The details of these observations led to the proposal of a model consisting of stacks (Fig. 15) of near-neighbor interacting dipoles described by the following parameters: θ is the angle made by the dipoles with respect to the stack axis, r is the distance between dipoles, $U(\uparrow\downarrow)$ and $U(\uparrow\uparrow)$ are the interaction energies between antiparallel and parallel neighbors, respectively, and $U(\uparrow)$ and $U(\downarrow)$ are the dipolar interaction energies in the direction of and against the field, respectively. The model predicts that for $\theta < 54°44'$ the parallel configuration will dominate. The spectral red shift of the aggregates is consistent with the parallel coupling of the induced dipoles[50]; if they are almost parallel

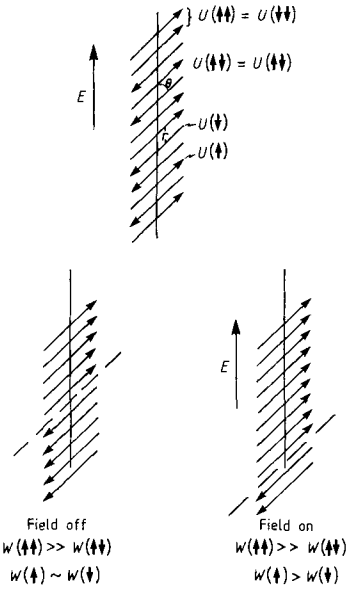

Fig. 15. Top: Parameters for a stack of molecular dipoles separated by r and making an angle θ with respect to the stack axis. Only the near-neighbor interaction energies $U(\uparrow\uparrow)=U(\downarrow\downarrow)$ and $U(\uparrow\downarrow)=U(\downarrow\uparrow)$ and dipolar energies against ($U(\downarrow)$) and in ($U(\uparrow)$) the direction of the applied field are considered. Bottom: For $\theta<54°44'$, long sequences of parallel dipoles are favored. A field increases the relative number of dipoles in the direction of the field (W denotes the appropriate probability distribution [39]).

to the permanent molecular dipoles, the red shift is a strong indicator of a parallel arrangement of molecular dipoles. The model uses the classical partition function to calculate the probability distributions $W(\uparrow\uparrow)$, $W(\downarrow\uparrow)$, $W(\uparrow)$, $W(\downarrow)$. For aggregates formed in the absence of a field and with $\theta<54°44'$, randomly oriented aggregates consisting of arrays of parallel dipoles with occasional changes in phase would be expected. This is consistent with the lack of SHG observed for samples formed in the absence of a field. When a field is subsequently applied, a signal with a quadratic field dependence due to movement of the phase boundary is expected and indeed observed. For aggregates formed in the presence of a field we would expect not only a much larger signal, owing to preferential orientation of the aggregates as they are formed, but also a quadratic field-dependent signal; these features are in fact observed. The overall agreement between experiment and theory is gratifying for such a complex system. Owing to the particulate nature and size of the aggregates, however, it was not possible to extract a value for $\chi^{(2)}$ for this system.

4. Outlook

Although considerable progress has been made, both in understanding the electronic origins of molecular nonlinearities in organic π systems, as well as in our ability to explain quantitatively the relationship of molecular arrangements in a crystal or polymer to the observed nonlinearities a posteriori, the design and fabrication of new systems with optimized nonlinear optical properties, linear optical properties, and adjunct properties remains a major challenge for chemical research. The major areas of solid-state chemical research that will affect this field are crystal design and growth, crystal thin-film technology, and polymer thin-film technology.

The design of crystalline materials that lend themselves to the growth of high-quality, large single crystals at a reasonable cost is a major challenge. Since the categories of application for such materials span a wide variety of requirements in terms of device design (frequency doublers, frequency mixers, parametric oscillators, etc.), available laser power, transparency, and cost, no attempt will be made to enumerate a specific set of requirements as a target for future research. One special case worth mentioning, however, is the use of urea crystals to extend the range of usability of dye lasers to 240 nm and double the output of the popular blue/green argon ion laser at 480 nm via SHG[52]. Due to its phase-matching characteristics, urea exhibits high SHG efficiency relative to the popular inorganic crystals; furthermore, it has a high nonlinear coefficient, and it is possible to grow large high-quality crystals that have high damage threshold and can be cleaved and polished. These characteristics have spawned commercial development efforts for nonlinear crystals of urea. In contrast, dimethylurea crystals[53], although they extend the phase-matching range even further into the UV and have other desirable optical properties, nevertheless have poor mechanical properties, which make them unsuitable for manufacturing.

In addition to the applicability of single-crystal technologies, a variety of opportunities exist for thin-film structures where planar processing techniques might permit deposition onto Si or other substrates. Large $\chi^{(2)}$ or $\chi^{(3)}$ values might permit the fabrication of the active components for optical circuitry, making use of the nonlinear refractive index of such materials. Three promising approaches have emerged for obtaining the required asymmetry for large $\chi^{(2)}$: 1) Molecularly doped polymers with electric field alignment, 2) topochemical polymerization of asymmetric diacetylene monomers[54], and 3) Langmuir-Blodgett multilayer techniques[54]. The first approach offers considerable flexibility in terms of design and selection of materials, but requires that permanent alignment be imparted by application of an external electric field. The second approach is still beset with problems regarding single-crystal growth and the restrictions of the highly conjugated polymerized diacetylene chain. Langmuir-Blodgett techniques may offer the ultimate in chemical design flexibility but require extensive resources and expertise.

Many of the electro-optic functions occurring through $\chi^{(2)}$ could also be achieved through the quadratic electro-optic effect if materials with sufficiently large $\chi^{(3)}$ could be developed without the stringent symmetry requirements of the linear electro-optic materials. Thin films containing the polydiacetylene chain formed by Langmuir-Blodgett techniques have one of the largest known values of $\chi^{(3)}$[55] ($\sim 10^{-11}$ esu), which may be useful for certain applications. An additional advantage of Langmuir-Blodgett films is that radiation-induced polymerization leads to a convenient method of patterning that might be used for device fabrication.

Although considerable progress has been made in this multidisciplinary field over the past several years, much creative chemistry still remains to be done if broad tech-

nological utility of organic/polymeric, nonlinear optical materials is to be brought to fruition.

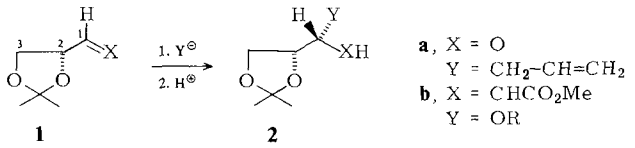
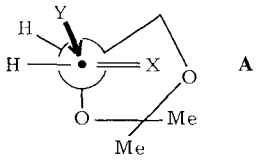
Optional Diastereo- and Enantioselective Synthesis of Vicinal *threo*- or *erythro*-Dihydroxy Derivatives**

By *Johann Mulzer**, *Michael Kappert*, *Gottfried Huttner*, and *Ibrahim Jibril*

Diastereo- and enantioselective synthesis of compounds having the 1,2-di-*O*-structural element (such as **2**) are gaining increasingly in importance[1]. Our general method for the preparation of compounds of this structure type exploits the finding that the isopropylidenediol moiety in **1** induces *ul*-selective nucleophilic attacks at the neighboring prochiral C-1 via transition state **A**[2]. Depending on the sequence in which the residues X and Y are introduced, adduct **2** is obtained in either *threo*- or *erythro*-configuration[2]. Since **1** is available in either (*R*)- or (*S*)-configuration[3], all four stereoisomers of **2** can be prepared.

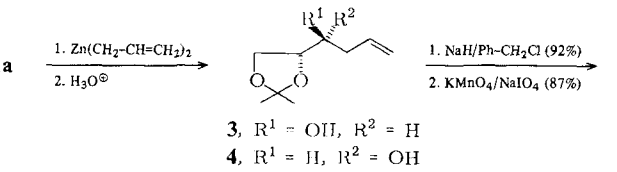


1 **2**

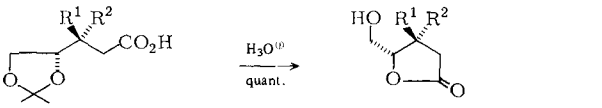


A

Diallylzinc reacts *erythro*-selectively with the aldehyde **1a** to afford **3**, which together with the minor isomer **4** (**3** : **4** = 9 : 1) is converted via the 3-benzyloxycarboxylic acids **5/6** into the γ-lactones **7c/8c**. The isomers are separated by column chromatography (SiO_2, pentane/ether 4 : 1) either via the methyl ester of **5/6** or at the stage of the lactones **7c/8c**. The configuration of the adducts **3/4** and, hence, that of all the subsequent products, has previously been determined unequivocally by correlation with known compounds[4].



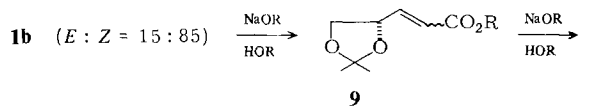
3, R^1 = OH, R^2 = H
4, R^1 = H, R^2 = OH



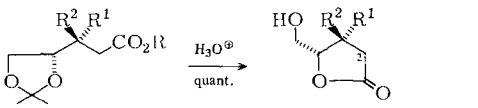
5, R^1 = OCH_2Ph, R^2 = H
6, R^1 = H, R^2 = OCH_2Ph

7c, R^1 = OCH_2Ph, R^2 = H
8c, R^1 = H, R^2 = OCH_2Ph

The second route makes avail of the *threo*-selective addition of sodium alkoxides to the acrylic esters **1b** (Table 1), readily accessible from **1a**[5], which leads to the Michael adducts **10/11**. Separation of **10/11** by column chromatography and "recyclization" affords **7** and **8**, respectively;



9



10, R^1 = OR, R^2 = H
11, R^1 = H, R^2 = OR

8, R^1 = OR, R^2 = H
7, R^1 = H, R^2 = OR

7-11: **a**, R = Me, **b**, R = Et; **c**, R = CH_2Ph

Table 1. Diastereomers **10/11** (**8/7**) formed in the addition of 1 mol equiv. NaOR to **9** (3 M in HOR). Total yields of **10** and **11** > 85%.

No.	R	*T* [°C]	*t* [min]	Products	Ratio [a] **10** : **11**
1	Me	25	6	**10a/11a**	60 : 40
2	Me	0	6	**10a/11a**	75 : 25
3	Me	−20	6	**10a/11a**	85 : 15
4	Me	−50	6	**10a/11a**	91 : 9
5	Me	−78	60	**10a/11a**	95 : 5
6	Et	0	6	**10b/11b**	63 : 37
7	Et	−50	60	**10b/11b**	86 : 14
8	CH_2Ph	−10	120	**10c/11c**	76 : 24
9	CH_2Ph	−50	[b]	[b]	[b]

[a] Determined by ^{1}H-NMR for **10a/11a** (OMe singlet at δ = 3.45 (**10a**) and 3.42 (**11a**), respectively, in $CDCl_3$, TMS) and by ^{13}C-NMR for **10b/11b** and **10c/11c** (C-2 signals (80 MHz, $CDCl_3$, TMS)) at $\delta \approx 36.10$ (**10b**), 37.52 (**11b**), 35.98 (**10c**), 37.31 (**11c**). [b] Solution solidifies at ca. −20°C; no reaction.

derivatives **7c** and **8c** are identical with the compounds obtained by the first route[6]. In addition, a crystal structure analysis is available for **8a**[7].

Alkoxide addition to the double bond[8,9] of **1b** in the synthesis of **7b** and **7c** is preceded by rapid transesterification to **9b** and **9c**, respectively, which is >95% complete before appreciable amounts of **10/11** are formed. The product ratio **10/11** depends in the first instance on the reaction temperature; appreciable selectivities occur below −50°C. Complete conversion can only be achieved if the alkoxide is added in equimolar amounts. The reaction rate decreases along the sequence $^{\ominus}$OMe, $^{\ominus}$OEt, $^{\ominus}OCH_2Ph$: Only $^{\ominus}$OMe still adds completely to **1b** at −78°C; for $^{\ominus}$OEt this occurs only down to −50°C (Table 1, No. 7), and $^{\ominus}OCH_2Ph$ does not react with **1b** below −20°C. At the same temperature (Nos. 2, 6, 8), the differences in selectivity are small. The reaction proceeds under conditions of kinetic control; at room temperature, **10a/11a** undergo only transesterification with sodium benzylate, and no exchange of the 3-OMe occurs. The same is true for **10c/11c** and sodium methoxide.

The central diol unit in **2a** and **2b** is ideally suited for transformation into natural-product derivatives since the hydroxy groups can be differentiated easily. The terminal functional groups CH_2–O, CH_2=CH_2, and CO_2Me may be used for chain extension on both sides. The OMe-protecting group in **10a** can be removed at a later stage of the reaction[10].

Carbanion-Induced Skeletal Rearrangements: From the Dibenzo[*a,e*]cyclooctene to the Indeno[2,1-*a*]indene Framework**

By *Dieter Hellwinkel**, *Hans-Joachim Hasselbach*, and *Frank Lämmerzahl*

In our studies of peripherally bridged tetraphenylene derivatives[1], we have explored methods of introducing substituents suitable for further annellations[3] by nucleophilic substitution of the bromine atoms of 5,6,11,12-tetrabromodibenzo[*a,e*]cyclooctene **1**[2].

If **1** is allowed to react with excess organolithium compounds in tetrahydrofuran between −78°C and room temperature, not the tetraorganobenzo[*a,e*]cyclooctenes **2**, products of a simple addition-elimination mechanism[4,5], but only isomers with the indeno[2,1-*a*]indene framework are obtained. In this way, methyl- and *n*-butyllithium afford up to 70% of the 5,5,10,10-tetraalkyl-5,10-dihydroindeno[2,1-*a*]indenes **3**, **4**, whereas with *tert*-butyllithium mixtures of the tri- and di-*tert*-butyl derivatives **5**, **6** and, with a large excess of *t*BuLi, moderate yields of the tri-*tert*-butyl derivative **5** are obtained. In contrast, with phenyllithium the red-brown 5,10-diphenylindeno[2,1-*a*]indene **10** is obtained, which is identical with a reference compound synthesized using an independent procedure[6] [m.p. = 247–248°C, ^{1}H-NMR ($CDCl_3$): δ=6.84 (td, 2H), 6.90 (td, 2H), 7.03 (dm, 2H), 7.24 (dm, 2H), 7.45 (tt, 2H), 7.52 (tm, 4H), 7.67 (dm, 4H)].

Treatment of the phenyllithium reaction mixtures, which like the others are deeply colored, with ethanolic hydrogen chloride, iodomethane, or iodobenzene at low temperatures affords the derivatives **7**–**9** of 5,10-dihydroindeno[2,1-*a*]indene.

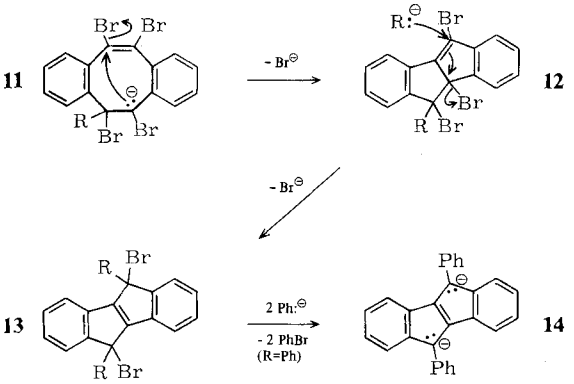
[a] ^{1}H-NMR ($CDCl_3$, δ-values): **3**: 1.53 (s, 12H), 7.22 (td, 2H), 7.29 (td, 2H), 7.40 (d, 2H), 7.42 (d, 2H); **4**: 0.65 (t, 12H), 0.71—1.3 (m, 16H), 2.00 (t, 8H), 7.1—7.4 (m, 8H); **5**: 1.03, 1.08 (each s, together 18H), 1.28 (s, 9H), 3.59 (s, 1H), 7.00—7.90 (m, 8H); **6**: 1.18 (s, 18H), 3.46 (s, 2H), 7.06 (td, 2H), 7.22 (td, 2H), 7.42 (d, 2H), 7.48 (d, 2H); **7**: 4.97 (s, 2H), 7.05—7.20 (m, 6H), 7.20—7.35 (m, 12H); **8** [b]: 1.94, 1.99 (each s, together 6H), 7.0—7.5 (m, 18H). [b] As a *cis/trans*-mixture which melts at 240°C.

A preliminary reaction scheme which accounts for all the products isolated involves initial addition of an $R^{\ominus}$ ion to **1** to yield **11**, which subsequently undergoes transannular addition-elimination to give **12**[7]. Compound **12** could then react with additional $R^{\ominus}$ to afford intermediate **13**, which can react in various ways: with alkyllithium, further substitution occurs to furnish the tetra-, tri-, and dialkyl derivatives **3**—**6**. Phenyllithium can either attack a bromine atom to form, via elimination, **10**, or can undergo a double halogen-metal exchange affording the dianion **14**[8], which can be trapped with electrophiles to give **7**-**9**.



In only one instance have we observed nucleophilic substitution at **1** with retention of the skeleton: reaction of **1** with copper(I) cyanide in *N*-methylpyrrolidone gives rise to 30% 5,6,11,12-dibenzo[*a*,*e*]cyclooctenetetracarbonitrile **2** (R = CN) [m.p. = 350°C, ν_{CN} = 2210 cm^{-1}], whose symmetrical ^{1}H-NMR signal pattern ($\delta_{AA'}$ = 7.59, $\delta_{BB'}$ = 7.48) substantiates that the framework has not undergone rearrangement.

In the meantime, we have obtained evidence which indicates that reactions of **6** with less polar Grignard compounds and organolithium compounds in less polar solvents such as diethyl ether also proceed with retention of the skeleton.

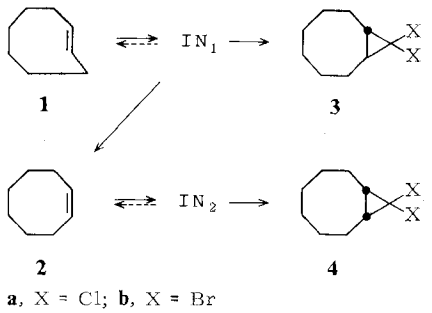
Stereochemical Evidence Supporting the Intermediate Mechanism of Dihalocarbene Addition**

By *Eckehard V. Dehmlow** and *Roland Kramer*

Singlet halocarbenes generally react with alkenes via *cis*-addition, which is often envisaged as a concerted (one-step) process. More recent kinetic data on the additions of CCl_2, CBr_2, and C_6H_5Cl have nevertheless been interpreted in terms of reversible, intermediate formation of a charge-transfer complex[1-3]. These results corroborate the two-step mechanism proposed by *Skell* et al. for CX_2 as early as 1956[4]. Products which demand a mechanism involving an intermediate arise, to the best of our knowledge, in halocarbene reactions[5] in only three cases[6-8]. In particular, for the reaction of *trans*-cyclooctene **1** with CBr_2 both the stereospecific formation of **3b**[9] and the formation of a large amount of **3b** in addition to a little **4b**[8] were reported in 1970. According to [8], partial isomerization **1** → **2** occurs under the reaction conditions.

With the aid of 300 MHz ^{1}H-NMR spectroscopy it is easy today to test the purity of *trans*- and *cis*-cyclooctene **1** and **2**[10], respectively, as well as of adducts **3a**, **b** and **4a**, **b**[11]. Mixtures of **3** and **4** can also be analyzed using capillary gas chromatography[12]. We found that after 10 min (±)-**1** has reacted completely and stereospecifically with CCl_2 generated by phase transfer catalysis (PTC) (conc. NaOH/$HCCl_3$/methyltrioctylammonium chloride (Aliquat 336)) to afford (±)-**3a**. In the analogous reaction with $HCBr_3$/EtOH (trace) a mixture of **3b**/**4b** (92 : 8) is formed after 10 min (30–40% conversion); furthermore, a *cis*/*trans*-isomerism of the alkene occurred (**1** : **2** ≈ 8 : 9). After 30 min (80–90% conversion), **3b** and **4b** are present in the ratio 77 : 23, and the unreacted alkene consists to ca. 90% of **2**. Upon being stirred with tetrabutylammonium bromide/NaOH or with Aliquat 336/NaOH in CD_2Cl_2, *trans*-cyclooctene **1** does not rearrange into **2**. Under these reaction conditions, **3b** is also stable, and the course of the reaction is not affected by atmospheric oxygen.



a, X = Cl; **b**, X = Br

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

The results found are consistent only with the occurrence of intermediates ($IN_{1,2}$) in the course of the reaction, as sketched in Scheme 1. Upon retro-cleavage, the high-energy IN_1 is converted essentially into the less strained **2**. Moreover, under PTC conditions the reversibility of IN-formation may be particularly propitious since the carbene generation is also a reversible process[13]:

$$\text{Preceding PTC steps} \rightleftharpoons NR_4^{\oplus}CBr_3^{\ominus} \rightleftharpoons NR_4^{\oplus}Br^{\ominus} + CBr_2$$

Apparently the IN_1 formed from **1** and the less reactive CCl_2 is lower in energy and, hence, in this instance, further reaction to **3a** wins out over retro-reaction to give **2**. Presumably IN_1 is not a diradical, since the very sensitive 1,1-dicyclopropylethene does not give rearranged products with CBr_2[14]; in addition, one is certain today that triplet CBr_2[15] does not occur in reactions of this type[16]. IN_1 and IN_2 must be charge-transfer complexes[17]. This would account also for the occasionally observed 1,4-addition of CX_2 to dienes, which according to calculations[18] cannot occur directly.

[17] Unfortunately, no alternative method of generating CBr_2 can be used here (cf. [15, 16]). An experiment in the presence of excess cumene (radical scavenger and competitor for CBr_2) resulted in the following: After 75 min, the product of insertion, 1,1-dibromo-2-methyl-2-phenylpropane, was formed in high yield. **1** and **2** were consumed, and **3b/4b** were present in the ratio 34:66 (!). This result also provides evidence against involvement of a radical process, and the participation of IN_1/IN_2 is further corroborated by the fact that the re-formed CBr_2 is now trapped by both NR_4Br and cumene.

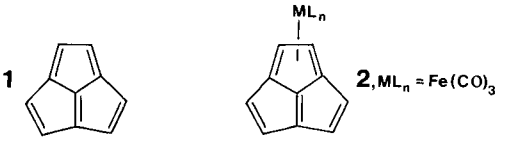
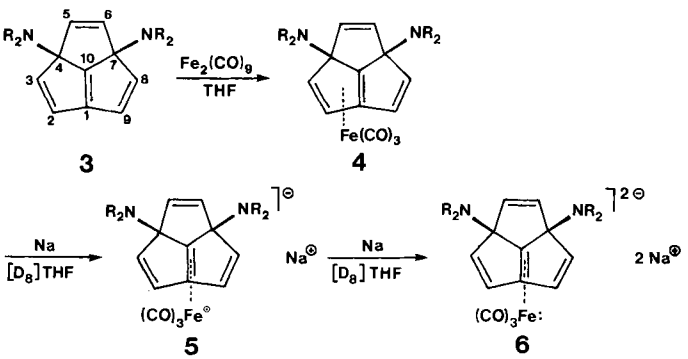
Novel Tricarbonyl(η^4-dihydroacepentalene)iron Complexes and Tricarbonyl(η^2-dihydroacepentalene)ferrates(−2)**

By *Holger Butenschön* and *Armin de Meijere**

Otherwise extremely unstable and/or reactive cyclic polyenes such as unsubstituted cyclobutadiene and pentalene have been isolated as transition-metal complexes[1,2]. No reports have appeared yet on the application of this principle to generate acepentalene **1** (cyclopenta[*cd*]pentalene). Whereas **1** has long been predicted to have a triplet ground state[3], complexes of type **2** should be closed-shell systems[4].



Since the 4,7-bis(dialkylamino)tricyclo[5.2.1.0^{4,10}]deca-1(10),2,5,8-tetraenes (2a,6a-bis(dialkylamino)-2a,6a-dihydroacepentalenes) **3** are readily accessible from 1,4,7-trichloro- and 1,4,7-tribromotriquinacenes and secondary amines[5], we tested whether **3** could be complexed and subsequently defunctionalized. Tricarbonyl(η^4-diene)iron complexes **4** were indeed obtained from **3** and $Fe_2(CO)_9$ in tetrahydrofuran (THF) and were isolated as yellow or orange oils (yields 24–60%) by column chromatography. The compounds were fully characterized by IR, mass, ^{1}H-NMR and ^{13}C-NMR spectroscopy (see Table 1). Although there is no conclusive evidence, the $Fe(CO)_3$ group is most probably oriented *trans* to the two dialkylamino groups. The complexes **4** are new representatives of a class with cross-conjugated triene units and their ^{1}H-NMR data are in accord with those of the few known examples[6]. The conceivable degenerate metallotropic rearrangement[4] of **4** was not observed in **4b** at temperatures up to +150 °C, above which decomposition occurred.



In order to enable the dialkylamino groups to leave, complexes **4a** and **4b** were reduced with sodium and monitored by NMR spectroscopy[7]. In each case, the yellow color changed within 3 h to a deep green, and no NMR signals were detectable at this stage. The apparently para-

magnetic species thus generated from **4b** did, however, show a broad ESR signal at $g = 2.01598$, which indicates substantial unpaired electron spin density at the iron atom[8]. The green radical is persistent for several weeks if the solution is removed from the sodium. Further contact with the metal causes the solution to become yellow again within 15 h; no further change was observed after 3 d.

Table 1. Dihydroacepentalene complexes: reaction conditions, yields, characteristic data (δ_{TMS}).

5b: green, persistent.—ESR (9.236 GHz, [D$_8$]THF): $g = 2.01598$ (bs).

6a: yellow.—^{1}H-NMR (270 MHz, [D$_8$]THF): $\delta = 0.99$ (t, 12H, 2′-H, $^3J_{1',2'} = 7.0$ Hz), 2.73 (mc, 4H, 1′-H, $^2J_{1'a,1'b} = -14.2$ Hz), 3.38 (mc, 4H, 1′-H), 4.70 (d, 3(8)-H, $^3J_{3(8),2(9)} = 4.9$ Hz), 5.97 (s, 5(6)-H), 6.11 (d, 2(9)-H).—^{13}C-NMR (67.92 MHz, [D$_8$]THF): $\delta = 14.2$ (q, C-2′, $^1J_{C,H} = 124.1$ Hz), 43.7 (t, C-1′, $^1J_{C,H} = 133.7$ Hz), 68.7 (bs, C-10), 78.7 (bs, C-1), 86.6 (bs, C-4(7)), 122.3 (dd, C-5, $^1J_{C,H} = 158.8$ Hz, $^2J_{C,H} = 4.4$ Hz), 136.8 (d, C-2(9), $^1J_{C,H} = 160.2$ Hz), 142.8 (C-3(8), $^1J_{C,H} = 160.1$ Hz), 237.6 (s, CO).

6b: yellow.—^{1}H-NMR (80 MHz, [D$_8$]THF): $\delta = 1.20-1.60$ (m, 2′-H, 3′-H), 2.10—3.20 (m, 1′-H), 4.72 (d, 3(8)-H, $^3J_{2(9),3(8)} = 4.8$ Hz), 5.90 (s, 5(6)-H), 6.16 (d, 2(9)-H).

The ^{1}H-NMR spectra of the new complexes (see Table 1) are simpler than those of the precursors **4a** and **4b**. Both this and the number of ^{13}C-NMR signals indicate the presence of a plane of symmetry. The number, the chemical shifts, and the multiplicity of the ^{13}C signals are consistent only if the new complexes have structures of the 1,10-η^2-type **6**. In particular, the resonances of the quarternary olefinic carbon atoms C-1/C-10 at 78.7/68.7 and the low-field value of the carbonyl group at $\delta = 237.8$[9] corroborate the structure as tricarbonyl(olefin)ferrate(−2) **6**. All attempts to isolate these ionic complexes, which are extremely oxygen sensitive, have failed so far.

6a and **6b** are the first spectroscopically characterized representatives of this class of compounds. The few reports on the reduction of tricarbonyl(diene)iron complexes only describe indirect evidence for such ferrate complexes from cyclic voltammetry and polarography[10]. The cyclic voltamogram of **4a** shows two irreversible reduction waves at −2.19 and −2.63 V (vs. SCE). This proves the intermediacy of a radical anion as detected in the sodium reductions.

It appears noteworthy that upon reduction of **4** only the 1,10-η^2-complexes **6** are formed and not the less symmetric 2,3-η^2-isomers. This may be due to a favorable stabilization of the symmetric intermediate **5**. The well-known reduction of $Fe(CO)_5$ with sodium to afford disodium tetracarbonylferrate(−2)[11] in the presence of benzophenone as an electron transfer catalyst[12] thus finds its counterpart in the formation of **6** from **4**, where the tetraenic ligand may act as the electron-transfer catalyst.

Homocyclobutadienes and Cyclopropenes by Reaction of a Stable Cyclobutadiene with Diazo Compounds**

By *Uwe-Josef Vogelbacher, Philipp Eisenbarth*, and *Manfred Regitz**

Bicyclo[2.1.0]pentenes ("homocyclobutadienes") are prepared by irradiation of 1,3-cyclopentadienes; they are thermally unstable and undergo electrocyclic retro-reactions even at room temperature[1]. Herein, we report a novel entry to this class of compounds: Reaction of the cyclobutadiene **1** with diazo compounds leads, inter alia, to formation of the dihydropyrazoles **2**, whose photolysis furnishes thermally stable homocyclobutadienes. The scope of this synthetic strategy depends upon the pattern of substitution in the diazo compounds and is restricted, by an as yet unknown diazoalkane reaction, to cyclopropenylazines.

The reaction of **1**[2] with diazomethane (fourfold excess) is extraordinarily rapid, but in no way specific. [3 + 2]-Cycloaddition at the electron-deficient and sterically best accessible double bond dominates, giving the stable dihydropyrazoles **2** (24%) and **3** (30%); cycloaddition at the di-*tert*-butyl-substituted double bond to give **4** also takes place,

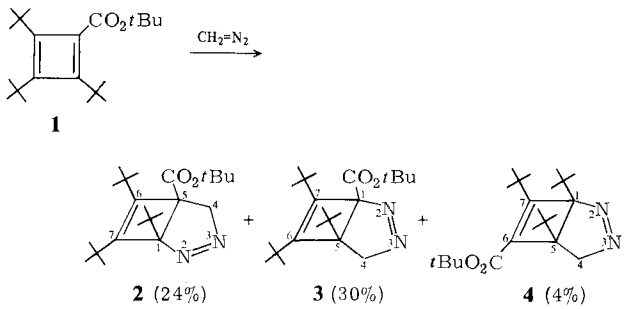
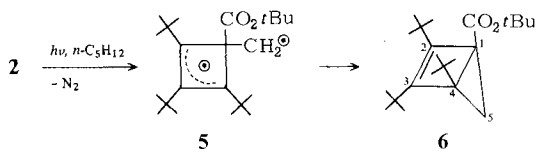
[**] Syntheses with Cyclobutadienes, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 5: M. Regitz, P. Eisenbarth, *Chem. Ber. 117* (1984) 1991.

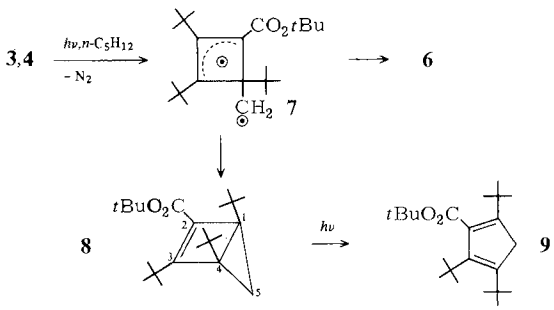
but only to the extent of 4% (separation of products by column chromatography on silica gel with hexane/ether 4:1).



Photolysis of **2** in pentane (Philips HPK 125 W, Pyrex filter) leads quantitatively—presumably via the diradical **5**—to formation of the homocyclobutadiene **6**, which does not isomerize to the corresponding cyclopentadiene, even on distillation (b.p. 110°C/3 × 10^{-6} mbar[3]).



The irradiation of **3** is much more complex, since the diradical **7** cyclizes to the isomeric homocyclobutadienes **6** and **8** (65:35, ^{1}H-NMR). **6** is photostable, whereas the α,β-unsaturated ester **8** slowly rearranges photochemically in an electrocyclic reaction to the cyclopentadiene **9** [^{1}H-NMR, 90 MHz, $CDCl_3$: $\delta = 1.20$, 1.30, 1.36, 1.53 (4 s, each 9 H, *t*Bu, 1,3,4 and ester), 3.05 (s, 2 H, CH_2)]. The same product pattern results on photolysis of **4**, a further proof of its structure and composition.



1 reacts stereospecifically with diazoethane to give exclusively the 4-methyl derivative of **2** (yield 65%, b.p. 125°C/3 × 10^{-6} mbar[3]); the homocyclobutadiene prepared from this compound is also thermally stable (95%, b.p. 125°C/3 × 10^{-6} mbar[3]). Whether the methyl group of the two compounds is *endo*- or *exo*-oriented can not be deduced from the spectroscopic data. The high activation barrier of the homocyclobutadiene/cyclopentadiene isomerization is obviously due to steric reasons.

1 reacts with the doubly acylated or arylated diazomethanes **10** at 20°C in pentane in a novel reaction involving ring contraction[6] to give the yellow (**12a—e, f**) or red cyclopropenylazines (**12d**). We presume that the sterically less favorable cycloaddition is circumvented by attack of

the terminal, electrophilic nitrogen atom of **10** at C-2 of the cyclobutadiene[4]; initially the homocyclopropenylium betaines **11**[5] are formed in which the charge is optimally stabilized.

The constitution of the azines is supported not only by their colors and analytical data but, in particular, by the ^{13}C-NMR spectra (50.28 MHz, $CDCl_3$); the spectra show, inter alia, separated signals for two azomethine C atoms ($\delta = 141.10-177.04$); the olefinic three-membered ring atoms ($\delta = 117.89-119.30$) as well as the two C-type atoms of the *tert*-butyl groups attached to this ring, and the sp^3 cyclopropene C-atom ($\delta = 37.64-42.60$) each give only one signal. The signals of the cyclopropene C atoms are virtually identical with those observed for *tert*-butyl(1,2,3-tri-*tert*-butyl-2-cyclopropenyl)diazoacetate[2].

Since the diazomethane substituents are identical, the azines occur only as *E*/*Z* isomers **12** and **12'**, as also follows from the NMR spectra in the case of **12e** and **12f** (see Table 1; the isomeric ratios are 60:40 and 50:50, respectively). That the same phenomenon is not observed in the case of **12a**—**12d** can only be ascribed to a rapid inversion at N-1, enforced by the other half of the azomethine moiety, which is a stronger electron-acceptor[7].

Facile Synthesis of Heteroalkenes $CF_3E{=}CF_2$ (E = P, As)**

By *Joseph Grobe** and *Duc Le Van*

The phosphaalkene $CF_3P{=}CF_2$ **2a** was previously prepared by base-induced cleavage of HF from $(CF_3)_2PH$[1] or by base-catalyzed reaction of dimethylzinc with $(CF_3)_2PH$[2], i.e. by methods which afford **2a** in impure form or in low yield. On re-investigating the decomposition reaction of the stannanes **1**[3], we have now discovered a simple method for the quantitative synthesis of **2**.

[**] Reactive E=C–(p-p)π Systems, Part 1. This work was supported by the Landesamt für Forschung des Landes Nordrhein-Westfalen.

$$Me_3SnE(CF_3)_2 \xrightarrow[-Me_3SnF]{300-340\,^\circ C} CR_3E{=}CF_2$$
1 **2**

a, E = P; **b**, E = As

The heteroalkenes **2** are formed on thermolysis of **1** at 10^{-3} torr in a pyrolysis tube and are quenched from the gas phase at −196°C. Pyrolysis experiments at the inlet of a mass spectrometer showed that an optimal temperature range for this process is 300—340°C. Unreacted **1** is repeatedly fed through the hot zone until the conversion into **2** is complete[4]. The phosphaalkene **2a** can be recondensed in a high vacuum at 10^{-3} torr without any detectable loss, whereas the new arsaalkene **2b** rapidly dimerizes or polymerizes. Despite its high reactivity, **2b** could be unequivocally characterized by its ^{19}F-NMR spectrum at −110°C (Fig. 1) and finally identified by its dimerization products.

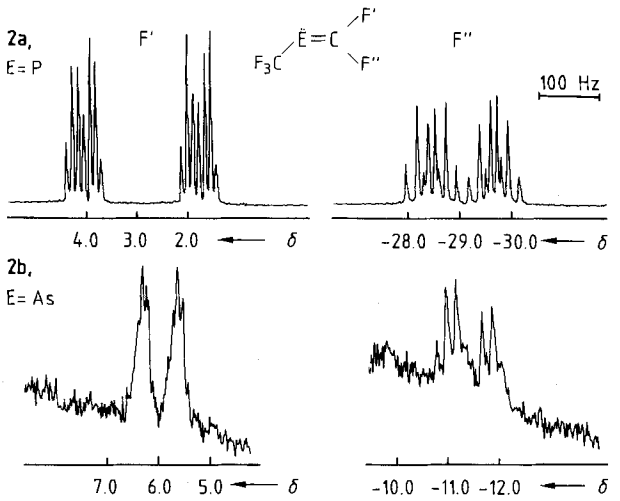

Fig. 1. Sections from the ^{19}F-NMR spectra of **2a** (top) and **2b** (bottom); in each case the region for the CF_2-group is shown.

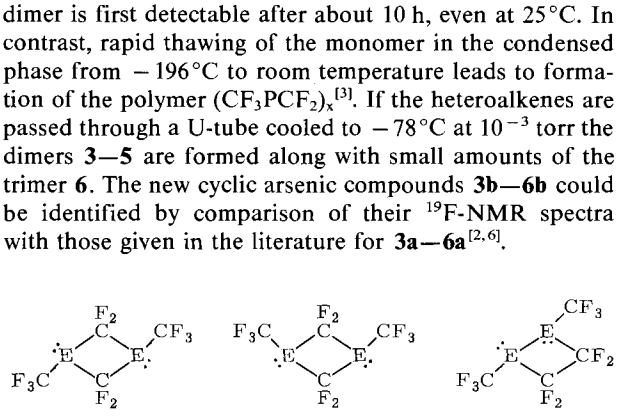
Apart from the molecular peaks [**2a**: *m/z* 150 ($M^\oplus$); **2b**: *m/z* 194 ($M^\oplus$)] the mass spectra of the two compounds show similar degradation patterns. $CF_3As{=}CF_2$ is the smallest As=C–(p-p)π-system so far isolated[5].

The kinetic stability observed for **2a** in ca. 10% organic solutions (e.g. toluene, pentane) is surprising: thus, the dimer is first detectable after about 10 h, even at 25°C. In contrast, rapid thawing of the monomer in the condensed phase from −196°C to room temperature leads to formation of the polymer $(CF_3PCF_2)_x$[3]. If the heteroalkenes are passed through a U-tube cooled to −78°C at 10^{-3} torr the dimers **3**—**5** are formed along with small amounts of the trimer **6**. The new cyclic arsenic compounds **3b**—**6b** could be identified by comparison of their ^{19}F-NMR spectra with those given in the literature for **3a**—**6a**[2,6].



3 **4** **5**

a, E = P; **b**, E = As

The four-membered heterocycles **3** with *trans*-oriented CF_3 groups are the major products of the [2+2]-cycloaddition, whereas only small amounts of the *cis*-compounds **4** and head-to-head isomers **5** are formed; the product patterns for phosphorus and arsenic compounds under the same reaction conditions are different.

3a : **4a** : **5a** : **6a** = 85 : 9 : 2 : 4
3b : **4b** : **5b** : **6b** = 64 : 21 : 3 : 12

This could be due to the greater activity of **2b**, which also facilitates reactions between monomers less favorably oriented with respect to each other. In solution, the *cis*-isomers **4a** and **4b** are transformed only very slowly into the more stable *trans*-isomers **3a** and **3b**, respectively.

The ^{19}F-NMR spectrum of **3b** is especially simple; it shows two signal groups in the intensity ratio 3 : 2 for the two CF_3 moieties (quintet) and the CF_2 ring members (septet), thus indicating a planar ring structure (see Table 1).

Table 1. ^{19}F-NMR data of **2a** and **2b**—**6b** [a]. For F′ and F″, see Figure 1.

2a: $\delta = -44.4$ (ddd) CF_3, 2.9 (ddq) F′, −29.1 (ddq) F; $^2J(PF) = 57.4$, $^2J(PF') = 192.0$, $^2J(PF'') = 103.0$, $^2J(F'F'') = 29.2$, $^4J(FF') = 10.0$, $^4J(FF'') = 18.0$

2b: $\delta = -41.2$ (dd) CF_3, 6.0 (dq) F′, −11.4 (dq) F″; $^2J(F'F'') = 60.0$, $^4J(FF') = 8.5$, $^4J(FF'') = 17.0$

3b: $\delta = -44.3$ (quint) CF_3, −90.4 (sept) CF_2; $^4J(FF) = 7.5$

4b: $\delta = -43.3$ (tt) CF_3, CF_2: AB system, $\delta_A = -77.8$, $\delta_B = -96.2$; $^2J(F(AB)) = 260$, $^4J(FF) = 10.5$, 4.5

5b: $\delta = -39.6$ (quint, br.) CF_3, −92.9 (br.) CF_2; $^4J(FF) = 7.0$

6b: $\delta = -42.1$ (quint), −41.1 (m, br.) CF_3; −72.4 (m, br.), −74.1 (m, br.), −80.7 (m, br.) CF_2; $^4J(FF) = 7.0$

[a] The data for **3a**—**6a** agree with those quoted in the literature [2, 6]. ^{19}F-NMR data (84.66 MHz) **2a**: [D_8]toluene, −60°C; **2b**: [D_6]dimethyl ether, −110°C; **3b**—**6b**: [D_8]toluene, 28°C; external standard: CCl_3F: *J* [Hz]. Data for **2a** in [1] not complete.

The elimination of Me_3SnF could also be exploited for the preparation of other heteroalkenes. Thus, the novel compound $Me_3SnP{=}CF_2$ is formed on thermolysis of $(Me_3Sn)_2PCF_3$, and the known, unstable thia- and selenaalkenes $E'{=}CF_2$ (E′ = S, Se)[7] can be obtained quantitatively from $Me_3SnE'CF_3$.

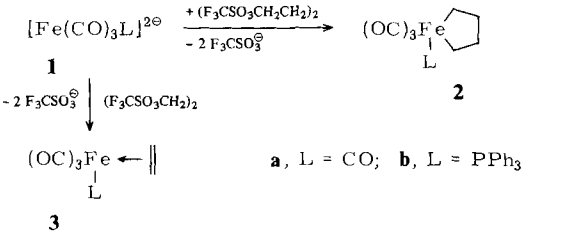
Facile Synthesis of Highly Reactive Ferracycloalkanes**

By *Ekkehard Lindner**, *Eckard Schauss*, *Wolfgang Hiller*, and *Riad Fawzi*

Dedicated to Professor Walter Rüdorff on the occasion of his 75th birthday

Metallacyclopentanes occur as reactive intermediates in numerous metal-catalyzed cycloadditions and cycloreversions of alkenes. For model studies of such systems, several five-membered metallacycles of some transition metals have been prepared or implicated as intermediates[1]. Although *Stone* et al.[2] and *Wilkinson* et al.[3] described perfluorinated ferracyclopentane, $(OC)_4FeC_4F_8$, as early as 1961, only now have we succeeded, for the first time, in synthesizing the parent compound, tetracarbonylferracyclopentane **2a**. The stereochemistry of the ring closure reaction of $(\eta^2\text{-}C_2H_4)_2Fe(CO)_3$[4] to **2a** has been analyzed



theoretically by *Hoffmann* et al[5]. The nucleophilic elimination-cycloaddition of tetramethylenebis(trifluoromethanesulfonate)[6] with $[Fe(CO)_4]^{2\ominus}$ now facilitates a straightforward route to the extremely volatile ferracyclopentane **2a**, which precipitates at −78°C from *n*-butane as colorless crystals that are heat- and air-sensitive and readily soluble in all organic solvents.

X-ray structure analysis[7] indicates that the more stable **2b**[8], which is obtained analogously, has a twist conformation (Fig. 1). Because of conformational chirality, C6 and C7 are disordered[9]. This was taken into consideration in calculating the structure by introducing split positions ob-

[**] Preparation and Properties of, and Reactions with, Metal-Containing Heterocycles, Part 43. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 42: E. Lindner, C.-P. Krieg, W. Hiller, R. Fawzi, *Chem. Ber.*, in press.

tained by a difference Fourier synthesis. The C6C7 and C6′C7′ distances correspond to the length of a single bond. **2a**, **b** were further characterized by elemental analysis as well as by mass, IR, and $^{13}C\{^1H\}$-NMR spectra (Table 1). In **2a**, the C atoms in the α- and β-positions, respectively, are magnetically equivalent. In contrast, because of the PPh_3 ligand, in **2b** four signals occur which are split into doublets for C5, C7, and C8. The larger coupling constant is ascribed to the *trans*-C8-Fe-P group. The assignment of the signals is corroborated by studies of **2a**, **b** in which the β-positions of the ferracyclopentanes were labeled by deuterium (Table 1).

[a] In *n*-hexane. [b] In $CDCl_3$, 20.115 MHz, δ-value rel. TMS. [c] $^2J(CP)=10.2$ Hz. [d] $^2J(CP)=5.1$ Hz. [e] $^3J(CP)=8.9$ Hz. [f] $^2J(CP)=10.0$ Hz. [g] $^2J(CP)=14.0$ Hz. [h] FD-MS (8 kV).

In the presence of CO, **2a** is remarkably stable, and the expected formation of cyclopentanone is observed only at 20°C[10]. In the absence of CO, **2a** decomposes already at −35°C to afford $Fe_3(CO)_{12}$ as well as *cis*- and *trans*-butene in the molar ratio 1:2.

The ethene complexes **3a**[11] and **3b**[5] can be obtained analogously and have been characterized by mass, IR, and $^{13}C\{^1H\}$-NMR spectroscopy (Table 1). **3a**[11] has previously been prepared from $Fe_2(CO)_9$ and C_2H_4, a method associated with tedious, laborious separation from $Fe(CO)_5$. X-ray structure analysis of **3b**[7] confirms the predicted equatorial arrangement[12] of ethene (Fig. 2).

[7] Triclinic crystals of **2b** (space group $P\bar{1}$) from *n*-butane. Refinement in the non-centrosymmetric space group P1 did not lead to an improvement of the structure model and confirmed the assumption of a disorder of atoms C(6) and C(7). Lattice constants at 183 K ($Mo_{K\alpha}$ radiation): $a=969.4(4)$, $b=976.4(6)$, $c=1348.9(5)$ pm, $\alpha=103.75(5)$, $\beta=108.77(3)$, $\gamma=70.16(3)°$, $Z=2$, $\rho_{calc.}=1.352$ g/cm³. Structure solved with MULTAN, $R=0.039$, 3833 reflections with $I\geq 3\sigma(I)$. Monoclinic crystals of **3b** (C2/c) from *n*-pentane. Lattice constants at 193 K ($Mo_{K\alpha}$ radiation): $a=2350.4(3)$, $b=1425.4(3)$, $c=1917.1(5)$ pm, $\beta=140.99(4)°$, $Z=8$, $\rho_{calc.}=1.414$ g/cm³. Structure solved with MULTAN, $R=0.039$, 1639 reflections with $I\geq 3\sigma(I)$. Further details on the crystal structure investigations can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50942, the names of the authors, and the journal citation.
[8] Procedure: A solution of 10 mmol $(F_3CSO_3CH_2CH_2)_2$ or $(F_3CSO_3CH_2)_2$ in 150 mL dimethyl ether is added dropwise at −50°C to a suspension of **1a**, **b** (10 mmol) in 100 mL dimethyl ether. After 12 h, the dark red solution is concentrated to a third at −80°C in vacuo and diluted with *n*-butane to the original volume. After the residue is decanted off, the solution is concentrated in vacuo until the colorless (**2a**, **3a**) or yellow (**2b**, **3b**) compounds precipitate; purification follows by recrystallization from *n*-butane (**2a**, **3a**: −78°C) and *n*-pentane (**2b**, **3b**: −25°C), respectively. Yields 60–90%.

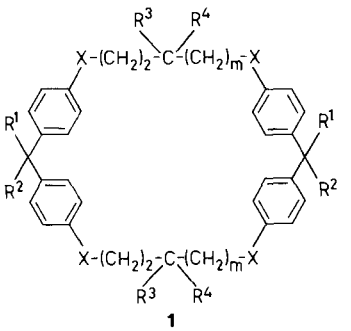
Novel Host Structures for the Selective Inclusion of Aromatic and Aliphatic Guests in Aqueous Solution**

By *Fritz Vögtle** and *Walter M. Müller*

Tetraammonium salts of the [n.1.n.1]cyclophane type **1** (m = 1–3, X or R^1–R^4 may contain an $N^{\oplus}$) with units derived from diphenylmethane form an elongated cavity and are suitable, water-soluble host structures for neutral aromatic guest molecules[1].



1

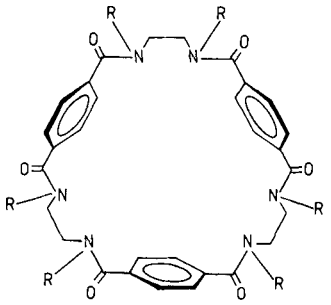
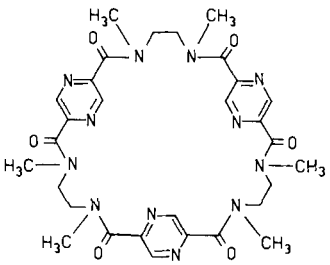
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (FRG)

[**] Frau *U. Werner* is thanked for her assistance.

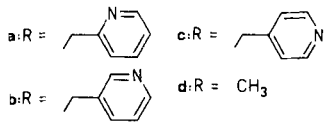
We now report the host structures **2a-c**, which differ principally from **1**, and which are just as effective as hosts. They are marked by their propitious and variable syntheses—starting from standard reagents such as terephthaloyl dichloride, ethylenediamine, and pyridinecarbaldehyde.



2a-d



3



a: R = c: R =

b: R = d: R = CH_3

The 30-membered sixfold acid amides **2a-c** of the [6.6.6]paracyclophane type, which are relevant for receptor- and enzyme-model studies, and which have, respectively, six α-, β-, and γ-pyridylmethyl side arms[2], exhibit in aqueous acidic solution (e.g. $pD = 1.2$) similar guest-binding properties as hosts of the type **1**, but have different substrate selectivity (vide infra). The large high-yield shifts of the ^{1}H-NMR signals of the aromatic *guest* molecules (resorcinol, 2,6- and 2,7-naphthalenediol) and of the *host* protons differ little from those caused by the host **1**[3]. In addition, Table 1 contains data on the new macrocycles **2d** and **3**—the latter with pyrazine structural elements—which also function as host compounds.

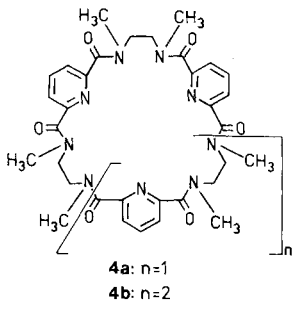
Under analogous conditions, **2b** induces the largest high-field shifts. A 1:1-mixture of hosts **2b** and **2c** with the guest 2,6-naphthalenediol exhibits predominantly the characteristic high-field shift pattern of the **2b** complex. These differences in the host/guest binding are possibly attributable, inter alia, to the different spatial separation of the six pyridine nitrogen atoms from the formally similar cavity in **2a-c** and to the presence of H bonds between the OH groups of the naphthalenediols and the nitrogen atoms of the pyridine rings, as indicated by inspection of molecular models.

Table 1. ^{1}H-NMR high-field shifts $\Delta\delta$ [ppm] of guest protons by the host compounds **2a—d** and **3** (400 MHz, in D_2O/DCl at $pD = 1.2$ and 21°C. Standard defined as HDO at $\delta = 4.8$. Concentrations: host 2.5×10^{-2} M, guest: 1.25×10^{-2} M). The chemical shifts for the guests are 2,6-naphthalenediol: $\delta = 7.13$ (H-1), 7.06 (H-3), 7.61 (H-4); 2,7-naphthalenediol: $\delta = 7.03$ (H-1), 6.93 (H-3), 7.69 (H-4); resorcinol: $\delta = 6.35$ (H-2), 6.42 (H-4), 7.11 (H-5).

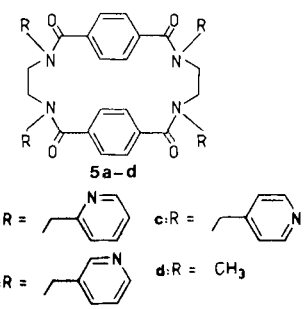
	Guests								
Host	H-1	H-3	H-4	H-1	H-3	H-4	H-2	H-4	H-5
2a	0.61	0.44	0.58	0.52	0.20	0.41	0.27	0.23	0.25
2b	0.76	0.54	0.78	0.64	0.35	0.53	0.42	0.36	0.38
2c	0.61	0.32	0.60	0.63	0.21	0.42	0.26	0.19	0.20
2d	0.34	0.23	0.23	0.26	0.24	0.25	0.21	0.19	0.20
3	0.26	0.26	0.24	0.31	0.30	0.31	0.32	0.32	0.32

Studies of comparable substances corroborate the conclusion that the high-field shifts in the system **2** indicate molecular guest-inclusion in aqueous solution. The methyl-substituted 27- and 36-membered pyridinophanes **4a**, **b**, which are also water-soluble when protonated[4], do not—as pyridine and 2- and 3-methylpyridine—exhibit analogous high-field shifts, although the H/D exchange rate of added phenols is also—if only slightly—accelerated (vide infra): the guest molecules described apparently require an approximately 30-membered macrocycle, such as in ring **2**, but not in **4** or **5**.

Of especial note for the novel host structures **2a-c** is that in addition to aromatic also *aliphatic* guests such as *trans*-1,4-cyclohexanediol, *trans*-1,4-cyclohexanedicarboxylic acid, adamantanecarboxylic acid, and adamantanethiol are dissolved by complexation in aqueous acidic solution. Accordingly, the high-field shifts of the cyclohexane- and adamantane-CH protons can be taken as also indicating the inclusion of those aliphatic guests into the cavity. Inspection of molecular models suggests that the cavity in **2a-c** is more "circular" than in **1**.



4a: n=1
4b: n=2



5a-d

a: R = c: R =

b: R = d: R = CH_3

In contrast to the host system **1**[5], *rapid* H/D-exchange of the 1,5-(1,8)protons of 2,6-(2,7-)naphthalenediol and of the 2-proton of resorcinol occur in the presence of the hosts **2a-c**. We ascribe this to a catalysis effected by the pyridine nitrogen atoms of the side arms[6].

The hosts **2** and the analogously synthesized new ligand **3** are concipated to complex not only neutral guests but also cations, just as in the cocomplexation in enzymes. An illustration of their capacity to bind cations is the ability of the hosts **2** to solvate sodium permanganate into lipophilic phases (CH_2Cl_2), a phenomenon previously known only for efficient crown ethers, cryptands, and podands. Host ligands of the type **2** should also function as catalysts for proton transfers, nucleophilic substitution[7], and as models for NADH[8].

General procedure for the macrocycles using the example of 2a-c

A solution of 40.0 mmol of the corresponding *N,N'*-substituted ethylenediamine (prepared from ethylenediamine and the corresponding pyridine carbaldehyde and subsequent hydrogenation with 5% Pd/$CaCO_3$) in 250 mL benzene is allowed to react at room temperature with a solution of 20.0 mmol terephthaloyl dichloride in 250 mL benzene under high dilution conditions (7 h simultaneous dropwise addition into 1 L benzene). The oligomers, which were extracted with dichloromethane, are separated by chromatography, column chromatography (Al_2O_3, CH_2Cl_2/EtOH as eluent), dry column chromatography (Al_2O_3), or preparative thin-layer chromatography (Al_2O_3, CH_2Cl_2/EtOH as eluent). **2a**: Yield (in each case relative to the dicarboxylic acid dichloride): 1.9%, m.p. = 149—155°C; **2b**: 3.6%, 143—149°C, phase transition 205°C, 271—273°C; **2c**: 1.0%, 163—170°C, phase transition 235°C, 263—266°C; **2d**: 8.2%, 114—123°C; **3**: 7.8%, 115—126°C; **4a**: 16.6%, 123—129°C; **4b**: 7.9%, 132—136°C.

Yamamura, *ibid. 113* (1983) 145; g) cf. also C. J. Suckling, *J. Chem. Soc. Chem. Commun. 1982*, 661.

[2] Correct elemental analyses, ^{1}H-NMR, and mass spectra were obtained for all the new compounds.

[3] The shifts arise from anisotropic effects between host and guest as well as from the influences of the positive charges on the pyridinium groups; cf. [1b, c].

[4] Since **2** (R = benzyl), in contrast to **2a—c**, is not soluble in acids, analogous inclusions in water are ruled out; cf. F. Vögtle, H. Puff, E. Friedrichs, W. M. Müller, *J. Chem. Soc. Chem. Commun. 1982*, 1398.

[5] Prof. *K. Koga*, Kyoto, is thanked for this personal communication.

[6] Cf. G. W. Kirby, L. Ogunkoya, *J. Chem. Soc. 1965*, 6914, and references cited therein.

[7] Attempts to hydrolyze lipophilic *p*-nitrophenyl esters in the presence of **2a**, **b** as catalyst in aqueous acidic solution indicate an inhibition attributable either to a strong host/guest binding or to an unfavorable position of the nucleophilic centers of the host.

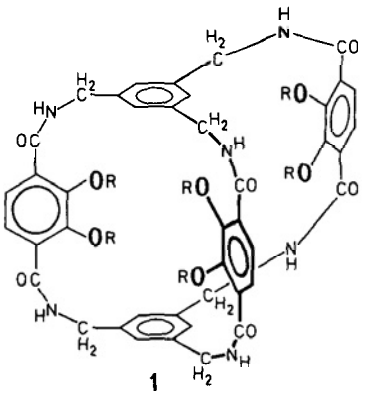
Functionalized, Oligocyclic Large Cavities—A Novel Siderophore**

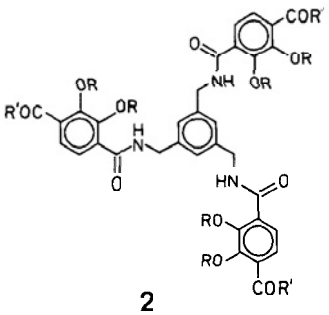
By *Wolfgang Kiggen* and *Fritz Vögtle**

We have succeeded in synthesizing a novel complex ligand-type **1**, which cannot be described as a crown ether, cryptand, or spherand. Moreover, the new ligand is a cage-like macrooligocycle which exhibits a cavity bounded on three sides and has functional groups suitable for complex formation[1].



1

a: R = CH_3 b: R = H



2

a: R = CH_3, R' = CH_3O b: R = CH_3, R' = NaO
c: R = CH_3, R' = Cl d: R = H, R' = HO

The colorless hexalactam **1a** can be synthesized by two routes using high dilution conditions[2] via Stetter cyclization[3]: a) from 2,3-dimethoxyterephthaloyl dichloride[4] and 1,3,5-benzenetriyltris(methaneamine) in 1.5% yield; and b) from the new tris(acid chloride) **2c** and 1,3,5-benzenetriyltris(methaneamine) in 13% yield (790 mg per charge!). The hexamethoxy compound **1a** (decomp. 290°C) dissolves remarkably readily in chloroform, but less well in dichloromethane.

The ^{1}H-NMR spectrum reflects the symmetry of the molecule[5]. The singlet of the methoxy protons is shifted characteristically to high field. On the NMR time scale, the OCH_3 groups apparently rotate relatively unhindered about the *p*-phenylene axis and thus gain access to the anisotropic region of the two 1,3,5-substituted benzene rings. At −109°C the high-field shift is still marked; all signals are broadened. Inspection of space-filling models indicates that not all of the six methyl groups of **1a** can be accommodated *simultaneously* in the interior of the molecule. Accordingly, this provides an explanation why **1a**, unlike other neutral ligands, is not able to solvate inorganic salts into lipophilic phases.

Cleavage of the methoxy groups in **1a** by BBr_3 in dichloromethane liberates the hexahydroxy compound **1b** (decomp. 285°C). **1b** fluoresces intensely bright blue in light of wavelength 366 nm, both in the solid state and in solution in dimethyl sulfoxide. Alkaline solutions are scarcely air sensitive. The FAB mass spectrum of **1b** in a glycerine matrix exhibits a significant $[M+H]^{\oplus}$ peak[6].

Examination of molecular models suggests that in the hexaanion of **1b** an octahedral donor geometry for metal cations is formed; upon complexation, a helical-chiral configuration results (Fig. 1).

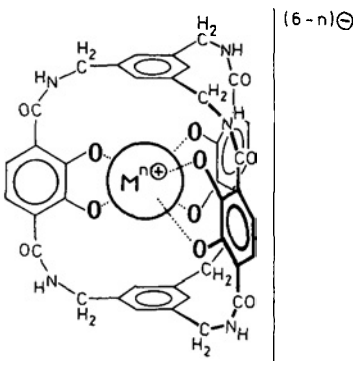


Fig. 1. Octahedral metal complex of **1b**.

"Siderophores" (iron carriers) which contain catechol moieties form octahedral complexes with $Fe^{3\oplus}$[7]. That **1b** is a remarkably stronger complexing ligand emerges from the observation that moist **1b** attacks 18/8 stainless steel, producing a blue-black coloration. Iron and nickel powder are dissolved in minutes, and chromium powder is dissolved within a few hours to form blue-green, green-grey, and pink solutions, respectively, on exposure to air.

Addition of $Fe^{3\oplus}$ salts to a solution of the novel ligand **1b** in water at pH 11 leads to the characteristic red-violet tint ($\lambda_{max} = 544$ nm, $\varepsilon \approx 4680$). For comparison, we prepared from **2a** the colorless, open-chained, hexadentate ligand **2d**, whose solution in water at pH 11—in contrast to **1b**—becomes red-brown ($\lambda_{max} = 508$ nm, $\varepsilon \approx 5120$) upon addition of $Fe^{3\oplus}$ salts. Titrations of the two ligands against $Fe^{3\oplus}$, with UV/VIS monitoring, indicate a 1:1 stoichiometry. Upon acidification of the $Fe^{3\oplus}$-complex solutions of **1b** and **2d**, blue-black compounds precipitate out. The occurrence of a $[(lig)H_3Fe+H]^{\oplus}$ peak in the FAB mass spectrum of the $Fe^{3\oplus}$ complex of **1b** in a diethanolamine matrix[6] corroborates the 1:1 stoichiometry, which suggests the presence of one cation in the cavity, as shown in Figure 1[8]

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.

Extinction measurements indicate that EDTA, even when present in 1000 fold excess (pH 11), cannot compete with the Fe^{III}-complexes of **1b** and **2d**, although the formation constant K_f for the Fe^{III}-EDTA complex is 10^{25}[9]. Finally, the superiority of the ligand **1b** becomes clear from competition experiments with **2d**, in which ca. 70% of the iron(III) ions are complexed by **1b**; however, in order to establish equilibria, the solutions require to be heated for several hours at 100°C.

Our synthetic methodology allows construction of even roomier cavities by using spacers larger than the two 1,3,5-substituted benzene nuclei, e.g. 1,3,5-triphenylbenzene building blocks, as we have previously employed in another connection (cyclophanes)[10]. In this respect, these macrooligocycles are also of interest for chemical reactions in cavity interiors as well as for model studies of receptors with larger guests[1].

Synthesis and Crystal Structure of $[Ph_4As]_4[Au_{12}S_8]$, a Distorted Cubane-Like Thioaurate(I)**

By *Gerolf Marbach* and *Joachim Strähle**

In aqueous solutions of polysulfides, gold salts form thio- or polysulfidoaurates(I); the thioaurates(I) $[AuS]^{\ominus}$ and $[AuS_2]^{3\ominus}$ as well as the trisulfidoaurate(I) $[AuS_3]^{\ominus}$ were reported in the older literature[1]. Recently, we reported the synthesis and structure of $[Ph_4As][AuS_9]$, a cyclic nonasulfidoaurate(I)[2]. This species is formed from ethanolic solutions of $K[Au(SCN)_2]$ and tetraphenylarsonium polysulfide. Depending on the sulfur content of the polysulfide solution, salts of the cyclic anion $[Au_2S_8]^{2\ominus}$ are also obtained[3,4]. Thioaurates should be important for the chemical sensitization of photographic silver halide layers[5], in which $Ag[AuS]$[6,7] and $Ag_3[AuS_2]$[7] may occur. We have now obtained the thioaurate(I) $[Ph_4As]_4[Au_{12}S_8]$ **1**.

The gold sulfides Au_2S and Au_2S_3 as well as tetrachloroaurates(III) can be dissolved in concentrated aqueous solutions of Na_2S; presumably, thioaurate(I) ions $[AuS_2]^{3\ominus}$ are predominantly formed, whereby the Au^{III} compounds are reduced. Upon addition of Ph_4AsCl, **1** precipitates quantitatively from these solutions as light yellow crystalline needles[8].

1 forms intensely yellow solutions in dimethylformamide and dimethyl sulfoxide; columnular single crystals of **1** precipitate out from dimethyl sulfoxide when the solution slowly takes up H_2O from exposure to an atmosphere of water vapor. **1** is light sensitive and upon irradiation decomposes with a dark coloration. Decomposition also occurs at the melting point (230°C). In the mass spectrum, only fragments of the cation can be detected. Apart from the shoulder for ν(Au–S) at 330 cm^{-1}, the IR spectrum exhibits only the characteristic bands of the cation. The X-ray structure investigations were carried out at −60°C[9]. Compound **1** is isotypic with the thiocuprate(I) $[Ph_4P]_4[Cu_{12}S_8]$[10].

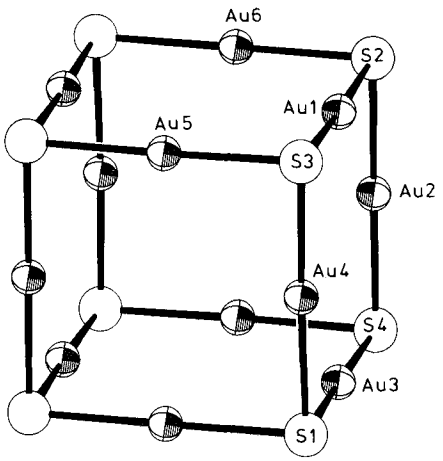

Fig. 1. Structure of the thioaurate(I) $[Au_{12}S_8]^{4\ominus}$ in the crystal of **1**. For clarity, the Au and S atoms are each represented by circles of the same diameter. Selected distances [pm] and angles [°]: Au-S 223.7(5)–234.6(5); Au-Au 317.9(1)–335.1(1), S-Au-S 177.8(2)–179.4(2), Au-S-Au 86.7(2)–93.1(2).

In the crystal, the anion of **1**, $[Au_{12}S_8]^{4\ominus}$, adopts a distorted cubic structure whose corners and edge midpoints are occupied by sulfur and gold atoms, respectively (Fig. 1). Gold(I) thus achieves its preferred linear coordination with bond angles S-Au-S between 177.8 and 179.4°. The average distance Au-S (230.6 pm) suggests a covalent single bond; the S atoms each bridge three Au atoms and enclose Au-S-Au angles of between 86.7 and 93.1°. A comparable arrangement occurs in the complex ion $[S(AuPPh_3)_3]^{\oplus}$ (Au-S: 230.2–234.2 pm, Au-S-Au 82.9–95.0°)[11].

In the anion $[Au_{12}S_8]^{4\ominus}$, the Au atoms are arranged cluster-like in the form of an almost ideal cuboctahedron. The Au-Au distances are between 318 and 335 pm. No Au-Au or Au-S contacts occur between the individual anions. In contrast to **1**, in the analogous thiocuprate $[Ph_4P]_4[Cu_{12}S_8]$[10] the Cu atoms are displaced towards the center of the cuboctahedron. Accordingly, the shorter Cu-Cu distances give rise to a marked bending of the S-Cu-S moiety.

2-(Pyridyl)ethyl Esters as Secure yet Readily Removable Polarophilic Carboxy-Protection in Peptide Synthesis**

By *Horst Kunz** and *Michael Kneip*

Dedicated to Professor Jan Thesing on the occasion of his 60th birthday

For the synthesis of sensitive peptides and glycopeptides, we have developed protective groups which are introduced in a stable form and only converted into a labile form immediately prior to their cleavage[1]. Among these two-step protecting groups, the 2-(pyridyl)ethoxycarbonyl (Pyoc) residues[2,3], both of which are stable to acids and bases, show the additional effect of increasing the solubility of the blocked amino acids and peptides in polar media. After methylation to the pyridinium form, they can be removed from the blocked amino group even with morpholine in dichloromethane.

To extend exploitation of the advantages of this protecting principle to the carboxy function, we have synthesized amino acid-2-(2-pyridyl)ethyl (2-Pet)[4] and amino acid-2-(4-pyridyl)ethyl (4-Pet) esters and checked their suitability for use in peptide synthesis. Because of their Lewis-base character, 2-(pyridyl)ethanols **3** and **4**[5] cannot be esterified directly with amino acids. In contrast, both benzyloxycarbonyl- **1** as well as *tert*-butoxycarbonyl-amino acids **2** react with dicyclohexylcarbodiimide (DCC)/4-dimethylaminopyridine (DMAP)[6] and **3** or **4** to give the *N*-protected amino acid-Pet esters **5**—**7**[7] in high yields (Scheme 1, Table 1).

With exception of **5a** (m.p. 67 °C) and **5g** (m.p. 76 °C), the 2-Pet esters are oily. The 2-Pet esters show, as characteristic ^{1}H-NMR signals ($CDCl_3$), two triplets ($\delta=3.15$ and 4.5, $J=6$ Hz) of the ethylene protons as well as a multiplet ($\delta=7.3$) and a doublet ($\delta=8.4$, $J=6$ Hz, α-H) of the pyridyl protons, while the latter give rise to doublets ($\delta=8.4$ and 7.15) in the spectra of the 4-isomer **7**.

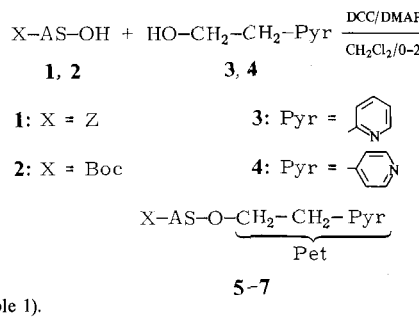


Scheme 1 (see Table 1).

Table 1. Synthesis of *N*-protected amino acid-(2-Pet) esters **5**, **6** and amino acid-(4-Pet) esters **7** according to Scheme 1.

	AA	X	Yield [%]	$[\alpha]_D^{22}$	(*c* in $CHCl_3$)
5a	Gly	Z	87	–	
5b	Ala	Z	88	– 3.5	(0.8)
5c	Val	Z	90	+ 2.8	(1.9)
5d	Leu	Z	92	– 6.2	(2.2)
5e	Ile	Z	81	+ 7.5	(2.1)
5f	Phe	Z	90	+23.5	(1.9)
5g	Ser [8]	Z	61	–43.4	(1.5)
6a	Leu	Boc	86	– 7.9	(2.0)
6b	Val	Boc	94	+ 2.8	(1.8)
7a	Val	Z	83	+ 2.5	(1.9)
7b	Phe	Z	90	+23.5	(2.1)

The peptide synthesis reactions were carried out with the derivatives **5**, **6** of the commercially available 2-isomer **3**. The hydrogenolysis of the Z-group in the compounds **5** takes place slowly. In contrast, the acidolysis of the two amino-protecting groups proceeds selectively and in high yields (Scheme 2).

5 $\xrightarrow{HBr/AcOH}$ H-AA-O-(2-Pet)·2 HBr
8a: AA = Val, 88%
8b: AA = Phe, 92%
8c: AA = Ile, 89%

6a $\xrightarrow{HCl/CH_2Cl_2}$ H-Leu-O-(2-Pet)·2 HCl
8d, 92%

Scheme 2.

The amino acid-Pet esters are formed as analytically pure dihydrohalides (elemental analysis). The dihydro salt is likewise formed on cleavage of Boc with trifluoroacetic acid. For the peptide coupling, the bases liberated from **8** are allowed to react with *N*-protected amino acids and ethyl-2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ)[9] (**A**) or with dicyclohexylcarbodiimide (DCC)/1-hydroxybenzotriazole (HOBT)[10] (**B**) (Scheme 3, Table 2).

1, 2 + **8** $\xrightarrow[\substack{\mathbf{A}:\text{EEDQ}\\ \mathbf{B}:\text{DCC/HOBT}}]{2\,NEt_3/CH_2Cl_2}$ X-AA^1-AA^2-O-(2-Pet)
9: X = Z
10: X = Boc

Scheme 3 (see Table 2).

Once again, the amino protecting groups can be removed selectively from the analytically pure dipeptides **9** and **10** by acidolysis.

9f $\xrightarrow{HBr/AcOH}$ H-Leu-Phe-O-(2-Pet)·2 HBr
11a, 95%

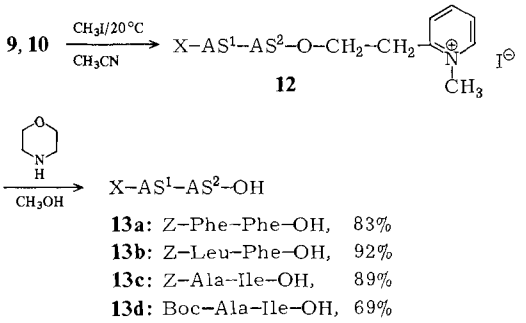
10a $\xrightarrow{HCl/CH_2Cl_2}$ H-Val-Leu-O-(2-Pet)·2 HCl
11b, 97%

10c $\xrightarrow{CF_3COOH}$ H-Gly-Leu-O-(2-Pet)·2 CF_3COOH
11c, 96%

Table 2. Synthesis of *N*-protected dipeptide-(2-Pet) esters according to Scheme 3.

	AA[1]	AA[2]	Yield [%] A	Yield [%] B	M.p. [°C]	$[\alpha]_D^{22}$ (c in $CHCl_3$)
9a	Ala	Phe	91	—	92–93	+13.3 (2.1)
9b	Gly	Phe	95	91	95	+29.0 (1.7)
9c	Phe	Phe	86	—	129	+21.8 (1.6)
9d	Phe	Ile	87	—	88–89	+ 7.3 (1.7)
9e	Leu	Ile	—	95	oil	− 6.5 (2.4)
9f	Leu	Phe	78	—	100	+ 8.6 (1.3)
10a	Val	Leu	—	88	66–68	−17.8 (1.5)
10b	Ala	Ile	76	—	oil	−18.4 (1.0)
10c	Gly	Leu	—	75	oil	+ 1.8 (2.1)

By analogy to the *N*-terminal Pyoc protecting groups[3], the Pet esters are activated by methylation in acetonitrile prior to cleavage (Scheme 4).



Scheme 4.

At room temperature, the methylation of the 2-Pet ester requires ca. 4 d. As a rule the isolable and characterizable pyridinium salts **12** are decomposed directly with 15% morpholine in methanol at room temperature in a E1cB reaction, which is complete after 2 h.

Methylation of the 4-Pet esters under the same conditions requires only 3 h. It was demonstrated with phenylalanine as example that the introduction and removal of the two isomeric Pet-esters proceeds almost without any racemization. Reaction of Z-Phe-OH **1f** ($[\alpha]_D^{22} = +4.6$ ($c = 2$, AcOH) with **3** or **4** yields, according to Scheme 1, the Pet-esters **5f** and **7b**, respectively, which can be cleaved again, according to Scheme 4, to give **1f** ($[\alpha]_D^{22} = 4.5$ ($c = 2$, AcOH)).

The Pet-esters are thus cleavable under mild conditions. Their polarophilic properties also enable an effective linking in the case of hindered hydrophobic building blocks.

13a + **8b** $\xrightarrow{\text{EEDQ}}$ Z-Phe-Phe-Phe-O-(2-Pet)
14a, 97%

13c + **8d** $\xrightarrow{\text{EEDQ}}$ Z-Ala-Ile-Leu-O-(2-Pet)
14b, 92%

The methylation necessary for the activation, however, precludes any application to sulfur-containing amino acids.

[7] Procedure: A solution of **1** or **2** (10 mmol), **3** or **4** (1.2 g, 10 mmol) and DMAP (0.6 g, 0.5 mmol) in CH_2Cl_2 (30 mL) was treated at −20°C with 2.2 g (11 mmol) DCC. After 10 min the cooling bath was removed, the mixture was stirred for 3 h at 20°C, cooled to 0°C, and filtered free of dicyclohexylurea; the rest of this compound was then removed by dissolution in acetone at 0°C. The solution of the products **5**–**7** in 50 mL ether was washed with $NaHCO_3$ solution and water, dried over Na_2SO_4, and evaporated to dryness in vacuo. Filtration through a short silica gel column (20–30 g silica gel, eluent: chloroform) furnished analytically pure products.
[8] In contrast to [7], **3** was used here in tenfold excess. After completion of the reaction, the mixture was filtered and the product isolated directly by flash chromatography on silica gel (eluent: petroleum ether/ethyl acetate 1:20).

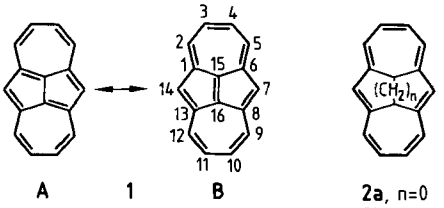
Novel Synthesis and Molecular Structure of the Pyrene Isomer Dicyclohepta[*cd,gh*]pentalene (Azuleno[2,1,8-*ija*]azulene)

By *Emanuel Vogel**, *Herbert Wieland*, *Lutz Schmalstieg*, and *Johann Lex*

Dedicated to Professor Virgil Boekelheide on the occasion of his 65th birthday

The pyrene isomer dicyclohepta[*cd,gh*]pentalene (azuleno[2,1,8-*ija*]azulene) **1**[1], according to the results of spectroscopic studies[2], can be viewed to a crude approximation as a 14π-Hückel perimeter with a central C=C bridge (large contribution from the numbered resonance structure). Thus, the relationship of **1** to the bridged [14]annulenes **2**[3] not only rests on a formal structural analogy, but also extends to the nature of the π-electron system. Previous attempts to perform an X-ray structure analysis of **1** failed because of the poor quality of the crystals and, hence, the alleged planarity of the molecule was not corroborated. Limited access to **1**, on the other hand, left unsettled the interesting question as to whether **1** might undergo additions to the central "double bond" to form **2a** or derivatives thereof. Both questions have recently become topical due to the surprising observation that 15,16-dioxo-*syn*-1,6:8,13-bismethano[14]annulene undergoes thermal deoxygenation—via a metathesis reaction sequence—to yield **1**[5].

The novel synthesis of **1** reported here (Scheme 1) now permits a more detailed investigation of the compound. The synthetic plan was based on the preparation of the α-chloro sulfoxide **8**, since we expected that this decisive intermediate could be directly converted into **1** via a Ramberg-Bäcklund-type rearrangement[6].



2a, n=0
2b, n=1
2c, n=2
2d, n=3

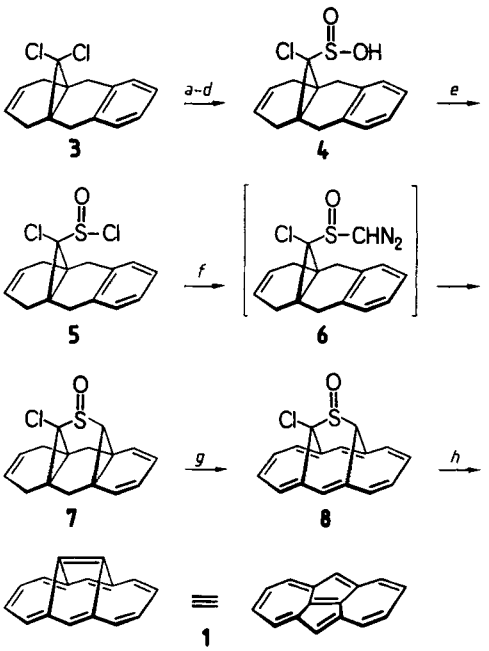
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (FRG)



Scheme 1. *a:* *n*BuLi, THF (tetrahydrofuran) −78°C. *b:* SO_2 (gas), −78°C (until color changes from red to yellow). *c:* Cation exchange resin Lewatit S 100 as Na form, RT. *d:* H_2O/HCl; 59% (crude product) rel. to **3**. *e:* $SOCl_2$, THF (with pyridine) RT, 30 min. *f:* **5** (in THF) treated with CH_2N_2/ether, −70°C up to RT, 2 h; 28–33% rel. to **4**. *g:* 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, chlorobenzene, 140°C, 3 h; 60%. *h:* KO*t*Bu, THF, −78°C up to RT, 1 h; 95%.

1,4,9,10-Tetrahydroanthracene, readily accessible by Birch reduction of 9,10-dihydroanthracene[7], selectively takes up dichlorocarbene at the tetrasubstituted double bond when allowed to react with chloroform and 25% aqueous potassium hydroxide in the presence of benzyltriethylammonium chloride (Makosza method) to afford adduct **3**, which is isolated by high-vacuum distillation (removal of nonvolatile bis-adduct) and crystallization from toluene (m.p. = 107°C; yield 40%). The dichloro compound **3** (Table 1) proved to be more suitable than the analogous dibromide used previously for the synthesis of bridged [14]annulenes, since lithiation of **3** proceeds with higher *endo*-selectivity than that of the dibromide (>90% compared to ca. 75%), as inferred from the protonation and carboxylation of the anion formed. Successive treatment of **3** with butyllithium and sulfur dioxide yields the lithium salt of the sulfinic acid **4** [or the stereoisomer of **4**] (Table 1), which is converted into the readily isolable crystalline sodium salt. If an aqueous solution of the sodium salt at 0°C is treated with concentrated hydrochloric acid, and the amorphous product thus precipitated taken up in ether, the practically pure microcrystalline *endo*-sulfinic acid **4**, which requires no additional purification [a sample recrystallized from ether melted at 139–141°C (decomp.)], is obtained after removal of the solvent. A solution of the acid chloride **5** in THF, prepared from **4** by treatment with sulfinyl chloride in THF, was allowed to react with excess diazomethane to furnish the diazo sulfoxide **6**. Since diazo sulfoxides have a strong tendency to decompose into carbenes[8], it was feasible that **6** might react further in statu nascendi to yield **7**. In fact, **7** is the major, readily separable product obtained upon chromatographic filtration through aluminum oxide (THF) [m.p. = 219–221°C (decomp.), colorless crystals from dioxane; see Table 1]. **7** can be straightforwardly dehydrogenated to **8** [m.p. = 240°C (decomp.), orange needles from dioxane; see Table 1].

Table 1. Spectral data for **3**, **4**, **7**, and **8**. ^{1}H-NMR (90 MHz, $CDCl_3$); MS (70 eV).

4: ^{1}H-NMR: δ = 2.10–2.75 (m, 4H), 3.17 and 3.34 (AB system, 2×2H), 5.60 (s, 2H), 7.00 (s, 1H), 7.00–7.25 (AA'BB' system, 4H); MS: *m/z* 294/296 ($M^{\oplus}$, <1%), 240 ($M^{\oplus}$ − H_2O − HCl, 8), 178 (100); IR (KBr): 2900, 2460 cm^{-1} (O–H), 1095 (S=O), 830 (S–O)

7: ^{1}H-NMR: δ = 1.67 (s, 1H), 2.05–3.53 (m, 8H), 5.60 (s, 2H), 5.75–6.20 (ABCD system, 4H); MS: *m/z* 290/292 ($M^{\oplus}$, 6/2%), 273 ($M^{\oplus}$ − OH, 25), 255 ($M^{\oplus}$ − Cl, 5), 237 ($M^{\oplus}$ − H_2O − Cl, 18), 165 (100); UV/VIS (dioxane): λ_{max} = 225 nm (ε = 2840) sh, 258 (2920), 280 (1780) sh; IR (KBr): 1064 cm^{-1} (S=O)

8: ^{1}H-NMR: δ = 0.20 (s, 1H), 7.45–8.10 (m, 8H), 7.95 (s, 1H), 8.35 (s, 1H); MS: *m/z* 286/288 ($M^{\oplus}$, 18/8%), 235 ($M^{\oplus}$ − O − Cl, 5), 234 ($M^{\oplus}$ − OH − Cl, 5), 203 ($M^{\oplus}$ − SO − Cl, 100); UV/VIS (dioxane): λ_{max} = 237 nm (ε = 5200), 303 (111000), 356 (5350), 437 (110) sh, 503 (330); IR (CsI): 1079 cm^{-1} (S=O)

The expectation that the α-chloro sulfone can be omitted as intermediate in the conversion of **8** into **1** proved to be correct. The α-chloro sulfoxide **8** gives **1**[13], almost quantitatively, which crystallizes from cyclohexane as greenish black needles (m.p. = 142°C); the spectral data of the compound agree with those reported previously[2].

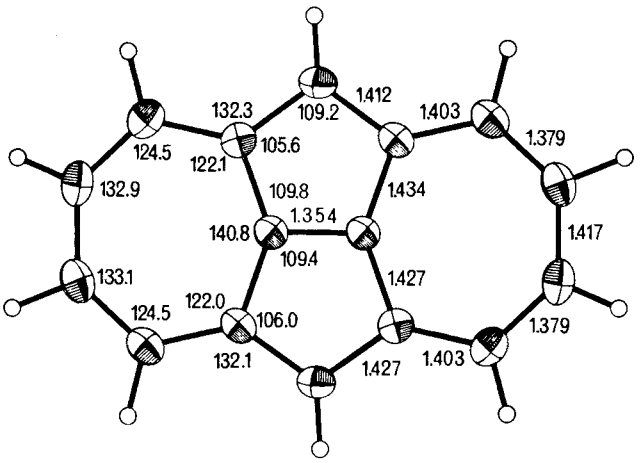

Fig. 1. Structure of **1** in the crystal. The bond lengths [Å] and bond angles [°], respectively, are shown in the right and left halves of the centrosymmetric molecules.

It was now found to be possible to carry out an X-ray structure investigation of **1** (see Fig. 1)[9]. The principal result is the verification of the assumed planarity of the molecular framework (maximum deviation of the C atoms from the mean plane through the ring skeleton: 0.013 Å). The molecule has a center of inversion and, within the limits of error, D_{2h} symmetry. The C_{14}-perimeter exhibits CC bonds of length 1.379 to 1.427 Å, which closely correspond to the respective bond distances in the peripheral annulene ring of the bridged aromatic [14]annulenes **2a** and **2b**[10]. The central bond C15–C16 is conspicuously short. This result suggests a relatively strong π-bond character for this bond, even when it is taken into account that a certain compression of the C15–C16 distance is brought about by the ring strain in **1**[10]. The concept that **1** is a [14]annulene perturbed by a central C=C bridge is thus supported not only by the spectral but also by the structural findings[11, 12]

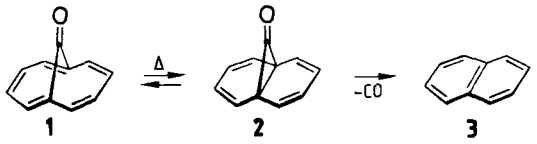
Thermal Deoxygenation of *syn*-15,16-Dioxo-1,6:8,13-bismethano[14]annulene to the Pyrene Isomer Dicyclohepta[*cd,gh*]pentalene (Azuleno[2,1,8-*ija*]azulene)

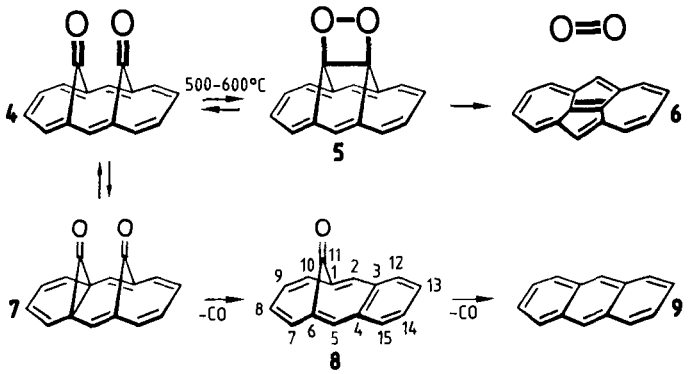
By *Emanuel Vogel*, Gerd Markowitz, Lutz Schmalstieg, Shô Itô, Rolf Breuckmann,* and *Wolfgang R. Roth*

The 10π-arene 11-oxo-1,6-methano[10]annulene **1**[1] is stable up to ca. 200°C. Above this temperature, it undergoes quantitative decarbonylation to yield naphthalene **3**, a reaction which in the gas phase is found to have the activation parameters $E_a=35.6\pm0.1$ kcal/mol and $A=(7.2\pm0.7)\times10^{13}$ s^{-1}. The relatively high thermal stability of **1**[2] can be rationalized if one assumes that the decarbonylation of the "masked tropone" **1** occurs via its energy-rich norcaradienone valence tautomer **2**. In view of the lack of knowledge on the properties of norcaradienones[3], it is an open question whether the formation or decomposition of **2** is rate determining.



The thermolysis behavior of **1** suggests that the most probable thermolytic reaction of the aromatic *syn*-15,16-dioxo-1,6:8,13-bismethano[14]annulene **4**[1c] would be fragmentation via the norcaradienone **7** to anthracene **9** and carbon monoxide. **4** should even exceed **1** in thermal stability since the formation of **7** is without doubt energetically more costly than that of **2**, because a) loss of resonance energy on going to the respective norcaradienone intermediate is greater for **4** than for **1** and b) increase of the annulene perimeter from ten to fourteen carbon atoms is associated with reduction of ring strain (the bridgehead angle of **1** is 106.1°[1d] as compared to 112.4°[4] in **4**). In fact, **4** is unexpectedly stable for a molecule of this structural type. As indicated by preliminary studies, **4** survives gas-phase pyrolysis at 500°C in vacuo virtually unscathed[5].

A more detailed investigation has now revealed that between 500 and 600°C **4** is deoxygenated to 70% to give the pyrene isomer dicyclohepta[*cd,gh*]pentalene **6**[6] (azuleno[2,1,8-*ija*]azulene), whereas decarbonylation to anthracene and carbon monoxide, which was anticipated to be the favored decomposition mode, only occurs to 30%. **6** was identified by comparison of its mass, NMR, and UV/VIS spectra with those of an authentic sample[6b].



Thermal deoxygenation of **4** to **6** can hardly be explained unless it is assumed that the 1,2-dioxetane **5** is formed initially; this then decomposes into **6** and singlet oxygen (as yet undetected), a reaction which competes with re-formation of **4**. To the best of our knowledge, there is no precedence for a metathesis reaction sequence of this type—reversal of the thoroughly studied oxidative cleavage of electron-rich double bonds by singlet oxygen[7]. That **4** proves to be a suitable substrate for the observation of such a reaction sequence must have its origins in the interplay of the following factors:

1) The rigid, approximately parallel arrangement of the carbonyl groups in **4** appears to make a 1,2-dioxetane ring closure favorable for entropy reasons.

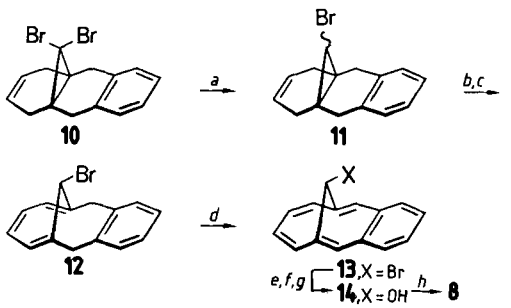
2) The reaction conditions (flow thermolysis) permit kinetic control of the products, thereby fulfilling an important requirement for the realization of the strongly endothermic 1,2-dioxetane formation.
3) The pyrolysis temperature of 500—600 °C is sufficient to reach the high activation threshold[8] expected for establishment of the equilibrium **4** ⇄ **5**.
4) Liberation of singlet oxygen from **5** should benefit from formation of an aromatic product[9]. **6** is planar[6b] and, so corresponding to its enthalpy of hydrogenation ($\Delta H = -165.2$ kcal/mol), has a high resonance energy.

Apart from **4**, the majority of other known diketones with neighboring, parallely orientated carbonyl groups are cage compounds[10]. Thermal cleavage in the sense of the metathesis reaction sequence **4** → **5** → **6** is not possible in such diketones since extremely strained olefins would result.

The decarbonylation of **4** to **9**, which competes with the deoxygenation, proceeds in all probability via **8**. In order to corroborate this supposition experimentally, **8** was synthesized independently (Scheme 1) and its thermal behavior studied.



Scheme 1. *a*: Tri-*n*-butyltin hydride, toluene, reflux, 24 h; 95% (crude product). *b*: Br_2/CH_2Cl_2, −78 °C. *c*: DBN in THF (tetrahydrofuran), RT, 4d; 20% rel. to **10**. *d*: 2,3-Dibromo-5,6-dicyano-*p*-benzoquinone, toluene, reflux, 15 h; 7%. *e*: *n*BuLi, THF, −78 °C. *f*: $B(OCH_3)_3$, −78 to 15 °C, 1 h. *g*: 5% NaOH/30% H_2O_2, −15 °C, 1 h; 26%. *h*: DMSO/CH_2Cl_2/$(CF_3CO)_2O$, −78 °C, 1 h; 59%.

Reduction of the known dibromo compound **10** afforded the monobromide **11** as a mixture of the *exo/endo*-isomers (ca. 1 : 1.7). Attempts to isolate *endo*-**11** were unsatisfactory; however, after carrying out a bromination-dehydrobromination reaction sequence, product separation presented no difficulties. The *endo/exo*-**11** isomers readily took up bromine to form the tribromides. Treatment of this mixture with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) resulted in dehydrobromination of the *endo*-isomer to **12**, whereas, in contrast, the *exo*-isomer remained intact. Extraction of the reaction mixture with methanol (room temperature) and subsequent chromatography on silica gel (pentane) led to pure **12** [m.p. = 56—57 °C (from methanol), see Table 1], which could be dehydrogenated to **13** [m.p. = 173—174 °C (from methanol), see Table 1] albeit in low yield[12]. Successive treatment of the solvolytically rather inert bromide **13** with butyllithium, trimethyl borate, and alkaline hydrogen peroxide caused smooth Br/OH-exchange, leading to **14** [m.p. = 130—131 °C (from ether/pentane), see Table 1]. For the conversion of **14** into **8**, oxidation with dimethyl sulfoxide/trifluoroacetic anhydride proved to be the method of choice; yellow needles of **8** [m.p. = 206—207 °C (decomp.)] were obtained after chromatography on silica gel and crystallization from ether (Table 1).

In both solution and in the solid state, 11-oxo-3,4-benzo-1,6-methano[10]annulene **8** is stable up to ca. 200 °C, which corresponds to the stability behavior of the parent compound **1**. At higher temperatures, **8** is quantitatively decarbonylated to **9**. Accordingly, the thermal behavior of **8** is consistent with its assumed occurrence as intermediate in the decarbonylation of **4**.

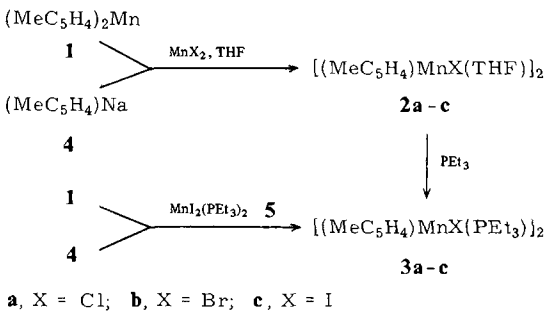
General Entry to Novel Manganese(II) Half-Sandwich Complexes**

By *Frank H. Köhler*, Nikolaus Hebendanz, Ulf Thewalt, Basil Kanellakopulos,* and *Reinhardt Klenze*

Numerous diamagnetic, and even some paramagnetic[1], transition-metal compounds with a π-bonded aromatic ligand (half-sandwich complexes) are effective functional groups for the stabilization of molecules and molecular fragments. Despite the reported involvement of "CpMnCl" intermediates in certain reactions[2], manganese(II) half-sandwich compounds of this type have hitherto never been isolated[3]. Herein, we report on the formation and properties of compounds of the type $CpMnXL_2$ and their dimers.

Bis(η-methylcyclopentadienyl)manganese **1** reacts with manganese(II) halides to give the compounds **2** (Scheme 1), in which the tetrahydrofuran (THF) ligand can be readily replaced by triethylphosphane. The complexes **3** thus formed can also be prepared by reaction of methylcyclopentadienylsodium **4** with the recently described bis(triethylphosphane)manganese diiodide **5**[4] (Scheme 1). **2a** and **3** are confirmed by elemental analysis. The complexes are very sensitive towards air and moisture.



Scheme 1.

According to an X-ray structure analysis[5], **3a** is dimeric, which also should be the case for **2** and **3b/3c**. Linkage by chloro bridges results in a tetrahedral environment of the Mn atoms (Fig. 1); the central Mn–Cl–Mn*–Cl* unit is almost square planar and thus, as in the case of $[CpCrCl_2]_2$[1g], **3a** can be expected to be antiferromagnetic. According to the ^{1}H-NMR spectrum (Fig. 2) and a cryoscopic determination of the molar mass of **3c** (790 ± 40, in benzene), the same type of structure is present in solution. The signals of the methylcyclopentadienyl protons are shifted similarly to the analogous signals in $(i\text{PrC}_5\text{H}_4)_2\text{Mn}$[6], thus indicating the presence (at 303 K) of ten unpaired electrons in the dimer. NMR spectroscopic investigations at various temperatures, however, show deviations from ideal paramagnetic behavior. More precise

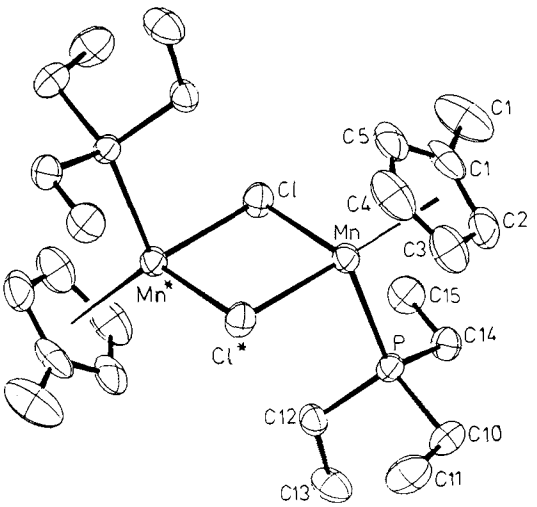


Fig. 1. Structure of **3a** in the crystal. Selected bond lengths [pm] and bond angles [°]: Mn-Cl 248.2(2), Mn-Cl* 248.0(2), Mn-P 256.7(2), Mn-Z 217.1(10), Mn-Mn* 351.4(2); Cl-Mn-Cl* 89.8, Cl-Mn-P 98.9, Cl*-Mn-P 99.3, Mn-Cl-Mn* 90.2. Z = center of the five-membered ring.

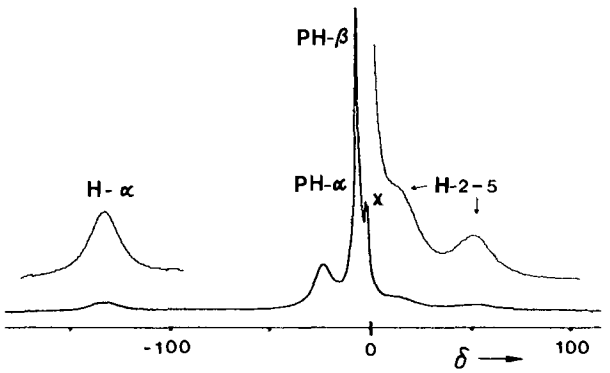

Fig. 2. 200-MHz ^{1}H-NMR spectrum of **3c** in $CD_3C_6D_5$ at 303 K. For assignment of signals cf. Figure 1: H-α ≙ H-1', PH-α ≙ H-10/12/14, PH-β ≙ H-11/13/15. X = residual methyl-H of the solvent and free PEt_3.

information is provided by the measurement of the magnetic susceptibility of **3a** (crystal powder) between 1.3 and 332.9 K (Fig. 3): **3a** couples antiferromagnetically via Cl bridges. Referred to a magnetically normal complex, the data can be interpreted in terms of a coupling constant $J = -4.7\ \text{cm}^{-1}$ over the whole temperature range.

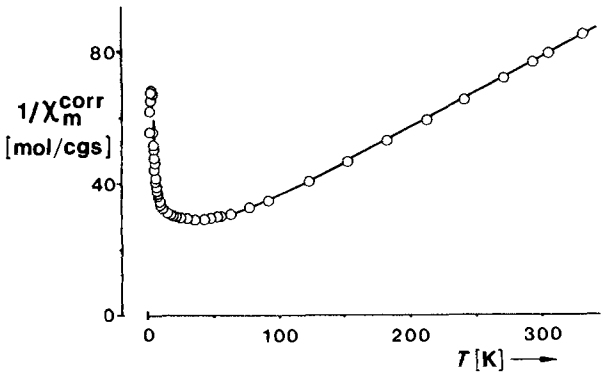

Fig. 3. Inverse molar magnetic susceptibility between 1.3 and 332.9 K.

[†] Visiting Professor from the Sektion Röntgen- und Elektronenbeugung der Universität Ulm (FRG).

[**] This work was supported by the Fonds der Chemischen Industrie.

On reaction of **2c** with trimethylphosphane, we did not isolate dimers such as **3**, but the species **6** (confirmed by elemental analysis).

$$\underset{\mathbf{2c}}{[(MeC_5H_4)MnI(THF)]_2} \xrightarrow{PMe_3} 2\underset{\mathbf{6}}{(MeC_5H_4)MnI(PMe_3)_2}$$

Complex **6** differs characteristically in the paramagnetic shifts δ^{para} (^{1}H)[7] of its phosphane ligands from **3a**–**c**, which themselves exhibit very similar δ^{para} (^{1}H) values. In the PEt_3 derivatives **3**, coordinative saturation is achieved by dimerization, whereas the sterically undemanding PMe_3[8] moiety in **6** enables formation of the monomer. **6** is thus a particularly simple example of a manganese(II) half-sandwich complex.

TMEDA Adducts of CpMnCl and Manganocene**

By *Jürgen Heck**, *Werner Massa*, and *Peter Weinig*

Cyclopentadienyl halogeno complexes of 4th, 5th and 6th sub-group elements have interesting magnetic properties and are of great preparative importance because of their reactive halogeno groups and their Lewis acidity[1]. We have now prepared and isolated, in a very simple reaction, the base-stabilized cyclopentadienylmanganese(II) chloride, whose methyl derivative $(CH_3C_5H_4)MnCl$ was reported as long ago as 1957 to be an intermediate in the synthesis of $(CH_3C_5H_4)Mn(C_6H_6)$[2]. Since monomeric cyclopentadienyl halogeno complexes $CpMCl_2$ (M = Ti, V, Cr; Cp = cyclopentadienyl) containing 11–13 valence electrons are obviously not isolable without Lewis bases under normal conditions[1] we resorted to the reaction of equimolar amounts of anhydrous $MnCl_2$, *N,N,N',N'*-tetramethylethylenediamine (TMEDA), and NaCp in tetrahydrofuran (THF). In this way, the air- and moisture-sensitive complex CpMn(TMEDA)Cl **1** was formed in very good yields[3,4] [Reaction (a)].

$$MnCl_2 + TMEDA \xrightarrow[\text{2. NaCp, 220 K}]{\text{1. THF, reflux}} \underset{\mathbf{1}}{CpMn(TMEDA)Cl} + NaCl \quad (a)$$

On attempting to split TMEDA by heating in a high vacuum, CpMnCl was not formed, but **2** as sublimate [Reaction (b)].

$$2\,\mathbf{1} \xrightarrow[390-410\ K]{10^{-3}-10^{-4}\ mbar} \underset{\mathbf{2}}{Cp_2Mn(TMEDA)} + MnCl_2 + TMEDA \quad (b)$$

2 is formed in almost quantitative yield on reaction of manganocene **3** with TMEDA in toluene[5] [Reaction (c)].

$$\underset{\mathbf{3}}{MnCp_2} + TMEDA \xrightarrow[290\ K,\ 2\ d]{toluene} \mathbf{2} \quad (c)$$

Magnetic measurements by NMR methods in solution[6] and ESR investigations[7] showed **1** and **2** to be high-spin complexes.

As in the case of **3**, the Cp signal in the ^{1}H-NMR spectra of **1** is found at higher field than the methyl signal of toluene[9], whereas the signals of the TMEDA ligands in **1** and **2** are shifted downfield (Fig. 1). Because of the paramagnetism of **1** and **2** ($S=5/2$) the δ^{para} values show characteristic temperature dependencies (Fig. 1)[10].

According to an X-ray structure analysis, Mn in **2** forms an η^5- as well as an η^1-bond to the Cp rings (Fig. 2); there is no tilted sandwich structure with two η^5-bonded Cp rings as in the pyridine adduct of the propano-bridged manganocene[11]. The average distance of the central metal from the C-atom of the η^5-Cp ring (250.7 pm, Table 1) is consistent with an ionic bonding[11a]. Surprisingly, the η^1-bonded Cp-ring shows no bond alternation[12] (Table 1), but similar CC bond lengths as in the Cp-ring of the ionic species Na(TMEDA)Cp[13]. Besides the relatively small angle between the Mn–C11 bond and the C11–C15 plane

(100.2°, Table 1) and the angle between the plane C11–C15 and the C11–H bond (13°), a Mn–C11 distance markedly larger than that found for covalent Mn–C bonds is observed, which likewise indicates ionic character of the Mn-η^1-Cp bond. Hence, there are distinct similarities with a section of the chain structure of Cp_2Mn[14]. The two N-atoms of the TMEDA ligand occupy two further coordination sites on Mn[11], resulting in a strongly distorted tetrahedral structure in **2**. The ESR findings on rigid solutions of **2**[7] and the magnetic findings in solution are in agreement with this structure.

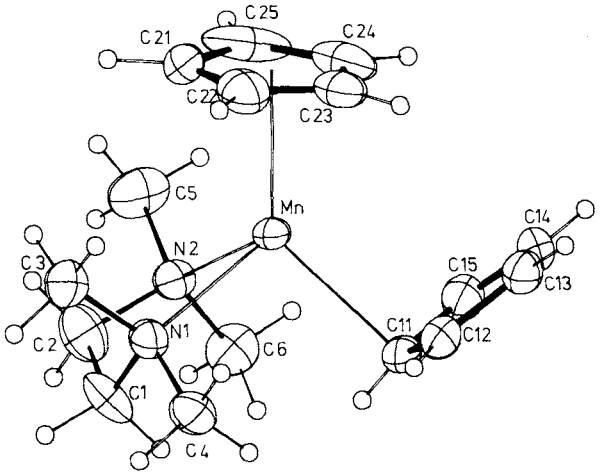

Fig. 2. Structure of Cp_2Mn(TMEDA) in the crystal (ORTEP diagram, thermal ellipsoids at the 30% probability level), Space group $P2_1/n$, $Z=4$, $a=1237.4(3)$, $b=969.4(1)$, $c=1342.3(1)$ pm, $\beta=101.24°$. $R_w=0.038$ (weighting $w=1/2\sigma^2(F_0)$ for 1445 independent reflections with $F_0>2\sigma$; CAD4, Enraf-Nonius, $Mo_{K\alpha}$ radiation). Important bond lengths and angles in Table 1. Maximum deviation of the C-atoms of the Cp rings from "best planes" 0.6 pm. [3] A stirred solution of anhydrous $MnCl_2$ (8.19 g, 65.1 mmol) and TMEDA (9.7 mL, 65.1 mmol) in THF (400 mL) was heated under reflux for 3 h in the absence of air and H_2O. After cooling to 220 K a solution of NaCp (5.13 g, 65.1 mmol) in THF (100 mL) was added dropwise and after 3 h the mixture was allowed to warm to room temperature, evaporated to dryness, and the residue extracted at 350 K with 500 mL toluene. After cooling to 250 K for 3 d, **1** could be isolated as bright green crystals (yield 15.3 g, 86%).

[4] Concomitantly, and independently, *Köhler* et al. have synthesized a dimeric methylcyclopentadienylmanganese(II) chloride stabilized with PEt_3; F. H. Köhler, N. Hebendanz, V. Thewalt, B. Kanellakopulos, R. Klenze, *Angew. Chem. 96* (1984) 697; *Angew. Chem. Int. Ed. Engl. 23* (1984) 721.

[5] The suspension of 5 mmol of **2** obtained according to Reaction (c) was extracted at 340 K with 250 mL toluene (yield: 94.6%). The almost colorless crystalline **2** decomposes to dark brown products in the presence of traces of air.

[6] D. F. Evans, *J. Chem. Soc. 1959*, 2003. Solvent: toluene. **1**: $\mu_{eff}^{corr}=5.9$; **2**: $\mu_{eff}^{corr}=5.5$ B.M.

[7] Solutions of **1** in toluene at 4 K give a strong ESR signal at $g=5.8$ with a ^{55}Mn-HFS and a line interval of 81–84 G as well as weak signals for $g>6$. At 115 K an intense signal appears for $g=2.02$ without HFS. The ESR spectrum of **2** at 115 K contains the characteristic signals of distorted tetrahedra of the type MnA_2B_2 [8]. In liquid solutions, ESR signals without HFS are observed for **1** and **2**: (**1**: $g_{iso}=2.001$; **2**: $g_{iso}=2.010$).

chiral acyloins **2** constitutes one of the most important C–C bond formations[1]; all attempts to synthesize **2** highly stereoselectively via lithiated sulfoxides[2a] or formamides[2b] have hitherto failed; the selectivity achieved is low[2b] or moderate[2a], and the reagents are in some cases difficultly accessible. We report here on the highly stereoselective addition of a crotonaldehyde-d^1 synthon **3** to benzaldehyde using the vinyllithium reagent **5a** obtained from (*S*)-lactic acid.

MEM = $CH_2OCH_2CH_2OCH_3$

Reduction of ethyl (*S*)-lactate with diisobutylaluminum hydride, after protection of the hydroxy group as (2-methoxyethoxy)methyl (MEM) ether, affords the aldehyde **6a**[3], which is converted by a Wittig-Horner reaction[4] into the vinyl sulfide **5b**. This reaction proceeds without racemization, as shown by a comparison of the optical rotations of the ether **6b**, obtained from **5b** by desulfuration with Raney nickel, and of the sample obtained from commercial (*R*)-2-butanol after introduction of the MEM protecting group. The (*Z*)-diastereomer of **5b** is not observed, not even in trace amounts thereof. Metalation of the vinyl sulfide **5b** with *n*-butyllithium in tetrahydrofuran (THF) affords the lithium reagent **5a** – as reprotonation shows, racemization-free; **5a** is then allowed to react in situ with benzaldehyde. The ratio of the diastereomers **7a** and **7b** thus formed in quantitative crude yield can be determined directly from the ^{1}H-NMR spectrum: on using THF/pentane as solvent it is 96 : 4[5]. Separation of the isomers could be achieved by layer chromatography, purification of the excess diastereomer **7a** by column chromatography on neutral aluminum oxide.

Treatment of the crude product **7a/7b** with mercury(II) chloride[6] in aqueous acetonitrile leads directly to the hydroxyenone **4**, whose absolute configuration and optical purity were proven as follows: On reaction of (*R*)-mandelic acid amide **8**[7a] with *n*-propylmagnesium bromide, (*R*)-**9** ($[\alpha]_{578} = -117°$, ethanol) is obtained. Since catalytic hydrogenation of the enone **4** affords the (+)-α-hydroxyketone **9** ($[\alpha]_{578} = +108°$, ethanol), this – and thus also the unsaturated ketone **4** – must be (*S*)-configurated. Hence, the structure **7a** can be assigned to the diastereomer formed in excess on addition of **5a** to benzaldehyde. The optical purity of (*S*)-**9** (92%) is consistent with the NMR spectroscopically determined diastereomeric ratio **7a** : **7b**. Since the occurrence of partial racemization in the reaction of the amide **8** with propylmagnesium bromide cannot, a priori, be ruled out with certainty[7b], the dioxolanes **10a** and **10b**, respectively, were prepared both from (*S*)-**9** as well as (*R*)-**9** by reaction with (*S,S*)-2,3-butanediol; **10a**, and **10b** differ markedly in their ^{1}H-NMR spectra. The acetal **10b** obtained from the amide **8** is free of **10a**, and the isomeric purity of **10a** prepared from **4a** via (*S*)-**9** is at least 95%.

A diastereomeric ratio 95 : 5 is likewise achieved on addition of **5a** to acetophenone. Since (*R*)-lactic acid is now readily obtainable by a biotechnological method[8] either of the two enantiomers of the enones of type **4** are easily accessible.

Experimental

(*S*)-**4**: A mixture of **5b** (0.90 g, 4.40 mmol) and THF (30 mL) was treated at –78 °C under an N_2-atmosphere with 3.9 mL of a 1.5 M solution of *n*-butyllithium in hexane. After 2 hours' stirring at –78 °C a solution of benzaldehyde (0.58 g, 0.55 mmol) in THF (10 mL) was added and the mixture stirred for a further 12 h at –78 °C. After the usual aqueous work-up, 1.37 g (ca. 100%) of the mixture **7a/7b** was obtained. This was dissolved in 40 mL acetonitrile and 20 mL water, treated with 2.42 g (8.9 mmol) $HgCl_2$ and heated under reflux for 1 h. After filtration and washing of the precipitate with ether, washing of the purified filtrate with $NaHCO_3$ solution, NaCl solution, and water, drying, removal of the solvent, and recrystallization of the residue from pentane there remained 0.45 g (57%) (*S*)-**4**. M.p. 54–56 °C ((±)-**4**: m.p. 56–57 °C [9]); the ^{1}H-NMR data are in good agreement with those given in the literature [9]; $[\alpha]_D = +271°$ ($c = 0.59$; $CHCl_3$).

Synthetic Studies on the Elucidation of the Structure and Configuration of Dolastatin 3**

By *Ulrich Schmidt** and *Roland Utz*

Dedicated to Professor Karl Schlögl on the occasion of his 60th birthday

Dolastatin 3, isolated from the Indian Ocean sea hare *Dolabella auricularia*, exhibits strong in vitro antineoplastic activity (P-388 leukemia cells: $ED_{50} = 1 \times 10^{-4}$ to 1×10^{-7} µg/mL). On the basis of the amino acid analysis and mass spectrum, *Pettit* et al.[1], who isolated ca. 1 mg of Dolastatin 3, proposed structure **16** for this compound, without determining its configuration. The (*S*)-configuration of the amino acids was presumed; the opposite "ring direction" (corresponding to **17**) was not ruled out, but was held to be less probable for biogenetic reasons.—Since the natural product is only accessible in small amounts, and with difficulty, its structure and configuration can only be elucidated by comparison with a synthetic product obtained by an unequivocal route.

Characteristic building blocks for the cyclopeptide are two 2-(aminoalkyl)-4-thiazolecarboxylic acids. Analogous compounds with (*R*)-configuration have been found in the cyclopeptides from other lower marine creatures by *Ireland* et al.[2]. Since racemic thiazole derivatives are obtained from thioamides of optically active α-acylamino acids[3], we employed α-acyloxy acids such as **1**, whose thioamides **4** afford optically active hydroxyalkylthiazolecarboxylates such as **6** and **7** with ethyl bromopyruvate (Scheme 1). This thiazole synthesis proceeds without racemization; thus, (1*S*,2*S*)-2-methyl-1-thiocarbamoylbutyl acetate ("(2*S*,3*S*)-2-acetoxy-3-methylvaleric acid thioamide") forms no diastereomeric thiazole with (1*R*,2*S*)-configurated side chain.

Mitsunobu reaction[4] of **7** leads to the azidoalkylthiazolecarboxylic acid ester **8**, which can be readily hydrogenated to the amino compound **9**. Since introduction of the azide functionality proceeds with inversion, but the optically active hydroxy acids (precursors of **1**) are formed from α-amino acids with retention of configuration, (*R*)-aminoalkylthiazolecarboxylic acid esters are obtained from natural (*S*)-amino acids. Ethyl (*R*)-2-(1-amino-3-cyanopropyl)-4-thiazolecarboxylate **9** is thus accessible from (*S*)-glutamic acid.

As shown in Scheme 1, **9** is allowed to react with an *R*-Val derivative to yield **10**, to which the dipeptide Boc-*R*-Pro-*R*-Leu is attached. The compound **11** thus obtained is coupled (after hydrolysis of the ethyl ester group) to ethyl 2-aminomethyl-4-thiazolecarboxylate to afford **13**. The pentafluorophenyl ester **14** prepared from this serves as a linear educt for the ring closure. After cleavage of the Boc group cyclization proceeds upon slow injection of the

tris(trifluoroacetate) of **14** into a solution of pyrrolidinopyridine (molar ratio 1:3) in alcoholic dioxane at 95°C (70% yield). Hydrolysis of the nitrile **15** to the amide furnished a product **16**[5], which is *not identical* to Dolastatin 3. The spectra[6] of the seven other diastereomers are also not consistent with the data published for Dolastatin 3.

In an analogous way, we have also synthesized the eight diastereomers having reverse order of the amino acids in

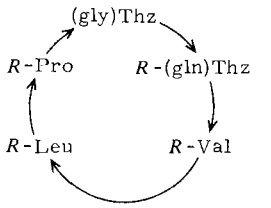
16



R,R,R,R-17

the ring (**17**)[7]. These compounds were also not identical with Dolastatin 3. The following characteristic differences in the NMR spectra of the 16 diastereomers and that of Dolastatin 3 were found: 1) Different chemical shift and coupling for the amide protons, 2) different chemical shift and coupling for the two methylene protons in the 2-position of a thiazole moiety, 3) consistently greater difference in the chemical shift of the two 5-thiazole protons, and 4) different chemical shift for all the methyl protons.

The structure proposed for Dolastatin 3 is therefore not correct. The scheme described for the synthesis of 16 isomers with the structures **16** and **17** in good yields may be used for the economic synthesis of other isomers with different amino acid sequences.

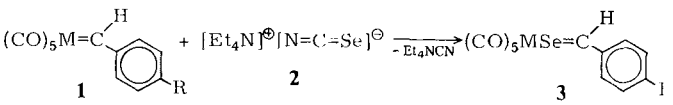
Unusual Equilibrium between η^1- and η^2-Isomers of Selenobenzaldehyde Complexes**

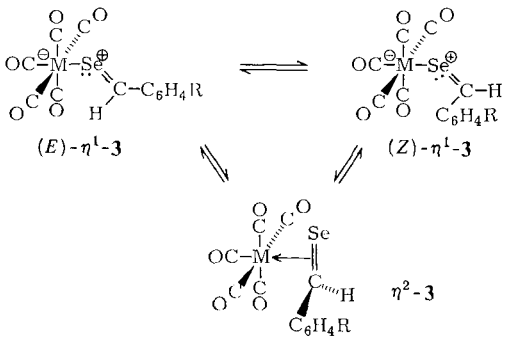
By *Helmut Fischer**, *Siegfried Zeuner*, and *Jürgen Riede*

Seleno- and telluroketones are not stable in the monomeric form; since complexation stabilizes these reactive species, they can be synthesized by reaction of pentacarbonyl(diarylcarbene)chromium and -tungsten with seleno- and tellurocyanate in the ligand spheres of chromium and tungsten, respectively[1,2]. Having recently been able to isolate and characterize benzylidene(pentacarbonyl)chromium and -tungsten complexes[3], it should also be possible to prepare complexes with selenobenzaldehyde, which is likewise unstable in the free form. $(CO)_5W{=}C(H)Ph$ **1a**, which is generated in situ by reaction of $[Et_4N][(CO)_5W{-}C(H)(OMe)Ph]$ with $HBF_4\cdot Et_2O$ at −90°C in dichloromethane, reacts instantaneously with $[Et_4N]NCSe$ **2** in a CH_2Cl_2/pentane mixture at −78°C with formation of $(CO)_5W[Se{=}C(H)Ph]$ **3a**[4].



a, M = W, R = H; **b**, M = W, R = OMe; **c**, M = W, R = CF_3; **d**, M = Cr, R = OMe

Crystals of **3a** are stable for a short while at room temperature. In solution, **3a** is present in an equilibrium of three isomers in which the Se=C(H)Ph-ligand is η^1- or η^2-bonded. Additionally, the η^1-isomer, can either be (*Z*)- or (*E*)-configurated.



The IR spectrum shows nine absorptions of the η^1- and η^2-isomers in the ν(CO) region (hexane): η^1-**3a**: 2068 (w), 1957 (m), 1950 (s), 1944 (m) cm^{-1}; η^2-**3a**: 2096 (s), 2027 (m), 2000 (s), 1985 (vs), 1975 (s) cm^{-1}. The intensity distribution and band positions of the η^1-**3a** absorptions correspond very closely to those of $(CO)_5W(Se{=}CPh_2)$, in which the $Se{=}CPh_2$-ligand is exclusively η^1-bonded. Since Se=C(H)Ph is a poorer σ-donor/π-acceptor than $Se{=}CPh_2$, η^1-**3a** absorbs at somewhat shorter wavelengths. The IR bands of η^2-**3a** lie in a region in which η^2-alkene and -alkyne complexes, e.g. $(CO)_5W(H_2C{=}CH_2)$ and $(CO)_5W(HC{\equiv}CH)$[5], also absorb. On cooling the solution of **3a**, the intensities of the bands of the η^1-isomers decrease, and those of the η^2-isomer increase. That is, the equilibrium (in hexane at room temperature: $K=[\eta^1\text{-}\mathbf{3a}]/[\eta^2\text{-}\mathbf{3a}]=0.2$) shifts in favor of the η^2-form with decreasing temperature. The temperature dependence of the equilibrium constant $K([\eta^1\text{-}\mathbf{3a}]/[\eta^2\text{-}\mathbf{3a}])$ in CH_2Cl_2 yields an enthalpy difference ΔH of 6.6±0.9 kJ/mol. A lower polarity of the solvent also favors the η^2-form.

The ^{1}H-NMR spectrum of **3a** (solvent and standard: CD_2Cl_2) at room temperature shows a multiplet at δ=7.4 for the phenyl protons, as well as a singlet at δ=8.65 for the aldehyde proton (rapid interconversion of the isomers). On cooling, this signal broadens and, eventually, disap-

pears at ca. −65 °C; then, below −80 °C, a singlet appears at $\delta = 8.2$, which we assign to the η^2-form. A singlet for the aldehyde proton of the η^1-form could not be observed, either because of too low a concentration of the η^1-form—<8% at −80 °C (extrapolated)—or because the signal is excessively broadened due to the *E/Z* isomerization. The ^{13}C-NMR spectrum of **3a** is also temperature-dependent: At −80 °C (CD_2Cl_2), the resonance of the C(Se)-atom appears at $\delta = 74.0$ (for comparison, C(Se) in $(CO)_5W(\eta^1$-$Se{=}CPh_2)$: 240.0[1], $[\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2(\mu_2\eta^2\text{-}Se{=}CH_2)]$: 56.7[6]); at −15 °C on the other hand, a C(Se)-signal can no longer be observed.

η^1-**3a** and η^2-**3a** also differ in the UV/VIS spectrum: η^1-**3a** is deep blue ($\lambda_{max} = 597$ nm), like the η^1-selenoketone complexes, whereas η^2-**3a** is yellow-green ($\lambda_{max} = 425$ nm). Hence, on cooling from room temperature to −78 °C, a solution of **3a** in hexane changes its color reversibly from blue to yellow-green.

The X-ray structure analysis of a crystal of **3a** obtained from hexane at −78 °C shows the η^2-coordination of the Se=C(H)Ph ligand (Fig. 1). The C–Se distance is only slightly shorter than the sum of the carbon and selenium single-bond radii. The selenobenzaldehyde ligand is almost coincident with O4-C4-W-C5-O5, CO(4) and CO(5) are bent away from it, while CO(2) and CO(3) are bent towards it.

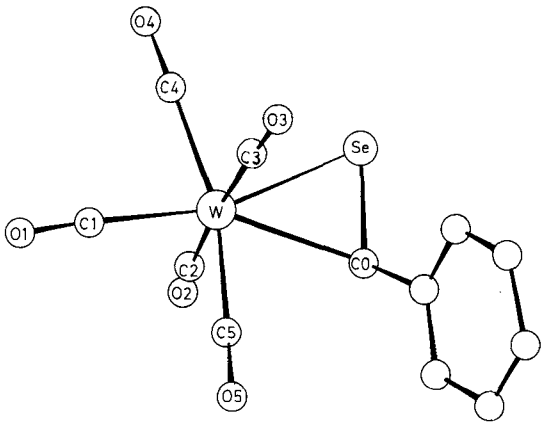

Fig. 1. Structure of the η^2-isomer in the crystal of the selenobenzaldehyde complex **3a**. The asymmetric moiety contains two independent molecules (M1, M2) which, however, on taking the standard deviations into consideration, do not differ significantly. Selected bond lengths [pm] and angles [°], M1 [M2]: W-Se 263.5(2) [263.7(2)], W-C0 240.9(14) [238.4(15)], C0-Se 186.4(13) [187.6(15)], Se-W-C0 43.10(32) [43.51(35)], W-Se-C0 61.98(41) [(61.05(45)]; dihedral angle between the W-Se-C0 and C1-C4-C5 planes: 5° [5°] [7].

The *para*-substituted selenobenzaldehyde complexes of tungsten, **3b** and **3c**, as well as that of chromium, **3d**, can also be prepared in a similar way to that of **3a**[8]. Other than with **3a**, in the case of **3b** the η^1/η^2-equilibrium already lies largely on the side of the η^1-isomer at room temperature, even in apolar solvents, while in the case of **3d**, the η^2-isomer cannot even be detected IR spectroscopically. In **3c**, the η^1-isomer is present only to the extent of <2% in the equilibrium at room temperature in hexane. Thus, increasing donor strength of the aryl groups ($C_6H_4CF_3 < C_6H_5 < C_6H_4OMe$) and replacement of the aldehyde H-atom by an aryl group[1] favor the η^1-isomer over η^2-isomer.

$[(NH_3)_5Ru^{15}NN]^{2\oplus}$ shows an η^1-η^2-η^1-isomerization sequence[9]; in the case of $(\eta^5\text{-}C_5H_5)_2Ti(N_2)$ the η^1- and η^2-isomers could be detected alongside each other below −62 °C by NMR spectroscopy[10]. Generally, $L_nM(XY)$ complexes ($XY = N_2$, O_2, $S{=}CR_2$, $Se{=}CR_2$, $RP{=}CR_2$ etc.) are present *either* in the η^1- *or* the η^2-form. η^1/η^2-Equilibria, which are of importance in a series of stoichiometric and catalytic reactions[11], can now be measured directly as a function of the central metal, the substituents, the solvent, and the temperature.

[4] Procedure: All operations were carried out under N_2 and in anhydrous solvents. A solution of $[Et_4N][(CO)_5W{-}C(H)(OMe)Ph]$ (1.0 g, 1.7 mmol) in CH_2Cl_2 (30 mL) was treated at −90 °C with a solution of HBF_4 (54% in Et_2O) in CH_2Cl_2 (10 mL). After one minute's stirring the deep red solution was treated, firstly with 100 mL pentane (cooled to −90 °C), and then with 0.4 g (1.7 mmol) $[Et_4N]NCSe$ in 7 mL CH_2Cl_2. The resulting deep blue solution was chromatographed at −75 °C with pentane/CH_2Cl_2 (3:1) on silica gel and the green zone eluted. The green residue remaining after removal of the solvent was recrystallized from pentane at −30 °C. Yield 500 mg (60%).

A Novel Entry to 17α-Bromo- and 17α-Iodoethynyl Steroids

By *Helmut Hofmeister**, *Klaus Annen*, *Henry Laurent*, and *Rudolf Wiechert*

The 17α-ethynyl group in steroids is decisive for their hormonal action upon oral administration[1]. Steroids containing a substituted ethynyl group, e.g. 17α-chloroethynyl derivatives, are also biologically active[2]. 17α-Bromo- and 17α-iodoethynyl compounds of the estradiol series—after exchange with radioactive iodine or bromine—have recently attracted interest for radiological diagnoses in the case of hormone-dependent tumors[3].

Whereas 17α-chloroethynyl steroids[2,4] can be prepared by reaction of 17-keto compounds with lithium chloroacetylide, unfortunately the same synthetic strategy fails in the case of the analogous bromo- and iodo-derivatives **2** and

[*] Dr. H. Hofmeister, Dr. K. Annen, Dr. H. Laurent,

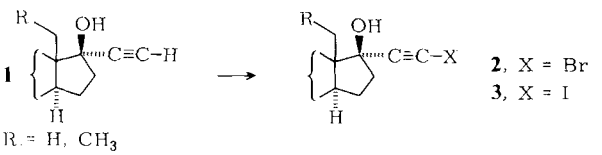
Forschungslaboratorien der Schering AG Berlin/Bergkamen
Müllerstrasse 170—178, D-1000 Berlin 65

3, respectively. Suitable educts for the synthesis of these analogues, however, are the 17-ethynyl alcohols **1**, whose ethynyl H-atoms can be replaced by a bromine or iodine atom via alkali metal acetylide[2,4,5]. The ethynyl H-atom in steroids can only be substituted by iodine directly, by means of the iodine-morpholine complex[3,4,6]. The hypohalide method[7] frequently employed in acetylene chemistry is unsuitable for the hydrogen/halogen exchange in the case of ethynyl steroids because of the strongly alkaline conditions and, in some cases, the poor solubility of the steroids. The disadvantage of the procedures used so far is that hydroxy and carbonyl groups in the molecule have to be protected. We have now found a simple method for the conversion of the 17α-ethynyl alcohols **1** into the 17α-haloethynyl alcohols **2** and **3** (Table 1), which does not require any protecting groups whatsoever.



When a solution or suspension of the 17-ethynyl compound **1** is allowed to react with equimolar amounts of *N*-bromo- or *N*-iodosuccinimide in the presence of catalytic amounts of silver nitrate, complete conversion into the 17α-haloethynyl compounds **2** and **3**, respectively, usually takes place within 60 min. 1,3-Dibromo-5,5-dimethylhydantoin may be used instead of *N*-bromosuccinimide; *N*-bromoacetamide reacts to some extent with **1**, while bromine and iodine[8] do not react at all. The halogenation reactions are generally carried out in acetone, but, with exception of dimethyl sulfoxide, other solvents such as tetrahydrofuran, ethanol, or 1-methyl-2-pyrrolidone can be used. Suitable catalysts are any of the silver salts which dissociate in the solvent (silver salt : steroid ratio ≈ 1 : 10).

Remarkably, *N*-chlorosuccinimide and other *N*-chloro compounds do not react under the above mentioned conditions. The method can also be used in the case of other alkynes (see the last two examples[9–11] listed in Table 1). We assume that the silver ions activate the terminal hydrogen atom for a hydrogen exchange by formation of a π-complex with the triple bond[12]; in the absence of catalyst, *N*-bromosuccinimide does not react with alkynes.

Experimental

A solution (or suspension) of the alkyne (3.0 mmol) in acetone (20 mL) is treated at room temperature with 3.5 mmol *N*-bromo- or *N*-iodosuccinimide and 50 mg silver nitrate. After 15—60 min (Table 1), the reaction mixture is poured with stirring into ice-water and the precipitate that is formed is filtered off and dissolved in ethyl acetate. The resulting solution is washed with water, dried, evaporated to dryness in vacuo, and the final product is purified by crystallization.

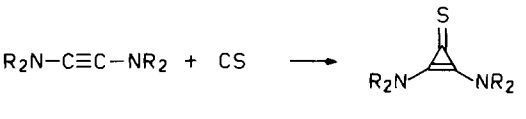
[2+1]-Cycloadditions of Ynamines and Ynediamines to Carbon Monosulfide**

By *Adolf Krebs**, *Andreas Güntner*, *Alexander Senning**, *Ejner K. Moltzen*, *Kenneth J. Klabunde*, and *Michael P. Kramer*

Until recently carbon monosulfide (CS) was little used as a reagent in organic synthesis, its principal application being insertion reactions into S–Cl bonds[1,2]. We wish to report the first [2+1]-cycloaddition of alkynes to CS, yielding the cyclopropenethiones **2a**, **b** and **5**. Since the resonance stabilization of bis(dialkylamino)cyclopropenethiones[3] should make itself felt even in the transition state of the addition reaction, we used the extremely electron-rich ynediamines **1a**, **b** and the ynamine 1-diethylamino-1-propyne **4** as scavengers.

Carbon monosulfide, generated by decomposition of CS_2 in a discharge tube (8000 V) at 10^{-2}–10^{-1} torr[1], was passed over the surface of an approximately 1 M solution



1a: R = CH_3 **2a**: R = CH_3
b: R = C_2H_5 **b**: R = C_2H_5

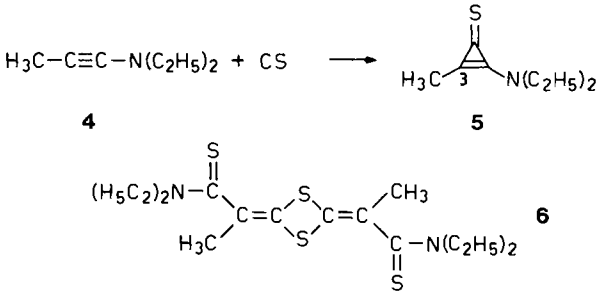
of **1a**, **b** or **4** in toluene at −78 °C. Use of a cold trap (−95 °C; at lower temperatures solid CS freezes out) does not separate out undecomposed CS_2 completely; thus the yields of CS adducts were diminished by reaction of **1a**, **b** or **4** with CS_2.

Compound **2a** was obtained in 67% yield (relative to **1a**; m.p. = 147 °C) and identified by comparison with an authentic sample[4]; **2b** (32%; m.p. = 49 °C) was identical with a sample prepared by treatment of the corresponding cyclopropenone **3**[5] with P_4S_{10}[6].

From the reaction of CS with **4** we obtained the novel cyclopropenethione **5** (24%; m.p. = 51–53 °C), which was characterized by spectroscopy and elemental analysis[7]; in addition **4** and CS_2 formed the known desaurin **6**[8].



4 **5**

6

With diphenylacetylene only polymerization of CS occurred[1].

ate carbonyls even in media containing ethanol or water (70 to 220 mol protic solvent per mol Mo=C compound)[1]; the question now arises whether alkyl-transition metal compounds also exist which are able to alkylate carbonyls in alcoholic or aqueous media[2]. Nucleophilic alkylating reagents which are inert towards OH groups would be of particular interest for the alkylation of hydroxyaldehydes and hydroxyketones.

The chromium(III) compounds **1**[3], which are stable in aqueous solution at room temperature, do not alkylate aldehydes. The alkylchromium(III) reagents **2** and **3** which alkylate aldehydes in tetrahydrofuran (THF)[4] do this also in the presence of ethanol or water. As indicated by a series of experiments with heptanal (Fig. 1), addition of ethanol or water increases even the alkylating effect of the methyl compound **2**. The best yields were obtained in the reactions of the bisallyl compound **4**[5] with heptanal and benzaldehyde in the presence of ethanol. The bis-2-butenyl compound **5** reacts with ethanol (molar ratio 1 : 1) to yield an active species which is stable towards protonolysis.

Scheme 1.

The reactions (Fig. 1, Scheme 2) indicate that, despite a 2—10 fold excess of protic solvent (relative to Cr-alkyl residue; allyl and 2-butenyl = special alkyl), aldehyde can still be alkylated in high yield.

The finding that addition of 1–3 mol protic solvent maximizes the yield (or for reagent **5** increases the yield, which remains constant upon further addition) indicates that 1–3

solvent molecules are incorporated into the ligand sphere of a reagent molecule, without leading to cleavage of the Cr—C bond. In this respect, THF molecules may be displaced or Cr-ligand-Cr bridges ruptured. Driving force for the reaction is probably the formation of a more stable solvent sheath.

Alkylation of heptanal in ethanol-containing media was effected also by the Ti^{IV} reagents **8** and **9**[5] (Scheme 3). However, ethanol led, not to an increase, but rather to a decrease in the yield of alkylation product. Nevertheless, these experiments indicate that the cleavage of a Ti-alkyl bond by alcoholic groups is also surprisingly slow compared to the aldehyde alkylation. Similar results were found with reagents **10**—**12**[5].

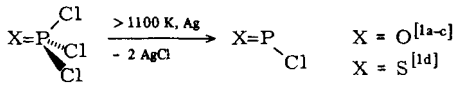
O=P–Cl and S=P–Cl: Gas-Phase Ionization**

By *Michael Binnewies**, *Bahman Solouki*, *Hans Bock**, *Ralf Becherer*, and *Reinhart Ahlrichs**

O=P–Cl and S=P–Cl[1] each contain 18 valence electrons and are therefore iso(valence)electronic with compounds exhibiting bent structures[2] such as ONCl, OSO, OOO, FCF, and NSF. They are also of interest as prototype molecules of recently prepared compounds such as the diphosphenes R–P=P–R[3], in which phosphorus of coordination number 2 is kinetically stabilized by bulky substituents. O=P–Cl and S=P–Cl can be prepared in the gas phase by dechlorination of the corresponding trichlorides with silver turnings above 1100 K.



Both compounds have already been detected in the gas phase by mass spectroscopy and their structures elucidated by IR spectroscopy after isolation[1c,e] in an argon matrix at 15 K[1c,e,4]. We report here the PE spectroscopic ionization patterns[5] and their assignments based on ab initio SCF calculations[6].

Upon pyrolysis at 1150 K, the ionization pattern of the starting material $SPCl_3$[7] disappears completely (Fig. 1a, b; cf., e.g., the bands at 10.6, 12.9, and 15.2 eV). The pyrolyzate contains PCl_3, identified by PE spectroscopy as side product[1a,7]; its ionization bands can be eliminated by computer subtraction (Fig. 1b, c).

The He(I)PE spectra of SPCl and OPCl between 9 and 19 eV thus obtained each display six ionization bands, in accord with the reliable (np_E+1s_H) valence-electron counting rule[7] and with the assignment used for the ab initio SCF calculations[6]. Comparison of the corresponding radical cation states (Fig. 1c, d, dotted connecting lines) shows that the smaller effective nuclear charge of the sulfur atom causes a lowering of all ionization energies by approximately 1 eV. From the MO contour-line diagrams (Fig. 1e), the $M^{\odot\oplus}$ ground states $\tilde{X}(^2A')$ of both molecules can be characterized as electron pair ionizations with a major P-contribution. In both cases, a π state $\tilde{A}(^2A'')$ follows, with predominant Cl-contribution in OPCl and S-contribution in SPCl; for the π states at 13.3 and 14.3 eV, respectively, these relations are inverted. The third $M^{\odot\oplus}$ states $\tilde{B}(^2A')$ correspond within the MO picture to the antibonding combinations of the electron pairs $n_{Cl}-n_O$ and n_S-n_{Cl}. In general, the radical cation states of A' symmetry are characterized at low ionization energies by a larger contribution of the electron lone-pairs and at higher energies by σ-bonding electrons[2,6].

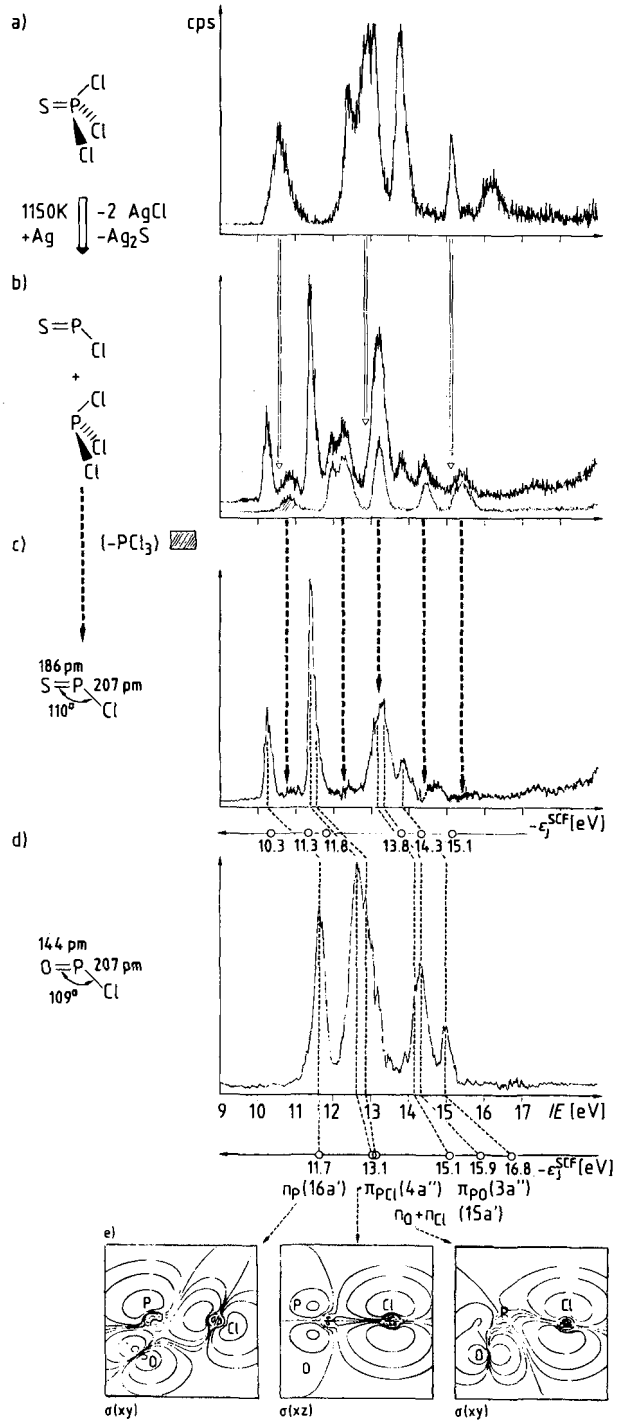


Fig. 1. He(I)PE spectra between 9 and 19 eV of a) $SPCl_3$ at 300 K and b) the product mixture, after reaction with silver at 1150 K, consisting mainly of SPCl and PCl_3 [5]. The PE spectrum c) of SPCl was obtained by computer-subtraction (----→) of the ionization bands of the side product PCl_3 (hatched) [7]. Use of *Koopmans'* correlation $IE_n^v = -\varepsilon_j^{SCF}$ permits assignment of the bands to the ab initio SCF eigenvalues [6]. d) The ionization pattern of OPCl is obtained in an analogous way (subtraction of the PE spectrum of HCl, presumably formed by surface reactions). The assignment is corroborated by comparison with the corresponding states of the radical cation of SPCl as well as by *Koopmans'* correlation with the ab initio SCF eigenvalues [6]. e) The three $M^{\odot\oplus}$ states of lowest energy are characterized by MO contour-line diagrams. The structural data listed for SPCl and OPCl are those calculated for the minimum total energy [6] in each case.

The structural data of SPCl and OPCl calculated for the respective minima of the total energies (Fig. 1) differ only slightly from those of the educts $SPCl_3$ and $OPCl_3$[8]: the influence of the electron pair at the P atom generated by

[**] Gas-Phase Reactions, Part 47. This work was supported by the Länder Hessen, Nordrhein-Westfalen, and Baden-Württemberg, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.— Part 46: H. Bock, P. Rosmus, B. Solouki, G. Maier, *J. Organomet. Chem.*, in press.

chlorine split-off is manifested by contraction of the OPCl angle from 115 to 109° and by that of the SPCl angle from 116 to 110°C. According to the calculations, the P=O and P=S bond lengths are 1—2 pm shorter and the PCl distances 6 pm longer than in the corresponding trichlorides.

The dehalogenation of the oxide chlorides is due to the thermal instability of Ag_2O above 570 K; by this route, numerous other molecules containing central atoms with low coordination number can be prepared, e.g. OPF[1a], $OPBr$[1a], SPF[1a], $OAsCl$[1f], $OSbCl$[1f], and O_2PCl[1g].

[5] PE spectrometer: Leybold Heraeus UPG 200 (resolution 20 meV, calibration with $^2P_{3/2}(Ar) = 15.76$ eV). The high-temperature inlet system (cf. B. Solouki, H. Bock, R. Appel, A. Westerhaus, G. Becker, G. Uhl, *Chem. Ber. 115* (1982) 3747) contains the silver turnings. PE spectra were recorded and subtracted using a PDP 11/40 computer.

[6] The ab initio SCF calculations were carried out at the Hochschulrechenzentrum Karlsruhe, using basis sets of "double zeta" quality augmented by d-polarization functions. The following basis sets were employed: For O (9s, 5p, 1d) contracted to (5s, 3p, 1d) with $\eta_d = 1.25$, and for 2nd row elements (11s, 7p, 1d) contracted to (7s, 4p, 1d) with $\eta_d = 0.50$ (P), 0.55 (S), and 0.65 (Cl). The structures calculated for the minima of total energy should be precise to ±2° and ±2 pm. Since in *Koopmans'* correlations, reorganization- and electron-correlation effects are not considered, changes in the sequences in the assignment of energetically closely lying radical cation states cannot be precluded.

[7] For the assignment of the PE spectra of $SPCl_3$ and PCl_3 cf. K. Wittel, H. Bock in S. Patai, Z. Rappaport: *The Chemistry of Functional Groups, Suppl. D*, Wiley, London 1983, p. 1560 and 1563, and literature cited therein.

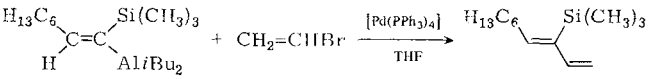
Metal-Catalyzed Carbonylations of Benzyl and Aryl Bromides in the Presence of Aluminum Alkoxides; A Straightforward Ester Synthesis**

By *Howard Alper**, *Shlomo Antebi*, and *James B. Woell*

There has been increasing interest in the use of organometallic complexes as catalysts for reactions involving main-group organometallic compounds[1]. *Negishi* et al.[2] have described the $[Pd(PPh_3)_4]$-catalyzed cross-coupling reaction of α-hetero-substituted alkenylaluminum (and -zinc) compounds with vinyl or aryl halides[3].



Here, we report the first examples of metal-catalyzed reactions of aluminum alkoxides, relatively inexpensive, easy-to-handle compounds which have been used in several syntheses[4–9].

Benzylic bromides react with aluminum ethoxide and carbon monoxide in heptane in the presence of catalytic quantities of 1,5-hexadienerhodium(I) chloride dimer ([1,5-hd]RhCl]$_2$) to afford ethyl esters. This reaction occurs under mild conditions (75°C, 1 atm), is easy to execute and work-up, and product yields are good (Table 1). It is applicable to other aluminum compounds, including aluminum isopropoxide and aluminum *sec*-butoxide, but only starting material was recovered when aluminum *tert*-butoxide was used as the reactant. The corresponding alcohol cannot be substituted for the aluminum alkoxide in these reactions, and the presence of the Rh-catalyst is essential. Chlorides are much less reactive than bromides since, for example, ethyl phenylacetate is formed in 21% yield from benzyl chloride compared with a 100% yield in the case of benzyl bromide.

β-Bromostyrene undergoes carbonylation with aluminum ethoxide in the presence of the Rh-catalyst, affording

the ethyl cinnamate in only 25% yield; however, with the bimetallic catalyst $[(1,5\text{-hd})RhCl]_2/[(PPh_3)_4Pd]$ (1.5 : 1.0) and a reaction temperature of 150°C the yield of ester increases to 66%. Similarly, aryl bromides such as 1-bromonaphthalene and bromobenzene can be converted into esters in reasonable yields using the bimetallic catalysis system (Table 1), a reaction which does not proceed when only the rhodium(I) or palladium(0) catalyst is used. Alkyl bromides, e.g., 1-bromoheptane, fail to react in the presence of the monometallic or bimetallic catalysts.

Experimental

Carbon monoxide is bubbled through a solution of the Rh-catalyst (0.22 mmol), aluminum alkoxide (2.5 mmol), and halide (2.0 mmol) in 3 mL heptane. The reaction mixture is stirred for 16 h at 75° and then cooled to 0°C. Ether (10 mL) is added, followed by 1 M NaOH (5 mL), and the mixture filtered through Celite. Extraction with ether affords the crude ester, which is purified by flash chromatography. In the case of the bimetallic catalyst, $[(1,5\text{-hd})RhCl]_2$ (0.22 mmol) and $[(PPh_3)_4Pd]$ (0.15 mmol) are used.

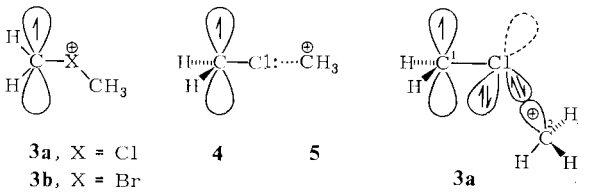
Reactivity of $CH_2{-}X{-}CH_3^{\oplus\odot}$ (X = Cl, Br) with Electrophiles and Nucleophiles in the Gas Phase, a Fourier Transform Ion Cyclotron Resonance Investigation**

By *Thomas Weiske, Hans van der Wel, Nico M. M. Nibbering,* and *Helmut Schwarz**

Radical cations of type **1**, also called ion/dipole complexes in the literature and whose neutral counterparts **2** are unknown in many cases, appear to play a central role as intermediates not only in unimolecular decomposition reactions, but also in the formation of organic molecules in interstellar space[1]. Among the numerous complexes that have become known so far, the non-classical halonium radical ions **3** which are accessible by dissociative ionization (electron impact ionization of methyl chloro- or bromoacetate)[2] deserve special attention, since they exhibit unusual structural features. According to ab initio calculations[2b] **3a** can best be described in terms of a complex consisting of the chloromethyl radical **4** and a methyl cation **5**, whereby the electrophile **5** interacts with a non-bonding electron pair of the halogen atom of **4**. In the complex **3a** the spin is localized predominantly on C-1 (0.98 electrons), whereas the positive charge is distributed mainly over C-2 and its hydrogen periphery. The two C–Cl bonds are unequal: C^1–Cl (1.76 Å, 6-31G*) is about 0.1 Å shorter than C^2–Cl.

1 **2**

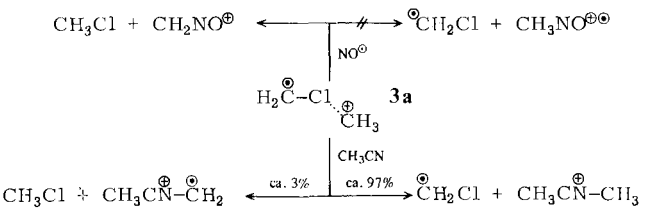
X: Halogen, OH, OAlkyl, SH, NH_2, PH_2
R^1, R^2: H, Alkyl, Halogen
R^3: H, Alkyl



3a, X = Cl
3b, X = Br

4 **5** **3a**

The description of **3** as an ion/dipole complex would suggest that **3** undergoes well-defined reactions with nucleophiles and electrophiles in ion/molecule reactions. The $CH_3^{\oplus}$ ion should be transferred preferably to nucleophiles, the $CH_2^{\oplus\odot}$ radical cation to electrophiles. This prediction is confirmed neatly in a Fourier transform ion cyclotron resonance (FT-ICR) experiment[3]: At reaction times of $t = 1.5$ s CH_3CN extracts from **3a** a $CH_3^{\oplus}$ ion for ~97% and a $CH_2^{\oplus\odot}$ group for only ~3%; the electrophile $NO^{\odot}$, on the other hand, induces exclusively $CH_2^{\oplus\odot}$ transfer (Scheme 1). Similar product ratios are found when one extrapolates to $t = 0$. A completely analogous reactivity is shown by **3b**, which transfers a $CH_3^{\oplus}$ group to CH_3CN to the extent of ~95% (ca. 5% transfer of $CH_2^{\oplus\odot}$), but only the $CH_2^{\oplus\odot}$ radical cation to $NO^{\odot}$[4].



Scheme 1.

$NO^{\odot}$ also reacts to a slight extent with $C_2H_5X^{\oplus\odot}$ (X = Cl, Br) by electron transfer to give $NO^{\oplus}$; we assume, however, that **3** does not participate in this reaction, but rather the isomer $CH_3CH_2X^{\oplus\odot}$, which could be formed by thermolysis of the acetate in the proximity of the hot fila-

ment, and subsequent ionization. This interpretation is supported by the observation that the molecular ion generated by direct ionization of CH_3CH_2X (X = Cl, Br) reacts with $NO^{\odot}$ exclusively by electron transfer. Thermally induced processes could also be responsible for the $C_2H_5X^{\oplus\odot}$ ions (X = Cl, Br) generated from the esters transferring a proton to CH_3CN, a reaction which also occurs in the case of the directly generated $CH_3CH_2X^{\oplus\odot}$ species.

Preliminary investigations on the ion/dipole complex $H_2\overset{\odot}{C}-\overset{\oplus}{X}H$ (X = Cl, Br) revealed that its reactivity corresponds completely to that of its higher homologs **3**. **6** reacts with bases such as CH_3CN, CH_2O, H_2O or CF_2O by proton transfer from the X–H group, whereas $CH_2^{\oplus\odot}$ transfer takes place in the reaction with $NO^{\odot}$.

Experimental

The FT-ICR studies were carried out on a home-built FT-ICR mass spectrometer [3a, b] under the following conditions [3c, d]: Total pressure 10^{-4}–10^{-5} Pa (same partial pressures of the individual components in each case). In a typical experiment positive ions were generated by an electron beam pulse (pulse duration 5 ms, energy 15 eV, emission current 500 nA). Positive ions were trapped in the cubic ICR cell (15.6 cm^3) at a magnetic field of 1.4 T by application of a small positive potential (+1 V) to the trapping plates. The ions to be investigated were isolated first by creation of a notch in the wave-form of the excitation pulse [3e, f] and then their reactions with the neutral molecules were studied.

Iron Clusters with Coupled Phosphido-Phosphane Bridges**

By *David J. Brauer, Sibbele Hietkamp, Herbert Sommer,* and *Othmar Stelzer**

Ditertiary phosphanes $R_2P-CH_2-PR_2$ are able to bridge metal-metal bonds to form an M_2P_2C five-membered ring (**A**)[1]. Until now, no example of ring systems of this type or of chain-like complexes **B**[2] were known with the PH-functional ligands R_2P-CH_2-PRH and $RHP-CH_2-PRH$. Both binuclear complexes are of interest for the synthesis of ligand-stabilized clusters since the $H-P-CH_2-P$ skeleton can insert a third metal atom between P and H to form **C**. The small distance of the metal atoms in **C** favors their linkage to afford cluster **D**.

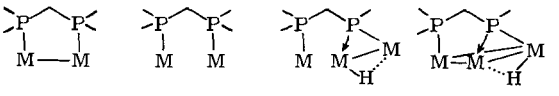
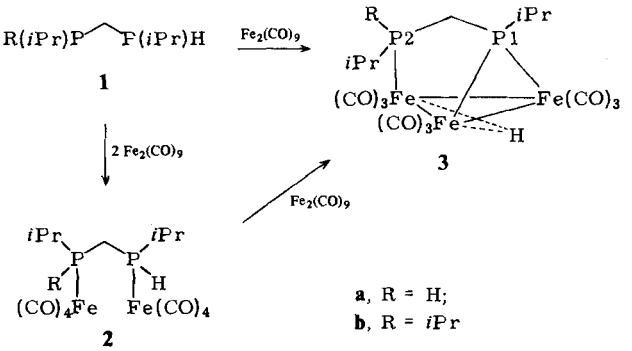
[**] Linear Oligophosphaalkanes, Part 8.—This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.—Part 7: H. Sommer, S. Hietkamp, O. Stelzer, *Chem. Ber.*, in press.

The phosphido-phosphane group $RR'P-CH_2-PR$ (R' = R, H) is a novel bridging unit for trinuclear clusters **D**, and is functionally related to other known μ_3-ligands[3].



Clusters **3a** and **3b** (type **D**) (see Table 1) are formed spontaneously when ligands **1a** and **1b**[4], respectively, are allowed to react with $Fe_2(CO)_9$ in a molar ratio of 1:6. As intermediates the orange, binuclear metal complexes **2a** and **2b** (type **B**) can be isolated[5].



3a and **3b** (intense violet) exhibit $^{31}P\{^1H\}$-NMR spectra (32.2 MHz, 85% H_3PO_4 ext.) of type AB with chemical shifts and coupling constants for the P–C–P system typical of μ_2-phosphido and Fe–P(*i*Pr)R groups (R = H, *i*Pr): δP2 **3a**: 37.8, **3b**: 55.2; δP(1) **3a**: 201.2, **3b**: 189.5, ^2J(PP) **3a**: 86.5, **3b**: 79.2 Hz. The ^{1}H-NMR signals for the H atoms bonded to Fe at $\delta = -19.3$ (**3a**) and -22.5 (**3b**) are split into doublets of doublets by coupling to the phosphorus atoms 1 and 2. J(PH) **3a**: 47.6, 8.9, **3b**: 28.0, 17.5 Hz. In the $^{13}C\{^1H\}$-NMR spectra of **3a** and **3b**, asymmetry and pseudoasymmetry effects lead to doubling of the number of lines for the Me groups of the *i*Pr substituents on P1 (Table 1).

Table 1. $^{13}C\{^1H\}$-NMR spectra of **3a** and **3b**, δ-values (20.0 MHz, CD_2Cl_2, TMS int.). Coupling constants [Hz] in parenthesis; (A) and (B) refer to the *i*Pr groups at P2 and P1, respectively.

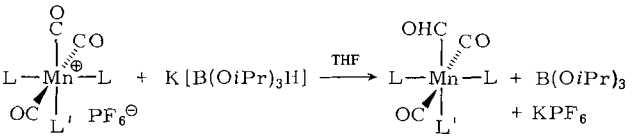
Stable Formylmanganese Complexes**

By *Heinz Berke**, *Gottfried Huttner*, *Olaf Scheidsteger*, and *Gertrud Weiler*

Formyl complexes have been postulated as intermediates in catalytic cycles leading to homogeneous hydrogenation of CO[1–3]. Until now, only neutral η^1-formyl complexes of heavy transition metals could be isolated[4–7]; neutral formyl compounds of 3d metals are particularly unstable and have been detected only by spectroscopy[8,9]. The prototype of this type of complex, $(OC)_5MnCHO$, has not yet been prepared[10]. We therefore wished to investigate whether a modification of the ligand sphere, e.g. substitution of carbon monoxide by phosphite ligands, stabilizes formyl complexes of this type.

Reaction of the salts of the *trans*-diphosphite- or *mer*-triphosphite-substituted carbonylmanganese cations **1**[11] with potassium hydro(triisopropoxoborate) in tetrahydrofuran (THF) leads to high yields of the isolable formyl complexes **2**[12].



1 **2**

a, L = $P(OPh)_3$, L' = CO; **b**, L = $P(o\text{-}OC_6H_4CH_3)_3$, L' = CO; **c**, L = L' = $P(OPh)_3$

The IR and ^{1}H-NMR spectroscopic data for **2** are consistent with the constitution proposed[13]. The novel formyl complexes are stable; **2a** undergoes decarbonylation above 56°C via a 1st order reaction ($k = 2.12 \times 10^{-4}$ s^{-1}):

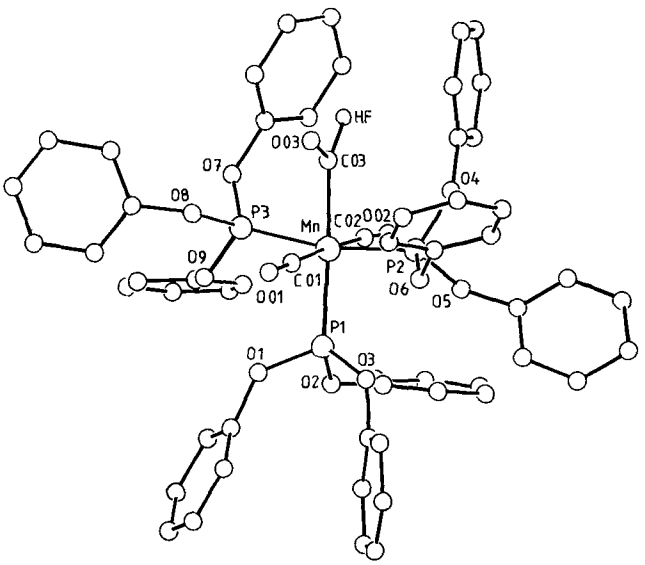


Fig. 1. Structure of **2c** in the crystal. Selected bond lengths [pm] and angles [°]: Mn-C03 204(1), C03-O03 121(1), C03-HF 120, Mn-P1,P2,P3 220.7(3), 220.2(3), 219.7(3); Mn-C02-O03 126.5(5), Mn-C03-HF 131.3, P2-Mn-P3 168.8(1), P1-Mn-P2 94.3(1), P1-Mn-P3 96.8(1), C01-Mn-C02 177.3(2).

Fakultät für Chemie der Universität
Postfach 5560, D-7750 Konstanz (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

The isotope effect ($k_H/k_D = 3.24$) indicates that rupture of the $(C-H)_{formyl}$ bond is rate-determining for the elimination of CO.

X-ray structure analysis of **2c**[14] showed that the Mn atom is almost octahedrally coordinated (Fig. 1). P2 and P3 are displaced slightly towards the formyl group, which in turn is strongly shielded by the phenyl rings of the phosphite ligands. The formyl groups and Mn, CO1, CO2 as well as P1 are coplanar and hence an optimal π-acceptor bond to the formyl ligand arises. The Mn–CO3 bond is ca. 10 pm shorter than the Mn-alkyl[15], but approximately the same length as the Mn-acyl bonds in neutral complexes[16]. The $(C-O)_{formyl}$ bond lengths and $(Mn-C-O)_{formyl}$ bond angles are largely consistent with those in $CpRe(NO)(PPh_3)CHO$[5].

Aryl phosphite ligands can therefore sterically and electronically stabilize formyl complexes of 3d metals. The degree of stabilization depends on the type and arrangement of the ligands in the complex.

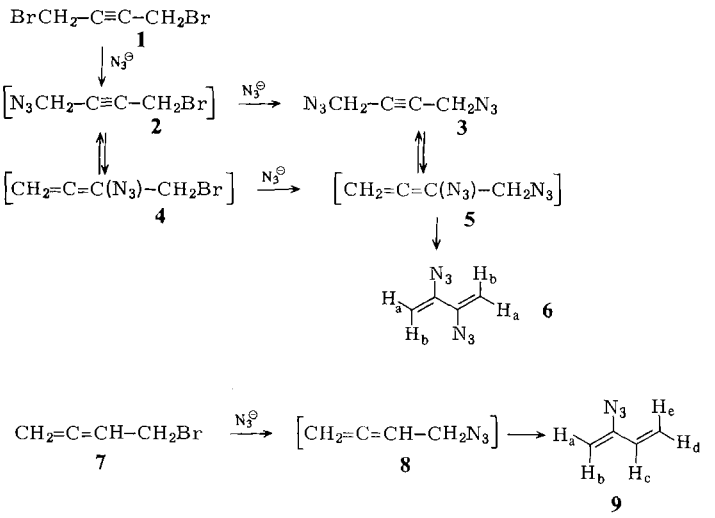
Synthesis of Azidobutadienes**

By *Hanno Priebe**

Unsaturated azides have attracted increasing attention as intermediates in recent years. In the case of vinyl azides the spectrum of reaction covers thermolyses, photolyses, cycloadditions, as well as nucleophilic and electrophilic additions[1]. They are prepared by halogenoazide addition to an olefin and subsequent hydrogen halide elimination[2]. Herein, a convenient route to azidobutadienes is described; for the first time, a N_3-group is directed, via allyl rearrangement, into a vinyl position. Hitherto, only allyl rearrangements in propene and butene systems were known, in which the N_3-group migrates from one allyl position to another[3].



1,4-Dibromo-2-butyne **1** reacts in aqueous ethanolic sodium azide solution with initial formation of 1,4-diazido-2-butyne **3**[4]. When solutions of **3** in benzene, chloroform, or aqueous acetone are heated to 40–70°C, 2,3-diazido-1,3-butadiene **6** is formed. The rate of formation of **6** from **3** was measured NMR spectroscopically between 25 and 70°C[5]. The activation parameters of this first-order reaction are listed in Table 1.

Table 1. Activation parameters of the rearrangement **3** → **6**.

Solvent	lg*A*	E_a [kJ]	$\Delta H^{\ddagger}_{298}$ [kJ]	$\Delta S^{\ddagger}_{298}$ [J/mol K]
70% [D$_6$]acetone/D_2O	8.88	84.82	82.35	−82.90
$CDCl_3$	8.86	85.45	82.98	−83.32
C_6D_6	8.07	80.18	77.71	−98.39

In aqueous acetone, no products were obtained which could have been formed in an ionic reaction. The polarity of the solvent has very little, if any, influence on the rate of the reaction. The negative activation entropy is indicative of an ordered transition state. This means that the two N_3-groups in **3** migrate one after the other in intramolecular

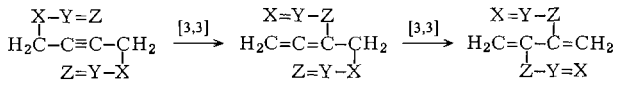
Present address: Institut für Organische Chemie der Technischen Universität, Schleinitzstrasse, D-3300 Braunschweig (FRG)

[**] Organic Azides, Part 4. This work was supported by the Royal Norwegian Council for Scientific and Industrial Research.—Part 3: [4].

reactions to give **6** via intermediacy of 3,4-diazido-1,2-butadiene **5**. The diazide **6** can be most simply prepared in a one-pot reaction by heating **1**[6a] in an aqueous ethanolic solution of sodium azide[7]. In principle, the reaction can proceed both via the diazide **3** as well as via 3-azido-4-bromo-1,2-butadiene **4**. Both reaction paths lead to the diazide **5**. Neither 1-azido-4-bromo-2-butyne **2** nor the compounds **4** and **5** could be isolated.

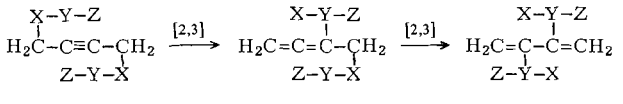
On allowing an aqueous methanolic sodium azide solution of 4-bromo-1,2-butadiene **7**[6b] to stand for 5 d, complete conversion into 2-azido-1,3-butadiene **9** takes place. **9** is most conveniently prepared by reaction of **7** with tetramethylguanidinium azide[8] in sulfolane. The postulated intermediate 4-azido-1,2-butadiene **8** could not be isolated; apparently it rapidly rearranges to the vinyl azide **9**.

The reaction **3**→**6** is a hetero-Claisen rearrangement (Scheme 1); this rearrangement is also known in the case of the hydrocarbon analogue (XYZ = $-CH_2-CH=CH_2$).



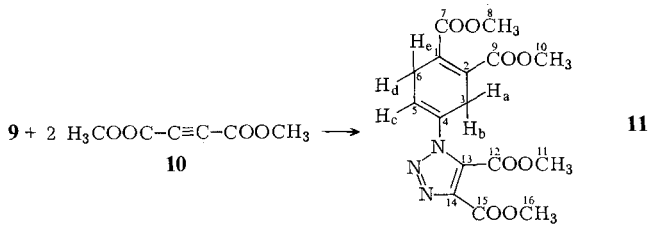
Scheme 1. XYZ = N_3.

A related reaction is the sulfenate ester rearrangement (Scheme 2)[14]. Such reactions open up a convenient entry to 2,3-disubstituted 1,3-butadienes.

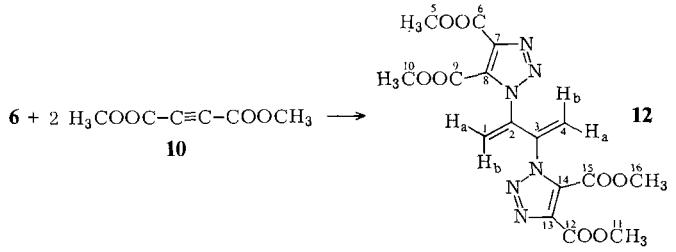


Scheme 2. XYZ = −O−S−Ph.

Since dimethyl acetylenedicarboxylate **10** reacts with azides to give 1,2,3-triazoles and with 1,3-butadienes to give 1,4-cyclohexadienes[10], the azides **6** and **9** were allowed to react with this reagent (Scheme 3). On allowing an etheral solution of the monoazide **9** and the dienophile



11



12

Scheme 3. Reaction of the azides **6** and **9** with dimethyl acetylenedicarboxylate **10** to give the adducts **11** and **12** [11, 12], respectively. Arbitrary numbering for assignment of the ^{13}C-NMR data.

10 (excess) to stand at room temperature for 6 months, the bisadduct **11** crystallized out[11]. Under the same conditions, the diazide **6** likewise only adds two equivalents of **10**; in the product **12**, the butadiene moiety is *trans*-configurated, thus hindering a Diels-Alder reaction.

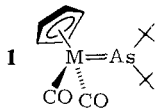
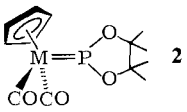
Novel Synthesis of Complexes with Metal-Phosphorus Double Bonds**

By *Elisabeth Gross, Klaus Jörg, Klaus Fiederling, Axel Göttlein, Wolfgang Malisch**, and *Roland Boese*

As recently shown for a series of compounds, transition-metal-substituted phosphanes, arsanes, and stibanes $Cp(CO)_3M-ER_2$ (E = P, As, Sb; M = Cr, Mo, W) can be decarbonylated to $Cp(CO)_2M=ER_2$ complexes[1,2]. However, the M-E double bonds are only isolable provided that are protected by bulky ligands R[3] and CO elimination can be easily induced thermally. In this way, **1a**, **b**[1] and **2a**, **b**[4,5] were obtained, whereas the precursor of **2c** is transformed into a binuclear complex upon decarbonylation[4].



a, M = Mo; **b**, M = W



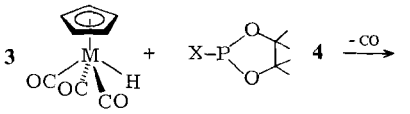
a, M = Cr; **b**, M = Mo; **c**, M = W

Important for the extension of this novel class of compounds are, therefore, mild synthetic methods. One possibility is 1,2-elimination at phosphane complexes having functionalized metal and phosphorus atoms:

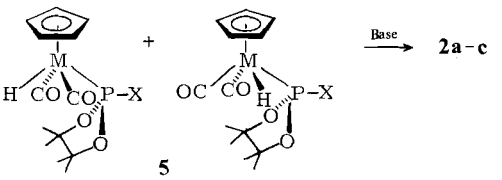
$$M(X)-P(Y) \longrightarrow M=P + XY$$

Ideal precursors are the complexes **5a**—**e**, which can be readily prepared as a mixture of the cis- and trans-isomers by CO substitution from **3a**—**c** and **4a**, **b**. Addition of the base Et_3N or $Me_3P=CH_2$ in benzene at room temperature leads, within minutes, via elimination of HCl or Me_2NH, to **2a**—**c** having an M-P double bond; **2c** could previously not be isolated, and **2c**, **b** are formed in higher yields than via the decarbonylation route[4].

X-ray structure analysis of **2c** (Fig. 1)[7] indicates that the phosphorus atom has trigonal-planar coordination (sum of angles 360°) and that the dioxaphospholane group is arranged perpendicularly to the cyclopentadienyl- and $M(CO)_2$-plane[8]. This orthogonal arrangement was expected, since **2c** is related electronically to the complex ion $[Cp(CO)_2Fe=CR_2]^{\oplus}$, for which theoretical considerations predict this kind of orientation. The W1-P1 distance of 2.181(1) Å is even shorter than the value expected for a W—P double bond (2.26 Å)[9]. A further proof of the sp^2-



a, M = Cr; **b**, M = Mo; **c**, M = W **a**, X = Cl; **b**, X = NMe_2



a, M = Cr, X = Cl; **b**, M = Mo, X = Cl; **c**, M = W, X = Cl; **d**, M = Mo, X = NMe_2; **e**, M = W, X = NMe_2

hybridization of the phosphorus atom in **2c** is provided by the coupling constant J_{PW}, which, relative to that in $Cp(CO)_3W-POCMe_2-CMe_2O$, containing an sp^3-hybridized phosphorus atom increases from 5 to 847 Hz (!). This corresponds to a significant increase in the s-electron density at the phosphorus atom and in the W—P bond.

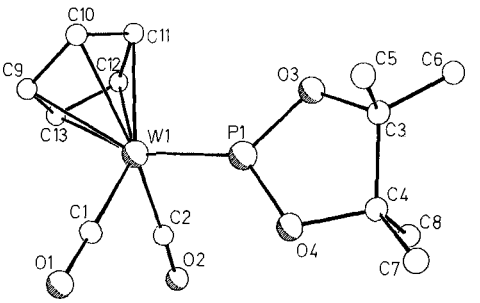


Fig. 1. Structure of **2c** in the crystal. Hydrogen atoms have been omitted for the sake of clarity. Selected bond lengths [Å] and angles [°]: W1-P1 2.181(1), P1-O3 1.619(3), O3-C3 1.458(6); W1-P1-O3 132.3(1), W1-P1-O4 132.6(1), O3-P1-O4 95.1(2), C1-W1-C2 84.7(2). Further details of the crystal structure determination can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50939, the names of the authors, and the journal citation.

The importance of the route to systems with M-P double bonds described here is illustrated by the syntheses of such different complexes as **7** and **9**. A base is required for the double dehydrohalogenation of the binuclear complex **6**, obtained as a 57:40:3-mixture of the *trans/trans*-(sketched), *cis/trans*-, and *cis/cis*-isomers from 3,9-dichloro-2,4,8,10,3,9-tetraoxodiphosphaspiro[5.5]undecane and **3b**. **8a**, **b**, prepared from $(Me_2N)_3P$ and **3b** or $C_5Me_5(CO)_3Mo-H$, reacts in the absence of additional base to afford **9a**, **b** since the starting phosphane itself acts as a bases; **8a**, **b** are therefore only transiently stable in solution.

Preliminary reactions with **9a** indicate that the novel phosphorus-metal double bonds are extraordinarily reac-

Synthesis, Structure, and Reactions of Cluster-Stabilized Phosphaalkenes**

By *Konrad Knoll, Gottfried Huttner*, Marek Wasiucionek,* and *Laszlo Zsolnai*

Phosphanediyl ligands RP are useful groups in neutral clusters forming inert μ_3-bridges which do not interfere in the reactions of the cluster[1]. Herein, we show that after twofold deprotonation the cluster $[(\mu_3\text{-RP})Fe_3(CO)_9(\mu_2\text{-H})_2]$ **1** reacts via the μ_3-RP group with electrophiles. With CH_2I_2, the cluster **3** is formed, in which for the first time a phosphaalkene, $RP{=}CH_2$, is stabilized as a μ_3-η^2 bridge; it can be reduced in the cluster to a novel μ_3-η^3-phosphino ligand $RPCH_3$. The cluster **4** thus formed is also accessible directly from the phosphanediyl complex **1**.

The dihydrido-Fe_3 cluster **1** (R = *p*-$CH_3OC_6H_4$)[2] undergoes deprotonation on reaction with $NaNH_2$; short reaction times lead at 20 °C to the monoanion, which can be

isolated as the $Bu_4N^{\oplus}$ salt **2**. According to the X-ray structure analysis[3], the tetrahedral skeleton of the anion of **2** closely resembles that of $[(\mu_3\text{-}C_6H_5P)Fe_3(CO)_9(\mu_2\text{-}H)_2]$[2]. The position of the H-bridge could be determined directly; the different Fe–Fe distances (267.8(3), 267.9(2), 271.8(3) pm) also give an indication of the position of the H-atom, which as expected bridges the long bond[2]. The FeP distances (214.3(5), 216.3(3), 216.3(3) pm) are, on average, 1 pm shorter than in $[(\mu_3\text{-}C_6H_5P)Fe_3(CO)_9(\mu_2\text{-}H)_2]$[2].

When **1** is allowed to react with $NaNH_2$ in tetrahydrofuran (THF) at 60 °C for 2 h, a highly air-sensitive substance is formed, which, according to its reactivity and IR spectrum, is a dianion. It differs from the monoanion of **2** in its ν_{CO} absorptions: the ν_{CO} bands of the anion of **2** are, on average, shifted about 55 cm^{-1}, and those of the dianion, about 120 cm^{-1} to longer wavelengths compared to those of **1**. The dianion reacts with CH_2I_2 to give the neutral complex **3**.

One of the PFe bonds in **3** is bridged by a CH_2-group. The loss of the μ_2-H bridges of **1** is electronically compensated for by a μ_2-CO group. The $RP{=}CH_2$ ligand can be regarded as a coordinatively stabilized phosphaalkene. This interpretation is supported by the X-ray structure analysis of **3**[3], which shows a relatively short[4] PC distance (176(1) pm). In free phosphaalkenes the bond is even shorter (168–172 pm)[5]. A similar coordination is observed in reduced nitrile[6a] and isonitrile ligands[6b] in Fe_3 clusters.

The phosphaalkene complex **3** can be hydrogenated in a $H^{\ominus}/H^{\oplus}$ addition sequence ($NaBH_4$, THF, 20 °C, 15 min) to **4a**. **3** splits off a CO group, and the resulting vacant coordination is filled by one of the π bonds of the aryl ligand. This new type of coordination of an alkylarylphosphino ligand was confirmed by a structure analysis of **4c**[3]: FeC_α 235.2(8), FeC_β 286.3(8) pm; $C_{\beta'}$ is not coordinated ($FeC_{\beta'}$ 314.3(8) pm). On steric grounds, the P atom is bonded only to the two Fe atoms which carry the bridge H atom (FeP: 219.9(3), 217.1(3) pm); the distance to the third Fe atom is 252.5(3) pm. The H-bridged FeFe bond with a length of 270.3(3) pm is, as usual, longer than the other two FeFe bonds (265.0(3), 264.7(3) pm). The ^{1}H-NMR spectrum of **4a**, with its A_2B_2 pattern, indicates that the β and β' positions rapidly exchange in solution.

4a–c are more easily accessible from **1** by double deprotonation, alkylation, and protonation. This reaction sequence, like the formation of **3**, shows that μ_3-RP ligands in anionic clusters are nucleophilic centers which enable the synthesis of unusual ligand systems.

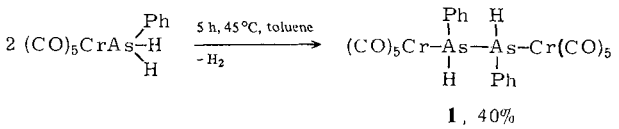
Facile Synthesis of PhAs=AsPh Complexes**

By *Gottfried Huttner** and *Ibrahim Jibril*

Ligands RX=XR (X = P, As, Sb) in which the reactive double bond is protected by side-on coordination[1] are, in contrast to the free ligands[2], stable even for small substituents R. They may be used as sources of molecules with free X=X double bonds[1]. We have now found that the dehydrogenation of complex-bound diarsanes provides a facile and high-yield route to the otherwise difficultly accessible diarsinidene ligands[3].



1, 40%

The diarsane complex **1** is formed on prolonged heating of $(CO)_5Cr(Ph)AsH_2$[4] at 45 °C in toluene. Irradiation, as in the case of the synthesis of $Cp(CO)_2MnPhAs(H)\text{–}(H)AsPhMn(CO)_2Cp$[4] from $Cp(CO)_2MnPhAsH_2$, is not necessary. Reaction of **1** with Pd/C in a molar ratio of 10 : 1 at 20 °C in CH_2Cl_2 leads, within 30 min, to evolution of 1 mol H_2, but the black compounds formed in the reaction, which are soluble in CH_2Cl_2, cannot be separated chromatographically. If, however, equimolar amounts of $P(OMe)_3$ or bpy, the complex

$(CO)_5Cr(Ph)As{=}As(Ph)Cr(CO)_5$ **2**

presumably formed in the initial stage of the reaction, is stabilized as the Pd-derivative **3**.

According to X-ray structure analyses[5], in the complexes **3a** and **3b** the palladium is planar coordinated: two coordination sites are occupied by the donor atoms of the ligand L, the third site by the π-bond of the "arsenobenzene" ligand PhAs=AsPh[6]. The Pd–As distances in **3a** and **3b** are 246(2) and 239(1) pm, respectively. The length of the coordinated As=As bond in **3a** is 236.6 pm and in **3b**, 236.0 pm. The $Cr(CO)_5$ groups bound to the "free electron pair" of the coordinated arsenobenzene ligand show As–Cr distances of 251(3) pm in **3a** and 248(1) pm in **3b**. Thus, the coordination of the RAs=AsR ligand to Pd resembles the coordination of $C_6F_5P{=}PC_6F_5$ to Pt in $(Ph_3P)_2Pt(C_6F_5P{=}PC_6F_5)$[7]. The coordination of the arsenobenzene ligand to three organometallic fragments compares with that in $[(CO)_5M]_3PhX{=}XPh$ (M = Cr, X = P[1a]; M = Cr, X = As[3a]; M = W, X = Sb[8]).

If Pt/C is used instead of Pd/C, the reaction takes a different course, since Pt is not dissolved from the metal under the reaction conditions. Besides cycloarsane com-

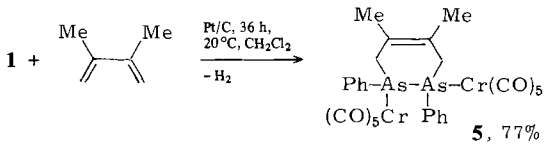
plexes, of which $(PhAs)_5(Cr(CO)_5)_2$ could, as a crystalline substance, be characterized by X-ray structure analysis, complex **4** was obtained, whose structure[5] (As=As 234(1), As–$Cr_{end\text{-}on}$ 249(1), As–$Cr_{side\text{-}on}$ 260(1) pm) compares with that of $((CO)_5Cr)_3PhAs{=}AsPh$[3a]. The substitution of a CO group by $P(OMe)_3$ in the formation of **4** is presumably heterogeneously catalyzed[9]; **2** may be regarded as an intermediate in this reaction too. The following trapping reaction supports this postulation:



5 can be regarded as the product of a [4+2]-cycloaddition of 2,3-dimethylbutadiene to the intermediate **2** initially formed during the dehydrogenation. This is supported not only by the high yields of **5** but also by the observation that the homologous compound $(CO)_5CrPhP{=}PPhCr(CO)_5$ and free ligands RP=PR[10] undergo cycloadditions with cyclopentadiene or 2,3-dimethylbutadiene[1b].

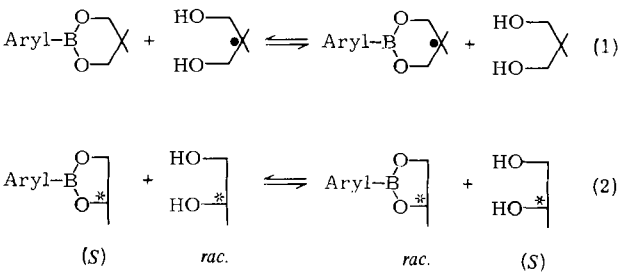
Rapid Proton Transfer as Cause of an Unusually Large Neighboring Group Effect**

By *Günter Wulff**, *Manfred Lauer*, and *Helmut Böhnke*

In connection with our studies on chemoselective affinity chromatography[1], we have investigated the esterification of arylboronic acids with diols in organic solvents. Our aim was to accelerate the establishment of equilibrium in order to make the reaction also useful for very rapid chromatography (HPLC) on polymer bound boronic acid[2]. We recently found[3] that the establishment of equilibrium in the case of *o*-(dimethylaminomethyl)phenylboronic acids is many orders of magnitude faster than in the case of the non-substituted phenylboronic acid. We have now synthesized further compounds[4], which, in some cases, show considerably greater acceleration and from whose structures and reactivities conclusions can be drawn about the mechanism of neighboring group participation.



For investigation of the reactivity, the rate of transesterification in the degenerate equilibria (1) and (2) were measured (see also [3]). In the case of rapid reactions, the rate given in Equation (1) could be determined by dynamic NMR spectroscopy, whereby the coalescence temperatures (T_c) for the methyl groups of the diol moiety were ascertained. Less reactive esters could not be investigated by this method. In these cases the transesterification of the optically active (*S*)-1,2-propanediol esters (ester **b**) with racemic 1,2-propanediol [Eq. (2)] is monitored polarimetrically. The range of measurement by the two methods over-

[**] On the Chemistry of Binding Sites, Part 5. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie. We thank Frau *I. Karnuth* and Herr *A. Kahnert* for valuable assistance, and Herr *A. Dölle*, Institut für Physikalische Chemie der Universität Düsseldorf, for recording the ^{11}B-NMR spectra.—Part 4: [3].

laps in the case of the esters **5a** and **5b**, so the values can, to some extent, be correlated (for the evaluation and estimation of the relative rates see [3], footnote 37).

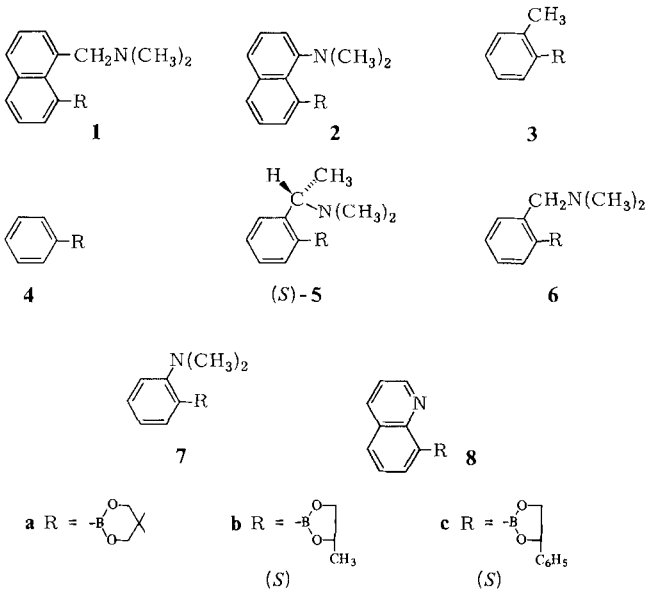

Table 1 shows that differences in reactivity of an unusual order of magnitude occur in similarly structured nitrogen-containing aryl boronates (more than 14 orders of magnitude between **1** and **8**). In the case of compounds **6a**, **7a**, and **8a**, a basic nitrogen atom located at a favorable distance from the boronate ester causes an acceleration of about 8×10^7, 2×10^8 and 4×10^9, respectively, compared to the unsubstituted phenylboronate **4**. The acceleration measured for the quinolineboronates **8a** points to a neighboring group effect of an order of magnitude very rarely met with in other compounds[6].

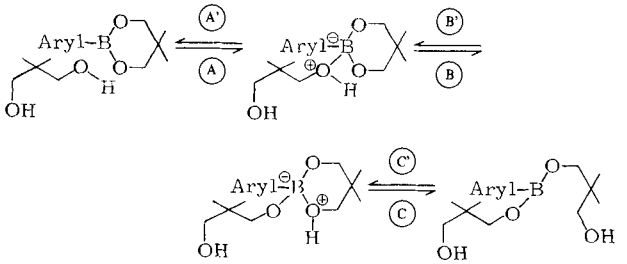
[b] $\Delta G_c^{\neq}$ values for B–N bond breaking determined from the coalescence of the N-methyl groups of ester **c**; T_c = coalescence temperature (methodology see [5]). [c] $\tau_{1/2}$ for the transesterification of the ester **b** determined by polarimetric measurement at 20.0°C (ester **b** and *rac*-1,2-propanediol each 0.01 M in acetone. Methodology see [3]). [d] Coalescence temperatures for the methyl groups of the diol moiety (ester *a* and diol each 0.2 M in acetone. Methodology see [3]). [e] A free rotation of the two substituents is blocked by steric hindrance here, independently of a B–N coordination. [f] Hardly any reaction detectable after 14 d.

The large differences in reactivity cannot be explained in terms of the different degree of hybridization on boron, as is determined by ^{11}B-NMR spectroscopy[7]. In Table 1, sp^2-hybridized esters (**3a**, **4a**, **7a**, **8a**) are readily recognizable alongside those with more or less strong sp^3-hybridization (**2a** < **6a** < **5a** < **1a**). Even in the case of substantial sp^3-hybridization in **6a**, a similarly rapid transesterification occurs as in **7a**: The attack of a nucleophile in **6a** is not significantly hindered by B–N interaction since the equilibrium between forms with closed and open B–N bonding is established very rapidly, as is shown by the low $\Delta G_c^{\neq}$ values (Table 1) for the B–N bond opening. However, in the case of a very tight B–N interaction as in **1b** the primary nucleophilic attack of the alcohol at the boron (step A, Scheme 1) is so firmly blocked that the reaction rate is drastically lowered.



Scheme 1.

The large acceleration in the reaction of **6a**, **7a**, and **8a** is not due to a preceding quick equilibrium caused by the basic amino group with formation of alkoxide, since added amines, such as quinoline, dimethylbenzylamine, dimethylaniline, or triethylamine in the reactions of esters of **3**, have only a slight accelerating effect.

The transesterification reaction (2) of the esters **3b** and **4b** shows, on using diol which is deuterated at the OH groups, a kinetic deuterium isotope effect of $k_H/k_D = 4-5$. Such an isotope effect could not be detected in the case of esters **5a**, **6b**, and **8b**. Therefore, it must be concluded that the proton transfer (step B, Scheme 1) is rate determining in the transesterification of esters **3** and **4**. In the case of esters **6** and **8** (and perhaps also **7**) this proton transfer is apparently accelerated so strongly by a suitably spaced basic grouping that another step (probable C) now becomes the slowest. In the case of esters **1**, step A might be rate determining because of the competition with the B–N bond, in the case of esters **2** and **5**[8] because of steric hindrance.

[8] The extraordinary large drop in rate on introduction of an α-methyl group (on going from **6a** to **5a**) is not fully explainable with the present data.

Stereoelectronic Effects in Organic Chemistry. By *P. Deslongchamps*. Pergamon Press, Oxford 1983. xi, 375 pp., paperback, £ 15.25.

This book constitutes the first volume of the "Organic Chemistry Series" edited by *J. E. Baldwin*. It is to be welcomed that an author, who has himself made important advances in this area, provides a review of stereoelectronic effects, whose importance has come to be increasingly appreciated in the last few years.

After a somewhat short introduction—there is no general historical synopsis—the second chapter treats in detail the conformation, formation and hydrolysis of *O, N,* and *S* acetals. Here the author—and the reviewer—prefers the explanation involving the concept of anomeric effect and *exo*-anomeric effect as stabilizing delocalization of nonbonding electron pairs in σ^* orbitals rather than the alternative interpretation as the destabilizing interaction of nonbonding electron pairs (rabbit ear effect). The oxidation of the acetal C–H bond makes the transition to the next two main chapters, which treat the conformation, formation and hydrolysis of esters, amides and similar compounds. The author adeptly presents his theory concerning the formation and decomposition of tetrahedral ortho ester structures and comments on the results obtained by his and other groups since the famous report in Tetrahedron (1975).

The next three chapters are dedicated to stereoelectronic effects in reactions at saturated and sp^2- and sp-unsaturated systems. The reactions discussed include the S_N2 and S_N2' reactions, the rearrangements of secondary and tertiary alcohols with vicinal leaving groups, the Wagner-Meerwein rearrangement, the nucleophilic addition at carbonyl and iminium compounds and α,β-unsaturated ketones, the reduction of α,β-unsaturated carbonyl compounds, E2 and E1cB reactions, the Grob fragmentation, the addition of electrophiles to enolates and the addition of nucleophiles to triple bonds. The next chapter, entitled "Potpourri", discusses further rearrangements, including the reaction of ortho esters with Grignard reagents, the intramolecular aldol reaction, the ring opening of β-lactams, and the dipolar cycloaddition of glycosylnitrones. A new synthesis by the author's group of erythronolide A is also included. In this an intermediate 1,7-dioxaspiro[5.5]undecane was synthesized by the exploitation of stereoelectronic effects. The last chapter deals with such effects in enzymic reactions. The book is rounded off by comprehensive author and subject indexes.

This monograph is distinguished by its clear organization, precise language and cleanly designed formula diagrams. The author has succeeded in extracting the essential stereoelectronic aspects from the voluminous literature and in discussing them pertinently. He presents the work of his own group just as clearly and develops his theories therefrom in a factual manner which is easily understood. The wide range of reactions treated and the plethora of references at the end of every chapter (over 700 references in all) make this book an important work of reference for every chemist or student with an interest in organic chemistry.

Pyrolysis: Theory and Industrial Practice. Edited by *L. F. Albright, B. L. Crynes,* and *W. H. Corcoran*. Academic Press, New York 1983, xviii, 482 pp., bound, $ 65.00.

In 18 chapters several authors principally deal with the manufacture of ethylene and other olefins, diolefins and aromatics from various feeds. The carbonization of solid fuels such as coal, oil shale and biomass for the production of liquid products, the widely utilized coke oven technology, and the pyrolysis of plastic wastes are only treated briefly. The coking of heavy oils and tar sands, which also belongs to the broad area of pyrolysis is not considered.

The theoretical treatise in the initial chapters is mainly concerned with the reaction mechanisms of cracking methane through butane and other paraffins and olefins, diolefins, naphthenes and aromatics. Practice leads theory in cracking mixtures; data on the production of light cracking products from feeds not originating from crude oil such as coal, tar, shale oil, polyolefins, and biomass are mainly empirical in nature.

A further theoretical chapter deals with the mathematical modelling of the reactor and the pyrolysis reactions of hydrocarbon gases, naphtha and gas oils. Sensibly defined peripheral conditions yield reliable predictions with an acceptable amount of effort.

Coke formation and gasification are of considerable importance in running industrial pyrolysis plants. The treatment of these complex problems reveals the limits of knowledge in this area. A separate chapter is devoted to undesirable reactions on the metal surfaces of reactors such as carbonization, coke formation, and the decomposition of ethylene. Measures for prevention and control are presented.

The discussion of the theory and application of laboratory reactors to investigate the kinetics of pyrolytic reactions covers the most important types of reactors.

The rest of the book is aimed at those readers who are mainly interested in the technology and operation of pyrolysis plants for the production of base products for the petrochemical industry. The topics not only include cracking in tube furnaces as normally used nowadays, together with the preparation of the feedstock, but also other technologies such as cracking with gaseous or solid heat transport media or in the presence of catalysts. The cracking reactors discussed include not only the normal tube furnace but also alternatives such as molten bath, entrained bed or fluidized bed reactors; the economic aspects of the technologies are also discussed. Furthermore, the economic questions concerning olefin production are discussed both retrospectively and with an eye to the future.

Descriptions of material problems in tube furnace construction, process monitoring and quench coolers for the recovery of heat from the furnace effluent gases complete a book primarily intended for engineers and chemists concerned with the building and operation of pyrolysis plants.

Bibliographies for every chapter permit more intensive study. When American units are quoted, they are usually accompanied by their SI equivalents. In spite of the fact that the book is focussed on the question of producing low molecular weight olefins, it is also useful for understanding other thermal processes.

Chemie der Räucherung. By *L. Toth*. A publication of the Deutsche Forschungsgemeinschaft. Verlag Chemie, Weinheim 1982. xi, 331 pp., stitched, DM 68.00.

This monograph provides a comprehensive 100-page literature survey of the smoking of foods (smoke production, manufacture of smoke condensates, composition of the curing smoke, the effects of smoking). Then follows a discussion by the author of the investigations of the phenol fraction of curing smoke (ca. 140 p.) that he carried out at the Bundesanstalt für Fleischforschung at Kulmbach (production and condensation of curing smoke, analysis of the phenol extracts, the influence of the smoking technique on the composition of the phenol fraction, phenols in smoke essences and smoke flavors, phenols in smoked meat products).

Then follows an experimental portion (ca. 25 p.), a list of all the smoke components so far described, classified according to compound type (306 compounds on ca. 50 p.) and a bibliography (147 references).

This book is an excellent source of information for every type of chemical and technological question concerning the smoking of food and hence a solid basis for toxicological discussions. It belongs in every relevant library.

Computeranwendungen in der Chemie. By *K. Ebert* and *H. Ederer*. Verlag Chemie, Weinheim 1983. ix, 359 pp., bound, DM 63.00.

Almost every scientifically definable field requires the participation of another on many occasions. Classically these are spoken of as auxiliary sciences, a phrase that sounds somewhat condescending and is often meant to be so. If a scientist combines this auxiliary science intensively with his original field, he is often treated as an outsider and may become an object of amusement. However, it can happen that what was once an auxiliary science penetrates large portions of the original and transforms it. Amongst the natural sciences one only needs to mention the thrust of mathematics into physics, and chemistry into biology. Recently mathematics, information science, and computer science have been extending their role within chemistry. Theoretical chemistry without mathematics and high performance instrumental analysis (FT-IR, GC-MS, FT-NMR etc.) without data processing are unthinkable. But techniques of instrumental analysis that are now regarded as being classical (IR, UV, GC etc.) have also been conquered by information science and data processing since the application of microprocessors. Nevertheless, the university education of German chemists takes but slight account of these trends. This gap has to be filled at the moment by the further education program of the GDCh (German Chemical Society).

This present book is aimed at filling just this gap. The hurdle of learning a high level programming language (in this case BASIC) is skillfully bypassed. Using simple chemically oriented examples a didactically very clever introduction is presented to the programming of personal computers. The exemplary programs are concisely and clearly constructed: commentary, input, calculation and output. They are written using the minimum of BASIC which is available with the cheapest personal computer. However, in certain cases reference to more capable computers would have been sensible; even though they seem costly, programming time would have been saved.

The severity of both the problems treated and the programming technique has been chosen in a didactically very refined manner. Numerical integration, equations, linear systems, differential equations, and nonlinear systems are treated. In some cases a somewhat more critical presentation of the mathematics would have been desirable. Examples are numerical problems in matrix inversion or the problem of the linearization of measured data (it is treated using the Arrhenius equation). In other cases (e.g. Fourier series) a more detailed presentation of the problem would have been very useful in the book.

This book can be recommended to every chemistry student as a textbook and a book to work through, as an introduction to personal computers. The simple utilization of the programs is not to be recommended since it is without didactic worth. It would be even more senseless, for those who wish to learn, to purchase the programs ready for use as diskettes or tapes. The undeniable virtue of this book lies in the fact that it offers the possibility of familiarizing oneself independently with the fascinating world of small computers.

Organic Synthesis. Concepts, Methods, Starting Materials. By *J. Fuhrhop* and *G. Penzlin*. Verlag Chemie, Weinheim 1983. xi, 355 pp., bound, DM 78.00.

With the increasing importance of chemical synthesis, the problems of synthesis planning and execution have become focuses of interest. The number of recently published books, dealing with the strategy and techniques of synthesis, mirror this development. This book is intended to provide advanced students and research chemists with knowledge of educts, target molecules and the concepts and methods concerning their transformation.

The first chapter deals with the construction of carbon chains and carbocycles, whereby the authors apply Corey's synthon concept including the idea of "Umpolung" as a useful heuristic principle. Here, as in many other publications, there is no strict differentiation between a synthon as originally formulated by *Corey* and the reagents corresponding to this concept. It is inevitable that this point of view—analysis of the target compound into synthons—should lead to the neglect of one of the most important aspects of organic chemistry, namely stereochemistry.

The steric course of the reaction is then discussed using individual examples. Some methods of carbon-carbon bond formation, e.g. the Wittig reaction, are thoroughly discussed mechanistically, at the same time drawing stereochemical conclusions. Just as thorough a discussion of the aldol reaction would have been desirable, since, in its many newly developed variations, it vividly demonstrates the powerful nature of organic chemical synthesis.

The pattern is similar in the next chapter which deals with the transformation of functional groups. The Sharpless epoxidation for the stereoselective synthesis of polyhydroxy compounds is amongst the omissions here; no account is taken of recent highly selective reducing agents or microbiological reductions; some important protecting

groups remain unmentioned although a special section is devoted to them.

The third section returns to the subject of the first and retrosynthetic analysis is undertaken of simple organic compounds by use of the synthon concept. A comprehensive list of commercially available fine chemicals, which is contained in the chapter, indicates to the reader how far back the retrosynthesis must be taken.

The fourth chapter constitutes nearly half of the whole work and presents the synthesis of particular compound classes. Instead of developing the retrosynthetic discussion, begun in Chapter 3, at the level of more complex molecules an enormous range of synthetic examples has been assembled and once again stereochemical problems are only treated superficially.

In the chapter on steroids, the toys with which stereoselective syntheses were developed, a chance has been lost of emphasizing the synthesis of pure enantiomers, in particular by the application of asymmetry-inducing synthetic steps. The choice of other synthetic examples would have easily made this possible. For the vitamin B_{12} syntheses, which are attached to a section dealing with porphyrins, chlorophyll a and corrins, the authors ought to have been able to include examples concerning the strategies for the solution of stereochemical problems alongside those dealing with the construction of the skeleton. The syntheses of vitamin B_{12} are copybook examples in this respect. The macrolide syntheses are another example that could be cited, of which only one is mentioned. Here it would have been possible to illustrate various synthesis strategies by means of other examples. Since the macrolides were the test bed for the development of stereoselective aldol reactions, this offered the possibility of renewed discussion of the theme, which was introduced in the first chapter, at a more advanced level.

The reader is confronted by a superfluity of examples without the interrelationships being revealed. The authors would have been well advised to discuss fewer examples in terms of the synthon concept and to bring out the important stereochemical aspect by adept choice of the right examples of syntheses.

Gas Chromatographic Separation of Enantiomers on Optically Active Metal-Complex-Free Stationary Phases**

New Analytical Methods (24)

By Volker Schurig*

If a stationary phase A employed in gas chromatography possesses a chemical affinity for substance B, which is to be separated, then the retention behavior is not only determined by the normal *physical* equilibrium between the gas and liquid phases but also by the *chemical* equilibrium $A + B \rightleftharpoons AB$. If A and B are chiral and A is present in optically active form while B is a racemic mixture, then it is possible to achieve a gas chromatographic enantiomer resolution without the isolation of diastereomers: the energetically different diastereomeric associates $A_R B_R$ and $A_R B_S$ are formed rapidly and reversibly. This enantiospecific resolution principle was first demonstrated in 1966 by the quantitative resolution of racemic amino acid derivatives on optically active peptide phases in analogy to the well-known stereospecificity of enzymes. The anchoring of the chiral resolving agent to thermally stable polysiloxanes together with the employment of high resolution capillary columns and the use of appropriate derivatization strategies has led to the development of enantiomer resolution into a routine modern method for many classes of substances. The demonstration of enantiospecificity in the gas chromatographic separation process is of fundamental interest, and its systematic study can result in a significant contribution to the understanding of the molecular mechanism of "chiral recognition". The gas chromatographic separation of enantiomers has also proven to be an accurate and sensitive method for the determination of the enantiomeric composition of natural products and products of enantioselective transformations (asymmetric syntheses, "chiral pool" transformations, kinetic resolutions, biomimetic reactions) and for the quantification of racemization, e.g. in the synthesis and hydrolysis of peptides. In any research program devoted to the phenomenon of chirality, the gas chromatographic separation of the enantiomers of volatile compounds constitutes an indispensable modern instrumental technique.

1. Introduction

The phenomenon of optical activity is one of the most fascinating manifestations of living matter which has inspired the chemist to many imitations in the laboratory ever since the founding of stereochemistry. The resolution of synthetic racemic mixtures by methods analogous to those of *Pasteur* in his pioneering investigations is of undiminished importance both as a preparative method for the isolation of pure enantiomers and as an analytical tool for the determination of enantiomeric compositions. The availability of high-performance methods of enantiomer analysis has become urgently necessary in order to keep

[**] The separation of enantiomers on optically active metal-complex stationary phases ("complexation gas chromatography") will not be discussed here.

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/1010-0747 $ 02.50/0

pace with the development of highly enantioselective reactions[1] (asymmetric synthesis, kinetic resolution, "chiral pool" syntheses, enzymatic transformations) and to cope with the requirements of mechanistic investigations.

Enantiomer resolution by gas chromatography constitutes a technique that allows the exact determination of enantiomer composition, the determination of enantiomer purity up to 99.9%, and the assignment of absolute configurations employing subnanogram quantities for many groups of compounds[2]. Furthermore, the method is suitable for the investigation of the phenomenon of chiral recognition and can in this way contribute to an understanding of structure/activity relationships and the enantiospecific interaction of chiral selectors and selectands[3a].

The resolution of enantiomeric mixtures by gas chromatography can be performed in two **modes**[4]:

a) *Indirect method:* conversion of the enantiomers into diastereomeric derivatives by chemical reaction with an auxiliary, enantiomerically pure, chiral resolving agent and subsequent gas chromatographic separation of the resulting diastereomers on an achiral stationary phase.
b) *Direct method:* Gas chromatographic separation of the enantiomers on a *chiral* stationary phase containing an auxiliary resolving agent of high (but not necessarily complete) enantiomeric purity.

An alternative method, when the chiral agent is mixed with the mobile gas phase, has also been described[5a].

These processes rest on the use of a chiral non-racemic auxiliary agent and hence constitute variants of the classical method of enantiomer resolution via diastereomeric salts according to *Pasteur*. Chromatographic resolution of enantiomers *without* the employment of a chiral auxiliary agent is, in analogy to the construction of a perpetual motion machine, impossible according to the present state of scientific knowledge. Reports of enantiomer resolution in achiral systems seem either unreliable[5b, 5c], require a rigorous examination[5d], or they do in fact involve a chiral agent, e.g. as internal standard[6].

While method (a) involves the formation and isolation of *diastereomers* before separation, method (b) involves the rapid and reversible *diastereomeric interaction* between optically active selector and racemic selectands. A prerequisite for method (a) is the presence of a reactive chemical function in the enantiomers which allows quantitative reaction with an optical active reagent. Racemization of the sample on derivatization or kinetic resolution at incomplete conversion obscures the original enantiomer ratio. The diastereomeric ratio to be determined can also be altered by accidental fractionation during derivatization, work-up and chromatographic analysis (injection, detection). Systematic errors always occur if the chiral agent is not present in complete enantiomeric purity or is racemized during the derivatization reaction. Such sources of error can be detected by a combination of methods (a) and (b), i.e. by employing a chiral phase which resolves all four configurational isomers.

The direct resolution of enantiomers by method (b) is of necessity more difficult in that, apart from the chiroptical parameters, all physical and chemical properties of optical antipodes are identical in an achiral environment. If the gas chromatographic retention volume V' of the selectand is expressed as a product of the vapor pressure p^0 and the activity coefficient γ

$$V' = p^0 \cdot \gamma$$

then the resolution of enantiomers (R and S), which is expressed in terms of the separation factor α,

$$\alpha = p^0_R \cdot \gamma_R / p^0_S \cdot \gamma_S$$

can only take place as a result of a difference in the vapor pressure *or* the activity coefficient[7]. While the presence of an optically active component in the mobile phase would appear to alter the vapor pressures p_R and p_S, the employment of a chiral stationary phase can lead to a discrimination of γ_R and γ_R because of the differing stabilities of the diastereomeric associates of selector and selectand.

Method (b) is characterized by the introduction of chemical selectivity into the gas chromatographic separation process, whereby chiral recognition is caused by the molecular association between the racemic selectand and the optically active selector in the stationary phase.

An optically active stationary phase is of itself no guarantee for an effective enantiomer resolution. On using a high resolution capillary column, a quantitative resolution is achieved only when the difference between the free enthalpy of diastereomeric association for the enantiomers is at least 10 cal/mol (22 °C). The success of enantiomer resolution should always be verified by control experiments. Peak coalescence, when a racemic phase is used, and peak inversion of nonracemic mixtures on employment of chiral phases of the opposite configuration are unequivocal criteria of enantiomer resolution[8].

This progress report will only be concerned with the direct method (b) of gas chromatographic enantiomer resolution. At present two well-developed methods are available which are complementary to each other:

- *Resolution of enantiomers on optically active amino acid and peptide selectors via hydrogen bonding*[4, 9, 10].
- *Resolution of underivatized enantiomers on optically active metal chelates by coordination interaction ("complexation gas chromatography")*[11].

The first reproducible and quantitative gas chromatographic enantiomer resolution was achieved in 1966 by *Gil-Av, Feibush* and *Charles-Sigler* at the Weizmann Institute of Science[12]. *Gil-Av* had previously investigated the resolution of racemic amino acids by the indirect method[13] and now sought to employ the chiral agent not for derivatization but as an additive to the stationary phase. The contemporary state of the art of gas chromatographic enantiomer resolution should not blind us to the initial difficulties with which the method was beset: "with a state of frustration"[4]. In retrospect *Gil-Av* may be **quoted**[14]:

"A considerable number of workers all over the world have tried to solve the problem of the resolution of antipodes by this method (i.e. gas chromatographically) without any success. When we turned to this research topic al-

most all the workers in the field had given up the idea as impracticable. And not only that: because many reports of positive results had proved to be in error, the topic had fallen into disrepute".

"After long and painstaking effort, which was accompanied by many a disappointment, we finally discovered a solution to the problem. The core of the matter was to find a liquid for wetting the walls, that in some respects imitated an enzyme. ... To our surprise it turned out that amino acids ... retained to a certain extent the ability of the larger enzyme structures to distinguish between left- and right-handed molecules ... (cf. Fig. 1). We were thus able to add an important new method for the study of optically active molecules to those developed by *Pasteur* and other workers."

The demonstration of enantiospecificity in a gas chromatographic system as a counterpart to the already known liquid chromatographic racemate resolution[15-17] was of itself remarkable, particularly since the resolution occurred quantitatively (cf. Fig. 1). Furthermore, the manifold possibilities for its application, which result from the advantages of the gas chromatographic method (high performance, sensitivity, reproducibility, precision, simple detection), were realized immediately. The ability to resolve minute quantities of amino acid enantiomers coincided with the intensive efforts to demonstrate the presence of biogenic materials in interstellar space, in meteorites and in lunar samples from the NASA Apollo moon program. The cooperation of *Gil-Av* with biophysicists and peptide chemists at the University of Houston, Texas, *E. Bayer, J. Oró, W. Parr,* and *W. A. Koenig,* produced important advances which, with the employment of thermally stable chiral polysiloxane phases, laid the foundations for the rapid development of gas chromatographic enantiomer resolution as a routine, modern, high-performance method[9, 10].

In 1969 *Gil-Av* and *Schurig* attempted to extend the area of application of method (b) for gas chromatographic enantiomer resolution to other classes of compounds. Chiral unsaturated hydrocarbons, ethers, esters, ketones etc. are not resolvable or only resolvable with difficulty into their enantiomers via formation of diastereomeric salts. Thus the enantiospecific coordination interaction of racemic selectands with optically active organometallic selectors was regarded as an important complementary possibility for gas chromatographic chiral recognition because of the variety and variability of metal complex structures and of optically active ligands.

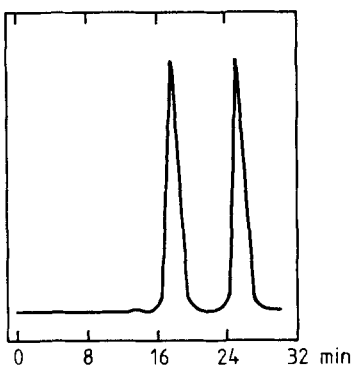

Fig. 1. Gas chromatographic resolution of a racemic amino acid mixture according to *Gil-Av* [14].

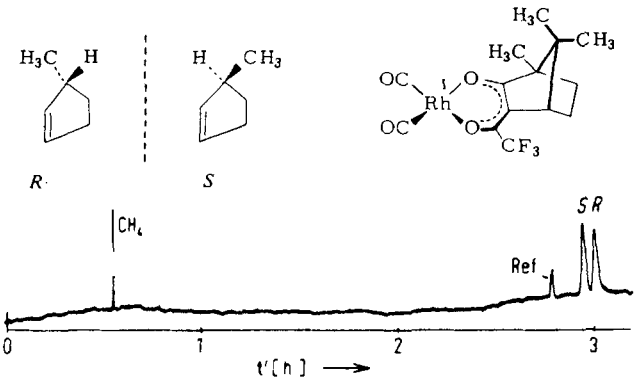

Fig. 2. Gas chromatographic resolution of racemic 3-methylcyclopentene on an optically active metal chelate by enantiospecific coordination interaction [8].

By analogy with the resolution of racemic *trans*-cyclooctene via crystallization of a diastereomeric platinum-π-complex by *Cope* et al.[18], it was decided to test whether a racemic olefin could be resolved gas chromatographically into its enantiomers without the isolation of diastereomers, on the basis of the diastereomeric interaction of the enantiomers with a chiral metal complex. This principle, whose practical realizability has at one time been doubted[19], was first realized in 1977, as a result of improvements in gas chromatographic instrumentation, with demonstration of the resolution of racemic 3-methylcyclopentene on dicarbonylrhodium-3-trifluoroacetyl 1*R*-camphorate[8], a selector-selectand system that was first conceived in 1971[20,21] (cf. Fig. 2):

Although this successful experiment demonstrated that gas chromatography possesses the necessary thermodynamic and kinetic prerequisites for chiral recognition by coordination interaction, this resolution principle has not yet been generalized for olefins. The method, however, was extended to oxygen, nitrogen, and sulfur-containing compounds by the employment of chiral bivalent transition metal bischelates and led to a rapid extension of complexation gas chromatography for the resolution of enantiomers[11,22] (see footnote [**] on p. 747).

The methods available today for the quantitative gas chromatographic resolution of enantiomers offer many possibilities for their application and investigation. It is appropriate here to differentiate between the information which is accessible from the various peak parameters[22] (Table I).

Table 1. Gas chromatographic parameters in enantiomer resolution.

Peak parameter	Definition
Peak retention	A thermodynamic measure of the selective interaction between the selector and the selectand (K, $-\Delta G°$)
Peak separation	A thermodynamic measure of the enantiomer discrimination between the enantiomerically pure selector and the racemic selectand ("chiral recognition") ($-\Delta_{R,S}(\Delta G°)$)
Peak ratio	A quantitative measure of the enantiomeric composition of the selectand ('enantiomeric excess' (*e.e.*) [2])
Peak assignment	Assignment of the absolute configuration of the selectand by correlation of the order of elution and the molecular configuration
Peak coalescence (second kind)	A kinetic measure of the enantiomerization of the selectand during resolution (ΔG^{+})

The *peak retention* of the selectand is determined by the (physical) partition equilibrium between the gas and liquid phases *and* by the (chemical) association equilibrium which arises when the selector exhibits chemical affinity towards the selectand. In the case of complexation gas chromatography the equilibrium constant for association K and, for variable temperature studies, the Gibbs-Helmholtz parameters ΔH° and ΔS° are easily accessible from relative retention data[23].

The *peak separation* of racemic selectands on chiral selectors is exclusively the result of the differences between the free enthalpies of association, $-\Delta_{R,S}(\Delta G^\circ)$. Although there should be no doubt that there will always be a difference in the free enthalpies of association for each chiral combination of selector and selectand, practical results are only anticipated with the employment of optimized systems that exhibit effective chiral recognition. Gas chromatography is an effective method of acquiring thermodynamic data of enantiomeric discrimination. In this respect, the question of the proportionality of ΔG° and $\Delta_{R,S}(\Delta G^\circ)$ is of interest. The intuitive assumption that an effective enantiomer discrimination is only to be expected via a strong chemical interactions turns out to be false and has been disproved in many instances. The impeding of molecular association, e.g. by steric effects, seems indeed to be advantageous for the discrimination of configurational isomers. Analogously to enzyme models, enantiomeric discrimination in chromatographic systems has been interpreted by *Dalgliesh* in terms of "three point interaction" between selector and selectand ("three point rule")[24]. The three point theory requires three effective bonds between selector and selectand for a favorable interaction. Later on, this model had to be altered so as to require a minimum of three stereochemically important interactions for enantiomer differentiation[7]. Along with bonding interactions (hydrogen bonds, charge transfer interactions, coordination) these can also include nonbonding interactions (steric hindrance). Thus, in principle, it ought to be possible to resolve a nonfunctionalized racemic alkane by host-guest interaction with a chiral clathrate forming compound by physical inclusion. The recently observed gas chromatographic resolution of racemic pinenes on an α-cyclodextrin inclusion compound points in this interesting direction[25].

In contrast to enzymes, chiral catalysts, and chiral NMR shift reagents, it is only possible for chromatography to distinguish between enantiomers ("enantiomorphy"), but not between enantiotopic groups or faces ("enantiotopy"). For this reason enantiospecific selector/selectand systems are only suitable model systems for the specificity of enzymes with respect to enantiomers or of receptors with respect to the enantiomers of pharmaceuticals, pheromones, odorants etc. A comparison of enantiospecificity is then only possible in a thermodynamic sense. The realm of enzymatic reactions, i.e. the reaction of prochiral educts to yield chiral products, has no analogue in a gas chromatographic experiment, since the prochiral substrate cannot be discriminated nor can a chemical reaction occur which leads to a chiral product.

The *ratio* of the peak areas is a direct measure of the ratio of the amounts of the enantiomers. The measured enantiomer ratio corresponds to the actual enantiomer ratio of the sample when all the chemical, physical and analytical manipulations, including injection and detection, are carried out in an achiral environment. A falsification of the enantiomer ratio, if any, would only be possible as a consequence of an enantioselective decomposition or an irreversible adsorption of the sample by the optically active stationary phase during chromatographic elution. The advantages of the gas chromatographic determination over other methods for the determination of the enantiomeric purity *e.e.* (enantiomeric excess)]

$$e.e. = \frac{R-S}{R+S} \times 100\%$$

have recently been discussed in detail by *Schurig*[2]. Typical advantages are sensitivity of detection, high accuracy, and reproducibility. The method is also independent of the chiroptical properties of the sample (e.g., the magnitude of the specific rotation) and optically active impurities do not interfere. Gas chromatography is particularly suitable for two limiting cases: for the detection of small enantiomeric excesses (e.g. during the investigation of the accumulation of optical activity in the laboratory under abiotic conditions) and for the proof of very high enantiomeric purity (e.g., for the determination of traces of enantiomers during investigations of the enantiospecificity of enzymes, during kinetic resolution experiments and enantioselective synthesis). When the separation factor is high, gas chromatography can even detect 0.1% of an enantiomer. Such a contamination corresponds, for an enantioselective reaction from a prochiral precursor (*e.e.* = 99.8%), to a difference in free enthalpy of the diastereomeric transition state of "only" $\Delta\Delta G^{\neq} = 4$ kcal/mol at 18 °C[2].

The derivatization-free resolution of enantiomers by complexation gas chromatography is particularly suitable for analytical applications, since this method allows the determination of the enantiomeric composition directly in the vapor phase without the necessity for substrate isolation. Thus, the course of an asymmetric reaction can be followed by repeated determinations without interrupting it, and, for example, alterations of enantioselectivity by autocatalysis or kinetic resolution of the product can be easily recognized[26].

The *peak assignment* requires a knowledge of the molecular configuration of the selectand. Since gas chromatographic enantiomer resolution depends on the enantiospecific association between selector and selectand, it ought to be possible to formulate rules for substrates that belong to homologous series, which correlate the retention time with the absolute configuration[27,28]. The absolute configuration can, if necessary, be determined with only 10^{-9} g of substance e.g. for an enzymatic reaction by the co-injection of a reference compound of known chirality. In the case of an *enantiomerically pure* sample or reference substance, an aliquot of the other enantiomer (or of the racemate) must be coinjected for purposes of peak identification. The determination of the configuration of the selectand by gas chromatography is independent of the chiroptical properties of the selector, which, in principle, is not required to be either enantiomerically pure or of known configuration.

A *peak coalescence (of the first kind)* is observed, as mentioned, if a racemic mixture is employed instead of the optically active selector. It is possible in this way to distinguish achiral diastereomers and other isomers from enantiomers, since only enantiomers coalesce. A *peak coalescence (of the second kind)* occurs during the chromatographic resolution when configurationally labile enantiomers invert. "Enantiomerization" of the selectand leads to an interconversion peak profile, from which kinetic parameters of inversion, as a reversible first order reaction, can be calculated[22,29]. Whereas at slow inversion a plateau, which is produced by the inverting molecules, appears between the terminal peaks, a rapid configurational interconversion destroys resolution.

Because of its high resolving power gas chromatography is particularly suitable for enantiomer analysis, while for liquid-chromatographic enantiomer resolution the emphasis is on the preparative aspect[30–32]. However, when the separation factor is large, $\alpha > 1.3$, gas chromatography may also be employed for the preparative resolution of enantiomers in the mg to g sample range. The isolation of pure enantiomers is suitable for chiroptical investigations, for biological tests or, in the case of chiral radiochemicals, for labeling experiments. In principle, it is possible to obtain 100% enantiomerically pure enantiomers even though the selector may not be enantiomerically pure.

Gas chromatographic methods of enantiomer resolution (see footnote [**] on page 747) and their applications and mechanisms will be discussed in the following section.

2. Gas Chromatographic Enantiomer Resolution via Hydrogen Bonding

2.1. Pioneering Investigations

The first claims of the resolution of racemic substrates (2-butanol, 2-bromobutane) on optically active stationary phases (starch, diethyl tartrate/Al_2O_3) were made by *Karagounis* and *Lippold*[33]. Other authors were unable to repeat the resolutions, which were only marginal anyway[34,35] or were caused, in the case of 2-bromobutane, by dehydrohalogenation to *E*- and *Z*-2-butene (1 : 1) in the injection port[36]. In spite of considerable instrumental shortcomings, later investigations by *Karagounis* and *Lemperle*[37] pointed the way to interesting future developments, e.g. preparative racemate resolution using polarimetry as an enantiospecific detection system or the use of chiral metal coordination compounds (Δ-$(Co(en)_3)Br_3/Al_2O_3$) as an enantiospecific stationary phase. An "inverse" system, namely the gas chromatographic resolution of volatile, racemic chromium(III) *tris*-hexafluoroacetylacetonate on pulverized *d*-quartz was also investigated[38]. It has since proved impossible to establish with certainty whether or not a marginal degree of enantiomer resolution was achieved in these experiments. Attempts to resolve racemic alcohols (2-alkanols, 3-menthanols) on various optically active stationary phases ((+)-2-octyl sebacate, (+)-dimethyl tartrate, peracetylated sucrose) were without success[35,39].

It was only with the introduction of high performance capillary columns for gas chromatography and the development of high sensitivity detection systems that the conditions were met which led to the development of tailored selector/selectand systems and their optimization to high resolution performance. Mainly those enantiospecific resolution systems that yield *quantitative* (baseline) resolutions of racemic mixtures under the instrumental conditions employed will be reviewed in the following discussion.

2.2. The Resolution of Derivatized Selectands on Optically Active Amino Acid and Peptide Selectors via Enantiospecific Hydrogen Bonding

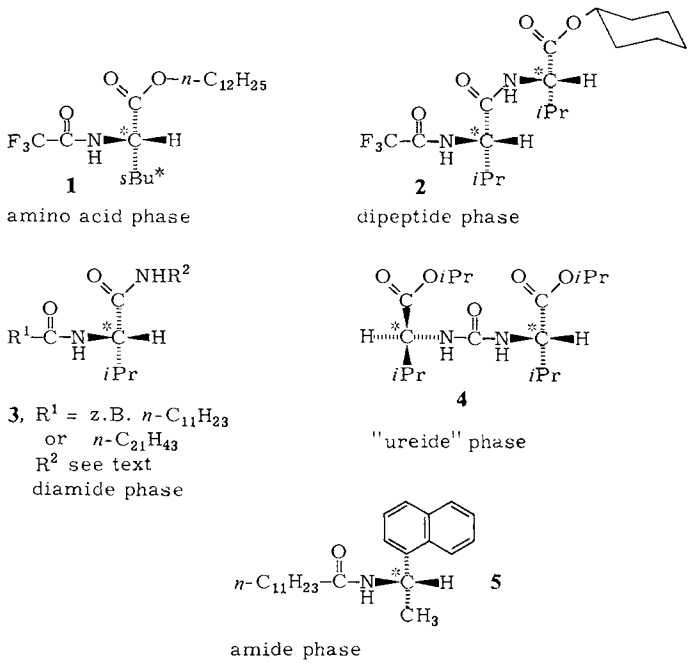
In 1966 *Gil-Av, Feibush,* and *Charles-Sigler* described the first reproducible resolution of 18 racemic, protein amino acids as their *N*-trifluoroacetyl(TFA) alkyl esters in glass capillaries coated with optically active *N*-TFA-L-isoleucine dodecyl ester **1** or *N*-TFA-phenylalanine cyclohexyl ester[12,40]. The design of this enantiospecific selector/selectand system was based on the idea of biomimetically imitating the stereospecific peptide enzyme interaction employing simple amino acid entities as model substances. In order to achieve this it was thought necessary to employ a high-performance capillary column to amplify the minute chiral recognition effect. This fundamental discovery by *Gil-Av* et al. was the starting point of a fruitful development, particularly by the research groups of *Gil-Av, Bayer,* and *König,* from a supposed curiosity with rather archaic-looking chromatograms[12] into a highly developed routine method for the resolution of the enantiomers of many important classes of compounds by gas chromatography[4,9,10]. This development was inspired by the multiplicity of possible applications on the one hand and by the interest in the mechanism of chiral recognition—as a model for the enantiospecific enzyme substrate interaction—on the other.

Gil-Av et al. ascribed the resolution to the rapid reversible molecular association of the enantiomers with the asymmetric molecules of the optically active stationary phase[12,40]. In order to increase the various steric and polar interactions between the diastereomeric associates, both the derivatization strategy for the amino acids to be resolved and the structure of the stationary phase were varied systematically. The results have been summarized in two detailed review articles[41,42].

Scheme 1 includes the structures of the most important optically active stationary phases for the enantiomeric resolution of amino acid derivatives and other nitrogen-containing racemates via hydrogen bonding.

The "second generation" phases **2**—**4** introduced by *Gil-Av* and *Feibush* exhibit better enantiospecificity than the amino acid phase **1** because of the presence of an additional amido function capable of hydrogen bonding[43–50] The first dipeptide phase tested, *N*-TFA-L-valyl-L-valine cyclohexyl ester **2**, already proved capable of the preparative resolution of racemic *N*-TFA-alanine *tert*-butyl ester on a packed 2-m column[51]. The arsenal of dipeptide phases[42] has been greatly enlarged by many investigations[52–66].

A systematic investigation has been made of the influence of the *N* and *C*-terminal amino acids of *N*-TFA-*O*-cyclohexyl derivatives of the dipeptides Val-Val[67] and

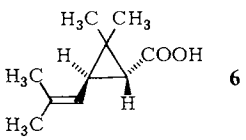


Scheme 1. Representative structures of optically active amino acid and amide stationary phases for the resolution of enantiomers via hydrogen bonding.

Phe-Leu[67,68] on the order of elution of *N*-TFA-amino acids. An expected peak inversion was observed with the mirror image phases L-Val-L-Val and D-Val-D-Val. On diastereomeric phases, e.g. L-Val-L-Val as compared to D-Val-L-Val or L-Val-D-Val, peak inversion only occurred on changing the configuration of the *N*-terminal amino acid. Hence the enantiospecificity of dipeptide phases is largely governed by the *N*-terminal amino acid. This was also confirmed by the finding that the dipeptide phase Gly-L-Val possesses significantly inferior separating properties than L-Val-Gly[67]. Accordingly the employment of tripeptide phases, e.g., *N*-TFA-L-valyl-L-valyl-L-valine isopropyl ester did not bring about any improvement in the separation factor but merely decreased the volatility as compared to dipeptide phases[44,68]. The diamide phases **3** developed by *Gil-Av* and *Feibush*[48-50,70-73] are derived from the peptide phases **2** by the removal of the *C*-terminal amino acid, which does not invoke any significant contribution to enantiomer discrimination. Phases of type **3** contain two thermally stable amide functions capable of hydrogen bonding, but only one asymmetric center, and are more enantiospecific than type **2** phases. A systematic investigation has been made of the influence of the alkyl residues R^1 and R^2 of the valine diamide phase **3** on the separation factors of *N*-TFA-α-amino acid alkyl esters[50]. The alkyl residues R^1 and R^2 influence the resolution because of their steric requirement, whereby R^2 plays a dominating role. It was found to be advantageous if R^1 constitutes the long chain residue necessary for thermal stability (n-$C_{11}H_{23}$). A decrease in the resolution in the order *tert*-butyl > cyclooctyl > neopentyl was observed for R^2. The thermally stable (up to 190°C) and less volatile phases **3**, R^2 = 1,1-dimethylhexadecyl[72] are very promising resolution phases for racemic amino acid derivatives; one phase is commercially available[71]. The high separation factors also permit preparative resolutions on packed columns[69,70]. Racemic β- and γ-amino acid derivatives[74] and derivatized 1,2- and 2,1-amino alkanols can also be separated on diamide phases **3**. Further applications of diamide phases **3** concern a diamide-diamide selector/selectand system, i.e. the resolution of racemic *N*-TFA-amino acid *tert*-butylamides on the *N*-lauroyl-*tert*-butylamides of optically active α-amino acids[75]. α-Methyl-α-amino acid amides and α-halogenocarboxylic acid amides have also been resolved on diamide phases **3**[76,77]. A concise summary of the synthesis and application of diamide phases in gas chromatographic enantiomer resolution is available[78a].

The *N,N'*-carbonyl-bis(amino acid ester) phase **4** (incorrectly named "ureide" phase in the original literature) is particularly suitable for the resolution of racemic *N*-TFA-substituted amines $RR'HC-NH_2$[43]. These phases contain two structurally equivalent NH- and CO-functions capable of hydrogen bonding in close proximity to the asymmetric center. The influence of the consistency of the "ureide" phases (liquid, liquid crystalline, solid) on the separation factor has been investigated in great detail[79-82]. Stationary phases in the solid state exhibited large separation factors α, but also a considerable amount of peak broadening, particularly for the amino acid enantiomers that were eluted as the second peak[79]. In spite of the anomalous peak shapes, the high separation factors α that could be achieved with the mesophases permitted quantitative resolutions on short packed columns[81]. *N,N'*-Carbonyl-bis(L-valine isopropyl ester) **4** and the D-leucine analogue have been employed in the smectic mesophase for the resolution of the racemic amines (*N*-perfluoroacylated 1-phenylethylamines)[82]. The close temperature range lying 10—20° below 100°C seems disadvantageous.

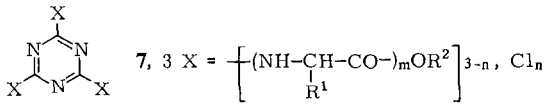
It was demonstrated by means of phase **5** (*N*-acylated chiral 1-(1-naphthyl)ethylamine) that the presence of an amide function and a single asymmetric center is sufficient for the enantiospecific resolution of racemic amides, e.g. *N*-acylamino acid esters, α-methyl-α-amino acid esters, aliphatic *N*-acylamines and α-substituted carboxylic acid amides[83]. Optically active stationary phases have also been synthesized by incorporation of a chiral acyl component in **5**, e.g. (1*R*,3*R*)-*trans*-chrysanthemic acid **6**, *O*-lauroylmandelic acid, and *N*-lauroylproline[84,85], which allow



6

the quantitative resolution of underivatized (±)-menthol, nitrile compounds, *cis* and *trans*-chrysanthemic acid **6**[86,87], macrolide lactones[88] as well as the improved resolution of racemic *N*-TFA amines and carboxylic acid *tert*-butylamides.

In order to improve temperature stability Ôi et al. incorporated the chiral structure elements shown in Scheme 1 into a triazine skeleton **7** via the *N*-terminus[89] and resolved, for instance, proline as the *tert*-butylamide[90], dipeptides (e.g. all four configurational isomers of *N*-TFA-alanylalanine isopropyl ester)[91], *O*-acyl-α-hydroxycarbox-



7, 3 X = $-[(NH-CH(R^1)-CO-)_mOR^2]_{3-n}$, Cl_n

ylic acid esters[92] and underivatized alcohols[93] into their antipodes.

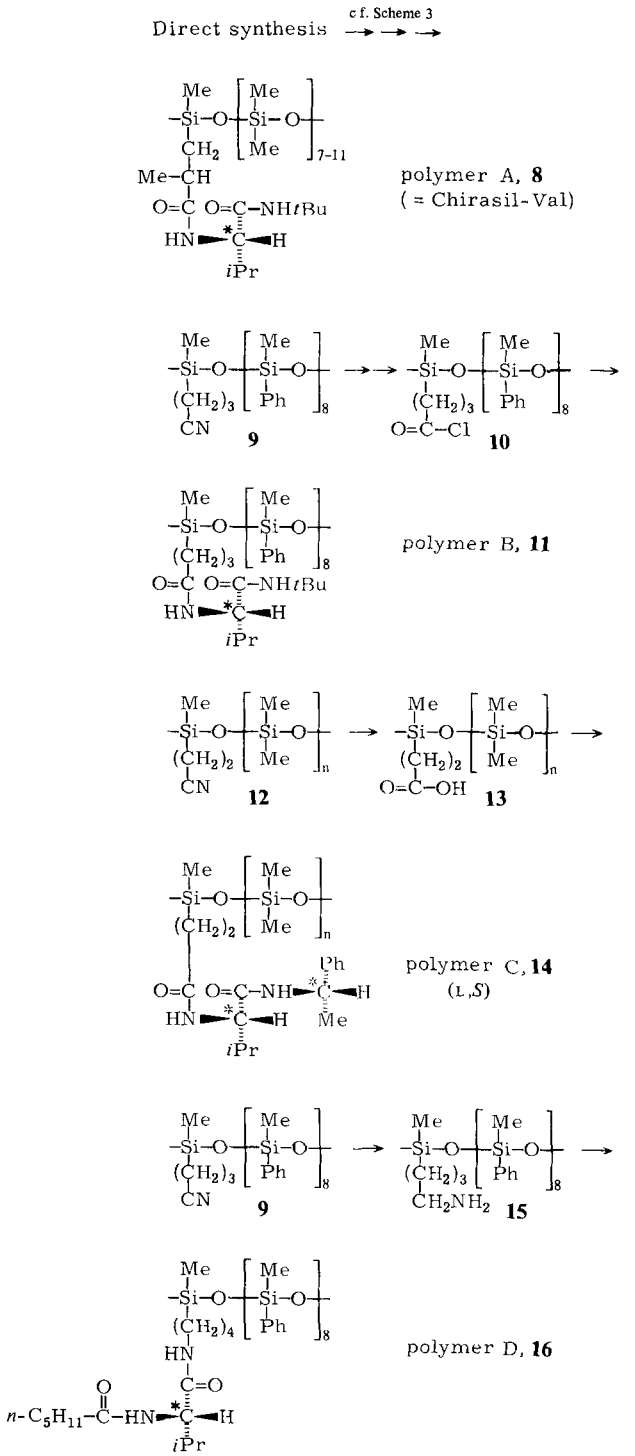
The observation that nitrogen-free racemic *O*-acyl-α-hydroxycarboxylic acid esters could be resolved into their antipodes via hydrogen bonding[92,96,97], led to the development of oxygen-containing, amide-free stationary phases, e.g. di-(−)-menthyl (+)-tartrate for the resolution of racemic *N*-acylamino acid esters, *N*-acylamines and carboxylic acid amides[94]. The results confirmed previous findings of a low degree of chiral recognition between racemic alcohols and didodecyl (+)-tartrate in a gas chromatographic system[95]. Nitrogen-free 2-hydroxycarboxylic acids were also resolved as *O*-TFA alkyl esters on *S*-mandelic acid *S*-α-phenylethylamide[96,97]. The disadvantage of these phases is their low thermal stability. The resolution of racemic, underivatized alcohols on deactivated glass capillary columns, coated with optically active polypropylene glycol (PPG) is remarkable in spite of the low separation factors obtained[98,99].

2.3. Optically Active Polymeric Siloxane Stationary Phases

The employment of low molecular weight stationary phases **1**—**5** (Scheme 1) is limited at high temperatures by thermal decomposition, racemization, and column bleeding. This precludes the resolution of many less volatile racemates in this manner. Only carefully purified amide phases **3** which are modified with long-chain substituents (e.g. R^1 = 1,1-dimethylhexadecyl, $R^2 = n\text{-}C_{21}H_{43}$) can be employed up to 200°C due to their low polarity and volatility[72]. The lower molecular weight stationary phases tend to crystallize at lower temperatures.

A new type of enantiospecific stationary phase was developed by *Frank, Nicholson,* and *Bayer,* where the amino acid amides which form the basis of the low molecular weight diamide phase **3** were attached via the free amino function to the carboxyl group of a polymeric matrix, a statistical copolymer of dimethylsiloxane and (2-carboxypropyl)methyl siloxane, having a high viscosity[100–102]. This stratergy enabled the chemical selectivity of the chiral component L-valine-*tert*-butylamide to be combined with the high thermal stability and involatility of organic polysiloxanes[103].

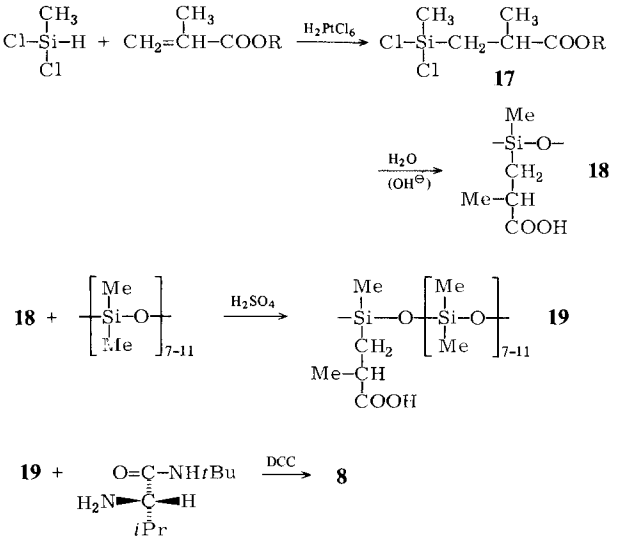
The optically active polymeric siloxane **8** (polymer A, Scheme 2), which is available commercially[104] under the name Chirasil-Val®, is characterized by high thermal stability and low column bleeding and, as a consequence, allows the resolution of enantiomers in temperature programs ranging from 70—240°C. The copolymer component dimethylsiloxane, whose proportion can be varied between wide limits, serves to increase the viscosity and to regulate the mean distance between the chiral side groups; the highest separation factors were observed for a separation of about eleven dimethylsiloxane units[10]. The resolving properties deteriorate with closer spacing because the functionalized polysiloxane tends to crystallize due to the interaction between neighboring peptide side chains. If the spacing is increased, then the cooperative effect between two chiral selectors for enantiomeric discrimination of the selectand begins to decrease. Incidentally, the mean distance bears no relationship to the actual molecular statistical distribution which has been calculated iteratively[105]. This analysis revealed that not all of the chiral centers can contribute to the enantiomer resolution[105]. It ought to be



Scheme 2. Entry to optically active polysiloxanes for gas chromatographic enantiomer resolution.

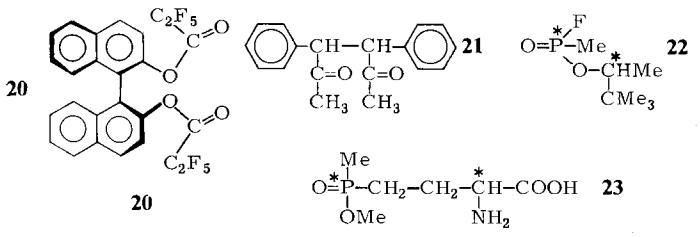
mentioned that Chirasil-Val **8** contains an additional chiral center in the (racemic) side chain.

The synthesis of **8** is outlined in Scheme 3[106]. The coating of deactivated glass capillary columns with **8** enabled the rapid baseline resolution of all 17 racemic protein amino acids for the first time as their *N*-pentafluoropropionyl isopropyl esters[107, 108] (see Fig. 3).



Scheme 3. Four-step synthesis of **8** (Polymer A). 1. Synthesis of the dichlorosilane monomer **17**. 2. Synthesis of the carboxyalkylmethylsiloxane **18**. 3. Synthesis of the copolymer **19**. 4. Coupling of **19** with Val-NH*t*Bu in presence of dicyclohexylcarbodiimide (DCC) to give **8**.—Derivatives of other amino acids and peptides can react analogously with **19**.

Even the analysis of the involatile amino acids Met, Phe, Glu, Tyr, Orn, Lys and Trp does not present any difficulties after suitable derivatization. The analysis of racemic drug metabolites is also possible employing pre-treated glass and, more recently, fused silica capillaries which have been coated with Chirasil-Val **8**[108, 109]. The range of applicability of **8** extends from the resolution of the racemates of aryl glycol esters, atropisomeric binaphthyl derivatives **20**[105], an underivatized diketone (*threo*-3,4-diphenyl-2,5-hexanedione, **21**)[105], alkyl 2-hydroxycarboxylates[110, 111], the nerve gas Soman **22** (four isomers)[112], amino acid sulfoxides[175], and the methyl ester of phosphinotricin **23**[175] which, like **23**, possesses an asymmetric phosphorus atom as well as a chiral carbon atom.



The high thermal stability and the low tendency to column bleeding of Chirasil-Val **8** is of prime importance for combined gas chromatography-mass spectroscopy[175].

The incorporation of phenyl groups[113] and polar modifiers (cf. **24**) in **8** allows the tailoring of the enantiospecificity and polarity of the chiral phase such that all protein amino acids can be resolved quantitatively without peak overlap[114]. (*S*)- or (*R*)-α-phenylethylamine and (*S*)- or (*R*)-1-(1-naphthyl)ethylamine have also been employed as additional chiral components as the amide substituent of L-valine (or L-leucine). The diastereomeric polysiloxane with L-valine-(*R*)-1-(1-naphthyl)ethylamide moieties was able to accomplish a partial resolution of the *O*-TFA derivative of the alcohol 1-cyclopropylethanol[114]. Furthermore, the amine (*R*)-1-(1-naphthyl)ethylamine has been coupled to a polysiloxane and employed to resolve the phenyl or methylurethane derivatives of alcohols into their enantiomers for the first time[114].

Verzele et al. have described a preparatively simple route to chiral polysiloxanes[115, 116]. Thus, the cyano groups of commercially available polysiloxanes of type **9**[103], e.g. OV-225 or Silar-10C are hydrolyzed and, after conversion into the acid chloride **10**, the carboxyl groups are coupled with the free *amino function* of L-valine-*tert*-butylamide[49] to yield polymeric diamide **11** (Polymer B, Scheme 2). *König* et al. prepared a variant of Polymer B from the commercially available XE-60 polysiloxane **12**, e.g. the diamide **14** (Polymer C, Scheme 2), which, in analogy to modified Chirasil-Val[114], contains (*R*)- or (*S*)-1-phenylethylamine as an additional chiral component in the amide function of the L-valine selector[117–119]. In the case of a diastereomeric selector the relative configurations of the chiral centers is decisive for an optimal enantiomer discrimination and this must be elucidated empirically. Both polysiloxanes **14** (Polymer C (L,*R*) and (L,*S*)) have been synthesized and their complementary resolving power has been compared by means of two capillary columns, each packed with diastereomeric phase[121]. Thus, polymer C (L,*R*) is especially suitable for the resolution of *N*-TFA-amines and *N,O*-bis(TFA)-amino alcohols, while polymer C (L,*S*) can be employed for the resolution of racemic *N*-TFA-amino acid isopropyl esters[9, 120–122]. Polymer C (L,*S*) has also proved valuable for the separation of constitutional and configurational isomers of carbohydrates[117, 118]. Polymer C (L,*S*) has become known as XE-60-L-valine-*S*-α-phenylethylamide[123].

Another synthetic strategy consists of the reduction of the cyano groups of OV-225 **9** with $LiAlH_4$ in diethyl ether and reaction of the resulting amine with the *carboxy function* of *N*-acyl-L-valine (or *N*-acyl-L-leucine) to form the polymeric diamide **16** (Polymer D, Scheme 2)[119]. While in Polymers A—C the macromolecular residue formally constitutes the acyl component, in Polymer D it formally functions as the amide component. Polymer D is particularly suitable for the resolution of racemic *N,O*-bis-acylamino alcohols and *N*-acyl amines[119].

One advantage of the direct synthesis of chiral polysiloxanes of the type **8** lies in the manifold possibilities for variation of copolymer composition, e.g. in the deliberate inclusion of polar modifiers, as in **24**[114].

Commercial polysiloxanes with varying amounts of cyanopropyl groups were employed for the synthesis of polymers B—D[115, 117, 119] which, after hydrolysis and coupling with established chiral selectors, yielded polysiloxanes with similar properties to those of Chirasil-Val **8**[10] or its variants[114]. However, the disadvantage of these pol-

ymer analogues is that the strongly acid or basic conditions necessary for hydrolysis of the cyano groups may also bring about some depolymerization, so that the relationship between the copolymers is uncontrollably altered and hence polarity and viscosity are affected[143]. The acid chloride group in **10** could also cause problems in the preparation of Polymer B, and the depolymerizing properties of $LiAlH_4$ must be taken into account in the synthesis of Polymer D[143].

2.4. Derivatization Strategies

The gas chromatographic resolution of enantiomers via hydrogen bonding must almost always be preceded by a derivatization of the racemic selectand (cf. Table 2 and [137, 138]). The derivatization is necessary, on the one hand, to transform involatile and/or polar substrates (e.g. amino acids) into derivatives which can be vaporized without decomposition and, on the other, to introduce further chemical functions into the molecule that are capable of forming hydrogen bonds and increasing the chiral recognition of the selector/selectand system. In this way the introduction of a chemically stable amide function can lead to the formation of additional hydrogen bonds with the optically ac-

Table 2. Resolution of enantiomers by gas chromatograhy on chiral polymers A–D (see Scheme 2). A selection of classes of compounds and derivatization.

Class of compound	Derivatization	Polymer	Reference
α-Amino acids	*N*-perfluoroacyl alkyl ester	A, B, C, D	[100, 115, 116, 120, 136]
N-Methyl-α-amino acids	*N*-alkylureido alkyl ester	C(L,*S*)	[124]
Amino alcohols	*N,O-bis*-(trifluoroacetyl)	C(L,*R*), D	[109, 118, 119]
Amines RR'HC–NH_2	*N*-isopropylcarbamoyl	C(L,*S*)	[125]
Amines RR'HC–NH_2	*N*-trifluoroacetyl	C(L,*R*), D	[118, 119, 126]
Hexoses, pentoses	*O*-trifluoroacetyl glycoside	C(L,*S*)	[117, 118, 127]
Hexoses	boronate	A	[128]
Cyclic polyols	*O*-trifluoroacetyl	C(L,*R*)	[126]
α-Hydroxycarboxylic acids	*O*-carbamoyl alkyl ester	A, C(L,*S*)	[111, 125]
α-Hydroxycarboxylic acids	alkyl ester	A	[110]
β-Hydroxycarboxyl acids	*N*-(*tert*-butylcarbamoyl *tert*-butylamide	C(L,*S*), A	[124]
Phenyl glycols	bis(pentafluoropropionate)	A	[105, 109, 175]
Atropisomeric binaphthyls	bis(pentafluoropropionate)	A	[105, 175]
Sulfur-containing amino acids	*N*-pentafluoropropionyl methyl ester	A	[187]
Sulfoxides (methionine-*S*-oxide)	none (perfluoracyl alkyl ester)	A	[147, 175]
sec-Alcohols	urethanes	A, C(L,*S*)	[114, 129]
1,2-Diols, 1,3-diols	cyclic carbonates	C(L,*R*)	[130]
Ketones	*syn, anti*-oximes	C(L,*S*)	[131]
Halocarboxylic acids	amides	A	[188]
Pharmaceuticals	various	A, B, C(L,*R*)	[108, 109, 116, 132–135]

tive selector. The design of an appropriate derivative can also lead to greater detector selectivity or sensitivity (e.g. by element-selective detectors).

The derivatization process should fulfill the following criteria:

1. quantitative reaction;
2. absence of side and rearrangement reactions;
3. exclusion of racemization.

For quantitative analysis, the yield of the derivative and its separation from solvent and derivatizing reagents must be reproducible. It is particularly necessary that derivatization reactions proceed without racemization, if the enantiomeric composition ("enantiomeric excess", *e.e.*) is to be determined gas chromatographically. The proof of absence of racemization is often not easy to perform.

The introduction of thermostable chiral polymer phases has widened the scope of derivatization strategies, since less volatile derivatives can now be analyzed. Thus, the often low separation factors can be compensated at high temperatures by increasing the enantiospecificity between the derivatized selectand and the selector with the advantage of shorter analysis times. Gas chromatographic derivatization methods are well established; recently, derivatization has been automated for quantitative amino acid analysis[139, 140].

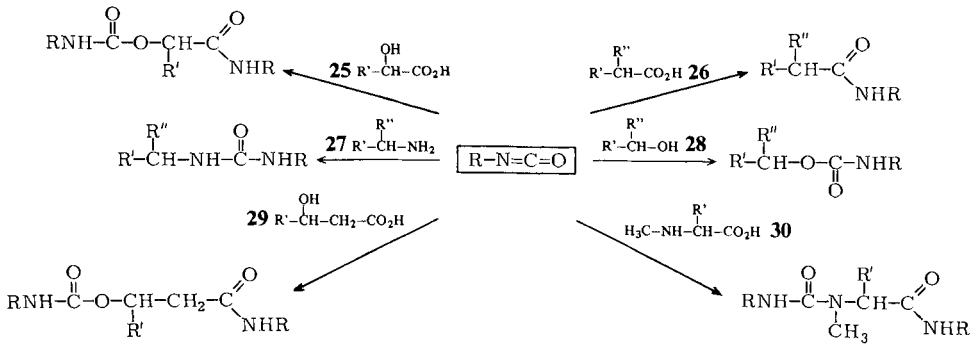
The classical method of derivatization of α-amino acids is their conversion into *N*-perfluoroacyl alkyl esters; OH- and SH-functions are likewise protected with perfluoroacyl groups[44, 46, 50, 52, 141, 142]. The *tert*-butyl esters exhibit the best properties as far as enantiomer resolution is concerned. However, since these are only accessible with difficulty, the isoalkyl esters (e.g. isopropyl esters) are preferred. Trifluoroacetyl (TFA), pentafluoropropionyl (PFP) and heptafluorobutyryl (HFB) are employed as perfluoroacyl residues[54, 142]. TFA derivatives exhibit higher separation factors, while PFP derivatives are more volatile.

The derivatization of α-hydroxycarboxylic acids was first performed by introducing amide functions, e.g. as the *O*-PFP cyclohexylamide for lactic acid[108], or as the *O*-carbamoylalkyl ester[111, 125]. Later resolutions were also achieved with nitrogen-free hydroxycarboxylic acids, e.g. as *O*-acyl esters[92, 96, 118] or even as free alkyl esters[92, 110, 111]. The peak tailing caused by the presence of a free hydroxy group could be suppressed by employing a fused silica capillary column[110]. The conversion of the easily racemizing mandelic acid into the 1-ethylpropyl ester (10% HCl, 110°C, 1 h) proceeded without racemization. In contrast a considerable degree of racemization was observed in the case of mandelic acid during the three-stage derivatization of 2-hydroxycarboxylic acids to *O*-acylated amides[110]. The conversion of the hydroxy groups of 2-hydroxycarboxylic acids into urethane by isocyanate is neither quantitative nor free from by-product formation.

The resolution of acylated secondary alcohols[84, 88, 114] is difficult. An improvement is achieved by chromatography on optically active polymer stationary phases as the urethane derivatives[114, 129]. Phosgene has recently been suggested as a derivatizing agent for 1,2- and 1,3-diols, α-amino alcohols, α-hydroxy acids, and *N*-methylamino acids[130], while isocyanates (see Scheme 4) can be employed to derivatize both functional groups of hydroxy and amino acids simultaneously[144]. The isocyanate method is particularly advantageous for the derivatization of *N*-methyl-α-amino acids **30**, since on acylation these react with complete racemization to yield alkylidene oxazolidin-5-ones[145].

Oximes have been employed for the resolution of racemic ketones[131]. The occurrence of *syn*- and *anti*-isomers may be regarded as a complication. Interconversion of the isomers during separation, which takes place in the case of 2,4-dinitrophenylhydrazones of carbonyl compounds, leading to characteristic interconversion peak profiles[146], has not been observed for oximes. Racemization has also been excluded for enantiomerically pure camphor and fenchone during derivatization to their oximes[131].

For practical purposes enantiomer resolution without resorting to derivatization procedures, as practised in com-



Scheme 4. Isocyanates (R = Me, *i*Pr, *t*Bu, Ph) as derivatizing reagents for α- **25** and β-hydroxycarboxylic acids **29**, 2-alkylcarboxylic acids **26** (each 100°C, 60 min), amines **27** (20°C, 30 min), *sec*-alcohols **28** (100°C, 10 min), and *N*-methyl-α-amino acids **30** (100°C, 60 min) [144].

plexation gas chromatography[2, 11], is advantageous. Only in isolated instances have underivatized selectands, e.g. 1-phenyl-2,2,2-trifluoroethanol[93], 3,4-diphenyl-2,5-hexanedione **21**[105], sulfoxides[147], barbiturates[132] and photodimers of cycloalkenones[148], been resolved on dipeptide phases and chiral polysiloxanes. The separation factors are often very small since no suitable functions are available for strong hydrogen bond formation. Complexation gas chromatography, which was designed following the realization that many racemic selectands do not possess functions suitable for derivatization (e.g. ethers, esters, lactones, unsaturated hydrocarbons) is particularly suitable for the resolution of underivatized alcohols and ketones[22] (see footnote [**] on page 747).

2.5. Thermodynamic Parameters of Gas Chromatographic Enantiomer Resolution

Gas chromatography retention parameters are an important source of data for the calculation of thermodynamic association constants of molecular complexation (see the literature cited in [23] and [149]). The difference in the free enthalpy of association for an enantiomer pair— $-\Delta_{R,S}(\Delta G^\circ)$ can be calculated from the difference in the association constants for the antipodes of the selectand and the chiral selector according to Eq. (1) (*R* refers arbitrarily to the later and *S* to the earlier eluting enantiomer, respectively):

$$-\Delta_{R,S}(\Delta G^\circ) = RT \ln K_R/K_S \tag{1}$$

The difference between the free enthalpies of association of selectands, which are resolved via hydrogen bonding with dipeptide and polysiloxane stationary phases, can be calculated from the difference in retention of the enantiomers via the separation factor α_{max}[50, 80, 81]:

$$-\Delta_{R,S}(\Delta G^\circ) = RT \ln(t'_R/t'_S) = RT \ln \alpha_{max} \tag{2}$$

The separation factor α_{max} represents the relationship between the net retention time t' (measured from the air or methane peak, t_M = dead time) of the more strongly and more weakly retained enantiomer. Since the net retention time is determined by both the physical *and* the chemical contributions to retention, the decisive chemical contribution of the enantiomer differentiation $-\Delta(\Delta G^\circ)$ is generally underestimated when using Equation (2). When a selector is used that is only partially optically enriched then knowledge of the degree of enantiomeric purity (*e.e.*) can be employed to obtain the maximum separation factor valid for quantitative enantiomeric purity by mathematical extrapolation[50].

The temperature dependence of the separation factor α_{max} can be employed to calculate the Gibbs-Helmholtz parameters $-\Delta_{R,S}(\Delta H^\circ)$ and $\Delta_{R,S}(\Delta S^\circ)$ of chiral recognition according to Eq. (3) and (4):

$$R \ln \alpha_{max} = -\frac{\Delta_{R,S}(\Delta H^\circ)}{T} + \Delta_{R,S}(\Delta S^\circ) \tag{3}$$

$$\left(\frac{\partial \ln \alpha_{max}}{\partial (1/T)}\right)_p = -\frac{\Delta_{R,S}(\Delta H^\circ)}{R} \tag{4}$$

According to Equation (3) a plot of $R \ln \alpha_{max}$ against $1/T$ is linear, whose slope is the difference between the enthalpy of association and whose intercept is the difference of the entropy of association of the highly dilute enantiomers in the stationary phase. The lower limit for enantiomer differentiation, which still yields complete peak separation in a high-performance capillary column can be estimated as 10 cal/mol for $-\Delta_{R,S}(\Delta G^\circ)$ corresponding to a separation factor $\alpha = 1.01$ at 25°C[7].

Values of $-\Delta(\Delta G^\circ)$ in the range 40—580 cal/mol were measured for the gas chromatographic resolution of *N*-TFA-2-amino alkanes on the "ureide" phase **4** (Scheme 1)[80]. As would be expected a linear relationship was observed between $\ln\alpha$ and $1/T$ for the resolution of the enantiomers of *N*-perfluoroacylnorleucine alkyl esters on the dipeptide phase *N*-TFA-phenylalanyl-L-leucine cyclohexyl esters[47]. The Gibbs-Helmholtz parameters of the enantiomer discrimination between racemic *N*-TFA-alanine and leucine esters and the diamide phase **3**, $R^1 = n\text{-}C_{11}H_{23}$, $R^2 = CH_2tBu$, have been determined[150]. The highest values for the selectand *N*-TFA-leucine (1-ethylpropyl ester) were $\Delta(\Delta H^\circ) = -1.611$ kcal/mol, $\Delta(\Delta G^\circ) = -338$ cal/mol, and $\Delta(\Delta S^\circ) = -3.32$ cal mol^{-1} K^{-1} at 110°C.

When chiral polysiloxanes are employed as stationary phases for enantiomer resolution the physical contribution of the achiral polymer network to the net retention time t' cannot be ignored. Otherwise, the actual contribution of the chiral side chain to enantiospecificity as calculated

from the ratio t'_R and t'_S will be underestimated. The separation of the physical and chemical contribution to the retention time can be attempted by employing a polysiloxane reference column (e.g. SE 30)[105].

The temperature dependence of the retention times of racemic aromatic diol diesters has been studied in order to determine the thermodynamic data for enantiomer discrimination on Chirasil-Val **8** (Polymer A)[105]. Enthalpy parameters were obtained from the approximation equation (5) (t' = net retention time, t_M = dead time):

$$\frac{\partial(\ln t')}{\partial(1/T)} - \frac{\partial(\ln t_M)}{\partial(1/T)} = -\frac{\Delta H^\circ}{R} \tag{5}$$

For gas chromatographic enantiomer resolutions reported up to now, a decrease in the separation factor α has always been observed on increasing the temperature. Since the separation factors are linked to changes in the free enthalpy of association, and the latter depends on the interplay between enthalpy change, entropy change, and temperature [Eq. (6)] according to the Gibbs-Helmholtz equation, at very high temperatures the separation factors may, in principle, increase again with simultaneous reversal of the order of elution[105].

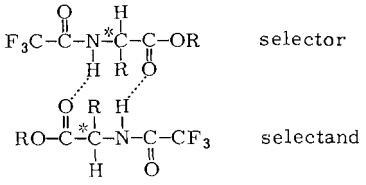
$$-\Delta_{R,S}(\Delta G^\circ) = -\Delta_{R,S}(\Delta H^\circ) + T\Delta_{R,S}(\Delta S^\circ) \tag{6}$$

Thus, the determination of the Gibbs-Helmholtz parameters provides a criterion for a more precise understanding of the mechanisms of chiral recognition. Gas chromatography constitutes an important tool (which has only been employed in isolated instances) for a deeper insight into the mechanisms and origins of enantiospecificity, which is a common phenomenon in living matter, with preference for the image over the mirror image.

2.6. Mechanistic Aspects of Gas Chromatographic Enantiomer Resolution via Hydrogen Bonding

The design of the first selector/selectand system for the gas chromatographic resolution of enantiomers on the basis of simple amino acid entities was inspired by the known stereospecificity of enzymes[4]. The observed enantiomer discrimination was attributed to the formation of diastereomeric associates between the racemic selectand and the optically active selector[12,40]. In their first interpretation *Feibush* and *Gil-Av* suggested that association complexes were formed rapidly and reversibly by hydrogen bonding between carbonyl and amide functions[44] (Scheme 5).

Depending on the configurations of the selector and the selectands, complexes possessing differing stabilities are



Scheme 5. Hydrogen bonding between selector and selectand.

produced during combination to diastereomeric associates. This thermodynamic expression of the enantiomer discrimination, caused by chemical selectivity, depends on a rapid establishment of the chemical equilibrium. This condition is fulfilled for hydrogen bonding even when preequilibria are involved[105].

A kinetic control of the enantiomeric resolution process can also be envisaged and could be recognized, on the one hand, by peak broadening and, on the other, by dependence of the retention time on the flow rate of the mobile phase.

Such effects have apparently been observed when liquid-crystalline stationary phases were employed[81,82]. The sharp peak elution observed in the overwhelming number of cases allows the exclusion of kinetic effects.

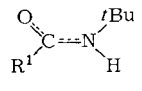
While only two hydrogen bonds can be formed in the association of *N*-TFA-amino acid alkyl esters with phase **1**, phases **2**—**4** can enter into a further association (due to the presence of an additional amido function (cf. Scheme 1).

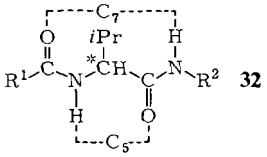
The order of elution of amide and amino acid derivatives on "ureide" phases has been interpreted by *Feibush* et al.[27] by employing the *Cram* model, in which the steric requirement of the substituents (l > m > s) at the asymmetric center is employed to explain enantiospecificity.

Enantiospecific interactions other than hydrogen bonds can also lead to enantiomer discrimination. Thus *Stölting* and *König*[64] observed a racemate resolution of *N*-TFA-proline esters on *N*-TFA-L-prolyl-L-proline cyclohexyl ester as stationary phase, a selector/selectand system which does not possess amide hydrogens capable of hydrogen bonding.

The original model of a dimeric association complex, comprising three hydrogen bonds[47], was abandoned by *Beitler* and *Feibush*[50] in a systematic investigation of the variations of residues R^1 and R^2 in the diamide phase **3**. More recent models take into account the common knowledge of the structure and conformation of peptides[4,69]. Assuming a planar *trans*-conformation **31** for the amide function, diamides at high dilution can form a planar five-membered ring (C_5 unit) or a puckered seven-membered ring (C_7 unit) by intramolecular hydrogen bonding (see **32**).

31





32

However, under the conditions of a gas chromatographic experiment oligomerization by intermolecular hydrogen bonding with the formation of "C_5–C_5", "C_7–C_7" and "C_5–C_7" associates is assumed in the molten diamide (cf. Fig. 6).

The β-pleated sheet structure of peptides constitutes a typical example of this interaction. According to Figure 7 associates of ring size 5 + 5 = 10 and 7 + 7 = 14 are formed when the chains are arranged parallel; antiparallel arrangement leads to associates of ring size 5 + 7 = 7 + 5 = 12. Numerous spectroscopic and structural investigations on

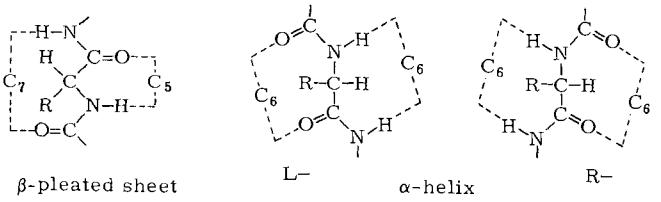


Fig. 6. Bifunctional coordination possibilities for hydrogen bonding in peptides [105].

N-acyl-α-amino acid alkylamides have confirmed these association mechanisms. It is important to note that (under the conditions of the gas chromatographic experiment) the preferred structure of the diamide in the crystalline state is largely preserved in the melt.

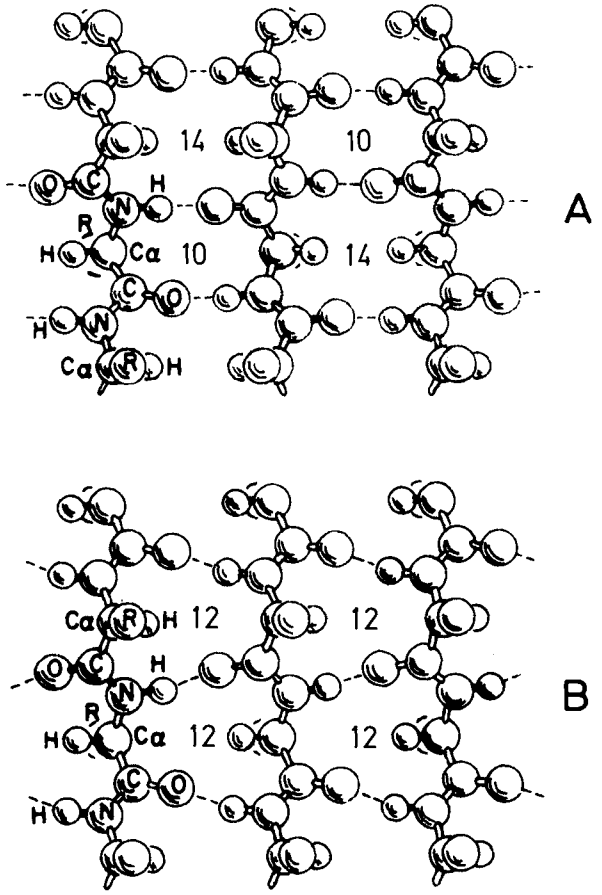

Fig. 7. β-Pleated sheet structure of polypeptides (A: parallel chains, B: antiparallel chains) [78]. The numbers signify ring size.

According to *Beitler* and *Feibush*[50], a selectand molecule associates with a diamide selector via two hydrogen bonds forming a $5+5=10$ ring in an analogous manner to the β-pleated sheet structure of polypeptides (cf. Fig. 8). The differing positions of the isopropyl group of valine in the diamide phase and the amino acid residue R^3 of the selectand in the diastereomeric associates L,L′ and L,D′ may explain the observed enantiospecificity, whereby it has been demonstrated experimentally that the L,L′ combination is more stable than the L,D′ one[50]. Later, an association by means of $7+7=14$ rings was postulated to explain

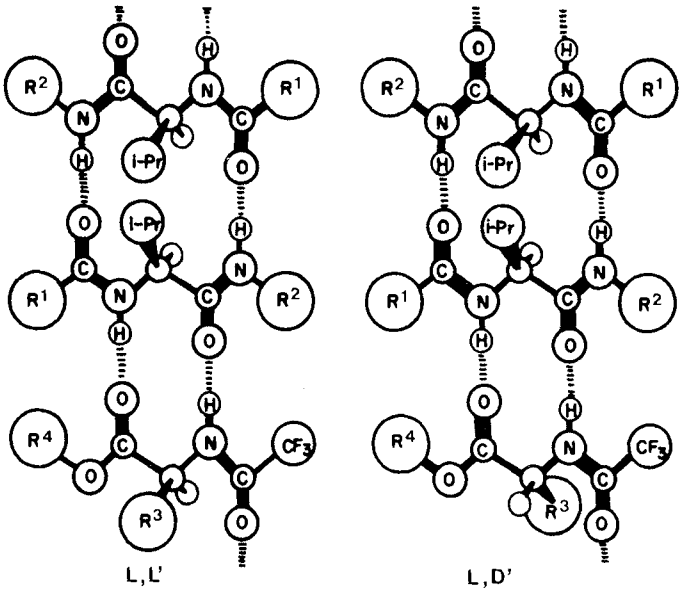

Fig. 8. The mechanism of association between amino acid derivatives and diamide phases [50].

the association of the *N*-TFA isopropyl ester of an L-α-amino acid with the diamide *N*-acyl-L-leucine-*tert*-butylamide and analogues (Fig. 9)[78]. Here too the differing steric situation of the residue R and the isobutyl group, which are aligned parallel in the case of amino acids of the same configuration, leads to differing stability for the associate and is assumed to be responsible for chiral recognition. All amino acid derivatives which possess a primary amino group (except proline) are resolved into their enantiomers by the same mechanism since the elution of D- and L-form is identical in all cases (see Section 2.7).

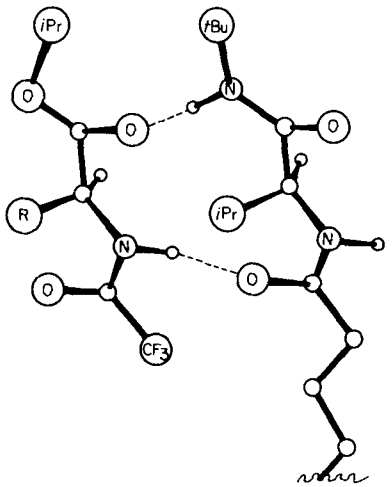

Fig. 9. Association of *N*-TFA amino acid isopropyl esters and a diamide of type **3** [78].

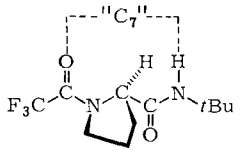
This model is able to explain the following experimental results[78a]:

1. The diamide phase *N*-lauroyl-*N*-methyl-L-leucine-*tert*-butylmethylamide, which does not possess any free am-

ide functions, does not exhibit any enantiospecificity for amino acid derivatives. This underlines the importance of hydrogen bonding for enantiospecificity.

2. Proline is intrinsically incapable of forming more than one hydrogen bond and, hence, is very difficult to resolve into its enantiomers. The transformation of the carboxy group to an amide **33**[75,90], however, allows an effective resolution of the enantiomers because of the presence of a C_7 unit[78a].



33

3. Only the *N*-terminal amino acid of dipeptide phase **2**[44] is capable of forming a "C_7" unit with associating selectands. Indeed, the *C*-terminal amino acid does not participate in enantiomer discrimination[67,68].

Since models only reflect the major part of an experimental finding, other association mechanisms can also come into play. For example, association by acyclic hydrogen bonding, van der Waals interactions, and dipole dipole interactions can also be considered. The multiplicity of possible enantiospecific selector/selectand interactions is clearly demonstrated by the resolvability of *N*-TFA-proline esters and *N*-acylamines[73], of 2-hydroxycarboxylic acid alkyl esters[96], and α-chlorocarboxylic acid amides[77] on diamide phases.

Apart from 1:1 association complexes there is also the possibility of 1:2 interaction, whereby the selectand, which is employed at great dilution, is sandwiched between two molecules of the undiluted selector which is present in large excess in the stationary phase. Such intercalation interactions have been postulated for amide phases of structure **5** (Scheme 1)[83]. According to Figure 10 the selector (*R*)-*N*-lauroyl-1-(1-naphthyl)ethylamine crystallizes with the formation of intermolecular hydrogen bonds along a 5-Å translation axis[150]. The parallel arrangement of the aromatic rings and the linearity of the alkyl side chains which are also retained in the melt are important structural features. The constitutionally and configurationally equivalent selectand (*R*)-*N*-TFA-1-(1-naphthyl)ethylamine fits ideally into this structure, while the intercalation of its enantiomer is more difficult. Hence, the gas chromatographically observed enantiospecificity can readily be attributed to the differing stability of the diastereomeric intercalation aggregates, which has been additionally confirmed by calculations of energy data[83,150].

The interpretation of the enantiospecificity of optically active polysiloxanes (Polymers A—D) must take into account both the (statistical) distance between the chiral side chains and the preferred conformation of the amino acid selector. According to statistical evaluation of valine residues in polypeptides and theoretical calculations valinamide exists preferentially in a β-pleated sheet type structure or α-helical form with a preference for the latter conformation[105,175].

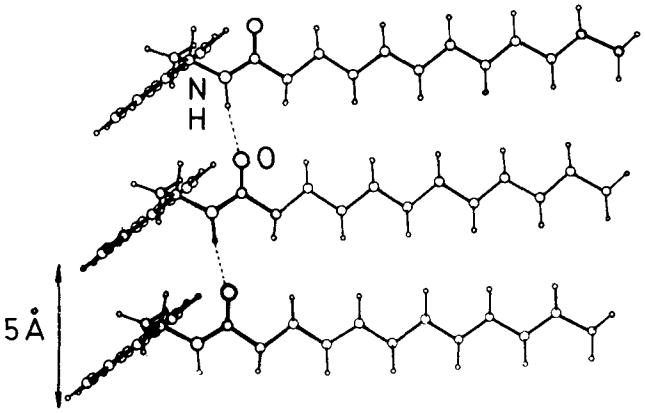


Abb. 10. Hydrogen bond formation along a 5-Å translation axis in (*R*)-*N*-lauroyl-1-(1-naphthyl)ethylamine (*R*)-**5** [150].

According to *Koppenhöfer*[105] the observed enantiospecificity of Chirasil-Val **8** for bifunctional oxygen-containing selectands containing no amide functions can, according to Figure 6, onl occur with a conformation of the valinamide selector in which both amide groups are directed towards the substrate (α-helix type), while a β-pleated sheet structure is to be expected for nitrogen-containing selectors[175].

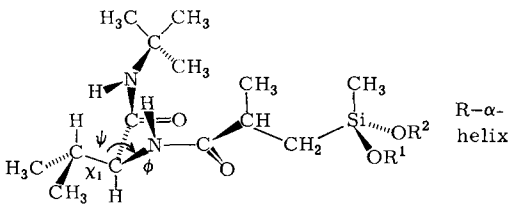

Figure 11 illustrates the postulated β-pleated sheet structure of an associate between Chirasil-Val and intercalated *O*-pentafluoropropionyl-L-lactic acid cyclohexylamide[108], which is characterized by the formation of the maximum number of hydrogen bonds. According to this model for the L,L′ combination the bulky isopropyl groups of **8** and the methyl groups of the lactic acid derivative are stacked in layers one above the other and stabilize the associate by

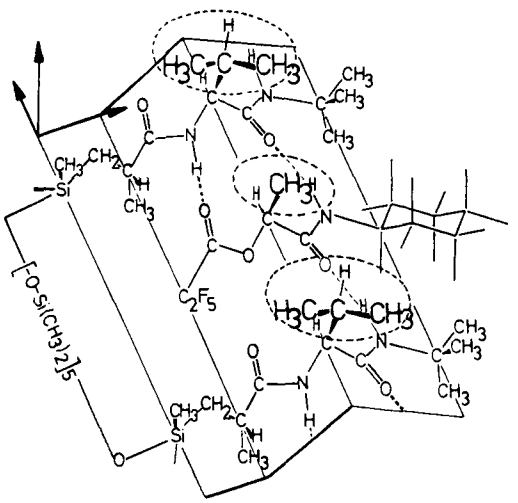

Fig. 11. β-Pleated sheet structure of an associate of Chirasil-Val **8** (Polymer A) with *O*-pentafluoropropionyl-L-lactic acid cyclohexylamide [108].

van der Waals forces[108]. The L,D′ combination does not allow of such a layer formation. The model also takes into account the importance of the main polysiloxane chain which separates the L-valinamide side chains.

These models assume that different conformations of the valinamide selector are required by nitrogen-containing and nitrogen-free selectands. This implies either that Chirasil-Val exists in various conformations or that a preferred conformation is induced during the "diastereotropic"[111] approach of selector and selectand.

2.7. The Correlation between Absolute Configuration and Retention Properties

The large degree of agreement between the retention properties of individual enantiomers of selectands with respect to their absolute configuration within an homologous series constitutes one of the significant characteristics of gas chromatographic selector/selectand systems. The correlation of absolute configuration with order of elution has acquired a place of great importance in enantiomer analysis. The basis for such correlations is the overwhelming analogy between the separation mechanism for structurally similar substrates on selectors of defined chirality.

Early on *Gil-Av* et al.[12] demonstrated that all the D-*N*-TFA-α-amino acid esters investigated eluted before their L-enantiomers on stationary phase **1**, if the selector possesses the L-configuration. As expected the order of elution is reversed if the mirror image D-stationary phase is employed (peak inversion). Likewise, the D-derivatives are eluted before L-*N*-TFA-amino acid esters on L-valine diamide phases regardless of whether the diamide is present in low molecular weight[50] or polymeric form (Polymers A, B, C, Scheme 2)[100, 115, 120]. The order of elution of β and γ-amino acid derivatives is, however, the reverse of that for α-amino acids on *N*-lauroyl-L-valine (1-pentylhexyl)amide[50].

A systematic investigation of the retention behavior of *N*-TFA amines and *N*-TFA α, β and γ amino acid esters on the "ureide" phase **4** revealed[27] that the order of elution and the separation factors depend on the steric requirements of the substituents at the asymmetric carbon atoms of the selectands. The substituents were ordered according to their effective size without taking any account of their chemical function in analogy to *Cram*'s model. If the substrate model is viewed from the asymmetric carbon atom in the direction of the nitrogen atom, then the substituents are arranged in decreasing size in either a clockwise or counterclockwise direction. All enantiomers whose substituents are arranged clockwise in this classification are eluted as the second peak on the L,L′ phase. The size of the separation factor α increases with increasing size difference of the substituents. This rule, which correlates the configuration with the order of elution, has been confirmed by many observations: Since the size of the substituents R and CO_2R' is reversed, D-*N*-TFA-alanine alkyl esters are eluted before the L-enantiomers while L-*N*-TFA-leucine methyl esters are eluted before the D-isomers; the separation factors become smaller as the effective size difference between R and CO_2R' decreases or become proportionally larger with a corresponding increase[27]. The correlation between configuration and retention behavior in gas chromatography has enabled a controversy to be resolved without resort to chiroptical methods[28] concerning the absolute configuration of 2-amino-3-methylbutane and 2-amino-4-methylbutane.

Derivatized amines, alcohols, ketones, hydroxycarboxylic acids and amino acids also exhibit consistent retention properties with respect to their absolute configuration on optically active polysiloxanes[10, 97]. In analogy to the differing separation mechanisms for nitrogen-containing and nitrogen-free selectands on Chirasil-Val (Polymer A), 2-hydroxycarboxylic acids exhibit varying retention relationships depending on the derivatization strategy. Thus the L-enantiomers of 2-hydroxycarboxylic acid alkyl esters are eluted before those with the D-configuration on Chirasil-L-Val, while the order of elution is reversed for the corresponding amides or urethanes[110, 111].

Needless to say, the correlation between molecular configuration and retention behavior of selectands in conjunction with the absolute configuration of the selector constitutes an important criterion for the mechanistic consideration of chiral recognition.

2.8. Applications of the Gas Chromatographic Method to the Resolution of Enantiomers

The suitability of gas chromatography for sensitive and precise determinations of enantiomer compositions[2] was recognized by several research groups after the first successful *quantitative* separation of amino acid derivatives and employed for many types of investigations, e.g. the demonstration of unnatural amino acids in bacterial cell walls and in peptide antibiotics, the monitoring of amino acid purity during peptide synthesis, the determination of the degree of racemization during peptide hydrolysis, the dating of paleontological and archeological finds by exploiting the time-dependence of amino acid racemization, the search for biogenic amino acids in extraterrestrial material, and the amplification of optical activity under abiotic conditions[4, 10, 14, 151, 175].

Thus a D/L ratio of up to 2.33 was observed gas chromatographically for alanine from the cell walls of staphylococci[152], and isovaline (2-amino-2-methylbutyric acid) from various peptide antibiotics could be assigned to the *R*-configuration[157]. During the hydrolysis of the dodecapeptide $(Leu\text{-}Ala)_6$, which had been synthesized by the *Merrifield* solid state method[153], less than 0.1% of unnatural amino acid antipodes could be detected, whereas the racemization of L-asparagine during the hydrolysis of the heptadodecapeptide desamidosecretin amounted to up to 2%[153]. By gas chromatography, it was also possible to demonstrate precisely the high optical purity of the amino acids of peptides synthesized according to the four component condensation reaction of *Ugi*[154]. Gas chromatographic methods have also been employed for the systematic stereochemical analysis of various peptide antibiotics (antiamoebin I, emerimicin, alamethicin I, II)[158, 159, 160].

The racemization of amino acids in living cells, which do not exhibit renewal processes, is of importance in the

study of ageing phenomena. The racemization of amino acids in dead, fossilized materials can be employed as a dating parameter. Knowledge of the effect of temperature, time, humidity, and other environmental conditions on the rate of inversion of natural amino acids is hence of great importance for gerontological, geochronometric (paleotemperature profiles), and archeometric investigations.

As a reversible first order reaction the rate constant for the inversion of amino acids can be determined from the following equation when using optically pure starting materials[161],

$$k = \frac{1}{2t} \cdot \ln \frac{\text{L}+\text{D}}{\text{L}-\text{D}}$$

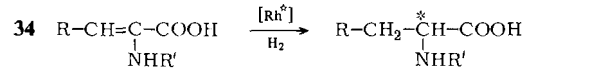
where L and D are the concentrations of the enantiomers determined gas chromatographically by peak area comparison at time t. As expected when plotted against $2t$, $\ln[(\text{L}+\text{D})/(\text{L}-\text{D})]$ yields a straight line passing through zero whose gradient corresponds to the rate constant k.

There is a great interest in the detection of organogenic material in interstellar space. If there were to be any preference of the image over the mirror image, it is to be expected from terrestrial evidence that this would involve biogenic material. In the case of meteorites the demonstration of racemic amino acids is an indication of either abiotic origins or of very great age, while the detection of L-amino acids can be attributed to terrestrial contamination. Investigations of the Murray and Murcheson meteorite and comparison with urban earth samples suggest considerable terrestrial contamination with L-amino acids[162]. No D,L-amino acids could be demonstrated gas chromatographically at the detection limit of 0.1 ppm in the Apollo moon samples[163]. Incidentally, this result eliminates the possibility of a terrestrial contamination of the carefully isolated samples from the lunar Sea of Tranquility. An interesting archeometric investigation was concerned with the determination of the D,L-asparagine ratio in parchment from the Dead Sea Scrolls, which provided information concerning the date of the degradational transformation of the collagen to gelatine[164, 165].

The gas chromatographic method of determining enantiomer composition is particularly suited to investigations concerned with the laboratory simulation of the origin of optical activity. Since only slight deviations from the racemic composition would be expected in such cases, the unbiased employment of polarimetric measurements may lead to grave misjudgements. In a gas chromatographic analysis employing diamide phase **3**[166], *Bonner* et al. were able to demonstrate small amounts of enantiomer enrichment (up to *e.e.* 2.5%) in the abiotic kinetic resolution of leucine[151]. It was demonstrated in preliminary experiments that the gas chromatographic method employing high performance capillary columns and digital peak integration yielded an accuracy and precision of 0.03%—0.7% absolute error and a standard deviation of 0.03%—0.6% with leucine mixtures of known enantiomeric composition[166]. Furthermore, the results were verified by the use of stationary phases with the opposite chirality. This strategy allows the recognition of a falsification of the analytical data by co-eluting (achiral) impurities, since a peak inversion only takes place with optical isomers[167].

The application of gas chromatographic enantiomer analysis in the field of enantioselective synthesis has recently been the subject of a detailed review[2]. It was pointed out that this reliable method finds astonishingly little employment in work claiming "quantitative enantiomeric purity". The determination of enantiomeric purity by polarimetry applying the criterion of optical purity may involve errors[2] and the employment of nuclear resonance methods with the aid of chiral shift reagents usually allows the determination of enantiomeric purity to about *e.e.* 97%.

The hydrogenation of dehydroamino acids **34** to amino acids in the presence of optically active rhodium complexes is an important asymmetric homogeneously catalyzed, reaction[168].



Gas chromatography has only been employed occasionally for the precise determination of the enantiomeric yield of the amino acids so produced[169, 170]. The enantiomeric yield for *N*-acetylphenylalanine, which has been underestimated in polarimetric determinations because the maximum optical rotation reported in the literature is too high, has been corrected by gas chromatographic methods and the correct specific rotation α_{max} obtained by extrapolation[171, 172]. For investigations concerning the homogeneously catalyzed, enantioselective synthesis of dipeptides by "double asymmetric induction"[173, 174], the chiral stationary phase described by *Ôi* et al.[91] can be employed to determine not only their diastereomeric composition but also the enantiomeric purity.

The introduction of thermally stable polymeric stationary phases (Polymers A—D, cf. Scheme 2) into gas chromatographic enantiomer analysis[175], and their commercialization[104, 123], had the effect of opening up a broad range of potential applications for a wide range of users. The suitability of the polymeric phases for GC-MS coupling due to their low rate of bleeding is worthy of special mention[176]. The employment of the SIM (selected ion monitoring) technique can bring about a further considerable increase in sensitivity and substrate selectivity.

Frank, Nicholson, and *Bayer*[178] have developed a complementary approach to amino acid analysis[139 140] by means of the "enantiomer labeling" method. Here the unnatural D-amino acid is employed as an internal standard[177, 178, 179] for the quantification of the L-enantiomer. Since the enantiomers possess identical (nonchiroptical) properties in an achiral environment, the enantiomeric ratio is neither affected by sample manipulation (isolation, derivatization, fractionation) nor by gas chromatographic manipulations (dilution of sample, injection, splitting, detection). Thermal or catalytic decomposition, loss of substance, incomplete isolation, and semiquantitative derivatization are all without effect on the analytical result. It is unnecessary to calibrate the detector, but detector response must be linear over a wide concentration range, a

requirement that is fulfilled by flame ionization detectors[105].

The method of enantiomer labeling presupposes a precise knowledge of the enantiomeric purity of both the sample and the standard, which must be determined separately[178]. The concentration of a racemate can also be measured by this method by employing an enantiomerically pure standard, just as can an enantiomerically pure substrate with a racemic standard. The method has been proposed for the precise determination of the chemical yield in enantioselective syntheses[2], whereby a known quantity of optically active standard is admixed with the reaction mixture (or an aliquot therefrom) and the amount of product is calculated from the change in enantiomeric composition before and after addition. This method is useful for enzymatic reactions, for instance, where the amounts of reaction products are so small that they cannot be isolated without losses.

The employment of optically active polysiloxane phases for the resolution of the enantiomers of various classes of compound (see Table 2) has led to important applications, e.g. investigations of amino acid racemization during peptide synthesis and hydrolysis. *Frank, Woiwode, Nicholson* and *Bayer*[180] investigated the rate of acid-catalyzed racemization of all the proteinogenic amino acids and differentiated between the rates of inversion of bound and free amino acids. Furthermore, with the aid of deuterium labeling and coupled GC-MS[176] it was possible to distinguish between the amount of unnatural amino acid originally present and the amount produced on hydrolysis[181] since the incorporation of deuterium is only to be expected on inversion of configuration.

The investigations of biological fluids, forensic chemistry, pharmaceuticals and therapeutics are important fields for the application of gas chromatographic enantiomer analysis[132, 133, 175, 176, 182–185], as is also the configurational analysis of polysaccharides[186].

It is to be expected that, in the future, gas chromatography will become established as one of the standard methods for the reliable enantiomeric analysis of volatile chiral compounds.

3. Summary and Outlook

Enantiospecific selector/selectand systems have been described which allow a quantitative gas chromatographic enantiomer resolution. Advances in glass and fused silica capillary column technology in combination with the development of thermally stable chiral polysiloxane phases and the employment of improved derivatization strategies has led to an extension of gas chromatographic enantiomer resolution to many classes of compounds. The polymeric phases are especially suitable for temperature programming and for the coupling of gas chromatography and mass spectroscopy. The method of "enantiomer labeling" permits the reliable quantification of enantiomers in biological fluids, of chiral pharmaceuticals, in forensic chemistry and of the products of enantioselective transformations. Gas chromatography provides unequivocal results in the determination of the enantiomeric composition (*e.e.*, enantiomeric excess) particularly in the boundary regions of slight enantiomeric excess (deviations from racemic composition) and high enantiomeric purity (detection of traces of the other enantiomer).

The large body of data on enantiomer resolution by gas chromatography allows a deliberate choice of selector/selectand systems for the detailed investigation of the molecular mechanisms of chiral recognition and of the correlation of the influence of the structural factors of selector and selectand on the enantiospecificity. The order of elution is constant within wide limits for analogous and homologous selectands. For this reason gas chromatography can be employed for the determination of absolute configuration without knowledge of chiroptical properties. The use of optically active phases of opposite configuration can confirm or exclude the enantiomeric origin of a peak separation.

For future development in chromatographic enantiomer separation it seems likely that GC and LC (HPLC) will complement each other and each method will find its own particular range of applications. Whereas preparative separation is of interest in LC, the main application of GC will be in enantiomer analysis. GC can be employed to resolve the enantiomers of many components simultaneously within a short time (e.g. amino acid analysis) and complications associated with the nature of the mobile phase are largely unknown. GC readily lends itself to automation.

It is surprising that all the GC systems known today are characterized by small separation factors in comparison with those obtained in LC. This, however, is not a practical disadvantage since together with the high separating performance, particularly of capillary columns, it allows in this way acceleration of the analysis and substances in mixtures can be resolved without peak overlap. The present enantiospecific selector/selectand systems of gas chromatography, however, seem quite unsuitable as models for stereospecific enzymes. Hence, the optimization of such systems remains a stimulating aim for the future. In particular the employment of alternative principles of chiral recognition, that are known in nature, will increase in importance. Mention should be made of enantiomer resolution on phases with host-guest interaction in chiral cavities *via* molecular inclusion, which has already been initiated employing cyclodextrin phases.

Besides hydrogen bonds, other intermolecular forces, or combinations thereof, can also be considered for the resolution of enantiomers by gas chromatography, e.g. charge transfer interactions and ionic and dipole-dipole attractions. The resolution of enantiomers by complexation gas chromatography based on the enantiospecific coordination interaction often yields high separation factors.

Preparative enantiomer resolution is possible by gas chromatography, too. The amounts isolated are small, however, but are suitable for the determination of chiroptical properties or for the correlation of configuration or determination of biological activity.

As far as the employment of commercially available enantiospecific stationary phases is concerned, the user must distinguish between the factors availability, performance, reproducibility and stability. The inspection of chromato-

grams, in so far as they are available, often provides decisive information.

The author was in the fortunate position to witness decisive developments in the methods described here 'on site' in the individual laboratories. V. S. wishes to express his sincere thanks to Professor E. Gil-Av, Dr. B. Feibush, Professor E. Bayer, Dr. H. Frank, G. J. Nicholson, Dr. B. Koppenhoefer and Prof. W. A. König for valuable discussions and advice, which constituted an important stimulation for this manuscript. Support of this work by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

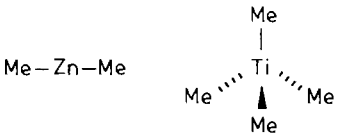
Photochemistry of Alkyltransition-Metal Complexes

By Helmut G. Alt*

Alkyltransition-metal complexes play an important role in catalytic processes (e.g. Ziegler-Natta low-pressure polymerization, hydroformylation, Fischer-Tropsch synthesis), in the biochemistry of humans and animals (e.g. coenzyme B_{12}), and in the classical theory of the chemical bond (e.g. multicenter bonding). The chemistry of alkyltransition-metal complexes is 30 years old, but only with the '70s came the understanding necessary for the systematic synthesis of thermally stable representatives of this class of compounds by blocking preferred decomposition pathways—e.g. β-hydrogen elimination—by the introduction of suitable ligands. In this article it is shown that thermally stable alkyltransition-metal complexes can be dealkylated under mild conditions (even at 12 K) with the help of UV light, thus producing highly reactive intermediates which can be trapped and used preparatively. Some alkyl complexes which do not react thermally with unsaturated compounds, e.g. olefins, under the influence of UV light display high activity as polymerization catalysts.

1. Introduction**

The chemistry of alkyltransition-metal complexes is only thirty years old. Although *Frankland* reported dimethylzinc and diethylzinc[1] in 1849—compounds now regarded as milestones in organometallic chemistry—the following 100 years saw no further alkyl- or aryl-compounds of a single transition metal. Organotransition-metal compounds were thought to be "non-existing compounds", especially since calculations[2] suggested that the thermodynamically weak transition metal-carbon σ-bond was responsible for their instability. Despite this dim prognosis, *Piper* and *Wilkinson* succeeded, in 1955, in preparing Cp_2TiMe_2[3], a typical representative of this class of compounds: only two years later, the first homoleptic alkyltransition-metal compound followed with $TiMe_4$[4]. The spell thus broken, a vigorous development of the chemistry of alkyltransition-metal complexes set in. Of decisive importance was firstly the realization that the lability[5,6] of the transition metal-carbon σ-bond is generally of kinetic origin[7,8] and, secondly, experience demonstrating the ability of suitable ligands—such as carbon monoxide, cyclopentadienyl, phosphanes, phosphites, etc.—to stabilize the metal-carbon σ-bond. In the '70s, *Lappert*, *Wilkinson*, and *Schrock* succeeded in preparing thermally stable homoleptic alkyltransition-metal compounds: they employed alkyl ligands in which the favored decomposition pathways, e.g. β-hydrogen elimination, were blocked. Today, alkyl compounds of practically all transition metals are known and their chemistry has been reviewed in a series of articles[9-11].



Why are alkyltransition-metal complexes interesting? They are considered key intermediates in many industrially important catalytic processes: low-pressure polymerization of olefins in the Ziegler-Natta process, olefin isomerization, hydroformylation, ethylene oxidation in the Wacker-Hoechst process, and the Fischer-Tropsch hydrocarbon synthesis. Outside the laboratory or chemical plant, nature presents us with an important representative of this class of compounds, namely vitamin B_{12} (a protective factor against pernicious anemia). It contains a cobalt-carbon σ-bond and is of vital importance for both human and animal life.

Although the chemistry of organotransition-metal compounds began to flourish in the late '50s, photoinduced transformations of alkyltransition-metal compounds were relatively unknown until ten years ago. Only a few isolated studies had been carried out on alkylcobalt compounds in connection with coenzyme B_{12}[12-16] and a few observations on the titanium complex $TiCl_3Me$[17] and the norbornyl complexes M(1-norbornyl)$_4$ (M = Ti, Zr, Hf, V, Cr, Mn, Fe, Co)[18] were reported. Apart from this, the reaction of isopropyl Grignard reagents with transition-metal halides had been studied, and the alkyl complexes thus formed could be used preparatively as photolabile intermediates for the preparation of low-valent oligoolefin complexes[19-22]. This late interest in photoreactions is surprising, since the light-sensitivity of carbonyltransition-metal complexes had been discovered as early as 1891[23] and exploited extensively in the last 25 years[24-29]. In 1979, for the first time, a short summary of the then known results on the photochemistry of alkyltransition-metal compounds appeared[29]. The present article is a review of the ten year history of this rapidly expanding area.

2. Mechanism of Photoinduced Dealkylation

2.1. General Considerations

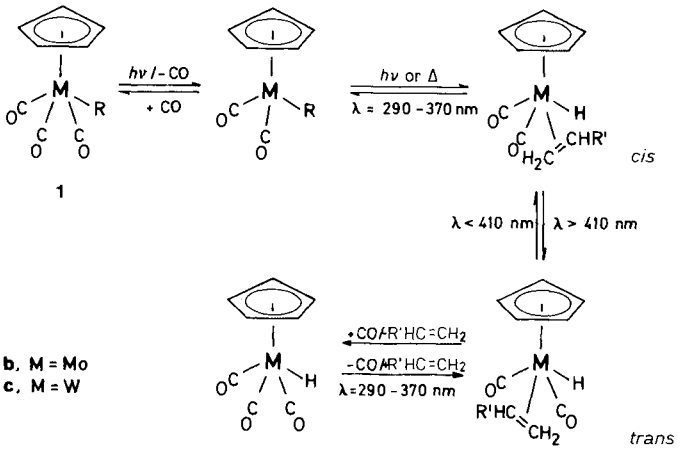
The bond energy of a transition metal-carbon σ-bond is comparable to that of a transition metal-carbonyl bond and varies between 100 and 300 kJ/mol; for structurally analogous compounds, its value depends on the position of the central metal in the periodic system, increasing in a given transition period from left to right and within a group on going from top to bottom, e.g. $Mn(CO)_5Me$: $D(Mn-Me) = 117$ kJ/mol; $Re(CO)_5Me$: $D(Re-Me) = 223$ kJ/mol[30]. Despite these relatively high dissociation energies, alkyltransition-metal compounds can decompose at low temperatures when the kinetic requirements are favorable. Their thermal stability can be markedly increased, however, when common decomposition pathways are blocked by suitable measures involving the alkyl ligand or the metal. Sometimes a high thermal stability may be coupled with an undesirably "braked" reactivity of the alkyl complex; in such cases, photochemical activation allows one to avoid harsh reaction conditions. A great advantage of the photochemical method is its independence of a fixed reaction temperature, thus allowing reactions to be conducted even at temperatures slightly above absolute zero.

The primary *physical* processes which occur immediately after photoexcitation, and which eventually cause the rupture of the metal-carbon σ-bond, are very complicated and are known only for a few, simple complexes. Depending on the complex type, a multitude of excited states must often be considered[29], i.e. the ligand internal excitation (LI), excitation of metal-centered d-electrons ("d-d" transitions; LF), metal-to-ligand charge-transfer excitations (MLCT), ligand-to-metal charge-transfer excitations (LMCT), or complex-to-solvent charge-transfer excitations (CSCT). These excited states often superimpose, are rarely separable, and, hence, occur together, especially when the photoexcitation is not conducted monochromatically.

Due to these problems, the photochemistry of alkyltransition-metal compounds is, as yet, the domain of the preparative chemist: identification of the primary *chemical* products from the photoreactions of model compounds allows conclusions to be drawn concerning the reaction mechanism. Matrix photolysis at 8–12 K has proven especially useful in this respect[31]. In the following discussion, the three most important mechanisms are briefly described: they may be—but are not necessarily—identical with the thermal decomposition mechanism.

2.2. Photoinduced Intramolecular β-Hydrogen Abstraction ("β-Elimination")

Intramolecular β-hydrogen abstraction can occur when the alkyl ligand has hydrogen atoms in the β-position with respect to the metal and the metal also has an empty coordination site. A well-studied example is the photoinduced dealkylation of the thermally stable complexes **1b**, **c** (R = Et, Pr, Bu[32,33], *n*Pe[34]); here, *all* the postulated intermediates could be characterized[33] (for reactions of **1a**, M = Cr, see Sections 2.3 and 3.3).



The first step consists of the reversible photoinduced dissociation of a carbonyl ligand, which produces an empty coordination site at the metal. In the subsequent β-hydrogen transfer to the metal, the newly formed olefin occupies this site, thus transforming the photolytically initially formed highly reactive 16-electron fragment $CpM(CO)_2R$ into a hydrido(olefin) complex with a noble gas configuration. During this transformation, the *cis*-isomer is formed, but rapidly converts into the thermodynamically more favorable *trans*-isomer. When the reaction is performed in pentane, the *trans*-isomer can be isolated and characterized and is surprisingly thermally stable.

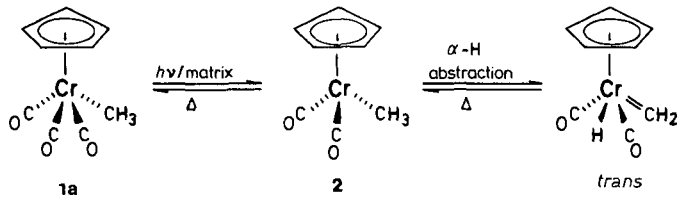
However, under photolysis conditions, the olefin ligand is easily replaced by carbon monoxide. The resulting hydrido complex $CpM(CO)_3H$ can be isolated from the reaction mixture, but either undergoes photolytic decomposition in the reaction solution[35,36] or reacts with unreacted starting material to give the corresponding alkane RH and the dimeric complex $[CpM(CO)_3]_2$. Photolyses in matrices at 12 K have shown that the various reactions in the scheme are reversible and that the concentrations of the intermediates can be influenced by the wavelength of the radiation used. In this fashion, the insertion of an olefin into the metal-hydrogen bond—a key reaction in hydroformylation—can be observed directly in a model system[37].

The complex $TiCl_3(Et)(Me_2PCH_2CH_2PMe_2)$[38] and the cation $[CpCo(Et)PR_3]^{\oplus}$ (R = *p*-tolyl)[39] are excellent candidates for β-elimination. Their molecular structures show a strong interaction between the metal and the hydrogen on the C_β atom; such agostic[*] ethyl groups can also be identified in the ^{1}H- and ^{13}C-NMR spectra.

2.3. Photoinduced α-Hydrogen Abstraction

Photoinduced α-hydrogen abstraction occurs under the same basic conditions as β-elimination; the difference is that the central metal can abstract hydrogen only from the α-position of an alkyl ligand. An example of such a reaction is the photolysis of the methyl compound **1a** (R = Me) leading to formation of a hydrido(methylene) complex[40].

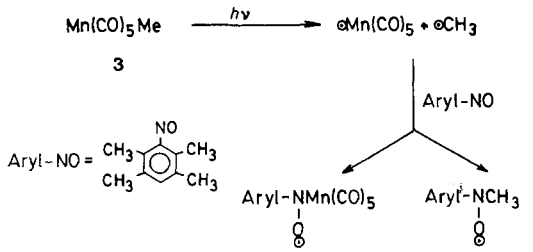
[*] The word agostic signifies a covalent interaction C–H–M in organotransition-metal compounds; M. Brookhart, M. L. H. Green, *J. Organomet. Chem. 250* (1983) 395.



An "α-abstraction" may also proceed intermolecularly, as was shown for CD_3TiCl_3[17]. If a complex fragment can undergo both α- and β-hydrogen elimination, the latter is favored almost exclusively. Due to their high reactivity, the (alkylidene)hydrido complexes formed in these photoinduced α-hydrogen abstractions can be detected only in matrices. In solution, the primary step is followed by undetermined subsequent reactions and, hence, the complete mechanism of the dealkylation remains open to speculation.

2.4. Photoinduced Cleavage of the Transition Metal-Carbon σ-Bond (Homolysis)

For the direct cleavage of a transition metal-carbon σ-bond, the required dissociation energy must be supplied by UV light. At first—similar to α- or β-elimination—the molecule absorbs light energy and is excited into one or several higher energy states[29]. The physical processes which occur at this stage proceed very quickly and are substantially more complicated than for organic molecules; they have, therefore, been elucidated unambiguously only in a few cases. Most frequently the photo-excitation is coupled with a charge transfer which causes the rupture of the metal-carbon bond. The initial products of this step are not stable; however, they may, in principle, be detected by suitable spectroscopic techniques (ESR and CIDNP) or indirectly, as in the photolysis of **3**, through trapping reactions[41].

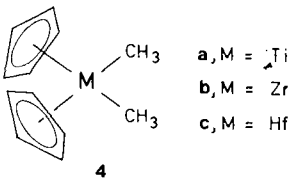


The alkyl radicals predominantly abstract hydrogen from other ligands or from the solvent; dimerization occurs only exceptionally.

3. Photoreactions of Alkyltransition-Metal Complexes

3.1. Photoreactions of Alkyl Complexes of Titanium, Zirconium, and Hafnium

The organometallic compounds of titanium, zirconium, and hafnium known up to 1973 are compiled in [42]; photoreactions of σ-organometallic complexes up to 1976 may be found in [43]. Among the known alkyl compounds containing metals of group IVB, results of photoreactions have been reported for the following: $TiCl_3Me$[17], M(1-norbornyl)$_4$ (M = Ti, Zr, Hf)[18], $M(CH_2Ph)_4$ (M = Ti, Zr)[44,45], Cp_2MMe_2 (M = Ti, Zr, Hf)[46-54], $(C_5H_4Me)_2MMe_2$ (M = Ti, Zr)[55], Ind_2MMe_2 (M = Ti, Zr, Hf)[67,68], Flu_2ZrMe_2[56], $Cp_2Ti(CH_2Ph)_2$[52], Cp_2MMeCl (M = Ti[53], Zr[57]), Cp_2ZrRX (R = CH_2Ph, CH_2SiMe_3, X = halogen)[57], Np_4Ti[58], and $Np_2ZrCl_2(PMe_3)_2$[59]. Photoreactions were first studied systematically for the complexes Cp_2MMe_2 (M = Ti, Zr, Hf) **4**[46,48].



4

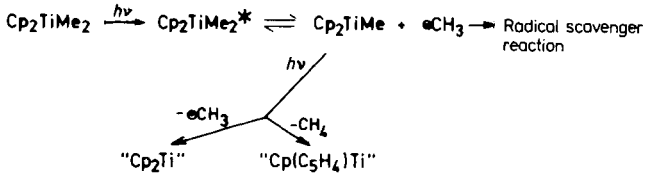
The complexes **4** can be completely dealkylated in solution by UV irradiation ($\lambda \geq 300$ nm); the gaseous product consists almost exclusively of methane (ca. 98%), with small amounts of ethylene and ethane. Photolysis reactions with partially deuterated **4a** in pentane show that the hydrogen required for methane formation—similar to the thermal decomposition[60-64] of the Cp_2MR_2 complexes (M = Ti, Zr, Hf; R = alkyl)—originates from the other methyl ligands as well as from the cyclopentadienyl ring, but not from the solvent. The mechanism of the hydrogen abstraction seems to be dependent both on the nature of the solvent and on the wavelength of the UV light employed: photolysis of **4a** in chloroform[50] leads to several chlorine-containing products and methane.

$$\underset{\mathbf{4a}}{Cp_2TiMe_2} \xrightarrow[-CH_4]{h\nu,\ CHCl_3} Cp_2TiMeCl,\ Cp_2TiCl_2,\ CpTiCl_3$$

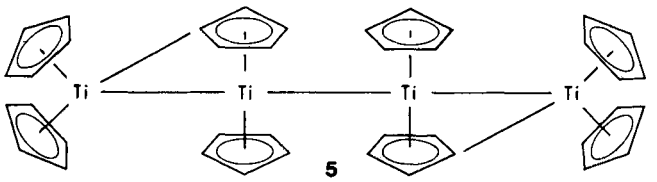
The production of $CpTiCl_3$ can be interpreted as evidence for the formation of cyclopentadienyl radicals during the photolysis, which, similar to methyl radicals, can be transferred to other substrates.

$$\underset{\mathbf{4a}}{Cp_2TiMe_2} + Mn_2(CO)_{10} \xrightarrow{h\nu} CpMn(CO)_3$$ [53]

In this dealkylation of **4a** the chloroform behaves in a manner which is known for other photoreactions in chlorinated solvents[65]. However, in the photoinduced decomposition of $Cp_2Ti(CD_3)_2$ with filtered UV light ($\lambda = 435.8$ nm) in deuterated solvents, only the cyclopentadienyl ligands suffer hydrogen abstraction—not other alkyl ligands[51]. ESR spectroscopic studies[52,53] of the photolysis of **4a** and Cp_2ZrR_2 (R = CH_2Ph, CH_2SiMe_3)[57] as well as radical trapping reactions with anthracene[47] indicate that alkyl radicals are generated during the irradiation. It can therefore be concluded that the primary step in the dealkylation is a photoinduced homolytic cleavage of the M–C σ-bond. CIDNP[55] experiments of the photolysis of $(C_5H_4Me)_2MMe_2$ (M = Ti, Zr) support this hypothesis and indicate that only very fast radical scavengers, such as nitrogen oxides, oxygen, or thiophenol, will be able to compete with the subsequent reactions:



The products of the dealkylation of **4** are gray to black, pyrophoric, and weakly paramagnetic. The best studied of these is "black titanocene" **5**, which is produced photochemically from **4a**. The thermal reaction of **5** with gaseous HCl at −78°C yields Cp_2TiCl_2 as the main product,



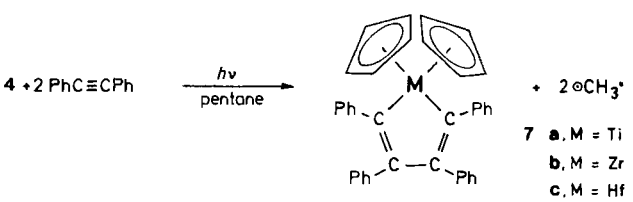
5

with small amounts of $CpTiCl_3$ and $(C_5H_4Cl)_3Ti_2Cl$. Excess bromine in benzene converts **5** into mainly $CpTiBr_3$ and Cp_2TiBr, accompanied by some $Cp(C_5H_4Br)_2TiBr$ and $Cp(C_5H_4Br)TiBr_2$. Carbon monoxide and **5** react in benzene in the dark to yield the monomeric dicarbonyl complex **6**, which has been characterized by X-ray structure determination[66].

During the photodealkylation of **4**, the cyclopentadienyl ligand is used as a hydrogen source, but when the photolysis is conducted in the presence of suitable ligands the metallocene skeleton remains intact. Thus, the photochemical reaction of **4a** with carbon monoxide in solution under normal conditions yields **6** within a few minutes.

6

However, this method for the preparation of $Cp_2Ti(CO)_2$ fails with the Zr and Hf complexes **4b**, **c**, because these add carbon monoxide in the dark to form the acetyl complexes $Cp_2MMe(COMe)$ (M = Zr, Hf)[67,68]. The photocarbonylation demonstrates that transition-metal carbonyl complexes can not only be induced photochemically to lose CO[24-29], but may also be derived from suitable alkyl complexes with the aid of UV light. Upon UV irradiation, **4** reacts with diphenylacetylene **4** to afford the metallacycles **7**, whose identity was confirmed by X-ray structural determinations (Fig. 1)[69,70].



A 1:1 adduct is formed in the reaction of **4a** with C_2Ph_2[47,49], in which the alkyne apparently inserts into a Ti–C σ-bond to form exclusively the *cis*-isomer **8**.

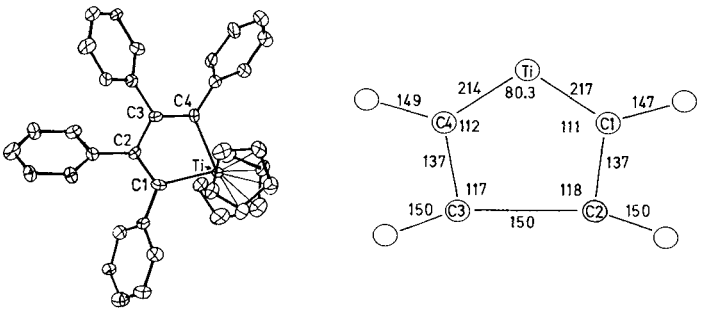


Fig. 1. Molecular structure of **7a** in the crystal (left); selected atomic distances [pm] and angles [°] (right).

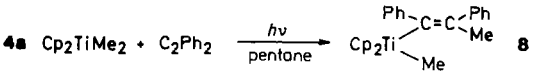
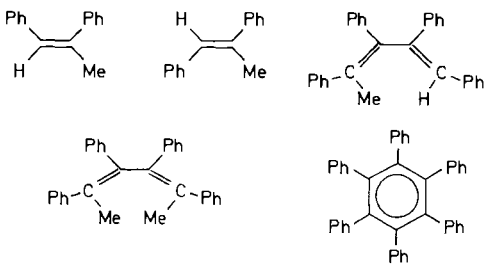
Under the same reaction conditions, $C_2(C_6F_5)_2$ does not yield a titanacycle but only a *cis/trans*-mixture of a derivative analogous to **8**.



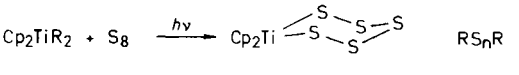
8

In the photoinduced reaction of **4a** with diphenylacetylene, much less methane is evolved than would be expected from the stoichiometry. During work-up of the reaction mixture, the following organic by-products which feature the former methyl ligands as substituents can be identified.



This mixture of products allows the conclusion to be made that either the free alkyne acts as a methyl trap or the Ti–C(Ph) σ-bond of **8** is ruptured homolytically. Subsequent uptake of hydrogen or dimerization of the radicals could then lead to the alkenes. Alkyne insertion into **7a** followed by elimination of the $(C_2Ph_2)_3$ moiety seems to be responsible for the formation of hexaphenylbenzene[71].

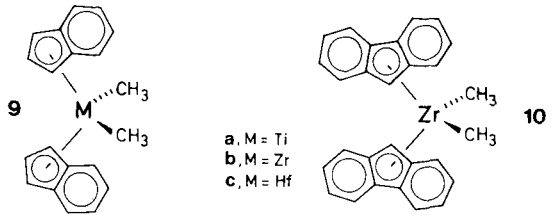
Another unusual reaction is the photochemical activation of elemental sulfur by **4a** or its phenyl derivative, which leads to Cp_2TiS_5 and other polysulfides[54]. With **4b** and **4c** this reaction does not occur.



R = Me, CH_2Ph

The indenyl complexes **9**[72,73], which are analogues of **4**, and the fluorenyl derivative **10** display similar reactivity to the parent cyclopentadienyl compounds[47]. Thus, pho-

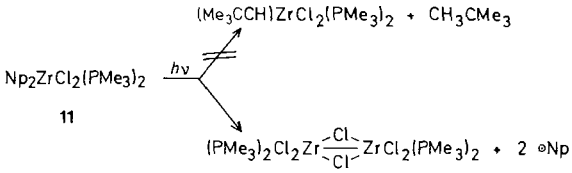
todealkylation results in almost exclusive formation of methane, with the aromatic five-membered ring serving as hydrogen source. The determination of the structures of the



metal-containing, pyrophoric photolysis products is complicated by their nonvolatility and insufficient solubility in noncoordinating solvents, which suggests the formation of polynuclear bisindenyl- or bisfluorenyl-complexes.

By analogy to **4a**, photochemical reaction of **9a** with carbon monoxide converts it into the corresponding dicarbonylbis(indenyl)titanium, $Ind_2Ti(CO)_2$[48].

An attempt to transform $Np_2ZrCl_2(PMe_3)_2$ **11** into the corresponding neopentylidene complex by photoinduced α-hydrogen abstraction failed[59].



It is assumed that homolysis of both Zr–C σ-bonds leads to a chlorine-bridged binuclear complex. The course of the reaction presumably reflects the fact that the electron deficiency on the central metal is not sufficiently large to activate the alkyl ligand to α-elimination.

In the dark, the alkyl complexes $M(CH_2Ph)_4$ (M = Ti, Zr)[44,45] and Np_4Ti[58] catalyze the polymerization of methyl methacrylate, styrene, or other olefins either slowly or not at all; however, upon irradiation with UV light they develop considerable catalytic activity. Ti^{III} or Zr^{III} species as well as alkyl radicals have been proposed as the initiators or catalysts for the onset of polymerization.

3.2. Photoreactions of Alkyl Complexes of Vanadium, Niobium, and Tantalum

Reports of photoreactions involving alkyl complexes of the metals of group VB are very sparse. The main reason could be that thermal reactions have opened up such an extensive chemistry as to make the photochemical variant seem unnecessary. In the last ten years, especially *Schrock* has elegantly shown how thermally induced α-eliminations can transform alkyl complexes into alkylidene and alkylidyne compounds[10,74]. The few photoreactions reported offer an alternative to the thermal reactions, inasmuch as they proceed faster and sometimes more selectively. Thus, the two-electron ligand C_2H_4 in complex **12** cannot be exchanged thermally for phosphane. The reaction[75]

$$Cp_2Ta(C_2H_4)Me + PMe_3 \xrightarrow[C_6D_6]{h\nu} Cp_2Ta(PMe_3)Me + C_2H_4$$

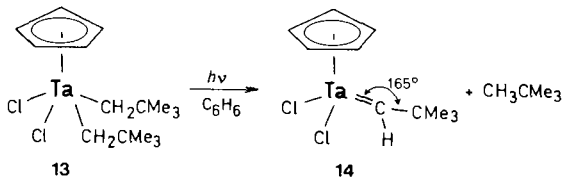
12

proceeds only photochemically and is initiated by the photoinduced loss of the olefin; the 16-electron fragment Cp_2TaMe then adds phosphane. Similarly, the reaction[75]

$$\mathbf{12} + Me_3P{=}CH_2 \xrightarrow{h\nu} Cp_2Ta(CH_2)Me + PMe_3 + C_2H_4$$

only proceeds under the influence of UV light, and the intermediate [Cp_2TaMe] again plays a key role. The decomposition of $Me_3P{=}CH_2$ is thus photochemically induced by **12**.

α-Hydrogen elimination in the dineopentyl complex **13** is accelerated by UV light[76,77].



13 **14**

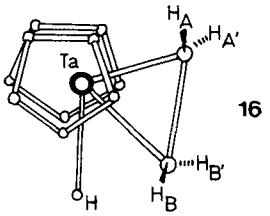
The difference with respect to the thermal reaction consists in the formation of considerable amounts of 2,2,5,5-tetramethylhexane, probably from photolytically generated neopentyl radicals. The driving force for these eliminations, i.e. the tendency of the metals to abstract hydrogen, seems to be strongly correlated with the electron deficiency of the metal (14-electron complex, formal oxidation state of Ta: +5).

The photolyses of the 16-electron complex Cp_2VMe and the 17-electron compounds Cp_2MMe_2 **15** (**a**, M = V; **b**, M = Nb; **c**, M = Ta) have also been reported[78,79]. Irradiation of **15**b, **c** in hydrocarbons yields methane as the main gaseous product (99%), mixed with traces of ethylene and ethane. Only the photoinduced decomposition of **15a** yields a methane/ethane mixture (2 : 1). It is assumed that this photoreaction proceeds analogously to that of complexes **4** via homolytic cleavage of the M–CH_3 bond. Reactions with partially deuterated starting materials demonstrate that the methyl ligands, the cyclopentadienyl rings, and the solvent serve as the hydrogen reservoir. These results differ from the thermal decomposition of **15a**, **b**[80,81], which yields only methane, and from the photolysis of **4a**, in which the methyl radicals do not abstract hydrogen from the solvent. The metal-containing photolysis products are not the well-known metallocenes of the metals of group VB, but rather nonvolatile, probably polynuclear complexes which could arise analogously to "black titanocene" **5**.

An exception is the photolysis of **15c** in pentane, during which Cp_2TaMe_3 could be detected—apparently produced by photoinduced alkyl-transfer.

$$Cp_2TaMe_2 \xrightarrow{h\nu} Cp_2TaMe + {}^{\ominus}CH_3 \xrightarrow{+\,15c} Cp_2TaMe_3 + \tfrac{1}{x}(Cp_2Ta)_x$$
15c

Remarkable is the photolysis of $Cp_2Ta(CO)Et$[82] in solution which leads to $Cp_2Ta(C_2H_4)H$ **16** via CO-loss and subsequent β-hydrogen elimination.



16

The spectroscopic characterization of the product indicates a metallacyclopropane complex in which the C–C axis lies in the plane of symmetry of the molecule.

3.3. Photoreactions of Alkyl Complexes of Chromium, Molybdenum, and Tungsten

The photochemistry of alkyl complexes of group VIB metals is easily reviewed: the most intensively studied photoinduced reactions by far are those of the cyclopentadienyl compounds $CpM(CO)_3R$ **1** (**a**, M = Cr; **b**, M = Mo; **c**, M = W; R = alkyl) and of a few analogous indenyl complexes. These reactions are characterized by the substitution of carbonyl ligands, while the alkyl ligand either maintains its terminal position or rearranges intramolecularly. To date, the photoinduced reactions of the two homoleptic alkyl compounds WMe_6[83] and $CrNp_4$ **17**[84], of the metallacyclobutane derivatives $Cp_2W(CHRCHRCH_2)$ (R = H, Me)[85], and of the cation in $[Cp_2WMe_2][PF_6]$ **19**[86] have only been reported briefly.

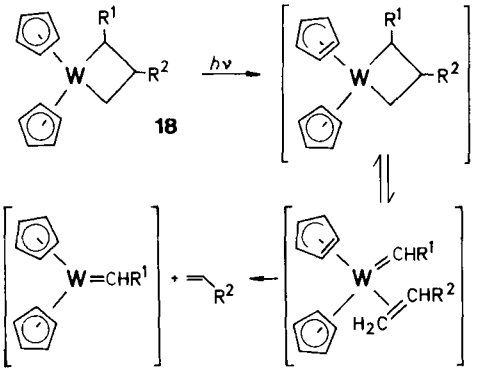
Instead of the desired complex "$W(CH_2)_3$", the thermal and photochemical "decomposition" of $WMe_6 \cdot PMe_3$ in trimethylphosphane led to isolation of *trans*-$Me_2W(PMe_3)_4$, which was characterized by X-ray structure analysis[83]. The four methyl ligands released form methane. No statement is made about the reaction mechanism.

Photolysis of $CrNp_4$ **17** in hexane or toluene yields neopentane, 2,2,5,5-tetramethylhexane, elemental chromium, and a black pyrophoric residue[84]. During the irradiation, unsaturated compounds such as styrene, methyl acrylate, methyl methacrylate, vinyl acetate, and ethylene can be polymerized under mild conditions; in the presence of carbon monoxide, $Cr(CO)_6$ is formed. These results indicate that the photolysis of **17** involves stepwise scission of chromium-carbon σ-bonds until the chromium finally reaches the oxidation state zero. Alkyl radicals are probably responsible for the initiation of polymerization.

$$Cr^{IV}Np_4 \xrightarrow{h\nu} Cr^{IV}Np_4^{*} \xrightarrow[-\odot Np]{} Cr^{III}Np_3$$
17

$$\xrightarrow[-\odot Np]{h\nu} Cr^{II}Np_2 \xrightarrow[-\odot Np]{h\nu} \cdots Cr^{0}$$

The metallacycle **18** decomposes thermally (80 °C) to afford a mixture of cyclopropane and propene ($R^1 = R^2 = H$) or 1-butene ($R^1 = Me$, $R^2 = H$) or isobutene ($R^1 = H$, $R^2 = Me$). In contrast, photochemical decomposition of **18** generates ethylene and some methane ($R^1 = R^2 = H$)[85]. The first step in the reaction is the change from η^5- to η^3-coordination of a cyclopentadienyl ligand ("ring slippage") followed by the breaking of the metallacyclobutane ring—as one step in the metathesis mechanism. However, none of the postulated intermediates could be isolated.



Photolysis of **19** in the presence of L (L = pyridine, acetonitrile, dimethylphenylphosphane) leads to **20**–**22**[86].

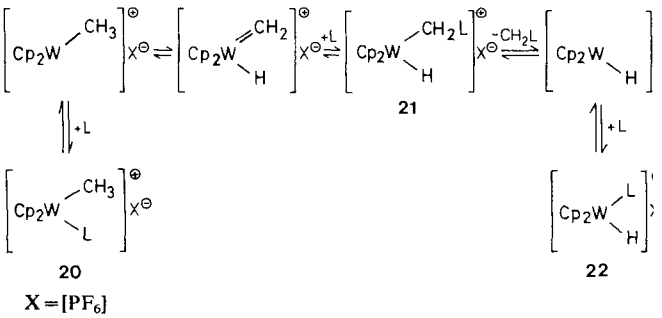
$$[Cp_2WMe_2]^{\oplus}X^{\ominus} \xrightarrow{h\nu,\,L} [Cp_2WMe(L)]^{\oplus}X^{\ominus}$$
19 **20** L = py, MeCN, PMe_2Ph

$$\mathbf{19} \xrightarrow{h\nu,\,L} [Cp_2WH(CH_2L)]^{\oplus}X^{\ominus}$$
21 L = PMe_2Ph

$$\mathbf{19} \xrightarrow{h\nu,\,L} [Cp_2WH(L)]^{\oplus}X^{\ominus}$$
22 L = py, MeCN

X = $[PF_6]$

The thermal reaction yields a completely different product mixture; MeCN does not react with **19** at all. The reaction is apparently initiated by homolytic dissociation of an alkyl ligand and—analogous to the thermal decomposition of $[Cp_2WMe(PR_3)][PF_6]$[87,88]—subsequent α-hydrogen elimination.



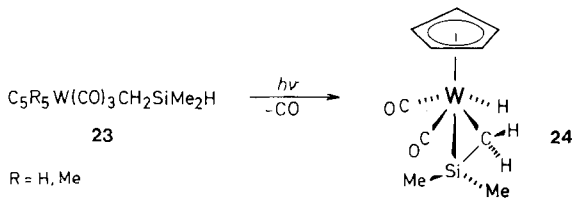
X = $[PF_6]$

The first step in this mechanism differs from that in the photolysis of **18**. No prediction can therefore be made, a priori, about the way in which the metal creates the empty coordination site required for the α- or β-hydrogen elimination.

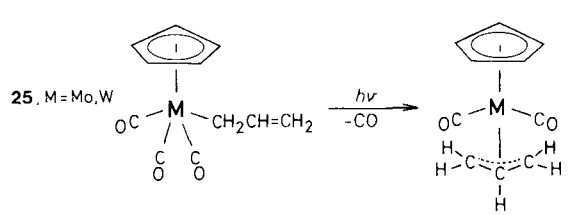
$CpM(CO)_3R$ complexes **1** (R = alkyl) have been of interest for some time, because the CO ligands can readily be substituted thermally or photochemically:

$$CpM(CO)_3R \xrightarrow[L]{h\nu \text{ or } \Delta} CpM(CO)_2(L)R + CO$$
1 and/or $CpM(CO)(L)_2R + 2CO$
and/or $CpM(CO)_2(L)COR$
L = n-donor

The resulting mono- and disubstitution products are well suited for IR- and NMR-spectroscopic studies, so that these complexes allow kinetic studies to be made on *cis/trans*-isomerizations. The mechanism of the substitution is well-known from the photochemistry of carbonyltransition-metal complexes[24–29]: in the first and rate-determining step a carbonyl ligand is lost, and the coordinatively unsaturated complex fragment $CpM(CO)_2R$ stabilizes itself by addition of a new ligand L. On the basis of photoelectron spectra[89] and X-ray structural studies[90], it is expected that in the compounds **1** not only the metal-carbonyl bond but also the metal-carbon σ-bond is subject to cleavage by UV light. Such a simultaneous cleavage is, for example, observed in the photolysis of $Mn(CO)_5Me$ **3**[41]. Photolysis of **1** in noncoordinating solvents indeed results in dealkylation and formation of $[CpM(CO)_3]_2$ as the major product. It is therefore tempting to assume a photoinduced homolysis of the metal-carbon σ-bond as the key reaction in the dealkylation. In reality, the mechanism seems to vary according to the type of alkyl ligand. The course of the photolysis of **1b, c** can be described completely when the alkyl ligand has hydrogen in the β-position[32–35] (cf. Section 2.2). This enables a photoinduced, intramolecular, β-hydrogen elimination which can be used preparatively to obtain olefin hydride complexes of the type *trans*-$CpM(CO)_2$(olefin)H or hydrides of the composition $CpM(CO)_3H$. Also interesting is the photolysis of **23**, which proceeds via β-hydrogen elimination and formation of the three-membered metallacycle **24**[91].

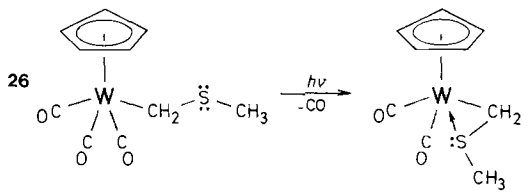


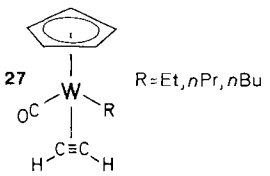
If the alkyl ligand in **1** contains a potential donor function, e.g. in the form of a double bond or a lone pair of electrons, the 16-electron fragment can stabilize itself without a hydrogen migration. Such $\sigma \rightarrow \pi$-rearrangements have long been known for $CpM(CO)_3(\eta^1$-allyl) complexes such as **25**[92–94] and also for the benzyl derivatives $CpM(CO)_3CH_2Ph$[33,95–98] (M = Mo, W).



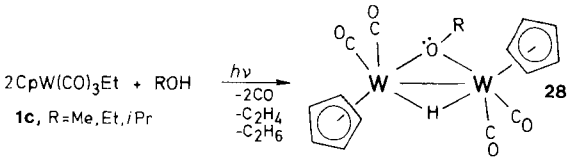
Similarly, upon UV irradiation **26** stabilizes itself via a lone pair of electrons on sulfur[99].

If the photolysis of $CpM(CO)_3R$ **1b,c** (M = Mo, W; R = Et, Pr, etc.) is conducted in the presence of potential ligands L, β-hydrogen elimination competes with the CO substitution. In the photoinduced reaction of **1b,c** (R = Et) with PMe_3 in pentane, not only the substitution product $CpM(CO)_2(PMe_3)Et$ but also $CpM(CO)_2(PMe_3)H$, $CpM(CO)_3H$, and ethene are detected[100]. Acetylenes serve as ligands: in the photoinduced reaction with **1c**, the complexes **27**[101] are formed, which are relatively resistant towards photoinduced β-hydrogen migration.





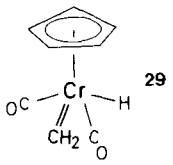
This behavior is an important indication of the presence of a four-electron alkyne ligand in **27**[101].



A β-hydrogen elimination is also the basis for the photoinduced reaction of **1** ($R \neq Me$) with alcohols, which leads to formation of alkoxo- and hydrido-bridged binuclear complexes **28**.

28 is also accessible via photoinduced reaction of $CpW(CO)_3H$ or $CpW(CO)_2$(olefin)H with alcohols. Thus, it can be assumed that the hydrido complexes are the true active species. Consequently, irradiation of the methyl derivative $CpW(CO)_3Me$ in the presence of alcohols does not yield **28**.

UV irradiation of the methyl derivatives of **1** also results in dealkylation and formation of the binuclear complexes $[CpM(CO)_3]_2$. The gas formed consists only of methane. Experiments with deuterium labeled starting materials show that the hydrogen required for the methane formation is mostly abstracted from the cyclopentadienyl ring[105]. The mechanism of the dealkylation appears to be very complicated and dependent on the solvent. As established by photolyses in gas matrices[106], polymer films[107,108], and in solution[98,104], the first step in all cases is a photoinduced dissociation of a carbonyl ligand. The resulting 16-electron fragment can then undergo a reversible α-elimination (cf. Section 2.3), as shown for the fragments $CpCr(CO)_2Me$[40] and $CpMo(CO)_2CF_3$[109]. The highly reactive species **29** then decomposes further via a reaction of undetermined mechanism in which binuclear methylene-bridged hydrido complexes could play a role.



29

However, the $CpM(CO)_2Me$ fragment can also undergo a photoinduced homolysis of the metal-carbon σ-bond[107, 108, 110].

$$CpM(CO)_3CH_3 \xrightarrow[\text{solvent}]{h\nu} CpM(CO)_3CH_3^*$$

1 (R = Me)

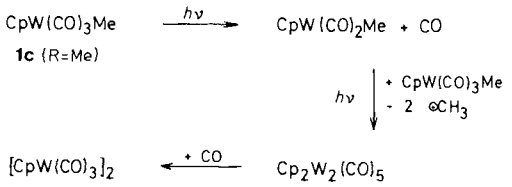
$$CpM(CO)_3CH_3^* \rightleftharpoons [CpM(CO)_2CH_3] + CO$$

$$[CpM(CO)_2CH_3] \xrightarrow{h\nu} [CpM(CO)_2]^{\odot} + {}^{\odot}CH_3$$

$$[CpM(CO)_2]^{\odot} \underset{-CO}{\overset{+CO}{\rightleftharpoons}} [CpM(CO)_3]^{\odot}$$

$$2[CpM(CO)_3]^{\odot} \rightleftharpoons [CpM(CO)_3]_2$$

An alternative mechanism for the photoinduced decomposition of **1c** (R = Me) is discussed in which methyl radicals abstract hydrogen from the solvent.



For such a mechanism one would expect dimerization of methyl radicals, leading to formation of ethane; however, this is not observed[110].

The influence of the solvent on the photolysis of **1** is especially marked for chloroform[98, 105, 111]: irrespective of the alkyl ligand, **1b** and **c** are transformed into $CpM(CO)_3Cl$, whereas **1a** suffers complete decarbonylation to give $[CpCrCl_2]_2$. $CpCr(CO)_3Cl$, which is unknown to date, could not be detected.

Besides coordinating solvents, ligands can trap the fragment $CpM(CO)_2R$ which results from the photolysis of **1** (R = Me), thereby producing the monosubstituted compounds $CpM(CO)_2(L)R$ (L = phosphane, phosphite, olefin). The thermal reaction also leads to substitution, but a CO-insertion or alkyl migration occurs simultaneously to produce an acyl ligand[100, 112].

$$CpM(CO)_3Me + L \xrightarrow[-CO]{h\nu} CpM(CO)_2(L)Me$$

1 (R = Me) *cis/trans* **30**

M = Mo, W; L = PPh_3[112]
M = Cr, Mo, W; L = $P(OMe)_3$, $P(OPh)_3$, PPh_3[103, 113–115]
M = Cr, Mo, W; L = PMe_3[116, 117]
M = W; L = C_2H_4[118, 119]

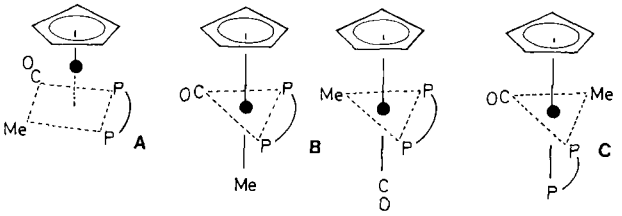
Some monosubstitution products **30** can undergo further CO substitution, generating the complexes **31**.

$$CpM(CO)_2(L)Me + L \xrightarrow[-CO]{h\nu} CpM(CO)(L)_2Me$$

cis/trans **31**

M = Cr, W; L = $P(OMe)_3$[103]
M = Cr, Mo, W; L = PMe_3[116]

Bidentate phosphanes can also be employed in this reaction and yield the isomers **A**, **B**, and **C**[120].



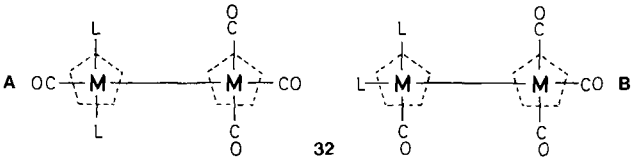
The analogous indenyl(methyl) complexes behave similarly to **1**[116]. In contrast to the cyclopentadienyl complexes, which always retain the cyclopentadienyl ring tightly bound, the photoinduced reaction of the indenyl complexes with trimethylphosphane results in loss of both the indenyl and methyl ligands. The reaction rate decreases along the series Cr ≫ Mo > W.

$$IndM(CO)_3Me + 4\,PMe_3 \xrightarrow[-CO]{h\nu} cis\text{-}M(CO)_2(PMe_3)_4 + {}^{\odot}CH_3 + {}^{\odot}Ind$$

The PMe_3-disubstitution products **31** and the corresponding indenyl derivatives are Lewis bases, because both the alkyl ligand and the PMe_3 ligands strongly increase the electron density at the metal. The alkyl ligand in these complexes can be exchanged cleanly for a chloride ligand:

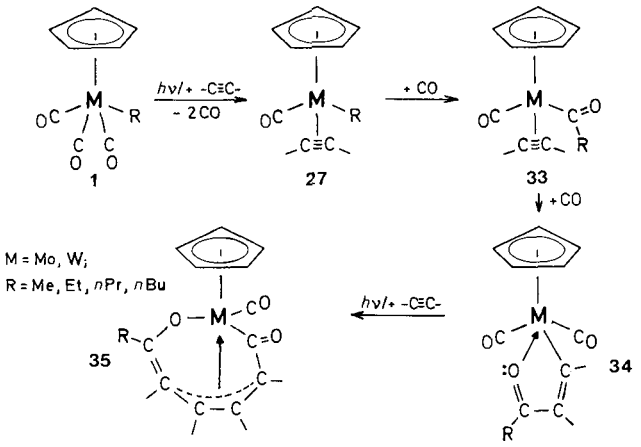
$$CpM(CO)(PMe_3)_2Me \xrightarrow[-{}^{\odot}CH_3]{CHCl_3/\text{silica gel}} CpM(CO)(PMe_3)_2Cl$$

The Lewis base character seems also to be the reason for the formation of the binuclear complexes **32** in the photoinduced reactions of **1** with L = PMe_3[116] (isomers **A** and/or **B**).

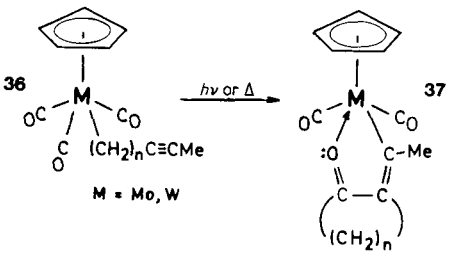


The photoinduced reactions of **1b**, **c** (R = Me) with alkynes are best studied with the tungsten complex, since the products are thermodynamically and kinetically more stable than those of the molybdenum complexes.

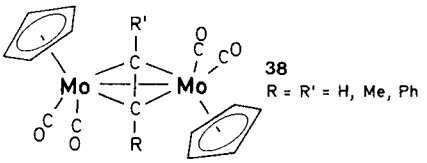
All intermediates in this reaction series, whose first and last steps require UV light, can be isolated and characterized for M = W[121–124] and used in a multitude of further reactions. For M = Mo, only the complexes **34**[122–126] and **35**[124, 126] can be detected. Analogous derivatives can be obtained from the indenyl complex $IndM(CO)_3Me$ (M = Mo, W)[127], the trifluoromethyl compound



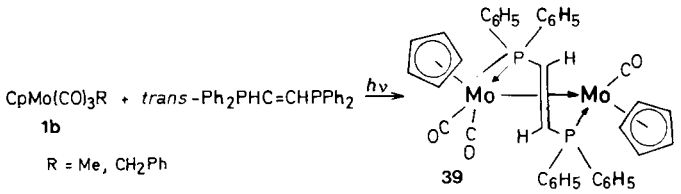
$CpMo(CO)_3CF_3$[128], and the η^1-allyl complex $CpMo(CO)_3(\eta^1\text{-}C_3H_5)$ **25** (M = Mo)[129]. Similarly, the thermal or photochemical rearrangement of **36** leads to **37**[130].



In contrast to this reaction scheme, the molybdenum complex **1b** forms binuclear complexes **38**[104] in low yields; these may also be generated by allowing $[CpM(CO)_2]_2$ (M = Cr, Mo, W) to react with alkynes[131-140] in the dark. In the photoinduced reaction with alkynes, **1b**

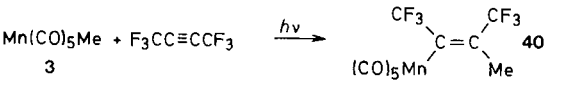


is apparently subject to a competition between dealkylation and a partial decarbonylation, which leads via $[CpMo(CO)_2]_2$ to complex **38**. A similar explanation also seems plausible for the formation of **39**[141].

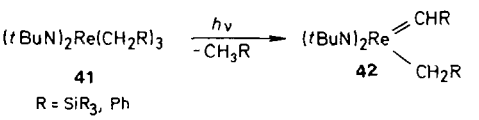


3.4. Photoreactions of Alkyl Complexes of Manganese and Rhenium

Only very few examples of photoreactions of alkyl compounds of manganese and rhenium are known. Of importance is the complex $Mn(CO)_5Me$ **3**, in which both the manganese-carbon σ-bond and the manganese-carbonyl bond can be cleaved homolytically[41] (Section 2.4). The insertion of alkynes into the Mn–C σ-bond of **3**[142], forming the complexes **40**, often proceeds only with the help of UV light[129].



α-Hydrogen elimination in some alkyl(imido) complexes proceeds only photochemically (**41** → **42**)[143,144]; however, this method fails to convert **41** into the methyl(methylene) complex $(t\text{BuN})_2Re(CH_2)Me$.



$Cp_2Re(alkyl)$ compounds[145] are surprisingly stable to UV radiation: the mass spectrum of Cp_2ReEt certainly shows the fragment $Cp_2ReH^{\oplus}$, which indicates β-hydrogen elimination; however, it was not possible to thermally or photochemically dealkylate $Cp_2Re(alkyl)$ complexes.

3.5. Photoreactions of Alkyl Complexes of Iron, Ruthenium, and Osmium

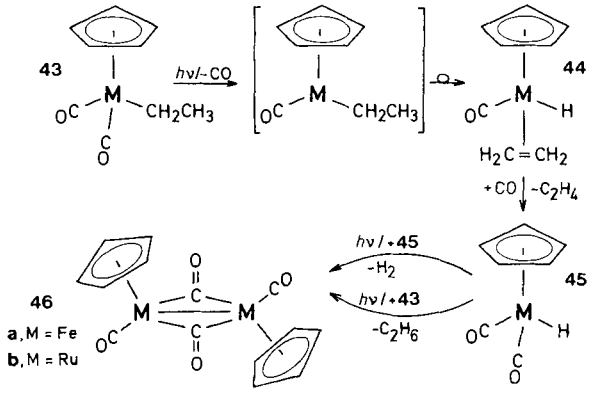
The first photoinduced reactions of alkyl complexes of iron, ruthenium, and osmium date back to 1962, when the light sensitivity of the unisolated isopropyl complexes $M(i\text{Pr})_3$ (M = Fe, Ru, Os) was exploited for the preparation of olefin complexes in which the metal was formally in the oxidation state zero[19-21].

Although the individual reaction steps were not elucidated in any detail, the formation of propene points to a β-hydrogen elimination and the intermediate formation of $Fe(i\text{Pr})_2(C_3H_6)H$. The loosely bound propene ligand could be displaced by free olefin C_6H_8, which then supplies the hydrogen for the two propyl leaving groups. Complexation of a further C_6H_8 molecule leads finally to $C_6H_6FeC_6H_8$.

The photochemistry of $CpM(CO)_2R$ complexes (M = Fe, Ru; R = Me, Et)[146-148] has been studied extensively. The mechanism of photodealkylation resembles that of the complexes **1**: thus, photolysis of **43a, b** certainly proceeds via a β-hydrogen elimination.

Only **44b** can be stabilized and identified in a matrix[147,148]. In contrast, the hydrido(olefin) compounds $CpRu(PPh_3)(olefin)H$, which are thermally accessible from $CpRu(PPh_3)_2R$ complexes, exhibit considerably higher kinetic and thermal stability[149,150].

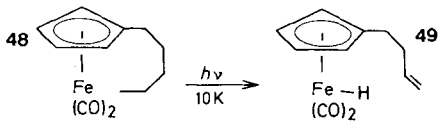
In the photolysis of **43b** in solution, the hydrido-bridged binuclear complex $[CpRu(CO)H]_2$ can be detected[148], which can be interpreted as a product of the photolysis of **45b**.



The methyl compounds **47** are easily dealkylated in solution; apart from a little carbon monoxide, only methane can be detected in the reaction gas.

$CpM(CO)_2Me$
47, **a**, M = Fe; **b**, M = Ru

The nearly quantitative formation of **46** arises because the cyclopentadienyl ring, the methyl ligands of other molecules, and the solvent serve as sources of hydrogen. Only traces (ca. 2%) of free radicals seem to be involved[146]. In the photolysis of **47a** in a carbon monoxide matrix at 12 K, $(\eta^3\text{-Cp})Fe(CO)_3Me$ can be identified[151]. Further support for such a "ring slippage" mechanism—which opens up a free coordination site at the metal—comes from the matrix photolysis of **48**, which leads to **49**[152].



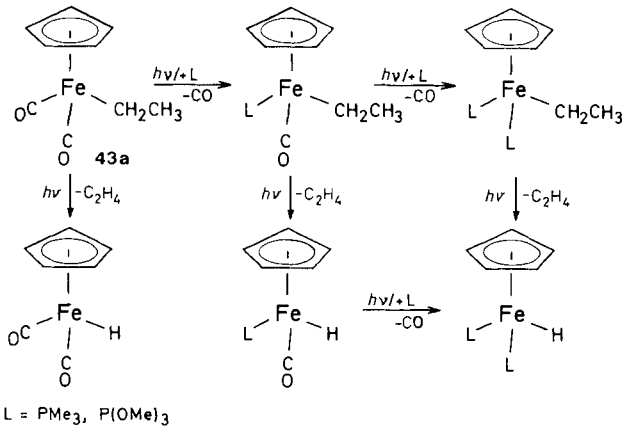
On the other hand, the photolyses of $CpFe(CO)_2(\eta^1\text{-}C_3H_5)$ **50**[93] and its η^1-1-(2,2-difluoro-1-trifluoromethylvinyl)-3,3,3-trifluoro-2-trifluoromethyl-1-propenyl derivative[153] generate the corresponding η^3-allyl complexes via CO-dissociation.

$$CpFe(CO)_2(\eta^1\text{-}C_3H_5) \xrightarrow[-CO]{h\nu} CpFe(CO)(\eta^3\text{-}C_3H_5)$$
50 **51**

Extensive studies have been undertaken on the photoinduced reaction of complexes **47a** and $(\eta^5\text{-}C_5H_3R'R'')Fe(CO)_2Me$ (R′ = R″ = alkyl) with phosphanes and phosphites L[154–166]. By analogy with the reactions of **1**, mono- and disubstitution products are formed; in contrast to the thermal reaction, however, the alkyl ligand maintains its terminal position. In this context, the ethene complexes $CpM(CO)(C_2H_4)Me$ (M = Fe, Ru)[148] should be mentioned, since they represent the only known alkyl complexes of this type.

If alkyl ligands with β-hydrogen are used, CO-ejection followed by β-hydrogen elimination can be observed, which proceeds with loss of the olefin ligand to afford the corresponding hydrido derivatives.

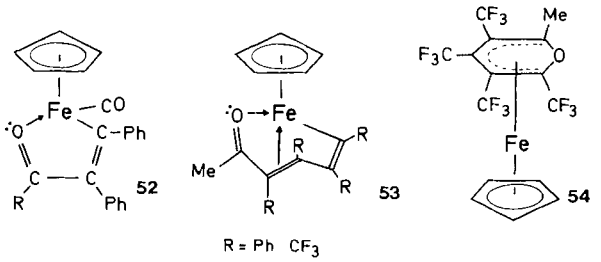
This subsequent reaction may be suppressed when a large excess of ligand is employed in the substitution reaction.



L = PMe_3, $P(OMe)_3$

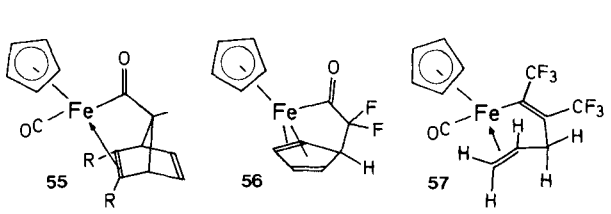
The photoinduced reaction of **43a** with ethene in pentane solution[148] is unusual: loss of the alkyl and one of the carbonyl ligands leads to the binuclear complex $[CpFe(CO)(C_2H_4)]_2$, which exhibits dynamic behavior similar to dimeric **46a**[167]. The analogous ruthenium compound **43b** does not undergo this reaction.

The $CpFe(CO)_2R$ complexes also react with alkynes: irradiation of a solution of **47a** and diphenylethyne yields a 1:1-adduct **52**, which is transformed into the seven-membered metallacycle **53** (R = Ph) via photoinduced alkyne insertion[146]. This type of complex ($R = CF_3$) together with **54** is also obtained in the reaction with hexafluoro-2-butyne[129]. Similar metallacycles are formed in the thermal reaction of $CpRu(PPh_3)_2H$ with alkynes[168].



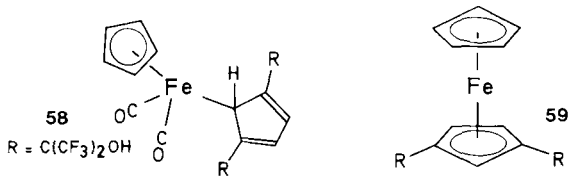
R = Ph CF_3

In the thermal reaction, however, only 1,2,3,4-tetraphenylferrocene can be detected[169]. A ruthenium complex $CpRu(PPh_3)(PhC{=}CMe{-}COMe)$ analogous to **52** is thermally accessible from $CpRu(PPh_3)_2Me$ and $PhC{\equiv}CCOMe$[170]. More complicated metallacyclic complexes of the type **55** ($R = CF_3$) and **56** are obtained in the

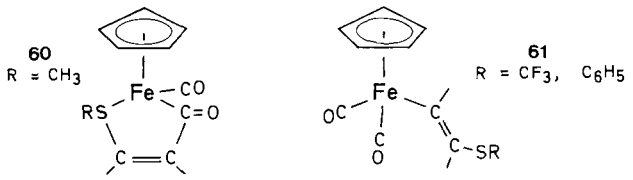


photoinduced reaction of $CpFe(CO)_2(\eta^1\text{-}C_5H_5)$ with $F_3CC{\equiv}CCF_3$ or C_2F_4[129]; the reaction of **50** and $F_3CC{\equiv}CCF_3$ leads to **57**. The photoinduced rearrange-

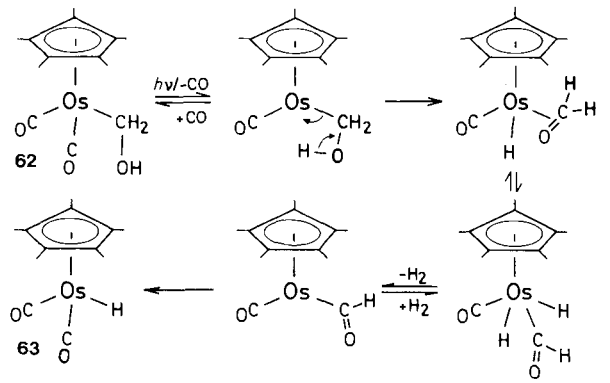
ment of the alkyl compound **58** yields the ferrocene derivative **59**[129], which can also be prepared thermally from ferrocene and hexafluoroacetone[171].



Completely different results are obtained from the reactions of alkynes with alkylthiolate complexes of the type $CpFe(CO)_2SR$: depending on whether R is electron-donating or electron-withdrawing, metallacyclic complexes **60**[172,173] or the insertion products **61**[174] are formed.



Remarkable is a retro-Fischer-Tropsch step which occurs in the photolysis of **62**, generating $C_5Me_5Os(CO)_2H$ **63**, CO, and H_2[175]. Based on studies with partially deuterated starting materials, a mechanism is proposed which involves abstraction of hydrogen from the β-position.

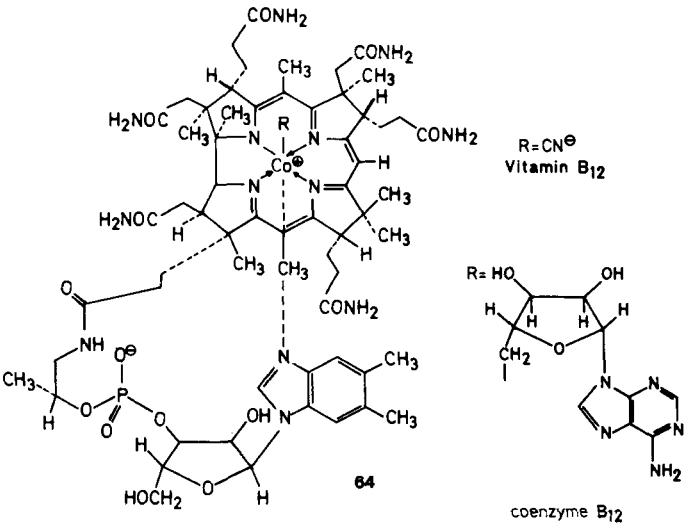


The metal-carbon σ-bonds of methylene bridges in polynuclear complexes prove to be very stable photochemically: thus, UV irradiation of $Cp_2Ru_2(CO)_4(\mu\text{-}CH_2)$ **63**[176] only results in loss of a CO to yield $Cp_2Ru_2(CO)_3(\mu\text{-}CH_2)$: the CH_2-bridge remains intact.

3.6. Photoreactions of Alkyl Complexes of Cobalt

All cobalt(III)-alkyl complexes are light sensitive, and the photochemical studies of this class of compounds are extensive. The most thorough studies have been carried out on vitamin B_{12} **64** and a series of simpler derivatives.

Vitamin B_{12} and "coenzyme B_{12}" contain a corrin ring system with a cobalt atom in the center. The central metal is formally in the oxidation state +3 and is axially coordinated by a base (5,6-dimethylbenzimidazole) and a cyanide



or 5′-deoxyadenosyl ligand. In order to obtain a "spectroscopic handle" on this complicated molecule, a multitude of simpler model compounds has been synthesized which exhibit the characteristic features of the parent molecule: thus, the cyanide ligand can be replaced by the methyl group (cobalamin), the corrin ring system can be substituted by other macrocyclic chelating ligands or the simple dimethylglyoxime, and the complicated base 5,6-dimethylbenzimidazole can be replaced with simple nitrogen bases such as pyridine. In the following discussion, all these species are abbreviated [Co]R.

Photoreactions of [Co]R compounds are covered extensively in [28,177–180], and hence only a brief recapitulation will be presented here: The alkylcobalamins show absorption bands of weak to medium intensity ($\varepsilon = 1000$—3000) in the range 350 to 470 nm. These bands are due to electronic transitions between axial orbitals. Upon irradiation with visible light, antibonding axial MOs are occupied[181]. The resulting photo-induced charge-transfer leads to cleavage of the relatively weak cobalt-carbon bond ($D = 85$—125 kJ/mol[182]). The photochemically induced dissociation is considered the rate-determining step in nearly all photolyses of cobalt-σ-organyl compounds.

$$[Co^{III}]R \overset{h\nu}{\rightleftharpoons} \{[Co^{II}] + {}^{\odot}R\}$$

The cobalt(II)-species and the alkyl radical coexist initially as a caged radical pair and can be detected by ESR spectroscopy[183–185] and flash photolysis[186]. If the lifetime of the alkyl radicals is sufficiently long, they can dimerize[187], disproportionate, or abstract hydrogen from other ligands or from the solvent. Alkyl compounds with β-hydrogen are preferentially dealkylated by this mechanism, but can also suffer β-hydrogen elimination[188]. The resulting reduced form of the cobalamin is known as B_{12r}.

Alkylcobaloximes and alkylcobalamins with electron-withdrawing substituents on the alkyl ligand deviate from this reaction scheme: photolysis of formylmethylcobaloxime or -cobalamin results in formation of acetaldehyde and cobalt(III) complexes[189].

$$[Co^{III}]-CH_2CHO \xrightarrow{h\nu} \{[Co^{II}] + {}^{\circ}CH_2CHO\}$$
$$\downarrow -[Co^{III}]$$
$$CH_3CHO \xleftarrow{+H^{\oplus}} {}^{\circ}CH_2CHO$$

Co^{II} intermediates cannot be detected in this reaction. Such an electron transfer, which oxidizes the originally formed Co^{II} back to Co^{III} and reduces the alkyl radical to the carbanion $R^{\ominus}$, can also be observed in the photolysis of 1,19-dimethyl-*AD*-bis(dehydrocorrinato)cobalt(III) complexes[190].

Halomethylcobalamins prefer a third variant of the photodealkylation: the initially-formed alkyl radical stabilizes itself by decomposition to a halocarbene which can be trapped[178, 191].

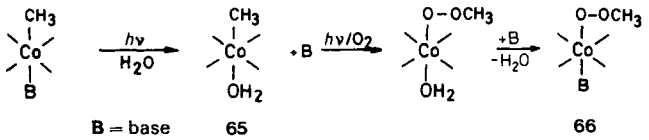
$$[Co^{III}]CHCl_2 \xrightarrow{h\nu} [Co^{II}] + Cl + :CHCl$$

In the presence of oxygen, the photolysis reactions of [Co]R follow a totally different course[192]: the diradical O_2 suppresses the reversible reaction

$$[Co^{II}] + {}^{\circ}R \rightleftharpoons [Co^{III}]R$$

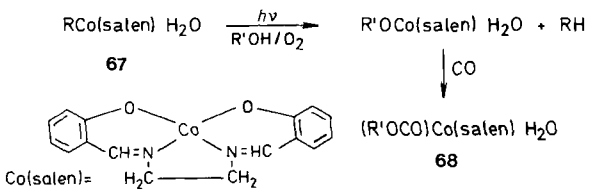
by undergoing subsequent reactions with one or both of the reaction products. Thus, photolysis of methylcobalamin in aqueous solution under aerobic conditions yields formaldehyde and aquo-Co^{III} complexes.

Cobaloximes insert a molecule of O_2 into the cobalt-carbon bond, generating peroxo complexes **66**[193, 194].



The mechanism proposed for this reaction differs from the previous reaction schemes in that its first step does not consist of a photoinduced dissociation of the cobalt-carbon bond, but rather of a loss of the base B from the metal. Only the aquo complex **65**, which is formed by coordination of water, undergoes the photoinduced dissociation[195]. The resulting methyl radical takes up dioxygen, and the radical ${}^{\circ}OOCH_3$ recombines with the Co^{II}-fragment to form the peroxo complex **66**, which can be isolated at low temperature. It is not yet clear why the homolytic bond cleavage is preceded by a photoinduced transformation into the aquo complex: the irradiation probably generates several competing excited states, and the most favored state leads to formation of **65**[178].

The photoinduced reaction of $RCo(salen)(H_2O)$ **67** (R = Me, Et, Pr, Bu) with carbon monoxide in the presence of oxygen in alcohols proceeds in a similar way via homolysis of the Co–C bond[196].



The radical ${}^{\circ}R$ stabilizes itself by hydrogen abstraction from the alcohol; the resulting ${}^{\circ}OR$ radical binds to $Co(salen)(H_2O)$. Only then does the insertion of CO into the newly formed cobalt oxygen bond occur to generate **68**. Apparently, the oxygen serves as a radical acceptor as well as an oxidant for $Co(salen)(H_2O)$. When O_2 is excluded from the reaction, CO insertion is not observed.

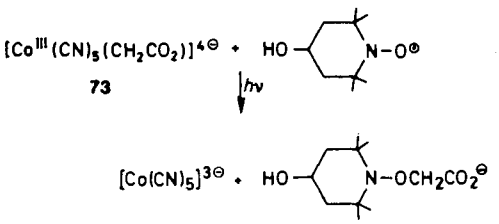
Also of note is the photolysis of **69**[197]. The homolytic cleavage of the cobalt-carbon bond is preceded by a photoinduced charge-transfer excitation benzyl→cobalt (LMCT). The benzyl radicals are stabilized by dimeriza-

$$2[Co(CN)_5(CH_2Ph)]^{3\ominus} \xrightarrow[\lambda = 313\ nm]{h\nu} 2[Co(CN)_5]^{3\ominus} + (CH_2Ph)_2$$
69 **70**

tion or—in the presence of oxygen—are trapped and form the addition product ${}^{\circ}OOCH_2Ph$, which binds to **70**, generating the peroxo complex **71**, which in aqueous solution decomposes to **72** and benzaldehyde.

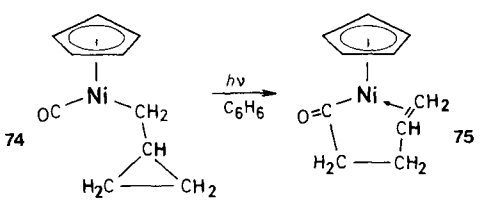
$$\mathbf{69} + O_2 \xrightarrow{h\nu} [Co(CN)_5(O_2CH_2Ph)]^{3\ominus}$$
71
$$\downarrow +H_2O$$
$$[Co(CN)_5H_2O]^{\ominus} + PhCHO + OH^{\ominus}$$
72

Similar photoreactions can also be observed with the complex **73**, which is especially suited to trapping nitroxides in biochemical reactions[198].



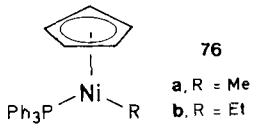
3.7. Photoreactions of Alkyl Complexes of Nickel, Palladium, and Platinum

Few studies exist on the photolyses of alkyl complexes of nickel. It is known that the cyclopropylmethylnickel complex **74** is converted by UV radiation into the light-stable metallacycle **75**[199].



A mechanism is proposed involving carbonyl insertion into the nickel-carbon σ-bond with synchronous opening of the three-membered ring and coordination of the resulting olefinic double bond.

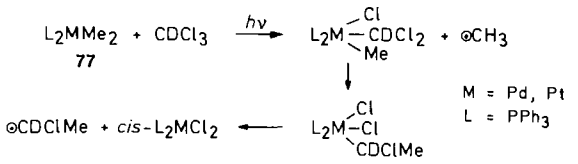
Photolysis of the methyl complex **76a** in benzene produces methane (96%) and ethane (4%)[200]. The hydrogen



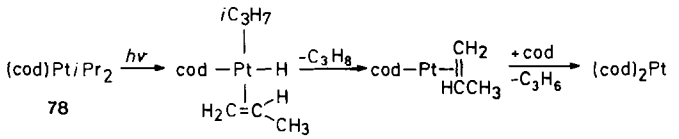
76
a, R = Me
b, R = Et

required for methane formation originates from the cyclopentadienyl ligand, other methyl ligands, and the solvent. Dimerization of methyl radicals seems to be responsible for the formation of ethane. Thermal decomposition of **76a** yields the same products[201], but in different relative amounts. The ethyl derivative **76b** is photodealkylated to form ethene and ethane, the β-hydrogen elimination being facilitated by the photoinduced dissociation of the phosphane ligand. No information is available on the metal-containing products of these photolyses.

Alkyl compounds of palladium and platinum are very stable to light in hydrocarbon solvents. In chlorinated solvents, however, they undergo alkyl-halogen exchange. On the basis of CIDNP experiments, the following mechanism is proposed for the photolysis of complexes **77**[202].



Surprisingly, photolysis of *cis*-L_2PtnBu_2 also involves radicals and does not proceed via β-hydrogen elimination, the mechanism followed by the thermal reaction[203]. UV irradiation of (cod)Pt*i*Pr$_2$ **78** in 1,5-cyclooctadiene (cod) leads to $(cod)_2Pt$[22]. Although the mechanism of this reaction has not been studied in any detail, a photoinduced β-hydrogen elimination seems to be a plausible initial step.

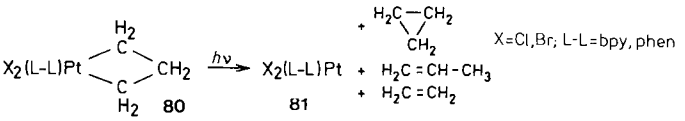


The trimethyl complex $CpPtMe_3$ **79** is photodealkylated via homolytic cleavage of the Pt–CH_3 bonds and formation of methane; the metal-containing product has not yet been characterized[204].

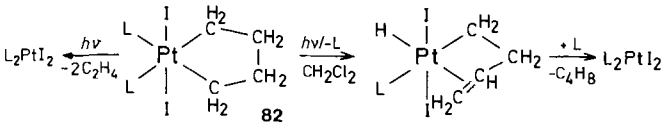
$$CpPtMe_3 \xrightarrow{h\nu} CpPtMe_2^{\odot} + {}^{\odot}CH_3$$
79

In this reaction, methyl radicals can be detected by ESR spectroscopy and trapping reactions; α-hydrogen abstraction and radical dimerization are negligible. The cyclopentadienyl ligand, methyl ligands, and the solvent serve as hydrogen sources for the formation of methane. Also interesting is the photolysis of the metallacycle **80**[205,206], since such four-membered ring systems are considered to be intermediates in olefin metathesis.

The reaction course proposed consists of simultaneous cleavage of the platinum-carbon and carbon-carbon bonds, which could produce cyclopropane or ethene, respectively. The formation of propene seems to arise from hydrogen transfer between adjacent methylene groups, but could also derive from a β-hydrogen elimination, which would generate an η^3-allyl(hydrido) intermediate. The latter compound loses propene to form **81**. The solvent is of great importance for the stabilization of the various intermediates.

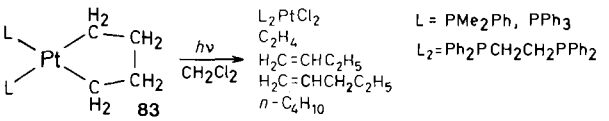


Photolysis of the five-membered metallacycle **82** in dichloromethane yields exclusively 1-butene and ethene[206].



Whereas the formation of ethene can be explained by a photoinduced ring fragmentation, 1-butene is unambiguously formed by a photoinduced β-hydrogen elimination. This is also observed in the photolysis of the related nickel complexes $L_3NiCH_2CH_2CH_2CH_2$ ($L = PR_3$, $PArYl_3$)[207].

The photoinduced decomposition of the platinum(II) complexes **83** via simultaneous homolysis and β-hydrogen elimination leads to *n*-butane and olefins.



The solvent is held responsible for the formation of 1-pentene; it provides a methylene ligand for the dealkylation, which causes the ring expansion.

The complexes **84**–**87** can be dealkylated in dichloromethane by UV light[208]. The scission of the platinum-carbon bond occurs irrespective of the number of alkyl ligands. The methyl radicals stabilize themselves by hydrogen abstraction from methyl ligands, other ligands, and the solvent.

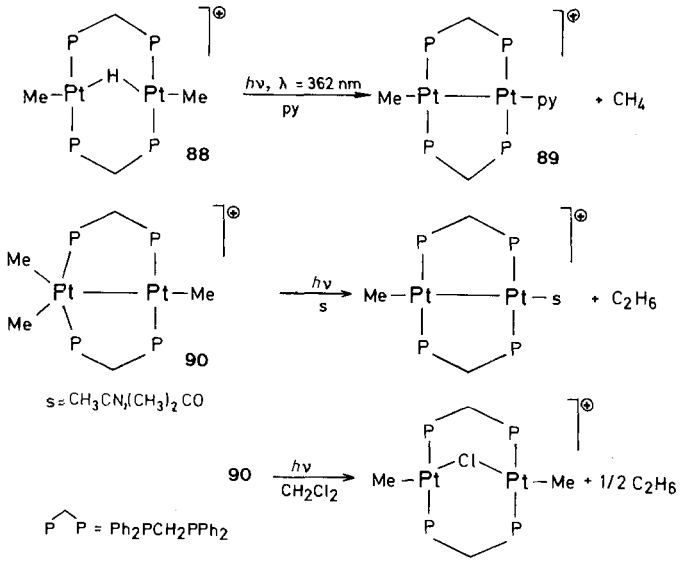
$$IPtMePh_2(bpy) \xrightarrow{h\nu} CH_4,\ C_2H_6,\ C_6H_5CH_3,\ Ph_2,\ PtIPh(bpy)$$
84

$$I_2PtMe_2(bpy) \xrightarrow{h\nu} CH_4,\ C_2H_6,\ PtI_2(bpy)$$
85

$$IPtMe_3(bpy) \xrightarrow{h\nu} CH_4,\ C_2H_4,\ PtIMe(bpy)$$
86

$$IPt(CD_3)_3(bpy) \xrightarrow{h\nu} CD_4,\ CD_3H,\ C_2D_4$$
87

Photolysis of **88** in pyridine leads to alkane elimination and formation of **89**, whereas **90** in acetone, acetonitrile,



or methylene chloride, reductively eliminates mainly ethane[209].

3.8. Photoreactions of Alkyl Complexes of Silver and Gold

The photochemistry of alkyl complexes with metals of group IB is largely undeveloped. **91** provides a good example for the observation that upon UV-irradiation some complexes undergo homolytic metal-carbon bond cleavage despite the availability of β-hydrogen[210].

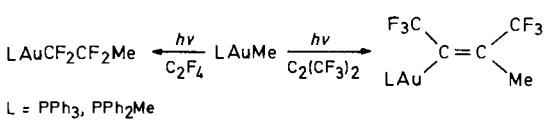
$$n\text{BuAgP}n\text{Bu}_3 \xrightarrow{h\nu} n\text{-}C_8H_{18}, n\text{-}C_4H_{10}, H_2C{=}CHC_2H_5, P n\text{Bu}_3, \text{Ag}$$
91

The photolysis of the analogous gold(I) compound **92** also involves radicals[211]. On the basis of CIDNP studies, UV irradiation excites the molecule into a singlet state, which undergoes intersystem crossing to an excited triplet state and from there reacts with the solvent $CDCl_3$.

The methyl radicals can undergo further reactions which generate CH_3D, C_2H_6, CH_3CDCl_2, and CH_3CCl_3.

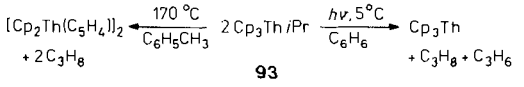
$$[Ph_3PAuMe]^T \xrightarrow[CDCl_3]{h\nu} Ph_3PAuCl + [{}^{\circ}Me + {}^{\circ}CDCl_2]^T$$
92

Potential ligands such as the fluoroolefins C_2F_4, C_3F_6, and C_2F_3Cl as well as hexafluorobutyne can be photochemically inserted into the Au–C bond[212].



3.9. Photoreactions of Alkyl Complexes of Thorium and Uranium

The difference between thermal and photochemical reactions is illustrated by the dealkylation of Cp_3ThiPr **93**[213].



Whereas the thermal decomposition involves radicals[214], the photochemical dealkylation proceeds via β-hydrogen elimination. The free coordination site, which is required on the metal, is probably provided by a photoinduced "ring slippage" ($\eta^5 \rightarrow \eta^3$) of a cyclopentadienyl ligand.

In contrast to **93**, photolysis of the analogous uranium compound Cp_3UR (R = *i*Pr, *n*Bu) **94** does not involve β-hydrogen elimination of the alkyl ligand but follows almost exclusively a radical pathway[215,216].

$$Cp_3U n\text{Bu} \xrightarrow[THF]{h\nu} Cp_3U(THF) + C_4H_{10} + C_4H_8$$
94a 93% 7%

The hydrogen required for alkane formation is provided by the cyclopentadienyl rings and the solvent. The surprising course of the reaction can be ascribed to the different redox potentials.

$$U^{IV} \longrightarrow U^{III}: -0.63\ V$$
$$Th^{IV} \longrightarrow Th^{III}: -3.7\ V$$

Uranium(IV) is much more easily reduced than thorium(IV). Another reason could be that the "ring slippage" mechanism, which provides the open coordination site on the metal, does not occur readily with uranium complexes.

4. Summary and Prospects

From the above excursion through the photochemistry of alkyltransition-metal complexes it is evident that this embryonic branch of organometallic chemistry has opened multifaceted preparative possibilities. The main advantage offered by photochemical compared to thermal reactions is that the former can be initiated and monitored spectroscopically, irrespective of the temperature. A whole series of highly reactive compounds and fragments such as alkene(hydrido) and alkylidene(hydrido) complexes, and free carbenes and alkyl radicals can be continuously generated in situ and used for preparative or catalytic reactions.

Photochemical methods nevertheless retain a hint of "alchemy" since for many alkyl complexes too little is known about what occurs in a given molecule after absorption of a quantum of light and what physical processes occur along the path to the primary chemical product. Even slight electronic changes in the complex, use of different solvents, or variation in the wavelength of the radiation can produce completely different reactions, indicating very sensitive and easily influenced processes. The combined use of physical methods such as flash photolysis, ESR, NMR (CIDNP), and IR spectroscopy may "throw more light" onto the nature of the primary and secondary processes. In the future, more attention must be given to the selective excitation of molecules through the use of mono-

chromatic light sources (lasers). Theoreticians are challenged too! Calculations on suitable model compounds may some day allow predictions to be made about the course of photodealkylations.

What can the preparative chemist expect? Today, a large number of attractive alkyltransition-metal complexes resemble "sleeping beauty", waiting to be awakened by UV light. The knowledge gained from the alkyl complexes should also be applicable to other σ-organyl complexes, e.g. acyl or aryl coordination compounds, which have been little studied. In this context, photolysis of the aryl complex Cp_2ZrPh_2[217] should be mentioned. The photochemically generated Cp_2Zr fragment can be used for a number of preparative reactions[218].

Thanks go to all my co-workers, who participated with great enthusiasm in our own studies, and to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

Chiral Macrocycles as Reagents and Catalysts**

By Richard M. Kellogg*

Ionophores, whether of natural or synthetic origin, encapsulate their ionic "guests" using noncovalent bonding. This encapsulation process resembles, at least superficially, the bonding of a substrate by an enzyme-active site. The analogy to enzymes can be extended further if the ionophore is provided with functional groups that can react with a suitable guest molecule bound in the cavity of the ionophore. We have embedded in the periphery of a macrocycle a 1,4-dihydropyridine, a mimic of the coenzyme NADH. The macrocycle, in addition to having (weak) ionophoric properties, is chiral. This strategy has led to compounds that react as artificial hydrogenases and which are capable of distinguishing, in a predictable fashion, between the prochiral faces of suitable carbonyl substrates. Ancillary developments from this approach have been many. A remarkably general method for the preparation of a wide variety of macrocycles has been developed which depends on some remarkable chemical idiosyncrasies of the cesium ion. In attempts to exploit the chemical possibilities of these macrocycles, unusual chemistry, possibly relevant to the action of the enzyme, 3-phosphoglyceraldehyde dehydrogenase, has been uncovered. In a similar vein, study of macrocycles has led to variants of the aldol condensation on chiral templates. Finally, catalytic CC bond formation mediated by transition metals is revealed to be an area in which chiral macrocycles can play a useful role by acting as chiral ligands for the transition metal.

[**] This article is based, in part, on the content of the "Middle Rhine Lecture Tour", November 1983.

1. Introduction

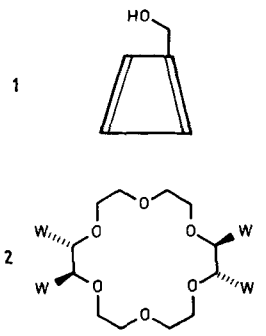
The architectural possibilities offered by synthesis together with the predictive power of mechanism can be harnassed for the design of molecular catalysts. A designed

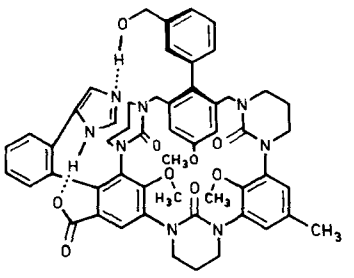
molecular catalyst might reasonably be expected to be capable of recognizing a substrate, inclusive of its chirality; to be complementary to the transition state of the reaction it catalyzes[1]; and to discharge the products after reaction and regenerate itself. These, and other functions, are, of course, achieved by those wonders of nature, enzymes, which accomplish their purpose, however, with the aid of frightening molecular complexity. It occasions little surprise that chemists interested in designing molecular catalysts do so, on the whole, by combining some inspiration drawn from enzymes, chiefly the active site, together with the enormous body of chemical knowledge drawn from other sources. It is unlikely that the products of such inspiration will approach in any degree the molecular complexity of most enzymes. Nor is it necessary that they do so.

Whatever the sources of inspiration, one thing that must be controlled is *noncovalent bonding*. This stems from the consideration that a catalyst can best have at least some of the aspects implicit in the classical Michaelis-Menten kinetic equation [eq. (a)][2]. The catalyst, in general, will have to complex with the substrate in an enzyme-like fashion and hold it in a defined orientation. This requires mastering the complexities of noncovalent bonding.

$$\underset{\text{(M)}}{\text{Enzyme model}} + \underset{\text{(S)}}{\text{Substrate}} \rightleftharpoons [\text{M}\cdot\text{S}] \longrightarrow \text{M} + \text{Product} \qquad \text{(a)}$$

One well-known route to molecular catalysts which illustrates clearly many of these considerations uses the naturally occurring cyclodextrins. **1** shows a schematic side view of the torus formed by these cyclic glucose oligomers: the smaller end is rimmed with primary hydroxyl groups and the larger end bears the secondary hydroxyls of the pyranose rings. A "substrate" is extracted from aqueous solution into the hydrophobic cavity, but once there the guest molecule is free to move within the constraints provided by the walls[3].





3

Particularly *Breslow*[4] and *Tabushi*[4] have developed methods of introducing catalytic groups via the hydroxyl moieties onto the rim of the cyclodextrin; these catalytic groups can operate in an enzyme-like fashion on a suitable encapsulated substrate.

Crown ethers such as **2** are, on the other hand, totally synthetic in origin. The predesigned cavity complexes rigidly, through three of the oxygen atoms, the three hydrogens of an ammonium ion $RNH_3^{\oplus}$, as shown elegantly by *Cram*. Functionalized "arms" (indicated as "W") at suitable positions on the periphery can react with substituents R on the bound ammonium ion, as described by *Lehn* et al.[5].

A lovely molecular design is **3**, a model for a protease designed by *Cram* et al.[6], but not yet completely synthesized. The "spherand" structure provides, via the amide oxygens, a prestructured cavity for the firm encapsulation of an ammonium ion. An ester or amide incorporated at the proper position of the R group of the encapsulated $RNH_3^{\oplus}$ can be acted on in an enzyme-like fashion by the surrogate groups about the periphery which mimic the serine hydroxyimidazole-aspartate combination of hydrolases such as chymotrypsin.

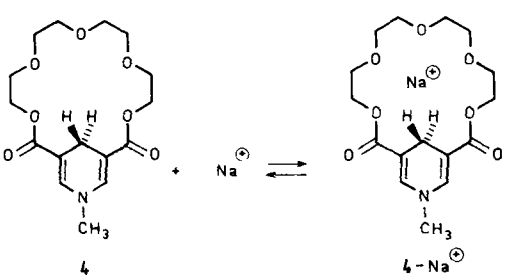
Compounds **1**—**3** are popular models for enzymes. Many variants can, and have been, thought of and realized. We will concentrate here chiefly on molecules into which, by rational synthesis (combined, if possible, with the structural bounty offered by Nature in the form of cyclodextrins, amino acids, etc.), a great deal of structural information has been incorporated in advance for regulation of noncovalent bonding to attach the substrate and possible activating ions or neutral molecules. The results are a blend of organic and inorganic chemistry that may, in certain cases, be significant for understanding related enzymic systems. Be that as it may, the results are interesting and useful in their own right as an extension of existing chemistry.

2. Enantioselective Reductions with Chiral Bridged 1,4-Dihydropyridines

In view of the introductory remarks, we have tried to use macrocycles as "templates" for chemical reactions. This was inspired, in part, by the imaginative work on "crown ethers", "cryptands", and cyclodextrins just discussed[7]. We have incorporated reactive functionalities into or onto the macrocycle and have used the enforced geometry and complexing ability to direct reactions on this macrocyclic template. The functionalities used so far have been chiefly related to coenzymes, in particular the redox couple $NAD(P)^{\oplus}/NAD(P)H$[8].

At the outset it should be emphasized that a major barrier we have encountered, even more serious than those problems associated with molecular design, is incomplete mechanistic knowledge and the occurrence of unique chemistry, which was not (or, in my opinion, could not) be predicted a priori.

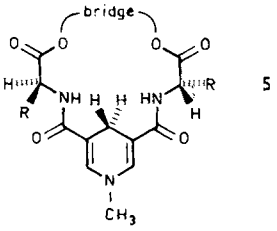
Some initial experiments were carried out with **4**, in which a Hantzsch 1,4-dihydropyridine has been included



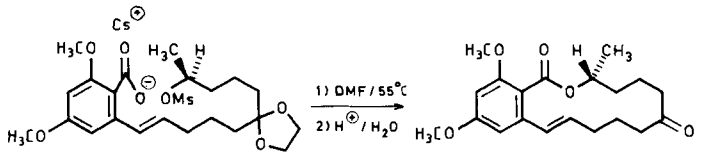
4 4-$Na^{\oplus}$

in the periphery of an 18-crown-6 macrocycle. The distortion of the periphery lowers the affinity towards cations as compared to 18-crown-6, but nevertheless complexation does occur to give isolable salts with $NaClO_4$ (and a mole of solvent)[9].

Although **4**-$Na^{\oplus}$ displays no enhanced reactivity, this observation encouraged us to try to improve the design. We were further encouraged by the fact that **4** rapidly reduces certain sulfonium salts after prior complexation of the sulfonium ion[10]. A reasonable synthetic goal was the general structure **5** in which chirality has now been built in by virtue of the inclusion of the two identical amino acids. As long as the structure of the bridge is symmetrical, a C_2 axis is present in the molecule. The two faces of the 1,4-dihydropyridine are equivalent and the hydrogens at the 4-position are homotopic, not diastereotopic, as in NAD(P)H.

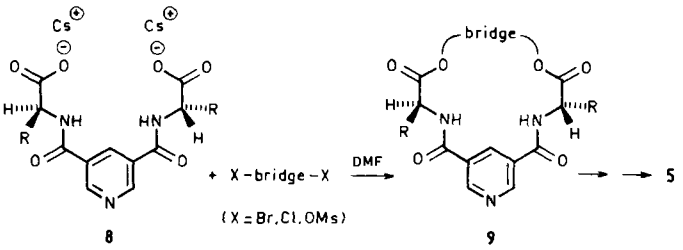


Before the rationale behind the choice of **5** is discussed, a pragmatic question of synthesis of such macrocycles must be addressed. We had, in connection with similar problems, developed a method based on the use of cesium salts to promote macrocycle formation via an anionic S_N2 substitution as the ring closure step. This technique works especially well for those cases where the probability of a "template effect" with a cation is less due to the absence of properly disposed heteroatoms in the open-chain compound to be cyclized. An illustration of this "cesium effect" is provided by the synthesis of (*R*)-zearalenone dimethyl ether **7** from (*S*)-**6**, a reaction which proceeds in 80% yield with the expected inversion at the secondary carbon atom[11]. Similar encouraging results are found for the



syntheses of a wide variety of macrocyclic lactones. This unanticipated behavior of cesium cations is thought to be related to the special properties of a "tight ion pair" formed in dimethyl formamide (DMF)[11,12]. The properties of these ion pairs are currently being studied by ^{133}Cs-NMR spectroscopy[13].

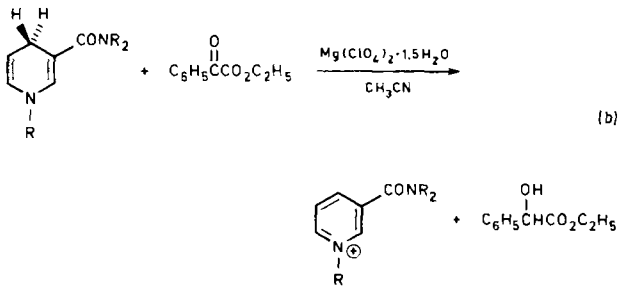
Application of the "cesium salt" method enables also the synthesis of *di*lactones such as **9**, which by further routine transformations can be converted into **5**. The restrictions are that the bridge is at least four atoms long (17-membered macrocyclic ring is formed) and that the terminal C atoms of the bridge are (preferably) primary so as to ensure smooth S_N2 displacement and the absence of additional stereochemical problems. Valine (the natural L-enantiomer is shown in the formula) has been used most ex-



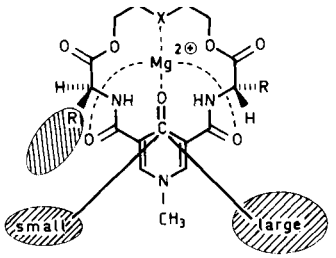
tensively because of its good solubility and polarity properties. Phenylalanine, alanine, and proline have been used to obtain supplementary information. Compounds derived from phenylglycine have been prepared, but problems with partial racemization have been serious[14].

Rather than present extensive lists of compounds and results, I will try to illustrate the main points that have emerged from the study of these compounds. Exhaustive coverage of details is available elsewhere in the literature[14].

Let us return to the rationale behind the use of **5**. Consider first enantioselective reductions. Other groups had established that in the presence of metal ions, (especially $Mg^{2\oplus}$) activated carbonyl compounds (e.g., alkyl phenylglyoxylate esters) are reduced by 1,4-dihydronicotinamide derivatives [Eq. (b)][15].



Even after extended drying, the metal salt $Mg(ClO_4)_2$ contains ca. 1.5 equivalents of H_2O. *Ohno* et al.[16] have elegantly demonstrated that in several cases high transfer of chirality could be obtained with 4-methylated-1,4-dihydropyridines if the carboxamide side chain is substituted with an (optically pure) amino acid. We thought that it would be advantageous if a ternary complex could be formed in which the $Mg^{2\oplus}$ ion were held in a defined position in the macrocycle **5**. The carbonyl oxygen atom of the phenylglyoxylate to be reduced should be coordinated to $Mg^{2\oplus}$ and lie on the macrocyclic surface, as illustrated in Scheme 1, to minimize steric interactions, while placing the carbon atom to be reduced in a stereoelectronically reasonable position relative to the 4-position of the 1,4-dihydropyridine[17]. The amino acid substituents, related by a C_2 opera-

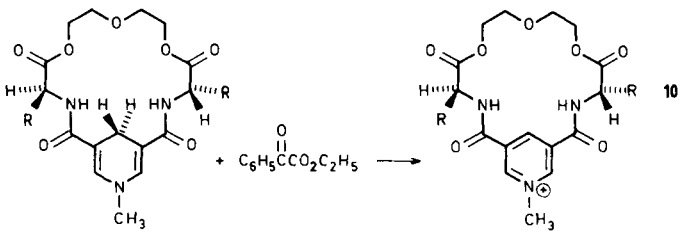


5-$Mg^{2\oplus}$-ketone

Scheme 1. Structure of the ternary complex 5-$Mg^{2\oplus}$-ketone.

tion, provide a steric barrier which influences the face selectivity of binding of the carbonyl group. This type of coordination entails an out-of-plane movement of the macrocyclic ring to allow the carboxamide groups to complex. Although this model turns out to be over-idealized, its predictive power, especially in terms of the absolute configuration of the alcohol formed, is indeed remarkable.

The chiral recognition is predicated from the steric effects that arise from the amino acid substituents. That these substituents—none of which are large—have an effect is nicely illustrated by the comparison in Scheme 2[14,18]. A macrocycle into which an (*S*)-amino acid has

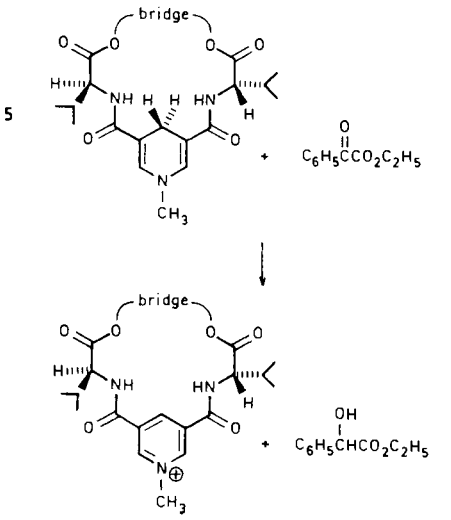


R	*ee* [%]	config.
CH_3	61	*S*
$C_6H_5CH_2$	86	*S*
$(CH_3)_2CH$	87	*S*

Scheme 2.

been incorporated provides the (*S*)-enantiomer of ethyl mandelate. There are, however, no significant accelerations in rate relative to the nonbridged analogues. The enantiomeric excesses for these room-temperature reductions are quite good, and, as seen from inspection of the complex 5-$Mg^{2\oplus}$ ketone, are also in accord with the predictions of our simple model that the *re*-face of the carbonyl group should be attacked since phenyl is the "large" group.

This general picture, and, in particular, this overall stereochemical result, is even more convincingly established when the size and shape of the bridge bearing the amino acid "arms" are varied. The enantiomeric excesses with $R=(CH_3)_2CH$ for polymethylene bridges of successively greater length are shown in Scheme 3. The enantiomeric excesses remain excellent up to and including eight methylene groups in the bridge before beginning to decline. And even for the dodecamethylene bridge, a compound with a 25-membered macrocyclic ring, chirality is still transferred with surprising faithfulness and with the same stereochemical bias. The reaction appears to proceed via a rather generally applicable mechanism.



bridge	*ee* [%]	config.

$(CH_2)_6$	88	*S*
$(CH_2)_8$	82	*S*
$(CH_2)_{10}$	52	*S*
$(CH_2)_{12}$	42	*S*

Scheme 3.

This impression that general principles can be involved in all these reductions is strongly reinforced by the fact that we have not observed a single exception to the above mentioned stereochemical pattern for all the 28 chiral bridged 1,4-dihydropyridines which we have synthesized and examined, and in which length, composition, and shape of the bridge have been extensively changed

Some additional points deserve to be mentioned, however, before an attempt is made to define general principles. One is that the two arms must be locked together by a bridge to obtain adequate transfer of chirality. Some typical results for nonbridged compounds are shown in Scheme 4. Apparently in these cases the "side arms" can assume a variety of conformations from which reactions can occur[19]. When the conformations are locked by joining the arms with a bridge, greatly improved chiral recognition results.

One must realize, however, that a bridge does not provide a total conformational lock. The conformations of these macrocyclic compounds, with their great variation in bridge lengths, can differ greatly. Some factor must operate to provide a conformational bias. This point can best

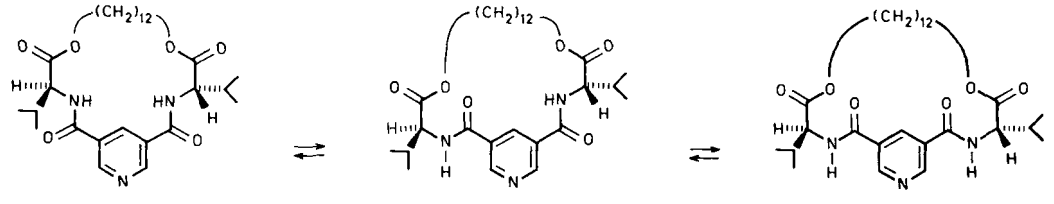
Scheme 4.

be illustrated with compound **9**, which has the greatest degree of conformational mobility. There are three minimum energy conformations for this compound (Scheme 5):



inside / inside — outside / outside — outside / outside

9 (bridge = $(CH_2)_{12}$)

Scheme 5.

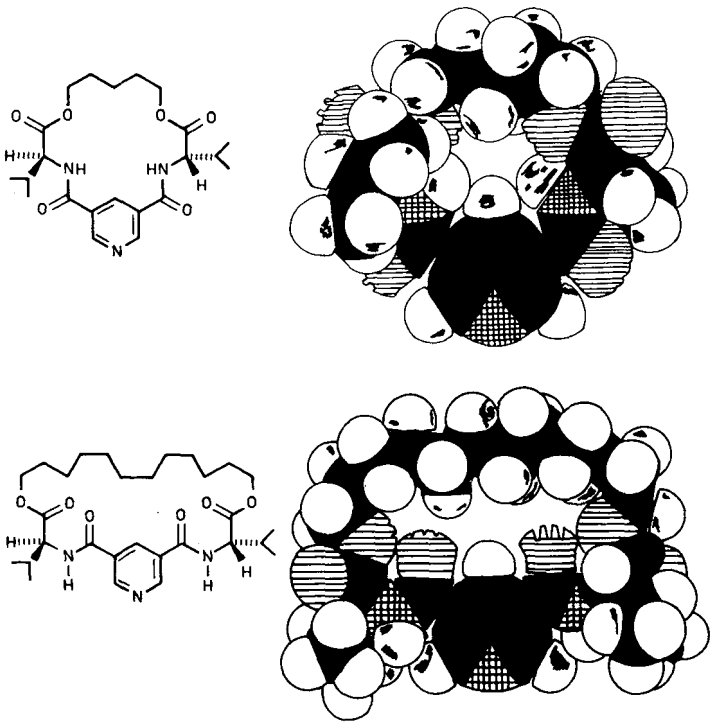


Fig. 1. Space-filling model (right) of the favorable conformations of an inside/inside and outside/outside conformation of two pyridine macrocycles. In the space-filling models the view is from the top; the pyridine nitrogen and the amide nitrogens are crosshatched.

one with both amide hydrogens inside the macrocycle (inside/inside), another in which the entire amide has rotated 180° about the carbonyl-ring bond (inside/outside), and a third conformation in which both amide groups have rotated (outside/outside). We assume that the amide units will not deviate from the *trans*-conformations indicated. There are adequate grounds to support this assumption. The inside/outside and outside/outside conformations are only attainable for bridges of length 10 atoms or more; otherwise, the compound is held in the inside/inside conformation with only restricted possibilities for further external conformational motion owing to the rigidity of the amide functionalities and the aromatic ring. These arguments are based on the results of temperature-dependent circular dichroism and ^{13}C-NMR measurements[20]. Measurements were carried out on pyridines **9** for stability reasons, but the same arguments apply also to 1,4-dihydropyridines **5**.

The inside/outside and outside/outside conformers have morphologies which are strongly at variance with those of the inside/inside conformer, in particular with respect to the placement of the chiral barriers, which effect the chirality recognition. (A comparison of bridged pyridines and 1,4-dihydropyridines has just been made. The latter are in general too unstable to allow conformational studies. There is, however, little reason to believe that the steric situation for a bridged 1,4-dihydropyridine is fundamentally different from that in pyridines.) The fundamental differences in morphologies of the various conformers are illustrated in Figure 1. Why is this difference not reflected all that strongly in the enantiomeric excesses obtained when these macrocycles are used as reagents for the reduction of prochiral carbonyl compounds?

Still another point must be made: The stability constants of these macrocycles with $Mg^{2\oplus}$ ions are not large. As can be seen from the data in Figure 2, a heavy debt in complexing power (but not so much so in enantioselectivity) has been paid for the extensive modification of the macrocyclic periphery.

The $Mg^{2\oplus}$ ion, a powerful electrophile, must have the cardinal function of organizing the structure of the macrocyclic system, as shown in Figure 3. The $Mg^{2\oplus}$ ion associates with the oxygen atom of an amide group; at the same time, it acts as an electrophile towards the carbonyl group to be reduced. If we confine ourselves to phenylglyoxylate esters as substrates, we expect that this carbonyl-$Mg^{2\oplus}$ unit will orient itself *trans* to the amino acid substituent. In Figure 3 this is indicated by complexation on the right-hand side of the molecule (an arbitrary choice since the amides are related by a C_2 axis in the uncom-

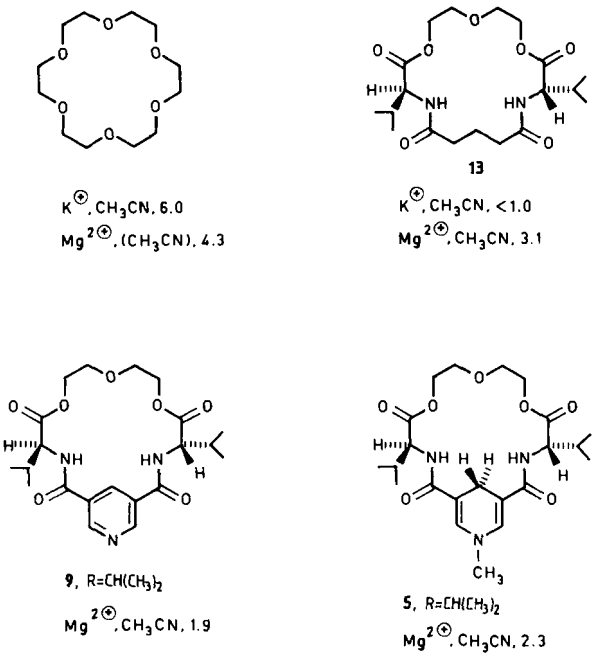

Fig. 2. Comparison of the complexing ability of various compounds. For **5**, **9**, and **13** the association constants were determined conductometrically. The value for 18-crown-6 with $K^{\oplus}$ was measured by H. K. Frensdorf (*J. Am. Chem. Soc. 93* (1971) 600). The cation is shown first, followed by the solvent and $\log K_{ass}$.

plexed macrocycle). On complexation, the C_2 axis is lost. Reduction requires replacement of the carbonyl carbon atom above the 4-position of the 1,4-dihydropyridine. This can be achieved only by placing the carbonyl substituents "astraddle" the chiral barrier on the left-hand side of the molecule. Examination of CPK models shows that the phenyl ring must indeed be oriented over the dihydropyridine moiety[21].

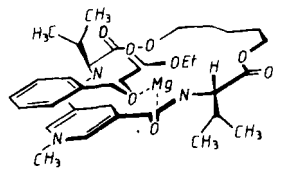

Fig. 3. View of the ternary complex that is presumed to be the intermediate in the reduction.

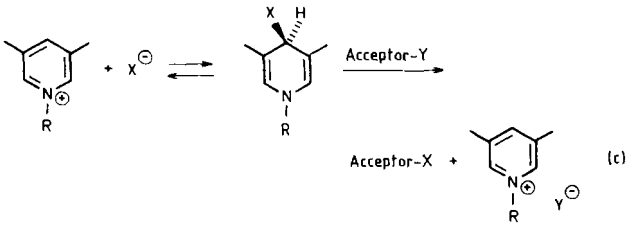
The orientation shown in Figure 3 differs from the original model **5**-$Mg^{2\oplus}$ complex in that complexation with the bridge is not involved, as established unequivocally by structure-reactivity studies. In Figure 3 the carbonyl group is rotated about 90°, but the *re*-face of the carbonyl group is still that exposed for acceptance of "hydride".

The essential point is that $Mg^{2\oplus}$, although it complexes only relatively weakly, organizes the structure of the macrocycle; this is accomplished by noncovalent forces. Such organizational effects are quite common in chemistry, although not often so dramatically apparent as here.

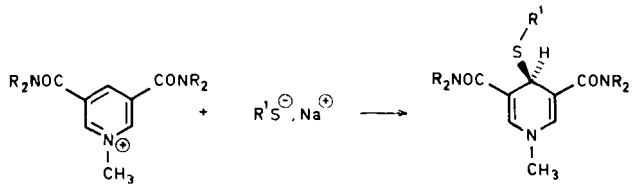
3. The Problems of Ion Pairing in Pyridinium Ion/Thiolate Adducts

With these bridged chiral macrocycles in hand, we now searched for other applications in addition to the reductions described. One could, in general, inquire to what extent a pyridinium salt (or for that matter other aromatic, positively charged heterocycle) possesses a wider ligand-transfer ability. This is illustrated schematically in equation (c). All the anions $X^{\ominus}$ shown have been reported to add to pyridinium salts[23].

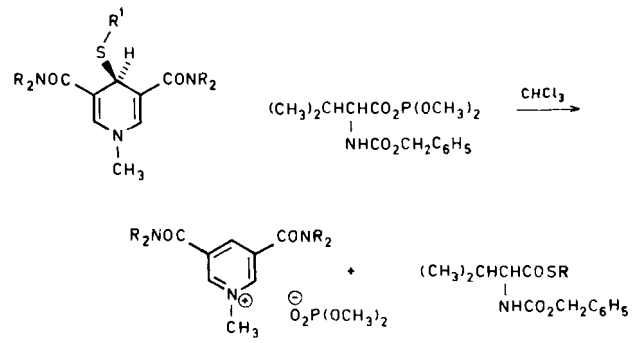
In order to simplify matters, the anion $X^{\ominus}$ is assumed to add only to the 4-position[22]. X is initially present as an anion in the reaction and is then transferred to a substrate (acceptor X). Are there any advantages to be gained from this circuitous pathway? Certainly for transfer of "hydride" there appear to be; this is, of course, the general function of the $NAD^{\oplus}$/NADH(H) coenzyme couple!



Pyridinium salts **14** from amides of pyridine-3,5-dicarboxylic acid, the basic building block of the macrocycles **9**, also undergo clean, regioselective addition of thiolate to provide covalent adducts of the general structure **15**.



Under completely neutral reaction conditions the adducts **15** transfer smoothly, via the covalent forms, the thiolate group to, for example, activated esters to form thioesters. This possibility is illustrated for the synthesis of an amino acid thioester in Scheme 6[23h]. Purification of the



Scheme 6.

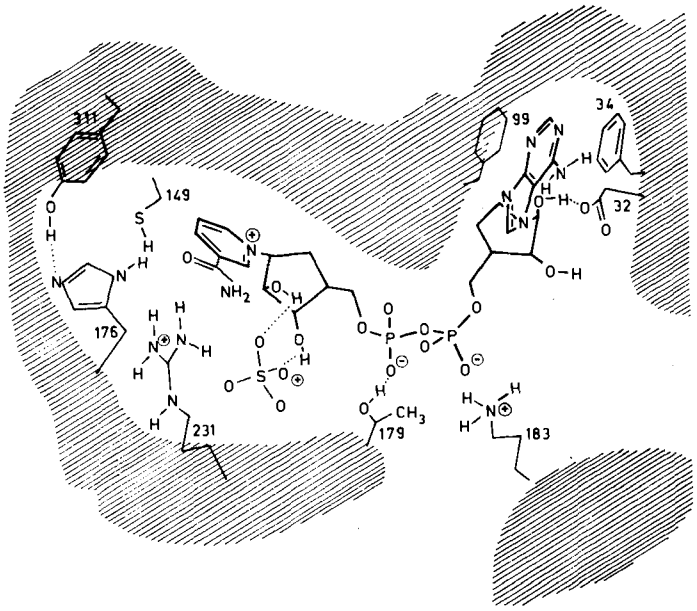


Fig. 4. View of the active site of 3-phosphoglyceraldehyde dehydrogenase with bound NAD⊕. Reproduced with kind permission of the publishers from *M. Rossmann* et al. in P. Boyer: *The Enzymes, Vol. 11*, Academic Press, New York 1975, p. 87.

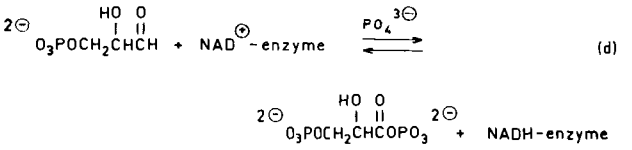
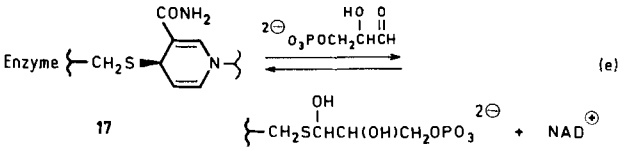


(d)

of groups at the active side is illustrated in Figure 4. The enzyme catalyzes the overall oxidation of 3-phosphoglyceraldehyde to the acyl phosphate [eq. (d)]. The initial product is, however, an acyl ester with Cys-149, which is transphosphorylated at a second active site of the enzyme. The essential reaction scheme is given in Figure 5[24]. If, however, Cys-149 were first to add to NAD⊕, **17** would be formed. If this compound is to be a viable intermediate, however, there must be a pathway for its conversion into



(e)

thioesters is especially easy because the only side product is the polar pyridinium salt. In the case of chiral bridged pyridinium salts, this type of reaction offers the possibility of transfer of thiolate under asymmetrie conditions. Various ways of realizing this idea can be envisaged. The unexpected over whelmed us at this point, however.

the hemithioacetal intermediate shown in Figure 5 [see eq. (e)].

This proposed thiolate addition to NAD⊕ is not original. It was first made more than thirty years ago by *Racker* and *Krimsky*[25]. This idea seems, however, to have fallen by the wayside in favor of charge-transfer explanations of

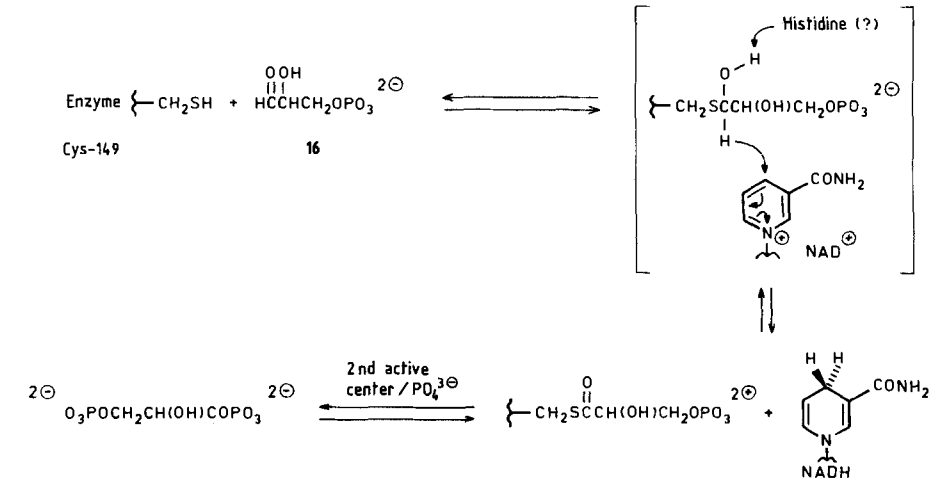


Fig. 5. Mechanism of the reaction of glyceraldehyde 3-phosphate with glyceraldehyde 3-phosphate dehydrogenase.

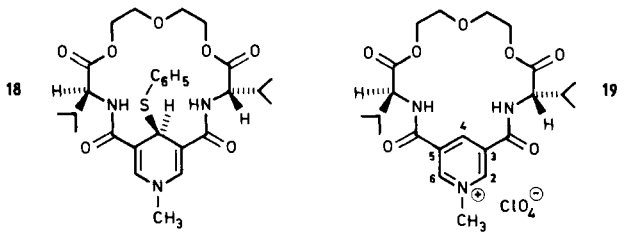
But before describing this in detail, we shall make a small detour into biochemistry. Thiolate addition to a pyridinium salt, NAD⊕ to be specific, could be significant in the mechanism of action of the enzyme glyceraldehyde phosphate dehydrogenase. At the active site of this enzyme there is a reactive cysteine (Cys-149), which, together with its catalytic action, is involved in the formation of the yellow color characteristic of this enzyme. The arrangement

the yellow color[26]. It is striking, however, that the long-wavelength maximum for the NAD⊕-3-phosphoglyceraldehyde dehydrogenase complex from rabbit muscle has $\lambda_{max} = 360$ nm, whereas **18**, a compound that will figure in subsequent discussions, has $\lambda_{max} = 340-350$ nm, depending on the solvent[27]. The UV spectra of **18** are representative for the thiolate addition products from 3- or 3,5-mono or disubstituted carboxamidopyridinium salts in general[27].



I return now to the unexpected: The ^{1}H- and ^{13}C-NMR spectra (and abnormal reactivity behavior, which first led to a close examination of the spectra) of **18** and related compounds, including examples without a bridge, are found to have a puzzling dependence on solvent. The most important aspects of the NMR spectroscopic behavior are summarized in Figures 6 and 7, which show the solvent-dependent ^{1}H- and ^{13}C-NMR absorptions at room temperature. No attempt has been made to reproduce temperature-dependent behavior. The spectroscopic behavior in CD_3OD is also similar to that in CD_3COCD_3, CD_3CN, and CD_3SOCD_3. Of note is that, on dissolution in a polar solvent, the signals for C-4 and H-4 have a pronounced

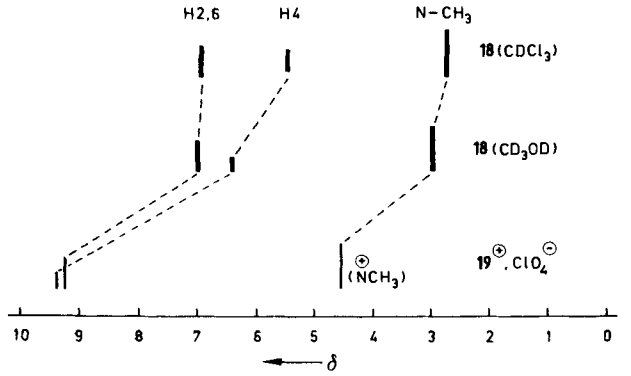


Fig. 6. Solvent-dependent ^{1}H-NMR signals (all other signals have been deleted for clarity) of **18** in $CDCl_3$ (top) and in CD_3OD (middle), as compared to the signals of the pyridinium salt **19** (bottom). In polar solvents the signals of N–CH_3, H-4, and H-2/H-6 of **18** shift in the direction of the corresponding signals of **19**. Full details are given in [27].

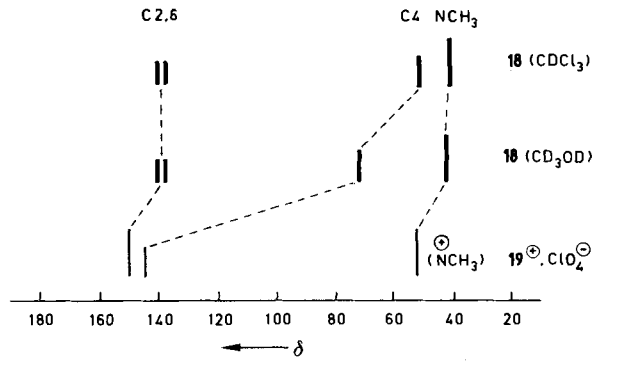

Fig. 7. Solvent-dependent, proton-decoupled ^{13}C-NMR signals of N–CH_3, C-4, and C-2/C-6 in $CDCl_3$ (top), CD_3OD (middle) compared with those of the pyridinium salt **19** (bottom). All other absorptions have been deleted for clarity. Full details are available in [27]. Note for C-2 and C-6 that the effect of the diastereotopicity of these carbons (and the attached protons) can just be observed.

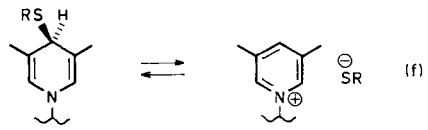
tendency to shift downfield towards the characteristic absorption positions of the signals of pyridinium salts. The effect is smaller for C-2, C-6, H-2, H-6, and NCH_3.

There could be a reasonable, and not particularly surprising, explanation for this behavior. The adducts with thiolate are clearly covalent in solvents such as $CDCl_3$, but they might ionize partially in more polar solvents to give a pyridinium/thiolate ion pair [eq. (f)]. If the concentration



of thiolate is low and the rates of dissociation and recombination are, within an order of magnitude, comparable with the NMR time scale, a simple and not especially dramatic explanation of the spectroscopic analomies might be at hand.

This is, however, not the case. We have shown[27] for **18** and related compounds that

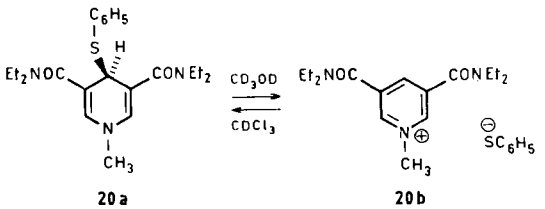
a) Thiolate does not dissociate from the pyridine to which it is originally bonded. No "crossover" of thiolates from one molecule to another has been detected, as would be expected with the ion pair in equation (f).

b) No appreciable change in the magnitude of $^1J_{^1H,^{13}C}$ of C-4 in **18** (ca. 150 Hz) is observed on change of solvent. The pyridinium salt **19** has a $^1J_{^1H,^{13}C} = 180$ Hz, as expected for an sp^2-carbon atom.

c) The magnitude of the downfield shifts correlates qualitatively with the basicity of the thiolates. Ionization of the appropriate addition products of **19** is observed for 4-nitrothiophenolate, whereas the benzylthiolate addition product with **19** behaves like the phenylthiolate addition product **18**, except that the downfield shifts are smaller but increase in magnitude as the temperature is raised.

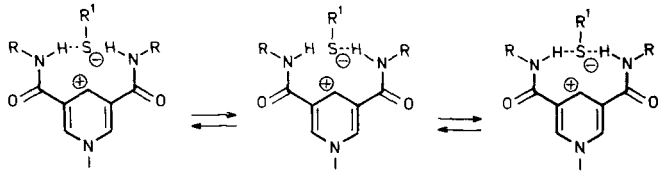
d) Isomerization to 1,2-substituted systems is not involved.

e) This analomous behavior is found only when the amide functionalities bear a proton. This is illustrated, for example, with **20a**, which ionizes virtually instantaneously and completely to the pyridinium thiolate **20b** when dissolved in CD_3OD or other polar solvents.



f) The NMR observations are corroborated by the UV spectra, which are consistent with formation in polar solvents of an intermediate other than the pyridinium salt.

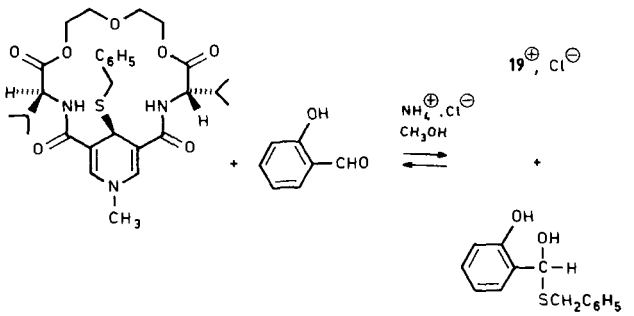
These observations bear an obvious resemblance to the seminal work of *Wallenfels* et al.[23a], some thirty years ago, on a variety of pyridinium salt/nucleophilic addition products. *Wallenfels* did not have available for his work the powerful tool of NMR spectroscopy.



21a **21b** **21c**

We have suggested[27] that our observations can be accommodated by an intermediate having the general structure **21a**–**c**. The complete solvolytic cleavage of the thiolate in polar, mildly nucleophilic solvents is prevented by hydrogen bonding to the amide proton (actually, deuterium under the reaction conditions). The exact hybridization of C-4 in **21** is currently an open question. We view **21**, in fact, as an intimate ion pair in the sense defined by *Sneen*[28]. Our observations are doubtless related to the elegant work on other pyridinium salt ion pairs carried out previously by *Steglich* and *Höfle*[29].

Returning to possible implications for 3-phosphoglyceraldehyde dehydrogenase[30], we have shown that the reversible reaction shown in Scheme 7 smoothly occurs in CH_3OH, but not in $CHCl_3$. This is completely analogous to the step necessary for the enzymic mechanism postulated in equation (c).



Scheme 7.

There remain many unanswered questions. For 3-phosphoglyceraldehyde dehydrogenase, the validity or not of our mechanistic suggestion can be established only with the aid of appropriate biochemical experiments. A special role is played by the carboxamides in **21**, namely hydrogen bonding. One may speculate that in $NAD^{\oplus}$/NADH similar hydrogen bonding effects might be important, a surmise already made in a different context by *Buck* and *Donkersloot*[31] on the basis of ab initio calculations. In particular, the conformation of the carboxamide group with respect to the ring could become a factor governing reactivity. Other unanswered questions have to do with the exact structure of **21**. Is it truly an ion pair with non-covalent bonding of the pyridinium and thiolate ions or is some type of "stretched" carbon-sulfur bonding involved? And exactly how does **21** (but not the covalent precursor) manage to transfer thiolate? We suspect that again some general, but not broadly recognized, principles are involved; we hope in time to define these better.

4. Transfer of Other Nucleophiles

In the course of our investigations of the chemistry described in the previous section, it occurred to us that one might also be able to use these chiral, bridged pyridinium salts as templates on which to carry out enantioselective aldol condensations[32]. This is illustrated in general terms in Figure 8. The enolate of **23** is expected to leave readily in

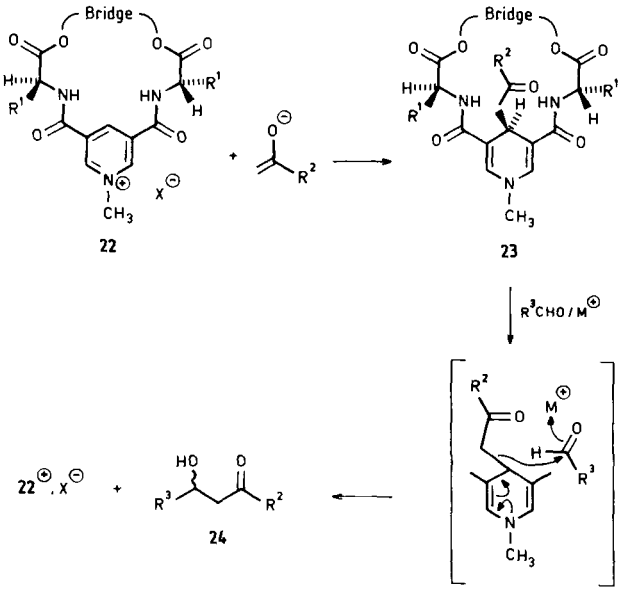


Fig. 8. Schematic mechanism for the aldol condensation using **22** as matrix.

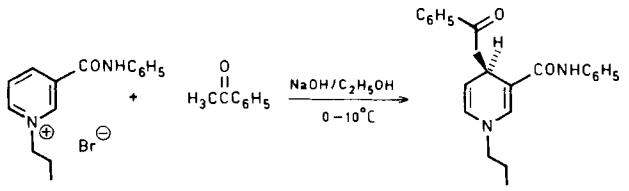
the presence of an electrophile such as $SnCl_4$, $Mg(ClO_4)_2$, or $BF_3 \cdot O(C_2H_5)_2$, producing the aromatic pyridinium salt **22**. Some assumptions are, however, associated with this mechanism. The most important of these are a) that regioselective addition of enolates or their equivalents to **22** is possible and b) that the aldol condensation occurs on the chiral surface of the macrocycle rather then via an achiral metal enolate that has completely left **23**. The question of ion pairing as discussed in the previous section might also play an important role here.

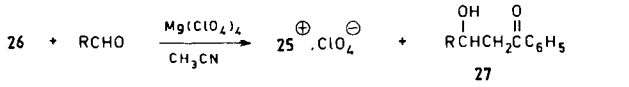
Adequate precedent exists for the addition of enolates to pyridinium salts[23j-o,33] and, moreover, an unusual precedent for the transformations outlined in Figure 8 has been described by *Steglich* and *Höfle*[23m,34]. We first established that enolate transfer as delineated in Figure 8 could be ac-

complished in a reasonably general fashion using a racemic enolate-pyridinium salt adduct. From **25** the adduct **26** could be prepared in good yield and in high regioselectivity. In CH_3CN at room temperature in the presence of a



25 **26**

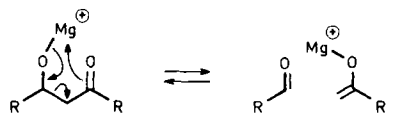
stoichiometric amount of $Mg(ClO_4)_2 \cdot 1.5\,H_2O$, condensation occurs smoothly to produce aldols **27** in 37—90% yield[35].



27

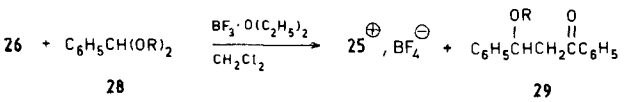
a, $R = C_6H_5$ (78–85%); b, $R = 2\text{-}CH_3OC_6H_4$ (85%); c, 2-furyl (90%); d, $(CH_3)_3C$ (47%); e, *trans*-$C_6H_5CH{=}CH_2$ (67%); f, $2\text{-}HOC_6H_5$ (37%)

Although these results are encouraging in that the desired reaction took place, two problems arise. Firstly, the addition of enolates to other pyridinium salts, especially those of general structure **22** shown in Figure 8, were not particularly regioselective; appreciable amounts of 1,2-adducts are formed. This is, of course, not too surprising; the addition tends to become more charge-controlled with harder nucleophiles, e.g. C nucleophiles which attack the more electron deficient 2-position[22,36]. Softer S-nucleophiles attack, within the detection limits of NMR spectroscopy, exclusively the 4-position. Secondly, under the conditions used here the aldol condensation is reversible; in other words, any transfer of chirality from a derivative of **23** is lost (Scheme 8)[37].



Scheme 8.

We have yet to provide a satisfactory solution to the problem of regioselectivity. The difficulty associated with reversibility is more easily attacked by changing the enolate acceptor from a carbonyl to an acetal group. This is, in essence, a variation of a method developed by *Mukaiyama* et al.[38]. For example, **26** condenses smoothly with the dimethyl acetal **28a** or diacetoxy derivative of benzaldehyde **28b**. Use of **28b** and related 1,1-diacetates leads under irreversible conditions to acylated aldols; the acetyl protect-

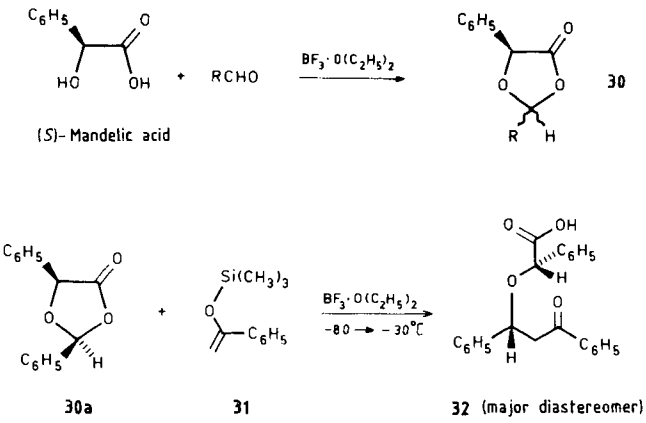


28 **29**

a, $R = CH_3$; b, $R = COCH_3$

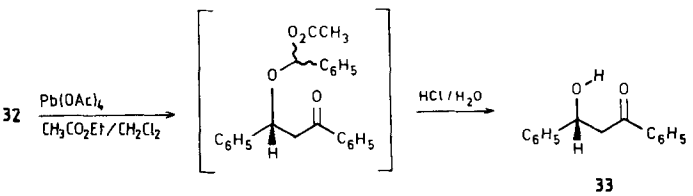
ing group can be subsequently removed with ease. This is not the case for **29a** and other methyl ethers. However, this method has yet to be applied successfully to the bridged chiral systems due to complications arising from the aforementioned problems of the regioselectivity of the addition.

One aspect may nevertheless be briefly mentioned. The ease with which the diacetoxy derivatives of benzaldehyde **28b** react with **26** led us to investigate the chemistry of compounds of the type **30**, prepared by condensation of the appropriate mandelic acid ((*S*)-enantiomer illustrated) with an aldehyde (or ketone) in the presence of $BF_3 \cdot O(C_2H_5)_2$[39]. For conformational reasons, the *cis*-isomers of **30** are the most stable[40] and can usually be isolated quite easily. Under the conditions developed by *Mukaiyama* et al.[38a], **30a** condenses with **31** in 98% yield to form a 93.5:6.5 mixture of diastereomers **32**. In other



(*S*)-Mandelic acid **30** **30a** **31** **32** (major diastereomer)

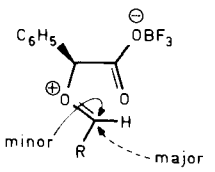
words, the more reactive carboxy group functions selectively as the leaving group under the reaction conditions. The major diastereomer of **32** is readily isolated pure by flash chromatography. The mandelate functionality is then removed by oxidative decarboxylation and hydrolysis to produce optically pure **33**[41].



33

This approach has been used with the trimethylsilyl enol ether of isobutyraldehyde and trimethylallylsilane as well

as the 1,3-dioxolan-4-ones **30** of 2-furaldehyde, acetophenone, propionaldehyde, and isobutyraldehyde. Good diastereomeric excesses are obtained, and, since both enantiomers of mandelic acid are commercially available, either enantiomer of the desired product is obtainable. The ste-



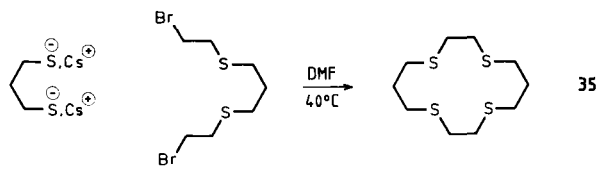
34

reochemistries of the major diastereomers formed on condensation can all be accounted for by assuming that **34** is a common intermediate which is attacked preferentially *trans* to the phenyl group of the mandelic acid. If this is the case, the initial stereochemistry of **30** should not be reflected in the condensation product. This is essentially what is found experimentally (and indeed *cis,trans*-isomers equilibrate under the experimental conditions). This has the consequence that the *cis,trans*-mixture of **30** formed initially can be used without prior separation[42].

5. Macrocycles as Chiral Ligands for Transition Metal-Catalyzed Reactions

One problem which has concerned us greatly is the "turnover" number with macrocycles. In other words, how does one prepare a macrocycle that regenerates itself after each reaction cycle? The answer, clearly, depends on the reaction[43]. The problem does not arise if the reaction concerned is intrinsically catalytic. Such a situation is encountered in the synthetically enormously interesting area of transition-metal catalyzed CC bond forming reactions[44].

We became interested in reactions of this type as the result of our finding that using the cesium salt method described in Section 2 we could also prepare macrocyclic sulfides[45]. The value of the method is illustrated by the fact that the yield of **35**, of interest as a ligand for copper ions, is only 7.5% following the approach in Scheme 9, but with $K^{\oplus}$ as counterion (in ethanol)[46]; however, **35** is produced routinely in 75—80% yield using $Cs^{\oplus}$[45,47].

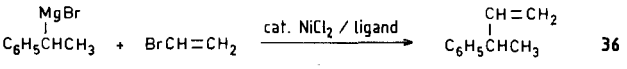


35

Scheme 9.

Cesium salts have also been used with success by several other groups for the synthesis of various macrocycles[48]; moreover, solutions of cesium salts in dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) seem, in general, to have high nucleophilicities, which fact has been used to introduce oxygen[49] or sulfur[50] functionalities with clean inversion of configuration at centers prone to racemization or elimination. The various applications of cesium salts have recently been reviewed by *Vögtle* et al.[51,52].

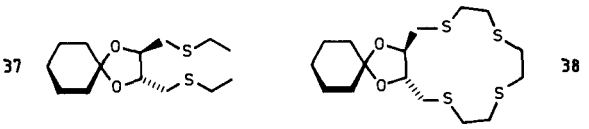
Sulfides have a firmly established reputation as poisons for various transition metal-catalysts. We judged it wise to first check whether simple macrocyclic ligands containing sulfur are compatible with a reaction involving transition metal-catalyzed bond formation. As model reaction, we selected the synthesis of 3-phenyl-1-butene **36**, which has been studied in great detail by *Consiglio* et al.[53] and *Kumada* et al.[54].



36

The nickel dichloride is solubilized with the aid of a ligand such as 1,2-di(diphenylphosphino)ethane. The catalytic cycle is believed to involve a Ni^0 intermediate which undergoes oxidative addition of vinyl bromide; ligand exchange with the Grignard reagent, followed by reductive elimination provides the coupling product **36**. Although its synthetic scope is still limited, this reaction is well suited for examining effects caused by changing the structure of the solubilizing ligands. With chiral phosphanes as ligands, enantiomeric excesses of up to 83% have been attained in this reaction[54b].

We were encouraged to find that racemic **36** was produced nearly quantitatively with 0.5% $NiCl_2$ and an equivalent amount of achiral **35**. This clearly indicates that the sulfide **35** does not poison the coupling reaction, but rather functions as an efficient ligand. Chiral sulfides **37** and **38** are readily available from (*S,S*)-tartaric acid. The macrocycle is synthesized with the aid of the cesium salt method. The coupling reaction proceeds rather sluggishly in the presence of **37** to provide virtually racemic **36** in 53% yield. On the other hand, cyclic **38** is an efficient li-



37 **38**

gand which in the presence of a catalytic amount of $NiCl_2$ smoothly induces formation of **36** in quantitative yield and a modest enantiomeric excess of 17%[55]. Recently, a series of macrocyclic sulfides made chiral by the inclusion of amino acids have been prepared and used in the synthesis of **36**; enantiomeric excesses of around 50% have been obtained with these ligands, whose design is steadily improving and which are currently being applied to other enantioselective CC bond forming reactions[56].

6. Perspectives

In this article, I have described organic and organometallic chemistry in which macrocycles play a central role. Such macrocycles can be prepared on a routine basis in

gram quantities with the investment of a few days work. This does not make them commonly used reagents, but it does mean that it is now feasible to perform chemistry with them; not so long ago their difficult syntheses condemned most macrocycles to the realm of chemical curiosities. Nevertheless, it is advantageous to work catalytically for the pragmatic reason of reaping a greater return for the synthetic effort invested. Hence, our interest in transition metal-catalyzed reactions.

The macrocycles described here are certainly not enzymes, but sometimes they carry out functions reminiscent of enzymes—enantioselective reductions and catalytic formation of CC bonds are good examples—but under abiotic conditions. This is an advantage, since the full power of chemical synthesis can be brought to bear without having to deal either with the limitations of water as a solvent or the usual restrictions of temperature.

Perhaps in the long run the use of macrocycles will not prove to be the best alternative to enzymes. On the one hand, they present the opportunity of introducing functional groups according to a pre-designed plan; on the other hand, some of the best systems so far found, for example, catalytic asymmetric synthesis, depend to a great extent on self organization of the reactants. One might mention the Sharpless[57] method for epoxidation of allylic alcohols, alkaloid-catalyzed Michael additions as studied by *Hiemstra* and *Wynberg*[58], enolate alkylations[58], and rhodium-catalyzed hydrogenations of α,β-unsaturated amino acids as developed by *Knowles* et al.[60] inter alia[61]. Moreover, the ability of molecules to orient themselves spontaneously is rarely illustrated so clearly as by micelles and vesicles; some of the aspects of this type of chemistry have recently been discussed by *Fendler*[62].

I think that the task of preparing an "artificial enzyme", i.e. a synthetic molecule that replaces the function of a natural enzyme in all respects, is well-nigh impossible (and not even especially desirable) using the approaches described here. The peptide structure plays too great a role in enzymes. It is certainly difficult to envisage how one could mimic, for example, the effects of the local dipole formed by the α-helix extending from the active site in a thiol protease such as papain[63], short of synthesizing the peptide section and attaching it with the proper orientation to the synthetic enzyme. This structural aspect has virtually inimitable consequences for the active site. On the other hand, the totally different approach to the rational design and synthesis of peptides discussed by *Kaiser* and *Kézdy*[64], should allow one, at least in principle, to reconstruct (a better word than "mimic", here) such special structural features.

Chemists are learning how to design molecules to carry out particular tasks for them. As knowledge about biological structures increases, the combination of this architectural insight with the not inconsiderable powers of mechanism and synthesis developed in the last decades will open roads to new understanding. The problem, as always, will be the proper application of the information gained.

A considerable part of this review is based on sections of the doctoral theses of J. G. de Vries (1979), C. B. Troostwijk (1981), B. J. van Keulen (1984), and A. G. Talma (1984). The very special contributions over the years by J. Buter, W. H. Kruizinga, S. H. Mashraqui, M. Lemaire, P. Jouin, B. K. Vriesema, and T. J. van Bergen must also be mentioned. I have been priviliged to have these and other talented coworkers mentioned in the references. Present-day chemistry is a question of cooperation among many people; my thanks indeed to all those, who with so much good will, dedication, and enthusiasm, have made this cooperation a reality.

[17] $Mg(ClO_4)_2$ is a powerful abiotic electrophilic catalyst. In alcohol dehydrogenase, however, the catalytic metal ion is tetrahedrally coordinated $Zn^{2\oplus}$ ligated to the two cysteine moieties and a histidine. The fourth coordination site is occupied by water or alcohol, which acts as hydride donor for $NAD^{\oplus}$: a) H. Eklund, B. Nordström, F. Zeppezauer, G. Söderlund, I. Ohlsson, T. Boine, C. I. Brändén, *FEBS Lett. 44* (1974) 200; b) H. Eklund, B. Nordström, E. Zeppezauer, G. Söderlund, I. Ohlsson, T. Boine, B. O. Söderberg, O. Tapia, C. J. Brändén, *J. Mol. Biol. 102* (1976) 27; c) H. Eklund, C. I. Brändén, J. Jörnvall, *J. Mol. Biol. 102* (1976) 61. We are currently attempting to prepare a $Zn^{2\oplus}$ complex with this arrangement of ligands in order to investigate its possible catalytic activity.

[19] *Ohno* et al. [16] have obtained excellent enantiomeric excesses using 1,4-dihydronicotinamides provided with a single amino acid-containing side arm but methylated at the 2,4-positions of the dihydropyridine ring. This latter factor appears to lead to loss of rotational mobility about the carboxamide-ring bond with resulting conformational restriction of the compound, see: a) P. M. van Lier, G. H. W. M. Meulendijks, H. M. Buck, *Recl. Trav. Chim. Pays-Bas 102* (1983) 337; b) H. J. G. van Hooff, P. M. van Lier, L. A. M. Bastiaansen, H. M. Buck, *Recl. Trav. Chim.*

[21] There has been considerable controversy about the proper orientation of the carbonyl group relative to the 1,4-dihydropyridine ring. The longest standing model, suggested by *Prelog*, has the oxygen atom of the carbonyl group pointing towards the pyridinium nitrogen: a) V. Prelog, *Pure Appl. Chem. 9* (1964) 119; b) J. B. Jones in J. B. Jones, C. J. Sih, D. Perlman: *Applications of Biochemical Systems in Organic Chemistry, Part 1* (A. Weissberger: *Techniques in Chemistry, Vol. X*), Wiley, New York 1976, pp. 107—401. The model suggested here has the carbonyl group turned virtually perpendicular to the 1,4-dihydropyridine ring. The apparent lack of agreement with regard to the optimal orientation may possibly be resolved by the observation from ab initio calculations that a linear transition state for hydride transfer from 1,4-dihydropyridine to the carbonyl carbonyl is required, but that there is *no* rotational barrier for rotation of the two reactants relative to each other: S. M. van der Kerk, W. van Gerresheim, J. W. Verhoeven, *Recl. Trav. Chim. Pays-Bas 103* (1984) 143; see also M. F. Powell, T. C. Bruice, *J. Am. Chem. Soc. 105* (1983) 7139.

[22] This assumption is, on the whole, good for kinetic addition of nucleophiles derived from weak acids such as dithionite (which leads to the 1,4-dihydro compounds), thiols, and HCN. It appears, however, to be less trustworthy for nucleophiles derived from poorer acids such as simple ketones (with enolates as nucleophiles), etc.

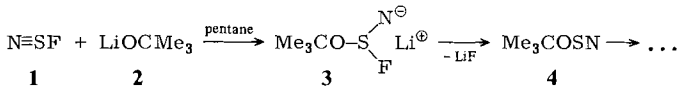
Conversion of "LiNS(F)OCMe$_3$" into an (Li$_8$)$_2$ Double Cluster**

By *Wilhelm Isenberg, Rüdiger Mews**, and *George M. Sheldrick*

Nucleophilic substitutions at thiazyl fluoride **1**[1] should open up access to thiazyl derivatives R–S≡N. Members of this class of compounds are, however, only stable in a few cases; in many instances, complex secondary reactions are observed[2]. Addition of the nucleophile **2** to **1** is expected



1 **2** **3** **4**

to be the initial step in a substitution of this type; cleavage of LiF and additional reactions follow whose products have not yet been identified. Alternatively, **3** is converted into the more stable mixed salt of composition **5**[3]:

$\{Li_8[Me_3COS(N)F]_4F_2\}[Li_4(OCMe_3)_5]_2 \cdot 4C_5H_{12}$ **5**

When less than the stoichiometric amount of **1** is used, LiF is only partially eliminated and some **3** is obtained. In the formation of **5**, four moieties of **3** combine with four additional $Li^{\oplus}$ to give two "$Li_4(N/F)_4$ eight-membered rings" linked by four Me_3CO–S bridges; an $F^{\ominus}$ ion is located over the midpoints of the respective rings (Fig. 1)[5]. F and N atoms are distributed statistically over the puckered, eight-membered rings. Formally, a section of this type has the charge +2 and is neutralized by two $[Li_4(OCMe_3)_5]^{\ominus}$ fragments which enclose the central eight-membered rings. It cannot be stated whether the $[Li_4(OCMe_3)_5]^{\ominus}$ moiety is a section from the structure of the educt $LiOCMe_3$, since its structure is unknown[4].

In reactions of organolithium compounds and lithium amides in which lithium halides are formed, self-inhibition frequently arises[6,7] due to formation of complexes between the educts and lithium halides. Intermediates can also be stabilized by formation of "mixed compounds" such as **5** (mixed salts of lithium and fluoride, alkoxide, and imide).

5 is of considerable interest not only for NSF chemistry, but also for the chemistry of Li. Previously, numerous lithium clusters have been described which consist of Li_nR_n moieties with n = 4[7–13], 5[14], and 6[15–17] (R = organo[7,8,11,13,16], O-[12], N-[9,10,14,15], Si-residues[17], as well as halogen[7,9,11]). From this point of view, **5** can be considered as arising from the linkage of two $Li_8(OCMe_3)_5F$ clusters (Fig. 1) by four anions of **3**, which act as bridges. The eight lithium atoms form a tetragonal antiprism; the distances of the inner Li′ atoms, which are bridged by F or N, are 264–270, those of the outer, O-bridged Li″ atoms are 233–243, and the distances Li′–Li″ are between 275 and 280 pm. Bond lengths of a similar order of magnitude are found also in smaller clusters. The triangular faces of the antiprism are bridged by four Me_3CO groups (O–Li″ 188.3, O–Li′ 190.1 pm), and the outer quadrangular face is capped by an additional moiety of this type (O–Li″ 199.1 pm). The fluorine ligand which bridges the inner quadrangular face lies within the antiprism and, hence, F interacts with all the lithium atoms (Li′–F 198.5, Li″–F 246.4 pm); in this way it probably contributes towards the stabilization of the cluster (Fig. 1).

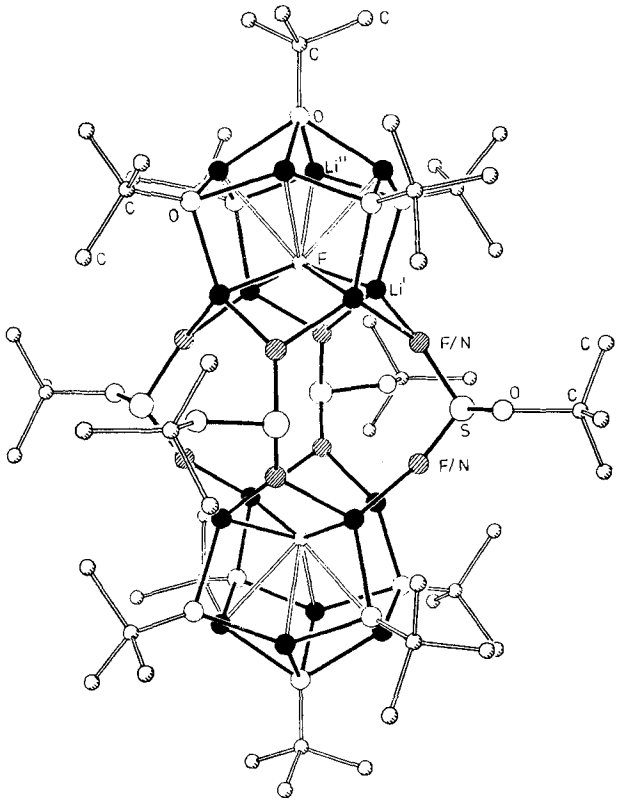


Fig. 1. Structure of **5** in the crystal (without hydrogen atoms, solvent, and second orientations of disordered *tert*-butyl groups).

[3] 1 (10.9 mmol) in a stream of dry N_2 is passed into a stirred solution of $LiOCMe_3$ (30.5 mmol) in 40 mL *n*-pentane at −60 °C. The coolant is removed and the mixture gently warmed up to room temperature and stirred for 12 h. The solvent is then carefully removed, resulting in formation of a yellow, glass-like solid, which is taken up in *n*-pentane and cooled to −35 °C. The solvent is slowly removed at this temperature. Crystals of **5**, which can be separated manually, are included in the residual solid. **5** decomposes immediately at room temperature in vacuo, but under N_2 is stable for a few hours. If they are imbedded into KelF wax, the crystals can be stored for several weeks.

Asymmetric Microsomal Epoxidation of Simple Prochiral Olefins**

By *Volker Schurig** and *Dorothee Wistuba*

As highly selective catalysts, enzymes can distinguish not only between enantiotopic groups and faces of prochiral molecules *(product enantioselectivity)* but also between the enantiomers of racemic mixtures *(substrate enantioselectivity)*[1].

In the metabolism of xenobiotics having aromatic or olefinic double bonds in the endoplasmic reticulum of liver cells, reactive oxiranes (epoxides) are formed enantioselectively. Thus, cytochrome P-450 dependent monooxygenases epoxidize aromatic polycyclic hydrocarbons with high enantioselectivity[2]. The asymmetric epoxidation of prochiral olefins (styrene, 1-octene) is also known[3]. The reactive oxiranes formed often exhibit a high mutagenic and carcinogenic potential which frequently depends on the enantiomer composition and the absolute configuration[4]. Until now, the methods used to determine the enantiomeric purity in studies of enantioselective epoxidations have been time consuming and imprecise[5].

We have found that in microsomal epoxidations monooxygenases can differentiate between the enantiotopic faces of the double bond of small, aliphatic, nonfunctionalized, prochiral olefins **1**; the extent of product enantioselectivity is found to depend critically on the structure of the olefin. In order to determine rapidly and precisely the enantiomeric excess and absolute configuration of the oxiranes **2** formed, complexation gas chromatography was used[6]. By means of this method, even highly volatile oxiranes which are difficult to isolate can be analyzed reliably on the nanogram scale by head-space analysis of incubation mixtures without recourse to derivatization procedures. In this way, the enantioselective conversion can be monitored continuously without requiring to interrupt the reaction; this is a prerequisite for distinguishing between product and substrate selectivity.

We studied the product enantioselectivity of the enzyme-catalyzed aerobic epoxidation of prochiral olefins **1** to oxiranes **2** by liver microsomes of male, phenobarbital-induced Wistar rats. The results are summarized in Table 1[7]. Figure 1 shows a representative complexation gas chromatogram.

Table 1. Microsomal enantioselective epoxidation of simple olefins [7]. The formula refers to the enantiomers of (2*R*)-configuration (**2e**: (3*R*)-configuration.

	R^1	R^2	R^3	R^4	Enantiomer ratio [a]	*e.e.* [%] [b]
a	H	H	Me	H	30 (*R*) : 70 (*S*)	40 ± 1.4 [c]
b	H	H	Et	H	30 (*R*) : 70 (*S*)	40 ± 1.0
c	H	H	$HC=CH_2$	H	30 (*R*) : 70 (*S*)	40 ± 1.4
d	H	Me	Me	H	43 (2*R*,3*R*) : 57 (2*S*,3*S*)	14 ± 1.0
e	H	Me	Me	Me	0 : 0	0
f	H	H	Et	Me	39 (*R*) : 61 (*S*)	22 ± 4.0
g	H	Me	Et	H	48 (2*R*,3*R*) : 52 (2*S*,3*S*)	4 ± 1.2
h	Me	H	Et	H	48 (2*R*,3*S*) : 52 (2*S*,3*R*)	4 ± 1.1

[a] Absolute configurations were determined by coinjecting oxiranes of known chirality (K. Hintzer, dissertation, Universität Tübingen 1983). The absolute configuration of vinyloxirane **2c** was assigned using the "quadrant rule" [6]. [b] The error limits refer to the reproducibility of a minimum of seven incubations with one microsome preparation. [c] When racemic methyloxirane **2a** was incubated with 2-(trichloromethyl)oxirane-inhibited microsomes the *e.e.* did not change by 0 ± 1% in the gas phase. This therefore ensures that the *e.e.* values determined by complexation gas chromatography are not altered by enantioselective associations in the incubation medium (e.g. by chiral cell membranes).

The highest enantioselectivity of the cytochrome P-450 dependent monooxygenases was observed in the epoxidation of olefins with terminal double bonds (**1a**, **b**, **c**, **f**). Neither extension of the length of the carbon chain nor alteration of its degree of hybridization has an effect on the enantiomeric composition. In contrast, the enantioselectivity of the enzyme system is markedly influenced by the degree of substitution of the olefinic double bond. Thus, the enantiomeric excess decreases noticeably along the series methyloxirane **2a** > *trans*-2,3-dimethyloxirane **2d** > trimethyloxirane **2e** (= zero). The (*S*)-enantiomer is always formed preferably. The molecular geometry of the olefin **1** also influences the enantioselective behavior of monooxygenases. Comparison of the microsomal epoxidation of isomeric pentenes indicates that the enantiomeric excess is higher for the 2,2-disubstituted oxirane **2f** than for the *cis*/*trans*-2,3-disubstituted isomers **2h** and **2g**. These *cis*/*trans*-oxiranes exhibit only a slight (equal) enantiomeric excess.

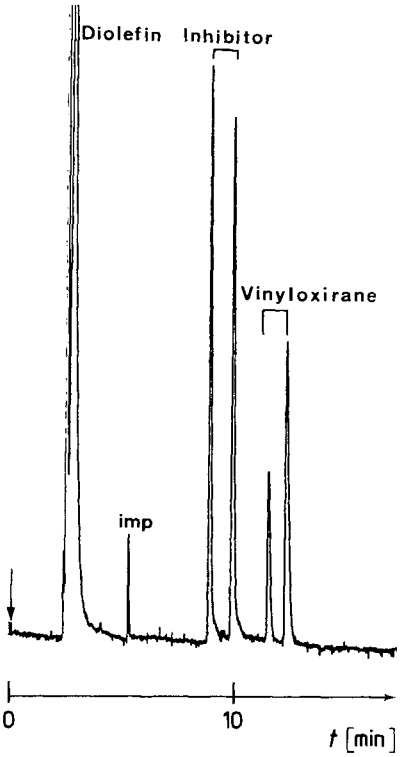

Fig. 1. Detection of the enantioselective microsomal epoxidation of 1,3-butadiene (="diolefin") **1c** to vinyloxirane **2e**. First enantiomeric pair: 2-(trichloromethyl)oxirane (inhibitor). Second enantiomeric pair: vinyloxirane (*e.e.*: 40% (*S*)). Column: 40 m × 0.25 mm deactivated glass capillary coated with 0.125 *m* nickel bis(3-heptafluorobutyryl-(1*R*)-camphorate) [6] in OV 101. 70°C, 2 bar N_2. imp. = impurity.

The oxiranes **2** occur in "steady-state" concentrations since they are hydrolyzed to diols by the epoxide hydrolase present in the microsomal fraction. The continuous determination of the enantiomeric composition of the oxiranes indicates that this secondary reaction also proceeds asymmetrically ("kinetic resolution"). In **2a**—**h** the (*S*)-enantiomer reacts more rapidly than the (*R*)-enantiomer[8]. Informative data with respect to the product enantioselectivity of the oxirane can therefore be obtained only by effective inhibition of the epoxide hydrolase[9]. For this purpose, 2-(trichloromethyl)oxirane has been used as an inhibitor. In the complexation gas chromatogram, the enantiomers of the inhibitor are eluted before the oxiranes **2a**—**h** (cf. also Fig. 1). If the enantiomer composition of the oxiranes formed is determined by complexation gas chromatography as a function of the incubation time, a constant value is found (enantioselective formation reaction) provided the inhibitor is present in excess; thereafter, hydrolysis (enantioselective reaction) of the oxiranes commences. These results underline the necessity of continuously monitoring both the enantiomeric excess and the concentration of the oxirane during incubation. The method of complexation gas chromatography used here for the first time has therefore proved to be a reliable probe for the investigation of asymmetric enzymatic reactions.

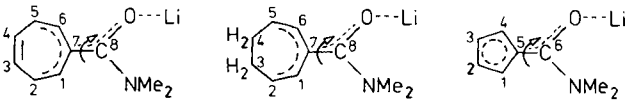
Easy Rotation about the Exocyclic Carbon-Carbon Bond in Lithium α-Aminoenolates: A Comparison**

By *Gernot Boche**, *Ferdinand Bosold*, and *Robert Eiben*

In the α-aminoenolates ("amide enolates") **1**, **2**, and **3** we found for the first time an easy rotation about the exocyclic CC double bond[1] in a compound of this sort.



1 **2** **3**

The 100-MHz ^{1}H-NMR spectra of lithium dimethylamino(cycloheptatrienylidene) methoxide **1** are temperature-dependent[2]. At 39°C, the signals of H^1 and H^6 ($\delta = 5.17$ and 4.93; an assignment was not made) are noticeably separated, whereas at 70°C they coalesce due to rapid rotation about the C^7C^8 bond, and at 83°C split into a doublet.

A free activation enthalpy of $\Delta G^+(70°C) = 17.5 \pm 0.5$ kcal/mol is calculated for the barrier to rotation in **1**. The barrier for rotation about C^7C^8 in the dihydro analogue **2** was determined in a similar way (ΔG^+ (25°C) 14.0 ± 0.5 kcal/mol). The rotation about C^5C^6 in **3**, on the other hand, could not be frozen-in even at −106°C, i.e. $\Delta G^+(-106°C) < 8$ kcal/mol[3,4].

In **2**, the negative charge is stabilized in the cross-conjugated pentadienide moiety, in **3**, in the cyclopentadienide moiety. The energetic advantage of the cyclic 6π-delocalization ("aromaticity") in **3** explains the low barrier to ro-

[*] Prof. Dr. G. Boche, F. Bosold, Dipl.-Chem. R. Eiben
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

tation in **3** ($\Delta\Delta G^{+} > 6$ kcal/mol). 8π-"Antiaromaticity" in the cycloheptatrienide ion, on the other hand, cannot be of much significance *energetically*, since the difference in barriers for **1** and **2** is only 3.5 kcal/mol. According to the X-ray structure analysis, **1**·2THF has a "pentadienide ion" structure (long C^2C^3 and C^4C^5 bonds and a short C^3C^4 bond)[4]. Likewise, MO calculations on diverse cycloheptatrienyl anions lead to similar structures[5], which is in accordance with the small $\Delta\Delta G^{+}$ value for **1** and **2**. At the same time, cycloheptatrienide ion derivatives show paratropic shifts of the signals in the ^{1}H-NMR spectrum[2b,6].

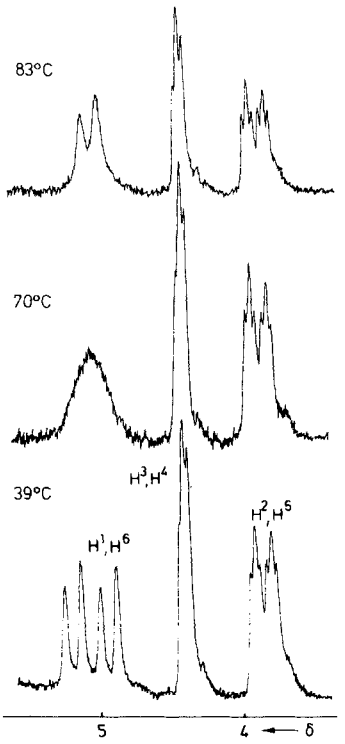


Fig. 1. ^{1}H-NMR spectra (100 MHz) of **1** in [D_8]tetrahydrofuran (THF) at 83, 70, and 39°C.

Iterative Cyclopentane Annulation of α,β-Enones**

By *Maria Dorsch, Volker Jäger**, and *Wolfgang Spönlein*

There is currently extensive interest in the synthesis of polycyclopentanoids[1], primarily because this structural moiety is present in a variety of biologically active natural products and theoretically interesting molecules. However, efficient protocol for *iterative* cyclopentane annulation is rare[1,2]. The following communication reports a four-step sequence of this kind, to convert substituted α,β-unsaturated carbonyl compounds into ring-homologous cyclopentenones. To-date, this has enabled the synthesis of several mono- and bicyclic enones, as well as a tricyclic derivative.

A 
The new annulation sequence is summarized by formula **A**. The key steps (see Scheme 1) are:

(1) Preparation of an allylic alcohol from an α,β-enone by $LiAlH_4$ reduction or Grignard addition;
(2) Claisen rearrangement of the allylic alcohol involving *Johnson*'s orthoester[3a,b] or *Ireland*'s ketene acetal modification[3b–d], followed by hydrolysis to 4-alkenoic acids[3e];
(3) Polyphosphoric acid (PPA)-induced cyclodehydration[1,4] to cyclopentenones, with appropriate C=C migration.

Some of the results are given in Table 1. The synthesis of the bicyclic enone **7c**[5a] (an intermediate in a synthesis of isocomene by *Paquette* et al.[1a]) serves as an example to illustrate both the principle and the details of this sequence: Reaction of methacrolein **1c** with ethylmagnesium bromide afforded 2-methyl-1-penten-3-ol **2c** in 88% yield, which with triethyl orthoacetate, at ca. 140°C, was transformed into the 4-methyl-4-heptenoate and subsequently hydrolyzed to **3c**. Heating **3c** in PPA led to the 2,3-dialkylcyclopentenone **4c**, which was isolated in 96% yield (GC purity: 97%). The allylic alcohol required for the second cycle was obtained cleanly and quantitatively by $LiAlH_4$ reduction.

	R^1	R^2	R^3	Yield [%] 1→4	4→7
a	H	H	H	24	4
b	CH_3	H	H	49	25
c	CH_3	CH_3	H	69	45
d	CH_3	*n*Bu	H	75	69
e	CH_3	*n*Bu	CH_3	67	— [a]

[a] Not investigated.

However, the reaction of cyclopentenols with orthoacetate either did not proceed as desired, or gave unsatisfactory yields, as checked with **5a**, **5b**, and **5d**. To overcome this difficulty, **5c** was acetylated (94%) and rearranged via the ketene acetal (formed by lithium cyclohexylisopropylamide (LICA)/*tert*-butyldimethylchlorosilane[3d]) to yield the cyclopentenylacetic acid **6c** (59%) containing *one quaternary center*. PPA cyclization proceeded smoothly and gave the bicyclo[3.3.0]octenone **7c** (82%). As anticipated, the *endo* double bond of **6c** first had been shifted into the *exo* position; the resulting isomer then had selectively been trapped from the mixture by acylium ion attack.

How many times can one repeat this sequence? In order to demonstrate the utility of this iterative process for a *third* cycle, **7d** was reduced by $LiAlH_4$ to the bicyclooctenol **8d**, with high stereoselectivity and in quantitative yield. However, contrary to expectation (Dreiding models) this turned out to be the *endo* alcohol (NOE difference measurements), unsuitable for the Claisen rearrangement to follow[5b].

Obtaining the wrong stereoisomer (*endo*) was of no serious consequence, since it was readily converted into the desired *exo* acetate via the azodicarboxylate method (*Mitsunobu*)[6] in 82% yield (ca. 80% purity according to ^{1}H- and ^{13}C-NMR). The *exo* acetate, obtained as above, was lithiated and silylated to afford the ketene acetal[3d], which after isolation was subjected to the rearrangement and gave the carboxylic acid **9d** containing *two vicinal quaternary centers* in 42% yield[3f]. Reaction of the latter with PPA, followed by MPLC purification of the crude product, furnished the tricycle **10d** in 60% yield, with an overall yield of 21% for the third cycle.

The additional entries in Table 1 demonstrate the potential of this synthetic scheme. For example, dihydrojasmone **4d**[4a,c] and the unnatural methyldihydrojasmone **4e** are now easily accessible on a 10g-scale. With less substituted substrates, the PPA cyclization proved to be unsatisfactory; e.g., 2-methylcyclopentenone was obtained in 32% yield from **3a**[4b]. The crucial step in the annulations is the Claisen-Ireland rearrangement which introduces the acetic acid side chain. The remaining steps all proceed in good to very good yield. Numerous applications of this methodology are conceivable, specifically when taking advantage of the PPA-induced C=C isomerization/cyclodehydration step.

Red α-Indium(III) Iodide**

By *Rüdiger Kniep** and *Peter Blees*

InI_3 is generally prepared from the elements, with subsequent purification by sublimation, and is obtained as yellow crystals. This yellow form of InI_3, namely β-InI_3, con-

tains isolated In_2I_6 units each consisting of two $InI_2I_{2/2}$ tetrahedra linked via a common edge[1,2]. Prolonged storage at or below room temperature can lead—irreproducibly—to the transformation of individual domains of the yellow β-phase into a red α-phase; a concomitant change in the crystal structure has already been demonstrated by X-ray powder and Raman investigations[3,4]. A sample of the α-phase suitable enough for single crystal investigations cannot be obtained via this solid-solid transformation.

According to our differential thermoanalytical investigations, α-InI_3 transforms endothermically into the β-phase at +57 °C on heating ($\Delta H = 6.70$ kJ/mol). The transformation β→α is apparently kinetically inhibited; at +5 °C, however, β-InI_3 could be converted quantitatively into the α-phase within ca. three weeks.

Figure 1 shows the phase diagram of InI_3–$InBr_3$. Starting from InI_3, the InI_3–$InBr_3$ system has an extensive mixed-crystal phase, α-$InI_{3-x}Br_x$, adjacent to a two-phase domain between 184 and 194 °C in which α-mixed crystals ($x \cong 1$) are in equilibrium with an InI_3-rich melt. In this region it is possible to cultivate mixed crystals of the α-phase from the melt by cooling, albeit only in small yields. Information about the structures of the additional intermediary γ-, δ-, and ε-phases occurring at higher temperatures and increasing $InBr_3$ contents are not available[5]; $InBr_3$ crystallizes in the high-temperature $CrCl_3(YCl_3)$-type structure[6] with almost cubic close packing of the anions[7].

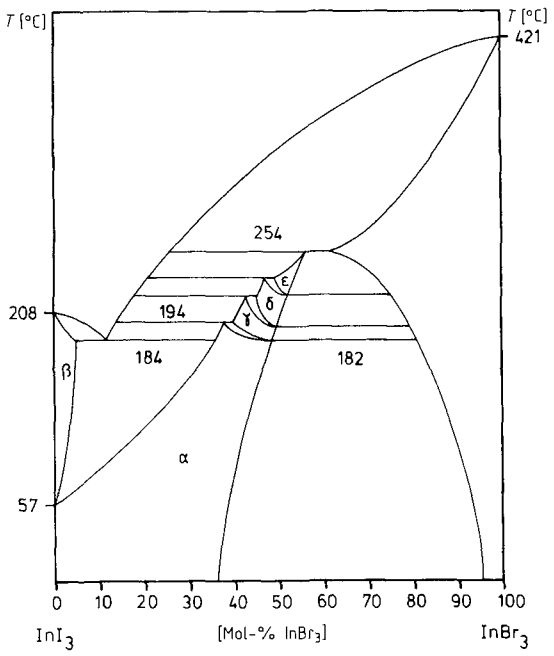

Fig. 1. Phase relationships at the quasi-binary section InI_3–$InBr_3$.

According to a crystal structure analysis[8] on a tabular pseudohexagonal single crystal of α-$InI_{3-x}Br_x$ ($x = 1$), the phase crystallizes in the low-temperature $CrCl_3$-type structure[9] with almost hexagonal close packing of the halogen atoms and ordered 2/3 occupation of the octahedral holes of every second octahedral layer by indium. The structural model was refined to convergence in the space groups R3 ($R = 0.046$) and $R\bar{3}$ ($R = 0.050$); according to the Hamilton significance test[10] the space group R3 is preferred with a probability of >99.5%. The temperature factors of the halogen positions also indicate negligible anisotropy by hexagonal treatment. For the "mixed atom" $I_{2/3}Br_{1/3}$, the atomic scattering factor of iodine[10] was applied with release of the occupation factor. Split positions, which would have taken into account the differences in the bond lengths In–I and In–Br, could not be consistently refined.

The lattice constants of α-InI_3 were ascertained by indexing the Guinier diagram ($a_{rh} = 8.011(5)$ Å, $\alpha = 53.64(4)°$; $a_{hex} = 7.229(1)$, $c_{hex} = 20.514(7)$ Å); α-InI_3 proves to have a substantially higher density (5.32 g/cm³) than β-InI_3 (4.70 g/cm³)[2].

Further examples of dimorphic aluminum, gallium, and indium trihalides have so far not been reported in the literature. However, in the framework of our current studies we recently found indications of $AlBr_3$ also being dimorphic: besides the known white modification (hexagonal close packing of the anions; isolated Al_2Br_6 units[11]) there exists a red modification, which crystallizes in flat hexagonal prisms.

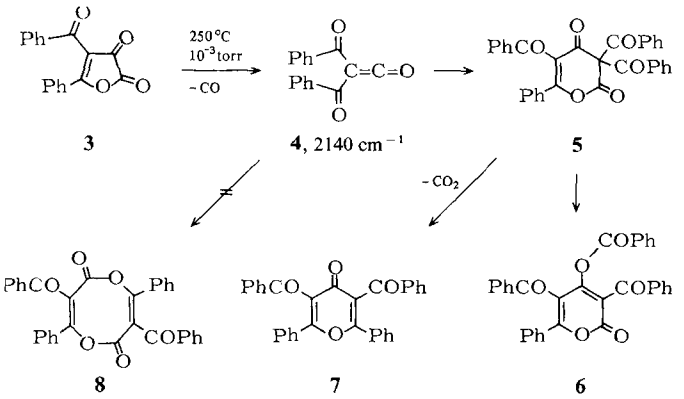
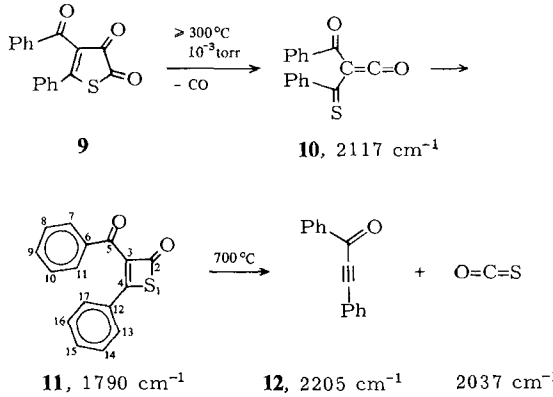
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

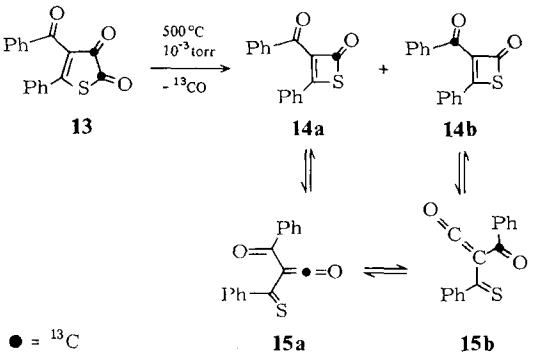
We have studied this problem using gas-phase pyrolysis of the furandione **3** and the thiophenedione **9** in conjunction with low-temperature spectroscopy. Pyrolysis of **3** at 250°C/10^{-3} torr resulted in CO extrusion and formation of the dibenzoylketene **4**, identified by a very strong absorption at 2140 cm^{-1} in its IR spectrum (−196°C) which disappeared on warming above −75°C. Attempts to obtain **4** on a preparative scale resulted in the isolation of a dimer **6** together with the γ-pyrone **7**. The formation of a dimer as well as **7** on decomposition of **3** in solution at 130°C has already been observed by *Ziegler* et al.[2], who assigned the structure **8** to the dimer. Since this would correspond to an unusual, if not impossible, [4+4]-cyclodimerization of dibenzoylketene **4**, the true nature of the dimer was established by X-ray crystallography and found to be **6**[3]. The formation of **6** is now readily understood in terms of a [2+4]-cyclodimerization of **4**, giving initially **5** which, under the experimental conditions (≥120°C) undergoes a 1,3-benzoyl shift to give **6**. There is precedence for thermal 1,3-benzoyl shifts in other systems[4].



The corresponding thiophenedione **9** is thermally more stable than **3** and at 300°C/10^{-3} torr decomposes only slightly, resulting in the appearance of a new band at 1790 cm^{-1} in the IR spectrum. At 500°C/10^{-3} torr, decomposition was complete, and the main product detected by IR spectroscopy (−196°C) absorbs at 1790, 1630, and 1515 cm^{-1}. A further, weak absorption at 2117 cm^{-1} is assigned to the ketene **10**. The "1790 cm^{-1}" and "2117 cm^{-1}" species both disappeared on warming above −40 and −80°C, respectively. On pyrolysis at higher temperatures (600—700°C), both the "1790 cm^{-1}" and the "2117 cm^{-1}" species disappeared, and new bands were observed at 2205 and 2037 cm^{-1} which arise from benzoyl(phenyl)acetylene **12** and OCS, respectively, as verified by isolation of the compounds (IR, MS, and GC).



Although the neat "1790 cm^{-1}" species oligomerizes, it was possible to obtain ^1H- and ^{13}C-NMR spectra of solutions of this compound in $CDCl_3$ at −40°C[5]. The ^1H-NMR spectrum is consistent with the presence of a phenyl and a benzoyl group. The ^{13}C-NMR chemical shifts and long-range couplings allow complete assignment as the thietone **11**. This is the first monocyclic thietone to be observed in solution. On the basis of the NMR spectra, the compound is virtually pure when formed from **9** at 500°C. At this temperature the decomposition products **12** and OCS do not form, and the ketene **10**, observable by IR spectroscopy, disappears at −80°C, presumably by cyclization to **11**.



The ^{13}C-NMR data for **11** are supported by increment calculations and by comparison with the only other completely characterized thietone, naphtho[2,3-*b*]thiet-2-one[1]. Nevertheless, in order to substantiate the chemical shift of the thietone carbonyl group in **11** ($\delta = 166.4$[5]), the doubly ^{13}C-labeled starting material **13** was prepared from 1,3-diphenyl-3-thiono-1-propanone) and [1,2-$^{13}C_2$]oxalyl chloride (90 atom-% ^{13}C). Pyrolysis of **13** at 500°C and examination of the product by IR spectroscopy (−196°C), mass spectrometry[6], and ^{13}C-NMR spectroscopy (−40°C) established that: 1) ^{13}CO had been eliminated, 2) the thietone **14** was labeled with one ^{13}C atom (90 atom-%), 3) *half* of this label was located on C-2 (**14a**), and 4) the other half was located in the carbonyl group of the benzoyl substituent (**14b**). In order to explain this unusual and unexpected result, we postulate that the thietone **14** interconverts with the ketene **15** in the gas-phase, *and* that the ketenes **15a** and **15b** undergo rapid interconversion by way of a 1,3-shift of a phenyl group. We have obtained proof for this novel reaction in a different system[7].

In conclusion, the diacylketene **4** does not appear to cyclize to an oxetone (**2**, X=O), but instead dimerizes. In contrast, the acyl(thioacyl)ketene **10** is thermodynamically less stable than the thietone **11**, to which it smoothly cyclizes. Nevertheless, an equilibrium **1** ⇌ **2** (X=S) prevails in the gas phase.

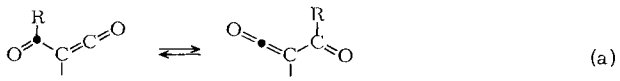
A Novel Ketoketene–Ketoketene Rearrangement**

By *Curt Wentrup** and *Klaus-Peter Netsch*

In the previous communication[1] we reported experiments which led us to believe that acylketenes can undergo carbon scrambling via thermal 1,3-shift of a phenyl group [Eq. (a), R = Ph].



(a)

Since ketenes are important intermediates in numerous reactions, and many labeling studies have been carried out on the Wolff rearrangement[2], of which ketenes are the products, it is clearly of importance to determine whether the proposed ketoketene-ketoketene rearrangement [Eq. (a)] is realistic and general. We now wish to report a proof for this reaction using ^{13}C-labeled benzoylketene.

Treatment of [carbonyl-^{13}C]acetophenone **1**[3] (90 atom-%^{13}C) with methoxy(methoxycarbonyloxy)magnesium (MMC)[4] (dimethylformamide, 115°C, 1 h) gave [3-^{13}C]benzoylacetic acid **2** in 52% yield, which was converted into the methyl ester **3** (90%), the starting material for the study, by esterification with diazomethane (diethylether, 0°C). Compound **3** exists in solution as a mixture of the keto and enol forms **3** and **4**, respectively (^{1}H- and ^{13}C-NMR). Proof for the specific and complete (90 atom-%) incorporation of ^{13}C at C-3 in **3** is provided by observation of a ^{13}C-H coupling for the methylene group ($\delta = 4.0$) in the ^{1}H-NMR spectrum ($^2J_{^{13}C,H} = 6.2$ Hz). A central peak which originates from the CH_2 group of the unlabeled material had an integrated area ca. 10% of that of the total integral for the CH_2 group. Similarly, in the enol form **4** the signal for the vinylic H atom ($\delta = 5.66$) was split into a doublet ($^2J_{^{13}C,H} = 3.7$ Hz). In the ^{13}C-NMR spectrum the labeled carbonyl group in **3** appeared at $\delta = 192.2$, and a signal for the methylene group at $\delta = 45.5$ ($J_{^{13}C,^{13}C} = 40.5$ Hz). The enol C atom in **4** exhibited a signal at $\delta = 171.5$ ppm. In the IR spectrum of unlabeled **3**, two carbonyl bands appeared at 1685 (C=O) and 1740 cm^{-1} ($COOCH_3$). In ^{13}C-labeled **3** the former peak was shifted to 1650 cm^{-1}, whereas the latter remained unchanged[5].

Unlabeled benzoylketene **5** was generated by pyrolysis of unlabeled **3** (5 cm quartz tube, 700°C/10^{-4} torr). The pyrolysis product was isolated on a KBr disk at 82 K and the ketene identified by its intense, sharp absorption at 2133 cm^{-1} in the IR spectrum. This band disappeared on warming to 185 K due to reaction with the co-condensed methanol to re-form the starting material.

In the corresponding pyrolysis of labeled **3**, *two* ketene bands (intensity ratio ca. 55:45) appeared at 2133 and 2080 cm^{-1}, clearly showing that the ketene function now contained ca. 50% of the ^{13}C label[6]. Upon warming this ketene in the presence of methanol, the ester **7** was formed, in which *both* carbonyl groups were now labeled as seen, for example, by the appearance of *four* carbonyl bands in the IR spectrum (1650, 1685, 1710, and 1740 cm^{-1}) and *four* labeled C atoms in the ^{13}C-NMR spectrum (two from the keto, and two from the enol form of **7**)[7].

The thermal 1,3-shift of a phenyl group in a ketoketene has therefore been demonstrated (**5** ⇌ **6**). Furthermore, by pyrolyzing **3** at different temperatures, it was established that there is a significant activation energy for the phenyl group migration. At 400°C/10^{-4} torr *no* isotopic scrambling was observed: the ketene **5** ($\nu(CO) = 2133$ cm^{-1}) was the sole product. At 550°C ca. 50% rearrangement was observed, giving rise to two IR bands at 2133 and 2080 cm^{-1} in a ca. 2:1 ratio.

Although suprafacial thermal 1,3-shifts are "forbidden" by the rules of orbital symmetry[8], such shifts become possible in ketenes due to the presence of orthogonal orbitals. Further work is aimed at clarifying a dependence on the nature of the migrating group R in Eq. (a).

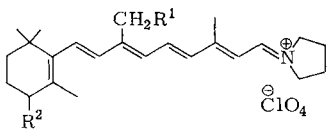
C=C Stretching Frequencies in Model Compounds of the Protonated Retinal Schiff Base**

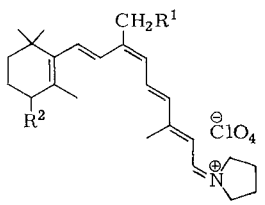
By *Timor Baasov* and *Mordechai Sheves**

Visual pigments and bacteriorhodopsin, the proton pump of the purple membrane of *Halobacterium halobium*, contain retinal chromophores (11-*cis* in the case of visual pigment and all-*trans* in bacteriorhodopsin) which is linked to a protein via a protonated Schiff base[1]. These pigments are transformed in a photochemical cycle into a number of intermediates possessing different absorption maxima. It is well established[2] that the absorption maxima of these species can be correlated with the C=C stretching frequencies observed in resonance Raman spectroscopy. Thus, a bathochromic shift of ca. 60 nm in λ_{max} is comparable to a shift of the C=C mode by ca. 20 cm^{-1} to lower frequency. It was first pointed out by *Rimai* et al.[3] that the position of the C=C stretching mode is a sensitive indication of charge delocalization. Thus, a decreased bond alternation results in a shift of the C=C bond stretching mode to higher frequency. According to a model proposed by *Nakanishi* and *Honig*[4], the shifts in λ_{max} of bovine rhodopsin and bacteriorhodopsin are regulated by through-space interaction of the chromophore with external negative charges.

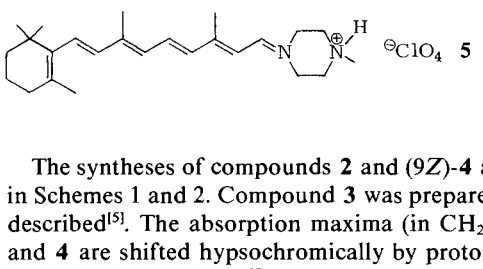
It is reasonable to assume that external charges influence the absorption of the photocycle intermediates. We therefore suggest that the changes observed in the C=C stretching frequency of visual pigments, bacteriorhodopsin, and the various photocycle intermediates may also originate from electrostatic interaction with non-conjugated charges introduced by the protein. To test this hypothesis, we have measured the C=C stretching frequencies of **2a**, **3a**, **4a**, and **5**, which bear positive charges at different positions of the retinal skeleton, by FT-IR spectroscopy.



1, $R^1 = R^2 = H$
2, $R^1 = (CH_3)_2N$, $R^2 = H$
2a, $R^1 = (CH_3)_2\overset{\oplus}{N}H$, $R^2 = H$
3, $R^1 = H$, $R^2 = (CH_3)_2N$
3a, $R^1 = H$, $R^2 = (CH_3)_2\overset{\oplus}{N}H$



4, $R^1 = R^2 = (CH_3)_2N$
4a, $R^1 = R^2 = (CH_3)_2\overset{\oplus}{N}H$



5

The syntheses of compounds **2** and (9*Z*)-**4** are described in Schemes 1 and 2. Compound **3** was prepared as recently described[5]. The absorption maxima (in CH_2Cl_2) of **2**, **3**, and **4** are shifted hypsochromically by protonation of the dimethylamino groups[5,6] in the vicinity of the polyene skeleton (**2a**, **3a**, and **4a**). However, a larger hypsochromic shift is observed in **4** ($\Delta\lambda_{max} \approx 50$ nm), which can be doubly protonated, than in **2** and **3** (Table 1).

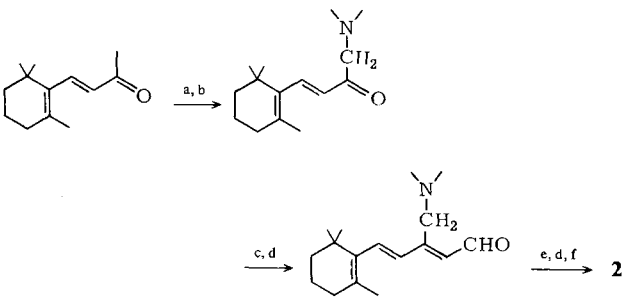
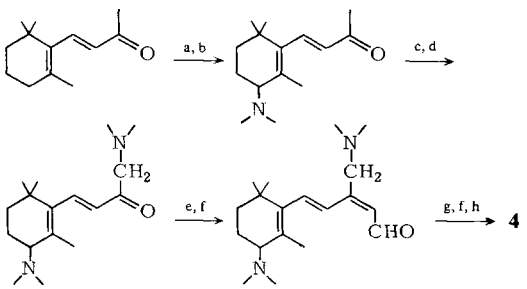
5	520		1534	1626

[a] Difference between the absorption maxima of the protonated and the nonprotonated species.



Scheme 1. a) 5,5-Dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione/tetrahydrofuran (THF), RT, 12 h; b) $(CH_3)_2NH/K_2CO_3/THF$, RT, 1 h; c) $(EtO)_2P(O)CH_2CN/NaH/THF$, RT, 30 min; d) diisobutylaluminum hydride (dibal)/hexane, −78°C, 1 h/silicagel, −78°C to RT/separation of isomers; e) $(EtO)_2P(O)CH_2C(CH_3)=CHCN/NaH/THF$, RT, 1 h; f) pyrrolidine perchlorate/EtOH/0°C, 1 h.



Scheme 2. a) *N*-bromosuccinimide/CCl_4, reflux, 30 min; b) $(CH_3)_2NH/K_2CO_3/THF$, RT, 10 h; c) 5,5-dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione/THF, RT, 12 h; d) $(CH_3)_2NH/K_2CO_3/THF$, RT, 1 h; e) $(EtO)_2P(O)CH_2CN/NaH/THF$, RT, 30 min; f) dibal/hexane, −78°C, 1 h/silicagel, −78°C to RT/separation of isomers; g) $(EtO)_2P(O)CH_2C(CH_3)=CHCN/NaH/THF$, RT, 1 h; h) pyrrolidine perchlorate/EtOH/0°C, 1 h.

Protonation of the dimethylamino groups in retinals **2**, **3**, and **4** also influences the position of the C=C stretching frequency (in CH_2Cl_2), shifting it to higher frequency. These C=C bands can be correlated with the UV/VIS-absorption maxima of the chromophores: a hypsochromic shift in the absorption spectrum is accompanied by a higher frequency of the C=C band (Fig. 1). Furthermore, comparison of the IR and UV/VIS spectra of **5** which possesses a positive charge in the vicinity of the alkylideneammonium ion, and of the pyrrolidine perchlorate of retinal reveals a bathochromic shift in the absorption spectra[7] and a shift to a lower frequency of the C=C stretching mode, in accordance with the results found for **2**−**4**.

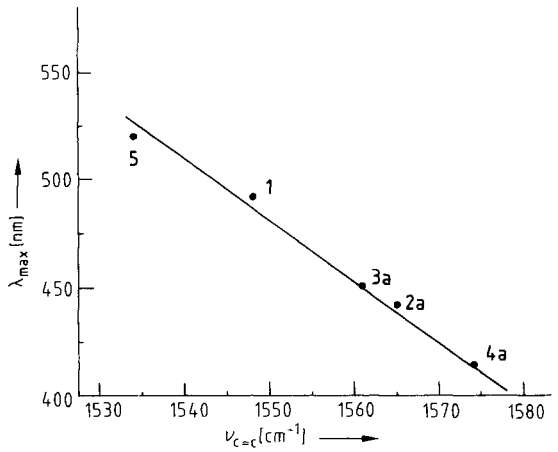


Fig. 1. Correlation between the C=C stretching frequencies and absorption maxima in the model compounds **1**, **2a**, **3a**, **4a**, and **5**.

It should be noted that protonation of the dimethylamino groups in the vicinity of the polyene skeleton in **2**—**5** does not significantly change the position of the C=N stretching frequency (Table 1). This result is consistent with the observed insensitivity of $\nu_{C=N}$ to λ_{max} in visual pigments[8].

Our results reveal that a positive charge in the vicinity of the retinal polyene decreases charge delocalization, causing an increase in the C=C frequency. However, an *external* positive charge near alkylideneammonium ion (**5**) increases the charge delocalization and decreases bond alternation, thus causing a shift of the C=C stretching mode to a lower frequency. It is evident that external positive charge affects not only the excited state but also the ground state.

The external point-charge model for bacteriorhodopsin assumes interaction with a negative charge in the vicinity of the ring moiety of the retinal skeleton. Here, we have investigated the effect of a positive charge, which is expected to give an opposite effect. However, the observation that a *positive* charge influences the absorption maximum and the C=C stretching frequency of a protonated retinal Schiff base supports the external point-charge model for bacteriorhodopsin and also our assumption that the different C=C stretching frequencies found in bacteriorhodopsin, visual pigments, and their photochemically induced intermediates may originate from through-space interaction with external negative charges.

Vanadium Thiolate Complexes with VS_5- and VOS_4-Centers: Synthesis and Structure of $[VS(SC_2H_4S)_2]^{2\ominus}$ and $Na_2[VO(SC_2H_4S)_2]\cdot 8\,MeOH$**

By *Detlef Szeymies, Bernt Krebs,* and *Gerald Henkel**

The importance of S(Cys)-metal bonds in a variety of metalloproteins has created a general interest in the thiolate chemistry of biologically essential trace elements, one of which is vanadium. Investigations on the problem of V-nitrogenase[1,2] have furnished evidence of a possible vanadium-sulfur coordination in proteins. The anion $[VS(edt)_2]^{2\ominus}$ **1** ($edt^{2\ominus}$ = ethane-1,2-dithiolate) and the salt $Na_2[VO(edt)_2]\cdot 8\,MeOH$ **2** mentioned in the title, as well as the anion $[VO(edt)_2]^{2\ominus}$ **3** occurring in solutions of **2** and the polynuclear complexes $[V_2(edt)_4]^{2\ominus}$ **4** and $[Fe_2VS_4(SPh)_4]^{3\ominus}$[3], could be useful as reference compounds for the identification of vanadium-sulfur centers in metalloproteins.

On reaction of $VS_4^{3\ominus}$ with $[V_2(edt)_4]^{2\ominus}$ or with an excess of $edt^{2\ominus}$ in methanol, **3** is formed as main product together with the thiovanadyl complex $[VS(edt)_2]^{2\ominus}$ **1**, which crystallizes as $(Ph_4P)_2[VS(edt)_2]\cdot MeOH$ **5** in the form of brownish-red columns along with green $Na_2[VO(edt)_2]\cdot 8\,MeOH$ **2** after addition of Ph_4PBr[4]. **3** is also formed on oxidation of **4** with Na_2S_2 in methanol, or from $[VO(acac)_2]$ ($acac^{\ominus}$ = acetylacetonate) by ligand exchange reaction[3c]. Besides [VS(acen)] **6** ($acen^{2\ominus}$ = *N,N'*-ethylenebis(acetylacetonylideneamine) dianion)[5], the mononuclear anion **1** is the second thiovanadyl complex whose structure could be determined; furthermore, **1** is the first pentacoordinated vanadium complex with a complete sulfur ligand sphere and also the first sulfide-thiolate complex of vanadium.

The anions **1** (Fig. 1) contain metal centers which are surrounded by four S atoms of two $edt^{2\ominus}$ ligands and one

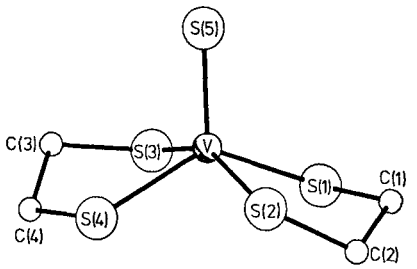

Fig. 1. Structure of the anion **1** in crystals of **5** with assignment of atoms (H atoms omitted). Important bond lengths [Å]: V-S_a 2.098(2), V-S_b 2.348(2)—2.386(2); range of angles [°]: S_a-V-S_b 103.48(7)—113.88(7); S_b-V-S_b 82.96(6)—85.86(6) and 132.54(6)—152.96(6) (S_a = S(5); S_b = S(1)—S(4)).

inorganic S atom. The coordination polyhedron is a strongly distorted square pyramid with the sulfide substituent located at the axial position. The V=S bond in **1** (2.098(2) Å) is slightly longer than in **6** (2.061(1) Å). The other V–S bonds (2.348(2)–2.386(2) Å) are on average about 0.02 Å shorter than those of the oxovanadyl compound **2**.

In contrast to **1**, **3** can be isolated from methanol as the solvated sodium salt **2** (Fig. 2). In crystals of **2**, which are extremely sensitive because of the high methanol content, the metal atom is surrounded by four almost coplanar thiolate S atoms at a distance of 2.387 Å (mean value) as well as an O atom at a distance of 1.607(6) Å. This O atom is additionally bonded to two Na atoms which occupy the centers of two oxygen octahedra which share a common face. The eight methanol O atoms participate in the Na coordination (Na···(μ_2-O) 2.430(5)–2.490(5) Å, Na···O_{term} 2.288(6)–2.407(6) Å). The Na atoms are separated by 3.283(3) Å from each other and by 3.775(3) Å from vanadium. As the Na atoms occupy coordination sites in crystals of **2** which are characteristic for transition metal atoms, **2** can also be described as a neutral vanadium-sodium complex that is stabilized by solid-state effects.

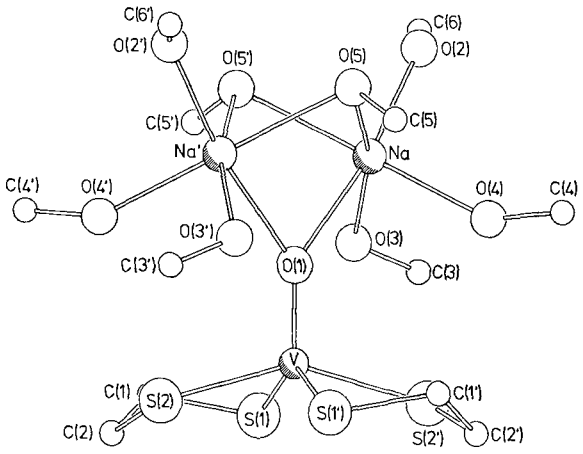

Fig. 2. Structure of **2** in crystals with assignment of atoms (H atoms omitted). Important bond lengths [Å]: V-O(1) 1.607(6), V-S(1) 2.366(2), V-S(2) 2.407(2); range of angles [°]: O(1)-V-S 104.8(1)–109.9(1); S-V-S 84.71(7)–85.35(7) and 140.26(8)–150.45(8).

In the context of the formation of **1** and **3** from $VS_4^{3\ominus}$, the mechanistic aspects are of interest. In the course of the reduction of $VS_4^{3\ominus}$, **1** is presumably the immediate precursor of **3**, which is formed in a subsequent step by substitution of the thiovanadyl S atom. For the formation of **1** there are several conceivable mechanisms in which mixed complexes such as $[VS_x(edt)_y]^{n\ominus}$ $(9 > x+2y > 3)$ could occur as intermediates. Thus, e.g., the (hypothetical) complex $[VS_2(edt)_2]^{3\ominus}$ with a sixfold sulfur coordination would be a thio-analogue of the well known dioxovanadium(V) compounds such as $(NH_4)_3[VO_2(C_2O_4)_2]$[6]. The fact that a rhenium analogue of **1**, namely $[ReS(edt)_2]^{\ominus}$, is known[7], confirms once again the principle of cross-relationship; the existence of mononuclear sulfide-ethanedithiolate complexes of molybdenum can also be expected.

The V=O stretching frequencies determined by IR spectroscopy in crystals of **2** (948 cm^{-1}) and in $(Me_4N)Na[VO(edt)_2]\cdot 2\,EtOH$[3c] (928 cm^{-1}) are correlated with the V=O bond lengths (1.607(6) and 1.625(2) Å, respectively). The V=S stretching vibration of **5** (ca. 515 cm^{-1}) is comparable with those of [VS(salen)] (salen$^{2\ominus}$ = *N,N'*-ethylene(salicylideneamine) dianion) and **6** (543 and 556 cm^{-1}, respectively)[8].

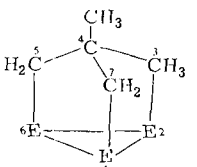
Synthesis of an all-*cis*-Organocyclotriphosphane (P_3-Nortricyclane) and its Pentacarbonylchromium Complex**

By *Jochen Ellermann** and *Alfons A. M. Demuth*

Dedicated to Professor Ekkehard Lindner on the occasion of his 50th birthday

We have previously reported the nortricyclanes **1a**[1], **b**[2], which contain an Sb_3- and an As_3-ring, respectively. The complex chemistry of the homologous phosphorus compound **1c** is of particular interest, since, of the structurally analogous heteronortricyclanes $P(SiMe_2)_3P_3$[3] and $(Me_3Si)_3P_7$[4], only the latter surprisingly exhibits no coordination tendencies[5].



1a, E = Sb
1b, E = As
1c, E = P

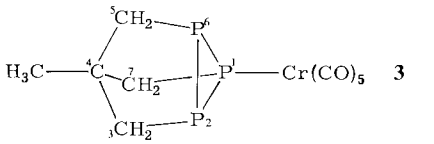
[**] Contributions to the Chemistry of Polyfunctional Molecules, Part 84. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by Hoechst AG.—Part 83: J. Ellermann, G. Szucsanyi, *Chem. Ber.*, in press.

Whereas **1a**, **b** are accessible from $CH_3C(CH_2EPh_2)_3$ (E = Sb, As) via selective cleavage of the phenyl groups with HCl and HI, respectively, followed by reduction of the initially formed products $CH_3C(CH_2SbCl_2)_3$ or $CH_3C(CH_2AsI_2)_3$ with sodium, this method cannot be used for the preparation of **1c** since $CH_3C(CH_2PPh_2)_3$ does not undergo selective phenyl-group cleavage with hydrogen halides[6]. 4-Methyl-1,2,6-triphosphatricyclo[2.2.1.$0^{2,6}$]heptane **1c** was therefore synthesized in a batch reaction from 1,3-dibromo-2-bromomethyl-2-methylpropane **2** and NaP/KP[7] in refluxing monoglyme.

$$\underset{\mathbf{2}}{CH_3C(CH_2Br)_3} + 3\,MP \xrightarrow{80\,^\circ C} \mathbf{1c} + 3\,MBr \qquad M = Na,\ K$$

The composition and structure of the colorless, crystalline **1c** are based on the results of elemental analyses and spectroscopic studies (^1H- and ^{31}P-NMR, Raman, MS (FD, EI)[8]). **1c**, which is readily oxidized in solution, can be sublimed and is highly soluble in tetrahydrofuran (THF) and di- and trichloromethane, moderately soluble in benzene, diethyl ether, and heptane, sparingly soluble in methanol, and insoluble in acetone and water. The $^1H\{^{31}P\}$-NMR spectrum ($CDCl_3$, TMS int.) of **1c** exhibits two singlets at $\delta = 1.30$ (6H, CH_2) and 1.50 (3H, CH_3); in the $^{31}P\{^1H\}$-NMR spectrum (rel. 85% H_3PO_4) only one singlet at $\delta = -203.7$ occurs. The most intense band in the Raman spectrum of a solution of **1c** in CH_2Cl_2 (530 (p) cm^{-1}) is assigned to the A_1 stretching frequency of the P_3-ring; assuming C_{3v} molecular symmetry, we assign the medium-strong band at 394 (dp) cm^{-1} [IR (KBr): 394 (m) cm^{-1}] to the $\nu(P_3)$ vibration (E).

$Cr(CO)_5 \cdot thf$, prepared by UV irradiation of hexacarbonylchromium(0) in THF, reacts with **1c** in the molar ratio 1:1 to give the complex **3** (molecular symmetry: C_s, local symmetry of the $PCr(CO)_5$ group: C_{4v})[9].



3

η^1-Coordination of **1c** to $Cr(CO)_5$ splits the $\nu(P_3)$ band (E) at 394 cm^{-1} in the Raman spectrum [391 (vs, p) and 403 (m, dp) cm^{-1}, A′ + A″]; simultaneously, a new band of medium intensity occurs at 179 (p) cm^{-1}, which we assign to the Cr–P stretching frequency. Because only one P atom is coordinated in **3**, the $^{31}P\{^1H\}$-NMR spectrum[9] exhibits the eight lines of an AB_2 system, corresponding to the A_2B systems of cyclotriphosphanes with C_s symmetry[10].

Procedure

All operations were performed in a nitrogen atmosphere in anhydrous solvents. — **1c**: Na/K alloy (18.9 mL, 542 mmol) is added dropwise directly to a vigorously stirred suspension of white phosphorus (15.2 g, 492 mmol) in 300 mL monoglyme at 80°C. After 3 h at 80°C, **2** (24.8 mL, 164 mmol) is added dropwise and the mixture refluxed for 4 h. After filtration and removal of the solvent, **1c** is separated by sublimation and recrystallized from THF. Yield 2.5 g (9.4%), colorless crystals, m.p. = 128°C. — **3**: A stirred solution of $Cr(CO)_6$ (455 mg, 2.07 mmol) in 50 mL THF is irradiated for 3 h with UV light, and the solution added dropwise over 5 min to a solution of **1c** (290 mg, 1.79 mmol) in 20 mL THF. After stirring for 1 h at 20°C, the solvent is removed and unreacted $Cr(CO)_6$ sublimed out at 70°C, 1 Pa. The residual solid is taken up in 5 mL CH_2Cl_2 and insoluble material filtered off. The yellow solution is evaporated almost to dryness, and precipitated **3** dissolved in 2 mL pentane and 0.4 mL CH_2Cl_2 (heating). After cooling to −20°C, analytically pure **3** crystallizes: yield 201 mg (32%), yellow crystals, m.p. = 100°C.

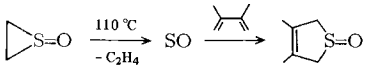
Stabilization of Sulfur Monoxide by Coordination to Transition Metals**

By *Wolfdieter A. Schenk**, *Johanna Leissner*, and *Christian Burschka*

Sulfur monoxide, SO, is one of the classical, unstable small molecules[1,2]; herein we report on its stabilization by incorporation into square-planar rhodium and iridium complexes. Compounds with an SO bridge between two[3] and three[4] metal centers are already known, but, consistent with their mode of formation, they are better regarded as oxidized sulfido clusters; the constitution of two complexes reportedly having terminal SO ligands[5,6] is still controversial. Complex-stabilized S_2O and S_2O_2 are obtained by oxidation of $[(dppe)_2IrS_2]^{\oplus}$ (dppe = $Ph_2PCH_2CH_2PPh_2$)[6,7].



Sulfur monoxide can be generated in solution by thermolysis of thiirane *S*-oxide **1**[8] and trapped with, e.g., 1,3-dienes[9]. We have prepared SO-complexes by fragmentation of **1** in the coordination sphere of a transition metal;

[*] Prof. Dr. W. A. Schenk, Dipl.-Chem. J. Leissner, Dr. C. Burschka
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Ciba-Geigy AG, Degussa AG, and the Fonds der Chemischen Industrie.

the SO is thus stabilized immediately on formation[5]. When the 14-electron complexes **2** and **3**[10] (which are readily obtainable in solution) are allowed to react with **1** at −70 °C and 0 °C, respectively, the deep-green crystalline products **4** and **5** (correct elemental analyses) are formed in moderate to good yields[11]. On carrying out ^{31}P-NMR spectroscopic investigations at low temperature, we were able to detect momentarily stable intermediates, presumably adducts of **1** and the coordinatively unsaturated complexes **2** and **3**.

$$[M(PiPr_3)_2Cl] \xrightarrow{+\,1} [M(PiPr_3)_2(C_2H_4SO)Cl] \xrightarrow{-C_2H_4} [M(PiPr_3)_2(SO)Cl]$$

2, M = Rh; **3**, M = Ir

4, M = Rh; **5**, M = Ir

Table 1. Spectroscopic data of the SO complexes **4** and **5**.

Complex	IR (Nujol) [cm^{-1}]	^{31}P-NMR ([D$_8$]toluene) δ	^1J(Rh–P) [Hz]	MS m/z ($M^{\oplus}$)
4	1075 s ν(SO), 455 m δ(RhSO), 341 m ν(RhCl), 271 m ν(RhS)	42.4	153	506
5	1071 s ν(SO), 475 m δ(IrSO), 337 m ν(IrCl), 279 m ν(IrS)	28.1		596

According to spectroscopic investigations (Table 1), the new compounds have a square-planar structure with the bulky phosphane ligands arranged *trans* to each other and the M–S=O moiety in an angular disposition. Such an array is confirmed by the X-ray structure analysis of the iridium complex **5** (Fig. 1). The metal atom is located in an almost square but perfectly planar environment [Ir–P 237.1(2), Ir–Cl and Ir–S 223.6(3) pm (disorder between Cl and S in the space group $P2_1/c$)]. The SO-group [S–O 132(2) pm, Ir–S–O 130(1)°] is turned through an angle of 20° from the plane of coordination. **4** and **5** are thus closely related to the corresponding SO_2-complexes[12].

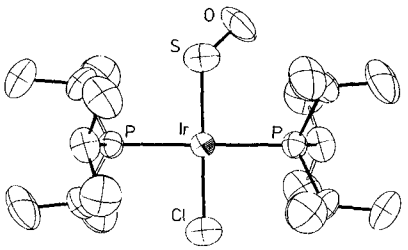


Fig. 1. Structure of the complex **5** in the crystal. Space group $P2_1/c$ (No. 14), $Z=2$, $a=8.128(3)$, $b=9.075(3)$, $c=16.659(4)$ Å, $\beta=93.18(3)°$, $\rho_{calc}=1.62$, $\rho_{exp}=1.615$ mg/mm^3, $R_1=0.028$ (0.034), $R_2=0.036$ (0.037) for 1772 (2167) reflections ($I_{obs}>3\sigma(I)$). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2 on quoting the CSD number 51005, the names of the authors, and the journal citation.

A Facile Route to 1,4,7-Trithiacyclononane

By *Dieter Sellmann** and *Lothar Zapf*

Although the synthesis of crown ethers and related compounds has attained a high standard[1], medium-sized heterocyclic rings of this type are still difficult to obtain. For example, 1,4,7-trioxacyclononane and 1,4,7-trithiacyclononane (TTCN) were previously only accessible in 1–4% yield[2,3]. The conformation adopted by TTCN is the theoretically most stable in which the three S atoms are *endo*-orientated[4]. This "frozen" conformation is probably the reason why TTCN forms surprisingly stable Ni^{II}, Co^{II}, and Cu^{II} complexes, which have recently been the center of interest as model compounds for metal-sulfur enzyme centers and electron-transfer reactions[3b,5]. In the meantime, the yields of TTCN obtained via high-dilution reactions could be increased from 0.04 to 4.4%[3], but these are still too low to permit more thorough studies of the chemistry of TTCN.

In the course of investigations of the reactivity of sulfur-coordinated metal centers, we have now discovered a route involving a "template" alkylation reaction which affords TTCN straightforwardly and in 60% yield. Since the starting complex is regenerated in the third reaction step, the synthesis can, in principle, be performed catalytically.

Treatment of $[Mo(CO)_3(CH_3CN)_3]$ **1**[6] with an equimolar amount of bis(tetramethylammonium) 3-thia-1,5-pentanedithiolate **2** furnishes yellow crystals of the previously unknown complex **3** in 95% yield [ν_{CO}(DMSO) 1865, 1740, 1710 cm^{-1}; ^{1}H-NMR ([D$_6$]DMSO): $\delta=3.2$ (24, s), 2.0–2.9 (8, m)]. Subsequent equimolar reaction with 1,2-dibromoethane affords the neutral complex **4** smoothly in 98% yield [ν_{CO}(DMSO): 1925, (A_1), 1815 cm^{-1} (E); ^{1}H-NMR ([D$_6$]DMSO): $\delta=2.65$ (s)]. The title compound TTCN can be liberated in the third step of the reaction by treating **4** with **2**, and at the same time **3** is regenerated in 84% yield. **3** can be realkylated to **4**[7].

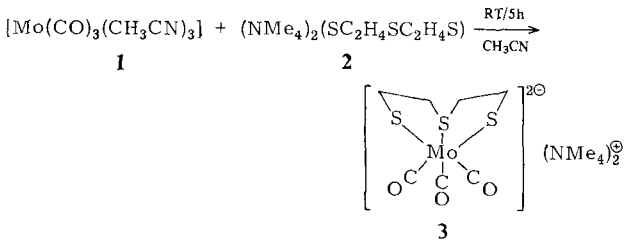
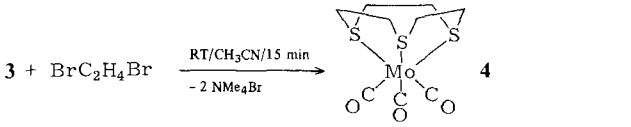
Egerlandstrasse 1, D-8520 Erlangen (FRG)





Procedure:

3: **1** (6.06 g, 20 mmol) and **2** (6 g, 20 mmol) in 120 mL CH_3CN are stirred for 5 h at room temperature, in the course of which yellow **3** precipitates. The mixture is cooled to -20 °C, the precipitate filtered off, washed with tetrahydrofuran and dried to yield 9.12 g analytically pure **3** (95%).—**4**: **3** (8.64 g, 18 mmol) is suspended in 150 mL CH_3CN and stirred with $BrCH_2CH_2Br$ (3.4 g, 18.1 mmol) for 15 min at room temperature. The precipitate of pale yellow **4** is filtered off, washed with MeOH (5 × 40 mL) to remove NMe_4Br, and dried. Yield: 6.35 g (98%).—TTCN: A mixture of **4** (6 g, 16.7 mmol) and **2** (5 g, 16.7 mmol) in 50 mL dimethyl sulfoxide (DMSO) is stirred for 48 h at room temperature and subsequently extracted with Et_2O (3 × 100 mL). EtO_2 is removed in vacuo from the combined extracts at room temperature. TTCN dissolved in the remaining DMSO is precipitated with 200 mL H_2O, filtered off, and recrystallized from MeOH. Yield 1.8 g (60%) analytically pure TTCN (^{1}H-NMR (CCl_4): $\delta = 3.15$; MS (EI): *m/z* 180 ($M^{\oplus}$).—In the extraction, regenerated **3** remains as a highly viscous, yellow paste; stirring for 1 h with 80 mL CH_3CN gives 6.73 g crystalline **3** (84%).

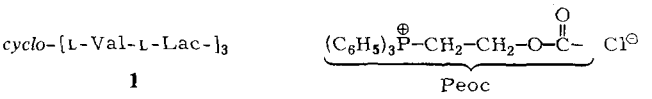
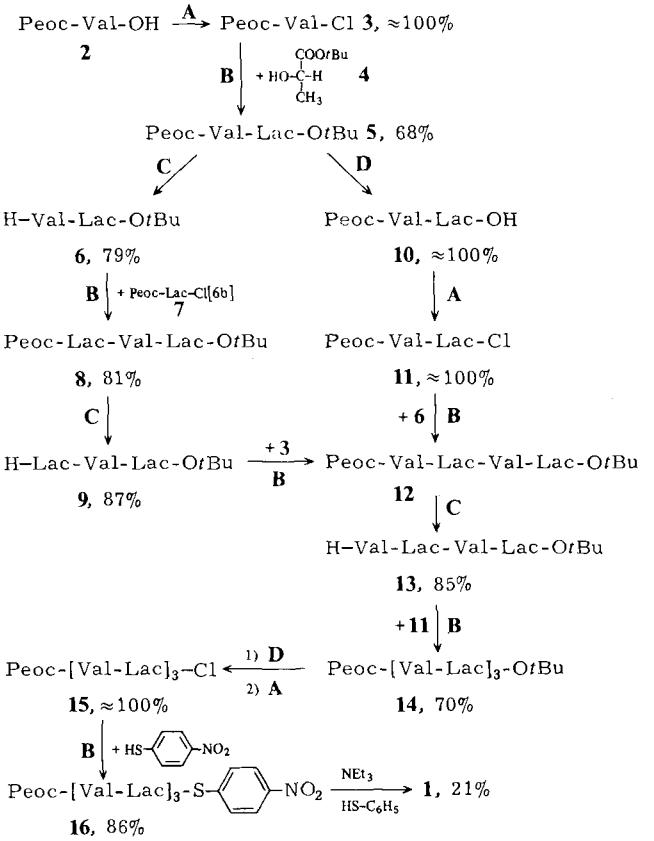
Synthesis of the all-L-Configurated Cyclohexadepsipeptide *cyclo*-[L-Val-L-Lac]$_3$ by the Peoc/Acid Chloride Method**

By *Horst Kunz** and *Hans-Georg Lerchen*

Because of their antibiotic and complexing effects[1], depsipeptides are interesting objects for synthesis. Compared to peptides, the synthesis of depsipeptides is complicated by the presence of the ester groups. If α-hydroxy carboxylic acids are members of the chain, active esters are involved. The synthesis of depsipeptides therefore requires considerable carboxy activation. These difficulties impair particularly the cyclization step in both the acid chloride[2], the phosphite[3], or active ester method[4]. In addition, the cyclization yields are particularly low if all the building blocks have the same configuration and the amino acids contain no *N*-methyl groups[5]. In the cyclohexadepsipeptide **1**, which consists of alternating L-valine and L-lactic acid moieties, all these complicating factors are combined.



For the synthesis of **1**, we investigated the efficiency of the acid chloride method using building blocks consisting of 2-(triphenylphosphonio)ethoxycarbonyl(Peoc)-protected amino acids and hydroxy acids[6]. Linear depsipeptides are synthesized both by single-step chain extension and by coupling two building blocks (Scheme 1).



Scheme 1. **A**: $(COCl_2)$ in CH_2Cl_2; **B**: pyridine/CH_2Cl_2/0 °C; **C**: $HN(CH_3)_2/CH_3OH$/0 °C; **D**: HCl/CH_2Cl_2/room temperature.—Val and Lac have L-configuration. The step **13**→**14** can be carried out analogously to **6**→**12**. Yield: **11**→**12**: 66%.

The basic building block **5** for both synthetic routes is obtained from Peoc-valine chloride **3**[6b] and *t*-butyl L-lactate **4** and deblocked at the *N*-terminal to afford the amino component **6**.

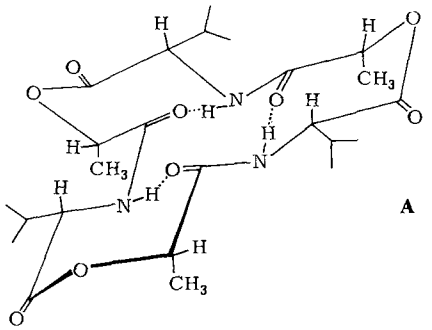
[*] Prof. Dr. H. Kunz, Dipl.-Chem. H.-G. Lerchen
Institut für Organische Chemie der Universität
Johann-Joachim-Becher-Weg 18–20, D-6500 Mainz (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

A process of alternately coupling the Peoc-protected single building blocks (and the double building block **11**) and mild basic deblocking (Scheme 1, left half) leads to the protected hexadepsipeptide **14**. In previous syntheses, the late formation of the esters of the oligodepsipeptides was not possible.

Alternatively, the chain can be constructed by linking ester-like bound didepsipeptides, whereby the reactivity of the Peoc-protected acid chloride **11** is exploited (Scheme 1, right half). By this means, **14** is attained in a few steps. The physical data[7] of crystalline samples of **14** prepared by the two routes are mutually consistent.

The advantages presented by the Peoc/acid chloride method became clear in the cyclization of **14** to **1**, a step which appeared to be almost unrealizable in view of the experiences reported by *Shemyakin* et al.[5]. **14** is deblocked at the *C*-terminal and converted into the acid chloride **15**. In order to avoid that the carboxy activation is lost upon removal of the Peoc group by base, the *p*-nitrophenyl thioester **16** is prepared, from which the Peoc group can be removed by trimethylamine/thiophenol[8] in dilute acetonitrile solution. Despite numerous side reactions, the fact that 1) all the building blocks have the same configuration and 2) *N*-methyl groups are absent, the intramolecular aminolysis nevertheless affords the cyclohexadepsipeptide **1** in 21% yield after chromatography. The structure of **1** is confirmed by the FD and FAB mass spectra (base peak *m/z* 514 $(M+1)$[9]). Of particular note is that the 400-MHz ^{1}H-NMR spectrum exhibits only one signal, respectively, for the amide protons, the methine protons of the lactic acid residue, those of the valine moiety, and for the side-chain protons. From this it has to be concluded that conformation **A** with C_3 symmetry is preferred in chloroform.



A

It is clear from **A** why the cyclization of depsipeptides consisting of building blocks having the same configuration is so strongly hindered: The side chain of every second building block (in **A** the lactic acid) is constrained to occupy the "axial" position.

[7] Correct elemental analysis; $[\alpha]_D^{22} = -65.3$ ($c = 1.2$, CH_3OH).
[8] Thiophenol serves as a trapping nucleophile for the vinylphosphonium salt; see H. Kunz, *Chem. Ber. 109* (1976) 2670.
[9] Interestingly, in the FAB-MS recorded in tetraethylene glycol a peak occurs at *m/z* 619 which corresponds to an adduct of diethylene glycol and **1**.
[10] The low-field position of the N–H doublet ($\delta = 7.15$) in **1** and the result that the quartet of the lactic acid methine proton ($\delta = 5.23$) is shifted to low field relative to the corresponding signal of comparable open-chain compounds (e.g. **13**) by ca. 0.15, while the doublet of doublet of the valine methine proton ($\delta = 4.33$), in contrast, is shifted to high field by ca. 0.25, suggests the following: In the preferred conformation, the isopropyl side chains adopt approximately equatorial positions, whereas the methyl groups in the lactic building blocks must be practically axially orientated. The position of the ester carbonyl bands ($\nu = 1755\ cm^{-1}$) and those of the associated typical amide I bands of the amide groups at $\nu = 1650\ cm^{-1}$ are also consistent with conformation **A**.

Unusual Conversion of an Alkynetungsten Complex into a Tungstenacyclopropane Compound by Nitrosyl Chloride**

By *Helmut Guido Alt**, *Heidi Ingrid Hayen*, *Heinz-Peter Klein*, and *Ulf Thewalt*

Neutral transition-metal carbonyl complexes typically react with nitrosyl chloride to give chloronitrosyl complexes[1]. The reaction of the acetylalkyne complex **1**[2] with ClNO also affords, via insertion of the alkyne ligand into the tungsten-acetyl bond, a chloronitrosyl complex **2**, but as a minor product. The major products isolated are

the tungstenacyclopropane complexes **3a**, **b**, which are characterized by IR, ^{1}H-NMR, ^{13}C-NMR, and mass spectroscopy. Only two of the four possible diastereomers, those with *trans*-oriented hydrogen atoms on the three-membered ring, are observed.

From **3a**, **b**, novel tungstenacyclopropane complexes are accessible which cannot be prepared by photoinduced substitution reactions of the parent compound $CpW(CO)_2NO$ with olefins. We infer that the cationic intermediate **A** can be attacked by its $Cl^{\ominus}$ counterion both at the tungsten atom to form **2a** and at C-3 to afford **3a**, **b**.

The description of the bonding in **3a**, **b** as tungstenacyclopropanes and not olefin complexes derives from the ^{1}H- and ^{13}C-NMR spectra (Tables 1 and 2), which indicate that the atomic nuclei of the three-membered ring are strongly deshielded. Also the magnitude of ^3J(H,H) (**3a**, 9.0; **3b**, 8.4 Hz) is characteristic of a metallacyclopropane. Furthermore, ^2J(W,H) as well as ^1J(C,H) and ^1J(W,C) are observed (Tables 1 and 2), couplings that are typical for cyclopropane[4] and for the metallacyclopropane complexes $Cp_2MoC_2H_4$[5], $Cp_2Ta(C_2H_4)H$[6], and $Cp(CO)_2\overline{MCH(PMe_3)-CHCOR}$ (M = Mo, W; R = alkyl)[7]. The ^{1}H-NMR spectra of **3a**, **b** at different temperatures in [D$_8$]toluene reveal that there is no rotation which would be expected for a π-"olefin" type bonding. The reaction of **3a**, **b** with the strong donor trimethylphosphane, which substitutes not an "olefin" but rather the CO ligand, is also evidence against the formulation as an olefin complex. Thus, the diastereomerically pure tungstenacyclopropane **3c** (Tables 1 and 2) is formed. In contrast, the olefin ligand in $Fe(CO)_4(ClHC{=}CHCOMe)$ is easily displaced, even by the weak donor NMe_3[3]. **3a** and **3b** are transformed by gaseous HCl and HBr (or Br_2) into **2a** and **2b**, respectively, without elimination of an alkene or alkane.

The X-ray structure analysis of **3a** corroborates the interpretation of the spectroscopic results. Tungsten displays approximately square-pyramidal coordination, and the atomic distances are those expected for a metallacyclopropane complex[7].

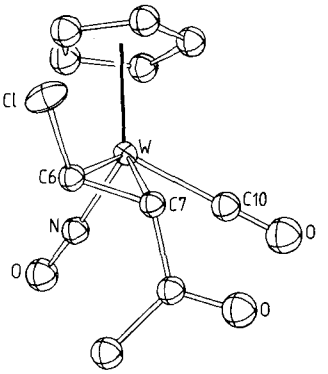

Fig. 1. Crystal structure of **3a**. Selected bond lengths [Å] and angles [°]: W–C6 2.213, W–C7 2.272, C6–C7 1.451, W–C10 1.983, W–N 1.802; C6–W–C7 37.7(4), W–C6–C7 73.3(6), W–C7–C6 68.9(6). Procedure:

2a, **3a**, **b**: **1**[2] (0.18 g, 0.52 mmol) is dissolved in 50 mL CH_2Cl_2 and 0.8 mL ClNO in CH_2Cl_2 (0.7 mol/L) added to the stirred solution at −30 °C. In the subsequent column chromatographic separation (silica gel/pentane), yellow **3a**, **b** (toluene/ether 5 : 1) and orange **2a** are eluted (ether). After removal of the solvent, the products are crystallized from methanol and acetone, respectively. **2a**: yield 0.04 g (20%); decomposes at 175 °C (under argon); MS: *m/z* 383 ($M^{\oplus}$) relative to ^{184}W. — **3a**, **b**: yield 0.11 g (52%); decomposes at 105–108 °C (under argon); MS: *m/z* 412 ($M^{\oplus}$) relative to ^{184}W.

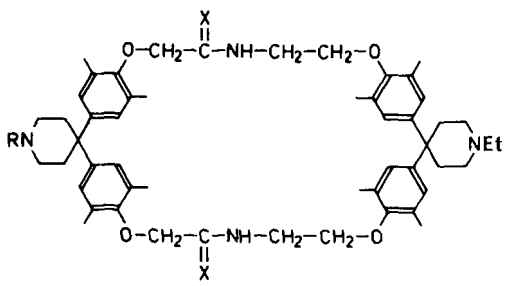
drocarbons in aqueous solution[1]. The properties of the complexes of spherical host molecules with anionic or cationic guests[2] stimulated us to prepare spherical, water-soluble macrocycles with an apolar cavity of defined size which complexes neutral arenes in aqueous solution.

The synthesis of the precursors **3**, **5**, and **7** necessary for the cyclization steps starts from *N*-acetyl-4,4-bis(3,5-dimethyl-4-hydroxyphenyl)piperidine[1a,b]. Reaction with ethyl bromoacetate afforded the diester **1** (KOH, tetrahydrofuran (THF); 67%; m.p. 108—109 °C)[3], which was hydrolyzed to give the dicarboxylic acid **2** (K_2CO_3, EtOH/H_2O; 98%; m.p. 236 °C)[3]. For the preparation of the bis(*N*-hydroxysuccinimide ester) **3** as activated carboxylic acid component for the amide-cyclization to give **8**, **2** was allowed to react with *N*-hydroxysuccinimide (dicyclohexylcarbodiimide, dioxane; 84%; m.p. 156 °C)[3,4]. Passage of ammonia into the reaction solution of **3** led to formation of the triamide **4** (84%; m.p. 240—241 °C)[3], which was reduced to the cyclization component **5** (B_2H_6, THF; colorless glass; 96%)[3]. **3** reacts with **5** to give the macrocycle **8** (CH_2Cl_2, 0 °C, dilution principle; 41%; m.p. > 335 °C, decomp.)[3], which on reduction yielded the cyclic precursor **9** for the cyclization to the macrobicycle (B_2H_6, THF; 96%; m.p. 240—241 °C)[3].

	R	R'
1	EtO–CO	Ac
2	HO–CO	Ac
3	succinimido-O–CO	Ac
4	H_2N–CO	Ac
5	H_2N–CH_2	Et
6	HO–CO	$PhCH_2O$–CO
7	Cl–CO	$PhCH_2O$–CO



8, R = Ac, X = O
9, R = Et, X = 2H

For the preparation of the second component **7** necessary for the cyclization, **1** was hydrolyzed (2 N NaOH, 6 h, 100 °C), and the crude product was allowed to react with benzyl chloroformate to give the dicarboxylic acid **6** (92%; m.p. 95 °C decomp.)[3]. The dichloride **7** obtained by reaction of **6** with sulfinyl chloride in benzene was then cyclized, without further purification, with **9** to give the macrobicycle **10**, [toluene, 0 °C, dilution principle; 38%; m.p. 189 °C, decomp.; FAB-MS[5]: *m/z* 1385 [100%, ($M^{\oplus}$ + H)], 929 (37), 693 (30), 553 (24), 465 (55)]. Catalytic cleavage of the amine-protecting group furnished **11** [H_2/Pd (10%), EtOH, 98%; m.p. 185 °C][3]; reductive alkylation of **11** yielded the host molecule **12** (CH_3COOH, $NaBH_4$, 55 °C, 12 h; 55%; m.p. 180 °C)[3]. **11** was acetylated to give **13** (Ac_2O; 85%; m.p. 200 °C)[3], which could be reduced to the host molecule **14** (B_2H_6, THF; 79%; m.p. 146 °C). Alternatively, **14** could be prepared by reduction of **12** (B_2H_6, THF; 83%). The simple 360-MHz ^{1}H-NMR spectrum reflects the higher symmetry (D_{3h}) of the macrobicycle **14** compared to **10**—**13**[3].

	R	X		R	X
10	$PhCH_2O$–CO	O	**13**	Ac	O
11	H	O	**14**	Et	2H
12	Et	O			

12 and **14** are readily soluble in aqueous solution at pH < 5. Their ^{1}H-NMR spectra [360 MHz, 303 K, 0.5 M solution of KD_2PO_4 in D_2O, pD 4.3, sodium 2,2,3,3-tetradeuterio-3-(trimethylsilyl)propionate (TSP) ext.] show concentration-independent shifts at [**12**] < 10^{-3} mol·L^{-1} and [**14**] < 5×10^{-3} mol·L^{-1}. All complexation experiments in aqueous solution were carried out at pH < 5 and [host] < 10^{-3} mol·L^{-1}.

In weakly acid solution, **12** contains a predominately apolar cavity, since the protonated amine nitrogen atoms are directed outwards. **12** is therefore a very good host for appropriately sized neutral arenes. With [**12**] = 5.0×10^{-4} mol·L^{-1} in a 0.5 M aqueous solution of KH_2PO_4, a $\approx 2.3 \times 10^{-4}$ M aqueous solution of pyrene was obtained by solid-liquid extraction[1a,b]. Using the maximum solubility of pyrene in such a solution in the absence of **12** (2.0×10^{-7} mol·L^{-1}), the association constant K_a of the 1:1 complex could be calculated to be $K_a = (4.1 \pm 0.5) \times 10^6$ L·mol^{-1} (293—295 K)[1b]. For the 1:1 complex of the recently described flat macrocyclic host molecule with pyrene in D_2O (293—295 K) a value of $K_a = 1.1 \times 10^6$ L·mol^{-1} was found[1b]. For the **12**-naphthalene complex, $K_a = (1.2 \pm 0.2) \times 10^4$ L·mol^{-1} was obtained. The complexation between **12** and arenes is virtually independent of the nature of the inorganic ions present in the solution up to ionic strengths of 1 mol·L^{-1}. The ^{1}H-NMR spectrum (for conditions, see above) demonstrates the strong complexation between **12** and pyrene. The exchange between host and guest is slow: In the ^{1}H-NMR spectrum of the solution with [**12**] = 5×10^{-4} mol·L^{-1} and [pyrene] = 2.3×10^{-4} mol·L^{-1}, signals of the free and complexed host are present in an intensity ratio $\approx 2.7 : 2.3$

along with the signals of the complexed pyrene. The pyrene lies in the plane of **12** which runs through the three spiro carbon atoms. This orientation, which naphthalene also assumes (NMR), is supported by the large upfield shift of the signals of the pyrene protons in the complex solution (H1: $\Delta\delta = +2.04$, H2: $+1.03$[7], H4: $+1.99$), the upfield shift of the resonances of the protons of the host molecule **12** which lie about perpendicular to this plane ($O-CH_2-CH_2-N-C(O)-CH_2-O$), and the downfield shift of the signals of the protons of **12** in this plane (e.g. aryl-*H*).

The two protonated amine nitrogen atoms in the cavity of **14** in weakly acid solutions, on the other hand, considerably reduce the hydrophobic character of this cavity. The complexation of arenes is weaker: With a 0.5 M aqueous KH_2PO_4 solution ($[\mathbf{14}] = 5.0 \times 10^{-4}$ mol·L^{-1}), only a $\approx 2.3 \times 10^{-6}$ M solution of pyrene was obtained by solid-liquid extraction. With 0.1 M aqueous hydrochloric acid ($[\mathbf{14}] = 5 \times 10^{-4}$ mol·L^{-1}), the extraction by complexation is even weaker. That the weak complexation of arenes is due to the two protonated nitrogen atoms in the cavity of **14** and not to geometric factors is supported by the observation that the complexation between pyrene and non-protonated host **14** in methanol is surprisingly strong. In the ^{1}H-NMR spectrum (360 MHz, 303 K, [D$_4$]methanol, TSP ext., $[\mathbf{14}] = 6 \times 10^{-3}$ mol·L^{-1}, [pyrene] $= 3 \times 10^{-3}$ mol·L^{-1}) the signals of the pyrene protons are shifted upfield very strongly (H1: $\Delta\delta = +1.77$, H2: $+1.19$, H4: $+1.97$). This upfield shift as well as specific upfield and downfield shifts of the signals of host protons in the complex solution indicate that pyrene is located similarly as in the cavity of **12**. The very different complexing behavior of **12** and **14** towards arenes in aqueous solution underscores the significance of the outward directing ionic groups responsible for promoting solubility in water.

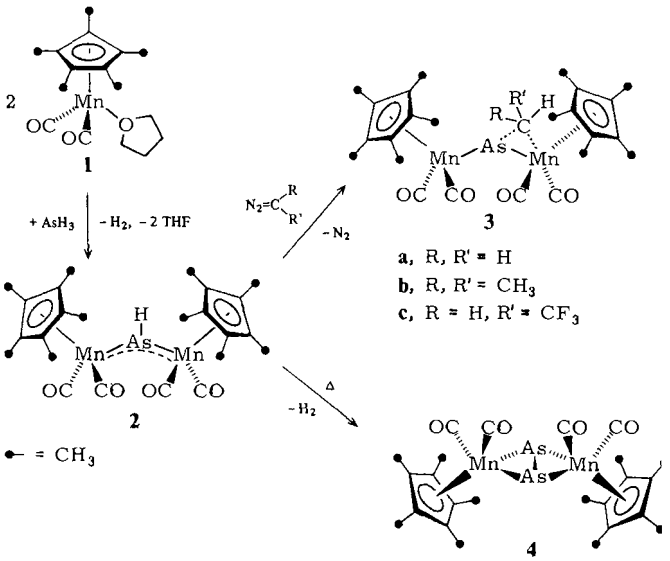
Arsanediyl (Arsinidene) and Diarsene Complexes by Metal-Induced Degradation of Monoarsane**

By *Wolfgang A. Herrmann**, *Basile Koumbouris*, *Thomas Zahn*, and *Manfred L. Ziegler*

Dedicated to Professor Margot Becke on the occasion of her 70th birthday

Complexes exhibiting multiple bonds between transition metals and ligand-free ("naked") main group elements are highly reactive[1]. They add smoothly, for example, to small, unsaturated species such as the methylene fragment[2]. For the systematic introduction of bare main group elements into organometallic complexes not only the elements themselves, but also their binary hydrides appear promising reagents. Following the recently reported use of GeH_4[2] and TeH_2[3] in the synthesis of unusual multinuclear germanium and tellurium complexes, respectively, we have now, for the first time, successfully synthesized arsanediyl (arsinidene) and diarsene complexes using monoarsane.



Although the coordination chemistry of monoarsane appeared to have already been basically investigated[4], we treated this reactive compound with the solvent complex **1** at room temperature and obtained the deep-blue, extremely air-sensitive binuclear complex **2** (ca. 80%)[5]. According to the NMR spectra and the results of a single-crystal X-ray structure analysis (Fig. 1), the basic skeleton of **2** contains, for the first time, the arsanediyl ligand, AsH, in a symmetrical bridging position. Substituted derivatives exhibiting AsR groups (R = alkyl, phenyl, halogen) have been known for some time from the work of *Huttner* et

[**] Multiple Bonds between Main Group Elements and Transition Metals, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft, the Herbert-Quandt-Stiftung of Varta Batterie AG, Hoechst AG, and the Bundesministerium für Forschung und Technologie.—Part 10: W. A. Herrmann, C. Hecht, M. L. Ziegler, T. Zahn, *J. Organomet. Chem.*, in press.

al.[6]. As in these latter complexes, the arsanediyl bridge in **2** is bonded to both manganese atoms via two very short bonds, resulting in a three-center, four-electron bonding system (Mn–As 224.7(1) pm; Mn–As–Mn′ 139.3(1)°). In solution, **2** forms a mixture of rotamers (IR), whose components rapidly interconvert on the NMR time scale.

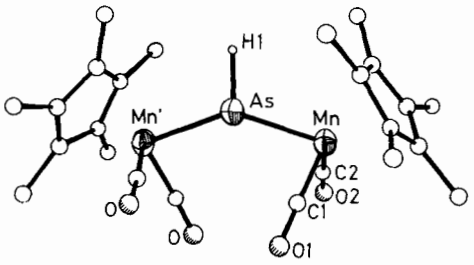

Fig. 1. Molecular structure of **2** in the crystal. Space group Fdd2-C_{2v}^{19}, $Z=8$, $a=804.8(2)$, $b=1559.7(3)$, $c=4167.0(8)$ pm; $R_{iso}=0.092$, $R_{aniso}=0.039$, $R_w=0.034$.—Selected distances [pm] and angles [°]: Mn–As 224.7(1), Mn–C1 173.7(8), Mn–C2 172.6(9), C1–O1 116.1(10), C2–O2 116.9(11); Mn–As–Mn′ 139.3(1), As–Mn–C1 89.1(2), Mn–C1–O1 177.3(7), Mn–C2–O2 176.9(6).

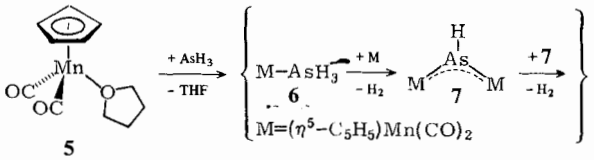
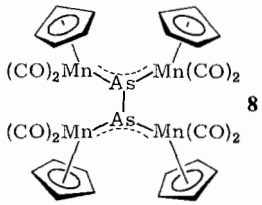
The AsH bridge in **2** can be functionalized: thus, at −80°C diazoalkanes undergo carbene insertion within seconds to afford almost quantitatively the unsymmetrical derivatives **3**, in which one of the two As–Mn bonds is probably bridged by an alkyl group[5,7]. Furthermore, clean cleavage of the As–H bond is achieved upon solid-state thermolysis of the pure arsinidine complex **2** at 120–140°C in vacuo. The novel Mn_2As_2 complex **4** thus formed in >85% yield is surprisingly thermally stable up to above 250°C; according to a single-crystal X-ray structure analysis it does not have the expected tetrahedrane- but rather a "butterfly"-skeleton (Fig. 2)[5] with the two As_2Mn triangles forming an interplanar angle of 121.8°. Whereas the Mn–Mn distance (402 pm) is too large for a bonding interaction[8], the extremely short As–As bond (222.5 pm) exhibits considerable multiple bond character (As–As single bonds 243–246, double bonds ca. 222 pm[9]). The Mn–As bonds (251–257 pm) are much longer than in the μ-arsanediyl complex **2** and therefore can be interpreted as single bonds. Mn_2As_2 complexes (M = Mo, W) having tetrahedrane-type structures have recently been synthesized in low yields[10]; the As–As bonds in these cases are significantly longer than in **4** (231–232 pm[10]), but are, nevertheless, formally double bonds.

The stepwise metal-induced degradation of arsane via AsH- to As_2-complexes with concomitant elimination of hydrogen (GC) as observed for the first time with the reaction sequence **1** → **2** → **4** occasioned the investigation of the reported reaction of the solvent complex **5** with monoarsane from which the extremely thermolabile complex **6** had been isolated in 1.5% yield by *Fischer* et al.[4a]. We were able to detect **6** in the product mixture (IR, MS), but it appeared only to be an intermediate: in >80% yield, the major product formed is the tetranuclear μ-diarsane complex **8**[5,11], which results formally from the coupling of two arsanediyl complexes **7** by elimination of H_2; once again, this reaction reflects the lability of the As–H bonds. Because of the bulky pentamethylcyclopentadienyl ligands, **2** does not undergo this type of coupling reaction.



5



8

From the reactions described here, the instability of AsH_3 complexes[4] appears to be kinetic in nature and to involve spontaneous elimination of H_2, which the metal-arsenic bonds initially leave intact. The reactive AsH bridge in **2** facilitates both carbene insertions and intermolecular As–As couplings. The readily accessible monoarsane is hence a suitable precursor for organometallic complexes containing AsH or unsubstituted (bare) As_x skeletal building blocks.

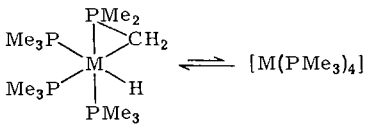
[11] Compound **8** can be prepared from the corresponding μ-chloroarsanediyl complex by reductive AsAs-coupling with zinc dust; a single-crystal X-ray structure analysis is consistent with our proposed structure: B. Sigwarth, Ph.D. Thesis, Universität Konstanz, Germany 1983.

$(PMe_3)_3MS_7$ (M = Ru, Os): The First Polysulfido Metal Complexes with a Tridentate $S_n^{2\ominus}$ Ligand**

By *Josef Gotzig, Arnold L. Rheingold,* and *Helmut Werner**

In contrast to the pentacarbonyl complexes $M(CO)_5$, analogous pentakis(trimethylphosphane)metal complexes $M(PMe_3)_5$ (M = Fe, Ru, Os) are unknown. During attempts to prepare these complexes, compounds **1** were obtained. In the solid state **1** has a structure in which three PMe_3 groups and an H atom are bonded to the metal M of a phosphametallacyclopropane ring; M is therefore octahedrally coordinated[1]. In solution, the complexes exist in equilibrium with the corresponding coordinatively unsaturated isomers; however, the position of the equilibrium lies mainly to the side of the phosphametallacyclopropanes.

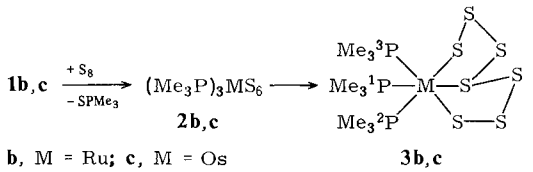


1

a, M = Fe; **b**, M = Ru; **c**, M = Os

The chemistry of the complexes **1** is dominated by their enhanced reactivity towards electrophiles. Whereas the constitution of the products formed in the reactions of **1a** indicate that *both* isomers present in the equilibrium react[2], similar evidence is lacking for **1b**, **c**[1b,c]. It was our aim to find such evidence by studying the reaction of **1b**, **c** with sulfur, since it is known that the 16-electron complexes $[C_5H_5M(PR_3)]$ (M = Co, Rh; R = Me, Ph) prepared in situ, which are comparable to the coordinatively unsaturated $[M(PMe_3)_4]$, can be trapped by S_8 to form the thiametallacycles $C_5H_5(PR_3)MS_5$[3].

If a solution of **1b** or **1c** is therefore treated with S_8 in the molar ratio 1:5/8, the starting material is not completely consumed. Only when the reactants are mixed in the molar ratio 1:1 does the reaction go to completion to yield $SPMe_3$ (NMR) and a dark precipitate which is insoluble in benzene. After chromatography[4a], *dark brown*, air-stable solids **2b**, **c** are isolated[4b].



Attempts to prepare single crystals of **2b**, **c** led to an unexpected result. Slow diffusion of hexane in solutions of **2b** and **2c** in acetone affords *orange-red* crystals which are not identical with the dissolved compound. According to elemental analysis, the ratio M:S = 1:7[4b]. In the NMR spectra, however, there is no detectable difference between **2b**, **c** and **3b**, **c**. Thus, in the ^{1}H- and in the ^{31}P-NMR spectra two types of CH_3 protons and phosphorus nuclei are observed, the latter forming an AB_2 spin pattern[5]. At present, no conclusive statement can be made about the mechanism of formation of **3** from **2**. A more detailed investigation of the *clear* solution (from which the crystals precipitate) is planned as soon as larger quantities of the starting material are available.

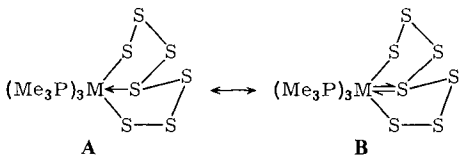
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by gifts of chemicals from Degussa AG.

The molecular structure of the osmium complex **3c** was determined by X-ray structural analysis (Fig. 1)[6]. The $S_7^{2\ominus}$ unit is linked via S1, S4, and S7 to Os, which attains the preferred octahedral coordination for oxidation state +2. As far as the structural data are concerned, special attention is drawn to the different Os–S and S–S bond lengths. Compared to Os-S1 and Os-S7, the significantly shorter Os-S4 distance indicates that in addition to the donor bond from S4 to the Os atom an acceptor bond may be present, i.e., not only **A** but also the resonance structure **B** must be considered in a description of the bonding in **3b, c**. The unique role of S4 in the OsS_7 bicyclic system can also be seen in the larger Os-P1 bond (*trans* to S4) and in the elongation of the S3-S4 and S4-S5 bonds.



A **B**

To the best of our knowledge, **3b, c** are the first metal complexes in which an MS_7 unit is present and an $S_7^{2\ominus}$ ion is coordinated as a *tri*dentate ligand. Recently, monocyclic MS_n ring systems with $n = 6$[7a] and $n = 9$[7b] have been prepared with M = Cu or Au and their structures characterized. It seems interesting that the bicyclic OsS_7 moiety has the same "paddle-wheel"-like *exo/endo*-conformation as the $S_8^{2\oplus}$ ion in $S_8(AsF_6)_2$[8].

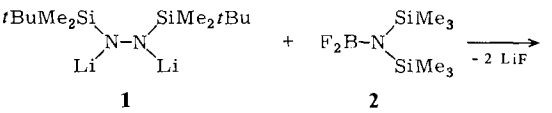
Diazaboracyclopropane**

By *Uwe Klingebiel**

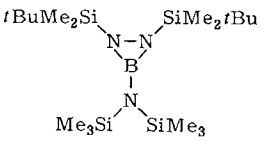
Strained boron-phosphorus[1–3] and boron-carbon[4–6] three-membered ring systems have been synthesized in the last ten years by several groups. Among the thoroughly studied boron-nitrogen heterocycles[7,8], no strained BN_2-ring compound was previously known.

Like dihalosilanes[8,9], dihaloboranes[8,10] react with lithiated hydrazines to afford, preferentially, six-membered rings. The synthesis of an SiN_2 three-membered ring using the bulky di-*tert*-butyldifluorosilane was recently reported. Preparation of a BN_2 three-membered ring should also be favored by the presence of sterically demanding substituents on the nitrogen and boron atoms.

As expected, reaction of the doubly lithiated *N,N'*-bis(*tert*-butyldimethylsilyl)hydrazine **1** with difluorobis(trimethylsilyl)aminoborane **2** leads to the diazaboracyclopropane 1,2-bis(*tert*-butyldimethylsilyl)-3-[bis(trimethylsilyl)amino]diazaboriridine) **3**.



1 **2**



3

The structure of the BN_2 ring system was elucidated by CH elemental analysis and by cryoscopic determination of the molecular mass in cyclohexane ($M_r = 432$); the presence of a dimer, i.e. a B_2N_4 ring system[10], can therefore be excluded also in solution. Since it has not yet proved possible to isolate single crystals suitable for an X-ray structure investigation, the configuration assigned to this three-membered ring is corroborated by NMR data. The ^{11}B-NMR shift ($\delta = 27.2$) occurs in the region associated with sp^2-hybridized boron. The nitrogen is—in part, certainly because of the bonded silyl groups—sp^2-hybridized; the ^{14}N-NMR shift is observed at $\delta = -329$ (rel. CH_3NO_2). The sharp ^{1}H- and ^{13}C-NMR signals indicate the presence of equivalent substituents in the ring plane. The ^{29}Si-NMR signals occur in the region expected.

Hence, the NMR data for this silyl- and silylamine-substituted three-membered ring differ also from those of the recently synthesized BN_2 ring which bears isopropyl groups at the nitrogen.

[**] This work was supported by the Fonds der Chemischen Industrie.

Procedure

A solution of **1** (0.05 mol) in 200 mL *n*-hexane is cooled to −30°C and to this is added over 4 h, with constant stirring, a solution of **2** (0.05 mol) in 150 mL *n*-hexane. After being warmed up to room temperature, precipitated LiF is centrifuged off. The solvent is removed using an oil pump and **3**, which precipitates out even at this stage, is purified by dissolution in a little *n*-hexane at room temperature and precipitation at −30°C. Yield: 10.5 g (85%); Fp = 69°C; MS (70 eV): *m/z* 429 (15) $M^{\oplus}$ (with theoretical B-isotope abundance), 414 (5) ($M^{\oplus} - CH_3$), 372 (100) ($M^{\oplus} - C_4H_9$); ^{1}H-NMR (CH_2Cl_2, TMS int.): $\delta = 0.10$ ($SiMe_2$), 0.26 ($SiMe_3$), 0.97 (CMe_3); ^{11}B-NMR (CH_2Cl_2/C_6D_6, $BF_3 \cdot OEt_2$ ext.): $\delta = 27.2$; ^{13}C-NMR (CH_2Cl_2/C_6D_6, TMS int.): $\delta = -3.34$ ($SiMe_2$), 3.24 ($SiMe_3$), 19.72 ($SiCMe_3$), 27.26 [$SiC(CH_3)_3$]; ^{14}N-NMR ($CDCl_3$, CH_3NO_2 ext.): $\delta = -329$; ^{29}Si-NMR (CH_2Cl_2/C_6D_6, TMS int.): $\delta = 7.25$ ($SiMe_2CMe_3$), 12.88 ($SiMe_3$).

P_4-Degradation with and without Disproportionation**

By *Alfred Schmidpeter**, *Günther Burget*, *Hans Georg von Schnering*, and *Dieter Weber*

White phosphorus is degraded nucleophilically by aqueous solutions of alkali metal hydroxides, e.g. according to the following equation

$$P_4 + 3\,OH^{\ominus} + H_2O \longrightarrow 3\,H_2PO_2^{\ominus} + PH_3$$

and thereby formally disproportionates into the P_4-fragments $3\,P^{\oplus}$ and $P^{3\ominus}$, which are however strongly modified by taking up $OH^{\ominus}$ and $H^{\oplus}$, respectively. Instead of using the hydroxide ion, we have now studied P_4-degradation with soft anionic bases $X^{\ominus}$ and obtained products in which the P_4-fragments are more easily recognized. The 4-valence electron particle $P^{\oplus}$ is stabilized by addition of the two ligands $X^{\ominus}$ to give the anion $PX_2^{\ominus}$ with an octet configuration at P, and the charge on $P^{3\ominus}$ is shared with a larger or smaller number of phosphorus atoms to form a polyphosphide [eq. (1)].

$$(n+1)/4\;\; P_4 + 2\,X^{\ominus} \longrightarrow PX_2^{\ominus} + P_n^{\ominus} \qquad (1)$$

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

With X = CN, on a preparative scale, this reaction yields salts of the dicyanophosphide ion[2], which has previously been obtained by reduction of $P(CN)_3$[1]. Lithium triphenylstannide, alkali-metal alkyl- and arylphosphides[3], as well as alkali-metal phosphites, phosphonites, and phosphinites react analogously[4].

Moreover, in certain favorable cases P_4 may be degraded without disproportionation [eq. (2)]. Here, the base $X^{\ominus}$ effects breakdown of P_4 into two P_2-halves. Their 10-valence electron system (which in contrast to N_2 cannot sufficiently π-stabilize) is supplemented in this way with four electrons by addition of two $X^{\ominus}$ ligands.

$$1/2\,P_4 + 2\,X^{\ominus} \longrightarrow P_2X_2^{2\ominus} \qquad (2)$$

With NaX = sodium diethyl- and sodium diphenylphosphinite, both reactions were verified. Decisive is the molar ratio of P_4 to $X^{\ominus}$: If the molar ratio is 1 : 4 in tetrahydrofuran, the salt **1** forms momentarily and completely at room temperature [eq. (3) ≙ (2), X = PR_2O]. Excess base remains unreacted. Reduction of the amount of base to a level such that two phosphinite ligands are no longer available per P_2 moiety leads to disproportionation of a fraction of the phosphorus into **2a** and Na_3P_7 [(eq. (4) ≙ (1), X = PR_2O, n = 7/3]. At the molar ratio 1 : 2.4, only disproportionation occurs. Addition of still less base gives [e.g., according to eq. (5) ≙ (1), n = 8] as reduction products higher sodium polyphosphides which finally precipitate.

$$P_4 + 4\,NaOPR_2 \longrightarrow 2\,Na_2 \left[\begin{array}{l} R\quad\;\; R \\ O{=}P{-}P{-}P{=}O \\ R\quad\;\; R \\ \updownarrow \\ R\quad\;\; R \\ O{-}P{=}P{-}P{-}O \\ R\quad\;\; R \end{array}\right] \qquad (3)$$

1 : 4

1

$$5\,P_4 + 12\,MOPR_2 \longrightarrow 6\,M \left[\begin{array}{l} R\quad\;\; R \\ O{=}P{-}P{-}P{=}O \\ R\quad\;\; R \\ \updownarrow \\ R\quad\;\; R \\ O{=}P{-}P{=}P{-}O \\ R\quad\;\; R \end{array}\right] + 2\,M_3P_7 \qquad (4)$$

1 : 2.4

2

$$9\,P_4 + 8\,MOPR_2 \longrightarrow 4\,\mathbf{2} + 2\,M_2P_{16} \qquad (5)$$

1 : 0.9

a, M = Na; **b**, M = Li; R = Et, Ph

1a and **2a** differ markedly in their hydrolytic sensitivity: whereas **1a** is decomposed instantaneously by water, **2a** remains stable for several days.

In contrast to sodium phosphinites, lithium phosphinites react, even when present in a large excess, only in the molar ratio 1 : 2.4 according to eq. (4) with disproportionation to afford **2b** and Li_3P_7. The latter compound (just as Na_3P_7) can be identified by comparison of the ^{31}P-NMR spectra with those of authentic material[3b,5]. If the molar ratio P_4 : base is reduced to 1 : 0.9, in addition to **2b** an insoluble polyphosphide is formed; its composition, based on the stoichiometry of eq. (5), is Li_2P_{16}[3c]. Upon use of

even less lithium phosphinite, a part of the white phosphorus remains unreacted.

The structures of the compounds **2** and **1** are established by their characteristic ^{31}P-NMR signals (A_2X and $[AX]_2$ system, resp.) (Table 1); in addition, the structure of

Table 1. ^{31}P-NMR data for compounds **1** and **2** (in THF at room temperature) [a].

1 **2**

2a	Na	Et	77.3	−154.3	395.0		
	Na	Ph	55.6	−116.4	397.7		
2b	Li	Et	79.1	−166.0	402.0		
	Li	Ph	58.8	−127.9	402.5		

[a] At lower temperatures, two isomers of the anion with almost identical ^{31}P-NMR data are observed for each of the compounds **1**.

2b (R = Ph) is confirmed by an X-ray structure analysis[6] (Fig. 1). In **2b** (R = Ph), lithium is not (as, for example, in $LiP(tBu)_2$[7] coordinated to phosphorus, but to the two oxygen atoms of the anion, underscoring the larger contribution of the mesomeric structure with the anionic charge at oxygen. The chelate six-membered ring has a boat conformation (with P1 and lithium out of the P_2O_2 plane). The PPP angle of 95.3(1)° corresponds, in particular, to that in

[Li(tmeda)]$_3P_7$—A Solvated Ion Complex of Trilithium Heptaphosphide**

By *Wolfgang Hönle, Hans Georg von Schnering**, *Alfred Schmidpeter*, and *Günther Burget*

Crystalline solvates of salt-like compounds are intermediates of the transition from the polymeric structure formed by cations and anions to the solution in which solvated and separated ions predominate. The interchange from the structure with highly coordinated M^+ and X^- ions to the solvated ion complex or molecule involves a drastic reorganization. This is neatly exemplified in the case of the lithium phosphide Li_3P_7. The brilliant-yellow, *solvent-free* Li_3P_7[1] forms a highly coordinated structure without any indication of "Li_3P_7" units but with bonds from lithium to all phosphorus atoms. Crystalline Li_3P_7 does not dissolve in toluene, but does so very slowly in ethers, and only slowly so in ethylenediamine to give *colorless* solutions[2]. Solvated Li_3P_7 is also obtained as the *colorless solvate* $Li_3P_7(solv)_3$, however, in reactions in ethers[3–5]. In solution a valence fluctuation is observed in the P_7^{3-} ion[3–5]. The ^{31}P-NMR signals indicate ^{7}Li couplings[3]; hence, solvated Li_3P_7 ionic complexes are also present in solution, but no isolated P_7^{3-} ions, which is significant for the course of the valence fluctuation[6]. Consequently, the determination of the structure of a solvate seemed of utmost importance[7].

The first solvate isolated in crystalline form was [Li(tmeda)]$_3P_7$, formed on reaction of white phosphorus with $LiCH_2PPh_2$(tmeda) (tmeda = tetramethylethylenediamine)[8]. Alkali metal salts of Ph_2PX^- (X = O, NPh) effect a

disproportionation of P_4 in $(XPPh_2)_2P^-$ with P^I as oxidized step and a polyphosphide as reduced step[9]. In the present case ($X=CH_2$) the oxidation product separated as a red oil and could not be identified, while the reduction product $[Li(tmeda)]_3P_7$ remained in solution and could be crystallized. Its ^{31}P-NMR spectrum shows a broad signal ($\delta=-122$, upfield) at room temperature, as in other $Li_3P_7(solv)_3$ solvates (solv = tetrahydrofuran, monoglyme)[3,4]. When solv = ethylenediamine, on the other hand, a sharp singlet with the same chemical shift is observed. This indicates that the fluctuation frequency depends not only on the cation but also on the coordinating solvent.

$[Li(tmeda)]_3P_7$ crystals already effloresce at room temperature, with loss of tmeda (analysis), and do not melt. The loss of tmeda can be monitored mass spectroscopically; it increases steadily with temperature up to 100 °C and, thereafter, very rapidly. The mass spectrum (180 °C, 70 eV) shows signals of high intensity for the ions $tmeda^+$ and P_4^- and, in particular, for fragments related with a—presumably tetrahedral—species $LiP_3(tmeda)^+$. The X-ray structure analysis shows the presence of an isolated, solvated ionic complex $[Li^+(tmeda)]_3P_7^{3-}$ with approximate 3m (C_{3v}) symmetry. The Li atoms are each coordinated in a distorted tetrahedron to two twofold bonded P atoms and the two N atoms of one tmeda molecule (Fig. 1). A particularly important feature is the bridge function of the Li atoms at the heptaphosphane(3) moiety, which apparently is also typical for other cations[1,2] and whose significance in organolithium compounds has recently again been pointed out[10]. The threefold bonded P atoms do not participate in the coordination of the Li atoms, which is typical for solvent-free polyphosphides. The bond lengths (Fig. 1)

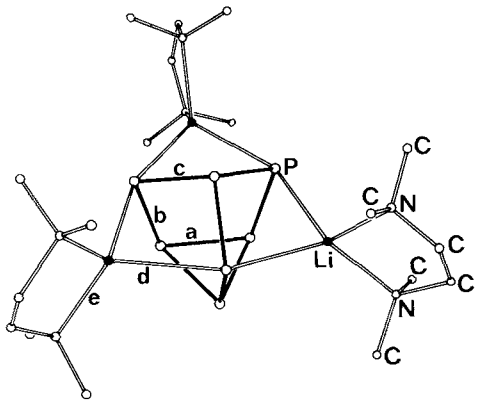

Fig. 1. Structure of the solvated ion complex $[Li(tmeda)]_3P_7$ in the crystal. Mean bond lengths: a = 225.5, b = 215.0, c = 220.4, d = 255.5, e = 207.1 pm.

show, with the sequence a > c > b and the relative height Q* of the polycycle, Q* = h/a = 302 pm/226 pm = 1.34 (h = distance between the apical P atom and the trigonal P_3 base), unequivocally the presence of an ionic P_7^{3-} framework[11]. The Li(tmeda) rings are twisted. The strong anisotropy of the thermal ellipsoids of the atoms in the Li(tmeda) rings can be ascribed to orientational disorder or, possibly also, to dynamic conformational changes.

Novel Double-Layered Annulenes—Models for the Investigation of Successive Electron Transfers**

By *Wolfgang Irmen, Walter Huber, Johann Lex,* and *Klaus Müllen**

The title compounds **1a**—**1c**, whose synthesis and structure elucidation will be described, form a novel type of double-layered molecules. In **1a**—**1c**, perimeter π-systems are linked by internal bridges, instead of by external side arms as, e.g., in phanes[1]. In principle, **1a**—**1c** can exist both in a *syn*(**A**) and an *anti*(**B**) conformation; the distance between layers can be controlled by the length of the alkanediyl bridge. The compounds **1a**—**1c** of this type, which are constructed from two separate electroactive groups, thus seem to be ideal models for successive electron transfers[2]. The characterization of the redox sequences from the monoanion up to the tetraanion show that the intramolecular through-space interaction between the electrophoric ring systems differs significantly for geometric reasons.

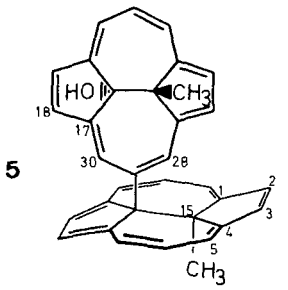
$\mathbf{1c}^{\ominus\ominus}$	0.152(4H)	0.098(4H)	0.482(2H)	0.018(3H)		

[a] −0.98 (H-γ); −0.49 (H-δ). [b] 0.1 to −0.71 (H-γ, H-δ). [c] −0.51 (H-γ); 0.22 (H-δ). [d] 4.39 (H-γ); 2.38 (H-δ).

Reductive methylation of **2** with dimethylsulfate in liquid ammonia (Li, −78°C) affords the monomethyl derivative **3b** [m.p. 125°C, red needles; see Table 1]. **4** can be smoothly generated by deprotonation of **3b** [n-butyllithium, tetrahydrofuran (THF), 0°C]. The resonance of C-16 at $\delta = 103.0$ (sp^2-hybridized C-atom with strong charge-induced shielding) indicates the existence of the highest π-charge density in this position and explains the regioselective formation of **3a** in the second alkylation of **4**[5].

The system **4** has proven especially useful as central intermediate for further syntheses. Trapping of **4** with oxygen affords equal amounts of the alcohol **3c** and the coupling product **5**[6]. On reaction of **4** with 1-bromoalkanes or 1,n-dibromoalkanes, annulenes such as **3d**—**3f** or **3g**—**3j**, respectively, containing differently substituted bridges are formed. When a solution of **4** (THF, 0°C) is treated with an equal amount of **3h**—**3j** (THF) as alkylating agent under strict exclusion of air, the "double layers" of bridged annulenes **1a**—**1c** are formed in good yields (95, 86, and 95%, respectively). In the analogous reaction of **4** with the bromoethyl derivative **3g** the desired coupling product is not formed.



5

The electron absorption spectrum of **1c**[7]—with "decoupled" subunits—corresponds very closely to that of the model system **3a**; in **1a**, the extinctions are markedly smaller than in **3a**. The influence exerted by the superposed magnetic anisotropy of the two strongly diatropic annulene moieties in **1a**—**1c** on the bridge protons is verified by the resonance of these nuclei at extremely high field (see Table 1). Very informative here is a comparison with the chemical shifts of the "individual systems", e.g. **3d** and **3f**. Using the resonances of the bridge protons as probes, it was possible to measure experimentally the secondary magnetic fields due to ring currents.

Preliminary results of an X-ray structure analysis of **1b** show[8] that an *anti*-orientation of the annulene moieties with respect to the alkanediyl bridge (with all-*trans* conformation) is preferred in the crystal (cf. **B**).

The radical anions of **1a**—**1c** are generated by electrochemical reduction [dimethoxyethane (DME), $[N(C_4H_9)_4]ClO_4$] and by reduction with potassium in DME/hexamethylphosphoric acid triamide (HMPT) or in methyltetrahydrofuran (MTHF). They could be characterized by ESR and ENDOR spectroscopy; the radical anion of the [14]annulene **3a**[9] serves as reference system (see Table 1).

The magnitude and multiplicity of the ESR coupling constants derived from the primary spectrum of $\mathbf{1a}^{\ominus\ominus}$ prove that the spin density is delocalized over both annulene moieties. This bonding situation, however, necessitates a certain minimum separation of the π-systems: The radical anion $\mathbf{1c}^{\ominus\ominus}$ forms a structure with localization of the spin density within *one* π-fragment under all experimental conditions. The analogue $\mathbf{1b}^{\ominus\ominus}$ assumes a medium position, for its primary ESR spectrum can only be explained in terms of the concomitant existence of a spin-delocalized (70%) radical anion and a spin localized radical anion. Both in $\mathbf{1a}^{\ominus\ominus}$[10] as well as in $\mathbf{1b}^{\ominus\ominus}$ the relative proportion of the spin localized species can be increased by further reduction, i.e. by increasing the radical concentration. The same can be achieved with MTHF as solvent, which enhances the tendency to tight (contact) ion pairs, and thus impairs intramolecular electron transfer[2]. A transformation of the alternative radical anion struc-

tures[11] cannot be observed in the accessible temperature range (−90 to +20 °C).

Further reduction (K/DME/HMPT) of **1a**$^{\ominus\ominus}$ and **1b**$^{\ominus\ominus}$ brings about a decrease in the intensity of the ESR signals. The glassy, rigid solutions (−160 °C) give the typical (ESR-) splitting pattern of triplet radicals **1a**$^{2\ominus}$ and **1b**$^{2\ominus}$. From the zero field parameters [D = 6.75 mT (**1a**$^{2\ominus}$); 4.38 mT (**1b**$^{2\ominus}$)], the average separation of the electrons in the triplet can be estimated to be 7.4 and 8.6 Å, respectively[12]. These values would indicate an all-*trans* conformation of the alkanediyl chain, which guarantees the largest possible separation of the electrons in the individual π-fragments.

After longer reduction times, all compounds show the same ESR spectrum (in the case of **1a** and **1b** after the appearance of the triplet radical), which resembles the spectrum of a spin-localized monoanion, and is to be assigned to the respective radical trianion.

The end products of the reduction are, in all cases, the diamagnetic tetraanions (potassium salts), in whose ^{1}H-NMR spectroscopic description (see Table 1) that of the "monomeric" dianion **3d**$^{2\ominus}$ (2 K$^{\oplus}$) should be included:

- the conversion of the [14]annulene **3d** into a 16π-dianion generates a strongly paratropic compound, recognizable by the high-field resonance of the ring protons and the extreme down-field resonance of the bridge protons[13];
- the observation of corresponding signal positions, e.g., for **1b**$^{4\ominus}$ leads to the conclusion that the tetraanion is made up of two paratropic 16π-moieties. The down-field shift of the signal of the methylene protons H-α during the transition to the tetraanion is $\Delta\delta = 22.4$;
- according to the ^{1}H-NMR spectrum, the tetraanion **1b**$^{4\ominus}$ is present in two structural forms, **1b**$^{4\ominus}$**A** and **1b**$^{4\ominus}$**B** (6 : 5), which do not transform from one into the other even at room temperature. The ^{1}H-NMR chemical shifts of **1b**$^{4\ominus}$**B** are much more similar to those of **3d**$^{2\ominus}$ than those of **1b**$^{4\ominus}$**A** [shifts of the signals of the methyl protons: $\Delta\delta = 17.8$ (**1b**$^{4\ominus}$**A**), 16.2 (**1b**$^{4\ominus}$**B**), 16.5 (**3d**$^{2\ominus}$); center of gravity of the signals of the protons in the ion: $\delta = 0.51$ (**1b**$^{4\ominus}$**A**), 0.16 (**1b**$^{4\ominus}$**B**), −0.08 (**3d**$^{2\ominus}$)]. In **1b**$^{4\ominus}$**A**, both the bridge protons as well as the ring protons are additionally exposed to the deshielding effect of the "second" annulene system, whereas in **1b**$^{4\ominus}$**B** two "independent" perimeters appear to exist. It might therefore be assumed that the two ion-pair structures of the tetraanion differ in the conformation of the 1,4-disubstituted butane system.

Since the alkylation of the ionic intermediates **2**$^{2\ominus}$ and **4** is also suitable for the synthesis of oligomeric π-systems with more than two layers, redox studies on electroactive "polylayers" should be possible.

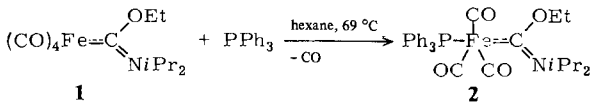
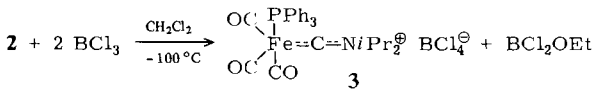
[(CO)$_3$PPh$_3$FeCN*i*Pr$_2$]$^{\oplus}$, a Novel Stable Carbyneiron-Complex Cation**

By *Ernst Otto Fischer**, *Johannes Schneider*, and *Dietmar Neugebauer*

Carbyne-transition metal complexes can be prepared from carbene complexes and halides of main group 3 elements[1]. If the iron is linked only to the carbene ligand and CO ligands in the educt this method fails. We therefore replaced the carbonyl group *trans* to the carbene ligand in the carbene complex tetracarbonyl[diisopropylamino(ethoxy)carbene]iron **1**[2] by a triphenylphosphane group and so obtained the stable compound **2**, which could be converted by reaction with boron trichloride into **3**. Tricarbonyl(diisopropylaminocarbyne)triphenylphosphaneiron tetrachloroborate **3** is a novel, isolable compound containing a complex cation with an iron-carbon triple bond[3]. A neutral *trans*-carbynehalogeno complex is not formed in this case, apparently because of the occupation of the *trans*-position by triphenylphosphane.



1 **2**



3

In the solid state, complexes **2** and **3** are briefly stable towards air at room temperature. **2** is only sparingly soluble in pentane, moderately soluble in diethyl ether, and readily soluble in dichloromethane; it crystallizes from pentane/dichloromethane (1 : 1) as a bright yellow powder. **3** is soluble only in polar solvents such as dichlorome-

thane; it crystallizes in yellow-orange rhombs from diethyl ether/dichloromethane (1 : 1).

The spectroscopic data of **2** and **3** are listed in Table 1; Figure 1 shows the structure of the cation **3** (without coordinated dichloromethane).

Table 1. Spectroscopic data of **2** (top) and **3** (bottom).

IR (ν(CO), pentane): 1886 (m), 1878 (m) cm^{-1} [4, 5]

^{1}H-NMR ([D$_6$]acetone, rel. CD_3COCD_2H): $\delta = 7.43-7.72$ (15H, m; PPh_3), 6.19, 3.87 (each 1H, sept; $NCH(CH_3)_2$, *E/Z* isomerism), 4.79 (2H, q; OCH_2CH_3), 1.21–1.64 (15H, m; OCH_2CH_3, $NCH(CH_3)_2$, *E/Z* isomerism)

^{13}C-NMR (CD_2Cl_2, −20°C, rel. CD_2Cl_2): $\delta = 241.37$ (C(carbene), $^2J(CP) = 14.64$ Hz), 217.49 (C(CO), $^2J(CP) = 29.30$ Hz), 138.39, 135.47, 133.52, 132.87, 129.79, 128.49, 127.84 (C(PPh_3), 71.80 (OCH_2CH_3), 57.18, 50.03 ($NCH(CH_3)_2$, *E/Z* isomerism), 21.93, 19.65 ($NCH(CH_3)_2$, *E/Z* isomerism), 15.27 (OCH_2CH_3)

^{31}P-NMR ([D$_6$]acetone, rel. H_3PO_4): $\delta = 85.8$

MS (EI source): *m/z* 559 ($M^{\oplus}$), 531 ($M^{\oplus} - CO$), 475 ($M^{\oplus} - 3CO$)

IR (ν(CO), CH_2Cl_2): 2081 (vs), 2031 (s), 2009 (vs) cm^{-1} [4]

^{13}C-NMR (CD_2Cl_2, −20°C, rel. CD_2Cl_2): $\delta = 264.65$ (C10, $^2J(CP) = 43.95$ Hz), 203.78 C1,2,3, $^2J(CP) = 24.41$ Hz), 133.14, 132.49, 132.16, 129.56, 128.74 (C11,21,31), 22.14, 21.16 (C41,42,51,52, conformational isomerism). Signals of C4,5 presumably under the solvent signal

^{31}P-NMR (CD_2Cl_2, rel. H_3PO_4): $\delta = 57.3$

MS (FD source): *m/z* 514 ($M^{\oplus} - BCl_4$)

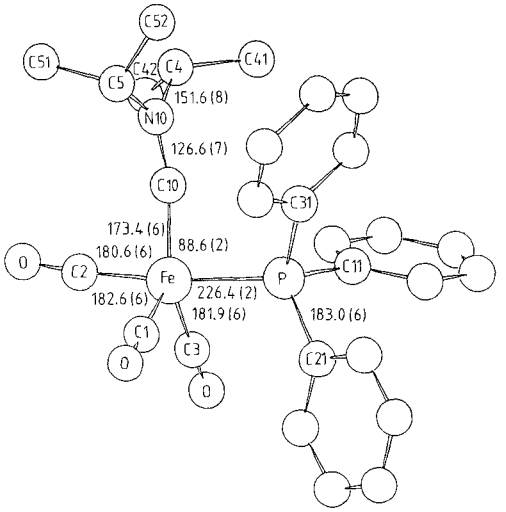

Fig. 1. Structure of the cation of **3** in the crystal (coordinated dichloromethane omitted) with important bond lengths [pm] and one angle [°].

The X-ray structure analysis[6] shows that the iron in **3** is coordinated in a distorted trigonal-bipyramid with the triphenylphosphane ligand and one carbonyl ligand in the apical positions. That is, the carbyne ligand is not in the *trans*-position to the triphenylphosphane group. The iron-carbyne carbon bond length (173.4(6) pm) is the shortest iron-carbon bond length so far observed, and is 28 pm shorter than the comparable iron-carbene carbon bond length in **1**[2]. The carbyne group is inclined towards the phosphane ligand, while the equatorial carbonyl groups are inclined away from it. The Fe–P bond length is 226.4(2) pm (for comparison, in carbynechromium complexes Cr–P 246.4 pm[7]); the Fe–C (carbonyl) bond length in the case of the axial CO groups (180.6(6) pm) is shorter than in the case of the equatorial groups (Fe–C1 182.6(6), Fe–C3 181.9(6) pm).

Experimental:

All operations were carried out under N_2 with anhydrous, oxygen-free solvents. **2**: A solution of **1** (8 g, 24.6 mmol) [2] in *n*-hexane (500 mL) was treated with 5.15 g (19.6 mmol) triphenylphosphane and the mixture heated under reflux for 5 h. On completion of reaction, **2** precipitated. The solvent was removed in a vacuum and the residue chromatographed on silica gel. After separation from unreacted carbene complex with pentane, **2** could be eluted with CH_2Cl_2. After removal of solvent, **2** was recrystallized from pentane/CH_2Cl_2; yield 8.11 g (59%), yellow crystals, m.p. 110–115°C (decomp.).—**3**: A solution of **2** (4.88 g, 8.7 mmol) in CH_2Cl_2 (100 mL) was treated at −100°C with 2 mL (23.0 mmol) BCl_3. The originally dark green solution was then allowed to warm within 3 h to −25°C, evaporated to 30 mL, and subsequently treated with precooled diethyl ether. **3** precipitated as yellow flocs. Analytically pure **3** was obtained as yellow-orange rhombs by repeated recrystallization from Et_2O/CH_2Cl_2 (1 : 1); yield 1.63 g (28%), m.p. 110–118°C (decomp.).

Macrobicyclic Polyethers as V-Shaped Hosts for *cis*-Diammine-Transition Metal Complexes**

By *David R. Alston, Alexandra M. Z. Slawin, J. Fraser Stoddart**, and *David J. Williams*

In the supramolecular structures of the 1 : 1 adducts formed[1] between dibenzo-crown ethers of the general type DB3nCn (n = 8–10) and diammine-transition metal complexes such as $[Pt(bipy)(NH_3)_2][PF_6]_2$ {bipy = 2,2′-bipyridyl} and $[RhL(NH_3)_2][PF_6]$ {L = 1,5-cyclooctadiene (cod) or norbornadiene (nbd)}, X-ray analyses have shown that, without exception, the two NH_3 ligands straddle *one* of the polyether chains. This arrangement fails to make full use of the H bonding potential of these ligands. We have, therefore, designed host molecules (**1**) incorporating a *third* polyether chain between the *two* benzene rings. This constitutional modification produces *two* 20- or 23-membered

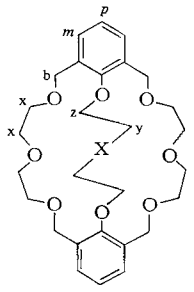
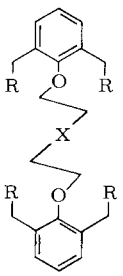
crown ether rings oriented side-by-side in an appropriate manner to facilitate H bonding with *both* of the NH_3 ligands.



1



2, R = H
3, R = Br

a, X = O; **b**, X = OCH_2CH_2O; **c**, X = O–*o*-C_6H_4O; **d**, X = $OCMe_2CMe_2O$

Hosts[2] **1a**—**1d** which fulfill this constitutional criterion, have been synthesized from 2,6-dimethylphenol[3]. ^{1}H-NMR Chemical shift data reveal (Table 1) **1a**—**1d** form stable 1:1 adducts with $[Rh(cod)(NH_3)_2][PF_6]$ in CD_2Cl_2 solutions. Upfield shifts of the guest protons are accompanied by downfield shifts for the protons in the bridging aromatic rings of the hosts. Both **1a** and **1b** are conformationally mobile[4] on the ^{1}H-NMR time scale at room temperature as a result of rapid passage of the central polyether chain (seven atoms in **1a** and ten atoms in **1b**) through the middle of the (24-membered) macroring. This inversion process can be slowed down, as evidenced by the AB system ($\Delta\nu_{AB}=127$ Hz, $J_{AB}=10$ Hz) observed[4] for the benzylic-methylene protons in **1b** below the coalescence temperature ($T_c=-50$°C) and the line broadening observed[4] for the same protons in **1a** below −85°C (T_c=*ca.* −105°C). The rate constant (k_c) of 287 s^{-1} obtained[4] at the coalescence temperatures afforded $\Delta G_c^{\neq}$ values of *ca.* 7.8 and 10.4 kcal mol^{-1} for **1a** and **1b**, respectively. In the presence of 1 mol equiv of $[Rh(cod)(NH_3)_2][PF_6]$, the coalescence temperatures of the AB systems for the same probe protons in **1a** ($\Delta\nu_{AB}=85$ Hz, $J_{AB}=9.8$ Hz, $T_c=-48$°C) and **1b** ($\Delta\nu_{AB}=100$ Hz, $J_{AB}=9$ Hz, $T_c=12$°C) are much higher, corresponding to $k_c=196$ s^{-1} ($\Delta G_c^{\neq}=10.7$ kcal mol^{-1}) and to $k_c=228$ s^{-1} ($\Delta G_c^{\neq}=13.6$ kcal mol^{-1}), respectively. The $\Delta\Delta G_c^{\neq}$ values of *ca.* 2.9 and 3.2 kcal mol^{-1} for **1a** and **1b**, respectively, in the presence and absence of $[Rh(cod)(NH_3)_2][PF_6]$, indicate that these hosts form 1:1 adducts of comparable stabilities. This suggests that the macroring and phenolic oxygen atoms in the host are major sources of binding in these adducts, *i.e.* the constitution of the middle portion of the central polyether chain is relatively unimportant in this respect. This view is supported by (i) chemical shift data (Table 1) obtained on adduct formation by the more conformationally rigid[4] hosts **1c** and **1d**—the shifts compare favorably with those observed for **1a** and **1b**— and (ii) X-ray analyses[5] of the adducts with **1b** and **1c** (Fig. 1 and 2, resp.), which confirm the elegant structural suitability of these large bicyclic systems with 24-membered macrorings for optimum H bonding with *cis*-NH_3 ligands. Moreover, there is an obvious redundancy in the middle *two* oxygen atoms of the central polyether chains in *both* hosts. With one exception, namely N1···O40 in the **1c**-adduct (where N···O is 3.43 Å), the distances of the nitrogen atoms to the middle *two* oxygen atoms are all greater than 3.6 Å. The polyether components of the macrorings in the *two* hosts adopt very similar conformations (i.e. *a ag*$^-$*a ag*$^+$*a a*) from C1 to C9 and from C15 to C23, ensuring the encirclement of *both* *cis*-NH_3 ligands in the guest (cf. Fig. 1 and 2). Although alternating *gauche* helicities (i.e. *ag*$^-$*a ag*$^+$*a ag*$^-$*a* from C30 to C39) also characterize the C–C bonds in the central polyether chain of the **1b**-adduct, the enforced *syn*-rela-

Table 1. Selected ^{1}H-NMR data [a] for the 1:1 adducts of $[Rh(cod)(NH_3)_2][PF_6]$ and **1a**—**1d** in CD_2Cl_2 (δ values, TMS as int. standard).

[a] The spectra were recorded at room temperature on a 220-MHz spectrometer (Perkin Elmer R34). [b] The values in brackets indicate the extent to which signals of the guest protons (H^e=equatorial methylene proton; H^a=axial methylene proton; H^o=olefinic proton) are shifted relative to the corresponding signals in $[Rh(cod)(NH_3)_2\cdot 18C6][PF_6]$. [c] The values in brackets indicate the extent to which the signals of the bridging aromatic ring protons are shifted relative to the corresponding signals in the free hosts. [d] Signal obscured by signals for OCH_2 protons.

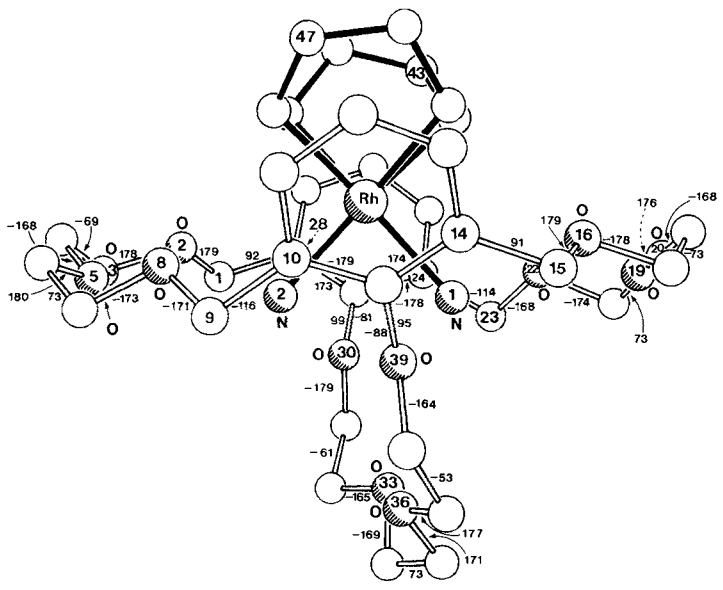

Fig. 1. Structure of $[Rh(cod)(NH_3)_2\cdot$ **1b**$][PF_6][CH_2Cl_2]$ in the crystal. Crystal data: monoclinic, $a=17.406(2)$, $b=14.768(2)$, $c=19.407(2)$ Å, $\beta=102.82(1)$°, $V=4865$ Å^3, space group, $P2_1/c$, $Z=4$, $\rho_c=1.42$ g cm^{-3}, μCu-$K_\alpha=49$ cm^{-1}, 4123 independent reflections with [$|F_o|>3\sigma(|F_o|)$, $\theta\leq 50$°], $R=0.063$, $R_w=0.069$. Torsional angles [°] associated with the polyether chains are shown beside the relevant bonds. *Both* NH_3 ligands have *two* distinct orientations. Distances for N1 to O16, O19, O22, and O39: 3.19, 3.05, 3.17, and 3.04 Å, respectively. Those for N2 to O2, O5, O8, and O30: 3.17, 3.07, 3.20, and 3.01 Å, respectively. Atoms N1 and N2 are inserted 0.56 and 0.53 Å, respectively, below the mean plane of the six peripheral oxygen atoms. Cleft angle between the mean planes of the aromatic rings is 63°. Separations between these mean planes and the nearest cod hydrogen atoms: [C10/14···H°(47)] 3.20, [C24/28···H$_c$(43)] 2.98 Å.

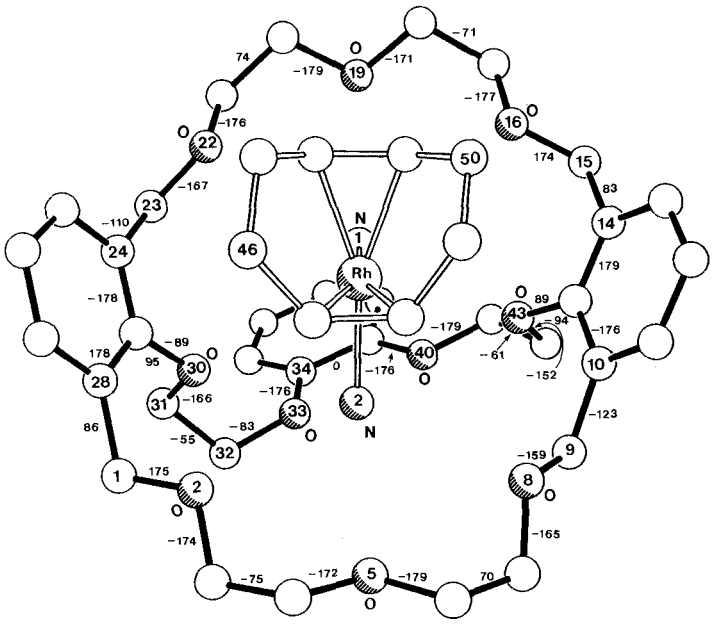

Fig. 2. Structure of $[Rh(cod)(NH_3)_2 \cdot \mathbf{1c}][PF_6][CH_2Cl_2]$ in the crystal. Crystal data: triclinic $a = 12.984(2)$, $b = 13.674(4)$, $c = 13.973(2)$ Å, $\alpha = 89.02(2)$, $\beta = 84.13(1)$, $\gamma = 86.05(2)°$, $V = 2462$ Å, space group $P\bar{1}$, $Z = 2$, $\rho_c = 1.47$ g cm^{-3}, 4400 independent reflections with $[|F_0| > 3\sigma(|F_0|)$, $\theta \leq 50°]$, $R = 0.042$, $R_w = 0.046$. Torsional angles [°] associated with the polyether chains are shown beside the relevant bonds. *One* NH_3 ligand has *two* distinct orientations. Distances for N1 to O16, O19, O22, and O43: 3.26, 3.04, 3.05, and 3.00 Å, respectively. Those for N2 to O2, O5, O8, and O30: 3.13, 3.08, 3.12, and 3.07 Å, respectively. Atoms N1 and N2 are inserted 0.62 and 0.63 Å, respectively, below the mean plane of the six peripheral oxygen atoms. Cleft angle between the mean planes of the aromatic rings is 68°. Separation between these planes and the nearest cod hydrogen atoms: [C10/14···H^c(50)] 3.13; [C24/28···H^c(46)] 3.24.

tionship of the catechol oxygen atoms, O33 and O40, in the **1c**-adduct is accommodated by a substantial distortion of the C31–C32–O33–C34 torsional angle.

The X-ray structure analysis[5] of free **1b** (Fig. 3) reveals the extent to which the polyether chains have to reorganize themselves conformationally in order to bind the guest.

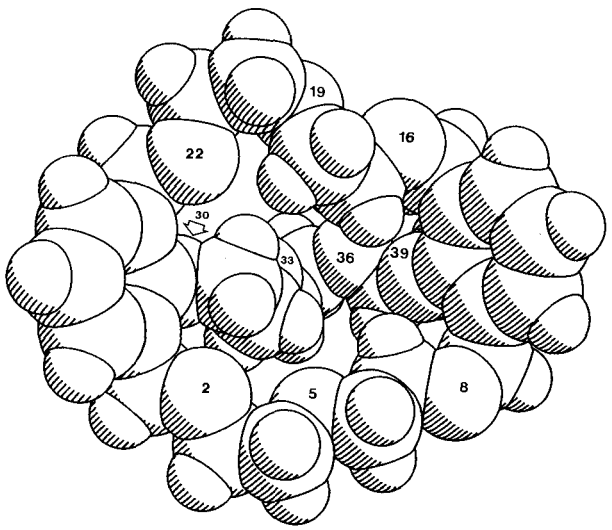

Fig. 3. Space-filling representation of the structure of **1b** with the oxygen atoms numbered. Crystal data: orthorhombic, $a = 12.997(3)$, $b = 14.139(2)$, $c = 16.072(2)$ Å, $V = 2953$ Å^3, space group $P2_12_12_1$, $Z = 4$, $\rho_c = 1.27$ g cm^{-3}, 2068 independent reflections with $[|F_0| > 3\sigma(|F_0|)$, $\theta \leq 58°]$, $R = 0.046$, $R_w = 0.049$. Cleft angle between the mean planes of the aromatic rings is 76°.

With its V-shaped conformation, free **1b** has structural characteristics similar to those of bound **1b**. However, it is noticeable that *four* of the oxygen atoms (O8, O16, O19, and O30) are no longer directed into the cavity and instead *five* methylene groups (on C7, C17, C18, C31, and C32) are oriented inwards. Although these particular conformational changes reflect the inability of **1b** to sustain an organized cavity in the absence of a guest, the host and its analogues (**1a**, **1c**, **1d**) clearly offer a much improved molecular receptor design for transition metal *cis*-diammines over the simpler DB3nCn ethers[1].

Int. Ed. Engl. 23* (1984) 235.

[2] Since the first report (F. Vögtle, E. Weber, *Angew. Chem. 86* (1974) 126; *Angew. Chem. Int. Ed. Engl. 13* (1974) 149) of the use of 2-substituted-1,3-xylylene units in macrocyclic hosts, they have found wide application: see, for example, M. Newcomh, S. S. Moore, D. J. Cram, *J. Am. Chem. Soc. 99* (1977) 6405; M. van der Leij, H. J. Oosternik, R. H. Hall, D. N. Reinhoudt, *Tetrahedron 37* (1981) 3661; M. A. McKervey, T. O'Connor, *J. Chem. Soc. Chem. Commun. 1982*, 655.

[3] A strategy similar to that adopted (W. D. Curtis, J. F. Stoddart, G. H. Jones, *J. Chem. Soc. Perkin Trans. I 1977*, 785) in the preparation of 1,6,13,18,25,30-hexaoxa[6.6.6](1,3,5)cyclophane from phloroglucinol was employed. Experimental: Reactions (NaH, THF) of 2,6-dimethylphenol with the bistosylates (J. Dale, P. O. Kristiansen, *Acta Chem. Scand. 26* (1972) 1471) of diethylene and triethylene glycols, and with the bistosylates (L. C. Hodgkinson, I. O. Sutherland, *J. Chem. Soc. Perkin Trans. I 1979*, 1908 and N. Ando, S. Ohi, Y. Yamamoto, J. Oda, Y. Inouye, *Bull. Inst. Chem. Res., Kyoto Univ. 58* (1980) 293, respectively) of the bis-2-hydroxyethyl ethers derived from catechol and pinacol, afforded the acyclic polyethers **2a** (88%, m.p. 28—30°C), **2b** (67%, m.p. 37—39°C), **2c** (18%, m.p. 102—103°C), and **2d** (68%, m.p. 77—77.5°C), respectively. Photochemical bromination (NBS, CCl_4) of **2a**—**2d** gave the corresponding tetrabromides **3a** (10%, m.p. 125—126°C), **3b** (28%, m.p. 116—117°C), **3c** (27%, m.p. 121—123°C), and **3d** (9%, m.p. 116—117°C). Reactions (NaH, THF, high dil.) of **3a**—**3d** with diethylene glycol in the molar ratio 1:2 afforded, **1a** [27%, oil, ^{1}H-NMR (CD_2Cl_2): $\delta = 3.55$—3.73 (16 H^x, m), 3.88 (4 H^y, t), 4.16 (4 H^z, t), 4.52 (8 H^b, s), 7.01 (2 H^p, t), 7.25 (4 H^m, t)]: **1b** [21%, m.p. 113—115°C, single crystals suitable for X-ray (cf. Fig. 3) from EtOAc-light petroleum, ^{1}H-NMR (CD_2Cl_2): $\delta = 3.56$ (16 H^x, bs), 3.77 (4 H, s, OCH_2CH_2O), 3.91 (4 H^y, t), 4.04 (4 H^z, t), 4.52 (8 H^b, s), 7.00 (2 H^p, t), 7.25 (4 H^m, d)]; **1c** [31%, m.p. 122—124°C, ^{1}H-NMR (CD_2Cl_2): $\delta = 3.55$ (16 H^x, bs), 4.25 and 4.85 (8 H^b, AB system), 4.25—4.42 (4 H^y + 4 H^z, m), 6.99—7.16 (2 H^p + C_6H_4, m), 7.28 (4 H^m, d)]; **1d** [45%, m.p. 123—124°C, ^{1}H-NMR (CD_2Cl_2): $\delta = 1.30$ (12 H, s, CH_3), 3.58 (16 H^x, bs), 3.96 (4 H^y + 4 H^z, s), 4.24 and 4.80 (8 H^b, AB system), 7.02 (2 H^p, t), 7.28 (4 H^m, d). The crystalline **1b**- and **1c**-adducts, m.p. 155—157°C and 136—139°C, respectively, were obtained by layering Et_2O on top of CH_2Cl_2 solutions (1:1 stoichiometries). All new compounds and crystalline adducts gave satisfactory elemental analyses and spectroscopic data.

[4] The benzylic methylene protons H^b of the hosts **1a** and **1b** appear as singlets in CD_2Cl_2 at room temperature, whereas those of the hosts **1c** and **1d** gave AB systems. In both cases, the AB systems showed no signs of coalescence to singlets when $Cl_2C{=}CCl_2$ solutions of **1c** and **1d** were heated up to +120°C. Values for k_c were calculated using the approximation

$$k_c = \pi[(\nu_A - \nu_B)^2 + 6J_{AB}^2]^{1/2}/(2)^{1/2}.$$

For **1a**, where $\Delta\nu_{AB}$ and J_{AB} were not accessible in CD_2Cl_2, these parameters and hence k_c were assumed to be similar to those obtained for **1b**. In fact the $\Delta G_c^{\ddagger}$ value quoted for **1a** remains almost unchanged over a ±25 Hz uncertainty range in $\Delta\nu_{AB}$.

[5] Data were measured on a Nicolet R3m diffractometer using the ω-scan routine with graphite-monochromated $Cu_{K\alpha}$ radiation. The data for the two adducts were corrected for absorption. The structures of these adducts were solved by the heavy atom method and that of the free crown **1b** by direct methods. All three structures were refined anisotropically. Further details of the crystal structure investigations can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW. Crown Ether Complexes of Phosphonium Salts—The X-Ray Structure Analysis of $[(Ph_3PMe)_2 \cdot [18]Crown\text{-}6][PF_6]_2$**

By *Billy L. Allwood, Howard M. Colquhoun, John Crosby, David A. Pears, J. Fraser Stoddart**, and *David J. Williams*

The acidity of α-CH groups in alkylphosphonium cations, which has long been recognized and which forms the basis of the phosphonium ylide chemistry of *Wittig*[1], suggested to us that such cations[2] might form discrete complexes with crown ethers through C–H···O hydrogen bonding. Moreover, it has been shown[3–6] that certain neutral molecules such as $MeNO_2$, MeCN, and Me_2SO_2, $NCCH_2CN$, which also contain polar C–H bonds, do indeed bind to [18]crown-6 (18C6) *via* C–H···O interactions.

Here, we report on the ability[7] of $[Ph_3PMe][PF_6]$ to form a crystalline complex with 18C6 and on the X-ray crystal structure (Fig. 1 and 2) of this complex[8] with its many interesting and unusual features. The two $[Ph_3PMe]^{\oplus}$ ions lie propeller-like on a common 3-fold axis with the axial symmetry coincident with the P–Me···Me′–P′ direction, and the 18C6 host with its all-*gauche* conformation is positioned about a 3-fold inversion center. As a whole, the 2:1 complex has very high crystallographic $\bar{3}$ (S_6) symmetry[9]. All methyl H atoms are involved in discrete H bonds to single O atoms. The C–H···O bond distances of 3.600 Å are exceptionally long (H···O distance = 2.67 Å). The most significant feature of the H bonding is that it is directed to the face of the crown furthest away from the bound substrate, i.e. each $[Ph_3PMe]^{\oplus}$ ion H bonds, respectively, to the *further* triangle of O atoms. Although this disposition of H bonding, involving the so-called[10] nesting arrangement, has been reported previously[11] for the 1:1 crystalline complex formed between $[H_2NNH_3][ClO_4]$ and 18C6, this is the first occasion, to our knowledge, where *both* guests in a 2:1 complex with 18C6 adopt nesting positions rather than so-called[10] perching arrangements[12]. An interesting minor, and not necessarily statistically significant feature of this unexpected H bonding pattern is the contraction of the Me group H–C–H angles. These are reduced[13] from normal tetrahedral values to 102°, thus allowing the H atoms to penetrate more deeply into the 18C6 host without bringing the C atoms of the Me and Me′ groups in the bound guests unacceptably close together (C(Me)···C(Me′) = 4.10 Å). A further repercussion of the nesting geometries of the twin guests is an unusual almost perpendicular approach of the C–O and H–O vectors to the associated COC planes ($\theta_C = 78°$; $\theta_H = 82°$); by the same token, the *nearer* triangles of oxygen atoms are oriented ($\theta_C = 6°$, $\theta_P = 14°$) towards the positively charged guest cations with C(Me,Me′)···O = 3.36 Å and P,P′···O = 4.6 Å, thus probably conferring some electrostatic stabilization upon the 2:1 complex.

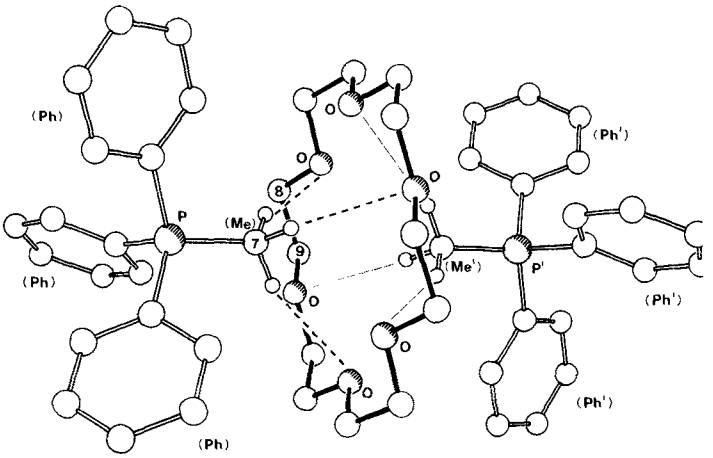

Fig. 1. Structure of $[(Ph_3PMe)_2 \cdot 18C6][PF_6]_2$ in the crystal. Bond lengths [Å] in host: C8-C9 1.495(5), C8-O 1.419(4), C(9)-O 1.413(4). Bond angles [°] in host: CCO 108.9(3), 109.7(3), COC 112.4(3). Torsional angles [°] in host: |CCOC| 179.6(3), 178.5(3), |OCCO| 66.2(5). Bond lengths [Å] in guest: P-C(Ph) 1.796(3), P-C(Me) 1.779(6), C(Me)-H 0.97(3). Bond angles [°] in guest: C(Me)-P-C(Ph) 109.8(1), P-C(Me)-H 116(3), H-C(Me)-H 102(3). C-H···O bond distance 3.600 Å. C-H···O bond angle 163°.—Distance [Å] of C(Me) to mean plane of the (a) near and (b) far triangles of O atoms 1.841 and 2.258, respectively.

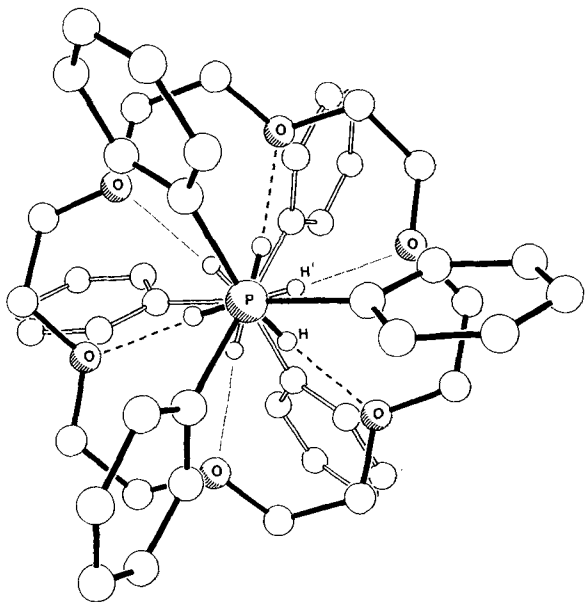

Fig. 2. View of $[(Ph_3PMe)_2 \cdot 18C6][PF_6]_2$ along the C_3 axis. The bonds in the distant guest cation are open.

The ^{1}H-NMR spectrum of $[Ph_3PMe][PF_6]$ in CD_2Cl_2 is identical (the Me doublet appears at $\delta = 2.77$) with that observed[7] for the 2:1 complex. Although this observation could be interpreted as evidence for marked dissociation of the complex in CD_2Cl_2 solution, it is revealing that, when the ^{1}H-NMR spectra of $[Ph_3PMe][PF_6]$, free and in the presence of 1 mol equiv of 18C6 are recorded in CD_2Cl_2–C_6D_6 (1:1), the methyl doublet resonates at $\delta = 2.45$ and 2.42, respectively. Moreover, addition of another molar equivalent of 18C6 causes the methyl doublet to move to even higher field ($\delta = 2.38$) indicating indeed

that binding is weak. The upfield shift of the methyl signal on complexation is in marked contrast[14] to the downfield shifts characteristic of most H bonded systems. However, this shift may reflect slight changes induced in the relative orientations of the phenyl and methyl groups by the approach of the crown ether to the guest cation. Under such circumstances, intramolecular aromatic ring current effects will probably influence the observed chemical shift of the methyl group in the $[Ph_3PMe]^{\oplus}$ cation.

[6] A. Elbasyouny, H. J. Brügge, K. von Deuten, M. Dickel, A. Knöchel, K. U. Koch, J. Kopf, D. Melzer, G. Rudolph, *J. Am. Chem. Soc. 105* (1983) 6568.

[7] Experimental: $[(Ph_3PMe)_2 \cdot 18C6][PF_6]_2$: $[Ph_3PMe][PF_6]$ (64 mg, 0.151 mmol) and 18C6 (20 mg, 0.075 mmol) were dissolved in the minimum volume of warm MeOH; long needle-shaped crystals, suitable for X-ray investigation, were obtained by vapor diffusion using light petroleum (P. G. Jones, *Chem. Brit. 17* (1981) 222). After 16 h, the crystals were filtered off, washed with Et_2O, and dried. Yield 62 mg (75%); m.p. 141–143 °C; ^{1}H-NMR (CD_2Cl_2): $\delta = 2.77$ (6H, d, $J_{PH} = 12$ Hz, Me), 3.59 (24H, s, OCH_2), 7.55–7.94 (30H, m, Ph).

[8] The complex is rhombohedral, $a = 11.592(3)$ Å, $\gamma = 71.39(2)°$, $U = 1357$ Å, space group $R\bar{3}$, $Z = 1$, $\rho_c = 1.36$ g cm^{-3}. Data were measured on a Nicolet R3m diffractometer with $Cu_{K\alpha}$ radiation (graphite monochromated) and using ω-scans. The structure was solved by the heavy atom method. The unique methyl hydrogen atom was clearly located in a ΔF map and refined isotropically; the remaining non-hydrogen atoms were refined anisotropically to give $R = 0.064$ ($R_w = 0.079$) for 1192 independent observed reflections [$\theta \leq 58°$, $|F_o| > 3\sigma(|F_o|)$]. Further details of the crystal structure investigation can be obtained from the Director of Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW. Any request should be accompanied by the full literature citation for this communication.

[9] The $PF_6^{\ominus}$ ion lies on a crystallographic 3-fold axis and is involved in only one short intermolecular contact (3.25 Å) between one of the F atoms and a phenyl ring C atom; the H···F distance is 2.65 Å.

[10] D. J. Cram, K. N. Trueblood, *Top. Curr. Chem. 98* (1981) 43.

[11] K. N. Trueblood, C. B. Knobler, D. S. Lawrence, R. V. Stevens, *J. Am. Chem. Soc. 104* (1982) 1355.

[12] The double perching arrangement has been observed in the X-ray crystal structures of a number of 2:1 complexes between CH-acidic neutral guests and 18C6: for example, Me_2SO_2 [4] and $MeNO_2$ [5].

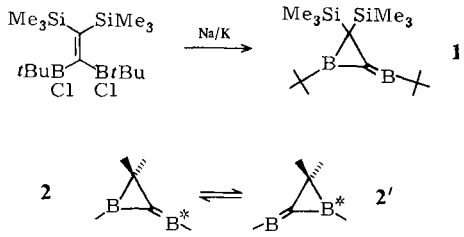
[13] Apart from exhibiting a P-C(Ph) bond length (1.795 Å) that is slightly longer than the P-C(Me) bond length (1.796 Å), the structure of the guest cation is very similar to those reported (see, for example, F. J. Hollander, D. H. Templeton, A. Zalkin, *Inorg. Chem. 12* (1973) 2262 and R. E. Cramer, D. M. Ho, W. van Doorne, J. A. Ibers, T. Norton, M. Kashiwagi, *ibid. 20* (1981) 2457) for the $[Ph_3PMe]^{\oplus}$ cation.

[14] Indeed, the Me doublet in [Ph$_3$PMe]Br resonates at $\delta = 3.18$ in CD_2Cl_2–C_6D_6 (1:1) indicating a strong C–H···Br hydrogen bonding interaction.

An Extraordinary Structure and Topomerization Mechanism for "Diboramethylenecyclopropane"**

By *Peter H. M. Budzelaar, Paul von Ragué Schleyer**, and *Karsten Krogh-Jespersen**

Compounds containing a B–C double bond were unknown until the recent report by *Berndt* et al., claiming the synthesis of a diboramethylenecyclopropane, **1**[1]. The compound was found to undergo a rapid topomerization at room temperature (activation energy 11.4 kcal/mol), represented by the equilibrium **2** ⇌ **2′**.



Our further theoretical study of various $C_2B_2H_4$ isomers[2] now leads us to propose a related but significantly different structure (still containing a B=C bond) for **1**, and also to confirm a pathway for its topomerization suggested by *Berndt* et al.[3]. The $C_2B_2H_4$ species relevant to the present discussion are the isomers **2**–**6**. Geometries were optimized at the Hartree-Fock (HF) level using the split-valence plus polarization 6-31G* basis set, and energies were then obtained from single-point calculations at these optimized geometries using Møller-Plesset electron correlation estimates to third order (MP3)[4]. Table 1 gives the relative energies of **3**–**6**.

While the "classical" diboramethylene-cyclopropane structure **2** is indicated to be a local minimum with small

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *P. H. M. B.* expresses his gratitude for a Fellowship sponsored by the Netherlands Organization for the Advancement of Pure Research (Z.W.O.). We thank Dr. *T. Clark* for preliminary calculations on **2** and **6** and general assistance.

basis sets (e.g., 3-21G), this is *not* so at the HF/6-31G* level: optimization (starting with the 3-21G geometry for **2**) gives structure **3** directly. The carbene **4**[2d,3] (C_{2v} symmetry) corresponded to a local minimum at all theoretical levels employed. This means that a transition state (roughly resembling **2**) must separate **3** and **4**. This was located (**5**) at 6-31G*; some geometrical details are provided (Fig. 1). Finally, structure **6**, another possible species on the rearrangement pathway was considered (Table 1)[2]. Since **3** is by far the most stable of the $C_2B_2H_4$ isomers examined here, we suggest that *Berndt*'s "diboramethylenecyclopropane" **1**[1] may have a similar structure.—The spectroscopic data obtained for **1** may also be reconciled with a structure related to **3**.

The curious species **3** has normal B1–C1 and C1–C2 σ-bonds and a three-center π-bond (C2-B2-B1) (see Fig. 1). Only four electrons are involved in bonding the σ-framework of the B1C2B2 ring (Fig. 1). The bonding Walsh-type orbital σ_2 is occupied, but there is no antibonding counterpart to σ_2. This results in weak B1-C2 and B1-B2 bonds (represented here by dotted lines) and a strong C2-B2 double bond[5].

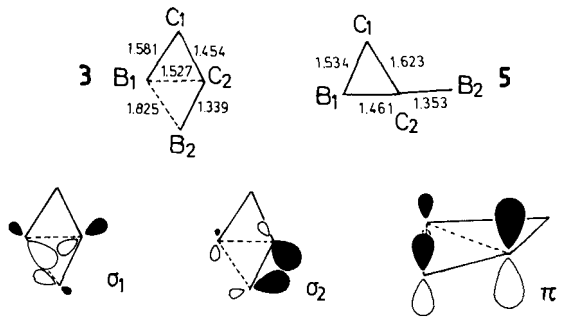

Fig. 1. Calculated bond lengths [Å] in **3** and **5** (top) and a schematic representation of the orbitals responsible for the bonding in the B1C2B2-ring of **3** (bottom).

What is the mechanism of the topomerization of **1** (modeled in our study by **3**)? The two obvious possibilities involving only planar species are:

$$\mathbf{4} \rightleftharpoons [\mathbf{5}] \rightleftharpoons \mathbf{3} \rightleftharpoons [\mathbf{6}]$$
(path 1) (path 1)

We have also searched for possible non-planar pathways, but have not found any likely candidates. Thus, the barrier for the topomerization of **3** is either 26.2 kcal/mol (path 1) or 23.7 kcal/mol (path 2). Before comparing this with the experimental value of 11.4 kcal/mol[1] for *Berndt*'s compound **1**, however, we have to take into account the electronic and steric effects of the substituents. The electronic effects have been estimated by modeling $SiMe_3$ and *t*Bu in **1** by SiH_3 and CH_3 groups, respectively. Relative to **3**, these groups lower the energy of **4** and **5**, but hardly affect that of **6** (Table 1, last column). Thus, the energy of path 1 is lowered while that of path 2 remains virtually unchanged. Hence, for the particular choice of substituents in **1**, path 2 can be ruled out, since it is ca. 10 kcal/mol higher in energy. Steric effects will be important for **3**, where the larger *t*Bu substituents on boron are forced close together. This should destabilize **3** by a few kcal/mol relative to **4** and **5**, and reduce the topomerization barrier further below the estimated value of 15.3 kcal/mol obtained by assuming additivity of the substituent effects. We conclude that path 1 can account for the observed topomerization barrier. The intermediacy of **4** in the proposed mechanism can also explain some of the observed reactions of **1**[3].

1,3-Diboretanes**

By *Rolf Wehrmann, Hartmut Klusik,* and *Armin Berndt**

Dedicated to Professor Roland Köster on the occasion of his 60th birthday

1,3-Diboretane has so far merely been the subject of theoretical studies[1]. Herein we report the synthesis and characterization of the derivatives **3**—**5**.

The ethenylidene-1,3-diboretane **3** is formed as sole product on heating a mixture of 2-*tert*-butylborandiylborirane **1**[2,3] and bis(trimethylsilyl)acetylene in pentane under reflux for ten days. In this reaction, **1** behaves as if it is initially converted into the carbene **2**[4,5]. This behavior is also observed in the reaction of **1** with triphenylarsane and the well known carbene trapping reagent[6] triphenylphosphane, which leads at 20°C to the ylides **4a** and **4b**; the reaction with PPh_3 leads to formation of equal amounts of **4b** and the 1,3-dihydro-1,3-diborete **6**[7], which is also obtained on heating **4b** to 180°C. The ylides **4a** and **4b** can be protonated with trifluoromethanesulfonic acid in chloroform to give the 1,3-diboretanes **5a** and **5b**, respectively. Reduction of **3** with K/Na alloy in tetrahydrofuran/dimethoxyethane furnishes the radical anion $\mathbf{3}^{\odot\ominus}$ ($a(^{11}B) = 0.58$ mT, $a(^{29}Si) = 3.43$ mT, $g = 2.0024$).

The structure of the compounds **3**—**5** follows from their ^1H-, ^{13}C-, ^{11}B-, ^{31}P-NMR-, and mass spectra[8]; in its IR spectrum, **3** shows an allene band at 1870 cm^{-1}. The shielding of the boron atoms in **4a**, **b** ($\delta(^{11}B) = 61$ and 59, respectively) compared to that in **3** ($\delta = 78$) reflects the delocalization of the negative charge of the ylidic C-atoms ($\delta(^{13}C) = 83.1$ and 81.5, respectively). In the meantime, similar ^{11}B-NMR shifts ($\delta = 51$—58) have been described for dialkylboryltriphenylphosphonium ylides[9]. The ylide structure of **4b** is also supported by the ^{31}P-^{13}C coupling

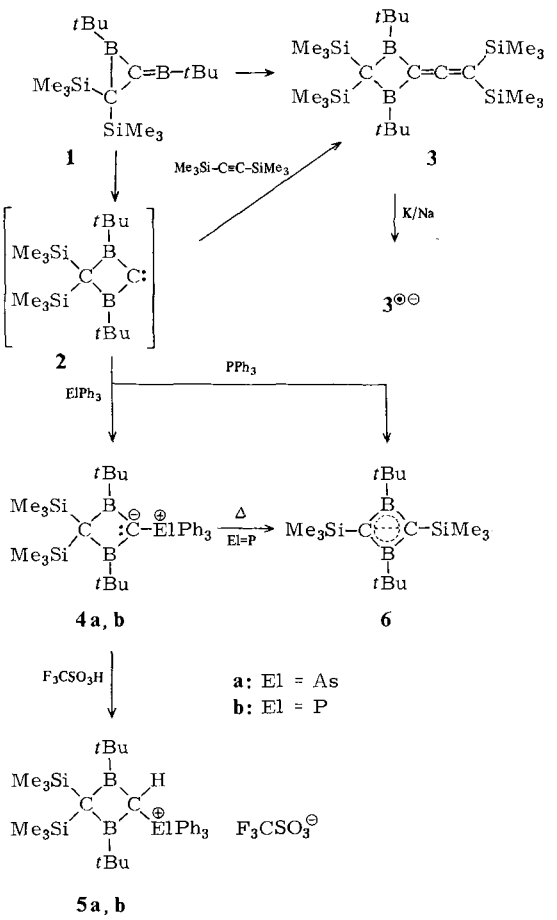
constants of the phenyl C-atoms, which compare with those of other triphenylphosphoranes[10]. The structures of **5a, b** follow from the splitting of the signals of the protonated C-atoms into a doublet and the appearance of two different signals for the trimethylsilyl groups. On cooling,



the ^{13}C-signals of the phenyl groups of **5a, b** become broader[8]; this is indicative of hindered rotation about the C–$\overset{\oplus}{\text{E}}lPh_3$ bond, to our knowledge the first observation of hindered rotation of a triphenylphosphonium- and triphenylarsonium-group.

BOOK REVIEWS

Chemical Research Faculties. An International Directory. American Chemical Society, Washington DC 1984. xxxv, 407 pp., bound, $ 129.95 (USA and Canada), $ 155.95 (all other countries).

This book, sister volume to the excellent *ACS Directory of Graduate Research 1983,* which surveys chemical research faculties (names of institutions, lists of faculty members, etc.) in the USA and Canada, purports to supply analogous information about faculties in the rest of the world. With this aim, source data were collected from 62 countries, and the names of 9,900 faculty members from 737 departments are included. Information is organized according to country, institution, and by an alphabetical listing of the respective faculty members. Inclusion of cross indexes facilitates location of individual researchers in a given area of chemistry. Additionally, a statistical survey of the numbers of academic staff, research workers, and of masters' and doctoral degrees awarded for the academic years 1980—81 and 1981—82 is presented on an institutional basis in tabular form. Since data collection for

the volume began in August 1982, entries are probably only accurate up to this date.

Alone the collection of such a vast amount of data presents a difficult task to the editorial staff involved; publication of a compendium of research faculties around the world that could be of real value to the chemical community is a problem which assumes gargantuan proportions. Clearly not every chemical research institution can be covered. What is required is the judicious selection of institutions, comprehensive coverage of those selected, and a critical appraisal to guard against the omission of reputable scientists from smaller institutions.

Unfortunately, however, it would appear that the zeal to appear in print rather than to provide a balanced, fairly comprehensive reference volume has been the guiding principle in publishing *Chemical Research Faculties 1984*. With the exception of its treatment of the English-speaking world, which is acceptable, coverage of research faculties in the rest of the world falls well short of expectations. The book's particularly disappointing coverage of continental European research institutions is conspicuous. By its omission, one can only assume, for example, that the editors are unaware that the ETH Zürich has a chemistry faculty! Other institutions which fail to get a mention are too legion to list individually; suffice it to say that of the ca. 50 chemical institutions in the Federal Republic of Germany only 21 appear. And of those, only a skeleton faculty appears in many instances: according to the information presented, the chemistry faculty of the Universität Heidelberg has only one member! Similar fates are suffered, inter alia, by many chemical research faculties in France, Italy, and Spain.

In summary, this book falls well short of providing a well-balanced, useful directory for the scientific community and in no way justifies its extremely high cost. One hopes that the shortcomings delineated here will be improved in a 2nd edition, for there is certainly a need for a comprehensive reference work of this type.

Ian G. Neil [NB 653 IE]
Angewandte Chemie, Weinheim (FRG)

Das Nitrosamin-Problem. Edited by *R. Preussman*. A publication of the Deutsche Forschungsgemeinschaft. Verlag Chemie, Weinheim 1983. xi, 326 pp., paperback, DM 75.00.

This book quotes the detailed final reports of 30 scientists participating in the DFG program "Analysis and Formation of *N*-Nitroso Compounds". Because of the importance of nitrosamines as possible carcinogens, about five million DM have been made available for this research over the last ten years. As a result of this intensive support, suitable measures have been discovered for reducing their formation, thus allowing the prejudice of the human organism to be lessened.

The individual reports have been assembled into ten chapters. Each theme is introduced in a review by an expert. This concept guarantees that both a comprehensive general presentation of the problems and a more detailed treatment of specific questions is offered to the reader.

K. Heyns devotes his introductory remarks to a history of the "nitrosamine problem" and reviews the present state of research. The determination of very low concentrations of these carcinogens in foods was, as is reported on by *G. Eisenbrand*, only possible after the development of a highly sensitive and specific method. From the review by *B. Spiegelhalder* it can be seen that carcinogenic nitrosamines are not only detectable in foods but also in other requisites, medicaments, tobacco and tobacco smoke as well as in the air of various industrial plants.

The first routine findings from foodstuff monitoring are reported by *R. Frommberger* and *H. Allmann* for the Federal Republic of Germany and by *G. Ellen* and *P. L. Schuller* for the Netherlands.

A solution of the "nitrosamine problem" is only possible with the possession of an extensive knowledge of the chemistry and the formation of these substances. These questions are treated by 13 authors in two voluminous chapters (ca. 150 pages).

As the review articles of *G. Eisenbrand* and *R. Loeppky* make clear, preventative measures could greatly reduce the exposure of our bodies to nitrosamines.

However, because of the widespread occurrence of amines and nitrites—that is, the precursors of nitrosamines—in the environment it is impossible to avoid the formation and intake of small quantities of these carcinogenic substances. This makes the remarks of *R. Preussmann* concerning the biological effect of *N*-nitroso compounds worthy of particular attention.

László Tóth [NB 633 IE]
Institut für Lebensmittelchemie
der Universität Frankfurt am Main

Copper Coordination Chemistry: Biochemical and Inorganic Perspectives. Edited by *K. D. Karlin* and *J. Zubieta*. Adenine Press, Guilderland 1983. 488 pp., bound, $ 69.00.

This book is a summary of the "1st Conversation in Copper Coordination Chemistry" held at Albany State University from the 1st to the 4th of June 1982. It presents a series of investigations concerning the role of copper in biological and inorganic electron transport processes and in general catalysis, as well as new developments concerning the chemistry of Cu^{I} and Cu^{II} complexes with nitrogen- and oxygen-containing ligands. The two editors wish to use this volume to effect a connection between classical inorganic chemistry and biology. Bioinorganic chemists seek to gain an insight into the complicated and multifaceted activities of proteins and enzymes by investigating the structural and electronic properties of their active centers. Chemical and spectroscopic investigations of simple, low molecular weight model complexes yield vital information when compared with the corresponding high molecular weight biologically active substances.

In his introductory survey *E. Solomon* characterizes known Cu-enzymes and -proteins according to spectroscopic criteria and emphasizes the necessity of working out the basics using inorganic complexes. Absorption transitions in the UV/VIS range, EPR, CD, and MCD as well as the relatively new EXAFS spectroscopy were amongst the spectroscopic techniques which found application here as well as in the following contributions.

An EXAFS evaluation of the binuclear bonding center of several derivatives of arthropod and mollusc haemocyanins by *T. G. Spiro* et al. begins the first section of the book, which summarizes investigations of spectroscopy, kinetics, structure and redox behavior. These include the

steric and electronic influence of various ligands on coordination at Cu^{I} and Cu^{II} and on the Cu^{I}/Cu^{II} potential. Alongside the methods already mentioned results obtained by X-ray structural determinations, cyclovoltammetry, coulometric and potentiometric measurement and MO calculations are also discussed.

The second part of the book is devoted to the behavior of O_2 and of CO bound to Cu^{I} and Cu^{II}. The catalytic role in the oxidation of organic substrates with molecular oxygen is treated in detail. Copper compounds are involved in electron transfer reactions and serve to activate oxygen.

The book provides a comprehensive coverage of the current status of investigations into the structure/function relationships of Cu^{I} and Cu^{II} coordination complexes—binuclear ones in particular. The literature is covered up to and including 1982. There is no appended list of ligands discussed which would be an aid to gaining a general picture. Unfortunately, the biochemical perspectives mentioned in the title are on the whole limited to the first two contributions. Afterwards biochemical problems are virtually only alluded to in the various introductions.

This book offers a wealth of information to the chemist or physicist who works with model systems. It can be recommended to the functionally interested biochemist as a reference work. It is also of use to the advanced student who wishes to familiarize himself with coordination complex-oriented bioinorganic chemistry.

Ulrich Weser [NB 626 IE]
Anorganische Biochemie,
Physiologisch-chemisches Institut
der Universität Tübingen (FRG)

Handbuch der photometrischen Analyse organischer Verbindungen. By *B. Kakáč* and *Z. J. Vejdělek*. Verlag Chemie, Weinheim. Band 1 (1974): viii, 718 pp., bound; Band 2 (1974): vi, 598 pp., bound; together DM 360.00. 1st supplementary volume (1977): xxv, 464 pp., bound, DM 138.00. 2nd supplementary volume (1983): xxxi, 506 pp., bound, DM 198.00.

Nowadays there are so many instrumental molecular spectroscopic techniques (e.g. UV, IR, Raman and fluorescence spectroscopy) and mass spectroscopic methods available for the identification and determination of organic substances, mainly used in combination with TLC, GC or HPLC that photometric methods based on color reactions may seem a little antiquated. However, this is quite untrue. The large response to the original two-volume handbook on photometric analysis, which first appeared in 1974, has stimulated the authors and publishers to bring out supplements about every five years. The two supplementary volumes covering the literature from 1970 to 1975 and 1975 to 1980, are scarcely smaller in extent than the main volumes covering the literature up to 1970. As before, chemical reactions of organic compounds leading to photometrically determinable coloration have an important, and possibly increasingly important, place in many areas of analytical laboratory practice (e.g. biochemistry, biology, medicine, pharmacy, food chemistry). This is now particularly the case for microliter scale reaction volumes (flow injection technique) and for photometric detection systems for the very powerful HPLC methods, which allow the determination of more and more classes of organic compounds economically at very low concentrations. From this point of view, this carefully compiled systematic review of the color reactions of organic compounds is a valuable aid. Principles, reaction mechanisms, reaction conditions, absorption maxima, selectivity, avoidance of interference and exact instructions for carrying out the determinations are very clearly outlined for 18 classes of compounds according to the Beilstein system, and are easily traceable because of the comprehensive reagent, author and subject indices. In order to find a particular photometric method for a chosen organic compound, the reader requires the subject indexes of all four volumes that have been published up to now, but this does not cause any problems because the whole work is systematically organized.

The following classes of substance are treated in both supplementary volumes: unsaturated hydrocarbon compounds, hydroxy compounds, thiols and related compounds, keto compounds, carboxylic acids and their derivatives, organic sulfates and sulfonates, amino compounds, hydroxylamines, hydrazine compounds, azo and diazo compounds, nitro and nitroso compounds, halogen compounds, organic compounds of metals and of non-metals, nitrogen-free heterocyclics, nitrogen-containing heterocyclics, carbohydrates and their derivatives, amino acids, peptides and proteins, as well as steroids and related compounds.

Unfortunately, the work only covers the determination of organic compounds, so that the reactions of the ions of elements are only dealt with from this viewpoint. An exception is the section dealing with organic compounds of metals and non-metals, which is very valuable for methods of determining organo-element compounds (e.g. of Hg, Sn, Pb, As) particularly in environmental analysis.

The value of this work lies principally in its thorough literature coverage, which is not limited to the normal analytical journals, but also includes the partially inaccessible literature of the neighboring disciplines (such as pharmacy, medicine and food chemistry), and in the critical choice of important substances and methods, which are described in detail. For less important topics, it is necessary to refer back to the original literature.

This synoptic, clearly written handbook, which is kept up-to-date by the supplementary volumes, should be of interest to a large number of scientists of differing disciplines who have to analyze organic compounds of synthetic and natural origin in a wide variety of different matrices. For this reason, this book ought to be obligatory for every analytical chemistry library, despite its high cost, which is justified by the content and the production.

Günter Tölg [NB 624 IE]
Institut für Spektrochemie, Dortmund (FRG)

Heteropoly and Isopoly Oxometalates. By *M. T. Pope*. Springer-Verlag, Berlin 1983. xiii, 180 pp., bound, DM 124.00.

The chemistry of the polyoxoanions of the transition metals occupies an important intermediary position between solid state chemistry and the chemistry of aqueous solutions. This fact is emphasized in this book which has been published as Volume 8 of the series "Inorganic Chemistry Concepts". A competent authority provides a comprehensive review of the chemistry, structure, possible applications and future trends of this class of compounds. The state of knowledge in this classical field of inorganic chemistry has developed rapidly since the last monograph devoted to it, *P. Souchay*'s "Ions Minéraux Condensés",

was published at the end of the 1960s. The roots of the field stretch back into the last century and the first climax, reached in 1920 by *Rosenheim*, was soon built upon. This was a result of the contribution of newer methods, such as the wide availability of X-ray methods for the determination of solid state structures or ^{17}O-, ^{91}V-, ^{95}Mo-, and ^{183}W-NMR spectroscopy in solution. Accordingly, this book begins with a description of the methods of investigation, their scope and their limits. A further introductory chapter deals with the synthetic methods in aqueous and non-aqueous solutions, with the most important structural types, and with applications in biochemistry and catalysis.

The two sections of 24 and 33 pages concerning the isopolyanions of the elements V, Nb, Ta, Mo, and W and their heteropolyanions constitute the main part of the book and are laid out according to the coordination number of the heteroatom. The author limits himself essentially to compounds with "finite" structures and to species that exist in solution. The complex structures are explained using easily understood language; reactions between individual species are presented in clear graphics. The diagrams of the structures, which have been drawn with great artistic skill by *Howard T. Evans Jr.* are a valuable contribution as well as being aesthetically pleasing.

Two further chapters are dedicated to the specific properties of heteropolyanions: a) to the metal complexes: polyanions themselves or species derived from them having open structures can function as ligands or cryptands; b) the redox chemistry and electronic structure of reduced polyanions: recent developments are reviewed here for the first time. Chapter 7 treats polyanions with covalently bound organic groups. Interest in this type of compound has recently increased in connection with their being viewed as models for heterogeneous catalysis. Amongst the topics dealt with by the author in the last section are the ability of other elements to act as addenda in polyoxometalates (e.g. Sb^{IV}, Te^{VI}, I^{VII}) or to replace oxygen (e.g. fluorine or sulphur).

Y. Yeannin and *M. Fournier* develop rules for a systematic nomenclature of this class of compound in an appendix; this will be of particular value for literature searches. The three indexes at the end of the book are exemplary; they are a list of 771 references including publications up to the beginning of 1982, an author index, and finally a general index containing almost 400 headings. The clear construction of this book and its excellent contents guarantee a rapid synopsis not just to inorganic chemists. It should be in every library.

Cyclic Voltammetry—"Electrochemical Spectroscopy"

New Analytical Methods (25)

By Jürgen Heinze*

Polarography is still the best known classical measuring method in electroanalytical chemistry. However, in recent years its position has been challenged by cyclic voltammetry (CV). Simple diagnostic criteria and relatively easily acquired measuring techniques have hastened this development. Cyclic voltammetry has the further attraction of providing information not only on the thermodynamics of redox processes but also on the kinetics of heterogeneous electron-transfer reactions and coupled chemical reactions. The characteristic shapes of the voltammetric waves and their unequivocal position on the potential scale virtually fingerprint the individual electrochemical properties of redox systems. For this reason the method has been labeled "electrochemical spectroscopy".

1. Introduction

Chemical research has only recently reacted to the fact that chemical reactions very often involve electron-transfer processes[1–3]. Recognition has been slow probably because of the widely held view that electron-transfer processes were purely thermodynamic phenomena, which, e.g., the electrochemist interpreted, with the aid of the Nernst equation, as redox equilibria. The kinetics of electron-transfer processes went virtually unrecognized. Accordingly, electrochemistry, as the science of the properties of charge carriers in condensed matter, was long regarded as a domain of thermodynamics. The electrode was solely a probe for measuring equilibrium potentials.

This view changed fundamentally once it became clear that electron-transfer processes, whether homogeneous or heterogeneous, have, on the one hand, a finite rate whose value is dependent on the activation parameters[4–6] and, on the other, that they are often preceded and followed by chemical reactions[7–9]. Thus, in electrochemistry the methodical emphasis gradually shifted from the static determination of potentials to the dynamic determination of current.

Numerous dynamic methods in electroanalytical chemistry have been developed in recent decades. Of these, cyclic voltammetry (CV) has gained the greatest popularity[10]. It has already largely supplanted classical polarography—except for purely analytical problems. Its applications range from the study of simple redox processes in organic and inorganic chemistry to the characterization of multielectron-transfer processes in biochemistry and macromolecular chemistry.

There are two main reasons for this development. An exact mathematical analysis of the theoretical basis of the method has existed for the past 15—20 years. Hence, it has been possible to provide a quantitative interpretation of all the important variants of electrochemical processes in terms of their voltammetric response[11–18]. Moreover, modern numerical methods facilitate calculation of voltammetric curves for complex electrochemical processes[19,20]. A second consideration has been decisive for the popularity of the method: With the aid of a few simple diagnostic criteria, it is possible to obtain, even without complicated mathematics, a fair amount of information on the electrochemical properties of the species being studied[21–23].

The available data do not refer only to thermodynamic parameters such as, e.g., the redox potential; the CV experiment also provides direct insights into the kinetics of electrode reactions, which include both heterogeneous and homogeneous electron-transfer steps as well as coupled

chemical reactions. The determination of reactive intermediates and their kinetic analysis promise to become major applications of cyclic voltammetry together with the characterization of the thermodynamics of redox systems.

Furthermore, voltammetry is increasingly being used as a technique of studying all types of potential-dependent interfacial process. These include, inter alia, adsorption processes[24,25], electrocrystallization phenomena[26,27], and charge-transfer reactions at semiconductor electrodes[28,29] or between nonmiscible electrolytes[30].

2. Experimental Basis

Normally, routine voltammetric experiments are performed using a stationary working electrode in a quiet solution. Starting from an initial potential E_i, a linear potential sweep (potential ramp) is applied to this electrode. After reaching a switching potential E_λ, the sweep is reversed and the potential returns linearly to its initial value. Although it is technically possible to generate sweep rates, $v = dE/dt$ [V/s], of up to 10000 V/s, in practice the rate lies between 5 mv/s and 1 V/s, with a maximum of 3000 V/s under favorable conditions. The sweep rate is one of the most important variables in voltammetry, for it controls the time scale of the experiment.

In cyclic voltammetry, mass transport of the reducible or oxidizable electroactive species occurs only by diffusion. Thus, in order to avoid migration currents and ensure conductivity, a ca. 0.1 M solution of a ground or supporting electrolyte is added to the solution. Alkali metal and especially tetraalkylammonium salts have proved the most effective. The latter can also be used in aprotic solvents and some, e.g. tetra-*n*-butylammonium hexafluorophosphate [TBA]PF_6 (Fig. 4), are characterized by extraordinarily high decomposition voltages. The concentrations of the electroactive substance normally lie between 10^{-3} and 10^{-5} M.

Besides the Faradaic current based on the heterogeneous charge transfer at the phase boundary, there is also a capacitive current from the charging of the electrochemical double layer without charge transfer between electrode and electrolyte. This is measured with suitable equipment and recorded as a characteristic current-voltage curve—a cyclic voltammogram (Fig. 1).

As it is impossible to monitor absolute single electrode potentials, the working electrode (WE) potential E always refers to a nonpolarized reference electrode (RE), e.g. Ag/AgCl or the saturated calomel electrode (SCE). If the currents are low and the solvent-electrolyte system has a high conductivity, this type of two-electrode cell is sufficient for voltammetric measuring. Its use is well-known from classical polarography[31-33].

For large currents and/or a low-conductivity solution, such as, e.g., is the case with aprotic solvents, the applied voltage is no longer identical to the desired real potential at the working electrode. With current $i(t)$ in the system, the internal resistance of the electrolyte causes an additional drop in potential, so that the WE potential $E(t)$ will be smaller than the applied cell voltage $E_{appl}(t)$ by an amount corresponding to the Ohmic potential drop (iR-drop) [Eq. (1)].

$$E(t) = E_{appl}(t) - i(t)R \qquad (1)$$

In addition, large currents, as observed at high sweep rates, destroy the reference electrode.

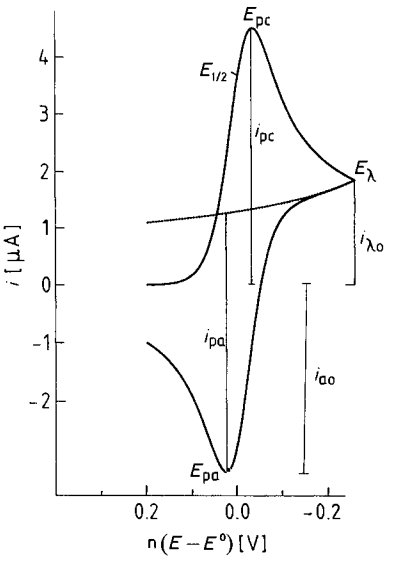

Fig. 1. Cyclic voltammogram for a reversible charge transfer; E_{pc}: cathodic peak potential, E_{pa}: anodic peak potential, E_λ: switching potential, $E_{1/2}$: half-wave potential, i_{pc}: cathodic peak current, i_{pa}: anodic peak current, $i_{\lambda o}$: current at E_λ, i_{ao}: anodic peak current at baseline.

Both effects can be largely avoided by using potentiostats together with a three-electrode cell arrangement[25,34-36]. In this technique current is passed through the working and an additional auxiliary electrode (AE), while almost no current flows through the RE on account of its high impedance. In order to keep the existing uncompensated iR-drop as small as possible, the reference electrode is placed as close as possible to the WE using a Luggin's capillary. Potentiostatic control ensures that the real potential $E(t)$ at the WE with respect to the RE is, by and large, the same as the applied cell voltage generated by the function generator. Operational amplifiers in the control circuit adjust the current passing through the WE and AE until the potential $E(t)$ corresponds to E_{appl}.

Besides potentiostats with the electrochemical cell arrangement, the standard device for voltammetric experiments comprises a voltage scan generator, which supplies the desired potential program, as well as an XY recorder (or a suitable fast transient recorder) which registers the current-voltage curve (Fig. 2). Suitable equipment, mostly in the form of modular systems, is commercially available.

For the study of reductions, mercury has proved to be the material of choice for the WE. It is used in voltamme-

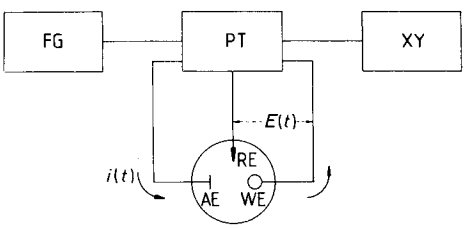

Fig. 2. Schematic experimental setup for cyclic voltammetry; FG: voltage scan generator, PT: potentiostat, XY: recorder, WE: working electrode, RE: reference electrode, AE: auxiliary electrode.

try as a stationary hanging mercury drop electrode (HMDE) and is superior to all other materials for experiments in aqueous solutions because of its high hydrogen overpotential. But mercury also has certain advantages in aprotic solutions since its surface can be reproduced at will. For anodic measurements above +0.4 V vs. Ag/AgCl (mercury is oxidized!) as well as for other special purposes, solid electrodes have to be used, preferably of an inert material such as platinum, gold, or graphite[22]. In this case, however, it is often difficult to clean the electrode surfaces.

Optimal preparation of the samples, the electrolytic solution, and the measuring cell are essential for the success of the experiments. Impurities, even in traces, can considerably impair the quality of the cyclic voltammograms. In aqueous solutions usually only oxygen, reducible in the range −0.2 to −0.8 V vs. SCE, must be removed from electrolytic solutions, prepared under standard analytical conditions. The requirements for aprotic solvents are far more stringent, affecting both the purification of the solvent and the preparation of the samples. The main problem lies in removing protic impurities, principally water. Numerous techniques have been developed for purifying organic solvents for use in voltammetric measurements[37–41], and *Coetzee* has published a survey in a recent IUPAC monograph[42].

Careful purification of solvents together with a standard sample preparation technique, as practised by various research groups, produces a solvent-electrolyte system which, in electrochemical jargon, is "waterfree"[35,43–45]. However, it is impossible to remove all traces of water from the walls of the cell and the supporting electrolyte. Thus, on the one hand, the available potential range is smaller than theoretically possible and, on the other, reactive ions formed at the electrode undergo follow-up reactions. *Hammerich* and *Parker*[46] developed a very elegant solution to this problem by directly adding superactive alumina to the voltammetric cell, thereby creating a superdry medium.

This method is not always suitable when sensitive materials are being studied or for quantitative measurements, particularly spectroscopic experiments. More recently, cells and equipment have been developed which avoid direct contact between the solvent-electrolyte system and the alumina *during* the voltammetric experiment, without impairing efficiency[47–49].

Figure 3 is a schematic representation of such an analytical cell. The drying procedure is as follows: the already highly purified solvent is transferred by distillation under high vacuum from the voltammetric cell, which already contains the supporting electrolyte, to superactive alumina in a separate vessel and then similarly returned to the voltammetric cell. By means of this procedure, the protic impurities on the glass walls of the cell and in the supporting electrolyte are "extracted" into the solvent and then adsorbed onto the alumina. A voltammetric background curve for superdry propionitrile is shown in Figure 4. The available potential range in this case is more than 6.5 V. The vacuum-condensation method cannot always be used with high boiling solvents or other low volatile additives (e.g. complexing agents). A cell with an integrated alumina

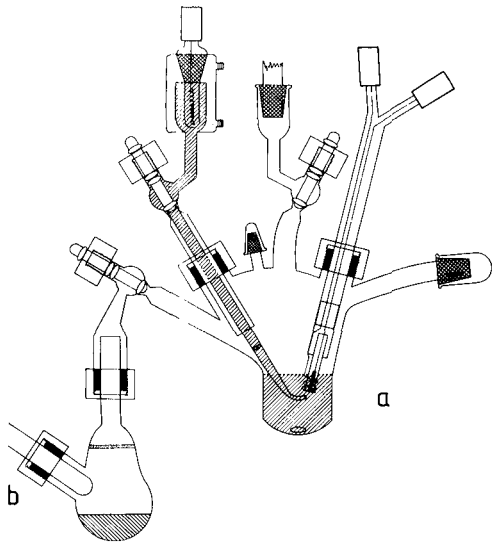

Fig. 3. Electrochemical cell for voltammetric experiments under "superdry" conditions: a) measuring cell with three-electrode arrangement; b) drying vessel with superactive alumina (Woelm, ICN Super I).

tube developed by *Kiesele*[49] has proved extremely efficient in such cases. Voltammetric measurements under superdry conditions are often an essential prerequisite for the quantitative evaluation of experimental data.

3. Electrode Reactions in the CV Experiment

3.1. Simple Electron Transfer: E Mechanism

The simplest Faradaic electrode reaction is the heterogeneous charge transfer from an electroactive species **A** to the electrode or vice versa, in which, dependent on the given electrode potential, **A** is either oxidized or reduced to **B** (electron-transfer mechanism: E mechanism[50]).

$$\mathbf{A} \pm e \overset{E}{\rightleftharpoons} \mathbf{B} \tag{2}$$

In order to simplify the theoretical analysis, only reduction processes will be discussed. Two processes determine the shape of the voltammetric current-voltage curve. These are heterogeneous charge transfer and diffusional mass transport. The heterogeneous charge-transfer at the electrode interface is described by the Butler-Volmer equation [Eq. (3)], the basic equation in electrochemical kinetics[4].

$$j_A(0,t) = \frac{i}{nFA} = C_A(0,t)k^0 \exp\left[-\alpha \frac{nF}{RT}(E-E^0)\right] - C_B(0,t)k^0 \exp\left[(1-\alpha)\frac{nF}{RT}(E-E^0)\right] \tag{3}$$

where k^0 = heterogeneous standard rate constant,
α = transfer coefficient,
E^0 = standard potential,
A = electrode area,
j = flux at the electrode interface, F = Faraday constant.

In accordance with Eq. (3), the heterogeneous flux, i.e. the measurable current density, depends on the surface concentrations of the redox partners involved, the actual electrode potential $E(t)$, and the heterogeneous standard rate constant k^0. The standard potential E^0 characterizes a situation in which the surface concentrations of the oxidized and reduced forms are equal under conditions of *thermodynamic* equilibrium. Because of the difference between the resulting potential-dependent surface concentrations $C_A(0,t)$ and $C_B(0,t)$ and the concentrations in the rest of the solution, a gradient emerges, along which diffusion-controlled mass transport occurs. The time-dependent concentration distribution in the expanding diffusion layer can be derived from Fick's 2nd law [Eq. (4)].

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial^2 c_i}{\partial x^2} \tag{4}$$

where i = **A**, **B**

Eq. (4) holds only for purely linear semi-infinite diffusion, a situation which does, in fact, apply in most cases. In the case of smaller electrode areas, $A \leq 1 \cdot 10^{-6}$ m^2 (such as, e.g., the hanging mercury drop electrode), the diffusion equations must be modified to take account of the spherical or other shape of the electrode[51,52].

If voltammetry is used for analytical purposes, an extremely large electrode area/volume ratio is often chosen to increase sensitivity, e.g., in inverse voltammetry or when working with thin-layer cells. Under these conditions, diffusion is no longer semi-infinite but finite, i.e. the thickness of the diffusion layer is limited by the volume, and this changes the characteristics of the diffusion gradient[53,54].

The concentration gradient at the electrode surface is directly proportional to the charge flux [Eq. (5)].

$$j_A(0,t) = -D_A \left(\frac{\partial C_A}{\partial x}\right)_{x=0} = D_B \left(\frac{\partial C_B}{\partial x}\right)_{x=0} \tag{5}$$

Comparison of Eqs. (3) and (5) shows that the measurable current at the WE has two components; one for the heterogeneous charge transfer and one for the mass transport. However, there are two exceptions: the reversible and the irreversible cases.

1. *Reversible Case:* $k^0 > 10^{-1}$ cm/s

The rate of heterogeneous charge transfer is so high that a dynamic equilibrium is established at the phase boundary. The Butler-Volmer equation [Eq. (3)] is reduced to the Nernst equation, i.e. the surface concentrations $C_A(0,t)$ and $C_B(0,t)$ depend only on the actual electrode potential and are no longer influenced by heterogeneous kinetic effects. This case is termed reversible (Fig. 5a) because a thermodynamic equilibrium exists at the phase boundary. The current, as a measurable quantity for the charge flux at the electrode surface, is influenced solely by the mass transport, the slowest step (diffusion control). The characteristic shape of the cyclic voltammogram is a result of the potential-dependent changes in the surface concentrations of the redox system and the simultaneous diffusion processes. The surface concentration of the reactant **A** decreases and that of **B** increases with the time-dependent potential $E(t)$. Simultaneously, and as a consequence, the gradient and, hence, also the charge flux increase, until the E_0 potential has been exceeded and the surface concentration of **A** becomes negligible. The current reaches a maximum ($\rightarrow i_p$) and the diffusion layer continues to expand, as a result of which the concentration gradient at the electrode surface decreases virtually independently of the actual potential. The current curve decays. Analogous phenomena occur in the opposite potential direction. The reverse flux direction, the result of the potential-dependent conversion of **B** into **A**, produces a corresponding negative current which reaches a corresponding minimum value and then slowly decays as the species **B** in the diffusion layer is used up.

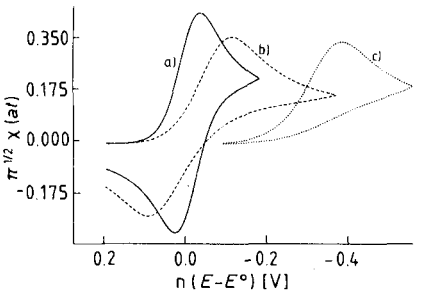

Fig. 5. Cyclic voltammograms for a) the reversible (—, $k^0 = 1$ cm/s), b) the quasi-reversible (– – –, $k^0 = 1.25 \cdot 10^{-3}$ cm/s), and c) the irreversible charge transfer (· · ·, $k^0 = 6.25 \cdot 10^{-6}$ cm/s); $D = 1 \cdot 10^{-5}$ cm^2/s, $v = 0.1$ V/s, $\pi^{1/2}\chi(at)$: normalized current function [16], dimensionless.

2. *Irreversible Case:* $k^0 < 10^{-5}$ cm/s

Charge transfer at the electrode is extremely slow. Depending on the potential, only one of the cathodic and anodic heterogeneous reactions has a measurable rate. Thus, the current is largely controlled by the rate of the charge-transfer reaction (charge-transfer control). Since the surface concentrations at the electrode are dependent on the heterogeneous reaction and are far removed from thermodynamic equilibrium, one speaks of an irreversible process (Fig. 5c). Under such conditions, the Nernst equation does not apply. Furthermore, this means that the measured potential values cannot be compared with thermodynamic equilibrium potentials.

3. *Quasi-reversible Case:* $10^{-1} > k^0 > 10^{-5}$ cm/s

Both the charge transfer [Eq. (3)] and the mass transport [Eqs. (4), (5)] determine the current. The Nernst equation is only approximately satisfied. The charge transfer is therefore termed quasi-reversible (Fig. 5b).

The special feature of voltammetry is that the properties of the redox system itself do not predetermine which of the three cases will occur. The time scale of the CV experiment can be varied over a wide range using the sweep rate.

This permits electrode reactions to be steered out of the range of charge-transfer control into that of diffusion control and vice versa. Depending on which of the two components dominates in the electrode processes, the corresponding characteristics are reflected in the cyclic voltammetric curve. In practice, under standard measuring conditions reversible and quasi-reversible cases occur most frequently.

Over the last twenty-five years appropriate theoretical analyses have been published[11-16]. In analytical approaches the diffusion equation (4) is transformed into an integral equation which takes into account the initial and boundary conditions [Eq. (3) and (5)] and is then solved either numerically or by series expansion. The best known studies are those of *Nicholson* and *Shain*, whose nomenclature has generally been adopted in the literature. Tables can be compiled for the theoretically determined current function $\pi^{1/2}\chi(at)$ in the reversible case (Table 1). Using this function together with the assigned experimental parameters in accordance with Eq. (6), one can calculate the cyclic voltammetric curves[16].

$$i = \mathrm{n}FA\, C_{\mathrm{A}}^{*}\,(D_{\mathrm{A}}\, a)^{1/2}\pi^{1/2}\chi(at) \tag{6}$$

where $at = \dfrac{\mathrm{n}Fvt}{RT} = \dfrac{\mathrm{n}F}{RT}(E(t) - E_{\mathrm{i}})$

and C_{A}^{*} = substrate concentration the electrolyte

0	0.3801	−120	0.3803
−5	0.4014	−150	0.2449
		−200	0.2074

It transpires that to study simple electron-transfer reactions so-called diagnostic criteria are often sufficient to obtain qualitative and quantitative information about thermodynamic and kinetic properties of the system, without having to analyze the entire cyclic voltammogram. The most important quantities are the two peak potentials E_{pc} and E_{pa} as well as the assigned peak currents i_{pa} and i_{pc} (Fig. 1). For reversible and quasi-reversible ($\alpha = 0.5$) charge transfer without coupled chemical reactions, the following equation holds irrespective of the sweep rate

$$i_{\mathrm{pa}}/i_{\mathrm{pc}} = 1 \tag{7}$$

However, it is not quite so easy to determine the current base line in the reverse sweep. Various methods of evaluation have been proposed[18,55]. The most suitable, however, is an empirical formula derived by *Nicholson* [Eq. (8)], whose sole precondition is that the switching potential E_{λ} lies ca. 60 mV/n after the peak potential[56] (Fig. 1).

$$\frac{i_{\mathrm{pa}}}{i_{\mathrm{pc}}} = \frac{i_{\mathrm{ao}}}{i_{\mathrm{pc}}} + \frac{0.485\, i_{\lambda 0}}{i_{\mathrm{pc}}} + 0.086 \tag{8}$$

The evaluation of the separation of the peak potentials [Eq. (9)] is even more informative for the interpretation of pure E processes

$$\Delta E_{\mathrm{p}} = E_{\mathrm{pa}} - E_{\mathrm{pc}} \tag{9}$$

This permits the determination of the half-wave potential of the measured redox reactions, a concept borrowed from classical polarography [Eq. (10)].

$$E_{1/2} = E_{\mathrm{pa}} - \Delta E_{\mathrm{p}}/2 = (E_{\mathrm{pa}} + E_{\mathrm{pc}})/2 \tag{10}$$

$$0.3 \leqq \alpha \leqq 0.7;\ E_{\lambda} \leqq E_{\mathrm{pc}} - 100\ \mathrm{mV}$$

In terms of Eq. (11), $E_{1/2}$ is associated with the thermodynamic standard redox potential E^{0}

$$E_{1/2} = E^{0} + (RT/\mathrm{n}F)\ln(D_{\mathrm{R}}/D_{0})^{1/2} \tag{11}$$

As there is generally little difference between the diffusion coefficients of the oxidized and reduced forms, $E_{1/2}$ largely corresponds to the thermodynamic redox potential of the redox pair studied.

ΔE_{p} is also a measure for the reversibility of the charge transfer. Under Nernst conditions, i.e. for very fast charge transfer, ΔE_{p} is given by

$$\Delta E_{\mathrm{p}} = \frac{2.3\,RT}{\mathrm{n}F} = \frac{56.5}{\mathrm{n}}\ \mathrm{mV}\ (25\,^{\circ}\mathrm{C}) \tag{12}$$

ΔE_{p} increases as the heterogeneous standard rate of the charge transfer decreases and/or the sweep rate, which controls the experimental time-scale and can be varied over several orders of magnitude, is raised. The peak potential separation can be correlated unequivocally with the heterogeneous standard rate constant k^{0} of the electrode reactions to be analyzed using the kinetic parameter ψ, introduced by *Nicholson* [Eqs. (13) and (14)][57].

$$\psi = \frac{D_{0}^{\alpha/2}/D_{\mathrm{R}}^{\alpha/2}\cdot k^{0}}{\left(D_{0}\pi\dfrac{\mathrm{n}F}{RT}v\right)^{1/2}} \approx \frac{k^{0}}{\left(D_{0}\pi\dfrac{\mathrm{n}F}{RT}v\right)^{1/2}} \tag{13}$$

$$\Delta E_{\mathrm{p}} = \mathrm{f}(\psi) \tag{14}$$

It should be clear from Table 2[52,57] that for $\psi > 10$ the electrode reactions in the chosen time-scale are reversible. At the usual sweep rate of 100 mV/s, k^{0} values of up to 10^{-1} cm/s be derived from a cyclic voltammogram.

Besides the above-mentioned diagnostic criteria, there is a series of other significant characteristics of simple charge transfer. These are described in the literature[21,23]; most of them, however, have only special applications.

Table 2. Separation of the anodic and cathodic peak potentials as a function of the kinetic parameter ψ [Eqn. (13)] in the cyclic voltammogramm at $T = 25\,^{\circ}C$; position of the switching potential $|E_\lambda - E^0| = 150$ mV.

3.2. Multielectron Transfer Processes

3.2.1. *The EE Mechanism*

The reduction of many inorganic ions such as Zn^{2+}, Pb^{2+} and Fe^{2+} is formally a "2e" transfer process. In fact, pure "2e" transfers in *one* elementary step are extremely unlikely because of the activation barrier. Multielectron transfer usually takes place in separate steps. For each heterogeneous electron transfer there is a rate relationship, as expressed by Eq. (2), characterized by the heterogeneous rate constant as well as the standard potential. Depending on the separation between the theoretical potentials of the redox reactions, several cases have to be distinguished. Again, in the interests of simplicity only a reduction is discussed here.

$$Ox \overset{E_1^0}{\rightleftharpoons} Red_1 \tag{15a}$$

$$Red_1 \overset{E_2^0}{\rightleftharpoons} Red_2 \tag{15b}$$

Case 1: $E_1^0 > E_2^0$

If the separation of the potentials between the redox transfers is large ($\Delta E^0 > 150$ mV), the resulting cyclic voltammogram consists of two typical, additively superimposed, one-electron transfer waves (Fig. 6). However, the electrode process as a whole is more complicated than appears at first sight. At the same time as the heterogeneous electron-transfer at the electrode interface, fast homogeneous electron-transfer reactions also occur, which, in multielectron transfer systems, lead to disproportionation or comproportionation. Hence, every EE mechanism can in principle be treated as an E_{disp} mechanism[59].

$$2\,Red_1 \underset{k_b}{\overset{k_f}{\rightleftharpoons}} Ox + Red_2 \tag{16}$$

The equilibrium position for the disproportionation is usually reached within the time scale of voltammetric measurements. The disproportionation constant

$$K = [Ox][Red_2]/[Red_1]^2 \tag{17}$$

can be derived from the difference between the standard potentials using Eq. (18).

$$-RT\ln K = nF(E_1^0 - E_2^0) \tag{18}$$

In recent years improvements in sample preparation techniques[46,48,49] and the use of unconventional solvent/electrolyte systems such as SO_2/tetra-*n*-butylammonium perchlorate (TBAP) or NH_3/KI[60,61] have made it considerably simpler to determine standard potentials and disproportionation constants. It has thus become possible to generate electrochemically stable dianions and dications[60-64] from pure aromatics as well as from their substituted derivatives. In addition, the use of ultramicroelectrodes together with extremely high sweep rates (v = 10000 V/s) has facilitated the measurement of redox potentials of very reactive systems[65]. The disproportionation which occurs simultaneously with the electrode reactions in solution causes the concentration profiles of the redox couples to adapt to the equilibrium during diffusion. However, as long as Nernst conditions hold at the electrode, the dispro-

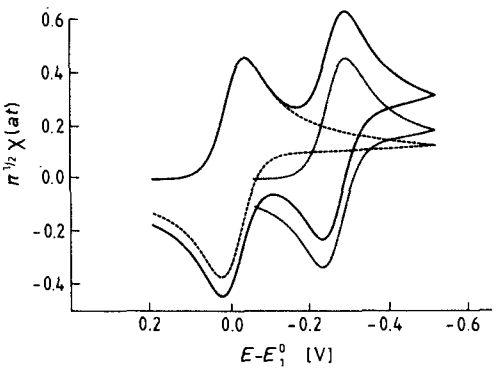

Fig. 6. Cyclic voltammogram for the EE mechanism: (——) 1e⁻ transfer at $E_1^0 = 0.0$ V *and* at $E_2^0 = -0.25$ V; (----) 1e⁻ transfer at E_1^0, (· · · ·) 1e⁻ transfer at E_2^0.

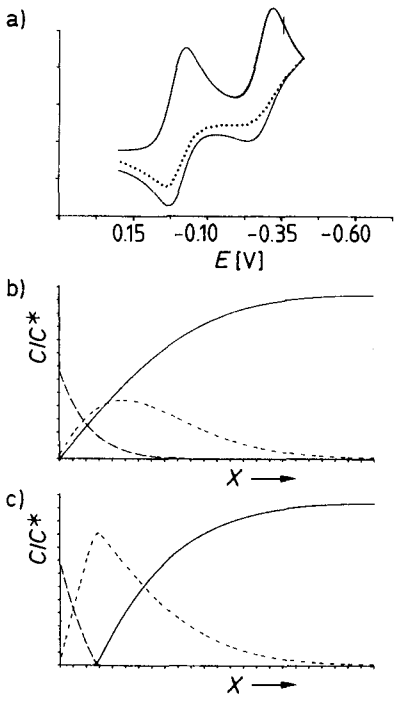

Fig. 7. a) Cyclic voltammograms for the EEC mechanism, $k_f/a = 0.5$, k_f = homogeneous rate constant of the follow-up reaction, a = sweep rate; (——) with disproportionation, (· · ·) without disproportionation; concentration profiles at $E = -0.35$ V; b) without disproportionation; and c) with disproportionation; (——) A, (– – –) $A^{\ominus}$, (— — —) $A^{2\ominus}$.

portionation is not directly visible in the cyclic voltammogram[62]. Significant changes occur only with quasi- or irreversible charge transfer or with subsequent chemical follow-up reactions (Fig. 7), and these must be taken into account in interpretating experimental data.

Case 2: $E_1^0 = E_2^0$

If the difference between the standard potentials of the two redox reactions is less than 100 mV, only a single wave appears in the voltammogram. When $\Delta E^0 = 0$, ΔE_p drops to 42 mV and the current function has a value 2.41 times that of a one-electron transfer (Fig. 8). The situation where structurally identical redox centers in one molecule do not interact constitutes a special case. Under these conditions electron transfers to the two centers are purely statistical[66,67]. The formal separation in standard potentials is then

$$\Delta E^0 = -\frac{RT}{F} \ln 4 = -35.7 \text{ mV } (25\,^\circ\text{C}) \qquad (19)$$

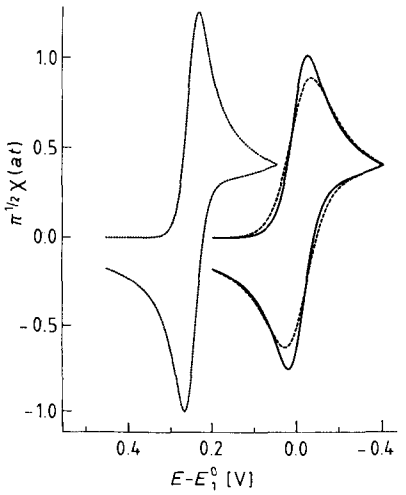

Fig. 8. Cyclic voltammograms for EE mechanisms with different E_1^0, E_2^0 potentials: (—) $E_1^0 = E_2^0 = 0.0$ V, $\Delta E_p = 42$ mV; (----) $E_1^0 = 0.0$ V, $E_2^0 = -0.035$ V, $\Delta E_p = 58$ mV; (····) $E_1^0 = 0.0$ V, $E_2^0 = 0.500$ V, $\Delta E_p = 29$ mV.

The resulting voltammograms (Fig. 8) are consistent with the normal E mechanism with $\Delta E_p = 58$ mV, but the current is twice as high. Two-step redox systems of this nature are usually present when the redox centers are separated from one another by either a fairly long polyene chain ($n \geq 4-5$) or an alkane chain ($n \geq 3$) or are in the *meta*-position in an arene[68]. *Hünig* et al. have studied numerous examples, but have not theoretically analyzed the cyclic voltammograms[69].

Case 3: $E_1^0 < E_2^0$

The energy required for the second electron transfer is less than for the first. In the ideal case ($\Delta E^0 < -180$ mV) such redox processes can be identified thus: in the cyclic voltammogram the ΔE_p splitting drops to 28.5 mV (25 °C) and the measurable current rises to a value equal to 2.82 times ($= 2^{3/2}$) that of a corresponding 1e-transfer. In contrast, it is not easy to determine the individual standard potentials, as the formal measurable half-wave potential

$$E_{1/2} = (E_1^0 + E_2^0)/2 \qquad (20)$$

corresponds to the mean value of both standard potentials.

Numerous examples of these "classical" 2e reactions, especially from inorganic and organometallic chemistry, have been discussed in the literature[70,71]. However, the diagnostic pattern for characterizing such processes can be applied only to fast heterogeneous charge-transfer reactions[62]. The picture for analogous 2e reactions of organic compounds is often quite different, as illustrated, for example, by slow heterogeneous reactions. The best-known example of this is cyclooctotetraene, for which in NH_3/KI the potential for the second, fast reaction step is 160 mV more positive than that for the kinetically slower first step[72]. Under these conditions quantitative analysis is possible only by numerical computation of the whole current-voltage curve (cf. Section 6).

3.2.2. *EEEE... Mechanisms*

Previously, more than two reversible charge-transfer steps were seldom observed in monomeric systems. Examples are mostly restricted to organotransition-metal compounds[1,73]. However, improvements in experimental techniques (cf. Section 2) have facilitated the reduction of highly reactive arenes possessing appropriate structural properties—e.g. 9,9′-bianthryl (Fig. 21) and its homologues or decacyclene **1**—to tetraanions or even hexaanions (Fig. 9)[74–76]. It is possible to completely evaluate the voltammogram provided the waves are clearly separated and the reactions are reversible. Otherwise one has to revert to digital simulation.

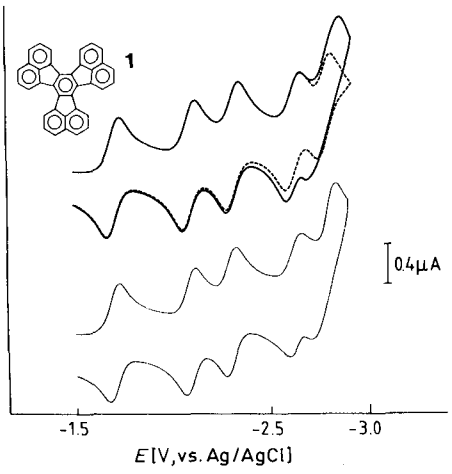

Fig. 9. Experimental (bottom) and simulated (top) cyclic voltammograms for **1** at −10 °C in tetrahydrofuran (THF)/$NaBPh_4$; (----) simulation with five redox steps, (——) simulation with six redox steps; $\vartheta = 50$ mV/s.

The majority of multicharge transfer reactions occur in polymers. These comprise, on the one hand, redox polymers, including biopolymers[77] with largely isolated cen-

ters and low intramolecular interaction and, on the other hand, conducting polymers whose charged redox centers interact strongly[78].

Evaluations are complicated by the fact that polymers are often insoluble or, if soluble, are quickly adsorbed at the electrode surface. Provided there are no interactions between chemically identical centers, theory predicts for an n-fold charge transfer voltammograms whose form corresponds to the $1e^-$ transfer case, but whose current values have the n-fold value of the $1e^-$ transfer[67]. For chemically non-equivalent, weakly interacting redox centers, as observed, e.g. in enzymes such as cytochrome, the cyclic voltammograms have to be analyzed by computer simulation[79] (cf. Section 6).

The cyclic voltammograms of insoluble redox polymers formally resemble those obtained in thin-layer cells[54] with a high surface/volume ratio; however, they are more consistent with models which describe the properties of totally adsorbed redox systems[80]. In the meantime, several research groups have developed other model concepts which discuss, inter alia, electron hopping mechanisms and the diffusion of the electrolyte counterion as rate determining steps[81–83]. Cyclic voltammograms are also being increasingly used to analyze the electrochemical properties of conducting polymers[84], graphite, and intercalated compounds[85]. However, interpretations are primarily phenomenological, concerning, for instance, the reversible charging and discharging of such systems as a function of potential and solution parameters (Fig. 10).

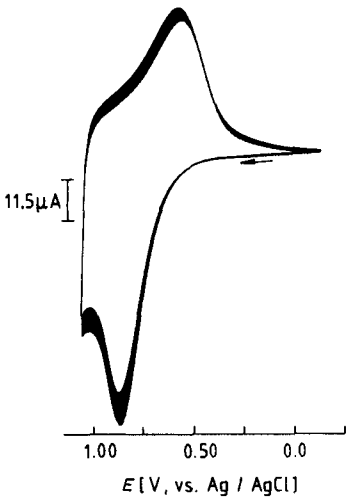

Fig. 10. Experimental cyclic voltammogram for the reversible oxidation (increasing current characteristics!) of polyacetylene in propionitrile/[TBA]PF_6. The CV was measured using a polymer-coated Pt electrode, $v = 200$ mV/s.

4. Electron Transfer with Coupled Chemical Reactions

Although charge-transfer processes are an important part of the entire spectrum of chemical reactions, they seldom occur as isolated elementary steps. In contrast, electron-transfer reactions coupled with bonding or bond-breaking steps are very frequent. Cyclic voltammetric experiments show the stability of both the educt and the product of the charge transfer. Accordingly, the method is suitable for both qualitative and quantitative characterization of chemical reactions which either precede or follow the charge transfer[21,23,86–91]. Scheme 1 lists the most important mechanisms for which cyclic voltammograms have been analyzed theoretically. A few examples are discussed in the following sections.

E	$A \overset{e}{\rightleftharpoons} B$	[11–16, 57]
EE_{disp}	$A \overset{e}{\rightleftharpoons} B$ $B \overset{e}{\rightleftharpoons} C$ $2B \overset{K_d}{\rightleftharpoons} A + C$	[18, 62, 66, 171]
EEEE...	$A \overset{e}{\rightleftharpoons} B \overset{e}{\rightleftharpoons} C \ldots$	[67, 171, 177]
$C_{1rev}E$	$A \underset{k_b}{\overset{k_f}{\rightleftharpoons}} B \overset{e}{\rightleftharpoons} C$	[16, 153]
$C_{1rev}EE$	$A \underset{k_b}{\overset{k_f}{\rightleftharpoons}} B \overset{e}{\rightleftharpoons} C$ (e)	[160, 155]
$EC_{1rev,irr}$	$A \overset{e}{\rightleftharpoons} B$ $B \underset{k_b}{\overset{k_f}{\rightleftharpoons}} C$	[16, 56, 101, 177]
$EC_{2rev,irr}$	$A \overset{e}{\rightleftharpoons} B$ $2B \underset{k_b}{\overset{k_f}{\rightleftharpoons}} C$	[96–101, 115]
$EC_{2rev,irr}$	..... $B + A \underset{k_b}{\overset{k_f}{\rightleftharpoons}} C$	[97]
$EC_{2rev,irr}$	..... $B + Z \xrightarrow{k_f} C$	[101]
EC_{nrev}	..... $nB \underset{k_b}{\overset{k_f}{\rightleftharpoons}} qC$	[99]
EC_{cat}	$A \overset{e}{\rightleftharpoons} B$ $B + Z$	[16]
ECE_{disp}	$A \overset{e}{\rightleftharpoons} B$ $B \overset{k}{\rightleftharpoons} C$ $C \overset{e}{\rightleftharpoons} D$ $B + C \overset{K_d}{\rightleftharpoons} A + D$	[17, 101, 124–127, 97]
$\bar{E}C\bar{E}_{disp}$	$A \overset{+e}{\rightleftharpoons} B^{\ominus}$ $B^{\ominus} \overset{k}{\rightleftharpoons} C^{\ominus}$ $C^{\ominus} \overset{-e}{\rightleftharpoons} D$ $C^{\ominus} + A \overset{K_d}{\rightleftharpoons} D + B^{\ominus}$	[143, 147, 151]

Scheme 1. List of the most important electrochemical mechanisms whose cyclic voltammograms have been theoretically analyzed.

4.1. EC Mechanisms

The simplest mechanism is electron transfer with a subsequent first-order, irreversible chemical follow-up reaction (EC_{irr}).

$$A \overset{e}{\rightleftharpoons} A^{\ominus} \tag{21}$$

$$A^{\ominus} \xrightarrow{k_f} B \tag{22}$$

In the follow-up reaction the initially formed anion $A^{\ominus}$ decays and a new species **B** is formed (Fig. 11). In consequence, only a small amount of the primary anion is avail-

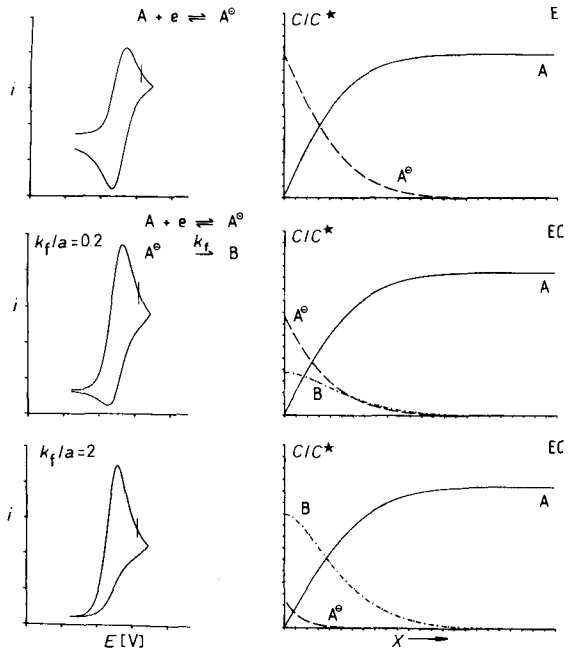

Fig. 11. Cyclic voltammograms (left) and accompanying concentration profiles for a coupled chemical, first-order, irreversible, follow-up reaction; k_f/a = dimensionless rate constant, | potential value at which concentration profiles were calculated.

able for oxidation in the reverse sweep, depending on the rate of the follow-up reaction and the sweep rate. Accordingly, the corresponding anodic current in the cyclic voltammogram decreases until it disappears at high rate constants and low sweep rates. The rate constant of the follow-up reaction can be determined from the ratio of the anodic and cathodic peak currents of the cyclic voltammetric curve at an appropriate sweep rate. The current ratio and the homogeneous kinetic parameters are correlated using theoretical working curves in which — to save computer time and effort — the kinetic parameters are dimensionless[18]. Because of this simplification, experimental data from different measurements can be evaluated with just a few working curves (Fig. 12). Thus, the dimensionless kinetic parameter for a first-order reaction is $k_{f_1} \cdot \tau$ (τ = time

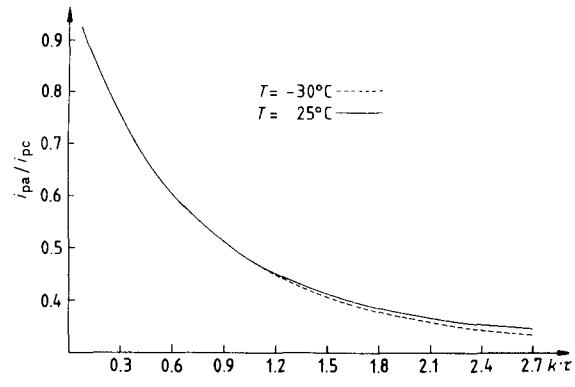

Fig. 12. Working curves for a coupled first-order (irreversible), follow-up reaction (EC_{irr}), τ: time elapsed between passing the E^0 potential and reaching the switching potential E_λ; k [s^{-1}] = homogeneous rate constant of the follow-up reaction.

between passing the E° potential and reaching the switching potential E_λ) and for a second-order reaction, $k_{f_2} \cdot c^* / a$.

In addition to the current ratio, other (diagnostic) criteria also indicate a coupled chemical reaction, e.g. a shift in the peak potential as a function of the kinetic parameters. Details are provided in the literature[21,23,86]. However, they can be used to quantitatively interpret electrochemical reaction mechanisms only if characteristic reference parameters of the undisturbed charge transfer are available, e.g. E°, or if, as in the case of second-order reactions, the peak potential shift can be measured as a function of the substrate concentration. As a general rule, for reduction processes the peak potential values shift in the anodic direction as the rate constants of the subsequent reactions increase. Hence, they do not correspond to thermodynamic redox potentials.

Although the coupled irreversible first-order, chemical follow-reactions form an elementary step in many electrochemical processes, only in a few favorable cases can the "pure" EC mechanism be recognized in the cyclic voltammogram. A further prerequisite for a successful kinetic analysis using cyclic voltammograms is that the intermediate should have a life-time $\geq 10^{-4}$ s. The reason for this is technical, since at scan rates above 1000 V/s the capacitive currents, which are directly proportional to v, gradually overlap with the Faradaic part of the current. In principle, the rate constants of the follow-up reaction can also be derived from irreversible waves provided the half-wave potential of the reversible electrode reaction is known.

Slow first-order EC reactions have been observed and analyzed in the following cases: electron-transfer induced valence isomerizations[92] and conformational changes[93], as well as the reduction of aryl halides[94,95].

Second-order EC reactions are far more common. Several variants are possible: reactions of the electron-transfer product with itself[96–100], with the educt[97], or with another compound present in the solution[101]. In addition, one must distinguish between reversible and irreversible processes. Second-order follow-up reactions can usually be recognized by the concentration dependence of corresponding cyclic voltammograms: with decreasing substrate concentrations, reversible currentvoltage curves are observed even at low sweep rates. The quantitative evaluation can be made with the aid of either calculated working curves[98,102] or by digital simulation[103].

The mechanistic analysis of such processes became relevant as a result of the technologically important reductive dimerization of activated olefins[104–108], as performed industrially in the electrosynthesis of adipodinitrile from acrylonitrile. Studies conducted with different electroanalytical methods show that for the most part radical-radical dimerization dominates over radical-educt coupling. Apart from the coupling reactions of neutral phenoxyl[109,110] and pyranyl radicals[111] or of inorganic radical ions such as SO_2[112], cyclic voltammetry has recently also been used to investigate and, in part, quantitatively evaluate the dimerizations of aromatic radical anions[113–115].

The radical-radical coupling of the anion of 9-anthracenecarbonitrile **2** is one of the most interesting examples of reversible chemical dimerization [Eq. (23)].

$$\mathrm{A} \overset{e}{\rightleftharpoons} \mathrm{A}^{\ominus}$$
$$2\,\mathrm{A}^{\ominus} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} \mathrm{A}_2^{2\ominus} \qquad (23)$$

Contrary to expectations, this gives at low sweep rates a cyclic voltammogram whose wave-form is reversible and whose anodic current peak gradually disappears as v (V/s) increases (Fig. 13)[103,113-115]. The explanation of this phenomenon is that at low scan rates the chemical reaction is in thermodynamic equilibrium. The cyclic voltammogram is shifted anodically as the value of the equilibrium constant increases but retains its characteristic reversible form[96]. As v increases the system falls under kinetic control, i.e. on this time scale chiefly the dimer is produced at the cost of the slow reverse reaction. The cyclic voltammogram becomes irreversible. If the time scale is short enough, the kinetics of dimerization remain incomplete, and the (true) reversible state is approached. By using the dimensionless kinetic paramter ψ, which takes into account the substrate concentration c^*, the equilibrium constant K, the rate constants k_f [L mol^{-1} s^{-1}] and k_b [s^{-1}] of the forward and reverse reactions as well as the scan rate, the limiting cases of this EC_{2rev} mechanism can be formulated [Eq. (24)]

$$\psi = \frac{Kc^*}{[(k_f c^* + k_b c^*)/a]^{1/2}} = \frac{Kc^*}{(lc^*/a)^{1/2}} \qquad (24)$$

where $l = k_f + k_b$

1. k_f and $k_b \to \infty$ or $a \to 0$: system in dynamic dimerization equilibrium, reversible *potential-shifted* cyclic voltammograms;
2. k_f and $k_b \to 0$ or $a \to \infty$: no follow-up reaction, pure charge-transfer process;
3. $l/a \to \infty$ and $\psi \to \infty$, $k_f \gg k_b$, $K \gg 1$: irreversible follow-up chemical reaction.

The quantitative evaluation of the voltammograms of **2** (propionitrile, 20 °C) using digital simulation methods (cf. Section 6) gives a value of 2×10^4 L·mol^{-1}·s^{-1} for the dimerization rate constant k_f and 3.5 s^{-1} for k_b. Accordingly, the thermodynamic equilibrium constant $K = 5.7 \times 10^3$ L·mol^{-1} [103].

In contrast to the dimerizations of radical anions, the radical-substrate coupling seems to be an important reaction

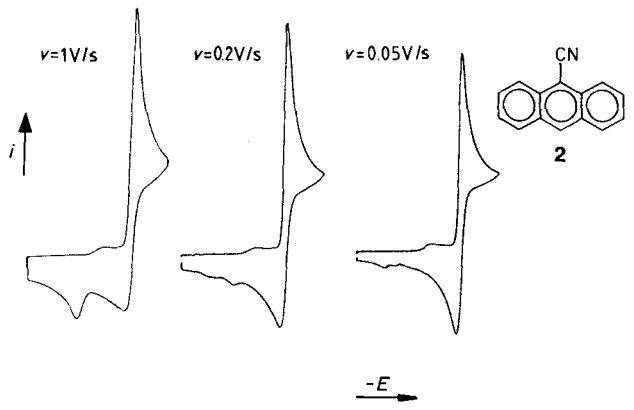

Fig. 13. Cyclic voltammograms for the reduction of **2** in propionitrile/[TBA]PF_6 at different scan rates.

path for radical cations[116-118]. This is due to the quantum mechanical exchange interactions between the cation and the neutral species[119], which facilitate formation of a charge-transfer bond.

Important examples of radical-substrate dimerization have been shown to occur in the electrocrystallization of radical cations of aromatic compounds[26].

Due to their high conductivity, crystalline radical cation salts are "organic metals", and for this reason are studied intensively by solid-state physicists[120]. X-ray structure analysis has shown that, besides the ideal composition $A_2^{\oplus}X^{\ominus}$, as observed in the electrocrystallization of fluoroanthene **3** ($X = PF_6$), different stoichiometries occur in many systems depending on the reaction conditions (solvent, temperature, concentration)[121,122]. The type and kinetics of coupled chemical reactions, whose products in solution determine the stoichiometry of the crystals, were clarified for some exemplary systems with the aid of cyclic voltammetric measurements in conjunction with digital simulation (Scheme 2)[123].

$$\begin{aligned}
&\mathrm{A} && \overset{E_1}{\rightleftharpoons} \mathrm{A}^{\odot\oplus} + \mathrm{e}\\

&\{[\mathrm{A}_2]^{n\oplus}(\mathrm{X}^{\ominus})_n\}_{\mathrm{ads.}} && \longrightarrow \{[\mathrm{A}_2]^{n\oplus}(\mathrm{X}^{\ominus})_n\}_{\mathrm{cryst.}}
\end{aligned}$$

Scheme 2. Reaction steps in the electrocrystallization of salts with radical cations; the indices compl. and ads. indicate complexation and adsorption at the metal electrode, respectively.

The radical cations $A^{\odot\oplus}$ produced at the electrode form dimeric monocations $A_2^{\odot\oplus}$ with the substrate present in solution in an equilibrium reaction. At a slightly more positive potential these are oxidized to the much more unstable dimeric dications $A_2^{2\oplus}$, which are simultaneously also products of a direct radical-radical dimerization. The stability of the dimeric monocations $A_2^{\odot\oplus}$ is apparent from the voltammograms. For **3** these show a high formation constant — the amount of oxidizable $A_2^{\odot\oplus}$ is large, but pyrene **4**, in contrast, has a much smaller constant and the oxidizable amount of $A_2^{\odot\oplus}$ is small (Fig. 14). For **4** ($X = PF_6$, AsF_6, ClO_4) the stoichiometry of the crystals is influenced by the high proportion of monomeric cations as well as by unreacted substrate, whereas **3** ($X = PF_6$, AsF_6, ClO_4) contains almost exclusively crystalline material of composition $A_2^{\oplus}X^{\ominus}$.

4.2. ECE Mechanism

The two-step mechanisms with coupled chemical reaction described in the previous section are, as the last example has shown, often part processes in a complicated reaction. In most cases the product of a subsequent reaction is itself once again electroactive. The result is the well-known ECE mechanism, in which the chemical reaction can be of either the first[17,101,124-127] or second[97] order.

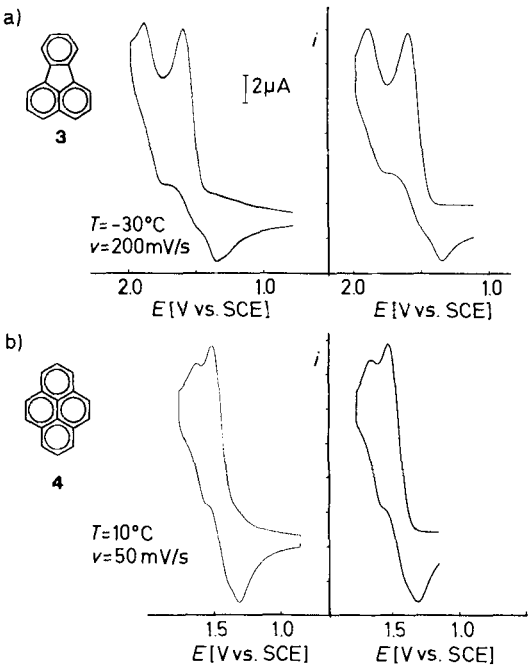

Fig. 14. a) Experimental (left) and simulated (right) cyclic voltammograms for the oxidation of a) **3** and b) **4** in CH_2Cl_2.

$$\mathbf{A} \overset{E_1^0}{\rightleftharpoons} \mathbf{B} \tag{25}$$

$$\mathbf{B} \overset{k_f}{\rightleftharpoons} \mathbf{C} \tag{26}$$

$$\mathbf{C} \overset{E_2^0}{\rightleftharpoons} \mathbf{D} \tag{27}$$

$$\mathbf{B} + \mathbf{C} \overset{K_D}{\rightleftharpoons} \mathbf{A} + \mathbf{D} \tag{28}$$

Depending on the separation of the standard potentials of the two redox couples, one must distinguish between three situations (Fig. 15). Provided that the potential of the second redox step is much lower than that of the first (i.e., $E_1^0 > E_2^0$ for reduction), the homogeneous kinetic parameters can be determined without difficulty from the CV data of the first redox wave by analogy to a normal EC reaction. In other words by using appropriate sweep rates and switching potentials E_λ the rate constants can be deduced from the current ratio i_{pa}/i_{pc} with the help of suitable

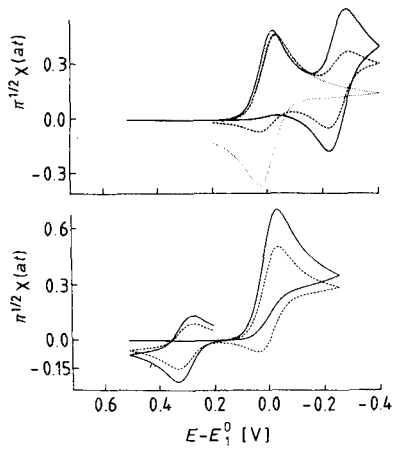

Fig. 15. Simulated cyclic voltammograms of the ECE mechanism with homogeneous disproportionation; (····) $k_f/a = 0.0$, (---) $k_f/a = 0.1$, (—) $k_f/a = 1.0$; above: $E_1^0 = 0.0$, $E_2^0 = -0.25$ V; below: $E_1^0 = 0.0$, $E_2^0 = 0.3$ V.

working curves. The second wave can also be used to analyze the kinetics of the follow-up reaction, in which the peak current is an unequivocal function of the ΔE^0 separation, the sweep rate, and the homogeneous rate constant.

For equal standard potentials ($E_1^0 = E_2^0$), one observes as a rule a single apparently reversible wave whose current ratio, however, is always less than 1 and, for large rate constants, can drop as low as 0.5.

If $E_1^0 < E_2^0$, the CV has an irreversible step in the first cycle at ca. E_1^0; the value of its current amplitude in fast follow-up reactions is *twice* that of a one-electron transfer reaction[128] (Fig. 15). The increase in the current amplitude arises because the second electron transfer, although thermodynamically favored, can occur only after the first electron transfer and formation of the follow-up product **C**. Accordingly, reoxidation of the **C/D** redox pair only becomes visible at ca. E_2^0 in the anodic part of the voltammogram after the E_1^0 potential has again been passed. The irreversibility of the E_1^0 wave, a consequence of the chemical follow-up reaction, corresponds to the amplitude of the current in the second redox step.

The obvious comparison between the ECE mechanism and the EE reaction (cf. Section 3.2.1.) shows that both electron-transfer steps are coupled in a similar way to one another via a homogeneous disproportionation[124–127]. Hence, the product **D** is not only formed by heterogeneous electron-transfer but, in accordance with Eq. (28) (for reduction reactions where $E_2^0 \geqslant E_1^0$), also by homogeneous electron-transfers in a competing reaction. The influence of the disproportionation on the shape of the cyclic voltammogram is complicated and can cause considerable difficulties in its evaluation. Hence, the quantitative analysis of ECE mechanisms requires digital simulations and a direct comparison between the experimental and calculated cyclic voltammograms.

For a long time there was little experimental data on ECE mechanisms. The standard example described in the literature was usually the reduction of nitrosophenols[129, 130]. Only since the late 1960s has it become obvious, especially through the experimental research of *Adams, Nelson* et al.[22, 131–133] and *Parker* et al.[134, 135], that the ECE mechanism, including the homogeneous disproportionation, embodied an important mechanistic principle in electrochemical reactions. It is now almost impossible to keep up with all new work in the field. The ECE mechanism occurs in virtually all chemical reactions induced by electron transfer, including, inter alia, isomerizations, couplings, substitutions, additions, and eliminations[89, 136–139]. In most of these reactions the second e-transfer is energetically more favorable than the first, so that the appearence of a single irreversible wave with *twice* the current amplitude of the 1e norm in the forward sweep of the cyclic voltammogram is a hallmark of the ECE reaction (Fig. 15). However, improved experimental and theoretical methods of monitoring and evaluating cyclic voltammograms verify that the simple ECE scheme is often disturbed by competing parallel reactions or further follow-up reactions[88, 140–142].

The efficiency of cyclic voltammetric measurements in characterizing elementary steps and determining kinetic parameters of electron-transfer induced reactions is im-

pressively illustrated by one variant of the ECE mechanism. This development was initiated by *Feldberg* et al.[143]. In this case, after the chemical follow-up product has been formed the second electron transfer occurs, in contrast to the normal case, in the *reverse* direction to the E_1^0 step.

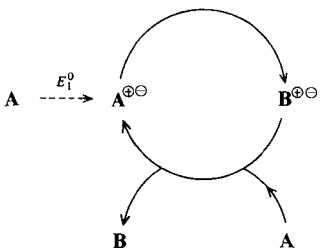
$$\mathbf{A} \mp e \rightleftharpoons \mathbf{A}^{\oplus\ominus}[*] \quad (29)$$

$$\mathbf{A}^{\oplus\ominus} \xrightarrow{k} \mathbf{B}^{\oplus\ominus} \quad (30)$$

$$\mathbf{B}^{\oplus\ominus} \pm e \rightleftharpoons \mathbf{B} \quad (31)$$

$$\mathbf{B}^{\oplus\ominus} + \mathbf{A} \rightleftharpoons \mathbf{B} + \mathbf{A}^{\oplus\ominus} \quad (32)$$

The ion **A** formed at the potential E_1^0 is transformed in one (or more) chemical steps into the species $\mathbf{B}^{\oplus\ominus}$, which, provided $|E_2^0| > |E_1^0|$, in turn spontaneously changes into the product **B**. The electron transfer from $\mathbf{B}^{\oplus\ominus}$ to **B** can occur both heterogeneously at the electrode [Eq. (31)] or homogeneously in solution [Eq. (32)]. The homogeneous electron transfer is of crucial importance, since by this means the chemically unstable species $\mathbf{A}^{\oplus\ominus}$ is permanently reproduced [Eq. (32)]. A chain reaction takes place which, under favorable conditions — i.e. no terminating reactions — is catalyzed by a single electron transfer from **A** to $\mathbf{A}^{\oplus\ominus}$; **A** is transformed quantitatively into **B** (Scheme 3).



Scheme 3.

Such ETC processes (*e*lectron *t*ransfer *c*hain) can be recognized in cyclic voltammograms since with small sweep rates and large values for the dimensionless kinetic parameter k_f/a the wave of the redox pair $\mathbf{A}/\mathbf{A}^{\oplus\ominus}$ disappears virtually completely (Fig. 16). The chain reaction induced by electron transfer ($\Delta G^\circ < 0$!) does not require any current. If the sweep rate is incremented the chemical reactions leading from $\mathbf{A}^{\oplus\ominus}$ to $\mathbf{B}^{\oplus\ominus}$ cannot be completed on the time scale of the experiment, with the result that in the cyclic voltammogram the redox wave of $\mathbf{A}/\mathbf{A}^{\oplus\ominus}$ increases, while the corresponding $\mathbf{B}/\mathbf{B}^{\oplus\ominus}$ wave disappears.

Initially the ETC concept was largely disregarded, but since the discovery by *Russell* et al. and *Bunnett*[144,145] of radical-nucleophilic aromatic substitution, the $S_{RN}1$ reaction, it has acquired great significance. Aryl halides ArX react with electron-rich nucleophiles (e.g. thiophenolate or diethylphosphite ions) via the radical anion intermediate $ArX^{\odot\ominus}$ to the corresponding substituted products. *Savéant* et al. have shown that the $S_{RN}1$ reaction can also be electrochemically triggered and, moreover, accurately analyzed by cyclic voltammetry[9,146,147]. Other ĒCĒ processes, which occur via rapid chain reactions include, e.g., the *cis-trans* isomerization of enol ethers[148], the transformation of epoxides into ketones[149], or the ligand substitution reactions of carbonylmetal complexes[150]. *Kochi* et al.[151] describe a particularly impressive example which is proved by cyclic voltammograms and digital simulation, namely ligand substitution reactions with carbonylmanganese complexes. Recently, cycloadditions have also been discussed in terms of ETC mechanisms[152]. Cyclic voltammetry could possible supply proof for this mechanistic hypothesis.

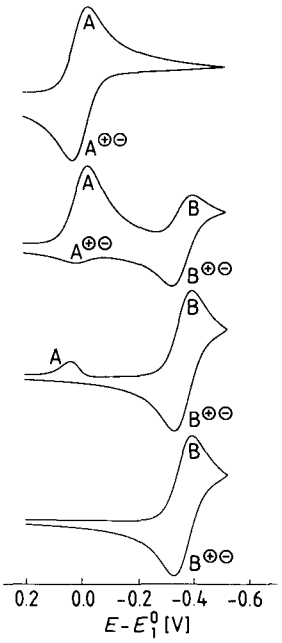


Fig. 16. Simulated cyclic voltammograms for the catalytic ĒCĒ mechanism; $E_1^0 = 0.0$ V, $E_2^0 = -0.35$ V; from top to bottom: $k_f/a = 0.0, 0.1, 10, \geq 100$.

4.3. The ECCEE Mechanism

The mechanisms analyzed in the previous sections constitute a small but experimentally significant part of the spectrum of elementary electrochemical reactions. Omissions include, e.g., CE mechanisms; although their theory has been studied in depth[116,153], only a few examples have been confirmed by voltammetric measurements[154,155]. Notwithstanding this, the number of different reaction channels is exceptionally large, and the interpretation of any one cyclic voltammogram should not follow standard schemes alone. An instructive example of this is the reduction of 10-fluoro-9-anthracenecarbonitrile **5**; at the same time it is a demonstration of the power of digital simulation[156].

As a rule, halogenated arenes are reduced electrochemically to the corresponding hydrocarbons by eliminating halides (ECEC reaction)[157]. Therefore, if one starts with **5** the expected final product of the electrode reaction is 9-anthracenecarbonitrile **2**. Cyclic voltammograms recorded at 0.5 V/s support this assumption in that the value of the peak current ratio of the first wave is less than 1 and in the reduction range of **2** the expected smaller, reversible wave appears. The only unusual aspect is the peak potential separation ΔE_p of ca. 200 mV in the first reduction wave (Fig.

[*] $\mathbf{A}^{\oplus\ominus}$ symbolizes both the cation $\mathbf{A}^{\oplus}$ and the anion $\mathbf{A}^{\ominus}$.

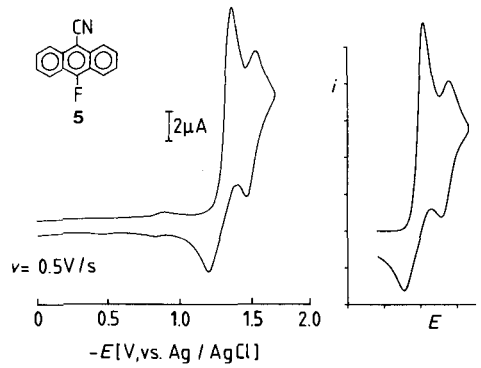

Fig. 17. Experimental (left) (propionitrile, [TBA]PF_6, 20°C) and simulated cyclic voltammograms for the reduction of **5** at 0.5 V/s.

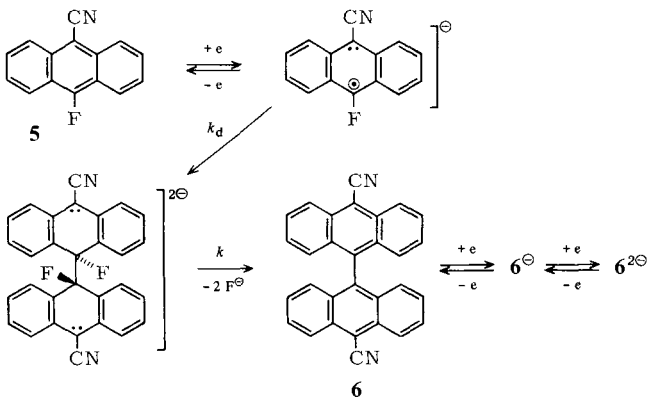
17). But as soon as the sweep rate is increased to 10 V/s the misinterpretation becomes apparent: in the anodic part of the first wave a second peak appears (Fig. 18). As the sweep rate is increased the first anodic wave grows smaller; above 50 V/s the cyclic voltammogram approaches that of the reversible reduction of **5**. Both digital simulation of the voltammograms (Figs. 17, 18) and the results of the



product analysis — 10,10'-bi-9-anthracenecarbonitrile **6** is formed — reveal that the radical anion of **5** does not react further by eliminating fluoride but, by analogy to **2**, dimerizes to the dianion. A further one or two chemical steps follow in which the fluoride ions are eliminated and **6** is formed. The rate-determining step for the whole reaction is the dimerization, for which a rate constant $k_f = 1.2 \times 10^3$ L mol^{-1} s^{-1} was determined by computer simulation (20°C).

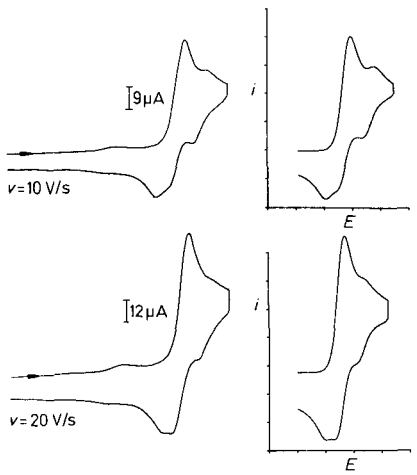


Fig. 18. Experimental (propionitrile, [TBA]PF_6, 20°C) and simulated cyclic voltammograms for the reduction of **5** at 10 and 20 V/s.

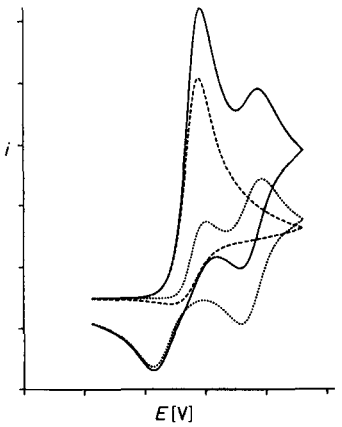

Fig. 19. Simulated cyclic voltammograms for the ECCEE mechanism: (—) complete cyclic voltammogram; (-----) cyclic voltammogram of the ECC reaction omitting the reduction of the electroactive follow-up product; (·····) reduction of the electroactive follow-up product (EE) in an ECCEE reaction.

Figure 19 gives an impression of the "fine structure" of the voltammogram of an ECCEE reaction. Accordingly, the first anodic peak essentially corresponds to the oxidation of the anion of the follow-up product **6**; in contrast, the first cathodic wave is composed of the reduction waves of **5** and **6**. The whole of the second wave of the cyclic voltammogram is the result of the formation of the dianions $6^{2\ominus}$.

5. Low Temperature Voltammetry

Recent developments have shown that low temperature experiments in voltammetry are extremely useful for qualitative and quantitative mechanistic studies.

Originally, low temperature experiments served to stabilize reactive intermediates whose existence could not be established on the time scale of cyclic voltammetry at room temperature[58]. The pioneering work of *Van Duyne* and *Reilley*[159] laid the experimental and theoretical basis for this technique. In their studies, the authors were able to prove, for the first time, that the instability of electrochemically produced radical cations is often due to the presence of nucleophilic impurities (H_2O) in the aprotic solvent or to the nucleophilic properties of the solvent itself (dimethylformamide, acetonitrile).

In recent studies low temperature voltammetry has been used to analyze conformational equilibria which precede electron transfer (CEE mechanism[160]). Since conformational isomers are usually separated by low activation barriers, this technique is the method of choice. So far, the thermodynamics and kinetics of the conformational interconversions of cyclic dialkylhydrazines[155] and vicinal dibromides[161,162] have been studied by cyclic voltammetry in butyronitrile at $T \leq -55$°C. However, a crucial prere-

quisite for the success of such experiments is that the heterogeneous electron-transfer reactions at the isomers, which have virtually identical redox potentials, occur at different rates, thereby facilitating the observation of separate current waves.

Although the determination of activation parameters has long been routine in experimental kinetics[163], examples are still rare in voltammetry. Measurements of the activation energies in the reductive dimerization of **2** and other anthracene derivatives (cf. Section 4.1.) are the best known examples, perhaps because the unexpectedly low activation energies and slow kinetics have generated an intense — and unresolved — controversy in the literature[114,115]. As an explanation for this finding, *Parker* et al.[114] postulated a two-step mechanism, the first of which is the formation of an intermediate complex; in contrast, *Savéant* et al.[115] take the view, based on the assumption of direct radical ion dimerization, that steric factors are responsible for the slow kinetics.

Heinze and *Schwart*[95] concluded from the change in the Arrhenius data for the reduction of 10-chloro-9-anthracenecarbonitrile **7** that there are two competing reactions (Fig. 20). Since then it has been shown that **7** is dimerized by reduction (EC_2...) and in a competing, parallel elimination of the halide (EC_1...) transformed into **2**[103,164].

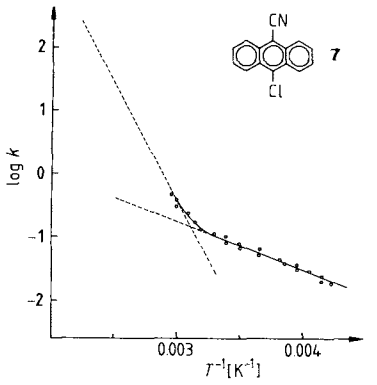

Fig. 20. Arrhenius plot for the decomposition of the radical anion of **7** (butyronitrile, [TBA]PF_6), experimental data from cyclic voltammetric experiments (+50 to −40°C).

Besides the kinetic perspectives, there have recently been indications that low temperature voltammetry may be used to characterize thermodynamic parameters. Reducing arenes in THF in the presence of $NaBPh_4$ as ground electrolyte, one observes in the cyclic voltammograms that with decreasing temperature there are large shifts in the redox waves of the multicharged anions in the cathodic direction[76,92] (Fig. 21). These effects result from a change in the ion pair equilibria caused by increasing solvent permittivity: at low temperatures they are transformed from contact ion pairs into solvent-separated ion pairs. In extreme cases this shift can amount to 600 mV. This corresponds to a change in the ion pair formation constant of ten orders of magnitude. Low temperature voltammetry, like the spectroscopic methods[165], has thus proved a sensitive tool for the study of ion pair effects.

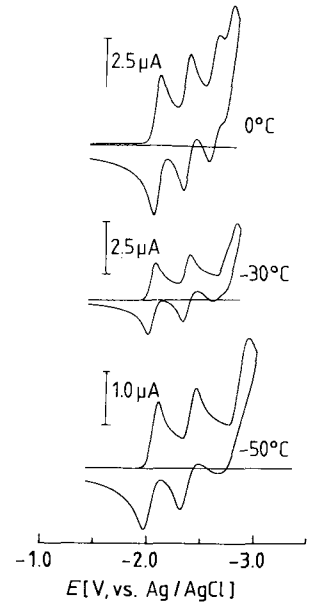

Fig. 21. Cyclic voltammograms for the reduction of 9,9'-bianthryl in THF/$NaBPh_4$ over the temperature range 0 to −50°C. Strong ion-pairing effects cause large cathodic shifts of the redox steps as the temperature decreases.

6. Digital Simulation

The variety of electrochemical reaction mechanisms and the individuality of the systems investigated reveal again and again that diagnostic criteria or known working curves are not sufficient for a quantitative evaluation of cyclic voltammetric experiments. Ambiguity is often removed only by completely calculating the current-voltage curves for different experimental parameters.

Numerical methods have proved themselves in the theoretical analysis of cyclic voltammograms[19,20]. Most of them are based on finite difference approximations[166], but over the last three years the use of finite element methods has been discussed[167–169], some variants of which are as efficient as the difference methods[170].

The finite difference approximations have become very popular due to their simplicity and clearness. *Feldberg*'s classical works[19,171] popularized them under the concept of *digital simulation*. The principle of the calculation is based on transforming the differential form of the mass transport equation [Eq. (4)] into a difference equation [Eq. (33)].

$$\frac{c_i'-c}{t'-t} \equiv \frac{\Delta c}{\Delta t} = \frac{D}{\Delta x^2}(c_{i+1}-2c_i+c_{i-1}) \qquad (33)$$

$i = 0, 1, 2, \ldots, N$

The mass transport problem is discretized in time and space. This means that within each respective time interval Δt the concentration values of the diffusion layer at i grid points at intervals Δx are calculated from the difference in the corresponding fluxes to and from each individual grid point (Fig. 22). The electrode process [heterogeneous charge-transfer—Eq. (3)] which controls the mass transport is a boundary condition of the simulation model. Coupled chemical reactions, as a rule the reason for simulations, are

taken into account in the difference model through the simple addition of the kinetic terms.

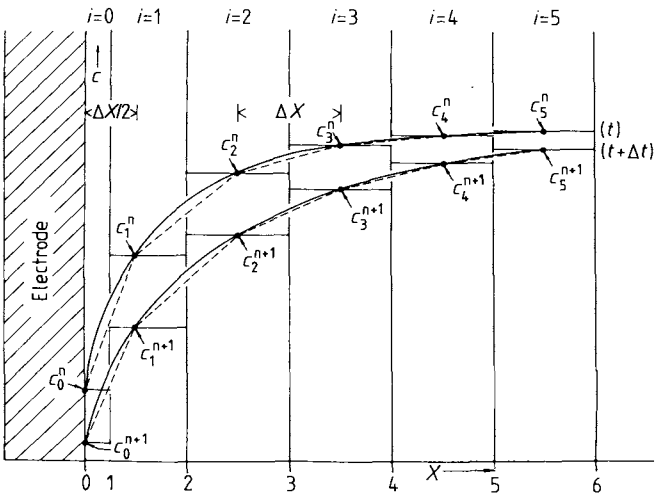

Fig. 22. Equidistant grid for the simulation of diffusive mass transport using finite difference approximation. The discrete values of a concentration profile are calculated in Δx intervals using Eq. (33) or (34).

In this way all important mechanisms can, in principle, be simulated numerically. However, the explicit method favored previously met with problems caused by computer time and stability for fast processes, both of which were never really overcome[172–175]. For this reason the use of implicit methods for digital simulation has gained ground, especially the efficient Crank-Nicholson technique[176, 177]. Whereas in explicit methods the new concentration values c_i' are determined point by point from the differences of the "old" concentrations [Eq. (33)], in the implicit method they are obtained by solving a system of simultaneous equations [Eq. (34)].

$$\frac{c_i'-c_i}{\Delta t}=\frac{D}{2\Delta x^2}(c_{i+1}'-2c_i'+c_{i-1}'+c_{i+1}-2c_i+c_{i-1}) \qquad (34)$$

$i=0, 1, 2, \ldots, N$

Although the associated computer programming is more complicated, the Cranck-Nicholson method is unconditionally stable and very accurate for all combinations of parameters. Furthermore, the computer time for the simulation of fast reactions is considerably shorter than with the explicit method.

7. Prospects

In recent years cyclic voltammetry has developed into an efficient technique for characterizing heterogeneous and homogeneous electron-transfer mechanisms.

In this article, space has not permitted more than a small selection of examples to be delineated, with emphasis being placed on organic reactions, but those selected should illustrate the *potential* of the method. The knowledge that numerous reactions which have so far been interpreted only in chemical terms are also coupled with electron transfer processes or catalyzed by them should ensure a wider field of application. Moreover, the quantification of measurements will become routine as soon as simulation programs and evaluation methods become available which can be fairly easily mastered by chemists without special mathematical training.

Two paths of potential development are already apparent. The increasing use of faster, more efficient data processing systems will promote new presentations of voltametric experiments, e.g. the convolutive or semi-integral technique[178–180] or derivative voltammetry[181]. These methods have considerable advantages over conventional voltammetry in that they simplify the acquisition and evaluation of kinetic data.

The prospective introduction of ultramicroelectrodes will in principle expand the measuring possibilities[52, 182]. Firstly, this will extend the time scale of voltammetry by two to three orders of magnitude. Secondly, the extremely small measuring currents will soon permit routine experiments in low-conductivity solutions, which will facilitate the study of electron-transfer reactions in solvent electrolyte systems virtually free of supporting electrolytes[65].

I am indebted to my colleagues whose names appear in the literature citations for the successful collaboration. Our work has been generously supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, and the Fonds der Chemischen Industrie, to whom I once again express my gratitude.

Prostaglandin Syntheses by Three-Component Coupling

New Synthetic Methods (49)

By Ryoji Noyori* and Masaaki Suzuki

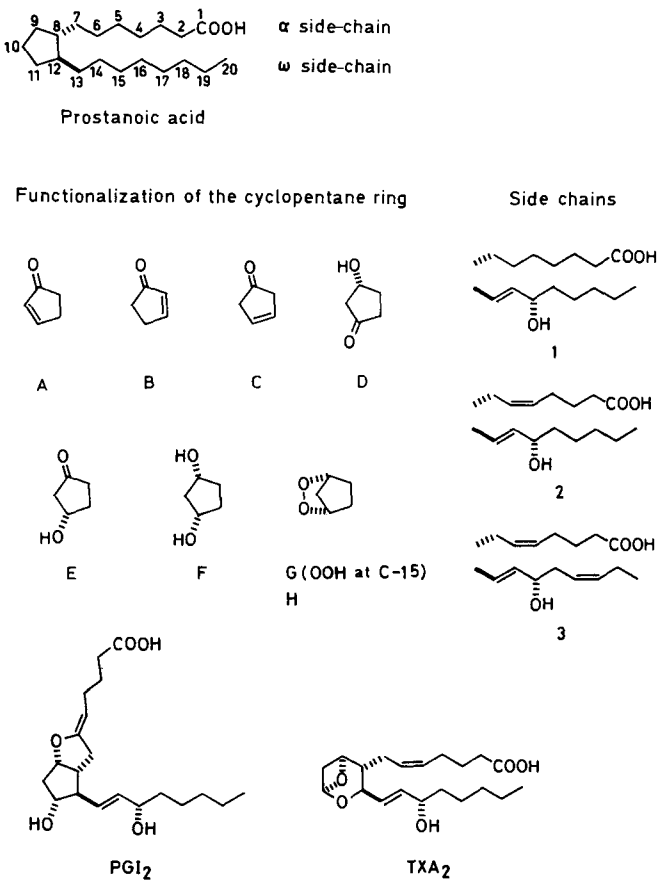
The role played by prostaglandins (PGs) in the human body is bewitching. Following the elucidation of their structures in the early 1960s, tremendous efforts were made for the realization of an efficient chemical synthesis, since a sufficient supply of such very rare, naturally occurring local hormones relies solely on their total synthesis. Of the many synthetic routes described in the literature, the majority of which are linear or sequential in nature, the Corey synthesis is perhaps the most versatile; so far more than 5000 prostaglandin analogues have been prepared and have been tested biologically. Some natural prostaglandins and their analogues are already in clinical use. In view of the continuing expansion of this field, we have been fascinated with the concept of developing a highly convergent entry to prostaglandins based on a new strategy. The discovery of a highly enantioselective method for the reduction of prochiral ketones and the elaboration of a procedure for double vicinal CC-coupling with enones have enabled a one-pot synthesis of the complete prostaglandin skeleton by linking a chiral 4-oxygenated 2-cyclopentenone unit and two side-chain blocks. This approach is efficient and flexible and allows the direct production of all the naturally occurring prostaglandins and a wide spectrum of analogues.

1. Introduction

Prostaglandins exhibit diverse pharmacological properties and are now recognized as local hormones that control a multitude of important physiological processes[1]. The chemical, biological, and medicinal investigations being carried out in this area stand in the forefront of the life sciences. Since the elucidation of the structure of the prostaglandins (Scheme 1) in the early 1960s, their chemical synthesis has occupied one of the central, exciting places in synthetic organic chemistry, because a total synthesis is the only means by which sufficient quantities of these

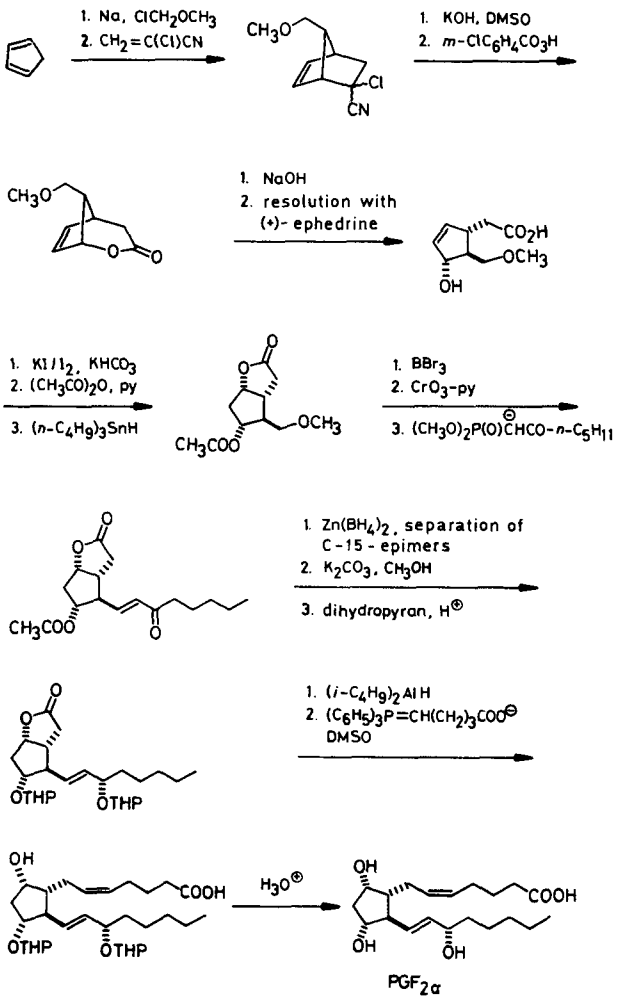
[*] Prof. Dr. R. Noyori, Assoc. Prof. Dr. M. Suzuki
Department of Chemistry, Nagoya University
Chikusa, Nagoya 464 (Japan)

physiologically bewildering but rare, naturally occurring substances can be made available. Their biosynthesis simply cannot meet the ever increasing demand for these substances[2] nor provide adequate amounts of precursors for the production of medicinally important compounds possessing modified structures. A tremendous number of chemists have so far been involved in the synthesis of prostaglandins and more than 450 publications on this topic appeared in the literature up to 1982[3]. It is not the intention of this article, however, to present a comprehensive and detailed account of such works. Of the many elegant synthetic routes so far elaborated, the most practical are perhaps those outlined in Schemes 2 and 3. The former was developed in 1969 by *Corey* et al.[4], while the latter was first described in 1967 by *Just* et al.[5] and later established by the Upjohn Company[6]. These two synthetic strategies are feasible on a large scale (up to 50 kg of $PGF_{2\alpha}$ or equivalent compounds per year) and are more than one hundred times as effective as the biosynthetic pathway using crude enzymes and polyunsaturated fatty acid substrates such as arachidonic acid or dihomo-γ-linolenic acid[1d].



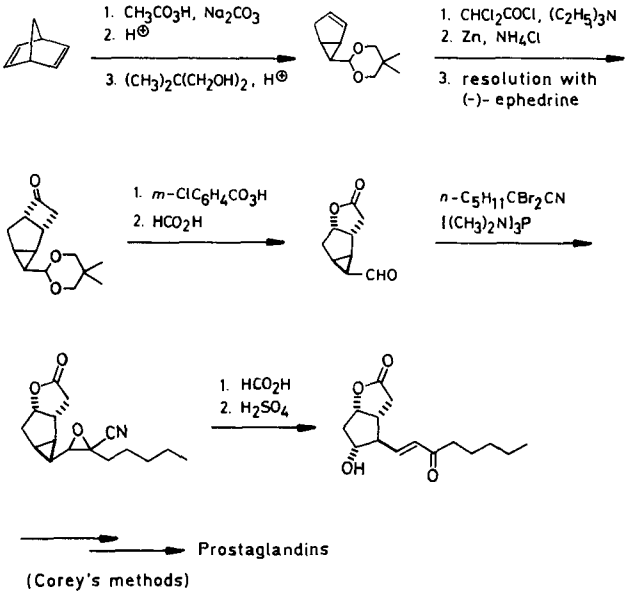
Scheme 1. Classification of the prostaglandins (PG). PGI_2 and TXA_2 are prostacyclin and thromboxane A_2, respectively.

Both methods cleverly solved the main problems in prostaglandin synthesis: 1) selective creation of the four or five asymmetric centers in the prostaglandins of the E and F series, respectively, 2) stereoselective insertion of the CC



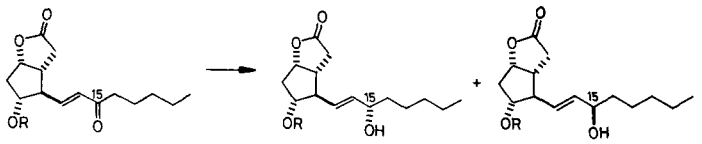
Scheme 2. *Corey*'s prostaglandin synthesis. DMSO = dimethyl sulfoxide.

double bonds, and 3) overcoming the instability of the β-hydroxycyclopentanone structures in prostaglandins. Since these routes start with cyclopentadiene or norbornadiene,



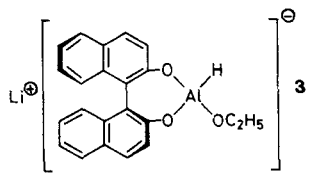
Scheme 3. The Just-Upjohn procedure.

rigid bicyclic intermediates are formed, which make the perfect stereochemical control about the five-membered ring possible. A number of other routes for the preparation of such versatile lactone intermediates are also known. Stereoselective formation of the C=C bonds can be achieved by Wittig-type condensation. The unstable hydroxy ketone unit in the prostaglandins of the E series is constructed at the final stage of the synthesis. A long-standing problem in the original procedure was a lack of means of controlling the absolute stereochemistry at C-15; the customary industrial processes include hydride reduction of the enones of type **1** and tedious chromatographic separation of the resulting C-15-epimeric alcohols (*S*)-**2** and (*R*)-**2** (Scheme 4).



Scheme 4. Reduction of the Corey lactone **1d**. THP = tetrahydropyranyl.

In endeavoring to solve this problem, *Corey* et al. found that reduction of the enone **1a** having a special protective group at C-11 with a reagent prepared from (+)- or (±)-limonene, thexylborane[7], and *tert*-butyllithium at −120 °C affords the alcohols (*S*)-**2a** and (*R*)-**2a** in the ratio 92 : 8[8]. Recently developed methodologies provide practical solutions to this problem. The chiral aluminum hydride reagent **3** discovered in our laboratories enables the highly stereoselective reduction of **1b** — **1d** to give the desired products (*S*)-**2b** to (*S*)-**2d**[9]. Regardless of the nature of the protective groups at position 11 or whether or not the hydroxyl function is protected, the *S*/*R* ratio is generally greater than 99%. This reagent is far more stereoselective than any of the other known reagents. The Ono group as well as *Yamamoto* et al. have reported that the unprotected enone **1d** could be reduced with a large excess of diisobutylaluminum hydride modified with 2,6-di-*tert*-butyl-4-methylphenol to give (*S*)-**2d** and (*R*)-**2d** in the ratio 92 : 8[10].

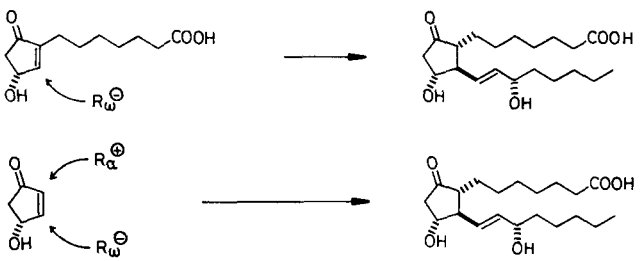


Prostaglandin endoperoxides PGH_2[11] and PGG_2[12] as well as prostacyclin (PGI_2)[13] have been prepared by way of $PGF_{2\alpha}$. The extremely unstable thromboxane A_2 (TXA_2, Scheme 1), however, has not yet been synthesized. The processes outlined in Schemes 2 and 3 are flexible and not only enable the synthesis of natural prostaglandins but also of a great number of analogues. Consequently, the total synthesis constitutes a notable landmark in the progress of modern organic chemistry; it has made a great contribution to the advancement of our knowledge on the biological properties of the prostaglandins.

2. Approaches Involving Conjugate Addition

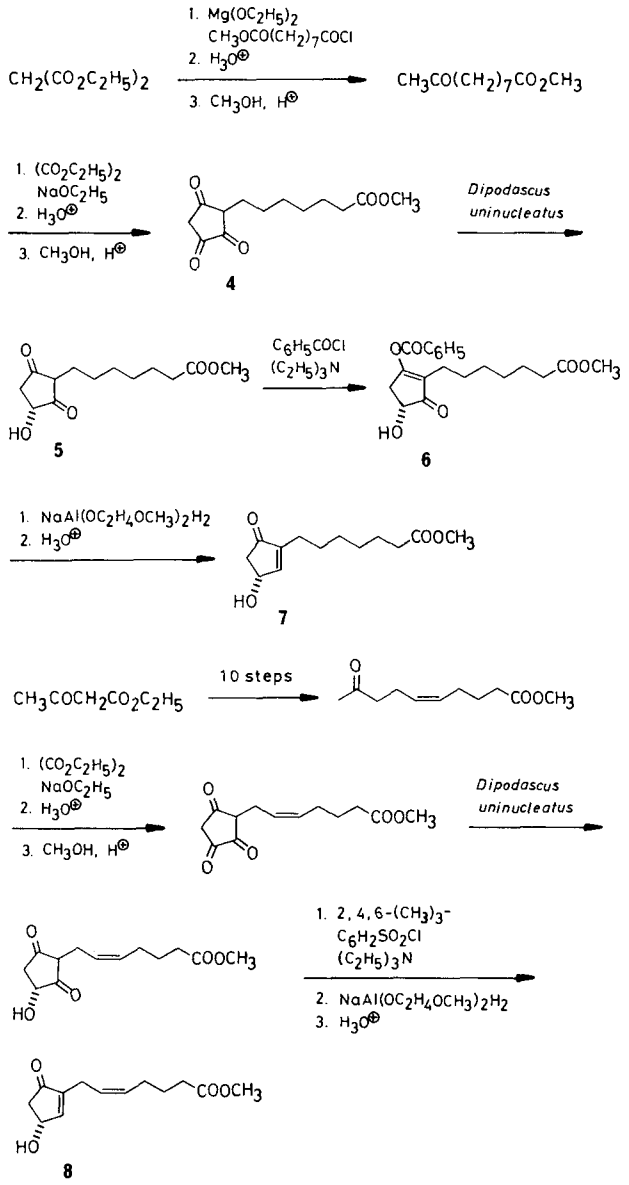
The approaches depicted in Schemes 2 and 3 are classified as linear or sequential syntheses, in which the whole structure is constructed step-by-step. *Corey*'s route involves 17 steps for the preparation of (±)-$PGF_{2\alpha}$ from cyclopentadiene, and 19 steps for the synthesis of (±)-PGE_1. Four synthetic steps are required for the formation of the five carbon-carbon bonds, while the remaining 13 to 16 steps constitute functional group transformations such as oxidation, reduction, protection, deprotection, etc. The Just-Upjohn synthesis also proceeds via the *Corey* lactone **1d** and requires a total of 16 steps from norbornadiene to (±)-$PGF_{2\alpha}$, of which three are required for the creation of the carbon-carbon bonds. In addition, optical resolution is conducted at the stage of the lactone intermediate so as to obtain the naturally occurring forms.

The above described procedures are clearly successful. However, shorter, highly convergent entries via a combination of suitably chosen building blocks are obviously much more desirable. In this context, approaches involving "conjugate addition" are among the most attractive and have been studied extensively since the early days of the synthetic investigation. The obvious dissection of the prostanoic acid skeleton would immediately suggest two possible routes for this strategy (Scheme 5): 1) introduction of



Scheme 5. Prostaglandin syntheses via conjugate additions.

the "lower" side chain (ω side-chain) into a 4-hydroxy-2-cyclopentenone which already possesses the "upper" side chain (α side-chain), and 2) the consecutive linking of ω and α side-chains to cyclopentenones. In both cases, nucleophilic introduction of the ω side-chain into a 2-cyclopentenone with formation of the bond between C-12 and C-13 provides an obvious route for this purpose; hereby, organometallic chemistry plays an important role. Many other synthetic routes are conceivable but would perhaps require the development of some new synthetic methodologies. Several methods providing access to the chiral cyclopentenone intermediates have been elaborated. *Sih* et al. have used microbiological asymmetric reactions (Scheme 6)[14]. First, the triketone **4** was prepared in 75—80% yield by sodium ethoxide-catalyzed condensation of methyl 9-oxodecanoate and ethyl oxalate. Of the various microbes investigated, *Dipodascus uninucleatus* was found

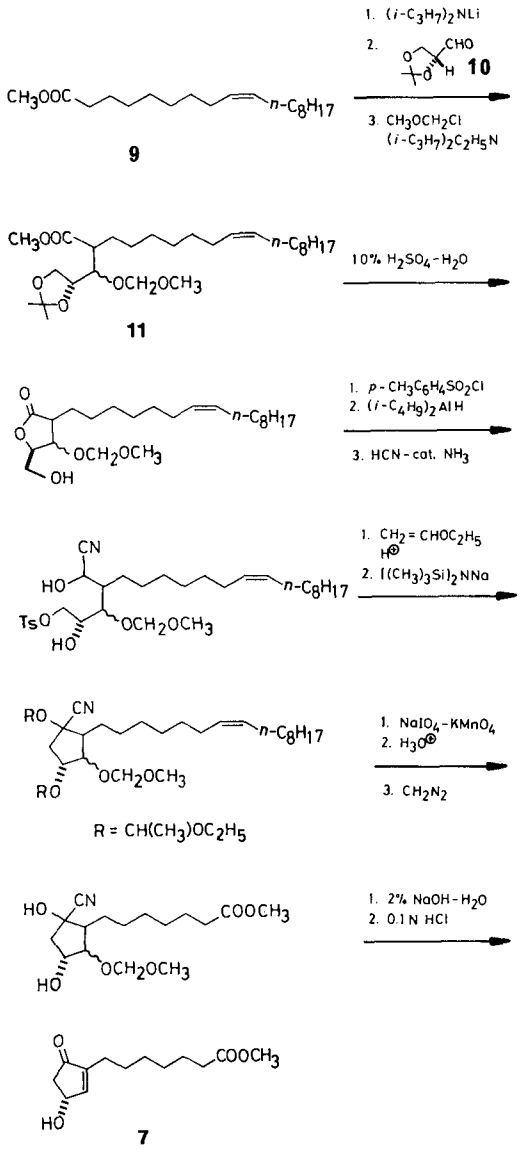


Scheme 6. Synthesis of 2-substituted (*R*)-4-hydroxy-2-cyclopentenones 7 and 8 via asymmetric microbial reactions.

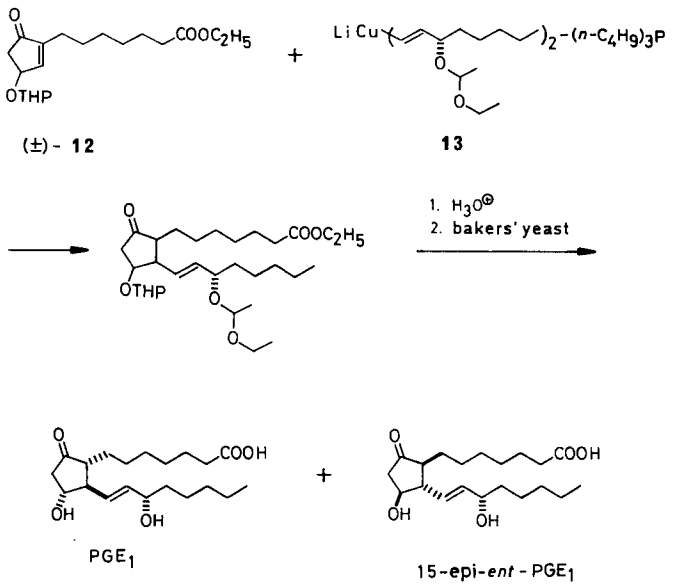
to be the most suitable for reducing the triketone **4** in a soybean-glucose medium to the optically pure (4*R*)-hydroxy diketone **5** (75% chemical yield). The partial asymmetric hydrogenation was achieved with a soluble chiral catalyst, (1,5-cyclooctadiene)bis[cyclohexyl(*o*-methoxyphenyl)methylphosphane]rhodium(I) tetrafluoroborate, giving **5** in 75% yield and 30% optical purity. Recrystallization increased the optical purity of **5** to 68%. Selective benzoylation of the β-diketone, giving **6** (70%), followed by reduction with sodium bis(2-methoxyethoxy)dihydridoaluminate and debenzoylation afforded without racemization the chiral hydroxyenone **7** in 60% yield (21% referred to **4**). In a similar manner, the hydroxy enone **8** with unsaturated α side chain was prepared via 17 steps in 4% overall yield (referred to the educt ethyl acetoacetate).

Stork and *Takahashi* used D-glyceraldehyde as chiral source for securing the (4*R*)-configuration (Scheme 7)[15]. A base-catalyzed condensation of the unsaturated ester **9** with protected D-glyceraldehyde **10** was followed by methoxymethylation of the resulting alcohol to the ether **11**. Subsequent acid-catalyzed lactonization and multistep carbocycle formation gives ultimately the desired cyclopentenone **7**. The chiral building blocks **7** and **8** are also accessible by resolution[16] of the racemates[17,20b,21], by multistep synthesis using a resolved intermediate[18], or by enzymatic oxygenation of a 2-substituted 2-cyclopentenone[19].

In 1972, *Sih* et al. reported for the first time on a successful prostaglandin synthesis of this type (Scheme 8)[20]. The chiral cuprate **13**, prepared from the organolithium derivative of the ω side chain, was condensed with (±)-**12** at 0°C in ether. After removal of the alcohol protective group and hydrolysis of the ester by bakers' yeast, PGE_1 (21%) and 15-epi-*ent*-PGE_1 (23%) were obtained. The organocuprate apparently attacks the five-membered ring from the less hindered side. In addition, when a small quantity of unprotected (±)-**7** is present, some 11,15-epi-*ent*-PGE_1 is also formed. The vinylogous addition of the cuprate to the optically active cyclopentenone derivative **14** afforded,

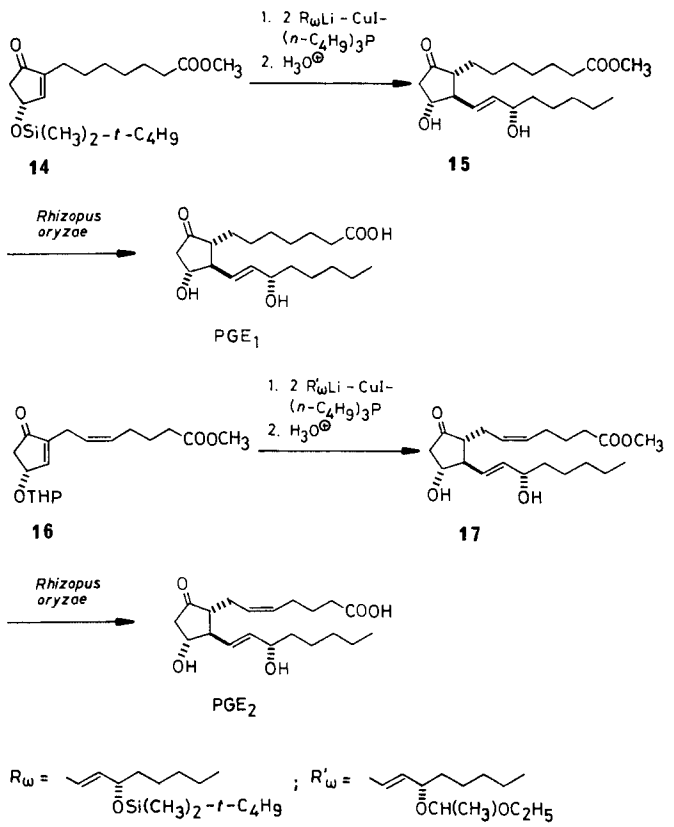


Scheme 7. Synthesis of the optically active 2-substituted (*R*)-4-hydroxy-2-cyclopentenone 7 from D-glyceraldehyde.



Scheme 8. Synthesis of PGE_1 by conjugate cuprate addition.

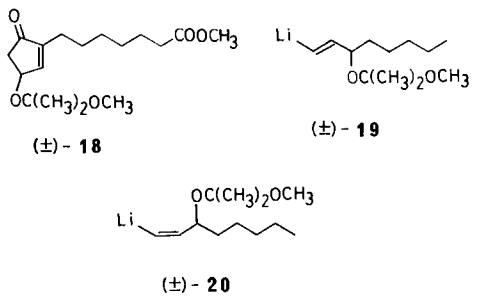
after deprotection, the PGE_1 methyl ester **15** in 60% yield (Scheme 9)[14].



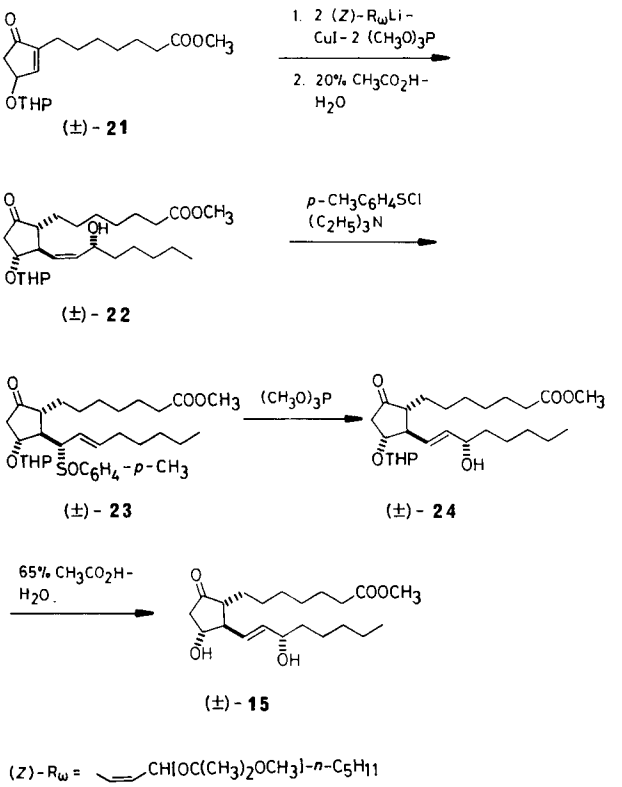
Scheme 9. Synthesis of PGE_1 and PGE_2 via the two-component coupling process.

Among a variety of organocopper reagents examined, the cuprate generated from the $(n\text{-}C_4H_9)_3P$–CuI complex and vinyllithium (molar ratio 1:2) was found to be the most effective. The ester **15** was hydrolyzed with the microorganism *Rhizopus oryzae* to give PGE_1 in 95% yield. In a similar manner, the cyclopentenone **16** afforded the methyl ester **17** in 50% yield. Enzymatic hydrolysis of **17** gave PGE_2 in 82% yield[14].

Independently, a Syntex group chose a similar strategy but with different cuprate reagents[21]. Reactions of the protected 2-cyclopentenone derivative (±)-**18** with an organocuprate reagent formed from $CuI[(CH_3O)_3P]_2$ and the (*E*)-vinyllithium compound (±)-**19** furnished the desired product of a conjugate addition only in very low yield; after alcohol deprotection, methyl esters of (±)-PGE_1 (1%) and (±)-15-epi-PGE_1 (0.3%) were obtained together with 80% of recovered 4-hydroxy-2-cyclopentenone derivative (±)-**7**. However, when the (*Z*)-cuprates, formed from the (*Z*)-vinyllithium compounds (±)-**20** (the corresponding

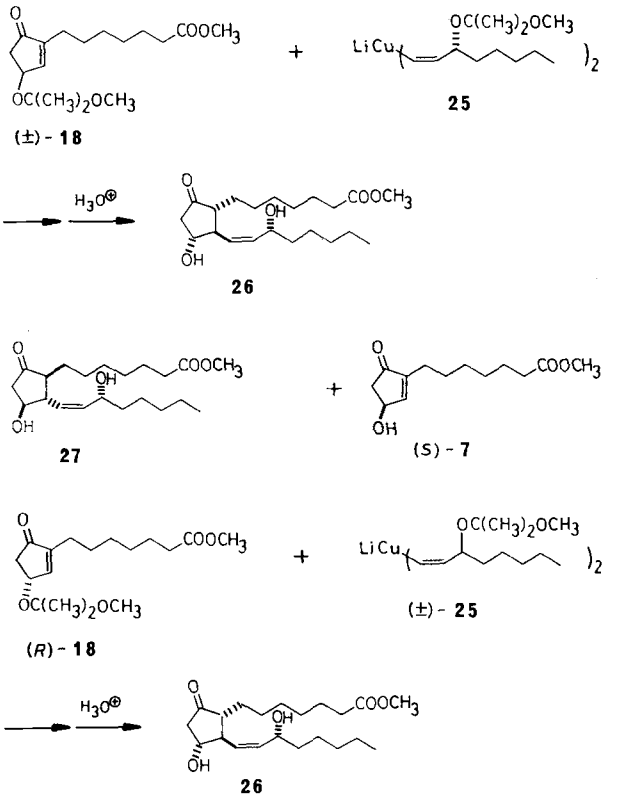


iodoallyl alcohol is accessible in ca. 65% yield from the propynol), were used in the vinylogous addition to (±)-**21**, the adduct (±)-**22** was obtained in 45% yield, the 15*R*/15*S* ratio being >97:3 (Scheme 10)[22]. The requisite inversion of the configuration of the OH-groups on C-15 was accomplished by the procedure of *Evans* et al.[23], via the steps



Scheme 10. Prostaglandin synthesis by conjugate addition of a (*Z*)-vinyl cuprate.

22 → **23** → **24**, in 71% total yield. The chirality of the carbon was transferred with perfect stereocontrol, and no trace of the isomer with 13*Z*,15*R*-configuration was detected. After removal of the tetrahydropyranyl protecting groups, the racemic PGE_1 methyl ester (±)-**15** was obtained in 90% yield.

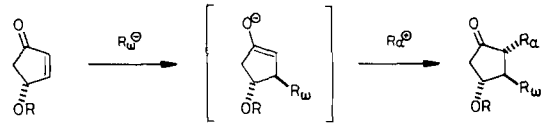


Scheme 11. Kinetic resolution by conjugate addition of a (*Z*)-vinyl cuprate.

The high degree of diastereoselectivity of the conjugate cuprate addition enables the kinetic resolution of racemic 2-cyclopentenones or ω side chains by chiral counterparts (Scheme 11). The Syntex group and *Stork* found that reaction of the racemic cyclopentenone (±)-**18** with the optically active cuprate **25** (molar ratio 1:3) gave an 86:14 mixture of **26** and **27** together with ca. 30% of unreacted (*S*)-**7**[21c,22]. Later, *Stork* and *Takahashi* carried out this reaction by combining one equivalent of the optically active enone (*R*)-**18** and three equivalents of the racemic cuprate (±)-**25**; they obtained a single stereoisomer (**26**), thus confirming complete kinetic resolution[15]. In the reaction of the optically active (*E*)-cuprate and the racemic enone (±)-**18**, no noticeable kinetic resolution took place[20].

The organocuprate-mediated method was also applied to the synthesis of racemic PGD_1[24]. Such attempts were also made with organoaluminum compounds and with Grignard reagents in the presence of copper salt catalysts[25]. In principle, such synthetic routes via two-component coupling processes have paved the way but, as yet, they do not appear to be industrially viable. The major practical problems encountered in this approach are: 1) the lack of efficient ways to obtain the key chiral cyclopentenones, and 2) the inefficiency of the direct introduction of "natural" (*E*)-alkenyl side-chains by conjugate addition procedures.

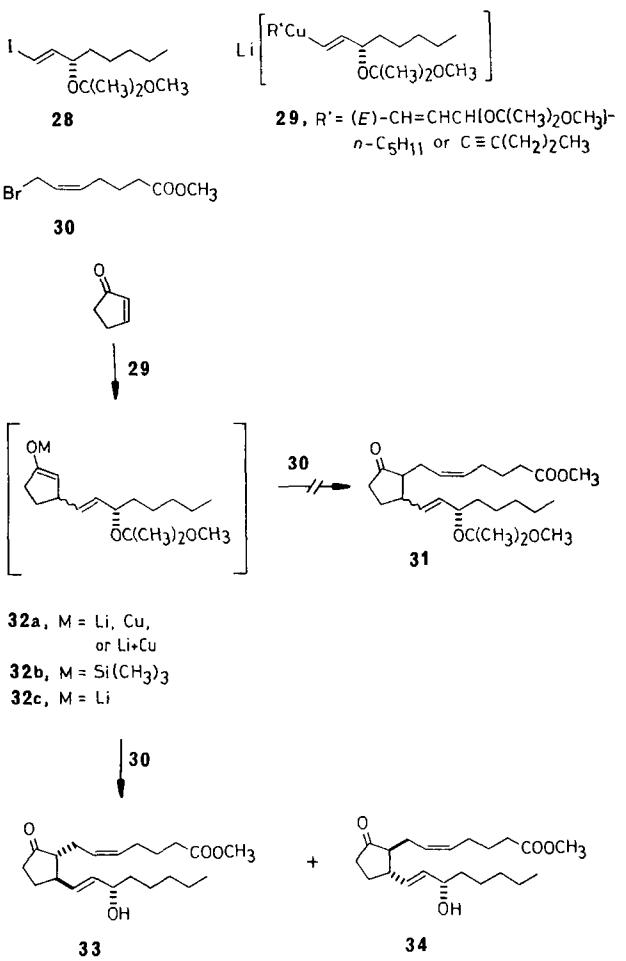
The three-component coupling process, namely, a single-pot combination of a five-membered ring unit and the two side chains would be the ultimate goal in effective prostaglandin syntheses. Such entries, if feasible, are superior to other methods in view of their directness and high flexibility. Scheme 12 actualizes the concept by way



Scheme 12. Basic strategy of the three-component coupling process.

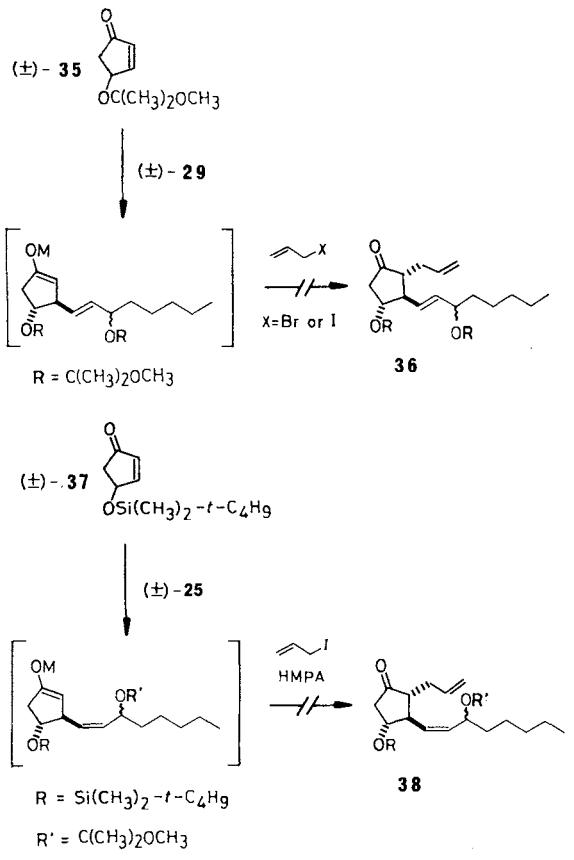
of example of the nucleophilic transfer of the ω side-chain unit to a protected 4-hydroxy-2-cyclopentenone followed by electrophilic assembling of an α side-chain equivalent. At first sight, this approach looks very simple, but, when we started our investigations, very little success had been obtained with such a strategy.

Since organocuprate reagents have been widely used for the addition of organic groups to the β-position of α,β-unsaturated ketones[26], one may simply expect that the cuprate-mediated conjugate addition of an ω side-chain block to a 4-oxygenated 2-cyclopentenone followed by al-



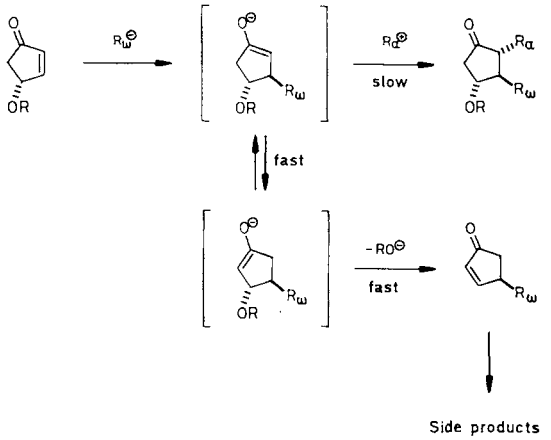
Scheme 13. Attempted double vicinal CC-coupling with 2-cyclopentenone.

kylation of the enolate intermediate with α side-chain halides could lead directly to PGE derivatives. In reality, however, such processes appear to be quite difficult to realize. In 1974, a Syntex research group was the first to report the results of model experiments for double vicinal CC-coupling with 2-cyclopentenones (Scheme 13)[27]. Symmetrical or mixed vinyl cuprates **29** were prepared from the (*E*)-configurated iodide **28**. However, vinylogous addition of **29** to unsubstituted 2-cyclopentenone and subsequent reaction with the allyl bromide **30** failed to give the condensation product **31**, even though a variety of conditions were tested. The enolate **32a** formed initially was then converted into the trimethylsilyl ether **32b**. Regeneration of the lithium enolate **32c** by lithium amide in liquid ammonia followed by trapping with two equivalents of the bromide **30** at −35°C gave, after deprotection, methyl esters of 11-deoxy-PGE_2 **33** and 11-deoxy-8,12-epi-PGE_2 **34** in 17 and 13% yield, respectively. Reaction of the lithium enolate (±)-**32c** with methyl 7-iodo-5-heptynoate furnished a diastereomeric mixture of the corresponding alkynes in 19.5% yield. Other Syntex chemists examined in detail the possibility of a direct linking of three synthetic building blocks using an (*E*)- or (*Z*)-vinyl cuprate; they reconfirmed the previously encountered difficulties (Scheme 14)[28]. When the racemic 4-hydroxy-2-cyclopentenone derivative (±)-**35** was subjected to the conjugate addition using two equivalents of the (*E*)-cuprate (±)-**29** in ether, and then to reaction with 1.1 equivalents of allyl bromide or iodide in the presence of 15 vol-% hexamethylphosphoric triamide, no trace of the desired product **36** was obtained.



Scheme 14. Attempted double vicinal CC-coupling with protected 4-hydroxy-2-cyclopentenones. HMPA = hexamethylphosphoric triamide.

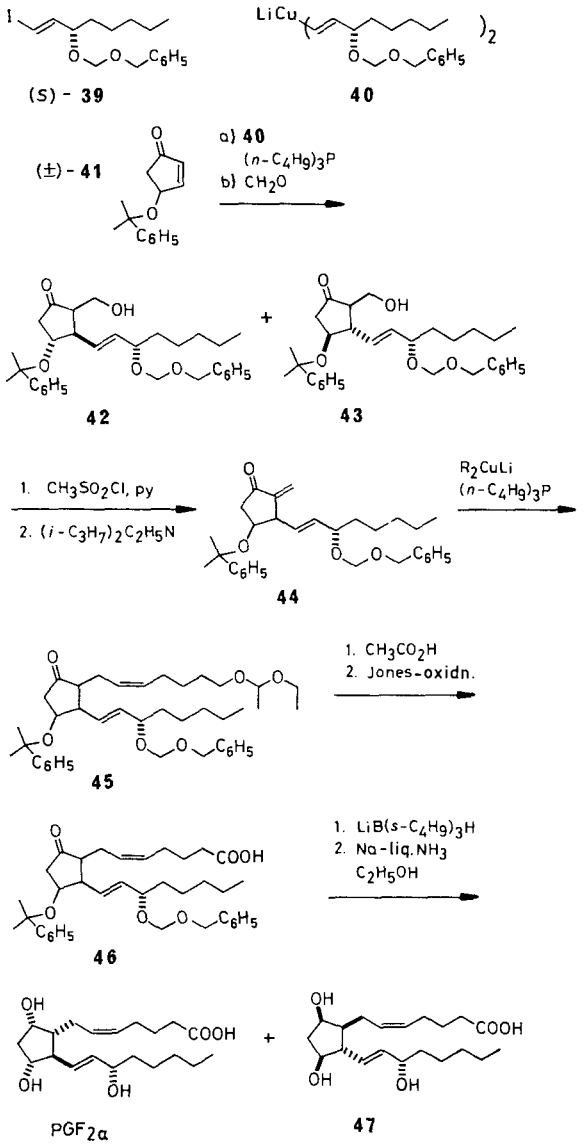
An attempt with the silyl protected cyclopentenone (±)-**37** and two equivalents of the (*Z*)-vinyl cuprate (±)-**25** also did not afford the allylation product **38**. The failure of these attempts is presumably due to the complex nature of the reaction system[29], in which an equilibration of the enolates and a cleavage of water from the five-membered ring can take place concomitantly (Scheme 15). The proton transfer occurs at a rate faster than the desired regiospecific alkylation reaction. The cuprate-generated intermediate species could be a lithium enolate, but the presence of copper salts and other ligands might retard the alkylation with organic halides.



Scheme 15. Equilibration of intermediates of the cuprate addition.

In the mid 1970's, investigations along these lines were shifted to the development of somewhat modified, indirect routes. In 1975, *Stork* and *Isobe* reported a successful synthesis of $PGF_{2\alpha}$ (Scheme 16)[30]. They first converted the optically active (*E*)-vinyl iodide **39** into the lithium cuprate **40** by reaction of the lithium compound with the complex $(n\text{-}C_4H_9)_3P\text{—}CuI$ (molar ratio 2 : 1) in ether. Conjugate addition of **40** to one equivalent of the racemic α,α-dimethylbenzyl-protected hydroxy enone (±)-**41** was then carried out in ether at −78 to −20°C and the resulting enolate formed under kinetic control was trapped by about four equivalents of monomeric formaldehyde[31], an unusually powerful electrophile, in the same solvent at −78 to −50°C to produce a mixture of **42** (28—34%) and **43** (22—26%).

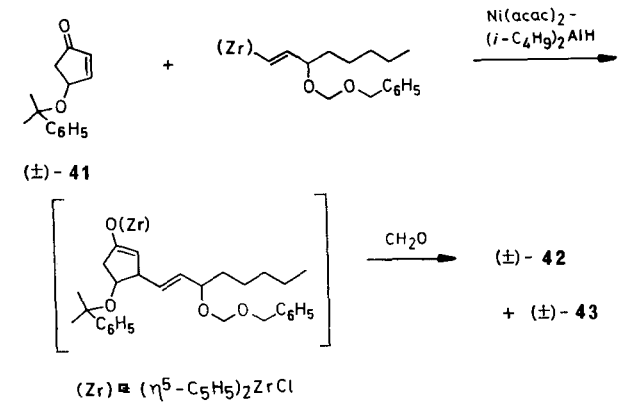
Dehydration of the adducts, to give the 2-methylenecyclopentanones **44**, followed by the second conjugate addition of a (*Z*)-vinyl cuprate led to the C_{20}-skeleton **45** with extended α-chain. Acid-catalyzed removal of the alcohol protecting group at C-1 and subsequent Jones oxidation gave the prostanoic acid **46**. Stereoselective reduction of the 9-keto function with lithium tri-*sec*-butyl hydridoborate to give the 9α-alcohol and subsequent removal of the C-11-protecting group by sodium metal dissolved in a liquid ammonia/ethanol mixture led to a stereoisomeric mixture of $PGF_{2\alpha}$ and 15-epi-*ent*-$PGF_{2\alpha}$ **47**. A pure sample of natural $PGF_{2\alpha}$ was obtained by chromatographic separation of the methyl esters and alkaline hydrolysis. The authors claim that the overall yields of $PGF_{2\alpha}$ and 15-epi-*ent*-$PGF_{2\alpha}$ **47** are approximately 9% and 7%, respectively (referred to **41**). Instead of the cuprate reagents, *Schwartz* et



R = (*Z*)-CH=CH(CH$_2$)$_3$CH$_2$OCH(CH$_3$)OC$_2$H$_5$

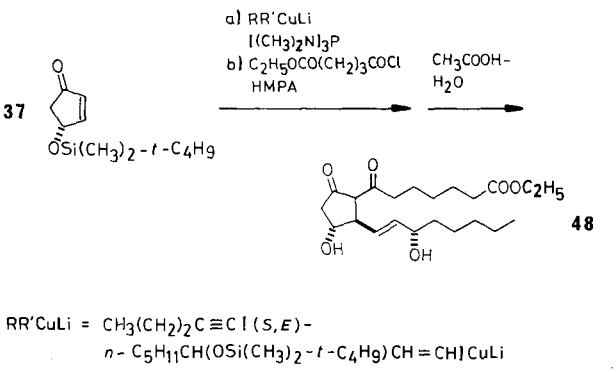
Scheme 16. The Stork-Isobe synthesis of PGF$_{2\alpha}$.

al. used a zirconium compound combined with a nickel catalyst for the conjugate addition reaction[32]. By this method, a mixture of racemic **42** and **43** was obtained in 69% yield (Scheme 17).



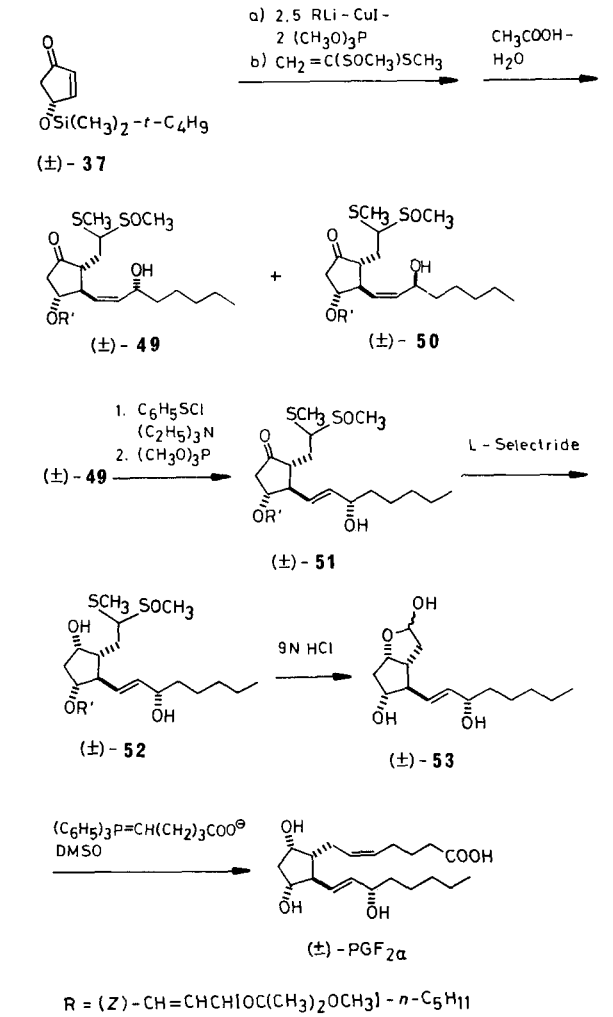
Scheme 17. Synthesis of the prostaglandin intermediates **42** and **43** via organozirconium reagents.

A Teijin research group found that reaction of acid chlorides with enolates formed from enones and mixed cuprates[33] occurs at the C-termini. The 7-oxo-PGE$_1$ derivative **48** was obtained in this way (Scheme 18)[34].



Scheme 18. Reaction of an organocuprate-generated enolate with an acyl chloride.

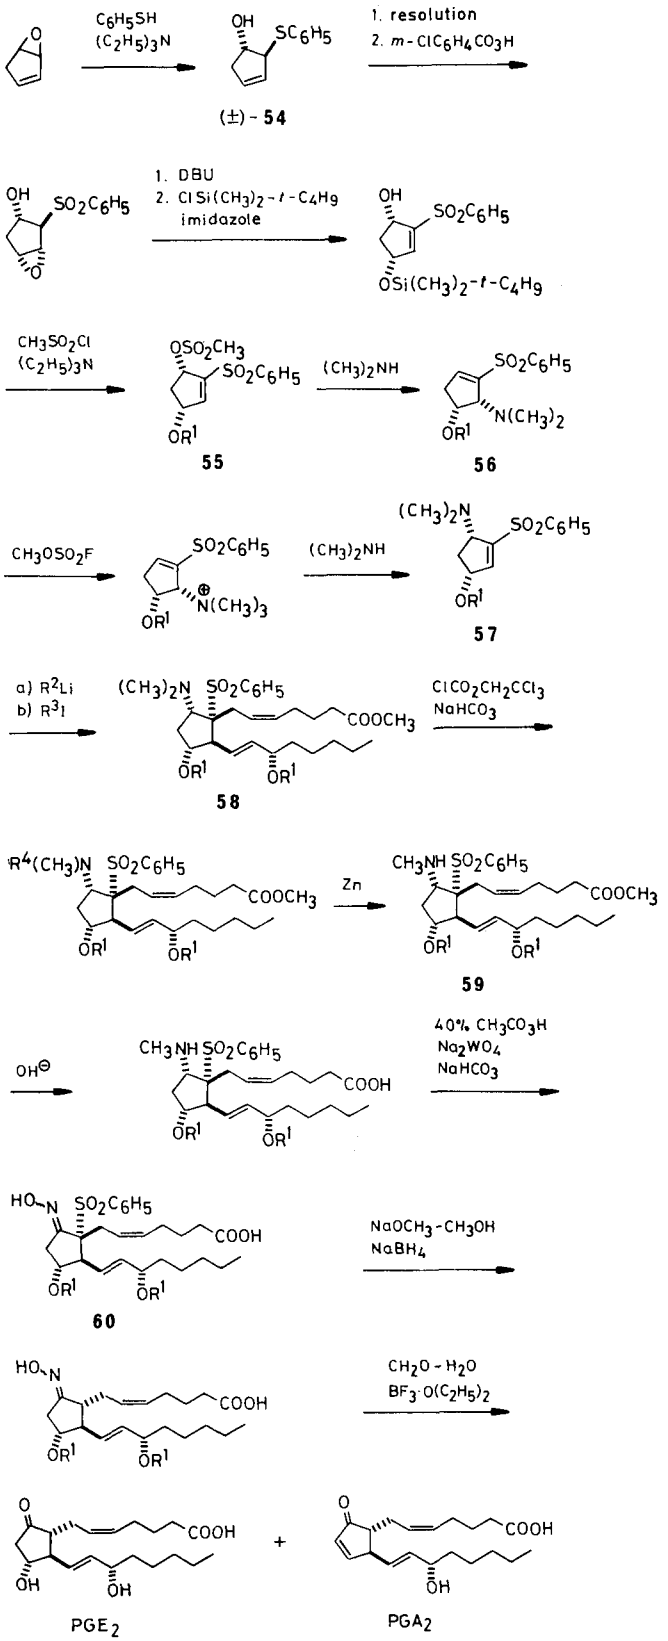
As first demonstrated by a Syntex group in 1979, some Michael acceptors that are synthetically convertible into PG α side chains can also serve as trapping agents for the enolate intermediates formed under kinetic control



R = (*Z*)-CH=CHCH[OC(CH$_3$)$_2$OCH$_3$]-*n*-C$_5$H$_{11}$

R' = Si(CH$_3$)$_2$-*t*-C$_4$H$_9$

Scheme 19. Prostaglandin synthesis via Michael-trapping of the organocuprate-generated enolate. L-Selectide = lithium tri-*sec*-butyl hydridoborate.



Scheme 20. Synthesis of PGE_2 according to *Fuchs* et al. DBU = diazabicycloundecane.

(Scheme 19)[28]. Reaction of the phosphite-complexed (*Z*)-divinyl cuprate (±)-**25** with the racemic enone **37** (1.4:1 ratio) in ether and subsequent treatment with two equivalents of 1,1-bis(methylthio)ethene *S*-oxide, an efficient Michael acceptor originally introduced by *Schlessinger* et al.[35], at −78 to 0 °C afforded (±)-**49** in 45% yield together with a small amount (8%) of the 15-epimer (±)-**50**. In the Michael addition reaction, which leads to a racemic (13*Z*,15*R*)-isomers, a high degree of diastereoselectivity is noticeable[15,21c,22]. The 4-siloxy group was not eliminated during the reaction. A sulfenate-sulfoxide sigmatropic rearrangement[22,23] corrected the stereochemistry of the major product and led to the racemic (13*E*,15*S*)-isomer (±)-**51**. Stereoselective reduction of the 9-keto group by L-Selectride gave (±)-**52** in 95% yield. Since the dithioacetal monoxide functionality is a masked aldehyde, (±)-**52** could be converted with hydrochloric acid into the lactol (±)-**53**, which, in turn, was converted into racemic $PGF_{2\alpha}$ by the procedure of *Corey* et al.[4]. The overall yield from (±)-**37** to (±)-$PGF_{2\alpha}$ was 18%.

Fuchs et al. have reported a different type of triply convergent synthesis of PGE_2 (Scheme 20)[36]. Instead of the protected 4-hydroxy-2-cyclopentenone derivatives, they employed a cyclopentenyl sulfone, which is later converted into the desired ketol structure. The racemic alcohol (±)-**54**[37], formed by ring-opening of cyclopentadiene monoepoxide with thiophenol and triethylamine, can be resolved into its enantiomers[38] by the method of *Pirkle* et al.[39]. The seven-step conversion of (+)-**54** having correct stereochemistry led to the functionalized cyclopentenyl sulfone **57**, a key chiral intermediate, in 64% yield. A stereospecific Lawton-type S_N2'-displacement[40] of the cyclopentenyl sulfone (**55** → **56**) plays an important role in this sequence. Consecutive conjugate addition (in tetrahydrofuran (THF)/hexane at −60 °C) of a chiral vinyllithium compound corresponding to the ω side-chain and in situ alkylation of the resulting sulfonyl-stabilized carbanion with a C_7-allylic iodide having an α side-chain structure afforded the C_{20}-skeleton **58** in 67% yield. The stereochemical control at C-12 (PG numbering) was at least 97%. Treatment of **58** with trichloroethyl chloroformate followed by reduction with zinc gave the *N*-demethylated product **59**. Alkaline hydrolysis of the ester function and oxidation of the methylamino function with peracetic acid with added sodium tungstate catalyst gave the oxime **60**. Stereospecific reductive desulfonation, deoximation, and alcohol deblocking completed the synthesis of PGE_2. In the deoximation step, some β-elimination took place and ca. 10% of PGA_2 was formed as a byproduct. This prostaglandin synthesis starting from (±)-**54** requires 15 steps and an optical resolution. The overall yield is 13%.

3. The Three-Component Coupling Process

In spite of the discouraging results recorded by pioneers in this field, our interest was still fostered by the possibility of constructing the prostanoic acid framework in a single-step (Scheme 12) and, thereby, of realizing our goal—a direct, convergent PG synthesis. It emerged that: 1) a reliable method, which enables combination of the five-membered

enone unit and the ω and α side-chain units to give the complete C_{20}-carboxylic acid skeleton, had to be developed, and 2) easy access to chiral building blocks with the natural (11*R*,15*S*)-configuration had to be created. It seems reasonable to assume that generation of the (12*R*)-configuration is strongly controlled by the direction of the nucleophilic attack of the ω side-chain (*trans* to the substituents on C-4 of the cyclopentenone). The (8*R*)-configuration should also be favored kinetically or, even if not, this could be accomplished by some thermodynamically controlled operations.

3.1. Access to Optically Active Building Blocks

The racemic iodovinyl alcohol (±)-**64** having the ω side-chain structure was first prepared by *Corey* and *Beams*[33] and a Syntex group[21b] by hydride reduction of the iodovinyl ketone **61**, which is readily obtainable from the chlorovinyl ketone **63** by halogen exchange with sodium iodide. The bromoallyl alcohol (±)-**62** was prepared in a similar manner[25b]. Both alcohols were resolved via their hydrogen phthalates with (−)-1-phenylethylamine; the requisite (3*S*)-alcohols were obtained in 10% yield (referred to the racemates)[21b].

61, X = I
62, X = Br
63, X = Cl

(±)-**64**, X = I
(±)-**65**, X = Br

Sih et al. have carried out the microbiological reduction of **61** with *Penicillium decumbens* and obtained the (3*S*)-alcohol with an optical purity of 74%, but only in 10% chemical yield[14c]. We found that asymmetric reduction using the chiral BINAL-H reagent is far superior to such methods[9]. Thus, as shown in Scheme 21, the reduction of the prochiral ketones **61** and **62** with **3** gave the desired optically active alcohols **64** and **65** in 97 and 96% *ee*, respectively, and in high chemical yield (>95%). The iodoallyl alcohol **64** was likewise prepared by hydroalumination of the optically active acetylenic alcohol **68** and subsequent treatment with iodine (yield 47%)[20b]. Hydroboration instead of hydroalumination led to **64** in 42% yield[21b]. Optically active **68** was accessible by a classical resolution method[41], but asymmetric reduction proved to be much more efficient. Reduction of **66** with the BINAL-H reagent **67** in THF at low temperature gave **68** (84% optical purity) in 87% yield[42, 114d]. Reduction of **66** with *Midland*'s alpine-borane reagent led to **68** in 92% *ee* (65% yield)[43a]. *Mukaiyama* and *Suzuki* prepared trimethylsilyl-protected **68** (76% *ee*, 87% yield)[44] by condensation of lithium trimethylsilylacetylide and hexanal in the presence of a chiral auxiliary reagent.

The optically active cyclopentenone building blocks can be obtained in various ways: by resolution of the racemic hydroxy enones, by preparation from chiral natural products via resolved synthetic intermediates, by asymmetric synthesis, by microbial or enzymatic techniques, etc. Racemic 4-hydroxy-2-cyclopentenone (±)-**70** is easily obtainable from furan derivatives or cyclopentadiene. *Clauson-Kaas* and *Limborg* et al. found that oxidative dimethoxylation[45a] of 2-methylfuran **69** with bromine and methanol, followed by treatment with a phosphate buffer (pH 7.4) afforded (±)-**70** in 55% overall yield (Scheme 22)[46].

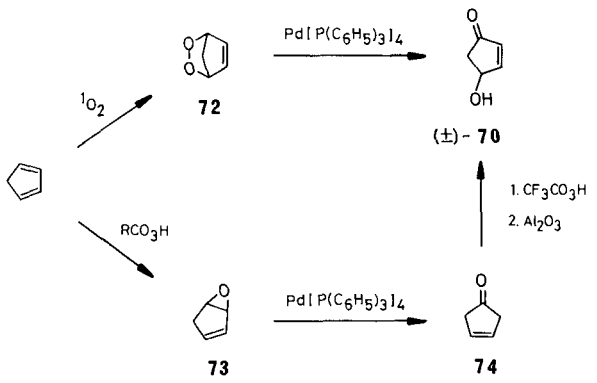
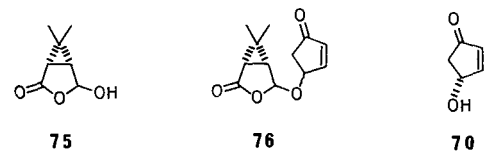
Scheme 22. Synthesis of 4-hydroxy-2-cyclopentenone (±)-**70** from furan derivatives.

The hydroxy ketone is also produced by simple acid-catalyzed rearrangement of 2-furfuryl alcohol **71**[47]. We found that regiospecific 1,4-oxygenation of cyclopentadiene leads to the same enone, where a palladium(0) complex plays an important role in the catalytic isomerization of strained oxygen-containing compounds (Scheme 23)[48]. When the 1,4-epidioxide **72**, formed by dye-sensitized photooxygenation of cyclopentadiene, was treated with 10 mol-% of tetrakis(triphenylphosphane)palladium(0) in dichloromethane, (±)-**70** was produced in 54% yield[48b]. On the other hand, treatment of cyclopentadiene epoxide **73** with this palladium complex in dichloromethane at 0 to 10°C gave exclusively 3-cyclopentenone **74** in 88% yield[48a].

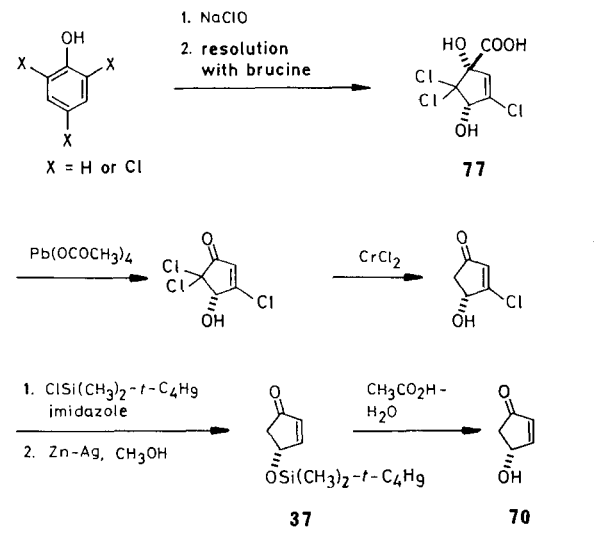


Scheme 23. Synthesis of 4-hydroxy-2-cyclopentenone (±)-**70** from cyclopentadiene.

This catalysis is very effective and the turnover number reaches 10^6! Further oxidation of **74** with trifluoroperacetic acid and treatment of the resulting epoxy ketone with alumina gave (±)-**70**. The hydroxy enone is a rather sensitive compound and hence the optical resolution is not easy by conventional methods. Fortunately, however, the bicyclic species **75**[49], derived from (1*S*,3*S*)-*trans*-chrysanthemic acid, proved to be an efficient resolving agent[50]. Pyridinium tosylate-catalyzed condensation of the racemic keto alcohol with **75** gave the diastereomeric adducts **76**, which could be easily separated on a silica gel column. Hydrolysis of the more polar isomer in a 1:2 mixture of dioxane and water at 70°C furnished the desired (*R*)-4-hydroxy-2-cyclopentenone **70**. The optical purity was greater than 97% and the overall yield was 88%.



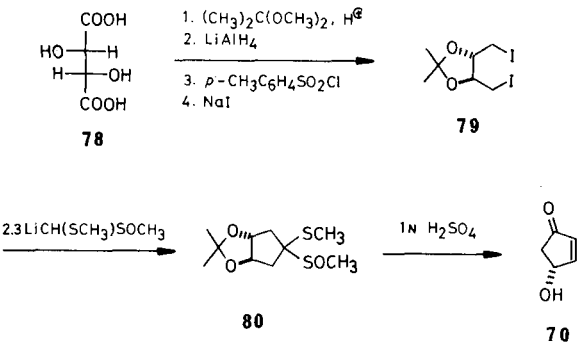
Gill and *Rickards* prepared **70** from phenol or 2,4,6-trichlorophenol as outlined in Scheme 24[18b,51]. This route



Scheme 24. Synthesis of (*R*)-4-hydroxy-2-cyclopentenone **70** from phenol derivatives.

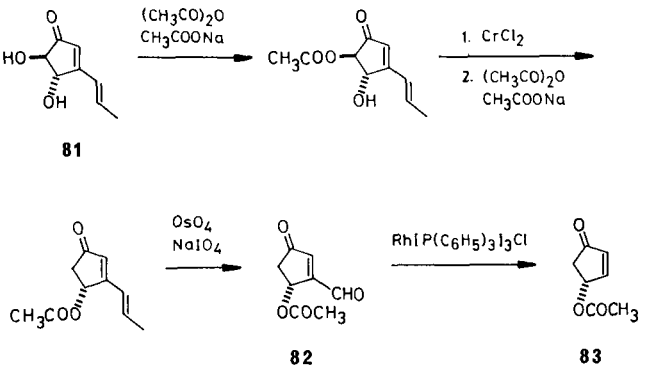
involves resolution of the hydroxy acid intermediate (±)-**77**[52] with brucine (37% yield, 74% of theory). The 1*S*,4*S* compound was transformed into the silyl protected hydroxy enone **37** in four steps in 56% overall yield. Hydrolysis of **37** gave optically pure free hydroxy ketone **70**.

Tsuchihashi et al. used unnatural D-tartaric acid **78** as a chiral pool for the synthesis of optically active **70** (Scheme 25)[53]. Using the known, four-step procedure[54], **78** was



Scheme 25. Synthesis of (*R*)-4-hydroxy-2-cyclopentenone **70** from D-tartaric acid.

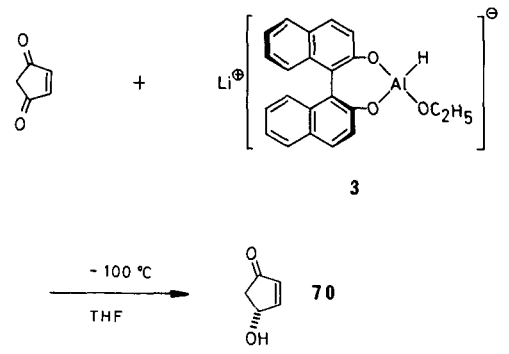
converted into the diiodide **79** in 42% yield. Base-induced condensation of **79** with methyl methylthiomethyl sulfoxide afforded **80**, which on subsequent acid-catalyzed hydrolysis gave the hydroxy enone **70** (85% optical purity) in 52.5% yield. As found by *Mitscher* et al.[55], naturally occurring terrein **81**, a metabolite of *Aspergillus fischerii*, can also serve as starting material.



Scheme 26. Synthesis of (*R*)-4-oxo-2-cyclopentenyl acetate **83** from terrein **81**.

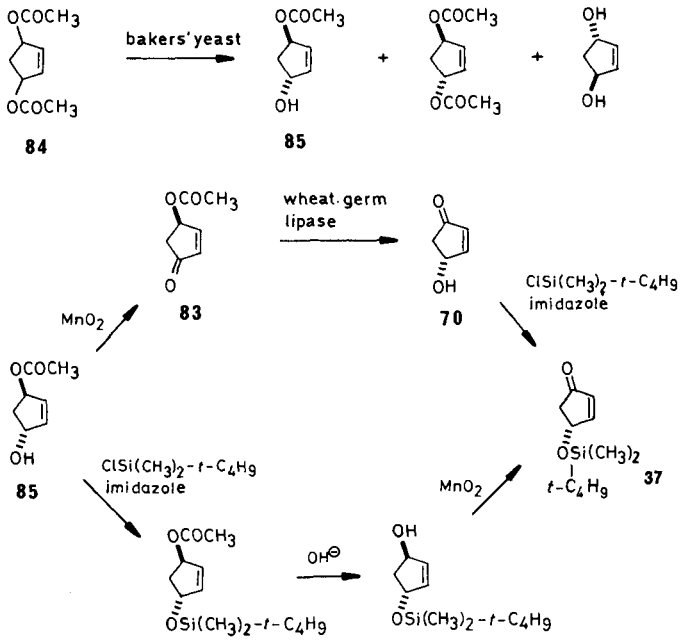
Scheme 26 illustrates the transformation of the highly functionalized chiral cyclopentenone into the protected hydroxy enone **83**. The olefinic side chain was removed by oxidative cleavage, giving the aldehyde **82**, followed by rhodium(I)-catalyzed decarbonylation (56%). The overall yield of the five-step synthesis was 33%. **83** was converted into **70** by enzymatic hydrolysis[57].

Asymmetric synthesis is also employable (Scheme 27); reduction of 4-cyclopentene-1,3-dione with (*S*)-BINAL-H reagent **3** in THF at −100°C afforded the hydroxy enone **70** in 94% *ee* (65% yield)[56,114d].



Scheme 27. Asymmetric synthesis of (*R*)-4-hydroxy-2-cyclopentenone **70**.

An enzymatic kinetic resolution technique was utilized by a Teijin research group (Scheme 28)[57]. When a stereoisomeric mixture of the 1,4-diacetate **84**, prepared from cyclopentadiene by bromination[58] and substitution with acetate, was hydrolyzed by bakers' yeast, the optically actife (3*R*,5*R*)-form of the half ester **85** (90% *ee*) was obtained in 3.2% yield. Oxidation of **85** with manganese dioxide (78%) and deacetylation by wheat germ lipase afforded the hydroxy enone **70** (90% optical purity) in 87% yield. Reaction of **70** with *tert*-butyldimethylsilyl chloride and imidazole furnished the protected cyclopentenone **37**. The same compound can also be obtained from **85** by silylation, hydrolysis, and oxidation (88% overall yield).

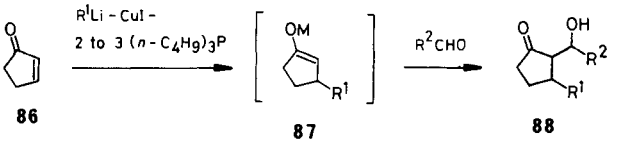


Scheme 28. Synthesis of (*R*)-4-hydroxy-2-cyclopentenone **70** using an enzymatic technique.

3.2. Double Vicinal CC-Coupling with α,β-Unsaturated Ketones

Having various procedures available for obtaining optically active building blocks, it was now necessary to develop an efficient method for assembling them. As described above (Section 2), the existing procedures for consecutive introduction of two side chains into 4-oxygenated 2-cyclopentenones are totally unsatisfactory. The main difficulty lies in the clean trapping of the organometallic-generated enolates with an α side-chain equivalent with preservation of the oxygen functionalities on C-4. Only very few electrophiles are capable of reacting with the non-equilibrated enolates in a desired manner[28].

Simple conjugate additions for the β-substitution of α,β-unsaturated ketones are usually carried out with the organocopper reagent in excess in order to ensure respectable results[26]. In reactions of the cuprates of type $LiCuR_2$ (Gilman reagents) one equivalent of the R group is inevitably wasted even in the ideal case. This becomes a severe disadvantage when the organic group is expensive or difficult to prepare. We considered, that the use of an excess of the ω side-chain equivalent in the key steps of a reaction such as the double vicinal CC-coupling of protected 4-hydroxy-2-cyclopentenones is unreasonable, not only from the economic but also from the chemical standpoint. The excess of organometallic compound makes the reaction system complicated[29] and thereby disturbs reaction between the enolate species and α side-chain electrophiles, resulting in the formation of complex mixtures[28]. On the other hand, if the nucleophilic delivery of the ω side chain is attained ideally by using only one equivalent of the reagent, the resulting enolate becomes the only strong nucleophile present in the reaction system and, therefore, it is anticipated that it will react cleanly with an equimolar amount of an α side-chain electrophile. In this context, we reinvestigated the existing procedures using 2-cyclopentenone **86** as a model substrate and found a simple, general solution to this problem[50,59]. First, we prepared the organocopper reagent from equimolar amounts of copper(I) iodide and organolithium compound and 2—3 equivalents of tri-*n*-butylphosphane. When such reagents were allowed to react with **86** (1 : 1 molar ratio) in ether or THF at low temperatures, the corresponding conjugate addition products were obtained in high yield. The requisite double vicinal CC-coupling is also possible in this way. As depicted in Scheme 29, the regiochemically defined enolate intermediate **87** could be trapped efficiently with one equivalent of an aldehyde as the aldol adduct **88**[50]. No α',β-condensation products associated with possible enolate equilibration were detected.

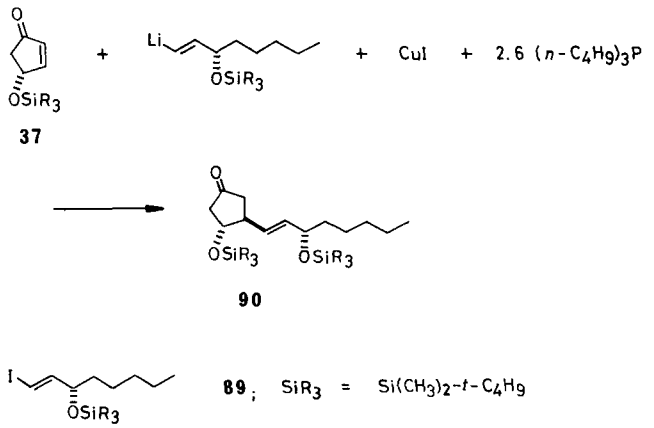


Scheme 29. Double vicinal CC-coupling of organocopper reagents with the model compound 2-cyclopentenone **86**. M = Li, Cu or Li + Cu; R^1 = *prim-*, *sec-*, *tert*-alkyl, -alkenyl etc.

3.3. Synthesis of Prostaglandins of Series 1

With an efficient method for consecutive nucleophilic/electrophilic double vicinal CC-coupling with enones, on the one hand, and diverse proven methods for obtaining

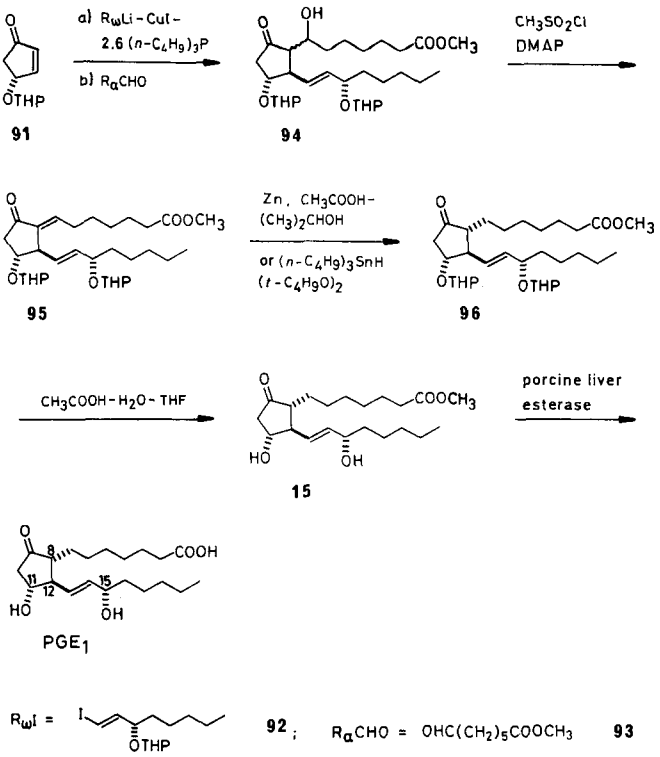
chiral building blocks, on the other, the three-component coupling process (see Scheme 12) held promise as a very straightforward entry to prostaglandins. First, we investigated the stereochemistry of the organocopper-mediated coupling of protected 4-hydroxy-2-cyclopentenones and the ω side-chain unit. The copper reagent was prepared by sequential treatment of the optically pure vinyl iodide **89** at −95 to −78°C with two equivalents of *tert*-butyllithium, one equivalent of copper(I) iodide, and 2.6 equivalents of tri-*n*-butylphosphane in ether. When this reagent was coupled to the (*R*)-4-siloxy enone **37** in THF at −78°C, as anticipated, a single *trans* adduct **90** was obtained after aqueous work-up (Scheme 30)[60]. Thus, the simple 4-oxygenated 2-cyclopentenone underwent high-yield conjugate addition with the natural (*E*)-vinylcopper reagent, whereby the C-3/C-4 *trans* relationship was established simply by steric interactions between the C-4 functionality and the entering organometallic reagent.



Scheme 30. Stereochemistry of the conjugate addition of an ω side-chain with organocopper reagents.

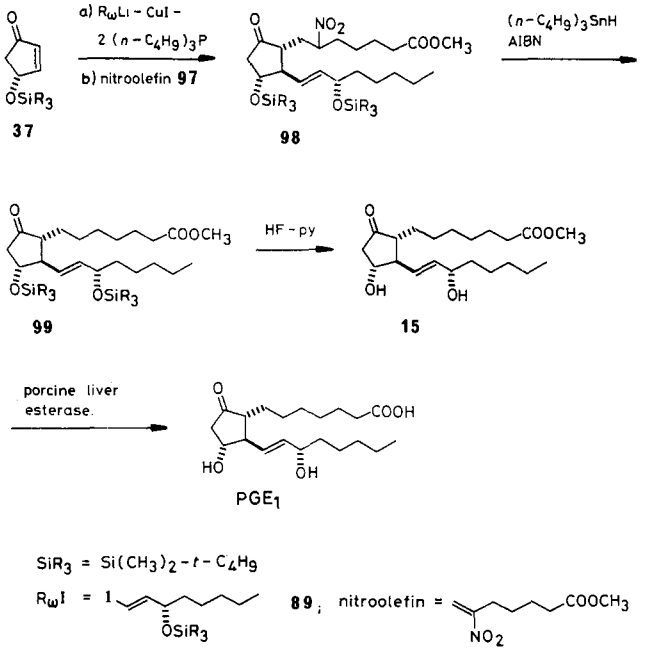
Scheme 31 outlines the convergent synthesis of PGE_1[50] which we have realized on this basis.

Our newly elaborated three-component coupling procedure using the enone **91**, the iodide **92** (as building block for the ω side-chain), and the aldehyde **93** (building block for the α side-chain) led to the aldol **94** as a mixture of diastereomers. The one-pot, direct construction of the functionalized prostaglandin skeleton was achieved in 83% yield[61]. Dehydration of **94** with methanesulfonyl chloride and 4-dimethylaminopyridine gave the enone **95** in 92% yield, which, on treatment with an excess of zinc dust in 2-propanol/acetic acid (95:5) gave the ketone **96** in 84% yield. Use of tri-*n*-butyltin hydride and di-*tert*-butyl peroxide increased the product yield to 90%. Removal of the tetrahydropyranyl protective groups in a 3:1:1 mixture of acetic acid, THF, and water afforded the PGE_1 methyl ester **15** in 92% yield. Finally, hydrolysis of the ester function by porcine liver esterase (86%)[62,63] completed the synthesis of natural PGE_1. This five-step synthesis of PGE_1 from the enone **91** was accomplished in 56% overall yield. Here, the absolute configuration at C-11 and C-15 are inherently determined at the stage of the starting materials, and the *trans* relationship of the ring-substituents is effected by the conjugate addition of the organocopper compound and subsequent operations.



Scheme 31. Convergent synthesis of PGE_1 (aldol route). DMAP = 4-dimethylaminopyridine.

Yet another short entry to PGE_1 has been opened up (Scheme 32)[63].

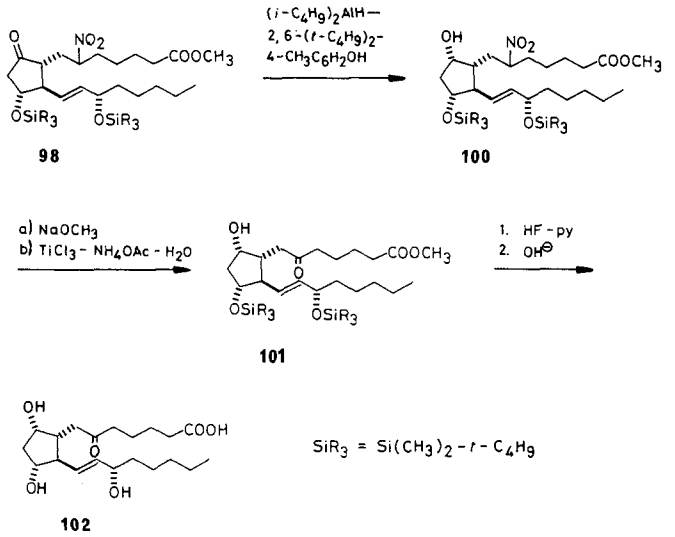


Scheme 32. Short synthesis of PGE_1 (nitro-intermediate route). AIBN = azobisisobutyronitrile.

The enolate intermediate generated by the reaction of the chiral enone **37** and the phosphane-complexed (*E*)-vinylcopper reagent, formed from **89**, underwent Michael

addition across the nitroolefin **97** in ether at −78 to −40 °C to give the adduct **98** in 58% yield. Removal of the 5-nitro group was effected by tri-*n*-butyltin hydride and azobisisobutyronitrile[64], giving **99** (30%); desilylation with hydrogen fluoride and pyridine in acetonitrile furnished the PGE_1 methyl ester **15** in 86% yield. Its enzymatic hydrolysis led to PGE_1[62]. Although this route must still be optimized, it nevertheless provides the shortest entry (only four steps from **37**) to natural PGE_1. Stereoselective reduction of **99** with the reagent formed from diisobutylaluminum hydride and a hindered phenol[10] affords **116**, which can be converted into $PGF_{1\alpha}$[77] (see Scheme 38).

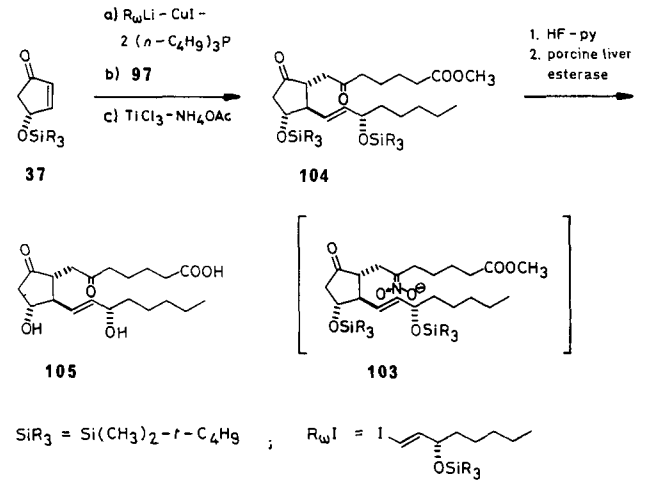
The stereoselective hydride reduction[10] of **98** gave the 9α-alcohol **100** as the major isomer (9α : 9β = 89 : 11, total yield 80%) (Scheme 33). The nitro compound was then



98 **100** **101** **102**

Scheme 33. Synthesis of 6-oxo-$PGF_{1\alpha}$ **102**.

converted into the 6-oxo derivative **101** (70% yield) under the Nef conditions[65]. Desilylation and saponification afforded 6-oxo-$PGF_{1\alpha}$ **102**, a degradation product of PGI_2, in 57% yield[66]. The utility of the nitroolefin trapping technique was further demonstrated by the short synthesis[67] of 6-oxo-PGE_1 **105**[68] (Scheme 34), which was previously

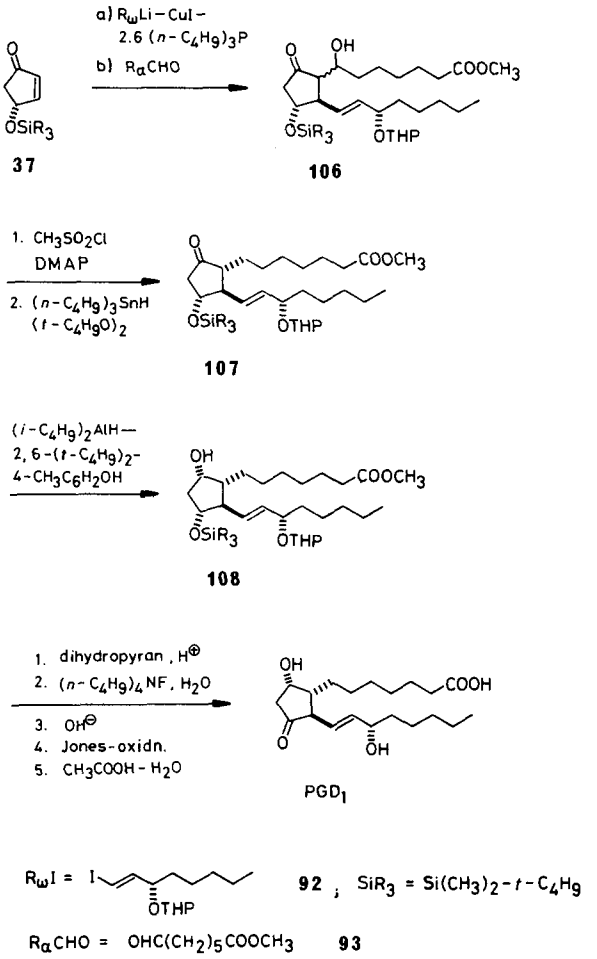


37 **104** **105** **103**

Scheme 34. Synthesis of 6-oxo-PGE_1 **105**.

prepared by a multistep synthesis via a PGI_2 derivative[69]. When the nitronate ion **103**, derived in situ by trapping of the enolate intermediate with the nitroolefin **97**, was treated with titanium(III) chloride/ammonium acetate[65], the ketonic product **104** was obtained in 76% yield. Deprotection (92%) and enzymatic hydrolysis (89%)[62] completed the three-step synthesis of 6-oxo-PGE_1 **105**.

Prostaglandins of the D series—like the analogues of the E series—have a β-hydroxycyclopentanone structure, but contain a hydroxy group at C-9 and a keto function at C-11. By choosing suitable protective groups in the synthetic building blocks, PGD_1 is, in principle, also accessible by the same pathway (Scheme 35)[70]. Silyl protection of 4-hydroxy-2-cyclopentenone and tetrahydropyranyl blocking



37 **106** **107** **108**

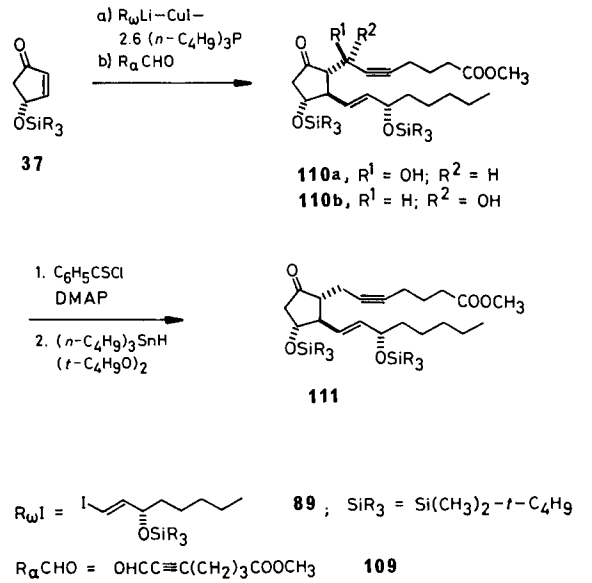
Scheme 35. Synthesis of PGD_1.

of the ω side-chain alcohol would appear to be among the most suitable. Thus, union of the cyclopentenone **37**, the ω side-chain **92**, and the α side-chain **93** by the tandem organocopper conjugate addition/aldol reaction gave rise to the prostanoic acid skeleton **106** (as a *threo/erythro* mixture of the aldols) in 70% yield. Dehydration of **106** by the standard procedure followed by reduction with tri-*n*-butyltin hydride gave the protected PGE_1 methyl ester **107** in 66% yield. The oxidation states of the C-9 and C-11 positions were easily rectified as follows: Reaction of **107** with *Yamamoto*'s phenol-modified diisobutylaluminum hydride reagent[10] resulted in the stereoselective reduction of

the 9-keto group (9α:9β = 88:12, 98% total yield); the main isomer of alcohol **108** was protected as tetrahydropyranyl ether (81%). Removal of the silyl group with tetra-*n*-butylammonium fluoride, alkaline hydrolysis of the ester, Jones oxidation of the 11-hydroxy function at −30°C, and deblocking of the tetrahydropyranyl groups furnished crystalline PGD_1 in 61% overall yield. The ester hydrolysis at the stage of 9,15-*O*-bis(tetrahydropyranyl)-$PGF_{1\alpha}$, rather than the final step, turned out to be more appropriate in view of the instability of PGD_1.

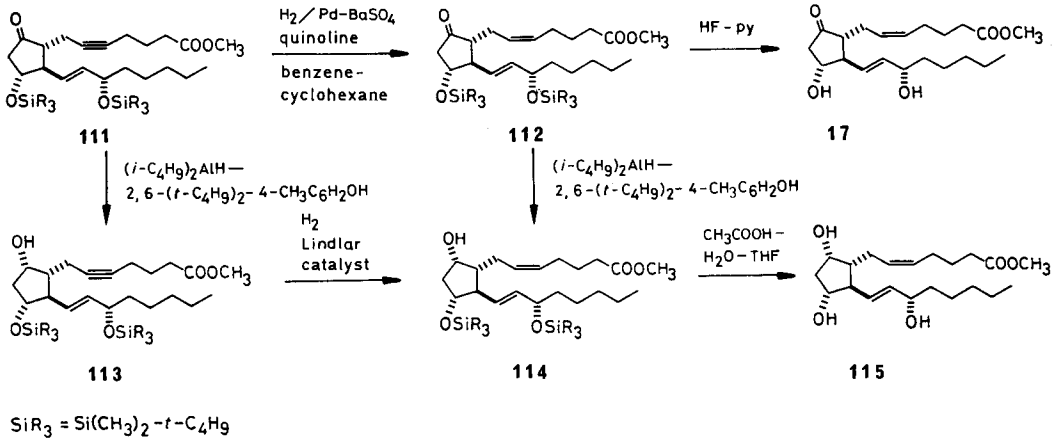
3.4. General Synthesis of Primary Prostaglandins

The conditions which an efficient prostaglandin synthesis must fulfill are wide generality and high flexibility. In the hope of opening a general route to primary prostaglandins, we chose as building block for the α side-chain methyl 6-formyl-5-hexynoate **109**, an acetylenic aldehyde which is readily obtainable by chain extension of propargyl tetrahydropyranyl ether[71] and *Swern* oxidation[72] of the corresponding alcohol. The tandem organocopper conjugate addition/aldol reaction was carried out with the cyclopentenone **37**, an (*E*)-alkenylcopper reagent derived from **89**, and the acetylenic aldehyde **109** in ether at −78°C to give the aldol adduct **110** (a 1:1 mixture of C-7 epimers)[73] (Scheme 36)[77]. The yield of the double vicinal CC-coupling is highly dependent on the structures of the building blocks, particularly the nature of the hydroxy protective groups, as well as the reaction and work-up conditions. The adduct **110** is obtainable in 83% yield if the conjugate addition is carried out in THF at −78°C and one equivalent of $BF_3 \cdot O(C_2H_5)_2$ is added prior to the reaction with the aldehyde **109**[60]. This procedure is quite reliable and reproducible. The 7-hydroxy group could not be removed by dehydration and reduction; however, the *Barton* method[78] proved successful. Thus, reaction of the aldols **110** with thiobenzoyl chloride and 4-dimethylaminopyridine afforded the thiobenzoate (71%), which upon heating at 50°C with tri-*n*-butyltin hydride in the presence of di-*tert*-butyl peroxide afforded a single deoxygenated compound **111** in 98% yield[79]. The smooth removal of the thiobenzoate moiety relies heavily on the presence of the 5,6-triple bond, which provides propargylic resonance stabilization to the radical intermediate. It is well known that simple β-ketoalkyl radicals undergo facile skeletal rearrangement via the tautomeric cyclopropyloxy radicals[80].



Scheme 36. Synthesis of the 5,6-dehydro-PGE_2 derivative **111**.

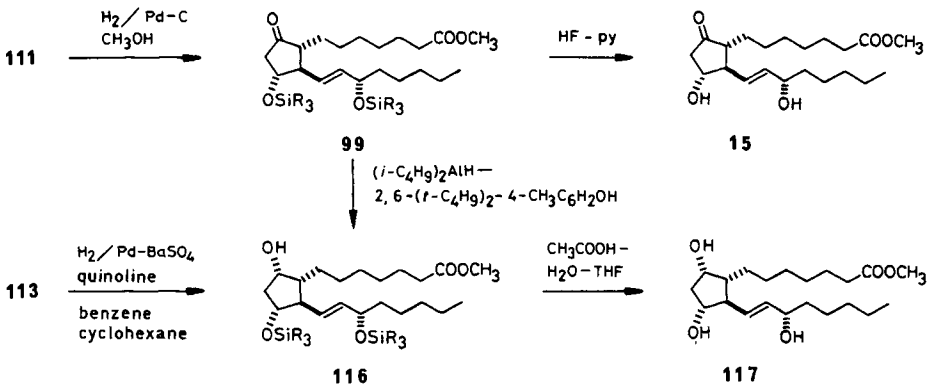
Clearly, the 5,6-dehydro-PGE_2 derivative **111** can serve as common intermediate for the synthesis of a variety of primary prostaglandins. Partial hydrogenation of the triple bond over 5% $Pd/BaSO_4$ catalyst in benzene/cyclohexane in the presence of quinoline led to **112** in 87% yield (Scheme 37). Removal of the silyl groups with hydrogen fluoride/pyridine gave the PGE_2 methyl ester **17** (98%), which could be converted into PGE_2 by an enzymatic technique[14c]. Reduction of the ketone **111** with the aforementioned phenol-modified diisobutylaluminum hydride reagent[10] in toluene at −25 to −20°C afforded the 9α-alcohol **113** with high stereoselectivity (α:β = 92:8) in 92% yield. **113** was also obtained (in 73% yield) from the thiobenzoate of the aldol **110** by stereoselective reduction with $NaBH_4$ (α:β = 9:1) and subsequent treatment with tri-*n*-butyltin hydride/di-*tert*-butyl peroxide. Catalytic hydrogenation of **113** over a Lindlar catalyst in benzene/cyclohexane with hydrogen at atmospheric pressure afforded **114** (81%). This compound was identical with the sample



Scheme 37. Synthesis of the PGE_2 methyl ester **17** and $PGF_{2\alpha}$ methyl ester **115**.

obtained in 87% yield by the stereoselective hydride reduction[10] of the PGE_2 derivative **112** (9α:9β = 91:9). Finally, deprotection of the disilyl derivative **114** with acetic acid/water/THF (10:3:1) furnished the $PGF_{2\alpha}$ methyl ester **115** (85%), whose ester group can be removed by alkaline hydrolysis.

Prostaglandins of the series 1 are also accessible from **111** and **113** by controlled reduction of the triple bond under conditions in which the CC double bond remains intact (Scheme 38)[77]. Thus, hydrogenation of **111** over 5% Pd/C in methanol to give **99** (71%) and subsequent desilylation with HF/pyridine gave the PGE_1 methyl ester **15** in 95% yield. Catalytic hydrogenation of **113** over 5% Pd/$BaSO_4$ in benzene/cyclohexane in the presence of quinoline afforded **116** (60%). Stereoselective reduction of **99** with diisobutylaluminum hydride/2,6-di-*tert*-butyl-4-methylphenol also gave predominantly the same alcohol (9α:9β = 91:9) in 76% yield. Deprotection of **116** under standard conditions furnished the $PGF_{1\alpha}$ methyl ester **117**.



SiR_3 = $Si(CH_3)_2$-*t*-C_4H_9

Scheme 38. Synthesis of PGE_1 methyl ester **15** and $PGF_{1\alpha}$ methyl ester **117** from the common intermediate **111**.

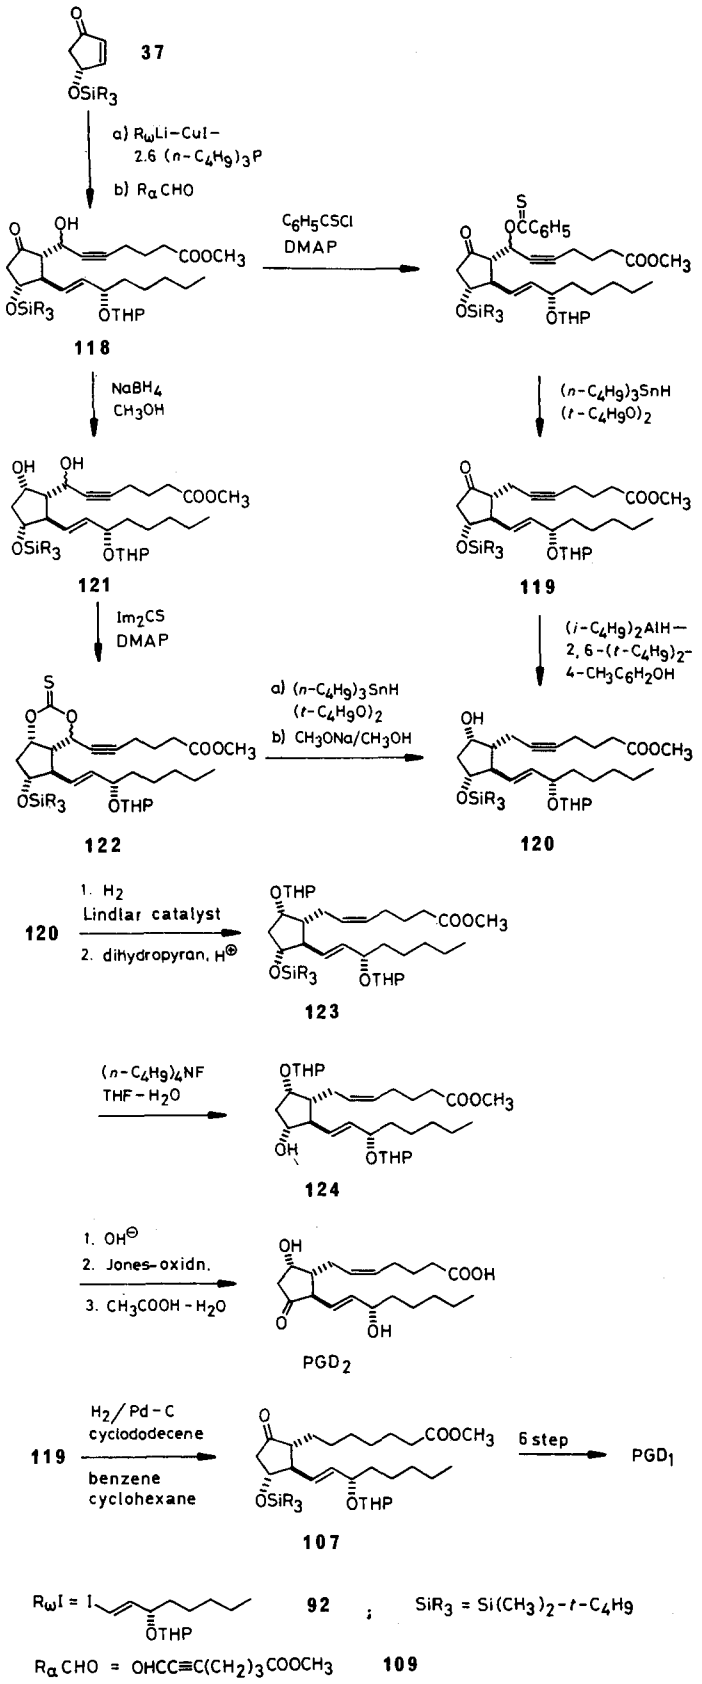
This strategy also allows the general synthesis of prostaglandins of type D, as illustrated in Scheme 39[70]. The aldol **118** (mixture of C-7 epimers) was obtained by double vicinal CC-coupling of the silylated hydroxycyclopentenone **37** with equimolar amounts of the tetrahydropyranyl-protected ω side-chain alcohol **92** and the acetylenic aldehyde **109** (yield 65%). Application of *Barton*'s procedure[78] to remove the 7-hydroxy group gave the deoxy compound **119** in ca. 66% yield. Reversal of the oxidation states of C-9 and C-11 was achieved in the above described manner. Reduction of **119** with excess diisobutylaluminum hydride/di-*tert*-butyl-4-methylphenol reagent[10] at −78 to −20 °C gave the 9α-alcohol **120** in 86% yield together with 8% of the 9β-isomer. **120** was also accessible by an alternative route from **118** via cyclic thiocarbonate intermediates **122**. When the more polar isomer of the aldol **118** was reduced with $NaBH_4$ in methanol at 0 °C, the corresponding 7,9-diol **121** was produced in a highly stereoselective fashion (9α:9β = 97.5:2.5, 77% yield). Formation of the cyclic thiocarbonate **122** with thiocarbonyl diimidazolide and 4-dimethylaminopyridine (92%) was followed by reduction with tri-*n*-butyltin hydride and alkaline hydrolysis of the ester function[81] to give the 7-deoxy product **120** (77%). The less polar isomer of the aldol **118** could also be converted into **120**, but the stereoselectivity of the hydride reduction was only moderate (9α:9β = 79:21). Partial hydrogenation of the acetylenic linkage of **120** was then effected over Lindlar catalyst in benzene/cyclohexane/cyclohexene with hydrogen at atmospheric pressure (96%); subsequent tetrahydropyranyl protection of the 9-hydroxy moiety (100%) afforded the suitably protected $PGF_{2\alpha}$ derivative **123**. Desilylation of **123** with tetra-*n*-butylammonium fluoride, to give **124** (95%), and subsequent saponification, Jones oxidation of the hydroxy carboxylic acid, and deblocking of the tetrahydropyranyl group completed the synthesis of PGD_2 (75%). Catalytic hydrogenation of **119** over 5% Pd/C in benzene/cyclohexane in the presence of cyclododecene afforded a PGD_1-precursor **107** in 68% yield (see also Scheme 35).

Prostaglandins of the A to C series can be derived from primary prostaglandins—hence, this method marks the realization of a new general synthesis of prostaglandins.

3.5. Synthesis of Prostacyclin and Related Compounds

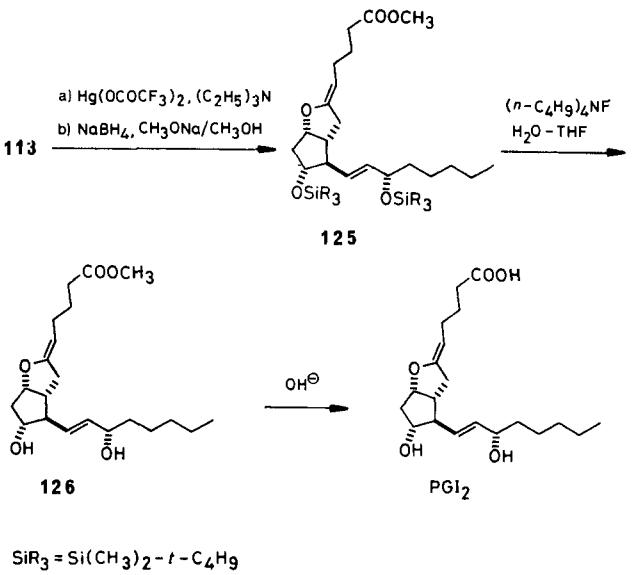
Prostacyclin (PGI_2), with its unique enol ether structure, has been synthesized in a roundabout way via $PGF_{2\alpha}$[13]. We found a simple *de novo* synthesis by way of the acetylenic intermediate **113**[82].

One may consider that intramolecular alkoxymercuration of 5-alkynols such as **113** in a 5-*exo-dig* manner[83] followed by reductive removal of the mercury moiety from the organometal intermediate counts among the most promising strategies for constructing a 2-alkylidenetetrahydrofuran structure. Actually, the efficiency of such a transformation is highly influenced by the substitution pattern of the substrates and the reaction conditions[84]; in some cases the reaction is quite complicated because of the concomitant side reactions such as double alkoxymercuration, acetal formation by solvent addition to the alkenyl ether intermediate, hydrolysis of the products during work-up, etc. Fortunately, we have found that the acetylenic alcohol



Scheme 39. Synthesis of prostaglandins D_1 and D_2.

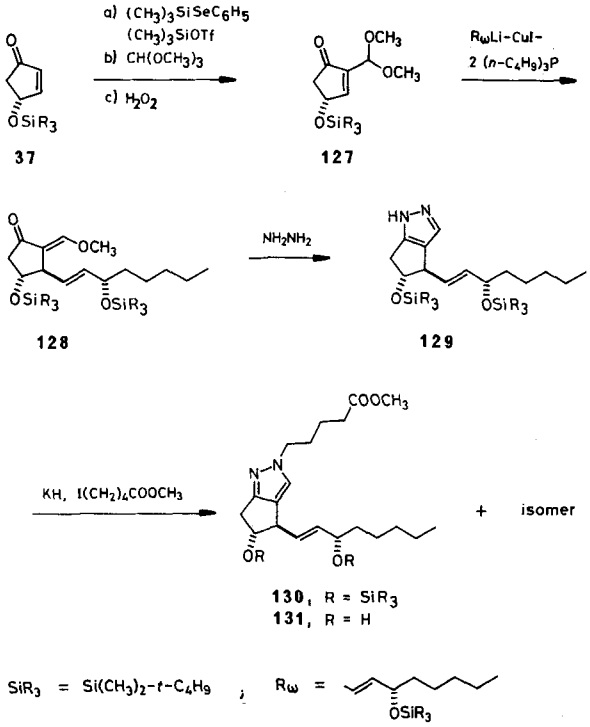
113 can be converted into a PGI_2 derivative **125** by sequential treatment with a mixture of a small excess of mercury(II) trifluoroacetate and triethylamine in THF at −78 °C and a 1 M methanolic sodium methoxide solution



Scheme 40. Synthesis of prostacyclin (PGI_2).

containing five equivalents of $NaBH_4$[82] (Scheme 40). After careful work-up and chromatography with added triethylamine, the cyclization product **125** (67% yield, 96% yield based on consumed starting material) and recovered **113** (30%) were obtained. The overall transformation appeared to proceed in a stereospecific manner, giving the (5*Z*)-isomer as sole product[85]. The intramolecular alkoxymercuration of the triple bond was accomplished stereospecifically in an *anti* fashion. Remarkably, the reductive demercuration of the resulting alkenylmercury trifluoroacetate with $NaBH_4$ in the protic medium occurred via a non-radical mechanism[86] with retention of the stereochemical integrity. This is in marked contrast with the reduction of alkylmercury compounds, which generates free alkyl radicals[87], and leads to stereorandom reactions. Deblocking of the silyl derivative **125** by tetra-*n*-butylammonium fluoride gave the PGI_2 methyl ester **126** (74%). Its alkaline hydrolysis leads to PGI_2[13]. Thus, PGI_2 is accessible in only seven steps from the chiral cyclopentenone **37**.

Prostacyclin, being the most potent natural inhibitor of blood platelet aggregation and a powerful vasodilator[1a, 1e], is recognized as one of the most significant compounds in the prostaglandin family. Unfortunately, however, it is exceedingly labile and is readily hydrolyzed to 6-oxo-$PGF_{1\alpha}$ **102** (half-life under physiological conditions only 5 min)[88]. One way of increasing the chemical stability is by replacing the alkylidenetetrahydrofuran skeleton by heteroaromatic rings; extensive efforts have been made in this direction[89]. We have synthesized a pyrazole-prostacyclin, as outlined in Scheme 41[90]. The optically pure siloxycyclopentenone **37** was first converted into the dimethoxymethyl derivative **127** in 79% yield by sequential treatment in dichloromethane with 1) one equivalent of phenylselenotrimethylsilane and a catalytic amount of trimethylsilyl triflate[91], 2) one equivalent of trimethyl orthoformate[92], 3) a small amount of pyridine, and 4) an excess of 30% hydrogen peroxide[93]. Subsequent conjugate addition in ether of an organocopper reagent prepared from equimolar amounts of copper(I) iodide, the lithium compound de-



37 127 128 129

131, R = H

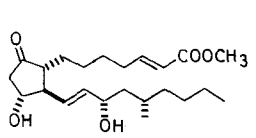
Scheme 41. Synthesis of the PGI_2 analogue **131**. Tf = trifluoromethanesulfonyl.

rived from the ω side-chain iodide **89**, and two equivalents of tri-*n*-butylphosphane gave the adduct **128** in 48% yield[49]. Ring closure was accomplished by reaction with excess hydrazine hydrate and the resulting pyrazole derivative **129** (84%) was alkylated with potassium hydride and methyl 5-iodopentanoate to give an approximately 1:1 mixture of **130** and its positional isomer (total yield 67%). Finally, deprotection of **130** with tetra-*n*-butylammonium fluoride completed the synthesis of **131** (77%). Although no significant biological properties of this compound have as yet been uncovered, such a method constitutes an attractive new way to a number of heteroaromatic prostacyclin analogues in optically active form.

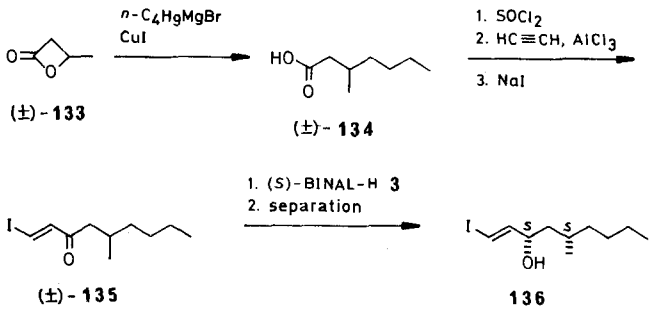
3.6. Some Physiologically Interesting Analogues

The three-component coupling process enables the synthesis of a wide range of physiologically significant analogues by choosing appropriately modified side-chain units.

First, this direct method provides a rapid entry to some prostaglandin analogues which have been prepared by the existing procedures and are presently undergoing clinical trials. A typical example is provided by the efficient synthesis[94] of (17*S*)-17,20-dimethyl-Δ^2-PGE_1 **132**[95], a powerful antithrombotic agent[95b], starting from the optically active cyclopentenone **37**, the (3*S*,5*S*)-iodovinyl alcohol **136**, and (*E*)-methyl 6-formyl-2-hexenoate. Scheme 42[67,96] illustrates the access to **136**, the optically active building block of the ω side chain (*ee* > 99%), starting from racemic 3-butanolide **133**[97].



132

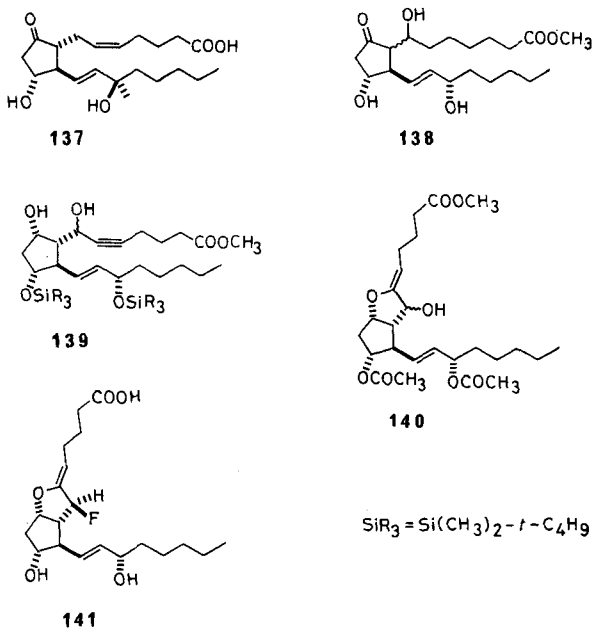


(±)-133 (±)-134 (±)-135 136

Scheme 42. Synthesis of optically active building blocks for ω side chains.

The absolute configuration of **136** was determined by the exciton chirality method using the derived *p*-bromobenzoate[74]. The alcohol **136** can also be prepared by a sequence involving an asymmetric synthesis[67,98].

(15*R*)-15-Methyl-PGE_2 **137** is known as a unique antiulcer drug[99]. This compound could also be conveniently prepared by the aldol route[94,100].



137 138 139 140

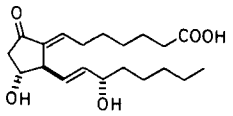
$SiR_3 = Si(CH_3)_2$-t-C_4H_9

141

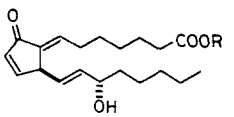
The functional groups on C-7 or C-6 of the three-component linked products not only serve as triggers of further chemical transformations but also of biological activities. For instance, the readily accessible 7-hydroxy-PGE_1 **138**[101] was found to be a potent inhibitor of platelet aggregation[102]. The acetylenic diol **139**[76] is convertible into the 7-hydroxy-PGI_2 derivative **140** by the alkoxymercuration technique[76]. Treatment of a mixture of the C-7 epimers with diethylaminosulfur trifluoride followed by deprotection and saponification gave stereoselectively (7*S*)-fluoro-PGI_2 **141**[76,103a] as the sodium salt. Such a 7-fluoro-PGI_2 derivative enjoys greater stability than PGI_2 under physiological conditions[103]. The inhibitory activity of **141** on rabbit platelet aggregation induced by ADP is only one tenth of that of the natural PGI_2, but both are equally po-

tent with regard to human platelets. **141** possesses lower hypotensive activity than PGI_2 and hence is a candidate for useful anti-platelet agents[103a].

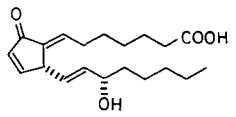
Recently, intense interest has been attached to the anti-neoplastic activities of primary and other prostaglandins such as PGA_2, PGD_2, and PGJ_2 (9-deoxy-Δ^9-PGD_2)[104]. Δ^7-PG derivatives[105] obtained by dehydration of the aldol intermediates are noteworthy in this respect. Many analogues of this type, **142**—**145**, as well as clavulone[106] (or claviridenone[107]) **146** isolated from *Clavularia viridis* were



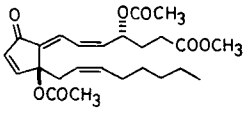
142



143, R = CH_3
144, R = H



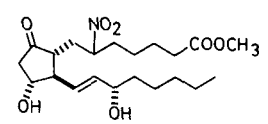
145



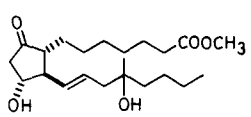
146

found to exhibit profound antineoplastic effects *in vitro* and *in vivo*[108]. For example, Δ^7-PGA_1 **144** inhibited the growth of L1210 tumor cells at concentrations of 0.2—0.4 μg/mL (IC_{50}) and suppressed the growth of Ehrlich ascites tumors at doses of 20 mg/kg (i.p. administration)[108b]. These derivatives are far more active than ordinary prostaglandin derivatives. Remarkably, 12-*epi*-Δ^7-PGA_1 **145** exhibits a similar activity, which indicates the possible separation of anti-neoplastic effects from the undesired prostaglandin activities.

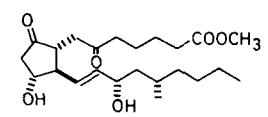
The tandem organocopper conjugate addition/nitroolefin Michael reaction is also useful. The 6-nitro-PGE_1 methyl ester **147** thus obtained has a more selective hypotensive activity than PGE_1[94,109]. 15-Deoxy-16-hydroxy-16-methyl-PGE_1 methyl ester **148**, an anti-ulcer agent which was developed by a Searle group[110], is accessible from the



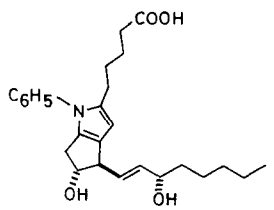
147



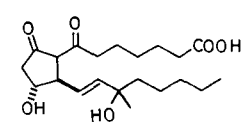
148



149



150



151

corresponding 6-nitro derivative by reduction with tri-*n*-butyltin hydride[63,94]. Ono and Upjohn have jointly been developing the 6-oxo-PGE_1 derivative **149**[69] as an anti-ulcer agent possessing cytoprotective properties. This three-component coupling process combined with the Nef reaction provides a two-step entry to this compound from **37**, **97**, and **136**[67]. Furthermore, a pyrrole derivative **150**, known as a leukotriene antagonist and an inhibitor of the leukotriene biosynthesis[111], is also accessible from **104** by a simple treatment with aniline followed by deprotection and saponification[94].

The 15-methyl-7-oxo-PGE_1 derivative **151** could be prepared quickly via the route described here using an acid chloride as the α side-chain unit[34]. This analogue[112] exhibits double the anti-ulcer activity of PGE_2 on oral administration, but, on the other hand, has a weaker diarrhea-inducing effect. **151** is relatively inert in terms of smooth muscle contraction, and is 100 times less potent than PGE_2 and $PGF_{2\alpha}$.

4. New Methods in Prostaglandin Synthesis

The realization of the new convergent synthesis of prostaglandins relies heavily on the discovery of versatile synthetic methodologies[113]. Some novel methods elaborated in our laboratories are described below.

4.1. Enantioselective Reduction of Prochiral Carbonyl Compounds

A new chiral aluminum hydride agent, abbreviated as BINAL-H [(*R*)- or (*S*)-**152** (empirical form), cf. also **3** and **67**], was devised by modification of $LiAlH_4$ with equimolar amounts of optically pure 1,1'-bi-2-naphthol and a lower alcohol, R'OH[114]. This hydride reagent containing an axially dissymmetric auxiliary of C_2 chirality exhibits exceptionally high chiral recognition ability[115,116] in the reaction with prochiral unsaturated carbonyl compounds, giving the alcohols in high optical purity[9a,56]. As shown in Table 1, this reducing agent can be applied to a wide range of structurally diverse unsaturated carbonyl compounds such as aromatic ketones[114a,c], alkynyl ketones[42,114d], alkenyl ketones[9,56,114d], and aldehydes[114b,d] as well as dienones[114d]. Either of the enantiomers is obtainable with equal ease by appropriate choice of handedness of the auxiliary binaphthol ligand. The chiral ligands can be recovered from the reaction mixtures in reusable form. Asymmetric reductions of this kind are not only extremely useful in prostaglandin syntheses[9,56,114d], but are also of general utility, as has been substantiated by the effective stereocontrolled syntheses of insect pheromones[42,114d], chiral primary terpene alcohols[114b,d], styrene oxide[114d], steroid side chains[117], etc.

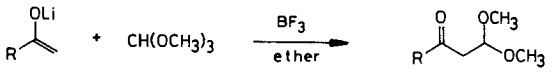
[1D](*E*,*Z*)-Farnesal	*R*	93	82	*R*
[α-D]Benzaldehyde	*R*	100	87	*R*

[a] Prepared by successive mixing of lithium aluminium hydride with equimolar amounts of a simple acohol, usually ethanol, and (*R*)-or (*S*)-1,1′-bi-2-napthol in THF. Usually, reduction was conducted at −100 to −78 °C using 2–3 equivalents of BINAL-H. [b] Reaction at −100 °C to room temperature. [c] Value for styrene oxide formed on treatment with aquous NaOH. [d] Reduction with methanol-modified BINAL-H. [e] (*S*)-(+)-Methyl 7-(3-hydroxy-5-oxo-1-cyclopentenyl)heptanoate. [f] (15*S*)/(15*R*) (PG numbering) diastereomeric ratio. [g] Conversion was 43%. [h] Conversion was 63%.

From a mechanistic point of view, the empirical rule given in Scheme 43, which enables prediction of the configuration of the product in the reaction of BINAL-H **152** with simple substrates, is highly interesting: aryl, alkenyl, and alkynyl groups exert approximately the same directing influence in the creation of a new asymmetric center. This suggests that the BINAL-H reagents differentiate the saturated and unsaturated groups attached to the carbonyl function primarily by the difference in the electronic properties rather than the relative bulkiness[9, 56, 114c].

4.2. α-Dialkoxymethylation of Preformed Enolates

A formyl group-equivalent can be introduced into ketones in a regiocontrolled manner under mild conditions[118]. Preformed lithium enolates[119] react with an equimolar amount of trimethyl orthoformate at −78 °C in the presence of boron trifluoride to give the corresponding dimethoxymethylated ketones in good yields (Scheme 44,



Scheme 44. α-Dialkoxymethylation of enolates.

Table 2. Dimethoxymethylation of lithium enolates [a].

Enolate precursor	Yield [%] (*cis* : *trans*)
Acetophenone	84

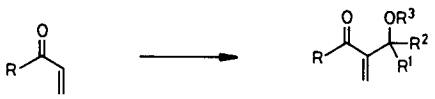
Cyclohexanone	87
4-*tert*-Butylcyclohexanone	72 (50 : 50)
4-Methylcyclohexanone [b]	79 (28 : 72)
2-Methylcyclohexanone [c]	68

[a] All reactions were conducted using equimolar amounts of trimethyl orthoformate and $BF_3 \cdot O(C_2H_5)_2$ in ether (1 h at −78 °C). [b] Less substituted enolate. [c] More substituted enolate.

Table 2). In this reaction, only mono-dimethoxymethylation takes place. The regiochemistry is defined at the stage of the lithium enolate. The stereochemistry at the α-position to the carbonyl group is kinetically controlled; the products do not undergo epimerization under the reaction conditions. This condensation is applicable to fully substituted enolates; with the conventional ketone formylation, using formates and sodium alkoxides, this is not possible, since it relies on the high stability of the resulting β-dicarbonyl compounds[120].

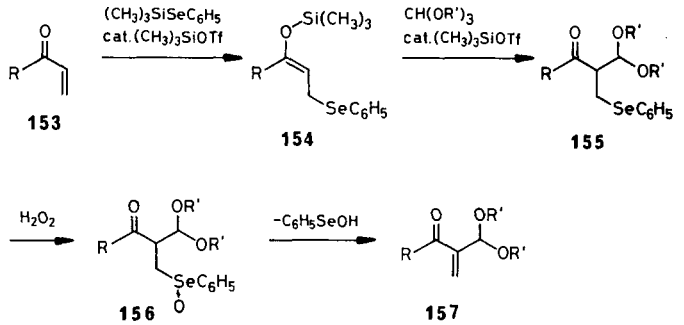
4.3. α-Alkoxyalkylation of α,β-Unsaturated Ketones

Although α-functionalized α,β-unsaturated ketones are versatile intermediates, direct introduction of substituents into the sp^2-hybridized α-position of enones is not an easy task[121]. We found a convenient procedure for converting cyclic or acyclic α,β-unsaturated ketones into α-alkoxyalkyl or -dialkoxyalkyl enones (Scheme 45)[122].



Scheme 45. α-Alkoxyalkylation of α,β-unsaturated ketones.

As shown in Scheme 46, conjugate addition of phenyl trimethylsilyl selenide to an enone substrate **153** generates the regiochemically defined silyl enol ether **154**[123], which in turn is condensed with a trialkyl orthoformate (or acetal)[91,92] to give the vicinally functionalized ketone **155**. Trimethylsilyl triflate serves as catalyst. Oxidative removal of the phenylseleno function by hydrogen peroxide[93] leads to the desired alkylation product (**155** → **156** → **157**). All the operations are accomplishable in dichloromethane in one pot without isolation of the intermediates, **154**—**156** (Scheme 46, Table 3). Trimethylsilyl triflate appears to



153 154 155 156 157

Scheme 46. Dialkoxymethylation of enones as a one-pot reaction.

Table 3. α-Alkoxyalkylation of α,β-unsaturated ketones [a].

Enone	Acetal or orthoester	Product	Yield [%]
Methyl vinyl ketone	Benzaldehyde-dimethyl acetal	3-(α-Methoxybenzyl)-3-buten-2-one	57
Methyl vinyl ketone	Triethyl orthoformate	3-(Diethoxymethyl)-3-buten-2-one	53
2-Cyclopentenone	Trimethyl orthoformate	2-(Dimethoxymethyl)-2-cyclopentenone	58
2-Cyclohexenone	Benzaldehyde dimethyl acetal	2-(α-Methoxybenzyl)-2-cyclohexenone	75
2-Cyclohexenone	Acetophenone dimethyl acetal	2-(α-Methoxy-α-methylbenzyl)-2-cyclohexenone	30
2-Cyclohexenone	Cinnmaldehyde dimethyl acetal	2-(1-Methoxy-3-phenyl-2-propenyl)-2-cyclohexenone	83
2-Cyclohexenone	Triethyl orthoformate	2-(Diethoxymethyl)-2-cyclohexenone	76

[a] Usually, reaction of phenyl(trimethylsilyl) selenide and an enone (1 : 1 mol ratio) was conducted in dichloromethane in the presence of a catalytic amount (2–2.5 mol%) of trimethylsilyl triflate at −78 °C for 30 min. Reaction of the resulting silyl enol ether and an acetal or orthoester was performed at −50 to −20 °C for 0.5 to 1 h. Subsequent removal of the phenylseleno group was achieved by oxidation (30% H_2O_2, 0 °C) followed by heating of the system (15–40 °C).

play a unique role in such transformations[91]. The reaction conditions are mild enough for prostaglandin syntheses[90] which involve chemically and optically labile 4-oxygenated 2-cyclopentenones.

4.4. Conjugate Addition of Organocopper Compounds to α,β-Unsaturated Ketones

An effective method for the nucleophilic transfer of organic moieties to conjugate enones is of crucial importance in prostaglandin synthesis. In place of the classical Kharasch procedure using Grignard reagents and copper salt catalysts, many modern organic syntheses make use of lithium cuprates of the type $LiCuR_2$ (Gilman reagents) because of the higher efficiency, increased selectivity, and reproducibility[26]. Mixed cuprates of type LiCuRR' (R' = C≡C-*n*-C_3H_7[33], C≡CC$(CH_3)_3$[124], C$(CH_3)_3$[125], CN[126], OC$(CH_3)_3$[29a], OC_6H_5[29a], SC_6H_5[29a], PR_2[127] etc.) or higher-order cuprates, $Li_2Cu(CN)R_2$[128], may be used for this operation. The rationale described in Section 3.2 prompted us to search for a procedure which effects a smooth reaction using a minimum amount of organometallic reagent and, as a consequence, use of the organocopper reagents derived from copper(I) iodide, organolithium compounds, and tri-*n*-butylphosphane (molar ratio 1 : 1 : 2—3) turned out to be among the best[59]. Hexamethylphosphoric triamide is also usable as the phosphorus auxiliary[59]. The reaction proceeds smoothly with a wide variety of conjugated enones **153** in ether (yellow solution) or THF (heterogeneous) at −78 to −40 °C and leads, after aqueous work-up, to the β-substituted ketones **158** in high yields (Scheme 47, Table 4). This method is economical

Scheme 47. Conjugate addition of phosphane-complexed organocopper reagents to enones.

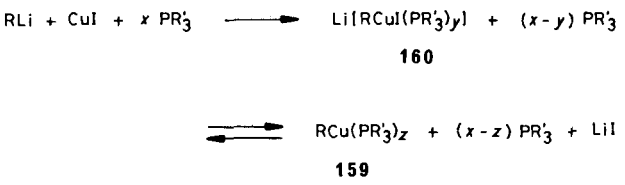
Table 4. Conjugate addition of organocopper compounds to enones [a].

Enone	Entering group	Yield [%]
(*E*)-5-Methyl-3-hexen-2-one	*n*-Butyl	94
(*E*)-5-Methyl-3-hexen-2-one	Isopropyl	95
(*E*)-5-Methyl-3-hexen-2-one	*tert*-Butyl	86
(*E*)-5-Methyl-3-hexen-2-one	Phenyl	84
4-Methyl-3-penten-2-one	*n*-Butyl	88 [b]
4-Methyl-3-penten-2-one	Isopropyl	99 [b]
4-Methyl-3-penten-2-one	Phenyl	70 [b]
4-Methyl-3-penten-2-one	Isopropenyl	66
2-Cyclopentenone	Methyl	73
2-Cyclopentenone	*n*-Butyl	98 [c]
2-Cyclopentenone	Isopropyl	90
2-Cyclopentenone	*tert*-Butyl	73
2-Cyclopentenone	Isopropenyl	98
2-Cyclopentenone	[d]	84 [c]
2-Cyclohexenone	Methyl	95 [b]
2-Cyclohexenone	*n*-Butyl	100
2-Cyclohexenone	Isopropyl	94
2-Cyclohexenone	*tert*-Butyl	91
2-Cyclohexenone	Isopropenyl	100
2-Cyclohexenone	[d]	75
3,5,5-Trimethyl-2-cyclohexenone	Methyl	28
3,5,5-Trimethyl-2-cyclohexenone	*n*-Butyl	100 [e]
3,5,5-Trimethyl-2-cyclohexenone	Isopropyl	100 [b, f]
3,5,5-Trimethyl-2-cyclohexenone	Isopropenyl	100

[a] Unless otherwise stated, reaction was carried out using a reagent prepared in situ by mixing copper(I) iodide, an organolithium compound, and tri-*n*-butylphosphane in the molar ratio 1 : 1 : 2–3 in ether (−78 °C for 0.5–1 h and then −40 °C, for 1–3 h). [b] Reaction at 0 °C for 5–10 min. [c] THF was used as solvent. [d] (*E*)-3-(2-Tetrahydropyranyloxy)-1-octenyl. [e] Yield based on the consumed sustrate. Conversion was 86%. [f] Yield based on the consumed enone. Conversion was 44%.

(enone/LiR = 1 : 1 to 1.25), can be applied to various sp^2- and sp^3-hybridized entering groups (methyl and primary, secondary, and tertiary alkyl), and compares well with the

existing reactions. The actual reaction system consists of a complex mixture of equilibrating species, as illustrated in Scheme 48. The organic group may be transferred to the lithium cation-coordinated enone substrates from the neutral organocopper complex **159** or from the anionic species **160**[129]. This still remains unclear.



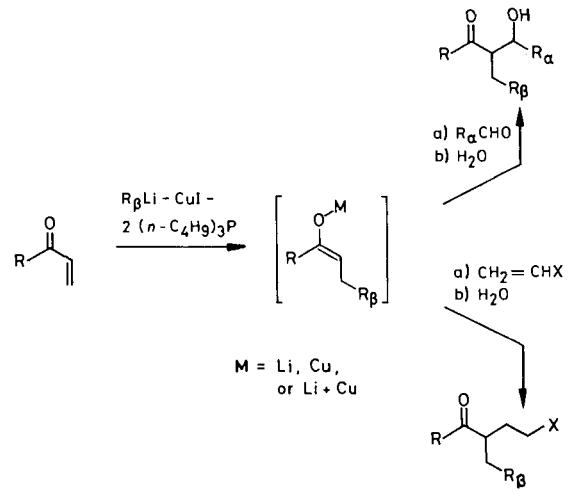
Scheme 48. Equilibration of organocopper species.

4.5. Double Vicinal CC-Coupling with Enones

4.5.1. Trapping Reactions of the Enolates Generated by Organocopper Compounds

Reactions of the enolates formed from enones and the phosphane-complexed organocopper reagents are easier to control than the reactions of such enolates generated from cuprates[29b, c, 130]. In fact, the regiochemically-defined enolates are capable of being trapped cleanly with aldehydes to give the corresponding aldol adducts (see Section 3.2 and Scheme 29)[50]. The three-component coupling process (Scheme 49, Table 5) is quite generally applicable. The enone : organolithium reagent (as precursor of the organocopper component) : aldehyde ratio is usually 1 : 1 : 1. Aliphatic aldehydes as trapping agents produce a single aldol adduct, whereas aromatic or α,β-unsaturated aldehydes give rise to a mixture of diastereomeric aldols (*threo* and *erythro*)[131].

The enolate intermediates undergo regiospecific Michael addition to nitroolefins (cf. Section 3.3)[63] and α,β-unsaturated ketones to give 2,3-disubstituted ketones (Scheme 49). The latter reaction has been used in the synthesis of steroids[132].



Scheme 49. Three-component coupling of enone, organocopper reagent, and electrophile. X = electron-withdrawing group.

Table 5. Double vicinal CC-coupling with α,β-unsaturated ketones via an organocupper/aldehyde joining process [a]. $R_\beta = n$-butyl.

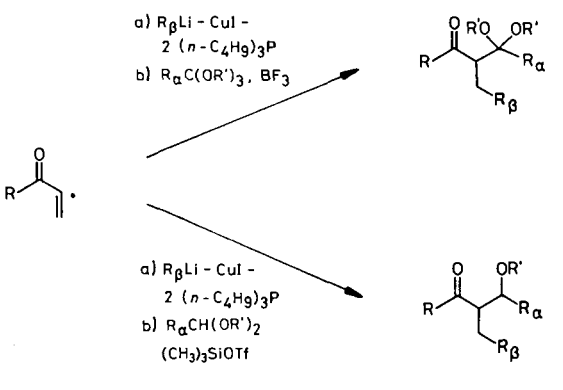
Enone	Aldehyde R_α–CHO	Aldol Yield [%]
2-Cyclohexenone	Formaldehyde [b]	60
2-Cyclohexenone	Acetoacetaldehyde	91
2-Cyclohexenone	(*E*)-Cinnamaldehyde	92 [c]
2-Cyclohexenone	Butanal	88 [d]
2-Cyclohexenone	2-Methylpropanal	94 [d, e]
2-Cyclohexenone	Benzaldehyde	85 [c]
2-Cyclopentenone	Butanal	98 [d]
2-Cyclopentenone	2-Methylpropanal	93 [d]
2-Cyclopentenone	2,2-Dimethylpropanal	71 [d]
2-Cyclopentenone	Benzaldehyde	91 [c]
2-Cyclopentenone	(*E*)-Cinnamaldehyde	94 [c]
2-Cyclopentenone	2-Hexynal	72 [c]

[a] The organocuprate-phosphane complex was prepared in situ by mixing copper(I) iodide, *n*-butyllithium, and tri-*n*-butylphosphane in the molar ratio 1 : 1 : 2 in ether. The conjugate addition was conducted at −40 to −70°C. Enolate trapping was carried out at −78°C for 5–60 min. [b] Introduced with an argon stream after cracking of paraformaldehyde. [c] A mixture of stereoisomeres. [d] A single isomer. [e] (2*R**,3*R**)-3-Butyl-2-((1*R**)-1-hydroxy-2-methylpropyl)cyclohexanone. This structure was determined by X-ray structure analysis of its *p*-bromobenzoate.

4.5.2. Trapping Reactions of the Enolates with Orthoesters or Acetals

Enolates formed from an enone by conjugate addition of an organocopper compound in stoichiometric amounts react with orthoesters at −78°C in the presence of boron trifluoride to give the three-component coupling product (Scheme 50, Table 6)[113]. Here again, incorporation of the organometallics and the electrophiles occurs regiospecifically at vicinal positions of the enone. Aminal esters may also be employed as electrophilic component. Other Lewis acids such as aluminum trichloride or titanium tetrachloride also accelerate the reaction, but are less effective than boron trifluoride (see Table 6).

Acetals are much less reactive than orthoesters. The condensation is made possible, however, when trimethylsilyl triflate is used in place of ordinary Lewis acid promoters (Scheme 50, Table 6)[133]. The enolates initially formed are probably converted into the silyl enol ethers, which are



Scheme 50. Three-component coupling of enone, organocopper reagent, and orthoester or acetal.

Table 6. Double vicinal CC-coupling of enones with organocopper reagents and orthoesters [a], aminal esters [a] or acetals [b].

Enone	R_β	Third component	Yield [%]
2-Cyclohexenone	*n*-Butyl	Trimethyl orthoformate	63 [c, d]
2-Cyclohexenone	*tert*-Butyl	Trimethyl orthoformate	66 [d, e]
2-Cyclohexenone	Isopropenyl	Trimethyl orthoformate	60
2-Cyclopentenone	*n*-Butyl	Trimethyl orthoformate	86
2-Cyclopentenone	Isopropenyl	Trimethyl orthoformate	80
2-Cyclopentenone	*n*-Butyl	Triethyl orthoacetate [f]	60 [g]
4-(*tert*-Butyldimethylsiloxy)-2-cyclopentenone	*n*-Butyl	Trimethyl orthoformate	59
2-Cyclopentenone	(*Z*)-3-(*tert*-Butyldimethylsiloxy)-1-octenyl	Trimethyl orthoformate	69
2-Cyclopentenone	*n*-Butyl	Dimethylformamide dimethyl acetal [f]	58 [h]

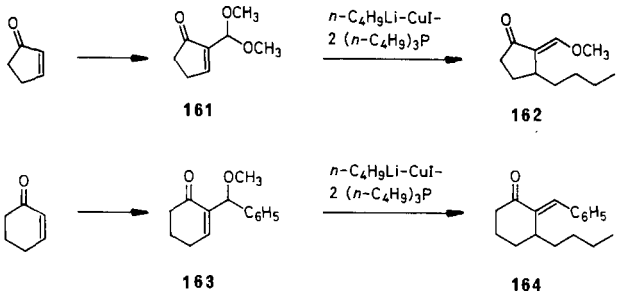
2-Cyclohexenone	Methyl [j]	Benzaldehyde dimethyl acetal	75
5-Methyl-3-hexen-2-one	(*Z*)-4,4-Diethoxy-1-butenyl	— [k]	50
2-Cyclohexenone	(*Z*)-4,4-Diethoxy-1-butenyl	— [k]	43 [l]

[a] The Organocopper reagent was added at −78 °C. The enolate trapping was performed using stoichiometric amounts of an orthoester or aminal ester and boron trifluoride at −95 to −78 °C. [b] The Organocopper reagent was added at −78 °C. The enolate trapping was conducted using 1.5–3 equiv of an acetal and trimethylsilyl triflate at −78 °C to −40 °C. [c] *trans*-3-Butyl-2-(dimethoxymethyl)cyclohexanone. [d] The stereochemistry was determined by X-ray structure analysis of a crystalline derivative. [e] *trans*-3-*tert*-Butyl-2-(dimethoxymethyl)cyclohexanone. [f] Reaction at −40 °C to room temperature. [g] 3-Butyl-2-(1-ethoxyethylidene)cyclopentanone. [h] 3-Butyl-2-(dimethylaminomethylene)cyclopentanone. [i] Reaction at −78 to 0 °C. [j] CH_3MgBr (1 equiv) − Li_2CuCl_4 (0.1 equiv) was used for conjugate addition. [k] Intramolecular acetal trapping was performed at 15 °C. [l] Bicyclo[4.4.0]deca-1(10),7-dien-2-one was formed.

capable of undergoing the silyl triflate-catalyzed reaction[91,92] with acetals. The intramolecular variant of this reaction provides a novel annelation procedure.

4.5.3. Conjugate Addition of Organocopper Compounds to α-Alkoxyalkylated Enones

Application of the conjugate cuprate addition to α-(di)alkoxyalkylated α,β-unsaturated ketones allows preparation of authentic 3-alkyl-2-alkylidenealkanones. The utility of the new double vicinal CC-coupling process is demonstrated in Scheme 51[122]. The products, **162** and **164**, were obtained from **161** and **163** in 60 and 89% yield, respectively. This procedure is particularly useful for the synthesis of heterocyclic compounds[90].

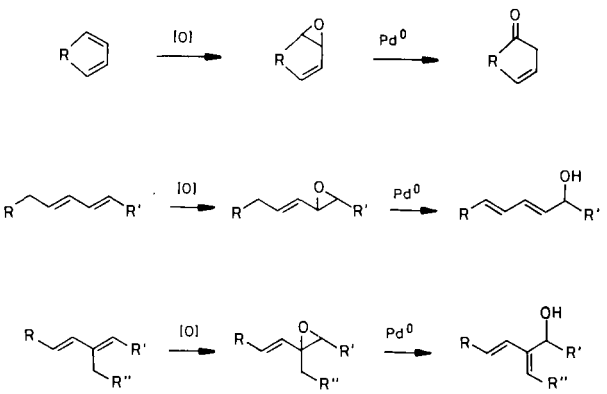


Scheme 51. Regiospecific synthesis of 2-alkylidene-3-alkylalkanones.

4.6. Palladium(0)-Catalyzed Isomerization of Epoxides

4.6.1. Isomerization of the 1,2-Epoxides of 1,3-Dienes

In connection with our search for access to the prostaglandin intermediates starting from cyclopentadiene, we have also examined the isomerization of the 1,2-epoxides of 1,3-dienes. This reaction is catalyzed by tetrakis(triphenylphosphane)palladium(0)[48a]. The course of the reaction appears to be highly dependent on the structures and substitution patterns of the substrates (Scheme 52). Epoxides



Scheme 52. Palladium(0)-catalyzed isomerization of the 1,2-epoxides of 1,3-dienes.

derived from 1,3-dienes afford the corresponding 3-cycloalkenones. Noteworthy, is the selective formation of β,γ-unsaturated ketones, which are usually less stable than their α,β-unsaturated analogues. The epoxy compounds derived from flexible 1,3-dienes isomerize, with shifting of the double bond, to give the dienols; the overall transformation can be formally regarded as an ene-reaction or vinylogous ene-reaction of 1,3-dienes caused by a singlet oxygen atom[134]. Examples of the catalyzed reaction are given in Table 7. The divergence of the reaction pathway results from differences in the structures of the organopalladium intermediates. Zwitterions of the type **165**, which are formed by nucleophilic attack of the palladium(0) reagent on the epoxides of the cyclic dienes, readily undergo hydrogen reorganization via palladium hydride species[135],

Table 7. Palladium(0)-catalyzed reaction of the 1,2-epoxides of 1,3-dienes [a].

Epoxide	T [°C] (t [h])	Product	Yield [%]
3,4-Epoxycyclopentene	0–10 [b, c] (2)	3-Cyclopentenone	88
3,4-Epoxycyclohexene	25 [c] (3)	3-Cyclohexenone	94
3,4-Epoxycycloheptene	120–140 [d]	3-Cycloheptenone	56
3,4-Epoxycyclooctene	120 [e] (22)	3-Cyclooctenone	74
3,4-Epoxycyclododecene [f]	120 [g] (24)	3-Cyclododecenone	79 [f]
		2,4-Cyclododecadien-1-ol	13 [f]
(*E*)-*trans*-7,8-Epoxy-5-dodecene	110 [e] (24)	6,8-Dodecadien-5-ol	95 [f]
4,5-Epoxy-2,5-dimethyl-2-hexene	130 [g] (36)	(*E*)-2,5-Dimethyl-3,5-hexadien-2-ol	81
3,4-Epoxy-2,3-dimethyl-1-butene	60 [h] (24)	3-Methyl-2-methylene-3-buten-1-ol	70

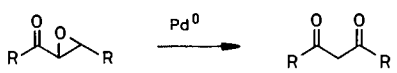
3,4-Epoxy-2,3-tetramethylene-1-butene	50 [e] (24)	(6-Methylene-1-cyclohexenyl)methanol	90
1-Vinyl-1,2-epoxycyclohexane	60 [e] (25)	2-Vinyl-2-cyclohexen-1-ol	39

[a] Reaction was carried out under argon atmosphere using 0.1–1 mol-% of tetrakis(triphenylphosphane)palladium(0) as catalyst. In most cases, some triphenylphosphane (1–2 equiv referred to the catalyst) was added. [b] With only 0.00013 mol-% of palladium(0)catalyst. No triphenylphosphane was added. [c] Dichloromethane as solvent. [d] Vapor-phase reaction. [e] In THF. [f] Stereoisomers. [g] In benzene. [h] In ether.

giving β,γ-unsaturated ketones, whereas the alkoxypalladium(II) complexes of type **166**, formed from the structurally flexible substrates, cause hydrogen transfer from RCH_2 to Pd and, hence, formation of the dienol. This reaction provides a new means for regiospecific oxygenation of 1,3-dienes. That the intermediate **166** could be trapped by some stabilized carbanions[136], extends the usefulness of this catalytic reaction.

4.6.2. *Synthesis of β-Diketones from Epoxy Ketones*

The efficiency of the epoxide isomerization occurring under aprotic, neutral conditions is due to the excellent nucleophilicity of palladium(0) species and the ability of palladium(II) species to carry hydrogen. These properties have been exploited for the synthesis of β-diketones (Scheme 53, Table 8)[139]. Thus, on heating a toluene solution of a 2,3-epoxy ketone and catalytic amounts of tetrakis(triphenylphosphane)palladium(0) and 1,2-bis(diphenylphosphino)ethane at 80 to 140°C, the β-diketone was formed. Table 8 shows some examples, including a high-yield synthesis of 1,3-cyclopentanedione, a prized compound[138].



Scheme 53. Palladium(0)-catalyzed isomerization of epoxy ketones to β-diketones.

Table 8. Palladium(0)-catalyzed isomerization of α,β-epoxy ketones to β-diketones [a].

Epoxy ketone	Product	Yield [%]
trans-3,4-Epoxy-2-pentanone	2,4-Pentanedione	81
trans-3,4-Epoxy-5-methyl-2-hexanone	5-Methyl-2,4-hexanedione	80

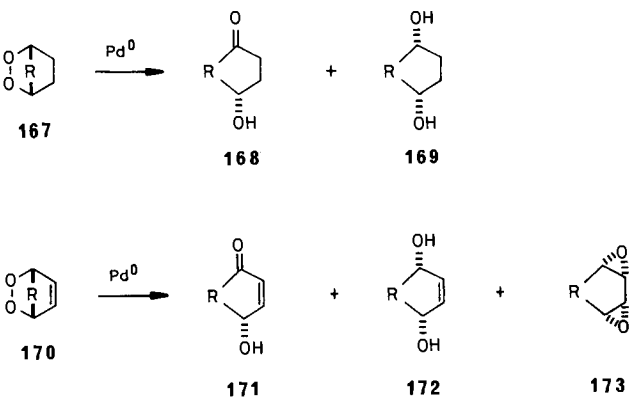
trans-1,2-Epoxy-1-phenyl-3-nonanone	1-Phenyl-1,3-nonanedione	82
trans-2,3-Epoxy-1,3-diphenyl-1-propanone	1,3-Diphenyl-1,3-propanedione	84
trans-2,3-Epoxycyclododecanone	1,3-Cyclododecanedione	54
2,3-Epoxycyclooctanone	1,3-Cyclooctanedione	52
2,3-Epoxycycloheptanone	1,3-Cycloheptanedione	60
2,3-Epoxycyclohexanone	1,3-Cyclohexanedione	62
5-Isopropyl-2-methyl-2,3-epoxycyclohexanone	5-Isopropyl-2-methyl-1,3-cyclohexanedione	18
2,3-Epoxycyclopentanone	1,3-Cyclopentanedione	94

[a] Reaction was carried out using tetrakis(triphenylphosphane)palladium(0) and 1,2-Bis(diphenylphosphino)ethane (1.5–10 mol-%) in toluene at 80–140°C under argon.

4.7. Transition Metal-Catalyzed Reactions of 1,4-Epidioxides

4.7.1. *Palladium(0)-Catalyzed Reactions*

1,4-Epidioxides (endoperoxides) have become increasingly important as synthetic intermediates[139]. Dye-sensitized photooxygenation of 1,3-dienes affords 2,3-unsaturated 1,4-epidioxides in good yields[134], from which the saturated analogues are obtainable by diimide reduction[140]. First, we chose to concentrate on the catalytic reaction with a soluble palladium(0) complex, which has a tendency to recycle the metal by way of a two-electron redox process[48a, 137]. Actually, when purified epidioxides of the type **167** [R = $(CH_2)_{1-4}$] were treated with a catalytic amount of tetrakis(triphenylphosphane)palladium(0) in dichloromethane or benzene, the 4-hydroxy ketone **168** and the 1,4-diol **169** were formed as the major products via competing two- and one-electron exchange reactions (Scheme 54, Table 9)[48b, 141]. 2,3-Dehydro-1,4-epidioxides **170** behave similarly[48b] and give **171** and **172**. In some cases, the diepoxide **173** is also formed. The reactivity and selectivity are highly influenced by the ring systems.



Scheme 54. Palladium(0)-catalyzed reaction of 1,4-epidioxides.

Table 9. Palladium(0)-catalyzed reaction of1,4-epidioxides [a].

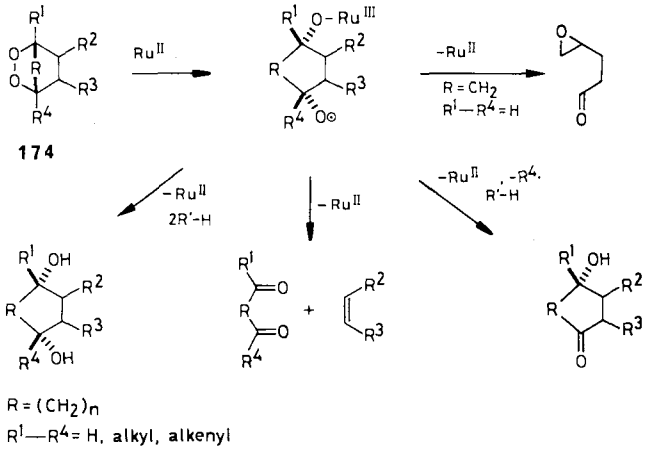
1,4-Epidioxy-4-methyl-1-phenyl-2-pentene	100	15	(*E*)-4-Hydroxy-4-methyl-1-phenyl-2-penten-1-one	66

[a] Reaction was carried out with 5–10 mol-% of tetrakis(triphenylphosphane)palladium(0) in dichloromethane. [b] Benzene as solvent. [c] As hemiacetal. [d] The catalyst and the substrate were mixed at −78°C.

4.7.2. *Ruthenium(II)-Catalyzed Reactions*

Dichlorotris(triphenylphosphane)ruthenium(II), which is soluble in aprotic organic solvents, is another interesting catalyst. This complex is capable of inducing reactions via one-electron exchange mechanisms[142]. As outlined in Scheme 55, when the substrates of type **174** are exposed to a catalytic amount of the ruthenium catalyst, the O–O linkage is cleaved and a mixture of products arising from fragmentation, reduction, and disproportionation is obtained[143]. The reactions proceed via radical intermediates, but they behave differently than photolytically or thermolytically free radicals. The reaction profile is interpretable in terms of "inner-sphere radicals"[142].



Scheme 55. Ruthenium(II)-catalyzed reaction of saturated 1,4-epidioxides.

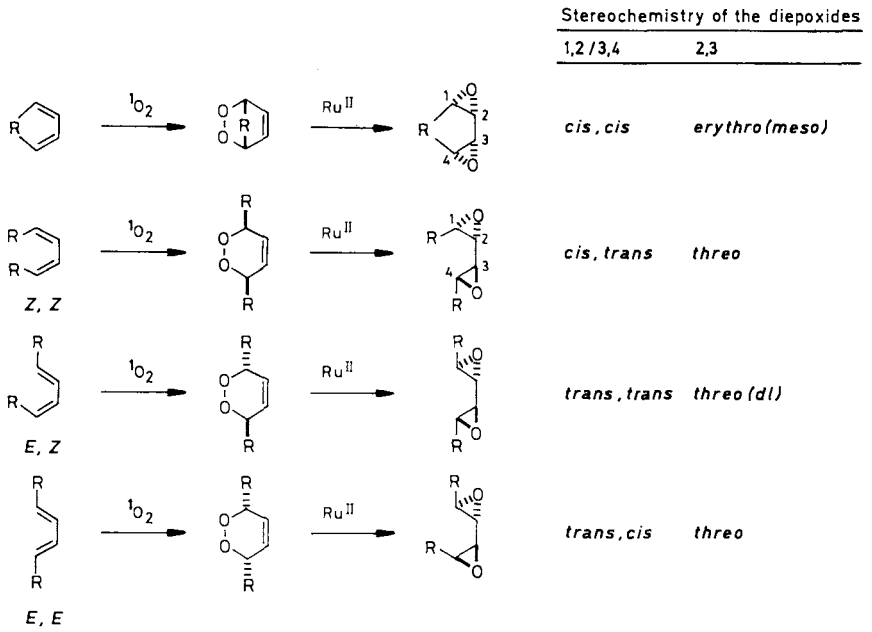
	6-Hydroxy-2,2,7,7-tetramethyl-4-octen-3-one	23 [d]

[a] Reaction was conducted with 1–8 mol-% dichlorotris(triphenylphosphane)ruthenium(II) in dichloromethane at 0–45°C under argon atmosphere. [b] Reaction at −25°C. [c] Reaction at −78°C. [d] A 1:1 mixture of the *Z*- and *E*-isomers.

In the case of 2,3-unsaturated 1,4-epidioxides, on the other hand, highly selective changes take place in the molecular framework. The bicyclic substrates are cleanly converted into the 2,3-*erythro*-1,2;3,4-diepoxides[143]. The monocyclic substrates generally give mixtures of the diepoxide and furan derivatives (Table 10)[144]. As illustrated in Scheme 56, the conversion of epidioxide into diepoxide takes a characteristic stereochemical course. Thus, epidioxides derived from (*E,E*)- or (*Z,Z*)-1,3-dienes produce predominantly the 1,2-*cis*-3,4-*trans*-diepoxides, whereas the epidioxides of (*Z,E*)-dienes afford the *trans,trans*-diepoxides. All these products—in contrast to the bicyclic system—have 2,3-*threo* relative configurations. This strikingly contrasting stereochemistry originates from differences in the ground-state geometry of the substrates: C_s-symmetry of the bicyclic endoperoxides and the C_2 chirality of the monocyclic dioxy compounds.

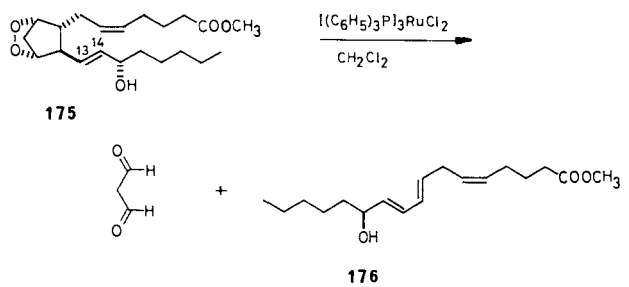


Scheme 56. Ruthenium(II)-catalyzed formation of 1,2 : 3,4-diepoxides.

4.7.3. Transition Metal-Catalyzed Transformations of Prostaglandin Endoperoxides

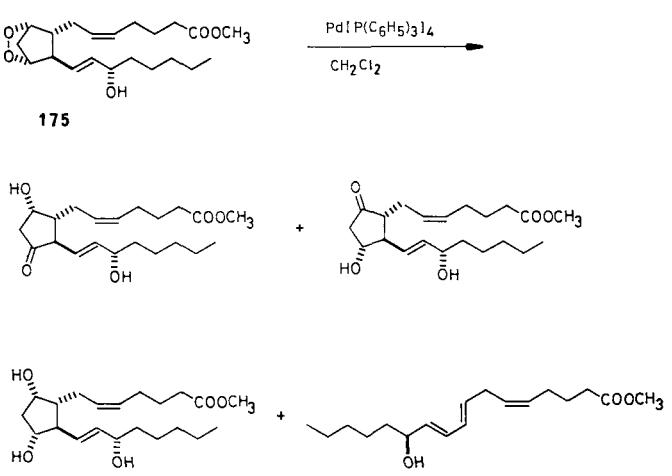
Prostaglandin endoperoxides serve as key substances in prostaglandin biosynthesis[1], and a variety of hypotheses have been advanced for their enzymatic transformation into primary prostaglandins, prostacyclin, and thromboxanes[145]. We have been intrigued by the homogeneous catalysis with transition metals possessing known chemical properties, since such an approach could provide some chemical interpretation of the mechanism of bioconversion[146].

The reaction of PGH_2 methyl ester **175** with 3 mol-% of dichlorotris(triphenylphosphane)ruthenium(II) catalyst in dichloromethane is remarkably clean, and only malonaldehyde and methyl (5*Z*,8*E*,10*E*,12*S*)-12-hydroxy-5,8,10-heptadecatrienoate (**176**, HHT methyl ester) are formed (Scheme 57)[143]. The fragmentation is stereospecific in nature with respect to the side-chains on C-8 and C-12. Obviously, the presence of the double bond between C-13 and C-14 facilitates the oxygen radical-induced fragmentation (cf. Scheme 55). No primary prostaglandin methyl esters are formed by this reaction. It should be added that thromboxane synthetase converts PGH_2 into a mixture of thromboxane A_2 and HHT[147].



Scheme 57. Stereospecific fragmentation of PGH_2 methyl ester **175** catalyzed by a ruthenium(II) catalyst.

As shown in Scheme 58, catalytic decomposition of PGH_2 methyl ester **175** with 10 mol-% of tetrakis(triphenylphosphane)palladium(0) in dichloromethane gives rise to a mixture of methyl esters of PGD_2 (17%), PGE_2 (11%), $PGF_{2\alpha}$ (41%), and HHT (4%). Here primary prostaglandins are the major products[148].



Scheme 58. Palladium(0)-catalyzed reaction of PGH_2 methyl ester **175**.

5. Outlook

Contributions to prostaglandin research can come from various scientific disciplines independently or cooperatively. One of the major challenges facing the synthetic organic chemist is to find an efficient entry to these substances which satisfies the demands of industrial applicability. We have developed a new purposive entry to prostaglandins. Here, adequate methodologies were available from the field of organometallic chemistry to perform the

vital functions in its convergency and to overcome all the major obstacles which existed at the threshold of prostaglandin synthesis. The present method is direct, efficiently stereocontrolled, general, and flexible. It is capable, not only of producing natural prostaglandins expenditiously but also of creating a variety of artificial analogues by the same technique.

The prostaglandin family controls a wide variety of physiological responses in body tissues, especially relating to regulation of functions of the circulatory system, respiratory and digestive organs etc. With the progress being made in our understanding of their pharmacological importance, several natural prostaglandins and their analogues are already available on the market for therapeutic use. For instance, PGE_2 and $PGF_{2\alpha}$ are drugs for inducing labor in women at term, for first-trimester abortion, for paralytic ileus, etc. PGE_1, a powerful vasodilator, is used for the treatment of severe peripheral vascular diseases such as Bürger disease and Raynaud's disease. PGI_2 is used for kidney dialysis and prevention of platelet loss in cardiopulmonary operations. In addition, numerous other clinical trials have been made and the outlook is bright. Further, $PGF_{2\alpha}$ and its analogues are now used for the treatment of reproductive difficulties in livestocks and for the synchronization of ovulation in breeding management. Obviously animal husbandry demands a plentiful supply of such synthetic materials. The efficiency of the syntheses via Corey lactones has been amply demonstrated by supplying sufficient material to meet current demands.

The spectrum of biological activities of the prostaglandins is unique and broad. PGI_2 and TXA_2 exhibit extremely potent but opposite behavior. These compounds are labile under physiological conditions; their half-lives are about five minutes and 30 seconds, respectively. The design and synthesis of stable PGI_2 analogues are subjects of current interest. Since intestinal motility and diarrhea occur as side effects, a separation of the activies and the specific effects are highly desirable through chemical modification of the molecules.

Prostaglandins and related compounds from the arachidonic acid cascade continue to attract a great deal of attention from biochemists and biomedical scientists. Some prostaglandins are now recognized to have a profound relation to cancer[104, 149] and brain physiology[150]. The prostaglandins have also received entomological interest since the discovery of PGE_2 in female crickets[151]. Recent information about prostaglandins in gonadal histology has now been extended from a variety of vertebrates to the maturation or spawning of marine invertebrates[152].

We hope that the chemical process presented here is viable as the second practical synthesis, and that it will beneficially contribute to the progress being made in this wide field through the efficient supply of known or newly created biologically significant substances.

We wish to acknowledge the significant contributions of collaborators at Nagoya University through their sustained intellectual and experimental efforts. The team includes, among others, Dr. M. Nishizawa and Messrs. T. Kawagishi, Y. Morita, Y. Oda, H. Ohtake, S. Sugiura, T. Suzuki, Y. Tanimoto, I. Tomino, M. Yamada, M. Yamaya, A. Yanagisawa, and A. Watanabe. Financial assistance from the Ministry of Education, Japanese Government, is gratefully acknowledged. In addition, this research has been generously supported by the Teijin Company and Ono Pharmaceutical Company in many respects. Finally, one of the authors (R. N.) who spent a postdoctoral year in 1969—1970 at Harvard University expresses deep appreciation to Professor E. J. Corey for being introduced to this fascinating scientific field.

[2] *Weinheimer* and *Spraggins* have discovered an attractive source of PGs in a gorgonian coral called *Plexaura homomalla:* A. J. Weinheimer, R. L. Spraggins, *Tetrahedron Lett. 1969*, 5185, and Chapter 3 in Ref. [3c]. However, PGA_2, a major component (1.5% of the wet weight) of this coral, contains about 3 to 15% of the "unnatural" 5-*trans* isomer which is difficult to remove. In addition, little knowledge has been obtained on the regrowth of this organism. These problems prevent practical use of such natural resources [1d].

[73] The stereochemistry of the C-7 hydroxy group was determined by the exciton chirality method [74] after conversion into the 7-benzoyloxy PGE_2 derivative [75]. The more polar isomer **110a** has 7*R* configuration and the less polar isomer **110b** possesses 7*S* configuration. This assignment was confirmed chemically by transformation into 7-hydroxy PGI_2 derivatives [76].

Asymmetric Diels-Alder and Ene Reactions in Organic Synthesis

New Synthetic Methods (48)

By Wolfgang Oppolzer*

Rapidly accumulating evidence shows the value of asymmetric Diels-Alder and ene reactions for the syntheses of enantiomerically pure molecules. This article presents a systematic and critical treatment of various stereoface-differentiating principles, including very recent spectacular advances. The chiral information is mainly provided by covalently bound auxiliaries, some of which are crystalline, inexpensive, and readily available from naturally occurring monoterpenes, hydroxy acids, amino acids, steroids, and sugars. Nondestructive transfer of chirality leads to the efficient creation of up to four chiral centers with predictable relative and absolute configurations. Regenerative cleavage of the auxiliary group from the diastereomerically pure adducts furnishes a range of polyfunctional, optically pure building blocks. Their synthetic potential is illustrated by strategic applications to the syntheses of physiologically interesting, chiral natural products such as prostaglandins, antibiotics, terpenoids, shikimic acid, alkaloids, and kainoids.

1. Introduction

The efficient construction of enantiomerically pure, structurally complex molecules is a fundamental challenge in organic synthesis. Only recently have extensive efforts been made to induce asymmetry in carbon-carbon bond forming reactions[1]. Among these the Diels-Alder reaction merits particular attention. Accordingly, this review focuses on the achievement of absolute configurational control in Diels-Alder reactions, underscoring various principles and illustrating their strategic applications to natural product syntheses. Furthermore, the employment of analogous concepts in asymmetric ene reactions is outlined. Pertinent examples are selected based on the criteria of high stereodifferentiation and removability of the chiral control group from the product. Mechanistic discussions provide insight into the three-dimensional nature of the corresponding transition states, assuming the operation of kinetic control.

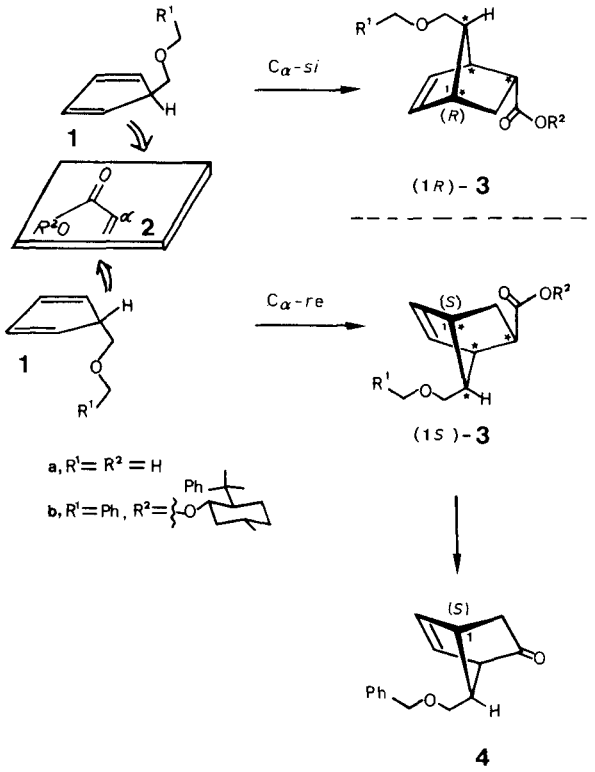
2. Asymmetric Diels-Alder Reactions—General

Since its discovery in 1928 the Diels-Alder reaction has been refined to become one of the most powerful tools in organic synthesis[2]. A most attractive feature is the simultaneous, regioselective formation of two bonds leading to the creation of up to four chiral centers at the binding sites with largely predictable relative stereochemistry. Studies of the control of the absolute topicity started in 1961, but substantial progress has only been achieved in recent years. At present, this field is expanding rapidly, which justifies a selective rather than exhaustive review.

To illustrate the overall stereochemical features, we mention the first reported example of a strategic application in synthesis.

Addition of 5-(methoxymethyl)cyclopentadiene **1a** to acrylic acid **2a** proceeded *endo*-selectively and *anti* with respect to the diene substituent[3]. Consequently, the relative configuration of the four new chiral centers in **3a** is determined and, of four possible diastereoisomers, one is formed selectively. As expected, the diene added at the same rate to the two enantiotopic dienophile π-faces affording a 1:1-mixture of the enantiomers (1*R*)-**3a** and

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/1111-0876 $ 02.50/0



(1*S*)-**3a**. Since only the (1*S*)-enantiomer is suitable for the synthesis of prostaglandins, exclusive diene addition from the C_α-*re*-face was required. Indeed, attachment of an appropriate chiral ester group R^2 to the dienophile **2** caused steric shielding of the now diastereotopic C_α-*si*-face thereby directing the $AlCl_3$-promoted diene addition to the C_α-*re*-face. As a result of this π-face differentiation, the desired (1*S*)-**3b** was obtained from **2b** in significant excess over the undesired (1*R*)-isomer. Degradation of this mixture involving cleavage of the chiral control element R^2 furnished ketone **4** in high enantiomeric purity[4]. This example also serves to illustrate the definition of diastereomeric excess (d.e.) used throughout this review. For instance, a hypothetical ratio (1*S*)-**3b**/(1*R*)-**3b** = 95 : 5 amounts to 90% diastereomeric excess (d.e.) of (1*S*)-**3b** over (1*R*)-**3b** and leads to the (1*S*)-ketone **4** in 90% enantiomeric excess (e.e.). Accordingly, the π-face differentiation-related diastereomeric excess (e.g. 90% d.e. of (*S*)-**3b**) translates in general into enantiomeric excess (e.g. 90% e.e. of **4**) after removal of the chiral auxiliary.

The above example demonstrates the addition of a prochiral diene to a chiral dienophile which carries a removable chiral auxiliary. Further options for π-topological differentiation in Diels-Alder reactions include the temporary attachment of a chiral control group to the diene or, more elegantly, the employment of a chiral catalyst. So far the stoichiometric use of covalently bound chiral control groups has proved to be more efficient and predictable. In practical terms, the ideal prosthetic group should meet the following criteria:

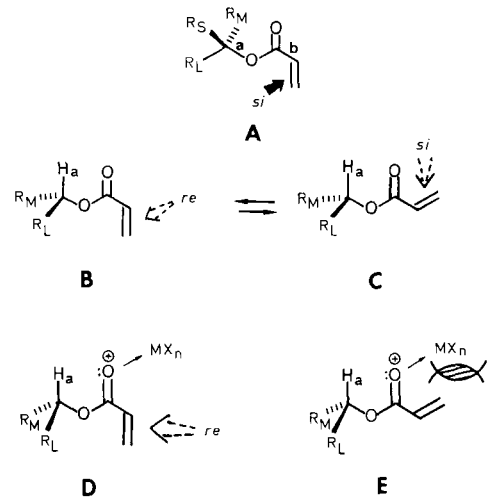
1) Provide a wide range of Diels-Alder adducts in high chemical yield with virtually quantitative and predictable π-face stereodifferentiation.
2) Both enantiomers or alternative topological counterparts should be readily available.
3) Be capable of efficient attachment and nondestructive removal from the adduct with complete retention of the induced configuration.
4) Permit facile purification of the major cycloadduct to almost 100% d.e.
5) Impose crystallinity on intermediates and products.

Consequently, success in this research area relies on logical design and imagination, but also on numerous empirical parameters.

3. Chiral Dienophiles

3.1. Acrylates

The vast majority of work on asymmetric Diels-Alder reactions deals with additions of 1,3-dienes to chiral, conjugated carboxylic esters. In this context, the relevant conformers of acrylates derived from secondary alcohols are discussed briefly.

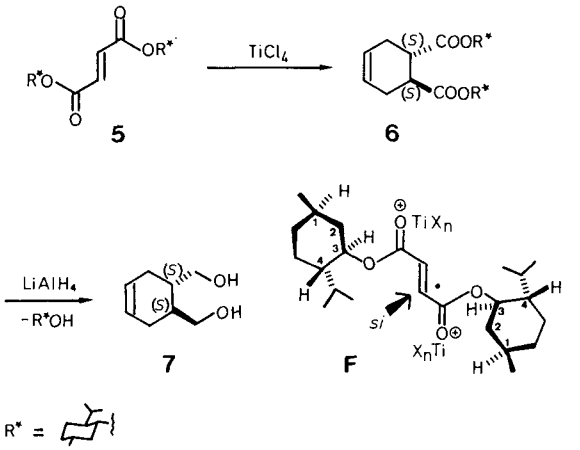


Conformation **A**, postulated by *Prelog* et al.[5], implies an *anti*-orientation of the large substituent R_L and the C=O group which is antiplanar to the olefinic bond. This model differs slightly from conformer **B**, which, according to X-ray data[6], exhibits a synperiplanar C–H_a/C=O-relationship in the crystal. In solution, however, spectroscopic evidence[7] indicates an equilibrium between conformers **B** and **C**, where the synplanar C=O/C=C-disposition of the latter is disfavored by only $\Delta H = 0.32$ kcal/mol. If the diene adds exclusively to the π-face opposite the larger substituent, conformers **B** and **C** display reversed topicity. Consistent with this element of unpredictability, no thermal Diels-Alder reactions of acrylates have ever surpassed the threshold of 65% d.e. However, the situation changes dramatically when the acrylate coordinates to a Lewis acid. Supported by the results of X-ray[8] and spectroscopic studies[9], we assume predominant coordination of various Lewis acids (notably $TiCl_4$ and $SnCl_4$) with the carbonyl oxygen *anti* to the ester oxygen. This precludes conforma-

tion **E** on steric grounds and secures the C=O/C=C *anti*-conformation **D**. Moreover, Lewis-acid coordination to acrylates increases the regio- and *endo*-selectivity as well as the rate of their [4+2]-addition to 1,3-dienes. As a result of this advantageous coincidence of effects, successful asymmetric Diels-Alder reactions are generally carried out at low temperatures in the presence of a Lewis acid. This dichotomous influence of coordination on the activation energies for conformer interconversion and cycloaddition is also of predictive value for the rational design of chiral control groups. One limitation, nevertheless, should be mentioned. If the diene adds to the complex **D** from the side opposite to the large group R_L, tetragonalization of the enoate centers may be sterically hindered. In fact, enoates which carry a bulky ester substituent generally show a decreased dienophile reactivity which restricts their application to asymmetric Diels-Alder additions of mutually reactive diene and dienophile partners.

3.1.1. Addition of Bis(menthyl) Fumarate to 1,3-Butadiene

In 1963 *Walborsky* published his pioneering work on the addition of bis(menthyl) fumarate **5** to 1,3-butadiene promoted by Lewis acids, affording the cyclohexene derivative **6**[10]. Optimal results (80% yield, 78% d.e.) were obtained using $TiCl_4$ (1 mol per mol **5**) in toluene at +25°C. The reported rationalization refers to the Prelog model **A** involving conformation **F**. Regardless of the validity of this model, it should be considered that the high level of diastereodifferentiation relies on the cooperative influence of *two* chiral prosthetic groups (R* = (−)-menthyl).



3.1.2. Additions of Acrylates Derived from (−)-Menthol to Cyclopentadiene

Employment of only *one* menthyl auxiliary, as in the addition of menthyl acrylate to (the even more reactive) cyclopentadiene at lower temperatures (**8**→**9**, R=H), does not show the same degree of stereoselection as indicated in Table 1 (entry 3[11]). Early studies (entries 1, 2)[12,13] relied entirely on chiroptic comparisons, which are insufficient to assess the extent of an induction[1a]. The significantly higher diastereotopic face differentiation exerted by the 8-phenylmenthyl auxiliary was first reported to result in an

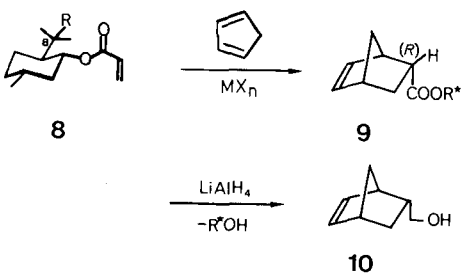


Table 1. Examples of reaction **8**→**9** in the presence of MX_n at −20°C in CH_2Cl_2.

Entry	R	**8** : MX_n	MX_n	Yield [%]	*endo* [%]	d.e. [%]
1 [a]	H	1 : 1.0	$SnCl_4$	76	89	41

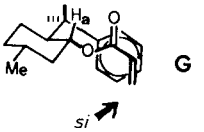
induction of 99% d.e. based on the optical rotation of **10**[4]. This value was subsequently corrected to 89% (entries 4, 5)[11] as a result of a study which also showed how significantly the extent of *si*-face selection depends (entries 5–7) on the nature of the Lewis acid. The topological bias of the 8-phenylmenthyl group reported by *Corey* et al.[4] represents without doubt a landmark in asymmetric synthesis. It



G

is readily rationalized by postulating a conformationally rigid cyclohexane **G** featuring an acrylate conformation **D** and *re*-face shielding by the *α-trans* 1-methyl-1-phenylethyl group[14]. The enhanced diastereoselection may be a consequence of complementary steric and aryl-acrylate π-stacking effects. Nevertheless, limitations include the oily nature of (−)-8-phenylmenthol, the need for careful purification by medium pressure chromatography during its preparation from (+)-pulegone, and the difficult accessibility of its *re*-face directing (+)-enantiomer[15].

3.1.3. Addition of (S)-(+)-1,2,2-Trimethylpropyl Acrylate to Cyclopentadiene

A comparatively efficient C_α-*re*-face directing auxiliary had been reported previously. Thus, $BF_3 \cdot OEt_2$-induced addition of the ester **12** to cyclopentadiene furnished the (5*S*)-adduct **13** with high *endo*- and π-face stereoselectivity[13]. The initially reported modest yield (Table 2, entry 1) has been improved to 75% more recently (Table 2, entry 2)[16]. It is worth noting that the absolute topicity is consistent with diene attack at the side opposite to the bulky *tert*-

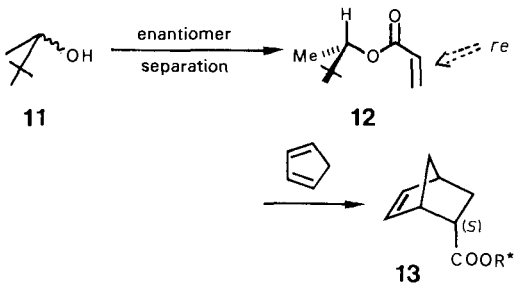


Table 2. Examples of the reaction **12** → **13** in the presence of $BF_3 \cdot OEt_2$ (1 mol per mol **12**) at −70°C in CH_2Cl_2.

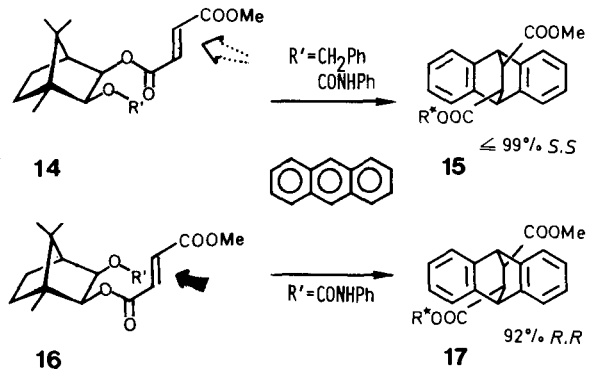
Entry	Yield [%]	*endo* [%]	d.e. [%]	Ref.
1	44	>95	88	[13]
2	75	97	80–85	[16]

butyl group of acrylate conformers **B** or **D** but *not* **A**. The practical applicability suffers from the necessary separation of the oily auxiliary alcohol **11** from its enantiomer.

3.1.4. Additions of Fumarates Derived from 3-Hydroxyisoborneol to Anthracene

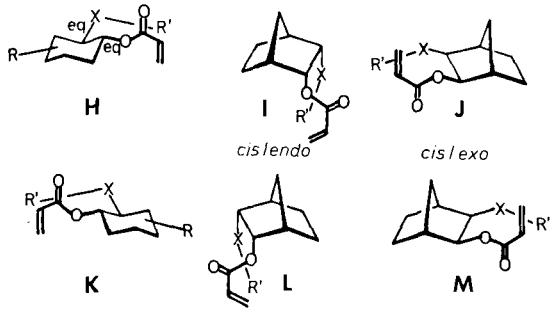
In the course of a model experiment, fumarates **14** and **16** were added efficiently to anthracene at −30°C in CH_2Cl_2 in the presence of $AlCl_3$ (1 mol per mol educt)[17].



The shielding of the fumarate π-faces by the benzyloxy- or *N*-phenylcarbamoyl substituents led to the (11*S*,12*S*)-adduct **15** (from **14**) in up to 99% d.e. or to the (11*R*,12*R*)-isomer **17** (from **16**) in up to 92% d.e.

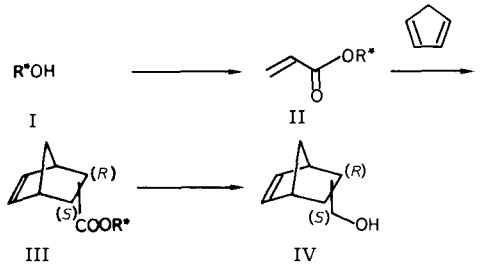
3.2. Working Concept for the Development of π-Face Differentiating Acrylates

The properties of phenylmenthol stimulated a search for more practical auxiliary alcohols: cyclohexanols locked in a chair conformation (cf. **H** and **K**) and conformationally rigid cyclopentanols[14a]. Accordingly, a number of studies focused on the *si*-face directing acrylates **H**, **I**, and **J** and their *re*-face directing counterparts **K**, **L**, and **M**.

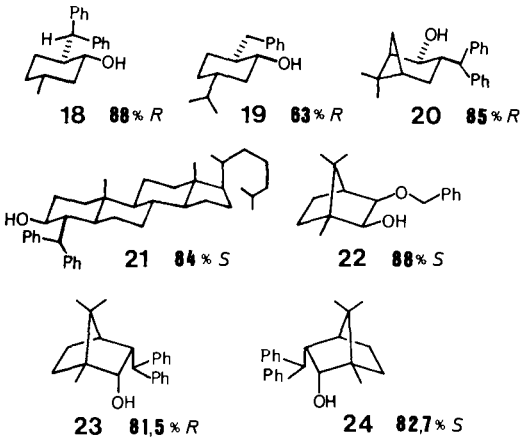


3.2.1. Acrylates of the Types H to M

Using the guidelines in Section 2, a number of alcohols **I** were prepared and converted into the acrylates **II**. To compare the sign and extent of the topological bias provided by each auxiliary, the Lewis-acid promoted addition to cyclopentadiene (**II** → **III**) served as a test reaction.

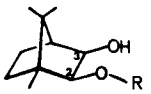


Acrylates from Various Auxiliary Alcohols: Alcohols **18** to **24** represent a cross-section of various, chiral auxiliary compounds which emerged initially from this work. $TiCl_4$-mediated additions of their acrylates **II** to cyclopentadiene afforded, predictably, either the (5*R*)- or the (5*S*)-2-norbornene adducts **III** with up to 88% diastereoselection[14].

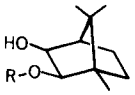


Acrylates from cis-3-Hydroxyisobornyl Ethers: Pursuing the hypothetical role assigned to aryl/acrylate π-stacking and exploiting the ready availability of (+)- and (−)-camphor, the acrylates of the diphenylmethyl, α-naphthylmethyl, and β-naphthylmethyl ethers **25a**–**c** were added to cyclopentadiene. Whereas attempted catalysis by $TiCl_4$ failed because of rapid ether cleavage, high chemical

yields and up to 92% d.e. (Table 3) were conveniently obtained using the mild Lewis acid $TiCl_2(OiPr)_2$ [$TiCl_4$/$Ti(OiPr)_4$, 1 : 1].



25

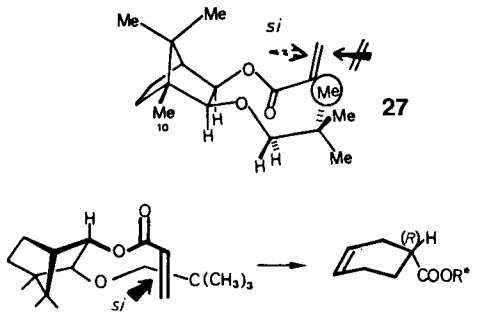


26

Table 3. Examples of the reaction of acrylates **II** derived from alcohols **I** (*cis*-3-hydroxyisonorbornyl ethers **25** and **26**) with cyclopentadiene to give adducts **III** (for conditions, see text).

Entry	I	R	Yield [%]	Adduct III *endo* [%]	C-5	d.e. [%]
1	**25a**	CH_2Ph	74	95	*R*	91
2	**25b**	2-Naphthylmethyl	98	95	*R*	92
3	**25c**	1-Naphthylmethyl	97	93	*R*	88
4	**25d**	Neopentyl	94	96	*R*	99.3
5	**26**	Neopentyl	98	95	*S*	99.3

On testing the effect of steric bulk on acrylate π-face shielding, it was found that the neopentyl ether **25d** displayed a dramatically superior chirality directing ability[18] which is considerably greater than that of 8-phenylmenthol. Inspection of models having a staggered conformation of the neopentyl ether chain (consistent with X-ray-data[19]) indeed revealed that the *tert*-butyl group sterically blocks the C_α-*re*-face in the acrylate **27**.

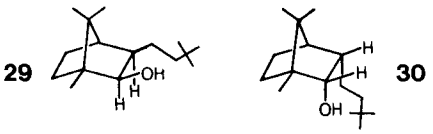


27

27 28

From the practical standpoint, it is worthwhile mentioning that the low melting, but crystalline auxiliaries **25d** and **26** are readily accessible from either (+)- or (−)-camphor in 60% overall yields. Their acrylates provide either the (5*R*)- or the (5*S*)-adducts **III** in 94 to 98% chemical yield with 93 to 96% *endo*-selectivity and with over 99% diastereofacial differentiation (Table 3). Moreover, the auxiliaries are nondestructively removed from the cycloadducts by reduction with $LiAlH_4$ and can be readily separated from the virtually enantiomerically pure alcohols **IV** by chromatography. The analogous Diels-Alder reaction of acrylate **27** with 1,3-butadiene in the presence of $TiCl_4$ (molar ratio 1 : 4 : 1.4, 112 h at −8 °C in CH_2Cl_2) gave the (*R*)-3-cyclohexenyl carboxylate **28** in 98% yield with ≥95.6% diastereofacial selection[20].

Acrylates Derived from 3-Alkylborneols and -isoborneols: Further readily crystallizable auxiliary alcohols **I** such as **29** and **30** carry a *tert*-butyl shielding group attached to the bornanol skeleton by a chain of two carbon atoms[21]. In the $TiCl_2(OiPr)_2$-induced addition of the acrylates of **29** (*cis-exo*) and **30** (*cis-endo*) to cyclopentadiene the topological bias provided by **30** is significantly higher than that of **29** (Table 4).



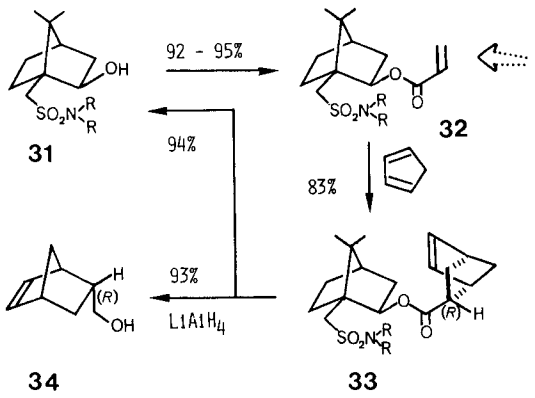
29 30

Table 4. Examples of the reaction of acrylates **II** derived from alcohols **I** (3-alkylisoborneols **29** and 3-alkylborneols **30**) with cyclopentadiene to give adducts **III** (for conditions, see text to Table 3).

Entry	I	Adduct III Yield [%]	*endo* [%]	C-5	d.e. [%]
1	**29**	75	89	*S*	66
2	**30**	89	92	*R*	94

3.2.2. *Acrylates Derived from Camphor-10-sulfonic Acid*

A new class of practical auxiliaries exploits the accessibility and crystalline nature of camphor-10-sulfonic acid derivatives.



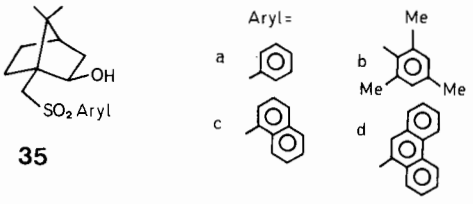
31 32 33 34

a, R = $CH(CH_3)_2$; **b**, R = cyclohexyl

Starting from (+)-camphor-10-sulfonyl chloride, successive amidation and reduction with L-Selectride[*] furnished the crystalline sulfonamides **31** in 57 to 68% overall yield. Their crystalline acrylates **32** undergo highly *endo*-selective $TiCl_2(OiPr)_2$-promoted additions to cyclopentadiene at −20 °C to give adducts **33** (97 to 98% yield) in 88 to 93% d.e.[22,23]. Intermediates and products were conveniently purified by crystallization which, for example, increased the diastereoisomeric purity of adduct **33a** from 88% to 99% d.e. The auxiliaries **31** were regenerated straightforwardly by reducing the adducts **33** with $LiAlH_4$ and subsequent separation from alcohol **34** by direct crystallization.

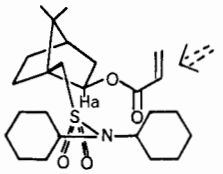
Similarly, a series of aryl sulfones **35** were readily prepared in three steps from camphor-10-sulfonic acid. Their usefulness as control groups in acrylate/cyclopentadiene

[*] L-Selectride = lithium tri-*sec*-butyl hydridoborate.

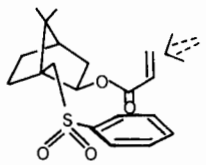


35

cycloadditions suffers from inferior π-face stereodifferentiation (64 to 69% d.e.) which outweighs other practical advantages[22,24].



32 b

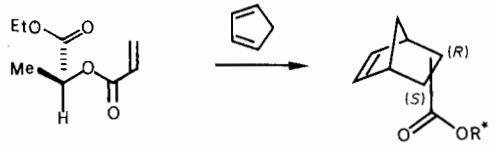


36

The superior topological differentiation of the sulfonamide-shielded acrylate **32b** is consistent with the results of an X-ray diffraction study[23]. In the crystal the uncomplexed acrylate adopts a strictly antiplanar arrangement of the $C_\alpha{=}C_\beta$ and C=O bonds, the latter of which lies ca. 30° out of the $C{-}H_a$ plane. As a result of sulfonamide conjugation, the nitrogen is planar, projecting the surface of one cyclohexane ring firmly on top of the olefinic bond. X-ray crystal structure analysis of the phenyl sulfone **36** indicates an almost identical acrylate conformation but less distinct shielding of its C_α-*re*-face, which is perpendicular to the sulfone-conjugated aryl group[24].

3.2.3. (S)-Ethyl-O-acryloyl Lactate

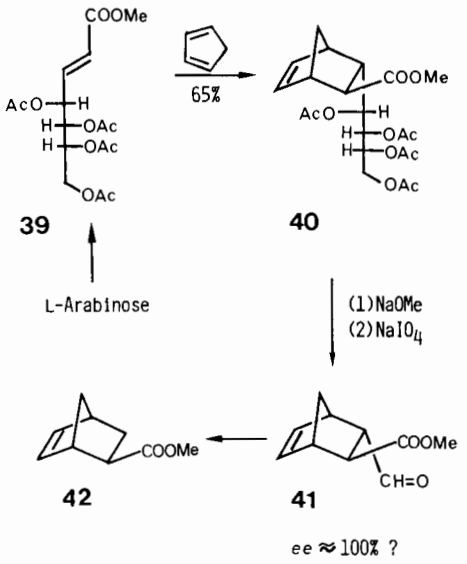
Interestingly, addition of the acrylate of (*S*)-ethyl lactate **37** to cyclopentadiene was reported to proceed with 86% C_α-*re*-face selection in the presence of $TiCl_4$, whereas the topicity was inverted (although to the extent of only 32% d.e.) by using $BF_3{\cdot}OEt_2$[25]. The (5*S*)-adduct **38** was purified by medium-pressure chromatography and saponified with retention of configuration.



37 38

3.2.4. α,β-Enoates with Chiral β-Substituents

High diastereotopic face differentiation has been claimed for the thermal (110°C!) addition of the enoate **39** derived from L-arabinose to cyclopentadiene, which after crystallization gave adduct **40** in 65% yield[26]. However, the composition of the mother liquor was not reported. Destructive cleavage of the sugar template gave aldehyde **41**, which was converted into ester **42**. The confusing chiroptic comparison of the rotation of **42** ($[\alpha]_D$ −10°, $CHCl_3$)

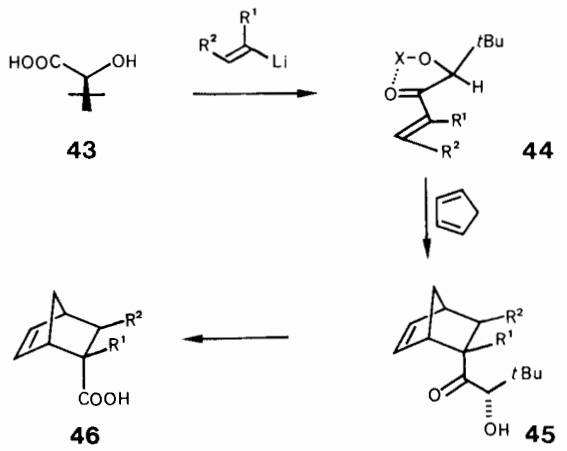


39 40 42 41

with a value published for enantiomerically impure **42** (e.e. ~25%) ($[\alpha]_D^{25}$ −10.2°, 95% EtOH, $c = 1.8$[27]) together with the lack of reliable HPLC or GC data suggests that this work should be evaluated with caution.

3.3. α,β-Unsaturated Ketones

A series of interesting features distinguishes conjugated α-hydroxy ketones **44** (X = H) and their enantiomers as chiral dienophiles[28,29]. Their preparation involves separation of acid **43** from its enantiomer followed by successive



43 44 46 45

Table 5. Examples for the reaction of α,β-unsaturated ketones **44** with cyclopentadiene to give adducts **45**; "*endo*" refers to the C=O group.

Entry	R^1	R^2	"Catalyst"	T [°C]	t [h]	Yield [%]	**45** *endo* [%]	d.e. [%]
1 **a**	H	H	—	−20	24	90	89	99
2 **a**	H	H	$ZnCl_2$	−43	1	95	94	>99
3 **b**	H	Me	—	+20	72	84	83	97
4 **b**	H	Me	$ZnCl_2$	−20	16	90	94	99

treatment with *n*BuLi and the appropriate vinyllithium reagent (molar ratio 1:2:1.5). Addition of cyclopentadiene occurs readily at −20°C even in the absence of a Lewis

acid (Table 5, entry 1) to give adduct **45a** with 99% diastereotopic π-face differentiation. This high selectivity undoubtedly derives from hydrogen bonding which locates the chiral center within a rigid five-membered ring. The bulky *tert*-butyl group enforces the C=O/C=C *syn*-conformation and directs the diene to the opposite enone face. The unusually high reaction rate can also be assigned to the hydrogen bond. In the presence of $ZnCl_2$, $BF_3 \cdot OEt_2$, or $Ti(OiPr)_4$, Diels-Alder additions to **44** proceed at even lower temperatures with improved *endo*- and π-face selectivities (entries 3, 4). Apparently, the dienophile system becomes more conformationally rigid and "activated" by chelation (**44**, X = metal), permitting efficient asymmetric Diels-Alder additions of less reactive dienophiles (entries 4, 5) and of various acyclic dienes (see Sections 7.6 and 7.7). However, the inevitable destruction of the valuable chiral auxiliary on oxidative removal (**45** → **46**) (successive reaction with iBu_2AlH, $NaIO_4$, Jones reagent) is an obvious shortcoming.

3.4. *N*-Acryloyl and *N*-Crotonyl Compounds

3.4.1. N-Acyloxazolidones

As an extension of elegant applications of chiral *N*-acryloyloxazolidones to asymmetric aldolizations and enolate alkylations[30], Diels-Alder reactions of the unsaturated secondary amides **47** and **49** were examined[31].

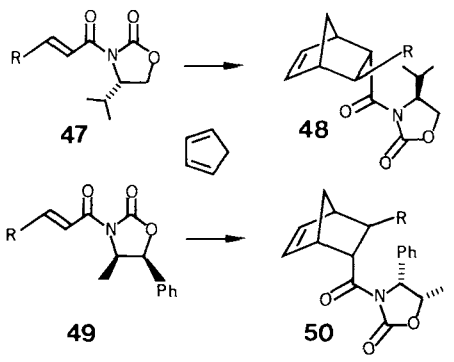

Table 6. Examples for the reaction of *N*-acyloxazolidones **47** and **49** with cyclopentadiene to give adducts **48** and **50**, respectively, in the presence of Et_2AlCl (1.4 mol per mol educt, −100 °C, 2 min). "*endo*" refers to the C=O group.

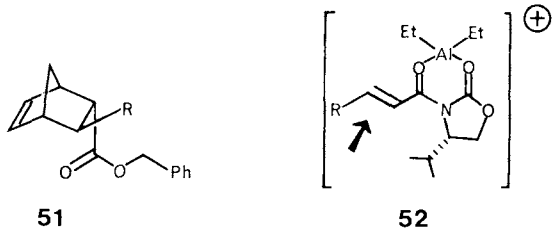
Entry	Educt	R	Adduct	Yield [%] [a]	*endo* [%]	d.e. [%] [b]	d.e. [%] [a]
1	**47**	H	**48**	81	>99	86	>98
2	**47**	Me	**48**	82	98	90	>98
3	**49**	H	**50**	82	99	90	>98
4	**49**	Me	**50**	88	98	96	>98

[a] Purified. [b] Crude.

Comparative studies of several Lewis acids revealed the essential advantage of using more than 1 equivalent of Et_2AlCl. Thus, Et_2AlCl-induced (1.4 equivalent) additions of the valinol derivatives **47** to cyclopentadiene were complete within 2 min at −100 °C and gave norbornenes **48** with 98 to 99% *endo*-selection and with 86 to 90% diastereofacial differentiation[31]. Inverse π-face topicity was displayed with similar efficacy by the norephedrine-derived dienophiles **49**. After recrystallization or chromatography, the resulting cycloadducts **48** and **50** were obtained in 81 to 88% yield and ≥98% d.e. Nondestructive cleavage of the oxazolidine auxiliaries from the adducts **48** and **50** by "transesterification" with lithium benzyloxide furnished the benzyl esters **51** or their enantiomers. The influence



exerted by Et_2AlCl on the Diels-Alder additions of dienophiles **47** is most plausibly ascribed to the intermediacy of the bidentate complex **52** which exhibits C=C/C=O-*syn*-planarity. The electron deficiency and rigid structure of **52** account for the high reactivity and good π-face differentiation. Even less reactive acyclic dienes add smoothly to such chelated dienophiles at temperatures ≤ −30 °C (6 h); interestingly, in this case the (*S*)-benzyl derivatives **53** (Table 7) displayed much higher diastereoselectivity than the isopropyl derivatives **47**.

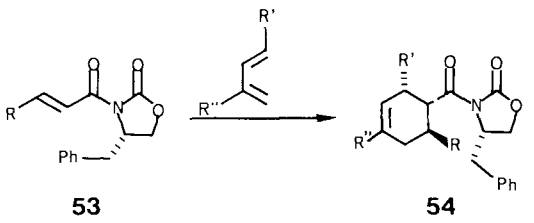


Table 7. Examples for the reaction of the *N*-acryloyloxazolidones **53** with butadienes in the presence of Et_2AlCl (1.4 mol per mol **53**, −100 to −30 °C) to give the adducts **54**.

4	Me	Me	H	77	90	>98

[a] Purified. [b] Crude.

3.4.2. N-Acylsultams Derived from Camphor

Exceptional dienophile "activation" coupled with the practical advantages of camphor-10-sulfonamides distinguish the sultam auxiliary **55**[32]. The highly crystalline sultam is available in two to three convenient synthetic operations from camphor-10-sulfonyl chloride in 76% overall yield. Efficient *N*-acylation furnished the crystalline, stable *N*-acryloyl and *N*-crotonyl derivatives **56** and **57**. $EtAlCl_2$-promoted Diels-Alder addition of butadiene to **56** proceeded readily at −78 °C to give the (5*S*)-adduct **58** in 93% yield with 97% π-face selection (Table 8, entry 1). In the presence of $EtAlCl_2$ or $TiCl_4$, cyclopentadiene added

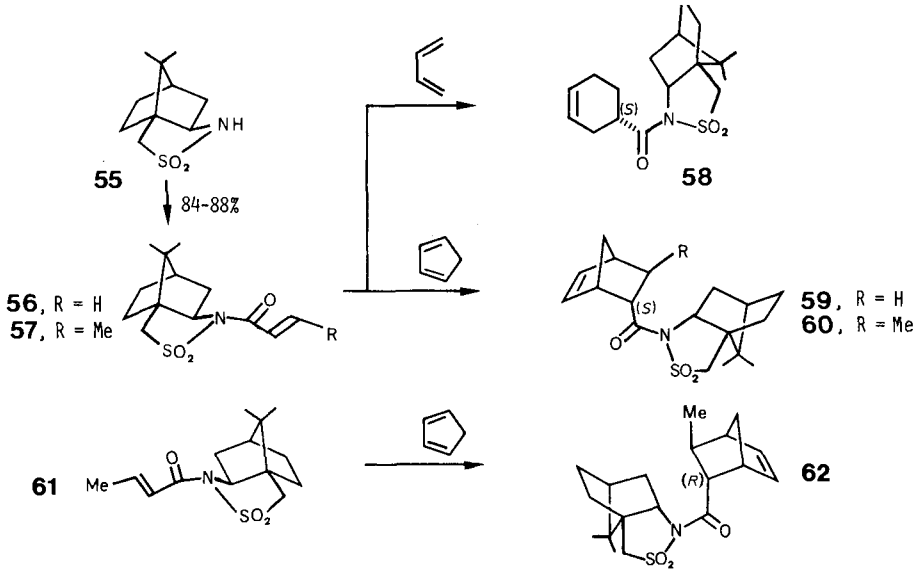

Table 8. Examples for the reaction of *N*-acryloylsultams **56**, **57** and **61** to give the adducts **58**–**60** and **62**; "*endo*" refers to the C=O group.

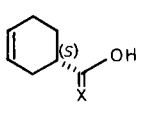
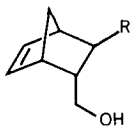
Entry	Educt	Conditions [a]	Adduct	Yield [%] [b]	*endo* [%]	d.e. [%] [c]	d.e. [%] [d]
1	**56**	A	**58**	81	—	97	99
2	**56**	B	**59**	84	99.5	95	99
3	**57**	C	**60**	83	99	93	99
4	**57**	A	**60**	—	96	98	—
5	**61**	A	**62**	—	98	94	—

[a] A: $EtAlCl_2$ (1.5 mol per mol educt), CH_2Cl_2, −78°C, 18 h. B: $EtAlCl_2$ (1.5 mol per mol educt), EtCl, −130°C, 6 h. C: $TiCl_4$ (0.5 mol per mol educt), CH_2Cl_2, −78°C, 1 h. [b] Recrystallized adducts, yields relative to dienophile. [c] Crude. [d] Recrystallized adducts, ≈ 100% *endo*.

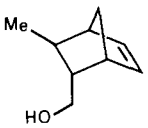
smoothly to **56** even at −130°C and to the less reactive **57** at −78°C (entries 2, 3, 4). Under these conditions, 96–99.5% *endo* and 93–98% π-face selectivities were achieved. Moreover, each of the butadiene and cyclopentadiene adducts (**58**, **59**, **60**) was obtained virtually pure in 82 to 84% yield after simple recrystallization. The sense of asymmetric induction could be easily reversed (**61** → **62**, entry 5) by exploiting the ready availability of (−)-camphor.



63, X = H_2
67, X = O

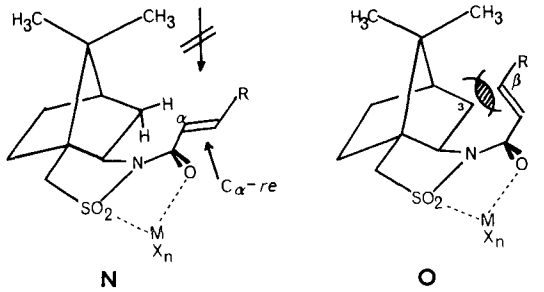


64, R = H
65, R = Me



66

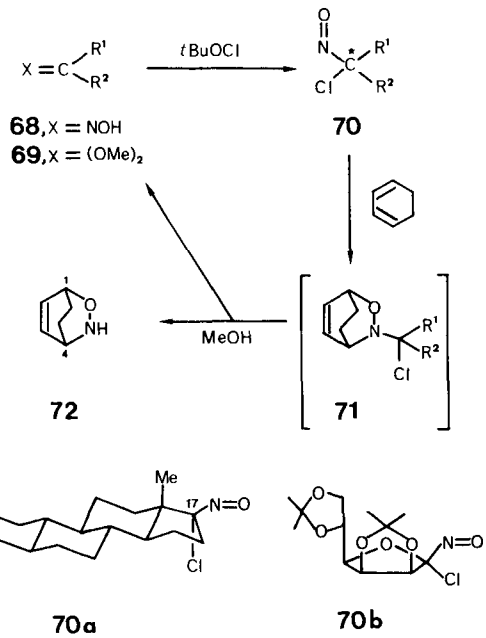
Reduction of the cycloadducts **58**—**60** with $LiAlH_4$ refurnished the sultam **55** (or its enantiomer from **62**) in 89—95% yield after crystallization and gave the pure alcohols **63** to **66** in 89—95% yield on subsequent kugelrohr distillation. Alternatively, saponification of adduct **58** with LiOH gave the acid **67** *without* epimerization. It appears that the remarkable Diels-Alder reactivity of the otherwise stable *N*-acylsultams **56** and **57** is based on chelation of the SO_2 and C=O groups. The postulated chelate would be locked into conformation **N** (**O** then being excluded), which directs the diene to the less hindered bottom face (C_α-*re*).



N **O**

3.5. α-Chloronitroso Dienophiles

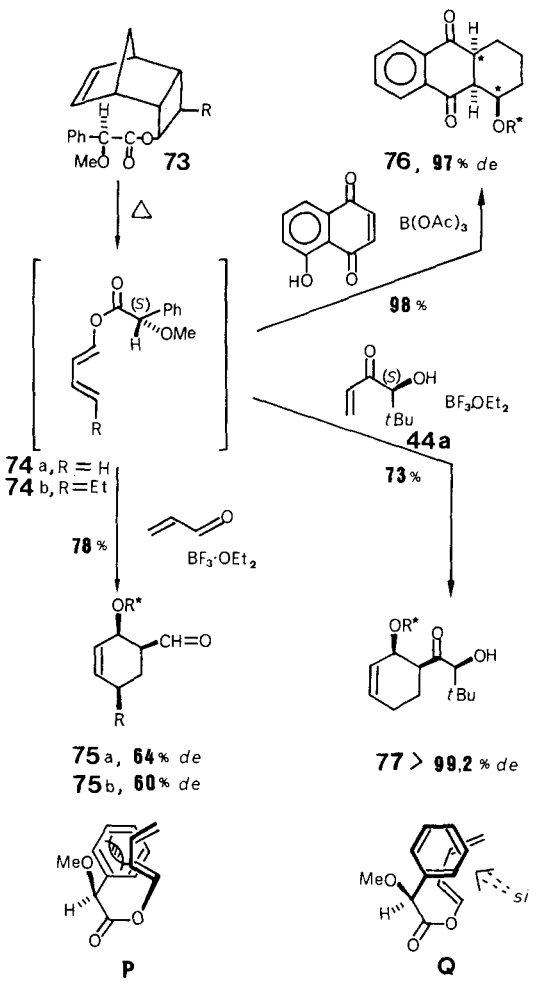
An original approach to the enantiomerically pure oxazine derivatives **72** (>95% e.e.) involves hetero Diels-



Alder additions of 1,3-cyclohexadiene to chloronitroso compounds **70**, readily prepared from oximes **68**. Methanolysis of the non-isolated adducts **71** in situ furnished acetals **69** and oxazines **72**. Thus, (1*R*,4*S*)-**72** was obtained from the steroid derivative **70a** (with 72% regeneration of the C-17 ketone)[33]; the chloronitroso ether **70b** derived from mannonolactone reacted considerably faster with cyclohexadiene to give (after removal of the inexpensive auxiliary reagent) (1*S*,4*R*)-**72**[34].

4. Chiral Dienes

Asymmetric Diels-Alder reactions of dienes substituted with a removable chiral moiety to prochiral dienophiles have been less extensively studied. Thermal additions of 1,3-dienol ethers derived from sugars suffer from low *endo*-selectivity[35]. So far, disappointing inductions have been achieved in Diels-Alder reactions accelerated by high pressure, as exemplified by the additions of chiral 2,4-pentadienoates to *p*-benzoquinone; at 15 kbar the expected adducts were obtained in 58—98% yield, but in humble (2—50% d.e.) stereofacial selectivity[36]. The general advantage of Lewis-acid coordination is again illustrated by the [4+2]-addition of the dienes **74** derived from (*S*)-*O*-methylmandelic acid (readily accessible from **73**) to acrolein in the presence of $BF_3 \cdot OEt_2$ (0.15 mol per mol **74**, toluene, −20°C, 48 h) which gave adducts **75** in 98% yield with 60 to 64% diastereofacial differentiation[37].



Virtually complete asymmetric induction was observed on addition of **74a** to juglone [$B(OAc)_3$ 1.6 mol per mol **74a**, $CHCl_3$, 0→20°C], giving **76** in 98% yield and >97% d.e. These findings have been rationalized in terms of a binding diene/aryl π-orbital overlap. In this π-stacking model, methoxy/diene repulsion disfavors conformer **P** over conformer **Q**, which undergoes preferential dienophile addition opposite to the phenyl-shielded diene-face. The destruction of the chiral auxiliary on hydrogenolysis constitutes a practical disadvantage.

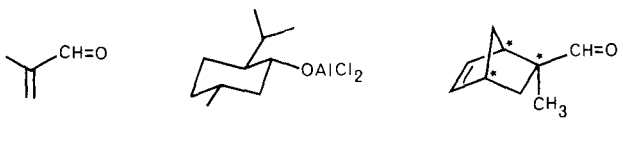
The cooperative effect of chiral auxiliaries at the diene *and* dienophile units is exemplified by the double diastereoface selective addition **74a** + **44a** → **77** (99% d.e.). On analogous addition of the enantiomer of **74a** to **44a**, the dienophile face-directing efficiency exceeds that of the diene, leading to the adduct **77** (R* = (*R*)-*O*-methylmandeloyl) in 94% d.e.[29].

5. Chiral Catalysts

At first sight, the use of a chiral catalyst appears to be the potentially most attractive method to achieve asymmetric Diels-Alder reactions of prochiral dienes and dienophiles. Compared to the stoichiometric use of a covalently attached prosthetic group, two synthetic steps would be avoided.

5.1. Chiral Alkyloxy-Substituted Lewis Acids

The addition of cyclopentadiene to methacrolein **78** → **80** catalyzed by (−)-menthyloxyaluminum dichloride **79** is so far the *only* reported example that affords greater than 60% asymmetric induction[38]. Although when we attempted to reproduce this work, we obtained no more than 55% enantiomerically pure adduct **80**, other [4+2]-cycloadditions of cyclopentadiene to diverse dienophiles using various chiral Lewis acids were far less π-face selective[39].



78 **79** **80**

5.2. Interaction between Chiral Catalyst and Chiral Diene Auxiliary Reagent

Traces (0.5 to 5 mol%) of soluble europium complexes catalyze hetero Diels-Alder reactions of silyloxydienes to arylaldehydes. Thus, dienes **81** reacted smoothly with benzaldehyde at room temperature in a highly *endo*-selective manner to give exclusively *cis*-substituted dihydropyrans **82**, which on acid-promoted elimination furnished dihydropyrones **83** in good overall yield. Using $Eu(hfc)_3$ as a chiral catalyst (Table 9), (*R*)-**83** was obtained from the prochiral diene **81a** in only moderate e.e. (42%), but in an impressive 86% e.e. from the chiral diene **81b**[40]. Interestingly, the interactivity of diene auxiliary reagent and catalyst

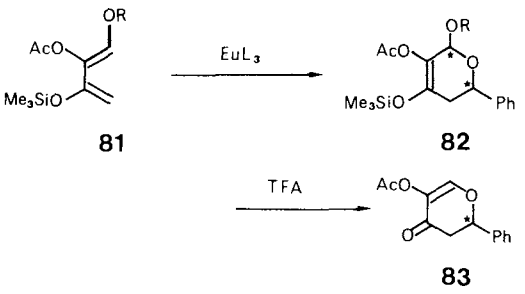


Table 9. Examples for the reaction of siloxydienes **81** with benzaldehyde to give adducts **83** in the presence of europium compounds.

4	**b**	(3*R*)-menthyl	$Eu(fod)_3$	*S*	10

is maximal when the individual π-facial biases are of opposite sense (entries 1—4).

6. Intramolecular Diels-Alder Reactions

Because of their high regio- and diastereoselectivity[41], intramolecular cycloadditions have been widely used for the efficient synthesis of numerous cyclic molecules. Absolute configurational control by means of removable chiral auxiliaries is, however, at a comparatively early stage.

6.1. Chiral Dienophile Auxiliary Groups

Not surprisingly, concepts developed successfully for bimolecular asymmetric Diels-Alder reactions have been applied to intramolecular versions such as the transformations **84** → **85** and **84** → **86**. Dienophile π-face shielding by the 8-phenylmenthyl moiety proved to be less efficient (Table 10, entries 1, 2)[42] than that by the *N*-oxazolidone groups (entries 3—6)[43]. Moreover, the secondary amides **84c** to **84f** cyclized with superior *endo*-selectivity, and products **85** or **86** were obtained in good yields and >99% d.e. after chromatography.

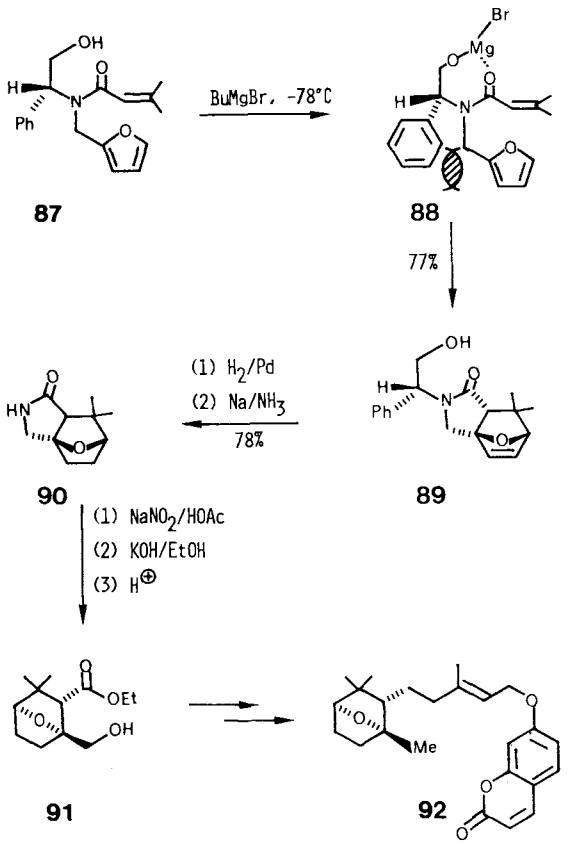
[a] A: [(−)-bornyloxy]$AlCl_2$ (1.6 mol per mol **84**), 8°C, 336 h; B: [(−)-bornyloxy]$AlCl_2$ (1.8 mol per mol **84**), 23°C, 92 h; C: Me_2AlCl (1.4 mol per mol **84**), −30°C, 5 h. [b] Overall yield **85** + **86**. [c] Yield of >99% diastereomerically pure major product.

6.2. Chiral Auxiliary Reagents as Part of the Bridge

An interesting example is the thermal cycloaddition of magnesium salt **88** to give adduct **89** in 76% d.e.[44]. In contrast, analogous addition of free **87** proceeded slower and without π-face selectivity. It thus appears that chelation of the dienophile carbonyl group with the bridge-residing control moiety accelerates the rate of addition and provides the essential conformational rigidity of **88**. Repulsion between the α-furyl methylene group and the phenyl ring is minimized in the transition state which leads to **89**.



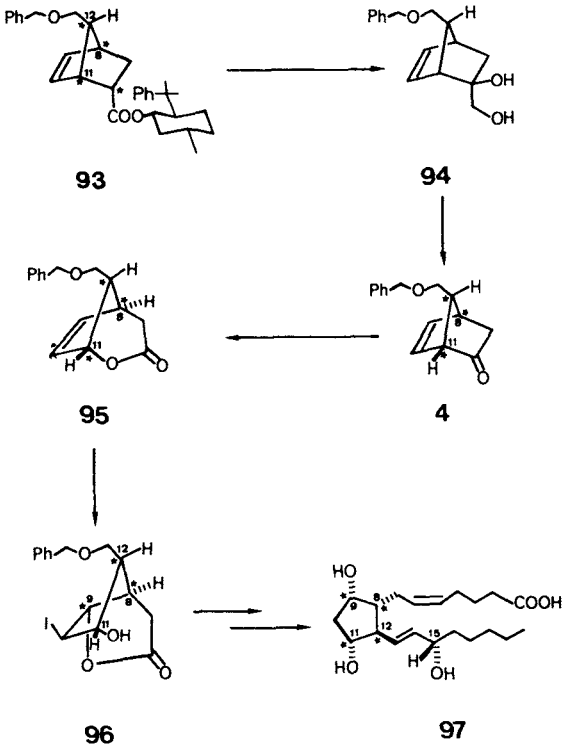
After hydrogenation of the olefinic bond in **89**, the chiral auxiliary reagent was destructively cleaved by reduction to give lactam **90**, which was converted into **92**, the enantiomer of naturally occurring farnesiferol-C.

7. Applications in Organic Synthesis

Natural product synthesis has often led to important methodological advances by provoking either the discovery of new methods or the rigorous testing and refining of existing ones. This holds also for the asymmetric Diels-Alder reaction as outlined below.

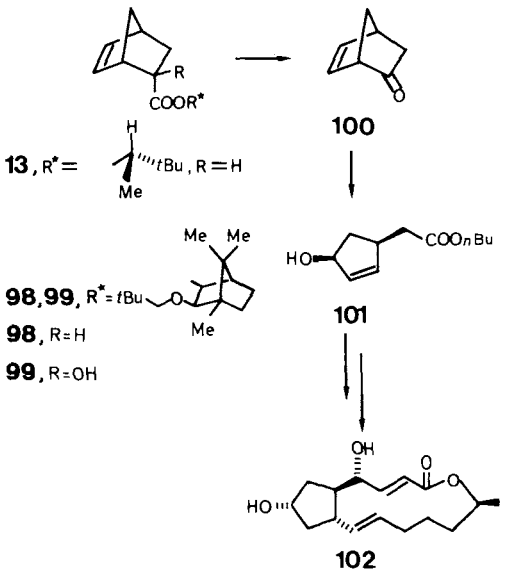
7.1. Prostaglandins

In the course of attempts to synthesize the enantiomerically pure prostaglandin **97** the 8-phenylmenthyl auxiliary reagent has been developed. Thus, the addition **1b** + **2b** → (1*S*)-**3b** ≡ **93** (Section 2) simultaneously generated three enantiomerically enriched centers which correspond to the carbon atoms C-8, C-11, and C-12 of the prostaglandin target molecule. The correct oxidation state of C-11 was then established by Baeyer-Villiger oxidation **94** → **95**, and the center C-9 was induced by center C-8 during the transformation **95** → **96**. Crystallization provided enantiomerically pure **96**[4], which was converted into **97** by established procedures.



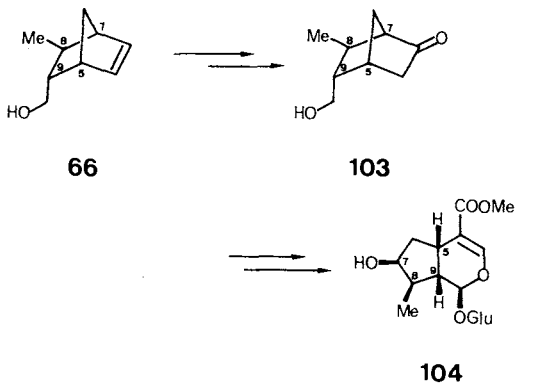
7.2. (+)-Brefeldin-A

One synthesis of (+)-brefeldin-A **102** started from the diastereomerically enriched cycloadduct **13**[16]. Degradation of this furnished norbornenone **100** (80–85% e.e.), which was transformed into crude **102**. The final product was purified by HPLC and crystallization to afford ca. 100% e.e. Alternatively, the cycloadduct **98** gave on hydroxylation and crystallization diastereomerically pure **99**, which on degradation refurnished the auxiliary reagent (88%) and afforded **100** in >99% e.e.[45].



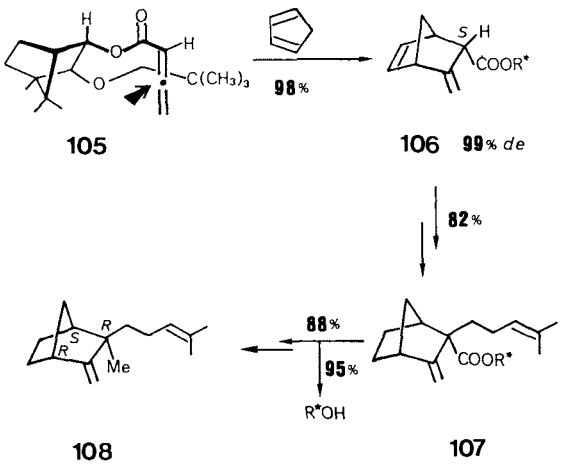
7.3. Loganin

The synthetic potential of enantiomerically pure cyclopentadiene-Diels-Alder adducts is further exemplified by the synthesis of (±)-loganin **104** from (±)-**66**[46]. Accordingly, the asymmetric [4+2]-additions **47** → **48**[31] and **61** → **62**[32] generate the correct relative and absolute configuration of the centers C-5, C-7, C-8, and C-9 of the loganin precursor **66**.



7.4. (−)-β-Santalene

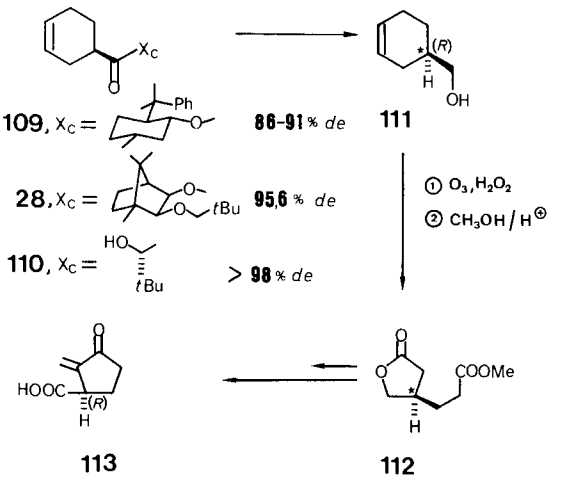
A synthesis of the sandalwood constituent (−)-β-santalene **108** (ca. 100% e.e.)[47] relies on the $TiCl_2(OiPr)_2$-pro-



moted cycloaddition of the chiral allenic ester **105** to cyclopentadiene (−20 °C, 6 h) which gave adduct **106** in 98% yield with 98% *endo*-selectively and 99% d.e. Subsequently, **106** was transformed into **108** following a protocol previously reported for the synthesis of racemic β-santalene[48]. Notably, approximately 100% diastereomerically pure intermediate **107** was obtained after crystallization in 82% yield (from crude **106**).

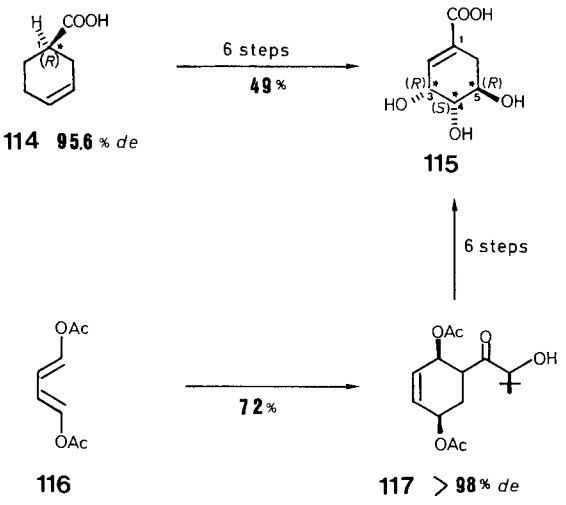
7.5. (−)-Sarkomycin

For a possible synthesis of (*R*)-(−)-sarkomycin **113**[49] the butadiene cycloadducts **109**[49], **28**[20], and **110**[29] furnish the (*R*)-precursor **111** in high e.e.



7.6. (−)-Shikimic Acid

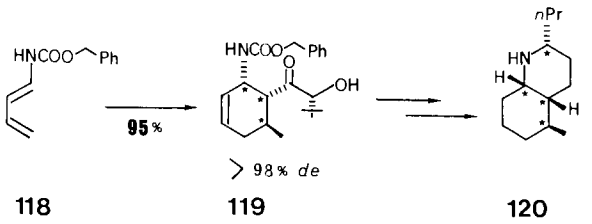
The (*R*)-carboxylic acid **114**, accessible from adduct **28** in 83% yield by reduction with $LiAlH_4$ and subsequent oxidation of **111** with Jones reagent[20], is a potential precursor of (−)-shikimic acid **115**[50]. Another route to (−)-**115**



involves $BF_3 \cdot OEt_2$-promoted [4+2]-addition of diene **116** to **44a**, $X = R^1 = R^2 = H$ (−43 °C, 5 h) giving **117** in 98% d.e.[29].

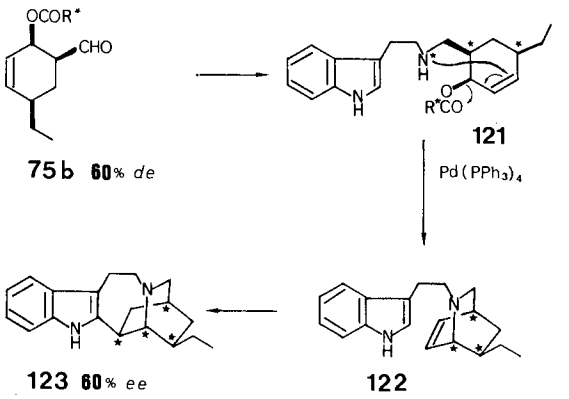
7.7. (+)-Pumiliotoxin-C

Addition of diene **118** to the enantiomer of **44b**, $X = R^1 = H$, $R^2 = Me$, ($BF_3 \cdot OEt_2$, toluene, −78 °C, 0.5 h) afforded adduct **119** (>98% d.e.), which was transformed into the pure enantiomer **120** of naturally occurring (−)-pumiliotoxin-C[29].



7.8. (+)-Ibogamine

The goal of synthesizing (+)-ibogamine **123** has initiated the study of asymmetric Diels-Alder additions of chiral dienes[51]. Adduct **75b** (60% d.e.) gave on reductive



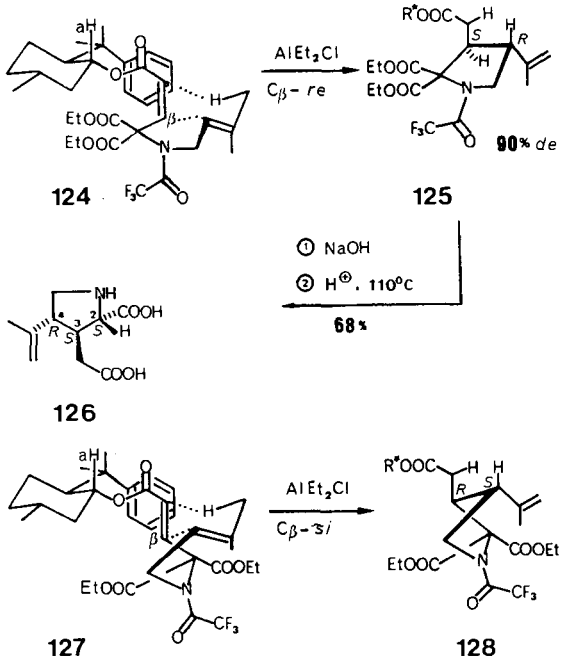
amination with tryptophan the secondary amine **121**. Subsequent Pd^0-catalyzed allylic displacement of the *O*-methylmandeloyl auxiliary yielded quinuclidine **122**, which was cyclized to give enantiomerically enriched **123**.

8. Asymmetric Ene-Reactions

The mechanistic similarity between the Diels-Alder cycloaddition and the ene-process[52] leads one to expect the applicability of analogous π-face differentiation concepts.

8.1. Synthesis of (+)-α-Allokainic Acid

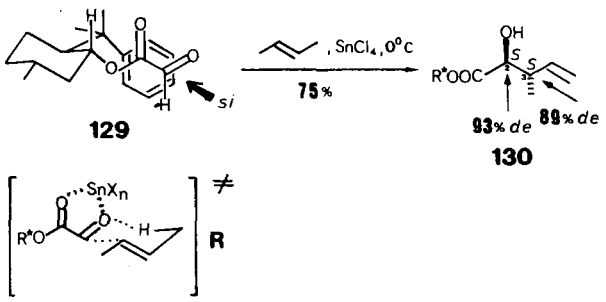
In accord with this postulate, the total synthesis of (+)-α-allokainic acid **126** features an Me_2AlCl-mediated, intramolecular ene-reaction **124** → **125** which controls the relative (100%) and the absolute (90% d.e.) configuration of the developing centers at C-3 and C-4[53]. Subsequent saponification, decarboxylation, and crystallization yielded the pure natural product **126** (ca. 100% e.e.) and refurnished the auxiliary reagent (−)-8-phenylmenthol. The strong enophile face-directing influence of the control group has been explained by an antiplanar $C_\alpha = C_\beta / C = O$



and a synperiplanar C=O/C–H_a enoate conformation where the phenyl ring shields the C_β-*si*-face. Evidence provided by ^{1}H-NMR spectroscopy indicates that this shielding occurs even in the absence of the Lewis acid. Coordination with R_2AlCl, however, was found to be essential for the high reaction rate as well as for the diastereofacial- and *exo*-selectivity. As expected, the sense of asymmetric induction could be reversed (78% d.e.) by using the same control group but changing the enoate geometry (**127** → **128**) which led to pure (−)-α-allokainic acid. The topological considerations and practical problems encountered here prompted the careful reinvestigation of the phenylmenthyl-directed Diels-Alder reaction[11], which has stimulated the discovery of more practical and efficient chiral auxiliaries[18,22,23,32].

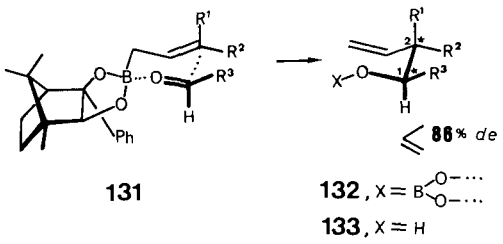
8.2. Chiral Glyoxalates

Similar enophile facial selection occurs in the $SnCl_4$-promoted addition of *trans*-2-butene to phenylmenthyl glyoxalate **129** → **130**[54]. The excellent control over the (2*S*)-configuration in **130** was attributed to a selective *re*-face shielding of the aldehyde C=O bond which is *syn* to that of the ester carbonyl. This *syn*-relation might result from chelation as depicted in transition state **R**. The preferred *exo*-mode of addition governs the relative configuration C-2/C-3 in **130**.



8.3. Additions of Allylboronates to Aldehydes

Another asymmetric ene-type process, the addition of allylboronates to aldehydes (**131** → **132**)[55] involves the transfer of boron from carbon to oxygen and thus represents a version of the "metallo-ene reaction"[20]. The chiral auxiliary is attached to the boron atom and regenerated from the adduct **132** by B/O-cleavage with nitrilotriethanol, which also affords the free homoallylic alcohols **133**.



This first use of a camphor glycol as a chirality directing group provides ene-face differentiations (C-1) of between 52 and 89% d.e. The preferred "*exo*"-mode of addition controls the relative topicity C-1/C-2 (86—94%).

8.4. Addendum

A crystal structure analysis of the 1 : 1 complex of ethyl (*S*)-acryloyllactate **37** with $TiCl_4$ indicates chelation of both ester carbonyl oxygen atoms by titanium and a synplanar C=O/C_α=C_β conformation. The selective blocking of the C_α-*re*-face is consistent with the results observed for the $TiCl_4$-assisted addition **37** → (5*R*)-**38** (Section 3.2.3). In the presence of $BF_3 \cdot OEt_2$ or $EtAlCl_2$ the addition **37** → (5*S*)-**38** (≤ 56% d.e.) proceeds with the opposite topology and is in accord with a reactive conformation **D** (Section 3.1)[56].

9. Conclusions and Outlook

The asymmetric Diels-Alder reaction is a powerful tool for the synthesis of enantiomerically pure, complex molecules. Regenerable chiral dienophile auxiliaries in combination with a Lewis acid provide a number of advantages such as conformational rigidity, acceleration in rate, improved *endo*-selectivity, and ease of purification by chromatography or crystallization. The capacity of chiral auxiliaries to override the influence of pre-existing chiral centers in the substrate(s) simplifies stereorational design in synthesis. The relatively unexplored areas of diene auxiliaries and intramolecular versions are certain to receive more attention. Progress in the development of chiral catalysts may be spurred on either by new structural information on coordinated dienophiles and dienes or by purely empirical discoveries. The still modest performance of the high-pressure methodology might benefit from technological advances. The potential of the same π-face differentiating principles in absolute acyclic stereoselection, as exemplified here by the ene process, applies also to other classes of reaction.

It is clear that the field covered by this review has entered the stage of practical use in organic synthesis which will put its scope and limits to the test in the near future.

It is a privilege to acknowledge the contributions of my very able collaborators. Their names are cited in the appropriate references. Donor-Substituted Thiocarbonyl Functions as Heterodienophiles in [4+2]-Cycloadditions with Inverse Electron Demand**

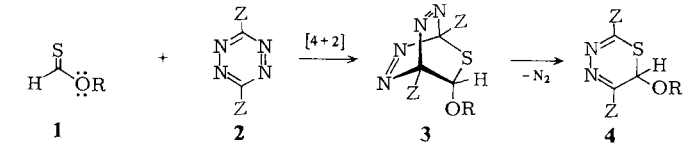
By *Gunther Seitz**, *Rolf Mohr*, *Wolfgang Overheu*, *Rudolf Allmann*, and *Michael Nagel*

Because of their extraordinary reactivity in both bimolecular[1-3] and intramolecular[2] [4+2]-cycloadditions, thiocarbonyl dienophiles have been the subject of wide interest in recent years. This synthesis, which for substituted thiopyran systems proceeds under extremely mild conditions, was nevertheless essentially limited to reactions of electron-rich dienes with acceptor-substituted thiocarbonyl dienophiles[1].

Our results now show, for the first time, that thiocarbonyl compounds also function as excellent heterodienophiles in Diels-Alder cycloadditions with inverse electron demand[4], provided the donor groups are sufficiently activated. Thiocarbonyl compounds react smoothly with the *s-cis*-fixed azine system in the tetrazines **2**, which because of the trifluoromethyl or ester groups are extremely electron



1 **2** **3** **4**

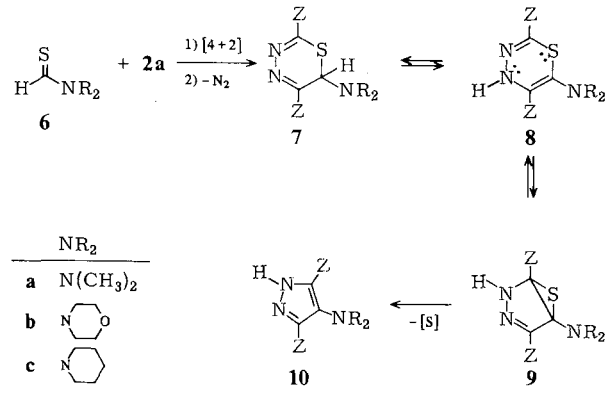
deficient, to afford the novel 6*H*-1,3,4-thiadiazines **4**, **5**, **7**, and **15**. Depending on the substitution pattern, the products can fragment more or less easily to pyrazoles and sulfur[5].

In the first step of the reaction, e.g. of the thioformate esters **1** with the tetrazines **2**, the electron-rich thiocarbonyl function adds to the acceptor-substituted diazadiene system via [4+2]-cycloaddition. The non-isolable bicyclic Diels-Alder adduct **3** is formed, whose considerable ring strain facilitates rapid elimination of nitrogen via a [4+2]-cycloreversion[6] in a fast follow-up reaction. The chiral, lemon-yellow 6*H*-1,3,4-thiadiazines **4** and **5**, which are, respectively, liquids distillable in vacuo and crystalline compounds, are thereby produced in 50—70% yield[7].

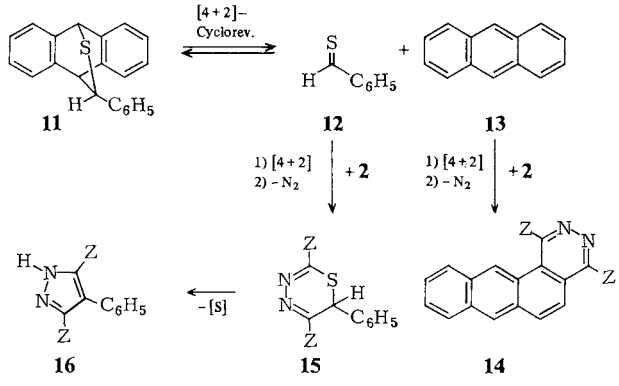


6 **7** **8**

a $N(CH_3)_2$
b
c

10 **9**

With the thioformamides **6** as heterodienophiles, the pharmacologically interesting 4-aminopyrazoles **10** are isolated as the sole products of the reaction[7]. The results of a preliminary crystal structure analysis[8] of the compound obtained from **6a** and **2a** are consistent with the constitution **10a**. 6*H*-1,3,4-Thiadiazines of type **7** may primarily be formed as intermediates which exist in equilibrium with the higher energy 4*H*-tautomers **8**. As cyclic 8π systems, these undergo valence isomerization to the bicycles **9**; subsequent elimination of sulfur leads to the pyrazoles **10** in ca. 20% yield[9].



11 **12** **13**

16 **15** **14**

Thioaldehydes can also undergo "inverse" [4+2]-cycloadditions with **2**. As we discovered, the thiobenzaldehyde **12**, generated in a retro Diels-Alder reaction from the adduct **11**[2], can be trapped by **2**. By analogy to the reaction sequence **7**→**10**, a ring contraction of the 6*H*-1,3,4-thiadiazines **15** to the 4-phenylpyrazoles **16** occurs. The structure of **16b** is based on independent synthesis ([3+2]-cycloaddition of methyl diazoacetate to methyl phenylpropiolate)[10]. Interestingly, the tetrazines **2** react under the necessarily drastic conditions of the [4+2]-cycloreversion of **11** also with anthracene **13** to give naphthophthalazines **14**, and hence a total of three [4+2]-cycloadditions compete with each other in the reaction mixture. With **2a** as educt, predominantly **16a** is formed (63%, m.p. = 160°C; **14a**: 4%, m.p. = 210°C); with **2b**, **14b** is preferentially formed (31%, m.p. = 191°C; **16b**: 11%, m.p. = 151°C).

Procedure

2a, **b** (5 mmol) and **1a**, **b** (5 mmol) are dissolved in 30 mL anhydrous toluene and the mixture is heated until the red color of **2** disappears. The products **4** (yellow oils) are distilled in vacuo; the crystalline products **5** are purified by recrystallization from *n*-hexane/cyclohexane (1:1). In order to obtain **10a**–**c**, **2a** is allowed to react analogously with **6a**–**c** at room temperature in 30 mL CCl_4; after preparative thin-layer chromatography on silica gel (eluent benzene), the products are recrystallized from *n*-hexane.

Synthesis of a Stable Aminosilanol and a Lithium Aminosilanolate with Cubane Structure**

By *Onno Graalmann, Uwe Klingebiel*, William Clegg, Martin Haase,* and *George M. Sheldrick*

Although chloroalcohols of type $R_2C(Cl)OH$ and aminoalcohols of type $R_2C(NH_2)OH$ are, to our knowledge, unknown, we recently succeeded in preparing stable chlorosilanols[1] by reaction of silanediols with PCl_5 accompanied by formation of HCl and $POCl_3$, despite their existence being considered highly improbable because of easy loss of HCl[2]. We now report the synthesis of a stable aminosilanol **2**[3], which is formed in a simple reaction on treatment of di-*tert*-butylchlorosilanol **1**[1] with ammonia.

1 $tBu_2Si(Cl)OH \xrightarrow[-NH_4Cl]{+2NH_3} tBu_2Si(NH_2)OH$ **2**

A condensation involving inter- or intramolecular NH_3- or H_2O-cleavage was not observed. **2** reacts with butyllithium in the molar ratio 1:1 with formation of a lithium aminosilanolate **3**[4] and butane.

2 $\xrightarrow[-BuH]{+NuLi} tBu_2Si(NH_2)OLi$ **3**

A primary metalation of the amino group can, according to the ^{1}H-NMR spectrum, be ruled out. Because of the voluminous *tert*-butyl groups, **3** is not very sensitive to hydrolysis. According to its EI mass spectrum, **3** is tetrameric in the gas phase. In the ^{29}Si-NMR spectrum of **3** the resonance signal is, as expected, shifted upfield compared to the corresponding signal of **2**.

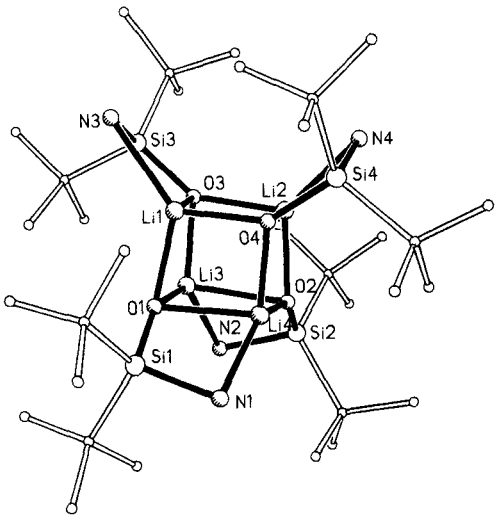

Fig. 1. Molecular structure of **3** in the crystal [8].

In the solid state, **3** is tetrameric and has a pseudo-cubane structure[5–8]. The distorted cubic cluster is made up of interpenetrating Li_4 and O_4 tetrahedra (bond lengths [pm]: Li–Li 255–262, O–O 291–312, Li–O 191–211; bond angles [°]: O–Li–O 93.6–101.5, Li–O–Li 78.6–85.6). Each Li atom achieves its usual fourfold coordination by the formation of a Li–N bond (220–230 pm) with the nitrogen of the aminosilanolate. The particularly long Si–N bonds (178–180 pm), the indicated positions of the hydrogen atoms on the nitrogen[8], and the upfield shift of the NH_2 resonances in the ^{1}H-NMR spectrum of **3** compared to those of **2** point to tetrahedral nitrogen coordination. The two sorts of *tert*-butyl groups found in the solid by a crystal structure investigation are equilibrated in solution. Temperature-dependent ^{1}H-NMR measurements down to −80°C in toluene showed only one resonance signal for the *tert*-butyl groups. It can therefore be concluded that no tetrameric structure is present in solution.

Thermospray Mass Spectrometry of Diquaternary Ammonium Salts**

By *Günter Schmelzeisen-Redeker, Ulrich Giessmann,* and *Franz-Wilhelm Röllgen**

Molecular weight determination and identification of diquaternary salts is hindered by difficulties in obtaining analytically useful mass spectra. Recent applications of secondary ion, fast atom-bombardment and laser desorption mass spectrometry to diquaternary ammonium salts have shown[1–4] that in these mass spectra intact dications are rarely observed, and then only in very low abundance. Dications are more frequently present in field desorption mass spectra[3,5,6] and their relative intensities are strongly dependent on the experimental conditions. In general, decomposition products of the dications dominate the spectra[7]. Dications of good intensity have so far only been observed in mass spectra obtained by electrohydrodynamic ionization[8]. In this method, solvated ions are extracted by high electric fields from liquids such as glycerol.

We report here the use of the new technique of thermospray (TSP) mass spectrometry[9,10] for the detection of intact dications from quaternary salts. In the TSP technique an electrolytic solution is sprayed into vacuum by passing the solution through a heated capillary, thus forming a jet of randomly charged droplets. Desolvation of ions is accomplished by heat transfer to the droplets. The TSP technique has been developed for on-line coupling of a mass spectrometer and a high-performance liquid chromatograph (HPLC). It is also possible to utilize a TSP/mass spectrometer system to obtain soft ionization spectra of unchromatographed samples that are thermally labile.

We have constructed a TSP system using a steel capillary of 80 μm i.d. One end of the capillary is heated to 250°C and connected to a jet chamber, which is maintained at 180°C, which, in turn, is linked via an orifice to a quadrupole mass analyzer (Finnigan 400, mass range 1–420). Aqueous solutions of the samples (2×10^{-4} mol L^{-1}) were introduced into the mass spectrometer via the heated capillary system. No further electrolyte was added.

The results of the TSP mass spectrometric studies of the diquaternary ammonium ions **1**–**6**[11] are displayed in Table 1. For all six compounds the $M^{2\oplus}$ dication forms the base peak of the mass spectrum. Additional information about the intact dication is provided by the $(M+1)^{\oplus}$ ion. Products arising from attachment of water to dications and other ions listed in Table 1 may also be present in the spectra; however, the intensities of these ions are generally weak (< 10%). Samples of 10 ng could readily be detected.

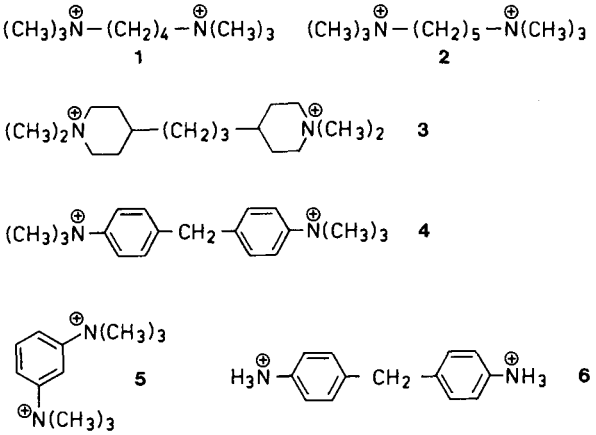

Table 1. Characteristic ions in the thermospray mass spectra of the diquaternary ammonium salts $\mathbf{1}2\mathbf{1}^{\ominus}$–$\mathbf{6}2\mathbf{1}^{\ominus}$ ($M^{2\oplus}2\mathbf{1}^{\ominus}$). $M^{2\oplus}$ is the base peak in all the spectra.

	Ions observed
1	$M^{2\oplus}$, $(M+1)^{\oplus}$ (m)
2	$M^{2\oplus}$, $(M+1)^{\oplus}$ (m)
3	$M^{2\oplus}$, $(M+1)^{\oplus}$ (w)
4	$M^{2\oplus}$, $(M-CH_3)^{\oplus}$ (m), $(M-2CH_3+H)^{\oplus}$ (w), $(M+1)^{\oplus}$ (w)
5	$M^{2\oplus}$, $(M-CH_3)^{\oplus}$ (m), $(M-2CH_3+H)^{\oplus}$ (m), $(M+1)^{\oplus}$ (w)
6	$M^{2\oplus}$, $(M-H)^{\oplus}$ (m), $(2M-3H)^{\oplus}$ (m)

m = intensity 10–50%, w = intensity < 10%.

Doubly charged ions have so far only been observed in TSP mass spectra of peptides of higher molecular weight[10]. The appearance of doubly charged ions has been taken as providing evidence for the participation of field effects in ion formation[10,12]. This assumption is supported by the close resemblance between the TSP spectra and the electrohydrodynamic ionization mass spectra[8] of the same diquaternary salts. However, it is surprising that in the electrohydrodynamic ionization spectrum of **5** the dication is absent. Thermospray mass spectrometry provides, so far without exception, abundant dications that are directly indicative of the molecular weight of diquaternary salts.

Elementary Steps in Catalytic 1-Alkyne Coupling to Substituted Cyclooctatetraenes**

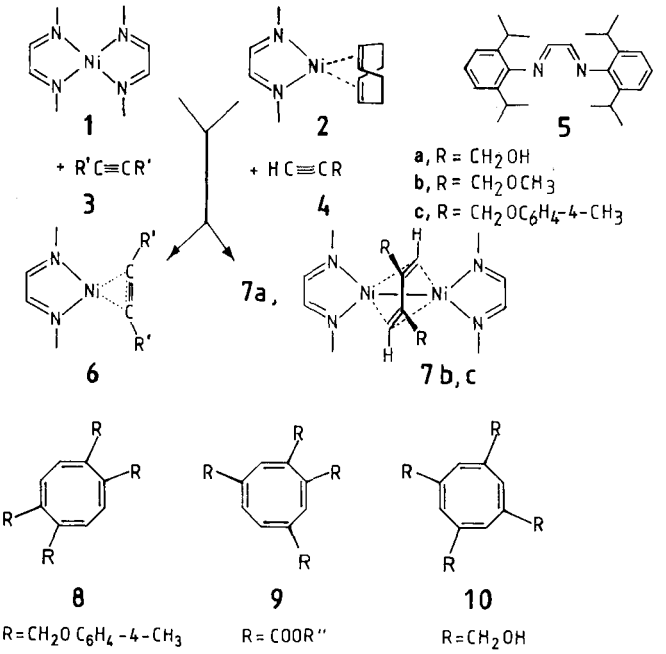
By *Rainer Diercks, Lutz Stamp, Jürgen Kopf*, and *Heindirk tom Dieck**

Nickel compounds have been well established as catalysts for the cyclotetramerization of acetylene to cyclooctatetraene (COT) ever since the publication of *Reppe*'s studies in this sector, but it was not until 1978 before a mechanism could be proposed that suitably describes the reaction of a COT-dinickel matrix and satisfactorily explains the competition between benzene formation and the thermodynamically unfavorable formation of an eight-membered ring[2].

The diazadiene(dad)-nickel(0) systems $(dad)_2Ni$ **1** and (dad)Ni(cod) **2** are the only precatalysts which exclusively cyclotetramerize alkynes[1,3]. The occurrence of new compounds in the reaction of **1** and **2** with the alkynes **3** and **4**, respectively, which are recognizable by a change in color from red-violet (**1**, **2**) to blue, prompted us to investigate the intermediates of the catalytic reaction. *N,N'*-ethanediylidenebis(2,6-diisopropylaniline) **5** served as diazadiene (dad).

Reaction of the disubstituted acetylenes **3** with **1** affords blue complexes **6** in which the alkyne and dad are coordinated to nickel[4] (UV/VIS: $\lambda_{max} \approx 620$ nm, IR: $\nu_{C\equiv C} = 1770-1820$ cm^{-1}). The reaction of **2** with 1-alkynes **4** leads to very similar blue intermediates **7** (UV/VIS: $\lambda_{max} \approx 640$ nm), which surprisingly show no vibration attributable to coordinated alkynes in the IR spectrum. Molecular mass determinations in benzene according to the method of *Beckmann* show that **7a** is present as a dimer. Hydrolysis of **7b** in an acid medium furnishes a product of mass $2M_{4b}+2$, which has been detected solely by mass spectroscopy.

In the 80-MHz ^{1}H-NMR spectrum of **6**, $R' = CH_2OCH_3$, the resonance of the OCH_2 protons appears as a sharp singlet at $\delta = 5.02$[11], whereas the resonance of the OCH_2 protons of **7b** appears as an AB system at $\delta = 3.10$, thus indicating diastereotopism of the H atoms. A lowering of symmetry can also be concluded from the ^{13}C-NMR spectrum, in which ten signals (from a maximum of twelve) are resolved for CH_3 and CH—C-atoms of the isopropyl groups.



7b was obtained from ethanolic solution in the form of bluish colored, almost cubic crystals which were suitable for an X-ray crystal structure analysis (Fig. 1).

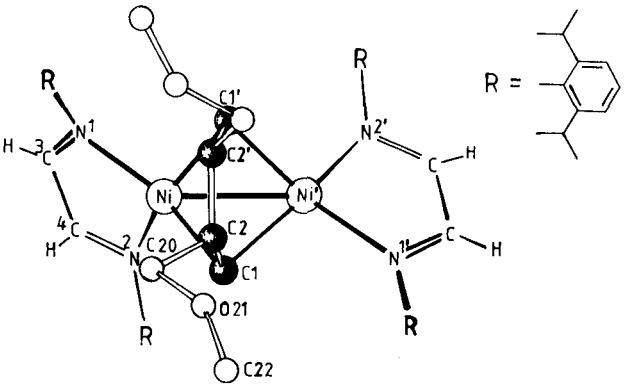


Fig. 1. Structure of **7b** in the crystal. $P4_12_12$, $a = 13.938(5)$, $c = 29.871(10)$ Å, $V = 5803.4$ Å^3, $Z = 4$, $R = 0.099$ for 2914 reflections with $I \geq 3\sigma(I)$; bond lengths Å; bond angles and torsion angles [°]; standard deviations (in brackets), given in units of the last decimal place: Ni-Ni' 2.541(2), Ni-N1 1.92(1), Ni-N2 1.95(1), Ni-C1 1.95(2), Ni-C2 2.43(2), Ni-C1' 2.00(2), Ni-C2' 2.41(2), C1-C2 1.29(3), C2-C2' 1.49(3), N1-C3 1.31(2), N2-C4 1.31(2), C3-C4 1.41(2), C2-C20 1.60(4), C20-O21 1.36(4), O21-C22 1.38(3); C1-Ni-C2 31.9(6), C2-Ni-C2' 35.9(7), C1-Ni-C1' 82.8(7), Ni-C1-Ni' 80.2(6), Ni-C1-C2 95.1(12), Ni-C1'-C2' 91.7(13), N1-Ni-N2 83.4(5), Ni-N1-C3 111.7(10), N1-C3-C4 117.1(14); N1-Ni-Ni'-N1' 79.5(6), N2-Ni-Ni'-N2' 156.3(10), C1-C2-C2'-C1' 7.4(27). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50960, the names of the authors, and the journal citation.

According to the analysis, reaction of **2** and **4b** leads, presumably via an intermediate **6**, to formation of a binuclear nickel compound in which two alkyne molecules are coupled to a C_4 chain. This cisoid butadienediyl moiety lies C_2-symmetrically in a plane almost perpendicular to the Ni—Ni bond (2.54 Å); the planes of the two dad control ligands are rotated through ca. 90° to each other, so that a C_2 axis exists in the molecule, through the central C—C bond and the mid-point of the Ni—Ni bond. Also

[**] Diazadienes as Control Ligands in Homogeneous Catalysis, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft. *R. D.* thanks the Fonds der Chemischen Industrie for a fellowship.—Part 9: [1].

surprising is that the alkynes are coupled via the substituted centers.

The cyclotetramer **8** of the propargyl-*p*-tolyl ether **4c**, as sole low-molecular product of a catalyst reaction on **1**, has a highly symmetric 1,4,5,8-substitution pattern[3b]. The coupling of the alkynes in **7b** allows only this one substitution pattern for highly symmetric COT derivatives, not 1,3,5,7-substitution, and probably not 1,2,5,6-substitution.

The tetramerization of propargylates to **9**, R″ = Me, Et[1], could in principle, proceed via a structure **7**, since two substituents are adjacent in **9**. The major product **10** of the tetramerization of propargyl alcohol **4c**[3c] requires, by way of necessity, another alkyne coupling in the intermediate **7a**, which according to the NMR spectrum has a higher symmetry than **7b**; the structure of **7a**, is, however, still unknown.

The (dad)-nickel system thus apparently responds quite flexibly towards steric and/or electronic properties of the alkyne. The structure of **7b** clearly demonstrates that the reaction circumvents the formation of benzene derivatives, since a Diels-Alder reaction—as for example of a metallacyclopentadiene[5]—is no longer possible. The correlation in the unexpected stereochemistry between **7** and **8** and the finding that induction periods occur in catalyses with **1** and **2**—but not in reactions of **7** with 1-alkynes—suggest that **7** is indeed an intermediate of the catalytic sequence **4** → **6** → **7** → **8** and not a "parking lot" for 1-alkynes.

Experimental

7b: A solution of **4b** (100 mg, 1.43 mmol) in THF (10 mL) was added slowly in the absence of air to a solution of **2** (709.8 mg, 1.31 mmol) in 40 mL tetrahydrofuran (THF). After 24 hours' stirring at room temperature, all volatile components were removed from the deep-blue solution in vacuo at room temperature; the oily residue was dissolved in hot ethanol and filtered. Blue, cubic-shaped crystals of **7b** (490 mg, 74.2%) precipitated from the filtrate at room temperature. ^{1}H-NMR (CD_2Cl_2, TMS int.): $\delta = 0.52-1.22$ (more than 10 signals, CH_3), 2.55 (s, OCH_3), 2.71 (m, $CH(CH_3)_2$), 3.10 (dd, OCH_2), 3.83 (m, $CH(CH_3)_2$), 5.14 (s, "alkyne"-CH), 6.82—7.15 (H(aromat.)), 7.30 and 7.84 (N=C*H*).—^{13}C-NMR (CD_2Cl_2, TMS int.): $\delta = 22.4-28.4$ (10 signals resolved for CH, CH_3), 57.5 (OCH_3), 70.7 (OCH_2), 122.8—128.1 ($\approx$5 signals, CH), 128.3, 140.5, 141.8, 142.3, 151.9, 153.6 (at least 6 signals C quarternary).—UV/VIS (THF): $\lambda_{max} = 642$ nm.

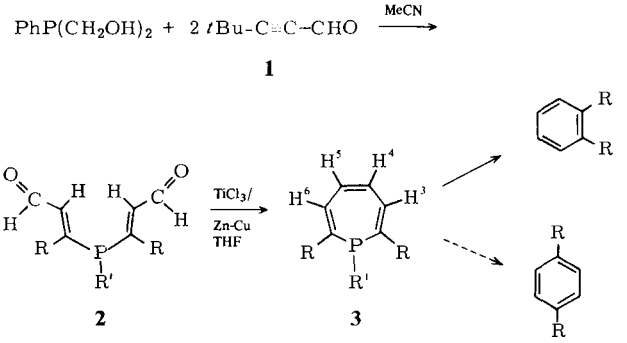
2,7-Di-*tert*-butyl-1-phenyl-1*H*-phosphepine—The First Stable, Monocyclic Phosphepine

By *Gottfried Märkl** and *Willibald Burger*

Of the 8π-heterocycles, oxepins and azepines are well-known stable compounds[1], whereas thiepins eliminate sulfur and readily decompose via bicyclic thianorcaradiene isomers to give benzene derivatives[2]. In contrast, 2,7-di-*tert*-butyl-substituted thiepins, which for steric reasons (eclipsed arrangement of the *tert*-butyl groups) cannot isomerize to the bicyclic isomers, are stable[3].

Monocyclic phosphepines were previously unknown. The 1-oxo-1-phenyl-λ^5-phosphepine[4] described by us previously decomposes in all attempts at its reduction—probably via the phosphanorcaradiene—with elimination of [PhP]; the recently prepared 3-phenyl-3-benzophosphepine[5] is also thermolabile and even at room temperature in solution is slowly converted into naphthalene.

With the synthesis of 2,7-di-*tert*-butyl-1-phenyl-1*H*-phosphepine **3a** we have now shown that for phosphepines substitution of the 2,7-positions by *tert*-butyl groups also prevents formation of the norcaradiene structure necessary for the decomposition.



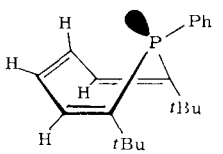
a, R′ = Ph, R = *t*Bu; **b**, R′ = Me, R = *t*Bu; **c**, R′ = R = Ph

Scheme 1.

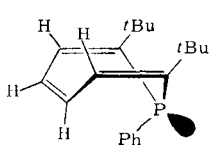
Phosphepine **3a** can be prepared as shown in Scheme 1. 4,4-Dimethyl-2-pentinal **1** is prepared from 3,3-dimethyl-1-butyne (*tert*-butylacetylene)[6] by reaction of the Mg-acetylide with ethyl orthoformate (yield 47%)[7]. The bis-adduct **2a** is obtained in 17—20% yield by Michael-like addition of bis(hydroxymethyl)phenylphosphane to **1** in acetonitrile (molar ratio 1 : 2, 16 h at room temperature, 2 h refluxing) via elimination of formaldehyde.

The key step in the synthesis of phosphepine **3a** is the reductive coupling **2a** → **3a** via a McMurry reaction[9, 10].

The $J_{H,H}$ coupling constants suggest[11] that **3a**, like all "epines" whose structure has been investigated analytically, is present in the boat form. Because of the stability of tertiary phosphanes to inversion it must be assumed that **3a** consists of a *syn/anti*-mixture of isomers.



anti-**3a**



syn-**3a**

3a is thermally stable. Whereas at 130 °C, 2,7-di-*tert*-butylthiepin undergoes sulfur extrusion to afford *o*-di-*tert*-butylbenzene[3], this is detected neither in the preparation of **3a** nor after its distillative purification. The *p*-di-*tert*-bu-

[*] Prof. Dr. G. Märkl, Dipl.-Chem. W. Burger
Institut für Organische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (FRG)

tylbenzene isolated must therefore arise either from the reaction **2a** → **3a** or from **3a** under the conditions used for the McMurry reaction. This assumption is also suggested by the reaction of the dialdehydes **2b**, **c** with $TiCl_3$/Zn–Cu, where the phosphepines **3b**, **c** cannot be isolated.

2b undergoes a McMurry reaction to give *p*-di-*tert*-butylbenzene in 14% yield; under these conditions **2c** reacts to afford only traces of *p*-terphenyl, but *o*-terphenyl (m.p. 56 °C) is obtained in 15% yield. Formation of *o*-terphenyl is consistent only with decomposition of 1,2,7-triphenylphosphepine **3c**, which is not expected to be thermally stable.

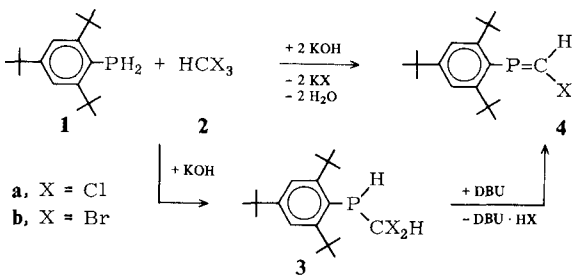
Easy Synthesis of Phosphaalkenes by a Phosphorus-Analogous Isocyanide Reaction and an Atypical Crystal Structure of a Tetracarbonyl(phosphaalkene)iron Complex**

By *Rolf Appel**, *Carl Casser*, *Michael Immenkeppel*, and *Falk Knoch*

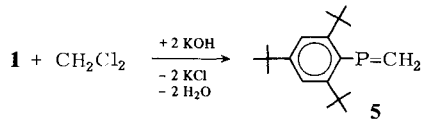
In recent years several reports have appeared on the synthetic possibilities offered by phosphaalkenes[1]. By analogy to the well-known isocyanide reaction, we have now discovered an additional easy synthesis of previously inaccessible phosphaalkenes substituted by hydrogen and halogen at the carbon.

The stable 2,4,6-tri-*tert*-butylphenylphosphane **1** reacts smoothly with trihalomethanes HCX_3 **2a**, **b** in the presence of potassium hydroxide to afford the phosphaalkenes **4a**, **b**. By observing the course of the reaction spectroscopically, the phosphanes **3a**, **b** formed from the dihalocarbene generated in situ and **1** can be unequivocally detected. Addition of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) converts **3a**, **b** quantitatively into **4a**, **b**.



In the crude product **4a**, **b** occur as a mixture of the *E*/*Z*-isomers from which one isomer could be isolated after chromatographic purification and recrystallization from acetonitrile/toluene (2:1). According to the spectroscopic results, **4b** is the isomer which we recently described and obtained only in low concentration using an alternative synthetic procedure[2]. We have therefore succeeded for the first time in isolating both isomers of a phosphaalkene in pure form. NMR data[3] and the results of elemental analysis and high resolution mass spectroscopy are in accord with the proposed structures. Attempts to prepare the phosphorus-analogous isocyanides by α-elimination of hydrogen halide from **4a**, **b** were unsuccessful until now.

In the analogously performed reaction of **1** with dichloromethane, methylene(2,4,6-tri-*tert*-butylphenyl)phosphane **5** is formed as colorless crystals. **5** was already obtained in 1982 by thermal elimination of chlorotrimethylsilane[4], but could only be detected by ^{31}P-NMR spectroscopy in the product mixture.



Phosphaalkenes can coordinate to transition-metal centers. The X-ray structure analysis of tetracarbonyl[2,4,6-tri-*tert*-butylphenyl(α-trimethylsilylbenzylidene)phosphane]-

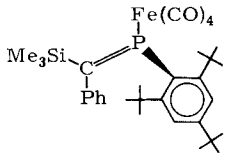
iron(0) **6**[2,5] reveals an unusual trigonal bipyramidal type structure with the η^1-bonded phosphaalkene ligand occupying an axial position. In view of its spatial requirements, this ligand should occupy an equatorial (bond angle 120°) rather than an axial position (bond angle 90°) as found for the recently described carbonyliron complex with a phosphaalkene ligand[6] and for a tetracarbonyliron compound with the very bulky diphosphene ligand[7].



6

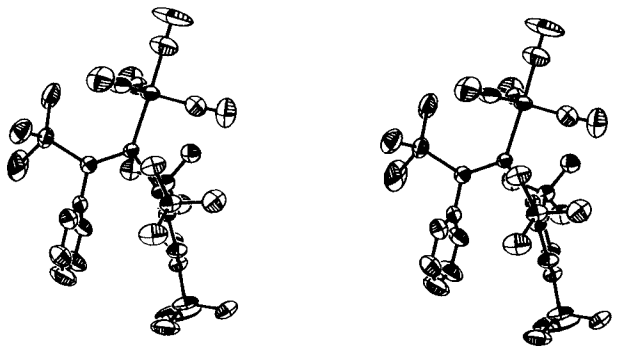


Fig. 1. Stereodiagram of the molecular structure of **6** [5].

Procedure

4a, b: Dry, powdered KOH (2.5 g) is added to a solution of **1** (2.78 g, 10 mmol) and **2a, b** (20 mmol) in 30 mL tetrahydrofuran. After completion of the exothermic reaction, the mixture is stirred for 24 h.

For the quantitative conversion (^{31}P-NMR monitoring), the solution is treated with 1–1.5 mL DBU. The solvent is removed and the residue taken up in 50 mL *n*-pentane. After the mixture has been filtered and the solvent removed in vacuo, the crude product is purified by column chromatography on silica gel (eluent, **4a**: *n*-hexane, **4b** ethyl acetate). The white solid thus obtained is recrystallized from acetonitrile/toluene (2:1). **4a**: m.p. = 108 °C. Yield **4a**: 1.02 g, **4b**: 0.5 g.

5: **1** (2.78 g, 10 mmol) is dissolved in 30 mL dichloromethane and dry, powdered KOH (2.5 g) added to this solution. After being stirred for 3 d at 25 °C, the solvent is removed in vacuo and the residue taken up in 50 mL *n*-pentane and separated from insoluble salts. The solvent is removed and the solid residue recrystallized from acetonitrile/toluene (2:1). M.p. 80 °C. Yield: 1.85 g.

Conformation of Glycosyl Radicals: Radical Stabilization by β-CO Bonds**

By *Jacques Dupuis, Bernd Giese*, Daniel Rüegge, Hanns Fischer, Hans-Gert Korth,* and *Reiner Sustmann*

Reaction of tetraacetylglucosyl bromide **1a** (X = Br) with nBu$_3$SnH in the presence of acrylonitrile or methyl acrylate affords the CC coupling product **2** with axial arrangement of the substituents on C-1[1]. This stereoselectivity was evidenced by the occurrence of the σ-radical **4**[1,2], which, because of interaction with the non-bonding electron pair on the ring oxygen atom, should be more stable[2] and more nucleophilic[3] than the σ-radical **5**. However, the high stereoselectivity of this reaction decreases from over 50 (**2a** : **3a** = >98 : <2) to 3.5 (**2b** : **3b** = 78 : 22) if the tetramethylglucosyl bromide **1b** (X = Br) is employed instead of **1a** (X = Br). This finding prompted us to measure the ESR spectra of the intermediate glucosyl radicals.

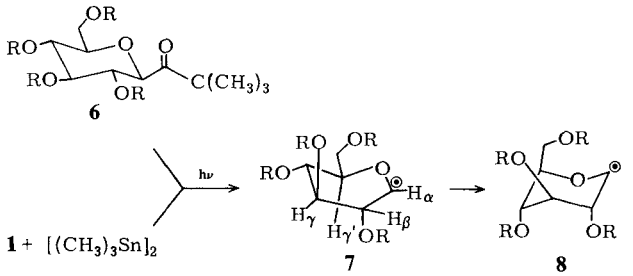
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Schweizerische Nationalfonds für Wissenschaft und Forschung, and by the Fonds der Chemischen Industrie.

Photolysis of the ketones **6**[4] or abstraction of bromine from **1a** (X = Br) with trimethyltin radicals led to radicals whose ESR spectra are reconcilable with a boat conformation, as in the radical **7** in which the substituents on C-2 and C-3 are axial. Supporting evidence for this structure is provided by a) the small β-coupling constant, which points to an equatorial arrangement of the β-CH bond[5], b) the occurrence of a relatively large γ-coupling, caused by a W-arrangement of the electrons and, hence, an extensively equatorial γ-CH bond, and c) the unusually large α-coupling constants for radicals of the type RĊHOR′, indicating an almost planar radical[6] (Table 1).



a, R = Ac; **b**, R = CH_3

Table 1. ESR data of the glucosyl and mannosyl radicals **7**, **10**, and **12**.

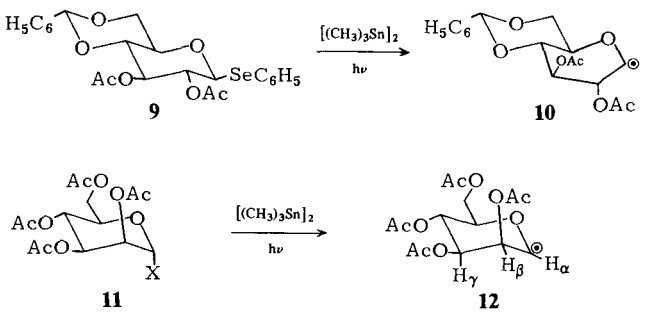
[a] Photolysis of **6a** in 2-propanol. [b] Photolysis of $[(CH_3)_3Sn]_2$ in the presence of **1a** (X = Br) in tetrahydrofuran. [c] Photolysis of **6b** in 2-propanol. [d] Photolysis of $[(CH_3)_3Sn]_2$ in the presence of **9** in toluene. [e] Photolysis of $[(CH_3)_3Sn]_2$ in the presence of **11** in tetrahydrofuran.

The transformation of the $^4C_1$ conformation of the educts **1** and **6** into the $B_{2,5}$ conformation[7] of the radical **7** involves an interconversion of the substituents on C-2 and C-3 from the equatorial into the axial position. The ESR spectra leave it open as to whether the $^1C_4$ conformation **8**, in which all substituents are axial, is also realized by inverting the ring at C-5. In order to differentiate between these two possibilities, the corresponding bicyclic glucosyl radical was generated from the bicyclic selenoglucoside **9**[8]. The α-, β-, and γ-coupling constants (Table 1) of the radicals generated from **1**, **6**, and **9** are to a great extent consistent in magnitude and temperature dependence. In the case of the bicyclic glucosyl radical, this is reconcilable only with the boat conformation **10**, since the *trans*-coupling of the two rings makes an inversion into the $^1C_4$ chair conformation impossible. The similarity of the ESR signals of the radicals generated from **1**, **6**, and **9** suggests that the monocyclic glucosyl radicals are also present in the boat conformation **7**.

In contrast, in the mannosyl radical **12** the $^4C_1$ conformation of the educt **11** is preserved. This is evidenced by a) the small β-coupling constant of about 4 G, which is reconcilable only with an equatorial arrangement of the β-CH bond and b) the disappearance of the resulting γ-coupling over two CC bonds (Table 1).



Accordingly, the glycosyl radicals generated from the glucose derivatives **1**, **6** and **9** and the mannose derivative **11** have a largely coplanar arrangement of the β-CO bond and the half-occupied orbital. *Gilbert* and *Norman* et al. have observed an analogously preferred conformation in open-chain radicals of the type RŌCHCHR′OR″[6], which can be explained in terms of an interaction between the half-occupied orbital at the radical center and σ* orbital of the C–OR bond. The SOMO/LUMO interaction is especially pronounced in the glycosyl radicals, since the SOMO energy of the radicals is enhanced by the neighboring oxygen atom. In the glucosyl radicals it can apparently overcompensate the repulsive interactions in the transition from the chair to the boat conformation.

The radical-stabilizing effect of the axial β-CO bond is also noticeable in the rates of abstraction of halogen from glycosyl chlorides. Thus, kinetic measurements of competition reactions in benzene at 80 °C show that tributyltin radicals abstract the halogen atom of the mannosyl chloride **11** (X = Cl) 7.8 times more rapidly than the halogen atom of the glucosyl chloride **1a** (X = Cl). Only in the reaction of the mannose derivative is the β-CO bond axial in the transition state of the radical formation; in the glucose derivative the stabilizing effect of the β-CO bond can only be effective after change of conformation. Thus, this stereoelectronic effect also has an influence on the rate of formation of the radicals[9].

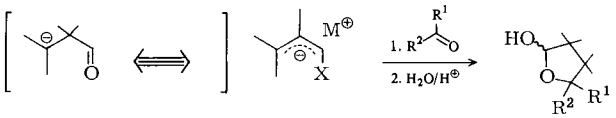
Highly Enantioselective Homoaldol Additions with Chiral *N*-Allylureas—Application to the Synthesis of Optically Pure γ-Lactones**

By *Hanno Roder, Günter Helmchen*, Eva-Maria Peters, Karl Peters,* and *Hans-Georg von Schnering*

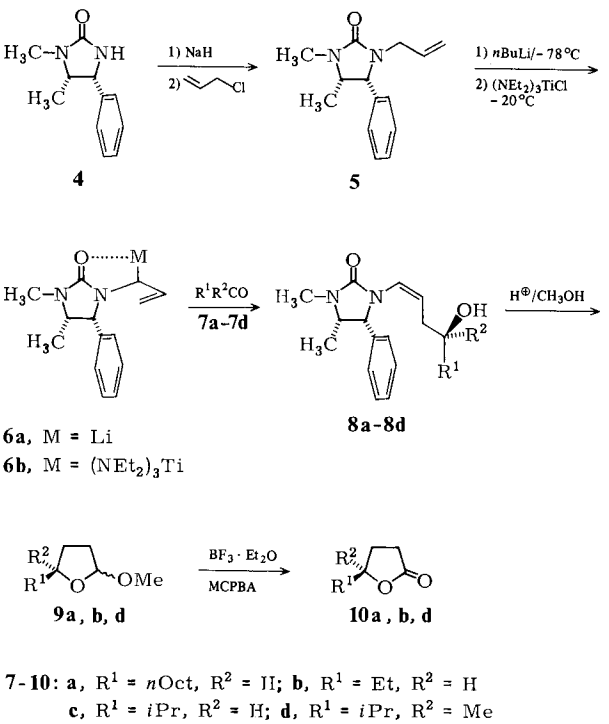
Dedicated to Professor Ulrich Schmidt on the occasion of his 60th birthday

In favorable cases, the reaction of aldehydes and ketones with hetero-substituted allylmetal compounds **2** proceeds with high regio- and diastereoselectivity (X = OCON*i*Pr$_2$[1a], X = NR–CO–NR$'_2$[1b]). Since the products can be hydrolyzed to aldehydes, which react to lactols **3**, compounds **2** function as synthetic equivalents of homoenolates **1**. Oxidation of the lactols affords lactones, many of which are important pheromones, terpenes, or chiral synthetic building blocks which are accessible via the "homoaldol reaction" in only one CC coupling step.



1 **2** **3**

We have now developed the first enantioselective homoaldol reaction involving a chiral allyl system of type **2**[2,3]. For this purpose we use as a novel reagent for asymmetric synthesis the cyclic urea derivative **4**, accessible in one step by fusing (−)-ephedrinium chloride with urea[4] [55–65%, m.p. = 177–179 °C, $[\alpha]_D^{25}$ −44.5 (*c* = 3, methanol)]. Using standard methods, one obtains from **4** the *N*-allyl derivative **5** [92%, m.p. = 68–69.5 °C, $[\alpha]_D^{22}$ +22.7 (*c* = 3, methanol)]. **5** can be smoothly deprotonated with *n*-butyllithium to the allyllithium compound **6a** and transmetalated[1a] to **6b** (−20 °C, red-orange solution) with chlorotris(diethylamino)titanium[5]. Reaction of the titanium compound **6b** with the aldehydes **7a–c** as well as, surprisingly, *with the methyl ketone* **7d** leads highly stereoselectively to the homoaldol adducts **8a–d**. These adducts have, as expected, a *cis*-configurated double bond[1,6] and can be obtained diastereomerically pure by recrystallization[7] (Table 1). The pure enamides **8a**, **b**, **d** are methanolyzed analogously to that described in [1b] to the *O*-methyllactols **9a**, **b**, **d**; the reagent **4** can be re-isolated in 95–98% yield by extraction. The crude compounds **9** can be directly oxidized with *m*-chloroperbenzoic acid (MCPBA) to the γ-lactones **10a**, **b**, **d** (Table 2) using the method described by *Grieco* et al.[8]. The configuration of **10a** and **10b**, whose enantiomers are the pheromones of various species of beetles[9], as well as that of **10d** were determined by comparison of the optical rotations with reliable literature data (Table 2). The configuration of the reagent **4** is



7-10: **a**, R^1 = *n*Oct, R^2 = H; **b**, R^1 = Et, R^2 = H
c, R^1 = *i*Pr, R^2 = H; **d**, R^1 = *i*Pr, R^2 = Me

Table 1. Reaction of the allyltitanium compound **6b** with the carbonyl compounds R^{1}R^{2}CO, **7a–d**, to give the homoaldol adducts **8a–d** (THF, −20 °C).

Homoaldol adduct [a]	Yield [%] [b]	Diastereosel. [c]	Yield [%] [d]	Diastereomeric ratio [d]
8a	96	94 : 6	61	≥200 : 1
8b	94	96 : 4	63	>200 : 1
8c	95	96 : 4	—	
8d	93	98 : 2	81	150 : 1

[a] Predominant homoaldol adduct. All compounds were characterized by CHN analyses (±0.3%) as well as by ^{1}H-NMR (400 MHz) and mass spectra. [b] Relative to **5**. [c] Diastereoselectivity was determined for **8a**, **b** by HPLC and for **8a**, **c**, **d** by ^{1}H-NMR (400 MHz). [d] After recrystallization from *n*-hexane or *n*-hexane/ethyl acetate.

Table 2. Methanolysis of the homoaldol adducts **8a**, **b**, **d** to the *O*-methyllactols **9a**, **b**, **d** and their Grieco oxidation [8] to the optically active γ-lactones **10a**, **b**, **d**.

γ-Lactone [a]	Yield [%] [b]	$[\alpha]_D$	Absol. config.
10a	99	$[\alpha]_D^{20}$ −41.1 [c] (*c* = 5, CH_3OH)	*S*
10b	79	$[\alpha]_D^{22.5}$ −53.7 [d] (*c* = 1, CH_3OH)	*S*

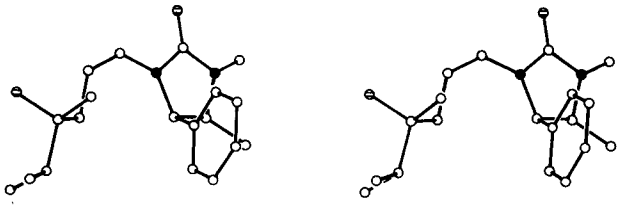
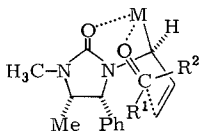
established by a crystal structure analysis of the enamide **8d** (Fig. 1).



„Fig. 1. Stereoscopic projection of the structure of **8d** in the crystal. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50966, the names of the authors and the journal citation.

For rationalization of configurative correlational relationships of the homoaldol addition, we assume that the reaction proceeds via a chair-like transition state in which the larger substituent at the carbonyl group preferentially adopts the equatorial position[10].



11, M = $Ti(NEt_2)_3$

The homoaldol additions described do not depend on the concentration of the reactants and, because of the ready accessibility and re-isolability of the reagent **4**, can be performed on a large scale. Both enantiomers of **4** are available. Because of the high stereoselectivity of the reaction and the possibility of subsequent purification by crystallization, the products can be obtained enantiomerically pure.

General Procedure

8: *n*-Butyllithium (0.11 mol, ca. 2 M in hexane) is added to 30 mL tetrahydrofuran (THF) (under an inert gas atmosphere at −78 °C) and the mixture stirred. A solution of **5** (0.1 mol) in 75 mL THF is added dropwise to this mixture, and after 25 min a solution of chlorotris(diethylamino)titanium (0.11 mol) in 30 mL THF is also added dropwise. The mixture is warmed up to −20 °C and 45 min later a solution of **7** (0.10 mol) in 10 mL THF is injected in. After ca. 2 h, water is added and the mixture is taken up in ether and extracted with 10% $NaHSO_3$ and with water. The enamides **8** obtained from the ether solution after drying and concentrating are chemically largely pure (see Table 1).

A Binuclear, Mixed-Valence $Mo^{VI/V}$-Complex; The Crystal Structure of $[(C_9H_{21}N_3)_2Mo_2^{VI}O_5](Br_3)_2$

By *Karl Wieghardt**, *Gabriele Backes-Dahmann*, *Willy Herrmann*, and *Johannes Weiss*

Binuclear, oxo-bridged complexes of molybdenum(VI-IV) have been discussed as active centers in the enzymes nitrate-reductase, sulfite-oxidase, and xanthine-oxidase[1]. ESR spectra of the active forms of these enzymes indicate an O,N,S-coordinated Mo^V center, thus suggesting that mixed-valence complexes of the type Mo^V/Mo^{IV} or Mo^{VI}/Mo^V could be present. For the former type there is only one well characterized example[2]; we report here on the characterization of the first mixed-valence Mo^{VI}/Mo^V complex.

Oxidation of $LMo(CO)_3$[3] with semiconcentrated nitric acid furnishes the yellow, diamagnetic cation $[L_2Mo_2^{VI}O_5]^{2\oplus}$ **1**, where L is the facially coordinated *N,N',N''*-trimethyl-1,4,7-triazacyclononane ligand. Salts of **1** with $(Br_3)^{\ominus}$, $PF_6^{\ominus}$ and $ClO_4^{\ominus}$ have been isolated in the crystalline state[4].

According to the X-ray structure analysis of **1** $(Br_3)_2$[5] a binuclear, μ_2-oxo-bridged cation with two pseudooctahedrally coordinated molybdenum(VI) centers is present (Fig.

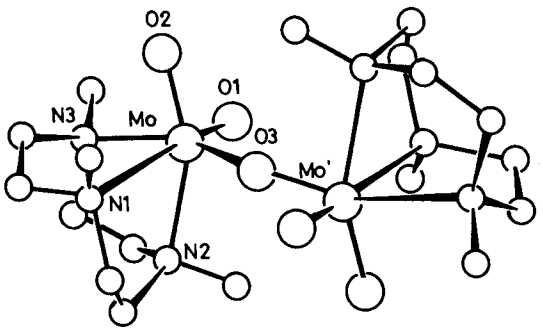

Fig. 1. Structure of **1** in the crystal of **1** $(Br_3)_2$; selected bond lengths [Å] and angles [°]. Mo-O1 1.694(7), Mo-O2 1.696(7), Mo-O3 1.898(1), Mo-N1 2.325(8), Mo-N2 2.355(8), Mo-N3 2.290(9); O1-Mo-O2 104.7(4), O2-Mo-O3 103.6(2), O1-Mo-O3 104.4(3), N1-Mo-O3 90.0(2), N1-Mo-N2 73.2(3), N2-Mo-N3 74.2(3), N1-Mo-N3 74.3(3), Mo-O3-Mo' 180.0.

1). Each Mo^{VI} ion is surrounded by two terminal oxo groups, a bridging oxygen atom and three N atoms of the cyclic amine. The cation has C_i symmetry; the Mo–O–Mo-group is linear. The structural details of the $Mo_2O_5^{2\oplus}$ moiety compare well with those of other analogous complexes[6].

The chemical reduction of **1** with $Na[BH_4]$ or N_2H_4 in H_2O or acetonitrile leads to deep-blue, paramagnetic solutions of $[L_2Mo_2O_5]^{\oplus}$ **2**; this reduction can also be carried out electrochemically. The electron excitation spectrum of **2** shows intervalence bands at 753 ($\varepsilon = 2.6 \times 10^3$ L mol^{-1} cm^{-1}) and 909 nm (2.7×10^3). An effective magnetic moment of 1.7 μ_B was determined for **2** in solution at 25 °C by NMR spectroscopy using the method of *Evans*. The cyclovoltammogram of $\mathbf{1}(PF_6)_2$ in acetonitrile (Fig. 2) shows two electrochemically and chemically reversible electron transfers between +1.8 and −1.7 V (vs. Ag/AgCl) at redox potentials of −0.77 and −1.88 V referred to the internal redox system ferrocenium/ferrocene[7]. The following redox scheme can therefore be formulated.

$$[L_2Mo_2O_5]^{2\oplus} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [L_2Mo_2O_5]^{\oplus} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [L_2Mo_2O_5]$$

1 **2** **3**

3 is a binuclear Mo_2^V species.

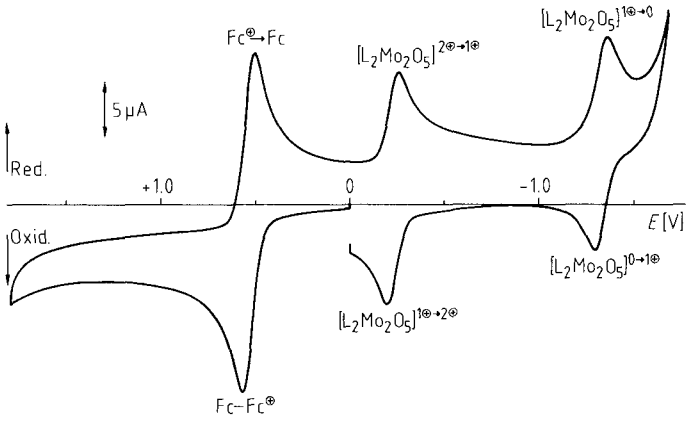

Fig. 2. Cyclovoltammogram of $\mathbf{1}(PF_6)_2$ (0.56×10^{-3} mol L^{-1}) in acetonitrile (supporting electrolyte: 0.1 mol L^{-1} ($NnBu_4$)PF_6; internal standard: 0.7×10^{-3} mol L^{-1} ferrocene (Fc); scan rate 0.1 V/s; platinum electrode: 7.1 mm^2 surface area; vs. Ag/AgCl).

A measure of the stability of the mixed valence Mo^{VI}/Mo^V binuclear complex is the comproportionation constant K_c, which, calculated from the two redox potentials, is 6×10^{18}.

$$Mo_2^{VI} + Mo_2^V \overset{K_c}{\rightleftharpoons} 2[Mo^{VI}Mo^V]$$

1 **3** **2**

Such a large value would indicate a complete delocalization of the unpaired electron in **2**[8].

[4] *Procedure:* A suspension of 0.36 g $LMo(CO)_3$ [3] (L = *N,N,N''*-trimethyl-1,4,7-triazacyclononane) in 15 mL semiconcentrated nitric acid was stirred for 6 h at 22 °C. The resulting clear, orange solution was treated carefully with 5 mL of a saturated NaBr solution (evolution of Br_2), whereupon **1** $(Br_3)_2$ separated out as a yellow solid. This was filtered off, rapidly washed with cold ethanol and ether, and dried (yield 0.12 g). The compound can be recrystallized from water or acetonitrile, and precipitated as $\mathbf{1}(PF_6)_2$ or $\mathbf{1}(ClO_4)_2$ by addition of $NaPF_6$ or $NaClO_4$, respectively.—All salts free of water of crystallization gave correct elemental analyses.—IR (KBr [cm^{-1}]): ν(Mo=O): 930 vs, 905 vs; ν(as)(Mo–O–Mo): 770 vs. Solutions of $\mathbf{1}(PF_6)_2$ in H_2O or CH_3CN can be reduced in an argon atmosphere with N_2H_4 or $Na[BH_4]$ to the blue Mo^V/Mo^{VI} mixed-valence species **2**. Electrochemical reduction gives the same product. Oxidation with O_2 leads to reformation of yellow **1**. Attempts to isolate **2** as a salt failed.

[5] X-Ray structure analysis: $\mathbf{1}(Br_3)_2$: $P2_1/n$, $a = 8.959(2)$, $b = 11.076(2)$, $c = 17.208(2)$ Å, $\beta = 91.56(1)°$ at 22 °C, $V = 1707$ Å^3, $Z = 2$; 1652 independent reflections ($I \geq 2.5\sigma(I)$); Syntex $P2_1$, $Mo_{K\alpha}$, $\lambda = 0.71069$ Å, ϑ-2ϑ-scan ($3° \leq 2\vartheta \leq 60°$C); empirical absorption correction ($\mu = 77.1$ cm^{-1}); solution by Patterson and Fourier syntheses; $R = 0.049$, $R_w = 0.040$, atoms other than H anisotropic, H atoms (calculated) constantly isotropic (SHELXTL). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50967, the names of the authors, and the journal citation.

[6] E. Stiefel, *Prog. Inorg. Chem. 22* (1977) 1.

[7] Electrochemistry: In each case the two peak potential differences (ΔE_p) are ca. 65 mV; the peak current functions for both electron transfers are independent of the variation in voltage and are almost equal in magnitude.—The coulometric reduction of $\mathbf{1}(PF_6)_2$ at a mercury-pool electrode at −0.9 V (vs. Ag/AgCl) yields 1.02 ± 0.02 electrons per dimeric cation. During the electrolysis the color of the sample solution changes from bright yellow to deep blue. The coulometric reduction could not be accomplished at −1.7 V (vs. Ag/AgCl) since the product of reduction is not stable on such a time scale (ca. 30 min). However, here also, the diagnostic criteria clearly point to a one-electron transfer.

[3+2]-Cycloaddition Reactions of a Stable Phosphaalkyne—Transition from Singly to Doubly Coordinated Phosphorus**

By *Wolfgang Rösch* and *Manfred Regitz**

The potential of phosphaalkynes to undergo cycloadditions has largely been untapped[1]. Accordingly, we have studied the cycloadditions of the only phosphaalkyne which is stable at room temperature, 2,2-dimethylpropylidynephosphane ("1-phospha-2-*tert*-butylacetylene"), **1**, with 1,3-dipoles of the diazoalkane, azide, nitrile oxide, and nitrilimine type. Reactions involving conversion of singly into doubly coordinated phosphorus open up access to a multitude of novel, aromatic, five-membered phosphorus heterocycles.

The diazomethane derivatives **2a**—**f** react with **1** in ether at 20 °C to afford the 1*H*-1,2,4-diazaphospholes **4a**—**f**. Only in the case of **2e** did it prove possible to isolate the initially formed 3*H*-1,3,4-diazaphosphole **3e** [^{1}H-NMR ($CDCl_3$): $\delta = 3.50$ (d, 1 H, $^2J_{P,H} = 8.1$ Hz, H-3)], which isomerizes to **4e** in solution. All compounds exhibit NH absorptions in the IR (KBr, $\nu = 3100$—3180) and ^{1}H-NMR spectra ($CDCl_3$, $\delta = 11.8$—13.1).

Both cycloadditions of diazomethane derivatives to chloro(2-trimethylsilylbenzylidene)phosphane ("1-chloro-

R^2	H	H	H	H	H	H		

2-phenyl-2-trimethylsilyl-1-phosphaethene"), which involve elimination of chlorotrimethylsilane, and condensations of 1,3-bis(dimethylamino)-2-phosphaallyl chlorides with hydrazine derivatives[4] lead via independent routes to the same series of heterocycles. In the case of α-diazocarbonyl compounds such as **2g, h**, formation of **3g, h** is rapidly followed by sigmatropic [1,5]-shift of the acyl group to give the annelated diazaphospholes **4g, h**[5].

Diazaphospholes are distinguished by their ^{31}P- and ^{13}C-NMR signals (for C-3 and C-5) (Table 1). The magnitude of the phosphorus coupling with C-5 rules out an inverted dipole orientation as do the P couplings with the 5-substituents [e.g. ^1H-NMR ($CDCl_3$): **4a**: $\delta = 8.22$ (d, 1H), $^2J_{P,H} = 43.6$ Hz, H-5); **4b**: $\delta = 2.55$ (d, 3H, $^3J_{P,H} = 9.3$ Hz, 5-Me)].

The azide dipoles **5a—c, e**, even the hydrazoic acid **5a**, add smoothly to **1** in ether at 20°C to give the 3*H*-1,2,3,4-triazaphospholes **6**; the ^{31}P-NMR signals are accordingly strongly shifted to low field (Table 1).

From the phosphorus coupling constants with the original azide moieties in **6a—c**, the same regiochemistry as that of the diazoalkane dipoles can be derived and allows a subsequent substituent shift to be excluded [e.g. ^1H-NMR ($CDCl_3$): **6a**: $\delta = 3.85$ (d, 3H, $^3J_{P,H} = 7.2$ Hz, 3-Me); **6b**: $\delta = 4.73$ (d, 2H, $^3J_{P,H} = 5.8$ Hz, 3-CH_2); ^{13}C-NMR

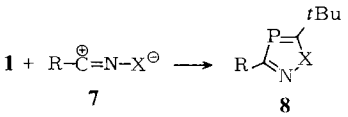
[a] After recrystallization from *n*-pentane (**4a—g**), tetrahydrofuran (**4h**), cyclopentane (**8b**), or kugelrohr distillation (**6a—e, 8a**); all compounds except **4h** (orange) are colorless and air-stable. [b] Oven temperature. [c] $CDCl_3$, 85% H_3PO_4 (ext.). [d] $CDCl_3$, TMS (int.) with $^1J(P,C)$ data [Hz] in parentheses. [e] The identity of both absorptions indicates electron delocalization in the ring and suggests rapid positional mobility of the hydrogen between the two nitrogen atoms. [f] Not measured.

($CDCl_3$): **6c**: $\delta = 151.3$ (d, $^2J_{P,C} = 22.0$ Hz, CO)]. It is, however, an open question as to which N atom of **6d** and **6e** the hydrogen and $SiMe_3$ group, respectively, is bonded.



7 **8**

	a	b
R	Mes	Ph
X	O	NPh

Finally the nitrile oxide and nitrilimine dipoles **7a** and **7b**, respectively, also undergo regiospecific [3+2]-cycloaddition to **1** to give the phospholes **8a** and **8b**; however, with the inverted dipole orientation. At least for **7a** this may stem from steric effects (Mes = mesityl). This can be unequivocally deduced from the ^{31}P-NMR signals of **8a** and **b** (Table 1), which lie in the same region as those of the diazoalkane adducts **4**.

Hydrogen chloride adds to benzylidynephosphane (P≡C–Ph), in contrast to nitriles, to afford benzylidene(chloro)phosphane[6]; cycloaddition of **2** and **5** to **1** proceeds analogously. The extraordinary tendency of phosphaalkynes **1** to undergo cycloadditions is comparable with that of the more electron-deficient acetylenes and differs markedly from the sluggishness of the nitrile group[7].

Procedure:

4e: A solution of **2e** (5.0 mmol) in 5 mL ether (anhydrous) is added dropwise to a solution of **1** (550 mg, 5.5 mmol) in 10 mL ether (anhydrous). At the end of the reaction (2 h, IR monitoring) the mixture is concentrated and the residue recrystallized at −30°C from *n*-pentane. Yield 860 mg (86%) colorless crystals of m.p. = 135°C.

[1] As far as we know, only the reaction of α-pyrones and cyclopentadienones with chloro(α-trimethylsilylbenzylidene)phosphane and with the benzylidynephosphanes (P≡C–Ph) prepared from these in situ, respectively, leads to phosphinynes without the necessity of isolating the initial cycloadducts: G. Märkl, G. Yu Jin, E. Silbereisen, *Angew. Chem. 94* (1982) 383; *Angew. Chem. Int. Ed. Engl. 21* (1982) 370; *Angew. Chem. Suppl. 1982*, 881.

1*H*-1,2,4-Diazaphospholes by [3+2]-Cycloaddition of Diazoalkanes to Phosphaalkenes

By *Gottfried Märkl** and *Irene Trötsch*

Cycloadditions to open-chain, non-resonance stabilized phosphaalkenes are attracting increasing interest. We were recently able to show that chloro(α-trimethylsilylbenzylidene)phosphane (1-chloro-2-phenyl-2-trimethylsilyl-1-

[*] Prof. Dr. G. Märkl, Dipl.-Chem. I. Trötsch

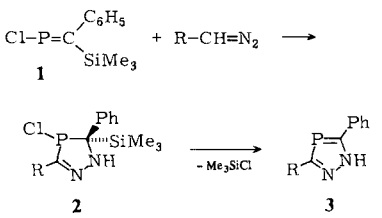
phosphaethane) **1**[1] reacts as a dienophile with α-pyrones and cyclopentadienones via [4+2]-cycloadditions to give phosphinines (intermediate formation of 2-phenyl-1-phosphaethyne (P≡C–Ph) cannot be ruled out)[2]. *Appel* et al.[3] have since reported on the Diels-Alder reaction of 1-alkoxy-2-phenyl-2-trimethylsilyl-1-phosphaethene with 2,3-dimethylbutadiene, while 1-mesityl-2,2-diphenyl-1-phosphaethene—presumably for steric reasons—no longer reacts as dienophile[4].

The first [8+2]-cycloaddition of **1** to 8-methoxyheptafulvene provided access for the first time to a 2-phosphaazulene derivative[5]. [3+2]-Cycloadditions of PC double bonds in 1,2,3-diazaphospholes with 1,3-dipoles (diazoalkanes[6], nitrile oxides[7], nitrile imines[8], azides[9]) have been the subject of numerous studies in recent years.

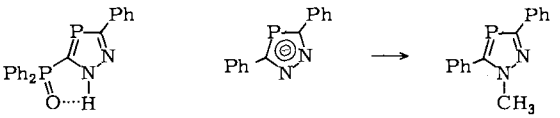
The dipolarophile-reactivity of the phosphaalkanes is—presumably because of the polarity of the P=C bond—much more pronounced than their diene reactivity. According to *Bickelhaupt* et al.[4], 1-mesityl-2,2-diphenyl-1-phosphaethene reacts with phenyl azide and with diphenyldiazomethane to give 4,5-dihydro-1,2,3,4-triazaphospholes and 4,5-dihydro-1,2,3-diazaphospholes, respectively.

We have now found that diazoalkanes almost instantaneously undergo [3+2]-cycloaddition with phosphaalkenes **1**, even at room temperature. The cycloadducts **2** expected to be formed initially aromatize under the reaction conditions by spontaneous elimination of trimethylchlorosilane to give the 1*H*-1,2,4-diazaphospholes **3** with triple-bonded phosphorus of coordination number two (see Table 1).



1 **2** **3**

The regioselectivity of the cycloaddition corresponds to the polarity of the P=C bond. Whereas all formally possible 1,3,2-, 1,3,4- and 1,2,3-diazaphospholes are already known, the 1,2,4-diazaphospholes have hitherto remained inaccessible. The synthesis of this novel ring system has now been accomplished by *Regitz* et al.[10] by [3+2]-cycloaddition of diazoalkanes to the phosphaethyne P≡C–*t*Bu and, at the same time, by *Schmidpeter* et al.[11] by cyclization of 1,3-bis(dimethylamino)-2-phosphaallyl chlorides with hydrazines.



3g′ **4b** **5**

The spectroscopic data of **3** are consistent with the proposed structure (^{31}P-NMR: $\delta = +75.9$ to $+113.4$, Table 1). The broad absorption bands for the NH stretching vibration point to the formation of hydrogen bridges; in the case of **3c**—**g** the presence of the tautomers **3′** with intramolecular H-bridges, e.g. **3g′**, cannot be ruled out. The position and splitting of the P=O stretching vibrations in the IR spectra also lend support to this assumption[12]. Reaction of **3** with *n*BuLi in tetrahydrofuran at −78 °C leads to formation of the phosphole anions **4**; on treatment with methyl iodide, the symmetrical **4b** is alkylated to the 1-methyl-3,5-diphenyl-1,2,4-diazaphosphole **5** (m.p. 104—106 °; ^{31}P-NMR: $\delta = 88.7$)[11].

The cycloaddition of the phosphaalkenes as dipolarophiles to 1,3-dipoles is not restricted to **1**. In preliminary

[a] Baked at 160 °C; at 200 °C, a viscous brown film is formed. [b] Viscous brown film. [c] We thank Prof. Dr. *M. Regitz* and Doz. Dr. *G. Maas* for gifts of the appropriate diazoalkanes. [d] The $[M+CH_2]^{\odot\oplus}$ signals occurring along with $M^{\odot\oplus}$ lend support for a thermally induced intermolecular *N*-methylation in the inlet system of the mass spectrometer.

experiments we could show that 1-chloro-2,2-bis(trimethylsilyl)-1-phosphaethene[13] also undergoes [3+2]-cycloaddition with diazoalkanes. **1** also reacts with azides, nitrile imines, and nitrile oxides.

Experimental

3d: **1** (1.60 g, 7.00 mmol) was treated with a solution of benzoyldiazomethane (1.00 g, 6.8 mmol) in anhydrous ether (10 mL) at 0°C under pure nitrogen in a 25 mL flask fitted with a capillary side-arm and stopcock. The solution slowly turned dark brown. After stirring for 3 h at room temperature the solvent was removed and the viscous, dark residue dissolved in chloroform and treated with *n*-pentane. **3d** separated from the solution as a brown powder, which could be purified by distillation from a microdistillation apparatus at 10^{-5} torr. **3d** distilled off as a bright yellow oil which rapidly crystallized; pale yellow crystals, m.p. 142°C (from ethyl acetate/pentane), yield 0.65 g (35%).

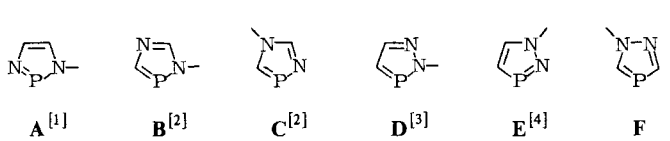
1*H*-1,2,4-Diazaphospholes via 2-Phosphaallyl Chlorides**

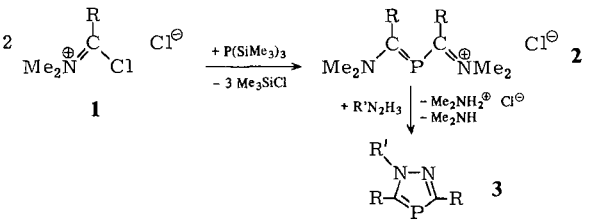
By *Alfred Schmidpeter** and *Angela Willhalm*

Of the diazaphospholes **A**—**F**, five (**A**—**E**) contain at least one PN bond and can be synthesized by condensing phosphorus in the form of PCl_3 or $ClCH_2PCl_2$ onto a chain with a terminal amino group.

Diazaphospholes of the still outstanding type **F** are not accessible via a comparable route. In terms of the bonding situation of the phosphorus, they should correspond to the phosphinyines (phosphabenzenes) and thus lead one to expect a behavior different to that observed in the other isomers. Condensation of 1,3-bis(dimethylamino)-2-phosphaallyl chlorides **2** with hydrazines now opens up a general approach to 1*H*-1,2,4-diazaphospholes **3** (**F**). An additional synthetic pathway to substituted derivatives of **F** is the cycloaddition of diazoalkanes to a phosphaethyne[5] or to a 1-chloro-2-trimethylsilyl-1-phosphaethene with spontaneous elimination of trimethylchlorosilane[6].



A[1] **B**[2] **C**[2] **D**[3] **E**[4] **F**



1 **2** **3**

Reaction of salts derived from imidoyl chlorides **1** with tris(trimethylsilyl)phosphane, a method described previously for tetrakis(dimethylamino)-2-phosphaallyl chloride **2f**[7], permits the synthesis of further phosphaallyl chlorides **2** in almost quantitative yield[8]. These are stable compounds which are not sensitive towards oxidation and hydrolysis and, depending on the substituents R, are yellow to red-brown crystalline solids (Table 1). Their ^{31}P-NMR shifts extend over a remarkably large range $\Delta\delta(^{31}P) = 210$[7].

Table 1. Properties and ^{31}P-NMR data of 2-phosphaallyl chlorides **2** and 1,2,4-diazaphospholes **3**. The diazaphospholes **3d**, **e** are colorless liquids; **3h** is a colorless oil which cannot be distilled.

Meiserstrasse 1, D-8000 München 2 (FRG)

[**] Four- and Five-Membered Phosphorus Heterocycles, Part 64. This work was supported by the Fonds der Chemischen Industrie.—Part 63: J. Högel, A. Schmidpeter, *Chem. Ber.*, in press.

E, they are also not hydrolyzed by conc. hydrochloric acid. **3a**—**c** can be deprotonated with sodium hydroxide and acylated at the nitrogen.

Although in the 1,2,4-diazaphospholes a 1,3-diamino-2-phosphaallyl system is still formally present, the ring closure is associated with an essential change: the color fades, the effect of R on $\delta(^{31}P)$ decreases, and J_{PCH} increases considerably (to around 40 Hz, the normal value for phosphaarenes[4]). These correspond to a change from the (presumed) *cis,cis*-position of the hydrogen in **2a** to the *trans,trans*-position in **3a**, **d**, **g** governed by the ring[10]. As in pyrazoles[11], the hydrogen atom on the nitrogen in **3a-c** exchanges between the two N atoms so rapidly that the compounds appear symmetrical and, e.g., **3a** exhibits two identical (averaged) PCH couplings (Table 1).

[8] General procedure. **2**: $P(SiMe_3)_3$ (50 mmol) is added dropwise over 45 min to **1** (100 mmol) in 200 mL anhydrous acetonitrile. After 10 h at room temperature the solution is concentrated and the residue washed several times with ether; 80—96% yield.—**3**: The particular hydrazine (10 mmol) is added to a solution of **2** (10 mmol) in 30 mL solvent. After completion of the reaction (see Table 1), the solvent is removed, the residue digested with 30 mL ether, the suspension formed filtered through a fine-pore frit after 1—2 d at room temperature, and the filtrate concentrated. The residue consisting of **3** is dried, distilled (**3d**, **e**), or sublimed (**3g** at 20°C/0.001 torr); 40—98% yield.

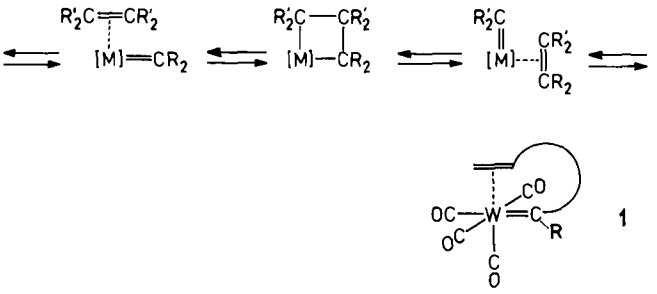
Synthesis and Structure of a (Carbene)(η^2-olefin)$W(CO)_4$ Complex

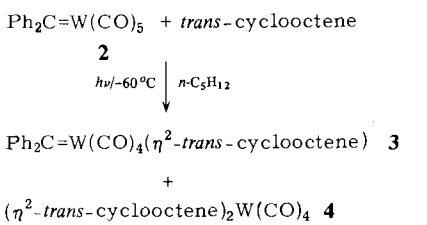
By *Klaus Angermund, Friedrich-Wilhelm Grevels*, Carl Krüger,* and *Volker Skibbe*

According to a generally accepted reaction mechanism[2], carbene(olefin) and metallacyclobutane complexes participate as reactive intermediates in transition metal-catalyzed olefin metathesis[1]. As model compounds, $W(CO)_4$ complexes of the type **1** were synthesized[3,4] in which a carbene(olefin) chelate ligand occupies two *cis*-positions. The stability of these compounds and the orientation of the carbene and the olefin groups—which is of importance for a ring closure to the metallacyclobutane[5]—are strongly influenced by the chelate ring.



1

We have now synthesized a (carbene)(η^2-olefin)$W(CO)_4$ complex without recourse to a stabilizing chelate ligand. The photochemical reaction of the carbene complex **2**[6] in *n*-pentane at −60°C with *trans*-cyclooctene, which proved to be a good coordinating ligand in the preparation of the first (η^2-olefin)$_2Cr(CO)_4$ complex[7], affords the carbene(olefin) complex **3**[8] as major product; small amounts of the bis(olefin) complex **4** are formed concomitantly[10]. Although complex **3** is stable at room temperature in apolar solvents such as *n*-hexane or toluene, work-up and purification of the crude product is recommended to be performed with cooling.



On attempting to introduce the two organic ligands in the reverse sequence using $W(CO)_6$ as starting substance, we obtained pentacarbonyl(η^2-*trans*-cyclooctene)tungsten **5**[11] in the first step. However, attempts to convert a carbonyl group of **5** into a carbene ligand by the usual method[12] failed.

The IR spectrum of **3** shows four bands [2057.5 (w), 1997.5 (w), 1970.5 (vs), 1962 (vs) cm^{-1}; *n*-hexane] in the CO stretching vibration region, which could be indicative of a *cis* arrangement of the carbene and the olefin ligand. The relative intensities of these bands, however, point to an almost square-planar $W(CO)_4$ unit with two *trans* oriented organic ligands[13].

The X-ray structure analysis of **3** (Fig. 1) confirms that the olefin and the carbene ligands occupy *trans* positions on the octahedrally coordinated tungsten; the C13, C14, C15 plane of the carbene and the C=C axis of *trans*-cyclooctene are almost coplanar. Thus, the metal→ligand back-bondings became as strong as possible: because of the almost orthogonal disposition of their π-acceptor orbitals, the organic ligands can employ *two* metal d-orbitals for the back-bonding, and there is no competition with a *trans*-oriented CO group.

The bonding situation in *trans*-(η^2-olefin)$_2ML_4$ complexes is explained in much the same way[13,14]. Such an arrangement of two "single-faced" ligands is always to be expected when π back-bonding contributes substantially to the metal-ligand bond; chelate ligands can, however, command a different geometry.

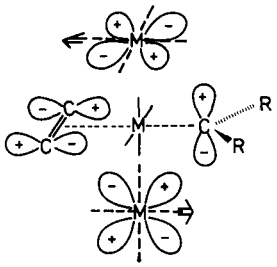
Structure of **3** in the crystal. $P\bar{1}$, $a = 12.193(2)$, $b = 13.359(1)$, $c = 7.0813(7)$ Å, $\alpha = 93.469(7)$, $\beta = 106.873(8)$, $\gamma = 89.017(8)°$, $Z = 2$, $\rho_{ber.} = 1.73$ g cm^{-3}; $\lambda = 0.71069$ Å, $\mu = 53.8$ cm^{-1} (analytical absorption corrections), $R = 0.030$, $R_w = 0.038$; 6706 reflections observed [$I > 2\sigma(I)$], 1512 reflections unobserved; 271 refined parameters; maximal residual density 2.56 eÅ^{-3} (on W). The planes through the atoms W, C5, C6 and the compensating planes through W, C13, C14, C15 form an angle of 8.8°. Selected bond lengths [Å] and bond angles [°]: W-C1 2.072(4), W-C2 2.064(4), W-C3 2.078(4), W-C4 2.055(4), W-C5 2.341(4), W-C6 2.341(4), W-C13 2.067(4), C1-O1 1.138(6), C2-O2 1.131(5), C3-O3 1.134(6), C4-O4 1.142(5), C5-C6 1.389(6); C6-W-C13 162.7(1), C5-W-C13 162.8(1), torsion angle C12-C5-C6-C7 −125.4. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50970, the names of the authors, and the journal citation.

Metallacyclobutane ring closure is not possible in the case of *trans*-oriented olefin and carbene ligands, so it is not surprising that metathesis catalysts usually contain the metal in a higher oxidation state. In these systems the π



back-bonding is weaker and thus its directing influence, smaller. It therefore appears questionable whether carbonylmetal(0) complexes of the type **1** are realistic models for olefin metathesis.

A Novel Entry to the Taxane Structural Unit**

By *Harribert Neh, Siegfried Blechert*, Wolfgang Schnick,* and *Martin Jansen*

Taxanes, such as, e.g., taxinin B **1** or taxol **2**, are unusual hydroxylated diterpenes which occur in plants of the family Taxaceae, to which the yew tree *(Taxus baccata L.)* belongs[1]. The antileukemic and antitumoral activities of some taxanes[1] and the problems encountered in the synthesis of the unusual tricyclic carbon skeleton **3** have aroused increasing interest in recent years[3]. According to in vitro experiments[4], less substituted taxane derivatives could also be biologically active. For this reason it appeared to us that the synthesis of a tricyclic taxane skeleton with functional groups in ring A and ring B which should be readily convertible into hydroxy groups might prove rewarding. We report here on a stereoselective route to the tricycle **4**.

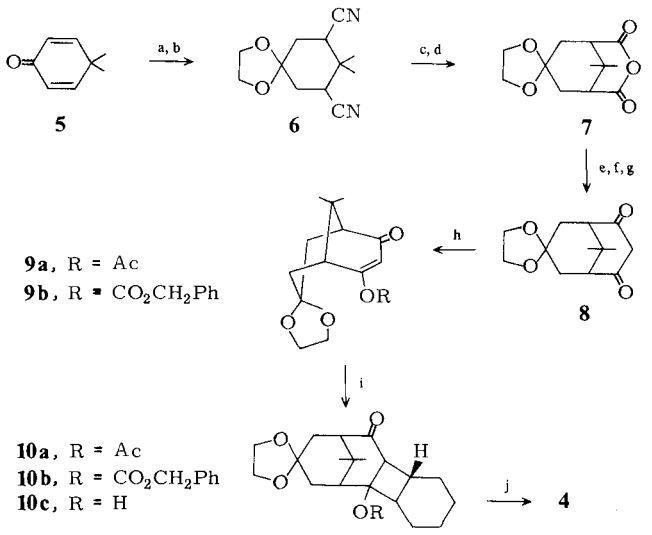
[+] X-Ray structure analysis.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *V. Wray*, Gesellschaft für Biotechnologische Forschung (GBF), Braunschweig-Stöckheim for recording the 400-MHz ^{1}H-NMR spectra.

A problem in the synthesis of the taxane framework is the formation of the eight-membered ring. This has previously been achieved by way of intramolecular Diels-Alder reactions, but this approach involved an aromatic ring C[5] or simply dispensed of the bulky geminal dimethyl group[6]. For preparation of the central ring, we used the de Mayo reaction[7,8]. The key step of our reaction sequence **5**→**4** (Scheme 1) is the stereoselective [2+2]-photocycloaddition of cyclohexenes to the bicycle **9**, since in this way the configuration at C-8 of the taxane framework is fixed. A C-8-α-ring coupling should be possible by a β-*exo* attack of the cyclohexene. As directing substituent we chose a ketal, which we expected would, according to model considerations, favor the formation of a β-adduct.



Scheme 1. a) KCN, NH_4Cl, $(DMF)/H_2O$, 68% yield; b) $HOCH_2CH_2OH$, *p*-toluenesulfonic acid, benzene, 83% yield; c) KOH, H_2O_2/H_2O, 3 d reflux, yield 88%; d) dicyclohexylcarbodiimide, CH_2Cl_2, 91% yield; e) MeLi, −60°C, 55% yield; f) CH_2N_2, 95% yield; g) KH, xylene, reflux, 85% yield; h) Ac_2O/NaOAc, 96% yield or $ClCO_2CH_2Ph$, CH_2Cl_2, aq. $NaHCO_3$, 86% yield; i) cyclohexene/CH_2Cl_2, hv, −78°C, **10a**: 56% yield +15% educt, **10b**: 65% yield +30% educt; j) 0.5 N KOH/EtOH, 15 h, 56% yield.

Our strategy for the synthesis of the 1,3-diketone **8** enabled us to investigate intramolecular photocycloadditions also, since substituted 1,3-diketones can be synthesized from the anhydride **7** by reactions with alkyllithium compounds other than MeLi. Irradiation of the enol acetate **9a** (500 W Hg high-pressure lamp (Pyrex filter), 4 h, −78°C) in a 4:1 mixture of dichloromethane/cyclohexene led to **10a**, which, however, was less suited for the ring-opening, since elimination readily takes place with formation of cyclobutene. The benzyl carbonate **10b**, which is obtainable in 65% yield (30% recovered educt) from **9b** after chromatography can, on the other hand, be converted quantitatively by hydrogenolysis (H_2, Pd/C) into the alcohol **10c**. The very slow retroaldol cleavage leading to formation of **4** (15 h, 0.5 N ethanolic KOH solution) is remarkable. After chromatography on silica gel, during which larger losses occur, the diketone **4** is obtained in 56% yield (m.p. 129—130°C, crystallization from petroleum ether). The configuration at C-3 and C-8 could not be determined unequivocally on the basis of the NMR data[9] in the case of the strongly strained tricycle **4**; however, this could only be established by X-ray structure analysis[10].

$Ag_{1.8}Mn_8O_{16}$: Square Planar Coordinated $Ag^{\oplus}$ Ions in the Channels of a Novel Hollandite Variant**

By *Fung Ming Chang* and *Martin Jansen**

Compounds crystallizing in the hollandite structure (idealized formula $A^{n\oplus}_{(2/n-x)}B_8O_{16}$, n = 1, 2) are currently the subject of numerous studies in the field of solid-state

[*] Prof. Dr. M. Jansen, Dipl.-Chem. F. M. Chang
Institut für Anorganische Chemie der Universität
Callinstr. 9, D-3000 Hannover (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

chemistry[1]. The great amount of interest being shown in these compounds is due to their zeolite-like structure, their possible use as a matrix for the disposal of nuclear waste (^{137}Cs), and as ionic conductors. Furthermore, the hollandite structure is of geochemical significance as a high-pressure form of the feldspars. Hence, it is not surprising that detailed expositions have already been published on the systematic structural classification of this type of structure, and quite clear concepts have so far been presented (and in each case confirmed) about its range of existence as a function of the effective radii of the monovalent and divalent cations A[1b]. During investigations on the thermal degradation of $AgMnO_4$ we obtained $Ag_{1.8}Mn_8O_{16}$, the first compound with hollandite structure which lies outside this range.

$Ag_{1.8}Mn_8O_{16}$ is formed from a mixture of $AgMnO_4$ and Ag_2O in the molar ratio 1:1 at 970°C under 5 kbar oxygen (stainless steel autoclave) within 7 d. Under these conditions $Ag_{1.8}Mn_8O_{16}$ already separates out in coarsely crystalline form (needle-like crystals, maximum dimensions $0.1 \times 0.4 \times 1.0$ mm^3). The by-products, Mn_2O_3 and Ag_2O, can be removed by successive treatment with semiconcentrated nitric acid and dilute hydrochloric acid; $Ag_{1.8}Mn_8O_{16}$ is not attacked by these acids during short periods of reaction.

The complete X-ray structure analysis[2] shows that a Mn_8O_{16} skeletal framework of corner- and edge-sharing MnO_6 octahedra is present in the new compound, which compares in all essential structural features with the corresponding structural unit in $Ba_{1-x}Mn_8O_{16}$, the prototype of this substance class. The channel-like cavities (along [001]) of this skeletal unit consist of cubes coupled via common opposite faces. Surprisingly, the silver atoms do not occupy the centers, but rather the common faces of these cubes (Fig. 1). This leads to unusual square-planar coordination, observed here for the first time, for $Ag^{\oplus}$. A higher oxidation state (2+ or 3+) of silver (with corresponding charge compensation in the Mn_8O_{16} sublattice), for which this coordination would be characteristic, can be ruled out on the basis of the observed bond lengths (Ag–O: 244, in Ag_2O_3[3], e.g., 202 pm). Other than in almost all cases[4], the lattice sites available for $A^{n\oplus}$ ions are, to a large extent, occupied[5]. We ascribe both these peculiarities to a pronounced adaptability of monovalent silver to a given matrix. In oxo compounds $Ag^{\oplus}$ can deviate from the linear double coordination with formation of atypical surroundings with coordination numbers three or four[6]; the short distances between the positions A, which frequently preclude their complete occupation, are, according to recent findings[7], unproblematical in the case of $Ag^{\oplus}$.

As a consequence of the above results, the region of existence of the hollandite structure must be redefined, and arguments regarding the influence of the size of the $A^{n\oplus}$ ion on symmetry-lowering distortions[1b] of the B_8O_{16} framework must be reconsidered.

Hollandites are model substances for the study of one-dimensional ionic conductors. In $Ag_{1.8}Mn_8O_{16}$, the repulsive forces (Born repulsion) on passage of $Ag^{\oplus}$ through a face of its coordination polyhedron, which otherwise are to be overcome during migration of ions in a solid, cannot occur because the silver ions occupy the narrowest siges of the one-dimensional diffusion channels as regular lattice sites. An especially low activation is to be expected for the ionic conduction.

A Novel Iron-Sulfur Cluster with Central Fe_8-Cube: Synthesis and Structure of $(Et_4N)_3Fe_8S_6I_8 \cdot 2\,CH_2Cl_2$**

By *Siegfried Pohl** and *Wolfgang Saak*

Concomitant with the synthesis of a series of iron-sulfur clusters[1-5] in the last few years, models have also been developed for the synthesis of the active center of the FeMo protein of nitrogenase[3,6]. Starting from $(Et_4N)_2Fe_6S_6I_6$[4], we were able to synthesize according to the equation

$$Fe_6S_6I_6^{2\ominus} + 2\,Fe + I^{\ominus} + 1/2\,I_2 \xrightarrow{CH_2Cl_2} Fe_8S_6I_8^{3\ominus}$$

[*] Priv.-Doz. Dr. S. Pohl, Dipl.-Chem. W. Saak
Fakultät für Chemie der Universität

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

a novel Fe–S cluster, whose skeletal structure very closely approaches these model concepts. $Fe_8S_6I_8^{3\ominus}$ was isolated as the salt $(Et_4N)_3Fe_8S_6I_8 \cdot 2CH_2Cl_2$ **1**, which crystallizes in the form of black octahedron. According to an X-ray structure analysis **1** contains discrete $Fe_8S_6I_8^{3\ominus}$ cluster anions (Fig. 1), which, with crystallographic C_{2h} symmetry, exhibit almost O_h symmetry. The eight iron atoms with FeFeFe angles of 90° and Fe–Fe distances of 270.4(8)–273.3(9) pm form an almost ideal cube. With the six sulfur atoms μ_4-bonded over the faces of the cube (Fe–S distances: 230.9(9)–233.2(10) pm) this gives an almost regular dodecahedral array of twelve quadrilateral faces. Hence, with respect to the terminal iodine atoms, this results in a slightly distorted tetrahedral arrangement of the iron atoms with angles between 107.5(5) and 112.6(3)°. The formal oxidation state for all iron atoms is +2.125. We assume that the corresponding fourfold negatively charged cluster, in which the iron atoms would be exclusively divalent, could likewise be prepared on modification of the synthesis conditions; an analogous thiolate-substituted Co cluster has already been described[6].

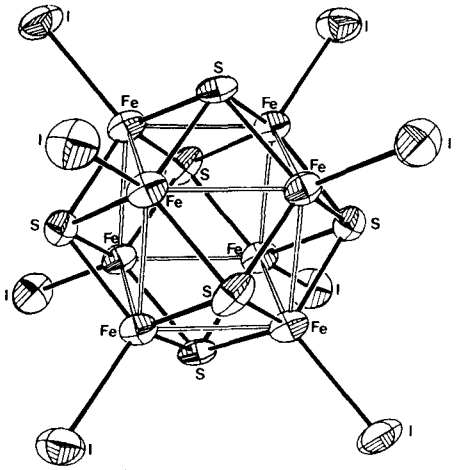

Fig. 1. Structure of the anion $Fe_8S_6I_8^{3\ominus}$ in the crystal of **1**; vibration ellipsoids with 50% probability. Structural data: C2/m, $a = 1707.3(4)$, $b = 2269.4(7)$, $c = 1206.1(2)$ pm, $\beta = 135.22(2)°$, $Z = 2$; 1612 symmetry-independent reflections, 947 observed ($I > 1.96\sigma(I)$); $R_w = 0.072$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51081, the names of the authors, and the journal citation.

According to our investigations on the redox system $Fe/I_2/S/I^{\ominus}$, which previously led to the synthesis of the cluster anions $Fe_2S_2I_4^{2\ominus}$, $Fe_4S_4I_4^{2\ominus}$[7], $Fe_6S_6I_6^{2\ominus}$[4], and now also to $Fe_8S_6I_8^{3\ominus}$, ligand deficiency for the iron atoms is a prerequisite for the formation of a Fe_8S_6 cluster with exclusively μ_4-bonded sulfur. Thus, we could previously only isolate **1** from CH_2Cl_2, a solvent which does not function as a coordinating entity towards Fe. Consistent with this concept, excess sulfur is reduced by iron in the complex, i.e. made available as ligand, with the result that the Fe_8S_6 cluster is converted into products such as $Fe_6S_6I_6^{2\ominus}$ or $Fe_4S_4I_4^{2\ominus}$ containing μ_3-bonded sulfur.

Replacement of an iron atom in the Fe_8S_6 cluster by molybdenum furnishes an atomic ratio which corresponds to that in the FeMo cofactor of *Azobacter vinelandii*[8,9] (cf. also [3]). The synthesis of **1** is thus probably an essential step en route to a compound which can be described as a model substance in the context of the above-mentioned investigations.

Experimental

All operations were carried out under nitrogen in anhydrous, oxygen-free solvents. A suspension of Fe (0.06 g, 1.07 mmol), Et_4NI (0.13 g, 0.52 mmol), and I_2 (0.07 g, 0.27 mmol) in CH_2Cl_2 (60 mL) was heated for 24 h at room temperature. After addition of 1.0 g (0.52 mmol) $[Et_4N]_2Fe_6S_6I_6$, the suspension was repeatedly heated to ca. 60°C in a sealed flask (under pressure). The amorphous precipitate that was formed partly converted into crystalline **1** on being allowed to stand for several weeks at room temperature. The well-formed crystals could be mechanically separated from the amorphous residue in 40% yield. The long time required for crystallization is due to the low solubility of **1** in CH_2Cl_2. It has so far not been possible, however, to synthesize **1** in more strongly polar solvents.

Structure- and Solvent-Dependence in the Complexation of Lipophilic Substrates in a Water-Soluble Azacyclophane**

By *Hans-Jörg Schneider**, *Klaus Philippi*, and *Jürgen Pöhlmann*

Macrocyclic host molecules with cavities of suitable dimensions can bind lipophilic substrates selectively in aqueous solutions[1]. Monitoring the course of such a complexation by the shifts of NMR signals not only affords information about the encapsulation of the substrate[2] but at the same time also serves as a suitable method for measuring small complexation energies which cannot be determined by, e.g., fluorescence spectroscopic methods[3].

A comparison of the complexation energies of substrates of various sizes and polarity provides important information regarding the dominating non-covalent interactions, e.g. in biological systems. The hitherto rarely investigated influence of solvent- and salt-effects is not only of significance for the mechanism of the complexation, but also for the analytical and catalytic uses of such host compounds[4].

Using the cyclization methods described by *Stetter*[2a,5,9], we have prepared the azacyclophane **1**, which, in contrast

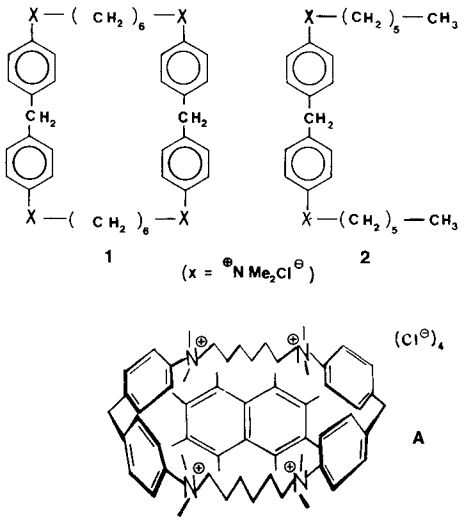
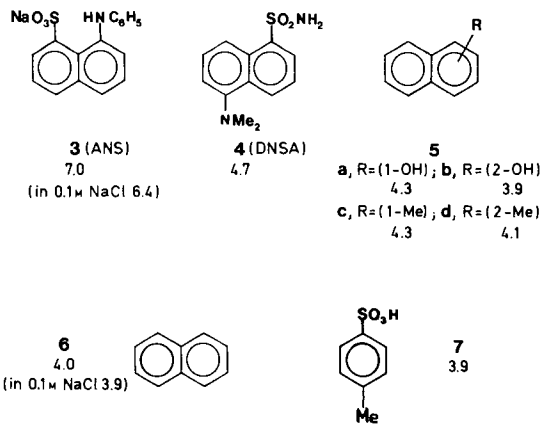
[**] Host-Guest Chemistry, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 1: H.-J. Schneider, K. Philippi, *Chem. Ber. 117* (1984) 3056.

to the analogous host compounds used by *Koga* et al.[2a,b], is, through permethylation, also employable in neutral aqueous solutions and has sufficient methylene groups to accomodate naphthalene derivatives with preservation of a continuous *anti*-conformation of the chain. The shifts of the ^{1}H-NMR resonances of H1 and H2 of $\Delta\delta = -0.91$ and -0.95, respectively, observed in the complexation of naphthalene **6** were analyzed in terms of the anisotropic effects and the significant electric field effects of the ammonium ions. The $\Delta\delta$ values indicate that naphthalene is mainly accomodated equatorially or pseudoaxially (e.g. type **A**); an equilibrium between these forms and small amounts of a conformation with axial orientation cannot be ruled out. Complexations with open-chain host compounds such as **2**, on the other hand, do not lead to any significant shifts in the ^{1}H-NMR resonances.



By NMR spectroscopic monitoring of the reaction of **1** with the guest compounds **4**—**7**, and fluorescence titration of **1** with **3** and **4** in aqueous solutions, we obtained the complexation energies listed in Scheme 1. A numerically simulated curve-fitting was used for the evaluation of binding constants: e.g., the shifts of the ^{1}H-NMR signals of **6** were monitored in water/methanol mixtures (80/20 v/v) between 4×10^{-4}—7×10^{-4} M **6** in the presence of 1.5×10^{-3}—8×10^{-3} M **1**. In the fluorescence titrations the concentrations in water were e.g. 2×10^{-6} mol/L **4** and 0.2×10^{-5}—6×10^{-5} mol/L **1**. The results show that the lipophilic/hydrophobic binding is inadequate in the case of the less voluminous benzene derivatives, whereas in the case of guest molecules having suitable dimensions (**3**—**6**) the complexation energy is increased by about 1/3 by anionic substituents such as in **3**. That compounds without polar substituents are not necessarily more weakly bound (compare **5b** with **5d**, **6**) is consistent with an enhanced hydrophobic effect in the complexation of pure hydrocarbons.

The dominating hydrophobic/lipophilic binding of **3** to **1** is also manifested by the large decrease in complexation energy on increasing the amount of organic solvent. (With predominantly polar bonding the complexation should be stronger in the less polar solvent.) The increase in fluorescence ΔI can serve as a measure of the hydrophobicity (lipophilicity) of a solvent[6]. On plotting the complexation energies ΔG^0 versus the logarithm of the increase in fluorescence ΔI for complexation in water and alcohol mixtures, straight lines are obtained (Fig. 1) whose slopes in the case of the pure hydrocarbon **6** are about twice as



Scheme 1. Complexation energies $\Delta G^0 = RT\ln K$ [kcal/mol] $\pm(0.1-0.2)$ kcal/mol in CH_3OH/H_2O (20/80 v/v) or CD_3OD/D_2O (isotope effect neglected [8]).

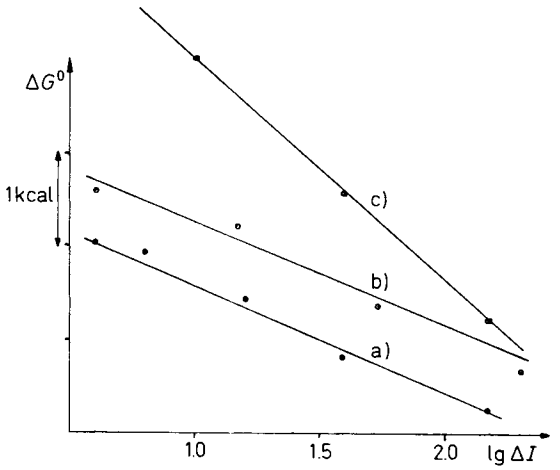


Fig. 1. Free energy of complexation ΔG^0 vs logarithm of the increase in fluorescence $\lg\Delta I$. Solvents: a) **3** + **1** in $MeOH/H_2O$; b) **3** + **1** in $EtOH/H_2O$; c) **6** + **1** in $MeOH/H_2O$.

steep as in the case of **3**. If the transfer energies measured by *Abraham*[7a], e.g. of tetramethyltin from methanol into methanol-water mixtures, are used instead of the ΔI values for the characterization of the hydrophobic properties, a linear correlation ($r = 0.9948$) likewise results with a slope $m = 0.46$ (cf. plot of ΔG^0_{cplx} of **3**). These results underscore the comparable mechanism in the binding of hydrophobic substrates in lipophilic cavities. The substantial decrease in complexation energy observed in some cases upon addition of salts (see Scheme 1) is strongly pronounced in the case of substrates with highly polar substituents, due to electrostatic interactions.

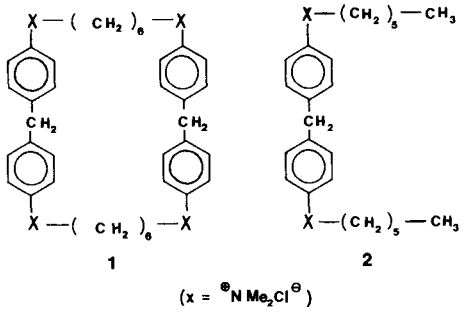
Thin Layer Chromatography with an Immobilized Azacyclophane Derivative as Analytical Agent and Probe for Host-Guest Interactions**

By *Hans-Jörg Schneider**, *Walter Müller*, and *Detlev Güttes*

Dedicated to Professor Egon Stahl on the occasion of his 60th birthday

Macrocyclic compounds enable chromatographic separations of guest molecules by selective inclusion, as demonstrated hitherto mainly with ions[1]. We have found that easily handleable chromatographic techniques are accessible by immobilization of the azacyclophane **1** on silica gel layers. As a rule, the azacyclophane derivative does not hinder detection by fluorescence under the UV lamp or by customary developing reagents[2]. On application of the dissolved substances the starting spots are usually less spread out than on untreated layers. We hoped, by means of this technique, also to obtain information about the nature of host-guest interactions.



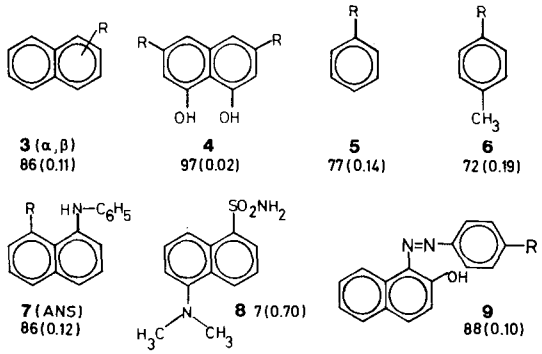
Experiments with aromatic guest molecules, inter alia with azo dyes, show that only compounds with acidic groups, particularly groups such as $R=SO_3H$, are selectively bound. Hereby, we define the selectivity S by the percent decrease in R_f obtained with **1**.

$$S\,[\%] = (1 - R_f/R_{fo}) \times 100$$

[*] Prof. Dr. H.-J. Schneider, Dr. W. Müller, D. Güttes
FR Organische Chemie der Universität
D-6600 Saarbrücken 11 (FRG)

[**] Host-Guest Chemistry, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 2: [3].

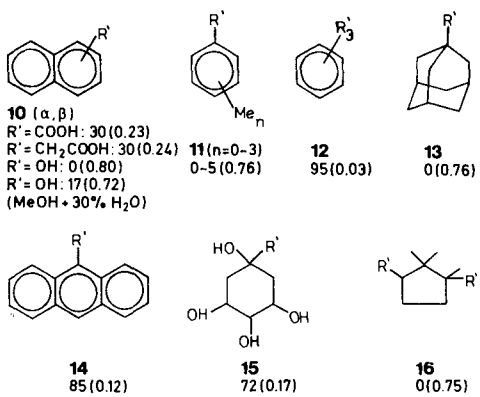
S can reach up to approximately 100%. The S values and, in brackets, R_f values observed for the complexation of **3**—**25** on the chromatographic plates loaded with **1** are given in Schemes 1, 2, and 3.



Scheme 1. $R=SO_3H$, methanol as eluent; error in S: ±4%.

Besides the acidity of the substituents, the geometry of the hydrocarbon framework also has a decisive influence on the selectivity (cf. **5**, **6**); this is consistent with the order of lipophilicity and complexation observed, inter alia, in solution by NMR spectroscopy[3]. For the selective binding of different substrates, a most effective inclusion as possible in the cavity of immobilized **1** is essential. This follows from the generally far higher selectivities of naphthyl derivatives compared to the corresponding phenyl derivatives as well as from the considerably lower selectivities which are found with the immobilized open-chain analogue **2**: Here the S values obtained with sulfonic acids are only 20—40% instead of an average of 88%.

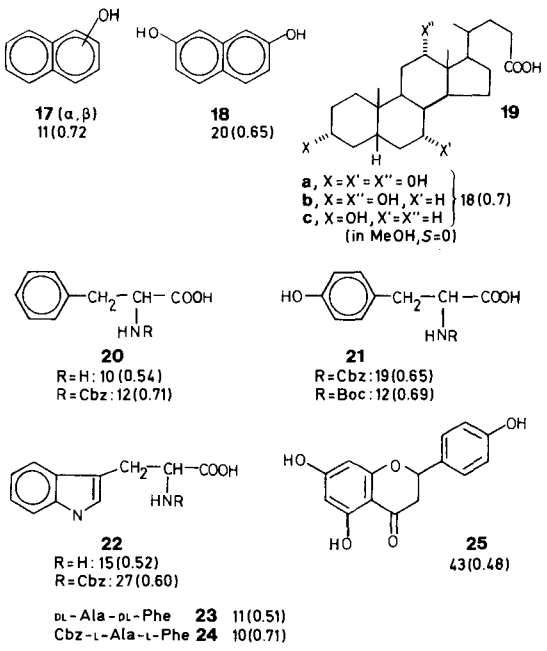
Carboxylic acids are still complexed selectively if the lipophilic residue fits in the cavity of **1** (Scheme 2, compare **10** with **11** and **13**) or if the electrostatic attraction can be realized by several substituents (cf. **12**, **15**). Phenolic groups are not acidic enough to lead to selectivity in methanol. On the other hand, the addition of water in this case leads, as also in solution[1], to a strengthening of the binding (cf. **10**, Scheme 2).



Scheme 2. R'=COOH, methanol as eluent; error in S: ±(4—8%).

A simple strategy for increasing the selectivity in the case of substrates with weakly dissociating groups consists in the use of an alkaline solvent, which enables novel separations to be realized, also in the case of natural products (Scheme 3). In the case of amino acids and peptides, protecting groups on the nitrogen which reduce the betaine participation and enhance the lipophilicity usually effect an increase in the selectivity.

 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/1111-0910 $ 02.50/0



Scheme 3. Methanol with 2% conc. NH_3-solution as eluent; error in S: ±4%; Cbz = benzoyloxycarbonyl, Boc = *tert*-butoxycarbonyl.

According to the selectivities measured here and the findings of spectroscopic investigations in solution[3], the vital factors of the complexation are the lipophilic/hydrophobic binding in the cavity of the macrocycle and the electrostatic attraction between polar substituents in the substrate and the positive charges in the host molecule. The participation of electrostatic attraction should increase in a solvent less polar than water (e.g. methanol)[3], and dominates in the binding to the immobilized macrocycle. This is consistent with the hypothesis that conformational perturbations by the immobilization very strongly affect the dispersive participation of lipophilic interactions, whereas coulomb attractions are notably less geometry-dependent.

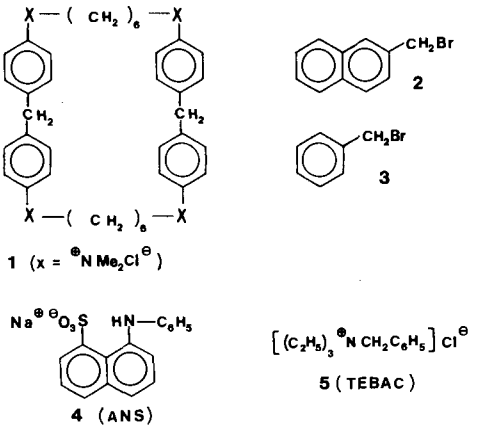
An Azacyclophane Derivative as Catalyst of Substrate- and Product-Selective Reactions with Ambident Anions**

By *Hans-Jörg Schneider** and *Rainer Busch*

The utilization of macrocyclic host compounds as selective catalysts and as enzyme models represents one of the major breakthroughs in organic chemistry[1]. Crown ethers have often been employed for the acceleration of nucleophilic exchange reactions, but mainly as unspecific phase-transfer catalysts[2]. Although cases of a selective complexation of the anion and concomitant enhancement of reactivity are known[3], to our knowledge there are no examples of such reactions with enzyme-like selective substrate binding. After having demonstrated, both spectroscopically as well as by thin-layer chromatography, that naphthalene derivatives are inserted selectively into the relatively easily accessible macrocycle **1**[1a,b], we have investigated the use of **1** in nucleophilic exchange reactions.



Reaction of 2-bromomethylnaphthalene **2** with an excess of sodium nitrite (for concentrations, see Table 1) is accelerated in the presence of **1**, e.g. in a 0.4 M solution of **1** by a factor of 20; concomitantly, the product ratio [R–ONO]:[R–NO_2] obtained with the ambident nucleophile changes from 0.50:1 to 0.16:1 (Fig. 1). However, since **1** is an ammonium salt, the product ratio must be compared with that which is obtained in the presence of Me_4NCl. Considering it this way, the product ratio changes by a factor of about 50 (Table 1). The phase-transfer catalyst benzyltriethylammonium chloride **5** also steers the product pattern in the opposite sense to **1** and without any increase in the reaction rate, thus proving the absence of unspecific effects or micelle effects. Using the pseudo-first order rate constants obtained at the initial stage of the reaction in combination with a numerical curve-fitting, the stability constants of the complex and the rate constants of

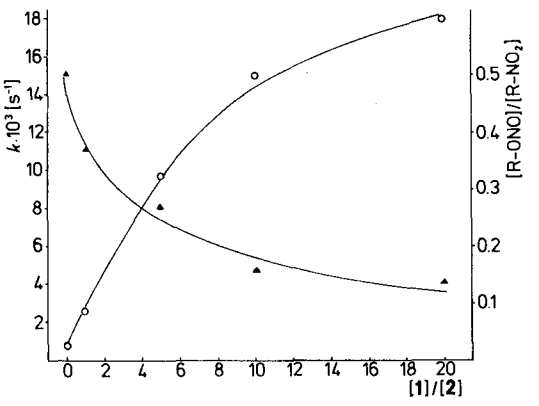


Fig. 1. Experimental rate constants of the catalyzed reaction; o–o–o–o–, left-hand scale; product ratio [R–ONO]/[R–NO_2] as a function of the ratio [catalyst]/[substrate]; ▲–▲–▲–, right-hand scale.

[a] In dioxane/water (1 : 1) at 30 °C. Conditions: nucleophile [Nu] 0.43 M; substrate [**2**] or [**3**] as well as catalyst [**1**] and inhibitor [**4**] 0.043 M in each case; [**5**] 0.43 M; [Me_4NCl] 0.43 M. [b] Rate constant k pseudo-first order [s^{-1}] ± 10%. Kinetics and product compositions analyzed ^{1}H-NMR spectroscopically.

the ensuing reaction (Fig. 1) can be estimated as being ca. $K_a = 4.1$ L/mol and $k_c = 2.1 \times 10^{-2}\ s^{-1}$, respectively[4]. This leads to a value of $k_c/k_o \approx 30$ as a measure of the effectiveness of **1** ("effective concentration"[5]) under the conditions mentioned in Table 1. Both the observed acceleration of the reaction as well as the product control can be interpreted in terms of a "proximity effect"[5] or in terms of an accumulation of nitrite ions at the positively charged centers of **1** in the complex. This leads to an increase in the proportion of S_N2-reaction and thus to increased attack at the nitrogen atom instead of the oxygen atom of the ambident anion.

In the case of $CN^{\ominus}$ and $SCN^{\ominus}$ ions the attack at the carbon or sulfur atom, respectively, predominates to such an extent[6] that **1** no longer effects a change in the product ratio, though a marked increase in the rate of reaction is still observed (Table 1).

On addition of the fluorescence indicator **4**, which binds very strongly to the macrocycle **1**[1a,b], the catalyst becomes inhibited; this also manifests itself in an unchanged product ratio (Table 1).

In contrast to the naphthyl derivative **2**, benzyl bromide **3** leads neither to a change in the product ratio nor to an increase in the reaction rate, since phenyl derivatives are far more weakly bound in the cavity of **1**[1a,b]. This is confirmed by the energies of complexation of **2** and **3** with **1** obtained by NMR spectroscopic measurements (**2**: $K_{ass} = 25$, **3**: $K_{ass} = 3.5$ L/mol, measured in dioxane/water (1 : 1) without added salt). The shifts of the ^{1}H-NMR resonances observed only in the complexation of **2** with **1** indicate the formation of the inclusion complex responsible for the catalysis.

The system presented here combines many features typical for an enzyme: Increase in reaction rate, saturation kinetics, substrate specificity, selective control of reaction, competitive inhibition.

Isocyanide Insertion into a Uranium-Carbon Double Bond**

By *Roger E. Cramer**, *K. Panchanatheswaran*, and *John W. Gilje**

Carbon monoxide is known to insert into actinoid-carbon double[1] and single bonds[2,3]. However, the chemically similar, but often more reactive, isocyanides have not been reported[3] to undergo similar reactions.

We have previously reported[4] that acetonitrile reacts at the uranium-carbon multiple bond[5,6] of **3** to produce an imido complex containing a U–N bond with approximately triple-bond character. In related hydrido(organo)-yttrium chemistry, *tert*-butyl isocyanide inserts into the Y–H bond of **1** to afford **2**[7]. The same yttrium hydride reacts with nitriles to produce dimeric complexes containing bridging alkylideneamido ligands[8].

$$\underset{\mathbf{1}}{[Cp_2YH(THF)]_2} + CN\mathit{t}Bu \longrightarrow \underset{\mathbf{2}}{[Cp_2Y(\eta^1 : \eta^2\text{-}HC{=}N\mathit{t}Bu)]_2}$$

$$\underset{\mathbf{3}}{Cp_3U{=}CHPPh_2Me} + CNC_6H_{11} \longrightarrow \underset{\mathbf{4}}{Cp_3U\begin{matrix}\diagup N{-}C_6H_{11} \\ \diagdown C{=}CH{-}PPh_2Me\end{matrix}}$$

Scheme 1. Cp = η^5-C_5H_5, thf = tetrahydrofuran.

In view of the affinity of U^{IV} for hard Lewis bases, the known carbon monoxide chemistry, and related yttrium chemistry, we investigated the reaction between **3** and cyclohexyl isocyanide. In this reaction $C_6H_{11}NC$ inserts into the UC double bond in **3** forming a unique uranaazacyclopropene **4** in which both nitrogen and carbon atoms are

[**] Uranium-Carbon Multiple Bond Chemistry, Part 6. The support of this work by the United States National Science Foundation (Grant No. CHE82-10244 (*J. W. G.* and *R. E. C.*)) and by the Petroleum Research Fund, administered by the American Chemical Society, is gratefully acknowledged.—Part 5: R. E. Cramer, K. T. Higa, J. W. Gilje, unpublished.

tightly bonded to uranium. In contrast to metal-carbon single bonds, where CC single bonds form during insertion reactions, insertion at the U=C double bond leads to a new *unsaturated* ligand.

The reaction of **3** and $C_6H_{11}NC$ (molar ratio 1 : 1, 1 h) in ether produces a red solution from which **4** can be isolated as red crystals in 53% yield after evaporation of the solvent followed by recrystallization from a 1 : 1 benzene-pentane mixture. The ^{1}H-NMR spectrum shows paramagnetically shifted peaks [7], and the IR spectrum is complex, but does not exhibit a peak at ca. 2136 cm^{-1}, a characteristic frequency for $C_6H_{11}NC$[10].

4 can be stored for months in vacuo or under anhydrous nitrogen, but decomposes within seconds if exposed to the atmosphere. It is very soluble in aromatic solvents and ethers, but only slightly soluble in aliphatic hydrocarbons.

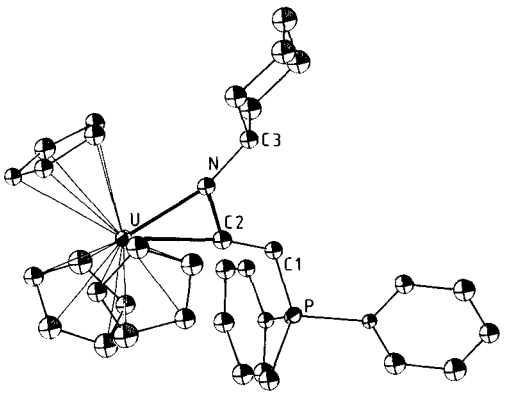

Fig. 1. ORTEP representation of **4**. Angles [°]: U-N-C2 78(1), U-C2-N 68(1), N-C2-C1 122(2), C2-N-C3 120(2), P-C1-C2 124(2), N-U-C2 33.8(9), U-N-C3 161(2). For distances, see text.

The X-ray crystal structure of **4**[11] (Fig. 1) shows that the molecule contains three Cp rings and an η^2-$CN(C_6H_{11})CHPh_2Me$ ligand. The UN distance (2.31(2) Å) is not statistically different from that in Cp_3UNPh_2 (2.29(1) Å), where the UN bond order is between 1 and 2[12], and the UC2 distance (2.44(3) Å) can be compared to the UC single bond distance in $Cp_3UC_4H_9$ (2.43(2) Å)[13]. The distance C1C2 (1.33(3) Å) is typical of a CC double bond, the distance PC1 (1.74(2) Å) is not significantly shorter than that of P–C single bonds in phosphonium ions, and the distance N-C2 (1.39(4) Å) is not statistically different from that of a normal single bond. In contrast, the length of the CN double bond in **2** is 1.275(6) Å[7]. The best description of the bonding is shown in Scheme 1.

Organoactinoid complexes tend to be sterically shielded, but electronically unsaturated[4]. The formation of **4** demonstrates the tendency of U^{IV} to partially relieve its electron deficiency by interaction with multielectron donor ligands.

Di-(μ-amido)dirhodium Complexes: Structure of $[Rh_2(\mu\text{-}(NH)_2naphth)I_2(CO)_2(PPh_3)_2]$

By *Luis A. Oro**, *Maria J. Fernández, Javier Modrego, Concha Foces-Foces,* and *Felix H. Cano*

Dinuclear transition-metal complexes and their reactions have been the subject of considerable interest in recent years[1]. As part of our studies exploring the use of nitrogen donor ligands for the construction of di- or multinuclear rhodium complexes[2], we describe a facile route to di(μ-amido)dirhodium complexes. Amido-bridged compounds are relatively rare[3], and to the best of our knowledge no related di(μ-amido)-bridged metal complexes have been described.

We report here on the synthesis of a novel family of dinuclear amido complexes containing deprotonated 1,8-diaminonaphthalene $[(NH)_2naphth]^{2\ominus}$ as a bisdihapto-bridging ligand. The isolated complexes **1**—**3**[4] were prepared as outlined in Scheme 1[5].

$$2\ Rh(acac)(CO)_2 \xrightarrow[-\ 2\ acacH]{+\ (NH_2)_2naphth} \underset{\mathbf{1}}{Rh_2(\mu\text{-}(NH)_2naphth)(CO)_4} \xrightarrow[-\ 2\ CO]{+\ 2\ PPh_3} \underset{\mathbf{2}}{Rh_2(\mu\text{-}(NH)_2naphth)(CO)_2(PPh_3)_2} \xrightarrow{+\ I_2} \underset{\mathbf{3}}{Rh_2(\mu\text{-}(NH)_2naphth)I_2(CO)_2(PPh_3)_2}$$

Complex **1** exhibits C_{2v} symmetry, and complexes **2** and **3** each show one broad ν(CO) band; the observed shift of the ν(CO) band ($\Delta\nu$(CO) = 70 cm^{-1}) is consistent with a two-center oxidative addition of I_2 to both Rh centers with concurrent formation of an Rh–Rh bond[4].

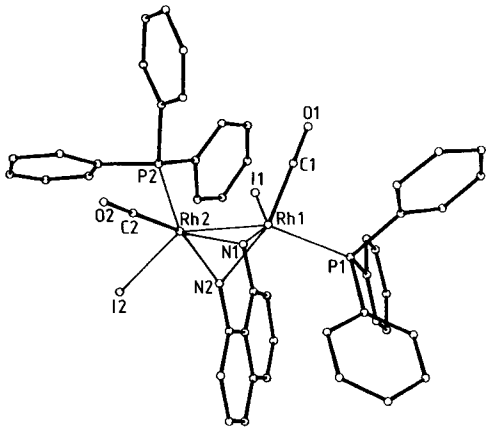

Fig. 1. Structure of $3 \cdot 1/2\,CH_2Cl_2$ in the crystal. Selected bond distances [Å] and torsion angles [°]: Rh1-C1 1.831(23), Rh1-I1 2.692(2), Rh1-P1 2.374(4), Rh2-C2 1.806(17), Rh2-I2 2.742(1), Rh2-P2 2.307(4) and I1-Rh1-Rh2-I2 −127.1(1); cf. also text.

The structure of complex **3** has been confirmed by single-crystal, X-ray analysis[6] and appears to be the first example wherein a rhodium-rhodium bond is bridged by a di(μ-amido) ligand (Fig. 1). The dinuclear molecule has no crystallographic symmetry. The molecule would exhibit a mirror plane through the di(μ-amido) ligand if the sets of P, C, I ligands were mutually twisted through −120°. Interesting features of the structure are the short distance between the Rh atoms (2.540(1) Å) and the low value of the RhN-Rh angles (75.5(4) and 74.5(4)°). The Rh-N bond lengths (2.078(12), 2.072(10), 2.081(12) and 2.117(12) Å) are similar to those found in some related amido-bridged platinum(II) complexes[3].

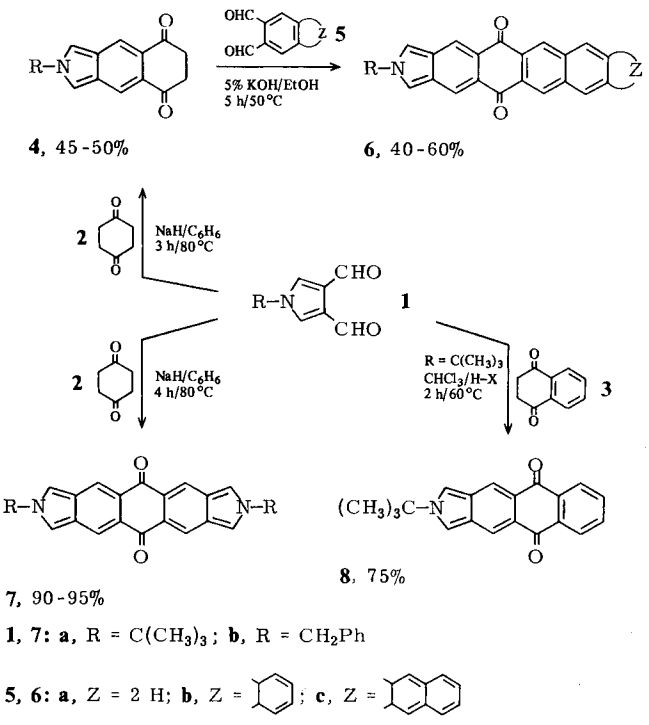
Oligocyclic Hetarenes with Quinonoid Structure; Synthesis by Sequential Cyclizing Condensation**

By *Richard P. Kreher** and *Jürgen Pfister*

Due to the *o*-quinonoid structure[1], the synthesis of annelated 2*H*-isoindoles is very exacting. For the rational preparation of oligocyclic hetarenes **6**, **7** and **8**, practicable, universally applicable synthetic steps are required. According to our findings the cyclizing condensation[2] of hetero- and carbocyclic dicarbaldehydes **1** and **5**, respectively, with 1,2-bifunctional CH-acidic dicarbonyl compounds **2**, **3**, or **4** fulfills these requirements.

A general method has been developed for the preparation of the requisite 1-alkyl-1*H*-pyrrole-3,4-dicarbaldehydes **1** from the readily accessible *N*-alkyl-*N*-formylglycines[3–5].



1, 7: a, R = $C(CH_3)_3$; **b**, R = CH_2Ph

5, 6: a, Z = 2 H; **b**, Z = ; **c**, Z =

1a and **1b** are condensable with 1,4-cyclohexanedione **2**[6] if sodium hydride in anhydrous benzene is used for the deprotonation and induction of the twofold elimination of water. Reaction of equimolar amounts of **1** and dione leads to formation of the isolable primary condensation

[**] Structure and Reactivity of Isoannelated Heterocyclic Systems with $4n\pi$- and $(4n+2)\pi$-Electrons, Part 11. This work was supported by the Fonds der Chemischen Industrie.—Part 10: R. Kreher, K. Mildenberger, *Chem.-Ztg. 108* (1984) 317.

products **4**, which according to the spectroscopic findings are present in the carbonyl form [ν(CO) = 1680 cm^{-1}]; in trifluoroacetic acid the tautomeric hydroxy form of the condensation product is formed.

Due to the carbonyl structure, the tricycles **4** are ideal components for the synthesis of oligocyclic (4n + 2)π-systems with *o*- and *p*-quinonoid structure. We have now found that further sequential condensation with **1** affords access to the 2*H*-isoindoles **7**, which are fused via carbonyl groups in the 5,6-position [ν(CO) = 1660 cm^{-1}]; these symmetric pentacyclic hetarenes can be prepared in one step from the educts **1** and **2** in the molar ratio 2 : 1. The alternative condensation of **4** with the carbocyclic 1,2-dicarbaldehydes **5a—c** opens up an entry to the oligocyclic hetarenes **6a—c** [ν(CO) = 1670 cm^{-1}]. The synthesis of these topologically interesting N-heterocycles by the methods commonly used so far[1] would be too tedious and expensive.

1,4-Naphthalenediol, which, in the carbonyl form **3**, reacts as a 1,2-bifunctional CH-acidic component, can be used instead of **2**. Cyclizing condensation of **3** with **1a** provides a rational access to the tetracyclic hetarene **8** [ν(CO) = 1650 and 1660 cm^{-1}][7].

The ochre to red colored oligocyclic hetarenes **6a—c** [λ_{max}(CHCl$_3$) = 415—525 nm] and **8** [λ_{max}(CHCl$_3$) = 465 nm] are soluble in trifluoroacetic acid and concentrated sulfuric acid; the colors of these solutions are different (green to violet) and are presumably determined by solvation and association. The extremely high melting points of **6** (m.p. > 350°C), **7** (m.p. > 350°C) and **8** (m.p. = 264—265°C) demonstrate the astonishingly high thermal stability of these compounds and are indicative of association in the solid state. The IR bands for the carbonyl groups [ν(CO) = 1650—1670 cm^{-1}] differ very little from those of the structurally similar acenoquinones[8] [ν(CO) = 1670—1675 cm^{-1}].

In the ^{1}H-NMR spectra ($CDCl_3$) the chemical shifts for 1-H and 3-H (δ = 7.58—7.66) in the position adjacent to nitrogen are dependent upon the degree of annelation; the deshielding effect of the acene system gives rise to a downfield shift. According to the ^{1}H-NMR spectra in trifluoroacetic acid, **6** and **8** are protonated exclusively at the position adjacent to the nitrogen; no evidence has been found for a protonation of the carbonyl groups. Hence, the vinylogous acid amide structure has no influence on the reactivity of the oligocyclic hetarenes **6** and **8**. In the case of the pentacyclic benzo[1,2-*f*;4,5-*f*']diisoindoles **7** a protonation of the two terminal pyrrole rings is detectable.

Despite multiple annelation, the characteristic properties of 2*H*-isoindoles[1] are preserved: **6** and **8** react with dimethyl acetylenedicarboxylate at room temperature; cycloaddition at the 1,3 position leads to formation of crystalline 1 : 1 adducts **9**. In the case of **7**, twofold cycloaddition affords 1,2-adducts **10** with *syn*- and *anti*-configuration.

The reactivity and regioselectivity towards dienophiles is accordingly not changed by the linear annelation; regiospecific reactions of the *peri*-positions are not detectable—even in the case of the heptacyclic hetarene **6c**. In this respect there are marked differences to the π-isoelectronic acenes[9].

The oligocyclic hetarenes[10] **6**, **7**, and **8** are of interest to us as colored redox systems and as precursors for the reduction to 2*H*-aceno[2,3-*f*]isoindoles.

Carbanion Chemistry. By *R. B. Bates* and *C. A. Ogle*. Springer-Verlag, Berlin 1983. vii, 117 pp., bound, DM 48.00.

The title and size of this work raise hopes of an introduction to carbanion chemistry; there is an unfilled need here, since the most recent introduction is already ten years old.

However, the foreword reveals that the authors' aspirations are much lower: "This book was prepared with the idea of collecting together some of the multitudinous new literature on carbanions and presenting it along with the fundamentals of carbanion chemistry". Furthermore, an emphasis is promised on results published in the years 1976—1982 with about half of the 785 references.

Eight chapters (74 pp.) deal with the structure, synthesis and reactions of carbanions and organoalkali metal, alkaline earth, aluminium, zinc and cadmium compounds in an exceedingly compressed form. Chapter IX (2 pp.) "Carbanion Equivalents" might well have been omitted without incurring any loss of relevant information; the compilation of (very arbitrarily) chosen synthetic equivalents for not directly accessible carbanions, without commentary, is scarcely helpful. The alternative—a detailed inclusion of preparative applications—would fall outside the framework of this little book.

The number of topics covered in such a small space means that problems can only be touched upon and deeper insights cannot be conveyed. Attempts to extract principles are only occasionally made and even then seem mostly superficial. Thus, concerning the regioselectivity of electrophilic substitution of dianions (a field in which *Bates* is involved) we are only presented with the following rule of thumb (p. 42): "... the first reaction with an electrophile will occur where the last proton came off (assuming the dianion was generated by removal of protons)". Apart from the fact that there are many exceptions to the rule (amongst other reasons because several CH acids can act as precursors for the same dianion), the reader is given no aid in further understanding.

Recent developments, such as dominate the carbanion literature today and which were already in full progress in 1981 (e.g. the stereoselective substitution of carbanions, the change of selectivity by metal exchange, and lithiations directed by heteroatoms), can be recognized by the insider but they merge in the uniformity of the material.

Did the authors just wish to offer assistance in the rapid tracing of original publications? If so there are some minus points to be awarded here. First, they do not fulfill completely the promise they give in the foreword, since only five publications are cited from 1982 (of which three are the authors' own). Furthermore, the reviewer was not able to discover what the criteria were for selecting the literature. Which of the publications are the most important is usually controversial. Apart from this, the literature from German-speaking areas seems to be greatly underrepresented. Only a few groups from this sector may find their contributions adequately represented. The number of references (from a total of 785) is a rough and ready but telling measure: *Seebach* (21), *Schlosser* (6), *Schöllkopf* (5), *Kauffmann* (4), *Hünig* (2), *Bestmann* (1), *R. R. Schmidt* (1), *Reetz* (1), etc. Basic publications also remain unmentioned. For example, there is no mention of the extremely useful allopolarization principle (*Gompper*, review 1976) or of *Boche*'s publications concerning the torsion dynamics of allyl anions; the list could be extended. It is also troublesome that reviews are not labeled and that there is no author index.

The numbers of mistakes and printing errors have been held down to acceptable levels. In spite of the inadequacies discussed this book can be recommended to all who are concerned with carbanions, because everyone will find topics of interest to him amongst the abundance. The newcomer, however, is recommended for introduction, the exciting reading of "Schlosser" (published by the same company in 1973)—Struktur und Reaktivität polarer Organometalle—as a preliminary.

Dynamic NMR Spectroscopy. By *J. Sandström*. Academic Press, London 1982. x, 226 pp., bound, $ 39.50.

This book is neither a new edition nor a substitute for the standard work of the same name published by *Jackman* and *Cotton* in 1975. Those expecting a survey of the most important new DNMR investigations will be disappointed. To be sure almost all the techniques (with the exception of 2 D experiments) are mentioned and typical areas of application presented using examples (ligand permutations of transition metal complexes are missing); however the book is not intended to be a literature compendium but an introduction, stimulation and reference work for the planning and execution of one's own experiments.

Three chapters cover the theoretical basis: the modified Bloch equations for exchange, the application of density matrix formalism to coupled spin systems, the theory of T_1 and T_1 and saturation transfer experiments. The density matrix chapter assumes knowledge of the quantum mechanical description of NMR spectra and linear algebra. A large proportion of interested chemists will probably omit these sections and utilize the currently available computer programs on a "black box" basis.

The following three chapters introduce the practice of spectrum recording and analysis. Thus, sample production, choice of solvent, temperature measurement, line shape evaluation using approximation formulas or total line shape simulation and statistical and systematic errors in activation parameters are among the subjects that are given a detailed and competent treatment. This central section of the book together with the next two chapters. covering specialized techniques (the application of lanthanoid shift reagents, ^{13}C-DNMR, DNMR in the gas phase, etc.) and worked out examples, constitute the most impressive part of the book. A great deal of information scattered throughout individual publications, is summarized here. Even readers already experienced in DNMR spectroscopy will come across some useful information.

The latter part of the book is an introduction to computational methods for the determination of activation barriers. Alongside a short synopsis of quantum mechanical calculations, force field calculations are presented for pseudorotation in ring systems and for rotation in triarylmethyl compounds.

"Sandström" is a book that should be on everyone's desk who is a starter in dynamic NMR spectroscopy. Had

such a book been available in the infancy of DNMR spectroscopy then a large proportion of the false enthalpies and entropies of activation that have given DNMR spectroscopy its reputation for inaccuracy would never have been published.

Membranbiochemie. By *H. Sandermann*. Springer-Verlag, Berlin 1983. v, 131 pp., bound, DM 44.00.

Membrane biochemistry sounds attractive.—The author promises an introduction at the molecular level to biological processes in and at membranes, with emphasis on the properties of the proteins, the lipids, and the polysaccharides bound to them. The book is intended as a university text for students who have completed a basic course in biochemistry and wish to know more about the molecular aspects of membranes, a topic that usually receives only a short treatment in biochemistry textbooks. The requirement is there; one is full of wonderment as to how the topic will be treated in 125 pages.

Many key words of membrane investigation are sketched out in ten chapters: types of membranes, membrane isolation, structure and properties of lipids and biological membranes, methodological approaches to the study of membranes, detergents, membrane proteins including their biosynthesis and isolation, lipid protein interactions, transport through membranes, regulation of the activity of membrane-bound enzymes, chemiosmosis and ATP production, the importance of the polysaccharides on the cell surface including the biosynthesis of glycoproteins and as far as the metabolism of environmental chemicals.

In view of the size of this little book the abundant and highly interesting range of topics damps expectations from the start: it can only consist of a synopsis, which provides the student with key words and hints for further reading—which is no bad thing in itself.

Here, however, one of the failings of the book becomes evident: there is a dearth of references. Methodological approaches to membrane and protein isolation are sketched using several examples. The labeling of a method with a name or a classification as a pioneering piece of work is of little use to the reader. Experimental data, thermodynamic quantities and their interpretation originating from a topical and continually changing area of investigation must be made capable of being placed chronologically and subjected to verification by quoting their sources. This is of particular importance when, as on p. 64, models and analysis are contradictory or various models are compared. Alone the sources of figures are quoted in the figure legends. The general reference to two review journals at the end of the book is valueless without further specification. Standard biochemistry textbooks cannot be recommended for *further reading*, since this little book is intended to supplement them.

The book is derived from a course of lectures and is in its first edition. Because of this there are mistakes; however, they pass the bounds of the acceptable: printing errors, forgotten or wrong units, unacceptable abbreviations and units, errors in chemical formulas and incorrect labeling of axes characterize the book and bewilder the student.

In addition to this there are, particularly in the physicochemical observations, imprecisions of language and confusing argumentations. Unexplained and uncheckable values, as for example on p. 109 concerning the statistics of hexose combinations, should be avoided. Displaced and irregular print in almost all the mathematical formulas make reading more difficult.

What a pity—a good idea, a good beginning, very well chosen material. The strength of this book lies in the descriptive biochemical-biological aspects. The molecular principles, reproduced through physical-biochemical considerations, leave much to be desired, and there is a lack of clear presentation. Perhaps this little book is a beginning; it is certainly not a matured textbook and at a price of 44 DM cannot be recommended to university students, at least in its present form.

Elementary Statistical Thermodynamics. A Problems Approach. By *N. O. Smith*. Plenum Press, New York 1982. xiv, 216 pp., bound, $ 25.00.

Much of the evidence concerning the properties of molecules and their behavior depends on the application of statistical thermodynamics. It should therefore occupy a relevant place in the education of chemists. One of the reasons why this is not universally true may well be that access to this field is not particularly easy: Firstly it is not immediately obvious to the student how the chances of a gambler in a numbers game are related to the specific heat of an alcohol or the lifetime of an activated complex. It is not surprising that American authors in particular attempt to provide students with as smooth an entry as possible into statistical thermodynamics. This little book is an example of a compromised attempt: Some knowledge of chemical thermodynamics, simple functions, differentiation and integration, the treatment of series and some combinatorial analysis is assumed. Even the reminder that $0! = 1$ has not been forgotten. The author employs IUPAC nomenclature and SI units.

The individual chapters of the book cover the usual topics: The statistical mechanics of distinguishable particles; the statistical basis of entropy; thermodynamic functions for systems of localized and distinguishable particles (with the Einstein and the Debye crystal models); systems of non-localized and indistinguishable particles; the thermodynamic functions of ideal gases: Here there is a careful explanation of translational, rotational, vibrational and electronic partition functions, the contribution of the atomic nucleus, ortho- and parahydrogen, and of the influence of internal rotation. This is followed by the statistical thermodynamic calculation of chemical equilibria.

Each chapter is accompanied by cleverly chosen exercises, which not only improve understanding of the basic material but also communicate a feeling for the magnitudes of the relevant thermodynamic probabilities, partition functions, entropies, etc. Some of the exercises are worked through in the text, the solutions to the others are included in an appendix.

The book seems to incorporate a great deal of teaching experience. It can be recommended as an introduction to students of chemistry and other sciences who have sufficient knowledge of English—it is also suitable as a "teach

yourself" book. The price may well ensure a certain exclusivity.

DNA Methylation: Site-Specific Methylations Cause Gene Inactivation

By Walter Doerfler*

In the molecular biology of eukaryotic organisms, the elucidation of mechanisms involved in the regulation of gene expression has assumed an important role. All cells of an organism carry the same genes, but differ in the patterns of genes they express. There is an increasing amount of evidence that cancer cells exhibit a pattern of gene expression which can be very different from that of normal cells. One of the molecular signals that has been recognized in the regulation of gene expression in eukaryotes is the modified nucleotide 5-methylcytosine (5-mC). Through experiments in well-characterized eukaryotic systems, evidence has been adduced that the introduction of 5-mC into highly specific sequences, particularly into the 5′ and promoter regions of a gene, can cause gene inactivation. Viral and other eukaryotic systems have helped in the recognition of this cause-and-effect relationship. Inactive genes are frequently hypermethylated in the promoter region; active genes are hypomethylated. However, these correlations are not always as simple and straightforward. The biochemical mechanisms by which site-specific DNA methylations cause gene inactivation have not yet been determined. It is plausible to postulate that promoter methylations could somehow affect the binding of cellular enzymes involved in recognizing the promoter of a gene. Structural alterations of DNA promoter sequences arising from DNA methylations could also be important. DNA methylation is likely to represent a long-term inactivation signal, since it is presently thought that patterns of DNA methylation can be changed only by DNA replication and specific inhibition of post-replicative maintenance methylation.

1. Introduction

The primary genetic code, the nucleotide triplets in deoxyribonucleic acid (DNA), and its coding function for amino acids in proteins have been deciphered practically completely[1]. In comparing genetic coding principles with those known from linguistics[2], one could equate, metaphorically, the primary genetic code to the vocabulary of a language. Knowledge of the vocabulary of a language, however, does not provide any inkling of its grammar and syntactic intricacies. Similarly, the primary genetic code lacks a description of the rules that dominate the expression of the genetic text and its regulation. It has proved a major task, occupying a sizeable portion of current research in molecular biology, to recognize regulatory signals in the more complex part of the genetic code (secondary and tertiary coding principles). Particularly in higher organisms, the eukaryotes, these regulatory principles of the genetic code appear to be complicated and have not yet been completely unravelled. In this overview article, I shall concentrate on the evaluation of one—seemingly simple—genetic signal: the modulating function of the modified nucleotide 5-methylcytosine (5-mC). There is considerable experimental evidence derived from many different eukaryotic systems which indicates that, as a constituent of specific nucleotide sequences, 5-mC can play an important role in the long-term inactivation of eukaryotic genes[3–6].

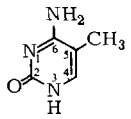
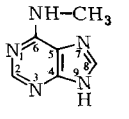
 © Verlag Chemie GmbH, D-6940 Weinheim, 1984 0570-0833/84/1212-0919 $ 02.50/0

The coding and signal values of the four deoxyribonucleotide bases adenine, cytidine, guanine, and thymidine in naturally occurring DNAs can be complemented by specific modifications of some of these nucleotides. The modified nucleotides found in DNA are 5-mC and N^6-methyladenine (N^6mA). The occurrence of additional modifications cannot be ruled out, but they are extremely infrequent and not detectable by the techniques usually employed (see Section 2).



5-Methylcytosine (5-mC)



N^6-Methyladenine (N^6mA)

DNA obtained from prokaryotes can contain 5-mC and N^6mA. In the DNA of higher eukaryotes 5-mC is the predominant modified nucleotide. The biological functions of 5-mC and N^6mA have long been enigmatic. The most clearly established role that DNA modifications have been shown to play is in their generally protective effect against the activity of restriction endonucleases in microorganisms[7]. In almost all instances, restriction endonucleases[8] cannot cleave DNA at nucleotide sequences that have been specifically methylated (Table 1), since interaction between restriction endonucleases and DNA is no longer possible. However, there are interesting exceptions to this "rule". The restriction endonuclease pair *Dpn*I and *Dpn*II from *Diplococcus pneumoniae* are isoschizomeric in that they recognize and cut at the nucleotide sequence 5′-GATC-3′. *Dpn*I is dependent for its activity on the presence of N^6mA in the recognition sequence, whereas *Dpn*II is completely inhibited by the modified nucleotide[9] (Table 1). This example serves to demonstrate that the biological function of a small modifying signal, such as the methyl group in N^6mA or 5-mC, can exert a positive or negative effect on the interaction between specific proteins, in this instance restriction endonucleases and DNA. Thus, the directional significance of this functional modifier is not uniquely determined a priori and seems to depend crucially on the nucleotide sequence and the specific type of protein-DNA interaction it is going to influence.

Table 1. Restriction endonucleases are inhibited by sequence-specific DNA methylation [a].

[a] This table shows examples of methylation-sensitive restrictases. [b] The sequence for one strand is presented in 5′→3′ direction. The vertical arrow designates the phosphodiester bond which is cleaved. All sequences presented are palindromic. [c] Isoschizomeric pair of restrictases which recognize and cleave at the same sequence.

DNA methylation or alterations of specific patterns of DNA methylation have also been implicated to play a role in the repair of DNA, in genetic recombination, in virus latency, in differentiation, in the inactivation of one of the X chromosomes, and possibly in the alterations leading to the transformation of normal cells into cancer cells. In particular, in the more complex biological processes mentioned it is likely that changes in the patterns of DNA methylation directly or indirectly affect the expression of specific genes or of sets of genes. Altered expression patterns of a cell may then cause or be related to more complex changes in the functional phenotype of differentiated cells and cancer cells.

In this review article the evidence will be summarized that has led to the hypothesis that in the higher eukaryotes DNA methylations at highly specific sequences in the promoter and 5′ regions of a gene can lead to its inactivation. It will be apparent from the preceding discussion that the gene inactivating effect of 5-mC can be mediated by modulating specific protein-DNA interactions at specific sequence motifs in the promoter site of a gene (see Fig. 1), by structural alterations of the DNA or by a combination of both. Since demethylation of DNA has as yet not been established, patterns of DNA methylation can only be changed by DNA replication and concomitant inhibition of maintenance DNA methyltransferases (see Section 2). It is therefore plausible to assume that methylations of specific nucleotides in the promoter sequence of a gene will lead to its long-term inactivation. In this context, it is important to realize that a gene can also be inactivated without promoter methylation, e.g. simply due to specific protein-DNA interactions at certain promoter sites. The additional measure of methylation of promoter sites would probably safeguard this inactivation and would render it long-term. Clearly, unmethylated promoter sites do not guarantee gene activity: "An unlocked door is not necessarily open"[10].

The number of publications on DNA methylation and its possible biological functions has grown rapidly in recent years, and I do not intend to present a complete survey of this exciting field. Many review articles on DNA methylation have been published[3-6, 10-18] and three monographs edited by *Taylor*[19], *Trautner*[20], and by *Razin, Cedar,* and *Riggs*[21] have appeared. There is no need to duplicate these efforts. I shall concentrate instead on recent developments and future trends in the field.

2. Basic Facts about DNA Methylation

Methods used to determine methylated bases in DNA are summarized in Table 2. In the DNA, particularly of the higher eukaryotes (vertebrates), 5-mC is predominantly found in the dinucleotide sequence CpG and less frequently in the dinucleotide combinations CpC CpT or CpA[29]. In mammalian DNA up to 90% of the 5-mC residues are found in the dinucleotide CpG. It is interesting to note that this dinucleotide is statistically strikingly under-

Table 2. Methods of determining methylated bases in DNA.

1) Acid hydrolysis of DNA followed by
   a) Two-dimensional chromatographic or chromatographic and electrophoretic procedures [22]
   b) High-pressure liquid chromatography, e.g. [23]
   c) Mass spectrometry
   Disadvantages: low sensitivity, fails to detect sequence specificities.
2) Analysis by methylation-sensitive restriction endonucleases coupled with Southern transfer [24] and DNA-DNA hybridization.
   a) isoschizomeric restrictases [25] [a]
   b) single restrictase [b]—comparison with cloned gene [4]
   Disadvantages: analysis limited to certain sequences. Does not detect all 5-mC residues.
3) Genomic sequencing method [26]
   Direct determination of all 5-mC residues in a DNA sequence.
   Disadvantage: analysis limited to short sequences (ca. 100 to 200 nucleotides).
4) Immunologic methods—antisera against 5-mC.
   Disadvantag: questionable specificity.

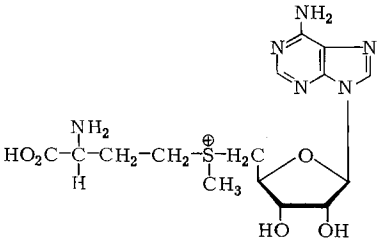
[a] Cellular DNA is cleaved by *Hpa*II or *Msp*I (Table 1), which both cut at 5′-CCGG-3′ sequences. 5′-C^{m}CGG-3′ is refractory to *Hpa*II, 5′-^{m}CCGG-3′ to *Msp*I. Thus it is possible to distinguish 5′-CCGG-3′ sequences from methylated forms of the same sequence. Upon cleavage, DNA fragments are separated by electrophoresis on agarose or polyacrylamide gels, transferred [24] to nitrocellulose filters, and specific sequences are recognized by hybridization to the [^{32}P]-labeled [27], cloned gene followed by autoradiography.—[b] For most sequences containing 5-mC, isoschizomeric restrictase pairs are not available. To a certain extent, one can still recognize these modifications by using restriction endonucleases. The gene to be analyzed has to be cloned and propagated in a C methylation-deficient (mec$^-$ [28] host. The cleavage pattern of the cloned, unmethylated gene is then compared to that of the genomic sequence. E.g.: Methylation of the 5′-GCGC-3′ sequence (5′-G^{m}CGC-3′) can be determined by using the methylation-sensitive restriction endonuclease *Hha*I.

represented in the DNA of eukaryotes[30]. In vertebrates the CpG dinucleotide accounts for 1% of all dinucleotides, whereas statistics would predict 4%. In general, the nucleotide sequences in nature are not assembled statistically, but are highly selected products of millenia of functional optimization. The statistical counter-selection of the CpG dinucleotide in the DNA of eukaryotes suggests that it has a special functional significance. This hypothesis is further enhanced by the finding that the CpG dinucleotide is also the main site of modification by methylation which can lead to inactivation of gene expression.

It has been proposed that the underrepresentation of CpG dinucleotides in the DNA of vertebrates arises because of the high degree of methylation of the cytosine residue in this dinucleotide and the propensity of 5-mC to be deaminated to thymidine. This leads, of course, to the loss of a CpG dinucleotide and its conversion into TpG[31]. On the other hand, in prokaryotes CpG underrepresentation is not found, hence it is difficult to envisage that the deamination hypothesis provides an explanation for the underrepresentation of the CpG dinucleotide.

Although the CpG dinucleotide is drastically underrepresented in vertebrate DNA, clusters of CpG dinucleotides have been observed at the 5′ end of the globin gene[32] and at the 5′ and promoter end of the E1 region of adenovirus type 12 (Ad12) and adenovirus type 2 (Ad2) DNA[4,33]. CpG clusters also occur strikingly frequently around the polymorphic exons of genes of the major histocompatibility complex (MHC) in mouse and man, and at the 5′ end of the mouse dihydrofolate reductase gene and of the chicken α 2-collagen gene[34]. One can only speculate about the significance of these CpG clusters.

DNA methylation is a post-replicative event catalyzed by specific enzymes, the DNA methyltransferases. Some of these DNA methyltransferases from prokaryotes have been highly purified and well characterized, but much less is known about DNA methyltransferases in eukaryotes



S-Adenosylmethionine (SAM)

(see [11,35]). DNA methyltransferases utilize *S*-adenosyl methionine (SAM) as a methyl donor. Functionally, two types of DNA methyltransferases can be distinguished: 1) de novo DNA methyltransferases methylate specific sequences of previously unmethylated DNA; 2) maintenance DNA methyltransferases recognize hemimethylated DNA, i.e. a double-stranded DNA molecule with methyl groups in only one of its strands. Such a hemimethylated DNA duplex is generated, e.g., by one round of DNA replication leaving only one strand methylated. Maintenance DNA methyltransferases recognize methylated bases in hemimethylated DNA and attach a methyl group to the cytidine residue in the symmetrically-opposite position in the complementary DNA strand (Fig. 1). It is not known whether the two types of DNA methyltransferase activities reside in the same enzyme or represent separate entities.

Direct evidence for the occurrence of de novo methylation in eukaryotes comes from a viral system. Viral systems

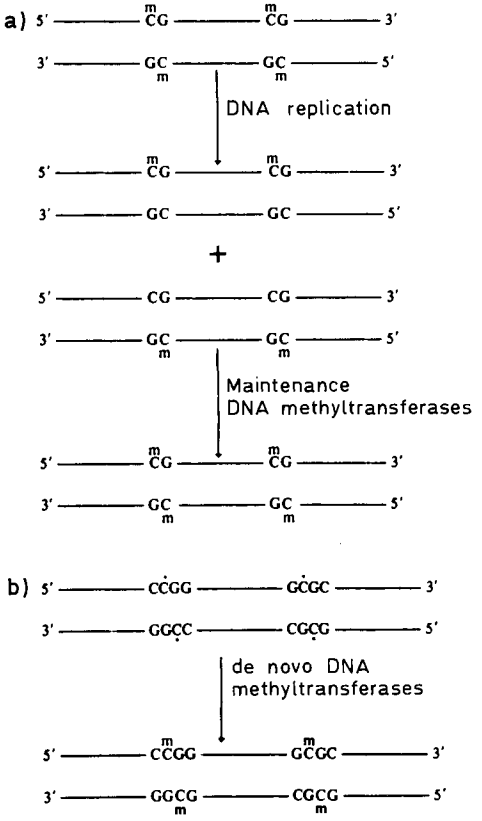


Fig. 1. a) Maintenance and b) de novo DNA methylation [5].

have played an important role in elucidating the function of sequence-specific DNA methylations in vertebrate systems[4]. The DNA of the human adenoviruses, for example, is methylated only when the viral DNA has been integrated into the DNA of the host and has persisted in that state for some time[36–38]. DNA isolated from the virion (virus particle)[22, 23, 39] or extrachromosomal forms of intracellular viral DNA are not methylated (Table 3)[40, 41]. It is therefore compelling to conclude that adenovirus DNA must have undergone de novo methylation some time after integration[46–48] into the DNA of the host cell. It still remains an enigma how the host-DNA-methyltransferases are instructed to highly specifically methylate the foreign, viral DNA molecules previously inserted into the host DNA[42, 43, 45]. Since the parental viral DNA was devoid of 5-mC groups, the methylation had to be de novo.

Table 3. DNA methylation of the genome of human adenoviruses [a].

Type of adenovirus DNA	State of methylation	Ref.
DNA packaged into virus particles	Unmethylated [b]	[22, 23, 39]
Free viral DNA in infected mammalian cells (productive and abortive systems) both parental and newly synthesized	Unmethylated	[40, 41]
Integrated adenovirus DNA in established cell lines	Methylated in highly specific patterns: Active genes are hypomethylated; inactive genes are hypermethylated	[40, 42—45]
Integrated adenovirus DNA in recently produced tumor cells	Hypomethylated. Gradual increase in DNA methylation with passage of tumor cells. Shift in methylation is nonrandom	[37, 38]

[a] The only methylated base detectable is 5-mC [22, 23]. [b] Limit of detectability <0.04% 5-mC [23].

It should be mentioned that the genomes of some cytoplasmic DNA viruses, e.g. of the iridovirus FV3 (frog virus 3), are highly methylated (>20% of all C residues are 5-mC)[49]. There is evidence that FV3 can code for its own DNA methyltransferase, which modifies viral DNA in the cytoplasm of the infected cell[50].

It is important to investigate whether eukaryotic cells have an (enzymatic) mechanism of active demethylation. One report[51] has appeared describing demethylating activity in the nucleus of murine erythroleukemia cells. If a demethylating activity did not exist, the only way of altering patterns of methylation by removal of methyl groups would be DNA replication and concomitant specific inhibition of the maintenance DNA methyltransferases. The element of specifically altering patterns of methylation would remain a puzzle even if a "demethylase" were found.

There is still another problem to be considered. Evidence has been adduced[52] that DNA replication in mammals is temporally bimodal. A certain group of genes, the so-called household genes, which function in practically every cell, replicate during the first half of the S phase of the cell cycle. Tissue-specific genes, which are expressed only in certain organs, e.g. the insulin gene in the β cells of the Langerhans islets in the pancreas, replicate early in those cells in which they are expressed and late in tissues in which they usually are not. As a consequence of those temporally highly specific patterns of replication of certain groups of genes, these may become transiently hemimethylated (cf. Fig. 1), at least until they are fully re-methylated by maintenance DNA methyltransferase. The question arises whether during the transient state of hemimethylation the genes could be expressed for a short period of time. Thus, even for "inactive genes" in the classical sense of this concept there may be a narrow temporal window during which they could become active. For the further investigation of this concept, it will be important to determine whether hemimethylated genes are active or inactive.

A number of laboratories are now actively pursuing the possibility that specific DNA methylations may alter highly selective protein-DNA interactions. Recently, a protein from human placenta has been purified that binds somewhat better to 5-mC-rich DNA sequences[53]. Undoubtedly, there is already a flourish of experimental activity in this interesting field of biochemistry.

3. The Basic Structure of Eukaryotic Genes

Some of the concepts to be developed in this review article will be more readily comprehensible if the basic structure of the eukaryotic gene is first described[54, 55]. Eukaryotic genes consist of a control region located at the 5′ end of the DNA and the gene proper, the body of the gene, located at the 3′ end (Fig. 2). The designations 5′ and 3′ re-

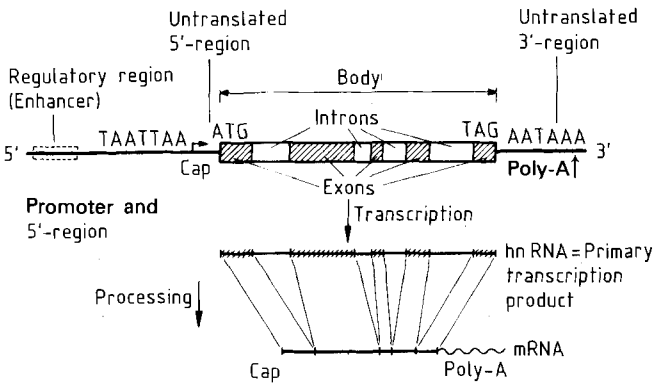

Fig. 2. Schematic representation of the basic features of eukaryotic genes, including transcription and processing of the RNA.

late to positions on the plus[*] strand of the DNA molecule, conventionally written 5′→3′ from left to right, as European languages are written. That part of the control region responsible for binding the transcribing enzyme(s) is called the promoter. The control region is characterized by several features, the TAATAAA (Hogness-Goldberg) box, the cap site (initiation of transcription), and the upstream (5′) controlling elements. These motifs have been shown to be essential for gene expression, some of them presumably functioning by mediating specific protein-DNA interactions, but their exact biochemical functions are not yet

[*] By definition the plus strand of DNA has the same sequence as mRNA.

known. The body of the eukaryotic gene has 5′ and 3′ untranslated regions attached which do not code for protein sequences. At the 3′ end of the gene is situated an ATAAA signal which is involved in specifying the addition of a polyadenylic acid tail to the messenger RNA. The body of a gene consists of introns (intervening sequences) which are spliced out during processing of the primary transcription product (hnRNA = high molecular weight heterogeneous nuclear RNA) to messenger RNA. The exons (expressed sequences) are spliced together during processing of hnRNA to the functional messenger RNA molecule which is actually translated, beginning at the first functional AUG triplet. In a rigorous definition, it is only the sum of the linked-up exons which constitutes the functional gene, because the message is eventually translated into a polypeptide sequence. The role played by the 5′ untranslated sequence (between the cap site and the ATG initiation codon) and of the 3′ untranslated sequence (beyond the termination codon) is not well understood. The DNA sequences that are functionally modulated by site-specific methylation, thus leading to inactivation of genes, reside in the promoter and 5′ sequences of genes.

4. What Evidence Led to the Concept that DNA Methylation Can Cause Gene Inactivation?

The first speculations relating DNA methylation to the control of gene activity date back to 1964[56] and emanated from work on bacterial systems. More clearly defined hypotheses formulated in 1975 were related to higher eukaryotes[57–59]. Shortly thereafter, experimental evidence was obtained which directly supported the view that inactive genes were hypermethylated and active genes, hypomethylated. *Inverse correlations* of this type[43] were observed in quite different eukaryotic systems in a large number of laboratories. Since the experimental development of these ideas has been extensively reviewed[3–6], I shall only briefly summarize the results.

4.1. Inverse Correlations between DNA Methylation and Gene Expression

Inverse correlations between the extent of DNA methylation and the level of expression of a given gene have been established by analyzing a number of eukaryotic and viral genes in different systems. Since these correlations have so far been mainly restricted to 5′-CCGG-3′ and 5′-GCGC-3′ sequences, it cannot be expected that they apply without exceptions to all the genes investigated since other CG-containing sequences might also be involved. The establishment of such inverse correlations does not, however, allow statements to be made on whether DNA methylation is the cause or the consequence of gene inactivation.

Experimental evidence for such inverse correlations was provided by studies on DNA methylation of a certain gene in different organs of one organism and by studies on viral systems[37,42–45,60–72]. Viral systems yielded strikingly clear results. For a given gene that was actively expressed in one organ, many of the 5′-CCGG-3′ sequences were found to be unmethylated, whereas the DNA in the same gene in other organs where it was not expressed was completely methylated at these sequences.

In integrated viral genomes, unexpressed genes were hypermethylated, while transcribed genes showed low levels of methylation. In Table 4 examples of cell lines transformed by adenovirus type 2 are shown in relation to the expression and methylation of the E2a gene of adenovirus type 2 DNA[40]. The 5′-CCGG-3′ sequences were investigated because of the availability of the isoschizomeric restriction endonuclease pair *Hpa*II and *Msp*I[25], which permitted determination of the state of methylation at all the 5′-CCGG-3′ sites. In many genes this state of methylation appears to have special significance. In some cases[37,45], these inverse correlations have been extended to other sequences containing 5′-CpG-3′ dinucleotides, e.g. the sequence 5′-GCGC-3′, the recognition sequence of the restriction endonuclease *Hha*I.

Table 4. Inverse correlations between DNA methylation and E2a expression in cell lines HE1, HE2, and HE3.

Cell line [73]	E2a gene and late promoter [44] persisting in integrated form	mRNA [74]	E2a protein [75]	Methylation [40] of 14 CCGG sites in E2a gene
HE1	+	+	+	−
HE2	+	−	−	+
HE3	+	−	−	+

As expected, inverse correlations between gene activity and DNA methylation at 5′-CCGG-3′ and 5′-GCGC-3′ sequences do not invariably exist. Such apparent discrepancies lack significance unless substantiated by very careful analyses of the gene investigated. In some genes DNA methylation at sites other than *Hpa*II or *Hha*I sites may be important for regulation. Unusual methylation patterns with respect to expression have been reported for the estrogen-inducible vitellogenin genes A1 and A2 in the hepatocytes of *Xenopuls laevis*[76]. These genes are heavily methylated irrespective of expression, while other Xenopus laevis genes show the usual inverse correlations.

4.2. Studies on Expression of in vitro-Methylated Genes

The establishment of correlations raises interesting questions in biology, but does not help to determine a cause-and-effect relationship. In order to resolve whether DNA methylation was the cause or the consequence of gene inactivation, in vitro-methylated cloned genes were microinjected into the nuclei of Xenopus laevis oocytes[77–81] or into mammalian cells in culture[82–84] and the activities of these genes subsequently studied. Genes methylated at specific sites were not expressed. The use of sequence-specific de novo DNA-methyltransferases from prokaryotic organisms allowed the determination of highly specific sequences involved in the control of gene expression. Other sequences, e.g. the 5′-GGCC-3′ sequence methylated in vitro, did not exhibit any effect on gene expression[33,79]. These data derived from studies of different systems in different laboratories provided direct support for the concept that methylated sequences at highly specific sites play an

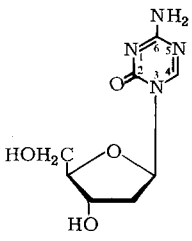
important role in the regulation of gene expression. Furthermore, these observations demonstrated that DNA methylation caused transcriptional inactivation, at least in the genes studied, and was not a consequence of gene inactivation.

Other authors[85] used a DNA methyltransferase from rat liver which methylated all 5′-CpG-3′ dinucleotides in a Moloney murine leukemia proviral DNA clone. The biological activity of the methylated clone was found to be reduced by three orders of magnitude in transfection assays, whereas methylation of thirty-five 5′-CCGG-3′ sites by the prokaryotic *Hpa*II DNA methyltransferase had a lesser effect. However, in vitro methylation of all the CpG dinucleotides of polyoma DNA and SV40 DNA by the same rat liver enzyme led to viral DNAs which were still fully infectious[86]. In these experiments, however, it could not be ruled out that the transfected DNA had replicated and thus had become demethylated. When the cloned murine leukemia provirus was methylated with *Hpa*II DNA methyltransferase, it was also only slightly inactivated[71]. It is apparent that the sequences susceptible to methylation may be quite different for individual genes.

From our own contributions to this particular problem, it appeared important that work on the in vitro methylation of adenoviral genes be preceded by a thorough investigation of the state of methylation of the same gene in the integrated form in transformed cells[40,43,45]. Since only two DNA methyltransferases, *Hpa*II and *Hha*I, were available for these studies, we had to ascertain whether the 5′-CCGG-3′ and 5′-GCGC-3′ sites were actually involved in the regulation of this particular gene. Thus, in vivo studies proved to be an important prerequisite for the successful design of in vitro investigations. Moreover, it was essential to ascertain that in vitro DNA methylation of a gene was complete before attempting to test its transcriptional activity. Complete methylation was tested by cleavage with *Hpa*II, *Msp*I, or *Hha*I, followed by Southern[24] blotting and hybridization. As discussed in Sections 5 and 6, in vitro specific DNA methylation and the ensuing analyses of the effects of these modifications on gene expression has been refined by methylating only specific parts of genes.

4.3. Inhibition of DNA Methyltransferases by 5-Azacytidine

Further evidence for the role played by DNA methylation in the regulation of gene expression comes from studies with the cytidine analogue 5-azacytidine (deoxyribonucleoside).



5-Azacytidine
(Deoxyribonucleoside)

This modified nucleoside can be incorporated into replicating DNA, but cannot be methylated in the 5-position. However, the main inhibitory role of 5-azacytidine toward DNA methylation stems from its ability to inhibit DNA methyltransferases[87-90]. In a number of different systems it has been possible to activate dormant genes and to induce their expression[90-94]. The original report on the gene activating property of 5-azacytidine described the activation of a complex set of cellular functions leading to in vitro differentiation of mouse fibroblasts to muscle cells which were shown to contract in culture[95]. Specific genes could be turned on even in animals by treatment with 5-azacytidine[96] and in humans[97]. In this way fetal hemoglobin synthesis was stimulated in anemic baboons and γ-globin synthesis selectively increased in patients with β^+-thalassemia. Concomitant demethylations in the genes involved could also be shown[97]. Since 5-azacytidine is a highly toxic agent, patients must not be treated without carefully weighing the risks and benefits in each individual case.

It is not to be expected that all dormant cellular genes can be reactivated by treating cells with 5-azacytidine. Absence of DNA methylation appears a necessary but not a sufficient condition for gene activation[37,67,98,99]. A mechanism as essential as gene activity is probably subject to several regulatory mechanisms, DNA methylation being one important parameter. Thus, depending on the stringency of inactivation for a given gene, 5-azacytidine treatment may or may not lead to the activation of a certain gene or set of genes. For example, in an Ad12-transformed hamster cell line (T637), the inactive and hypermethylated late viral genes, which are integrated into the host genome, could not be activated by 5-azacytidine, although changes in patterns of DNA methylation were detected[33]. The results obtained by 5-azacytidine induction are interesting but are also problematic to some degree, since a toxic analogue could always have additional, poorly understood effects, and the interpretation of the induction phenomena may be more complicated than previously thought.

Interestingly, in vitro studies using DNA methyltransferase from mouse spleen indicate that chemical carcinogens inhibit the transfer of methyl groups to hemimethylated DNA. Perhaps carcinogenic agents might lead to heritable changes in DNA methylation patterns by a variety of mechanisms[100] and thus alter the patterns of gene expression in cancer cells (see Section 8.3).

5. The Promoter and the 5′ End of Genes are Sensitive to DNA Methylation

In several eukaryotic and viral systems, absence of DNA methylation at the 5′ ends and/or promoter sites of genes correlates with the active state of genes[45,98,99,101-105]. The vitellogenin gene in chickens could be activated by treatment with estrogen, the activation being accompanied by demethylation of a 5′-CCGG-3′ site at the 5′ end of this gene[104]. Since the decisive interactions between the DNA sequence of a gene and the transcriptional machinery of the cell have to occur at the promoter and 5′ end, DNA methylation should affect gene expression chiefly at these sites. Within the promoter region different sequences could be important for the regulation of individual genes.

We have analyzed in detail the state of methylation of a large number of 5′-CCGG-3′ and 5′-GCGC-3′ sequences in

integrated adenovirus genes in three different Ad12-transformed hamster cell lines[45]. Most of the early viral genes are expressed in these cell lines (horizontal arrows in Fig. 3), and the 5′ and promoter regions of these genes are unmethylated at the 5′-CCGG-3′ (◇ in Fig. 3) and 5′-GCGC-3′ sequences (not shown in Fig. 3). The states of methylation of the 3′-main parts of the early viral genes do not correlate with their activity. The 5′-CCGG-3′ and 5′-GCGC-3′ sequences in the integrated late viral genes, which are not expressed, are all methylated[43] (data not shown in Fig. 3). In the cell line HA12/7 (Fig. 3), the E3 region is not expressed (no horizontal arrow), and accordingly the 5′-CCGG-3′ (and 5′-GCGC-3′) sequences at the 5′ and promoter ends of this region are all methylated.

of these cells. Thus, those cells in which the methylation patterns of viral genes assured permanent inactivation of late viral genes were selected as the stably transformed cells. This particularly stringent mode of selection might explain the very striking inverse correlations between DNA methylation and gene activity described for many integrated viral genes[4].

6. Effect of in vitro Methylation of the Promoter and 5′ Ends of Eukaryotic Genes

The importance of the promoter region in DNA methylation and gene inactivation can be demonstrated experi-

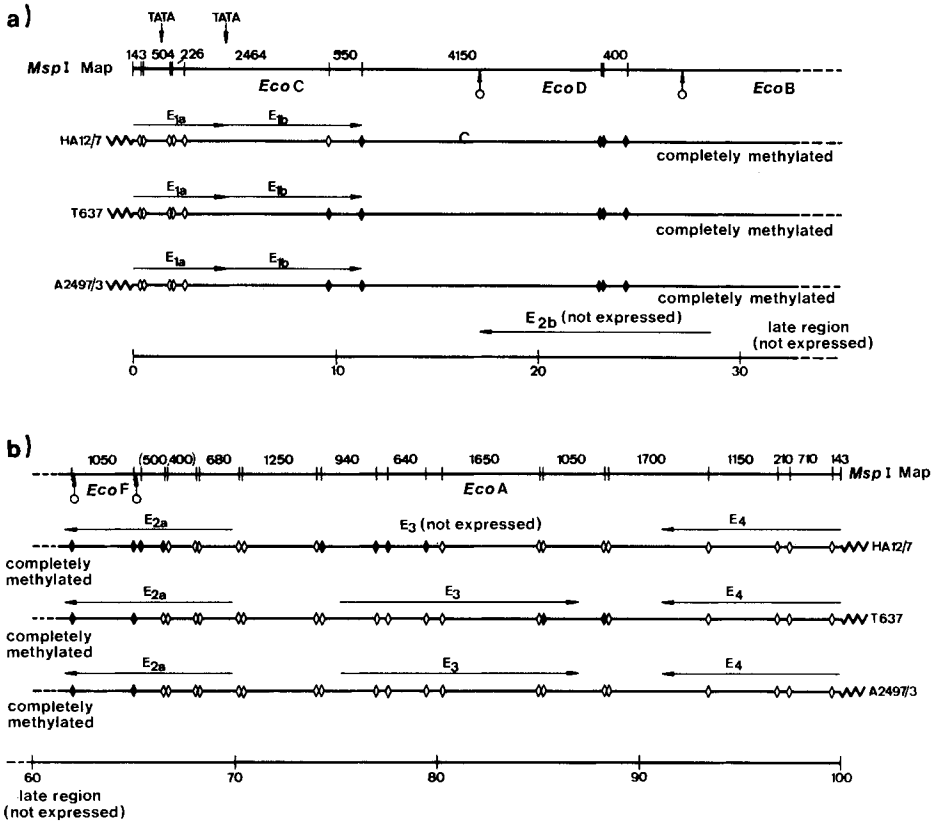


Fig. 3. Functional maps of the left (a) and the right (b) halves of the adenovirus type 12 DNA molecule integrated into cell lines HA12/7, T637, or A2497-3. The horizontal lines represent the Ad12 genomes (—) integrated into the genomes of cell lines (〰) as indicated. The *Msp*I maps of the left (a) and right (b) ends of Ad12 DNA are represented in the top line. Vertical bars on and figures above the horizontal lines indicate the locations of the *Msp*I sites and the sizes of some of the *Msp*I fragments, respectively. The symbols (δ) designate *Eco*RI sites. TATA marks the locations of presumptive Goldberg-Hogness signals in the E1a region. The unmethylated and methylated 5′-CCGG-3′ sites in the integrated Ad12 genomes in the lines HA12/7, T637, and A2497-3 are designated by open (◇) and closed symbols (◆), respectively. The horizontal arrows indicate map positions and the directions of transcription of the individual early regions in each of the cell lines. The presence of an arrow indicates expression of corresponding regions of the Ad12 genome. *Msp*I sites to the right of the *Eco*RI-D/B and to the left of the *Eco*RI-A/F junctions have not been mapped. The early regions of Ad12 DNA [106, 107] are also indicated. The scales at the bottom of each figure show the lengths of fractional units of the viral genome subdividing the molecule into 100 equal units. The map of the E1 region of Ad12 DNA is as described in [108]. This figure was taken from [45].

In viral systems, correlative studies on DNA methylation and gene expression have frequently yielded particularly clear results[4, 5]. Conceivably, in virus-transformed cells the late viral genes have to be inactivated and maintained in the inactive state by particular safeguards, e.g. by the introduction of methyl groups; otherwise, activation of these genes might lead to viral replication and destruction

mentally. The results of three different experimental approaches will be described here: 1) Methylation of the promoter region of the globin gene[109]. Upon insertion of the methylated gene into the genome of a recipient cell, the globin gene was inactive. In a similar experiment, the unmethylated globin gene remained active. 2) The E1a promoter of adenovirus type 12 DNA was inserted in front of

the chloramphenicol acetyl transferase (CAT) gene[102] in a construct[*], pSVO CAT, that permitted promoter insertion[110]. Upon transfection into mammalian cells, the unmethylated promoter was active; however, the 5′-CCGG-3′ or 5′-GCGC-3′ methylated promoter, was inactivated when the methyl groups were positioned upstream from the TAATAAA box. 3) We have tested the transcriptional activity of the cloned E2a gene of adenovirus type 2 after microinjection into oocytes of *Xenopus laevis*[77,78]. This gene encodes a DNA-binding protein[111]. When three 5′-CCGG-3′ sites in the 5′ region of the E2a gene were methylated, the gene was inactive after microinjection. Methylation of eleven such sites in the 3′ main part of the gene left its activity intact[105].

These results are consistent with the idea that the methylation of only very few nucleotides, perhaps only of one nucleotide, in a decisive region of the promoter can inactivate genes. Whether this also applies to other eukaryotic genes remains to be seen.

At this point an important caveat has to be mentioned: In designing in vitro methylation experiments, one must be careful in selecting the sequences that are methylated in vitro: Selection should be based on the results of analyses on the same gene in the inactive state as it exists in living cells. Only then, can one be certain that modified sites are formed that have a function in the permanent shut-off of that particular gene. As an example let us reconsider the E2a gene of adenovirus type 2 DNA (Table 4): In Ad2-transformed cells that do not express this gene, all fourteen 5′-CCGG-3′ sequences are methylated at the second C, suggesting, but not proving, a regulatory role for 5-mC in that sequence. In contrast, in Ad2-transformed cells that do express the E2a gene the same sites are unmethylated[40]. The results of the in vitro methylation experiments detailed in the following section, provide strong experimental evidence for the general concept and identify the 5′-CCGG-3′ sequences in the 5′ region, at least in this gene as decisive sites in gene regulation by DNA methylation. Haphazard approaches to in vitro methylation experiments, in particular with enzymes of as yet questionable specificity, may lack functional significance.

6.1. Inhibition of Transcription of the γ-Globin Gene by Specific Methylations of the Promoter

The complete methylation of CpG sequences in the 5′ region of the γ-globin gene between nucleotides −760 to +100 prevents its transcription[109]. There are eleven CpG dinucleotides in this stretch of 860 nucleotides. It has not yet been elucidated which of these nucleotides are decisive in shutting off gene expression. The authors used the in vitro methylation procedure[82] based on replicating a gene, in this case the γ-globin gene, in the single-stranded vector M13 in the presence of 5-methyl dCTP. By choosing the appropriate primer fragment for this in vitro replication reaction, specific segments of the gene and its flanking sequences can be methylated. In this way, the cytidine residues in a certain segment are methylated; this method therefore does not permit identification of the functionally significant nucleotides. The cloned γ-globin gene, various regions of which were thus hemimethylated, was then cotransfected into Ltk$^-$ murine cells, an established mouse cell line, with the thymidine kinase gene of herpes simplex virus. Cell clones containing both the γ-globin and thymidine kinase genes were selected. It was found that the CpG methylation pattern introduced in vitro was maintained in both strands of the gene and was faithfully inherited in this system, as previously reported for other genes[112]. Methylation in the region from −760 in the 5′ flanking region of the γ-globin gene suppressed globin expression, whereas methylation of C residues of the γ-globin gene (from +100 to +1950) in the 3′ region had no effect on globin gene transcription[109]. These data are in excellent agreement with those described for the adenovirus system. In this context it is interesting that in 15 different mammalian genes the 5′ flanking sequences are enriched in 5′-CpG-3′ dinucleotides, whereas the 3′ regions are rather depleted in these sequences[113]. A high frequency of 5′-CpG-3′ sequences at the left terminus of adenovirus DNA has also been described[4,33]. This 5′-CpG-3′ rich area precedes the E1a region that is important in the regulation of the expression of most other early adenovirus genes[114].

6.2. Methylation of Three 5′-CCGG-3′ Sites in the 5′ Region of the E2a Gene of Adenovirus Type 2 Inhibits its Transcription in Xenopus laevis Oocytes

In Section 4.1, we described perfect inverse correlations between the methylation of all 5′-CCGG-3′ sequences in the Ad2-E2a gene in virus-transformed hamster cells containing viral DNA sequences in an integrated state and the extent to which this gene is expressed (Table 4)[40]. We subsequently showed that in vitro methylation of all fourteen 5′-CCGG-3′ sequences in the cloned E2a gene by prokaryotic *Hpa*II DNA methyltransferase leads to transcriptional inactivation after microinjection into Xenopus laevis oocytes[77,78]. The unmethylated cloned E2a gene is expressed in these cells. We have also reported on the construction of partly methylated clones of the E2a gene[105]. In the promoter (5′)-methylated construct, three 5′-CCGG-3′ sequences at the 5′ end of the subclone were methylated. One of these sites is located 215 base pairs (bp) upstream (bp 26169 of Ad2 DNA), and two sites are located 5 and 23 bp "downstream" from the cap site (bp 25931 and 25949 of Ad2 DNA) of the E2a gene (Fig. 4). This construct was found to be transcriptionally inactive upon microinjection into nuclei of Xenopus laevis oocytes. In the gene (3′)-methylated construct, eleven 5′-CCGG-3′ sequences in the main part of the transcribed gene region were methylated in vitro (Fig. 4). This construct was transcribed in Xenopus laevis oocytes, and at least some of the Ad2-specific RNA synthesized was initiated at the same sites as in Ad2-infected human cells in culture (Fig. 5)[105]. Both mock-methylated constructs were transcribed into Ad2-specific RNA in Xenopus laevis oocytes. Mock methylation experiments were carried out similarly to methylation experiments, except that the methyl donor (SAM) was omitted. These results demonstrate that DNA methylations at or close to the promoter and 5′ end of the E2a

[*] A construct is a highly manipulated plasmid vector into which foreign DNA is often inserted.

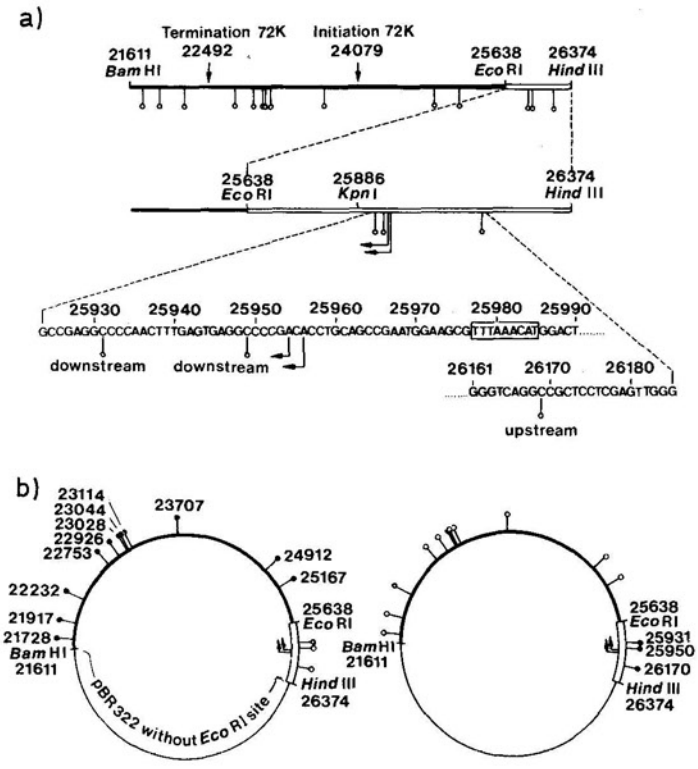

Fig. 4. a) Above: Detailed map of the E2a subclone (*Bam*HI-*Hind*III fragment) of Ad2 of DNA and maps of the promoter (5′)-methylated and gene (3′)-methylated constructs. The DNA-binding protein (DBP = 72 kilodalton protein) is read from right to left. ↓, Initiation and termination sites of translation of the 72 kilodalton protein; ⚲, 5′-CCGG-3′ site; ☤, 5′ C-mCGG-3′ site. The nucleotide sequences of part of the promoter and cap regions (⟵) are shown. The E2a region lacks a canonical TATA (Hogness-Goldberg) signal. The possible equivalent of such a signal has been indicated in a box at ca. 25980. b) Below: Construct which is not methylated (left) or is methylated (right). After injection into Xenopus laevis oozytes, Ad2-specific RNA is found specifically in the first case, but not in the second one. This figure was taken from [105].

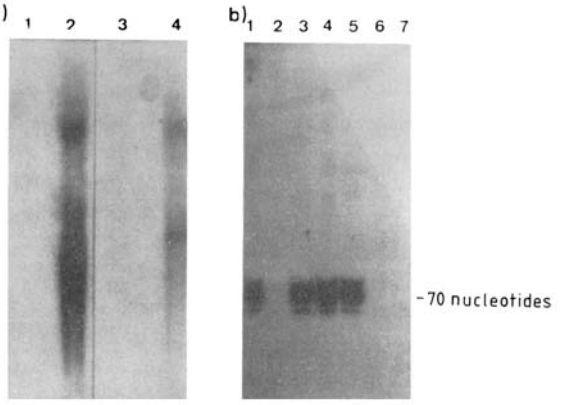

Fig. 5. Methylation of the three 5′-CCGG-3′ sequences in the *Hind*III-*Eco*RI fragment of gene E2a Ad2 DNA (Fig. 4) causes transcriptional inactivation. *Xenopus laevis* oocytes were microinjected with the *Hpa*II methylated (lane 1) or the unmethylated (lane 2) plasmid clone containing the entire *Bam*HI-*Hind*III fragment of gene E2a, the *Eco*RI-*Hind*III promoter (5′)-methylated construct (lane 3), or the *Bam*HI-*Eco*RI gene (3′)-methylated construct (lane 4), as indicated. In each experiment, 5 ng of DNA per oocyte was injected. The total intracellular RNA from 15 oocytes was extracted 24 h after microinjection and fractionated on an 0.8% agarose slab gel containing 2.2 M formaldehyde. The RNA was subsequently transferred to a nitrocellulose filter, and adenovirus type 2-specific RNA sequences were detected by hybridization to ^{32}P-labeled Ad2 DNA followed by autoradiography. b) As indicated below, RNAs were hybridized to the *Kpn*I-*Hind*III fragment of the E2a region of Ad2 DNA (Fig. 4). This fragment was previously 5′-labeled with γ-^{32}P ATP and polynucleotide kinase. The hybrids were treated with S1 nuclease (200 units), separated on a sequencing gel, and identified by autoradiography. Sources of RNA in individual lanes: 1: Ad2-infected human cells, 12 h after inoculation; 2: oocytes injected with the promoter (5′)-methylated construct; 3: oocytes injected with the gene (3′)-methylated construct; 4: oocytes injected with the cloned unmethylated E2a gene; 5: same as lane 4 except that the E2a gene was grown on a dam$^-$ E. coli strain; 6: same as lane 5, except that dam$^-$ plasmid was completely methylated at the 5′-CCGG-3′ sites; 7: RNA from *Zea mays*, negative control. This figure was taken from [105].

gene cause transcriptional inactivation. Perhaps only one methyl group may be adequate for inactivation; in vivo methylation of more than one cytosine may be a form of safeguard or redundancy.

The E2a promoter of Ad2 DNA was also inserted into the pSVO CAT construct and the activity of the unmethylated or the methylated DNA was tested after transfection into human HeLa cells. The results of in vitro promoter methylations were the same in the mammalian system as compared to the amphibian oocyte system: The methylated promoter was inactive, and the unmethylated promoter, active[115].

6.3. Expression of the CAT Gene in Mammalian Cells under the Control of Adenovirus Type 12 Promoters: Effects of Promoter Methylation on Gene Expression

The effect of DNA methylation at specific promoter sites on gene expression was tested by using a sensitive and quantitative assay system. The plasmid pSVO CAT contains the prokaryotic gene chloramphenicol acetyltransferase (CAT) preceded by a *Hind*III site for experimental promoter insertion. Upon insertion into pSVO CAT, the E1a and protein IX gene promoters from adenovirus type 12 DNA were capable of mediating CAT expression upon transfection into mouse cells (Fig. 6, 7)[102].

The CAT-promoting activity of the early simian virus 40 promoter in plasmid pSV2 CAT is insensitive to methylation by *Hpa*II and *Hha*I DNA methyltransferase at the 5′-CCGG-3′ and 5′-GCGC-3′ sequences, respectively, because the promoter lacks such sites. The CAT coding sequence of this plasmid carries four *Hpa*II but no *Hha*I sites. Methylation of the *Hpa*II sites in the coding region does not affect expression. The E1a promoter of Ad12 DNA, comprising the leftmost 525 base pairs of the viral genome, carries two 5′-CCGG-3′ and three 5′-GCGC-3′ sites upstream from the leftmost TATA signal. Methylation of the *Hpa*II or *Hha*I sites incapacitates this promoter in mouse cells (Fig. 7)[102]. Similar results were obtained with the E1a promoter in human HeLa cells and hamster BHK21 cells. Again, methylation inactivated this promoter[127]. The promoter of protein IX gene of Ad12 DNA contains one 5′-CCGG-3′ and one 5′-GCGC-3′ site downstream and two 5′-GCGC-3′ sites >300 base pairs upstream from the TATA motif. The protein IX promoter is not inactivated by methylation of these sites[102]. These data demonstrate that critical 5′ methylations in the promoter region decrease or eliminate transcription; methylations of sites too far upstream and probably sites downstream from the TATA site do not seem to affect expression.

The results discussed in the three preceding sections attest to the methylation sensitivity of two adenovirus pro-

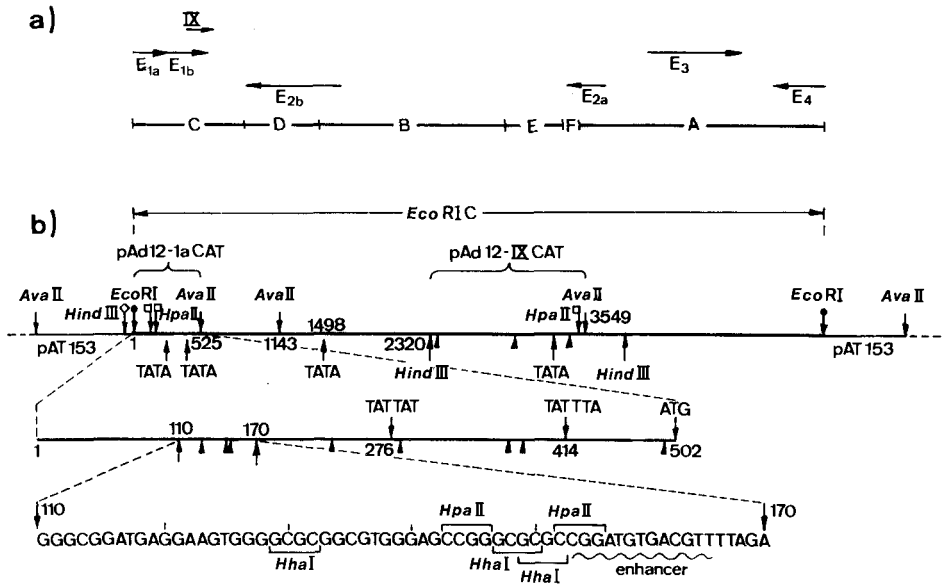

Fig. 6. Map of the Ad12 genome and functional anatomy of its leftmost *Eco*RI-C fragment. a) Functional map of Ad12 DNA [45]. E1a, E1b, E2a, E2b, E3, and E4 designate the early regions of the viral genome; IX designates the location of the protein IX gene of Ad12. Letters refer to DNA fragments on the restriction maps. b) Detailed map of the left-terminal *Eco*RI-C fragment with restriction sites as indicated. Numbers refer to base pairs (bp) counted from the left terminus of viral DNA. TATA (TATTAT, TATTTA) designate the presumptive Hogness-Goldberg boxes. The nucleotide sequence between bp 1 and 502, and 110 and 170, resp., [108] is also included. *Hpa*II (5'-CCGG-3') and *Hha*I (5'-GCGC-3') sites (Δ) are indicated. This figure was taken from [102].

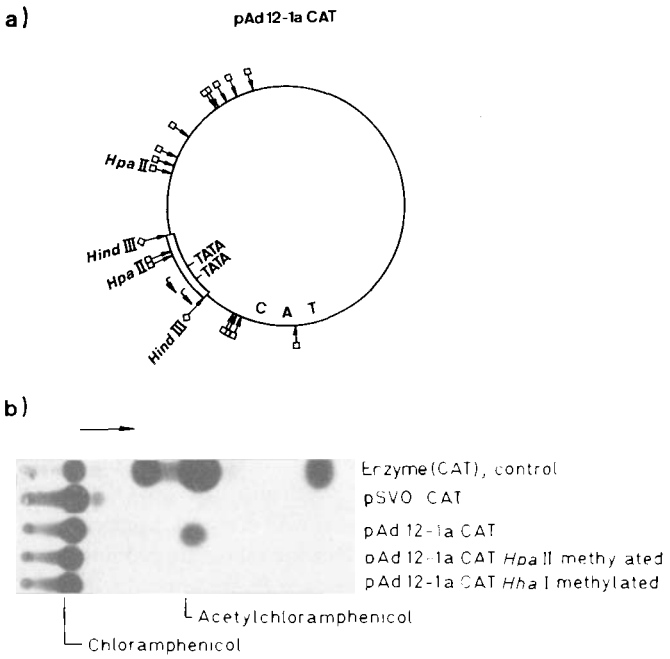

Fig. 7. The E1a promoter of Ad12 DNA mediates CAT expression and is inhibited by methylation. a) Map of the pAd12-1a CAT construct; ⍒ designates 5'-CCGG-3' (*Hpa*II) sites; ⌐→ esignates the approximate TATA positions. b) The pAd12-1a CAT preparation was in vitro methylated by the *Hpa*II or *Hha*I DNA methyltransferase. This figure was taken from [102].

moters and of the globin gene promoter. The data on the viral systems demonstrated that methylation had to occur at specific sites to elicit gene inactivation. One of the viral promoters (E2a of adenovirus type 2) was tested in amphibian oocytes and in mammalian cells; sensitivity toward methylation was the same in both vertebrate systems. Gene activity and its shut-down by site-specific promoter methylation were investigated with the viral gene in the extrachromosomal state[102, 105] or with the globin gene integrated into the recipient cell DNA[109]. In conjunction with the bulk of evidence derived from correlative experiments discussed in Section 4, the data make a strong case for the regulatory function of site-specific promoter methylations in higher eukaryotes.

7. The Occurrence of 5-mC in *Drosophila* is Questionable

The genetics and the molecular biology of *Drosophila* have been studied in considerable detail, and it now represents one of the most thoroughly investigated eukaryotic systems. It is still questionable whether the DNA of Drosophila cells contains any 5-mC. Many of the standard methods have consistently yielded negative results[23, 116, 117] (the modified base also seems to be absent from the DNA of *Saccharomyces cerevisiae*[118]). Recently, it has been claimed that immunological methods have revealed one 5-mC residue per ca. 12500 bases in Drosophila DNA[119]. It is conceivable that even very low levels of 5-mC could exert regulatory functions when positioned in highly strategic points. On the other hand, it has been argued that DNA methylation as a regulatory function is a late addition to the phylogenetic series. Hence, *Drosophila* and other lower eukaryotes—apparently like the prokaryotes—might well be capable of functioning without this regulatory tool. More research will be required to answer these questions, which I consider to be still unresolved.

8. The Possible Role of DNA Methylation in Complex Biological Phenomena: Differentiation, Mutagenesis, and Oncogenesis

It has been convincingly demonstrated that the inactivation of one of the X chromosomes in female cells can—at least in part—be ascribed to site-specific DNA methylation[90, 120]. Genes located on an inactivated X chromosome can be reactivated by growing cells in the presence of the 5-mC analogue, 5-azacytidine. Genes of the reactivated X chromosome could be identified by their products because heterokaryons had been used for the reactivation experiments. The inactive X chromosome was that of human cells in mouse-human hybrid cells. This interesting example emphasizes that complex patterns of differential gene expression or of the shut-off of entire groups of genes can be governed by DNA methylation as a long-term signal for gene inactivation. It is thus plausible that specific methylation patterns have been implicated in affecting other complex biological phenomena.

8.1. Differentiation

Differentiation of cells to functionally highly specific organs as well as the development of pluripotent, undifferentiated cells to organisms with many different highly specialized cell systems can be viewed as the result of a very complicated program of gene activations and inactivations. In highly specialized cells many genes have to be permanently inactivated, and DNA methylation is believed to be at least one of the decisive mechanisms involved in this long-term shut-off of genes. We do not yet understand what mechanisms could account for the apparent specificity of the de novo DNA methylation that would probably have to accompany this inactivation program. Speculations about a specialized arrangement of DNA in chromatin are not satisfactory, since the problem is then transferred to the question of how chromatin arrangements could be generated that are specific enough to attain signal function for DNA methyltransferases. In any event, high priority will have to be given in the future to detailed analyses on DNA methyltransferases.

If specific DNA methylations were a signal for long-term gene inactivation, one would not expect genes to be inactivated by methylation that require to be occasionally reactivated or that have a low level of activity. It is clear that mechanisms other than DNA methylation must be involved in gene inactivation, e.g. specific proteins binding to regulatory DNA sequences. DNA methylations may only modulate these protein-DNA interactions. For example, certain genes encoding essential functions may have to be occasionally reactivated and should not be shut off permanently. A further interesting example are genes that can be activated by steroid hormones; these genes are usually not methylated. For other genes we do not yet sufficiently understand their temporal activity patterns to predict the extent of DNA methylation. It is assumed that highly specialized genes remain active only in certain organs of an animal. Can one, however, be certain that these specific messages are not also occasionally produced in other cells of the organism? If such necessities arose, DNA methylation would not be the signal of choice to inactivate this set of genes. With this reasoning, a scheme can be developed that operationally subdivides genes into at least three classes[17]:

1) Permanently inactivated genes
2) Inactive genes that are occasionally reactivated
3) Active genes

This classification will undoubtedly have to be refined as an improved understanding of differential gene activities emerges. In this simple scheme, DNA methylation would be expected to be a signal of inactivation in class I genes only.

8.2. Mutagenesis

Reports have appeared[94] which demonstrate that the presumptive inactivation of a gene, the inactivation of the thymidine kinase (tk) gene in "tk^- mutants", is due to site-specific DNA methylation. The "mutation" in that particular case could be reversed by growing the "mutant" cells in the presence of 5-azacytidine. As explained in Section 4.3, this analogue inhibits the maintenance DNA-methyltransferases and hence leads to a decrease in DNA methylation and to the induction of previously inactivated genes. This interesting experiment points out the necessity of reexamining the definition and concept of mutation.

8.3. Malignant Tumors

There is an increasing amount of evidence that the DNA in many tumors is strongly hypomethylated compared to the DNA in normal cells[121]. This hypomethylation has been observed for DNA in general[122], as well as for specific genes[123]. Cancer cells differ from normal cells in many respects, certainly by altered patterns of expression of many genes, not only of the fashionable oncogenes[124, 125]. These two findings—decreased levels of DNA methylation and altered patterns of gene expression in cancer cells—are fully compatible with each other. The bulk of the work in the future will have to concentrate on demonstrating specificities in gene activation or inactivation and in differentiating between cause and effect. I caution the reader against drawing hasty conclusions. Hypomethylation has *not* been shown to be causally related to malignant transformation; it could be one of the many epiphenomena that have in the past sometimes been mistaken for etiologic leads. Nevertheless, the search for specificities in changes in methylation patterns in cancer cells will continue.

In conclusion, I should like to describe an example from our own work on the adenovirus system[37, 38, 126]. The analysis of methylation patterns of adenovirus type 12 DNA in virus-induced tumors revealed that in tumor cell DNA the integrated viral DNA sequences were still hypomethylated although viral DNA was not extensively expressed. Upon explantation of tumor cells into culture, the extent of methylation of viral DNA increased gradually with continued passage of the tumor cells in culture. This increase was not random but followed a certain pattern leading eventually to the hypermethylation of the integrated late viral genes[38]. Similar observations were made when the cells

were subcloned at an early stage after explantation from the tumor. At present, it is not understood what factors regulate the establishment of organized patterns of methylation of the viral genome after insertion into the host genome. Concomitant with, but perhaps only temporally related to the increase in viral DNA methylation, the viral genome had a tendency to be excised again and lost from the host cells during early passages after explantation[38].

9. Outlook

As is frequently the case in research, investigations on the biological role of DNA methylation have raised more questions than they have answered. Work on DNA methylation has developed into a rapidly expanding field. Among the most important issues under investigation in several laboratories are the following:

1) Promoter methylations at specific sites and sequences, and their effect on gene activity,
2) Significance and mode of generation of complex patterns of DNA methylation, particularly in the non-promoter parts of genes,
3) Specificity and regulation of activity of DNA methyltransferases in eukaryotic cells,
4) The problem of active demethylation,
5) Application of the genomic sequencing technique[26] to establish precise patterns of DNA methylation, particularly in inactivated promoter sequences,
6) Mechanism and biological significance of shifts in patterns of methylation,
7) Binding of (specific?) proteins to methylated DNA,
8) The role of DNA methylation in the formation of chromatin,
9) The function of DNA methylation in complex biological processes.

I am greatly indebted to Petra Böhm for her expert editorial assistance in preparing this manuscript. Research in the author's laboratory was supported by the Deutsche Forschungsgemeinschaft (SFB74-C1), by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, and by a donation from Hoechst AG.

The Homoaldol Reaction, or How to Overcome Problems of Regio- and Stereo-selectivity**

New Synthetic Methods (50)

By Dieter Hoppe*

Dedicated to Professor Wolfgang Lüttke on the occasion of his 65th birthday

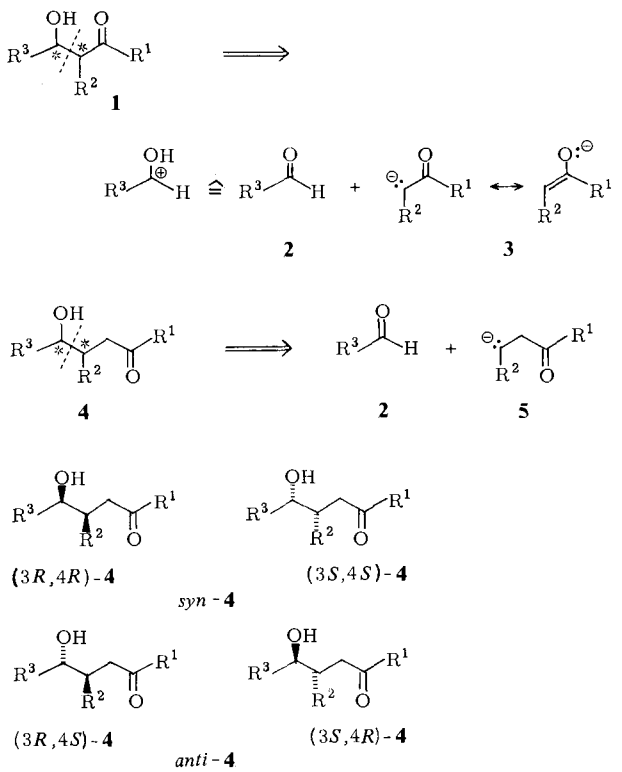
Even today, there are conspicuous gaps in the register of organic synthetic methods. Thus, numerous types of homoenolate reagents are listed; yet no generally applicable method for the homologue of the aldol addition, viz. the homoaldol addition, is to be found. The methods documented up to 1980 offer only singular solutions, and, moreover, are not stereoselective. The present article gives an overview of the existing possibilities and then describes how the gap can be closed by using a new class of homoenolate reagents: 2-alkenyl esters of *N,N*-diisopropylcarbamic acid are lithiated and the resulting allyllithium compounds tailored to high regio- and diastereoselectivity in addition reactions to the carbonyl group via metal exchange. Altogether, the homoaldol reactions now offer a general and reliable, highly stereoselective entry to γ-hydroxycarbonyl compounds, whereby the C(β)–C(γ) bond is formed. Furthermore, it is demonstrated how problems associated with the application of allyl anions as synthetic reagents can be solved today.

1. Introduction

Nowadays, in the synthesis of an organic compound it generally does not suffice to merely build up the carbon skeleton with a given constitution, i.e. with the correct sequence of atoms. Rather, the target molecule is desired as a pure diastereomer, at least as a racemate (i.e. with a particular relative configuration), or even in enantiomerically pure form (i.e. with a particular absolute configuration). A further difficulty is brought about by the complexity of many target molecules; they—and consequently also the many precursors and intermediates—often carry several functional groups of similar reactivity, of which only one may be transformed in each reaction step. Hence, selective methods and reagents are required, and all the more so the more complex the nature of the target molecule. In order to keep the number of steps small (and thus the overall yield high), each synthetic step should yield not only the correct constitution, but also the correct configuration.

The progress made over the past few years has largely been due to a mastering of these problems as far as standard synthetic building blocks are concerned. The aldol addition and its numerous close and distant relatives are striking examples[1]. For example, several good preparative methods are available for constructing β-hydroxycarbonyl compounds **1** (R^1 = H, aryl, or OH) from the synthons **2** and **3**, which were ascertained by the retrosynthetic analysis[2] of **1** (Scheme 1). They offer specific access to both diastereomers of **1** either as racemate or even in enantiomerically pure form; often, there is a choice of several methods of varying efficiency and simplicity.

Which methods are available for the diastereoselective synthesis of a *syn* or *anti*[4–6] γ-hydroxycarbonyl compound **4**, e.g., a precursor of one of the numerous naturally occurring γ-lactones (Scheme 1)? **4** is homologous to the aldol **1**. From experience gained with the aldol addition, a bond cleavage between the β- and γ-C's to give the aldehyde **2** and the homoenolate anion **5** would seem very tempting; it calls for a "homoaldol addition"[7]. An important consideration here is that the newly created centers of asymmetry, formed upon fusion of two prochiral centers, should be easily controllable.



Scheme 1. Retrosynthesis of aldols **1** and homoaldols **4**. The CIP-descriptors [3] are valid provided R^2 and R^3 = *n*-alkyl. Variation of R^1 has no influence.

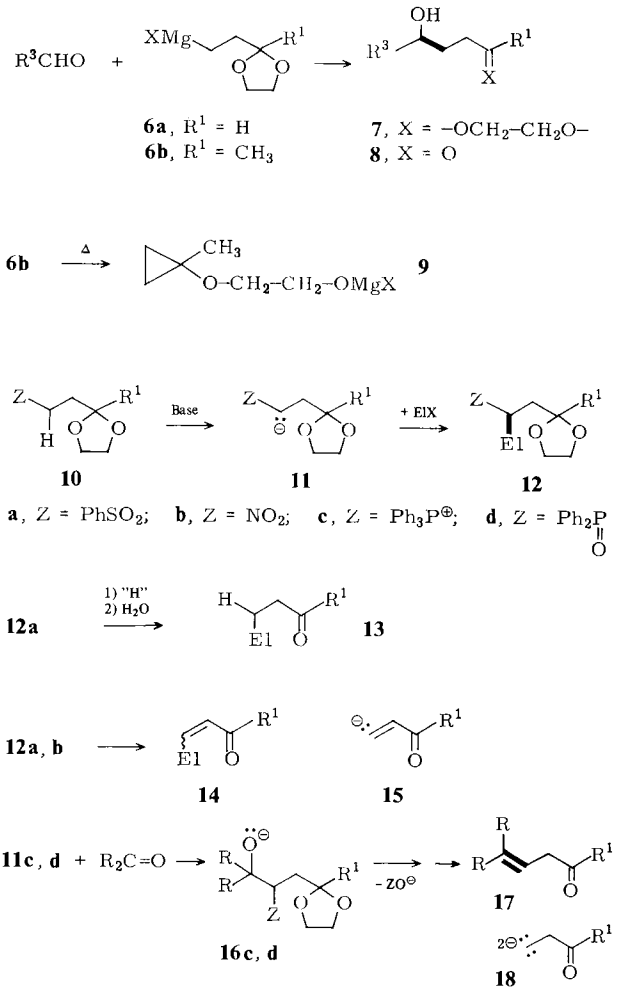
The problem is now to find a reagent[8] for the homoenolate ion **5**, viz. a d^3-synthon[9], which adds diastereoselectively to aldehydes. A literature search up to the year 1981 fails to bring any useful method to light. The difficulty is obvious: the synthon **5** has suffered "umpolung"[9]. In contrast to the enolates, where mesomeric stabilization is the driving force for their formation, the carbonyl group in **5** does not contribute to a stabilization of the negative charge. Furthermore, in enolates **3** the carbonyl group is protected by resonance against nucleophilic attack. Thus, the second problem is apparent: even if it were possible to generate a homoenolate by methods other than deprotonation (e.g. halogen-metal exchange), its carbonyl group and the neighboring hydrogen atoms would be susceptible to side reactions such as transprotonation to form the enolate or uncontrolled additions. Although homoenolates **5** have been detected as short-lived intermediates via deuteration in the β-deprotonation of nonenolizable ketones[8c] under drastic conditions, or in the ring opening of cyclopropanolates[8c], the concentrations of **5** so obtainable are too low for a preparative exploitation.

2. Homoenolate Reagents with Blocked Carbonyl Group—The Defensive Strategy

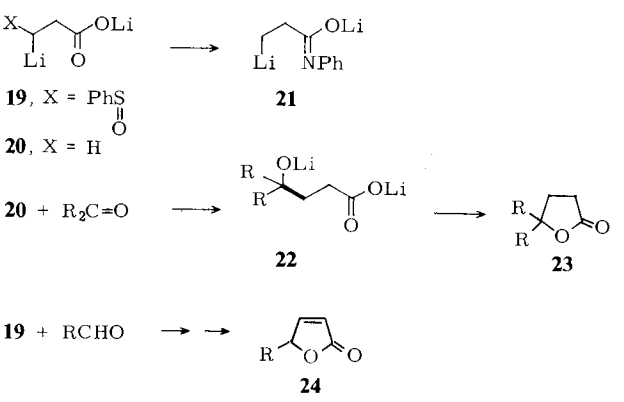
As a consequence of the above, at least the electrophilic carbonyl group must be protected in homoenolate reagents. This defensive strategy was probably used for the first time in 1969 by *Büchi* and *Wüest*[10], who added the Grignard reagent **6a** (generated from the β-bromoacetal) to an aldehyde and subsequently removed the protecting group in the adduct **7** by hydrolysis (Scheme 2). Although **6a**, **6b**, and similar magnesium[11], copper[12], or lithium compounds[13] are more frequently used for propanal- and 2-butanone-d^3-reagents, this solution is apparently not generally applicable, for it has not yet been described for β-alkylated homoenolates. The observations made by *Feugeas*[14] indicate the reason: there is a danger of a 1,3-cycloelimination in **6b** to give the cyclopropyl ether **9**. This tendency should increase with the degree of alkylation.

"Homoenolate ions" of the type **11a** are directly accessible from the acetals **10a** by deprotonation when a stabilizing arylsulfonyl group is present in position 3. However, this simplification in their generation must be paid for at the cost of a further reaction step, namely the reductive removal of the activating group. Some further d^3-reagents have been prepared according to the general principle presented in **11**, i.e. acetalized carbonyl group and strongly electron attracting β-substituent Z. Examples are nitroacetals **11b**[16], phosphonium compounds **11c**[17], and phosphane oxides **11d**[18]. Liberation of the carbonyl group in the adducts **12a** and **b** is followed by an elimination to the α,β-unsaturated carbonyl compound **14**, or else olefins **17** are formed from Wittig intermediates **16c**, **d**. Therefore, these reagents correspond to β-acylvinyl anions **15**[19] or β-carbonyl dianions **18**.

The carbonyl group and neighboring protons in carboxylic acid derivatives can also be deactivated "electronically" by carboxylate resonance (Scheme 3): first one equivalent of base is used to generate a carboxylate; the β-proton activated by the presence of the phenylsulfinyl group is now removed with lithium diisopropylamide to give the dianion **19**[20,21]. **19** has proven of value in the synthesis of 2-buten-4-olides **24**. Dilithium propionate **20**[22], as well as the anilide **21** [23] are also obtainable by way of a halogen or tin/lithium exchange reaction. They were used in the synthesis of γ-lactones **23**.



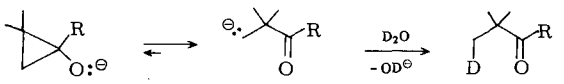
Scheme 2. Acetals as homoenolate reagents. The newly formed bonds are shown in bold print.



Scheme 3. Mesomerically protected homoenolates.

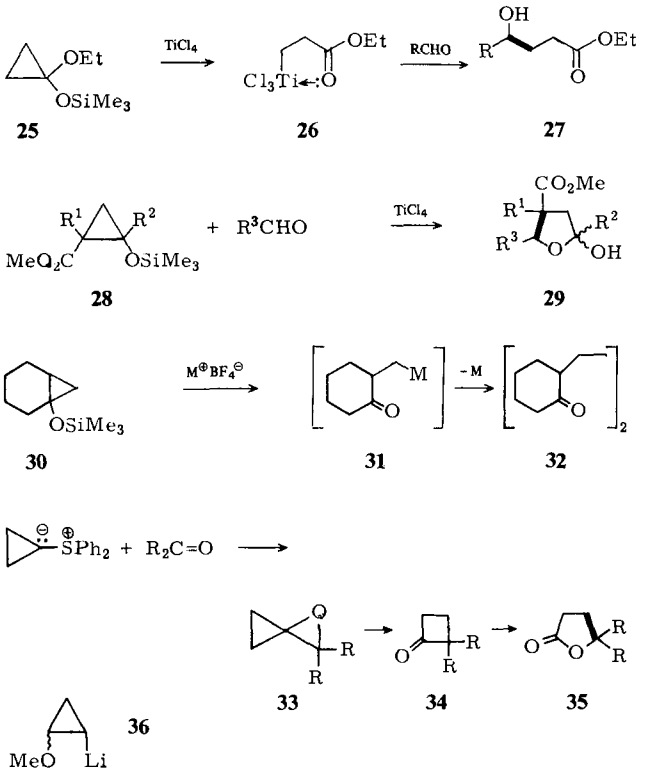
3. The Cyclopropane Route

Several studies have shown[8c] that the ring opening of cyclopropanolates in protic media occurs via β-enolates; yet the carbanion concentrations so obtainable are too low to allow their trapping by electrophiles of lower reactivity than $H^{\oplus}$ or $D^{\oplus}$. However, according to *Kuwajima* et al.[24],



hydroxyalkylation of acetals such as **25** with aldehydes to give γ-hydroxy esters **27** can be carried out in the presence of equimolar amounts of titanium tetrachloride (Scheme 4); the titanium homoenolate **26** has been characterized as an isolable intermediate[24b]. The analogous trichlorostannyl compound obtained with tin tetrachloride[25] has been characterized by X-ray analysis. *Reissig* has recently shown that 2-silyloxycyclopropanecarboxylic acid esters **28** react analogously to give the γ-lactols **29** with aldehydes[26]; thus, this reagent is more like a γ-oxoenolate and can only formally be regarded as a homoenolate equivalent. The "metal homoenolates" **31** have been proposed as intermediates in the oxidative dimerization of cyclopropyl trimethylsilyl ethers such as **30** to 1,6-diketones **32** in the presence of silver or copper tetrafluoroborate recently reported by *Murai* et al.[27]. Stable "mercury homoenolates"[28] (M = AcOHg in **31**) obtained with mercury(II) acetate are used by the *Giese* group[29] as radical precursors, e.g. in the synthesis of diketones of the type **32**.

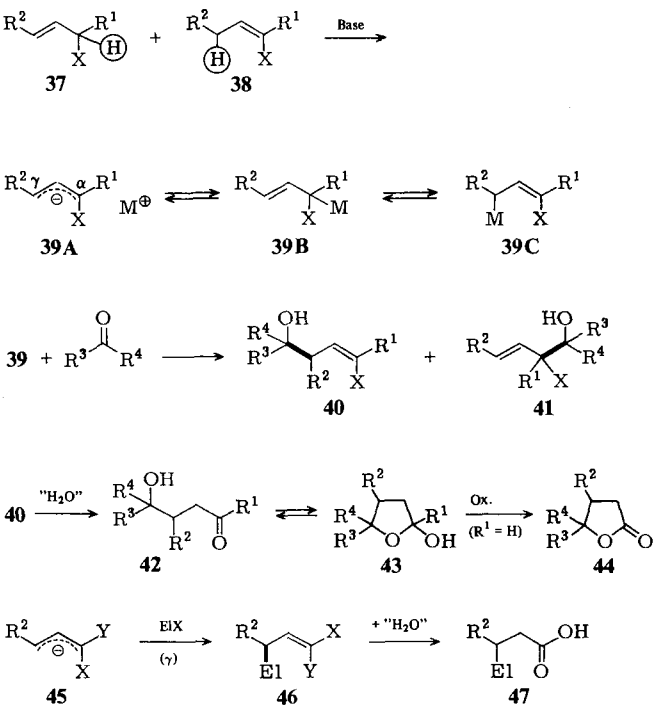
The ring strain in cyclopropanes has also been exploited in indirect reaction sequences to yield homoaldol derivatives. Thus, according to *Trost* et al.[30], the addition of a diphenylsulfonium cyclopropanide to a ketone gives the spirooxirane **33** which after rearrangement to the cyclobutanone **34** is subjected to a Baeyer-Villiger oxidation to give the γ-lactone **35**. The overall outcome of this sequence is only the addition of the propionic acid d^3-synthon to a carbonyl compound. This solution should be less attractive for the introduction of alkyl substituted homoenolate units because of problems with regioselectivity in the rearrangement step. 2-Methyloxycyclopropyllithium **36** has been used by *Corey*[31] since 1975 as a special homoenolate reagent.



Scheme 4. Cyclopropanes as homoenolate precursors.

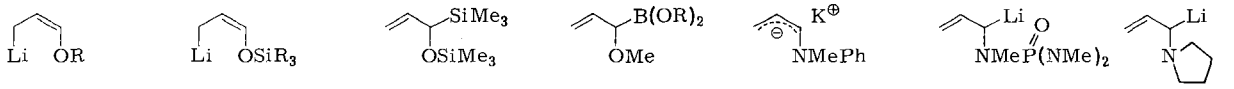
4. The Offensive Strategy— The Allyl Anion Route with Many Problems

The reagents described in Sections 2 and 3 offer solutions only for the parent compounds and a few special cases. The "allyl anion strategy" is found to be more versatile. This strategy was first used by *Biellmann* et al.[32,33] and *Corey* et al.[34], albeit with other objectives, and since 1972 by *Ahlbrecht* et al.[8a,35] from the point of view of homoenolate reagents. Here, the necessary functionality in position 1 is used offensively to build up an allylic resonance; occasionally, also the hetero substituent X (Schemes 5 and 6) is used to stabilize the allyl anion **39**. Generally, the precursor is the allylic compound **37** (or more rarely the less acidic vinylic isomer **38**[8a]), which is deprotonated with the aid of strong bases. The reaction between **39** and an aldehyde or ketone gives the regioisomeric adducts **40** and **41**. Provided the substituent X is attached through an electronegative atom (O, N, or S), the 4-hydroxyalkene **40** affords the homoaldol **42** on hydrolysis; the latter is in tautomeric equilibrium with the γ-lactol **43**.

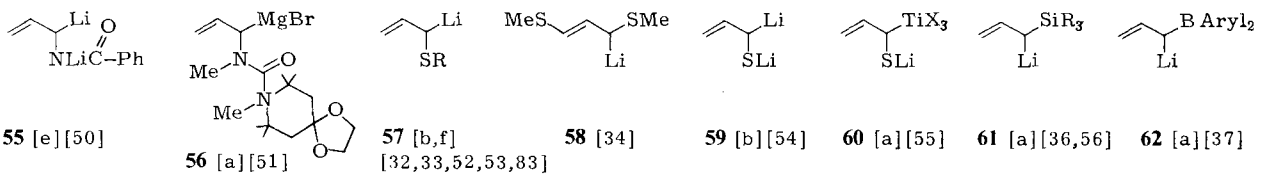


Scheme 5. General Scheme for homoaldol reactions with allylmetal compounds. A particular stereochemical outcome is not implied at this stage.

Propanal-d^3-reagents:

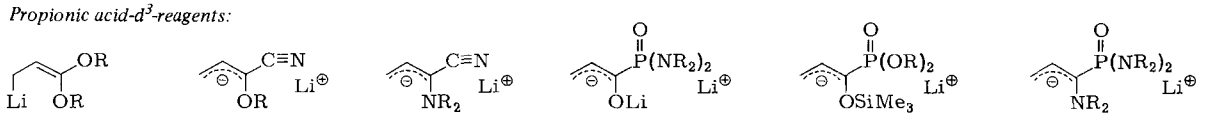


48 [d][38-41] **49** [d][42-44] **50** [e][45] **51** [a][46] **52** [c][47] **53** [e][48] **54** [c][49]



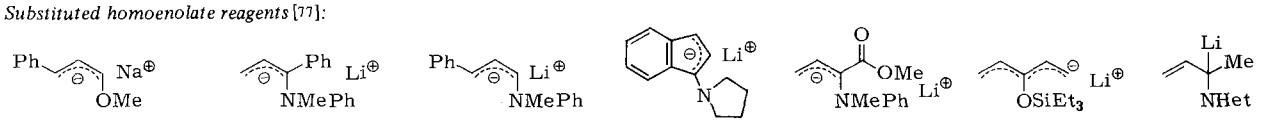
55 [e][50] **56** [a][51] **57** [b,f] [32,33,52,53,83] **58** [34] **59** [b][54] **60** [a][55] **61** [a][36,56] **62** [a][37]

Propionic acid-d^3-reagents:

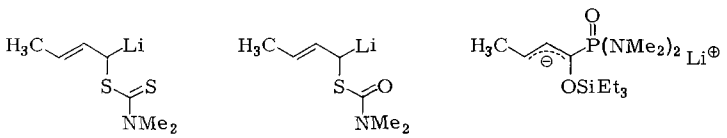


63 [e][57] **64** [a-d][58,59] **65** [a-d][60,61] **66** [a,b][62] **67** [a,b][63] **68** [a,b][64]

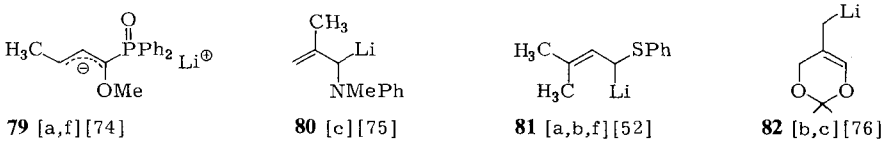
Substituted homoenolate reagents [77]:



69 [e][65] **70** [a][35] **71** [a][66] **72** [e][67] **73** [a][68] **74** [a][69] **75** [a,g][70]



76 [a,f][71] **77** [a,f][72] **78** [a][73]



79 [a,f][74] **80** [c][75] **81** [a,b,f][52] **82** [b,c][76]

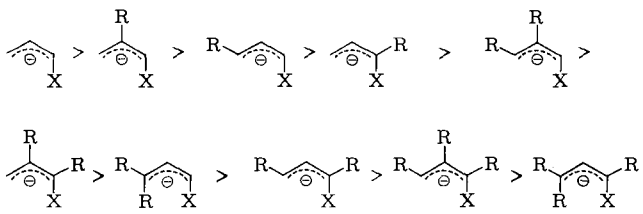
Scheme 6. Selected homoenolate reagents on the basis of allyl anions and the regioselectivity (*rs*) of their addition to carbonyl compounds. Here, regioselectivity (*rs*) means the amount (in %) of the regioisomer concerned. [a] High γ-regioselectivity, > 90% *rs*. [b] Medium γ-selectivity, > 65% *rs*. [c] No γ-selectivity, 60—40% *rs*. [d] α-Selective carbonyl addition. [e] Selectivity not known. [f] The deblocking of the γ-adducts has not been described. [g] NHet = 9-carbazolyl.

If the γ-adduct **40** carries electropositive residues X (e.g. trialkylsilyl[36], diarylboryl[37]) an additional oxidation step is necessary.

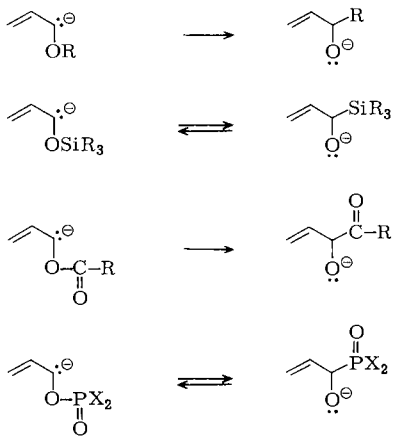
Further oxidation of the aldehyde derivatives **42** and **43** leads to acids which are mostly isolated as γ-lactones **44**. 1,1-Bisheterosubstituted allyl anions **45** (Y = e.g. phosphoryl, groups derived therefrom, and also CN, Scheme 6) are more direct, although not always more useful preparative solutions, because an acid, **47**, is directly obtained by hydrolysis of the γ-adducts **46** (Scheme 5).

The use of allyl anions as homoenolate reagents also brings new problems, however.

Stability and range of application: The stability of anions **39** is drastically reduced by alkyl groups R^1 and R^2, particularly in the electron rich α- and γ-positions; that is, increasing alkylation makes it more difficult to generate allyl anions, and they become more prone to decomposition (Scheme 7). 1-Oxyallyl anions in particular are prone to rearrangement, such as the Wittig[78] and Brook[43-45,79] rearrangements as well as acyl[80] and phosphoryl[62] migrations (Scheme 8). However, the reversibility of the Brook rearrangement can also be exploited for the preparation of anions **49** in low stationary concentrations from 1-trialkylsilyl-2-alkenolates[43-45]. In contrast, electron-withdrawing substituents R^1 and R^2 contribute to the stabilization of allyl anions of the type **39** and it is no surprise, therefore, that many substituted homoenolate reagents carry phenyl, vinyl, or carbonyl groups (Scheme 6).



Scheme 7. Hindrance of the deprotonation of allylic compounds with increasing degree of alkylation. X is constant, R = alkyl (e.g. CH_3).



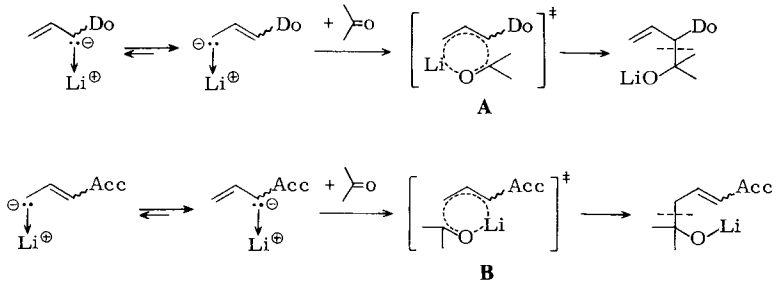
Scheme 8. Rearrangements of 1-oxyallyl anions.

Regioselectivity: The isomer ratio **40/41** (γ/α adduct) of the kinetically controlled electrophilic substitution of ambident anions[81] such as **39** is influenced in a complicated manner by substituents, by counterions, by the solvent, and by the electrophile[91]. Often a reversal of the regioselectivity accompanies a change from alkyl halides to carbonyl compounds. Thus, lithiated 2-propenyl ethers **48** or **49**—investigated since 1974 by *Evans*[38], *Schlosser*[39], *Still*[42], and several other groups[40,41,43–45]—are selectively alkylated in the γ-position, but hydroxyalkylation takes place selectively in the α-position. This tendency is enhanced by metal exchange[38,41,42] with magnesium bromide, zinc chloride, or diethylaluminum chloride[82]. The opposite trend applies in the case of the corresponding metalated thioethers **57**[32,33,41,53,83]. Since the perturbation of the allylic system due to the substituents R^1 and R^2 in **39** is of the same order of magnitude as that due to the substituents X, the regioselectivities obtained for the parent systems (R^1 and R^2=H) seldom pertain to substituted derivatives. A rule of thumb, unshaken by many exceptions, whereby the steric situation, influence of solvent, and bonding of the cations are left out of consideration, can be formulated as follows:

> An introduction of donor substituents[81] (including alkyl groups) in "allyl anions", where M=Li, shifts the carbonyl attack in the direction of α-selectivity. In contrast, acceptor substituents cause increased γ-selectivity (Scheme 9). These influences are reversed in alkylations and silylations[81].

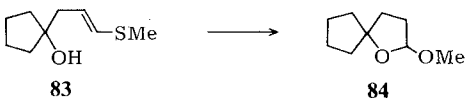
The selectivity rules for addition to the carbonyl group are most closely obeyed for less stabilized allylic compounds in nonpolar media because here the formation of tight ion pairs is particularly pronounced (Scheme 9).

A high degree of γ-selective carbonyl addition (Scheme 6) is shown, for example, by the pentadienyl derivative **74** of *Oppolzer* et al.[69], the 1-phenyl compound **70** of *Ahlbrecht* et al.[8a,35], the 3-methylated phosphoric amide **78** of *Evans* et al.[73], and the prenyl derivative **81**[52]. The ion pairing, determined by the anion polarization[81], can, however, be reversed by chelation using good complexing ligands and appropriate cations. The magnesium-urea derivative **56** reported by *Seebach* et al.[51] is hydroxyalkylated with a high degree of γ-selectivity.



Scheme 9. Model concept for guiding the regiochemistry of carbonyl additions through the position of the counterion. Do=donor-, Acc=acceptor-substituent. **A**, **B**: Transition states.

Deblocking: Among the reagents indicated in Scheme 6 the 1-thio-substituted allyl anions of the types **57**, **76**, and **77** tolerate the highest number of attached alkyl groups. Yet, a mild deblocking of the resulting thioenol derivatives of the type **40** (X=SR') is difficult or has even been unsuccessful so far[84]. Thus, the methanolysis of the cyclopentanone adduct **83** leading to the spiroacetal **84** requires the addition of 3 molar equivalents of mercury(II) chloride[55b]. The acid-catalyzed hydrolysis[8a] of enamines (X=NR_2 in **40**) and enol ethers[84] (X=OR in **40**) to aldehydes and ketones is, however, in general easy to perform.



83 **84**

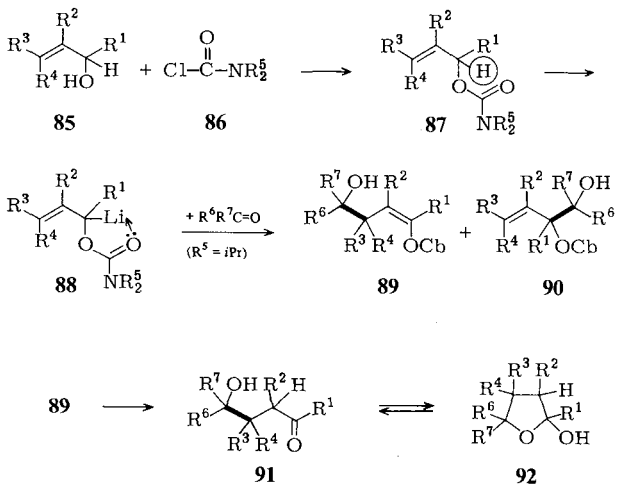
5. The Solution: Metalated Allyl Carbamates

The problems described above lead to the following demands on any new class of generally applicable reagents for the homoaldol reaction:

- Reliable γ-selectivity in the carbonyl additions, independent of the substituent pattern.
- General, facile access.
- Mild and selective deblocking of the adducts.
- Option on stereoselective versions.

When we became aware of the problem in 1979[85], no type of reagent was known which would satisfy all requirements. However, the ground had been prepared for a satisfactory solution. *A. I. Meyers, Beak,* and many others had demonstrated the importance of the long known "chelate effect"[87] for directed lithiations. The investigations on allylic boranes by *R. W. Hoffmann*[88a] had made it clear that, in nonpolar media, the regiochemistry of the addition to the carbonyl group is controlled to a large extent by the position of the "cation" (which directs the incoming carbonyl group to the γ-position in the pericyclic process with allylic inversion). The sequence is similar to the isoelectronic aldol addition[1] and hence uniform prochirality in the starting material **39** is the key to high diastereoselectivity.

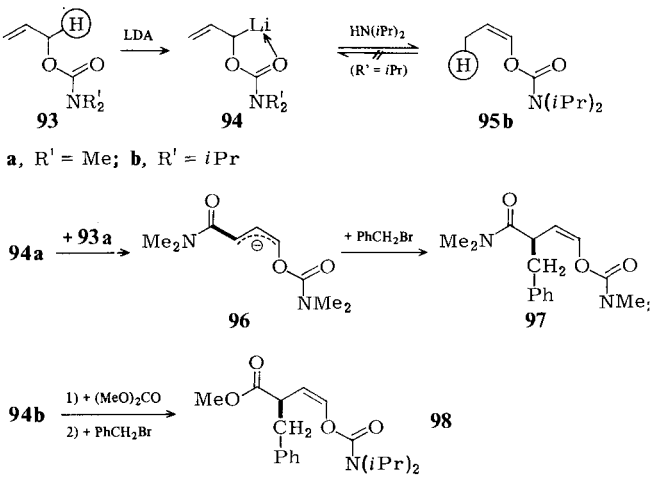
Conclusion: The "cation" in the allylmetal compound **39** has to be located in the 1-position (see **39B**). Therefore, the group X must actively participate in locating the cation there. Increased thermodynamic stability of the species **39** and a high kinetic acidity of the precursor **37** would be "additional bonuses", as an interaction between the residue X and the cation should take place already in the transition state and lower the energy of deprotonation; both of the aforementioned effects are essential for a wide range of applicability. Which groups X are capable of providing all this? Since we have been concerned with metalated thiocarbamic acid esters[72,89], e.g. of the type **77**, *N,N*-dialkylcarbamoyloxy groups appeared to be promising candidates (Scheme 10). 2-Alkenyl esters **87** of carbamic acid are easily and generally accessible from allyl alcohols **85** and chlorides **86** under the action of pyridine[90] or other bases[91,72b], whereby the regio- and stereochemistry of the educt are left unaltered[92]. Since γ-addition of aldehydes and ketones to lithium compound **88** leads to the enol esters **89**, no problems are expected in the solvolytic deblocking to the homoaldols **91**.



Scheme 10. Homoaldol reaction with allyl carbamates. Reaction **87**→**88** with *n*-butyllithium/tetramethylethylenediamine (TMEDA) in tetrahydrofuran (THF)/hexane, −78°C (standard conditions). Cb = *N,N*-dialkylcarbamoyl; unless otherwise stated, Cb = C(O)–N(*i*Pr)$_2$.

As a first test, 2-propenyl *N,N*-dimethylcarbamate **93a** was stirred with lithium diisopropylamide (LDA) in THF/hexane at −78°C and the mixture treated with benzyl bromide in order to detect any anions formed. The 3-butenoic acid amide with *Z*-configuration **97**[93,72b] was isolated in 40% yield (based on LDA). Thus, it was ascertained that the allyllithium compound **94a** is an intermediate, but it rapidly reacts with the ester **93a** with transposition of the dimethylcarbamoyl group and, after a second deprotonation, forms the vinylogous amide enolate **96**. Finally, the latter is benzylated in the position alpha to the acceptor[81] (Scheme 11).

This "self-condensation" is decelerated by bulky *N*-substituents; the *N,N*-diisopropyl derivative **93b** merely isomerizes under the reaction conditions mentioned[93,72b] to give the (*Z*)-1-propenyl carbamate **95b**. The intermediary anion **94b** is trapped in situ with dimethyl carbonate (which is inert to LDA below −70°C!) and, after benzylation, affords the (*Z*)-butenoic ester **98** together with smaller amounts of the α-adduct. Thus, the procedure offers a simple and flexible access to masked 4-oxoesters[93].



Scheme 11. *In situ* generation and trapping of lithium compounds **94**.

Accordingly, the basicity of LDA suffices for the generation of low concentrations of **94b**, but in the absence of a reactive electrophile this compound is irreversibly protonated by diisopropylamine, giving the more stable enolic carbamate **95b**. According to *Hine*[94], the energy difference ΔG° between the two isomers **93b** and **95b** is estimated as ca. 3 kcal/mol, corresponding to less than 3 pK_a units at −78°C. Hence, the ion pair acidity of the allyl carbamate **93b** in THF should be slightly less than that of diisopropylamine (p$K_a \approx 36$)[95].

n-Butyllithium in the presence of 1.0–1.1 molar equivalents of the complexing agent tetramethylethylenediamine (TMEDA)[96] in ether/hexane or even pure hydrocarbons at −78°C to −70°C proves to be the best reagent for the complete deprotonation of *N,N*-diisopropyl carbamates **87** (R^5 = *i*Pr). No products derived from an addition of butyllithium to the sterically blocked carbonyl group are formed.

As shown by silylation[72b], the extent of lithiation of the parent compound **93b** is already at least 88% after 5 min (see also Scheme 14). Introduction of a methyl group in the α, β, or γ positions in the carbamates **99**–**102** (Scheme 12) leads to only a slight decrease in kinetic acidity (complete lithiation in $t = 15$–30 min[72b]). The system even allows the presence of two alkyl groups in any desired positions without difficulty, as shown by the carbamates **105** ($t = 30$ min) and **106** ($t = 3.5$ h). However, the limit is exceeded in the case of the 1,3,3-trimethyl derivative **112**, which is inert toward *n*-butyllithium[97]. The allylic unit may also be part of a six-membered ring (as in **107** or **111**), or parts thereof may be comprised in five- or six-membered rings as in **108**–**110** ($t = 3$–5 h)[97]. Other ring sizes have not, so far, been investigated. Surprisingly, the 2-cyclopentenyl and the *trans-p*-menthadienyl carbamates **115** and **113** are not lithiated under standard conditions[97]. Possibly, conformational effects lower the kinetic acidity of these carbamates because the C–H bond to be

broken experiences an unfavorable "dihedral" angle with the π system.

As expected, a 3-phenyl substituent increases the acidity considerably: **103** is completely deprotonated in less than 1 min by LDA[72b]. The investigation of hetero-substituted analogs such as the 3-trimethylsilyl derivative **104** has just begun[98].

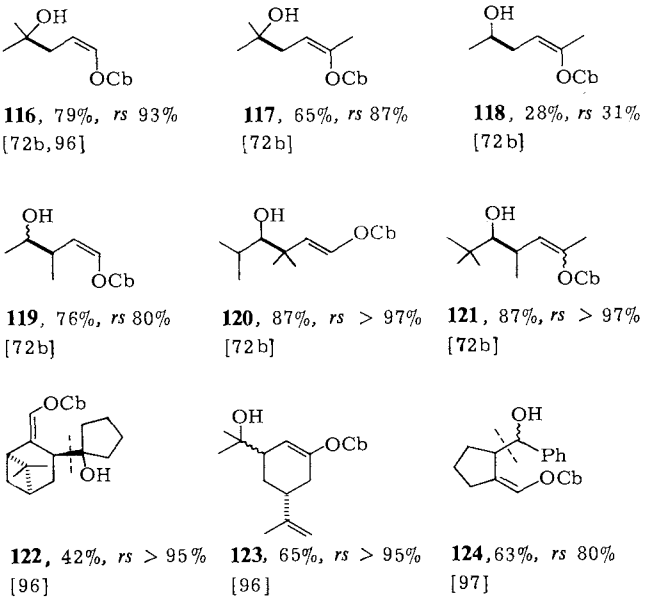
Scheme 12. Limits of the lithiation of 2-alkenyl carbamates **87** under standard conditions (see text). **112**–**115** are not lithiated.

All in all, the lithiation of allyl carbamates provides a general entry to 1-oxyallyl anions with a structural variety previously inaccessible, and thus also to potential homoenolate reagents.

The reaction[96,72b] between solutions of allyllithium compounds of the type **88** and aldehydes or ketones is rapid at $-78\,^{\circ}C$, giving mainly γ-hydroxyenolcarbamates **89** together with varying amounts of the α-adducts **90** (Scheme 10). Some representative examples which also illustrate the limits of the lithium variants are given in Scheme 13.



116, 79%, *rs* 93% [72b,96]

117, 65%, *rs* 87% [72b]

118, 28%, *rs* 31% [72b]

119, 76%, *rs* 80% [72b]

120, 87%, *rs* > 97% [72b]

121, 87%, *rs* > 97% [72b]

122, 42%, *rs* > 95% [96]

123, 65%, *rs* > 95% [96]

124, 63%, *rs* 80% [97]

Scheme 13. Examples of the addition of **88** to aldehydes and ketones. The respective yields and regioselectivity are given; in the case of **116**–**124** % *rs* refers to the amount of the γ-adduct in the regioisomer mixture.

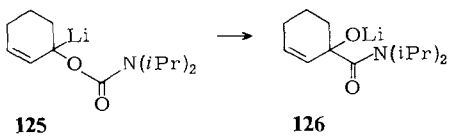
The γ-selectivity of the carbonyl addition increases with increasing 3-substitution and with decreasing 1-substitution in the allyl anion **88** and also with decreasing reactivity of the carbonyl group in the reaction partner. Ketones are better than aldehydes. Both factors favor a cyclic transition state of the type **B** (Scheme 9) and disfavor other alternatives. The second parameter is the most important: The addition reactions of the allyl and 1-methylallyl derivatives **93b** and **99** to acetone to give **116** and **117**, respectively, have similar regioselectivities[72b] (Scheme 13), whereas replacement of acetone by acetaldehyde leads to a loss of γ-selectivity in the product **118**[99].

6. Structure and Properties of Lithiated Carbamates

Although as yet no X-ray structure determination is available, the reactivity of the lithium compounds **88** allows informed speculation about their structure.

a) The lithiation of the esters **87** succeeds only in the presence of at least one molar equivalent of a bidentate complexing agent such as TMEDA; this being satisfied, the reaction is fast even in hydrocarbon solvents[100].

b) The lithium compounds **88** are persistent in nonpolar solvents, at least below $-70\,^{\circ}C$. In donating solvents like THF or 1,2-dimethoxyethane, however, they rearrange to salts of α-hydroxyamides such as **126**[97]; this is also the case when lithium is exchanged for potassium.



125 **126**

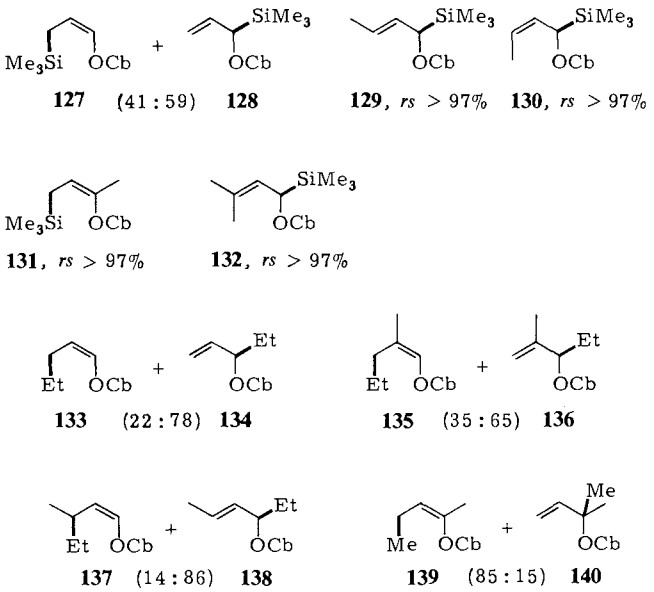
c) As long as the allylic system **88** does not carry a 3-*cis*-substituent and the molecular framework does not enforce (1*E*)-configuration (e.g. in cycloalkenyl derivatives such as **125**), the (1*Z*)-configuration is trapped in the products independently of the nature of the electrophile (Schemes 13 and 14). Accordingly, the carbamoyloxy group prefers the *endo* position in the reacting species **88**.

d) The 2,3-bond in the lithiated (*E*)- and (*Z*)-2-butenyl derivatives **101** and **102** is torsionally stable at $-70\,^{\circ}C$[98,101,102] since metalation and silylation take place "stereodefensively"[103] (Scheme 14).

e) The carbonyl addition shows a high preference for the γ-position. This is further enhanced by increasing γ-substitution in the allylic moiety.

f) The regiochemistry of alkylation and silylation (Scheme 14) is largely controlled by the position of the alkyl groups present. The carbamoyloxy group has very little influence[72b,104].

Thus, the species **88** exhibit properties typical of both allyl anions[102,105] and covalent allylmetal compounds[88]. Accordingly, they are probably best described as tight ion



Scheme 14. Regio- and *cis/trans*-selectivity of silylation [72b] and alkylation [104] of some lithium compounds **88**. In the *cis/trans* mixture of isomers the amount of **127**, **129**, **130**, **131**, **133**, **135** and **137**–**139** is more than 97% in each case.

pairs (Fig. 1, formulated for **94b**) in which the carbamoyloxy group positions the lithium ion at the α-carbon atom above the π surface[106]. Two further coordination sites of the cation are occupied by the diamine TMEDA.

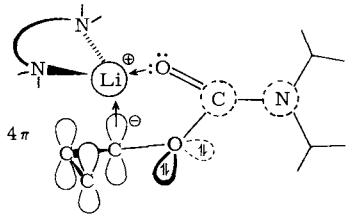


Fig. 1. Assumed structure of the carbamoyloxyallyllithium compound **94b**·TMEDA (type **88**) [96], cf. Scheme 15.

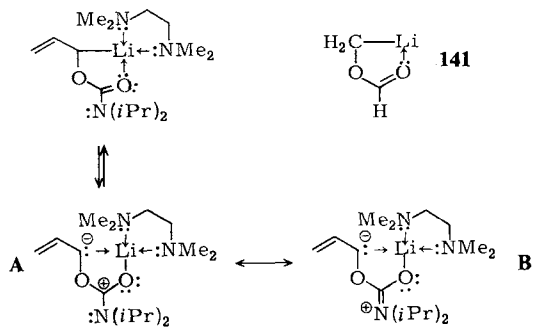
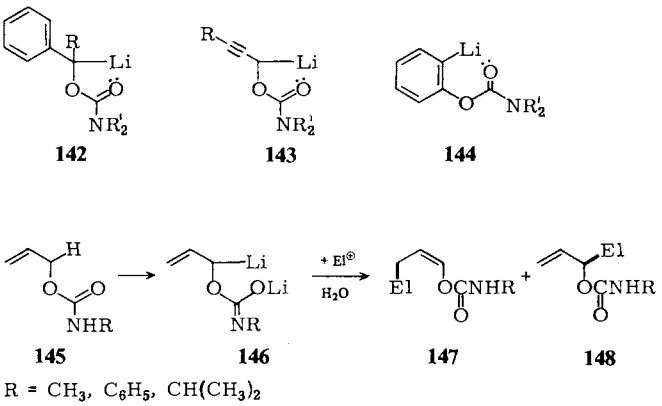
The favorable chelation should contribute to the stabilization of **88** in addition to its entropic share since the interaction between the cation and the oxo group increases the acceptor properties of the carbamoyloxy group according to the resonance formulas **A** and **B** (Scheme 15, "induced dipole stabilization")[107,108]. The importance of this factor is underlined by ab initio SCF calculations on lithiomethyl formate **141** by *Houk, Beak,* and *Schleyer*[109].



Scheme 15. Induced dipole stabilization of **94b**·TMEDA (cf. Fig. 1).

The complexing power of the carbamoyloxy group is also the reason for the high kinetic acidity of carbamic acid esters **87**. Results obtained by *Beak* et al.[110] and *A. I. Meyers* et al.[111] for similar cases indicate the existence of a pre-equilibrium with a complex composed of the substrate **87**, *n*-butyllithium, and TMEDA. This sets the course for a rapid deprotonation.

The activating and stabilizing influence of *N,N*-dialkylcarbamoyloxy groups also provides its worth in the generation of corresponding α-oxybenzyl-[93,112] and 1-oxyalkynyllithium[113] compounds of the types **142** and **143**, as well as in the *ortho*-lithiation of aryl carbamates to **144** as more recently shown by *Snieckus* et al.[114] (Scheme 16).



Scheme 16. Various lithiated carbamic acid esters.

Allyl *N*-phenyl- or *N*-alkyl carbamates **145**, prepared from allyl alcohol and isocyanates, are doubly deprotonated by *n*-butyllithium[115], giving the dilithio derivatives **146**. The carbonyl group in the latter is sufficiently protected "electronically" toward nucleophilic attack because of resonance; "small" *N*-substituents here are sufficient. Subsequent alkylation, silylation, or sulfenylation gives (*Z*)-enolic carbamates **147** with 65–97% *rs* besides the α-adducts **148**. Regrettably, satisfactory results have so far only been obtained with the parent compound[104]. According to *Gompper* and *Wagner*[81], the improved γ-selectivity in alkylation and silylation exhibited by **146** compared to **94b** (Scheme 11) is explained by a stronger donating power of the oxy group; this, however, also decreases the stability of the allyl anion.

7. Diastereoselective Homoaldol Additions

7.1. Metal Exchange—The Key to Higher Regio- and Diastereoselectivity

Allylmetal compounds with covalent metal-carbon bonds show appreciable chemo-, regio-, and diastereoselectivity in the addition reaction with aldehydes[88]. In cases where the configurations of starting materials and products have been unambiguously correlated[88a], the stereochemical results are best interpreted on the basis of the Zimmerman-Traxler model[116,117]. This assumes that the addition proceeds through six-membered chair-like transition states whose energies are qualitatively described by

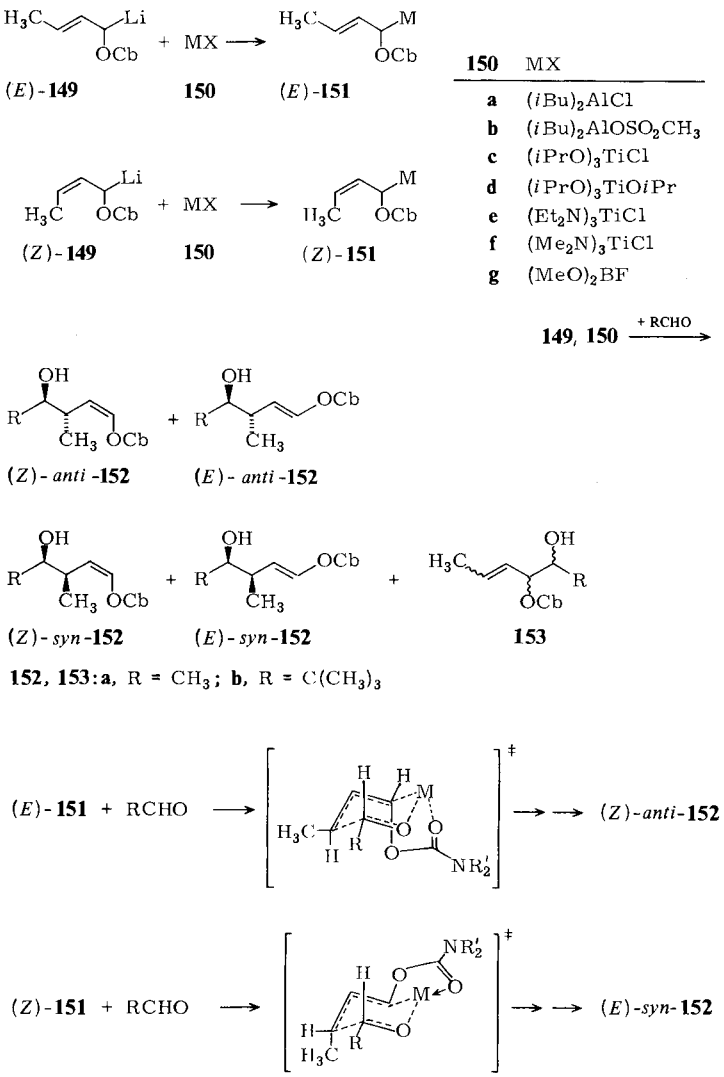
the same rules as for substituted cyclohexanes. In other words, whereas the position of the C-3 substituent is determined by the configuration of the allyl residue[118], the aldehydic alkyl group seeks to attain a (pseudo)equatorial position. Thus, (2*E*)-carbamates **151** should give predominately *anti*-adducts[4] **152** in a *lk*-process[5], as is also true for other allylmetals[88]. In contrast, (2*Z*)-carbamates should furnish the *syn*-diastereomers **152** in a *ul*-process. In both cases, the products will be in racemic form[119] (Scheme 17). As it turned out, the energy differences between the competing diastereomeric transition states are insufficient for the lithium compounds (*E*)- and (*Z*)-**149**[72b,96] (Table 1). This obviously suggested improving them by metal exchange.

Which cation is the most appropriate? Exchanged for lithium it must reliably occupy the 1-position, independently of the substituent pattern, i.e., it must respond well to complexation with the carbamoyloxy group. Furthermore, the metal should carry large, rigidly oriented ligands so as to ensure a high degree of diastereoselectivity[1]. In order to ascertain uniform prochirality of the starting materials, the metal exchange must not alter the geometry of the 2,3-bonding in **149** (stereodefensive strategy[103]), or, if it does cause equilibration, this should be rapid and lead completely in one direction (stereoconvergent strategy[103]).

The choice fell to di(isobutyl)aluminum derivatives (since work by *Still*[120] had indicated configurational stability of (*Z*)-2-butenylaluminum) and especially to titanium(IV) reagents, which had come into focus through work by *Reetz*[121] and *Seebach*[122]. Solution of the lithium compounds (*E*)- and (*Z*)-**149** were treated below −70°C with at least equimolar amounts of the metal reagents **150**; the allylmetal compounds **151** reacted at this temperature[123] with acetaldehyde or 2,2-dimethylpropanal to give the adducts **152a**, **b** and **153a**, **b**[124,125,100,101]. The regio- and diastereomeric ratios were in most cases determined by capillary column gas chromatography (Table 1).

The *anti/syn*-selectivities obtained for the lithium derivatives (*E*)- and (*Z*)-**149** are of a similar order of magnitude as observed by *Hayashi* et al.[71a] for butenyl dithiocarbamates **76** and by ourselves[72a,b] for the corresponding *S*-butenyl thiocarbamates **77**; yet the change from *S*- to *O*-esters causes a pronounced shift in favor of the (*Z*)-isomers.

With titanated (*E*)-2-alkenyl carbamates virtually only the (*Z*)-*anti*-adducts are obtained[125,126] (cf. also Scheme 18). In most cases very good (*Z*)-*anti*-selectivities are ob-



Scheme 17. Stereochemistry of the addition of metalated (*E*)- and (*Z*)-2-butenyl carbamates to aldehydes [119].

tained even after metal exchange with the easily accessible[121,122] tri(isopropoxy)titanium chloride **150c** or tetra(isopropoxy)titanium[127] **150d**. The more strongly "oxophilic"[121] tris(dialkylamino)titanium derivatives[128] **150e, f** give superior regioselectivities when the metallic moiety is "contrastedly" forced into the more highly substituted position or when ketones are used as reaction partners (see **159**, **158**, Scheme 18). Even prochiral ketones, e.g. acetophenone[129], are added in highly diastereoselective fashion[126]. So far the titanium variants have failed with 3-*endo*-substituted and (1*E*)-configurated lithium compounds[97,100] such as (*Z*)-**149**; the reasons for this are unclear[130].

[d] With $ClTi(NMe_2)_3$ **150f**. Here, the diastereoselectivity (*ds*) is the amount of the relevant diastereomer in %.

(*E*)-*anti*-Adducts **152** predominate as products of the aldehyde addition of (*E*)-**149** after cation exchange with diisobutylaluminum chloride or methanesulfonate (**150a** or **b**)[124]. (*E*)-*syn*-Adducts **152** are obtained when aluminum derivatives of (*Z*)-configuration[101] (prepared from (*Z*)-**149**) are employed. However, the regio- and diastereoselectivities are smaller in both cases (Table 1; Scheme 19). The mesylate **150b**, freshly prepared from the hydride and methanesulfonic acid, turns out to be superior to the commercially available chloride **150a** in this respect[101,131]. The methyl pyruvate adduct **164** demonstrates that aluminum reagents discriminate quite well between ester and keto-groups. Apparently, however, dialkylaluminum groups respond more sensitively to the steric situation than to complexing with the carbamoyloxy residue; hence the γ-selectivity of the aluminum variants may be lost in unfavorable cases (cf. **166**)[97,99].

Exploratory experiments have shown that various boron reagents are unsuitable (e.g. **150g**)[132] because of poor reactivity, regioselectivity, and diastereoselectivity[100].

7.2. Further *anti*-Diastereoselective Homoaldol Reactions

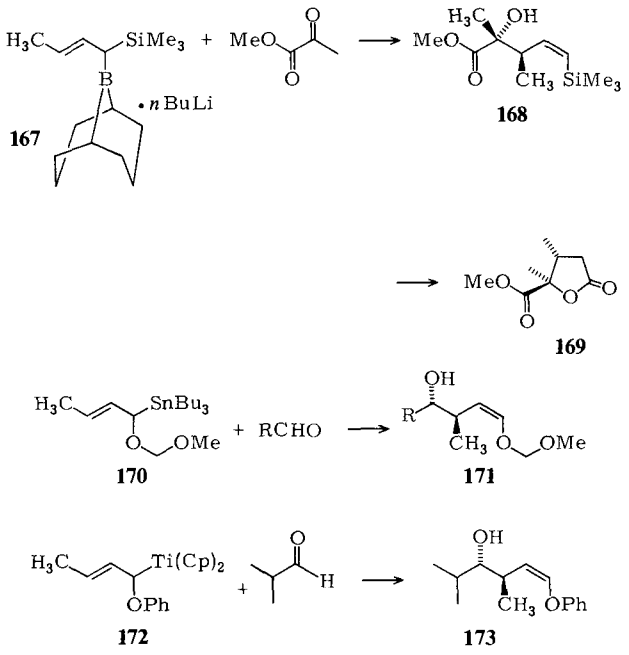
During the course of our work some further methods for the *anti*-diastereoselective homoaldol reaction with 1-heterosubstituted (*E*)-crotylmetal compounds became known (Scheme 20):

Y. Yamamoto et al.[133] added the borane **167** (as "ate" complex with *n*-butyllithium) to methyl pyruvate, giving the (*Z*)-*anti*-silane **168**, which in three further steps was transformed into methyl (±)-*cis*-crobarbate **169** in 70% yield. The low γ-selectivity (63% *rs*) together with the cumbersome preparation[134] of **167** currently make the method less attractive.

Thomas and *Pratt*[135a] used the stannane **170**, obtained from crotonaldehyde, tributylstannyllithium, and chloromethyl methyl ether, as a butanal-d^3-reagent. It reacts highly *anti*-selectively with aldehydes on warming to 140°C, giving the (*Z*)-enol ethers **171**. However, the yields were at most 40% (based on **170**).

Sato et al.[136] found that the bis(cyclopentadienyl)titanium(III) complex **172**, generated from the lithiated (*E*)-butenyl phenyl ether, gave the enol ether **173** with excellent (*Z*)-*anti*-selectivity on reaction with 2-methylpropanal. The scope of this procedure, however, is likely to be severely limited because of difficult access to higher metalated 2-alkenyl ethers[172].

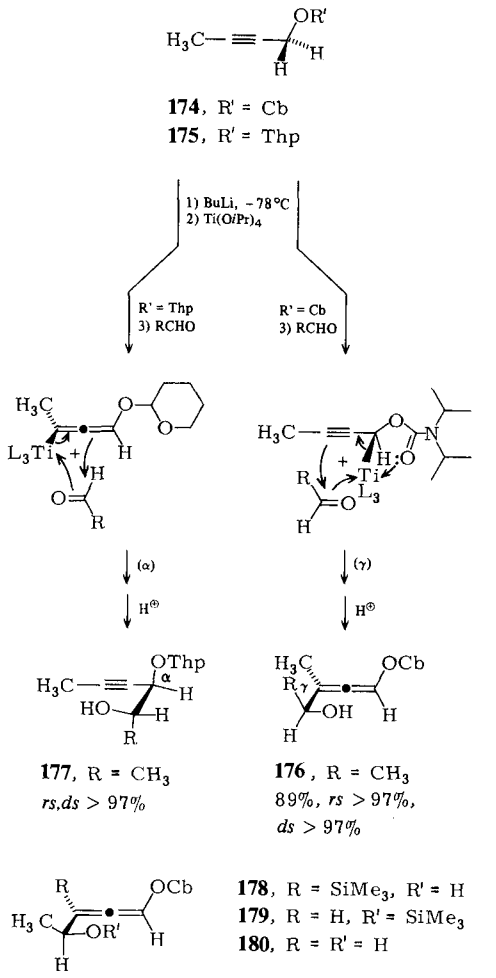
So far, no further methods for the *syn*-selective homoaldol reaction (see Section 7.1) have been reported[172].



Scheme 20. *anti*-Selective homoaldol reactions [119]. Cp = cyclopentadienyl.

7.3. Diastereoselective Allene Synthesis with Titanated Alkynyl Carbamates

The 2-butynyl carbamate **174** is rapidly deprotonated to the lithium compound under standard conditions. After exchanging the cation with titanium reagents such as **150c** or **d**, addition to aliphatic aldehydes gives diastereomerically pure α-allene alcohol **176** with over 95% *ds*[113]. The (*R*S**)-configuration[137] of the acetaldehyde adduct **176** has been established by an X-ray structure analysis of the phenyl urethane[138]. By lithium hydride induced rearrangement[139,140] of the 3-trimethylsilyl-derivative **178** to the ether **179** and subsequent fluoride-catalyzed desilylation, the allenes **180** with only one substituent on C-3 can also be obtained (90% *ds*)[141] (Scheme 21).



Scheme 21. Aldehyde addition of titanated 2-butynyl derivatives [119]. Cb = *N,N*-diisopropylcarbamoyl; Thp = 2-tetrahydropyranyl.

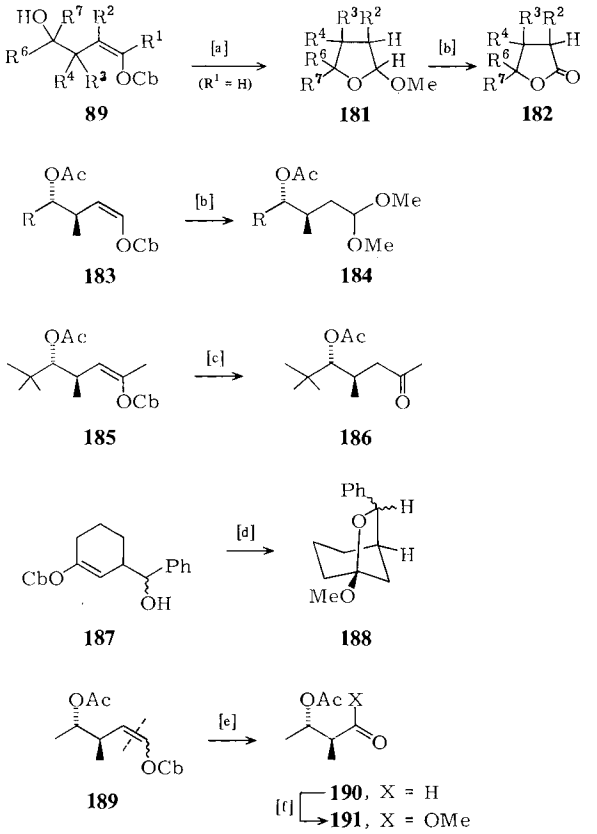
The reaction sequence is remarkable in two respects: According to a study by *H. Yamamoto*[142], the tetrahydropyranol ether **175** gives only the α-adduct **177** upon lithiation and titanation under conditions nearly identical with the above; an allenic titanium intermediate was indicated by IR spectroscopy. The complete inversion of regioselectivity upon changing the oxygen substituent clearly demonstrates the active role of the carbamoyloxy residue in locating the cation. A second surprise is the high degree of "simple diastereoselectivity" encountered on fusion of axial prochiral and centro-prochiral groups; such diastereoselective allene syntheses appear to have been unknown hitherto[144].

8. Transformations of the Enol Carbamates; Synthetic Applications

The enol carbamate moiety in the adducts of type **89** is unusually stable toward acid catalyzed solvolysis[144]: It survives heating with 2 N sulfuric acid in methanol or tetrahydrofuran/water for 2 h unchanged; at most, elimination or ether formation takes place at the 4-hydroxy group. Presumably, the donating power of the oxygen atom is strongly reduced due the presence of the electron-attracting dialkylcarbamoyl group, thus preventing stabilization of an intermediary α-oxy cation by the carbamoyloxy substituent. In addition it acts more basic than the olefinic double bond, as a "proton trap". The alternative, namely to initiate deblocking via an attack on the carbonyl group, is also deemed to fail because the sterically protected *N,N*-diisopropyl derivatives **89** are inert to sodium methoxide (methanol, 65 °C), lithium diethylamide (THF, 65 °C), lithium aluminum hydride (THF, 65 °C), and diisobutylaluminum hydride (dichloromethane, 20 °C)[97]. An attack on the double bond can be expected only from "softer" electrophiles, e.g. bromine, chlorine, peracids, mercury(II) or palladium(II) salts. The advantage of a decreased reactivity lies in maintaining the original carbonyl protection for several synthetic steps, thus often obviating the need to change it.

Deblocking is selective and effective under mild conditions: In the presence of 1 mol-% mercury(II) acetate or 0.5 mol-% of palladium(II) chloride as catalyst, together with methanesulfonic acid (to remove the liberated diisopropylamine) in the molar ratio 1:1, the methanolysis[124,126] of

the adducts **89** ($R^1 = H$) proceeds rapidly at room temperature, giving *O*-methyl-γ-lactols **181** (Scheme 22). The corresponding dimethyl acetals **184** are obtained under the same conditions from *O*-protected derivatives such as the acetates **183**[124]. Direct hydrolysis of the adducts **89** to homoaldols **91** is possible if methanol is replaced by tetrahydrofuran/water[145]; however, the purification is made tedious because of the tautomeric equilibrium with γ-lactols **92**. Ketone-derived enolic carbamates such as **185** or **187** can, on the other hand, also be cleaved with titanium tetrachloride/methanol/water[72b] or boron tribromide/methanol[97]. Thus, (*Z*)-*anti*-**185** gives the diastereomerically pure ketone **186** in 90% yield on reaction with $TiCl_4$[72b],



Scheme 22. Deblocking of 4-hydroxyenol carbamates [119]. [a] Methanol, methanesulfonic acid, 1 mol-% mercury(II) acetate, 3—15 h, 20—30°C. [b] *m*-Chloroperbenzoic acid/boron trifluoride etherate, dichloromethane, 3—15 h, 20—30°C. [c] Titanium tetrachloride in dichloromethane, −78 to 0°C; methanol; water. while the mixture of diastereomers **187** gives the bicyclic ketal **188** on treatment with BBr_3[97].

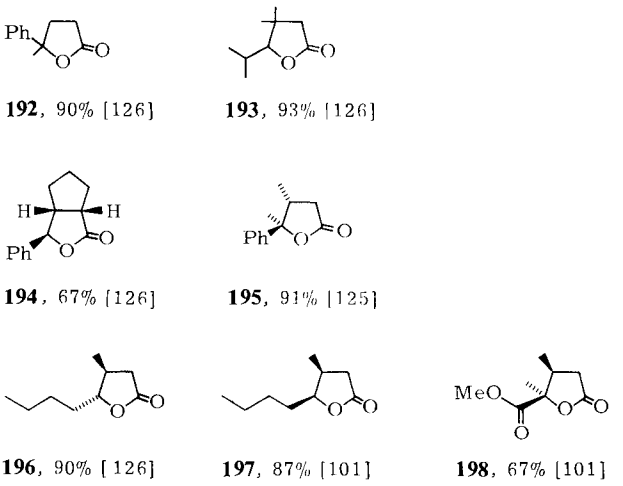
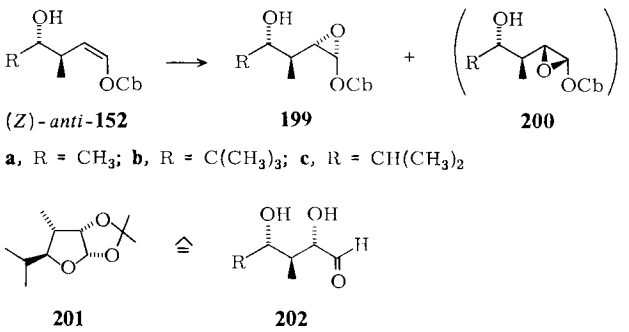
Oxidation[146] of 2-methoxytetrahydrofurans **181** according to the method of *Grieco* et al. furnishes the γ-lactones **182** in high yields[126, 101]. Examples are **192**—**195** and (±)-quercus lactone A **196**[126] and B **197**[101], components of oak bark, and (±)-*trans*-crobarbatic acid methyl ester **198**[101, 133], a degradation product of pyrrolizidine alkaloids (Scheme 23).



Scheme 23. γ-Lactones prepared from adducts of the type **89** [119, 101, 126].

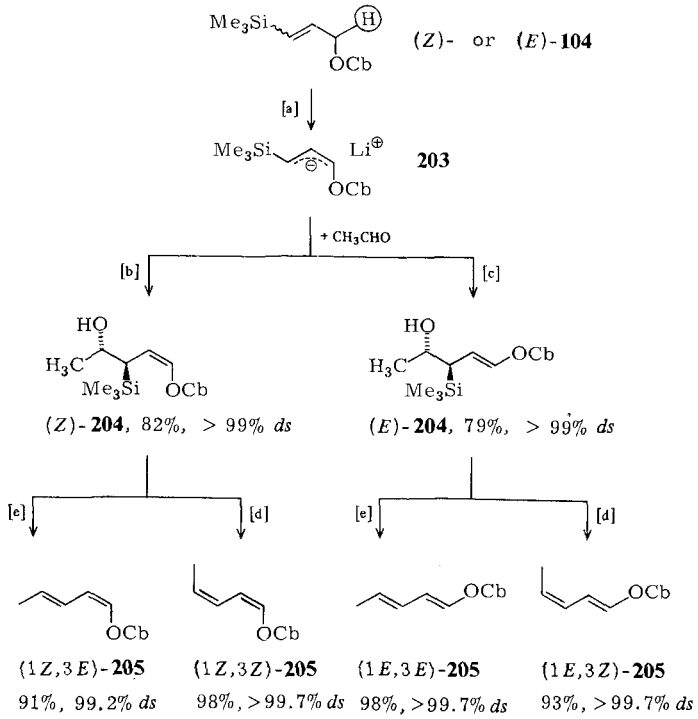
Ozonolysis of *O*-acetylated enolic carbamates such as **189** and subsequent reductive work-up affords the aldol acetates **190**; after oxidation[147] and esterification, the β-acetoxycarboxylic esters **191** are obtained (Scheme 22). In this way we correlated the relative configurations of the adducts **152** with those of stereochemically secured compounds[124].

The uniform prochirality of the enol double bond in the adducts **152** invites further stereocontrolled substitution. In analogy to the corresponding homoallyl alcohols (alkyl in place of OCb in **152**)[148], the epoxidation[149] of the adducts (*Z*)-*anti*-**152** proceeds highly diastereoselectively. Whereas *m*-chloroperbenzoic acid in dichloromethane at 0°C gives the diastereomers **199** and **200** in a ratio of 6 : 1, the vanadium-catalyzed oxidation with *tert*-butyl hydroperoxide[150] gives only the isomer **199** (>97%)[151, 152] (Scheme 24), whereby the selectivity is independent of the residue R. The relative configuration of the isopropyl-derivative **199c** was confirmed by X-ray structure analysis[153]. Although the epoxy carbamates **199** can be purified by chromatography or recrystallization without decomposition, they prove highly reactive under Lewis acid catalysis. Thus, reaction of **199c** with acetone/boron trifluoride furnishes the furanoid product **201** in 80% yield[151]. Accordingly, the oxiranes **199** correspond to diastereomerically pure (racemic) 2,4-dihydroxyalkanals **202**.



Scheme 24. Epoxidation of (*Z*)-*anti*-derivatives **152** [119, 151].

1-Oxy-1,3-alkadienes are attracting considerable interest as Diels-Alder components[154,155]. Each of the four possible 1,3-alkadienyl carbamates **205** can be obtained highly stereoselectively via the β-silyl alcohols **204**[98] (Scheme 25). The procedure is stereoconvergent in the first step[103] since only the (2*E*)-anion **203** is obtained after lithiation, irrespective of whether (*E*)- or (*Z*)-alkenyl carbamate **104** is used as the precursor[156]. The next two steps are now performed in a doubly stereodivergent manner: The titanium-mediated aldehyde addition gives the adducts (*Z*)-*anti*-**204** (>99% *ds*); the aluminum variant gives the isomeric (*E*)-*anti*-**204** (>99% *ds*). A subsequent Peterson elimination[157,158] determines the configuration of the newly created γ,δ-double bond in the alkadiene **205**. In basic media the stereospecific *syn*-silanolate elimination leads to the (*Z*)-configuration and hence to (1*Z*,3*Z*)- or (1*E*,3*Z*)-**205**. In contrast, Lewis acid catalyzed *anti*-elimination leads to a (3*E*)-double bond in (1*Z*,3*E*)- or (1*E*,3*E*)-**205**. Overall yields of 80% and purities of >99% (determined by capillary gas chromatography) are obtained in these reactions.



Scheme 25. Highly stereoselective synthesis [98] of 1,3-alkadienyl carbamates **205** [119]. [a] *n*-BuLi/TMEDA in ether/hexane, −78°C, 1 h. [b] $ClTi(NMe_2)_3$ **150f**; aldehyde, 3 h at −78°C to −70°C; chromatography or crystallization. [c] $CH_3SO_2OAl(iBu)_2$ **150b**, otherwise as in [b]. [d] 2.5 mol equivalents of sodium hydride, THF/ether, 3 h at 0°C. [e] 2.5 mol equivalents of $BF_3 \cdot OEt_2$, 15 h at −78°C.

9. The Challenge: Asymmetric Homoaldol Reactions

We have so far considered only racemic homoaldols. In order to synthesize these in optically active form, only one of the reaction partners need, in principle, be enantiomerically pure. The art is to find the conditions whereby the auxiliary chirality center induces high asymmetry on the newly created one[159]. This means that ΔG^{+} of the competing diastereomeric transition states should differ by at least 1.5 kcal/mol (corresponding to ≥98% *ds* or ≥96% *ee* at −78°C). In principle, asymmetric induction can originate in the allylic moiety of the homoenolate reagent, in the dialkylamino group, in the counterion M or its ligand sphere, or in the carbonyl compound (Fig. 2).

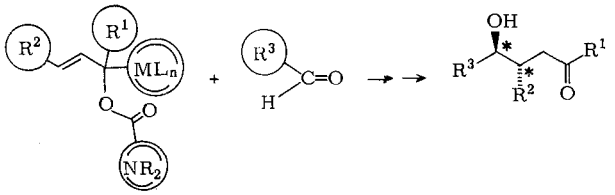


Fig. 2. Theoretically possible asymmetric homoaldol reactions. For explanation see text.

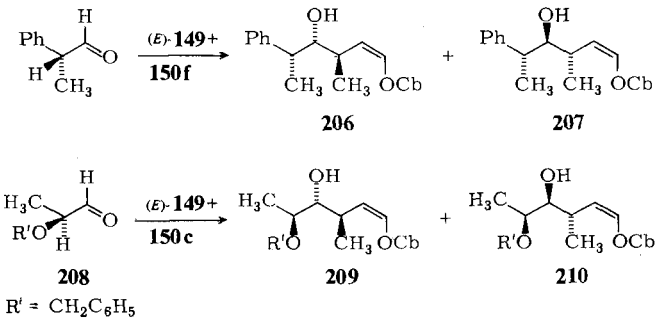
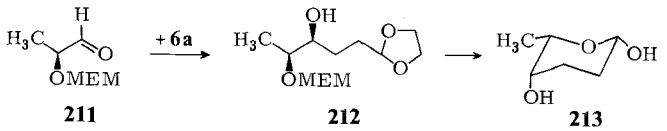
The lithium compound derived from the carbamate **108** of (−)-myrtenol gives a single adduct **122** with cyclopentanone[96] (Scheme 13). The good stereodifferentiation is a result of the diastereotopic faces of the rigid bicycle **108**. Promising results are also obtained with α-chiral aldehydes: Of the eight possible diastereomers only two, *rac*-**206** and *rac*-**207** (ratio 93:7) are obtained from racemic[160] 2-phenylpropanal with the titanium reagent (*E*)-**151f**[161] (Scheme 26). Here, one reaction step at once controls (93% *ds*) the relative configurations of three chirality centers and two prochirality centers. (*S*)-2-Benzyloxypropanal **208**, obtainable from ethyl lactate in two steps[162], reacts with lower diastereoselectivity under standard conditions, but not all possibilities for steric approach control or chelation control[163] have been exhausted. The two optically active (*Z*)-*anti*-diastereomers **209** ("Cram adduct") and **210** ("*anti*-Cram-adduct") are obtained in a 70:30 ratio using the titanium reagent (*E*)-**151c**[161]. The lower selectivity is compensated by the fact that the two isomers of very differing polarity are already separated by filtration through silica gel.



Scheme 26. Homoaldol reactions with α-chiral aldehydes.

The classical reagent **6a**[10] is a good choice when only the incorporation of an unsubstituted propanal-d^3-unit in a chiral 2-alkoxyalkanal is required: *Kelly* et al.[164] obtained **212** with 95% *ds* by chelation-controlled addition from the (*S*)-2-[(2-methoxyethoxy)methoxy]propanal **211** at −100°C. After removal of the protecting group the antibiotic sugar L-rhodinose **213** was obtained in an overall yield of 48% based on **211** (Scheme 27).

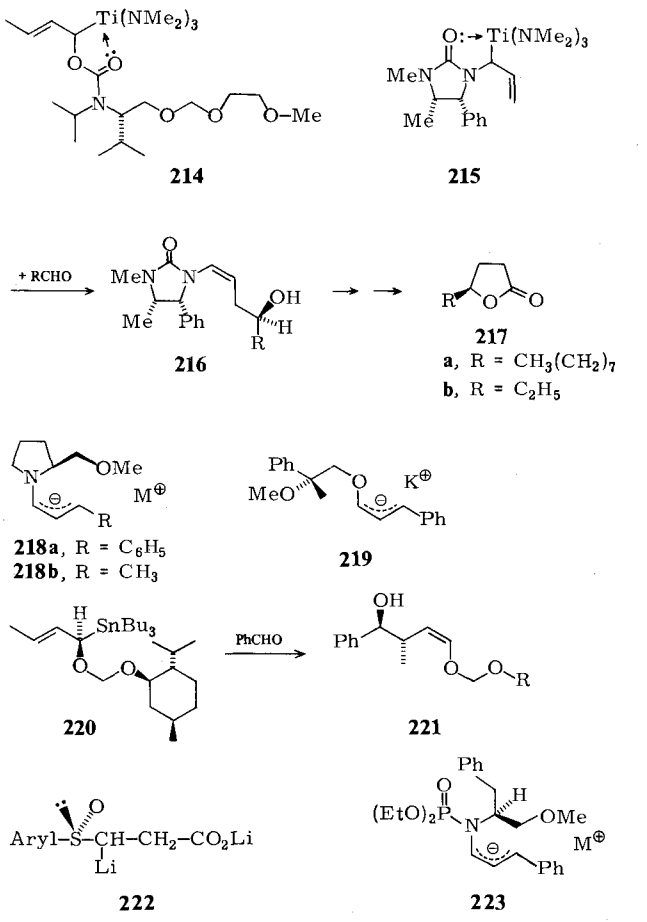


MEM = $CH_3OCH_2CH_2OCH_2$

Scheme 27.

A wider variety of target molecules are accessible using reactants with detachable auxiliary groups (doubly circled in Fig. 2). We therefore examined the butanal-d^3-reagent **214**, whose amide group originates in (*S*)-valinol[165] (Scheme 28). Although high (*Z*)-*anti*-selectivity is maintained in the addition to acetaldehyde, the diastereomeric ratio is at best 60:40. The direction of the induction was not determined.

Better results were obtained by *Helmchen* et al.[166] using a rigid system, fixed through a favorable intramolecular complexation. The allylurea derivative **215** obtained in a short sequence from (−)-ephedrine adds with high diastereofacial selection (94—98% *ds*) to aliphatic aldehydes and to some prochiral ketones. The minor isomer *epi*-**216** is almost completely removed by recrystallization. Methanolysis of **216** and subsequent Grieco oxidation[146] affords the enantiomerically pure γ-lactone **217**; *ent*-**217a** and **b** occur in nature as insect pheromones. It is still questionable, however, whether the system can be extended to substituted and less acidic allylureas. Although the magnesium



Scheme 28. Asymmetric homoenolate reagents.

derivative (MgBr in place of $Ti(NMe_2)_3$ in **215**) exhibits high γ-regioselectivity just like its achiral prototype[51], it shows no stereoselectivity.

Two chiral 3-phenylpropenal-d^3-reagents have been used for asymmetric alkylation; **218a** by *Enders* and *Ahlbrecht* et al.[167,173] and **219** by *Mukaiyama* et al.[168]. In the alkylation, silylation and phosphorylation reactions, the butenyl derivative **218b** generally gives diastereomeric excesses of between 85 and 95% *de*, but the γ-regioselectivity rarely exceeds 70%[174]. Chiral phosphoramidates, such as **223** react with only moderate diastereoselectivity[173]. Homoaldol reactions with the reagents **218**, **219** and **223** have so far not been reported; the problem may lie in the control of regioselectivity.

A remarkable result has just been published by *E. J. Thomas* et al.[135b]: The stannane **220**, obtained by chromatographic separation of the diastereomers, adds to benzaldehyde giving the enol ether **221** with practically complete transfer of chirality (>98% *ee*). Equally efficiently, 1-*epi*-**220** induces the opposite configuration of the newly created chirality center. The chiral dilithiated sulfoxide **222** has recently been used by *Bravo* et al.[21] in the synthesis of enantiomerically pure butenolides of the type **24**. However, moderate asymmetric induction necessitates separation of the diastereomers.

10. Outlook

In the five years that have passed since the first reported studies in this sector, homoaldol reactions with metalated *N,N*-diisopropyl carbamates have reached a high standard, comparable to the racemic variants of the aldol addition as regards scope, regioselectivity and diastereoselectivity. Properly scheduled in a synthetic scheme, there is a good chance that homoaldol reactions will do their job well. However, the "homoaldol retron" is rarely openly incorporated in the natural products whose synthesis is challenging, for the homoaldol reaction is "antibiomimetic". Nature does not appear to use it. At the same time, this is an advantage, which will incite the development of new synthetic strategies. Thus, an exceedingly flexible route to branched desoxy sugars with various chain lengths, substitution patterns, and relative as well as absolute configurations, can already be envisaged. In this process, optically active hydroxyaldehydes are extended by three C-units. The option of stereocontrolled 1,2-epoxidation of enol carbamates further extends the access to polychiral structures.

The "chiralization" of our homoenolate reagents is a stimulating problem for a method-oriented research group. We see the most promising possibility of asymmetric homoaldol reaction in the incorporation of an asymmetric "cation" M, because this will be in close contact with the developing chirality center at C-4. The promising results obtained by *R. W. Hoffmann*[88a], *Midland*[169], *Matteson*[170], and *H. C. Brown*[171] with allyl boranes, and by *Reetz*[121] and *Seebach*[122] with chirally modified titanium reagents, as well as our own experience from unsuccessful attempts at this chiralization[165], make the solution appear tangibly close.

Our own work has enjoyed continuous and generous support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Thanks are due to my co-workers, whose names will be found in the references, and in particular to Dr. Rudolf Hanko, who during his graduate work, untaunted by initial failure, brought an idea that had been conceived on paper to a successful conclusion. The determinations of configurations were greatly facilitated by X-ray analyses; we thank Professor G. M. Sheldrick, Dr. E. Egert and Dr. P. G. Jones, Institut für Anorganische Chemie der Universität Göttingen, for extremely valuable cooperation.

[4] The CIP system allows the assignment of the configuration of diastereomers in general formulas only when additional postulates are added [5]. For the purpose of rapid assignment to diastereomeric series we therefore use the *syn-anti* prefixes of *Masamune* et al. [6]. If necessary, they are to be defined through structural formulas.

[7] The term "homoaldol addition" implies that the addition of the starting material leads immediately to homoaldols. Therefore, we name versions that require further deblocking steps as "homoaldol reactions".

[118] This is true for high torsional barriers around the 2,3-bond. - The configuration of the 1-double bond cannot be predicted by the model. High torsional barriers around the 1,2-bond or a very large energy difference between the torsional isomers, as well as transition states resembling the starting materials (presumably true for **149**, M = Li) lead to ground state control of the double bond configuration. For low barriers (true for **151**, $M = R_2Al$) the energy difference between equatorial and axial carbamoyloxy groups in the transition state is the dominant factor.

[127] *Reetz* [121] has in many cases observed an influence of the leaving group in the reagent **150** on the selectivity and postulated the formation of "*ate*" complexes; cf. also: M. T. Reetz, B. Wenderoth, *Tetrahedron Lett. 23* (1982) 5259. Where tested, we obtained identical results with the chloride **150c** and the isopropoxide **150d**; only in the case of **150d** is the metal exchange slower, which led us to a false interpretation [126].
[128] For the preparation, see: E. Benzing, W. Kornicker, *Chem. Ber. 94* (1961) 2262; simplified preparation: M. T. Reetz, R. Urz, T. Schuster, *Synthesis 1983,* 540.

[130] Results so far obtained allow two hypotheses: titanium compounds of this type are not formed on exchange, or else they react with low selectivity. *Z/E*-isomerization is slow (Table 1); cf. also K. Mashima, H. Yasuda, K. Asami, A. Nakamura, *Chem. Lett. 1983,* 219.
[131] The reason may be an improved α-selectivity of the exchange. Moreover, the hydride is commercially available in higher purity than the chloride.

The Dendralenes— a Neglected Group of Highly Unsaturated Hydrocarbons

By Henning Hopf*

Dedicated to Professor Wolfgang Lüttke on the occasion of his 65th birthday

Dendralenes are acyclic and cyclic cross-conjugated polyolefins derived from 3-methylene-1,4-pentadiene. This review summarizes and compares, for the first time, the methods developed for the synthesis of this class of hydrocarbons. Because of their particular arrangement of π-electrons, the dendralenes are novel substrates for addition and rearrangement reactions, and model compounds for spectroscopic studies.

For where will it get one, on the Day of Judgment, when mankind's works are weighed in the balance, to come forward with three treatises on formic acid—or thirty, for that matter? On the other hand, what can one know about the Day of Judgment if one does not even know what may have come of formic acid by then?

Robert Musil[1].

Chains, rings, substituents—those are the building blocks of the marvelous edifice of modern organic chemistry. Any hydrocarbon may be constructed on paper from methyl groups (CH_3), methylenes (CH_2), methynes (CH), and carbon atoms (C).

Roald Hoffmann[2].

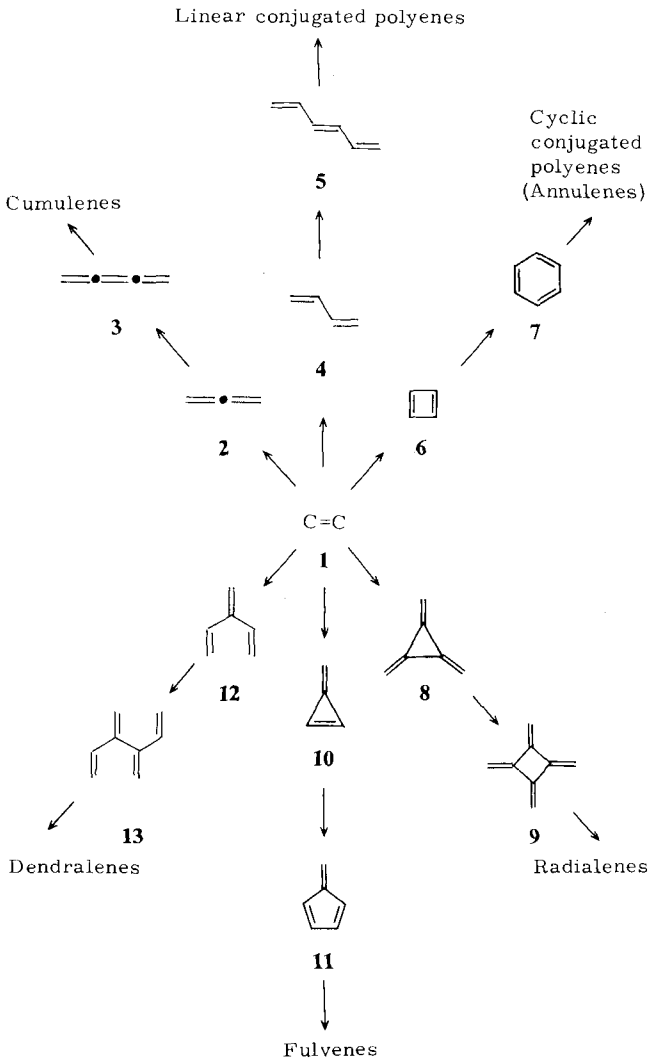
1. Polyenes by Coupling Ethylene Units

After considerably more than a hundred years of scientific work on hydrocarbons, one might assume that everything "that may come of" the two basic elements of organic chemistry is known. This may be the case "on paper"; in reality, however, in the preparation or the study of the chemical properties of many hydrocarbons, this is far from true. Even today many groups of compounds in this class of substances are represented by a few examples only, many of which have often only been studied cursorily. There are often no comparative studies of reactivity, as illustrated here using the example of the polyolefins.

Neglecting molecules with isolated double bonds, we can use the fragment "C=C" **1** to construct the basic types summarized in Scheme 1.



Scheme 1. Construction of polyolefins from ethylene building blocks (schematic).

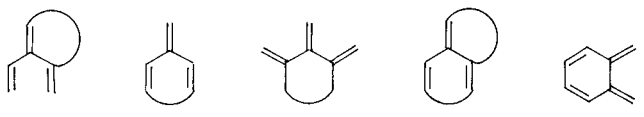
Coupling etheno units via common carbon atoms leads to allenes **2**[3,4] and cumulenes **3**[4]. If the C_2-units are connected via single bonds, conjugated di- **4**, tri- **5**, and finally polyenes are formed. Contrasting with this linear coupling is a cyclic one, which produces—via cyclobutadiene **6** and benzene **7**—the cyclic, conjugated polyenes, the annulenes. In this group of hydrocarbons the double bond always occupies an endocyclic position. The so-called radialenes, on the other hand, have entirely exocyclic double bonds, the simplest representatives being [3]radialene **8**[5] and [4]radialene **9**[6]. If both types of double bond arrangements occur in the polyolefin, fulvenes result, triafulvene **10**[7] and fulvene **11** being the simplest members.

Of the compounds presented so far, the conjugated acyclic and cyclic systems have been the most extensively investigated and occupy a central role in organic chemistry. However, compounds with cumulated double bonds are also beginning to enjoy a steadily increasing interest[3,4]. The number of the radialenes is still quite small. Among the parent systems, for example, the next higher homologue of **9**, [5]radialene, is still unknown. On the other hand, the radialenes form the parent molecules of the, in the meantime, quite thoroughly investigated oxocarbons and their derivatives[8]. The fulvenes and their derivatives exhibit a broad structural richness and varied chemical behavior, as shown recently by *Prinzbach* et al.[9], *Neuenschwander* et al.[10a,11], and *Hafner* et al.[10b]. Fulvenes and radialenes are so-called *cross-conjugated* systems and are their most important *cyclic* representatives. Far less is known, on the other hand, about *acyclic cross-conjugated* polyenes. These so-called *dendralenes*[12] are formally derived from the building block **1** by 1,1-coupling: the simplest dendralene is therefore 3-methylene-1,4-pentadiene **12**, and the next higher homologue is 3,4-bismethylene-1,5-hexadiene **13** ([4]dendralene). Dendralenes may also be formally derived by rupture of certain C–C bonds of cross-conjugated cyclopolyolefins: for example, **13** is obtained from **9** by cleavage (and saturation) of one cyclobutane bond, and **12** from **11** by removal of the C_3–C_4 bond. In fact, *Staudinger*, who was among the first to prepare a derivative of **12** (see Section 2.1), called these compounds "open fulvenes"[13].

In recent years cross-conjugated molecules of the dendralene type have received increasing attention. Rather than merely isolating and characterizing these hydrocarbons, more and more workers are attempting to synthesize specifically substituted and functionalized dendralenes. On the one hand, this growing interest has its roots in preparative chemistry. Dendralenes, for example, are suitable educts for multiple additions of the Diels-Alder type (see Section 2.1), since each addition of a dienophile molecule generates a new diene system which can undergo further cycloaddition. With the aid of dendralenes, therefore, large sections of the carbon framework of complex polycycles may, in principle, be built up. In thermal and photochemical rearrangements, novel results are to be expected, too, since the dendralenes should undergo these reactions like some of the other π-systems shown in Scheme 1.

On the other hand, molecules like **12** and **13** are also interesting from the structural viewpoint since a priori it is not at all clear whether they should prefer a planar structure. In fact this is not very likely, as discussed in Section 3. Unsaturated hydrocarbons have always been preferred as model compounds for spectroscopic studies, and the dendralenes are no exception in this respect[103–108]. Finally, cross-conjugation is a commonly encountered phenomenon in natural product and dyestuff chemistry, although in

the majority of cases the various π-systems are polarized either by heteroatoms and/or by electron-donating or -accepting substituents. This review article summarizes the preparative methods leading to this group of polyolefins; cyclic molecules are also included, if the ring-producing structural element does not generate radialenes, fulvenes, or related structures (see Section 3). Appropriate derivatives of **12** would for example be the bridged compounds **14**—**17**. This restriction also precludes the preparatively extraordinarily useful *o*-quinodimethanes **18**[14,15]—quasi "shortcircuited" [4]dendralenes—from this review.



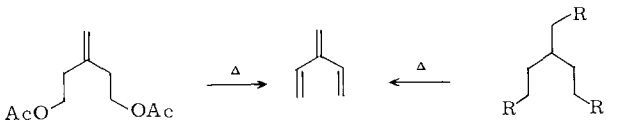
14 **15** **16** **17** **18**

As an ordering principle in this article, the degree of structural complexity of the target molecules, and not the various methods of preparation was selected. It comes as no surprise that among these, the standard methods for the preparation of double bonds occur widely (above all, eliminations and Wittig reactions). However, as a novel and variable synthetic approach to the dendralenes, thermal isomerization of polyenes, alkynes, and allenes has recently gained importance.

2. Acyclic Dendralenes

2.1. 3-Methylene-1,4-pentadiene 12 ([3]Dendralene) and its Derivatives

Although the first derivatives of **12** were prepared around the turn of the century (vide infra), the parent hydrocarbon was only synthesized in 1955. Ester pyrolysis of the readily available diacetate **19**[16] (485 °C, flow tube) as

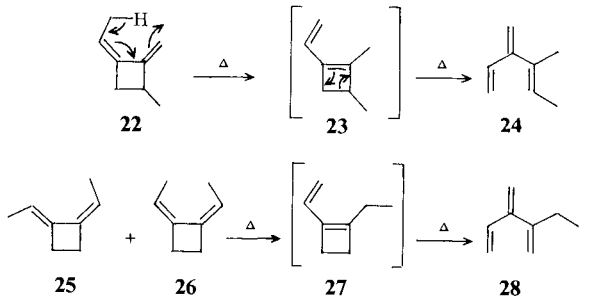


19 **12** **20**, R = OAc; **21**, R = $^{\oplus}NMe_3\ OH^{\ominus}$

well as of the triacetate **20**[17] (540 °C, flow tube) afford **12** in acceptable yields (ca. 30 and 45%, respectively). In a novel variant of this approach, the triene is obtained by Hofmann elimination of the ammonium salt **21**[18].

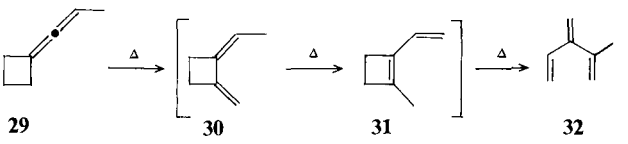
Several alkyl derivatives of **12** have been prepared by thermal isomerizations. Gas-phase pyrolysis of **22** at 260 °C leads to (4*E*)-3-methylene-4-methyl-1,4-hexadiene **24** in 90% yield, presumably by two successive concerted reactions (1,5-hydrogen shift to **23**, which undergoes electrocyclic ring opening[19]). **25** and **26** isomerize analogously via the presumed intermediate **27** to the 2-ethyl derivative **28**[19].

Preparatively even simpler is the thermal rearrangement of the propenylidenecyclobutane **29**, which is readily con-



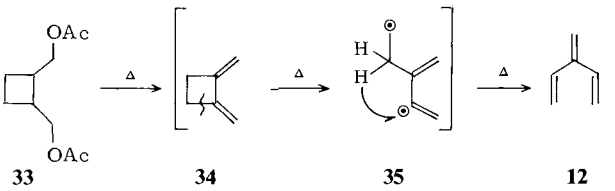
22 **23** **24** **25** **26** **27** **28**

verted into **32** by gas-phase pyrolysis[20]. The most probable intermediates in this reaction are the (not isolated) diene isomers **30** and **31** of **29**, the driving force of the process being provided both by the ring strain of **29** and



29 **30** **31** **32**

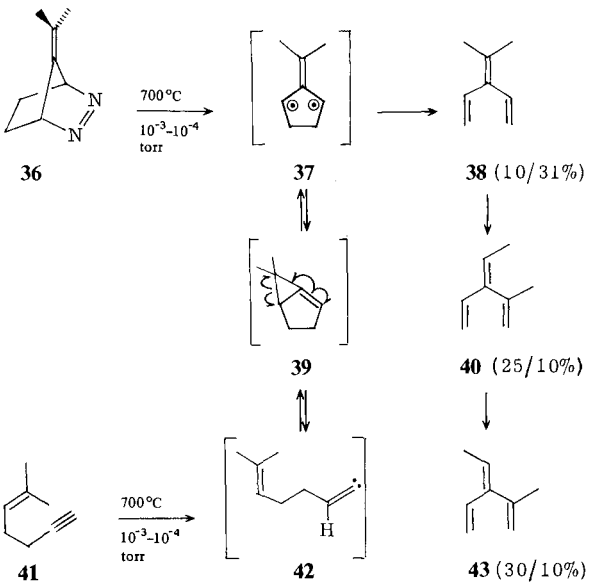
by the high energy of the allene group[21]. Hydrocarbon **12** is possibly also formed from 1,2-dimethylenecyclobutane **34**. In several attempts[22,23] to prepare **34** by ester pyroly-



33 **34** **35** **12**

sis of **33** the only hydrocarbon isolated was small amounts of [3]dendralene. Its formation can be rationalized by "vertical" cleavage of the four-membered ring of the initially produced **34**. The diradical **35** can subsequently stabilize itself by a 1,3-hydrogen shift.

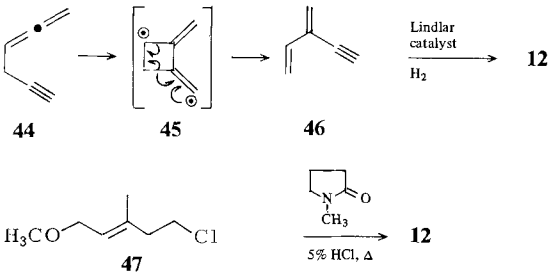
Using a completely different, but nevertheless pyrolytic route, *Berson* et al. prepared the methyl [3]dendralenes **38**,



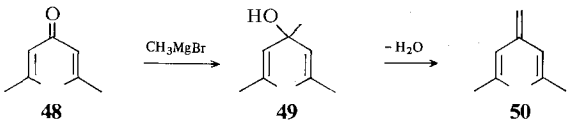
36 **37** **38** (10/31%) **39** **40** (25/10%) **41** **42** **43** (30/10%)

40, and **43**[24]. These trienes are formed, on the one hand, by vacuum flash pyrolysis of the diazene **36**, whereby **38** is the initially formed product, which subsequently equilibrates to **40** and **43** via 1,5-hydrogen shifts. The 2-isopropylidene-1,3-cyclopentanediyl **37** initially produced from **36** by N_2 loss is, on the other hand, also accessible via a remarkable series of rearrangements from the enyne **41**. By means of the well-known isomerization of terminal alkynes to vinylidenecarbenes, **41** rearranges to **42**, which ring-closes to afford the bicyclo[3.1.0]hex-1-ene **39**; finally **39** undergoes ring-opening to give **37**. The yields given in the second position of the parentheses for **38**, **40**, and **43** refer to the last-mentioned route.

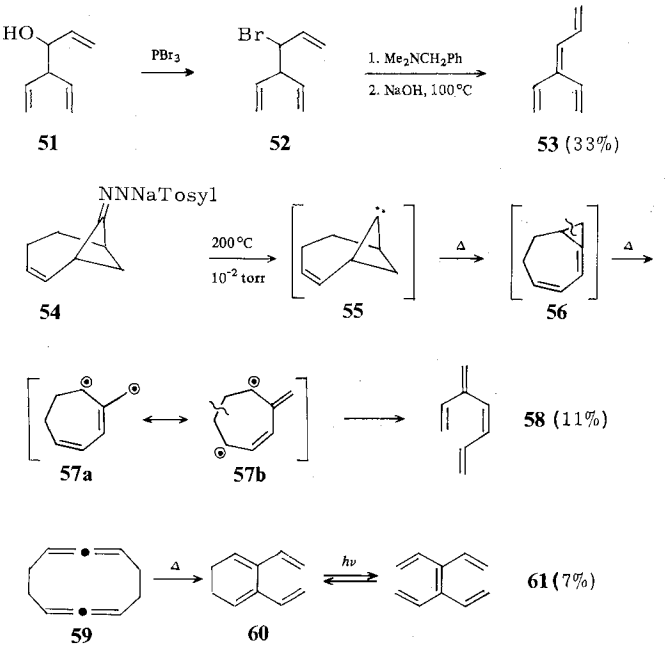
An acetylene derivative has also been employed in the preparation of the simplest cross-conjugated dienyne **46**[25]. Gas-phase pyrolysis of 1,2-hexadiene-5-yne **44** furnishes 3-methylene-1-penten-4-yne **46** in ca. 45% yield. The mechanism of this formal 1,3-ethynyl migration is unknown; however, the diradical **45** is a conceivable intermediate[26]. Lindlar hydrogenation of **46** affords another route to 2-vinyl-1,3-butadiene **12**[27], which can also be produced by subjecting 5-chloro-3-methyl-2-pentenyl methyl ether **47** to a multiple elimination sequence[28].



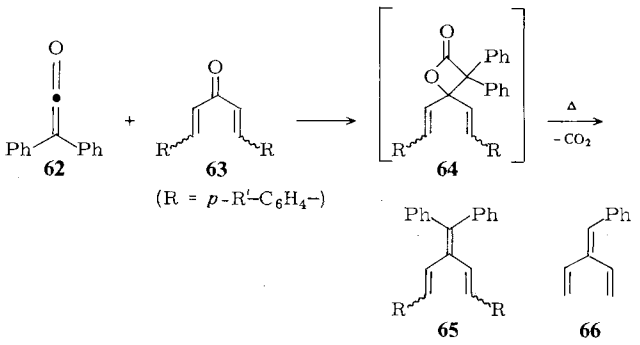
Cross-conjugated dienones have been employed occasionally for the preparation of the corresponding trienes (cf. Section 3.1). In a very early example, Grignard reaction of phorone **48** provided the tertiary alcohol **49**, which during distillation dehydrates to the tetramethyl[3]dendralene **50**[29].



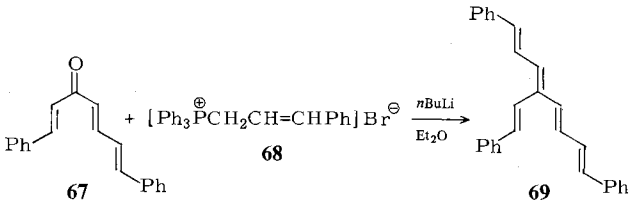
Several vinyl[3]dendralenes have been prepared by eliminations (**52**→**53**[30]) and rearrangements (**55**→**58**[31]; **60**→**61**[32]). Whereas multistep isomerization of the carbene **55**—prepared by vacuum flash pyrolysis of the sodium salt of bicyclo[4.1.1]oct-2-en-7-one tosylhydrazone **54**—is unspecific (in addition to 5-methylene-1,3,6-heptatriene **58**, at least six other hydrocarbons are formed[31])—photoisomerization of **60**, which itself is a (bridged) [4]dendralene (see Section 3.1) leads exclusively to **61**[32]. As precursor for **60** an allenic hydrocarbon **59** is used once again (cf. Section 3.3).



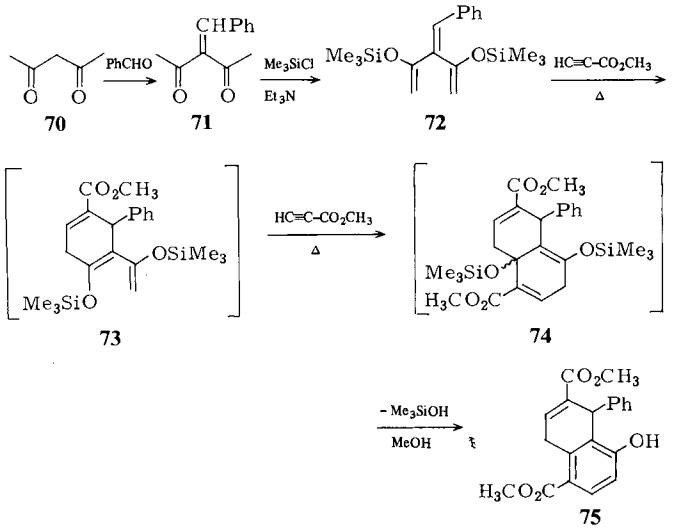
The phenyl derivatives **65**, *Staudinger*'s "open fulvenes", previously referred to, have been known for decades. They are produced by addition of diphenylketene **62** to *p*-substituted dibenzylidene acetones **63** (R′=H, CH_3O, Cl, styryl), with the (not isolated) β-lactone **64** as primary adduct. The reaction fails with the phorone **48**[33]; however, in view of the currently available, much more reactive ketenes[34] this elegant approach employing easily obtainable substrates should be reinvestigated. Dehydrobromination of 3-(bromo(phenyl)methyl)-1,4-pentadiene with potassium hydroxide in methanol provides the monophenyl derivative **66** of [3]dendralene[35].



The Wittig reaction has apparently not—or only unsuccessfully—been used to prepare alkyl derivatives of **12**. In marked contrast is the aryl-substituted series, where *Bohlmann* has described the synthesis of numerous cross-conjugated hydrocarbons. A case in point is provided by the olefination of **67** with the ylide from **68** to afford **69**.

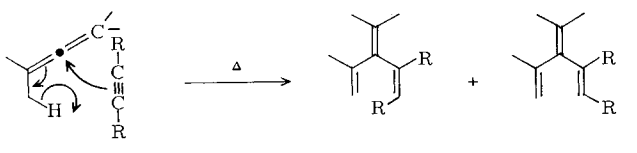


The dendralenes described so far in this section are useful model compounds for the investigation of the stereochemical and spectroscopic properties of the different connectivity and substitution types, and can also be used to study the elementary reaction modes. For the solution of more demanding synthetic tasks, the value of the unsubstituted or alkyl, alkenyl, or aryl substituted hydrocarbons is limited. For these purposes more reactive and chemically more variable substituents are required. Appropriately functionalized [3]dendralenes have indeed been described very recently. Thus the benzylidene derivative **71** of acetylacetone **70** is easily transformed into the bisenol ether **72**[37,38].



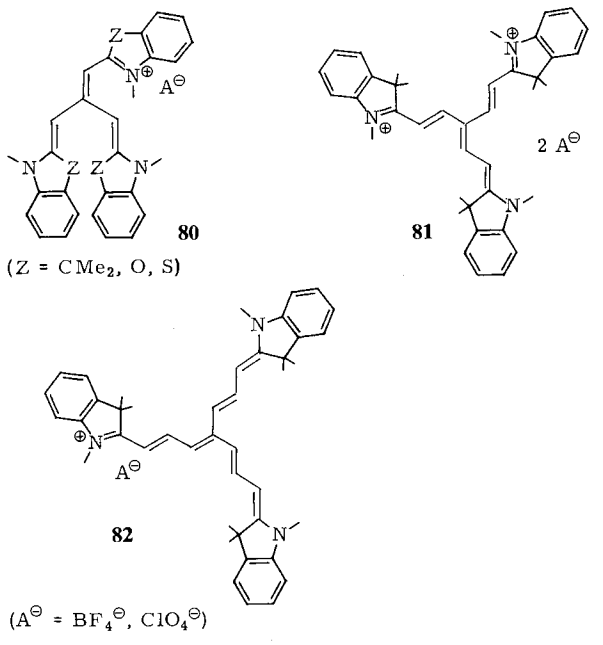
70 **71** **72** **73** **74** **75**

In Diels-Alder additions with double and triple bond dienophiles **72** functions as a double diene: initial Diels-Alder addition generates a new diene system in the 1:1-adduct **73**, which is capable of binding a second dienophile molecule. The resulting 2:1-adducts (here **74**) may not be stable under the addition conditions (aromatization to **75**); in any case, however, a highly functionalized product results. These so-called "diene-transmissive Diels-Alder reactions"[37,38] also occur in the reaction of **12** with maleic anhydride and quinones[16,17]; their designed use in organic synthesis is, however, of more recent origin[37,38]. Functionalized [3]dendralenes such as **78** and **79** are also obtained when alkylallenes, e.g. tetramethylallene **76**, react with electron-deficient acetylenes **77** (R=CF_3, CO_2CH_3, etc.) in an ene reaction (yields: 30—70%)[39,40].



76 **77** **78** **79**

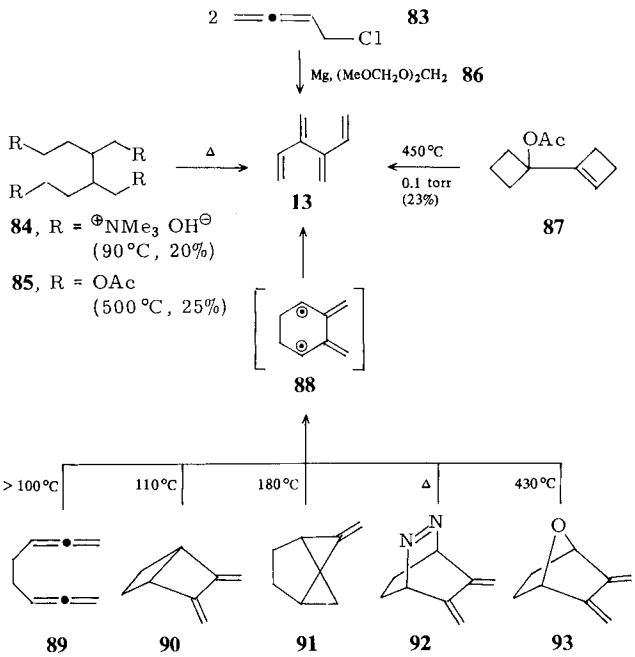
It should also be mentioned that cross-conjugation is a phenomenon widely known in dyestuff chemistry[41,42]. The numerous examples provided by di- and triarylcarbenium dyes and their aza-analogues as well as by many carbonyl dyes by far exceed the scope of this review. One example is the large number of (formal) derivatives of **12** among the trinuclear polymethyne dyes, e.g. the mono- and dications **80**—**82**, in which the π-electrons of the respective "dendralene parts" are delocalized over the entire system[43-45].



80 **81** **82**

2.2. 3,4-Dimethylene-1,5-hexadiene 13 ([4]Dendralene) and its Derivatives

For the preparation of **13** (Scheme 2), the methods that have already proven of value in the synthesis of **12** and its derivatives are used again (cf. Section 2.1). On the one hand, these are elimination reactions (**84** → **13**[46]; **85** → **13**[47]), which are easy to carry out, but require considerable synthetic effort to prepare the different substrates; on the other hand, thermal rearrangements are used that either start from isomeric allenes (**89** → **13**[48,49])

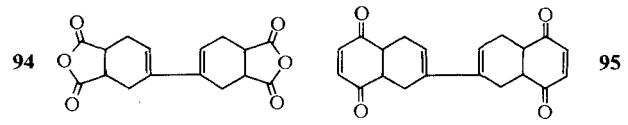


83 **86** **13** **87** **88** **89** **90** **91** **92** **93**

Scheme 2. Methods for the preparation of **13**.

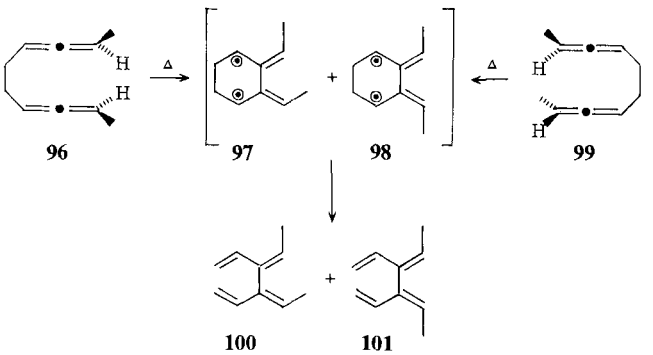
or strained ring compounds (**90** → **13**[49b,50]; **91** → **13**[49b,51]). Fragmentation of the bicyclic systems **92**[50] and **93**[49b] also provides **13**, which in these reactions is formed—in addition to other hydrocarbons—via the 2,3-dimethylene-1,4-cyclohexadiyl diradical **88**[52,53]. The synthesis of **13** from **87** proceeds via a combination of elimination and rearrangement[54]; this polyolefin is also obtained by oxidative dimerization of the Grignard reagent prepared from 1-chloro-2,3-butadiene **83** (Scheme 2)[55].

Although many methods are therefore known for the preparation of **13**, it must be pointed out that several of these do not satisfy preparative requirements. The chemical behavior of the polymerization-prone **13** remains largely unexplored. Cycloadditions with maleic anhydride and *p*-benzoquinone are claimed to yield the adducts **94** and **95**[46], i.e. the diene-transmissive Diels-Alder addition ceases at the 2:1-stage. Since the reactivity of the diene system in **94** and **95** (whose diketoform appears less likely) is not to be expected to be particularly low, these experiments should be repeated.



94 **95**

No designed syntheses of specifically substituted [4]dendralenes have been reported. *Skattebøl* and *Becher* isolated the diastereomeric dimethyl derivatives **100** and **101** on pyrolyzing *meso*- and (±)-2,3,7,8-decatetraene **96** and **99**, respectively. The composition of the product is independent of the configuration of the starting allene; the 1,4-diyls **97** and **98** have been proposed as reaction intermediates[56]. Alkyl derivatives of **13** are possibly also formed as side-products in the dimerization of α-bromoallenes with magnesium[57].

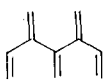


96 **97** **98** **99**

100 **101**

2.3. 3,4,5-Trimethylene-1,6-heptadiene 102 ([5]Dendralene)

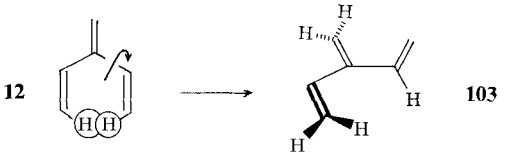
Like many other acyclic cross-conjugated polyenes, [5]dendralene **102** has been the subject of quantum mechanical calculations[58], although it has not been prepared so far. Even if **102** could be obtained by a preparatively simple route, it would presumably be difficult to study its chemical properties since it is probably a very reactive substance. As is frequently the case in hydrocarbon chemistry, polyalkyl or aryl substitution should lead to a marked decrease in reactivity.



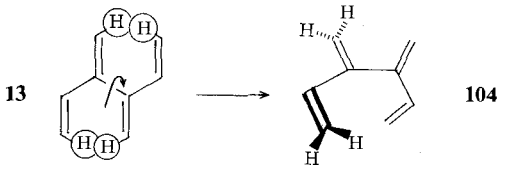
102

3. Cyclic Dendralenes

Astonishingly, the UV spectra of **12** (λ_{max} = 224 nm, $\log\varepsilon$ = 4.41)[16,17] and **13** (216.5 nm, 4.56)[46–48] hardly differ from that of 1,3-butadiene **4** (217 nm, 4.32)[59]. It is assumed that the nonplanarity of the dendralenes is responsible for this effect. As indicated by inspection of molecular models, planar structures for **12** and **13** would cause severe steric hindrance between the "*endo*"-hydrogen atoms. To avoid this accumulation of substituents, the polyenes prefer twisted conformations as shown in **103** and **104**, respectively. As a consequence, the *p*-orbitals can no longer assume the parallel alignment required for maximum overlap, and the absorption maxima are shifted to lower wavelengths. In order to study the spectroscopic and chemical properties of a planar dendralene, rotation about



12 **103**

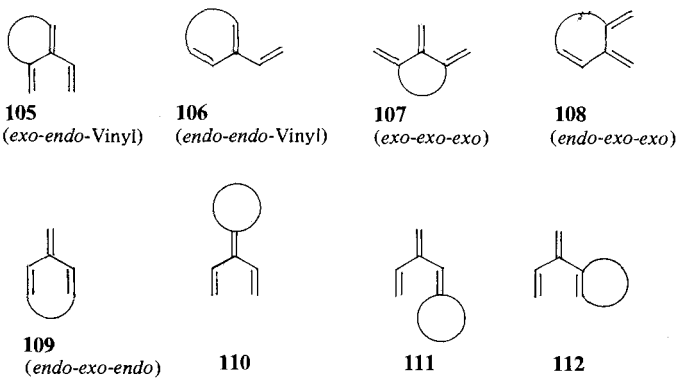


13 **104**

the single bonds must be prevented. This is accomplished most effectively by bridging, i.e. by incorporating the dendralene system into a cyclic molecule. The bridging permits only very specific arrangements of the double bonds and, hence, should also influence the chemical behavior of the various dendralenes.

3.1. Monocyclic [3]Dendralenes

If we disregard *E*/*Z*-isomers, [3]dendralene **12** may be bridged in eight different ways (Scheme 3). Whereas in types **105** and **106** the rotation about only one single



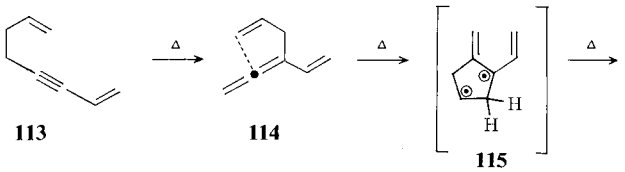
105 (*exo-endo*-Vinyl) **106** (*endo-endo*-Vinyl) **107** (*exo-exo-exo*) **108** (*endo-exo-exo*)

109 (*endo-exo-endo*) **110** **111** **112**

Scheme 3. Monocyclic [3]dendralenes.

bond is not possible, the dendralenes **107**—**109** are locked in a coplanar structure, especially with short molecular bridges. Systems **110**—**112** still possess "free" vinyl groups, but their rotational barriers should be higher than those of the parent compound **12**.

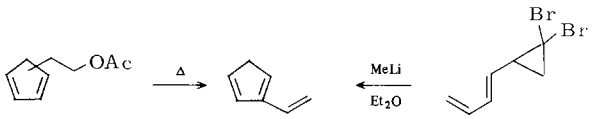
As shown in the following sections, representatives of practically all bridging types are known today, and thermal isomerizations again play a decisive role in their preparation (for types **110**—**112** no literature search was carried out). In a novel multi-step rearrangement which affords [3]dendralenes of the *exo,endo*-vinyl type **105**, 1,7-octadien-3-yne **113** undergoes thermal isomerization via a [3,3]sigmatropic rearrangement to give the (isolable) allene **114**, which via diradical **115** and 1,2-hydrogen shift stabilizes either to the dendralene **116** (44%) or to the triene **117** (52%)[27]. 6-Methyl derivatives of **113** lead to the expected methyl compounds **118**[60].



113 **114** **115**

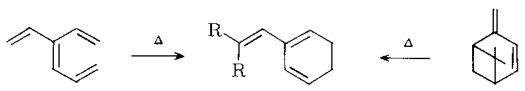
116 **117** **118a**, $R^1 = R^2 = CH_3$; **118b**, $R^1 = H$, $R^2 = CH_3$

Although the lower homologues of the *endo,endo*-vinyl series **106** are known, the lack of specificity makes the routes leading to them essentially worthless for practical purposes. Thus 2-vinyl-1,3-cyclopentadiene **120** is formed together with two dozen other hydrocarbons upon pyrolysis of the isomeric acetates **119**[61]. Treatment of the dibromocyclopropane **121** with an excess of methyllithium in ether at 0°C furnishes **120**, its 1-vinyl isomer, as well as 1,2,4,6-heptaetraene[62].



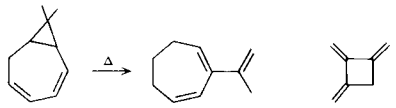
119 **120** **121**

The next higher homologue, **122a**, is obtained by electrocyclizing the vinyl [3]dendralene **53** (cf. Section 2.1), surprisingly, cyclization of 3-ethyl-1,3,5-hexatriene is 30 times slower[30].



53 **122a**, R = H; **122b**, R = CH_3 **123**

Compound **122a** has also been shown to be a decomposition product of **54**[31]. The 2-methyl-1-propenyl derivative of 1,3-cyclohexadiene **122b** is formed in 14% yield accompanied by three isomeric hydrocarbons upon gas phase pyrolysis of (+)-verbenene **123** at 390°C[63]. Thermal isomerization also affords the seven-membered ring compound **125** (pyrolysis of 8,8-dimethylbicyclo[5.1.0]octa-2,4-diene **124** at 250°C[64,65]).

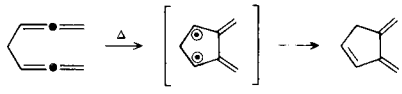


124 **125** **126**

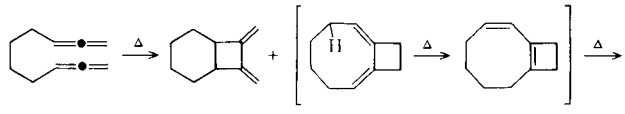
The only known representative of the *exo,exo,exo*-type **107** is 1,2,3-trismethylenecyclobutane **126**, prepared by conventional methods from cyclobutanetricarboxylic acid[66,67]. Isomers of the higher homologues have been described[3,4]; none, however, with three *exo*-methylene groups arranged consecutively.

For the synthesis of the *endo,exo,exo*-[3]dendralenes **108** allenic substrates or intermediates may again be employed. The parent hydrocarbon of this series, 3,4-bismethylenecyclopentene **129**, is obtained from 1,2,5,6-heptatetraene **127** by intramolecular cycloaddition via the diradical **128**[68]:

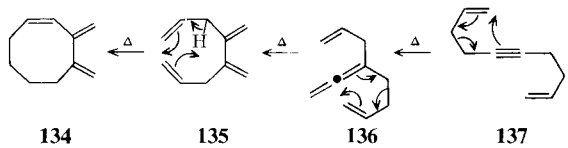
An analogous cycloaddition initiates the formation of 3,4-bismethylenecyclooctene **134**, which is isolated together with the cycloadduct **131** when **130** is pyrolyzed above 300°C[48,69]. The precursor of **134** could be the regioisomer **132**, which in turn could rearrange to **133** by 1,5-hydrogen shift. Under the pyrolysis conditions, the latter intermediate could undergo conrotatory ring opening to **134**. By means of on entire cascade of pericyclic reactions, **134** has recently been prepared from the acyclic trienyne **137**[70]: a tandem Cope rearrangement first produces 4,5-bismethylene-1,7-octadiene **135** via the (isolable) allene **136**; **135** is unstable under the pyrolysis conditions and cyclizes to **134** by an intramolecular ene-reaction[71].



127 **128** **129**

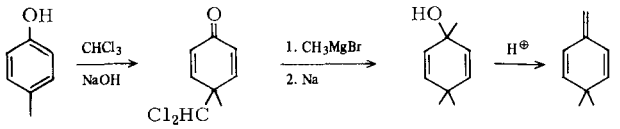


130 **131** **132** **133**



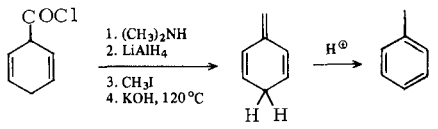
134 **135** **136** **137**

Of all known dendralenes, the *endo,exo,endo*-derivatives **109** are the most thoroughly studied. Derivatives of the lowest member of this homologous series were studied around the turn of the century by *Karl Auwers* et al. in the course of investigations on semibenzenes. As the most simple hydrocarbon, the 3,3-dimethyl compound **141** was obtained.



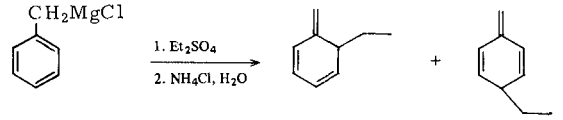
138 139 140 141

Under the conditions of the Reimer-Tiemann reaction *p*-cresol **138** affords the cyclohexadienone **139**, which was reduced by standard methods to the tertiary alcohol **140**. As expected, this is acid-sensitive and is readily dehydrated to **141**[72]. By a similar approach, semibenzenes with chlorine substituents in the nucleus were obtained[73]; *Auwers* et al. suspected that 3-methylene-1,4-cyclohexadienes bearing one or no substituents at the 6-position could not be prepared, since they would "presumably easily isomerize to benzene derivatives". This assumption was proven to be correct 60 years later by *Plieninger* and *Maier-Borst*, who first synthesized 3-methylene-1,4-cyclohexadiene **143** from 1,4-dihydrobenzoyl chloride **142**[74,75]. Traces of acid induce isomerization of **143** to toluene **144**. This so-called semibenzene rearrangement may also be initiated thermally, as shown with numerous derivatives of **143**[76–82].



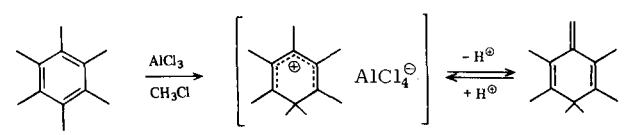
142 143 144

3-Methylene-1,4-cyclohexadienes monosubstituted in the 6-position, including the ethyl derivative **147**, are obtained when benzylmagnesium halides **145** are first alkylated and the reaction mixtures subsequently carefully hydrolyzed with saturated ammonium chloride solution[83]. Besides the dendralene, its linear conjugated isomer is produced, here **146** (**146** : **147** = 3 : 1)[84].



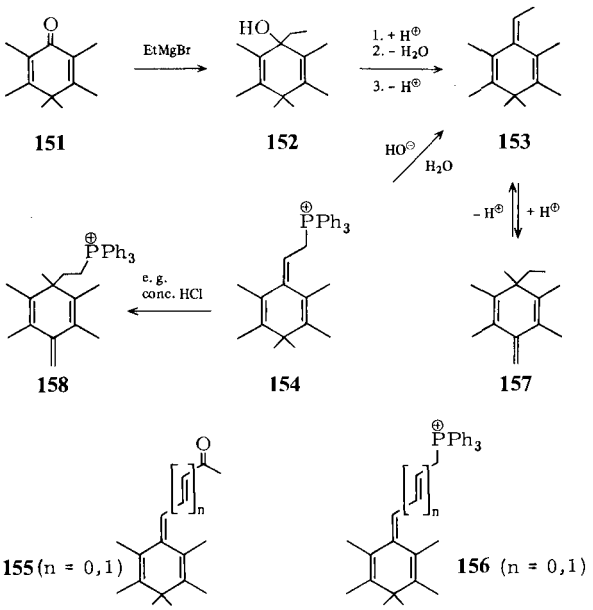
145 146 147

Polyalkylated derivatives of **143** (e.g. **150**) are, on the other hand, obtained via cationic intermediates by a method discovered by *Doering* et al.[85], and later generalized particularly by *Hünig* and *Schilling*[86]. In their most simple form, polyalkylbenzenes such as hexamethylbenzene **148** serve as substrates which are converted by Friedel-Crafts alkylation in an initial step into isolable σ-complexes **149** ("heptamethylbenzenium ion"). Rather than aromatizing to the starting material by loss of a methyl group, **149** loses a proton to generate the ring-permethylated hydrocarbon **150**. Its formation is reversible: aqueous hydrochloric acid suffices to establish the equilibrium **150** ⇄ **149**[85,88].



148 149 150

In the *Hünig* variant[86], **151** and **154** are employed as substrates for the ethylidene derivative **153**. On treatment with acid, **153** equilibrates with its isomer **157**, and **154** is correspondingly converted into the isomeric dendralene **158**. *Doering*'s triene **150** has been used as starting material for a whole series of vinylogous cross-conjugated systems[89]. The aldehydes **155** and phosphonium salts **156** are mentioned explicitly since certain bicyclic dendralenes with very extended π-systems (cf. Section 3.2) can be prepared from them.

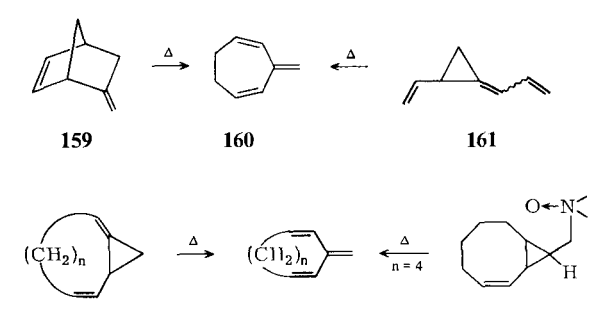


151 152 153 158 154 157

155 (n = 0,1) 156 (n = 0,1)

Apart from elimination reactions, the cyclic [3]dendralenes of type **109** have also been obtained by Wittig reaction from the corresponding cyclohexadienones[90,91].

The syntheses of the higher homologues of 3-methylene-1,4-cyclohexadiene **143** are again dominated by thermal processes: 3-methylene-1,4-cycloheptadiene **160** is formed—in low yield and accompanied by many other products—on gas-phase pyrolysis (670 °C, 3 torr) of 5-methylenebicyclo[2.2.1]hept-2-ene **159**[92] as well as by thermal isomerization of 1-allylidene-2-vinylcyclopropane **161**; 4-vinyl-3-methylenecyclopentene is formed as sole byproduct[93]. The 8- to 10-membered ring trienes **163** are



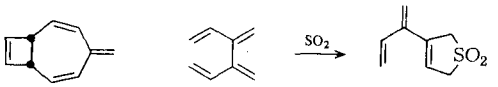
159 160 161

162 (n = 3-5) 163 (n = 3-5) 164

generated smoothly by pyrolysis of the bicycloalkadienes **162**[94,95]; alternatively 3-methylene-1,4-cyclononadiene has been obtained from **164** in 50% yield by Cope-elimination[96].

165, a bicyclic derivative of **160**, has been prepared by a similar route[96], and a 3,7-bismethylene-1,4-cyclooctadiene is described in Section 3.3[97].

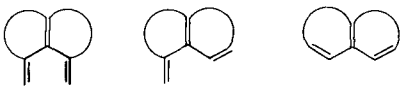
As a curiosity, it might be mentioned that the addition of sulfur dioxide to [4]dendralene **13** yields the sulfone **166** i.e. an example of the bridging type **112**[49c].



165 **13** **166**

3.2. Bicyclic [3]Dendralenes

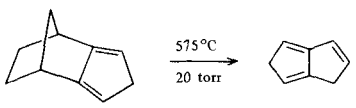
Not surprisingly, the number of ways of bridging a [3]dendralene increase rapidly when a second bridge is introduced. Altogether, 38 bicyclic molecular frameworks with a [3]dendralene subunit are conceivable, but of these, we will only deal with those molecules whose molecular bridges hold the triene in a coplanar arrangement. As shown by the (selected[98]) general structures **167**—**171**, the relative mutual orientation of the double bonds may be predetermined by the designed introduction of the bridge. This again makes the resulting polyenes interesting model substrates for spectroscopic and chemical studies.



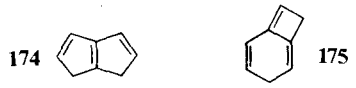
167 **168** **169**

170 **171**

At present, however, only very few of these structural types are accessible. The simplest bicyclic coplanar [3]dendralenes possess the molecular formula C_8H_8, i.e. these hydrocarbons must either be the bicyclo[3.3.0]trienes **173** and **174** or the bicyclo[4.2.0]octatriene **175**; with the last-mentioned most probably being a very highly strained and, therefore, extremely short-lived molecule.

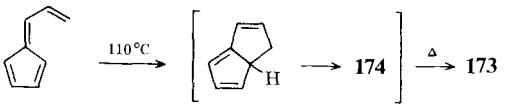


172 **173**



174 **175**

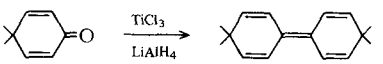
Of the two dihydropentalenes **173** and **174**, *Katz* and *Rosenberger* generated **173** by gas-phase pyrolysis of isodicyclopentadiene **172**; **173** was used for the first synthesis of the pentalenyl dianion[99]. In a remarkable isomerization described by *Gajewski* and *Cavender*, 6-vinylfulvene **176** is connected via **177** and **174** to **173**[100].



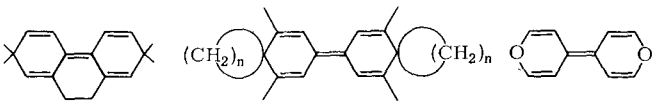
176 **177**

Analogously, 6-propenylfulvene rearranges to methyl derivatives of **173**[100]. A third route to **173** involves flow pyrolysis (400—665 °C) of cyclooctatetraene, with the semibullvalenyl diradical as the most probable intermediate[101]. Six-membered ring trienes of the types **167**—**171** have, as for as I know, not yet been described. These compounds should aromatize easily, as has been observed for 1,3- and 1,4-cyclohexadiene under relatively mild conditions[102]. In the case of condensed cyclobutene rings, (thermal) ring-opening is to be expected.

178



179

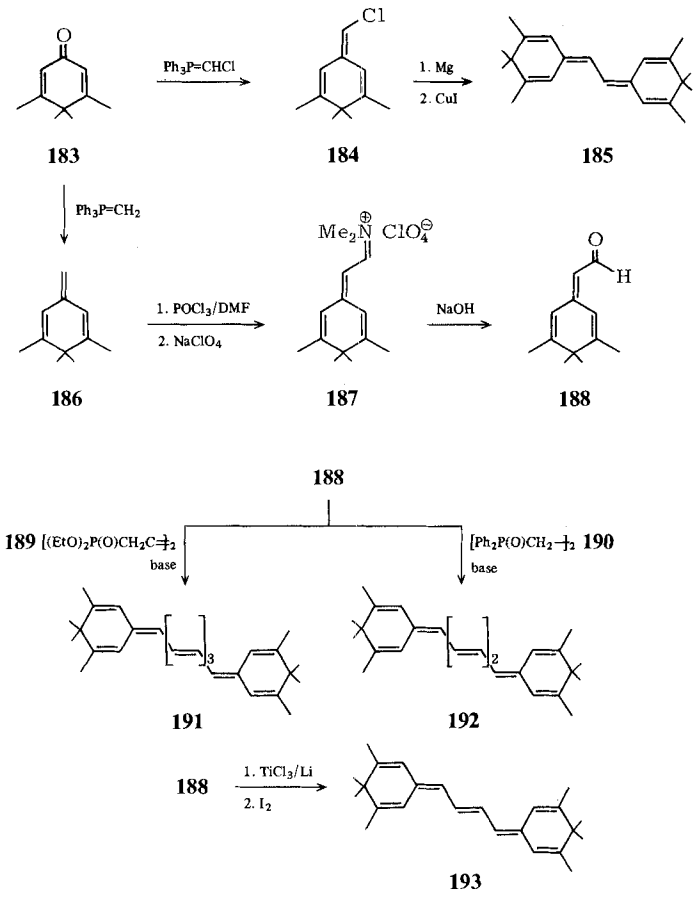


180 **181a**, n = 4 **182**
181b, n = 5

178, which may be regarded as a doubly bridged derivative of **61** (cf. Section 2.1), is a special bicyclic polyene with cross-conjugated double bonds. The first hydrocarbon of this type, 4,4,4′,4′-tetramethylbi(2,5-cyclohexadienylidene) **179** was prepared by *Lüttke* and *Janssen* by a simple and effective method[103]: McMurry coupling[104] of a dimethyl derivative of the ketone **139**, which had already been used for the preparation of **141**, gave the pentaene **179** in 97% yield. Comparable procedures lead to some derivatives of **179**, among them **180**[103], **181a**, **b**[105], and **182**[103,106]. Structurally and spectroscopically **179** belongs to the most carefully and widely studied cross-conjugated polyolefins yet known[107a-e].

Hünig et al. have used dendralenic substrates to prepare vinylogous derivatives of **179**[89,105], and Scheme 4 presents some characteristic examples of their extensive work[108].

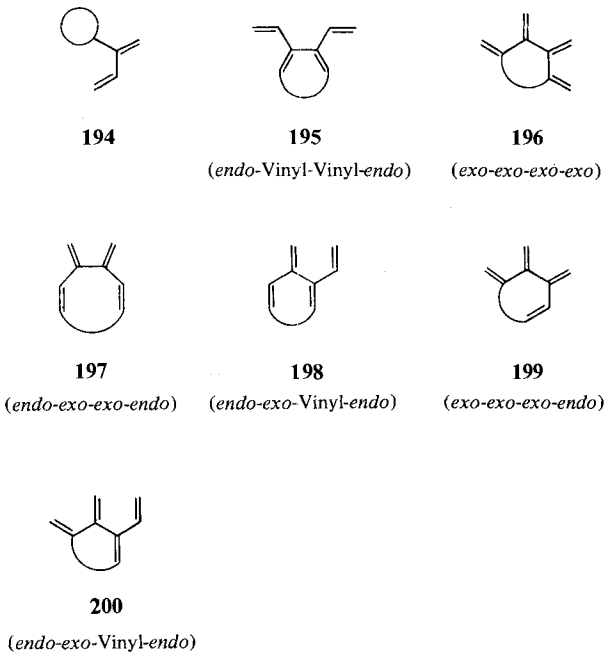
Key intermediate in this reaction is the cross-conjugated dienone **183** which can be olefinated to **186** or to its chloro derivative **184**, as desired. Reductive coupling of the triene **184** leads to **185**, whereas **186** can be readily converted into the aldehyde **188**, a second key compound, via the Vilsmeier salt **187**. Double Wittig reaction with the ylides of **189** and **190** furnishes **191** and **192**, respectively, and McMurry coupling of **188** finally yields **193**.



Scheme 4. Synthesis of extended cross-conjugated polyenes from monocyclic [3]dendralenes. DMF = dimethylformamide.

3.3. Mono- and Bicyclic [4]Dendralenes

[4]Dendralene **13** may be incorporated into a monocyclic ring system in eleven ways. If all structures still possessing a "free" butadienyl group (**194**) are neglected, six arrangements **195**–**200** remain whose double bond systems are sterically more or less fixed.



194

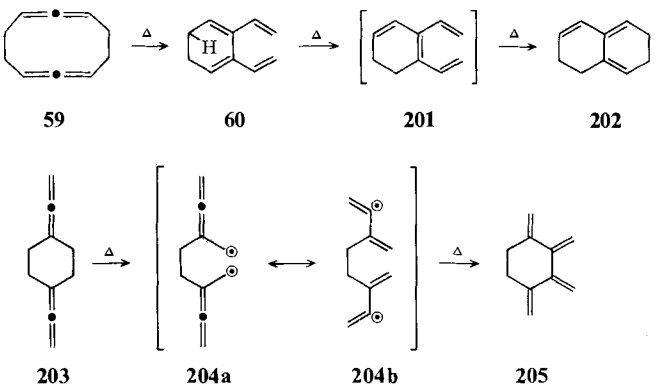
198 (*endo-exo*-Vinyl-*endo*)

199 (*exo-exo-exo-endo*)

200 (*endo-exo*-Vinyl-*endo*)

The first compounds of these structural types have been prepared recently, and thermal rearrangements of allenes again play a decisive role in their preparation.

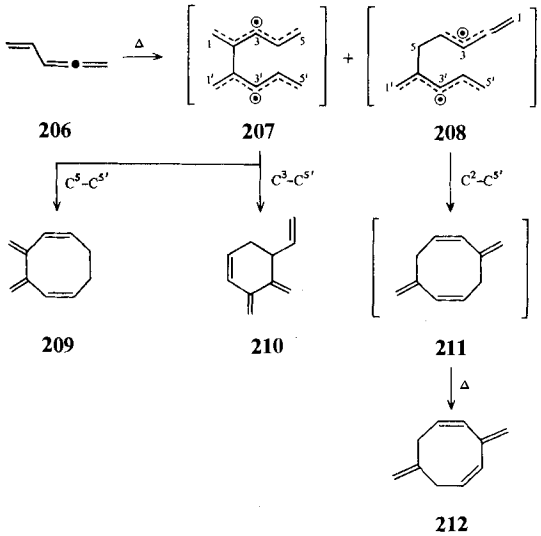
The isomerization (300 °C, gas phase) of 1,2,6,7-cyclodecatetraene **59** to 2,3-divinyl-1,3-cyclohexadiene **60** has already been mentioned[48] (see Section 2.1). At higher temperatures **60** is unstable and isomerizes by a 1,5-hydrogen shift via **201** and its electrocyclic ring closure to **202**, i.e. it is converted into a bicyclic [3]dendralene of type **170**[109]. Hydrocarbon **203**, an isomer of **59** with two exocyclic allene groups, isomerizes upon gas-phase pyrolysis (500 °C, 0.1 torr) to afford a monocyclic [4]dendralene, 1,2,3,4-tetramethylenecyclohexane **205**[110]. The most likely primary intermediate in this process is the diradical **204a,b**, which recyclizes in surprisingly high yield (82%).



59 **60** **201** **202**

203 **204a** **204b** **205**

Three different cross-conjugated monocycles are produced—in addition to three other dimers—when 1,2,4-pentatriene **206** (vinylallene) is heated to 170 °C[97]. The



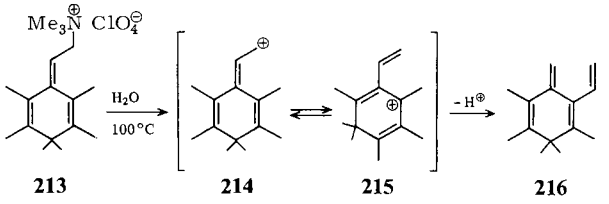
206 **207** **208**

209 **210** **211**

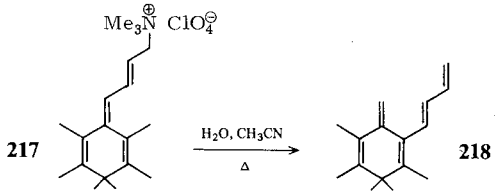
212

formation of the monocyclic [4]dendralene **209** (25%, GC-analysis) by C^5–$C^{5'}$ coupling of the diradical **207** competes with formation of the [3]dendralenes **210** (19%; type **107**) and **212** (5%; type **108**). Whereas **207** also serves as a precursor of the six-membered ring compound (C^3–$C^{5'}$ coupling), **212** is preceded by the isomeric tetraolefin **211**. This last-mentioned compound should arise from diradical **208** by C^2–$C^{5'}$ coupling and rearranges under the pyrolysis conditions via 1,3-hydrogen shift to the final product[97].

A partially coplanar [4]dendralene of type **198**, the pentamethyl derivative **216**, was obtained by *Hünig* and *Schilling* by hydrolysis of the perchlorate **213**. Primary intermediate is the cation **214**, which isomerizes to the more stable **215**; deprotonation subsequently provides the tetraene **216**. Likewise, the vinylogous salt **217** is converted into the cross-conjugated pentaene **218** (major product[86]).



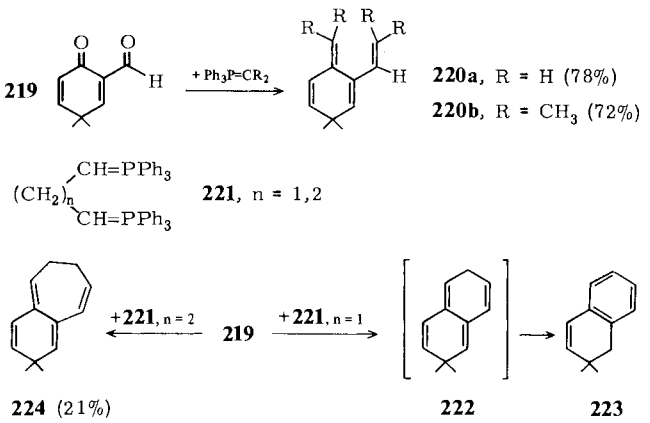
213 **214** **215** **216**



217 **218**

The Wittig reaction may also be employed for the synthesis of derivatives of **198** and **216**, as shown by *Cassens* and *Lüttke*[111].

Key intermediate in this instance is 2-formyl-4,4-dimethylcyclohexadienone **219**, a cross-conjugated molecule. With simple ylides it is olefinated readily to the tetraenes **220**, but with the bisylide **221** (n = 1) instead of **222** its



isomerization product **223** is obtained. In view of the high tendency of 3-methylene-1,4-cyclohexadienes to aromatize (see Section 3.1), this result comes as no surprise. With **221** (n = 2), however, the first doubly-bridged [4]dendralene, 9,9-dimethylbicyclo[5.4.0]undeca-1,5,7,10-tetraene **224**, is isolated. Its spectroscopic data clearly show that this hydrocarbon is indeed a coplanar [4]dendralene[111].

4. Concluding Remarks and Outlook

It was the purpose of this review to collect for the first time the widely scattered experimental material on the synthesis of cross-conjugated polyenes of the dendralene type. That at least one hundred compounds of this type are known seems at first sight to contradict the title of this article; nevertheless, it is justified and does not even require a question mark.

Neglected so far have been comprehensive and comparative studies on the chemical behavior of the dendralenes, which more often than not were obtained more or less serendipitously in various chemical transformations rather than by carefully planned syntheses. Like all olefinic π-systems, the dendralenes are suitable educts for addition reactions of all types; the Diels-Alder addition discussed above illustrate this[112]. The thermal and photochemical behavior of these hydrocarbons ought also to be studied, as should their possible application as ligands for novel metal complexes. A systematic attempt to broaden the experimental basis via carbocations[113, 114] and carbanions[115] derived from the simple cross-conjugated hydrocarbons would be welcome. These ions very probably possess interesting spectroscopic properties, and may be valuable for the introduction of preparatively useful functional groups[116].

Dendralenes with sterically fixed structures are interesting objects for spectroscopic studies, as shown very recently by the investigations of *Lüttke* et al.[107, 111]. But more attention should also be given to the spectroscopic and structural properties of the acyclic dendralenes. It has, for example, up to now not been verified experimentally whether [3]dendralene **12** really possesses the "twisted" structure suggested by formula **103** (and several theoretical calculations[111]). In fact, the numerous theoretical studies on the electronic structure and bonding properties of cross-conjugated hydrocarbons should be confirmed by experimental work.

For our own work reported in this review, I would like to thank my co-workers whose names appear in the appropriate references. Their interest and experimental expertise made this work possible, under conditions often far from ideal. For literature references and helpful discussions I would like to thank Professors S. Hünig (Würzburg), M. Neuenschwander (Bern), the Dozenten W. Grahn (Braunschweig), H. Hauptmann (Regensburg), and especially Professor W. Lüttke (Göttingen); without the many discussions I had with him on hydrocarbons (and other matters), this review would probably not have been written. For permanent and generous support of our work on highly unsaturated hydrocarbons I am very grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie as well as to BASF, Bayer, Hoechst, Degussa, and Metallgesellschaft.

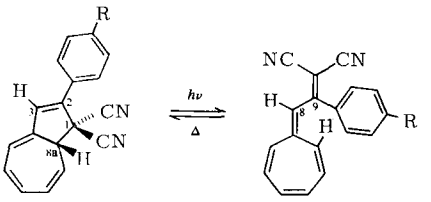
Photosensitive Dihydroazulenes with Chromogenic Properties**

By *Jörg Daub**, *Thomas Knöchel*, and *Albrecht Mannschreck*

Compounds having photochromic and thermochromic properties are useful for solar energy conversion and for information storage[1]. In the case of organic compounds, this behavior is often associated with reversible valence isomerizations. For instance, the pair of compounds norbornadiene/quadricyclane have been exhaustively examined regarding their use in energy conversion[2]. In the following communication it is shown that the "ten-electron reaction" between the dihydroazulene **1** and the 8-vinylheptafulvene **2** can be driven thermally in the direction **2**→**1**, and by daylight in the direction **1**→**2**. This reaction behavior, which very strongly depends on the aryl groups at C-2 and C-9, in the compounds **1** and **2**, respectively, could find application in information storage[3].



1 **2**

a, R = OCH_3; **b**, R = NO_2

The dihydroazulenes **1**[6] were prepared from 8-methoxyheptafulvene **3**[4] and the dicyanoethylenes **4**. [8+2]-Cycloaddition leads regiospecifically and quantitatively to **5**.

[**] These investigations were supported by the Deutsche Forschungsgemeinschaft and by BASF AG. We thank *D. Andert, F. Kastner, P. Kölbl*, and *M. Muschiol* for technical assistance.

Both **5a** as well as **5b** are formed as diastereomeric mixtures[5,6]. The double bond between C-2 and C-3 is introduced by elimination of methanol with phosphorus pentoxide. In **1** the bond between C-1 and C-8a is thermally stable in solution at room temperature. To prove this, (+)-**1a** and (−)-**1a** were enriched by liquid chromatography on swollen triacetylcellulose[7] in the absence of light[8]. Ethanolic solutions of the enantiomers do not racemize in the dark.

In contrast, the yellow solutions of **1** turn dark-red on exposure to daylight. **1a** reacts more rapidly than **1b**. For instance, Figure 1 shows the change in the UV/VIS spectrum of **1a**. It was demonstrated by ^{1}H-NMR spectroscopy that **1a** is converted exclusively and completely into **2a** on irradiation (sunlight or Osram HWLS 500 W electric bulb)[6]. **2a** remains unaltered, even on prolonged irradiation (44 h). **1b** behaves differently: The exposure to light leads not only to **2b**[6], but also to secondary products which manifest themselves in the electronic spectrum by new bands at 260, 295, and 315 nm, while the characteristic bands (483 nm for **2b** and 385 nm for **1b**) disappear on prolonged irradiation.

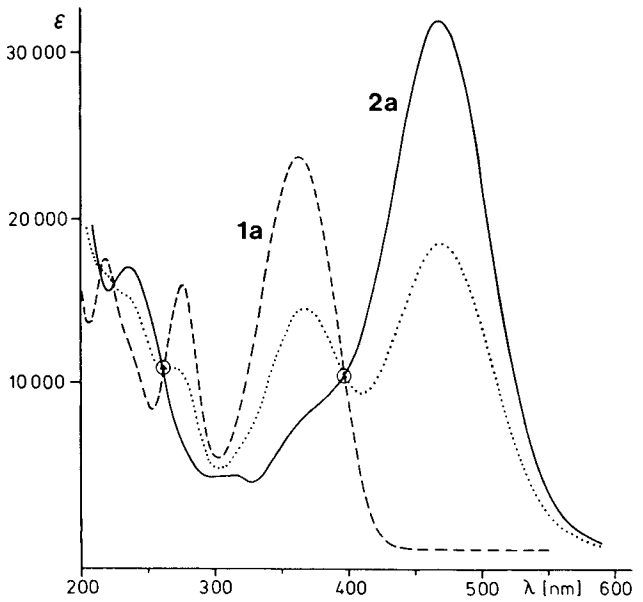

Fig. 1. Photochemistry of **1a** in acetonitrile ($c = 4.9 \times 10^{-5}$ mol/L), irradiation by daylight. (---) Start, (....) after 1 min, (—) after 7 min.

According to the spectroscopic data, the compounds which are formed in the photochemical conversions of **1** and which are found to absorb at long wavelengths have the heptafulvene structure **2**[6,9]. Characteristic for **2** are the strong-intensity bands of the nitrile groups at 2220 cm^{-1} in the IR spectrum and the absorptions at $\lambda = 467$ nm for **2a** and 483 nm for **2b**. Consistent with this are also changes in the chiroptic properties. For example, when a solution of (+)-**1a** in acetonitrile is exposed to daylight, the bands at 220 nm ($\Delta\varepsilon = +6.5$ L·mol^{-1}·cm^{-1}), 275 nm ($\Delta\varepsilon = -6.9$ L·mol^{-1}·cm^{-1}) and 365 nm ($\Delta\varepsilon = +1.7$ L·mol^{-1} cm^{-1}) in the CD spectrum disappear[10].

On the other hand, the heptafulvenes **2** are thermolabile. In the dark, **2a** ($c = 5 \times 10^{-5}$ mol/L in CH_3CN) rearranges quantitatively within 70 h at 25 °C into **1a**. Under the same conditions, this electrocyclic ring closure requires 16 h in the case of **2b**; the formation of a by-product with UV/VIS bands at 315 nm can also be observed in this reaction. In contrast to **1b**/**2b**, the chemical oscillation between **1a** and **2a** proceeds without any losses, even on prolonged reaction. Thus, no decrease in extinction was observed, even after 15 oscillations at room temperature.

Chemoenzymatic Synthesis of a Functional Gene for Human Gamma Interferon**

By *Joachim Engels**, *Michael Leineweber,* and *Eugen Uhlmann*

Gamma interferon (γ-IFN), previously called immune interferon, is a lymphokine having important antiproliferative and immunoregulatory properties[1]. In 1982, two research groups[2,3] working independently of each other succeeded in deriving the primary structure of γ-IFN from its gene sequence. The gene was then incorporated and expressed in bacteria. If the amino acid sequence of a protein is known, chemoenzymatic gene synthesis offers the following advantages over the biochemical DNA isolation from biological material: 1) The frequently very difficult step of isolating the relevant mRNA or genomic DNA is avoided. 2) The desired DNA sequence is obtained directly without additional "tailoring" or processing of the isolated DNA. 3) Those codons, which code highly expressed pro-

teins in the respective host organisms, can be used. 4) Later modifications of genes, be it shortening or lengthening, are easily made possible by introducing appropriate cleavage sites for restriction enzymes. Consequently, structure-activity studies can even be extended to relatively large peptides.

Based on the genetic code, we derived a DNA sequence coding for 146 amino acids of gamma interferon. We then selected codons of proteins which are highly expressed in *E. coli,* introduced suitable restriction enzyme cutting sites and avoided unnecessary symmetries or redundancies within the DNA sequence. In addition to the 146 coding nucleotide triplets, a start codon was attached at the 5′-terminal as well as two translation stop codons at the 3′-terminal. To this are attached the recognition sites for the restriction endonucleases *Eco*RI and *Sal*I. The whole gene, consisting of 452 base pairs was divided into three subunits, **IFN-I**, **IFN-II**, and **IFN-III** (Fig. 1), whose ends carry recognition sequences for restriction enzymes which otherwise are not present in the gene and which enable insertion into the plasmids in the desired orientation. The advantage of the subcloning principle, in which our synthetic strategy differs from the earlier gene syntheses[4,5], is that one-pot ligation steps are easily performable. Accordingly, cloning in *E. coli* and reisolation leads to a purification of the subfragments, whose sequences are confirmed by analysis. In earlier gene syntheses, mutated gene intermediates could only be separated with difficulty, if at all, since physical methods of purification were used. By subcloning, on the one hand the frequency of mutation in the whole gene is reduced and, on the other, an almost inexhaustable reservoir of the respective subfragments is available for subsequent alteration of the gene.

The subfragments were cut retrosynthetically into oligonucleotides in such a way (18 to 33 nucleotides) that overlapping sequences of six base pairs are present at the linkage points. The requisite 34 oligonucleotides were synthesized by the phosphoramidite method on solid phase as described by *Caruthers* et al.[6] and the crude products then purified by electrophoresis on polyacrylamide gel or by HPLC (C18 reversed phase or ion-exchange (Partisil SAX)). The oligonucleotides Ia—IIl were obtained as 5′-hydroxy compounds. Hence, the oligomers Ib—Ii, IIb—IIk, and IIIb—IIIk to be coupled at both termini were phosphorylated at the 5′-terminal with adenosine triphosphate and T4-polynucleotide kinase. For the enzymatic linkage, 1 nmol each of the oligomers Ia—Ij was heated in aqueous solution for 5 min at 90°C and then slowly (2—3 h) cooled to 16°C in order to achieve a hybridization to the DNA double strand. After addition of the enzyme polynucleotide ligase the solution was incubated for 18 h at 16°C and the subfragment **IFN-I** thus formed was isolated by electrophoresis on polyacrylamide gel. In the same way, the subfragments **IFN-II** and **IFN-III** were also prepared from the oligonucleotides IIa—IIl and IIIa—IIIl, respectively. After the subcloning of the gene fragments in suitable plasmids, an inexhaustable source of these fragments was available, since, after cleavage they could be reisolated with the restriction enzymes *Eco*RI and *Bam*HI from **IFN-I**, with *Bam*HI and *Hind*III from **IFN-II**, and with *Hind*III and *Sal*I from **IFN-III**. In each case the DNA sequence was verified by sequencing[7].

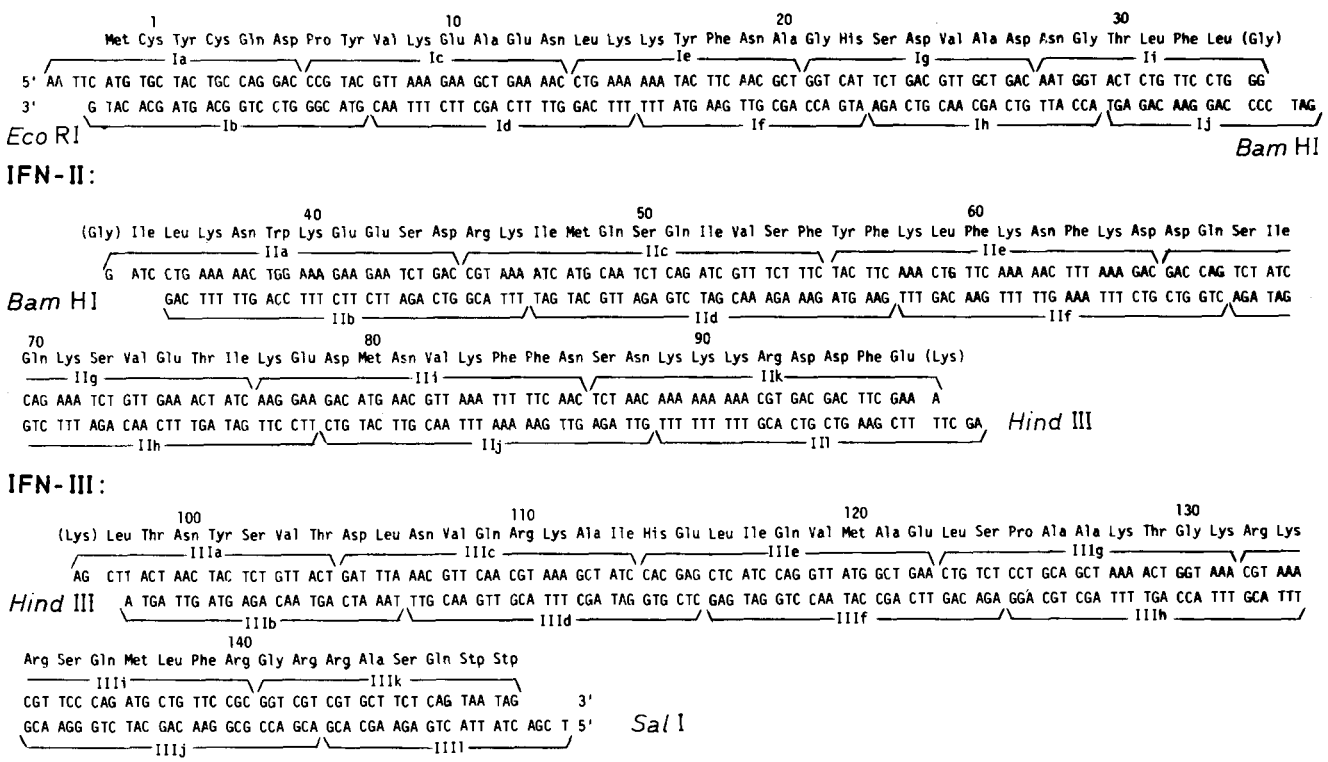

Fig. 1. Amino acid and nucleotide sequences of the synthetic human gamma interferon. The synthetic oligonucleotides Ia—IIl are bracketed. The numbering of the amino acids shows the native human γ-IFN sequence. For the synthesis of the oligonucleotides Ia—IIl, in each case 1 μmol of the 5′-OH nucleoside bonded via the 3′-hydroxy group on controlled pore glass (cpg) was allowed to react with 10 μmol 5′-*O*-dimethoxytritylnucleoside-3′-phosphoramidite and 50 μmol tetrazole in acetonitrile. After the capping of unreacted 5′-OH components with acetic anhydride/4-dimethylaminopyridine in tetrahydrofuran (THF), the internucleotidic phosphite ester was oxidized with I_2 in collidine/water/THF. For further lengthening of the chain the 5′-*O*-dimethoxytrityl group then had to be cleaved off with 3% trichloroacetic acid in 1,2-dichloroethane (w/v). The oligonucleotides were purified by polyacrylamide gel electrophoresis (15% polyacrylamide, 7 M urea) and, after elution from the gel, desalted on a Sephadex G50 column.

The gene fragments were ligated with the aid of polynucleotide ligase to form the complete gene (Fig. 2), which was then inserted into a plasmid opened with *Eco*RI and

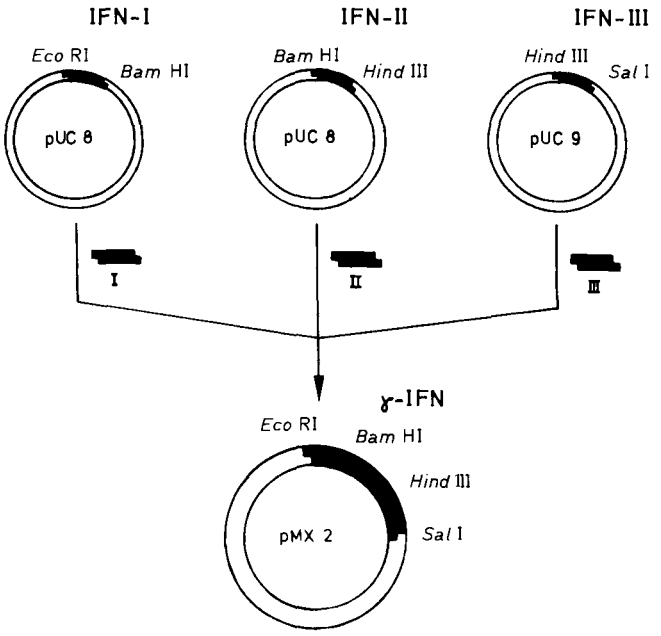

Fig. 2. Cloning vectors pUC8 and pUC9 with the gene fragments **IFN-I—IFN-III** and expression vectors pMX2 with the tac-regulation unit. For the construction of the expression vector pMX2 the gene fragments **IFN-I—IFN-III** were first subcloned in pUC8 and pUC9, respectively, as follows: 1 μg of the pUC plasmid (BRL, Neu-Isenberg) was digested with 2 to 5 units of the desired restriction endonucleases at 37 °C for 2 h in a buffer according to the manufacturers instructions. The back-bone plasmid was then separated from the cleaved oligonucleotides by electrophoresis on a 0.7% low melting point agarose gel. After cutting out the desired bands, melting the gel at 60 °C, phenol and ether extraction of the aqueous phase, the plasmid-DNA was isolated by precipitation with ethanol. 0.1 μg of the opened plasmid was subsequently ligated with 0.2 μg of the respective synthetic DNA fragment with the aid of 10 units T4-DNA-ligase at 4 °C for ca. 15 h and transformed by the usual $CaCl_2$-method in *E. coli* 7902. Clones with hybrid plasmids were worked-up according to a rapid lysate-method by treatment with alkali [9] and analyzed on the basis of the restriction enzyme cleavage pattern on 10% agarose gels. The gene fragments **IFN-I—IFN-III** were cleaved from the pUC vectors with the respective restriction endonucleases, reisolated by electroelution, phenol extracted, and precipitated with ethanol. The correctness of the two DNA strands was verified by sequencing according to the method of *Maxam* and *Gilbert* [7]. The total gene for γ-IFN was then obtained by ligation of the three gene fragments **IFN-I**, **IFN-II**, and **IFN-III** and once again incorporated into an expression plasmid "downstream" from the control region (trp-lac fusion promotor, lac-operator) [8], in the same way as described for the subfragments.

*Sal*I directly behind an expression regulation unit (tac-promotor[8]). After transformation and cloning in *E. coli* we were able to verify the correctness of the whole gene by restriction enzyme mapping and total sequencing according to the method of *Maxam* and *Gilbert*[7]. For the expression of the human gamma interferon gene, transformed cells of *E. coli* 7902 were cultivated in a shaking culture up to an optical density of 1 at 578 nm. The synthesis of the gamma interferon was then induced for 2 h by addition of isopropyl-β-D-thiogalactoside (IPTG; 10^{-3} M). After harvesting the cells by centrifugation and subsequent cell lysis by treatment with lysozyme/EDTA, the gamma interferon titers obtained in the cell residues were determined both by a specific radioimmunoassay for human gamma interferon (Celltech, Slough, UK) as well as by a biological test of the protective effect of the gamma interferon against a viral infection (vesicular stomatitis virus) in the case of vero cells. Induced cultures exhibit interferon titers of 1 mg per liter and OD (optical density unity at 578 nm), whereas non-induced cultures produced only 0.01 mg gamma interferon per liter and OD. The interferon-containing residues were finally purified with monoclonal antibodies (Celltech) bound to affinity columns. The fraction specifically bound by the antibodies were analyzed on SDS polyacrylamide gels. The observed protein bands corresponded to a protein with a molecular weight of about 16000 (molecular weight of γ-IFN).

Second Order Jahn-Teller Effect in Hexahalogenotellurates(IV): Statically Distorted Anion in $Ca(H_2O,HF)_7TeBr_6$**

By *Walter Abriel** and *Hartmut Ehrhardt*

According to the VEPA theory[1], a distorted octahedral coordination is expected for systems of the type AX_6E (six bonding electron pairs, one nonbonding electron pair in the valence shell of the central atom). In the case of XeF_6 this can be detected in the gas phase, but the deformed species oscillates between energetically equivalent configurations (dynamic second order Jahn-Teller effect)[2,3]. According to the initial X-ray structure analyses (293 K) the analogous anions $TeX_6^{2\ominus}$ (X = Cl, Br, I), containing 14-electron systems, showed a regular octahedral structure[4]; consequently *Gillespie* classified these systems as exceptions to the rule[5].

The IR-active vibrations T_{1u} (ν_3 and ν_4) of the $TeX_6^{2\ominus}$ octahedron are, however, relatively broad; an indication of vibronic couplings between the ground state (configuration $a_{1g}\sigma^*$) and the first excited state (configuration $a_{1g}\sigma^*$, $t_{1u}\sigma^*$)[6]. Expectations of detecting a distorted species by X-ray structure analyses at temperatures up to 12 K were, however, not fulfilled in investigations on Rb_2TeBr_6[7]. As *Pearson*[2] presumed, the octahedrally enforced, dynamic structure is stabilized by a highly symmetrical crystal field,

[*] Priv.-Doz. Dr. W. Abriel, Dr. H. Ehrhardt
Institut für Anorganische Chemie der Universität
Callinstrasse 9, D-3000 Hannover 1 (FRG)

[**] This work was begun in the framework of the special research sector 127 (Crystal Structure and Chemical Bonding) at the FB Chemie der Universität Marburg (by *W. A.*). We thank Prof. *D. Reinen*, Marburg, for useful discussions.

which, e.g., is realized in the A_2TeX_6 phases (A = K, NH_4, Rb, Cs; X = Cl, Br, I)[8] by an anti-fluorite arrangement of the cations and anions.

The transition from the dynamically distorted structure of the $TeBr_6^{2\ominus}$ ion to the statically distorted species is now described for the first time. This transition is achieved, on the one hand, by the lowering of the symmetry of the crystal field and, on the other, by the substitution of two monovalent cations by a stronger polarizing bivalent cation. Figure 1 shows the relevant IR absorption bands for the $TeBr_6^{2\ominus}$ ion[9]. The T_{1u} deformation vibrations (ν_3 and ν_4) for the cubic ($Fm\bar{3}m$) phase Rb_2TeBr_6 are reproduced in Figure 1a. In the case of $[Na(H_2O)_3]_2TeBr_6$ (a compound with monoclinic (C2/m) crystal structure, but according to the X-ray structure analysis with a regular octahedral anion[10]) a shoulder can be detected on the ν_4 bands as a result of the strongly anisotropic crystal field (Fig. 1b). Compared to the bands in the Figures 1a and 1b (dynamic distortion), which are already broad, in the spectra of the new compounds $Ca(H_2O,HF)_7TeBr_6$ and $Ca(H_2O)_7TeBr_6$ (Figs. 1c and 1d[11]) a further broadening with marked triple splitting occurs; in the case of the pure hydrate $Ca(H_2O)_7TeBr_6$ (Fig. 1d) the ν_3 band is shifted towards the blue region compared to that of $Ca(H_2O,HF)_7TeBr_6$ (Fig. 1c) because of the strong crystal field (smaller volume of the unit cell[12]). The splitting pattern is consistent with the point symmetry mm2 (C_{2v}).

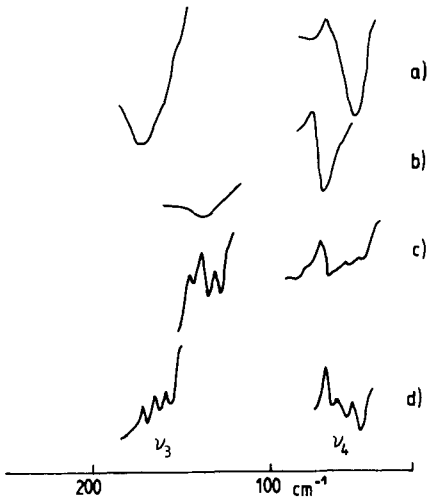

Fig. 1. FIR spectra of a) Rb_2TeBr_6, b) $[Na(H_2O)_3]_2TeBr_6$, c) $Ca(H_2O,HF)_7TeBr_6$, and d) $Ca(H_2O)_7TeBr_6$; for details see text.

The static distortion of the $TeBr_6^{2\ominus}$ ion could be detected by a single crystal X-ray structure analysis on $Ca(H_2O,HF)_7TeBr_6$[12], thus confirming the symmetry deduced from the vibration spectra (Fig. 2). The packing of the $Ca^{2\oplus}$ and $TeBr_6^{2\ominus}$ ions (Fig. 3) resembles that observed in the scheelite structure (e.g. $CaWO_4$[13]) regarding the ionic centroids.

The threefold degenerated T_{1u} deformation vibration of the octahedron, which alone can effect the above-mentioned vibronic coupling, has three independent components. These point to a distorted structure, resulting in the symmetries 4mm (C_{4v}), 3m (C_{3v}), and mm2 (C_{2v})[2]. The structure of the statically distorted $TeBr_6^{2\ominus}$ ion verifies these theoretical considerations. IR spectroscopic investigations of the solvate molecules of the calcium and the sodium compound give no indication of anion-oriented hydrogen bonding; consequently, the stronger polarizing effect of the bivalent cation in an anisotropic crystal field is

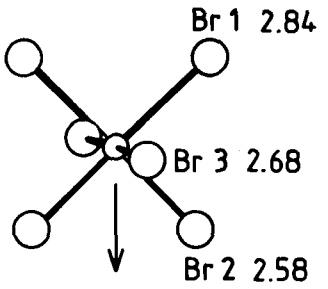

Fig. 2. Structure of the $TeBr_6^{2\ominus}$ ion in the crystal of $Ca(H_2O,HF)_7TeBr_6$; distances of the Br atoms from Te [Å] ($\sigma < 0.01$); angles [°] ($\sigma < 0.3$): Br1–Te–Br1 94.6, Br2–Te–Br2 91.0, Br3–Te–Br3 177.6, Br1–Te–Br2 87.2, Br1–Te–Br3 90.8, Br2–Te–Br3 89.1.

to be regarded as the primary cause for the stable static distortion.

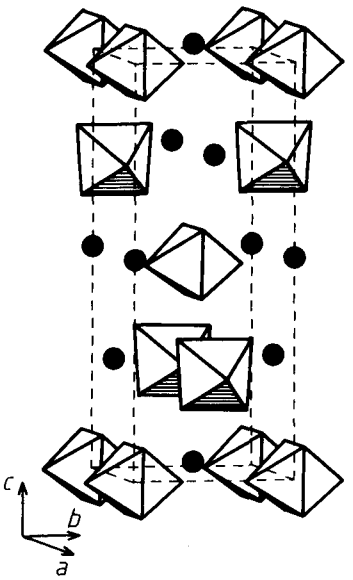

Fig. 3. Packing of the $Ca^{2\oplus}$ ions (spheres) and the distorted $TeBr_6^{2\ominus}$ octahedra in the unit cell of $Ca(H_2O,HF)_7TeBr_6$.

Apparently, these two conditions must be fulfilled for the stabilizing of the static distortion. For example, in the case of $Mg(H_2O)_6TeBr_6$—a compound whose crystal structure can be characterized with an arrangement of the cations and anions corresponding to that in the NaCl type structure (space group Pa3)—the regular (O_h) octahedronal array is found for the $TeBr_6^{2\ominus}$ group[14].

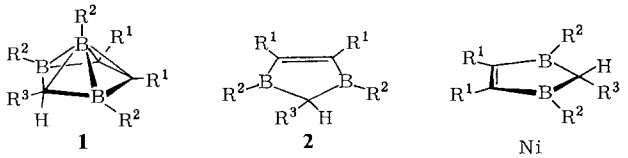
Carbaboranylnickel Complexes with the Novel η^5-2,3,5-Tricarbahexaboranyl Ligand**

By *Thomas Kuhlmann, Hans Pritzkow, Ulrich Zenneck,* and *Walter Siebert**

In Memoriam Earl M. Muetterties

Polyhedral *nido*-dicarbaborates $C_2B_{n-2}H_n^{2\ominus}$ undergo reactions at the pentagonal opening with metal ions and metal complex fragments to yield *closo*-carbametallaboranes[1]. In the case of the *nido*-tricarbahexaborate ion $C_3B_3H_6^{\ominus}$, alkyl derivatives of the 2,3,4-isomer[2] and of the tricarbonylmanganese complex $(\eta^5\text{-}C_3B_3H_4R_2)Mn(CO)_3$ (R = H, Me) have already been described. Attempts to prepare the 2,3,5-tricarbahexaborane **1** from the 2,3-dihydro-1*H*-1,3-diborole **2** and potential boranediyl generators have hitherto failed[3].



1 **2** Ni **3**

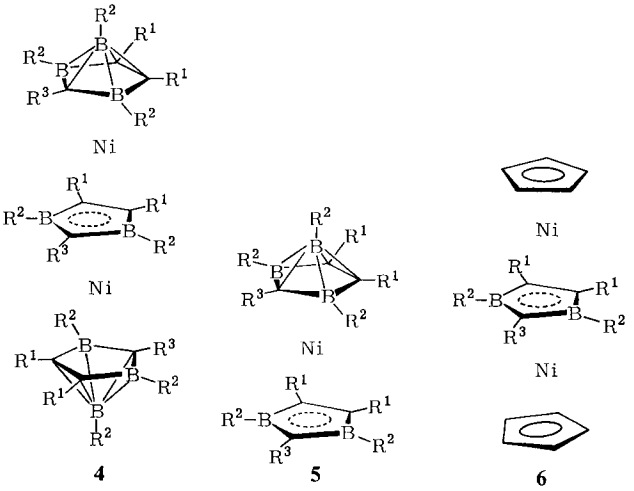
a	Et	Et	Me
b	Et	Me	H
c	Me	Me	H

Scheme 1

We report here on the unexpected formation of the (η^5-2,3,5-tricarbahexaboranyl)nickel complexes **4**, **5**, and $Ni(\mathbf{5})_2$ by reacting bis(allyl)nickel with **2** in the molar ratio 1:2. The green, paramagnetic bis(carbaboranyl) triple-decker sandwich **4b** was obtained for the first time in trace amounts during the synthesis of bis[(η^3-allyl(μ,η^5-2,3-dihydro-1*H*-1,3-diborolyl)nickel]nickel complexes[4]. **4b**[5] and small amounts of **5b**[5] and $Ni(\mathbf{5b})_2$ are formed from the primary product **3b** by a methylboranediyl-transfer and stacking; a reaction whose mechanism still has to be clarified. Proof of the formation of the carbaborane from **3** was provided by the reaction of $Ni(\eta^3\text{-}C_3H_5)_2$ with **2c** under mild conditions. The golden-yellow sandwich complex **3c**[6] is slowly converted at 20 °C into **4c**, the turquoise-colored tetradecker sandwich complex $Ni(\mathbf{5c})_2$ and dark-colored oligomers[7]. In contrast, the formation of a (tricarbahexaboranyl)nickel complex is not observed with the sterically well shielded **3a**[8].



4 **5** **6**

Scheme 2. **a**, **b**, **c**: see Scheme 1.

Mass spectroscopic investigations of **4b** and the NMR data of the diamagnetic anion $\mathbf{4b}^{\ominus}$[5] indicate a triple-decker sandwich arrangement, which has been confirmed by an X-ray structure analysis[9]. Adjacent ligands in the molecule (Fig. 1) adopt an almost *trans*-conformation. The planes through the central ring and the base of the carbaboranyl ligands (deviations ≤ 0.04 Å) are parallel. The nickel atoms are closer to the carbaboranyl ring than to the μ-ligand (1.69, 1.70 and 1.73, 1.74 Å, respectively). The

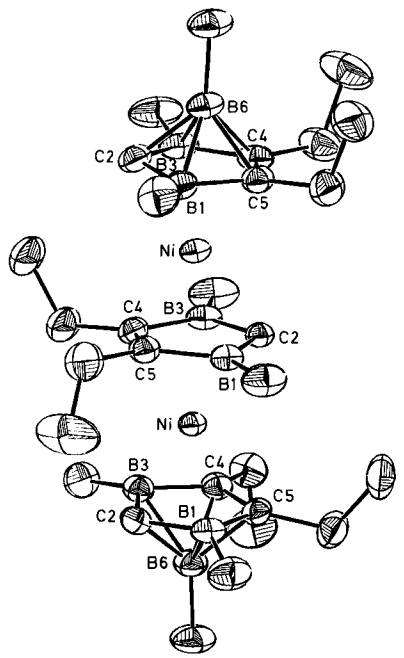


Fig. 1. Structure of **4b** in the crystal. Important bond lengths Å (standard deviations ±0.005 Å). Carbaboranyl ligand: B1(3)–C2 1.549–1.559, B1(3)–C4(5) 1.558–1.566, C4–C5 1.484, 1.485, B6–B1(3) 1.810–1.822, B6–C2 1.661, 1.674, B6–C4(5) 1.694–1.730; μ-ligand: B1(3)–C2 1.534, 1.542, B1(3)–C4(5) 1.586, 1.577, C4–C5 1.436.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

bond lengths and angles in the carbaboranyl sandwich **5b** are similar to those in **4b**[10]. Since the isolobal $C_3B_3H_6^{\ominus}$- and $C_5H_5^{\ominus}$-ligands each contribute five electrons to the complex formation, the 2,3,5-tricarbahexaboranyl compounds **4**, **5**, and Ni(**5**)$_2$ are the electronic analogues of the corresponding η^5-cyclopentadienyl(2,3-dihydro-1*H*-1,3-diborolyl)nickel complexes. Thus, like the paramagnetic triple-decker sandwich **6**[11], **4** has 33 valence electrons.

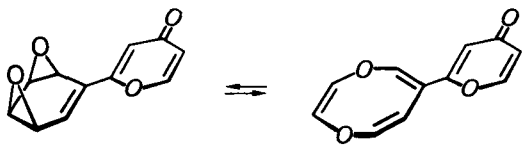
Synthesis of the Antibiotic LL-Z1120—Contribution to an Understanding of the 1,4-Dioxocine System

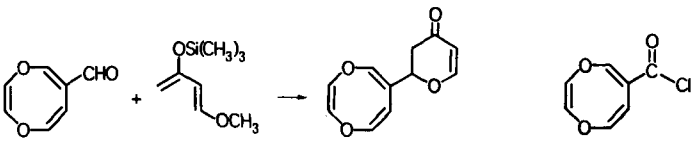
By *Hans-Josef Altenbach*, Johann Lex, Dieter Linkenheil, Burkhard Voss,* and *Emanuel Vogel**

Following their synthesis some 20 years ago[1], arene monoxides were soon recognized as primary intermediates of the oxidative metabolism of aromatic compounds[2]. This finding gave ample justification for assuming that representatives of the subsequently synthesized benzene di-[3] and trioxides[4] also occur in nature. Indeed, in 1972 *Borders* and *Lancaster* were able to isolate from an unspecified type of fungus the antibiotic **1** known as LL-Z1220[5], a benzene dioxide with a γ-pyrone substituent. Evidence for the existence of a *syn*-benzene dioxide derivative was provided by an NMR comparison with the *syn*- and *anti*-benzene dioxide parent compounds[3] and by the fact that **1** thermally equilibrates with the 1,4-dioxocine valence tautomer **2**, which is likewise antibiotically active[5c]. We report here on the first synthesis of **1**.



1, LL-Z1220 **2**

In view of the chemical sensitivity of *syn*-benzene dioxides it seemed appropriate to construct the target molecule in the following stages: 1) Preparation of 1,4-dioxocine-6-carbaldehyde **3**[6] as the key compound of the synthesis; 2) conversion of **3** into **2** using the aldehyde function for the building up of the γ-pyrone substituent; and 3) thermal equilibration of **2** with **1** and separation of **1** from the equilibrium mixture frozen at room temperature. In the light of previous studies[5c, 6] the actual synthetic problem is reduced to the conversion of the aldehyde **3** into the valence tautomer **2** of the natural product. This step should be realizable[9] by reaction of **3** with the Danishefsky diene **4**[7] or with lithiated 4-methoxy-3-buten-2-one **7**, and subsequent dehydrogenation of the expected product, dihydro-γ-pyrone **5**, according to one of the methods[8] that have already proven useful in flavone and chromone chemistry.



3 **4** **5** **6**

Scheme 1. **3**→**5**: 1) THF, −40 °C, 1 equiv. BF_3–OEt_2, 4 h; 0 °C, H_2O, $NaHCO_3$ solution.

3 was allowed to react with **4** (1 equivalent of each) in tetrahydrofuran (THF) in the presence of boron trifluoride-etherate at −40 °C; after neutralization with sodium bicarbonate solution and work-up by chromatography on silica gel (ether) the expected **5** was obtained [colorless needles, m.p. 61–62 °C (ether/pentane, 1:1); yield 25%][12], together with the very labile **8** (ca. 10%)[12] and unchanged **3**. The compound **8**, apparently the product of a Mukaiyama aldol addition[13], readily cyclizes to **5** on subsequent treatment with trifluoroacetic acid, from which it can be concluded that **5** is formed, at least in part, via **8**. For the generation of **5** it is, however, more advantageous to react **3** with the enolate **7** prepared from 4-methoxy-3-buten-2-one and lithium bis(trimethylsilyl)amide and to cyclize compound **8** thus formed to **5** with trifluoroacetic

[*] Prof. Dr. E. Vogel, Priv.-Doz. Dr. H.-J. Altenbach, Dr. J. Lex, D. Linkenheil, Dr. B. Voss
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (FRG)

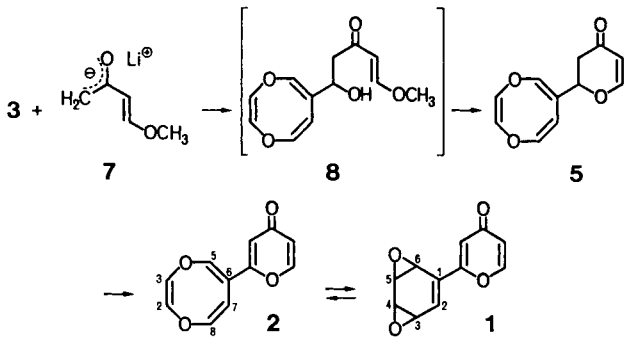
acid in benzene (yield 60%). Attempts to dehydrogenate **5** to **2** conventionally, invariably led to undefined product mixtures, even on using relatively mild conditions[8]. It was therefore surprising that the reaction of **5** with iodine/dimethyl sulfoxide/conc. sulfuric acid[14] at 90°C gave the desired compound **2**. After separation by preparative thin-layer chromatography (silica gel, ethyl acetate), the compound **2** crystallized from ether in the form of colorless needles [m.p. 85—87°C (lit. [5c]: 84—87°C), yield 5%]. The identity of the compound with the 1,4-dioxocine valence tautomer of LL-Z1220 was verified by a comparison of the spectra[5c, 12].



Scheme 2. **7**: THF, −78°C, $LiN[Si(CH_3)_3]_2$, 10 min; **3**→**8**: solution of **3** in THF added dropwise to **7** at −78°C, 15 min, 0°C, H_2O; **8**→**5**: benzene/trifluoroacetic acid, RT, 18 h; **5**→**2**: DMSO/I_2/conc. H_2SO_4, 90°C, 20 min; **2**⇄**1**: acetone, 5 h, reflux.

The thermal isomerization of **2** to **1** was carried out in acetone (5 h, reflux), since a ^{1}H-NMR study of the solvent-dependence of the equilibrium **1**⇄**2** had revealed that the concentration of **1** in this solvent is relatively high (ca. 30%). The large difference in polarity of **1** and **2** allowed the ready separation of the two valence tautomers by chromatography on silica gel (ethyl acetate). Racemic **1**, recrystallized from ethyl acetate [colorless needles, m.p. 159—160°C (decomp.)], shows the same spectra as optically active LL-Z1220 [m.p. 148°C (decomp.)][5a, 12].

In view of the current interest in 1,4-diheterocines (potential 10π arenes)[15]—especially regarding the influence of the heteroatoms on the properties of these compounds—knowledge of the molecular structure of the 1,4-dioxocine **2** was desirable. According to the ^{1}H-NMR spectrum, 1,4-dioxocine itself contains localized π bonds and should therefore have a twist-boat-chair or half-chair conformation. The reason why 1,4-dioxocine—in contrast to the 1,4-dihydro-1,4-diazocine[15b] and 4*H*-1,4-oxazocine[15c]—does not qualify as a 10π arene is because of the lower tendency of the oxygen atoms to undergo π-electron delocalization. The X-ray structure analysis of **2** confirms the presumed non-planar conformation of the 1,4-dioxocine moiety (Fig. 1, left). The eight-membered ring has a twist-boat-chair conformation with the 5,6-double bond and the γ-pyrone ring being almost coplanar[16].

Since the ^{1}H-NMR signals of H-2, 3, 7, and 8 of 1,4-dioxocine-6-carbaldehyde **3** and 1,4-dioxocine-6-carboxylic acid chloride **6**[6] show a—possibly geometry-related—slight downfield shift compared to the corresponding signals of **2**, we also subjected crystalline **6** to a structure analysis. The eight-membered ring in **6**, with a coplanar arrangement of the substituent, is practically planar (Fig. 1, right)[16]. If it is assumed that unsubstituted 1,4-dioxocine

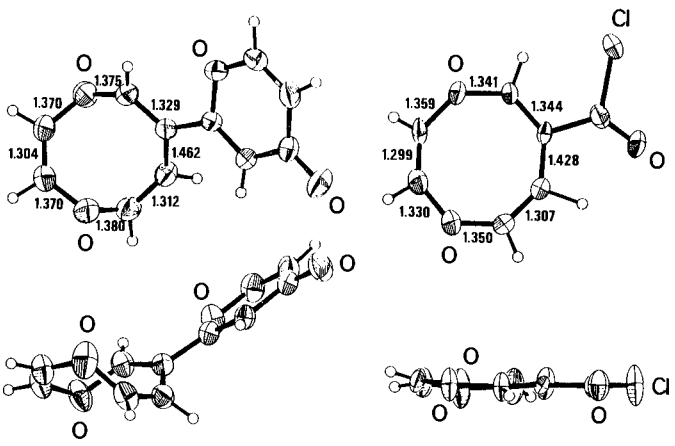


Fig. 1. Molecular structure of **2** (left) and **6** (right) in the crystal [16]. Top-view (top) and sideview (bottom). Selected bond lengths [Å].

is nonplanar, then the conjugative effect of the acceptor substituent COCl must be decisive for the planarization of the eight-membered ring in **6**. In the case of **2**, with the γ-pyrone ring as acceptor, this effect does not operate, because the substituent in a planarized 1,4-dioxocine ring is hindered by H—H interactions from assuming a coplanar arrangement.

$Cp_2Mo_2(CO)_4P_2$ as Complex Ligand**

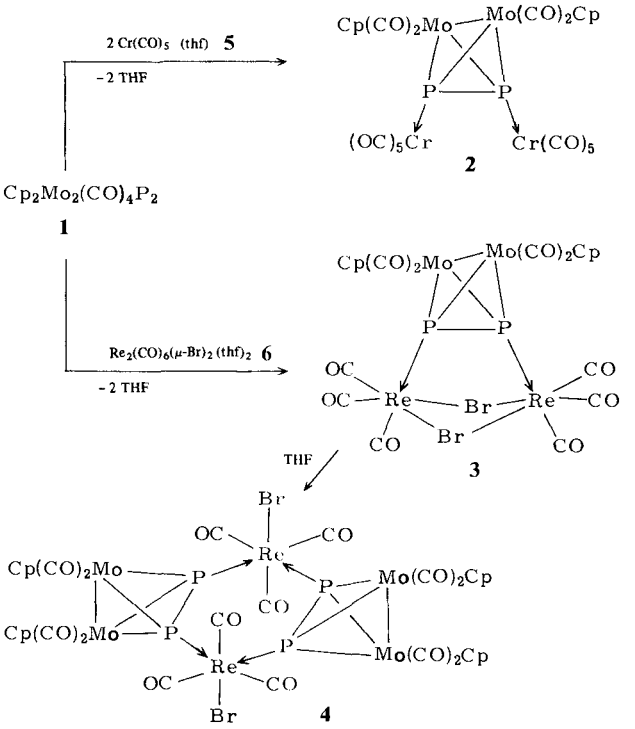
By *Otto J. Scherer**, *Helmut Sitzmann*, and *Gotthelf Wolmershäuser*

Dedicated to Professor Kurt Issleib on the occasion of his 65th birthday

All attempts to coordinate the lone electron pairs of the P_2 unit of the isolated complex $Co_2(CO)_6P_2$ with transition metals were unsuccessful[1a] and led to the assumption that this molecular moiety has only very weak donor properties[1a,b]. If, however, halogenophosphanediyl or halogenophosphane complexes are allowed to react with tetracarbonylcobaltate, then, e.g., $Co_2(CO)_6P_2[Cr(CO)_5]_2$ can be synthesized, a complex in which for the first time P_2 functions as an eight-electron ligand[2].

The complex $Cp_2Mo_2(CO)_4P_2$ **1**[3] prepared by us is suitable for both terminal as well as for bridging P-coordination. Thus, **1** reacts with the chromium complex **5** to give **2**, and with the rhenium complex **6** to give **3**; in tetrahydrofuran, **3** is transformed into **4**. Complexes **2** (readily soluble in CH_2Cl_2) and **4** (soluble in CH_2Cl_2 in traces) form dark red crystals[4], while **3** (sparingly soluble in CH_2Cl_2) forms orange-red crystals[4].

The crystal structure analysis[5] shows that in the case of **3** (Fig. 1) a Re_2Br_2 four-membered ring (angle between the normals to the $ReBr_2$ planes 37.9°) is bridged by the P_2 edge of the P_2Mo_2 cluster. In the case of the centrosymmetric molecule **4** (Fig. 2), the two Re atoms (undistorted octahedral environment) and the P_2 units form a planar six-membered ring (sum of angles 719.6°). The bond lengths and angles of the coordinated P_2Mo_2 tetrahedron



in **3** and **4** differ very little from those of the free ligand **1**[3a]. The Re–P bond lengths lie within the range of bond lengths found in $[Re_2(\mu\text{-}Br)_2(CO)_6(\mu\text{-}Ph_2P\text{–}PPh_2)]$[6a], $[Re_2(\mu\text{-}Br)_2(CO)_6(\mu\text{-}RR'N\text{–}P{=}NR)]$[6b], and $[Re_2(\mu\text{-}Br)_2(CO)_6(\mu\text{-}H_3CPNR)_2]$[6c], R = CMe_3, R' = $SiMe_3$.

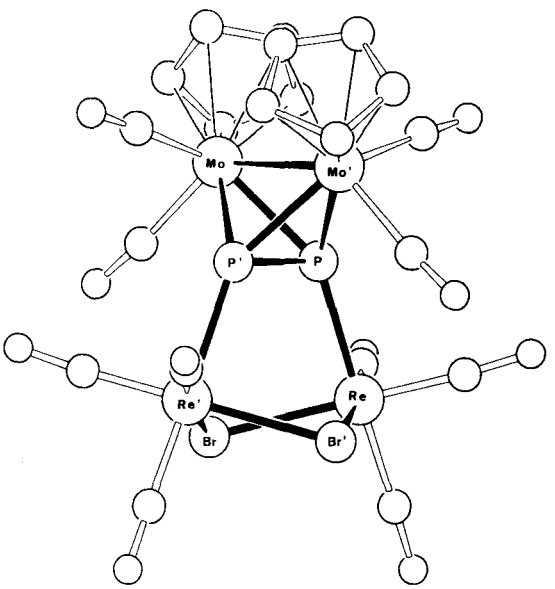


Fig. 1. Structure of **3** in the crystal. Selected bond lengths [Å] and angles [°]: P–P' 2.093(8), Mo–Mo' 3.077(2), Re···Re' 3.878(1), P–Mo 2.507(4), P'–Mo 2.427(4), Re–P 2.490(4), Re–Br 2.662(2), Re'–Br 2.661(2); P'–P–Re 110.7(6), Re–Br–Re' 93.5(1), Br–Re–Br' 79.2(1), P–Re–C(tr) 179.7(3); the molecule has crystallographic C_2 symmetry.

The synthesis of **2**, **3**, and **4** demonstrates the universal ligand properties of **1** and extends the hitherto only known type of complex with P_2 as eight-electron ligand[2] by the first examples with bridging coordination.

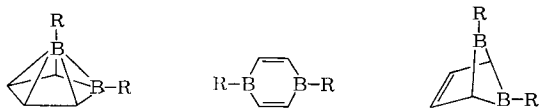
$C_4B_2H_6$ Isomers: Destabilization of the *nido*-Carbaborane Structure by Amino Substituents and a Novel Classical Isomer

By *Gerhard E. Herberich**, *Holger Ohst*, and *Horst Mayer*

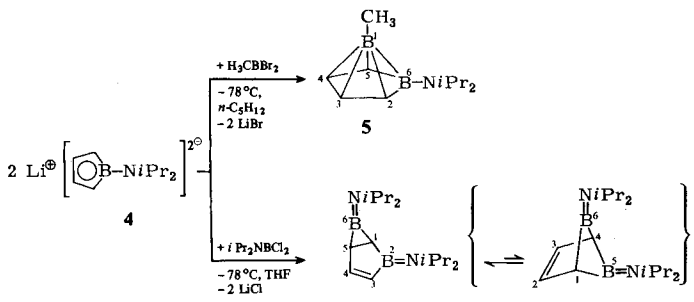
Previously known $C_4B_2H_6$ derivatives exist in either the *nido*-carbaborane **1**[1] or 1,4-dibora-2,5-cyclohexadiene **2**[2] structural form. According to quantum chemical calculations the substituent at the boron atom governs the thermodynamic stability of the isomers. For R = H the carbaborane structure **1** is more stable, and for R = F the 1,4-dibora-2,5-cyclohexadiene structure **2**; in both cases the hypothecital isomer **3** is least favourable energetically[3]. π-Interactions between R and the boron atom reduce the electron deficiency in **2** and **3** and, hence, stabilize the classical structures.



1 **2** **3**

We report here the first amino derivatives of the $C_4B_2H_6$ family. These can be synthesized in a designed way from the borole dianion **4**[4]. Thus, we obtained **5** (Scheme 1), the first carbaborane amino-substituted at a boron atom[5], and **6**, the first 2,6-diborabicyclo[3.1.0]hex-3-ene derivative[6]. With *one* amino substituent the carbaborane structure is labilized and, in contrast to the parent compound **1** (R = H), **5** is surprisingly sensitive towards air and protic reagents. With *two* amino substituents the novel classical structure **6** is now stable.

Variable temperature ^{1}H-NMR spectroscopic studies indicate that **6** undergoes a tautomeric skeletal rearrangement with $\Delta G^+ = 45 \pm 3$ kJ mol^{-1}[7]. At room temperature **6** has effectively C_{2v} symmetry and the iPr$_2$N groups rotate rapidly about the B–N bond; all eight CH_3 groups are equivalent and the signals of all four ring C atoms in the ^{13}C-NMR spectrum are broadened by ^{11}B(^{10}B) quadrupo-



Scheme 1.

lar interaction. Presumably **6** therefore exists in equilibrium with the less stable isomer **7** involving $[1,3]_s$-sigmatropic shifts; an alternative mechanism via a *nido*-carbaborane structure **1** ($R=iPr_2N$) is improbable, since the known derivatives of **1** have static structures with nonequivalent RB groups[1]. No evidence was found for the occurrence of **2** ($R=iPr_2N$).

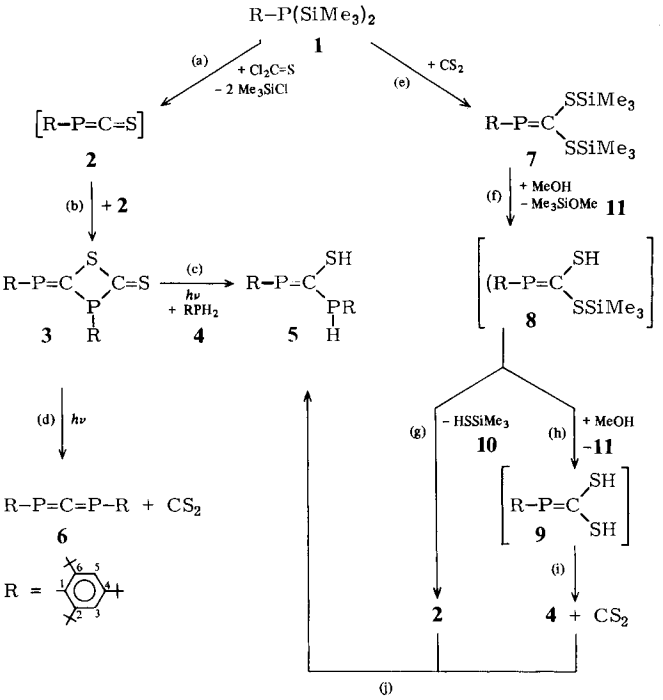
First Evidence for the Existence of a Phosphathioketene**

By *Rolf Appel*, Peter Fölling, Lothar Krieger, Mustafa Siray,* and *Falk Knoch*

The number of compounds containing cumulated double bonds with participation of λ^3-phosphorus in groups such as −P=C=O[1], −P=C=N−[2], −P=C=C<[3], and −P=C=P−[3b,4] has increased tremendously in recent years. As a further extension in this series of compounds it has now been possible to demonstrate the presumed existence of a compound containing the −P=C=S− sequence.

In analogy to the synthesis of the first stable phosphaketene[1b], we allowed 2,4,6-tri-*tert*-butylphenylbis(trimethylsilyl)phosphane **1** to react with thiophosgene in dioxane. On addition of acetonitrile, red crystals precipitate, which according to elemental analysis, molar mass determination, NMR spectroscopic and mass spectroscopic investigations, and X-ray structure analysis constitute the dimer **3** of the phosphathioketene **2**[5] (Fig. 1) [reactions (a) and (b)]. The phosphathioketone **2** assumed to be formed as intermediate dimerizes, like ketenes[6], in an unsymmetrical [2+2]-cycloaddition.



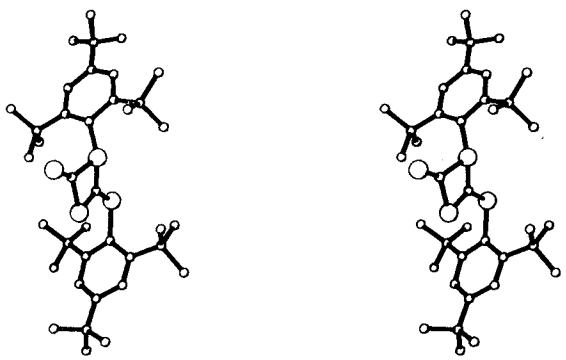


Fig. 1. Stereoscopic diagram of the structure of **3** in the crystal.

Phosphaketenes behave differently: the dimerization of *tert*-butylphosphaketene proceeds symmetrically at the PC double bond[1a], and in the case of the stable 2,4,6-tri-*tert*-

[**] Lower Coordinated Phosphorus Compounds, Part 35.—Part 34: R. Appel, C. Casser, M. Immenkeppel, F. Knoch, *Angew. Chem. 96* (1984) 905; *Angew. Chem. Int. Ed. Engl. 23* (1984) 895.

butylphenylphosphaketene no dimerization has hitherto been observed, but, instead, a trimerization with elimination of a CO molecule to give a five-membered heterocycle[7].

An additional indication of the intermediate formation of the apparently very reactive **2** was afforded on irradiation of **3** in the presence of the phosphane **4** [reaction (c)]. It was found that the 1,3-diphosphapropene **5**[8] is formed, presumably by addition of **4** to the species **2** formed by cycloreversion of **3**. The structure of **5** is confirmed by X-ray structure analysis[8b] (Fig. 2); SH/PH tautomerization to give a symmetric diphosphathiourea can be ruled out, both in the crystal as well as in solution. Not only symmetric but also unsymmetric cleavage of the four-membered ring of **3** is observed. UV-Irradiation of **3** in the absence of the phosphane **4** leads to formation of carbon disulfide and the 1,3-diphosphaallene **6**[3a,4] [reaction (d)]. The cleavage of diketene into allene and CO_2 proceeds analogously[9].

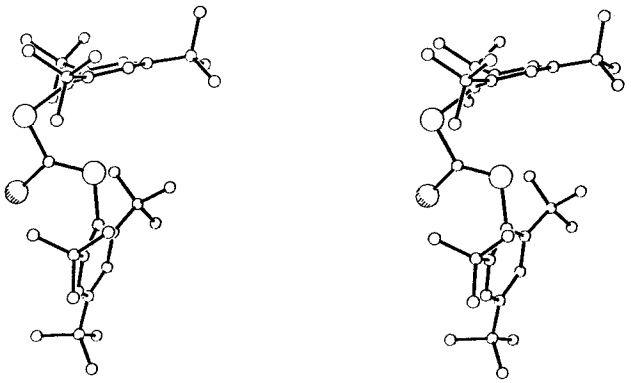

Fig. 2. Stereoscopic diagram of the structure of **5** in the crystal.

An independent synthesis of the readily isolable diphosphapropene **5** was accomplished by careful methanolysis of the [bis(silylthio)methylene]phosphane **7**[11], obtainable by reaction of **1** with carbon disulfide according to the method of *Becker* et al.[10] [reaction (e)]. We assume that cleavage of methoxytrimethylsilane **11** and silanethiol **10** likewise leads, via **8**, to intermediary formation of phosphathioketene **2** [reactions (f) and (g)]. In the reactions (h) and (i), methanolysis of **8** leads to the dithiol **9**, which decomposes into the phosphane **4** and carbon disulfide. **2** reacts with **4** to give the 1,3-diphosphapropene **5** [reaction (j)].

The phosphaallene **6** and methoxytrimethylsilane **11** were identified by comparison with authentic samples. The carbon disulfide formed according to route (i) and the hydrogen sulfide formed by hydrolysis of **10** could be detected by Dräger inspection tubes.

Insertion of Platinum into the Sulfur-Nitrogen Bond of a 1,2,4-Thiadiazole: Synthesis of a Six-membered Metallaheterocycle**

By *Herbert W. Roesky**, *Hartmut Hofmann*, *Peter G. Jones*, and *George M. Sheldrick*

Dedicated to Professor Gerhard Fritz on the occasion of his 65th birthday

The importance of platinum coordination compounds has increased enormously in recent years, particular interest being attached to their use in homogeneous catalysis and in cancer therapy[1].

Ethenebis(triphenylphosphane)platinum(0) reacts with 1,2,4-thiadiazole-3,5-dicarbonitrile **1**, which is readily accessible from cyanogen and sulfur[2,3], with formation of

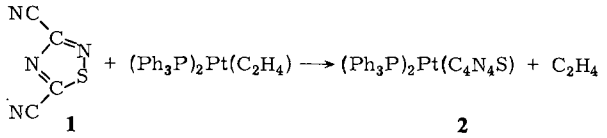
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the chelate complex **2**, a complex containing a novel C_2N_2SPt heterocycle.



1 **2**

Insertion of Pt takes place at the SN-bond of **1**. Similar products are also formed on reaction of 1,2,5-thiadiazoles and 1,2,5-selenadiazoles with the Pt^0 complex[4].

The reaction **1**→**2** proceeds smoothly in high yields at room temperature[5]. The compound **2** is sensitive neither to oxygen nor to hydrolysis. On recrystallization[5], solvent molecules are incorporated into the crystal lattice, but are easily given up again. The IR spectrum of **2**[5] shows an absorption band at 2230 cm^{-1} in the C≡N stretching vibration region; this is not observed in the spectrum of **1**. The X-ray structure analysis confirms the presence of a six-membered ring (Fig. 1).

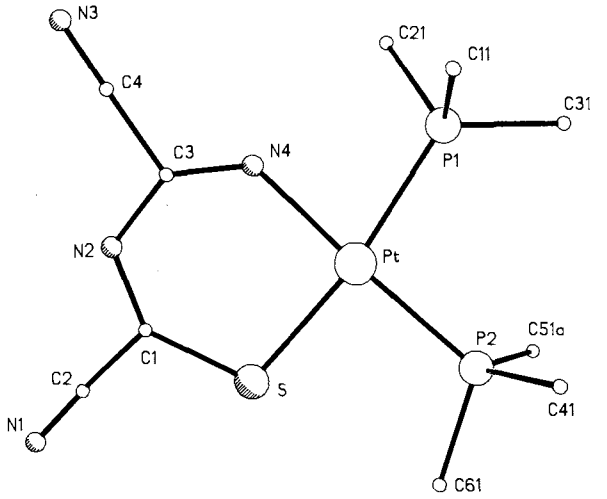


Fig. 1. Structure of the platinum complex **2** in the crystal. (For the sake of clarity, only the first carbon of each phenyl ring is shown.) Space group $P\bar{1}$, $a=1002.0(3)$, $b=1294.2(3)$, $c=1794.7(5)$ pm, $\alpha=96.24(2)$, $\beta=101.98(2)$, $\gamma=103.30(2)°$, $Z=2$; $R=0.050$ for 6828 absorption-corrected reflections with $F>4\sigma(F)$, $Mo_{K\alpha}$ radiation, $2\theta_{max}=52°$. The refinement was rendered difficult by the fact that the asymmetric unit contains 1.5 disordered molecules of dioxane and that a phenyl ring is disordered. Important bond lengths [pm] and angles [°]: Pt–S 229.2(5), Pt–P1 231.1(4), Pt–P2 230.8(4), Pt–N4 201.6(8), S–C1 172(1), C1–N2 130(2), N2–C3 140(1), C3–N4 126(1); P1–Pt–P2 98.5(3), P1–Pt–N4 78.4(4), P2–Pt–S 89.9(2), N4–Pt–S 93.3(4), Pt–S–C1 106.9(6), S–C1–N2 134(1), C1–N2–C3 120(1), N2–C3–N4 134(1), C3–N4–Pt 128(1). The platinum atom is planar coordinated (largest deviation 7 pm for N4); the chelate ligand (S to N4) is likewise planar; however, the platinum atom deviates about 34 pm from this plane. The angle between the two planes is 12.8°. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 50865, the names of the authors, and the journal citation.

[5] A solution of the ethene-complex $(Ph_3P)_2Pt(C_2H_4)$ (1.04 g, 1.40 mmol) in toluene (15 mL) was added dropwise slowly at room temperature to a solution of **1** (0.19 g, 1.40 mmol) in anhydrous toluene (10 mL). A bright yellow microcrystalline precipitate was formed, which, after 12 h, was filtred off and recrystallized from dioxane or tetrahydrofuran. Orange crystals of **2** (0.95 g, 80% yield) were obtained. IR (Nujol mull): 2230, 1445, 1100, 1025, 740, 695 cm^{-1}.

The in situ Preparation of 2-Sulfidophenolate Ligands by Copper-Catalyzed Oxygen Insertion into Thiophenolates; Crystal Structure of $[PPh_4]_2[Mo_2O_5(SC_6H_4O)_2]$**

By *C. David Garner*, John R. Nicholson,* and *William Clegg*

Recently, the syntheses of several Mo–S–Cu clusters have been reported[1], including that of the complex anion $[MoOS_3(CuCl)_3]^{2\ominus}$[1f,g]. In an attempt to prepare the thiophenolate derivative of this $OMoS_3Cu_3$ core, we treated a solution of $[PPh_4]_2[MoOS_3(CuCl)_3]$ in acetonitrile with KSPh (molar ratio 1:3)[2]. The ensuing reaction appears to be complicated and, so far, the only compound we have been able to characterize is $[PPh_4]_2[Mo_2O_5(SC_6H_4O)_2]$ **1**.

According to the results of an X-ray structure investigation, the anion of **1** (Fig. 1) possesses a crystallographic two-fold symmetry axis passing through the μ-oxide ligand, perpendicular to the Mo–Mo vector. The structure

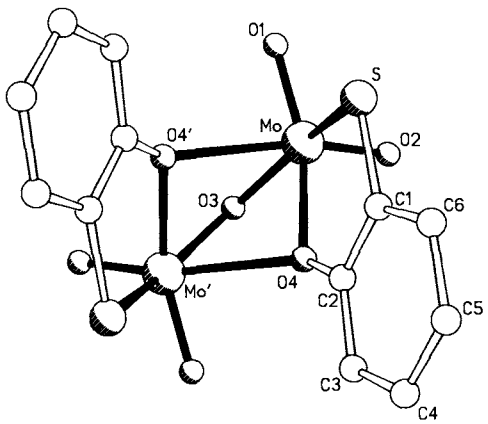

Fig. 1. Structure of the anion of **1** in the crystal, viewed along the two-fold symmetry axis. Space group C2/c, $a=18.317(2)$, $b=12.025(1)$, $c=25.195(3)$ Å, $\beta=108.28(1)°$, $Z=4$, $R=0.039$ for 5104 absorption-corrected reflections with $F>4\sigma(F)$. Key bond lengths [Å]: Mo-O1 1.712(2), Mo-O2 1.699(2), Mo-O3 1.929(2), Mo-O4 2.117(2), Mo-O4' 2.482(2), Mo-S 2.441(1), S-C1 1.763(3), O4-C2 1.346(3) Å. Further details on the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 51032, the names of the authors, and the journal citation.

[**] This work was supported by the Science and Engineering Research Council, the Deutsche Akademische Austauschdienst, and the Fonds der Chemischen Industrie.

of the anion closely resembles that of $[Mo_2O_5(o\text{-benzenediolate})_2]^{2\ominus}$[3] and of $[Mo_2O_5(3,5\text{-di-}tert\text{-}1,2\text{-benzenediolate})_2]^{2\ominus}$[4] and possesses two *cis*-dioxomolybdenum(VI) centers bridged by one μ_2-oxido- and two μ_2-*O*-2-sulfidophenolate ligands. The last-mentioned bridges are asymmetric and involve Mo-O distances of 2.117(2) and 2.482(2) Å. The Mo atom has a very distorted octahedral environment of five O and one S donor atoms, with the largest and the smallest bond angles being O2MoO4′ = 167.4(1)° and O3MoO4′ = 67.4(1)°, respectively. The UV/VIS spectrum of $[PPh_4]_2[Mo_2O_5(SC_6H_4O)_2]$ contains two bands of a comparable intensity with $\lambda_{max} \approx 400$ and 350 nm and an absorption of higher intensity with $\lambda_{max} = 297$ nm.

Complexes containing the $(Mo_2O_5)^{2\oplus}$ core usually exhibit two $\nu(Mo-O_{terminal})$ bands in the IR spectrum in the region 910—935 cm^{-1} separated by $\leqslant 20$ cm^{-1}[5]. We therefore propose that the bands observed at ca. 918 and 924 cm^{-1} in the IR spectrum of **1** are due to $\nu(Mo-O_{terminal})$ stretching vibrations. $(Mo_2O_5)^{2\oplus}$ complexes generally absorb at ca. 775 cm^{-1}[5], but although **1** has an absorption at ca. 765 cm^{-1}, its assignment to the ν(Mo-O3-Mo) vibration is complicated by the presence of 2-sulfidophenolate vibrations in this region.

2-Mercaptophenol and its singly and doubly deprotonated anions are of considerable potential interest as ligands, especially as this last form is intermediate between catecholates and *ortho*-benzenedithiolates which form complexes with notable redox properties. However, the chemistry of 2-mercaptophenol derivatives is presently very limited. The study described herein represents the first structural characterization of a complex of the $SC_6H_4O^{2\ominus}$ ligand. The lengths of the C—O and C—S bonds (1.346(3) and 1.763(3) Å, respectively) are taken to indicate that the ligand is present as a dianion rather than in an oxidized form[6]. The singly charged form $HOC_6H_4S^{\ominus}$ has been observed in both a monodentate (through S) and chelating (through O and S) coordination mode in the same FeS cluster compound[7].

The in situ synthesis of the 2-sulfidophenolate ligand appears to involve the aerial oxygenation of benzenethiolate and, given the reaction conditions and known precedents[8], is presumed to be a Cu-assisted process. This approach could offer a potentially attractive alternative to the synthesis[9] of 2-mercaptophenol and related systems.

[2] $[PPh_4]_2[MoOS_3(CuCl)_3]$ (0.7 g, 0.59 mmol) was dissolved in CH_3CN (ca. 40 mL) under an atmosphere of N_2. Addition of solid KSPh (0.26 g, 1.8 mmol) and stirring overnight at room temperature led to the precipitation of KCl, which was separated off by filtration. Et_2O (ca. 30 mL) was added to the deep red filtrate to give a small amount of black precipitate. Separation of this product by filtration and further addition of Et_2O led to the formation of a black tar. The solution was decanted and more Et_2O added with the same result. After standing at room temperature for ca. 3 weeks, with limited exposure to air, the tar was transformed into a black powder and relatively large deep red crystals had developed. Yield ca. 0.04 g (10%).

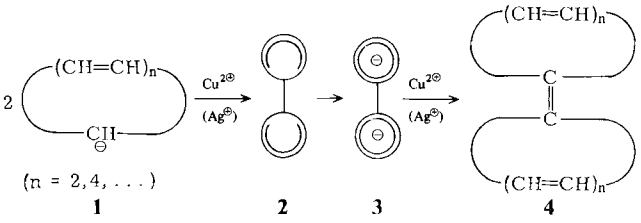
Nonapentafulvalene by Oxidative Coupling of Cyclononatetraenide and Cyclopentadienide**

By *André Escher* and *Markus Neuenschwander**

According to *Doering*, pentafulvalenes[1] can be prepared by reaction of cyclopentadienides with iodine, followed by deprotonation and subsequent oxidation with O_2[2]; however, the atmospheric oxidation is often problematic. We recently reported the oxidative coupling of the Hückel anions **1** with Ag^{I} or Cu^{II} salts[3]. After deprotonation to **3**, the almost quantitatively formed dihydrofulvalenes **2** are again reacted with Ag^{I} or Cu^{II}. This procedure allowed concentration of the reactive pentafulvalene **4** (n = 2)[2] to be increased to a level sufficient for NMR



spectroscopic studies[3]. Recently the same method has been applied to the synthesis of the 2,5-di-*tert*-butylcyclopenta[*a*]pentalenide ion[4]. Here we describe the first synthesis of nonapentafulvalene **12** (9-(2,4-cyclopentadienylidene)-1,3,5,7-cyclononatetraene)[1].

When 1 mmol each of Na-cyclopentadienide (Na-CPD) and *cis,cis,cis,trans*-Na-cyclononatetraenide (Na-CNT)[5] are allowed to react with 2.2 mmol of $CuCl_2$ in 10 mL of tetrahydrofuran (THF) at −50°C, a mixture of the dihydrofulvalenes **5**, **6**, and **7**[6,3] is formed in the ratio 5 : 4 : 1 (yield 85%, calculated from the NMR and GC). In contrast, if 5 mmol Na-CPD and 1 mmol of Na-CNT are coupled using 6.6 mmol $CuCl_2$ in THF, in addition to **5** and **6** (ratio 1 : 4) the product mixture contains only traces of **7**. For the tautomerizations **5** ⇄ **5′** and **6** → **8**, the mixture is treated with aluminum oxide (basic I) at −20°C. The tautomeric 9-(cyclopentadienyl)-1,3,5,7-cyclononatetraenes **5′**

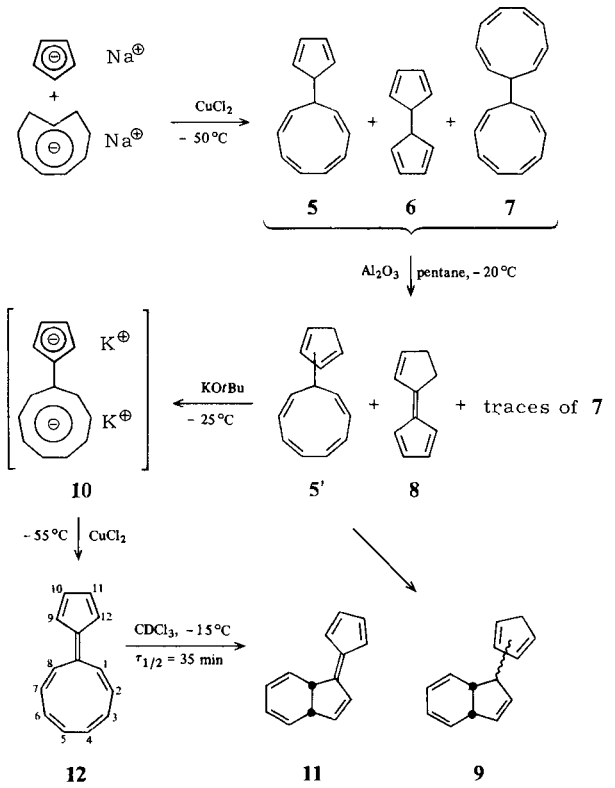
[**] Fulvenes, Fulvalenes, Part 41. This work was supported by the Schweizerischer Nationalfonds (Project No. 2.402-0.82) and by Ciba-Geigy AG, Basel. We thank Dr. *T. Jenny*, Organisch-chemisches Institut, Universität Fribourg (Switzerland) for the high-field NMR spectra.—Part 40: [3].

can be separated by chromatography on silica gel (pentane, −20°C) from the slower moving red dihydrofulvalene **8**[7,3] (70% yield relative to CNT). The structure of **5′** is proved by the spectroscopic data as well as by the cyclization **5′**→**9**, which is rapid at 20°C.



For the synthesis of **12**, a solution of **5′** in THF is deprotonated at −25°C with potassium *tert*-butoxide, whereupon the dipotassium salt **10** precipitates. Reaction with $CuCl_2$ at −55°C affords a red suspension which is worked-up by filtration (silica gel, pentane) and concentrated at −50°C to yield **12** (ca. 30% relative to **5′**).—Nonapentafulvalene **12** is a red hydrocarbon which crystallizes at −50°C, but is so reactive that it has as yet eluded attempts at recrystallization. According to the NMR spectrum, the half-life of the cyclization **12**→**11** is ca. 35 min in $CDCl_3$ at −15°C. Therefore, **12** is even more reactive than nonafulvene[8].

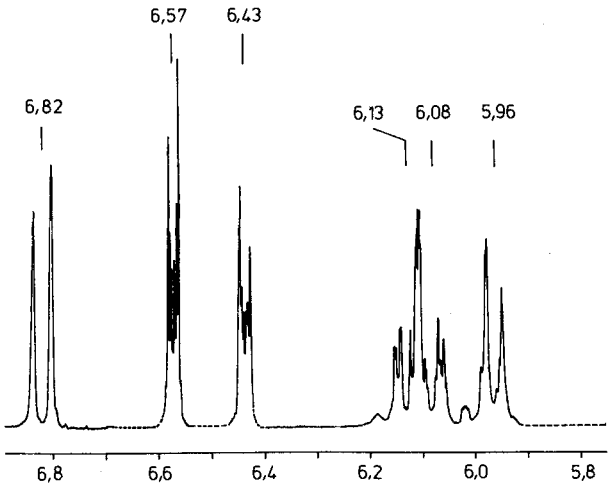


Fig. 1. ^{1}H-NMR spectrum of **12** (360 MHz, [D$_6$]acetone, −40°C; δ values). The breaks in the region $\delta = 5.85$, 6.4, 6.5 and 6.65 signify that the original spectrum contains signals from 9% **11**.

Structure elucidation of **12** is based on the low temperature NMR spectra and on the cyclization **12**→**11**. In the ^{1}H-NMR spectrum (Fig. 1), the ring protons are pairwise equivalent. The key protons 1-H/8-H appear as a doublet at $\delta = 6.82$. Assignment of the remaining protons of the nine-membered ring (2-H/7-H: 6.08; 3-H/6-H: 6.13; 4-H/5-H: 5.96 ppm) follows from decoupling experiments. The centers of the AA′XX′ system of the five-membered ring protons at $\delta = 6.57$ and 6.43 absorb similarly to those of pentafulvalene **4** (n = 2)[3]. In the ^{13}C-NMR spectrum, the signals of the pairwise equivalent C atoms of the nine-membered ring (C^1/C^8: $\delta = 128.0$; C^2/C^7: 133.0; C^3/C^6: 129.5; C^4/C^5: 128.5) appear in the narrow range $\delta = 128$—133 typical for nonpolar nonafulvenes[9]. Furthermore, the positions of the five-membered ring C atoms (C^9/C^{12}: $\delta = 121.2$; C^{10}/C^{11}: 132.2) are very similar to those of pentafulvalene **4** (n = 2) as well as of pentafulvenes[3]. Finally, the disrotatory cyclization **12**→**11**, which is very rapid relative to that of 10,10-bis(dimethylamino)nonafulvene[10] stabilized by electron-donating groups, is consistent with the olefinic character of the cyclononatetraene unit of **12**. The structure of **11** has been confirmed by spectroscopic studies (^{1}H-NMR, ^{13}C-NMR, IR, UV, MS).

[1] Fulvalenes are cyclic, cross-conjugated molecules in which two fully conjugated rings with an odd number of carbon atoms are linked via a central double bond. Penta-, hepta-, and nonafulvalenes consist of two five-, seven-, and nine-membered rings, respectively; nonapentafulvalene **12** consists of one nine- and one five-membered ring.

[a] Of compounds isolated. [b] Determination by GC with 2-butyne as internal standard. [c] As for [b], but with biphenyl. [d] On injection into an analytical GC, **4** decomposes completely to **8** (temp.: column 180°C, inj. 220°C). [e] Not analyzed, since **10** and **11** escape during the photolysis. [f] Not determined.

time (see Table 1). **10** and **11** are the typical products of the *intra*molecular reaction of the cyclobutylidene **7** generated from **2**[2a,7]. The 1,3-dipolar cycloaddition of **2** to the styrenes **3a**, **b** to give **4a**, **b** proceeds regioselectively[8]. Apparently, due to the *trans* oriented methyl group in **3c**, there is such a strong steric hindrance in the transition state that the reaction to give **4c**[6] is almost precluded. No spiro[2.3]hexanes **8** are formed under the reaction conditions employed, as could be demonstrated by analytical HPLC in the reaction of **2** with **3a**. Liberation of N_2 from **4a** with formation of **8a** only takes place on heating above ca. 120°C (760 torr). In CCl_4 at 80°C, **4a** rearranges within 10 minutes to give mainly the 4,5-dihydro-1*H*-pyrazole **5a**[6]. Irradiation (Philips HPK 125 W, 20 min) of **4a** in ether affords **8a** in 83% yield. The spirohexanes **8a**—**c**, on the other hand, are obtained via **4** by photolysis of a solution of **1** with styrenes **3a**—**c**.

The organometallic generation of **7** (carbenoid)[7c] at −70°C by reaction of 1,1-dibromocyclobutane **6** with methyllithium in the presence of the olefins **3** affords the spiro[2.3]hexanes **8**[9]. In each case, 5—10% 1-bromo-1-methylcyclobutane[10] is also obtained; this could result from methylation of the organolithium compound generated from **6**. Compound **7** (carbenoid) adds stereospecifically to *cis*- and *trans*-butenes **3d** and **3e**. The competing reactions in **7** to give **10** and **11** take place only to a small extent. The yields of spirohexanes are higher or similar to those of the spiropentanes which are formed by *inter*molecular alkene additions of cyclopropylidenes[2,11], whose *intra*molecular reactions are impaired.

The novel C_4+C_2-coupling presented here opens up a convenient entry to a variety of interesting spiro[2.3]hexanes, which otherwise are only obtainable by circuitous synthetic routes[12].

Synthesis and Characterization of $[(C_5Me_5)Mn(CO)_2(SR)]$; RS Radicals as Ligands**

By *Andreas Winter, Gottfried Huttner*, Laszlo Zsolnai, Peter Kroneck,* and *Margarete Gottlieb*

We report here on manganese complexes in which RS radicals are formally stabilized as ligands. $[CpMn(CO)_2 \cdot thf]$ ($Cp = \eta^5\text{-}C_5H_5$) reacts with thiols RSH in tetrahydrofuran (THF) to afford honey-colored solutions which probably contain complexes of the type $[CpMn(CO)_2(HSR)]$[1]. In the presence of oxygen, these solutions become violet. Deep violet compounds of composition $CpMn(CO)_2SR$ are obtained as the sole products upon chromatographic work-up. More stable complexes are formed via the same reaction sequence from the complex $[Cp^*Mn(CO)_2 \cdot thf]$ **1**[2] ($Cp^* = \eta^5\text{-}C_5Me_5$).

The paramagnetic complexes **2** contain one unpaired electron per molecule[3]. According to the EPR spectrum of

2a, R = *t*-C$_4$H$_9$ (33%)
2b, R = 2-Adamantyl (29%)

2a (sextet at $g=2.031(9)$, $a^{55}_{Mn}=5.14$ mT), the unpaired electron occupies a molecular orbital (MO) with strong metallic character. In the EPR spectrum of the analogous selenium complex [CpMn(CO)$_2$(SePh)][4] ($g=2.069(9)$, $a^{55}_{Mn}=4.61$ mT) the signals are markedly broadened. Although the superhyperfine splitting by ^{77}Se ($I=1/2$) could not be resolved, the broadening indicates a contribution by selenium to the singly occupied MO (SOMO).

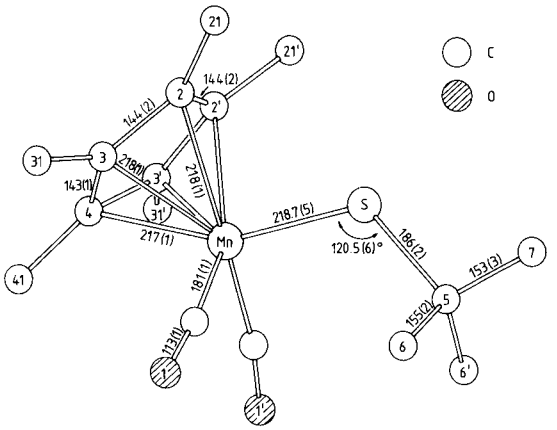

Fig. 1. Structure of the radical complex **2a** in the crystal. Distances in pm (standard deviations in brackets).

Isolated molecules of **2a** occur in the crystal (Fig. 1)[5]. The molecules possess crystallographic mirror symmetry, with the RS ligand lying in the mirror plane of the molecule. The radical complexes are isoelectronic with the radical anions of the carbene complexes [L$_n$M=CR$_2$]$^{\ominus}$[6] and with the aminyl complexes [L$_n$M(HNR)][7], whose bonding behavior has been described in terms of the extended Hückel model by *Sellmann* and *Hoffmann* et al.[8]: Because of the repulsive interaction between the a″-HOMO of the CpMn(CO)$_2$-fragment and the p-orbital of the radical ligand, the SOMO lies at a relatively high energy[7]. This explanation is also consistent with the intense coloration of the complexes **2**[9]. The high energy level of the SOMO[7] also explains the ease with which **2**$^{\ominus}$ can be oxidized to **2** in comparison to other [CpMn(CO)$_2$L] complexes; the reversible reduction of **2** can be detected by cyclic voltammetry[10] (single electron reduction, $E_{1/2}$(**2a**) = −0.98 V and $E_{1/2}$(**2b**) = −0.93 V). The selenium compound [CpMn(CO)$_2$SePh][4] undergoes reversible reduction even more easily ($E_{1/2}$ = −0.55 V). In this way the redox behavior of **2** corresponds to the internal electron transfer postulated for the axial thiolate ligands in cytochrome P450[11].

Thermally and Photochemically Controlled Insertion of Alkynes into Clusters: A Route to Organometallic π-Ligands**

By *Konrad Knoll, Olli Orama,* and *Gottfried Huttner**

Dedicated to Professor Kurt Issleib on the occasion of his 65th birthday

Cluster **1**, readily accessible[2] by oxidation of [μ_3-RPFe$_3$(CO)$_9$H]$^{\ominus}$ **1**[1], reacts upon thermal activation with alkynes to afford almost exclusively **2**, whereas under photochemical conditions **3** is formed.

2 arises via insertion of R′C≡CR″ into one of the P–Fe bonds of **1**. The reaction proceeds remarkably smoothly and regioselectively. Presumably[1] formation of **2** is preceded by scission of a P–Fe bond followed by addition of the nucleophilic Fe$_2$PR group to the alkyne. The observed regioselectivity arises from the formation of the more stable carbanion. Homologues of the expected intermediate $Fe_2R\overset{\oplus}{P}-CR'=\overset{\ominus}{C}R''$ building group have been postulated as ylidic intermediates $R_3\overset{\oplus}{P}-CH=\overset{\ominus}{C}R$[3] and are also known as ligands[4].

The distances and angles in **2**[5] suggest that the almost planar FeCCP moiety be described as a "heterobutadiene" ligand (see Scheme 1). The conformation of the Fe(CO)$_3$ group also corresponds to this illuminative view[6]. In

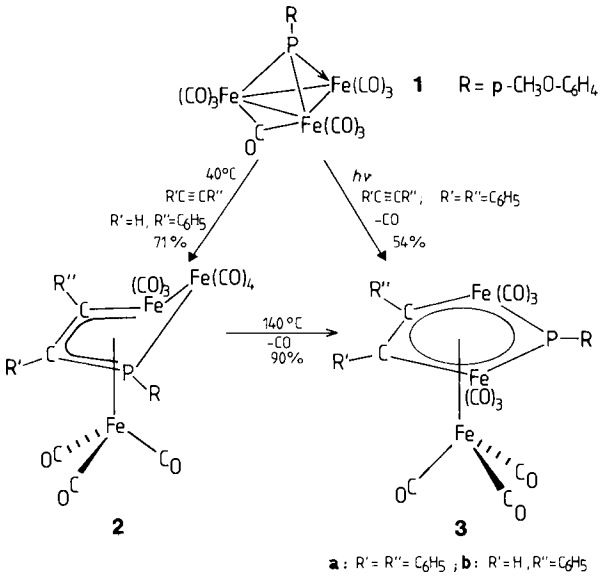
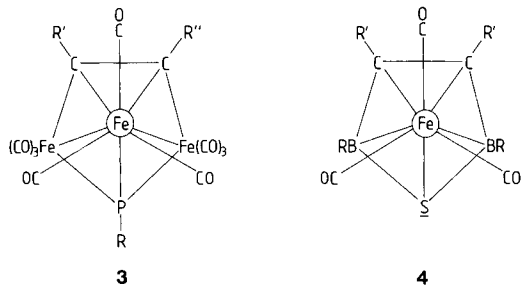


Scheme 1.

terms of *Wade*'s rules[7], **2** is an *arachno*-system which can be converted into the *nido*-cluster **3** upon decarbonylation. **3** forms directly in the photochemical reaction of **1** with alkynes (Scheme 1). In this connection, either the decarbonylation of **1** to afford an unsaturated cluster or the rupture of one of the Fe–Fe bonds can be considered as the initial reaction; in both cases cycloaddition of the alkyne ensues. Formation of **3** formally corresponds to the rare insertion mode of an alkyne into an M–M bond with "parallel" coordination of the alkyne[8].

The conversion of **2** into **3** requires reorganization of the cluster skeleton (Scheme 1), which is typical of carbaboranes. This analogy is also corroborated by the structure of **3**, which contains a planar (deviation ≤ 7 pm), five-membered organometallic heterocycle with adjusted bond lengths, and which, according to *Wade*'s rules[7] and to the criteria stated by *Hoffmann*, is isoelectronic in a wider sense with organoboron 4π-electron ligands such as the thiadiboroles[10] in **4** (Scheme 2).



Scheme 2.

A further notable aspect of the structure of **3** is the incorporation of a trigonal-planar (deviation ≤ 1 pm) "phosphanediyl"[11] into the organometallic heterocycle. With their conjugated organometallic π-ligands, the complexes **2** and **3** are special cases of an as yet small class of compounds.

Crown Ether Complexes of Sulfonium Salts—The X-Ray Crystal Structures of $[PhCOCH_2SMe_2 \cdot [18]Crown\text{-}6]_n[PF_6]_n$ and $[(PhCOCHPhSMe_2)_2 \cdot [18]Crown\text{-}6][PF_6]_2$**

By *Billy L. Allwood, John Crosby, David A. Pears, J. Fraser Stoddart**, and *David J. Williams*

The recent observation[1] that $[Ph_3PMe][PF_6]$ forms a 2:1 complex with [18]crown-6 (18C6) through [C–H···O] hydrogen bonding has led us to investigate whether alkylsulfonium cations also form discrete complexes with crown ethers. Complexation should be favored by the fact that the α-CH group in alkylsulfonium cations, like those in alkylphosphonium ions, are sufficiently acidic to lead to[2] the formation of stable ylides under basic conditions. We were also encouraged in our investigation in the knowledge that, even the neutral molecule Me_2SO_2 forms[3] a crystalline 2:1 complex with 18C6 in which the main source of bonding is undoubtedly [C–H···O] hydrogen bonding. Here, we report on the ability of salts[4] of the ca-

tions $[1]^{\oplus}$ to $[5]^{\oplus}$ to form crystalline 1 : 1 (polymeric) or 2 : 1 (discrete) complexes with 18C6[5].

$[Ph_2SMe]^{\oplus}$ $[1]^{\oplus}$ $[PhSMe_2]^{\oplus}$ $[2]^{\oplus}$ $[PhCH_2SMe_2]^{\oplus}$ $[3]^{\oplus}$

$[PhCOCH_2SMe_2]^{\oplus}$ $[4]^{\oplus}$ $[PhCOCHPhSMe_2]^{\oplus}$ $[5]^{\oplus}$

In the case of the complexes involving $[4][PF_6]$ and $[5][PF_6]$, the solid state supramolecular structures, as indicated by X-ray crystallography[6], reveal that, although the former exists as a polymeric 1 : 1 structure (Fig. 1), the latter is a discrete 2 : 1 complex (Figs. 2 and 3).

ring B (and B') is partially disordered, thus precluding definitive assessment of its conformational features. It appears that only *one* of the methyl groups, namely $C(19)H_3$, interacts with an 18C6 ring (A), whilst the other 18C6 ring (B) experiences an interaction with the methylene group $C(21)H_2$ only. The methyl group $C(24)H_3$ does not interact with ring B despite apparently being directed towards its center. This may be a contributory factor to the disorder[8] of this ring.

Inspection of space-filling molecular models led us to suspect that replacement of one of the methylene H atoms in $[4]^{\oplus}$ by a bulky group, e.g. phenyl, might discourage polymeric complexation. This is so, as demonstrated by the X-ray crystal structure of the discrete 2 : 1 complex,

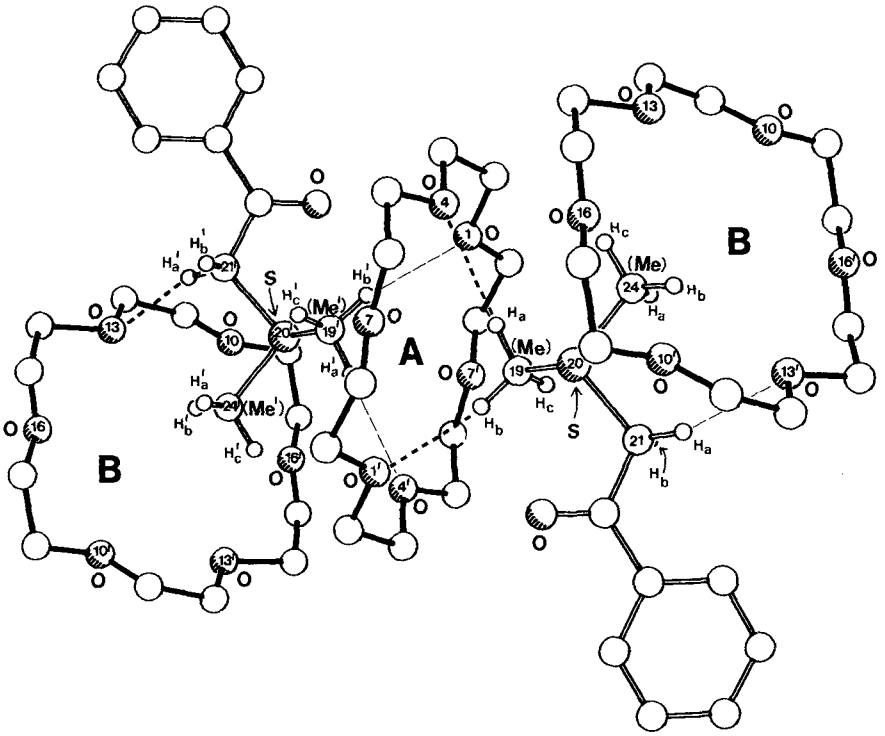

Fig. 1. The supramolecular structure of $[4 \cdot 18C6]_n[PF_6]_n$. Ring A experiences *four*, and ring B *two*, C–H···O contacts of less than 3.4 Å. Distances C···O, H···O [Å] and angles C–H···O [°]: [C(19)···O(1')]H_b: 3.35, 2.43, 163; [C(19)···O(4)]H_a: 3.39, 2.51, 152; [C(21)···O(13')]H_a: 3.30, 2.37, 164. The two shortest contacts between the C(24) methyl group and ring B are 3.29 Å between C(24) and O(16) but the associated H···O distance is 2.94 Å. Me···Me distances [Å]: C(19)···C(19'): 3.88; C(24)···C(24'): 4.53.

Figure 1 shows that the two 18C6 rings in $[4 \cdot 18C6]_n[PF_6]_n$ are situated on crystallographically independent centers of symmetry within the unit cell. The cations $[4]^{\oplus}$ are in general positions sandwiched between the two independent 18C6 rings, which provide different facial relationships to the cations. Ring A adopts a normal all-*gauche* conformation[7] with pseudo D_{3d} symmetry, whilst $[(5)_2 \cdot 18C6][PF_6]_2$ (Fig. 2). The 18C6 ring adopts an all-*gauche* conformation[7] with pseudo D_{3d} symmetry. There is a crystallographic center of symmetry at the center of the ring; all four methyl groups are directed towards the ring. Two methyl groups approach axially towards the center of the ring, whilst the other two bind to the periphery. In both cases, the contacts to the O atoms are long, though in ac-

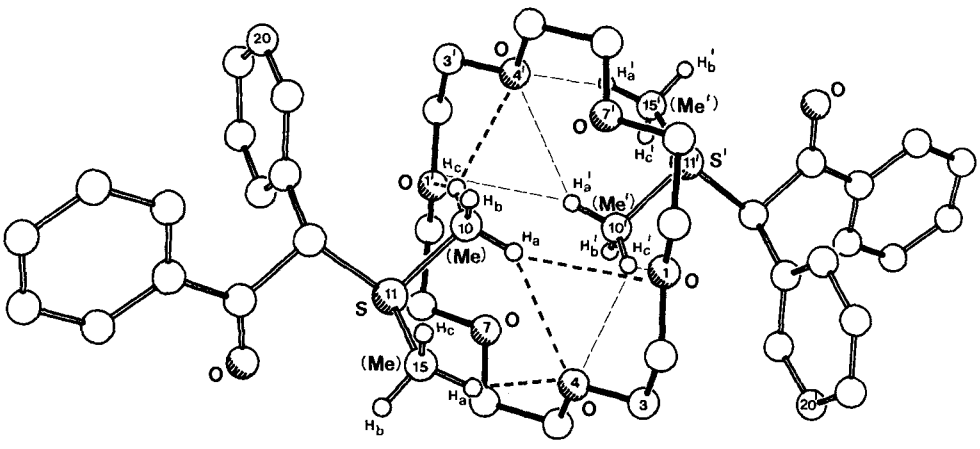

Fig. 2. The supramolecular structure of $[(5)_2 \cdot 18C6][PF_6]_2$. The 18C6 ring experiences *ten* C–H···O contacts of less than or equal to 3.5 Å. Distances C···O, H···O [Å] and angles C–H···O [°]: [C(10)···O(1)]H_a: 3.50, 2.67, 145; [C(10)···O(4)]H_a: 3.41, 2.58, 144; [C(10)···O(1')]H_c: 3.31, 2.53, 139; [C(10)···O(4')]H_c: 3.43, 2.61, 143; [C(15)···O(4)]H_a: 3.38, 2.60, 139. Me···Me distance [Å]: C(10)–C(10') 3.80. The S–C(10) bond is inclined by 53° to the normal to the mean plane of the six-ring oxygen atoms.

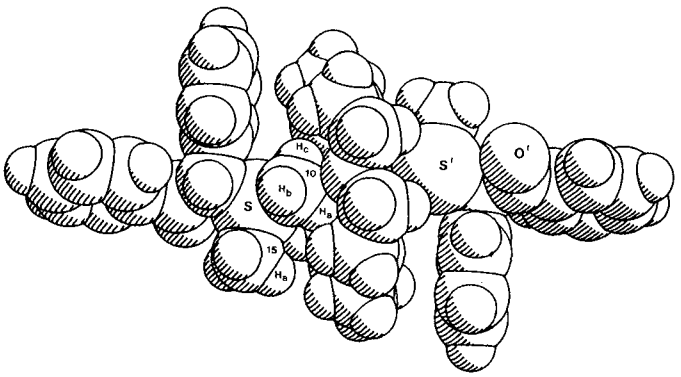

Fig. 3. Space-filling representation of $[(\mathbf{5})_2 \cdot 18C6]^{2\oplus}$.

cord with distances observed for similar interactions[1,3,9]. The two phenyl ring planes are orthogonal to each other (Fig. 3), one adopting a near normal relationship with the 18C6 plane, the other lying nearly parallel (17° between their mean planes). The closest approach by one of the 18C6 H atoms[10] to the mean plane of this phenyl ring is 2.79 Å. The axial methyl groups are tilted and involved in two pairs of bifurcated H bonds to O(1) and O(4), and to O(1') and O(4'). This binding involves simultaneous complexation by each Me group to both near and far oxygen atoms of the 18C6 ring, i.e. a cross between a nesting and perching arrangement[11], as distinct from the conventional perching arrangement observed in $[(Me_2SO_2)_2 \cdot 18C6]$. Although binding differently to the $[Ph_3PMe]^{\oplus}$ ion, the cation $[\mathbf{5}]^{\oplus}$ can still penetrate the 18C6 cavity.

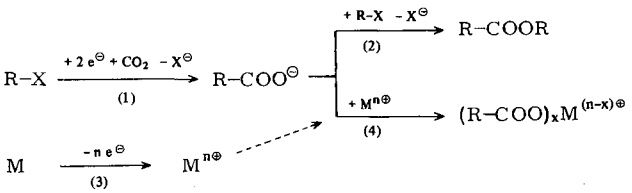
Sacrificial Anodes in the Electrocarboxylation of Organic Chlorides**

By *Giuseppe Silvestri**, *Salvatore Gambino*, *Giuseppe Filardo* and *Antonio Gulotta*

By and large, the electrochemical carboxylation of organic halides has severely limited application, for the carboxylate ion formed cathodically and the still unreacted halide react chemically with each other to form an ester[1-4] [reactions (1) and (2)]. The yields of the carboxylation can therefore not exceed 50% even under the most favorable circumstances.

We wish to report here that in the case of benzylic chlorides it is possible to hinder the esterification by introducing suitable inorganic species into the electrolytic solution. These species are released by sacrificial anodes and substantially improve the yields of the electrocarboxylation. Metal ions arising from the anodic reaction (3) form stable salts with the carboxylate ions which can be isolated on completion of the electrolysis [reaction (4)].



Sacrificial anodes have already been proposed on several occasions for reactions involving carbon dioxide, such as in the production of oxalic acid (with aluminum[5] and zinc[6]) or in the electrocarboxylations of ethylene[7], acenaphthylene[8], and, more recently, a series of thioethers[9]. In all these cases it was possible to perform the syntheses in diaphragm-less cells, and, in many cases, the salts of the carboxylate ions could easily be recovered during the work-up by filtration. The electrocarboxylation of benzylic chlorides described here also has all these advantages.

The metals to be used as sacrificial anodes must have an anodic dissolution potential less positive than that of the oxidation of the organic species present, or to be formed, in the electrolytic medium, and the metal ions released in the electrolytic solution should not to be reduced at the cathode. Aluminum, zinc, and magnesium gave satisfactory results; the most reliable for large-scale electrolyses, how-

[a] Solvent: Dimethylformamide (50 mL); supporting electrolyte: tetrabutylammonium bromide (1.5 g); cathode: graphite (25 cm^2); anode: aluminum 99.9% (50 cm^2); T: 20 ± 1 °C; CO_2 pressure: 1 atm. [b] Reference system $Ag/AgI/I^{\ominus}$ 0.1 M. [c] Amperostatic experiments, $i = 50$ mA.

Alkyl chlorides were already known to be very poor substrates for carboxylation processes[4], and rather low yields were also found even in this case (entries 1 and 2 in Table 1). The only noticeable effect was the absence of the esters obtained by the other authors. The nature of the side products of the synthesis was not investigated. The best results were obtained with benzyl chlorides (entries 3—7 in Table 1), which gave product and current yields of up to 75—80% at atmospheric pressure, and of up to 90% in tests performed under carbon dioxide pressurized at 20 atm. Among the benzylic chlorides, the α-methyl derivatives (entries 4—7) are of greater interest, for the substituted 2-arylpropionic acids obtained from them are currently used in the pharmaceutical field as anti-inflammatory and antirheumatic agents. The reliability of the synthesis on a preparative scale was tested for the preparation of 2-(4-isobutylphenyl)propionic acid (Ibuprofen) from 1-chloro-1-(4-isobutylphenyl)ethane. The acid was prepared at atmospheric pressure, with 83% product yield and 75% current yield, under the following conditions: 20 g of chloride (20% in DMF), 3.25 g of Bu_4NBr (3%), cathode potential: 1.9 V (vs. $Ag/AgI/I^{\ominus}$ 0.1 M); overall cell voltage = 2.5—3 V; initial current intensity 1 A. After consumption of 19650 coulombs, 1.9 g of unreacted halide (conversion 90.5%) and 15.75 g of the acid were recovered. The preparation of 1 g of acid required 1.2 g of chloride, 0.116 g of aluminum, 0.3 g of DMF, and 0.2 g of Bu_4NBr.

Due to their inactivity towards nucleophilic reagents, aryl halides do not undergo any esterification after the electrocarboxylation. Several examples of electrocarboxylations of aryl chlorides have already been published[10–12]. We have verified that these electrocarboxylations take place in good yields even with sacrificial anodes (entries 8—10 in Table 1).

The controlled potential electrolyses were all performed in diaphragm-less cells with 99.9% aluminum anodes and compact graphite cathodes. The mixing of the solution and the saturation with CO_2 was effected by continuous bubbling of anhydrous CO_2 between the electrodes. The electrolyzed solution was distilled off at reduced pressure and the residue was hydrolyzed at room temperature with diluted HCl, then extracted with ether. The removal of ether after drying gave the acids, which were purified by recrystallization[13].

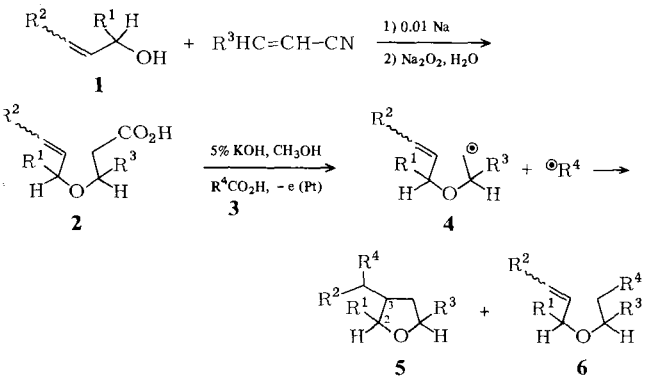
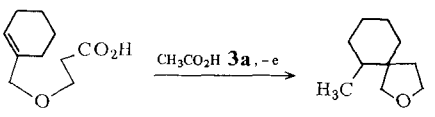
In the mixed Kolbe electrolysis of unsaturated carboxylic acids R–CH=CH–$(CH_2)_n$–CO_2H we found that with n = 4 or 5 substituted cyclopentanes or cyclohexanes were formed as side products[5]. We have now been able to show that this anodic cyclization can be used to convert 3-allyloxycarboxylic acids **2** into substituted tetrahydrofurans **5** (Table 1). 3-Allyloxycarboxylic acids are accessible in 47–80% yield by Michael addition of substituted allyl alcohols **1** to α,β-unsaturated nitriles[6] and subsequent saponification of the nitrile group (alkaline H_2O_2, room temperature)[7].



1 **2** **3** **4** **5** **6**

The 3-substituent can be varied at will by the choice of acid R^4CO_2H **3**; in previous radical heterocyclizations this was not possible, since, because of the radical chain addition, R^4 was usually[9] hydrogen.

With allyl ethers such as **7** the reaction leads to spirotetrahydrofurans such as **8** (molar ratio **7** : **3a** = 1 : 3.5, 23% as determined by gas chromatography).



7 **8**

Procedure:

5ed: **2e** (0.5 g, 3.2 mmol) and **3d** (2.1 g, 16 mmol) are dissolved in 25 mL methanol, partially neutralized with 5% KOH, and electrolyzed using platinum electrodes (3 cm^2/electrode) in an undivided cell using a current density of $i = 360$ mA/cm^2 at 40 °C until pH 8 was reached. The mixture was worked-up with brine (20 mL water and 10 g NaCl) and then extracted for 12 h with ether. After evaporation of the ether, the esters are saponified by refluxing for 3 h with KOH (molar ratio 1 : 2) in 30 mL ethanol and 15 mL water. After the usual work-up procedure, **5ed** is separated from the succinic acid by extraction with refluxing petroleum ether; kugelrohr distillation gives: 0.24 g (41%) **5ed** (b.p. = 135 °C/0.03 torr).—IR: $\tilde{\nu}$ = 3500–2500 (OH), 1760–1740 (C=O) cm^{-1}.—^{1}H-NMR ($CDCl_3$): δ = 10.8 (s, 1H), 4.45 (m, 1H), 3.9–3.5 (m, 2H), 2.35 (t, 2H), 2.2–1.5 (m, 9H), 1.25 (m, 1H).—MS (methyl ester) (70 eV): *m/z* 198 (5%, $M^{\oplus}$), 111 (100%, $M^{\oplus} - CH_2CH_2CO_2CH_3$).

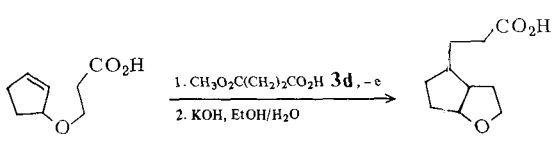
9	**2e**	$-(CH_2)_2-$		H	**3e**	$CH_2CO_2CH_3$	1 : 5	**5ee**	41 [e, f]		
10	**2f**	$-(CH_2)_3-$		H	**3a**	CH_3	1 : 3	**5fa**	53 [b]		

[a] Molar ratio. [b] Yield determined by gas chromatography. [c] *trans*-Isomer. [d] $R^4 = (CH_2)_2CO_2H$. [e] $R^4 = CH_2CO_2H$. [f] After saponification.

Formation of the products can be accounted for as follows: The potassium salt of **2** undergoes anodic decarboxylation to give the alkyl radical **4**, which then adds intramolecularly to the double bond and couples with the radical $^{\odot}R^4$ of the co-acid to afford **5**. At the same time, before cyclization **4** combines with $^{\odot}R^4$ to yield the allyl ether **6**. Methyl groups (R^1, $R^3 = CH_3$), which in the product are located directly on the ring, promote the cyclization via the *gem*-dialkyl effect[8] (Table 1, Nos. 3, 4). In the combinations **2e** and **3a**, **d**, **e** or **2f** and **3a** two diastereomers are formed in the ratio 3 : 2 or 1 : 1 (Nos. 7–10). Because of the geometry of the transition state in the cyclization, the tetrahydrofuran and cyclopentane, or cyclohexane rings are constrained to be *cis*-annelated. Furthermore, steric factors in the radical combination make it likely that the substituent in the predominant diastereomer of **5ea**, **5ed** and **5ee** adopts an *exo*-position.



2e **5ed**

$[Ni_8(\mu_4\text{-}PPh)_6(PPh_3)_4]$ and $[Ni_9(\mu_4\text{-}PPh)_6(PPh_3)_4]$; Clusters with Coordinatively Unsaturated Ni-Atoms**

By *Dieter Fenske**, *Johannes Hachgenei*, and *Friedhelm Rogel*

Dedicated to Professor Gerhard Fritz on the occasion of his 65th birthday

Recently we reported a straightforward method for the preparation of nickel clusters. For this purpose, $NiCl_2$ is allowed to react with $PhP(SiMe_3)_2$ in the presence of PPh_3. Upon addition of CH_3COCl, a mixture of $[Ni_8(CO)_4(PPh)_6(PPh_3)_4]$ **1** and $[Ni_8Cl_4(PPh)_6(PPh_3)_4]$ **2** is obtained[1]. The mechanism of formation of **1** and **2** remained unknown. Apparently **1** is formed first and then reacts with further CH_3COCl to afford **2**. In accord with this, $[Ni_8Br_4(PPh)_6(PPh_3)_4]$ is obtained from **1** and CH_3COBr. To throw some light on the reactive intermediates, we covered the reaction solution of $NiCl_2$, PPh_3, and $PhP(SiMe_3)_2$ with a layer of heptane. In this way, the extremely oxygen-sensitive crystalline compound $[Ni_8(PPh)_6(PPh_3)_4]$ **3** is isolated. This compound is also obtained by reducing **2** with Na/Hg[2].

$$NiCl_2 \xrightarrow[PhP(SiMe_3)_2]{PPh_3} \underset{\mathbf{3}}{[Ni_8(PPh)_6(PPh_3)_4]} \xleftarrow[Hg]{Na} \underset{\mathbf{2}}{[Ni_8Cl_4(PPh)_6(PPh_3)_4]}$$

The IR spectra of **2** and **3** are identical; like **2**, compound **3** is also paramagnetic. This manifests itself in the ^1H-NMR spectrum of **3**, where the phenyl protons have a chemical shift $\delta = 0.31-11.09$. No P resonance signal was observed in the ^{31}P-NMR spectrum of **3**.

According to the results of the crystal structure analysis (Fig. 1), **3** consists of a distorted Ni_8-cube, each face of which bears a μ_4-PPh ligand. Ni1, Ni3, Ni6, and Ni7 are tetrahedrally coordinated by the P atoms of the PPh_3- and μ_4-PPh ligands. In contrast, Ni2, Ni4, Ni5, and Ni8 are bound only to the P atoms of three μ_4-PPh ligands and are, therefore, coordinatively unsaturated. This means that the cluster contains Ni atoms with 18 (Ni1, Ni3, Ni6, and Ni7) and with 16 (Ni2, Ni4, Ni5, and Ni8) valence electrons. With 112 valence electrons, **3** has eight electrons less than one would expect for a stable M_8-cluster[3].

In both **1** and **2** a regular Ni_8 cube is found. As a consequence of the electron deficiency, **3** is distorted. This is expressed by the fact that the Ni atoms with 16 valence electrons have a nonbonding distance of 323—325 pm. In contrast, this distance (384—387 pm) is considerably larger between the Ni atoms with 18 valence electrons. In this way the (Ni–Ni–Ni) bond angles of the cube are distorted: 79.2—80°, (Ni1, Ni3, Ni6, Ni7) and 99.2—100.1° (Ni2, Ni4, Ni5, Ni8). The different distances between the Ni atoms are expressed, moreover, by the bond lengths to μ_4-P. Furthermore, the Ni–Ni distances of 251—254 pm are considerably shorter than in **1** (265—268 pm) and **2** (259—262 pm).

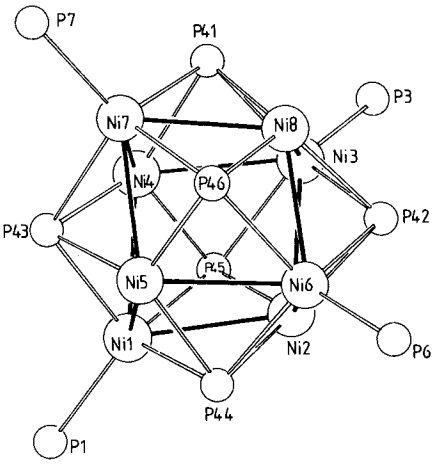

Fig. 1. Structure of the cluster **3** in the crystal (without phenyl groups). P1, P3, P6, P7 and P41—P46, respectively, are the P atoms of the PPh_3 and PPh ligands. Crystals from toluene; **3** crystallizes with 1 mol toluene per formula unit, C_c, $Z=4$, $a=1583.2(8)$, $b=2768.5(10)$, $c=2509.5(11)$ pm, $\beta=99.82(4)°$ (180 K). $\mu(Mo_{K\alpha})=15.3$ cm^{-1}. Syntex R3, up to $2\theta=35°$, 5915 independent reflections, 3534 of which with $I>2\sigma(I)$, empirical absorption correction. Patterson methods, all atoms (without H) refined isotropically, phenyl groups treated as rigid groups (C–C 139.5 pm). $R_1=0.088$, $R_2=0.083$. Selected distances [pm]:Ni–Ni 251—254(1), Ni2,4,5,8-μ_4-P 212—216(1), Ni1,3,6,7-μ_4-P 224—228(1), Ni1–P1 221(1), Ni3–P3 220.3(10), Ni6–P6 218.0(11), Ni7–P7 218.4(12); selected bond angles [°]: Ni(18e)–Ni(16e)–Ni–(18e) 99.2—100.1(2), Ni(16e)–Ni(18e)–Ni(16e) 79.2—80.0(2), Ni(18e)–(μ_4-P)–Ni(18e) 115.2—118.5(6), Ni(16e)–(μ_4-P)–Ni(16e) 97.0—99.2(5), Ni(18e)–(μ_4-P)–Ni(16e) 68.8—71.2(4) [4].

In **3**, the tricoordinated Ni atoms (Ni2, Ni4, Ni5, Ni8) are surrounded in a crown-like manner by the six phenyl groups of the PPh_3 and PPh ligands. In the solid state this arrangement results in the formation of canals having a diameter of 400—500 pm, as illustrated in Figure 2 for the example of the coordination gap at Ni5.

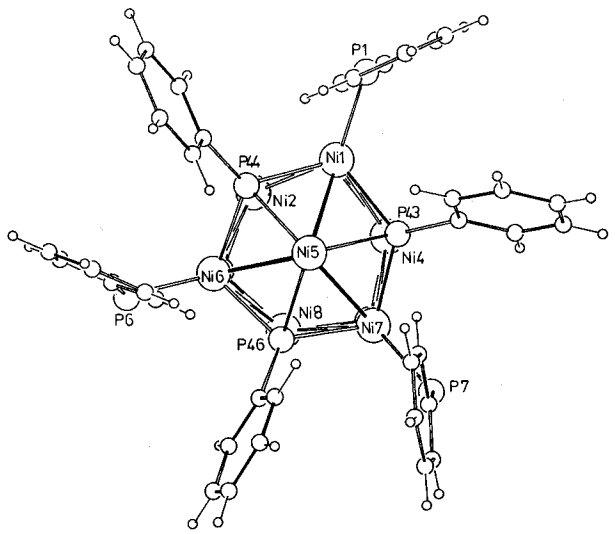

Fig. 2. Structure of the coordination gap at Ni5 in **3**. For reasons of clarity the remaining pheny groups are not shown.

The reason for the stability of **3** is possibly that only molecules of suitable size can be coordinated by Ni2, Ni4, Ni5, and Ni8. In accord with this, compound **3** reacts in

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. The crystallographic data were measured at the Institut für Kristallographie der Universität Karlsruhe.

tetrahydrofuran (THF) with CO, NO, and RNC to form $[Ni_8X_4(PPh)_6(PPh_3)_4]$ (X = CO, NO, t-C_4H_9NC). These compounds are also obtained when **2** is reduced with sodium amalgam in the presence of CO, NO, and RNC.

Reduction of a solution of **2** and $NiCl_2$ in THF with sodium amalgam affords the paramagnetic compound $[Ni_9(PPh)_6(PPh_3)_4]$ **4**.

$$\underset{\mathbf{2}}{[Ni_8Cl_4(PPh)_6(PPh_3)_4]} \xrightarrow[NiCl_2]{Na/Hg} \underset{\mathbf{4}}{[Ni_9(PPh)_6(PPh_3)_4]}$$

In the ^{31}P-NMR spectrum of **4** resonances at $\delta = 430$ (μ_4-PPh) and 25.1 (PPh_3) are observed. For the phenyl protons, signals are found between $\delta = 0.04$ and 7.59. According to the results of the crystal structure analysis, **4** contains a distorted Ni_8-cube to which a further Ni atom (Ni9) is bound[4].

Within the limits of the standard deviations, the bond lengths in **4** are identical with those of the corresponding bonds in **3**. The distance Ni5–Ni9 of 268.6(2) pm lies in the region of a Ni–Ni single bond[5].

The electron balance of **4** indicates that both the Ni_8 and Ni_9 clusters contain less electrons than would be expected from the noble gas rule.

Comparison of the structures of **3** and **4** indicates that the latter arises formally by occupation of a coordination gap in **3** by Ni9. Thereby, the structure of the gap shown in Figure 2 is not changed. The stability of **4** possibly arises because Ni9 participates in weak interactions with the π electrons of the adjacent phenyl groups (distances of Ni9 to the nearest C atoms: 326–380 pm). We have not yet been able to incorporate other metal atoms into **3**.

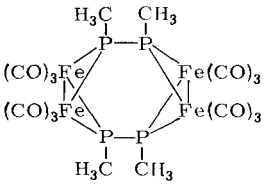
$[(CO)_3FePCH_3]_4$, an Organometallic Analogue of Octabisvalene**

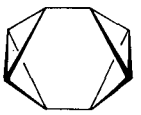
By *Rajib Lal De* and *Heinrich Vahrenkamp**

Dedicated to Professor Kurt Issleib on the occasion of his 65th birthday

According to *Hoffmann*'s isolobal relationship[1], the $(CO)_3Fe$ unit is related to the fundamental species BH or $CH^{\oplus}$ and the ER (E = P, As) unit, to NH or $CH^{\ominus}$. Complexes of the composition $[(CO)_3FeER]_n$ should therefore exhibit a relationship to the hydrocarbons $(CH)_{2n}$. We have previously been able to confirm this for the tetrahedrane analogue $[(CO)_3FeP{t}C_4H_9]_2$[2] and for the cubane analogue $[(CO)_3FeAsCH_3]_4$[3]. The novel Fe_4E_4 isomer $[(CO)_3FePCH_3]_4$ **1**, an analogue of the as yet unknown hydrocarbon octabisvalene **2**[4], represents the third example of a relationship of this type.



1



2

The orange-red tetranuclear complex **1** is formed in 8% yield, analogously to $[(CO)_3FeP{t}C_4H_9]_2$[2], by deprotonation of $[(CO)_3Fe{-}PHCH_3]_2$ with methyllithium in ether, subsequent oxidation with 1,2-dibromomethane, and chromatography on silica gel; complexes of the type $[Fe_2(CO)_6(PR_2)_2]$ also form. According to the IR spectrum (cyclohexane: $\nu = 2048$ (s), 2032 (s), 1989 (s), 1973 (m) cm^{-1}), **1** is an $[Fe_2(CO)_6(\mu\text{-}PX_2)_2]$-derivative. The ^1H-NMR spectrum (broad singlet at $\delta = 1.07$ in C_6D_6) and EI mass spectrum of **1** ($M^{\oplus} - CO$, 100%) are equivocal, and for its identification we therefore resorted to a crystal structure analysis[5] (Fig. 1).

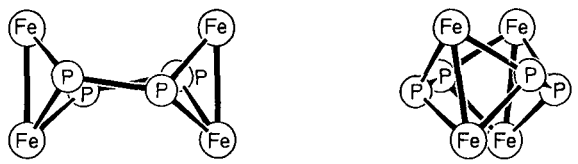


Fig. 1. Two views of the framework of **1** in the crystal [5]. Distances: Fe–Fe 261.8(1), Fe–P 221.0–223.7(2); P–P 222.6(4), P···P 279.6(4) pm.

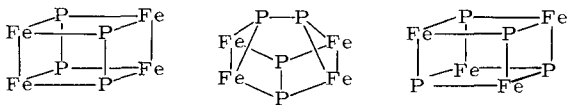
The molecule **1** consists of two $[Fe_2(CO)_6(\mu\text{-}PRX)_2]$ moieties; a twofold axis passes through the middle of the molecule and runs roughly in the direction of the Fe–Fe bonds. Within the molecular halves all bond lengths and angles are normal[6]. The linking P–P bonds (223 pm) correspond to a single bond length. In contrast to the R_2P_2 ligands in $[(CO)_3FeP{t}C_4H_9]_2$[2], the R_2P_2 ligands in **1** *cannot* be designated as diphosphene moieties. Figure 1 indicates that the framework of **1** is highly symmetric and ought to be similar to that of octabisvalene.

[*] Prof. Dr. H. Vahrenkamp Dr. R. L. De
Institut für Anorganische und Analytische Chemie der Universität
Albertstrasse 21, D-7800 Freiburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Rechenzentrum der Universität Freiburg.

The tetrahedrane framework with R = *t*Bu and the octabisvalene framework with R = CH_3 presumably form because of steric reasons. Whereas the hydrocarbon **2** is highly strained, the arrangement in **1** is largely strain-free, based on the intermolecular contact distances.

With other residues R the occurrence of not only the tetrahedrane- but also the octabisvalene-analogous $[(CO)_3FePR]_x$ complexes and, possibly, their interconversion is to be expected.



3 **4** **5**

Further $[(CO)_3FePR]_4$ isomers with the molecular frameworks **3**, **4**, and **5** are conceivable: these already exist in the form of the hydrocarbons cubane and cuneane and as the As analogue of **5**. The skeletons of **3** and **4** could arise from **1** without rupture of the P–P bonds, whereas formation of framework **5**, which is to be expected on the basis of the P–As analogy, presumably has a higher energy of activation. It is conceivable that compounds of the as yet unknown $[(CO)_3FePR]_3$-type are also formed in such reactions.

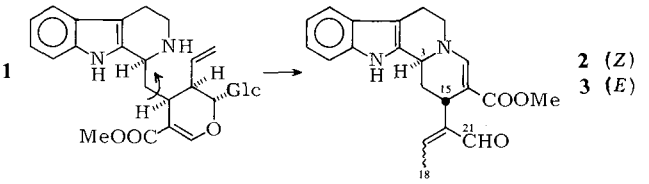
Total Synthesis of the Indole Alkaloid Vallesiachotamine

By *Dietrich Spitzner** and *Ernest Wenkert*

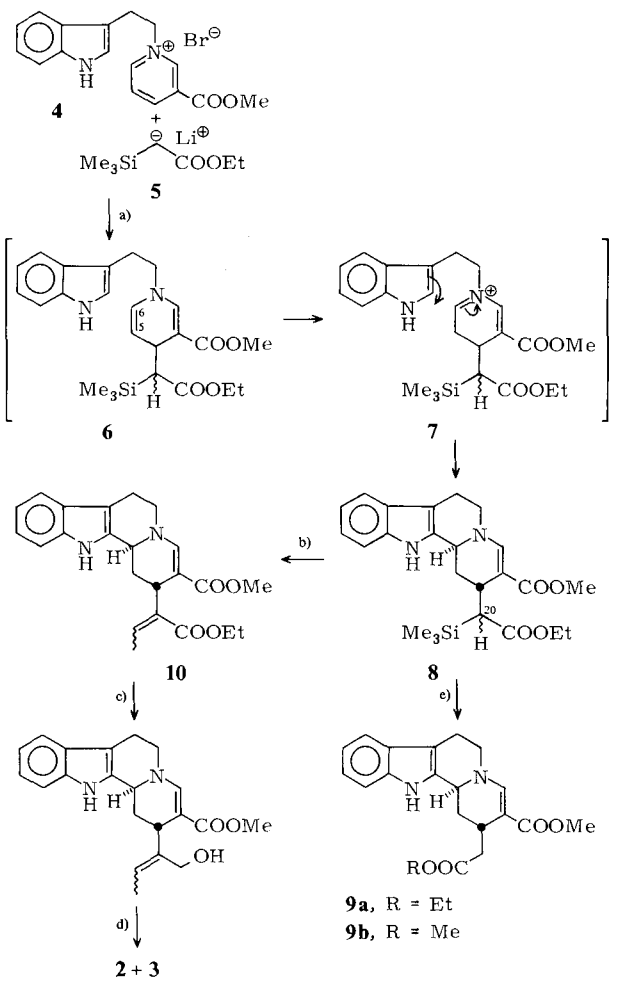
Dedicated to Professor Wolfgang Lüttke on the occasion of his 65th birthday

Tryptamine and secologanin are biosynthetic precursors of a vast number of structurally different indole alkaloids[1], some of which exhibit interesting biological activity. Extensive evidence has established the initial formation of strictosidine **1**[2], which in vivo can then undergo numerous rearrangements and cyclizations. Vallesiachotamine **2** and its (*E*)-isomer isovallesiachotamine **3** are "early" end products formed from **1**, which can also be formed by mild in vitro hydrolysis[3]. As early as 1966, *Djerassi* et al. obtained **2** (presumably as a mixture with **3**) as a minor constituent (0.001%) of the alkaloid fraction from the Peruvian plant *Vallesia dichotoma Riuz et Pav* (family, Apocynaceae)[4].



2 (*Z*)
3 (*E*)

In the course of investigations of the addition of silicon-stabilized anions to pyridinium salts[5], we have now found a short, convergent synthetic route to **2** (Scheme 1). Reaction of the ester enolate **5**[6] with the pyridinium salt **4**, readily accessible from tryptophyl bromide and methyl nicotinate, affords the tetracycle **8** (mixture of epimers). This addition proceeds similarly to that of malonic ester anion to pyridinium salts: addition to 1,4-dihydropyridine **6**,



Scheme 1. a) 1. THF −50 to 23 °C; 2. benzene/HBr; 47%; b) 1. LDA, −78 °C; 2. acetaldehyde, −78 to 23 °C; 68.5%; c) $LiAlH_4$, THF, 5 °C; 81%; d) 1. activ. MnO_2, CH_2Cl_2, 23 °C; 2. prep. TLC (silica gel G/ether); 60%; e) KF in MeOH; quantitative.

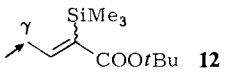
whose 5,6-double bond is protonated to give the intermediate iminium salt **7**. Compound **7** can cyclize to the quinolizidine derivative **8** via a Pictet-Spengler reaction, a reaction which has already proven valuable in yohimbine syntheses[7]. At pH 3 we observed exclusively 1,4-addition of **5** to **4** and practically no desilylation. As expected, **8** is readily desilylated by potassium fluoride in methanol to furnish the diester **9a**, whose ^{1}H- and ^{13}C-NMR spectra—except for the ester group (Et instead of Me in **9a**)—are in accord with those of the known **9b**[8,9]. In this way, the stereochemistry of **8**, with the exception of the relative configuration at C^{20}, which for our synthesis of **2** (and **3**) is unimportant, could be determined: 3-H and 15-H are *trans*-orientated. In the subsequent Peterson olefination [double deprotonation with lithium diisopropylamide (LDA) and reaction with acetaldehyde] no nitrogen protecting group was required, and we obtained the α,β-unsaturated esters **10** in 68.5% as a (*Z,E*)-mixture (3 : 1). Controlled reduction of **10** with lithium aluminum hydride in tetrahydrofuran (THF) yielded the dihydrovallesiachotamines **11**, which were oxidized to **2** and **3** with activated manganese dioxide. Our synthetic **2** (and **3**) was found to be identical (except for its chiroptical properties) with an authentic sample from plant cell cultures[10]. In the ^{1}H-NMR spectrum of **2**, we observed a weak nuclear Overhauser effect (NOE) between the aldehyde proton and C-18 proton, which suggests that the 19,20-double bond has a (*Z*)-configuration.



12

An attempt to prepare **2** by direct addition of the anion of **12**[11] to **4** failed, due to exclusive γ-addition.

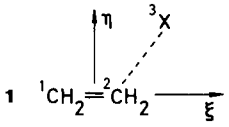
Simple Model for Radical Additions

By *Udo Höweler* and *Martin Klessinger**

Dedicated to Professor Wolfgang Lüttke on the occasion of his 65th birthday

Starting from a VB approach, we have recently developed a model for nonpolar radical reactions[1], which extends beyond the possibilities offered by known MO considerations[2] in that it permits estimation of the energies and geometries of the transition states as well as substituent effects. We demonstrate this here by describing the first applications of the model: intermolecular addition of a radical X to alkenes **1** and concerted [1,2]-migration in radicals.



The majority of reactions undergone by free radicals can be described by a three-center, three-electron system[1,3]; Figure 1 shows the characteristics of the potential surface for the ground-state reactions of such a system as a function of the position of center 3 in the ξ,η-plane, the separation of centers 1 and 2 being fixed; for a linear transition state the center 3 lies on the ξ-axis, and for a cyclic one, on the η-axis. The solid curve describes those geometries at which the 2,3-bond is formed and, hence, at which an activation barrier for intermolecular reactions occurs. The dotted curve designates the geometries at which the 1,2-bond is broken, so that reactions crossing this curve imply scission of this bond. The positions of both curves can be readily estimated qualitatively from

$$S_{12}^2 = \frac{1}{2}\left(\frac{m_{13}}{m_{12}} S_{13}^2 + \frac{m_{23}}{m_{12}} S_{23}^2\right) \quad (1a)$$

$$S_{23}^2 = \frac{1}{2}\left(\frac{m_{12}}{m_{23}} S_{12}^2 + \frac{m_{13}}{m_{23}} S_{13}^2\right) \quad (1b)$$

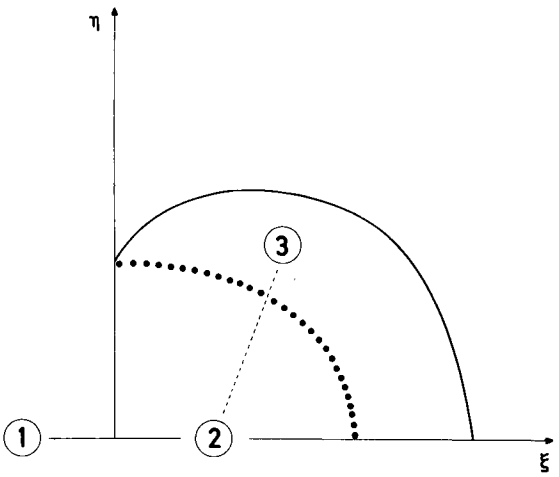


Fig. 1. Characteristics of the potential surfaces of the three-center, three-electron system (cf. text); geometries from equation (1a) (· · · ·) and equation (1b) (——) correspond to scission of the 1,2-bond and formation of the 2,3-bond, respectively.

and the height $E_a - |\varepsilon_\infty|$ of the activation barrier relative to the energy $|\varepsilon_\infty|$ of the separated centers is given by

$$E_a = |\varepsilon_\infty| - m_{12}\left(S_{12}^2 + \frac{m_{13}}{m_{12}} S_{13}^2\right) \quad (2)$$

If both the overlap integrals $S_{\mu\nu}$ and the one-center energies h_ρ necessary for calculation of the parameter

$$m_{\mu\nu} = 1.75(h_\mu + h_\nu) + h_\kappa$$

are also known, the positions of the curves can be estimated quantitatively, thus forming the basis for a straightforward and illustrative discussion of free radical reactions.

By this means the following generalizations about the course of addition of a radical X to an alkene can be deduced from Figure 1 and from the dependence of the overlap integral $S_{\mu\nu}$ on the nuclear distance $R_{\mu\nu}$ and on the atomic number of the radical center:

- Thermal addition reactions proceed preferentially via linear transition states.
- In the linear transition state the length of the educt bond is almost unchanged. A shorter bond would lead to a "tighter" transition state.
- Cyclic transition states are unfavorable in reactions from the ground state and are only favorable if the bonds are lengthened.
- Within a given period the transition state becomes tighter as the atomic number of the radical center increases.
- Stabilizing substituents at the radical center, e.g. alkyl and aryl moieties, promote the reaction.

The effect of substituents on the radical center X was estimated as follows: If the one-center energies of the C atoms and of the radical center X are designated by h and $h_X = h + \Delta h$, respectively, then $m_{13}/m_{23} = 1$ and $m_{12}/m_{23} < 1$ or $m_{12}/m_{23} > 1$, depending on whether $\Delta h < 0$ or $\Delta h > 0$. Stabilization of the radical center ($\Delta h < 0$, $m_{12}/m_{23} < 1$) leads to a shift of the energy barrier to greater distances (cf. Fig. 2a) and to a smaller activation energy, whereas for the destabilization ($\Delta h > 0$, $m_{12}/m_{23} > 1$) the reverse behavior is expected (cf. Fig. 2b).

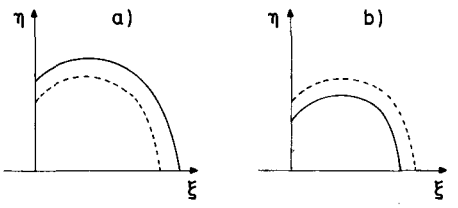

Fig. 2. Position of the activation barrier as a function of the one-center energies of the radical center: a) $\Delta h < 0$; b) $\Delta h > 0$. (The broken curve corresponds to $\Delta h = 0$.)

Table 1 summarizes the geometries (calculated using standard STO exponents for determination of the overlap integrals and EHT valence state ionization potentials for the one-center energies h_ρ[5] in determining the parameters $m_{\mu\nu}$ in eq. (1b)) of some transition states for the approach of the radical X along the direction of the newly formed bond (linear) and towards the middle of the original bond (perpendicular). The opening up of the transition state geometries due to stabilization of the radical center (for all X, $\Delta h \leq 0$) is indicated by the values in parentheses, which were obtained by neglecting the differences in the one-center energies ($\Delta h = 0$, $m_{12}/m_{23} = 1$).

Table 1. Distance R_{CX} [pm] in the transition state for the radical addition of X to ethylene for various 1,2-bond lengths R_{CC} (values in parenthesis refer to $m_{12}/m_{23} = 1$).

X	$\frac{m_{12}}{m_{23}}$	Linear		Perpendicular	
		$R_{CC} = 130$ pm	$R_{CC} = 150$ pm	$R_{CC} = 130$ pm	$R_{CC} = 150$ pm
H	0.97	190	210(210)	145	175 (170)
C	1.00	210	230(230)	[a]	190 (190)
N	0.96	200	220(220)	[a]	175 (165)
O	0.92	190	210(220)	[a]	160 (— [a])
F	0.89	175	195(190)	[a]	140 (— [a])
Cl	0.95	230	250(250)	165	210 (200)

[a] Condition (1a, b) not fulfilled.

The general course of the reaction and the structure of the quantum chemically calculated transition states in Table 2 are in excellent agreement with our results. The angle of approach is greater than 90° in all cases and the original bond is almost unchanged. The greatest deviation occurs with the fluorine atom, from which it can be concluded that the effect of the one-center energies (Δh) is not sufficiently reflected in this model derived for nonpolar reactions.

Table 2. Transition states for radical addition reactions to ethylene and acetylene.

X		R_{CC} [pm]	α [°]	R_{CX} [pm]	Ref.
H	C=C	136	106	203	[4a]
CH_3	C=C	132	109	230	[4b]
NH_2	C=C	148	>90	198	[4c]
F	C=C	—	>90	210	[4d]
H	C≡C	122	110	193	[4e]

Intramolecular reactions such as concerted [1,2]-migrations in radicals proceed along the energy valley between the two curves in Figure 1 and, hence, require lengthening of the 1,2-bond before the cyclic transition state is reached. The data in Table 1, in fact, show that for the simple model an activation barrier at $R_{12} = 130$ pm is found only for X = H and Cl, but at $R_{12} = 150$ pm a barrier and hence a cyclic transition-state is found for all X. This result is consistent with the transition-state geometries calculated by *Fossey* et al.[6].

The model we have developed therefore correctly treats those parameters which are decisive for estimating both the transition-state geometries and the activation energies of radical reactions and is comprehensive enough to be generally applicable.

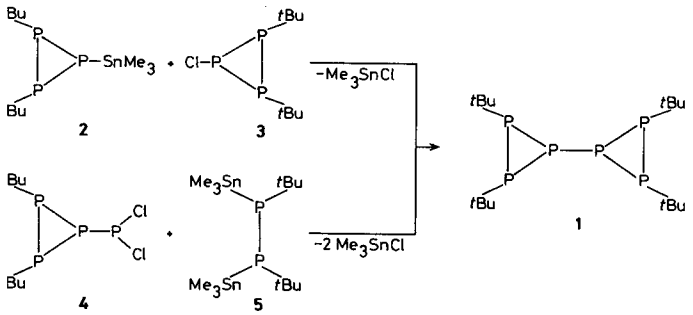
P_6tBu_4—The First 1,1'-Bicyclotriphosphane**

By *Marianne Baudler** and *Bernd Makowka*

Dedicated to Professor Kurt Issleib on the occasion of his 65th birthday

Triorganocyclotriphosphanes $(PR)_3$ are well-known compounds[1]. However, the synthetic potential of phosphorus three-membered ring compounds has scarcely been exploited. Starting from functionalized cyclotriphosphanes of the type $(PR)_2PX$ (X = functional group), we have now succeeded in linking two P_3 ring skeletons via a σ-bond.



2,2',3,3'-Tetra-*tert*-butyl-1,1'-bicyclotriphosphane **1** is obtained by reaction of 1,2-di-*tert*-butyl-3-trimethylstannylcyclotriphosphane **2**[2] with 1,2-di-*tert*-butyl-3-chlorocyclotriphosphane **3**[2] or by [1+2]-cyclocondensation of 1,2-di-*tert*-butyl-3-(dichlorophosphino)cyclotriphosphane **4**[2] with 1,2-di-*tert*-butyl-1,2-bis(trimethylstannyl)diphosphane **5**[2]. In contrast, demetalation of 1-potassium-2,3-di-*tert*-butylcyclotriphosphide[3] with iodine, 1,2-dihaloalkanes, or *N*-haloamines affords preferentially $(PtBu)_4$[4] and also other *tert*-butylphosphanes.

The pure, isolable **1**[5] is a colorless, crystalline solid (m.p. = 122—124°C, decomp. sealed tube), which is stable under an inert gas atmosphere. It is readily soluble in tetrahydrofuran (THF) as well as in aliphatic and aromatic hydrocarbons, but only moderately soluble in methanol. The compound, which in the solid state is only slightly sensitive to atmospheric oxygen, is rapidly oxidized in solution. Its composition is corroborated by the results of elemental analysis and by the mass spectrum [12 eV, 40°C, *m/z* 414, ($M^{\oplus}$, 8%), 357 ($M^{\oplus} - C_4H_9$, 100%)]. The IR and Raman spectra show bands in the P—P stretching- and deformation-regions[6]. The constitution of **1** follows from the NMR data (Table 1), in particular from a complete analysis of its $^{31}P\{^1H\}$-NMR spectrum (Fig. 1).

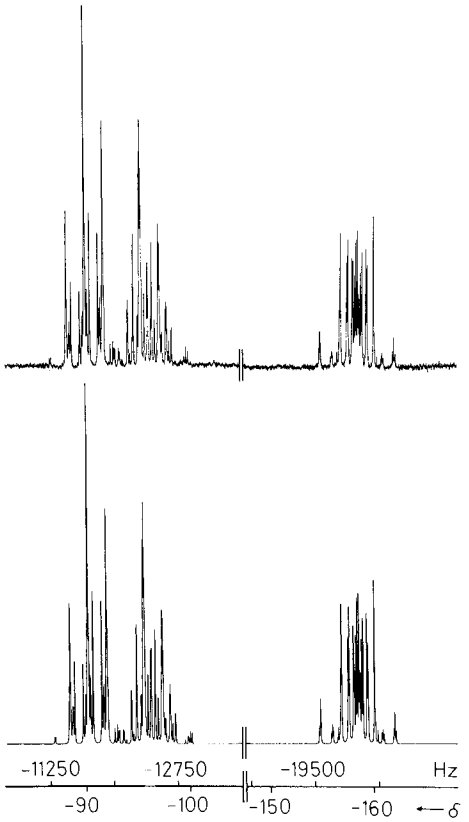


Fig. 1. Above: Observed 121.497 MHz $^{31}P\{^1H\}$-NMR spectrum of **1** in THF at 298 K. Below: Calculated spectrum of **1**.

	+33.23 (P_BCC)		

[a] THF, 298 K. [b] [D_6]Benzene, 299 K. [c] The assignment followed from selective decoupling experiments.

The chemical shifts of all P atoms lie in the high-field region characteristic for phosphorus three-membered ring compounds[1]. Whereas the positions of the signals of the *tert*-butyl substituted atoms are largely in accord with the mean of the $\delta(^{31}P)$ values of tri-*tert*-butylcyclotriphosphane ($\delta_{cis} = -71.0$, $\delta_{trans} = -109.6$[7]), those of the P atoms connected only to other phosphorus atoms are shifted strongly to high field. This may be attributable to a contraction of the exocyclic bond angles[8] upon substituting a *tert*-butyl group in $(PtBu)_3$ by a "P side-chain", which is also observed in similar compounds $[(PtBu)_2P-P(tBu)Cl$:

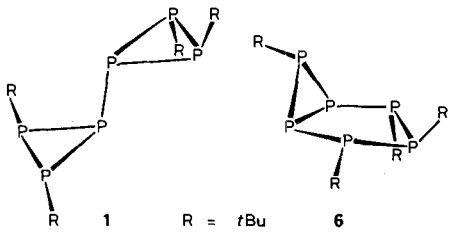
Greinstrasse 6, D-5000 Köln 41 (FRG)

[**] Contributions to the Chemistry of Phosphorus, Part 149. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 148: M. Baudler, M. Hintze, *Z. Anorg. Allg. Chem.*, in press.

$\delta = -157.6$[2]; $(PtBu)_2P-P(cyclo\text{-}C_6H_{12})_2$: $\delta = -159.4$[9]]. Proof of the structure is furthermore provided by the large positive coupling constant $^2J(P_AP_{C'}) = {}^2J(P_{A'}P_C)$, which indicates approach of the lone-pairs of electrons on the P atoms involved[10].

According to the IR and Raman spectra (non-fulfillment of the alternative rule)[6] as well as to the order of magnitude of the $^3J_{PP}$ coupling constants [$^3J(P_AP_{A'}) > {}^3J(P_BP_{B'})$][10], of the two possible configurational isomers, which differ from each other in the relative arrangement of the *trans*-oriented *tert*-butyl groups at the two three-membered rings, the sterically more favorable all-*trans*-isomer (C_2 symmetry) is present as an enantiomeric pair.



1 R = *t*Bu 6

The 1,1'-bicyclotriphosphane **1** is a constitutional isomer of the bicyclo[3.1.0]hexaphosphane **6**, formed by dehalogenation of a mixture of $tBuPCl_2$ and PCl_3 with magnesium[10c]. Thermolysis of **1** (128 °C) leads not only to disproportionation into $PtBu_3$, P_8tBu_6[11], and *tert*-butylphosphanes richer in P, but also, on a limited scale, to isomerization to **6**.

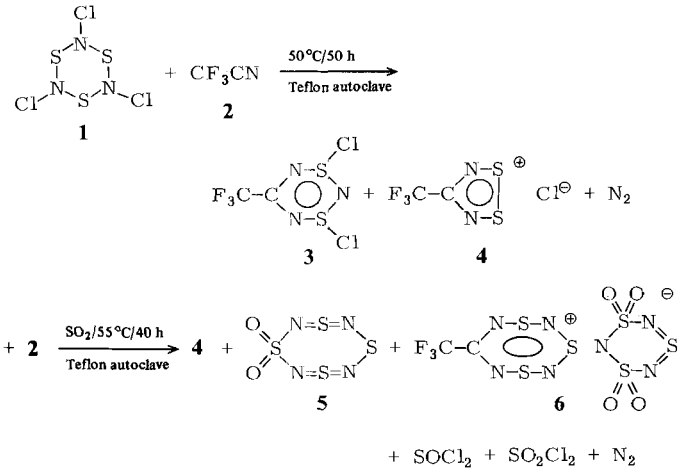
Synthesis and Structure of the 7-Trifluoromethyl-1,3,5,2,4,6,8-trithiatetrazocine Cation**

By *Hans-Ulrich Höfs, Gabriele Hartmann, Rüdiger Mews**, and *George M. Sheldrick*

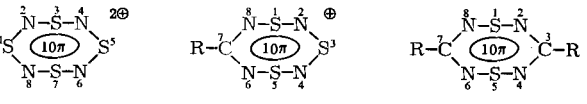
Dedicated to Professor Wolfgang Lüttke on the occasion of this 65th birthday

The reactions of 1,3,5-trichloro-1,3,5,2,4,6-trithiatriazine **1** with trifluoroacetonitrile are very complex; depending on the reaction conditions, the solvent, and the material of the reaction vessel[1], different products can be obtained. On carrying out the reaction in the absence of solvent, the dithiatriazine **3** (21%)[2] and the dithiadiazolylium chloride **4** (45%)[3] are obtained; when SO_2 is used as solvent, it enters into the reaction: In addition to **4**, the *S,S*-dioxide **5** is formed, along with about 4% of the salt **6**[5], which contains the cyclic, eight-membered 7-trifluoromethyl-1,3,5,2,4,6,8-trithiatetrazocine cation and the well known 1,1,3,3-tetraoxo-1,3,5,2,4,6-trithiatriazine anion[6,7]. **5** is accessible via an alternative route[4].



+ $SOCl_2$ + SO_2Cl_2 + N_2

The cation in **6** is the missing link in the series of isoelectronic heterocycles $S_4N_4^{2\oplus}$ **7**[8] $RCS_3N_4^{\oplus}$, and 3,7-$(RC)_2S_2N_4$ **8**[9–11], which have attracted increasing interest in recent years, both preparatively[9,10] as well as theoretically[9–11]. Systems such as these are especially suitable for checking the general applicability of theoretical models developed for organic compounds.



7 8

The "electron-rich" 10π-dication $S_4N_4^{2\oplus}$ **7**, which can be prepared by oxidation of the 12π S_4N_4-cage, is (as expected according to the Hückel rule) planar and exhibits almost equal SN distances (mean length 155.2 pm). Formal replacement of "$S^{\oplus}$" in the 1,5-position by the isolobal sp^2 carbon should lead to very little change in the electronic

[**] This work was supported by the Land Niedersachsen and the Deutsche Forschungsgemeinschaft.

structure of the ring system. Model calculations on **8** show[10] that this 10π ring system, with alkyl and aryl substituents, has a planar monocyclic structure; π-donor ligands can induce a pseudo-Jahn-Teller distortion, which leads to a bicyclic 8π system with *trans*-annular S–S bonding[10, 14]. The cation is therefore expected to have a planar structure; this has been confirmed by an X-ray structure analysis of **6** (Fig. 1)[12]. C1,S5 and S3,S7 respectively lie

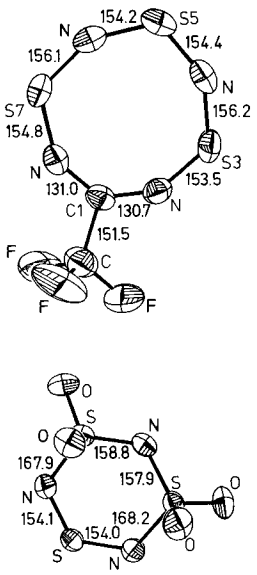

Fig. 1. The structure of **6** in the crystal [12], with bond lengths [pm]. The mean S–O distance is 143.0 pm.

only slightly above and slightly below the plane through the four N atoms (6.2, 7.2, −7.7, −9.0 pm); this slight folding of S3/S7 does not, however, lead to any *trans*-annular S–S interaction (S–S 400.8 pm). The S–N distances (mean value 154.9 pm) are almost identical; they alternate very little more than in the $S_4N_4^{2\oplus}$ ion. In both systems the average S–N bond lengths are very nearly equal and are about 1.5 pm shorter than in the neutral aryl derivatives of **8**[9]; a similar shortening is observed for the C–N bonds. The anion $S_3N_3O_4^{\ominus}$ has almost the same geometry as has been found in $S_5N_5^{\oplus}S_3N_3O_4^{\ominus}$[7] and $(S_3N_2^{\oplus})_2(S_3N_3O_4^{\ominus})_2$[6].

1,2,4,6-Tetraphenylphosphininium Tetrachloroaluminate, the First Phosphininium Salt Analogous to the Pyridinium Salts**

By *Trupti N. Dave, Hans Kaletsch,* and *Karl Dimroth**

Dedicated to Professor Kurt Issleib on the occasion of his 65th birthday

Whereas pyridine and its derivatives are readily alkylated or protonated to pyridinium salts, all attempts to prepare phosphininium salts from phosphinines in an analogous way have so far failed. Presumably the reason for this is the opposite distribution of electrons in the two ring systems. The electropositive phosphorus atom lowers the nucleophilicity of the phosphinine[1a], and the larger C(ring)–P–C(ring) angle increases the s-character of the lone pair of electrons. Hence, any bonding to an electrophile requires additional energy because of the rehybridization associated with a change in geometry of the ring system[1b]. Phosphininium ions bearing three organic groups on the phosphorus have been postulated as intermediates in some reactions of phosphinines[2], but no salt of such a cation has thus far been obtained. All the previously reported salts containing phosphorus cations of coordination 3 have at least one substituent bearing a lone pair of electrons, e.g. a dialkylamino-[3] or a pentamethyl-2,4-cyclopentadienyl group[4]. In both these cases it is assumed that the n-electrons of the neighboring atom or the

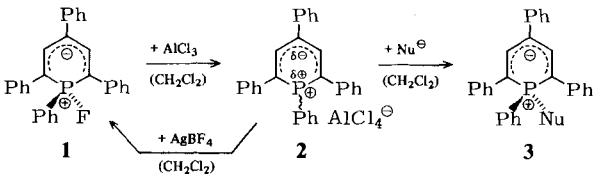
[**] This work was supported by the Fonds der Chemischen Industrie. *T.N.D.* thanks the DAAD for a Fellowship grant. Phosphininium is the newly recommended name for phosphorin (*Pure and Appl. Chem. 55* (1983) 409).

π-electrons, as in the case of the cyclopentadienyl moiety, contribute to stabilization of the cation by satisfying the electron deficit on the phosphorus.

Herein, we describe the first synthesis of a stable, crystalline phosphininium salt with three carbon residues bonded to the phosphorus, namely the 1,2,4,6-tetraphenylphosphininium tetrachloroaluminate **2**. As starting material we used 1-fluoro-1,2,4,6-tetraphenyl-λ^5-phosphinine **1**. **2** was obtained on treatment of **1** (m.p. 155–156 °C, 51% yield, prepared by reaction of 2,4,6-triphenylphosphinine with phenyldiazonium tetrafluoroborate, in analogy to the procedure described in ref. [5]) with 1.5 mol of freshly sublimed aluminum chloride per mol **1** in dichloromethane at −78 °C under argon. The yellow crystals of **2** precipitated on stirring and slowly heating the solution to room temperature. According to elemental analysis the crystals contain 0.5 mol CH_2Cl_2.



In the ^{31}P-NMR spectrum the $^1J_{PF}$ coupling of **1** (1116 Hz) disappears completely during the reaction. The ^{31}P resonance at $\delta = 27$ in the ^{1}H-decoupled spectrum of **1** is transformed into a sharp signal at $\delta = 103$. In the case of **2** the NMR signals of the ring protons (**1**: $\delta = 7.9$, 2H, dd, $^4J_{HF} = 6$ Hz, $^3J_{HP} = 38$ Hz) lie at $\delta = 8.28$ (2H, d, $^3J_{HP} = 33.9$ Hz). A ^{13}C-NMR low-temperature spectrum of **2** could not be recorded because of the poor solubility and high sensitivity of **2**; however, the $AlCl_4^⊖$ formed by halogen exchange was easily recognizable by its intense ^{27}Al-NMR signal at $\delta = 103$[6]. As expected the MS/FD spectrum did not contain a peak at $m/z = 401$ for the non-volatile cation **2**. Peaks were observed, however, for the radical cation of 2,4,6-triphenylphosphinine ($m/z = 324$ (48%)) and the radical cations of the OH- and the Cl-addition products ($m/z = 418$ (42%) and 436 (100%), respectively), which are formed during the recording of the spectrum.

2 reacts immediately and quantitatively with nucleophiles such as methanol, ethanol, phenyllithium or chloride ions to give the known λ^5-phosphinine derivatives **3** (Nu = OMe, OEt, Ph[7], Cl), of which the latter loses chlorobenzene (detected gas-chromatographically) with formation of 2,4,6-triphenylphosphinine on gently warming. With water, **2** forms 1-hydroxy-1,2,4,6-tetraphenylphosphinine, which rearranges via a known route into 1-oxo-1,2,4,6-tetraphenyl-1,2-dihydrophosphinine. Addition of $AgBF_4$ to **2** in CH_2Cl_2 gives **1** in quantitative yield. This confirms the strong electrophilicity of the phosphorus in **2**, which must be far greater than that of the boron in BF_3 (see also [5]).

1-Chloro-1,2,4,6-tetraphenyl-λ^5-phosphinine (**1**, Cl instead of F) is unstable. Reaction of 1,1-dichloro-2,4,6-triphenylphosphinine with aluminum chloride or antimony pentachloride in dichloromethane leads to formation of sparingly soluble 1-chloro-2,4,6-triphenylphosphininium salts of type **2** (^{31}P-NMR: $\delta = +96.9$ and $+96.2$, respectively) which, however, could not be isolated completely pure.

The formula of **2**, which would indicate very little, if any, flow of electrons from the 6π-system of the five C-atoms to the $P^⊕$-center, is consistent with its unusual electrophilicity, even towards $BF_4^⊖$. Conclusive statements about the ground state, however, cannot be made until a complete evaluation of the X-ray structure analysis of **2**[8] and measurement of ^{13}C-NMR spectra of similar phosphininium salts have been carried out.

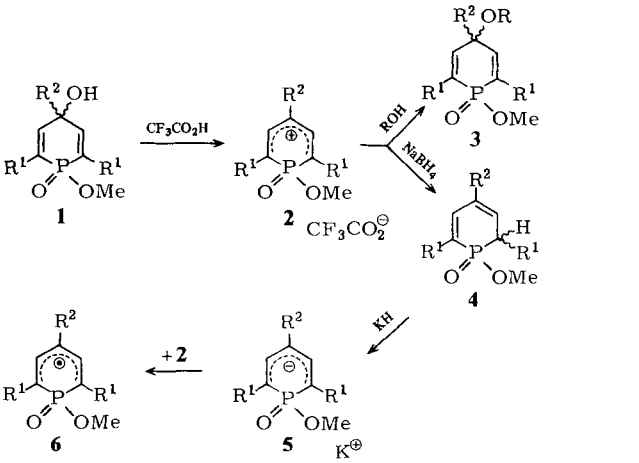
Delocalized Carbocations, Carbanions and Radicals of 2,4,6-Substituted 1-Methoxy-1-oxo-λ^5-phosphinines**

By *Karl Dimroth**, *Hans Kaletsch*, and *Trupti N. Dave*

Triphenylphosphonium salts, phosphonates and phosphinates, as well as well as phosphane oxides with an α-CH group are readily deprotonated to stable carbanions. Their reactions with various types of electrophiles are among the most important ones in preparative organic chemistry[1]. According to *Creary* et al.[2], phosphonates which contain a mesyloxy group on a secondary or tertiary α-C atom react with nucleophiles. In such reactions, destabilized carbocations[3] must be assumed as intermediates.

Some years ago we obtained the salt **2a**, containing a deep-blue, stable, delocalized carbocation, on reaction of



a, $R^1 = R^2 = Ph$; **b**, $R^1 = R^2 = C_6H_4OMe(4)$
c, $R^1 = Ph$, $R^2 = C_6H_4OMe(4)$; **d**, $R^1 = tBu$, $R^2 = C_6H_4OMe(4)$

[**] This work was supported by the Fonds der Chemischen Industrie.

both the pure *E*- as well as the pure *Z*-isomer of the cyclic phosphinate **1a** with trifluoroacetate acid[4]. **2a** adds nucleophiles such as water, methanol or ethanol at C-4 to give the *E/Z*-mixture **3a** (R = H, Me, Et); hydride ions add at C-2 to give the *E/Z*-mixture **4a**.

The 5π delocalization, competing for the destabilization by the phosphinic acid group, accounts for the stability of the carbocation of **2**. The species **2b** is known[4a,b]. Recent, independent experiments[2,3] encouraged us to prepare the salts **2c** and **2d** (containing deep-blue and deep-red cations, respectively[6]) from **1c** and **1d** by reaction with trifluoroacetic acid or aluminum chloride in dichloromethane. **2c** and **2d** likewise add nucleophiles such as water, methanol or ethanol to give the *E/Z* mixture of **3c** and **3d**, respectively (R = H, Me, Et); hydride ions add to C-2 to give **4c** and **4d**, respectively. **4c** and **4d** react with potassium hydride in tetrahydrofuran (THF) to give the salts **5c** and **5d** containing stable delocalized anions. A mixture of equimolar amounts of **2c** and **2d** in dichloromethane and of **5c** and **5d**, respectively, in THF at room temperature, leads to formation of the radicals **6c** and **6d**, respectively, which are stable for days in the absence of air; their phosphorus coupling constants $a_p = 2.3$ mT compare very well with those of the well known radicals **6a** ($a_p = 2.31$ mT), and **6**, $R^1 = t\text{Bu}$, $R^2 = C_6H_3(t\text{Bu})_2(3,5)$ ($a_p = 2.35$ mT)[7]. Table 1 contains the relevant ^{1}H-, ^{13}C- and ^{31}P-NMR data of

Table 1. Most important NMR data of **1c**, **d**, **2c**, **d**, and **5c**, **d**. *J* in Hz. Standard: ^{1}H-NMR (TMS); ^{13}C-NMR (TMS); ^{31}P{^{1}H}-NMR: 85% H_3PO_4 ext.

the most important compounds described here; in the case of **2c**, however, the assignment of the ^{13}C-NMR signals is not absolutely certain because of the many phenyl C-atoms. The salt **2c** is very easily accessible, if 1,1-dimethoxy-4-(4-methoxyphenyl)-2,6-diphenyl-λ^5-phosphinine[5] is first converted with $SOCl_2$ or PCl_5 in dichloromethane into the *E/Z*-4-chloroderivative **3c** (Cl instead of OR) and then allowed to react with aluminum chloride.

Total Synthesis of Hexaacetylcelenamide A**

By *Ulrich Schmidt** and *Jochen Wild*

Three types of cyclic peptide alkaloids containing 12-, 13-, and 14-membered ring systems have so far been isolated from plants[1]. Their occurrence is strictly confined to the Rhamnaceae and Sterculiaceae. The isolation of closely related linear compounds from pacific sponges—i.e. a completely different type of biological substrate—by *Andersen* et al.[2] was therefore very surprising. These linear peptide alkaloids—e.g., celenamide A **1a**, which were all isolated as peracetyl derivatives—formally derive from the peptide alkaloid derivatives, e.g. interregin **2**, by ring-opening with β-elimination (dotted arrow in **1**) and transformation into the *trans-N*-styrylamide. As extension to the total synthesis of 13- and 15-membered cyclic peptide alkaloids[3,4] and of dihydro derivatives of the 14-membered cyclic peptide alkaloids[5] we now describe the first total synthesis of a linear peptide alkaloid, the hexaacetylcelenamide A **1b**. Key reactions in the total synthesis are two condensation reactions with phosphonoglycine esters **3** and **9**[6] for the synthesis of dehydroamino acids and dehydropeptides.

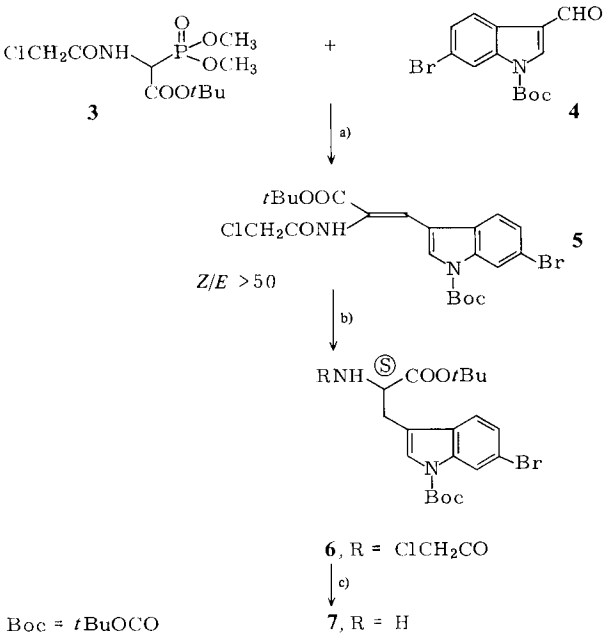
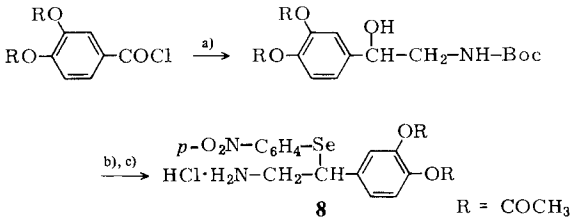
[**] Synthesis of Peptide Alkaloids, Part 10; Amino Acids and Peptides, Part 49. This work was supported by the Fonds der Chemischen Industrie, The Deutsche Forschungsgemeinschaft, and BASF AG. We thank Prof. Dr. *G. Jung* for determining the conformation of the leucine in the hydrolyzate and Prof. Dr. *J. Andersen* for supplying us with the original NMR and IR spectra of hexaacetylcelenamide A.—Part 9: [4]; Part 48: U. Schmidt, A. Lieberknecht, H. Griesser, H. Bökens, *Liebigs Ann. Chem.*, in press.

Like clionamide, which was likewise isolated from *Cliona celata*[7], celenamide also contains 6-bromotryptophan—apparently a characteristic amino acid for marine animals. In our synthesis of clionamide[8] we constructed this amino acid from 6-bromoindole and the oxime of ethyl bromopyruvate[9] and separated the *S*-compound from the racemate by cleavage with acylase. More convenient for this synthesis is the condensation of **3**[6] with **4**[10] to give the dehydroamino acid derivative **5**, whose enantioselective homogeneous hydrogenation with Monsanto catalyst[11] leads with high enantioselectivity (*ee* > 98%) to

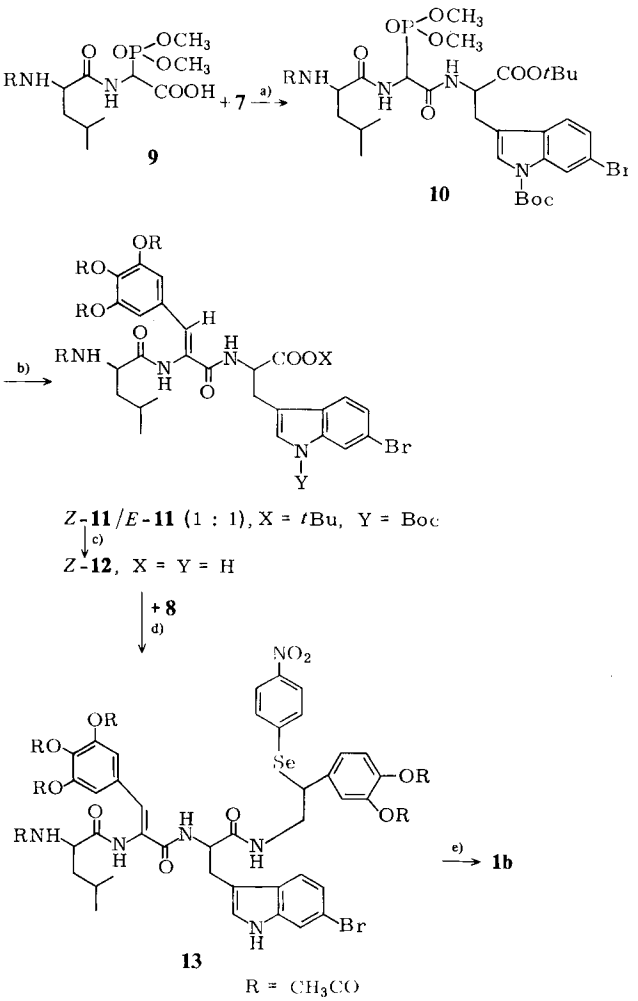


Scheme 1. Enantioselective synthesis of the (*S*)-6-bromotryptophan derivative **7**. a) KO*t*Bu/CH_2Cl_2/ −30°C. b) Monsanto catalyst ([Rh(1,5-cod)(*R,R*-dipamp)]$^{\oplus}BF_4^{\ominus}$)/H_2, EtOH (40°C, 18 h) (cod = 1,5-cyclooctadiene, dipamp = *P,P'*-ethylenebis[*o*-methoxyphenyl(phenyl)phosphane]. Enantiomeric excess: 98% *S*, determined by chromatography on a HPLC column with chiral stationary phase (BAKERBOND) (eluent mixture: 2-propanol/hexane 1 : 19) and the racemate as reference compound. c) *N*-piperidinethiocarbamide, EtOH (80°C).

the (*S*)-*N*-chloroacetyl-6-bromotryptophan **6**. The chloroacetyl group was cleaved with *N*-piperidinethiocarbamide[12] to give **7** (Scheme 1); **7** was then coupled with the (*S*)-leucyl derivative **9**[6] to give the phosphono-tripeptide **10**, which condensed directly with triacetoxybenzaldehyde to give the *E/Z* mixture of the two dehydropeptides *E*-**11**,*Z*-**11**. These isomers were separated by medium pressure chromatography and further worked up individually[13]. On removing the Boc protecting group, the *tert*-butyl ester was cleaved at the same time; *Z*-**12** was obtained. Amide formation using the selenium reagent **8** (Scheme 2) furnished the educt **13** for the oxidative elimination step to the hexaacetylcelenamide **1b** (Scheme 3). In the cleavage



Scheme 2. Synthesis of the selenium reagent **8**. a) Successive reaction with CH_2N_2; HCl; KI cat. + NaN_3; H_2/Pd + $(Boc)_2O$; $NaCNBH_3$; b) *p*-Nitrophenylselenium cyanide, tributylphosphane; c) HCl/dioxane, resorcin dimethyl ether.



Scheme 3. Total synthesis of hexaacetylcelenamide A **1b**. a) Dicyclohexylcarbodiimide (DCCD)/CH_3CN; b) Lithium diisopropylamide/tetrahydrofuran; 3,4,5-triacetoxybenzaldehyde; medium pressure chromatographic separation of the isomers; c) HCOOH/40°C; d) DCCD, hydroxysuccinimide, NEt_3, acetonitrile; e) $NaIO_4$/dioxane/water.

reaction, only the (*E*)-*N*-styrylamide was formed. The NMR and IR spectra of the synthetic and natural products were identical. The synthesis concomitantly proved the configuration of the double bond in the dehydroamino acid moiety.

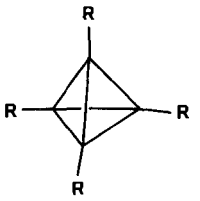
Tetra-*tert*-butyltetrahedrane—Crystal and Molecular Structure**

By *Hermann Irngartinger**, *Annette Goldmann*, *Reiner Jahn*, *Matthias Nixdorf*, *Hans Rodewald*, *Günther Maier*, *Klaus-Dieter Malsch*, and *Rolf Emrich*

So far tetra-*tert*-butyltetrahedrane **1** is the only isolated and unequivocally identified tetrahedrane derivative[1]; however, although its spectroscopic properties have been intensively investigated[2,9], an X-ray structure analysis, which we report here, was missing. At room temperature under various conditions, **1** crystallizes only in a trigonal-rhombohedral modification[3], which affords insufficient reflections in the high-angle region as a result of disorder. Despite measurements between -160 °C and room temperature, no real improvements could be achieved. At -60 °C however a hexagonal modification[3] with a higher order could be grown.



1, R = *t*Bu
2, R = Me
3, R = H

In the hexagonal modification the tetrahedrane molecules **1** lie on a crystallographic mirror plane (Fig. 1); however the atomic coordinates exhibit only slight deviations from the highest possible molecular T_d symmetry. All the groups have a staggered conformation (Fig. 1). Nevertheless, force field[4a,c] and MNDO calculations[4b] indicate that the isolated molecule should deviate from this symmetry. Accordingly, because of mutual repulsion, all the *tert*-butyl groups should be twisted by 10.5—14°[4] in the same direction out of an arrangement with mirror symmetry, resulting in chiral T symmetry for the isolated molecule. Because of mirror symmetry in the crystal, such an arrangement is not possible in space group $P6_3/m$[3]. Nevertheless a disordered, chiral conformation can be derived from the magnitude and direction of the thermal vibration parameters of the atoms of **1**.

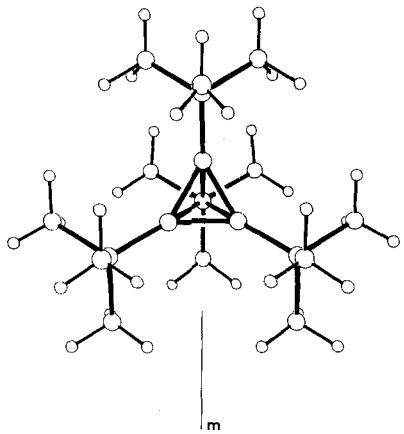


Fig. 1. Projection of the structure of **1** onto a tetrahedral plane (with crystallographic mirror plane).

Whereas the vibrations of the atoms of the tetrahedron and of the quaternary C atoms are small and almost isotropic, those of the carbon atoms of the methyl groups are relatively large and very much anisotropic (Fig. 2). Analysis of the vibration parameters using the method of rigid body motion[5] affords intramolecular torsional vibrations (9—15°) for individual *tert*-butyl groups around the C—C bonds linking these groups to the tetrahedron. Vibration parameters of this type can be produced by real torsional vibrations in a molecule of T or T_d symmetry or be caused by torsional disorder of the *tert*-butyl groups with the same occupancy at both terminal points of the vibrational amplitudes. In this way, two enantiomeric molecules of chiral T symmetry can be disordered at both sides of the mirror plane (enantiomeric disorder). The values measured for the central region of the tetrahedron are only slightly influenced by these effects.

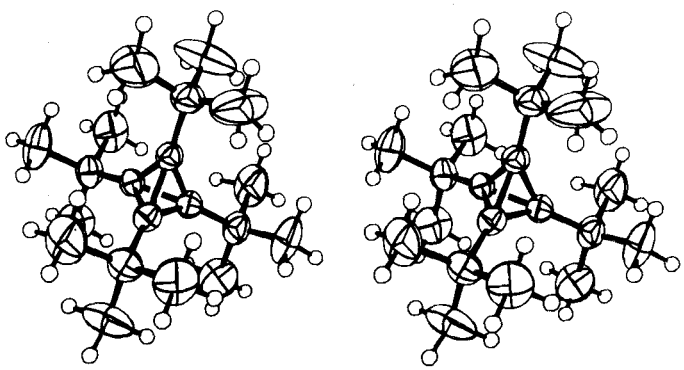

Fig. 2. Stereoscopic view of **1** with the ellipsoids of thermal vibration for the C-atoms (50% probability).

Compared with normal C—C single bonds (1.54 Å), the C_R—C_R bond lengths in the tetrahedron (average value 1.485 Å, Fig. 3) are relatively short due to the considerable steric strain in this system and the bending of these bonds. The tetrahedrane system cannot be regarded as a bicyclo[1.1.0]butane with a zero bridge in the 2,4-positions, since a shorter bond length would be expected with an interplanar angle of 70.5° between the three-membered

rings[6]. Semiempirical calculations gave larger, and ab initio methods (for the unsubstituted tetrahedrane **3**) smaller values for the C_R-C_R bond (Table 1). Compared with $C(sp^3)-C(sp^3)$ single bonds (1.54 Å), the C_R-C_Q bonds (1.490, corrected[7] 1.502 Å) are short, but they have the

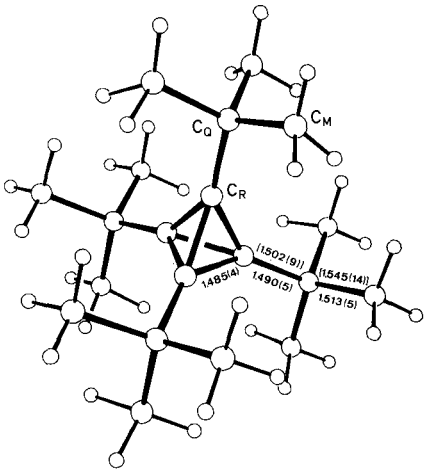

Fig. 3. Structures of **1** with averaged bond lengths [Å] (in round brackets: values of scatter; in square brackets: corrected values [7]). Individual values [Å] (in round brackets: standard deviations; in square brackets: corrected values [7]); C_R-C_R: 1.487(5), 1.487(3), 1.480(3), 1.487(5); C_R-C_Q: 1.503(4) [1.512], 1.480(7) [1.499], 1.486(4) [1.495]; C_Q-C_M: 1.477(5) [1.531]—1.539(4) [1.561]. The C–C–C bond angles at the tetrahedron are consistent with the 60.0° and 144.7° angles of a regular tetrahedron, as is the interplanar angle of 70.5° between the planes of the three-membered rings.

same order of magnitude as the $C(sp)-C(sp^3)$ single bonds in *tert*-butylacetylene (1.498 Å from electron diffraction measurements[8]). According to ^{13}C-NMR measurements, the orbitals of the tetrahedrane atoms in these bonds are, in fact, sp-hybridized[9]. Because of torsional vibration or disorder the C_Q-C_M bonds (average length 1.513 Å) appear shortened; however after correction for thermal motion the value of 1.545 Å[7] is within the normal order of magnitude.

Cations of Boron with Coordination Number Three: 1,3,2,4-Diazadiboretidinium Salts

By *Heinrich Nöth** and *Siegfried Weber*

The readily accessible *tert*-butylimino-(2,2,6,6-tetramethylpiperidino)borane **1** is haloborated by boron halides; for example BBr_3 yields the four-membered heterocycle **2**[1]. Addition of dibromo(methyl)borane to **1** leads, via methyloboration[2], to the heterocycle **3**, whose structure can be unequivocally derived from the NMR data. In contrast, **1** undergoes a phenyloboration with dichloro(phenyl)borane to give **4** and a chloroboration to afford **5**. We have not yet succeeded in separating these isomers.

Unexpectedly, addition of bromodimethylborane to **1** affords a 1:1 adduct, whose ^{11}B-NMR spectrum exhibits only one signal at $\delta=48.9$; furthermore, only one ^{1}H- and ^{13}C-NMR signal is observed for the B-methyl and the methyl groups on the piperidine ring. These data indicate a higher symmetry for the adduct than, e.g., in **2**. A considerable electrical conductivity in CH_2Cl_2 solution and the

[*] Prof. Dr. H. Nöth, Dr. S. Weber

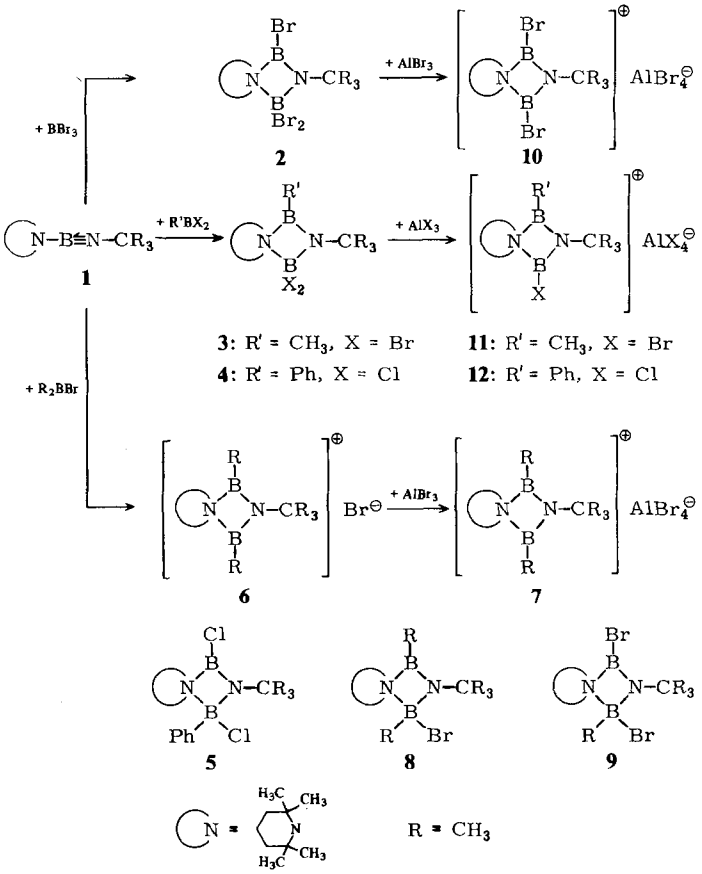
spectroscopic data suggest the spirocyclic 1,3,2,4-diazadiboretidinium bromide **6**. This assignment is corroborated by the addition of $AlBr_3$: The ^1H-, ^{13}C-, and ^{11}B-NMR parameters of **6** hardly change, since the Lewis acid $AlBr_3$ only converts the bromide **6** into the tetrabromoaluminate **7**.



These results indicate that the expected adduct **8** is unstable because of the insufficient acidity of the CH_3BN_2 moiety, and at the same time explains the fact that **1** undergoes methyl- and not bromoboration with CH_3BBr_2[2]: The product of bromoboration, **9**, is formed first, and then rapidly rearranges to the more stable **3** via bromide migration.

The high mobility of the halides in **2**, **3**, **4**, and **5** at the tetracoordinated boron atom is also underlined by the fact that aluminum halides abstract a halide ion from the heterocycles, forming the tetrahalogenoaluminates **10**, **11**, and **12**; as expected, the isomeric mixture **4**, **5** leads to the same cation. Characteristic data are shown in Table 1.

The novel cations **6**, **7**, **10**, **11**, and **12**, in which boron has the coordination number 3, contain a diborylamine structural element ($>B-\ddot{N}-B<$); this is isoelectronic with allyl cations, and we regard this as the reason for their high tendency of formation.

Tetralithiomethane**

By *Adalbert Maercker** and *Manfred Theis*

Tetralithiomethane **5** was first described by *Lagow* et al.[1] who were able to generate it in a maximum yield of 40.5% (detected as CD_4 in addition to other deuterated products) by reaction of tetrachloromethane and lithium vapor. The major side product in this reaction is lithium carbide in addition to traces of perlithioethene and perlithioethane. An increase of the reaction temperature from 750 to 800 °C reduces the yield of CLi_4 to 14% in favor of perlithioethene.

Lagow et al.[2] have also investigated the pyrolysis behavior of tetralithiomethane, reporting that the compound is thermolabile referred to decomposition into lithium carbide via perlithioethene and perlithiopropyne.

By analogy to previously published procedures for the synthesis of polylithiated hydrocarbons[3,4] bearing several Li atoms on one C atom ("isocentric"), we have now found two further methods of generating **5**. Reaction of octamethyl methanetetraboronate **1**[5] with mercury(II) acetate affords tetrakis(acetoxymercurio)methane **2**, which in turn can be converted by sodium chloride into tetrakis(chloromercurio)methane **4**[6,7]. If instead of mercury(II) acetate, ethylmercury acetate is employed, tetrakis(ethylmercurio)methane **3** is obtained, an approach based on the synthesis of the corresponding methyl compound developed by *Breitinger* and *Kress*[9].

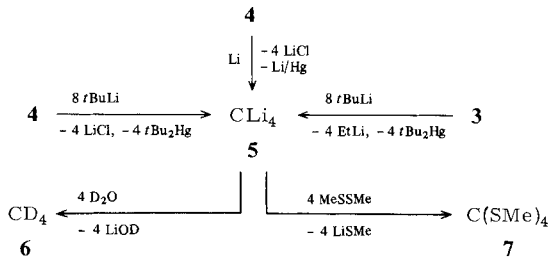
[**] Polylithiumorganic Compounds. Part 3. This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. *D. Breitinger* and Prof. Dr. *P. v. R. Schleyer*, Erlangen, for discussions.—Part 2: [4].

Reaction of **4** with lithium dust in diethyl ether using the method described in [3] leads within 3 h to a black suspension, which, following standard and inverse deuteriolysis, affords comparatively little tetradeuteriomethane in addition to predominantly tetradeuterioethene and hexadeuterioethane[10]. Interestingly, this product distribution is qualitatively in accord with that described by *Lagow* et al.[1], and is attributable to dimerization of radical intermediates.

Because of the atypical reaction behavior of isocentric polylithiated hydrocarbons with anion trapping reagents, derivatization with chlorotrimethylsilane/tetrahydrofuran leads to a large number of substances, among which tetrakis(trimethylsilyl)methane is present only in $<5\%$.

Much better results are obtained if excess *tert*-butyllithium is used for the transmetalation of **4** as previously described for analogous compounds[3,4]. In this case, the transmetalation mechanism changes from radical to ionic and, hence, no coupling products arise. In cyclopentane, an amalgam-free, insoluble product, which still contains lithium chloride, is formed; after the product had been filtered and freed from adherent di-*tert*-butylmercury it was deuteriolyzed for the qualitative determination of **5**. Apart from traces of dideuterioacetylene, the reaction gases contained only tetradeuteriomethane **6**, which, however, could not be separated by gas chromatography from the argon used as inert gas atmosphere. Here, again, silylation proceeded unsatisfactorily.



Use of **3** instead of **4** as substrate and of at least stoichiometric amounts of *tert*-butyllithium in cyclopentane yields, after stirring for one day at room temperature, a deep red-brown *solution*, whose deuteriolysis furnishes **6** and traces of dideuterioacetylene as derivatives; these arise directly or indirectly from CLi_4 **5**. Additionally, as a major product the reaction gas contains CH_3CH_2D (from EtLi) and, occasionally, $(CH_3)_3CD$ (from excess *t*BuLi). In contrast, silylation again proceeds unsatisfactorily.

The particular demands of polylithioalkanes on a derivatization reagent are apparently met by dimethyl disulfide. Hence, the dark colored solutions can be quasi-titrated with dimethyl disulfide in hexane at $-50\,^{\circ}C$. Work-up afforded quantitative crude yields of tetrakis(methylthio)methane **7** (m.p. = 36—40 °C), which after two recrystallizations from ethanol melted at 64 °C (m.p. = 65 °C[11]). Under these conditions **3** and **4** do not react with dimethyl disulfide; in contrast, *tert*-butyllithium reacts more rapidly with dimethyl disulfide than with **3** or **4**.

^{13}C- and ^{6}Li-NMR spectroscopic studies of solutions of ^{6}Li-labeled **5** in [D_{12}]cyclohexane did not provide reliable results, because of accompanying substances (EtLi, tBu_2Hg, *t*BuLi), the low concentration of CLi_4, and the expected low sensitivity of this carbon atom (high multiplicity, absence of NOE). A qualitatively very good product **5**—a deep red-brown, extremely pyrophoric *solid*—is obtained if the solvent and readily volatile and sublimable accompanying products are removed[12]. The original solution presumably contained a complex of CLi_4 **5** and di-*tert*-butylmercury, particularly since the solutions are highly light-sensitive (more sensitive than tBu_2Hg) and the fact that **5** no longer dissolves in hexane after removal of tBu_2Hg.

[11] H. Böhme, G. Ahrens, *Liebigs Ann. Chem. 1982*, 1022.
[12] *Procedure:* Thoroughly dry **3** (0.93 g, 1 mmol) is added portionwise to 10 mmol of a 0.25 M solution of *tert*-butyllithium under argon, a large batch of which was prepared previously from di-*tert*-butylmercury and lithium (molar ratio 1:10) in cyclohexane, and the mixture stirred for 24 h at room temperature in the dark. The deep red-brown solution is transferred to a sublimation apparatus with argon inlet and frozen using liquid nitrogen. Subsequently the apparatus is evacuated to 10^{-3} torr, the external cooling source removed, and the distilled solvent collected in a cold trap. After removal of all the solvent from the mixture, the solid residue is heated in the dark to 100 °C, whereupon the side products di-*tert*-butylmercury and ethyllithium as well as excess *tert*-butyllithium sublime out at 10^{-3} torr. A deep red-brown, extremely pyrophoric residue of CLi_4 **5** remains. For derivatization, this product is suspended in 5 mL hexane and treated with a solution of dimethyl disulfide (0.5 g, 5.32 mmol) in 5 mL hexane at $-30\,^{\circ}C$ with stirring. The mixture is allowed to warm to room temperature, the lithium thiomethanolate is filtered off, and the filtrate concentrated to dryness using a water pump. 0.16 g (80%) **7** is obtained (m.p. = 50—54 °C), which after two recrystallizations from ethanol melts at 63—64 °C (m.p. = 65 °C [11]).

Biosynthesis of Moniliformin, A Fungal Toxin with Cyclobutanedione Structure**

By *Burchard Franck** and *Gerhard Breipohl*

The mycotoxin moniliformin **1**[1] is formed in high concentrations[2] by the maize fungi *Fusarium moniliforme* and *Gibberella fujikuroi*. Because of its intense toxicity[3], high acidity ($pK_a = 0.88$[4]), and structural relationship with squaric acid **2**, compound **1** is particularly important. We now report on incorporation experiments which throw light on the biogenesis of **1**.

We considered three hypotheses for the biosynthesis of **1**: 1) cyclization and further conversion of erythrose **5**; 2) condensation of two acetate moieties via malonyl coen-

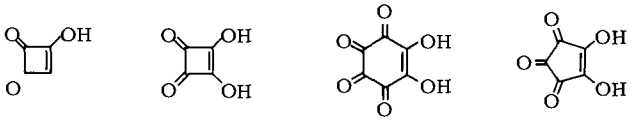
[**] Biologically Active Substances from Fungi, Part 34. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen as well as by the Fonds der Chemischen Industrie.—Part 33: B. Franck, *Angew. Chem. 96* (1984) 462; *Angew. Chem. Int. Ed. Engl. 23* (1984) 493. Part 32: B. Franck, A. Stange, *Liebigs Ann. Chem. 1981*, 2106.

zyme A **8** to afford 1,3-cyclobutanedione **9**, followed by oxidation to the tautomeric derivatives **10a**—**10c**, and dehydration; 3) biosynthesis from inositol **7** via rhodizonic acid **3** and croconic acid **4**[5,6].

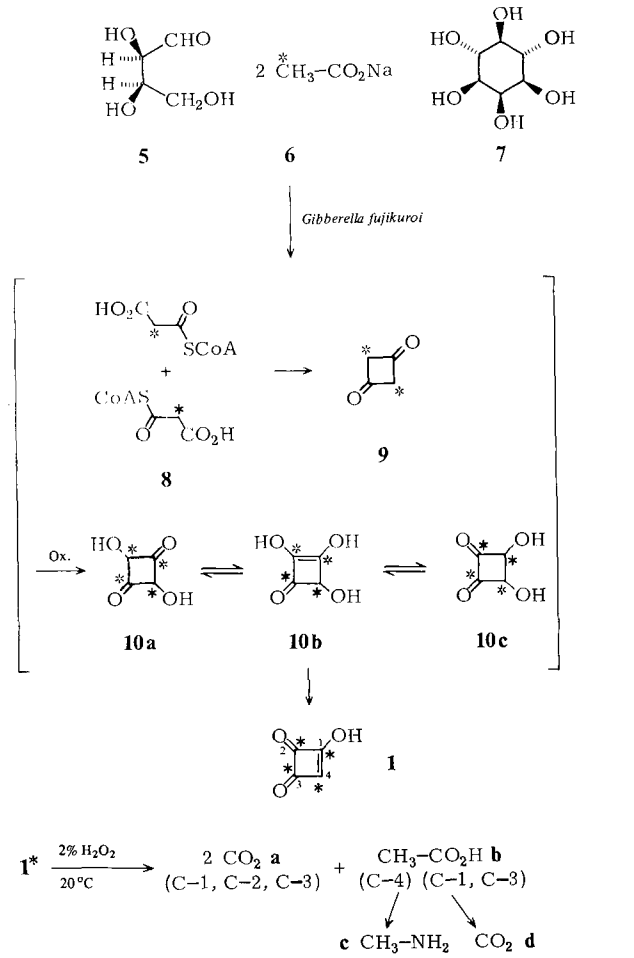


1 **2** **3** **4**

To test these hypotheses, we applied [1-^{14}C]erythrose **5**, [2-^{14}C]acetate **6**, and [U-^{14}C]inositol **7**, respectively, to four cultures of *G. fujikuroi* (ATCC 12763) growing on a maize solid nutrient medium (50 g maize, 70 mL water). After 7—14 d the fungal mycelia were freeze-dried and extracted with MeOH. **1** was separated off on an anion exchanger (Dowex AG 1 X2) and recrystallized from methanol to constant radioactivity as the sodium salt dihydrate.

Table 1. Incorporation studies on the biosynthesis of monoliformin **1**.

Precursor	Spec. radioact. [mCi/mmol]	Isolated **1*** Amount [mg]	Spec. ratioact. [nCi/mmol]	Spec. incorp. rate [%]
[1-^{14}C]Erythrose **5**	0.667	18.5	263	0.039
[2-^{14}C]Acetate **6**	0.146	145	514	0.180
[U-^{14}C]Inositol **7**	278	75.2	8.36	4.5×10^{-6}



5 **6** **7** **8** **9**

Scheme 1. Precursors, biosynthesis and degradation of moniliformin **1**.

According to the results in Table 1, compounds **5** and **7** can be ruled out as biosynthetic precursors of **1**. Similarly, [U-^{14}C]glucose, [U-^{14}C]erythritol, [U-^{14}C]asparagine, [U-^{14}C]pyruvate, [U-^{14}C]shikimic acid, [β-^{14}C]cinnamic acid, [U-^{14}C]phenylalanine, and [methyl-^{14}C]methionine exhibited no significant incorporation. In contrast, [2-^{14}C]acetate **6**, although it is involved in numerous metabolic pathways, exhibits a specific incorporation rate of 0.18% and is, hence, a precursor of **1**. Of the large group of natural products formed by cyclization of polyketides, **1** is therefore the first example derived from a diketide $[CH_3\text{-}CO\text{-}CH_2\text{-}]_nCO_2H$, n = 1].

To gain some insight into the *course of the biosynthesis*, we studied the isotopic distribution in moniliformin **1*** obtained using **6** as precursor (Scheme 1). H_2O_2-Oxidation of moniliformin **1*** diluted with inactive **1** to 130000 dpm/mmol[7] afforded, apart from CO_2 **a** from C-1, C-2, and C-3, radiolabeled acetic acid **b**. In **b** the radioactivity of the methyl group originates from C-4 and that of the carboxy groups in equal parts from C-1 and C-3 of **1***. The distribution of radioactivity (Table 2) in these degradation products as well as that in the products CO_2 **d** and methylamine **c** obtained by chemical degradation of the acetic acid **b** corresponds to a moniliformin in which the radioactivity is distributed over all C atoms and not only over C-2 and C-4. This result is consistent with an equilibrating intermediate **10a**—**10c** having four oxygen substituents.

Table 2. Distribution of radioactivity in the degradation products of moniliformin **1*** from the biosynthetic experiments (cf. Scheme 1).

Product	Spec. Radioact. (dpm/mmol)	Radioactive C atoms Found[a]	calc. for 	calc. for
1*	130000	2	2	2
CO_2 **a**	39000	0.61	0.5	0.5
Acetic acid **b**	66000	1.02	1.0	1.0
Methylamine **c**	32000	0.49	0.5	1.0
CO_2 **d**	32600	0.50	0.5	0

[a] For determination of the number of radioactive C atoms *found* in **1***, the specific radioactivities of the degradation products were divided by those of **1*** and multiplied by 2.

Because of the uniform distribution of radioactivity in the moniliformin **1*** obtained using [2-^{14}C]acetate nutrient, it could be argued that the acetate moieties are not incorporated directly, but rather via an indirect route. In this case the specific incorporation rate would, however, be considerably less than the value found (0.18%). We have observed a similar equipartition of the radioactivity in a total synthesis of **1*** from [1-^{14}C]acetate modelled on the biosynthesis.

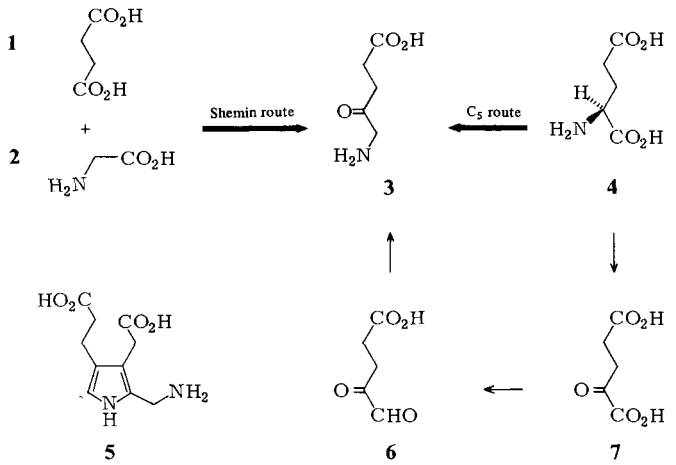
Heme Biosynthesis from L-Glutamic Acid**

By *Burchard Franck*, Manfred Bruse,* and *Jürgen Dahmer*

Textbooks of chemistry and biochemistry state that the red blood pigment heme **8** is synthesized in higher organisms from succinic acid **1** and glycine **2**. The two last-mentioned compounds initially react to form 5-aminolevulinic acid **3**, two molecules of which condense to afford the heme building block porphobilinogen **5**[1]. In contrast to this *Shemin route*[2], the large amounts of 5-aminolevulinic acid **3** required in plants for the biosynthesis of chlorophylls are principally formed via a C_5 *route* from L-glutamic acid **4**[3] via 2-oxoglutaric acid **7** and 4,5-dioxovaleric acid **6**. We now report on incorporation experiments which indicate that the C_5 route is also involved to a considerable extent in animal organisms.



For the purpose of this study, we employed the enzyme system obtained from duck blood[4] (which was also used to prove the Shemin route of heme biosynthesis). Three important requirements had to be met:

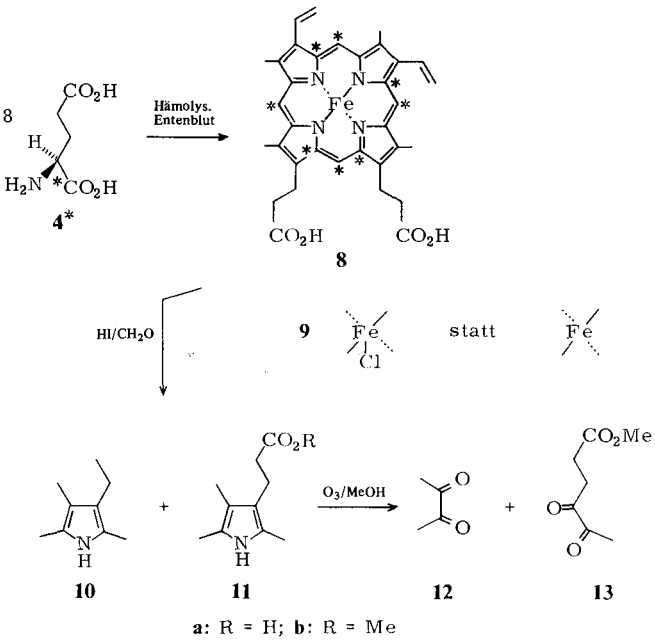
1) *Reproducibility:* The incorporation experiments with hemolyzed duck blood[4] were repeated several times over three years, systematically varying the season the blood was taken, the concentration, and the incubation time.

2) *Exclusion of the possibility that incorporation of 4 is not feigned by its degradation to 1:* Use of [1-^{14}C]-L-glutamic acid **4***, whose labeling would be eliminated upon decarboxylation to **1**.

3) *Proof that 4 is incorporated directly:* Determination of the labeled positions in the product of the biosynthetic heme **8** by chemical degradation.

Table 1. Comparison of the results of incorporation studies on the biosynthesis of the red blood pigment heme **8**.

Precursor	Precursor Amount [μmol]	Precursor Total radioact. [μCi]	Isolated hemin **9** Total radioact. [nCi]	Isolated hemin **9** Absolute incorp. rate [5] [% × 10^3]
[2-^{14}C]glycine **2**	0.96	50	14.7	29.5
[1,4-$^{14}C_2$]succinic acid **1**	0.86	100	8.04	8.04
[1-^{14}C]L-glutamic acid **4***	1.01	50	3.74	7.49



75 mL Hemolyzed duck blood[4] was incubated for 24 h with 1 μmol of each of the radioactive precursors; the hemin **9** isolated was purified by recrystallization to constant radioactivity. Table 1 summarizes the data obtained from the various mixtures. The absolute incorporation rates proved to be independent of further increase in incubation time.

The value of the absolute incorporation rate for [2-^{14}C]-glycine **2** provides a measure for the biosynthesis of 5-aminolevulinic acid **3** by the Shemin route. The incorporation rate of [1-^{14}C]L-glutamic acid **4*** indicates that the C_5 route is involved to 25.4%. Relative to the incorporation of [1,4-$^{14}C_2$]succinic acid **1** (Shemin route), the extent of glutamic acid incorporation and the C_5 route are even larger.

Upon *direct* incorporation of **4***, its radioactive C atoms should distributive over the eight C atoms of heme **8** marked with a cross. In order to prove this, the radioactive hemin **9** obtained was degraded in two steps[6]. Cleavage with HI/CH_2O yielded phyllopyrrole **10** and phyllopyrrolecarboxylic acid **11a**; the latter compound was esterified to **11b** with diazomethane. Ozonolysis of **11b** afforded 2,3-butanedione **12** (analyzed as dioxime) and methyl 4,5-dioxohexanoate **13**. The specific radioactivities of the degradation products (Table 2) correspond to the values cal-

[5] The total radioactivity of the isolated, radioactive hemin **9** divided by that of the ^{14}C-labeled precursor × 100. As a consequence of the participation of this precursor in competing metabolic pathways, particularly in protein biosynthesis, its incorporation rates are relatively low, as observed in similar studies [2]; however, in our case they lie > 10 fold above the significance level.

[6] Cf. [4b, c] and literature cited therein. Isolation of **12** and **13** in the molar ratio 1:1 can be ascribed to induction of the 2*H*-pyrrole structure upon electrophilic attack of ozone.

A Novel Double-Stacked Structure in Bis[(oxamide oximato)(oxamide oxime)platinum(II)]-[{tris(tetracyanoquinodimethane)}diide], a Molecular Electron Conductor**

By *Helmut Endres**

"Organic metals" contain stacks of planar radical ions with a fractional average charge per molecule[1]. In some solids containing organic radical cations and simple inorganic counterions, even superconductivity is observed[2]. The radical anion of tetracyanoquinodimethane ["tcnq", 2,2'-(2,5-cyclohexadien-1,4-diylidene)bispropanedinitrile] is a frequently used component of electrically conducting molecular solids[1]. We have already reported on the salt **1**, the first solid consisting of segregated, parallel, regularly stacked planar complex cations and organic radical anions[3]. As is to be expected it is a semiconductor, whereas the analogous Ni-compound is metallic at room temperature and consequently in this case, we assume a fractional average charge per molecule[4].

$[Pt(oaoH)(oaoH_2)]^{\oplus}tcnq^{\ominus}$ **1**
$oaoH_2$ = oxamide oxime, $HON{=}C(NH_2){-}C(NH_2){=}NOH$

$\{[Pt(oaoH)(oaoH_2)]^{\oplus}\}_2(tcnq)_3^{2\ominus}$ **2**

The title compound **2**, which is formed as a byproduct on growing crystals of **1**[5], clearly contains tcnq species with different charges. As in the case of **1**, the growth of the crystals is associated with the shift of the equilibrium in the protolysis

$$[Pt(oaoH_2)_2]^{2\oplus} \rightleftharpoons [Pt(oaoH)(oaoH_2)]^{\oplus} + H^{\oplus}$$

to the right. In addition, $tcnq^{\ominus}$ is partially oxidized to neutral tcnq, some of which crystallizes out, and is partly used in the formation of **2**. The X-ray structure analysis[6] shows the presence of an unusual double-stacked structure (Fig. 1): The crystals contain pure tcnq stacks, whereby it can be

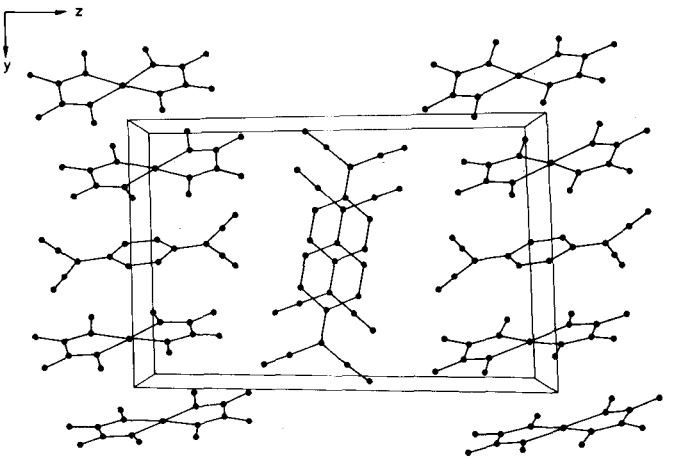

Fig. 1. Projection of the structure of **2** along the $tcnq^{\frac{1}{2}\ominus}$ stack.

estimated from the bond lengths (Fig. 2)[7] that the (crystallographically equivalent) tcnq units of the stack carry an average charge of $-1/2$. Hence, both criteria for metallic behavior—pure stack and fractional charge—are fulfilled. The d.c. conductivity at room temperature is 12 Ω^{-1} cm^{-1}[8]; more detailed investigations of the transport properties are under way. A surprising feature is that the tcnq molecules form a zig-zag arrangement along the stack (Fig. 3), as is typical for the radical cation stacks of some organic superconductors[2b], but is rarely to be found in tcnq salts.

Perpendicular to the tcnq stacks there is a second type of stacking (Fig. 1): mixed stacks of two complex cations and one $tcnq^{\ominus}$ anion with full negative charge. Mixed stacks of this kind occur more frequently than segregated stacks in charge transfer complexes[1], even though the observed sequence (one acceptor after each two donors) is rare. Such stacks do not lead to high electrical conductivity. The title compound **2**, in which pure stacks and mixed stacks are arranged perpendicularly to each other, represents a novel type of structure for molecular electron conductors.

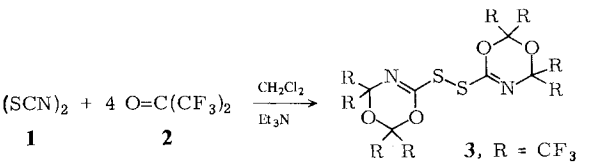
Dithiocyanogen Reaction without Cleavage of the S–S Bond: Cycloaddition with Hexafluoroacetone**

By *Herbert W. Roesky**, *Nayla K. Homsy*, *Mathias Noltemeyer*, and *George M. Sheldrick*

Dedicated to Professor Kurt Issleib on the occasion of his 65th birthday

Dithiocyanogen **1**, first described in 1919 by *Söderbäck*[1], shows the characteristic reactions of a pseudohalogen and serves as a universal reagent for the synthesis of thiocyanates; the reactions proceed with cleavage of the sulfur-sulfur bond. We report here on the cycloaddition of **1** with hexafluoroacetone **2**, which leads to formation of the 4*H*-dioxazine derivative **3** in 82% yield[2].



An X-ray structure analysis of **3** (colorless solid, m.p. 50–51°C) revealed that two 4*H*-dioxazine rings are coupled via a disulfide bridge in such a way that the molecule has an almost twofold symmetry axis perpendicular to the S–S bond (see Fig. 1). The S–S bond length is 202.0(2) pm, the C–S–S–C torsion angle −86.6(2)°.

3 can be cleaved at the S–S bond by chlorine to give the sulfenic acid chloride **4** (45% yield, yellow liquid, b.p. 69°C/64 mbar).

Institut für Anorganische Chemie der Universität
Tammannstrasse 4, D-3400 Göttingen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Hoechst AG.

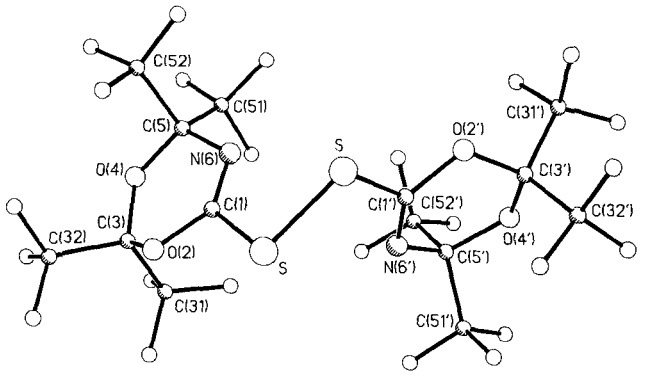

Fig. 1. Structure of **3** in the crystal. Crystal data: space group $P2_1/c$, $a=1290.3(5)$, $b=1362.8(7)$, $c=1416.8(6)$ pm, $\beta=95.76(3)°$, $Z=4$, $R=0.044$ for 2295 independent reflections with $F>4\sigma(F)$; $Mo_{K\alpha}$ radiation, $2\theta_{max}=45°$. The structure was solved by direct methods and anisotropically refined. The assignment of nitrogen and oxygen [O(2)/N(6), O(2')/N(6')] was carried out on the basis of the thermal parameters and bond lengths. Selected bond lengths: C–S 175.9(6), C=N 125.0(6), N–C 142.3(6), C–O 139.7(9), C–C 154.1(7), and C–F 131.7(7) pm. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51 129, the names of the authors, and the journal citation.

Cycloaddition also takes place on reaction of $S(SCN)_2$ $Hg(SCN)_2$, $P(NCS)_3$ or $As(NCS)_3$ with hexafluoroacetone[3]. The novel compounds thus formed are crystalline, some of which could be characterized by X-ray structure analysis[3]. $P(NCS)_3$ and $As(NCS)_3$ probably first isomerize to $P(SCN)_3$ and $As(SCN)_3$ before they form the adducts **5** and **6** with hexafluoroacetone.

BOOK REVIEWS

Organometallic Chemistry of Rhodium and Iridium by *Ronald S. Dickson*, Academic Press, New York 1983. x, 421 pp., bound, $ 85.00.—ISBN 0-12-215480-0.

This book is a volume in the Series "Organometallic Chemistry" edited by *P. M. Maitlis, F. G. A. Stone*, and *R. West*. It contains a comprehensive discussion of the organometallic chemistry of Rhodium and Iridium. The literature has been covered to the end of 1978, while some key references for 1979 and 1980 are also included.

Anyone working in this field will realize the enormous amount of work which has been involved in the writing of this book. It has, however, been a worthwhile task, not only because of the author's thoroughness but also since the organometallic chemistry of rhodium and iridium has been and still is of central importance for a great variety of disciplines and diverse fields, such as organic chemistry and catalysis.

In addition to a short general introduction to the chemistry of rhodium and iridium, the book contains chapters on carbonyl compounds and their substitution products, carbonyl-halide and carbonyl-hydride complexes, complexes involving thiocarbonyl, trifluorphosphane, isonitrile and aryldiazo ligands, organorhodium and organoiridium complexes, complexes formed from alkynes and finally σ-alkyl, σ-aryl and related complexes. There is a reference list containing more than two thousand references, an addendum containing an extensive list of key references, and a subject index.

It is clear that with a book containing so many references the treatment of each subject necessarily has to be superficial. Nevertheless, the literature is so well covered, as I have checked myself for a great number of references, that the book may be used as an excellent reference work to the original literature—and this is of enormous importance particularly when dealing with the chemistry of rhodium and iridium. The book, however, is more than a reference work only, since the author has succeeded well in presenting the material in a logical way useful to the reader who wishes to gain a broad idea of what has been done in the various fields covered. He has also attempted to present, where possible, the bonding theories involved, such as for example the electronic structures of carbonyl cluster complexes. Again such treatments are not discussed in depth, but are sufficient for the interested reader to find his own way in the original literature.

Finally, it should be mentioned that this book presents in a very concise and clear way the vast amount of research that was carried out in the sixties and seventies. Furthermore, I would like to emphasize the fact that I have found very few errors, even in the printing itself; this is undoubt-

edly due to the thorough editing which is characteristic for the books in this series. It is to be hoped that a follow up of this work will appear in the future covering the more recent literature.

Lecture Notes in Chemistry. Vol. 34: Unified Valence Bond Theory of Electronic Structure. Applications. By *N. D. Epiotis*. Springer-Verlag, Berlin 1983. viii, 585 pp., paperback, DM 96.00.

The complete work by *Epiotis* on the theory of chemical reactivity deserves a great deal of respect: it is exemplary, comprehensive, of wide applicability, and eschews traditional viewpoints. The author considers the most widely referred to quantum chemical method, the qualitative one-determinant MO method, as being insufficient and exploits, in a skillful way, the positive features of both fundamental quantum chemical techniques, namely the molecular orbital and the valence bond methods. His procedure permits analysis of a wide spectrum of diverse problems concerning chemical reactivity in the electronic ground state and in the excited state. The theoretical foundation of the Epiotis procedure formed the subject of the 29th volume of the Series. With this procedure, relationships can be brought to light which at first are unexpected or at least not obvious. The scope of application of the theory is very broad. This is reflected in the titles of the chapters; for example: Why do organolithium monomers have strange structures? Conformational isomerism of N_2H_4 and its derivatives. Saga of "hypervalent" molecules. Why benzene prefers to substitute and an olefin likes to add? Frontier configuration and a new classification of annulenes. The qualitative rationalization and prediction of "correlation effects" in "complex" ground state molecules. The author analyses these and numerous other problems in a way which has some formal resemblance to the procedures of *Woodward* and *Hoffmann, Longuet-Higgins,* and *Abrahamson,* but the level of sophistication is higher and it corresponds to the level of configuration interaction. All these features are, no doubt, very attractive.

I am afraid, however, that in spite of all the positive features, attempts to exploit the Epiotis theory can meet with serious difficulties. Namely, I expect that it will not be easy to convince chemists not only to read about the new procedure but also to master it in order to make proper use of it. I am afraid that even for good chemists who are open-minded towards new theories it would be too laborious. Admittedly, chemists have been able to manage even more involved concepts and theories; however, these frequently offer numerical values useful for correlations or even for calculating absolute values of physical characteristics. On the other hand simple, cheap, and efficient tools introduced by *Woodward* and *Hoffmann* and by *Fukui* are also reliable and widely applicable (though not as widely as the present theory). But in spite of the above-mentioned feeling the Epiotis procedure does represent an important contribution: do not hesitate to read it.

SUBJECT INDEX

(R) = Review Article (C) = Short Communication (B) = Book Review

ACEPENTALENE, Novel tricarbonyl(η^4-dihydroacepentalene)iron complexes and tricarbonyl(η^2-dihydroacepentalene)ferrates(—2) (C) 707

Acetylene equivalent, 3-Trimethylsilylacrylic acid as an acetylene equivalent in Diels-Alder reactions; olefins via anodic decarboxylation-desilylation (C) 233

Acetylene-vinylidene rearrangements, A "cluster-centered" acetylene-vinylidene rearrangement (C) 141

Acid esters, Enzymatic syntheses of chiral building blocks from prochiral substrates: enantioselective synthesis of monoalkyl malonates (C) 66
Enzymatic syntheses of chiral building blocks from prochiral *meso*-substrates: preparation of methyl(hydrogen)-1,2-cycloalkanedicarboxylates (C) 67

Acylketenes, Acyl- and thioacylketenes: synthesis of 3-benzoyl-4-phenylthiet-2-one (C) 800
A novel ketoketene—ketoketene rearrangement (C) 802

Addition compounds, Second sphere coordination of cationic rhodium complexes by dibenzo[3*n*]crown-*n* ethers (C) 235

Additions, Chelation or non-chelation control in addition reactions of chiral α- and β-alkoxy carbonyl compounds (R) 556
Transfer of chirality in the addition of chiral α-chloroallylboronate esters to aldehydes (C) 437
Stereochemical evidence supporting the intermediate mechanism of dihalocarbene addition (C) 706

Adducts of the ketene (1*E*,3*Z*)-1,2,3,4,5-pentamethyl-6-oxo-1,3,5-hexatrienyl acetate (C) 442

Alamethicin sequence, Peptide structures of the alamethicin sequence: the *C*-terminal $\alpha/3_{10}$ helical nonapeptide and two pentapeptides with opposite 3_{10} helicity (C) 450

Alkylation, Selective synthesis of carbonyl olefinating or alkylating reagents from $MoCl_5$ and MeLi by changing the solvent or the rate of addition of MeLi (C) 532

Alkylthio radicals, Synthesis and characterization of $[(C_5Me_5)Mn(CO)_2(SR)]$: RS radicals as ligands (C) 975

Alkyltransition-metal complexes, Photochemistry of alkyltransition-metal complexes (R) 766

Alkynes, Elementary steps in catalytic 1-alkyne coupling to substituted cyclooctatetraenes (C) 893

Alkynetungsten complex, Unusual conversion of an alkynetungsten complex into a tungstacyclopropane compound by nitrosyl chloride (C) 809

Allenes, The chemistry of the allenes (B) 461

Allyl acetates, Oxidation with palladium salts: catalytic preparation of allyl acetates from monoolefins using a three-component oxidation system (C) 453

Allyl cations, The cycloaddition of allyl cations to 1,3-dienes: general method for the synthesis of seven-membered carbocycles (R) 1

Allyl group, The allyl group as mildly and selectively removable carboxy-protecting group for the synthesis of labile *O*-glycopeptides (C) 71

N-Allylureas, Highly enantioselective homoaldol additions with chiral *N*-allylureas—application to the synthesis of optically pure γ-lactones (C) 898

Aloc, The allyloxycarbonyl (Aloc) moiety—conversion of an unsuitable into a valuable amino protecting group for peptide synthesis (C) 436

Aluminum alkoxides, Metal-catalyzed carbonylations of benzyl and aryl bromides in the presence of aluminum alkoxides; a straightforward ester synthesis (C) 732

Ambidentate behavior, Ambidentate behavior of mononuclear vinylidenerhodium complexes—novel C—C coupling of a methyl to a vinylidene group (C) 431

Amido bridges, Di-(μ-amido)dirhodium complexes: structure of $[Rh_2(\mu\text{-}(NH)_2\text{-naphth})I_2(CO)_2(PPh_3)_2]$ (C) 913

Amines, *N*,*N*-Bis(trimethylsilyl)aminomethylation of Grignard compounds—a versatile amine synthesis (C) 53
Enantioselective synthesis of β-substituted primary amines; α-alkylation/reductive amination of aldehydes via SAMP-hydrazones (C) 365

Aminocarbaboranes, $C_4B_2H_6$ isomers: destabilization of the *nido*-carbaborane structure by amino substituents and a novel classical isomer (C) 969

Aminoenolates, Easy rotation about the exocyclic carbon-carbon bond in lithium α-aminoenolates: a comparison (C) 797

Aminoglycosidic antibiotics, Total synthesis of a fortimicin aglycone (C) 167

Amino protecting group, The allyloxycarbonyl (Aloc) moiety—conversion of an unsuitable into a valuable amino protecting group for peptide synthesis (C) 436

Aminosilanol, Synthesis of a stable aminosilanol and a lithium aminosilanolate with cubane structure (C) 891

Amino-5-sulfinylfurans, 2-Amino-5-sulfinylfurans from sulfonylacetylenes and ynamines (C) 321

Amorphous materials, Synthesis of new amorphous metallic spin glasses M_2SnTe_4 (M = Cr, Mn, Fe, Co): solvent induced metal-insulator transformations (C) 169

Analytical chemistry, Handbuch der photometrischen Analyse organischer Verbindungen (B) 829

Analytical methods, Cyclic voltammetry—"electrochemical spectroscopy" (R) 831
Gas chromatographic separation of enantiomers on optically active metal-complex-free stationary phases (R) 747

Annulenes, Novel double-layered annulenes—models for the investigation of successive electron transfers (C) 818

Anthracycline, Macrocycles by intramolecular Diels-Alder reaction—regioselective synthesis of anthracycline precursors (C) 74

Antibiotics, Synthesis of the antibiotic LL-Z1220—contribution to an understanding of the 1,4-dioxocine system (C) 966

Antimetabolites, Dextran-linked N^6-(2-isopentenyl)adenosine—a polymer-bound antimetabolite with a predetermined cleavage position (C) 385

Antineoplastic compounds, Ferrocenium salts—the first antineoplastic iron compounds (C) 456

Arene-indium complex, Bis(1,3,5-trimethylbenzene)indium(I) tetrabromoindate(III), the first arene complex of indium (C) 386

Aromaticity, A novel aromatic hydrocarbon with 16π-electron periphery: "cyclic bicalicene" (C) 63
4*H*-1,4-Oxazocine, a planar, diatropic 10π-dihetero[8]annulene? (C) 309
Puckered structures of 1,3-dihydro-1,3-diboretes and bicyclobutane-2,4-dione: nonplanar Hückel 2π-electron aromatic molecules (C) 374
Temperature dependence of the UV spectrum of 1,5-dimethyl-2,6-semibullvalenedicarbonitrile; evidence for an equilibrium with a delocalized, homoaromatic isomer (C) 631

Arsaalkenes, Facile synthesis of heteroalkenes $CF_3E{=}CF_2$ (E = P, As) (C) 710

Arsanediyl (arsinidene) complexes, Arsanediyl (arsinidene) and diarsene complexes by metal-induced degradation of monoarsane (C) 812

Arsenic ligands, Ligand extrusion from the As_4S_4-cage by $[C_5Me_5(CO)_2Mo]_2$: formation of $(C_5Me_5)_2Mo_2(CO)_4(\mu,\eta^2\text{-}As_2)$, $C_5Me_5(CO)_2Mo(\eta^3\text{-}As_3)$, and $(C_5Me_5)_2Mo_2As_2S_3$ (C) 438

Arylalkanoic acids, Synthesis of anti-inflammatory α-arylalkanoic acids by 1,2-aryl shift (R) 413

Arylcarboxylic acids, Optically active α-arylcarboxylic acids by kinetic resolution: pyrethroid acids (C) 162

Aryldihydropyridines, Rotational barriers of 4-aryl-1,4-dihydropyridines (Ca antagonists) (C) 301

Arylmethylenedehydroalanine esters, Synthesis of *N*-(arylmethylene)dehydroalanine esters (C) 380

Aryl shift, Synthesis of anti-inflammatory α-arylalkanoic acids by 1,2-aryl shift (R) 413

Astrophysics, Experimental and theoretical nuclear astrophysics; the quest for the origin of the elements (Nobel lecture) (R) 645
On stars, their evolution and their stability (Nobel lecture) (R) 679

Asymmetric alkylation, Preparation of enantiomerically pure chiral alcohols by asymmetric alkylation of glycolates (C) 60

Asymmetric catalysis, Microbial asymmetric catalysis - enantioselective reduction of ketones (R) 570

Asymmetric hydrogenation of α-(acetylamino)cinnamic acid with a novel rhodium complex; the design of an optimal ligand (C) 435

Asymmetric microsomal epoxidation of simple prochiral olefins (C) 796

Asymmetric synthesis, Asymmetric Diels-Alder and ene reactions in organic synthesis (R) 876
Highly enantioselective alkylation of tetrahydroisoquinolines via a valine chiral auxiliary; asymmetric synthesis of (*S*)-isoquinoline alkaloids (C) 458
Highly enantioselective synthesis of a 2,3-dihydroindole mediated by *N*-methylephedrine (C) 165

Atomic radii, Remarks on *Simon*'s review article "Intermetallic compounds and the use of atomic radii in their description"—Cell dimensions of phases with a given crystal structure do not generally form a homogeneous data-set (C) 324
Intermetallic compounds and the use of atomic radii in their description—reply (C) 325

Aurates, Synthesis and crystal structure of $[Ph_4As]_4[Au_{12}S_8]$, a distorted cubane-like thioaurate(I) (C) 715
Autoxidation, Thermally stable ethylperoxyboron unit by regioselective autoxidation (C) 155
Azacyclophane, An azacyclophane derivative as catalyst of substrate- and product-selective reactions with ambident anions (C) 911
Structure- and solvent-dependence in the complexation of lipophilic substrates in a water-soluble azacyclophane (C) 908
Thin layer chromatography with an immobilized azacyclophane derivative as analytical agent and probe for host-guest interactions (C) 910
Azidobutadienes, Synthesis of azidobutadienes (C) 736
Azulene, A novel rearrangement of the azulene skeleton: ring contraction of a dihydroazulene to an indene derivative (C) 237
Azuleno[2,1,8-*ija*]azulene, Novel synthesis and molecular structure of the pyrene isomer dicyclohepta[*cd,gh*]pentalene (azuleno[2,1,8-*ija*]azulene) (C) 717
Thermal deoxygenation of *syn*-15,16-dioxo-1,6:8,13-bismethano[14]annulene to the pyrene isomer dicyclohepta[*cd,gh*]pentalene (azuleno[2,1,8-*ija*]azulene) (C) 719

BACK BONDING, π-Back bonding and stability of the oxidation states in tetracarbonyldicyclopentadienyl-(μ-pyrazine)dimanganese(I) complexes (C) 614
Bacteriorhodopsin, Sterically fixed retinal-analogue prevents proton-pumping activity in bacteriorhodopsin (C) 81
Bay boletus, Pigments from the cap cuticle of the bay boletus *(Xerocomus badius)* (C) 445
Benz[*d*]isothiazole, Ring expansion of benzothiete to 2,3-dihydrobenz[*d*]isothiazoles (C) 244
Benzene, The electrochemical reduction of benzene—first direct determination of the reduction potential (C) 84
Benzene ring, Molecular structure of 8,11-dichloro[5]metacyclophane: a strongly bent benzene ring (C) 238
Benzonitrile, Stepwise hydrogenation of benzonitrile on a Ru_3-cluster (C) 381
Benzothiete, Ring expansion of benzothiete to 2,3-dihydrobenz[*d*]isothiazoles (C) 244
Benzoxadiazole, 1,2,3-Benzoxadiazole—detection in an argon matrix and in solution (C) 509
Benzoyl-4-phenylthiet-2-one, Acyl- and thioacylketenes: synthesis of 3-benzoyl-4-phenylthiet-2-one (C) 800
Biacetyl, Photoreaction of biacetyl and 1,3-dioxole derivatives: modification of the mechanism of the photoreaction of carbonyl compounds with electron-rich olefins (C) 249
Bicalicene, A novel aromatic hydrocarbon with 16π-electron periphery: "cyclic bicalicene" (C) 63
Bicyclobutane-2,4-dione, Puckered structures of 1,3-dihydro-1,3-diboretes and bicyclobutane-2,4-dione: nonplanar Hückel 2π-electron aromatic molecules (C) 374
Bicyclohexylcarbonitriles, Liquid-crystalline 4-bicyclohexylcarbonitriles with extraordinary physical properties (C) 147
Bicyclo[4.2.0]octane, Direct photochemical cleavage of the cyclobutane ring in bicyclo[4.2.0]octane on 185 nm irradiation in solution (C) 641
Bicyclo[2.1.0]pentenes, Homocyclobutadienes and cyclopropenes by reaction of a stable cyclobutadiene with diazo compounds (C) 708
Bicyclo[1.1.0]tetraarsane, As_4tBu_2—the first bicyclo[1.1.0]tetraarsane (C) 379
Bicyclotriphosphane, P_6tBu_4—the first 1,1'-bicyclotriphosphane (C) 987
Binaphtho[2,3-*a*]azulenequinone, Chiral electron transfer compounds: binaphtho[2,3-*a*]azulenequinone and binaphtho[2,3-*a*]azulenehydroquinone derivatives by oxidative coupling (C) 314
Biomembranes, Phospholipids as functional constituents of biomembranes (R) 257
Biphenylenediporphyrin, A biphenylenediporphyrin: two cofacially arranged porphyrins with a biphenylene bridge (C) 164
Bis(dialkylamino)-1,3-diethoxyallenes, Transallenation of 1,3-bis(dialkylamino)-1,3-diethoxyallenes with disubstituted malonyl chlorides (C) 637
Bisphosphanes, Asymmetric hydrogenation of α-(acetylamino)cinnamic acid with a novel rhodium complex; the design of an optimal ligand (C) 435
The reaction of [2,3-bis(diphenylphosphino)-*N*-methylmaleimide]nickel(II) chloride with $PhE(SiMe_3)_2$ (E=P, As) (C) 635
Bis(tri-*tert*-butylsilyl)triazene, 1,3-Bis(tri-*tert*-butylsilyl)triazene (C) 59
Bis(1,3,5-trimethylbenzene)indium(I) tetrabromoindate(III), the first arene complex of indium (C) 386
Bond formation, The scope of radical CC-coupling by the "tin method" (C) 69
Bonding, Chemical bonding in higher main group elements (R) 272
Bonding electron density, Chemical bonds without bonding electron density—does the difference electron-density analysis suffice for a description of the chemical bond? (C) 627
Boranediyl, Photochemical generation of triphenylsilylboranediyl $(C_6H_5)_3SiB$: from organosilylboranes (C) 454
Borirenes, 1-*tert*-Butylborirenes (C) 313
Boronate esters, Transfer of chirality in the addition of chiral α-chloroallylboronate esters to aldehydes (C) 437
Boron compounds, Cyclic carboxylic acid-organoboron compounds with BHB bridge bonding (C) 153
Boron heterocycles, An extraordinary structure and topomerization mechanism for "diboramethylenecyclopropane" (C) 825
Diazaboracyclopropane (C) 815
1,3-Diboretanes (C) 826
1,2-Dihydroborete: structure of a potential homoaromatic system (C) 370
1,3-Dihydro-1,3-diboretes and their radical anions (C) 372
Puckered structures of 1,3-dihydro-1,3-diboretes and bicyclobutane-2,4-dione: nonplanar Hückel 2π-electron aromatic molecules (C) 374
Strong 1,3-interaction in 1,2-dihydroboretes: homoborirenes (C) 369
Synthesis and structure of a 1,3-dihydro-1,3-diborete (C) 371
Thermally stable ethylperoxyboron unit by regioselective autoxidation (C) 155
Boron-hydrogen-boron bridge bonding, Cyclic carboxylic acid-organoboron compounds with BHB bridge bonding (C) 153
Boron-nitrogen compounds, Synthesis and structure of a B_6N_7 phenalene (C) 303
Boron-phosphorus compounds, Dialkylboryl-substituted triphenylphosphonium ylides (C) 381
Brefeldin A, Asymmetric total synthesis of the macrolides brefeldin A and 7-*epi*-brefeldin A (C) 145
Bridge ligands, $F_3CN{=}C{=}C{=}NCF_3$, a new bridge ligand: formation by CC linkage of two CF_3NC ligands and cleavage of a Mo≡Mo bond (C) 525
Heterometal binuclear complexes with thio- and selenoformaldehyde as bridge ligands (C) 58
Iron clusters with coupled phosphidophosphane bridges (C) 734
Sulfur imide as *bisdihapto*-bridging ligand in the complex $Fe_2(CO)_6(HNS)$ (C) 80
Broad band decoupling, ^{13}C-NMR INADEQUATE spectrum with broad band decoupling by supercycles (C) 152
Bromoethynyl steroids, 17α-Bromoethynyl steroids, A novel entry to 17α-bromo- and 17α-iodoethynyl steroids (C) 727
Butoxycarbonylpyrroles, *tert*-Butyloxycarbonylpyrroles, A convenient method for the preparation of 1-(*tert*-butyloxycarbonyl)pyrroles (C) 296
Butylborirenes, *tert*-Butylborirenes, 1-*tert*-Butylborirenes (C) 313
Butyl hydroperoxide, α-Keto esters and α-keto nitriles via ruthenium-catalyzed dehydrogenation of α-hydroxy esters and cyanohydrins with *tert*-butyl hydroperoxide (C) 518

CAGE MOLECULES, Topological charge stabilization and the equilibrium between P_4S_3 and As_4S_3 (C) 506
Calcium antagonists, Rotational barriers of 4-aryl-1,4-dihydropyridines (Ca antagonists) (C) 301
Carbaboranes, $C_4B_2H_6$ isomers: destabilization of the *nido*-carbaborane structure by amino substituents and a novel classical isomer (C) 969
The first C_4B_6 carbaborane (C) 512
Carbaboranylnickel complexes with the novel η^5-2,3,5-tricarbahexaboranyl ligand (C) 965
Carbanions, Carbanion chemistry (B) 916
Delocalized carbocations, carbanions and radicals of 2,4,6-substituted 1-methoxy-1-oxo-λ^5-phosphinines (C) 990
Carbene complexes in organic synthesis (R) 587
Stoichiometric and catalytic metathesis of carbodiimides and pentacarbonylcarbenetungsten complexes (C) 629
Synthesis and structure of a (carbene)(η^2-olefin)$W(CO)_4$ complex (C) 904
Carbenes, Cyclopropenylidene (C) 641
Carbido cluster, Synthesis and crystal structure of the dicarbido bimetallic cluster $[Co_6Ni_2C_2(CO)_{16}]^{2-}$ (C) 322
Carbocations, Delocalized carbocations, carbanions and radicals of 2,4,6-substituted 1-methoxy-1-oxo-λ^5-phosphinines (C) 990
Destabilized carbocations (R) 20
Stable cyclopentadienylium salts (C) 53
Carbodiimides, Stoichiometric and catalytic metathesis of carbodiimides and pentacarbonylcarbenetungsten complexes (C) 629
Carbohydrates, The scope of radical CC-coupling by the "tin method" (C) 69
Synthesis of 3-deoxy-D-*manno*-2-octulosonic acid (KDO) (C) 430
Carbon-carbon coupling, Acid-induced carbyne-acyl rearrangement—an unexpected CC coupling reaction (C) 640
Carbon monosulfide, [2 + 1]-Cycloadditions of ynamines and ynediamines to carbon monosulfide (C) 729
Carbon monoxide, Acid-induced carbyne-acyl rearrangement—an unexpected CC coupling reaction (C) 640
Nickel-catalyzed reduction of carbon monoxide by hexamethyldisilane: a new reaction leading to a novel synthesis of siloxanes (C) 460
Carbon-sulfur triple bonds, Trifluoroethylidynesulfur trifluoride, $F_3C{-}C{\equiv}SF_3$ (C) 150
Carbonylations, Metal-catalyzed carbonylations of benzyl and aryl bromides in the presence of aluminum alkoxides; a straightforward ester synthesis (C) 732
Carbonyl olefinations, Selective synthesis of carbonyl olefinating or alkylating reagents from $MoCl_5$ and MeLi by changing the solvent or the rate of addition of MeLi (C) 532
Carbonyl olefinations with methylenemolybdenum reagents in aqueous or ethanolic media (C) 531

Carboxylation, Sacrificial anodes in the electrocarboxylation of organic chlorides (C) 979
Carboxy-protection, 2-(Pyridyl)ethyl esters as secure yet readily removable polarophilic carboxy-protection in peptide synthesis (C) 716
Carbyne-acyl rearrangement, Acid-induced carbyne-acyl rearrangement—an unexpected CC coupling reaction (C) 640
Carbyne complexes, $[(CO)_3PPh_3FeCNiPr_2]^{\oplus}$, a novel stable carbyneiron-complex cation (C) 820
Carbyneiron-complex cation, $[(CO)_3PPh_3FeCNiPr_2]^{\oplus}$, a novel stable carbyneiron-complex cation (C) 820
Caronic acid, Enzymatic syntheses of chiral building blocks from racemates: preparation of (1*R*,3*R*)-chrysanthemic, -permethrinic and -caronic acids from racemic, diastereomeric mixtures (C) 64
Carrier-linking, Dextran-linked N^6-(2-isopentenyl)adenosine—a polymer-bound antimetabolite with a predetermined cleavage position (C) 385
Catalysis, Cobalt-mediated [2+2+2]-cycloadditions: a maturing synthetic strategy (R) 539
Covalent catalysis by enzymes (B) 87
Elementary steps in catalytic 1-alkyne coupling to substituted cyclooctatetraenes (C) 893
Enantioselective Michael additions with optically active Co^{II}/diamine catalysts (C) 312
Highly enantioselective synthesis of a 2,3-dihydroindole mediated by *N*-methylephedrine (C) 165
Mercury(II)- and palladium(II)-catalyzed [3,3]-sigmatropic rearrangements (R) 579
Metal-catalyzed carbonylations of benzyl and aryl bromides in the presence of aluminum alkoxides; a straightforward ester synthesis (C) 732
Nickel-catalyzed reduction of carbon monoxide by hexamethyldisilane: a new reaction leading to a novel synthesis of siloxanes (C) 460
Oxidation with palladium salts: catalytic preparation of allyl acetates from monoolefins using a three-component oxidation system (C) 453
Stable formylmanganese complexes (C) 735
Catalysts, An azacyclophane derivative as catalyst of substrate- and product-selective reactions with ambident anions (C) 911
Chiral macrocycles as reagents and catalysts (R) 782
X-Ray spectroscopic studies of the surface species in Co-Mo-Al_2O_3 hydrodesulfurization catalysts (C) 323
Celenamide A, Total synthesis of hexaacetylcelenamide A (C) 991
Cell dimensions, Remarks on *Simon*'s review article "Intermetallic compounds and the use of atomic radii in their description"—Cell dimensions of phases with a given crystal structure do not generally form a homogeneous data-set (C) 324
Intermetallic compounds and the use of atomic radii in their description—reply (C) 325
Centrotriquinanes, A facile route to benzoannelated centrotriquinanes (C) 508
Channel structure, $Ag_{1.8}Mn_8O_{16}$: square planar coordinated $Ag^{\oplus}$ ions in the channels of a novel hollandite variant (C) 906
Charge stabilization, Topological charge stabilization and the equilibrium between P_4S_3 and As_4S_3 (C) 506
Charge-transfer complex, Crystal structure and conductivity of a novel charge-transfer complex of *N*,*N*'-dicyano-1,4-naphthoquinonediimine and tetrathiafulvalene (C) 449
Charge-transfer interactions, Synthesis of a porphyrin sandwiched between two parallel *p*-benzoquinone units (C) 623
Chelation control, Chelation or non-chelation control in addition reactions of chiral α- and β-alkoxy carbonyl compounds (R) 556
Chemical bonds, Electron distributions and the chemical bond (B) 86
Chemical bonding in higher main group elements (R) 272
Chemical bonds without bonding electron density—does the difference electron-density analysis suffice for a description of the chemical bond? (C) 627
Chemical technology, Ullmanns Encyklopädie der technischen Chemie (B) 255
Ullmanns Encyklopädie der technischen Chemie (B) 536
Technische Chemie I. Grundverfahren (B) 537
Chemiluminescence, 1,2-Dioxetane: synthesis, characterization, stability, and chemiluminescence (C) 166
Electrochemiluminescence of tetrakis(diphosphonato)diplatinate(II) (C) 316
Chemoenzymatic gene synthesis, Chemoenzymatic synthesis of a functional gene for human gamma interferon (C) 961
Chiral alcohols, Preparation of enantiomerically pure chiral alcohols by asymmetric alkylation of glycolates (C) 60
Chiral building blocks, Enzymatic syntheses of chiral building blocks from prochiral substrates: enantioselective synthesis of monoalkyl malonates (C) 66
Enzymatic syntheses of chiral building blocks from prochiral *meso*-substrates: preparation of methyl(hydrogen)-1,2-cycloalkanedicarboxylates (C) 67
Enzymatic syntheses of chiral building blocks from racemates: preparation of (1*R*,3*R*)-chrysanthemic, -permethrinic and -caronic acids from racemic, diastereomeric mixtures (C) 64
Chiral electron transfer compounds: binaphtho[2,3-*a*]azulenequinone and binaphtho[2,3-*a*]azulenehydroquinone derivatives by oxidative coupling (C) 314
Chirality, Liquid crystals: a tool for studies on chirality (R) 348
Transfer of chirality in the addition of chiral α-chloroallylboronate esters to aldehydes (C) 437
Chiral macrocycles as reagents and catalysts (R) 782
Chitin, CP/MAS-^{13}C-NMR spectra of sclerotized insect cuticle and of chitin (C) 638
Chlamydocin, Stereoselective total synthesis of chlamydocin and dihydrochlamydocin (C) 318
Cholinergic excitation, Biochemical aspects of cholinergic excitation (R) 195
Chromium(III) reagents, Surprising stability of nucleophilic Cr^{III}-alkylating and Cr^{III}-allylating reagents towards ethanol and water (C) 729
Chrysanthemic acid, Enzymatic syntheses of chiral building blocks from racemates: preparation of (1*R*,3*R*)-chrysanthemic, -permethrinic and -caronic acids from racemic, diastereomeric mixtures (C) 64
Clusters, A new route to iron-sulfur clusters: synthesis and structure of $[(C_2H_5)_4N]_2Fe_6S_6I_6$ (C) 150
Conversion of "LiNS(F)OCMe$_3$" into an $(Li_8)_2$ double cluster (C) 795
Novel clusters of cobalt and nickel with organophosphorus ligands (C) 160
Preparation and structure of (η^6-hexamethylbenzene)gallium(I) tetrabromogallate(III): π-complex and *nido*-cluster (C) 76
$Sn_3(NtBu)_2(OtBu)_2$, a molecule with a novel, heptaatomic, polycyclic framework (C) 158
Stepwise assembly of a cluster with four different metal atoms (C) 140
Synthesis of the first Pt-Au cluster by an unexpected $H^{\ominus}$-substitution at *trans*-$PtH(Cl)L_2$ (C) 304
Thermally and photochemically controlled insertion of alkynes into clusters: a route to organometallic π-ligands (C) 976
Thiolate chemistry of the iron group elements: synthesis and structure of the complexes $[Co_2\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2\ominus}$ and $[Ni_3\{o\text{-}(SCH_2)_2C_6H_4\}_4]^{2\ominus}$ (C) 634
Coenzymes, The pyridine nucleotide coenzymes (B) 85
COLOC, Determination of connectivities via small proton-carbon couplings with a new two-dimensional NMR technique (C) 444
Computer graphics, Modelling the chemistry of zeolites by computer graphics (R) 671
Computers, Computeranwendungen in der Chemie (B) 744
Condensation, Hydrolysis products of the monomeric amine complex $(C_6H_{15}N_3)FeCl_3$: the structure of the octameric iron(III) cation of $\{[(C_6H_{15}N_3)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)\}Br\cdot 8H_2O$ (C) 77
Oligocyclic hetarenes with quinonoid structure; synthesis by sequential cyclizing condensation (C) 914
Conductivity, Crystal structure and conductivity of a novel charge-transfer complex of *N*,*N*'-dicyano-1,4-naphthoquinonediimine and tetrathiafulvalene (C) 449
Configurational stability of vinyllithium derivatives with 1-trimethylsilyl and 1-alkoxy substituents (C) 366
Conformation of glycosyl radicals: radical stabilization by β-CO bonds (C) 896
Connatin, Unusual components of the toadstool *Lyophyllum connatum* (Agaricales) (C) 72
Connectivities, Determination of connectivities via small proton-carbon couplings with a new two-dimensional NMR technique (C) 444
Coordination, $Ag_{1.8}Mn_8O_{16}$: square planar coordinated $Ag^{\oplus}$ ions in the channels of a novel hollandite variant (C) 906
Cations of boron with coordination number three: 1,3,2,4-diazadiboretidinium salts (C) 994
[3+2]-Cycloaddition reactions of a stable phosphaalkyne—transition from singly to doubly coordinated phosphorus (C) 900
Preparation and crystal structure of $CuCo(CO)_4$: a carbonylheterometal complex containing a Cu_4Co_4-ring (C) 307
Preparation and structure of (η^6-hexamethylbenzene)gallium(I) tetrabromogallate(III): π-complex and *nido*-cluster (C) 76
Stable olefin complexes of Pt(II) containing trichlorostannate(II) ligands: structure of $[Ph_4As][Pt(SnCl_3)_3(1,5\text{-cod})]$ (C) 78
Synthesis and structure of a five-coordinate manganese(I) complex (C) 156
Coordination gap, $[Ni_8(\mu_4\text{-}PPh)_6(PPh_3)_4]$ and $[Ni_9(\mu_4\text{-}PPh)_6(PPh_3)_4]$; clusters with coordinatively unsaturated Ni atoms (C) 982
Copper-cobalt rings, Preparation and crystal structure of $CuCo(CO)_4$: a carbonylheterometal complex containing a Cu_4Co_4-ring (C) 307
Copper compounds, $[Cu_6I_{11}]^{5\ominus}$—a polyanion with trigonal-prismatic arrangement of six metal atoms (C) 514
Novel inorganic ring systems and fixation of the $S_8^{2\ominus}$ ion: $[(S_6)Cu(S_8)Cu(S_6)]^{4\ominus}$ and $[Cu_3(S_4)_3]^{3\ominus}$ (C) 632
Copper iodide, $[Cu_5I_7]^{2\ominus}$—an isopolyanion with cyclic face-to-face linking of CuI_4 tetrahedra (C) 378
Copper(I) sulfide cage, $[Cu_{12}S_8]^{4\ominus}$: a closed binary copper(I) sulfide cage with cuboctahedral metal and cubic sulfur arrangements (C) 311
Copper coordination chemistry: biochemical and inorganic perspectives (B) 828

Coupling constants, ^{15}N-^{15}N coupling constants and rotational barriers of nitrosamines (C) 363
Crotonaldehyde-d^1 reagent, Stereoselective nucleophilic acylation of benzaldehyde with a crotonaldehyde-d^1 reagent (C) 723
Crown ether complexes, Crown ether complexes of sulfonium salts—the X-ray crystal structures of $[PhCOCH_2SMe_2 \cdot [18]crown\text{-}6]_n[PF_6]_n$ and $[(PhCOCHPhSMe_2]_2 \cdot [18]crown\text{-}6][PF_6]_2$ (C) 977
Crown ether complexes of phosphonium salts—the X-ray structure analysis of $[(Ph_3PMe)_2 \cdot [18]crown\text{-}6][PF_6]_2$ (C) 824
Crown ether-metal complex interaction, Second sphere coordination of cationic rhodium complexes by dibenzo[3*n*]crown-*n* ethers (C) 235
Crown ethers, Radical anion-substituted crown ethers as cages for metal cations (C) 57
Silver-catalyzed formation of crown ethers; synthesis and structure of $[Ag([12]crown\text{-}4)_2][AsF_6]$ (C) 376
Cryptands, Oxidation reactions with "naked" permanganate ions under aprotic conditions (C) 305
Cubane-like clusters, A novel iron-cluster with a central Fe_8-cube: synthesis and structure of $(Et_4N)_3Fe_8S_6I_8 \cdot 2CH_2Cl_2$ (C) 907
$[Mo_4(\mu_3\text{-}S)_4(\mu\text{-}S_2CNEt_2)_2(S_2CNEt_2)_4]$, a compound containing a cubane-like Mo_4S_4 cluster (C) 391
$[Ni_8(\mu_4\text{-}PPh_6)(PPh_3)_4]$ and $[Ni_9(\mu_4\text{-}PPh)_6(PPh_3)_4]$; clusters with coordinatively unsaturated Ni atoms (C) 982
Cyanimines, One-step entry to *N*-cyanimines and to *N,N'*-dicyanoquinonediimines, a novel class of electron-acceptors (C) 447
Cyanometal acids, Reactions of the cyanometal acids $H_4M(CN)_6$ (M = Fe, Ru, Os), $H_2Pt(CN)_4$, and $HAu(CN)_2$ with epoxides: β-hydroxyalkyl isocyanide- and oxazolidine-2-ylide-metal complexes (C) 377
Cyclic bicalicene, A novel aromatic hydrocarbon with 16π-electron periphery: "cyclic bicalicene" (C) 63
Cyclic face-to-face linking, $[Cu_5I_7]^{2\ominus}$—an isopolyanion with cyclic face-to-face linking of CuI_4 tetrahedra (C) 378
Cyclic voltammetry—"electrochemical spectroscopy" (R) 831
Cycloadditions, Cobalt-mediated [2+2+2]-cycloadditions: a maturing synthetic strategy (R) 539
[3+2]-Cycloaddition reactions of a stable phosphaalkyne—transition from singly to doubly coordinated phosphorus (C) 900
[2+1]-Cycloadditions of ynamines and ynediamines to carbon monosulfide (C) 729
1*H*-1,2,4-Diazaphospholes by [3+2]-cycloaddition of diazoalkanes to phosphaalkenes (C) 901
Donor-substituted thiocarbonyl functions as heterodienophiles in [4+2]-cycloadditions with inverse electron demand (C) 890
The cycloaddition of allyl cations to 1,3-dienes: general method for the synthesis of seven-membered carbocycles (R) 1
Cyclocotrimerization, Mechanism of the cyclocotrimerization of diethyl(hydrido)thiophosphorus with alkynes (C) 523
Cycloheptane derivatives, The cycloaddition of allyl cations to 1,3-dienes: a general method for the synthesis of seven-membered carbocycles (R) 1
Cyclohexadepsipeptide, Synthesis of the all-L-configurated cyclohexadepsipeptide *cyclo*-[L-Val-L-Lac]$_3$ by the Peoc/acid chloride method (C) 808
Cyclooctatetraene, Elementary steps in catalytic 1-alkyne coupling to substituted cyclooctatetraenes (C) 893
Cyclooligopeptides, Synthetic studies on the elucidation of the structure and configuration of Dolastatin 3 (C) 725
Cyclopentadienylium salts, Stable cyclopentadienylium salts (C) 53
Cyclopentane annulation, Iterative cyclopentane annulation of α,β-enones (C) 798
Cyclopentane derivatives, Enantioselective and enantioconvergent syntheses of building blocks for the total synthesis of cyclopentanoid natural products (C) 142
Cyclophosphanes, P_6tBu_4—the first 1,1'-bicyclotriphosphane (C) 987
Cyclopropane "walk" rearrangement, The mechanism of the cyclopropane "walk" rearrangement: synthesis and properties of the 2-diazopropane adduct of cyclooctatetraene (C) 73
Cyclopropenes, Homocyclobutadienes and cyclopropenes by reaction of a stable cyclobutadiene with diazo compounds (C) 708
Cyclopropenylidene (C) 641
Cyclotrisilane, Hexa-*tert*-butylcyclotrisilane, a strained molecule with unusually long Si—Si and Si—C bonds (C) 302

DEHYDROALANINE ESTERS, Synthesis of *N*-(arylmethylene)dehydroalanine esters (C) 380
Dehydrogenation, α-Keto esters and α-keto nitriles via ruthenium-catalyzed dehydrogenation of α-hydroxy esters and cyanohydrins with *tert*-butyl hydroperoxide (C) 518
Delesserine, Synthesis and determination of the absolute configuration of (+)-delesserine, a metabolite of the red marine alga *Delesseria sanguinea* (Lamouroux) (C) 530
Dendralenes, The dendralenes—a neglected group of highly unsaturated hydrocarbons (R) 948
Deoxygenation, Thermal deoxygenation of *syn*-15,16-dioxo-1,6:8,13-bismethano[14]-annulene to the pyrene isomer dicyclohepta[*cd,gh*]pentalene (azuleno[2,1,8-*ija*]-azulene) (C) 719
Deoxy-D-*manno*-2-octulosonic acid, Synthesis of 3-deoxy-D-*manno*-2-octulosonic acid (KDO) (C) 430
Depsipeptide, Synthesis of the all-L-configurated cyclohexadepsipeptide *cyclo*-[L-Val-L-Lac]$_3$ by the Peoc/acid chloride method (C) 808
Description of structure, Remarks on *Simon*'s review article "Intermetallic compounds and the use of atomic radii in their description"—Cell dimensions of phases with a given crystal structure do not generally form a homogeneous dataset (C) 324
Intermetallic compounds and the use of atomic radii in their description—reply (C) 325
Deuteration, Hydroxide ion-initiated deuteration of very weak CH acids under phase transfer catalysis conditions (C) 54
Diarsene complexes, Arsanediyl (arsinidene) and diarsene complexes by metal-induced degradation of monoarsane (C) 812
Facile synthesis of PhAs=AsPh complexes (C) 740
Diastereoselective formation of substituted $(\eta^3\text{-allyl})(\eta^4\text{-diene})ZrCp$ complexes by intramolecular ligand interaction (C) 625
Diastereoselective homoaldol reactions, *syn*-Diastereoselective homoaldol reactions: γ-hydroxyalkylation of (*Z*)-2-butenyl carbamates and synthesis of β,γ-*cis*-di- and -trisubstituted γ-lactones (C) 239
Diastereoselective hydroxyalkylation of the 1-position of 2-pivaloyl-1,2,3,4-tetrahydroisoquinoline via magnesium derivatives (C) 248
Diastereoselective synthesis, Optional diastereo- and enantioselective synthesis of vicinal *threo*- or *erythro*-dihydroxy derivatives (C) 704
Diastereoselective synthesis of spiro[4.5]-decanones by intramolecular Sakurai reactions (C) 308
Diazaboracyclopropane (C) 815
Diazadiboretidinium salts, Cations of boron with coordination number three: 1,3,2,4-diazadiboretidinium salts (C) 994
Diazaphospholes, [3+2]-Cycloaddition reactions of a stable phosphaalkyne—transition from singly to doubly coordinated phosphorus (C) 900
1*H*-1,2,4-Diazaphospholes by [3+2]-cycloaddition of diazoalkanes to phosphaalkenes (C) 901
1*H*-1,2,4-Diazaphospholes via 2-phosphaallyl chlorides (C) 903
Dibenzo[*a,e*]cyclooctene, Carbanion-induced skeletal rearrangements: from the dibenzo[*a,e*]cyclooctene to the indeno[2,1-*a*]indene framework (C) 705
Diboramethylenecyclopropane, An extraordinary structure and topomerization mechanism for "diboramethylenecyclopropane" (C) 825
Diboretanes, 1,3-Diboretanes (C) 826
Di-*tert*-butyl-1-phenyl-1*H*-phosphepine, 2,7-Di-*tert*-butyl-1-phenyl-1*H*-phosphepine—the first stable, monocyclic phosphepine (C) 894
Dicarbido bimetallic cluster, Synthesis and crystal structure of the dicarbido bimetallic cluster $[Co_6Ni_2C_2(CO)_{16}]^{2-}$ (C) 322
Dichloro[5]metacyclophane, Molecular structure of 8,11-dichloro[5]metacyclophane: a strongly bent benzene ring (C) 238
Dicyanoquinonediimines, One-step entry to *N*-cyanimines and to *N,N'*-dicyanoquinonediimines, a novel class of electron-acceptors (C) 447
Dicyclohepta[*cd,gh*]pentalene, Novel synthesis and molecular structure of the pyrene isomer dicyclohepta[*cd,gh*]pentalene (azuleno[2,1,8-*ija*]azulene) (C) 717
Thermal deoxygenation of *syn*-15,16-dioxo-1,6:8,13-bismethano[14]annulene to the pyrene isomer dicyclohepta[*cd,gh*]pentalene (azuleno[2,1,8-*ija*]azulene) (C) 719
Diels-Alder reactions, Asymmetric Diels-Alder and ene reactions in organic synthesis (R) 876
Macrocycles by intramolecular Diels-Alder reaction—regioselective synthesis of anthracycline precursors (C) 74
3-Trimethylsilylacrylic acid as an acetylene equivalent in Diels-Alder reactions; olefins via anodic decarboxylation-desilylation (C) 233
Diethyl(hydrido)thiophosphorus, Mechanism of the cyclocotrimerization of diethyl(hydrido)thiophosphorus with alkynes (C) 523
Difference electron-density analysis, Chemical bonds without bonding electron density—does the difference electron-density analysis suffice for a description of the chemical bond? (C) 627
Dihalocarbene addition, Stereochemical evidence supporting the intermediate mechanism of dihalocarbene addition (C) 706
Dihydroacepentaleneferrates(—2), Novel tricarbonyl(η^4-dihydroacepentalene)iron complexes and tricarbonyl(η^2-dihydroacepentalene)ferrates(—2) (C) 707
Dihydroacepentaleneiron complexes, Novel tricarbonyl(η^4-dihydroacepentalene)iron complexes and tricarbonyl(η^2-dihydroacepentalene)ferrates(—2) (C) 707
Dihydroazulenes, Photosensitive dihydroazulenes with chromogenic properties (C) 960
Dihydroboretes, 1,2-Dihydroborete: structure of a potential homoaromatic system (C) 370
Strong 1,3-interaction in 1,2-dihydroboretes: homoborirenes (C) 369

Dihydrochlamydocin, Stereoselective total synthesis of chlamydocin and dihydrochlamydocin (C) 318
Dihydrodiboretes, 1,3-Dihydro-1,3-diboretes and their radical anions (C) 372
Puckered structures of 1,3-dihydro-1,3-diboretes and bicyclobutane-2,4-dione: nonplanar Hückel 2π-electron aromatic molecules (C) 374
Synthesis and structure of a 1,3-dihydro-1,3-diborete (C) 371
Dihydroindole, Highly enantioselective synthesis of a 2,3-dihydroindole mediated by *N*-methylephedrine (C) 165
erythro-Dihydroxy derivatives, Optional diastereo- and enantioselective synthesis of vicinal *threo*- or *erythro*-dihydroxy derivatives (C) 704
threo-Dihydroxy derivatives, Optional diastereo- and enantioselective synthesis of vicinal *threo*- or *erythro*-dihydroxy derivatives (C) 704
Dilithioacetone, The ab initio calculation of the structure of 1,3-dilithioacetone (C) 620
Dilithiodibenzyl ketone, Structure of a "Y-conjugated" dilithium salt of an α,α'-keto dianion: 1,3-dilithiodibenzyl ketone-$(Me_2NCH_2CH_2NMe_2)_2$ (C) 621
Dilithiomethylenecyclohexane—a stable 1,1-dilithioalkene (C) 224
Dimanganese(I) complexes, π-Back bonding and stability of the oxidation states in tetracarbonyldicyclopentadienyl-(μ-pyrazine)dimanganese(I) complexes (C) 614
Dimerization, Metal template for the symmetrical [2+2]-dimerization of ketenimines (C) 223
Unexpected secondary reaction of the simple CH_3I-quaternization of vinylidenebis(diphenylphosphane) (C) 247
Dimetallacyclopropane complexes, Ring-opening of methylene-bridged dimetal complexes by bases (C) 432
Dimethylphosphoniobis(methanide), Pentamethylcyclopentadienyllutetium derivatives of dimethylphosphoniobis(methanide) (C) 522
Dioxaspiro[5.5]undecanes, Synthesis of enantiomerically pure 1,7-dioxaspiro[5.5]undecanes, pheromone components of the olive fly *(Dacus oleae)* (C) 519
Dioxazine, Dithiocyanogen Reaction without cleavage of the S—S bond: cycloaddition with hexafluoroacetone (C) 1000
Dioxetane, 1,2-Dioxetane: synthesis, characterization, stability, and chemiluminescence (C) 166
Dioxo-1,6:8,13-bismethano[14]annulene, Thermal deoxygenation of *syn*-15,16-dioxo-1,6:8,13-bismethano[14]annulene to the pyrene isomer *dicyclohepta[cd,gh]*-pentalene (azuleno[2,1,8-*ija*]azulene) (C) 719
Dioxocine system, Synthesis of the antibiotic LL-Z1220—contribution to an understanding of the 1,4-dioxocine system (C) 966
Diphenyldiarsene, Facile synthesis of PhAs=AsPh complexes (C) 740
Diphosphaallenes, Molecular structure of a 1,3-diphosphaallene: $(2,4,6\text{-}tBu_3C_6H_2)$-P=C=P$(2,4,6\text{-}tBu_3C_6H_2)$, a phosphorus analogue of carbon disulfide (C) 618
Diphosphorus unit, $Cp_2Mo_2(CO)_4P_2$ as complex ligand (C) 968
Discotic liquid crystals, Hexa-*O*-alkanoyl-*scyllo*-inositols, the first alicyclic, saturated, discotic liquid crystals (C) 82
Dithiocyanogen reaction without cleavage of the S—S bond: cycloaddition with hexafluoroacetone (C) 1000
DNA methylation: Site-specific methylations cause gene inactivation (R) 919
Dolastatin 3, Synthetic studies on the elucidation of the structure and configuration of Dolastatin 3 (C) 725
Double bonds, Structure of tetracyclo-[6.2.1.1^{3,6}.0^{2,7}]dodeca-4,9-diene: a diolefin with close double bonds (C) 55
Double clusters, Conversion of "LiNS(F)OCMe$_3$" into an $(Li_8)_2$ double cluster (C) 795
Double-stacked structure, A novel double-stacked structure in bis[(oxamide oximato)(oxamide oxime)platinum (II)][{tris(tetracyanoquinodimethane)}diide], a molecular electron conductor (C) 999

ELECTROCARBOXYLATION, Sacrificial anodes in the electrocarboxylation of organic chlorides (C) 979
Electrochemical reduction, The electrochemical reduction of benzene—first direct determination of the reduction potential (C) 84
Electrochemiluminescence of tetrakis(disphosphonato)diplatinate(II) (C) 316
Electrochemistry, 1,4,7,10-Tetraphenyldibenzo[*a,e*]cyclooctene-5,6,11,12-tetrone from 3,6-diphenylphthalic anhydride (C) 622
3-Trimethylsilylacrylic acid as an acetylene equivalent in Diels-Alder reactions; olefins via anodic decarboxylation-desilylation (C) 233
Electron-acceptors, One-step entry to *N*-cyanimines and to *N,N'*-dicyanoquinonediimines, a novel class of electron-acceptors (C) 447
Electron conductor, A novel double-stacked structure in bis[(oxamide oximato)(oxamide oxime)platinum (II)][{tris(tetracyanoquinodimethane)}diide], a molecular electron conductor (C) 999
Electron distributions and the chemical bond (B) 86
Electron microscopy, Electron and ion microscopy and microanalysis (B) 464
Electron transfer, Novel double-layered annulenes—models for the investigation of successive electron transfers (C) 818
Electron transfer between metal complexes—a retrospective view (Nobel lecture) (R) 329
Electron transfer compounds, Chiral electron transfer compounds: binaphtho[2,3-*a*]azulenequinone and binaphtho[2,3-*a*]azulenehydroquinone derivatives by oxidative coupling (C) 314
Elements, Experimental and theoretical nuclear astrophysics; the quest for the origin of the elements (Nobel lecture) (R) 645
Enantioconvergent syntheses, Enantioselective and enantioconvergent syntheses of building blocks for the total synthesis of cyclopentanoid natural products (C) 142
Enantiomeric resolution, Gas chromatographic separation of enantiomers on optically active metal-complex-free stationary phases (R) 747
Phosgene as a reagent for the enantiomeric resolution of 1,2- and 1,3-diols, α-amino alcohols, α-hydroxy acids, and *N*-methyl-α-amino acids by gas chromatography (C) 527
Thin-layer chromatographic enantiomeric resolution via ligand exchange (C) 506
Enantioselective alkylation, Highly enantioselective alkylation of tetrahydroisoquinolines via a valine chiral auxiliary; asymmetric synthesis of (*S*)-isoquinoline alkaloids (C) 458
Enantioselective homoaldol additions, Highly enantioselective homoaldol additions with chiral *N*-allylureas—application to the synthesis of optically pure γ-lactones (C) 898
Enantioselective hydrosilylation, Enantioselective catalytic hydrosilylation of oximes (C) 222
Enantioselective Michael additions with optically active Co^{II}/diamine catalysts (C) 312
Enantioselective reduction, Microbial asymmetric catalysis - enantioselective reduction of ketones (R) 570
Enantioselective synthesis of β-substituted primary amines; α-alkylation/reductive amination of aldehydes via SAMP-hydrazones (C) 365
Optional diastereo- and enantioselective synthesis of vicinal *threo*- or *erythro*-dihydroxy derivatives (C) 704
ENDOR spectroscopy—a promising technique for investigating the structure of organic radicals (R) 173
Ene reactions, Asymmetric Diels-Alder and ene reactions in organic synthesis (R) 876
Enzymatic analysis, Methods of enzymatic analysis. Volume I. Fundamentals (B) 171
Enzymatic syntheses of chiral building blocks from prochiral substrates: enantioselective synthesis of monoalkyl malonates (C) 66
from prochiral *meso*-substrates: preparation of methyl(hydrogen)-1,2-cycloalkanedicarboxylates (C) 67
from racemates: preparation of (1*R*,3*R*)-chrysanthemic, -permethrinic and -caronic acids from racemic, diastereomeric mixtures (C) 64
Enzymes, Covalent catalysis by enzymes (B) 87
Enzyme structure and activity, Analysis of enzyme structure and activity by protein engineering (R) 467
Epoxides, Synthesis of 1,2:3,4:5,6-trianhydrohexitols with *gluco-*, *manno-*, and *ido*-configuration (C) 242
Ester synthesis, Metal-catalyzed carbonylations of benzyl and aryl bromides in the presence of aluminum alkoxides; a straightforward ester synthesis (C) 732
Ethyl lithiopropiolate, Stereoselective synthesis of (*E*)-4-hydroxy-2-alkenoic acid esters from aldehydes and the d^3-building block ethyl lithiopropiolate (C) 143
Excited states, Chemical and biological generation of excited states (B) 535

FENESTRANES, All-*cis*-[5.5.5.5]fenestrane (C) 390
Ferracycloalkanes, Facile synthesis of highly reactive ferracycloalkanes (C) 711
Ferrocene, Nitrosoferrocene (C) 521
Ferrocenium salts—the first antineoplastic iron compounds (C) 456
Fischer-Tropsch synthesis, Ring-opening of methylene-bridged dimetal complexes by bases (C) 432
Flash thermolysis, Cyclopropenylidene (C) 641
Folding, Protein folding and protein association (R) 395
Food chemistry, Lehrbuch der Lebensmittelchemie (B) 253
Formylmanganese complexes, Stable formylmanganese complexes (C) 735
Fortimicin aglycone, Total synthesis of a fortimicin aglycone (C) 167
Fragrance chemistry: the science of the sense of smell (B) 253
Fulvalenes, Nonapentafulvalene; synthesis by oxidative coupling of cyclononatetraenide and cyclopentadienide (C) 973
Furans, 2-Amino-5-sulfinylfurans from sulfonylacetylenes and ynamines (C) 321

GALLIUM COMPOUNDS, Preparation and structure of (η^6-hexamethylbenzene)gallium(I) tetrabromogallate(III): π-complex and *nido*-cluster (C) 76
Gas chromatography, Gas chromatographic separation of enantiomers on optically active metal-complex-free stationary phases (R) 747
Phosgene as a reagent for the enantiomeric resolution of 1,2- and 1,3-diols, α-amino alcohols, α-hydroxy acids, and *N*-methyl-α-amino acids by gas chromatography (C) 527

Gene inactivation, DNA methylation: site-specific methylations cause gene inactivation (R) 919
Gene synthesis, Chemoenzymatic synthesis of a functional gene for human gamma interferon (C) 961
German chemical community, The formation of the German chemical community (B) 392
Germanides, High-pressure phases of KSi, KGe, RbSi, RbGe, CsSi, and CsGe with the NaPb-type structure (C) 528
Germanium(II) compounds, Novel structures containing germanium(II): germanocene and dimeric tricarbonyl(di-*tert*-butoxygermylene)nickel(0) (C) 61
Germanocene, Novel structures containing germanium(II): germanocene and dimeric tricarbonyl(di-*tert*-butoxygermylene)nickel(0) (C) 61
Glycine complex, μ_3-Oxo-$Fe_2^{III}Cr^{III}$-glycine complex, Trinuclear complexes, structure of a novel μ_3-oxo-$Fe_2^{III}Cr^{III}$-glycine complex (C) 434
Glycopeptides, The allyl group as mildly and selectively removable carboxy-protecting group for the synthesis of labile *O*-glycopeptides (C) 71
Glycosyl radicals, Conformation of glycosyl radicals: radical stabilization by β-CO bonds (C) 896
Gold compounds, Synthesis and structure of $[Ph_4As][AuS_9]$, a cyclic nonasulfidoaurate(I) (C) 246
Graphite-potassium intercalates, Formation of phenanthrenequinone from benzil: a novel reaction of graphite-potassium intercalates (C) 642
Grignard compounds, *N,N*-Bis(trimethylsilyl)aminomethylation of Grignard compounds—a versatile amine synthesis (C) 53

HALF-SANDWICH COMPLEXES, Chemistry of the novel oxo half-sandwich complex $(\eta^5\text{-}C_5Me_5)ReO_3$: functionalization and aggregation (C) 515
General entry to novel manganese(II) half-sandwich complexes (C) 721
TMEDA adducts of CpMnCl and manganocene (C) 722
Halonium radical ions, Reactivity of $CH_2\text{–}X\text{–}CH_3^{\oplus\odot}$ (X=Cl, Br) with electrophiles and nucleophiles in the gas phase, a Fourier transform ion cyclotron resonance investigation (C) 733
Heme biosynthesis from L-glutamic acid (C) 998
Henry reaction, High-pressure syntheses: the Henry reaction (C) 617
Hetarenes, Oligocyclic hetarenes with quinonoid structure; synthesis by sequential cyclizing condensation (C) 914
Heteroannulenes, 4*H*-1,4-Oxazocine, a planar, diatropic 10π-dihetero[8]annulene? (C) 309
Heterocumulenes, $F_3CN{=}C{=}C{=}NCF_3$, a new bridge ligand: formation by CC linkage of two CF_3NC ligands and cleavage of a Mo≡Mo bond (C) 525
First evidence for the existence of a phosphathioketene (C) 970
Hexaacetylcelenamide A, Total synthesis of hexaacetylcelenamide A (C) 991
Hexa-*tert*-butylcyclotrisilane, a strained molecule with unusually long Si—Si and Si—C bonds (C) 302
Hexachlorocyclohexane, Hexachlorcyclohexan als Schadstoff in Lebensmitteln (B) 393
Hexamethyldisilane, Nickel-catalyzed reduction of carbon monoxide by hexamethyldisilane: a new reaction leading to a novel synthesis of siloxanes (C) 460
Hexasulfido ligands, Isolation of a sulfur-rich binary mercury species from a sulfide-containing solution: $[Hg(S_6)_2]^{2\ominus}$, a complex with $S_6^{2\ominus}$ ligands (C) 159
Hexatrienyl acetate, Adducts of the ketene (1*E*,3*Z*)-1,2,3,4,5-pentamethyl-6-oxo-1,3,5-hexatrienyl acetate (C) 442
High-pressure phases of KSi, KGe, RbSi, RbGe, CsSi, and CsGe with the NaPb-type structure (C) 528
High-pressure syntheses: the Henry reaction (C) 617
History of chemistry, Liebigs Experimentalvorlesung, Vorlesungsbuch und Kekulés Mitschrift (B) 255
The formation of the German chemical community (B) 392
"... to make chemistry more applicable and generally beneficial"—the transition in scientific perspective in eighteenth century chemistry (R) 339
Hole burning, Photochemical hole burning: a spectroscopic study of relaxation processes in polymers and glasses (R) 113
Hollandite, $Ag_{1.8}Mn_8O_{16}$: square planar coordinated $Ag^{\oplus}$ ions in the channels of a novel hollandite variant (C) 906
Homoaldol reactions, *syn*-Diastereoselective homoaldol reactions: γ-hydroxyalkylation of (*Z*)-2-butenyl carbamates and synthesis of β,γ-*cis*-di- and -trisubstituted γ-lactones (C) 239
Highly enantioselective homoaldol additions with chiral *N*-allylureas—application to the synthesis of optically pure γ-lactones (C) 898
The homoaldol reaction, or how to overcome problems of regio- and stereo-selectivity (R) 932
Homoaromaticity, 1,2-Dihydroborete: structure of a potential homoaromatic system (C) 370
Temperature dependence of the UV spectrum of 1,5-dimethyl-2,6-semibullvalenedicarbonitrile; evidence for an equilibrium with a delocalized, homoaromatic isomer (C) 631
Homoborirenes, Strong 1,3-interaction in 1,2-dihydroboretes: homoborirenes (C) 369
Homocyclobutadienes and cyclopropenes by reaction of a stable cyclobutadiene with diazo compounds (C) 708
Human gamma interferon, Chemoenzymatic synthesis of a functional gene for human gamma interferon (C) 961
Humic substances, Aliphatic polyethers, basic building blocks from naturally occurring humic substances: detection by solid state ^{13}C-NMR spectroscopy (C) 147
Hydrazido(3−) *N*-ligands, A binuclear molybdenum complex with two μ-hydrazido(3−) *N*-ligands (C) 382
Hydridoplatinum(II) complexes with phosphites and phosphonites and their reactions with methyl acrylate (C) 529
Hydrodesulfurization, X-Ray spectroscopic studies of the surface species in Co-Mo-Al_2O_3 hydrodesulfurization catalysts (C) 323
Hydrogenation, Stepwise hydrogenation of benzonitrile on a Ru_3-cluster (C) 381
Hydrolysis products of the monomeric amine complex $(C_6H_{15}N_3)FeCl_3$: the structure of the octameric iron(III) cation of $[[(C_6H_{15}N_3)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)]Br\cdot 8H_2O$ (C) 77
Hydrosilylation, Enantioselective catalytic hydrosilylation of oximes (C) 222
Hydroxyalkenoic acid esters, Stereoselective synthesis of (*E*)-4-hydroxy-2-alkenoic acid esters from aldehydes and the d^3-building block ethyl lithiopropiolate (C) 143
Hydroxyalkylation, *syn*-Diastereoselective homoaldol reactions: γ-hydroxyalkylation of (*Z*)-2-butenyl carbamates and synthesis of β,γ-*cis*-di- and -trisubstituted γ-lactones (C) 239
Diastereoselective hydroxylalkylation of the 1-position of 2-pivaloyl-1,2,3,4-tetrahydroisoquinoline via magnesium derivatives (C) 248
Hydroxyalkyl isocyanide-metal complexes, Reactions of the cyanometal acids $H_4M(CN)_6$ (M=Fe, Ru, Os), $H_2Pt(CN)_4$, and $HAu(CN)_2$ with epoxides: β-hydroxyalkyl isocyanide- and oxazolidine-2-ylidemetal complexes (C) 377
Hydrozirconation of nitriles: proof of a linear heteroallene structure in (benzylideneamido)zirconocene chloride (C) 68

INCLUSION COMPOUNDS, Functionalized, oligocyclic large cavities—a novel siderophore (C) 714
Macrobicyclic polyethers as V-shaped hosts for *cis*-diammine-transition metal complexes (C) 821
Novel host structures for the selective inclusion of aromatic and aliphatic guests in aqueous solution (C) 712
Spherical host molecules for the complexation of aromatic hydrocarbons in aqueous solution (C) 810
Structure- and solvent-dependence in the complexation of lipophilic substrates in a water-soluble azacyclophane (C) 908
Indeno[2,1-*a*]indene, Carbanion-induced skeletal rearrangements: from the dibenzo[*a,e*]cyclooctene to the indeno[2,1-*a*]indene framework (C) 705
Indium compounds, Bis(1,3,5-trimethylbenzene)indium(I) tetrabromoindate(III), the first arene complex of indium (C) 386
Indium(III) iodide, Red α-indium(III) iodide (C) 799
Indole alkaloid, Total synthesis of the indole alkaloid vallesiachotamine (C) 984
Insect cuticle, CP/MAS-^{13}C-NMR spectra of sclerotized insect cuticle and of chitin (C) 638
Insertion of platinum into the sulfur-nitrogen bond of a 1,2,4-thiadiazole: synthesis of a six-membered metallaheterocycle (C) 971
Reactions of diphenyl(trimethylsilyl)phosphane with alkyl(pentacarbonyl)manganese; synthesis of the ylide complexes $(CO)_4MnCr(OSiMe_3)PPh_2$ and a new driving force for CO insertion (C) 245
Interaction, Strong 1,3-interaction in 1,2-dihydroboretes: homoborirenes (C) 369
Interferon, Chemoenzymatic synthesis of a functional gene for human gamma interferon (C) 961
Intermediates, Reactive intermediates (B) 254
Intermetallic compounds, Remarks on *Simon*'s review article "Intermetallic compounds and the use of atomic radii in their description"—Cell dimensions of phases with a given crystal structure do not generally form a homogeneous dataset (C) 324
and the use of atomic radii in their description—reply (C) 325
Inverse electron demand, Donor-substituted thiocarbonyl functions as heterodienophiles in [4+2]-cycloadditions with inverse electron demand (C) 890
17α-Iodoethynyl steroids, A novel entry to 17α-bromo- and 17α-iodoethynyl steroids (C) 727
Ion cyclotron resonance, Reactivity of $CH_2\text{–}X\text{–}CH_3^{\oplus\odot}$ (X=Cl, Br) with electrophiles and nucleophiles in the gas phase, a Fourier transform ion cyclotron resonance investigation (C) 733
Iron-clusters, A novel iron-sulfur cluster with a central Fe_8-cube: synthesis and structure of $(Et_4N)_3Fe_8S_6I_8\cdot 2CH_2Cl_2$ (C) 907
Synthesis, structure, and reactions of cluster-stabilized phosphaalkenes (C) 739
Iron clusters with coupled phosphido-phosphane bridges (C) 734
Iron-sulfur clusters, A new route to iron-sulfur clusters: synthesis and structure of $[(C_2H_5)_4N]_2Fe_6S_6I_6$ (C) 150

Iron compounds, Hydrolysis products of the monomeric amine complex $(C_6H_{15}N_3)FeCl_3$: the structure of the octameric iron(III) cation of $\{[(C_6H_{15}N_3)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7\text{-}(H_2O)\}Br\cdot 8\,H_2O$ (C) 77
Iron-phosphorus compounds, $[(CO)_3FePCH_3]_4$, an organometallic analogue of octabisvalene (C) 983
Isocyanide insertion into a uranium-carbon double bond (C) 912
Isoindoles, A rational synthetic method for 2*H*-isoindoles (C) 517
Isolobal connection, Metal-carbon and metal-metal multiple bonds as ligands in transition-metal chemistry: the isolobal connection (R) 89
Isomerization, Detection of intramolecular linkage isomerization of a (pseudo)tetrahedral nickel(II) bis(chelate) (C) 368
Unusual equilibrium between η^1- and η^2-isomers of selenobenzaldehyde complexes (C) 726
Isomers, $(\eta^3\text{-Allyl})(\eta^4\text{-butadiene})(\eta^5\text{-cyclopentadienyl})$zirconium, a system of isomeric monocyclopentadienylzirconium(II) compounds (C) 455
Isopentenyladenosine, Dextran-linked N^6-(2-isopentenyl)adenosine — a polymer-bound antimetabolite with a predetermined cleavage position (C) 385
Isopolyanion, $[Cu_5I_7]^{2\ominus}$ — an isopolyanion with cyclic face-to-face linking of CuI_4 tetrahedra (C) 378
Isoquinoline alkaloids, Highly enantioselective alkylation of tetrahydroisoquinolines via a valine chiral auxiliary; asymmetric synthesis of (*S*)-isoquinoline alkaloids (C) 458
Isoquinolines, Diastereoselective hydroxyalkylation of the 1-position of 2-pivaloyl-1,2,3,4-tetrahydroisoquinoline via magnesium derivatives (C) 248
Isotetrazenido(4−) complexes, $(Ph_4As)_2$-$[Cl_5W(\mu\text{-}N_4)WCl_5]$, a μ-isotetrazenido-(4−) complex of Tungsten(VI) (C) 149
Isotope effects, Isotopeneffekte bei chemischen Reaktionen (B) 537

JAHN-TELLER EFFECT, Second order Jahn-Teller effect in hexahalogenotellurates(IV): statistically distorted anion in $Ca(H_2O,HF)_7TeBr_6$ (C) 963

KDO, Synthesis of 3-deoxy-D-*manno*-2-octulosonic acid (KDO) (C) 430
Ketenes, Adducts of the ketene (1*E*,3*Z*)-1,2,3,4,5-pentamethyl-6-oxo-1,3,5-hexatrienyl acetate (C) 442
Ketenimines, Metal template for the symmetrical [2+2]-dimerization of ketenimines (C) 223
Keto dianions, Structure of a "Y-conjugated" dilithium salt of an α,α′-keto dianion: 1,3-dilithiodibenzyl ketone-$(Me_2NCH_2CH_2NMe_2)_2$ (C) 621
The ab initio calculation of the structure of 1,3-dilithioacetone (C) 620
α-Keto esters and α-keto nitriles via ruthenium-catalyzed dehydrogenation of α-hydroxy esters and cyanohydrins with *tert*-butyl hydroperoxide (C) 518
Ketoketene—ketoketene rearrangement, A novel ketoketene—ketoketene rearrangement (C) 802
α-Keto nitriles, α-Keto esters and α-keto nitriles via ruthenium-catalyzed dehydrogenation of α-hydroxy esters and cyanohydrins with *tert*-butyl hydroperoxide (C) 518
Kinetic resolution, Optically active α-arylcarboxylic acids by kinetic resolution: pyrethroid acids (C) 162
Kolbe electrolysis, Cyclization of 3-allyloxycarboxylic acids to tetrahydrofurans by Kolbe electrolysis (C) 980

LACTAM, β-Lactam antibiotics, Chemistry and biology of β-lactam antibiotics (B) 463
Lactones, A photochemical entry to macrocyclic mono- and dilactones (C) 440
syn-Diastereoselective homoaldol reactions: γ-hydroxyalkylation of (*Z*)-2-butenyl carbamates and synthesis of β,γ-*cis*-di- and -trisubstituted γ-lactones (C) 239
Highly enantioselective homoaldol additions with chiral *N*-allylureas—application to the synthesis of optically pure γ-lactones (C) 898
Lanthanoid compounds, Organolanthanoid compounds (R) 474
Ligand exchange, Thin-layer chromatographic enantiomeric resolution via ligand exchange (C) 506
Ligand extrusion from the As_4S_4-cage by $[C_5Me_5(CO)_2Mo]_2$: formation of $(C_5Me_5)_2Mo_2(CO)_4(\mu,\eta^2\text{-}As_2)$, $C_5Me_5(CO)_2Mo(\eta^3\text{-}As_3)$, and $(C_5Me_5)_2Mo_2As_2S_3$ (C) 438
Ligand interaction, Diastereoselective formation of substituted $(\eta^3\text{-allyl})(\eta^4\text{-diene})$ZrCp complexes by intramolecular ligand interaction (C) 625
Ligands, An iridium(III) complex containing a PF_4-group bound to the metal (C) 630
Asymmetric hydrogenation of α-(acetylamino)cinnamic acid with a novel rhodium complex; the design of an optimal ligand (C) 435
Carbaboranylnickel complexes with the novel η^5-2,3,5-tricarbahexaboranyl ligand (C) 965
$Cp_2Mo_2(CO)_4P_2$ as complex ligand (C) 968
Hydridoplatinum(II) complexes with phosphites and phosphonites and their reactions with methyl acrylate (C) 529
Second sphere coordination of cationic rhodium complexes by dibenzo[3*n*]crown-*n* ethers (C) 235
Synthesis and characterization of $[(C_5Me_5)Mn(CO)_2(SR)]$: RS radicals as ligands (C) 975
Thermally and photochemically controlled insertion of alkynes into clusters: a route to organometallic π-ligands (C) 976
Lignites, Aliphatic polyethers, basic building blocks from naturally occurring humic substances: detection by solid state ^{13}C-NMR spectroscopy (C) 147
Linkage isomerization, Detection of intramolecular linkage isomerization of a (pseudo)tetrahedral nickel(II) bis(chelate) (C) 368
Liquid crystals: A tool for studies on chirality (R) 348
Hexa-*O*-alkanoyl-*scyllo*-inositols, the first alicyclic, saturated, discotic liquid crystals (C) 82
Liquid-crystalline 4-bicyclohexylcarbonitriles with extraordinary physical properties (C) 147
Lithioalkenes, Dilithiomethylenecyclohexane—a stable 1,1-dilithioalkene (C) 224
Lithium α-aminoenolates, Easy rotation about the exocyclic carbon-carbon bond in lithium α-aminoenolates: a comparison (C) 797
Lithium aminosilanolate, Synthesis of a stable aminosilanol and a lithium aminosilanolate with cubane structure (C) 891
Lithium compounds, Configurational stability of vinyllithium derivatives with 1-trimethylsilyl and 1-alkoxy substituents (C) 366
Tetralithiomethane (C) 995
Lutetium derivatives, Pentamethylcyclopentadienyllutetium derivatives of dimethylphosphoniobis(methanide) (C) 522
Lyophyllin, Unusual components of the toadstool *Lyophyllum connatum* (Agaricales) (C) 72

MACROCYCLES, An azacyclophane derivative as catalyst of substrate- and product-selective reactions with ambident anions (C) 911
A photochemical entry to macrocyclic mono- and dilactones (C) 440
Chiral macrocycles as reagents and catalysts (R) 782
Functionalized, oligocyclic large cavities—a novel siderophore (C) 714
Macrobicyclic polyethers as V-shaped hosts for *cis*-diammine-transition metal complexes (C) 821
Macrocycles by intramolecular Diels-Alder reaction—regioselective synthesis of anthracycline precursors (C) 74
Novel host structures for the selective inclusion of aromatic and aliphatic guests in aqueous solution (C) 712
Spherical host molecules for the complexation of aromatic hydrocarbons in aqueous solution (C) 810
Structure- and solvent-dependence in the complexation of lipophilic substrates in a water-soluble azacyclophane (C) 908
Thin layer chromatography with an immobilized azacyclophane derivative as analytical agent and probe for host-guest interactions (C) 910
Macrolides, Asymmetric total synthesis of the macrolides brefeldin A and 7-*epi*-brefeldin A (C) 145
Main group elements, Chemical bonding in higher main group elements (R) 272
Manganese compounds, Reactions of diphenyl(trimethylsilyl)phosphane with alkyl(pentacarbonyl)manganese; synthesis of the ylide complexes $(CO)_4\overline{MnCr(OSiMe_3)}PPh_2$ and a new driving force for CO insertion (C) 245
Synthesis and structure of a five-coordinate manganese(I) complex (C) 156
Manganese(II) half-sandwich complexes, General entry to novel manganese(II) half-sandwich complexes (C) 721
TMEDA adducts of CpMnCl and manganocene (C) 722
Manganocene, TMEDA adducts of CpMnCl and manganocene (C) 722
Mass spectrometry, Thermospray mass spectrometry of diquaternary ammonium salts (C) 892
Membranbiochemie (B) 917
Membranes, Phospholipids as functional constituents of biomembranes (R) 257
Routes to functional vesicle membranes without proteins (R) 100
Mercury compounds, Isolation of a sulfur-rich binary mercury species from a sulfide-containing solution: $[Hg(S_6)_2]^{2\ominus}$, a complex with $S_6^{2\ominus}$ ligands (C) 159
Metal-carbon multiple bonds, Metal-carbon and metal-metal multiple bonds as ligands in transition-metal chemistry: the isolobal connection (R) 89
Metal cations, Radical anion-substituted crown ethers as cages for metal cations (C) 57
Metal complexes, Electron transfer between metal complexes—a retrospective view (Nobel lecture) (R) 329
Metal-insulator transformations, Synthesis of new amorphous metallic spin glasses M_2SnTe_4 (M = Cr, Mn, Fe, Co): solvent induced metal-insulator transformations (C) 169
Metal-metal multiple bonds, Metal-carbon and metal-metal multiple bonds as ligands in transition-metal chemistry: the isolobal connection (R) 89
Metal-phosphorus double bonds, Novel synthesis of complexes with metal-phosphorus double bonds (C) 738
Metathesis, Stoichiometric and catalytic metathesis of carbodiimides and pentacarbonylcarbenetungsten complexes (C) 629
Synthesis and structure of a (carbene)$(\eta^2$-olefin)$W(CO)_4$ complex (C) 904
Methylenemolybdenum reagents, Carbonyl olefinations with methylenemolybdenum

reagents in aqueous or ethanolic media (C) 531
Methyleneoxophosphoranes, The first stable methyleneoxophosphorane (C) 157
Methylene(phenyl)arsane, Complexation of $PhAs{=}CH_2$ and synthesis of a novel $RhAs_3$-metallaheterocycle (C) 626
Methylephedrine, Highly enantioselective synthesis of a 2,3-dihydroindole mediated by *N*-methylephedrine (C) 165
Methyl(thioxo)phosphane: generation and trapping reaction with $Mn_2(CO)_{10}$ (C) 320
Michael additions, Enantioselective Michael additions with optically active Co^{III}/diamine catalysts (C) 312
Microbial asymmetric catalysis - enantioselective reduction of ketones (R) 570
Microbial reduction, Preparative microbial reduction of β-oxoesters with *Thermoanaerobium brockii* (C) 151
Microsomal epoxidation, Asymmetric microsomal epoxidation of simple prochiral olefins (C) 796
Mixed crystals containing the diamagnetic complex $[Mo_2(SO_2)(S_2)(CN)_8]^{4\ominus}$ and the paramagnetic complex $[Mo_2(SO_2)(S_2)(CN)_8]^{5\ominus}$ (C) 389
Mixed-valence complexes, A binuclear, mixed-valence $Mo^{VI/V}$-complex; the crystal structure of $[(C_9H_{21}N_3)_2Mo_2{}^{VI}O_5](Br_3)_2$ (C) 899
Mold fungi, Mycotoxins from mold fungi—weapons of uninivited fellow-boarders of man and animal: structures, biological activity, biosynthesis, and precautions (R) 493
Molecular biology of the cell (B) 643
Molybdenum compounds, A binuclear, mixed-valence $Mo^{VI/V}$-complex; the crystal structure of $[(C_9H_{21}N_3)_2Mo_2{}^{VI}O_5](Br_3)_2$ (C) 899
A binuclear molybdenum complex with two μ-hydrazido(3−) *N*-ligands (C) 382
Carbonyl olefinations with methylenemolybdenum reagents in aqueous or ethanolic media (C) 531
Selective synthesis of carbonyl olefinating or alkylating reagents from $MoCl_5$ and MeLi by changing the solvent or the rate of addition of MeLi (C) 532
Molybdenum-sulfur compounds, A facile route to 1,4,7-trithiacyclononane (C) 807
Mixed crystals containing the diamagnetic complex $[Mo_2(SO_2)(S_2)(CN)_8]^{4\ominus}$ and the paramagnetic complex $[Mo_2(SO_2)(S_2)(CN)_8]^{5\ominus}$ (C) 389
$[Mo_4(\mu_3\text{-}S)_4(\mu\text{-}S_2CNEt_2)_2(S_2CNEt_2)_4]$, a compound containing a cubane-like Mo_4S_4 cluster (C) 391
Moniliformin, Biosynthesis of moniliformin, a fungal toxin with cyclobutanedione structure (C) 996
Monoalkyl malonates, Enzymatic syntheses of chiral building blocks from prochiral substrates: enantioselective synthesis of monoalkyl malonates (C) 66
Monocyclopentadienylzirconium(II) compounds, $(\eta^3\text{-Allyl})(\eta^4\text{-butadiene})(\eta^5\text{-cyclopentadienyl})$zirconium, a system of isomeric monocyclopentadienylzirconium(II) compounds (C) 455
Mushrooms, Unusual components of the toadstool *Lyophyllum connatum* (Agaricales) (C) 72
Mycotoxins from mold fungi—weapons of uninivited fellow-boarders of man and animal: structures, biological activity, biosynthesis, and precautions (R) 493
Biosynthesis of moniliformin, a fungal toxin with cyclobutanedione structure (C) 996

NAKED PERMANGANATE IONS, Oxidation reactions with "naked" permanganate ions under aprotic conditions (C) 305
Natural products, Enantioselective and enantioconvergent syntheses of building blocks for the total synthesis of cyclopentanoid natural products (C) 142
Pigments from the cap cuticle of the bay boletus *(Xerocomus badius)* (C) 445
Stereoselective synthesis of (*E*)-4-hydroxy-2-alkenoic acid esters from aldehydes and the d^3-building block ethyl lithiopropiolate (C) 143
Synthesis and determination of the absolute configuration of (+)-delesserine, a metabolite of the red marine alga *Delesseria sanguinea* (Lamouroux) (C) 530
Unusual components of the toadstool *Lyophyllum connatum* (agaricales) (C) 72
Neighboring group effect, Rapid proton transfer as cause of an unusually large neighboring group effect (C) 741
Neurochemistry, Biochemical aspects of cholinergic excitation (R) 195
Nickel compounds, The reaction of [2,3-bis(diphenylphosphino)-*N*-methylmaleimide]nickel(II) chloride with $PhE(SiMe_3)_2$ (E=P, As) (C) 635
Nickel(II) bis(chelate), Detection of intramolecular linkage isomerization of a (pseudo)tetrahedral nickel(II) bis(chelate) (C) 368
Nitrilo-λ^5-phosphane, First evidence for an intermediate nitrilo-λ^5-phosphane $>P{\equiv}N$ (C) 459
Nitrosamines, Das Nitrosamin-Problem (B) 828
^{15}N-^{15}N coupling constants and rotational barriers of nitrosamines (C) 363
Nitrosoferrocene (C) 521
NMR Spectroscopy, Aliphatic polyethers, basic building blocks from naturally occurring humic substances: detection by solid state ^{13}C-NMR spectroscopy (C) 147
CP/MAS-^{13}C-NMR spectra of sclerotized insect cuticle and of chitin (C) 638
Determination of connectivities via small proton-carbon couplings with a new two-dimensional NMR technique (C) 444
Dynamic NMR spectroscopy (B) 916
^{13}C-NMR INADEQUATE spectrum with broad band decoupling by supercycles (C) 152
^{25}Mg-NMR: a method for the characterization of organomagnesium compounds, their complexes, and Schlenk equilibria (C) 534
Nobel lecture, Electron transfer between metal complexes—a retrospective view (Nobel lecture) (R) 329
Experimental and theoretical nuclear astrophysics; the quest for the origin of the elements (Nobel lecture) (R) 645
On stars, their evolution and their stability (Nobel lecture) (R) 679
Nomenclature, Nodal nomenclature II — specific nomenclature for parent hydrides, free radicals, ions, and substituents (R) 33
Nonapentafulvalene; synthesis by oxidative coupling of cyclononatetraenide and cyclopentadienide (C) 973
Nonasulfidoaurate(I), Synthesis and structure of $[Ph_4As][AuS_9]$, a cyclic nonasulfidoaurate(I) (C) 246
Nucleophilic acylation, Stereoselective nucleophilic acylation of benzaldehyde with a crotonaldehyde-d^1 reagent (C) 723

OCTABISVALENE, $[(CO)_3FePCH_3]_4$, an organometallic analogue of octabisvalene (C) 983
Octairon(III) cation, Hydrolysis products of the monomeric amine complex $(C_6H_{15}N_3)FeCl_3$: the structure of the octameric iron(III) cation of $[\{(C_6H_{15}N_3)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}\}Br_7(H_2O)]Br\cdot 8H_2O$ (C) 77
Olefin complexes, Synthesis and structure of a (carbene)$(\eta^2$-olefin)$W(CO)_4$ complex (C) 904
Olefin platinum(II) complexes, Stable olefin complexes of Pt(II) containing trichlorostannate(II) ligands: structure of $[Ph_4As][Pt(SnCl_3)_3(1,5\text{-cod})]$ (C) 78
Olefins, Photoreaction of biacetyl and 1,3-dioxole derivatives: modification of the mechanism of the photoreaction of carbonyl compounds with electron-rich olefins (C) 249
3-Trimethylsilylacrylic acid as an acetylene equivalent in Diels-Alder reactions; olefins via anodic decarboxylation-desilylation (C) 233
Oligophosphides, $[Li(tmeda)]_3P_7$ — a solvated ion complex of trilithium heptaphosphide (C) 817
P_4-Degradation with and without disproportionation (C) 816
Optical Nonlinearities, Organic polymeric and non-polymeric materials with large optical nonlinearities (R) 690
Organic metals, A novel double-stacked structure in bis[(oxamide oximato)(oxamide oxime)platinum (II)][{tris(tetracyanoquinodimethane)}diide], a molecular electron conductor (C) 999
Organic synthesis. Concepts, methods, starting materials (B) 744
Organochromium compounds, Surprising stability of nucleophilic Cr^{III}-alkylating and Cr^{III}-allylating reagents towards ethanol and water (C) 729
Organocyclotriphosphane, Synthesis of an all-*cis*-organocyclotriphosphane (P_3-nortricyclane) and its pentacarbonylchromium complex (C) 805
Organoiridium compounds, Organometallic chemistry of rhodium and iridium (B) 1001
Organolanthanoid compounds (R) 474
Organomagnesium compounds, ^{25}Mg-NMR: a method for the characterization of organomagnesium compounds, their complexes, and Schlenk equilibria (C) 534
Organometallic π-ligands, Thermally and photochemically controlled insertion of alkynes into clusters: a route to organometallic π-ligands (C) 976
Organorhodium compounds, Organometallic chemistry of rhodium and iridium (B) 1001
Organotransition metal chemistry (B) 643
Oxazocine, 4*H*-1,4-Oxazocine, a planar, diatropic 10π-dihetero[8]annulene? (C) 309
Oxazolidine-2-ylide-metal complexes, Reactions of the cyanometal acids $H_4M(CN)_6$ (M=Fe, Ru, Os), $H_2Pt(CN)_4$, and $HAu(CN)_2$ with epoxides: β-hydroxyalkyl isocyanide- and oxazolidine-2-ylide-metal complexes (C) 377
Oxidation reactions with "naked" permanganate ions under aprotic conditions (C) 305
Oxidation with palladium salts: catalytic preparation of allyl acetates from monoolefins using a three-component oxidation system (C) 453
Oxidative coupling, Nonapentafulvalene; synthesis by oxidative coupling of cyclononatetraenide and cyclopentadienide (C) 973
Oximes, Enantioselective catalytic hydrosilylation of oximes (C) 222
Oxiranes, Synthesis of 1,2:3,4:5,6-trianhydrohexitols with *gluco-*, *manno-*, and *ido*-configuration (C) 242
Oxo half-sandwich complexes, Chemistry of the novel oxo half-sandwich complex $(\eta^5\text{-}C_5Me_5)ReO_3$: functionalization and aggregation (C) 515
Exhaustive oxidative decarbonylation of metal carbonyls by light and oxygen: the example of $(\eta^5\text{-}C_5Me_5)ReO_3$ (C) 383
Oxometalates, Heteropoly and isopoly oxometalates (B) 829
Ozonation in Organic Chemistry (B) 326

PEOC/ACID CHLORIDE method, Synthesis of the all-L-configurated cyclohexa-

depsipeptide *cyclo*-[L-Val-L-Lac]$_3$ by the Peoc/acid chloride method (C) 808
Peptide alkaloids, Total synthesis of hexaacetylcelenamide A (C) 991
Peptide structures of the alamethicin sequence: the *C*-terminal $\alpha/3_{10}$ helical nonapeptide and two pentapeptides with opposite 3_{10} helicity (C) 450
Peptide synthesis, 2-(Pyridyl)ethyl esters as secure yet readily removable polarophilic carboxy-protection in peptide synthesis (C) 716
The allyloxycarbonyl (Aloc) moiety—conversion of an unsuitable into a valuable amino protecting group for peptide synthesis (C) 436
Permanganate ions, Oxidation reactions with "naked" permanganate ions under aprotic conditions (C) 305
Permethrinic acid, Enzymatic syntheses of chiral building blocks from racemates: preparation of (1*R*,3*R*)-chrysanthemic, -permethrinic and -caronic acids from racemic, diastereomeric mixtures (C) 64
Peroxoplatinum compounds, Novel synthesis of an unsymmetrical Pt(η^2-O_2) complex (C) 375
Peroxyboron unit, Thermally stable ethylperoxyboron unit by regioselective autoxidation (C) 155
PE spectroscopy, O=P–Cl and S=P–Cl: gas-phase ionization (C) 731
Phanes, Molecular structure of 8,11-dichloro[5]metacyclophane: a strongly bent benzene ring (C) 238
Phase transfer catalysis, Hydroxide ion-initiated deuteration of very weak CH acids under phase transfer catalysis conditions (C) 54
p-Phenylenediboranes: mirror images of *p*-phenylenediamines? (C) 615
Pheromone components, Synthesis of enantiomerically pure 1,7-dioxaspiro[5.5]undecanes, pheromone components of the olive fly *(Dacus oleae)* (C) 519
Phosgene as a reagent for the enantiomeric resolution of 1,2- and 1,3-diols, α-amino alcohols, α-hydroxy acids, and *N*-methyl-α-amino acids by gas chromatography (C) 527
Phosphaalkenes, Easy synthesis of phosphaalkenes by a phosphorus-analogous isocyanide and an atypical crystal structure of a tetracarbonyl(phosphaalkene)iron complex (C) 895
Facile synthesis of heteroalkenes $CF_3E{=}CF_2$ (E=P, As) (C) 710
Synthesis, structure, and reactions of cluster-stabilized phosphaalkenes (C) 739
Phosphaalkynes, [3+2]-Cycloaddition reactions of a stable phosphaalkyne—transition from singly to doubly coordinated phosphorus (C) 900
Phosphaallenes (C) 619
Phosphaallyl chlorides, 1*H*-1,2,4-diazaphospholes via 2-phosphaallyl chlorides (C) 903
Phosphates, P_4-Degradation with and without disproportionation (C) 816
Phosphathioketene, First evidence for the existence of a phosphathioketene (C) 970
Phosphepines, 2,7-Di-*tert*-butyl-1-phenyl-1*H*-phosphepine—the first stable, monocyclic phosphepine (C) 894
Phosphido-phosphane bridges, Iron clusters with coupled phosphido-phosphane bridges (C) 734
Phosphinines, Delocalized carbocations, carbanions and radicals of 2,4,6-substituted 1-methoxy-1-oxo-λ^5-phosphinines (C) 990
Phosphininium salts, 1,2,4,6-Tetraphenylphosphininium tetrachloroaluminate, the first phosphininium salt analogous to the pyridinium salts (C) 989
Phospholipids as functional constituents of biomembranes (R) 257
Phosphonium salts, Crown ether complexes of phosphonium salts—the X-ray structure analysis of $[(Ph_3PMe)_2\cdot[18]crown\text{-}6][PF_6]_2$ (C) 824
Phosphorus, P_4-Degradation with and without disproportionation (C) 816
Phosphorus-cobalt clusters, Novel clusters of cobalt and nickel with organophosphorus ligands (C) 160
Phosphorus-nickel clusters, Novel clusters of cobalt and nickel with organophosphorus ligands (C) 160
Phosphorus polycycles, Na_3P_{21} and Li_3P_{21}, the first polyphosphides with isolated P_{21}^{3-} groups (C) 317
Phosphorus ylides, Dialkylboryl-substituted triphenylphosphonium ylides (C) 381
Phosphoryl chloride, O=P–Cl and S=P–Cl: gas-phase ionization (C) 731
Photochemical cleavage, Direct photochemical cleavage of the cyclobutane ring in bicyclo[4.2.0]octane on 185 nm irradiation in solution (C) 641
Photochemistry of alkyltransition-metal complexes (R) 766
Photochemical hole burning: a spectroscopic study of relaxation processes in polymers and glasses (R) 113
Photochromic systems, Tailor-made photochromic systems: first bichromophoric spiro-1,8a-dihydroindolizines (C) 241
Photochromism, Photosensitive dihydroazulenes with chromogenic properties (C) 960
Photo-induced reactions, Synthesis of tetrahydro-3-thienylacetic acid esters by consecutive photo-induced reactions (C) 364
Photoreaction of biacetyl and 1,3-dioxole derivatives: modification of the mechanism of the photoreaction of carbonyl compounds with electron-rich olefins (C) 249
Photosensitive dihydroazulenes with chromogenic properties (C) 960
Physical chemistry, Lehrbuch der Physikalischen Chemie (B) 252
Platinaheterocycle, Insertion of platinum into the sulfur-nitrogen bond of a 1,2,4-thiadiazole: synthesis of a six-membered metallaheterocycle (C) 971
Platinum compounds, Novel synthesis of an unsymmetrical Pt(η^2-O_2)-complex (C) 375
Platinum-gold cluster, Synthesis of the first Pt-Au cluster by an unexpected $H^{\oplus}$-substitution at *trans*-$PtH(Cl)L_2$ (C) 304
Platinum(II) complexes, Hydridoplatinum(II) complexes with phosphites and phosphonites and their reactions with methyl acrylate (C) 529
Polyanion, $[Cu_6I_{11}]^{5\ominus}$—a polyanion with trigonal-prismatic arrangement of six metal atoms (C) 514
Polycycles, All-*cis*-[5.5.5.5]fenestrane (C) 390
Iterative cyclopentane annulation of α,β-enones (C) 798
Novel double-layered annulenes—models for the investigation of successive electron transfers (C) 818
Polycycloborazanes, Synthesis and structure of a B_6N_7 phenalene (C) 303
Polyenes, The dendralenes—a neglected group of highly unsaturated hydrocarbons (R) 948
Polyethers, Macrobicyclic polyethers as V-shaped hosts for *cis*-diammine-transition metal complexes (C) 821
Polymers, Organic polymeric and non-polymeric materials with large optical nonlinearities (R) 690
Polyphosphides, Na_3P_{21} and Li_3P_{21}, the first polyphosphides with isolated P_{21}^{3-} groups (C) 317
Polysulfide ions, Novel inorganic ring systems and fixation of the $S_8^{2\ominus}$ ion: $[(S_6)Cu(S_8)Cu(S_6)]^{4\ominus}$ and $[Cu_3(S_4)_3]^{3\ominus}$ (C) 632
Polysulfido metal complexes, $(PMe_3)_3MS_7$ (M=Ru, Os): the first polysulfido metal complexes with a tridentate $S_n^{2\ominus}$ ligand (C) 814
Porphyrin-quinone systems, Synthesis of a porphyrin sandwiched between two parallel *p*-benzoquinone units (C) 623
Porphyrins, A biphenylenediporphyrin: two cofacially arranged porphyrins with a biphenylene bridge (C) 164
Porphyrin synthesis, Non-toxic alternative for a key step in porphyrin synthesis (C) 226
Prostaglandin building block, Asymmetric synthesis of a novel enantiomerically pure prostaglandin building block (C) 511
Prostaglandin syntheses by three-component coupling (R) 847
Protective groups, A convenient method for the preparation of 1-(*tert*-butyloxycarbonyl)pyrroles (C) 296
2-(Pyridyl)ethyl esters as secure yet readily removable polarophilic carboxy-protection in peptide synthesis (C) 716
The allyl group as mildly and selectively removable carboxy-protecting group for the synthesis of labile *O*-glycopeptides (C) 71
The allyloxycarbonyl (Aloc) moiety—conversion of an unsuitable into a valuable amino protecting group for peptide synthesis (C) 436
Vanadium thiolate complexes with VS_5- and VOS_4-centers: synthesis and structure of $[VS(SC_2H_4S)_2]^{2\ominus}$ and $Na_2[VO(SC_2H_4S)_2]\cdot 8\,MeOH$ (C) 804
Protein engineering, Analysis of enzyme structure and activity by protein engineering (R) 467
Protein folding and protein association (R) 395
Protein folding (B) 327
Proton transfer, Rapid proton transfer as cause of an unusually large neighboring group effect (C) 741
Pyrethroid acids, Optically active α-arylcarboxylic acids by kinetic resolution: pyrethroid acids (C) 162
Pyridine nucleotide coenzymes, The pyridine nucleotide coenzymes (B) 85
Pyridinium salts, Pyrylium mediated transformations of primary amino groups into other functional groups (R) 420
Pyridylethyl esters, 2-(Pyridyl)ethyl esters as secure yet readily removable polarophilic carboxy-protection in peptide synthesis (C) 716
Pyrocatechol-2,3-dioxygenase, Oxidative cleavage of pyrocatechol at the *meta*-position; a model reaction for cleavage by pyrocatechol-2,3-dioxygenase? (C) 79
Pyrolysis: theory and industrial practice (B) 743
Pyrrole nitrogen, A convenient method for the preparation of 1-(*tert*-butyloxycarbonyl)pyrroles (C) 296
Pyrrolo[1,2-*d*][1,2,4]triazines, Synthesis of substituted, partially hydrogenated [1,2,4]triazino[4,5-*a*]indoles and pyrrolo[1,2-*d*][1,2,4]triazines (C) 518
Pyrylium salts, Pyrylium mediated transformations of primary amino groups into other functional groups (R) 420

QUATERNIZATION, Unexpected secondary reaction of the simple CH_3I-quaternization of vinylidenebis(diphenylphosphane) (C) 247
Quinones, Oligocyclic hetarenes with quinonoid structure; synthesis by sequential cyclizing condensation (C) 914

RADICAL ANIONS, 1,3-Dihydro-1,3-diboretes and their radical anions (C) 372
Radical anion/radical cation pairs, Isoelectronic radical ions from single-electron transfer reactions: direct observation of persistent solvent-separated radical anion/radical cation pairs (C) 613
Radical anion-substituted crown ethers as cages for metal cations (C) 57

Radical cations, Hindered rotation of *tert*-butyl groups in radical cations of highly substituted alkenes (C) 526
Reactivity of $CH_2-X-CH_3^{\oplus\odot}$ (X=Cl, Br) with electrophiles and nucleophiles in the gas phase, a Fourier transform ion cyclotron resonance investigation (C) 733
$[S_4N_4]^{\oplus}[FeCl_4]^{\ominus}$, a compound with cyclic radical cation (C) 237
Radical ions, Isoelectronic radical ions from single-electron transfer reactions: direct observation of persistent solvent-separated radical anion/radical cation pairs (C) 613
Radicals, Delocalized carbocations, carbanions and radicals of 2,4,6-substituted 1-methoxy-1-oxo-λ^5-phosphinines (C) 990
ENDOR spectroscopy—a promising technique for investigating the structure of organic radicals (R) 173
Simple model for radical additions (C) 985
Synthesis and characterization of $[(C_5Me_5)Mn(CO)_2(SR)]$: RS radicals as ligands (C) 975
The scope of radical CC-coupling by the "tin method" (C) 69
Radical stabilization, Conformation of glycosyl radicals: radical stabilization by β-CO bonds (C) 896
Reaction mechanisms, Photoreaction of biacetyl and 1,3-dioxole derivatives: modification of the mechanism of the photoreaction of carbonyl compounds with electron-rich olefins (C) 249
Simple model for radical additions (C) 985
Stereochemical evidence supporting the intermediate mechanism of dihalocarbene addition (C) 706
Rearrangements, A "cluster-centered" acetylene-vinylidene rearrangement (C) 141
A novel ketoketene—ketoketene rearrangement (C) 802
A novel rearrangement of the azulene skeleton: ring contraction of a dihydroazulene to an indene derivative (C) 237
Carbanion-induced skeletal rearrangements: from the dibenzo[*a*,*e*]cyclooctene to the indeno[2,1-*a*]indene framework (C) 705
Mechanism of the cyclopropane "walk" rearrangement: synthesis and properties of the 2-diazopropane adduct of cyclooctatetraene (C) 73
Mercury(II)- and palladium(II)-catalyzed [3,3]-sigmatropic rearrangements (R) 579
Non-toxic alternative for a key step in porphyrin synthesis (C) 226
1,2,3-Triaminocyclopentadienide ions—preparation via an unusually rapid vinylcyclopropene-cyclopentadiene rearrangement (C) 225
Receptors, Biochemical aspects of cholinergic excitation (R) 195
Reduction, Acid-induced carbyne-acyl rearrangement—an unexpected CC coupling reaction (C) 640
Preparative microbial reduction of β-oxoesters with *Thermoanaerobium brockii* (C) 151
Reduction potential, The electrochemical reduction of benzene—first direct determination of the reduction potential (C) 84
Research faculties. Chemical research faculties. An international directory (B) 827
Resolution, Gas chromatographic separation of enantiomers on optically active metal-complex-free stationary phases (R) 747
Optically active α-arylcarboxylic acids by kinetic resolution: pyrethroid acids (C) 162
Retinal, C=C stretching frequencies in model compounds of the protonated retinal Schiff base (C) 803
Retinal-analogue, Sterically fixed retinal-analogue prevents proton-pumping activity in bacteriorhodopsin (C) 81
Retinoids, Preparation of spiroretinal and related retinoids (C) 251
Rhenium compounds, Chemistry of the novel oxo half-sandwich complex $(\eta^5\text{-}C_5Me_5)ReO_3$: functionalization and aggregation (C) 515
Exhaustive oxidative decarbonylation of metal carbonyls by light and oxygen: the example of $(\eta^5\text{-}C_5Me_5)ReO_3$ (C) 383
Rhodium compounds, Ambidentate behavior of mononuclear vinylidenerhodium complexes—novel C—C coupling of a methyl to a vinylidene group (C) 431
Asymmetric hydrogenation of α-(acetylamino)cinnamic acid with a novel rhodium complex; the design of an optimal ligand (C) 435
Di-(μ-amido)dirhodium complexes: structure of $[Rh_2(\mu\text{-}(NH)_2\text{-naphth})I_2(CO)_2(PPh_3)_2]$ (C) 913
Second sphere coordination of cationic rhodium complexes by dibenzo[3*n*]crown-*n* ethers (C) 235
Ring contraction, A novel rearrangement of the azulene skeleton: ring contraction of a dihydroazulene to an indene derivative (C) 237
Ring expansion of benzothiete to 2,3-dihydrobenz[*d*]isothiazoles (C) 244
Ring opening, Direct photochemical cleavage of the cyclobutane ring in bicyclo[4.2.0]octane on 185 nm irradiation in solution (C) 641
Oxidative cleavage of pyrocatechol at the *meta*-position; a model reaction for cleavage by pyrocatechol-2,3-dioxygenase? (C) 79
Ring-opening of methylene-bridged dimetal complexes by bases (C) 432
Rotation, Easy rotation about the exocyclic carbon-carbon bond in lithium α-aminoenolates: a comparison (C) 797
Hindered rotation of *tert*-butyl groups in radical cations of highly substituted alkenes (C) 526
Rotational barriers, $^{15}N\text{-}^{15}N$ coupling constants and rotational barriers of nitrosamines (C) 363
Rotational barriers of 4-aryl-1,4-dihydropyridines (Ca antagonists) (C) 301

SAKURAI REACTION, Diastereoselective synthesis of spiro[4.5]decanones by intramolecular Sakurai reactions (C) 308
SAMP-Hydrazones, Enantioselective synthesis of β-substituted primary amines; α-alkylation/reductive amination of aldehydes via SAMP-hydrazones (C) 365
Sandwich complexes, Carbaboranylnickel complexes with the novel η^5-2,3,5-tricarbahexaboranyl ligand (C) 965
Selenium-sulfur rings, Isolation of the first six- and seven-membered selenium-sulfur rings and mechanism of their conversion into other-sized rings (C) 362
Selenium tetrafluoride, Bonding attitudes in crystalline SeF_4 and TeF_4 (C) 388
Selenobenzaldehyde complexes, Unusual equilibrium between η^1- and η^2-isomers of selenobenzaldehyde complexes (C) 726
Selenoformaldehyde, Heterometal binuclear complexes with thio- and selenoformaldehyde as bridge ligands (C) 58
Semibullvalene, Temperature dependence of the UV spectrum of 1,5-dimethyl-2,6-semibullvalenedicarbonitrile; evidence for an equilibrium with a delocalized, homoaromatic isomer (C) 631
SET reactions, Isoelectronic radical ions from single-electron transfer reactions: direct observation of persistent solvent-separated radical anion/radical cation pairs (C) 613
Siderophore, Functionalized, oligocyclic large cavities—a novel siderophore (C) 714
Sigmatropic rearrangements, Mercury(II)- and palladium(II)-catalyzed [3,3]-sigmatropic rearrangements (R) 579
Silicides, High-pressure phases of KSi, KGe, RbSi, RbGe, CsSi, and CsGe with the NaPb-type structure (C) 528
Siloxanes, Nickel-catalyzed reduction of carbon monoxide by hexamethyldisilane: a new reaction leading to a novel synthesis of siloxanes (C) 460
Silver-crown ether complexes, Silver-catalyzed formation of crown ethers; synthesis and structure of $[Ag([12]crown\text{-}4)_2][AsF_6]$ (C) 376
Silyl-stannocene, Sequential lithiation and silylation of stannocene (C) 616
Smoking of foods, Chemie der Räucherung (B) 744
Spectroscopy, Photochemical hole burning: a spectroscopic study of relaxation processes in polymers and glasses (R) 113
Spin glasses, Synthesis of new amorphous metallic spin glasses M_2SnTe_4 (M=Cr, Mn, Fe, Co): solvent induced metal-insulator transformations (C) 169
Spiro[4.5]decanones, Diastereoselective synthesis of spiro[4.5]decanones by intramolecular Sakurai reactions (C) 308
Spiro-1,8a-dihydroindolizines, Tailor-made photochromic systems: first bichromophoric spiro-1,8a-dihydroindolizines (C) 241
Spiro[2.3]hexanes by C_4+C_2-coupling (C) 974
Spiroretinal, Preparation of spiroretinal and related retinoids (C) 251
Stannocene, Sequential lithiation and silylation of stannocene (C) 616
Stars, On stars, their evolution and their stability (Nobel lecture) (R) 679
Stereochemical analysis, Methods in stereochemical analysis I. Stereochemical applications of NMR studies in rigid bicyclic systems (B) 87
Stereoelectronic effects in organic chemistry (B) 743
Stereoselective nucleophilic acylation of benzaldehyde with a crotonaldehyde-d^1 reagent (C) 723
Stereoselectivity, Chelation or non-chelation control in addition reactions of chiral α- and β-alkoxy carbonyl compounds (R) 556
The homoaldol reaction or how to overcome problems of regio- and stereo-selectivity (R) 932
Sulfidophenolate ligands, The in situ preparation of 2-sulfidophenolate ligands, by copper-catalyzed oxygen insertion into thiophenolates: crystal structure of $[Ph_4]_2[Mo_2O_5(SC_6H_4O)_2]$ (C) 972
Sulfonium salts, Crown ether complexes of sulfonium salts—the X-ray crystal structures of $[PhCOCH_2SMe_2\cdot[18]crown\text{-}6]_n[PF_6]_n$ and $[(PhCOCHPhSMe_2]_2\cdot[18]crown\text{-}6][PF_6]_2$ (C) 977
Sulfur(VI) dication, $[(Me_2N)_2SF_2]^{2\oplus}$, a sulfur(VI) dication (C) 507
Sulfur imide as *bisdihapto*-bridging ligand in the complex $Fe_2(CO)_6(HNS)$ (C) 80
Sulfur monoxide, Stabilization of sulfur monoxide by coordination to transition metals (C) 806
Sulfur-nitrogen-ligands, $[Ph_4P]_2[Ni_3N_8S_8]$, a novel trinuclear complex with sulfur-nitrogen ligands (C) 225
Sulfur-nitrogen radical cation, $[S_4N_4]^{\oplus}[FeCl_4]^{\ominus}$, a compound with cyclic radical cation (C) 237
Surfaces, X-Ray spectroscopic studies of the surface species in Co-Mo-Al_2O_3 hydrodesulfurization catalysts (C) 323
Synthesis, organic synthesis. Concepts, methods, starting materials (B) 744
Synthetic methods, Asymmetric Diels-Alder and ene reactions in organic synthesis (R) 876
Carbene complexes in organic synthesis (R) 587

Chelation or non-chelation control in addition reactions of chiral α- and β-alkoxy carbonyl compounds (R) 556
Cobalt-mediated [2+2+2]-cycloadditions: a maturing synthetic strategy (R) 539
Mercury(II)- and palladium(II)-catalyzed [3,3]-sigmatropic rearrangements (R) 579
Microbial asymmetric catalysis – enantioselective reduction of ketones (R) 570
Prostaglandin syntheses by three-component coupling (R) 847
Pyrylium mediated transformations of primary amino groups into other functional groups (R) 420
Synthesis of *anti-inflammatory* α-arylalkanoic acids by 1,2-aryl shift (R) 413
The cycloaddition of allyl cations to 1,3-dienes: general method for the synthesis of seven-membered carbocycles (R) 1
The homoaldol reaction, or how to overcome problems of regio- and stereo-selectivity (R) 932

TAXANE, A novel entry to the taxane structural unit (C) 905
Tellurium tetrafluoride, Bonding attitudes in crystalline SeF_4 and TeF_4 (C) 388
Templates, Metal template for the symmetrical [2+2]-dimerization of ketenimines (C) 223
Terpenoids, Encyclopaedia of the terpenoids (B) 462
Tetraarsane, As_4tBu_2 – the first bicyclo[1.1.0]tetraarsane (C) 379
Tetraborinane, Synthesis and structure of a 1,2,4,5-tetraborinane (C) 608
Tetra-*tert*-butyltetrahedrane – crystal and molecular structure (C) 993
Tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodeca-4,9-diene, Structure of tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodeca-4,9-diene: a diolefin with close double bonds (C) 55
Tetrafluorophosphoranyl group, An iridium(III) complex containing a PF_4-group bound to the metal (C) 630
Tetrahedrane, Tetra-*tert*-butyltetrahedrane – crystal and molecular structure (C) 993
Tetrahydrofurans, Cyclization of 3-allyloxycarboxylic acids to tetrahydrofurans by Kolbe electrolysis (C) 980
Tetralithiomethane (C) 995
Tetraphenyldibenzo[*a,e*]cyclooctene-5,6,11,12-tetrone, 1,4,7,10-Tetraphenyldibenzo[*a,e*]cyclooctene-5,6,11,12-tetrone from 3,6-diphenylphthalic anhydride (C) 622
Tetraphenylphosphininium tetrachloroaluminate, 1,2,4,6-Tetraphenylphosphininium tetrachloroaluminate, the first phosphininium salt analogous to the pyridinium salts (C) 989
Thermochromism, Photosensitive dihydroazulenes with chromogenic properties (C) 960
Thermodynamics, Elementary statistical thermodynamics. A problems approach (B) 917
Thermospray mass spectrometry of diquaternary ammonium salts (C) 892
Thiazyl fluoride, Conversion of "LiNS(F)OCMe$_3$" into an $(Li_8)_2$ double cluster (C) 795
Thienylacetic acid esters, Synthesis of tetrahydro-3-thienylacetic acid esters by consecutive photo-induced reactions (C) 364
Thietone, Acyl- and thioacylketenes: synthesis of 3-benzoyl-4-phenylthiet-2-one (C) 800
Thin-layer chromatographic enantiomeric resolution via ligand exchange (C) 506
Thin layer chromatography with an immobilized azacyclophane derivative as analytical agent and probe for host-guest interactions (C) 910
Thioaurate(I), Synthesis and crystal structure of $[Ph_4As]_4[Au_{12}S_8]$, a distorted cubane-like thioaurate(I) (C) 715
Synthesis and structure of $[Ph_4As][AuS_9]$, a cyclic nonasulfidoaurate(I) (C) 246
Thiocarbonyl functions, Donor-substituted thiocarbonyl functions as heterodienophiles in [4+2]-cycloadditions with inverse electron demand (C) 890
Thioformaldehyde, Heterometal binuclear complexes with thio- and selenoformaldehyde as bridge ligands (C) 58
Thiolate complexes, Vanadium thiolate complexes with VS_5- and VOS_4-centers: synthesis and structure of $[VS(SC_2H_4S)_2]^{2\ominus}$ and $Na_2[VO(SC_2H_4S)_2]\cdot 8\,MeOH$ (C) 804
Thiolate ligands, Thiolate chemistry of the Fe group elements: synthesis and structure of the complexes $[Co_2\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2\ominus}$ and $[Ni_3\{o\text{-}(SCH_2)_2C_6H_4\}_4]^{2\ominus}$ (C) 634
Thiopenam derivatives from alkynyl silyl sulfides and 4,5-dihydrothiazoles (C) 439
Thiophosphoryl chloride, O=P–Cl and S=P–Cl: gas-phase ionization (C) 731
Thiophosphoryl group, Mechanism of the cyclocotrimerization of diethyl(hydrido)thiophosphorus with alkynes (C) 523
Thioxophosphanes, Methyl(thioxo)phosphane: generation and trapping reaction with $Mn_2(CO)_{10}$ (C) 320
Three-component oxidation system, Oxidation with palladium salts: catalytic preparation of allyl acetates from monoolefins using a three-component oxidation system (C) 453
Tin compounds, $Sn_3(NtBu)_2(OtBu)_2$, a molecule with a novel, heptaatomic, polycyclic framework (C) 158
Tin method, The scope of radical CC-coupling by the "tin method" (C) 69
Topological charge stabilization and the equilibrium between P_4S_3 and As_4S_3 (C) 506
Topomerization, An extraordinary structure and topomerization mechanism for "diboramethylenecyclopropane" (C) 825
Trace analysis, Atomspektrometrische Spurenanalytik (B) 85
Enrichment techniques for inorganic trace analysis (B) 463
Transallenation of 1,3-bis(dialkylamino)-1,3-diethoxyallenes with disubstituted malonyl chlorides (C) 637
Transition-metal complexes, Photochemistry of alkyltransition-metal complexes (R) 766
Triaminocyclopentadienide ions, 1,2,3-Triaminocyclopentadienide ions–preparation via an unusually rapid vinylcyclopropene-cyclopentadiene rearrangement (C) 225
Trianhydrohexitols, Synthesis of 1,2:3,4:5,6-trianhydrohexitols with *gluco-*, *manno-*, and *ido*-configuration (C) 242
Triarsarhodacyclobutane, Complexation of $PhAs{=}CH_2$ and synthesis of a novel $RhAs_3$-metallaheterocycle (C) 626
Triazene, 1,3-Bis(tri-*tert*-butylsilyl)triazene (C) 59
Triazino[4,5-*a*]indoles, Synthesis of substituted, partially hydrogenated [1,2,4]triazino[4,5-*a*]indoles and pyrrolo[1,2-*d*][1,2,4]-triazines (C) 518
Tricarbahexaboranyl ligands, Carbaboranylnickel complexes with the novel η^5-2,3,5-tricarbahexaboranyl ligand (C) 965
Trichlorostannate(II), Stable olefin complexes of Pt(II) containing trichlorostannate(II) ligands: structure of $[Ph_4As][Pt(SnCl_3)_3(1,5\text{-cod})]$ (C) 78
Trifluoroethylidynesulfur trifluoride, $F_3C{-}C{\equiv}SF_3$ (C) 150
Trifluoromethyl-1,3,5,2,4,6,8-trithiatetrazocine cation, Synthesis and structure of the 7-trifluoromethyl-1,3,5,2,4,6,8-trithiatetrazocine cation (C) 988
Trilithium heptaphosphide, $[Li(tmeda)]_3P_7$ – a solvated ion complex of trilithium heptaphosphide (C) 817
Trimethylsilylacrylic acid, 3-Trimethylsilylacrylic acid as an acetylene equivalent in Diels-Alder reactions; olefins via anodic decarboxylation-desilylation (C) 233
Trinuclear complexes, $[Ph_4P]_2[Ni_3N_8S_8]$, a novel trinuclear complex with sulfur-nitrogen ligands (C) 225
Structure of a novel μ_3-oxo-$Fe^{III}_2Cr^{III}$-glycine complex (C) 434
Triphenylsilylboranediyl, Photochemical generation of triphenylsilylboranediyl $(C_6H_5)_3SiB$: from organosilylboranes (C) 454
Triphosphanortricyclane, Synthesis of an all-*cis*-organocyclotriphosphane (P_3-nortricyclane) and its pentacarbonylchromium complex (C) 805
Triple bond, First evidence for an intermediate nitrilo-λ^5-phosphane $>P{\equiv}N$ (C) 459
Triruthenium clusters, Stepwise hydrogenation of benzonitrile on a Ru_3-cluster (C) 381
Trithiacyclononane, A facile route to 1,4,7-trithiacyclononane (C) 807
Trithiatetrazocine cation, Synthesis and structure of the 7-trifluoromethyl-1,3,5,2,4,6,8-trithiatetrazocine cation (C) 988
Tungstacyclopropane compound, Unusual conversion of an alkynetungsten complex into a tungstacyclopropane compound by nitrosyl chloride (C) 809
Tungsten compounds, $(Ph_4As)_2[Cl_5W(\mu\text{-}N_4)WCl_5]$, a μ-isotetrazenido(4–) complex of Tungsten(VI) (C) 149

ULLMANNS Encyklopädie der technischen Chemie (B) 536
Uranium-carbon double bond, Isocyanide insertion into a uranium-carbon double bond (C) 912

VALENCE bond theory, Lecture notes in chemistry. Vol. 34: Unified valence bond theory of electronic structure. Applications (B) 1002
Vallesiachotamine, Total synthesis of the indole alkaloid vallesiachotamine (C) 984
Vanadium thiolate complexes with VS_5- and VOS_4-centers: synthesis and structure of $[VS(SC_2H_4S)_2]^{2\ominus}$ and $Na_2[VO(SC_2H_4S)_2]\cdot 8\,MeOH$ (C) 804
VEPA theory, Second order Jahn-Teller effect in hexahalogenotellurates(IV): statistically distorted anion in $Ca(H_2O,HF)_7TeBr_6$ (C) 963
Vesicle membranes, Routes to functional vesicle membranes without proteins (R) 100
Vinylcyclopropene-cyclopentadiene rearrangement, 1,2,3-Triaminocyclopentadienide ions–preparation via an unusually rapid vinylcyclopropene-cyclopentadiene rearrangement (C) 225
Vinylidenebis(diphenylphosphane), Unexpected secondary reaction of the simple CH_3I-quaternization of vinylidenebis(diphenylphosphane) (C) 247
Vinylidenerhodium complexes, Ambidentate behavior of mononuclear vinylidenerhodium complexes–novel C–C coupling of a methyl to a vinylidene group (C) 431
Vinyllithium derivatives, Configurational stability of vinyllithium derivatives with 1-trimethylsilyl and 1-alkoxy substituents (C) 366
Visual pigments, C=C stretching frequencies in model compounds of the protonated retinal Schiff base (C) 803
Vitamin B_{12}. Vol. 1: Chemistry; Vol. 2: Biochemistry and medicine (B) 536

YLIDE complexes, Reactions of diphenyl(trimethylsilyl)phosphane with alkyl(pentacarbonyl)manganese; synthesis of the ylide complexes $(CO)_4MnCr(OSiMe_3)PPh_2$ and a new driving force for CO insertion (C) 245

Ylides, Unexpected secondary reaction of the simple CH_3I-quaternization of vinylidenebis(diphenylphosphane) (C) 247

Ynamines, [2 + 1]-Cycloadditions of ynamines and ynediamines to carbon monosulfide (C) 729

Ynediamines, [2 + 1]-Cycloadditions of ynamines and ynediamines to carbon monosulfide (C) 729

ZEOLITES, Modelling the chemistry of zeolites by computer graphics (R) 671

Zirconium compounds, (η^3-Allyl)(η^4-butadiene)(η^5-cyclopentadienyl)zirconium, a system of isomeric monocyclopentadienylzirconium(II) compounds (C) 455

Diastereoselective formation of substituted (η^3-allyl)(η^4-diene)ZrCp complexes by intramolecular ligand interaction (C) 625

Hydrozirconation of nitriles: proof of a linear heteroallene structure in (benzylideneamido)zirconocene chloride (C) 68
