in all aspects of Nuclear Astrophysics.

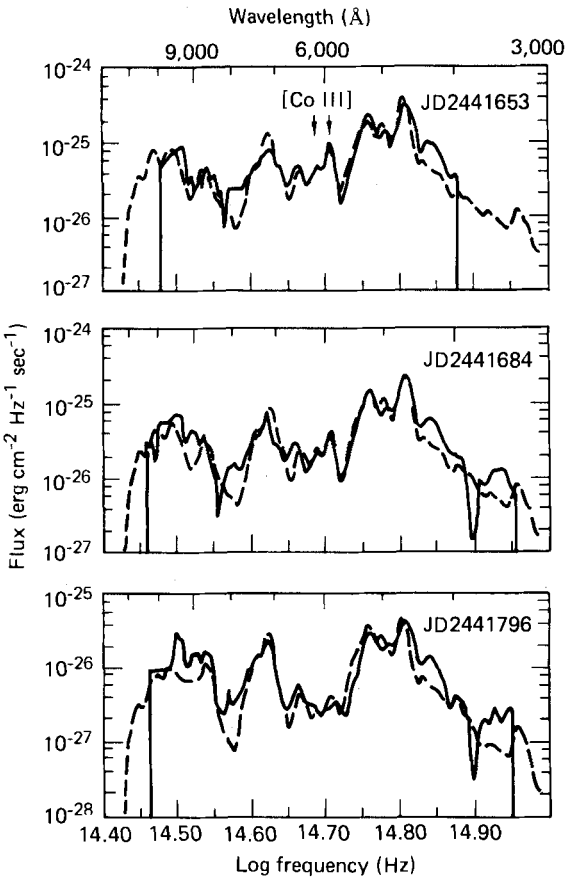

Fig. 24. Analysis by *Axelrod* [91], yielding two emission lines from Co^{III} in the observations on SN 1972e obtained by *Kirshner* and *Oke* [92]. The observations were made 233, 264 and 376 days after JD2441420, assigned as the initial day of the supernova explosion. The mean lifetime of ^{56}Co is 114 days; the Co^{III} lines appear to decay in keeping with their emission from radioactive ^{56}Co.

Explosive silicon burning in the shell just outside a collapsing supernova core primarily produces ^{56}Ni, as shown in Figure 16. It is generally believed that the initial energy source for the light curves of type I supernovae is electron capture by ^{56}Ni ($\bar{\tau}=8.80$ days) to the excited state of ^{56}Co at 1.720 MeV, with subsequent gamma ray cascades to the ground state. These gamma rays are absorbed and provide energy to the ejected envelope. The subsequent source of energy is electron capture and positron emission by ^{56}Co ($\bar{\tau}=114$ days) to a number of excited states of ^{56}Fe, with gamma ray cascades to the stable ground state of ^{56}Fe. Both the positrons and the gamma rays heat the ejected material. If ^{56}Co is an energy source, there should be spectral evidence for cobalt in newly discovered Type I supernovae, since its lifetime is long enough for detailed observations to be possible after the initial discovery.

The cobalt has been observed! *Axelrod*[91] studied the optical spectra of SN1972e obtained by *Kirshner* and *Oke*[92]. The spectra obtained at 233, 264, and 376, days after Julian day 2441420, assigned as the initial day of the explosive event, are shown in Figure 24. *Axelrod* assigned the two emission lines near 6000 Å ($\log v=14.7$) to Co^{III}. They are clearly evident at 233 and 264 days, but are only marginally evident at 376 days ($\approx\bar{\tau}$). The lines decay in reasonable agreement with the mean lifetime of ^{56}Co.

Branch et al.[93] have studied absorption spectra obtained during the first hundred days of SN1981b. Their results at maximum light are shown in the top curve of Figure 25. Using the carbon deflagration model for Type I supernovae of *Nomoto*[67], *Branch*[94] has calculated the spectrum shown in the lower curve of Figure 25. Deep absorption lines of Co^{II} are clearly evident near 3300 and 4000 Å.

It is my conclusion that there is substantial evidence for nucleosynthesis in supernovae of elements produced in oxygen and silicon burning. The role of neutron capture processes in supernovae will be discussed in the next section.

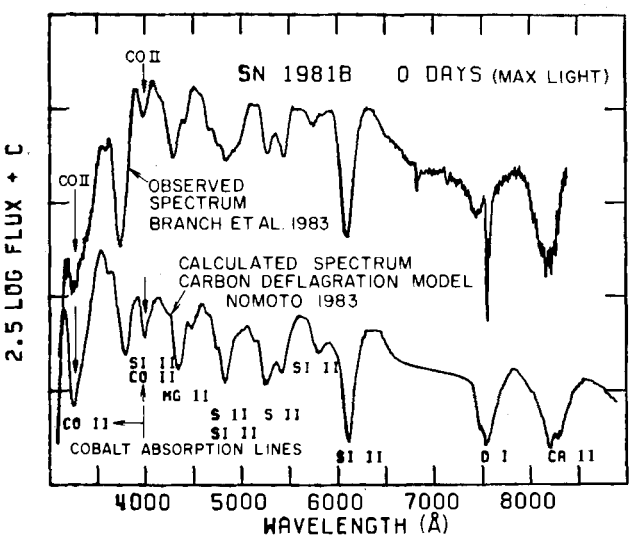

Fig. 25. Top: Analysis by *Branch* et al. [93] of their absorption spectrum of SN 1981b at maximum light showing evidence for Co^{II} absorption features. Bottom: Comparison with the calculated spectrum expected from the carbon deflagration model for Type I supernovae, according to the calculations of *Nomoto* [67].

XI. Neutron Capture Processes in Nucleosynthesis

In Section I the need for two neutron capture processes for nucleosynthesis beyond $A \gtrsim 60$ was discussed in terms of early historical developments in Nuclear Astrophysics. These two processes were designated the *s*-process, for neutron capture slow (*s*) compared to electron beta-decay, and the *r*-process, for neutron capture rapid (*r*) compared to electron beta-decay in the process networks.

For a given element, the heavier isotopes are frequently by-passed in the *s*-process and are produced only in the *r*-process; thus, the designation *r*-only. Lighter isotopes are frequently shielded by more neutron-rich stable isobars in the *r*-process and are produced only in the *s*-process; thus, the designation s-only. The lightest isotopes are frequently very rare because they are not produced in either the *s*-process or the *r*-process and are thought to be produced in what is called the *p*-process. The *p*-process involves positron production and capture, proton-capture, neutron-photoproduction, and/or (p,n)-reactions and will not be discussed further. The reader is referred to *Audouze* and *Vauclair*[95]. The results of the *s*-process, the *r*-process, and the *p*-process are frequently illustrated by reference to the ten stable isotopes of tin. The reader is referred to Figures 10 and 11 of the first reference in [96].

It is fair to say that the *s*-process has the clearest phenomenological basis of all processes of nucleosynthesis. This is primarily the result of the correlation of *s*-process abundances, first delineated by *Seeger, Fowler,* and *Clayton*[97], with the beautiful series of measurements on neutron capture cross sections in the 1 to 100 keV range carried out at the Oak Ridge National Laboratory group under *Macklin* and *Gibbons*[98].

The correlation is illustrated in Figure 26, which shows the product of neutron capture cross sections (σ) at 30 keV multiplied by *s*-process abundances (N) as a function of atomic mass for *s*-only nuclei and those produced predominately by the *s*-process. It is not difficult to understand in first-order approximation that the product σN should be constant in the *s*-process synthesis. A nucleus with a small (large) neutron capture cross-section must have a large (small) abundance to maintain continuity in the *s*-capture path. Figure 26 demonstrates this in the *plateaus* shown from $A = 90$ to 140 and from $A = 140$ to 206. The anomalous behavior below $A = 80$ is discussed in *Almeida* and *Käppeler*[99], from which Figure 26 is taken.

Nuclear shell structure introduces the *precipices* shown in Figure 26 at $A \approx 84$, $A \approx 138$, and $A \approx 208$, which correspond to the *s*-process abundance peaks in Figure 2. At these values of A, the neutron numbers are "magic", $N = 50$, 82, and 126. The cross sections for neutron capture into new neutron shells are very small at these magic numbers. With a finite supply of neutrons, it follows that the product σN must drop to a new plateau, just as is observed. Quantitative explanations of this effect have been given by *Ulrich*[100] and by *Clayton* and *Ward*[101].

What is the site of the *s*-process, and what is the source of the neutrons? A very convincing answer has been given by *Iben*[102] that the site is the He-burning shell of a pulsating Red Giant with the $^{22}Ne(\alpha,n)^{25}Mg$ reaction as the neutron source. Critical discussions have been given by *Almeida* and *Käppeler*[99] and by *Truran*[103]. The latter reference reserves the possibility that the $^{13}C(\alpha,n)^{16}O$ reaction is the neutron source.

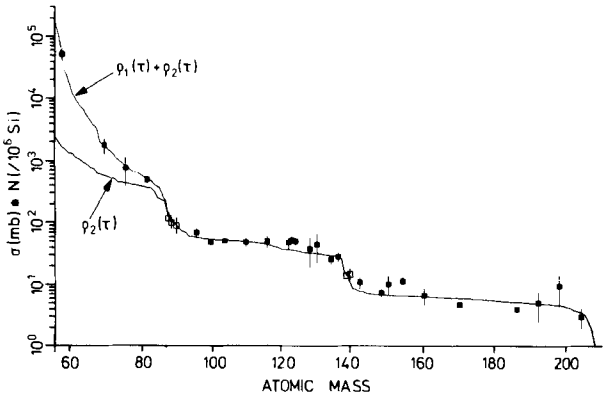

Fig. 26. Neutron capture cross section at 30 keV in millibarns multiplied by solar system abundances relative to Si = 10^6 versus atomic mass for nuclei produced in the s-process from *Almeida* and *Käppeler* [99]. Theoretical calculations are shown for a single exponential distribution, in neutron exposure, τ, $\rho_2(\tau)$, and for two such distributions $\rho_1(\tau)+\rho_2(\tau)$.

We turn now to the *r*-process. This process has been customarily treated by the *waiting point* method of B^2FH[18]. Under explosive conditions, a large flux of neutrons drives nuclear seeds to the neutron-rich side of the valley of stability where, depending on the temperature, the (n,γ)-reaction and the (γ,n)-reaction reach equality. The nuclei wait at this point until electron beta-decay transforms neutrons in the nuclei into protons, whence further neutron capture can occur. At the cessation of the *r*-process, the neutron-rich nuclei decay to their stable isobars. In the first order, this means that the abundance of an *r*-process nucleus multiplied by the electron beta-decay rate of its neutron rich *r*-process isobar progenitor will be roughly constant. At magic neutron numbers in the neutron-rich progenitors, beta-decay must perforce open the closed neutron shell in transforming a neutron into a proton and there the rate will be relatively small. Accordingly, the abundance of progenitors with $N = 50$, 82, and 126 will be large. The associated number of protons will be less than in the corresponding *s*-process nuclei with a magic number of neutrons. It follows that the stable daughter isobars will have smaller mass numbers, and this is indeed the case, the *r*-process abundance peaks occurring at $A \approx 80$, $A \approx 130$, and $A \approx 195$—all below the corresponding s-process peaks, as illustrated in Figure 2.

A phenomenological correlation of *r*-process abundances with beta-decay rates made by *Becker* and *Fowler*[104] and a detailed illustration of this correlation between solar system *r*-process abundances and theory are given in Figure 13 of the first reference in [96]. It is too phenomenological to satisfy critical nuclear astrophysicists. They wish to know the site of the high neutron fluxes demanded for *r*-process nucleosynthesis and the details of the *r*-process path through nuclei far from the line of beta-stability.

There is also general belief at the present time that the waiting point approximation is a poor one and must be replaced by dynamical *r*-process flow calculations taking into account explicit (n,γ), (γ,n) and beta-decay rates with time-varying temperature and neutron flux. *Schramm*[105]

has discussed such calculations in some detail and has emphasized that nonequilibrium effects are particularly important during the freeze-out at the end of the *r*-process when the temperature drops and the neutron flux falls to zero.

Simple dynamical calculations have been made by *Blake* and *Schramm*[106] for a process they designated as the *n*-process, and by *Sandler, Fowler,* and *Koonin*[85] for their *nβ*-process discussed in Section IX. The most ambitious calculations have been made by *Cameron, Cowan,* and *Truran*[107]. This paper gives references to their previous herculean efforts in dynamical *r*-process calculations. An example of their results is shown in Figure 27. They emphasize that they have not been able to find a plausible astrophysical scenario for the initial ambient conditions required for Figure 27. In spite of this, I am convinced that they are on the right track to an eventual understanding of the dynamics and site of the *r*-process.

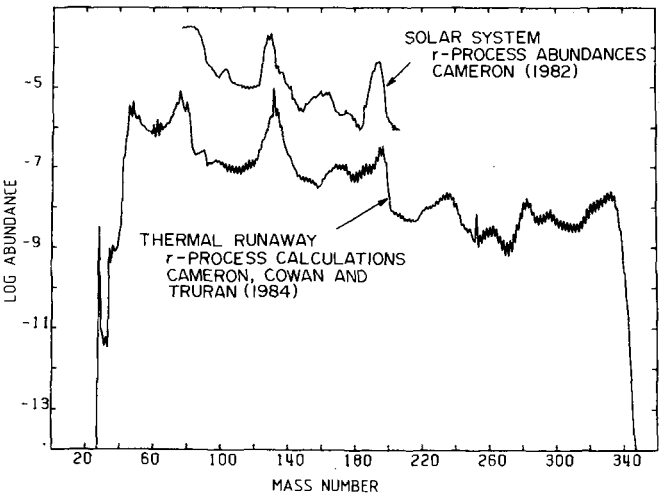

Fig. 27. Abundances produced in the *r*-process versus atomic mass number in the thermal runaway model (lower curve) of *Cameron, Cowan,* and *Truran* [107] compared with the solar system *r*-process abundances (upper curve) of *Cameron* [3].

Many suggestions have been made for possible sites of the *r*-process, almost all in supernovae explosions where the basic requirement of a large neutron flux of short duration is met. These suggestions are reviewed by *Schramm*[105] and *Truran*[103]. To my mind, the helium-core, thermal runaway *r*-process of *Cameron, Cowan,* and *Truran*[107] is the most promising. These authors do not rule out the $^{22}Ne(\alpha,n)^{25}Mg$ reactions as the source of the neutrons, but their detailed results shown in Figure 27 are based on the $^{13}C(\alpha,n)^{16}O$ reaction as the source. They start with a star formed from material with the same heavy-element abundance distribution as in the solar system but with smaller total amount. They assume a significant amount of ^{13}C in the helium core of the star after hydrogen burning. This ^{13}C was produced previously by the introduction of hydrogen into the core which had already burned half of its helium into ^{12}C. For Figure 27, they assume a ^{13}C abundance of 14.3 percent by mass, density equal to 10^6 gm cm^{-3}, and an initial temperature of 1.6×10^8 K, which is raised by the initial slow ^{13}C-burning to an eventual maximum of 3.6×10^8 K. The electrons in the core are initially degenerate but the rise in temperature lifts the degeneracy, producing a thermal runaway with expansion and subsequent cooling of the core. This event is the second helium-flash episode in the history of the core and, if it occurs, only a small amount of the *r*-process material produced need escape into the interstellar medium to contribute the *r*-process abundance in solar system material. It is my belief that a realistic astrophysical site for the thermal runaway, perhaps with different initial conditions, will be found. I rest the case.

XII. Nucleocosmochronology

Armed with their *r*-process calculations of the abundances of the long-lived parents of the natural radioactive series ^{232}Th, ^{235}U, and ^{238}U and with the then current solar system abundances of these nuclei, B^2FH[18] were able to determine the duration of *r*-process nucleosynthesis from its beginning in the first stars in the Galaxy up to the last events before the formation of the solar system. The general idea was originally suggested by *Rutherford*[108]. B^2FH[18] made a major advance by taking into account the contributions to the abundance of the long-lived *eon glasses* from the decay of their short-lived progenitors also produced in the *r*-process. The parents of the natural radioactive series are indeed excellent *eon glasses* with their mean lifetimes: ^{232}Th, 20.0×10^9 years; ^{238}U, 6.51×10^9 years; ^{235}U, 1.03×10^9 years. The analogy with *hour glasses* is fairly good; the sand in the top of the *hours glass* is the radioactive parent, that in the bottom is the daughter. The analogy fails in that in the *eon glasses* "sand" (Th, U) is being added or removed, top and bottom, by nucleosynthesis (production in stars) and astration (destruction in stars). Properly expressed differential equations can compensate for this failure.

The abundances used were those observed in meteorites assumed to be closed systems since their formation, taken to have occurred 4.55 billion years ago. It was necessary to correct for free decay during this period to obtain abundances for comparison with calculations based on *r*-process production plus decay over the duration of Galactic nucleosynthesis before the meteorites became closed systems. Fortunately, ratios of abundances, $^{232}Th/^{238}U$ and $^{235}U/^{238}U$, sufficed since absolute abundances could not, and still cannot, be calculated with the necessary precision. The calculations required only the elemental ratio Th/U in meteorites since the isotopic ratio $^{235}U/^{238}U$ was assumed to be the same for meteoritic and terrestrial samples. The Apollo Program has added lunar data to the meteoritic and terrestrial in recent years.

B^2FH[18] considered a number of possible models, one of which assumed *r*-process nucleosynthesis *uniform* in time and an arbitrary time interval between the last *r*-process contribution to the material of the solar nebula and the closure of the meteorite systems. A zero value for this time interval indicated that the production of uranium started 18 billion years ago. When this time interval was taken to be 0.5 billion years, the production started 11.5 billion years ago. These values are in remarkable, if coincidental, concordance with current values.

It is appropriate to indicate at this point that nucleocosmochronology yields, with additional assumptions, an estimate for the age of the expanding Universe completely independent of red shift-distance observations in astronomy on distant galaxies. The assumptions referred to in the previous sentence are that the *r*-process started soon, less than a billion years, after the formation of the Galaxy, and that the Galaxy formed soon, less than a billion years, after the "big bang" origin of the Universe. Addition of a billion years or so to the start of *r*-process nucleosynthesis yields an independent value, based on radioactivity, for the age or time back to the origin of the expanding Universe.

Much has transpired over the recent years in the field of nucleocosmochronology. I have kept my hand in most recently in [109]. Exponentially decreasing nucleosynthesis with the time constant in the negative exponent a free parameter to be determined by the observed abundance ratios along with the duration of nucleosynthesis was introduced by *Fowler* and *Hoyle*[110]. For the time constant in the denominator of the exponent set to infinity, uniform synthesis results. When it is set to zero, a single spike of synthesis results. With two observed ratios, two free parameters in a model can be determined. As time went on, the ratios $^{129}I/^{127}I$ and $^{244}Pu/^{238}U$ with $\bar{\tau}(^{129}I) = 0.023 \times 10^9$ years and $\bar{\tau}(^{244}Pu) = 0.117 \times 10^9$ years were added to nucleocosmochronology to permit the determination of two additional free parameters, the arbitrary time interval of B^2FH[18] previously discussed and the fraction of *r*-process nucleosynthesis produced in a last gasp "spike" at the end of the exponential time dependence.

Sophisticated models of Galactic evolution were introduced by *Tinsley*[111]. A method for model-independent determinations of the mean age of nuclear chronometers at the time of solar system formation was developed by *Schramm* and *Wasserburg*[112]. In this method, the mean age is one-half the duration for uniform synthesis and is equal to the actual time of single-spike nucleosynthesis. This indicates that one can expect no more than a range of a factor of two in the time back to the beginning of nucleosynthesis in widely different models for its time variation. These developments are reviewed by *Schramm*[105].

The most recent calculations are those of *Thielemann, Metzinger,* and *Klapdor*[113]. Their results, revised by his own most recent calculations, are shown in Figure 28, prepared by *F.-K. Thielemann*. The pre-solar spike and its time of occurrence before the meteorites became closed systems depend primarily on the *minute glasses,* ^{129}I and ^{244}Pu. The *eon glasses,* $^{232}Th/^{238}U$ and $^{235}U/^{238}U$, indicate that *r*-process nucleosynthesis in the Galaxy started 17.9 billion years ago, with uncertainties of $+2$ billion years and -4 billion years according to [113]. This value is to be compared with my value of 10.5 ± 2.3 billion years ago given in [109]. Inputs of production and final abundance ratios have changed[113]! *Thielemann* and I are now recomputing the new value for the duration using an initial spike in Galactic synthesis plus uniform synthesis thereafter.

Reference[113] indicates that the age of the expanding Universe is 19 billion years, give or take several billion years. This is to be compared to the Hubble time or reciprocal of Hubble's constant given by *Sandage* and *Tammann*[114] as 19.5 ± 3 billion years. However, the Hubble

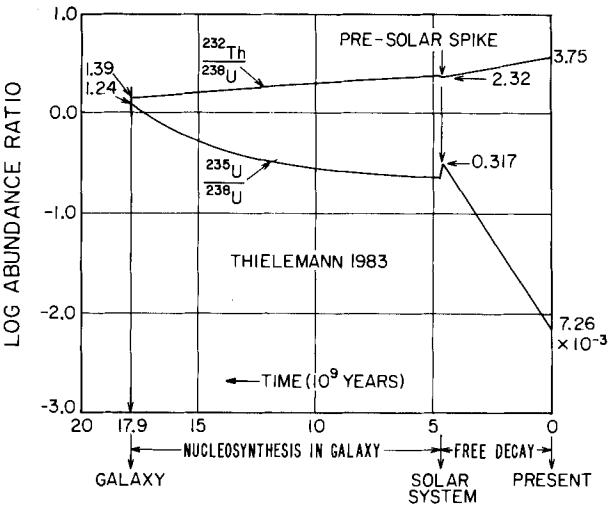

Fig. 28. The abundance ratios for $^{232}Th/^{238}U$ and for $^{235}U/^{238}U$ produced by theoretical *r*-process nucleosynthesis over the lifetime of the Galaxy prior to the formation of the solar system, from *Thielemann, Metzinger,* and *Klapdor* [113]. The free decays over the lifetime of the solar system to reach the present values for these ratios, $(^{232}Th/^{238}U)_0 = 3.75$ and $(^{235}U/^{238}U)_0 = 7.26 \times 10^{-3}$ are also shown. The production ratios in each *r*-process event was theoretically calculated to be 1.39 for $^{232}Th/^{238}U$ and 1.24 for $^{235}U/^{238}U$. Compare with Figure 10 in first reference under [109].

time is equal to the age of the expanding Universe only for a completely open Universe with mean matter density much less than the critical density for closure, which can be calculated from the value for the Hubble time just given to be 7×10^{-30} g cm^{-3}. The observed visible matter in galaxies is estimated to be ten percent of this, which reduces the age of the Universe to 16.5 billions years. Invisible matter, neutrinos, black holes, etc. may add to the gravitational forces which decrease the velocity of expansion and may thus decrease the age to that corresponding to critical density, which is 11.1 billion years. If the expansion velocity was greater in the past, the time to the present radius of the Universe is correspondingly less. Moreover, there are those who obtain results for the Hubble time equal to about one-half that of *Sandage* and *Tammann*[114], as reviewed in *van den Bergh*[115]. There is much to be done on all fronts!

A completely independent nuclear chronology involving the radiogenic ^{187}Os produced during Galactic nucleosynthesis by the decay of ^{187}Re ($\bar{\tau} = 65 \times 10^9$ years) was suggested by *Clayton*[116]. *Schramm*[105] discusses still other chronometric pairs. *Clayton*'s suggestion involves the *s*-process, even though the ^{187}Re is produced in the *r*-process. It requires that the abundance of ^{187}Re, the parent, be compared to that of its daughter, ^{187}Os, when the *s*-only production of this daughter nucleus is substracted from its total solar system abundance. This was to be done by comparing the neutron capture cross section of ^{187}Os with that of its neighboring *s*-only isotope ^{186}Os, which does not have a longlived radioactive parent, and using the $N\sigma = constant$ rule for the *s*-process.

Fowler[117] threw a monkey wrench into the works by pointing out that ^{187}Os has a low-lying excited state at 9.75 keV which is practically fully populated at $kt = 30$ keV, corresponding to the temperature $T = 3.5 \times 10^8$ K, at which the *s*-process is customarily assumed to occur. Moreover with

spin $J=3/2$ this state has twice the statistical weight $(2J+1)$ of the ground state with spin $J=1/2$. Measurements of the ground state neutron-capture cross-section yields only one-third of what one needs to know.

All of this has led to a series of beautiful and difficult measurements for neutron-induced reactions on the isotopes of osmium. *Winters* and *Macklin*[118] found the Maxwell-Boltzmann average ground state (laboratory) cross-section ratio for $^{186}Os(n,\gamma)$ relative to that for $^{187}Os(n,\gamma)$ to be 0.478 ± 0.022 at $kT=30$ keV with a slow dependence on temperature. This ratio must be multiplied by a theoretical factor to correct the ^{187}Os cross section in the denominator of the cross-section ratio for that of its excited state. The larger the theoretical ^{187}Os excited state capture, the smaller this factor. *Woosley* and *Fowler*[119] used Hauser-Feshbach theory to give an estimate for this factor in the range 0.8 to 1.10, which is little comfort because it multiplies one number comparable to the number from which it must be subtracted. These factors translated into a time for the beginning of the *r*-process in the Galaxy in the range 14 to 19 billion years. In despiration, I suggested privately that inelastic neutron scattering off the ground state of ^{187}Os to its excited state at 9.75 keV might yield information on the properties of the excited state. Measurements by *Macklin* et al.[120] and *Hershberger* et al.[121] determined these inelastic neutron scattering cross sections, which yielded inherent support of the lower value of the *Woosley* and *Fowler*[119] factor and thus a greater value for the time back to the beginning of *r*-process nucleosynthesis on the 18 to 20 billion year range. It has to be admitted that this is concordant with the latest value from the Th/U-nucleocosmochronology.

Once again in despiration I privately suggested that measurement of the neutron capture cross section on the ground state of ^{189}Os might be helpful. In ^{189}Os the ground state has the same spin and Nilsson numbers as the excited state of ^{187}Os and an excited state corresponding to the ground state of ^{187}Os. Measurements by *Browne* and *Berman*[122] are available but are now being checked by an Oak Ridge National Laboratory, Denison University and University of Kentucky consortium.

It will be clear that the lifetime of ^{187}Re comes directly into the calculations under discussion. There has been some discrepancy in the past between lifetimes measured geochemically and those measured directly by counting the electrons emitted in the 2.6 keV decay $^{187}Re(e^-\nu)^{187}Os$. Direct measurement yields only the lifetime for electron-emission to the continuum, while geochemistry yields the lifetime for electron-emission both to the continuum and to bound states in ^{187}Os. The entire matter is treated in considerable theoretical detail by *Williams, Fowler,* and *Koonin*[123], who found that the bound-state decay is negligible and that the direct measurements by *Payne* and *Drever*[124], which agree with the geochemical measurements of *Hirt* et al.[125], are correct.

There is also the vexing problem of the possible decrease in the effective lifetime of ^{187}Re in the Galactic environment. The ^{187}Re included in the material of the interstellar medium which forms new stars is subject to destruction by the *s*-process (astration) as well as being produced by the *r*-process. This decreases the effective lifetime of the ^{187}Re and all chronometric times based on the Re/Os chronology. This problem is discussed in elaborate detail by *Yokoi, Takahashi,* and *Arnould*[126]. The time back to the beginning of *r*-process nucleosynthesis could be as low as 12 billion years. It is appropriate to end this last section before the concluding section with considerable uncertainty in nucleocosmochronology indicating that, as in all nuclear astrophysics, there is much exciting experimental and theoretical work to be done for many years to come. Amen!

XIII. Conclusion

In spite of the past and current researches in experimental and theoretical Nuclear Astrophysics, illustrated in what I have just shown you, the ultimate goal of the field has not been attained. *Hoyle*'s grand concept of element synthesis in the stars will not be truly established until we attain a deeper and more precise understanding of many nuclear processes operating in astrophysical environments. Hard work must continue on all aspects of the cycle: experiment, theory, observation. It is not just a matter of filling in the details. There are puzzles and problems in each part of the cycle which challenge the basic ideas underlying nucleosynthesis in stars. Not to worry—that is what makes the field active, exciting and fun! It is a great source of satisfaction to me that the Kellogg Laboratory continues to play a leading role in experimental and theoretical Nuclear Astrophysics.

And now permit me to pass along one final thought in concluding my lecture. My major theme has been that all of the heavy elements from carbon to uranium have been synthesized in stars. Let me remind you that your bodies consist for the most part of these heavy elements. Apart from hydrogen you are 65 percent oxygen and 18 percent carbon with smaller percentages of nitrogen, sodium, magnesium, phosphorus, sulphur, chlorine, potassium, and traces of still heavier elements. Thus it is possible to say that you and your neighbor and I, each one of us and all of us, are truly and literally a little bit of stardust.

Charles Christian Lauritsen taught me a Swedish toast. I conclude with this toast to my Swedish friends: "*Din skål, min skål, alla vackra flickor skål. Skål!*"

My work in Nuclear Astrophysics has involved collaborative team work with many people, and I am especially grateful to Fay Ajzenberg-Selove, Jean Audouze, C. A. Barnes, E. M. Burbidge, G. R. Burbidge, G. R. Caughlan, R. F. Christy, D. D. Clayton, G. M. Fuller, L. J. Greenstein, Fred Hoyle, Jean Humblet, R. W. Kavanagh, S. E. Koonin, C. C. Lauritsen, Thomas Lauritsen, D. N. Schramm, T. A. Tombrello, R. V. Wagoner, G. J. Wasserburg, Ward Whaling, S. E. Woosley and B. A. Zimmerman. For aid and helpful cooperation in all aspects of my scientific work, especially in the preparation of publications, I am grateful to Evaline Gibbs, Jan Rasmussen, Kim Stapp, Marty Watson and Elizabeth Wood. I acknowledge support for my research over the years by the Office of Naval Research (1957 to 1970) and by the National Science Foundation (1968 to present).

Modelling the Chemistry of Zeolites by Computer Graphics**

By Subramaniam Ramdas, John M. Thomas*, Paul W. Betteridge, Anthony K. Cheetham, and E. Keith Davies

The unique structural, adsorptive, and catalytic properties of zeolites are particularly amenable to illustration by computer (especially color) graphics. The siting of cations, the accommodation of guest reactant or product species, as well as the occurrence of various kinds of intergrowths (e.g. twin planes and coincidence boundaries) within these microporous solids can all be effectively portrayed by graphical means in such a manner as to emphasize the shape-selective character of the host zeolite. The dynamics of translational and angular motion of guest species (for example benzene) in a channel of molecular dimensions within a typical zeolitic solid (for example silicalite) can also be probed interactively using appropriate potential functions.

[**] The defect structure simulations outlined in Section 3 were displayed on a Sigma 5684 raster graphics terminal linked to an IBM 3081 computer, using locally written routines. The calculations described in Section 4 were carried out using the CHEMGRAF suite of programs on a VAX 11/750 computer (E. K. Davies: CHEMGRAF User Manual, Chemical Crystallography Laboratory, University of Oxford, Oxford, UK 1984). A Sigma 5688 raster graphics terminal was used to display the results, which were photographed directly from the terminal.

1. Introduction

Zeolites were discovered more than two hundred years ago. They have been used for decades as water softeners and cation exchangers, as well as vehicles for the separation of molecules according to shape and size. In addition to their use as molecular sieves, they have, since the mid-sixties, been extensively employed as industrial catalysts[1], and, of late, highly siliceous variants of zeolites have led to important new developments in shape-selective heterogeneous catalysis[2].

 © *Verlag Chemie GmbH, D-6940 Weinheim, 1984* *0570-0833/84/0909-0671 $ 02.50/0*

Zeolites can be described by the general formula $M_{x/n}[(AlO_2)_x(SiO_2)_y]\cdot m\,H_2O$, where the cations M of valence n neutralize the charges on the aluminosilicate framework, which in turn is composed of corner-sharing SiO_4 and AlO_4 tetrahedra. The linkages between these units generate cages or pores of molecular dimensions (3 to 8 Å in diameter). Their surface area, which lies largely within the bulk, is typically 500 $m^2\,g^{-1}$. The neutralizing cations are located in more or less well defined sites in the various cavities that exist within the structure, and the water molecules fill up the voids; the water can be expelled upon heating and evacuation. In view of their exceptional porosity, the process of cation exchange in zeolites takes place very readily. Likewise, they permit facile movement of small neutral molecules into or out of the bulk structure. By adjusting the valency and the size of the exchangeable cation, the sieving and separation processes can, as it were, be fine tuned[3]. Moreover, by increasing the silicon to aluminum ratio of the macro-anionic framework by dealumination[4], the microporosity can be further enhanced. Introduction of hydrocarbons is easier when the Si/Al ratio of the dehydrated framework is higher, not only because there are fewer exchangeable cations but also because the framework itself becomes progressively more hydrophobic (i.e. more oleophilic) as aluminum is eliminated. A further advantage possessed by these structures is that Brønsted acid sites, one type of which may be rather crudely represented as

are distributed quite uniformly throughout the structure. These are active sites for many catalytic reactions involving hydrocarbons; and since they are situated at internal surfaces accessible to reactant species, many subtle, shape-selective chemical conversions can be carried out using zeolitic catalysts.

In order to understand all the various nuances of structural chemistry exhibited by zeolites, it is often essential to construct appropriate models which, inter alia, emphasize the framework topology and the shapes and sizes of the cavities and tunnels. A beautiful illustration of such models of some of the zeolites has been shown by *Sten Andersson* in his review on the description of complex inorganic crystal structures[5]. Although such models are invaluable for visual comprehension, their construction is usually time consuming and they often have real limitations. For example, a satisfactory representation of the extra-framework cations is difficult using conventional modelling techniques, but the chemistry of zeolites is intimately linked with the locations of these ions. This is one respect in which computer graphics can play a useful role. But we can go much further than merely providing effective illustrations for the understanding of structures. A computer model can readily be manipulated to permit examination of various structural features; for instance, the locations of the cations can be rearranged, suspected order-disorder phenomena in the cation sublattice can be monitored, and defects of various kinds can be introduced. Furthermore, calculations of the interaction energies can be performed, provided suitable theoretical models exist, to monitor the energetics of various operations that simulate the physicochemical aspects of adsorption, diffusion, etc. For example, interaction energies between the zeolite framework and a guest molecule can be investigated using such procedures. We shall describe computer simulations that combine a facility for carrying out "experiments" (some of which are, as yet, impossible with real substances) with a powerful method for displaying and evaluating the results. The possibilities of computer modelling and graphics have been nicely appreciated in other areas of chemistry. For example, in the last few years, pharmacologists have been quick to capitalize on the scope and utility of these techniques in the design of drugs[6a] and other biologically important materials[6b].

In this paper, we provide an introduction to the application of computer graphics to the study of some problems in zeolite chemistry, and in so doing we outline some of the more significant results obtained to date. Three aspects of computer graphics are emphasized:

1. The provision of clear illustrations depicting many features of zeolitic structures determined by X-ray studies.
2. More sophisticated applications, such as the modelling of possible intergrowths, twinning, and other planar faults of the kind commonly encountered among zeolites.
3. Dynamic simulation of interactions between organic molecules and the framework.

Such studies provide novel and convenient methods for probing the behavior of zeolitic catalysts under conditions quite close to those used in catalytic reactions. Although we will give typical examples of reactant and product shape-selectivity, we expect that suitable extension of these techniques will allow one to investigate even the "transition state" selectivity of reaction intermediates[7], in real time.

2. Color Illustrations of Zeolite Frameworks

2.1. Zeolites X and Y

Zeolites X and Y are structurally analogous to the mineral faujasite. The building units are truncated octahedra, also known as sodalite cages, β-cages, or tetrakaidecahedra (the three terms are synonymous), which are linked to adjacent cages via hexagonal biprisms, thereby yielding larger "supercages", also known as α-cages (Fig. 1). The principal sites for the extra-framework cations are known as the S(I), S(I′), S(II), and S(II′) sites. The Si–O–Al framework and the locations of the principal cation sites are shown in Figure 1, from which we can readily grasp the significance of the occupancy factors reported for the various sites. The features to be noted are: (i) adjacent S(I) and S(I′) sites are not simultaneously occupied by cations, whereas almost all the S(II) sites in the wall of the supercage are occupied; (ii) cations preferring higher coordination numbers usually occupy the S(I) sites. The tetrahedral

clustering of S(II′) sites within the β-cage precludes any significant occupancy.

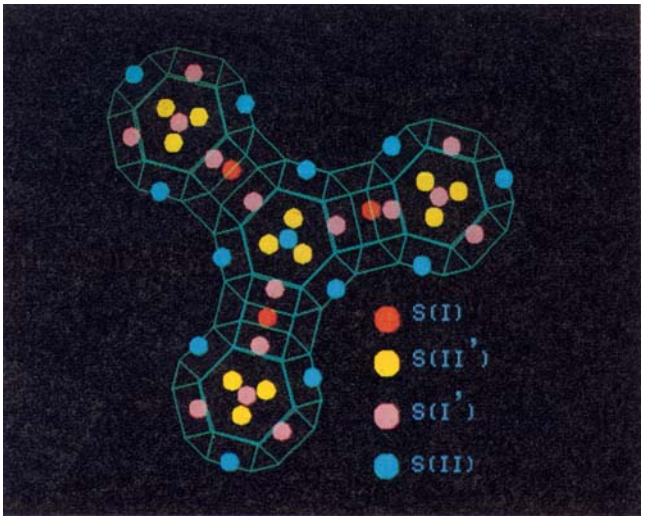

Fig. 1. Faujasite framework (oxygens not shown) with principal cation sites. Whereas, sites S(I′) and S(II′) are within the β-cages, S(I) and S(II) are in the hexagonal biprisms and the supercages, respectively. In addition, there are cation sites which are also known to be in the supercages.

New methods of achieving the isomorphous replacement of aluminum by silicon[4] have made it possible to render a zeolite cavity or channel relatively free from cations. As mentioned earlier, this changes the zeolite's affinity towards neutral organic molecules by increasing the free space available and also by enlarging the channel size; there is also a reduction in the polarity of the zeolite. As a typical example, in Figure 2 (top) we show an ethane molecule within the supercage in zeolite Y. The 12-membered ring entrance to the α-cage is wide enough to accommodate a large organic molecule, for example azoisobutyronitrile (AIBN). The introduction of molecules like AIBN is interesting because of the possible photogeneration of radicals[8] that recombine to yield the tetramethyl dinitrile with loss of N_2. Preferential formation of this product over other unsymmetrical ones[9] is a possibility because of the restricted rotation and translation of the trapped radicals within the supercage. This is reflected in Figure 2 (bottom), where the least squares best plane projection of AIBN gives a maximum "van der Waals length" of 8.9 Å, which is within the diameter of the supercage (9.2 Å). Also, the "maximum overlap projection" of the molecule has a diameter of 6.2 Å, well within the 7 Å aperture (shown in Figure 2b).

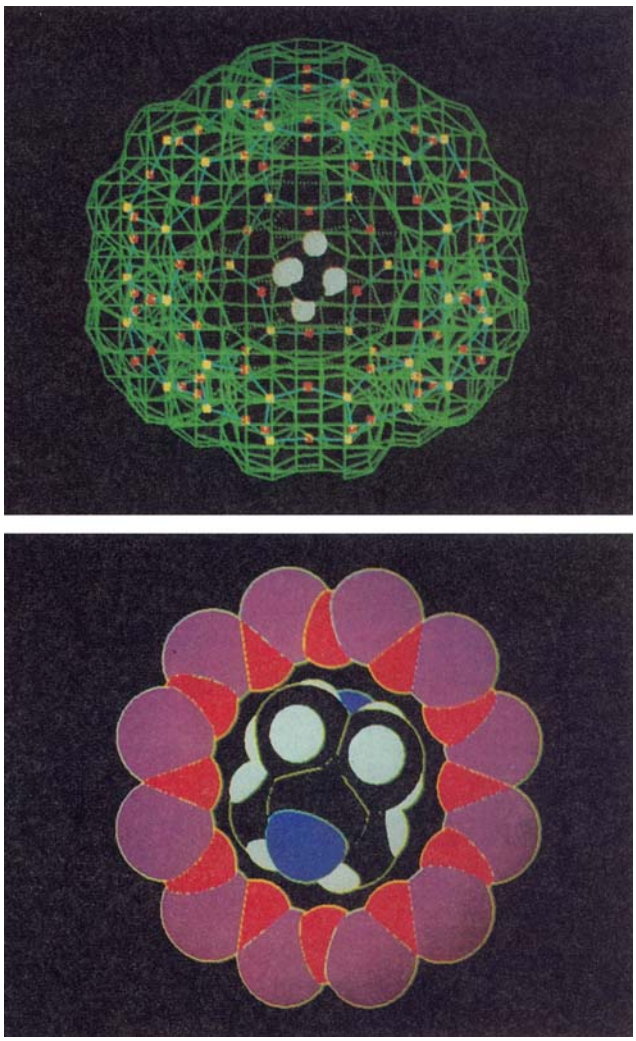

Fig. 2. The molecules, (top) ethane and (bottom) azoisobutyronitrile within the supercage of the faujasitic framework. For clarity, the twelve-membered ring opening to the supercage is alone shown in the bottom picture, with Si and O colored in magenta and red (in their van der Waals radii), respectively.

2.2. Zeolites A and ZK-4

The structure of zeolite A is also made up of connected sodalite cages, but in this case the tetrakaidecahedra are linked via cubes rather than hexagonal prisms. The locations of the extra-framework cations in the $K^{\oplus}$-form[10] of zeolite A are shown in Figure 3. This clearly shows that the 'blue' cations occupy most of the centers of the six-membered rings (O atoms (red) not counted), slightly altering the kinetic diameter of the channels and reducing the free volume of the supercage. In addition, the large "blue" cations block the eight-membered ring channels. One way of altering the zeolite to allow hydrocarbon molecules to diffuse through is to replace the monovalent cation by a divalent ion such as strontium. Not only is the number of ions required to neutralize the framework charge halved, but also the remaining ions tend to occupy the sites in the six-membered ring windows leaving the channels free. Alternatively, and preferably, one may increase the silicon to aluminum ratio, as in the zeolite ZK-4, which has a framework structure the same as that of zeolite A but with a Si/Al ratio of at least 2.5. Zeolite ZK-4, therefore, requires fewer cations than zeolite A to balance framework charge, leading to freer channels. A straight chain hydrocarbon can diffuse relatively freely through such channels.

This shape-selectivity of zeolites for some reactant and product molecules, which is responsible for their novel catalytic role, rivaling that of certain enzymes, can be proved effectively with computer graphics. In Figure 4 we show

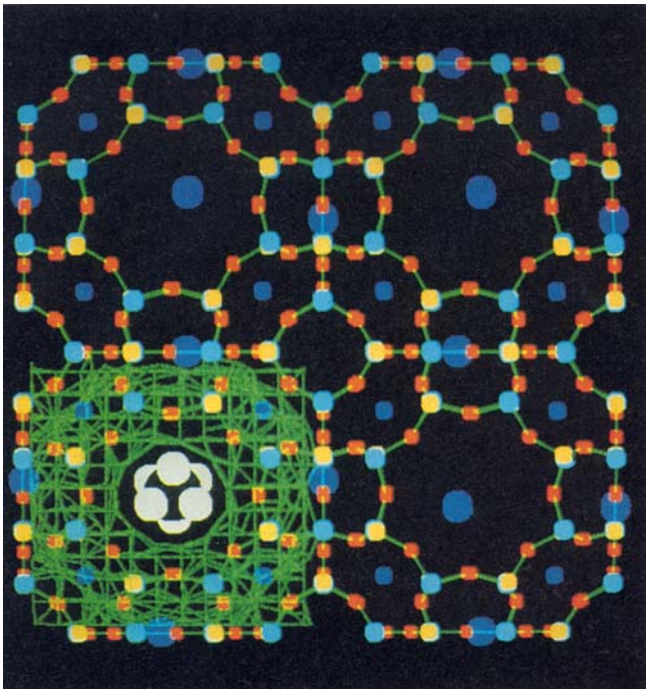

Fig. 3. The framework and the cations in the $K^{\oplus}$-form of zeolite A. Red: O, yellow/light blue: Si/Al, dark blue (small and large): cation sites. The network covering the van der Waals surface is shown, with a molecule of ethane in the channel. To permit adsorption and diffusion of this molecule, the $K^{\oplus}$ ions blocking the eight-membered rings must be removed. This is effected either by increasing the Si/Al ratio (thereby decreasing the number of exchangeable cations per unit-cell, as in ZK-4) or, for a fixed Si/Al ratio, by replacement of monovalent by divalent ions.

the ease with which a methanol molecule can diffuse through the straight channels of the zeolite ZSM-5, yielding products including *n*-alkanes in the gasoline range. On the other hand, branched hydrocarbons are trapped inside the channel intersections and undergo further isomerization to yield the above-mentioned products selectively. Similarly, the fraction of *p*-xylene in xylene mixtures can be increased. Figure 5 also shows how acid sites on the surface with large pores and cavities can be effectively blocked by 4-methylquinoline, leaving only the bulk acid sites available to smaller bases that diffuse through the pores.

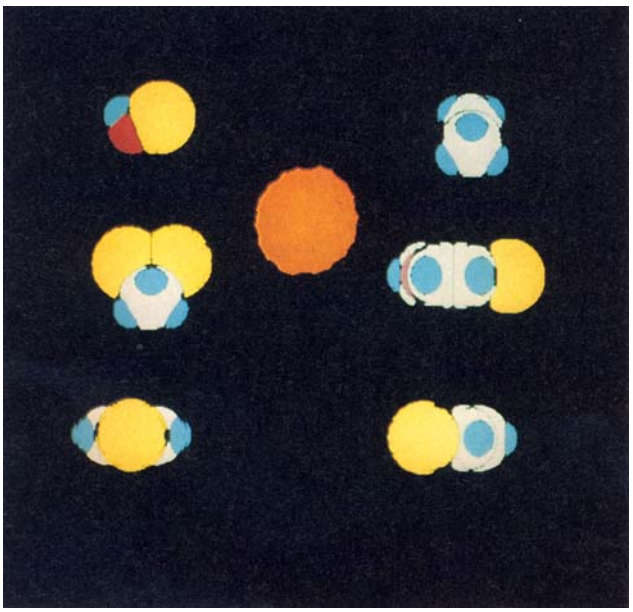

Fig. 4. Illustration of shape selectivity of ZSM-5. The cross section of the straight channel can be compared with the size and shape of the molecules shown (approximately viewed along their molecular axis). Left, from top to bottom: methanol, 2,2-dimethylpentane, *p*-xylene. Right, from top to bottom: *n*-pentane, 4-methylquinoline, *m*-xylene. Yellow: CH_3, white: C, pink: N, red: O, blue: H.

3. Modelling of Defects and Intergrowth Phenomena

3.1. The Zeolites ZSM-5 and ZSM-11

In addition to the illustrative capability that we have described so far, computer simulations can be used to test various structural hypotheses and to check suggested models against the observed results, particularly in the electron microscope. Electron microscopy is probably the most direct technique for identifying intergrowth phenomena in crystalline solids. One recent success has been the identification of the precise nature of the intergrowths involving the closely related zeolites ZSM-5 and ZSM-11[11]. In both ZSM-5 and ZSM-11, chains of five-membered ring building units run parallel to the *c*-axis. The adjacent chains along *a*, however, are related by inversion centers (denoted by i) in ZSM-5 and by mirror planes (denoted by σ) in ZSM-11. Figure 5 illustrates schematically the presence of strips of ZSM-11 in a ZSM-5 matrix. In the computer experiment, various models of ZSM-5/ZSM-11 intergrowths can be constructed by invoking mirror or inversion operations. By placing a "dot" at the locations of the silicon or aluminum atoms, we can create a mask[*] for optical diffraction. The optical diffraction pattern can then be compared with the observed electron diffraction pattern. A typical example characterizing the nature of a particular intergrowth of ZSM-5 and ZSM-11 is shown in Figure 6.

3.2. Twinning in Zeolite Y

Similar studies have been carried out on the twinning across the (111) planes in zeolite Y. If every layer of the (111) planes is twinned with respect to the adjacent layer, the framework, mask, and corresponding optical diffraction pattern in the [111] projection, will be as shown in Figures 7a, b, and c, respectively. The hexagonal symmetry of the pattern is exactly what one would expect[12] for the extended defect structure, which incidentally is identical to that of the zeolite ZSM-3, originally reported by *Kokotailo* and *Ciric*[13]. This can be compared with the results for an untwinned zeolite Y shown in Figure 8. In the [111] projection, even if the twinned layers are juxtaposed between (111) planes, the diffraction pattern and the mask will be

[*] The 'mask' we refer to is the positive film of the structure of an object (Fig. 6a). In an experiment using an optical bench consisting of a laser source, a series of convergent and diffraction lenses, and a recording medium, optical transformation of this mask produces the diffraction pattern shown in Figure 6b. The advantage of such graphical techniques lies in the ability to create large supercells of non-periodic defects of the kind identified here.

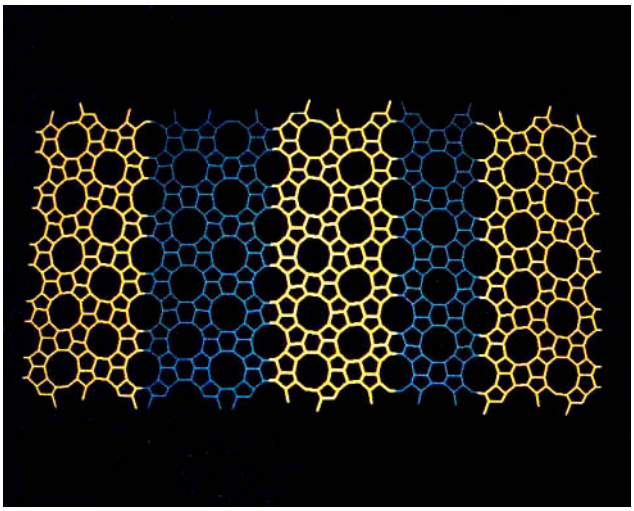

Fig. 5. Schematic view, along the *b*-axis, representing intergrowths between ZSM-5 and ZSM-11 structures. Both these structures are built of five-membered rings forming a chain along the *c*-axis. Adjacent chains, in ZSM-5 (yellow) are related by centers of inversion, whereas those in ZSM-11 (blue) are related by mirror planes, perpendicular to the *a*-axis. The framework remains continuous despite the presence of these defects.

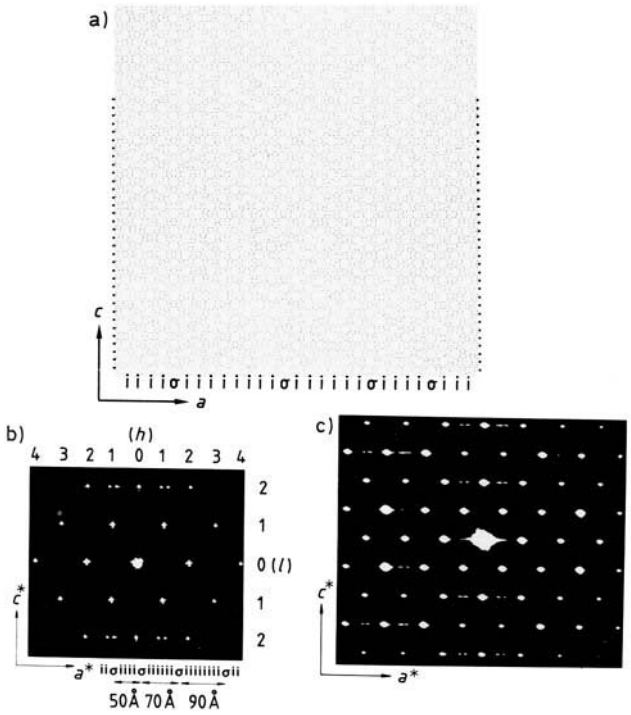

Fig. 6. a) A non-regular model of ZSM-5/ZSM-11 intergrowth of average periodicity $a = 70$ Å (see text). Adjacent strips along a are related by inversion centers i or minor planes σ. The typical minor planes σ in ZSM-11 are separated from each other by various distances (50, 70, 90 Å), which, however, give a, on average. — b) Optical Fourier transform of a) with the reciprocal vectors a^* and c^*, as well as the diffraction orders h and l belonging to the principal reflections of the determined structure ($a_0 = 18.4$ Å). — c) The electron diffraction pattern showing the 66 Å pseudo-periodicity superimposed on the streaks along [100].

the same as those in Figure 8, except for differences in the relative intensities[14]. However, viewing along [110] one can identify the defect regions of the crystal. For a hypothetical case in which every third layer is a twin of the second layer of the (111) planes, the optical mask is shown in

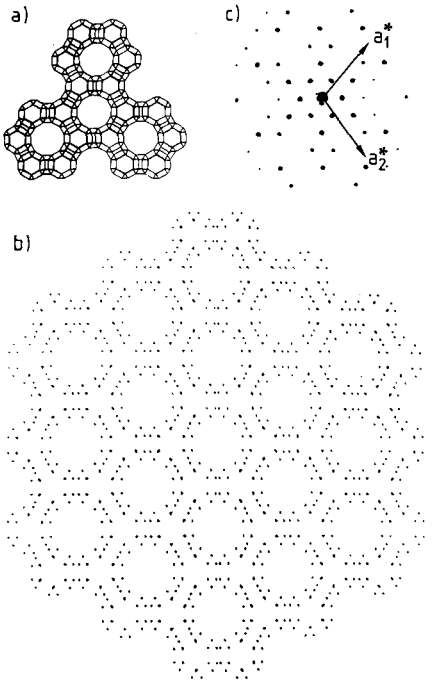

Fig. 7. a) Framework of the recurrently twinned faujasite. Here twinning occurs at every adjacent (111) plane in the faujasite structure. The resulting structure is hexagonal and the plane of projection now becomes $(001)_{hex}$. b) The mask representing the framework is the same projection but depicting the location of Si (or Al) atoms, without the bonds. c) The optical transform of b), the zone axis being $[001]_{hex}$.

color (Fig. 9) to distinguish the twinned layers. If the twinning had been random, the optical diffraction pattern of the corresponding model would show streaking along [111].

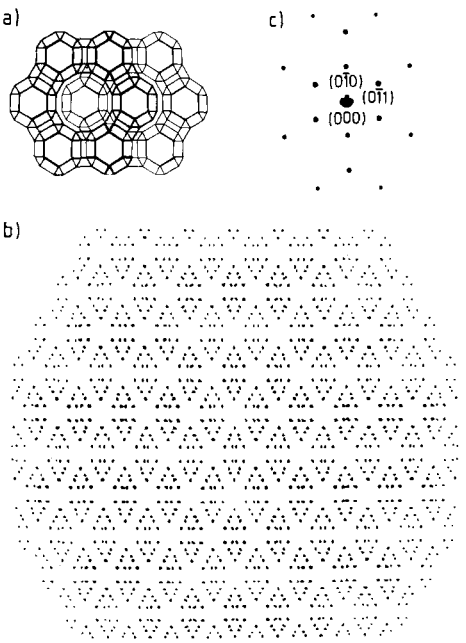

Fig. 8. a) Framework of the faujasite structure in the [111] projection; b) a "mask" depicting the locations of the Si (or Al) atoms; c) the corresponding optical transform of b).

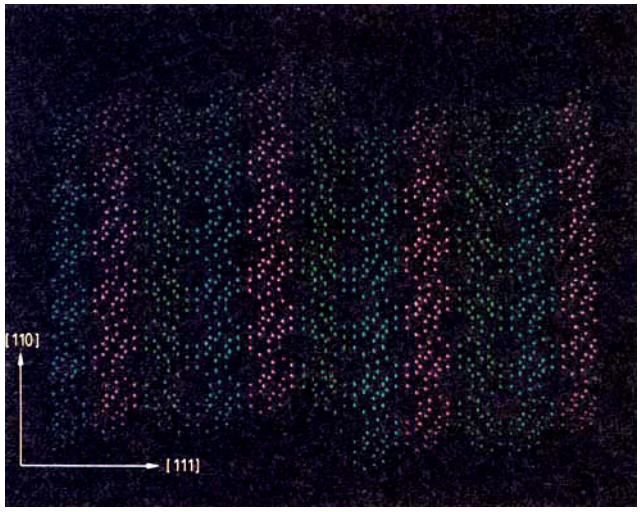

Fig. 9. A hypothetical model of faujasite, viewed along [110], in which twinning occurs at every third layer of (111) planes (blue-red-green) running parallel to the vertical axis in the figure.

3.3. Variations in Stacking Sequences

There is a whole family of related zeolitic structures of similar chemical composition with six-membered rings of SiO_4 tetrahedra that are stacked in three different ways (A, B, and C, see Fig. 10) along the hexagonal *c*-axis, giving rise to an almost infinite number of framework structures[15]. Although, by convention, these structures can be classified as polytypes, their steric arrangements actually differ. If only two types of sequences are present in a structure in any order, they will have large open channels in the *c* direction, as in offretite (see Fig. 10 (top)). On the other hand, if all three stacking arrangements are present, there will be long and short cages, (with 12-membered ring apertures effectively blocked, as shown in Figure 10 (middle)) depending on the precise sequence present; e.g. liottite and afghanite. In Table 1 we list some of the known zeolites possessing stacking variations of this kind. Stacking faults in the parent structures have often been noticed, particularly in high resolution lattice images[16] in the electron microscope. Depending on the stacking sequence present, the relative positions of the 8-membered ring apertures in the [110] zone differ and are easily seen in the image, provided the material is electron-beam stable and the zone axis is accessible.

Table 1. Chabazite family of zeolites with their stacking properties.

Name	Abbr.	Space group	Lattice parameters [Å] *a*	*c*	Stacking sequence
Afghanite	AFG	$P6_3/mmc$	12.8	21.4	ABABACAC
Cancrinite	CAN	$P6_3/mmc$	12.8	5.1	AB
Chabazite	CHA	$R\bar{3}m$	13.2	15.1	AABBCC
TMA-E(AB)	EAB	$P6_3/mmc$	13.3	15.2	ABBACC
Erionite	ERI	$P6_3/mmc$	13.3	15.1	AABAAC
Gmelinite	GME	$P6_3/mmc$	13.8	10.0	AABB
Levyne	LEV	$R\bar{3}m$	13.3	23.0	AABCCABBC
Liottite	LIO	$P\bar{6}m2$	12.8	16.1	ABABAC
Losode	LOS	$P6_3/mmc$	12.9	10.5	ABAC
Offretite	OFF	$P\bar{6}m2$	13.3	7.6	AAB
Sodalite	SOD	$I\bar{4}3m$	8.9	—	ABC

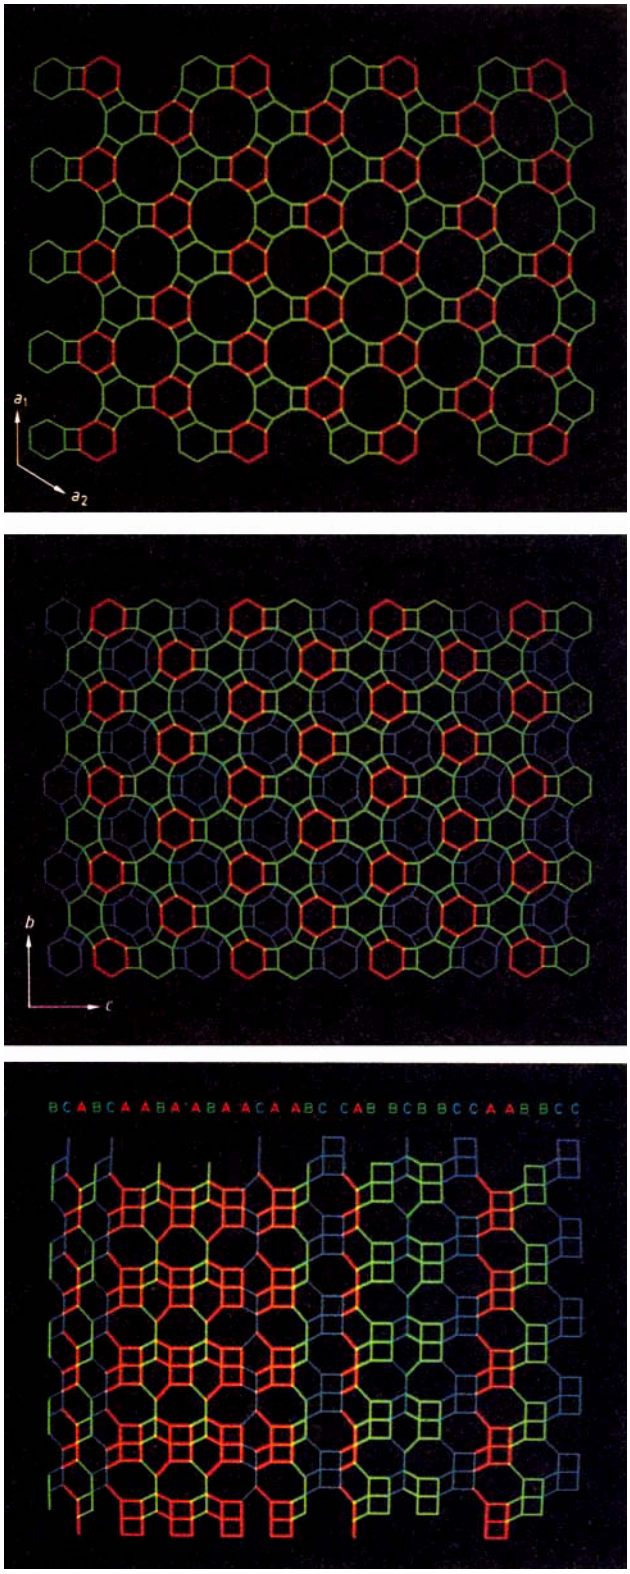

Fig. 10. Schematic representation of the "chabazite" family of zeolites: top: "AB" and middle: "ABC" stacking sequences viewed along the hexagonal axis; bottom: The possibility of intergrowths and stacking faults among these zeolites is shown schematically, viewed on the *bc* plane.

We have devised a novel method[17] of simulating any desired stacking sequence, from which we make a direct comparison with the lattice image. In this way, one may identify even an isolated stacking fault in such materials. Figure 10 (bottom) describes schematically the principle

behind such computer experiments. It clearly demonstrates how various zeolites, differing in their ordered sequences, can intergrow with each other. We would particularly like to draw attention to the relative arrangements of the eight-membered ring apertures resulting from such intergrowths, which, with continuing improvements in technique, will become identifiable in the high resolution image[17].

3.4. Simulation of Non-Coherent Interfaces between Crystallites

There is increasing experimental evidence to suggest growths of two different, yet related frameworks of zeolitic structures upon one another. One such piece of evidence was uncovered by *Kerr* et al.[18] in the case of zeolite L and offretite (or erionite) growing across a common interface. Similar occurrences in the cases of synthetic mazzite and offretite, and mazzite and zeolite Y have also been observed[19]. Simulation of such interfaces requires large periodicities in the growth plane, sometimes in excess of 100 Å. Manipulation of such large unit cells in a graphics system is probably a convenient way of visualizing the structural consequences of such phenomena. We give below one specific example, namely the presence of the $\sqrt{13}\sqrt{13}$ R32.2° coincident lattice in the growth of zeolite L (see Fig. 11). Similar descriptions apply to the systems mentioned above[20].

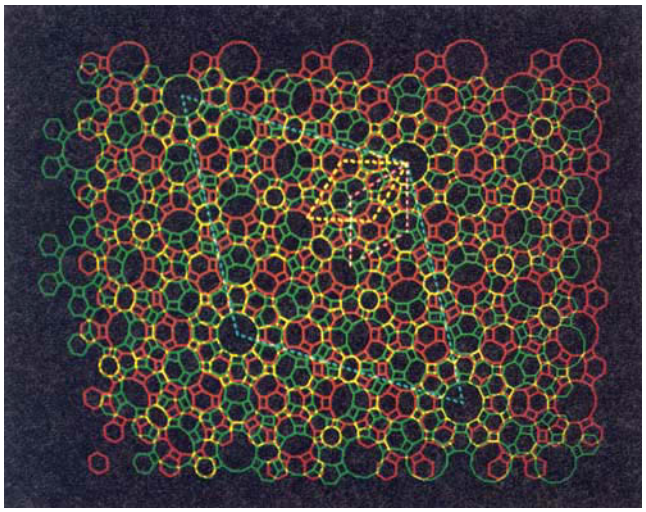

Fig. 11. Plan view (down [001]) of the coincidence boundary ($\sqrt{13}\sqrt{13}$ R32.2°) generated by rotating one half of the crystal of zeolite "L" about [001] by 32.2° with respect to the other (each vertex denotes a Si or Al site joined together via oxygens, not shown here). The repeat distances in the coincident lattice exceeds the original hexagonal mesh ($a_0 = 18.4$ Å) by $\sqrt{13}$.

In the high resolution lattice image of zeolite L in the [001] zone, small domains of lattice periodicity $a_0\sqrt{13}$ ($a_0 = 18.4$ Å) were frequently observed. Optical diffractograms of the image indicated a near 30° rotation of one half of the crystal over another. Exact coincidence of the lattice at the interface, however, occurs at 32.2°. A schematic diagram of such a coincidence boundary and its consequence, the overlap of fewer open tunnels, is shown in Figure 11. One may note that even though there is a coincidence of lattice there is no coincidence of atomic positions. Figure 11 clearly shows that following the introduction of one such boundary there is a reduction in the number of open channels per unit area (only 8 percent in zeolite L) with a concomitant reduction in the diffusivity of molecules along [001] channels.

4. Interaction Energies of Organic Molecules and Zeolites

The sorption and diffusion of an organic molecule within the zeolite is primarily governed by the shape and size of the cages and channels in the framework, and we have seen the capability of computer graphics in illustrating these aspects. In this section, we describe how an organic molecule can be "guided" through the cavities and how one can estimate, quantitatively, the energetics involved in such a process. This work is ideally carried out interactively using a graphics terminal; the movement of the molecule within the framework and the interaction energies associated with the locations and orientation of the molecule can be monitored in real time.

In order to calculate the interaction energies, we require a model that is both reasonably accurate and, for interactive computations, uses relatively fast algorithms. For simplicity we ignore the interactions between the organic molecules themselves, i.e. we consider an infinitely dilute system. Similarly we assume that the framework remains unaltered by the introduction of the guest molecules. (There are good physico-chemical reasons for supposing that some organic molecules will perturb the zeolitic framework structure. The nature of this perturbation could itself be monitored by computer graphical methods of the kind described in this article.)

The model used in this work is a simple empirical treatment of van der Waals energy, with the addition of an electrostatic term. The expression used for non-bonded atom pairs is

$$U(r) = \frac{A\exp(-Br)}{r^D} - \frac{C}{r^6} + \frac{Kq_1q_2}{r}$$

where A, B, C and D are constants, q_1 and q_2 are the atomic charges, K is a unit conversion constant, and r is the distance between the atom pair.

The parameterization of the van der Waals part of this equation is that due to *Del Re* et al.[21], using the coefficients of *Kiselev* et al.[22]. Most of the organic molecules of interest are electrically neutral, but the net charges on the atoms can be calculated using molecular orbital methods[23]. Similarly, theoretical estimates[24] of the charges on the framework atoms are necessary in order to describe the electrostatic interactions, which are relatively long range. The value of the permittivity can be included in the constant K, and in this work a value of unity was used.

The total interaction energy is derived from the sum of the atom-atom terms, an assumption widely and successfully used in predicting the conformations of proteins and the packing of molecules in the solid state. A further ap-

proximation has been made to speed up the calculation for widely separated atoms: the short-range repulsive terms are ignored, and the attractive and electrostatic terms are estimated for groups of atoms, rather than for individual atoms[25].

We illustrate the application of the above procedure by describing results on the adsorption of benzene in silicalite, an aluminum-free zeolite that is isostructural with ZSM-5. We have chosen this system not only because of its industrial importance, but also for simplicity, since the calculations are not hampered by uncertainties in the locations of aluminum atoms and extra-framework cations. The benzene molecule is placed at a suitable starting position within the straight channel of a fragment of zeolite containing about 3500 atoms (Fig. 12). The interaction energy between the benzene molecule and the silicate framework is then calculated at intervals of 0.4 Å along the channel for a range of angular orientations of the molecule about the two-fold axis of the channel.

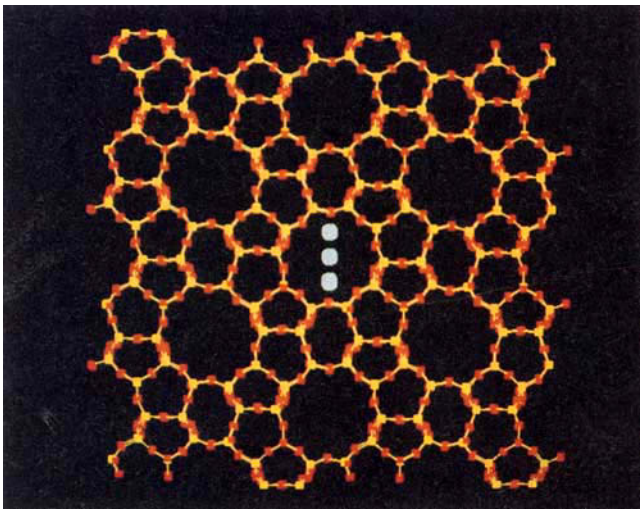

Fig. 12. A molecule of benzene in the straight channel of ZSM-5. For the energy calculations, the orientation of the molecule is varied such that the long molecular axis remains always parallel to the channel axis b. It is the angle θ between the short molecular axis and the maximum diameter (in projection) of the channel that is changed at regular intervals; in this case $\theta = 0°$.

In a typical calculation, over 1600 values of the interaction energy are stored with the corresponding position and orientation of the molecule. Figure 13 shows the energy at a fixed angular orientation as a function of the distance along the straight channel. A more effective method of displaying these results is in the form of a contour map using colored regions to represent different energy levels in areas of the conformational space over which the calculation was performed. The maps reproduce geometrical features such as the symmetry of the system, and they also reveal the restrictions on the movement of the molecule within the channel. For example, from Figure 14 one readily sees that facile molecular diffusion along the channel occurs only for a limited range of angular orientations. The colored contours also show the energy barriers and the greater conformational freedom encountered at the intersections where the straight and sinusoidal channels meet.

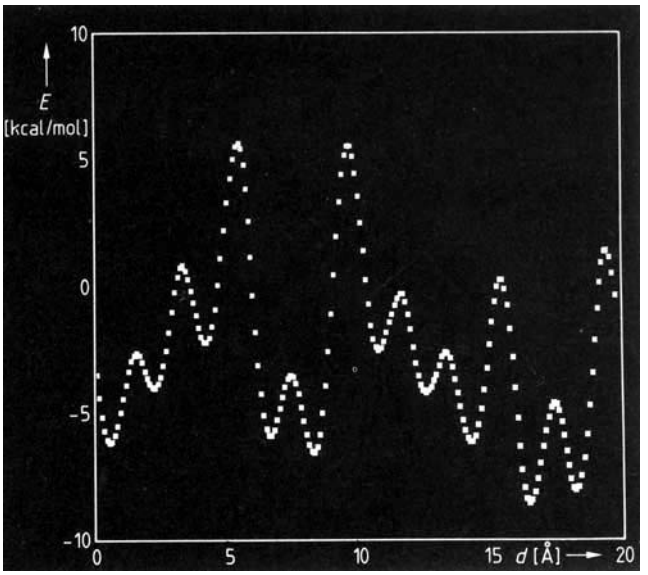

Fig. 13. A plot of interaction energy E against distance of travel (from an arbitrary origin through the entire unit cell length of 20 Å) for a benzene molecule moving along the straight channel direction, b, in silicalite, the pure silica variety of ZSM-5 (cf. Fig. 12), at a fixed orientation, i.e. $\theta = 30°$.

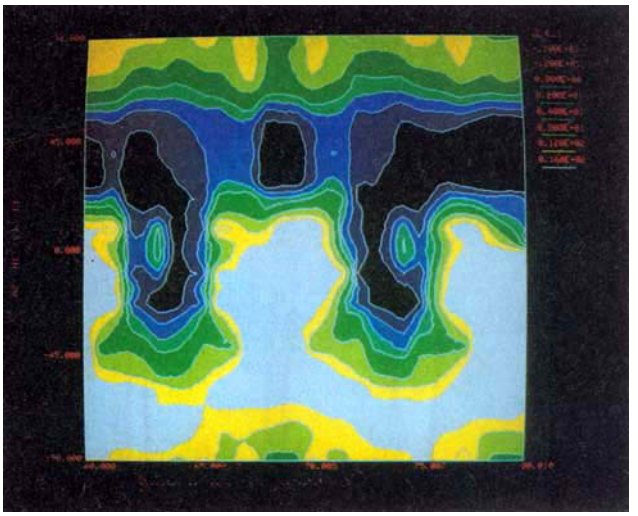

Fig. 14. Adsorption energy contours based on the results of plots like Figure 13 for all possible orientations of θ graded from positive to negative values in terms of color codes (black -10, dark blue -2, marine blue 0, light-green 2, dark green 4, yellow-green 8, yellow 12, light blue 16 kcal/mol) are plotted as a function of θ (ordinate) and the distance (Å) along the b channel. The abscissa values (from left to right) are 60, 65, 70, 75, and 80 Å; the ordinate values (from bottom to top), -90, -45, 0, 45, and 90°.

One of the great merits of using interactive graphics procedures is the ability to freeze these optimum configurations to allow for more detailed studies, including the influence of refined potentials and larger segments of the framework. We expect that this approach will play an important role in future studies on adsorption and diffusion processes in zeolites.

We express our appreciation to many of our colleagues at Oxford and Cambridge and to the following organizations who in various ways and at various stages supported parts of this work: The University of Cambridge, The University of

Oxford, Exxon, and BP. We are most grateful to our photographic experts, Messrs. E. L. Smith, I. A. Cannell, and N. F. Cray for their cooperation and skill.

On Stars, Their Evolution and Their Stability (Nobel Lecture)**

By Subrahmanyan Chandrasekhar*

1. Introduction

When we think of atoms, we have a clear picture in our minds: a central nucleus and a swarm of electrons surrounding it. We conceive them as small objects of sizes measured in Ångstroms ($\sim 10^{-8}$ cm); and we know that some hundred different species of them exist. This picture is, of course, quantified and made precise in modern quantum theory. And the success of the entire theory may be traced to two basic facts: *first*, the Bohr radius of the ground state of the hydrogen atom, namely

$$\frac{h^2}{4\pi^2 m e^2} \sim 0.5 \times 10^{-8}\ \text{cm} \qquad (1)$$

where h is Planck's constant, m is the mass of the electron, and e is its charge, provides a correct measure of atomic dimensions; and *second*, the reciprocal of *Sommerfeld's fine-structure constant*,

$$\frac{hc}{2\pi e^2} \sim 137 \qquad (2)$$

gives the maximum positive charge of the central nucleus that will allow a stable electron-orbit around it. This maximum charge for the central nucleus arises from the effects of special relativity on the motions of the orbiting electrons.

We now ask: can we understand the basic facts concerning stars as simply as we understand atoms in terms of the two combinations of natural constants (1) and (2)? In this lecture, I shall attempt to show that in a limited sense we can.

The most important fact concerning a star is its mass. It is measured in units of the mass of the sun, $\odot$, which is 2×10^{33} g; stars with masses very much less than, or very much more than, the mass of the sun are relatively infrequent. The current theories of stellar structure and stellar evolution derive their successes largely from the fact that the following combination of the dimensions of a mass provides a correct measure of stellar masses:

$$\left(\frac{hc}{G}\right)^{3/2} \frac{1}{H^2} \simeq 29.2\ \odot \qquad (3)$$

where G is the constant of gravitation and H is the mass of the hydrogen atom. In the first half of the lecture, I shall essentially be concerned with the question: how does this come about?

2. The Role of Radiation Pressure

A central fact concerning normal stars is the role which radiation pressure plays as a factor in their hydrostatic equilibrium, Precisely, the equation governing the hydrostatic equilibrium of a star is

$$\frac{dP}{dr} = -\frac{GM(r)}{r^2}\rho \tag{4}$$

where P denotes the total pressure, ρ the density, and $M(r)$ is the mass interior to a sphere of radius r. There are two contributions to the total pressure P: that due to the material and that due to the radiation. On the assumption that the matter is in the state of a perfect gas in the classical Maxwellian sense, the material or the gas pressure is given by

$$p_{\text{gas}} = \frac{k}{\mu H}\rho T \tag{5}$$

where T is the absolute temperature, k is the Boltzmann constant, and μ is the mean molecular weight (which under normal stellar conditions is ≈ 1.0). The pressure due to radiation is given by

$$p_{\text{rad}} = \frac{1}{3}aT^4 \tag{6}$$

where a denotes Stefan's radiation-constant. Consequently, if radiation contributes a fraction $(1-\beta)$ to the total pressure, we may write

$$P = \frac{1}{3}\frac{1}{1-\beta}aT^4 = \frac{1}{\beta}\frac{k}{\mu H}\rho T \tag{7}$$

To bring out explicitly the role of the radiation pressure in the equilibrium of a star, we may eliminate the temperature, T, from the foregoing equations and express P in terms of ρ and β, instead of in terms of ρ and T. We find

$$T = \left(\frac{k}{\mu H}\frac{3}{a}\frac{1-\beta}{\beta}\right)^{1/3}\rho^{1/3} \tag{8}$$

and

$$P = \left[\left(\frac{k}{\mu H}\right)^4\frac{3}{a}\frac{1-\beta}{\beta^4}\right]^{1/3}\rho^{4/3} = C(\beta)\rho^{4/3} \text{ (say)} \tag{9}$$

The importance of this ratio, $(1-\beta)$, for the theory of stellar structure was first emphasized by *Eddington*. Indeed, he related it, in a famous passage in his book on *The Internal Constitution of the Stars*, to the "happening of the stars"[1]. A more rational version of *Eddington*'s argument which, at the same time, isolates the combination (3) of the natural constants is the following:

There is a general theorem[2] which states that the pressure, P_c, at the centre of a star of a mass M in hydrostatic equilibrium in which the density, $\rho(r)$, at a point at a radial distance, r, from the centre does not exceed the mean density, $\bar{\rho}(r)$, interior to the same point r, must satisfy the inequality

$$\tfrac{1}{2}G(\tfrac{4}{3}\pi)^{1/3}\bar{\rho}^{4/3}M^{2/3} \le P_c \le \tfrac{1}{2}G(\tfrac{4}{3}\pi)^{1/3}\rho_c^{4/3}M^{2/3} \tag{10}$$

where $\bar{\rho}$ denotes the mean density of the star and ρ_c its density at the centre. The content of the theorem is no more than the assertion that the actual pressure at the centre of a star must be intermediate between those at the centres of the two configurations of uniform density, one at a density equal to the mean density of the star, and the other at a density equal to the density ρ_c at the centre (see Fig. 1). If the inequality (10) should be violated then there must, in general, be some regions in which adverse density gradients must prevail; and this implies instability. In other words, we may consider conformity with the inequality (10) as equivalent to the condition for the stable existence of stars.

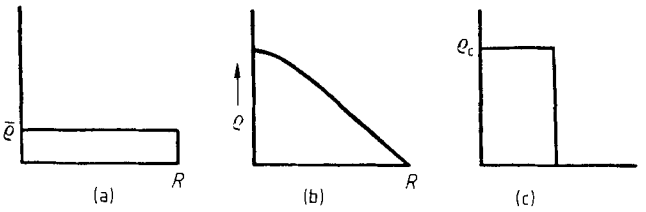

Fig. 1. A comparison of an inhomogeneous distribution of density in a star (b) with the two homogeneous configurations with the constant density equal to the mean density (a) and equal to the density at the centre (c).

The right-hand side of the inequality (10) together with P given by equation (9), yields, for the stable existence of stars, the condition

$$\left[\left(\frac{k}{\mu H}\right)^4\frac{3}{a}\frac{1-\beta_c}{\beta_c^4}\right]^{1/3} \le \left(\frac{\pi}{6}\right)^{1/3}GM^{2/3} \tag{11}$$

or, equivalently

$$M \ge \left(\frac{6}{\pi}\right)^{1/2}\left[\left(\frac{k}{\mu H}\right)^4\frac{3}{a}\frac{1-\beta_c}{\beta_c^4}\right]^{1/2}\frac{1}{G^{3/2}} \tag{12}$$

where in the foregoing inequalities, β_c is a value of β at the centre of the star. Now Stefan's constant, a, by virtue of Planck's law, has the value

$$a = \frac{8\pi^5k^4}{15h^3c^3} \tag{13}$$

Inserting this value a in the equality (12), we obtain

$$\mu^2M\left(\frac{\beta_c^4}{1-\beta_c}\right)^{1/2} \ge \frac{(135)^{1/2}}{2\pi^3}\left(\frac{hc}{G}\right)^{3/2}\frac{1}{H^2} = 0.1873\left(\frac{hc}{G}\right)^{3/2}\frac{1}{H^2} \tag{14}$$

We observe that the inequality (14) has isolated the combination (3) of natural constants of the dimensions of a mass; by inserting its numerical value given in equation (3), we obtain the inequality

$$\mu^2M\left(\frac{\beta_c^4}{1-\beta_c}\right)^{1/2} \ge 5.48\,\odot \tag{15}$$

This inequality provides an upper limit to $(1-\beta_c)$ for a star of a given mass. Thus,

$$1-\beta_c \leq 1-\beta_* \tag{16}$$

where $(1-\beta_*)$ is uniquely determined by the mass M of the star and the mean molecular weight, μ, by the quartic equation (17):

$$\mu^2 M = 5.48 \left(\frac{1-\beta_*}{\beta_*^4}\right)^{1/2} \odot \tag{17}$$

In Table 1, we list the values of $1-\beta_*$ for several values of $\mu_2 M$. From this table it follows in particular, that for a star of solar mass with a mean molecular weight equal to 1, the radiation pressure at the centre cannot exceed 3 percent of the total pressure.

Table 1. The maximum radiation pressure, $(1-\beta_*)$, at the centre of a star of a given mass, M.

$1-\beta_*$	$M\mu^2/\odot$	$1-\beta_*$	$M\mu^2/\odot$
0.01	0.56	0.50	15.49
0.03	1.01	0.60	26.52
0.10	2.14	0.70	50.92
0.20	3.83	0.80	122.5
0.30	6.12	0.85	224.4
0.40	9.62	0.90	519.6

What do we conclude from the foregoing calculation? We conclude that to the extent equation (17) is at the base of the equilibrium of actual stars, to that extent the combination of natural constants (3), providing a mass of proper magnitude for the measurement of stellar masses, is at the base of a physical theory of stellar structure.

3. Do Stars have Enough Energy to Cool?

The same combination of natural constants (3) emerged soon afterwards in a much more fundamental context of resolving a paradox *Eddington* had formulated in the form of an aphorism: "a star will need energy to cool". The paradox arose while considering the ultimate fate of a gaseous star in the light of the then new knowledge that white-dwarf stars, such as the companion of Sirius, exist which have mean densities in the range 10^5-10^7 g cm^{-3}. As *Eddington* stated[3]:

> I do not see how a star which has once got into this compressed state is ever going to get out of it. ... It would seem that the star will be in an awkward predicament when its supply of subatomic energy fails.

The paradox posed by *Eddington* was reformulated in clearer physical terms by *R. H. Fowler*[4]. His formulation was the following:

> The stellar material, in the white-dwarf state, will have radiated so much energy that it has less energy than the same matter in normal atoms expanded at the absolute zero of temperature. If part of it were removed from the star and the pressure taken off, what could it do?

Quantitatively, *Fowler*'s question arises in this way:

An estimate of the electrostatic energy, E_V, per unit volume of an assembly of atoms, of atomic number Z, ionized down to bare nuclei, is given by

$$E_V = 1.32 \times 10^{11} Z^2 \rho^{4/3} \tag{18}$$

while the kinetic energy of thermal motions, E_{kin}, per unit volume of free particles in the form of a perfect gas of density, ρ, and temperature, T, is given by

$$E_{kin} = \frac{3}{2}\frac{k}{\mu H}\rho T = \frac{1.24 \times 10^8}{\mu}\rho T \tag{19}$$

Now if such matter were released of the pressure to which it is subject, it can resume a state of ordinary normal atoms only if

$$E_{kin} > E_V \tag{20}$$

or, according to equations (18) and (19), only if

$$\rho < \left(0.94 \times 10^{-3} \frac{T}{\mu Z^2}\right)^3 \tag{21}$$

This inequality will be clearly violated if the density is sufficiently high. This is the essence of *Eddington*'s paradox as formulated by *Fowler*. And *Fowler* resolved this paradox in 1926 in a paper[4] entitled "Dense Matter"—one of the great landmark papers in the realm of stellar structure: in it, the notions of Fermi statistics and of electron degeneracy are introduced for the first time.

4. *Fowler*'s Resolution of Eddington's Paradox; the Degeneracy of the Electrons in White-Dwarf Stars

In a completely degenerate electron gas, all the available parts of the phase space with momenta less than a certain "threshold" value p_0—the Fermi threshold—are occupied consistently with the Pauli exclusion-principle, i.e., with two electrons per "cell" of volume h^3 of the six-dimensional phase space. Therefore, if $n(p)\,dp$ denotes the number of electrons per unit volume between p and $p+dp$, then the assumption of complete degeneracy is equivalent to the assertion

$$\begin{aligned} n(p) &= \frac{8\pi}{h^3}p^2 \quad (p \leq p_0) \\ &= 0 \qquad (p > p_0) \end{aligned} \tag{22}$$

The value of the threshold momentum, p_0, is determined by the normalization condition

$$n = \int_0^{p_0} n(p)\,dp = \frac{8\pi}{3h^3}p_0^3 \tag{23}$$

where n denotes the total number of electrons per unit volume.

For the distribution given by (22), the pressure p and the kinetic energy E_{kin} of the electrons (per unit volume) are given by

$$P=\frac{8\pi}{3h^3}\int_0^{p_0} p^3 v_p \, dp \tag{24}$$

and

$$E_{kin}=\frac{8\pi}{h^3}\int_0^{p_0} p^2 T_p \, dp, \tag{25}$$

where v_p and T_p are the velocity and the kinetic energy of an electron having momentum p, respectively.

If we set

$$v_p=p/m \quad \text{and} \quad T_p=p^2/2m, \tag{26}$$

appropriate for non-relativistic mechanics, in equations (24) and (25), we find

$$P=\frac{8\pi}{15h^3m}p_0^5=\frac{1}{20}\left(\frac{3}{\pi}\right)^{2/3}\frac{h^2}{m}n^{5/3} \tag{27}$$

and

$$E_{kin}=\frac{8\pi}{10h^3m}p_0^5=\frac{3}{40}\left(\frac{3}{\pi}\right)^{2/3}\frac{h^2}{m}n^{5/3} \tag{28}$$

Fowler's resolution of *Eddington*'s paradox consists in this: at the temperatures and densities that may be expected to prevail in the interiors of the white-dwarf stars, the electron will be highly degenerate and E_{kin} must be evaluated in accordance with equation (28) and *not* in accordance with equation (19); and equation (28) gives

$$E_{kin}=1.39\times 10^{13}(\rho/\mu)^{5/3} \tag{29}$$

Comparing now the two estimates (18) and (29), we see that for matter of the density occurring in the white dwarfs, namely $\rho\approx 10^5$ g cm^{-3}, the total kinetic energy is about two to four times the negative potential-energy; and *Eddington*'s paradox does not arise. *Fowler* concluded his paper with the following highly perceptive statement:

> The black-dwarf material is best likened to a single gigantic molecule in its lowest quantum state. On the Fermi-Dirac statistics, its high density can be achieved in one and only one way, in virtue of a correspondingly great energy content. But this energy can no more be expended in radiation than the energy of a normal atom or molecule. The only difference between black-dwarf matter and a normal molecule is that the molecule can exist in a free state while the black-dwarf matter can only so exist under very high external pressure.

5. The Theory of the White-Dwarf Stars; the Limiting Mass

The internal energy $(3P/2)$ of a degenerate electron gas that is associated with a pressure P is *zero-point energy*; and the essential content of *Fowler*'s paper is that this zero-point energy is so great that we may expect a star to eventually settle down to a state in which all of its energy is of this kind. *Fowler*'s argument can be more explicitly formulated in the following manner[5].

According to the expression for the pressure given by equation (27), we have the relation

$$P=K_1\rho^{5/3} \quad \text{where} \quad K_1=\frac{1}{20}\left(\frac{3}{\pi}\right)^{2/3}\frac{h^2}{m(\mu_e H)^{5/3}} \tag{30}$$

where μ_e is the mean molecular weight per electron. An equilibrium configuration in which the pressure, P, and the density, ρ, are related in the manner

$$P=K\rho^{1+1/n} \tag{31}$$

is an *Emden polytrope* of index n. The degenerate configurations built on the equation of state (30) are therefore polytropes of index 3/2; and the theory of polytropes immediately provides the relation

$$K_1=0.4242\,(GM^{1/3}R) \tag{32}$$

or, numerically, for K_1 given by equation (30)

$$\log_{10}(R/R_\odot)=-\tfrac{1}{3}\log_{10}(M/\odot)-\tfrac{5}{3}\log_{10}\mu_e-1.397 \tag{33}$$

For a mass equal to the solar mass and $\mu_e=2$, the relation (33) predicts $R=1.26\times 10^{-2}R_\odot$ and a mean density of 7.0×10^5 gm/cm^3. These values are precisely of the order of the radii and mean densities encountered in white-dwarf stars. Moreover, according to equations (32) and (33), the radius of the white-dwarf configuration is inversely proportional to the cube-root of the mass. On this account, finite equilibrium configurations are predicted for all masses. And it came to be accepted that the white-dwarfs represent the last stages in the evolution of all stars.

But it soon became clear that the foregoing simple theory based on *Fowler*'s premises required modifications. For, the electrons at their threshold energies at the centres of the degenerate stars begin to have velocities comparable to that of light as the mass increases. Thus, already for a degenerate star of solar mass (with $\mu_e=2$) the central density ρ_c (which is about six times the mean density) is 4.19×10^6 g/cm^3; and this density corresponds to a threshold momentum $p_0=1.29\,mc$ and a velocity which is $0.63c$. Consequently, the equation of state must be modified to take into account the effects of special relativity. And this is easily done by inserting in equations (24) and (25) the relations

$$v_p=\frac{p}{m(1+p^2/m^2c^2)^{1/2}} \quad \text{and} \quad T_p=mc^2[(1+p^2/m^2c^2)^{1/2}-1] \tag{34}$$

in place of the non-relativistic relations (26). We find that the resulting equation of state can be expressed parametrically in the form

$$P=Af(x) \quad \text{and} \quad \rho=Bx^3 \tag{35}$$

where

$$A = \frac{\pi m^4 c^5}{3h^3}, \quad B = \frac{8\pi m^3 c^3 \mu_e H}{3h^3} \tag{36}$$

and

$$f(x) = x(x^2+1)^{1/2}(2x^2-3) + 3\sinh^{-1} x \tag{37}$$

And similarly

$$E_{kin} = A\,g(x) \tag{38}$$

where

$$g(x) = 8x^3[(x^2+1)^{1/2} - 1] - f(x) \tag{39}$$

According to equations (35) and (36), the pressure approximates the relation (30) for low enough electron concentrations ($x \ll 1$); but for increasing electron concentrations ($x \gg 1$), the pressure tends to[6]

$$P = \frac{1}{8}\left(\frac{3}{\pi}\right)^{1/3} hc\, n^{4/3} \tag{40}$$

This limiting form of relation can be obtained very simply by setting $v_p = c$ in equation (24); then

$$P = \frac{8\pi c}{3h^3}\int_0^{p_0} p^3\,dp = \frac{2\pi c}{3h^3}p_0^4 \tag{41}$$

and the elimination of p_0 with aid of equation (23) directly leads to equation (40).

While the modification of the equation of state required by the special theory of relativity appears harmless enough, it has, as we shall presently show, a dramatic effect on the predicted mass-radius relation for degenerate configurations.

The relation between P and ρ corresponding to the limiting form (41) is

$$P = K_2\rho^{4/3} \quad \text{where} \quad K_2 = \frac{1}{8}\left(\frac{3}{\pi}\right)^{1/3}\frac{hc}{(\mu_e H)^{4/3}} \tag{42}$$

In this limit, the configuration is an Emden polytrope of index 3. And it is well known that when the polytropic index is 3, the mass of the resulting equilibrium configuration is uniquely determined by the constant of proportionality, K_2, in the pressure-density relation. We have accordingly

$$\begin{aligned} M_{limit} &= 4\pi\left(\frac{K_2}{\pi G}\right)^{3/2}(2.018) \\ &= 0.197\left(\frac{hc}{G}\right)^{3/2}\frac{1}{(\mu_e H)^2} = 5.76\mu_e^{-2}\odot \end{aligned} \tag{43}$$

(In equation (43), 2.018 is a numerical constant derived from the explicit solution of the Lane-Emden equation for $n = 3$.)

It is clear from general considerations[7] that *the exact mass-radius relation for the degenerate configurations must provide an upper limit to the mass of such configurations given by equation* (43); *and further, that the mean density of the configuration must tend to infinity,* while the radius tends to zero, and $M \to M_{limit}$. These conditions, straightforward as they are, can be established directly by considering the equilibrium of configurations built on the exact equation of state given by equations (35)—(37). It is found that the equation governing the equilibrium of such configurations can be reduced to the form[8,9]

$$\frac{1}{\eta^2}\frac{d}{d\eta}\left(\eta^2\frac{d\phi}{d\eta}\right) = -\left(\phi^2 - \frac{1}{y_0^2}\right)^{3/2} \tag{44}$$

where

$$y_0^2 = x_0^2 + 1 \tag{45}$$

mcx_0 denotes the threshold momentum of the electrons at the centre of the configuration, and η measures the radial distance in the unit

$$\left(\frac{2A}{\pi G}\right)^{1/2}\frac{1}{By_0} = l_1 y_0^{-1} \tag{46}$$

By integrating equation (44), with suitable boundary conditions and for various initially prescribed values of y_0, we can derive the exact mass-radius relation, as well as the other equilibrium properties, of the degenerate configurations. The principal results of such calculations are illustrated in Figures 2 and 3.

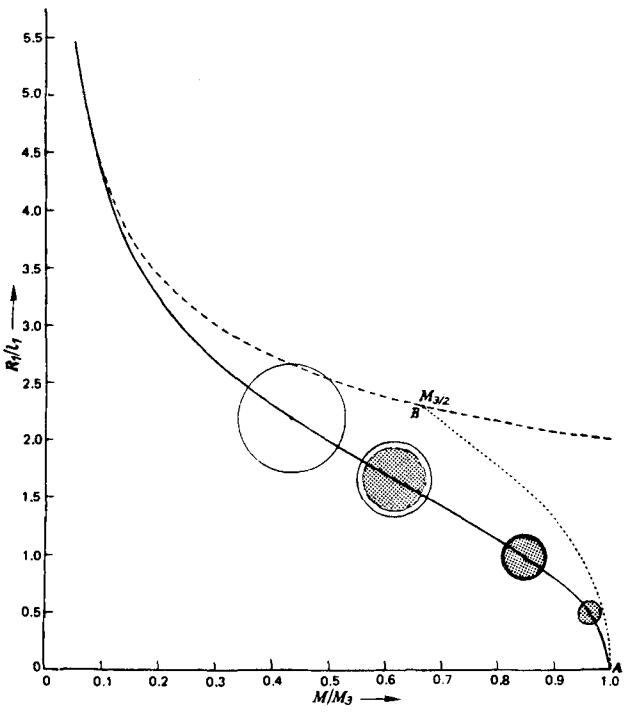

Fig. 2. The full-line curve represents the exact (mass-radius)-relation (l_1 is defined in equation (46) and M_3 denotes the limiting mass). This curve tends asymptotically to the ---- curve appropriate to the low-mass degenerate configurations, approximated by polytropes of index 3/2. The regions of the configurations which may be considered as relativistic [$\rho > (K_1/K_2)^3$] are shown shaded (from [9]).

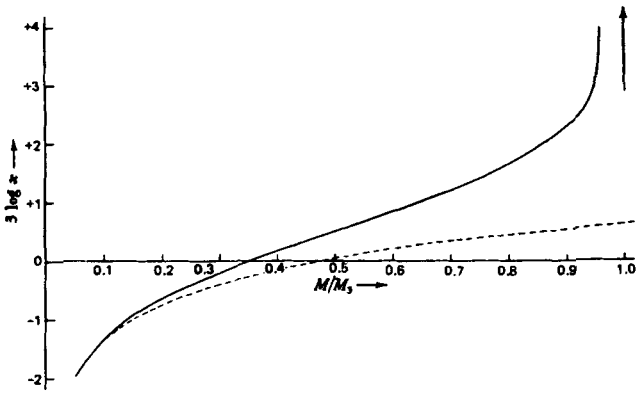

Fig. 3. The full-line curve represents the exact (mass-density)-relation for the highly collapsed configurations. This curve tends asymptotically to the dotted curve as $M \to 0$ (from [9]).

The important conclusions which follow from the foregoing considerations are: *first,* there is an upper limit, M_{limit}, to the mass of stars which can become degenerate configurations, as the last stage in their evolution; and *second,* that stars with $M > M_{\text{limit}}$ must have end states which cannot be predicted from the considerations we have presented so far. And finally, we observe that the combination of the natural constant (3) now emerges in the fundamental context of M_{limit} given by equation (43): its significance for the theory of stellar structure and stellar evolution can no longer be doubted.

6. Under What Conditions Can Normal Stars Develop Degenerate Cores?

Once the upper limit to the mass of completely degenerate configurations had been established, the question required to be resolved was how to relate its existence to the evolution of stars from their gaseous state. If a star has a mass less than M_{limit}, the assumption that it will eventually evolve towards the completely degenerate state appears reasonable. But what if its mass is greater than M_{limit}? Clues as to what might ensue were sought in terms of the equations and inequalities of Sections 2 and 3[10,11].

The first question that had to be resolved concerns the circumstances under which a star, initially gaseous, will develop degenerate cores. From the physical side, the question, when departures from the perfect-gas equation of state (5) will set in and the effects of electron degeneracy will be manifested, can be readily answered.

Suppose, for example, that we continually and steadily increase the density, at constant temperature, of an assembly of free electrons and atomic nuclei in a highly ionized state and initially in the form of a perfect gas governed by the equation of state (5). At first the electron pressure will increase linearly with ρ; but soon departures will set in and eventually the density will increase in accordance with the equation of state that describes the fully degenerate electron-gas (see Fig. 4). The remarkable fact is that this limiting form of the equation of state is independent of temperature.

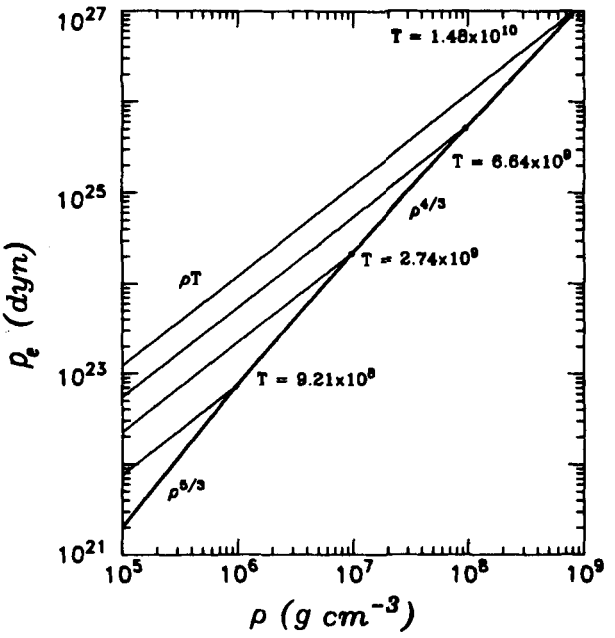

Fig. 4. Illustrating how by increasing the density at constant temperature degeneracy always sets in.

However, to examine the circumstances when, during the course of evolution, a star will develop degenerate cores, it is more convenient to express the electron pressure (as given by the classical perfect-gas equation of state) in terms of ρ and β_e [cf. equation (7)], defined in the manner

$$p_e = \frac{k}{\mu_e H}\rho T = \frac{\beta_e}{1-\beta_e}\frac{1}{3}aT^4 \tag{47}$$

where p_e now denotes the electron pressure. Then, analogous to equation (9), we can write

$$p_e = \left[\left(\frac{k}{\mu_e H}\right)^4 \frac{3}{a}\frac{1-\beta_e}{\beta_e}\right]^{1/3} \rho^{4/3} \tag{48}$$

Comparing this with equation (42), we conclude that if

$$\left[\left(\frac{k}{\mu_e H}\right)^4 \frac{3}{a}\frac{1-\beta_e}{\beta_e}\right]^{1/3} > K_2 = \frac{1}{8}\left(\frac{3}{\pi}\right)^{1/3}\frac{hc}{(\mu_e H)^{4/3}} \tag{49}$$

the pressure p_e given by the classical perfect-gas equation of state will be greater than that given by the equation if degeneracy were to prevail, not only for the prescribed ρ and T, but for *all* ρ and T having the same β_e.

Inserting for a its value given in equation (13), we find that the inequality (49) reduces to

$$\frac{960}{\pi^4}\frac{1-\beta_e}{\beta_e} > 1 \tag{50}$$

or, equivalently,

$$1-\beta_e > 0.0921 = 1-\beta_\omega \tag{51}$$

(see Fig. 5).

For our present purposes, the principal content of the inequality (51) is the criterion that for a star to develop degeneracy it is necessary that the radiation pressure be less than 9.2 percent of (p_e+p_{rad}). This last inference is so central to all current schemes of stellar evolution that the directness and the simplicity of the early arguments are worth repeating.

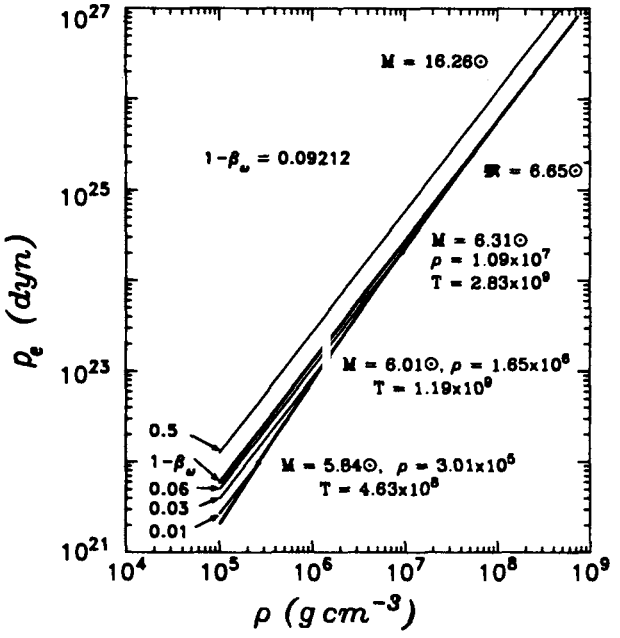

Fig. 5. Illustrating the onset of degeneracy for increasing density at constant β. Notice that there are no intersections for $1-\beta>0.09212$. In the figure, $1-\beta$ is converted into the mass of a star built on the standard model.

The two principal elements of the early arguments were these: *first,* that radiation pressure becomes increasingly dominant as the mass of the star increases; and *second,* that the degeneracy of electrons is possible only so long as the radiation pressure is not a significant fraction of the total pressure—indeed, as we have seen, it must not exceed 9.2 percent of (p_e+p_{rad}). The second of these elements in the arguments is a direct and an elementary consequence of the physics of degeneracy; but the first requires some amplification.

That radiation pressure must play an increasingly dominant role as the mass of the star increases is one of the earliest results in the study of stellar structure that was established by *Eddington.* A quantitative expression for this fact is given by *Eddington*'s *standard model* which lay at the base of his early studies summarized in his *The Internal Constitution of the Stars.*

On the standard model, the fraction β (=gas pressure/total pressure) is a constant through a star. On this assumption, the star is a polytrope of index 3 as is apparent from equation (9); and, in consequence, we have the relation [cf. equation (43)]

$$M=4\pi\left(\frac{C(\beta)}{\pi G}\right)^{3/2}(2.018) \tag{52}$$

where $C(\beta)$ is defined in equation (9). Equation (52) provides a quartic equation for β analogous to equation (17) for β_*. Equation (52) for $\beta=\beta_\omega$ gives

$$M=0.197\beta_\omega^{-3/2}\left(\frac{hc}{G}\right)^{3/2}\frac{1}{(\mu H)^2}=6.65\mu^{-2}\odot=\mathfrak{M} \tag{53}$$

On the standard model, then, stars with masses exceeding $\mathfrak{M}$ will have radiation pressures which exceed 9.2 percent of the total pressure. Consequently stars with $M>\mathfrak{M}$ cannot, at any stage during the course of their evolution, develop degeneracy in their interiors. Therefore, for such stars an eventual white-dwarf state is not possible unless they are able to eject a substantial fraction of their mass.

The standard model is, of course, only a model. Nevertheless, except under special circumstances, briefly noted below, experience has confirmed the essential qualitative correctness of the conclusions drawn from the standard model, namely that the evolution of stars of masses exceeding $7-8\odot$ must proceed along lines very different from those of less massive stars. These conclusions, which were arrived at some fifty years ago, appeared then so convincing that assertions such as these were made with confidence:

> Given an enclosure containing electrons and atomic nuclei (total charge zero) what happens if we go on compressing the material indefinitely? (1932)[10].
>
> The life history of a star of small mass must be essentially different from the life history of a star of large mass. For a star of small mass the natural white-dwarf stage is an initial step towards complete extinction. A star of large mass cannot pass into the white-dwarf stage and one is left speculating on other possibilities (1934)[8].

And these statements have retained their validity.

While the evolution of the massive stars was thus left uncertain, there was no such uncertainty regarding the final states of stars of sufficiently low mass[11]. The reason is that by virtue, again, of the inequality (10), the maximum central pressure attainable in a star must be less than that provided by the degenerate equation of state, so long as

$$\tfrac{1}{2}G(\tfrac{4}{3}\pi)^{1/3}M^{2/3}<K_2=\frac{1}{8}\left(\frac{3}{\pi}\right)^{1/3}\frac{hc}{(\mu_e H)^{4/3}} \tag{54}$$

or, equivalently

$$M<\frac{3}{16\pi}\left(\frac{hc}{G}\right)^{3/2}\frac{1}{(\mu_e H)^2}=1.74\mu_e^{-2}\odot \tag{55}$$

We conclude that there can be no surprises in the evolution of stars of mass less than $0.43\odot$ (if $\mu_e=2$). The end stage in the evolution of such stars can only be that of the white dwarfs. (Parenthetically, we may note here that the inequality (55) implies that the so-called "mini" black-holes of mass $\approx 10^{15}$ g cannot naturally be formed in the present astronomical universe.)

7. Some Brief Remarks on Recent Progress in the Evolution of Massive Stars and the Onset of Gravitational Collapse

It became clear, already from the early considerations, that the inability of the massive stars to become white dwarfs must result in the development of much more extreme conditions in their interiors and, eventually, in the onset of gravitational collapse attended by the super-nova phenomenon. But the precise manner in which all this will happen has been difficult to ascertain, in spite of great effort by several competent groups of investigators. The facts which must be taken into account appear to be the following[*].

In the first instance, the density and the temperature will steadily increase without the inhibiting effect of degeneracy since for the massive stars considered $1-\beta_e > 1-\beta_\omega$. On this account, "nuclear ignition" of carbon, say, will take place which will be attended by the emission of neutrinos. This emission of neutrinos will effect a cooling and a lowering of $(1-\beta_e)$; but it will still be in excess of $1-\beta_\omega$. The important point here is that the emission of neutrinos acts selectively in the central regions and is the cause of the lowering of $(1-\beta_e)$ in these regions. The density and the temperature will continue to increase till the next ignition of neon takes place followed by further emission of neutrinos and a further lowering of $(1-\beta_e)$. This succession of nuclear ignitions and lowering of $(1-\beta_e)$ will continue till $1-\beta_e < 1-\beta_\omega$ and a relativistically degenerate core with a mass approximately that of the limiting mass ($=1.4\odot$ for $\mu_e=2$) forms at the centre. By this stage, or soon afterwards, instability of some sort is expected to set in (see Section 8) followed by gravitational collapse and the phenomenon of the super-nova (of type II). In some instances, what was originally the highly relativistic degenerate core of approximately $1.4\odot$ will be left behind as a neutron star. That this happens sometimes is confirmed by the fact that in those cases for which reliable estimates of the masses of pulsars exist, they are consistently close to $1.4\odot$. However, in other instances—perhaps, in the majority of the instances—what is left behind, after all "the dust has settled", will have masses in excess of that allowed for stable neutron stars; and in these instances black holes will form.

In the case of less massive stars ($M \approx 6-8\odot$) the degenerate cores, which are initially formed, are not highly relativistic. But the mass of the core increases with the further burning of the nuclear fuel at the interface of the core and the mantle; and when the core reaches the limiting mass, an explosion occurs following instability; and it is believed that this is the cause underlying super-nova phenomenon of type I.

From the foregoing brief description of what may happen during the late stages in the evolution of massive stars, it is clear that the problems one encounters are of exceptional complexity, in which a great variety of physical factors compete. This is clearly not the occasion for me to enter into a detailed discussion of these various questions.

[*] I am grateful to Professor *D. Arnett* for guiding me through the recent literature and giving me advice in the writing of this section.

8. Instabilities of Relativistic Origin: (1) The Vibrational Instability of Spherical Stars

I now turn to the consideration of certain types of stellar instabilities which are derived from the effects of general relativity and which have no counterparts in the Newtonian framework. It will appear that these new types of instabilities of relativistic origin may have essential roles to play in discussions pertaining to gravitational collapse and the late stages in the evolution of massive stars.

We shall consider first the stability of spherical stars for purely radial perturbations. The criterion for such stability follows directly from the linearized equations governing the spherically symmetric radial oscillations of stars. In the framework of the Newtonian theory of gravitation, the stability for radial perturbations depends only on an average value of the adiabatic exponent, Γ_1, which is the ratio of the fractional Lagrangian changes in the pressure and in the density experienced by a fluid element following the motion; thus

$$\Delta P/P = \Gamma_1 \Delta\rho/\rho \tag{56}$$

And the Newtonian criterion for stability is

$$\bar{\Gamma}_1 = \int_0^M \Gamma_1(r) P(r)\, dM(r) \div \int_0^M P(r)\, dM(r) > \tfrac{4}{3} \tag{57}$$

If $\Gamma_1 < 4/3$, *dynamical instability* of a global character will ensue with an *e*-folding time measured by the time taken by a sound wave to travel from the centre to the surface.

When one examines the same problem in the framework of the general theory of relativity, one finds[12] that, again, the stability depends on an average value of Γ_1; but contrary to the Newtonian result, the stability now depends on the radius of the star as well. Thus, one finds that no matter how high $\bar{\Gamma}_1$ may be, instability will set in provided the radius is less than a certain determinate multiple of the *Schwarzschild radius*:

$$R_S = 2GM/c^2 \tag{58}$$

Thus, if for the sake of simplicity, we assume that Γ_1 is a constant through the star and equal to 5/3, then the star will become dynamically unstable for radial perturbations, if $R_1 < 2.4 R_S$. And further, if $\Gamma_1 \to \infty$, instability will set in for all $R < (9/8) R_S$. *The radius* $(9/8) R_S$ *defines, in fact, the minimum radius which any gravitating mass, in hydrostatic equilibrium, can have in the framework of general relativity.* This important result is implicit in a fundamental paper by *Karl Schwarzschild* published in 1916. (*Schwarzschild* actually proved that for a star in which the energy density is a uniform $R > (9/8) R_S$.)

In one sense, the most important consequence of this instability of relativistic origin is that if Γ_1 (again assumed to be a constant for the sake of simplicity) differs from and is greater than 4/3 only by a small positive constant, then the instability will set in for a radius R which is a large multiple of R_S; and, therefore, under circumstances when the effects of general relativity, on the structure of the equilibrium configuration itself, are hardly relevant. Indeed, it

follows[13] from the equations governing radial oscillations of a star, in a first post-Newtonian approximation to the general theory of relativity, that instability for radial perturbations will set in for all

$$R < \frac{K}{\Gamma_1 - 4/3}\frac{2GM}{c^2} \tag{59}$$

where K is a constant which depends on the *entire*[*] march of density and pressure in the equilibrium configuration in the Newtonian framework. Thus, for a polytrope of index n, the value of the constant is given by

$$K = \frac{5-n}{18}\left[\frac{2(11-n)}{(n+1)\xi_1^4|\theta_1'|^3}\int_0^{\xi_1}\theta\left(\frac{d\theta}{d\xi}\right)^2\xi^2 d\xi + 1\right] \tag{60}$$

where θ is the Lane-Emden function in its standard normalization ($\theta = 1$ at $\xi = 0$), ξ is the dimensionless radial coordinate, ξ_1 defines the boundary of the polytrope (where $\theta = 0$) and θ_1' is the derivative of θ at ξ_1.

Table 2. Values of the constant K in the inequality (59) for various polytropic indices, n.

n	K	n	K
0	0.452381	3.25	1.28503
1.0	0.565382	3.5	1.49953
1.5	0.645063	4.0	2.25338
2.0	0.751296	4.5	4.5303
2.5	0.900302	4.9	22.906
3.0	1.12447	4.95	45.94

In Table 2, we list the values of K for different polytropic indices. It should be particularly noted that K increases without limit as $n \to 5$ and the configuration becomes increasingly centrally condensed[**]. Thus, already for $n = 4.95$ (for which polytropic index $\rho_c = 8.09 \times 10^6 \bar{\rho}$), $K \sim 46$. In other words, for the highly centrally condensed massive stars (for which Γ_1 may differ from 4/3 by as little as 0.01)[***], the instability of relativistic origin will set in, already, when its radius falls below $5 \times 10^3 R_S$. Clearly this relativistic instability must be considered in the contexts of these problems.

A further application of the result described in the preceding paragraph is to degenerate configurations near the limiting mass[14]. Since the electrons in these highly relativistic configurations have velocities close to the velocity of light, the effective value of Γ_1 will be very close to 4/3 and the post-Newtonian relativistic instability will set in for a mass slightly less than that of the limiting mass. On account of the instability for radial oscillations setting in for a mass less than M_{limit}, the period of oscillation, along the sequence of the degenerate configurations, must have a minimum. This minimum can be estimated to be about two seconds (see Fig. 6). Since pulsars, when they were discovered, were known to have periods much less than this minimum value, the possibility of their being degenerate configurations near the limiting mass was ruled out; and this was one of the deciding factors in favor of the pulsars being neutron stars. (But by a strange irony, for reasons we have briefly explained in Section 7, pulsars which have resulted from super-nova explosions have masses close to $1.4\,\odot$!)

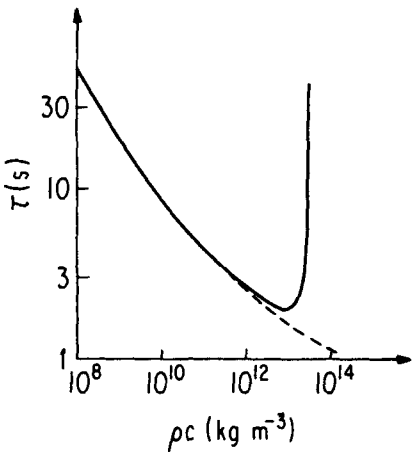

Fig. 6. The variation of the period of radial oscillation along the completely degenerate configurations. Notice that the period tends to infinity for a mass close to the limiting mass. There is consequently a minimum period of oscillation along these configurations; and the minimum period is approximately 2 seconds. (From J. Skilling: *Pulsating Stars*, Plenum Press, New York 1968, p. 59.)

Finally, we may note that the radial instability of relativistic origin is the underlying cause for the *existence* of a maximum mass for stability: it is a direct consequence of the equations governing hydrostatic equilibrium in general relativity. (For a complete investigation on the periods of radial oscillation of neutron stars for various admissible equations of state, see a recent paper by *Detweiler* and *Lindblom*[15].)

9. Instabilities of Relativistic Origin: (2) The Secular Instability of Rotating Stars Derived from the Emission of Gravitational Radiation by Non-Axisymmetric Modes of Oscillation

I now turn to a different type of instability which the general theory of relativity predicts for rotating configurations. This new type of instability[16] has its origin in the fact that the general theory of relativity builds into rotating masses a dissipative mechanism derived from the possibility of the emission of gravitational radiation by non-axisymmetric modes of oscillation. It appears that this insta-

[*] It is for this reason that we describe the instability as *global*.

[**] Since this was written, it has been possible to show (Chandrasekhar and Lebovitz, *Mon. Not. R. Astron. Soc. 207* (1984) 13P) that for $n \to 5$, the asymptotic behavior of K is given by

$$K \to 2.3056/(5-n)$$

and, further, that along the polytropic sequence, the criterion for instability (59) can be expressed alternatively in the form

$$R < 0.2264\left(\frac{\rho_c}{\bar{\rho}}\right)^{1/3}\frac{2GM}{c^2}\frac{1}{\Gamma_1 - 4/3}\quad(\rho_c/\bar{\rho} \gtrsim 10^6).$$

[***] By reason of the dominance of the radiation pressure in these massive stars and of β being very close to zero.

bility limits the periods of rotation of pulsars. But first, I shall explain the nature and the origin of this type of instability.

It is well known that a possible sequence of equilibrium figures of rotating homogeneous masses is the Maclaurin sequence of oblate spheroids[17]. When one examines the second harmonic oscillations of the Maclaurin spheroid, in a frame of reference rotating with its angular velocity, one finds that for two of these modes, whose dependence on the azimuthal angle is given by $e^{2i\varphi}$, the characteristic frequencies of oscillation, σ, depend on the eccentricity e in the manner illustrated in Figure 7. It will be observed that

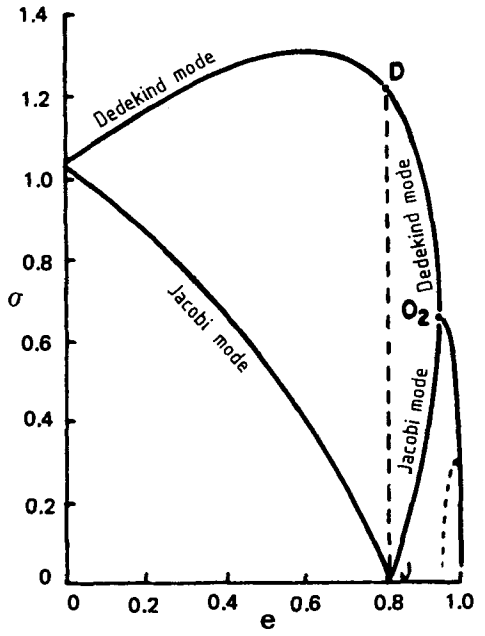

Fig. 7. The characteristic frequencies (in units of $(\pi G\rho)^{1/2}$) of the two even modes of second-harmonic oscillation of the Maclaurin spheroid. The Jacobi sequence bifurcates from the Maclaurin sequence by the mode that is neutral ($\sigma=0$) at $e=0.813$; and the Dedekind sequence bifurcates by the alternative mode at D. At O_2 ($e=0.9529$) the Maclaurin spheroid becomes dynamically unstable. The real and the imaginary parts of the frequency, beyond O_2, are shown by the full line and the dashed curves, respectively. Viscous dissipation induces instability in the branch of the Jacobi mode; and radiation-reaction induces instability in the branch DO_2 of the Dedekind mode.

one of these modes becomes neutral (i.e., $\sigma=0$) when $e=0.813$ and that the two modes coalesce when $e=0.953$ and become complex conjugates of one another beyond this point. Accordingly, the Maclaurin spheroid becomes *dynamically unstable* at the latter point (first isolated by *Riemann*). On the other hand, the origin of the neutral mode at $e=0.813$ is that at this point a new equilibrium sequence of triaxial ellipsoids—the ellipsoids of Jacobi—bifurcate. On this latter account, *Lord Kelvin* conjectured in 1883 that:

> if there be any viscosity, however slight ... the equilibrium beyond $e=0.81$ cannot be secularly stable.

Kelvin's reasoning was this: viscosity dissipates energy but not angular momentum. And since for equal angular momenta, the Jacobi ellipsoid has a lower energy content than the Maclaurin spheroid, one may expect that the action of viscosity will be to dissipate the excess energy of the Maclaurin spheroid and transform it into the Jacobi ellipsoid with the lower energy. A detailed calculation[18] of the effect of viscous dissipation on the two modes of oscillation, illustrated in Figure 7, does confirm *Lord Kelvin*'s conjecture. It is found that viscous dissipation makes the mode, which becomes neutral at $e=0.813$, unstable beyond this point with an e-folding time which depends inversely on the magnitude of the kinematic viscosity and which further decreases monotonically to zero at the point $e=0.953$, where the dynamical instability sets in.

Since the emission of gravitational radiation dissipates *both* energy and angular momentum, it does *not* induce instability in the Jacobi mode; instead it induces instability in the *alternative* mode at the same eccentricity. In the first instance this may appear surprising; but the situation we encounter here clarifies some important issues.

If instead of analyzing the normal modes in the rotating frame, we had analyzed them in the inertial frame, we would have found that the mode which becomes unstable by radiation reaction at $e=0.813$, is in fact neutral at this point. And the neutrality of *this* mode in the inertial frame corresponds to the fact that the neutral deformation at this point is associated with the bifurcation (at this point) of a new triaxial sequence—the sequence of the Dedekind ellipsoids. These Dedekind ellipsoids, while they are congruent to the Jacobi ellipsoids, they differ from them in that they are at rest in the inertial frame and owe their triaxial figures to internal vertical motions. An important conclusion that would appear to follow from these facts is that in the framework of general relativity we can expect secular instability, derived from radiation-reaction to arise from a Dedekind mode of deformation (which is quasi-stationary in the inertial frame) rather than the Jacobi mode (which is quasi-stationary in the rotating frame).

A further fact concerning the secular instability induced by radiation-reaction, discovered subsequently by *Friedman*[19] and by *Comins*[20], is that the modes belonging to higher values of m ($=3, 4, \ldots$) become unstable at smaller eccentricities, though the e-folding times for the instability become rapidly longer. Nevertheless, it appears from some preliminary calculations of *Friedman*[21] that it is the secular instability derived from modes belonging to $m=3$ (or 4) that limit the periods of rotation of the pulsars.

It is clear from the foregoing discussions that the two types of instabilities of relativistic origin we have discussed are destined to play significant roles in the contexts we have considered.

10. The Mathematical Theory of Black Holes

So far, I have considered only the restrictions on the last stages of stellar evolution that follow from the existence of an upper limit to the mass of completely degenerate configurations and from the instabilities of relativistic origin. From these and related considerations, the conclusion is inescapable that black holes will form as one of the natural end products of stellar evolution of massive stars; and further that they must exist in large numbers in the present astronomical universe. In this last section I want to consider

very briefly what the general theory of relativity has to say about them. But first, I must define precisely what a black hole is.

A black hole partitions three-dimensional space into two regions: an inner region which is bounded by a smooth two-dimensional surface called the *event horizon*; and an outer region, external to the event horizon, which is asymptotically flat; and it is required (as a part of the definition) that no point in the inner region can communicate with any point of the outer region. This incommunicability is guaranteed by the impossibility of any light signal, originating in the inner region, crossing the event horizon. The requirement of asymptotic flatness of the outer region is equivalent to the requirement that the black hole is isolated in space and that far from the event horizon the space-time approaches the customary space-time of terrestrial physics.

In the general theory of relativity, we must seek solutions of *Einstein*'s vacuum equations compatible with the two requirements I have stated. It is a startling fact that compatible with these very simple and necessary requirements, the general theory of relativity allows for stationary (i.e., time-independent) black-holes exactly a single, unique, two-parameter family of solutions. This is the Kerr family, in which the two parameters are the mass of the black hole and the angular momentum of the black hole. What is even more remarkable, the metric describing these solutions is simple and can be explicitly written down.

I do not know if the full import of what I have said is clear. Let me explain.

Black holes are macroscopic objects with masses varying from a few solar masses to millions of solar masses. To the extent they may be considered as stationary and isolated, to that extent, they are all, every single one of them, described *exactly* by the Kerr solution. This is the only instance we have of an exact description of a macroscopic object. Macroscopic objects, as we see them all around us, are governed by a variety of forces, derived from a variety of approximations to a variety of physical theories. In contrast, the only elements in the construction of black holes are our basic concepts of space and time. They are, thus, almost by definition, the most perfect macroscopic objects there are in the universe. And since the general theory of relativity provides a single unique two-parameter family of solutions for their descriptions, they are the simplest objects as well.

Turning to the physical properties of the black holes, we can study them best by examining their reaction to external perturbations such as the incidence of waves of different sorts. Such studies reveal an analytic richness of the Kerr space-time which one could hardly have expected. This is not the occasion to elaborate on these technical matters[22]. Let it suffice to say that, contrary to every prior expectation, all the standard equations of mathematical physics can be solved exactly in the Kerr space-time. And the solutions predict a variety and range of physical phenomena which black holes must exhibit in their interaction with the world outside.

The mathematical theory of black holes is a subject of immense complexity. But its study has convinced me of the basic truth of the ancient mottoes:

The simple is the seal of the true

and

Beauty is the splendour of truth.

Organic Polymeric and Non-Polymeric Materials with Large Optical Nonlinearities

By David J. Williams

Nonlinear optical properties are a sensitive probe of the electronic and solid-state structure of organic compounds and as a consequence find various applications in many areas of optoelectronics including optical communications, laser scanning and control functions, and integrated optics technology. Because of their strongly delocalized π electronic systems, polymeric and non-polymeric aromatic compounds show highly nonlinear optical effects. Nowadays, polymer chemists are able to tailor specific materials properties for various applications. Some organic substances with π electronic systems exhibit the largest known nonlinear coefficients, often considerably larger than those of the more conventional inorganic dielectrics and semiconductors, and thus show promise for thin-film fabrication, allowing the enormous function and cost advantages of integrated electronic circuitry. The electronic origins of nonlinear optical effects in organic π electronic systems are reviewed, with special emphasis being given to second-order nonlinear optical effects. Methods for measuring nonlinear optical responses are outlined, and the critical relationships of the propagation characteristics of light to observed nonlinear optical effects and to solid-state structure are discussed. Finally, the synthesis and characterization of organic crystals and polymer films with large second-order optical nonlinearities are summarized.

1. Introduction

Interest in nonlinear optics has grown tremendously in recent years, primarily because of the telecommunications industry's need for high-bandwidth optical switching and processing devices to service the information and data transmission needs of the computer age, and of the proliferation of sophisticated laser tools, which has nurtured and necessitated research on new methods for tailoring individual laser pulses to perform specific functions or be readily detected in complex experiments.

Nonlinear optics is concerned with the interactions of electromagnetic fields in various media to produce new fields altered in phase, frequency, amplitude, or other propagation characteristics from the incident fields. The media in which these effects occur are becoming the subject of intense interest, since their adjunct properties (stability, ease of preparation, compatibility with microelectronic processing methods, adhesion, mechanical, and other properties) as well as their nonlinear optical properties will ultimately determine the technological utility of the effect.

The origin of nonlinear optical effects will be described here in a phenomenological manner, and several specific effects and their experimental detection and characterization will be described in some detail. Recent efforts in chemical research have been aimed at achieving large second-order nonlinear responses in organic and polymeric materials[1], and several of these will be reviewed.

1.1. Nonlinearity of a Molecular Dielectric Response

In order to gain an insight into the origin of nonlinear optical effects, the polarization P induced in a molecule by a local electric field E is expanded in powers of the electric field [Eq. (1)].

$$P = \alpha E + \beta E^2 + \gamma E^3 + \cdots \quad (1)$$

For the moment, it will be assumed that the polarization is a scalar quantity (as opposed to a vector). The first term α in the expansion is the familiar linear polarization and is the origin of the refractive index if the field E is associated with an electromagnetic wave in the optical frequency range. The coefficients are actually complex numbers, the real part in α corresponding to the index of refraction and the imaginary part to absorption of a photon by the molecule. When an electromagnetic field interacts with a molecule or a medium consisting of many molecules, the field polarizes the molecules. These, in turn, act as oscillating dipoles broadcasting electromagnetic radiation, which can then be detected at some point in space outside of the medium. In a nonlinear medium the induced polarization is a nonlinear function of the applied field. This is illustrated in Figure 1 for a medium where the first nonlinear term β makes a significant contribution to the induced-frequency components. In this example the medium exhibits an asymmetric nonlinear response to the applied field $E(\omega)$. A medium exhibiting such a response might consist of a crystal composed of molecules with asymmetric charge distributions, as shown, arranged in the crystal in such a way that a polar orientation is maintained throughout the crystal. From chemical intuition it is clear that the molecules are more easily polarized in the direction from the elec-

tron-rich substituent D (donor) to electron-deficient substituent A (acceptor).

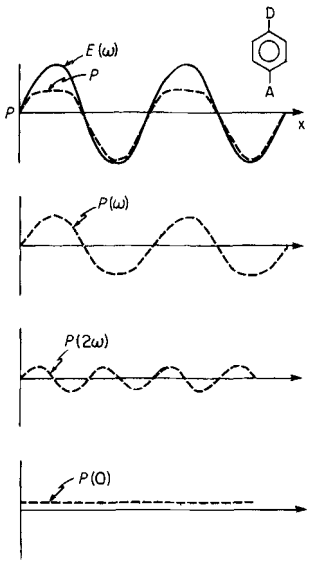

Fig. 1. Top: Plot of the polarization response P to an incident electromagnetic wave of field strength $E(\omega)$ at frequency ω in a noncentrosymmetric medium. Bottom: Fourier components of P at frequencies ω, 2ω, and 0. See also text.

An important general statement can now be made regarding β. If the molecule (or medium in the illustration) is centrosymmetric, then $\beta \equiv 0$. This can be readily seen by the following argument. If a field $+E$ is applied to the molecule (medium), Equation (1) predicts that the polarization induced by the first nonlinear term is $+\beta E^2$. If a field $-E$ is applied, the polarization is still predicted to be $+\beta E^2$, yet if the medium is centrosymmetric the polarization should be $-\beta E^2$. This contradiction can be resolved only if $\beta \equiv 0$ in centrosymmetric media. If we use the same arguments for the next higher order term, $+E$ produces polarization $+\gamma E^3$ and $-E$ produces $-\gamma E^3$ so that γ is the first nonzero nonlinear term in centrosymmetric media.

Referring to Figure 1 again, the Fourier theorem states that a nonsinusoidal periodic response such as P can be described by the sum of a series of sinusoidal functions with appropriate coefficients of harmonics of the fundamental frequency ω[2]. If this response P is asymmetric, an appropriate summation of the even harmonics (the Fourier components consisting of sinusoidal functions of the harmonics 0, 2ω, 4ω, 6ω, etc.) describe the function P. If the nonlinear response is symmetric, however, the odd terms ω, 3ω, 5ω, etc. describe the response. Figure 2 shows an example of a nonlinear response in a centrosymmetric medium such as benzene, where the polarizable π system is responsible for the symmetric nonlinear polarization. The Fourier decomposition would consist of responses at ω, 3ω, 5ω, etc. with progressively decreasing amplitudes (coefficients) of the higher order components. As the incident field $E(\omega)$ in either example becomes more intense, the nonlinear terms contribute more significantly.

Noncentrosymmetric crystals can exhibit harmonic generation (2ω) or frequency doubling (SHG, second harmonic generation), i.e. conversion of coherent light of frequency ω into light frequency 2ω, and optical rectification, i.e. the ability to induce a DC voltage between electrodes placed on the surface of the crystal when an intense laser beam is directed into the crystal. On the other hand, liquids such as benzene or vapors of a polarizable medium exhibit a light intensity dependent refractive index (ω), third-harmonic generation (3ω), and fifth- or higher order harmonics for very intense laser beams in certain metal vapors.

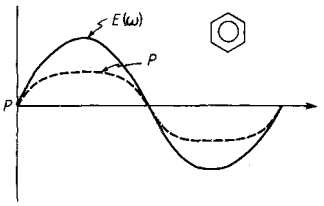

Fig. 2. Plot of the nonlinear polarization response P to an incident electromagnetic field in a centrosymmetric medium.

Another example of a second-order nonlinear optical effect is the linear electro-optic or Pockels effect. Here a DC field is applied to a medium through which an optical wave propagates. Once again this effect arises through β, but the polarization now has a contribution arising from $E(0)E(\omega)$ rather than $E(\omega)^2$ as in second-harmonic generation. The change in polarization due to the presence of these two interacting field components effectively alters the refractive index of the medium η, giving it a field dependence $\eta(E)$.

1.2. Microscopic Nonlinearities

The intuitive description of nonlinear optical processes in Section 1.1 could be extended to additional nonlinear effects, but many of the important aspects and consequences of nonlinear optics cannot be discussed without putting the effects on a more rigorous physical basis. In this section the constitutive relationships will be precisely stated and the reader will be referred to some of the treatises on the subject for additional background.

The polarization induced in a molecule by an applied electric field is

$$P_i = \alpha_{ij}E_j + \beta_{ijk}E_{jk} + \gamma_{ijkl}E_jE_kE_l + \cdots \quad (2)$$

where the subscripts i, j, k, l refer to the molecular coordinate system and E_j, E_{jk}, etc. denote the components of the applied field[3]. Rather than being scalar quantities as expressed in Equation (1), it is obvious that the induced polarization in a molecule is a vector and is related to the electric-field vectors through the components of the tensor coefficients. The third-rank tensor β_{ijk} has properties similar to a vector[4], but γ, a fourth-rank tensor, has the properties of a scalar. This can be seen more readily by relating the values of β and γ obtained in experimental measurements to the components of the tensors [Eqs. (3) and (4)].

$$\beta = \beta_{zxx} + \beta_{zyy} + \beta_{zzz} \quad (3)$$

$$\gamma = 1/5(\gamma_{xxxx} + \gamma_{yyyy} + \gamma_{zzzz} + 2\gamma_{xxyy} + 2\gamma_{xxzz} + 2\gamma_{yyzz}) \quad (4)$$

Recalling that the indices indicate the projection of field components in the direction indicated by the second two indices, ($\beta_{z\underline{xx}}$) on the molecular axis indicated by the first index ($\beta_{\underline{z}xx}$), the vectorial nature of β for fixed molecular and field directions is clear. Referring to Figure 3, where the z axis of the molecule is designated as passing through the carbon atoms to which the electron-rich substituent D (donor) and electron-deficient substituent A (acceptor) are attached, it is clear that the components of the arbitrarily chosen field direction will polarize the molecule most strongly in the z direction. If we devise an experiment where the applied field is pointed in the direction of the molecular z axis, it is clear that β_{zzz} will be the dominant contributor to the nonlinear response. γ, on the other hand, has the characteristics of a scalar with field projections contributing in all molecular directions. To demonstrate these points, an analysis of the properties of even- and odd-rank tensors is required[4].

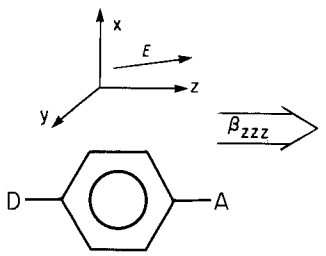

Fig. 3. Organic compound with electron-rich (donor) and -deficient (acceptor) substituents which provide the asymmetric charge distribution in the π system required for large β. Also shown is a reference coordinate system with z parallel to the dipolar axis of the molecule. Since the molecule is most easily polarized for field components parallel to the z axis, β_{zzz} is the largest component of the β_{ijk} tensor.

1.3. Macroscopic Nonlinearities

Nonlinear optical properties are measured on macroscopic samples that consist of many individual molecules. Although it is possible to infer the values of the molecular hyperpolarizabilities from measurements on macroscopic samples, great care must be taken to determine the values of the *internal* electric fields, and the propagation characteristics of the generated fields must be carefully considered[5].

The polarization induced in a medium by an external electric field is given by Equation (5)[6].

$$P=\chi^{(1)}E+\chi^{(2)}E^2+\chi^{(3)}E^3+\cdots \tag{5}$$

E is the applied field and the $\chi^{(n)}$ have meanings similar to the molecular coefficients in Equation (2). The odd-order coefficients $\chi^{(1)}, \chi^{(3)}, \ldots$ are readily related to the molecular properties by Equations (6) and (7)[7].

$$\chi^{(1)}=N\alpha F(\omega) \tag{6}$$
$$\chi^{(3)}=N\gamma F(\omega_1)F(\omega_2)F(\omega_3)F(\omega_4) \tag{7}$$

N is the number of molecules per unit volume and F is a local field factor at frequency ω which determines the value of the electric field at the site of the molecule[7]. The even-order coefficients $\chi^{(2)}$ require a detailed knowledge of the projection of the molecular hyperpolarizability tensors onto the unit cell of the noncentrosymmetric crystal containing that molecule. Here, therefore, we will only state the relationship for the simplest possible case, a rigid lattice-oriented gas[8] (all molecules pointing in the same direction and fixed in space).

$$\chi^{(2)}=N\beta F(\omega_1)F(\omega_2)F(\omega_3) \tag{8}$$

The field factors for nonassociating liquids which were determined by *Onsager*[9,10] are generally used in these expressions [Eq. (9)].

$$F(\omega_i)=(\varepsilon_\infty^i+2)\varepsilon_\omega/(\varepsilon_\infty^i+2\varepsilon_\omega) \tag{9}$$

Zyss and *Oudar*[11,12] recently analyzed the relation between β and $\chi^{(2)}$ for molecules in various space groups and showed that polar molecules that crystallize in the 1, 2, m, and mm2 point groups have the largest potential nonlinear coefficients and that within those point groups the orientation of the molecule is critical.

The coefficient $\chi^{(2)}$ is used below to illustrate several further points about the nature of the induced nonlinear polarization. The coefficient is often written as

$$\chi^{(2)}_{ijk}(-\omega_3;\omega_2,\omega_1) \tag{10}$$

where i, j, k refer to the principal axes of the medium and indicate the tensorial characteristics of $\chi^{(2)}$. The frequency arguments indicate the frequency of the resultant field ω_3 for input frequencies ω_2, ω_1. The minus sign is a convention indicating momentum conservation given by the vector sum

$$k_3+k_2+k_1=0 \tag{11}$$

where k_i (i = 1, 2, 3) is the wave vector given by $k_i=2\pi/\lambda_i$ and points in the direction of propagation of the wave. Thus, for second-harmonic generation the expression (10) would be written $\chi^{(2)}_{ijk}(-2\omega;\omega,\omega)$, and for the linear electro-optic (Pockels) effect $\chi^{(2)}_{ijk}(-\omega;0,\omega)$. A variety of nonlinear optical effects can occur through $\chi^{(2)}$ and $\chi^{(3)}$, depending on the exact nature of the input frequencies, the proximity of molecular vibrational or electronic resonances to the input frequencies or frequency combinations, and the phase-matching conditions, as indicated by Equation (11) and similar equations for $\chi^{(3)}$. A wide variety of conditions can lead to interesting nonlinear effects. Various susceptibility functions and frequency arguments are listed in Table 1 for $\chi^{(2)}$ and $\chi^{(3)}$.

Several comments are warranted concerning the information in the table. Since the incident field components can be in or out of phase with the natural electronic oscillations of the molecules constituting the nonlinear medium, χ is a complex number. Most of the effects listed and all of those discussed thus far occur through the real part Re(χ). The phenomenon of two-photon absorption occurs through the imaginary part Im($\chi^{(3)}$). It is beyond the scope of any single article to discuss the myriad of nonlinear effects occurring through $\chi^{(2)}$ and $\chi^{(3)}$[13-19]. In the fol-

Table 1. Electric susceptibility functions $\chi^{(2)}$, $\chi^{(3)}$ for various types of interacting field components (frequency arguments explained in text), terminology used for the effect, and known applications.

Susceptibility	Effect	Application
$\chi^{(2)}(0;\omega,-\omega)$	optical rectification	hybrid bistable device [13]
$\chi^{(2)}(-\omega;\omega,0)$	electro-optic (Pockels) effect	modulators [14], variable phase retarders
$\chi^{(2)}(-2\omega;\omega,\omega)$	frequency doubling	harmonic generation [15]
$\chi^{(2)}(-\omega_0;\omega_a,\omega_b)$	frequency mixing	parametric amplifiers [16], I. R. up convertors
$\chi^{(3)}(0;0,0,0)$	dielectric saturation	poling
$\chi^{(3)}(0;0,-\omega,\omega)$	second-order optical rectification	—
$\chi^{(3)}(-\omega;\omega,0,0)$	quadratic electro-optic effect	variable phase retardation, liquid-crystal displays
$\chi^{(3)}(-\omega_0;\omega_a,\omega_b,-\omega_b)$	AC electro-optic effect AC Kerr effect Brillouin scattering Raman scattering	high-speed optical gates [17]
$\mathrm{Im}(\chi^{(3)})(-\omega_a;\omega_0,\omega_b,-\omega_b)$	two-photon adsorption	—
$\chi^{(3)}(-\omega;\omega,\omega,-\omega)$	AC electro-optic effect AC Kerr effect self-focusing degenerate four-wave mixing	optical bistability [18], phase conjugation [19] (image processing), real-time holography, optical transistors
$\chi^{(3)}(-3\omega;\omega,\omega,\omega)$	frequency tripling	deep UV conversion

lowing, we will merely concern ourselves with the origin and characterization of β and $\chi^{(2)}$ in organic materials.

2. Experimental Methods

2.1. Determination of β

From a chemical point of view, one aim of research in nonlinear optics might be to synthesize materials with useful nonlinear optical and other properties for specific applications. Characterization of β of the constituent molecules is essential for a structure-property based understanding of molecules. A technique has been developed for measuring β without necessitating the incorporation of the molecule into noncentrosymmetric crystal structures. In this technique, called electric-field-induced second-harmonic generation (EFISH), a strong DC electric field is applied to a liquid or a solution of the molecules of interest in order to remove the orientational averaging by statistical alignment of molecular dipoles in the medium[4]. The induced second-order nonlinearity can then produce a signal at 2ω, from which β can be extracted[20–23].

Figure 4 shows schematically the essential elements of an EFISH experiment[5,22–24]. The 1.06 μm output of a Nd^{3+}: YAG laser is split and directed into a sample and a reference cell. The sample cell (Fig. 5) is translated by a stepper-motor-controlled stage across the beam. The laser pulse is synchronized with a high-voltage DC pulse to induce harmonic generation in the cell. The 0.53 μm radiation is separated from the 1.06 μm pump beam by filters and a monochromator, and the harmonic intensity is detected by a photomultiplier tube. The signal-to-noise ratio can be improved with a boxcar averager. The reference beam is directed into a crystal such as quartz, whose sec-

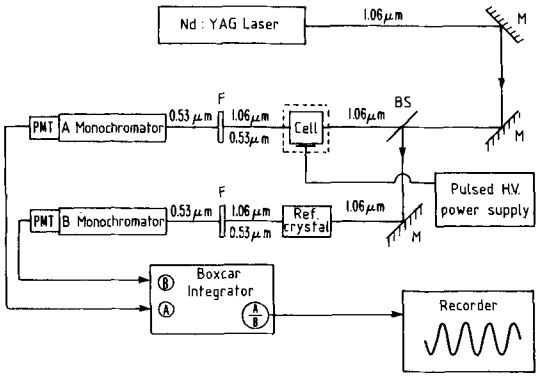

Fig. 4. Schematic diagram of an experimental system for measurement of β by the EFISH (electric-field-induced second-harmonic-generation) technique [24, 25]. M = mirror, BS = beam splitter, F = filters, PMT = photomultiplier tube. Lens and timing pulses are not shown.

ond-order properties are well known, so that fluctuations in beam intensity can be readily corrected in the output data. The value of the nonlinear coefficient is obtained from the ratio of the signals of the sample cell and a reference material such as quartz or $LiNbO_3$ with known $\chi^{(2)}$ [Eq. (12)].

$$\frac{l_{c(\text{sample})}}{l_{c(\text{reference})}}\left[\frac{\chi^{(2)}_{\text{sample}}}{\chi^{(2)}_{\text{reference}}}\right]^2 \propto \frac{I(2\omega)_{\text{sample}}}{I(2\omega)_{\text{reference}}} \tag{12}$$

l_c = the coherence length (see Fig. 6).

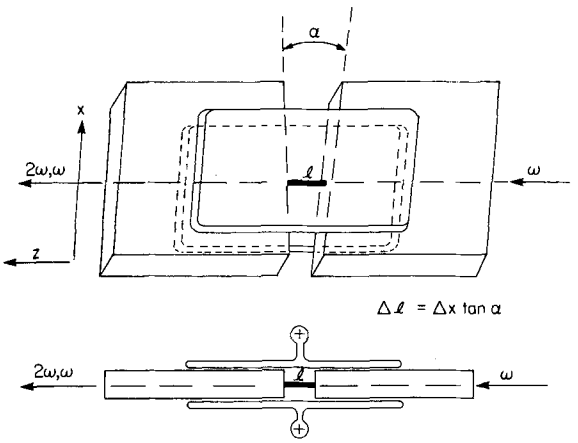

Fig. 5. Top view (above) and edge view (below) of a cell used for EFISH measurements. The glass is ca. 3 mm thick and ca. 1 cm long. The gap in which the liquid is confined is 1–2 mm, and the electrodes extend about five times the gap spacing to avoid nonuniform electric fields at the glass-liquid interface. The cell is translated in the x direction with respect to the beam to produce the fringes described in Figure 6.

The geometry of the sample cell is shown in greater detail in Figure 5. The cell consists of two glass rectangles set at an angle α with respect to each other (Fig. 5, top). Electrodes are placed above and below the glass surfaces (Fig.

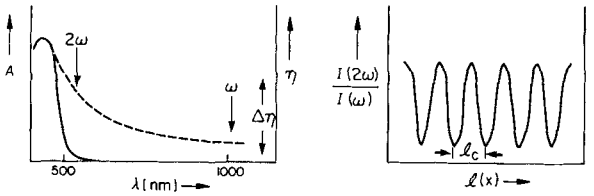

Fig. 6. Left: Schematic of an absorption band A (unbroken line) and dispersive refractive index (η, broken line) as a function of the wavelength λ for a typical aromatic ring system. The phase retardation ($\Delta\phi$) for light at the fundamental frequency ω and harmonic 2ω is determined by the dispersion in the refractive index ($\Delta\eta$) and the path length travelled (l) (c = speed of light).

$$\Delta\phi = \frac{\omega l}{c}\Delta\eta$$

For $\Delta\phi = 0$, $I(2\omega)/I(\omega)$ is a maximum; for $\Delta\phi = \pi/2$ the same expression is a minimum. Right: Ratio of harmonic to fundamental intensity when the path length refractive index discontinuities (boundaries of the cell in Fig. 5) is varied in the x direction. The harmonic conversion depends on the phases of the electric fields and thus also on the path length.

5, bottom), and the liquid to be measured is poured into the wedge-shaped gap between the glass pieces. Translation of the cell in the x direction produces a path length variation Δl depending on the distance traversed. The need for the wedge geometry and translation of the cell is best understood by referring to Figure 6. The left-hand side of the figure shows the wavelength dependence of the refractive index η and the absorption A for an aromatic molecule at the fundamental and harmonic frequencies. A convenient representation of the electric field associated with a light wave is given by Equation (13):

$$E(z) = E_0 e^{i(\omega t - \phi(z))} + c.c \tag{13}$$

E_0 is the amplitude, ω is the frequency, and $\phi(z)$ is a phase angle. Since the difference in the refractive index $\Delta\eta$ at ω and 2ω generates a phase-angle difference $\Delta\phi$, which is also a function of the distance traversed $l(z)$, the fundamental and harmonic fields will change their relative phases over some characteristic distance l_c. Since the flow of energy from fundamental to harmonic field or harmonic to fundamental field is a phase-sensitive process, we would expect to see oscillations in the harmonic intensity as the beam traverses the wedged cell with a defined characteristic coherence length l_c (Fig. 6, right). The intensity distribution between fundamental and harmonic is determined solely by the phase relationships that exist at the last liquid/glass boundary. *Oudar*[25] analyzed the propagation of the various waves in a nonlinear medium with the boundary conditions of the liquid cell. In the absence of optical absorption, the functional dependence $I(2\omega)/I(\omega)$ is expressed in terms of Equations (14a) and (14b).

$$I(2\omega)/I(\omega) = D + K\sin^2\psi \tag{14a}$$

$$\psi = -\frac{\omega}{2c} l\Delta\eta \tag{14b}$$

D and K are calibration factors[24,25].

The "nonphase-matched" wedge technique can be extended to all nonlinear media (liquids, films, crystals), as long as the sample can be shaped into a wedge or otherwise manipulated to produce a periodic phase-matched condition. The reference sample in Figure 4 could, for example, be a polished quartz crystal with a wedge cut perpendicular to the direction of largest nonlinearity.

In order to relate the experimental data obtained from the EFISH measurement to β, it is necessary to consider the expressions for microscopic and macroscopic nonlinearities. Since the experiment generates a harmonic field at 2ω from the interaction of three waves (two optical field components (E^{ω}) and a DC field component (E^0)), the induced nonlinear polarization must arise from a third-order nonlinear process

$$P^{2\omega} = \Gamma_{ijkl} E^{\omega} E^{\omega} E^0 \tag{15}$$

where

$$\Gamma_{ijkl} = \chi^{(3)}(-2\omega;\omega,\omega,0)$$

We can define an effective second-order coefficient

$$d_{ijk} = \Gamma_{ijkl} E_l \tag{16}$$

so that

$$P^{2\omega} = d_{ijk} \cdot E^{\omega} \cdot E^{\omega} \tag{17}$$

resembles a second-order nonlinear optical effect. For a pure liquid we can define a microscopic hyperpolarizability

$$\Gamma = NF\gamma^0 \tag{18}$$

where N is the density of molecules, and F is a local field correction $EF(\omega_i) = F$ (the internal field). The relationship of γ^0 to the hyperpolarizabilities of the molecules β_{ijk} and γ_{ijkl} requires a statistical analysis[26], and the result is

$$\gamma^0 = \gamma + \frac{\mu_z\beta_z}{5kT} \tag{19}$$

where the z axis is aligned with the dipole moment of the molecule. For conjugated organic systems $\mu_z\beta_z/5kT \gg \gamma$, so that with this analysis β has been obtained for a wide variety of organic molecules.

$$[I(2\omega)]^{1/2} \propto NF\frac{\mu_z\beta_z E^0}{5kT} \tag{20}$$

2.2. Kurtz Powder Technique

The Kurtz powder technique[27] is a convenient method for screening large numbers of powdered materials for second-order nonlinear optical activity without needing to grow large single crystals. A laser is directed onto a powdered sample, and the emitted light is collected, filtered, and detected with a photomultiplier tube. The technique is crude in the sense that it detects a convolution of all the

tensor components of $\chi^{(2)}$ and makes little attempt to account for the propagation characteristics of the beams. Nevertheless, general trends can be observed and candidates for single-crystal studies identified.

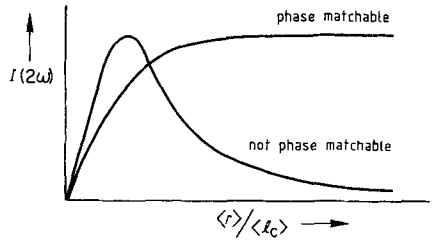

Fig. 7. Dependence of the second-harmonic intensity on the dimensionless quantity $\langle r\rangle/\langle l_c\rangle$, where $\langle r\rangle$ is the average particle size and $\langle l_c\rangle$ is the average coherence length according to the Kurtz powder method [27].

Figure 7 illustrates the application of this technique for phase-matchable and nonphase-matchable powders. Many crystals are birefringent; thus it is often possible to find a direction in a crystal in which a component of the nonlinear tensor $\chi^{(2)}_{ijk}$ will produce a harmonic wave that propagates with the same effective refractive index as the fundamental beam. This can be seen more easily in Figure 8 (top), where the refractive index for a uniaxial crystal is an ellipse. A light wave propagating through the crystal in a direction s has allowed polarization components at the major and minor axes of the ellipse perpendicular to s. One of these components η_0 (ordinary component of the refractive index) is independent of the direction of s, and the other depends on the angle θ between s and the y axis. A similar ellipse with different dimensions could be drawn at 2ω. If the two ellipses intersect, the possibility of a phase-matched tensor component exists. The lower plot indicates that an angle θ_p exists for phase matching.

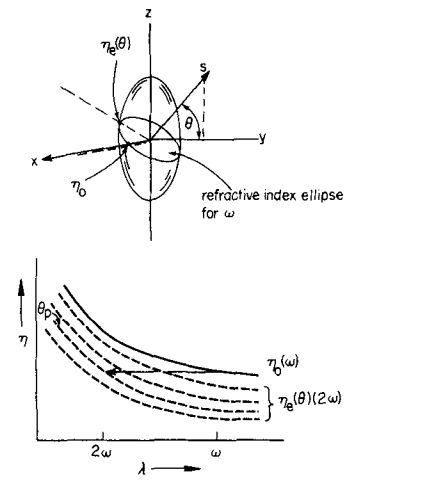

Fig. 8. Top: Refractive index ellipsoid for a uniaxial medium. s indicates the direction of an incident beam of light, and the semimajor and semiminor axes of the ellipse formed by the plane perpendicular to s with the refractive index ellipsoid define the allowed polarization directions for the propagating polarization. The refractive indices corresponding to those directions are the η_0 (ordinary) and $\eta_e(\theta)$ (extraordinary) components. The value of $\eta_e(\theta)$ depends on the angle between s and the x-y plane.—Bottom: If a direction in the medium can be found where $\eta_o(\omega)=\eta_e(\theta)_{2\omega}$, one type of phase matching is possible and large conversion efficiencies can be expected; θ_p is the phase-match angle.

It is possible to tell if a crystalline powder is phase matchable from a study of $I(2\omega)$ versus particle size (Fig. 7). Since phase-matched second harmonic generation is extremely efficient, the random particles which fortuitously sit at the phase-match angle provide most of the signal when the normal coherence length for nonphase-matched harmonic generation is exceeded. Great care must be used in applying this technique quantitatively, since the results are particle-size dependent.

3. Second-Order Nonlinear Optical Properties

As was indicated earlier, in the design of materials with large second-order nonlinear optical coefficients and other useful properties, the molecular hyperpolarizability must be optimized and then oriented in a medium (polymer, liquid, crystal) so that the propagating field can be transmitted from the medium. The electronic contributions to β and various approaches for obtaining the required noncentrosymmetry in the medium are discussed in this section.

3.1. Molecular Hyperpolarizability

Molecules containing conjugated π electronic systems with charge asymmetry exhibit extremely large values of β. The largest values are obtained when the molecule contains substituents that lead to low-lying charge-transfer resonance states (Fig. 9). The polarization can be visualized

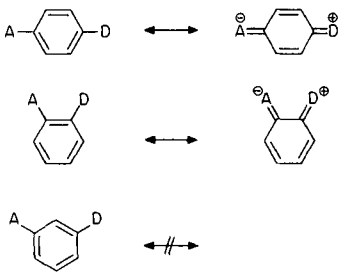

Fig. 9. Ground-state and lowest energy polar resonance forms for *p*- and *o*-substitution. Resonance is forbidden in the case of *m*-substitution.

as arising from contributions of the substituent-induced asymmetry of the π cloud and the σ skeleton of the molecule, as well as from field-induced mixing of the excited state (polar character) into the ground electronic configuration. The contributions to β have been separated into two parts for nitroanilines[28,29] [Eq. (21)].

$$\beta=\beta_{add}+\beta_{CT} \tag{21}$$

β_{add} is an additive part due to substituent-induced asymmetry in the charge distribution and β_{CT} is the charge-transfer term. Table 2 lists experimentally determined values of β for various nitroanilines and the monosubstituted parent compounds[29]. Also listed are values for β_{add}, obtained by simple vector addition of the experimentally determined values of β for nitrobenzene and aniline, and β_{CT}, obtained by a quantum mechanical calculation based on a charge-resonance two-level model described below. Note

Table 2. Experimental values of β for various nitroanilines as well as nitrobenzene and aniline. Also listed are the additive contribution β_{add} determined from summing the values for aniline and nitrobenzene and the charge-transfer contribution β_{CT} determined by the two-level model.

	$\beta_{exp} \times 10^{30}$ [esu]	β_{add}	β_{CT}
	34.5	3.4	19.6
	10.2	1.7	10.9
	6	3.3	4
	2.2	—	—
	1.1	—	—

the general agreement between the experimentally determined values for the disubstituted systems and the results of the calculations. Also note the obvious importance of the charge resonance structure, which, according to theory, should make its strongest contribution to β in the *p*-nitroaniline derivative.

In order to understand the origin of the additive term, it is useful to consider briefly the equivalent internal field model (EIF) for β in monosubstituted organic molecules[30]. In this model the charge asymmetry in the π system arises from the inductive effect of the substituent on the π system, leading to a "mesomeric" dipole moment $\Delta\mu$ in the aryl ring; $\Delta\mu$ is proportional to an internal field E_0 arising from the substituent [Eq. (22)].

$$\Delta\mu = \alpha E_0 + \gamma E_0^3 \simeq \alpha E_0 \tag{22}$$

Thus when an external field is applied, the total field is $E_T = E + E_0$, and Equation (2) becomes

$$P = \alpha E_T + \gamma E_T^3 \tag{23}$$

and by substitution

$$P = \alpha E_0 + \gamma E_0^3 + (\alpha + 3\gamma E_0^2) E + 3\gamma E_0 E^2 + \gamma E^3 \tag{24}$$

Chemical substitution on the ring therefore slightly modifies the linear polarizability (term 3), with appearance of a quadratic response (term 4). β, therefore, is given by the fourth term as

$$\beta = 3\gamma E_0 \tag{25}$$

and by substitution from Eq. (22)

$$\beta = \frac{6\gamma\Delta\mu}{\alpha} \tag{26}$$

Figure 10 shows a plot of experimentally determined values of β for a variety of monosubstituted benzenes versus the "mesomeric" dipole moment $\Delta\mu$[25]. Although there is

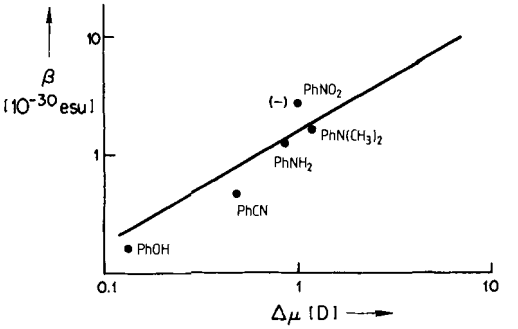

Fig. 10. Log/log plot of β versus the "mesomeric" dipole moment for some monosubstituted benzene derivatives [25].

some disagreement regarding the validity of the procedures for obtaining $\Delta\mu$[4], the agreement between experiment and theory is good and is supported by more-refined estimates of the induced dipole moment in the π system[31]. The certainty of the procedure for obtaining the additive components of β in Table 2 seems reasonable in view of the success of the EIF model for monosubstituted benzene derivatives. The vector-addition procedure assumes independent influences of the substituents.

The second term in Equation (21), β_{CT}, has been accounted for by various methods and degrees of sophistication ranging from Pariser-Parr-Pople calculations[25,32] to CNDO(S) studies with configuration interaction[33] and other SCF-LCAO methods[34], but a particularly useful approach for the physical organic chemist is the perturbation approach employing a two-level model[29]. In this model the β_{CT} term can be described in terms of a ground and first excited state having charge-transfer character (Fig. 9) and is related to the energy of the optical transition W, its oscillator strength f, and the difference between ground- and excited-state dipole moments $\Delta\mu_{g,e}$ by Equation (27).

$$\beta_{CT} = \frac{3e^2\hbar^2}{2m} F(\omega) f \Delta\mu_{g,e} \tag{27}$$

$$F(\omega) = \frac{W}{[W - (2\hbar\omega)^2][W^2 - (\hbar\omega)^2]}$$

The term $F(\omega)$ accounts for dispersion and enhances β_{CT} as the fundamental frequency (ω) and harmonic (2ω) approach the energy of the charge-transfer function. Good agreement was obtained between the value of β_{CT} predicted by this expression and β_{exp} (assuming $\beta_{exp} = \beta_{CT}$) for a series of disubstituted benzene and stilbene derivatives[25] (Table 3).

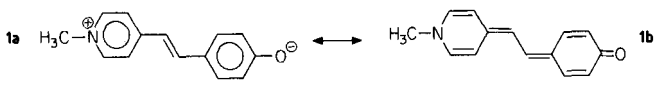
Morrell and *Albrecht*[33] tested the two-level model for *p*-nitroaniline by calculating β from CNDO(S)-determined electronic states using limited configuration interaction. They found that on using only the ground and first excited charge-transfer state, 75% of the value of β_{exp} could be accounted for. They obtained $\beta_{CT} = -25.1 \times 10^{-30}$ esu by this procedure. Inclusion of 60 excited configurations to more closely approximate the eigenstate associated with the first excited state gave $\beta = -34.3 \times 10^{-30}$ esu, which is in excellent agreement with β_{exp}. For the more extensively conjugated systems, the charge-transfer state is lower in energy with respect to other excited configurations, and we would

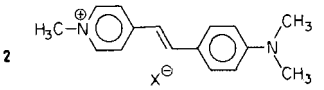
Table 3. Charge-transfer contribution β_{CT}, calculated from the two-level model, and experimental values β_{exp} for a series of benzene and stilbene derivatives.

	$\beta_{CT} \times 10^{30}$ [esu]	$\beta_{exp} \times 10^{30}$ [esu]
	19	34.5
	227	260
	383	450
	217	220
	715	650

expect the two-level scheme to agree even better with experimental data. The data in Table 3 appear to confirm this.

The success of the two-level model makes chromophore selection simple in many cases. If a molecule can be viewed as a superposition of resonating electronic structures with charge migration in the same direction along the molecular axis, β should be large. By this procedure, merocyanine dyes such as **1**[35] were shown to have the largest





known molecular hyperpolarizability, and a noncentrosymmetric crystal containing the related dimethylaminostilbazolium chromophore **2**[5,36] was shown to have the largest known value of $\chi^{(2)}$ by the powder method. The product $\mu\beta$ was measured for a series of merocyanine-like compounds (Table 4). The importance of the charge resonance contribution is evident from the table. The reason for the low value of $\mu\beta$ for **6** (Table 4) is not clear, but the S atom may perturb the system in such a way that neither resonance form is predominant.

Table 4. Product of the dipole moment and β for molecules related to the merocyanine structure with the wavelength of the long wave absorption band λ_{CT}.

		$\mu\beta \times 10^{47}$ [esu]	λ_{CT} [nm]
	**3**	3.6	307
	**4**	760	570
	**5**	510	660
	**6**	50	560
	**7**	370	408
	**8**	150	498

Based on the theoretical notions described above, the effects of substituent patterns on a given chromophore are readily correlated with the electron donating and accepting strength of the substitution. Table 5 presents data on the effects of various substituents on β and λ_{CT}. Except for *p*-aminoacetophenone, the trends in λ_{CT} and β with the nature of the donor and acceptor are consistent with contribution of the charge-transfer state to β.

Table 5. Longest-wavelength absorption band and β for a series of *p*-disubstituted benzene derivatives.

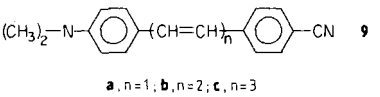
CHO		(5.67)		352 (19.5)
$COCH_3$			310 (2.40)	
NO_2	280 (9.12)	314 (17.35)	378 (47.67)	418 (52.75)



a, n = 1; **b**, n = 2; **c**, n = 3

Dulcic et al.[37,38] investigated the dependence of β on the length of the conjugated π-system for the compounds **9a**—**9c**; they found it obeyed an empirical law [Eq. (28)].

$$\mu_0\beta = Cn^k \tag{28}$$

$k \approx 2$, n = number of conjugated double bonds in **9**.

Although there appears to be a discrepancy in the sign of β, later experimental work reports the sign as being (−); the data in Table 3 therefore confirm this. The two-level model has generally been successful in accounting for the features of various classes of molecules, but caution should be ercercised when it is resorted to for predictions, since fortuitous combinations of ground- and excited-state electronic properties could exist where $\beta \approx 0$. This should be apparent, since β has not only a magnitude but also a sign.

3.2. Crystals and Polymers with Large $\chi^{(2)}$

From the regularities observed in β for various chromophore types, substituent patterns, and conjugation lengths, it is clear that a wide variety of molecular structures would exhibit extremely large second-order susceptibilities if they

could be incorporated into noncentrosymmetric structures. In this section various approaches to achieving this will be discussed.

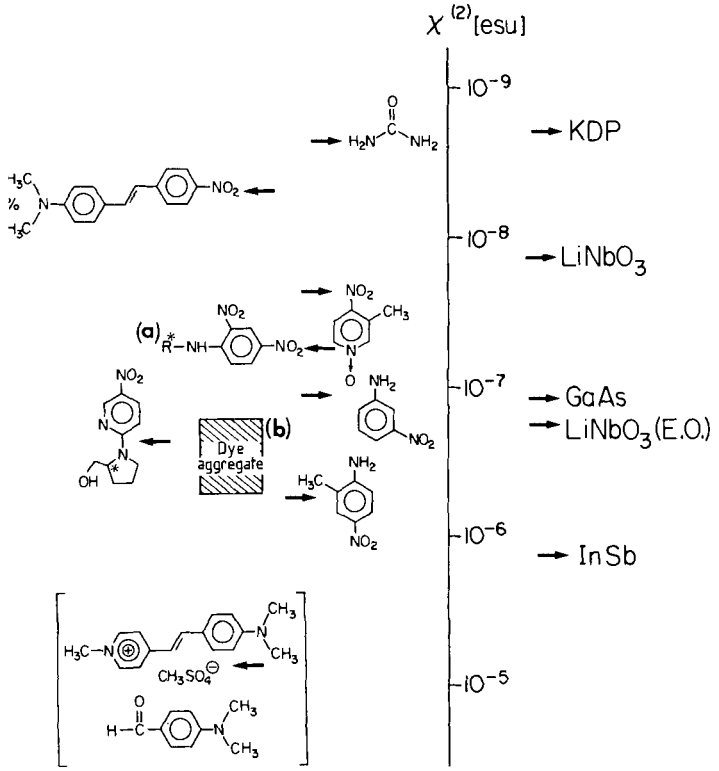


Fig. 11. $\chi^{(2)}$ scale for various inorganic crystals (right) and organic crystals and films (left). (a) R* = methoxycarbonylethyl. (b) Dye aggregate formed from an indolinobenzospiropyran and its ring-opened merocyanine form [39, 40]. *p*-Dimethylamino(nitro)stilbene was investigated in a poled liquid crystalline polymer. The arrows to the left and the right indicate the values of the substances.

Figure 11 depicts a $\chi^{(2)}$ scale with values of the susceptibility, generally obtained from second-harmonic-generation measurements for various organic and inorganic materials (for comparison). InSb has one of the largest known value of $\chi^{(2)}$, but, being a semiconductor, it is highly absorbing in the visible region of the spectrum and is therefore not useful for many applications. $LiNbO_3$ is the most extensively studied material for device applications involving the linear electro-optic effect. It suffers, however, from degradative photorefractive effects, which can cause history-dependent performance in various device applications. Potassium dihydrogen phosphate (KDP) has been used widely for phase-matched SHG of high-powdered near-IR lasers. In $LiNbO_3$, $\chi^{(2)}$(SHG) results from electronic polarization, whereas $\chi^{(2)}$(EO) results from polarization of the positions of the nuclei. In organic π electronic systems, $\chi^{(2)}$(SHG) and $\chi^{(2)}$(EO) both result from polarization of the π cloud, resulting in nearly identical values for the two effects. The measured values of $\chi^{(2)}(-2\omega;\omega,\omega)$[41] and $\chi^{(2)}(-\omega;\omega,0)$[42] for 2-methyl-4-nitroaniline (MNA), which are 540×10^{-12} and 500×10^{-12} esu, respectively, verify that the π electronic system is the primary contributor to both effects.

On the left side of Figure 11 are $\chi^{(2)}$ values for various organic materials. The nonlinear optical tensor components have been studied in detail for the five crystals indicated by the arrows closest to the scale. The principal $\chi^{(2)}$ tensor component was determined for *p*-dimethylaminonitrostilbene doped into a liquid-crystalline polymer, and the remaining materials were studied as powders.

Several points should be noted regarding Figure 11: Organic systems exhibit nonlinear coefficients which can exceed the best values for inorganic dielectrics and semiconductors. Furthermore, they are generally more useful because of increased transparency and resistance to laser damage. Although a number of crystalline organic materials have sufficiently large values of $\chi^{(2)}$ to be useful in integrated optics and for other applications, so far no polymer or other thin-film has been shown to have values of $\chi^{(2)}$(EO) approaching that of $LiNbO_3$. Considerable research on polymeric and non-polymeric organic materials remains to be done if technological utility is to be realized. Finally, the largest known value of $\chi^{(2)}$ (estimated by powder measurements) has been realized in an organic material.

The significance of the magnitude of $\chi^{(2)}$ immediately becomes apparent in equation (29), i.e. the equation for the efficiency of harmonic conversion by a plane wave propagating through a nonlinear material in the limit of low conversion[43].

$$\frac{I(2\omega)}{I(\omega)} = \Gamma^2 l^2 \,\mathrm{sinc}^2 \frac{\Delta k l}{2} \tag{29}$$

where

$$\Gamma^2 = \frac{(\chi^{(2)})^2 \omega^2 I(\omega)}{\eta^3 c^3 \varepsilon_0} \tag{30}$$

Here, l is the path length, ω is the fundamental frequency, η is the refractive index, c is the speed of light, ε_0 is the dielectric constant of a vacuum, and Δk (the phase mismatch) is $\omega/c\Delta\eta$. The sinc(x) function is defined as

$$\frac{\sin x}{x} = \mathrm{sinc}\, x \tag{31}$$

and sinc x approaches 1 as x approaches zero. Since the conversion efficiency is proportional to $(\chi^{(2)})^2$, a crystal of the type shown at the bottom of Figure 11 could be ca. 10^7 times more efficient than KDP or urea, which are normally used for megawatt lasers. A material of this type could provide large conversion efficiencies for solid-state diode lasers (≈ 10 mW power) if the appropriate nonlinear optical characteristics could be incorporated into the crystal. Thus, nonlinear optics could be extended to very low-power lasers. In designing technical devices many other advantages could be realized with coefficients in the 10^{-6} esu range. Another important consideration is brought out in Eq. (29): the implications for phase matching. At the phase-match condition $\Delta k = 0$ or $\eta_{2\omega} - \eta_\omega = 0$, $\mathrm{sinc}^2(x) = 1$, and the conversion efficiency is simply related to $\chi^{(2)} l^2$. (Other beam propagation characteristics, however, may lead to "walk off" or spatial divergence of the interacting fields, thus limiting the harmonic conversion.) If $\Delta k \neq 0$ the function oscillates as indicated previously. For Gaussian

beams and real crystals the situation is somewhat more complicated, but the same basic behavior, as illustrated by the plane-wave case, is followed.

In the following sections the properties of several of the materials in Figure 11 that illustrate key aspects or problems in second-order nonlinear materials will becommented on in more detail.

3.2.1. 2-Methyl-4-Nitroaniline (MNA)

The crystal growth and properties of MNA have been studied in detail by *Levine* et al.[41], who determined $\chi^{(2)}$ from harmonic generation studies, and by *Lipscomb* et al.[42], who measured the electro-optic coefficients. Earlier studies of β for *p*-nitroaniline[28] indicated that a noncentrosymmetric crystal containing the chromophore in an appropriate geometry could have very large $\chi^{(2)}$. It was hypothesized that a bulky substituent creating a sterically asymmetric ring could lead to the required crystal structure, and this was indeed verified by examination of a variety of monosubstituted *p*-nitroaniline derivatives. From powder measurements, MNA was identified as a candidate for single-crystal growth, and vapor transport and solvent growth techniques were used to obtain the crystals. The unit cell structure is illustrated in Figure 12. The Cc space group, which is contained in the m point group (monoclinic), has the unit cell symmetry elements indicated. Note that the polar axis P has a projection of the dipole moment onto the P axis determined by θ and ϕ.

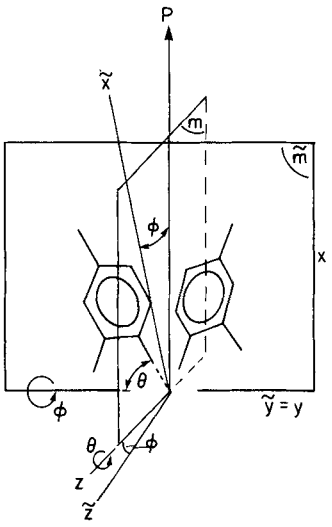

Fig. 12. View of the unit cell of 2-methyl-4-nitroaniline (MNA). The space group Cc is isomorphous with the C_s point group, which has a polar axis P and mirror plane m̃. θ and ϕ are 70 and 8°, respectively; x, y, z are the dielectric principal axes, m is a pseudo-mirror plane. The large projection of the molecular polar z axis onto P makes this an ideal candidate for electro-optic applications. Structural data from [12].

Oudar and *Zyss*[12] have analyzed the relationship between the various components of the hyperpolarizability tensor β_{ijk} and the macroscopic nonlinear coefficients $\chi^{(2)}_{ijk}$ for various crystal symmetries. Their objective was to determine the space groups that would give the largest achievable nonlinearities as well as the dependence of the various nonlinear coefficients on the geometry of the molecule in the unit cell. For MNA the coefficient $\chi^{(2)}_{zzz}$ should be maximized when the angle θ is 90°. This should be apparent, since for a small dihedral angle ϕ the projection of the polar charge-transfer axis will be maximum when it is parallel to the crystal polar axis. $\chi^{(2)}_{zzz}$ therefore gives a very large electro-optic coefficient[42], but since the polarization and field directions are colinear, this could not possibly be a phase-matchable coefficient for SHG. χ_{zyy}, on the other hand, is a phase-matchable coefficient and for this space group is a maximum for $\theta = 54°$, $\phi = 0$: *Oudar* and *Zyss*'s analysis[12] predicts an increase in $\chi^{(2)}$ by a factor of 3.5 and more than an order of magnitude greater conversion efficiency for optimum orientation of an MNA type molecule over that actually observed [41, 42]. Although the relationship between crystal structure and second-order nonlinear properties is complex, the details have been elucidated and summarized[12]. The maximum achievable value $\chi^{(2)}_{(max)}$ as a fraction of what one would predict from the oriented rigid gas model described earlier is given in Table 6.

Table 6. Polar point groups and maximum fractional value of the rigid oriented gas $\chi^{(2)}$ for a phase-matched interaction and for optimum molecular orientation in the unit cell.

222, 6mm, 6, 4mm, 42M, 23, 43M	0.19
4	(no possible phase interaction)

3.2.2. trans-4'-Dimethylamino-N-Methylstilbazolium Methyl Sulfate (DSMS)

The title chromophore, DSMS **2**, $X = H_3COSO_3^{\ominus}$, was selected according to the principles outlined at the end of Section 3.1. It contains extremely electron-rich and electron-deficient groups linked in a *trans*-stilbene fashion, leading to an expanded conjugated π-system. The possibility of metastasis of the counterion suggests investigating a variety of steric and coulombic influences on the crystal structure of a common chromophore. SHG harmonic intensity measurements are shown in Table 7 for a variety of materials[5,36]. The caution with which data of this type must be viewed is illustrated by comparison of *m*-nitroanil-

Table 7. Harmonic intensity (relative to *m*-nitroaniline) determined by the Kurtz powder method.

Crystalline powder	Relative harmonic intensity
α-Quarz	0.008
m-Nitroaniline	1
MNA	3
$1^{\oplus}$(+)-Campher sulfonate$^{\ominus}$	0.007
$2^{\oplus}$ $I^{\ominus}$	0
$2^{\oplus}$ $IO_3^{\ominus}$	0.01
$2^{\oplus}$ $NO_3^{\ominus}$	0.5
$2^{\oplus}$ $C_6H_5CH{=}CHCO_2^{\ominus}$	1.5
$2^{\oplus}$ $ClO_4^{\ominus}$	5
$2^{\oplus}$ $BF_4^{\ominus}$	10
$2^{\oplus}$ $ReO_4^{\ominus}$	18
$2^{\oplus}$ $CH_3OSO_3^{\ominus}$	30

ine and MNA. Their coefficients $\chi^{(2)}$ differ by a factor of about 3, yet their harmonic intensities differ by a factor of only about 3 rather and not—as we might expect from Equation (29)—by a factor of 9. Since no attempt was made to classify particle sizes, and the powder technique is known to be very dependent on this and other factors, variances of this sort might be expected. Nevertheless, the DSMS powder showed an order of magnitude higher conversion efficiency than MNA, which has the largest known $\chi^{(2)}$ value reported to date for a crystal. This constituted justification for growing DSMS single crystals and characterizing the linear and nonlinear properties of the crystal. Preliminary crystal structure studies have shown that the crystal is described in the mm2 point group, for which a large value of $\chi^{(2)}$ is expected (Table 6). Furthermore, the molecular dipolar axis is tilted at an angle of 34° with respect to the twofold screw (polar) c axis. Since a tilt axis of 54° 74′ would be optimum for phase-matched SHG and 0° for the linear electro-optic coefficient[11], the crystal structure is a compromise and is expected to give large values for both effects.

3.2.3. Materials Optimized for SHG with Semiconductor Lasers

Twieg and *Jain*[44] exhaustively studied molecules containing the nitroaniline and related chromophores for SHG activity by the powder technique. Their objective was to identify powders with large SHG conversions and transparency suitable for use with 0.80—1.5 μm lasers. Table 8 lists harmonic efficiency measurements for powders of various classes of substances. Generally, only the compound showing the largest efficiency for a particular class is shown. For instance, **10** is a substituted urea derivative, **11** a push-pull alkene, **13** a MAP analogue, etc. Given the uncertainties of the powder technique as applied here, any of these compounds would be reasonable candidates for further study, depending on factors such as the ease of crystal growth, oxidative stability, toxicity, etc. Compound **19** is particularly interesting because its powder efficiency is about half that of the stilbazolium salt mentioned previously, yet it is very transparent in the visible region owing to the blue shift attributed to the nitrogen heteroatom (cut off ≈430 nm).

3.2.4. Molecularly Doped and Aligned Polymers

A possible route to preparing polymeric films with large second-order nonlinear coefficients is to remove the orientational averaging of a dopant molecule with large β by application of an external DC electric field to a softened film. This might be accomplished by heating the film above the host polymer glass-transition temperature T_g, then cooling the film below T_g in the presence of the external field. The poling would provide the alignment predicted by the Boltzmann distribution law and impart $C_{\infty v}$ symmetry to the film. Such a process is illustrated schematically in Figure 13. For this particular symmetry group[45] there are two nonvanishing coefficients, $\chi^{(2)}_{zzz}$ and $\chi^{(2)}_{zxx}$, i.e. incident beam polarized parallel (zz) and perpendicular

Table 8. Harmonic intensity (relative to that of urea) for a series of powders. The numbers in parentheses are relative to *m*-nitroaniline and are obtained by comparing the MNA values in Tables 7 and 8 and applying the appropriate multiplier to the values in Table 8.

Crystalline powder		Rel. harmonic intensity
		1.0 (0.13)
	**10**	8.8 (1.20)
	**11**	7.5 (1.02)
	**12**	10.0 (1.36)
	**13**	32.0 (4.36)
	**14**	22.0 (3.0)
	**15**	80.0 (10.9)
	**16**	115.0 (15.6)
	**17**	80.0 (10.9)
	**18**	70.0 (9.55)
	**19**	160.0 (21.8)

(xx) to the z polar axis. A film with these properties would have an electro-optic coefficient proportional to $\chi^{(2)}_{zzz}$, and phase matching for SHG could be achieved through the smaller $\chi^{(2)}_{zxx}$ [46]. Alternatively, harmonic generation could be achieved by wave guiding, which would impart additional flexibility in phase matching. The advantages of wave-guided SHG[47] will not be discussed here, but a tremendous potential advantage of polymer films over crystals lies in the fabrication of thin films for wave-guided nonlinear optical devices.

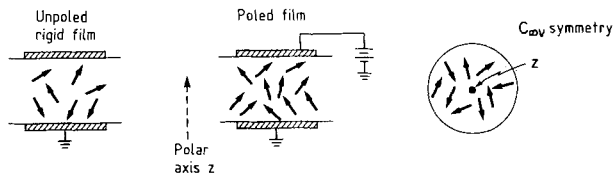

Fig. 13. Schematic of imparting $C_{\infty v}$ symmetry (polar axis, isotropic perpendicular to the polar axis) to an isotropic medium containing permanent dipoles with an external electric field E.

To predict the value of $\chi^{(2)}$ after poling, one needs to evaluate the expressions (32) and (33).

$$\chi^{(2)}_{zzz} = NF\beta_{zzz}\langle\cos^3\theta\rangle \tag{32}$$

$$\chi^{(2)}_{zxx} = NF\beta_{zzz}\langle(\cos\theta)(\sin^2\theta)(\cos\phi)\rangle \tag{33}$$

These expressions resemble that for the oriented rigid gas [Eq. (7)], where F is the total local field-factor correction, θ is the angle between the molecular polar z axis and the laboratory (field-induced) z axis, and ϕ is the projection of the molecular z axis onto the laboratory x axis. Since these projections are induced by an external field, which competes with thermal randomizing effects, the Boltzmann thermal averages of these projections must be computed [Eqs. (34) and (35)][46].

$$\langle\cos^2\theta\rangle = \mu \cdot E/5kT \tag{34}$$

$$\langle(\cos\theta)(\sin^2\theta)(\cos\phi)\rangle = \mu \cdot E/15kT \tag{35}$$

μ is the dipole moment of the dopant molecule and E is the applied DC field. The $\langle(\cos\phi)\rangle$ is isotropic, since no polar alignment is induced orthogonal to the field direction.

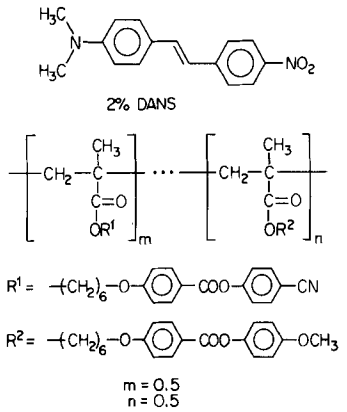

Fig. 14. Components of a molecularly doped liquid-crystalline polymer film oriented by an external field and which exhibited large SHG [46].

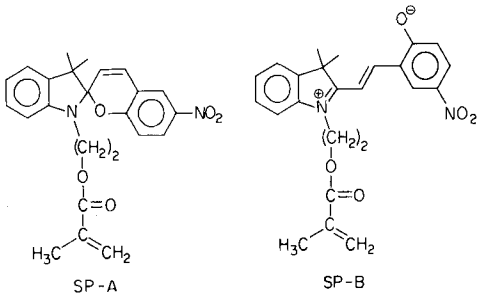
The principles outlined above were used to induce a second-order nonlinearity in *p,p'*-dimethylaminonitrostilbene (DANS) doped at 2 wt% into a liquid-crystalline polymer host (Fig. 14). The host polymer belongs to a class of polymers in which mesogenic chromophores are attached via a flexible $(CH_2)_n$-spacer to the rigid backbone[48]. It was shown that polymers of this general structure, which exhibit a nematic mesophase above T_g, could be aligned by an external field, eliminating the light-scattering nematic texture, and that the alignment was retained upon cooling below T_g. DANS, for which $\beta = 4.5 \times 10^{-28}$ esu[49], showed a pleochroic effect in the polymer host; the molecular z axis tended to align with the long axis of the mesogens, causing it to exhibit linear dichroism in its absorption band. Under these circumstances the electric-field-induced *polar* alignment, as opposed to the *axial* alignment associated with pleochroism, requires the thermal averages discussed above. If Ising model statistics are assumed to describe polar alignment in an axial environment, Equation (32) must be multiplied by a factor of 5. Equation (36) then holds.

$$\chi^{(2)}_{zzz}(\text{Ising}) = NF\beta_{zzz}\mu \cdot E/kT \tag{36}$$

$\chi^{(2)}_{zzz}$ was measured as 6×10^{-9} esu for an alignment field of 0.6 V/μm, while $\chi^{(2)}_{zzz}$(Ising) was calculated to be 3×10^{-9} esu. This is remarkable and perhaps coincidentally good agreement in view of the approximations made in the calculations and the experimental complications. Nevertheless, the experiments demonstrate that electric-field-induced alignments that can be retained in the film upon removal of the field can give rise to large second-order nonlinear coefficients.

3.2.6. Field-Induced Alignment of Quasicrystalline Dye Aggregates

A final example of a noncrystalline but highly ordered system where SHG can be induced by an external field is provided by "quasicrystals" obtained from the photolysis of indolinobenzospiropyrans in nonpolar solvents in the presence of an external field[50]. Upon irradiation, the spiro form (SP-A) undergoes a sequence of photochemical steps[51] leading to the formation of complexes A_nB, which in turn form polar aggregates. The insoluble aggregates



can be isolated between the electrodes used to apply the fields and show threadlike morphologies along the field lines. In SHG studies on threads formed in the presence and absence of external fields[39], the following observations were made:

1. Threads formed in the absence of a field exhibit no SHG.
2. SHG could be induced in these samples when DC external fields were applied.
3. Threads formed in the presence of electric fields exhibit strong SHG when measured with radiation polarized parallel to the threads, but the SHG was considerably weakened with light perpendicular to the threads. In each case these measurements were carried out with the field removed.
4. A larger SHG response was detected when a secondary field was applied parallel to the threads.
